As long as $I \gg \beta$, the energy of A is lower than that of B irrespective of the sign of $\Delta\alpha$, so that A is the stable configuration. The minimum of Eq. 46 gives Q_0 as the same as Eq. 45. The distributions of the excess charge and spin are illustrated in Fig. 5. The effect of the electron-repulsion is drastic. The odd electron polarizes the electrons at the levels of $n=0, \pm 1$ which already exist in the neutral benzene, and leads to the negative spin density at sites 3 and 6.

Numerical Results

For the whole range of I, the numerical analysis is performed. We give values of the parameters as follows.

$$\Delta\alpha = 0.01,$$
$$g = 0.04,$$
$$Q = 0.02.$$

The sign of $\Delta\alpha$ represents the electrophilicity or the nucleophilicity of the solvent. The absolute value of $\Delta\alpha$ and g can be selected rather arbitrarily, because they affect hardly on the results. Q is the value that lets the total energy minimize on $I=3$ (this value of I would probably correspond to the electron correlation for the benzene molecule.).

The results are shown in Figs. 6—10. All the resultant values for $I \geqq 15$ are very close to the analytic solutions given in the previous section. The I dependence of C_σ, D_σ/I and that of energy E are represented in Figs. 6 and 7, respectively. As illustrated in figures, two classes of self-consistent solutions, one stable and one unstable, exist as mentioned before. The solid and dashed curves correspond to the stable solution A and the unstable one B, respectively. The orbital patterns corresponding to the two classes of solutions for $I=3$ and 12 are illustrsted in Fig. 8. It is easy to see that the patterns for unstable solution does not give the proper ground state.

Figure 9 shows the behavior of the charge density and the spin density *versus* I. In this figure the solid and dashed curves correspond to the values on sites 1 and 6, respectively.

Figure 10 represents the relation between the total energy E and the displacement Q, and shows the stabilization of energy due to the Jahn-Teller effect. On calculating the total energy, we assigned the value of 4.12 for the parameter $M\Omega^2$ which is calculated from

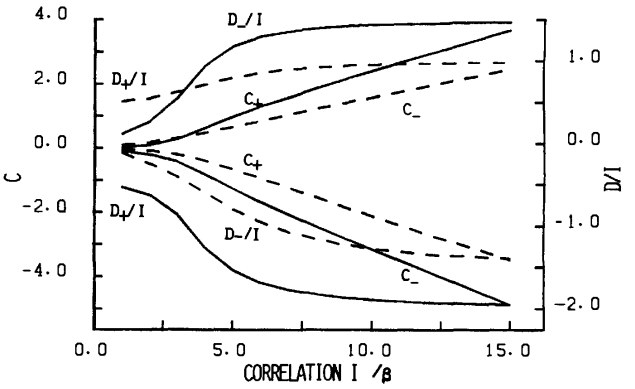

Fig. 6. C_σ and D_σ/I *vs.* I. I is represented in the unit $\beta=1$. We give values of the parameters as follows: $\Delta\alpha=0.01$, $g=0.04$, $Q=0.02$. The solid and dashed curves correspond to the stable and unstable solutions, respectively.

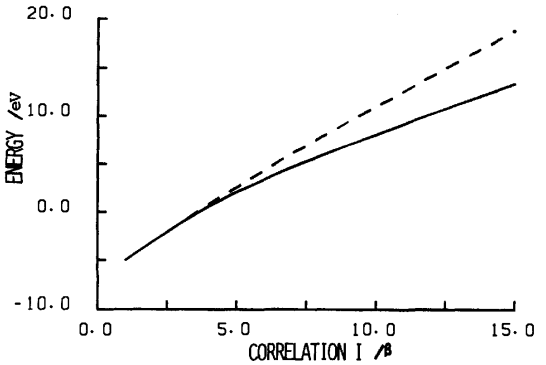

Fig. 7. E *vs.* I. All parameters and curves are the same as Fig. 6.

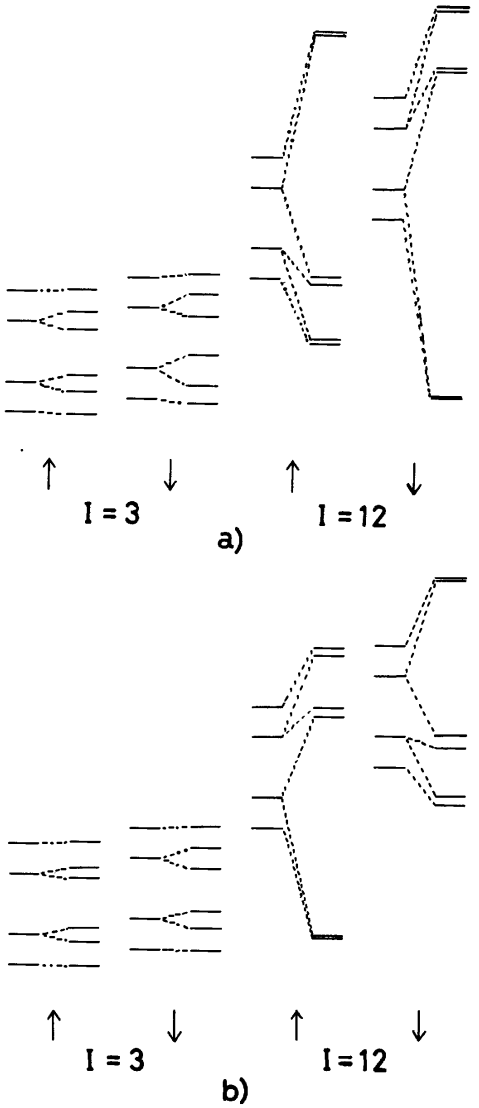

Fig. 8. The orbital patterns for the undistorted and distorted cases with $I=3$ and 12 are compared. a) Orbital patterns for stable solution, b) For unstable one. The up and down arrows represent the up and down spin orbitals, respectively. All parameters are the same as Fig. 6.

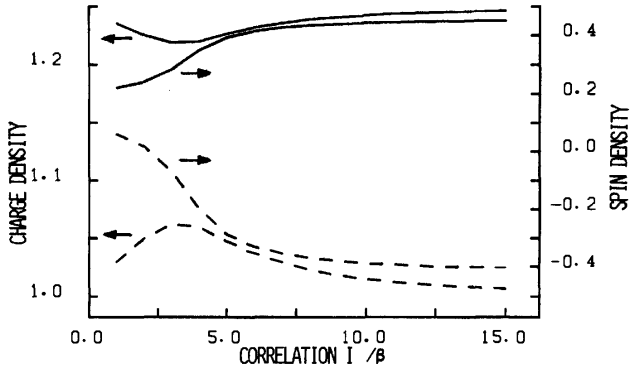

Fig. 9. The charge density and the spin density *vs.* I. The solid and dashed curves correspond to the densities for the case of the stable solution on sites 1 and 6, respectively. All parameters are the same as Fig. 6.

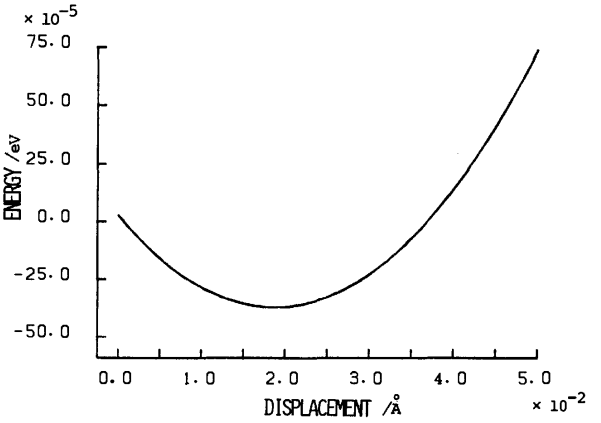

Fig. 10. The energy gain due to the distortion Q. The energy is expressed in eV and Q in Å. $\Delta\alpha=0.01$, $g=0.04$, $I=3$, $M\Omega^2=4.12$.

the force constant of the E_g^+ vibronic mode of the benzene molecule.[13] The energy is minimized at $Q=0.02$ Å.

Concluding Remarks

We have analyzed the Jahn-Teller distortion of the benzene anion on the basis of the modified P.P.P. models. As far as the repulsion is weak, our results confirm the simple theory considering only the odd electron of the anion.[3] But if the repulsion becomes strong, *i.e.*, $I/\beta>15$ the effect of other π electrons becomes significant. This effect appears more remarkably on the distribution of the spin than that of the charge. The discrepancy between the distributions of the spin and charge originates from the exchange interaction between the π electrons which is not considered in the single electron theory.

We wish to stress a few points. Look at Fig. 11 which displays the amplitude of the unoccupied, degenerate wave functions with $n=\pm2$ of benzene. The odd electron of the benzene anion is equally distributed on these two states. However, this picture is only for pictorial understanding and each pattern of the charge density distribution given by a) or b) in Fig. 11 is of less meaning by itself, but the mean of them would correspond to usual experimental observations. This

aspect holds even if the vibronic interaction is introduced in Eq. 7 to remove the degeneracy, since the phase of the electron distribution remains still arbitrary.

The external perturbation which reduces the molecular symmetry from C_6 to C_2 and fixes the phase φ is given by the last term of Eq. 7. Let this perturbation work during a characteristic time τ. So long as τ is large enough compared with the time scale during which the position determining experimental observation can be made, the states indicated in Fig. 11 a) and b), and the similar ones in Fig. 5 become meaningfull. The curious distributions of the odd electron density or the spin density shown in Fig. 5 are to be understood as an event taking place in the characteristic time τ. In other words, we may imagine that during this time the solvent molecules are located near the positions 3 and 6. If τ is quite small, we would observe time averaged uniform distributions for the charge and spin densities. Such consideration plays an important role in the analysis of the observed ESR spectra of this ion.[14]

Finally we stress that the negative spin densities at sites 3 and 6 induced by the strong electron interaction are interesting, because it makes an excellent contrast to the case of the single electron theories.

Appendix

In this appendix we derive Eq. 27 for the total energy.[15] First, the Hamiltonian (Eqs. 5—7) are re-written as

$$H_{el} = H_1 + H_2, \tag{48}$$

where

$$H_1 = -\beta\sum_{r,\sigma}(a^+_{r\sigma}a_{r+1\sigma}+\text{h.c.}) + \frac{1}{2}\Delta\alpha\sum_{r,\sigma}n_{r\sigma}(\delta_{r,3}+\delta_{r,6}) + g\sum_{r,\sigma}Q_r n_{r\sigma}, \tag{49}$$

$$H_2 = \frac{1}{2}I\sum_{r,\sigma}n_{r\sigma}n_{r-\sigma}. \tag{50}$$

The expectation value of H_1 is expressed as

$$\langle H_1\rangle = -i[-\beta\sum_{r,\sigma}\{G^{\sigma}_{r+1,r}(t)+G^{\sigma}_{r-1,r}(t)\} + \sum_{r,\sigma}(gQ_r+\frac{1}{2}\Delta\alpha(\delta_{r,3}+\delta_{r,6})G^{\sigma}_{r,r}(t)]_{t\to 0^-}. \tag{51}$$

The expectation value of H_2 is written as

$$\langle H_2\rangle = \frac{1}{2}I\sum_{r,\sigma}\langle a^+_{r\sigma}a^+_{r-\sigma}a_{r-\sigma}a_{r\sigma}\rangle. \tag{52}$$

Comparing Eq. 52 with Eqs. 28 and 29, we obtain

$$\langle H_2\rangle = -\frac{i}{2}\sum_{r,\sigma}[(i\frac{\partial}{\partial t}-gQ_r-\Delta\alpha\delta_{r,6})G^{\sigma}_{r,r}(t) + \beta\{G^{\sigma}_{r+1,r}(t) + G^{\sigma}_{r-1,r}(t)\}]_{t\to 0^-}. \tag{53}$$

Adding Eqs. 51, 53, and the elastic energy Eq. 8, we obtain Eq. 27.

ESR Spectra of Benzene Anion

Minoru KIMURA,† Hiroyuki KAWABE, Kiyoshi NISHIKAWA, and Shigeyuki AONO*
†*Department of Physics, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa 920*
Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa 920
(Received April 27, 1985)

Based on the spin density calculated in our previous paper,[1] the ESR spectra of the benzene anion (exactly the dihydrophenylide ion) are analyzed by the Bloch equation. A hyperfine spectrum broader than those of usual aromatic radicals attributes to the chemical exchange process that the ion in question surrounded by solvent molecules undergoes a rotational motion characterized by the time τ which is the life time of chemical exchange. The line shape for each hyperfine spectrum is given in terms of $1/T_2$ and τ under the condition of $\tau/T_2 \ll 1$.

It is an old story that, in the liquid state, the ESR spectra of the benzene anion were considerably broader[2] than those of usual aromatic radicals with less symmetric character as naphthalene anion (dihydronaphthylide ion). The similar phenomena have been observed in coronene and triphenylene,[2] which suggest that the unusual broad lines may be associated with the Jahn-Teller distortion. The normal states of those ions would be orbitally degenerate if the original symmetries of the parent molecules were retained. If the vibronic interaction is introduced to this system, the orbital degeneracy will be removed and the lattice distortion should arise (the Jahn-Teller effect). McConnell and McLachlan[3] have studied this in such a way that the electronic part is based on the Hückel approximation and the vibronic part is considerably elaborated. In our previous paper,[1] we have investigated the same problem by the Hubbard Hamiltonian with the vibronic interaction (including the dominant part of electron correlation). Both results agree with each other in the limitting case of the electron correlation being negligible. However, the latter demonstrates the important effect of the electron correlation which causes the negative spin densities at opposing corners of the benzene anion. In the second half of their paper,[3] McConnell and McLachlan discussed about the broad lines from the view points of chemical exchange briefly and only qualitatively. The main purpose of the present paper is to analyze the line shape in more detail, using the Bloch equation with chemical exchange.

A deutrium substitution of a hydrogen has been used in order to lift experimentally the orbital degeneracy. In this way, the complicated but sometimes well resolved spectra have been observed not only for the benzene anion[4] but also for more complicated radicals.[5] We consider that these observations partly support the chemical exchange mechanism with the reduction of symmetry due to the Jahn-Teller distortion for the unusual broad line.

Line Shape Analysis of Bloch Equation with Chemical Exchange

Let us consider the Bloch equation for some conformation X which appears during the chemical exchange process,[6]

$$\frac{dG_X}{dt} + \eta_X G_X = -i\omega_1 M_0, \tag{1}$$

where

$$G_X = u_X + iv_X,$$
$$\eta_X = \frac{1}{T_2} - i(\Delta\omega + \omega_X), \tag{2}$$

and u and v are the in-phase and out-of-phase magnetization. The latter being responsible for the absorption process, we are interested in the imaginary part of G. And $\omega_1 = \gamma_e H_1$, γ_e is the gyromagnetic ratio of electron, H_1 is the magnitude of the applied microwave field, assuming no saturation, $M_0 \approx M_z$, M_z is the static magnetization along the direction of the external field, T_2 is the transverse relaxation time without taking into account of chemical exchange, ω_X is the hyperfine shift due to proton, $\Delta\omega = \omega_0 - \omega$ with $\omega_0 = \gamma_e H_0$, H_0 is the intensity of the external field along the z-axis and ω is the frequency.

Equation 1 gives the result,

$$G_X(t) = -\frac{i\omega_1 M_0}{\eta_X}\{1 - \exp(-\eta_X t)\} + G_X^0 \exp(-\eta_X t), \tag{3}$$

where

$$G_X^0 = G_X(t=0). \tag{4}$$

Assuming the characteristic time τ_X for the conformation X, we have the time average of $G_X(t)$ as,

$$\bar{G}_X = \frac{1}{\tau_X}\int_0^\infty G_X(t) \exp(-t/\tau_X) dt$$
$$= -\frac{i\omega_1 M_0}{1+\eta_X \tau_X} + \frac{G_X^0}{1+\eta_X \tau_X}. \tag{5}$$

In order to relate $\bar{G}_X$ with the observation we have to average over all possible values of G_X^0. The value of G_X^0 depends on the immediate past of the system. If the molecular conformation changes to the conformation X from the conformations I's with the probabilities ρ_I's, it follows that

$$\langle G_X^0 \rangle = \sum_I{}' \rho_I \langle \bar{G}_I \rangle, \tag{6}$$

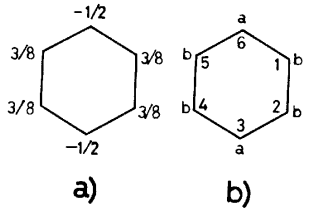

Fig. 1. Spin distribution in the benzene anion. a): Strong correlation limit, b): General case. The numbers indicate the site.

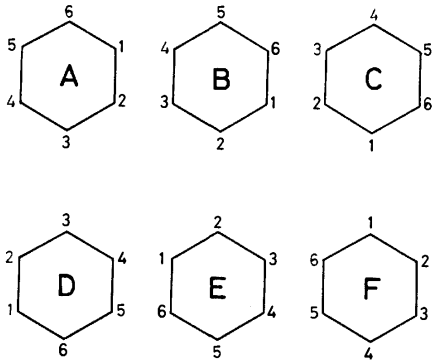

Fig. 2. Various orientations of the benzene anion. The conformations *A*—*F* appear with the rotational motion of anion. The numbers indicate the sites and the spin densities are *a* at the sites 3 and 6, and *b* at the other sites.

but the summation with a prime is restricted to the immediate past conformations for *X*. From Eqs. 5 and 6 we get the following relation,

$$\langle\bar{G}_X\rangle = -\frac{i\omega_1 M_0}{1+\eta_X\tau_X} + \frac{1}{1+\eta_X\tau_X}\sum_I{}'\rho_I\langle\bar{G}_I\rangle. \tag{7}$$

This procedure of incorporating the second term corresponds to including chemical exchange. The actual observation can be interpreted from

$$\langle G\rangle = \sum_X P_X\langle\bar{G}_X\rangle, \tag{8}$$

where P_x is the existing probability of conformation *X* and the summation is over the all possible conformations.

Physical Model

In our previous paper,[1] we obtained for the benzene anion the state in which the spin distribution is shown in Fig. 1a (the strong correlation limit) and in Fig. 1b (general case). As was stressed there, these are the cases that the anion is fixed for a characteristic time τ by the solvent effect. We assume that the anion rotates from time to time to take various orientations as shown in Fig. 2 and each conformation has the same characteristic time τ and the same probability of existance, namely, $P_x=1/6$.

Look at the conformation A in Fig. 2. The immediate past history of this conformation should be either B or F, each of which changes into A with the same probability 1/2. Therefore. Eq. 7 becomes

$$\langle\bar{G}_A\rangle = -\frac{i\omega_1 M_0\tau}{1+\eta_A\tau} + \frac{\langle\bar{G}_B\rangle+\langle\bar{G}_F\rangle}{2(1+\eta_A\tau)}, \tag{9}$$

which is abbreviated as

$$g_A + c_A(g_B+g_F) = d_A \tag{10}$$

where

$$g_A = \langle\bar{G}_A\rangle,$$
$$c_A = -\frac{1}{2(1+\eta_A\tau)},$$
$$d_A = -\frac{i\omega_1 M_0\tau}{1+\eta_A\tau}. \tag{11}$$

For the other conformations similar equations hold. They are altogether written in matrix form as

$$\begin{bmatrix} g_A \\ g_B \\ g_C \\ g_D \\ g_E \\ g_F \end{bmatrix} = \begin{bmatrix} 1 & c_A & 0 & 0 & 0 & c_A \\ c_B & 1 & c_B & 0 & 0 & 0 \\ 0 & c_C & 1 & c_C & 0 & 0 \\ 0 & 0 & c_D & 1 & c_D & 0 \\ 0 & 0 & 0 & c_E & 1 & c_E \\ c_F & 0 & 0 & 0 & c_F & 1 \end{bmatrix}^{-1} \begin{bmatrix} d_A \\ d_B \\ d_C \\ d_D \\ d_E \\ d_F \end{bmatrix}, \tag{12}$$

and $\langle G\rangle$ related to the actual observation can be obtained by

$$\langle G\rangle = \frac{1}{6}\sum_X g_X. \tag{13}$$

From Eqs. 12 and 13 we obtain

$$\langle G\rangle = \frac{1}{6}\frac{1}{\det}\sum_X d_X F_X, \tag{14}$$

where

$$\det = \begin{vmatrix} 1 & c_A & 0 & 0 & 0 & c_A \\ c_B & 1 & c_B & 0 & 0 & 0 \\ 0 & c_C & 1 & c_C & 0 & 0 \\ 0 & 0 & c_D & 1 & c_D & 0 \\ 0 & 0 & 0 & c_E & 1 & c_E \\ c_F & 0 & 0 & 0 & c_F & 1 \end{vmatrix},$$

$$F_A = 1 - c_B - c_F - c_C c_D - c_D c_E + c_B(c_D c_E + c_E c_F) + c_F(c_B c_C + c_C c_D) + c_B c_C c_D c_E - c_E c_F(c_B c_C - c_C c_D) - 2c_B c_C c_D c_E c_F. \tag{15}$$

In obtaining F_B—F_F, we need only the cyclic permutation of suffixes in the second formula in Eq. 15, step by step.

Now we turn to evaluate the hyperfine shifts.

(1) I_Z=3: Every protons have the up spin.

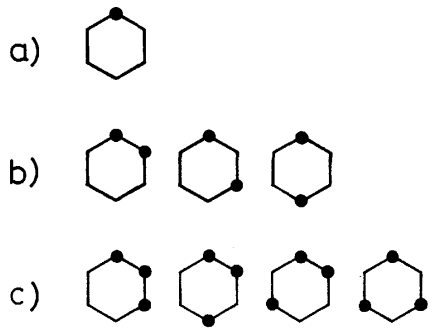

Fig. 3. Irreducible patterns. The solid circles indicate the sites to which the protons with down spin link.
a): For $I_z=2$, b): For $I_z=1$, c): For $I_z=0$.

In this case, every conformations designated by A—F in Fig. 2 have the same proton hyperfine shift. *i.e.*,

$$\omega_A = \omega_B = \omega_C = \omega_D = \omega_E = \omega_F = 2a + 4b \quad [1],$$

where we omit the multiplicative constant, Q ($\approx$23 G, 1 G=10^{-4} T), for simplicity, a is the spin density at the sites 3 and 6, b at the other sites and the number in the square bracket indicates the degeneracy number.

(2) $I_Z=2$: One of the six protons has the down spin.

This case is displayed by the irreducible pattern shown in Fig. 3a. Combining this with the patterns shown in Fig. 2, we obtain

$$\omega_A = \omega_D = 4b,$$
$$\omega_B = \omega_C = \omega_E = \omega_F = 2a + 2b \quad [6].$$

(3) $I_Z=1$: Two of the six protons have the down spin.

This case is classified into three subcases as displayed by the irreducible patterns shown in Fig. 3b. The hyperfine shift will be calculated for each,

$$\text{(3a)} \quad \omega_A = \omega_B = \omega_D = \omega_E = 2b,$$
$$\omega_C = \omega_F = 2a \quad [6],$$
$$\text{(3b)} \quad \omega_A = \omega_C = \omega_D = \omega_F = 2b,$$
$$\omega_B = \omega_E = 2a \quad [6].$$
$$\text{(3c)} \quad \omega_B = \omega_C = \omega_E = \omega_F = 2a,$$
$$\omega_A = \omega_D = -2a + 2b \quad [6].$$

(4) $I_Z=0$: A half of the six protons have the down spin.

This case has four subcases which are displayed in Fig. 3c. The hyperfine shift is expressed as follows

$$\text{(4a)} \quad \omega_A = \omega_B = \omega_C = \omega_D = \omega_E = \omega_F = 0 \quad [6],$$
$$\text{(4b)} \quad \omega_A = \omega_D = -2a + 2b,$$
$$\omega_B = \omega_E = 0,$$
$$\omega_C = \omega_F = 2a - 2b \quad [6],$$
$$\text{(4c)} \quad \omega_A = \omega_D = 0,$$
$$\omega_B = \omega_E = -2a + 2b,$$
$$\omega_C = \omega_F = 2a - 2b \quad [6],$$
$$\text{(4d)} \quad \omega_A = \omega_B = \omega_C = \omega_D = \omega_E = \omega_F = 0 \quad [2].$$

Line Shape

In order to obtain the line shape for every hyperfine components, it is convenient to re-classify the above mentioned cases as follows.

Group 1: $\omega_A=\omega_B=\omega_C=\omega_D=\omega_E=\omega_F$.

This group consists of the three cases (1), (4a), and (4d). We calculate $\langle G\rangle$ by Eq. 14, and obtain

$$\langle G\rangle = \frac{d}{(1+2c)}, \tag{16}$$

where we used the relation

$$c = c_A = c_B = c_C = c_D = c_E = c_F,$$
$$d = d_A = d_B = d_C = d_D = d_E = d_F. \tag{17}$$

Substituting Eqs. 1 and 11 into Eq. 16, we have

$$\langle G\rangle = \frac{1}{(1/T_2)^2+(\Delta\omega+\omega_A)^2}\left\{-\omega_1 M_0 \Delta\omega + i\omega_1 M_0 \frac{1}{T_2}\right\}, \tag{18}$$

of which the imaginary part is

$$v = \frac{\omega_1 M_0/T_2}{(1/T_2)^2+(\Delta\omega+\omega_A)^2}. \tag{19}$$

Thus we get a Lorentzian line shape with the resonance frequency $\Delta\omega$, the peak height v_{peak} and the natural width $\Delta\omega_{1/2}$ given by

$$\Delta\omega = -\omega_A,$$
$$v_{peak} = \omega_1 M_0 T_2,$$
$$\Delta\omega_{1/2} = \frac{1}{T_2}. \tag{20}$$

Group 2: $\omega_A=\omega_D$, $\omega_B=\omega_C=\omega_E=\omega_F$.

This group consists of the two cases (2) and (3c). In the present case we have

$$\langle G\rangle = \frac{1}{6}\left\{\frac{2d_A(1-c_B)+4d_B(1-c_A)}{1-2c_Ac_B+c_B}\right\}. \tag{21}$$

Thus

$$v = \frac{-\omega_1 M_0\{1/T_2+4/27\cdot(\omega_A-\omega_B)^2\tau\}}{\{1/T_2-2/3\cdot(\Delta\omega+\omega_A)(\Delta\omega+\omega_B)\tau\}^2+\{\Delta\omega+1/3\cdot(\omega_A+2\omega_B)\}^2}. \tag{22}$$

In getting this result, we have assumed $\tau/T_2 \ll 1$, since $\tau\approx10^{-10}$ s[7] and for free radicals in solution the natural width of resonance lines is typically $\approx$0.1 G,[8] which is correspond to $T_2\approx10^{-6}$ s.

We proceed further by carrying out an approximate calculation. Obviously we have a resonance line around $\Delta\omega=-\omega_A$ where v takes the value given by

$$v_{\text{peak}} = -\omega_1 M_0 \left[\frac{1/T_2 + 4/27 \cdot (\omega_A - \omega_B)^2 \tau}{(1/T_2)^2 + 4/9 \cdot (\omega_A - \omega_B)^2} \right]. \quad (23)$$

Noting that $\omega_A - \omega_B \approx 10^7\ \text{s}^{-1}$, $\tau(\omega_A - \omega_B) \approx 10^{-3}$ and $\tau/T_2 \approx 10^{-4}$, we have $v_{\text{peak}} \fallingdotseq -\omega_1 M_0/(3/\tau)$. The corresponding half width being $3/\tau$, we add this to the natural width $1/T_2$ to obtain

$$v_{\text{peak}} = \frac{-\omega_1 M_0}{3/\tau + 1/T_2},$$
$$\Delta\omega_{1/2} = \frac{3}{\tau} + \frac{1}{T_2}. \quad (24)$$

In the same way, we obtain the corresponding expressions for another resonance at $\Delta\omega = -\omega_B$

$$v_{\text{peak}} = \frac{-\omega_1 M_0}{3/4\tau + 1/T_2},$$
$$\Delta\omega_{1/2} = \frac{3}{4\tau} + \frac{1}{T_2}. \quad (25)$$

and for the one at $\Delta\omega = -(\omega_A + 2\omega_B)/3$,

$$v_{\text{peak}} = \frac{-\omega_1 M_0}{4/27 \cdot (\omega_A - \omega_B)^2 \tau + 1/T_2},$$
$$\Delta\omega_{1/2} = \frac{4}{27}(\omega_A - \omega_B)^2 \tau + \frac{1}{T_2}. \quad (26)$$

Group 3: $\omega_B = \omega_E$, $\omega_A = \omega_C = \omega_D = \omega_F$.

This group consists of the single case (3b). Various lines belonging to this group can be described by interchanging suffixes A and B of Eqs. 24—26, that is,

$$\Delta\omega = -\omega_B,$$
$$v_{\text{peak}} = \frac{-\omega_1 M_0}{3/\tau + 1/T_2},$$
$$\Delta\omega_{1/2} = \frac{3}{\tau} + \frac{1}{T_2}, \quad (27)$$

and

$$\Delta\omega = -\omega_A,$$
$$v_{\text{peak}} = \frac{-\omega_1 M_0}{3/4\tau + 1/T_2},$$
$$\Delta\omega_{1/2} = \frac{3}{4\tau} + \frac{1}{T_2}, \quad (28)$$

and

$$\Delta\omega = -\frac{1}{3}(\omega_B + 2\omega_A),$$
$$v_{\text{peak}} = \frac{-\omega_1 M_0}{4/27 \cdot (\omega_B - \omega_A)^2 \tau + 1/T_2},$$
$$\Delta\omega_{1/2} = \frac{4}{27}(\omega_B - \omega_A)^2 \tau + \frac{1}{T_2}. \quad (29)$$

Group 4: $\omega_C = \omega_F$, $\omega_A = \omega_B = \omega_D = \omega_E$.

This group also consists of the single case (3a). In this case, replacing B in the equations obtained in Group 3 by C, we obtain

$$\Delta\omega = -\omega_C,$$
$$v_{\text{peak}} = \frac{-\omega_1 M_0}{3/\tau + 1/T_2},$$
$$\Delta\omega_{1/2} = \frac{3}{\tau} + \frac{1}{T_2}, \quad (30)$$

and

$$\Delta\omega = -\omega_A,$$
$$v_{\text{peak}} = \frac{-\omega_1 M_0}{3/4\tau + 1/T_2},$$
$$\Delta\omega_{1/2} = \frac{3}{4\tau} + \frac{1}{T_2}, \quad (31)$$

and

$$\Delta\omega = -\frac{1}{3}(\omega_C + 2\omega_A),$$
$$v_{\text{peak}} = \frac{-\omega_1 M_0}{4/27 \cdot (\omega_C - \omega_A)^2 \tau + 1/T_2},$$
$$\Delta\omega_{1/2} = \frac{4}{27}(\omega_C - \omega_A)^2 \tau + \frac{1}{T_2}. \quad (32)$$

Group 5: $\omega_A = \omega_D$, $\omega_B = \omega_E$, $\omega_C = \omega_F$.

This group consists of the two cases (4b) and (4c). In a similar way as used in the previous cases, we obtain

$$\langle G \rangle = \frac{1}{3} \frac{[d_A(1 - c_B - c_C + c_B c_C) + d_B(1 - c_C - c_A + c_C c_A) + d_C(1 - c_A - c_B + c_A c_B)]}{(1 - c_A c_B - c_B c_C - c_C c_A + 2 c_A c_B c_C)}. \quad (33)$$

Thus

$$v = \frac{-\omega_1 M_0 [1/T_2 + 4\tau/9 \cdot W(\Delta\omega)]}{[1/T_2 + 4\tau/9 \cdot X^2(\Delta\omega)]^2 + 1/9 \cdot Y^2(\Delta\omega)}, \quad (34)$$

where

$$X^2(\Delta\omega) = \Delta_A\Delta_B + \Delta_B\Delta_C + \Delta_C\Delta_A,$$
$$Y(\Delta\omega) = \Delta_A + \Delta_B + \Delta_C, \quad (35)$$

with the abbreviations of, for example,

$$\Delta_A = \Delta\omega + \omega_A,$$
$$W(\Delta\omega) = X^2(\Delta\omega) - \frac{1}{3}Y^2(\Delta\omega)$$
$$= \Delta_A\Delta_B + \Delta_B\Delta_C + \Delta_C\Delta_A - \frac{1}{3}(\Delta_A + \Delta_B + \Delta_C)^2. \quad (36)$$

Resonance lines will appear at the frequencies obtained from $X^2(\Delta\omega) = 0$ and $Y^2(\Delta\omega) = 0$.

In the latter case, the situation is rather simple and we obtain

$$\Delta\omega = -\frac{1}{3}(\omega_A + \omega_B + \omega_C),$$
$$v_{\text{peak}} = \frac{-\omega_1 M_0}{1/T_2 + 4\tau/9 \cdot W(\Delta\omega)},$$

$$\Delta\omega_{1/2} = \frac{1}{T_2} + \frac{4\tau}{9} W(\Delta\omega). \tag{37}$$

In the former, we begin with solving $X^2(\Delta\omega)=0$ and obtain two solutions,

$$\begin{aligned}\Delta\omega &= \omega_+ \text{ and } \omega_- \\ &= -(\omega_A+\omega_B+\omega_C) \\ &\quad \pm \sqrt{(\omega_A+\omega_B+\omega_C)^2 - 1/3\cdot(\omega_A\omega_B+\omega_B\omega_C+\omega_C\omega_A)}.\end{aligned} \tag{38}$$

At $\Delta\omega=\omega_+$ for example, we have

$$v_{\text{peak}} = \frac{-\omega_1 M_0[1/T_2+4\tau/9\cdot W(\omega_+)]}{(1/T_2)^2+1/9\cdot Y^2(\omega_+)}. \tag{39}$$

Employing the approximate procedure to obtain Eq. 24, we get

$$\begin{aligned}&\Delta\omega = \omega_k \quad (k \text{ is } + \text{ or } -.), \\ &v_{\text{peak}} = \frac{-\omega_1 M_0}{Y^2(\omega_k)/[4\tau W(\omega_k)]+1/T_2}, \\ &\Delta\omega_{1/2} = \frac{Y^2(\omega_k)}{4\tau W(\omega_k)} + \frac{1}{T_2}.\end{aligned} \tag{40}$$

We should like to emphasize that there are three kinds of lines from the view point of the τ dependence. The first one has the peak height which is independent of τ, as given in Eq. 20, the second one is given by Eqs. 26, 29, 32, and 37, roughly speaking, v_{peak} is inversely proportional to τ and the third one is given by Eqs. 24, 25, 27, 28, 30, 31, and 40, v_{peak} is inversely proportional to τ^{-1}, namely proportional to τ. Let us consider the usual (high temperature) case. Although the value of τ becomes smaller and smaller with increasing temperature, the line shape of the first one is temperature independent, while in the second one the line shape is determined mainly by $1/T_2$ and the third one disappears.

Numerical Analysis and Discussions

In order to help our understanding, we deal with the high temperature limit. *i.e.*, $\tau=0$. In this case, the resonance lines of which peak heights are independent of τ and are inversely proportional to τ will appear. From Eqs. 19 and 26 we can see $\Delta\omega=1/T_2$ and $v_{\text{peak}}=-\omega_1 M_0 T_2$ by putting $\tau=0$. Therefore, the peak heights are determined by the number of degeneracy. In Table 1 the groups in the previous section, the resonance frequencies and the degeneracy numbers are listed. Obviously the peak heights for each resonance line are described by the binomical coefficients and the resonance frequencies are equally spaced. Note that as seen from Fig. 1b 2a+4b is the total spin density. Therefore, in the high temperature limit the spaces are independent of the spin density distribution.

For various values of τ, we can simulate the line shapes as shown in Figs. 4 and 5. We can see how the

a) ω_R is the resonance frequency, Q is the constant which relate the spin density to the hyperfine splitting, so ω_R/Q is the resonance frequency in Q unit and D is the number of degeneracy.

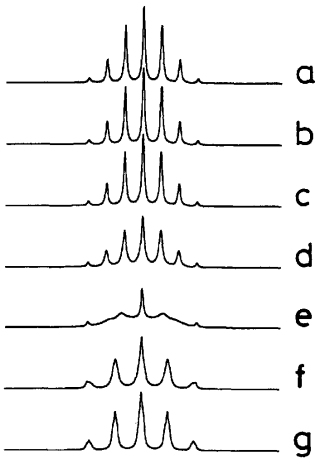

Fig. 4. Line shapes. $T_2=1.0\times10^{-6}$ s, $a=0.24$, $b=0.005$. a): $\tau=1.0\times10^{-12}$ s, b): $\tau=1.0\times10^{-11}$ s, c): $\tau=1.0\times10^{-10}$ s, d): $\tau=1.0\times10^{-9}$ s, e): $\tau=1.0\times10^{-8}$ s, f): $\tau=1.0\times10^{-7}$ s, g): $\tau=1.0\times10^{-6}$ s.

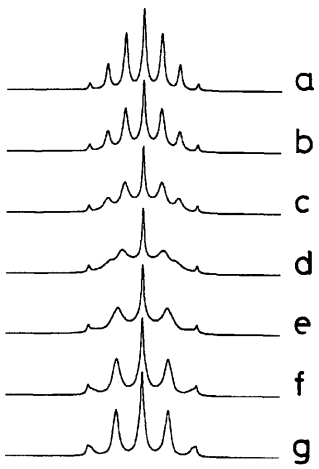

Fig. 5. The qualitative change of line shapes. $T_2=1.0\times10^{-6}$ s, $a=0.24$, $b=0.005$. a): $\tau=1.25\times10^{-9}$ s, b): $\tau=2.5\times10^{-9}$ s, c): $\tau=5.0\times10^{-9}$ s, d): $\tau=1.0\times10^{-8}$ s, e): $\tau=2.0\times10^{-8}$ s, f): $\tau=4.0\times10^{-8}$ s, g): $\tau=8.0\times10^{-8}$ s.

line shapes change as the values of τ are increased: The different behaviors of three type of lines as mentioned in the last part of the previous section are discernible. Under the condition of $\tau/T_2 \ll 1$ (the cases Figs. 4a—d), the lines whose intensities are proportional to τ hardly appear. This should correspond to the actual experiment.[2] The extremely narrow lines with $\tau=10^{-12}$ s in Fig. 4a are such ones as observed in the aromatic anions of the less symmetry, *e.g.*, naphthalene anion. The lines in Fig. 4c or Fig. 4d which correspond to $\tau=10^{-10}$ or 10^{-9} s, respectively, have considerable likeliness with the observed ones. We can guess that the benzene anion tumbles in this time scale in solution.

As τ gets larger, the lines which are neglected in the case of $\tau \fallingdotseq 0$ are seen. This makes the line structure complicated and results in the apparent broad lines as seen in Figs. 4e—g. Note that in computer simulation line shapes are directly described without the condition of $\tau/T_2 \ll 1$. From Figs. 4f and 4g, we can see patterns which are qualitatively different from Figs. 4a—e. The last three cases have not been observed in experiments yet. The transient patterns in this change are shown in Fig. 5. Here we can observe that the second line from the edge is gradually disappearing.

(Received May 2, 1985)

A Chemically Induced Dynamic Electron Polarization (CIDEP) signal of 1,4-naphthosemiquinone (NQH·) was examined by intermittent-light irradiation to a system of 1,4-naphthoquinone (NQ) and phenol (PhOH) in toluene–2-propanol (2:3), toluene–ethanol (2:3), and neat 2-propanol. The enhancement factors of the initial polarization and the F-pair polarization of the systems were determined separately. From the unusual pattern of a time profile of the ESR signal with a CIDEP phenomenon observed on the photoirradiated NQ–PhOH system in ethanol, it is concluded that in ethanol the photoexcited NQ first abstracts a hydrogen to give NQH·, then NQH· releases a proton to form NQ^-.

Quinones are important compounds in biochemistry, especielly as a component of an acceptor or a carrier of electrons in an electron-transport system in photosynthesis. The photochemistry of quinones in alcohols has been extensively investigated. The primary process has been generally considered to be that of hydrogen abstraction from a solvent by photoexcited quinones. But, the anionic mechanism for the photoreduction of *p*-benzoquinone to the hydronquinone was proposed by Yoshida *et al.*[1] They also reported that when 1,4-naphthoquinone (NQ) in ethanol is photoirradiated, the ESR signal of two types of radicals, *i.e.* semiquinone anion (NQ^-) and semiquinone neutral radical (NQH·), are observed at the same time.[2] Each of these radicals is known to exhibit strong signals due to Chemically Induced Dynamic Electron Polarization (CIDEP) by selecting the conditions of their formation.[3–5]

In a previous paper,[6] we treated a system of duroquinone and phenol (PhOH) in neat 2-propanol or in various organic solvents mixed with 2-propanol and detected the CIDEP signal of durosemiquinone (using a sector system and the usual ESR spectometer with a 100 kHz field modulation). In this paper, we report on a separate determination of the initial polarization (V^I) and the F-pair polarization (V^F) of NQH· which is produced photochemically from NQ and PhOH in a mixed solvent of alcohols and toluene and in neat 2-propanol. We also report on the reaction mechanism of the photoreduction of NQ with PhOH in alcohols (ethanol and 2-propanol) by taking advantage of a CIDEP phenomenon observed on its semiquinone.

Experimentals

Materials. NQ (Nakarai Chemical Co., G. R. grade) was refined by a sublimation method after being recrystallized from methanol. PhOH, ethanol and 2-propanol (Wako Junyaku, G. R. grade) were used without further purification.

Procedures. The concentrations of NQ and PhOH in alcohols were fixed to 0.05 (or sometimes 0.08) and 2.0 mol dm^{-3}, respectively. The temperature upon irradiation was −40 °C. The CIDEP observation system was almost the same as that used in a previous paper[6] except that a Boxcar integrator (NF Model BX-531 with PB-10 Sampling unit) online with a microcomputer (NEC PC-8001) and a plotter (Watanabe Model WX-4675) were used instead of a minicomputer (JEOL EC-6) and the recorder used in the previous study, respectively. The electronic absorption spectra were taken with a Hitachi 228 double-beam spectrophotometer.

Results and Discussion

Aspects of Absorption Spectra. In order to observe the outline of the photoreaction of NQ in alcohols, the absorption spectra of the systems and their change upon irradiation were observed. A typical example is shown in Fig. 1-a. The difference spectrum (spectrum (4)) obtained from the spectrum (1) (0.05 mol dm^{-3} NQ and 2.0 mol dm^{-3} PhOH in 2-propanol) and (2) (0.05 mol dm^{-3} NQ in 2-propanol) has a new peak at 360 nm. This indicates that an interaction takes place between NQ and PhOH in their ground states. When the light from a high-pressure mercury lamp was irradiated without a filter, the absorption spectrum of the 2-propanol solution containing NQ and PhOH changed with isosbestic points at 346 and 402 nm. Except for the unknown weak band appearing at 420—430 nm, the general feature of the spectral change reflected a decrease of NQ, accompanied with an increase of dihydronaphthoquinone or naphthalenediol (NQH_2), as shown in Fig. 1-b.

ESR Spectra and Its Time Profile. Some examples of the observed ESR spectra are shown in Fig. 2. When 2-propanol was used as a solvent, only the NQH· signal was observed in the photostationary state in cases with or without PhOH. When ethanol was used, the NQ^- signal was detected overlapping that of NQH·. Especially, in the system containing PhOH, the NQ^- signal predominated. The hf coupling constants of protons were determined to be 0.324 mT (2H) and 0.064 mT (4H) for NQ^- and 0.701 mT (1H) and 0.174 mT (3H) for NQH·. These values are consistent with those in the literatures[2,7] within the error limit. The time profile of the ESR signal was observed at magnetic fields fixed at several points along the resonance line. Typical examples are given in Fig. 3 for a NQ

and PhOH system in a toluene–2-propanol (2:3) mixed solvent. The fixed position of the magnetic field is pointed out by the arrows above the ESR spectrum in the figure. Since we chose 0.2 mT (or sometimes 0.08 mT) as the field-modulation width, the spectrum of NQH· formed a doublet of quartet with a broad linewidth and that of NQ^- also became a broad triplet. At the end of the light-ON period, a steady state condition regarding radical concentration was achieved. The zero level of the signal intensity was determined by an analysis of the decay curve.[8]

The Enhancement Factor for NQH· Radical.
Three kinds of solvent systems, *i.e.* toluene–2-propanol (2:3), toluene–ethanol (2:3) and neat 2-propanol systems, were used for the determination of the enhancement factors V^I and V^F. It is noteworthy that no NQ^- signal was detected in the solvent systems containing toluene. V^I and V^F were calculated as follows.[8] First, I and I_0 were taken from the pettern in the figure as the difference between the zero level and level e, and that between the zero level and level a, respectively. The dimensionless quantity V' was defined to be $(I-I_0)/I_0$. This is represented as Eq. 1 by using V^I (net effect) and V^F (multiplet effect),

$$V' \equiv \frac{I-I_0}{I_0} = \frac{V^I}{1+V^F} \tag{1}$$

As the signal of NQH· radical had no hf line at the center of the spectrum, V^I and V^F were obtainied by using Eq. 2.

$$\left.\begin{aligned} V^I &= 2\left(\frac{1}{V'(n)} - \frac{1}{V'(n')}\right)^{-1} \\ \bar{V}^F(n) &= \frac{\dfrac{1}{V'(n)} - \dfrac{1}{V'(n')}}{\dfrac{1}{V'(n)} + \dfrac{1}{V'(n')}} \end{aligned}\right\} \tag{2}$$

Here, n and n' are the numbers assigned to a pair of hf lines at the symmetric and mutually opposite positions to the center of the spectrum. $V'(n)$ is the value of V' at line n. $\bar{V}^F(n)$ is the mean value of $|V^F(n)|$ and $|V^F(n')|$, and was derived on the condition that $V^F(n) = -V^F(n')$. The time profile was observed at eight field points, each of which corresponded to the maximum or the minimum of hf lines 2, 3, 3′, and 2′, in Fig. 3. The velue of V' was found to be larger at higher field lines. This indicates the presence of a contribution from E/A type F-pair polarization in addition to initial polarization. By the method mentioned above, V^I and V^F values were separately estimated for three solvent systems containing 2.0 mol dm^{-3} PhOH, as listed in Table 1. These values are, however, the apparent enhancement factors. In order to obtain V^I values which can be compared with the values for other solvent systems, the corrections for the radical halflife $t_{1/2}$ and for the spin-lattice relaxation time of the radical T_1 must be made.[9,10] $t_{1/2}$ was evaluated from an

analysis of the decay curve after light-OFF in Fig. 3.[8] As T_1 was considered to be independent of a solvent, $\bar{V}^I_{av}$ $t_{1/2}$ values were calculated and were found to be in good agreement among three solvent systems (see Table 1). When toluene is mixed with the solvent, the viscosity decreases. Consequently, the radical lifetime $t_{1/2}$ becomes shorter. The fact results in an observation of the larger V' (Table 1). Further the intrinsic $\bar{V}^I_{av}t_{1/2}$ value was determined in a toluene-2-propanol system to be 7.1 ms by extrapolating the concentration of PhOH to infinite,[9] as shown in Fig. 4. If we borrow a T_1 value of $\approx$10 μs from the data by Frydkjear and Muus,[5] the intrinsic enhancement factor V^{∞}_{int} is calculated to be -7.1×10^2. According to the Eq. 14 of the previous paper,[6] (DK+3EI)$=-0.3\,cm^{-1}$ is obtained. Here, D and E are zero-field splitting constants, and K and I are parameters showing anisotropy of $S_1\rightarrow T_n$ intersystem crossing rate. (S_1: the excited singlet state, T_n: the n'th excited triplet state). Although the value is based on many assumptions, it seems to be reasonable and be in good agreement with the date obtained by Murai *et al.*[11] They estimated the D and E of the 1,4-naphthoquinone triplet state to be −0.330 and $0.019\,cm^{-1}$, respectively, by observing the time-resolved ESR spectrum of the triplet state in glassy matrices at 77 K. The longitudinal relaxation time $^3T_1$ of the triplet NQ was estimated to be 13 ns from the slope of the plot in Fig. 4, using the value of k_q (the NQ triplet quenching rate constant by PhOH)$=0.58\times10^8$ $mol^{-1}\,dm^3\,s^{-1}$.[12]

V^F values are given in Table 1 as the form of the ratios of $\bar{V}^F/\bar{V}^I_{av}$ to exclude the effect of the exciting light intensity. The ratio of $\bar{V}^F_2/\bar{V}^F_3$ is a little larger than the theoretical one based on the radical pair mechanism[13] ($\approx$1.3 by rough estimation) but is reasonable in comparison with the literature.[5]

Mechanism of Photoreduction in Ethanol. The broad triplet line obtained by the use of the modulation of 0.2 mT was assigned to the signal of a NQ^- radical. To take the time profiles, the magnetic field was fixed at a minimum and a maximum signal points of each resonance line of the derivative curve. All six patterns that were recorded were unusual when we assumed the presence of only one radical species. Among them, two most unusual patterns concerning the central resonance line are shown in Fig. 5. At the field point (1) in Fig. 5-a, the absorption of the photostationary signal is represented by the downward one. If the emission of NQ^- occurs immediately after irradiation, the signal level should move upwards. In addition to this, runs both during light-ON and after light-OFF were not simple. These unusual facts can be understood by considering that in this system, first NQH· is formed and it changes to NQ^- during the time scale of the measurement. The following is an explanation for the observation: the *g*-value of NQ^- is a little larger than

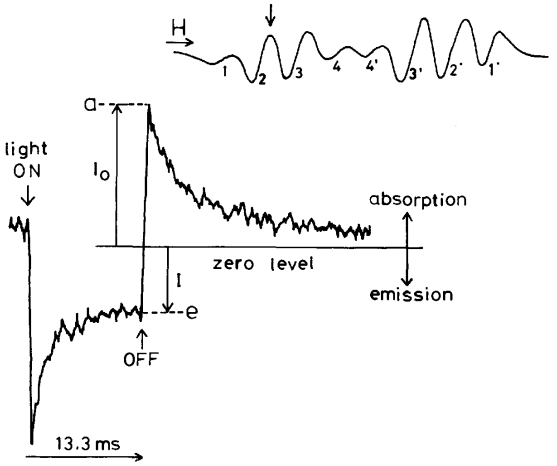

Fig. 3. Time profile of ESR signal intensity observed on NQ and PhOH system in toluene-2-propanol (2:3) mixed solvent.

c: The time profiles extracted from the runs (1) and (2) in b.

that of NQH·; thus, their spectra overlap with each other as shown in Fig. 5-a. The feature of the run was extracted and is depicted in Fig. 5-c. At time t_1, almost all radical species present were the polarized naphthosemiquinone, NQH·*. Thus, this level is only a reflection of the amount of NQH·*. At t_2, the signal level comprizes those from NQH·*, NQH· (in thermal equilibrium) and NQ^- (in thermal equilibrium, produced from NQH·). At t_3, the level is the sum of those of NQH· and NQ^-, both in thermal equilibrium. Thus, the following relation holds for these levels:

$$\text{level}(t_2) - \text{level}(t_1) = \text{level}(t_3) \quad (3)$$

The zero level of this run is determined by Eq. 3, as shown by the horizontal line in the figure. Further, we can infer the time dependence of the formation and disappearance of NQ^- qualitatively. It may be given by the broken line in the figure, if we assume that $V'(\text{NQH}\cdot)=-1$ and the signal intensity ratio of NQH· to NQ^- at t_2 is -1. The circumstances are the same as with those mentioned above in the case of the field position (2), except that the level movement is upside-down (Fig. 5-c).

In order to make clear that NQ^- exhibited no CIDEP signal, we carefully chose a field position where NQH· had a zero signal intensity ((3) in Fig. 5-a) and examined the time profile there. The run had much noise but no CIDEP signal appeared. There was some time-lag before a riseup of the signal and the shape of the signal-decay after light-OFF was also unusual. The facts may support the idea that NQ^- is not formed initially but second in the reaction sequence. Thus, it is concluded that in ethanol photoexcited NQ abstracts a hydrogen atom from PhOH first and changes to NQH··. Then NQH· promptly releases a proton to convert to NQ^-. This is the reason why the NQ^- signal is observed with continuous light irradiation and no CIDEP signal for NQ^- is detected in ethanol. In 2-propanol, NQH· does not release a proton. The difference in the behavior of NQH· might be attributed to the slight difference in the dielectric constants of the two alcohols. The idea is consistent with the fact that no NQ^- signal appeared in a toluene–ethanol system. NQ^- may be more stabilized in a polar media than NQH··. This conclusion is in contrast to that of Wong,[4] who also observed a CIDEP signal of NQH· produced photochemically in 2-propanol or 2-butanol. In his case, the reductant was a solvent. By the addition of pyridine to the solution, NQH· changed to NQ^-, which exhibited no CIDEP signal.

Stopped-flow Studies on Binding of Cu^{2+} Ion to Human Serum Albumin

Naohisa KURE, Thoru NAKATSUKA, Takayuki SANO,* and Tatsuya YASUNAGA
Department of Materials Science, Faculty of Science, Hiroshima University, Naka-ku, Higashisenda-machi, Hiroshima 730
(Received May 11, 1985)

Both static and kinetic investigations have been carried out regarding the interaction between Cu^{2+} and human serum albumin (HSA). The static experiment, using a UV spectrophotometric technique, shows the presence of one primary binding site and other weaker binding sites at pH 5.2. The kinetic experiment, using stopped-flow apparatus, revealed a reaction process on the order of several seconds and a rapid absorbance change within the dead-time of the apparatus. These results are discussed from the viewpoint of the substitution effect of the second residue of the N-terminal position in the protein with reference to the previously reported results for a Cu^{2+}–bovine serum albumin (BSA) system.

The bindig of the Cu^{2+} ion to bovine serum albumin (BSA) and/or human serum albumin (HSA) has been widely studied. Extensive investigations by Peters,[1-5] Breslow,[6] Gurd,[5,7] and Sarker[8-10] revealed that a specific binding site of Cu^{2+} is located at the N-terminal sequence of both albumins (Asp-Thr-His- for BSA and Asp-Ala-His- for HSA), and that the chelation of a Cu^{2+} ion formed at this site involves coordination by α-amino, imidazolyl, and two peptide nitrogens in the neutral pH range. Different types of bound species were also evident at low pH from visible and circular dichroism spectroscopies.[2,6,10] In previous studies of the kinetics of a Cu^{2+}–BSA system,[11] we revealed that one low-pH type complex is also formed at the N-terminal sequence of BSA in competition with a chelation complex. This present report is concerned with a further kinetic study on the binding of a Cu^{2+} ion to serum albumin by using HSA from the viewpoint of the substitution effects of alanin for threonin at the second residue of the N-terminal position in serum albumin.

Experimental

Materials. Human serum albumin (essentially fatty acid-free) was purchased from Sigma Chem. Co. and fractionated on a Sephadex G-150 column to obtain a monomeric form. The concentration of the HSA monomer was determined spectrophotometrically.[12] Solutions of Cu^{2+} ions were produced by direct weighing of anhydrous $CuSO_4$. The pH values of solutions were adjusted by H_2SO_4 and/or KOH, and no pH buffer was added. All measurements were made in a 1-mM† solution of K_2SO_4. Analyticalgrade reagents were used throughout.

Equilibrium Dialysis. The extent of binding was measured using the equilibrium dialysis technique with a dialysis cell (Sanko Plastics Co. type 5044-05) having ten separate chambers. After 70 to 80 h of dialysis at 25 °C, concentration of Cu^{2+} in the dialyzed solutions were determined with a Perkin-Elmer Model 5000 atomic absorption spectrophotometer. The detection limit of this method for the Cu^{2+} concentration was 1.5×10^{-7} M. The pH values of the dialyzed solutions were 5.02±0.07.

Spectrophotometry. The difference spectra of HSA solutions in the presence and absence of Cu^{2+} ions were measured in the ultraviolet region using a Union Giken SM 401 spectrophotometer at 25±0.2 °C.

Stopped-flow Experiments. The kinetic measurements were carried out using a Union Giken Stopped-flow spectrophotometer RA 401. The dead-time of the apparatus is 5 ms. For the case of very small signal amplitudes, its relaxation time was obtained by signal averaging 2—10 measurements using the averaging capabilities of a wave-memory apparatus. All kinetic measurements were made at 25±0.2 °C.

† 1 M=1 mol dm^{-3}.

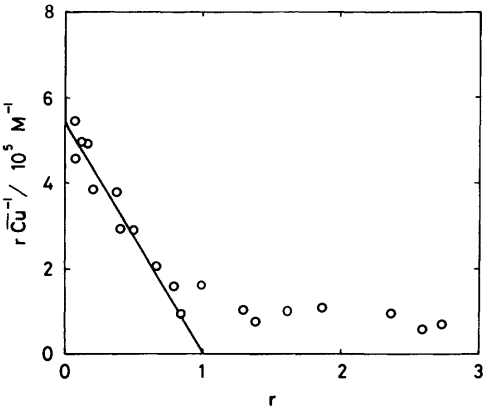

Fig. 1. Scatchard plot of the binding of Cu^{2+} ion to HSA in 1 mM K_2SO_4 solution at pH 5.02±0.07 and 25±0.2 °C. The slope of the solid line yields $K_p=(5.3\pm0.5)\times10^5$ M^{-1} for the binding constant of the primary site.

Results

Static Measurements. Figure 1 illustrates a Scatchard plot of the binding of the Cu^{2+} ion to HSA monomer obtained by an equilibrium dialysis technique at pH 5.02±0.07. The shape of the isotherm clearly demonstrates the presence of one primary binding site with high affinity and number of secondary sites with low affinities. From the slope of this isotherm in the range of $r<1$ (r is binding ratio of bound Cu^{2+} to protein), the binding constant for the primary site was estimated to be $K_p=(5.3\pm0.5)\times10^5$ M^{-1}; where subscript p refers to the value for the primary site.

The binding of Cu^{2+} to HSA was also examined spectrophotometrically at pH 5.0 by monitoring the absorbance change at a wave length 255 nm which is specific to a charge-transfer transition from amino,

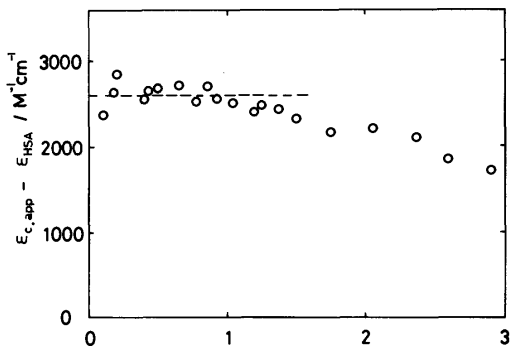

Fig. 2. A plot of $\varepsilon_{c,app}-\varepsilon_{HSA}$ *vs.* binding ratio r. The data were obtained from the spectrophotometric titration of HSA (2.0×10^{-5} M) solutions with various amounts of Cu^{2+} ions at 255 nm, pH 5.0±0.02, and 25±0.2°C.

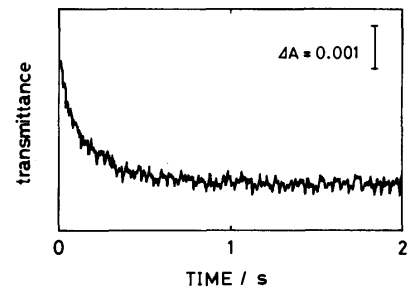

Fig. 3. A typical oscillographic trace of the stopped-flow experiments of the reaction between Cu^{2+} ion (4.0×10^{-6} M) and HSA (2.0×10^{-5} M) monitored by the change in the transmittance intensity (increasing upward) at 255 nm, pH 4.6 and 25±0.2°C in 1 mM K_2SO_4 solution. The magnitude of the absorbance change is indicated by the bar in the upper right-hand corner.

carboxylato, imidazolyl groups, and ionized peptide nitrogens to bound Cu^{2+}.[11] Since the contribution from the free Cu^{2+} ion to the absorbance is negligibly small at the present wave length of 255 nm, the observed change in absorbance (ΔA^{255}) may be written as

$$\Delta A^{255}/\text{cm} = (\varepsilon_{c,app}-\varepsilon_{HSA})\cdot\bar{C}, \qquad (1)$$

where ε_{HSA}, $\varepsilon_{c,app}$, and $\bar{C}$ denote the molar extinction coefficient of HSA at 255 nm, the apparent molar extinction coefficient of the complex and its equilibrium concentration, respectively. The variation of $\varepsilon_{c,app}-\varepsilon_{HSA}$, which is given by calculating $\Delta A^{255}/\bar{C}$ using the binding data obtained above, was represented as a function of the binding ratio r in Fig. 2. The constancy of the value of $(\varepsilon_{c,app}-\varepsilon_{HSA})$ up to an r value of unity gives further evidence for the presence of one primary site. Since the highest affinity site on HSA for the Cu^{2+} ion has been identified to be the three N-terminal peptides (Asp-Ala-His),[8-10] the primary site found in the present study is most likely attributable to this sequence. The apparent molar extinction coefficient of the complex formed at this site ($\varepsilon_{c,app}$) was estimated to be 22100 $M^{-1}cm^{-1}$ by using a value of 19500 $M^{-1}cm^{-1}$ for ε_{HSA}.

Kinetic Measurements. In order to detect a reaction between the Cu^{2+} ion and the primary site of HSA, stopped-flow experiments were carried out at a small *M/P* (metal to protein ratio) of 0.2 by using a change in the absorbance at 255 nm. As shown in Fig. 3, a single relaxation process was observed in the sec range under various pH and concentration values. Other reaction processes were not discernible within the time resolution of the apparatus (5 ms—100 s). The spectra of the solutions after mixing were quite stable over a period of 2 d.

The reciprocal relaxation time (τ^{-1}) was determined by a semilogarithmic plot of the reaction curve near the equilibrium point. The pH and concentration dependences of the obtained τ^{-1} are represented in Figs.

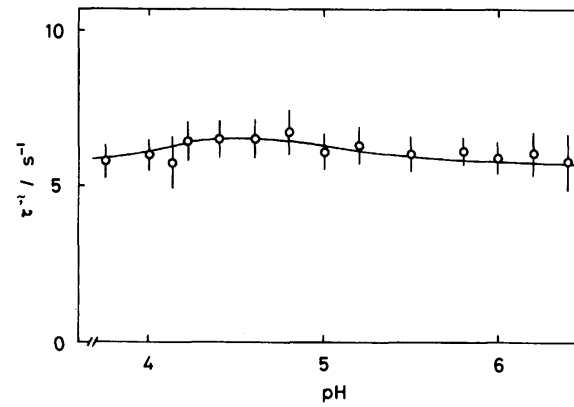

Fig. 4. The pH dependence of τ^{-1} at a fixed concentrations of Cu^{2+} (4.0×10^{-6} M) and HSA (2.0×10^{-5} M).

4 and 5, respectively. The behaviors for τ^{-1} (shown in these figures) are quite similar to a previous observation in a Cu^{2+}–BSA system,[11] but the present τ^{-1} is several times larger.

On the other hand, the absorbance changes (ΔA_{SF}) at 255 nm (estimated directly from the reaction traces observed by the stopped-flow measurements) are represented as a function of pH in Fig. 6, together with the total absorbance changes (ΔA_{total}) measured during static spectrophotometrical experiments at the same wavelength. Disagreement between ΔA_{SF} and ΔA_{total} implies the presence of at least one more reaction process within the dead-time of the stopped-flow apparatus accompanied by the absorbance changes (ΔA_{DT}) corresponding to the difference between ΔA_{total} and ΔA_{SF}. As judged from the pH dependence of ΔA_{DT} and ΔA_{SF}, a complex formed within the dead-time of the apparatus predominates above pH 5.5, and the other complex yielded by the observed reaction process around pH 4.5. These features in the complexation of Cu^{2+} ion with HSA are also quite similar to those previously observed for a Cu^{2+}–BSA system.[11]

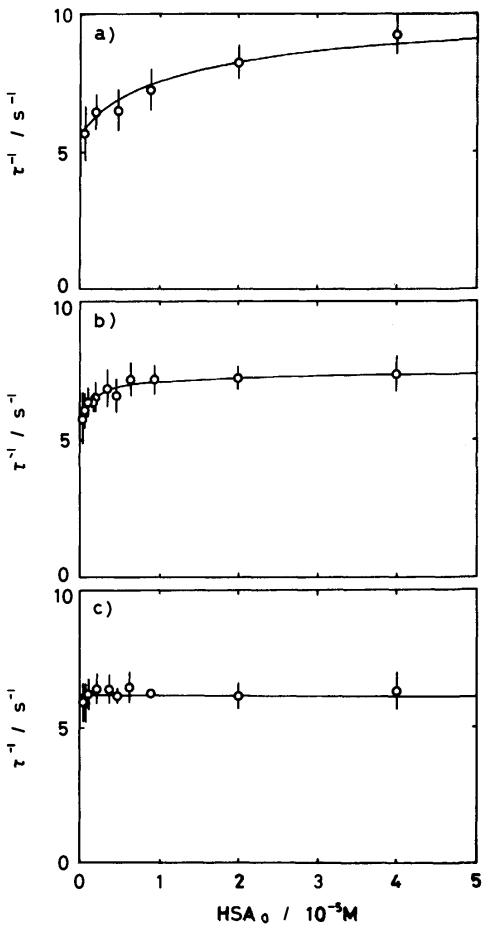

Fig. 5. The variation of τ^{-1} with the total concentration of HSA (HSA_0) at a fixed M/P of 0.2: (a), pH 4.2; (b), pH 4.6; (c), pH 5.2.

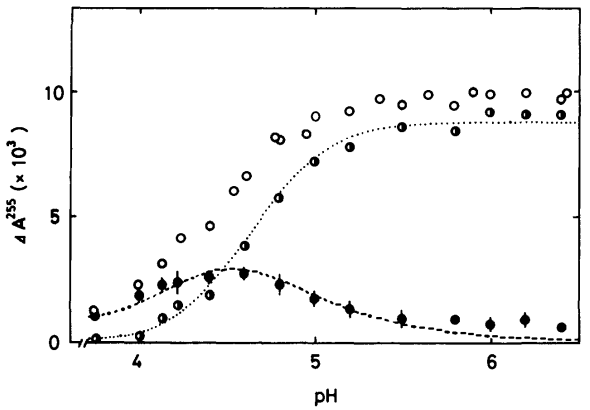

Fig. 6. The pH dependence of absorbance changes at 255 nm due to the reaction between Cu^{2+} (4.0×10^{-6} M) and HSA (2.0×10^{-5} M): ○, the total absorbance change (ΔA_{total}) measured spectrophotometrically; ●, the absorbance change (ΔA_{SF}) observed by stopped-flow method; ○, the absorbance change within the dead-time of the stopped-flow apparatus (ΔA_{DT}) determined from $\Delta A_{total}-\Delta A_{SF}$ at each pH value.

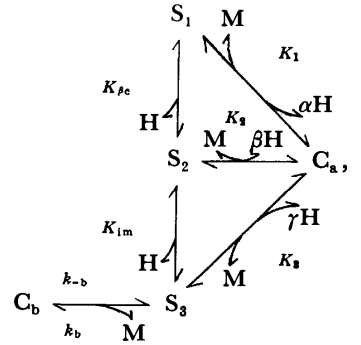
Examination of Reaction Mechanism. Looking for close simillarities regarding the kinetic behaviors for Cu^{2+}–BSA and Cu^{2+}–HSA systems, the following reaction mechanism is proposed for the binding of a Cu^{2+} ion to the three N-terminal peptides of BSA. This is also being applied to the present system.



(I)

with

$$K_b = \frac{k_b}{k_{-b}}, \tag{2}$$

K_i (i=1, 2, 3, b), k_i (i=b, -b), H, M, C_a, and C_b denote binding constants, rate constants, protons, free Cu^{2+} ions, complex formed from the rapid reaction, and the other complex formed during the observed reaction, respectively. α, β, and γ are the number of protons released in each step and S_i (i=1, 2, 3) refers to the possible protonated states of the three N-terminal peptides of HSA, defined as S_1: Asp(protonated β-carboxyl)-Ala-His(protonated imidazolyl), S_2: Asp(deprotonated β-carboxyl)-Ala-His(protonated imidazolyl), S_3: Asp(deprotonated β-carboxyl)-Ala-His(deprotonated imidazolyl). The equilibria among these states are characterized by two acid dissociation constants of $K_{\beta c}$ (for β-carboxyl group) and K_{im} (for imidazolyl group), since the α-amino group of the terminal aspartyl residue (pK_a=7.73[10]) is almost acidic under the present pH conditions of 3.7—6.4. The values of $K_{\beta c}$ and K_{im} were calculated using pK_a values (2.98 for β-carboxyl group and 6.55 for imidazolyl group) obtained from titration studies of a synthetic tripeptide of HSA primary site by Iyer *et al.*[10]

Firstly, the observed absorbance changes (ΔA_{DT}) within the dead-time of the apparatus were analyzed on the basis of the rapid equilibria represented in the right-hand side of Mechanism I. The cyclic nature of the scheme requires

$$K_1 = K_{\beta c}K_2 = K_{\beta c}K_{Im}K_3, \tag{3}$$

$$\alpha = \beta + 1 = \gamma + 2. \tag{4}$$

By use of the molar extinction coefficients, ε of C_a and HSA, the equation of a net absorbance change resulting from the formation of C_a is given by

$$\Delta A_{DT}/\text{cm} = (\varepsilon_{C_a}-\varepsilon_{HSA})\cdot\bar{C}_{a,r}, \tag{5}$$

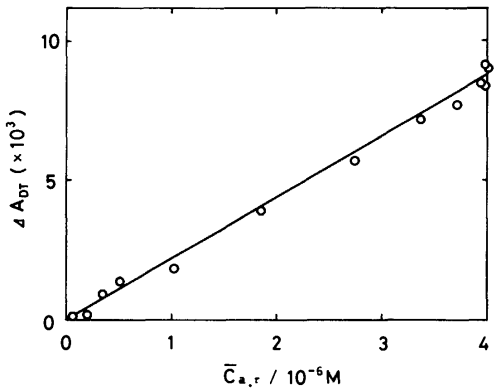


Fig. 7. A plot of ΔA_{DT} *vs.* $\bar{C}_{a,r}$ calculated for $\gamma=1$ and $K_3=105$.

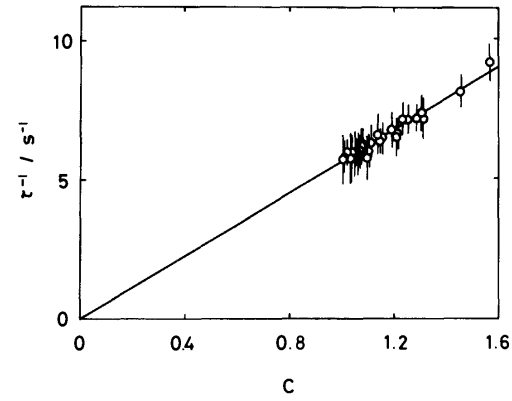

Fig. 8. A plot of τ^{-1} obtained at various pH and concentrations *vs.* the concentration term in Eq. 9, designated by C in this figure and calculated for $K_b=1.9\times10^{-6}\,M^{-1}$.

with

$$\bar{C}_{a,r}=\frac{1}{2A}\{A(M_0+S_0)+B-\sqrt{A^2(M_0-S_0)+2AB(M_0+S_0)+B^2}\}, \quad (6)$$

$$A=K_1/\bar{H}_r^{r+2}, \quad (7)$$

$$B=1+K_{\beta c}/\bar{H}_r+K_{\beta c}K_{1m}/\bar{H}_r^2, \quad (8)$$

where the bar with subscripts r and 0 refer to the equilibrium concentration after rapid equilibria and the total concentration of each species, respectively. In the present analyses, the equilibrium proton concentrations were approximated by the final concentrations since pH changes in solutions after mixing were within ±0.03 of the initial pH values. As shown in Fig. 7, a plot of experimental values of ΔA_{DT} *vs.* $\bar{C}_{a,r}$ calculated using $\gamma=1$ and $K_3=105\pm8$ gives an excellent straight line through the origin. From the slope of this line, the value of ε_{C_a} was estimated to be 21700 $M^{-1}cm^{-1}$. As can be seen from Fig. 6, data regarding ΔA_{DT} fall on the theoretical curve (dotted line) calculated from Eqs. 5—8 while using this value. This demonstrates the plausibility of a reaction scheme involving a rapid equilibria.

Subsequently, the reaction given by the left-hand side of the proposed mechanism was examined on the basis of data for both τ^{-1} and ΔA_{SF} obtained from the present stopped-flow measurements. By coupling with a rapid equilibria, the equations for τ^{-1} and ΔA_{SF} in the present process can be written as

$$\tau^{-1}=k_{-b}\left[K_b\frac{\bar{S}_3(F-K_3\bar{M}/\bar{H})}{F(1+K_3\bar{S}_3/\bar{H})}+\frac{\bar{M}}{F}+1\right], \quad (9)$$

with

$$F=(1+\bar{H}/K_{\beta c})(\bar{H}+K_3\bar{S})/K_{1m}+K_3(\bar{M}+\bar{S}_3)/\bar{H}+1, \quad (10)$$

and

$$\Delta A_{SF}/cm=(\varepsilon_{C_a}-\varepsilon_{HSA})(\bar{C}_a-\bar{C}_{a,r})+(\varepsilon_{C_b}-\varepsilon_{BSA})C_b, \quad (11)$$

respectively. The overbar and ε_{C_b} denote the equilibrium concentration of each reacting species and the molar extinction coefficient of C_b, respectively. The concentration term in brackets in Eq. 9 was calculated for various values of K_b. As shown in Fig. 8, a plot of τ^{-1} obtained at various pH values and concentrations *vs.* the concentration term calculated by using $K_b=1.9\times10^6\,M^{-1}$ gives a good proportionality through the origin. From the slope of this line, k_{-b} was determined to be 5.1 s^{-1} and k_b was calculated to be $9.7\times10\ M^{-1}s^{-1}$. All the data of τ^{-1} fall on the theoretical curves calculated using these values, as can be seen from Figs. 4 and 5. Furthermore, the theoretical curve of ΔA_{SF}, drawn with a dashed line in Fig. 6, was calculated from Eq. 11 by using $\varepsilon_{C_b}=24000\ M^{-1}cm^{-1}$ and gives a good fit with the data at each pH value. This good agreement between the theoretical curves and the experimental data confirms the validity of Mechanism I.

The apparent association constant K_{app}, defined as $(C_a+C_b)/(\bar{S}_1+\bar{S}_2+\bar{S}_3)\cdot M$, and the apparent molar extinction coefficient $\varepsilon_{c,app}$ can be calculated from the following relations:

$$K_{app}=\frac{K_1/\bar{H}+K_{\beta c}K_{1m}K_b/\bar{H}^2}{1+K_{\beta c}/\bar{H}+K_{\beta c}K_{1m}\bar{H}^2}, \quad (12)$$

and

$$\varepsilon_{c,app}=\frac{\varepsilon_{C_a}\bar{C}_a+\varepsilon_{C_b}\bar{C}_b}{\bar{C}_a+\bar{C}_b}. \quad (13)$$

Calculations using these equations yield $K_{app}=3.1\times10^5\ M^{-1}$ and $\varepsilon_{c,app}=22200\ M^{-1}cm^{-1}$ for pH 5.0. Good agreement with the values ($K_p=5.3\times10^5\,M^{-1}$ and $\varepsilon_{c,app}=22100\ M^{-1}cm^{-1}$) obtained statically also strongly supports the present assignments.

Discussion

Both the static and kinetic studies in the present

a) This work. b) Previous work.[11] c) Values of α and β can be calculated from Eq. 3. d) Values of K_1 and K_2 can be calculated from Eq. 4.

work clearly showed that two types of Cu^{2+} complexs (C_a and C_b) are formed at the three N-terminal peptides of HSA (Asp-Ala-His) by the same mechanism proposed for the binding of a Cu^{2+} ion to BSA terminal peptides (Asp-Thr-His-). In previous work regarding a Cu^{2+}-BSA system,[11] we revealed that C_a is a chelated complex with a square-planar configuration involving α-amino, imidazolyl and two peptide nitrogens. This was originally proposed by Peters and Blumenstock.[2] We also proposed that C_b is a low-pH type complex with a ring structure made by coordinations with imidazolyl nitrogen and β-carboxylato oxygen. In order to see the substitition effect on the complexation, the stoichiometric constants, kinetic constants, and the molar extinction coefficients of the complexes were determined for both albumins and are summarized in Table 1. The molar extinction coefficients in this table involve the absorption of the albumin molecule itself (at 255 nm), which arises mainly from the aromatic groups in the protein. Thus, the net changes in the molar extinction coefficients due to complexation ($\Delta\varepsilon_{C_a}$ and $\Delta\varepsilon_{C_b}$) were estimated by the substraction of ε_{HSA} or ε_{BSA} from the corresponding ε_{C_a} and ε_{C_b}, and are given within parentheses in Table 1. Good agreement between the obtained values for HSA ($\Delta\varepsilon_{C_a}$=2200, $\Delta\varepsilon_{C_b}$=4500) and those for BSA ($\Delta\varepsilon_{C_a}$=2300, $\Delta\varepsilon_{C_b}$=4800) confirm the formation of the same types of complexes at the terminal sites of both albumins. However, the equilibrium and rate constants are somewhat different for each albumin beyond the experimental uncertainties. Especially, the value of k_{-b} obtained for BSA ($1.3\,s^{-1}$) is about one-fourth of that for HSA ($5.1\,s^{-1}$). This result can be explained on the basis of the ring structure of C_b. The construction of molecular models for this complex showed that the side chain of the second residue (α-hydroxyethyl group for BSA, methyl group for HSA) is always outside of the peptide ring. In such a configuration, a bulky and hydrophilic 1-hydroxyethyl group would not only interfere with the binding of a peptide chain to the outside, but would participate in the ordering of water molecules around the complex. These functions of this group are most likely responsible for the stabilization of an already formed ring structure of C_b. This is consistent with the observed k_{-b} reduction for a BSA system.

Finally, it is worth noting that the complexation of Cu^{2+} with the N-terminal site of albumin can be easily understood without any consideration of the N-F transition of albumin occurring in the range of pH 3.5—4.5. This is presumably because the N-terminal domain of albumin is maintained in a compact form through the N-F transition, in contrast to the disordered C-terminal domain.[13]

Volume Changes and Equilibrium Constants for Protonation of $[M(edta)]^{2-}$

Kouzou YOSHITANI
Faculty of General Education, Gifu University, Yanagido, Gifu 501-11
(Received February 27, 1985)

The volume changes and the equilibrium constants for the first protonation of $[Co(edta)]^{2-}$, $[Ni(edta)]^{2-}$, and $[Cu(edta)]^{2-}$ (H_4edta=ethylenediaminetetraacetic acid) have been determined from density and pH measurements at 25 °C. In the case of $[Cu(edta)]^{2-}$, a second protonation is assumed to successively occur. The volume change and the equilibrium constant for the second protonation have been estimated. The volume changes for the first protonation of Co(II)-, Ni(II)-, and Cu(II)-edta chelates were small and positive (3.5, 3.3, and 4.8 $cm^3\,mol^{-1}$, respectively) and that for the second protonation of a Cu(II)-edta chelate was larger than the first one (8 $cm^3\,mol^{-1}$).

Although the structures of a number of metal-edta chelates in the solid state have been established by X-ray studies,[1] their structures in aqueous solutions are still not so clear. Much attention has been given to determining their structures using a variety of experimental techniques.[2-5] Recently, the partial molal volumes and volume changes for the complex formation of $[M(edta)]^{2-}$ have been determined and useful information about solution structures of the edta-chelates has been obtained.[6]

In this study, the volume changes and the equilibrium constants for the protonation of $[M(edta)]^{2-}$ (M= Co(II), Ni(II), and Cu(II)) are determined and discussed in relation to their structures in neutral and acidic solutions.

Experimental

The edta-chelates, $Na_2[Co(edta)]\cdot 3.5H_2O$, $Na_2[Ni(edta)]\cdot 3H_2O$, and $Na_2[Cu(edta)]\cdot 3H_2O$, were as previously used.[6] The metal chelates were dried *in vacuo* for one week at 110 °C before use. The concentrations of the metal chelate electrolytes were determined by weight. $HClO_4$ was obtained from Nakarai Chemicals, Ltd. and was used as received. All the solutions were prepared with distilled and deionized water. The specific conductivity was less than $2\times10^{-7}\ \Omega^{-1}\,cm^{-1}$. The densities were measured with a digital density meter (Shibayama Scientific Co., Ltd. Model SSD-200). Details of the measurements have been described elsewhere.[7] The pH values of the solutions were determined with a digital pH meter (TOA Electronics Ltd. Model HM-15A), which was calibrated by using standard buffer solutions (Merck). The temperature of the water bath was controlled to 25.00±0.002°C.

Results and Discussion

The aqueous solutions of edta-chelates (*ca.* 0.02 mol dm^{-3}) were mixed with the $HClO_4$ solutions (*ca.* 0.02 mol dm^{-3}). The volume changes on the first protonation, ΔV_1, for eqilibrium, $MY^{2-}+H^+=MHY^-$, have been determined from the equation:

$$\Delta V_{mix}=\frac{1000d}{w_1+w_2}\left(\frac{w_1+w_2}{d}-\frac{w_1}{d_1}-\frac{w_2}{d_2}\right)=\alpha[M]\Delta V_1, \quad (1)$$

where ΔV_{mix} is the volume change of mixing per 1 dm^3 of the mixed solution, w_1, w_2 and d_1, d_2 are the weights and densities of the edta-chelates and the $HClO_4$ solutions before mixing, d is the density of the mixed solution, [M] is the total molar concentration of the edta-chelates in the mixed solution, $[M]=[MY^{2-}]+[MHY^-]$, and α is the degree of the protonation, ($\alpha=[MHY^-]/([MY^{2-}]+[MHY^-])$), respectively. No correction for the volume change of the dilution was made, which was assumed to be within the experimental error. The α value can be calculated from the pH value of the mixed solution by a successive iteration as follows. First, the activity coefficients of the ions are assumed to be unity and an approximate α value is obtained from the equation:

$$\alpha=([A]-[H^+])/[M], \quad (2)$$

where [A] is the total molar concentration of H^+ and MHY^- in the mixed solution, $[A]=[H^+]+[MHY^-]$, and can be calculated from the initial concentration of the $HClO_4$ solution. By using this estimated α value, the ionic strength and the activity coefficients of the ions according to the Davies' equation[8] are obtained. A more accurate α can then be obtained from the pH value, the activity coefficient of H^+ and Eq. 2. The iteration process is repeated until the consistent α value is obtained. The thermodynamic equilibrium constant for the first protonation of MY^{2-} can be calculated from the obtained consistent α value and activity coefficients:

$$K_1^\circ=\frac{\alpha[M]y_1}{[H^+]y_1(1-\alpha)[M]y_2}, \quad (3)$$

where y_1 and y_2 are the molar activity coefficients of the monovalent and divalent ions, respectively. In Table 1, the total concentrations, [M] and [A], pH, $\log K_1^\circ$ and ΔV_1 are listed. In these mixed solutions, the metal chelate ions are considered to be stably present from their stability constants[9] and the pH values of the mixed solutions. The constant $\log K_1^\circ$ and ΔV_1 values are obtained for $[Co(edta)]^{2-}$ ($\log K_1^\circ=3.55\pm0.01$ $mol^{-1}\,dm^3$, $\Delta V_1=3.5\pm0.2$ $cm^3\,mol^{-1}$) and for $[Ni(edta)]^{2-}$ ($\log K_1^\circ=3.53\pm0.01$ $mol^{-1}\,dm^3$, $\Delta V_1=3.3\pm0.3$ $cm^3\,mol^{-1}$). However, the $\log K_1^\circ$ values for $[Cu(edta)]^{2-}$ increase with decreasing the pH values of the mixed solutions.

This indicates that the second protonation occurs successively. Therefore, the first and second protonations for $[Cu(edta)]^{2-}$ in these mixed solutions are considered:

$$MY^{2-} + H^+ = MHY^-, \qquad K_1° = [MHY^-]/[MY^{2-}][H^+]y_2, \tag{4}$$

$$MHY^- + H^+ = MH_2Y, \qquad K_2° = [MH_2Y]/[MHY^-][H^+]y_1^2. \tag{5}$$

The total molar concentrations are defined by:

$$[M] = [MY^{2-}] + [MHY^-] + [MH_2Y], \tag{6}$$

$$[A] = [H^+] + [MHY^-] + 2[MH_2Y]. \tag{7}$$

Combining Eqs. 4—7 gives:

$$\frac{[A]-[H^+]}{\{2[M]-([A]-[H^+])\}[H^+]^2y_1^2y_2} = \frac{[M]-([A]-[H^+])}{\{2[M]-([A]-[H^+])\}[H^+]y_1^2}K_1° + K_1°K_2°. \tag{8}$$

A plot of the values of the left-hand side of Eq. 8 against the corresponding values for the coefficients of K_1° enables both K_1° and K_2° to be obtained. The required

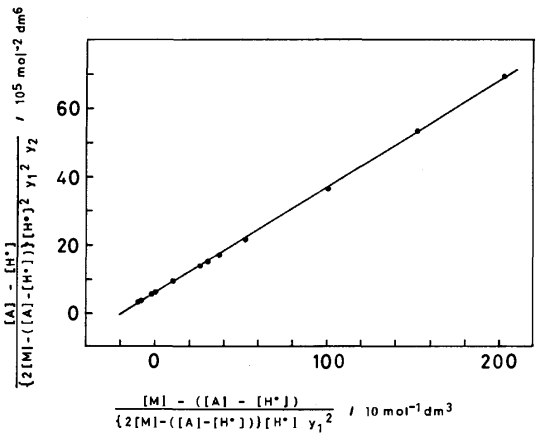

Fig. 1. The best fitted plot of Eq. 8.

values of $[H^+]$, y_1 and y_2 are obtained by similar successive iterations as before. The best fitted plot of Eq. 8 is obtained by four iterations and is shown in Fig. 1. Thus, K_1° and K_2° values for the first and second protonations are evaluated from Fig. 1 by a least squares-method ($\log K_1° = 3.49 \pm 0.01$ mol^{-1} dm^3 and $\log K_2° = 2.26 \pm 0.01$ mol^{-1} dm^3, respectively). The volume changes for the first and the second protonation for $[Cu(edta)]^{2-}$, ΔV_1 and ΔV_2, are calculated using the equation:

$$\Delta V_{mix} = [M]\{\alpha_1\Delta V_1 + \alpha_2(\Delta V_1 + \Delta V_2)\}, \tag{9}$$

where α_1 and α_2 are the fractions of $CuHY^-$ and CuH_2Y, respectively, and can be estimated from the obtained values for K_1° and K_2°. The values of ΔV_1 and ΔV_2 are 4.8 ± 0.2 cm^3 mol^{-1} and 8 ± 1 cm^3 mol^{-1}, respectively.

The estimated values for $\log K$ ($K = [MHY^-]/[MY^{2-}][H^+]$) of $[Co(edta)]^{2-}$, $[Ni(edta)]^{2-}$, $[Cu(edta)]^{2-}$ at the 0.1 mol dm^{-3} ionic strength (3.10, 3.08, and 3.04 mol^{-1} dm^3, respectively) are in good agreement with the literature values (3.0, 3.2, and 3.0 mol^{-1} dm^3, respectively).[9]

It is well known that the first and second protonations to a free $edta^{4-}$ ion take place at the nitrogen atoms.[10,11] However, spectrophotometric studies indicate that the first protonation to stable edta-chelate ions takes place at the oxygen atom in the carboxylate group of the ligand.[12,13] Then, the monoprotonated edta-chelate, in which edta acts as a pentadentate ligand, one carboxyl group is free and the water molecule occupies the sixth coordination site, is expressed as $[M(edtaH)(H_2O)]^-$. The volume changes for the first protonation, ΔV_1, of the edta-chelates of Co(II), Ni(II), and Cu(II) (3.5, 3.3, and 4.8 cm^3 mol^{-1}, respectively) are considerably smaller than that for the protonation of the simple acetate ion, which is reported to be 11.3 cm^3 mol^{-1}.[14] The same has been found for the entropy changes for the protonation of these edta-chelates:[15] They are considerably smaller than that for the protonation of H_2edta^{2-}, which relates to the protonation of the carboxylate group in the free ligand.[15] This may

be explained by the fact that the first protonation reaction of the edta-chelate involves the substitution reaction of the coordinated carboxylate group by a water molecule prior to actual protonation. The protonation of the free carboxylate group of the edta chelate is accompanied by a positive volume change. However, the substitution reaction may be considered to be accompained by a negative volume change due to the electrostriction of the coordinated water molecule and due to the localized charge of the free carboxylate group.

It has been proposed that, in neutral solutions of these edta chelates, there are dynamic equilibria between the dominant sexidentate form and the quinquedentate form, the latter having a water molecule and a free carboxylate group.[3-5] The amount of the dominant sexidentate form has been estimated by a NMR study as 81, 67, and 62% for Co(II)-, Ni(II)-, and Cu(II)-edta chelate, respectively.[5] The volume change from the sexidentate form to the quinquedentate form for the Co(II)-edta chelate has been estimated to be -4.9 $cm^3 mol^{-1}$ from an ultrasonic study.[4] If this value is assumed to be independent of the central metal cation, the volume changes due to the protonation of the free carboxylate group of the edta chelate are calculated to be 7.5, 6.6, and 7.8 $cm^3 mol^{-1}$ for Co(II)-, Ni(II)-, and Cu(II)-edta chelates, respectively. These values are smaller than that of the volume change for the protonation of the acetate anion (11.3 $cm^3 mol^{-1}$). However, they are comparable in magnitude with that of the formate anion (8.5 $cm^3 mol^{-1}$).[4] Taking into account the difference that one is a simple carboxylate anion and the other is a complex ion, the ΔV_1 values seem to be reasonable.

For simple dibasic carboxylate anions, such as the malonate and the oxalate ions, the volume changes for the first and second protonation, ΔV_1 and ΔV_2, are in the order, $\Delta V_1 > \Delta V_2$,[16] which is expected from simple electrostatic theory such as the Drude-Nernst formulation.[17] The differences between ΔV_1 and ΔV_2 diminish when the two charged centers are sufficiently separeted.[16] However, the ΔV_1 and ΔV_2 obtained for the Cu(II)-edta chelate are in a reverse order. If the second protonation of the Cu(II)-edta chelate takes place at the free carboxylate group in the same manner as the first one, the ΔV_2 should be smaller than that of the ΔV_1, or at least the same magnitude. In the solid state, the diprotonated Cu(II)-edta has a tetragonally distorted structure with a free carboxyl arm and a water molecule occupying the sixth coordination site and two elongated bonds of metal-nitrogen and metal-oxygen of the carboxylate.[18] The second protonation has been assummed to take place at the uncoordinated oxygen atom in the longer bonded carboxylate group.[18] If the diprotonated Cu(II)-edta in the solution has a similar structure to that in the the solid state, the smaller ΔV_1 compared to ΔV_2 for the Cu(II)-edta may be understandable.

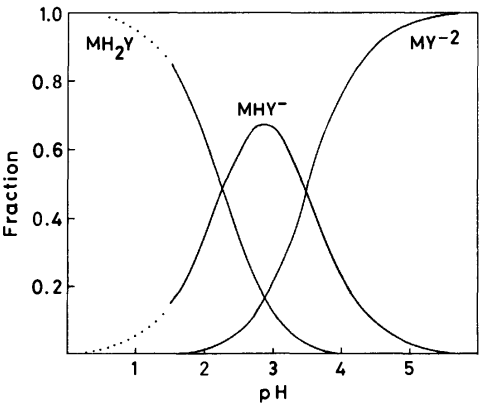

Fig. 2. Distribution of the Cu(II)-edta chelate species as a function of pH.

Although the equilibrium constants for the first protonation of the stable edta-chelate ions have been determined by spectrophotometric studies[3,19] or the by-product of the determination of the stability constants of the edta-chelates, a study of the second protonation is thought to be difficult because of the low solubility of the diprotonated edta-chelate. In this study, the concentrations of the Cu(II)-edta chelate in the mixed solutions were sufficiently low (0.015—0.008 mol dm^{-3}) and precise pH measurements have enabled us to determine the equilibrium constants for the second protonation of Cu(II)-edta chelate. In Fig. 2, the fractions of three species of the Cu(II)-edta chelate at the acidic medium are shown. The monoprotonated Cu(II)-edta chelate starts to form at around pH 5, and the maximum in the fraction is attained at around pH 3 with a fraction of 0.6. The diprotonated Cu(II)-edta chelate begins to form at around pH 4 and the monoprotonated and diprotonated species are present in an equimolar condition around at pH 2.3.

The author wishes to thank Professor Yuroku Yamamoto and Dr. Manabu Yamamoto of Hiroshima University for their helpful discussions.

(Received April 22, 1985)

The new complex indicated in the title was synthesized and its crystal and molecular structures were determined by the use of a single-crystal X-ray diffraction method. The crystal is tetragonal, with the space group $P\bar{4}$, and the cell constants are $a=12.124(5)$ and $c=7.985(2)$ Å. The structure was solved using the heavy-atom method, and the final R value was 0.039. Two kinds of crystallographically independent mercury atoms in the unit cell are tetra-coordinated and they are in the tetrahedral geometry, where four sulfur atoms of the thiocyanate ions are ligated, respectively. The cobalt atom is hexa-coordinated, and is in an octahedral geometry, where four nitrogen atoms of the thiocyanate ions are coordinated equatorially, and two water oxygen atoms axially. Thiocyanate ions span mercury and cobalt atoms to form two-dimensional networks parallel to the (001) plane. The planar polymeric complexes are linked to the c-axis direction, through hydrogen bonds between coordinated water molecules and *N,N*-dimethylacetamide.

The tetrakis(thiocyanato)cobalt(II)mercury(II), $CoHg(SCN)_4$ (**1**), has a so called "diamond-like" three-dimensional polymeric structure,[1] and to study such complexes is attractive. Some of the Lewis-base adducts of **1** were synthesized,[2,3] and the structure of some adducts, $CoHg(SCN)_4L_2$ (where L=pyridine (**2**),[4] *N,N*-dimethylformamide (**3**),[5] and triphenylphosphine (**4**)[6]), as well as $CoHg(SCN)_4(tu)_4$ (**5**) (where tu=thiourea)[7] were already elucidated. Complexes **2** and **3** have a three-dimensional polymeric structure, where both of the base ligands are coordinated as an unidentate, taking *trans* positions in **2** and *cis* positions in **3**. Compex **4** has a one-dimensional "ladder-like" structure, where each dimer ring is linked to their neighbors on both sides by a pair of weak Hg–S bonds, respectively. Complex **5** consists of discrete anionic and cationic complexes, $[Hg(tu)_4]^{2+}$ and $[Co(SCN)_4]^{2-}$, and no bridging exists between them.

In this research we could obtain a new type Lewis-base adduct, indicated in the title (**6**), which includes two moles of water and two moles of *N,N*-dimethylacetamide (DMA) per one mole of the core complex **1**. The cobalt(II) atom in this complex was expected to be in an octahedral configuration since the complex is reddish-brown in color. However, no more details regarding its structure were clarified by the spectroscopic method. Although the structure of the *N,N*-dimethylformamide adduct, **3**, was already known, this complex has not only DMA molecules but also water molecules. It is of the $CoHg(SCN)_4L_2L'_2$ type. Consequently, we have determined its structure using an X-ray diffraction technique with its single crystal.

Experimental

Synthesis of Diaquatetrakis(thiocyanato)cobalt(II)mercury(II)-DMA (1/2) 6. To a finely powdered **1** (1.00 g, 2.0 mmol), was added about 10 cm^3 of a mixed solvent of DMA and water (1:1=v/v). This mixture was warmed and stirred until **1** was dissolved. The solution, which was reddish violet in color, was left standing at about 15 °C over night. The deposited crystals were separated, washed with mixed solvent and water and dried by pressing between filter paper sheets. The yield was 1.28 g (85—91%). The crystals used for the X-ray structure analysis were obtained from a more dilute solution of the mixed solvent after being left standing for several days. Anal. Found: Co, 8.35; C, 20.41; H, 3.19; N, 12.26%. Calcd for $CoHgC_{12}H_{22}N_6O_4S_4$: Co, 8.39; C, 20.53; H, 3.16; N, 11.97%.

Intensity-data Collection. A parallelepiped crystal with the dimensions of 0.28×0.22×0.11 mm^3 along the unit cell axes was used for the intensity measurement. Crystallographic data are: $CoHgC_{12}H_{22}N_6O_4S_4$, F.W.=702.13, tetragonal, space group $P\bar{4}$, $Z=4$, $a=12.124(5)$, $c=7.958(2)$ Å, $U=1169.4(8)$ Å^3, $D_m=1.99(3)$, $D_x=1.99$ Mg m^{-3}, μ(Mo $K\alpha$)=7.80 mm^{-1}. Reflections within a range of $3°<2\theta<70°$ were collected on a Rigaku Denki AFC-6A automated four circle X-ray diffractometer, with graphite-monochromated Mo $K\alpha$ radiation. The ω—2θ scan technique was employed (scan speed, 4° min^{-1} in 2θ; scan width, $\Delta\omega=1.05+0.5\tan\theta$°). The crystal was stable during the measurement process. Of the 5597 reflections measured in a quartant of the reciprocal space, 1081 independent reflections with $|F_o|>3\sigma(|F_o|)$ were used for the structure determination. The intensities were corrected for the Lorentz and polarization factors as well as for the absorption. The latter correction was made using numerical Gaussian integration.[8]

Structure Determination. The structure was solved by the heavy-atom method. The positions of the mercury(II) and cobalt(II) atoms were deduced from a three-dimensional Patterson map, while the other non-hydrogen atoms were located by means of succesive Fourier syntheses. Their positions and thermal parameters (firstly isotropic and finally anisotropic) were refined by a block-diagonal least squares method. At the final refinement step, shifts of all the parameters were less than $\sigma/3$'s. The final R value[9] (applying anisotropic temperature parameters) was 0.039. The R value was 0.041 for the structure with an inverse chirality. We carried also out a refinement using an alternate space group P4, where two kinds of cobalt atoms are on four-fold axes and mercury atoms lie on two-fold axes. However, the $CoHg(SCN)_4$ skeleton was almost equivalent to that of $P\bar{4}$. The main difference lies in the orientation of the DMA mole-

cules. As unreasonably short contacts occured between the DMA molecules in this ordered structure, an orientational disorder of the DMA molecules was introduced into the refinement. This disorder shows favor to a hydrogen-bond formation regarding all coordinated water molecules. The refinement converged R=0.065 and no improvement was attained in the R value. From these points, the space group P4 is thought to be less probable.

Although the space group P4/m is also possible, it was apparent that an adoption of this group implies that no ordered arrangement could be realized for almost all the atoms. Consequently, the space group was considered unacceptable.

All the calculations were carried out on a HITAC M-280H computer at the Computer Center of the University of Tokyo using the local version of the UNICS program system.[10] The atomic-scattering factors were taken from the tables.[11]

Other Measurements. The magnetic moment of the solid sample was measured at 20 °C using a Gouy balance. The infrared absorption spectra were obtained by means of a JASCO A202 grating infrared spectrophotometer using Nujol and hexachloro-1,3-butadiene mull. The visible diffuse reflectance spectrum of the solid complex was measured by means of a Hitachi 124 spectrophotometer using MgO as the reference.

Results and Discussion

The final atomic parameters of the non-hydrogen atoms are listed in Table 1, while the selected bond lengths, bond angles, and some of the short interatomic distances that were assumed to be hydrogen bonds are tabulated in Table 2.[12] In Figs 1 and 2, perspective drawings of the complex around a mercury atom Hg (1), and that around a cobalt atom, together with the hydrogen-bond bridging between the neighboring cobalt atoms along the c-axis, respectively, are given. The numbering scheme is also shown in the figures. The geometry atound the Hg (2) atom is nearly the same that around the Hg(1) atom. The projection of the structure along the c-axis is shown in Fig. 3.

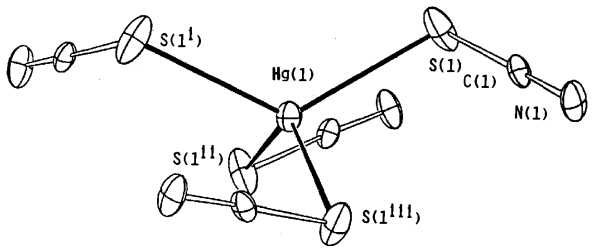

Fig. 1. A perspective drawing of the complex around a mercury(II) atom (Hg(I)), with the numbering scheme.

Each mercury atom is coordinated tetrahedrally to four thiocyanate ions, and lies on a four-fold improper rotation axis. The tetrahedron around Hg (2) is almost regular. However, that around Hg (1) is a little deformed. The Hg-S bond lengths are normal and are nearly equal to the sum of both the atomic radii, r_{Hg}=1.48 and r_S=1.04 Å.[13a] The angles Hg-S-C, 102.4(4) and 98.5(5)°, are a little larger than those in related complexes such as **1**, **2**, and **3**.

The cobalt atom is hexa-coordinated and is in a octahedral geometry, where four nitrogen atoms of

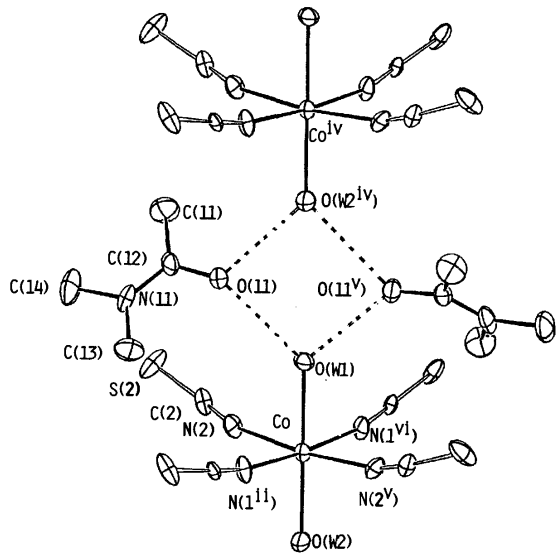

Fig. 2. A perspective drawing of the complex around a cobalt(II) atom and the hydrogen-bond bridging to the next metal atom, with the numbering scheme.

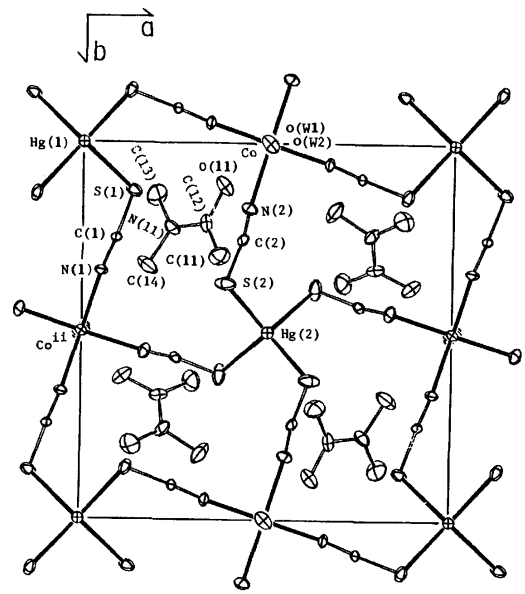

Fig. 3. The crystal packing diagram of the complex.

the thiocyanate ions are ligated equatorially and two water oxygen atoms axially along the c-axis directions. The cobalt atom as well as two oxygen atoms lie on the two-fold axis. All Co-N and Co-O bond lengths are normal, considering the respective atomic radii: r_{Co}=1.32, r_N=0.70, and r_O=0.66 Å.[13a]

The Co-N-C angles are 164.2(10) and 168.4(8)°, and are far from linear. In many isothiocyanato complexes, the M-N-C angles are approximately 180°; and in some related compounds such as **1** and **3**, the angles are not much different from 180°.[1,5] However, more deformed angles in this complex are found in **2** and **4** (about 165°).[4,6] Therefore, the angles in this complex are not exceptional. The N-C-S angles, 176.8(9) and 170.0(12)°, are a little less than 180°. Such a deformation was scarcely found in the common thiocyanato complexes, including **1**—**4**. In Cd(ben)$(SCN)_2$ (where ben=bis(2-aminoethyl)amine) the angles are 167.8(9) and 170.8(10)°,[14] and in $Hg(SCN)_2[(C_6H_5)_3P]$ one of them is 164.2°.[15] Therefore, the relatively large deviations of the bond angles in this complex are thought to be due to a crystal packing effect. Consequently, the bridgings in this complex may be deformed and stressed.

As shown in Table 2, the bond lengths and angles of the DMA molecule are normal except for C(12)-O(11). The length 1.332(17) Å is longer than the values observed in the carbonyl group of common organic compounds, 1.20—1.22 Å.[16] This fact is probably due to hydrogen bondings which are described later. The bond length (C(12)-N(11), 1.313(19) Å) almost corresponds with Pauling's double-bonding C=N distance, 1.29 Å.[13b] Such a short C-N bond is also found in many amide molecules.

The crystal consists of layers parallel to the (001) plane. In a layer, the cobalt atoms slightly deviate (by 0.387 Å) above or below the plane on which the mercury atoms are situated. The cobalt and mercury atoms are bridged by thiocyanate ions to form a two-dimensional network. No bridging ligand exists between the network. The cobalt atoms are linked along the [001] direction through hydrogen bonds between the coordinated water and the DMA oxygen atoms; the hydrogen bonds are shown in Fig. 2. The angles, $O(11)\cdots O(W1)\cdots O(11^V)$ and $O(11)\cdots O(W2^{IV})\cdots O(11^V)$ are 95.9(5) and 91.9(5)°, which are smaller than the H-O-H angles of water molecule, 104.5°.

When **6** in a powder state was kept in an organic solvent such as benzene or acetone at 15°C, it turned blue in color within one day. The residual solid found to be **1**. Thus, the DMA and water molecules in **6** could be easily removed. From this, the bonds of the additional molecules, DMA and water, in **6** are thought not to be stable.

The infrared absorption spectra of complex **6**, as well as **1** and DMA were measured and compared with each other. Some of the results are shown in Table 3. The corresponding absorption maximum wave numbers of the main peaks of the free DMA, such as 1508, 1400, 1265, 1190, 1018, and 592 cm^{-1}, are also found in the spectrum of **6**. As shown in the table, the ν(C=O) peaks of **6** are red shifted by 40 cm^{-1}, probably due to the strong hydrogen bonds to the oxygen atom of DMA in **6**. The peaks concerned with the thiocyanate ion appear almost at the same region in the spectra of **1** and **6**, as shown in the table. The ν(O-H)peaks of **6** appear at 3360 and 3250 cm^{-1}, which are near to those of the ν_1 and ν_3 peaks of free water in the solid state (3400 and 3220 cm^{-1}).[17] Therefore, the splitting is likely to be due to the strong hydrogen bonds of the water molecules in **6**.

The magnetic moment of **6** is about 4.83 BM (1 BM=9.274078(36)$\times 10^{-24}$ JT^{-1}) at 20°C. Its visible

reflectance spectrum shows the main peak of the d-d band at 517 nm with an intense shoulder at about 485 nm. These values are almost the same as those of the related adducts, such as **2** or **3**.[2] These facts are explained by the octahedral geometry around the cobalt atom in this complex as shown by the result of the X-ray structure analysis mentioned above.

(Received May 18, 1985)

The EXAFS spectroscopy has been used to determine the structure of the bis(glycinato) complexes of nickel(II) and zinc(II) ions of low solubility (0.1—0.3 mol dm^{-3}) in aqueous solution. The structural parameters were evaluated by the least-squares analysis both in the reciprocal and in the real spaces on the basis of various standard samples of known structures. Analysis of the EXAFS spectra of aqueous solutions containing the bis(glycinato) complexes of nickel(II) and zinc(II) ions has revealed that both complexes have two additional water molecules bound to the central metal ions to complete the octahedral structure. The structure of the nickel(II) complex is similar both in crystals and in solution, whereas the bis(glycinato)zinc(II) in solution is coordinated with two water molecules instead of two neighboring glycinato carbonyl oxygen atoms in the solid state.

X-Ray and neutron diffraction techniques have long been used in the investigations of the structure of metal complexes in solution.[1,2] In recent years the EXAFS (extended X-ray absorption fine structure) spectroscopy has been proved to be successful for studies of the short-range order of atoms in solution.[3–5] From both diffraction and EXAFS methods can be obtained structural information related to the radial distribution of atom pairs in a system; the number of neighboring atoms around a central atom, the interatomic distance between them and its root-mean-square deviation. However, there are some differences in the nature of information to be obtained from both methods. EXAFS data bear on the near-neighbor environment of an X-ray absorbing atom only, while scatterings of all atom pairs with different distances are detected by conventional diffraction techniques. Since the contribution of the structures of the solvent and solvated anions to the total diffraction pattern is very large particularly in dilute solutions, structural information on metal complexes may sometimes be hidden by it. The difficulity may be overcome by increasing the concentration of metal ions and by selecting an appropriate counter anion, however. The diffraction method thus has a limited use in the case of dilute solutions. In the EXAFS spectra, on the contrary, the contribution from the solvent structure is absent and the interaction of the nearest neighbors with an absorbing atom is most emphasized, and hence the EXAFS method may be the most suitable for structural determination of metal complexes of low concentration in solution.

According to the single-electron and single-scattering theory of the EXAFS,[6–8] it is essential in structural analysis to evaluate the backscattering amplitude of the scatterer and the phase shifts due to the absorber and scatterers. The method of estimation of these parameter values, as well as data reduction procedures, differs in different groups and laboratories. It seems ambiguous to what extent different treatments and analyses of EXAFS spectra affect the final structure data to be obtained. The first aim of the present study is, therefore, to examine uncertainties in structural data obtained by the EXAFS method. To this aim, EXAFS oscillations are extracted by using two different programs. The phase-shifts and the backscattering amplitudes are estimated either from Teo-Lee's values[9] based on pseudo *ab initio* calculations or from the EXAFS spectra of standard references of known structure. Least-squares fitting calculations are then made both in the reciprocal and in the real spaces on the basis of the various standard references.

The structure of the mono- and tris(glycinato) complexes of nickel(II),[10] copper(II),[11] and zinc(II)[12] ions in aqueous solutions has been determined by means of X-ray diffraction. However, the structure of the relevant bis(glycinato) complexes in solution is not determinable by the conventional X-ray analysis due to their low solubility in water (less than 0.3 mol dm^{-3}). The second aim is, therefore, to determine the structure of the bis(glycinato) complexes of nickel(II) and zinc(II) in solution by the EXAFS method. The solubility of the bis(glycinato)copper(II) complex in water was too low (≈0.025 mol dm^{-3}) to determine the structure of the complex even by the present transmission mode EXAFS experiment.

Experimental

EXAFS Measurements. EXAFS spectra were measured on a laboratory X-ray absorption spectrometer consisting of a Johansson cut bent crystal (Ge(220)), a rotating anode generator (Rigaku Ru-200) and a fast solid-state detector. Details of the spectrometer have been described elsewhere.[13]

Samples measured were aqueous solutions containing the $[M(gly)_3]^-$ (1 mol dm^{-3}) or $[M(gly)_2]$ (0.1—0.3 mol dm^{-3}) (M= Ni(II), Zn(II), and gly=glycinate ion) complex as a main species, which were prepared in the same way as previously described.[10,12] Crystalline samples of the bis(glycinato) complexes of both metals, the structure of which has been investigated by an X-ray diffraction method,[15,16] were also measured for comparison. Aqueous metal nitrate solutions (1 mol dm^{-3}) containing haxaaqua ions and crystalline

Table 1. Samples for EXAFS measurements

Sample	Species	Mole ratio C_{gly}/C_M	C_M/mol dm^{-3}
Powder A	NiO	0	—
Solution B	$[Ni(OH_2)_6]^{2+}$	0	1.023
Solution C	$[Ni(gly)_3]^-$	3.94	1.000
Solution D	$[Ni(gly)_2]$	2.00	0.1225
Powder E	$[Ni(gly)_2(OH_2)_2]$	2.00	—
Powder F	ZnO	0	—
Solution G	$[Zn(OH_2)_6]^{2+}$	0	1.004
Solution H	$[Zn(gly)_3]^-$	5.09	1.245
Solution I	$[Zn(gly)_2]$	2.00	0.2919
Powder J	$[Zn(gly)_2]\cdot H_2O$	2.00	—

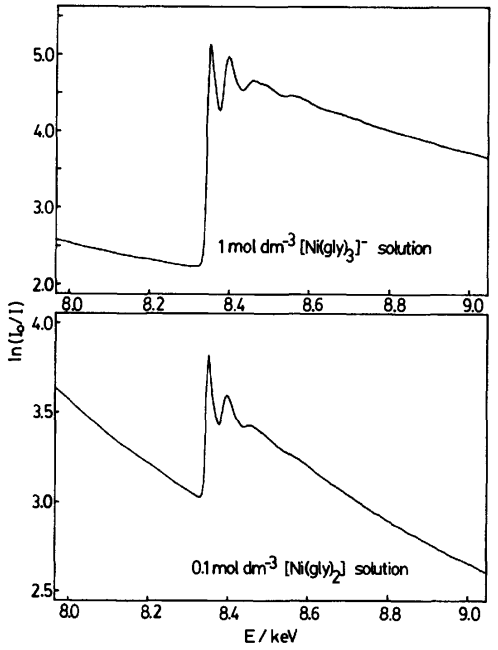

Fig. 1. The absorption spectra for the solutions containing the $[Ni(gly)_3]^-$ (upper part) and $[Ni(gly)_2]$ (lower part) complexes.

powders of the metal oxides were measured as structure standards.[14,17] Details of the samples are summarized in Table 1.

The solution samples were held between thin Mylar windows by the use of a spacer with an adequate thickness to obtain an effective jump at the absorption edge (μx=1—2 with the absorption coefficient μ and the sample thickness x). The powder samples were mixed and ground with boron nitride to dilute the sample, and finally pressed to thin pellets.

The absorbance μx is given as $\ln(I_0/I)$, where I and I_0 are the X-ray intensities with and without a sample, respectively. The intensities I_0 and I were measured at the same time by a partially transmitting ion chamber and an SSD, respectively. The data collection time for covering the required energy region was approximately 10 h and more than 1×10^7 counts of I_0 were obtained at each data point. Measurements were repeated at least twice in order to examine the reproducibility of the results.

An example of the absorption spectra for the solution samples containing high and low concentrations of main species ($[Ni(gly)_3]^-$ and $[Ni(gly)_2]$ complexes) is depicted in Fig. 1.

Data Reduction Procedure. The EXAFS data were analyzed by two different programs, *i.e.* ours (program I) and the one used in the Xerox Palo Alto Laboratory (program II).

Program I. Background absorption other than that for the K edge of an absorption atom of interest was evaluated by least-squares fitting Victoreen's formula[19] to the preedge and was subtracted from the total absorption by extrapolation. The smooth K-shell absorption μ_0 due to an isolated atom was estimated by fitting a smooth curve to the observed absorption spectrum using a cubic spline function.[20] Two or three knots over the whole region were enough to give a good approximation for μ_0.

The modulation $\chi(k)$ was extracted and normalized by the following equation;

$$\chi(k) = \{\mu(k)-\mu_0(k)\}/\mu_0(k) \quad (1)$$

where k is the photoelectron wave vector ejected and is given as $\sqrt{2m(E-E_0)/\hbar^2}$. E denotes the energy of the incident X-rays and E_0 is the binding energy of a K-shell electron.

Program II. Details of the data treatments are referred to the literature.[18] Background absorption was approximated with a function of $A+B\cdot E^{-p}$, where A, B, and p were empirical parameters which were determined by a least-squares fit to the absorption data below the K-edge of interest. In practice, p is found to be between 1 and 3, consistent with Victoreen's formula used in program I. The EXAFS pattern was extracted by assuming a 6th-order polynomial function for the smooth K-shell absorption μ_0.

The $k\cdot\chi(k)$ values obtained by both programs are compared in Fig. 2. As seen in Fig. 2, an approximation of μ_0 by either program I or II is equally good for the extraction of $\chi(k)$. The oscillation of the EXAFS data weighted by k^n was converted by the Fourier transformation into the radial distribution in the r-space as

$$\phi(r) = \sqrt{(1/2\pi)}\int_{k_{min}}^{k_{max}} k^n\cdot\chi(k)\cdot W(k)\cdot\exp(-2ikr)dk. \quad (2)$$

Here $W(k)$ is the window function to reduce ripples due to the truncation effect. The window functions employed in programs I and II were, respectively, of the Hanning type[21] and of Gaussian type. The resulting $\phi(r)$ values obtained with n=2 by using program I are shown in Fig. 3.

Least-squares Calculation. The structure parameters (interatomic distances, mean square displacements and coordination numbers) were obtained by comparing the observed EXAFS spectra and the model function given by the single scattering theory[6-8,22] as,

$$\chi(k)_{calcd} = \sum_j\{n_j/(k\cdot r_j^2)\}\exp(-2\sigma_j^2k^2)B_jF_j(\pi,k) \times\sin(2kr_j+\alpha_j(k)), \quad (3)$$

where $F_j(\pi,k)$ is the backscattering amplitude from each of n_j scatterers j at distance r_j from the X-ray absorbing atom. σ_j^2 is the mean square displacement of the equilibrium distance r_j and B_j is the amplitude reduction factor related to inelastic losses at the absorbing atom due to the many-body effect.[22] $\alpha_j(k)$ is the total scattering phase shift experienced by the photoelectron.

The observed spectra can be compared with the theoretical ones by a least-squares procedure in either r- or k-space. The

A: NiO powder, B: $[Ni(OH_2)_6]^{2+}$ in solution, C: $[Ni(gly)_3]^-$ in solution, D: $[Ni(gly)_2]$ in solution, E: $[Ni(gly)_2(OH_2)_2]$ powder, F: ZnO powder, G: $[Zn(OH_2)_6]^{2+}$ in solution, H: $[Zn(gly)_3]^-$ in solution, I: $[Zn(gly)_2]$ in solution and J: $[Zn(gly)_2]\cdot H_2O$ powder.

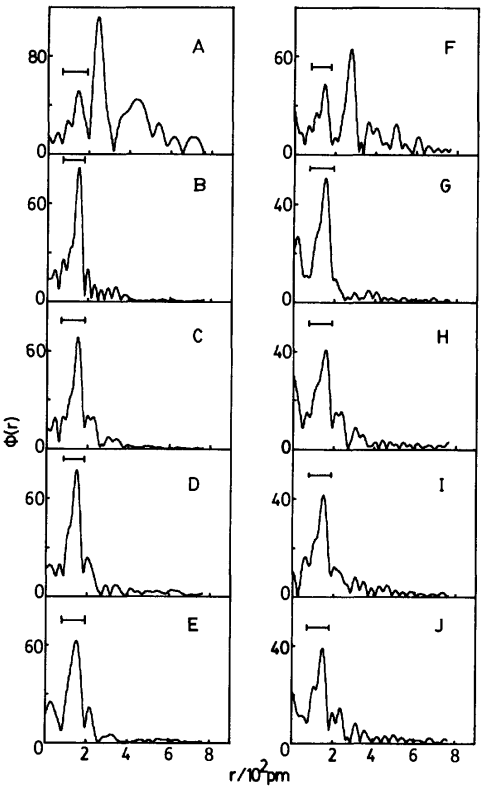

Fig. 3. The Fourier transform $\phi(r)$ of the EXAFS spectra shown in Fig. 1, uncorrected for the phase shifts. The bars indicate the r-range of the inverse Fourier transform shown in Fig. 4 (dots).

latter procedure needs an additional Fourier backfiltering of the peak of interest in the $\phi(r)$ curve. Theoretically both analyses in the k- or r-space should give equivalent results.

We examined least-squares calculations both in the r- and k-spaces.

Analysis in the k-*Space (program I).* A curve fitting procedure in the k-space was applied to the Fourier filtered $k^2\cdot\chi(k)_{obsd}$ values to minimize the error-square sum U_1,

$$U_1 = \sum_{k_{min}}^{k_{max}} k^4(\chi(k)_{obsd}-\chi(k)_{calcd})^2. \quad (4)$$

The values of $F_j(\pi,k)$ and $\alpha_j(k)$ for $\chi(k)$ in Eq. 3 were quoted from the tables reported by Teo and Lee.[9] The values are given against the absolute k-values and thus an improper evaluation of E_0 should result in a systematic distortion of the k-scale and affect the interatomic distances to be determined. Furthermore, the theoretical values of the backscattering amplitudes $F_j(\pi,k)$ are usually larger by *ca.* 50% than those observed,[23] which sometimes give unreasonable bond lengths between an X-ray absorbing central atom and its neighboring ones and the coordination numbers. In this procedure the parameters E_0 and B were estimated from the standard samples of known structure (here we employed the $[M(OH_2)_6]^{2+}$ and MO (M^{2+}=Ni^{2+} and Zn^{2+})) and then they were used as constant values in the course of the analysis of the EXAFS spectra of unknown samples, while r, σ, and n were refined as variables.

Analysis in the r-*Space (program II).* The analysis of the first peak in the r-space followed the procedure, the details of which have been described elsewhere.[18] The E_0 values were fixed to the values estimated in the previous section. The essential formulae are described below.

The $\phi(r)$ values can be expressed by the convolution of two functions as

$$\phi_j(r) = \sum_j \int_0^\infty \frac{dr'}{r'^2} p_{ij}(r')\xi_{ij}(r-r'). \quad (5)$$

$p_{ij}(r)$ is the pair correlation function and ξ_{ij} is the peak function which contains the information on the electron scattering process such as the backscattering amplitude, photoelectron phase-shift and so on. The pair correlation function was assumed to be a Gaussian expressed by

$$p_{ij}(r) = n_j/\sqrt{(2\pi\sigma_j^2)}\ \exp\left[-(r-r_j)^2/2\sigma_j^2\right]. \quad (6)$$

The peak function ξ_{ij} including the phase-shifts and the backscattering amplitudes can be empirically extracted from the $\phi(r)$ values of the standard references of known structure according to Eqs. 5 and 6. Since the ξ_{ij} is insensitive to crystal structure, local bonding, *etc.*,[18] the ξ_{ij} values thus evaluated were adopted in the structure analysis of unknown samples. The model function $\phi_m(r)$ for unknown samples was calculated by using Eq. 5 with the ξ_{ij} values.

The curve fits were carried out by comparing the real (Re) and the imaginary (Im) parts of the $\phi(r)$ with $\phi_m(r)$ values to minimize the error-square sum U_2,

$$U_2 = (2N)^{-1}\sum^N \{\mathrm{Re}(\phi-\phi_m)^2/[(\mathrm{Re}\phi)^2+\{\mathrm{Re}(d\phi/dr)\}^2] + \mathrm{Im}(\phi-\phi_m)^2/[(\mathrm{Im}\phi)^2+\{\mathrm{Im}(d\phi/dr)\}^2]\}. \quad (7)$$

In the course of the calculation, parameters of the radial shift Δr, additional broadening $\Delta\sigma$ and coordination number n were allowed to vary as independent variables. The bond length of the structural references was fixed at the values established from the X-ray diffraction method.

Raman Spectroscopic Measurement. Raman spectra for the bis(glycinato)zinc(II) complex in the solid and solution states were measured with a JEOL laser Raman spectrometer JRS-S1 with the use of the 514.5 nm excited line of Ar^+ laser.

Results and Discussion

Selection of Structure Standards. In order to examine the applicability of the structural standard to the structure analysis of complexes in solution, we examined the spectra of crystalline powder of metal oxides and aqueous metal nitrate solutions containing hexaaqua $[M(OH_2)_6]^{2+}$ ions, the structure of both species having been known.[14,17] The EXAFS spectra $k\cdot\chi(k)$ and the Fourier-transformed function $\phi(r)$ for the structure references are shown in Figs. 2 (A, B, F, and G) and 3 (A, B, F, and G), respectively. In the course of the least-squares fits in the k-space (program I) for the M–O signature within the crystalline metal oxides and within the $[M(OH_2)_6]^{2+}$ in the solutios, parameters E_0, B, and σ were all allowed to vary simultaneously, while the coordination number n was fixed at the known value (6 for NiO, 4 for ZnO and 6 for the aquanickel(II) and -zinc(II) ions). The values for the central atom phase-shift of atom M and those for the backscattering phase-shift and amplitude of atom O were taken from the theoretical values by Teo and Lee. The M–O distance r, which has been determined by the X-ray diffraction method,[14,17] was also allowed to vary in order to check the reproducibility of the value. The results are given in Table 2. The values of E_0 thus estimated agreed with each other in the standard substances of a given metal and seemed reasonable because the interatomic distances converged to the literature values.[14,17] However, the B values obtained for the metal oxides were smaller by a factor of 1.2—1.5 than those for the aqueous solutions. This leads to 20—50% larger coordination number when we use the metal oxides as a standard for the analysis of unknown samples than one uses the solution standard, although the bond length determined may be independent of the selection of the references. Agreements between experimental and calculated $k^2\cdot\chi(k)$ curves are shown in Fig. 4 (A, B, F, and G).

Least-squares fits in the r-space, in which the $\phi(r)$ peak due to the M–O bonds within the $[M(OH_2)_6]^{2+}$ ions were compared with those of the M–O bonds in the metal oxides as the standard, gave larger coordination number than the correct value of six, whereas the bond lengths obtained were in good agreement with those determined by the X-ray diffraction method.

Thus, we concluded that the metal nitrate solutions were more suitable structural references for the solution samples than the metal oxides, even though both of them have the same coordination atoms at the similar distance.

Table 2. Comparison of E_0 and B values obtained by the least-squares fits from different standard materials. Standard deviations are given in parentheses

Material	E_0/eV	10^3B	r/pm	σ/pm	$r_{X\text{-ray}}$/pm

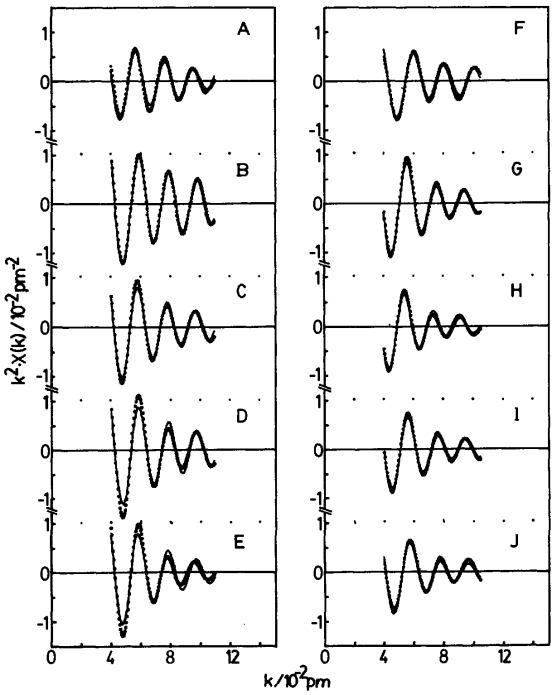

Fig. 4. The Fourier filtered $k^2\cdot\chi(k)$ curves of the main peak depicted in Fig. 3. The dotted and solid lines represent, respectively, the observed and calculated values by using parameter values in Tables 3 and 4.

In the course of the analysis of the EXAFS spectra of glycinato complexes by adopting the phase-shifts empirically evaluated, they should be evaluated from compounds of well established structure including M–O and M–N bonds. However, since phase shifts can be well approximated to be the same for atoms having similar number of electrons,[24] the phase-shift of the backscattering atom N (sometimes even atom C) was assumed to be the same as that of atom O, which was evaluated from the $[M(OH_2)_6]^{2+}$ ions.

Ni(II) Complexes. The $k\cdot\chi(k)$ curves and the $\phi(r)$ values of the solution samples containing the tris- and bis(glycinato) complexes and the crystalline powders of the bis(glycinato) complex are depicted in Figs. 2 (C, D, and E) and 3 (C, D, and E), respectively.

Table 3. Results of the curve fits for the nickel (II)-glycinato complexes with distance r and root-mean-square displacement σ. $\Delta\sigma$ denotes the difference between the sample and the standard $[Ni(OH_2)_6]^{2+}$. Standard deviations are given in parentheses

Complex	Scatterer	Program I		Program II		X-ray
		r/pm	σ/pm	r/pm	$\Delta\sigma$/pm	
$[Ni(OH_2)_6]^{2+}$(aq)	O	202(1)	1.4(5)	204[b]	—	204[c]
$[Ni(gly)_3]^-$(aq)	O or N	205(1)	5.5(1)	209	6.4	
	O	201(1)	1.4[a]	204	0.0	203[d]

$[Ni(gly)_2(OH_2)_2]$(c)	O or N	204(1)	4.7(4)	205	4.7	210[e] (2×Ni−OH_2)
						206[e] (2×Ni−O)
						208[e] (2×Ni−N)

a) The values were kept constant during the calculation. b) Employed as a standard from Ref. 14. c) Ref. 14. d) Ref. 10. e) Ref. 15.

A small but significant shoulder at about 6×10^{-2} pm^{-1} appearing in the $k\cdot\chi(k)$ curves of samples C, D, and E, which has not been observed in solution B, indicated that there should be at least two interactions with different distances contributing to the EXAFS oscillations.

In the $\phi(r)$ curve for sample solution C containing the tris(glycinato)nickelate(II) complex as the predominant species, two peaks were observed at about 150 and 220 pm. The first peak at 150 pm was ascribable to the first neighbor Ni-O and Ni-N pairs within the $[Ni(gly)_3]^-$ complex. The small and slightly split second peak at 220 pm was not significantly affected by different estimations of the smooth background μ_0 and the selections of k_{min} and k_{max} values for the Fourier transformation, and hence it indicated a significant signature. The peak might be assignable to the next nearest neighbor Ni···C distance within the tris(glycinato) complexes, although the peak might also contain a spurious one due to the truncation effect of the Fourier transform.

Firstly, the predominant peak at 150 pm, indicated by a bar in the figure, was analyzed by using the least-squares method in the k-space for the Fourier filtered $k^2\cdot\chi(k)$ values. Theoretical values by Teo and Lee[9] were used for the phase-shifts and the backscattering functions in combination with program I. The coordination number was fixed to the known value (n=6). The model of only one backscatterer (O or N) gave a satisfactory agreement between the calculated and observed $k^2\cdot\chi(k)$ values with the bond length of 205 pm and the σ value of 5.5 pm. However, the σ value estimated from this model was about four times larger than that (1.4 pm) obtained for the Ni-O bond within the reference $[Ni(OH_2)_6]^{2+}$ ion (see Table 3). The σ value thus obtained for the Ni-O and Ni-N bonds within the $[Ni(gly)_3]^-$ complex seemed unreasonably large, because the temperature factors for the Ni-O and Ni-N bonds within the complex were virtually the same as that of the Ni-OH_2 bond within the $[Ni(OH_2)_6]^{2+}$ complex.[10,14] Therefore, we assumed that the σ values of the both Ni-O and Ni-N were the same as the value of the standard hexaaqua complex (σ=1.4 pm) and allowed the lengths of the both Ni-O and Ni-N bonds to vary independently. As a result, the least-squares calculation converged to two different lengths of the Ni-O (201 pm) and Ni-N (210 pm) bonds, independent of the initial value inserted for the lengths of the two bonds (Table 3).

A similar consideration was examined in the data analysis in the r-space. The first peak at 150 pm was directly analyzed in the r-space by using program II by assuming one and two Gaussian models, the peak due to the Ni-O bonds within the $[Ni(OH_2)_6]^{2+}$ being employed as the standard. The results are given in Table 3.

As seen in Table 3, both calculations for the data in the k- and r-spaces gave similar results that under the assumption of one kind of the bond length the Ni-O and Ni-N distances were 205—209 pm, while the Ni-O and Ni-N bond lengths were 201—204 and 210—212 pm, respectively, under the assumption of two different lengths for the Ni-O and Ni-N bonds. The difference in calculations between two programs I and II was less than 3 pm, which was compared with the difference in the standard Ni-O distance estimated by the different programs for the $[Ni(OH_2)_6]^{2+}$ ion.

The analysis of the first peak both in the k- and r-spaces thus gives almost the same results and thus errors caused by a Fourier backfiltering are within experimental errors. In addition, the choice of either theoretical or empirical values for the phase-shifts and backscattering amplitudes does not significantly affect the result as long as suitable standard samples are adopted in order to obtain reasonable E_0 and B values. We can recommend to employ the $[Ni(OH_2)_6]^{2+}$ complex in solution as the standard rather than NiO in the course of the structural analysis of the $[Ni(gly)_3]^-$ in solution, because the former standard gives a better B value leading to more reasonable coordination number of the complexes in solution.

The present EXAFS analysis by using both programs I and II gave the results consistent with those from X-ray diffraction.[10]

The analysis of the second peak at 220 pm was not possible because it was too small to apply the curve-fit

TABLE 4. RESULTS OF THE CURVE FITS FOR THE ZINC(II)-GLYCINATO COMPLEXES WITH DISTANCE r AND ROOT-MEAN-SQUARE DISPLACEMENT σ. $\Delta\sigma$ DENOTES THE DIFFERENCE BETWEEN THE SAMPLE AND THE STANDARD $[Zn(OH_2)_6]^{2+}$. STANDARD DEVIATIONS ARE GIVEN IN PARENTHESES

Complex	Scatterer	Program I		Program II		X-ray
		r/pm	σ/pm	r/pm	$\Delta\sigma$/pm	
$[Zn(OH_2)_6]^{2+}$(aq)	O	207(1)	6.5(3)	208[b]	—	208[c]
$[Zn(gly)_3]^-$(aq)	O or N	213(1)	6.8(1)	214	7.7	
	O	213(1)	6.5[a]	210	0.2	212[d]
	N	213(1)	6.5[a]	219	8.9	212[d]
$[Zn(gly)_2(OH_2)_2]$(aq)	O or N	207(1)	6.6(2)	208	5.5	
$[Zn(gly)_2]\cdot H_2O$(c)	O or N	203(1)	7.0(3)	204	8.7	

a) The values were kept constant during the calculation. b) Employed as a standard from Ref. 14. c) Ref. 14. d) Ref. 12.

procedure, although we could approximately estimate the Ni···C distance to be about 280 pm from the peak position after the correction for the phase-shift, which reasonably agreed with the literature value determined by means of solution X-ray diffraction (290 pm).[10]

The same analytical procedure was applied to the solution and powder samples of the bis(glycinato)nickel(II) complex. The amplitude of the first peak in the Fourier transform was similar in both samples (Fig. 3, D and E) and hence the curve-fits gave very similar results (Table 3), which implied that the environment of the Ni(II) ions should be very similar in both states. Therefore, the bis(glycinato)nickel(II) in the aqueous solution was expected to have a six-coordination with two additional water molecules to complete the octahedral configuration as in the crystalline state.[12] A mean value (208 pm) of the distances found in the X-ray crystallographic investigation[15] was slightly longer than the value found by the EXAFS measurement (204 pm for the average bond length), but the difference was almost within uncertainties of the latter.

Zinc(II) Complexes. The $k\cdot\chi(k)$ and $\phi(r)$ values of the solution samples containing the tris- and bis(glycinato) complexes and of the bis(glycinato)-zinc(II) complex in powder are shown in Figs. 2 and 3 (H, I, and J). The predominant first peak at 150 pm in Fig. 3 (H, I, and J) are due to the first neighbor Zn-O and Zn-N bonds within the glycinato complexes.

The structure of the Zn(II)-glycinato complexes was analyzed in the same manner as decribed in the previous section for the nickel(II) complexes. For solution H containing the $[Zn(gly)_3]^-$ complex as a predominant species, the least-squares calculations for the first peak at 150 pm in the $\phi(r)$ curve (Fig. 3H) were performed both in the k- and r-spaces with two models with the same length for the Zn-O and Zn-N bonds and with the different lengths of the two bonds. Both model calculations gave the similar results (see Table 4). The interatomic distances thus determined are consistent with those reported in an X-ray diffraction study.[12]

The structure of the bis(glycinato)zinc(II) complex in the solid state was reported to be apically distorted octahedral with additional two carbonyl oxygen atoms within the glycinate ions coordinated to adjacent Zn-(II) ions,[16] although the complete structural analysis was not yet achieved. Bis-complexes of zinc(II) ion with various bidentate ligands are known to have the tetrahedral structure. However, as is seen in Fig. 3 (I and J) the amplitude of the first peak for both solution and powder samples is very similar, which indicates a similar coordination number for the bis-complex in both states. The curve fit analysis in the k-space for the first peak in Fig. 3I gave the coordination number of nearly six independent of the initial value at the least-squares approach. Thus, it was concluded that the bis(glycinato)zinc(II) complex has an octahedral structure with two additional water molecules in aqueous solution.

The mean bond distance (203 pm) for the powder sample seemed to be slightly shorter than that found in the solution (207 pm). This trend was not observed in the case of the bis(glycinato)nickel(II) complexes.

In Raman spectral measurements of the Zn-N stretching frequency in the bis(glycinato)zinc(II) complex the band observed at $(467\pm5)\,cm^{-1}$ in the crystal shifted to $(434\pm5)\,cm^{-1}$ in the aqueous solution. The shift of the Zn-N stretching frequency by *ca.* $33\,cm^{-1}$ found in the present study has also been reported by Krishnan and Plane,[23] which suggested lengthening of the Zn-N bond in the solution state. The longer Zn-N bond in solution than in crystal found in the present EXAFS study may correspond to the shift of the Zn-N stretching frequency toward the lower frequency side in the Raman spectra in solution. The weakening of the Zn-N bond (and probably in the Zn-O bond, too) of the bis(glycinato)zinc(II) complex in solution compared with that in crystal may be caused by a stronger electron donation from coordinated water molecules in the bis-complex in solution than that from carbonyl oxygen atoms in the solid state.

This work was supported by the Joint Studies Program (1983—1984) of the Institute for Molecular Science and by the Grant-in-Aid for Scientific Reseach No. 57470054 from the Ministry of Education, Science and Culture. The authors (T. Y. and H. O.) thank Dr. J. B. Boyce (Xerox Palo Alto Reseach Centers) for his kind help in using their computer program and his valuable

discussion. A part of the calculations was carried out at the Institute for Molecular Science in Okazaki.

Preparation and Stereochemistry of Cobalt(III) Complexes Containing 1,1,10,10-Tetraphenyl-4,7-diaza-1,10-diphosphadecane or 2,11-Dimethyl-5,8-diaza-2,11-diphosphadodecane, $R_2PCH_2CH_2NHCH_2CH_2NHCH_2CH_2PR_2$ ($R=C_6H_5$ or CH_3)

Masamichi ATOH, Kazuo KASHIWABARA, and Junnosuke FUJITA*

(Received May 23, 1985)

New quadridentate phosphine ligands, 1,1,10,10-tetraphenyl-4,7-diaza-1,10-diphosphadecane (pp-PNNP) and 2,11-dimethyl-5,8-diaza-2,11-diphosphadodecane (mm-PNNP), were prepared from $(ClCH_2CH_2NHCH_2-)_2 \cdot 2HCl$ and $NaPR_2$ ($R=C_6H_5$, CH_3) and purified through their Ni(II) complexes. Seven new cobalt(III) complexes containing the phosphine ligand were prepared: $[CoX_2(pp\text{- or }mm\text{-}PNNP)]^{n+}$ ($X_2=(Cl)_2$, $(NCS)_2$, $C_5H_7O_2^-$(2,4-pentanedionate ion), and CO_3^{2-}). Four complexes of $[CoX_2(pp\text{- or }mm\text{-}PNNP)]^+$ (X=Cl, NCS) afforded only a trans(X,X) isomer, and $[Co(acac)(pp\text{- or }mm\text{-}PNNP)]^{2+}$ and $[Co(CO_3)(pp\text{-}PNNP)]^+$ complexes yielded a cisβ isomer. The geometrical structures were assigned on the basis of the NMR and visible-ultraviolet absorption spectra.

As an extension of the studies on cobalt(III)-phosphine complexes, we have prepared quadridentate phosphine ligands, $R_2PCH_2CH_2NHCH_2CH_2NHCH_2CH_2PR_2$ ($R=C_6H_5$ or CH_3) which have a set of PNNP donor atoms, and their cobalt(III) complexes. The skeleton of the ligand is an intermediate one of $NH_2CH_2CH_2NHCH_2CH_2NHCH_2CH_2NH_2$ (trien) and $(C_6H_5)_2PCH_2CH_2P(C_6H_5)CH_2CH_2P(C_6H_5)CH_2CH_2P(C_6H_5)_2$ (tetraphos). The $[CoCl_2(trien)]^+$ complex forms all possible geometrical isomers, trans, cisα, and cisβ,[1] while the $[CoX_2(tetraphos)]^+$ (X=Cl, Br) complexes[2] yield only the cisβ isomer. It is of interest to examine the stereoselectivity for complexes containing the above intermediate ligand. An analogous ligand, $(C_6H_5)_2PCH_2CH_2N(CH_3)CH_2CH_2N(CH_3)CH_2CH_2P(C_6H_5)_2$, and its cobalt(II) and nickel(II) complexes have been prepared by Sacconi and Dei,[3] but there has been no report on the cobalt(III) complexes containing such a quadridentate PNNP-type ligand.

The following abbreviations are used for the ligands: $(C_6H_5)_2PCH_2CH_2NHCH_2CH_2NHCH_2CH_2P(C_6H_5)_2$=pp-PNNP and $(CH_3)_2PCH_2CH_2NHCH_2CH_2NHCH_2CH_2P(CH_3)_2$=mm-PNNP.

Experimental

The phosphine ligands were prepared and handled under an atmosphere of nitrogen until they formed cobalt(III) complexes. All solvents used for the preparation were deoxygenated by bubbling nitrogen for 20 min immediately before use. Tetramethyldiphosphine,[4] diphenylphosphine,[5] and $(ClCH_2CH_2NHCH_2-)_2 \cdot 2HCl$[6] were prepared according to the literature methods. Absorption and ^{13}C NMR specta were recorded on a Hitachi 323 spectrophotometer and a Jeol JNM-GX 400 spectrometer, respectively.

Preparation of Ligands. 1,1,10,10-Tetraphenyl-4,7-diaza-1,10-diphosphadecane (pp-PNNP). To liquid ammonia (300 cm^3) containing metallic sodium (1.84 g, 80 mmol) in a 500 cm^3 three-necked round bottom flask with a mechanical stirrer and an ammonia gas inlet was added dropwise diphenylphosphine (14.89 g, 80 mmol) over 5 min with stirring at −78 °C. On stirring for 1 h the color of the solution changed from deep blue to orange. To the orange solution was added $(ClCH_2CH_2NHCH_2-)_2 \cdot 2HCl$ (5.16 g, 20 mmol) in small portions with stirring. Stirring was continued for 1 h, giving a colorless solution. After liquid ammonia had been evaporated, water (50 cm^3) and then diethyl ether (100 cm^3) were added to the residue with stirring. The ethereal layer separated from the aqueous layer was dried over $MgSO_4$ (*ca.* 5 g) overnight. A viscous liquid (8.5 g) was obtained by removing the solvent and unreacted diphenylphosphine by vacuum distillation. The liquid was mixed with a methanol solution (*ca.* 40 cm^3) of $Ni(ClO_4)_2 \cdot 6H_2O$ (10 g, 27 mmol) with stirring, affording immediately a yellow precipitate. It was filtered and dissolved in hot methanol (600 cm^3), and then the solution was filtered. The filtrate was stored in a refrigerator overnight to yield yellow crystals, which were filtered, washed with water and then diethyl ether, and air-dried. Yield: 7.35 g. The filtrate was concentrated to 150 cm^3 and stored in a refrigerator to give additional crystals (0.8 g). Total yield: 8.15 g. Found: C, 47.78; H, 4.44; N, 3.63%. Calcd for $C_{30}H_{36}N_2O_9P_2Cl_2Ni$=[Ni(pp-PNNP)]$(ClO_4)_2 \cdot H_2O$: C, 47.40; H, 4.47; N, 3.68%. The nickel complex is soluble in methanol, ethanol, and CH_2Cl_2, but not in water.

[Ni(pp-PNNP)]$(ClO_4)_2 \cdot H_2O$ (8.15 g, 10.7 mmol) and KCN (14 g, 210 mmol) were stirred in a mixture of CH_2Cl_2 (30 cm^3) and water (100 cm^3) for 20 min, and then benzene (100 cm^3) was added to the mixture. The organic layer was separated from water, dried over $MgSO_4$ (*ca.* 3 g), and evaporated under reduced pressure to yield a viscous liquid, which solidified on standing. Yield: 4.7 g. mp 59 °C. Found: C, 71.54; H, 7.02; N, 5.40%. Calcd for $C_{30}H_{36}N_2OP_2$=pp-PNNP$\cdot H_2O$: C, 71.70; H, 7.22; N, 5.57%.

2,11-Dimethyl-5,8-diaza-2,11-diphosphadodecane (mm-PNNP). To liquid ammonia (150 cm^3) containing metallic sodium (1.90 g, 83 mmol) in a 300 cm^3 three-necked flask was added dropwise tetramethyldiphosphine (5.05 g, 41 mmol) with stirring at −78 °C. The solution was stirred for 1 h. To the resulting orange solution was added $(ClCH_2CH_2NHCH_2-)_2 \cdot 2HCl$ (5.33 g, 21 mmol) in small portions with stirring. After stirring for 1 h, liquid ammonia was evaporated, and then water (50 cm^3) and diethyl ether (40 cm^3) were added to the residue with stirring. The ethereal layer was separated from the aqueous layer and dried over $MgSO_4$ (*ca.* 3 g) overnight.

The solvent and unreacted dimethylphosphine were removed by vacuum distillation. The colorless oily product (2.5 g) thus obtained was used for preparing cobalt(III) complexes without further purification because of a small amount. The ligand can be purified *via* the Nickel(II) complex in the same manner as for pp-PNNP.

Preparation of Complexes. trans*(Cl,Cl)-[CoCl$_2$(pp-PNNP)]ClO$_4$·H$_2$O.* To a methanol solution (20 cm^3) of Co(ClO$_4$)$_2$·6H$_2$O (830 mg, 2.27 mmol) was added pp-PNNP (1.10 g, 2.27 mmol) with stirring, affording orange crystals. Methanol was removed under vacuum, and the residue was dissolved in CH_2Cl_2. Chlorine gas was bubbled into the CH_2Cl_2 solution for 10 min, and then nitrogen gas for 20 min to remove excess Cl_2. To the resulting green solution was added methanol (20 cm^3), and the solution was evaporated to a small volume under reduced pressure, yielding a green precipitate (the solution should not be evporated to dryness since perchlorates of complexes are potentially explosive in a solid state). Additional methanol (250 cm^3) was added to the concentrate. The mixture was warmed at 70 °C for 10 min and then mixed with $NaClO_4 \cdot H_2O$ (20 g) in methanol (20 cm^3). On cooling green crystals were obtained, filtered, washed with water and then diethyl ether, and air-dried. Yield: 1.0 g. Found: C, 49.31; H, 4.95; N, 3.80%. Calcd for $C_{30}H_{36}N_2O_5P_2Cl_3Co$: C, 49.23; H, 4.96; N, 3.83%. The complex is soluble in methanol, CH_2Cl_2, and $CHCl_3$, but not in water and diethyl ether.

trans*(Cl,Cl)-[CoCl$_2$(mm-PNNP)]ClO$_4$.* To *cis*-[CoCl$_2$(en)$_2$]Cl[7] (en=ethylenediamine) (3.5 g, 12 mmol) in a mixture of water (10 cm^3) and methanol (30 cm^3) was added mm-PNNP (1.12 g, 4.75 mmol) with stirring. The solution was stirred for 3 h at room temperature and filtered to remove [Co(en)$_3$]Cl$_3$ precipitated. The filtrate was warmed with concd HCl (4 cm^3) at 60 °C for 1 h, and then evaporated to dryness under reduced pressure. The residue was dissolved in water (200 cm^3), and the solution was applied on a column (ϕ7 cm×15 cm) of SP-Sephadex C-25 (Na^+ form). By elution with 0.05 mol dm^{-3} HCl, a blue eluate was obtained, a red brown band remaining on the top of the column. The blue eluate was evaporated to dryness under reduced pressure, and the blue product was extracted with ethanol. The extract was evaporated again to dryness under reduced pressure, and the residue was mixed with $NaClO_4 \cdot H_2O$ (2.0 g) in water (10 cm^3), yielding blue crystals, which were filtered, washed with water and then diethyl ether, and air-dried. Yield: 282 mg. Found: C, 25.89; H, 5.94; N, 6.00%. Calcd for $C_{10}H_{26}N_2O_4P_2Cl_3Co$: C, 25.80; H, 5.63; N, 6.02%. The complex is soluble in methanol and acetone, slightly in water, but not in diethyl ether, $CHCl_3$, and CH_2Cl_2.

cis*β-[Co(acac)(pp-PNNP)](ClO$_4$)$_2$·H$_2$O.* A methanol solution (50 cm^3) containing *trans*(Cl,Cl)-[CoCl$_2$(pp-PNNP)]ClO$_4$·H$_2$O (150 mg, 0.21 mmol) and Li(acac) (60 mg, 0.57 mmol) was stirred for 20 min at room temperature. The resulting orange-red solution was diluted with water (200 cm^3), and the solution was applied on a column (ϕ3.5 cm×70 cm) of SP-Sephadex C-25. By elution with 0.2 mol dm^{-3} NaCl, two very small orange bands and a large red one were eluted successively. The eluate of the large red band was collected and concentrated to 40 cm^3 under reduced pressure. On addition of $NaClO_4 \cdot H_2O$ the concentrate gave a red precipitate, which was filtered, washed with a small amount of water, and air-dried. Yield: 47 mg. Found: C, 48.69; H, 4.83; N, 3.27%. Calcd for $C_{35}H_{43}N_2O_{11}P_2Cl_2Co$: C, 48.91; H, 5.04; N, 3.26%. The complex is soluble in water, methanol, and CH_2Cl_2, but not in diethyl ether.

cis*β-[Co(acac)(mm-PNNP)](ClO$_4$)$_2$·H$_2$O.* A mixture of [Co(acac)$_3$][8] (870 mg, 2.44 mmol) and mm-PNNP (580 mg, 2.45 mmol) in methanol (100 cm^3) was stirred at room temperature for 3 h. To the resulting solution was added water (200 cm^3), and then unreacted mm-PNNP and [Co(acac)$_3$] were extracted with diethyl ether three times (50 cm^3 ×3). The aqueous layer was diluted with water to 1 dm^3, and the solution was applied on a column (ϕ3.5 cm×10 cm) of SP-Sephadex C-25. After complexes with the +1 charge contained in the adsorbed product had been eluted with 0.05 mol dm^{-3} NaCl, those with the +2 charge were eluted with 0.2 mol dm^{-3} NaCl. The orange eluate collected was evaporated to dryness under reduced pressure, and the orange product was extracted with ethanol (70 cm^3). The extract was diluted with water (200 cm^3) and rechromatographed with a column (ϕ3.5 cm×100 cm) of SP-Sephadex C-25 and an eluent of 0.2 mol dm^{-3} NaCl. The column showed a very small violet and a large red band. The eluate of the red band was concentrated to 50 cm^3 under reduced pressure. The concentrate was mixed with $NaClO_4 \cdot H_2O$ (3 g) to yield an orange-red precipitate, which was recrystallized from hot water (60 °C), giving red crystals. Yield: 505 mg. Found: C, 29.55; H, 5.42; N, 4.55%. Calcd for $C_{15}H_{35}N_2O_{11}P_2Cl_2Co$: C, 29.48; H, 5.77; N, 4.58%. The complex is soluble in water, methanol, and acetone, but not in $CHCl_3$, CH_2Cl_2, and diethyl ether.

cis*β-[Co(CO$_3$)(pp-PNNP)]Cl·NaCl·H$_2$O.* To a methanol solution (100 cm^3) of *trans*(Cl,Cl)-[CoCl$_2$(pp-PNNP)]ClO$_4$·H$_2$O (500 mg, 0.68 mmol) were added $(NH_4)_2CO_3$ (200 mg, 2.08 mmol) and active charcoal (100 mg). The mixture was stirred for 8 h at room temperature, and then filtered. The filtrate was diluted with water (1 dm^3), and the solution was applied on a column (ϕ3.5 cm×40 cm) of SP-Sephadex C-25. The adsorbed product was eluted with 0.05 mol dm^{-3} NaCl. The eluate of the first main red band was collected and concentratred to 30 cm^3 under reduced pressure. The concentrate was mixed with NaCl (*ca.* 10 g) and stored in a refrigerator to yield red crystals, which were filtered, washed with a small amount of water and then diethyl ether, and air-dried. Yield: 74 mg. Found: C, 52.15; H, 4.92; N, 3.55%. Calcd for $C_{31}H_{36}N_2O_4P_2Cl_2CoNa$: C, 52.05; H, 5.07; N, 3.92%. An additional amount of the complex was obtained as the perchlorate by adding excess $NaClO_4 \cdot H_2O$ to the filtrate. Yield: 53 mg. Found: C, 52.52; H, 4.64; N, 3.79%. Calcd for $C_{31}H_{34}N_2P_2O_7ClCo$=[Co(CO$_3$)(pp-PNNP)](ClO$_4$): C, 52.97; H, 4.87; N, 3.99%. Both the chloride and perclorate are soluble in water, methanol, and CH_2Cl_2, but not in diethyl ether.

trans*(NCS,NCS)-[Co(NCS)$_2$(pp-PNNP)]Cl·4H$_2$O.* A methanol solution (20 cm^3) containing *trans*(Cl,Cl)-[CoCl$_2$(pp-PNNP)]ClO$_4$·H$_2$O (100 mg, 0.14 mmol) and KNCS (70 mg, 0.7 mmol) was stirred at 50 °C for 30 min. The resulting red solution was diluted with a mixture of water (50 cm^3) and methanol (30 cm^3), and the solution was applied on a column (ϕ3.5 cm×50 cm) of SP-Sephadex C-25. By elution with a 0.05 mol dm^{-3} NaCl methanol–water (1:3) solution, the eluate of the first red band was collected. The complex in the eluate was extracted with chloroform two times (30 cm^3×2), and the extract was evaporated to dryness under reduced pressure. The residue was dissolved again in methanol (5 cm^3), and the solution was mixed with NaCl (2 g) in water (20 cm^3), giving a red precipitate. Red crystals

were obtained by dissolving the precipitate in a mixture of methanol and water (1:1) and by evaporating the solution slowly at room temperature. Yield: 23 mg. Found: C, 50.35; H, 5.32; N, 7.63%. Calcd for $C_{32}H_{42}N_4O_4P_2S_2ClCo$: C, 50.10; H, 5.51; N, 7.30%. The complex is soluble in methanol, acetone, $CHCl_3$, and CH_2Cl_2, but not in water and diethyl ether.

trans(NCS,NCS)-[Co(NCS)$_2$(mm-PNNP)]Cl·1/2(NaCl)·H$_2$O. A methanol solution (50 cm^3) containing *trans*(Cl,Cl)-[$CoCl_2$(mm-PNNP)]ClO_4 (140 mg, 0.30 mmol) and KNCS (140 mg, 1.44 mmol) was stirred at 60 °C for 40 min. The resulting red solution was diluted with water (1 dm^3), and applied on a column (ϕ3.5 cm×50 cm) of SP-Sephadex C-25. By elution with 0.05 mol dm^{-3} NaCl, orange and blue bands were obtained. The eluate of the orange band was collected and evaporated to dryness under reduced pressure, and the complex was extracted from the residue with ethanol (100 cm^3). The extract was evaporated to dryness under reduced pressure, and the residue was again dissolved in water (5 cm^3). The solution was mixed with NaCl (1.5 g) at 50 °C, and stored in a refrigerator to yield red crystals, which were filtered, washed with a small amount of cold water, and air-dried. Yield 71 mg. Found: C, 29.21; H, 5.64; N, 11.46%. Calcd for $C_{12}H_{28}N_4OP_2S_2Cl_{1.5}Na_{0.5}Co$: C, 29.17; H, 5.71; N, 11.34%. The complex is soluble in water, methanol, and ethanol, but not in diethyl ether and $CHCl_3$.

Results and Discussion

Preparation. Multidentate ligands containing both nitrogen and phosphorus donor atoms have been usually prepared by reaction of ω-chloroalkylamines with phosphides.[9] Sacconi and Dei[3] prepared a linear-quadridentate ligand, $(C_6H_5)_2PCH_2CH_2N(CH_3)CH_2$-$CH_2N(CH_3)CH_2CH_2P(C_6H_5)_2$ which has a set of PNNP donor atoms, from $(ClCH_2CH_2N(CH_3)CH_2-)_2\cdot 2HCl$ and $KP(C_6H_5)_2\cdot$(dioxane)$_2$. We have prepared pp-PNNP and mm-PNNP by a similar method using $NaP(C_6H_5)_2$ and $NaP(CH_3)_2$, respectively, generated from $PH(C_6H_5)_2$ or $(CH_3)_2PP(CH_3)_2$ and metallic sodium in liquid ammonia. These quadridentate ligands were not purified by vacuum distillation because of a high boiling point. The purification was achieved through their Ni(II) complexes. Pure pp-PNNP solidified on standing at room temperature, whereas mm-PNNP remained oily. Yields of the ligands seemed to depend largely on the purity of reactants and the presence of moisture. The pp-PNNP ligand was also prepared from (2-aminoethyl)diphenylphosphine(edpp) and 1,2-dibromoethane, but the separation of the ligand from unreacted edpp was somewhat troublesome. In the air pp-PNNP is rather stable, but mm-PNNP is readily oxidized.

The $[CoCl_2(pp\text{-}PNNP)]^+$ complex was prepared by oxidizing the Co(II)–pp-PNNP complex with chlorine in a moderate yield. However, the corresponding mm-PNNP complex was not obtained by this method, but done by reaction of the ligand with $[CoCl_2(en)_2]^+$ in a fairly poor yield. The oxidizing method by chlorine is not effective either for a trialkylphosphine complex, *trans*(Cl,Cl)-$[CoCl_2(edmp)_2]^+$ (edmp=(2-aminoethyl)-dimethylphosphine),[10] although the corresponding (2-aminoethyl)diphenylphosphine(edpp) complex is obtained easily by this method.[11] Green $[CoCl_2(pp\text{-}PNNP)](ClO_4)\cdot H_2O$ was used for preparing other complexes of $[CoX_2(pp\text{-}PNNP)]^{n+}$ (X=NCS$^-$, X$_2$=CO$_3^{2-}$, and acac). Although several geometrical isomers are possible for the pp-PNNP complex, only one isomer was formed for each complex as confirmed by column chromatography and ^{13}C NMR spectra. On the contrary, the corresponding NCS$^-$ and acac complexes of edpp, $[CoX_2(edpp)_2]^{n+}$, form two geometrical isomers, trans(NCS, NCS)cis(P,P) and cis(NCS,NCS)trans(P,P),[12] and trans-(P,P) and trans(P,N),[11] respectively, by similar reactions with $[CoCl_2(edpp)_2]^+$. The mm-PNNP complexes also yielded only one isomer. The $[Co(NCS)_2(mm\text{-}PNNP)]^+$ complex was obtained by the reaction of $[CoCl_2(mm\text{-}PNNP)]^+$ with KNCS in a 48% yield. The reaction between $[CoCl_2(mm\text{-}PNNP)]^+$ and Li(acac) yielded $[Co(acac)(mm\text{-}PNNP)]^{2+}$ in a poor yield (7%), but that between mm-PNNP and $[Co(acac)_3]$ gave the complex in a better yield (36%). This is quite in contrast to the reactions of pp-PNNP with $[Co(acac)_3]$ and of $[CoCl_2(pp\text{-}PNNP)]^+$ with Li(acac) resulting in 8 and 27% yields, respectively. Synthetic methods for Co(III)–phosphine complexes should be designed carefully by considering the kind of phosphine ligands.[13] The reaction between $[CoCl_2(mm\text{-}PNNP)]^+$ and $(NH_4)_2CO_3$ at room temperature scarcely proceeded, and decomposition occurred at a higher temperature. The reaction of $[CoCl_2(mm\text{-}PNNP)]$ with a large excess of $(NH_4)_2CO_3$ gave a trace amount of an orange complex assignable to $[CoCO_3(mm\text{-}PNNP)]^+$. However, it was not isolated because of a extremely low yield. Attempts to prepare [Co(en)(pp-PNNP or mm-PNNP)]$^{3+}$ from the dichloro complex and en were all unsuccessful.

Stereochemistry. There are three possible geometrical isomers for X=Cl$^-$ and NCS$^-$, and two for X$_2$=CO$_3^{2-}$ and acac in the $[CoX_2(PNNP)]$-type complex. The geometrical structures were assigned on the basis of the NMR and ligand field absorption spectra. The ^{13}C NMR and absorption spectral data are summarized in Tables 1 and 2, respectively.

The ^{13}C NMR spectra of $[CoX_2(pp\text{- or mm-}PNNP)]^+$ (X=Cl$^-$ and NCS$^-$) indicate the complexes to be either the trans or cisα isomer which have C_2 symmetry (Fig. 1). Each of these complexes shows two kinds of phenyl or methyl signals (Table 1). Since both trans and cisα isomers are chiral (the trans isomer having chiral nitrogen donor atoms), the two phenyl or methyl groups on a phosphorus atom are diastereomeric to each other, and should be magnetically unequivalent. Thus geometrical structures of the complexes can not be assigned unequivocally from the NMR spectra. In Fig. 2 are compared the absorption spectra of $[CoCl_2(pp\text{- or mm-}PNNP)]^+$ and $[Co(NCS)_2(pp\text{-}PNNP)]^+$ with those of the corresponding bis(edpp) and bis(edmp) complexes. Molecular structures of $[CoCl_2(edpp)_2]^+$ and

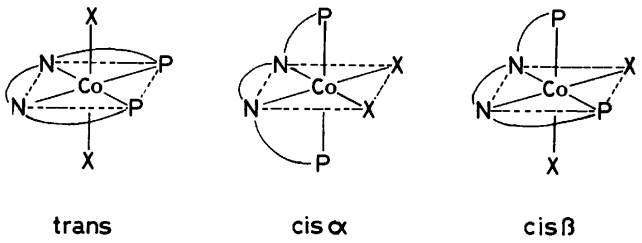

Fig. 1. Geometrical isomers of the $[CoX_2(PNNP)]$-type complex.

$[Co(NCS)_2(edpp)_2]^+$ given in Fig. 2 have been determined to trans(Cl,Cl)cis(P,P)[10] and trans(NCS,NCS)-cis(P,P),[12] respectively, by X-ray analysis, and that of $[CoCl_2(edmp)_2]^+$ assigned to trans(Cl,Cl)cis(P,P) by comparing the absorption spectrum with those of the corresponding isomers of edpp and ebpp ((2-aminoethyl)butylphenylphosphine) complexes.[10] From a comparison of these spectra, $[CoCl_2(pp\text{- and mm-}PNNP)]^+$ and $[Co(NCS)_2(pp\text{-}PNNP)]^+$ can be assigned to the trans isomer. The spectrum of $[Co(NCS)_2(mm\text{-}PNNP)]^+$ is somewhat different from that of $[Co(NCS)_2(pp\text{-}PNNP)]^+$. However, the mm-PNNP complex shows a very similar ^{13}C NMR spectrum to that of $[CoCl_2(mm\text{-}PNNP)]^+$, indicating the trans isomer.

The *trans*(X,X)-$[CoX_2(pp\text{- or mm-}PNNP)]^+$ complex can have two diastereomers, racemic (*RR* and *SS*) and meso (*RS*) forms for the chiral nitrogen donor atoms. Both the NMR spectra and column chromatograms indicate that each of the trans isomers yielded only one of these two diastereomers selectively. When the complexes are the racemic form, the structures can be assigned by optical resolution. However, attempts to resolve the complexes by column chromatography using Sephadex LH-20 or SP-Sephadex C-25 were unsuccessful. The ^{13}C NMR spectra of $[Co(NCS)_2(pp\text{- or mm-}PNNP)]^+$ indicate that the two NCS^- groups are magnetically equivalent, although the observed signals (pp-PNNP: 143.25 ppm, mm-PNNP: 144.72 ppm) were very weak. Thus the complexes can be assigned to the racemic form (C_2 symmetry), since the two NCS^- groups in the meso form (C_s symmetry) should be magnetically unequivalent.

The ^{13}C NMR spectra of $[Co(acac)(pp\text{- or mm-}PNNP)]^{2+}$ and $[Co(CO_3)(pp\text{-}PNNP)]^+$ clearly indicate that the complexes are the cisβ isomer which has only C_1 symmetry (Table 1). The arrangement of donor atoms in the cisβ isomer is the same as that in trans(P,N) isomers of the corresponding edpp and edmp complexes. In the ^{13}C NMR spectra of [Co-

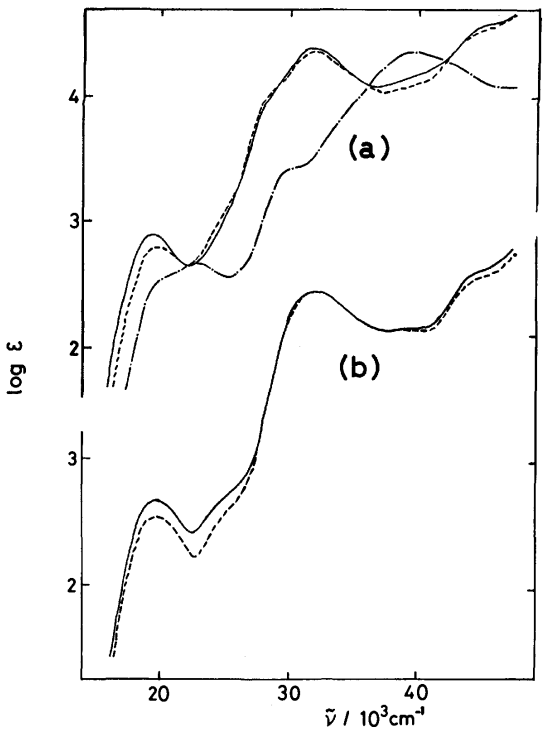

Fig. 3. Absorption spectra of *cisβ*-[Co(O-O)(PNNP)]-type Complexes. (a): *cisβ*-[Co(acac)(pp-PNNP)]$^{2+}$ (——), *trans*(P,N)-[Co(acac)(edpp)$_2$]$^{2+}$ (------), and *cisβ*-[Co(acac)(mm-PNNP)]$^{2+}$ (—·—·—), (b): *cisβ*-[Co(CO_3)(pp-PNNP)]$^+$ (——) and *trans*(P,N)-[Co(CO_3)(edpp)$_2$]$^+$ (------).

(acac)(pp- or mm-PNNP)]$^{2+}$, one of two methyl groups of acac which resonates at a lower magnetic field exhibits a coupling with the phosphorus atom trans to the oxygen donor atom of acac. The same coupling has been observed for the *trans*(P,N)-[Co(acac)-(edpp)$_2$]$^{2+}$.[11]

The absorption spectra of [Co(acac or CO_3)(pp-PNNP)]$^{n+}$ also resemble remarkably those of respective *trans*(P,N)-[Co(acac or CO_3)(edpp)$_2$]$^{n+}$. (Fig. 3) The absorption spectral pattern of [Co(acac)(pp- and mm-PNNP)]$^{2+}$ are different from each other over the whole region. The pp-PNNP complex shows the single first absorption band at 19500 cm^{-1}, and the pattern is also similar to that of [Co(acac)(en)(dppe)]$^{2+}$(dppe=1,2-bis-(diphenylphosphino)ethane).[11] On the other hand, the mm-PNNP complex exhibits a peak at 22750 cm^{-1} and a shoulder at *ca.* 20000 cm^{-1} in the first absorption region, and the pattern of which is quite similar to that of [Co(acac)(en)(dmpe)]$^{2+}$ (dmpe=1,2-bis(dimethylphosphino)ethane).[14] The ligand field strengths of mm-PNNP and dmpe may be much stronger than those of pp-PNNP and edpp to cause a splitting of the first absorption band of the complex.

Reduction of Aryl Halides and *N*-Hydroxy Nitrogen Compounds in Fast Atom Bombardment Mass Spectrometry

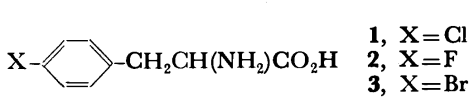
Takemichi NAKAMURA,* Hidemi NAGAKI, and Takeshi KINOSHITA
Analytical and Metabolic Research Laboratories, Sankyo Co., Ltd., 2-58, Hiromachi 1-Chome, Shinagawa-ku, Tokyo 140
(Received April 13, 1985)

Aromatic halogenated compounds and *N*-hydroxy nitrogen compounds were reduced to dehalogenated and deoxy analogs, respectively, in the fast atom bombardment ion source of a mass spectrometer. The reaction was found to occur in the liquid phase on exposure to a neutral fast atom beam.

Fast atom bombardment mass spectrometry (FAB/MS) and mass spectrometry mass spectrometry (MS/MS)[1,2] are very useful tools for characterizing polar or nonvolatile organic compounds.[3,4] In connection with a study on the FAB/MS of naturally occurring chlorinated peptide antibiotics (*e.g.* vancomycin[5,6]), we found that ions which might be assigned to quasi-molecular ions of the original compounds and those of mono-dechlorinated analogs were observed at the same time. These dechlorinated species seemed to exist regardless of the purity of the original samples. So this phenomenon was considered to be attributable to reduction of the corresponding chlorinated compounds. To confirm the assumption, halogenated model compounds were examined. Furthermore, several *N*-hydroxy nitrogen compounds were also tested for reduction under FAB measurement conditions.

Results and Discussion

The FAB spectrum of *p*-chlorophenylalanine (**1**) is shown in Fig. 1. A protonated molecular ion (*m/z* 200) was observed in the spectrum. Surprisingly, a



1, X=Cl
2, X=F
3, X=Br

non-chlorine-containing ion (*m/z* 166) corresponding to MH^+ of phenylalanine was also recorded at a notable relative intensity (23% of the sum of *m/z* 200 and 202). This ion (*m/z* 166) can not be derived from

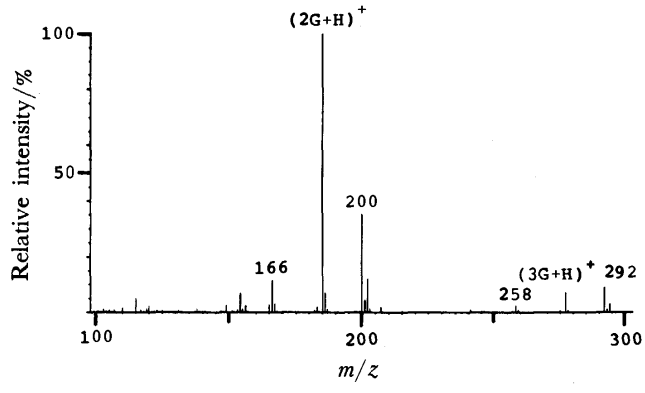


Fig. 1. Positive ion FAB spectrum of **1**. Glycerol is represented by G. The ions at *m/z* 258 and 292 are glycerol adducts of *m/z* 166 and 200, respectively.

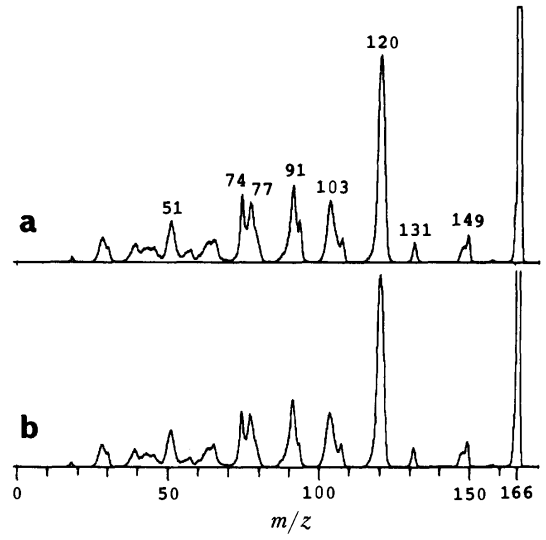

Fig. 2. CAD spectra of (a) *m/z* 166 in the FAB spectrum of **1** and (b) protonated molecular ion of phenylalanine yielded by FAB ionization. The precursor ions were resolved at high resolution (10,000).

MH^+ of **1** (*m/z* 200) since mass difference between these ions (34 u) is smaller than mass number of chlorine. The structure of the ion at *m/z* 166 was determined to be the same as that of MH^+ of phenylalanine, because the collisionally activated dissociation (CAD) spectra of both ions were identical (Fig. 2).

The relative abundance of *m/z* 166 was dependent on the kinetic energy of the neutral fast atom beam (16, 23, and 26% for 4, 6, and 8 keV, respectively) and increased over the period of irradiation (Fig. 3). These results suggest that the ion at *m/z* 166 was formed by bombardment of the fast atom beam at the surface of the sample solution.

The FAB spectra of *p*-fluorophenylalanine (**2**) and *p*-bromophenylalanine (**3**) also showed identical ions (*m/z* 166). The relative abundances of the ions at *m/z* 166 were 3.3% to *m/z* 186 and 51% to the sum of *m/z* 244 and 246, respectively. It seemed that the carbon–halogen bond strength directly reflected the amount of the reduced species.

Very recently, similar results on halogenated nucleosides have been reported by McCloskey *et al.*[7] They proposed the process that the halogen atoms on aromatic rings were replaced by hydrogen atoms of

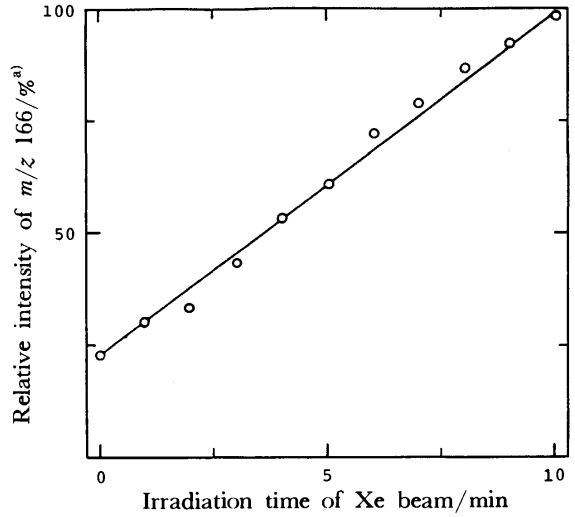

Fig. 3. Relationship between irradiation time and relative abundances of m/z 166 in FAB spectra of **1**. a) Calculated based on the sum of m/z 200 and 202.

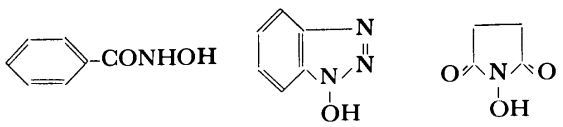
glycerol molecules *via* radical intermediates based on deuterium labeling experiments. In present MS/MS studies, on the other hand, the structure of reduced products of **1**—**3** have been confirmed directly.

Such reductions occur not only in the case of halogenated compounds. Other examples were found in the case of *N*-hydroxy nitrogen compounds, namely, benzohydroxamic acid (**4**), 1-hydroxybenzotriazole (**5**), and *N*-hydroxysuccinimide (**6**).



4 **5** **6**

The FAB spectrum of **4** (Fig. 4) exhibits MH^+ of **4** (m/z 138) and $MH^+ - 16$ (m/z 122, 60% of m/z 138). The ion at m/z 122 was not derived from MH^+ (m/z 138), because the metastable ion (MI) spectrum and CAD spectrum of MH^+ did not show any peak at m/z 122. The CAD spectrum of m/z 122 is identical to that of MH^+ of benzamide (Fig. 5). These results indicate that **4** was reduced to benzamide during the measurement of the FAB spectrum.

Similar phenomena were observed in the cases of **5** and **6**. The FAB spectra of **5** and **6** showed m/z 120 ($MH^+ - 16$, 51% of MH^+) and m/z 100 ($MH^+ - 16$, 31% of MH^+), respectively. The MS/MS experiments revealed that the ions ($MH^+ - 16$) were not derived from MH^+ but were identical to MH^+ of the corresponding reduced products in each case.

Since trace amounts of reduced products were recovered from the sample matrix solutions after FAB measurement of compounds **1**, **3**, **4**, and **5**, it was determined that the reactions occurred in the liquid

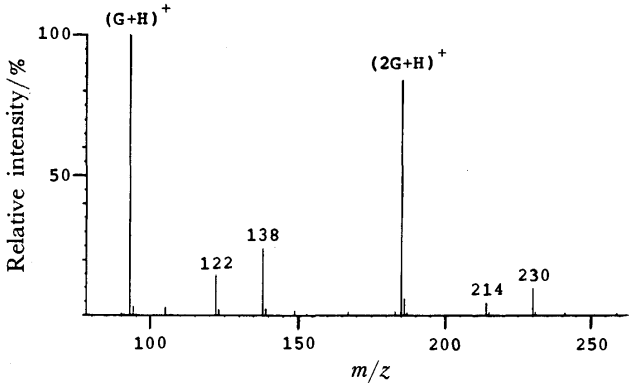


Fig. 4. Positive ion FAB spectrum of **4**. Glycerol is represented by G. The ions at m/z 214 and 230 are glycerol adducts of m/z 122 and 138, respectively.

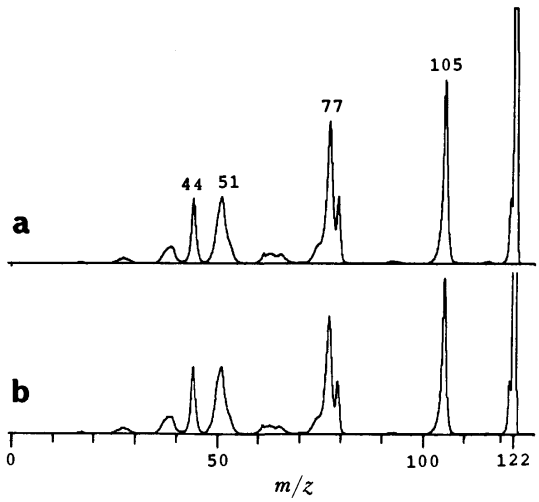

Fig. 5. CAD spectra of (a) m/z 122 in the FAB spectrum of **4** and (b) protonated molecular ion of benzamide yielded by FAB ionization. The precursor ions were resolved at high resolution (10,000).

phase as a result of bombardment by fast atoms, at least in part. Accumulation and time dependence of the relative intensities of MH^+ of the reduced products were not observed in previous work.[7] This disagreement may be caused by some differences of experimental conditions, *e.g.*, sample concentration, density of neutral atom beams, sputtering efficiency of sample molecules, and pressure of ion sources.

The results presented in this paper indicate that it is difficult to determine the purity or quantity of the above types of compounds by FAB/MS. However, in the cases that the purity of the samples has been established on the basis of other data, the phenomena described above are very useful for characterization of these compounds.

Experimental

Materials. All compounds were obtained from commercial sources: **1**, **2**, **4**, **5**, and **6**, Tokyo Kasei Kogyo Co.; **3** and glycerol (99.5%), Aldrich Chemical Co. They were

used without further purification. Compounds **1**—**6** were examined by GC/MS as trimethylsilyl derivatives (for **4**—**6**) or *N*-trifluoroacetyl trimethylsilyl esters (for **1**—**3**). Dehalogenated analogs of **1**—**3** or *N*-deoxy analogs of **4**—**6** could not be detected in each case (the limits of detection were 0.25% for dehalogenated analogs and 1% for deoxy analogs). Xenon (99.998%) was purchased from Showa Denko Co.

Apparatus and Procedures. All FAB mass spectra and MS/MS (MI and CAD) spectra were obtained using a JEOL JMS-HX100 mass spectrometer, which consists of a conventional geometry high resolution mass spectrometer followed by a second electrostatic analyzer (ESA-2). The kinetic energy of the xenon fast atom beam was made up to 6 keV unless otherwise stated.

The methanolic or aqueous ethanolic solutions of 10μg samples were mixed with glycerol (1 μl), then applied on stainless steel probe tips and introduced into a FAB ion source through a vacuum lock. Scanning of the magnetic field and irradiation of a fast atom beam were started at the same time and FAB spectra were recorded.

The MI and CAD spectra were obtained with the ESA-2 scanning. Collisionally activated dissociation experiments were performed at a high collision energy (5 keV).[2] Chemically pure argon was used as a neutral target gas introduced into the collision cell placed between the magnetic field and the ESA-2.

Sample solutions were recovered after irradiation by a fast atom beam (*ca.* 30 min) and examined by TLC.

Reactions of Enolic Biotin Models

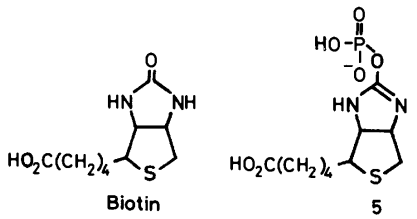
Hiroki KONDO,* Katsuhito MIURA, Eiji SEKI, and Junzo SUNAMOTO
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
(Received April 27, 1985)

In order to delineate the mechanism of biotin-dependent carboxylation reactions, the following model experiments have been carried out. In reactions of carbonate derivatives such as methyl chloroformate with 2-ethoxy-2-imidazoline (**1**), a putative enolic biotin model, or 2-imidazolidinone (**2**), the former showed a much higher reactivity to provide the methoxycarbonylated **1** (**3**). Reactions of **3** with benzenethiolate, cyclohexylamine and carbanions have also been investigated as a model of transcarboxylation from *N*-carboxybiotin to an acceptor substrate. Only carbanions attack the carbonyl carbon of **3**, leading to rupture of the C–O bond, but not of the N–C bond. A net "carboxyl" transfer was effected with 1-methoxycarbonylimidazole (**9**) as a donor substrate. Implications of these results in biotin catalysis are discussed.

Biotin is the coenzyme involved in the synthesis of long-chain fatty acids in biological systems.[1-3] This enzymatic carboxylation takes place in two discrete steps as shown in Eqs. 1a and 1b. Biotin-dependent carboxylation reactions are interesting from a synthetic as well as a biochemical point of view. Despite efforts it has been unsuccessful to duplicate biotin-mediated carboxylation in nonenzymatic systems. One of the major reasons for this lies in the poor reactivity of the ureido nitrogen of biotin upon which carboxylation occurs.[4] Enzymes appear to overcome this problem by utilizing the free energy released upon hydrolysis of ATP to activate one or more of the reactants (Eq. 1a). Several hypotheses have been proposed to account in chemical terms for the role of ATP in biotin carboxylation. One of the attractive hypotheses claims that ATP might phosphorylate the ureido oxygen of biotin to generate an enolic structure (**5**).[5] This mechanism attracted considerable attention in recent years,[6-8] though rigorous structural proof of the thermodynamically unstable **5** has not been provided. In this article we attempted to assess the reactivity of a stable model compound of putative **5** toward several carbonate derivatives. Furthermore, model carboxyl-transfer reactions from a methoxycarbonylated biotin model to an acceptor substrate have also been investigated.

$$\text{E-Biotin} + HCO_3^- + \text{ATP} \rightleftharpoons \text{E-Biotin-}CO_2^- + \text{ADP} + \text{Pi} \quad (1a)$$

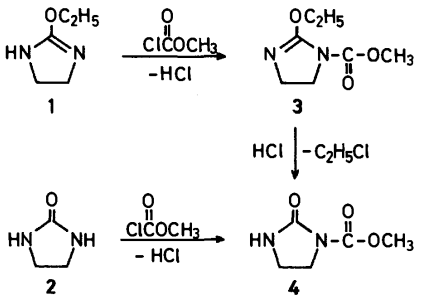
$$\text{E-Biotin-}CO_2^- + \text{RH} \rightleftharpoons \text{E-Biotin} + RCO_2H \quad (1b)$$



Results

Reactions of 1 and 2 with Carbonate Derivatives.

We have chosen 2-ethoxy-2-imidazoline (**1**) as a model for the enolic form of biotin and compared its reactivity with that of the keto model compound (**2**) toward several carbonate derivatives, methyl chloroformate, methoxycarbonyl dimethyl phosphate (MDP), and methyl *p*-nitrophenyl carbonate (MPNC). The reactions were routinely followed by ^1H NMR or HPLC, but the products were isolated, where necessary, for identification by a comparison with the authentic specimen. A reaction of **2** with methyl chloroformate gives **4** (Scheme 1), but a large excess of reagent and



Scheme 1.

refluxing (≈60 °C) of the reaction mixture for several hours are usually needed to drive the reaction to completion. On the other hand, a mild condition (one equiv of methyl chloroformate and room temperature) is sufficient to methoxycarbonylate **1** with methyl chloroformate, thus demonstrating that **1** is by far the more reactive than **2** toward this reagent. Conversely, treatment of **1** with methyl chloroformate under the condition adopted for **2** (see above) gave **4** in quantitative yield. It was later found that **4** was produced *via* **3** as stated above and that because of its acid lability **3** is transformed into **4** by the hydrochloric acid generated in the preceeding reaction (Scheme 1).[9]

In addition to methyl chloroformate both MDP and MPNC are able to methoxycarbonylate **1** under mild conditions. Thus treatment of **1** with one equiv of MDP or MPNC at room temperature yielded **3** in excellent yield. MDP possesses potentially two sites for nucleophilic attack,[10] but the reaction with **1** took place solely on the carbon. No conversion of **3** into **4** was observed

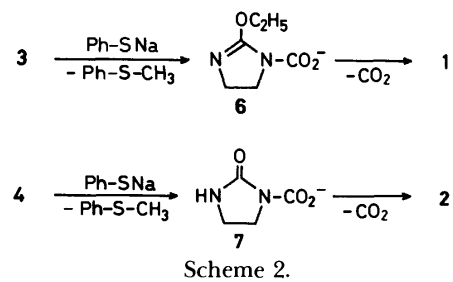
TABLE 1. REACTION OF 1 WITH CARBONATE DERIVATIVES AT 25 °C. THE EXTENT OF REACTION WAS EVALUATED BY INTEGRATING THE ^{1}H NMR SIGNAL INTENSITIES.

Reagent[a]	[Reagent]/[1]	Solvent	Conversion/%	
			6 min	32 min
$ClCO_2CH_3$	1.0	$CDCl_3$	100	—
MDP	1.1	$CDCl_3$	75±5	100
MPNC	1.0	DMSO-d_6	40±5	80±5

a) MDP, methoxycarbonyl dimethyl phosphate; MNPC, methyl *p*-nitrophenyl carbonate.

when the reaction mixture of **1** and MDP or MPNC was refluxed in chloroform for 30 min, because the acids liberated in these reactions, dimethyl hydrogenphosphate and *p*-nitrophenol, are not acidic enough to bring about such a transformation.[9] The rates of methoxycarbonylation of **1** by these reagents are compared in Table 1. No reaction took place between **2** and MDP or MPNC even after 2 d in refluxing chloroform. This indicates that these two reagents are not electrophilic enough to methoxycarbonylate **2** and that there is a sharp difference between **1** and **2** in the reactivity toward carbonate carbonyls. The difference is too large to allow comparison of the reactivity of both compounds directly on the same scale.

Reactions of 3 and 4 with Nucleophiles. Reactions of **3**, **4**, and related compounds with sulfur and nitrogen bases as well as carbanions have been studied as a model of carboxyl transfer reactions (Eq. 1b). Similar reactions of **3** and **4** with hydroxide ions in water have already been reported.[11] A sample of **3** or **4** was allowed to react with 2 equiv of sodium benzenethiolate in DMSO-d_6 and the progress of reaction was followed by ^{13}C NMR. As has been reported previously,[12] compound **4** reacts with benzenethiolate at room temperature (≈20 °C) to provide methyl phenyl sulfide and **2**. The half time of the reaction was estimated as 30 min. By reference to the similar reaction of hydroxide ions in water,[11] the reaction was presumed to follow the sequence given in Scheme 2.[12] Unlike in the saponification in water, however, compound **7** has never been detected by ^{13}C NMR during the reaction in the present system, indicating that decarboxylation of **7** is fast compared to the demethylation step. The reaction of **3** follows the identical pathway, albeit at a decreased rate. The half time was estimated to be ≈25 min at 66 °C. The nucleophilic attack of benzenethiolate on the methyl carbon of **3** is the rate-determining step and the reaction products obtained were exclusively methyl phenyl sulfide and **1**. The lability of the intermediates (**6** and **7**) hampered comparison of the rates of their decarboxylation.

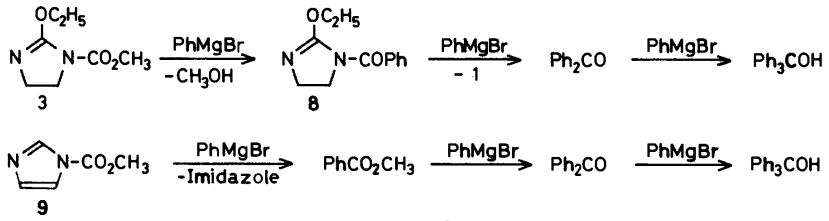


Scheme 2.

A reaction of **3** with cyclohexylamine afforded 1-methoxycarbonyl-2-cyclohexylaminoimidazolidine quantitatively (isolated yield 75%). In contrast, the attack of secondary or tertiary amines on the compound carrying an extra methyl group on 3-N of **3** takes place on the ethyl carbon, not on the 2-position.[7] The presence of a positive charge on the 3-N in the latter substrate appears to be responsible for this difference. Because of the charge the molecule is rendered electron-deficient, thus making the ethyl migration to a nucleophile possible. Compound **4** followed a similar pathway to that for **3** in the reaction with primary amines; initial nucleophilic attack on the ureido carbonyl provided a ring-opened product of substrate.[12]

A reaction of **3** with 3 molar equiv of phenylmagnesium bromide was carried out in THF at 0 °C for 10 h. The reaction mixture was worked up as usual. Inspection of the products by ^{1}H NMR in CCl_4 with CH_2Cl_2 as the internal standard revealed that following compounds had been obtained: 1-benzoyl-2-ethoxy-2-imidazoline (**8**) 52%, benzophenone 6%, triphenylmethanol 11%, and unreacted **3** 14%. This mode of product distribution is consistent with a sequence of reactions shown in Scheme 3. Initial attack of the Grignard reagent on the carbonyl carbon of **3** is followed by scission of the C–O bond, but not of the N–C bond. The product (**8**) undergoes further reactions with phenylmagnesium bromide to give benzophenone and triphenylmethanol. The possibility of an alternative pathway by way of methyl benzoate is ruled out, because the ester, if produced, could have survived under the present reaction conditions (see below). Analogous results were obtained for the reaction of **4** with phenylmagnesium bromide,[13] indicating that the electronic structure of the electrophilic center is not different significantly between the two compounds.

The above results suggest that net carboxyl transfer might be achieved if the basicity of the pertinent nitrogen is lowered. Hence 1-methoxycarbonylimidazole (**9**) was chosen as a donor substrate. Reaction of **9** with phenylmagnesium bromide, indeed, provided methyl benzoate (Scheme 3). For example, a reaction of **9** with 2 molar equiv of phenylmagnesium bromide yielded the following products: methyl benzoate 51%, benzophenone 1%, triphenylmethanol 5%, and unreacted **9** 8%. This result clearly indicates that the N–C bond cleavage or "the carboxyl" transfer has taken place. An alternative pathway that produces 1-benzoylimidazole as the initial product may also be envisioned, because the latter two products can be generated from either methyl benzoate or 1-benzoylimidazole. Furthermore, only 65% of the substrate initially present were identi-



Scheme 3.

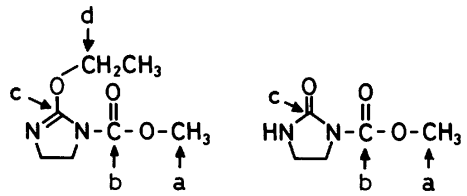
fied as above and the rest might be, at least in part, accounted for by 1-benzoylimidazole, which may be lost during work-up due to its water lability. Nevertheless, the methyl benzoate pathway is the main one, since the ester was obtained as the major product at least in one instance (above).

Discussion

From the results presented above, two main conclusions have been drawn. First, the stable enolic biotin model (**1**) possesses a much higher nucleophilicity than the corresponding keto model (**2**) toward a carbonyl carbon of the carbonate derivatives (a hydrogencarbonate surrogate). A similar behavior of both models was reported briefly for the hydrolytic reaction of carboxylic esters in water.[14] Also consistent with these is the observation that whereas 3-methyl-2-imidazolidinone was unable to add to the carbonyl carbon of a carbamate, the corresponding enol could.[15] All these phenomena may be rationalized in terms of a difference in the basicity of the pertinent nitrogen of the two compounds: The pK_a for the conjugate acid of **1** is $\approx$9[14] while the corresponding value for **2** ≈ -1.[16] Taken together, it is suggested that the ultimate function of ATP in the first partial reaction of carboxylation (Eq. 1a) is to enhance basicity and hence nucleophilicity of the nitrogen of biotin in question through phosphorylation of the ureido carbonyl.

It is, however, noted that despite suggestions for the participation of *O*-phosphono enolic structure (**5**) in biotin catalysis, its existence has not been proven in an explicit manner. The enolic structure of biotin in its unphosphorylated form is predicted theoretically to be unstable.[17] It is also pointed out that an alternative explanation may be invoked for the role of ATP, *e.g.*, phosphorylation of hydrogencarbonate, another substrate in the carboxylation of biotin (Eq. 1a).[18] The resulting mixed anhydride is expected to exhibit a higher reactivity than hydrogencarbonate. In fact, this mode of activation of a carboxyl group by ATP is rather general in synthase reactions in which an amide or ester bond is formed concomitant with ATP hydrolysis.[19]

Secondly, it was found that compound **3** undergoes reaction with various nucleophiles in a way quite analogous to that for compound **4**,[12] demonstrating that the electronic structure around the reaction center is not different significantly between the two. Compounds **3** and **4** have several potential sites for nucleophilic attack (Scheme 4), of which sites b and c are present in the *N*-carboxybiotin intermediate as well.



Scheme 4.

As noted above and previously,[7,11,12] oxygen and sulfur nucleophiles attack site a and nitrogen nucleophiles attack mostly site c. Only carbanions attack site b, an observation reminiscent of the fact that the enzymatic carboxyl transfer takes place on the ("active") carbon in most cases.[1-3] The initial addition of a carbanion to the ester carbonyl (site b) of **3** and **4** is followed by scission of the C-O bond. A "carboxyl" transfer was effected by employing 1-methoxycarbonylimidazole (**9**) as the donor substrate. The lower basicity of the imidazole nitrogen to which the methoxycarbonyl group is linked appears to be responsible for this difference; the pK_a of imidazole being $\approx$14,[20] while that of urea 25—33.[21] This implies that the N-C bond cleavage becomes feasible where the basicity of the pertinent nitrogen is low enough to make it a good leaving group. This result might be of value in relation to the mechanism of the enzymatic carboxyl transfer. As shown above, the carboxyl carbon bonded to the ureido nitrogen is a poor electrophile. To achieve transfer of the carboxyl group, one might have to enhance the electrophilicity of the carboxyl carbon and/or the nucleophilicity of the carboxyl-acceptor substrate. One way of doing this would be the electrophilic catalysis. For example, protonation or metal coordination to the ureido ring should bring about an electronic shift from the carboxyl group,[22,23] thereby facilitating nucleophilic attack of the incoming nucleophile on that site (Scheme 4). To corraborate this hypothesis further work is being continued in this laboratory.

Experimental

Materials. Common chemicals including 2-imidazolidinone (**2**, ethyleneurea) were obtained from commercial sources. The following compounds were prepared by the

literature methods specified; 2-ethoxy-2-imidazoline (**1**),[24] 1-methoxycarbonyl-2-ethoxy-2-imidazoline (**3**),[25] 1-methoxycarbonyl-2-imidazolidinone (**4**),[4] 1-methoxycarbonylimidazole,[26] methoxycarbonyl dimethyl phosphate.[27] 1-Benzoyl-2-ethoxy-2-imidazoline (**8**) was prepared by reaction of 1-benzoyl-2-imidazolidinone with triethyloxonium tetrafluoroborate. The crude product was purified by column chromatography on silica gel with acetonitrile as an eluant and by recrystallization from hexane, mp 46—48 °C. IR (KBr) 1673 (C=O), 1648 cm^{-1} (C=N). NMR (CCl_4): δ=0.84 (t, 3H, $-CH_3$), 3.52 (t, 2H, $-CH_2-$), 3.93 (t, 2H, $-CH_2-$), 4.01 (q, 2H, $-CH_2-CH_3$), 7.10—7.28 (m, 5H, $-C_6H_5$). Found: C, 66.27; H, 6.45; N, 12.92%. Calcd for $C_{12}H_{14}N_2O_2$: C, 66.03; H, 6.46; N, 12.83%.

Apparatus. Electronic and infrared absorption spectra were determined on a Hitachi 124 and Jasco A-100 spectrophotometer, respectively. ^1H NMR spectra were taken on a Jeol JNM-MH-100 spectrometer. Chemical shifts are expressed in parts per million relative to internal TMS. ^{13}C NMR spectra were determined on a Jeol JNM-FX-90Q spectrometer operating at 22.5 MHz. Typical experimental parameters were the following: spectral width of 5000 Hz with acquisition of 8 K data points, 10-μs pulse, and a recovery time of 3s. Mass spectra were determined with a Jeol JMS-DX 300 mass spectrometer. High-performance liquid chromatography (HPLC) was run on a Toyo Soda HLC 802 UR with Merck LiChrospher Si-100 as the stationary phase (4×300 mm) and chloroform–methanol (98:2 by vol.) as the eluant. When run at a flow rate ≈1.0 ml/min following retention times (min) were obtained MPNC 2.7, methyl chloroformate 3.2, **1** 3.8, **3** 4.7, *p*-nitrophenol 6.2, **4** 8.2.

Reaction of 1 with MPNC. A mixture of 120 mg (1.03 mmol) of **1** and 220 mg (1.12 mmol) of MPNC in 20 ml of $CHCl_3$ was refluxed for 12 h. The solvent was removed *in vacuo* and the residue was purified by column chromatography on silica gel (1.6×22 cm) with acetonitrile as an eluant in 62% yield, mp 67.5—70.0 °C (lit,[25] 67—70 °C).

Reaction of 3 with Cyclohexylamine. A sample of **3** (50 mg, 0.29 mmol) and cyclohexylamine (70 μl, 0.58 mmol) were allowed to react in chloroform at 60 °C for 24 h. Evaporation of the solvent *in vacuo* left an oil, to which was added hydrochloric acid equimolar to **3**. The product obtained as a hydrochloride in 75% yield was recrystallized from ethanol, mp 142—145 °C. R_f 0.59 ($CHCl_3$). IR(KBr) 1728 cm^{-1} (C=O). MS *m/z* 225.14715 (M^+). Calcd for $C_{11}H_{19}N_3O_2$ as free base: 225.14761.

Reaction of 9 with Phenylmagnesium Bromide. To a THF solution (12 ml) of phenylmagnesium bromide (24.6 mmol) was added a THF solution (40 ml) of **9** (1.68 g, 13.3 mmol) at 0 °C. The mixture was stirred for 10 h. The reaction was terminated by the addition of 10 ml of water and the solid formed was removed by filtration. The filtrate was extracted with ether (3×10 ml) and chloroform (3×10 ml). The combined extracts were dried over $MgSO_4$. Evaporation of the solvents left an oil, which was dissolved in carbon tetrachloride together with 846 μl (13.3 mmol) of dichloromethane for submission to NMR measurements.

The authors are grateful to prof. A. Marquet for informing them of her unpublished results and for helpful discussions. They also thank Drs. K. Sakata and N. Nishino for determining mass spectra. This work was supported by a Grant-in-Aid for Special Project Research 57102007 from the Ministry of Education, Science and Culture.

Chemical Synthesis of a Heat-stable Enterotoxin of *Yersinia enterocolitica*

Shoko YOSHIMURA and Yasutsugu SHIMONISHI*
Institute for Protein Research, Osaka University, Yamada-oka 3-2, Suita, Osaka 565
(Received May 23, 1985)

A peptide with the amino acid sequence Ser-Ser-Asp-Trp-Asp-Cys-Cys-Asp-Val-Cys-Cys-Asn-Pro-Ala-Cys-Ala-Gly-Cys of heat-stable enterotoxin (ST) produced by *Yersinia enterocolitica* was synthesized by a conventional method. The synthetic peptide was found to be identical with the corresponding natural peptide by chemical and physicochemical criteria, thus establishing the amino acid sequence of an ST of *Yersinia enterocolitica*.

Low-molecular-weight heat-stable enterotoxins (ST's) responsible for acute diarrhea in man and domestic animals are produced by several enteric bacteria such as enterotoxigenic *Escherichia coli* [1] and *Yersinia enterocolitica* [2,3]. The ST's isolated from these two kinds of bacteria have similar biological properties and their toxicities are neutralized by both homologous and heterologous anti-sera against these ST's [4]. These facts imply the similarity of at least the biologically and immunologically active structures of these ST's. Recently, we purified six molecular species of the enterotoxin to homogeneity from the culture supernatant of *Y. enterocolitica* by high-performance liquid chromatography and determined their amino acid sequences [5,6], as shown in Fig. 1. The sequence of the 13 amino acid residues in the C-terminal portion except for Asp and Val at positions 20 and 21, respectively, was identical with those of ST's produced by enterotoxigenic *E. coli* from the near-N-terminal Cys residue to the Cys residue at the 2nd position from the C-terminus, which were previously determined [7—10] and are shown in Fig. 1. These findings provided evidence that ST's of *Y. enterocolitica* and enterotoxigenic *E. coli* have common biological and immunological properties. However, the N-terminal sequences of the ST's isolated from these bacteria were quite different. These results raised the question of whether the divergence in the N-terminal portions reflects solely mutation in the transposon gene encoding ST [11] or a difference of the biological and physicochemical properties of the ST's. Therefore, it seemed interesting to examine the effect of the N-terminal sequence on various properties of these ST's.

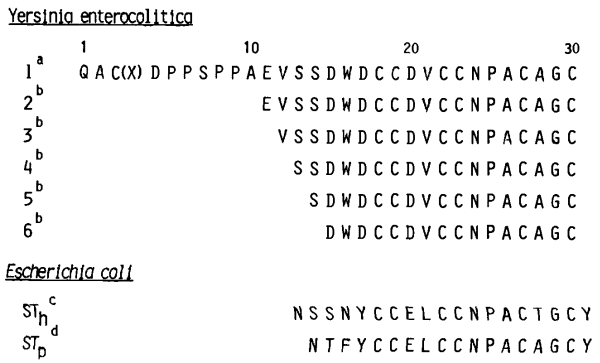

Fig. 1. Amino acid sequences of ST's of *Y. enterocolitica* and enterotoxigenic *E. coli*: a) cited from Ref. 5, b) from Ref. 6, c) from Ref. 7, and d) from Ref. 8—10.

In this work, we synthesized peptide 4 in Fig. 1, which consists of 18 amino acid residues from Ser at position 13 from the N-terminus to the C-terminal Cys, and compared the chemical and physicochemical properties of the synthetic peptide with those of natural peptide 4. This study also forms part of an investigation of the structure-activity relationship of heat-stable enterotoxins of *Y. enterocolitica* and enterotoxigenic *E. coli*, which will be reported in a subsequent paper [12].

Experimental

The general and analytical methods used were described in the preceding paper [13,14]. All chemicals used for preparative experiments were of reagent grade, those used for analysis were of guaranteed grade and solvents were distilled before use. The general procedure for purification of a product from a reaction mixture was as follows: The precipitate formed in the reaction mixture was filtered off and the filtrate was concentrated to a syrup or solid. The syrup or solid was dissolved in AcOEt and washed successively with 0.1 M† HCl, 5% aq $NaHCO_3$, and water. The washed solution was dried over anhydrous Na_2SO_4 and concentrated to dryness. In general, the concentration of solution was carried out under reduced pressure. Aminopeptidase M was purchased from the Protein Research Foundation (Minoh, Osaka). The HPLC apparatus consisted of a Hitachi 655 Liquid Chromatograph equipped with a multi-wave UV monitor, type 635M (Tokyo). YMC-ODS resin (S-5) was obtained from Yamamura Chemical Laboratories Co. (Kyoto) and was packed in our laboratory into columns of 4×250 mm and 8×300 mm for analytical and preparative experiments, respectively. The abbreviations used in this paper are those recommended by the IUPAC-IUB [*J. Biol. Chem.*, **247**, 977 (1972)]. Additional abbreviations are: MBzl, *p*-methylbenzyl; TFA, trifluoroacetic acid; DMF, *N,N*-dimethylformamide; TEA, triethylamine; DMSO, dimethyl sulfoxide.

Boc-Gly-Cys(MBzl)-OBzl (Ia). H-Cys(MBzl)-OBzl·Tos-OH (10.4 g, 33 mmol) was dissolved in CH_2Cl_2 (300 ml) and cooled to 0°C. The chilled solution was mixed with TEA (4.6 ml, 33 mmol) and Boc-Gly-OH (5.3 g, 30 mmol) with

† 1 M=1 mol dm^{-3}.

stirring. The solution was then mixed with DCC (6.8 g, 33 mmol) at below −20 °C and stirred at the same temperature for 1 h and at room temperature overnight. The syrup separated from the reaction mixture was crystallized from a mixture of $CHCl_3$, ether, and hexane, wt 9.6 g (67.3%), mp 55—56 °C, $[\alpha]_D^{20}$ −28.2° (*c* 1.0, DMF).

Found: C, 63.49; H, 7.11; N, 6.14; S, 6.91%. Calcd for $C_{25}H_{32}O_5N_2S$: C, 63.54; H, 6.83; N, 5.93; S, 6.77%.

*Boc-Cys(MBzl)-Ala-OMe (**Ib**).* Boc-Cys(MBzl)-OH·DCHA (15.2 g, 30 mmol) was dissolved with H-Ala-OMe·HCl (4.2 g, 30 mmol) in CH_2Cl_2 (150 ml), cooled below −20 °C and mixed with DCC (6.9 g, 33 mmol). The solution was stirred at below −20 °C for 1 h and at room temperature for 2.5 h. The syrup obtained from the reaction mixture was crystallized from ether and hexane; wt 10.3 g (83.7%), mp 87—88 °C, $[\alpha]_D^{20}$ −35.2° (*c* 1.0, DMF).

Found: C, 58.50; H, 7.49; N, 6.75; S, 7.68%. Calcd for $C_{20}H_{30}O_5N_2S$: C, 58.52; H, 7.37; N, 6.83; S, 7.80%.

*Boc-Cys(MBzl)-Ala-N_2H_3 (**Ic**).* Compound **Ib** (8.2 g, 20 mmol) was dissolved in MeOH (150 ml) and mixed with 100% hydrazine hydrate (30 ml). The solution was stirred at room temperature for 1 h and concentrated to a solid. The solid was recrystallized from MeOH and ether; wt 7.9 g (96.3%), mp 136—137 °C, $[\alpha]_D^{20}$ −14.0° (*c* 1.0, DMF).

Found: C, 55.42; H, 7.42; N, 13.60; S, 7.89%. Calcd for $C_{19}H_{30}N_4O_4S$: C, 55.60; H, 7.37; N, 13.65; S, 7.80%.

*Boc-Cys(MBzl)-Ala-Gly-Gys(MBzl)-OBzl (**I**).* Compound **Ia** (2.36 g, 5.0 mmol) was dissolved in TFA (10 ml) and stirred at room temperature for 30 min. The solution was concentrated to a syrup. Meanwhile, compound **Ic** (2.26 g, 5.5 mmol) was dissolved in DMF (20 ml) and cooled below −20 °C. The solution was stirred with 6.72 M HCl in dioxane (3.5 ml) and isopentyl nitrite (0.78 ml, 6 mmol) at the same temperature for 30 min, and then mixed with a solution of the above syrup in DMF (20 ml) and TEA (3.3 ml) and stirred at 0 °C for 1 h. The solid isolated from the reaction mixture was crystallized from a mixture of MeOH, ether, and hexane; wt 3.0 g (80.0%), mp 144—145 °C, $[\alpha]_D^{20}$ −20.3° (*c* 1.0, DMF).

Found : C, 62.08; H, 6.75; N, 7.40; S, 8.66%. Calcd for $C_{39}H_{50}O_7N_4S_2$: C, 62.38; H, 6.71; N, 7.46; S, 8.52%.

*Boc-Cys(MBzl)-Cys(MBzl)-Asn-Pro-Ala-Cys(MBzl)-Ala-Gly-Cys(MBzl)-OBzl (**II**).* Compound **I** (2.63 g, 3.5 mmol) was dissolved in TFA (10 ml) and stirred at room temperature for 30 min. The solution was concentrated to a syrup, which was triturated in ether. Meanwhile, Boc-Cys(MBzl)-Cys(MBzl)-Asn-Pro-Ala-N_2H_3 [14] (3.32 g, 4.0 mmol) was dissolved in DMF (15 ml) and cooled below −20 °C. The chilled solution was mixed with 6.72 M HCl in dioxane (2.6 ml) and isopentyl nitrite (0.59 ml, 4.5 mmol). The mixture was stirred at below −20 °C for 30 min, and then with a solution of the above solid in DMF (15 ml) and TEA (3 ml) at 0 °C for 4 d. The product separated from the reaction mixture was recrystallized from EtOH and ether; wt 5.0 g (98.5%), mp 179—180 °C, $[\alpha]_D^{20}$ −78.4° (*c* 1.0, DMF).

Found: C, 60.16; H, 6.65; N, 9.58; S, 8.78%. Calcd for $C_{73}H_{94}O_{13}N_{10}S_4$: C, 60.57; H, 6.55; N, 9.68; S, 8.84%.

*Boc-Cys(MBzl)-Cys(MBzl)-Asp(OBu^t)-Val-OMe (**IIIa**).* Z-Asp(OBu^t)-OH·DCHA (5.05 g, 10 mmol) and H-Val-OMe·HCl (1.68 g, 10 mmol) were dissolved in CH_2Cl_2 (50 ml) and cooled to −20 °C. The chilled solution was stirred with DCC (2.3 g, 11 mmol) at the same temperature for 1 h and at room temperature for 3 h. The syrup isolated from the reaction mixture was dissolved in MeOH (200 ml) and hydrogenated over 5% palladium-charcoal in the presence of 1 equiv of HCl at room temperature for 3 h. The catalyst was filtered off and the filtrate was concentrated to a syrup. Meanwhile, Boc-Cys(MBzl)-Cys(MBzl)-N_2H_3 [14] (6.0 g, 11 mmol) was dissolved in DMF (15 ml), cooled below −20 °C and stirred with 6.72 M HCl in dioxane (2.62 ml) and isopentyl nitrite (1.56 ml, 12 mmol) for 30 min. The solution was mixed with a solution of the above syrup in DMF (15 ml) and TEA (3.86 ml) and stirred at 0 °C for 3 d. The syrup isolated from the reaction mixture was solidified to an amorphous powder in ether and hexane; wt 8.16 g (100%).

*Boc-Cys(MBzl)-Cys(MBzl)-Asp(OBu^t)-Val-N_2H_3 (**III**).* Compound **IIIa** (8.16 g, 10 mmol) was dissolved in MeOH (200 ml) and cooled to 0 °C. The solution was mixed with 100% hydrazine hydrate, stirred at room temperature for 2 h and then concentrated to a solid. The solid was recrystallized from EtOH; wt 5.8 g (71.6%), mp 184—185 °C, $[\alpha]_D^{20}$ −35.4° (*c* 1.0, DMF).

Found: C, 57.82; H, 7.32; N, 10.57; S, 7.80%. Calcd for $C_{40}H_{60}O_8N_6S_2 \cdot 1/2H_2O$: C, 58.16; H, 7.44; N, 10.18; S, 7.75%.

*Boc-Cys(MBzl)-Cys(MBzl)-Asp(OBu^t)-Val-Cys(MBzl)-Cys-(MBzl)-Asn-Pro-Ala-Cys(MBzl)-Ala-Gly-Cys(MBzl)-OBzl (**IV**).* Compound **II** (2.17 g, 1.5 mmol) was dissolved in TFA (10 ml) and stirred at room temperature for 30 min. The solution was concentrated to a syrup, which was solidified in ether. Meanwhile, compound **III** (1.47 g, 1.8 mmol) was dissolved in DMF (8 ml) and cooled below −20 °C. The solution was stirred with 6.72 M HCl in dioxane (1.4 ml) and isopentyl nitrite (0.26 ml, 2.0 mmol) at −20 °C for 30 min and then mixed with a solution of the above solid in DMSO (5 ml) and TEA (1.53 ml). The mixture was stirred at 0 °C for 5 d in a refrigerator and then concentrated to a syrup, which was triturated in ice water. The solid was recrystallized from DMF and EtOH; wt 2.7 g (83.1%), mp 222 °C (dec), $[\alpha]_D^{20}$ −64.6° (*c* 0.5, DMSO).

Found: C, 60.43; H, 6.81; N, 9.18; S, 9.06%. Calcd for $C_{108}H_{142}O_{19}N_{14}S_6$: C, 60.83; H, 6.71; N, 9.20; S, 9.00%.

*Boc-Asp(OBu^t)-Cys(MBzl)-Cys(MBzl)-Asp-Val-Cys(MBzl)-Cys(MBzl)-Asn-Pro-Ala-Cys(MBzl)-Ala-Gly-Cys(MBzl)-OBzl (**V**).* Compound **IV** (2.13 g, 1.0 mmol) was dissolved in TFA (10 ml), stirred at room temperature for 2 h and concentrated to a syrup, which was triturated in ether. The solid was dissolved in a mixture of DMF (5 ml) and DMSO (5 ml), cooled to 0 °C and mixted with TEA (0.28 ml) and a solution of Boc-Asp(OBu^t)-ONSu (0.53 g, 1.5 ml) in 1-methyl-2-pyridone (5 ml). The solution was stirred at room temperature for 1 d and concentrated to a semisolid, which was collected with AcOEt and ether. The solid was recrystallized from EtOH; wt 1.9 g (84.8%), mp 219—220 °C (dec), $[\alpha]_D^{20}$ −63.4° (*c* 0.5, DMSO).

Found: C, 59.57; H, 6.46; N, 9.27; S, 8.42%. Calcd for $C_{112}H_{147}O_{22}N_{15}S_6$: C, 59.85; H, 6.59; N, 9.35; S, 8.54%.

*Z-Asp(OBu^t)-Trp-OMe (**VIa**).* Z-Asp(OBu^t)-OH·DCHA (10.1 g, 20 mmol) and H-Trp-OMe·HCl (5.09 g, 20 mmol) were dissolved in CH_2Cl_2 (200 ml), cooled below −10 °C and mixed with a solution of DCC (4.54 g, 22 mmol) in CH_2Cl_2 (50 ml). The mixture was stirred at room temperature overnight. The resulting precipitate was filtered off and the filtrate was concentrated to a syrup. The syrup was purified as described above and triturated in hexane; wt 10.5 g (100%), mp 55—56 °C, $[\alpha]_D^{20}$ +2.8° (*c* 1.0, DMF).

Found: C, 64.04; H, 6.41; N, 7.95%. Calcd for $C_{28}H_{33}O_7N_3$:

C, 64.23; H, 6.35; N, 8.03%.

*Boc-Ser-Ser-OMe (**VIb**).* Boc-Ser-N_2H_3 (2.20 g, 10 mmol) was dissolved in DMF (30 ml), cooled below −20 °C and mixed with 6.72 M HCl in dioxane (5.24 ml) and isopentyl nitrite (1.43 ml, 11 mmol). The solution was stirred at −20 °C for 30 min, and then mixed with H-Ser-OMe·HCl (1.56 g, 10 mmol) and TEA (6.3 ml). The mixture was stirred at 0 °C for 2 d in a refrigerator. The precipitate formed was filtered off and the filtrate was concentrated to a syrup. The syrup was washed with ether and hexane and crystalllized from a mixture of AcOEt, ether, and hexane; wt 3.0 g (98.0%), mp 62—64 °C.

Found: C, 46.92; H, 7.20; N, 9.34%. Calcd for $C_{12}H_{22}O_7N_2$: C, 47.05; H, 7.24; N, 9.15%.

*Boc-Ser-Ser-N_2H_3 (**VIc**).* Compound **VIb** (3.0 g, 9.8 mmol) was dissolved in MeOH (150 ml), cooled below 0 °C and mixed with 100% hydrazine hydrate (20 ml). The mixture was stirred at room temperature for 2 h and then concentrated to a solid. The solid was recrystallized from MeOH and ether; wt 2.9 g (94.8%), mp 146—147 °C, $[\alpha]_D^{20}$ +3.8° (*c* 1.0, DMF).

Found: C, 38.42; H, 7.61; N, 16.94%. Calcd for $C_{11}H_{12}O_6N_4 \cdot 2H_2O$: C, 38.59; H, 7.64; N, 16.37%.

*Boc-Ser-Ser-Asp(OBu^t)-Trp-OMe (**VId**).* Compound **VIa** (2.62 g, 5.0 mmol) was dissolved in MeOH (100 ml) and hydrogenated over 5% palladium-charcoal in the presence of 1 eq of HCl at room temperature for 1.5 h. The catalyst was filtered off and the filtrate was concentrated to a syrup. Meanwhile, compound **VIc** (1.84 g, 6.0 mmol) was dissolved in DMF (20 ml) and cooled below −20 °C. The chilled solution was stirred with 6.72 M HCl in dioxane (3.5 ml) and isopentyl nitrite (0.91 ml, 7.0 mmol) at the same temperature for 30 min, and then with a solution of the above syrup in DMF (20 ml) and TEA (4.0 ml) at 0 °C for 1 d. The resulting precipitate was filtered off and the filtrate was concentrated to a syrup. The syrup was purified as described above and triturated in ether and hexane; wt 2.45 g (73.8 %).

*Boc-Ser-Ser-Asp(OBu^t)-Trp-N_2H_3 (**VI**).* Compound **VId** (1.2 g, 1.8 mmol) was dissolved in MeOH (40 ml), cooled to 0 °C and mixed with 100% hydrazine hydrate (4 ml). The solution was stirred at room temperature for 2.5 h and concentrated to a syrup. The syrup was triturated in ether and reprecipitated from EtOH and ether; wt 0.99 g (82.5 %), mp 166—168 °C, $[\alpha]_D^{20}$ −13.4° (*c* 1.0, DMF).

Found: C, 50.31; H, 6.83; N, 17.81%. Calcd for $C_{30}H_{45}O_{10}N_7 \cdot N_2H_4 \cdot H_2O$: C, 50.48; H, 7.19; N, 17.67%.

*Boc-Ser-Ser-Asp(OBu^t)-Trp-Asp-Cys(MBzl)-Cys(MBzl)-Asp-Val-Cys(MBzl)-Cys(MBzl)-Asn-Pro-Ala-Cys(MBzl)-Ala-Gly-Cys(MBzl)-OBzl (**VII**).* Compound **V** (1.12 g, 0.5 mmol) was dissolved in TFA (10 ml) and stirred at room temperature for 2 h. The solution was concentrated to a syrup, which was solidified in ether. Meanwhile, compound **VI** (0.40 g, 0.6 mmol) was dissolved in DMF (4 ml) and cooled below −20 °C. The solution was mixed with 6.72 M HCl in dioxane (0.7 ml) and isopentyl nitrite (0.1 ml, 0.7 mmol), stirred at the same temperature for 30 min, and mixed with a solution of the above solid in 1-methyl-2-pyridone (6 ml) and TEA (0.87 ml). The mixture was stirred at 0 °C for 5 d in a refrigerator. The resulting precipitate was filtered off and the filtrate was concentrated to a solid, which was recrystallized from DMF and EtOH; wt 0.68 g (50.0%), mp 207—208 °C, $[\alpha]_D^{20}$ −62.0° (*c* 0.35, DMSO). Amino acid ratio in the acid hydrolysate: Asp, 3.45 (3); Ser, 1.42 (2); Pro, 0.94 (1); Gly, 1.02 (1); Ala, 2.00 (2); Cys, not determined; Val, 0.66 (1); Trp, 0.58 (1).

Found: C, 57.64; H, 6.10; N, 10.22; S, 7.23%. Calcd for $C_{133}H_{172}O_{30}N_{20}S_6 \cdot 2H_2O$: C, 57.90; H, 6.32; N, 10.15; S, 6.96%.

Removal of Protecting Groups and Air Oxidation. Compound **VII** (68 mg, 25 μmol) was mixed with anisole (0.2 ml) and treated with anhydrous liquid hydrogen fluoride (4 ml) at 0 °C for 1 h [15]. The hydrogen fluoride was removed by evaporation under reduced pressure and the residue was dissolved in 99% formic acid (1.5 ml). The solution was washed twice with hexane and diluted with water to 500 ml. The solution was adjusted to pH 8.0 by adding aqueous ammonia and stood at room temperature for 3 d with occasional stirring. Then it was adjusted to pH *ca.* 7.0 with acetic acid and lyophilized. The residue was purified by high-performance liquid chromatography, as described below.

High-performance Liquid Chromatography (HPLC). The HPLC column was equilibrated with 10% acetonitrile in 0.05% trifluoroacetic acid and after injection of the sample, was developed with a linear-gradient of 10—40% acetonitrile with increase in acetonitrile concentration of 1%/min at a flow rate of 1 ml min^{-1}. Eluates were monitored simultaneously for absorbance at 220 and 280 nm using a double-wavelength flow-through spectrophotometer.

Aminopeptidase M Digestion. Synthetic or natural peptide 4 (60 μg) was dissolved in 0.01 M pyridinium acetate buffer (pH 7.0) (100 μl) and digested with aminopeptidase M (5 μg) at 38 °C for 20 h. The reaction was stopped by addition of acetic acid. The solution was applied to a reversed-phase column of HPLC and the adsorbed material was eluted as described above.

Edman-degradation. Synthetic peptide was degraded by the Edman method, as described previously [16]. The degraded product was analyzed by HPLC, as described above.

Heat Stability. The synthetic peptide was dissolved at a concentration of 200 μg ml^{-1} in 0.01 M phosphate buffered saline (pH 7.2). The solution was sealed in capillary tubes and heated for a given period at the required temperature. Then the solution was cooled in an ice-bath and analyzed by HPLC, as described above.

Results and Discussion

Synthesis. The protected linear peptide **VII** consisting of 18 amino acid residues from Ser at position 13 from the N-terminus to the C-terminal Cys was synthesized by a similar procedure to that used for the synthesis of a heat-stable enterotoxin of enterotoxigenic *E. coli* [13], as shown in Fig. 2. All protecting groups were removed with anhydrous liquid hydrogen fluoride [15], and the resulting free linear peptide was air-oxidized in a dilute solution (5×10^{-5} M) until no free mercapto groups could be detected. The air-oxidized product had the HPLC profile shown in Fig. 3A on a reversed-phase column. The fraction shown by a vertical bar was most toxic and was eluted at the same retention time as natural peptide 4, as shown in Fig. 3B. The separated fraction was confirmed to be pure by repeated HPLC, as shown in Fig. 3C. The yield of the purified peptide was about 2.8% on the basis of the protected peptide **VII**. This low yield was considered to be due to various side-reactions

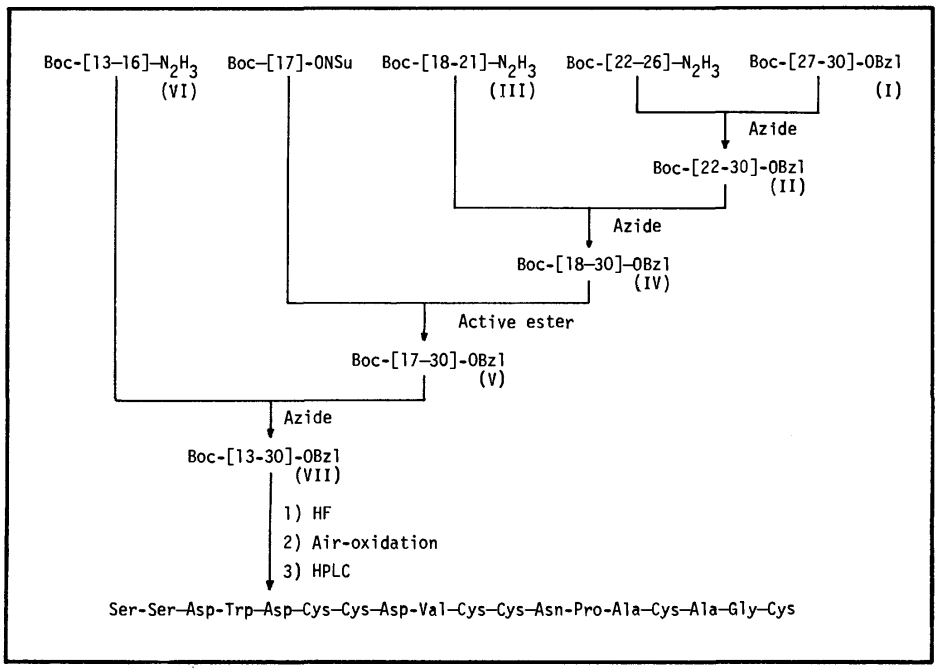

Fig. 2. Scheme for synthesis of a heat-stable enterotoxin of *Y. enterocolitica*.

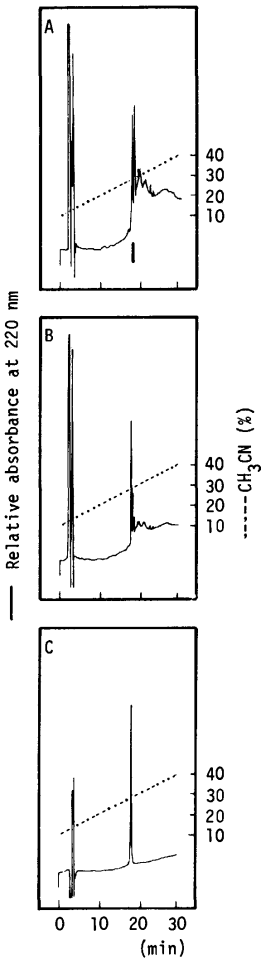

Fig. 3. HPLC profiles on a reversed-phase column (YMC-ODS S-5, 4×250 mm) of A) a deprotected, air-oxidized solution of synthetic peptide, B) a mixture of A) and natural peptide 4, and C) purified synthetic peptide.

during deprotection and air oxidation of the protected peptide **VII**, as shown in Fig. 3A. The amino acid composition and mass value of the purified synthetic peptide were identical with those of natural peptide 4, as shown in Table 1. The toxicity of this synthetic peptide was in the same order as that of natural peptide 4 in a fluid accumulation test in suckling mice [17]. The biological and immunological properties of the synthetic peptide and its shorter peptides will be described elsewhere [12].

Identification of the Synthetic Peptide with the Natural Peptide. To confirm that the synthetic peptide had the same structure as the natural peptide 4, we treated both with aminopeptidase M and compared the digests by HPLC, as shown in Fig. 4. The digest of the synthetic peptide was eluted later than that of the original peptide (Fig. 4B), but had the same retention time as natural peptide 6 lacking the two N-terminal amino acid residues of natural peptide 4 (Fig. 4C). The digest of natural peptide 4 was also eluted in the same position as natural peptide 6 and the digest of the synthetic peptide (not shown). The peak fraction in Fig. 4A was isolated and subjected to amino acid analysis and FAB mass spectrometry, as described in Table 1. Results indicated that the N-terminal Ser-Ser sequence of the synthetic peptide was removed by treatment with aminopeptidase M yielding natural peptide 6.

Then, we subjected the synthetic peptide to one step of Edman degradation. The degraded peptide was eluted at the same retention time on HPLC as natural peptide 5 and had the same amino acid composition and mass value as those of natural peptide 5, as shown in Fig. 5 and Table 1, respectively. Namely, removal of

a) Values were calculated as mol/mol of Ala; numbers in parentheses indicate nearest integer values. b) Cited from Ref. 6.

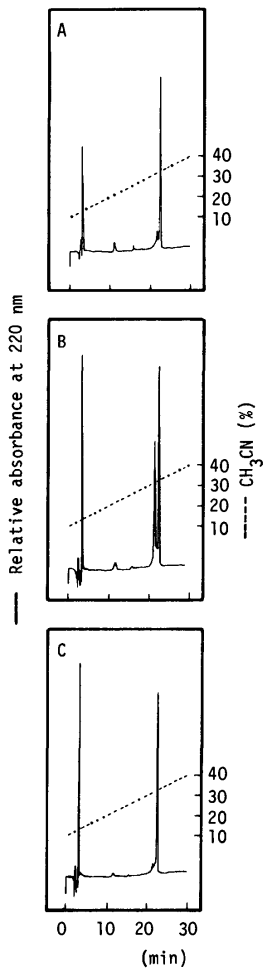

Fig. 4. HPLC profiles on a reversed-phase column (YMC-ODS S-5, 4×250 mm) of A) the aminopeptidase M digest of synthetic peptide, B) a mixture of A) and the undigested synthetic peptide, and C) a mixture of A) and natural peptide 6.

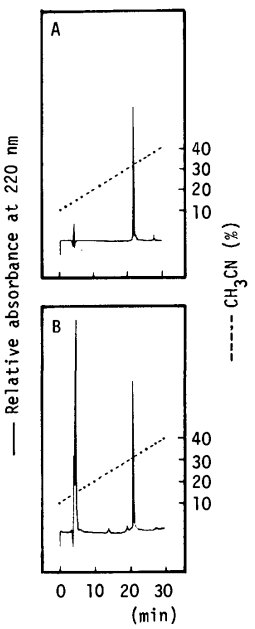

Fig. 5. HPLC profiles on a reversed-phase column (YMC-ODS S-5, 4×250 mm) of A) the synthetic peptide after one step of Edman degradation and B) a mixture of A) and the natural peptide 5.

the N-terminal Ser residue from the synthetic peptide resulted in formation of a peptide identical with natural peptide 5. These results clearly indicate that the synthetic peptide had the same primary and secondary structures as those of natural peptide 4.

Heat Stability. A crude ST isolated from *Y. enterocolitica* has been reported to be more heat-resistant than ST of enterotoxigenic *E. coli*, when assayed in suckling mouse [18]. However, the temperature stability of ST of *Y. enterocolitica* has not yet

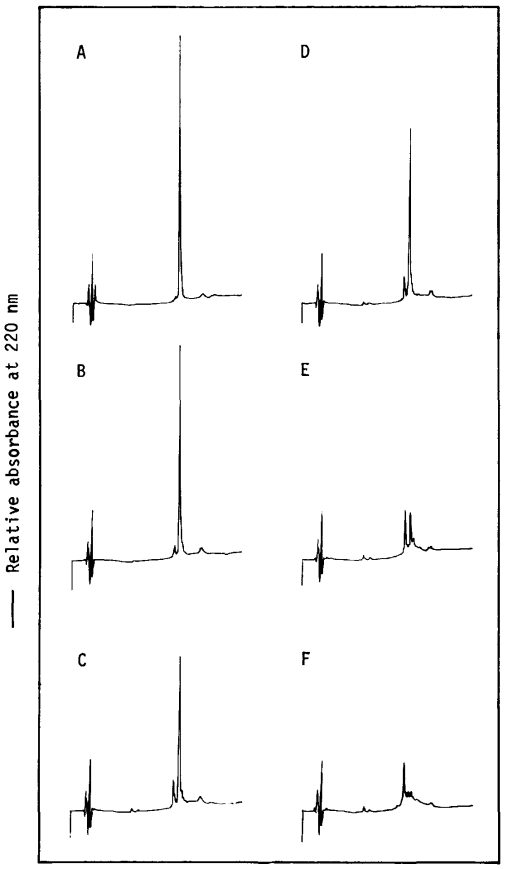

Fig. 6. HPLC profiles on a reversed-phase column (YMC-ODS S-5, 4×250 mm) of heat-treated synthetic peptide: (left column) A) after 10 min at 100 °C, B) after 30 min at 100 °C, C) after 60 min at 100 °C; (right column) D) after 10 min at 120 °C, E) after 30 min at 120 °C, and F) after 60 min at 120 °C.

been examined quantitatively, because purified ST could not be obtained. Since we obtain pure synthetic ST of *Y. enterocolitica* in the present study, we examined its heat stability by the same method as that used for testing the heat stability of ST of enterotoxigenic *E. coli* by HPLC [19]. The stabilities of the natural and synthetic ST's could not be compared, because the natural toxin could be isolated only in minute quantity [6]. Figure 6 illustrates the HPLC profiles of the synthetic toxin after heating at 100 °C and 120 °C for various periods. When the synthetic ST was heated at 100 °C for 30 min, its peak area on HPLC was reduced only to about 75% of that of the untreated ST, while ST of enterotoxigenic *E. coli* was destroyed significantly under the same conditions [19]. Furthermore, after heating at 100 °C for 60 min or at 120 °C for 10 min, about two-thirds of the original peak remained unchanged and the biological activity remained almost unchanged. These results support a previous qualitative experiment [18] which showed that ST of *Y. enterocolitica* was highly heat-resistant, showing no reduction of enterotoxigenic activity after heating for 30 min at 100 °C or 120 °C. This stability of ST of *Y. enterocolitica* was comparable to that of shorter analogues of ST of enterotoxigenic *E. coli*, which consist of 13 and 14 amino acid residues from near the N-terminal Cys residue to the Cys residue at position 2 from the C-terminus and the C-terminal Tyr residue [19,20], respectively. This high heat stability of ST of *Y. enterocolitica* may be due to the difference of its N-terminal sequence from that of enterotoxigenic *E. coli* or the presence of Asp-Val in place of Glu-Leu in ST of enterotoxigenic *E. coli*. We are now examining the relation of the thermodynamic stability and the biological activity.

We are indebted to Dr. S. Hara, Department of Chemistry, College of Science, Osaka University, for amino acid analyses. This work was supported in part by Grants-in-Aid for Scientific Research, No. 58122002 and 59340034 (to Y. S.) from the Ministry of Education, Science and Culture of Japan.

(Received January 5, 1985)

The title compound, the key intermediate for a total synthesis of bicyclomycin, was synthesized from *N,N'*-diacetyl anhydroglycine through twelve steps. The three-carbon branch for the construction of the bicyclic skeleton was introduced to the 2,5-piperazinedione ring as an alkylidene substituent, and then the olefinic function was converted into a diol function. The formation of bicyclic ring was achieved by treatment with *N*-bromosuccinimide followed by the intramoleculer substitution of the primary hydroxyl group in the side chain, and finally the secondary hydroxyl group was converted to the methylene function by an improved Peterson reaction.

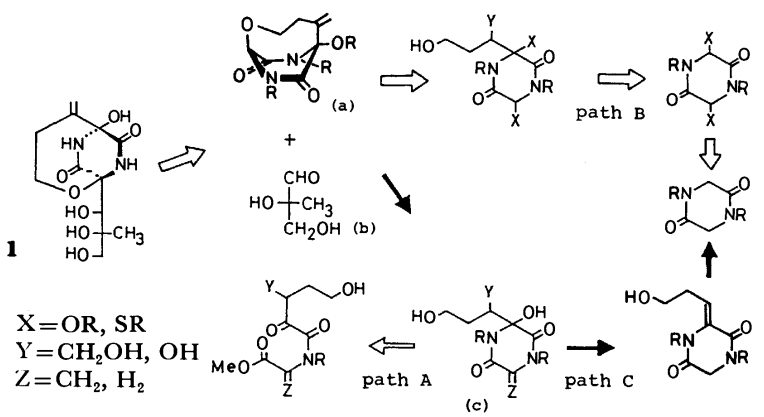
Bicyclomycin (**1**) produced by *Streptomyces sapporonensis*[1] and *S. Aizunensis*[2] from leucine and isoleucine[3] is a member of the large class of naturally occurring 2,5-piperazinediones (PDO) with an unusual structure.[4] Several synthetic efforts have been made for **1**, and both racemic[5] and optically active **1**[6,7] were recently synthesized.

Two strategies have been selected for synthesis of **1**, that is, the introduction of a carbon chain, which is necessary for the bicyclic bridge, before (path A)[8] or after formation of PDO ring (paths B and C). However, no report which reached the final goal through path A has appeared because the reaction steps are rather complicated. In the path B,[9] the substituent X for activation of C-3 and C-6 was used for both the introduction of methylene-branched four-carbon unit and cyclization into the bicyclic key intermediate (a), and it was converted into **1** by the aldol condensation with methyl-branched four-carbon unit (b).[5,6] In our previous communication,[10] the olefinic function of an alkylidene-PDO was oxidized stereoselectively to a diol function (c: Y=OH, Z=H_2), then cyclized by the treatment with *N*-bromosuccinimide (NBS), and finally the secondary hydroxyl group was converted into the methylene group to yield the title compound. This paper describes detailed data of the communication.

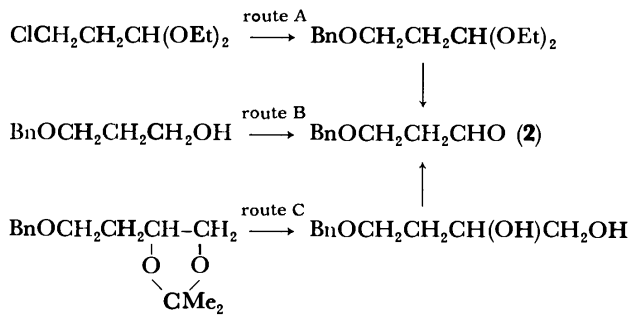
Results and Discussion

First of all, three different synthetic routes of 3-benzyloxypropanal (**2**) which is the three-carbon unit for the construction of bicyclic ring were examined. In the first route, the reaction of benzyl alcohol with 3 equivalents of 3-chloro-1,1-diethoxypropane[11] gave 3-benzyloxy-1,1-diethoxypropane in 71% yield, acidic hydrolysis of which gave **2** in 97% yield (route A). In the second one, oxidation of 3-benzyloxy-1-propanol[12] with chromium trioxide and pyridine gave **2** in 72% yield (route B). In the last one, partial hydrolysis of 4-benzyloxy-1,2-*O*-isopropylidene-1,2-butanediol[13] and oxidation of the product with lead tetraacetate gave **2** in 90% overall yield (route C). This route was the most convenient for large scale preparation of **2**.

Then, condensation of *N,N'*-diacetylanhydroglycine with **2** in *N,N*-dimethylformamide (DMF) in the presence of equimolar potassium *t*-butoxide[14] gave only one isomer of 1-acetyl-3-(3-benzyloxypropylidene)-PDO (**3**) in 82% yield, whose configuration was deduced to be *Z* from the fact that its *N*-acetylation with acetic anhydride did not proceed.[15] Oxidation with lead tetraacetate[16] and *m*-chloroperbenzoic acid[8d] which were successful in the case of 3-benzylidene-1,4-dialkyl-PDO and 3-alkylidene-1,4-dialkyl-PDO could



Scheme 1. Retro-synthesis of bicyclomycin



Scheme 2. Syntheses of 3-benzyloxypropanal (**2**)

not be applied to **3**, probably due to the electron-withdrawing effect of *N*-acetyl group. Reaction of **3** with osmium tetraoxide and sodium chlorate[17a] gave the corresponding diol (**6**) in 58% yield, but, the use of *N*-methylmorpholine-*N*-oxide[17b] or hydrogen peroxide[17c] as the cooxidant gave poor results. An osmium oxidation of 3-(3-benzyloxypropylidene)-1,4-bis(*p*-methoxybenzyl)-PDO (**5**) which was prepared from **3** *via* *N*-deacetylated product (**4**) in 72% overall yield, gave **7** in 46% yield, in which a partial oxidative *N*-de(*p*-methoxybenzyl)ation was deduced by the formation of *p*-anisaldehyde.

Isopropylidenation of the diol function in **6** with 2-methoxypropene–pyridinium *p*-toluenesulfonate in acetone gave the desired product (**9a**) and its 3-epimer (**9b**) in 95 and 2% yield, respectively. In this reaction, the suspended **6** dissolved by addition of a small amount of acetone within 5 min and then **9a** deposited from the reaction mixture. In a similar way, **7** was converted into the *O*-isopropylidene derivative (**12**) in 94% yield. However, the isopropylidenation of **6** with 2,2-dimethoxypropane–*p*-toluenesulfonic acid gave a 1:2 mixture of **9a** and partial *O*-methylation product (**8**) in 94% yield. The formation of **8** indicates the acid-catalyzed substitution of the tertiary hydroxyl group of **6** with methanol liberated by acetal exchange. On the other hand, the reaction of **6** with acetone-anhydrous copper(II) sulfate and acetone–acid (*p*-toluenesulfonic acid or sulfuric acid) gave negative and complex results, respectively.

On the other hand, mono(*p*-methoxybenzyl)ation of deacetylated derivative (**10**), which was obtained quantitatively by treatment of **9a** with hydrazine, with equimolar sodium hydride and *p*-methoxybenzyl bromide gave **11** in 87% yield. A further *p*-methoxybenzylation of **11** gave **12** in 76% yield, together with a enol ether (**18**: 11%). When *p*-methoxybenzyl chloride instead of the bromide is used, a 1:1 mixture of **12** and **18** was formed. The yield of one step synthesis of **12** from **10** was 62%. Hydrogenolysis of **9a** in methanol in the presence of palladium–carbon gave the *O*-debenzylated product (**13**) in 75% yield. This conversion could be also achieved by treatment of **9a** with equimolar NBS to afford **13** and *O*-benzoylated by-product (**14**) in 92 and 6% yields, respectively. A similar reduction of **11** or **18** and **12** gave the same **15** and **16** in quantitative yields, respectively. Compound **16** was also obtained from **15** by successive *p*-methoxybenzylation (**17**) and hydrogenolysis.

Cyclization of **16** in chloroform with 1.1 equimolar NBS[8b] and excess barium carbonate at room temperature for 4 d gave the corresponding bicyclic derivative (**19**) in 86% yield. The use of 2 equimolar NBS gave **19** in only 11% yield, due to the oxidation of *p*-methoxybenzyl groups. The same reaction without barium carbonate for 24 h gave **19**, the corresponding spiro cyclic compound (**21**), starting material (**16**) in 12, 63, and 7% yields, respectively. However, a similar reaction of **15** for 24 h in the presence of barium carbonate gave the corresponding bicyclic (**20**), spiro (**22**), and recovered **16** in 30, 16, and 42% yields, respectively. The structures of spiro derivatives, **21** and **22**, were proved by conversion into acetates, **23a**,

23b, and **24**, respectively. Compounds **23a** and **23b** were an epimeric pair of spiro configuration. The formation of spiro derivatives accompanied with *O*-deisopropylidenation may be the acid-assisted formation of iminium (**25**) or imino intermediate. An attempted similar reaction of **13** did not proceed and the starting material was recovered, probably due to electron-withdrawing effect of *N*-acetyl group. Considering that the reaction of *N,N'*-diacetylanhydroglycine with equimolar NBS and successive treatment of the unstable monobromo derivative (**26**) with sodium acetate or potassium thioacetate gave the corresponding 2-substituted PDO (**27** and **28**) in 71 and 68% yields, respectively, the difference in the reactivity between **13** and *N,N'*-diacetylanhydroglycine may be attributed to the absence and presence of a resonance system in the PDO-ring.

Then, the treatment of **19** with a 1:1 mixture of 2 M (M=mol dm^{-3}) hydrochloric acid and tetrahydrofuran (THF) at 40 °C for 24 h gave the corresponding *O*-deisopropylidenated product (**29**) in 83% yield. The reaction with 70% acetic acid at an elevated temperature or with trifluoroacetic acid at room temperature gave a complex result. The selective oxidation of the secondary hydroxyl group of **29** with dimethyl sulfoxide-oxalyl dichloride[18] gave the desired 5-oxo compound (**30**) in 91% yield, while oxidation with pyridinium chlorochromate gave an undesired ring-cleavaged compound **34** in 61% yield. Direct conversion of carbonyl function of **30** into methylene group with the Witting reagent $Ph_3P{=}CH_2$, methylenedimagnesium dibromide,[19] and Tabbe reagent $Cp_2TiCH_2AlClMe_2$[20] could not be performed. Therefore, an improved Peterson reaction as stepwise conversion was used for this purpose. Addition of trimethylsilylmethylmagnesium chloride to **30** gave the addition product (**31**) in 52% yield, as a 4:1 mixture of diastereomers. However, the next elimination reaction did not proceed under the usual conditions,[21] and barely the treatment with 0.08 M sulfuric acid in THF at room temperature for 3 d gave the methylene derivative (**32**) in 48% yield. Because an activation method by introduction of *O*-sulfonyl or halogen function[21] can not be used in this case, the elimination was accomplished by treatment of 5,6-ditrifluoroacetate of **31** with tetrabutylammonium fluoride followed by removal of the remaining trifluoroacetyl group at *O*-6 to give **32** in 81% yield. Treatment of **32** with *t*-butyldimethylsilyl triflate[22] gave the corresponding 6-*O*-protected derivative (**33**) in 80% yield.

^{1}H NMR data of 6-substituted PDO, spiro cyclic and bicyclic derivatives, and ^{13}C NMR data of 6-substituted PDO are summarized in Tables 1—4, respectively.

Among *O*-isopropylidene derivatives (Table 1), the chemical shift of H-1' protons of **9a** is lower than that of **9b** by 0.78 ppm. This phenomenon indicates that the carbonyl group in PDO ring and H-1' of **9a** are in *cis*-relation in regard with the isopropylidene ring. It is interesting that the difference in the chemical shift of two methyl protons of isopropylidene group in 4-(*p*-methoxybenzyl)-PDO (**12**, **16**, and **17**) is commonly 0.22 ppm, whereas those in others are within 0.07 ppm. These facts support that the mono(*p*-methoxybenzyl)-ation of **10** occurred selectively at the farer nitrogen from oxolane-ring to give 1-substituted product (**11**). The lower chemical shift of methylene protons of *O*-(*p*-methoxybenzyl) group and singlet signal of methyl protons of isopropylidene group in **18** prove the enol ether structure. Some of above-mentioned observations are also supported from ^{13}C NMR data (Table 4). In a comparison of ^{13}C NMR chemical shifts for **9a** and **9b** the larger differences were observed for C-1' and acetyl carbon. The lower field shift of C-3 and C-1' in 4-substituted derivatives (**12** and **16**) may be due to the anisotropic effect of the 4-(*p*-methoxybenzyl) group. In the case of **18**, the enolated carbonyl carbon shifted markedly to the upper field, whereas C-6 resonates in slightly higher field.

Spiro cyclic (Table 2) and bicyclic derivatives (Table 3) can be easily distinguished from the appearance of an AB-quartet of H-8a and H-8b and of a singlet of H-1, respectively, and the large coupling of the former is characteristic to H-6 of original PDO-ring. The absence and the presence of isopropylidene protons also support their structures. Moreover, it is characteristic that one of methylene protons at C-3 of the bicyclic derivatives resonated at extraordinary higher field than the other proton at C-3 as well as the corresponding methylene protons of spiro cyclic derivatives, which indicates the diamagnetic anisotropy in the perpendicular direction of the PDO-ring.

In the cases of **23a** and **23b**, a larger difference was observed in the chemical shift of H-4 protons, indicating that H-4 and carbonyl group in PDO-ring of **23a** are in *cis*-relation in regard with the five-membered ring. The configuration of **24** is probably similar to that of **23a**. The presence of sp^2 C-5 carbon in **30** and **33** in clearly shown by ^{13}C NMR (see Experimental).

Experimental

General. Melting points were determined with a Mel-Temp apparatus or with a Yanagimoto micro melting-point apparatus, and were not corrected. IR spectra (cm^{-1}) were recorded with a Hitachi EPI-G2 grating spectrometer. ^{1}H and ^{13}C NMR spectra were recorded with a JEOL JMN PS-100 and a JEOL FX-90Q spectrometers, respectively, in $CDCl_3$ with tetramethylsilane as the internal standard, unless otherwise noted. Column chromatography was performed on Wakogel C-200 or C-300.

Preparation of 3-Benzyloxypropanal (2). a) A mixture of 3-chloro-1,1-diethoxypropane (257 g, 1.54 mol), benzyl alcohol (55.5 g, 0.513 mol), sodium hydroxide (103 g, 2.57 mol), and tetrabutylammonium hydrogensulfate (17.4 g, 0.051 mol) in saturated sodium chloride (410 cm^3) was vigorously stirred at 60 °C for 12 h and then at 100 °C for 48 h, poured into ice-water, and extracted with benzene. The usual processing of

a) Measured in DMSO-d_6. b) The Assignment may be exchanged. c) The same numbering of carbon skeleton as those of PDO derivative is used.

the extract gave a crude oil which was purified by distillation to give colorless oily 3-benzyloxy-1,1-diethoxypropane (86.2 g, 71%). Bp 118—120 °C/11 Torr[†]; ^{1}H NMR: δ=7.72 (s, 5H, Ph), 4.69 (t, 1H, $J_{1,2}$=6.0 Hz, H-1), 4.49 (s, 2H, CH_2Ph), 3.85—3.3 (m, 6H, H-3 and 2×OCH_2 in Et) 1.93 (dt, 2H, $J_{2,3}$=6.0 Hz, H-2), 1.19 (t, 6H, J=7.5 Hz, 2× Me in Et). A solution of the above oil (30.0 g, 126 mmol) in acetone (60 cm^3) and 1 M hydrochloric acid (60 cm^3) was stirred at room temperature for 3 h, evaporated to a half volume, and extracted with chloroform. The usual processing of the extract and distillation of the product gave **2** (20.0 g, 97%). Bp 71—74 °C/1.3 Torr, IR: 1720 (C=O), ^{1}H NMR: δ=9.72 (t, 1H, $J_{1,2}$=2.0 Hz, H-1), 7.32 (s, 5H, Ph), 4.52 (s, 2H, CH_2Ph), 3.78 (t, 2H, $J_{2,3}$=6.0 Hz, H-3), 2.56 (dt, 2H, H-2).

Found: C, 73.09; H, 7.20%. Calcd for $C_{10}H_{12}O_2$: C, 73.14; H, 7.34%.

b) A mixed solution of chromium trioxide (55.0 g, 550 mmol) and pyridine (90 cm^3) in dry dichloromethane (1.1 dm^3) was vigorously stirred at room temperature for 30 min, 3-benzyloxy-1-butanol (15.2 g, 92.0 mmol) was added dropwise to it, then stirred for 2 h, and filtered. After the usual

[†] 1 Torr≈133.322 Pa.

work-up, the rough product was passed through a short silica-gel column, and purified by distillation to give **2** (10.9 g, 72%).

c) A mixed solution of 4-benzyloxy-1,2-*O*-isopropylidene-1,2-butanediol (112 g, 0.474 mol) in dioxane (400 cm^3) and 1 M hydrochloric acid (400 cm^3) was kept at room temperature for 12 h, poured into ice-water, and then extracted with dichloromethane. The usual processing of the extract gave a crude syrupy 4-benzyloxy-1,2-butanediol. ^1H NMR: δ=7.33 (s, 5H, Ph), 4.52 (s, 2H, CH_2Ph), 4.2—3.4 (m, 5H, H-1, 2, and 4), 3.2 and 2.6 (each bs, 2H, 2×OH), 1.9—1.6 (m, 2 H, H-3). To a solution of the above syrup in benzene (900 cm^3) was added lead tetraacetate (280 g, 0.576 mol) with stirring, the mixture was kept for 12 h at room temperature, and then filtered. The filtrate was poured into water and extracted with ethyl acetate. The usual processing of the extract and distillation of the oily product gave colorless **2** (69.8 g, 90%).

1-Acetyl-3-(3-benzyloxypropylidene)-2,5-piperazinedione (3). To a solution of 1,4-diacetyl-PDO (20.0 g, 101 mmol) and **2** (21.5 g, 131 mmol) in *N,N*-dimethylformamide (DMF, 80 cm^3) was added dropwise a solution of potassium *t*-butoxide (11.8 g, 106 mmol) in *t*-butyl alcohol (212 cm^3) at 0 °C with stirring, and the mixture was kept at 0 °C for 2 h and at room temperature for 12 h, neutralized with acetic acid and poured into ice-water. The crystals formed were filtered and recrystallized from ethanol-ether to give **3** (25.0 g, 82%) as prisms. Mp 119 °C; IR: 3180 (NH), 1715 (Ac), 1680 (amide), 1640 (C=C).

Found: C, 63.85; H, 5.83; N, 9.27%. Calcd for $C_{16}H_{18}N_2O_4$: C, 63.56; H, 6.00; N, 9.27%.

*3-(3-Benzyloxypropylidene)-1,4-bis-(*p*-methoxybenzyl)-2,5-piperazinedione (5).* To a solution of **3** (5.0 g, 16.6 mmol) in DMF (20 cm^3) was added 70% hydrazine hydrate (2.37 g, 33.2 mmol) at 0 °C, and the mixture was kept at 0 °C for 3 h, poured into ice-water. The *N*-deacetylated product (**4**) deposited (4.32 g) was filtered and dried. To a suspension of sodium hydride in DMF was added dropwise a solution of **4** in DMF (50 cm^3) at 0 °C with stirring, and after 2 h, *p*-methoxybenzyl bromide (7.67 g, 38.2 mmol) was further added dropwise. The reaction mixture was stirred for 2 h at 0 °C and for 12 h at room temperature, neutralized with acetic acid, poured into ice-water, and then extracted with ethyl acetate. The usual work-up of the extract gave a crude syrup, which was purifield on a silica-gel column (hexane-ethyl acetate 7:3) to give colorless syrupy **5** (5.97 g, 72%).

Found: C, 71.72; H, 6.58; N, 5.52%. Calcd for $C_{30}H_{32}N_2O_5$: C, 71.98; H, 6.44; N, 5.60%.

Oxidation of 3 and 5 with Osmium Tetraoxide. To a solution of **3** (7.40 g, 24.5 mmol) in dioxane (120 cm^3) was added a solution of sodium chlorate (10.4 g, 98.0 mmol) in water (30 cm^3) and osmium tetraoxide (62 mg, 0.24 mmol) with stirring. After 3 days at room temperature, the reaction mixture was evaporated to a half volume, poured into water, and then extracted with chloroform. The usual work-up of the extract gave a crude syrup, which was crystallized from ethyl acetate-ether to give 1-acetyl-3-(3-benzyloxy-1-hydroxypropyl)-3-hydroxy-PDO (**6**) as colorless prisms. Purification of the residue obtained from the filtrate on a silica-gel column (dichloromethane-acetone 4:1) gave the second crops of **6** as a monohydrate. Total yield of **6** was 5.04 g (58%). Mp 92 °C, IR: 3250 (OH, NH), 1735 (Ac), 1710, and 1680 (amide).

Found: C, 54.10; H, 6.41; N, 7.75%. Calcd for $C_{16}H_{20}N_2O_6 \cdot H_2O$: C, 54.23; H, 6.26; N, 7.91%.

A similar oxidation of **5** (380 mg, 0.759 mmol) gave a crude syrup, which was crystallized from acetone-ether to give 3-(3-benzyloxy-1-hydroxypropyl)-3-hydroxy-1,4-bis(*p*-methoxybenzyl)-PDO (**7**) as colorless prisms in 46% (187 mg) yield. Mp 140—141 °C; IR: 3450 (OH), 1665 (amide).

Found: C, 66.92; H, 6.48; N, 5.27%. Calcd for $C_{30}H_{34}N_2O_7$: C, 67.40; H, 6.41, N, 5.24%.

Isopropylidenation of 6 and 7. Method A: To a suspension of dried **6** (3.90 g, 11.6 mmol) in acetone (16 cm^3) was added 2-methoxypropene (9.6 cm^3) and catalytic amount of pyridinium *p*-toluenesulfonate with stirring. Compound **6** once dissolved within 5 min and new precipitate deposited after 15 min. After keeping the mixture for 24 h at room temperature, the precipitate was filtered and recrystallized from chloroform-ether to give 1-acetyl-3-(3-benzyloxy-1-hydroxy propyl)-3-hydroxy-3,1′-*O*-isopropylidene-PDO (**9a**) as colorless prisms. The residue from the filtrate was purified on a silica-gel column (chloroform-acetone 9:1) to give **9a** and its 3-epimer (**9b**).

9a: yield, 4.15 g (95%). Mp 151 °C, IR: 3200 (NH), 1730sh (Ac), 1710, and 1685 (amide).

9b: yield, 92 mg (2.1%), mp 138—140 °C (prisms from chloroform-ether).

Found for **9a**: C, 60.52; H, 6.42; N, 7.23%, and for **9b**: C, 60.73; H, 6.51; N, 7.30%. Calcd for $C_{19}H_{24}N_2O_6$: C, 60.62; H, 6.43; N, 7.44%.

Method B: To a solution of **6** (500 mg, 1.45 mmol) in acetone (20 cm^3) was added 2,2-dimethoxypropane (1 cm^3) and catalytic amount of *p*-toluenesulfonic acid with stirring at room temperature. After 12 h, the reaction mixture was neutralized with pyridine, and evaporated. The residue was separated on a silice-gel column (chloroform-acetone 9:1) to give **9a** (169 mg, 31%) and syrupy 1-acetyl-3-(3-benzyloxy-1-hydroxypropyl)-3-methoxy-PDO (**8**: 343 mg, 63%).

Found: C, 58.06; H, 6.21; N, 7.89%. Calcd for $C_{17}H_{22}N_2O_6$: C, 58.27; H, 6.33; N, 8.00%.

A similar treatment of **7** (3.90 g, 7.30 mmol) by the method A, and purification of the product on a silica-gel column (hexane-ethyl acetate 4:1) gave 3-(3-benzyloxy-1-hydroxypropyl)-3-hydroxy-3,1′-*O*-isopropyridene-1,4-bis(*p*-methoxybenzyl)-PDO (**12**: 3.92 g, 94%). Mp 131 °C (prisms from ether-hexane).

Found: C, 68.68; H, 6.69; N, 4.84%. Calcd for $C_{33}H_{38}N_2O_7$: C, 68.97; H, 6.67; N, 4.88%.

3-(3-Benzyloxy-1-hydroxypropyl)-3-hydroxy-3,1′-O-isopropylidene-2,5-piperazinedione (10). A solution of **9a** (530 mg, 1.41 mmol) in DMF (5 cm^3) and 70% hydrazine (0.20 cm^3) was stirred at 0 °C for 3 h, and poured into ice-water. The precipitate deposited was filtered and recrystallized from methanol-ether to give **10** (470 mg, 99%) as colorless needles of mp 164 °C.

Found: C, 60.86; H, 6.54; N, 8.25%. Calcd for $C_{17}H_{22}N_2O_5$: C, 61.06; H, 6.63; N, 8.38%.

p-*Methoxybenzylation of 10, 11, and 15.* The reaction procedure is exemplified by the preparation of 3-(3-benzyloxy-1-hydroxypropyl)-3-hydroxy-3,1′-*O*-isopropylidene-1-(*p*-methoxybenzyl)-PDO (**11**). To a suspension of 50% sodium hydride (316 mg, 6.58 mmol) in DMF (50 cm^3) was added dropwise a solution of **10** (2.0 g, 5.98 mmol) in DMF (20 cm^3) at 0 °C with stirring. After keeping the conditions for 1 h, *p*-methoxybenzyl bromide (1.44 g, 7.16 mmol) was further added. The mixture was stirred at 0 °C for 2 h and then

at room temperature for 12 h, neutralized with acetic acid, poured into ice-water, and extracted with ethyl acetate. The usual work-up of the extract gave crude crystals, which were recrystallized from ethanol–ether to give **11** as colorless prisms. The residue from the filtrate was separated on a silica-gel column (hexane–ethyl acetate 7:3) to give **11** and **12** (242 mg, 7.0%). **11**: yield, 2.35 g (87%). Mp 131 °C, IR: 3190 (NH), 1690 (amide).

Found: C, 65.98; H, 6.75; N, 5.88%. Calcd for $C_{25}H_{30}N_2O_6$: C, 66.06; H, 6.65; H, 6.16%.

A repeating similar reaction of **11** (410 mg, 0.903 mmol), and separation of products on a silica-gel column (hexane–ethyl acetate 4:1) gave **12** (392 mg, 76%) and 3-(3-benzyloxy-1-hydroxypropyl)-3-hydroxy-3,1′-*O*-isopropylidene-1-(*p*-methoxybenzyl)-5-(*p*-methoxybenzyloxy)-3,6-dihydro-2(1*H*)-pyrazinone (**18**: 58 mg, 11%) as a colorless syrup.

Found: C, 68.81; H, 6.84; N, 4.73%. Calcd for $C_{33}H_{38}N_2O_7$: C, 68.97; H, 6.67; N, 4.88%.

One-step reaction of **10** (2.0 g, 5.98 mmol) with 2 equimolar sodium hydride and *p*-methoxybenzyl bromide gave **12** (2.13 g, 62%) and **18** (441 mg, 13%). A similar reaction of **15** (623 mg, 1.71 mmol) with 2 equimolar reagents gave syrupy 3-hydroxy-3-[1-hydroxypropyl-3-(*p*-methoxybenzyloxy)]-3,1′-*O*-isopropylidene-1,4-bis(*p*-methoxybenzyl)-PDO (**17**) in 57% (568 mg) yield.

Found: C, 67.42; H, 6.64; N, 4.47%. Calcd for $C_{34}H_{40}N_2O_8$: C, 67.53; H, 6.67; N, 4.63%.

Hydrogenolysis of O-*Benzyl Group of* **9a**, **11**, *and* **12**. The reaction procedure is exemplified by the preparation of 3-(1,3-dihydroxypropyl)-3-hydroxy-3,1′-*O*-isopropylidene-1,4-bis(*p*-methoxybenzyl)-PDO (**16**). A solution of **12** (74 m, 0.13 mmol) in ethanol (50 cm³) was catalytically hydrogenated with 10% palladium–carbon (30 mg) at room temperature for 24 h. The usual processing of the reaction mixture gave **16** (62 mg, 98%) which was crystallized from ether–hexane. Mp 159 °C (prisms), IR: 3500 (OH), 1670 (amide).

Found: C, 64.21; H, 6.61; N, 5.70%. Calcd for $C_{26}H_{32}N_2O_7$: C, 64.45; H, 6.61; N, 5.78%.

A similar hydrogenolysis of **11** (1.16 g, 2.56 mmol) gave 3-(1,3-dihydroxypropyl)-3-hydroxy-3,1,-*O*-isopropylidene-1-(*p*-methoxybenzyl)-PDO (**15**) in quantitative (930 mg) yield. Mp 180 °C (prisms from ethanol–ether), IR: 3450 (OH), 3220 (NH), 1680 (amide).

Found: C, 59.48; H, 6.48; N, 7.53%. Calcd for $C_{18}H_{24}N_2O_6$: C, 59.33; H, 6.64; N, 7.69%.

Compounds **15** and **16** were also obtained from **18** (83 mg, 0.144 mmol) and **17** (96 mg, 0.165 mmol) in 92% (48 mg) and 99% (79 mg) yields, respectively. 1-Acetyl-3-(1,3-dihydroxypropyl)-3-hydroxy-3,1′-*O*-isopropylidene-PDO (**13**) was obtained from **9a** (0.500 g, 1.33 mmol) in 75% (286 mg) yield. Mp 194—195 °C (prisms from ethanol–ether).

Found: C, 50.21; H, 6.29; N, 9.65%. Calcd for $C_{12}H_{18}N_2O_6$: C, 50.35; H, 6.34; N, 9.79%.

Oxidative Removal of O-*Benzyl Group of* **9a** *with* N-*Bromosuccinimide*. A mixed suspension of **9a** (100 mg, 0.266 mmol) in chloroform (40 cm³), trilead(II) dicarbonate dihydroxide (1 g) and NBS (57 mg, 0.32 mmol) was vigorously stirred at room temperature for 24 h, and then filtered. The filtrate was treated by usual procedure and the products were separated on a silica-gel column (benzene–ethyl acetate 5:2) to give **13** (66 mg, 92%) and 1-acetyl-3-(3-benzoyloxyl-1-hydroxypropyl)-3-hydroxy-3,1′-*O*-isopropylidene-PDO (**14**: 6 mg, 6%) as a colorless hard syrup.

Found: C, 58.33; H, 5.71; N, 7.08%. Calcd for $C_{19}H_{22}N_2O_7$: C, 58.45; H, 5.68; N, 7.18%.

Cyclization of **15** *and* **16** *with* N-*Bromosuccinimide*. The reaction procedure is exemplified by the preparation of 5,6-dihydroxy-5,6-*O*-isopropylidene-7,9-bis(*p*-methoxybenzyl)-2-oxa-7,9-diazabicyclo[4.2.2]decane-8,10-dione (**19**). A suspension of **16** (97 mg, 0.20 mmol), barium carbonate (1.0 g) and powdered 4 A molecular sieves (1 g) in dry chloroform (10 cm³) was vigorously stirred at room temperature for 12 h, NBS (39.2 mg, 0.22 mmol) was added to it, and the resulting mixture was further stirred for 72 h, then filtered. The filtrate was poured into saturated sodium hydrogencarbonate and extracted with chloroform. The usual work-up of the extract gave a crude syrup, which was purified on a silica-gel column (hexane–ethyl acetate 7:3) to give **19** (83 mg, 86%). Mp 130 °C (prisms from ether–hexane); IR: 1705, 1685 (amide). ^{13}C NMR: δ=166.6s and 164.5s (C-8,10), 159.3s, 158.4s, 130.0d, 129.0d, 128.8d, 126.8s, 114.0d, and 113.4d (aromatic), 113.0s, 25.4q and 24.2q (Ip), 91.5s (C-6), 86.6d and 82.3d (C-1,5), 60.8t (C-3), 54.9q (2×OMe), 48.0t and 45.9t (2×NCH_2), 28.2t (C-4).

Found: C, 64.38; H, 6.28; N, 5.76%. Calcd for $C_{26}H_{30}N_2O_7$: C, 64.71; H, 6.27; N, 5.81%.

A similar cyclization of **16** (97 mg, 0.20 mmol) in chloroform (10 cm³) without barium carbonate and molecular sieves at room temperature for 24 h gave **19** (12 mg, 12%) and 4-hydroxy-6,9-bis(*p*-methoxybenzyl)-1-oxa-6,9-diazaspiro[4.5]-decane-7,10-dione (**21**: 54 mg, 63%). The usual acetylation of **21** in pyridine with acetic anhydride, and purification of the product on a silica-gel column (hexane–ethyl acetate 2:3) gave the 4-acetate (**23a**: 46 mg, 41%, mp 171 °C, prisms from ethanol–ether) and it's 5-epimer (**23b**, 48 mg, 44%) as colorless syrup.

^{13}C NMR for **23a**: δ=170.0s and 20.2q (Ac), 166.2s and 163.9s (C-7, 10), 159.2s, 158.5s, 129.7s, 126.6s, 129.5d, 114.1d, and 113.3d (aromatic), 93.2s (C-5), 77.7d (C-4), 67.1t (C-2), 55.0q (2×OMe), 48.8t and 48.7t (NCH_2×2), 46.8t (C-8), 31.1t (C-3), and for **23b**: δ=169.5s, and 20.3q (Ac), 164.1s (C-7, 10), 159.5s, 158.5s, 129.7s, 129.5s, 126.6s, 114.1d, and 113.3d (aromatic), 93.3s (C-5), 78.3d (C-4), 68.6t (C-2), 55.2q, 55.1q (2×OMe), 49.1t (2×NCH_2), 44.5t (C-8), 29.6t (C-3).

*6-(2-Formylethoxy)-1,4-bis(*p*-methoxybenzyl)-2,3,5-piperazinetrione* (**34**). To a solution of **29** (12.0 mg, 0.027 mmol) in dichloromethane (1 cm^3) was added sodium acetate (4.8 mg, 0.059 mmol) and pyridinium chlorochromate (11.6 mg, 0.054 mmol) with vigorous stirring at room temperature. After stirring for 24 h, the mixture was poured into water, and extracted with dichloromethane. The usual processing of the extract gave a crude product, which was purified on preparative TLC (ether) to give **34** (7.2 mg, 61%) as a colorless syrup. ^1H NMR: δ=9.59 (t, 1H, $J_{3',4'}$=1.5 Hz, CHO), 7.29, 6.84, 7.24, and 6.78 (each d, 8H, J=8.5 Hz, MBn×2), 5.17 and 4.17 (ABq, 2H, J=13.5 Hz, CH_2 in MBn), 4.89 (s, 2H, CH_2 in MBn), 4.85 (s, 1H, H-6), 3.9—3.7 (m, 2H, H-2'), 3.81 and 3.88 (each s, 6H, 2×OMe), 2.63 (dt, 2H, $J_{2',3'}$=6.0 Hz, H-3').

Found: C, 62.93; H, 5.52; N, 6.20%. Calcd for $C_{23}H_{24}N_2O_7$: C, 62.72; H, 5.49; N, 6.36%.

*6-Hydroxy-7,9-bis(*p*-methoxybenzyl)-5-methylene-2-oxa-7,9-diazabicyclo[4.2.2]decane-8,10-dione* (**32**). To a mixture of magnesium (49.7 mg, 2.05 mmol) and trimethylsilylmethyl chloride (418 mg, 1.05 mmol) in dry ether (10 cm^3) was added catalytic amount of iodine with vigorous stirring at 40 °C. After the stirring was continued for 30 min, the mixture was diluted with dry ether (120 cm^3), cooled to −30 °C, and a solution of **29** (300 mg, 0.682 mmol) in THF (10 cm^3) was further added dropwise to it. The reaction mixture was stirred at −30 °C for 4 h, poured into saturated ammonium chloride, and extracted with chloroform. The usual processing of the extract gave a crude syrup, which was purified on a flash column (hexane–ethyl acetate 7:3) to give colorless syrupy 5,6-dihydroxy-7,9-bis(*p*-methoxybenzyl)-5-trimethylsilylmethyl-2-oxa-7,9-diazabicyclo[4.2.2]decane-8,10-dione (**31**: 192 mg, 52%) as a mixture of 5-epimers. To a solution of **31** (192 mg, 0.354 mmol) in dichloromethane (6 cm^3) was added 4-dimethylaminopyridine (864 mg, 7.08 mmol) and trifluoroacetic anhydride (743 mg, 3.54 mmol) with vigorous stirring at room temperature. After stirring was continued for 1 h, a solution of tetrabutylammonium chloride (1.48 g, 5.32 mg) in acetonitrile (30 cm^3) and potassium fluoride (616 mg, 10.6 mmol) was further added, and the mixture was heated at 40 °C for 12 h, then *O*-detrifluoroacetylated by addition of methanol (5 cm^3), poured into saturated ammonium chloride, and extracted with chloroform. The usual processing of the extract gave a crude syrup, which was purified on a flash column (hexane–ethyl acetate 4:1) to give colorless syrupy **32** (125 mg, 81%).

Found: C, 65.82; H, 6.11; N, 6.28%. Calcd for $C_{24}H_{26}N_2O_6$: C, 65.74; H, 5.98; N, 6.39%.

Another method for the elimination reaction was accomplished as follows: a solution of **31** (14.0 mg, 0.0267 mmol) in 0.08 M sulfuric acid in THF (0.5 cm^3) was permitted to stand for 12 h at room temperature, poured into saturated sodium hydrogencarbonate, and extracted with chloroform. The usual processing of the extract gave a crude syrup, which was purified on a flash column (hexane–ethyl acetate 7:3) to give **32** (5.6 mg, 48%).

*6-(t-Butyldimethylsilyloxy)-1,9-bis(*p*-methoxybenzyl)-5-methylene-2-oxa-7,9-diazabicyclo[4.2.2]decane-8,10-dione* (**33**).
To a solution of **32** (10.0 mg, 0.0228 mmol) in dichloromethane (1 cm^3) was added 2,6-lutidine (12.2 mg, 0.114 mmol)

and 0.1 M *t*-butyldimethylsilyl triflate (0.342 cm^3, 0.0342 mmol) solution in dichloromethane with vigorous stirring at room temperature. The mixture was stirred for 12 h, poured into saturated ammonium chloride, and extracted with ethyl acetate. The extract was washed successively with 0.1 M hydrochloric acid, saturated sodium hydrogencarbonate, and saturated sodium chloride, dried over anhydrous magnesium sulfate, and then evaporated. The residue was purified on a flash column (hexane–ethyl acetate 4:1) to give **33** (10.1 mg, 80.2%) as a colorless hard syrup. ^{13}C NMR: δ=167.7s and 163.4s (C-8,10), 159.4s, 158.9s, 130.7d, 130.3d, 128.0s, 126.7s, 114.4d, and 113.3d, (aromatic), 148.6s and 118.0t (olefinic), 87.9s (C-6), 81.5d (C-1), 63.8t (C-3), 55.3q and 55.2q (2×OMe), 47.2t and 44.0t (NCH_2X2), 35.7t (C-4).

Found: C, 65.41; H, 7.28; N, 5.03%. Calcd for $C_{30}H_{40}N_2O_6Si$: C, 65.20; H, 7.30; N, 5.07%.

Benzofuran Derivatives. II. Synthesis of 2,3-Dihydrobenzofurans from Ethyl 2-Acylphenoxyacetates

Tsuneo SUZUKI
Nippon Dental University, Niigata, 1-8, Hamaura-cho, Niigata 951
(Received January 24, 1985)

Ethyl 3-alkyl-3-hydroxy-5-nitro-2,3-dihydro-2-benzofurancarboxylates were obtained from the reaction of ethyl 2-acyl-4-nitrophenoxyacetates with potassium hydroxide in dry dioxane. The relative ratios of the *cis* and *trans* isomers with respect to C-2 and C-3 stereochemistry varied according to the structure of the acyl group. When the acyl group was acetyl, propionyl, or isobutyryl group, the *cis* isomers (2-alkoxycarbonyl groups and 3-hydroxyl groups are *cis*) were exclusively obtained in high yields. On the other hand, a nearly equimolecular amount of the *cis* and *trans* isomers was obtained from the reaction of 2-formyl derivatives under the same conditions.

A number of 2,3-dihydrobenzofuran derivatives have been synthesized from the reaction of salicylaldehydes with ethyl α-bromophenylacetates[1] or by its modified reactions.[2,3] The stereochemistry of the *cis* and *trans* isomers of 2,3-dihydrobenzofurans was determined by ^{1}H NMR spectra and chemical reactions.[2,4]

In the previous paper,[5] it was suggested that the *cis* and *trans* isomers of 3-alkyl-3-hydroxy-2,3-dihydro-2-benzofurancarboxylate ions were important intermediates for the production of benzofurans and 2-benzofurancarboxylic acids in the Rössing reaction of 4-substituted 2-acylphenoxyacetic acids.[6] However, such intermediates were not obtained at that time. In this paper, the author reports the syntheses and the stereochemistry of *cis*- and *trans*-2,3-dihydrobenzofurans obtained by the base-catalyzed intramolecular cyclization reaction of ethyl 2-acyl-4-nitrophenoxyacetates (the *cis* isomer is shown by an *cis* relationship between C-2 alkoxycarbonyl groups or carboxyl groups and C-3 hydroxyl groups).[7]

Results and Discussion

The syntheses of ethyl esters **1c** and **1d** were carried out according to the reported method.[5] Ethyl esters **1a** and **1b** were prepared by esterification of the corresponding carboxylic acids.

When esters **1a—d** were refluxed with three equivalents of potassium hydroxide in dry dioxane, 2,3-dihydrobenzofurans (**2a—d** and **3a,b**), ethyl 2-benzofurancarboxylates (**4a—d**), 2-benzofurancarboxylic acids (**5a—d**), and 2,3-dihydro-2-benzofurancarboxylic acids (**6b, d**) were obtained, respectively. The isolated yields of compounds **2—6** are summarized in Table 1. In the case of esters **1b—d**, 2,3-dihydrobenzofurans (**2b** and **3b**, **2c**, and **2d**) were obtained in high yields (65—70%), whereas ester **1a** afforded 2,3-dihydrobenzofurans (**2a** and **3a**) in a poor yield (8%). The spectral data of **2a,b** and **3a,b** are listed in Table 2.

A mixture of the two isomers **2a** and **3a** (3:2 mole ratio) was produced by the treatment of **1a** with base. The structural assignments of the two isomers are as follows. The ^{1}H NMR spectrum of the major component **2a** showed the C-2 methine proton signal at δ 5.26 (d, J=6.8 Hz) and that of the minor component **3a** gave the C-2 methine proton signal at δ 5.17 (d, J= 3.3 Hz). In general, the coupling constants due to C-2 and C-3 protons of 2,3-disubstituted 2,3-dihydrobenzofurans are $J_{cis} > J_{trans}$[8] as predicted by the Karplus equation.[9] The ^{1}H NMR signal of the C-2 proton of **3a** was located about δ 0.1 upfield from that of the C-2 proton of **2a** by the anisotropic effect of C-3 hydroxyl groups.[10] Additionally, a large nuclear Overhauser effect (15%) was observed between C_2–H and C_3–H in the major product **2a**, whereas a small effect (8%) in the minor product **3a** as shown in Table 3.[11,12] A large NOE is measured when the irradiation proton and the measured proton have *cis*-configura-

TABLE 1. THE REACTION OF ETHYL 2-ACYL-4-NITROPHENOXYACETATES (**1a—d**) WITH POTASSIUM HYDROXIDE IN DRY DIOXANE[a]

Starting Materials **1** (R)	Recovery of **1**/%	Isolated Yields of Products/%				Total Yields/%
		2 and **3** (**2**:**3**[b])	**4**	**5**[c]	**6**[c]	
1a (H)	62	8 (3:2)	1	0.5		71.5
1b (CH_3)	5	70 (16:1)	8	1	3	87
1c (CH_2CH_3)	2	67 (1:0)	10	2		81
1d ($CH(CH_3)_2$)	0	65 (1:0)	5	4	18	92

a) Esters **1a—d** were refluxed with potassium hydroxide in a 1:3 mole ratio in 30 ml of dry dioxane for 1 h. b) The ratios of the two isomers were determined by ^{1}H NMR analyses on the products **2** and **3** separated by silica-gel column chromatography. The isomerization of the two isomers was not recognized during chromatography. c) Acids **4** and **5** were analysed as the corresponding methyl esters.

Table 2. Physical data of 2,3-dihydrobenzofurans (**2a,b** and **3a,b**)

Compounds	R	^{1}H NMR[a,b] C_2-H	C_3-R
2a	H	5.26 (d) ($J_{2H,3H}$=6.8 Hz)	5.62 (t)
3a	H	5.17 (d) ($J_{2H,3H}$=3.3 Hz)	5.56 (dd)
2b[c]	CH_3	4.99 (s)	1.88 (s)
3b[c]	CH_3	5.18 (s)	1.65 (s)

a) The chemical shifts in ppm down field from internal TMS in $CDCl_3$. b) Carefully argon degassed solution of **2a,b** and **3a,b** were used for the measurement. c) The structure of **2b** and **3b** were not assigned by IR measurements in $CHCl_3$ or $CDCl_3$.

Table 3. The NOE values (%) for 2,3-dihydrobenzofurans (**2a—d** and **3a,b**)

Compounds	Observed Signal [Irradiated Signal] NOE/%
2a	C_2-H [C_3-H] 15
3a	C_2-H [C_3-H] 8
2b	C_2-H [C_3-CH_3] 34
3b	C_2-H [C_3-CH_3] 15
2c	C_2-H [C_3-CH_2-] 8; C_2-H [C_3-C-CH_3] 17
2d	C_2-H [C_3-CH-] 5; C_2-H [C_3-C-CH_3[a]] 15; C_2-H [C_3-C-CH_3[b]] 12

The gas dissolved in solution was removed by bubbling with argon. a) The chemical shift of the methyl proton is δ 0.90. b) The chemical shift of the methyl proton is δ 1.08.

tions.[11] All these results suggest that the major product **2a** is *cis*, and the minor product **3a** is *trans*.

The ethyl ester **1b** afforded a mixture of the two isomers **2b** and **3b** in a 16:1 mole ratio. The chemical shift of the C-2 methine proton of **3b** is located about δ 0.2 downfield from that of the methine proton of **2b** by the anisotropic effect of C-3 methyl group.[8c,13] A large NOE (34%) was observed between C_2-H and C_3-Me in the product **2b**, whereas a small NOE (15%) was obtained in the product **3b**.[11,12] Thus, the major component **2b** was assigned to the *cis* isomer and the minor component **3b** to the *trans* isomer.

Ethyl esters **1c** and **1d** afforded the corresponding 2,3-dihydrobenzofurans **2c** and **2d** in high yields, respectively. Only one component of two isomers was detected with ^{1}H NMR measurement of the products. Similarly, the structure of **2c** and **2d** was concluded to be *cis* from the NOE measurement as described for the *cis* isomers **2a** and **2b**. An acid **6d** was assigned to *cis* stereochemistry by methylation followed by comparison with an authentic sample **8d** obtained from the reaction of methyl ester **7d** with potassium hydroxide.

As shown in Table 1, the relative ratios of the two isomers were varied according to the structure of the acyl group. In the case of **1b—d**, the exclusive production of the *cis* isomers **2b—d** is explained by the steric repulsion of the ethoxycarbonyl group and the methyl, ethyl, or isopropyl group at the cyclization step. On the other hand, in the case of **1a**, compounds **2a** and **3a** were obtained in a nearly equimolecular ratio because the steric repulsion between the ethoxycarbonyl group and hydrogen atom is small.

2,3-Dihydrobenzofurans **2b** and **3b** were treated with potassium hydroxide in dry dioxane to elucidate the reaction mechanism, respectively. The results are listed in Table 4.

In the case of the *cis* isomer **2b**, products **4b, 5b,** and **6b** were obtained in 9, 2, and 13% yields, respectively. A mixture of the two isomers **2b** and **3b** (70%; **2b**:**3b**=14:1) were recovered. On the other hand, in the case of the *trans* isomer **3b**, compounds **4b** and **5b** were produced in 71 and 15% yields, respectively. A mixture of compounds **2b** and **3b** (14%; **2b**:**3b**=2:1) was recovered. The structure of the acid **6b** was assigned to the *cis*-configuration by methylation followed by comparison with an authentic sample **8b**, prepared later, in which a NOE (33%) of C-2 methine proton was observed by the irradiation of C-3 methyl proton. These results showed that isomerization between the two isomers took place and the *cis* isomer

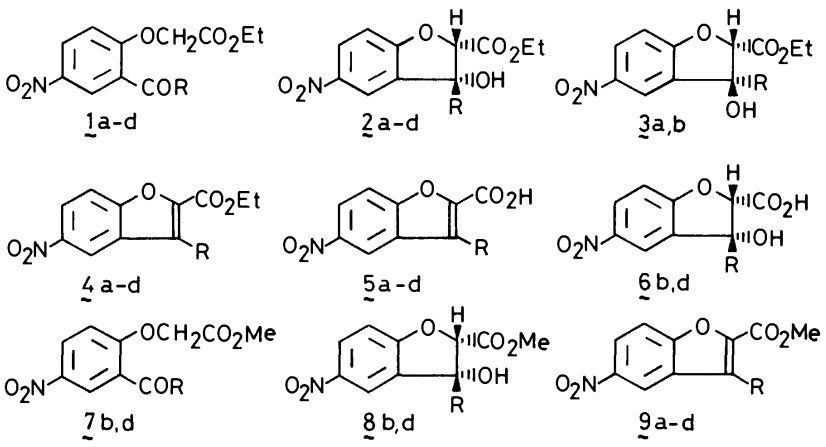

TABLE 4. THE REACTION OF 2,3-DIHYDROBENZOFURANS (**2b** AND **3b**) WITH POTASSIUM HYDROXIDE IN DRY DIOXANE

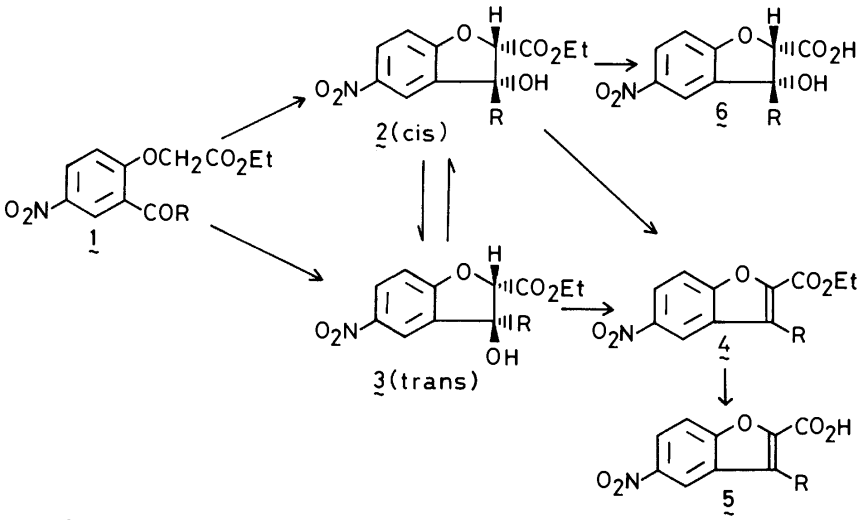
Starting Materials	Recovery of **2** and **3**/%(**2**:**3**[a])	Isolated Yields of Products/%			Total Yields/%
		4	**5**[b]	**6**[b]	
2b	70 (14:1)	9	2	13	94
3b	14 (2:1)	71	15		100

a) The ratios of the two isomers were determined by ^{1}H NMR measurement. b) Acids **4** and **5** were analysed as the corresponding methyl esters.



Scheme 1. The reaction pathways for the production of 2,3-dihydrobenzofurans (**2** and **3**) and related compounds (**4**, **5**, and **6**).

2b was more stable than the *trans* isomer **3b** as the steric repulsion between the ethoxycarbonyl group and the methyl group in **2b** was smaller than that in **3b**;[8a] compound **3b** was more prone to dehydration than the *cis* isomer **2b** because the *trans* isomer **3b** was sterically less hindered to the approach of the base.

As shown in Scheme 1, the ester **4b** must be obtained mainly from the *cis* isomer **2b** in the reaction of the ester **1b** and base because the product composition of **4b** and **5b** from the ester **1b** was similar to that of products from **2b**, though the *trans* isomer **3b** afforded the ester **4b** in a high yield.

Experimental

All the melting points are uncorrected. The infrared absorption spectra (IR) were determined on a JASCO IRA-2 spectrometer. The nuclear magnetic resonance spectra (^{1}H) and nuclear Overhauser effects were determined at 90 MHz on a JEOL JNM-FX 90Q FT NMR spectrometer, using tetramethylsilane as an internal standard. Analytical and preparative HPLC were carried out with a YANACO Liquid Chromatograph L-4000 W apparatus equipped with a UV detector. A Yanapak ODS-T column (4 mm×25 cm) was used. The solvent system of 18—20% acetonitrile and 0.05 M (1 M=1 mol dm^{-3}) potassium dihydrogenphosphate buffer (pH=3.1) (vol/vol) was used as eluent. Wakogel C-200 (Wako) was used for column chromatography. Dry dioxane was prepared by the method of Fieser.[14] Unless otherwise stated, anhydrous sodium sulfate was employed as the drying agent.

A General Procedure for the Reaction of Ethyl 2-Acyl-4-nitrophenoxyacetates (1a—d) with Potassium Hydroxide in a 1:3 Mole Ratio. A typical procedure will be described for the reaction of **1b**. A mixture of **1b** (300 mg, 1.12 mmol), potassium hydroxide powder (191 mg, 3.40 mmol), and dry dioxane (30 ml) was refluxed for 1 h. After cooling, insoluble materials in the reaction mixture were removed by filtration. The residue obtained upon evaporation of the dioxane was dissolved in benzene and insoluble materials were filtered. After evaporation of the benzene, the residue (254 mg) was chromatographed on silica gel (30 g). The first fraction eluted with benzene gave 23 mg (8%) of **4b** as crystals. The second fraction eluted with benzene–ether (30:1) gave 15 mg (5%) of **1b** as crystals. The third fraction eluted with benzene–ether (20:3) gave 210 mg (70%) of a mixture of **2b** and **3b** as crystals. The relative ratio of **2b** and **3b** (16:1) was determined by ^{1}H NMR spectroscopy.

The insoluble materials obtained above were combined and dissolved in water and acidified with 6 M hydrochloric acid. The resulting acids were extracted with ether and methylated with diazomethane. The residue (40 mg) obtained upon evaporation of the ether was chromatographed on silica gel (15 g). The first fraction eluted with benzene gave the methyl ester of **5b** (3 mg, 1%) as colorless crystals, which were identified by comparison with an authentic sample of **9b** obtained later. The second fraction eluted with benzene–ether (20:3) gave the methyl ester of **6b** (9 mg, 3%) as crystals. This was identified by comparison with an authentic sample **8b** obtained from the reaction of **7b** with potassium hydroxide.

The results of the reaction of esters **1a**, **1c**, and **1d** with potassium hydroxide in dry dioxane are listed in Table 1. Methyl esters of **5a**, **5c**, **5d**, and **6d** were identified by comparison with authentic samples **9a**, **9c**, **9d**, and **8d** obtain-

ed later.

2c: Colorless crystals from benzene, mp 108—110 °C. IR(KBr): ν_{max} 3420 (OH) and 1735 cm^{-1} (CO_2). Found: C, 55.29; H, 5.35%. Calcd for $C_{13}H_{15}NO_6$: C, 55.51; H, 5.38%.

2d: Colorless plates from hexane-benzene, mp 106—107 °C. IR(KBr): ν_{max} 3432 (OH) and 1739 cm^{-1} (CO_2). Found: C, 56.80; H, 5.72%. Calcd for $C_{14}H_{17}NO_6$: C, 56.95; H, 5.80%.

4a: Colorless prisms from benzene, mp 152—153 °C. IR(KBr): ν_{max} 1729 cm^{-1}(CO_2). Found: C, 56.21; H, 3.86%. Calcd for $C_{11}H_9NO_5$: C, 56.17; H, 3.85%.

4b: Colorless short needles from hexane-benzene, mp 146.0—147.5 °C. IR(KBr): ν_{max} 1700 cm^{-1} (CO_2). Found: C, 57.87; H, 4.53%. Calcd for $C_{12}H_{11}NO_5$: C, 57.83; H, 4.44%.

4c: Colorless short needles from benzene, mp 110.5—111.0 °C. IR(KBr): ν_{max} 1722 cm^{-1} (CO_2). Found: C, 59.61; H, 5.07%. Calcd for $C_{13}H_{13}NO_5$: C, 59.31; H, 4.98%.

4d: Colorless short needles from benzene-hexane, mp 103.5—106.0 °C. IR (KBr): ν_{max} 1719 and 1707 cm^{-1} (CO_2). Found; C, 60.38; H, 5.36; N, 5.20%. Calcd for $C_{14}H_{15}NO_5$: C, 60.65; H, 5.45; N, 5.05%.

Separation and Identification of cis- *and* trans-*2,3-Dihydrobenzofurans (**2a, b** and **3a, b**).*

*Ethyl Esters **2a** and **3a**.* The *cis* isomer **2a** was obtained by fractional crystallization of the mixture of **2a** and **3a** (5:2 mole ratio) from benzene-ether followed by ether. The *trans* isomer **3a** was separated from the mixture of two isomers by using an HPLC and purified by recrystallization of the crude compound **3a**.

2a: Colorless plates from benzene-hexane, mp 134—135 °C.[15] IR(KBr): ν_{max} 3540 (OH) and 1727 cm^{-1} (CO_2). Found: C, 52.07; H, 4.33; N, 5.38%. Calcd for $C_{11}H_{11}NO_6$: C, 52.17; H, 4.38; N, 5.53%.

3a: Colorless short needles from benzene-hexane, mp 96—97 °C.[15] IR(KBr): ν_{max} 3440 (OH) and 1728 cm^{-1} (CO_2). Found: C, 52.33; H, 4.38; N, 5.35%. Calcd for $C_{11}H_{11}NO_6$: C, 52.17; H, 4.38; N, 5.53%.

*Ethyl Esters **2b** and **3b**.* The *cis* isomer **2b** was obtained by fractional crystallization of the mixture of **2b** and **3b** (14:1 mole ratio) from benzene. The *trans* isomer **3b** was obtained by column chromatography of the residue obtained by concentration of the mother liquor on silica gel and eluted with benzene-ether (30:1).

2b: Colorless plates, mp 156.0—157.5 °C. IR(KBr): ν_{max} 3440 (OH) and 1740 cm^{-1} (CO_2). Found: C, 53.67; H, 4.85%. Calcd for $C_{12}H_{13}NO_6$: C, 53.93; H, 4.90%.

3b: Crystals, mp 52.5—54.0 °C. IR(KBr): ν_{max} 3430 (OH) and 1725 cm^{-1} (CO_2). Found: C, 54.00; H, 5.02; N, 5.21%. Calcd for $C_{12}H_{13}NO_6$: C, 53.93; H, 4.90; N, 5.24%.

*The Reaction of 2,3-Dihydrobenzofurans (**2b** and **3b**) with Potassium Hydroxide.* A typical procedure will be described for the reaction of **2b**. A mixture of **2b** (100 mg, 0.37 mmol), potassium hydroxide powder (63 mg, 1.12 mmol), and dry dioxane (10 ml) was refluxed for 1 h. The reaction mixture was worked up as described for the reaction of **1b** with potassium hydroxide. From the residue obtained upon evaporation of benzene, ethyl ester **4b** (8 mg) was obtained in 9% yield. Seventy percent of a mixture of **2b** and **3b** (70 mg, 14:1 mole ratio) was recovered. Methyl esters of **5b** (2 mg) and **6b** (12 mg) were obtained by methylation in 2 and 13% yields, respectively. The result of the reaction of **3b** with potassium hydroxide in dry dioxane is listed in Table 4.

*Preparation of Materials (**1a—d, 7b, 7d, 8b, 8d,** and **9a—d**).* Compounds **1c** and **1d** were prepared according to the reported method.[5] Ethyl ester **1a** was prepared from 2-formyl-4-nitrophenoxyacetic acid[5] by heating with ethanol and sulfuric acid. Similarly, ethyl ester **1b** was prepared from 2-acetyl-4-nitrophenoxyacetic acid[5] obtained by nitration[16] of 2-acetylphenoxyacetic acid.[17] Compound **1b** was identified by comparison with an authentic sample obtained by the reported method.[5] Methyl esters **7b** and **7d** were obtained from the corresponding phenoxyacetic acids[5] by methylation with diazomethane, respectively. In the same manner as has been described for **2b**, 2,3-dihydrobenzofurans **8b** and **8d** were obtained from the corresponding methyl esters **7b** and **7d**, respectively. Methyl esters **9a—d** were prepared by methylation of acids **5a**[18] and **5b—d**[5] with diazomethane, respectively.

1a: Colorless short needles from ethanol, mp 91—93 °C. Found: C, 52.40; H, 4.38%. Calcd for $C_{11}H_{11}NO_6$; C, 52.17; H, 4.38%.

7b: Colorless short needles from methanol, mp 105.0—106.5 °C. Found: C, 52.16; H, 4.29%. Calcd for $C_{11}H_{11}NO_6$: C, 52.17; H, 4.38%.

7d: Yellow crystals from hexane-ether, mp 57.0—57.8 °C. Found: C, 55.32; H, 5.35; N, 4.89%. Calcd for $C_{13}H_{15}NO_6$: C, 55.51; H, 5.38; N, 4.98%.

8b: Colorless short needles from benzene, mp 133.0—134.0 °C. IR (KBr): ν_{max} 3415 (OH) and 1750 cm^{-1} (CO_2). Found: C, 52.09; H, 4.38; N, 5.40%. Calcd for $C_{11}H_{11}NO_6$: C, 52.17; H, 4.38; N, 5.53%.

8d: Pale yellow prisms from ether-hexane, mp 96.0—97.5 °C(bp 156 °C at 2 Torr; 1 Torr=133.322 Pa). IR(KBr): ν_{max} 3420 (OH) and 1748 cm^{-1}(CO_2). Found: C, 55.54; H, 5.32%. Calcd for $C_{13}H_{15}NO_6$: C, 55.51; H, 5.38%.

9a: Colorless short needles from benzene, mp 163.5—164.5 °C. Found: C, 54.32; H, 3.14%. Calcd for $C_{10}H_7NO_5$: C, 54.32; H, 3.19%.

9b: Colorless short needles from methanol, mp 147.0—148.5 °C. Found: C, 56.29; H, 3.98%. Calcd for $C_{11}H_9NO_5$: C, 56.17; H, 3.85%.

9c: Colorless plates from benzene-hexane, mp 120—121 °C. Found: C, 58.06; H, 4.52%. Calcd for $C_{12}H_{11}NO_5$: C, 57.83; H, 4.44%.

9d: Colorless short needles from benzene-hexane, mp 110 °C. Found: C, 59.19: H, 4.96%. Calcd for $C_{13}H_{13}NO_5$: C, 59.31; H, 4.98%.

The Nuclear Overhauser Effect Measurement. The solution (calcd 5% wt/vol) was filtered and carefully degassed by argon. A small amount of tetramethylsilane was used as an internal standard. The irradiation power of the second radio frequency field was checked by using a standard sample of 4% 3-hydroxy-4-methoxybenzaldehyde-[$^2H_1$]chloroform solution (wt/vol) as the NOE (20%) of C-5 hydrogen atom was observed by the irradiation of C-4 methoxyl group. The homogated decoupling technique was employed in the measurement (at least three measurements were made).

The author is grateful to Mr. Yoshiaki Matsuda for the elemental analyses and to Mr. Naohiro Hiratsuka for the nuclear magnetic resonance analyses.

Surface Behaviors of Nucleic Acid Base-Containing Lipids in Monolayer and Bilayer Systems

Hiromi KITANO* and Helmut RINGSDORF†
Department of Polymer Chemistry, Kyoto University, Kyoto 606
†*Institute of Organic Chemistry, Mainz University, Mainz, West Germany*
(Received Feburary 12, 1985)

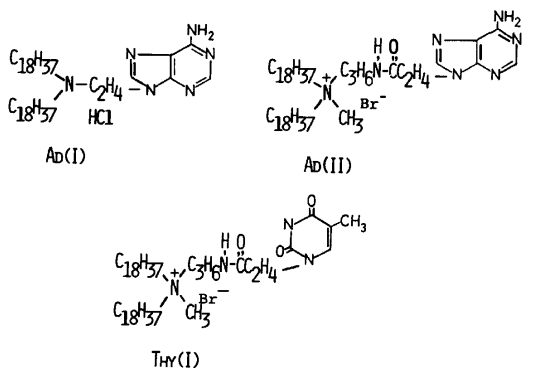
Three kinds of nucleic acid base-containing lipids were synthesized and the surface behaviors of these compounds in monolayer and bilayer systems were examined. In the monolayer systems, the addition of a complementary nucleoside to a subphase solution extended the monolayer much more efficiently than that of other nucleosides because of hydrogen bonding between a pair of complementary bases. In the monolayer and bilayer systems, the photodimerization reaction of a thymine ring was confirmed by the change in the surface pressure of the monolayer and the decrease in absorbance and the broadening of the phase-transition peak in the DSC curve of the liposome solution.

Mutual recognition of complementary nucleic acid bases is a fairly essential factor for the reproduction and generation of cells. To mimic these phenomena, many researchers have introduced nucleic acid bases into soluble polymers, polymer gels and micelles.[1-3] Considering the fact that replication of DNA occurs in cells, it is worthwhile to examine the mutual recognition of nucleic acid bases in model cell systems. In this project we studied the mutual recognition of nucleic acid bases in monolayer and bilayer systems which resembled membrane systems. Nucleic acid bases with lipophilic groups are also very interesting as both drug delivery systems and drugs themselves. Researchers have observed various remarkable effects of lipophilic nucleotides as anti-tumor reagents,[4a-c] and it is worthwhile to obtain basic information about the properties of nucleic acid base derivatives with long alkyl chains.

Experimantal

Materials. Three kinds of amphiphiles with nucleic acid bases (Ad(I), Ad(II), and Thy(I)) were synthesized (Scheme 1).

a) Ad(I). 9-(2-Chloroethyl)adenine was synthesized by the method of Ueda *et al.*[5,6] Dioctadecylamine (Fluka, three times recrystallized from acetone before use) (0.625 g, 1.2 mmol) and 0.12 g (0.607 mmol) of 9-(2-chloroethyl)-adenine were dissolved in 1-butanol (50 cm³) and the solution was refluxed for 5 d. After evaporating the solvent, an oily mixture was purified by silica-gel column chromatography using ethanol as an eluent. The eluate was evaporated and the oily product was precipitated in cold acetonitrile (Ad(I) 67 mg, 14.2% yield). Found; C, 69.45; H, 11.72; N, 10.40. Calcd for $C_{43}H_{83}N_6Cl$; C, 71.82; H, 11.55; N, 11.69.



Scheme 1. Chemical structures of nucleic acid base-containig lipids examined here.

b) Ad(II). A *p*-Nitrophenyl ester of 9-(2-carboxyethyl)adenine was synthesized by the same method of Overberger and Inaki.[7] (3-Aminopropyl)methyldioctadecylammonium bromide hydrochloride[8] (1.22 g, 1.72 mmol) and 0.548 g (1.5 mmol) of 9-(2-carboxyethyl)adenine *p*-nitrophenyl ester were dissolved in 50 cm³ of a dichloromethane-*N*,*N*-dimethylformamide mixture (4:1) and 0.5 cm³ (3.59 mmol) of triethylamine was added. The mixture was continuously stirred for 2 d at room temperature. After evaporating the solvent, an oily yellow mixture was purified using silica-gel column chromatography with ethanol as an eluent. Just after the yellow colored *p*-nitrophenol flowed out of the column, the eluent was changed to $CHCl_3$–methanol (2:1). After the addition of a few drops of concd HBr, the collected eluate was evaporated and the oily product was precipitated in cold acetonitrile (HBr salt of Ad(II) 0.573 g, 40.5% yield). Found; C, 60.38; H, 9.83; N, 10.24. Calcd for $C_{48}H_{93}N_7OBr_2$; C, 61.06; H, 9.93; N, 10.38.

c) Thy(I). One g (1.41 mmol) of (3-aminopropyl)-methyldioctadecylammonium bromide hydrochloride[8] and 0.5 g (1.57 mmol) of 1-(2-carboxyethyl)thymine *p*-nitrophenyl ester[7] were reacted using a similar method for Ad(II) (Thy(I) 0.412 g, 34.2% yield). Found; C, 66.85; H, 11.02; N, 6.50. Calcd for $C_{48}H_{93}N_4O_3Br$; C, 67.49; H, 10.97; N, 6.56.

Monolayer Measurements. Surface-pressure measurements were carried out using a Wilhelmy system connected to a Commodore PET 4032 microprocessor with a floppy-disc memory system. The volume of the subphase solution was about 200 cm³. Millipore water was used for the preparation of a subphase solution. The temperature of the subphase was maintained by circulating water using a Lauda K4R water bath.

Bilayer Structure Formation. The necessary amount of nucleic acid base-containing amphiphile was suspended in distilled water using a vortex mixer. The solution was ultrasonicated using a Branson sonifier (Model B15P, 200 W 20 kHz) at 60 °C for 5 min. The liposome that was obtained was negatively stained using a 2(w/v)% ammonium molybdate solution on a carbon-evaporated copper mesh (10 nm thickness on G200 mesh, Polaron Equipment Ltd., Watford, England)

—·—·—, in the presence of thymidine, ----, in the presence of adenosine.

for measurements using a JEM-100U electron microscope (Nihon Denshi, Tokyo, Japan).

UV Measurements. To observe any decrease in the absorption of the Thy(I) liposome solution due to photodimerization, a Beckman spectrophotometer (Model DU-6) was used.

UV Irradiation. To examine the photodimerization reaction of a Thy(I) liposome solution, a 200-V mercury lamp (Oriel) was used at 100 mA. The sample solution (10 mg cm^{-3}) was poured into a quarz cuvette (1×1×4 cm) and was placed at the distance of 20 cm from the light source at room temperature. The surface behavior of the Thy(I) monolayer was also observed before and after UV-irradiation. During a photo-reaction involving the monolayer of Thy(I) for 45 min (at 14°C), the surface tension of the monolayer was automatically maintained at 30 mN m^{-1}.

DSC Measurements. Phase transition behaviors of the Ad(II)- and Thy(I)-liposomes were observed using a Perkin Elmer DSC-2C. The volumes and concentration of samples in DSC alminium cells were 70×10^{-6} dm^3 and 10 mg cm^{-3}, respectively. The temperature was increased at a rate of 2.5°C min^{-1}.

Results and Discussion

A. Monolayer System. At first, we observed the surface behavior of the nucleic acid-base-containing amphiphiles in the monolayer system. Figure 1 shows the effects of adenosine and thymidine on the Ad(I) monolayer. Upon an addition of thymidine to the subphase, the monolayer expanded extraordinarily. However, an addition of adenosine induced a relatively smaller expansion. The smaller increase in the surface area in the Ad(I)–adenosine system can be attributed to a hydrophobic base-stacking effect since purine rings of adenosine and adenine are more hydrophobic than a pyrimidine ring of thymine. On the contrary, the larger expansion effects observed for an Ad(I)–thymidine system is due to the hydrogen-bonding-induced complementary base pairs between thymine and adenine rings. By the addition of 0.01 M (1 M=1 mol dm^{-3}) or 0.1 M of HCl to the subphase solution, the expanding effect of thymidine became much smaller because of a protonation of the amino group of Ad(I). This is consistent with the hydrogen-bonding effect regarding the thymidine–adenine ring interaction. Similar tendencies were also observed in the Ad(II)- and Thy(I)-monolayer systems. The surface area of the Thy(I) monolayer was, for example, 0.78 nm^2 molecule^{-1} at 15 mN m^{-1}. In the presence of 1 mM of adenosine, the surface area of the Thy(I) monolayer was increased by 0.24 nm^2 molecule^{-1}, whereas a smaller increase (0.10 nm^2 molecule^{-1}) was observed in the presence of 1 mM of thymidine.

The UV irradiation of the Thy(I) monolayer at 30 mN m^{-1} (densely packed conditions) for 45 min increased the surface area (surface area at 40 mN m^{-1}; from 0.54 nm^2 molecule^{-1} to 0.62 nm^2 molecule^{-1}). Though the amount of the reaction product was too small for a confirmation, the photodimerization of the thymine moiety of Thy(I) probably occured. In the case of the photodimerization of an amphiphilic cinnamic acid derivative in the monolayer system, a slight decrease in the surface area was observed.[9] In this case, the cinnamic acid moiety existed in the lipophilic region. On the contrary, the thymine moiety of Thy(I) existed near the ammonium head group. These differences might be the reason for the different tendencies regarding the photodimerization.

Bilayer System. Upon ultrasonication, suspended solutions of both Ad(II) and Thy(I) turned opaque and the diameters of the liposomes formed were estimated to be 60—300 nm (widely distributed) from electron micrographs. The bilayer structures of these solutions were confirmed by a small-angle X-ray scattering method (SAXS) using a Kratky U-slit system with a position-sensitive-proportional counter (Rigaku Denki, Tokyo, Japan).[10] In plots of the relative intensities *vs.* the scattering vectors of the Thy(I) solution, for example, a sharp peak at 4.3—4.2 nm, which reflects the thickness of the bilayer of Thy(I), was clearly observed (using a CPK model, the length of the octadecyl chain of a stretched Thy(I) molecule was estimated to be about 2.1 nm). The phase-transition temperatures of these liposome solutions were quite similar (Ad(II), 42.1°C, Thy(I), 42.5°C) with each other. This was probably due to a similar structure regarding the lipophilic parts.

Upon UV irradiation of the Thy(I)-liposome solution, a decrease in absorbance at 270 nm could be observed and attributed to the photodimerization of the thymine moiety (Fig. 2). This was because upon dimerization the thymine ring loses its aromaticity. There was no recovery of absorption at 270 nm after heating at 60°C for 10 min. This excludes the probability of a hydration of the thymine moiety during the UV irradiation. From electron micrographs and SAXS measurements, the liposome structure was observed to be maintained both before and after UV

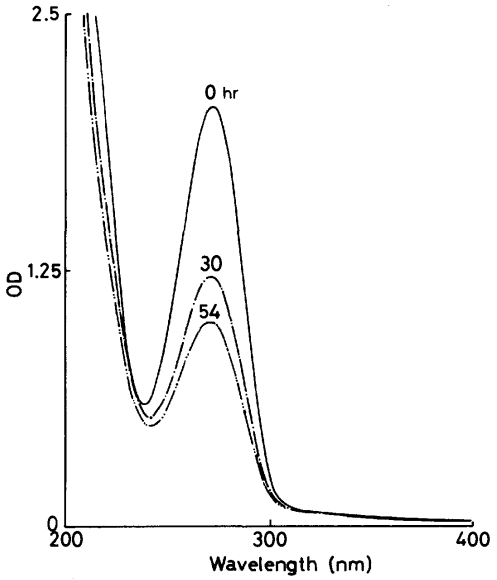

Fig. 2. Effect of uv irradiation on the absorbance of Thy(I)-liposome solution. [Thy(I)]=0.2 mmol dm^{-3}.

irradiation. Dimerization of Thy(I) was also confirmed by gel-permeation chromatography. After UV irradiation, a Thy(I) liposome solution was lyophilized and the obtained powder was dissolved in dichloromethane and carried on a Pharmacia Sephadex LH-20 column (2×20 cm). It was then eluted using dichloromethane. Elution of dimeric compounds from a column was observed using a Shodex SE-11 refractometer and the conversion of the dimerization reaction was estimated to be 50% after UV irradiation for 54 h. We tried to evaluate the structure of the dimerization product using ^{13}C NMR. However, the conversion of the reaction was so low and the amount of product was so small that it was very difficult to resolve the ^{13}C NMR spectra. At present we consider that a head-to-head and cis form dimerization is most probable from the molecular structure of Thy(I). The rate of the observed dimerization was much smaller than the polymer solution system.[11] This was probably because the long distance between thymine moieties was unfavorable for realizing dimerization (the distance between thymine moieties must be shorter than 0.4—0.5 nm for photodimerization).[12] Due to the bulkiness of the head group of the liposome-forming molecule, such a tight packing might be difficult. The unfavorable turbidity of the liposome solution and the lack of a cooperative action of the neighboring thymine ring might also be possible reasons for the slow dimerization reaction observed. After dimerization, the peak of a Thy(I)-liposome solution in DSC measurements was observed to be broader than that of the starting Thy(I)-liposome solution (peak width at half height; 3.7 °C→6.8 °C). This is probably because of the heterogenicity of the partially dimerized membrane surface. Upon mixing Ad(II) and Thy(I) liposome solutions, no large change in the DSC profiles was observed compared to those of Ad(II)- and Thy(I)-liposome solutions. This is probably because of the electrostatic repulsive forces between the cationic liposome particles. After incubating the mixed liposome solution at 350 K for 8 h, the peak was observed to be much broader than the starting solution (peak width at half height; 3.7 °C→7.1 °C) and the transition temperature shifted to a lower region by 2.3 °C during the slow fusion of these Ad(II)- and Thy(I)-liposomes and the following base-base interaction in the same liposome particle.

In conclusion, a mutual recognition of complementary nucleic acid bases could be observed in a monolayer system. A dimerization reaction involving thymine derivatives could also be observed in these systems. Especially in the liposome system, a clear decrease in the absorption of the thymine ring was observed. Further systematic studies of various kinds of nucleic acid base-containing lipids are presently in progress.

We wish to thank Professor Norio Ise, Kyoto University, for his helpful suggestions and Mr. Hideki Matsuoka, Kyoto University, for technical assistance. We also thank Dr. Hirokazu Hasegawa, Kyoto University, for taking electron micrographs of liposomes. H. K. thanks the Alexander von Humboldt Foundation, Bonn, and the Naito Memorial Science Foundation, Tokyo, for their fellowships.

Ozonolysis of 3-Methyl-1-phenyl-4-phenylazo-5-pyrazolone

Masaki MATSUI,* Akihiro KONDA, and Katsuyoshi SHIBATA
Department of Industrial Chemistry, Faculty of Engineering, Gifu University, Yanagido, Gifu 501-11
(Received March 18, 1985)

In chlorinated solvents, 3-methyl-1-phenyl-4-phenylazo-5-pyrazolone (**1**) easily reacts with ozone to give benzene (**2**), phenol (**3**), chlorobenzene (**4**), *o*-chlorophenol (**5**), biphenyl (**6**), and 3-methyl-1-phenyl-2-pyrazoline-4,5-dione (**7**). The formation of these products is explained by an electrophilic ozone attack on the hydrazone tautomer **1'**.

It is of interest to study the reaction of coloring matter with ozone in view of an ozone treatment of dye wastewater and the ozone fading of dyes.

The authors have reported a series of ozonization reactions of dyes and their model compounds.[1)]

We discuss here the ozonolysis of 3-methyl-1-phenyl-4-phenylazo-5-pyrazolone, a model compound of azo-pyrazolone dyes.

Experimental

Instruments. Ozone was generated by a Nihon Ozon 0-1-2 type ozonizer. Melting points were measured with a Yanagimoto micro melting-point apparatus. Gas chromatography was performed on Shimadzu 4CPF and Ohkura 802 gas chromatographs. IR, UV, NMR, and MS spectra were obtained with Hitachi EPI-S2, Hitachi EPS-3T, JEOL JUM-GX 270, and Hitachi M-52 spectrometers, respectively.

Materials. 3-Methyl-1-phenyl-4-phenylazo-5-pyrazolone (**1**) was synthesized by a diazotization-coupling method and recrystallized from ethanol; mp 157°C (lit,[2)] 155°C). 4-Arylazo-3-methyl-1-phenyl-5-pyrazolones were also synthesized by the same procedure. Benzene (**2**), phenol (**3**), chlorobenzene (**4**), *o*-chlorophenol (**5**), and biphenyl (**6**) were pure grades which were available commercially. 3-Methyl-1-phenyl-2-pyrazoline-4,5-dione (**7**) was isolated from the reaction mixture by glc using a Silicone OV-1 column; mp 118°C (lit,[3)] 119°C). The purity of materials was confirmed by gas chromatography.

Ozonolysis Reaction. Ozonolysis was carried out with an ozone-nitrogen mixture (ozone: 0.39—1.10 mmol, nitrogen: 200 ml min^{-1}) on 1 mmol of substrate in 50 ml of solvent at 0°C. The reaction mixture was allowed to stand for 40 min and was treated with dimethyl sulfide. The disappearence of peroxide activity was confirmed by a KI test. The products were analyzed by gas chromatography using 2% OV-1, 2% FFAP, and Gaskuropak 54 columns. Product identification was made by comparing the mass spectra with those of authentic samples. Product determination was also made by gas chromatography.

Calculation of Rate Constant. Ozonolysis was carried out with an ozone-oxygen mixture (ozone: 0.15 mmol min^{-1}, oxygen 200 ml min^{-1}) on 0.5 mmol of substrate in 200 ml of chloroform at 0°C. The reaction was followed by measuring the absorption maximum (395 nm) every 1 min. The reaction was then applied to pseudo first-order kinetics, shown in Eq. 1.

$$\ln S_0/S_t = k_x(\text{obsd}) \times t, \quad (1)$$

where S_0 is an initial concentration of substrate, S_t is the concentration after ozonolysis reaction for t min, and k_x (obsd) is a pseudo first-order rate constant. The treatment gave a good relation and the rate constant was calculated. The obtained rate constant was then corrected for the existence ratio of the hydrazone tautomer, as shown in Eq. 2.

$$k_x(\text{corr}) = \frac{k_x(\text{obsd})}{R_{\text{Hydrazone}}} \times 100, \quad (2)$$

where k_x (corr) is a pseudo first-order rate constant corrected, and $R_{\text{Hydrazone}}$ is an existence ratio (%) of the hydrazone tautomer in chloroform. The result is shown in Table 1.

Table 1. Pseudo first-order rate constants on the ozonization of 4-(substituted phenylazo)-3-methyl-1-phenyl-5-pyrazolones[a)]

Substituent	k_X(obsd) / min^{-1}	Existence ratio of hydrazone tautomer[b)] / %	k_X(corr) / min^{-1}	log k_X(corr)/k_H(corr)
4-OCH_3	1.75	97	1.80	0.269
4-CH_3	1.45	96	1.51	0.192
3-CH_3	0.95	96	0.99	0.009
H	0.92	95	0.97	0
3-OCH_3	0.78	91	0.86	−0.052
4-Cl	0.71	87	0.82	−0.073
4-$COCH_3$	0.36	86	0.42	−0.363
4-NO_2	0.30	85	0.35	−0.442

a) Ozonization was carried out with an ozone-oxygen mixture (ozone: 0.15 mmol min^{-1}, oxygen: 200 ml min^{-1}) on 0.5 mmol of substrate in 200 ml of chloroform at 0°C. b) The existence ratio was determined by the ^{1}H NMR analysis.

TABLE 2. OZONOLYSIS OF 3-METHYL-1-PHENYL-4-PHENYLAZO-5-PYRAZOLONE[a)]

Run	Sol	Ozone introduced	Conv	Yield[b)]/%				Reactivity[c)]	Dissolved[d)] ozone	Hydrazone[e)] form	Viscosity[f)]
		mmol	%	2	3	4	7		mmol dm^{-1}	%	cp
1	$CHCl_3$	0.39	25	70	16	7	77	0.64	3.6	95	0.701
2	$CHCl_3$	0.71	45	54	7	5	30	0.63	3.6	95	0.701
3	CH_2Cl_2	0.74	54	54	6	10	14	0.73	3.7	98	0.537
4	CCl_4	1.10	50	—	5	22	26	0.45	4.7	87	0.734

a) The reaction was carried out with an ozone–nitrogen mixture (nitrogen: 200 ml min^{-1}) on 1.0 mmol of 3-methyl-4-phenylazo-5-pyrazolone in 50 ml of solvent at 0°C. Trace amounts of *o*-chlorophenol (**5**) and biphenyl (**6**) were also detected in each case. b) Yield was based on the substrate reacted with ozone. c) Reactivity was based on **1** (reacted)/ozone(introduced). d) Dissolved ozone was determined by iodometric titration. e) The ratio was based on the ^{1}H NMR analysis. f) η Value at 0°C.

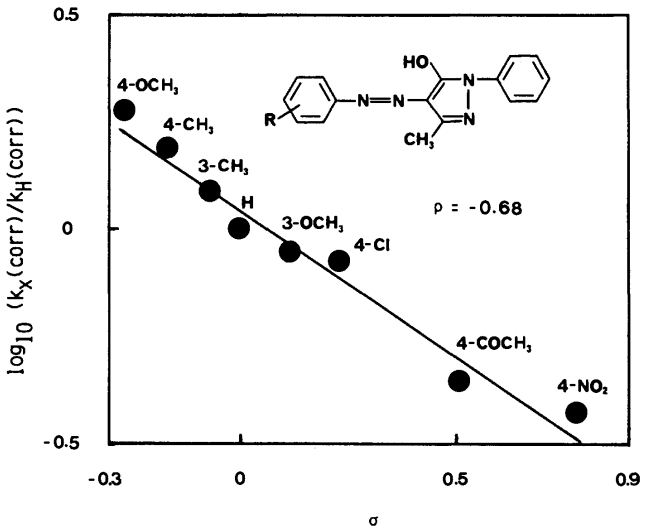

Fig. 1. Hammett's plot for the ozonolysis of 4-arylazo-3-methyl-1-phenyl-5-pyrazolones.
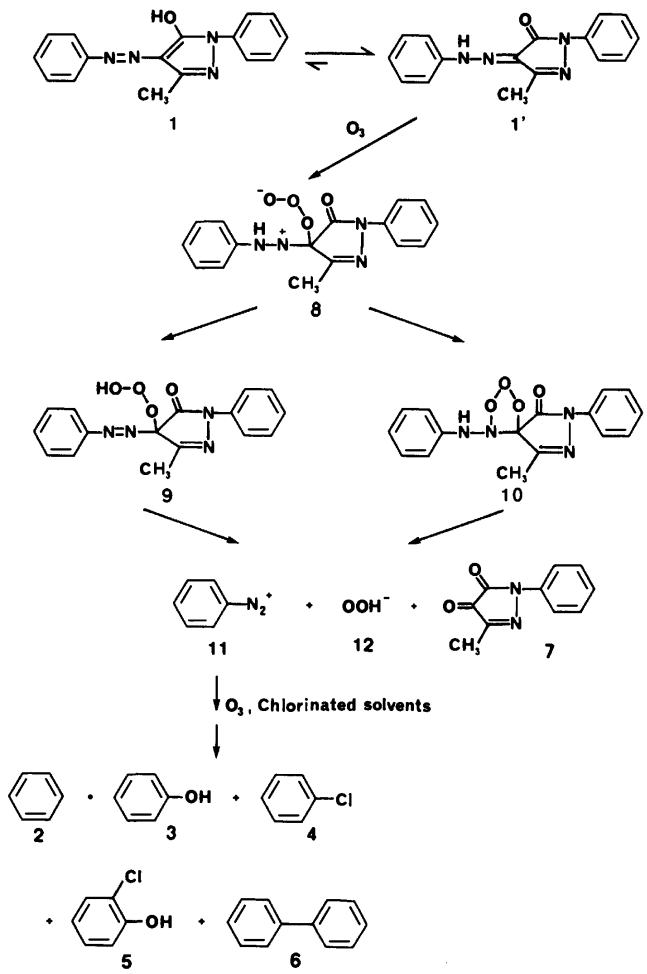
The reaction was carried out with an ozone-oxygen mixture on 0.5 mmol of substrate in 200 ml of chloroform at 0°C.



Scheme 1.

Results and Discussion

When 3-methyl-1-phenyl-4-phenylazo-5-pyrazolone (**1**) was ozonized in chloroform, benzene (**2**), phenol (**3**), chlorobenzene (**4**), *o*-chlorophenol (**5**), biphenyl (**6**), and 3-methyl-1-phenyl-2-pyrazoline-4,5-dione (**7**), were detected in the reaction mixture. The formation of trace amounts of hygroscopic compounds were also observed. The result is shown in Table 2. The reactivity of **1** with ozone in carbon tetrachloride was smaller than in the other solvents. The possible factors controlling the rate are the viscosity of the solvent, the amount of dissolved ozone, and the ratio of the hydrazone tautomer. The amount of dissolved ozone in each solvent was then measured by iodometric titration. Generally, *o*-hydroxy azo compounds exist as equiribrium mixture of azo-hydrazone tautomers. In 1963, Jones *et al.* determined the structure of the hydrazone tautomer of **1** as the quinone hydrazone form **1'**.[4)] The IR and ^{1}H NMR spectra showed a presence of the NH and C=O groups (IR: 3400 (weak, ν_{NH}) and 1655 ($\nu_{C=O}$) cm^{-1} and ^{1}H NMR δ=13.70 (br. s)), suggesting that the hydrazone tautomer is predominant. The ratio of **1'** in each solvent was then calculated from an ^{1}H NMR analysis. Under the reaction conditions, the reactivity of **1** with ozone seems to depend on both the ratio of the hydrazone tautomer and the viscosity of the solvent. The reactivity increased with an increasing ratio of the hydrazone tautomer **1'** and a decreasing viscosity of the solvent.

The effect of a substituent on the ozonolysis reaction

of **1** was investigated. Since treatment by pseudo first-order kinetics gave a good relation, the rate constant was calculated in the same way. On the other hand, the effect of a substituent on the azo-hydrazone tautomeric equiribrium of *o*-hydroxy azo compounds has been reported.[5] As shown in Table 1, an existence ratio of 4-(substituted phenylazo)-3-methyl-1-phenyl-5-pyrazolones was in the following order of substituent, 4-OCH_3>3-CH_3,4-CH_3>H>3-OCH_3>4-Cl>4-$COCH_3$>4-NO_2. This is consistent with that of the electron-donative ability of the substituent. Then, the rates of the ozonolysis reactions of 4-(substituted phenylazo)-3-methyl-1-phenyl-5-pyrazolones were corrected for the existence ratio of the hydrazone tautomer. The results are shown in Table 1. The plots of the logarithms of the relative rates k(corr) thus obtained against Hammett's σ constants gave a straight line whose slope was found to be $\rho=-0.68$ ($r=-0.98$). The result is shown in Fig. 1. The negative value of ρ appears consistent with the electrophilicity of ozone.

The probable ozonolysis mechanism is shown in Scheme 1. Ozone electrophilically attacks the hydrazone tautomer **1'** to give a primary ozonide **9** and/or the hydrotrioxide **10** *via* **8**. These unstable intermediates could not be isolated. They cleave to benzenediazonium ion (**11**), hydroperoxide ion (**12**), and 3-methyl-1-phenyl-2-pyrazoline-4,5-dione (**7**). When the ozonolysis reaction was carried out in the presence of 2-naphthol, 1-phenylazo-2-naphthol was detected, suggesting the formation of **11** during the reaction. The diazonium ion **11** is converted into benzene (**2**), phenol (**3**), chlorobenzene (**4**), *o*-chlorophenol (**5**), biphenyl (**6**), and nitrogen gas in the chlorinated solvent. From the results that when 2-naphthol was added to the hygroscopic compound formed during the ozonolysis reaction of **1**, 1-phenylazo-2-naphthol was detected, and that the hygroscopic compound showed the presence of chlorine ions by a Beilstein test, it was concluded that benzenediazonium chloride is at least one of the components of the hygroscopic material.

The Carbon-13 NMR Spectra and Electronic Structure of 3*H*-Phenoxazin-3-ones

Kan-ichi HASEGAWA* and Yoshio UENO†

Department of Natural Science, Nagoya University of Arts, Shikatsu-cho, Nishikasugai-gun, Aichi 481
†*Department of Industrial Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466*

(Received March 27, 1985)

The ^{13}C NMR chemical shifts of 3*H*-phenoxazin-3-one (**1**) and eighteen of its derivatives are reported. The chemical shifts of **1** can be explained in terms of a successive polarization of the π-conjugated framework by an electron-withdrawing carbonyl group and a π-donating ether oxygen. The principal factor solution for the chemical shifts of the 2-substituted 3*H*-phenoxazin-3-ones suggests that the first and the second factors collectively controlling the 2-substituent effect are electronic and steric effects, respectively. A dual substituent parameter analysis elucidated the transmission modes of the polar and resonance effects of the 2-substituents, and that the first and the fourth factor loadings multiplied by the corresponding standard deviation of the chemical shifts correlate with the CNDO/2 substituent-induced σ and π charge densities.

Phenoxazin-3-ones and their imine analogues are the chromophores in a number of synthetic dyestuffs such as oxazine dyes and redox indicators.[1] As is well known, 3*H*-phenoxazin-3-one (**1**) is the chromophore part of the actinomycins produced by a Streptomyces species of soil bacteria and the initial step of the bonding between actinomycin D and DNA to inhibit RNA synthesis is considered to be the intercalation of a phenoxazin-3-one ring system between the guanine-cytosine base pairs.[2]

There have been few investigations of the electronic properties of 3*H*-phenoxazin-3-ones,[3] although many papers have been devoted to their syntheses and analyses of their IR,[4,5] UV,[4] and ^1H NMR spectra[6] in connection with advanced dye and medical chemistry. Pashkevich *et al.* have studied the annelation effect of a benzene ring on the electronic structure of all possible mono- and diannelated derivatives of **1** by means of the Hückel MO method and found a satisfactory correlation between the experimental and calculated energies of the $\pi \rightarrow \pi^*$ transitions.[3]

^{13}C NMR is a very powerful analytical tool to study the electronic structure of a carbon skeleton and the nature of bonding. In a previous paper, we reported the ^{13}C NMR chemical shifts of 3*H*-phenothiazin-3-one and eleven of its methyl derivatives.[7] In this paper, we extend the ^{13}C NMR chemical shifts of **1** and its derivatives, including the 2-substituents, and elucidate the transmission pattern of an electronic substituent effect by means of both Taft's dual substituent parameter (DSP) treatment[8] and the principal factor method.[9]

Experimental

Materials. The syntheses of **1**[10] and its 2-amino- (**4**),[10] 2-acetamido- (**7**),[10] 2-anilino- (**8**),[11] 2-hydroxy- (**10**),[12] 7-methoxy- (**13**),[13] 7-ethoxy- (**14**),[14] 7-acetoxy- (**15**),[14] 2-amino-1,9-dimethyl- (**18**),[5] and 2-amino-4,6-dimethyl- (**19**)[5] derivatives were performed according to the usual methods. 2-Methyl- (**2**),[15] 2-ethyl- (**3**),[15] 2-methylamino- (**5**),[16] 2-ethylamino-(**6**),[16] 2-(*N*-methylanilino)- (**9**),[17] 4-methyl- (**11**),[15] 2,4-dimethyl- (**16**),[15] and 2,4-diethyl-3*H*-phenoxazin-3-ones (**17**)[15] were prepared as described in previous papers. *N*-Phenyl-*p*-benzoquinone monoimine (**20**) was prepared according to the method of Uemura and Abe.[18] All the compounds were purified by TLC and column chromatography and checked by means of their IR and ^1H NMR spectra. Their spectral and physical properties were in agreement with available data from the literature. 4-Ethyl-3*H*-phenoxazin-3-one (**12**) was synthesized as in the case of **11**; mp 150—151 °C. Anal. Found: C, 74.42; H, 4.78; N, 5.91%. Calcd for $C_{14}H_{11}NO_2$: C, 74.65; H, 4.92; N, 6.22%.

Procedures. The ^{13}C NMR spectra were recorded on a Varian XL-200 Fourier-transform spectrometer at room temperature at 50.3 MHz using 10-mm sample tubes and a deuterium lock. Samples were prepared in a $CDCl_3$ solvent with tetramethylsilane as an internal reference except for **10** in dimethyl-d_6 sulfoxide. In the case of the dimethyl sulfoxide solvent, the ^{13}C NMR data were converted on the basis of 39.5 ppm of the dimethyl sulfoxide reference peak. A linear least-squares analysis for Taft's DSP equation was carried out by means of the Gauss-Newton method. The values of substituent constants, such as σ_I, σ_R^0, σ_R^{BA}, σ_R^+, F, and R for the electronic effect on the 2-substituents, were taken from Refs. 8c and 19. The values of the substituent constants not found in the literature were estimated from the known values of the corresponding σ_m, σ_p^{BA}, σ_p^+, and σ_p^0 by using the equations $\sigma_I = 1.5\sigma_m - 0.5\sigma_p$ and $\sigma_R^A = \sigma_p^A - \sigma_I$ where suffix A stands for 0, BA or +. The values of the Inamoto-Masuda group electronegativity χ and the inductive scale ι not found in Ref. 20 are as follows: $NHCH_3$, 3.031, 2.496; NHC_2H_5, 3.032, 2.496; NHC_6H_5, 3.034, 2.498; $NCH_3C_6H_5$, 3.016, 2.486.[21] Melting points were determined on a Yanagimoto micromelting apparatus and are uncorrected.

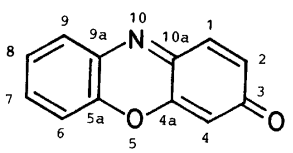

Fig. 1. Numbering of **1**.

Theoretical

CNDO/2 calculations[22] were carried out as in a previous paper.[7] The planar geometry of **1** was determined from the X-ray data[2] of actinomycin D obtained by means of a light-atom analysis and transferred to its

derivatives. The atomic coordinates of substituents were computed from known data regarding the corresponding bond lengths and bond angles.[23)] The CNDO/2 calculations of **4** shows that the pyramidal structure of an amino group, where one of the NH bonds is coplanar with the quinonoid ring and turns toward the CO group, is more stable than the planar structure. Therefore, CNDO/2 calculations of the 2-amino derivatives were carried out for the pyramidal structure. The geometry of *N*-phenyl-*p*-benzoquinone monoimine was estimated using the data of *N*-chloro-*p*-benzoquinone monoimine described in a preceding paper[7)] and assuming a torsional angle of 30° between the phenyl and quinonoid rings.

Results and Discussion

*^{13}C Chemical Shifts of 3*H*-Phenoxazin-3-one.* The ^{13}C chemical shifts of 3*H*-phenoxazin-3-ones are listed in Table 1. Their chemical shifts can be assigned on the basis of those of 3*H*-phenothiazin-3-ones[7)] and phenyl vinyl ether,[24)] and the estimation from the substituent-induced chemical shifts (SCS) of the corresponding group on benzenes and olefins.[25)] The replacement of the bridged S atom of 3*H*-phenothiazin-3-one by an O atom resulted in downfield shifts of C-3, C-4a, C-5a, and C-7, and upfield shifts of the other carbons, *i.e.*, a symmetrical change in the sign of the SCS toward the N–O axis.

The signal at δ 186.4 for the carbonyl carbon of **1** appeared at a lower field (by 3.8 ppm) than that of 3*H*-phenothiazin-3-one, but higher (by 0.9 ppm) than that of **20**. A similar result has been observed regarding the difference (4.2 ppm) of the chemical shifts of the carbonyl carbons between 3-ethylthio-5,6-dimethyl- and 3-ethoxy-2-cyclohexenones.[19b)] The remarkably high shielding of C-4 of **1** suggests a resonance of the vinyl ether type, *i.e.*, a strong π-polarization of the olefinic double bond by the ether oxygen. The high shielding of C-6 and C-8 is ascribed to the increased $2p_\pi$ electron densities because of the ortho and para positions with respect to the ether oxygen. The values of the upfield shifts of C-4, C-6, C-8, and C-9a caused by the oxygen substitution of 3*H*-phenothiazin-3-one were lower than those of the corresponding carbons between the phenyl vinyl ether and the phenyl vinyl sulfide.[24)] From the chemical shifts of C-1, C-3, and C-9, the partial positive charge of the carbonyl carbon of **1** seems to be less delocalized than that of the 3*H*-phenothiazin-3-one.

It is considered that **20** may serve as a reference compound to elucidate the relative abilities of O and S atoms interposed between two conjugated rings to transmit electronic effects. However, the finding that the ^{13}C chemical shifts of **20** are similar to those of the corresponding carbons of aniline[25)] and *N*-chloro-*p*-benzoquinone monoimine[7)] suggests a remarkably twisted structure between the phenyl and the quinonoid rings of **20** owing to a steric hindrance. Therefore, it is reasonable that the introduction of the bridged oxygen on **20** resulted in an SCS similar to or a little more than those of vinyl ether toward benzene

TABLE 2. THE FACTOR SCORES OF THE 2-SUBSTITUENTS OBTAINED BY THE PRINCIPAL FACTOR METHOD

for the ortho and the ipso carbons but the remarkable downfield shift for the meta carbon. C-10a moves to a higher field by 13.2 ppm relative to the imino carbon of **20**; the considerable upfield shift may be explained in terms of the nature of the oxazine ring rather than the substituent effect on the quinone imine.

Substituent Effect. To evaluate the factors controlling the chemical shifts of all the carbons of the 2-substituted phenoxazin-3-ones and their contributions, data analyses of the chemical shifts of **1—10** were performed using the principal factor method.[9] In the factor analysis, the chemical shift (or SCS) data matrix was transformed into a standard score matrix composed of 10×12 elements using Eq. 1:

$$z_{ij} = (\delta_{ij} - \bar{\delta}_j)/\sigma_j \quad (1)$$

where z_{ij} and δ_{ij} are the elements of the standard score matrix and the original chemical shift (or SCS) data matrix for the carbon j on substituent i, respectively; $\bar{\delta}_j$ and σ_j are mean and the standard deviations of variable j, respectively. The factor-loading and score matrices were derived from the correlation matrix, between the variables, whose diagonal elements are equal to communality by maximizing the sum of the squared loadings of the first factor (F_I). Thus,

$$z_{ij} = \sum_{m=1}^{M} f_{im} a_{jm} \quad (2)$$

where a_{jm} is the m th factor loading for variable j and f_{im} the m th factor score for substituent i, equivalent to the substituent constant. M indicates the upper limit of m and is equal to the number of positive eigenvalues obtained by the diagonalization of the correlation matrix, 11 in this case. From Eqs. 1 and 2

$$\delta_{ij} = \sum_{m=1}^{M} f_{im} a_{jm} \sigma_j + \bar{\delta}_j. \quad (3)$$

Table 2 shows the factor scores of the 2-substituents of 3*H*-phenoxazin-3-ones calculated by the principal-factor method. None of the factor score series obtained were found to be parallel to a single known substituent parameter. From the correlation of the factor scores with various substituent scales, the following multiparameter equations were found to be statistically sufficient to interpret F_I—F_{IV}.[26]

$$F_I = -2.55\Delta\iota + 0.67\sigma_R^+ + 1.76 \quad (r=0.985, n=7) \quad (4)$$

$$F_{II} = -21.89(C_2\text{-X}) + 23.25B_3 - 4.65B_3^2 + 4.89 \quad (r=0.967, n=8) \quad (5)$$

$$F_{III} = 12.24\sigma_I + 5.95\sigma_R^0 + 0.36B_4' - 0.17 \quad (r=0.975, n=7) \quad (6)$$

$$F_{IV}[27] = 29.27\Delta\iota + 3.92\sigma_R^+ - 0.79B_2 - 4.91N - 1.30 \quad (r=0.973, n=7) \quad (7)$$

where C_2–X represents the atomic distance[23] between C-2 and the substituent X, and B_2, B_3, and B_4' stand for the STERIMOL parameters[28] of the substituent. B_4' cooperates with B_1 as the wide scale of the substituent and corresponds to B_4 except for B_2 in the cases of the NH_2 and $NHCOCH_3$ groups. N in Eq. 7 denotes the number of lone-pair electrons of the central atom of substituent X.

As Eqs. 4 and 5 suggest, the F_I and F_{II} terms are associated with the electronic and the steric effects of the substituents, respectively. The F_{III} and the F_{IV} scales seem to depend not only on the electronic effect, but also on the steric effect, provided that F_{IV} can also be explained mainly in terms of the STERIMOL B_2 parameter as well as the electronic substituent parameter.[27]

Table 3 lists the factor loadings of the carbons along with the average and standard-deviation values of the chemical shifts. The above four factors account for 96% of the variability in the chemical-shift data matrix. The chemical shifts for C-1 induced by the 2-substituents can be explained mainly in terms of the first factor, *i.e.*, only the electronic parameter. As the contribution of the first factor (for the chemical shifts of all the carbons of the 2-substituted 3*H*-phenoxazin-3-ones) is only 67.4%, two or three factors including the steric factors are, in general, necessary to accurately evaluate the substituent effects that affect the chemical shifts for the other carbons; in particular, for the SCS of C-2, F_I and F_{IV} are taken into consideration.

As the product of the factor loading and the standard deviation of the chemical shifts shows, the first factor has a maximum effect on the chemical shift of C-1 and its electronic variation is transmitted to the alternative carbons (C-3, and C-9, C-5a, and C-7) which are the benzenoid ortho and para carbons relative to the N atom. The attenuation factors are 13, 7, 7, and 12%, respectively. Although F_I, F_{III}, and F_{IV} are associated with the resonance effect of the 2-substituents, the sign of the factor loading of the first factor coincides with that of the corresponding transmission coefficient of the resonance effect in Taft's DSP treatment because of

a) Along with the product of the factor loading and the standard deviation of the ^{13}C chemical shifts. b) The contribution of the factor loading clearing the lower limit (a_{if}^2>0.10) is important. c) The average of the chemical shift. d) The average of the SCS. e) The standard deviation of the chemical shift. f) The fifth factor contribution. g) The sixth factor contribution.

the high contribution (*vide infra*). In the factor loading of the second factor having a steric character, the sign for almost all the quinonoid carbons is opposite to that for most benzenoid carbons. It is reasonable that the second factor causes the relatively large changes in the chemical shifts of C-1 and C-3.

Plots of the chemical shifts of C-2 versus the Inamoto-Masuda group electronegativities χ of the 2-substituents (**1**, **4**—**10**) excluding alkyl group afforded the excellent correlation;

$$\delta = 16.25\chi + 100.37 \quad (r=0.985,\ n=8) \tag{8}$$

This finding reinforces such an explanation that the contributions of the σ_R^+ terms in F_I and F_{IV} mainly controlling the SCS of C-2 offset each other by multiplicating their factor loadings.[29] The C_α or C_{ipso} SCS of monosubstituted methanes,[30,31] ethanes,[30] and benzenes[30,31] have also been reported to be proportional to the group electronegativity of the substituent.

Taft's DSP analysis is convenient for a simple interpretation of substituent effects in terms of the relative proportions of field/inductive and resonance effects shown by Eq. 9.

$$\delta = \rho_I\sigma_I + \rho_R\sigma_R + \delta_0 \tag{9}$$

where δ and δ_0 indicate the ^{13}C chemical shift of the carbon of interest and the intercept of the DSP equation respectively. ρ_I and ρ_R represent the transmission coefficients of the field/inductive and the resonance effects, respectively.

Although the pairs of substituent parameters giving the best correlation with the chemical shifts depend on the positions of the carbons, the chemical shifts of C-1 correlate very well with all of the substituent constants used for the DSP equation. As Eq. 7 shows, the behavior of the alkyl groups for C-2 appears to be different from that of the other 2-substituents in terms of an orbital-repulsion effect due to the absence of lone-pair electrons. The ρ values were obtained by applying Eq. 9 to the chemical shifts of **1** and six 2-substituted analogues (**2**, **3**, **4**, **7**, **8**, and **10**).

The polar and resonance effects will be discussed on the basis of both the ρ_I—ρ_R^0 values which are well applied to other compounds and the ρ_I—ρ_R^+ values having generally high correlation coefficients for the quinonoid carbons. Table 4 shows the ρ values for all the carbons of 2-substituted 3*H*-phenoxazin-3-ones. The resonance effect of the 2-substituents is most strongly transmitted to C-1; the magnitude (ρ_R^0= 70.73) for the resonance effect is similar to those (ρ_R^0= 63.03 and 75.54 respectively) for the effects in 3-substituted 2-cyclohexenes[32] and 2-substituted 1,4-naphthoquinoes.[33] The resonance effect of C-1 is transmitted to the alternant carbons, C-3 and C-4a, with attenuation factors of 20—22% and 2—3%, respectively. The magnitude of the reverse resonance effect of C-2 is 46—53% as high as that for the normal resonance effect of C-1. Those attenuation ratios are somewhat high relative to the values estimated by the first factor because not only the first factor but also the third and the fourth factors contribute to the resonance effect. The ρ_R^+ values of the benzenoid meta carbons, C-6 and C-8, relative to the N atom are almost zero.

It is reasonable from the resonance of the α,β-unsaturated ketone or imine between C-4a and C-3 or N that the ρ_R^+ value of C-4a is positive; the presence of an enone resonance between C-3 and C-4a is supported by indications that the signs of factor loadings from F_I to F_{IV} for C-4a are equal to those for C-3.

There are several main factors such as classical σ-inductive, π-inductive, direct through-space field, and

a) *N*-Phenyl-*p*-benzoquinone monoimine numbered as for **1**.

orbital repulsion effects which contribute to ρ_I.[34] In the case of the σ-inductive effect, the σ electron-deficient state of the carbon of interest induced by a σ-acceptor substituent decreases rapidly with an increasing number of intervening bonds between the substituent and the carbon.

The signs of the ρ_I values shown in Table 4 are consistent with those of the π-charge densities induced by the 2-substituents, except for the cases of C-6 and C-10a. Therefore, it is concluded that the main factors determining the ρ_I values, except for those of the carbon which is linked directly to the substituent, originate from π-inductive/field and orbital-repulsion effects rather than from a σ-inductive effect. A part of these polar effects spread along the π framework in the same manner as the resonance effect but with the different

attenuation ratios; the observed negative or positive ρ_I values in Table 4 suggest that the polar effect of the 2-substituents such as NH_2 and OH groups cooperates with the corresponding resonance effect in upfield or downfield shifts of all the carbons other than C-4a, C-5a, and C-8, respectively. The absolute ρ_I values for the quinonoid carbons indicate the lowering of the polar effect on going from C-2 to C-4a in the clockwise direction as well as the anticlockwise one of C-1→C-4a.

The ρ_I value (−6.11) for C-2 of 3-substituted 2-cyclohexenones[32] is much less negative than that (−18.38) for C-1 of **1**. The π electron density of the substituted carbon of the former is decreased by the π acceptor carbonyl group. The lesser polar effect for the olefinic β carbon may be ascribed to the lesser orbital repulsion responsible for the more decreased π electron density of the substituted carbon.

Judging from the SCS of 2-methyl, 4-methyl, and 2,4-dimethyl groups, the SCS values for all the carbons of 3*H*-phenoxazin-3-ones do not alter greatly in comparison with those of 3*H*-phenothiazin-3-ones. It is shown from the comparison between mono- and disubstituted analogues of methyl and ethyl groups on the 2- and 4-positions that an additivity relationship can be applied for 3*H*-phenoxazin-3-ones as well as for 3*H*-phenothiazin-3-ones.

Electronic Structure of 3H-Phenoxazin-3-ones. As Taft's DSP analysis for 3*H*-phenoxazin-3-ones shows, problems may arise during attempts to rationalize the ^{13}C chemical shifts on the basis of either π or the total electron densities alone. Table 5 lists the CNDO/2 π and total electron densities of 3*H*-phenoxazin-3-ones for the planar structure of their backbones. The ^{13}C chemical shifts gave a better correlation with the dual parameter system (r=0.940) composed of the π and σ electron densities than the π (r=0.908) or total electron density (r=0.919).

$$\delta = -100.29\sigma - 225.12\pi + 656.96 \quad (r=0.940,\ n=180) \quad (10)$$

Using INDO π and σ electron densities, the value of the correlation coefficient, r, for the chemical shifts of all the carbons of **1** is enhanced to be 0.955.[35] As Eq. 10 shows, the ^{13}C chemical shifts are much more sensitive to the π electron densities than the σ electron densities.

Figure 2 shows the CNDO/2 charge densities for **1** and the substituent-induced charge densities for **2**, **4**, and **11**. The π charge densities of all the carbons of **1** show alternative polarizations due to the presence of the electron-withdrawing carbonyl group and the π electron-donating ether oxygen. The CNDO/2 σ charge densities of their carbons of **1** indicate the partial positive charges on the carbons bonded to the heteroatoms and the lesser positive charges on C-6 and C-8. C-2 has the highest σ electron density among the twelve carbons of **1**.

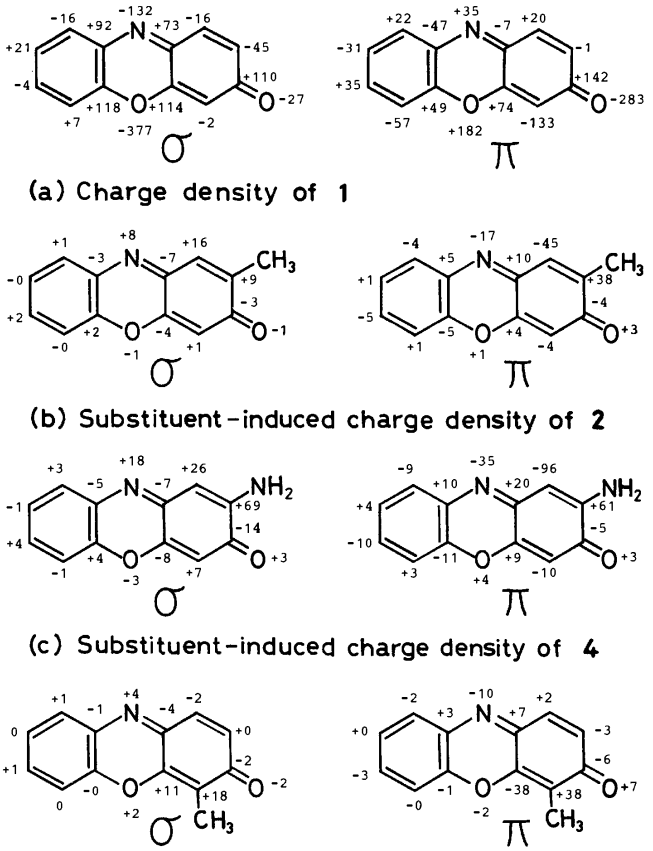

Fig. 2. CNDO/2 σ and π charge densities of **1** and substituent-induced σ and π charge densities. The values shown should be divided by 1000 to obtain electron charge units.

The delocalization of the lone-pair or pseudo-π electrons of the 2-substituent resulted in the increased π electron densities at C-1, C-3, C-5a, C-7, and C-9. The negative substituent-induced π charge density of C-4 suggests the polarization of the C-4–C-4a bond by the ether oxygen. The upfield shift of C-10a by the 2-substituent, contrary to the estimation from the CNDO/2 calculations, may be explained in terms of an enimine resonance between C-4 and C-10a.

From the correlation of the CNDO/2 π or σ charge density induced by the 2-substituents such as methyl, ethyl, amino, and hydroxyl groups with the parameters obtained by the principal factor method, Eq. 11 holds for all substituents with r=0.94—0.99;

$$10^4\Delta q_i = \mathrm{A}a_{i_1}\sigma_i + \mathrm{B}a_{i_4}\sigma_i + \mathrm{C} \quad (11)$$

where Δq_i indicates the substituent-induced CNDO/2 π or σ charge density of the carbon i and A, B, and C are constants; a_{ij} and σ_i stand for the j th factor loading and the standard deviation of the chemical shifts for the carbon i shown in Table 3, respectively.

Table 6 lists the values of these constants for the 2-substituents. In the case of the π-electron system, A and

TABLE 6. THE CORRELATION OF THE SUBSTITUENT-INDUCED CNDO/2 π OR σ CHARGE DENSITIES OF 2-SUBSTITUTED 3H-PHENOXAZIN-3-ONES WITH THE FACTORS OBTAINED BY PRINCIPAL FACTOR METHOD[a)]

Substituent	π-Electron system				σ-Electron system			
	A	B	C	r	A	B	C	r
2-Me(**2**)	−39.36	65.30	28.19	0.973	11.35	64.83	−22.62	0.940
2-Et(**3**)	−47.54	75.01	33.96	0.973	15.34	45.89	−25.14	0.935
2-NH_2(**4**)	−80.92	68.92	60.90	0.973	10.40	307.61	−40.53	0.987
2-OH(**10**)	−91.85	51.78	66.87	0.978	2.59	527.20	−43.41	0.991

a) The constants of A, B, and C are equal to those in Eq. 11; r denotes correlation coefficient.

C become negatively and positively larger, respectively, with an increasing group-electronegativity of the 2-substituents. In the case of the σ-electron system, as σ_I of the 2-substituents increases, A decreases while B becomes larger; the more the group electronegativity of the 2-substituents increases, the more C increases negatively. The F_I—F_{IV} pair rather than the F_I—F_{II} or F_I—F_{III} pair gave a better correlation with the σ-electron densities as well as the π-electron densities. The $a_i\sigma_i$ terms can be replaced by the transmission coefficients, obtained by a DSP treatment, with little change of r for the π-electron system but with a considerable lowering of r for σ-electron system.

In the case of **11**, the substituent-induced partial charges distribute in contrast with the polarization of **1** except for those of C-1 and C-4a for the σ system and those of C-1 and C-2 for the π system. The partial charges of C-4a is dispersed by the enone and the enimine resonances.

From a comparison of **2**, **11**, **16**, and the corresponding 3*H*-phenothiazin-3-ones, the significant difference for the relative abilities of the O and the S atoms to transmit the electronic effect of substituents was not observed because the π-electron transfer between the benzenoid and the quinonoid rings was carried out chiefly through the N atom.

The present work was supported by a Grant-in-Aid for Scientific Research No. 59550570 from the Ministry of Education, Science and Culture. Thanks are due to the Computer Center of the Institute for Molecular Science for its assistance in the CNDO/2 calculations.

Intermolecular Bromine Transfer of 2-Amino-7-bromotropone Derivatives Catalyzed by Strong Acid[1)]

Hidetsugu WAKABAYASHI,* Sumio ISHIKAWA, Harue OKAI,† and Tetsuo NOZOE†
Department of Chemistry, Faculty of Science, Josai University, Sakado, Saitama 350-02
†*Tokyo Research Laboratories, Kao Corporation, 1-3 Bunka, Sumida-ku, Tokyo 131*
(Received April 17, 1985)

Upon heating acetic acid containg a trace amount of concd sulfuric acid at 120 °C under nitrogen, 2-bromo-7-(2-hydroxyanilino)tropone (**1a**) gave 6-bromocyclohepta[*b*][1,4]benzoxazine (**2a**) as the main product and cyclohepta[*b*][1,4]benzoxazine, its 6,8-dibromo derivative and trace amounts of other mono-, di-, and tribromo compounds. This reaction became much more complex in the presence of oxygen. A similar bromine transfer was observed for 2-bromo-7-(dimethylamino)-, 7-(2-hydroxy-5-methylanilino)-, and 7-(2-methoxyanilino)tropone although the cite of the intermolecular bromine transfer depended upon the structures of the substrates and the reaction conditions. In contrast, **2a** and 2-amino-5-bromotropone derivatives were completely stable towards the strong acid. Possible reaction pathways for this bromine transfer reaction are discussed.

We previously reported that 2-bromo-7-(2-hydroxyanilino)tropone (**1a**) afforded an almost quantitative yield of 6-bromocyclohepta[*b*][1,4]benzoxazine (**2a**) upon heating at 120 °C in acetic acid containing a trace amount of concd sulfuric acid.[2)] However, upon repeating the preparation of **2a** and carefully separating the reaction products by chromatography, we isolated unexpected and interesting by-products. The structures of these compounds are reported in this paper together with a mechanistic study regarding the unique bromine transfer involved in the formation of these compounds. This can be regarded as another example of our frequent observation[3)] that a subtle change of reaction conditions causes a considerable alteration of product ratios.

Results and Discussion

When **1a** was heated at 120 °C for 2 h in acetic acid containing a trace amount of concd sulfuric acid, a detailed observation using HPLC showed that the reaction mixture contained, besides the main product **2a**, a large number of simultaneously formed by-products. The separation of these reaction products using silica-gel centrifugal chromatography afforded **2a**[2)] (55% yield), the parent cyclohepta[*b*][1,4]benzoxazine[2)] (**2b**, brown needles, 4% yield), the 6,8-dibromo derivative (**2c**, brown needles, 10% yield), cyclohepta[*b*][1,4]benzoxazin-10(11*H*)-one[4)] (**3a**, red needles, 3% yield), and its 9-bromo derivative (**3b**, red needles, 11% yield) as well as unreacted starting material (**1a**, 14% yield) and small proportions of 8-bromo (**2d**), 6,10-dibromo (**2e**), and 6,8,10-tribromo compound (**2f**). Furthermore, it was confirmed that 2-aminotropone derivatives **1b** and **1c** were also present in small quantities. Structures of these products were established either on the basis of their spectral data (see Experimental section) or by separate syntheses.

When conducted under nitrogen, the above reaction yielded **2a** (71%), **2b** (7.4%), and **2c** (6.8%) along with trace amounts of **2d**—**f**, but no oxo derivatives, **3a** and **3b**. As compound **3a** was produced from **2b** upon exposure to air for a long period or upon airation at 120 °C in acetic acid, **3a** was apparently a secondary, autoxidation product of **2b**. On the other hand, compound **3b** was formed from **1a** by oxygenation at 120 °C in acetic acid, suggesting that **3b** was most likely produced by the autoxidation of the cyclic tautomer, as shown in Scheme 1.

Scheme 1.

A similar acidic treatment of 2-bromo-7-(2-hydroxy-5-methylanilino)tropone (**1e**) under nitrogen resulted in a ring-closure to give **4a**[5)] (66% yield), the bromine-free compound (**4b**, 6.4% yield), and the 3,6-dibromo-2-methyl derivative (**4c**, 6.4% yield). The structures were based on their spectral data; the ABCX signal pattern

of the four protons on the seven-membered ring of **4c** in the ^{1}H NMR closely resembles those of **2a**. Thus, the cite of the second bromine atom on the benzene ring [at C-3 based on the small J value (<1 Hz) between the remaining two ring-proton signals] was established. It was confirmed that the 6-bromocyclohepta[*b*][1,4]benzoxazines **2a** and **4a** were completely stable under these conditions.

These results suggested that a bromine migration reaction under strongly acidic conditions had taken place at the stage of the anilinotropones (**1a**, **1e**) prior to the ring-closure. Indeed, when the methyl ether (**5a**)[2] that was prevented from cyclizing to the benzoxazine was subjected under the same conditions, 2-(2-methoxyanilino)tropone (**5b**)[6] and its dibromo derivative (**5c**) were obtained.

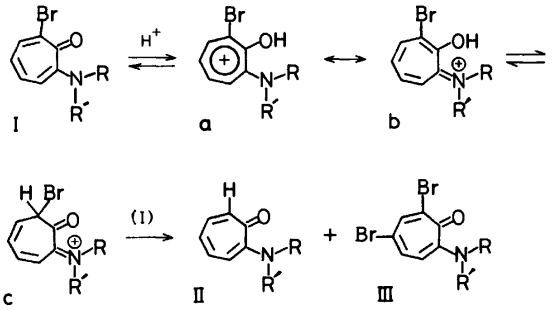
7b: R=Me

Then, in order to examine the role of the arylamino group in this bromine-transfer reaction, 2-bromo-7-(dimethylamino)tropone (**6a**) was similarly treated with concd sulfuric acid-acetic acid at 120°C. The reaction was followed by time-dependent HPLC, which clearly showed the simultaneous formation of three main products. A spectroscopic analysis, as well as a comparison with the authentic specimens prepared separately, clarified the structures of these compounds to be bromine-free 2-(dimethylamino)tropone (**6b**),[7] its 5,7-dibromo (**6c**), and 5-bromo derivative (**6d**). Treatment of 2-amino- and 2-(methylamino)-7-bromotropone (**7a,b**)[8] with the same mixed acid afforded a similar type of products derived by the apparent disproportionation reaction.

The use of perchloric acid or phosphoric acid (instead of concd sulfuric acid) in acetic acid for the ring-closure of **1a** also caused a bromine transfer, but yields of products **2b** and **2c** became considerably lower. The use of concd hydrochloric acid afforded 6-chloro compound (**2g**) besides **2a**—c; **2g** was confirmed to be produced from the 6-bromo compound (**2a**) (but not from the ring-opened precursor **1a**) by the halogen-exchange reaction. It should be noted that, when **1a** was heated at 120°C under nitrogen in acetic acid containing concd hydrobromic acid, 8-bromocyclohepta[*b*][1,4]benzoxazine (**2d**) became the main product (47% yield) instead of **2a** (3% yield) or **2b**,c (8% yield each).

The fact that the described acid-catalyzed bromine migration takes place only when the bromine atom is situated at C-7** of the 2-aminotropone form (**I**), suggests the following probable reaction pathways (Scheme 2).



Scheme 2.

The 2-(arylamino)- and 2-(dimethylamino)-7-bromotropone (**1a** and **6a**) give their protonated tropylium species (**a**). It was stabilized as an iminium form (**b**) and existed in equilibrium with the tautomeric keto form (c). The latter presumably reacts as an electrophilic reagent towards the unprotonated substrate (**I**), resulting in a transfer of the bromine atom to give 2-aminotropones (**II**) and the 5,7-dibromo derivatives **III** in a manner analogous to a disproportionation reaction. The reactive intermediate c is most likely to undergo electrophilic bromination at a position having the highest nucleophilicity in the molecule **I**.[9] This gives rise to a dibromo product in which, in some cases, the second bromine atom is on the benzene ring (*e.g.*, **4c**). The formation of a larger proportion of the 8-bromo compound **2d** from **1a** upon heating in HBr-AcOH could be explained by the transformation of the intermediate c (Scheme 2) to **II**, assisted by the bromide anion. This liberated a certain quantity of bromine atoms. Subsequently, this resulted in bromination at the 5-position of 2-aminotropones (**II**), followed by an acid-catalyzed ring-closure to afford **2d**. This pathway is supported by the fact that **1b** gave only **2b** under the same conditions.

Although the exact mechanisms of this unusual substitution and the ring-closure involving an interesting intermolecular bromine shift are currently under a detailed investigation, the present experimental results clearly demonstrate a further example of the diversity of chemical reactions and the intricate character of troponoid compounds.

Experimental

Melting points are uncorrected. The IR and electronic spectra were taken on a Shimadzu IR-450 and a Shimadzu UV-202 spectrometer, respectively. The UV spectra in acid and alkali were taken after adding a few drops of 3 M HCl or 3 M NaOH (1 M=1 mol dm^{-3}) to a sample solution. The

**2-Amino-5-bromotropones are stable under these acidic condition.

NMR spectra were measured in $CDCl_3$ (unless otherwise specified) on a JEOL JNM-PS/PFT (100 MHz) and a JEOL JNM-GX270 (270 MHz) spectrometer using TMS as an internal standard. The mass spectra were taken on a JEOL JMS-DX300 mass spectrometer and a Shimadzu LKB 9000 GC-mass spectrometer at 75 eV. The HPLC was carried out with Hitachi gel #3011 with MeOH–hexane (9:1) as a solvent. The centrifugal chromatography was performed with a Hitachi CLC-5 instrument in a Fuji silica-gel layer (KT-2151, 5-mm thick) using benzene as an eluant.

Reaction of 2-Bromo-7-(2-hydroxyanilino)tropone (1a).

A. Under Aerobic Conditions: A trace amount of concd sulfuric acid was added to a solution of **1a** (700 mg) in acetic acid (8 ml). The mixture was heated at 120 °C for 2 h and evaporated *in vacuo*. The residue was neutralized with aqueous $NaHCO_3$ and extracted with benzene. The combined extracts were washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The residual solid was chromatographed centrifugally in a layer of silica gel with benzene as the eluant, giving **2a**[2] (360 mg, 55% yield), **2b**[2] (20 mg, 4% yield), **2c** (see below, 85 mg, 10% yield), **3a**[4] (15 mg, 3%), **3b** (see below, 75 mg, 11%), **2d** (see below, 5 mg, 0.8%), **2e** (see below, <1%), and **2f** (see below, <1%). The starting material **1a** (≃100 mg, 14%) containing a small proportion of **1b**,[2] and **1c** (see below) were recovered by eluating the silica-gel layer with MeOH.

B. Under Nitrogen. A solution of **1a** (393 mg) in acetic acid (4 ml) containing a trace amount of concd sulfuric acid was heated under nitrogen at 120 °C for 2 h, followed by the same work-up procedures as above, giving **2a** (262 mg, 71%), **2b** (19.5 mg, 7.4%), **2c** (32.5 mg, 6.8%), and **2d—f** (6 mg, <2%), along with **1a** containing **1b** and **1c** (50 mg, 13%).

2,4-Dibromo-7-(2-hydroxyanilino)tropone (1c). A mixture of 2,4-dibromo-7-methoxytropone[10] (500 mg, 1.70 mmol) and *o*-aminophenol (287 mg, 2.63 mmol) in 1-butanol was heated at 120 °C for 2 h. After cooling, the precipitates were filtered off and recrystallized from methanol to give 565 mg (90%) of **1c** [2,4-dibromo-7-methoxytropone (30 mg, 6%) was recovered from the filtrate]: yellow needles; mp 198—199 °C; UV λ_{max} (MeOH) 264 (log ε, 4.20), 359 (3.89), and 438 nm (4.00); IR (KBr) 3400 (OH), 3350 (NH), and 1588 cm^{-1} (C=O); ^1H NMR (100 MHz) δ=8.65 (1H, bs, NH), 8.42 (1H, d, $J_{3,5}$=2.0 Hz, H-3), 7.50 (1H, dd, $J_{5,6}$=11.2 Hz, H-5), 7.0—7.2 (4 H, m, H-3′, 4′, 5′, 6′), and 6.59 (1H, d, H-6).

Found: C, 42.10; H, 2.49; N, 3.78%; M^+, 373. Calcd for $C_{13}H_9NO_2Br_2$: C, 42.08; H, 2.48; N, 3.78%; M, 373.

6,8-Dibromocyclohepta[b][1,4]benzoxazine (2c). A solution of **1c** (161 mg) in acetic acid (5 ml) containing a trace amount of concd sulfuric acid was heated at 120 °C for 1.5 h under nitrogen, followed by the same procedures as those described for **1a**. The residual solid was recrystallized from benzene to give 132 mg (86%) of **2c**: brown needles; mp 165—166 °C; UV λ_{max}(MeOH) 262 (log ε, 4.47), 306 (3.66), and 415 nm (3.86); IR (KBr) 3080 (CH) and 1637 cm^{-1} (C=N); ^1H NMR (270 MHz) δ=6.8—6.9 (3H, m, H-1, 2, 3), 6.79 (1H, d, $J_{7,9}$=2.2 Hz, H-7), 6.60 (1H, m, H-4), 6.19 (1H, dd, $J_{9,10}$=12.9 Hz, H-9), and 5.89 (1H, d, H-10), ($CDCl_3$+CF_3COOD) δ=8.00 (1H, d, $J_{7,9}$=2.2 Hz, H-7), 7.44 (1H, dd, $J_{9,10}$=11.9 Hz, H-9), 7.05 (1H, td, J=8.0 and 1.5 Hz, H-2 or 3), 6.96 (1H, td, J=8.0 and 1.5 Hz, H-3 or 2), 6.70—6.85 (2H, m, H-1, 4), and 6.75 (1H, d, H-10).

Found: C, 44.43; H, 2.13; N, 3.77%; M^+, 355. Calcd for $C_{13}H_7NOBr_2$: C, 44.23; H, 2.00; N, 3.97%; M, 355.

9-Bromocyclohepta[b][1,4]benzoxazin-10(11H)-one (3b): Red needles (from benzene); mp 223—224 °C; UV λ_{max} (MeOH) 240 (log ε, 4.22), 270 (4.08), 294 (4.04), 330 (3.80), and 500 nm (3.79); IR (KBr) 3300 (NH) and 1574 cm^{-1} (C=O); ^1H NMR (270 MHz) δ=7.79 (1H, dd, $J_{6,8}$=1.0 and $J_{7,8}$=9.5 Hz, H-8), 6.79 (1H, dd, $J_{6,7}$=11.1 Hz, H-6), 6.5—6.8 (4H, m, H-1, 2, 3, 4), and 6.42 (1H, dd, H-7).

Found: C, 53.55; H, 2.83; N, 4.91%; M^+, 291. Calcd for $C_{13}H_8NO_2Br$: C, 53.82; H, 2.78; N, 4.83%; M, 291.

8-Bromocyclohepta[b][1,4]benzoxazine (2d): Red brown needles (from benzene); mp 163—164 °C; UV λ_{max} (MeOH) 262 (log ε, 4.43), 271 (4.35), 298 (3.93), and 414 (4.12), (MeOH+3 M HCl) 265 (log ε, 4.43), 273 (4.35), 325 (3.95), and 447 nm (4.06); IR (KBr) 1580 cm^{-1} (C=N); ^1H NMR (270 MHz) δ=6.7—6.8 (3H, m, H-1, 2, 3), 6.38 (1H, m, H-4), 6.24 (1H, dd, $J_{7,9}$=2.0 and $J_{6,7}$=10.2 Hz, H-7), 6.21 (1H, dd, $J_{9,10}$=13.2 Hz, H-9), 5.84 (1H, d, H-10), and 5.12 (1H, d, H-6).

Found: C, 56.92; H, 3.22; N, 5.13%; M^+, 275. Calcd for $C_{13}H_8NOBr$: C, 56.96; H, 2.94; N, 5.11%; M, 275.

6,10-Dibromocyclohepta[b][1,4]benzoxazine (2e): Red brown solid; UV λ_{max} (MeOH) 261, 270, 313, and 414 nm, (MeOH+3 M HCl) 268, 273, 325, 448, and 480 nm; M^+, 355.

6,8,10-Tribromocyclohepta[b][1,4]benzoxazine (2f): Red brown solid; UV λ_{max} (MeOH) 238, 263, 271, 400, 416, and 445 nm, (MeOH+3 M HCl) 258, 309, and 393 nm; M^+, 435.

Reaction of 2-Bromo-7-(2-hydroxy-4-methylanilino)tropone (1e). A similar treatment (to that for **1a**) of **1e** (500 mg) with acetic acid (10 ml) containing a trace amount of concd sulfuric acid at 120 °C for 1.5 h under nitrogen gave **4a**[5] (310 mg, 66%), **4b** (see below, 22 mg, 6.4%), and **4c** (see below, 38 mg, 6.4%), besides the recovered **1e** (100 mg, 20%) containing **1f** and **1g** (<2% each).

2-Methylcyclohepta[b][1,4]benzoxazine (4b). A mixture of 2-chlorotropone (370 mg, 2.63 mmol) and 2-amino-4-methylphenol (486 mg, 3.95 mmol) in acetic acid (5 ml) was heated at 120 °C for 3 h, followed by the same work-up procedures as for **1a**. This gave 280 mg (51%) of **4b**: red brown needles (from benzene); mp 86—87 °C; UV λ_{max} (MeOH) 256 (log ε, 4.28), 264 (4.35), 273 (4.31), 305 (3.73), and 415 nm (4.01), (MeOH+3 M HCl) 226 (log ε, 4.38), 268 (4.38), 275 (4.40), 326 (3.88), and 440 (3.98); IR (KBr) 2930 (CH) and 1600 cm^{-1} (C=N); ^1H NMR (270 MHz) δ=6.61 (1 H, d, $J_{1,3}$=2 Hz, H-1), 6.55 (1H, dd, $J_{3,4}$=8 Hz, H-3), 6.28 (1H, d, H-4), 6.16 (2H, m, H-9, 10), 5.99 (1H, ddd, $J_{7,8}$=10.7, $J_{6,7}$=9.4, and $J_{7,9}$=1.5 Hz, H-7), 5.79 (1H, td, $J_{8,10}$=3.9 and $J_{8,9}$=10.7 Hz, H-8), 5.46 (1H, d, H-6), and 2.12 (3H, s, CH_3).

Found: M^+, 209.0813. Calcd for $C_{14}H_{11}NO$: M, 209.0840.

3,6-Dibromo-2-methylcyclohepta[b][1,4]benzoxazine (4c): Red brown needles (from benzene); mp 121—122 °C; UV λ_{max} (MeOH) 232 (log ε, 4.20), 268 (4.28), 275 (4.25), 305 (3.83), and 415 nm (3.94), (MeOH+3 M HCl) 235 (log ε, 4.18), 275 (4.25), 281 (4.26), 325 (3.84), and 450 nm (3.83); IR (KBr) 1631 cm^{-1} (C=N); ^1H NMR (100 MHz) δ=6.80 (1H, s, H-4), 6.72 (1H, s, H-1), 6.39 (1H, td, $J_{7,9}$=0.5 and $J_{7,8}$=11.7 Hz, H-7), 6.05 (2H, m, H-9, 10), 5.58 (1H, $J_{8,9}$=4.4 Hz, H-8), and 2.20 (3H, s, CH_3).

Found: M^+, 364.9059, 366.9056, and 368.9024 (1:2:1). Calcd for $C_{14}H_9NOBr_2$: M, 364.9051, 366.9032, and 368.9012.

2,4-Dibromo-7-(2-methoxyanilino)tropone (5c). A suspension of **1c** (80 mg) in ether was treated with an excess of ethereal diazomethane. After allowing it to stand for 1 d, the solvent was evaporated *in vacuo* and the residual solid was chromatographed in a short column of alumina with ether as an eluant, giving 80 mg (96%) of **5c**: yellow needless (from

methanol); mp 165—166°C; UV λ_{max} (MeOH) 264 (log ε, 4.18), 359 (3.95), and 438 nm (4.17); IR (KBr) 3250 (NH) and 1584 cm^{-1} (C=O); ^1H NMR (100 MHz, CD_3OD) δ=8.51 (1H, d, $J_{3,5}$=2.0 Hz, H-3), 7.57 (1H, dd, $J_{5,6}$=11.2 Hz, H-5), 7.1—7.4 (4H, m, H-3′, 4′, 5′, 6′), 6.91 (1H, d, H-6), and 3.88 (3H, s, CH_3).

Found: C, 43.70; H, 2.80; N, 3.64%; M^+, 387. Calcd for $C_{14}H_{11}NO_2Br_2$: C, 43.67; H, 2.88; N, 3.64%; M, 387.

*2-Bromo-7-(dimethylamino)tropone (**6a**).* A solution of 2-bromo-7-methoxytropone[11] (230 mg) and an excess of 40% aqueous dimethylamine in ethanol (5 ml) was heated at 70°C for 4 h. The solvent was evaporated *in vacuo* and the crude product was chromatographed in a column of silica gel with benzene–methanol (50:1) and recrystallized from methanol, giving 196 mg (80%) of **6a**, besides the recovered staring material (30 mg, 13%): yellow needles (from methanol); mp 93—94°C; UV λ_{max} (MeOH) 264 (log ε, 4.31), 358 (4.14), and 437 nm (4.05), (MeOH+3 M HCl) 255 (log ε, 4.27), 273 (4.10), 324 (3.80), 356 (4.01), and 437 nm (3.81); IR (KBr) 1580 cm^{-1} (C=O); ^1H NMR (270 MHz) δ= 7.93 (1H, d, $J_{3,4}$=9.5 Hz, H-3), 7.07 (1H, dd, $J_{5,6}$=10.2 and $J_{4,5}$=10.5 Hz, H-5), 6.52 (1H, d, H-6), 6.33 (1H, dd, H-4), and 3.14 (6H, s, $2CH_3$).

*2,4-Dibromo-7-(dimethylamino)tropone (**6c**).* Procedures similar to those for **6a** were followed. 2,4-Dibromo-7-methoxytropone (50 mg) afforded 35 mg (67%) of **6c** after purification by HPLC and recrystallization from methanol (10 mg of the starting material was recovered): yellow needles (from methanol); mp 96—97°C; UV λ_{max} (MeOH) 270 (log ε, 4.22), 356 (4.04), 369 (4.14), 443 (3.87), and 461 (3.86); IR (KBr) 1580 cm^{-1} (C=O); ^1H NMR (270 MHz) δ=8.16 (1H, d, $J_{3,5}$=2.2 Hz, H-3), 7.33 (1H, dd, $J_{5,6}$=11.7 Hz, H-5), 6.24 (1H, d, H-6), and 3.13 (6H, s, $2CH_3$).

*5-Bromo-2-(dimethylamino)tropone (**6d**).* 5-Bromo-2-methoxytropone[8] (270 mg) was similarly treated with an excess of 40% dimethylamine, giving 270 mg (94%) of **6d** after purification by chromatography in a column of silica gel with 50:1 benzene–MeOH: yellow oil; UV λ_{max} (MeOH) 257 (log ε, 4.23), 361 (4.18), and 430 nm (3.88), (MeOH+3 M HCl) 252 (log ε, 4.24), 364 (3.93), and 388 nm (3.92); IR (neat) 1590 cm^{-1} (C=O); ^1H NMR (270 MHz) δ=7.30 (1H, dd, $J_{3,4}$=11.2 and $J_{4,6}$=2.2 Hz, H-4), 7.26 (1H, dd, $J_{6,7}$=12.7 Hz, H-6), 6.70 (1H, d, H-7), 6.21 (1H, d, H-3), and 3.09 (6H, s, $2CH_3$).

*2-Bromo-7-(methylamino)tropone (**7b**).* A mixture of 7-bromo-2-methoxytropone (144 mg, 0.67 mmol), methylamine hydrochloride (184 mg, 2.72 mmol), and sodium hydride (48 mg, 2.0 mmol) in ethanol (3 ml) was heated at 80°C for 20 h. After cooling, the precipitates were filtered off and recrystallized from ethanol (removing NaCl by filtration), giving 133 mg (93%) of **7b**: yellow plates; mp 169—170°C; UV λ_{max} (MeOH) 250 (log ε, 4.27), 258 (4.36), 277 (3.81), 332 (3.95), 342 (4.06), 398 (3.89), and 420 nm (4.12); IR (KBr) 3280 (NH) and 1585 cm^{-1} (C=O); ^1H NMR (270 MHz) δ=8.14 (1H, dd, $J_{3,4}$=10.1 and $J_{3,5}$=1.0 Hz, H-3), 7.64 (1H, bs, NH), 7.33 (1H, td, $J_{4,5}$=$J_{5,6}$=10.1 Hz, H-5), 6.58 (1H, dd, $J_{4,6}$=1.0 Hz, H-6), 6.52 (1H, td, H-4), and 3.09 (3H, s, CH_3).

*Reaction of 2-Bromo-7-(2-hydroxyanilino)tropone (**1a**) Catalyzed by concd Hydrochloric Acid.* A similar treatment of **1a** (100 mg, 0.34 mmol) with acetic acid (5 ml) containing a trace amount of concd hydrochloric acid at 120°C for 4 h under nitrogen gave **2g** (see below, 20 mg, 25%), **2a** (27 mg, 29%), **2b** (4 mg, 6%), and **2c** (6 mg, 5%), besides the recovered **1a** (30 mg, 30%).

*6-Chlorocyclohepta[b][1,4]benzoxazine (**2g**)*: Brown needles (from benzene); mp 96—97°C; UV λ_{max} (MeOH) 224 (log ε, 4.21), 260 (4.29), 267 (4.26), 296 (3.77), and 413 nm (3.98), (MeOH+3 M HCl) 228 (log ε, 4.25), 264 (4.23), 270 (4.23), 324 (3.83), 425 (3.87), and 458 nm (3.81); IR (KBr) 1625 cm^{-1} (C=N); ^1H NMR (270 MHz) δ=6.87 (1H, m, $J_{2,3}$=$J_{3,4}$=7.8 and $J_{1,3}$=1.5 Hz, H-3), 6.86 (1H, m, $J_{1,2}$=7.8 Hz, H-1), 6.82 (1H, m, H-2), 6.59 (1H, dd, H-4), 6.18 (1H, d, $J_{7,8}$=11.8 Hz, H-7), 6.14 (1H, d, $J_{9,10}$=12.8 Hz, H-10), 6.08 (1H, dd, $J_{8,9}$=7.5 Hz, H-9), and 5.69 (1H, dd, H-8).

Found: M^+, 229.0301 and 231.0150 (3:1). Calcd for $C_{13}H_8NOCl$: M, 229.0294 and 231.0264.

*Reaction of 2-Bromo-7-(2-hydroxyanilino)tropone (**1a**) Catalyzed by Concd Hydrobromic Acid.* A similar treatment of **1a** (500 mg, 1.71 mmol) with acetic acid (10 ml) containing a trace amount of concd hydrobromic acid at 120°C for 4 h under nitrogen gave **2d** (220 mg, 47%), **2a** (15 mg, 3%), **2b** (28 mg, 8%), and **2c** (50 mg, 8%), besides the recovered **1a** (80 mg, 16%).

We thank Professors K. Takase (Tohoku Univ.) and H. Yamamoto (Okayama Univ.) for their helpful discussions.

Electronic and Steric Effects of Alkyl Group on Denitrosation of 3-Alkyl-1-methyl-1-nitrosothioureas

Masayoshi Isobe
Department of Chemistry, Saitama Medical School, 981 Kawakado, Moroyama, Iruma-gun, Saitama 350-04
(Received April 23, 1985)

A series of 3-alkyl-1-methyl-1-nitrosothioureas with R=CH_3, C_2H_5, *cyclo*-C_6H_{11} (**3**), $(CH_3)_2CH$ (**4**), $C_2H_5(CH_3)CH$, and $(CH_3)_3C$ were synthesized and their rates of acid catalyzed (pH<6.5) denitrosation measured. According to rate measurements in CH_3COOD-D_2O, the kinetic isotope effect $k_H:k_D$ is 1.25 for **4**. Except **3**, a linear plot of log k_R/k_{Me} for the denitrosation of $RNHCSN(NO)CH_3$ *vs.* σ^* provides $\rho^*=-0.98$ ($r=-0.997$). The significant factor affecting the rate-determining step of the denitrosation of these *N*-nitrosothioureas at pH 4.6 is the electronic effect of the substituent at the N_3 position.

Carcinogenic nitrosamines are caused to result from reaction of a dietary or endogenous nitrite with ingested amines.[1] However, nitrite *in vivo* is not the only possible origin of nitroso compounds. Certain aromatic nitrosamines[2,3] and many aliphatic nitrosamines[4] act as nitrosating agents toward naturally occurring amines under acidic conditions. In aqueous acid solutions, nucleophiles usually attack the protonated form of nitrosamine in the rate-determining step,[5] but when strongly electron-withdrawing groups are present in nitrosamine, proton transfer to nitrosamine is believed to be rate-limiting. The latter situation arises in reactions of *N*-nitroso amides[6-9] and *N*-nitroso sulfonamide.[10] Besides the above *N*-nitroso compounds 3-cyclohexyl-1-methyl-1-nitrosothiourea was also found to be protonated in the rate-determining step in denitrosation.[11]

On the other hand, reactions of thiourea (or alkylthiourea) with nitrous acid[12] or *N*-methyl-*N*-nitrosoaniline[13] have been investigated, with a conclusion that *S*-nitrosation occurs to form the intermediate $(NH_2)_2C=\overset{+}{S}-N=O$, which is capable of acting directly as a nitrosating agent. Synthesis and decomposition of a series of *N*-nitrosothioureas have recently been studied with an anticipation that isothiocyanate released from them should be less reactive toward proteins than isocyanate, and the formation mechanism and conformation of *N*-nitrosothioureas and stereoelectronic control of their aqueous decomposition have been revealed by Lown and Chauhan,[14] but no effect of substituents at N_3 on the denitrosation has been examined. In relation to isothiocyanates it should be noted that some isothiocyanates have exhibited antitumor properties in their own right.[15] Therefore, it is interesting and necessary for understanding the mechanism of denitrosation to study the effect of substituents at the N_3 position of 3-alkyl-1-methyl-1-nitrosothioureas quantitatively and evaluate their trans-

nitrosating abilities from a chemical viewpoint. In this research the denitrosation of a series of *N*-methyl-*N*-nitrosothioureas having various substituents at the N_3 position has been studied under acidic conditions.

Results and Discussion

Decomposition of **3** and **4** in acetate buffer (pH 4.6) produced predominantly 3-cyclohexyl-1-methylthiourea (**3a**) (66%) and 3-isopropyl-1-methylthiourea (**4a**) (38%), respectively, and that of **1** in acetate buffer (pH 5.0) produced 1,3-dimethylthiourea (**1a**) (80%). These results suggest that in the decomposition of **1**, **3**, or **4** under these acidic conditions the protonated *N*-nitrosothioureas are led markedly to the unimolecular excision of the NO^+ group or the denitrosation by the attack of nucleophile. Decomposition of **6** in acetate buffer (pH 4.6) produced a mixture of 3-*t*-butyl-1-methylthiourea (**6a**) and 3-*t*-butyl-1-methylurea (**6b**) in a ratio of **6a**:**6b**=37:63, which implies formation of protonated *N*-nitrosothiourea and *S*-nitrosoisothiourea, followed by unimolecular denitrosation or nucleophilic attack leading to thiourea or urea derivative (Scheme 1). The results are summarized in Table 1. The formation of these products is different from that of products (urea, nitrosourea, and propyl isothiocyanate) from 1,3-dipropyl-1-nitrosothiourea under acidic conditions (acetone:1 M HCl=5:1)(1 M=1 mol dm^{-3}) studied by Lown and Chauhan.[14]

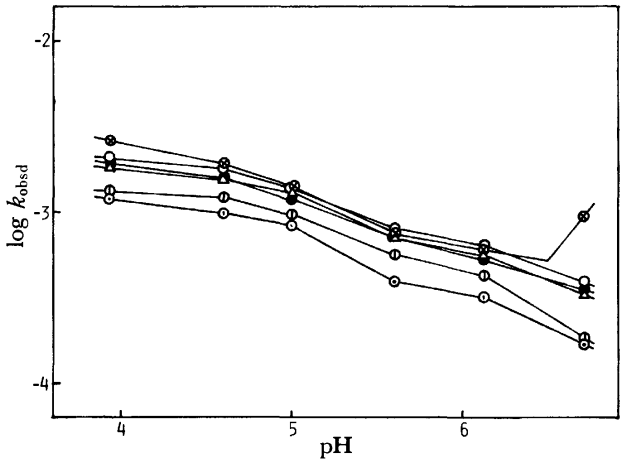

Fig. 1. pH-Rate profiles for decomposition of **1** — **6** at 36.9°C, pH 3.90—5.60 (acetate buffer), pH 6.12 (imidazole buffer), and pH 6.70 (Tris buffer), 0.05 M, μ=0.2 (NaCl), **1** (⊙), **2** (Φ), **3** (○), **4** (△), **5** (●), and **6** (⊗).

0.176 M NaSCN	1.63±0.03
1.05 M NaSCN	1.56±0.01
0.176 M NaI	1.70±0.02
0.176 M NaN_3	1.72±0.04

a) [**4**]=8.28×10^{-5} M in acetate buffer at 36.9°C. b) The errors are given by deviation from average of two runs.

pH-log k_{obsd} plots (pH 3.9—6.7) for the decomposition of compounds **1—6** are shown in Fig. 1. As shown in Fig. 1, decomposition rate constants for **1—6** decrease with increase in pH (pH<6.5), which indicates that all of them are subject to acid catalysis[11] and that the reactivity follows the sequence **6>3>5>4>2>1** at pH 4.6. The pH-rate profile for the decomposition of **6** shows an inverted-bell curve around pH 6.5, exhibiting the highest reactivity in this series above pH 6.5. The rate constant for the denitrosation of **4** at pH 4.6 is almost unaffected by the presence of nucleophile Br^- or SCN^-, as shown by the data in Table 2. This feature contrasts with the denitrosation of nitrosamine previously studied[5] but resembles the pattern of denitrosation for *N*-nitroso amide[9] and *N*-nitroso sulfonamide.[10]

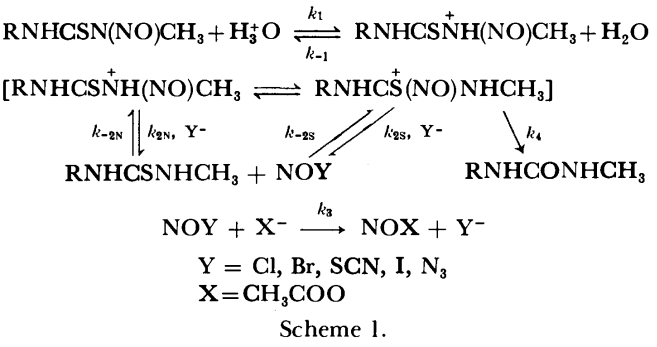
To evaluate the solvent deuterium isotope effect, the rate of denitrosation at 36.9°C was measured in CH_3COOD-D_2O. Results obtained at the same buffer ratio ([HA(DA)]/[A^-]=1.04, 0.05 M, μ=0.2) revealed that the denitrosation of **4** is slower in CH_3COOD-D_2O than in CH_3COOH-H_2O by a factor of 1.25 (Table 3). This feature argues against fast pre-equilibrium formation of the protonated form of *N*-nitrosothiourea, and rather suggests that the proton transfer is rate-limiting. The above results resemble those of *N*-nitroso amide (k_H/k_D=1.9 or 1.3)[6,8] and nitroso sulfonamide (k_H/k_D=1.5)[10] rather than those of nitrosamine (k_H/k_D=*ca.* 0.5—0.6).[16,17]

Table 3. Solvent deuterium isotope effect[a] in the denitrosation of **4**

$10^3k_H/s^{-1}$	1.56±0.03[b]
$10^3k_D/s^{-1}$	1.24±0.01
k_H/k_D	1.25

a) [HA(DA)]/[A^-]=1.04 (A=CH_3COO), [**4**]=8.28×10^{-5} M, and μ=0.2 (NaCl) at 36.9°C. b) The errors are given by deviation from average of two runs.

Scheme 1 is a probable outline mechanism for the denitrosation presented as capable of explaining the observations. The initial *N*-protonation of *N*-nitroso-



Scheme 1.

thiourea is written as a one-stage process for simplicity and *O*-protonation is not considered. The rate constant k_2 is composed of k_{2N} and k_{2S}. The step k_{-2}(*i.e.*, $k_{-2N}+k_{-2S}$) is negligible in the presence of excess X^-. The general expression of rate constant derived from Scheme 1

$$k_0 = k_1k_2[H_3^+O][Y^-]/(k_{-1}+k_2[Y^-]) \quad (1)$$

is simplified to two limiting forms

$$k_0 = k_1k_2[H_3^+O][Y^-]/k_{-1}, \quad (2)$$

$$k_0 = k_1[H_3^+O], \quad (3)$$

which correspond to different reaction patterns based on the inequalities $k_{-1} \gg k_2[Y^-]$ and $k_{-1} \ll k_2[Y^-]$, respectively. The catalysis by Y^- is in effect caused to disappear only if $k_{-1} \ll k_2[Y^-]$, with a result that Eq. 1 reduces to $k_0=k_1[H_3^+O]$, which is the form observed in this work.

In order to know electronic and steric effects of substituents at N_3 on denitrosation, Taft's Eq.[18]

$$\log k_R/k_{Me} = \rho^*\sigma^* + \delta Es \quad (4)$$

was applied to the data at pH 4.6 in Fig. 1. The ρ^* and δ values computed by using the least squares

method are −0.70 and −0.048, respectively. A plot of log $k_R/k_{Me}-\rho^*\sigma^*$ against *Es* gave an inferior correlation coefficient (r=−0.529) (Fig. 2). This indicates that the steric effect of substituent R is small for the transition state of protonation of these compounds **1—6**. Therefore, to know the electronic effect of substituents at the N_3 position on the protonation, log k_R/k_{Me} values from the data at pH 4.6 in Fig. 1 are plotted against σ^* into Fig. 3. The points for R=CH_3, C_2H_5, $(CH_3)_2CH$, $C_2H_5(CH_3)CH$, and $(CH_3)_3C$ provide a linear relationship (slope ρ^*=−0.98, r=−0.997) as given by

$$\log k_R/k_{Me} = \rho^*\sigma^* = -0.98\sigma^*. \quad (5)$$

This indicates that the denitrosation is influenced mainly by the electronic effect of substituents at the N_3 position. The more the substituent at N_3 releases electrons and increases the electron density at the N_1 position, the more the protonation on N_1 is facilitated.[19] The above result supports that the protonation on the N_1 nitrogen atom is the rate-determining step in the denitrosation of **1—6**. The positive deviation for R=*cyclo*-C_6H_{11}, which becomes pronounced at higher temperatures (36.9°C) at pH 5.0 (Table 4), may be due to inversion of the cyclohexyl group which permits the favorable conformation for the protonation on the N_1 position. This electronic effect (ρ^*=−0.98) of substituent R on the denitrosation is much smaller than that on alkaline hydrolyses of alkyl nitrite (ρ^*=2.67).[20]

In the denitrosation process of **6** (Scheme 1), the increase in electron density at the N_1 nitrogen atom by the electron-releasing effect of the *t*-butyl group may facilitate the protonation on the N_1 nitrogen atom to form a protonated intermediate. For **6**, the transition state to form a protonated *N*-nitroso or *S*-nitroso intermediate must be stabilized, by the electron-releasing effect of the *t*-butyl group, more than for **1**, **3**,

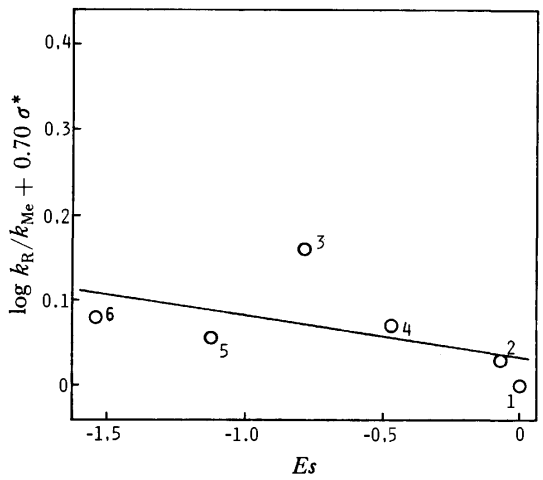


Fig. 2. Plot of log k_R/k_{Me}+0.70σ^* for the denitrosation of the $RNHCSN(NO)CH_3$ in acetate buffer (pH 4.6) against Taft's Es values, δ=−0.048 (r=−0.529).

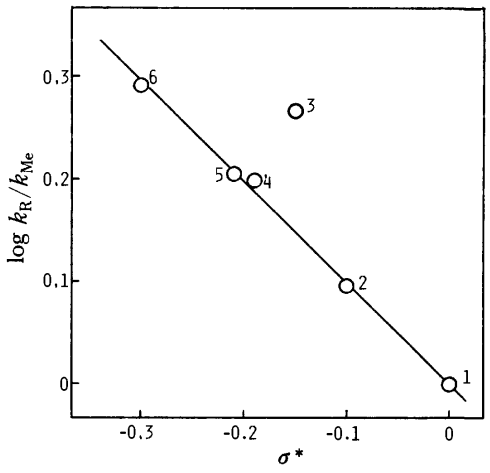

Fig. 3. Plot of log k_R/k_{Me} *vs.* σ^* for the denitrosation of the $RNHCSN(NO)CH_3$ series (pH 4.6). ρ^*=−0.98 (r=−0.997) for the R=CH_3, C_2H_5, $(CH_3)_2CH$, $C_2H_5(CH_3)CH$, and $(CH_3)_3C$.

Table 4. Kinetic data for denitrosation of 3-alkyl-1-methyl-1-nitrosothioureas

Nitrosothiourea[a]	Temp/°C	$10^4k_0/s^{-1}$[b]	ΔH^*/kJ mol^{-1}	ΔS^*/J mol^{-1}K^{-1}
1	17.0	1.05±0.02		
	25.0	2.50±0.03		
	36.9	8.32±0.02	75.3	−61.5
3	17.0	1.84±0.02		
	25.0	4.01±0.04		
	36.9	14.21±0.04	76.6	−52.3
4	17.0	1.80±0.02		
	25.0	3.97±0.03		
	36.9	12.98±0.02	72.8	−65.7
5	17.0	1.82±0.01		
	25.0	4.03±0.01		
	36.9	11.85±0.74	67.3	−83.7
6	17.0	2.26±0.01		
	25.0	5.03±0.02		
	36.9	14.27±0.18	65.7	−87.4

a) 8.28×10^{-5} M, acetate buffer (pH 5.0), 0.05 M, and μ=0.2 (NaCl). b) The errors are given by deviation from average of two runs.

and **4** so as to result in a larger increase of solvation, which may in turn lead to a larger decrease (21.7—35.1 $J\,mol^{-1}K^{-1}$) in the activation entropy of **6** than those of the others (**1**, **3**, and **4**) (Table 4). In nitrosation of thiourea (EtNHCSNHEt) by an equimolar amount of $NaNO_2$ and 0.5 M HCl in acetone at −10°C, the *S*-nitroso intermediate leads to urea *via* elimination of HSNO and addition of water to the carbodiimide thus formed.[14] But the decomposition of **6** in this acetate buffer solution (pH 4.6) at 37°C in the absence of oxygen (under nitrogen atmosphere) produced **6b** in one fifth amount of **6a**. This distribution of products suggests that the existence of oxygen greatly influences the production of **6b**.[21] Williams[13] has reported that the reaction of thiourea with *N*-methyl-*N*-nitrosoaniline in acid solution in the absence of oxygen forms no Fischer-Hepp rearrangement products but merely the denitrosation product *N*-methylaniline, which suggests that the nitrous acid can be regenerated using oxygen dissolved in the solution according to

$$2NO + O_2 = 2NO_2$$
$$NO_2 + NO = N_2O_3$$
$$N_2O_3 + H_2O = 2HNO_2$$

Scheme 2.

In fact, the decomposition of **6** in acetate buffer (pH 4.6) containing sodium nitrite under nitrogen atmosphere produced a mixture of **6a** and **6b** in a ratio of **6a**:**6b**=1:1 (Table 1). Therefore, the protonated intermediate of **6** is attacked mainly by the nitrous acid formed from oxygen to produce **6b** with no production of carbodiimide followed by addition of water.

These results lead to a conclusion that the electronic effect of substituents at the N_3 position has a predominant effect on the protonation on the N_1 nitrogen atom. It is probable that the denitrosation in this system (**1**—**6**) is not greatly affected by the steric factor of substituent R lying remote from the nitroso group. In this series, acid catalysis is a prerequisite for the denitrosation process different from hydrolysis of alkyl nitrite under neutral conditions[22] and the rate constants of denitrosation of these *N*-nitrosothioureas are in good correlation to σ^* values with one exception, which indicates that the values may be useful as an index of transnitrosating abilities of *N*-nitrosothioureas.

Experimental

Melting points were determined on a Yamato MP-21 melting point apparatus and are uncorrected. IR spectra were recorded on a Shimadzu IR-400 spectrophotometer and ^1H NMR spectra were recorded with a Hitachi R-24 instrument. Microanalyses were performed in the Microanalytical Laboratory of the Institute of Physical and Chemical Research, Wako-shi.

Materials. Ethylamine, *t*-butylamine, and methyl isothiocyanate were obtained from Wako Pure Chemical Co., and cyclohexylamine, isopropylamine, and *s*-butylamine from Tokyo Kasei Co.

General Method for the Preparation of N-Nitrosothioureas. 3-Alkyl-1-methylthiourea were synthesized through reaction of the corresponding alkylamines and methyl isothiocyanate. A dilute solution of HCl (0.07 M, 20 ml) was added dropwise for 20 min to a suspension of 3-alkyl-1-methylthiourea (2.0—6.0 mmol) and sodium nitrite (2.0—6.0 mmol) in CH_2Cl_2 (20 ml) with stirring and cooling (0°C) under a nitrogen atmosphere, and the mixture was stirred with cooling (0°C) for additional 40 min by following the method of Lown and Chauhan.[14] After the reaction was over, the organic layer was taken out, washed with water, dried ($MgSO_4$), and subjected to evaporation to afford crude *N*-nitrosothioureas **1**—**6**, which were purified except **2** by either crystallization from pentane or by chromatography over silica gel.

1,3-Dimethyl-1-nitrosothiourea (1): mp 46—47°C (lit,[14] mp 46°C).

3-Isopropyl-1-methyl-1-nitrosothiourea (4) (56%): An oil, IR (neat) 3340 (NH), 2990, 1505, 1405 (N=O), 1175 (C=S), and 1020 cm^{-1}; NMR ($CDCl_3$) δ=1.36 (6H, d, J=6.0 Hz, $C(CH_3)_2$), 3.46 (3H, s, N-CH_3), 4.67 (1H, q, J=6.4 Hz, $C\underline{H}Me_2$), and 8.26 (1H, br s, NH). Found: C, 37.32; H, 6.89; N, 26.12; S, 19.94. Calcd fo $C_5H_{11}N_3OS$: C, 37.25; H, 6.88; N, 26.06; S, 19.89.

3-s-Butyl-1-methyl-1-nitrosothiourea (5) (51%): An oil; IR (neat) 3330 (NH), 2980, 1505, 1405 (N=O), 1170 (C=S), and 1010 cm^{-1}; NMR ($CDCl_3$) δ=0.98 (3H, t, J=6.8 Hz, $CH_2C\underline{H}_3$), 1.30 (3H, d, J=6.0 Hz, $CHC\underline{H}_3$), 1.68 (2H, q, $C\underline{H}_2CH_3$), 3.48 (3H, s, N-CH_3), 4.85—4.25 (1H, m, $C\underline{H}(CH_3)C_2H_5$), and 8.40 (1H, br s, NH). Found: C, 41.10; H. 7.43; N, 24.16; S, 18.32. Calcd for $C_6H_{13}N_3OS$: C, 41.12; H, 7.48; N 23.98; S, 18.30.

3-t-Buthyl-1-methyl-1-nitrosothiourea (6) (69%): An oil; IR (neat) 3375 (NH), 2980, 1520, 1500, 1420 (N=O), 1200, 1160, and 935 cm^{-1}; NMR ($CDCl_3$) δ=1.59 (9H, s, $C(CH_3)_3$), 3.43 (3H, s, N-CH_3), 8.55 (1H, br s, NH). Found: C, 41.07; H, 7.46; N, 23.92; S, 18.39. Calcd for $C_6H_{13}N_3OS$: C, 41.12; H, 7.48; N, 23.98; S, 18.30.

Kinetic Measurements. The kinetic method was the same as described previously.[11] Reactions were monitored spectrophotometrically by following the disappearance of the absorption maximum at 266—270 nm with a Shimadzu UV 200 spectrophotometer. The reaction followed pseudo first-order kinetics; infinity readings were obtained after 8—10 half lives. The value of the pH of buffer was determined with a Toa Denpa HM-5A pH meter. A mixture of 3-ethyl-1-methyl-1-nitrosothiourea (**2**) and 3-methyl-1-ethyl-1-nitrosothiourea (**2′**) was obtained from nitrosation of 3-ethyl-1-methylthiourea and its separation by column chromatography (silica gel) with 30% ether-hexane as eluent failed of success after successive two trials. Therefore the rate constant of **2** was obtained from kinetic measurements on both the first fraction (**2**:**2′**=68:32) and the last fraction (**2**:**2′**=23:77) separated by column chromatography. Estimated values in acetate buffer (pH 4.6, 36.9°C) are as follows: $k=1.22\times10^{-3}\,s^{-1}$ for **2** and $k=2.08\times10^{-3}\,s^{-1}$ for **2′**; NMR ($CDCl_3$) for **2** δ=1.37 (3H, t, J=7.2 Hz, $CH_2C\underline{H}_3$), 3.46 (3H, s, N-CH_3), 3.56—4.02 (2H, m, $C\underline{H}_2CH_3$), and 8.58 (1H, br s, NH) and for **2′** δ=1.04 (3H, t, J=7.0 Hz, $CH_2C\underline{H}_3$), 3.26 (3H, d, J=5.0 Hz, N-CH_3), 4.24 (2H, q, J=7.2 Hz, $C\underline{H}_2CH_3$), and 8.52 (1H, br s, NH). The first fraction (**2**:**2′**=68:32): an oil. Found; C, 33.08; H, 6.21; N, 27.88; S, 21.44. Calcd

for $C_4H_9N_3OS$: C, 32.64; H, 6.16; N, 28.55; S, 21.78.

Product Analyses. A solution of **1** (15 mg, 0.144 mmol) in 3 ml of MeOH was added to 100 ml of acetate buffer solution (pH 5.0, 0.05 M, μ=0.2 with NaCl) and stirred for 2 h and 50 min at 37 °C. After cooling, the contents were neutralized with 0.1 M NaOH and saturated with NaCl and extracted with chloroform (40 ml×3) and the combined extracts were washed with saturated NaCl solution, dried ($MgSO_4$), and evaporated to give 1,3-dimethylthiourea (9 mg, 80%): mp 62—63 °C; NMR ($CDCl_3$) δ=2.99 (6H, d, J=4.8 Hz, CH_3) and 6.30 (2H, br s, NH). **3** (50 mg, 0.248 mmol) in acetate buffer solution (pH 4.6) for 1 h at 37 °C was allowed to produce 3-cyclohexyl-1-methylthiourea (**3a**) and 3-cyclohexyl-1-methylurea (**3b**) (white solids, 34.7 mg, 83%, **3a**:**3b**=80:20 from NMR spectrum) by following a similar procedure as described above. **3a**: mp 163—164 °C; NMR ($CDCl_3$) δ=1.00—2.20 (10H, m, CH_2), 2.94 (3H, d, J=5.2 Hz, N-CH_3), 3.55—4.00 (1H, m, CH-N), 5.66 (1H, br s, NH), and 5.90 (1H, br s, NH). **4** (16 mg, 0.099 mmol) in acetate buffer solution (pH 4.6) for 1 h at 37 °C produced mainly 3-isopropyl-1-methylthiourea (**4a**) together with 3-isopropyl-1-methylurea (**4b**) (9.3 mg, 50%, **4a**:**4b**=78:22 from NMR spectrum). **4a**: NMR ($CDCl_3$) δ=1.21 (6H, d, J=6.6 Hz, $C(CH_3)_2$), 2.96 (3H, d, J=4.8 Hz, N-CH_3), 4.24 (1H, o, 7.0 Hz, $C\underline{H}(CH_3)_2$), 5.90 (1H, br s, NH), and 6.26 (1H, br s, NH). **6** (100 mg, 0.571 mmol) in acetate buffer solution (pH 4.6) for 1 h at 37 °C through a similar course as described above produced a mixture of white solids (**6x** and 3-*t*-butyl-1-methylurea (**6b**), 49 mg, 64%, **6x**:**6b**=37:63 from NMR spectrum). **6b** was isolated by recrystallization from hexane-acetone; **6x** was not isolated from the mixture but its IR and NMR spectra were in accord with those of **6a**. **6b**: mp 134—135 °C; IR (KBr) 3390 (NH), 3330 (NH), 1625 (C=O), 1560, 1360, 1275, and 1215 cm^{-1}; NMR ($CDCl_3$) δ=1.30 (9H, s, $C(CH_3)_3$), 2.65 (3H, d, J=4.8 Hz, N-CH_3), 5.01 (1H, br s, NH), and 5.21 (1H, br s, NH); UV λ_{max}^{MeOH} 245 (ε 170) and 206 nm (1940). Found: C, 55.29; H, 10.95; N, 21.38. Calcd for $C_6H_{14}N_2O$: C, 55.35; H, 10.84; N, 21.52. **6x**=**6a**: NMR ($CDCl_3$) δ=1.42 (9H, s, $C(CH_3)_3$), 3.02 (3H, d, J=4.8 Hz, N-CH_3), 6.14 (2H, br s, NH); UV λ_{max}^{MeOH} 245 (ε 11600) and 212 nm (9300). **6** (51 mg, 0.291 mmol) in acetate buffer solution (pH 4.6) for 1 h at 37 °C under nitrogen atmosphere produced a mixture of white solids (**6a** and **6b**, 11 mg, 27%, **6a**:**6b**=83:17 from NMR spectrum). **6** (51 mg, 0.291 mmol) in acetate buffer solution (pH 4.6) containing sodium nitrite (20 mg, 0.291 mmol) for 1 h at 37 °C under nitrogen atmosphere produced a mixture of white solids (**6a** and **6b**, 30 mg, 74%, **6a**:**6b**=50:50 from NMR spectrum).

The author wishes to thank Professor Kazuo Nagamatsu and Dr. Kazuyuki Yano at Saitama Medical School for their helpful comments and useful discussions. This work was supported in part by a Grant-in-Aid for Scientific Research No. 57771470 from the Ministry of Education, Science, and Culture.

α,β-Epoxy Sulfoxides as Useful Intermediates in Organic Synthesis. II.[1] A Novel Synthesis of α-Sulfenylated Ketones and α-Sulfenylated Aldehydes from α,β-Epoxy Sulfoxides

Tsuyoshi SATOH, Takumi KUMAGAWA, and Koji YAMAKAWA*

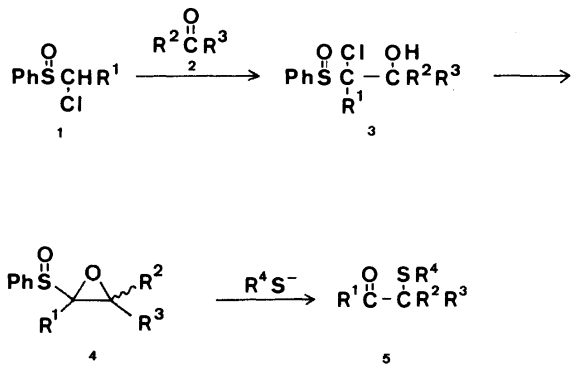
Faculty of Pharmaceutical Sciences, Science University of Tokyo, Ichigaya-funagawara-machi, Shinjuku-ku, Tokyo 162

(Received April 26, 1985)

Treatment of α,β-epoxy sulfoxides, prepared from 1-chloroalkyl phenyl sulfoxides and carbonyl compounds, with various kinds of alkane- or arenethiolates afforded α-sulfenylated ketones in good yields. This method also offered a novel procedure for a synthesis of α-sulfenylated aldehydes.

Since the pioneering work of Trost and others, it is recognized that α-sulfenylated carbonyl compounds, including α-sulfinylated and α-sulfonylated carbonyl compounds, are useful and versatile compounds in synthetic organic chemistry.[2] The synthetic methods of α-sulfenylated carbonyl compounds are classified into two categories. One is the S_N2 displacement of α-halo ketones with alkanethiolates[3] and the other is the sulfenylation of carbanions (ketone enolate anions) with dialkyl disulfides or other electrophilic sulfenylating reagents.[4] These methods are widely used in the synthesis of α-sulfenylated carbonyl compounds but they have some drawbacks. The former method is useful only when regio-selectively halogenated carbonyl compounds are easily available. The latter has four fundamental problems. The first is a regioselectivity. Especially when simple unsymmetrical ketones are sulfenylated; it is very difficult to obtain regioselectively sulfenylated ketones exclusively by this method. The second one is the feasibility for bis-sulfenylation. The third one is the availability of dialkyl disulfide or other electrophilic sulfenylating reagents. The last one is the applicability of these methods to a synthesis of α-sulfenylated aldehydes.

In previous papers,[1,5] we have reported a method for the preparation of dialkyl ketones, aldehydes, and α-sulfenylated ketones from α,β-epoxy sulfoxides. In this paper we describe, in detail, a simple and useful method for a synthesis of α-sulfenylated ketones and α-sulfenylated aldehydes through the reaction of α,β-epoxy sulfoxides (**4**) with sodium alkanethiolates or sodium arenethiolates according to Scheme 1.



Scheme 1.

Results and Discussion

α,β-Epoxy sulfoxides (**4**) were initially reported by Durst in 1969.[6] They are easily prepared from chloromethyl phenyl sulfoxide (**1**; R^1=H) or 1-chloroalkyl phenyl sulfoxides (**1**; R^1=alkyl)[7] and carbonyl compounds (**2**) *via* chlorohydrins (**3**) in good overall yields. A few synthetic methods have already been reported[8] by using α,β-epoxy sulfoxides (**4**) but these interesting compounds have scarcely been used in organic synthesis. We have found that the β carbon of α,β-epoxy sulfoxides is highly reactive to various kinds of thiolates to afford α-sulfenylated ketones in good to excellent yields.[5]

The results of the reaction of α,β-epoxy sulfoxides (**4a—i**) with sodium benzenethiolate are summarized in Table 1. As shown in Table 1, various kinds of α-phenylsulfenylated ketones (**5a—i**) were synthesized through this method in good yields. More notable is the regiochemistry of the products. Treatment of 3,4-epoxy-3-phenylsulfinylnonane (**4a**) and 2,3-epoxy-3-phenylsulfinylnonane (**4b**) with two equivalents of sodium benzenethiolate in ethanol gave 4-phenylthio-3-nonanone (**5a**) and 2-phenylthio-3-nonanone (**5b**) in 87 and 80% yields, respectively, without any contamination by their regioisomers as shown in Table 1. Similarly, the epoxy sulfoxides (**4c**) and (**4d**) afforded single phenylsulfenylated ketones (**5c**) and (**5d**) in good yields without their regioisomers. As described above, the sulfenylation of ketones through the reaction of ketone enolate anions with electrophilic sulfenylating reagents possess a big problem, that is, the regioselectivity. Actually, the sulfenylation of 3-nonanone (**6**) and 1-phenyl-2-butanone (**7**) according to Trost's procedure[4e] gave a mixture of **5a** and **5b** (ratio 3:4),[9] a mixture of **5c** and **5d** (ratio 16:1)[9] in moderate

a) Isolated yields after silica-gel column chromatography. b) Calculated from consumed starting material.

yields as shown in Scheme 2. Both sulfenylated ketones **5a** and **5b**, **5c** and **5d** have the same R_f values on silica-gel thin-layer chromatography and they are hardly separable by the usual techniques. From these results, it can be understood that the present method is one of the best ways for the preparation of relatively simple sulfenylated ketones. The synthesis of α-phenylsulfenylated ketones (**5e**) and (**5f**) is another example of the preparation of regioselectively sulfenylated isomers.

Attention should be called to the reaction of **4d** and **4h** with sodium benzenethiolate. Treatment of **4d** with three equivalents of sodium benzenethiolate in ethanol at room temperature for 20 min gave the desired **5d** and bis-sulfenylated ketone (**8**) in 47 and 52% yields, respectively. Similary, treatment of **4h** with three equivalents of sodium benzenethiolate at room temperature for 6 h gave a sulfenylated ketone (**5h**) and a bis-sulfenylated ketone (**9**) in 54 and 30% yields, respectively. The formation of these bis-sulfenylated ketones may be interpreted as shown in Scheme 3. The reaction of **4d** and **4h** with sodium benzenethiolate gives α-sulfenylated ketones **5d** and **5h** along with sodium benzenesulfenate. This sulfenate oxidizes thiophenol to give diphenyl disulfide. On the other hand, the hydrogen on the benzyl carbon of **5d** and **5h**

(these hydrogens are very acidic because of adjacent carbonyl group and phenyl ring) is deprotonated by sodium benzenethiolate giving a carbanion, which attacks the diphenyl disulfide[10] to afford the bis-sulfenylated ketones (**8**) and (**9**). The formation of these bis-sulfenylated ketones were simply prevented by using a large excess of benzenethiolate at a lower reaction temperature as shown in Table 1.

The present method also permits thiolates other than benzenethiolate to be easily introduced at the β-carbon of α,β-epoxy sulfoxides (**4**) to afford α-sulfenylated carbonyl compounds in good yields under very mild conditions, as is shown in Table 2. As mentioned above, only limited numbers of dialkyl or diaryl disulfides, or electrophilic sulfenylating reagents are available, these sulfenylated ketones in Table 2 (**5j**—n) are not easily obtained by the reaction of ketone enolate anions with electrophilic sulfenylating reagents. To prevent the formation of by-products, such as phenylsulfenylated compounds[11] or products deriving from the desired sulfenylated ketones, excess (five to ten-fold excess) thiolate and low temperature (0°C to room temperature) were found to be suitable for obtaining the desired α-sulfenylated ketones.

As mentioned above, direct sulfenylation of aldehydes through the reaction of enolate anion of aldehyde with sulfenylating reagents is difficult and no good methods have been reported to make α-sulfenylated aldehydes. From the equation in Scheme 1, one would expect that the reaction of **4** having hydrogen as R^1 with thiolates may give α-sulenylated aldehydes (**5**; R^1=H).

The α,β-epoxy sulfoxide (**4k**), prepared from 2-indanone and chloromethyl phenyl sulfoxide in good overall yield, on treatment with two equivalents of sodium benzenethiolate in ethanol at room temperature for 40 min gave α-phenylsulfenylated aldehyde (**5o**) in 83% yield. Other results are summarized in Table 3. All the epoxy sulfoxides in Table 3 reacted with sodium benzenethiolate under mild conditions to afford the desired aldehydes in moderate to good yields. When **4o** was treated with benzenethiolate under room temperature, some chloro aldehyde (**10**) was obtained along with **5s**. This implies that the rate of opening of the epoxide of **4o** by thiolate is slightly faster than that of the substitution of chloro substituent.

In conclusion a novel and versatile procedure for a synthesis of α-sulfenylated ketones and α-sulfenylated aldehydes has been developed from chloromethyl phenyl sulfoxide and carbonyl compounds through the reaction of α,β-epoxy sulfoxides with various kinds of thiolates. The commercial availability of starting materials and ease of handling, mildness of the reaction conditions, and high yields of the products, the present method offers a simple and useful approach to a synthesis of relatively simple α-sulfenylated carbonyl compounds.

Experimental

General. All melting points and boiling points are uncorrected. A Shibata GTO-250 glass tube oven was used for bulb-to-bulb distillation and boiling points are given as the temperature of the heating bath. The isomeric ratio of the products was determined by gas-liquid phase chromatography (GLC) using a Shimadzu GC-6AM (OV-101, 20 m) instrument. Infrared (IR) spectra were measured directly on an NaCl plate or in KBr disks with a Hitachi 215 spectrometer. ^{1}H-NMR spectra were measured in $CDCl_3$ solution with a JEOL FX-100 pulse Fourier-transform spectrometer using Me_4Si as an internal standard. Electron impact mass spectra (MS) were obtained on a Hitachi M-80 double focusing spectrometer at 70 eV by direct insertion. For TLC analysis throughout this work, Merck precoated TLC plates (Kieselgel 60 F_{254}, 0.25 mm) were used. Silica gel BW-127 ZH (Fuji-Davison) containing 2% fluorescence 254 and quartz column were used for column chromatography and the products having UV absorption were detected by UV irradiation. In experiments requiring dry solvent, THF was distilled from benzophenone ketyl; ethanol was dried by sodium metal and distilled.

General Procedure for the Preparation of α,β-Epoxy Sulfoxides (4): A synthesis of 3,4-epoxy-3-phenylsulfinylnonanone (**4a**) is described. To a solution of lithium diisopropylamide (3 mmol) in dry THF (8 ml) at −60 °C under N_2 was added a solution of 1-chloropropyl phenyl sulfoxide[7] (2.5 mmol) in 2 ml of dry THF dropwise with stirring and the solution was stirred for 15 min. Hexanal (3.75 mmol) was added to the reaction mixture through a syringe and the reaction was immediately quenched by aq NH_4Cl. The whole was extracted with ether–benzene and the organic layer was washed with sat. aq NH_4Cl. After the usual work-up, the crude products were purified by silica-gel column chromatography to give chlorohydrins (**3a-L**)[12] and (**3a-P**).[12] **3a-L** (30% yield): Colorless oil; IR (neat): 3250 (OH), 1030, 1020 (SO) cm^{-1}; NMR: δ=0.83 (3H, t, *J*=6.5 Hz), 1.36 (3H, t, *J*=7 Hz), 1.9—2.5, 2.5—3.0 (each 1H, m), 3.80 (1H, m), 7.4—7.9 (5H, m); MS *m/z* (%): 126 ([M−$C_9H_{17}ClO$]$^+$, 100), 105 (15), 78(31). **3a-P** (37% yield): Colorless oil; IR (neat): 3380 (OH), 1080, 1040 (SO) cm^{-1}; NMR: δ=0.89 (3H, t, *J*=6.5 Hz), 1.19 (3H, t, *J*=7 Hz), 2.10 (2H, m), 3.74 (1H, dd, *J*=9, 2 Hz), 7.4—7.8 (5H, m); MS *m/z* (%): 126 ([M−$C_9H_{17}ClO$]$^+$, 100), 105(78), 78(31).

To a solution of **3a-L** (1 mmol) in 12 ml of MeOH was added 30% aq KOH (2.5 ml) dropwise with stirring and the mixture was stirred at room temperature for 1 h. The reaction mixture was neutralized by NH_4Cl and the MeOH was evaporated. The residue was extracted with benzene and the organic layer washed with sat. aq NH_4Cl. After the usual work-up, the product was purified by silica-gel column chromatography to afford 89% yield of **4a-L**.[13] Colorless oil; IR (neat): 1090, 1055 (SO) cm^{-1}; NMR: δ=0.82 (3H, t, *J*=7 Hz), 0.88 (3H, t, *J*=6.5 Hz), 3.64 (1H, t, *J*=6 Hz), 7.4—7.8 (5H, m); MS m/z (%): 266 (M$^+$, trace), 126(10), 77(10), 57(100); Found: *m/z* 266.1321. Calcd for $C_{15}H_{22}O_2S$: M, 266.1338. The epoxy sulfoxide (**4a-P**)[13] was synthesized from **3a-P** as similar procedure described above in 90% yield as a colorless oil. IR (neat): 1090, 1050 (SO) cm^{-1}; NMR: δ=0.70 (3H, t, *J*=7 Hz), 0.94 (3H, t, *J*=6.5 Hz), 3.25 (1H, t, *J*=6 Hz), 7.4—7.7 (5H, m); MS *m/z* (%): 266 (M$^+$, trace), 126(8), 77(6), 57(100); Found: *m/z* 266.1333. Calcd for $C_{15}H_{22}O_2S$: M, 266.1339.

1,2-Epoxy-1-phenyl-2-phenylsulfinylbutane (4c). Chlorohydrin **3c-L** (45% yield): Colorless prisms; mp 140—142 °C; IR (KBr): 3210 (OH), 1035 (SO) cm^{-1}; NMR: δ=1.29 (3H, t, *J*=7 Hz), 2.02 (1H, dq, *J*=15, 7 Hz), 2.97 (1H, dq, *J*=15, 7 Hz), 4.93 (1H, s), 7.23 (5H, s), 7.5—8.0 (5H, m); MS *m/z* (%): 309 ([M+1]$^+$, trace), 126(100), 105(40), 91(47); Found: C, 62.45; H, 5.52; Cl, 11.65; S, 10.44%. Calcd for $C_{16}H_{17}ClO_2S$: C, 62.23; H, 5.55; Cl, 11.48; S, 10.38%. **3c-P** (52% yield): Colorless prisms; mp 110 °C (dec); IR (KBr): 3370 (OH), 1035 (SO) cm^{-1}; NMR: δ=0.94 (3H, t, *J*=7 Hz), 1.3—2.3 (2H, m), 5.31 (1H, s), 7.2—7.9 (10H, m); MS *m/z* (%): 182(11), 147(27), 126(100), 105(38); Found: C, 62.30; H, 5.49; Cl, 11.62; S, 10.58%. Calcd for $C_{16}H_{17}ClO_2S$: C, 62.23; H, 5.55, Cl, 11.48; S, 10.38%. Epoxy sulfoxide **4c-L** (99% yield): Colorless oil; IR (neat): 1045, (SO) cm^{-1}; NMR: δ=0.76 (3H, t, *J*=7 Hz), 1.1—2.0 (2H, m), 4.77 (1H, s), 7.1—7.9 (10H, m); MS *m/z* (%): 272 (M$^+$, 0.6), 147 ([M−PhSO]$^+$, 47), 91(100); Found *m/z* 272.0846. Calcd for $C_{16}H_{16}O_2S$: M, 272.0869. **4c-P** (99% yield): Colorless oil; IR (neat): 1045 (SO) cm^{-1}; NMR: δ=0.85 (3H, t, *J*=7 Hz), 1.4—1.8 (1H, m), 2.37 (1H, sextet, *J*=7 Hz), 4.42 (1H, s), 7.2—7.8 (10H, m); MS *m/z* (%): 272 (M$^+$, trace), 147 ([M−PhSO]$^+$, 35), 91(100); Found *m/z* 272.0909. Calcd for $C_{16}H_{16}O_2S$: M, 272.0870.

1,2-Epoxy-1-cyclohexyl-1-phenylsulfinylheptane (4f). Chlorohydrin **3f-L** (46% yield): IR (neat): 3375 (OH), 1040 (SO) cm^{-1}; NMR: δ=0.80 (3H, t, *J*=6 Hz), 3.95 (1H, t, *J*=6 Hz), 7.4—7.9 (5H, m). **3f-P** (47% yield): Colorless oil; IR (neat): 3410 (OH), 1085, 1060, 1030, (SO) cm^{-1}; NMR: δ=0.89 (3H, t, *J*=6 Hz), 3.70 (1H, bd, *J*=8 Hz), 7.3—7.8 (5H, m). Epoxy sulfoxide **4f-L** (85% yield): Colorless oil; IR (neat): 1095, 1060 (SO) cm^{-1}; NMR: δ=0.91 (3H, t, *J*=7 Hz), 3.55 (1H, dd, *J*=7, 5 Hz), 7.4—7.7 (5H, m); MS *m/z* (%): 320 (M$^+$, 0.3), 304 (0.7), 195 ([M−PhSO]$^+$, 8), 126(7), 111(24),

83(100); Found: *m/z* 320.1829. Calcd for $C_{19}H_{28}O_2S$: M, 320.1809. **4f-P** (93% yield): Colorless oil; IR (neat): 1090, 1050 (SO) cm^{-1}; NMR: δ=0.95 (3H, t, *J*=6 Hz), 3.26 (1H, t, *J*=6 Hz), 7.4—7.8 (5H, m).

2,3-Epoxy-2-methyl-3-phenylsulfinylpentane (4g). Chlorohydrin **3g** (99% yield): Colorless prisms; mp 76—77 °C; IR (KBr): 3350 (OH), 1035 (SO) cm^{-1}; NMR: δ=0.93 (3H, t, *J*=7 Hz), 1.43, 1.67 (each 3H, s), 1.99 (2H, m), 7.3—7.8 (5H, m); MS *m/z* (%): 162 ([M−$C_6H_{11}ClO$]$^+$, 86), 78 (32), 43 (100); Found: C, 55.10; H, 7.31; Cl, 13.67; S, 12.33%. Calcd for $C_{12}H_{17}ClO_2S$: C, 55.27; H, 6.57; Cl, 13.59; S, 12.30%. Epoxy sulfoxide **4g** (75% yield): Colorless oil; IR (neat): 1075, 1040 (SO) cm^{-1}; NMR:δ=0.50 (3H, t, *J*=7 Hz), 1.41, 1.83 (5H, m); MS *m/z* (%): 224 (M$^+$, trace), 126(48), 99 ([M−PhSO]$^+$, 79), 43 (100).

α,β-Epoxy Sulfoxide (4m). Chlorohydrin **3m** (85% yield): Colorless prisms; mp 165 °C (dec); IR (KBr): 3400 (OH), 1085, 1040 (SO) cm^{-1}; MS *m/z* (%): 287 (M$^+$, 0.4), 272 ([M−CH_3]$^+$, 40), 270(99), 126(58), 70(83), 42(100). Epoxy sulfoxide **4m** (95% yield): Colorless oil; IR (neat): 1090, 1050 (SO) cm^{-1}; NMR: δ=2.37 (3H, s), 4.76 (1H, s), 7.5—7.8 (5H, m); MS *m/z* (%): 251 (M$^+$, 1.8), 234(46), 126(32), 96(26), 83 (100); Found: *m/z* 251.1003. Calcd for $C_{13}H_{17}NO_2S$: M, 251.0979.

1,2-Epoxy-5-chloro-2-methyl-1-phenylsulfinylpentane (4o). Chlorohydrin **3o** (97% yield): Diastereomeric mixture; colorless needles; mp 138—145 °C; IR (KBr): 3360 (OH), 1045 (SO) cm^{-1}; MS *m/z* (%): 126 ([M−$C_6H_{10}Cl_2O$]$^+$, 100), 78(37), 43(50). Epoxy sulfoxide **4o** (12% yield): Colorless oil; IR (neat): 1085, 1045 (SO) cm^{-1}; NMR: δ=1.44 (3H, s), 3.72 (1H, s), 4.04 (1H, t, *J*=6 Hz), 7.5—7.9 (5H, m); MS *m/z* (%): 258 (M$^+$, 0.1), 133 ([M−PhSO]$^+$, 41), 126(100); Found: *m/z* 258.0457. Calcd for $C_{12}H_{15}ClO_2S$: M, 258.0479.

All other α,β-epoxy sulfoxides (**4**) are reported in Ref. 1.

General Procedure for the Preparation of α-Sulfenylated Ketones and α-Sulfenylated Aldehydes: A synthesis of 4-phenylthio-3-nonanone (**5a**) is described. To 2 ml of dry EtOH NaH (60% oil suspension; 20 mg; 0.5 matom) was added followed by thiophenol (52 μl; 0.5 mmol) at 0 °C under N_2 atmosphere. A solution of 3,4-epoxy-3-phenylsulfinylnonane (**4a**) (68 mg; 0.25 mmol) in 0.5 ml of EtOH was added to the benzenethiolate solution and the reaction mixture was stirred at room temperature under N_2 atmosphere for 45 min. The reaction mixture was neutralized by adding NH_4Cl and the EtOH evaporated. The residue was extracted with benzene and the organic layer was washed with sat. aq NH_4Cl, dried and concentrated. The crude product was purified by silica-gel column chromatography to afford 54.5 mg (87%) of 4-phenylthio-3-nonanone (**5a**) as a colorless oil. IR (neat): 1705 (CO) cm^{-1}; NMR: δ=0.88 (3H, t, *J*=7 Hz), 1.03 (3H, t, *J*=7 Hz), 3.58, 3.59 (each 1H, q, *J*=7 Hz), 3.63 (1H, t, *J*=7 Hz), 7.1—7.5 (5H, m); MS *m/z* (%): 250 (M$^+$, 24), 193 ([M−C_2H_5CO]$^+$, 100), 123(73), 109(18), 83(29); Found: *m/z* 250.1384. Calcd for $C_{15}H_{22}OS$: M, 250.1389.

2-Phenylthio-3-nonanone (5b). Colorless oil; IR (neat): 1710 (CO) cm^{-1}; NMR: δ=0.87 (3H, t, *J*=7 Hz), 1.40 (3H, d, *J*=7 Hz), 2.60 (2H, m), 3.76 (1H, q, *J*=7 Hz), 7.1—7.4 (5H, m); MS *m/z* (%): 250 (M$^+$, 10), 137 ([M−$C_6H_{13}CO$]$^+$, 100), 109 (16); Found: *m/z* 250.1363. Calcd for $C_{15}H_{22}OS$: M, 250.1389.

1-Phenyl-1-phenylthio-2-butanone (5c). Colorless prisms; mp 35—36 °C (sublimation); IR (neat): 1710 (CO) cm^{-1}; NMR: δ=0.98 (3H, t, *J*=7 Hz), 2.44, 2.64 (each 1H, dq, *J*=18, 7 Hz), 4.95 (1H, s), 7.1—7.4 (10H, m); MS *m/z* (%): 256 (M$^+$, 5), 200 (16), 199 ([M−C_2H_5CO]$^+$, 100), 165 (10), 91(16); Found: *m/z* 256.0907. Calcd for $C_{16}H_{16}OS$: M, 256.0920.

1-Phenyl-1,3-bis(phenylthio)-2-butanone (8). Diastereomeric mixture; colorless oil; IR (neat): 1720 (CO) cm^{-1}; NMR: δ=1.26, 1.30 (each d, *J*=7 Hz), 3.71, 3.94 (each q, *J*=7 Hz), 5.32, 5.46 (each s), 7.0—7.5 (m); MS *m/z* (%): 364 (M$^+$, 9), 255 ([M−PhS]$^+$, 14), 227 (11), 199 ([M−C_9H_9OS]$^+$, 100).

1-(1-Phenylthiocyclohexyl)-1-heptanone (5e). Colorless oil; IR (neat): 1705 (CO) cm^{-1}; NMR: δ=0.90 (3H, t, *J*=7 Hz), 2.74 (2H, t, *J*=7 Hz), 7.26 (5H, s); MS *m/z* (%): 304 (M$^+$, 2), 191 ([M−$C_7H_{13}O$]$^+$, 100); Found: *m/z* 304.1839. Calcd for $C_{19}H_{28}OS$: 304.1858.

1-Cyclohexyl-2-phenylthio-1-heptanone (5f). Colorless oil; IR (neat): 1710 (CO) cm^{-1}; NMR: δ=0.87 (3H, t, *J*=7 Hz), 2.68 (1H, m), 3.68 (1H, dd, *J*=8, 7 Hz), 7.1—7.4 (5H, m); MS *m/z* (%): 304 (M$^+$, 13), 193 ([M−$C_7H_{11}O$]$^+$, 100), 123 (38); Found: *m/z* 304.1857. Calcd for $C_{19}H_{28}OS$: M, 304.1859.

2-Methyl-2-phenylthio-3-pentanone (5g). Colorless oil; IR (neat): 1695 (CO) cm^{-1}; NMR: δ=1.10 (3H, t, *J*=7 Hz), 1.41 (6H, s), 2.79 (2H, q, *J*=7 Hz), 7.27 (5H, s); MS *m/z* (%): 208 (M$^+$, 7), 191 (3), 151 ([M−C_2H_5CO]$^+$, 100), 109 (13); Found: *m/z* 208.0911. Calcd for $C_{12}H_{16}OS$: M, 208.0920.

3-Methyl-1-phenyl-3-phenylthio-2-butanone (5h). Colorless oil; IR (neat): 1715 (CO) cm^{-1}; NMR: δ=1.44 (6H, s), 4.07 (2H, s), 7.1—7.3 (10H, m); MS *m/z* (%): 270 (M$^+$, 4), 151 ([M−$PhCH_2CO$]$^+$, 100); Found: *m/z* 270.1083. Calcd for $C_{17}H_{18}OS$: M, 270.1078.

3-Methyl-1-phenyl-1,3-bis(phenylthio)-2-butanone (9). Colorless crystals; mp 97—98 °C; IR (KBr): 1695 (CO) cm^{-1}; NMR: δ=1.25, 1.42 (each 3H, s), 5.60 (1H, s), 7.0—7.4 (15H, m); MS *m/z* (%): 378 (M$^+$, 4), 269(5), 199(36), 151 ([M−$C_{14}H_{11}OS$]$^+$, 100); Found: *m/z* 378.1084. Calcd for $C_{23}H_{22}OS_2$: M, 378.1111.

2-Methyl-1-(4,4-ethylenedioxy-1-phenylthiocyclohexyl)-1-propanone (5i). Colorless oil; IR (neat): 1700 (CO) cm^{-1}; NMR: δ=1.20 (6H, d, *J*=7 Hz), 3.40 (1H, septet, *J*=7 Hz), 3.92 (4H, bs), 7.26 (5H, bs); MS *m/z* (%): 320 (M$^+$, 4), 249 ([M−C_4H_7O]$^+$, 90), 205(8), 187(26), 99(100); Found: *m/z* 320.1457. Calcd for $C_{18}H_{24}O_3S$: M, 320.1444.

1-Butylthio-1-phenyl-2-butanone (5j). Colorless oil; IR (neat): 1715 (CO) cm^{-1}; NMR: δ=0.87 (3H, t, *J*=7 Hz), 1.00 (3H, t, *J*=7 Hz), 2.3—2.7 (4H, m), 4.61 (1H, s), 7.1—7.4 (5H, m); MS *m/z* (%): 236 (M$^+$, 2), 199(11), 179 ([M−C_2H_5CO]$^+$, 100), 123(43), 91(38); Found: *m/z* 236.1214. Calcd for $C_{14}H_{20}OS$: M, 236.1233.

1-Cyclohexylthio-1-phenyl-2-butanone (5k). Colorless oil; bp 170 °C/ 5 mmHg[†]; IR (neat): 1720 (CO) cm^{-1}; NMR : δ=0.99 (3H, t, *J*=7 Hz), 2.4—2.8 (3H, m), 4.68 (1H, s), 7.1—7.4 (5H, m); MS *m/z* (%): 262 (M$^+$, 1), 205 ([M−C_2H_5CO]$^+$, 69), 199(4), 123(100); Found: *m/z* 262.1387. Calcd for $C_{16}H_{22}OS$: M, 262.1390.

1-(2-Hydroxyethylthio)-1-phenyl-2-butanone (5l). Colorless oil; IR (neat): 3400 (OH), 1710 (CO) cm^{-1}; NMR: δ= 1.01 (3H, t, *J*=7 Hz), 2.3—2.7 (2H, m), 2.63 (2H, t, *J*=6 Hz), 3.67 (2H, bt, *J*=6 Hz), 4.73 (1H, s), 7.32 (5H, bs); MS *m/z* (%): 224 (M$^+$, 1), 167 ([M−C_2H_5CO]$^+$, 100), 150(10), 123 (12), 91 (54); Found: *m/z* 224.0861. Calcd for $C_{12}H_{16}O_2S$: M, 224.0870.

1-(Benzimidazol-2-ylthio)-1-phenyl-2-butanone (5m). Colorless powder; mp 141—142 °C; IR (KBr): 1725 (CO)

[†] 1 mmHg≈133.322 Pa.

cm^{-1}; NMR: δ=0.99, 1.12 (each t, J=7 Hz), 2.0—2.7 (2H, m), 5.34, 5.84 (each s), 6.9—7.8 (m); The complexity of the signals is thought to be due to the restricted rotation of the imidazolylthio group; MS m/z (%): 296 (M^+, 33), 240 (100), 239 ([M−C_2H_5CO]$^+$, 56), 207 (40); Found: C, 68.89; H, 5.35; N, 9.42; S, 10.83%; M^+ 296.0987. Calcd for $C_{17}H_{16}N_2OS$: C, 68.89; H, 5.44; N, 9.45; S, 10.82%; M, 296.0983.

3-Methoxycarbonylmethylthio-1-phenyl-2-butanone (5n). Colorless oil; IR (neat): 1745, 1715 (CO) cm^{-1}; NMR: δ= 1.39 (3H, d, J=7 Hz), 3.18 (2H, s), 3.61 (1H, q, J=7 Hz), 3.69 (3H, s), 3.91, 3.96 (each 1H, d, J=15 Hz), 7.23 (5H, m); MS m/z (%): 252 (M^+, 20), 193 ([M−$C_2H_3O_2$]$^+$, 3), 133 ([M−$PhCH_2CO$]$^+$, 78), 91 (100); Found: m/z 252.0791. Calcd for $C_{13}H_{16}O_3S$: M, 252.0818.

2-Phenylthio-2-indancarbaldehyde (5o). Colorless oil; IR (neat); 2725 (CHO), 1730, 1725 (CO) cm^{-1}; NMR: δ=3.13, 3.47 (each 2H, d, J=16 Hz), 7.21 (4H, s), 7.2—7.5 (5H, m), 9.57 (1H, s); MS m/z (%): 220 (M^+, 17), 191 ([M−CHO]$^+$, 81), 123 (28), 110 (40), 109 (26), 81 (100).

1-Phenylthio-1-cyclohexanecarbaldehyde (5p). Colorless oil; IR (neat): 2720 (CHO), 1720 (CO) cm^{-1}; NMR: δ=1.1— 2.0 (10H, m), 7.1—7.5 (5H, m), 9.29 (1H, s); MS m/z (%): 254 (M^+, 13), 225 ([M−CHO]$^+$, 33), 145 ([M−PhS]$^+$, 27), 116 (49), 115 (100).

4-Formyl-N-methyl-4-phenylthiopiperidine (5q). Colorless oil; IR (neat): 1710 (CO) cm^{-1}; NMR: δ=1.8—2.3 (6H, m), 2.29 (3H, s), 2.6—2.9 (2H, m), 7.2—7.5 (5H, m), 9.30 (1H, s); MS m/z (%): 235 (M^+, 11), 207 ([M−CO]$^+$, 17), 174 (3), 126 ([M−PhS]$^+$, 79), 109(13), 96(44), 83(100); Found: m/z 235.1020. Calcd for $C_{13}H_{17}NOS$: M, 235.1030.

2-Methyl-2-phenylthio-3-tetrahydropyranyloxypropanal (5r). Diastereomeric mixture; colorless oil; IR (neat): 1730 (CO), 1020 (COC) cm^{-1}; NMR: δ=1.34, 1.38 (each s), 3.49, 3.64, 3.93, 4.05 (each d, J=10 Hz), 4.62 (1H, bs), 7.2—7.6 (m), 9.46, 9.47 (each s); MS m/z (%): 280 (M^+, 2), 179 ([M− THPO]$^+$, 8), 166(51), 140(34), 109(29), 85(100).

2-Methyl-2,5-bis(phenylthio)pentanal (5s). Colorless oil; IR (neat): 2720 (CHO), 1720 (CO) cm^{-1}; NMR: δ=1.24 (3H, s), 2.93 (2H, t, J=7 Hz), 7.1—7.4 (10H, m), 9.35 (1H, s); MS m/z (%) 316 (M^+, 30), 287 ([M−CHO]$^+$, 8), 207 ([M−PhS]$^+$, 39), 177(64), 150(42), 123(58), 109(100); Found: m/z 316.0943. Calcd for $C_{18}H_{20}OS_2$: M, 316.0954.

The authors are grateful to Dr. S. Saito, Tanabe Seiyaku Co., for elemental analysis and Miss Sawabe, Mrs. Yamatani, and Miss Khim of this laboratory for NMR and mass spectral measurements. This work was supported in part by a Grant-in-Aid for Scientific Research No. 59771658 from the Ministry of Education, Science and Culture.

Preparation and Thermolysis of *N*-Ammonioamidates Containing Hydroxyl Group in Acyl Moiety

Araki MASUYAMA, Kikuo TSUCHIYA, and Mitsuo OKAHARA*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka 2-1, Suita, Osaka 565
(Received May 2, 1985)

The title *N*-ammonioamidates (aminimides) were prepared in satisfactory yields from lactones or α-hydroxy carboxylates. By the thermolysis of these aminimides in mesitylene, some types of urethane compounds were formed, depending on the structure of the aminimide and on the concentration of the solutions.

N-Ammonioamidates (aminimides) have been studied on the application to surfactants,[1,2] phase transfer catalysts,[3] and ion carriers in membrane transport systems.[4] As it is well known that they readily rearrange to isocyanates upon heating,[5] aminimides are considered as precursors of urethane or urea derivatives since isocyanates are convertible into urethane or urea compounds through a reaction with alcohols or amines.

On the other hand, the segmented-polyether-urethane polymer has recently been utilized as a "biomedical polymer material" for artificial hearts and artificial blood vessels.[6,7] Investigations of a new precursor of this type of urethane have been developed. As one of them, the preparation of a so-called "AB type" urethane-precursor which contains both a hydroxyl- and a functional group convertible into isocyanate in the same molecule have been reported.[8,9] But these are only a few studies regarding aminimide as an "AB type" precursor.[10,11]

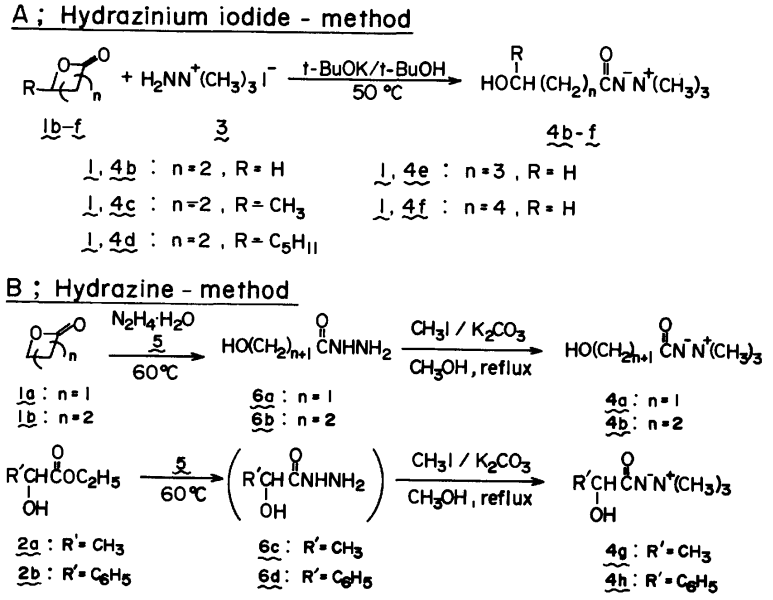
We have previously reported the synthesis of urethane-type crown ethers by a thermolytic reaction of aminimides containing an α-hydroxyoligo(ethylenoxy) group.[12] In the present paper, the preparations and properties of aminimides with a hydroxyl group in an acyl moiety from commercially available lactones or α-hydroxy carboxylates are described. Futhermore, the effects of the structure of aminimide and the solution concentration on the types of urethane compounds that were formed by thermolyses of aminimides in mesitylene are discussed.

Results and Discussion

Aminimides (**4**) were prepared from lactones (**1**) or α-hydroxy carboxylates (**2**) by the following two methods (Scheme 1).

(A) Hydrazinium Iodide Method. Aminimides were obtained by a one-step reaction between **1** and *N,N,N*-trimethylhydrazinium iodide (**3**), which was formed in quantitative yield from *N,N*-dimethylhydrazine and methyl iodide, in *t*-butyl alcohol in the presence of potassium *t*-butoxide.[13]

(B) Hydrazine Method. This method consisted of two-steps reactions. The preparation of acylhydrazines (**6**) from **1** or **2** and excess hydrazine hydrate (80%) (**5**) followed by a reaction with a large excess of methyl iodide (more than six folds to **1**) in methanol in the presence of potassium carbonate yielded aminimides.



Scheme 1.

Table 1. Yield and melting point of aminimides (**4**)

Aminimide	Method[a)]	Yield[b,c)] %	Mp θ_m/°C
4a	B	75 (53)	125—126
4b	A	80 (62)	107—108
4b	B	82	
4c	A	93 (69)	92—94
4d	A	85 (63)	86—88
4e	A	94 (61)	95—96
4f	A	85 (68)	116—117
4g	B	86 (55)	108—109
4h	B	81 (59)	140(dec)

a) A; Hydrazinium iodide method, B; Hydrazine method. b) Crude yields based on **1** or **2**. c) Values in parentheses are yields after recrystallization.

After reactions involving both methods, crude products of aminimides were separated by extraction with dichloromethane and pure compounds were obtained by recrystallization from acetone or ethyl acetate. The isolated products were characterized by spectral and elemental analyses (Tables 4 and 5). The yields and melting points of **4** are listed on Table 1. Differences in the yields of *N*-trimethylammonio-4-hydroxybutanamidate (**4b**) from 4-butanolide (**1b**) were not observed between both methods, and **4b** was obtained in good yield (above 80%) by each method. However, in the hydrazinium iodide-method, aminimides were hardly obtained from 3-propanolide (**1a**) and α-hydroxy carboxylates (**2**). The hydrazine-method has some advantages: Using an inexpensive hydrazine hydrate (**5**) instead of *N,N,N*-trimethylhydrazinium iodide and being applicable to both lactones and α-hydroxy carboxylates. Intermediates, 3-hydroxypropanohydrazide (**6a**) and 4-hydroxybutanohydrazide (**6b**), obtained from **1a** and **1b**, respectively, were isolated by recrystallization from ethanol and identified by spectral analyses (Table 4). However, there was no difference in yield when crude acylhydrazine was used in a following reaction without further purification.

The thermolysis of prepared aminimides (**4a**—h) was carried out in mesitylene as an inert and high-boiling-point solvent. The aminimide was stirred at 160°C in mesitylene under a nitrogen atmosphere until the carbonyl absorption in the IR spectrum shifted to about 1700 cm^{-1} due to the formation of a urethane bond. The solvent was evaporated off and the residue (solid or semisolid) was extracted with chloroform to separate the soluble and insoluble portions (insoluble one; Fraction 3). The chloroform-soluble portion was further separated into the distillate (Fraction 1) and the residue (Fraction 2) by distillation at 120°C/2.7 Pa using a Kugelrohr apparatus.

The thermolysis was carried out in both dilute (1.00 g of aminimide/100 ml of mesitylene) and concentrated (1.00 g of aminimide/10 ml of mesitylene) conditions. The yields of reaction products and the weight percentage of each fraction are shown in Table 2.

In the thermolyses of **4a—f**, the distillates (Fraction 1) were white solids which showed one peak in GLC. Also, needle-like crystals were obtained by recrystallization from ethyl acetate. From their spectral data and elemental analyses, these fractions were identified as cyclic urethanes (**7a—f**). These compounds may be formed by the intramolecular addition of a hydroxyl group to an isocyanato group which was introduced by a thermolytic rearrangement of the aminimides. The properties and an elemental analysis of **7a—f** are shown in Tables 3 and 5.

The residual compounds in the distillation (Frac-

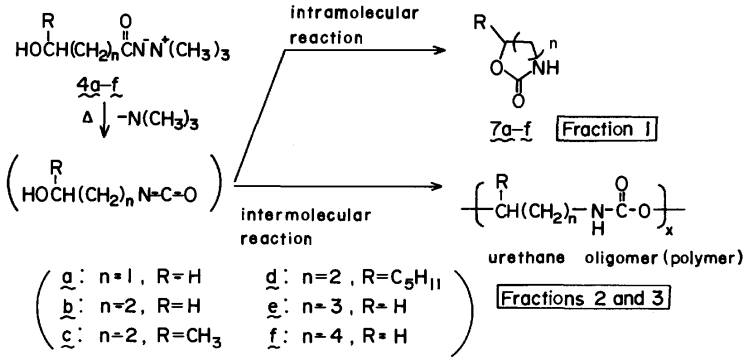

Scheme 2.

tion 2) were semisolids which showed some peaks for longer retention times than that of the corresponding Fraction 1 in GLC. But their IR spectra and both the chemical shifts and integral ratios in their ^{1}H NMR were similar to those of the corresponding Fraction 1. Their molecular weights were determined by a VPO method (Table 2) and they were considered as the urethane oligomers with low molecular weights which might be formed by the intermolecular reaction between hydroxyl and isocyanato groups. It is probable that Fraction 2 was for the most part cyclic oligomers since their molecular weights were not so large and the existence of expected terminal groups in linear structures were not observed in the ^{1}H NMR spectra.

The chloroform-insoluble matter (Fraction 3) was a white or pale-brown solid and showed the same IR spectra as the corresponding Fraction 2. Thus, Fraction 3 could be considered as a linear or cyclic urethane polymer with a higher molecular weight than Fraction 2. However, their molecular weights and ^{1}H NMR spectra were not measured since they were only slightly soluble in water, alcohols, tetrachloromethane or other organic solvents.

The mechanism of the formation of the urethane compounds mentioned above is shown in Scheme 2.

In the thermolyses of α-hydroxyl type aminimides (**4g,h**), Fraction 1 was obtained as a pale-yellow liquid which showed some peaks in GLC and absorption peaks at 1830 and 1760 cm^{-1}, besides 1710 cm^{-1} in IR spectra. But the formation of compound **7**- type cyclic urethane was not detected by mass spectra. Additionally, their ^{1}H NMR spectra were complicated, so that their ingredients could not be identified. The IR spectra of Fraction 2 was similar to that of Fraction 1. Fraction 3 was a white solid which showed a strong absorption peak at 1740 cm^{-1}.

As shown in Table 2, the formation ratios of cyclic urethanes (**7**), urethane oligomers with low molecular weights, and urethane polymers was considerably affected by both the chain length (defined as the number of carbons between carbonyl and hydroxyl group of **4**) and the concentration of the solution. In the case of dilute conditions, five-membered (**7a**) and six-membered rings (**7b—d**) of cyclic urethanes were quantitatively formed from **4a** (chain length=2) and **4b—d** (chain length=3), respectively, and the formation of oligomer and polymer was not observed

(Table 2. Runs 1, 3, 5, and 7). On the other hand, oligomers were mainly obtained in the thermolysis of **4e** and **4f**. It seems reasonable that an intermolecular reaction took place prior to an intramolecular reaction in which a seven- (**7e**) or eight-membered ring (**7f**) compound was formed (Runs 9 and 11). In concentrated conditions, oligomer was also formed in a reaction of **4a—d** (Runs 2, 4, 6, and 8) and a polymer was obtained (for the most part) in the case of **4e** and **4f** (Runs 10 and 12).

Experimental

The ^{1}H NMR and IR spectra were taken on a JEOL JNM-PS-100 spectrometer and a Hitachi 260 spectrometer, respectively. The mass spectra were measured with a Hitachi RMU-6E mass spectrometer at an ionization potential of 70 eV. The GLC analyses were performed on a Shimadzu gas chromatograph GC-4CPT using a 1 m×3 mm column packed with 10% Silicone OV-1 on Uniport KS. The number-averaged molecular weight was measured with a Hitachi Perkin Elemer 115-type vapor-pressure osmometer in a chloroform solution at 25 °C. The starting materials were the commercial products of analytical reagent grade. Their purities were checked by GLC and IR, and they were purified by distillation when necessary. *N,N,N*-Trimethylhydrazinium iodide (**3**) was obtained as a white solid by the interaction of equivalent *N,N*-dimethylhydrazine and methyl iodide in diethyl ether at 20 °C and used without further purification. Mesitylene was distilled under a reduced pressure before use.

Preparation of N-*Trimethylammonio-4-hydroxybutanamidate (4b) by the Hydrazinium Iodide Method.* Potassium metal (4.7 g, 0.12 mol) was dissolved in 300 ml of *t*-butyl alcohol, and then **3** (20.2 g, 0.10 mol) and 4-butanolide (**1b**, 8.6 g, 0.10 mol) were slowly added, in turn, to the solution. After 5 h of stirring at 50 °C and subsequent neutralization by hydrochloric acid (to pH 8.0), the reaction mixture was filtered. The precipitate was washed with dichloromethane, and the solvent was removed from a combined solution of filterate and washings. The solid-liquid extraction of the residue with dichloromethane several times was followed by the filteration and evaporation of the extracts. This afforded 12.8 g of crude aminimide, as white solids (80%). The pure **4b** was obtained by recrystallization from acetone as fine white needles (9.9 g, 62%). Crude aminimide showed a similar IR spectrum as the corresponding pure one. Using a similar procedure, *N*-(trimethylammonio)hydroxyalkanamidates (**4c—5**) were also obtained (Table 1).

Preparation of N-*Trimethylammonio-3-hydroxypropanamidate (4a) by the Hydrazine Method.* A mixture of 3-propanolide (**1a**, 7.2 g, 0.10 mol) and hydrazine hydrate (80%) (9.4 g, 0.15 mol) was stirred at 60 °C for 5 h. After evaporation of the unreacted hydrazine, methyl iodide (85.2 g, 0.60 mol) was dropped into the suspension of the crude 3-hydroxypropanohydrazide (**6a**, 10.9 g, about 0.1 mol) and potassium carbonate (27.6 g, 0.20 mol) in 300 ml of methanol at 20 °C. The reaction mixture was stirred for 8 h at reflux temperature, and then an insoluble solid was separated by filtration. Excess methyl iodide and the solvent of the

filtrate were evaporated off. The residue was extracted with acetone several times followed by filtration and evaporation of the extracts. This afforded 11.0 g of crude aminimide as white solids (75%). The pure **4a** was obtained by recrystallization from acetone as fine white needles (7.7 g, 53%). Using a similar procedure, aminimides (**4b**, **4g**, and **4h**) were also obtained (Table 1). A characterization of the aminimides (**4a**—**h**) and the isolated acylhydrazines (**6a** and **6b**) (recrystallization from ethanol) was accomplished by a standard method (Table 4). The elemental analysis of **4a**—**h** is shown in Table 5.

Thermolysis of 4a under Dilute Conditions. Dry mesitylene (100 ml) was heated at 160 °C in a 200-ml separable reaction flask under a nitrogen atmosphere. After the addition of **4a** (1.00 g, 6.84 mmol) to hot mesitylene, the solution was stirred until the absorption peak (based on the carbonyl group in the IR spectrum of aliquot) completely shifted to about 1700 cm^{-1} (6 h). Then, the solvent was evaporated off and the residue (0.57 g, solid), which was entirely dissolved in chloroform and showed one main peak in GLC, was distilled using a Kugelrohr apparatus (120 °C/2.7 Pa) to give 0.55 g of 2-oxazolidinone (**7a**) as fine white needles (92% yield based on **4a**). A very small amount of residue was observed. The thermolysis and work-up of the thermolytic products of **4b**—**d** under dilute conditions were undertaken in the same way as above since the crude product in each case was also wholly dissolved in chloroform. Perhydro-1,3-oxazin-2-one (**7b**, 86%), 6-methylperhydro-1,3-oxazin-2-one (**7c**, 95%), and 6-pentylperhydro-1,3-oxazin-2-one (**7d**, 90%) were obtained from **4b**, **4c**, and **4d**, respectively.

Thermolysis of 4e under Dilute Conditions. A solution of **4e** (1.00 g, 5.74 mmol) in dry mesitylene (100 ml) was heated as described above. The solvent was evaporated off and the residue (0.56 g, semisolid) was extracted with chloroform (100 ml) and filtered. The insoluble solid was washed with chloroform and dried *in vacuo* (pale brown; 0.17 g after drying). The chloroform extracts were combined, the solvent was evaporated off, and the residue (0.39 g) was distilled using the Kugelrohr apparatus at 120 °C/2.7 Pa to separate a distillate (0.18 g) as fine white needles and a residue (0.21 g) as a pale-brown solid. The distillate was identified as perhydro-1,3-oxazepin-2-one (**7e**, 27% yield based on **4e**). Perhydro-1,3-oxazocin-2-one (**7f**, 0.06 g, 8% yield based on **4f**) as a distillate, 0.37 g of a residue, and a 0.14 g of chloroform-insoluble solid were obtained from **4f** using a similar procedure.

The elemental analysis of **7a**—**f** is shown in Table 5.

Thermolysis of 4a under Concentrated Conditions. A solution of **4a** (1.00 g, 6.84 mmol) in dry mesitylene (10 ml) in a 50-ml separable reaction flask was heated at 160 °C for 3 h with stirring under a nitrogen atmosphere. The work-up of the reaction product was performed in the same way as the case of the thermolysis of **4e** under dilute conditions. Cyclic urethane (**7a**, 0.22 g, 37% yield based on **4a**) as a distillate, a 0.31 g of residue, and a 0.02 g of chloroform-insoluble solid were afforded. A thermolysis of aminimides (**4b**—**f**) under concentrated conditions was carried out using a similar procedure.

The results of thermolytic reactions, including α-hydroxyl type aminimides (**4g**,**h**), are presented in Table 2.

The Structure of Cellulose Produced by *Acetobacter xylinum* in the Presence of a Fluorescent Brightener. The Influence of Concentration of a Brightener in the Medium on the Structure of Cellulose

Akira KAI* and Hitoshi KITAMURA†
Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received May 13, 1985)

The influence of the concentration of a brightener on the structure of cellulose from an *Acetobacter* culture in the presence of a fluorescent brightener was examined. At a brightener concentration above 0.05 wt%, the X-ray diffraction diagram of cellulose from an incubated medium was observed. Except for the intensity of the diffraction corresponding to the (020) plane of cellulose I, the intensity of diffraction of the (110) plane became very weak and diffraction of the ($1\bar{1}0$) plane disappeared. A new diffraction, not corresponding to cellulose I or II, occurred inside. The position of each diffraction pattern was constant and independent of the concentration of the brightener. As the brightener concentration of the medium became lower, in the X-ray diagram of the dyed cellulose that was produced, the diffraction intensity of both the ($1\bar{1}0$) and (110) planes of cellulose I increased, and a new diffraction pattern gradually disappeared. In the case of an extraction of dyed cellulose from an incubated medium with a brightener (above 0.05 wt%), the same result was obtained. The above results suggest that the monomolecular layer of a brightener is included between the ($1\bar{1}0$) planes of the produced cellulose.

Acetobacter xylinum (A. xylinum) extrudes cellulose in an amorphous state from a cell.[1-3] However, it inevitably continues to form cellulose I crystals. Therefore, it is essential to determine the structure of the nascent cellulose in order to elucidate the biogenesis of a bacterial cellulose microfibril.

Brown *et al.* reported that when *A. xylinum* is cultured in the presence of a fluorescent brightener having a strong affinity toward cellulose, the morphology of the produced cellulose changes.[2] We found that the X-ray diffraction diagram of the specimen obtained from the incubated medium with a fluorescent brightener shows the characteristic diffraction patterns of a cellulose-brightener complex.[4,5] However, when the brightener was extracted from the complex, the diffraction patterns of cellulose I occurred in its X-ray diagram.[4] These facts showed that an examination of the structure of the dyed cellulose produced in the presence of a brightener is very essential in order to elucidate the structure of the nascent cellulose produced by *A. xylinum*.

In this paper, the influence of the brightener concentration of the medium on the structure of cellulose obtained from incubation in the presence of a fluorescent brightener was examined.

Experimental

Cultures of Cells and Preparations of the Samples for X-ray Photographing. Previously described methods were employed.[3]

Culture of A. xylinum (IFO 13693) in the Presence of a Fluorescent Brightener: 60 ml of a cellulose-free cell suspension[3] (pH 7.0) was added to 140 ml of a complex medium with a fluorescent brightener (Nippon Kayaku, Kayaphor FB conc: 4,4′-bis[4-anilino-6-bis(2-hydroxyethyl)amino-1,3,5-triazin-2-ylamino]-2,2′-stilbenedisulfonic acid) of various concentration (ranging from 10^{-4} to 10^{-1} wt%) and was then incubated for 24 h at 28 °C.

Preparations of the Samples: The collected cellulose was washed with a weak aqueous alkali solution several times, and from this the following samples were prepared after further treatment. T-1: the cellulose was washed with a 70 vol% aqueous ethanol solution several times to remove the free brightener at room temperature. T-2: the aqueous ethanol washed cellulose was extracted by boiling in a solution of 70 vol% aqueous ethanol for 18 h (aqueous ethanol was exchanged for fresh one every 3 h). T-3: the ethanol extracted cellulose was refined in a boiling 1 wt% aqueous NaOH solution for 10 h under a N_2 atmosphere.

X-Ray Photographing: Each sample was compressed to an isotropic disk with a diameter of 1.5 mm and a thickness of about 1 mm. X-ray diffraction diagrams of the samples were made with a flat-film camera (with the X-ray beam perpendicular to a flat surface of the disks) with Ni filtered Cu $K\alpha$ radiation (35 kV, 15 mA, time of exposure: about 35 min) at a specimen film distance of 50 mm. A Rigaku Denki made Rota-Unit RU-3v was used for photographing.

Results and Discussion

In the X-ray diffraction diagram of the sample (after a rejection of any free brightener from the incubated medium at a brightener concentration greater than 0.05 wt%) except for the intensity of the diffraction corresponding to the (020) plane of cellulose I, the diffraction intensity of the (110) plane becomes very weak and the diffraction of the ($1\bar{1}0$) plane disappears (Fig. 1b, 1c). A new diffraction which does not correspond to cellulose I or II occurred inside. As the concentration of the brightener in the medium became lower, the diffraction intensity of both the ($1\bar{1}0$) and (110) planes of cellulose I increased. On the contrary, a new diffraction pattern disappeared gradually. In the case of the medium with a brightener of less than about 0.001 wt%, the intensity of each

The brightener concentration of the medium (wt%); a: 0 (Cellulose I sample), b: 0.1, c: 0.05, d: 0.01, e: a little under 0.001.

diffraction of the cellulose was almost the same that of cellulose I (Fig. 1).

Brown *et al.* reported that for concentrations of a brightener greater than 0.1 mM (0.0086 wt%), the brightener disrupts the assembly of crystalline cellulose I microfibrils and their integration into a composite ribbon by a stoichiometric binding to glucose residues of newly-polymerized glucan chains.[6] The minimum concentration, at that the morphological change of cellulose takes place, generally corresponds to the result from the X-ray test on the complex in this study.

On the other hand, in the case of an extraction of the cellulose-brightener complex obtained from an incubated medium with a brightener above 0.05 wt%, the same result was found as in the case of lowering

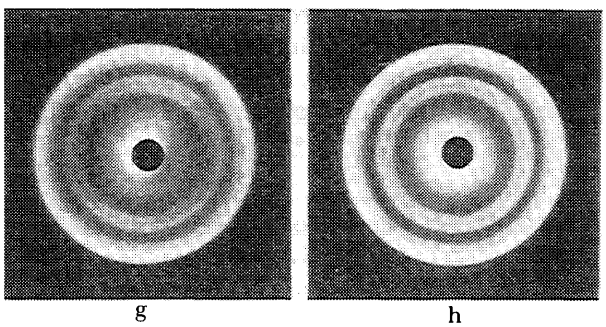

Fig. 2. Change in the X-ray diffraction diagram of the dyed cellulose with extraction.
a: Cellulose I sample, b: T-1-treated sample, which was obtained from the medium with a brightener of 0.1 wt%. c: T-2-treated sample b, d: T-3-treated sample c, e: T-1-treated sample, which was obtained from the medium with a brightener of 0.05 wt%. f: T-3-treated sample e, g: T-1-treated sample, which was obtained from the medium with a brightener of 0.01 wt%. h: T-3-treated sample g.

the brightener concentration of the medium. When the complex was treated with methods T-2 and T-3, in

its X-ray diagram the intensity of each diffraction of cellulose I increased as removing a brightener from it. The intensity of a new diffraction pattern gradually became weaker (Fig. 2). However, the intensities of the diffractions of each sample differed with the brightener concentration of the medium.

We reported previously, from a calculation regarding an X-ray diagram of the cellulose-brightener complex obtained from the incubated medium with a brightener of 0.1 wt%, that a new diffraction corresponds to $(1\bar{1}0)$ plane of the complex, and that a brightener is included between the $(1\bar{1}0)$ planes.[5] Therefore, the spacing of the $(1\bar{1}0)$ plane of the complex becomes 7.4 Å broader than that of cellulose I. The spacing of the $(1\bar{1}0)$ plane of the complex was unchanged even if the amount of the brightener in a complex differed. This fact suggests that a monomolecular layer of a brightener is included between the $(1\bar{1}0)$ planes of the complex. In the sample obtained from the incubated medium with a brightener of above 0.05 wt% (as its X-ray diagram was unchanged), the surfaces of cellulose sheets (corresponding to the $(1\bar{1}0)$ plane of the complex) capable of being dyed seemed to be saturated by a brightener. As the given concentration of a brightener in the medium becomes lower, the surfaces of cellulose sheets become dotted with the brightener. Therefore, it is suggested that the intensity of the diffraction of the $(1\bar{1}0)$ plane of cellulose I increased for the possibility of an increased mutual binding of the cellulose sheet.

Brown *et al.* suggested from the observation of the morphology of cellulose produced in the presence of a fluorescent brightener that the cellulose chains are extruded from a bacterial cell to be in the form of sheets corresponding to the (020) plane of cellulose I, and that the cellulose sheet is formed by hydrogen bonding of cellulose chains.[6] Therefore, they suggested that a fluorescent brightener is included between the (020) planes. However, the fact, that both the intensity and the spacing of the diffraction pattern corresponding to the (020) plane of cellulose I are scarcely changed even with the amount of brightener in a sample, suggests that their theory is inadequate.

The fact that the spacing of the $(1\bar{1}0)$ plane of the cellulose produced in the presence of a fluorescent brightener widens with a definite value and that the spacing of the (020) plane is unchanged independent of the concentration of a brightener, indicates that cellulose chains in the form of a monomolecular layer corresponding to the $(1\bar{1}0)$ plane of cellulose I are extruded from a cell. The behavior of the nascent cellulose toward a fluorescent brightener shows that between the cellulose sheets, the medium components are included. This view is equivalent to that obtained from an examination of the behavior of the nascent cellulose toward sodium tungstophosphate.[3] It is well known that the spacing of the $(1\bar{1}0)$ plane widens preferentially when natural cellulose is exposed either to intracrystalline swelling reagents (such as sodium hydroxide and potassium acetate) or to chemical substitution reactions (such as acetylation and nitration).[7] A cellulose sheet corresponding to the $(1\bar{1}0)$ plane may be an elementary unit of natural cellulose.

Photochemical Electron-transfer Reactions of Biphenyl-2,2′-dicarboximide and Naphthalene-1,8-dicarboximide with Olefin. Dependence of the Reaction Course on the Structure of the Aromatic Imide[1)]

Yasuo KUBO,* Takeo ARAKI, and Kazuhiro MARUYAMA†

Department of Chemistry, Faculty of Science, Shimane University, Matsue, Shimane 690

†*Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606*

(Received May 16, 1985)

Photoreactions of *N*-methylbiphenyl-2,2′-dicarboximide and *N*-ethylnaphthalene-1,8-dicarboximide (**2**) with 1,1-diphenylethylene (**3**) in methanol gave methanol-incorporated 1 : 1 : 1-adduct (**7**) and 2,2-diphenylethyl methyl ether (**6**), an anti-Markovnikov adduct of methanol to **3**. The ratio of the two types of products largely depends on the structure of the aromatic imides. Probably the spin densities of the radical anions of the aromatic imides seem to play an important role to determine the reaction courses after the photochemical electron-transfer process. Similar results were obtained in the photoreaction of *N*-(2-phenylallyl) aromatic imides; elimination induced by methanol-incorporation *vs. anti*-Markovnikov addition of methanol. Photoreactions of *N*-(*trans*-3-phenylallyl) aromatic imides in methanol gave methanol-incorporated *O*-cyclized products (**20** and **27**) and *C*-cyclized products (**21** and **28**). A tentative mechanism for the *O*-cyclization is proposed; *i.e.*, intramolecular electron transfer followed by *anti*-Markovnikov addition of methanol to the radical cation of the double bond moiety, nucleophilic attack of the aromatic imide radical anion moiety, secondary electron-transfer, and then polar addition of methanol.

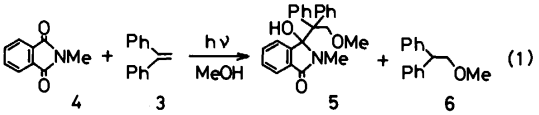
Recently, photoreactions involving electron-transfer process have received much attention from synthetic and mechanistic aspects in organic photochemistry.[2)] Numerous photo-reactions between electron-donor (D) and electron-acceptor (A) molecules have been studied in view of ion radical intermediate.[3)] For example, nucleophiles such as methanol can add to photochemically generated cation radicals of olefins.[4)] However, factors which control the reaction courses after the photochemical electron-transfer between D and A molecules, seem to be not always clear. Little systematic investigation has been known in this field.

In the course of studies on the photochemistry of imides,[5)] we and other groups have found in the photoreactions of phthalimide-olefin systems a variety of alcohol(solvent)-incorporated intermolecular addition[6)] and intramolecular cyclization products,[7)] which seem to occur *via* electron-transfer process. However, the imides employed in the previous investigations have been confined to phthalimides, and little information has been reported on the effects of arene structures of arenedicarboximides (aromatic imides).[8)] Our studies have been focused on the effects of extended π-conjugation system in the arene structure.[9)]

Here we report the results of intermolecular photoreactions of *N*-methylbiphenyl-2,2′-dicarboximide (**1**) and *N*-ethylnaphthalene-1,8-dicarboximide (**2**) with 1,1-diphenylethylene (**3**), and intramolecular photoreactions of *N*-(2- and 3-phenylallyl)biphenyl-2,2′- and naphthalene-1,8-dicarboximides in methanol, comparing with those of the phthalimide derivatives. The results indicate that the structure of the aromatic imide play an important role to determine the reaction courses after the photochemical electron-transfer process.

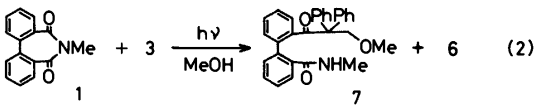
Results

Intermolecular Photoreactions of Aromatic Imides with 3 in Methanol. Photoreaction of *N*-methylphthalimide (**4**) (9.9 mM, 1 mM = 1×10^{-3} mol dm^{-3}) with **3** (12 mM) under N_2 for 5 h gave methanol-incorporated adduct (**5**) (44%) and 2,2-diphenylethyl methyl ether (**6**) (12% based on used **4**) together with recovered **4** (36%) (Eq. 1) as previously reported.[6a,d)] Irradiation of **1**



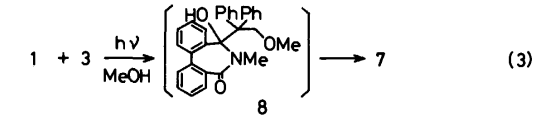
(1)

and **3** in similar conditions gave **7** (31%) and **6** (44%) together with recovered **1** (58%) (Eq. 2). The product



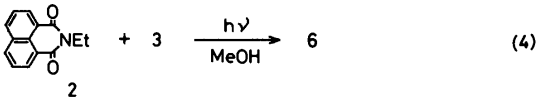
(2)

(**7**) is probably derived from a primary adduct (**8**) by 1,3-hydrogen migration which is the familiar reaction in the imide photochemistry (Eq. 3).[10)] Irradiation



(3)

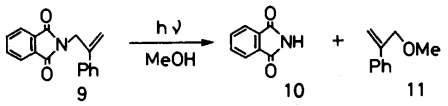
of **2** and **3** in similar conditions gave **6** (70%) together with recovered **2** (93%) (Eq. 4). In Eq. 4, **2** acts as a



(4)

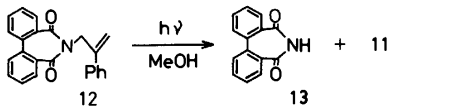
typical electron-transfer photosensitizer for the *anti*-Markovnikov addition of methanol to **3**.[4] The results of the intermolecular reaction show that the yields of the methanol-incorporated adducts (**5** and **7**) decreases, and at the same time the yield of **6** increases, with extension of the conjugated aromatic π-system of the aromatic imide.

Intramolecular Photoreactions of N-(2-Phenylallyl) Aromatic Imides in Methanol. Photoreaction of *N*-(2-phenylallyl)phthalimide (**9**) (0.6 mM) in methanol was reported to give methanol-incorporated elimination products, phthalimide (**10**) (30%) and 3-methoxy-2-phenyl-1-propene (**11**) (30%) (Eq. 5).[7a]



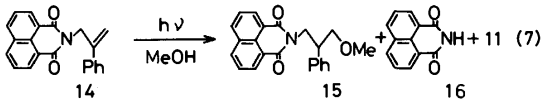
9 10 11 (5)

Irradiation of *N*-(2-phenylallyl)biphenyl-2,2′-dicarboximide (**12**) (0.4 mM) in methanol similarly gave biphenyl-2,2′-dicarboximide (**13**) (25%) and **11** (25%) (Eq. 6). Irradiation of *N*-(2-phenylallyl)naphtha-



12 13 (6)

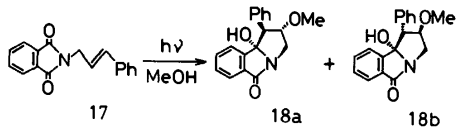
lene-1,8-dicarboximide (**14**) (0.5 mM) in methanol gave an *anti*-Markovnikov adduct of methanol (**15**) (27%), naphthalene-1,8-dicarboximide (**16**) (20%), and **11** (22%) (Eq. 7). Thus, the electron-transfer photo-



14 15 16 (7)

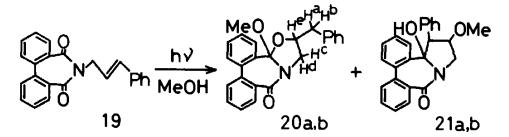
sensitized addition of methanol was observed only in the reaction of **14** which had the most extended aromatic π-system.

Intramolecular Photoreactions of N-(trans-3-Phenylallyl) Aromatic Imides in Methanol. Photoreaction of *N*-(*trans*-3-phenylallyl)phthalimide (**17**) (5 mM) in methanol was reported to give methanol-incorporated *C*-cyclized products [**18a** (68%) and **18b** (17%)] (Eq. 8).[7a,e]



17 18a 18b (8)

Irradiation of *N*-(*trans*-3-phenylallyl)biphenyl-2,2′-dicarboximide (**19**) (3.3 mM) in methanol gave a mixture of two groups of products; *i.e.*, two stereoisomers of methanol-incorporated *O*-cyclized products [**20a** (30%) and **20b** (5%)], and two stereoisomers of methanol-incorporated *C*-cyclized products [**21a** (21%) and **21b** (17%)] (Eq. 9). The isomers were isolated by

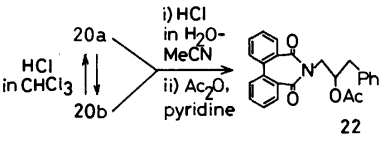


19 20a,b 21a,b (9)

chromatography.

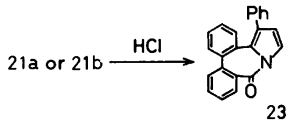
The structures of **20a** and **20b** were assigned on the basis of the spectral data and chemical manipulations outlined below. Combination of the ^{1}H and ^{13}CNMR multiplicity and chemical shifts, and the IR data gave rise to at least four characteristic common features in the structures of **20a** and **20b**. Namely, (i) one amide group [**20a**: IR-1640 cm^{-1}: ^{13}C NMR δ=165.1 (s), **20b**: IR-1628 cm^{-1}: ^{13}C NMR δ=165.1 (s)], but no hydroxyl group (IR), is present. (ii) The benzyl moiety is directly bonded to a ring system and characterized by having the triplet carbon [**20a**: δ=39.6 (t), **20b**: δ=39.3 (t)], and the nonequivalent methylene protons (H^a and H^b). (iii) One quaternary carbon atom [**20a**: δ=108.8 (s), **20b**: δ=109.5 (s)] corresponds reasonably to the acetal carbon [arom-*C*(OMe)(O-)N] adjacent to an aromatic system. (iv) Protons in the methoxyl group [**20a**: δ=2.83 (s), **20b**: δ=2.90 (s)] are strongly shielded by the biphenyl group.

As expected from the acetal structures, **20a** and **20b** were found to be highly sensitive to acid. Thus, on treatment with hydrochloric acid in chloroform, both of pure **20a** and **20b** were converted to an equilibrium mixture of **20a**:**20b**=0.63:1, probably *via* a stable tertiary carbonium ion intermediate. In addition, treatment of a mixture of **20a** and **20b** (6:1) with hydrochloric acid in acetonitrile-water (4/1 volume ratio) followed by acetylation with acetic anhydride and pyridine gave an imide (**22**) (70%) (Eq. 10).



22 (10)

The structures of **21a** and **21b** were deduced from the similarity of the spectral data to those of **18a** and **18b**.[7a] As expected, an elimination product (**23**) was formed quantitatively from each of **21a** and **21b** upon treatment with hydrochloric acid in chloroform (Eq. 11).

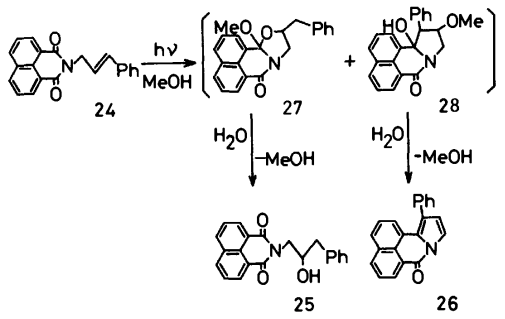


23 (11)

Photoreaction of **19** (3.3 mM) in 50 ml of methanol-d_1 (>99%) was carried out to examine the deuterium incorporation in **21a**. The ^{1}H NMR spectrum of the isolated **21a** showed that the integration of H^a and H^b signals was reduced to 55±5% compared with those of

the other signals, although the ratio of the integration of H^a to that of H^b could not be determined because of the considerable overlapping of these signals. The result indicates almost quantitative one-deuterium incorporation at the benzylic position (H^a and H^b) of **21a**.

Irradiation of *N*-(*trans*-3-phenylallyl)naphthalene-1,8-dicarboximide (**24**) (3.5 mM) in methanol followed by chromatographic (SiO_2) separation gave **25** (58%) and **26** (trace) (Scheme 1). That the products **25** and



Scheme 1.

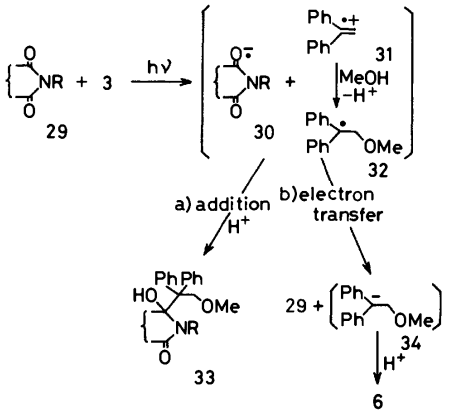
26 were not observed in the reaction mixture immediately after the photolysis suggested the isolated products were derived from primary products during the separation. The primary products could not be obtained probably due to their instability. However, the primary photoproducts are presumed to be methanol-incorporated *O*-cyclized products (**27**) for **25**, and methanol-incorporated *C*-cyclized products (**28**) for **26**, respectively, in view of the results obtained in the photolysis of **19**.

Triplet Photosensitization of 19. The photocyclization of **19** (styryl moiety, E_T=59.8 kcal mol^{-1})[11] was not sensitized by benzophenone (E_T=69.2 kcal mol^{-1})[12] as a triplet sensitizer. The benzophenone sensitization in methanol gave only an equilibrium mixture of **19** and the *cis* isomer (0.4:0.6). The result seems to indicate that the photocyclization of **19** directly occurs from the singlet excited state of the aromatic imide moiety.

Discussion

Mechanism on the Intermolecular Photoreactions of Aromatic Imides with 3 and Intramolecular Photoreactions of N-(2-Phenylallyl) Aromatic Imides. Photoreaction of *N*-methylnaphthalene-1,8-dicarboximide and **3** in benzene, a nonpolar solvent, was reported to give a cyclobutane.[9a] In benzene no photoreaction of **1** and **3** was observed even on the prolonged irradiation. However, in methanol the distinct mode of photoreactions was observed as described above.

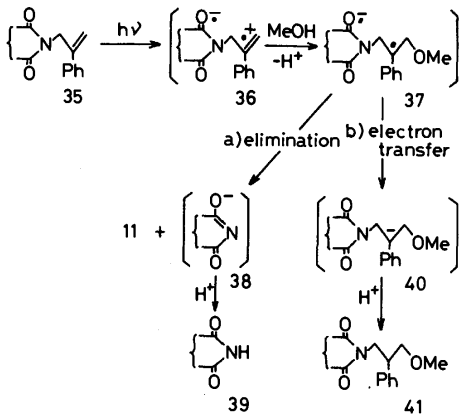
A reasonable mechanism for the intermolecular photoreactions of **1**, **2**, and **4** with **3** is shown in Scheme 2, where **1**, **2**, and **4** are denoted as **29**. The singlet excited state of the imides readily undergoes



Scheme 2.

one-electron reduction through interaction with the electron-rich olefin **3** to give **30** and **31**. The cation radicals **31** are captured by methanol to give **32**. Whether the methanol-incorporated addition to the imide carbonyl group or the *anti*-Markovnikov addition of methanol to **3** predominates is controlled at this stage by the relative rate of bond formation between **30** and **32** to generate the coupling products **33** (path a) *vs.* electron-transfer from **30** to **32** to produce an alkyl anion (**34**) (path b). The results of photoreaction of **1**, **2**, and **4** with **3** suggest the path b is more efficient than the path a in the photoreaction of imide which has the more extended aromatic π-system.

A mechanism for the intramolecular photoreactions of **9**, **12**, and **14** is shown in Scheme 3, where **9**,



Scheme 3.

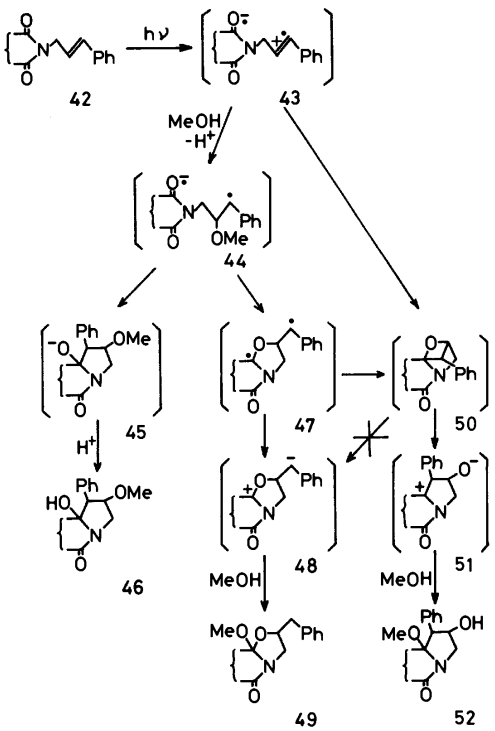
12, and **14** are denoted as **35**. Whether the elimination induced by methanol-incorporation or the *anti*-Markovnikov addition of methanol to the olefinic moiety predominates is also controlled by the relative rate of bond cleavage of the 1,4-biradical (**37**) to generate the elimination products (**11** and **39**) (path a) *vs.* the intramolecular electron transfer within **37** to produce an alkyl anion (**40**). The results suggest that the path b can compete with the path a only in the photoreaction of imide **14** which has the most extended aromatic π-system.

The alternative of the path a or the path b in the both photoreactions might be due to the ability of the radical anion of the imide moiety to serve as a reducing agent in reduction of the alkyl radical moiety in path b.[13] The relative reduction potentials of the imide moiety can be used to estimate the energetics and, thus, the rate for the electron transfer processes. However, the one-electron reduction potential of phthalimide (**10**) ($E_{1/2}=-1.47$ V)[14] is somewhat lower than that of naphthalene-1,8-dicarboximide (**16**) ($E_{1/2}=-1.25$ V).[14] Thus, the electron-transfer from the radical anion of naphthalene-1,8-dicarboximide moiety to the alkyl radical moiety (path b) would be expected to be less competitive with the path a than for the case of the corresponding phthalimide moiety, inconsistently with the results.

The alternative of the path a or the path b may be due to the ability of the radical anion of the imide moiety to serve as a radical reactant with the alkyl radical moiety in path a. In the case the relative spin densities of the radical anion of imide moieties can be used to estimate the rate for the radical reaction processes. In accord with the results, the calculated spin density (McLachlan method) at the carbonyl carbon of the radical anion of **10** (0.174) was reported to be considerably larger than that of **16** (0.067).[14] Consequently, whether the reaction proceeds by the path a or the path b seems to mainly depend on the ability of the radical anion of the imide moiety to serve as a radical reactant with the alkyl radical moiety in path a, which is reflected in the relative spin densities of the radical anion of the aromatic imide.

Mechanism on the Intramolecular Photoreactions of N-(trans-*3-Phenylallyl) Aromatic Imides.* The two types of products, *O*-cyclized and *C*-cyclized products, were obtained in the photoreaction of **19** and **24**. Especially, the *O*-cyclization seems to be novel in the photochemistry of the carbonyl compounds.

A possible mechanistic scheme for the intramolecular photo-reaction of **17**, **19**, and **24** is shown in Scheme 4, where **17**, **19**, and **24** are denoted as **42**. The initial step is photoinduced intramolecular electron-transfer from the electron-donating double bond to the excited imide moiety to form an intermediate (**43**), in analogy with the cases of the other systems. Successive anti-Markovnikov addition of methanol to the radical cation moiety results in the formation of **44**. The divergent behavior of these systems stems from the variable reactivity of the intermediate (**44**). From the intermediate, intramolecular coupling (cyclization) of the aromatic imide radical anion moiety and alkyl radical moiety (**44**→**45**), followed by protonation (**45**→**46**), gives *C*-cyclized products (**46**).[7a] Alternatively, intramolecular nucleophilic attack of the aromatic imide radical anion moiety accompanying elimination of methoxide ion (**44**→**47**), followed by intramolecular electron transfer (**47**→**48**) and polar addition of methanol (**48**→**49**), results in



Scheme 4.

the formation of the *O*-cyclized products (**49**). One deuterium incorporation at the benzylic position of **21a** in the photoreaction in methanol-d_1 supports the presence of the zwitter-ionic precursor (**48**). Whether the intramolecular coupling (radical reaction) (**44**→**45**) or the nucleophilic attack (**44**→**47**) predominates seems to depend on the ability of the radical anion of the imide moiety to serve as a radical reactant with the alkyl radical moiety, which is reflected in the relative spin densities of the radical anion of the aromatic imide, in analogy with the cases of the intermolecular photoreaction and the intramolecular photo-reaction of *N*-(2-phenylallyl) aromatic imides.

Another mechanism for the *O*-cyclization of **42**, involving intramolecular oxetane formation might be considered, as the oxetane formation was sometimes reported in photoreactions of aromatic imides and olefins.[9b,15] However, heterolytic cleavage of the oxetane (**50**) derived from **43** or **47** was expected to occur at the C–O bond to give the more stable zwitter ion (**51**), rather than at the C–C bond of the oxetane ring to give **48**. Thus, the mechanism involving the oxetane formation could not rationalize the observed structures of the products. Furthermore, the expected methanol-adduct (**52**) from **51** was not observed in the photoreaction.

In conclusion, this work demonstrates that the structure of the aromatic imide (electron acceptor) play an important role to determine the reaction course after the photochemical electron transfer between the aromatic imide and the olefin (electron donor). These results are also of interest in terms of the effect of the geometrical situation between the acceptor and the

donor on the reaction course after the electron-transfer process.

Experimental

The mps were measured by a Yanagimoto micromelting point apparatus, and are uncorrected. ^{1}H NMR spectra were determined on a JEOL JNM-MH-100 spectrometer in $CDCl_3$ solution. IR spectra were obtained with a Hitachi 260-50 spectrophotometer. Mass spectra were measured on a JEOL JMS-DX-300 apparatus. Microanalyses were performed on a Yanagimoto CHN corder MT-2. UV irradiation was carried out with an Eikosha PIH 300-W high-pressure Hg-lamp through Pyrex filter under N_2 at ambient temperature. Column chromatography was done on Wakogel C-200 (silica gel, 74—149 μ). HPLC analyses were performed on a Hitachi 635 A apparatus.

Materials. *N*-Methylbiphenyl-2,2′-dicarboximide (**1**) and *N*-ethylnaphthalene-1,8-dicarboximide (**2**)[16] were prepared by the reaction of the corresponding anhydride and amine.

1: Mp 167—169 °C; ^{1}H NMR δ=3.51 (s, 3H, NMe), 7.4—8.0 (m, 8H, Arom H); IR (KBr) 1695 (imide), 1658 (imide), 1606, 1352, 1322, 740 cm^{-1}. Found: C, 75.89; H, 4.82; N, 5.96%. Calcd for $C_{15}H_{11}NO_2$: C, 75.93; H, 4.67; N, 5.90%.

The imides (**12**, **14**, **19**, and **24**) were prepared by the reaction of the corresponding imide and halide in an analogous manner as described in the preparation of *N*-alkenylphthalimides.[7a]

N-(2-Phenylallyl)biphenyl-2,2′-dicarboximide (12): From the reaction of **13** and 3-bromo-2-phenyl-1-propene,[17] 60% based on the bromide; mp 95—97 °C (from ethanol): ^{1}H NMR δ=5.01 (s, 1H, C=CH_2), 5.11 (s, 2H, NCH_2), 5.29 (s, 1H, C=CH_2), 7.2—8.0 (m, 13H, arom H); IR (KBr) 1688 (imide), 1640 (imide), 1358, 1238, 736 cm^{-1}. Found: C, 81.50; H, 5.20; N, 4.08%. Calcd for $C_{23}H_{17}NO_2$: C, 81.39; H, 5.05; N, 4.13%.

N-(2-Phenylallyl)naphthalene-1,8-dicarboximide (14): From the reaction of **16** and 3-bromo-2-phenyl-1-propene, 53% based on the bromide; mp 181—183 °C (from ethanol); ^{1}H NMR δ=4.97 (s, 1H, C=CH_2), 5.19 (s, 2H, NCH_2), 5.32 (s, 1H, C=CH_2), 7.2—7.7 (m, 5H, Ph), 7.74 (t, 2H, arom H), 8.23 (d, 2H, arom H), 8.63 (d, 2H, arom H); IR (KBr) 1698 (imide), 1658 (imide), 1348, 1236, 782 cm^{-1}. Found: C 80.58; H, 4.96; N, 4.50%. Calcd for $C_{21}H_{15}NO_2$: C, 80.49; H, 4.83; N, 4.47%.

N-(trans-3-Phenylallyl)biphenyl-2,2′-dicarboximide (19): From the reaction of **13** and cinnamyl chloride,[18] 80% based on the chloride; mp 155—157 °C (from ethanol); ^{1}H NMR δ=4.81 (d, *J*=6 Hz, 2H, NCH_2), 6.28 (dt, *J*=6, 16 Hz, 1H, CH_2CH=C), 6.66 (d, *J*=16 Hz, 1H, PhC*H*=C), 7.1—8.0 (m, 13H, arom H); IR (KBr) 1702 (imide), 1662 (imide), 1340, 1328, 746 cm^{-1}. Found: C, 81.63; H, 5.26; N, 4.16%. Calcd for $C_{23}H_{17}NO_2$: C, 81.39; H, 5.05; N, 4.13%.

N-(trans-3-Phenylallyl)naphthalene-1,8-dicarboximide (24): From the reaction of **16** and cinnamyl chloride, 75% based on the chloride; mp 149—151 °C (from ethanol); ^{1}H NMR δ=4.93 (d, *J*=6 Hz, 2H, NCH_2), 6.37 (dt, *J*=6, 16 Hz, 1H, CH_2CH=C), 6.76 (d, *J*=16 Hz, 1H, PhC*H*=C), 7.0—7.5 (m, 5H, Ph), 7.72 (t, 2H, arom H), 8.18 (d, 2H, arom H), 8.58 (d, 2H, arom H); IR (KBr) 1704 (imide), 1670 (imide), 1388, 1340, 1242, 786 cm^{-1}. Found: C, 80.27; H, 5.02; N, 4.41%. Calcd for $C_{21}H_{15}NO_2$: C, 80.49; H, 4.83; N, 4.47%.

1,1-Diphenylethylene (**3**) was a commercial sample from Tokyo Chemical Industry.

Intermolecular Photoreactions of Aromatic Imides with 3. Solutions of aromatic imide (**1** and **2**) (9.9 mM) and **3** (12 mM) in 20 cm^3 of methanol were irradiated for 5 h. After evaporation of the solvent, the residue was subjected to chromatography to give the products. 2,2-Diphenylethyl methyl ether (**6**) was identical with a sample prepared by irradiation of *p*-dicyanobenzene, **3**, and phenanthrene (sensitizer) in methanol.[4a] On the other hand, the irradiated methanol solutions were analyzed by HPLC and ^{1}H NMR measurements with an internal standard to determine the yields of the products.

N-Methyl-2′-(2,2-diphenyl-3-methoxy-1-oxopropyl)biphenyl-2-carboxamide (7): Mp 156—158 °C; ^{1}H NMR δ=2.49 (d, *J*=4 Hz, 3H, NH*Me*, these signals were changed to s by shaking with D_2O), 3.14 (s, 3H, OMe), 4.23 and 4.37 (ABq, *J*=19 Hz, 2H, CH_2OMe), 6.9—7.9 (m, 19H, arom H+NH); IR (KBr) 3370 (NH), 1672 (amide and ketone), 1542, 1232, 758, 702 cm^{-1}. Found: C, 80.31; H, 6.00; N, 3.15%; M$^+$, 449. Calcd for $C_{30}H_{27}NO_3$: C, 80.15; H, 6.05; N, 3.12%; M, 449.

Intramolecular Photoreactions of N-(2-Phenylallyl) Aromatic Imides. Solutions of *N*-(2-phenylallyl) aromatic imides (**12** and **14**) in 400 cm^3 of methanol were irradiated for 5 h. After evaporation of the solvent, the residue was subjected to chromatography to give the products. 3-Methoxy-2-phenyl-1-propene (**11**) was identical with an authentic sample.[19] Biphenyl-2,2′-dicarboximide (**13**) was identical with an authentic sample.[20] Naphthalene-1,8-dicarboximide (**16**) was also identical with a commercial sample from Nakarai Chemical Industry. On the other hand, the irradiated methanol solutions were analyzed by HPLC and ^{1}H NMR measurements with an internal standard to determine the yields of the products.

N-(3-Methoxy-2-phenylpropyl)naphthalene-1,8-dicarboximide (15): Mp 115—117 °C; ^{1}H NMR δ=3.21 (s, 3H, OMe), 3.5—3.8 [m, 3H, PhC(*H*)CH_2OMe], 4.36 (dd, *J*=7, 12 Hz, 1H, NCH_2), 4.58 (dd, *J*=6, 12 Hz, 1H, NCH_2), 7.1—7.5 (m, 5H, Ph), 7.71 (t, 2H, arom H), 8.17 (d, 2H, arom H), 8.57 (d, 2H, arom H); IR (KBr) 1709 (imide), 1678 (imide), 1602, 1354, 1248, 802 cm^{-1}. Found: C, 76.41; H, 5.81; N, 3.97% M$^+$, 345. Calcd for $C_{22}H_{19}NO_3$: C, 76.50; H, 5.55; N, 4.06%; M, 345.

Intramolecular Photo-reaction of 19. A solution of **19** in 400 cm^3 of methanol was irradiated for 5 h. After evaporation of the solvent, the residue was subjected to chromatography to give the products. On the other hand, the irradiated methanol solution was analyzed by HPLC and ^{1}H NMR measurement with an internal standard to determine the yields of the products.

6-Benzyl-4b-methoxy-6,7-dihydro-4bH,9H-dibenz-[3′,4′:5′,6′]-azepino[2,1-b]oxazol-9-one Isomer A (20a): Mp 156—158 °C; ^{1}H NMR δ=2.83 (s, 3H, OMe), 2.95 (dd, *J*=6.1, 13.5 Hz, 1H, H^a), 3.27 (dd, *J*=6.4, 13.5 Hz, 1H, H^b), 3.42 (dd, *J*=9.6, 11.2 Hz, 1H, H^c), 4.19 (dd, *J*=5.9, 11.2 Hz, 1H, H^d), 4.5—5.0 (m, 1H, H^e), 7.1—8.1 (m, 13H, arom H); ^{13}C NMR δ=39.6 (t, CH_2Ph), 50.8 (q, OMe), 50.9 (t, NCH_2), 76.1 (d, OCH), 108.8 [s, Ph*C*(OMe)(O–)N], 125.1, 126.9, 127.7, 128.2, 128.4, 128.6, 129.2, 129.5, 129.7, 129.8, 129.9, 130.3, 130.9, 132.9, 135.7, 136.4, 137.3, 137.6 (18C, arom C), 165.1 (amide); IR (KBr) 1640 (amide), 1455, 1408, 1079, 1045, 742 cm^{-1}. Found: C, 77.62; H, 5.97; N, 3.68% M$^+$, 371. Calcd for $C_{24}H_{21}NO_3$: C, 77.60; H, 5.70; N, 3.77%; M, 371.

Isomer B (20b): Mp 150—152 °C; ^{1}H NMR δ=2.90 (s, 3H, OMe), 3.06 (dd, *J*=6.6, 13.9 Hz, 1H, H^a), 3.27 (dd, *J*=6.0, 13.9 Hz, 1H, H^b), 3.57 (dd, *J*=9.2, 11.0 Hz, 1H, H^c), 4.03 (dd, *J*=5.9, 11.0 Hz, 1H, H^d), 4.3—4.7 (m, 1H, H^e), 7.1—8.1 (m,

13H, arom H); ^{13}C NMR δ=39.3 (t, CH_2Ph), 49.7 (q, OMe), 50.5 (t, NCH_2), 75.6 (d, OCH), 109.5 [s, Ph*C*(OMe)(O-)N], 123.0, 125.2, 127.0, 127.5, 128.0, 128.5, 128.7, 128.9, 129.2, 129.5, 129.9, 130.7, 131.4, 131.8, 136.0, 136.2, 138.0, 138.4 (18C, arom C), 165.1 (amide); IR (KBr) 1628 (amide), 1458, 1419, 1122, 742 cm^{-1}. Found: C, 77.86; H, 5.91; N, 3.82%; M$^+$, 371. Calcd for $C_{24}H_{21}NO_3$: C, 77.60; H, 5.70; N, 3.77% M, 371.

4b-Hydroxy-6-methoxy-5-phenyl-4b,5,6,7-tetrahydro-9H-dibenzo[c,e]pyrrolo[1,2-a]azepin-9-one Isomer A (21a): Mp 191—192.5 °C; ^{1}H NMR δ=3.51 (s, 3H, OMe), 3.86 (dd, J=4, 13 Hz, 1H), 4.2 (br s, 1H, OH), 4.24 (dd, J=7, 13 Hz, 1H), 4.28 (d, J=3 Hz, 1H), 4.2—4.5 (m, 1H), 6.9—7.0 (m, 2H, arom H), 7.1—7.6 (m, 9H, arom H), 7.9—8.1 (m, 1H, arom H); IR (KBr) 3280 (OH), 1640 (amide), 1460, 1420, 1130, 755, 713 cm^{-1}. Found: C, 77.46; H, 5.62; N, 3.80%; M$^+$, 371. Calcd for $C_{24}H_{21}NO_3$: C, 77.60; H, 5.70; N, 3.77%; M, 371.

Isomer B (21b): Mp 213—215 °C; ^{1}H NMR δ=2.8 (br s, 1H, OH), 3.26 (s, 3H, OMe), 3.34 (d, J=10 Hz, 1H), 4.2—4.4 (m, 1H), 4.5—4.7 (m, 1H), 7.1—8.0 (m, 13H, arom H); IR (KBr) 3280 (OH), 1610 (amide), 1455, 1416, 1108, 743, 708 cm^{-1}. Found: C, 77.87; H, 5.50; N, 3.85%; M$^+$, 371. Calcd for $C_{24}H_{21}NO_3$: C, 77.60; H, 5.70; N, 3.77%; M, 371.

Acid Isomerization and Degradation of 20a and 20b. To a solution of 30 mg of **20a** in 10 cm^3 of chloroform was added a few drops of hydrochloric acid. After 1 d, the solution was washed with water and dried. Then, after evaporation of the solvent, the residue was examined by measurement of ^{1}H NMR spectrum with an internal standard to contain a mixture of **20a** and **20b** (the isomer ratio was 0.63:1, the total yield was 78%). A similar result was obtained starting from 15 mg of **20b**.

To a solution of 30 mg of a mixture of **20a** and **20b** (6:1) in 30 cm^3 of acetonitrile-water (4/1 volume ratio) added a few drops of hydrochloric acid. After 1 d, the solvent was evaporated and the residue was subjected to chromatography to give an alcohol. ^{1}H NMR spectrum of the alcohol could not be obtained due to the low solubility in $CDCl_3$. Thus, the alcohol was converted to its acetate (**22**) (70% based on **20a**+**20b**) by acetic anhydride and pyridine.

N-(2-Acetoxy-3-phenylpropyl)biphenyl-2,2'-dicarboximide (22): Mp 117—120 °C; ^{1}H NMR δ=2.44 (s, 3H, OAc), 2.7—2.8 (m, 2H, CH_2Ph), 3.51 (dd, J=6, 14 Hz, 1H, NCH_2), 4.34 (dd, J=3, 14 Hz, 1H, NCH_2), 5.5—5.7 (m, 1H, CHOAc), 6.9—7.7 (m, 12H, arom H), 8.2 (dd, J=2, 7 Hz, 1H, arom H); IR (KBr) 1740 (ester), 1700 (imide), 1655 (imide), 1338, 1242, 1035, 744 cm^{-1}. Found: C, 74.91; H, 5.59; N, 3.48%; M$^+$, 399. Calcd for $C_{25}H_{21}NO_4$: C, 75.17; H, 5.30; N, 3.51%; M, 399.

Acid Degradation of 21a and 21b. To a solution of 30 mg of **21a** in 10 cm^3 of chloroform was added a few drops of hydrochloric acid. After 1 d, the solution was washed with water and dried. Then, after evaporation of the solvent, chromatography of the residue gave 22 mg (85%) of **23**. A similar result was obtained starting from 30 mg of **21b** (yield 76%).

5-Phenyl-9H-dibenzo[c,e]pyrrolo[1,2-a]azepin-9-one (23): Mp 169—171.5 °C; ^{1}H NMR δ=6.58 (d, J=3 Hz, 1H), 7.0—7.9 (m, 13H, arom H), 8.07 (d, 1H, arom H); IR (KBr) 1708 (amide), 1364, 1340, 704, 753 cm^{-1}. Found: C, 86.13; H, 4.62; N, 4.36%; M$^+$, 321. Calcd for $C_{23}H_{15}NO$: C, 85.96; H, 4.71; N, 4.36%; M, 321.

Intramolecular Photoreaction of 24. A solution of **24** in 400 cm^3 of methanol was irradiated for 5 h. After evaporation of the solvent, the residue was subjected to chromatography to give **25** and **26**. The primary photoproducts could not be obtained probably due to the instability on the separation. Chromatography on aluminium oxide also gave **25** and **26**. The ^{1}H NMR spectrum of the irradiation mixture revealed that the **25** and **26** were not the primary products, and the primary products showed mainly two methoxy singlets at δ=2.84 and 3.02 (intensity ratio 4:1).

N-(2-Hydroxy-3-phenylpropyl)naphthalene-1,8-dicarboximide (25): Mp 148—150 °C; ^{1}H NMR δ=2.5—2.7 (br s, 1H, OH), 2.8—3.0 (m, 2H, CH_2Ph), 4.2—4.4 (m, 3H, NCH_2CH OH), 7.1—7.4 (m, 5H, Ph), 7.67 (t, 2H, arom H), 8.14 (d, 2H, arom H), 8.51 (d, 2H, arom H); IR (KBr) 3500 (OH), 1702 (imide), 1644 (imide), 1592, 1236, 782 cm^{-1}. Found: C 76.10; H, 4.99; N, 4.31%; M$^+$, 331. Calcd for $C_{21}H_{17}NO_3$: C, 76.12; H, 5.17; N, 4.23%; M, 331. Its acetate: mp 117—120 °C; ^{1}H NMR δ=1.81 (s, 3H, OAc), 3.02 (d, J=7 Hz, 2H, CH_2Ph), 4.23 (dd, J=3, 13 Hz, 1H, NCH_2), 4.59 (dd, J=9, 13 Hz, 1H, NCH_2), 5.6—5.8 (m, 1H, CHOAc), 7.0—7.4 (m, 5H, Ph), 7.67 (t, 2H, arom H), 8.14 (d, 2H, arom H), 8.53 (d, 2H, arom H); IR (KBr) 1732 (ester), 1703 (imide), 1672 (imide), 1596, 1341, 1243, 786 cm^{-1}. Found: C, 73.84; H, 5.29; N, 3.72%; M$^+$, 373. Calcd for $C_{23}H_{19}NO_4$: C, 73.98; H, 5.13; N, 3.75%; M, 373.

11-Phenyl-7H-benzo[de]pyrrolo[2,1-a]isoquinolin-7-one (26): Mp 171—173 °C; ^{1}H NMR δ=6.49 (d, J=4 Hz, 1H), 7.1—8.0 (m, 10H, arom H), 8.13 (d, J=7 Hz, 1H, arom H), 8.69 (d, J=7 Hz, 1H, arom H); IR (KBr) 1715 (amide), 1590, 1321, 785 cm^{-1}. Found: C, 85.47; H, 4.30; N, 4.77%; M$^+$, 295. Calcd for $C_{21}H_{13}NO$: C, 85.40; H, 4.44; N, 4.74%; M, 295.

Triplet Photosensitization of 19. The photoreaction of **19** (3.3 mM) in the presence of benzophenone (30 mM) was carried out with light of >340 nm (filter: Pyrex and aq 5,7-dimethyl-1,4-diazacyclohepta-4,7-dienium perchlorate[21]) in methanol. The irradiated methanol solution was analyzed by HPLC with an internal standard to determine the yields of the products. The *cis* isomer of **19** was obtained by the repeated recrystallization (ethanol) of the irradiated mixture.

N-(cis-3-Phenylallyl)biphenyl-2,2'-dicarboximide: Mp 136—138 °C; ^{1}H NMR δ=4.98 (dd, J=2, 7 Hz, 2H, NCH_2), 5.65 (dt, J=7, 12 Hz, 1H, NCH_2CH=C), 6.58 (dt, J=2, 12 Hz, 1H, C=CHPh), 7.2—8.0 (m, 13H, arom H); IR (KBr) 1692 (imide), 1658 (imide), 1360, 1342, 1318, 738 cm^{-1}. Found: C, 81.11; H, 5.10; N, 4.05%. Calcd for $C_{23}H_{17}NO_2$: C, 81.39; H, 5.05; N, 4.13%.

The authors wish to express their thanks to Mrs. Yukimi Kinuta and Mr. Tetsufumi Misawa for their experimental assistance. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 574199 from the Ministry of Education, Science and Culture.

Interaction of Hydrophobic Cyclic Dipeptides and Acylbenzenes as Studied by Fluorescent Quenching

Toshiro Ootubo, Shunsaku Kimura, and Yukio Imanishi*
Department of Polymer Chemistry, Kyoto University, Yoshida Honmachi, Sakyo-ku, Kyoto 606
(Received May 24, 1985)

The effect of the hydrophobic interaction on the association in aqueous media of tyrosine-containing cyclic dipeptides and 1-acyl-4-bromobenzenes having various lengths of acyl chain was investigated by quenching of the fluorescence of the former compounds by the latters. In ethanol, the change of fluorescence intensity (I_0/I) was linearly related to the quencher concentration according to the Stern-Volmer's plot, which was attributed to a dynamic quenching. In this case, structures of fluorophores and quenchers did not affect the quenching constant. However, in a buffer solution, I_0/I was linearly related to the quencher concentration according to the Perrin's plot, which was attributed to a static quenching. Perrin's quenching constants depended on the structure of fluorophores and quenchers. In some cases, a quencher molecule was bound to a fluorophore by hydrophobic interaction in a favorable arrangement for fluorescent quenching. In aqueous solution, fluorophores and quenchers formed comparatively large aggregates with nonspecific arrangement for fluorescent quenching. In this case, Perrin's quenching constants were independent of the nature of quenchers and related with the size of formed aggregates.

Recognition of substrates by enzymes and of agonists by receptors is very important as the beginning step of physiological responses. Hydrophobic and electrostatic interactions are particularly important in biological host-guest interactions. However, the contribution of the hydrophobic interaction has not quantitatively been investigated.[1] Cyclic peptides provide a useful model system for the study of the hydrophobic interaction in the enzyme-mimetic reaction, because the possible conformations of cyclic peptides are very restricted due to the cyclic structure.[2] Histidine-containing cyclic dipeptides have been investigated for the hydrolytic catalyst.[3-8] Tanihara, *et al.* showed that a substrate was bound to a cyclic peptide by hydrophobic interaction and the rate of the hydrolysis of the substrate was enhanced because of a favorable orientation of the bound substrate toward a catalytic group of the cyclic dipeptide.[9] However, since the observed reaction rate constant is a function of either the substrate binding or the intramolecular attack by a catalytic group, the hydrophobic effect on the binding step was not estimated in a quantitative way.

In the present investigation cyclic dipeptides, which consist of a tyrosine and an aliphatic amino acid, were synthesized and their interactions with 1-acyl-4-bromobenzenes having various lengths of acyl chain were investigated by the fluorescence quenching measurement. The interaction between them in aqueous media was believed to occur by hydrophobic forces. A quenching of tyrosine fluorescence by the bromobenzene moiety of the substrate is not affected by the orientation of functional groups in the associate, so that the interactions involved in the binding step can be characterized in a more quantitative way.

Experimental

Cyclic dipeptides, *cyclo*(D-Ala-CM-L-Tyr) (F(D-Ala)), *cyclo*(L-Leu-CM-L-Tyr) (F(L-Leu)), and *cyclo*(D-Leu-CM-L-Tyr) (F(D-Leu)), were synthesized according to the method reported by Kopple, *et al.*,[10] in which CM represents a carboxymethyl group introduced to the hydroxyl group of tyrosine to increase the water-solubility of cyclic dipeptides.

Quenchers, 1-acyl-4-bromobenzenes, used in the present investigation were $CH_3(CH_2)_nCOC_6H_4Br$(p) (n=0 (Q_1), 2 (Q_3), and 4 (Q_5)) and $HOOC(CH_2)_nCOC_6H_4Br$(p) (n=4 (Q_5^-) and 8 (Q_9^-)). Q_1, Q_3, and Q_5 were synthesized from bromobenzene and corresponding acyl chlorides using $AlCl_3$ as a catalyst, and Q_5^- and Q_9^- were synthesized by the hy-

drolysis of the reaction product between bromobenzene and monoethyl ester chloride of the corresponding diacid catalyzed by $AlCl_3$. All of the synthesized compounds were identified by IR, ^1H NMR, and elementary analysis.

Fluorescence measurements were carried out on a Hitachi MPF-4 spectrofluorometer at 50 °C. Excitation wavelengths were 277 and 278 nm in ethanol and aqueous solution, respectively. The concentration of fluorophore was 1×10^{-5} M (1 M=1 mol dm^{-3}). The quencher was added with an aliquot of ethanol solution (2×10^{-2} M). Buffer solution was prepared from tris(hydroxymethyl)aminomethane (pH 7.5, 10 mM).

Results and Discussion

Solvent Effect on the Interaction between Cyclic Dipeptides and Quenchers. The change of the fluorescence intensity of a fluorophore F(L-Leu) with the addition of a quencher Q_5 was determined and is shown in Fig. 1 in the form of the Stern-Volmer's plot. In ethanol, I_0/I (the fluorescence intensity without the quencher relative to that with the quencher) is linearly related to the quencher concentration. Therefore, the fluorophore is quenched by the quencher in diffusion-controlled collisions, which is a dynamic quenching.[11] On the other hand, in aqueous solution the plot between I_0/I and the quencher concentration gave a concave curve. However, Perrin's plot of I_0/I against the quencher concentration showed a linear relation in aqueous solution throughout this range of quencher concentration, whereas it led to a convex curve for quenching in ethanol solution (Fig. 2). Therefore, in aqueous solution, fluorophores and quenchers should form aggregates due to the hydrophobic interaction, which is a static quenching.[12]

The efficiency of quenching decreased in the order

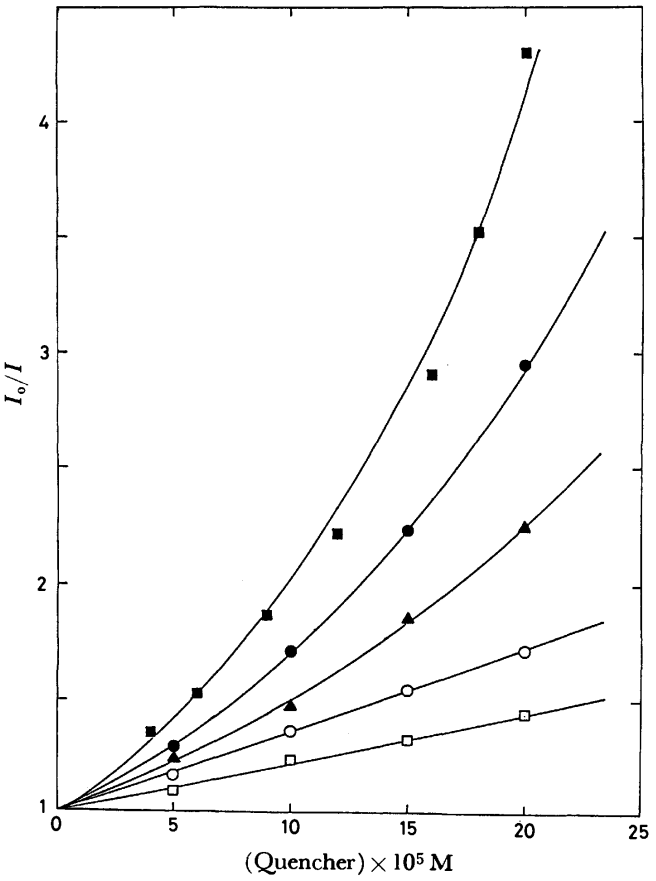

Fig. 3. Stern-Volmer's plot of the change of fluorescence intensity of F(L-Leu) with the addition of Q_5 in 20% dioxane/H_2O (■), 40% dioxane/H_2O (●), 60% dioxane/H_2O (▲), 80% dioxane/H_2O (○), and dioxane (□).

Table 1. Stern-Volmer's quenching constants ($k_Q \times 10^3\,M^{-1}$) in ethanol

Quencher	*Cyclo*(L-Leu-CM-L-Tyr)	*Cyclo*(D-Leu-CM-L-Tyr)	*Cyclo*(D-Ala-CM-L-Tyr)
$CH_3COC_6H_4Br(p)$	5.35	5.28	5.26
$CH_3(CH_2)_2COC_6H_4Br(p)$	5.31	5.19	5.28
$CH_3(CH_2)_4COC_6H_4Br(p)$	5.24	5.33	5.37

Table 2. Perrin's quenching constants ($k_Q \times 10^3\,M^{-1}$) in 20% dioxane/buffer

Quencher	*Cyclo*(L-Leu-CM-L-Tyr)	*Cyclo*(D-Leu-CM-L-Tyr)	*Cyclo*(D-Ala-CM-L-Tyr)
$CH_3COC_6H_4Br(p)$	6.14	6.00	5.77
$CH_3(CH_2)_4COC_6H_4Br(p)$	6.27	6.22	5.72
$HOOC(CH_2)_4COC_6H_4Br(p)$	5.94	5.72	5.69
$HOOC(CH_2)_8COC_6H_4Br(p)$	6.03	6.18	5.71

that 20% dioxane/H_2O>20% dioxane/buffer>ethanol. The influence of the solvent composition on the quenching of the fluorescence of F(L-Leu) by Q_5 was examined (Fig. 3). When the dioxane content was more than 80%, straight lines of the Stern-Volmer's plot was obtained. On the other hand, when the dioxane content was less than 80%, concave curves of the Stern-Volmer's plot were obtained. These results support the explanations for Figs. 1 and 2 that hydrophobic interactions are involved in the quenching process in aqueous solution.

Quenching in Ethanol. Stern-Volmer's quenching constants in ethanol were determined from the slope of the Stern-Volmer's plot and are summarized in Table 1. In all combinations of fluorophores and quenchers, a linear relation was obtained between I_0/I and the quencher concentration, and the quenching constants were almost the same for all combinations. Therefore, it is concluded that the fluorescence is quenched by the diffusion-controlled collision with a quencher, and that the structure of fluorophores and quenchers does not affect the quenching constant.

Quenching in 20% Dioxane/Buffer.

Perrin's quenching constants in 20% dioxane/buffer were determined from the slope of the Perrin's plot and are summarized in Table 2. In the case of F(D-Ala) the quenching constants by Q_1 and Q_5 or $Q_{\bar{5}}$ and $Q_{\bar{9}}$ were almost the same without the dependence on the length of acyl chain of the quencher. On the other hand, in the cases of F(L-Leu) and F(D-Leu) the quenching constants with Q_5 were larger than those with Q_1, and the quenching constants with $Q_{\bar{9}}$ were larger than those with $Q_{\bar{5}}$. These results can be explained by the difference of hydrophobic interactions between the cyclic dipeptides and the quenchers. The isobutyl substituent of F(L-Leu) or F(D-Leu) is hydrophobic enough to represent the difference of interaction due to different lengths of acyl chain. However, the methyl substituent of F(D-Ala) is not hydrophobic enough to represent different degrees of interaction.

When Q_1 and Q_5 were used as quenchers, the quenching constants decreased in the order that F(L-Leu)>F(D-Leu)>F(D-Ala). The same order was also found in the case of $Q_{\bar{5}}$ as a quencher. However, the quenching constant of F(D-Leu) with $Q_{\bar{9}}$ was larger than that of F(L-Leu). This is also shown in Fig. 4, which shows the change of Perrin's quenching constant as a function of the composition of F(D-Leu)/F(L-Leu) mixture. These results suggest that the orientation of F(D-Leu) with respect to $Q_{\bar{9}}$ might be specific as a result of the hydrophobic interaction between the long acyl chain of $Q_{\bar{9}}$ and the isobutyl substituent of F(D-Leu). In this case the bromobenzene moiety of the quencher could come close to the tyrosine residue. This consideration agrees with the result that *cyclo*(D-Leu-L-His) was a more efficient catalyst than *cyclo*(L-Leu-L-His) in the hydrolysis of *p*-nitrophenyl laurate and decanoate.[6,8] The efficient hydrolysis by *cyclo*(D-Leu-L-His) was explained in terms of the hydrophobic substrate bound by the hydrophobic interaction with isobutyl substituent of the cyclic dipeptide to a sterically favorable position for the intramolecular nucleophilic attack by the imidazolyl substituent.

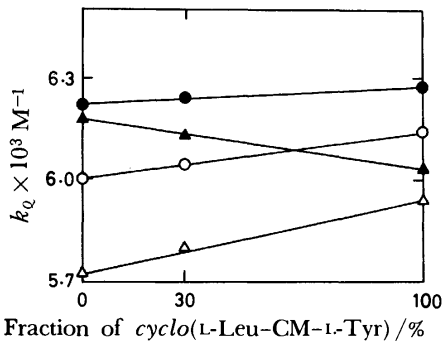

Fig. 4. Perrin's quenching constants of F(L-Leu), F(D-Leu), and their 3/7 mixture with the addition of Q_1 (○), Q_5 (●), $Q_{\bar{5}}$ (△), and $Q_{\bar{9}}$ (▲) in 20% dioxane/buffer.

Perrin's quenching constant of F(D-Leu) or F(L-Leu) with Q_5 was larger than that with $Q_{\bar{5}}$. The association of the fluorophore with $Q_{\bar{5}}$ might be weaker than that with Q_5 due to the electrostatic repulsion between the negative charges of the fluorophore and $Q_{\bar{5}}$.

TABLE 3. Perrin's QUENCHING CONSTANTS ($k_Q \times 10^3\ M^{-1}$) IN 20% DIOXANE/H_2O

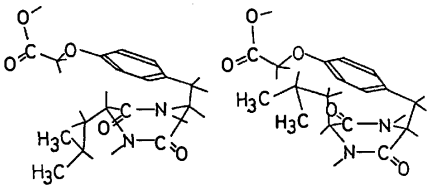
Quencher	*Cyclo*(L-Leu-CM-L-Tyr)	*Cyclo*(D-Leu-CM-L-Tyr)	*Cyclo*(D-Ala-CM-L-Tyr)
$CH_3COC_6H_4Br$(p)	7.00	6.32	6.04
$CH_3(CH_2)_2COC_6H_4Br$(p)	6.99	6.34	6.06
$CH_3(CH_2)_4COC_6H_4Br$(p)	7.01	6.34	6.07

TABLE 4. COUPLING CONSTANTS (Hz) OF $C^{\alpha}H$ AND $C^{\beta}H$ PROTONS, THE FRACTION OF SIDE CHAIN CONFORMERS (%), AND CHEMICAL SHIFTS (ppm) OF $C^{\alpha}H$ OF CYCLIC DIPEPTIDES

	Tyr residue				The other residue		
	$J_{\alpha-\beta}$		U/%	F/%	$C^{\alpha}H$	$C^{\alpha}H$	Solvent
Cyclo(L-Leu-CM-L-Tyr)	4.15	5.34	39.3	60.7	4.22	3.51	C_2D_5OD
	3.92	4.88	31.8	68.2	4.49	3.85	D_2O (pH=7.5)
Cyclo(D-Leu-CM-L-Tyr)	4.19	4.63	32.6	67.4	4.28	2.94	C_2D_5OD
	3.96	4.64	30.9	69.1	4.63	3.33	D_2O (pH=7.5)
Cyclo(D-Ala-CM-L-Tyr)	3.67	4.88	30.6	69.4	4.17	2.85	C_2D_5OD
	3.86	4.68	30.3	69.7	4.49	3.22	D_2O (pH=7.5)

Quenching in 20% Dioxane/H_2O. Perrin's quenching constants in 20% dioxane/H_2O were determined by the same method as employed in the preceding section, and are shown in Table 3. The quenching constants decreased in the order that F(L-Leu)> F(D-Leu)>F(D-Ala), and this order was obtained with any kinds of quenchers examined. Furthermore, the quenching constants are independent of the length of acyl chain of quenchers, indicating the absence of any specific interactions. Carboxyl groups do not completely dissociate under experimental conditions, and a large aggregate of cyclic dipeptides and quenchers might be formed by hydrophobic interaction. The aggregate is not expected to take any defined structure, which might be the reason for the absence of specific interaction in quenching process.

Different quenching constants between F(L-Leu) and F(D-Leu) should be attributable to different orientations of the side chains in the cyclic dipeptides, which were investigated by the H-C^{α}-C^{β}-H coupling constants ($J_{\alpha-\beta}$) of NMR spectra. The aromatic group can take either a folded form (F) or two unfolded forms (U). In the folded form, the aromatic group protrudes over the plane of the cyclic dipeptide. The fractions were calculated according to Pachler's equation[13] and are shown in Table 4. The predominant conformation was found to be the folded form for all cyclic dipeptides, and the solvent effect on the conformation was not remarkable. Another evidence for the aromatic group stacking over the 2,5-piperazinedione ring is obtained from the chemical shifts of $C^{\alpha}H$. The chemical shifts of $C^{\alpha}H$ of the Tyr residue and the other residue are shown in Table 4. The chemical shifts of Ala-$C^{\alpha}H$ of F(D-Ala) and Leu-$C^{\alpha}H$ of F(D-Leu) were found to shift to a higher magnetic field compared with 3.96 ppm for Leu-$C^{\alpha}H$ of *cyclo*(D-Leu-L-Leu) and 3.92 ppm for Leu-$C^{\alpha}H$ of *cyclo*(L-Leu-L-Leu), which do not contain an aromatic amino acid, in CD_3OD, and 3.51 ppm for Leu-$C^{\alpha}H$ of F(L-Leu) in C_2D_5OD. This observation may be explained in terms that in the cases of F(D-Ala) and F(D-Leu), $C^{\alpha}H$ of the Ala or Leu residue and the aromatic group of Tyr residue stick out on the same side of the cyclic skeleton, and that the aromatic group protrudes over the $C^{\alpha}H$, that is, indicating a folded structure. The folded conformations are depicted in Fig. 5, which may explain a larger quenching constant of F(L-Leu) than F(D-Leu). Since the molecular size of F(L-Leu) is more compact than that of F(D-Leu), the former is expected to form a larger hydrophobic aggregate than the latter, which, in turn, makes Perrin's active sphere overlap with each other and increases the ability of quencher apparently.



cyclo(D-Leu-CM-L-Tyr) *cyclo*(L-Leu-CM-L-Tyr)

Fig. 5 The folded conformations of F(D-Leu) and F(L-Leu).

In the case of the cyclic peptide, the specific interaction could be realized under the suitable combination of the hydrophobic and electrostatic interaction with the substrate.

Mechanism of the Direct and Triplet-sensitized Photolysis of *N*-(1-Naphthoyl)-*O*-(*p*-toluoyl)-*N*-phenylhydroxylamine

Tadamitsu SAKURAI,* Hidenori SUKEGAWA, and Hiroyasu INOUE
Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Kanagawa-ku, Yokohama 221
(Received May 29, 1985)

Quantum yields (Φ) were determined for benzophenone-sensitized and direct photolysis of the title hydroxylamine (NT). Analysis of linear Stern-Volmer plots of the reciprocal of Φ against the reciprocal of NT concentration reveals that the sensitized decomposition of NT takes place *via* its first triplet excited state (T_1) produced by triplet-triplet energy transfer from benzophenone to NT. The fact that the quantum yields for the direct photolysis are independent of NT concentration indicates no occurrence of both self-quenching and induced decomposition of NT by the photochemically generated radicals. Closer examination of the micellar and solvent viscosity effects on the quantum yields for the direct photolysis with 313-nm light shows the existence of at least two spin-correlated (singlet) radical pairs: One is a contact radical pair whose recombination eventually yields 1,3-toluoyloxyl-migrated product and the other a solvent-separated radical pair from which 1,5-toluoyloxyl-migrated product is derived in competition with diffusive escape from the solvent or micelle cage. Exclusive occurrence of the direct photolysis from the first singlet excited state (S_1) was explained on the basis of the large energy gap between S_1 and T_1 (31 kcal mol^{-1}) which is likely to make intersystem crossing from S_1 to T_1 very inefficient.

We have discussed qualitatively the mechanism of direct and triplet-sensitized photolysis of *N,O*-diacyl-*N*-phenylhydroxylamines on the basis of the chemical yields of photoproducts, and concluded that photoreactions under direct irradiations proceed exclusively through the singlet excited state affording 1,3- and 1,5-aroyloxyl-migrated products ("in-cage" products) along with the fragmentation products ("out-of-cage" products).[1] On the other hand, triplet-sensitized photolysis gives only the fragmentation products. These intriguing effects of spin multiplicity of the excited states that is responsible for the reaction on the product distribution gave an impetus to more quantitative investigation on the photolysis of *N,O*-diacylhydroxylamines. It has been also one of the important problems encountered in our previous work whether or not the "in-cage" products come from the reaction that takes place within the identical solvent cage. Thus the title hydroxylamine (NT) was chosen for the present study and quantum yields for the direct and sensitized photolysis of NT were determined in order to solve this problem and then shed more light on the mechanism of the photolysis under conditions where geminate radicals with different spin multiplicity are produced.

Results

Quenching of the Phosphorescence of Benzophenone by NT. To ensure the occurrence of triplet-triplet energy transfer from benzophenone (the first singlet excitation energy, E_{S_1}=74.4; the first triplet excitation energy, E_{T_1}=69.2 kcal mol^{-1}; 1 kcal=4.18 kJ)[2] to NT (E_{S_1}=90, E_{T_1}=59 kcal mol^{-1}),[1] phosphorescence quenching experiments were conducted under argon at room temperature (24±1 °C). This energy transfer can be clearly seen in the efficient quenching of sensitizer's emission that follows linear Stern-Volmer relationships with the slopes ($k_t\tau_T$ where k_t and τ_T are the rate constant for triplet energy transfer and the lifetime of triplet benzophenone without NT, respectively) of 1600 M^{-1} (1 M^{-1}=1 dm^3 mol^{-1}) in 1,2-dichloroethane and 2500 M^{-1} in acetonitrile (Fig. 1). These $k_t\tau_T$ values are collected in Table 1. From the reported lifetimes of triplet benzophenone in the absence of any quencher (τ_T=14 μs in carbon tetrachloride[3] and 26 μs in acetonitrile[4]), we obtain k_t=1.1×10^8 and 0.96×10^8 M^{-1}s^{-1} in 1,2-dichloroethane and acetonitrile, respectively. Under the present experimental conditions neither fluorescence nor phosphorescence of NT could be detected.

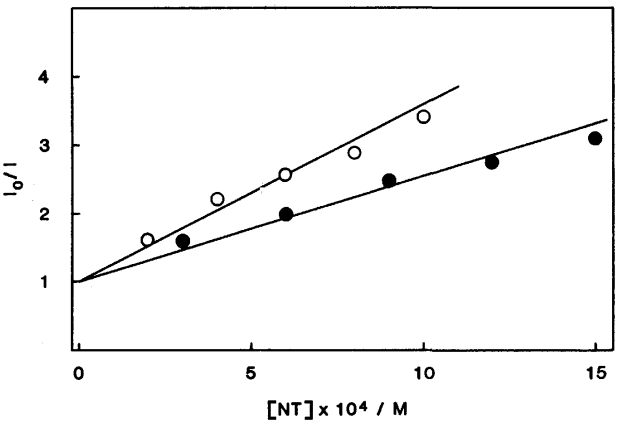

Fig. 1. Stern-Volmer plots of quenching of benzophenone (0.03 M) phosphorescence by NT in acetonitrile (○) and 1,2-dichloroethane (●) under argon at room temperature (24±1 °C). Excitation wavelength=366 nm. I and I_0 refer to the phosphorescence intensity of benzophenone with and without NT, respectively.

Quantum Yields for Triplet-sensitized Photolysis. As expected, irradiation of an N_2-saturated solution of NT (1.00—6.60 mM, 1 mM=10^{-3} mol dm^{-3}) in the presence of benzophenone (0.03 M) with 366-nm light led to only the fragmentation products **4—6**, as determined by HPLC analysis. Even trace amounts of

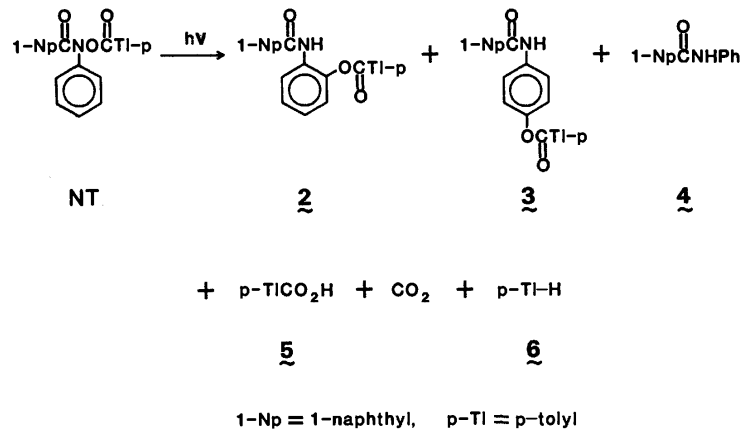
a) $\Phi_{-NT,lim}$, $\Phi_{4,lim}$, and $\Phi_{5,lim}$ are the limiting quantum yields (Φ_{lim}), *i.e.*, the quantum yields extrapolated to the infinite concentration of NT, for disappearance of NT and formation of **4** and **5**, respectively. b) Quantum yield for formation of **6** (GLC analysis) determined for 6.60 mM NT. c) Φ_2 and Φ_3 represent quantum yields for appearance of **2** and **3**, respectively. d) From quantum yield measurements. e) From quenching of sensitizer's phosphorescence by NT. f) From linear plot of $1/\Phi_{-NT}$ *vs.* 1/[NT]. g) From linear plot of $1/\Phi_5$ *vs.* 1/[NT]. h) From linear plot of $1/\Phi_4$ *vs.* 1/[NT].



the rearrangement products **2** and **3** could not be detected in this benzophenone-sensitized photolysis. The quantum yields (Φ) for the disappearance of NT and for the appearance of the products were determined by using a potassium trioxalatoferrate(III) actinometer. The large values of quantum yields indicate very efficient sensitized decomposition to take place (Table 1).

Control experiments demonstrate that no photolysis of NT occurs without the sensitizer and that the photoproducts **4**—**6** undergo negligible sensitized decomposition. One can see, however, some unknown HPLC peaks on the chromatograms in both solvents, which may be responsible for a little poor mass balance of the sensitized photolysis. No attempt to separate and identify these unknown products was made because this inevitable side reaction appears to make no serious trouble in discussing the reaction mechanism based on the quantum yields of the photoproducts in which we are interested. In addition, HPLC analysis of a 1,2-dichloroethane or an acetonitrile solution of benzophenone before and after the irradiation reveals that hydrogen abstraction from the solvent by the benzophenone triplet takes place to a negligible extent during the irradiation with 366-nm light.

If the triplet-sensitized reaction of NT with benzophenone (B) proceeds according to Scheme 1 in which Φ_{isc} refers to the quantum yield of intersystem crossing and is known to be unity, we expect a linear relation between $1/\Phi$ and 1/[NT] under the steady-state approximation as evident from Eqs. 1—3 even though reactions giving unknown products are taken into consideration. From the linear Stern-Volmer plots of $1/\Phi_{-NT}$,

$$1/\Phi_{-NT} = (1+k_d/k_r)(1+1/k_t\tau_T[NT]) \quad (1)$$

$$1/\Phi_4 = (1+k_d/k_r)(1+k_u^N/k_4)(1+1/k_t\tau_T[NT]) \quad (2)$$

$$1/\Phi_5 = (1+k_d/k_r)(1+(k_6+k_u^T)/k_5)(1+1/k_t\tau_T[NT]) \quad (3)$$

$1/\Phi_4$, and $1/\Phi_5$ *vs.* 1/[NT] (Fig. 2), we obtain the limiting quantum yields (Φ_{lim}) for both the disappearance of NT and the formation of **4** and **5**, which are collected in Table 1. The intercept/slope ratios of these linear plots give the $k_t\tau_T$ values, while the values of k_d/k_r can be estimated by using Eq. 1.

Quantum Yields for Direct Photolysis. In order

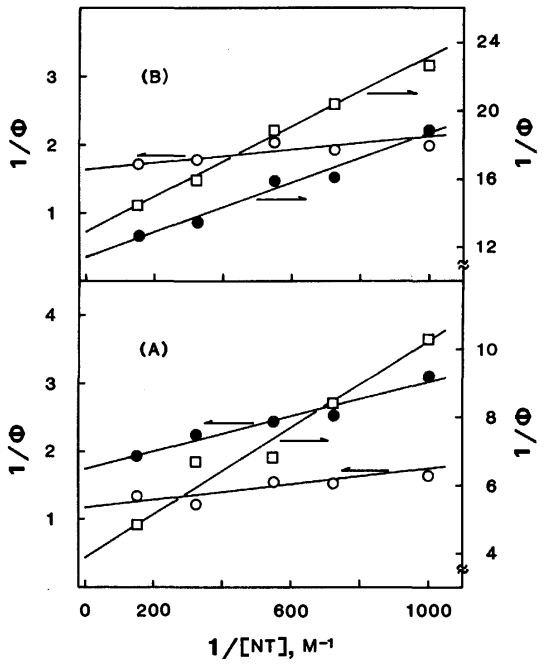


Fig. 2. Stern-Volmer plots of $1/\Phi_{-NT}$ (○), $1/\Phi_4$ (●), and $1/\Phi_5$ (□) *vs.* 1/[NT] for benzophenone (0.03 M)-sensitized photolysis with 366-nm light in 1,2-dichloroethane (A) and in acetonitrile (B).

to minimize undesired secondary photodecompositions of the products **2**—**5**, quantum yields for the direct photolysis with 313-nm light were determined at low conversions (5—10%) of starting NT. From Table 2 we see that the mass balance of the photolysis is fairly good. Direct irradiations of **2**—**5** indicate their very slight decomposition (less than 5%) to take place under conditions in which quantum yields shown in Table 2 were estimated.

Effects of solvents and hexadecyltrimethylammonium chloride (HTAC) micelle on the quantum yields for the disappearance of NT and for the formation of **2**—**5** were examined and results obtained are summarized in Table 2. In addition, quantum yield measurements were made on a 1,2-dichloroethane solution of NT whose initial concentration varied from 1.00×10^{-3} to 6.60×10^{-3} M (Fig. 3).

Discussion

Triplet Sensitization. The observation of a linear plot of $1/\Phi$ against the reciprocal of NT concentration is in accord with our suggested scheme for the sensitized photolysis (Scheme 1). Involvement of the benzophenone triplet in this sensitization is clearly seen in the finding that the $k_t\tau_T$ values (2500 M^{-1} in acetonitrile and 1600 M^{-1} in 1,2-dichloroethane), determined from the phosphorescence quenching experiments, are in satisfactory agreement with the average values of $k_t\tau_T$ (2800 M^{-1} in acetonitrile and 1600 M^{-1} in 1,2-dichloroethane), obtained from the linear plots of $1/\Phi$ *vs.* 1/[NT]. Because the rates of hydrogen abstraction from various compounds by the benzophenone triplet has been known to lie in the range 10^3—10^5 $M^{-1}s^{-1}$,[10] the estimated k_t values (0.96×10^8 and 1.1×10^8 $M^{-1}s^{-1}$ in acetonitrile and 1,2-dichloroethane, respectively) also show that benzophenone acts merely as an agent for energy transfer during the reaction, accompanying its negligible decomposition, and thus that NT undergoes sensitized decomposition

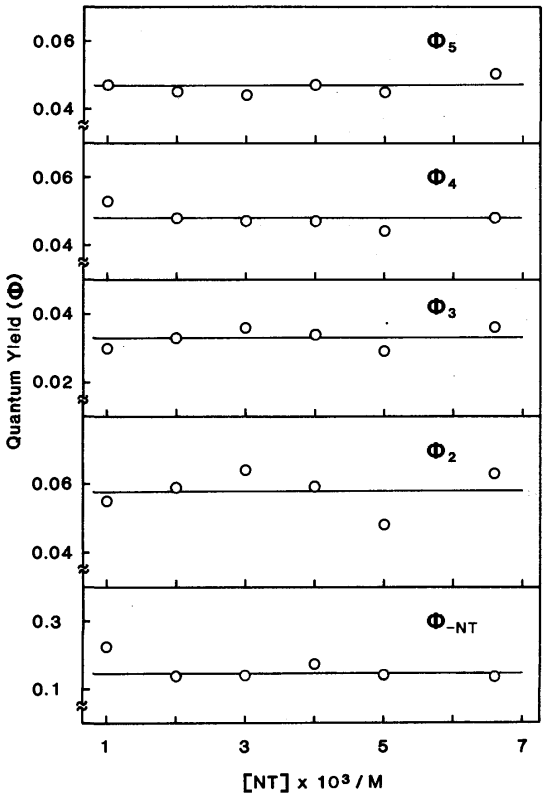

Fig. 3. Quantum yields for the direct photolysis with 313-nm light as a function of NT concentration in 1,2-dichloroethane.

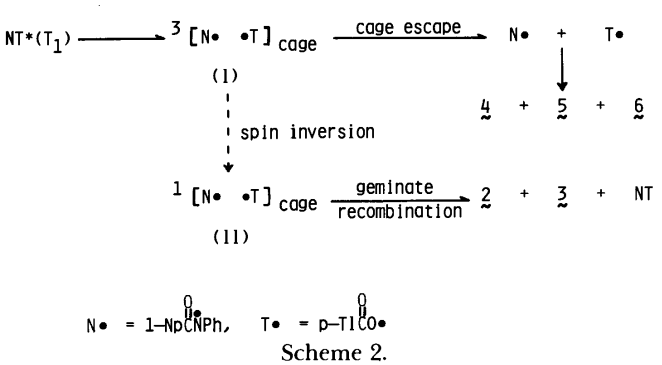
through triplet-triplet energy transfer from the sensitizer to NT.

On the other hand, our values of k_d/k_r require that the resulting NT triplet dissipates its energy in part without dissociating into the amido and aroyloxyl radicals. Comparison of these values in two solvents used establishes higher reactivity of the NT triplet in 1,2-dichloroethane than in acetonitrile. We can also estimate the values of k_u^N/k_4 and k_u^T/k_5 from Eqs. 2 and 3 with these k_d/k_r values: k_u^N/k_4=6 in acetonitrile and 0.4 in 1,2-dichloroethane; k_u^T/k_5=2 in the former and 0.6 in the latter on assuming $k_6/k_5=\Phi_6/\Phi_5$. The values of k_u^N/k_4 and k_u^T/k_5 thus evaluated show that a complicated fragmentation of the triplet-derived radicals takes place in acetonitrile, while hydrogen abstraction and decarboxylation constitute a major fragmentation process in 1,2-dichloroethane.

Similar decreased efficiency of geminate recombination of radical pairs has been observed in the triplet-sensitized photodecompositions of peroxides,[11] azo compounds,[12] and allyl phenyl ether.[13] The most reasonable explanation for these observations was that there is a barrier to recombination of a caged radical pair produced as a triplet because spin inversion of a triplet radical pair must precede its coupling in the cage. The presence of the barrier results in preferential diffusive separation of radicals from the cage. This concept of triplet→singlet spin inversion in a radical pair has been critically scrutinized and then verified to have a wide applicability to reactions of spin-correlated radical pairs.[14] No formation of **2** and **3** in our triplet-sensitized photolysis of NT can be nicely explained in terms of the idea mentioned above. An illustration of the sensitized photolysis of NT appears in Scheme



Scheme 2.

2. The observation that Φ_2 and Φ_3 are negligibly small compared to Φ_4, Φ_5, and Φ_6 suggests that in our system the rate of spin inversion from the triplet pair (I) to the singlet pair (II) should be slow enough to allow the exclusive escape of the radical pair from the cage.

Direct Irradiation. Our previous results of the direct photolysis of NT that occurs through the singlet excited state provided us some interesting problems to be solved:[1] (1) Is there self-quenching or induced decomposition of starting NT brought about by radicals produced? and (2) Are the rearrangement products **2** and **3** derived from recombination within the identical solvent cage?

Figure 3 shows that neither Φ_{-NT} nor Φ_{2-5} varies over the concentration range of NT investigated, allowing us to conclude that no starting NT meets with self-quenching and induced decomposition under conditions examined.

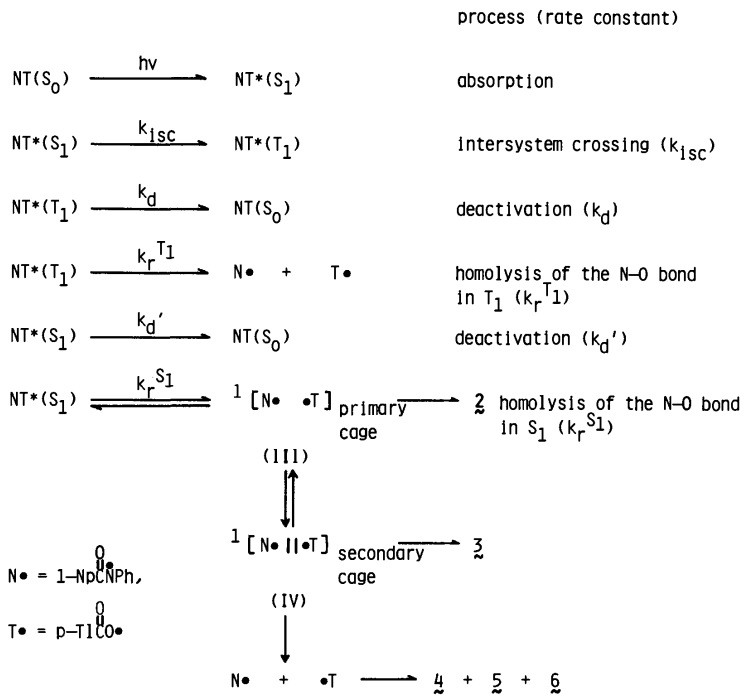
To answer the next question, we have studied solvent effects on the quantum yields for the photolysis with 313-nm light. It was suggested in the previous work[1] that the chemical yields of **2**, **3**, and **5** are not sensitive to both the polarity of solvents of comparable viscosity and the ease with which hydrogen atoms of solvents are abstracted by the photochemically generated toluoyloxyl radical, whereas the yield of **4** is very sensitive to this ease of solvents. Despite the secondary hydrogens of sulfolane and HTAC are very likely to be much more reactive toward hydrogen abstraction by free radicals compared with the primary hydrogens of acetonitrile,[15] the quantum yields of the fragmentation products (especially Φ_5) are much smaller in sulfolane and HTAC than in acetonitrile, indicating that the quantum yields shown in Table 2 correlate neither with the solvent polarity nor with the reactivity of a solvent hydrogen atom. This finding provides further support for the suggestion mentioned above. Thus the quantum yields for the direct photolysis seem to nicely correlate with the solvent viscosity although the slightly smaller value of Φ_5 in acetonitrile than that in 1,2-dichloroethane indicates that the reactivity of solvents toward hydrogen abstraction also plays a some but minor role in determining the relative extent of "out-of-cage" and "in-cage" reactions. The facts that decarboxylation of the toluoyloxyl radical giving eventually toluene is a minor process in the direct photolysis and that a complicated fragmentation of the amido radical occurs in relatively inert solvents toward hydrogen abstraction allow us to use Φ_5 rather than Φ_4 as a measure of the extent of "out-of-cage" reaction. These considerations force us to discuss solvent effects on Φ_{-NT}, Φ_2, and Φ_5 solely from the standpoint of micellar and solvent viscosity effects on the efficiency of geminate recombination of radical pairs.

On the other hand, micelles are known to become a good device for causing an efficient cage reaction of radical pair produced photochemically or thermally.[14] The photolysis in aqueous HTAC micelle is, therefore, expected to significantly reduce the rate of escape of the radical pair from the micelle cage, causing more efficient geminate recombination and hence leading to a decrease in Φ_{-NT} and Φ_5 and an increase in Φ_2 and Φ_3. An increase in the solvent viscosity will exert similar but less remarkable effects on these quantum yields.

Micellar effects on Φ_{-NT}, Φ_2, and Φ_5 are consistent with this expectation. However, a decrease in Φ_3 was observed in the photolysis in HTAC micelles. Almost no formation of the fragmentation products **4** and **5** is interpreted to mean that the recombination of the radical pair formed in the micelle is much faster than the exit of these hydrophobic radicals from the micelle. As expected the increased viscosity effects on the efficiency of geminate recombination are less remarkable compared to micellar effects on this efficiency, though both effects are similar, supporting the view that the hydrophobic micelle aggregate serves as a cage for causing more efficient cage reaction than that in homogeneous sulfolane solution whose macroscopic viscosity is comparable to the intramicellar microviscosity of HTAC.

Different dependence of Φ_2 and Φ_3 upon reaction environments indicates the existence of at least two spin-correlated radical pairs as originally inferred by Noyes:[16] One is a contact radical pair (III) whose recombination eventually yields 1,3-rearrangement product **2** and the other a solvent-separated radical pair (IV) from which 1,5-rearrangement product **3** is derived in competition with regeneration of (III) and diffusive escape out of the solvent or micelle cage as shown in Scheme 3.

According to Scheme 3, an increase in the solvent viscosity should impede primary cage reaction to a negligible extent whereas secondary cage and fragmentation reactions are suppressed to different extent by increasing the solvent viscosity.[17] Furthermore, this suppression of secondary cage and fragmentation reactions will result in an increase in Φ_2 and a decrease in Φ_{-NT}. These are consistent with the results obtained. The finding that the solubilized probe can move about within the micelle offers a good explanation for the formation of **3** in the photolysis in the micelle.[18] In micellar system hydrocarbon chain of the micelle-forming surfactant may serve as a solvent. Because the triplet radical pair generated selectively from the first triplet excited state (T_1) of NT results in the appearance of the cage coupling products **2** and **3** in a negligible quantum yield, the spin multiplicity of two caged radical pairs (III) and (IV) must be singlet. Exclusive occurrence of the direct photolysis from the first singlet excited state (S_1) should be due to the much slower rate of intersystem crossing relative to the rate of reaction which arises from S_1, namely, $k_{isc} \ll k_r^{S_1}$ in Scheme 3. In view of the fact that a large singlet-triplet energy gap reduces Franck-Condon factor,[19] it is reasonable to believe that the large energy gap between S_1 and T_1 for NT (ΔE_{ST}= 31 kcal mol^{-1}) renders the rate of intersystem crossing from S_1 to T_1 considerably slow.



Scheme 3.

Experimental

General Methods. HPLC analysis of the photoproducts was performed on a Hitachi 638-50 high-performance liquid chromatography apparatus with a 2.6×500-mm ODS (Hitachi gel #3050) column. Linear calibration curves for each compound, prepared under the same analytical conditions, were employed to quantify both disappearance of starting material and appearance of the products. GLC analysis was carried out on a Hitachi 663-50 gas chromatograph using 2-m column packed with 10% Silicone SE-30 on Uniport B (60/80 mesh, Gasukuro Kogyo Inc.). Phosphorescence of benzophenone with and without quencher was measured under argon with a Shimadzu RF-500 spectrophotofluorimeter. UV spectra were taken on a Shimadzu UV-210A spectrophotometer.

Materials and Solvents. *N*-(1-Naphthoyl)-*O*-(*p*-toluoyl)-*N*-phenylhydroxylamine (NT) and authentic compounds for the photoproducts **2**—**5** were prepared and purified according to the same procedure as previously described.[1] 1,2-Dichloroethane (spectrograde from Dojin Chemical Co.) and Sulfolane (Merck, Uvasol) were used without further purification. The same method as before[1] was employed to get highly-purified acetonitrile. Acetonitrile and water (HPLC grade from Wako Pure Chemical Industries, Ltd.) were used as received for HPLC analysis. Pure benzophenone was obtained by repeated recrystallization from aqueous ethanol. Hexadecyltrimethylammonium chloride (HTAC, Wako) was recrystallized twice from acetone–methanol and dried *in vacuo* at room temperature.

Quantum Yield Determinations. Quantum yields were determined according to the method of Hatchard and Parker[20] which employs a potassium trioxalatoferrate(III) actinometer solution. A 450 W high pressure Hg lamp was used as the light source from which 313-nm light for direct irradiation was isolated by means of a potassium chromate (0.002 M) in a 1% aqueous solution of potassium carbonate and Corning 7-54 filters. The 366-nm light from the same Hg lamp was selected with Corning 0-52, Corning 7-37, and Toshiba IRA-25S glass filters.

In the sensitized reaction, more than 99% of the incident light was absorbed by benzophenone because molar absorption coefficients of NT and benzophenone at 366 nm are 2.6 and 50 ($M^{-1}cm^{-1}$) in acetonitrile, respectively, and 3.1 and 58 ($M^{-1}cm^{-1}$) in 1,2-dichloroethane, respectively, at room temperature. All the quantum yields for the direct and sensitized photolysis are average of more than three determinations. Quantum yields for the photolysis in HTAC micelles were determined in the same manner as that used for homogeneous solutions.

On the other hand, the solubility of NT in water could not be determined accurately owing to turbidity of the solution. However, the saturated water solution gave no signs of the absorption of NT so that NT concentration in water should be less than 10^{-6} M. On solubilization of NT in HTAC micelles by ultrasonic dispersal the solution became clear and showed no turbidity. The possibility of hydrolysis of NT in this micellar solution before and after the photolysis can be ruled out because HPLC analysis of the micellar solution indicated no formation of *p*-toluic acid and *N*-(1-naphthoyl)-*N*-phenylhydroxylamine.

(Received May 23, 1985)

The Wittig-type reactions of *N*-sulfinyl-*p*-toluenesulfonamide with (1) O=C-, (2) C=C-, and (3) N=C-conjugated phosphorus ylides were investigated. In the reaction with (1), *N*-sulfinyl-*p*-toluenesulfonamide reacted at both the ylide and the carbonyl moiety to form TsN=C-conjugated thione *S*-imide, which underwent intramolecular 1,3-dipolar cycloaddition of the CSN group with the aromatic C=C bond of the tosyl group giving a structurally unique spiro-fused tricyclic adduct. The structure of the adduct was determined by means of X-ray diffraction. In the reactions with (2) and (3), 1-azadiene and sulfobetaines were obtained instead of the expected conjugated thione *S*-imides.

We recently reported the first synthesis of α,β-unsaturated (conjugated) thione *S*-imides by the reaction of 3-aminopropene-1-thiones with chloramine salts.[1] The imides showed an interesting chemical property namely that they cyclize reversibly to thiazoline compounds depending on the solvent.

In view of continued interest in conjugated thiocumulenes, we have attempted the synthesis of O=C-, C=C-, and N=C-conjugated thione *S*-imides by the Wittig-type reaction of *N*-sulfinylamines with the corresponding phosphorus ylides. This method is conceivable because of our previous successful preparation of fluorenethione *S*-tosylimides by this Wittig-type reaction.[2]

In the previous paper[2] we reported that (benzoylphenylmethylene)triphenylphosphorane **1a** reacted with *N*-sulfinyl-*p*-toluenesulfonamide (**2**) to form the imidoyl-conjugated thione *S*-tosylimide **3a**, which subsequently underwent an intramolecular 1,5-dipolar cyclization giving a 1,2,3-thiadiazoline compound **4a**. However, reinvestigation of the reaction products in a series of the reactions applying ^{13}C NMR and X-ray diffraction analysis reveals that we were previously misled by the spectral features. This paper deals with new and unexpected results including a revised structure (**5**).

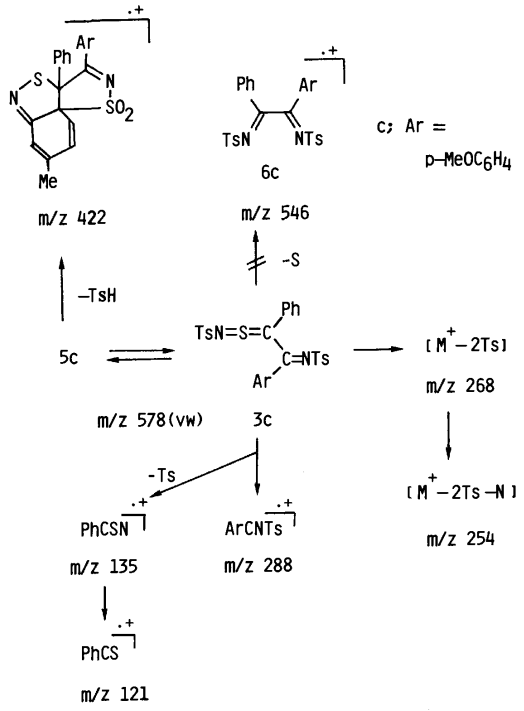
Results and Discussion

In refluxing benzene (acylarylmethylene)triphenylphosphoranes **1** reacted with *N*-sulfinyl-*p*-toluenesulfonamide (**2**) at the both functional sites, namely the ylide and the acyl moietiy, yielding compounds **5**—**7** (Scheme 1, Table 1).[3] The structures of **5a**, **b**, and **5d**—**h** were confirmed by comparisons of the spectroscopic data (IR, MS, ^1H, and ^{13}CNMR) with those of **5c**, of which the structure was proved by means of the X-ray diffraction analysis (*vide infra*). The reaction mixture was colored orange at the first stage of the reaction, and ultimately turned greenish blue.[4] Although the orange substances are rather labile, they could be isolated in the case of the reactions of **1b**, c when performed at room temperature or below, and were identified as the N=C-conjugated thione *S*-imides **3b**, c on the basis of the spectral analyses and the reactions described below (Scheme 3).

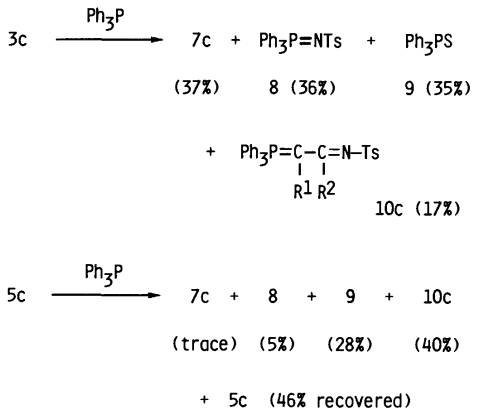
The thione *S*-imides **3b**,c exhibited characteristic absorption bands of νCSN at 990 cm^{-1} and of νC=NTs at 1550 cm^{-1} in the IR spectra. In the mass spectra of **3** and **5**, almost the same fragmentation patterns were observed (Table 2). This indicates the reversible transformation between **3** and **5**, *e.g.* for **3c** and **5c**, as shown in Scheme 2. Although molecular ion peaks and their desulfurized fragment peaks $\mathbf{6}^{\cdot+}$ were hardly detected (E.I. at 70 eV), the peaks [M^+ −TsH] are very indicative of these unique cycloadducts **5**, because facile elimination of TsH can be envisaged from **5** rather than from **3**. The ^1H NMR spectra of **3b**, c were in good agreement with the proposed structures. The assignments are given in Experimental Section. The geometrical isomerism of **3**, if present, about the bent CSN and C=NTs moieties was not determined. The geometrical rigidity is probably lost to a considerable extent by contribution of a 1,5-dipolar structure due to the conjugation. In the



Scheme 2.

^{13}CNMR spectra of **3b**,c, the cumulene and imine carbons resonated at a low field of δ=167.2 and 176.3 for **3b**, and 166.3 and 176.6 for **3c**, respectively.

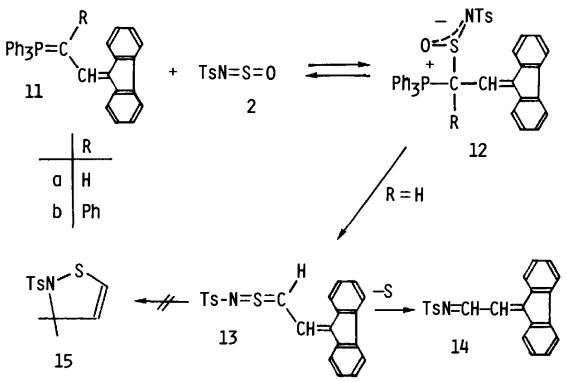
As expected, heating of the isolated imides **3b**, c in benzene gave **5b**, c and **6b**, c along with small amounts of **7b**, c. Interestingly, heating (>~110 °C) of **5c** in xylene gave reversion to **3c**, suggesting the existence of equilibrium between **3** and **5** at a higher temperature. This retro-cyclization is also observed during the reactions of **3c** and **5c** with triphenylphosphine; the reactions of both **3c** and **5c** with triphenylphosphine produced **7c**, **8**, **9**, and **10c** (Scheme 3). There is no doubt that in both reactions the products (**7**—**10**) are formed from **3c** by nucleophilic attack of triphenylphosphine at the CSN moiety. It should be



Scheme 3.

noted that the reaction of **3c** was facile even at low temperature (5—8°C) while that of **5c** took place only at higher temperature (>~70°C) which is required for the retro-cyclization to **3c**.

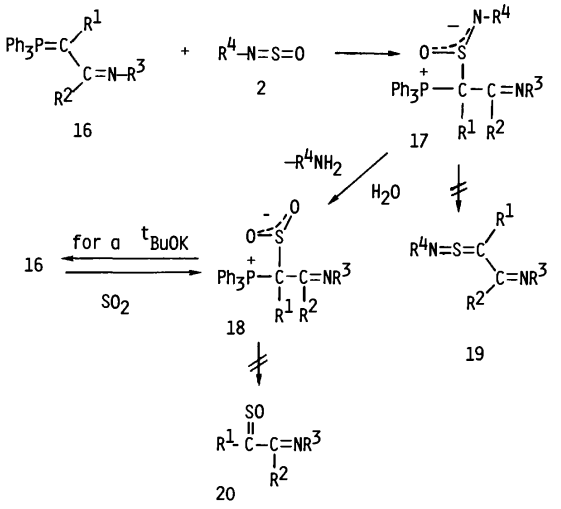
The reaction of C=C-conjugated phosphorus ylide **11a** with **2** yielded a 1-azadiene **14**, which might be formed from the conjugated thione *S*-imide **13** by sulfur extrusion *via* a thiaziridine ring[5] (Scheme 4).



Scheme 4.

Neither **13** nor its 1,5-dipolar cyclization product (**15**) was obtained. On the other hand, the reaction of **11b** with **2** stopped at the stage of the betaine **12** under the same reaction conditions, but an isolation of **12** failed.

Treatment of **16** having a N=C in conjugation with the ylide function with **2** formed a hygroscopic betaine **17** which was ultimately hydrolyzed to give a betaine of sulfur dioxide, **18** (Scheme 5). Treatment of the betaine **18a** with potassium *t*-butoxide led to reconversion to the starting ylide (**16a**). The betaine **18** was also obtained by bubbling sulfur dioxide into a solution of the ylide **16** (Table 3). From the betaines **17** and **18** the corresponding conjugated thione *S*-imides **19** and *S*-oxide **20**,[6] respectively, could not be obtained.



Scheme 5.

The present results of these Wittig-type reactions reveal that this methodology is promising to prepare conjugated thione *S*-imides, although a limited number of substituents leads a completion of the reaction and stabilizes these conjugated thione *S*-imides sufficiently.

Structure Determination of **5**.

4,5-Diaryl-10-methyl-7-tosyl-2,6-dithia-3,7-diazatricyclo-[6.4.0.0^{1,5}]dodeca-3,9,11-triene 2,2-Dioxides (**5**). In the ^{13}C NMR spectra of **5**, single-frequency off-resonance decoupling (SFORD) measurements showed signals of the tertiary and two quaternary carbons assigned to the carbons at C(8), C(5), and C(1), respectively (Table 4). This unambiguously excludes the structure **4**. In the ^{1}H NMR spectra H(8), H(9), CH_3(10), H(11), and H(12) protons exhibited plural couplings similar to those of 2-methyl-1,3-cyclohexadiene bicyclo compounds.[7] The assignments of the signals are compiled in Table 5.

X-Ray Diffraction. X-Ray diffraction data were collected on a Rigaku AFC automated four-circle diffractometer. The crystal data, details of experimental conditions, and the structure analysis procedures are listed in Table 6. Atomic parameters are given in Table 7. The atomic scattering factors and *f'*, *f''* values were taken from International Tables for X-Ray Crystallograpy.[8] The calculations were carried out on a FACOM M-380 computer using the UNICS-III[9] and ORTEP[10] programs. A stereoscopic drawing of the molecule is shown in Fig. 1, and the selected

a) **5e** is sparingly soluble in $CDCl_3$ or DMSO-d_6.

bond lengths and angles are given in Figs. 2 and 3. The reaction of **3** to **5** occurs through the bond formation between C(1) and C(3), and N(2) and C(4), which results the three fused rings system A, B, C. The torsion angles within these rings are shown in Fig. 4. The isothiazolidine ring B is considerably deformed. The distance C(1)-C(3), 1.587 Å, is longer than the ordinary single bond distance 1.54 Å. The six-membered ring C takes half chair form. The dihedral angles among the mean planes A, B, C are 74.8(1), 71.6(1), and 80.9(1)° for A-B, B-C, and C-A, respectively.

Complete F_o—F_c data, hydrogen atomic parameters and anisotropic thermal parameters are deposited as Document No. 8549 at the Office of the Editor of *Bull. Chem. Soc. Jpn.*

Experimental

All melting points are uncorrected. IR spectra were measured on a Hitachi Model 260-10 spectrometer. ^1H and ^{13}C NMR spectra were recorded on a JEOL JNM-FX 100 spectrometer in $CDCl_3$ solution using tetramethylsilane as an internal standard (^1H; at 100 MHz, ^{13}C; at 25.05 MHz). Mass spectra were recorded on a Hitachi double focusing mass spectrometer RMU-7M, operating at an ioninzing potential of 70 eV. Elemental analyses were performed using a Yanaco Model MT-3 CHN corder.

N-Sulfinylamines (**2**),[11] the conjugated ylides **1**,[12] **11a**,[13] **16**[14] were prepared by the methods reported in the literature. Ylide **11b** was newly synthesized by the modified method.[13]

11b: Deep red cubes, mp 197—198 °C. IR(KBr) 1540 and 1440 cm^{-1}. MS *m/z* 528 (2%, M^+). Found: C, 88.70; H, 5.51%. Calcd for $C_{39}H_{29}P$: C,88.61; H, 5.53%.

[*A*] *General Procedure for the Reaction of (Acylarylmethylene) triphenylphosphorane (1) with* N-*Sulfinyl*-p-*toluenesulfonamide (2).* A solution of **2** (6.6 mmol) in dry benzene (10 cm^3) was added dropwise to a benzene solution (50 cm^3) of **1** (3.0 mmol) with stirring at room temperature, and then the reaction mixture was heated under reflux for 9—20h until the orange color of **3** disappeared. Removal of the solvent and column chromatography (silica gel, benzene) of the residue gave **5** and **6** (Table 1). When **5** was contaminated with a small amount of blue **7**, the crude **5** was washed with diethyl ether-hexane and recrystallized from chloroform-hexane to give analytically pure **5** as colorless crystals.

4,5-Diaryl-10-methyl-7-tosyl-2,6-dithia-3,7-diazatricyclo[6.4.0.0^{1,5}]-dodeca-3,9,11-triene 2,2-Dioxide (5). **5a**: IR(KBr) 1555 (C=N), 1345, 1165 (SO_2) cm^{-1}. Found: C, 61.38; H, 4.17; N,

1-Phenyl-2-(p-methoxyphenyl)-2-tosylimino-1-ethanethione (7c): Blue oil, IR(neat) 1535 (C=N), 1315, and 1150 (SO_2) cm^{-1}. ^1H NMR ($CDCl_3$) 2.35 (s, 3H, CH_3(Ts)), 3.70 (s, 3H, OCH_3), 6.7—8.0 (m, 12H, Ar-H). ^{13}C NMR ($CDCl_3$) 235.52 (C=S), 175.94 (C=N), 55.49 (OCH_3), 21.50 (CH_3(Ts)). MS *m/z* 409 (2%, M^+), 288 (3, M^+—PhCS), 254 (56, M^+—Ts), 121 (100, PhCS·+).

1-p-Tolyl-2-phenyl-2-tosylimino-1-ethanethione (7e): Blue oil, IR (neat) 1560 (C=N), 1330 and 1160 (SO_2) cm^{-1}. ^1H NMR ($CDCl_3$) 2.35 (s, 3H, CH_3), 2.39 (s, 3H, CH_3(Ts)), 7.1—7.9 (m, 13H, Ar-H). ^{13}C NMR ($CDCl_3$) 233.35 (C=S), 176.18 (C=N), 21.96 (s, CH_3), 21.55 (s, CH_3(Ts)). MS *m/z* 393 (3, M^+), 238 (10, M^+—Ts), 135 (100, *p*-TolCS·+).

[*B*] *Isolation of 1,2-Diaryl-2-tosylimino-1-ethanethione S-Tosylimides **3b**, c.* To a solution of **2** (3.0 mmol) in benzene (50 cm^3) was added dropwise a solution of **1** (6.6 mmol) in benzene (10 cm^3) with stirring at 10—15 °C. The reaction mixture was stirred for 5—10h at room temperature until the materials were consumed (TLC). Evaporation of the solvent without heating and column chromatography (silica gel, 1/50 ethyl acetate/benzene) of the residue gave **3** as orange-red oil in 70—79% yields. The isolated thione *S*-imides **3b**,c (2 mmol) were heated at reflux in 50 cm^3 of benzene for 16—18 h. The work-up as described in the procedure A gave **5b** (40% yield) and **6b** (5% yield) or **5c** (40%) and **6c** (2%) along with **7b**,**c** (trace).

3b: IR($CHCl_3$) 1550 (C=N), and 990 (CSN) cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.37 (s, 6H, $2CH_3$), 2.42 (s, 3H, CH_3), 7.06—7.86 (m, 17H, Ar-H). ^{13}C NMR ($CDCl_3$) δ=176.28 (C=N), 167.22 (CSN), 146.26—125.06, 21.74, 21.54, and 21.35 (CH_3).

3c: IR(KBr) 1550 (C=N), and 990 (CSN) cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.30 (s, 3H, CH_3), 2.36 (s, 3H, CH_3), 3.74 (s, 3H, OCH_3), 6.62—7.78 (m, 17H, Ar-H). ^{13}C NMR ($CDCl_3$) δ= 176.60 (C=N), 166.27 (CSN), 165.15—114.66, 55.60 (OCH_3), 21.49 (CH_3), 21.25 (CH_3).

[*C*] *Thermolysis of 5c.* When the adduct **5c** (1.6 mmol) was heated at 112°C in xylene (75 cm^3)-benzene (35 cm^3), orange-colored **3c** appeared and was identified by TLC. After heating for 28 h, the usual work-up and column chromatography of the reaction mixture gave **6c** (19% yield), **7c** (2% yield) and an unidentified colorless oil.

[*D*] *Reaction of 3c with Triphenylphosphine.* To a benzene solution (40 cm^3) of **3c** (2.0 mmol) was added a benzene solution (10 cm^3) of triphenylphosphine (2.1 mmol) in a cold bath. After stirring at room temperature for 12 h, removal of the solvent and column chromatography (silica gel, benzene→ethyl acetate) of the residue gave 0.3 g of **7c** (37% yield), 0.31 g of **8** (36%), 0.20 g of **9** (35%), and 0.22 g of **10c** (17%).

10c: Colorless crystals, mp 248—251°C. IR(KBr) 1610, 1440, 1390, 1140, and 1090 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.21 (s, 3H, CH_3(Ts)), 3.62 (s, 3H, OCH_3), 6.5—7.6 (m, 28H, Ar-H). ^{13}C NMR ($CDCl_3$) δ=171.36 (d, J_{C-P}=7.3 Hz, C=N), 82.48 (d, J_{C-P}=101.3 Hz, C=P), 54.87 (OCH_3), 21.20 (CH_3(Ts)). MS *m/z* 639 (9, M^+), 484 (34, M^+—Ts), 262 (4, PPh_3), 222 (100, M^+—Ts-PPh_3).

[*E*] *Reaction of 5c with Triphenylphosphine.* To a solution of **5c** (1.2 mmol) in chloroform (5 cm^3) was added a benzene solution (35 cm^3) of an equimolar amount of triphenylphosphine. The reaction mixture was heated at reflux for 22 h. After cooling to room temperature, the precipitate (partial **5c**) was filtered. The work-up of the filtrate in the same manner as described in the procedure D gave **7c** (trace), **8** (5%), **9** (28%), **10c** (40%), *p*-toluenesulfonamide, and 46% (total)-recovered **5c**.

[*F*] *Reaction of C=C-conjugated Ylides 11 with N-Sulfinyl-p-toluenesulfonamide (2).* To a partial suspension of **11b** (1.24 g, 2.74 mmol) in benzene (30 cm^3) was added a benzene solution (20 cm^3) of **2** (0.71 g, 3.3 mmol) at temperatures of 10—15°C. The resulted reaction mixture was warmed for 10 min until the solution turned clear. The solvent was evaporated and the residue was recrystallized from dichloromethane-diethyl ether to give **14** in a 45% yield.

14: Yellow needles, mp 204—205°C. IR(KBr) 1600 and 1560 (C=N) cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.44 (s, 3H, CH_3(Ts)), 7.06 (d, *J*=10 Hz, 1H, =CH-), 7.12—7.96 (m, 12H, Ar-H), 9.68 (d, *J*=10 Hz, 1H, -CH=N-). MS *m/z* 359 (4, M^+), 204 (100, M^+—Ts), 91 (24, Tol^+). Found: C, 73.55; H, 4.81; N, 3.92%. Calcd for $C_{22}H_{17}O_2NS$: C, 73.51; H, 4.77; N, 3.90%.

[G] *Reaction of N=C-conjugated Ylides 16 with N-Sulfinylamines (2) and Sulfur Dioxide.* To a benzene solution (25 cm^3) of **16** (4.55 mmol) was added dropwise a benzene solution (10 cm^3) of **2** (4.51 mmol) at temperatures of about 10°C. The orange suspension turned to a clear solution. The reaction mixture was very hygroscopic. On standing in the air it hydrolyzes to form white crystals **18**, which were filtered off and washed with benzene.

18a: White needles, mp 133—135°C (dec). IR(KBr) 1570 (C=N), 1440 (P-C), and 1260 (SO_2) cm^{-1}. MS *m/z* 455 (58, M^+—SO_2), 378 (12, M^+—SO_2-Ph), 262 (100, Ph_3P).

18b: White needles, mp 252—254°C. IR(KBr) 1660 (C=N), 1445 (P-C), and 1265 (SO_2) cm^{-1}. MS *m/z* 587 (36, M^+—SO_2), 496 (100, M^+—SO_2-CH_2Ph), 262 (30, Ph_3P). Dry sulfur dioxide gas was bubbled into a benzene solution (20 cm^3) of **16** (2.0 mmol). After 2h orange suspension turned to a white suspension. The precipitate was collected by filtration to give **18a, b**, which were identical with the products obtained above.

[*H*] *Conversion of 18a to 16a by Base.* A suspended mixture of **18a** (0.52 g, 1.0 mmol) and potassium *t*-butoxide (0.62 g, 2.0 mmol) in benzene (20 cm^3) was stirred for 3 h. Removal of the solvent and extraction of the residue by chloroform gave **16a** in an 89% yield (recrystallized from chloroform-petroleum ether).

The authors wish to express their thanks to Professor Binne Zwanenburg of University of Nijmegen for his helpful discussions and revising manuscript.

Optical Resolution of β-Hydroxynorvaline

Masaki YAMADA† and Kenji OKAWA*
Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Nishinomiya 662
(Received June 14, 1985)

β-Hydroxy-DL-norvaline(HyNva) was successfully separated into its diastereoisomers by fractional crystallization from 2-propanol as *p*-toluenesulfonic acid(TsOH) salts. The two racemic diastereoisomers were resolved into four stereoisomers by Vogler's method, using diastereomers of the *N*-benzyloxycarbonyl DL-amino acid and L-tyrosine hydrazide.

β-Hydroxy-DL-norvaline (HyNva) is very useful as a threonine analogue[1] and is needed as a starting material in the synthesis of Actinomycin D analogues. However, optical resolution of the four isomers of HyNva had not been achieved. In the present study, we attempted to separate and optically resolve HyNva into its four stereoisomers.

HyNva was prepared by the condensation reaction of copper(II) glycinate with propionaldehyde, by a method originally proposed by Akabori, Okawa.[2] This method usually gives a mixture of two diastereoisomers, which is difficult to separate. Y. Ariyoshi *et al.*[3] did report separating HyNva into diastereoisomers, but the reagents used were not accessible. In the present study, we found that the *erythro*- and *threo*-forms of HyNva could be easily isolated as the TsOH salts by partial recrystallization from 2-propanol. The configurational assignment of HyNva was done by paper chromatography[4] and 60 MHz ^{1}H-NMR spectroscopy in aqueous solutions.[3] The ratio of the *erythro*- and *threo*-forms of synthetic HyNva was found to be 40:60 by HPLC analysis.[5]

Optical resolution of the two racemic compounds was attempted. First, enzymatic reaction was tried for the *threo*-form, but *N*-acetyl-HyNva(DL-*threo*) could not be resolved using aminoacylase in aqueous solution (pH=6.8). Using Vogler's method,[6] we were able to resolve the DL-*threo* (**Ia**) and DL-*erythro* (**Ib**) forms using the diastereomers of the *N*-benzyloxycarbonyl DL-amino acid (**III**) (**IV**) and L-tyrosine hydrazide. (Fig. 1).

Four stereoisomers were obtained and reduced by catalytic hydrogenation to obtain free HyNva (**Ia$_1$**) (**Ia$_2$**) (**Ib$_1$**) (**Ib$_2$**). The melting points and specific rotations of these isomers are summarized in Table 1.

The configuration of the α-carbon atom was elucidated by optical rotatory dispersion (ORD) spectroscopy in hydrochloric acid solutions (pH=1).[7] The ORD spectra of **Ia$_2$** and **Ib$_2$** exhibited a positive Cotton effect (positive absorption peaks at 225 nm), showing

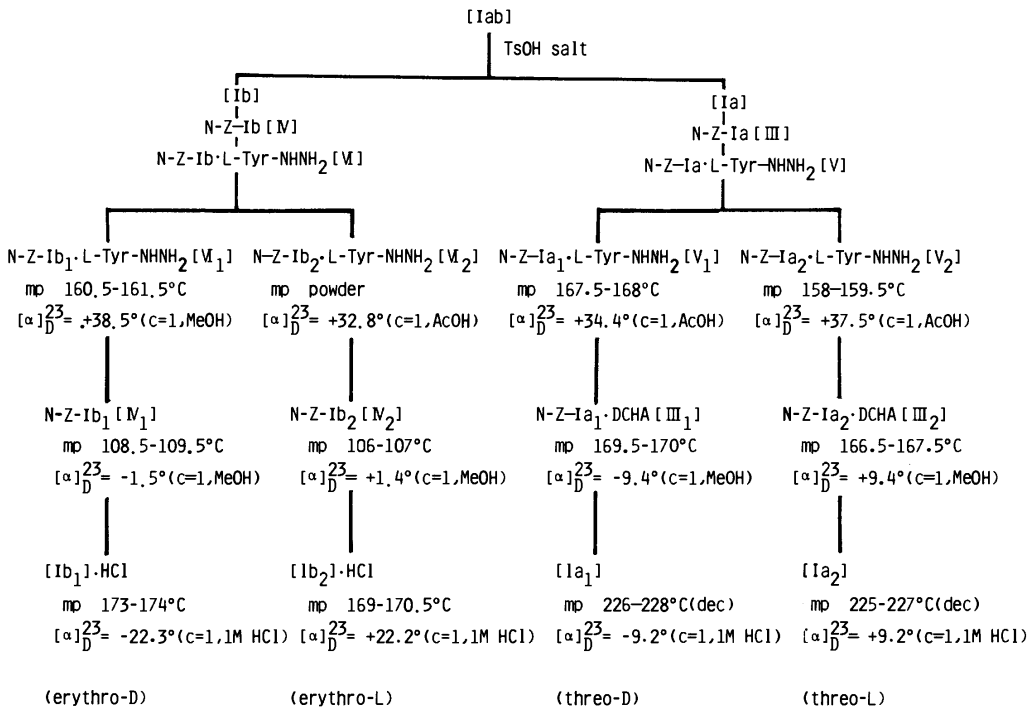

Fig. 1.

†Present address: Organic Chemistry Research Laboratory of Tanabe Seiyaku Co., Ltd., 2-2-50, Kawagishi, Toda 335.

TABLE 1. MELTING POINTS AND SPECIFIC ROTATION DATA

Form			Mp θ_m/°C	$[\alpha]_D^{23}$ °(c=1, 1M HCl)
threo	**Ia**$_1$	D	226—228(dec)	−9.2
	Ia$_2$	L	225—227(dec)	+9.2
erythro*	**Ib**$_1$	D	173—174	−22.3
	Ib$_2$	L	169—170.5	+22.2

*Hydrochloride.

these compounds to be of the L-form. **Ia**$_1$ and **Ib**$_1$ displayed a negative Cotton effect (negative absorption peak at 225 nm), which showed that they were of the D-form.

Experimental

β-Hydroxynorvaline (Iab). **Iab** was prepared by the glycine-copper method in 44% yield, mp 197—198°C (dec) Found: C, 44.91; H, 8.33; N, 10.46%. Calcd for $C_5H_{11}O_3N$: C, 45.10; H. 8.33; N, 10.52%.

Separation of Diastereomers. A suspension of **Iab** (7.4 g, 5.6 mmol) in methanol (100 ml) was added to a methanol solution of TsOH (10.7 g, 5.6 mmol) and the solvent was removed *in vacuo*. Crystals of **Iab** TsOH salt were obtained in *ca.* 100% yield and subjected to fractional crystallization from hot 2-propanol. The first crystals of **Ib** TsOH salt (6.4 g, 35%) were removed by filtration and **Ia** TsOH salt (6.5 g, 36%) was obtained from the filtrate. Both of amino acid TsOH salts were decomposed with the pyridine-methanol solution, and recrystallization from hot water gave **Ia** [mp 215—217°C(dec)] and **Ib** [mp 241—242°C(dec)] in quantitative yields.

N-Benzyloxycarbonyl-Ia (III). **III** was prepared from **Ia** and benzyloxycarbonyl chloride by the usual method in 85% yield as a syrup.

L-Tyrosine Hydrazide Salt of III (V). L-Tyrosine hydrazide (26.3 g, 0.14 mol) was added to a solution of **III** (36 g, 0.14 mol) in methanol (250 ml), and the solution was warmed at 65°C. After removal of the insoluble material, the solution was concentrated, and addition of tetrahydrofuran gave **V** in quantitative yield (62 g).

Resolution of Racemic III. A solution of **V** (62 g, 0.14 mol) in methanol (200 ml) was warmed at 65°C. The first crop (**V**$_1$) of **V** crystallized on cooling (18.5 g, 72%). $[\alpha]_D^{23}$=+34.4° (c 1.0, AcOH), mp 167.5—168°C. The mother solution was concentrated and the remaining crystals were dissolved in methanol (100 ml). This solution was left at room temperature for 24 h, and a second crop (**V**$_2$) of **V** was obtained (17 g, 64%). $[\alpha]_D^{23}$=+37.3° (c 1.0, AcOH), mp 158—159.5°C. From the mother solution of **V**$_2$, racemic **V** was obtained (8.5 g). Found: **V**$_1$ C, 57.01; H, 6.60; N, 12.09%. **V**$_2$ C, 57.35; H, 6.56; N, 12.12%. Calcd for $C_{22}H_{30}N_4O_7$: C, 57.13; H, 6.54; N, 12.11%.

III$_1$ was obtained from **V**$_1$ by treatment with 3 M[††] hydrochloric acid and purified as the dicyclohexylamine (DCHA) salt. mp 169.5—170°C, $[\alpha]_D^{23}$=−9.4° (c 1.0, MeOH). The DCHA salt of **III**$_2$ was obtained from **V**$_2$ in the same way. mp 166.5—167.5°C, $[\alpha]_D^{23}$=+9.4° (c 1.0, MeOH). Found: **III**$_1$ C, 67.18; H, 8.92; N, 6.29% **III**$_2$ C, 66.75; H, 8.92; N, 6.40%. Calcd for $C_{25}H_{40}O_5N_2$: C, 66.90; H. 8.99; N, 6.24%.

β-Hydroxynorvaline Ia$_1$, *Ia*$_2$. The mixture of **III**$_1$, palladium black and hydrochloric acid was stirred for 3 h at room temperature under bubbling with hydrogen gas. After removal of the catalyst, the solution was neutralized and concentrated under reduced pressure, giving **Ia**$_1$. Mp 226—228°C (dec), $[\alpha]_D^{23}$=−9.2° (c 1.0, 1 M HCl) **Ia**$_2$ was obtained by the catalytic hydrogenation described above. mp 225—227°C (dec), $[\alpha]_D^{23}$=+9.2°(c 1.0, 1 M HCl). Found: **Ia**$_1$ C, 45.10; H, 8.33; N, 10.52% **Ia**$_2$ C, 44.93; H, 7.99; N, 10.50%. Calcd for $C_5H_{11}O_3N$: C, 44.73; H, 8.30; N, 10.66%.

β-Hydroxynorvaline Ib$_1$, *Ib*$_2$. The *erythro*-form of HyNva (**Ib** series) was obtained like the *threo*-form of HyNva (**Ia** series) and **Ib**$_1$, **Ib**$_2$ were also obtained.

[Ib$_1$]·HCl $[\alpha]_D^{23}$=−22.3° (c 1.0, 1 M HCl), mp 173—174°C, [Ib$_2$]·HCl $[\alpha]_D^{23}$=+22.2° (c 1.0, 1 M HCl), mp 169—170.5°C, Found: [Ib$_1$]·HCl C, 35.04; H, 6.90; N, 8.13; Cl, 21.11%, [Ib$_2$]·HCl C, 34.87; H, 6.97; N, 8.28; Cl, 19.60%. Calcd for $C_5H_{12}O_3HCl$: C, 35.41; H, 7.13; N, 8.26; Cl, 20.90%.

The authors wish to thank Dr. T. Yamada, Konan University, for the HPLC analytical data; Dr. M. Fujino, Takeda Chemical Industries, Ltd., for the ORD spectra data; and Miss T. Higashino and Miss N. Okinaka for their assistance with the experimental work.

Reactions of NH Radicals. IV. Photolysis of HN_3 in the Presence of CH_4 at 313 nm

Sukeya KODAMA*

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received September 5, 1983)

The photolysis of HN_3 vapor in the presence of CH_4 was studied at 313 nm, 30 °C, and a low light intensity. The reaction products were N_2, H_2, NH_4N_3, $CH_3NH_2 \cdot HN_3$, and CH_3N_3. CH_3 radicals were also detected as intermediates. The quantum yields of these products were measured as a function of the CH_4 and HN_3 pressures. The following mechanisms for the main reactions were proposed: $HN_3+h\nu(313\,nm) \rightarrow N_2+NH(a^1\Delta)$; $NH(a^1\Delta)+HN_3 \rightarrow 2N_2+2H$(2a); $NH(a^1\Delta)+HN_3 \rightarrow N_3+NH_2$ (2b); $NH(a^1\Delta)+HN_3 \rightarrow N_2+N_2H_2^*$ (2c); $NH(a^1\Delta)+CH_4 \rightarrow CH_3NH_2^*$ (3); $NH(a^1\Delta)+CH_4 \rightarrow NH(X^3\Sigma^-)+CH_4$ (4); $CH_3NH_2^* \rightarrow H+CH_2NH_2$ or CH_3NH (5); $CH_3NH_2^* \rightarrow CH_3+NH_2$ (6). The rate-constant ratios at 30°C were: $k_3/k_2=0.175$; $k_4/k_2=0.177$; $k_6/k_5=0.133$. The collisional deactivation of $CH_3NH_2^*$ was not found in the total pressure range, from 6.4 to 24.3 kPa.

The photolysis of HN_3 in the presence of Xe,[1] C_2H_6,[2] and C_2H_4[3] at 313 nm has been studied previously, and the following facts were found: HN_3 is a useful source for the first excited singlet, NH ($a^1\Delta$); ethylamine is produced by the insertion of NH ($a^1\Delta$) into a C–H bond of C_2H_6, and the reactions of NH ($a^1\Delta$) with HN_3 and C_2H_4 having the π bond are much faster than that with C_2H_6 consisting of only the σ bond.

On the reactions of $NH(a^1\Delta)$ with C_2H_6, the collisional deactivation by C_2H_6 from $NH(a^1\Delta)$ to $NH(X^3\Sigma^-)$ was also found.[2] Therefore, it is of interest to compare these reactions between saturated hydrocarbons for the insertion and collisional deactivation reactions. In this work, methane, which is the simplest hydrocarbon, was chosen as the reactant.

On the reactions of NH with CH_4, Miller[4] has found N_2, H_2, and NH_4N_3 as the main products, with HCN and C_2H_6 as minor products, in the photolysis of HN_3 with CH_4. However, the formation of $CH_3NH_2 \cdot HN_3$ could not be found in the mass-spectrometric analysis. Cornell *et al.*[5] have studied the flash and steady photolyses of $HN_3(DN_3)$ with hydrocarbons including methane. They have found that the principal nitrogen-containing products are HCN and alkanenitriles in the steady state photolysis. Richardson and Setser[6] have studied the thermal decomposition of HN_3 in the presence of CH_4 and other hydrocarbons over the temperature range of 285—470°C. They have found N_2, NH_3, and a nonvolatile polymer as the products in the HN_3 and CH_4 system. However, the formations of H_2, CH_3NH_2, and N_2H_4 were negative in the mass-spectrometric and gas-liquid chromatographic analyses. Thus, they have concluded that the pyrolysis of HN_3 is not a good source of NH.

It appears to be significant to compare the insertion efficiencies of $NH(a^1\Delta)$ into C–H bonds of simple saturated hydrocarbons, the collisional spin-relaxation efficiencies of $NH(a^1\Delta)$ by such hydrocarbons, and the unimolecular decomposition rates of the alkylamines formed by the insertion reactions. From such a standpoint, the reaction mechanism and rates of the photolysis of HN_3 in the presence of CH_4 were investigated in this work to continue the study with C_2H_6.[2]

Experimental

The methane, obtained from the Takachiho Chemical Co., was 99.8% pure. It was purified each time before use by condensation and evacuation at −196°C and the temperature of solid nitrogen (about −220°C). The preparation and purification of HN_3, like the apparatus and procedure used for the reaction, were the same as those described previously.[1,2] All the runs in this work were carried out at 313 nm and 30°C. The light intensity was reduced with a screen to suppress any radical–radical reactions. The irradiation time was 90 min, and the degree of conversion of HN_3 was less than 4% for all the runs.

The reaction products were N_2, H_2, NH_4N_3, $CH_3NH_2 \cdot HN_3$, and CH_3N_3. The formation of CH_3N_3, passing through a Dry Ice–acetone trap, was found by gas-chromatographic analysis using a Silicone SE-30 column.[3] No HCN was detected by the pyridine-pyrazolone method.[7]

In order to inspect the radical intermediates, the products of the photolysis of HN_3 with CH_4 and NO were analysed by gas chromatography using an 1-m column of Silicone SE-30 at room temperature. Similarly, the products of the photolysis of $CH_3N_2CH_3$ with NO or NO_2 were also analysed gas-chromatographically where the same conditions. The retention times of the two peaks of the former products were in accord with those of the latter products. This suggests the formation of CH_3 radicals as intermediates.

For the identification of NH_4N_3 and $CH_3NH_2 \cdot HN_3$, the volatile, white products trapped at the temperature of Dry Ice–acetone were analyzed by means of a mass spectrometer (Hitachi RMU6E); the spectrum is shown in Fig. 1. The peaks of m/z=17, 18, 30, 31, 42, 43, and 57 correspond to NH_3^+, NH_4^+, $CH_2NH_2^+$ or CH_3NH^+, $CH_3NH_2^+$, N_3^+, HN_3^+, and $CH_3N_3^+$ respectively. However, the parent peaks of NH_4N_3 (m/z=60) and $CH_3NH_2 \cdot HN_3$ (m/z=74) were not found, although a low ionizing voltage of 15 V was applied. On the other hand, the volatile, white products were introduced into a solid-sodium-hydroxide column to remove the HN_3.[2] A mass spectrum of the HN_3-removed products at the ionizing voltage of 17 V is shown in Fig. 2. The peaks of m/z=17 and 31 indicate the molecular ions of NH_3 and CH_3NH_2 respectively. Thus, the formation of $CH_3NH_2 \cdot HN_3$ and NH_4N_3 was verified.

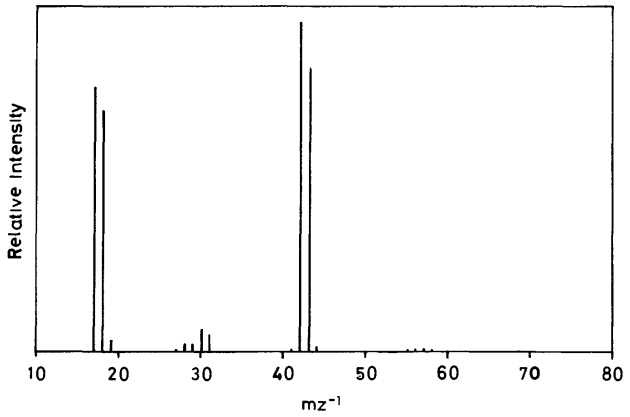

Fig. 1. Mass spectrum of the products trapped at the Dry Ice-acetone temperature. The ionizing voltage is 15 V.

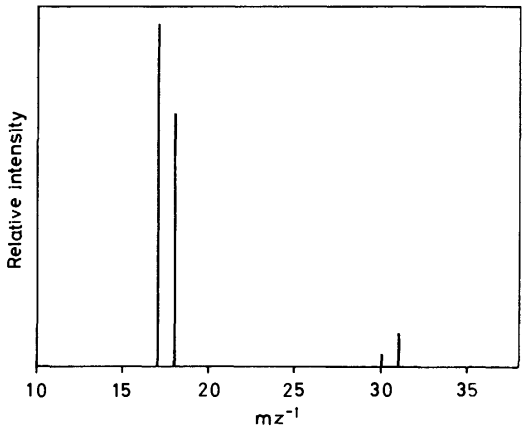

Fig. 2. Mass spectrum of the substances removed HN_3 from the products trapped at the Dry Ice-acetone temperature. The ionizing voltage is 17 V.

The HN_3-removed products were also subjected to gas-chromatographic analysis at 10°C using a 2-m column of KOH(5%)-paraffin liquid(20%) coated on Chromosorb WAW. The formation of CH_3NH_2 was thus confirmed. However, little CH_3NH_2 was formed in the presence of a small amount of NO.

On the quantitative analyses of N_2, H_2, NH_4N_3, and $CH_3NH_2 \cdot HN_3$, the reaction products were separated at the temperatures of solid nitrogen and Dry Ice-acetone. The gases passing through the trap at −220°C are N_2, H_2, and a part of the CH_4 used as the reactant. The separation of H_2 from the mixture was carried out using a silica-gel column at −196°C.[1] The separation of N_2 and CH_4 was achieved by gas chromatography using a 5A molecular-sieve column.[2]

NH_4N_3 and $CH_3NH_2 \cdot HN_3$, condensed at the temperature of Dry Ice-acetone, were introduced into a CuO column at about 550°C. The amounts of N_2, NO, N_2O, and CO_2 formed as combustion products were determined by the method described previously.[2] The amounts of $CH_3NH_2 \cdot HN_3$ and NH_4N_3 can be calculated from those equations: $[CH_3NH_2 \cdot HN_3]=[CO_2]$ and $[NH_4N_3]=([N_2]+[N_2O])/2+[NO]/4-[CO_2]$.

The quantum yields of the reaction products were determined using HN_3 as an actinometer.[1]

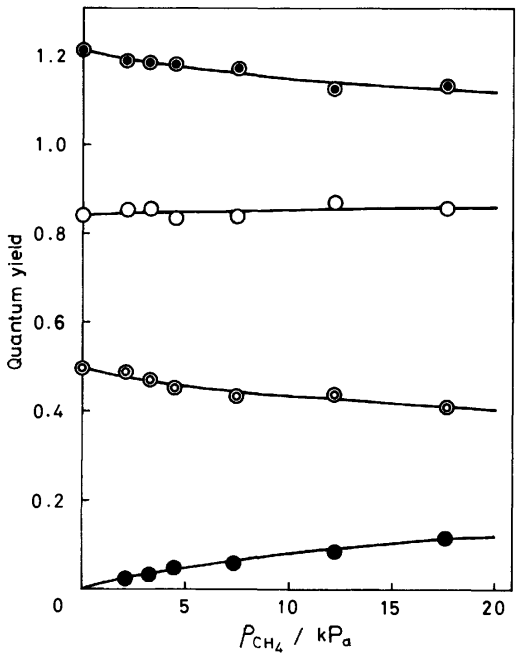

Fig. 3. Results of the photolysis of HN_3 of 6.67 kPa, measured as a function of CH_4 pressure at 313 nm, 30°C, and the low absorbed light intensity of 4.45×10^{14} quanta s^{-1}. ⊙, $\phi_{N_2}/4$; ○, $\phi_{NH_4N_3}$; ◎, ϕ_{H_2}; ●, $\phi_{CH_3NH_2 \cdot HN_3}$.

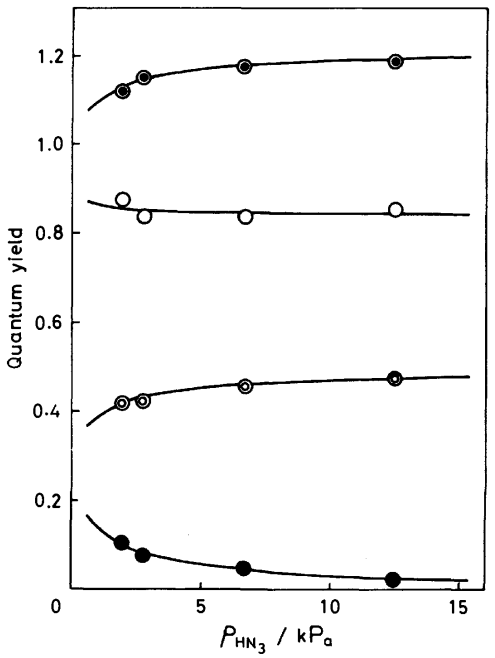

Fig. 4. Results of the photolysis measured as a function of HN_3 pressure at 4.44 kPa of CH_4, 30°C, 313 nm, and the incident light intensity of 3.83×10^{15} quanta s^{-1}. ⊙, $\phi_{N_2}/4$; ○, $\phi_{NH_4N_3}$; ◎, ϕ_{H_2}; ●, $\phi_{CH_3NH_2 \cdot HN_3}$.

Results

The results of the photolysis of HN_3 of 6.67 kPa, measured as a function of the CH_4 pressure at 313

nm and at 30°C, and the absorbed-light intensity of 4.45×10^{14} quanta s^{-1} are shown in Fig. 3. It may be seen in Fig. 3 that ϕ_{N_2} and ϕ_{H_2} decrease, but $\phi_{CH_3NH_2\cdot HN_3}$ and $\phi_{NH_4N_3}$ increase, as the CH_4 pressure increases.

Figure 4 shows the results of the photolysis measured as a function of the HN_3 pressure at 4.44 kPa of CH_4, 30°C, 313 nm, and at the incident-light intensity of 3.83×10^{15} quanta s^{-1}. In Fig. 4, it is found that ϕ_{N_2} and ϕ_{H_2} increase, but $\phi_{NH_4N_3}$ and $\phi_{CH_3NH_2\cdot HN_3}$ decrease, with an increase in the HN_3 pressure.

Discussion

Reaction Mechanism. On the basis of the experimental results in this work and in the light of the results achieved by previous investigators, the following reaction mechanism is postulated for the photolysis of HN_3 vapor in the presence of CH_4, where A and M denote HN_3 and CH_4 molecules respectively:

$$A + h\nu(313\,nm) \longrightarrow N_2 + NH(a^1\Delta) \quad (1)$$

$$NH(a^1\Delta) + A \longrightarrow 2N_2 + 2H \quad (2a)$$

$$NH(a^1\Delta) + A \longrightarrow N_3 + NH_2 \quad (2b)$$

$$NH(a^1\Delta) + A \longrightarrow N_2 + N_2H_2^* \quad (2c)$$

$$NH(a^1\Delta) + M \longrightarrow CH_3NH_2^* \quad (3)$$

$$NH(a^1\Delta) + M \longrightarrow NH(X^3\textstyle\sum^-) + M \quad (4)$$

$$CH_3NH_2^* \longrightarrow H + CNH_4 \quad (5)$$

$$CH_3NH_2^* \longrightarrow CH_3 + NH_2 \quad (6)$$

$$CNH_4 + A \longrightarrow CH_3NH_2 + N_3 \quad (7)$$

$$CNH_4 + A \longrightarrow CH_3N_3 + NH_2 \quad (8)$$

$$CH_3 + A \longrightarrow CH_4 + N_3 \quad (9)$$

$$CH_3NH_2 + A \longrightarrow CH_3NH_2\cdot HN_3. \quad (10)$$

The succeeding reactions for species consisting of only nitrogen and hydrogen atoms are as follows:[1] $NH(X^3\textstyle\sum^-)+A\rightarrow H_2+2N_2$ (11); $NH(X^3\textstyle\sum^-)+A\rightarrow NH_2+N_3$ (12); $H+A\rightarrow H_2+N_3$ (13); $H+A\rightarrow NH_2+N_2$ (14); $N_2H_2^*\rightarrow N_2H_2^{**}$ (15); $N_2H_2^*+A\rightarrow N_2+H_2+A$ (16); $N_2H_2^*+A\rightarrow NH_3+2N_2$ (17); $N_2H_2^{**}+A\rightarrow NH_3+2N_2$ (18); $NH_2+A\rightarrow NH_3+N_3$ (19); $NH_3+A\rightarrow NH_4N_3$ (20); $N_3+A\rightarrow N_3\cdot A$ (21); $2N_3\cdot A\rightarrow 3N_2+2A$ (22).

Since the formation of methylamine has been confirmed by the mass-spectrometric and gas-chromatographic measurements, it is clear that the first excited singlet, NH($a^1\Delta$), formed by the photolysis of HN_3 at 313 nm[1] reacts to give methylamine by insertion into a C–H bond of CH_4, just as in the case where the formation of $C_2H_5NH_2$ was found in the photolysis of HN_3 with C_2H_6.[2] Reaction 4 is a collisional spin-relaxation process by CH_4 from NH($a^1\Delta$) to NH($X^3\textstyle\sum^-$), as was found for Xe[1] and C_2H_6.[2]

Since the enthalpy change of Reaction 3 is −459.8 kJ mol^{-1}, Reactions 5 and 6 are energetically possible. The unimolecular decompositions of CH_3NH_2* to give $2H_2$+HCN, CH_2+NH_3, and H_2+CH_2=NH are also energetically possible. However, these reactions can probably be excluded for the following reasons: No HCN was detected; the formation of C_2H_6 by the insertion reaction, $CH_2+CH_4\rightarrow C_2H_6$, was not observed, and the detachment of H_2 from CH_3NH_2* by the molecular mechanism was not found in the reaction kinetics to be discussed later. Reactions other than those described above are not energetically possible for the unimolecular decompositions of CH_3NH_2*, judging from the standard heats of formation listed in Table 1.

For the CNH_4 formed by Reaction 5, two structures of CH_2NH_2 and CH_3NH are possible. Hadley and Volman[8] have found, by means of the ESR method, that the major radical formed by the photolysis of methylamine in a solid matrix at 184.9 nm is CH_3NH. Hatano *et al.*[9] have also found, by a ESR study that CH_3NH is preferentially formed in the photolysis, by the use of low-pressure mercury lamp, of methylamine adsorbed on the surface of the porous Vycor glass at 77 K. On the photolyses of CD_3NH_2 vapor at 184.9, 147.0, and 123.6 nm, the formations of both CD_2NH_2 and CD_3NH are considerable, judging from the amounts of H_2, HD, and D_2 formed in the absence and the presence of C_2D_4[10] or NO and O_2.[11] Fukui *et al.*[12] have observed that the production of CH_2NH_2 from methylamine is less than that of CH_3NH upon the electron impact, while the peak of $CD_2NH_2^+$ was much higher than that of CD_3NH^+ in the mass spectrum of CD_3NH_2. On the other hand, according to simple estimations made by the RRK theory,[13] the greater part of the CH_3NH_2* can be expected to decompose to give CH_2NH_2, because the bond-dissociation energy of CH_3NH–H is 19.7 kJ mol^{-1}, higher than that of H–CH_2NH_2.[14] Judging from the results cited above, it seems that both CH_2NH_2 and CH_3NH radicals are formed in Reaction 5.

Reaction 6 is supported by the fact that CH_3 radicals were detected as intermediates. The collisional deactivation of CH_3NH_2* by a third body is negative, because $\phi_{CH_3NH_2\cdot HN_3}$ depends on the concentration ratio $[CH_4]/[HN_3]$, but is independent of the total pressure of CH_4 and HN_3, as will be discussed later. Reaction 7 means that CH_3NH_2 is formed by the hydrogen abstraction of CNH_4 (CH_2NH_2 and CH_3NH) from HN_3. The idea of the existence of CNH_4 radicals is supported by the fact that the formation of CH_3NH_2 is suppressed in the presence of NO. In the same way as has been discussed previously for the succeeding reactions of CH_2NH_2 radicals,[2] Reaction

8 was introduced for the following reasons: the reaction is energetically possible, and CH_3N_3 was found, but no products other than those described above could be detected.

The possibility of the formation of CH_3NH_2 by means of the cross-combination reaction $CH_3+NH_2\rightarrow CH_3NH_2$ can be excluded, because no C_2H_6 or N_2H_4 (m/z=32) was found to be formed by the self-dimerization reactions of the CH_3 and NH_2 radicals. Miller[4] has found the formation of small amounts of C_2H_6 and HCN in the photolysis of HN_3 with CH_4. The formation of HCN was also observed in the photolysis of HN_3 with C_2H_6 at high light intensities.[2] It seems that these products are formed by these reactions: $2CH_3\rightarrow C_2H_6$ and $CNH_4+N_3\rightarrow HCN+N_2+NH_3$. However, these reactions are negative in the present work, because the photolysis was carried out at a low light intensity and no C_2H_6 and HCN could be detected.

Reaction 9 is a hydrogen-abstraction reaction by CH_3 radicals from HN_3. Konar and Darwent[15] have reported k_9 to be 1.48×10^{-16} cm^{3}molecule^{-1}s^{-1} at 25°C. Creak *et al.*[16] have reported that the specific rate of a hydrogen abstraction reaction by CH_3 radicals from CH_4 is $10^{-11.78}\exp[-62.34(\text{kJ mol}^{-1})/RT]$ cm^3 molecule^{-1}s^{-1}. From both data, it is found that the hydrogen-abstraction reaction from HN_3 is 7.6×10^6 times faster than that from CH_4 at 25°C. On the other hand, Bras and Combourieu[17] have found that the rate constant for the reactions of hydrogen atoms with HN_3 is $10^{-10.60}\exp[-19.25(\text{kJ mol}^{-1})/RT]$ cm^3 molecule^{-1}s^{-1}. Kurylo and Timmons[18] have reported that the specific rate of a hydrogen-abstraction reaction by hydrogen atoms from CH_4 is $10^{-9.94}\exp[-49.37(\text{kJ mol}^{-1})/RT]$ cm^{3}molecule^{-1}s^{-1}. From both results, it is found that the reactions of hydrogen atoms with HN_3, Reactions 13 and 14, is 3.4×10^4 times faster than that with CH_4 at 30°C.

Judging from these results, it seems that the reactions of CH_4 with the CH_3, $NH(X^3\Sigma^-)$, H, NH_2, and N_3 radicals are negligible, and that these radicals disappear upon such reactions with reactive HN_3 as Reactions 9, 11 to 14, 19, 21, and 22. Reactions 10, 15 to 18, and 20 have been discussed previously[1,2] and so are omitted here.

Reaction Kinetics. The following reaction kinetics were formulated to confirm the mechanism of Reactions 1 to 22 and to obtain the rate-constant ratios.

On the quantum yield of $CH_3NH_2\cdot HN_3$, this equation:

$$\frac{1}{\phi_{CH_3NH_2\cdot HN_3}} = \frac{k_5+k_6}{k_5}\frac{k_7+k_8}{k_7}\left(\frac{k_3+k_4}{k_3}+\frac{k_2}{k_3}\frac{[HN_3]}{[CH_4]}\right) \quad \text{(I)}$$

can be derived, where:

$$k_2 = k_{2a} + k_{2b} + k_{2c}.$$

The plot of $1/\phi_{CH_3NH_2\cdot HN_3}$ *vs.* $[HN_3]/[CH_4]$ is shown in Fig. 5.

On the formations of H_2 and $CH_3NH_2\cdot HN_3$, Eq. II can be derived:

$$\frac{\phi_{H_2}}{\phi_{CH_3NH_2\cdot HN_3}} = \frac{k_7+k_8}{k_7}\left(\frac{k_4}{k_3}\frac{k_5+k_6}{k_5}\frac{k_{11}}{k_{11}+k_{12}}+\frac{k_{13}}{k_{13}+k_{14}}\right) + \frac{k_5+k_6}{k_5}\frac{k_7+k_8}{k_7}\left(\frac{2k_{2a}}{k_3}\frac{k_{13}}{k_{13}+k_{14}} + \frac{k_{2c}}{k_3}\frac{k_{16}}{k_{16}+k_{17}+k_{15}/[HN_3]}\right)\frac{[HN_3]}{[CH_4]} \quad \text{(II)}$$

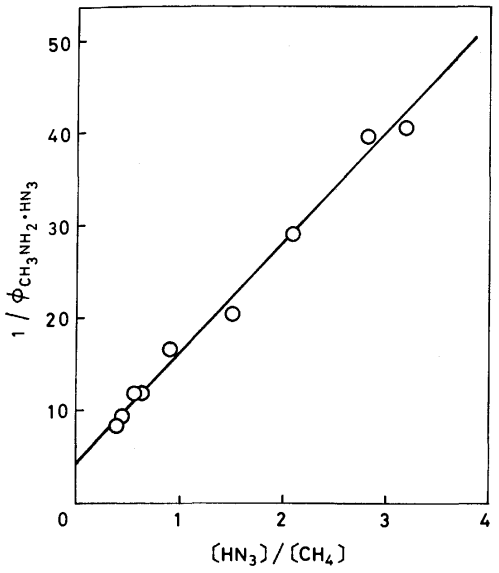

Fig. 5. Plot of $1/\phi_{CH_3NH_2\cdot HN_3}$ *vs.* $[HN_3]/[CH_4]$.

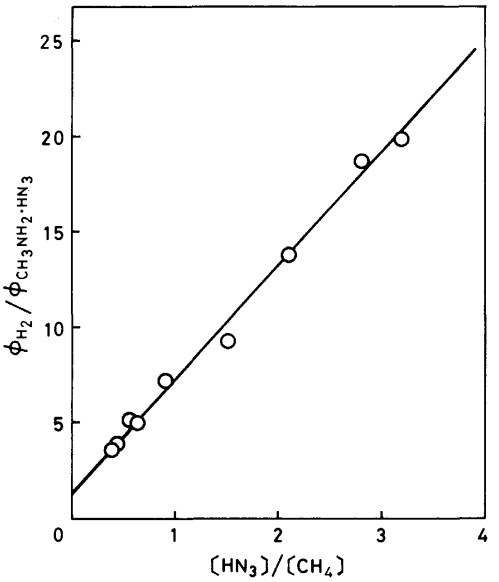

Fig. 6. Plot of $\phi_{H_2}/\phi_{CH_3NH_2\cdot HN_3}$ against $[HN_3]/[CH_4]$.

The plot of $\phi_{H_2}/\phi_{CH_3NH_2\cdot HN_3}$ *vs.* $[HN_3]/[CH_4]$ is shown in Fig. 6.

Equation III can be derived for the formations of N_2, H_2, and $CH_3NH_2\cdot HN_3$:

$$\frac{\phi_{N_2}+\phi_{H_2}}{\phi_{CH_3NH_2\cdot HN_3}} = \frac{k_7+k_8}{k_7}\left(1+4\frac{k_3+k_4}{k_3}\frac{k_5+k_6}{k_5}\right) + 4\frac{k_2+k_{2a}}{k_3}\frac{k_5+k_6}{k_5}\frac{k_7+k_8}{k_7}\frac{[HN_3]}{[CH_4]} \quad \text{(III)}$$

The plot of $(\phi_{N_2}+\phi_{H_2})/\phi_{CH_3NH_2\cdot HN_3}$ *vs.* $[HN_3]/[CH_4]$ is shown in Fig. 7.

By using the values obtained previously[1] of $k_{2a}/k_2=0.336$, $k_{2c}/k_2=0.414$, $k_{12}/k_{11}=3.22$, $k_{14}/k_{13}=1.15$, $k_{15}/k_{16}=2.27\times10^{-7}$ mol cm^{-3}, and $k_{17}/k_{16}=1.19$, the

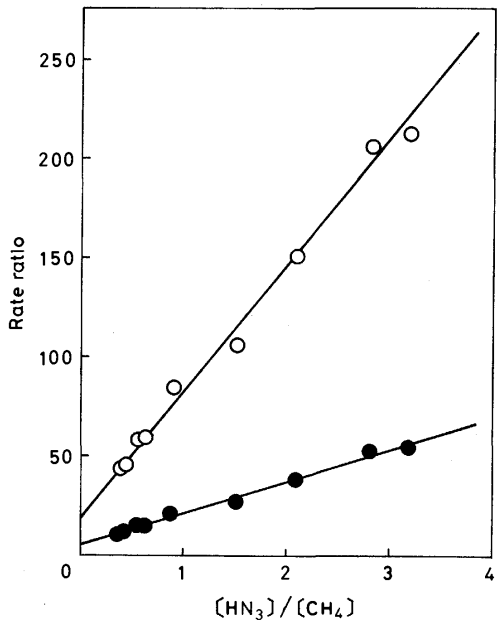

Fig. 7. Plots of $(\phi_{N_2}+\phi_{H_2})/\phi_{CH_3NH_2\cdot HN_3}$ (○) and $(\phi_{NH_4N_3}+\phi_{H_2})/\phi_{CH_3NH_2\cdot HN_3}$ (●) *vs.* $[HN_3]/[CH_4]$. The lower straight line was calculated from Eq. IV using the known rate constant ratios.

values of $k_3/k_2=0.175$, $k_4/k_2=0.177$, $k_6/k_5=0.133$, and $k_8/k_7=0.85$ can be obtained from the intercepts and the slopes in Figs. 5, 6, and 7. As to the value of k_8/k_7, a value similar to that for CH_2NH_2 radicals[2] was obtained.

In order to verify the rate-constant ratios obtained above, Eq. IV was derived for the formations of NH_4N_3, H_2, and $CH_3NH_2\cdot HN_3$:

$$\frac{\phi_{NH_4N_3}+\phi_{H_2}}{\phi_{CH_3NH_2\cdot HN_3}} = \frac{k_3+k_4}{k_3}\frac{k_5+k_6}{k_5}\frac{k_7+k_8}{k_7}+\frac{k_8}{k_7} + \frac{k_2+k_{2a}}{k_3}\frac{k_5+k_6}{k_5}\frac{k_7+k_8}{k_7}\frac{[HN_3]}{[CH_4]} \quad \text{(IV)}$$

The plot of $(\phi_{NH_4N_3}+\phi_{H_2})/\phi_{CH_3NH_2\cdot HN_3}$ *vs.* $[HN_3]/[CH_4]$ is also shown in Fig. 7. The values calculated from Eq. IV using the rate-constant ratios obtained above are shown by the lower straight line in Fig. 7. Fig. 7 shows that the straight line accords well with the experimental values.

Comparisons of Rate Constants. Chao *et al.*[19] have studied the decomposition rate of the chemically activated CH_3NH_2 which was formed by the reaction of NH_3 with the $^1CH_2$ produced by the photolysis of CH_2N_2. They have found that the specific rate of the unimolecular decomposition is 1.7×10^{10} s^{-1} for the photolysis at 435.8 nm and 2.3×10^{10} s^{-1} at 366 nm. The half-lifes for $C_2H_5NH_2$*[2] and n-$C_3H_7NH_2$*[20] were evaluated from these unimolecular decomposition rates. The half-life for CH_3NH_2* in this work was also calculated using the RRKM theory, as will be discussed below. These hallf-lifes are shown in Table 2. Here, the half-life (τ) was calculated from the

TABLE 2. HALF-LIFE AND DECOMPOSITION MODE OF CHEMICALLY ACTIVATED ALKYLAMINES

Alkylamine	Half life(τ) / s	Fraction by radical mechanism (R_r)	Fraction of R-CH_2NH_2 bond fission ($R_{R\text{-}CH_2NH_2}$)
CH_3NH_2[a]	$\approx 7.7\times10^{-12}$[e]	1.00	0.88[j]
CH_3NH_2[b]	4.1×10^{-11}[f], 3.0×10^{-11}[g]		
$C_2H_5NH_2$[c]	6.8×10^{-11}	0.96[h]	1.00
n-$C_3H_7NH_2$[d]	1.78×10^{-10}	0.28[i]	0.96[k]

a) This work. b) Ref. 19. c) Ref. 2. d) Ref. 20. e) From the RRKM calculation by the Gorin model. f) CH_2N_2 was photodecomposed at 435.8 nm. g) CH_2N_2 was photolyzed at 366 nm. h) The residual fraction is due to the $C_2H_5NH_2^* \rightarrow CH_3CN+2H_2$ reaction. i) The residual is caused by these reactions; n-$C_3H_7NH_2^* \rightarrow CH_4+C_2H_5N$, $C_2H_4+CH_3NH_2$, $C_2H_6+CH_2NH$, $H_2+C_3H_7N$, and $C_3H_6+NH_3$. j) This is the maximum value, because the CH_3NH-H bond fission may also be possible. The residual is due to $CH_3NH_2^* \rightarrow CH_3+NH_2$. k) This value was estimated from these relations: the formation ratio of n-$C_3H_7NH_2$ to i-$C_3H_7NH_2$ is 1.55; the decomposition rate to give C_2H_5 radicals from both n- and i-$C_3H_7NH_2^*$ is 1.39 times faster than the rate to give CH_3 radicals, and the half-life of n-$C_3H_7NH_2^*$ is almost the same as that of i-$C_3H_7NH_2^*$. The residual fraction is due to n-$C_3H_7NH_2^* \rightarrow CH_3+CH_2CH_2NH_2$.

$\tau=\ln 2/\sum_i k_i$ relation, where k_i is the specific rate of i-th unimolecular decomposition. It can be seen in Table 2 that the half-life increases with an increase in the carbon number of alkylamines and with a decrease in the total internal energy in the $CH_3NH_2^*$ molecules, as will be discussed below.

The ratio of the sum of the rates of decomposition caused by the radical mechanism to the sum of all the decomposition rates, R_r, is also shown in Table 2. The ratio for decompositions by the molecular mechanism increases with an increase in the carbon number of alkylamines. This may be because the chance for the formation of three- and four-center transition states, resulting in decompositions by the molecular mechanism, increases with an increase in the molecular complexity.

The ratio of the R-CH_2NH_2 bond fission rate to the sum of all single-bond fission rates by the radical mechanism, $R_{R-CH_2NH_2}$, is also shown in Table 2, where R means H for CH_3NH_2, CH_3 for $C_2H_5NH_2$, and C_2H_5 for n-$C_3H_7NH_2$. It is found that the ratio for the R-CH_2NH_2 bond fission is very high on these amines. Meanwhile, no C–N bond fission was observed on the unimolecular decomposition of $C_2H_5NH_2^*$,[2] although the C–N bond dissociation energy is 20.2 kJ mol^{-1} lower than that of the C–C bond. Similarly, hardly no C–N bond fission was found on the unimolecular decomposition of n-$C_3H_7NH_2^*$,[20] and the probability of the CH_3–$CH_2CH_2NH_2$ bond fission was also found to be very small. Such a high R-CH_2NH_2 bond fission efficiency may be because the CH_2NH_2 group of the activated complex which produces the R-CH_2NH_2 bond rupture is stabilized by the interaction of an unpaired electron of the C atom with nonbonding electrons of the N atom in the next position.[21]

Although the R-CH_2NH_2 bond fission proceeds with a high efficiency, the $k_5>k_6$ relation can not be explained in terms of the enthalpy, for the $CH_3NH_2 \rightarrow H+CH_2NH_2$ reaction is 54.4 kJ mol^{-1} more endothermic than the $CH_3NH_2 \rightarrow CH_3+NH_2(\tilde{X}^2B_1)$ reaction.

On the other hand, Kassab *et al.*[22] have computed the potential surface on the decomposition of CH_3NH_2 using *ab initio* methods; they have suggested this reaction:

$$CH_3NH_2 \longrightarrow CH_3 + NH_2(\tilde{A}^2A_1) \qquad (6)$$

for the decomposition of $CH_3NH_2(A')$ in the ground state, as well as where the $NH_3 \rightarrow H+NH_2(\tilde{A}^2A_1)$ reaction can be anticipated for the decomposition of ammonia in the ground state[23] from the correlation by symmetry.[24] Provided that the electronic state of NH_2 formed by Reaction 6 is $\tilde{A}^2A_1$, Reaction 6 becomes 68.2 kJ mol^{-1} more endothermic than Reaction 5. In this case, the $k_5>k_6$ relation is explainable.

As for the $HN_3+NH(a^1\Delta) \rightarrow N_3+NH_2(\tilde{A}^2A_1)$ reaction, of the same kind as Reaction 6, the formation of $NH_2(\tilde{A}^2A_1)$ has been observed by McDonald *et al.*[25] and Piper *et al.*[26] Kajimoto *et al.*[27] have also observed the emission of $NH_2(\tilde{A}^2A_1)$ formed by a similar reaction, $HN_3+H \rightarrow N_2+NH_2(\tilde{A}^2A_1)$. The formation of $NH_2(\tilde{A}^2A_1)$ by Reaction 6 is also supported by the fact that hardly no C–N bond rupture was found in the unimolecular decompositions of $C_2H_5NH_2^*$[2] and $C_3H_7NH_2^*$.[20]

In order to examine the adequacy of Reaction 6 bring about $NH_2(\tilde{A}^2A_1)$ and to obtain the absolute value of k_6, calculation by means of the RRKM theory was carried out. The specific rate calculated by means of the RRKM theory for the unimolecular decompositions of chemically activated molecules, k_E, is given by this equation:[28]

$$k_E = \frac{q_r^* q_{1r}^*}{q_r} \frac{\Gamma(s)}{\Gamma(s^*+r^*/2+1)} \frac{\prod_{i=1}^{s} h\nu_i}{h\prod_{i=1}^{s^*} h\nu_i^* (kT)^{r^*/2}} \times \frac{[E^*+a^*E_z^*]^{s^*+r^*/2}}{[E^*+E_0+aE_z]^{s-1}} \qquad (V)$$

Here, s, s^*, and r^* indicate the numbers of degrees of freedom for the vibrations of the molecule, and for the

vibrations and internal free rotations of the activated complex, respectively.

In the case of a single-bond fission, the activated complex should be very loose because of the critical state, and it must have the same structure as that for the radical recombination which is a reverse reaction. Thus, the Gorin model[29] was used in this case, assuming that the activated complex is an associated form of the CH_3 radical (planar, D_{3h}) and the $NH_2(\tilde{A}\,^2A_1(\Pi))$ radical (linear, $D_{\infty h}$). According to this "loosest" model, s, s^*, and r^* become 15, 10, and 5 respectively.

q_r and q_{ir}^* are the partition functions for the rotation of the molecule and the internal free rotation of the complex. By the Gorin model, the partition function for the rotation of the complex, q_r^*, can be expressed by this equation:[30]

$$q_r^* = \frac{8\pi^2 I(2/3)\mu kT}{\sigma h^2}\left(\frac{2A}{kT}\right)^{1/3} \qquad \text{(VI)}$$

Since both CH_3 and NH_2 groups are nonpolar, the attractive potential constant in the Lennard-Jones 12-6 intermolecular potential, A, can be calculated from the Slater and Kirkwood equation[3,31] for the dispersion term. The polarizabilities of the CH_3 and NH_2 groups were estimated to be 2.24 and 1.78×10^{-30} m^3 from the atomic polarizabilities of 1.039(C), 0.905(N), and $0.401(H)\times10^{-30}$ m^3. The number of outer-shell electrons is 7 for both CH_3 and NH_2 groups. The σ in Eq. VI is unity in this case.

The internal energy change of Reaction 6 at 0 K, E_o, was estimated to be 460.8 kJ mol^{-1} from the standard enthalpy change of 469.0 kJ mol^{-1}. The vibrational wave numbers ($\bar{\nu}_i$)[32] and the moments of inertia[19] for the CH_3NH_2 molecule and the vibrational wave numbers ($\bar{\nu}_i^*$)[33-35] and the moments of inertia for the complex are shown in Table 3. The last term in Eq. V was calculated from the relations derived by Rabinovitch *et al.*[36] The values of k_6 at 303 K, measured as a function of the excess energy (E^*) in the activated complex, are shown in Fig. 8.

On the photolysis of HN_3 at 313 nm, an excess energy of 177.9 kJ mol^{-1} is released and then distributed to N_2 and NH($a^1\Delta$) as fragments. Since the distribution fraction of the energy to NH($a^1\Delta$) is unclear, it was assumed that slightly less than one half of the excess energy is divided to NH($a^1\Delta$). Then, the total internal energy in CH_3NH_2* formed by Reaction 3 becomes about 540 kJ mol^{-1}. Since E_o is 460.8 kJ mol^{-1}, E^* becomes about 79 kJ mol^{-1}. The value of k_6 corresponding to this energy is 1.05×10^{10} s^{-1} as may be seen in Fig. 8. From $k_6/k_5=0.133$, $k_5=7.9\times10^{10}$ s^{-1} is obtained. Thus, the half-life of CH_3NH_2* obtained from $\tau=\ln 2/(k_5+k_6)$ becomes 7.7×10^{-12} s.

RRKM calculations by the methods described above were also carried out for the decomposition rates of the CH_3NH_2* formed under the reaction conditions

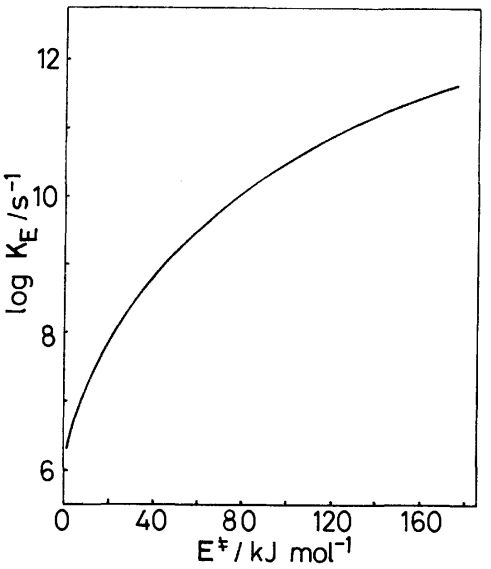

Fig. 8. Specific rate of Reaction 6 by the RRKM calculation, measured as a function of the excess energy.

performed by Chao *et al.*;[19] the calculated values were found to be consistent with their experimental values. The low E^* was the reason that the decomposition rates observed by them are slow as compared with that in this work.

On the other hand, the specific rate for the collisional deactivation of CH_3NH_2* by a third body(Q), k_z, can be calculated from the Lennard-Jones collision frequency as described previously.[2] The values of σ and ε/k used in the calculation are 4.30 and 500 for CH_3NH_2,[37] 3.82 and 137 for CH_4,[38] and 3.98 Å and 240 K for HN_3[2] respectively. The highest total pressure in the present work is 24.27 kPa (P_{HN_3}=6.67 and P_{CH_4}=17.60 kPa). In this case, the rate ratio of the collisional deactivation to the unimolecular decompositions of CH_3NH_2*, $k_z[Q]/(k_5+k_6)$, becomes 0.038. This result is consistent with the experimental finding that the collisional

deactivation of CH_3NH_2* could not be found within the limits of experimental accuracy. It thus appears that the calculated values of k_5, k_6, and τ obtained above are reasonable.

On the photolysis of CH_3NH_2 vapor, the primary processes are, in general, given by this mechanis:[10,11,39]

$$CH_3NH_2 + h\nu \begin{cases} \nearrow H + CNH_4 \\ \longrightarrow H_2 + CNH_3 \\ \searrow CH_3 + NH_2, \end{cases}$$

except for the decompositions of $CH_3NH_2+h\nu$(123.6 nm)→CH_4+NH($c^1\Pi$) and others in very-short-wavelength systems.[40] Provided that the succeeding reactions for H atoms and CH_3 radicals are H+RH→H_2+R, CH_3+RH→CH_4+R, and $2CH_3$→C_2H_6, the relative fractions for three photodissociation processes can be calculated by means of the following simplified relations: $[H_2-H_2(scav)]/[H_2+CH_4+2C_2H_6]$ for $H+CNH_4$; $[H_2(scav)]/[H_2+CH_4+2C_2H_6]$ for H_2+CNH_3; $[CH_4+2C_2H_6]/[H_2+CH_4+2C_2H_6]$ for CH_3+NH_2. Here, $[H_2(scav)]$ indicates the amount of H_2 formed in the presence of a scavenger such as O_2 and NO. The relative fractions are shown in Table 4, together with the fractions for the umimolecular decompositions of CH_3NH_2* formed by Reaction 3.

Table 4 shows that the relative fractions for the chemically activated CH_3NH_2* are very similar to those for the photochemically activated CH_3NH_2* at 244 to 194 nm, and that the fraction for the formation of H_2 by the molecular mechanism increases with an increase in the excitation energy. It is also found that the fraction for $H+CNH_4$ is always larger than the fraction for CH_3+NH_2. Regarding this trend, Kassab *et al.*[22] have found, from theoretical considerations, that the potential barrier resulting in the CH_3–NH_2 bond rupture is higher than that for the CH_3NH–H bond rupture on the photodissociation of the lowest excited singlet, CH_3NH_2.

On the efficiencies of the reactions of NH($a^1\Delta$) with saturated hydrocarbons, the rate-constant ratio of the insertion reaction of NH($a^1\Delta$) into a C–H bond to the reactions of NH($a^1\Delta$) with HN_3 is 0.175 (k_3/k_2) for CH_4 and 0.334 for C_2H_6.[2] The low efficiency for CH_4 may be due to the facts that the number of C–H bonds of CH_4 is less than that of C_2H_6 and that the C–H bond-dissociation energy of CH_4 is higher than that of C_2H_6. The rate-constant ratio of the collisional spin relaxation of NH($a^1\Delta$) to Reaction 2 is 0.177 (k_4/k_2) for CH_4, and 0.217 for C_2H_6.[2] The difference may be because the collisional spin-relaxation efficiency depends on the molecular complexity, that is, the number of atoms constituting a saturated hydrocarbon molecule. More details will be presented in a later work.[20]

Summary. The reaction efficiencies of NH($a^1\Delta$) with CH_4 and the unimolecular decomposition rates of the CH_3NH_2* formed by the insertion were investigated. The insertion efficiency of NH($a^1\Delta$) into a C–H bond of CH_4 was 0.52 as compared with that of C_2H_6. This difference appears to be caused by the higher C–H bond dissociation energy and the lower C–H bond number than those for C_2H_6. The collisional deactivation efficiency of NH($a^1\Delta$) to NH($X^3\Sigma^-$) by CH_4 was 0.82 of that by C_2H_6. The unimolecular decomposition, CH_3NH_2*→H+CNH_4 (5), was 7.5 times faster than the CH_3NH_2*→CH_3+NH_2 (6) decomposition, although the C–H or N–H bond dissociation energy is higher than that of the C–N bond. However, this is explainable provided that the electronic state of NH_2 formed by Reaction 6 is $\tilde{A}^2A_1$. From the RRKM calculation by the Gorin model, $k_5 \approx 7.9\times10^{10}$ s^{-1}, $k_6 \approx 1.05\times10^{10}$ s^{-1}, and τ (half-life of CH_3NH_2*)$\approx 7.7\times10^{-12}$ s were estimated. These results are in accord with the experimental result that the collisional deactivation of CH_3NH_2* was not observed in the total pressure range lower than 24.3 kPa.

I would like to thank Mr. Jun Fukuchi for his cooperation.

Reactions of NH Radicals. V. Photolysis of HN_3 in the Presence of C_3H_8 at 313 nm

Sukeya KODAMA*

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received September 5 , 1983)

The photolysis of HN_3 vapor in the presence of C_3H_8 was studied at 313 nm and 30 °C. The main products were N_2, H_2, CH_4, C_2H_6, C_3H_6, NH_4N_3, $CH_3NH_2 \cdot HN_3$, $C_2H_5NH_2 \cdot HN_3$, and *n*- and *i*-$C_3H_7NH_2 \cdot HN_3$. The quantum yields of these products were measured as a function of the pressure of HN_3 or C_3H_8. The following mechanisms for the main reactions was proposed: $HN_3+h\nu(313\text{ nm}) \rightarrow N_2+NH(a^1\Delta)$; $NH(a^1\Delta)+HN_3 \rightarrow 2N_2+2H$, NH_2+N_3, and $N_2+N_2H_2^*$ (2); $NH(a^1\Delta)+C_3H_8 \rightarrow C_3H_7NH_2^*$(*n*- and *i*-propylamine) (3); $NH(a^1\Delta)+C_3H_8 \rightarrow NH(X^3\Sigma^-)+C_3H_8$ (4); $C_3H_7NH_2^* \rightarrow CH_3+C_2H_4NH_2$ (5); $CH_4+C_2H_4NH$ (6), $C_2H_4+CH_3NH_2$ (7), $C_2H_5+CH_2NH_2$ (8), $C_2H_6+CH_2NH$ (9), $H_2+C_3H_6NH$ (10), and $NH_3+C_3H_6$ (11); $C_3H_7NH_2^*+HN_3 \rightarrow C_3H_7NH_2+HN_3$ (12); $C_3H_7NH_2^*+C_3H_8 \rightarrow C_3H_7NH_2+C_3H_8$ (13). The rate constant ratios are: $k_3/k_2=1.28$; $k_4/k_2=0.262$; $k_6/k_5=0.109$; $k_7/k_5=0.050$; $k_8/k_5=1.39$; $k_9/k_5=0.040$; $k_{10}/k_5=1.20$; $k_{11}/k_5=4.72$; $k_{12}/k_5=666$ dm^3 mol^{-1}; $k_{13}/k_5=860$ dm^3 mol^{-1}. The formation ratio of *n*-$C_3H_7NH_2$/*i*-$C_3H_7NH_2$ was 1.55, regardless of the total pressure. The half-life of 1.78×10^{-10} s for $C_3H_7NH_2^*$ was obtained by using the collision theory. The relative and absolute rate constants were compared for the reactions of $NH(a^1\Delta)$ with CH_4, C_2H_6, and C_3H_8; it was found that the relative yield for the insertion of $NH(a^1\Delta)$ into a C–H bond increases with a decrease in the C–H bond dissociation energy.

The reactions of $NH(a^1\Delta)$ with HN_3,[1] Xe,[1] C_2H_6,[2] C_2H_4,[3] and CH_4[4] have been studied previously. It was found that HN_3 is a useful source for the first excited singlet $NH(a^1\Delta)$ and that $NH(a^1\Delta)$ reacts to give amine by insertion into a C–H bond, such as CH_3NH_2 from CH_4[4] and $C_2H_5NH_2$ from C_2H_6.[2] It is of interest to compare the relative reactivities for the reactions of $NH(a^1\Delta)$ with simple saturated hydrocarbons, such as CH_4, C_2H_6, C_3H_8, and *i*-C_4H_{10}, and to compare the relative efficiencies of the insertion per C–H bond for primary, secondary, and tertiary C–H bonds.

For the reactions of NH with saturated hydrocarbons, Miller[5] has studied the photolysis of HN_3 in the presence of CH_4, C_3H_8, *n*-C_4H_{10}, *i*-C_4H_{10}, and $(CH_3)_4C$, and measured the amines formed by the reactions of NH with these hydrocarbons. He has found that the amine yield increases in this order: C_3H_8<*n*-C_4H_{10}<*i*-C_4H_{10}<$(CH_3)_4C$. Back *et al.* have studied the flash photolysis of HNCO in the presence of C_3H_8[6] and the steady photolysis of HNCO with C_2H_6, C_3H_8, and $(CH_3)_4C$ at 51 °C.[7] They have found that the yield of CO was reduced to about one-third of its value in pure HNCO, the yield of N_2 was reduced close to zero, and the yield of H_2 was markedly enhanced in the presence of parafins. However, no amines could be detected. Thus, they suggested the decomposition of the vibrationally excited amines formed by insertion reactions. Richardson and Setser[8] have studied the thermal decomposition of HN_3 in the presence of CH_4, C_2H_6, and C_3H_8. However, no evidence was found for the reaction of NH with these hydrocarbons in the temperature range from 285 to 470 °C. Konar *et al.*[9] have investigated the photolysis of HN_3 in the presence of C_2H_6 and *i*-C_4H_{10} at 214 nm and room temperature, and showed that the formation rates of N_2 and H_2 decrease with an increase in the hydrocarbon pressure.

Recently, Tsunashima *et al.*[10] have studied the photolysis of HN_3 in liquid ethane, propane, and isobutane at the Dry Ice–methanol temperature, they have found the formation of ethylamine from C_2H_6, propyl- and isopropylamine from C_3H_8, and of butyl- and *t*-butylamine from *i*-C_4H_{10}. They have also estimated that the relative efficiencies of the insertion of ^{1}NH into primary, secondary, and tertiary C–H bonds are 1.0, 1.9, and 2.3 respectively. Hamada *et al.*[11] have studied the photolysis of HN_3 in liquid cyclopropane and in binary solutions of ethane and cyclopropane at the Dry Ice–methanol temperature, and reported that the insertion rate of $NH(a^1\Delta)$ into a C–H bond of cyclopropane is 1.05 times faster than that of ethane.

Kajimoto and Fueno[12] have studied the photolysis of HN_3 with C_2H_6 in the gas phase at 254 nm. From the pressure dependences of the yields of the insertion product($C_2H_5NH_2$) and the fragmentation products (CH_3 and C_2H_5), they have found that the branching ratios for three pathways of the insertion of $NH(a^1\Delta)$ into a C–H bond of C_2H_6, the hydrogen abstraction from C_2H_6 by $NH(a^1\Delta)$, and the electronic quenching of $NH(a^1\Delta)$ to $NH(X^3\Sigma^-)$ were 0.6, 0.1, and 0.3 respectively. Kondo *et al.*[13] have studied the effects of the reactions of $NH(a^1\Delta)$ with C_3H_8 on the photolysis of HN_3 at 254 nm, and determined that the relative secondary/primary C–H bond reactivity per bond is 1.5 for the insertion and 7.5 for the abstraction, results based on the pressure dependence of the yields of the insertion products (*n*-$C_3H_7NH_2$ and *i*-$C_3H_7NH_2$) and the fragmentation products (C_2H_5, *n*-C_3H_7, and *i*-C_3H_7).

In order to compare the specific rates for the insertion of $NH(a^1\Delta)$ into C–H bonds of simple saturated hydrocarbons, the collisional deactivations of $NH(a^1\Delta)$ to $NH(X^3\Sigma^-)$ by the hydrocarbons, and the unimolecular decomposition of the alkylamines formed by the insertion, the photolysis of HN_3 in the presence of C_3H_8 was investigated in this work, a continuation of our earlier studies with C_2H_6[2] and CH_4.[4]

Experimental

The propane obtained from the Takachiho Chemical Co. was 99.8% pure. It was purified each time before use by means of condensation and evacuation at the temperature of liquid nitrogen. The preparation and purification of HN_3, and the apparatus and procedure for the reaction, were the same as have been described previously.[1,2] All the runs in this work were carried out at 313 nm and 30 °C. The light intensity was reduced by screens to eliminate radical-radical reactions. The irradiation time was usually 90 min, and the degree of conversion of HN_3 was below 3 per cent.

The detected reaction products were N_2, H_2, CH_4, C_2H_4, C_2H_6, C_3H_6, CH_3N_3, NH_4N_3, $CH_3NH_2 \cdot HN_3$, $C_2H_5NH_2 \cdot HN_3$, and n- and i-$C_3H_7NH_2 \cdot HN_3$. No HCN was detected in the analysis by the pyridine-pyrazolone method.[14]

In order to inspect the radical intermediates, the products formed by the photolysis of HN_3 with C_3H_8 and NO at 313 nm were analysed gas chromatographically by the use of a Silicone SE-30 1-m column at room temperature. The retention times of these products (RNO_x) were then compared with those of the products formed on the photolyses of $CH_3N_2CH_3$, $C_2H_5COC_2H_5$, $(i\text{-}C_3H_7)_2CO$, and n-$C_3H_7COCH_3$ with NO, in the same gas chromatographic conditions. From the comparisons, the formations of CH_3 and C_2H_5 radicals as intermediates were confirmed, but few n-C_3H_7 or i-C_3H_7 radicals were found. The photolysis of HN_3 with C_3H_8 and NO at 254 nm was also carried out in order to inspect the effect of the wavelength. Thus, the large two peaks for i-C_3H_7 radicals, together with the peaks for the CH_3, C_2H_5, and n-C_3H_7 radicals, were found. The results at 254 nm are in accord with the results of Kondo *et al.*,[13] except that they did not detect any CH_3 radicals.

For the identification of the nitrogen-containing products, white volatile products condensed at the Dry Ice-acetone temperature were introduced into a solid sodium hydroxide column in order to remove the HN_3 from the white volatile products.[2,10] A mass spectrum of the HN_3-removed products at the ionizing voltage of 15 V is shown in Fig. 1. The mass spectra of the n- and i-$C_3H_7NH_2$ samples were also observed at the ionizing voltage of 15 V. In the spectra, the large peaks of m/z=30 ($CH_2NH_2^+$) for n-$C_3H_7NH_2$ and of m/z=44 ($CH_3CHNH_2^+$) for i-$C_3H_7NH_2$ were found, together with the parent-molecule-ion ($C_3H_7NH_2^+$) peak and its protonated-ion ($C_3H_7NH_3^+$) peak.

The product peaks of m/z=17, 18, 31, 32, 45, 46, 59, and 60 in Fig. 1 correspond to NH_3^+, NH_4^+, $CH_3NH_2^+$, $CH_3NH_3^+$, $C_2H_5NH_2^+$, $C_2H_5NH_3^+$, $C_3H_7NH_2^+$, and $C_3H_7NH_3^+$ respectively. The large peak of m/z=30 ($CH_2NH_2^+$) seems to arise from the electron-impact reactions of $CH_3NH_2 \rightarrow H+CH_2NH_2^+ + e^-$, as found in the mass spectrum of CH_3NH_2,[2,4,15] and of n-$C_3H_7NH_2 \rightarrow C_2H_5+CH_2NH_2^+ + e^-$, as observed in the spectrum of the n-$C_3H_7NH_2$ sample. Similarly, the large peak of m/z=44 may be due to the electron-impact reactions of $C_2H_5NH_2 \rightarrow H+C_2H_4NH_2^+ + e^-$ and i-$C_3H_7NH_2 \rightarrow CH_3+CH_3CHNH_2^+ + e^-$. The peak of m/z=58 may result from the $C_3H_7NH_2 \rightarrow H+C_3H_6NH_2^+ + e^-$ reaction.

For the quantitative analyses of the reaction products, first, these products were separated at the temperature of solid nitrogen (about −220 °C), −160 °C, and the Dry Ice-acetone temperature. Quantitative separations of N_2, H_2, and CH_4 passing through a trap at −220 °C were carried out by the procedures described previously.[2] C_2H_4, C_2H_6, and a part of the unconverted C_3H_8, condensed at −220 °C, were collected into a Toepler gauge, and the total volume was determined. The separations of C_2H_4, C_2H_6, and C_3H_8 were carried out by gas chromatography using a silica-gel column (2 m) at 60 °C.

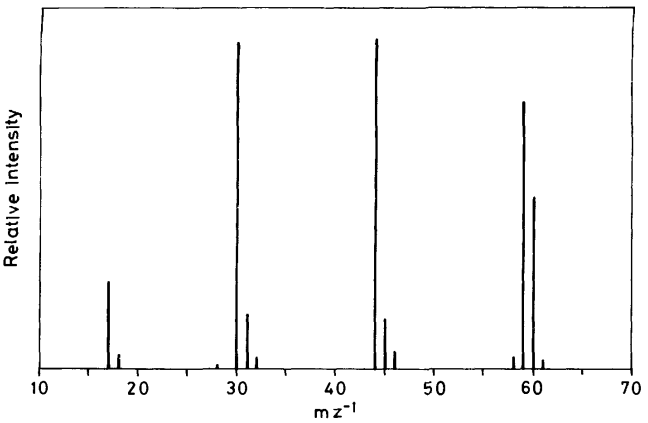

Fig. 1. Mass spectrum of the substances removed HN_3 from the white volatile products trapped at the Dry Ice-acetone temperature. The ionizing voltage is 15 V.

NH_4N_3 and the salts of amines with HN_3, condensed at the Dry Ice-acetone temperature, were introduced into a CuO column at about 550 °C. The amounts of N_2, NO, N_2O, and CO_2 produced as the combustion products were determined by a previously described method.[2] The total amount of nitrogen atoms, (N), is given by $(N)=2N_2+2N_2O+NO$. The total amount of carbon atoms in the products is identical with the amount of carbon dioxide formed by the combustion, (CO_2).

In order to determine the relative yields of CH_3NH_2, $C_2H_5NH_2$, i-$C_3H_7NH_2$, and n-$C_3H_7NH_2$, the HN_3-removed products were also analysed by means of gas chromatography at 10 °C using a 2-m columun of KOH (5%)-paraffin liquid (20%) coated on Chromosorb WAW.[16] The retention times of CH_3NH_2, $C_2H_5NH_2$, and i-$C_3H_7NH_2$ relative to n-$C_3H_7NH_2$ are 0,23, 0.36, and 0.56 respectively.

The quantum yields of the products were determined using HN_3 as an actinometer.[1]

Results

The photolysis of HN_3 of 6.7 kPa at 4.0 kPa of C_3H_8 was carried out as a function of the absorbed-light intensity in the range from 4.5 to 18.8×10^{14} quanta s^{-1}. The results, shown in Fig. 2, show that ϕ_{H_2} and ϕ_{CH_4} are independent of the light intensity, while ϕ_{N_2}, $\phi_{(N)}$, and $\phi_{(CO_2)}$ increase slightly with a decrease in the light intensity, but all the quantum yields converge to a constant value as the light intensity decreases.

The results for the photolysis of HN_3 of 6.7 kPa, measured as a function of the C_3H_8 pressure at the low absorbed-light intensity of 4.5×10^{14} quanta s^{-1}, are shown in Fig. 3. It may be seen in Fig. 3 that ϕ_{N_2} and ϕ_{H_2} decrease, $\phi_{(CO_2)}$ and $\phi_{(N)}$ increase, and ϕ_{CH_4}, $\phi_{C_2H_4}$, and

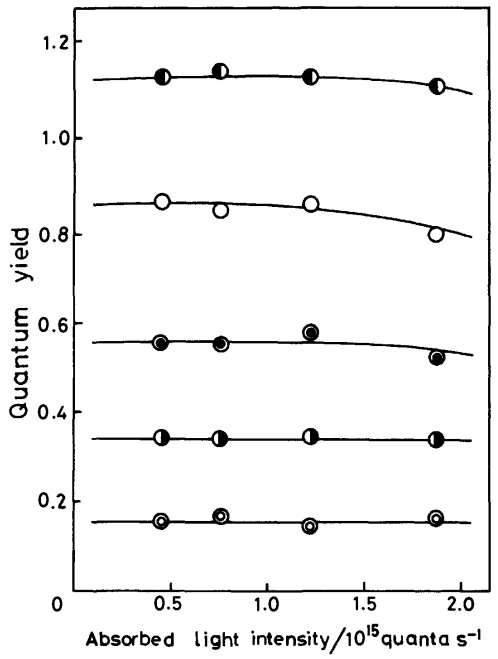

Fig. 2. Results for the photolysis of HN_3 of 6.7 kPa, measured as a function of the absorbed light intensity at 313 nm, 30 °C, and 4.0 kPa of C_3H_8. ◐, $\phi_{N_2}/3$; ○, $\phi_{(N)}/4$; ⊙, $\phi_{(CO_2)}$; ◑, ϕ_{H_2}; ◎, $4\phi_{CH_4}$.

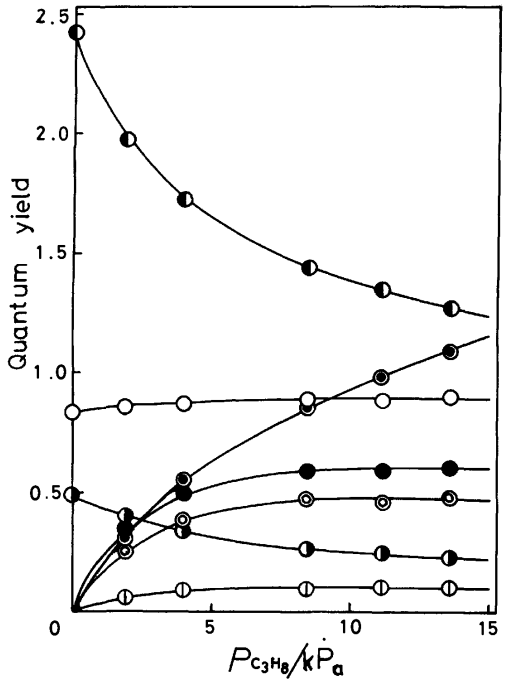

Fig. 3. Results of the photolysis of HN_3 of 6.7 kPa, measured as a function of C_3H_8 pressure at 313 nm, 30 °C, and the low absorbed light intensity of 4.5×10^{14} quanta s^{-1}. ◐, $\phi_{N_2}/2$; ⊙, $\phi_{(CO_2)}$; ○, $\phi_{(N)}/4$; ◑, ϕ_{H_2}; ◎, $10\phi_{CH_4}$; ●, $10\phi_{C_2H_6}$; ⊕, $50\phi_{C_2H_4}$.

$\phi_{C_2H_6}$ decrease *via* a maximum value at about 10 kPa as the C_3H_8 pressure increases.

Figure 4 shows the results of the photolysis measured as a function of the HN_3 pressure at 4.0 kPa of

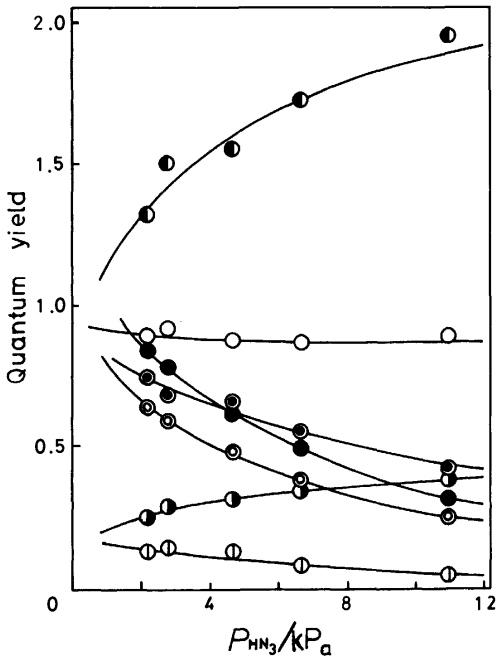

Fig. 4. Results of the photolysis measured as a function of HN_3 pressure at 4.0 kPa of C_3H_8, 30 °C, 313 nm, and the low incident light intensity of 3.9×10^{15} quanta s^{-1}. ◐, $\phi_{N_2}/2$; ⊙, $\phi_{(CO_2)}$; ○, $\phi_{(N)}/4$; ◑, ϕ_{H_2}; ◎, $10\phi_{CH_4}$; ●, $10\phi_{C_2H_6}$; ⊕, $50\phi_{C_2H_4}$.

C_3H_8 and the low incident-light intensity of 3.9×10^{15} quanta s^{-1}. In Fig. 4, it is found that ϕ_{N_2} and ϕ_{H_2} increase, but $\phi_{(N)}$, $\phi_{(CO_2)}$, ϕ_{CH_4}, $\phi_{C_2H_4}$, and $\phi_{C_2H_6}$ decrease, with an increase in the HN_3 pressure.

On the photolysis of HN_3 of 6.7 kPa with C_3H_8 of 4.0 kPa and NO of 0.47 kPa at the absorbed-light intensity of 4.5×10^{14} quanta s^{-1}, the ϕ_{CH_4}, $\phi_{C_2H_6}$, and $\phi_{C_2H_4}$ values were 0.00374 (1/10.2 of that without NO), 0.00138 (1/35.6 of that without NO), and 0.00172 (the same as that without NO) respectively.

The amines obtained under the same experimental conditions as those in Figs. 3 and 4 were analysed by means of gas chromatography. Table 1 shows the yields of CH_3NH_2, $C_2H_5NH_2$, and n-$C_3H_7NH_2$ relative to that of i-$C_3H_7NH_2$. It may be seen in Table 1 that CH_3NH_2/i-$C_3H_7NH_2$ and $C_2H_5NH_2/i$-$C_3H_7NH_2$ decrease with an increase in the C_3H_8 or HN_3 pressure, while n-$C_3H_7NH_2/i$-$C_3H_7NH_2$ is constant regardless of the total pressure and the concentration ratio $[HN_3]/[C_3H_8]$.

Discussion

Reaction Mechanism. On the basis of the present experimental results and in the light of the results achieved by previous investigations,[1-4] the following reaction mechanism was postulated for the photolysis of HN_3 in the presence of C_3H_8, where A and P denote HN_3 and C_3H_8 molecules:

$$A + h\nu(313\,nm) \longrightarrow N_2 + NH(a^1\Delta) \quad (1)$$

$$H + A \longrightarrow H_2 + N_3 \quad (16)$$

$$H + A \longrightarrow NH_2 + N_2 \quad (17)$$

$$H + P \longrightarrow H_2 + C_3H_7 \quad (18)$$

$$R_1\ (R_1=CH_3, C_2H_5, C_3H_7, C_2H_4NH_2) + A \longrightarrow R_1H + N_3 \quad (19)$$

$$R_2NH_2\ (R_2=CH_3, C_2H_5, C_3H_7) + A \longrightarrow R_2NH_2\cdot HN_3 \quad (20)$$

$$R_3NH\ (R_3=CH_2, C_2H_4, C_3H_6) + A \longrightarrow R_3NH\cdot HN_3. \quad (21)$$

The succeeding reactions for species consisting of only nitrogen and hydrogen atoms are as follows:[1] $NH(X^3\Sigma^-)+A\rightarrow H_2+2N_2$ (22); $NH(X^3\Sigma^-)+A\rightarrow NH_2+N_3$ (23); $N_2H_2^*\rightarrow N_2H_2^{**}$ (24); $N_2H_2^*+A\rightarrow N_2+H_2+A$ (25); $N_2H_2^*+A\rightarrow NH_3+2N_2$ (26); $N_2H_2^{**}+A\rightarrow NH_3+2N_2$ (27); $NH_2+A\rightarrow NH_3+N_3$ (28); $NH_3+A\rightarrow NH_4N_3$ (29); $N_3+A\rightarrow N_3\cdot A$ (30); $2N_3\cdot A\rightarrow 3N_2+2A$ (31).

Since the formation of propyl- and isopropylamines has been confirmed by the gas-chromatographic and mass-spectrometric measurements, it is clear that the first excited singlet, NH($a^1\Delta$), formed by the photolysis of HN_3 at 313 nm[1] reacts to give propylamine upon insertion into a C–H bond of C_3H_8. The $C_3H_7NH_2^*$ formed by Reaction 3 implies vibrationally excited propylamine and isopropylamine, because both insertions into primary and secondary C–H bonds for C_3H_8 are possible.[10,11]

On the reactions of NH($a^1\Delta$) with C_3H_8 as a saturated hydrocarbon, a possible process other than the insertion is the collisional deactivation by C_3H_8 to NH($X^3\Sigma^-$). The collisional spin-relaxation process, Reaction 4, was also found for Xe,[1] CH_4,[4] and C_2H_6.[2] Kondo *et al.*[13] have proposed a hydrogen-abstraction reaction: $NH(a^1\Delta)+C_3H_8\rightarrow n$-$C_3H_7$ or i-$C_3H_7+NH_2$, from C_3H_8 by NH($a^1\Delta$) upon photolysis at 254 nm. However, this reaction can be disregarded in the present work at 313 nm, because hardly no n-C_3H_7 or i-C_3H_7 radicals were formed. A non-abstraction mechanism is also supported by the fact that the intercept of the plot of NH_3/N_2 *vs.* $[HN_3]/[C_3H_8]$ is zero on the photolysis of HN_3 in liquid propane at from 250 to 320 nm.[10]

Reactions 5 and 8 show the unimolecular decompositions of $C_3H_7NH_2^*$ by the radical mechanism; they were established by the facts that CH_3 and C_2H_5 radicals were detected as intermediates and that ϕ_{CH_4} and $\phi_{C_2H_6}$ were reduced drastically in the presence of NO. The formations of CH_4, C_2H_4, and C_2H_6 from $C_3H_7NH_2^*$ by the molecular mechanism are represented by Reactions 6, 7, and 9; they are explainable by the facts that they are formed even in the presence of NO.

On the photolysis in the presence of NO, no drastical decrease for ϕ_{H_2} was observed. This suggests the formation of H_2 by a molecular mechanism such as

Reaction 10. Reaction 11 is supported by the fact that C_3H_6 was formed even in the presence of NO. Kondo *et al.*[13] have presented two fragmentation reactions, n-$C_3H_7NH_2^* \rightarrow n$-$C_3H_7+NH_2$ and i-$C_3H_7NH_2^* \rightarrow i$-$C_3H_7+NH_2$, in the photolysis at 254 nm. However, the fragmentations seem to be negligible in the photolysis at 313 nm, because scarcely no n-C_3H_7 or i-C_3H_7 radicals were detected. Reactions 12 and 13 are the collisional deactivation processes of $C_3H_7NH_2^*$ by HN_3 and C_3H_8 to give stable propyl- and isopropylamines, as was found for $C_2H_5NH_2^*$.[2]

Reaction 15 was introduced to explain the facts that the formation of CH_3N_3 was found and that the formation ratio $CH_3NH_2/C_2H_5NH_2$ is considerably less than $\phi_{C_2H_6}/\phi_{CH_4}$, although the yields of Reactions 6, 7, and 9 are very small as compared with those of Reactions 5 and 8. Reactions 14 and 15 were also found in the photolysis of HN_3 with C_2H_6.[2] Reaction 18 was introduced because the H atoms formed by Reaction 2a, exothermic with 370 kJ mol^{-1}, are in a "hot" state, and also because the rate of hydrogen abstraction from C_3H_8 by H atoms is much faster than that for C_2H_6.[17]

Reaction 19 is the hydrogen-abstraction reaction by CH_3, C_2H_5, C_3H_7, and $C_2H_4NH_2$ radicals from HN_3. Reaction 20 was supported by the experimental fact that basic amines (R_2NH_2) react with acidic HN_3 in the vapor phase to give the azide salts ($R_2NH_2 \cdot HN_3$) as a white volatile powder.[2]

Because of the unstable products, the chemical structures of the CH_2NH, C_2H_4NH, and C_3H_6NH formed by the molecular mechanisms of Reactions 6, 9, and 10 are not clear. However, these products (R_3NH) may have a basic imino or amino group, and they may be stabilized by forming the azide salts ($R_3NH \cdot HN_3$) with acidic HN_3, as in Reaction 21. The reactions other than those mentioned above have been discussed previously[1] and so are omitted here.

Reaction Kinetics. The reaction kinetics were carried out in order to confirm the mechanisms of Reactions 1 to 31, and in order to obtain the rate-constant ratios for these reactions. Since the formation ratio, n-$C_3H_7NH_2/i$-$C_3H_7NH_2$, is independent of the total pressure, as may be seen in Table 1, the ratio of collisional deactivation to unimolecular decomposition for n-$C_3H_7NH_2^*$ may be said to be the same as that for i-$C_3H_7NH_2^*$. Therefore, it is possible to treat the reaction kinetics for n-$C_3H_7NH_2^*$ and i-$C_3H_7NH_2^*$ collectively.

Regarding the formations of CH_4, C_2H_6, and C_2H_4, Eqs. I and II can be derived:

$$\phi_{C_2H_6}/\phi_{CH_4} = (k_8+k_9)/(k_5+k_6) \qquad \text{(I)}$$

$$\phi_{C_2H_4}/\phi_{CH_4} = k_7/(k_5+k_6) \qquad \text{(II)}$$

Plots of $\phi_{C_2H_6}/\phi_{CH_4}$ and $\phi_{C_2H_4}/\phi_{CH_4}$ *vs.* $[HN_3]/[C_3H_8]$ are shown in Fig. 5; both ratios are constant regardless of the $[HN_3]/[C_3H_8]$ ratio and the total pressure.

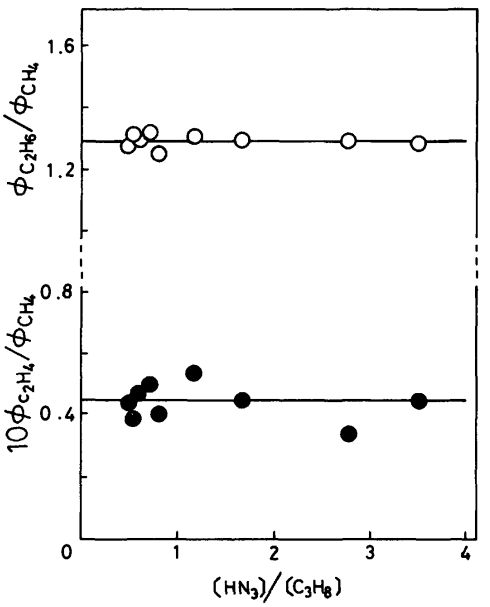

Fig. 5. Plots of $\phi_{C_2H_6}/\phi_{CH_4}$ (○) and $10\phi_{C_2H_4}/\phi_{CH_4}$ (●) *vs.* $[HN_3]/[C_3H_8]$.

When the quantum yields of CH_4 and C_2H_6 in the presence of NO, $\phi_{CH_4}(NO)$ and $\phi_{C_2H_6}(NO)$, are compared with those without NO, these relations:

$$\phi_{CH_4}(NO)/\phi_{CH_4} = k_6/(k_5+k_6) = 0.098 \qquad \text{(III)}$$

$$\phi_{C_2H_6}(NO)/\phi_{C_2H_6} = k_9/(k_8+k_9) = 0.028 \qquad \text{(IV)}$$

are obtained. From the values in Fig. 5 and Eqs. III and IV, k_6/k_5=0.109, k_7/k_5=0.050, k_8/k_5=1.39, and k_9/k_5=0.040 can be derived.

For the formations of CH_4 and (CO_2), Eq. V can be derived:

$$\frac{\phi_{(CO_2)}}{\phi_{CH_4}} = 2 + \frac{k_7+k_8k_{14}/(k_{14}+k_{15})+k_9+3k_{10}}{k_5+k_6} + \frac{3k_{12}[HN_3]}{k_5+k_6} + \frac{3k_{13}[C_3H_8]}{k_5+k_6} \qquad \text{(V)}$$

Plots of $\phi_{(CO_2)}/\phi_{CH_4}$ *vs.* P_{HN_3} or $P_{C_3H_8}$ are shown in Fig. 6. By using the k_{15}/k_{14}=0.852 obtained previously,[2] k_{10}/k_5=1.20, k_{12}/k_5=666 dm^3 mol^{-1}, and k_{13}/k_5=860 dm^3 mol^{-1} can be obtained from the intercepts and the slopes in Fig. 6.

Equation VI can be derived for the formations of N_2, H_2, (N), and CH_4:

$$\frac{\phi_{(N)}+3\phi_{H_2}-\phi_{N_2}}{3\phi_{CH_4}} = \frac{k_6+k_7+k_9+2k_{10}+k_{11}}{k_5+k_6} + \frac{k_{13}[M]}{k_5+k_6}, \qquad \text{(VI)}$$

where:

$$[M] = [C_3H_8] + (k_{12}/k_{13})[HN_3].$$

A plot of $(\phi_{(N)}+3\phi_{H_2}-\phi_{N_2})/3\phi_{CH_4}$ *vs.* P_M is shown in Fig. 7; k_{11}/k_5=4.72 was obtained from the intercept.

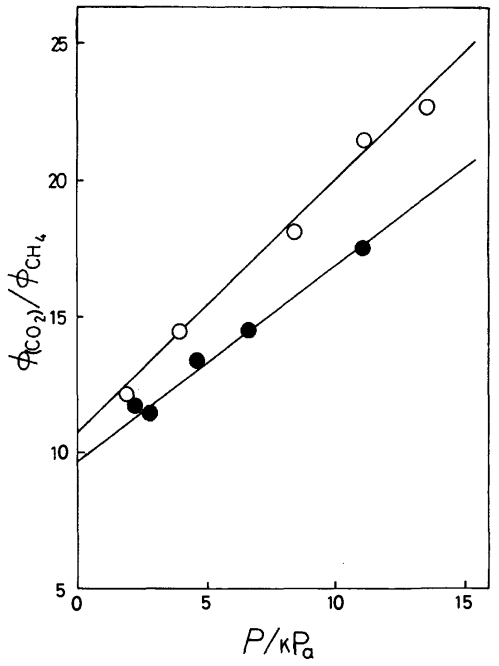

Fig. 6. Pressure dependences of $\phi_{(CO_2)}/\phi_{CH_4}$. ○, Measured as a function of C_3H_8 pressure at 6.7 kPa of HN_3; ●, measured as a function of HN_3 pressure at 4.0 kPa of C_3H_8.

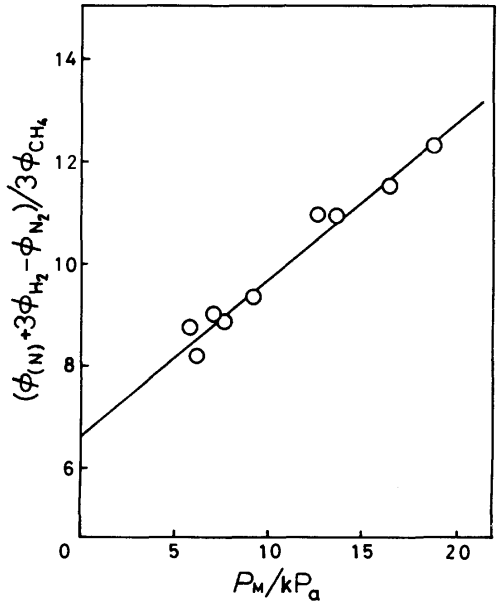

Fig. 7. Plot of $(\phi_{(N)}+3\phi_{H_2}-\phi_{N_2})/3\phi_{CH_4}$ *vs.* P_M.

Regarding the formation of amines, Eqs. VII and VIII can be derived:

$$\frac{CH_3NH_2}{C_2H_5NH_2} = \frac{k_7}{k_5} + \frac{k_8}{k_5}\frac{k_{14}}{k_{14}+k_{15}} \qquad \text{(VII)}$$

$$\frac{n\text{-}C_3H_7NH_2+i\text{-}C_3H_7NH_2}{C_2H_5NH_2} = \frac{k_{13}}{k_5}[M] \qquad \text{(VIII)}$$

Plots of $CH_3NH_2/C_2H_5NH_2$, (n-$C_3H_7NH_2$+i-$C_3H_7NH_2$)/$C_2H_5NH_2$, and n-$C_3H_7NH_2$/i-$C_3H_7NH_2$ *vs.* P_M are shown in Fig. 8. It may be found in Fig. 8 that the formation ratios of $CH_3NH_2/C_2H_5NH_2$ and n-$C_3H_7NH_2$/i-$C_3H_7NH_2$ are constant, regardless of the P_M, and that the (n-$C_3H_7NH_2$+i-$C_3H_7NH_2$)/$C_2H_5NH_2$ formation ratio is proportionate to P_M. The average value of the n-$C_3H_7NH_2$/i-$C_3H_7NH_2$ formation ratio was 1.55. The average value of $CH_3NH_2/C_2H_5NH_2$ is in accord with the value calculated using k_7/k_5=0.050, k_8/k_5=1.39, and k_{15}/k_{14}=0.852. The value of k_{13}/k_5 obtained from the slope in Fig. 8 is also consistent with those obtained from Figs. 6 and 7.

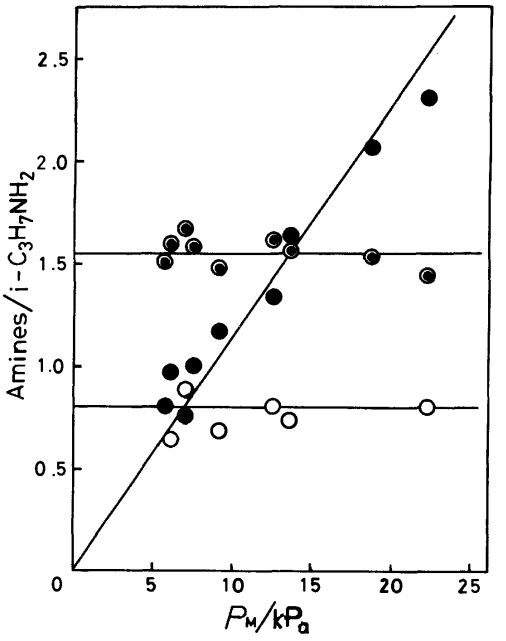

Fig. 8. Pressure dependences of $CH_3NH_2/C_2H_5NH_2$ (○), n-$C_3H_7NH_2$/i-$C_3H_7NH_2$ (⊙), and (n-$C_3H_7NH_2$+i-$C_3H_7NH_2$)/$3C_2H_5NH_2$ (●).

Regarding the formation of N_2, H_2, (N), and CH_4, Eqs. IX and X can be derived:

$$\left(\frac{\phi_{H_2}+\phi_{(N)}/4}{\phi_{CH_4}} - \frac{k_{10}}{k_5+k_6}\right)\Big/\alpha = 1 + \frac{k_4}{k_3} + \frac{k_2+k_{2a}}{k_3}\frac{[HN_3]}{[C_3H_8]} \qquad \text{(IX)}$$

$$\left(\frac{\phi_{N_2}+\phi_{H_2}}{\phi_{CH_4}} - \frac{3k_5+3k_8+k_{10}}{k_5+k_6}\right)\Big/4\alpha = \frac{1}{4} + \frac{k_4}{k_3} + \frac{k_2+k_{2a}}{k_3}\frac{[HN_3]}{[C_3H_8]}, \qquad \text{(X)}$$

where:

$$k_2 = k_{2a} + k_{2b} + k_{2c}$$

and:

$$\alpha = \frac{k_5+k_6+k_7+k_8+k_9+k_{10}+k_{11}+k_{12}[HN_3]+k_{13}[C_3H_8]}{k_5+k_6}.$$

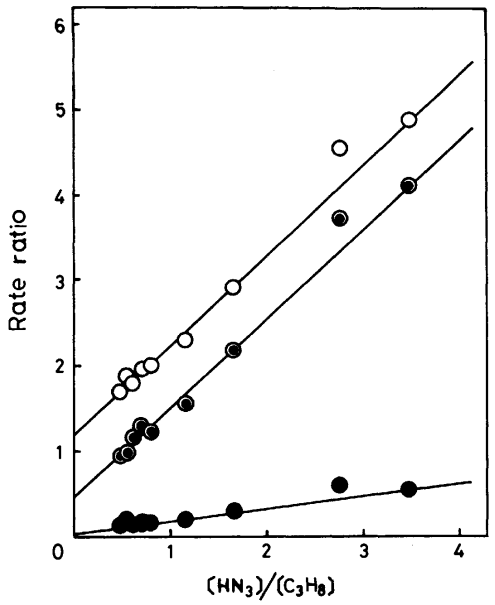

Fig. 9. Plots of the rate ratios *vs.* $[HN_3]/[C_3H_8]$. ○, $[(\phi_{H_2}+\phi_{(N)}/4)/\phi_{CH_4}-k_{10}/(k_5+k_6)]/\alpha$; ⊙, $[(\phi_{N_2}+\phi_{H_2})/\phi_{CH_4}-(3k_5+3k_8+k_{10})/(k_5+k_6)]/4\alpha$; ●, $[\phi_{H_2}/\phi_{CH_4}-k_{10}/(k_5+k_6)]/\alpha-\beta$.

Plots of $[(\phi_{H_2}+\phi_{(N)}/4)/\phi_{CH_4}-k_{10}/(k_5+k_6)]/\alpha$ and $[(\phi_{N_2}+\phi_{H_2})/\phi_{CH_4}-(3k_5+3k_8+k_{10})/(k_5+k_6)]/4\alpha$ *vs.* $[HN_3]/[C_3H_8]$ are shown in Fig. 9. From the intercept and the slope for Eq. IX and the $k_{2a}/k_2=0.336$ obtained previously,[1] $k_3/k_2=1.28$ and $k_4/k_2=0.262$ were obtained. The same values were also obtained for Eq. X.

For the formations of H_2 and CH_4, Eq. XI can be derived:

$$\left(\frac{\phi_{H_2}}{\phi_{CH_4}}-\frac{k_{10}}{k_5+k_6}\right)\Big/\alpha-\beta=\frac{k_4}{k_3}\frac{k_{22}}{k_{22}+k_{23}}+\frac{k_{2c}}{k_3}\frac{k_{25}}{k_{24}/[HN_3]+k_{25}+k_{26}}\frac{[HN_3]}{[C_3H_8]}, \quad \text{(XI)}$$

where:

$$\beta=\frac{2k_{2a}}{k_3}\frac{k_{16}[HN_3]+k_{18}[C_3H_8]}{(k_{16}+k_{17})[HN_3]+k_{18}[C_3H_8]}\frac{[HN_3]}{[C_3H_8]}.$$

A plot of $[\phi_{H_2}/\phi_{CH_4}-k_{10}/(k_5+k_6)]/\alpha-\beta$ against $[HN_3]/[C_3H_8]$ is also shown in Fig. 9. The solid circles denote the values of $[\phi_{H_2}/\phi_{CH_4}-k_{10}/(k_5+k_6)]/\alpha-\beta$ calculated using the experimental values of ϕ_{H_2}/ϕ_{CH_4}. The lowest straight line represents the calculated values for the right side of Eq. XI. In these calculations, the values obtained above and the values obtained previously[1] of $k_{2a}/k_2=0.336$, $k_{2c}/k_2=0.414$, $k_{17}/k_{16}=1.15$, $k_{23}/k_{22}=3.22$, $k_{24}/k_{25}=2.27\times10^{-4}$ mol dm^{-3}, and $k_{26}/k_{25}=1.19$ were used. As is shown in Fig. 9, the best fit for the experimental and calculated values was obtained when $k_{18}/k_{16}=0.51$.

Comparisons of Rate Constants. The specific rates of Reactions 12 and 13 can be estimated from these equations:

Table 2. Calculated values of k_z and k_5 at 30°C

M	σ_M	$\varepsilon_{M\text{-}M}/k$	k_z	$k_5(\eta=1)$
	Å	K	10^{14} cm^3 mol^{-1} s^{-1}	10^8 s^{-1}
HN_3	3.96[a]	240[a]	3.08	4.63
C_3H_8	4.84[b]	300[b]	3.90	4.53

a) Ref. 2. b) Ref. 19.

$$k_{12}=(\eta k_z)_{HN_3} \quad \text{(XII)}$$

$$k_{13}=(\eta k_z)_{C_3H_8}. \quad \text{(XIII)}$$

Here, k_z is the collision number of $C_3H_7NH_2$* per second and η is the collisional stabilization efficiency. The values of k_z can be calculated by means of the Lennard-Jones collision frequency:

$$k_z=N_A\sigma_{B\text{-}M}^2(8\pi kT/\mu_{B\text{-}M})^{1/2}\Omega_{B\text{-}M}^{(2,2)*}, \quad \text{(XIV)}$$

as has been described previously.[2] The values of $\Omega_{B\text{-}M}^{(2,2)*}$ can conveniently be tabulated[18] as a function of $kT/\varepsilon_{B\text{-}M}$ with the Lennard-Jones well depth, $\varepsilon_{B\text{-}M}=(\varepsilon_{B\text{-}B}\varepsilon_{M\text{-}M})^{1/2}$. The $\sigma_{B\text{-}M}$ is given by $\sigma_{B\text{-}M}=(\sigma_B+\sigma_M)/2$.

Assuming that the σ_B and $\varepsilon_{B\text{-}B}/k$ values of *n*-$C_3H_7NH_2$ are the same as those of *i*-$C_3H_7NH_2$, the values of $\sigma_B=5.04$ Å and $\varepsilon_{B\text{-}B}/k=380$ K for both propyl- and isopropylamines were estimated in the light of those for *n*-C_4H_{10},[19] *i*-C_4H_{10},[20] *n*-C_3H_7OH,[21] and $(CH_3)_2N$-NH_2.[22] The calculated values of k_z at 30°C are shown in Table 2. The $(k_z)_{C_3H_8}/(k_z)_{HN_3}$ ratio is almost equal to the experimentally obtained ratio, $(k_{13}/k_5)/(k_{12}/k_5)$. This means that the $C_3H_7NH_2$* is deactivated with every collision ($\eta=1$), just as in the collisional deactivations by CO_2, HN_3, and C_2H_6 of $C_2H_5NH_2$*.[2] In the photolysis of HN_3 in liquid C_3H_8 at the Dry Ice–methanol temperature, no decomposition products of $C_3H_7NH_2$* formed by the insertion could be found.[10] The main reason for this may be that the concentration of deactivator molecules is about 3500 times higher than that in the present system.

The absolute value of k_5 can be estimated from:

$$k_5=(\eta k_z)_{C_3H_8}/(k_{13}/k_5)_{obsd}. \quad \text{(XV)}$$

It was estimated to be 4.53×10^8 s^{-1} from the calculated value of k_z for C_3H_8, the observed value of k_{13}/k_5, and $\eta=1$. Similarly, the absolute value of k_5 obtained from k_z for HN_3, the observed value of k_{12}/k_5, and $\eta=1$ was 4.63×10^8 s^{-1}, as is shown in Table 2. From the average value of $k_5=4.58\times10^8$ s^{-1} and the rate-constant ratios of k_6/k_5 and others, the absolute values of k_6, k_7, k_8, k_9, k_{10}, and k_{11} were estimated to be 0.50, 0.23, 6.4, 0.18, 5.5, and 21.6×10^8 s^{-1} respectively. On the other hand, the rate-constant of the unimolecular decomposition of $C_2H_5NH_2$* formed by the reaction of $NH(a^1\Delta)$ with C_2H_6 was 9.8×10^9 s^{-1} for $C_2H_5NH_2^* \rightarrow CH_3+CH_2NH_2$ and 3.7×10^8 s^{-1} for $C_2H_5NH_2^* \rightarrow CH_3CN+2H_2$.[2]

TABLE 3. RELATIVE REACTIVITIES FOR THE REACTIONS OF NH($a^1\Delta$) WITH X AT 30°C

X	k_r/k_2	k_d/k_2	$(k_r+k_d)/k_2$	k_d/k_r
HN_3[a]	1.000	0	1.000	0
Xe[a]	0	0.187	0.187	—
C_2H_4[b]	1.637	0	1.637	0
CH_4[c]	0.175	0.177	0.352	1.011
C_2H_6[d]	0.334	0.217	0.551	0.650
C_3H_8[e]	1.279	0.262	1.541	0.205

a) Ref. 1. b) Ref. 3. c) Ref. 4. d) Ref. 2. e) This work.

The half-life of $C_3H_7NH_2$* obtained from the $\tau=\ln 2/(k_5+k_6+k_7+k_8+k_9+k_{10}+k_{11})$ relation is 1.78×10^{-10} s. On the other hand, the half-life of $C_2H_5NH_2$* is 6.8×10^{-11} s.[2] Thus, the half-life of $C_3H_7NH_2$* is 2.6 times longer than that of $C_2H_5NH_2$*. This trend is reasonable, because the rate of unimolecular decomposition decreases with an increase in the internal degree of freedom of the activated molecule.[23]

When the reactions of NH($a^1\Delta$) with a reactant (X) are represented by these general expressions:

$$NH(a^1\Delta) + X \longrightarrow \text{Products} \qquad k_r$$

$$NH(a^1\Delta) + X \longrightarrow NH(X^3\Sigma^-) + X, \quad k_d$$

the values of k_r/k_2, k_d/k_2, $(k_r+k_d)/k_2$, and k_d/k_r for C_3H_8 are shown in Table 3 together with those obtained previously.[1-4] It may be seen in Table 3 that k_r/k_2, k_d/k_2, and $(k_r+k_d)/k_2$ increase, but k_d/k_r decreases, with an increase in the carbon number in a saturated hydrocarbon molecule. Meanwhile, the k_r/k_2 ratio of the saturated hydrocarbons consisting of only the σ bond is, in general, low as compared with that of C_2H_4 having the π bond.

The values of $(k_r+k_d)/k_2$, $((k_r+k_d)/k_2)_{rel}$, $k_r/(k_r+k_d)$, and $(k_r/k_2)_{rel}$ for saturated hydrocarbons are shown in Table 4, where $((k_r+k_d)/k_2)_{rel}$ and $(k_r/k_2)_{rel}$ indicate the values of $(k_r+k_d)/k_2$ and k_r/k_2 relative to those of C_2H_6. It may be seen in Table 4 that the values of $((k_r+k_d)/k_2)_{rel}$, $k_r/(k_r+k_d)$, and $(k_r/k_2)_{rel}$ for our works are similar to those obtained by Tsunashima *et al.*[10] and by Kajimoto *et al.*[12,13] However, the values of $(k_r+k_d)/k_2$ obtained in the liquid phase by Tsunashima *et al.*[10] are much less than those in our works. The main reason for the large discrepancy seems to be due to the difference in phase (vapor and liquid), as has been discussed previously.[2] The values of $(k_r+k_d)/k_2$ obtained at 254 nm by Kajimoto *et al.*[12,13] are also small as compared with our values. This dissimilarity may be due to the effect of the wavelength.

The formation ratio of n-$C_3H_7NH_2$/i-$C_3H_7NH_2$ was 1.55, regardless of the total pressure. This ratio means that the insertion rate of NH($a^1\Delta$) into a secondary C–H bond of C_3H_8 is 1.94 times faster than that into a primary C–H bond. This value is well consistent with the value of 1.9 obtained by Tsunashima *et al.*[10] Kondo *et al.*[13] have obtained the insertion efficiency ratio of 1.5 in the photolysis at 254 nm. Tsunashima *et al.*[10] have also found that the insertion efficiency into a tertiary C–H bond of isobutane is 2.3 times higher than that for a primary C–H bond. In general, the insertion efficiency per C–H bond, ζ_i(C–H), can be represented by this equation:

$$\zeta_i(\text{C–H}) = f_i(k_r/k_2)_{obsd}/F, \qquad \text{(XVI)}$$

where $F=n_pf_p+n_sf_s+n_tf_t$. Here, n_p, n_s, and n_t indicate the number of primary, secondary, and tertiary C–H bonds respectively in a saturated hydrocarbon molecule. Similarly f_p, f_s, and f_t denote the relative efficiencies for the insertions into primary, secondary, and tertiary C–H bonds respectively. f_i means f_p, f_s, or f_t. If f_p is fixed as a basis, then f_p becomes unity.

The values of f_i, F, $(k_r/k_2)_{obsd}$, and ζ_i(C–H) are shown in Table 5, together with the ratio of the ζ_i(C–H) of X to the ζ_i(C–H) of CH_4, $\zeta_i(\text{C–H})_X/\zeta_p(\text{C–H})_{CH_4}$. The bond-dissociation energies of these C–H bonds, D_i(C–H), are also listed in Table 5. These bond-dissociation energies were calculated assuming that the standard heats of the formation of CH_4, C_2H_6, C_3H_8, i-C_4H_{10}, c-C_3H_6, H, CH_3, C_2H_5, n-C_3H_7, i-C_3H_7, i-C_4H_9, t-C_4H_9, and c-C_3H_5 were −74.9, −84.7, −103.8, −134.5, 53.3, 218.0, 145.2,[24] 117.2,[25] 87.9,[26] 73.6,[27] 58.6,[27] 35.1,[28] and 255.2[27] kJ mol^{-1} respectively. The plot of $\zeta_i(\text{C–H})_X/\zeta_p(\text{C–H})_{CH_4}$ *vs.* D_i(C–H) is shown in Fig. 10; it shows that $\zeta_i(\text{C–H})_X/\zeta_p(\text{C–H})_{CH_4}$ increases with a decrease in D_i(C–H), especially in the range lower than 420 kJ mol^{-1}. From the results shown in Fig. 10, it may be possible to predict the over-all insertion efficiency for reactions of NH($a^1\Delta$) with saturated hy-

drocarbons.

The absolute value of k_2 which was observed by Piper, Krech, and Taylor,[29] k_2(PKT), is 1.084×10^{14} cm^3 mol^{-1} s^{-1}. If this value is applied, the absolute rate-constant for the over-all quenching of NH($a^1\Delta$) by X, k_q(X), can be calculated by this equation:

$$k_q(X) = \frac{(k_r+k_d)_X}{k_2}k_2(PKT). \quad \text{(XVII)}$$

The values of k_q(X) calculated from $(k_r+k_d)_X/k_2$ in Table 3 and k_2(PKT) are shown in Table 6 ; the Table shows that k_q(X) increases with an increase in the carbon number in a X molecule.

On the other hand, the maximum rate-constant of the bimolecular reaction in the gas phase, k_b, can be calculated by this equation:[30]

$$k_b = \frac{2\Gamma(1-2/s)N_A}{\sigma}\left(\frac{2\pi kT}{\mu}\right)^{1/2}\left[\frac{(s-2)A}{2kT}\right]^{2/s}, \quad \text{(XVIII)}$$

when the intermolecular attractive potential, u, is expressed by $u=-A/r^s$. The attractive potential constant, A, can be calculated from the dispersion term reported by Slater and Kirkwood[31] and the induction term for NH and X:

$$A = \frac{3he\alpha_{NH}\alpha_X}{4\pi m_0^{1/2}[(\alpha/N_e)_{NH}^{1/2}+(\alpha/N_e)_X^{1/2}]} + \alpha_X\mu_D(NH)^2, \quad \text{(XIX)}$$

as has been described previously.[3] The values of k_b calculated using s=6, $\Gamma(2/3)$=1.354, σ=1, T=303 K, $\alpha_{NH}=1.38\times10^{-24}$ cm^3,[32] μ_D(NH)=1.627 debye,[33] and N_e(NH)=6 are shown in Table 6, together with $k_q(X)/k_b$. It may be found in Table 6 that k_b increases slightly with an increase in the carbon number in X, while $k_q(X)/k_b$ increases considerably from 1/10 for CH_4 to 1/2.6 for C_3H_8.

The absolute and relative quenching rates of C(2^1D_2),[34,35] O(2^1D_2),[36-38] S(3^1D_2),[39,40] and CH_2 ($^1A_1$)[41,42] by CH_4, C_2H_6, C_3H_8, and others have been observed widely. These over-all quenching-rate constants are shown in Table 7, together with those for

NH($a^1\Delta$). Table 7 shows that the absolute quenching rates of NH($a^1\Delta$) by Xe, C_2H_4, CH_4, C_2H_6, and C_3H_8 are very similar to those of C($^1D_2$), O($^1D_2$), S($^1D_2$), and $CH_2(^1A_1)$, which are isoelectronic with NH($a^1\Delta$).

Summary. From the formation ratio of the *n*-$C_3H_7NH_2$ and *i*-$C_3H_7NH_2$ produced in the photolysis of HN_3 at 313 nm and 30 °C in the presence of C_3H_8, the insertion efficiency of NH($a^1\Delta$) into a secondary C–H bond of C_3H_8 was found to be 1.94 times higher than that of a primary C–H bond. The relative insertion efficiencies per C–H bond were 1.00 for CH_4, 1.27 for C_2H_6, 2.96(p) and 5.73(s) for C_3H_8, 1.34 for *c*-C_3H_6, and 3.08(p) and 7.09(t) for *i*-C_4H_{10}, judging from comparisons of the present and previous results.[2,4,10,11] Here, p, s, and t indicate the primary, secondary, and tertiary C–H bonds. The insertion efficiency per C–H bond increases with a decrease in the C–H bond dissociation energy. The insertion-rate constants, as estimated from the absolute reaction rate of NH($a^1\Delta$) with HN_3,[29] were 1.90, 3.62, and 13.9×10^{13} cm^3 mol^{-1}s^{-1} for CH_4, C_2H_6, and C_3H_8 respectively. The over-all quenching-rate constants of NH($a^1\Delta$) by CH_4, C_2H_6, C_3H_8, C_2H_4,[3] and Xe[1] were, respectively, 3.82, 5.97, 16.7, 17.7, and 2.03×10^{13} cm^{3}mol^{-1}s^{-1}; they were found to be very similar to those of C($^1D_2$), O($^1D_2$), S($^1D_2$), and $CH_2(^1A_1)$, which are isoelectronic with NH($a^1\Delta$).

The author is grateful to Mr. Jun Fukuchi for his cooperation.

Shock-tube Studies of N_2O Decomposition and N_2O-H_2 Reaction

Yoshiaki HIDAKA,* Hirokazu TAKUMA,† and Masao SUGA†

Advanced Instrumentation Center for Chemical Analysis, Ehime University, Bunkyo-chō, Matsuyama 790

†*Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-chō, Matsuyama 790*

(Received February 6, 1985)

N_2O decomposition and N_2O-H_2 reaction were studied behind incident and reflected shock waves in the temperature range 1450—2200 K and pressure range 0.6—3.5 atm using both single-pulse and time-resolve techniques. A computer-simulation study was performed to determine the rate-constant expressions of important elementary reactions. Computer calculations showed that the values of the rate constant for $N_2O+O \xrightarrow{k_2} N_2+O_2$ and $N_2O+O \xrightarrow{k_3} NO+NO$ (cited in current papers) are too low. The rate-constant expressions were found to be $k_2=7.0\times10^{14}\exp(-28\,\text{kcal}/RT)$ cm^3 mol^{-1} s^{-1} and $k_3=5.6\times10^{14}\exp(-28\,\text{kcal}/RT)$ cm^3 mol^{-1} s^{-1}. The rate constant expression for $N_2O+H \xrightarrow{k_4} N_2+OH$, was found to be $k_4=1.5\times10^{14}\exp(-15\,\text{kcal}/RT)$ cm^3 mol^{-1} s^{-1}.

The decomposition of N_2O and the reaction of N_2O-H_2 have been extensively studied at high temperatures (above 1000 K) by many workers.[1-18] Previous experimental studies have shown that an initiation step in both the N_2O decomposition and the N_2O-H_2 reaction is the breaking of the nitrogen-oxygen bond.

$$N_2O + M \xrightarrow{k_1} N_2 + O + M. \quad (1)$$

The values of k_1 reported are in agreement within a factor of approximately 2 to 3. However, the reported activation energies (E_1's) scatter between 61 and 40 kcal/mol. Even in recent years, Sulzmann *et al.*,[18] Endo *et al.*,[17] Dean *et al.*[16] and Roth and Just[15] have reported E_1=56, 57.6, 51.7, and 61 kcal/mol, respectively. The oxygen atoms generated by reaction (1) react with N_2O or H_2 as follows,

$$N_2O + O \xrightarrow{k_2} N_2 + O_2, \quad (2)$$

$$N_2O + O \xrightarrow{k_3} NO + NO, \quad (3)$$

$$H_2 + O \xrightarrow{k_7} OH + H. \quad (7)$$

Values of the rate constants published for reactions (2) and (3) are widespread. The reported ratios of k_3/k_2 separate almost into two groups over the same temperature range; one is k_3/k_2=0.9—1.2,[5,6,8,13,18] other is k_3/k_2=0.3—0.5.[3,10] The reported values of the rate constant of reaction (4) are also scattered.

$$N_2O + H \xrightarrow{k_4} N_2 + OH. \quad (4)$$

In this study, we wish to report the rate constants k_1, k_2, k_3, and k_4, with which we can interpret both the N_2O decomposition and the N_2O-H_2 reaction over the temperature range 1450—2200 K.

Experimental

The apparatus and procedures have already been described in detail,[19,20] so only a brief description is given here. Infrared emission through two 0.8 mm slits and an interference filter (λ_{max}=4.68 μm, half-width=0.1 μm) was observed with a Fujitsu IV-200C4 InSb detector to study the time variation of the N_2O concentration. In runs using reflected shock waves, reacted gas mixtures were introduced to a pre-evacuated container made of Aluminum (25 cc in volume) through a valve near an end-plate after about 20 s from the infrared-emission measurements. The reacted mixtures were analyzed on a mass spectrometer (Nihondensi-JMS-01SG-2). In the analysis, the isotope ^{36}Ar (0.34%), which was included in ^{40}Ar, was used as a reference material. Since the concentration of ^{36}Ar was comparable to NO and O_2 concentrations produced in our experiment, it was possible to accurately determine these concentrations. The energy of the ionizing electron beam was 12 eV. The use of such a relatively low voltage has a major advantage. The formation of fragment ions was almost completely eliminated, thus simplifying the interpretation of the mass spectra. A measurement of absolute concentrations is possible using relative sensitivity factors. These factors were determined under conditions as close as possible to those used in the determination of the product concentration during the N_2O decomposition and the N_2O-H_2 reaction. The analyzed peaks of the reacted gases were of mass numbers, 44, 32, and 30, corresponding to N_2O, O_2, and NO, respectively. No peak was found at a mass number of 46 (NO_2). In the determination of the O_2 concentration, the background signal at a mass number of 32 was substracted from the O_2 signal.

Data interpretation was achieved by computer simulation. The computer calculations[20,21] and the effective heating time used[20] were essentially the same as described previously. The temperature of the reaction system increases as the reaction progressed because the decomposition of N_2O and N_2O-H_2 reaction are exothermic. This temperature change might affect the N_2O emission intensity greatly. Hence, simulations of time-variations were carried out with programs that considered the dependence of the emission-intensity on temperature.

The compositions of employed reaction mixtures were as follows: (A) 2.0% N_2O, 98.0% Ar; (B) 2.0% N_2O, 1.0% H_2, 97.0% Ar; (C) 1.0% N_2O, 0.5% H_2, 98.5% Ar; (D) 0.5% N_2O, 1.0% H_2, 98.5% Ar. The N_2O decomposition with mixture (A) and N_2O-H_2 reaction with mixtures (B)—(D) were studied behind incident (1500 K$<T_2<$2200 K, 0.6 atm$<P_2<$1.1 atm) and reflected (1500 K$<T_5<$2100 K, 2.0 atm$<$

P_5<3.5 atm) shock waves with both single-pulse and time-resolve techniques. H_2 and Ar, specified to be 99.9 and 99.99% pure, respectively, were obtained from commercial cylinders and were used without further purification. The N_2O gas obtained from a commercial cylinder was purified by trap-to-trap distillations. The purity (99.9% or higher) was confirmed by a gas-chromatographic analysis.[19]

Results and Discussion

The time variation of the N_2O concentration at 4.68 μm was observed behind incident and reflected shock waves with mixture (A). The observed rate constant, k_{obsd}, for N_2O decomposition was calculated from the intial slope (within 20 μs) of the time variation. The values of $k_{obsd}=2.6\times10^{15}\exp(-60.7\,\text{kcal}/RT)$ $cm^3 mol^{-1}s^{-1}$ obtained with incident shock waves are in good agreement with the values of the $2k_1$ reported by Roth and Just,[15] and are similar to the $2k_1$ reported by Olschewski *et al.*[4] and Endo *et al.*[17] as shown in Fig. 1. The values of $k_{obsd}=6.24\times10^{14}\exp(-56.9\,\text{kcal}/RT)$ $cm^3 mol^{-1}s^{-1}$ obtained with reflected shock waves, however, are slightly lower than those obtained with incident shock waves. The deviation between the two is larger at high temperatures than at low temperatures. This shows that the initial temperatures (within 20 μs) behind reflected shock waves are somewhat lower than those calculated from incident shock speeds. The real gas temperatures at the reflected shock front are considered to be 70±40 K lower than those calculated. This finding is consistent with that reported by Tsuchiya and Kuratani.[25] This phenomenon has also been reported by several workers,[22-25] who showed that the pressure and temperature slowly increased with time after the arival of reflected shock waves. The average temperature during the reaction time (about 1000 μs) was also shown to be comparable to the temperature calculated from the incident shock speed.[25] The temperature under our experimental condition, however, should be examined, since the temperature parameter is very important in calculating the rate constants. Since the mechanism and rate constant expressions of the H_2-O_2 reaction are known very well, it is possible to check the average temperature behind reflected shock waves by comparing the observed results with the calculated ones. By using the same method as mentioned in a previous paper,[21] the temperatures behind reflected shock waves were examined. The average temperature during 100—1200 μs was shown to be almost the same as that

calculated from the incident shock speed. Hence, the temperature T calculated from incident shock speeds was employed for the analysis of quenched reactant and product concentrations. The product distribution was determined by analyzing the product concentration on a mass spectrometer. The relationships of [NO] and [NO]/[O_2] *vs.* T with mixture (A) are shown in Figs. 2(a) and (b), respectively. The ratio [NO]/[O_2] is about 2 over the temperature range 1600—2000 K. This also shows $k_2/k_3\fallingdotseq1$. This result is in agreement with those of Gutman *et al.*,[5] Borisov,[6] Barton and Dove,[8] Dean,[13] and Sulzmann *et al.*[18] The relationships [NO] and [NO]/[O_2] *vs.* T with mixture (B) are shown in Figs. 3(a) and (b), respectively. In mixture (A), [NO] and [NO]/[O_2] observed at each temperature can be interpreted using the mechanism and rate-constant expressions recommended by Baulch *et al.*[26] However, the results calculated with Table 1 are better than those. While, in mixture (B),[NO] and [NO]/[O_2] observed at each temperature are bigger than those obtained by using their mechanism and rate constant expressions as shown in Figs. 3(a) and (b). The findings show that the values of k_2 and k_3 are too small to interpret these. When $k_2=7.0\times10^{14}\exp(-28\,\mathrm{kcal}/RT)$ $\mathrm{cm^3\,mol^{-1}\,s^{-1}}$ and $k_3=5.6\times10^{14}\exp(-28\,\mathrm{kcal}/RT)$ $\mathrm{cm^3\,mol^{-1}\,s^{-1}}$ are employed, the computed results are in good agreement with those measured as may be shown in Figs. 3(a) and (b). Our k_2 and k_3 values are about six, four, six and nineteen times those recommended by Baulch *et al.*[26] and recently reported Monat *et al.*,[14] Sulzmann *et al.*[18] and Dean *et al.*,[16] respectively, as may be shown in Fig. 4. While our values of k_2 and k_3 are found (Fig. 4) to be similar to and about one half of those reported by Lin and Bauer[27] and Henrici and Bauer,[7] respectively. Henrici and Bauer evaluated the k_3 value from a study with a N_2O–H_2 mixture and reported that the k_2 and k_3 values estimated in the study of N_2O decomposition were too low to account for the rate of formation of NO in the shock-heated reaction of N_2O with H_2. It is found that the values of k_2 and k_3

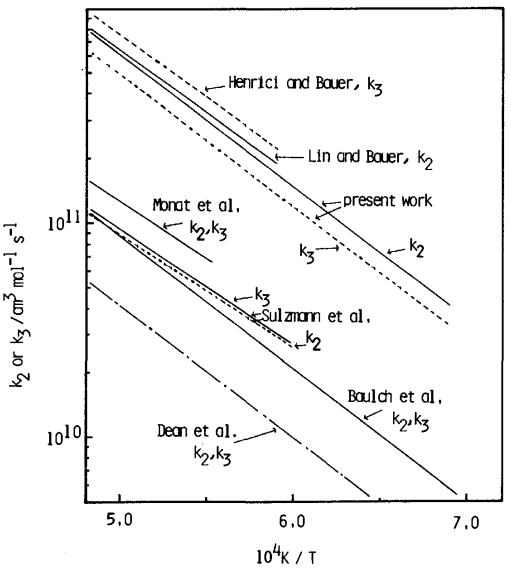

Fig. 4. Comparison of our k_2 or k_3 value with those reported in recent years. —·—: Extraporated value of Dean *et al.*.

reported in the study of N_2O decomposition are fairly smaller than those estimated with the N_2O–H_2 mixture.

The values of k_2 and k_3 reported by several workers except for Henrici and Bauer[7] and Lin and Bauer[27] have been estimated from results regarding the N_2O decomposition: The rate constants were obtained from measurements of the N_2O or NO concentration. When values between Dean's value[16] and ours are used as the rate constants of k_2 and k_3, the product concentrations calculated for the N_2O decomposition scarcely vary as may be seen in Figs. 2(a) and 2(b). The values of k_2 and k_3 between these are found to be insensitive regarding N_2O decomposition. If the values of k_2 and k_3 were estimated from the study of N_2O decomposition, one might always find smaller values for k_2 and k_3 than the real values. Thus, it is difficult to estimate relieable values of k_2 and k_3 from the study of N_2O decomposition. However, in the N_2O–H_2 reaction, the values of k_2 and k_3 are sensitive to

TABLE 2. ELEMENTARY REACTION AND RATE CONSTANT EXPRESSIONS

Reaction	A	n	E
$NO+OH=NO_2+H$	1.0×10^{14}	0.0	1200
$NO+N_2O=NO_2+N_2$	2.0×10^{14}	0.0	50000
$NO+O_2=NO_2+O$	1.0×10^{12}	0.0	45000
$H+NO+M=HNO+M$	3.1×10^{15}	0.0	−7000
$OH+HNO=NO+H_2O$	8.5×10^{13}	0.0	0
$H+NO_2=NO+OH$	5.4×10^{14}	0.0	1740
$N_2O+H=NO+NH$	1.0×10^{11}	0.0	30000
$NO_2+M=NO+O+M$	1.0×10^{16}	0.0	65000

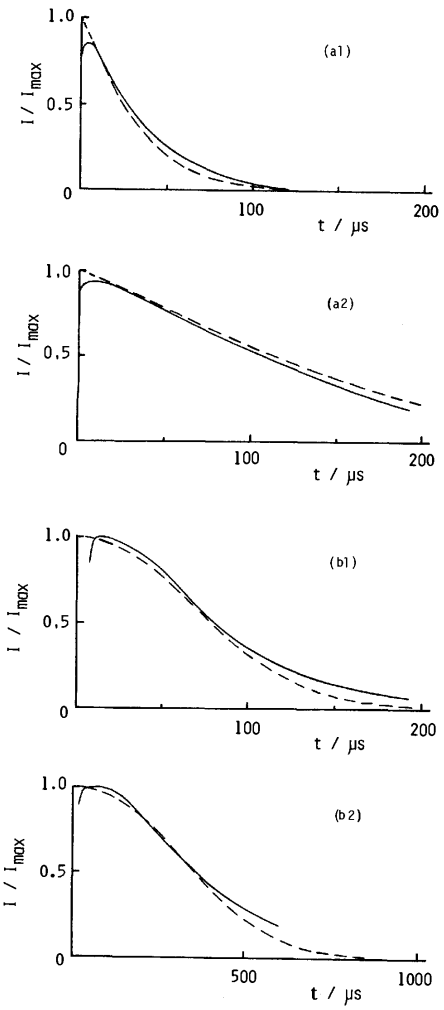

Fig. 5. Comparison of N_2O profiles computed using Table 1 with observed emissions. The broken and solid lines show values computed with Table 1 and observed, respectively.
(a1) Mixture (A), T_2=2151 K; (a2) mixture (A), T_2=1923 K; (b1) mixture (D), T_5=1774 K; (b2) mixture (D), T_5=1559 K.

product concentrations. In the N_2O–H_2 reaction, therefore, we can estimate relieable values for k_2 and k_3. Using these values, one can also interpret the results in the N_2O decomposition well, as shown in Fig. 2(a) and 2(b), Fig. 5(a) and Fig. 6(a).

The k_2 and k_3 expressions may be accurate to within ±20% under our experimental conditions. Systematic errors in the instrumentation and kinetic model may contribute this much again. We therefore, suggest that our k_2 and k_3 expressions are probably accurate to within ±50%.

Reaction (4) is also important for the interpretation of the H_2–N_2O reaction. The value of the rate constant k_4 strongly influences the N_2O consumption. When the expression $k_4=1.5\times10^{14}\exp(-15\,\mathrm{kcal}/RT)$ $\mathrm{cm^3\,mol^{-1}\,s^{-1}}$ was employed, the calculated results were in good agreement with the observed ones. This value is about one half of that reported by Fenimore and Jones[1] and is about twice that reported by Dixon-Lewis and Williams[28] or by Baulch *et al.*[26] The value of k_4 is also considered to be probably accurate to within ±50%.

Several reactions for the production and consumption of NO have been reported. They are shown in Table 2. The calculations with mechanism including reactions of Table 2 were carried out and the influence of these reactions on the NO concentration produced was examined. These reactions were found to be unimportant under our experimental conditions.

A comparison of the observed emission profiles with the computed N_2O profiles with mixtures (A) and (D) is shown in Figs. 5(a1)—(b2). In both the N_2O decomposition and the H_2–N_2O reaction, the curves calculated with Table 1 are in good agreement with the observed ones within experimental accuracy. t_{80}, t_{50}, and t_{20} were defined as the elapsed times between the shock arrival and the 80, 50, and 20% consumptions of the maximum $[N_2O]$, respectively. τ was also defined as the elapsed time between the shock arrival and the onset of the rapid decrease in the N_2O concentration.[29] Plots of τ, t_{80}, and t_{50} or t_{20} *vs.* $1/T$ for mixtures (A),(B), and (D) are shown in Figs. 6(a)—(c). The calculted τ, t_{80}, t_{50}, and t_{20} are in good agreement with experimental ones.

Henrici and Bauer[7] have measured the concentration profiles of OH in the reaction of H_2 with N_2O over the temperature range 1700—2600 K and over a total density 0.7×10^{-5}—1.4×10^{-5} mol $\mathrm{cm^{-3}}$. These are similar to our experimental conditions. Hence, we selected their results in order to check the OH concentration in the modeling. A comparison of calculated $[OH]_{max}/P_1$ with $[OH]_{max}/P_1$ measured by Henrich and Bauer[7] is shown in Fig. 7. The values computed using Table 1 explain their results well, as shown in Fig. 7. Hence, the values of k_2 and k_3, which are about six times those recommended by Baulch *et al.*,[26] are considered to be appropriate for an interpretation of the OH concentration in the N_2O–H_2 reaction.

Conclusion

N_2O decomposition and N_2O–H_2 reactions were studied behind incident and reflected shock waves in

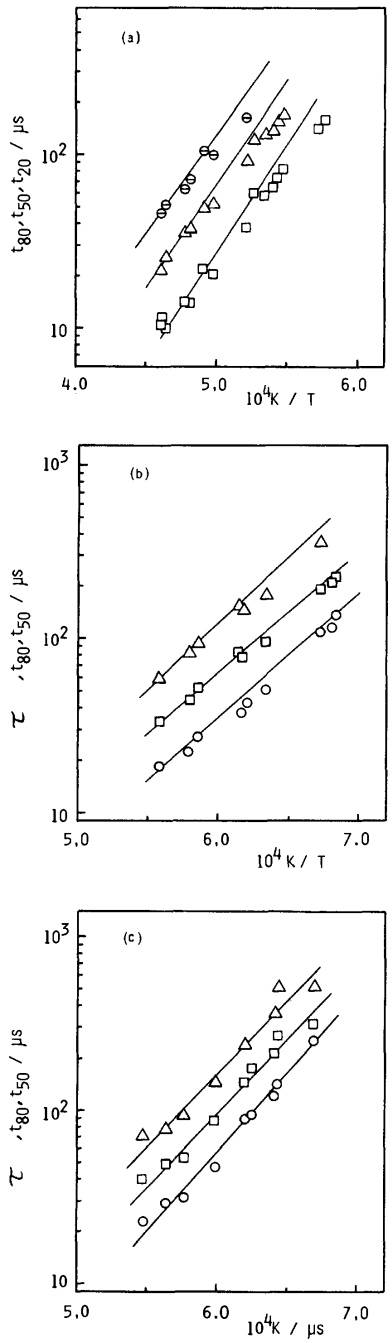

Fig. 6. Comparison of log t_{80}, log t_{50}, and log τ or log t_{20} computed using Table 1 with observed ones. The observed values at t_{20}, t_{50}, t_{80}, and τ are shown with symbols ⊖, △, □, and ○, respectively.
(a) results for mixture (A) behind incident shock waves; (b) results for mixture (B) behind incident shock waves; (c) results for mixture (D) behind reflected shock waves.

the temperature range 1450—2200 K with both single-pulse and time-resolve techniques. Our results support the value reported by Roth and Just[15] as the k_1 value. The rate constant expressions $k_2=7.0\times10^{14}$ exp(−28kcal/RT) $cm^3mol^{-1}s^{-1}$, $k_3=5.6\times10^{14}$ exp(−28 kcal/RT) $cm^3mol^{-1}s^{-1}$ and $k_4=1.5\times10^{14}$ exp(−15 kcal/RT) $cm^3mol^{-1}s^{-1}$ for reactions $N_2O+O\rightarrow N_2+O_2$,

Pressure and Temperature Effects on Conformational Equilibria between Rotational Isomers. II. Isobutyl and *s*-Butyl Halides in Hexane and Methanol

Hiroyasu NOMURA* and Shinobu KODA

Department of Chemical Engineering, School of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received March 22, 1985)

The conformational changes in isobutyl halides (*i*-BuX) and *s*-butyl halides (*s*-BuX) in hexane and methanol have been analyzed by Raman spectroscopy as a function of temperature and pressure. The enthalpy and volume differences in the conformational changes from P_C (*trans*) to P_H (*gauche*) of *i*-BuX and from S_{HH}(*trans*) to $S_{HH'}$(*gauche* I) and to S_{CH}(*gauche* II) of *s*-BuX in the dissolved state have been obtained. The enthalpy and volume differences, ΔH and ΔV, of all the conformational changes depended on the solvents and the concentration in solution. In the solution of hexane, the ΔH ($P_C \rightarrow P_H$) of *i*-BuCl and *i*-BuBr both increased with a decrease in the concentration of *i*-BuX. The ΔV ($P_C \rightarrow P_H$) of *i*-BuCl increased with an increase in the contents of the solvents, hexane, but that of *i*-BuBr decreased. The concentration dependences of ΔH and ΔV were discussed on the basis of the intermolecular interactions. The relation between ΔH and ΔV was also discussed on the basis of thermodynamic consideration.

In our previous papers,[1,2] the conformational changes in some halogenoalkanes, such as 1,2-dihalogenoethane and butyl halides, in the pure liquid state have been analyzed by Raman spectroscopy as a function of temperature and pressure. The enthalpy and volume differences in the rotational isomers of these halogenoalkanes have been obtained.

In the dissolved state, it is well known that the enthalpy differences in the conformers are strongly related to some physical properties of the solvents, such as the dielectric constant and specific solute-solvent interactions in solutions.[3-5] It is also expected that the volume difference in the conformers in solution will depend on the solvent. There have been a few papers concerning this subject.[6,7] However, as their measurements were fragmentary and not systematic, they have not been sufficient to elucidate the solvent effects of the volume difference between the rotational isomers of a molecule.

In this paper, we will report the enthalpy and volume differences of the conformers of 1-halogeno-2-methylpropane and 2-halogenobutane (hereafter abbreviated as *i*-BuX and *s*-BuX; X=halogene) in hexane and methanol as obtained by Raman spectroscopy. These solvents, hexane and methanol, were chosen for the following reasons: (i) the dielectric constant of hexane is smaller than those of the halogenoalkanes investigated here, while that of methanol is larger, and (ii) hexane is an inert solvent for the halogenoalkanes, but the solvent methanol can be expected to interact with the halogenoalkanes.

We discussed the solvent effects and the concentration dependences of the enthalpy and volume differences of *i*-BuX and *s*-BuX in hexane and methanol. The relation between ΔH and ΔV was also discussed.

Experimental

The characteristic bands of the X-sensitive modes of each halogenoalkane have been well investigated and assigned to the rotational isomers.[8-13] The structures of the isomers concerned here are illustrated in Fig. 1, where their characteristic vibrational frequencies used are also given.

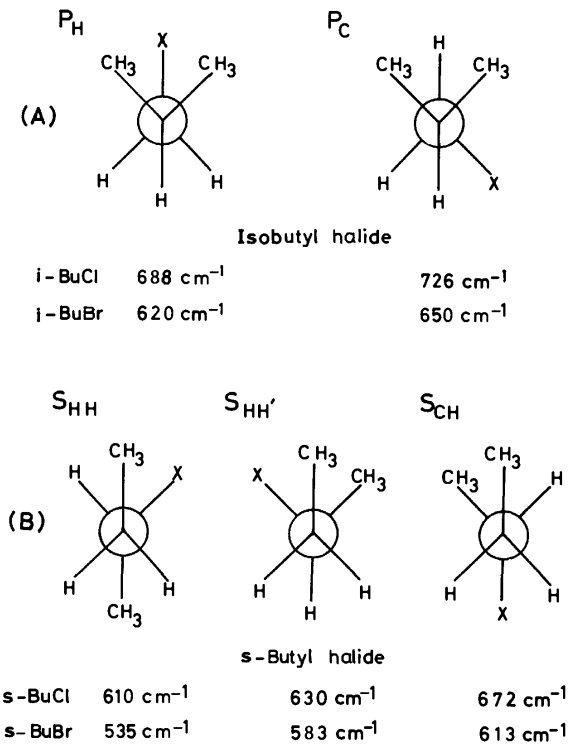

Fig. 1. Rotational isomers for butyl halides and the vibrational frequency of the C-X stretching mode, where X denotes Cl or Br.

Samples: The chemicals (commercial products) were purified by fractional distillation under reduced pressure. The solvents, hexane and methanol, were spectro-grade reagents (Nakarai Chemicals, Ltd.) and were used without further purification.

Raman Spectroscopy: The Raman spectra under high pressure were recorded using a laser Raman spectrometer, JEOL-Ul (manufactured by Japan Electron Optical Laboratory Co., Ltd.) and an argon-ion laser (NEC Co., Ltd.).

The pressure was measured by means of a Heise precision Bourdon-type gauge. The temperature dependence of the Raman spectra was measured at the atmospheric pressure, using a variable-temperature cell of the Harney-Miller type. The detailed experimental procedure and the data analysis have been described elsewhere.[1,2] The accuracy of the integrated intensities is within 3%.

Compressibility and Density Measurements: The densities of the solutions were measured by a pycnometer (20 cm^3) at temperatures from 15 to 30°C. The adiabatic compressibility was determined from the density and the sound velocity data using the Laplace equation. The sound velocity measurements of the solutions were carried out using an ultrasonic interferometer operating at a constant frequency of 5.000 MHz.

Results

For the samples investigated here, the Raman frequency of the X-sensitive stretching vibrational modes of each conformer did not change in the solutions of hexane and methanol, and it was independent of the temperature and pressure changes in the temperature and pressure ranges concerning in this work.

The equilibrium constant, K, of the conformational equilibrium, A⇌B, can be expressed as:[3]

$$K = \frac{n_B}{n_A} = \frac{I_B \Omega_A}{I_A \Omega_B} \tag{1}$$

where n is the number of molecules, I is the Raman intensity, and Ω is the absolute scattering cross-section. The suffixes A and B refer to the conformers. Assuming that the Ω_A/Ω_B ratio is independent of the temperature and pressure changes in the whole range of measurements, we can estimate the enthalpy and volume differences between the two conformers on the basis of Arrhenius and van't Hoff equations;

$$\Delta H = -R\left[\frac{\partial \ln [I_A/I_B]}{\partial [1/T]}\right] \tag{2}$$

$$\Delta V = -RT\left[\frac{\partial \ln [I_A/I_B]}{\partial P}\right] \tag{3}$$

As an illustration of typical data, Figs. 2 and 3 show $\ln[I_{PH}/I_{PC}]$ *vs.* $1/T$ and P plots for *i*-BuCl in hexane at 40 and 80 mol% of the *i*-BuCl solute. The enthalpy and volume differences, ΔH and ΔV, are estimated, respectively, from the slopes in Figs. 2 and 3. The values thus obtained are summarized in Tables 1 and 2, along with the data of these samples in the neat state previously.[2] For comparison, the enthalpy differences of these compounds in the gaseous state are also shown in Table 1.

As may be seen in Table 1 and 2, strong solvent and concentration dependences of ΔH and ΔV were observed. Especially in the case of *i*-BuBr, the ΔH in the neat state showed a negative value, −0.7±0.1 kJ mol^{-1}. It seems unreasonable, but the ΔH of *i*-BuBr

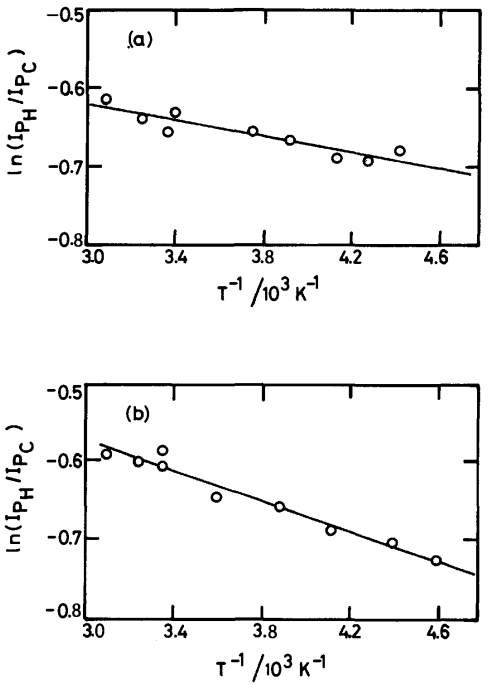

Fig. 2. Relationships between the logarithmic ratio of integrated intensities and temperature. (a) 80 mol% of *i*-BuCl in hexane. (b) 40 mol% of *i*-BuCl in hexane.

increased with a decrease in the contents of *i*-BuBr in solutions. Moreover, the positive volume difference of *i*-BuCl also decreased with an increase in the contents of hexane and changed to a negative value, −0.6₂±

0.0_4 cm^3 mol^{-1} at the 40 mol% of *i*-BuCl.

For *s*-BuCl and *s*-BuBr, the enthalpy changes from S_{HH} to $S_{HH'}$ are nearly equal to those from S_{HH} to S_{CH} in the liquid and dissolved states. Therefore, the potential energies of the conformers, $S_{HH'}$ and S_{CH}, may be almost the same. The values of ΔH of *s*-BuBr in hexane and methanol are comparable to those in the gaseous state. This indicates that the intermolecular contribution to ΔH is small. In the cases of *s*-BuCl and *s*-BuBr, the signs of the ΔV of $S_{HH}\rightarrow S_{HH'}$ and $S_{HH}\rightarrow S_{CH}$ in hexane are both negative, but in methanol they are positive for *s*-BuBr and negative for *s*-BuCl. The signs of the ΔV of these conformational changes of *s*-BuCl and *s*-BuBr in methanol are the same as in the neat state. These results indicate that molecules of *s*-butyl halides in the neat state as well as those placed in methanol are in a strongly interacting field, as a result of the high dielectric constants of the media surrounding the central *s*-butyl halides. The absolute values of the volume changes caused by the $S_{HH}\rightarrow S_{HH'}$ transformation are about two or three times larger than those of $S_{HH}\rightarrow S_{CH}$, although the energy differences in the corresponding conformational changes are nearly equal in the two solutions.

Discussion

The origin of the enthalpy and volume differences, ΔH and ΔV, between the rotational isomers in solution can be divided into two factors. One is caused by the intermolecular interaction, and the other, by the intramolecular character. The solvent and concentration dependences of both ΔH and ΔV indicate that the intermolecular effects are predominant.

The changes in the intrinsic volume of each conformer were often estimated and compared with those obtained experimentally.[6,14] The intrinsic volume differences between the rotational isomers were calculated by the Bondi's method.[15] The results and van der Waals volumes are summarized in Table 3. The calculated volume changes are one or two orders of magnitude smaller than those obtained experimentally, but for *s*-BuCl and *s*-BuBr the order of the volume change of $S_{HH}\rightarrow S_{HH'}$ and $S_{HH}\rightarrow S_{CH}$ agrees with the experimental one.

The concentration dependences of the volume differences between the two conformers of *i*-BuCl and *i*-BuBr are shown in Fig. 4 as a function of the contents of the solute in hexane solutions. The concentration dependences are quite different for *i*-BuCl and *i*-BuBr. For *i*-BuCl, the volume difference, ΔV, decreased with an increase in the contents of hexane in solutions, but for *i*-BuBr, ΔV increased. As is shown in Fig. 4, the ΔV values of those two compounds seem to level off to a constant value at higher contents of hexane in solutions. On the other hand, the volume changes

upon conformational change in the gaseous state are zero as is shown in Table 1. Therefore, ΔV becomes powerful measure of the changes in the packing of molecules in the liquid and dissolved states.

As may be seen in Table 1, the conformational enthalpy differences in *i*-BuCl and *i*-BuBr in hexane increase with an increase in the contents of hexane in solutions. In the neat state, such strong intermolecular interactions as dipole-dipole interactions are working. These strong intermolecular interactions will be reduced by the addition in solutions of hexane, which is an ineart solvent. Therefore, the enthalpy differences in these compounds increase with an increase in the concentration of hexane in solutions, and they tend to approach those in the gaseous state. The enthalpy difference in the gaseous state, ΔH_{gas}, corresponds to that of the intramolecular one. As a result, the enthalpy difference, $\Delta = \Delta H_{liq} - \Delta H_{gas}$, is a measure of the intermolecular interaction of the molecules in the liquid and dissolved states.

The enthalpy difference, $\Delta = \Delta H_{liq} - \Delta H_{gas}$, can be

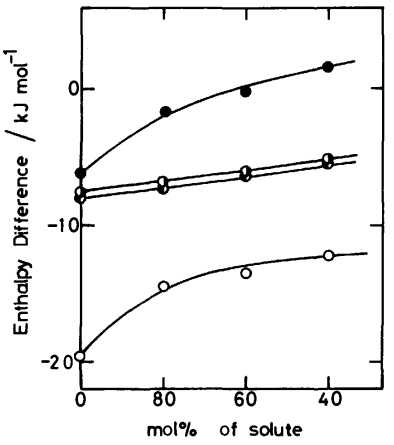

Fig. 5. Concentration dependence of enthalpy differences of isobutyl halides in hexane. $\Delta(=\Delta H_{liq} - \Delta H_{gas})$ of *i*-BuCl (●) and *i*-BuBr (○), obtained by the spectroscopic method. $\Delta H'$ of *i*-BuCl (○) and *i*-BuBr (○), calculated from Eq. 4.

estimated by the procedure proposed by Mizushima *et al.*,[16] using the reaction-field theory of Onsager:[17]

$$\Delta H' = \frac{\varepsilon - 1}{2\varepsilon + 1}\left[\left(\frac{\mu}{a^3}\right)_g - \left(\frac{\mu}{a^3}\right)_t\right] \quad (4)$$

where ε is the dielectric constant of the solvent and where μ and a are the dipole moment and the radius of the cavity of each conformer. The suffixes t and g refer to the states of *trans* and *gauche* respectively. The dipole moments of each conformer of the *i*-BuCl and *i*-BuBr were estimated by the method proposed by Miyagawa.[18] The radius of the cavity of these compounds was assumed to be the van der Waals radius of each conformer, whose value is indicated in Table 3. This assumption has been used by many investigators.[3,16] This dielectric constants of *i*-BuCl, *i*-BuBr, hexane, and methanol are found in the literature.[19] However, the dielectric constants of the solutions investigated here were not available; they were estimated using the following additivity rule of the molar polarization, $[p]$:

$$[p] = x_1[p_1] + x_2[p_2], \quad [p] = \frac{\varepsilon + 1}{\varepsilon - 2}\frac{M}{\rho}$$

where x_i refers to the mole fraction of the mixtures. The calculated values of the enthalpy difference, $\Delta H'$, are shown in Fig. 5, where the experimental values of $\Delta = \Delta H_{liq} - \Delta H_{gas}$ are also plotted. As may be seen in Fig. 5, the values of $\Delta H'$ increase with an increase in the contents of hexane in solutions. This trend well explains the experimental results, but the absolute numerical values of $\Delta H'$ are in very poor agreement with those obtained by experiments. This discrepancy between $\Delta H'$ and $\Delta(=\Delta H_{liq} - \Delta H_{gas})$ must be due to the poor estimation of the cavity radius, a, and the dipole moment, μ, of each conformer.

Equation 4 is the result of the first approximation, in which induced dipole moments were not taken into account. Besides, Eq. 4 involves only the long-range force; it does not take into account the short-range effects, especially the local packing effect of molecules. These short-range effects are all reflected in the term of the radius of the cavity. The estimation of the radius of the cavity of the rotational isomers is very important, but at present a precise estimation is very difficult.

Devauer and Lascombe[20] have thermodynamically related the enthalpy difference, Δ, to the volume change associated with the conformational change in liquids as following:

$$\Delta = \Delta H_{liq} - \Delta H_{gas} = RT^2\left(\frac{\partial f}{\partial T}\right)_V + \Delta V_{liq}\frac{\alpha T}{\beta_T} \quad (6)$$

where α and β_T are the expansion coefficient and compressibility respectively where f is $\ln[K/K_0]$, where K is the equilibrium constant for the liquid and/or dissolved state, K_0, that for gaseous state, and the other symbols have their usual meaning.

The thermodynamic parameters, α and β_T, of Eq. 6 for hexane solutions of *i*-BuCl and *i*-BuBr were determined as follows. The thermal expansion coefficient, α, was determined directly by the data of the temperature dependence of the density in solutions. The isothermal compressibility was calculated from the thermodynamic relation:

$$\beta_T = \beta_s + \frac{T\alpha^2 V}{C_p} \quad (7)$$

where the adiabatic compressibility, β_s, was determined with the aid of the Laplace equation, ($\beta_s = 1/(\rho u^2)$), from the data of density, ρ, and sound velocity, u, in solutions. The heat capacity of hexane and methanol was found in the literature,[19] but the halogenoalkanes investigated here no data were available. Therefore, the value for butyl chloride, 9.9 J/g.*K*.,[21] was adopted for the halogenoalkanes concerned in this work. The C_p's in solutions were estimated by assuming this relation

$$C_p = x_1 C_{p,1} + x_2 C_{p,2} \quad (8)$$

The values of $RT^2(\partial f/\partial T)_V$ thus obtained are summarized in Table 4. The values of $RT^2(\partial f/\partial T)_V$ are comparable in order with the values of Δ and $\Delta V_{liq}\alpha T/\beta_T$. Thermodynamically, the $RT^2\,(\partial f/\partial T)_V$ term corresponds to the internal energy difference between the liquid and gaseous states. The internal energy difference cannot be neglected in Eq. 6.

At this stage, it is difficult to calculate the physical properties concerning volume by statistical mechanical method. However, information about the internal energy of the solution is obtainable by the theoretical calculation on the basis of statistical mechanics and/or a computer-simulation experiment. The internal energy of the binary solution is calculated by the following equation:[22]

Table 4. The values of $RT^2(\partial f/\partial T)_V$ (kJ mol^{-1}) in Eq. 6.

		Hexane			Methanol
		80 mol%	60 mol%	40 mol%	40 mol%
i-BuCl					
$P_C \rightarrow P_H$	-0.7_6	-0.2_0	0.0_7	0.0_3	-0.1_8
i-BuBr					
$P_C \rightarrow P_H$	-1.4_1	-1.2_1	-1.2_8	-1.0_8	-1.2_9
s-BuBr					
$S_{HH} \rightarrow S_{HH}'$	0.2_3			0.9_5	0.9_5
$S_{HH} \rightarrow S_{CH}$	1.3_0			1.2_5	1.4_0

$$E = \frac{3}{2}NkT + \frac{2N^2}{V}\left[x_1^2\int_0^\infty u_{11}(r)g_{11}(r)r^2dr + 2x_1x_2\int_0^\infty u_{12}(r)g_{12}(r)r^2dr + x_2^2\int_0^\infty u_{22}(r)g_{22}(r)r^2dr\right]$$

$$x_1 = \frac{N_1}{N},\quad x_2 = \frac{N_2}{N},\quad N_1 + N_2 = N \quad (9)$$

where u_{ij} is the pair potential for molecules of i and j and g_{ij}, the radial distribution function. As may be seen in the equation, the short-range effects are involved in the term of the radial distribution function of each pair. We are now trying to calculate the internal energy using the theory of the reference interaction site model (RISM), which was proposed by Chandler *et al.*[23] We want to compare the calculated value with the experimental results obtained here.

The authors would like to express their appreciation to Prof. Teizo Kitagawa of the Institute for Molecular Science for permission to use the high-pressure apparatus. This work was financially supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education. (No. 59540259).

Assignment of Conjugate Double Bond Systems Produced in Heated PVA Film by Absorption and Excitation Spectra

Kazunori MARUYAMA, Hiroshi AKAHOSHI, Michio KOBAYASHI, and Yoshié TANIZAKI*
Department of Materials Science and Technology, Technological University of Nagaoka, Nagaoka, Niigata 949-54
(Received May 4, 1985)

Absorption, emission and excitation spectra of heat-treated PVA film have been interpreted as corresponding to mixtures of $-(CH=CH)_n-$ and $-(CH=CH)_n-CO-$, which are distinguishable from each other according to whether spectrum is accompanied with fine structures or not. The former shows fine structures and has had n determined to be 2—14 by analysis of peak locations on the basis of linearity for Lewis-Calvin's plot. For the latter, n has been determined to be 1—7, and Lewis-Calvin's plot between the wavelength of band maximum and n also shows a good linearity.

There are a number of reports concerning electronic spectra of heat-treated poly(vinyl alcohol) [PVA].[1] A somewhat troublesome problem for the analysis of spectra is that thermally decomposed products of PVA are mixtures of many different polymers and that it is not possible to extract each component for analysis.

Absorption spectra of a heat-treated PVA film are very much influenced by heating temperature, heating time, and impurities contained. The coloration of PVA by heat is promoted by various compounds such as sulfuric acid, hydrochloric acid, phosphoric acid,[2] and sodium acetate.[3] Actually, commercial PVA powder, which contains about 0.5 wt% sodium acetate produced by alkaline saponification, will get colored easily by heating.

PVA is a polymer composed of a main chain of C–C bond with an OH group attached. Therefore, the final pyrolytic product should be graphite. In the initial stage of heating, however, we can focus our concern on products of two types of polyenes and polyenones. In fact, electronic spectra of PVA films which underwent various treatments including heating as in this study, were explainable merely in terms of formation of conjugate doulble bonds by dehydration and dehydrogenation, nor their spectral data gave any positive suggestion for severance of the main chain of polymer. Accordingly, all kinds of π electron systems to be formed along the framework of the chain must be restricted to the two types mentioned above. Fortunately, electronic spectra of the two types are distinguishable from each other according to whether spectrum is accompanied with fine structures or not. Furthermore, a judgement on the kinds of polyenes with fine structures can be made by analysis of peak locations and their intervals. On the other hand, the kinds of polyenones which show band spectra should be distinguishable on the basis of the correlation between the wavelength of band maximum and the number n of conjugate double bonds, because the difference of adjacent band maxima is equivalent to the difference between n and $n+1$, *i.e.*, $-CH=CH-$. Practically, the authors have presupposed tacitly the above considerations and have pointed out the existence of polyenes $-(CH=CH)_n-$ and polyenones $-(CH=CH)_n-CO-$ with $n=2—5$ and 2—3, respectively.[4]

In the present study as a continuation, the authors will analyze the correlation between absorption and the number of conjugate double bonds, assuming that fine structures are due to polyenes, whereas bands are due to polyenones (to be called polyene-carbonyl in this paper).

Experimental

PVA used was a commercial one (Koso Chemical Co., Ltd.), of which the average polymerization degree was 1400 and alkaline saponification was 99—100%. PVA poweder of 10—30 g was dissolved in distilled water of 200 cm^3 at 90 °C, and the solution was poured on a horizontal glass plate (30×30 cm). After it was dried at room temperature in 10 d, a PVA film about 100—300 μm thick was obtained. This film was kept for 2 h at 80 °C and put into use as the original film to be called PVA-1.

The PVA film was digested in a mixed solution of 0.1 M (1 M=1 mol dm^{-3}) $NaBH_4$ and 0.1 M NaOH for 1 d to reduce carbonyl group, and was washed with 0.05 M HCl solution and then with distilled water. In addition, it was digested in the following solutions separately and was dried at room temperature: the film digested in CH_3COONa solution is called PVA-2; in HCl solution, PVA-3; in H_2SO_4 solution, PVA-4; in H_3PO_4 solution, PVA-5.

Heat treatment of sample film was carried out with a sample being fixed on a metal holder in order to avoid wrinkling by heating. A sample film was set in a heating compartment and heated up to the desired temperature at a rate of 10 °C min^{-1} in a 0.5 dm^3 min^{-1} flow of nitrogen.

Absorption spectra were measured with a Shimadzu UV-360 spectrophotometer, and emission and excitation spectra with a Shimadzu RF-502 spectrophotometer. Fluorescence spectra were measured from the front side of film with an incident angle of 35° in the region 260—650 nm.

Results

PVA-1. The film of PVA-1 itself is colorless and its spectrum shown as Fig. 1(a)-1 has two weak absorption bands at 280 and 330 nm, which are already assigned to $-(CH=H)_2-CO-$ and $-(CH=CH)_3-CO-$, respectively.[5] When the PVA-1 film is heated,

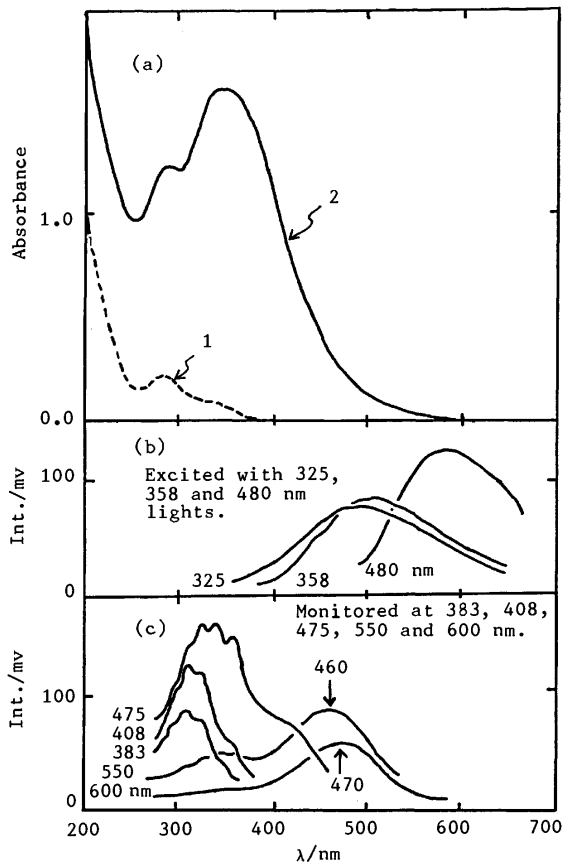

Fig. 1. Absorption (a), emission (b) and excitation spectra (c) of heat-treated PVA-1 film at 175 °C. Film thickness: 290 μm. (a)-1: Before heating, (a)-2: after heating.

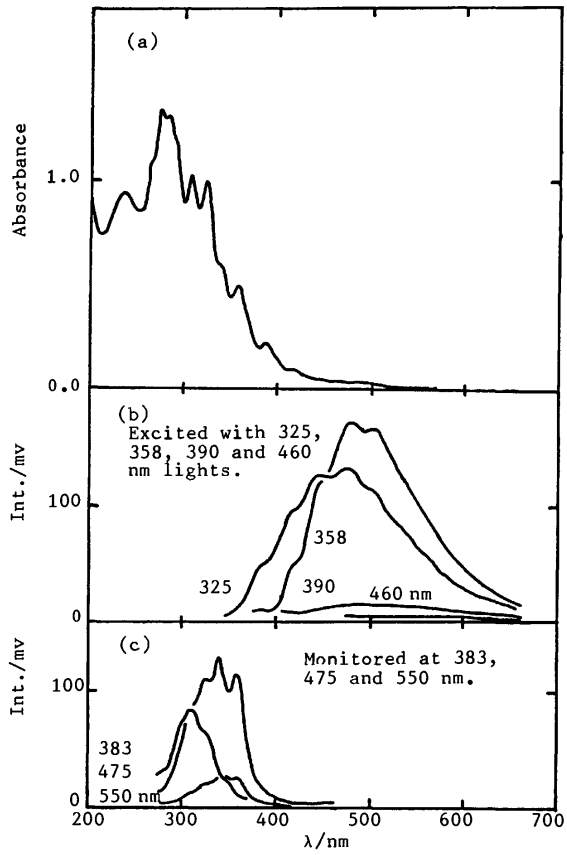

Fig. 2. Absorption (a), emission (b) and excitation spectra (c) after digestion of heated PVA-1 film (Fig. 1(a)-2) in 0.1 M NaOH-$BaBH_4$ mixed solution.

it becomes pale yellow and shows the spectrum of Fig. 1(a)-2 which has two strong bands at 280 and 340 nm. The spectral change from Fig. 1(a)-1 to (a)-2 is as follows: the 280 nm band grows without changing its maximum wavelength and the 330 nm band grows up to the 340 nm band. This indicates that the band maximum of triene-carbonyl is at 340 nm rather than at 330 nm.

Figures 1(b) and 1(c) show emission and excitation spectra for the absorption of Fig. 1(a)-2, respectively. For the emission spectra, it is noticed that the broad band at about 590 nm due to excitation by 480 nm light is most intense, in spite of the fact that the absorption intensity at 480 nm is weaker than those at the other excitation wavelengths. In the excitation spectra of Fig. 1(c), the peaks of the fine structures are at the same wavelengths as those of tetraene and pentaene assigned previously.[4] Therefore, the absorptions by these polyenes should be contained in the absorption spectrum of Fig. 1(a)-2, though any fine structures are not observable. In the excitation spectra, the other broad bands without fine structures appear at 460 and 470 nm. These bands changed their maximum wavelengths depending on monitor wavelengths, which indicates that respective bands consist of two overlapped bands.

The heat-treated PVA-1 film turned almost colorless in the aqueous solution of $NaBH_4$ in 1 d. Its absorption, emission, and excitation srectra are shown in Figs. 2(a), (b), and (c), respectively. By the treatment with $NaBH_4$, the 280 and 340 nm bands of Fig. 1(a)-2 are caused to disappear and instead a fine structure is caused to reveal itself as shown in Fig. 2(a). This change indicates that diene-carbonyl (280 nm band) and triene-carbonyl (340 nm) become diene and triene, respectively, as a result of reduction of the carbonyl group by $NaBH_4$, and that the other polyene-carbonyls (longer wavelengths) are reduced to the corresponding polyenes such as tetraene, pentaene, *etc.*

In the emission spectra of Fig. 2(b), any bands similar to the intense band at about 590 nm in Fig. 1(b) could not be observed. This may be due to too weak an absorption intensity (Fig. 2(a)) at the excitation wavelength (460 nm). In the excitation spectra of Fig. 2(c), such intense bands as shown at 460 nm in Fig. 1(c) are lacking completely for the monitor at 550 nm in spite of the sufficient intensity of emission (see Fig. 2(b)).

PVA-2. Figure 3(a)-1 shows the absorption spectrum for the purified PVA film called PVA-2.

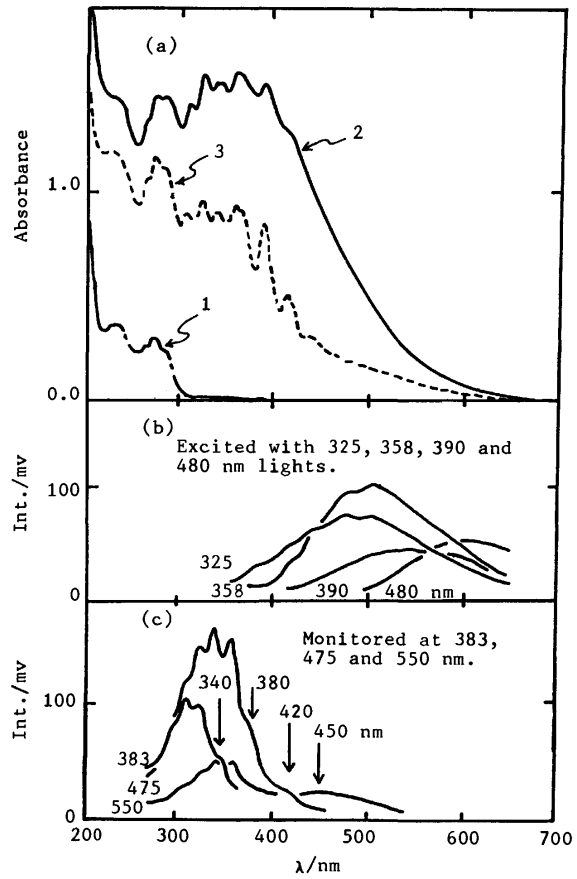

Fig. 3. Absorption (a), emission (b) and excitation spectra (c) of heated PVA-2 film at 175°C. Film thickness: 290 μm. (a)-1: Before heating, this is doubled spectrum in absorption, (a)-2: after heating, (a)-3: after digestion of heated PVA-2 film ((a)-2) in 0.1 M NaOH-$NaBH_4$ mixed solution.

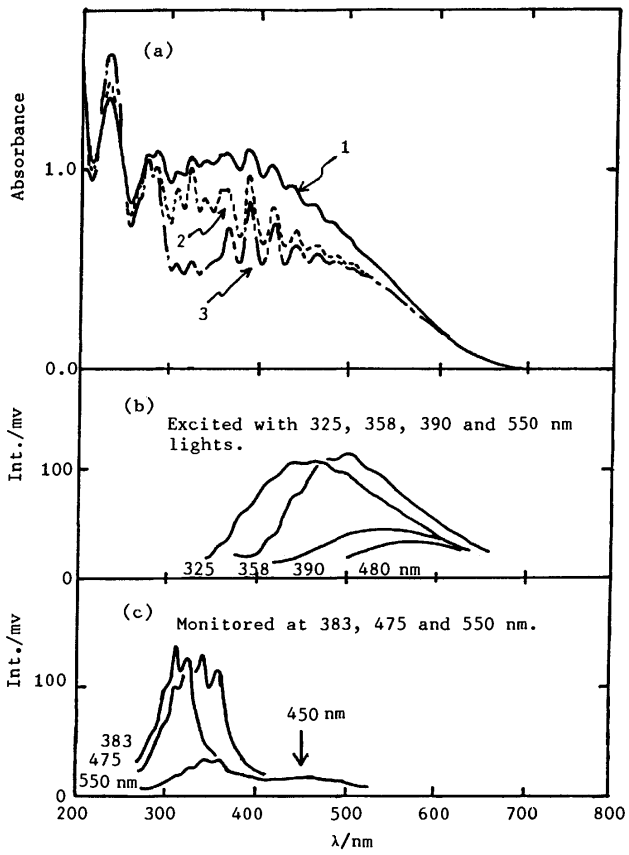

Fig. 4. Absorption (a), emission (b) and excitation spectra (c) of heated PVA-3 film at 120°C. Film thickness: 120 μm. (a)-1: After heating, (a)-2 and (a)-3: after digestion of heated PVA-3 film ((a)-1) for 1 day and further 3 days, respectively, in 0.1 M NaOH-$NaBH_4$ mixed solution.

There are two bands with maxima at 234 and 273 nm, and in both sides of each band faint fine structures are recognized. The spectral change from Fig. 1(a)-1 to 3(a)-1 shows that by purification diene-carbonyl (280 nm) changes to diene (234 nm) and triene-carbonyl (340 nm) to triene (273 nm).

Figures 3(a)-2, (b), and (c) show, respectively, the absorption, emission and excitation spectra of a brown film of heated PVA-2. The wavelengths of the peaks and shoulders of the fine structure in Fig. 3(a)-2 coincide well with those of the corresponding peaks appearing in Fig. 2(a). The emission spectra of Fig. 3(b) and the excitation spectra of Fig. 3(c) are similar in character to those of Figs. 1(b) and (c), respectively: the broad emission band at about 590 nm due to the excitation at 480 nm, and the excitation bands at 420 (shoulder) and 450 nm by the monitor at 475 and 550 nm, respectively. All the wavelengths of the peaks of the fine structures of Fig. 3(c) coincide with those of some peaks in Figs. 1(c) and 2(c).

Figure 3(a)-3 shows the absorption spectrum for the case when the heated PVA-2 film was reduced by $NaBH_4$. The emission and excitation spectra, which are not inserted here, did not show any emission (590 nm) or excitation bands (420—470 nm) in the longer wavelength region, in common with the cases of Figs. 2(b) and (c).

PVA-3 and PVA-4. When the films of PVA-3 and PVA-4 were heated, they got colored red. Both the red films showed similar absorption, emission, and excitation spectra. Therefore, only the case of PVA-3 is presented here in Fig. 4.

The emission and excitation spectra obtained for the absorption of Fig. 4(a)-1 are in Figs. 4(b) and (c), respectively, which resemble those of Figs. 3(b) and (c), respectively.

In the absorption spectra of Fig. 4(a), the fine structures continue over a longer wavelength region than those of the other samples. Figure 4(a)-1 shows the absorption spectrum of the heated PVA-3 film, and Figs. 4(a)-2 and -3 show the spectra after the treatment by $NaBH_4$, *i.e.*, 1 d digestion for the former and 3 d for the latter in 0.1 M NaOH-$NaBH_4$ mixed solution. By the 1 d digestion, the absorption intensity of Fig. 4(a)-1 is decreased in the range about 300—600 nm and the fine structure is sharpened (Fig. 4(a)-2). Further digestion causes the intensity to decrease further,

especially for the peaks at 310 and 325 nm (to be assigned to tetraene) and at 342 and 358 nm (to pentaene) (Fig. 4(a)-3). On the other hand, the 234 nm band of diene increases during the digestion. The change from Fig. 4(a)-1 to (a)-3 by the $NaBH_4$ treatment indicates that the conversion of long polyenes to diene and momoene is effected by the reduction, and that tetraene and pentaene are especially easier to be reduced.

PVA-5. When the PVA-5 film was heated, it turned yellowish brown. The absorption spectrum of this colored film is similar to that of Fig. 3(a)-3. The excitation spectra, however, show only the peaks of tetraene and pentaene lacking the broad band, in spite of the condition of heating temperature being similar with the heated PVA-2 film (Fig. 3(c)).

Discussion

Assignment of Peaks of Fine Structures. (a) Absorption Spectra: In our experiment, the peak wavelengths of fine structures revealed in the spectra of the treated PVA films almost coincide with one another regardless of any sorts of treatments upon PVA films. The peak wavelengths range from 226 to 540 nm. Of the peaks, those in the region 226—358 nm have been assigned to the 0←0, 1←0, and 2←0 transitions of polyenes $-(CH=CH)_n-$ with n=2—5.[4] Moreover, the peaks for each transition have resulted in a linear relation with respect to Lewis-Calvin's plot,[6] *i.e.*, the relationship between λ^2 (λ is peak wavelength) and n.[4]

In Fig. 5, λ^2 of the rest peaks over n=5 are plotted in white circles on the extended 0←0 line for n=2—5, except the solid circle at n=6 which is assigned to 1←0 (366 nm). The white circles fall on a line broken at the position n=9. However, if we shift horizontally the white circles by a unit of n to the right, the respective circles will fall into the extended straight line of the 1←0 transition as shown by the solid circles.

Sondheimer *et al.*[7] have plotted the relationship between λ^2 and n for the free polyenes $H-(CH=CH)_n-H$ (n=3—8 and 10). According to their plot, a linear relation is obtained while n is small, but the points for n=8 and 10 turn downwards off the line. As is likewise presupposed from the absorption spectra of polyacetylenes,[8] the value of λ^2 shows a tendency to approach a certain value as n increases. It is a matter of common knowledge that λ^2 of conjugate systems in the same series approaches a certain value for larger numbers of n, but the limits of n for which λ^2 changes linearly are not always definite.

As shown in Fig. 5, if all the peaks (white circles) are assigned to the 0←0 transitions, the limits of straight line would become equal to n=9, and if assigned to the 1←0 transitions, even the point for n=14 would be put on a straight line. Though it cannot definitely be answered which is true, the latter assignment may be considered to be right for the following reason.

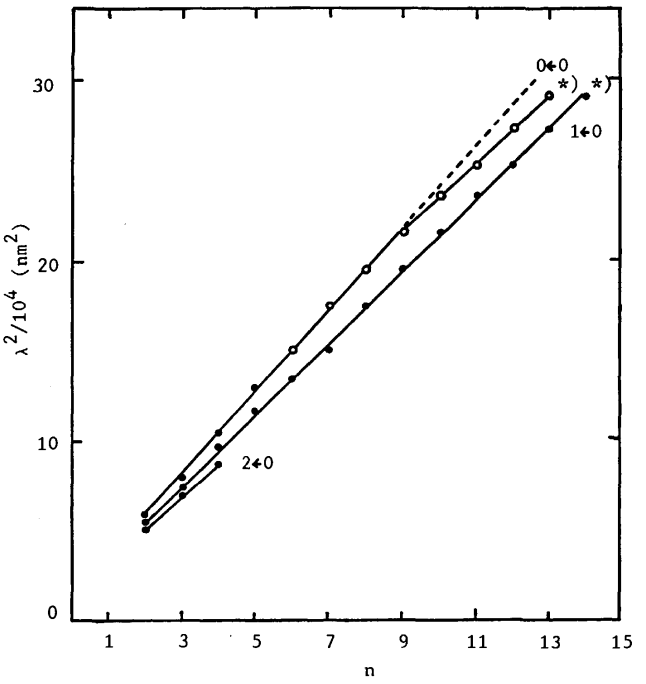

Fig. 5 Relationship of λ^2 *vs.* n for polyenes in heated PVA films. *) (539 nm) to be observed only when PVA film is uni-axially stretched before heating.

TABLE 1. ASSIGNMENT OF ABSORPTION PEAKS OF $-(CH=CH)_n-$ PRODUCED IN HEATED PVA FILM

n	Wavelength/nm

13		523	
14		540[a)]	

a) Observed when PVA film is uni-axially stretched before heating.

In the present experiment, a mixture of π electron systems of the polyene type is observed. In such mixtures, peaks of a system of conjugation number n may be influenced by the overlapping effect in the n+1 system, in such a way that the 0←0 peak is influenced more than the 1←0 and 2←0 peaks. At the same time, the 2←0 peak may be overlapped by the 0←0 peak of the n−1 system. And moreover, the intensity of the 2←0 peak is generally weaker than those of the 0←0 and 1←0 peaks. For this reason, the 1←0 peak is very liable

TABLE 2. ASSIGNMENT OF ABSORPTION AND EXCITATION BANDS OF POLYENE-CARBONYLS $-(CH=CH)_n-CO-$ PRODUCED IN HEATED PVA FILMS

a) Shoulder.

to be observed because of its least influence from other systems.

In Fig. 5, the linearity of the plot of 1←0 peaks is of remarkably long-range. At the present stage, we cannot explain the reason for the long-range linearity. However, a fact that the observed π electron system is formed locally within a very long C-C bond chain, may make a cause of the fact that the linear region extends to larger n's than in the case of free molecule.

Based on the above considerations, let us assume that all the observed peaks over n=5 are assigned to the 1←0 transitions, and we may obtain the assignment given in Table 1.

(b) Excitation Srectra: The absorption spectra of the heated PVA films shown in Figs. 1—4 are considerably different from one another, but in their excitation spectra only the fine structures of tetraene and pentaene are commonly observed and none of the other polyenes. The reason why any fine structures for n larger than 5 (pentaene) could not be observed, may be that the produced amount of polyenes is too small to be detected. We thus heated enough PVA-3 film till it turned deep reddish black. Nevertheless, its excitation spectra did show only the peaks of tetraene and pentaene, and again no peaks of the other polyenes. This result indicates that the fluorescence efficiency of the other polyenes is very small. In fact, D'Amico *et al.*[9] have shown that the efficiency is markedly decreased in going from tetraene to hexaene molecule. They have estimated that the fluorescence quantum yield of hexaene molecule is at most 1/50 that of tetraene, and predicted that longer conjugate polyene molecules show no fluorescence. Hence, our result supports their prediction positively.

Assignment of Absorption Bands of Polyene-Carbonyls. Let us regard the absorption bands without fine structures as those of the polyene-carbonyls of the type $-(CH=CH)_n-CO-$, types of $-(CH=CH)_n-CO-(CH=CH)_m-$ and others being neglected because the chance of their formation is considered to be small. All such bands and shoulders observed here are collected in the column headed "Observed wavelength" of Table 2.

The 280 and 340 nm bands in Table 2 (the column headed "Fig. 1(a)") have already been assigned to diene-carbonyl (n=2) and triene-carbonyl (n=3), respectively.[5] Since the minimum difference with $-(CH=CH)_n-CO-$ is one double bond -CH=CH-, the change in wavelength of the band maxima for successive n's ought to be step-like. In the case of polyenes $-(CH=CH)_n-$ (Table 1), for instance, the peak-intervals in the same kind of transitions are about 30—40 nm for the smaller n's. With this taken into consideration, with Table 2, it is reasonabe to assign the 380 and 420 nm shoulders to n=4 and 5 of $-(CH=CH)_n-CO-$, respectively.

As pointed out in the "Results" section, either of the 460 and 470 nm bands in Table 2 (the column headed "Fig. 1(c)") consist of two subbands. By supposing the main component of the 460 nm band is identical with the 450 nm band of the columns headed "Fig. 3(c)" and "Fig. 4(c)" in Table 2, the shift by overlapped band is estimated to be 10 nm. Therefore, if the 10 nm shift by overlapped band (train of 450 nm band) is expected for the 470 nm band, the wavelength of the main band can be estimated to be 480 nm.

According to the above consideration, the bands and shoulders regarded as the absorptions of polyene-carbonyls are all assigned as shown in the first and second columns of Table 2.

In the above we have found that the 1←0 peaks of polyenes furnish a linearity of Lewis-Calvin's plot in a wide range of n. Since the polyene-carbonyls assigned in Table 2 have the structure in which a C=O bond is joined to polyene at the terminal, the shift of the band maximum for successive n's of $-(CH=CH)_n-CO-$ is dependent upon the increase in number of -CH=CH- bonds. Therefore, a linearity of Lewis-Calvin's plot is also expected for the band maxima of polyene-carbonyls. The plot is shown by solid circles in Fig. 6, which meets our expectation. The white circles in Fig. 6 are of the same plot for $CH_3-(CH=CH)_n-CHO$, for which are used the band maxima reported by Blout and Fields.[10] Evidently, the Lewis-Calvin's plot is curved for the case of free molecule. The difference (Fig. 6) between $-(CH=CH)_n-CO-$ and $CH_3-(CH=CH)_n-CHO$ may be due to the same sequence as the case between $-(CH=CH)_n-$ (Fig. 5) and the corresponding free molecule.

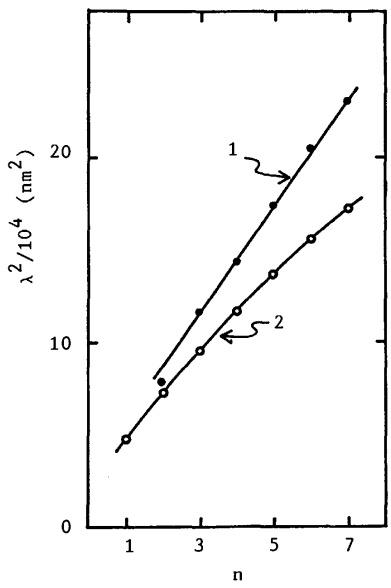

Fig. 6. Relationship of λ^2 *vs.* n for polyene-carbonyls in the heated PVA films. 1: This study, 2: cited from Ref. 10.

Das and Becker[11] have reported that the polyene-aldehydes CH_3-$(CH{=}CH)_n$-CHO of n=2—5 do not show fluorescence at room temperature but emit weak or moderately strong fluorescence at 77 K. In connection with their study, we point out that the solid PVA substrate film has a nature characterestic of a glassy solvent, though well known empirically. This is because, in our experiment, the fluoresence from polyene-carbonyls of n=3—7 could be detected, even at room temperature.

The Pressure Effect on Conductances of KCl in Ethanol-Water Mixtures at 25 °C

Masakatsu UENO,* Noriaki TSUCHIHASHI, and Kiyoshi SHIMIZU
Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
(Received May 17, 1985)

The molar conductances of KCl in 5, 10, 15, 20, and 30 mol% ethanol–water mixtures were measured in the dilute concentration range of (2—8)×10^{-4} M (1 M=1 mol dm^{-3}) at 25 °C up to 1500 kgf cm^{-2} (1 kgf cm^{-2}=0.9807×10^5 Pa). The Fuoss-Onsager conductance equation for unassociated electrolytes was used to determine the limiting molar conductance, $\Lambda°$, of KCl in 5 and 10 mol% of ethanol. In 15, 20, and 30 mol% of ethanol, where the ionic association takes place, the Shedlovsky equation was employed to obtain $\Lambda°$ and the association constant K_A of KCl. The limiting ionic molar conductances of the K^+ and Cl^- ions were determined by combining $\Lambda°$ with the limiting transference number for KCl. The Walden products of both K^+ and Cl^- ions decrease with an increase in the pressure in 5 mol% of ethanol, but in 15 mol% of ethanol and above they increase with an increase in the pressure. These facts indicate that the breaking effect of these ions appears prominently in about 5 mol% of ethanol.

Studies of the electrolytic conductance in binary solvent systems of alcohols and water are of interest because such systems are useful in elucidating not only the effect of a change in the dielectric constant on the association of electrolytes into ion pairs, but also the influence of the solvent structure on the limiting ionic conductances.

In previous papers,[1,2] we reported the pressure and temperature effects on the transference numbers for KCl in ethanol–water mixtures. Here we wish to present data on the electrolytic conductances of KCl in the same solvent systems at high pressures at 25 °C, and to discuss the variation in the ionic Walden products with the ethanol content and the pressure.

Experimental

Chemicals and Solutions. The chemicals used were the same as those described in the previous paper.[1] All the solutions of potassium chloride KCl were prepared by weight. A proper quantity of the stock solution (2×10^{-3} M KCl aqueous solution) was weighed into a dry weighing bottle of about 150 cm^3 and then diluted gravimetrically with conductivity water and ethanol in order to yield the desired composition of the solvent and concentration of the solution. The concentrations of the solutions in M were determined by assuming that the densities of dilute KCl solutions were equal to that of the solvent.

Apparatus. The high-pressure system for the conductance measurement is illustrated in Fig. 1. Pressure generated by means of a hand pump was measured to ±3 kgf cm^{-2} by means of a calibrated Bourdon gauge (Nagano Keiki Seisakusho, Ltd.). The temperature of the oil bath in which a pressure vessel was immersed was kept constant at (25±0.03) °C. The conductance cell installed in the pressure vessel was made by modifying a hypodermic syringe (capacity, 10 cm^3); the oil pressure was transmitted to the solution through a glass piston of the syringe.

Unplatinized electrodes were used for all the measurements, since the resistances of solutions decreased monotonously with the time when lightly platinized electrodes were employed. In order to eliminate electrode polarization errors caused by using unplatinized electrodes, the resistances of solutions were measured at 0.2, 0.5, 1, 2, and 5 kHz by means of a sine wave oscillator (Model 361B), a conductance bridge (Model 362B), and a standard resistor (Model 363B) manufactured by Fuso Seisakusho, Ltd. The measured resistances were found to be linear functions of the reciprocal of the frequency, f, except for 0.2 kHz, and to increase with a decrease in the frequency, as is typical of electrode polarization. The extrapolated value at $1/f$=0 was assumed to be the correct value. The cell constants at atmospheric pressure, as determined by this method from the conductances of 5×10^{-4}, 1×10^{-3}, and 1×10^{-2} M KCl aqueous solutions,[3] agreed within ±0.03%, which indicates that electrode polarization errors are eliminated. The cell constant thus determined was 0.3860 cm^{-1}, and it was assumed to be invariant with the pressure.

Results

The physical properties of the various solvent mixtures, the density, ρ,[4] the viscosity, η,[4,5] and the dielectric constant, ε,[6] at high pressures and at 25 °C used in the data analysis are from the literature; they are summarized in Table 1, where the ρ,[7] η,[8] and ε[9] values of water are also included. Table 2 shows the

molar conductances, Λ, of KCl in ethanol–water mixtures at 25 °C as a function of the pressure, P. The molar conductances were reproducible within±0.1%.

The limiting molar conductances, Λ°, of KCl in 5 and 10 mol% of ethanol were obtained by analyzing the conductance data with the aid of the Fuoss-Onsager conductance equation for unassociated electrolytes:[10,11]

$$\Lambda = \Lambda^\circ - Sc^{1/2} + Ec \log c + Jc, \tag{1}$$

where c is the molar concentration (M) and where S, E, and J are the parameters in Eq. 1; S is the Onsager limiting slope, the form of E is $(E_1\Lambda^\circ - 2E_2)$, in which both E_1 and E_2 depend only upon solvent properties, and J is a function of the ion-size parameter, $\mathring{a}$. However, in 15 mol% of ethanol and above, the data analysis obtained by the use of Eq. 1 gives a very low value of $\mathring{a}$, which means that KCl is slightly associated in these mixtures. Thus, the Shedlovsky equation:[12]

$$1/\Lambda S(z) = 1/\Lambda^\circ + K_A c\Lambda S(z) f_\pm^2/\Lambda^{\circ 2}, \tag{2}$$

where:

$$S(z) = \{z/2 + [1 + (z/2)^2]^{1/2}\}^2, \tag{3}$$

$$z = [8.204 \times 10^5 \Lambda^\circ/(\varepsilon T)^{3/2} + 82.50/\eta(\varepsilon T)^{1/2}] \times (c\Lambda/\Lambda^{\circ 3})^{1/2}, \tag{4}$$

and:

$$-\ln f_\pm^2 = 3.649\times10^6[c\Lambda S(z)/\Lambda°]^{1/2}/(\varepsilon T)^{3/2} \quad (5)$$

was employed to obtain $\Lambda°$ and the association constant, K_A, from Λ in 15 mol% of ethanol and above; here, $f_\pm$ and T are the mean activity coefficient by the Debye-Hückel limiting law and the absolute temperature respectively. The values of $\Lambda°$, $\mathring{a}$, and K_A thus obtained are listed in Table 3, together with those of $\Lambda°$ and $\mathring{a}$ in water, which were obtained by recalculating the data in Ref. 13 with the aid of Eq. 1. The present values of $\Lambda°$ at atmospheric pressure are in good agreement with the more accurate ones[14] within ±0.2%. No high-pressure data are available for comparison in these systems, however. As is shown in Table 3, $\Lambda°$ decreases with an increase in the ethanol content at each pressure and with an increase in the pressure in each solvent except for 5 mol% of ethanol, where the $\Lambda°$-*vs.*-pressure curve has a slight maximum, as in the case of water.

The limiting ionic molar conductances, $\lambda_i°$, of the K^+ and Cl^- ions listed in Table 3 were determined by combining $\Lambda°$ with the limiting cation-transference number, $t_+°$, for KCl as follows:

$$\lambda_+° = \Lambda° t_+°, \quad (6)$$

$$\lambda_-° = \Lambda° - \lambda_+°. \quad (7)$$

The limiting cation-transference numbers shown in Table 3 were obtained using the Kay-Dye equation:[15]

$$t_+° = t_+ + [(0.5-t_+)/\Lambda°]\Delta\Lambda_e, \quad (8)$$

where t_+ is the cation-transference number at the molar concentration c and where $\Delta\Lambda_e$ is the electrophoretic contribution to conductance, expressed by the Fuoss-Onsager conductance equation:[10]

$$\Delta\Lambda_e = \beta c^{1/2}/(1+\kappa'\mathring{a}), \quad (9)$$

$$\beta = 82.50/\eta(\varepsilon T)^{1/2}, \quad (10)$$

$$\kappa' = 50.3c^{1/2}/(\varepsilon T)^{1/2}, \quad (11)$$

where $\mathring{a}$ is the ion-size parameter in Å. The values of η and ε are given in Table 1, $\Lambda°$ is determined in this work, and the value of t_+ in 0.02 M KCl solution is taken from Ref. 1; the value of $\mathring{a}$ taken from Ref. 16, *i.e.*, 3.08 Å, is assumed to be independent of the solvent composition and the pressure. It should be noted that the ionic association has no direct effect on the transference number, since it is the ratio of the conductance of the ion to that of the salt, and that the value of $t_+°$ is little affected by the use of a nominal

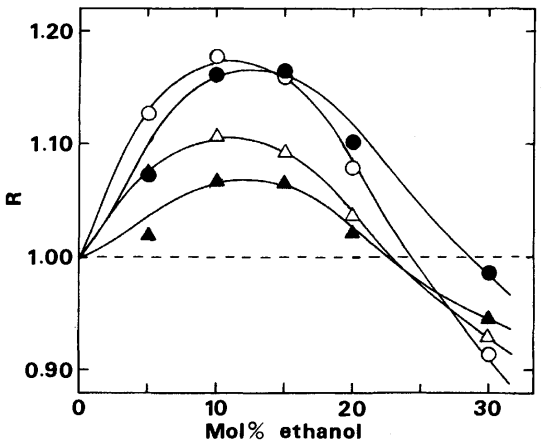

Fig. 2. Ionic Walden products normalized to their values in water as a function of mol% of ethanol. ○: 1 atm, ●: 1500 kgf cm^{-2} for the K^+ ion, and △: 1 atm, ▲: 1500 kgf cm^{-2} for the Cl^- ion.

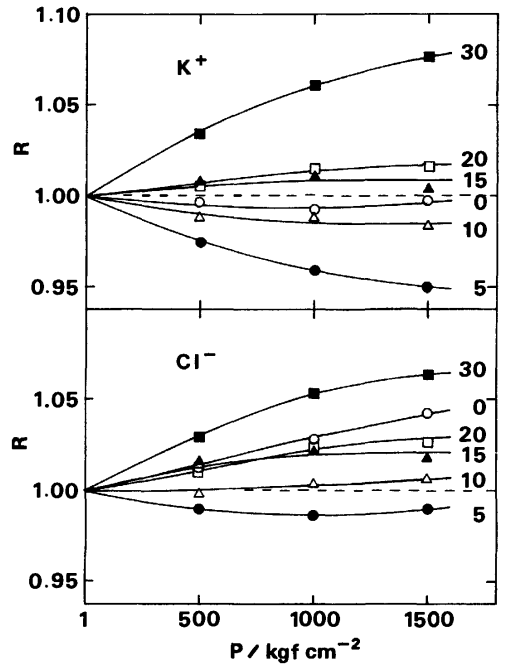

Fig. 3. Ionic Walden products normalized to their values at 1 atm as a function of the pressure. Mol% of ethanol is shown in the plot.

concentration (0.02 M) instead of a real concentration in Eqs. 9 and 11, since the ionic association is slight, the concentration of the solution is low enough, and the value of t_+ is close to 0.5 in our case.

The pressure dependence of $\lambda_i°$ in the various solvent mixtures agrees qualitatively with that of the fluidity of the solvent mixtures, $1/\eta$, except in the case of 5 mol% of ethanol, where $\lambda_+°$ decreases monotonously with an increase in the pressure, though $1/\eta$ has a maximum at about 900 kgf cm^{-2}.

Figures 2 and 3 show the variation in the ionic Walden products, $\lambda_i°\eta$, with the ethanol content and the pressure respectively. The ionic Walden products initially increase with the ethanol content up to about 10 mol% of ethanol and then decrease at each pressure studied. As is shown in Fig. 3, the pressure coefficient of the Walden product of the K^+ ion at atmospheric pressure is negative for water, 5, and 10 mol% of ethanol, is most negative for 5 mol% of ethanol, and becomes positive for 15 mol% of ethanol and above, while that of the Cl^- ion is negative for only 5 mol% of ethanol.

The association constant, K_A, increases with the ethanol content and decreases with the pressure, as is shown in Table 3. This trend coincides with the change in the dielectric constant of the solvent. The volume change on the ionic association, $\Delta\overline{V}°$, was estimated by means of the equation:[17]

$$\Delta\overline{V}° = -RT(\partial \ln K_A/\partial P)_T - RT\beta_s, \quad (12)$$

where β_s is the compressibility of the solvent and R is the gas constant. The values obtained at atmospheric pressure are 3.5, 4.0, and 4.8 cm^3 mol^{-1} for 15, 20, and 30 mol% of ethanol respectively.

Discussion

It is convenient to express the ionic Walden product as a sum of terms:[18]

$$\lambda_i°\eta = (\lambda_i°\eta)_{CS} + (\lambda_i°\eta)_{CE}, \quad (13)$$

where the charged-sphere contribution, $(\lambda_i°\eta)_{CS}$, is written as:

$$(1/\lambda_i°\eta)_{CS} = (1/\lambda_i°\eta)_{IS} + (1/\lambda_i°\eta)_{DR}. \quad (14)$$

Here, the term IS gives the contribution to the conductance to be expected from inert spheres, while the term subscripted DR gives the contribution to the conductance resulting from charging the spheres and is identified as a solvent dipole relaxation effect. The last term, subscripted CE, is a term that contains the effects resulting from changes in the solvent in the vicinity of an ion.

If we use, as the charged-sphere contribution, the Zwanzig dielectric friction theory,[19] which is based on a continuum model for the solvent, the ionic Walden product is expressed as:

$$\lambda_i°\eta = eF/[A_s\pi r_i + A_z\phi r_i^{-3}], \quad (15)$$

where ϕ is given by:

$$\phi = e^2(\tau/\eta)[(\varepsilon-\varepsilon_\infty)/\varepsilon(2\varepsilon+1)], \quad (16)$$

with A_s=6 and A_z=3/8 for complete sticking, and A_s=4 and A_z=3/4 for complete slipping. Here, e, F, r_i, τ, and ε_∞ are the protonic charge, the Faraday constant, the radius of an ion, the solvent dielectric relaxation time, and the infinite-frequency dielectric constant

respectively. Equation 15 predicts that the increase in ϕ will lead to a decrease in the ionic Walden product if r_i is taken to be the crystallographic radius of the ion and does not change with the solvent composition and the pressure. At atmospheric pressure, ϕ is shown to increase with the ethanol content by using the values of τ,[20] η, and ε of water, 20 and 30 mol% of ethanol, and on the assumption that ε_∞ is equal to that of water.[21] Therefore, the Zwanzig equation cannot explain the initial increase in the ionic Walden products with the ethanol content, as was pointed out by Kay *et al.*[22] However, the decrease in the ionic Walden products with the ethanol content in the range of (20—30) mol% of ethanol is qualitatively in agreement with the experimental results shown in Fig. 2.

Here, let us consider the pressure dependence of the ionic Walden products in each solvent. The pressure dependence of ϕ is expressed as follows:

$$\frac{1}{\phi}\left(\frac{\partial\phi}{\partial P}\right)_T = \left[\frac{-2\varepsilon(\varepsilon-2\varepsilon_\infty)+\varepsilon_\infty}{\varepsilon(\varepsilon-\varepsilon_\infty)(2\varepsilon+1)}\right]\left(\frac{\partial\varepsilon}{\partial P}\right)_T + \frac{1}{\tau}\left(\frac{\partial\tau}{\partial P}\right)_T - \frac{1}{\eta}\left(\frac{\partial\eta}{\partial P}\right)_T. \quad (17)$$

The first term on the right-hand side of Eq. 17 is negative for all the solvent mixtures studied, because ε increases with an increase in the pressure, as is shown in Table 1, and ε_∞ can be expected to be very small compared with ε. Although there is no available data on τ at high pressures in ethanol–water mixtures, τ is anticipated to decrease with an increase in the pressure, by analogy with the case of water.[23] The decrease in the τ of water with the pressure is attributed to the bending of hydrogen bonds between water molecules caused by pressure. Therefore, the second term can also be expected to be negative. The third term, except in the cases of water and 5 mol% of ethanol, is negative, since η increases with an increase in the pressure, as is shown in Table 1. Thus, ϕ decreases with an increase in the pressure in 10 mol% of ethanol and above. In the cases of water and 5 mol% of ethanol, η initially decreases with an increase in the pressure. However, this contribution to $(1/\phi)(\partial\phi/\partial P)_T$ is comparable with that of the first term, and the two contributions cancel each other out; in the case of water, the contribution of the second term is about twice as large as those of the first and third terms. Therefore, ϕ decreases with the pressure even in water and 5 mol% of ethanol. The Zwanzig equation predicts that the ionic Walden product will increase with the pressure. This prediction agrees with the experimental results in 15 mol% of ethanol and above, as is shown in Fig. 3. However, the pressure coefficients of the Walden product of the K^+ ion in water, 5, and 10 mol% of ethanol and that of the Cl^- ion in 5 mol% of ethanol, *i.e.*, in the water-rich region, do not agree with the predictions of the theory.

In the water-rich region, the water structure is more strengthened than that in water by the addition of a small amount of ethanol.[24] Thus, in this region the second term on the right-hand side of Eq. 13, $(\lambda_i^\circ\eta)_{CE}$, must be taken into consideration. If the effective viscosity in the vicinity of an ion is less than the bulk viscosity of a solvent, the ion obtains excess mobility. An increase in the pressure will cause the water structure to weaken by bending the hydrogen bonds between water molecules. Thus, the excess mobility will decrease with an increase in the pressure. This effect brings about the decrease in the ionic Walden product with an increase in the pressure. For the K^+ ion, this can be seen in water, 5, and 10 mol% of ethanol; it is most prominent in 5 mol% of ethanol. The Cl^- ion is also classified as a breaking ion. However, the Walden product in water increases with an increase in the pressure. The assumption that this is based on the contribution of the dielectric friction is curious, because the contribution of the dielectric friction to the conductance may be expected to be less for the Cl^- ion than for the K^+ ion, since the crystallographic radius of a Cl^- ion is larger than that of a K^+ ion.[25] Therefore, the specific interaction between the Cl^- ion and water molecules must be considered. The interaction between the Cl^- ion and water molecules includes the contribution of hydrogen bonds.[26] If the pressure weakens the hydrogen bonds, the Cl^- ion will obtain excess mobility. This effect may be gradually reduced by adding ethanol to water, thus enhancing the basicity of the solvent mixtures,[27] and the decrease in the Walden product of the Cl^- ion in 5 mol% of ethanol with the pressure may be attributed to the structure-breaking effect of the Cl^- ion, since the water structure is most strengthened in this region.

(Received May 27, 1985)

Mechanisms of resonant two-photon transitions *via* repulsive intermediate states are experimentally and theoretically studied. Polarization ratios, $\Omega=\sigma_{\infty}/\sigma_{11}$ (where σ_{∞} and σ_{11} are the cross section of the two-photon transitions obtained by the circularly polarized light and that by the linearly polarized light, respectively) of the two-photon excitation of iodine vapor have been measured in the wavelength range of 420—510 nm. An expression for the polarization ratio for the two-photon absorption in which both simultaneous and sequential processes take place has been presented. The polarization ratios calculated by using the δ-function approximation for the repulsive intermediate states as a function of the laser frequency for the iodine molecule system explain qualitatively the experimental result. This indicates that both the simultaneous and the sequential process take place in the frequency region measured.

Multi-photon spectroscopy has made a great contribution to clarifying structures of electronically excited states of molecules and the dynamical processes taking place in these states.[1] Most of papers so far reported were concerned with resonant multi-photon transitions *via* bound intermediate states. Resonant multi-photon transitions *via* repulsive intermediate states such as bound-free-bound or bound-free-free transition can be induced with production of fragments. These types of the multi-photon transition can be observed in iodine and halogen substituted compounds *etc.*[2,3] At present mechanisms of the multi-photon transitions involving repulsive intermediate states are not well known. It is interesting to investigate which is dominant, simultaneous or sequential process. The latter is induced by elastic collisions between molecules and perturbers.

One of the methods for identifying the mechanisms of the multi-photon transitions is to measure the polarization ratio Ω defined by ratio of the transition probability obtained by using circularly polarized light to that obtained by using parallel linearly polarized light. Kasatani *et al.*[4] have observed two- and three-photon transitions of I_2 *via* the repulsive intermediate states in gases. From the polarization measurement of the fluorescence excitation spectra, they have found that even though the I_2 molecule excited in the energy region beyond the attractive potential of the B state, the photon absorption proceeds *via* the real repulsive intermediate states. Another method is to analyze the vibronic structure appearing in the spectra.

The purpose of this paper is to investigate the mechanisms of resonant two-photon transitions *via* repulsive intermediate states from both experimental and theoretical points of view. We first report polarization ratios of two-photon fluorescence excitation spectra of gaseous I_2 in the laser wavelength range of 420—510 nm. Secondly effects of the repulsive intermediate states on the resonant two-photon absorption (TPA) probability are theoretically studied. Neglecting effects of molecular rotations, and assuming the molecules to be randomly oriented, we derive expressions for the transition probabilities of the simultaneous and sequential TPA processes. In the Born-Oppenheimer and Condon approximations, these expressions are divided into two terms. One involves electronic transition matrix elements relevant to the two-photon transitions with laser intensity. This term depends on the polarization of photon for the simultaneous TPA process. The other term is a line shape function which characterizes the vibronic intensity distribution. Expressions for the line shape functions for the simultaneous process and sequential one are derived by using the δ-function approximation to the repulsive intermediate states and the displaced harmonic oscillator approximation to the initial and final states. In deriving the expressions for the line shape functions, two cases can be considered, depending on the dimensionless potential displacement Δ between the initial and final states: one is the weak coupling case in which $\Delta \leq 1$, and the other is the strong coupling case which is characterized by a large potential displacement. Ion pair states in I_2 can be taken as belonging to the latter case. In this paper, we derive an expression for the line shape function of the TPA process of I_2 in the strong coupling case. Finally the frequency dependence of the polarization ratio is evaluated and is compared with that observed for the gaseous I_2 molecule.

Experimental

The Polarization Measurements of I_2 Vapor. Iodine vapor in a quartz cell at 90°C was excited by visible light from an N_2 laser pumped dye laser (Molectron UV-24 and DL-14) in the wavelength range of 420—510 nm. The laser intensity was $\lesssim$1 mj/pulse of a few nanoseconds. The

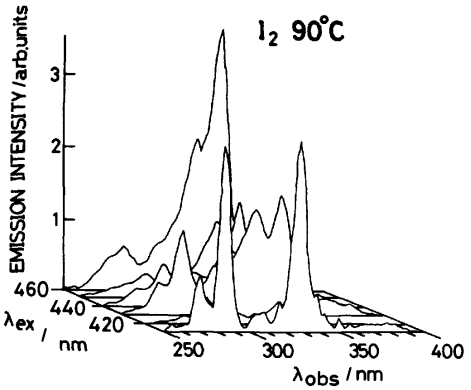

Fig. 1. Fluorescence spectra taken at various excitation wavelengths of I_2 vapor at 90°C.

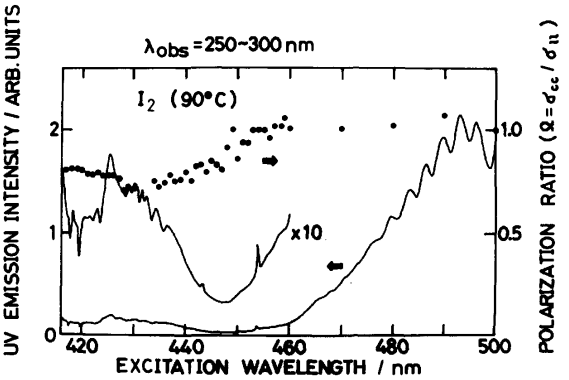

Fig. 2. Fluorescence excitation spectra (solid curves) and polarization ratios (points) of I_2 vapor at 90°C.

band width was around 0.4 cm^{-1}. The ultraviolet emission from iodine molecules was observed at right angles to the focused laser beam with a monochromator (or a filter), a telescope and a photomultiplier (Hamamatsu Photonics R-166 UH or 1P28). In order to measure the effect of the polarization of laser light on the two-photon absorptivity, the laser beam was passed through a rotatable double Fresnel rhomb followed by a single Fresnel rhomb. This optical arrangement provides linearly or circularly polarized light without changing the optical pass and intensity of the laser beam. At the lower vapor pressure, the polarization ratio could not be quantitatively measured because of low *S/N* ratios.

By the excitation of iodine vapor at $\lambda_{ex} \geq 498.9$ nm *i.e.*, below the dissociation limit of the B (0_u^+) state, the UV emission was observed at 385, 342, 320, 287, and 270 nm as reported previously.[4] When the energy of laser light was above the dissociation limit $\lambda_{ex} < 498.9$ nm, the UV emission was still observed at various wavelengths as shown in Fig. 1. When the UV emission intensity was measured as a function of excitation wavelength, the intensity decreased drastically at $\lambda_{ex} < 498.9$ nm with unfocused laser light. The excitation spectra were detected for two UV wavelength regions, one with an interference filter centered at 320 nm, and the other with a broad band pass filter (240—330 nm). UV excitation spectra taken by these two methods were essentially the same. The decrease in UV intensity is caused by the decrease in the number density of the intermediate B 0_u^+ state for two-photon absorption process,

$$I_2 + \hbar\omega_R \longrightarrow I_2^*(B\,0_u^+),$$

$$I_2^*(B\,0_u^+) + \hbar\omega_R \longrightarrow I_2^{**}.$$

Same sharp decrease in the excitation spectra at $\lambda_{ex} < 498.9$ nm has been reported when iodine vapor was irradiated by the visible laser light from a flash lamp pumped dye laser, the peak power of which was weaker than the N_2 laser pumped dye laser by a factor of ≈200. This drastic intensity change at $\lambda < 498.9$ nm, however, was not observed when the laser light was focused by a lens (f=30 mm). This is probably because the pumping rate to the upper state(s) by the focused laser light is comparable to the dissociation rate of the intermediate state.

The influence of the incident light polarization (circular or linear) on the rate of the photon absorption process was investigated at various laser wavelengths. The results for benzene were in good agreement with those obtained by Friedrich and McClain.[5] The polarization ratios for iodine vapor were measured by observing the UV emission with the UV band pass filter as shown in Fig. 2. They were found to be essentially unity in the laser wavelength range of 450—510 nm where iodine molecules absorb visible light in the transition from the ground states to the dissociative states B (0_u^+) and 1_u. Below 450 nm, one-photon absorption diminishes. When the laser wavelength became less than 450 nm, the transition probabilities or UV emission decreased and the polarization ratios began to deviate from unity as shown in Fig. 2. This deviation indicates that the contribution of two-photon absorption *via* the real dissociative state becomes less important and that *via* virtual states becomes important. The interaction time between photons and dissociative state becomes shorter with increasing the photon energy because the dissociative lifetime is classically a function of the incident photon energy. At the shorter wavelength region observed the polarization ratio became less than 1.0. This transition corresponds to $\Delta\Omega=0$, or $0_g^+ - X0_g^+$ two-photon transition *via* virtual states.[6] In the following sections we shall discuss theoretically both two-photon transition probabilities through a dissociative state and polarization ratios in more detail.

Theoretical

Transition Probabilities of Resonant TPA via Repulsive Intermediate States. We consider a resonant two-photon absorption (TPA) *via* repulsive intermediate states as shown in Fig. 3. The two-photon transition probability from vibronic state a to n, $W_{a\to n}(\omega_R)$ can be approximately expressed in terms of the simultaneous transition probability $W_{a\to n}^{sim}(\omega_R)$ and the sequential one $W_{a\to m}^{seq}(\omega_R)$ as

$$W_{a\to n}(\omega_R) \simeq W_{a\to n}^{sim}(\omega_R) + W_{a\to n}^{seq}(\omega_R), \quad (1)$$

where we have assumed that molecules absorb identical two-photons with frequency ω_R and polarization vector $\vec{\lambda}$, and mixed terms have been omitted though these may make a significant contribution

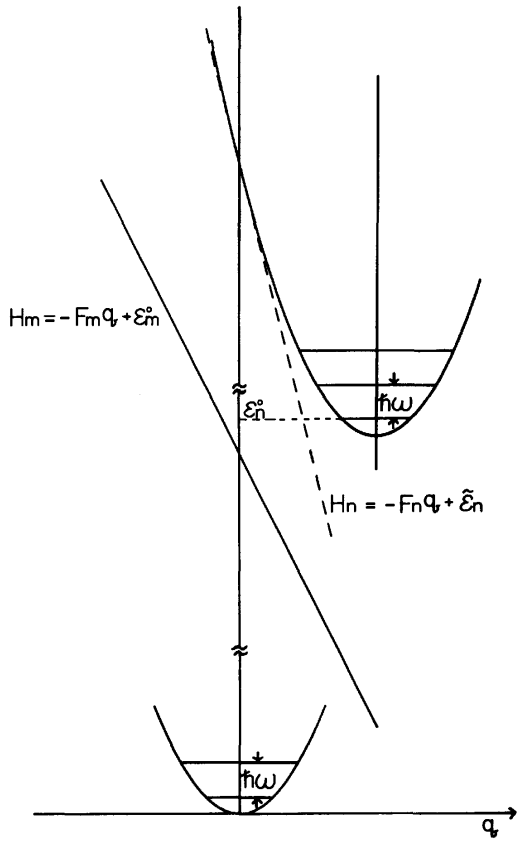

Fig. 3. Model potentials for TPA in the strong coupling case. Potentials of the initial and final states are expressed in terms of displaced harmonic ones with frequency ω and a large displacement Δ. Potential of the intermediate state is approximated by a linear one.

in some cases.[7] General forms for the transition probabilities have already been given elsewhere.[7] In the Born-Oppenheimer approximation in which wave functions can be expressed as a product of electronic (Φ) and vibrational (θ) ones, and in the Condon approximation, we can separate the simultaneous transition probability into two terms, a polarization dependent term P_λ and a line shape function $L(\omega_R)$:[8-12]

$$W^{sim}_{a\to n}(\omega_R) = P^{sim}_\lambda L^{sim}(\omega_R), \tag{2}$$

where

$$P^{sim}_\lambda = \langle\langle |\vec{H}'_{nm}\cdot\vec{\lambda}\,\vec{H}'_{ma}\cdot\vec{\lambda}|^2\rangle\rangle, \tag{3}$$

$$L^{sim}(\omega_R) = \frac{2}{\hbar^4}\mathrm{Re}\sum_a\sum_n \frac{\rho_{aa}}{i\omega_{na}+\Gamma_{na}} \times \left|\int d\omega_m \frac{\langle\theta_n|\theta_m\rangle\langle\theta_m|\theta_a\rangle}{i\omega_{ma}+\Gamma_{ma}}\right|^2, \tag{4}$$

where summations are carried out over the vibronic states of the a and n electronic states. In Eq. 3, double bracket $\ll\cdots\gg$ denotes averaging over orientations of the molecules, and $\vec{H}'_{nm}=\langle\Phi^0_n|\vec{H}'|\Phi^0_m\rangle$ is the matrix element of the molecule-photon interaction Hamiltonian. In Eq. 4, ρ_{aa} represents the population in the initial state, $\omega_{na}=\omega_n-\omega_a-2\omega_R$, $\omega_{ma}=\omega_m-\omega_a-\omega_R$ in which ω_n, ω_m, and ω_a denote molecular eigenfrequencies of the relevant states, and Γ, dephasing constant between two states, for example, is given by

$$\Gamma_{ma} = \frac{1}{2}(\Gamma_{mm}+\Gamma_{aa})+\Gamma^{(d)}_{ma}, \tag{5}$$

in which Γ_{mm} is the population decay constant of state m, and $\Gamma^{(d)}_{ma}$ the pure dephasing constant.[7,13,14]

Assuming the sequential process to be induced by intermolecular interactions between molecules and heat bath, we can express the two-photon transition probability in the similar way,

$$W^{seq}_{a\to n}(\omega_R) = P^{seq}L^{seq}(\omega_R), \tag{6}$$

where

$$P^{seq} = \langle\langle|\vec{H}'_{nm}\cdot\vec{\lambda}|^2\rangle\rangle\langle\langle\vec{H}'_{ma}\cdot\vec{\lambda}|^2\rangle\rangle \propto |\vec{H}'_{nm}|^2|\vec{H}'_{ma}|^2, \tag{7}$$

which is independent of polarization, and $L^{seq}(\omega_R)$, the line shape function for the sequential TPA is given as

$$L^{seq}(\Omega_R) = \frac{2}{\hbar^4}\mathrm{Re}\sum_a\rho_{aa}\sum_n\int d\omega_m\int d\omega_k(\Gamma_{ma}-\Gamma_{mk}+\Gamma_{ak}) \times \frac{\langle\theta_a|\theta_m\rangle\langle\theta_m|\theta_n\rangle\langle\theta_n|\theta_k\rangle\langle\theta_k|\theta_a\rangle}{(i\omega_{mn}+\Gamma_{mn})(i\omega_{ak}+\Gamma_{ak})(i\omega_{ma}+\Gamma_{ma})(i\omega_{mk}+\Gamma_{mk})}. \tag{8}$$

In order to evaluate ω_R-dependence of the transition probability of resonant TPA *via* repulsive intermediate states, we now derive expressions for the line shape functions $L^{sim}(\omega_R)$ and $L^{seq}(\omega_R)$ by using one dimensional model shown in Fig. 3.

Nuclear potentials of the initial a and final n electronic states are assumed to be characterized by displaced harmonic potentials with displacement Δ: The corresponding Hamiltonians $\hat{H}_a$ and $\hat{H}_n$ are expressed in the forms,

$$\hat{H}_a = \frac{\hbar\omega}{2}(\hat{p}^2+q^2), \tag{9a}$$

and

$$\hat{H}_n = \frac{\hbar\omega}{2}\{\hat{p}^2+(q-\Delta)^2\} + \varepsilon^0_n, \tag{9b}$$

where q and $\hat{p}$ are the dimensionless nuclear coordinate and the conjugated momentum, respectively. ω represents the frequency of the vibrational mode.

Vibronic Hamiltonian of repulsive intermediate states is assumed to be given by

$$\hat{H}_m = \frac{\hbar\omega}{2}\hat{p}^2 - F_m q + \varepsilon^0_m, \tag{10}$$

with $F_m>0$. We shall consider the line shape function

of the simultaneous TPA *via* repulsive intermediate states in the strong coupling case.

a) Simultaneous TPA: Applying the generating function method[15] to Eq. 4, we obtain

$$L^{\mathrm{sim}}(\omega_{\mathrm{R}}) = \frac{2}{\hbar^4}\int_{-\infty}^{\infty}\mathrm{d}t\int_0^{\infty}\mathrm{d}\tau\int_0^{\infty}\mathrm{d}\tau' \exp\left[-\Gamma_{na}|t| - \Gamma_{ma}(\tau+\tau') - 2i\omega_{\mathrm{R}}t - i\omega_{\mathrm{R}}(\tau'-\tau)\right]G(\tau,\tau',t), \quad (11)$$

where $G(\tau,\tau',t)$, generating function for the simultaneous TPA, is given as

$$G(\tau,\tau',t) = \sum_a \langle\theta_a|\rho_{aa}\exp\left[-\mathrm{i}\hat{H}_a(t+\tau'-\tau)/\hbar\right] \times \exp\left[\mathrm{i}\hat{H}_m\tau'/\hbar\right]\exp\left[\mathrm{i}\hat{H}_m t/\hbar\right] \times \exp\left[-\mathrm{i}\hat{H}_m\tau/\hbar\right]|\theta_a\rangle. \quad (12)$$

For simplicity we assume the vibrational mode of molecules to be in the low temperature limit. A temperature dependent line shape function can be derived by using the Boson operator technique.[16] In order to derive an expression for the line shape function within the δ-function approximation, we neglect the nuclear kinetic energy in the Hamiltonian for the repulsive intermediate states. In this approximation we obtain a line shape function as

$$L^{\mathrm{sim}}(\omega_{\mathrm{R}}) = \frac{2}{\hbar^4}\int_{-\infty}^{\infty}\mathrm{d}t\int_0^{\infty}\mathrm{d}\tau\int_0^{\infty}\mathrm{d}\tau' \exp\left[\mathrm{i}(\tilde{\varepsilon}_n/\hbar-\omega/2-2\omega_{\mathrm{R}})t - \Gamma_{na}|t| - (F_m\tau'-F_m\tau+F_n t)^2/4\hbar^2 + \mathrm{i}(\varepsilon_m^0/\hbar-\omega/2-\omega_{\mathrm{R}})\tau' - \mathrm{i}(\varepsilon_m^0/\hbar-\omega/2-\omega_{\mathrm{R}})\tau - (\tau+\tau')\Gamma_{ma}\right], \quad (13)$$

where quantum number dependences of Γ have been neglected. A brief derivation of Eq. 13 is given in Appendix A. In the case in which condition $\hbar\Gamma_{na}<F_n$ is satisfied, we can neglect effects of the dephasing constant Γ_{na} in Eq. 13. In this case after integration over t in Eq. 13 we obtain

$$L^{\mathrm{sim}}(\omega_{\mathrm{R}}) = \frac{4\sqrt{\pi}}{\hbar^3 F_n}\exp\left[-\left(\frac{\tilde{\varepsilon}_n-\hbar\omega/2-2\hbar\omega_{\mathrm{R}}}{F_n}\right)^2\right] \times\left|\int_0^{\infty}\mathrm{d}\tau\exp\left[-\mathrm{i}\left\{\varepsilon_m^0/\hbar-\omega/2-\omega_{\mathrm{R}} - (\tilde{\varepsilon}_n/\hbar-\omega/2-2\omega_{\mathrm{R}})\frac{F_m}{F_n}\right\}-\Gamma_{ma}\tau\right]\right|^2. \quad (14)$$

Integration over τ in Eq. 14 yields an analytical expression for the simultaneous TPA in the strong coupling case as,

$$L^{\mathrm{sim}}(\omega_{\mathrm{R}}) = \frac{4\sqrt{\pi}}{\hbar^3 F_n}\exp\left[-\left(\frac{\tilde{\varepsilon}_n-\hbar\omega/2-2\hbar\omega_{\mathrm{R}}}{F_n}\right)^2\right] \times\frac{r^2}{\{\tilde{\varepsilon}_n/\hbar-\omega/2-r(\varepsilon_m^0-\omega/2)-(2-r)\omega_{\mathrm{R}}\}^2+r^2\Gamma_{ma}^2}, \quad (15)$$

with $r=F_n/F_m$. The first term in Eq. 15 is equivalent to the band shape function for the one-photon bound-free transition with optical frequency $2\omega_{\mathrm{R}}$. In the usual case in which $F_n>\Gamma_{ma}r/|2-r|$, the band shape for the simultaneous TPA process is dominated by the second term in Eq. 15. This indicates that the maximum of the band locates at $\{\tilde{\varepsilon}_n/\hbar-\omega/2-r(\varepsilon_m^0-\omega/2)\}/(2-r)$ with the effective width $\Gamma_{ma}r/|2-r|$. The same expression for the line shape function as Eq. 15 can be derived if the vibronic Hamiltonian of the final state is assumed to be expressed in terms of a linear potential, $\hat{H}_n=-F_nq+\tilde{\varepsilon}_n$, in stead of using the approximation expansion Eq. A. 9.

b) Sequential TPA: The line shape function for the sequential TPA in the strong coupling case takes the form

$$L^{\mathrm{seq}}(\omega_{\mathrm{R}}) = \frac{2}{\hbar^4}\mathrm{Re}\sum_a\rho_{aa}\int\mathrm{d}\omega_n\int\mathrm{d}\omega_m\int\mathrm{d}\omega_k(\Gamma_{ma}-\Gamma_{mk}+\Gamma_{ak}) \times\frac{\langle\theta_a|\theta_m\rangle\langle\theta_m|\theta_n\rangle\langle\theta_n|\theta_k\rangle\langle\theta_k|\theta_a\rangle}{(\mathrm{i}\omega_{mn}+\Gamma_{mn})(\mathrm{i}\omega_{ak}+\Gamma_{ak})(\mathrm{i}\omega_{ma}+\Gamma_{ma})(\mathrm{i}\omega_{mk}+\Gamma_{mk})}. \quad (16)$$

For the strong coupling case, the linear potential approximation can be adopted both to the intermediate and final state potentials, and the overlap integral between the two states can be expressed as

$$\langle\theta_m|\theta_n\rangle = (F_nF_m)^{-1/2}\delta(q_m-q_n). \quad (17)$$

Applying Eq. 17 into Eq. 16 and integrating over the frequencies ω_n and ω_k, we obtain

$$L^{\mathrm{seq}}(\omega_{\mathrm{R}}) = \frac{2}{\hbar^4}\int_{-\infty}^{\infty}\mathrm{d}q_m\frac{(2\Gamma_{ma}-\Gamma_{mm})\Gamma_{mn}}{\Gamma_{mm}} \times\frac{1}{[\{(\tilde{\varepsilon}_n-F_nq_m)/\hbar-(\varepsilon_m^0-F_mq_m)/\hbar-\omega_{\mathrm{R}}\}^2+\Gamma_{mn}^2]} \times\frac{|\theta_a(q_m)|^2}{[\{(\varepsilon_m^0-F_mq_m-\hbar\omega/2)/\hbar-\omega_{\mathrm{R}}\}^2+\Gamma_{ma}^2]}, \quad (18)$$

where we have restricted ourselves to the TPA in the low temperature limit. In the case in which $F_m\gg\hbar\Gamma_{ma}$ is satisfied, the integrand in Eq. 18 involves the δ-function in the limit $\hbar\Gamma_{ma}/F_m\to0$. In this case the integration over q_m can be performed as

$$L^{\mathrm{seq}}(\omega_{\mathrm{R}}) = \frac{2\pi}{\hbar^3}\frac{(2\Gamma_{ma}-\Gamma_{mm})\Gamma_{mn}}{F_m\Gamma_{mm}\Gamma_{ma}} \times\frac{\exp\left[-\left(\frac{\varepsilon_m^0-\hbar\omega/2-\hbar\omega_{\mathrm{R}}}{F_m}\right)^2\right]}{\{\varepsilon_n^0/\hbar-\omega/2-2\omega_{\mathrm{R}}-r(\tilde{\varepsilon}_n/\hbar-\omega/2-\omega_{\mathrm{R}})\}^2+\Gamma_{mn}^2}. \quad (19)$$

From Eq. 19, we can see that the peak of the band for the sequential TPA process locates at the same frequency as that for the simultaneous process, and its effective width is given by $\Gamma_{mn}/|2-r|$.

Polarization Ratio of the Resonant TPA of I_2 Vapor. We consider the polarization ratio for the TPA in the presence of both simultaneous and sequential processes at the same time. In this case, the polarization ratio $\Omega(\omega_{\mathrm{R}})$ can be defined as

$$\Omega(\omega_{\mathrm{R}}) = \frac{W_{a\to n}^{\rightrightarrows}(\omega_{\mathrm{R}})}{W_{a\to n}^{\uparrow\uparrow}(\omega_{\mathrm{R}})} = \frac{P_{\rightrightarrows}^{\mathrm{sim}}L^{\mathrm{sim}}(\omega_{\mathrm{R}})+P^{\mathrm{seq}}L^{\mathrm{seq}}(\omega_{\mathrm{R}})}{P_{\uparrow\uparrow}^{\mathrm{sim}}L^{\mathrm{sim}}(\omega_{\mathrm{R}})+P^{\mathrm{seq}}L^{\mathrm{seq}}(\omega_{\mathrm{R}})}. \quad (20)$$

The polarization dependence of the simultaneous TPA

has been studied by McClain,[10] Monson and McClain,[9] Nascimento,[11] and Bray and Hochstrasser[12] included rotational effects. In order to calculate the polarization ratio, the values of $P_{\lambda}^{sim}/P^{seq}$ must be determined. Averaging the P_{λ}^{sim} of Eq. 3 over the orientation of the molecule, we obtain

$$P_{\uparrow\uparrow}^{sim} = \frac{1}{15}[3\{(M_{na}^{xx})^2+(M_{na}^{yy})^2+(M_{na}^{zz})^2\} + 4\{(M_{na}^{xy})^2+(M_{na}^{xz})^2+(M_{na}^{yz})^2\} + 2\{M_{na}^{xx}M_{na}^{yy}+M_{na}^{xx}M_{na}^{zz}+M_{na}^{yy}M_{na}^{zz}\}], \quad (21)$$

for the linearly polarized light, and

$$P_{\infty}^{sim} = \frac{1}{30}[4\{(M_{na}^{xx})^2+(M_{na}^{yy})^2+(M_{na}^{zz})^2\} + 12\{(M_{na}^{xy})^2+(M_{na}^{xz})^2+(M_{na}^{yz})^2\} - 4\{M_{na}^{xx}M_{na}^{yy}+M_{na}^{xx}M_{na}^{zz}+M_{na}^{yy}M_{na}^{zz}\}], \quad (22)$$

for the circularly polarized light, where M_{na} the two-photon electronic transition matrix element, for example, is given by

$$M_{na}^{xy} = \langle \Phi_n^0|x|\Phi_m^0\rangle\langle\Phi_m^0|y|\Phi_a^0\rangle. \quad (23)$$

In the similar way the P^{seq} given by Eq. 7 is written as

$$P^{seq} = \frac{1}{9}\{(H_{nm}^{x})^2+(H_{nm}^{y})^2+(H_{nm}^{z})^2\} \times \{(H_{ma}^{x})^2+(H_{ma}^{y})^2+(H_{ma}^{z})^2\}, \quad (24)$$

where, for example,

$$H_{nm}^{x} = \langle \Phi_n^0|x|\Phi_m^0\rangle. \quad (25)$$

From Eq. 24 we can see that the two-photon transition matrix element of the sequential process is independent of the polarization of light.

For the resonance TPA of I_2, the final state which is dipole allowed belongs to a Σ_g^+ or Π_g state in the optical frequency range reported in this paper. We consider the following two cases.

$$\text{(i)}\quad \Sigma_g^+ \text{ or } \Pi_{0g} \xleftarrow{x,\,y} \Pi_{1u} \xleftarrow{x,\,y} \Sigma_g^+.$$

By using $M_{na}^{xx}=M_{na}^{yy}$ in Eqs. 21 and 22, we obtain $P_{11}^{sim}=(8/15)(M_{na}^{xx})^2$ and $P_{\infty}^{sim}=(2/15)(M_{na}^{xx})^2$. Similary from Eq. 24 we obtain $P^{seq}=(4/9)(M_{na}^{xx})^2$. Using these expressions for the electronic matrix elements, we can express Eq. 20 in terms of the line shape functions as

$$\Omega(\omega_R) = \frac{3L^{sim}(\omega_R)+10L^{seq}(\omega_R)}{12L^{sim}(\omega_R)+10L^{seq}(\omega_R)}. \quad (26)$$

It should be noted that the polarization ratio $\Omega(\omega_R)$ is dependent only on the value of $L^{sim}(\omega_R)/L^{seq}(\omega_R)$ and independent of the position of the peak of the line shape functions for the simultaneous and sequential processes. In cases in which effects of elastic collisions can be neglected, and the simultaneous process dominates the TPA process, the polarization ratio is then independent of laser frequency ω_R and $\Omega(\omega_R)=0.25$. In other extreme cases in which sequential process is dominant, we obtain $\Omega(\omega_R)=1$.

$$\text{(ii)}\quad \Pi_{1g} \text{ or } \Pi_{2g} \xleftarrow{z} \Pi_{1u} \xleftarrow{x,\,y} \Sigma_g^+.$$

Substituting $M_{na}^{xz}=M_{na}^{yz}$ into Eqs. 21 and 22, we obtain $P_{11}^{sim}=(8/15)(M_{na}^{xz})^2$ and $P_{\infty}^{sim}=(12/15)(M_{na}^{xz})^2$. Similary we obtain $P^{seq}=2/9(M_{na}^{xz})^2$. From these relations, the polarization ratio is expressed as

$$\Omega(\omega_R) = \frac{18L^{sim}(\omega_R)+5L^{seq}(\omega_R)}{12L^{sim}(\omega_R)+5L^{seq}(\omega_R)}. \quad (27)$$

In cases in which effects of elastic collisions can be neglected, we obtain $\Omega(\omega_R)=1.5$. In other extreme cases in which sequential process is dominant, on the other hand, we obtain $\Omega(\omega_R)=1$. In the real system in which collisional dephasings take place and both simultaneous and sequential processes make a contribution to the TPA, we can see that the polarization ratio depends on the laser frequency used.

Discussion

It has experimentally been shown that the two-photon absorption process above the dissociation limit of the B state may occur before the excited iodines dissociate or during the dissociation process,

$$I_2 \xrightarrow{\hbar\omega_R} I_2^* \xrightarrow{\hbar\omega_R} I_2^{**}.$$

The dissociation rate is estimated to be faster than $10^{-12}\,s^{-1}$ from the results of photofragment spectroscopy,[17] and the pumping rate to I_2^{**} from the dissociative state must be comparable to it. Concerning the pumping process above the dissociation limit of the B state, the following recombination mechanism is another plausible one,

$$I_2 + \hbar\omega_R\ (<498.9\text{ nm}) \longrightarrow 2I,$$

$$I + I \xrightarrow{M} I_2^*\ (B\,0_u^+),$$

$$I_2^*\ (B\,0_u^+) + \hbar\omega_R \longrightarrow I_2^{**},$$

where M is an iodine parent molecule as a third body. If this is the case, both UV emission intensity and VIS emission intensity originating from bound levels of the B state increase with the pressure of the third body, M. When the pressure of I_2 increased from 0.2 Torr to 27 Torr (1 Torr=133.322 Pa) by changing the cell temperature from 20 °C to 90 °C, the VIS emission was still undetectable but the UV emission intensity increased ten-fold for irradiation at $\lambda_{ex}<498.9$ nm.

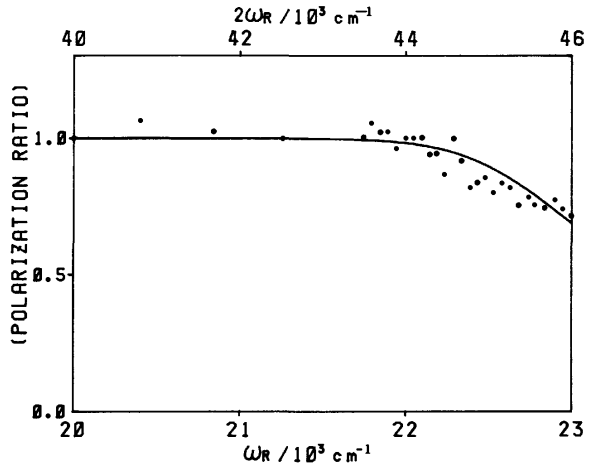

Fig. 4 The calculated polarization ratios for I_2 vapor. Points represent the experimental results (see Fig. 2). The molecular parameters used are ω=215 cm^{-1}, $\varepsilon_m^0/\hbar$=20300 cm^{-1}, $\tilde{\varepsilon}_n/\hbar$=48000 cm^{-1}, Γ_{ma}=5 cm^{-1}, Γ_{mn}=3 cm^{-1}, Γ_{mm}=4 cm^{-1}, $F_m/\hbar$=3200 cm^{-1}, and $F_n/\hbar$=2000 cm^{-1}.

Thus, the recombination mechanism should be excluded from the two-photon absorption process.

Expressions for the transition probabilities and the polarization ratio of TPA *via* repulsive intermediate states have been derived within the Born-Oppenheimer adiabatic approximation and the Condon approximation. It has been shown that abilities of the simultaneous and sequential TPA processes are dominated by two factors. One is the electronic transition matrix elements with polarization of photons. For the simultaneous process, this factor depends on the polarization of photons, and for the sequential process, on the other hand, it is independent of the polarization. The other factor is a line shape function representing the vibronic intensity distribution of the TPA spectra.

We are now in a position to calculate the polarization ratio for the resonant TPA of I_2. The nuclear potential of the ground state is assumed to be harmonic with a frequency ω=215 cm^{-1}; its equilibrium point is located at 2.66 Å. Analytical forms of the repulsive potential energy curve of the $^1\Pi_{1u}$ state have been proposed by Tellinghuisen,[18] and Williams *et al.*[19] In this calculation, we adopt $\varepsilon_m(q)=-3200q+20300$ (in cm^{-1} units), which is very close to the expression derived to reproduce the potential energy and its slope at the equilibrium nuclear position in the ground state.[14] The nuclear potential of the final state is not well known to our knowledge. A large equibibrium nuclear distance compared with that of the ground state is predicted. It will, therefore, be a good approximation to regard the TPA of the I_2 system as the strong coupling case. In Fig. 4 the Σ_g^+or $\Pi_{0g}\leftarrow\Pi_{1u}\leftarrow\Sigma_g^+$transition is considered; the polarization ratios calculated by using Eq. 22 are shown. The parameter used are $\tilde{\varepsilon}_n/\hbar$=48000 cm^{-1}, Γ_{ma}=5 cm^{-1}, Γ_{mn}=3 cm^{-1} and Γ_{mm}=4 cm^{-1}. These dephasing and damping constants have been assumed to be independent of ω_R, which should be valid in a restricted frequency range near the resonant region. Figure 4 shows that the polarization ratio is a decrease function with a constant value near the resonance as increasing the laser frequency. This indicates that the simultaneous process increases in its contribution to the resonant TPA process. For the comparison, the observed ratios are indicated by points. We can see that there is a good correlation between the observed and calculated polarization ratios. Thus, the polarization behavior measured can qualitatively be explained in terms of the gradual increase in the contribution of the simultaneous process.

In this paper it is assumed that the sequential process is induced by an elastic interaction between the molecules and heat bath from the basis of the pressure effect appeared in the UV emission intensity obtained by the puming process above the dissociation limit of the B state though the quantitative investigation of the pressure effect has not been reported. Dissociation processes of I_2 play an important role in the resonant multiphoton transition especially *via* the repulsive Franck-Condon state because in this state the magnitude of the dissociation rate constant is in the ps order which is much larger than that of the pure dephasing constant.[20] The dissociation rate constant is a function of the laser frequency. As the laser frequency increases, the rate constant increases with its magnitude comparable to that of the pure dephasing constant which is reflected in the pressure effect observed above the dissociation threshold.

We have neglected rotation of I_2 in the analysis of the polarization ratio for the resonant TPA. Polarization is destroyed by M-changing collisions when time of rotation is comparable or faster than the interaction time between photons and molecule. In this case rotational effects on the polarization dependence of the TPA have to be taken into account.[12] For the TPA *via* the dissociative intermediate states, the rotational effects can safely be neglected because the interaction time between photons and the dissociative state is much shorter than time of the rotation.

Finally it would be worth to mention that the theoretical treatment developed in this paper can be easily applied to resonance Raman scattering from molecules with repulsive resonant states.[21] The expression for the cross section for the resonance Raman scattering is obtained from that of the transition probability of the simultaneous TPA process by specifying both incident and emitted photons and by letting $\Delta\rightarrow 0$.

To summarize, experimental and theoretical studies have been carried out in order to clarify the mechanism of the resonant two-photon transition involving repulsive intermediate states. It has been shown from the polarization ratios measurement of the gaseous I_2 molecules that the sequential process makes a significant contribution even in a laser frequency range

belonging to the repulsive states. Both simultaneous and sequential two-photon transitions take place below the wavelength around 450 nm, which has qualitatively been explained by using the expression for the polarization ratio derived though the expression has been derived by using a simple model.

Appendix A. Derivation of Eq. 13

In this Appendix, we shall present a derivation of Eq. 13 on the basis of the Boson operator algebra. From Eq. 12, the generating function in the low temperature limits can be expressed as

$$G(\tau, \tau', t) = \langle 0|\exp(i\hat{H}_m\tau'/\hbar)\exp(i\hat{H}_n t/\hbar)\exp(i\hat{H}_m\tau/\hbar) \times \exp[-i\hat{H}_a(t-\tau+\tau')/\hbar]|0\rangle, \quad (A.1)$$

where $|0\rangle$ denotes the vibrational eigenket in the zeroth state of the ground electronic state. In terms of the Boson operators $\hat{b}$, $\hat{b}^\dagger$ which satisfy $[\hat{b}, \hat{b}^\dagger]=1$, the vibronic Hamiltonians related to TPA are given as

$$\hat{H}_a = \hbar\omega\left(\hat{b}^\dagger\hat{b} + \frac{1}{2}\right), \quad (A.2)$$

$$\hat{H}_m = -\frac{F_m}{\sqrt{2}}(\hat{b}+\hat{b}^\dagger) + \varepsilon_m^0, \quad (A.3)$$

and

$$\hat{H}_n = \hat{H}_a - \hbar\omega\Delta(\hat{b}+\hat{b}^\dagger) + \frac{\hbar\omega\Delta^2}{2} + \varepsilon_n^0. \quad (A.4)$$

In deriving Eq. A.3, the nuclear kinetic energy term has been omitted. This is equivalent to the delta function approximation for the repulsive state.

Using the expression,

$$\exp(i\hat{H}_n t/\hbar) = \exp\left[i\varepsilon_n^0 t/\hbar + \frac{\Delta^2}{2}\{\exp(i\omega t)-1\}\right] \times \exp(i\hat{H}_a t/\hbar)\exp[-\lambda(t)\hat{b}^\dagger]\exp[\lambda^*(t)\hat{b}], \quad (A.5)$$

where $\lambda(t)=(\Delta/\sqrt{2})[1-\exp(-i\omega t)]$, Eq. A.1 is rewritten as

$$G(\tau, \tau', t) = \exp\left[i\varepsilon_n^0 t/\hbar + \frac{\Delta^2}{2}\{\exp(i\omega t)-1\} + i\tau'(\varepsilon_a^0 - \hbar\omega/2)/\hbar - i\tau(\varepsilon_a^0 - \hbar\omega/2)/\hbar\right]U(\tau, \tau', t), \quad (A.6)$$

where

$$U(\tau, \tau', t) = \langle 0|\exp[-i\tau' F_m(\hat{b}+\hat{b}^\dagger)/\sqrt{2}\hbar]\exp[it\omega\hat{b}^\dagger\hat{b}] \times \exp[-\lambda(t)\hat{b}]\exp[\lambda^*(t)\hat{b}]\exp[i\tau F_m(\hat{b}+\hat{b}^\dagger)/\hbar]. \quad (A.7)$$

Utilizing the Boson operator algebra, Eq. A.7 is expressed as

$$U(\tau, \tau', t) = \exp\left[-F_m^2(\tau^2+\tau'^2)/4\hbar^2 + F_m^2\tau\tau'\exp(it\omega)/2\hbar^2 - iF_m\tau'\lambda^*(t)/\sqrt{2}\hbar + iF_m\tau\lambda^*(t)/\sqrt{2}\hbar\right]. \quad (A.8)$$

We expand $(\Delta/\sqrt{2})\exp(i\omega t)$ in Eq. A.6 to second order of t:

$$\frac{\Delta}{\sqrt{2}}\exp(i\omega t) \simeq \frac{\Delta}{\sqrt{2}}\left(1 + i\omega t - \frac{\omega^2 t^2}{2}\right). \quad (A.9)$$

Substitution of Eqs. A.8 and A.9 into Eq. A.6 results in

$$G(\tau, \tau', t) = \exp[i(\bar{\varepsilon}/\hbar - \omega/2)t + i(\varepsilon_m^0/\hbar - \omega/2)\tau' - i(\varepsilon_m^0/\hbar - \omega/2)\tau - (F_m\tau' - F_m\tau + F_n t)^2/4\hbar^2], \quad (A.10)$$

where $\bar{\varepsilon}_n=\varepsilon_n^0+\hbar\omega\Delta^2/2$, and $F_n=\Delta\omega$. Substituting Eq. A.10 into 11, we obtain the desired expression:

$$L^{sim}(\omega_R) = \frac{2}{\hbar^4}\int_{-\infty}^{\infty}dt\int_0^{\infty}d\tau\int_0^{\infty}d\tau'\exp[i(\bar{\varepsilon}_n/\hbar - \omega/2 - 2\omega_R)t - \Gamma_{na}|t| - (F_m\tau' - F_m\tau + F_n t)^2/4\hbar^2 + i(\varepsilon_m^0/\hbar - \omega/2 - \omega_R)\tau' - i(\varepsilon_m^0/\hbar - \omega/2 - \omega_R)\tau - (\tau+\tau')\Gamma_{ma}]. \quad (A.11)$$

20) To our knowledge, the magnitude of the pure electronic dephasing constant relevant to the transition

between the dissociative and bound states of I_2 has not been reported. The magnitude of the dephasing constant between the bound ($B^3\Pi_{0^+u}$) and bound ($^1\Sigma_g^+$) states has been measured by Brewer and Kano (R. G. Brewer and S. S. Kano, "Laser-Induced Processes in Molecules," ed by K. L. Kompa and S. D. Smith, Springer-Verlag, Berlin, (1979) p. 54). From the view point of the large potential energy change between the dissociative and bound states it is deduced that the magnitude of the pure dephasing constant relevant to the transition between the dissociative and bound states is larger than that reported by Brewer and Kano. See also Ref. 14.

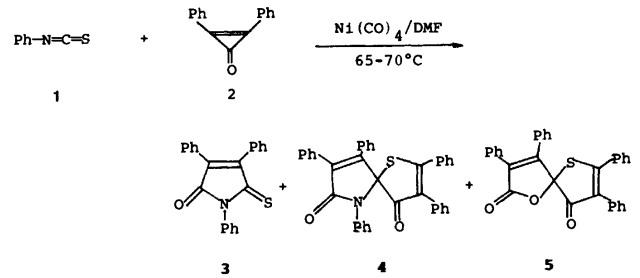
The Crystal and Molecular Structure of 2,3,6,8,9-Pentaphenyl-1-thia-6-azaspiro[4.4]nona-2,8-diene-4,7-dione

Noritake YASUOKA,† Yasushi KAI, and Nobutami KASAI*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565
(Received June 3, 1985)

The title compound crystallizes in monoclinic form, space group $P2_1/c$ with $a=20.810(1)$, $b=16.000(1)$, $c=18.131(1)$ Å, $\beta=107.77(1)°$, $Z=8$. The structure was established by the direct method and refined including all hydrogen atoms by the blockdiagonal least-squares procedure, $R=0.062$ for 4609 observed reflections. The heterocyclic spiran skeletons in two independent molecules have the same structure; however, four phenyl rings out of five take different conformations to the hetero rings to which they attached.

Very recently, T. Agawa and co-workers obtained heterocyclic spiran as a result of a metal carbonyl-promoted tandem cycloaddition to the sulfur-containing heterocumulenes.[1] Equimolar amounts of phenyl isothiocyanate (**1**), diphenylcyclopropenone (**2**), and tetracarbonylnickel(0) were reacted in DMF at 65—70°C to give the new heterocyclic spirans (**4** and **5**) in addition to the pyrroline (**3**). In relation with this



study, the molecular structure of **4** has been determined by means of X-ray diffraction in order to obtain informations on the exact syructure.

Experimental

Crystal Data. $C_{37}H_{25}NO_2S$, M 547.7, monoclinic, space group $P2_1/c$, $a=20.810(2)$, $b=16.000(1)$, $c=18.131(1)$ Å, $\beta=107.77(1)°$, $V=5748.7(6)$ Å^3, $D_c=1.266$ g cm^{-3} for $Z=8$, μ(Cu $K\alpha$)=12.3 cm^{-1}.

The integrated intensities were measured on a Rigaku four-circle diffractometer using nickel-filtered Cu $K\alpha$ radiation. The θ—2θ scan technique was employed at a 2θ rate of 4° min^{-1} and the scan width was $\Delta 2\theta=(2.0+0.3\tan\theta)°$. Backgrounds were measured for 7.5 s at both ends of a scan. Four standard reflections measured after every 60 reflections to monitor the stability and orientation of the crystal showed no significant decay throughout the data collection. Lorentz and polarization corrections were made but the absorption correction was ignored.

Structure Solution and Refinement

As the space group is $P2_1/c$ and $Z=8$, an asymmetric unit contains two independent molecules.

The structure was solved by the direct method (*MULTAN*).[2] Non-hydrogen atoms of the two crystallographically independent molecules were located on the E map with the highest figure of merit. The refinement was carried out anisotropically by the block-diagonal least-squares procedure (*HBLS* V),[3] the function minimized being $\sum\omega(\Delta F)^2$. Hydrogen atoms were located on the difference Fourier map, all of which were included in the refinement with isotropic temperature factors. Finally the R index converged to 0.062 for 4609 observed reflections. The weighting scheme used at the final cycle of the refinement was $\omega=\{\sigma^2(F_o)-0.0280|F_o|+0.0049|F_o|^2\}^{-1}$, where σ is the standard deviation obtained from the counting statistics. The final atomic coordinates with equivalent isotropic temperature factors[4] are listed in Table 1.†† Atomic scattering factors for non-hydrogen atoms were taken from the International Tables for X-Ray Crystallography,[5] and those for hydrogen atoms from Stewart, Davidson and Simpson.[6]

Results and Discussion

A perspective view (*ORTEP*)[7] of the two crystallographically independent molecules (A and B molecules) are depicted in Fig. 1. The molecules have 1-thia-6-azaspiro[4.4]nona-2,8-diene-4,7-dione skeleton (abbreviated as spiran skelton hereafter) as expected by the spectral data.[1] The present molecule is probably the first example of the spiro[4.4]nonane structure with two mixed heteroatoms (N and S) next to the spiro carbon determined by means of X-ray diffraction, whereas dioxa and dithia analogues have been reported, hitherto.[8] Bond lengths and bond angles in the spiran skeletons are given in Table 2. As seen in Fig. 1 and Table 2, the spiran skeltons in the A and B molecules have the same structure. The corresponding bond lengths and bond angles in the two molecules are all equal within the limits of errors. Of the four C=O bond lengths, the C(4)=O(41) bonds[1.148(5) and 1.165

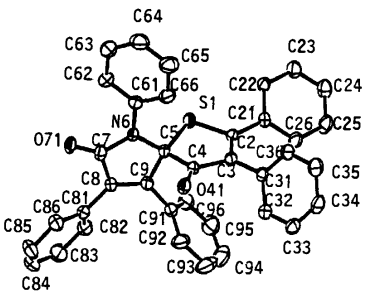

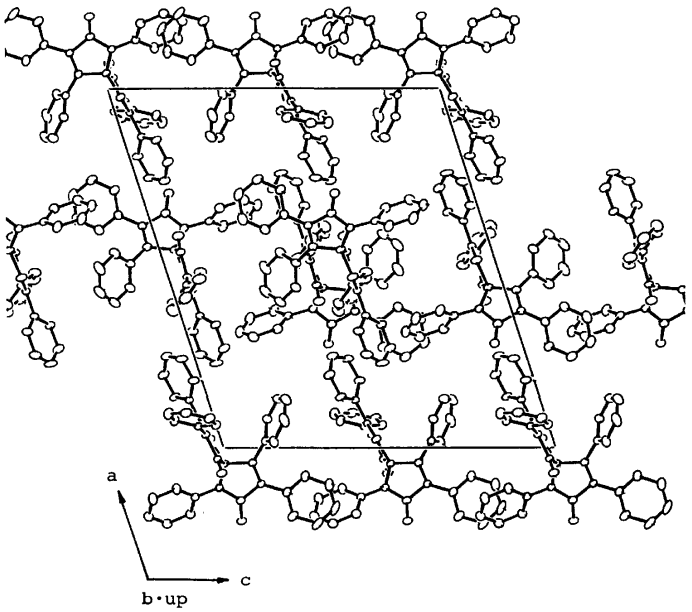

Fig. 2. Crystal structure projected down along the b axis.[7]

(5) Å] are much shorter than the C(7)=O(71)[1.218(5) and 1.211(5) Å].

Among the bond angles around the spiro carbon atom, the S(1)-C(5)-C(9), S(1)-C(5)-N(6) and C(4)-C(5)-N(6) angles are larger, whereas the other angles are smaller, than the tetrahedral angle. At the C(5) atom the dihedral angle between the plane defined by the S(1), C(4), and C(5) and that formed by the C(5), N(6), and C(9) atoms in the A molecule is 86.7°, and that in the B 86.4°. Both of them are slightly smaller than 90°. For both molecules the heterocyclic ring defined by the S(1), C(2), C(3), C(4), and C(5) atoms (heterocycle 1) and those made by the C(5), N(6), C(7), C(8), and C(9) atoms (heterocycle 2) are all approximately planar. In each molecule the planarity of the heterocycle 1 is slightly better than that of the heterocycle 2. The dihedral angles between these rings are 84.6 and 85.3° in the A and B molecules, respectively.

All the benzene rings attached to the heterocycles have normal structure, C-C(av)=1.383 Å and C-C-C(av)=120°. In each molecule most of them take different conformations to the hetero rings to which they attached except the phenyl group defined by the carbon atoms from C(81) to C(86). These benzene rings make equal dihedral angles [38.2 and 39.2°] to the heterocycle 2 in the A and B molecules.

Crystal Structure. The packing of molecules in the crystal is drawm in Fig. 2. The closest intermolecular atomic contact is 3.345(8) Å between the C(94A)(x, y, z) and C(22A)(x, 0.5−y, 0.5+z) atoms. Other short contacts are observed between the A and B molecules, C(63B)(x, y, z)···O(71A)=3.436(6) and C(64B)(x, y, z)···O(71A)=3.477(6) Å.

Computations were done mainly on a NEAC 2200-500 computer at the Computation Center, Osaka University. At the final stage an ACOS 850 computer was used at the Crystallographic Research Center, Institute for Protein Research, Osaka University.

The authors wish to express their deep thanks to Professor Toshio Agawa and coworkers of Osaka University for crystals and helpful discussion.

The temperature variation of ^1H and ^{19}F nuclear spin-lattice relaxation times T_1 in $[Cu_4(CF_3COO)_4]\cdot 2C_6H_6$ was observed at different resonance frequencies. From the NMR experiments, it was found that this complex undergoes a first order phase transition at 130 K, which was confirmed by DTA measurements. In the room-temperature phase, ^1H gave normal exponential magnetization recovery curves and $\log T_1$ linearly decreased with increasing $10^3\,T^{-1}$ whereas ^{19}F gave nonexponential magnetization recovery curves, from which long- and short-T_1 components could be derived. This indicates that the C_3 reorientation of CF_3 groups about their respective symmetry axis is responsible for ^{19}F T_1 and for ^1H T_1 as well through ^1H–^{19}F cross relaxation. This was confirmed from the coincidence of the $\log T_1$ *vs.* 10^3T^{-1} curve of the long component and that of ^1H T_1. A very small activation energy of 5.5 kJ mol^{-1} was obtained for the CF_3 reorientation. For the low-temperature phase, both ^1H and ^{19}F yielded nonexponential magnetization decay curves.

Recently, some Cu(I) complexes having capability to absorb and desorb CO, olefins, aromatic molecules *etc.* attract much attention from their usability as a carrier or a separator of those molecules.[1,2] Among these complexes, copper(I) trifluoroacetate is of interest in the formation of a fairly stable complex, $[Cu_4(CF_3COO)_4]\cdot 2C_6H_6$ by absorbing benzene vapor. It is so stable that we can investigate its solid state properties fairly in detail.[1,3,4]

According to Rodesiler and Amma,[3] this complex crystallizes in a monoclinic system $P2_1/n$ with $Z=4$. The structure can be described as a planar lozenge of four Cu atoms which are held together by bridging trifluoroacetate groups. Each CO_2^- group is approximately perpendicular to the Cu_4 plane but adjacent CO_2^- groups are on the opposite side of the plane. Two benzene molecules, between which the Cu_4 unit is placed, face each other. Although the Cu–C (in benzene) distances are longer than those determined in similar complexes,[5,6] all C atoms in each benzene ring having large thermal parameter are fairly definitely located. However, it is strange enough that no positional data of F atoms could be determined in their X-ray study. This suggests the presence of some disorder in the orientation of CF_3 groups and/or the occurrence of nearly free rotation of the groups. To clarify this point, the present investigation has been undertaken.

Experimental

Copper(I) trifluoroacetate synthesized by the method reported in literature[1] was purified by sublimation *in vacuo* at 140 °C. The compound was dissolved in benzene and the solvent was removed by vacuum distillation. The compound desorbs and adsorbs benzene molecules rather freely. The curve of the adsorption isotherm shows a plateau at 5 mmHg (1 mmHg=133.322 Pa) benzene vapor pressure, where the composition is determined as $[Cu_4(CF_3COO)_4]\cdot 2C_6H_6$. At higher benzene vapor pressure, the compound adsorbs additional benzene molecules physically giving $[Cu_4(CF_3COO)_4]\cdot nC_6H_6$ ($n>2$). Therefore, the number of "coordinated" benzene molecules was regulated by adjusting the equilibrium vapor pressure of benzene at 5 mmHg. The sample thus prepared was sealed in glass ampoules and employed for NMR and differential thermal analysis (DTA) measurements.

Two homemade pulsed NMR spectrometers[7,8] were employed for the determination of ^1H and ^{19}F nuclear spin-lattice relaxation times (T_1) at various temperatures using a conventional π-τ-$\pi/2$ pulse sequence. The experiments of DTA were carried out by means of a homemade apparatus.[9] Temperatures were determined by use of a copper-constantan thermocouple and were estimated to be accurate within ±1 K.

Results and Discussion

The $\log T_1$ values of ^1H observed at 20 and 45.500 MHz plotted against $10^3\,T^{-1}$ for $[Cu_4(CF_3COO)_4]\cdot 2C_6H_6$ are shown in Fig. 1. Figure 2 shows a similar plot for the ^1H and ^{19}F nuclei determined at 45.500 and 42.804 MHz, respectively, under the same strength of applied magnetic field.

At room temperature, ^1H T_1 determined at 20 MHz yielded a fairly large value of *ca.* 30 s. With decreasing temperature, $\log T_1$ decreased linearly against 10^3-T^{-1} down to *ca.* 100 K, below which temperature the magnetization recovery curves became suddenly nonexponential and yielded long- and short-T_1 components as given in Fig. 1. The $\log T_1$ value determined at 45.500 MHz decreased with decreasing temperature along the same line as that obtained at 20 MHz down to *ca.* 100 K. Below this temperature, nonexponential magnetization recovery curves were also detected. The foregoing observation suggests the occurrence of phase transition.

To confirm this point, we carried out the experiments of DTA below room temperature. When the sample was cooled, an exothermic anomaly appeared at *ca.* 100 K, while an endothermic peak was recorded at 130 K with increasing the temperature from *ca.*

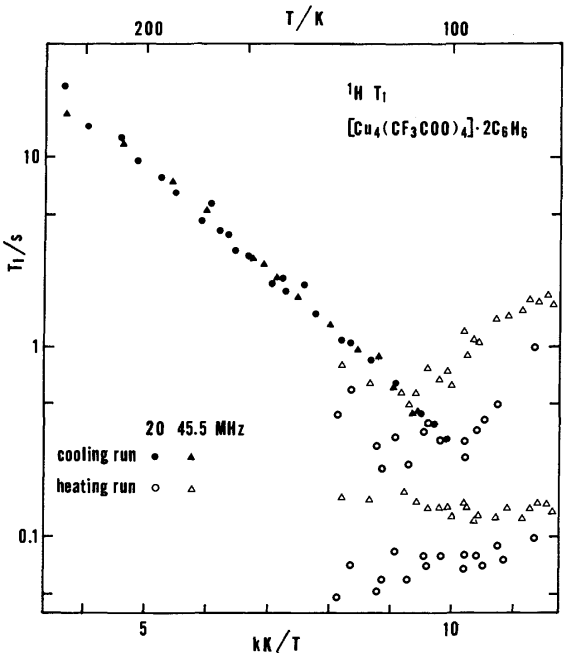

Fig. 1. Temperature dependences of ^{1}H T_1 in $[Cu_4(CF_3COO)_4]\cdot 2C_6H_6$ observed at 20 (●) and 45.500 (▲) MHz for the high-temperature phase and its supercooled one. For the low-temperature phase, long- and short-T_1 components observed with increasing temperature at the resonance frequencies of 20 (○) and 45.500 (△) MHz are plotted.

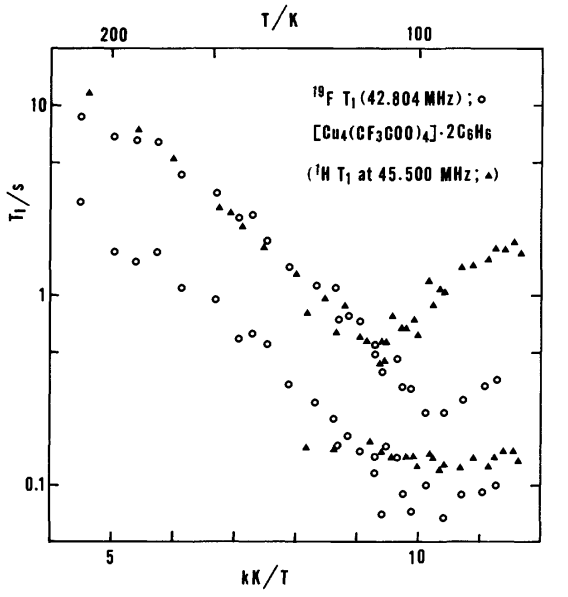

Fig. 2. Temperature dependences of ^{19}F T_1 in the complex observed at 42.804 MHz. The long- and short-T_1 components indicated by circles (○) observed for both phases are shown. Almost the same values were obtained for both cooling and heating runs. ^{1}H T_1 values determined at 45.500 MHz indicated by ▲ are shown for comparison.

80 K, showing the occurrence of thermal hysteresis. Accordingly, one can conclude that $[Cu_4(CF_3COO)_4]\cdot 2C_6H_6$ crystals undergo a first order phase transition at 130 K.

This complex contains ^{1}H and ^{19}F nuclei both of which have large magnetic moments and, therefore, it is expected that the T_1 values of both nuclei are governed by the motional process of benzene molecules and/or CF_3 groups through the mechanism of cross relaxation between them.[10] In solid benzene, the C_6 reorientation about the symmetry axis of the molecule is known to be activated near 100 K,[11] while Punkkinen *et al.* reported that CF_3 groups in solid CF_3COOAg perform the C_3 reorientation about their symmetry axis with the activation energy, E_a of 25 kJ mol^{-1}.[12] To obtain more detailed information about the motional process responsible for the ^{1}H T_1 values observed above, the T_1 measurements were performed on ^{19}F nuclei at the resonance frequency of 42.804 MHz. This frequency was selected so that the magnetic field where ^{19}F nuclei resonate at the above frequency was the same as that employed for the foregoing ^{1}H experiments.

It is characteristic for this complex that the magnetization of ^{19}F nuclei exhibits nonexponential recovery in both high- and low-temperature phases. The ^{19}F T_1 values of the former phase clearly belong to the hot side of the T_1 minimum because $\log T_1$ decreases linearly against $10^3\,T^{-1}$ down to *ca.* 100 K. The magnetization recovery curves observed could be explained as arising from two long- and short-T_1 components. It is interesting to note that both components yielded no discernible discontinuity at both transformation temperatures (T_{tr}) from high- to low-temperature phase on the cooling run and also from low- to high-temperature phase on the heating run. The $\log T_1$ *vs.* $10^3\,T^{-1}$ curve of the long component of ^{19}F T_1 in the high-temperature phase coincided with that of the ^{1}H T_1 as shown in Fig. 2. This indicates that the cross relaxation is operative between ^{1}H and ^{19}F nuclei and the same motional process governs the T_1 of both nuclei.

The existence of the short-T_1 component for the high-temperature phase in addition to the long one suggests that the motion responsible for the relaxation process of both nuclei is that of CF_3 groups, possibly the C_3 reorientation of the groups. The appearance of the nonexponential recovery curves for ^{19}F nuclear magnetization in the temperature region above its T_1 minimum can be interpreted in terms of cross correlation of ^{19}F–^{19}F dipolar interactions within a CF_3 group performing rapid reorientation about its C_3 axis. The nonexponential magnetization recovery curves explainable by the cross correlation have been found for ^{1}H T_1 in CH_3 groups of various organic compounds containing the group[13,14] and also for ^{19}F T_1 in CF_3COOAg.[12]

To confirm the C_3 reorientation of CF_3 groups activated in the present complex, we estimated the 2nd moment, M_2 of ^{19}F NMR from the analysis of free induction decay (FID) signals observed at 120 and 90 K. The FID curves $M_x(t)$ observed were as-

sumed to be expressed as a function of time, t by[15]

$$M_x(t) = M_x(0) \exp(-a^2t^2/2). \quad (1)$$

Here, a is a parameter determining the width of the Gaussian function. From this equation, M_2 can be given as

$$M_2 = a^2. \quad (2)$$

Least-squares-fitting calculation of Eq. 1 to the observed FID curves by use of SALS[16] at the Computation Center of Nagoya University afforded the approximate M_2 values of 1.9 and 2.3 G^2 (1 G=10^{-4} T) at 120 and 90 K, respectively.

The rigid lattice M_2 value of isolated CF_3 groups can be calculated as 7.3 G^2 by use of the geometrical parameters of a CF_3 group determined for CF_3COOAg crystals.[17] When isolated CF_3 groups perform the rapid C_3 reorientation, M_2 reduces the value to 1.8 G^2. In the present crystals, the ^{19}F M_2 value for the CF_3 group performing the C_3 reorientation is expected to become larger due to ^{19}F–^{19}F and ^{19}F–^1H dipolar interactions with ^{19}F in neighboring CF_3 groups and ^1H in neighboring benzene molecules, respectively. Accordingly, the above M_2 values estimated from FID observed indicate that the CF_3 groups perform the C_3 reorientation rapidly enough in the NMR time scale even at 90 K.

Figure 1 shows that ^{19}F T_1 detected by the spin-lattice relaxation of ^1H nuclei through cross relaxation between ^{19}F and ^1H in the high-temperature phase gives the same $\log T_1$ *vs.* 10^3 T^{-1} curve for the two different applied magnetic fields. This indicates that the observed ^{19}F T_1 can be interpreted in terms of usual dipolar interactions expressed by[18]

$$T_1^{-1} = C[\tau/(1+\omega^2\tau^2)+4\tau/(1+4\omega^2\tau^2)], \quad (3)$$

where C, τ, and ω denote the motional constant for the CF_3 groups, the correlation time of the C_3 reorientation of the group, and the angular resonance frequency, respectively. Here, we assume an Arrhenius relationship between τ and the activation energy E_a, for the motional process as

$$\tau = \tau_0 \exp(E_a/kT), \quad (4)$$

where τ_0 denotes the correlation time at the limit of infinite temperature. From the gradient of the $\log T_1$ *vs.* 10^3 T^{-1} curves obtained for both ^1H T_1 and ^{19}F T_1 in the room-temperature phase, one can evaluate E_a for the C_3 reorientation of the CF_3 groups using Eqs. 3,4 as 5.5 kJ mol^{-1}.

The obtained E_a value is very small as compared with that of 25 kJ mol^{-1} reported for the same motional mode in CF_3COOAg crystals.[12] Therefore, one can conclude that the CF_3 groups in the present complex are nearly free to rotate in the crystal. This is compatible with the result of X-ray analysis[3] which was incapable of locating the positions of the F atoms, although there still remains a possibility that the CF_3 groups are statistically disordered and undergo C_3 reorientation almost freely. The C_6 reorientation of benzene molecules in this crystal could not be detected for the present investigation possibly because the motion may be so rapid that it gives very short correlation time at least in the room-temperature phase.

For the low-temperature phase, nonexponential magnetization recovery curves were observed for both ^1H and ^{19}F nuclei. This may be due to the dipolar cross relaxation between ^{19}F and ^1H nuclei because they are usually observed on the low-temperature side of T_1 minima when cross relaxation between heteronuclei is effectively operative.[19,20] The T_1 values of both nuclei obtained for the low-temperature phase mostly belong to the cold side of T_1 minima. No further discussion for the results of T_1 measurements in this phase may be made because no structural data can be available.

It is noteworthy, however, that the ^{19}F T_1 value of both components changes almost smoothly with changing temperature across T_{tr} on both heating and cooling runs whereas the ^1H T_1 value changes drastically at T_{tr}. When the temperature was lowered, ^1H $\log T_1$ decreased linearly against 10^3 T^{-1} to *ca.* 100 K, where two T_1 values appeared suddenly. With increasing temperature in the low-temperature phase, two ^1H T_1 values were obtained up to 130 K, above which temperature the single ^1H T_1 of the high-temperature phase appeared. These facts suggest that the phase transition of this complex affects the motional state of the benzene molecules more strongly than that of the CF_3 groups.

Zn^{II}-bearing Green Rust II and Its Spontaneous Transformation into Zn^{II}-bearing Ferrite in Aqueous Solution

Yutaka TAMAURA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received January 16, 1985)

When solutions containing Fe^{II}, Zn^{II}, and SO_4^{2-} ions were oxidized by a mixed gas of air and nitrogen at pH 6.7 (25 °C), a Zn^{II}-bearing green rust II (GR-II), which is a uniform crystalline precipitate with a definite chemical composition, was formed. The mol ratio of Zn^{II}/Fe^{II} in the Zn^{II}-bearing GR-II increased linearly with an increase in the Zn^{II}/Fe^{II} mol ratio in the reaction solution. The distribution coeffient of Zn^{II} between the solid (Zn^{II}-bearing GR-II) and the solution phase is 3.3 times higher than that of Fe^{II}. The Zn^{II}-bearing GR-II was spontaneously transformed into Zn^{II}-bearing ferrite. In this reaction, Zn^{2+} ions in the Zn^{II}-bearing GR-II are preferentially incorporated into the ferrites.

Green rusts (hexagonal crystal), which are composed of Fe^{II}, Fe^{III}, and sulphate or halogenide ions are formed in the course of the atmospheric rusting of iron or mild steel, or in the course of the oxidation reaction of an $Fe(OH)_2$ suspension.[1-3] X-ray crystallographic study of the green rusts has been reported by Bernal *et al.*[1] In the previous paper,[4] we examined the synthesis of a pure green rust II having a definite chemical composition, $(Fe^{3+})_1(Fe^{2+})_2(SO_4^{2-})$-$(OH^-)_{5-2n}(O^{2-})_n$. This green rust II is obtained as a crystalline precipitate from a solution containing Fe^{II} and sulphate ions by air oxidation at pH 6.8 and 25 °C. In this reaction, one mol Fe^{III} ion, formed by the oxidation, combines with two mols of Fe^{II} and one mol of sulphate ions, to form the green rust II. Thus, this is a coprecipitation reaction of the metal ions forming a definite crystalline precipitate. In the present paper, we have studied the coprecipitation reaction of Zn^{II} ions into the green rust II (formation of the Zn^{II}-bearing GR-II). This paper also describes the spontaneous transformation of the Zn^{II}-bearing GR-II into the Zn^{II}-bearing ferrite. Generally, GR-II is considered to be transformed into ferrites only by an oxidation reaction.[4] The spontaneous transformation means that GR-II is transformed into ferrites without oxidation.

Experimental

Chemicals. All chemicals were of analytical grade, and distilled water was used for the preparation of chemical solutions. NaOH solutions were prepared by dissolving NaOH in distilled water through which nitrogen gas had been passed to remove dissolved oxygen.

Apparatus. The reaction vessel described in the previous paper[4] was used.

Chemical Analysis. The Fe^{II} and Fe_{total} contents were determined by the 2,2′-bipyridyl method[5] after dissolving the sample in HCl (1:1). The Zn^{II} content was analyzed by atomic absorption. The SO_4^{2-} content was determined by X-ray fluorescence (Toshiba X-ray Spectrometer Model AFV 777) from the intensity of sulfur in a $BaSO_4$ precipitate collected on a glass fiber filter (Toyo Roshi GA 100 type).

Synthesis of the Zn^{II}-bearing GR-II. A solution [0.7 dm³, $FeSO_4 \cdot 7H_2O$ (2.5—10.0 g), $ZnSO_4 \cdot 7H_2O$ (0—2.5 g), and Na_2SO_4(25 g)] was oxidized with a mixed gas of air and nitrogen [air/N_2=1:1 (1 atm), flow rate; 3.0 dm³ min^{-1}] at pH 6.7±0.05 and 25 °C. During the oxidation, an alkaline solution (0.10 mol dm^{-3}) was added to maintain a pH of 6.7. After 40 min, nitrogen gas was passed through in place of the mixed gas, and the reaction vessel was cooled in a water bath chilled with ice. The greenish precipitates formed were collected by centrifugation under a nitrogen atmosphere, washed with distilled water freed from oxygen (4 °C), and suspended in distilled water (4 °C). The Zn^{II}-bearing GR-II is stable under a nitrogen atmosphere at temperatures below 4 °C.

For the measurement of the metal ions in the Zn^{II}-bearing GR-II in the course of the air oxidation, 0.005 dm³ of the reaction suspension was transferred under a nitrogen atmosphere to a 0.05 dm³ centrifuging tube chilled in ice water. After centrifuging under a nitrogen atmosphere at 3000 r.p.m for 5 min, the precipitate was washed with cold distilled water freed from oxygen, and the contents of the Fe^{III}, Fe^{II}, and Zn^{II} ions were determined.

Spontaneous Transformation Reaction of the Zn^{II}-bearing GR-II. The suspension of the Zn^{II}-bearing GR-II (0.05 dm³, 25 °C) was transferred into 0.4 dm³ of distilled water freed from oxygen (the temperature of the distilled water had been adjusted to get 70 °C after the mixing). The pH of the reaction suspension was adjusted to 10.5 by adding NaOH solution during the reaction. After allowing the reaction suspension to stand at 70 °C under a nitrogen atmosphere for 12 h, the product was isolated by transferring 0.2 dm³ of the reaction suspension to 0.1 dm³ of an oxygen-free acetate buffer solution (pH 4.1, 0.05 mol dm^{-3}) to dissolve the metal ions released during the transformation reaction. The product was collected by centrifugation under a nitrogen atmosphere, washed with oxygen-free water and acetone, successively, and dried under a nitrogen atmosphere. The dried product was examined by X-ray diffractometry. The chemical composition was determined after dissolving it in HCl solution (1:1).

Results and Discussion

Formation of the Zn^{II}-bearing GR-II. When the solutions containing Fe^{II}, Zn^{II}, and SO_4^{2-} ions (the Zn^{II}/Fe^{II} mol ratio =0—1.0) were oxidized by a mixed gas of air and nitrogen at pH 6.7 (25 °C), the clear solutions became turbid, and greenish precipitates were formed. The amount of the precipitates in-

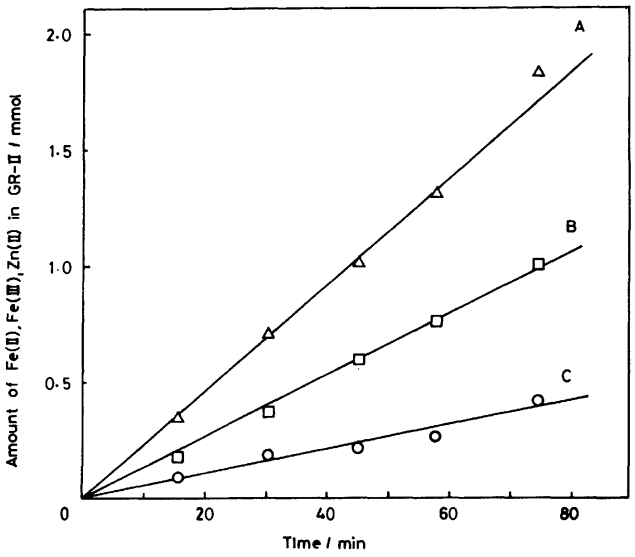

Fig. 1 Time variation of the amounts of Fe^{II}- (Curve A), Fe^{III}(B), and Zn^{II}(C) in the Zn^{II}-bearing GR-II formed during the oxidation reaction. The Zn^{II}/Fe^{II} mol ratio in the initial solution was 0.091.

creased with the oxidation time. Chemical analysis showed that the precipitates contained Fe^{III}, Fe^{II}, and Zn^{II} ions. As shown in Fig. 1, the amount of each metal ion coprecipitated as the greenish precipitates increased linearly with the oxidation time. This shows that the mol fractions of the metal ions in the precipitate are constant; a precipitate with a definite chemical composition was formed. The same results were obtained for the different mol ratios of Zn^{II}/Fe^{II} in the reaction solutions. In the following experiments, we used the greenish precipitates obtained at 40 min of the oxidation time. The X-ray diffraction pattern of the precipitate obtained at 40 min of the oxidation time corresponded to that of the green rust II.[1] In the IR spectrum, strong bands of SO_4^{2-} ion ($1100\,cm^{-1}$) appeared. These results show that Fe^{III} ions formed by the oxidation combine with the Fe^{II}, Zn^{II}, and SO_4^{2-} ions, and form the green rust II, which contains Zn^{II} ions.

The metal mol fraction of Zn^{II} in the Zn^{II}-bearing GR-II increased with an increase in the mol ratio of $Zn^{II}/(Zn^{II}+Fe^{II})$ in the initial solution, as shown by Curve A in Fig. 2. Contrarily, the mol fraction of Fe^{II} decreased (Curve C). However, the mol fraction of Fe^{III} (Curve B) remained nearly constant. The mol ratios of $(Zn^{II}+Fe^{II})/Fe^{III}$ in the Zn^{II}-bearing GR-II (the ratios of the bivalent to trivalent metal ions) are nearly equal to 2:1, which corresponds to the mol ratio of bivalent to trivalent metal ions in the green rust II having no Zn^{II} ions. This suggests that the Fe^{II} ions in the green rust II are preferentially replaced by the Zn^{II} ion. Chemical analysis showed that the chemical composition of the Zn^{II}-bearing GR-II was expressed by $(Zn^{2+})_x(Fe^{2+})_{2-x}(Fe^{3+})(SO_4^{2-})(OH^-)_5$.

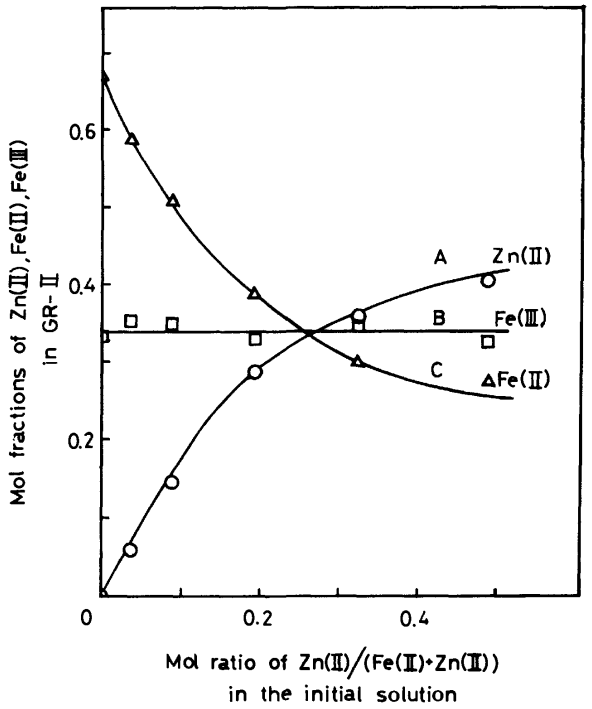

Fig. 2. The relationship between the mol fractions of metal ions (Zn^{II}; Curve A, Fe^{III}; B, and Fe^{II}; C) in the Zn^{II}-bearing GR-II and the mol ratio of $Zn^{II}/(Zn^{II}+Fe^{II})$ in the initial reaction solution. The Zn^{II}-bearing GR-II was obtained at 40 min of the oxidation time.

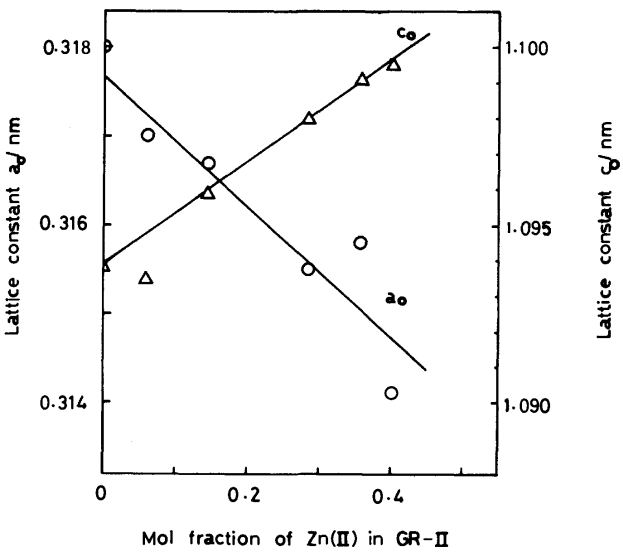

Fig. 3. The relationship between the lattice constants (a_o and c_o) and the mol fraction of Zn^{II} in the Zn^{II} bearing GR-II.

Figure 3 shows the relationship between the lattice constants and the Zn^{II} content in the Zn^{II}-bearing GR-II. As can be seen here, the lattice constant of c_o increased with an increase in the Zn^{II} content, but that of a_o decreased. Since the ion radius of Zn^{2+} is larger than that of Fe^{2+}, it is considered that the Fe^{II} ions arraied along c_o axis in the green rust II are

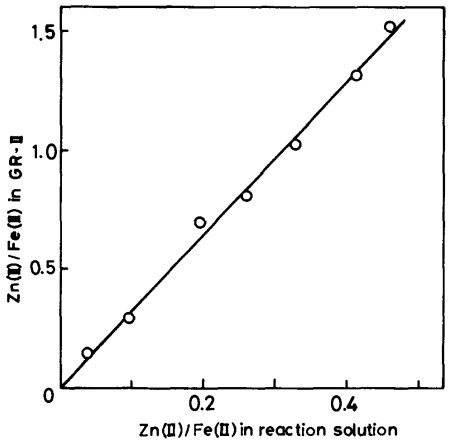

Fig. 4. The relationship between the Zn^{II}/Fe^{II} mol ratio (R_{grn}) in the Zn^{II}-bearing GR-II and those of the Zn^{II}/Fe^{II} mol ratio (R_{sol}) in the initial reaction solution.

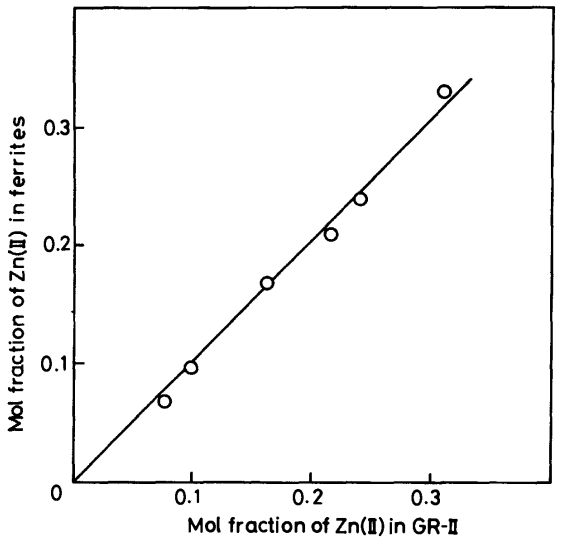

Fig. 5. The relationship between the mol fraction of the Zn^{II} in the Zn^{II}-bearing GR-II and that in the Zn^{II}-bearing ferrites formed by the spontaneous transformation reaction.

preferentially replaced by the Zn^{II} ions.

Figure 4 shows the relationship between the Zn^{II}/Fe^{II} mol ratio (R_{grn}) in the Zn^{II}-bearing GR-II and those of the Zn^{II}/Fe^{II} mol ratio (R_{sol}) in the initial reaction solution. As can be seen here, R_{grn} linearly increases with an increase in R_{sol}. The distribution coefficients of the partitioned ions (D_f and D_z for Fe^{II} and Zn^{II}, respectively) in solid (Zn^{II}-bearing GR-II) and solution phases are given by

$$D_f = [Fe^{II}_{grn}]/[Fe^{II}_{sol}] \quad (1)$$

$$D_z = [Zn^{II}_{grn}]/[Zn^{II}_{sol}]. \quad (2)$$

From these equations, we obtain

$$R_{grn} = \left(\frac{D_z}{D_f}\right)\frac{[Zn^{II}_{sol}]}{[Fe^{II}_{sol}]}. \quad (3)$$

After 40 min of oxidation time, about 8—10 mol% of the metal ions in the reaction solution was consumed with the formation of the Zn^{II}-bearing GR-II. As a first approximation, the concentrations of the Zn^{II} and Fe^{II} ions in the initial solution are substituted for $[Zn^{II}_{sol}]$ and $[Fe^{II}_{sol}]$ in Eq. 3, then

$$R_{grn} \simeq \left(\frac{D_z}{D_f}\right)R_{sol}. \quad (4)$$

Since the linear relationship in Fig. 4 is considered to be represented by Eq. 4, the slope of the line in Fig. 4 gives the value of D_z/D_f. This value suggests that the distribution coeffient of Zn^{II} between the solid (Zn^{II}-bearing GR-II) and the solution phases is 3.3 times higher than that of Fe^{II}. In general, the term "distribution coefficient" is adopted for the phenomena where substances are distributed between two phases without any chemical reactions. In the precipitation reaction studied here, the metal ions of Fe^{II} and Zn^{II} in the solution phase are transferred into the solid phase accompanying the chemical reactions; the physical meaning of D_z and D_f in Eqs. 1—4 are different from the general meaning of the distribution coeffient.

Spontaneous Transformation of the Zn^{II}-bearing GR-II into Zn-bearing Ferrites. X-Ray diffractometry showed that the product obtained by allowing the suspension of the Zn^{II}-bearing GR-II to stand under a nitrogen atmosphere at 70 °C was a spinel compound. The chemical composition of the product corresponded to a Zn^{II}-bearing ferrite.

Electron microscopic observation showed that the hexagonal particles characteristic of the GR-II changed to spherical or cubic particles characteristic of ferrites. In the IR spectrum of the product, only bands corresponding to the ferrite appeared (strong band at 570 cm^{-1}). Thus, the Zn^{II}-bearing GR-II is spontaneously transformed into the Zn^{II}-bearing ferrite.

The Zn^{II} content in the ferrites increased with an increase in the Zn^{II}-bearing GR-II. Figure 5 shows the relationship between the mol fraction of the Zn^{II} ion $[Zn^{II}/(Zn^{II}+Fe^{II}+Fe^{III})]$ in the ferrites and that in the Zn^{II}-bearing GR-II. As can be seen here, the mol fractions of the Zn^{II} in the ferrites are equal to that in the Zn^{II}-bearing GR-II. This suggests that the spontaneous transformation reaction is represented by

$$2(Zn^{2+})_x(Fe^{2+})_{2-x}(Fe^{3+})(SO_4^{2-})(OH^-)_5 + 2H^+ \longrightarrow (Zn_x^{2+}, Fe^{2+}_{1-x})(Fe^{3+})_2O_4 + xZn^{2+} + (3-x)Fe^{2+} + 2SO_4^{2-} + 6H_2O. \quad (5)$$

The mol ratio of Zn^{2+}/Fe^{2+} in the Zn^{II}-bearing GR-II $[x/(2-x)]$ is smaller than that in the ferrite $[x/(1-x)]$, suggesting that the Zn^{2+} ions in the Zn^{II}-bearing GR-II

are preferentially incorporated into the ferrites in the spontaneous transformation reaction.

Studies of the Hydrous Niobium(V) Oxide Ion Exchanger. II. Affinity for Various Cations

Yasushi INOUE,* Hiromichi YAMAZAKI, Kazushi OKADA, and Kazuhiko MORITA
Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980
(Received February 13, 1985)

In order to elucidate the fundamental properties of hydrous niobium(V) oxide as a cation exchanger, the stoichiometry of cation exchange and the selectivity for various cations were studied. As the reversibility and the equivalent exchange between the cations were confirmed, this material showed an ideal cation-exchange reaction. The affinity series for alkali metal ions and alkaline earth metal ions were $Cs^+ \gg K^+ \gg Li^+$ and $Ba^{2+} \gg Sr^{2+} \geqq Ca^{2+} > Mg^{2+}$ respectively; the values decreased in the order of the increase in the hydrated ionic radii of the cations. For transition metal ions, the distribution coefficients had a strong correlation with the first hydrolysis constants of the cations and/or the first stability constants of their acetato complexes. Based on this finding, the transition metal ions are considered to be adsorbed on the exchanger by a bond partially covalent in character, rather than by a pure ionic bond. The pH-dependency of the distribution coefficients of the cations was discussed in terms of the effects of the dissociation of the exchange sites on the overall ion-exchange equilibrium.

Through a comprehensive study of preparing the hydrous niobium(V) oxide ion exchanger, a recommended procedure for synthesizing the exchanger was established, as has been reported previously.[1] The method has the merits of simplicity and good reproducibility. The exchanger thus prepared is a semitransparent, amorphous solid which is hard enough to be used for column operation; it can be converted to the pure H^+ form by conditioning it with a 0.1 mol dm^{-3} HCl solution. The material has the cation-exchange capacity of 2.3 mmol Na^+ g^{-1} (at pH 10) and possesses at least two kinds of weakly dissociable ion-exchange sites. Its stability against various chemicals and during storage was also investigated, as has been described in the foregoing report.[1]

Abe and Ito reported that the exchanger exhibited only a cation-exchange property,[2] but Sukharov *et al.* reported anion exchange with $Cr_2O_7^{2-}$.[3] However, a systematic study has not been made of exchange reactions on hydrous niobium(V) oxide. In the present investigation, the distribution coefficients of various cations were determined as a function of the pH in order to study the ion-exchange mechanism.

Experimental

Reagents and Apparatus. The niobium(V) chloride, of the highest purity grade, was obtained from the Mitsuwa Kagaku Yakuhin Kaisha, Ltd. All the other reagents used were of the highest purity grade and were obtained from Wako Pure Chemical Industries, Ltd., or E. Merck AG. A well-type NaI(Tl) scintillation counter (Fuji Denki Model NHS-2) was employed for the measurement of the γ-radioactivity. All the other apparatuses were the same as those described previously.[1]

Preparation of the Exchanger. Synthetic method No. 4 was chosen from the various methods of preparation described in the preceeding paper: Twenty-five grams of niobium(V) chloride were dissolved in 50 cm^3 of a concentrated hydrochloric acid, followed by dilution to 1 dm^3 with distilled water. The solution was hydrolyzed thermally by boiling it for 2 h in a 3-dm^3, round-bottomed flask equipped with a reflux condenser. The precipitate thus formed was washed with distilled water until no chloride ion was detected in the filtrate. Then the precipitate was air-dried at room temperature. The dried product was then immersed in distilled water to break it down into fine particles. The granules were dried again at room temperature. Particles larger than desired, if any, were ground in a porcelain mortar and sieved to obtain the required particle sizes. The exchanger of a desired particle size(−100 +200 mesh) was converted to the H^+ form by treating it with a 0.1 mol dm^{-3} HCl solution by the procedure described previously.[1] Finally, the exchanger was air-dried and stored in a desiccator containing a saturated NH_4Cl solution (relative humidity, 79% at 25 °C). The exchanger had a composition of $Nb_2O_5 \cdot 5.3H_2O$ and an ion-exchange capacity of *ca.* 1.5 mmol Na^+ g^{-1} at pH 8, where an inflection point was observed in the titration curve of the material.

Distribution Coefficients. The distribution coefficients, K_d, were determined in the following way, unless otherwise noted.

A 0.30-g portion of the exchanger in the H^+ form was immersed in 18 cm^3 of the solution with a suitable pH value, adjusted by using a desired combination of 0.11 mol dm^{-3} NaCl and 0.11 mol dm^{-3} HCl or 0.11 mol dm^{-3} NaOH, for 2 d, at room temperature. A 2-cm^3 portion of the solution containing each metal ion was mixed with the above solution to make the concentration of the cation 1×10^{-4} mol dm^{-3} and the ionic strength 0.10 mol dm^{-3}. The mixture was then allowed to stand until the concentration of the cation in the supernatant solution became constant (about 2 to 9 d). The pH and the concentration of the cation in the supernatant solution were then measured. The K_d value, expressed in cm^3 g^{-1}, was calculated in the usual manner.

The metal ions were added as their chlorides, except Fe^{3+}, Th^{4+}, and UO_2^{2+}, for which the corresponding nitrates were used. The analyses of Cs, Sr, Ba, Mn, Fe, Co, Sc, Y, Ce, Eu, Np, and Am were carried out radiometrically using ^{137}Cs, ^{85}Sr, ^{133}Ba, ^{54}Mn, ^{59}Fe, ^{60}Co, ^{45}Sc, ^{88}Y, ^{144}Ce, ^{152}Eu, ^{239}Np, and ^{241}Am respectively as tracers. Their radioactive purities were confirmed by means of γ-ray spectrometry. The ^{239}Np tracer was prepared by milking it from ^{243}Am by the method of Sill.[4] The oxidation state of neptunium at a tracer concentration was adjusted by the method of Inoue and Tochiyama.[5] The Th^{4+} and the UO_2^{2+} were analyzed

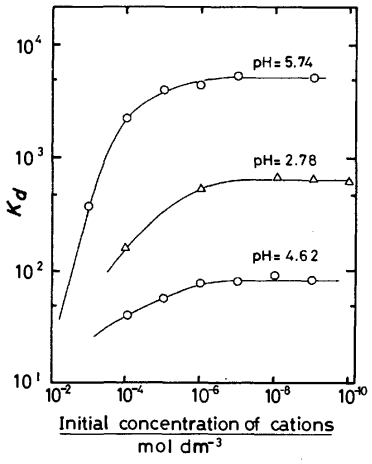

Fig. 1. Effect of the concentration of cations on their distribution coefficients.
○: Co^{2+}, △: Sc^{3+}.

spectrophotometrically using arsenazo III[6] and 2-(5-Bromo-2-pyridylazo)-5-(diethylamino)phenol[7] respectively as coloring reagents, while the concentrations of the other cations were determined by means of atomic-absorption spectrophotometry.

Ion-exchange Stoichiometry. The exchanger in the H^+ form was immersed in an alkaline solution of sodium ions, of a suitable concentration (ionic strength=0.016 mol dm^{-3}), for 2 d at room temperature, with intermittent shaking. This was followed by chemical analysis, and the ratio of the amount of sodium ions taken up in the exchanger to that of the hydrogen ions released from the exchanger was evaluated from the difference between the initial and final concentrations of the respective ions present in the solution. The Na^+ was converted to pure chloride and was indirectly determined by titrating the Cl^-. The OH^- and CO_3^{2-} were determined by differential titration.

Results and Discussion

The Dependency of K_d Values on the Concentration of the Cations. Figure 1 shows the K_d values for Co^{2+} and Sc^{3+} as a function of their initial concentrations at constant pH values. The K_d values were nearly constant in the concentration region lower than 10^{-8} mol dm^{-3}, wherefrom they decreased with an increase in the concentration. The concentration-dependency of the K_d values may be ascribed to the limited amount of cation-exchange sites in the pH region adopted in the present experiment, since the uptake of Na^+ on the exchanger commences at about pH 4.[1] Because of this observation, a strict comparison of the selectivity for various cations should be made at a concentration lower than 10^{-8} mol dm^{-3}. However, it is very difficult to set up the above situation because of the limits of analytical sensitivities for some cations. Thus, an initial concentration of 1×10^{-4} mol dm^{-3} was used mainly for the comparison of the K_d values of various cations.

Stoichiometry and Reversibility of the Exchange Reaction. Table 1 presents the results concerning the stoichiometry of the exchange reaction between H^+ on the exchanger and Na^+ in the solution. The equivalent ratio of the H^+ released to the Na^+ sorbed was unity, within the limits of experimental error (Table 1). Figure 2 shows the results concerning the reversibility of the ion-exchange reaction between Eu^{3+} and H^+. After the determination of the K_d values at several pH values (A, B in the figure), a small amount of a HCl solution (less than 0.5% in volume) was added to the supernatant solution to lower the pH. This new solution was then allowed to stand until a new equilibrium had been attained, and then the K_d values were measured again (A′, B′ in the fugure). The points A and B shifted to A′ and B′ respectively as a result of the change of the pH in the solutions. Since A′ and B′ fall on the same straight line as A and B, the exchange reaction between Eu^{3+} and H^+ is considered to be reversible. From the stoichiometry and the reversibility of the ion-exchange reaction, the hydrous niobium(V) oxide shows an ideal cation-exchange reaction.

Selectivity for Cations. Figure 3 shows the pH-dependency of the K_d values for the representative elements. The orders of selectivity for alkali metal ions: $Cs^+ \gg K^+ \gg Li^+$, and for alkaline earth metal

ions: $Ba^{2+} \gg Sr^{2+} \geqq Ca^{2+} > Mg^{2+}$, are similar to that of strongly acidic ion-exchange resin, in which the selectivity coefficients for ions with the same ionic charge increase with a decrease in the hydrated ionic radii of the cations. This may be due to the increase in the strength of the electrostatic interaction between the hydrated cations and the fixed anionic groups. Such interaction must be closely related to the ionic potential of hydrated cations (hydrated ionic potential). In fact, the log K_d value at pH 6 for these cations closely correlates to their hydrated ionic potentials (the correlation coefficient was 0.84), as is shown in Fig. 4. Here, the hydrated ionic radii were those reported by Wiklander.[8] The selectivity for Cs^+, however, was markedly high, in spite of the smaller

hydrated ionic potential.

Figure 5 shows that the pH-dependency of the K_d values for bi- and tervalent transition metal ions was: $UO_2^{2+} \geqq Fe^{3+} > Sc^{3+} \gg Eu^{3+} \geqq Ce^{3+} \geqq Y^{3+} \gg Co^{2+} \geqq Mn^{2+}$. By comparing the figure with Fig. 3, the affinity for bivalent transition metal ions (except UO_2^{2+}) may be seen to be similar to that for alkaline earth metal ions. Furthermore, the affinity of the exchanger for tervalent cations is, on the whole, much greater than that for bivalent cations. Hence, the electrostatic force may be an important factor in deciding the selectivity of the hydrous niobium(V) oxide. This affinity series, however, is the exact reverse of what would be expected from the selectivity for alkali- and alkaline earth metal ions. Figure 6 shows the results for some actinoid ions. The Am(III) ion appears to have an affinity similar to those of other transition metal ions with the same charge. The actinyl species, such as NpO_2^+, NpO_2^{2+} and UO_2^{2+}, had, however, higher K_d values than those to be expected from their charges; the affinity for those species was greater than, or similar to, that for tervalent transition metal ions. This finding cannot be explained only in terms of the electrostatic interaction between the hydrated ions and the anionic sites in the exchanger.

In order to understand the important factors affecting the selectivity for the transition metal ions, the K_d values for the metal ions at pH 3 were compared with their ionic potentials, their first hydrolysis constants,[9] and the first stability constants of their acetato complexes.[11] The results are shown in Table 2. Here, the ionic radii used were those obtained by using crystals in which the ion had the coordination number of 6[10] and the log K_d values which could not be obtained by the experiment were those estimated from the extrapolation of the log K_d *vs.* pH plot in Fig. 5. This table indicates that the K_d values correlate more strongly with the stability constants (R=0.96) and the hydrolysis constants (R=0.91) than with the ionic potential

Table 2. Interaction between exchanging cations and exchange sites

Metal ion	log K_d(at pH 3)	A[1]	B[2]	C[3]
UO_2^{2+}	3.66	—	2.61	−5.8
Fe^{3+}	3.62	4.35	3.36	−2.19
Sc^{3+}	3.40	3.39	—	−4.3
Eu^{3+}	2.10	2.76	2.13	−7.8
Ce^{3+}	1.90	2.61	1.91	−8.3
Y^{3+}	1.73	2.88	1.68	−7.7
Co^{2+}	0.14	2.53	1.10	−9.65
Mn^{2+}	0.02	2.46	0.8	−10.59
		R=0.83	R=0.96	R=0.91

1) A=z/r: Ionic potential; z=Change of cation, r=Ionic radius(coordination number (6)).[10] 2) B=log K_{11} (CH_3COO^-): First stability constant(equilibrium quotient at 25°C and ionic strength 0.1).[11] 3) C=log K_{11} (OH^-): First hydrolysis constant.[9]
R=Correlation coefficient.

(R=0.83). Therefore, we can conclude that, in the ion-exchange reactions for transition metal ions, the formation of a covalent bond between the anionic sites in the exchanger and metal ions is a factor in determining the selectivity of the exchanger, along with the remote coulombic interaction.

Selectivity for Cations in Tracer Concentrations. The cation-exchange reaction is expressed as a combination of the following two reactions:

$$HR \rightleftharpoons H^+ + R^-, \tag{1}$$

$$nR^- + M^{n+} \rightleftharpoons R_nM, \tag{2}$$

where R^- denotes the dissociated form of the exchanger, and M^{n+} the exchanging cations. The equilibrium constants for these reactions can be written as:

$$K_a = \frac{a_H\bar{a}_R}{\bar{a}_{HR}} = \frac{a_H\bar{m}_R\bar{\gamma}_R}{\bar{m}_{HR}\bar{\gamma}_{HR}}, \tag{3}$$

$$K = \frac{\bar{a}_{R_nM}}{\bar{a}_R{}^n a_M} = \frac{\bar{m}_{R_nM}\bar{\gamma}_{R_nM}}{\bar{m}_R{}^n\bar{\gamma}_R{}^n m_M\gamma_M}, \tag{4}$$

where a represents the activity; m, the concentration and γ, the activity coefficient. A bar refers to the exchanger phase. (For the sake of simplicity, the charge of the species is omitted in these expressions.)

From the material balance,

$$\bar{m}_R + \bar{m}_{HR} + n\,\bar{m}_{R_nM} = E \tag{5}$$

E is the total ion-exchange capacity. If the concentration of the exchanging cation, M^{n+}, is negligibly small,

$$\bar{m}_R + \bar{m}_{HR} = E \tag{5'}$$

holds.

From Eqs. 3 through 5′, distribution coefficients of M^{n+} can be written as:

$$K_d = \frac{KK_a{}^n\bar{\gamma}_{HR}{}^n\gamma_M}{\bar{\gamma}_{R_nM}} \cdot \frac{E^n}{\left[1+\frac{K_a\bar{\gamma}_{HR}}{a_H\bar{\gamma}_R}\right]^n} \cdot \frac{1}{a_H{}^n}. \tag{6}$$

If the pH of the solution is very low, Eq. 6 can be simplified to:

$$\log K_d = \text{constant} + n\text{pH}, \tag{7}$$

while in highly alkaline solutions:

$$\log K_d = \text{constant}. \tag{8}$$

As has been reported previously,[1] the exchanger commences the uptake of Na^+ at around pH 4, and it increases in its ion-exchange capacity for Na^+ with pH. Consequently, at the tracer concentration, the plot of log K_d *vs.* pH will show a straight line with a slope of n in the pH range lower than around 4. The deviation of the results in Figs. 5 and 6 from Eq. 7 may be ascribed to the strong dependency of the K_d values on the concentration of cations (Fig. 1), but it cannot be explained only from this reason, because the slope of the straight line was not appreciably affected by the concentration, as is evident from the results on Sr^{2+} (Fig. 7). Figure 7 also shows that the K_d value for Sr^{2+} is independent of the pH values in the pH region higher than 8; this agrees with Eq. 8. As is shown in Figs 6 and 8, for uni- and bi-charged cations, the straight lines have approximately the same slopes (Co^{2+}: 1.7, NpO_2^+: 0.97, NpO_2^{2+}: 1.8), as would be predicted from Eq. 7, while the ter-valent cations show slopes (Y^{3+}: 2.3, Sc^{3+}: 1.8, Am^{3+}:

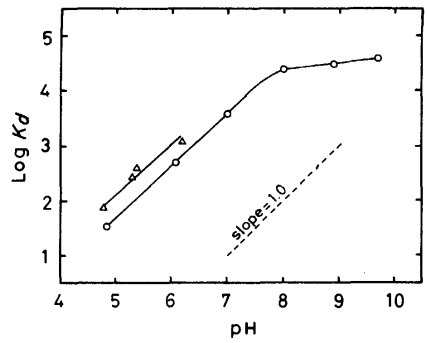

Fig. 7. Effect of the concentration of Sr^{2+} on the pH-dependency of the K_d values.
Ionic strength: 0.10 mol dm^{-3} (NaCl-NaOH) at room temperature, Initial concentration of Sr^{2+}/mol dm^{-3}; ○: 1×10^{-4}, △: 1×10^{-8}.

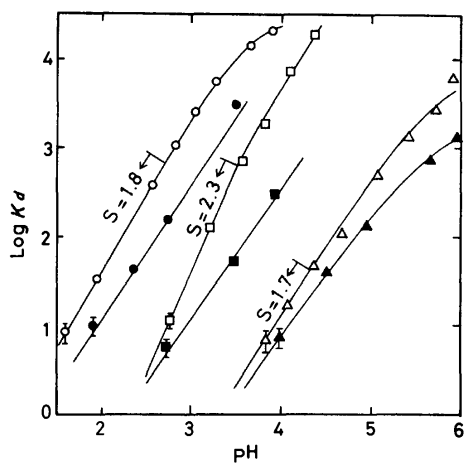

Fig. 8. Effect of the concentration of Co^{2+}, Y^{3+}, and Sc^{3+} on the K_d values.
Ionic strength: 0.10 mol dm^{-3} (HCl-NaCl-NaOH) at room temperature, Initial concentration of cations/mol dm^{-3}, Co^{2+}; ▲: 1×10^{-4}, △: 1×10^{-8}, Y^{3+}; ■: 1×10^{-4}, □: 1×10^{-10}, Sc^{3+}; ●: 1×10^{-4}, ○: 1×10^{-10}.

2.1) smaller than those to be expected from Eq. 7 in spite having the conditions which satisfy this equation. This contradiction may be solved by considering that the charge in the exchanger is not balanced only by these reactions, (1) and (2). The first explanation can be based on the Donnan exclusion principle, which claims that the electrolytes with counter ions (in this case, cations) of a higher charge will be more easily introduced in the exchanger than those of a lower charge, if the co-ions (anions) have the same charge. As the exchanger is mainly in the undissociated form in the pH range lower than 4, the chloride ions can easily diffuse into the exchanger by means of Donnan adsorption. Accordingly, the lowering of the slope of the straight lines will be more pronounced for tervalent than for uni- and bivalent cations. The second explanation is that the charge in the exchanger, instead of the H^+, will be balanced by the release of Na^+ which is trapped in an exchanger phase surrounded by a solution with a high Na^+-concentration, even in a solution with a low pH.

In any case, further investigation must be carried out before the cation-exchange mechanism can be unambiguously understood.

Adsorption and Orientation of Isomeric Phthalic Acids on Alumina Surface Observed by Inelastic Electron Tunneling Spectroscopy

Morihide HIGO,* Sinichi MIZUTARU, and Satuo KAMATA
Faculty of Engineering, Kagoshima University, Korimoto, Kagoshima 890
(Received April 20, 1985)

The vibrational spectra of phthalic, isophthalic and terephthalic acid adsorbed onto the alumina surface have been measured by using inelastic electron tunneling spectroscopy. The tunneling spectra of these acids were obtained by liquid-phase doping with water or various alcohol solutions. The detailed assignments for these spectra are given, together with a comparison of their infrared and Raman spectra. It has been found that both phthalic and isophthalic acid are adsorbed onto the alumina surface mainly as the dicarboxylate ions. However, a comparison between the tunneling spectra of terephthalic and *p*-acetylbenzoic acid shows that terephthalic acid is adsorbed predominantly as the monocarboxylate ion onto the surface when doped with alcohol solutions. Hydrogen bonding is observed among the adsorbed hydrogen terephthalate ions. These results show a difference in their orientation and different probabilities of chemical interaction between the alumina surface and the carboxyl groups of the adsorbed isomeric phthalic acids.

A great deal of interest has been paid to a new technique for investigating the adsorbed species on metal surfaces. The vibrational spectra of such species should give important information on their structure and the adsorption mechanism. Inelastic electron tunneling spectroscopy (IETS), discovered in 1966 by Jaklevic and Lambe,[1] reveals the vibrational spectrum of adsorbed species on the oxide surface of a metal-oxide-metal tunneling junction at cryogenic temperatures, as is shown in Fig. 1. Several authors[2-7] have reviewed the principle, apparatus and application; they have demonstrated the potential of IETS.

When a dc-bias voltage is applied across the junction, electrons can tunnel from one electrode through the oxide into the opposite electrode. A vibrational mode of frequency, ν, appears as a peak in the second derivative of the characteristic current-voltage (I-V) function of the junction, d^2I/dV^2, at a voltage of $V=h\nu/e$, where h is Planck's constant and e is the electron charge. Both infrared and Raman-active vibrational modes appear in the IET spectrum. The useful spectral range extends from 400 to 4000 cm^{-1} and includes all molecular vibrations. The high sensitivity and resolution of IETS enable us to measure the detailed spectrum of a fraction of a monolayer of adsorbed species. In general, the oscillating dipole moment perpendicular to the oxide surface couples to tunneling electrons more strongly than that parallel to the surface. Thus, IETS may be expected to be a powerful analytical technique for investigating the chemical interaction and the structure of molecules adsorbed onto the oxide surfaces.

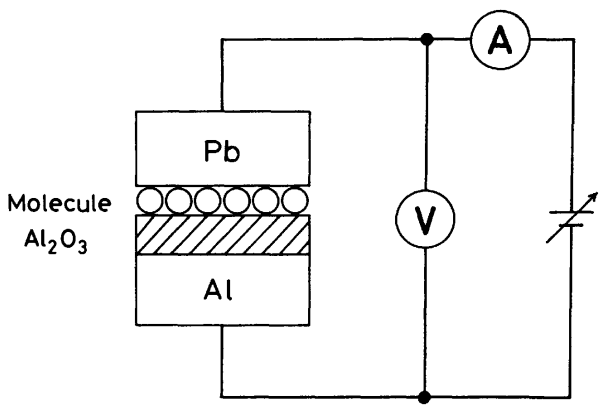

Fig. 1. Schematic representation of the tunneling junction.

The tunneling spectra of benzoic acid,[8] phenol,[9] and benzenesulfonic acid[10] have been measured and indicated their structures on the oxide surfaces. These molecules are found to be adsorbed onto the alumina as anions. The tunneling spectrum of benzaldehyde shows that this molecule reacts with alumina to give the adsorbed benzoate ion.[3,11] In the cases of molecules with two functional groups, however, not so many studies have been carried out. Lewis *et al.*[12] have observed the tunneling spectra of the isomers of catechol, *i.e.*, *o*-, *m*-, and *p*-$C_6H_4(OH)_2$, on Al_2O_3. They found that both catechol and resorcinol are adsorbed as dianions, whereas hydroquinone is adsorbed predominantly as a monoanion. Oxley *et al.*[13] have previously reported that the isomeric phthalic acids are adsorbed onto Al_2O_3 as benzenedicarboxylate ions. Monjushiro *et al.*[14] have studied the adsorption of some *o*-substituted benzoic acids onto Al_2O_3.

The vibrational spectra of isomeric phthalic acids[15] and their ions[16] were measured by means of infrared and Raman spectroscopy. Detailed diagrams for the atom motions involved in these modes can be found in the book by Varsányi.[17] A comparison between these spectra and the tunneling spectra gives valuable information on these molecules adsorbed onto Al_2O_3. Since alumina is widely used as a catalyst or catalyst support,[18] it is important to know the orientation and structure of adsorbed species in order to understand the reaction mechanism on the catalyst. The isomeric phthalic acids have two carboxyl groups. Their structure on the alumina surface can easily be clarified by examining the characteristic C=O group. In our previous paper,[19] it has been shown that terephthalic acid is adsorbed predominantly as the monocarbox-

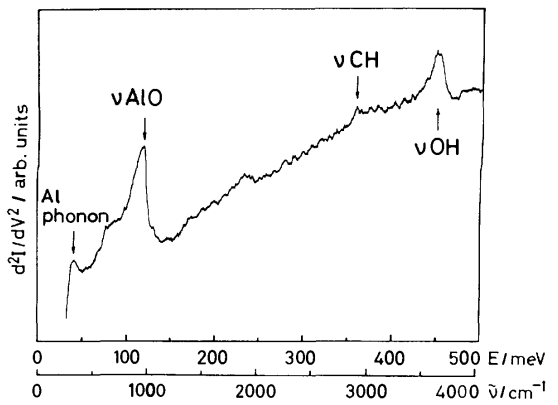

Fig. 3. Tunneling spectrum of the undoped Al-Al_2O_3-Pb junction made by an oxygen glow discharge. Junction resistance: 63 Ω; modulation voltage: 4 mVpp; time constant of the lock-in amplifier: 30 s; trace time: 109 min.

ylate ion onto the alumina surface when doped with alcohol solutions. In this paper, we will consider the tunneling spectra of phthalic, isophthalic, and terephthalic acid, together with their detailed assignments. The structure of these molecules on the alumina surface is clarified. The chemical interaction between the carboxyl groups and the surface is also discussed.

Experimental

The method of junction preparation involves evaporation and oxidation techniques in a liquid nitrogen-trapped diffusion-pumped bell jar. Aluminium (99.999%, Mituwa Chemicals) was evaporated from a molybdenum boat on a clean glass slide (13×37×1 mm) to form three strips (1 mm wide) at a pressure of 10^{-5} Torr (1 Torr=133.322 Pa). The strips were oxidized by exposure to pure oxygen (99.8%, 1 atom) or in an oxygen-dc glow discharge (400—800 V, 30 mTorr, 5 mA, 10—60 s) in the bell jar.[20]

The slide was removed from the vacuum system, dipped into a solution containing the sample molecules, and left for about 3 min to complete the adsorption. The phthalic, isophthalic, and terephthalic acid (Kanto Chemicals) were purified by recrystallization from water. Guaranteed-reagent grade methanol, ethanol and 1-propanol, and distilled water were used as the solvents.

The slide was returned to the vacuum system, and the junctions (1×1 mm area) were completed with an evaporated Pb (99.999%, Wako Chemicals) cross strip (1 mm wide). The resistance of the junction was measured with a digital multimeter (Kikusui 1502). The operations mentioned above were done in a class 10000 clean room (Airtech Japan AER-233C). The slide was mounted in a sample holder and preliminarily cooled with liquid nitrogen at 77 K. Silver paint and solder were used for attaching the leads to the junctions. The sample holder was then inserted into a liquid helium Dewar (Osaka Sanso Hi·CRIC-10), where the junctions were cooled at 4.2 K.

The tunneling spectrum was obtained by measuring the second derivative of the tunneling current through the junction at the liquid helium temperature. A diagram of the circuit is shown in Fig. 2. A 500 Hz ac modulation signal of 2.0—4.0 mV peak-to-peak from a low-distortion oscillator (NF E-1201) and a slowly varying dc voltage from a bias supply were applied to the junction. The aluminium electrode was negatively biased with respect to the Pb electrode. The modulation signal through an amplifier (LM 308H) was monitored with an oscilloscope (Kikusui 5513). The second harmonic signal was differentially amplified (LM 308AH) and detected with a lock-in amplifier (NF LI-574A), with a notch filter (NF 2BE) and a bandpass filter (NF 3BP), preceded by the bridge circuit developed by Adler and Jackson.[21] The bridge circuit achieved an ac rejection of 50 dB. The output of the lock-in amplifier was then applied to the y axis of an x-y recorder (Rikendenki F-35). The dc voltage across the junction was applied through a buffer amplifier (LM 308H) to the x axis. Acceptable resistances for the junctions were in the range of 30—3000 Ω, while matched resistances were in the range of 50—500 Ω.

Results

Performance Test of the Apparatus and Procedures. The tunneling spectrum of an undoped Al-Al_2O_3-Pb junction made by an oxygen glow discharge is shown in Fig. 3. There is a smoothly varying background due to the change in the elastic conductance as the bias voltage is increased. The features and the peak positions of the spectrum agree well with those previously reported.[1-7,22,23] The peaks at about 300 and 940 cm^{-1} are due to the aluminium phonon and the vibrational mode of the aluminium oxide respectively.[22,23] The broad peak at about 3600 cm^{-1} arises from the stretching vibration of the surface hydroxyl species. The OH bending mode appears at about 700 cm^{-1} as the shoulder of the strong peak at 940 cm^{-1}. The weak and broad structure at 1300—1900 cm^{-1} is caused by both the second harmonics of the bending mode of OH and the vibrational mode of AlO.[22] Recently, Gauthier *et al.*[23] have proposed other assignments: the structure near 1900 cm^{-1} and the shoulder at about 700 cm^{-1} are caused by the vibrational and bending mode of an aluminium hydride located near the Al-

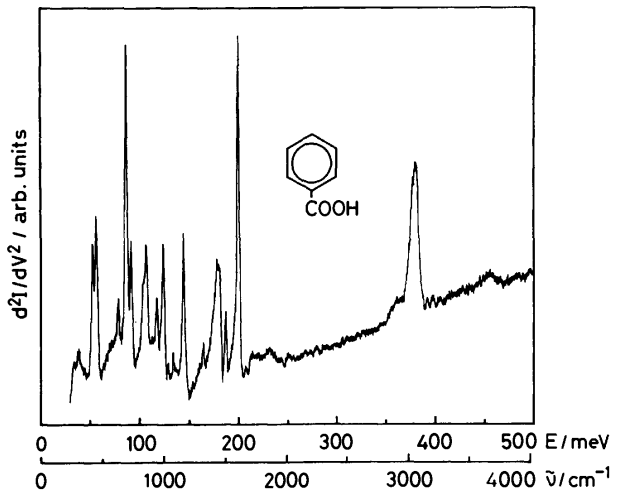

Fig. 4. Tunneling spectrum of benzoic acid doped with a methanol solution of 1.0 mg/ml. Junction resistance: 81 Ω; modulation voltage: 3 mVpp; time constant: 10 s; trace time: 154 min.

Al_2O_3 interface respectively. The peak of the OH bending mode is involved in the strong peak at 940 cm^{-1}.[23] The small peak at around 2900 cm^{-1} is due to the CH stretching mode of a hydrocarbon contamination; its very weak intensity shows that the contamination of the junction is negligible.

The tunneling spectra of benzoic acid have shown that benzoic acid is adsorbed onto the alumina surface as benzoate ion.[8,13] Tunneling spectroscopy shows that benzaldehyde reacts with Al_2O_3 and is also adsorbed as benzoate ion onto the surface.[3,11] Because of the clear features of its spectrum and the detailed assignment, the benzoate ion is a good sample for examining our apparatus and procedures.

The tunneling spectrum of benzoic acid is shown in Fig. 4. The junction was made by liquid doping with a methanol solution of 1.0 mg/ml. The spectrum was measured with a 10-s time constant of the lock-in amplifier and a 2.5-h trace time. In order to obtain a spectrum of good quality, a long trace time should be taken; it is important to spend six time constants per resolution element of the spectrum. Hansma[7] has shown that, if traces are swept faster than these times, shifts in peaks are observed. At 4.2 K, the top lead electrode is superconducting and a correction of −1 meV (−8 cm^{-1}) for the energy gap should be made to measure peak positions accurately.[24] The top lead electrode also causes the peak shifts due to the image dipole effect. The peak of the vibrational mode of the adsorbed hydroxyl species on the surface has a large shift. However, it has been shown that the shifts are less than of the order of 0.5 meV (4 cm^{-1}) for the peaks of the benzoate ion on Al_2O_3.[24] Oxley *et al.*[13] suggested that peaks may shift because of parasitic resistances of electrodes and connection leads when two-point probe measurements are carried out.

The resolution of the tunneling spectrum depends on two broadening contributions: modulation voltage broadening and thermal broadening. The tunneling spectrum in Fig. 4 was measured with a modulation voltage of 3 mV peak-to-peak at 4.2 K. The resolution was estimated to be 2.5 meV (20 cm^{-1}) by measuring the narrowest peak width in the spectrum. The peak positions of the spectrum are in good agreement with those of the spectra reported previously[3,8,11,13] as is shown in Table 1. The accuracy of the peak position of our spectrum is estimated to be ±0.5 meV (±4 cm^{-1}). These results show that our apparatus and procedures are suitable for the accurate measurement of a tunneling spectrum.

Spectra and Peak Assignments for Isomeric Phthalic Acids. The tunneling spectra of phthalic, isophthalic, and terephthalic acid doped from an ethanol solution of 0.5 mg/ml are shown in Fig. 5. For the sake of comparison, the tunneling spectrum of the ethanol solvent is also shown in the same figure. Evans and Weinberg[25] have reported that ethanol is adsorbed as ethoxide ion onto the alumina surface at room temperature. However, the weak peak intensity in the tunneling spectrum of ethanol shown in Fig. 5 indicates almost no contribution from this solvent to the tunneling spectra of isomeric phthalic acids. The tunneling spectra of methanol and 1-propanol have been measured; it has been found that their peak

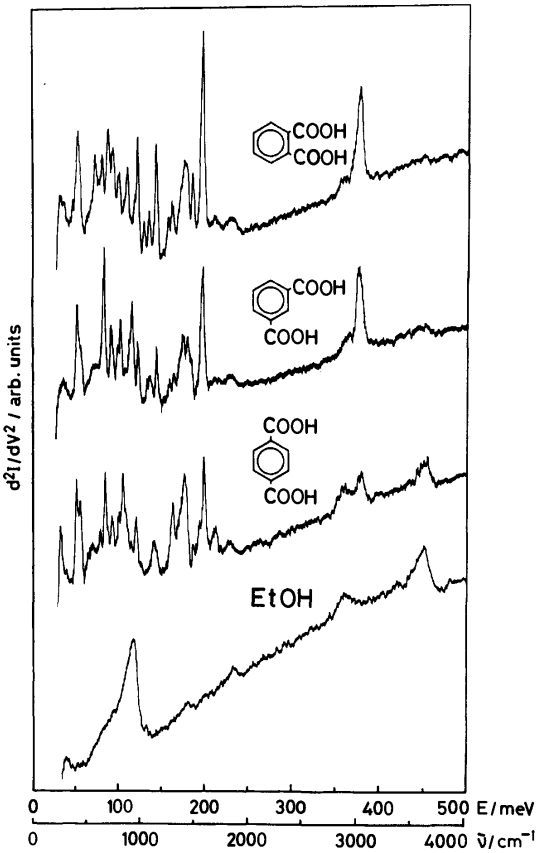

Fig. 5. Tunneling spectra of phthalic, isophthalic and terephthalic acid doped with an ethanol solution of 0.5 mg/ml. Junction resistances: 42—78 Ω; modulation voltage: 3 mVpp; time constant: 10 s; trace times: 145—200 min.

intensity is also weak enough to be neglected. Because the tunneling spectrum reveals both infrared and Raman-active vibrational modes, useful information on the adsorbed molecule is obtained by comparing the tunneling spectrum with its infrared and Raman spectrum.

Phthalic Acid: The tunneling spectrum of phthalic acid has a very weak C=O peak at 1704 cm^{-1}. The weak and broad peak at 3596 cm^{-1} is due to the vibrational mode of the surface OH species, as has been mentioned before. Instead, the tunneling spectrum has a strong symmetric stretching, a medium wagging, and a strong rocking mode of the COO^- groups at 1422, 644, and 422 cm^{-1} respectively. When a carboxylic acid is adsorbed onto the alumina surface as a carboxylate ion, the asymmetric vibrational mode of the COO^- group shares a change in the dipole moment parallel to the surface. The peak intensity of this vibrational mode in the tunneling spectrum is weak because of the orientational selection rule.[8,11] The peak of the asymmetric stretching mode of the COO^- groups of the phthalate ion is considered to be involved in the very strong peak at 1588 cm^{-1}. There is no peak corresponding to the scissoring mode of the COO^- groups. The tunneling spectra of phthalic acid doped with solutions of water, methanol, and 1-propanol

are identical with that doped with an ethanol solution. The spectrum is also independent of the acid concentration (0.1—1.0 mg/ml). These results show that phthalic acid reacts with Al_2O_3 by loosing the protons of the COOH groups and is adsorbed onto the surface as the benzenedicarboxylate ion.

The peak assignments for the tunneling spectrum are shown in Table 2, together with those for the vibrational modes of the ion obtained by means of infrared and Raman spectroscopy.[16] In this table, stretching vibrations are denoted by ν, in-plane bending modes are designated by β, and out-of-plane bending vibrations perpendicular to the plane, by γ. The symmetric or asymmetric vibration is indicated by the subscript of s or as respectively. Of the bending modes of the COO^- group, β_s designates the scissoring vibration, β_{as} denotes the rocking, and γ_s, the wagging mode. In parenthesis is shown the Wilson number for the normal vibration of the benzene ring.[16,17]

The COO^- groups of the phthalate ion are assumed to be rotated 33° with respect to the plane of the aromatic ring.[16] The phthalate ion has C_s symmetry and 42 normal vibrations, which are classified as 30 ring vibrations and 12 vibrations of the substituents. These modes are both infrared and Raman-active.[16] The ring vibrations are divided into 21 in-plane and 9 out-of-plane vibrations.[17]

Isophthalic Acid: A detailed analysis of the tunneling spectrum and a comparison with the infrared and Raman spectrum show that isophthalic acid is also

adsorbed onto the alumina surface as the benzenedicarboxylate ion. The tunneling spectrum is independent of the solvent used (water, methanol, ethanol, and 1-propanol) and the acid concentration (0.1—1.0 mg/ml). The peak assignments are shown in Table 3, together with those for the vibrational modes of the ion. The tunneling spectrum has a strong ν_s, a medium β_s, and a strong β_{as} COO$^-$ peak at 1402, 737, and 418 cm^{-1} respectively. The ν_{as}COO$^-$ peak is considered to be involved in the strong peak at 1587 cm^{-1}, as in the case of phthalic acid. There is no peak corresponding to the γ_sCOO$^-$ mode.

The isophthalate ion has 42 normal vibrations with C_{2v} symmetry. These vibrations are both infrared and Raman-active, and are classified as 30 ring vibrations and 12 vibrations of the substituents, as in the case of the phthalate ion.[16]

Terephthalic Acid: The tunneling spectrum of terephthalic acid has a medium νOH (3623 cm^{-1}) and a medium νC=O (1699 cm^{-1}) peak. The strong peak at 1423 cm^{-1} is due to the βOH and/or the ν_sCOO$^-$ mode. The peaks at 867, 619, and 436 cm^{-1} are caused by β_s, γ_s, and β_{as} of the COO group for the acid and/or the COO$^-$ group for the ion. The spectrum has a very weak ν_{as}COO$^-$ peak at 1550 cm^{-1}. This finding that the tunneling spectrum of terephthalic acid has the C=O peak and the COO$^-$ peaks indicates the presence of the monocarboxylate ion on the alumina surface. The peak assignments are shown in Table 4 with those for the vibrational modes of terephthalic acid[15] and its ion.[16]

Terephthalic acid and the terephthalate ion with a D_{2h} point group have 48 and 42 normal vibrations respectively. Of these vibrations, 30 are due to ring vibrations. In the case of these molecules, the mutual-exclusion principle holds and a vibrational mode with

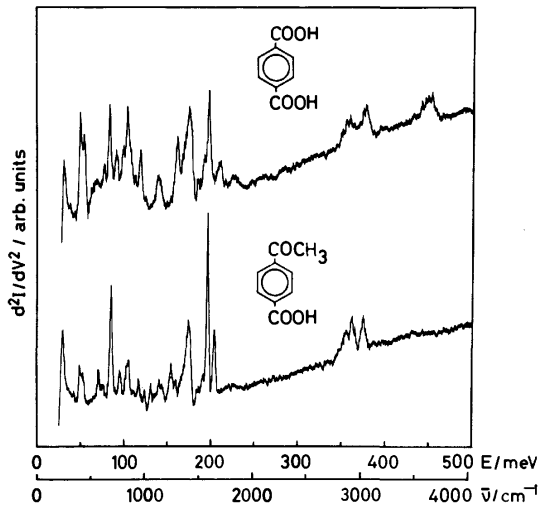

Fig. 6. Tunneling spectrum of *p*-acetylbenzoic acid doped with an ethanol solution of 0.5 mg/ml. Junction resistance: 376 Ω; modulation voltage: 3 mVpp; time constant: 10 s; trace time: 152 min. Tunneling spectrum of terephthalic acid is also shown for a comparison. The relative intensity of the C=O peak of terephthalic acid is similar to that of *p*-acetylbenzoic acid.

a symmetry species appears either in the infrared or Raman spectrum.[15,16] In Table 4, however, this principle is neglected for reasons of simplicity.

Discussion

Comparison of Tunneling Spectrum of Terephthalic and p-*Acetylbenzoic Acid.* Most peaks in the tunneling spectra of isomeric phthalic acids can be clearly identified, and their peak positions agree closely with those of the infrared and Raman spectra. This indicates that the phthalate ions on Al_2O_3 are not strongly perturbed by adsorption. However, these tunneling spectra show a difference in the chemical interaction between the COOH group and the alumina surface. It is found that both phthalic and isophthalic acid react with Al_2O_3 by loosing the protons of two COOH groups and are adsorbed onto the surface as benzenedicarboxylate ions. On the other hand, the tunneling spectrum of terephthalic acid clearly shows the unreacting COOH group, thus indicating the presence of the monocarboxylate ion on the surface. It seems that terephthalic acid is adsorbed onto Al_2O_3 as both the monoanion and the dianion.

The tunneling spectrum of *p*-acetylbenzoic acid (Aldrich Chemicals) is shown in Fig. 6, with that of terephthalic acid. The spectrum of *p*-acetylbenzoic acid has a strong νC=O (1663 cm^{-1}) and νCOO^- (1418 cm^{-1}) peak, showing that this molecule is adsorbed onto Al_2O_3 as the monocarboxylate ion.[26] The relative intensities of the νC=O to the νCOO^- peaks in both the tunneling spectra of terephthalic and *p*-acetylbenzoic acid are similar to each other. This similarity indicates that terephthalic acid is adsorbed predominantly as the monocarboxylate ion onto the Al_2O_3 such as *p*-acetylbenzoic acid.

Oxley *et al.*[13] have previously measured the tunneling spectra of terephthalic acid doped with solutions of both water and ethanol onto Al_2O_3 formed by an oxygen glow discharge. Their spectra, however, have no C=O peak, and they concluded that terephthalic acid is adsorbed onto the surface as the dicarboxylate ion. We examined the experimental conditions in detail and found that the tunneling spectra of terephthalic acid doped with a solution of 1-propanol or methanol onto Al_2O_3 formed by both exposure to oxygen and a glow discharge also have the C=O peak. The relative intensity of the C=O peak is almost independent of the acid concentration (0.01—1.5 mg/ml); this shows saturation coverage. In the case of a methanol solution, however, the relative intensity is somewhat weak. The spectrum from an aqueous solution has the very weak C=O peak. This finding may suggest that terephthalic acid is adsorbed as the dicarboxylate ion when doped with an aqueous solution. It is found that the tunneling spectrum of terephthalic acid strongly depends on the solvent used. Thus, judging from the results of a comparison between the tunneling spectra of terephthalic and *p*-acetylbenzoic acid, we conclude that terephthalic acid is adsorbed predominantly as the monocarboxylate ion onto the alumina surface at almost saturation coverage when doped with either ethanol or 1-propanol solution.

The tunneling spectrum of *p*-acetylbenzoic acid has no νOH peak, but it has the sharp and clear νC=O peak. It seems that the C=O group interacts with neither the adsorbed *p*-acetylbenzoic acid nor the alumina surface. On the other hand, the spectrum of terephthalic acid has the broad νOH and νC=O peak. Judging from the asymmetric tailing of the OH peak and the broadness of the C=O peak, hydrogen bonding seems to be present. Two types of hydrogen bonding seem to be important: hydrogen bonding among the adsorbed hydrogen terephthalate ions and hydrogen bonding between the hydroxylated alumina surface. Because terephthalic acid is adsorbed with its benzene ring nearly perpendicular to the surface at saturation coverage, as will be discussed later, and because it has the unreacting COOH group at the para position, hydrogen bonding among the adsorbed hydrogen terephthalate ions seems to be more important. A similar result has been obtained in the case of diphenol in IETS;[12] both catechol and resorcinol are adsorbed predominantly onto the alumina surface as diphenolate ions, while hydroquinone is adsorbed mainly as the monophenolate ion and extensive hydrogen bonding is observed.

Adsorption and Orientation of Isomeric Phthalic Acids. The adsorption mechanism and orientation of the isomeric phthalic acids on the alumina surface were

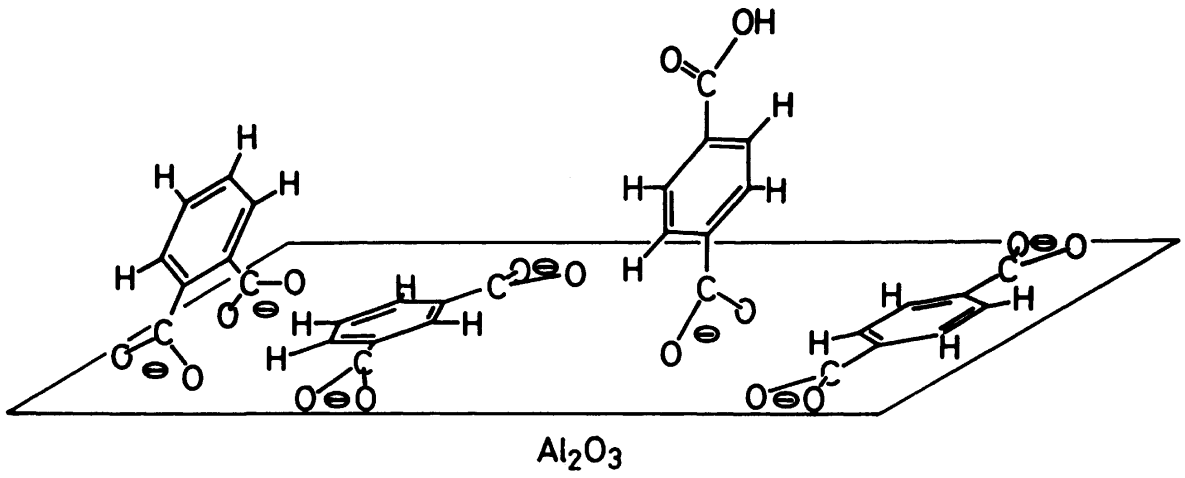

Fig. 7. Schematic representation of the adsorbed isomeric phthalic acids on Al_2O_3. Their dissociation constants in water are also shown.

studied by using a molecular model. A schematic representation of these acids on Al_2O_3 is shown in Fig. 7, with their dissociation constants in water. The isomeric phthalic acids have two carboxyl groups and they dissociate stepwise in water. For phthalic acid, the first dissociation constant is larger and the second is smaller than the others. Thus, phthalic acid may be expected to be adsorbed mainly as the monocarboxylate ion, if a similar tendency in the difference of dissociation constants holds in alcohol solutions. However, the tunneling spectra show that the structures of these acids adsorbed onto the surface are not explained by their dissociation constants; both phthalic and isophthalic acid are adsorbed mainly as dicarboxylate ions, while terephthalic acid is adsorbed predominantly as monocarboxylate ion. This finding indicates a difference in the geometry of the interaction between the alumina surface and the COOH groups of the adsorbed isomeric phthalic acids.

In the cases of phthalic and isophthalic acid, when they are adsorbed at one of the COOH groups, the other groups seem to be very close to the surface. Thus, the COOH group dissociates more easily than would be expected from their second dissociation constants. The tunneling spectra of these acids are independent of the solvent and their concentrations. These acids are considered to be adsorbed at saturation coverage. It seems that the benzene ring of the phthalate ion has a relatively large angle with respect to the surface, even if the COO^- groups are rotated, since the carbon and hydrogen atoms of the ring are not expected to interact with the alumina surface. On the other hand, because of the molecular model, the ring of the isophthalate ion is considered to be nearly parallel to the surface. The close agreement of the peak positions of the benzene ring of the tunneling spectrum of the isophthalate ion with those of the infrared and Raman spectrum shows that the ring has almost no interaction with the surface. A comparison of the tunneling spectra of the two acids indicates that the peak intensity of the out-of-plane and in-plane ring vibrational modes are comparable: Vibrations 4, 11, 10b, 5 (out-of-plane) and 6b, 1 (in-plane) for phthalic acid, and Vibrations 4, 5 (out-of-plane) and 1, 7b (in-plane) for isophthalic acid. This finding is unexpected in view of the orientational selection rule.

Kirtley and Hall[27] have calculated the peak intensity of the tunneling spectrum of the methanesulfonate ion adsorbed onto Al_2O_3 by using a transfer Hamiltonian theory. They have found that the calculated peak intensity depends strongly on the distance of the dipole from the Pb electrode; the orientational selection rule is favorable for a mode vibrating perpendicular to the surface when molecules are situated close to the interface. However, this rule does not hold for molecules deep within the insulator. Though no such calculation has been done for isomeric phthalic acids, it seems that the result of Kirtley and Hall is applicable qualitatively to the benzenedicarboxylate ions. Because the benzene rings of adsorbed phthalate and isophthalate ion are at some distance from the interface of the Pb electrode, the orientational selection rule is not expected to hold strictly. These results suggest that care must be taken to use the selection rule in discussing the orientation of the adsorbed species in tunneling spectroscopy.

In the case of terephthalic acid, since the molecule has the COOH groups at the para position, the molecule must fall and become parallel to the surface in order to be adsorbed as the dicarboxylate ion. If this process takes a longer time than the first process of

adsorption, many molecules will remain on the surface as monocarboxylate ions. The tunneling spectra doped with various alcohol solutions are independent of their concentrations and indicate saturation coverage. Langan and Hansma[28] have measured the surface concentration of the adsorbed benzoate ion on Al_2O_3. They have reported that this molecule occupies an area of 15 Å^2 at saturation coverage. This area is almost equal to that calculated from the diameter of the benzene ring (5 Å). According to this result, the adsorbed hydrogen terephthalate ion is also considered to occupy the same area of the surface and thus can not fall at saturation coverage. Therefore, the terephthalic acid remains on the surface as the monocarboxylate ion. The observed hydrogen bonding also supports the predominance of the hydrogen terephthalate ion on the surface.

Concluding Remarks. The detailed analysis of the vibrational spectra of the isomeric phthalic acids adsorbed onto Al_2O_3 from alcohol solutions makes it possible to clarify the difference in chemical interaction between the COOH group and the surface. This difference is caused by their orientations and the different probabilities of chemical interaction between the COOH group and the surface. These results suggest the importance of the orientation of adsorbed species for their reactivity and selectivity on an alumina catalyst. Inelastic electron tunneling spectroscopy is a useful analytical tool for investigating the adsorbed species on the oxide surface and their chemical interaction with it.

The authors wish to thank Professor Dr. Hirochika Enokiya of the Faculty of Science for his help in preparing liquid helium for our use. The authors also wish to thank Dr. Siegfried Ewert of Technische Hochschule Aachen (Fed. Rep. of Germany) for his valuable comments. The present study was partially supported by a Grant-in-Aid for Scientific Reserch No. 59750622 from the Ministry of Education, Science and Culture.

(Received April 26, 1985)

Eight isomorphous 2-naphthalenesulfonato complexes of lanthanoids(III) (Pr, Nd, Sm, Eu, Gd, Dy, Er, and Yb) were synthesized, and the structures of five of them were determined by the single-crystal X-ray-diffraction method. They are monoclinic, with the space group of $P2_1$; the cell constants of the Pr^{III} complex, for example, were $a=18.228(8)$, $b=7.498(4)$, $c=14.177(9)$ Å, $\beta=107.75(4)°$, $Z=2$, and its final R value was 0.043. The unit-cell size of the complex decreases with the increase in the atomic number of the metal atom. The central metal atom is in a square-antiprism geometry and is octa-coordinated with two unidentate 2-naphthalenesulfonato ligands and six water-oxygen atoms. Nonligated oxygen atoms of the sulfonato ions form hydrogen-bonds with the coordinated and lattice water molecules to form a double-layered network along the ab-plane. All the naphthalene rings stand together to form hydrophobic sheets between the hydrogen-bonding networks.

It has already been reported by several authors that the carboxylato or the oxoacid-anionic ligands are coordinated to the metal atoms in a variety of ways, especially in their lanthanoid complexes. In the cases of carboxylato ligands, they act not only as unidentate, but also as bidentate chelating or bridging ligands.[1-5] In the case of the sulfato complexes, the ligands act as bridging ligands or as the chelating bidentate.[6,7] Therefore, it is very interesting to examine the coordination geometry of some sulfonates of lanthanoid(III). The structure of the lanthanoid(III) ethyl sulfate enneahydrates has already been clarified.[8,9] In their crystals, not the ethyl sulfate ions but nine water molecules are ligated to the central metal atom, and the sulfate anions as well as the water molecules, including the coordinated ones, are linked by the network of hydrogen bonds.

This time, we have succeeded in obtaining the title complexes in the crystalline state. Therefore, we have tried to determine their structures by the single-crystal X-ray-diffraction method: not only the structure of one complex, but also a series of isomorphous ones were investigated comparatively, especially with regard to the changes resulting from the increase in the atomic number of the central metal atom.

Experimental

Synthesis of [Hexaaquabis(2-naphthalenesulfonato)praseodymium(III)] 2-Naphthalenesulfonate Trihydrate. Praseodymium(III) chloride hexahydrate (1.0 g, 2.8 mmol) and sodium 2-naphthalenesulfonate (2.1 g, 9.1 mmol) were dissolved in about 20 cm^3 of a warmed ethanol-water mixed solvent (2:1=v/v), after with the solution was stirred and filtered while it was hot. When the filtrate has cooled, the complex was deposited, and the product was collected and washed by the mixed solvent, ethanol, and diethyl ether, in that order. The yield was 1.5 g on the average (1.6 mmol, 58%). The neodymium, samarium, europium, gadolinium, dysprosium, erbium, and ytterbium complexes were also obtained in almost the same way; the yields were about 60% on the average. The complexes thus obtained could be recrystallized from the ethanol-water (2:1=v/v) mixed solvent. The crystals used for the single-crystal X-ray-diffraction method were those deposited from the 2-propanol-water (2:1=v/v) mixed solvent solution, which had been left standing in open vessels over a silica-gel desiccator at the ambient temperature. Attempts to obtain the lanthanum(III) and cerium(III) complexes using the same operation were not successful, probably because the stable forms of their complexes are different from those of the heavier lanthanoids. The europium(III) complex is colorless, implying that there is no charge-transfer band such as is observed in some *O,O'*-dialkyl dithiophosphates of the metal.[10] Anal. ($MC_{30}H_{39}O_{48}S_3$) M, C, H. (M=Pr, Nd, Sm, Eu, Gd, Dy, Er, and Yb).

Single-crystal X-Ray Analyses. All of these complexes were found to be isostructural from their X-ray powder patterns; the structures of five complexes (M=Pr, Eu, Gd, Er, and Yb) were determined by the single-crystal X-ray-diffraction method. They are monoclinic, space group $P2_1$, $Z=2$; their other crystallographic data are shown in Table 1, together with some experimental conditions and the final R values, obtained by applying the anisotropic thermal parameters to all the non-hydrogen atoms.[11]

The reflections in the ranges shown in Table 1 were collected on a Rigaku AFC-6A automated four-circle X-ray diffractometer with graphite-monochromated Mo$K\alpha$ radiation (the scan speed was 4°min^{-1}), the ω—2θ scan technique being employed; the scan widths were $(1.03+0.5\tan\theta)°$ for the praseodymium, europium, and ytterbium complexes, $(1.05+0.5\tan\theta)°$ for the samarium complex, and $(1.37+0.5\tan\theta)°$ for the erbium complex. The intensities were corrected for Lorentz and polarization factors, but not for absorption and extinction. Reflections with $|F_o|>3\sigma(|F_o|)$ were used for refinements.

Structure Determination. The structure of the praseodymium(III) complex was solved by the heavy-atom

method. The positions of the metal and some sulfur atoms were deduced from the three-dimensional Patterson map. The positional and thermal parameters were refined successively by the repeated block-diagonal least-squares method and by the Fourier syntheses.

At the end, all the non-hydrogen atoms were found. The positions of the naphthalene hydrogen atoms were calculated by assuming the C-H bond-length to be 1.08 Å; their B_{iso}'s were assumed to be 6.0. The parameters of the hydrogen atoms were fixed in the refinement.

The structures of the other isomorphous complexes were solved by starting with the parameters of the praseodymium(III) complex. As the crystals have no center of symmetry, refinements using inverse chirality were also carried out. For each complex, we adopted the chirality which gave a lower R-value; the respective final R-values for the alternate chirality are also shown in Table 1. According to our selection, europium and gadolinium complexes can be expected to have the structure opposite to that of the other three.

All the calculations were carried out on a HITAC M-280H apparatus at the Computer Center of The University of Tokyo, using the local version of the UNICS program.[12] The atomic-scattering factors were taken from Ref. 13.

Other Measurements. The X-ray powder patterns of these complexes were obtained by the use of a diffractometer, Model DX-GO-F JEOL, using Cu $K\alpha$ radiation in the range from 4° to 30° in 2θ. Their infrared absorption spectra were obtained by means of a JASCO A-202 grating infrared spectrophotometer, using Nujol and hexachloro-1,3-butadiene mull.

Results and Discussion

The final atomic parameters of the complexes are listed in Table 2 (1—5), while some bond lengths and angles as well as some interatomic distances, which are thought to be the hydrogen-bonding ones, are tabulated in Table 3.[14] A perspective drawing of the praseodymium(III) complex around the central

a) The equivalent isotropic temperature factors were computed using the following expression: $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{13}ac\cos\beta)$. The B_{ij}'s are defined by: $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2klB_{23}+2hlB_{13}+2hkB_{12})]$.

metal atom, as well as the numbering scheme, is shown in Fig. 1. The crystal packing diagram is shown in Fig. 2, and the linkages between the complex molecules, in Fig. 3, schematically.

The central metal atom is octa-coordinated and is in a deformed square-antiprism geometry, where two oxygen atoms of the respective 2-naphthalenesulfonato ligand, as well as six water-oxygen atoms, are ligated. The naphthyl group of the ligand is large and is, moreover, non-polar compared with the polar moiety around the central metal atoms. Therefore, two coor-

a) The average of M-O(Wn)(n=1—6), where the oxygen atom are ligated to the metal atom. b) The average of the bond lengths between the central metal atom and all the ligated oxygen atoms around it. c) The sum of the metal (tripositive, octacoordinated) and the oxygen (dinegative, dicoordinated) ionic radii proposed by Shannon.[15] d) The average of the S(1)-O(1) and S(2)-O(4), where both the oxygen atoms are ligated. e) The average of all nine S-O bond lengths of the sulfonate ions in the complex. f) Keys to the symmetric operations: ii, 1.0−x, −0.5+y, 1.0−z; iv, 2.0−x, −0.5+y, 1.0−z; v, 2.0−x, 0.5+y, 1.0−z; vi, x, 1.0+y, z for the Pr, Er and Yb comolexes, and the corresponding ones for the Eu and Gd complexes, which have the opposite structure.

dinated sulfonato ligands, and consequently the ligated O(1) and O(4) atoms, take the positions around the metal atom the most separated from each other.

As is shown in Table 3, the M-O distances to the ligated sulfonato oxygen atoms are shorter than those to the ligated water-oxygen atoms. The latter distances almost exactly agree with the sum of the respective metal (M^{3+}, in octa-coodination) and oxygen (O^{2-}, in di-coordination) ionic radii reported by Shannon.[15] On the other hand, as the former M-O bond lengths are shorter than the respective sums, the bondings can be expected to be stronger than the common M-O bonds of the lanthanoid complexes. Although the M-O(1) bond length is clearly shorter than the sum, even in the heavy lanthanoid complexes, the differeces between the M-O(4) bond length and the sum of the ionic radii are not very large, especially in the erbium and ytterbium complexes. In the case of the tetraacetato complexes of lanthanoids (M=La···Sm), the weakest M-O bond length in the complex was found to increase with the decrease in the atomic number of the central metal atom because of the loss of its coordination space around the metal atom, while the other M-O bond lengths decrease depending on the decrease in the metal atomic radius caused by the lanthanoid contraction.[3] In this case, the same tendency was recognized: the M-O(1) bond length, which is supposed to be stronger than M-O(4), is always shorter than the metal-aqueous oxygen-atom bond lengths, while the weaker M-O(4) bond is weakened to almost the same extent as the metal-water oxygen-atom ones when the atomic number of the central metal atom increases.

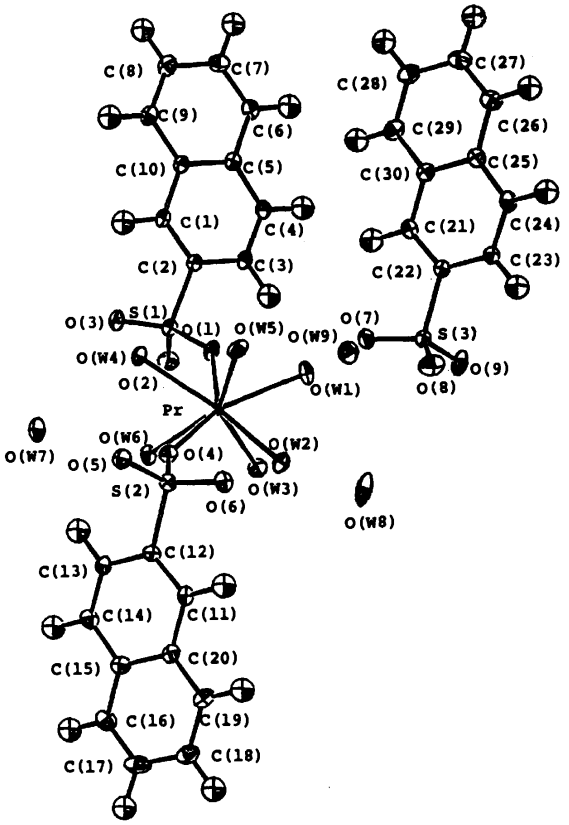

Fig. 1. A perspective drawing of the praseodymium (III) complex with the numbering scheme.

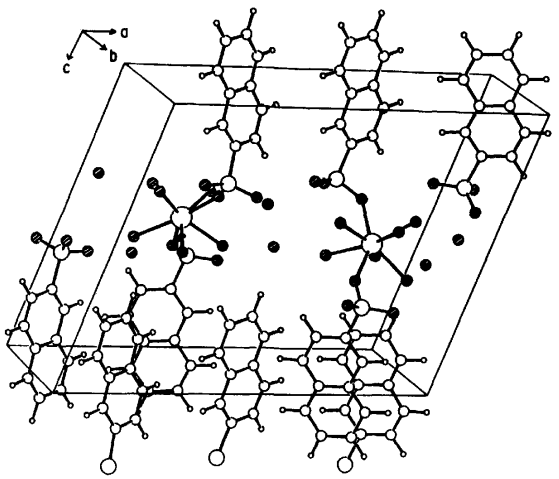

Fig. 2. Crystal packing diagram of the praseodymium(III) complex.

The planarity of the square of the square-antiprism geometry around the metal atom including O(1) is not so exact as that containing O(4). The deformation is caused by the M–O(1) bond, which is stronger than the M–O(4) bonding.

As is shown in Fig. 2, the crystal is composed of alternate layers of hydrophilic and hydrophobic groups parallel to the ab plane. The metal atoms are almost on the plane (0 0 2), and the oxygen atoms are coordinated from both sides of the plane. The oxygen atoms on each side form a hydrogen-bonding network; although there are some hydrogen bondings between the two networks, there are not many.

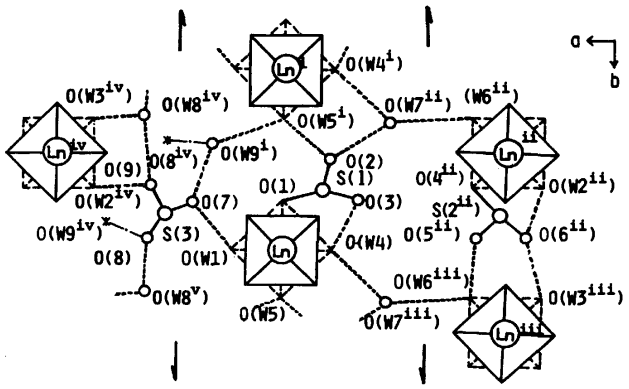

Fig. 3. The schematic presentation of the bridgings between the lanthanoid(III) complex molecules. The network shown in the figure is that in the layer lower than the metal atom plane. As the two-fold screw axes exist, which are shown in the figure, the same type of the linkage-network exists also in the upper layer. Keys to the symmetric operations: i, x, $-1.0+y$, z; ii, $1.0-x$, $-0.5+y$, $1.0-z$; iii, $1.0-x$, $0.5+y$, $1.0-z$; iv, $2.0-x$, $-0.5+y$, $1.0-z$; v, $2.0-x$, $0.5+y$, $1.0-z$.

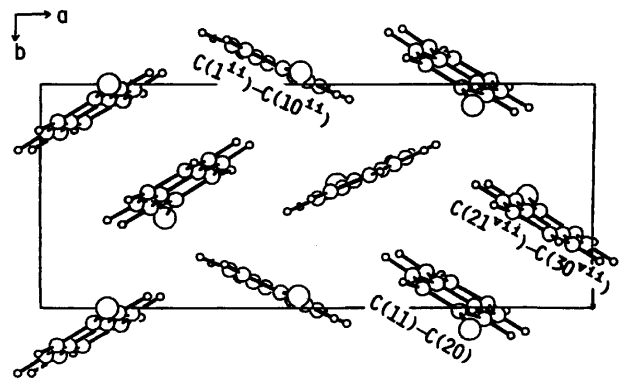

Fig. 4. Packing projection of the naphthalene rings together with the sulfonato sulfur atoms of the anions on the (0 0 1) plane. Keys to the symmetry operations: ii, $1.0-x$, $-0.5+y$, $1.0-z$; vii, x, y, $1.0+z$.

Figure 4 shows the packing of the naphthalene rings projected on the ab plane. They stand almost perpendicular to the ab plane. The angles between the ab plane and the C(1)–C(10), C(11)–C(20), and C(21)–C(30) rings are 89.1, 81.6, and 84.3° respectively in the praseodymium(III) complex. There is a tendency for these angles to become larger with the decrease in the unit-cell volumes. The C(11)–C(20) ring is almost parallel to the C(21)–C(30) ring, and when the former ring is projected on the latter plane, about 33% of the area overlaps. In the case of the praseodymium(III) complex, the distance between these rings is from 3.387 to 3.619 Å, which is almost the same as the thickness of the aromatic molecules;[16] however, the distance decreases with the decrease in

Table 4. The interfacial distances (l/Å) and the angles (ϕ/°) to the 001 plane of the sulfonato naphthalene rings

M=	Pr	Eu	Gd	Er	Yb
Interfacial min.	3.387	3.360	3.374	3.380	3.370
distances[a] max.	3.619	3.581	3.608	3.575	3.561
Angles of planes[b]					
C(1)-C(10)	89.09	89.18	89.27	89.35	89.52

a) The respective maximum and minimum interfacial distances between the naphthalene rings, C(11)-C(20) and C(21^{vii})-C(30^{vii}),[b,c] which are almost parallel to each other. b) Respective naphthalene rings are shown by the included carbon atoms. c) Key to the symmetric operation: vii x, y, 1.0+z.

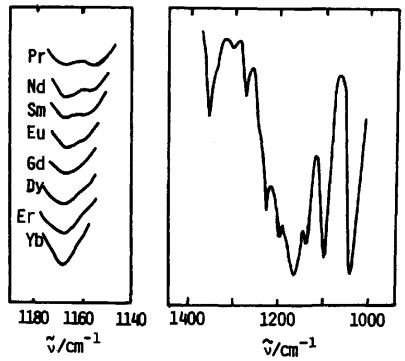

Fig. 5. Infrared absorption spectra of the complexes in the ν(S=O) region. Right; the spectrum of the gadolinium(III) complex in the region. Left; the peak of ν(S=O) of the complexes (the name of the central metal atoms are shown in the figure).

the unit-cell parameters because of the lanthanoid contraction of the central metal ion. The interfacial distances and the angles to the ab plane of the naphthalene rings are shown in Table 4. Thus, the naphthalene rings are packed quite closely to form a hydrophobic layer between hydrophilic layers.

The infrared spectrum of the ν(S=O) region of the gadolinium(III) complex is shown in Fig. 5; the general features of the spectra of the other complexes are almost the same throughout the region from 400 to 4000 cm^{-1}. A slight difference between them was, however, found in those of the peaks at about 1100 cm^{-1}; the peak at 1100 cm^{-1} is identified as one of the ν(S=O) peak of the sulfonato group.[17] The peak of the praseodymium(III) complex split into two; 1167 and 1156 cm^{-1}. The latter peak is weakened when the atomic number of the central metal atom increases; in the case of the ytterbium(III) complex, only a slight shoulder was observed at the lower-wave-number side of the 1167 cm^{-1} peak.

The authors wish to thank the Shin-Etsu Chemical Ind. Co., Ltd., for presenting the highly pure lanthanoid oxides.

Conductometric Study of Cobalt(II), Nickel(II), Copper(II), and Zinc(II) Perchlorates in Methanol–Ethylene Glycol Mixtures

Hidekazu DOE* and Toyokichi KITAGAWA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received April 30, 1985)

The ionic association constants of $M(ClO_4)_2$ (M=Co, Ni, Cu, Zn) were determined by conductometric measurements in methanol–ethylene glycol mixtures of 100, 80, 60, 40, 20, and 0 wt% methanol compositions at 5, 15, 25, 35, and 45 °C. The conductometric data were analyzed using a modified Fuoss and Edelson method. The association constant of an ion pair $M^{2+}ClO_4^-$, K_{1A}, was studied and thermodynamic functions, ΔH_{1A}° and ΔS_{1A}°, for that association were determined at 25 °C. Free-energy changes, ΔG_{1A}° ($=-RT\ln K_{1A}$), at 25 °C which slowly decreased with an increase in the ethylene glycol content in a solvent, are in good agreement with estimates from Fuoss' theory regarding ionic association. Values of both ΔH_{1A}° and ΔS_{1A}° were positive in many systems: *i.e.*, unfavorable enthalpy and favorable entropy changes, and those were obtained near to estimates from the Fuoss' theory in pure methanol, 100 wt%. However, there have been a few systems with a negative ΔH_{1A}° (Co, Ni, and Zn at 40 and 20 wt%, and Co at 0 wt%), contrary to theoretical expectations. These results are discussed from the standpoint of a changing solvation between M^{2+} and $MClO_4^+$. In all the solvents, moreover, the ΔH_{1A}° and ΔS_{1A}° values have been in a sequence according to Co<Ni<Cu>Zn. The results of limiting molar conductances, Λ_0, are discussed regarding Walden products.

Many problems concerning ionic solvation have been attracting the attention of chemists in various fields.[1] After taking some interest in the ionic associations between divalent metal cations and a perchlorate anion, we previously[2] made a study of various $M(ClO_4)_2$'s in methanol. In that study, conductometric data were treated using the Fuoss and Edelson method in which an ion-activity coefficient of M^{2+}, y_{2+}, was calculated using the Debye-Hückel second approximation in a manner different from the original paper. There, the Debye-Hückel limiting equation was used.[3] According to our calculation, the ionic association constant of $M^{2+}ClO_4^-$, K_{1A}, is about 10% less for the second approximation than for the limiting equation. The Fuoss and Edelson method was also established on the basis of the Onsager limiting equation. As done in the y_{2+}-calculation, it would therefore be more desirable to treat conductance data using an approximation involving the factor $1+\kappa a$ for moderate concentrations[4] than the Onsager limiting equation. Thus, using such a modified Fuoss and Edelson method, we have made a study of the ionic associations of Co(II), Ni(II), Cu(II), and Zn(II) perchlorates in methanol–ethylene glycol (EG) mixtures.

Both methanol and EG are amphiprotic nonaqueous solvents, but they are typical ionic media like water. The molecular volume of EG, which has a molecular structure that combines two methanol molecules, is less than twice that of methanol. The viscosity of EG is much larger than that of methanol. Their dielectric constants are also different from each other. Of course, methanol and EG resemble each other relatively, regarding their chemical properties as solvents. Therefore, research concerning their mixtures should yield good information concerning various solvent effects due to differences in physical properties: viscosity, dielectric constant, molecular volume, compressibility, *etc.*

Experimental

Materials. The preparation and purification of $M(ClO_4)_2\cdot 6H_2O$ salts were described previously.[2] Methanol and EG were dried over 3A molecular sieves and distilled fractionally. EG was distilled under a reduced pressure of 25 mmHg.† The electric conductivities of the purified methanol and EG were 1.5×10^{-7} and 1.6×10^{-8} S cm^{-1} at 25 °C, and the water contents were 0.023 and 0.024 wt%, respectively. The mixed solvents were prepared by weighing each solvent to an accuracy of $<\pm0.05$%. All reagents were special grade materials (Wako).

Physical Properties of Solvents. The densities of solvents at 25 °C were determined using a vibrating densimeter (Model 01D, Sodev Inc., Sherbrooke, Canada), with chlorobenzene and methylcyclohexane as standards.[5] The accuracy of the measurements was $\pm2\times10^{-5}$ g cm^{-3}. The densities of pure methanol and EG at other temperatures were calculated using $v=v_0(1+\alpha_1 t+\alpha_2 t^2+\alpha_3 t^3)$, where v and v_0 are the volumes of the solvents at t and 0 °C, respectively. The α's are the thermal-expansion coefficients (α_1, α_2, and α_3 are 1.1342×10^{-3}, 1.3635×10^{-6}, and 0.8741×10^{-8} for methanol, and 0.5657×10^{-3}, 1.7074×10^{-6}, and 0.293×10^{-8} for EG, respectively).[6] Densities of the mixtures at temperatures other than 25 °C were also calculated based on the densities of pure solvents at corresponding temperatures and volume change rates of mixing. Then, it was assumed that the rates at 25 °C, which can be calculated based on densities of the mixtures at 25 °C, are equal to those at the other temperatures. The results are shown in Table 1.

Using an Ostwald viscometer, viscosities were measured in the usual way. Water was used as a standard substance.[7] The viscosity results are summarized in Table 2.

Measurements of dielectric constants were carried out by a resonance method at a frequency of 1 MHz. Constants for the standard methanol are cited from Albright and Gosting.[8] The results are shown in Table 3.

Temperatures were controlled within an accuracy and

† 1 mmHg≈133.322 Pa.

precision of ±0.01 and ±0.0005 °C for density, ±0.05 and ±0.01 °C for viscosity, and ±0.05 and ±0.02 °C for the dielectric constant measurements, respectively.

Electric Conductances. The measurements were carried out with a Yanagimoto Model MY-8 conductivity outfit and a type C cell, which had a cell constant of 0.3801± 0.0006. This represents a mean value calibrated at 5, 15, 25, 35, and 45 °C with potassium chloride (Aldrich, 99.999% reagent).[9] All temperatures were controlled with an accuracy of $<\pm0.1$ °C using a Sharp TE-12K thermoelectric circulating system. The ClO_4^- concentrations, c, of the measured solutions were in the range of 1.5—20×10^{-4} M (M=mol dm^{-3}). When, therefore, a hexahydrated $M(ClO_4)_2$ solution of $c=2\times10^{-3}$ M was prepared, water of about 0.014 wt% was added to the solvents, inherently containing water of 0.023—0.024 wt%. However, this increase in water probably did not much affect our results and are negligible in comparison with other experimental errors. The measured solutions were prepared in an air-conditioned room (about 25 °C) and their molar concentrations were taken as those at 25.0 °C. Molarities at other temperatures were corrected using the densities of the corresponding temperatures.

Data Treatment

Conductometric data were treated using a modified Fuoss and Edelson method. According to the original method,[3] only the ionic equilibrium was considered:

$$M^{2+} + ClO_4^- \rightleftharpoons MClO_4^+ \quad (K_{1A}) \tag{1}$$

Then they derived the following equation based on the Onsager limiting law:

$$\Lambda F = \Lambda_0 - XK_{1A}/\Lambda_0 \tag{2}$$

where

$$X = cy_{2+}\Lambda F(\Lambda F - \Lambda_0/2)$$
$$F = \{(1-\delta c^{1/2})^{-1} + (\Lambda_0-\lambda_0)/2\Lambda\}/\{1+(\Lambda_0-\lambda_0)/2\Lambda_0\}$$

where Λ and Λ_0 are the molar and the limiting molar conductances of $1/2\,M(ClO_4)_2$, respectively. λ_0 and c are the limiting molar conductance of ClO_4^- and the total concentration of ClO_4^-, respectively. The symbol δ is Onsager's slope divided by Λ_0. In previous papers,[2,10] the ion activity coefficient of M^{2+}, y_{2+}, was calculated using the Debye-Hückel second approximation (Eq.3) with an ion-size parameter, a, of 6 Å:[2]

$$\log y = -Az_i^2 I^{1/2}/(1+BaI^{1/2}) \tag{3}$$

The Fuoss and Edelson function, F (in Eq. 2), has been calculated by us using Eq. 4 in which $\delta c^{1/2}/(1+BaI^{1/2})$ is used instead of $\delta c^{1/2}$:

$$F = [\{1-\delta c^{1/2}/(1+BaI^{1/2})\}^{-1} + (\Lambda_0-\lambda_0)/2\Lambda]/\{1+(\Lambda_0-\lambda_0)/2\Lambda_0\} \tag{4}$$

I indicates the ionic strength: $I=1.5\times c$.

λ_0 is 70.1 Scm^2 mol^{-1} in methanol at 25.0 °C.[11] Since, however, we had no data regarding the λ_0's at other conditions, solvents and temperatures, we calculated them on the basis of a value of 70.1. Briefly speaking, they were determined proportionally to mean Λ_0 values of $Co(ClO_4)_2$, $Ni(ClO_4)_2$, and $Zn(ClO_4)_2$ at the respective conditions. The evaluation procedure of λ_0 and the thermodynamic functions, $\Delta H_{1A}^\ominus$ and $\Delta S_{1A}^\ominus$, have been described in more detail elsewhere.[2]

Results and Discussion

Limiting Molar Conductances. The result of limiting molar conductances (Table 4) will be scrutinized *via* the Walden product, $\Lambda_0\eta$. Plots of the $\Lambda_0\eta$ of $Zn(ClO_4)_2$ are shown in Fig. 1 as functions of the wt% composition of methanol. As shown in this figure, there are three characteristics of the $\Lambda_0\eta$'s for all the $M(ClO_4)_2$'s. 1) $\Lambda_0\eta$ increases upon going from

methanol to EG; from 100 to 0 wt%, ($\Lambda_o\eta$'s of EG are about 1.6 times as large as those of methanol). 2) $\Lambda_o\eta$'s of all the systems except Cu in methanol decrease with an increase in temperature: negative temperature coefficients of $\Lambda_o\eta$. 3) The negative temperature coefficient (characteristic 2) is most significant at 40 wt% (in the 40 wt% mixture, $\Lambda_o\eta$'s at 5 °C are 1.06—1.09 times as large as those at 45 °C). Molar ionic conductances of these divalent metal ions are larger than those of hydrophilic structure-making ions like Li^+ and Na^+ in methanol. Probably the primary solvation shells of the M^{2+}'s are relatively firm and considerably structured in methanol.[2] We think the same situation can also be established in EG. Therefore, the M^{2+} must move with only the primary solvation shell in the solvents and the effect of the secondary solvation appears to be very small. The size of the primary solvated ion is expected to be smaller in EG than in methanol because of the high solvating power of EG.[12] Thus, this is probably a cause of

characteristic 1. In a previous work regarding methanol systems, a brief description concerning negative temperature coefficients was made using the thermal expansion of a solvated ion.[2] However, these coefficients are too negative in EG-rich solvents to be explained in terms of thermal expansion. According to a well known structure effect,[13] ClO_4^- (a typical structure-breaking ion) can exhibit a large negative temperature coefficient for the Walden product in EG-rich solvents, if EG is a highly structured solvent in comparison with methanol. If so, this could also be applied to an explanation of characteristic 1.

On the other hand, we think that the large negative temperature coefficients of $\Lambda_o\eta$ in EG-rich solvents might be closely related to the density, the molecular volume, and/or the compressibility of the solvents. Methanol has a larger molecular volume for its molecular structure (*cf.* introduction) and has a much higher compressibility than EG. That is to say, methanol is expected to have loose interactions and wide spaces among methanol molecules in comparison with EG. Hence, it appears that a change in the size of a solvated ion exerts a larger influence on $\Lambda_o\eta$ in dense EG than in methanol. In connection with an explanation of characteristic 1, it may be further inferred that the primary solvated M^{2+}, which moves as a single kinetic unit, exhibits a structure-breaking effect in dense and viscous (probably highly structured) EG. As shown in the density data (Table 1), mixed solvents of methanol-EG have negative excess volumes of mixing. The maximum volume decrease occurs at 40 wt%. Analogically, this may be a cause of the characteristic 3. As another cause of characteristic 3, we think that the sizes of solvated ions in the mixtures increase with a temperature increase because the proportion of methanol and EG molecules in the sheath of solvation (and/or the structure of the sheath) varies with temperature.

Ionic Association Constants. The results of K_{1A} are summarized in Table 5. Before a discussion regarding them, it is necessary to describe the difference between the previous[2] and the present results for pure methanol: in the previous study we took no account of the $1+\kappa a$ term in the conductance equation. Because the $1+\kappa a$ term has been introduced in the conductance equation of the present study (Eq. 4), the present K_{1A}'s have become larger than the previous ones though there are no changes in the order of magnitude of K_{1A}. The present values are 1.84 ($Co(ClO_4)_2$ at 45 °C) −2.45 ($Zn(ClO_4)_2$ at 5 °C) times larger than previous ones. These ratios seem to be larger, the smaller K_{1A} is, and to be smaller, the higher the temperature is. Similar results were obtained for K_{1A} of alkaline-earth metal perchlorates. Some of these have been reported elsewhere.[14]

The K_{1A} values (Table 5) will be discussed *via* the

a) Calculated by Fuoss' theory at a distance of closest approach of 6 Å.[15]

influences of the following three variables: metal element, solvent composition, and temperature. Regarding the influences from different metal elements, there are few remarkable characteristics. According to a discussion in a previous paper,[2] these metal ions make relatively firm primary solvation shells in methanol, probably much more in EG. Therefore, it is thought that specific properties of the metal ions hardly appear in the K_{1A} values. We have to get more information concerning ionic association in order to understand the small and vague variations in K_{1A}.

The K_{1A} values tend to decrease with an increase in the EG content of the solvent; the tendency is the stronger the higher the temperature is. It is sure that such a decrease in K_{1A} is partly due to an increase in the dielectric constants of EG-rich solvents. If, however, this decrease is observed more carefully, it is found that the K_{1A} values decrease sharply up to 40 wt%, but slightly and irregularly between 40 and 0 wt% for all the salts. This can not be interpreted by the increase in dielectric constants. However, it might be explained by a view that a change in the composition and/or structure of the M^{2+} solvation shell caused by the ionic association depresses the stabilization of ion pairs M^{2+}(solvated)ClO_4^- in mixed solvents.

The temperature influence, according to the results of ΔH_{1A}° at 25 °C (Table 6), is complicated, but interesting. Curves of $\ln K_{1A}$ plotted as a function of T^{-1}, $d(\ln K_{1A})/d(T^{-1})=-\Delta H_{1A}^\circ/R$, have various shapes in the present systems. Though there are some interesting characteristics regarding the shapes of these lines, we have too little information to discuss them here. The results of ΔS_{1A}° and ΔG_{1A}° at 25 °C are also summarized in Table 6, and their values are compared with theoretical values calculated using Fuoss' theory concerning ionic association with at the distance of closest approach (6 Å).[15] The previous results for methanol (the previous K_{1A}'s were smaller than the present ones) are compared with values calculated for a distance of 7.4 Å. This is an estimation for an ion pair $M(CH_3OH)_6^{2+}ClO_4^-$ perfectly separated by a primary solvation shell of M^{2+}.[2]

According to the results of ΔH_{1A}° (Table 6), only $Cu(ClO_4)_2$ has a tendency different from the other $M(ClO_4)_2$. The ΔH_{1A}°'s of $Cu(ClO_4)_2$ (except in pure methanol) are in good agreement with the theoretical values if their errors are considered. On the other hand, the ΔH_{1A}°'s of $M(ClO_4)_2$ (except $Cu(ClO_4)_2$) have common characteristics. ΔH_{1A}°'s at 100 wt% are in good agreement with theoretical values. These rapidly decrease with an increase in the EG content of the solvent until 40—20 wt% (where the composition goes to 0 wt%: pure EG, those get to increase reversely). It is especially noteworthy that the ΔH_{1A}° values at 40—20 wt% are negative (the electrostatic theory of ionic association never gives a negative value to ΔH_{1A}°).[2] If the positive value of ΔH_{1A}° (and/or the positive value of ΔS_{1A}°) is explained by the fact that a solvation of M^{2+} is weakened by the ion pairing of $M^{2+}ClO_4^-$, the small ΔH_{1A}°, including the negative one, (and the small ΔS_{1A}°) in EG rich solvents will probably mean that the degree of the weakening of the M^{2+} solvation is small because of the high solvating power of EG. The very small values of ΔH_{1A}° at 40—20 wt% may also be explained by the view that the enthalpic instabilization of a M^{2+} solvation attended by $M^{2+}ClO_4^-$ ion pairing is depressed due to the change in the com-

position and/or the structure of the solvation shell (simultaneously an entropic stabilization is depressed considerably). On the other hand, the positive ΔH_{1A}° of Cu probably has some relation to a Jahn-Teller distortion of its solvation shell,[2] though we can not present a detailed discussion now.

As mentioned in the discussion regarding K_{1A}, the ΔG_{1A}° values of all the $M(ClO_4)_2$ are similar to each other, and are in good agreement with the theoretical values. That is to say, because ΔS_{1A}° mutually complements ΔH_{1A}° for ΔG_{1A}°, the results of ΔS_{1A}° will also support the above discussion for the results of ΔH_{1A}°. Moreover, it is very interesting that the values of both ΔH_{1A}° and ΔS_{1A}° have been in the sequence of Co<Ni<Cu>Zn in all the solvents. In order to understand this, it will be necessary to make further investigations.

In conclusion, the primary solvated M^{2+} moves as a single kinetic unit and the secondary solvation only gives small effects on the Walden products of M^{2+} in the solvents. The size of the primary solvated M^{2+} will be smaller in EG-rich solvents than in methanol because of the high solvating power of EG. In EG-rich solvents, furthermore, the primary solvated M^{2+} may be rather a structure breaker. Thus, the Walden products of $M(ClO_4)_2$ probably result in the large values for EG-rich solvents. A strong solvation of M^{2+} with EG also causes a small ΔH_{1A}°. We thus suggest that the $\Delta H_{1A}^{\circ}/\Delta G_{1A}^{\circ}$ ratio increases with an increase in the solvating power of a solvent. In mixed solvents, especially in 40 or 20 wt%, it seems that the composition and/or structure of the solvation shell of M^{2+} varies with temperature and/or with the ionic association. If so, such a variation in the solvation shell must cause the large negative temperature coefficients of the Walden products, and must cause the small ΔH_{1A}° and ΔS_{1A}° (and also maybe the slightly small ΔG_{1A}° as a result of complementarity between ΔH_{1A}° and ΔS_{1A}°). The negative temperature coefficients of the Walden products may also result from the fact that ClO_4^- is a structure-breaking ion.

We thank Dr. Reiji Tanaka of Osaka City University for his very kind help and advice in the measurements of the physical properties of solvent. The present study has been partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Spectrophotometric and Polarimetric Investigations on Complex Formation between Copper(II) and Cyclodextrins in an Alkaline Solution

Yoshihisa MATSUI* and Kohji KINUGAWA
Department of Agricultural Chemistry, Shimane University, Nishikawatsu, Matsue 690
(Received May 10, 1985)

Copper(II) forms a 1:1 complex (CuCD), as well as a 2:1 complex (Cu_2CD), with cyclodextrin (CD) in an alkaline solution. An equilibrium constant (K_{dsp}) for the disproportionation reaction of Cuα-CD to $Cu_2\alpha$-CD and α-CD was determined by spectrophotometry and polarimetry to be *ca.* 17 in 1.0 mol dm^{-3} NaOH at 25 °C. The K_{dsp} value gradually decreased with increasing NaOH concentration. A ligand-exchange reaction of Cu_2CD with ethylenediaminetetraacetic acid (EDTA) to give Cu(edta)$^{2-}$ and CD was also examined by means of spectrophotometry and polarimetry. The equilibrium constants (K_{lex}) for the ligand-exchange reaction was evaluated to be *ca.* 2.1 for an α-CD system and *ca.* 1.2 for a β-CD system in 1.0 mol dm^{-3} NaOH at 25 °C. The K_{lex} value decreased rapidly with increasing NaOH concentration. The role of OH^- in the complexation of Cu(II) with CD is discussed on the basis of these results.

Cyclodextrins (CD) are cyclic oligomers composed of six (α-CD), seven (β-CD), or more α-D-glucopyranose units linked 1→4 as in amylose. It has been revealed that copper(II) forms a 2:1 complex (Cu_2CD) with CD in an alkaline solution.[1,2] Although the structure of the complex has not fully been elucidated, it has been suggested that the two pairs of C2 and C3′ secondary hydroxyl groups of contiguous glucose units of CD are cross-linked by the $Cu(OH^-)_2$ Cu or $Cu(OH^-)(O^{2-})$ Cu ion bridge.[2] The complex not only binds an organic substrate within the cavity of CD but also markedly affects the reaction rate of the substrate in a similar manner as metalloenzymes.[3]

In the course of a study on Cu_2CD, we found that Cu(II) forms a 1:1 complex (CuCD) with CD, as well as a 2:1 complex, especially when the CD concentration is much higher than the Cu(II) concentration. The present work was undertaken to examine the complexation of Cu(II) with CD in more detail by means of spectrophotometry and polarimetry. Furthermore, a ligand-exchange reaction of Cu_2CD with ethylenediaminetetraacetic acid (EDTA) was examined in order to obtain further insight into the thermodynamic stability of Cu_2CD.

Experimental

Materials. The α- and β-CD's and copper sulfate were commericially available and were recrystallized from water. The disodium salt of EDTA of a reagent grade was used without further purification.

Apparatus. Absorption spectra were recorded using a Hitachi Model 220 spectrophotometer. Polarimetric measurements were carried out with a Union Giken Model PM-101 polarimeter.

Spectrophotometry and Polarimetry of Complexation between Cu(II) and CD. Changes in absorbance and optical rotation of an alkaline CD solution with an addition of Cu(II) were followed by means of a spectrophotometer and a polarimeter at 25 °C. A typical run was as follows: Two kinds of aqueous NaOH solutions were prepared, *i.e.*, 100 mmol dm^{-3} CD solutions containing no (Soln A) and 100 mmol dm^{-3} (Soln B) $CuSO_4$. The concentration of NaOH was adjusted to 1.0, 1.5, 2.0, or 2.5 mol dm^{-3}. Two cm^3 portions of Soln A were pipetted into a pair of 1-cm quartz cells for spectrophotometry. The cells were maintained at 25 °C by means of jackets through which water was circulated from a constant-temperature bath. After the absorption spectrum of the control solution was recorded by scanning from 800 to 370 nm, 0.025 cm^3 portions of Soln B were consecutively added to a sample cell. For each addition of Soln B, the absorption spectrum of the resulting solution was recorded. The change of absorbance (*Abs*) at λ=685 nm, where *Abs* reaches close to a maximum, was used for an analysis of the data. Changes in the optical rotation (*P*) of Soln A upon consecutive additions of Soln B were similarly followed at λ=405 nm, where the resulting solution showed only a slight absorption of light.

Determination of Equilibrium Constants for the Disproportionation Reaction of CuCD to Cu_2CD and CD. The value of *Abs* at 685nm for an alkaline CD solution increased with an increase in the total concentration (*a*) of Cu(II). Then, molar absorbance (*Abs/a*) for Cu(II) was plotted against the ratio (*R*) of *a* to the total concentration (*b*) of CD (Figs. 1 and 2). If Cu(II) forms only a single CD complex such as Cu_2CD as had been suggested previously,[1] the value of *Abs/a* should be constant for any *R* value. However, the observed *Abs/a* value increased with an increasing *R* value. For a Cu-α-CD system, all the plots obtained were virtually fitted to a curved line, irrespective of the *b* value. On the other hand, the *Abs/a* value for a Cu-β-CD system changed not only with a change in *R* but also with a change in *b*. It was postulated that Cu(II) forms a 1:1 complex (CuCD) with CD as well as a 2:1 complex (Cu_2CD) at small *R* values. Then, the transformation of CuCD to Cu_2CD with an increase in *R* is represented by a disproportionation reaction as follows:

$$2CuCD = Cu_2CD + CD. \quad (1)$$

The equilibrium constant (K_{dsp}) for the disproportionation reaction is represented by

$$K_{dsp} = yz/x^2, \quad (2)$$

where *x*, *y*, and *z* are the equilibrium concentrations of CuCD, Cu_2CD, and CD respectively. The concentration of uncomplexed Cu(II) is neglected, since it may be very low in such an alkaline solution. Then,

$$a = x + 2y \quad (3)$$

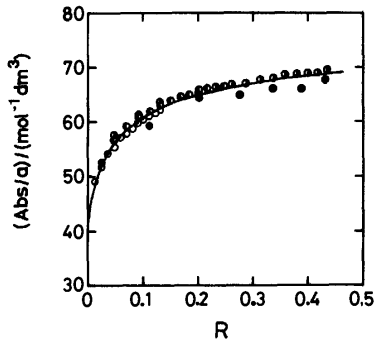

Fig. 1. Plots of Abs/a at λ=685 nm *vs.* R for a Cu-α-CD system in 1.5 mol dm^{-3} NaOH at 25 °C. [α-CD]=10 (●), 25 (◑), 50 (◐), and 100 (○) mmol dm^{-3}.

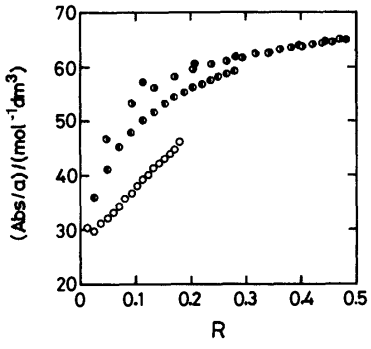

Fig. 2. Plots of Abs/a at λ=685 nm *vs.* R for a Cu-β-CD system in 1.5 mol dm^{-3} NaOH at 25 °C. [β-CD]=10 (●), 25 (◑), 50 (◐), and 100 (○) mmol dm^{-3}.

and

$$b = x + y + z. \tag{4}$$

Substitution of Eqs. 3 and 4 into Eq. 2 yields

$$x = ad \tag{5}$$

and

$$y = a(1-d)/2, \tag{6}$$

where

$$d = \frac{[R(2-R)(4K_{dsp}-1)+1]^{1/2}-1}{R(4K_{dsp}-1)}. \tag{7}$$

The total absorbance due to the Cu(II) complexes is given by

$$Abs = \varepsilon_1 x + \varepsilon_2 y, \tag{8}$$

where ε_1 and ε_2 are the molar absorption coefficients of CuCD and Cu_2CD, respectively. Upon introducing Eqs. 5 and 6 to Eq. 8, the following is derived:

$$Abs/a = \varepsilon_1 d + \varepsilon_2(1-d)/2. \tag{9}$$

Since d is only a function of R (Eq. 7), Abs/a is also dependent on R alone. This deduction agrees with the observed results for a α-CD system as shown in Fig. 1. In a Cu-β-CD system, the Abs/a value at a constant R value decreased with increasing b (Fig. 2). This suggests that some reaction other than the disproportionation of CuCD to Cu_2CD and CD occurs at high CD concentrations. However, no reasonable reaction mechanism can be offered to explain the observation at the present stage of investigation.

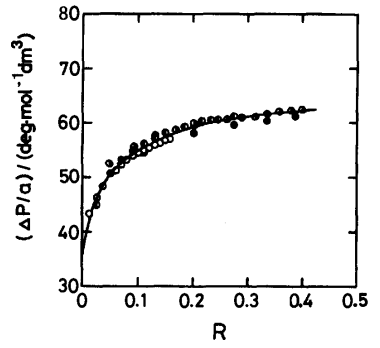

Fig. 3. Plots of $\Delta P/a$ at λ=405 nm *vs.* R for a Cu-α-CD system in 1.5 mol dm^{-3} NaOH at 25 °C. [α-CD]=10 (●), 25 (◑), 50 (◐), and 100 (○) mmol dm^{-3}.

In the case of polarimetry, the P value for Soln A decreased with an increasing a value. Figure 3 illustrates the plots of $\Delta P/a$ *vs.* R for a Cu-α-CD system, where ΔP is the difference (P_0-P) between optical rotations in the absence (P_0) and in the presence (P) of Cu(II). The plots were also virtually fitted to a curved line, irrespective of b. If the molar optical rotations of CD, CuCD, and Cu_2CD are denoted by f_0, f_1, and f_2 respectively, P_0 and P are given by

$$P_0 = f_0 b \tag{10}$$

and

$$P = f_0 z + f_1 x + f_2 y. \tag{11}$$

From Eqs. 4, 10, and 11, the following is derived:

$$\Delta P = \Delta f_1 x + \Delta f_2 y, \tag{12}$$

where $\Delta f_1 = f_0 - f_1$ and $\Delta f_2 = f_0 - f_2$. Upon introducing Eqs. 5 and 6 to Eq. 12, we obtain

$$\Delta P/a = \Delta f_1 d + \Delta f_2(1-d)/2. \tag{13}$$

This equation is very similar to Eq. 9, and $\Delta P/a$ is also dependent on d or R alone, as was shown in Fig. 3. The K_{dsp} values, as well as the values of ε_1 and ε_2 or Δf_1 and Δf_2, for Cu-α-CD systems at various NaOH concentrations were estimated by analyzing the relationships between Abs/a or $\Delta P/a$ and R by the least-squares curve-fitting method with a microcomputer. In a Cu-β-CD system, the $\Delta P/a$ value was dependent not only on R but also on b in a similar manner as the Abs/a value. Thus, no numerical analysis was attempted.

Spectrophotometry and Polarimetry of Ligand-exchange Reaction between Cu_2CD and EDTA. Changes in the absorbance and optical rotation of an alkaline Cu_2CD solution upon an addition of EDTA were followed using a spec-

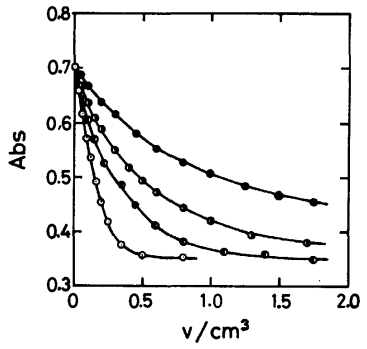

Fig. 4. Plots of *Abs vs. v* for a Cu_2 α-CD-EDTA system in 0.5 (○), 1.0 (◐), 1.5 (◑), and 2.0 (●) mmol dm^{-3} NaOH at 25 °C.

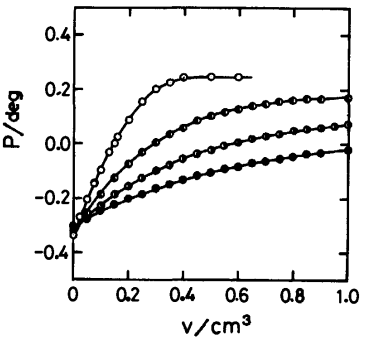

Fig. 5. Plots of ΔP *vs. v* for a Cu_2 α-CD-EDTA system in 0.5 (○), 1.0 (◐), 1.5 (◑), and 2.0 (●) mmol dm^{-3} NaOH at 25 °C.

trophotometer and a polarimeter at 25 °C. A typical run was as follows: Two kinds of aqueous solutions of NaOH at a given concentration (0.5, 1.0, 1.5, 2.0, or 2.5 mol dm^{-3} NaOH) were prepared, *i.e.*, (Soln A) an alkaline solution containing 10 mmol dm^{-3} CD and 10 mmol dm^{-3} $CuSO_4$, and (Soln B) an alkaline solution containing 100 mmol dm^{-3} EDTA and 10 mmol dm^{-3} $CuSO_4$. A portion (2.0 cm^3) of Soln A was pipetted into a sample cell, and absorption spectrum was recorded. Then, 0.025 to 0.30 cm^3 potions Soln B were consecutively added to a sample cell. For each addition of Soln B, the absorption spectrum of the resulting solution was recorded. Changes in absorbance (*Abs*) at 685 nm were used for an analysis of the data. Changes in optical rotation (*P*) of Soln A upon consecutive additions of Soln B were similarly followed at λ=405 nm.

Determination of Equilibrium Constant for the Ligand-exchange Reaction of Cu_2CD with EDTA. The value of *Abs* at 685 nm for Soln A decreased with an addition of Soln B. Figure 4 shows plots of *Abs vs. v*, where *v* is the cumulative volume (cm^3) of Soln B added to 2 cm^3 of Soln A. On the other hand, the value of *P* at 405 nm for Soln A increased with an addition of Soln B (Fig. 5). It was postulated that Cu_2CD in Soln A reacts with EDTA in Soln B to give $Cu(edta)^{2-}$ and CD (Eq. 14).

$$Cu_2CD + 2edta^{4-} = 2Cu(edta)^{2-} + CD \qquad (14)$$

The molar absorbance of Cu_2CD at 685 nm is more than double that of $Cu(edta)^{2-}$; thus, the *Abs* value for Soln A decreases upon an addition of Soln B. Both EDTA and CD are optically inert at 685 nm. The molar optical rotation of Cu_2CD at 405 nm is smaller than that of CD. Therefore, the *P* value for Soln A increases with an addition of Soln B. Both EDTA and $Cu(edta)^{2-}$ are polarimetrically inert at 405 nm.

An equilibrium constant (K_{lex}) for a ligand-exchange reaction expressed by Eq. 14 is given by

$$K_{lex} = w^2z/(yu^2), \qquad (15)$$

where *u*, *w*, *y*, and *z* are the equilibrium concentrations of EDTA, $Cu(edta)^{2-}$, Cu_2CD, and CD respectively. Let *a*, *b*, and *c* be the total concentrations of Cu, CD, and EDTA respectively,

$$a = 2y + w, \qquad (16)$$

$$b = y + z, \qquad (17)$$

and

$$c = u + w. \qquad (18)$$

From Eqs. 15 to 18, we obtain

$$(1+K_{lex})w^3 - [(a+2c)K_{lex}+a-2b]w^2 + cK_{lex}(2a+c)w - ac^2K_{lex} = 0. \qquad (19)$$

If the value of K_{lex} is given, it is possible to determine the *w* value by solving Eq. 19 under conditions where *w* is a positive real number and is smaller than *a* and *c*. When *w* is thus determined, the values of *y* and *z* are calculated by $y=(a-w)/2$ and $z=b-y$. Then, the observed *Abs* and *P* values are given by

$$Abs = \varepsilon_1 w + \varepsilon_2 y \qquad (20)$$

and

$$P = f_0 z + f_2 y, \qquad (21)$$

where ε_1 and ε_2 are the molar absorption coefficients at λ=685 nm for $Cu(edta)^{2-}$ and Cu_2CD respectively, and f_0 and f_2, the molar optical rotations at λ=405 nm for CD and Cu_2CD respectively. Although it is possible to determine directly the values of ε_1, ε_2, f_0, and f_2 by spectrophotometric and polarimetric measurements of solutions containing individual complexes, these quantities as well as K_{lex} were estimated by analyzing relationships between *Abs* or *P* and *v* (the cumulative volume of Soln B added to 2 cm^3 of Soln A) by use of the least-squares curve-fitting method with a FACOM M-140F computer at Shimane University. The values of ε_1 and ε_2, thus estimated, virtually agreed with those directly determined. However, the values of f_0 and f_2 did not always agree. Therefore, the value of f_0 was fixed in the analytical computation to be 32.8 deg cm^{-1} mol^{-1} dm^3 for α-CD and 41.4 deg cm^{-1} mol^{-1} dm^3 for β-CD, which were experimentally determined. This calculation improvement gave reasonable f_2 and K_{lex} values for both α- and β-CD systems.

Results and Discussion

Table 1 shows the K_{dsp} values as well as the molar

Table 1. Parameters for the disproportionation reaction of Cuα-CD to Cu_2 α-CD and α-CD at 25 °C

[NaOH]	Spectrophotometry			Polarimetry		
	ε_1	ε_2	K_{dsp}	Δf_1	Δf_2	K_{dsp}
mol dm^{-3}	cm^{-1} mol^{-1} dm^3	cm^{-1} mol^{-1} dm^3		deg cm^{-1} mol^{-1} dm^3	deg cm^{-1} mol^{-1} dm^3	
1.0	36	157	17.0	34	142	17.3
1.5	42	155	11.0	36	142	12.3
2.0	42	156	10.2	36	144	7.5
2.5	41	151	7.3	33	142	6.6

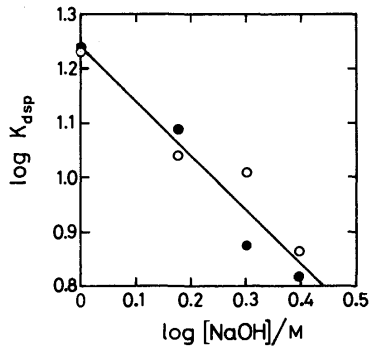

Fig. 6. Plots of log K_{dsp} *vs.* log [NaOH] for a Cu_2-α-CD system at 25 °C. The K_{dsp} values were determined by spectrophotometry (○) and polarimetry (●). 1 M = 1 mmol dm^{-3}.

absorption coefficients (ε_1 and ε_2) and the differences (Δf_1 and Δf_2) in molar optical rotation determined for a Cu-α-CD system by a least-squares analysis of the spectrophotometric and polarimetric data in Figs. 1 and 3. The K_{dsp} values estimated by the two methods agreed fairly well with each other at every NaOH concentration, and decreased with increasing NaOH concentration. The ε_1, ε_2, Δf_1, and Δf_2 values were virtually constant, irrespective of the NaOH concentration. The average values were $\varepsilon_1 = 40 \pm 2$ cm^{-1} mol^{-1} dm^3, $\varepsilon_2 = 154 \pm 2$ cm^{-1} mol^{-1} dm^3, $\Delta f_1 = 35 \pm 1$ deg cm^{-1} mol^{-1} dm^3, and $\Delta f_2 = 143 \pm 1$ deg cm^{-1} mol^{-1} dm^3. The molar optical rotation (f_0) of α-CD at $\lambda = 405$ nm was determined to be 32.8 deg cm^{-1} mol^{-1} dm^3, so that the molar optical rotations (f_1 and f_2) of Cuα-CD and $Cu_2\alpha$-CD were evaluated to be -2 ± 1 and -110 ± 1 deg cm^{-1} mol^{-1} dm^3, respectively.

Figure 6 shows a plot of log K_{dsp} *vs.* log [NaOH]. The plot is virtually linear, and the correlation analysis with the least-squares method gave Eq. 22.

$$\log K_{dsp} = 1.24 - 0.99 \log [\mathrm{NaOH}]; \quad n = 8,\ r = -0.969 \quad (22)$$

In this equation, n is the number of data and r, a correlation coefficient. The slope of the plot is *ca.* -1.0, which shows that the disproportionation reaction of Cuα-CD to $Cu_2\alpha$-CD and CD is accompanied by the release of 1 mole of OH$^-$. Thus, the stoichiometry for the disproportionation reaction is represented by

$$2[Cu(AH_2)(OH)_2]^{2-} \rightleftharpoons [Cu_2(A)(OH)_2]^{2-} + AH_3^- + OH^- + H_2O, \quad (23)$$

where AH_4 refers to α-CD. It is reasonable to consider that one of the hydroxyl groups of α-CD dissociates in such a strongly alkaline solution to give an alkoxide anion (AH_3^-), since the pK_a value for α-CD is 12.332 at 25 °C.[4]

Tables 2 and 3 show the K_{lex}, ε_1, ε_2, f_0, and f_2 values determined for the ligand-exchange reactions of $Cu_2\alpha$-CD and $Cu_2\beta$-CD respectively with EDTA by the least-squares analyses of spectrophotometric and polarimetric data. The K_{lex} values estimated by the two methods agreed well with each other at every NaOH concentration, and they decreased rapidly with an increasing concentration of NaOH. The values of ε_1, ε_2, and f_2 were virtually constant, irrespective of the NaOH concentration. The average values were $\varepsilon_1 = 32 \pm 1$ cm^{-1} mol^{-1} dm^3, $\varepsilon_2 = 135 \pm 2$ cm^{-1} mol^{-1} dm^3, and $f_2 = -97 \pm 2$ deg cm^{-1} mol^{-1} dm^3 for a α-CD system and $\varepsilon_1 = 32 \pm 1$ cm^{-1} mol^{-1} dm^3, $\varepsilon_2 = 132 \pm 1$ cm^{-1} mol^{-1} dm^3, and $f_2 = -85 \pm 2$ deg cm^{-1} mol^{-1} dm^3 for a β-CD system. The f_2 value, thus estimated for a α-CD system, is in fair agreement with the corresponding value estimated above from the disproportionation reaction.

Figure 7 shows plots of log K_{lex} *vs.* log [NaOH] for both α- and β-CD systems. The correlation analysis with the least-squares method gave Eq. 24 for a α-CD system and Eq. 25 for a β-CD system.

$$\log K_{lex} = 0.38 - 4.54 \log [\mathrm{NaOH}]; \quad n = 10,\ r = -0.995 \quad (24)$$

$$\log K_{lex} = 0.08 - 4.17 \log [\mathrm{NaOH}]; \quad n = 10,\ r = -0.995 \quad (25)$$

The slopes of the plots are *ca.* 4—5. These results suggest that the stoichiometry of the ligand-exchange reaction is mostly expressed by

$$[Cu_2(A)(OH)_2]^{2-} + 2\mathrm{edta}^{4-} + 3H_2O \rightleftharpoons 2[Cu(\mathrm{edta})]^{2-} + AH_3^- + 5OH^-. \quad (26)$$

According to Gorelova, *et al.*,[5] [Cu(edta)]$^{2-}$ reacts with OH$^-$ to afford [Cu(edta)(OH)]$^{3-}$ in an alkaline solution. Then, it is possible that a part of [Cu(edta)]$^{2-}$ in Eq. 26 is converted to [Cu(edta)(OH)]$^{3-}$

TABLE 2. PARAMETERS FOR THE LIGAND-EXCHANGE REACTION OF $Cu_2\alpha$-CD WITH EDTA AT 25°C

[NaOH]	Spectrophotometry			Polarimetry

2.0	31	131	0.0576	41.4	−84	0.0774
2.5	30	131	0.0257	41.4	−79	0.0397

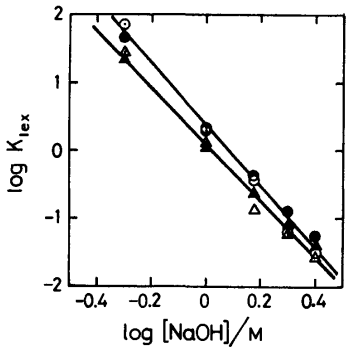

Fig. 7. Plots of log K_{lex} *vs.* log[NaOH] for Cu_2 α-CD-EDTA (○ and ●) and $Cu_2\beta$-CD-EDTA (△ and ▲) systems at 25°C. The K_{lex} values were determined by spectrophotometry (○ and △) and polarimetry (● and ▲). 1 M=1 mol dm^{-3}.

with the consumption of one mole of OH^-. This may be a reason why the slopes of the plots in Fig. 7 are less than 5.

Brunetti, *et al.*[6] have determined the log K value for a reaction represented by Eq. 27 to be 18.87.

$$Cu^{2+} + edta^{4-} \rightleftharpoons [Cu(edta)]^{2-} \quad (27)$$

By combining Eq. 27 with Eq. 26, we obtain

$$2Cu^{2+} + AH_3^- + 5OH^- \rightleftharpoons [Cu_2(A)(OH)_2]^{2-} + 3H_2O. \quad (28)$$

The log K value for this reaction was calculated to be 37.41 for a α-CD system and 37.66 for a β-CD system at [NaOH]=1.0 mol dm^{-3}. Furthermore, we obtain from Eqs. 23 and 28

$$Cu^{2+} + AH_3^- + 3OH^- \rightleftharpoons [Cu(AH_2)(OH)_2]^{2-} + H_2O. \quad (29)$$

The log K value for this reaction was calculated to be 18.09 for a α-CD system at [NaOH]=1.0 mol dm^{-3}. These results indicate that both of Cuα-CD and $Cu_2\alpha$-CD are very stable in 1.0 mol dm^{-3} NaOH, although they are unstable in a neutral aqueous solution.

It has been suggested in a previous paper[2] that the structure of a $Cu_2\beta$-CD complex is $[Cu_2(A)(OH)(O)]^{3-}$ rather than $[Cu_2(A)(OH)_2]^{2-}$. If this suggestion is valid, the stoichiometry of the ligand-exchange reaction for a β-CD system should be expressed by

$$[Cu_2(A)(OH)(O)]^{3-} + 2edta^{4-} + 4H_2O \rightleftharpoons 2[Cu(edta)]^{2-} + AH_3^- + 6OH^-, \quad (30)$$

instead of Eq. 26. Then, the slope of the plot of log K_{lex} *vs.* log [NaOH] should be equal to −6 for a β-CD system. However, the slope experimentally determined was −4.17. It is not clear why this discrepancy was brought about. It is possible to consider that the alkoxide ion (AH_3^-) of β-CD dissociates further into a divalent anion (AH_2^{-2}) in an solution higher in alkaline concentration than 1 mol dm^{-3}. The formation of AH_2^{2-}, together with the formation of $[Cu(edta)(OH)]^{3-}$, would consume OH^-, resulting in a decrease in the slope of the log K_{lex} *vs.* log [NaOH] plot. Although this explanation is plausible, there is no clear evidence supporting it at the present time. A more detailed examination is currently under way for a β-CD system.

ESR Studies on Salicylaldehyde Schiff Base Complexes of Copper(II). I. Bis(*N*-cyclohexyl- and *N*-cycloheptyl-salicylideneaminato)copper(II) Complexes and Their Derivatives in Polycrystals

Akira TAKEUCHI, Shoichiro YAMADA, and Hiroshi YOKOI†,*

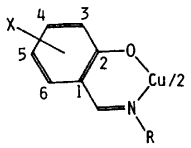
†*Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai 980*
(Received May 11, 1985)

Twelve of the title complexes including color isomers show powder ESR spectra of various line shapes. These complexes are a novel series of copper(II) complexes which have very weak intermolecular spin-exchange interactions in crystals. Brown complexes and most green complexes show monomer and dimer ESR spectra, respectively. It is demonstrated by ESR measurements that the above green complexes are transformed into the brown ones only by grinding those green crystals finely and forcefully with agate mortar and pestle.

There have been many works showing that metal(II) complexes with bidentate *N*-substituted salicylideneamines (I) (abbreviated as M(X-sal-R)$_2$) have various configurations, depending upon R and X.[1-3] These



I

complexes often show color isomerism. This kind of studies about the copper(II) complexes can also be carried out by the ESR method in new and interesting aspects. The purpose of this paper is to report powder ESR results for twelve of the complexes, in connection with their structures and properties in crystals. In this work, the complexes with R=cyclohexyl, 3,3,5-trimethylcyclohexyl, and cycloheptyl (abbreviated as Ch, Me$_3$Ch, and Cp, respectively) have been dealt with.

Experimental

All the salicylaldehyde Schiff base complexes of copper(II) were prepared according to the literature,[4] using commercially available reagents. Color isomers for some of the complexes were obtained as previously reported.[5] Twelve complexes prepared in this work are as follows: green Cu(H-sal-Ch)$_2$, brown Cu(H-sal-Ch)$_2$, green Cu(5-Cl-sal-Ch)$_2$, brown Cu(5-Cl-sal-Ch)$_2$, brown Cu(5-Br-sal-Ch)$_2$, green Cu(5-NO$_2$-sal-Ch)$_2$, greenish brown Cu(H-sal-Me$_3$Ch)$_2$, brown Cu(3-MeO-sal-Me$_3$Ch)$_2$, olive brown Cu(5,6-benzo-sal-Ch)$_2$, brown Cu(H-sal-Cp)$_2$, green Cu(5-Cl-sal-Cp)$_2$, and green Cu(5-Br-sal-Cp)$_2$, where Cu(5,6-benzo-sal-Ch)$_2$ denotes bis(*N*-cyclohexyl-2-hydroxy-1-naphthylmethyleneaminato)-copper(II).

X-Band ESR spectra for the above complexes in polycrystals were measured at room temperature and at the temperature of liquid nitrogen with a Varian E-4 ESR spectrometer. Sample powders for ESR measurements were obtained by grinding crystals of the complexes with agate mortar and pestle.

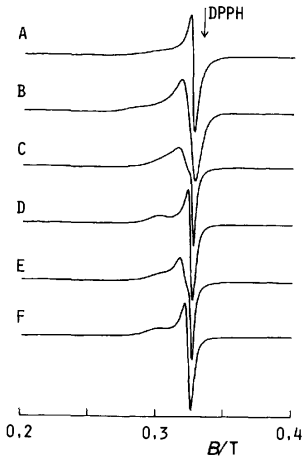


Fig. 1. Powder ESR spectra (X-band; room temperature); A, brown Cu(H-sal-Ch)$_2$; B, brown Cu(H-sal-Me$_3$Ch)$_2$; C, brown Cu(H-sal-Cp)$_2$; D, brown Cu(5-Cl-sal-Ch)$_2$; E, brown Cu(5-Br-sal-Ch)$_2$; F, green Cu(5-NO$_2$-sal-Ch)$_2$.

Results and Discussion

Powder ESR Spectra. The powder ESR spectra of the present complexes at room temperature have a wide variety of line shapes, as shown in Figs. 1—5. These spectra had almost no temperature dependence.

Figure 1 shows the powder ESR spectra of five brown or brownish complexes and green Cu(5-NO$_2$-sal-Ch)$_2$. These spectra appear within a comparatively narrow field range 0.26—0.35 T, and are of a common spectral type for polycrystals of monomeric copper(II) complexes,[6] except that the spectra are very broad in line shape. Brown Cu(H-sal-Ch)$_2$, one of the complexes in Fig. 1, really has one monomeric molecule in the unit cell, as determined by X-ray structural analysis;[7] interestingly, this complex has planar coordination. The spectra in Fig. 1 are so broad in line shape that g anisotropies are barely observed. This line broadening is probably due to insufficient spin-exchange narrowing toward the coalescense of four copper hyperfine lines to a single line, meaning that intermolecular spin-exchange interaction energies (J)

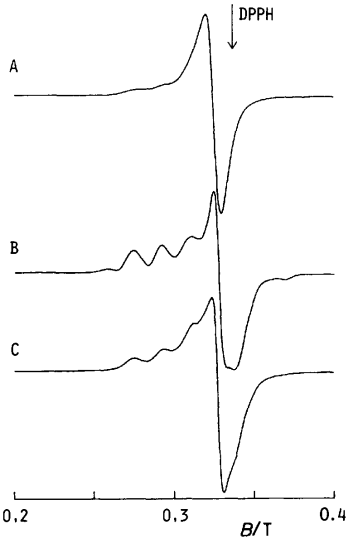

Fig. 2. Powder ESR spectra (X-band; room temperature); A, brown Cu(3-MeO-sal-Me_3Ch)$_2$; B, olive brown Cu(5,6-benzo-sal-Ch)$_2$ (softly and coarsely ground powder); C, olive brown Cu(5,6-benzo-sal-Ch)$_2$ (forcefully and finely ground powder).

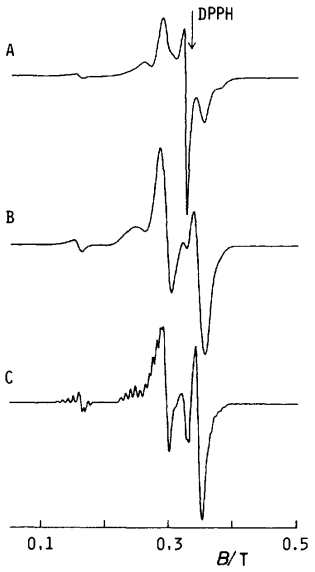

Fig. 3. Powder ESR spectra (X-band; room temperature) and frozen solution ESR spectrum (X-band; 77 K): A, green Cu(H-sal-Ch)$_2$; B, green Cu(5-Br-sal-Cp)$_2$; C, Cu(5-Br-sal-Ch)$_2$ in toluene (almost saturated).

are as small as the order of 0.1 cm^{-1},[8] On the other hand, in Fig. 2, hyperfine structures are clearly observed in the low-field spectral part. This fact indicates that the complexes of Fig. 2 are monomeric in the crystals with $|J| \lesssim 0.02$ cm^{-1}. The existence of such complexes in this series supports the above interpretation of the line broadening in Fig. 1. In Fig. 2(B), extra weak ESR signals at both sides of the monomer signal are clearly observed, but are of obscure origin at present. Further discussion on Fig. 2 (B) and (C) will be given later.

The powder ESR spectra in Fig. 3, whose signals occur over a much wider field range, are quite different in line shape from those in Figs. 1 and 2. The most remarkable feature of Fig. 3(A) and (B) is the appearance of weak half-field signals around 0.15 T. This spectral pattern is typical of triplet-state copper(II) dimers, as evidenced by the fact that Fig. 3(B) is almost identical in line shape with the frozen-solution spectrum of Cu(5-Br-sal-Ch)$_2$ shown in Fig. 3(C), which can be analyzed as a typical dimer spectrum by computer simulation;[9] detailed analyses of this kind of spectra with such well-resolved hyperfine structures as shown in Fig. 3(C) will be given in the next paper in this series of work.[10] Figure 3(B) is of the spectral type accompanying no spin-exchange narrowing effect of hyperfine lines, indicating that the inter-dimer spin-exchange interaction of green Cu(5-Br-sal-Cp)$_2$ is as extremely weak as $|J| \lesssim 0.01$ cm^{-1}. The powder ESR spectra of green Cu(5-Cl-sal-Cp)$_2$ and green Cu(5-Cl-sal-Ch)$_2$ were similar to Fig. 3(A) and (B), respectively. The peak positions of Fig. 3(A) in the range 0.2—0.4 T slightly shifts toward the center, compared with those of Fig. 3(B). This means that the $|J|$ value of the former system is a little larger than that of the latter one. All the copper(II) complexes in this work have thus been found to be a novel series of sample systems which have very weak intermolecular spin-exchange interactions in crystals, suggesting that bulky cyclohexyl and related groups may have some steric effect in breaking easy spin-exchange pathways in crystals. As has been estimated above, green Cu(H-sal-Ch)$_2$ exists as dimers in crystals. This is really consistent with the structural result obtained by X-ray analysis,[11] where monomeric halves in the dimer fundamentally have a flattened tetrahedral coordination. This work has revealed that all the complexes which show dimer ESR spectra are green ones, while brown or brownish complexes show monomer spectra; green Cu(5-NO_2-sal-Ch)$_2$ forms an exception, but this might result from some effect of the strong electron-withdrawing group of 5-NO_2.

Easy Transformation of Crystal Forms. We have found that some complexes in this study show different powder ESR spectra, according to how finely and forcefully their crystals are ground into powder with agate mortar and pestle, as exemplified in Figs. 2, 4, and 5; this will hereafter be called grinding effect. Figure 4 demonstrates this effect for green Cu(H-sal-Ch)$_2$; its softly and coarsely ground powder shows Fig. 4(A), and, by further grinding the powder finely and forcefully, the spectrum changes to Fig. 4(B), in which a sharp absorption near 0.32 T remarkably increases in intensity relatively to other signals. It is interesting to note that this sharp signal completely agrees with Fig. 1(A) for its brown complex, indicating that polycrystals of green Cu(H-sal-Ch)$_2$ are transformed into those of the brown form by the grinding

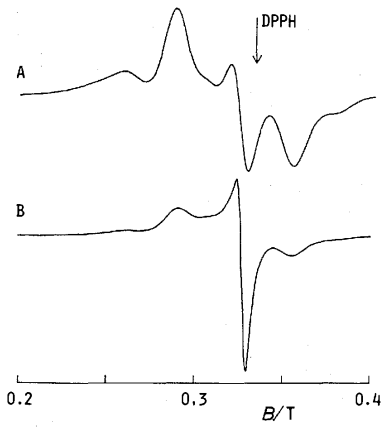

Fig. 4. Powder ESR spectra of green Cu(H-sal-Ch)$_2$ (X-band; room temperature): A, softly and coarsely ground powder; B, forcefully and finely ground powder.

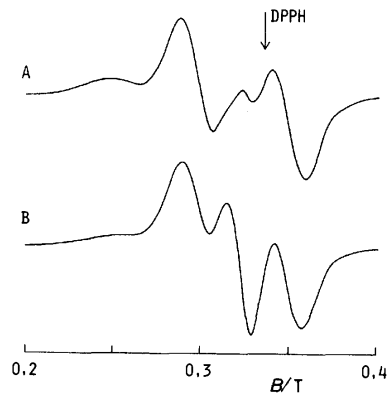

Fig. 5. Powder ESR spectra of green Cu(5-Cl-sal-Ch)$_2$ (X-band; room temperature): A, softly and coarsely ground powder; B, forcefully and finely ground powder.

effect. Roughly speaking, the grinding effect may be resolved into stress and frictional heat effects. Although heating the brown complex at 165—175 °C is known to yield the green one,[1,12] the brown complex showed no grinding effect. This fact suggests that the grinding effect is not always frictional heat effect, but may essentially be stress effect. The presumption that the brown form is favored by stress or pressure is also supported by the fact that the brown form of Cu(H-sal-Ch)$_2$ is slightly higher in density than the green one.[11] From a molecular-level point of view, the observation of the above grinding effect surprisingly means that a drastic molecular rearrangement from dimers to monomers, accompanied by molecular conformational changes, can take place easily in crystals without their melting.

Figure 5 shows another example of grinding effect for green Cu(5-Cl-sal-Ch)$_2$. Similarly, the green complex was transformed into the brown one by grinding effect. Green Cu(5-Cl-sal-Cp)$_2$ and green Cu(5-Br-sal-Cp)$_2$ showed spectral changes similar to those in Figs. 4 and 5, respectively, by grinding effect. A different spectral change due to the effect was also observed for olive brown Cu(5,6-benzo-sal-Ch)$_2$, as shown in Fig. 2. In this case, the grinding effect weakens the intensities of signals at both sides of the monomer's one, and slightly changes the monomer spectrum itself, suggesting that this complex possibly has two slightly different crystal forms. Judging from all these observations on the grinding effect, it is said that we must be careful of the possibility of the effect in any experiment where the grinding operation of crystals is needed.

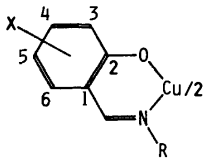
ESR Studies on Salicylaldehyde Schiff Base Complexes of Copper(II). II.[1] Bis(*N*-cyclohexyl- and *N*-cycloheptyl-salicylideneaminato)copper(II) Complexes and Their Derivatives in Solutions

Hiroshi YOKOI,* Akira TAKEUCHI,† and Shoichiro YAMADA†
Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai 980
†*Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560*
(Received May 11, 1985)

Ten of the title complexes in frozen toluene solutions and occasionally in other solutions have been studied by the ESR method. Most of the complexes showed both monomer and dimer ESR spectra simultaneously, and the equilibrium constant for 2 monomer ⇆ dimer has been determined by analyzing the concentration dependence of the intensity ratios of dimer and monomer ESR signals. The results indicate that the equilibrium constants of the complexes are dependent in a marked but subtle way, not upon the bulkiness of *N*-substituents, but upon both kind and position of the substituents introduced into the ligand benzene rings, and that the equilibrium constants are solvent-dependent. All the observed dimer ESR spectra were similar to each other, and computer simulation analysis of the spectra has revealed that the dimers formed in toluene have the same structures as that in green crystals of bis(*N*-cyclohexylsalicylideneaminato)copper(II). On the other hand, monomers of the title complexes have been found to show various degrees of tetrahedral distortion in the coordination geometry.

The title complexes (I) (abbreviated as Cu(X-sal-R)$_2$†) have various conformations, depending upon R



I

and X, and show color isomerism.[2–4] X-Ray structural analyses and ESR studies have confirmed that these complexes are monomeric or dimeric in crystals.[1,5,6] Coordination chemistry of these complexes in solutions is now of great interest. We report here ESR results of these complexes in solutions, especially in toluene, with the intention of elucidating their structures and properties.

Experimental

The same sample complexes as in the previous work were used here.[1] X-Band ESR spectra were measured for the complexes in solutions at the temperature of liquid nitrogen and at room temperature, with a Varian E-4 ESR spectrometer. Commercial Nakarai's "spectrograde" solvents were used without further purification. The solubilities of the complexes in toluene at room temperature were determined spectrophotometrically.

Results and Discussion

Monomeric Complexes. Most of the present complexes in frozen toluene solutions simultaneously showed both monomer and dimer ESR spectra superimposed on each other. In these solutions, monomers and dimers are in equilibrium, since the intensity ratio of dimer and monomer ESR signals for any of the complexes increases with its concentration,[7–9] as exemplified by Fig. 1. On the other hand, Cu(H-sal-Cp)$_2$ and Cu(3-MeO-sal-Ch)$_2$ at any concentration did not show dimer ESR spectra at all, but monomer spectra alone, as shown in Fig. 2; Cu(H-sal-*t*-Bu)$_2$ is just the same in this respect.[10,11] Figure 2(C) is the monomer ESR spectrum of Cu(H-sal-Ch)$_2$. Its line shape was invariant at any low concentration, but is slightly different from those of the other two spectra

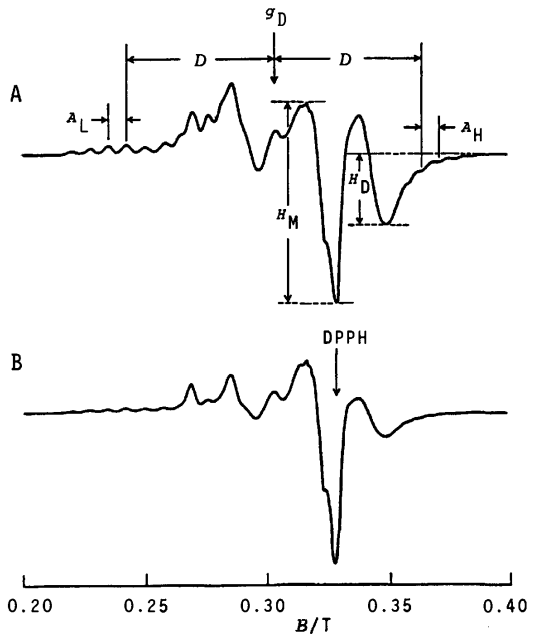


Fig. 1. X-Band ESR spectra of Cu(5-Br-sal-Cp)$_2$ in toluene at 77 K: A, 2.5×10^{-3} M; B, 5.0×10^{-4} M. The parameters of g_D, D, A_L, A_H, H_D, and H_M are defined in A (see text as to the meanings of these parameters).

†The abbreviations of substituents used in this work are as follows: Ch, cyclohexyl; Me$_3$Ch, 3,3,5-trimethylcyclohexyl; Cp, cycloheptyl; Me, methyl; MeO, methoxyl; *i*-Pr, isopropyl; *t*-Bu, *t*-butyl.

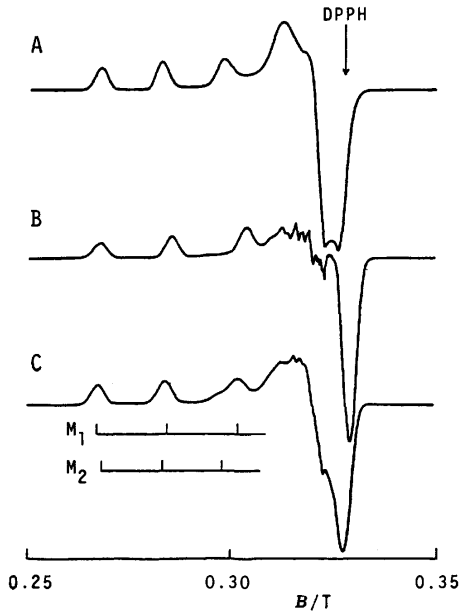

Fig. 2. X-Band ESR spectra of the monomeric Cu(X-sal-R)$_2$ complexes in toluene at 77 K: A, Cu(H-sal-Cp)$_2$, 2.5×10^{-3} M; B, Cu(3-MeO-sal-Ch)$_2$, 2.5×10^{-3} M; C, Cu(H-sal-Ch)$_2$, 5.0×10^{-4} M. In C, the low field spectral part is analyzed as due to two different monomeric species, M_1 and M_2.

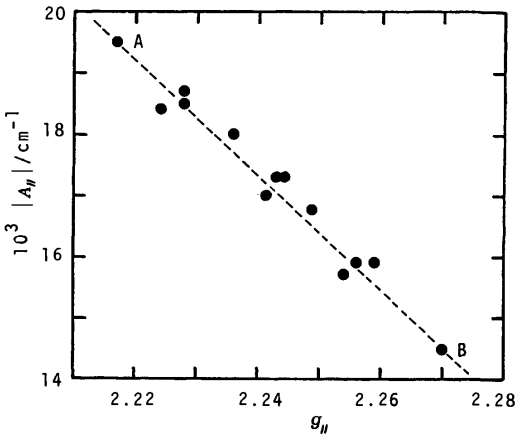

Fig. 3. Plot of $A_{\parallel}$ against $g_{\parallel}$ for the monomeric Cu(X-sal-R)$_2$ complexes; A and B, plots for Cu(H-sal-Me)$_2$ and Cu(H-sal-*t*-Bu)$_2$, respectively; the other plots, from Table 1.

in Fig. 2 at the low field part. These observations are quite similar to those of Cu(H-sal-*i*-Pr)$_2$,[11] showing that there are two different monomeric species for Cu(H-sal-Ch)$_2$ in toluene.

Table 1 summarizes the $g_{\parallel}$ and $A_{\parallel}$ values determined for all the monomeric complexes in frozen toluene solutions, together with the g_0 and A_0 values in fluid toluene solutions at room temperature. A series of Cu(H-sal-R)$_2$ are known to show various degrees of tetrahedral distortion in the coordination geometry, depending upon the bulkiness of R;[11,12] for instance, the dihedral angles between two chelate rings for Cu(H-sal-Me)$_2$ and Cu(H-sal-*t*-Bu)$_2$ in crystals are 0 and 62°, respectively, and the latter is the largest of the structures reported so far.[13] A linear relationship between $g_{\parallel}$ and $A_{\parallel}$ has been demonstrated for these complexes, as shown in Fig. 3 by a dotted straight line drawn through the data of Cu(H-sal-Me)$_2$ and Cu(H-sal-*t*-Bu)$_2$.[12] Plots of the $g_{\parallel}$ and $A_{\parallel}$ values from Table 1 have also been found to fall on the same straight line (Fig. 3), indicating that the present monomeric complexes in toluene show various degrees of the tetrahedral distortion ranging from almost null to that of Cu(H-sal-*t*-Bu)$_2$, in spite of the fact that Ch, Cp, and their derivatives are almost the same in bulkiness.

Dimer Formation Constants. Undoubtedly, a monomer (M)-dimer (D) equilibirum, $2M \rightleftharpoons D$, is established in the solution systems for which both monomer and dimer ESR spectra are simultaneously observed, as has been confirmed so far.[7-9] The value of $R=H_D/H_M \propto [D]/[M]$ can be directly obtained from each spectrum, where H_D and H_M are the peak heights of any specific dimer and monomer ESR signals,

Table 1. Monomer ESR parameters[a]

Cu(X-sal-R)$_2$ X	R	$g_{\parallel}$	$10^4\,\lvert A_{\parallel}\rvert$ / cm^{-1}	g_0	$10^4\,\lvert A_0\rvert$ / cm^{-1}

5-Br	Cp	2.244	173	2.119	65

a) The $g_{\parallel}$ and $A_{\parallel}$ values were determined from frozen toluene solution ESR spectra at 77 K, and the g_0 and A_0 values, from fluid toluene solution ESR spectra at room temperature. b) Two different species were identified.

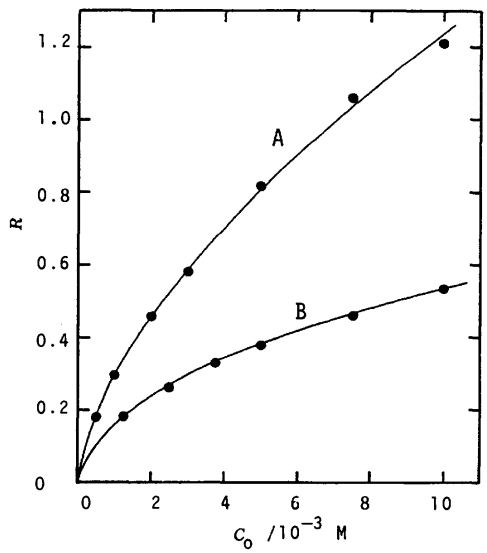

Fig. 4. Relationship between R and C_0 for Cu(5-Br-sal-Ch)$_2$ (A) and Cu(5-Cl-sal-Ch)$_2$ (B): (●), experimental; (——), calculated (see text).

respectively. Then, R is expressed as

$$R = (\sqrt{8KC_0+1}-1)/P$$

where K is the equilibrium or dimer formation constant, P the proportionality constant and C_0 the total concentration. K and P can be determined by fitting the above equation to experimental plots of R against C_0. The observation was made by quickly freezing a toluene solution in liquid nitrogen, using quartz sample tubes of the same size. The equilibrium constant obtained, therefore, is considered to be pertinent for a temperature somewhat lower than the freezing point of toluene. Throughout this work, the monomer and dimer ESR signals used for the determination of H_M and H_D respectively were selected as shown in Fig. 1. All the K, P, R, and C_0 values, together with the solubilities of the complexes in toluene, are listed in Table 2. Two examples of experimental plots of R against C_0 and their fitting curves are given in Fig. 4 for illustration.

As to the dimerization ability of the present complexes, much is elucidated from Table 2. Cu(H-sal-Cp)$_2$ has no dimerization ability, but its 5-halogeno derivatives have. Similarly, the 5-halogeno derivatives of Cu(H-sal-Ch)$_2$ dimerize much more easily than the parent complex. Cu(H-sal-Me$_3$Ch)$_2$ can dimerize a little more easily than Cu(H-sal-Ch)$_2$, but these complexes are roughly comparable in the K value to Cu(H-sal-Me)$_2$.[9] These facts indicate that the apparent bulkiness of N-substituents is not an important factor in the dimerization, except for N-t-Bu; not only Cu(H-sal-t-Bu)$_2$ but also its 5-halogeno and 5-NO$_2$ derivatives were found to have no dimerization ability. The intrinsic nature of the present dimerization, however, is so subtle that, for the 5-Cl and 5-Br derivatives of Cu(H-sal-Ch)$_2$, the former has a much larger K value than the latter, while, for those of Cu(H-sal-Cp)$_2$, the reverse is observed. It is noteworthy that drastic changes of K from 75 to 8.5×10^3 and 1.4×10^5 M^{-1} are brought about only by the introduction of 5-Cl and 5-NO$_2$ respectively into Cu(H-sal-Ch)$_2$. Similar enhancing effects of the nitro group on the dimerization ability of other kinds of planar complexes have been reported so far.[9,10] The K values of Cu(H-sal-Me)$_2$ and of its 5-Me, 5-Br, and 5-MeO derivatives were determined to be 2.4×10^2, 1.8×10^2, 2.3×10^3, and 2.1×10^3 M^{-1}, respectively;[8] clearly, the latter two are larger than the former two. The NO$_2$ and MeO substituents are representative π-electron-withdrawing and donating groups, respectively, and the halogeno substituents are also typical functional groups with remarkable substituent effects. From these facts it is clear that such influential groups as halogens, NO$_2$, and MeO at the 5-position have a common substituent effect of enhancing the present dimerization ability

a) See text (Fig. 1) as to the definition of dimer ESR parameters. b) Medium at 77 K. c) Values derived from the computer simulation spectrum (Fig. 5(A)), which was calculated with the following parameters, assuming a parallel planar dimer: $g_{\parallel}$=2.245, $g_{\perp}$=2.050, $A_{\parallel}$=0.0087 cm^{-1}, $A_{\perp}$=0.0015 cm^{-1}, r=3.67 Å, ξ=37°, ΔH_1=2.5 mT, ΔH_2=2.2 mT (ΔH_1, ΔM=1 spectral line width).

markedly. On the other hand, Cu(3-MeO-sal-Me_3Ch)$_2$ has no dimerization ability, as well as Cu(3-MeO-sal-Me)$_2$;[8)] furthermore, the K value of Cu(3-Me-sal-Me)$_2$ is smaller than that of Cu(H-sal-Me)$_2$,[8)] suggesting the possibility that 3-substituents depress the dimerization. Cu(5,6-benzo-sal-Ch)$_2$ dimerizes about twice more easily than Cu(H-sal-Ch)$_2$, suggesting that the enlargement of ligand π-electron systems may be a favorable factor in this dimerization, in conformity with the general belief that stacking interaction between planar molecules with π-electron systems is stronger, as the π-electron sytems are larger. In conclusion, there are remarkable substituent effects on the present dimerization ability, but further work is needed to analyze the dimerization ability in more detail.

Interestingly, Table 2 indicates that there is a tendency for the K value to increase with a decrease in the solubility. This seems to be qualitatively understandable from the generality that the solubility is lower, as the intermolecular interaction is stronger.

Dimeric Structures. The present dimer ESR spectral features can be described by the dimer ESR parameters, g_D, D, A_L, and A_H, which are defined in Fig. 1. Table 3 summarizes all these parameter values determined from frozen toluene solution spectra, together with those from several powder spectra.[1)] Inspection of this table indicates that all the dimers are essentially similar in structure, becasue their dimer ESR parameters are almost similar to each other. These dimer ESR spectra can be analyzed by the computer simulation method, assuming a parallel planar dimer with the distance (r) of 3.67 Å between the two copper atoms and the angle (ξ) of 37° between the $g_{\parallel}$ axis and the copper–copper axis, as has been applied previously;[14,15)] the simulation spectrum thus obtained is shown in Fig. 5(A), which approximately reproduces the observed spectrum of Cu(5-Br-sal-Ch)$_2$ (Fig. 5(B)). The dimer ESR parameters determined from this simulation spectrum are in good agreement with the observed ones, as shown in Table 3.

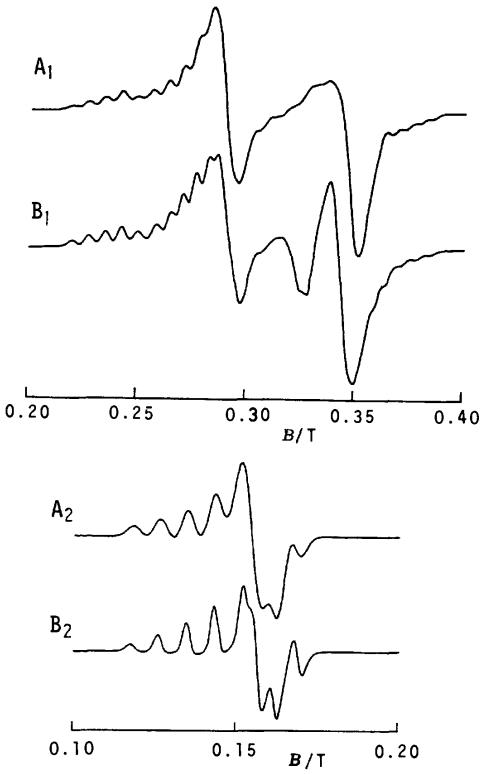

Fig. 5. Comparison between simulated and experimental dimer ESR spectra; A_1 and A_2, simulation spectra, calculated with the parameters of $g_{\parallel}$=2.245, $g_{\perp}$=2.050, $A_{\parallel}$=0.0087 cm^{-1}, $A_{\perp}$=0.0015 cm^{-1}, r=3.67 Å, ξ=37°, ΔH_1=2.5 mT, ΔH_2=2.2 mT, ν=9.23 GHz (the suffixes 1 and 2 correspond to ΔM=1 and 2 spectra, respectively; ΔH, line width; see text as to details of the computer simulation); B_1 and B_2, observed spectra for Cu(5-Br-sal-Ch)$_2$ in almost saturated toluene solutions at 77 K.

Interestingly, an X-ray crystal structure determina-

tion of green Cu(H-sal-Ch)$_2$ has revealed that the molecules exist as dimers of an approximately parallel planar type with r=3.38 Å and ξ=36°; actually, the monomeric halves of the dimers do not have a planar coordination geometry, but a somewhat tetrahedrally-distorted one with a dihedral angle of about 30°.[6] These r and ξ values are in fair agreement with those estimated above by the computer simulation method, in consideration of a point-dipole approximation used in the simulation in which the r value is generally estimated to be several % larger than the actual one.[16] Now, it is reasonably concluded that all the dimers formed in toluene have the same structures as that in green Cu(H-sal-Ch)$_2$ crystals.[††]

Solvent Effects of Dimerization. The dimer formation constants of the present complexes are remarkably solvent-dependent, as is usual with many other analogous systems.[15,18] The R values of Cu(5-Br-sal-Ch)$_2$ at 0.0050 M (1 M=1 mol dm^{-3}) in the mixtures of 4 parts of toluene and 1 part of pyridine, *N*,*N*-dimethylformamide (DMF), dichloromethane, methanol, and dimethyl sulfoxide (DMSO) were changed into 0, 6, 20, 38, and 98% of that in pure toluene, respectively. Interestingly, DMSO has almost no effects on the dimer formation, while DMF remarkably depresses it, in spite of both solvents being nearly equal in the basicity or donicity.[19] It seems likely that the above difference between DMSO and DMF is attributed to the presence of a π-system in the DMF molecule, because the so-called π-π interaction is considered as an important driving force for the dimerization of complexes with π-ligands; depressing effects of DMF on this kind of dimerization will be discussed elsewhere in more detail. Pyridine completely inhibits the dimerization by its strongly coordinating ability, the resultant complexes probably being sterically difficult of dimerization. It is to be noted that dichloromethane and methanol also have depressing effects on the dimerization. The solubility of Cu(5-Br-sal-Ch)$_2$ in methylcyclohexane, the saturated hydrocarbon of toluene, is remarkably low, compared with that in toluene. Accordingly, the dimer formation constant in methylcyclohexane was apparently larger than that in toluene, in agreement with the expectation discussed above.

[††] As seen in Table 3, green Cu(H-sal-Ch)$_2$ in polycrystals is somewhat different in the g_D value from others, but this might be a result of intricate magnetic interaction among dimers in the crystals.[1,17]

Physicochemical Speciation of Trace Elements in River Water by Means of Ultrafiltration

Yoshiyuki TANIZAKI,* Masao YAMAZAKI, and Sumiko NAGATSUKA
Tokyo Metropolitan Isotope Research Center, Fukazawa, Setagaya-ku, Tokyo 158
(Received May 21, 1985)

Ultrafiltration and Millipore filtration techniques have been used in the speciation of trace elements in Tama River water. The size distribution was clarified for 32 elements by means of neutron-activation analysis in order to discuss their chemical or physical forms. Alkali and alkaline-earth elements were primarily found in the dissolved-size fraction (<0.45 μm). Their dissolved species were mostly distributed in the smallest-molecular-weight fraction (<MW 500), although the alkaline-earth elements were also recognized to a significant extent (20—30%) in the middle-molecular-weight fraction (MW 10^4—500). Transition elements were principally associated with the suspended-size fraction (>0.45 μm) in the upper reaches of the river, but in the lower reaches they were chiefly fractionated as the dissolved species, with the exception of Sc and Fe. The dissolved V and Mn were distributed in the smallest-molecular-weight fraction, while the Co, Ni, and Zn were divided between two smaller-molecular-weight fractions (MW 10^4—500 and <MW 500). Light rare-earth elements were mostly associated with suspended materials. Heavier rare-earth elements were, on the contrary, mainly found in the dissolved-size fraction, while their dissolved species were concentrated in the middle-molecular-weight fraction. The dissolved species for As, Se, Sb, and W were divided into two smaller-molecular-weight fractions, although As, Se, and W were predominantly found in the middle-molecular-weight fraction and Sb was mainly detected in the smallest-molecular-weight fraction. Aluminium and Ag were mainly associated with suspended materials. Furthermore, the dissolved Al was mostly distributed in the smallest-molecular-weight fraction, while the Ag was concentrated in the largest-molecular-weight fraction (>MW 10^4).

Trace elements in natural water are found in various physical or chemical forms, such as simple ions, ion pairs, organic or inorganic complexes, and metal ions sorbed onto particulates or colloids. The determination of thier chemical species is of great importance not only in order to substantiate their geochemical behavior in natural water, but also in order to estimate their utilities and toxicities towards aquatic organisms. A variety of physicochemical separation techniques have been used in the study of trace-element characterizations in natural water.[1-3] The size-separation methods, such as filtration,[4-7] ultrafiltration,[8-11] gel filtration, and dialysis[12,13] are used the most commonly because of their simplicities. However, no one has yet applied the size-separation techniques to a systematic analysis of multi-elements. In a previous paper,[14] we ourselves reported on the physicochemical speciation of 31 elements in Tama River water, using a combination of the Millipore filtration (MF) technique and neutron-activation analysis (NAA). However, it was not possible to separate perfectly trace elements between "colloidals" and "true solutions," for the smallest pore size of commercially available Millipore filter is 0.025 μm, even though the boundary in size between the above two states probably lies in the range of 0.01—0.001 μm.[1,2,15] The ultrafiltration (UF) technique is extensively used to separate dissolved compounds into various molecular-weight ranges using a variety of membrane filters. In this paper, we tried to separate 32 elements and 6 major components dissolved in Tama River water into several molecular-weight fractions by utilizing the UF technique in order to estimate their chemical species.

Experimental

Water Samples. The river water samples were collected from three stations of the Tama River, Hamura (Station A), Kinuta (B), and Denenchofu (C). The sampling stations are shown in Fig. 1. The Hamura site lies near prime agricultural land, while the Kinuta and Denenchofu sites lie near industrial/urban stretches. Thirty liters of each water sample was placed in a clean Pyrex glass bottle and then immediately pre-filtrated using a Millipore filter with pore size of 8 μm in order to remove large particles. Another five liters of the water sample was taken as the original material in a polyethylene bottle without any filtration, it was then acidified immediately with 30 ml of nitric acid (Super Special Grade). The water qualities at the time of sampling are listed in Table 1 for the three stations.

Filtration. The pre-filtrated water samples were divided into six 5-liter portions. Two portions of the filtrate were used for the MF experiment, and the other four portions were used for the UF experiment. The sample from the Hamura site was not, however, submitted to the UF experiment.

(A) Millipore filtration. An all-glass Millipore apparatus and two kinds of Type HA Millipore filters, with a diameter of 142 mm and with average pore sizes of 0.45 and 0.05 μm, were used for the MF experiment. The procedures have been described in detail in the previous paper.[14]

(B) Ultrafiltration. A Model UHP-150 ultrafiltration cell (Toyo Roshi Corp.) and four kinds of ultrafilters, UK-200 (molecular-weight cut-off 2×10^5), UK-10 (10^4), UH-1 (1000), and UH-05 (500), with diameter of 150 mm, were employed for the UF experiment. The decontamination and washing of each filter were done by soaking them successively in a sodium hydroxide solution (1 mol dm^{-3}) for 1 d and a sodium hydrogencarbonate solution, followed by passing 5 liters of redistilled water through the filter under the pure-

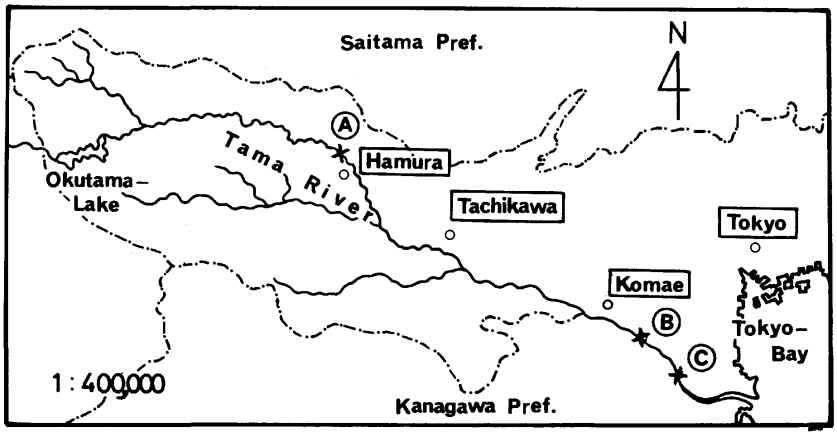

Fig. 1. Sampling locality.

a) Amount of evaporated residue. b) Total organic carbon.

nitrogen gas pressure. Four portions of pre-filtrated samples were filtered using the four kinds of ultrafilters, one by one. The filtration was carried out under stirring and under nitrogengas pressures of 2—4.5 atm according to the molecularweight cut-off of the filters. The resulting four filtrates were transferred to a clean 5-liter polyethylene bottle and then acidified with 30 ml of the nitric acid in order to prevent any adsorption of trace elements on the walls of the bottles.

Neutron-activation Analysis. The procedures for the NAA experiment, the preparation of the neutron-irradiation samples, the neutron irradiation, and the gamma-ray counting were reported in detail in our previous papers.[14,16,17]

Analysis of Major Components. The concentration of silica (SiO_2) in the river water was determined by colorimetry using ammonium molybdate, while the sulfate (SO_4^{2-}) concentration was measured by turbidimetry using a barium chloride-gelatin solution. The alkalinity (4.3 Bx) was titrated with sulfuric acid (0.01 $mol\,dm^{-3}$) in the presence of a Bromocresol Green (BCG) indicator. The concentration of chloride ions (Cl^-) was measured by Mohl's method. The determination of the total organic carbon (TOC) concentration was performed by utilizing a TOC analyzer (Shimazu Model 10A).

Results and Discussion

The concentrations of the 32 elements were determined for the six filtrates resulting from the MF and UF experiments and for the original (non-filtrated) water sample by means of NAA. The statistical errors based on the gamma-ray counting were 5—30% for Ag, Ba, Ce, Cr, Eu, Ho, K, Fe, La, Mg, Se, Tb, Tm, and U, and less than 5% for the other 18 elements.

The trace-element concentrations in the pre-filtrated water sample and the residual water in the ultrafiltration cell were also determined in order to calculate the mass balance of the trace elements during the UF experiment. The results show that the loss due to adsorption was 20—50% for Fe, Ag, U, La, Ce, Sm, Eu, and Tb. For the other elements, the loss or contamination was less than 10%.

The size distributions in diameter (μm) and in the molecular-weight ranges were calculated for the 32 elements and 6 major components by means of the scheme shown in Fig. 2. The results were classified by size into two fractions, F (>0.45 μm) and F (<0.45 μm); furthermore, in the later fraction, they were classified into three molecular-weight fractions, F (>MW 10^4), F (MW 10^4—500), and F (<MW 500). The results are shown in Tables 2—8.

As a general rule, chemical constituents with a size smaller than 0.45 μm are defined as "dissolved," while those with a size larger than 0.45 μm are clas-

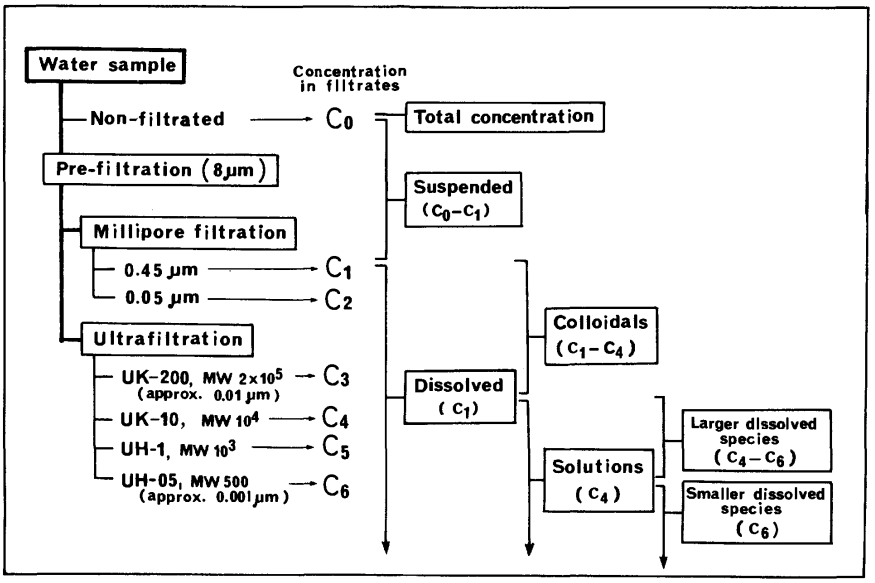

Fig. 2. Scheme for speciation of trace elements in river water by size fractionation techniques.

The values in parenthesis are the percentages of each fraction.

sified as "particulate" or "suspended." The "dissolved" constituents need not be in a true solution, but can include "colloidals."[3] In this paper, it is assumed that the constituents with a size larger than molecular weight 10^4 (>MW 10^4) are "colloidals," while those with a size smaller than molecular weight 10^4 are "true solution," according to the method reported by Steinnes.[2] Furthermore, the constituents with molecular weights ranging from 10^4 to 500 (MW 10^4—500) are defined as larger dissolved species, while those passing through the ultrafilter with a molecular-weight cut-off of 500 (<MW 500) are classified as smaller dissolved species. The larger dissolved species included organic complexes, polyhydroxo complexes, *etc.*, while the smaller dissolved species are made up of free ions, ion pairs, *etc.*[2]

Major Components (ER, SiO_2, 4.3 Bx, SO_4^{2-}, Cl^-, and TOC). The total contents of all the major components except for SiO_2 were higher in the lower reaches (Stations B and C) of the Tama River than those in the upper reaches (Station A), as can be seen in Table 2. Especially, the high enrichments in Cl^- and TOC concentrations for Stations B and C indicate that the lower reaches of the river are greatly influenced by anthropogeneous pollution. This is proved too by the enrichments of the other com-

ponents, such as Na, Mg, and heavy metals, which will be discussed later.

The major components were mostly fractionated as dissolved species (<0.45 μm), although 42, 14, and 10% of TOC for Stations A, B, and C respectively were associated with suspended materials (>0.45 μm). Most (81—99%) of the dissolved species for evaporated residue (ER), SiO_2, 4.3 Bx, and Cl^- was found in the smallest-molecular-weight fraction (<MW 500). Consequently, these four components are mainly present in the water as smaller dissolved species. The dissolved SO_4^{2-}, on the other hand, was chiefly divided between two smaller-molecular-weight fractions (MW 10^4—500 and <MW 500). This indicates that SO_4^{2-} is present in the water not only as simple ions, but also as larger molecules. The dissolved TOC was mainly distributed in the middle-molecular-weight fraction (MW 10^4—500), although 23—32% of the TOC was also found in the largest-molecular-weight fraction (>MW 10^4). Organic materials occurring in natural water have a very heterogeneous composition. The bulk of these natural organics is made up of fulvic and humic acids which have molecular-weight ranges of roughly 10^2—10^4 and 10^4—10^6 respectively, although their structures are generally poorly known and the above values are not to be regarded as definitive in any way.[2] These fulvic and humic acids contribute greatly to the dissolution of trace elements.[9,13,18,19]

Alkali and Alkaline-earth Elements (Na, K, Rb, Cs, Mg, Ca, Sr, and Ba). The total concentrations of Na, K, and Mg in the lower reaches of the river were higher than those in the upper reaches by a factor of 4—12, as can be seen in Tables 3 and 4. No significant differences in the total concentrations for Rb, Ca, Sr, and Ba could be found among the three sampling stations, even though they were also given in the higher values to some extent (about 2 times) for the lower reaches. On the other hand, higher Cs concentration was observed in the upper reaches.

Almost all the Na, K, and Rb was fractionated as dissolved species (<0.45 μm), although 46% of the Rb at Station A was distributed in the suspended-size fraction (>0.45 μm). Cesium was mainly associated with suspended materials at Station A. At Station C, on the contrary, it was predominantly found in the dissolved-size fraction. The Cs at Station B was divided between two fractions. Most (87—92%) of the dissolved alkali-metal elements were distributed in the smallest-molecular-weight fraction (<MW 500). It is well known that alkali-metal elements are dissolved in natural water as univalent cations. The

fractionation results are in fair agreement with this knowledge.

The Mg, Ca, and Sr were completely fractionated as dissolved species. For Ba, 47% in the upper reaches and 11—14% in the lower reaches were associated with suspended materials. Although the dissolved alkaline-earth elements were chiefly classified in the smallest-molecular-weight fraction, like the alkali-metal elements, considerable amounts (30—37%) of them were also found in two larger-molecular-weight fractions (>MW 10^4 and MW 10^4—500). This shows that a large portion (63—70%) of the alkaline-earth elements are dissolved in the river water as simple bivalent cations, while the remainder are present as complexes or colloids with a larger molecular weight.

Transition Elements (Sc, V, Cr, Mn, Fe, Co, Ni, and Zn). The total concentrations of Sc and Fe in the upper reaches (Station A) were higher than those in the lower reaches (Stations B and C). On the other hand, higher concentrations of V, Mn, Co, Ni, and Zn were observed for the lower reaches, as is shown in Table 5. This indicates that the Sc and Fe in the river water are mainly derived from rocks or their efflorescences in the drainage basin, while the other five heavy metals are chiefly supplied by anthropogeneous sources.[14]

The transition elements in the upper reaches were generally associated with the suspended-size fraction (>0.45 μm), except for Ni. In the lower reaches, however, they were mainly fractionated as dissolved species (<0.45 μm), although 64% of the Sc and 81% of the Fe were still recognized in the suspended-size fraction even at Station C. Exceptionally, Ni was found in the dissolved-size fraction from all the sampling stations. Large portions of the dissolved V and Mn (76—82% and 60—68% respectively) were distributed in the smallest-molecular-weight fraction (<MW 500). Therefore, V and Mn are mainly dissolved in the river water as inorganic ions, such as $VO_2(OH)_3^{2-}$, Mn^{2+} or their simple compounds.[20] A considerable part (21—34%) of the Mn was also found in the middle-molecular-weight fraction (MW 10^4—500), so that the possibility of the occurrence of a Mn-organic complex cannot be neglected. Although the majority of the Sc and Fe was associated with suspended materials, as has been stated above, the remaining, dissolved portions of these elements were mostly distributed in the middle- and the largest-molecular-weight fractions respectively. Only 5—12% of these could be detected in the smallest-molecular-weight fraction. This shows that the chief dissolved species of Sc is a larger complex such as polyhydroxide, while Fe is present in the colloidal state.[21] The dissolved Co, Ni, and Zn were mainly divided into two smaller-molecular-weight fractions (MW 10^4—500 and <MW 500), though a considerable part (25%) of the Zn from Station C was found in the largest-molecular-weight fraction (>MW 10^4). Therefore, these three elements may be expected to be present in the river water not only as bivalent cations (M^{2+}), but also as complexes with naturally occurring organic ligands. On the other hand, Cr was divided into three molecular-weight fractions. Consequently, the dissolved Cr in the river water is composed of a sexivalent ion (CrO_4^{2-}), an inorganic

or organic complex, and inorganic Cr(III), which is quantitative co-precipitated on colloidal iron(III) hydroxide.[22]

Rare-earth Elements (REEs; La, Ce, Sm, Eu, Tb, Ho, Tm, Yb, and Lu). The total concentrations of such light REEs as La, Ce, Sm, and Eu in the upper reaches (Station A) were higher than those in the lower reaches (Stations B and C). For such heavier REEs as Tb, Ho, Tm, Yb, and Lu, on the contrary, higher concentrations were observed in the lower reaches, as is shown in Table 6.

The light REEs were mostly found in the suspended-size fraction (>0.45 μm), even though a considerable part (20—32%) of these elements at Station C was fractionated as dissolved species (<0.45 μm). On the other hand, heavier REEs in the lower reaches were mainly distributed in the dissolved-size fraction, although, at Station B, 76% of the Tb and 41% of the Tm were still associated with suspended materials. In the upper reaches, these elements could not be detected. The dissolved light REEs were mainly divided between two larger-molecular-weight fractions (>MW 10^4 and MW 10^4—500). On the other hand, the heavier REEs were chiefly (65—82%) distributed in the middle-molecular-weight fraction (MW 10^4—500). These findings suggest that the REEs in the river water are primarily derived from rocks or their efflorescences, and then that heavier REEs are dissolved by forming complexes in the lower reaches of the river, where the water has an abundance of complexing ligands, such as natural organics and anions. In the upper reaches, with a poor TOC concentration, they cannot be detected. Light REEs tend to co-precipitate with iron(III) hydroxide,[14] so that they are still associated with suspended materials or colloids.

Others (As, Se, Sb, W, Al, Ag, and U). The total concentrations of Al and U in the upper reaches were considerably higher than those in the lower reaches, as is shown in Table 8. This indicates that these elements are derived from rocks in the drainage basin in a manner similar to Fe, Sc, Cs, and light REEs. On the contrary, a higher Ag concentration was observed in the lower reaches, where the river water was greatly polluted by artificial sources. In the upper reaches, Ag was not detected. There were no large differences in the total concentrations of As, Se, Sb, and W among the three sampling stations, as can be seen in Table 7.

Almost all the As, Se, Sb, and W was distributed in the dissolved-size fraction (<0.45 μm). The dissolved species of these elements were mainly divided into two smaller-molecular-weight fractions (MW 10^4—500 and <MW 500), although As, Se, and W were predominantly found in the middle-molecular-weight fraction, while Sb was more concentrated in the smallest-molecular-weight fraction. It is well known that these four elements tend to form oxoanions, such as $HAsO_4^{2-}$, SeO_3^{2-}, $Sb(OH)_6^-$, and WO_4^{2-}, in natural water, as do V or Cr. However, the fractionation

results show that As, Se, and W are present in the river water as such larger dissolved compounds as organic complexes,[23] in preference to those simple oxoanions.

Aluminium was, in the upper reaches, mainly distributed in the suspended-size fraction, while in the lower reaches it was fractionated as dissolved species to a considerable extent (25—44%). For Ag, 77% in Station B and 55% in Station C were associated with suspended materials. Most (77—88%) of the U was found in the dissolved-size fraction at all the sampling stations. The dissolved Al, Ag, and U were predominantly found in the smallest-, the largest-, and the middle-molecular-weight fractions respectively. This indicates that the dissolved Al exists as simple inorganic ions, and that the Ag is chiefly associated with colloidal materials, while the U can be expected to be present in the form of an uranil complex.

Conclusions

Using the UF technique and the NAA method, it was possible to obtain some knowledge about the dissolved species of trace elements existing in Tama River water. Alkali and alkaline-earth elements, Al, V, Mn, and Sb, dissolved in the river water were predominantly present as simple ions or their small molecule compounds, although a considerable part (20—30%) of the alkaline-earth elements, Mn, and Sb were also dissolved as complexes with larger-molecular-weight sizes. The dissolved Co, Ni, Zn, and As were mainly divided into the smallest- and middle-molecular-weight fractions, so that their chief dissolved species were probably both simple ions and complexes. The dissolved Sc, heavier REEs, Se, W, and U were mainly present by forming complexes. On the other hand, Fe, Ag, and some light REEs dissolved in the river water were primarily associated with colloidal materials.

Several tedious problems, however, still remain to be examined concerning the UF technique, much as with the MF technique.[14] For example, the pore diameter of the filter may show considerable variation, so that a precise separation of trace elements is difficult. Furthermore, a clogging of the filter pores, contamination from the filtering apparatus and the filter themselves, and losses due to adsorption on the filter are more insidious problems in the UF experiment. Further consideration in greater detail will be necessary to minimize analytical errors.

Preparation and Characterization of Cobalt(III) Complexes Containing $(CH_3)_2As(CH_2)_nAs(CH_3)_2$ (n=2, 3)

Katsumi IWATA, Masaaki KOJIMA, and Junnosuke FUJITA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received June 12, 1985)

Twelve new complexes, *trans*-$[CoX_2(dmae \text{ or } dmap)_2]^+$ (X=Cl, Br, I; dmae=1,2-bis(dimethylarsino)ethane, dmap=1,3-bis(dimethylarsino)propane), *cis*-$[CoX_2(dmap)_2]^+$ (X=Cl, Br), $[Co(CO_3)(dmae \text{ or } dmap)_2]^+$, and $[Co(acac)_{3-n}(dmap)_n]^{n+}$($n$=0, 1, 2; acac=2,4-pentanedionate ion) were prepared and characterized. From a comparison of the $^1A_{1g} \rightarrow {}^1E_g$ (D_{4h}) d-d absorption bands of analogous *trans*-dichloro complexes of phosphines and amines, the order of spectrochemical series for the group 5B elements was suggested to be P > As > N. Largely reduced interelectronic repulsions between the crystal field levels were observed for the carbonato complexes. Isomerization of *cis*-$[CoCl_2(dmap)_2]^+$ to the trans isomer was studied in methanol in the temperature range of 20.1—49.9 °C. The rate has a first-order dependence on the complex concentration. The rate constant at 54.9 °C, calculated from the $\Delta H^{\neq}$ (115.2 kJ mol^{-1}) and $\Delta S^{\neq}$ (53.8 J mol^{-1} K^{-1}) values, is 10^3 times as large as that reported for *cis*-$[CoCl_2(diars)_2]^+$ (diars=*o*-phenylenebis(dimethylarsine)) at the same temperature.

According to Pearson's HSAB model,[1] a cobalt(III) ion which belongs to a hard acid prefers a hard base such as ammonia or water to a soft base such as arsine ligands in complex formation. However, several arsine ligands such as *o*-phenylenebis(dimethylarsine) (diars)[2-6] and *cis*-bis(dimethylarsino)ethylene[7] have been reported to form stable cobalt(III) complexes. All the cobalt(III)–arsine complexes reported so far involve an unsaturated group which shows strong absorption bands in the ultraviolet region and sometimes makes band assignments of the complexes difficult.

In this paper we report the preparation and absorption spectra of cobalt(III) complexes containing a saturated arsine chelate, 1,2-bis(dimethylarsino)ethane (dmae) and 1,3-bis(dimethylarsino)propane (dmap). The paper also describes isomerization of *cis*-$[CoCl_2(dmap)_2]^+$ to the trans isomer in methanol.

Experimental

The arsine ligands, dmae and dmap were handled under a nitrogen atmosphere until they formed air-stable cobalt(III) complexes. Tetrahydrofuran was dried with sodium and deoxygenated by distillation in a stream of nitrogen.

1,2-Bis(dimethylarsino)ethane, dmae. This compound was prepared by the method of Sommer[8] from $(CH_3)_2AsSAs(CH_3)_2$, metallic sodium, and 1,2-dibromoethane in liquid ammonia. Yield: *ca.* 2%. The compound was not purified by fractional distillation because of the very low yield. Tetramethyldiarsine which was the most abundant by-product was removed by evaporation under reduced pressure, and the residue was used to prepare *trans*-$[CoCl_2(dmae)_2]ClO_4$ (*vide infra*).

1,3-Bis(dimethylarsino)propane, dmap. This compound was prepared by the method of Sommer[8] with a slight modification. A tetrahydrofuran solution (500 cm^3) of sodium dimethylarsenide (0.2 mol) was prepared by the method of Phillips and Vis[9] from sodium (10.3 g, 0.45 mol) and iododimethylarsine[10] (47.9 g, 0.207 mol). To this solution was added 1,3-dibromopropane (21.0 g, 0.104 mol) at 0 °C with stirring. Water (50 cm^3) was added to the resulting white suspension, and then tetrahydrofuran was evaporated under reduced pressure. The residue was shaken with diethyl ether to extract the diarsine. The ethereal layer was separated and dried with anhydrous calcium chloride. The desiccant was filtered off, the ether evaporated, and the residue was distilled at 86—90 °C and 2670 Pa to give a colorless liquid. Yield: 11.3 g (43%). ^{1}H NMR ($CDCl_3$) δ=0.93 (12H, s, $AsCH_3$), 1.26 (2H, m, β-CH_2), and 1.55 (4H, t, $AsCH_2$).

trans-[CoCl$_2$(dmae)$_2$]ClO$_4$. To an ethanol solution (20 cm^3) of $CoCl_2 \cdot 6H_2O$ (0.96 g, 4.0 mmol) was added an ethanol solution (10 cm^3) of dmae prepared from 13.4 g of $(CH_3)_2AsSAs(CH_3)_2$ and 10.5 g of $BrCH_2CH_2Br$ in the manner described above. Air was bubbled through the resulting green solution for 90 min, and then 1 mol dm^{-3} HCl (27 cm^3) was added, a dark green solution being yielded. The ethanol was evaporated under reduced pressure and to the concentrate was added $NaClO_4$ (0.42 g). A green solid which precipitated was collected by filtration, washed successively with 1 mol dm^{-3} $HClO_4$, methanol, ethanol, methanol–diethyl ether (1:10), and diethyl ether, and dried *in vacuo*. Yield: 0.39 g. Found: C, 20.73; H, 4.42%. Calcd for $C_{12}H_{32}As_4Cl_3CoO_4$: C, 20.43; H, 4.57%. ^{1}H NMR (CD_2Cl_2) δ=1.63 (24H, s, $AsCH_3$) and 2.43 (8H, s, $AsCH_2$). The complex is soluble in water and ethanol.

trans-[CoBr$_2$(dmae)$_2$]ClO$_4$. This complex was prepared from *trans*-$[CoCl_2(dmae)_2]ClO_4$ and KBr by metathesis. To a methanol solution (10 cm^3) of *trans*-$[CoCl_2(dmae)_2]ClO_4$ (0.100 g, 0.14 mmol) was added an aqueous solution (5 cm^3) of KBr (1.0 g, 8 mmol). The mixture was stirred overnight at 40 °C, and then evaporated to dryness under reduced pressure. The residue was extracted with dichloromethane (10 cm^3). The extract was mixed successively with methanol (10 cm^3), water (3 cm^3), and 70% $HClO_4$ (0.5 cm^3), and the solvent was evaporated slowly at room temperature to give a yellow-green precipitate. The product seemed to be impure, since the ^{1}H NMR spectrum in CD_2Cl_2 showed two singlets attributable to the As-methyl protons at 1.73 and 2.09 ppm. The pure complex was obtained by repeated recrystallization from dichloromethane–methanol–70% $HClO_4$ by the method as above until the signal at 2.09 ppm disappeared completely. Yield: 0.06 g (53%). Found: C, 18.63; H, 4.10%. Calcd for $C_{12}H_{32}As_4Br_2ClCoO_4$: C, 18.15; H, 4.06%. ^{1}H NMR (CD_2Cl_2) δ=1.73 (24H, s, $AsCH_3$) and 2.46 (8H, s, $AsCH_2$).

trans-[CoI$_2$(dmae)$_2$]ClO$_4$. This complex was prepared from *trans*-$[CoCl_2(dmae)_2]ClO_4$ and NaI by metathesis. To an ethanol solution (10 cm^3) of *trans*-$[CoCl_2(dmae)_2]ClO_4$ (0.053 g, 0.075 mmol) was added an excess of NaI (0.35 g, 2.3 mmol), the color of the solution changing from green to

brown. The solution was refluxed for 10 min, and to the resulting reddish brown solution was added an aqueous solution (5 cm^3) of $NaClO_4$ (0.50 g). The mixture was evaporated to *ca.* 5 cm^3 to yield reddish brown plates or needles, which were collected by filtration, washed successively with water, ethanol–diethyl ether (1:5), and diethyl ether. Yield: 0.050 g (75%). Found: C, 16.43; H, 3.55%. Calcd for $C_{12}H_{32}As_4ClCoI_2O_4$: C, 16.22; H, 3.63%. ^1H NMR (CD_3CN) δ=1.99 (24H, s, $AsCH_3$) and 2.51 (8H, s, $AsCH_2$).

[Co(CO$_3$)(dmae)$_2$]ClO$_4$·2NaClO$_4$. To a hot methanol solution (3 cm^3) of *trans*-[$CoCl_2$(dmae)$_2$]ClO_4 (0.223 g, 0.31 mmol) were added Li_2CO_3 (0.20 g, 2.7 mmol) and water (5 cm^3). The mixture was heated on a water-bath for 15 min, and then allowed to cool to room temperature. The resulting orange reaction mixture was filtered to remove remaining *trans*-[$CoCl_2$(dmae)$_2$]ClO_4 and Li_2CO_3. The filtrate was mixed with a saturated aqueous solution (2 cm^3) of $NaClO_4$, and the volume of the solution was reduced to *ca.* 5 cm^3 under reduced pressure. The concentrate was stored in a refrigerator to give an orange precipitate. The precipitate was collected by filtration, extracted with methanol, and the extract was mixed with a saturated aqueous solution (2 cm^3) of $NaClO_4$. By evaporating the methanol, the desired complex was obtained as orange plates. They were collected by filtration, washed with methanol–diethyl ether (1:5) and then diethyl ether. Yield: 0.107 g (36%). Found: C, 16.65; H, 3.43%. Calcd for $C_{13}H_{32}As_4Cl_3CoNa_2O_{15}$: C, 16.62; H, 3.43%. ^1H NMR (D_2O) δ=1.46 (6H, s, $AsCH_3$), 1.51 (6H, s, $AsCH_3$), 1.57 (6H, s, $AsCH_3$), 1.89 (6H, s, $AsCH_3$), and 2.3—2.7 (8H, m, $-CH_2-$).

trans-*[CoCl$_2$(dmap)$_2$]Cl·H$_2$O.* To an ethanol solution (20 cm^3) of $CoCl_2·6H_2O$ (1.23 g, 5.2 mmol) was added an ethanol solution (10 cm^3) of dmap (2.6 g, 10.3 mmol). The color of the solution changed from blue to dark green and a precipitate was formed. By adding concd HCl (4 cm^3) the precipitate was dissolved. Air was bubbled through the solution for 1 h, and then water (40 cm^3) was added. The ethanol was evaporated under reduced pressure to give a green precipitate. After cooling the mixture overnight in a refrigerator, the precipitate was collected by filtration and washed successively with 1 mol dm^{-3} HCl, ethanol–diethyl ether (1:10), and diethyl ether. Yield: 3.0 g (84%). Found: C, 24.13; H, 5.51%. Calcd for $C_{14}H_{38}As_4Cl_3CoO$: C, 24.46; H, 5.57%. The presence of water of crystallization was suggested from the IR spectrum. The complex is soluble in water, ethanol, acetonitrile, and dichloromethane.

trans-*[CoCl$_2$(dmap)$_2$]ClO$_4$.* This complex was obtained by adding 70% $HClO_4$ (0.1 cm^3) to a methanol solution (5 cm^3) of the chloride (0.30 g, 0.44 mmol). Diethyl ether (15 cm^3) was added to ensure the precipitation of the perchlorate. The green precipitate was collected by filtration and washed successively with 1 mol dm^{-3} $HClO_4$, methanol–diethyl ether (1:3), and diethyl ether. Yield: 0.30 g (94%). Found: C, 22.96; H, 4.95%. Calcd for $C_{14}H_{36}As_4Cl_3CoO_4$: C, 22.93; H, 4.95%. ^1H NMR (CD_2Cl_2) δ=1.52 (24H, s, $AsCH_3$) and 1.9—2.9 (12H, m, $-CH_2-$). The complex is soluble in ethanol, acetonitrile, and dichloromethane, but insoluble in water.

trans-*[CoBr$_2$(dmap)$_2$]ClO$_4$.* To an ethanol solution (10 cm^3) of $CoBr_2·6H_2O$ (0.23 g, 0.70 mmol) were added an ethanol solution (5 cm^3) of dmap (0.35 g, 1.4 mmol), and concd HBr (1 cm^3). Air was bubbled into the solution for 30 min, and then 5 mol dm^{-3} $HClO_4$ (5 cm^3) was added. Yellow-green flocculent crystals formed were collected by filtration and washed succesively with 1 mol dm^{-3} $HClO_4$, cold methanol, and diethyl ether. Yield: 0.51 g (90%). Found: C, 20.49; H, 4.46%. Calcd for $C_{14}H_{36}As_4Br_2ClCoO_4$: C, 20.45; H, 4.41%. ^1H NMR (CD_2Cl_2) δ=1.62 (24H, s, $AsCH_3$) and 2.0—2.6 (12H, m, $-CH_2-$).

[Co(CO$_3$)(dmap)$_2$]ClO$_4$·2NaClO$_4$·CH$_3$OH. This complex was prepared by a method similar to that for [Co(CO_3)(dmae)$_2$]ClO_4·2$NaClO_4$. To a hot methanol solution (3 cm^3) of *trans*-[$CoCl_2$(dmap)$_2$]Cl·H_2O (0.47 g, 0.68 mmol) were added Li_2CO_3 (0.20 g, 2.7 mmol) and water (3 cm^3). The mixture was heated on a water-bath for 15 min, the color of the solution changing from green to dark red. The methanol was removed under reduced pressure at 40 °C, and to the concentrate was added a saturated aqueous solution (1 cm^3) of $NaClO_4$. The mixture was cooled at 0 °C, mixed with 5 mol dm^{-3} $HClO_4$ in order to decompose residual Li_2CO_3, and then filtered to remove remaining *trans*-[$CoCl_2$(dmap)$_2$]-ClO_4. To the concentrate was added dichloromethane (5 cm^3), and the mixture was stirred for a while to form a red precipitate. A saturated solution (5 cm^3) of $NaClO_4$ was added, and the mixture was allowed to stand at 5 °C overnight. The red precipitate was collected by filtration and washed successively with cold water, cold methanol, dichloromethane, and diethyl ether. Yield: 0.21 g (31%). Found: C, 19.22; H, 4.03%. Calcd for $C_{16}H_{40}As_4CoCl_3Na_2O_{16}$: C, 19.18; H, 4.06%. The presence of 1 mol of methanol of crystallization was confirmed by the ^1H NMR spectrum. The complex is soluble in water, methanol, and acetonitrile, but insoluble in dichloromethane.

cis-*[CoCl$_2$(dmap)$_2$]ClO$_4$.* To a cold (*ca.* 0 °C), stirred suspension of the carbonato complex (0.50 g, 0.50 mmol) in water (10 cm^3) was added dropwise cold (*ca.* 0 °C) 6 mol dm^{-3} HCl (20 cm^3). The resulting purple solution was filtered, to the filtrate was added $NaClO_4$ (5 g), and the mixture was stored in a refrigerator for 3 h. Purple crystals which precipitated were collected by filtration and washed successively with water, ethanol, dichloromethane–diethyl ether (1:1), and diethyl ether. Yield: 0.32 g (87%). Found: C, 22.95; H, 4.89%. Calcd for $C_{14}H_{36}As_4Cl_3CoO_4$: C, 22.93; H, 4.95%. ^1H NMR (CD_2Cl_2) δ=1.48 (6H, s, $AsCH_3$), 1.56 (6H, s, $AsCH_3$), 1.59 (6H, s, $AsCH_3$), 1.66 (6H, s, $AsCH_3$), and 1.9—2.5 (12H, m, $-CH_2-$). The complex was not recrystallized, since it is liable to isomerization in solution to give the trans isomer (*vide infra*). However, the ^1H NMR spectrum of the complex prepared as above shows no signal attributable to the trans isomer.

cis-*[CoBr$_2$(dmap)$_2$]ClO$_4$.* This complex was obtained as dark violet crystals from the carbonato complex by a method similar to that for the corresponding dichloro complex using HBr instead of HCl. Yield: 68%. Found: C, 20.48; H, 4.48%. Calcd for $C_{14}H_{36}As_4Br_2ClCoO_4$: C, 20.46; H, 4.41%. ^1H NMR (CD_2Cl_2) δ=1.54 (6H, s, $AsCH_3$), 1.62 (6H, s, $AsCH_3$), 1.65 (6H, s, $AsCH_3$), 1.88 (6H, s, $AsCH_3$), and 2.0—2.5 (12H, m, $-CH_2-$).

trans-*[CoI$_2$(dmap)$_2$]ClO$_4$.* To a solution (12 cm^3) of the carbonato complex (0.10 g, 0.10 mmol) in water–acetonitrile (1:5) were added NaI (0.30 g, 2 mmol) and 5 mol dm^{-3} $HClO_4$ (4 cm^3). The mixture was stirred for 30 min, and then evaporated to a small volume under reduced pressure to form dark red plates. They were collected by filtration, washed successively with water, cold methanol, and diethyl ether, and dried *in vacuo*. Yield: 0.083 g (91%). Found: C, 18.41; H, 3.99%. Calcd for $C_{14}H_{36}As_4ClCoI_2O_4$: C, 18.35; H, 3.96%.

^1H NMR (CD_2Cl_2) δ=1.80 (24H, s, $AsCH_3$) and 2.0—2.5 (12H, m, $-CH_2-$). This complex is soluble in dichloromethane and acetonitrile, but insoluble in ethanol and water.

[Co(acac)(dmap)$_2$](ClO$_4$)$_2$·H$_2$O (acac=2,4-pentanedionate ion). To a warm solution (5 cm^3) of *trans*-[$CoCl_2$(dmap)$_2$]-ClO_4 (0.21 g, 0.29 mmol) in methanol was added an aqueous solution (10 cm^3) of lithium 2,4-pentanedionate (0.05 g, 0.47 mmol). The mixture was heated at 70 °C for 3 h. The resulting red solution was diluted with water (100 cm^3) and applied on a column (ϕ4.5 cm×22 cm) of SP-Sephadex C-25 (Na^+ form). On elution with 0.1 mol dm^{-3} $NaClO_4$, three bands developed; purple ([Co(acac)$_2$(dmap)]$^+$, small amount), yellow-green (*trans*-[$CoCl_2$(dmap)$_2$]$^+$, small amount), and red ([Co(acac)(dmap)$_2$]$^{2+}$, large amount) in the order of elution. The eluate containing the slowest-moving red band was collected and evaporated to *ca.* 20 cm^3 under reduced pressure. The concentrate was stored in a refrigerator to form a red precipitate. It was collected by filtration and washed successively with cold 1 mol dm^{-3} $HClO_4$, methanol–diethyl ether (1:3), and diethyl ether. Yield: 0.14 g (57%). Found: C, 25.57; H, 4.85%. Calcd for $C_{19}H_{45}As_4Cl_2CoO_{11}$: C, 25.96; H, 5.16%. ^1H NMR (CD_3NO_2) δ=1.56 (6H, s, $AsCH_3$), 1.60 (12H, s, $AsCH_3$), 1.69 (6H, s, $AsCH_3$), 1.9—2.5 (12H, m, $-CH_2-$), 2.19 (6H, s, CCH_3), and 5.89 (1H, s, $-CH-$). ^{13}C NMR (CD_3NO_2) δ=7.3 (q), 7.5 (q), 10.2 (q), 13.8 (q), 21.2 (t), 27.1 (q), 27.7 (t), 27.8 (t), and 102.3 (d). The complex is soluble in water and methanol, and slightly soluble in ethanol.

[Co(acac)$_2$(dmap)]ClO$_4$. To a methanol solution (10 cm^3) of [Co(acac)$_3$] (0.50 g, 1.4 mmol) were added an ethanol solution (10 cm^3) of dmap (0.10 g, 0.4 mmol) and active charcoal (0.10 g). The mixture was stirred for 2 d at room temperature and then filtered. The purple filtrate was diluted with water (20 cm^3), and the unreacted arsine ligand was extracted with petroleum ether. The aqueous phase was diluted with water (100 cm^3) and applied on a column (ϕ4.5 cm×10 cm) of SP-Sephadex C-25 (Na^+ form). The column was washed with water to remove remaining [Co(acac)$_3$]. By elution with 0.05 mol dm^{-3} NaCl, a purple ([Co(acac)$_2$-(dmap)]$^+$) and a red (a mixture of [Co(acac)(dmap)$_2$]$^{2+}$ and [$Co(H_2O)_6$]$^{2+}$) band developed in this order. The eluate containing the main purple band was collected and evaporated to a small volume under reduced pressure. To the concentrate was added $NaClO_4$ (0.2 g), and the complex was extracted with dichloromethane. The extract was washed with water, and mixed with a small amount of ethanol. The mixture was evaporated to a small volume, and to the concentrate was added diethyl ether. A purple precipitate was collected by filtration and washed successively with water, methanol–diethyl ether (1:5), and diethyl ether. Yield: 0.22 g (92%). Found: C, 33.57; H, 5.41%. Calcd for $C_{17}H_{32}As_2ClCoO_8$: C, 33.55; H, 5.30%. ^1H NMR (CD_2Cl_2) δ=1.23 (6H, s, $AsCH_3$), 1.43 (6H, s, $AsCH_3$), 1.7—2.2 (m, $-CH_2-$), 1.84 (6H, s, CCH_3), 2.19 (6H, s, CCH_3), and 5.48 (2H, s, $-CH-$). ^{13}C NMR (CD_2Cl_2) δ=4.9 (q), 5.6 (q), 20.6 (t), 22.9 (t), 26.6 (q), 27.3 (q), and 98.9 (d). The complex is soluble in ethanol and dichloromethane, but insoluble in water.

Measurements. Absorption spectra were obtained using a Hitachi 323 or a JASCO 610B spectrophotometer. ^1H NMR spectra were recorded on a JEOL PMX-60 or a JEOL FX 100 spectrometer, and ^{13}C NMR spectra on a JEOL FX 100 spectrometer.

Kinetics. Rates of isomerization of *cis*-[$CoCl_2$(dmap)$_2$]-ClO_4 to the trans isomer in methanol were followed by measuring the change in absorbance at 535 nm in the temperature range of 20.1—49.9 °C. The complex concentrations were *ca.* 1.3×10^{-3} mol dm^{-3}. The temperature of the solutions was kept constant within ±0.1 °C by use of a temperature-controlled circulating bath, Yamato-Komatsu CET-24W. In each kinetic run, the plot of $\ln(A_t-A_\infty)$ *vs.* time gave a straight line at least four half-lives, where A_t and A_∞ denote the absorbance at time t and at infinite time at 535 nm, respectively. The slope gave the first-order rate constant of isomerization, k, and Eyring treatment of $\log(k/T)$ *vs.* T^{-1} yielded the activation parameters.

Results and Discussion

Preparation and Characterization of the Complexes. Because of the very poor yield of the dmae ligand, most of the study has been done on the dmap complexes, although five-membered dmae chelate complexes would be more fundamental.

A *trans*-[$CoCl_2$(chelate)$_2$]$^+$ complex is known to be a good starting material for preparing various bis-(chelate)cobalt(III) complexes. The two chloride ions in the *trans*-[$CoCl_2$(dmae)$_2$]$^+$ and *trans*-[$CoCl_2$-(dmap)$_2$]$^+$ complexes are also easily replaced by such ligands as a carbonate and a 2,4-pentanedionate ion. Both *trans*-dichloro complexes were prepared in good yield by air-oxidation of a mixture of cobalt(II) chloride hexahydrate and the corresponding arsine ligand in ethanol, and by treating with hydrochloric acid. The trans configuration was suggested by green in color characteristic of a trans (Cl, Cl) configuration and confirmed by the ^1H NMR spectra. The *trans*-dichloro complexes give only one resonance attributable to the As–methyl protons. Since the puckering of the chelate rings will be rapid on the NMR time scale, four methyl groups in the trans isomer should be in equivalent environment. On the other hand, the purple [$CoCl_2$(dmap)$_2$]$^+$ complex prepared by treating [$Co(CO_3)$(dmap)$_2$]$^+$ with hydrochloric acid at *ca.* 0 °C exhibits four resonances in the As–methyl region (1.2—2.0 ppm) and is assigned to the cis isomer. The configurations of the dibromo and diiodo complexes were also assigned on the basis of the NMR and absorption spectra (*vide infra*). The *trans*-[$CoBr_2$(dmae)$_2$]$^+$ complex was prepared by reaction between *trans*-[$CoCl_2$(dmae)$_2$]$^+$ and potassium bromide in methanol. The complex thus yielded was necessary to recrystallize several times to purify; the most abundant impurity contained in the crude product may be the *trans*-bromochloro complex. In order to avoid contamination by the mixed halogeno complex, *trans*-[$CoBr_2$(dmap)$_2$]$^+$ was prepared by a method similar to that for the *trans*-dichloro complex using cobalt(II) bromide hexahydrate and hydrobromic acid instead of cobalt(II) chloride hexahydrate and hydrochloric acid. The *cis*-[$CoBr_2$(dmap)$_2$]$^+$ complex was prepared by a method similar to that for the corresponding *cis*-dichloro complex from [$Co(CO_3)$(dmap)$_2$]$^+$ and

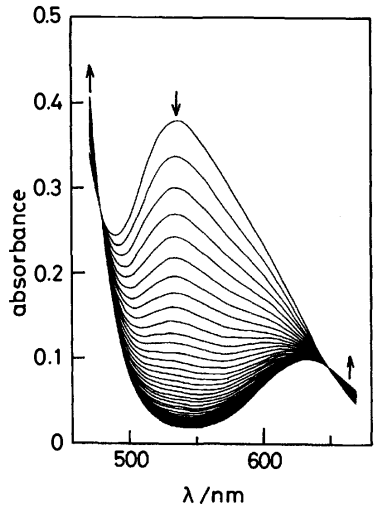

Fig. 1. Change in absorption spectrum of *cis*-[$CoCl_2(dmap)_2$]ClO_4 in methanol at 30.3 °C (recorded intervals: 30 min). Trends of spectral changes with time are shown by arrows.

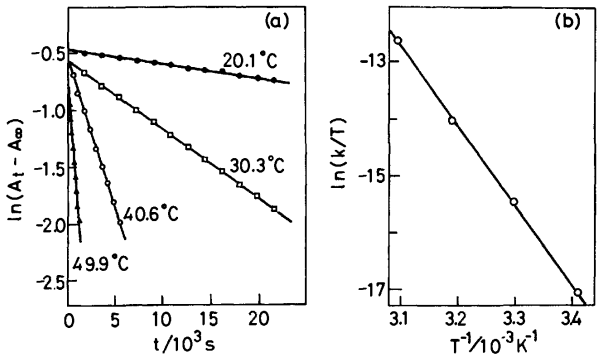

Fig. 2. (a) Plots of $\ln(A_t - A_\infty)$ against time at 20.1, 30.3, 40.6, and 49.9 °C and (b) Eyring treatment of $\ln(k/T)$ against T^{-1}.

hydrobromic acid.

Both *cis*-dichloro and dibromo complexes isomerize in solution to the trans isomer. Figure 1 shows the change in absorption spectrum at intervals during the isomerization of *cis*-[$CoCl_2(dmap)_2$]ClO_4 in methanol at 30.3 °C. Two isosbestic points were found at 649 and 478 nm in all the experiments (20.1—49.9 °C). The final spectrum was identical with that of a freshly prepared solution of *trans*-[$CoCl_2(dmap)_2$]ClO_4. When the experiment was carried out in deuterated methanol, the final ^1H NMR spectrum of the solution showed only signals attributable to the trans isomer. These results indicate that the cis isomer isomerizes to the trans isomer. Rates of the isomerization were followed by measuring the change in absorbance at 535 nm (Experimental, Fig. 2, and Tables 1 and 2). The rate constant 1.97×10^{-3} s^{-1} at 54.9 °C calculated from the ΔH^* and ΔS^* values is larger by a factor of 10^3 than that of *cis*-[$CoCl_2(diars)_2$]$^+$ at the same temperature (1.63×10^{-6} s^{-1}).[11,12] The isomerization of the dmap complex was also studied in the presence of 150 times molar amounts of lithium chloride. The first-order dependence in the complex concentration was maintained, the rates being decreased a little (Table 1).

TABLE 1. RATE CONSTANTS FOR ISOMERIZATION OF *cis*-[$CoCl_2(dmap)_2$]$^+$ IN METHANOL

t/°C	k/s^{-1}
20.1	$(1.18\pm0.01)\times10^{-5}$
30.3	$(5.92\pm0.02)\times10^{-5}$
40.6	$(2.61\pm0.01)\times10^{-4}$
49.9	$(1.04\pm0.01)\times10^{-3}$
20.2[a]	$(1.03\pm0.01)\times10^{-5}$
30.3[a]	$(4.89\pm0.01)\times10^{-5}$

49.8[a]	$(8.61\pm0.02)\times10^{-4}$

a) Lithium chloride added (0.195 mol dm^{-3}).

TABLE 2. THERMODYNAMIC PARAMETERS FOR ISOMERIZATION OF THE COMPLEXES

complex	ΔH^*/ kJ mol^{-1}	ΔS^*/ J mol^{-1} K^{-1}	$\Delta G^*_{25°C}$/ kJ mol^{-1}
cis-[$CoCl_2(dmap)_2$]$^+$	115.2±0.7	53.8±2.3	99.2±1.5
cis-[$CoCl_2(dmpp)_2$]$^+$[a]	106.4±0.9	2.1±2.9	105.8±1.7

a) From Ref. 13.

Table 2 compares the activation parameters of isomerization for *cis*-[$CoCl_2(dmap)_2$]$^+$ with those for the analogous phosphine complex, *cis*-[$CoCl_2(dmpp)_2$]$^+$ (dmpp=1,3-bis(dimethylphosphino)propane). Although the ΔH^* value for the dmap complex is larger than that for the dmpp complex, the former complex isomerizes faster than the latter one at 25 °C because of the large positive activation entropy. If we assume that the two complexes isomerize *via* the same mechanism, the difference in rate may be explained by a steric factor; differences in bond distance, Co–E and E–C (E=As, P), should cause different steric interactions around the E–CH_3 groups. More data are needed to discuss in detail.

The reaction of [$Co(CO_3)(dmap)_2$]$^+$ with sodium iodide and perchloric acid yielded *trans*-[$CoI_2(dmap)_2$]$^+$, and no cis isomer was formed even the reaction was carried out at 0 °C. The *cis*-diiodo complex will be sterically unstable because of the interaction between the two large iodide ions and will isomerize very rapidly to the stable trans isomer. The *trans*-[$CoI_2(dmae)_2$]$^+$ complex was obtained easily from *trans*-[$CoCl_2(dmae)_2$]$^+$ and sodium iodide in ethanol by metathesis. The first diiodo-arsine complex, [$CoI_2(diars)_2$]$^+$ which was prepared by Nyholm[2] was once assigned as the cis isomer from the absorption spectrum,[14] but later assigned as the trans isomer from the ^1H NMR spectrum.[5]

The [$Co(acac)_2(dmap)$]$^+$ complex was prepared in high yield from [$Co(acac)_3$] and dmap in methanol–ethanol (1:1) in the presence of active charcoal. Although the reaction was carried out with an excess of

$[Co(acac)_3]$, the formation of $[Co(acac)(dmap)_2]^{2+}$ was observed in column chromatography. The result suggests that the dmap ligand has a strong affinity toward cobalt(III) in $[Co(acac)_3]$ and $[Co(acac)_2(dmap)]^+$. However, attempts to prepare $[Co(dmap)_3]^{3+}$ by the reaction of $[Co(acac)_3]$ or *trans*-$[CoCl_2(dmap)_2]^+$ with a large excess of dmap were all unsuccessful. Examination of molecular models indicates that $[Co(dmap)_3]^{3+}$ involves severe steric interactions among the ligands in any conformation of the six-membered chelate rings. Ohishi *et al.*[15] have suceeded in preparing $[Co(dmpe)_3]^{3+}$(dmpe=1,2-bis(dimethylphosphino)ethane) from *trans*-$[CoCl_2(dmpe)_2]^+$ and dmpe. We have not attempted to prepare the analogous arsine complex, $[Co(dmae)_3]^{3+}$, because of the very poor yield of dmae. A complex of the $[Co^{III}As_6]^{3+}$-type has been prepared for the diars ligand by Burstall and Nyholm.[3]

Absorption Spectra. Figure 3 shows the absorption spectra of *trans*-$[CoCl_2(As\text{-}As)_2]^+$ where As–As denotes dmae, dmap, and diars,[4] and Table 3 lists the spectral data. The structure of the diars complex has been determined by X-ray analysis.[16] Thus the dmae and dmap complexes which give spectra similar to that of the diars complex can be assigned to the trans isomer. This assignment is in accord with that given from the ^1H NMR spectra. All the dichloro complexes exhibit a low energy absorption band with intensities $\log\varepsilon$= 1.8—2.1, and the bands are assigned to the split component (I_a, $^1A_{1g}\rightarrow{}^1E_g$ (D_{4h})) of the first absorption band ($^1A_{1g}\rightarrow{}^1T_{1g}(O_h)$) from a comparison with the spectrum of *trans*-$[CoCl_2(en)_2]^+$ (Fig. 3, en=ethylenediamine).[17,18] The I_b ($^1A_{1g}\rightarrow{}^1A_{2g}$ (D_{4h})) component and the second d-d band are not observed by overlapping of the strong bands (25000—26000 cm^{-1}), which can be assigned as mainly the Co–As and Co–Cl charge-transfer bands.[19] The spectrochemical series for the arsine ligands is determined from examination of maximum positions of the I_a components: diars>dmae>dmap. For a series of *trans*-dichloro cobalt(III) complexes with analogous phosphine ligands a similar order has been reported: *o*-phenylenebis(dimethylphosphine)>dmpe> dmpp.[13] The trend that the d-d absorption bands shift to lower energies as the number of ring members of a chelate ligand increases from five to six has been observed for cobalt(III)–diamine complexes such as *trans*-$[CoCl_2(en)_2]^+$ (I_a: 16100 cm^{-1})[17,18] and *trans*-$[CoCl_2(tn)_2]^+$ (I_a: 15400 cm^{-1}, tn=trimethylenediamine).[20] In a series of *trans*-dichloro cobalt(III) complexes with a five-membered chelate, dmae, dmpe, and en, the energy of the I_a component decreases in the order, dmpe (17300 cm^{-1})[13]>dmae (16100 cm^{-1}) ~en (16100 cm^{-1}). Thus the spectrochemical series for the group 5B elements seems to be P>As~N. However, dmpe and dmae are a di(tertiary phosphine) and a di(tertiary arsine), respectively, while en is a di(primary amine). It is known that cobalt(III) complexes containing *N,N,N',N'*-tetramethylethylenediamine (Me_4-en), an

Solvent, a): CH_3CN, b): CH_3OH.

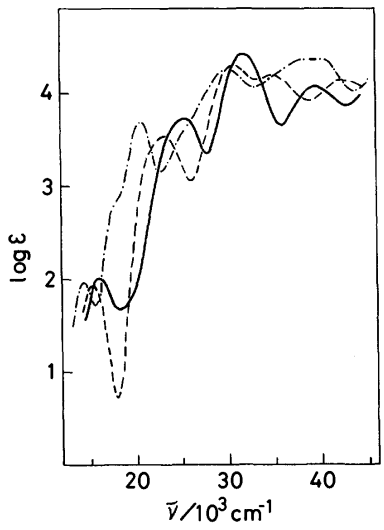

Fig. 4. Absorption spectra of *trans*-$[CoX_2(dmae)_2]^+$ in acetonitrile; X=Cl (——), Br (---), and I (—·—).

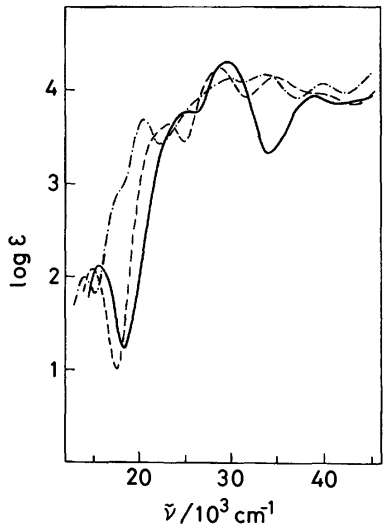

Fig. 5. Absorption spectra of *trans*-$[CoX_2(dmap)_2]^+$ in acetonitrile; X=Cl (——), Br (---), and I (—·—).

analogous ligand to dmpe and dmae, shift the d-d absorption bands to lower energy to a large extent compared with those of the corresponding en complexes (for example, $[Co(acac)_2(en)]^+$: 18450 cm^{-1}, $[Co(acac)_2(Me_4\text{-}en)]^+$: 16600 cm^{-1}).[21-23] Thus the appropriate order for the spectrochemical series would be dmpe (P)>dmae (As)>Me_4-en (N). A similar result (P>As) has been reported for $[PdCl_2\{NH_2CH_2CH_2E(n\text{-}C_4H_9)(C_6H_5)\}]$ (E=P, As).[24]

Figures 4 and 5 show the absorption spectra of *trans*-$[CoX_2(dmae)_2]^+$ and *trans*-$[CoX_2(dmap)_2]^+$ (X=Cl, Br, I), respectively. In either series, the energy of the I_a component decreases in the order Cl>Br>I. The diiodo complexes show a shoulder ($\log\varepsilon\approx2.8$) at *ca.* 18000 cm^{-1}. Such a shoulder is also observed for the analogous phosphine complex, *trans*-$[CoI_2(dmpe)_2]^+$,[13] however, the origin of the transition is unknown.

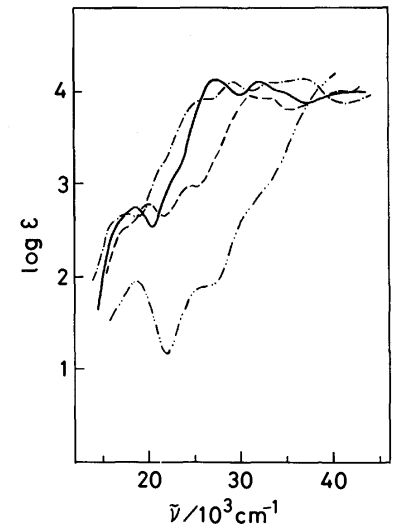

Fig. 6. Absorption spectra of *cis*-$[CoX_2(dmap)_2]^+$ in acetonitrile; X=Cl (——) and Br (—·—), *cis*-$[CoCl_2(diars)_2]^+$ (---, from Ref. 4) in ethanol, and *cis*-$[CoCl_2(en)_2]^+$ (—··—) in water.

The absorption spectra of *cis*-$[CoX_2(dmap)_2]^+$ (X=Cl, Br) are shown in Fig. 6 together with those of the diars and en complexes. The dichloro-dmap complex shows the first absorption band maximum at 18700 cm^{-1} with a shoulder at the low energy side (*ca.* 17000 cm^{-1}). The intensities of these bands are considerably higher than those of *cis*-$[CoCl_2(en)_2]^+$.[25] The large absorption coefficients are also observed for the d-d transitions of other *cis*-$[CoCl_2As_4]^+$-type complexes.[4,19,26,27] If the shoulder at *ca.* 22500 cm^{-1} in the spectrum of *cis*-$[CoCl_2(dmap)_2]^+$ is assigned as mainly the second absorption band, the dmap ligand will reduce largely the interelectronic repulsion of the central cobalt atom; the energy separation between the $^1T_{1g}$ and $^1T_{2g}$ manifolds is much smaller than that of *cis*-$[CoCl_2(en)_2]^+$[25] where the cobalt(III) ion is surrounded by hard donor atoms (Fig. 6). Such largely reduced interelectronic repulsion in a cobalt(III)-arsine complex is more clearly shown for $[Co(CO_3)(dmae)_2]^+$ and $[Co(CO_3)(dmap)_2]^+$; the energy differences (4000 and 4300 cm^{-1}, respectively) between the first and the second absorption bands are about half of that (8260 cm^{-1}) for $[Co(CO_3)(en)_2]^+$[28] (Fig. 7). Small energy differences between the first and the second absorption bands of cobalt(III) complexes have also been reported for phosphine complexes such as $[Co\{(CH_3)_2PCH_2CH_2NH_2\}_3]^{3+}$[29] and $[Co(dmpe)_3]^{3+}$.[15] The spectrum of *cis*-$[CoBr_2(dmap)_2]^+$ is similar to that of the corresponding dichloro complex except that the former is shifted to lower energy side compared to the latter.

Figure 8 shows the absorption spectra of a series of the $[Co(acac)_{3-n}(dmap)_n]^{n+}$($n$=0, 1, 2) complexes. The bands in the region of 16000 to 20000 cm^{-1}, which can be assigned to the first d-d absorption band, shift to higher energy and become more intense as the number

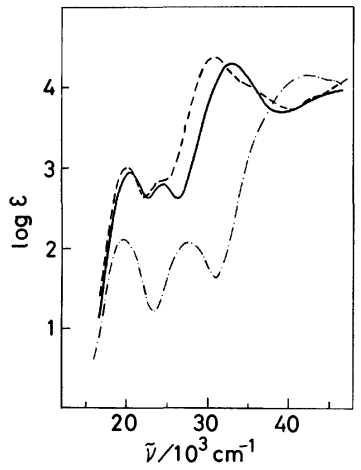

Fig. 7. Absorption spectra of $[Co(CO_3)(dmae)_2]^+$ (——) in methanol, $[Co(CO_3)(dmap)_2]^+$ (---) in methanol, and $[Co(CO_3)(en)_2]^+$ (---) in water.

Optical Energy Storage by Bilayer Electrodes, Polymerized Coordination Compounds of Ruthenium or Iron

Seiichi KANDA* and Royce W. MURRAY†

Department of Applied Chemistry, Faculty of Engineering, The University of Tokushima, Minamijosanjima, Tokushima 770

†*The Kenan Laboratory of Chemistry, University of North Carolina, Chapel Hill, North Carolina 27514, U.S.A*

(Received November 22, 1984)

Electrochemistry of bilayer electrodes has until now been investigated mainly in the dark. For the further development of the photoelectrochemistry of bilayer electrodes and its application to optical-energy storage, a polymer of *N*-[4-[2-(trimethoxysilyl)ethyl]benzyl]-*N'*-methyl-4,4'-bipyridinium dibromide ($BVSiBr_2$), a photoredox siloxane polymer, was employed as a photosensitive outer-layer, and bis(2,2'-bipyridine)bis(4-vinylpyridine)ruthenium(II) bis(hexafluorophosphate), $[Ru(bpy)_2(vpy)_2](PF_6)_2$, or tris(4-methyl-4'-viny-2,2'-bipyridine)iron(II) bis(hexafluorophosphate), $[Fe(vbpy)_3](PF_6)_2$ was electrochemically polymerized as the inner layer on the surface of an SnO_2 electrode. Direct and indirect photochemical reductions(trapping) of the outer layer siloxan polymer were attempted in the following ways: 1) the outer-layer, poly($BVSiBr_2$), was chemically trapped with a methylviologen radical, MV^+, produced photochemically in an illumination cell and transferred to the electrochemical cell, 2) the outer-layer was photochemically trapped by UV irradiation in the presence of photosensitive alcohols (*i*-PrOH and EtOH) and 3) by photochemical trapping with tris(2,2'-bipyridine)-ruthenium and triethanolamine. The lst and the 2nd methods yielded results expressed by cyclic voltammograms showing an accumulation of poly($BVSi^+$), that is, a storage of optical energy in the outer-layer. The result of the 3rd method was negative.

One of the authors (Murray) has presented a theory and an experimental demonstration of a "two-layer electrode" which comprises two electroactive layers on a conducting electrode.[1-3] These are physically discrete and are formed of electroactive materials (usually not a semiconductor) with different redox potentials. The essence of a two-layer or "bilayer" scheme is that an electron transfer between the conductor electrode and the outer electroactive layer is forced catalytically by an electron-transfer mediation through redox states of the inner electroactive layer.

When photoreductive or photooxidative materials are used as the outer-layer components, photochemically excited energy is stored within a specific range of the electrode potential, depending upon the redox potentials of the inner-layer compounds. The reduced or oxidized excited state of the outer layer has been named the "trapped state," and this phenomenon has potential use for solar energy storage cells. This paper presents a few examples of this type of electrode.

Experimental

Chemicals and Equipments. The organosilane monomer *N*-[4-[2-(trimethoxysilyl)ethyl]benzyl]-*N'*-methyl-4,4'-bipyridinium dibromide ($BVSiBr_2$) (**1**) was prepared as described in the literature.[2] Onto a deck-glass, SnO_2 films,

 –$CH_3(Br^-)_2$

or inner films, a drop of a methanolic solution of $BVSiBr_2$ (*ca.* 8×10^{-3} mg in a 9 μL solution) was spread. A rapid methanol evaporation is recommended for producing a uniform film. For condensation polymerization, a hydrogen chloride vapor and warm moisted air were blown successibly on the monomer films, then stored in a vacuum oven for more than two hours. *N,N'*-dimethyl-4,4'-bipyridinium dichloride, methylviologen, ($MVCl_2$) hydrate, benzophenone and Et_4NClO_4 (TEAP) were reagent grade. The potentiostat and electrochemical cells were of conventional design and the SnO_2 electrodes were highly doped films on glass, as previously used.[2] Electrochemical potentials are with reference to a NaCl-saturated calomel electrode (SSCE). Before taking cyclic voltammograms, the electrolytic solution was flushed with N_2. An Hg lamp (Baush and Lomb 33-86-25-01) and a monochromator system were used for irradiations at 313 or 366 nm.

Electrochemical Polymerization of the Inner Films. The monomer complexes $[Ru(bpy)_2(vpy)_2]$ $(PF_6)_2$ (vpy=4-vinylpyridine) and $[Fe(vbpy)_3](PF_6)_2$(vbpy=4-methyl-4'-vinyl-2,2'-bipyridine) were prepared by a method from the literature by Mr. C. R. Leidner.[1] The electrochemical polymerization processes were carried out in a 2-mM** concentration of each complex in 0.1 M Et_4NClO_4/CH_3CN. The potentials applied to the electrode, SnO_2, in these solutions were cyclically swept between −0.8 and −1.8 volt *vs.* SSCE for about 20 min.[2] The coverages, Γ, of the insoluble polymers was determined electrochemically.

Results and Discussion

Photochemistry of $BVSi^{2+}$ Monomer. For a preliminary check of the photochemistry of a $BVSi^{2+}$ monomer solution, the following types of reductive solvents were used. The ratio of components CH_3OH, C_2H_5OH, *i*-C_3H_7OH, and CH_3CN in a mixed solvent A was 1:1:1:1 in volume, for solvent B 0.1:0:1:3; and for solvent C 0:1:0:4. Primes are used to designate solvents (A' and B') of which 4 mL were added to 5 mg of benzophenone. To purge the dissolved oxygen, nitrogen gas was bubbled into the solutions A, A',

** 1 M = 1 mol dm^{-3}.

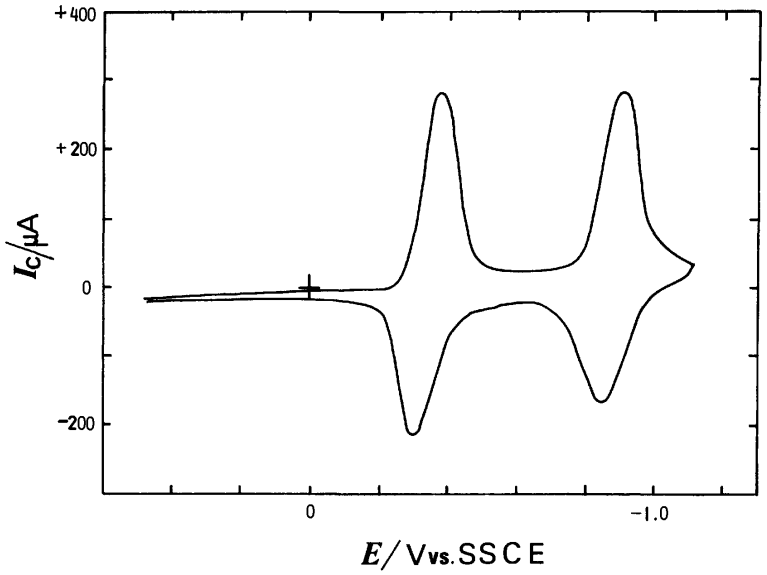

Fig. 1. Cyclic voltammetry of SnO_2/poly($BVSiBr_2$) layer electrode at 0.1 V/s in 0.1 M Et_4NClO_4/CH_3CN.

B and B′ of 2×10^{-4} M $BVSiBr_2$ for 20 min. The solutions were then irradiated at 313 and 366 nm. In solutions A and A′, a violet color emerged and increased in intensity for 50—60 min. It then slowly faded and after 3—4 h the solution became light yellow. In solutions B and B′ of $BVSiBr_2$ of the same concentration, the irradiation instantly made them intense violet; however the color tended to fade sooner than in the previous cases (solvents A and A′) with irradiation. To produce a more complete deoxygenation, a freeze-pump-thaw (FPT) method (4 or 5 cycles) was applied to solutions B′ and C. The $BVSiBr_2$ (2×10^{-4} M) in solution B′ exhibited a violet color even in the room light during the process of FPT. Then, the color faded away after one hour. Thereafter, no color appeared even upon irradiation with an intense light source.

$BVSi^{2+}$ (8×10^{-3} M) in solvent B′ exhibited intense violet upon Hg-lamp irradiation. By shaking the sealed Pyrex tube, the violet color quickly faded. This procedure was repeated more than ten times. The time needed for one cycle became longer and longer; finally, the blue-violet color faded away without further recovery. Upon Hg-lamp irradiation, 8×10^{-3} M $BVSi^{2+}$ in solvent C exhibited a blue color which was much weaker in intensity than in the previous case. Shaking the tube did not cause a weakening of the color and continuous irradiation caused the color to intensify to a certain degree. Fading was very slow and a recovery of the color was possible with UV irradiation.

Such nonpermanent colorations of a $BVSiBr_2$ monomer in several solvents indicate:

1) a photochemical generation of the $BVSi^{+}$ radical;

2) a more or less slow reoxidation of $BVSi^{+}$ to $BVSi^{2+}$ by some oxidants which probably exsist as impurities, even in the purified solutions by freeze-pump-thaw (FPT) method; and that

3) the mechanisms of the coloration are different, depending upon the solvent and/or the photoactive reductants.

Poly($BVSiBr_2$) Film on SnO_2 or Glass. The coverage of the polymer on the substrate can be first calculated from the concentration and the spread volume of the stock solution. This is shown to be $7—8\times10^{-9}$ mol/cm^2 upon assuming uniform films. Secondly the electrochemically determined coverage was calculated from the cathodic peaks on the cyclic voltammogram ($BVSi^{2+/1+/0}$) in CH_3CN (0.1 M TEAP), and the values obtained are 2.36, 3.9, 2.16, and 2.93×10^{-9} mol/cm^2 (average value $2.8\pm0.7\times10^{-9}$ mol/cm^2), as shown in Fig. 1. The difference in the coverages estimated by the above two methods (2.8/8=0.35) can be attributed to a nonuniformity of the film thickness and/or a partial polymerization which might have resulted in the dissolution of a monomer or oligomer of $BVSiBr_2$. The nonuniformity resulted in an underestimation of the coverage in the electrochemical determination.

Preliminary qualitative tests regarding solvents for the photochemical reduction of a poly ($BVSiBr_2$) film on a substrate were as follows. Solvent A dissolves films slowly under UV irradiation, and both the solution and the films became violet. This lasted for a while. In solvent B′, the irradiation caused changes in the colors of the films on both glass and SnO_2 to black or violet. These lasted for more than one month in vessels isolated from oxygen. The stability of the color of a polymer film which differs from the case of the monomer can be attributed to the insensitivity of polymeric solids towards oxidants in comparison with that of a monomer.

TABLE 1. COMPARISON OF AMOUNTS OF THE OUTER-LAYER POLY ($BVSi^{2+}$) AND THE EFFECTIVE AMOUNTS OF ($BVSi^{+}$) COMPONENTS ON THE INNER-LAYER $[Ru(bpy)_2(vpy)_2](PF_6)_2$ OR $[Fe(vbpy)_3](PF_6)_2$ IN THREE WAYS

Chemical Trapping with Photochemically Produced MV^{+} Representative examples of a bilayer electrode for chemical trapping are as follows: 5×10^{-7} mol of $BVSi^{2+}$/5×10^{-8} mol of poly($[Ru(bpy)_2(vpy)_2](PF_6)_2$)/$SnO_2$ and 1.5×10^{-8} mol of $BVSi^{2+}$/8×10^{-9} mol of poly($[Fe(vbpy)_3](PF_6)_2$)/SnO_2. The amounts of $BVSi^{2+}$ were estimated from the spread volumes and the concentrations of the stock solutions, whereas those of inner complex films were evaluated from cyclic voltammograms. As shown in Table 1, the iron-polymer film was adjusted to be thinner than the ruthenium-polymer film, since the structure of poly-($[Fe(vbpy)_3](PF_6)_2$) is tighter and stabler than that of poly($[Ru(bpy)_2(vpy)_2](PF_6)_2$). When the inner film is not tight enough to separate the outer film from the electrode, a leak causes cathodic current peaks of the $BVSi^{2+}$ at the usual potentials of $BVSi^{2+/1+}$ and $BVS^{1+/0}$, that is, at -0.34 and -0.865 V *vs.* SSCE, respectively. For this reason, Ru-complex films were made to be about ten times as thick as Fe-complex films (in moles). In order to obtain precise amounts of trapped poly ($BVSi^{+\cdot}$) in the process of untrapping, the outer films, poly ($BVSi^{2+}$), were made to be more than twice that of the inner films (in moles).

Poly($BVSi^{2+}$) in outer films was reduced using photochemically reduced methylviologen (MV^{+}) as follows; 4×10^{-3} M of a $MVCl_2$ hydrate stock solution in a mixed solvent (1 mL, C_2H_5OH+9 mL, CH_3CN) was irradiated with an Hg lamp in a glass vial under nitrogen bubbling and an addition of 10 mg of benzophenone. One mL of the intense-blue solution produced photochemically within 5 min was transferred through Teflon tubing using the pressure of the nitrogen gas to the electrochemical cell where the bilayers on SnO_2 were set in 10 mL CH_3CN(TEAP). After holding it in the (MV^{2+}/MV^{+}) solution at an open circuit for 10 to 15 min, cyclic voltammograms of the Ru-complex bilayers were recorded between +0.5 and +2.0 V, and between +0.5 and +1.8 V for the Fe-complex bilayer.

As shown in Figs. 2A and 2B, the first anodic peaks are much larger than the cathodic peaks and the successive anodic peaks in the second and the third cycles. These differences are mainly attributed to the theoretically expected untrapping currents of the poly ($BVSi^{+}$). In these potential ranges, the oxidation of poly ($BVSi^{+}$, $BVSi^{0}$) in the outer films and Ru^{2+} in the inner films takes place, but poly ($BVSi^{2+}$) is not reduced (owing to the rule of the bilayer). The integrated values of anodic and cathodic currents during the 2nd and 3rd cycles are expected to be equal if the untrapping of poly ($BVSi^{+}$) is completed during the first anodic scan. However, it is apparent from Fig. 2A that even in the 2nd and 3rd cycles the equalities do not hold. As the voltammogram was taken in a solution which still contained MV^{+}, the untrapped $BVSi^{2+}$-unit would be trapped to form $BVSi^{+}$-unit again in the whole period of time. This causes the above-mentioned inequality between the integrated cathodic and anodic currents. This tendency is emphasized when the inner film is resistive for the transport of the charge which originates from the outer film, as is shown in the case of a Ru-complex inner film.

In order to avoid this ambiguity, based on a continuing trapping by MV^{+} in the calculation of the untrapping charge ($BVSi^{+}\rightarrow BVSi^{2+}$), the trapped bilayer electrodes were quickly washed with aceton and were untrapped in a methylviologen-free acetonitrile (TEAP) solution. For the bilayer with a Ru-complex, the results were calculated using

$$\int I_a dt - \int I_c dt = \int I_a(BVSi^{+\cdot}) dt. \quad (1)$$

These are shown in the 3rd row of Table 1. The expected equality on the 2nd and 3rd reverse processes was satisfactorily effected.

By scanning from -1.5 to +2.0 V *vs.* SSCE at 20 mVs^{-1} in CH_3CN (TEAP), the outer layer can be trapped (reduced) and untrapped electrochemically; by this method, an effective amount of the electrochemically reducible $BVSi^{2+}$ through the inner film (Ru-complex) under the experimental conditions was estimated and is shown in the 2nd row of the table. The values in the 2nd and 3rd rows are nearly equal, whereas that in the lst row (estimated from the volume of the solution) is very much different. This can presumably be attributed to an incomplete untrapping process due to the thickness of the inner film, which

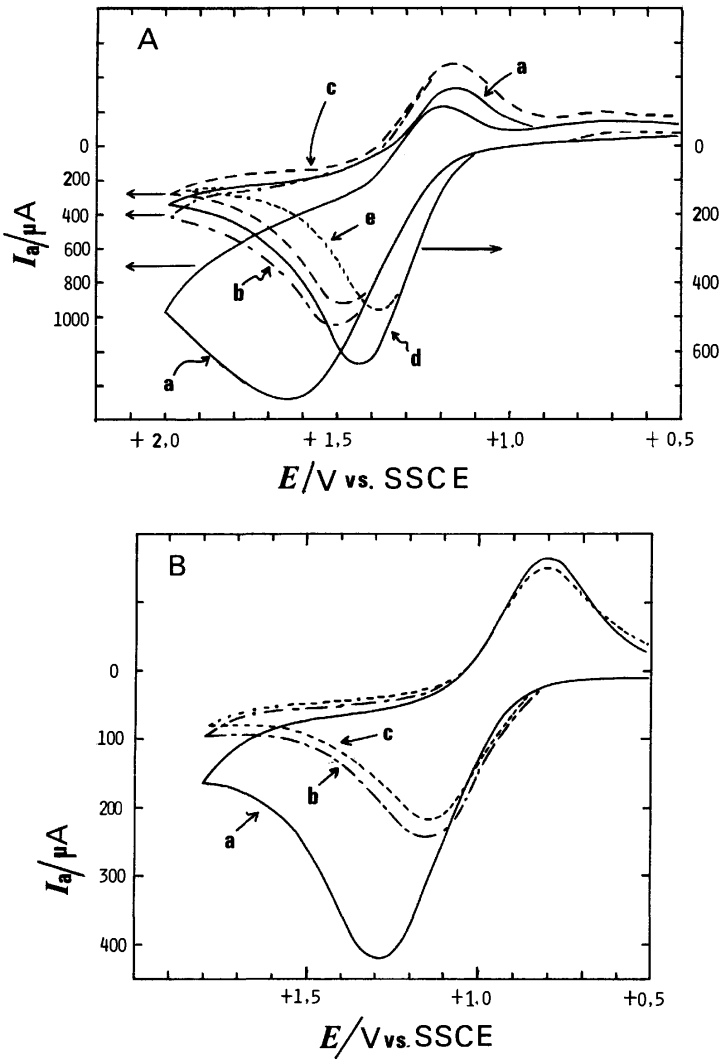

Fig. 2. Untrapping of outer-layer poly($BVSi^{+}$) trapped by MV^{+} in CH_3CN (0.1 M Et_4NClO_4). A) $[Ru(bpy)_2(vpy)_2](PF_6)_2$ inner layer, curve a: 1st scan at 100 mV/s after an exposure for 15 min to MV^{+}, b: 2nd scan at 100 mV/s immediately after the 1st scan, c: 4th scan at 100 mV/s immediately after the 3rd scan, d: 1st scan at 20 mV/s after an exposure for 13 min to MV^{+}, e: 2nd scan at 20 mV/s immediately after the 1st scan. B) $[Fe(vbpy)_3](PF_6)_2$ inner layer. curve a: 1st scan at 100 mV/s an exposure for 14 min to MV^{+}, b: 2nd scan at 100 mV/s immediately after the 1st scan, c: 3rd scan at 100 mV/s immediately after the 2nd scan.

causes the large electrical resistance. It also corresponds to the fact that the untrapped-charge value calculated with Eq. 1 for a fast scan rate (100 mVs^{-1}), is smaller than that for the above case (20 mVs^{-1}).

Contrary, in the case of an iron-complex inner film, the three values in the table were in fair agreement each other. This is probably because of a complete untrapping of outer film species due to the smooth transport of the charge through the inner/outer-film interface and the bulk of the inner film. Also the smoothness is consistent with the independence of the untrapped charge value using Eq. 1 for the scan rates. However, there is still a small discrepancy between the values in the 1st and those in the 3rd row. This is attributable to the nonuniformity of the thickness of the outer film, which might result in an incomplete untrapping in the thicker parts.

In all these speculations uncertainties regarding an evaluation of the electrode area and graphical integrations of cyclic voltammograms were inevitable. Upon considering this, any detailed discussion concerning these minor discrepancies are unnecessary.

trode was dipped in a 1% ethanol solution in CH_3CN (TEAP). The solution was then irradiated with 366 nm light from a xenon lamp with an UV cut filter (<350 nm) for 15 to 25 min. A cyclic voltammogram between +0.5 and +1.5 V *vs.* a AgCl/Ag electrode on the bilayer electrode suggested a gradual photodecomposition of the layers. Thus, the trapping and untrapping can be evaluated by

$$\gamma = (Q_a^{(1)} - Q_a^{(3)})/Q_a^{(3)}, \quad (2)$$

where graphically integrated electrical charge values, $Q_a^{(1)}$ and $Q_a^{(3)}$, stand for electrochemically oxidized amounts of poly (BVSi^{+}) in the lst cycle and the 3rd cycle, respectively. $Q_c^{(i)}$ (the *i*-th cathodically reduced amount) and $Q_a^{(i)}$ in several trials involving different solvents where 2-propanol (4%) and benzophenone (45 mg in 20 mL of solution) were successively added, are tabulated in Table 2 as well as γ values for each. As can be seen from the Table 2 and Fig. 3, ethanol and 2-propanol are effective in photochemical reductions; but, a further addition of benzophenone caused a simultaneous reduction of Q_a, Q_c, and γ. Irradiation with 366 nm light in the presence of benzophenone caused the photoactive substances in the bilayers to be decomposed, resulting in the disappearance of the cathodic and the anodic peaks.

Expecting a trapping of poly(BVSi^{2+}) in the outer film, the Ru-complex bilayer was immersed in a CH_3CN (TEAP) solution which contained a sensitizer 8×10^{-6} M [Ru(bpy)$_3$]$^{2+}$, and a sacrificial reductant, 4×10^{-5} M triethanolamine. It was then irradiated at 450 nm (200 Watt xenon lamp, monochromatized, with UV cut filter). No remarkable effect was ob-

served except a gradual decrease in the redox currents in the cyclic voltammogram.

Conclusion

Three types of photoenergy conversion to chemical energy and its storage have been attempted using bilayer electrodes which were composed of a poly ($BVSi^{2+}$) outer layer and an Fe- or Ru-complex inner layer:

1. The outer layers were trapped by MV^{+} (reductant) derived photochemically from MV^{2+},
2. The outer layers were photochemically trapped in the presence of ethanol and 2-propanol, and
3. Photochemically excited $[Ru(bpy)_3]^{2+}$ with a sacrificial reductant, *i.e.*, triethanolamine, was not reductive to the outer layer.

The results show that the stable radical, MV^{+}, and the alcohols which are permeable through the poly($BVSi^{2+}$) film, are effective for the outer film. However, the excited species of $[Ru(bpy)_3]^{2+}$, with a lifetime of about 10^{-6} s, is not effective in such a heterogeneous redox reaction.

This research was supported by the Japan Society for the Promotion of Science for the Cooperative Photoconversion and Photosynthesis Research Program. S. Kanda acknowledges the hospitality of Murrays' group and the valuable advice given by Prof. Whitten and Dr. Chandrasekaran during his visit in the last quarter of 1981. The assistance during these experiments provided by Mr. L. D. Margerum and Mr. C. R. Leidner is noteworthy.

Oxidation of Coals in Liquid Phases. VII. Oxidation of Oxygen-containing Model Compounds of Coal by Oxygen in Concentrated Sodium Hydroxide Solutions

Hirohide FURUYA, Ryoichi UWABE, Nobuyuki SUTOH, Akitsugu OKUWAKI,*
Akira AMANO, and Taijiro OKABE
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980
(Received December 26, 1984)

Oxidation of 26 model compounds of low-ranked coal was performed to study the formation mechanisms of oxalic acid from coal. A mixture of 0.02 mol of the model compound, 4—60 g of NaOH, and 50 g of water was placed in a 300 cm^3 autoclave and oxidized at 523 K and P_{O_2}=5 MPa for 120 min. Acetic acid was produced from phenols within 15 min and oxidized selectively to oxalic acid. The yield ratio(yield of oxalic acid(%)/yield of CO_2 (%)) from most of the model compounds was higher than 1. These phenomena agreed well with those of low-ranked coal under the same oxidation conditions. The overall reaction rates, yields of oxalic acid, and yield ratios increased rapidly with an increasing concentration of NaOH as in the oxidation of coal. This behavior can be explained resonably well by an alkali-catalyzed oxidation mechanism regarding organic substances.

Oxalic acid is produced in high yields, 40—50%, on a carbon base during the oxidation of low-ranked coal by O_2 in concentrated NaOH solutions.[1] The mechanism of this reaction has been discussed.[2]

Oxidation of coal-model compounds by HNO_3[3] or by $KMnO_4$[3,4] has been carried out to elucidate the basic structure of coal, since it is very complicated. In this previous work, including $KMnO_4$ oxidation of lignite and peat,[5] the yield of oxalic acid was appreciably low. In the present study, 26 oxygen-containing model compounds were oxidized to investigate the formation mechanism of oxalic acid in high yield during the oxidation of coal by O_2 in concentrated NaOH solutions. The model compounds are classified as follows: (a) aliphatic carboxylic acids, (b) aromatic compounds such as phenols and carboxylic acids, and (c) alicyclic or heterocyclic compounds. Low-ranked coal contains these types of functional groups[2] and we may disclose what kinds of the functional groups in coal give oxalic acid in good yield during oxidation using these model compounds. The effect of the NaOH concentration on the oxidation of acetic acid, hydroxyacetic acid, 1,2-benzenediol, and 4-hydroxycinnamic acid is also examined, and the high selectivity in the formation of oxalic acid from acetic acid is explained in terms of the alkali-catalyzed oxidation mechanism.

Experimental

Reagents. Instead of free acid, the sodium salts of acetic acid, propionic acid, and butyric acid were used. The chemicals used were reagent grade except NaOH. Sodium hydroxide was the only guaranteed reagent and the amount of carbon contained in the NaOH as a carbonate was corrected in the calculation of the CO_2 yield for the model compounds.

Oxidation. A 240 cm^3 SUS 316 beaker was put in a 300-cm^3 autoclave fitted with a magnetic stirrer. A mixture 0.02-mol mixture of the model compound (0.03 mol only for acetic acid), 4-60 g of NaOH, and 50 g of water were placed in the beaker and heated to 523 K within 40—60 min after replacing the air with N_2. The O_2 partial pressure was kept at 5±0.2 MPa while stirring at 1200 min^{-1}. After a reaction time of 120 or 15 min, the autoclave was cooled and the reaction mixture was washed and diluted to 1 dm^3. Oxalate, carbonate, and the sodium salts of volatile acids contained in the solution were determined by a previously described methods.[2] In the present work, it was confirmed by a GC-MS analysis that the volatile acids were composed of acetic acid. For this reason, the yield of volatile acids was expressed as the yield of acetic acid.

Results and Discussion

Effect of Types of Model Compounds. The yields of oxalic acid, CO_2, and acetic acid and the yield ratios of oxalic acid to CO_2 are summarized in Table 1 for the oxidation of 26 model compounds for 120 min at 523 K. The numbers (from **1** to **9**) in the lefthand side of Table 1 correspond to each model compound in the following text.

Aliphatic Carboxylic Acids: The oxidation of acetic acid gave a 75% yield of oxalic acid, and the yield ratio (yield of oxalic acid(%)/yield of CO_2(%)) was very high. The overall yields of oxalic acid at 120 min for acetic acid, propionic acid, and butyric acid were larger than those of the aromatic carboxylic acids as shown in Table 1B; however, there was not a great difference in the overall yield (93—98%) among these monocarboxylic acids. The yield ratio for propionic acid was the smallest among the monocarboxylic acids. Clearly, this indicates that propionic acid gives CO_2 and a certain C_2 compound. If the C_2 compound is acetic acid or hydroxyacetic acid, the yield ratio must be 1.0 or 1.7, respectively, since the yield ratios for acetic acid and hydroxyacetic acid were 3.4 and 18.9 at 120 min. The yield ratio for adipic acid was high but the reaction rate was slower than those of the three monocarboxylic acids. This tendency was also noted in $KMnO_4$ oxidation of dicarboxylic acids.[4] Both the reaction rate and the yield ratio for hydroxyacetic acid were extremely high.

Phenols and Aromatic Carboxylic Acids: Phenol was easily cleaved and gave oxalic acid in good yield and

a) Reaction time 1 h. b) Yield of oxalic acid(%)/yield of CO_2. c) Unreacted acetic acid.

yield ratio. There was not a great difference in the results among phenol and dihydric phenols as shown in Table 1B. Yield ratios among dihydric phenols were of the order of 1,2-≃1,3->1,4-benzenediol.

If one of the hydrogens on a benzene ring of phenol was substituted by a saturated aliphatic side chain such as **1** and **2**, the yield ratios were lowered from 1.7 to 1.0—1.2. These values are close to the yield ratios for low-ranked coal.[1] This may be caused by an increasing formation of CO_2 by the oxidation of the side chain. Compound **3** was easily oxidized and yielded a large amount of acetic acid but both yields of oxalic acid and CO_2 were small. The yield ratio for **4** was 1.1, however, the reaction rate was small. The benzenecarboxylic acids were more stable than the phenols during the oxidation as shown in Table 1C. 1,4-Benzenedicarboxylic acid was especially stable. This is due to the extremely slow reaction rate, as it hardly dissolves into concentrated NaOH solutions.[6] Although the reaction rates for **4**, **5**, 1-naphthalenecarboxylic acid, and 2-naphthalenecarboxylic acid were very small, the yield ratios for these naphthalene- and anthracenecarboxylic acids were as high as 1.2. The yield ratios for phenol and benzenediols (1.6—2.1) were a little larger than those for benzoic acid and benzenedicarboxylic acids (1.4—1.8). This may be caused by the difference in the yield of acetic acid since acetic acid afforded 75% oxalic acid. The phenols yielded 8.2—17.2% acetic acid whereas the benzenecarboxylic acids yielded only 0.2—2.5% as shown in Table 1B and 1C. The fact that the yield ratios for the above four phenols and benzenecarboxylic acids were as high as 1.4—2.1 indicates that the aliphatic carboxylic acids of even carbon numbers are predominantly formed during the cleavage of both aromatic rings. Such aliphatic carboxylic acids produced oxalic acid more than the aliphatic carboxylic acids of odd carbon numbers. Acetic and butyric acids afforded 75.4 and 61.6% oxalic acid respectively, whereas, propionic acid 54.6%. Work is in progress to clarify the cleavage products.

Model compounds **3** and **7** yielded 30% of oxalic acid: close to that for 1,2- and 1,3-benzenedicarboxylic acids. The important characteristics of these compounds are that a large amount of acetic acid was produced and the reaction rates were also large.

Alicyclic and Heterocyclic Compounds Containing Oxygen: The reaction rate for cyclohexanol was slow

Table 2. Formation of acetic acid at 15 minutes oxidation

Model Compound	Product yield/% Oxalic acid	CO_2	Acetic acid	Yield ratio[b]
Propionic acid	5.2	5.2	87.3[a]	1.0
1,2-Benzenediol	28.8	12.7	28.9	2.3
1	16.6	9.3	29.5	1.8
2	4.0	5.9	13.9	0.7
3	8.1	3.8	29.1	2.2
7	8.5	2.8	4.6	1.8

a) Unreacted propionic acid. b) Yield of oxalic acid(%)/yield of CO_2(%).

and the yield ratio was the smallest. Model compounds **8** and **9** were oxidized more easily than the corresponding aromatic compounds, 1,2-benzenedicarboxylic acid and **6**, respectively. A furan ring was cleaved as easily as phenol, however, the yield ratio was small, 0.8.

Formation of Acetic Acid in the Initial Stage of Oxidation. The results of oxidation for 15 min are shown in Table 2 for propionic acid, 1,2-benzenediol, **1**, **2**, **3**, and **7**. The yield of acetic acid for **7** was the smallest after 15 min of oxidation. This shows the effect of substituents on the reactivity of aromatic rings. Model compound **3** with a phenolic hydroxyl group was easily oxidized to afford a large amount of acetic acid compared to **7** with a methoxyl group as shown in Table 2.

The model compounds, except **7**, yielded acetic acid in large amounts. This behavior agreed well with that of low-ranked coal which also afforded 20—25% of acetic acid at 15 min of oxidation.[1] 1,2-Benzenediol yielded 29% of acetic acid and 41% of oxalic acid and CO_2, respectively. Clearly, the aromatic rings activated by the substitution of the hydroxyl group were easily cleaved and yielded large amounts of oxalic acid. 1,2-Benzenediol was cleaved to afford muconic acid derivatives.[7] The mechanism in which three hydrogen atoms combine with one carbon atom to produce a methyl group in acetic acid under such strong oxidative conditions may be a disproportionation of the double bonds in these intermediates.

In spite of the fact that the sum of the yield of oxalic acid and the yields of CO_2 for **1** and **3** were 26 and 12%, respectively, the corresponding yields of acetic acid were about 30%. Consequently, not only the cleavage of the aromatic rings but also the cleavage of side chains *via* peroxide anions[8] contribute to the formation of acetic acid. An identification of the cleavage products is necessary for a detailed determination of the mechanism.

Mechanism of the Oxidation. Concentration Effects Regarding NaOH: Figures 1—4 show the effects of the NaOH concentration on the yields of oxalic acid, CO_2, and acetic acid during the oxidation (120 min) of acetic acid, hydroxyacetic acid, 1,2-benzenediol, and **3**. The important phenomena regarding the oxidation are shown in Fig. 1 for acetic acid and can be summarized as

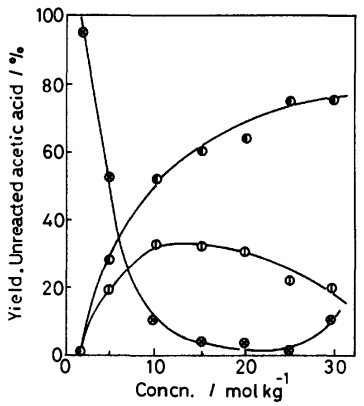

Fig. 1. Effect of NaOH concentration on the yields of oxalic acid, CO_2, and unreacted acetic acid in the oxidation of acetic acid: (◐) oxalic acid, (Φ) CO_2 (⊗) unreacted acetic acid.

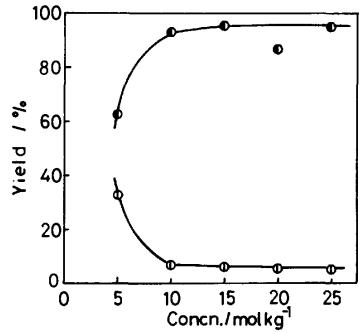

Fig. 2. Effect of NaOH concentration on the yields of oxalic acid and CO_2 in the oxidation of hydroxyacetic acid: (◐) oxalic acid, (Φ) CO_2.

follows:

I. Acetic acid was hardly oxidized at 2 mol kg^{-1}.

II. The reaction rate, yield of oxalic acid, and yield ratio increased rapidly upon increasing the NaOH concentration at 5—20 mol kg^{-1}.

III. The yield of CO_2 was held almost constant at 10—20 mol kg^{-1}.

IV. The reaction rate decreased at 20—30 mol kg^{-1} and the previously produced acetic acid remained.

The yield ratios for 1,2-benzenediol and **3** (Figs. 3 and 4) were lowered at concentrations of 20 mol kg^{-1} or higher; however, these yield ratios should

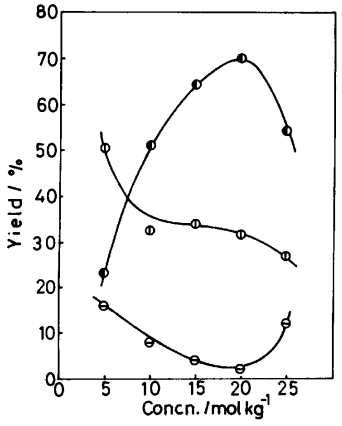

Fig. 3. Effect of NaOH concentration on the yields of oxalic acid, CO_2, and acetic acid in the oxidation of 1,2-benzenediol: (◐) oxalic acid, (Φ) CO_2, (⊖) acetic acid.

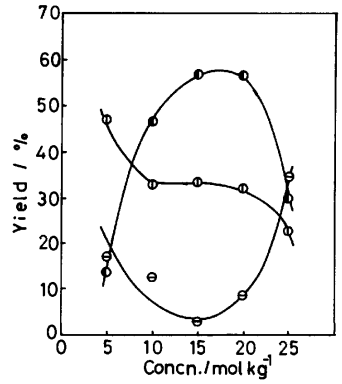

Fig. 4. Effect of NaOH concentration on the yields of oxalic acid, CO_2, and acetic acid in the oxidation of 4-hydroxycinnamic acid: (◐) oxalic acid, (Φ) CO_2, (⊖) acetic acid.

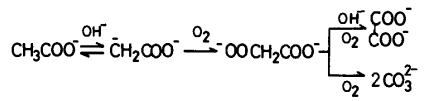
increase with longer reaction times (>120 min). The reason is that the large amount of acetic acid produced within 120 min produces selectively oxalic acid which increases the yield ratios with longer reaction times. The oxidation rates of oxalic acid are very small under such conditions.[2]

Mechanism: Scheme 1 shows a mechanism for the formation of oxalic acid and CO_2 from acetic acid. A carbanion is formed by the abstraction of a proton from the acetate ion with OH^- and yields an intermediate peroxide anion by the reaction with O_2. An oxalate ion may be produced by further abstraction of a proton and successive oxidation of the intermediate from which CO_2 may be formed competitively by the monomolecular cleavage of the C–C bond by a mechanism such as the epoxide mechanism or the Baeyer-Villiger mechanism.[9]



Scheme 1.

The above phenomena can essentially be explained by the following mechanism.

I. Equations 1 and 2 are the dissociation equilibrium in a NaOH–CH_3COONa solution at elevated tem-

$$CH_3COONa \longrightarrow CH_3COO^- + Na^+ \quad (1)$$

$$NaOH \rightleftharpoons OH^- + Na^+ \quad (2)$$

peratures. At 523 K, NaOH behaves as a weak electrolyte, as the pK_b is estimated to be 1.5.[10] Consequently, the concentration of OH^- is much smaller than the formal concentration of NaOH. In addition, the dissociation of NaOH is depressed by a common-ion effect of the Na^+ liberated from a complete dissociation of CH_3COONa (0.6 mol kg^{-1}). Thus, the reaction rate is very small because the equilibrium concentration of the carbanion is extremely low.

II. The formation of carbanion is promoted upon increasing the concentration of OH^- through the equilibrium. Thus, oxidation is accelerated. The yield of oxalic acid and the yield ratio increase with an increasing OH^- concentration. This is due to the effect of the abstraction of a proton by OH^- from the peroxide anion. This enhances the selective formation of oxalic acid in competitive reactions. On the other hand, the monomolecular cleavage of the C–C bond is not affected by the OH^- concentration.

III. The solubility of CH_3COONa decreases with an increasing concentration of NaOH. Such a tendency is observed in a great number of NaOH–sodium salt systems.[6] In contrast, the formation of the carbanion and the peroxide anion is promoted with an increasing NaOH concentration. In 10—20 mol kg^{-1} concentrations, these opposite effects compensate each other and the concentration of peroxide anions is kept almost constant. Thus, the yield of CO_2 *via* peroxide anions is held constant.

IV. In 20—30 mol kg^{-1} concentrations, the solubillity of CH_3COONa drops further and the concentration of the peroxide anion begins to fall. The rate-of-formation of oxalic acid drops, but the selectivity to form oxalic acid is relatively promoted. Thus, the yield ratio continues to increase, whereas, the overall reaction rate drops.

Based on this mechanism, the difference in the reactivities among several compounds can be explained in connection with the pK_a for the separation of hydrogen from the model compounds. The peroxide anions for acetic acid and hydroxyacetic acid may be $(^-OO)H_2CCOO^-$ and $OH(OO^-)HCCOO^-$, respectively. The value of pK_a for methylene hydrogen tends to be larger than that for methine hydrogen.[11] Thus, the reaction rate and yield ratio for hydroxyacetic acid are much larger than those for acetic acid. In the case of aliphatic monocarboxylic acids, the reactivities for acetic acid, propionic acid, and butyric acid were approximately equal. This may indicate that the reac-

tion takes place by the abstraction of hydrogen on the opposite carbon to the carboxyl carbon. Consequently, the reason for the low reactivity of adipic acid is that the opposite carbon is stabilized as a carboxyl carbon and no hydrogen is abstracted. The difference in the reactivities between 1,2-cyclohexanedicarboxylic acid and 1,2-benzenedicarboxylic acid or between **7** and **9** can be similarly explained.

Relationships between the Behavior of Model Compounds and That of Coal. The behavior of many model compounds and low-ranked coal such as Tempoku peat (C 54.7% daf), Yallourn coal (C 62.3% daf), and Nakayama coal (C 67.9% daf) agreed well with the formation of acetic acid and the high yield ratio of 1 or more.[1] This is because low-ranked coal contains a large amount of oxygen such as phenolic hydroxyl and carboxyl groups,[2] and the development of condensation of aromatic rings is inadequate. In contrast, a low yield ratio of 0.8 for high-ranked coal such as Goonyella coal (C 90.2% daf) and Miike coal (C 86.9% daf) was not obtained except with cyclohexanol and furfural. This is because most of the model compounds used were oxidized in an aqueous phase, and gas-phase oxidation of insoluble compounds did not take place as was observed in the oxidation of the high-ranked coal.[1] However, the reaction rate for the model compounds with fused aromatic rings such as **4**, 1-naphthalenecarboxylic acid, 2-naphthalenecarboxylic acid, and **9** were smaller than those for the model compounds with a benzene ring such as phenol, 1,2-benzenediol, benzoic acid, **6**, **7**, *etc.* Thus, regarding reaction rates, the behavior of model compounds with fused aromatic rings agreed with that of high-ranked coal.

The present work was partially supported by a Grant-in-Aid from the General Sekiyu Research Promotion Foundation.

Near-infrared Photocurrent of a Zinc Oxide Electrode Covered with Silver Atoms

Hatsumi TANEMURA, Yoshiro YONEZAWA,* and Hiroshi HADA
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606
(Received February 27, 1985)

Synopsis. A near-infrared photocurrent has been observed in a sintered ZnO electrode whose surface was covered with Ag atoms. The photocurrent became more evident when silver deposition was carried out with a relatively large charging current. The importance of H^+ reduction which competed with silver reduction is pointed out.

We have studied the electrochemistry of sintered zinc oxide (ZnO) electrodes to clarify the mechanism of the photoreduction of silver ions (Ag^+) at the surface of ZnO.[1] In the course of this research, it was noted that the ZnO surface suffered some changes in its physicochemical properties after the deposition of a considerable amount of Ag atoms. Kolb *et al.* have reported a near-infrared photocurrent regarding a ZnO single crystal electrode covered with a monolayer of Ag atoms.[2] It is worthwhile to examine the nature of the near-infrared photocurrent of ZnO electrodes in more detail.

A ZnO electrode was prepared from a ZnO powder, SASEX-4000, (Sakai Kagaku Co., Ltd.,) in the same manner as reported previously.[1] The surface area of the electrode was about 1 cm^2. The electrochemical cell contained a ZnO electrode, a platinum counter electrode, and a saturated KCl, Ag, AgCl reference electrode. The electrode potential in this Note referred to a saturated KCl, Ag, AgCl electrode. A Hokutodenko HA-104 potentiostat/galvanostat with an electronic picoammeter TR-8641 (Takeda Riken Co., Ltd.,) was used for the measurement of the photocurrent. As a light source, a 45-W tungsten-iodide lamp (Shimadzu Seisakusho Co., Ltd.,) was used in combination with a grating monochromator (Shimadzu Seisakusho Co., Ltd.,) and a glass filter, VR-67 (Toshiba Co., Ltd.,). The ratio of the number of incident photons was determined by means of a calibrated thermopile (Nihon Bunko Co., Ltd.,). The optical absorption spectrum of the electrolyte solution was taken into account in order to calibrate the number of incident photons at the electrode surface. The action spectrum of the photocurrent was corrected to a constant photon flux incident to the electrode surface at the wavelength, λ=700—1200 nm. All the measurements were carried out at the room temperature. Before the measurements, the ZnO surface was etched with 85% H_3PO_4 and washed in water. Dissolved oxygen in the electrolyte solution was purged by the introduction of high-purity nitrogen gas. We employed a galvanostatic method with a controlled charging current, i_{ch}, to deposit Ag atoms at the ZnO surface (electrochemical charging).

Cyclic current-voltage curves for the ZnO electrode were measured in the dark in 0.5 M KNO_3 (1 M=1 mol dm^{-3})(Fig. 1). On the cathodic scan, the current began to rise at about −0.7 V due to hydrogen evolution. When $AgClO_4$ was added to the solution, the

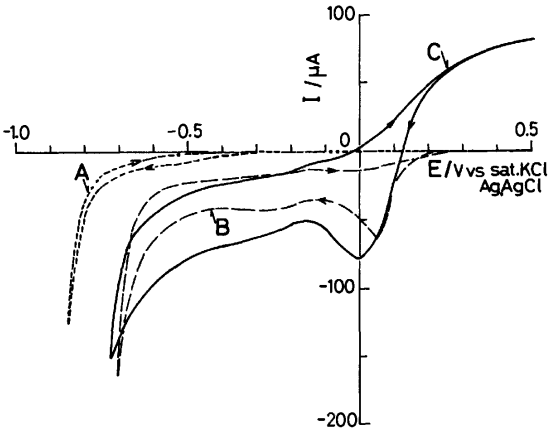

Fig. 1. Cyclic current (I)-voltage(E) curves of ZnO electrode.
Electrolyte: A: 0.5 M KNO_3 (———), B, C: 0.5 M KNO_3 and 10^{-3} M $AgClO_4$.
Curve B (— — — —) is obtained in the dark, curve C (———) by illumination with λ=365 nm light from 500 W xenon lamp. Scan rate is 20 mV s^{-1}.

Ag deposition was seen by a current rise of around +0.2 V on the cathodic scan. It was noticed that at the Ag-covered ZnO surface, hydrogen evolution commenced about 0.3 V earlier than at a bare electrode surface. Catalytic action of metal atoms at the semiconductor surface has been discussed by Kolb *et al.*[2] On the anodic scan, the photocurrent began to rise at *ca.* −0.2 V when the ZnO electrode in the electrolyte solution containing Ag^+ was illuminated with λ=365 nm light. The absence of a well-defined stripping peak of Ag indicates that photo-generated holes are consumed with the dissolution of ZnO.

We deposited the Ag atoms at the ZnO surface in an electrolyte solution composed of 0.5 M KNO_3 and 10^{-3} M $AgClO_4$. As the electrode potential during charging, E_{ch}, with i_{ch}=5 μA was about +0.2 V, a greater part of the charging current contributed to the reduction of Ag^+. The action spectra of the anodic photocurrent at +0.5 V are given in Fig. 2. The increase in the photocurrent, ΔI, being defined as the subtraction of the photocurrent before silver deposition, I_0, from that after silver deposition, I_{ch}, is also shown in Fig. 2. The dark anodic current was less than 1 nA at +0.5 V. The near-infrared photocurrent increased several times after charging the electrode by the quantity of electricity, Q_{ch}=6.0 mC. ΔI at λ=800—900 nm was about 2.5 nA. We next employed a relatively large i_{ch} of 200 μA. As E_{ch} was *ca.* −0.75 V, the reduction of both Ag^+ and H^+ was possible in view of Fig. 1. Some of the evolved hydrogen was absorbed inside of ZnO and silver layers. The action spectrum of the photocurrent (Fig. 3) shows that ΔI at λ=800—900 nm was *ca.* 30 nA for Q_{ch}=6.0 mC, which is about one order larger than ΔI of case C in Fig. 2. Figure 4 shows the

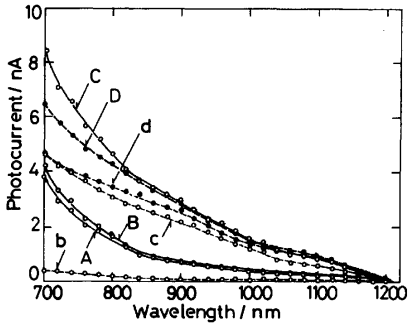

Fig. 2. Action spectra of anodic photocurrent of ZnO electrode.
Electrolyte: 0.5 M KNO_3 and 10^{-3}M $AgClO_4$, Electrode potential: +0.5 V.
A: Before charging, I_0, B: after electrochemical charging with i_{ch}=5 μA for 120 s (Q_{ch}=0.6 mC), I_{ch}, C: after electrochemical charging with i_{ch}=5 μA for 1200 s (Q_{ch}=6.0 mC), I_{ch}, D: after photochemical charging with λ=365 nm light (Q_{ch}=*ca.* 6.0 mC), I_{ch}.
The dashed lines b, c, and d denote the increase in photocurrent, $\Delta I=I_{ch}-I_0$, for B, C, and D, respectively. The magnitude of the photocurrent, D and d is reduced by one-half.

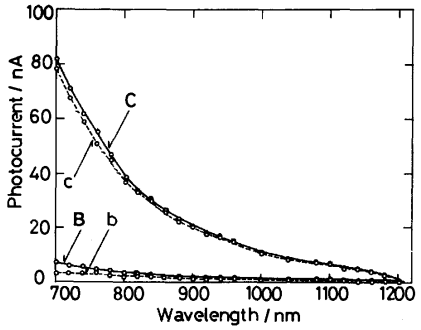

Fig. 3. Action spectra of anodic photocurrent of ZnO electrode.

B: After electrochemical charging with i_{ch}=200 μA for 3 s (Q_{ch}=0.6 mC), I_{ch}, C: after electrochemical charging with i_{ch}=200 μA for 30 s (Q_{ch}=6.0 mC), I_{ch}.
The dashed lines b, c denote ΔI for B, C, respectively.

action spectrum after charging the electrode in a 0.5 M KNO_3 solution with i_{ch}=200 μA. The main electrode reaction was the reduction of H^+, as E_{ch} was *ca.* −0.9 V in this case. ΔI for Q_{ch}=6.0 mC was only about 0.1 nA at λ=800—900 nm. We then tried to superpose hydrogen on the silver layer. In the first place, the ZnO electrode was charged in the same electrolyte solution as in Fig. 2 with i_{ch}=5 μA for 1200 s (silver deposition). Then, the second charging was carried out in a 0.5 M KNO_3 solution with i_{ch}=200 μA for 30 s (hydrogen evolution). The action spectrum of the photocurrent after two-step deposition is added to Fig. 4. The magnitude of ΔI proved to be smaller than that of case C in Fig. 3: ΔI at λ=800—900 nm was *ca.* 2.5 nA.

Kolb *et al.* have ascribed the near-infrared photocurrent to an optical interfacial electron transfer between Ag adatoms and the ZnO electrode.[2] It has often been observed that extrinsic surface states are introduced to a semiconductor surface when some chemical species are adsorbed on it.[3] We could assume that electronic excitation from the surface states to the conduction band of ZnO is important as an additional mechanism of the near-infrared photocurrent of the ZnO electrode covered with Ag atoms. The enhanced photocurrent in Fig. 3 is probably due to a relatively large i_{ch}. It has been found that the current efficiency of Ag^+ reduction amounts to *ca.* 100% for an i_{ch} smaller than 20 μA and is less than 50% for an i_{ch} greater than 100 μA.[4] As the photocurrent of the electrode after the superposition of silver and hydrogen in Fig. 4 was not so large, we can state that extrinsic surface states responsible to the near-infrared photocurrent are introduced to the ZnO surface during the co-deposition of silver and hydrogen under relatively large i_{ch} conditions. As the distinct structure of the action spectra in Figs. 2—4 is blurred, it seems that occupied energy levels of the surface states are located in a diffuse manner within the forbidden energy band of ZnO.

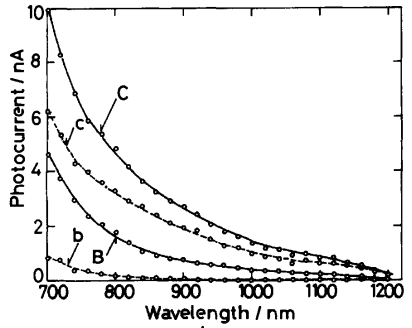

Fig. 4. Action spectra of anodic photocurrent of ZnO electrode.
Electrode potential: +0.5 V.
B: After electrochemical charging in 0.5 M KNO_3 with i_{ch}=200 μA for 30 s (Q_{ch}=6.0 mC), I_{ch}, C: after electrochemical charging firstly in 0.5 M KNO_3 and 10^{-3} M $AgClO_4$ with i_{ch}=5 μA for 1200 s (Q_{ch}=6.0 mC) and secondly in 0.5 M KNO_3 with i_{ch}=200 μA for 30 s (Q_{ch}=6.0 mC), I_{ch}.
The dashed lines, b, c denote ΔI for B, C, respectively.

We finally examined the possibility of the increase of near-infrared photocurrent as a result of the photodeposition of Ag atoms at the ZnO surface (photochemical charging). The ZnO electrode in a solution composed of 0.5 M KNO_3 and 10^{-3} M $AgClO_4$ was disconnected from the electric circuit and illuminated with λ=365 nm light from a 500 W xenon lamp.[1] After photochemical charging by Q_{ch}=*ca.* 6.0 mC, as estimated by a local-cell consideration,[1] the action spectrum of the near-infrared photocurrent was not so different from that obtained by electrochemical charging (Fig. 2). Therefore, the origin of the photocurrent is the same regarding both electrochemical and photochemical chargings.

Methods for Observing the Deformation of an Aqueous Paramagnetic Solution in a Magnetic Field

Takashi YASUOKA,* Tadahiko KIDOKORO, and Shunmei MITSUZAWA
Department of Chemistry, Faculty of Science, Tokai University, Kitakaname, Hiratsuka 259-12
(Received March 14, 1985)

Synopsis. Two methods have been worked out for the observation of the deformation of a paramagnetic aqueous solution in a magnetic field. The deformation was observed on: (1) a layer of a solution covered with a water-immiscible organic liquid and (2) a drop of the solution suspended in the liquid.

The paramagnetism of a solution of a heavy metal salt can be demonstrated by the deformation of the solution occurring in a magnetic field. If a test tube containing the solution is placed between the poles of an electromagnet, a distinct elevation of the surface takes places near the poles.[1] We have worked out two simple methods to magnify the deformation, so that a visual estimation of its magnitude is possible.

Our methods are based on the fact that the presence of a water-immiscible liquid in contact with the solution gives rise to an increase in the deformability of the solution in a magnetic field; this is a result of the reduction of the gravitational force acting on it. The experimental details are given below.

I. A JEOL JM-360 electromagnet (pole diam., 300 mm; pole distance, 60 mm, and maximum flux density, 1.4 tesla) was used. Three cm^3 of a paramagnetic salt solution (1 mol dm^{-3}) was poured into an acrylic plastic cell (10×60×60 mm) to a depth of 5 mm. Benzene was then added, forming an upper layer since the benzene and the solution do not mix with each other. The cell was then set between the poles of the electromagnet. The magnetic field was applied, and the resulting change in the form of the solution in the cell was photographed. Solutions of $CuCl_2$, $NiCl_2$ $CoCl_2$, and $FeCl_3$ were studied. Commercial reagents of a guaranteed grade were used without further purification.

Figure 1 shows the deformation of the layer of a $FeCl_3$ solution placed in magnetic fields of 0, 0.9, and 1.3 tesla. With an increase in the field intensity the solution is attracted towards the magnetic poles, finally splitting into two parts. The deformation of solutions of $CuCl_2$, $NiCl_2$, $CoCl_2$, and $FeCl_3$ in the field of 1.3 tesla is shown in Fig. 2. The change in the form of the solution layer in the magnetic field, as expressed by the difference in the height of the solution at its center and at its periphery, decreases in this order: $FeCl_3$, $CoCl_2$, $NiCl_2$, and $CuCl_2$. This is in line with the order of the number of unpaired electrons or Bohr magnetons in each metallic ion and enables a rough estimation of these numbers.

II. A straight-bar electromagnet (pole diam., 30 mm; maximum flux density, 0.18 tesla) was used. A single drop of a solution was suspended in a water-immiscible liquid with the same density as that of the drop, and its deformation in a magnetic field was observed. An acrylic cell (60×60×60 mm) containing the sample was set in contact with a pole of the magnet.

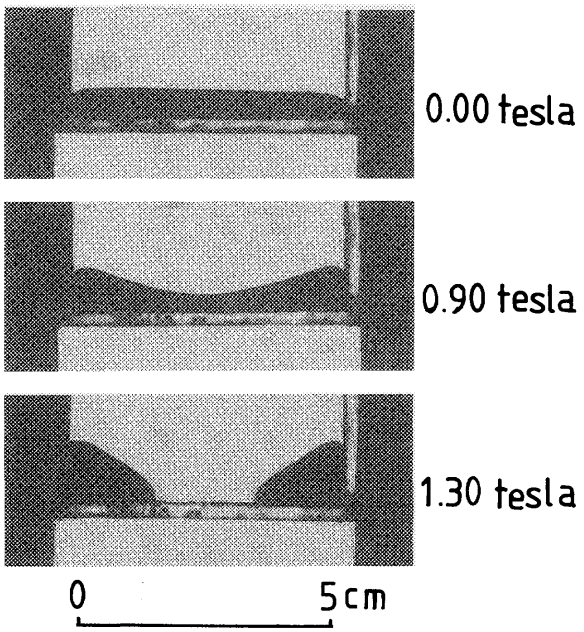

Fig. 1. Deformation of a $FeCl_3$ solutions in magnetic field.

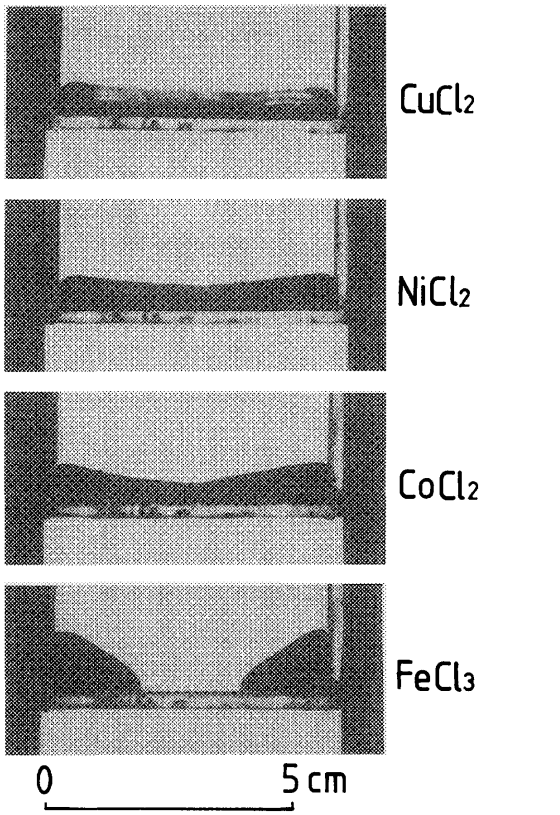

Fig. 2. Deformation of various solution in magnetic field of 1.3 tesla.

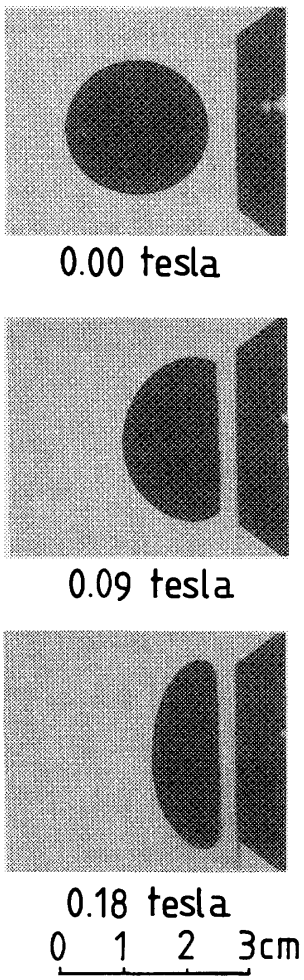

Fig. 3. Deformation of a drop of $FeCl_3$ solution in magnetic field.

The water-immiscible liquid of the desired density was prepared by adjusting the mixing ratio of benzene and carbon tetrachloride and was then poured into the cell. When 8 cm^3 of a $FeCl_3$ solution (3 mol dm^{-3}) was introduced into the liquid, it turned into a spherical drop. The deformation of the drop at 0, 0.9, and 0.18 tesla is shown in Fig. 3. The drop is spherical at 0 tesla, but it undergoes conspicuous deformation with an increase in the magnetic field. The deformation of the solution is far more marked in this case than in **I**.

These methods will be useful in demonstration experiments and also for a rough estimation of solution paramagnetism or magnetic-field strength.

The authors wish to thank Prof. Tsunetaka Sasaki for his kind interest in and suggestions for this work.

Concerning Bent Structures of Cumulenones

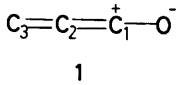
Hiroshi ICHIKAWA* and Yukiko EBISAWA
Hoshi College of Pharmacy, Shinagawa, Tokyo 142
(Received May 2, 1985)

Synopsis. The cause of the unusual bent structures of cumulenones has been studied by HF/6-31G and MP3/6-31G methods. It is concluded that participation of the lone pair electrons to the adjacent π-bond results in the deformed structures.

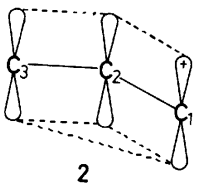
Cumulenones ($CH_2=(C)_n=0$, $n=0, 1, 2, \cdots$) are topic compounds in practical and theoretical respects. Practically, they are potential candidates for interstellar compounds as those discovered for $n=0$ and 1.[1] It is an urgent requirement to establish those structures in order to assign unidentified microwave spectra of unidentified intersteller molecules. The structures of cumulenones have also aroused considerable theoretical interest[2] since an unusual bent structure has been determined for $n=2$.[3] A question arises as to what causes the distortion on the structures of cumulenones. We have studied this problem and have reached a very plausible explanation.

Recently, Farnell and Radom[2a] reported that the theoretically most stable structures of propadienone and butatrienone are planar-bent and orthogonal-bent structures, respectively. Such distortions from a C_{2v} structure appear when the electron-correlation is included in the calculation. They also noted the results for the next members of the series, pentatetraenone ($CH_2(C)_4=0$) and hexapentaenone ($CH_2(C)_5=0$). Both of these molecules have been found to be bent even at the 4-31G[4] level.[2a] Thus, it seems that this bending of the carbon chain is a characteristic of cumulenones, alternating as a function of chain length between in-plane and out-of-plane structures.

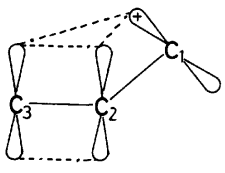
There are two plausible reasons that can be considered from the organic chemistry of a carbonyl group, both of which are not well expressed in the Hartree-Fock theory. An oxygen atom has a larger electronegativity than a carbon atom. The withdrawal of a π-electron to the oxygen atom produces a cationic center on the carbon atom of the carbonyl group (**1**). Such a carbocation can interact with the β-carbon atom (C_3) in either a π (**2**) or σ (**3**) way. But, only the former interaction agrees with the observed bending direction.



1

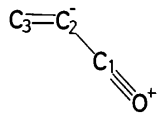


2



3

The alternating contribution of a carbonyl group represents a participation of one pair of the lone-pair electrons of the oxygen atom into an adjacent p-atomic orbital (AO) or a π-bond (**4**). This resonance concept has been proposed by Brown *et al.* to explain the bent structure of propadienone.[3b] Such a contribution is



4

regarded as a minor one from the point of view of the organic chemistry of a molecule. However, it often appears in ion chemistry as an acyl cation (R-C≡O$^+$). If this contribution takes place, the hybridization of the α-carbon atom (C_2) may be changed toward sp^2. This also explains the observed bending characteristics of cumulenones. In order to determine which resonance structure contributes the most, we examined a series of cumulenyliums and cumulenides which are regarded as canonical structures of cumulenones.

Table 1 shows the relationship between the total energies and the bond angles of cumulenyliums and cumulenides (using the HF/6-31G[5] and MP3/6-31G method[6]). Optimization was carried out by HF/6-31G for all geometrical parameters except the fixed bond angle.[7] Table 2 shows the results of similar calculations regarding referential compounds. These can be compared with the ions listed in Table 1.

From Table 1, it can be seen that the most stable structure for cumulenylium has a C_{2v} symmetry. Therefore, it should be understood that a cationic interaction does not make a major contribution to the distortion of cumulenone. Tables 1 and 2 indicate that a distortion of the bond by 10 degrees requires, by Hartree-Fock theory, only *ca.* 1 kcal/mol for both neutral molecules and cumulenyliums (either in-plane or out-of-plane). The existence of carbocation seems to have nothing to do with the flexibility. The inclusion of electron correlation reduces up to the half of such energy. This shows that cumulenyl groups are easily bent, although they look rigid according to the structural expressions of organic chemistry.

The C_{2v} structures of cumulenides have higher total energies than those of specifically distorted structures. The optimized structures are largely deformed from the C_{2v} symmetry and all have the Cs structures. The bending direction alternates as the number of carbon atoms increases, in accordance with the direction in cumulenones. Therefore, it is strongly suggested that the cause of a bent structure in cumulenones can be attributed to the participation of the lone-pair electrons. This theory can also explain why cumulenones with longer chains are apt to be deformed

Electrochemical Reduction Products of Carbon Dioxide at Some Metallic Electrodes in Nonaqueous Electrolytes

Kaname Ito,* Shoichiro Ikeda, Nobuhiro Yamauchi, Takaya Iida, and Takehiko Takagi
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received May 4, 1985)

Synopsis. Regarding the electrochemical reduction of carbon dioxide in nonaqueous electrolytes, it has been clarified that the main products are oxalic acid at a Pb electrode and carbon monoxide at Sn and In electrodes. In the case of a Zn electrode, substantial amounts of oxalic acid, glyoxylic acid and carbon monoxide have been produced.

According to previous papers,[1-3] the electrochemical reduction products of carbon dioxide dissolved in aqueous electrolytes under either ordinary or high pressures were mainly formic acids at electrodes of indium (In), lead (Pb), tin (Sn), zinc (Zn), and cadmium (Cd).

We have reported in another paper[4] that for nonaqueous electrolytes consisting of dimethyl sulfoxide (DMSO) and tetraalkylammonium salts, such as $(C_2H_5)_4NClO_4$ (TEAP), the main product is oxalic acid at a Pb electrode. It was suggested that carbon monoxide should probably form at In, Sn, and Zn electrodes.

Therefore, in the present paper a cyclic gas flow system for supplying CO_2 to an electolytic cell was employed in order to determine gaseous products on the electrochemical reduction of carbon dioxide at various metallic electrodes. This was investigated in nonaqueous electrolytes using propylene carbonate instead of DMSO. The effects of various electrode metals and electrlytic conditions on the products are described.

Experimental

An electolytic cell made of Teflon was designed for separating a cathode chamber from an anode chamber with an ion-exchange membrane, Nafion 315. This system was made gas tight. The cyclic gas flow system was designed to use a peristaltic mini-pump, a gas sampler and a manometer for supplying CO_2 gas to a cell. Gaseous products in the cyclic gas were determined as well as products at various electrolytes.

Working electrodes were prepared from solid-state metals such as Pb (purity 99.99%), Sn (99.999%), In (99.999%), and Zn (99.9999%). These have been employed as described in previous papers.[1-4] The reference electrode utilized in the present work consisted of a silver silver chloride electrode with a (0.01 M LiCl+0.1 M TEAP)(1 M=1 mol dm^{-3})/ propylen carbonate solution saturated with AgCl. The potentials given in the present paper are with respect to this Ag/AgCl reference electrode.

Since commercially obtained guaranteed reagent propylene carbonate possessed various impurities, it was purified using Jasinski and Kirkland's method.[5] The catholyte and the anolyte each utilized 10 ml of a 0.1 M TEAP/ propylen carbonate nonaqueous electrolyte prepared from the synthesized TEAP[3] and purified propylen carbonate. The water content of the electrolyte was determined by Karl Fischer's titration method[6] to be 320 ppm.

Electrolytic experiments for a determination of the reduction products of carbon dioxide were carried out using working-electrodes with surface areas of 2.47 to 7.20 cm^2. After an electrolyte within a cell was sufficiently saturated with CO_2 gas and the system was substituted by CO_2 gas, it was closed and the enclosed gas was made to flow at a rate of 0.9 cm^3 min^{-1} using a peristaltic pump. The electrolytic current was potentiostatically flowed at 100 or 200 C (coulombs). The products in the electrolytes were qualitatively and quantitatively determined by high-performance liquid

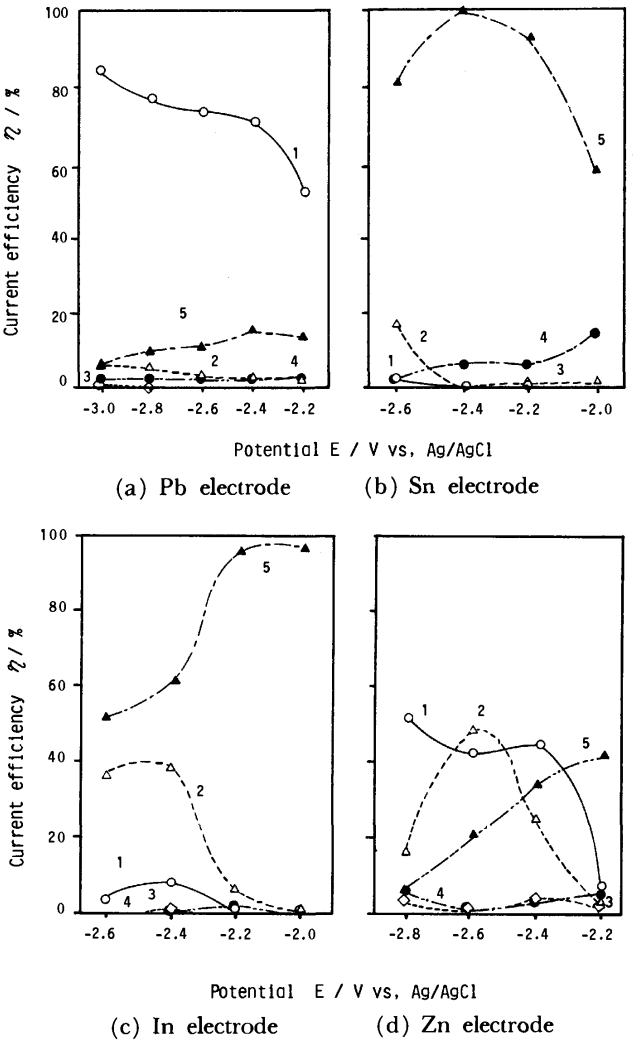

Fig. 1. Current efficiencies of electroreduction products of CO_2 in the cases of Pb(a), Sn(b), In(c), and Zn(d) electrodes.
Electrolyte: 0.1 M TEAP/propylen carbonate, Quantity of electricity passed: 100 C (a) or 200 C (b, c, d). Curve 1 (—○——): Oxalic acid, 2 (-△——): Glyoxylic acid, 3 (--◇---): Glycolic acid, 4 (-●----): Formic acid, 5 (—▲—·—): Carbon monoxide.

chromatgraphy. Gas chromatgraphy was used to determine the gaseous products in the cyclic gas. This equipment and the operating conditions were similar to that described in a previous paper.[4]

Results and Discussion

The electrochemical reduction products in both the electrolyte and the cyclic gas were determined. The obtained results are illustrated in Fig.1 as current efficiencies of products with respect to certain potentials (−2.0 to −3.0 V) for each electrode.

When a Pb electrode was employed, the main product was oxalic acid and the current efficiency increased to *ca.* 80% at −3.0 V, as shown in Fig. 1-(a). The efficiencies for formic, glyoxylic and glycolic acids were less than 5% in a potential range of −2.2 to −3.0 V, though 6 to 15% for carbon monoxide. On the other hand, when a Sn electrode was employed, the main product was carbon monoxide and its current efficiency increased to *ca.* 100% at −2.4 V, as shown in Fig. 1-(b). Other products had relatively lower efficiencies. In the case of an In electrode, as shown in Fig. 1-(c), the main product was also carbon monoxide at every potential measured; however, the current efficiencies, though *ca.* 95% in the potential range of −2.0 to −2.2 V, decreased to below 60% at potentials less than −2.4 V. Also, glyoxylic acid, instead of carbon monoxide, was produced with a current efficiency of *ca.* 40%. In the case of a Zn electrode, as shown in Fig. 1-(d), oxalic acid, glyoxylic acid and carbon monoxide were produced with substantial current efficiencies. According to these results, it has been experimentally comfirmed that carbon monoxide is the main product for Sn and In electrodes. This was not comfirmed in a previous paper.[4]

Consequently, although Saveant *et al.*[7] have reported that the production of oxalic acid by the electroreduction of carbon dioxide in a nonaqueous electrolyte was mainly dependent on the current densities from experimental results using only Pb and Hg electrodes, it may be concluded that the electroreduction products for carbon dioxide are primarily dependent on the electrode metals employed. Then, the main products are oxalic acid at a Pb electrode and carbon monoxide at Sn and In electrodes. Also, the current efficiencies regarding the products at each electrode are affected by the electrode potentials.

A Set of Rate Constants for the Reactions of OH Radicals with Aromatic Hydrocarbons

Tomohiro OHTA* and Toshiro OHYAMA†
Department of Environmental Sciences, Tokyo Metropolitan Research Laboratory of Public Health, Hyakunincho, 3-Chome, Shinjuku-ku, Tokyo 160

(Received May 10, 1985)

Synopsis. The rate constants for the reactions of OH radicals with seventeen aromatic hydrocarbons were determined at atmospheric pressure and room temperature from competitive reactions with hexane, using H_2O_2 as the OH-radical source. A useful trend was found in the structure-reactivity relationship.

Since aromatic hydrocarbons are important constituents of polluted urban air, and since they are believed to be consumed mainly by reactions with OH radicals, several papers have been published on the rate constants for the reactions of OH radicals with aromatic hydrocarbons.[1,2] Besides absolute rate constants determined by sophisticated techniques, relative rate constants determined by competitive reactions between aromatic hydrocarbons and a certain reference compound at atmospheric pressure and room temperature have been reported.[3,4] They used NO_x as a source of OH radicals, but we have proposed a different and simpler method to produce OH from the photolysis of hydrogen peroxide (H_2O_2, 90%) at 2537 A to obtain the rate constants for the reaction of OH with atmospheric elements of interest and have reported some empirical relationships between the reactivity towards OH and the structures of the olefins.[5,6] We here try to apply the method to aromatic hydrocarbons, using hexane as a reference compound, and propose a set of rate constants for the reactions of OH with a series of aromatic hydrocarbons; further, we try to find a useful trend in the reactivity-structure relationship.

The experimental procedure and data treatment were similar to those described in previous works.[5,6] Plots of $\ln([\text{aromatic}]_0/[\text{aromatic}]_t)$ against $\ln([\text{hexane}]_0/[\text{hexane}]_t)$ were on excellent straight lines for any compound; the slopes show the relative rate constants of aromatics to hexane. At least ten runs were carried out to determine the relative rate constants. The rate constants did not show any dependence on the variation in the initial concentrations of the reactants. Since methoxybenzene was photolyzed by the irradiation at 2537 A, methyl nitrite prepared by ourselves was used as another OH radical source by irradiating it in a mixture of reactants and oxygen at 360 nm.[7] No decomposition of other aromatics was observed because of short-time, weak irradiation.

A set of rate constants for the reactions of OH radicals with aromatic hydrocarbons is shown in Table 1, along with the literature data. The error limits in the table are the standard deviations for repeated runs. Most of the rate constants determined in this work showed fairy good agreement with literature values determined by completely different methods. For the compounds

TABLE 1. ROOM-TEMPERATURE RATE CONSTANTS FOR THE REACTIONS OF AROMATIC HYDROCARBONS WITH OH RADICALS

a) Absolute rate constants were derived using a rate constant for the reaction of OH with hexane of 5.9×10^{-12} cm^3 molecule^{-1} s^{-1}, the mean of three values in Ref. 1). b) Numbers in bracket indicate references.

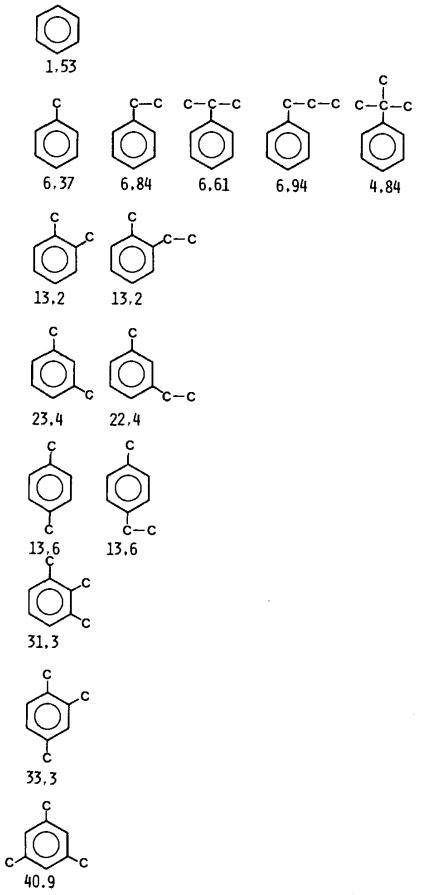

Fig. 1. Reactivity-structure relationship of aromatic hydrocarbons towards OH radicals. (all units in 10^{-12} cm^3 $molecule^{-1}$ s^{-1}).

whose literature values are diverse, our values generally agreed with the most recent values.

Since the set of rate constants for the series of aromatics was obtained under the same experimental conditions and using the same reference compound, it is possible for us to compare the rate constants one by one. Figure 1 shows the aromatic hydrocarbons classified by the positions and length of the substituents, along with the obtained rate constants in this work. It was confirmed that the OH-radical rate constants at room temperature increase as the degree of alkyl substitution increases, showing the same trend of degree and position of alkylation as in $O(^3P)$-atom reactions.[14] This implies that the major reaction path is the electrophilic addition of OH radicals to aromatic rings.

Furthermore, we notice that an empirical rule was derived from Fig. 1. The replacement of the methyl group on the aromatic ring by a longer alkyl chain (C_2, C_3) will not much affect the reactivity of methyl-substituted aromatics; the rate constants for aromatics on the same row in Fig. 1 are almost equal to each other except for *t*-butylbenzene in the row of toluene derivatives. There has been some uncertainty as to the branching ratio for the abstraction of methyl-H to the overall reaction in the reaction of toluene with OH radicals. The most recent work of Atkinson *et al.*[15] indicates that, at 300 K, the branching ratio is 0.08±0.03; however, the reported values have varied from 0.16,[10] 0.15±0.02,[16] to 0.1—0.02 (most probably 0.04).[11] The finding that toluene, ethylbenzene, isopropyl- and propylbenzenes have almost identical rate constants supports the lower value of the branching ratio of abstraction, because the loss of reactive methyl-H in toluene by replacement with methyl group (s) did not make the rate constant for unsubstituted toluene decrease significantly. *t*-Butylbenzene, apart from the four homologs, showed a smaller rate constant. The steric hindrance of the *t*-butyl group for the OH radical attack at the ortho position may explain it.

The trend found in this work is useful in getting an overall understanding of the reactivity of a series of aromatic hydrocarbons towards OH radicals and in evaluating the rate constants reported separately.

The authors wish to thank Professor Tanaka, Science University of Tokyo, for his valuable help.

Photoinduced Electron-transfer from Thiols to $[Ru(bpy)_3]^{2+}$ in Aqueous Solutions

Tokuji MIYASHITA and Minoru MATSUDA*
Chemical Research Institute of Nonaqueous Solutions, Tohoku University, Katahira 2-1-1, Sendai 980
(Received May 27, 1985)

Synopsis. The quenching of photoexcited $[Ru(bpy)_3]^{2+}$ by water-soluble thiols was studied by steady-state and time-resolved measurements. 2-Mercaptobenzoic acid and 4-mercaptopyridine which give the delocalized thiolate ions in water quenched $[Ru(bpy)_3]^{2+*}$ effectively, and $[Ru(bpy)_3]^{+}$ was formed by the quenching. No quenching occurred with cysteine and 2-mercaptoethanol.

Photoinduced electron-transfer with $[Ru(bpy)_3]^{2+}$ (bpy=2,2′-bipyridine) has been extensively investigated.[1] Previously, we reported that a photoexcited $[Ru(bpy)_3]^{2+}$ was quenched by benzenethiolate ion in nonaqueous solution (acetonitrile) and that $[Ru(bpy)_3]^{+}$ absorbing around 510 nm was formed in good yield.[2] The back electron-transfer reaction from $[Ru(bpy)_3]^{+}$ to PhS· was suppressed by the rapid dimerization reaction of thiyl radicals and $[Ru(bpy)_3]^{+}$ could exist with a relatively long lifetime in this system. The overall reaction can be expressed by Eq. 1 and the reverse process (the back electron-transfer reaction to disulfide) is slow.

$$2[Ru(bpy)_3]^{2+} + 2PhS^- \underset{\text{slow}}{\overset{h\nu}{\rightleftharpoons}} 2[Ru(bpy)_3]^{+} + PhSSPh \quad (1)$$

The application of this redox couple to photogalvanic cell was also reported.[3] Thermodynamically, $[Ru(bpy)_3]^{+}$ can reduce water to H_2.[4] In this letter we study the photoinduced electron-transfer from water-soluble thiols to $[Ru(bpy)_3]^{2+*}$ in order to search good redox couples used in aqueous solutions.

Experimental

$[Ru(bpy)_3]Cl_2 \cdot 6H_2O$ was synthesized according to published procedures.[5] Commercially available thiols were purified by recrystallization. The steady-state emission intensity was measured with Shimadzu RF 503A spectrofluorophotometer. Laser photolysis experiments for the lifetime quenching were carried out with a frequency-doubled Q-switched ruby laser system (347.1 nm pulse: 20 ns pulse width). The xenon-flash apparatus delivered a flash (10 μs pulse) with 112.5 joule was used for the detection of transient $[Ru(bpy)_3]^{+}$.

Results and Discussion

The quenching experiments of $[Ru(bpy)_3]^{2+*}$ by cysteine, 2-mercaptoethanol, 4-mercaptopyridine, and 2-mercaptobenzoic acid were carried out by steady-state measurement in deoxygenated solution. Cysteine and 2-mercaptoethanol did not quench the emission of $[Ru(bpy)_3]^{2+*}$ under a wide variation in pH (6-11; Borax buffer), whereas 2-mercaptobenzoic acid and 4-mercaptopyridine showed effective quenchings (Table 1). The Stern-Volmer plots for them are shown

TABLE 1. THE QUENCHING OF $[Ru(bpy)_3]^{2+*}$ BY WATER-SOLUBLE THIOLS

Thiols	pK_a	Quenching at pH>pK_a(−SH)
2-Mercaptobenzoic acid	3.0 (-COOH)	
	8.5 (-SH)	$k_q=1.7\times10^9$ dm^3 l^{-1} s^{-1}
4-Mercaptopyridine	10.6 (-SH)	$k_q=5\times10^7$ dm^3 l^{-1} s^{-1}
Cysteine	1.7 (-COOH)	
	8.3 (-SH)	No quenching
	10.8 (-NH_2)	
2-Mercaptoethanol	10 (-SH)	No quenching

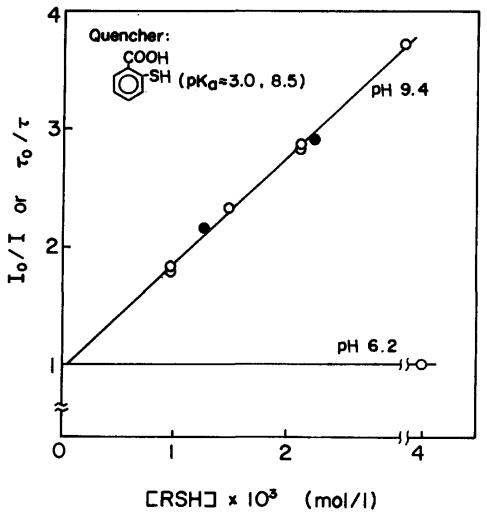

Fig. 1. Plots of I_0/I (○) and τ_0/τ (●) *vs.* [RSH] for quenching of $[Ru(bpy)_3]^{2+*}$ by 2-mercaptobenzoic acid.

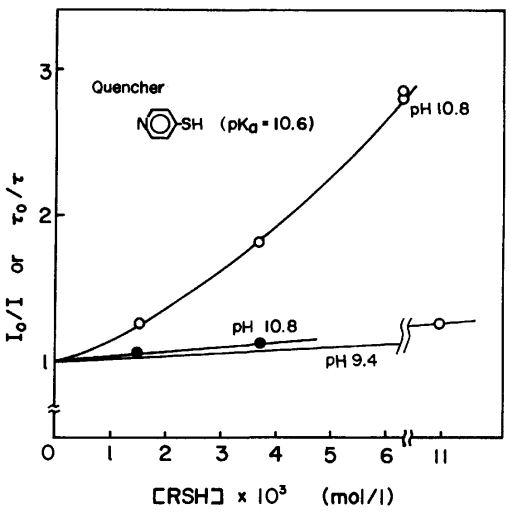

Fig. 2. Plots of I_0/I (○) and τ_0/τ (●) *vs.* [RSH] for quenching of $[Ru(bpy)_3]^{2+*}$ by 4-mercaptopyridine.

in Figs. 1 and 2. The quenchings are effective in pH region larger than their pK_a's. Apparently thiolate ion formed from the dissociation of -SH group is necessary for the quenching. The thiolate ions derived from 2-mercaptobenzoic acid and 4-mercaptopyridine are conjugated with aromatic moieties, and the delocalization is favorable to the orbital overlapping in electron-transfer process, resulting in the effective quenching.

The emission lifetimes were measured by exciting $[Ru(bpy)_3]^{2+}$ with a 347.1 nm-pulse (20 ns pulse width, ruby laser). The emission decays were single-exponential in the absence and the presence of quenchers, whose slopes varied with the concentration of the quencher. The plots of τ_0/τ *vs.* [RSH] were superimposed upon Figs. 1 and 2. The dynamic quenching rate constants for 2-mercaptobenzoic acid and 4-mercaptopyridine were obtained to be 1.7×10^9 (pH=9.4) and 5×10^7 $dm^3\,mol^{-1}\,s^{-1}$ (pH=10.8), respectively. As shown in Fig. 1, the slope of the plots of I_0/I *vs.* [RSH] was identical with that of the plots of τ_0/τ, suggesting that only dynamic quenching takes place and the quenching of $[Ru(bpy)_3]^{2+*}$ with *o*-sulfidobenzoate ion proceeds by the usual Stern-Volmer behavior. In contrast with this, the quenching by pyridinethiolate ion is almost static quenching (Fig. 2). Although the emission and the absorption spectra of $[Ru(bpy)_3]^{2+}$ were not changed in the presence of pyridinethiolate ion, somewhat association of $[Ru(bpy)_3]^{2+*}$ with the anion resulting in the static quenching seems to take place. The following xenon flash photolysis study is suggesting the association.

The formation of the transient species absorbing around 520 nm was detected by means of xenon flash photolysis of the aqueous solution (pH=9.4) containing $[Ru(bpy)_3]^{2+}$ and 2-mercaptobenzoic acid. The species can be assigned to $[Ru(bpy)_3]^{+}$ as shown elsewhere.[2,6] The decay profile is shown in Fig. 3. The decay obeyed good first-order kinetics with a rate constant $k=6.5\times10^3\,s^{-1}$, which implies that the back electron-transfer reaction was suppressed. It has been reported that when Eu(II) and aromatic amines were used as quenchers, the decays of $[Ru(bpy)_3]^{+}$ obeyed second-order kinetics with rate constants 2.7×10^7 and 10^7–10^{10} $dm^3\,mol^{-1}\,s^{-1}$, respectively.[7,8] On the other hand, the formation of $[Ru(bpy)_3]^{+}$ can not be detected in $[Ru(bpy)_3]^{2+}$-4-mercaptopyridine system. This may be caused by the rapid back electron-transfer in the static quenching pair.

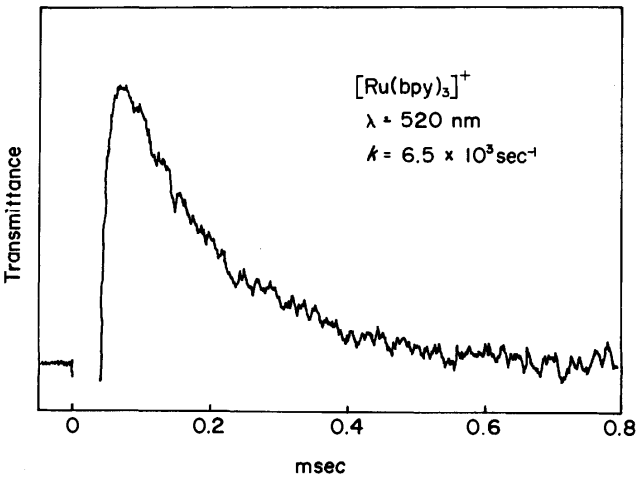

Fig. 3. Decay profile of transient absorption (λ= 520 nm) of $[Ru(bpy)_3]^{+}$ in aqueous solution (pH= 9.4; RSH: 2-mercaptobenzoic acid).

Steady-state irradiation on the buffer solution (pH=9.4) containing $[Ru(bpy)_3]^{2+}$, 2-mercaptobenzoic acid, and PtO_2 as preliminary experiments was carried out. H_2 evolution was confirmed by gas chromatography (Molecular sieves 5A, 60—80 mesh, 2 m, temp; 35 °C, carrier; N_2, TCD detector) though the yield is low.

Equilibrium Solubilities of Benzene, Toluene, Ethylbenzene, and Propylbenzene in Silver Nitrate Solutions

Isao SANEMASA,* Seiji ARAKAWA, Cheng Yun PIAO, and Toshio DEGUCHI
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received April 1, 1985)

Synopsis. By making use of the solute vapor, the equilibrium solubilities of benzene and three alkylbenzenes in $AgNO_3$ solutions have been measured. The complex formation constants of silver ions are estimated for each solute, and the results are compared with literature values.

It is well known that silver ions form complexes with a wide variety of organic compounds having C–C double bond(s). The formation constants for some aromatic hydrocarbons have been determined by measuring aqueous solubilities of the solutes in the presence of Ag^+ ions.[1-3]

We have reported a method of preparing aqueous solutions saturated with a solute such as aromatic hydrocarbons and iodine.[4,5] The technique involves introducing the solute vapor which is in equilibrium with a liquid or a solid solute, into water and circulating it in a closed system. Here we have applied the method to silver nitrate solutions to determine complex formation constants of Ag^+ with benzene and alkylbenzenes, and the results will be compared with the literature values.

Experimental

All the electrolytes and the nonelectrolytes used were of an analytical reagent grade. Deionized redistilled water was used to prepare silver nitrate solutions, an ionic strength of which was adjusted to 1.00 by adding a suitable amount of the KNO_3 stock solution. The concentration of Ag^+ in the $AgNO_3$ stock solution was determined in advance by the Fajans method. The experimental procedure and the apparatus employed in this work have been previously described in detail.[4] After the solubility equilibrium had been attained (*ca.* 10 min), definite portions of the aqueous phase were withdrawn, and the solute concentrations were determined by extraction with chloroform, followed by spectrophotometric measurements.

Results and Discussion

The complex formations of Ag^+ with aromatic hydrocarbons have been shown as follows:[1] $Ag^+ + \phi = Ag^+\cdot\phi^+$, K_1, and $Ag^+ + Ag\cdot\phi^+ = Ag_2\cdot\phi^{2+}$, K_2, where ϕ denotes hydrocarbon molecule, K_1 and K_2 being stepwise complexation constants. The total concentration of hydrocarbon, C_ϕ, and that of silver ions, C_{Ag}, present in the solution, are expressed as follows;

$$C_\phi = [\phi]_{eq}(1 + K_1[Ag^+]_{eq} + K_1K_2[Ag^+]_{eq}^2) \quad (1)$$

$$C_{Ag} = [Ag^+]_{eq}(1 + K_1[\Phi]_{eq} + 2K_1K_2[\Phi]_{eq}[Ag^+]_{eq}) \quad (2)$$

where the subscript means the equilibrium concentration. Let, in the absence and presence of Ag^+ ions, the hydrocarbon solubility in 1.00 mol dm^{-3} KNO_3 be S_o and S_{obsd}, respectively. Then, $[\phi]_{eq}$ and C_ϕ are equal to S_o and S_{obsd}, respectively, since the hydrocarbon molecules in the aqueous phase free from complexation with Ag^+ are also equilibrated with the solute in the vapor phase. The solubilities of hydrocarbons are small, and even K_1 which is larger than K_2, exhibits no more than a single figure for each hydrocarbon. Hence $[Ag^+]_{eq}$ can be made equal to C_{Ag}. Then, Eq. 1 becomes

$$S_{obsd}/S_0 = 1 + K_1C_{Ag} + K_1K_2C_{Ag}^2. \quad (3)$$

The results of the solubility measurements for each hydrocarbon in KNO_3 solutions containing Ag^+ ions up to 0.5 mol dm^{-3} are listed in Table 1. The K_1 and K_2 values have been determined with the aid of Eq. 3 by a curve-fitting method, and the results are summarized in Table 2 together with the literature values. The magnitude of our K_1 value is in the order of benzene<toluene>ethylbenzene>propylbenzene. It has been suggested that the K_1 value decreases due to a

steric hindrance as the carbon number of a homologous series increases.[1,3,6] With this view, the K_1 value reported in the literature seems to be overestimated for propylbenzene. Our K_2 values are considerably larger than the literature ones, but there is no criterion to judge which is more adequate. In order to determine the K_2 values with a minimum uncertainty, the solubility measurements should be made under higher Ag^+ concentrations. Such conditions, however, cause another uncertainty. In general, the aqueous solubility of a nonelectrolyte depends not only on the concentration, but also on the type of an electrolyte present in the solution, which is referred to the salting (-out or -in) effect. This effect may differ with Ag^+ and K^+, the latter having been added to keep the ionic strength constant, and the difference is to be pronounced at higher Ag^+ concentrations. It should be noted that the literature K_2 values have been determined at relatively higher Ag^+ concentrations up to 1.000 mol dm^{-3}.[1,3]

The present method of preparing aqueous solutions saturated with solute vapor is useful to see whether the solubility obeys Henry's law or not.[4] The solubility of toluene vapor obeys Henry's law in KNO_3 solutions

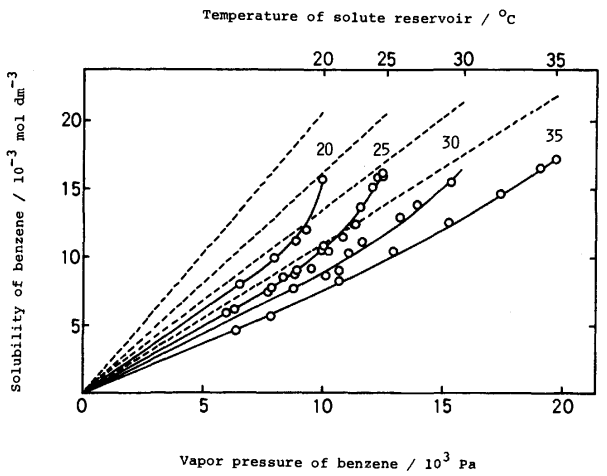

Fig. 2. Equilibrium solubilities of benzene in KNO_3 solutions *vs.* vapor pressure.

The figure near each line indicates the temperature of aqueous solution.

(Fig. 1). This is also the case for the other alkylbenzenes studied here. In sharp contrast, the solubility of benzene vapor has been found to deviate from the law (Fig. 2). Though the reason for the deviation observed for benzene is not clear at present time, a plausible interpretation is that benzene molecules dissolved in KNO_3 solutions associate with each other to dimerize. There have been reported two opposite observations in the literature, one supporting dimerization of benzene,[7] the other not.[8] If dimerization does occur due to hydrophobic interaction between benzene molecules in water,[7] the presence of electrolytes in the solution may be expected to promote dimerization owing to their hydration. It is to be noted that if benzene molecules dissolved in KNO_3 solutions exist as a dimer to an appreciable extent, the K_1 value for benzene determined by us and by others might have been underestimated. If we consider the steric effect to be a main factor as for alkylbenzenes, it seems likely that the K_1 of benzene is rather larger than that of toluene, though the larger K_1 value of toluene has been explained in terms of an inductive effect of the methyl substituent.[1]

The Crystal Structure of Ion-exchanged Mordenite

Masatoki ITO* and Yoshihiko SAITO*
Department of Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
(Received April 1, 1985)

Synopsis. The crystal structure of hydrated mordenite, yielded at Hokiyadake, Nagano City, Japan, $Na_{1.4}Ca_{2.9}Al_{7.2}Si_{40.8}O_{96}\cdot nH_2O$, were refined to R=0.070 for 1526 observed reflections. Notable ordering of the aluminum positions of the aluminosilicate framework was observed.

Study of the location of aluminum atom in mordenite provides a basis for the interpretation of its catalytic properties. All structure determinations for mordenite so far reported have been done on a specimen from Challis Valley, Idaho.[1-2] The structure revealed the weak electron density peaks other than the Cmcm stacking. Here we report the structure of another mordenite obtained at Hokiyadake, Nagano City, Japan, which has a distinct ordering of aluminum atoms in the $AlSi_5O_{12}$ silicate framework. The calcium atoms populated as dominant cations in this mordenite.

Experimental

Single crystals of natural mordenite from Hokiyadake, Nagano City, Japan were ion-exchanged with 1 M HCl solution at room temperature for 24 h, yielding the composition, $Na_{1.4}Ca_{2.9}Al_{7.2}Si_{40.8}O_{96}\cdot nH_2O$ from atomic absorption and ICP spectrometry. A needle crystal with dimensions of 0.20×0.08×0.06 mm was used for the X-ray measurements. The crystal data are: $Na_{1.4}Ca_{2.9}Al_{7.2}Si_{40.8}O_{96}\cdot nH_2O$, orthorhombic, Cmcm, a=18.089(3), b=20.412(4), c=7.504(1) Å, U=2771(2) Å^3, d_m=1.80 g cm^{-3}, μ(Mo $K\alpha$)=7.88 cm^{-1}, λ(Mo $K\alpha$)=0.7107 Å. Intensity data were collected on a Rigaku AFC-5 automated four-circle diffractometer with graphite monochromator up to 2θ=60°. Cell parameters were refined by a least-squares method on the basis of 15 2θ values for Mo $K\alpha$ radiation (20°<2θ<40°). 1526 unique reflections with $|F_o|>3\sigma(|F_o|)$ were measured. No absorption correction was made. Cations and water molecules were located and the structures were refined by the alternating use of least-squares and Fourier methods, the UNICS-III computation program system[3] being employed. Final R value for the hydrated sample is 0.070 for 1526 observed reflections. In the final cycle $(\Delta/\sigma)_{max}$ was 0.2 for the x coordinate of O(6). No peaks higher than 0.35 e Å^{-3} were observed in the final difference density map. Complex neutral atom scattering factors from the International Tables for X-Ray Crystallography[4] were used. Table 1 gives the positional parameters for the silicate framework atoms and the cations.*

Results and Discussion

Interatomic distances and bond angles in the mordenite framework are listed in Table 2. The fundamental framework showed no stacking faults in contrast to the previous results reported by Mortier *et al.*[2] Chemical analysis showed that Ca^{2+} and also Na^+ remained in spite of prolonged ion-exchange by 1 M HCl (1 M=1 mol dm^{-3}) and that the former dominates by far over the latter. Therefore, extra framework electron densities were assigned to Ca^{2+}, Na^+, and orderly adsorbed water molecules. Ca^{2+} is located at the center of the six-membered rings, whereas the cation in the main channel is ascribed to Na^+ since the former

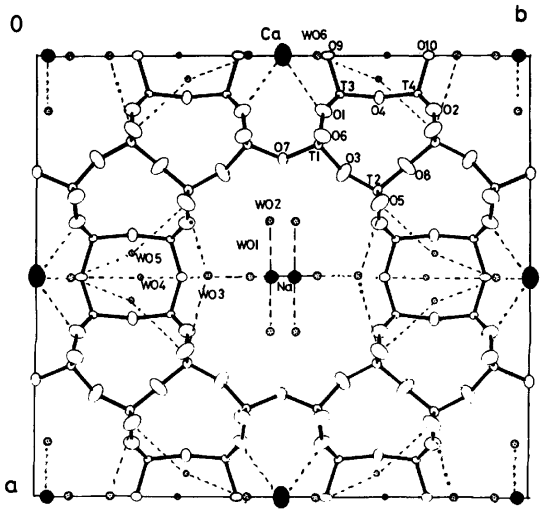

Fig. 1. The crystal structure viewed down along the c axis. WO stands for ordered water molecule.

electron density exceeded by far than the latter.

The T(Si or Al atoms)–O distance was influenced by the Si and Al contents and their positions in the framework. The overall mean T–O distance of 1.620 Å compares well with the typical values for the mordenite as shown in Table 2. The mean T3–O distance, 1.656 Å, is longer than the other T–O distances, which is suggestive of more probable accumulation of the aluminum atoms on the T3 site than on the remaining three. Figure 1 shows the crystal structure viewed down along the c axis. The Ca^{2+} at (0, 1/2, 0) was not exchanged by 1 M HCl. This is explained by the existence of ordered AlO_4^- tetrahedra at T3 site. The larger charge 2+ of Ca^{2+} rather than Na^+ could favor the charge compensation of AlO_4^-. The presence of the mirror plane (100) in Cmcm may lead to unfavorable charge distribution of the neighboring AlO_4^- tetrahedra. Thus, Al(T3) and adjacent symmetry related Al(T3′) atoms might be statistically disordered, and the space group Cmcm adopted in the present investigation represents a pseudo-symmetry.

The structure for dehydrated mordenite was also determined. The cell dimensions reduced to a= 17.941(4), b=20.276(6), c=7.482(2) Å by dehydrating a capillaried sample at 10^{-5} Torr and 350 °C for 48 h. During dehydration the Na^+ remaining in the center of the large channel, which occupied the two positions at random near the center, moved to the side wall of the main channel, and the T3-09-T3′ angle changed by up to 8.1° (1.4°) with mean change of 2.2°. The remarkable ring puckering of the framework skeletons reduced the symmetry from Cmcm to the lower space group.

The authors wish to thank Dr. A. Kato for supplying the mordenite sample.

Stereoisomers of the Bis(1,10-phenanthroline){(1*R*,2*R*)-1,2-cyclohexanediamine}cobalt(III) Complex

Akira TATEHATA* and Shigeru NATSUME
Department of Chemistry, Faculty of Science, Shizuoka University, Ohya, Shizuoka 422
(Received May 1, 1985)

Synopsis. The diastereomers of $[Co(R\text{-chxn})(phen)_2]^{3+}$ (R-chxn=$(-)_{589}$-(1*R*,2*R*)-1,2-cyclohexanediamine, phen= 1,10-phenanthroline) were prepared and characterized by absorption, circular dichroism, and ^1H NMR spectra. The preference of Δ-isomer in the complex formation was observed and the degree of the stereoselectivity was greater than that of the corresponding $[Co(R\text{-pn})(phen)_2]^{3+}$ (pn= 1,2-propanediamine).

Stereoselectivity in the formation of the mixed ligand Co(III) complexes of the type $[Co(aa)(phen)_2]^{n+}$ has been investigated. No remarkable stereoselectivity between Λ and Δ isomers was observed for certain complexes containing a chiral α-hydroxy carboxylate ion such as (*R*,*R*)- or (*S*,*S*)-tartrate and (*S*)-malate ions,[1] whereas fairly high stereoselectivity was observed for this type of (*S*)-α-amino acidato[2] and (*S*)- or (*R*)-pn[3] complexes. We report here the preparation,characterization, and stereoselectivity in the formation of the diastereomers of $[Co(R\text{-chxn})(phen)_2]^{3+}$.

Experimental

1,2-Cyclohexanediamine, chxn, (Aldrich Chemical Co.) was separated into cis and trans isomers by the procedure of Kidani *et al.*[4] Optically active *R*-chxn was obtained by resolving *trans*-chxn according to the method of Galsbøl *et al.*[5]

Preparation and Separation of Isomers. A methanol solution (2.3 cm^3, 10% v/v) of *R*-chxn was added to a suspension of *cis*-$[CoCl_2(phen)_2]Cl\cdot 3H_2O$ (1.0 g, 1.7 mmol) in methanol (50 cm^3). The mixture was stirred for 3 h at 40 °C, and then diluted with water. This solution was passed through an SP-Sephadex column (φ2.7×40 cm), and the adsorbed complexes were eluted with a 0.3 mol dm^{-3} NaCl solution. Yellow ($[Co(phen)_3]^{3+}$), yellowish-orange($[Co(R\text{-chxn})(phen)_2]^{3+}$), and orange ($[Co(R\text{-chxn})_2(phen)]^{3+}$) bands were developed in this order. The effluent of the second band containing the desired complex was diluted with water and passed through an SP-Sephadex column (φ2.7×3 cm). The adsorbed complex was transferred to the top of another SP-Sephadex column (φ2.7×130 cm) and eluted with a 0.15 mol dm^{-3} $Na_2[Sb_2(d\text{-tart})_2]$ solution to separate the diastereomers. The eluted bands of diastereomers were collected, and to them the same procedure was followed as for the corresponding pn complex.[3] Two diastereomers were obtained as crystals of the perchlorate. Found for the Λ isomer: C, 40.92; H, 3.68; N, 9.66%. Calcd for $C_{30}H_{36}N_6Cl_3CoO_{15}$ (trihydrate): C, 40.67; H, 4.10; N, 9.49%. Found for the Δ isomer: C, 41.51; H, 3.79; N, 9.72%. Calcd for $C_{30}H_{34}N_6Cl_3CoO_{14}$(dihydrate): C, 41.52; H, 3.95; N, 9.68%.

Measurements. Absorption and CD spectra were obtained on a Shimadzu MPS-50L recording spectrophotometer and a JASCO J-20 spectropolarimeter, respectively. The CD magnitude was corrected by the use of that of *Λ*-$(+)_{589}$-$[Co(en)_3]I_3\cdot H_2O$. ^1H NMR spectra (90 MHz) were measured on a Varian EM-390 spectrometer in both D_2O and CD_3OD solutions using DDS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate) and TMS(tetramethylsilane), respectively, as an internal standard reference.

Results and Discussion

The absorption and the CD spectra of $[Co(R\text{-chxn})(phen)_2]^{3+}$ are shown in Fig. 1, where their numerical data are also given. The absolute configurations of the isomers were assigned on the basis of the CD spectra in the regions of the first absortion band and the phenanthroline $\pi\cdot\pi^*$ transitions. The configurational and vicinal effect curves under the first absorption band estimated by the conventional method are shown in Fig. 2 together with the vicinal effect curve of the corresponding *R*-pn complex for comparison.[3] The vicinal effect curves of $[Co(R\text{-chxn})(phen)_2]^{3+}$ and $[Co(R\text{-pn})(phen)_2]^{3+}$ are quite similar to each other though the former slightly shifts to longer wavelengths, indicating that the chelate ring of *R*-pn has the same λ conformation as that of *R*-chxn fixed by the cyclohexane ring. ^1H NMR spectra of $[Co(R\text{-chxn})(phen)_2]^{3+}$ were at first measured in D_2O solution. Since the chemical shifts of H_{2a} and H_{3e} protons of the *R*-chxn coordinated in the Λ isomer were not distinct because of overlap with the methylene protons of DSS, the ^1H NMR spectra of the complexes were remeasured in CD_3OD solution. The signals of each proton of the cyclohexane ring have been assigned by the use of spin-decoupling technique and by reference to the corresponding proton signals of $[Co(R\text{-chxn})(CN)_4]^-$.[6] By measuring the midpoint of the multiplets, chemical shifts of the diastereomers of $[Co(R\text{-chxn})(phen)_2]^{3+}$

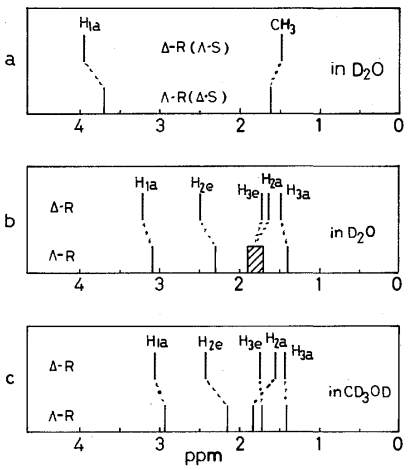

Fig. 3. The distribution of the chemical shifts of the *R*-pn of the [Co(*R*-pn)(phen)$_2$]$^{3+}$ in D_2O solution (a), and the *R*-chxn of the [Co(*R*-chxn)(phen)$_2$]$^{3+}$ in D_2O solution (b) and in CD_3OD solution (c). In each figure Δ-R isomer is shown at the upper part and Λ-R isomer at the lower part.

and [Co(*R*-pn)(phen)$_2$]$^{3+}$ are summerized in Fig. 3 with the assignment of the proton signals. The schematic structures and the numbering of protons of the *R*-chxn and *R*-pn complexes are shown in Fig. 4. There is a

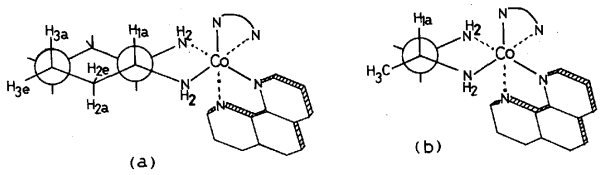

Fig. 4. Schematic structures of *R*-chxn moiety of Δ-[Co(*R*-chxn)(phen)$_2$]$^{3+}$ (a) and of *R*-pn moiety of Δ-[Co(*R*-pn)(phen)$_2$]$^{3+}$ (b) and their numbering of protons.

similar tendency between the spectra of the *R*-chxn complexes and those of the *R*-pn complexes owing to the ring-current effect of the aromatic phenanthroline ligand. The axial methine H_{1a} proton, the equatorial methylene H_{2e} proton, and axial and equatorial methylene H_{3a} and H_{3e} protons for the Δ-*R* chxn complex resonate at a lower field than the corresponding protons of the Λ-*R* chxn complex, as can be also seen for the axial methine H_{1a} proton of the Δ-*R* pn complex.[3] On the other hand, the signals due to the axial methylene H_{2a} proton of *R*-chxn complexes appear at a higher field by 0.28 ppm in the Δ isomer than in the Λ isomer, as observed for the methyl signals of the Δ-*R* pn complex. (Fig. 3) The diastereomeric ratio of the formation of [Co(*R*-chxn)(phen)$_2$]$^{3+}$ was Δ-*R*/Λ-*R*=5.9±0.2 in methanol at 40°C. Although the ring-current effect may play some role in causing the stereoselectivity, it is rather difficult to explain the favored diastereomer solely in terms of ring-current effect. This stereoselectivity may come mainly from a steric factor. Molecular models suggest a sterically less favored configuration for Λ-propellor owing to the serious repulsive interactions between H_{2a} and N–H protons of *R*-chxn and the α-proton of phenanthroline.

Preparation of $Cs_2ZrY(PO_4)_3$ and Related New Compounds

Akira ONO
National Institute for Research in Inorganic Materials, Namiki 1-1, Ibaraki, 305
(Received May 8, 1985)

Synopsis. New compounds have been prepared with the chemical formula $A_2ZrM(PO_4)_3$ with A=K, Rb or Cs and M=Y or In. X-Ray diffraction data can be indexed based on a cubic cell with a langbeinite-type structure. $CsTi_2(PO_4)_3$ could not be obtained but $CsTi_3P_5O_{19}$ was synthesized between 1100—1275 °C. It crystallized with a space group C2/c or Cc with $Z=4$.

Nasicon-type compounds have been studied in relation to sodium ion conductor.[1,2] However, recent studies regarding these substances have revealed the existence of a new structural family of low thermal-expansion materials.[3,4] These studies have been carried out mainly on sodium- or calcium-bearing Nasicon-type compounds; therfore, we have investigated potassium-, rubidium-, and caesium-bearing compounds. During this study, we obtained novel compounds, such as $K_2ZrY(PO_4)_3$, $K_2ZrIn(PO_4)_3$, $Rb_2ZrIn(PO_4)_3$, $Rb_2ZrY(PO_4)_3$, $Cs_2ZrY(PO_4)_3$, $Cs_2ZrIn(PO_4)_3$ and $CsTi_3P_5O_{19}$. This article reports on the preparation and properties of these compounds.

Experimental

Cs_2CO_3, Rb_2CO_3, TiO_2, ZrO_2, In_2O_3, Y_2O_3, KH_2PO_4, and $NH_4H_2PO_4$ were mixed in stoichiometric ratios in an agate mortar with ethyl alcohol and then dried in air. The mixtures were fired at 250 °C for 15 h and calcined at 600 °C for 2 h. The calcines were heated at 1100 °C for 5 min before sealing in a platinum tube of 6 mm in diameter. The sample in platinum capsules were heated at 950—1315 °C for 1—72 h, and then quenched in water.

The products were identified by optical microscopy and X-ray powder diffraction. Lattice constants were determined at room temperature with a Toshiba diffractometer, ADG-301, at a scanning rate of 0.25° 2θ per min. Powdered quartz or KCl was added as an internal standard.

Weissenberg and Precession photographs for a single crystal of $CsTi_3P_5O_{19}$ were obtained using Ni-filtered or unfiltered Cu $K\alpha$ radiation. The unit-cell dimensions of a single crystal were determined using an automatic four-circle X-ray diffractometer, Rigaku Denki Co., Ltd. with Mo $K\alpha$ radiation filtered with a graphite monochromator.

The chemical composition of $CsTi_3P_5O_{19}$ was analyzed using an electron-probe microanalyzer, JXA 5A. A single crystal of TiP_2O_7 was used as the standard for Ti and P.

Results and Discussion

$K_2ZrY(PO_4)_3$ and $K_2ZrIn(PO_4)_3$. These compounds were prepared below 1315 °C as isotropic granular aggregates. As shown in Table 1, X-ray patterns are similar to that of cubic $KTi_2(PO_4)_3$ with a langbeinite-type structure.[5] The lattice constant of $K_2ZrY(PO_4)_3$ is 1.0336 nm, and 1.0180 nm for $K_2ZrIn(PO_4)_3$. Solid solutions between rhombohedral $KZr_2(PO_4)_3$ and cubic $K_2ZrY(PO_4)_3$ or $K_2ZrIn(PO_4)_3$ were not produced judging from the lattice constants of the synthetic materials.

$Cs_2ZrY(PO_4)_3$ and $Cs_2ZrIn(PO_4)_3$. Single phases of isotropic crystals were prepared below 1315 °C

a) 1055 °C, b) 1115 °C.

from stoichiometric starting materials. The X-ray peaks could be indexed on the basis of a primitive isometric space lattice. The X-ray pattern was similar to that of K-bearing analogous compounds, but reflection peaks 111, 210, and 300 were very weak. The lattice constant of $Cs_2ZrY(PO_4)_3$ is 1.0471 nm and that of $Cs_2ZrIn(PO_4)_3$ is 1.0340 nm.

$Rb_2ZrY(PO_4)_3$ and $Rb_2ZrIn(PO_4)_3$. These compounds were prepared at 1115 °C for 24 h and these showed similar X-ray powder patterns. When these X-ray patterns were compared with those of K- and Cs-bearing analogous compounds, systematic changes were clearly observed. For example, the intensities of the 220 peaks increased with increasing sizes of the alkali metal atoms. On the other hand, the reverse was observed for the intensities of the 210 peaks. The lattice constant of $Rb_2ZrY(PO_4)_3$ is 1.0402 nm, and that of $Rb_2ZrIn(PO_4)_3$ is 1.0237 nm.

$CsTi_3P_5O_{19}$. Columnar crystal and glass were prepared by heating a stoichiometric mixture of $CsTi_2(PO_4)_3$ between 1100 and 1275 °C. The crystalline phase was formulated as $CsTi_3P_5O_{19}$ on the basis of a chemical analysis using an electron-probe microanalyzer. The single phase of $CsTi_3P_5O_{19}$ was obtained between 1100—1275 °C from a stoichiometric starting material. The X-ray powder pattern given in Table 1 was indexed on the basis of a monoclinic unit cell with a=1.0966 nm, b=1.6572 nm, c=0.8754 nm, β=100.11°. The density, measured by the method of Archimedes, was found to be 3.10 g cm^{-3}. This is in good agreement with the calculated value for four chemical formula units per cell.

The space-group of $CsTi_3P_5O_{19}$ was determined from the systematically missing reflections in the Weissenberg photographs. The single crystals were crystallized in a monoclinic symmetry with the following missing reflections: $h+k+l$: $h+k=2n$ (n: integer), $0kl$: $k=2n$, $h0l$: $l=2n$, $hk0$: $h+k=2n$, $h00$: $h=2n$ and $0k0$: $k=2n$. These extinctions indicate a space group of C2/c or Cc. Diffused streaks parallel to the a*-axis are present in an $h0l$ Precession photograph.

$CsTi_3P_5O_{19}$ melts incongruently at 1280 °C. TiP_2O_7 and glass are present in a product quenched from 1280 °C.

Crystalline materials prepared at 1055—1090 °C for 194 h showed the X-ray diffraction pattern given in Table 1. A single-crystal X-ray study of the low-temperature polymorph was impossible because of the small grain sizes. A chemical analysis using an electron-probe microanalyzer suggests that the Cs_2O contents of the crystals prepared from the starting materials with a $CsTi_3P_5O_{19}$ composition are consistent with that of $CsTi_3P_5O_{19}$; however, the Cs_2O contents of those prepared from starting materilas with a $CsTi_2(PO_4)_3$ composition were slightly higher than that of $CsTi_3P_5O_{19}$. We could not obtain $CsTi_2(PO_4)_3$ at any temperature, although analogous compounds such as $MTi_2(PO_4)_3$, M:Li, Na, K, Rb, or Tl, were crystallized in rhombohedral forms.[6]

The author thanks Dr. F. P. Okamura for instruction regarding X-ray methods for a single crystal.

(Received December 12, 1984)

Synopsis. Tetrakis[3,5-bis(trifluoromethyl)phenyl]-borate (TFPB) ion as an anionic phase-transfer catalyst promoted the formation of oxirane from various carbonyl substrates and trimethylsulfonium chloride in a two-phase mixture of dichloromethane and concentrated aqueous sodium hydroxide.

Sulfonium methylide can be conveniently generated in a hydrophobic organic medium under phase-transfer catalytic (PTC) conditions by use of a cationic catalyst which functions to incorporate hydroxide ions into the hydrophobic organic medium.[1] An anionic catalyst might also be useful for the same purpose, where the catalyst would help to incorporate the sulfonium ions into the organic phase. We have developed a highly lipophilic tetrakis[3,5-bis(trifluoromethyl)phenyl]borate (TFPB) ion[2] as an anionic phase-transfer catalyst.[3] This note is to describe the catalytic behavior of TFPB toward the formation of sulfonium methylide in an aqueous-organic two-phase system.

Results and Discussion

In the formation of phenyloxirane from benzaldehyde and trimethylsulfonium iodide under PTC conditions (see Table 1) the addition of a TFPB catalyst caused the reaction rate to approximately double, but still it took 9.5 h for the reaction to attain a quantitative yield. A similar catalytic effect seemed likely in some ketone reactions, though it would not be effective enough for preparative use.

Reactions involving reactive trimethylsulfonium chloride[4,5] with various carbonyl substrates are also summarized in Table 1. Benzaldehyde was completely converted to phenyloxirane within half an hour, irrespective of the presence or absence of a TFPB catalyst. The yield of phenyloxirane was quantitative when catalyzed with TFPB, while the yield without the catalyst was somewhat lower.

Cyclohexanone, acetophenone, and benzophenone afforded corresponding oxirane products in quantitative yields within 4 h. Without a TFPB catalyst a reaction mixture of the former two ketones formed an emulsion and suffered some difficulties in product separation. The last ketone was less reactive and gave the oxirane in a lower yield (71%) without the catalyst.

The concentration of the aqueous alkali was required to be as high as 50 w/w% for a satisfactory yield of oxirane.[5]

An increasing amount of the TFPB catalyst correspondingly accelerated the reaction rate, but also caused a decreased conversion of benzaldehyde. When the reaction started with equimolar amounts of trimethylsulfonium iodide and benzaldehyde, the conversion of benzaldehyde stopped at a stage where approximately an equimolar amount of benzaldehyde remained with the TFPB catalyst; *e. g.* when 25 and 50 mol% of sodium TFPB were added, the reactions stopped within 1.7 and 1 h with 25 and 55% of the benzaldehyde remaining unreacted, respectively.[6]

When an equimolar amount of sodium TFPB was added to the sulfonium salt, neither oxirane formation nor a Cannizzaro reaction occurred, even under prolonged vigorous agitation. This indicated that a 1:1 binary ion pair of trimethylsulfonium and TFPB ions was so stable as not to yield the sulfonium methylide in the two-phase system.

TFPB salts were found to disperse in the form of aggregates in solution phases.[7] The particle sizes of aggregates varied with the counter cation and the solvent. Also the sizes of sodium TFPB particles were measured using a light-scattering method.[8] Aggregates of 200 and 20 molecules were found in water and dichloromethane, respectively. The catalytic behavior of TFPB in the present PTC system might have some connection with the aggregation of TFPB and related ionic species.

TABLE 1. YIELDS OF OXIRANES IN PTC REACTION OF SULFONIUM HALIDES

Halide	Reaction conditions[a]	Yield[b]/% (Reaction time/h)			
		PhCHO	cy-C_6H_{10}=O	PhMeC=O	Ph_2C=O
Cl	(A)	97 (0.5)	Quant. (4)	Quant. (4)	Quant. (4)
Cl	(B)	91 (0.5)	Quant. (3)	Quant. (4)	71 (4)
I	(A)	98 (9.5)[c]	24 (48)	23 (48)	8 (48)
I	(B)	59 (9.5)	13 (48)	12 (48)	7 (48)

a) Reaction conditions (A); catalyzed with sodium TFPB (10 mol%). (B); without the catalyst. b) By GLC analyses of the reaction mixture. c) The use of 40 and 25 w/w% aqueous alkali afforded the phenyloxirane in the yields of 70% (22-h reaction) and 10% (19-h reaction), respectively, under the similar conditions.

TFPB salts were also shown to cause a suppression of the Cannizzaro reaction of benzaldehyde. In a separate run without the sulfonium salt under similar two-phase conditions, the addition of sodium TFPB reduced the yield of benzyl alcohol in the Cannizzaro reaction of benzaldehyde to one forth of that without the catalyst. Trimethylsulfonium TFPB was also effective in retarding the Cannizzaro reaction, though to a somewhat smaller extent than the sodium salt.

Thus, the anionic TFPB catalyst appeared to function in a similar way as the cationic ones in promoting oxirane formation with trimethylsulfonium halides under PTC conditions.

Experimental

Reaction of a Carbonyl Compound with Trimethylsulfonium Halide under PTC Conditions. A mixture of trimethylsulfonium chloride[9] (2.4 mmol), the aldehyde or ketone (1.6 mmol), 50 w/w% aqueous sodium hydroxide (20 cm^3), dichloromethane (20 cm^3) and an internal standard for GLC analysis (biphenyl for the reactions of benzaldehyde and benzophenone and tetradecane for those of cyclohexanone and acetophenone) was stirred at 1000 rpm by a mechanical stirrer at room temperature in both the presence and absence of sodium TFPB (0.24 mmol, (10 mol%)). The reaction was followed by GLC analyses of aliquots from the dichloromethane layer with reference to an internal standard. Results are summarized in Table 1.

The reaction products were characterized as follows: 1-Oxaspiro[2.5]octane; a colorless oil, IR and ^{1}H-NMR spectral comparisons with that of the authentic specimen separately prepared:[10] 1-Methyl-1-phenyloxirane; a colorless oil, ^{1}H-NMR ($CDCl_3$, TMS): 1.648 (d, J_{CH_3-H}=0.74 Hz, 3H of CH_3), 2.689 (d.q., J_{H-H}=5.61 Hz, J_{H-CH_3}=0.74 Hz, 1H of CH_2), 2.871 (d, J_{H-H}=5.61 Hz, 1H of CH_2), and 7.275 (m, 5H). (lit[11]: 1.63 (s, CH_3), 2.58 and 2.77 (two d. J=6 Hz, CH_2), 7.27 (s, ArH)): 1,1-Diphenyloxirane; colorless solid melting at 54—56 °C (lit,[12] mp 55—56 °C). ^{1}H-NMR ($CDCl_3$, TMS): 3.250 (s, 2H of CH_2) and 7.314 (s, 10H of ArH). (lit[12] 3.14 (CH_2) and 7.36 (ArH)).

Reactions of trimethylsulfonium iodide were carried out under similar PTC conditions.

Cannizzaro Reaction of Benzaldehyde in a Two-phase System. A mixture of benzaldehyde (2.3 mmol) in dichloromethane (20 cm^3) and 50 w/w% aqueous sodium hydroxide (20 cm^3) was stirred in a similar manner with or without the addition of a 10 mol% TFPB salt. The reaction was followed by GLC in a similar manner. After a 23-h reaction without a TFPB salt, 40% of the benzaldehyde was converted to give benzyl alcohol in a 19% yield. With the addition of sodium TFPB and trimethylsulfonium TFPB, 23-h reactions converted 10 and 21% of the aldehyde to form benzyl alcohol in yields of 5 and 11%, respectively.

(Received March 16, 1985)

Synopsis. The structure of 3a,5,6a-triphenyl-3,3a-dihydro-2*H*-furo[3,2-*b*]pyrrole-2,6(6a*H*)-dione in the crystalline state was determined by X-ray analysis. The crystals are monoclinic, space group P2/a, a=16.606(8), b=7.314(2), c=16.295(9)Å, β=111.67(4), z=4. The final R value was 0.067 for 2453 reflections.

Recently, we reported the formation of 3,3a-dihydro-2*H*-furo[3,2-*b*]pyrrole-2,6(6a*H*)-diones by the air-oxidation of the enamines which were formed by the condensation of 1,3-diketones with 3-aminopropanates.[1] In the IR spectra of this novel heterocycle, two carbonyl bands were characteristically observed at 1800—1790 and 1760—1755 cm^{-1}, respectively, measured as a KBr pellet. Of these, the one at the higher wave number is reasonably attributable to the carbonyl group of the cyclic ester, while the other seems unusual for the 1-pyrrolin-3-one carbonyl which is formally conjugated with the C=N bond.

In this context, the crystal structure of the titled compound (**1**) has been determined by X-ray analysis.

Results and Discussion

Crystal Data. $C_{24}H_{17}NO_3$, MW=367.4, monoclinic, space group P2/a, a=16.606(8), b=7.314(2), c=16.295(9) Å, β=111.67(4)°, Z=4, D_x=1.33 g cm^{-3}, μ(Cu K_α=1.5418Å)=0.67 mm^{-1}. The intensities of 2453 observable reflections with $F_o \geq 2\sigma F_0$ ($2\theta \leq 128°$) were collected on Rigaku AFC5 apparatus equipped with a rotating-anode X-ray generator and using a graphite monochromator. The structure was solved by direct methods using MULTAN[2] and refined by block-diagonal least-squares methods. All the H atoms were located in a difference Fourier map. Final cycles of least squares (non-hydrogen atoms anisotropic, H atoms isotropic) gave R=0.067 (R_w=0.071, w=1.0). The positional parameters for non-hydrogen atoms are listed in Table 1.[3]

A perspective drawing of the molecular structure is shown in Fig. 1, and the bond lengths and angles are listed in Tables 2 and 3, which are within usual values. The two carbonyl groups have almost the same bond lengths. The 1-pyrroline ring is planar within ±0.080(19)Å; the oxygen atom of the carbonyl group deviates by 0.254(19)Å from the plane and the torsion angle O(3)–C(5)–C(6)–N(1) is calculated to be 170.3(4)°. From the above results and the C(5)–C(6) bond length of 1.506(5)Å, it is suggested that there is less delocalization of electrons at the O=C–C=N moiety. The tetrahydrofuran ring is close to envelope conformation,

Thermal Decomposition of 2,2-Bis(*t*-butyldioxy)-3-methylbutane

Takeshi KOMAI* and Shuji SUYAMA
Chemicals and Explosives Research Laboratory, Nippon Oil & Fats Co., Taketoyo-cho, Chita-gun, Aichi 470-23
(Received April 1, 1985)

Synopsis. The activation parameters for decomposition of 2,2-bis(*t*-butyldioxy)-3-methylbutane (**2**) in diphenylmethane are ΔH^*=144.8 kJ mol^{-1} and ΔS^*=49.4 JK^{-1} mol^{-1}. The decomposition products of **2** are *t*-butyl alcohol, acetone, isopropyl methyl ketone and *t*-butyl peracetate. *t*-Butyl peracetate (**4**) is an intermediate which decomposes during reaction. This peroxide **2** decomposes with homolytic one-bond cleavage at one of the peroxide groups and the resulting 1-(*t*-butyldioxy)-1,2-dimethylpropoxyl radical (**3**) decomposes subsequently to *t*-butyldioxy or isopropyl groups with β-elimination.

A little report has been published on concerning the decomposition mechanism of peroxides with peroxyacetal structure. Dickey *et al.*[1] reported the thermal decomposition of 2,2-bis(*t*-butyldioxy)butane in cumene and dibutyl phthalate. Kinetic data indicate first order decomposition with an activation energy of 150.6 kJ mol^{-1}. They also obtained 92% of *t*-butyl alcohol per *t*-butoxyl radical as decomposition product. Mageli and co-workers[2] studied the thermal decomposition of butyl 4,4-bis(*t*-butyldioxy)valerate (**1**) in dodecane. As decomposition products they obtained acetone, *t*-butyl alcohol, butyl propionate and butyl levulinate. They proposed the decomposition mechanism of **1** based on some assumption. For example *t*-butyl peracetate (**4**) is proposed as one of the decomposition intermediates, but any amount of **4** was not detected in the decomposition products.

In the present paper, we have studied the thermal decomposition of 2,2-bis(*t*-butyldioxy)-3-methyl butane (**2**) in diphenylmethane.

Results and Discussion

The rates of thermal decomposition of **2** were obtained by the disappearance of **2** by GLPC. The results gave good first-order rate constants over two half reaction. When the peroxide concentration was varied over ten to forty-fold range, the variation in the rates was within the experimental error as shown in Table 1. Addition of *t*-butyl catechol as a radical trapper also did not change the rate significantly. These results rule out radical-induced homolysis reactions under the experimental conditions.

The thermal decomposition products of **2** in diphenylmethane were analyzed by GLPC and GLPC-MS techniques, being identified by comparison with the corresponding authentic samples. The liquid products of the decomposition at 110°C for 4 h are acetone, *t*-butyl alcohol, isopropyl methyl ketone, *t*-butyl peracetate and 1,1,2,2-tetraphenylethane. *t*-Butyl hydroperoxide was not detected. Decomposition products of 74 to 88 percent per the peroxide were obtained.

The dependence of these products on the reaction time is shown in Fig. 1. The decrease of **2** is compatible with the increase of the isopropyl methyl ketone (**5**) and **4**. However in the latter stage (after 12 h) the amount of consumed **2** does not agree with the sum of **4** and **5** because of consecutive decomposition of **4**.

The following scheme for the thermal decomposition of **2** explains the observed experimental data. The initial step is a homolytic one-bond cleavage to give a primary radical (**3**) rather than simultaneous fission of both peroxyl bonds as discussed below.

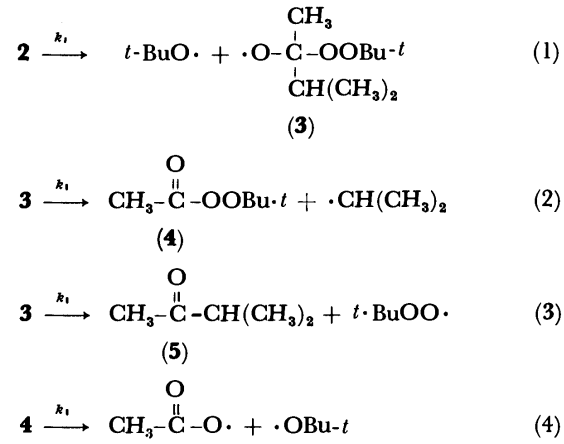

TABLE 1. RATE CONSTANTS AND ACTIVATION PARAMETERS FOR THE DECOMPOSITION OF 2,2-BIS(*t*-BUTYLDIOXY)-3-METHYLBUTANE IN Ph_2CH_2

Temp	Initial Concd	$k_d\times10^4$	Activation Parameters

90	0.0952	0.108±0.006	141.6±2.0	48.6±5.2
100	0.0952	0.375±1.006		
110	0.0116	1.29±0.06		
110	0.0981	1.38±0.01		
110	0.100[a]	1.36±0.01		
110	0.196	1.33±0.01		
110	0.448	1.37±0.01		
120	0.0952	4.11±0.03		

a) 0.025 M of *t*-butyl catechol is present.

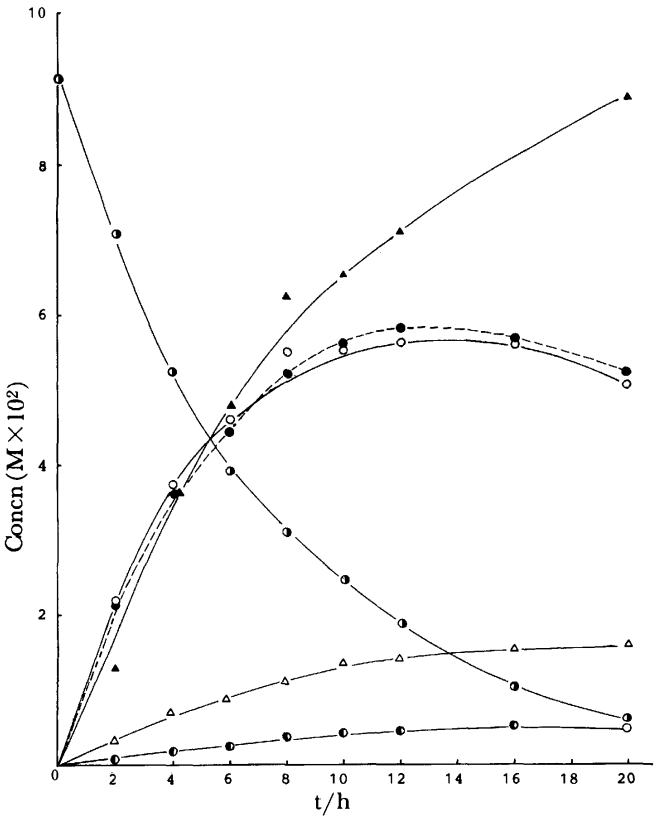

Fig. 1. Decomposition of **2** in Ph_2CH_2 at 100°C. ▲: *t*-BuOH, △: CH_3COCH_3, ◑: **2**, ◐: **5**, ○: **4**, Observed data. ●: **4**, Theoretical data calculated by Eq. 6 using $[\mathbf{2}]_0$=0.0915 M, $k_1=3.75\times10^{-5}\,s^{-1}$ and $k_4=1.23\times10^{-5}\,s^{-1}$.

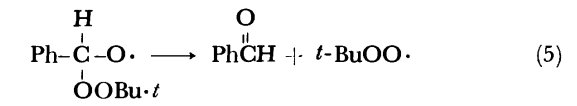
The first reason is that the activation parameters for the decomposition of **2** are similar to those of di-*t*-butyl peroxide[3] ($\Delta H^{\neq}$=153.8 kJ mol^{-1}, $\Delta S^{\neq}$=48.1 JK^{-1} mol^{-1}), which shows homolytic cleavage of the peroxyl bond. The second reason is that *t*-butyl peracetate (**4**) is formed in the initial stage of the reaction. From Table 1 and Fig. 1, *t*-butyl peracetate is assumed to be more stable than the peroxyacetal (**2**). In fact, we obtained $1.23\times10^{-5}\,s^{-1}$ at 100°C and $4.19\times10^{-5}\,s^{-1}$ at 110°C as the first order rate constants for **4** in diphenylmethane. These values are 30 to 40 percent lower than those of **2**.

The formation of **5** is possible by several paths. One possibility is that **3** abstracts hydrogen atom from solvent and resulting half peroxyacetal decomposes to **5** and *t*-butyl hydroperoxide. However, this route is ruled out with following reason. Table 2 shows yields of **4** and **5** in several solvents at 90°C. From these results, it is seen that amounts of **5** per consumed **2** and ratio of **4**/**5** are not changed by the solvents, indicating that the hydrogen abstraction is unimportant. Another possibility, the elimination of *t*-butyl peroxyl radical, is reasonable. (Eq. 3). This type of reaction has been already proposed for the decomposition of α,α-bis(*t*-butyldioxy)toluene.[6]



(5)

Table 2. Yields of isopropyl methyl ketone and *t*-butyl peracetate for the decomposition of **2** in several solvents at 90°C

Solvent	Consumed **2**	Product M mole		**4**/**5**
	M moles	**4**	**5**	
Ph_2CH_2	0.34	0.28	0.05	5.6
$CFCl_2$–$CFCl_2$	—[a]	0.17	0.03	5.7
t-BuOH	0.33	0.26	0.04	6.5
$PhC(CH_3)_3$	0.31	0.18	0.03	6.0

a) Not determined.

The methyl radical elimination from the radical **3** is unimportant, since the rate of the elimination of isopropyl radical is thousand order larger than that of methyl radical.[8]

Using equations (1),(2), and (3) and the steady-state assumption, the concentration of **4** is given by Eq. 5.

$$d[\mathbf{4}]/dt = \alpha k_1[\mathbf{2}] - k_4[\mathbf{4}] \quad (5)$$

where $\alpha = k_2/(k_2 + k_3)$,

Integration of Eq. 5 gives Eq. 6.

$$[\mathbf{4}] = k_1[\mathbf{2}]_0(e^{-k_4t} - e^{-\alpha k_1 t})/(\alpha k_1 - k_4) \quad (6)$$

Using $k_1=3.75\times10^{-5}\,s^{-1}$, $k_4=1.23\times10^{-5}\,s^{-1}$, and $[\mathbf{2}]_0$= 0.0915 M (1 M=1 mol dm^{-3}), the α value of 0.88 is obtained with simulation. The obtained curve is shown by the dotted line in Fig. 1. The elimination rate of *t*-butyldioxy radical from *t*-alkoxyl radical is about one-seventh of isopropyl radical.

Experimental

Materials. 2,2-Bis(*t*-butyldioxy)-3-methylbutane was prepared by the reaction of isopropyl methyl ketone with *t*-butyl hydroperoxide in the presence of 65% surfuric acid. The purity of this compound was determined by GLPC method was 98.9%: MS (70 eV) *m/z* (rel intensity) 159(2), 73(100), 59(28), and 43(44). IR(CCl_4) 2980, 2930, 2880, 1480, 1390, 1370, 1250, 1200, 1150, 1100, 1030 and 880 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=0.94 (6H, d, $CH(CH_3)_2$) δ=1.20 (21H, m, *t*-CH_3), δ=2.22 (1H, q, CH).

Analysis of Decomposition Products. Products were analyzed in comparison with an authentic sample by GLPC and GLPC-MS. GLPC analysis was performed on a Shimadzu GC-6A gas chromatograph with column of Silicone SE-30 on Shimalite W, 2m using undecane as an internal standard. The GLPC-MS analysis of the products was carried out with a JEOL JMS D300 mass spectrometer.

(Received April 20, 1985)

Synopsis. CD spectra of 2,4-dinitrophenyl (Dnp) derivatives of α-amino acids having polynuclear aromatic group in the side chain with L- and D-configuration showed negative and positive Cotton effect, respectively, around 400 nm in consistent with previously proposed Dnp-aromatic rule. Application of the rule revealed D-configuration of levorotatory 3-(9-anthryl)alanine, which was further confirmed by chiroptical comparison of the 2,4-dinitrophenyl derivative and its *p*-methoxyanilide.

CD spectra of 2,4-dinitrophenyl (Dnp) derivatives of L-α-amino acids having aromatic side chain exhibit characteristic negative Cotton effect around 400 nm.[1,2] A general rule named Dnp-aromatic rule was proposed as described in Fig. 1: *i.e.*, Dnp derivatives of general formula **1** and **1′**, having stereochemistry corresponding to aromatic α-amino acids with L- and D-configuration, show negative and positive Cotton effect, respectively, at the longest wavelength band of DnpNH chromophore.[2]

As examples of aromatic α-amino acids having polynuclear condensed aromatic group in the side chain, L-3-(1-naphthyl)alanine,[3] L-3-(2-naphthyl)alanine,[3] D-1-naphthylglycine,[4] D-2-naphthylglycine,[4] and D-3-(1-pyrenyl)alanine[5] were converted into the corresponding Dnp derivatives **2a—e**. As summarized in Table 1 all of these compounds exhibited intense Cotton effect around 400 nm, and in agreement with Dnp-aromatic rule the sign of the Cotton effect was negative and positive for the derivatives with L- and D-configuration, respectively. Thus Dnp-aromatic rule was shown to be valid for these polynuclear aromatic α-amino acid derivatives.

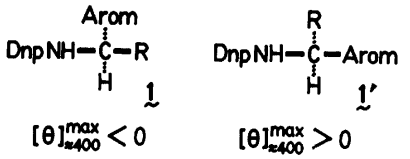

Fig. 1. Dnp-aromatic rule.
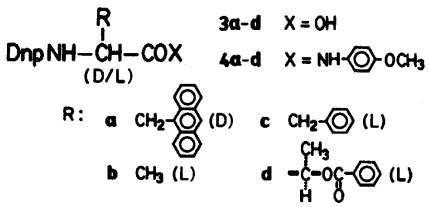
Arom implies an achiral group which contains an aromatic chromophore. R implies a nonaromatic group.

Optically active 3-(9-anthryl)alanine hydrochloride ($[\alpha]_D^{21}$ −43°, c 0.058, ethanol) was synthesized,[6] but its absolute configuration was not known yet. CD spectrum of Dnp derivative **3a** of the anthrylalanine exhibited an outstanding positive Cotton effect ([θ] +50800) at 414 nm, which indicated D-configuration of the amino acid.



p-Methoxyanilides, such as **4b**, of Dnp-L-α-amino acids with nonaromatic side chain, which correspond to general formula **1′**, exhibit prominent Cotton effect around 400 nm.[2,7] Positive contribution of the anilide chromophore to $[\theta]_{\approx 400}^{max}$ value of Dnp-L-α-amino acids was also observed for the *p*-methoxyanilides, **4c** and **4d**, of Dnp-L-phenylalanine **3c**[1,2] and *N*-Dnp-*O*-benzoyl-L-threonine **3d**,[8] respectively (Table 2). The threonine derivative **3d** was known to exhibit positive Cotton effect at 403 nm,[9] in spite of L-configuration of the α-carbon, which is due to the presence of additional chiral center in the chromophore-bearing side chain.[8] Thus introduction of *p*-methoxyanilide group to Dnp-α-amino acids with L- and D-configuration was assumed to give positive and negative contribution, respectively, to the Cotton effect.

Magnitude of the positive Cotton effect of Dnp-(9-anthryl)alanine *p*-methoxyanilide **4a** is smaller than that of **3a** as shown in Table 2 indicating negative contribution of the anilide chromophore, which is consistent with above-assigned D-configuration of this amino acid residue.

TABLE 1. COTTON EFFECT AROUND 400 nm OF Dnp DERIVATIVES OF α-AMINO ACIDS HAVING POLYNUCLEAR AROMATIC GROUP IN THE SIDE CHAIN

	Formula	Configuration of α-carbon	Arom	R	$[\theta]^{max}(\lambda/nm)$

Experimental

Dnp-amino acids were prepared from parent amino acids using 1-fluoro-2,4-dinitrobenzene and $NaHCO_3$ in ethanol-H_2O (2:1). *p*-Methoxyanilides, **4a** and **4c**, were synthesized from Dnp-amino acids, **3a** and **3c**, respectively, and *p*-anisidine using dicyclohexylcarbodiimide. *N*-Dnp-*O*-benzoyl-L-threonine *p*-methoxyanilide **4d** was prepared by benzoylation of Dnp-L-threonine *p*-methoxyanilide[2] with benzoyl chloride-pyridine.

Melting points were uncorrected and were listed in Table 3 along with solvents of recrystallization. CD spectra were recorded in methanol solutions at room temperature on a JASCO J-40C spectropolarimeter and were summarized in Table 4.

The authors are grateful to Kanegafuchi Chemical Industry Co. Ltd. for kind gift of naphthylglycines and to Dr. Ukon Nagai of Mitsubishi-Kasei Institute of Life Sciences for helpful discussions.

Photochemical Reaction of 1,4-Naphthoquinone Derivatives with Pyrrole Derivatives. Synthesis of 2-(2-Pyrrolyl)-1,4-naphthoquinone Derivatives

Kazuhiro MARUYAMA,* Tetsuo OTSUKI,† and Hitoshi TAMIAKI
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received April 24, 1985)

Synopsis. Photochemical reaction of 2-bromo-1,4-naphthoquinone derivatives with pyrrole derivatives in benzene gave regioselectively 2-(2-pyrrolyl)-1,4-naphthoquinone derivatives. Photoinduced electron transfer process may be involved in the reaction.

Thermal reaction of *p*-benzoquinone with pyrrole derivatives has attracted much attention from the viewpoint of dye development,[1] but that of less reactive 1,4-naphthoquinone derivatives has never been investigated. In our previous papers[2] it was reported that photochemical reactions of 2,3-dichloro-1,4-naphthoquinone (**1j**) with furan and thiophene derivatives gave 2-chloro-3-(2-furyl)- and (2-thienyl)-1,4-naphthoquinone derivatives. In this paper, we shall describe photochemical reactions of 1,4-naphthoquinone derivatives **1** with pyrrole derivatives **2**. Some of the reactions afforded 2-(2-pyrrolyl)-1,4-naphthoquinone derivatives **3**, but others failed to give the similar products **3**. The success of the photoreaction to yield **3** depends upon the formation of the charge transfer (CT) complex of **1** with **2** in the ground state.

Results and Discussion

When a benzene solution of 2-bromo-3-methoxy-1,4-naphthoquinone (**1a**) and 1-methylpyrrole (**2a**) was irradiated by a high pressure mercury arc lamp, the yellow solution immediately turned to pale red. Upon only five minutes irradiation at room temperature, 57% of **1a** was consumed and 2-methoxy-3-(1-methyl-2-pyrrolyl)-1,4-naphthoquinone **3a** was isolated as a sole product after the purification of the reaction mixture by column chromatography.

i; X = Cl

2b—e

2b; R = H
c; R = C_2H_5
d; R = $CH_2C_6H_5$
e; R = $COCH_3$

The photochemical reactions of a variety of 1,4-naphthoquinone derivatives **1b—j** with **2a** were examined. The reactions of **1b—d** with **2a** gave **3b—d**, but those of **1e—j** with **2a** gave no similar compounds **3**. The pyrrole **2a** formed CT complexes with **1a—d**, h—j depending upon their reduction potentials $E_{1/2}$.[3] The formation of the CT complexes whose formation constants K reflect $E_{1/2}$ of **1** is an important requisition for the photochemical reaction. Moreover, the rather weak C–Br bond is necessary for the successful formation of **3**. The important contribution of the CT complex formation was further suggested by perturbing the pyrrole moiety. Pyrrole derivatives **2b—d** formed CT complexes with **1a**. Photoreactions of **1a** with **2b—d** gave 2-methoxy-3-(2-pyrrolyl)-1,4-naphthoquinone derivatives **3e—g**. Pyrrole derivative **2e** containing electron-withdrawing substituent formed no CT complex and induced no similar reaction. On the other hand, 1,2,5-trimethylpyrrole (**2f**) formed CT complex with **1a**. The photoreaction of **1a** with **2f**, however, gave no similar product because both the reactive α-positions of the pyrrole were blocked by methyl groups. The reaction of **1a** with 1-methylindole (**2g**) also gave similar products. In this case, the products were consisted of two isomers; *i.e.*, α-substituted **3h** (50%) and isomeric β-substituted **3i** (10%) (see Scheme 1). Any products photosubstituted on positions of fused benzene ring of **2g** were not obtained.

g; R = $CH_2C_6H_5$

This reaction did not proceed by heat,[6] but only by light. The CT formation between two reactants seems to be prerequisite for the successful product formation as described above. In addition, it was reported that cyanide ion dominantly attacked α-position of cation radical of **2a** and attacked both α-position (85%) and β-position (15%) of cation radical of **2g**.[7] The photochemical reaction had the same regioselectivity. Judging from the above facts, the photo-

chemical reaction may include initial electron-transfer process from **2** to **1**.[8]

Experimental

General Procedure. A benzene solution (30 ml) of **1** (0.1 mmol) and 10 equivalents of **2** (1 mmol) was irradiated by a high pressure mercury arc lamp (300 W) through $CuSO_4$ aq solution filter under nitrogen atmosphere at room temperature. After irradiation for a suitable time[9] the starting quinone **1** and the photosubstituted product **3** were isolated by using column chromatography on silica gel with benzene as an eluent. All yields were based on consumed **1**.

Identification of the Products. *2-Methoxy-3-(1-methyl-2-pyrrolyl)-1,4-naphthoquinone* ***3a***: 64% yield; purple needles; mp 119—120 °C (from ethanol); UV (ethanol) 494.5 nm (ε 1800); IR (KBr) 1660 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=3.5 (3H, s), 3.75 (3H, s), 6.2—6.4 (2H, m, H_3 and H_4), 6.8—6.9 (1H, m, H_5), 7.7—7.9 (2H, m), and 8.1—8.3 (2H, m); ^{13}C NMR ($CDCl_3$) δ=35.00 (q), 60.59 (q), 108.51 (d, C-H_3), 113.78 (d, C-H_4), 121.66 (s), 121.99 (s), 124.50 (d, C-H_5), 126.29 (d), 126.61 (d), 131.33 (s), 131.98 (s), 133.44 (d), 134.09 (d), 157.89 (s), 181.28 (s), and 184.60 (s); MS *m/z* (rel intensity) 267 (M^+; 100), 252 (M^+-CH_3; 20), 238 (M^+-NCH_3; 10), 224 (30), 184 (8), 170 (17), 157 (14), 156 (45), and 142 (60); Found: C, 72.08; H, 4.92; N, 5.27%; *m/z* 267.0875. 5) D. W. Cameron and R. G. F. Giles, *J. Chem. Soc. (C)*, **1968**, 1461.

6) Reaction of **1** with **2** gave no similar product even by refluxing in benzene under nitrogen atmosphere.

7) K. Yoshida, *J. Am. Chem. Soc.*, **101**, 2116 (1979).

8) The electron transfer may occur *via* the excitation of the CT complex of **1** with **2** or the formation of the encounter complex of photo-excited **1** with **2**. Then the formed ion radical pair or exciplex seemed to give **3** (see Ref. 4). Therefore, the reaction showed solvent effect; in polar solvents (acetonitrile, methanol) it gave no **3** but in nonpolar solvents (hexane, carbon tetrachloride, benzene) it gave **3**.

9) Irradiation time was 5 min for **3a**, **f**, **g**, 10 min for **3e**, **h**, i, 30 min for **3b**,**c**, and 10 h for **3d**.

X-Ray Crystal Structure of 9-Methyl-3-oxo-2-oxabicyclo[4.4.0]dec-4-ene-6,9-carbolactone. Revised Structure of Iodolactonization Product of 9-Methyl-3-oxo-2-oxabicyclo[4.4.0]deca-4,8-diene-6-carboxylic Acid

(Received May 1, 1985)

Synopsis. The structure of the title compound, deiodo lactone compound, was determined by X-ray crystallographic analysis: The results lead to a revision of the previously proposed structure for iodolactonization product of 9-methyl-3-oxo-2-oxabicyclo[4.4.0]deca-4,8-diene-6-carboxylic acid.

Previously, we have reported that hydrolysis of the Diels-Alder adducts (**1a** and **1b**) of methyl 2-oxo-2*H*-pyran-5-carboxylate with isoprene to the corresponding acids, 9- and 8-methyl-3-oxo-2-oxabicyclo-[4.4.0]deca-4,8-diene-6-carboxylic acid (**2a** and **2b**), followed by iodolactonization, gave iodo lactones (**3a** and **3b**), respectively.[1] Since the proposed structure **3a** was inconsistent in some respects with a recent examination of the off-resonance ^{13}C-NMR spectrum, which showed doublet signal at δ 22.5 due to CH–I and singlet signal at δ 84.3 due to C–O,[2] the structure of the iodo lactone was reinvestigated in detail, resulting in a revision to 8-iodo-9-methyl-3-oxo-2-oxabicyclo-[4.4.0]dec-4-ene-6,9-carbolactone (**4**) from **3a**.[3] In addition, reduction of the iodo lactone with tributyltin hydride afforded the deiodonation product, whose structure was confirmed unambiguously to be 5,9-dioxatricyclo [6.2.2.0^{1,6}]dodecane compound (**5**) by X-ray crystallographic analysis. In this paper, we report on the crystal structure of **5** and the structural revision of iodolactonization product (**3a**→**4**).

Experimental

9-Methyl-3-oxo-2-oxabicyclo[4.4.0]dec-4-ene-6,9-carbolactone (5). To a solution of 120 mg of iodo lactone **4**[1] in 5 ml of dry toluene was added 200 mg of tributyltin hydride (97%) with stirring at 5 °C under N_2. After stirring was continued for 7 h at 5 °C and then for 24 h at room temperature, methanol was added to the reaction mixture. The solvent was removed *in vacuo* at room temperature to give colorless oil which was chromatographed on silica gel using dichloromethane as eluent to afford 55 mg of **5**; colorless prisms, mp 97—99 °C recrystd from benzene–hexane; IR($CHCl_3$) 1760—1730 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.46 (3H, s, C_9–CH_3), 1.72—2.66 (6H, m, 3X–CH_2–), 4.62 (1H, dd, J=4.8 and 9.6 Hz, C_1–H), 5.96 and 7.24 (each 1H, d, J=10.2 Hz, C_4– and C_5–H); MS m/z 208 (M^+); Found: C, 63.56; H, 5.81%. Calcd for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81%.

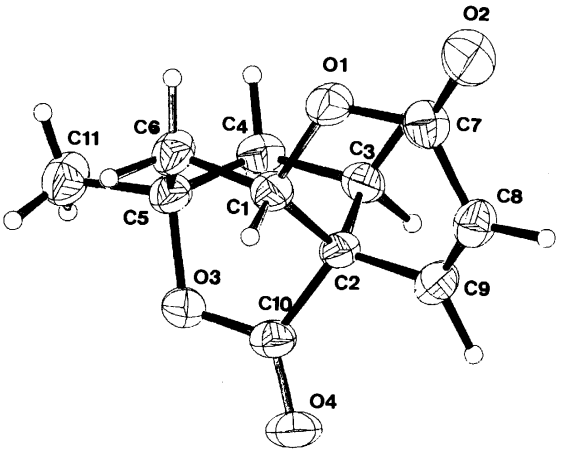

Fig. 1. Perspective view of the X molecule.

X-Ray Measurement. A colorless, single crystal with dimensions of about 0.4×0.4×0.4 mm^3 was used. The crystal data are as follows: $C_{11}H_{12}O_4$, mol wt 208.2, triclinic, space group $P\bar{1}$, a=7.601(1), b=11.179(1), c=12.147(1) Å, α=85.26(1), β=80.18(1), γ=80.57(1)°, Z=4, D_c=1.38 g cm^{-3}. The cell dimensions and diffraction intensities were measured on an automated, four-circle diffractometer with graphite-monochromated, Mo$K\alpha$ radiation (λ=0.7107 Å). The 2θ—ω scan technique was applied at a variable scan rate. Three standard reflections, measured at intervals of every 200 reflections, showed no significant decrease in intensities during the course of data collection. The intensities were corrected for the Lorentz and polarization factors, but not for the absorption or extinction effect. In the range of 2θ values up to 55°, 3707 unique structure factor magnitudes above the $3\sigma(F)$ level were selected for the structure determination.

Structure Determination

The structure was solved by direct method, MULTAN 78.[4] Tangent procedure was carried out using 220 $|E|$ values above 2.03. E-map revealed the locations of 24 non-hydrogen atoms. The rest 6 non-hydrogen atoms had been located in difference Fourier map. Some of hydrogen atoms had also been located in the above map and other hydrogen ones at calculated position. The structure refined by the block-diagonal least-squares method in UNICS III[5] program system with anisotropic temperature factor for non-hydrogen

Resolution of Alcohols as Esters by HPLC on (+)-Poly(triphenylmethyl methacrylate)[1]

Yoshio Okamoto,* Shiro Honda, Koichi Hatada, and Heimei Yuki†
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received May 2, 1985)

Synopsis. Various secondary alcohols were resolved as benzoates or 3,5-dichlorobenzoates by high-performance liquid chromatography on optically active (+)-poly(triphenylmethyl methacrylate). Almost completely resolved alcohols include 2-butanol, 2-pentanol, 2-octanol, 3-octanol, 1-phenylethanol, *cis*-2-methylcyclohexanol, *trans*- and *cis*-3-methyl-cyclohexanol, and tetrahydrofurfuryl alcohol.

A unique optically active polymer bearing a stable helical conformation, poly(triphenylmethyl methacrylate) (PTrMA),[2] has been widely used as a chiral stationary phase for high-performance liquid chromatography (HPLC) to resolve various racemic compounds.[3] The PTrMA usually resolves nonpolar compounds rather than polar ones under reversed-phase chromatographic conditions with a polar eluent like methanol. Thus, a direct resolution of alcohols was not effected but it was attained as esters and even 2-butanol was completely resolved in a form of 3,5-dichlorobenzoate. Usually, the resolution of simple aliphatic alcohols is not easy and is a time-consuming process.

Experimental

All esters used in this work were synthesized from racemic alcohols and acid chlorides. The preparations of (+)-PTrMA[4] and the packing material[3c,5] for HPLC were reported previously. The material was packed in a stainless steel column (25×0.46 (id) cm) by a slurry method. The resolution was accomplished with a JASCO TRIROTOR II chromatograph equipped with a JASCO UVIDEC-100-III UV detector at 15 °C, methanol being used as the eluent.

Results and Discussion

Figure 1 demonstrates the chromatograms of the resolution of *s*-butyl 3,5-dichlorobenzoate and 1-ethylhexyl benzoate on a (+)-PTrMA column. Both compounds were completely resolved. The resolution results are summarized in Table 1. In the resolution of 2-butanol and 2-pentanol, 3,5-dichlorobenzoates were better resolved than benzoates (Entries **1—4**). Separation factor (α) increased in the order of 2-octanol>2-pentanol>2-butanol (Entries **6**, **3**, and **1**). However, 3-methyl-2-butanol was not resolved even as 3,5-dichlorobenzoate (Entry **5**). 3-Octanol was resolved more efficiently than 2-octanol (Entries **6** and **7**). Simple primary alcohols were difficult to resolve (Entries **9** and **10**), although Yoshii and coworkers have reported that a racemic primary alcohol having a more bulky group is completely resolved as benzoate on a (+)-PTrMA column.[3h]

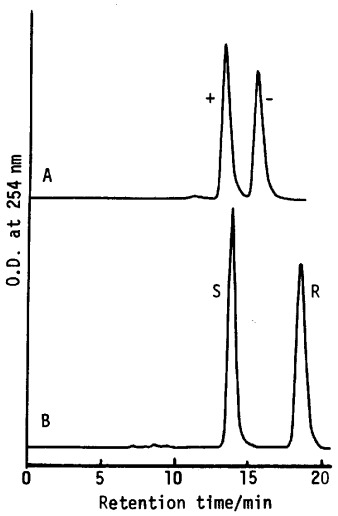

Fig. 1. Chromatograms of the resolution of *s*-butyl 3,5-dichlorobenzoate (A) and 1-ethylhexyl benzoate (B) on a (+)-PTrMA column. (Column: 25 cm×0.46 (id) cm, eluent: methanol (0.5 ml/min), 15 °C).

In the resolution of 1-phenylethanol, the benzoate was the most suitable ester (Entry **11**). Other esters showed rather broad peaks, which resulted in low resolution factors (R_s) as seen in Entries **12—15**. Several cyclic aliphatic alcohols were well resolved as benzoates (Entries **16—21**). *cis*- and *trans*-3-Methylcyclohexyl benzoates showed rather different capacity factors (k_1'), indicating that the separation of cis- and trans-isomers is possible as well as their resolution.

We have already reported that the resolution of dibenzoates of 2,4-pentanediol, *trans*-1,2- and *trans*-1,3-cyclohexanediol is also possible on (+)-PTrMA.[3b,c] These data indicate that the (+)-PTrMA column is useful for the resolution of various alcohols in the form of benzoate derivatives. Oi and Kitahara[6] reported the resolution of various alcohols as 3,5-dinitrophenylurethane derivatives on chiral columns consisting of chiral 1-(1-naphthyl)ethylamine and 2-(4-chlorophenyl)isovaleric acid; a hexane-1,2-dichloroethane mixture containing a small amount of ethanol was used as the eluent. A similar resolution has also been reported by Pirkle and Hyun.[7] The chiral recognition mechanism of our system seems different from such work in which a polar interaction plays an important role in chiral recognition. In our system, a nonpolar interaction or a π-π interaction is likely to be more important than the polar interaction.

This work was partly supported by the Grant-in-Aid for Developmental Scientific Research (58850188).

Replacement of a Carbonyl Group of Camphor by an Oxygen Atom. Synthesis of 1,7,7-Trimethyl-2-oxabicyclo[2.2.1]heptane[1)]

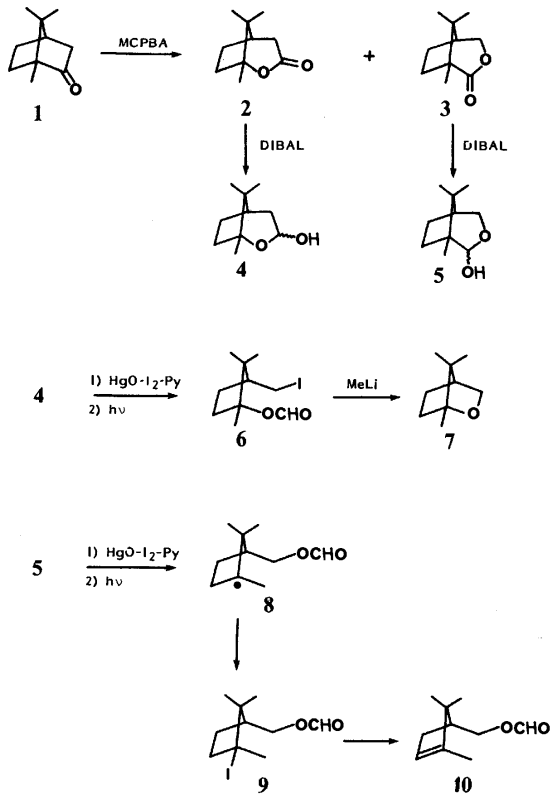
Hiroshi SUGINOME* and Shinji YAMADA
Organic Synthesis Division, Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received May 10, 1985)

Synopsis. A four-step transformation of (+)-camphor into a hitherto undescribed 1,7,7-trimethyl-2-oxabicyclo[2.2.1]-heptane is described.

Only a limited number of the general methods for the synthesis of cyclic ethers have been available. We have recently reported a new and versatile method involving β-scission of alkoxyl radicals for transforming cyclic ketones into cyclic ethers with the original ring size and the transformation of number of steroidal ketones[2,3)] and adamantanone[3)] into the corresponding cyclic ethers has been achieved by this method.

In this paper we report the transformation of camphor, a representative bridged bicyclic ketone, into a hitherto undescribed 1,7,7-trimethyl-2-oxabicyclo-[2.2.1]heptane by this method[3)]. The results may demonstrate that the method can be applied to the preparation of bridged oxabicyclics and oxaterpenoids in general by the substitution of the carbonyl group of a variety of bridged bicyclic ketones, mono- and sesquiterpenoids. These bridged oxabicyclic compounds and oxaterpenoids may be of potential utility as the molecules having interesting biological as well as physical properties.

The Baeyer-Villiger oxidation of camphor has been well investigated.[4)] We have found that the oxidation of (+)-camphor (**1**) with *m*-chloroperbenzoic acid in dichloromethane gives 1,8,8-trimethyl-2-oxabicyclo-[3.2.1]-octan-3-one (**2**) as the major product together with 1,8,8-trimethyl-3-oxabicyclo[3.2.1]octan-3-one (**3**). The isolated yields of these isomeric lactones were 48 and 26% respectively. Reduction of **2** with diisobutylaluminium hydride (DIBAL) gave a 5.5:1 ratio of *endo* to *exo* lactols **4**. A similar reduction of **3** afforded a 5:1 ratio of *endo* and *exo* lactol **5** as judged by the ^{1}H NMR spectra. A mixture of lactols **4** in benzene was transformed into the corresponding hypoiodite with mercury(II) oxide and iodine in the presence of pyridine and then irradiated in an atmosphere of a nitrogen with a Pyrex-filtered light to give an oily iodo formate **6** in a 60% yield with an accompanying formation of lactone **2** (26%). The treatment of iodo formate **6** with methyllithium gave 1,7,7-trimethyl-2-oxabicyclo[2.2.1]heptane (**7**) in a 79% yield. On the other hand, a similar photolysis of the hypoiodite derived from a mixture of lactol **5** as above afforded an oily product **10** in a 60% yield together with lactone **3** (21%). High-resolution mass spectrometry indicated that it had the molecular formula $C_{10}H_{16}O_2$ and the IR, ^{1}H NMR and mass spectra indicated that it was (*R*)-4-formyloxymethyl-2,3,3-trimethylcyclopentene (**10**). It is apparently formed *via* the elimination of HI from the intermediate **9** generated from a carbon-centered radical **8** as outlined in the Scheme. The major parts of parent lactones **2** and **3** in these photolysis are formed by disproportionation of the alkoxyl radicals.



Scheme

Experimental

Mp's were determined with a Yanagimoto micro mp apparatus. IR spectra were determined for Nujol mulls, unless stated otherwise, with a Hitachi Model 285 infrared spectrophotometer. ^{1}H NMR spectra were determined with a JEOL PS200 high-resolution FT-NMR spectrometer (200 MHz) (solvent, $CDCl_3$, $SiMe_4$ as an internal reference). TLC was carried out on Merck Kiesel gel 60, PF254. The high- and low-resolution mass spectra were recorded with a JEOL JMS-D-300 spectrometer (70 eV) (Faculty of Agriculture of this university).

Baeyer-Villiger Oxidation of (+)-Camphor (1). To a solution of (+)-camphor (1 g) (Wako Pure Chemical Ind. Ltd.) in dichloromethane (20 ml) was added *m*-chloroperbenzoic acid (2.5 g) and *p*-toluenesulfonic acid (0.5 g). The solution was set aside for a week at room temperature while stirring. The solution was worked up in the usual way to give a mixture of two lactones. The product was subjected to column chromatography (Merck Kiesel gel 60, 70—230 mesh, 50 g). Elution with a 10:1 benzene–diethyl ether afforded first the starting camphor (**1**) (90 mg) and then lactone **3** (312 mg) and finally lactone **2** (542 mg).

Reduction of 1,8,8-Trimethyl-2-oxabicyclo[3.2.1]octan-3-one (2) with DIBAL. To a solution of the lactone **2** (359 mg) in dry toluene (50 ml) cooled at −78 °C, was added dropwise DIBAL in hexane (3 ml). The solution was stirred for 1.5 h at −78 °C and poured into iced water. After the solution was filtered, the filtrate was worked up by the usual method. A crude product (365 mg) was subjected to column chromatography (Merck Kiesel gel 60, 70—230 mesh). Elution with a 5:1 benzene–diethyl ether gave an amorphous solid (309 mg) which was a 1:5.5 mixture of *endo* and *exo* lactols **4**. (Found: M^+, 170. 1316. Calcd for $C_{10}H_{18}O_2$: 170. 1306); IR; 3370 (OH), 1120, 1061, 1012, 927, and 855 cm^{-1}; ^1H NMR δ=0.86 (3H, s, Me), 1.09 (3H, s, Me), 1.11 (3H, s, Me), 3.41 (1H, d, J=6.35 Hz, OH), 5.14 (0.86 H, m, CHOH of the *endo* isomer), and 5.28; (0.14 H, m, CHOH of the *exo* isomer); MS. *m/z* (rel. intensity), 170 (M^+, 0.6%), 152 (M^+-H_2O, 0.7), 124 (3.5), 109 (100), 67 (23.9), 55 (21.1) and 41 (38.8).

Reduction of 1,8,8-Trimethyl-3-oxabicyclo[3.2.1]octan-2-one (3) with DIBAL. To a solution of the lactone **3** (300 mg) in dry toluene (50 ml) cooled at −78 °C, was added dropwise DIBAL in hexane (2.5 ml). The solution was stirred for 3 h at −78 °C and poured into iced water. After the solution had been filtered, the filtrate was worked up by the usual method. A crude product (298 mg) was subjected to preparative TLC with a 5:1 benzene–diethyl ether to give a lactol **5** (250 mg). (Found: M^+ 170. 1334. Calcd for $C_{10}H_{18}O_2$: 170, 1307); IR 3380 (OH), 1086, and 1009 cm^{-1}; ^1H NMR δ=0.86, 0.90, and 1.07 (each 3H, each s, 1,8,8-Me of *endo* isomer), 0.87, 0.92, and 1.00 (each 3H, each s, 1,8,8-Me of *exo* isomer), 3.50 (1H, dd, J=11.23 and 2.46, 4-H of *endo* isomer), 4.07 (1H, d, J=11.23, 4-H of *endo* isomer), 4.89 (1H, d, J=6.33, 3H of *endo* isomer), 3.39 (1H, dd, J=10.74 and 2.93, 4-H of *exo* isomer), 4.23 (1H, d, J=10.74, 4-H of *exo* isomer), and 4.70 (1H, d, J= 2.93, 3H of *exo* isomer); MS *m/z* (rel. intensity), 170 (M^+, 0.6), 152 (M^+-H_2O, 0.7), 124 (3.5), 109 (100%).

Irradiation of the Hypoiodite of the Lactol 4 in the Presence of Mercury(II) Oxide and Iodine. To the lactol **4** (200 mg) in dry benzene (59 ml) containing pyridine (0.5 ml) was added mercury(II) oxide (598 mg) and iodine (598 mg). The solution in a Pyrex vessel was flushed with nitrogen and irradiated with a 100-W high pressure Hg arc for 1.5 h. The solution was filtered and the filtrate was worked up in the usual manner to give a crude oily product (285 mg). This product was subjected to preparative TLC to give a TLC more mobile fraction A (208 mg) and a TLC less mobile fraction B (52 mg). The oily fraction A was an iodo formate **6**. (Found: M^+, 296. 0311), Calcd for $C_{10}H_{17}IO_2$: 296. 0274; IR (neat) 1724 (CHO), and 1180 cm^{-1} (OCHO); ^1H NMR, δ=0.87 (3H, s, Me), 0.99 (3H, s, Me), 1.43 (3H, s, Me), 2.03—2.22 (4H, s, $-CH_2CH_2-$), 3.00 (1H, dd, J=10.74 and 9.28 Hz, one of CH_2I), 3.34 (1H, dd, J=9.28 and 3.24 Hz, one of CH_2I) and 8.02 (1H, s, OCHO); MS *m/z* (rel. intensity) 296 (M^+, 0.2%), 250 (M^+-OCH_2O, 1.5), 123 ($M^+-I-OCH_2O$, 100), 81 (14.3), 71 (12.7), 55 (18.7), and 43 (28.5). The fraction B was lactone **2**.

Irradiation of the Hypoiodite of the Lactol 5 in the Presence of Mercury(II) Oxide and Iodine. To the lactol **5** (188 mg) in dry benzene (55 ml) containing pyridine (0.5 ml) was added mercury(II) oxide (477 mg) and iodine (564 mg). The solution in a Pyrex vessel was irradiated for 70 min as in the case of the lactol **4**. The solution was worked up as usual. The crude product was subjected to preparative TLC to give a TLC more mobile fraction A (111 mg) and a TLC less mobile fraction B (39 mg). The fraction A was an oily formate **10**. (Found: M^+ 168. 1121. Calcd for $C_{10}H_{18}O_2$: IR (neat) 1726 (CHO), and 1169 cm^{-1} (OCHO); ^1H NMR, δ=0.87 (3H, s, Me), 1.08 (3H, s, Me), 1.60 (3H, br, s, C=C-Me), 1.91—2.41 (3H, m, $\rangle CH-CH_2-CH=C\langle$ 5.22 (1H, br, s, CH=C) and 8.08 (1H, s, OCHO), MS *m/z* 168 (M^+, 0.4%), 122 (M^+-OCH_2O, 10.9), 107 (100) and 91 (15.0). The fraction B was lactone **3**.

1,7,7-Trimethyl-2-oxabicyclo[2.1.1]heptane (7). A solution of the formate (65 mg) in THF (25 ml) was cooled at −78 °C by Dry Ice–methanol. To this solution was added dropwise methyllithium in diethyl ether [1 M (1 M=1 mol dm^{-3}) solution] (0.6 ml). After the solution had been stirred for 1 h at −78 °C, the temperature of the solution rose to room temperature. The solvent was removed by a rotary evaporator as much as possible and the concentrate was diluted with diethyl ether. The solution was washed with water and dried over anhydrous Na_2SO_4. After the removal of Na_2SO_4, the residual solution was concentrated. The yield of 2-oxabicyclo[2.1.1]heptane (**7**) determined by GLC was 79%. The pure 2-oxabicyclo[2.1.1]heptane (**7**), mp 34—37 °C, was isolated by preparative gas chromatography. (Found: M^+, 140. 1192. Calcd for $C_9H_{16}O$: 140. 1199); IR (neat) 1089, 1022, 975, and 930 cm^{-1}; ^1H NMR, δ=0.95, 0.99 and 1.11 (each 3H, each s, 1,7,7-Me), 3.45 (1H, d, J=7.33, *endo* 3-H), 3.87 (1H, m, *exo* 3-H).

(Received May 22, 1985)

Synopsis. By using (−)-*trans*-2,5-bis(hydroxymethyl)-tetrahydrofuran (**1**) of known absolute configuration as a chiral diethylene glycol unit, 18-crown-6 derivatives **8**, **9**, **12**, and dibenzocrown ethers **14**, **15** containing *trans*-tetrahydrofuran-2,5-diylbis(methylene) unit were prepared in enantiomerically pure forms. Their abilities to extract alkali metal picrates were investigated.

A variety of crown ethers incorporating 2,5-disubstituted tetrahydrofuranocycle have been prepared. Most of them, however, were composed of achiral *cis*-tetrahydrofuran-2,5-diylbis(methylene) unit. Stoddart[1] prepared chiral 18-crown-6 derivative possessing *trans*-tetrahydrofuran-2,5-diylbis(methylene) unit by using 2,5-anhydro-D-mannitol. In our preceding paper,[2] we reported the synthesis of some dibenzo-18-crown-6 derivatives **16**, **17**, and **18** containing two *trans*-tetrahydrofuran-2,5-diylbis(methylene) units as a chiral diethylene glycol fragment. Here we describe the preparation of chiral 18-crown-6 derivatives **8**, **9**, and **12** containing one, two, and three *trans*-tetrahydrofuran-2,5-diylbis(methylene) units and chiral dibenzocrown ethers **14** and **15** incorporating the same unit, and the solvent extraction of alkali metal picrates with these crown ethers. Stereoisomers of **8** and **12** containing *cis*-tetrahydrofuran-2,5-diylbis(methylene) units have been prepared by Cram.[3]

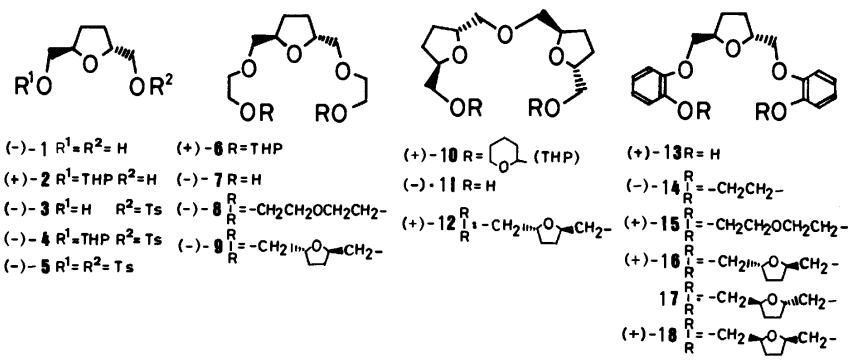
Condensation of (−)-**5**, obtained from (−)-(2*R*,5*R*)-2,5-bis(hydroxymethyl)tetrahydrofuran (**1**),[2] with tetraethylene glycol in THF and NaH provided a 42% yield of (−)-*trans*-tetrahydrofurano-18-crown-6 (**8**). Crown ether **9** composed of two tetrahydrofuranocycles was synthesized stepwise. Treatment of (−)-**5** with ethylene glycol mono(tetrahydropyranyl) ether in THF and NaH followed by acid hydrolysis gave (−)-**7** in 48% overall yield. The glycol **7** was condensed with (−)-**5** to provide a 12% yield of (−)-**9**. Crown ether **12** incorporating three tetrahydrofuranocycles was also prepared stepwise *via* the glycol **11**. Treatment of (−)-**1** with 1 equiv of 3,4-dihydro-2*H*-pyran gave (+)-**2**. Tosylation of (−)-**1** with 1 equiv of tosyl chloride gave the monotosylate **3** together with the ditosylate (−)-**5**, and tetrahydropyranylation of **3** provided (−)-**4**. Treatment of (+)-**2** with (−)-**4** and NaH gave (+)-**10**, hydrolysis of which afforded (−)-**11**. Condensation of (−)-**11** with (−)-**5** in DMSO–diethylene glycol dimethyl ether (diglyme) and NaH gave a 17% yield of (+)-**12**. Dibenzo-15-crown-5 derivative **14** and dibenzo-18-crown-6 derivative **15** were prepared *via* the common intermediate (+)-**13** which was obtained by condensation of (−)-**5** with pyrochatechol mono(tetrahydropyranyl) ether followed by acid hydrolysis. Treatment of (+)-**13** with ethylene glycol ditosylate in THF and KOBu^t provided a 30% yield of (−)-**14**, and (+)-**15** was prepared in 60% yield by condensation of (+)-**13** with diethylene glycol ditosylate. The cation-binding ability of crown ethers was assessed by solvent extraction of aqueous solution of alkali metal picrate with chloroform solution containing crown ether. The results are summerized in Table 1.

TABLE 1. EXTRACTION OF ALKALI METAL PICRATES[a]

Host	Extractability/%			
	Li^+	Na^+	K^+	Cs^+
8	3	5	54	24
9	2	4	53	22
12	2	3	48	19
18-crown-6	3	6	66	33
14	1	10	16	3
15	0	16	42	7
16	0	15	38	10
17	0	20	46	7
18	0	23	36	8
dibenzo-18-crown-6	0	3	35	7

a) The solvent extraction was carried out according to the procedure reported in our preceding paper.[4]

18-Crown-6 derivatives **8**,**9**, and **12** possess low extractabilities for alkali metal ions as compared with the parent 18-crown-6. The origin of the decrease in



extractabilities may be attributed to the restricted conformation of crown ether ring, resulting from incorporation of the constrained *trans*-2,5-disubstituted tetrahydrofuran moiety into the 18-crown-6 constitution. On the other hand, rather high extractabilities of dibenzo-18-crown-6 derivatives **15—18** are probably ascribed to the increased basicity of tetrahydrofuran oxygen atoms over ordinary crown ether oxygen atoms.

Experimental

(+)-(2R,5R)-2-Hydroxymethyl-5-(2-tetrahydropyranyloxymethyl)tetrahydrofuran (2). Tetrahydrophyranylation of (−)-**1**[2] (4.50 g, 34.0 mmol) was carried out according to Parham's procedure[5] to give **2** (3.35 g, 46% yield), bp 120—125 °C (air-bath temp) (1 mmHg); $[\alpha]_{405}^{22}$ +3.8° (*c* 0.798, EtOH). Found: C, 59.90; H, 9.28%. Calcd for $C_{11}H_{20}O_4$: C, 61.09; H, 9.32%.

(−)-(2R,5R)-2-(2-Tetrahydropyranyloxymethyl)-5-(tosylmethyl)tetrahydrofuran (4). Tosylation[2] of (−)-**1** (2.68 g, 20.3 mmol) with tosyl chloride (3.86 g, 20.3 mmol) in pyridine followed by chromatography on alumina gave (−)-**5** (2.05 g), $[\alpha]_D^{22}$ −10.8°[2] and **3** (1.31 g). Tetrahydropylanylation[4] of **3** (1.31 g) followed by chromatography (benzene eluent) provided **4** (1.33 g, 18% overall yield) as a liquid, $[\alpha]_{405}^{25}$ −4.2° (*c* 0.811, EtOH); MS *m/z* 370 (M^+).

(−)-(5R,8R)-5,8-Epoxy-3,10-dioxadodecane-1,12-diol (7). A mixture of ethylene glycol mono(tetrahydropyranyl) ether (2.32 g, 15.9 mmol) and NaH (760 mg, 31.8 mmol) in 50 mL of DMSO–diglyme (1/3 volume ratio) was stirred at 30—35 °C for 2.5 h under N_2 and then to the mixture was added a solution of (−)-**5** (3.50 g, 7.94 mmol), $[\alpha]_D^{22}$ −10.8°, in 25 mL of the same solvent. The mixture was stirred at 50—55 °C for further 24 h under N_2. After a usual workup, chromatography on alumina (benzene) gave (+)-**6** (1.69 g), $[\alpha]_{405}^{23}$ +4.6° (*c* 0.917, EtOH), acid hydrolysis of which in MeOH and *p*-toluenesulfonic acid[2] provided (−)-**7** (830 mg, 48% overall yield) as a liquid, $[\alpha]_D^{24}$ −18.8° (*c* 0.894, $CHCl_3$); MS *m/z* 220 (M^+).

(−)-(15R,18R)-15,18-Epoxy-1,4,7,10,13-pentaoxacyclononadecane (8). To a boiling suspension of NaH (720 mg, 30.0 mmol) in dry THF (180 mL) was added a solution of (−)-**5** (4.00 g, 9.08 mmol) and tetraethylene glycol (1.76 g, 9.08 mmol) in dry THF (270 mL) over a 22 h period under N_2. The mixture was refluxed for further 48 h. After a usual workup, alumina chromatography ($CHCl_3$) provided (−)-**8** (1.11 g, 42% yield) as a liquid, $[\alpha]_D^{22}$ −8.7° (*c* 0.963, $CHCl_3$); MS *m/z* 290 (M^+); ^{1}H NMR ($CDCl_3$) δ=1.45—2.05 (4H, m), 3.40—3.55 (4H, m), 3.69 (16H, t), 4.10—4.35 (2H, m). Found: C, 57.65; H, 9.01%. Calcd for $C_{14}H_{26}O_6$: C, 57.91; H, 9.03%.

(−)-(6R,9R,16R,19R)-6,9:16,19-Diepoxy-1,4,11,14-tetraoxacycloeicosane (9). Condensation of (−)-**7** (830 mg, 3.77 mmol) with (−)-**5** (1.66 g, 3.77 mmol) in DMSO–diglyme and NaH followed by alumina chromatography ($CHCl_3$) gave (−)-**9** (159 mg, 12% yield) as a viscous liquid, $[\alpha]_D^{25}$ −16.4° (*c* 0.825, $CHCl_3$); MS *m/z* 316 (M^+). Found: C, 60.65; H, 8.89%. Calcd for $C_{16}H_{28}O_6$: C, 60.74; H, 8.92%.

(−)-(2R,5R,9R,12R)-2,5:9,12-Diepoxy-7-oxatridecane-1,13-diol (11). Condensation of (+)-**2** (730 mg, 3.38 mmol) with (−)-**4** (1.25 g, 3.38 mmol) in DMSO–diglyme and NaH gave **10** (1.04 g), $[\alpha]_{405}^{24}$ +2.4° (*c* 0.639, EtOH). Hydrolysis of **10** (1.04 g) in MeOH and *p*-toluenesulfonic acid followed by chromatography (ether–MeOH 9:1) provided **11** (520 mg, 62% overall yield) as a liquid, $[\alpha]_D^{20}$ −3.7°(*c* 0.369, EtOH); MS *m/z* 246 (M^+). Found: C, 58.30; H, 8.91%. Calcd for $C_{12}H_{22}O_5$: C, 58.51; H, 9.00%.

(+)-(3R,6R,10R,13R,17R,20R)-3,6:10,13:17,20-Triepoxy-1,8,15-trioxacyclohenicosane (12). Condensation of (−)-**11** (457 mg, 1.85 mmol) with (−)-**5** (817 mg, 1.85 mmol) in DMSO–diglyme and NaH followed by alumina chromatography ($CHCl_3$) gave (+)-**12** (108 mg, 17% yield) as a viscous liquid, $[\alpha]_{405}^{22}$ −9.9° (*c* 0.527, $CHCl_3$); ^{1}H NMR ($CDCl_3$) δ=1.5—2.1 (12H, m), 3.45 (12H, d, *J*=5 Hz), 4.0—4.4 (6H, m); MS *m/z* 342 (M^+). Found: C, 62.95; H, 8.84%. Calcd for $C_{18}H_{30}O_6$: C, 63.13; H, 8.83%.

(−)-(6R,9R)-2,3:12,13-Dibenzo-6,9-epoxy-1,4,11,14-tetraoxacyclohexadeca-2,12-diene (14). Condensation of (+)-**13**[2] (1.00 g, 3.16 mmol), $[\alpha]_D^{22}$ +17.0°, with ethylene glycol ditosylate (980 mg, 6.32 mmol) in dry THF and KOBu^t was carried out according to the procedure as described for **16**.[2] Chromatography on alumina (benzene) followed by recrystallization (hexane) provided (−)-**14** (322 mg, 30% yield), mp 107—108 °C; $[\alpha]_D^{20}$ −23.1° (*c* 0.755, $CHCl_3$); ^{1}H NMR ($CDCl_3$) δ=1.6—2.2 (4H, m), 4.0—4.2 (4H, m), 4.32 (4H, s), 4.60 (2H, br s), 6.90 (8H, s); MS *m/z* 342 (M^+). Found: C, 69.91; H, 6.49%. Calcd for $C_{20}H_{22}O_5$: C, 70.15; H, 6.48%.

(+)-(6R,9R)-2,3:12,13-Dibenzo-6,9-epoxy-1,4,11,14-pentaoxacyclononadeca-2,12-diene (15). A procedure similar to that for **16**[2] using (+)-**13** (1.50 g, 4.74 mmol) and diethylene glycol ditosylate (1.64 g, 3.95 mmol) gave (+)-**15** (1.11 g, 60% yield), mp 172—174 °C (hexane–benzene); $[\alpha]_D^{22}$ +7.0° (*c* 0.840, $CHCl_3$); ^{1}H NMR ($CDCl_3$) δ=1.75—2.40 (4H, m), 4.0—4.2 (12H, m), 4.60 (2H, br s), 6.82 (8H, s); MS *m/z* 386 (M^+). Found: C, 68.29; H, 6.64%. Calcd for $C_{22}H_{26}O_6$: C, 68.38; H, 6.78%.

Selective Synthesis of LPG from Synthesis Gas

Kaoru FUJIMOTO,* Hitoshi SAIMA, and Hiro-o TOMINAGA
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Hongo, Tokyo 113
(Received February 21, 1985)

Synopsis. C_2–C_4 paraffins were produced from synthesis gas with selectivities higher than 80% at 300 °C and 21 atm by utilizing hybrid catalysts composed of a methanol-synthesis catalyst and a Y-type zeolite. The diffusion of lower olefins within zeolite pores and their hydrogenation on a methanol-synthesis catalyst were found to be important factors in controlling selectivity.

Liquified Petroleum Gas (LPG) is important for both home and transportation fuels. It is mainly composed of propane and butanes which maintain a proper vapor pressure at the ambient temperature. Several attempts have been made to produce LPG from synthesis gas with a precipitated Fe–Mn–Cu catalyst,[1] a fused-iron catalyst[2] and a supported molybdenum catalyst.[3] Since the above mentioned catalysts belong to the category of a Fischer -Tropsch catalyst, the hydrocarbon distribution follow the Anderson-Schluz-Flory distribution. This means that a significantly high selectivity regarding methane is inevitable.

Recently, Chang *et al.* have reported that the synthesis-gas conversions with H-ZSM-5 loading oxides of Cr, Zn, and Al give ethane with selectivities as high as 83% at around 400 °C and 100 atm.[4] The present authors showed that hydrocarbon mixtures with markedly different distributions were produced from synthsis gas using hybrid catalysts composed of a methanol-synthesis catalyst and zeolite.[5,6,7]

In the present paper, unique hybrid catalyst systems which give LPG with excellent selectivities are reported.

Experimental

The zeolite used as one component of the hybrid catalysts was prepared by treating a high-silica Y-type zeolite (supplied by Shokubai Kasei Inc., $SiO_2/Al_2O=7.6$) with steam at 450 °C for 1 hr(St-DAY). Methanol-synthesis catalysts, used as other components, were 4 wt% Pd/SiO_2,[6] home-made Cu–Zn–Al mixed oxide prepared following a method described by Shimomura *et al.*[8] (Cu:Zn:Al=40:23:37 in atomic ratio) or a commercially available Cu-based low-pressure methanol-synthesis catalyst (BASF S3-85). The Pd/SiO_2 catalyst was activated by treating with flowing hydrogen at 450 °C for 2 h. The copper-based catalysts were activated by flowing hydrogen at 300 °C for 3 h. The details of the preparative method regarding the hybrid catalysts has been described elsewhere.[5,6]

The reaction apparatus and procedures for a synthesis-gas reaction and a product analysis are the same as those described before.[6]

Results and Discussion

As demonstrated in Fig. 1, the methanol conversion on St-DAY and of synthesis-gas conversion with a hybrid catalyst composed of Cu–Zn(A) and St-DAY give hydrocarbon mixtures with extremely different compositions. The methanol conversion gives C_1–C_6 aliphatics containing significant amounts of olefins, aromatic hydrocarbons composed of mostly penta- and hexamethyl-benzenes (not shown in the figure), and coke. On the other hand, the synthesis-gas conversion gives C_2, C_3, C_4, and C_5 paraffins, exclusively, with a complete lack in aromatic hydrocarbons and a small amount of coke (0.6%).

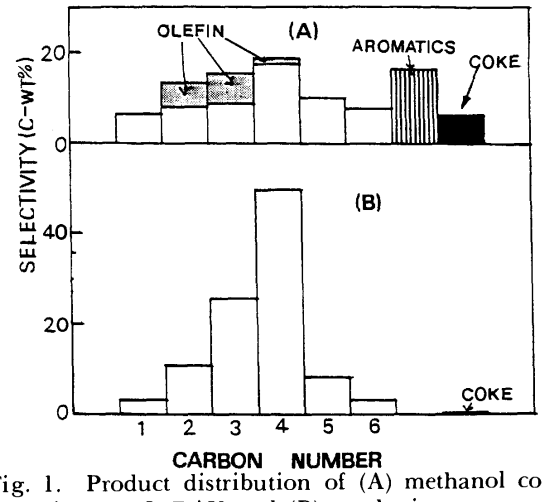

Fig. 1. Product distribution of (A) methanol conversion on St-DAY and (B) synthesis gas conversion on hybrid catalyst containing St-DAY.
(A): Methanol conversion on St-DAY only, 300 °C, 21 atm, 10% methanol in synthesis gas ($H_2/CO=2/1$), W/F=5g-cat h/mol, hydrocarbon yield= 97%, (B): Synthesis gas conversion on Cu-Zn(A)/St-DAY(1/1 weight ratio) 300 °C, 21 atm, $H_2/CO=2/1$, W/F= 10 g-cat h/mol, hydrocarbon yield=36.0%.

It has been known that methanol conversion with large-pore zeolite such as Y-type zeolite gives polymethylated benzenes as well as aliphatic hydrocarbons and coke because of its large pores. Thus, the new features of the products of synthesis-gas conversion with a hybrid catalyst, which are characterized by a lack of olefins, aromatics, and coke, should be attributed to some new catalytic effects caused by hybridization. This subject will be discussed later.

Table 1 shows the catalytic performances of 3 types of hybrid catalysts containing 3 different methanol-synthesis catalysts. It is apparent that all three catalysts give C_2–C_5 paraffins with selectivities higher than 90% and no aromatics while the hydrocarbon yield depends strongly on the catalyst. The distinction should be attributed to the activity of each methanol-synthesis catalyst since the first step of hydrocarbon formation in the present system is methanol formation. Although product patterns regarding the two hybrid catalysts containing Cu–Zn (A) and Cu–Zn (B) are quite similar, the pattern on the Pd/SiO_2 -based catalyst differs significantly from those on the former two catalysts. The latter one gives a product which is more rich in ethane and propane and is poorer in butanes. As discussed in more detail later, the most important reaction for controlling the product selectivity is the hydrogenation of the lower olefins which are inter-

a) With methanol-synthesis catalyst only.

mediates from methanol to aromatics. Thus, it is assumed that the hydrogenation of the lower olefins, which terminates the carbon-chain growth, is more prominent for a Pd/SiO_2 based catalyst.

It should also be noted that the hydrocarbon yield in a synthesis-gas conversion with the hybrid catalyst exceeds the yield of methanol from synthesis gas with the methanol-synthesis catalyst alone under the same reaction condition. This fact could be interpreted to mean that while methanol fromation is controlled by thermodynamic equilibrium under the conditions adopted here, a quick conversion of methanol to hydrocarbon in situ by zeolite lowers the concentration, which enables a further conversion of synthesis gas beyond the thermodynamic limit of methanol formation. A clear tendancy of the product pattern to sift to the lighter side with increasing temperature is recognized, and is identical to that of methanol conversion on zeolites.

The drastic change in the product patterns from the methanol conversion system to the synthesis-gas conversion system should be attributed to some new reactions generated by the hybridization of the zeolite with the methanol catalyst. The change is most likely interpreted by the following scheme. As pointed out already,[6] the hydrogenation of lower olefins and the methylation by methanol of aromatic hydrocarbons are new and important reactions which control the product pattern of a hybrid catalyst system, as demonstrated in Fig. 2. The methanol produced on the methanol-synthesis catalyst moves to the zeolite surface to be converted to dimethyl ether and then to lower olefins.[9] Either dimethyl ether or olefins diffuse in the zeolite pores and some of them come out of the pores to the bulk gas phase. Olefins in the bulk-gas phase have a chance to be hydrogenated to lower paraffins, which terminate the carbon chain growth since methanol synthesis catalysts are active for olefin hydrogenation. When the zeolites with middle-size pores are used, aromatic hydrocarbons and coke are formed since olefins stay in the pores long enough to polymerize into aromatics due to their slow diffusion.[4,7] In the case where a large-pore zeolite (such as a Y-type zeolite) is used, almost all of lower olefins come out of the pores, without polymirizing into aromatics, and are hydrogenated to paraffins on the methanol synthesis catalyst because of the three-times higher diffusion rate in the zeolite pores than that for a middle-pore zeolite (mordenite).[10]

Kinetic Study of the Decay of Chlorine Dioxide in Supercooled and Glassy Organic Solvents

Nobuaki OHTA*,† and Keiji KUWATA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka 560
(Received January 18, 1985)

Chlorine dioxide (ClO_2), which is a stable free radical, decayed in supercooled and glassy liquid 3-methylhexane (3MHX) and 3-methylpentane near their glass transition temperatures (T_g's). The decay of ClO_2, however, was not observed in toluene or 2-methyl-1-propanol. The kinetic analysis of the decay of ClO_2 in 3MHX is reasonably explained by its diffusional motion and dimer formation. The diffusion constants of ClO_2 in 3MHX at temperatures around T_g were estimated in the analysis.

Chlorine dioxide (ClO_2) is well-known to be a stable free redical at room temperature. It was found, however, that ClO_2 decayed in glassy and supercooled liquid 3-methylhexane near its glass transition temperature (T_g) and reappeared at temperatures higher than T_g by about 40 K. These observations have not previously been reported, hence there is a need to explain the mechanism responsible for this decay. The behavior of ClO_2 in some other organic glassy and supercooled liquids is also described.

Experimental

Chlorine dioxide was synthesized by dropping sulfuric acid into a mixture of potassium chlorate and oxalic acid, followed by a passage through an aqueous solution of sodium hydroxide and drying on phosphorus pentaoxide (P_2O_5). The product was further dried over P_2O_5 under vacuum and stored in a glass reservoir in a freezer to prevent decomposition.

3-Methylhexane and 3-methylpentane (99% purity) were purchased from Aldrich Chemicals Co. and heptane, toluene, and 2-methyl-1-propanol (ISB) were reagents of guaranteed grade from Wako Pure Chemicals. These materials were further purified by the methods recommended in the literature.[1] Purity of ISB was 99.54% and the impurities in the other materials were less than 0.01% on gas chromatographic analysis. The purified materials were dried under vacuum and stored in glass ampules. To avoid contamination from vacuum grease in storage, greaseless stopcock with Teflon plunges and ball joints with Teflon O-rings were used.

The purified solvent was degassed by several freeze-pump-thaw cycles and distilled into a calibrated measuring tube under vacuum. A desired amount of solvent was then distilled from the tube into a quartz tube for ESR measurement. Gaseous ClO_2 was taken from the reservoir to an ampule of known volume and introduced into the quartz tube by condensation. The amount of ClO_2 added to the solvent was determined from the volume of the ampule and the pressure of ClO_2. The vapor pressure of ClO_2 was estimated from the temperature of the reservoir. The sample solutions sealed in the ESR tubes were stored in a freezer to prevent loss of ClO_2.

ESR measurements were carried out using a home-built X-band spectrometer equipped with a cryostat using a stream of nitrogen as refrigerant. The cryostat was able to maintain a sample at any temperature from 79 K to 200 K within ±0.1 K for any desired period. The ESR spectrometer consisted of a homodyne-detection system with 450 kHz field modulation. The change in the sensitivity of the ESR measurement was monitored with manganese oxide doped in magnesium oxide.

Usually, the sample solution was kept at 200 K for 3 h to establish the saturation of ClO_2 into solvent, then vitrified by plunging in liquid nitrogen.[2] The glassy solution containing ClO_2 was immediately inserted in the sample became the same as that of the cryostat within 3 min after insertion of the sample.

Analysis of the decay of ClO_2 was carried out with a NEAC 2200/700-computer at Osaka University and a HITAC 8700-computer at Hiroshima University.

Results and Discussion

ESR of ClO_2 in glassy 3-methylhexane (3MHX) gave a pronounced anisotropic spectrum as shown in Fig. 1. When the sample solution was inserted in the cryostat at 97.0 K, the amplitude of the spectrum decreased with time as shown in Fig. 2. As the amplitude decreased, no change in the line shape was observed in the range of ±75 mT from the peak (2). Figure 3 shows the spectra for solutions at higher concentration than that of the solution whose spectrum is shown in Fig. 2 and at a different temperature. Although the difference of the ClO_2 concentration did not produce any remarkable spectral changes, the decay of the signal in the solution of higher concentration became more rapidly at 97.0 K. As the temperature of the solution was raised to 106.3 K, the ClO_2 signal was hardly observed as shown in Fig. 3(B). After the signal disappeared no precipitate was found in the solution. No ESR absorption due to a triplet-state molecule in the $g=4$ region was descernible even at a gain 200 times greater. On further heating a nearly isotropic

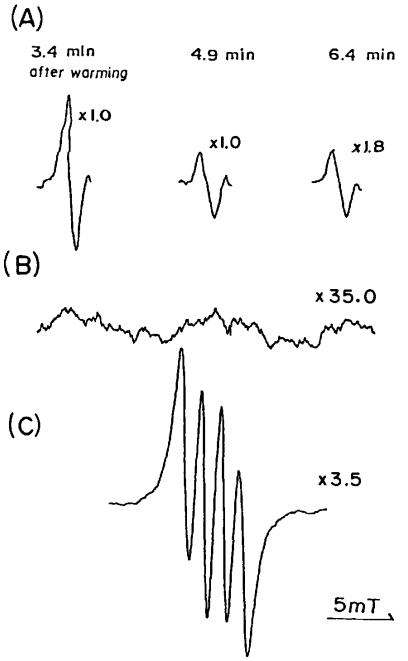

Fig. 3. The ESR spectra of ClO_2 in 3MHX containing ClO_2 of 1.8×10^{-2} mol dm^{-3} at various temperatures: 97.0 K (A), 106.3 K (B), and 131.6 K (C).

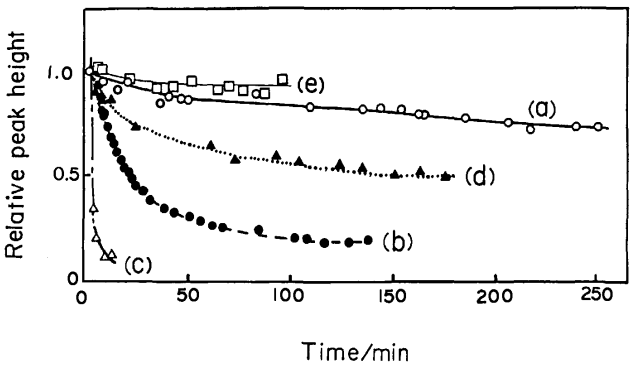

Fig. 4. The decay of peak (2) of Fig. 1 in 3MHX containing ClO_2 of 1.1×10^{-2} mol dm^{-3} at various temperatures: at 87.9 K (a), 96.2 K (b), 105.8 K (c), 115.7 K (d), and 125.3 K (e). The peak heights are normalized by the peak height of the first measurement.

spectrum of Fig. 3(C) for ClO_2 appeared at 131.6 K. As the solution was heated after vitrification and subsequent reinsertion in the cryostat at 97.0 K, the same results were obtained.

ClO_2 in 3-methylpentane (3MP) decayed near 80 K. The decay of ClO_2, however, was not observed in the supercooled and glassy liquids of toluene and 2-methyl-1-propanol (ISB) or in polycrystalline heptane at temperatures ranging from 79 K to about 200 K.

The decay of ClO_2 could be caused by the reaction of ClO_2 with impurities of the solvents and/or oxygen. On consideration of the high purities of the solvents and the use of degassed solutions, those reactions are not responsible for the decay. Besides ClO_2, chlorine monoxide and chlorine trioxide are paramagnetic. As their ESR spectra[3] differ from the spectra of ClO_2, the change of ClO_2 to the monoxide or the trioxide is not able to explain the results. No other phase transitions of 3MHX and of 3MP near their glass transition temperatures (88 K[4] and 77 K[5]), besides the glass transitions, have been reported as far as we know.

Figure 4 shows the decay of peak (2) in 3MHX at various temperatures near T_g. At 77 K, where 3MHX is in the glassy state, ClO_2 gradually decayed with a half life of one week. When the temperature was raised, the rate of decay increased between 77 K and 105 K, however, it decreased above 105 K.

Figure 5 shows the decay of ClO_2 at various

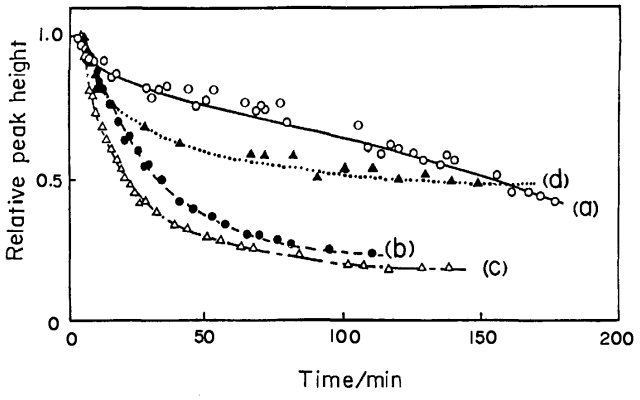

Fig. 5. Additive effect of ClO_2 on the decay of peak (2) of Fig. 1 in 3MHX at 96 K. The nominal concentration of ClO_2 are: 1.6×10^{-3} mol dm^{-3} (a), 5.5×10^{-3} (b), 1.1×10^{-2} (c), and 3.5×10^{-2} (d). The peak heights are normalized by the peak height of the first measurement.

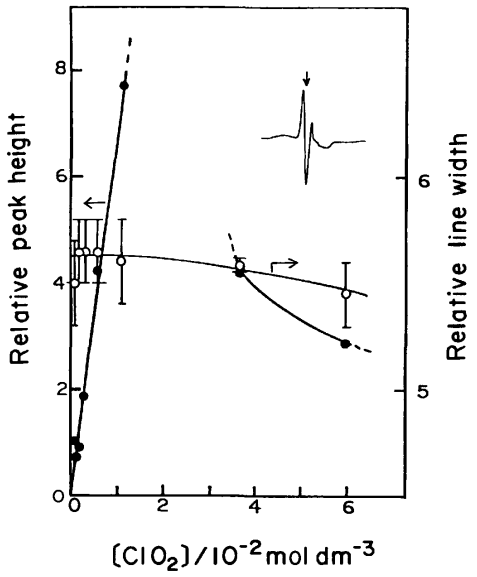

Fig. 6. Additive effect of ClO_2 on the heights and widths of peak (2) of Fig. 1 in 3MHX at 77 K.

nominal concentrations at 96.0 K. The concentrations were calculated from the added amounts of ClO_2 and the volume of the solvent at 77 K which was estimated from its density at 77 K.[6] The decay is faster with addition of ClO_2 until the concentration was increased at about 2×10^{-2} mol dm^{-3}. When the concentration is at 3.5×10^{-2} mol dm^{-3}, the decay slows down.

The plots of the widths and the heights of the peak (2) are shown in Fig. 6 against the nominal concentration of ClO_2 at 77 K. The peak widths seem to be effectively independent of the concentration. Assuming no change of ESR lineshape with the ClO_2 decay, the independence of the peak widths on the nominal concentration indicates that change of ClO_2 concentration can be related to the ESR peak-heights. The heights linearly increase with the addition of ClO_2 up to 1×10^{-2} mol dm^{-3}. In the range of the concentration, $(4—6)\times10^{-2}$ mol dm^{-3}, the peak heights gradually decrease with the addition of ClO_2. In this range the precipitation of ClO_2 was not observed. The decrease of the peak heights at high ClO_2 concentration will be discussed later.

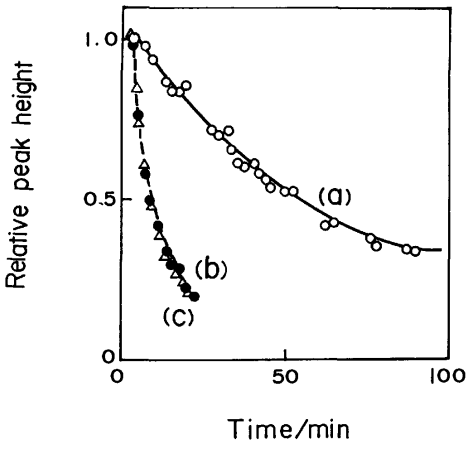

Fig. 7. The decay of peak (2) of Fig. 1 in 3MHX containing ClO_2 of 4.3×10^{-2} mol dm^{-3} at 105.9 K on various thermal treatments of the samples. Lines (a), ○; and (b), ●, are obtained after immediate inserition of the samples from 200 K and 77 K, respectively, into the cryostat of 105.9 K. After annealing for 1 d at 77 K, line (c), △, was obtained. The peak heights are normalized by the peak height of the first measurement.

Analysis of the Decay of ClO_2. Taking into consideration the above results, we assumed that the decay of ClO_2 in 3MHX is due to the formation of a diamagnetic dimer of ClO_2 ($[ClO_2]_2$) described in Eq. 1.

$$ClO_2 + ClO_2 \rightarrow [ClO_2]_2. \quad (1)$$

The dissociation of the dimer was considered in the explanation of the temperature dependence of the decay shown in Fig. 4. The diffusional motion of the ClO_2 molecule was also taken into consideration of the decay because of the high viscosity of 3MHX (about 10^{17} Pa s at T_g[7]).

Before analyses of the curves in Figs. 4 and 5 it is necessary to decide whether the initial distribution of ClO_2 is uniform or not.[8] Figure 7 shows the effects of various thermal treatments of the samples on the decay of the peak (2) of Fig. 1. The curves (a) and (b) were obtained after immediate insertion of the samples into the cryostat of 105 K from 200 K and 77 K, respectively. When the sample was inserted

into the cryostat of 105 K after annealing for 1 d at 77 K, the curve (c) was obtained. No uniform distribution of the ClO_2 molecules resulting from rapid cooling presumably accelerates the decay.

Waite obtained solutions of the kinetic equations of the diffusion-controlled bimolecular reaction A+B→AB with some boundary condition.[9] His theory has been applied and also extended to the analyses of the annealing of the radiation defects in the solid by several authors.[10] We applied Waite theory to the analysis of the decay of ClO_2 considering the reversibility of the reaction (Eq. 1).

According to his theory, the change in the ClO_2 concentration will be expressed by the change in the joint probability density $\rho_{ij}(t)$ between the ith reactant and the jth reactant at time t. As Waite demonstrated, the $\rho_{ij}(t)$ satisfies

$$D_i\nabla_i^2\rho_{ij}(t) + D_j\nabla_j^2\rho_{ij}(t) + f_{ij}(t)\rho_{ij}(t) = \partial_{ij}\rho(t)/\partial t, \quad (2)$$

where $f_{ij}(t)$ act as time-dependent chemical rate-of-raction coefficients. D_i and D_j are the diffusion constants of the ith and jth reactants, respectively; for the ClO_2 decay, $D_i=D_j=D$. The boundary conditions are given as

$$\rho_{ij}(t) = \rho_{eq} \quad \text{for } r \leqq R_0, \quad (3)$$

and

$$\rho_{ij}(t=0) - \rho_{eq} = N\exp[-r^2(\lambda R_0)^{-2}] \quad \text{for } r>R_0. \quad (4)$$

ρ_{eq} is the equilibrium joint probability, $r=|r_i-r_j|$, and R_0 is the radius of the capture sphere. N is a normalization constant and λ is a parameter to be determined from the experimental data. The boundary conditions show that at $r=R_0$ ClO_2 molecules over the equilibrium concentration (which may be propotional to solubility of ClO_2 in 3MHX) immediately react with the other molecules and the initial distribution of ClO_2 molecules is expressed by Eq. 4. Using the boundary conditions, we solved Eq. 2 and rewrote the solution in terms of the fraction of the decay ψ. The results are:

$$\begin{aligned} d\psi/dt = {} & 2\pi R_0^3 C_0'(\psi_{eq}-\psi)^2 z(1+2\pi^{-1/2}z^{-1}) \\ & + 2\pi R_0^3[2\pi^{-1/2}\exp(-\lambda^{-2})\lambda^4(z^2+\lambda^2)^{-2} \\ & + \{2\lambda^2(z^2+\lambda^2)^{-1} - 4\lambda^2(z_s+\lambda^2)^{-2}\} \\ & \times \lambda z(z^2+\lambda^2)^{-1/2}\exp\{-(z^2+\lambda^2)^{-1}\} \\ & \times \mathrm{erf}\{\lambda^{-1}z(z^2+\lambda^2)^{-1/2}\}](1-\phi_0)N \\ & \times \exp\left(\int_0^t f_{ii'}dt\right), \end{aligned} \quad (5)$$

where

$$\int_0^t f_{ii'}dt = -\int_0^z 4\pi R_0^3 C_0'(\psi_{eq}-\psi)(z+2\pi^{-1/2})dz, \quad (6)$$

$$\mathrm{erf}(x) = \int_x^\infty \pi^{-1/2}\exp(-\alpha^2)d\alpha, \quad (7)$$

$$\psi = (C_0'-C)/C_0', \quad (8)$$

and

$$z = (8Dt/R_0)^{1/2}. \quad (9)$$

C is the concentration of ClO_2 at time t and C_0' is the concentration of the first measurement. ψ_{eq} is the equilibrium fraction of the decay. For short times such that $8Dt \ll (\lambda R_0)^2$,

$$\psi - \psi_0 \simeq 8^{1/2}R_0^3 N\exp(-\lambda^{-2})(2Dt)^{1/2}, \quad (10)$$

where ψ_0 is the fraction of the decay at time $t=0$. Equation 10 indicates that at short times ψ is propotional to the square root of t. The Runge-Kutta technique was used in the computer-assisted evaluation of Eq. 5. The parameters taken in this calculation were ψ_0, ψ_{eq}, λ, R_0, and the initial slope of the plots of ψ *versus* $t^{1/2}$.

The best fits of ψ for the temperature dependence of the decay below 105 K (in Fig. 4) are shown in Fig. 8 as a function of $t^{1/2}$ with the experimental points of ψ. The results that at early stages ψ is propotional to $t^{1/2}$ agree with the expectations from Eq. 10. Table 1 summarizes some parameters used in those calculations. Decrease of R_0 with temperature is considered to indicate greater solvation of ClO_2. At a distance of λR_0 the probability density of other molecules around

$D/10^{-13}$ cm^2 min^{-1}	5.9×10^{-6}	2.3×10^{-4}	6.0×10^{-2}	2.3

a) The nominal concentration of ClO_2 is 1.1×10^{-2} mol dm^{-3}. b) For definition see the text. c) 1 cm = 10^{-2} m.

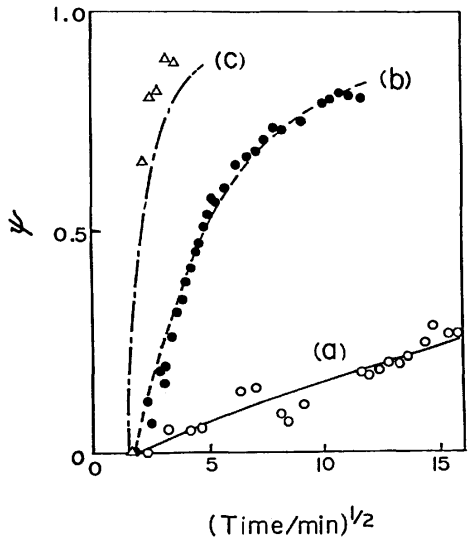

Fig. 8. The decay of ClO_2 in 3MHX containing ClO_2 of 1.1×10^{-2} mol dm^{-3} at various temperatures: 87.9 K (a), 96.2 K (b), and 105.8 K (c). The lines show the calculation by use of Eq. 5 in the text. The parameters used in these calculations are shown in Table 1.

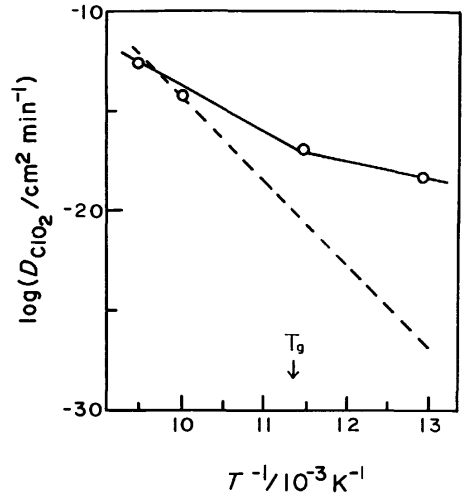

Fig. 9. The Arrhenius plots of diffusion constants of ClO_2 in 3MHX containing ClO_2 of 1.1×10^{-2} mol dm^{-3}. The open circles show the values of the constants shown in Table 1. The dashed line shows the calculation by use of Eq. 11.

one molecule has the maximum value. The constant value of λR_0 is to be expected since the sample solutions were always vitrified by plunging them into liquid nitrogen. Slower cooling of the solutions presumably produces sparse distribution of ClO_2 molecules, that is a large λR_0 value, and may retard the ClO_2 decay as shown in Fig. 7. The values of ψ_{eq} of the lines in Fig. 8 were greater than 0.98, but at $\psi_{eq}>0.975$ the calculated lines dis not change with the value of ψ_{eq}. From the estimated ψ_{eq}'s at various temperatures the change in the enthalpy of the formation of the ClO_2 dimer was estimated to be -17 KJ mol^{-1} at the lower limit. The reasonable fits of ψ for the temperature dependence over 105 K, however, were difficult to explain. As the solutions were heated to the proper temperature over 105 K, the ClO_2 molecules decayed at around 105 K. This situation probably made reasonable fits difficult.

Figure 9 shows Arrhenius plots of the diffusion constants (D's) of ClO_2. The dashed line is the plots of the diffusion constants (D_η's) calculated with Stokes-Einstein's relation given by

$$D_\eta = kT/6\pi\eta a. \quad (11)$$

Here k is the Boltzmann constant, T is the temperature, η is the viscosity, and a is the radius of the molecule. The values of η were taken from the reported values of Ling and Willard.[7] At temperatures around T_g the values of η were estimated by the extrapolation of the reported values. Below T_g the values of D are greater than those of D_η. Above T_g the values of D seem to be near those of D_η. The value of Arrhenius E factor of η was reported as 79 KJ mol^{-1},[7] while the value of D was estimated to be 68 KJ mol^{-1} above T_g.

The plots show that at T_g a translational motion of ClO_2 is accelerated. On the other hand the rotational correlation time of ClO_2 in 3MHX did not show any clear changes at T_g.[11] Seki *et al.*[12] studied the polymerization of vinyl acetate in the glassy state by differential thermal analyses and showed that it polymerizes at temperatures just above T_g, *i.e.* in the supercooled state. They considered that certain immobilized "motion freedom" in the glassy state melts at just above T_g and makes possible the rearrangement and the diffusion of reactant to occur at an appreciable rate. On considering their results and ours the immobilized freedom might be assigned to a translational motion of a molecule.

Figure 10 shows the calculation of the additive effect on the decay (Fig. 5) with the experimental points. The line (c) in Fig. 10 shows the calculation by the use of the initial concentration estimated from the peak height shown in Fig. 6. The calculations using the nominal concentration as the initial concentration failed to reproduce the experimental points. By the addition of ClO_2 the close pairs may convert into the diamagnetic dimers above a certain concentration of ClO_2 even at 77 K. The decrease of the ESR peak-height with addition of ClO_2 shown in Fig. 6 presumably results from the formation of the diamagnetic dimers. Some parameters used in those analyses are summarized in Table 2. In the table r^* is the mean separation of ClO_2 molecules when they uniformly distribute in 3MHX. As ClO_2 added, the

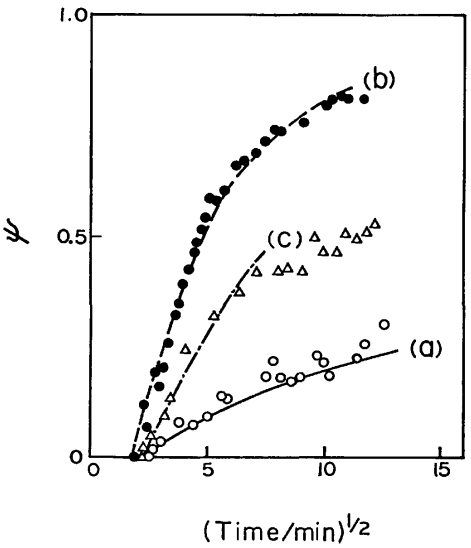

Fig. 10. Additive effect of ClO_2 on its decay in 3MHX at 96 K. The nominal concentration of ClO_2 are at 1.6×10^{-3} (a), 1.1×10^{-2} (b), and 3.5×10^{-2} (c) in units of mol dm^{-3}. The lines show the calculation by use of Eq. 5 in the text. The parameters used in these calculations are shown in Table 2.

TABLE 2. PARAMETERS USED FOR THE SIMULATION OF THE ADDITIVE EFFECT OF ClO_2 ON ITS DECAY IN 3-METHYLHEXANE AT 96 K

Parameter[a]	$[ClO_2]/10^{-3}$ mol dm^{-3}

a) For definition see the text.

values of r^* decrease, but, those of λR_0 are almost constant at 2×10^{-9} m. The difference of the diffusion constants at low and high concentrations may indicate some changes in the properties of the solvent induced by the addition of ClO_2.

As mentioned above, ClO_2 did not decay in supercooled and glassy liquids of toluene and ISB or in polycrystalline heptane. The well-resolved vibrational structure of the electronic absorption spectra of ClO_2 in liquid paraffins disappeared when a hydrogen-bonding solute was added.[13] Adams reported that the paramagnetic relaxation mechanisms of ClO_2 in hydrogen-bonding or electron-donating solvents, such as alcohols and aromatic hydrocarbons, were different from the mechanisms in paraffin solvents.[14] He considered that the difference was due to the ClO_2-solvent interaction which was stronger in hydrogen-bonding or electron-donating solvents than in paraffin solvents. On the basis of those studies no decay of ClO_2 in toluene and in ISB might be explained in consideration of the high activation energy arising from the ClO_2-solvent interactions. This speculation is not valid to explain why there is no decay of ClO_2 in heptane. This may result from the fact that heptane is in the polycrystalline state at the temperatures discussed in the present paper.

A few reports mentioned the formation of the ClO_2 dimer.[15,16] Norman and Porter reported that the electronic absorption spectra of ClO_2 in isopentane-methylcyclohexane rigid solutions were different from the spectra in the liquids.[15] They considered that the difference of the spectra was due to the formation of the ClO_2 dimer. Nielson and Woltz studied the infrared spectra of gaseous ClO_2.[16] They speculated that an absorption band at 1.9×10^4 m^{-1} was caused by the dimerization or higher ploymerization of ClO_2. Though those studies do not confirm the presence of a ClO_2 dimer, the reasonable fits of our kinetic analyses suggest that the presence of the ClO_2 dimer is a plausible explanation. To gain additional evidence for the ClO_2 dimer, a study of the optical absorption spectra of ClO_2 in 3MHX around T_g, and some theoretical calculations on the electronic states of ClO_2 and its dimer for assignment of the absorption bands are being planned.

We thank Professor Takahisa Ichikawa for financial assistance in the use of the computers of Hiroshima University.

The Theoretical Study of the Solvophobic Interaction

Masaharu OHBA and Kiyoshi ARAKAWA*
Research Institute of Applied Electricity, Hokkaido University, Sapporo 060
(Received February 2, 1985)

The relation between a solvophobic interaction (SI) and a solute-solute radial distribution function is discussed. The SI is defined as the difference between the indirect part of the solute-solute potential of the mean force in a solvent and that in a "homomorphic" solvent. It was calculated using the RHNC-like integral equation of RISM-1 for a dilute solution of hard spheres in a solvent composed of polar hard dumb-bells. The existence of a SI was comfirmed in a simple system. The SI in this system proved to have originated from the effect of a dipole-dipole interaction between solvent molecules making the excluded volume of the solute molecules small. It was found that the strength of a SI decreases with increasing temperature. It was also shown that Ben-Naim's measure [*J. Chem. Phys.*, **54**, 1387 (1971)] gives an incorrect conclusion with respect to the temperature dependence of the SI of this system because it includes an excess factor irrelevant to a SI.

Hydrophobic interactions have been investigated by many authors,[1-5] but from a microscopic point of view, their essential character is still not clear. Recently, molecular dynamical calculations were performed[6,7] and semiphenomenological theories were proposed on the basis of an integral equation for liquids.[8,9] However, no clear conclusions have been reached. Statistical mechanical studies from first principles are required in order to clarify the microscopic properties of the hydrophobic interactions, and then, an investigation on solvophobic interactions (SI) is expected to be fruitful as the first step for a thorough understanding of hydrophobic interactions.

There are two problems regarding a study of the SI. The first is how the SI is defined on the basis of statistical mechanics. Ben-Naim[10] related the SI to the potential of the mean force between two solute molecules. However, the potential of the mean force includes a contribution which has no direct connection with the SI, and in the definition of the SI it must be subtracted from the potential of the mean force. The second is to calculate the SI defined by statistical mechanics from first principles. To understand the fundamental aspects of the SI, we investigated the SI of a dilute solution of hard spheres in a polar solvent composed of dipolar hard dumb-bells using the RHNC-like integral equation of RISM-1.[11,12]

The Solvophobic Interaction and the Potential of the Mean Force

In this section, we consider the SI induced in a solution including nonpolar molecules in a solvent. For simplicity, consider the solute molecules to be spherical, and the interaction potential between two solute molecules $U_{AA}(r)$ to have no angular dependence. Hereafter, subscripts A and S denote the solute and the solvent species, respectively.

The potential of mean force between two solute molecules $W_{AA}(r)$ is defined by

$$W_{AA}(r) = -k_B T \ln g_{AA}(r), \tag{1}$$

where k_B is the Boltzmann constant, T the absolute temperature and $g_{AA}(r)$ the radial distribution function between two solute molecules. The physical meaning of $W_{AA}(r)$ is "the free energy change which is caused when two solute molecules move each other from an infinite separation to a distance r in a given solvent." The indirect part of $W_{AA}(r)$ is given by

$$w_{AA}(r) = W_{AA}(r) - U_{AA}(r) = -k_B T \ln y_{AA}(r), \tag{2}$$

where $y_{AA}(r)$ is the indirect pair correlation function between two solute molecules. $w_{AA}(r)$ is the effective potential between the two solute molecules induced by all the other molecules, and it is identical with Ben-Naim's $\delta A^{HI}(r)$.[10]

Here, we consider that the solvent-solvent interaction $U_{SS}(i_S, j_S)$ can be divided into two parts,[13]

$$U_{SS}(i_S, j_S) = U_{SS}^{(0)}(i_S, j_S) + U_{SS}^{(1)}(i_S, j_S). \tag{3}$$

$U_{SS}^{(0)}(i_S, j_S)$ is the hard-core potential including the dispersion force. $U_{SS}^{(1)}(i_S, j_S)$ is the interaction other than $U_{SS}^{(0)}(i_S, j_S)$, including the contribution of the dipole-dipole interaction, the hydrogen bond and others. i_S and j_S denote the positions and orientations of the i-th and the j-th solvent molecules, respectively. Then, we define $w_{AA}^{(0)}(r)$ as the indirect part of the potential of the mean force between two solute molecules in a homomorphic solvent in the same state as the solution, where a "homomorphic solvent" denotes a solvent composed of molecules whose intermolecular interaction is expressed as $U_{SS}^{(0)}(i_S, j_S)$. Since $w_{AA}^{(0)}(r)$ is the effective potential caused by the packing effect of molecules with a hard core in nonpolar solvents, it has no direct relation to the SI. It is equivalent to the indirect part of the potential of the mean force in liquids composed of nonpolar molecules. It must be subtracted from $w_{AA}(r)$. Here, we define $\delta w_{AA}(r)$ as follows,

$$\delta w_{AA}(r) = w_{AA}(r) - w_{AA}^{(0)}(r). \tag{4}$$

$\delta w_{AA}(r)$ is the effective potential between two solute molecules. This is the quantity which expresses the SI of a solution.

When the solute molecules are hard spheres, $w_{AA}(0)=-\Delta\mu_A$.[8,14] Here, $\Delta\mu_A$ is the chemical potential of solute molecules in a solution with respect to an ideal gas. Thus, we have

$$\delta w_{AA}(0) = \Delta\mu_A^{(0)} - \Delta\mu_A, \tag{5}$$

where $\Delta\mu_A^{(0)}$ is the chemical potential of the solute molecules in a homomorphic solvent. Equation 5 shows that $\delta w_{AA}(0)$ is the chemical potential change with respect to a transfer of the solute molecules from the solvent to the homomorphic solvent. Thus, Eq. 5 gives grounds for the fact that the chemical potential change with respect to the transfer of solutes from water to a hydrocarbon solvent is a good measure for the strength of the hydrophobic interaction.

In the following sections, we calculate $\delta w_{AA}(r)$ of the dilute solutions of hard spheres in a solvent composed of polar hard dumb-bells.[15]

The Application to the Dilute Solutions of Hard Spheres in Polar Solvents

The system considered is a dilute solution of nonpolar molecules in a polar solvent. Solute molecules are hard spheres with a diameter σ_{AA}. Solvent molecules are two fused hard spheres with the same diameter σ_{SS}, on whose center the charges $+q_S$ and $-q_S$ are sited. The bond length of a solvent molecule is l. An illustration of a molecule is shown in Fig. 1.

The total potential energy of the solution is assumed to be the sum of all pairs of intermolecular potentials. The intermolecular potential between the i-th molecule of type M and the j-th molecule of type M′ is given by

$$U_{MM'}(i_M, j_{M'}) = \sum_\alpha \sum_\gamma u_{\alpha M\gamma M'}(|r_{iM}^\alpha - r_{jM'}^\gamma|), \tag{6}$$

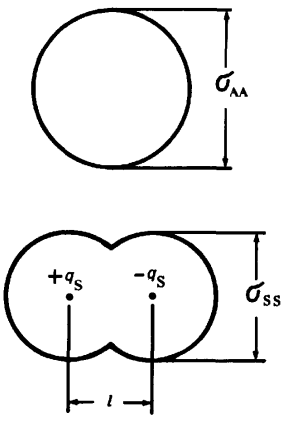

Fig. 1. The shapes of the solute molecule and the solvent molecule.

where $u_{\alpha M\gamma M'}(|r_{iM}^\alpha - r_{jM}^\gamma|)$ is the interaction potential between the α-th atom of the i-th molecule of type M (A or S) and the γ-th atom of the j-th molecule of type M′. r_{iM}^α is the position of the α-th atom of the i-th molecule of type M. The atom-atom interactions are given as

$$u_{\alpha S\gamma S}(r) = u_{SS}^{(0)}(r) + q_{\alpha S}q_{\gamma S}/4\pi\varepsilon_0 r, \tag{7}$$

$$u_{\alpha SA}(r) = u_{SA}^{(0)}(r), \tag{8}$$

$$u_{AA}(r) = u_{AA}^{(0)}(r), \tag{9}$$

$$u_{MM'}^{(0)}(r) = \begin{cases} \infty, & r<\sigma_{MM'} \\ 0, & r>\sigma_{MM'} \end{cases} \tag{10}$$

where we assume that $\sigma_{AS}=(\sigma_{AA}+\sigma_{SS})/2$. ε_0 is the dielectric constant of the vacuum. In this system, $U_{SS}^{(0)}(i_S, j_S)$ and $U_{SS}^{(1)}(i_S, j_S)$ in the previous section are given as

$$U_{SS}^{(0)}(i_S, j_S) = \sum_\alpha \sum_\gamma u_{SS}^{(0)}(|r_{iS}^\alpha - r_{jS}^\gamma|)$$

and

$$U_{SS}^{(1)}(i_S, j_S) = \sum_\alpha \sum_\gamma q_{\alpha S}q_{\gamma S}/4\pi\varepsilon_0|r_{iS}^\alpha - r_{jS}^\gamma|,$$

respectively.

Radial distribution functions and $\delta w_{AA}(r)$ were obtained by solving the RHNC-like integral equation of RISM-1,[11,12] and the procedures of the calculation are quite identical with those described in reference 12.

Results and Discussion

The present system is characterized by five parameters, as follows: the reduced number densities of solute molecules and solvent molecules $\rho_A^*=\rho_A\sigma_{AA}^3$ and $\rho_S^*=\rho_S d^3$, the reduced dipole moment of solvent molecules $\mu_S^*=(\mu_S^2/4\pi\varepsilon_0 k_B T d^3)^{1/2}$, the reduced bond length of solvent molecules $L^*=l/\sigma_{SS}$, and the ratio of σ_{AA} to σ_{SS} $\sigma_{AA}^*=\sigma_{AA}/\sigma_{SS}$. Here, ρ_A and ρ_S are the number densities of solute molecules and solvent molecules, respectively, $\mu_S=q_S l$ the magnitude of the dipole moment of solvent molecules, and d the diameter of a hard sphere whose volume is the same as a solvent molecule. It is given by the following equation

$$d^3 = \sigma_{SS}^3(1+3L^*/2-L^{*3}/2).$$

Because of symmetry, we have four types of atom-atom radial distribution functions, as follows; $g_{AA}(r)$, $g_{AS+}(r)=g_{S+A}(r)=g_{AS-}(r)=g_{S-A}(r)\equiv g_{AS}(r)$, $g_{S+S+}(r)=g_{S-S-}(r)$ and $g_{S+S-}(r)=g_{S-S+}(r)$.

The Structure of the Solution. The atom-atom radial distribution functions of the solution are shown in Figs. 2a—c. The broken curves indicate atom-atom radial distribution functions of the solution in a homomorphic solvent. Figure 2a shows

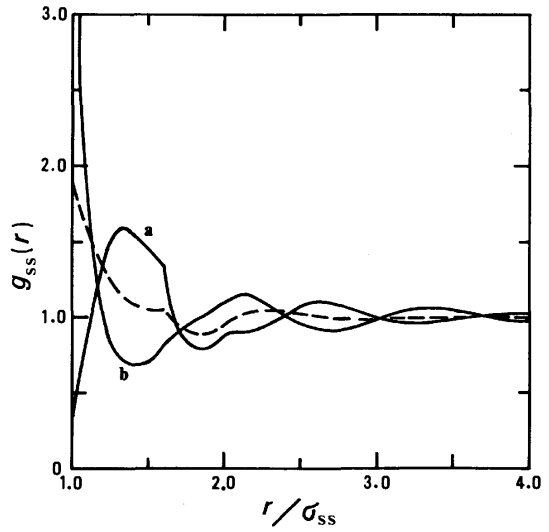

Fig. 2a. The solvent-solvent radial distribution functions for the solution at $\rho_A^*=0.001$, $\rho_S^*=0.8$, $\mu_S^*=3.0$, $L^*=0.6$ and $\sigma_{AA}^*=1.0$. a; $g_{S+S+}(r)$, b; $g_{S+S-}(r)$, ----; $g_{SS}^{(0)}(r)$.

that an orientational correlation between two solvent molecules exists over a considerably long-range region.[11] As seen in Fig. 2b, $g_{AA}(r)$ is larger than that in a homomorphic solvent at $r<2\sigma_{SS}$, and in Fig. 2c the contact value of $g_{AS}(r)$ is smaller than that in a homomorphic solvent. This result shows that the solvent molecules are atracted to each other by dipole-dipole interactions. Thus, the probability that solute molecules approach each other is enlarged. This confirms the presence of a solvophobic interaction in this system.

The Solvophobic Interaction. The potential of the mean force between two solute molecules and the solvophobic interaction $\delta w_{AA}(r)$ are shown in Fig. 3. These are calculated from the solute-solute radial distribution functions shown in Fig. 2b. $w_{AA}(r)$ and $w_{AA}^{(0)}(r)$ have maxima at $r\approx1.6\sigma_{AA}$ and have an oscilltory structure around the asymptotic value zero. $\delta w_{AA}(r)$ has a maximum at $r\approx2.1\sigma_{AA}$, but the maximum is very small. The value of $\delta w_{AA}(r)$ is negative at $r<r_{max}$ and nearly equal to zero at $r<r_{max}$, where r_{max} denotes the position of the first maximum of $\delta w_{AA}(r)$. This shows that the dipole-dipole

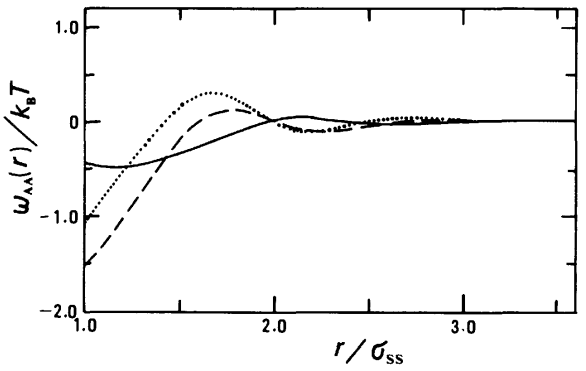

Fig. 3. The potential of mean force between two solute molecules for the same solution as Fig. 2. ——; $\delta w_{AA}(r)$, ----; $w_{AA}(r)$, ····; $w_{AA}^{(0)}(r)$.

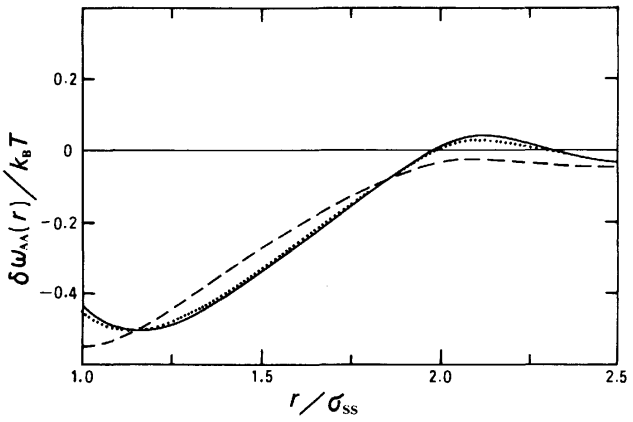

Fig. 4. The solvophobic interactions at $\rho_S^*=0.8$, $\mu_A^*=3.0$, $L^*=0.6$ and $\sigma_{AA}^*=1.0$. ——; $\rho_A^*=0.001$, ····; $\rho_A^*=0.01$, ----; $\rho_A^*=0.04$.

interaction between solvent molecules induces an apparent and effective attraction between the two solute molecules, that is, a solvophobic interaction. It is also shown that the SI is short ranged. $\delta w_{AA}(r)$ has a small minimum at $r \approx 1.2\sigma_{AA}$. The minimum is probably an artifact due to the approximation of the RHNC-like integral equation. $\delta w_{AA}(r)$ decreases with decreasing r near the contact distance.

The concentration dependence of $\delta w_{AA}(r)$ is shown in Fig. 4. $\delta w_{AA}(r)$ for $\rho_A^*=0.01$ is practically the same as that for $\rho_A^*=0.001$ and no appreciable difference between $\delta w_{AA}(r)$ for $\rho_A^*=0.001$ and that for more dilute solutions was found. This shows that $\rho w_{AA}(r)$ at $\rho_A^*=0.001$ can be safely regarded as that for a solution at infinite dilution. Figure 5 shows that the strength of the SI increases with increasing μ_S^* and the position of the maximum is unchanged. It is found from Fig. 6 that the bond length of solvent molecules has little effect on the SI when the dipole moment of solvent molecules is held constant.

Figures 7 and 8 show the effect of the size of solute molecules on the SI. Shapes of $g_{AS}(r)$ at $\sigma_{AA}^*=0.8$ and 1.6 are very similar (Fig. 7). This indicates that a change in the size of solute molecules has little effect on the solvent structure around the solute molecules. The magnitude of $|\delta w_{AA}(r)|$ at $r<r_{max}$ increases remarkably with an enlargement of the size of the solute molecules (Fig. 8), and the position of the maximum coincides with each other when the curves are plotted on the abscissa $(r-\sigma_{AA})/\sigma_{SS}$. It is found that the positions of the maximum of $\delta w_{AA}(r)$ of all systems shown in Figs. 3—6 and 8 are approximately expressed as $r_{max}=\sigma_{AA}+1.1\sigma_{SS}$, which is nearly equal to the diameter of the excluded volume of solute molecules $(\sigma_{AA}+\sigma_{SS})$. Thus, it is said that the SI is negligible when excluded volumes of two solute molecules do not overlap with each other and is attractive when the excluded volumes do overlap. Namely, the SI acts to make the total excluded volume of solute molecules small when the excluded volumes overlap. Then, taking account of the size dependence of $\delta w_{AA}(r)$ at $r<r_{max}$ (Fig. 8) together, it is concluded that the origin of the SI is the effect of the attractive dipole-dipole interaction between solvent molecules to make the excluded volume of solute

molecules small. In this respect, the SI of this system is an energetic effect. A solvophobic solvation like the ice-berg as stated by Némethy and Sheraga[3] does not exist, or hardly contributes to the SI even if the solvophobic solvation exists. If the solvophobic solvation is the main source of the SI, the range of the SI must be longer than $(\sigma_{AA}+2\sigma_{SS})$ which is the shortest distance when the solvation cells of two solute molecules contact each other.

The temperature dependence of the SI is shown in the Table 1. It is noted that $w_{AA}(\sigma_{AA})$ is identical with $\delta A^{SI}(\sigma_{AA})=\Delta\mu_D-2\Delta\mu_M$, Ben-Naim's measure of the SI,[4,10] where $\Delta\mu_D$ and $\Delta\mu_M$ are the chemical potentials of the dimer and the monomer of the solute molecules in the solution, respectively. $|\delta w_{AA}(\sigma_{AA})|$ decreases with increasing temperature, which means that the strength of the SI of this system decreases as the temperature increases. On the other hand, $|w_{AA}(\sigma_{AA})|$ increases with increasing temperature. This is because $\ln y_{AA}^{(0)}(r)=-w_{AA}^{(0)}(r)/k_BT$ of this system does not depend on the temperature. $|w_{AA}^{(0)}(\sigma_{AA})|$ becomes larger in propotion to the temperature, and resultantly the increment of $|w_{AA}^{(0)}(\sigma_{AA})|$ exceeds the decrement of $|\delta w_{AA}(\sigma_{AA})|$. Thus, Ben-Naim's measure, $w_{AA}(\sigma_{AA})$, gives an incorrect conclusion with respect to the temperature dependence of the SI of this system, because its temperature dependence is dominated by that of $w_{AA}^{(0)}(r)$ which is essentially irrelevant to the SI.

Concluding Remarks

It was shown that the SI can be expressed by $\delta w_{AA}(r)=w_{AA}(r)-w_{AA}^{(0)}(r)$, and that Ben-Naim's measure of the SI, which is identical with $w_{AA}(r)$, gives an incorrect temperature dependence because it includes an excess term, like $w_{AA}^{(0)}(r)$ which is irrelevant to the SI.

$\delta w_{AA}(r)$ of dilute solutions of hard spheres in a polar hard dumb-bell solvent was calculated by means of an RHNC-like integral equation of RISM-1 in order to clarify the microscopic properties of the SI. It was shown from this calculation that (1) the dipole–dipole interaction between solvent molecules can cause the SI, (2) the SI in this system mainly originates from the effect of a dipole–dipole interaction between solvent molecules to make the excluded volume of solute molecules small, and (3) a solvophobic solvation like the ice-berg does not exist or hardly contributes to the SI of this system.

Yields of Solvated Electrons at 30 Picoseconds in Water and Alcohols

Takashi SUMIYOSHI, Kazunori TSUGARU, Tatsuya YAMADA, and Meiseki KATAYAMA*
Department of Atomic Science and Nuclear Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received May 11, 1985)

Direct measurements of the yield of hydrated electrons in aqueous solutions and solvated electrons in alcohols were carried out using a stroboscopic picosecond pulse radiolysis system. The yield of solvated electrons was obtained by simultaneous consideration of the pulse shape and radiation doses. The yield at 30 ps after irradiation, $G(e^-_{aq})_{30ps}$, was determined to be 4.8±0.3 products per 100 eV as compared to the $G(e^-_{aq})_{100ns}$ of 2.7. Experimental values, including the present ones, are higher by 0.3 than the theoretical ones calculated using the spur diffusion model in the time period from 3×10^{-11} to 10^{-8} s. Nevertheless, both results show a quite similar time dependence, *i.e.*, fast decay of hydrated electrons in spur reactions. The *G*-values of solvated electrons at 30 ps were also determined in alcohols. The *G*-value of solvated electron is 3.4±0.3 in both methanol and ethanol, 2.0±0.3 in 1-propanol and 2.3±0.3 in ethylene glycol.

Hydrated electrons in aqueous solutions and solvated electrons in alcohols have been well known as one of the main products in radiation chemistry. Since the solvated electron reacts very rapidly in the spur in the time region from ps to ns, the experimental yield obtained depends on the time resolution of the apparatus. Radiation chemistry of aqueous solutions has been reasonably explained by the spur diffusion model.[1] This model was originally proposed by Samuel and Magee[2] and is now widely known in various forms. The model adequately explains the dependence of experimental molecular product yields with solute concentrations and also LET effects.[1,3] The initial yield of the hydrated electron before it escapes the spur is an extremely important parameter for the spur diffusion model. Calculations by Schwarz predict the initial yield of e^-_{aq} to be 4.78.[1] However, there is a substantial difference between the experimental *G*-values obtained in the time region 30—100 ps. Wolff *et al.*[4] reported $G(e^-_{aq})=4.0\pm0.2$ at 30 ps by measurements using a stroboscopic picosecond pulse radiolysis (SPR) system with a train of fine structure electron pulses. Recently Jonah *et al.*[5] reported $G(e^-_{aq})=4.6\pm0.2$ at 100 ps using a single picosecond electron pulse. This significant disagreement prompted us to measure the $G(e^-_{aq})$ at 30 ps.

The yields of solvated electrons in several alcohols were also measured.

Experimental

The experiment was carried out using an SPR system with a time resolution of about 30 ps and the radiation source of a 45 MeV electron pulse from the S-band LINAC at Hokkaido University.[6] The optical apparatus of the SPR system was basically the same as that designed by Bronskill *et al.*,[7] and the Čerenkov light produced in a 10 cm air path was used as an analyzing light. To obtain good linearity, the detection system was equipped with an amplifier (ORTEC 451) and A/D converter (NAIG 161) instead of a stretcher, a differential amplifier and an integrator.[7] The optical absorption signals of e^-_{aq} were observed at 633 nm in pure water and 0.5 M† $HClO_4$. The cell used had a 2 cm optical path length and two circular apertures of 3 mm at its front and rear. The pure water in 1 dm^3 reservoir was bubbled with pure argon before and during irradiation and circulated through the cell by a pump. The yield of e^-_{aq} at 30 ps was obtained by simulations considering the pulse shape and radiation doses. The shape of the macro pulse was measured by monitoring the Čerenkov light with a photomultiplier (HAMAMATSU TV R446UR) and a 500 MHz oscilloscope (TEXTRONIX 7904), and it could be approximated to a Gaussian with a half width of 11 ns. The dose was measured by the absorption signal of e^-_{aq} in pure water at 100 ns assuming $G(e^-_{aq})=2.7$.[8] The dose measurement was carried out by a conventional nanosecond pulse radiolysis technique using the SPR system, which allows a He-Ne laser (633 nm) to pass through the irradiation volume of the sample. The output of the photomultiplier was fed into a transient digitizer (IWATSU DM901) having the shortest resolvable time of 10 ns, and then displayed on an X-Y recorder. The observed dose was 4.3±0.3 krad/macro pulse as $\varepsilon_{633nm}=1.44\times10^4\ M^{-1}\ cm^{-1}$ for e^-_{aq}.[4] Aqueous solutions were prepared with triply distilled water. Alcohols were guaranteed reagents (Wako Junyaku) and were used without purifications.

Results and Discussion

Figure 1 shows the SPR signal of decay of e^-_{aq} observed at 633 nm in 0.5 M $HClO_4$. The dashed line and dotted line are computer simulated kinetic traces of e^-_{aq}. Since the observation time was limited up to 350 ps after each fine structure pulse, high acid concentrations were used to prevent the significant buildup of absorption signal from one fine structure pulse to the next.

The bimolecular rate constant for the scavenging reaction of e^-_{aq} has been measured as $(1.2\pm0.2)\times10^{10}\ M^{-1}\ s^{-1}$ for $[H^+_{aq}]$ from 0.5—5.0 M.[9] Therefore, the half lifetime of e^-_{aq}

† 1 M=1 mol dm^{-3}.

$$e^-_{aq} + H^+_{aq} \xrightarrow{k_2} H\cdot \quad (1)$$

in 0.5 M $HClO_4$ solutions is expected to be 120 ps. By this reason, the decay of e^-_{aq} during the pulse, which brought about a decrease in the initial step height by a factor of 0.88,[9] was taken into account, and correction for the density (1.03) of solutions was also made in the simulation.

The experimental kinetic trace of e^-_{aq} was best reproduced by adapting $G(e^-_{aq})_{30\,ps}=4.8$. A simulated trace with $G(e^-_{aq})_{30\,ps}=4.0$[4] is also shown in Fig. 1

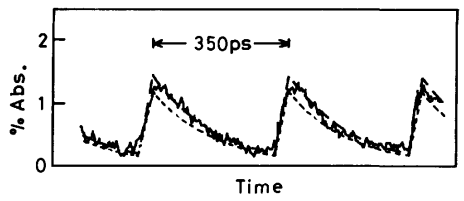

Fig. 1. The kinetic trace of e^-_{aq} observed at 633 nm in 0.5 M $HClO_4$. The dashed and dotted lines are simulated traces with $G(e^-_{aq})_{30ps}$ as 4.8 and 4.0 respectively. The dose was 4.3 krad/macro pulse and the half life time was 120 ps.

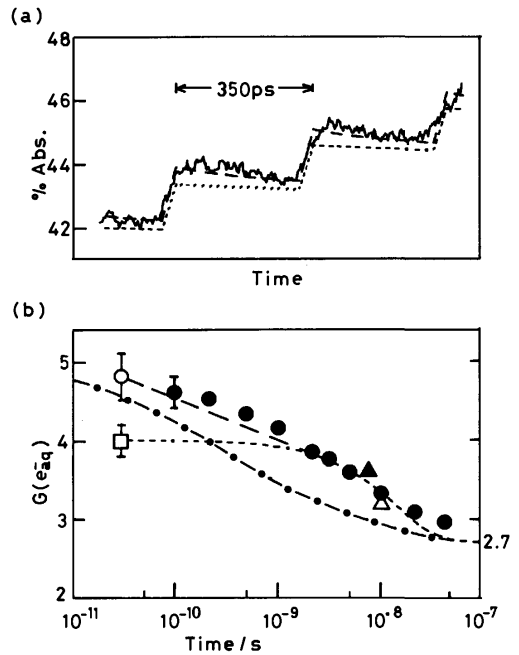

Fig. 2. (a) The kinetic trace of e^-_{aq} observed at 633 nm in pure water. The dashed and dotted lines are simulated traces with time dependences given in (b). (b) The time dependences of $G(e^-_{aq})$ in pure water. (○),[10] (□),[4] (●),[5] (▲),[13] and (△)[14] are experimental values.
(—·—·—) is the theoretical time dependence of $G(e^-_{aq})$ by Schwarz.[1]

(dotted line) for comparison. From several experimental results, we concluded that $G(e^-_{aq})_{30\,ps}=4.8\pm0.3$.[10]

The error of $G(e^-_{aq})_{30\,ps}$ depends directly on the error of radiation dose measurements, while it depends on the shape of the electron macro pulse only slightly. If the shorter pulse width of 10 ns was used to simulate instead of the 11 ns that was actually observed, the best fit was obtained with $G(e^-_{aq})_{30\,ps}=4.7\pm0.3$. It should be noted that the present experiments give a higher $G(e^-_{aq})_{30\,ps}$ value than that reported by Wolff *et al.*[4] irrespective of the similar experimental conditions; however, $G(e^-_{aq})$ values close to those of present studies have been suggested in some steady state studies.[11,12]

The solid line in Fig. 2a shows the kinetic trace of e^-_{aq} observed in pure water. The dashed line and the dotted line are computer simulated kinetic traces. In the case of pure water, the half lifetime of e^-_{aq} ($T_{1/2}>10$ ns) is much longer than the interval of fine structure pulses (350 ps). Therefore the observed step signals correspond to each fine structure pulse are superimposed on the level of absorption which is due to the buildup of the signals. To analyze the experimental data, two kinds of time dependence of $G(e^-_{aq})$ were considered. The dashed line in Fig. 2b is given by fitting to experimental data[4,5,13,14] which include the present experimental value, $G(e^-_{aq})_{30\,ps}=4.8$ and can be expressed by equations;

$$\begin{aligned} G(e^-_{aq}) &= -0.53\log t - 0.77 \\ &\text{for } 3\times10^{-11} < t < 2.7\times10^{-9}\,\text{s} \\ &= 1.3\exp(-t/1.4\times10^{-8}) + 2.7 \\ &\text{for } t > 2.7\times10^{-9}\,\text{s}. \end{aligned} \quad (2)$$

On the other hand, if we take the lower $G(e^-_{aq})$ value at 30 ps which had been reported by Wolff *et al.*[4] as 4.0, the time dependence of $G(e^-_{aq})$ which is shown by the dotted line in Fig. 2b can be given by

$$G(e^-_{aq}) = 1.3\exp(-t/1.4\times10^{-8}) + 2.7. \quad (3)$$

Corresponding simulation traces are shown in Fig. 2a and it is clear that the time dependence of $G(e^-_{aq})$ which contains $G(e^-_{aq})_{30ps}=4.8$ gives a satisfactory fitted trace.

In Fig. 2b, the typical theoretical time dependence of $G(e^-_{aq})$ calculated by Schwarz[1] is also shown for comparison. Experimental values, except one by Wolff *et al.*,[4] exhibit quite similar time dependence to the theoretical one, while they are higher by 0.3 than the theoretical one in the time period from 3×10^{-11} to 10^{-8} s. This may suggest that the spur diffusion model is not adequate in its present form.

Recently, Trumbore *et al.*[15] have improved the spur diffusion model and reported excellent agreement between calculated and experimental e^-_{aq} decay kinetics in pure water over a wide time range (10^{-11}—10^{-5} s).

Figire 3 shows the kinetic traces of decay of solvated

Table 1. Measured doses and other parameters used for kinetic simulations of the decay of solvated electrons in alcohols

	Methanol	Ethanol	1-Propanol	Ethylene glycol
Dose per macro pulse/krad	2.7	4.0	4.0	3.0
Wavelength/nm	630	700	700	580
Extinction coefficient/M^{-1} cm^{-1}	10200[16]	9300[16]	12800[17]	14000[17]
Half life time/ns	0.5	0.5	0.5	0.5
$G(e^-_{sol})_{30\ ps}$	3.4±0.3	3.4±0.3	2.0±0.3	2.3±0.3

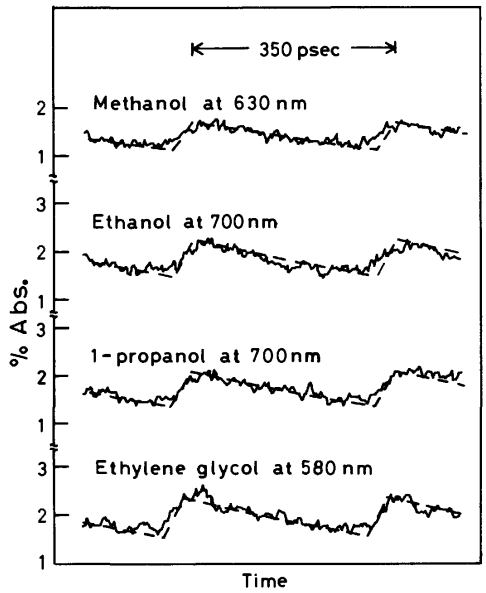

Fig. 3. Kinetic traces of solvated electrons in methanol (630 nm), ethanol (700 nm), 1-propanol (700 nm), and ethylene glycol (580 nm) in 0.10–0.15 M H_2SO_4 solutions. Dashed lines are simulated traces with parameters given in Table 1.

electrons in various alcohols at room temperature. Since in alcohols fast decaying infrared absorption was observed and attributed to the electrons in shallow traps,[18] 0.10—0.15 M H_2SO_4 was added to eliminate their contribution to the absorption of the normal solvated electron. The dashed lines are computer simulated kinetic traces which were calculated by adapting measured doses and other parameters given in Table 1. After several experimental runs, $G(e^-_{sol})_{30ps}$ values were determined to be 3.4±0.3 in both methanol and ethanol, 2.0±0.3 in 1-propanol and 2.3±0.3 in ethylene glycol.

It is expected that the radiolysis of alcohols should exhibit similar spur decay, but the spur diffusion model has not yet been applied to alcohols. The present $G(e^-_{sol})_{30ps}$ values should be useful in theoretical treatment of the spur model of alcohols.

The authors wish to acknowledge Dr. T. Enoto and Messrs. H. Tanida and K. Sato for their help in stabilizing and operating the LINAC.

Collisional Deactivation of N(2^2P) Atoms by Simple Molecules

Hironobu UMEMOTO,* Koichiro SUGIYAMA, Shigeru TSUNASHIMA, and Shin SATO†
Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received June 14, 1985)

Cross sections for the quenching of N(2^2P) by a variety of simple organic and inorganic compounds have been determined by using a pulse radiolysis-optical absorption technique. It was found that N(2^2P) is less reactive than N(2^2D) in every case, despite its higher energy. The quenching cross sections for unsaturated hydrocarbons were found to be about one tenth of that for gas kinetic collisions, while those for saturated hydrocarbons and most inorganic substances were much smaller. The quenching cross sections for alkane hydrocarbons increase with the number of C-H bonds, and show a minor dependence onC-H bond strengths.

In general, electronically excited-state atoms and molecules are more reactive than ground-state species. This is because the energies of these excited states are higher than those of the ground states, and more exit channels, both chemical and physical, are accessible. However, it is not necessarily true that the upper excited states are more reactive than the lower excited states. For example, the 2^1S_0 state of atomic oxygen is known to be generally less reactive than the lower excited state, O(2^1D_2).[1] The situation is also similar for the optically metastable states of atomic carbon and sulfur, the $^1S_0$ and $^1D_2$ states.[2,3]

The reactions of metastable excited nitrogen atoms have been given much attention since they are believed to be very long-lived in the upper atmosphere and play important roles in atmospheric and environmental chemistry. Pioneering work by Husain and his co-workers showed that the upper excited state, N($2^2P_{1/2,3/2}$), is also less reactive than the lower lying excited state, N($2^2D_{3/2,5/2}$), to some inorganic molecules.[4,5] However, no systematic work has been performed on the quenching of N(^2P) by organic molecules. In addition, some of the values obtained by Husain *et al.* have been questioned.[6] Therefore, we have measured the reaction rates of N(^2P) with simple organic and inorganic molecules and compared them with those of N(^2D).

Experimental

The experimental apparatus and the procedure were similar to those described elsewhere.[7,8] Briefly, 107±2 kPa of nitrogen gas containing a small amount of a quencher gas (< 3 Pa for efficient quenchers such as C_2H_4, <2.4 kPa for inefficient quenchers such as SF_6) was irradiated, through an aluminium foil (80 μm thick), with a pulsed electron beam generated by a Febetron 706 (Hewlett Packard Co.). Since the lifetimes of the charged and highly excited species are considered to be very short (<10 μs) compared with the time region in the present work (0.5—5 ms), only metastable atomic and molecular nitrogen, N(^2P, ^2D) and $N_2(A^3\Sigma_u^+)$, were important intermediates in the present system. Ground-state atomic nitrogen is very inert to most stable molecules.[7,9] The effect of metastable species other than N(^2P) will be discussed later. As has been discussed in a previous paper,[7] the concentration of N(^2P) is very small compared with that of the quenching gases, and it can be postulated that the reaction is pseudo-first-order and the rate constants can be determined by measuring the decay rates of N(^2P). The change in the concentration of N(^2P) atoms was measured by the absorption of atomic lines around 174 nm, which correspond to the $3^2P_J \leftarrow 2^2P_J$ transitions, derived from a cw microwave-powered discharge lamp with a flow of He and a trace amount of N_2. The linear relationship between the optical density and the atomic concentration has been checked in a previous study.[7] The reaction vessel was made of stainless steel and a pair of MgF_2 windows was attached to it, perpendicular to the path of the electron beam. Transmitted light at 174 nm was detected with a combination of a vuv monochromator (Shimadzu SGV-50) and a photomultiplier tube (Hamamatsu R976). Then, the signal was processed with a wave memory (NF Circuit Design Block Co. WM-852) and a computer (NEC PC-9801F) after amplification. In order to obtain a sufficient signal intensity, the slits of the monochromator were wide open (1 mm), and it was impossible to resolve the fine structures of the atomic lines. Therefore, the obtained rate constants in this work were those of the overall reactions of N($^2P_{1/2}$) and N($^2P_{3/2}$). Gas pressures were measured with a Wallace and Tiernan type pressure gauge (Nagano Keiki 62-075) and an MKS Baratron (220AHS-2A5-B-1). All experiments were performed at 295±3 K.

Research-grade N_2(Toyo Sanso), H_2 and D_2(both Takachiho Kako) were used after being passed through a furnace containing reduced copper chips at 590 K and a trap filled with molecular sieve 4A at 77 K. O_2(Nihon Sanso), CO(Takachiho Kako), and He(Suzuki Shokan) were used after having been passed through a cold trap at 77 K. Products of Takachiho Kako were used for Xe, CO_2, SF_6, CH_4, C_2H_6, *c*-C_3H_6, C_3H_8, *neo*-C_5H_{12}, C_2H_4, and C_2H_2. Sources and purities of fluoroethenes were the same as those reported previously.[8] Sources of other materials were: Showa Denko: N_2O, Matheson Gas Products: Cl_2, Tokyo Kasei: *n*- and *i*-C_4H_{10}, and Merck Frosst Canada: C_2D_6 and C_3D_8. All gases condensable at 77 K were purified by repeated trap-to-trap distillation using an appropriate slush bath. CH_4 was used after having been degassed at 77 K for a short time (*ca.* 30 s). Since a gas-chromatographic check showed that C_3D_8 contained a few percent of

C_3D_6, it was further purified by passing through a column of silica gel moistened with H_2SO_4. Isotopic purities of C_2D_6 and C_3D_8 were checked mass-spectroscopically. Their nominal isotopic purities (99.5%) were confirmed.

Results

In the presence of 107 kPa of N_2 without any quenchers, the decay rate of the N(²P) concentration was found to be $7.7\times10^2\ s^{-1}$ (average of 25 runs). Since the radiative lifetime of N(²P) is very long (12 s), there must be some deactivaion processes, even in this system. If this decay is due to the quenching by N_2, the corresponding bimolecular rate constant will be $18\ m^3\ mol^{-1}\ s^{-1}$; however this value should be regarded as the upper limit since there can be some deactivation contribution due to the walls. Although this cannot be a major process, since the decay rate increased with the increase in the N_2 pressure, this possibility cannot be completely ruled out. A diffusional loss from the optical path is not considered to make a contribution, since the decay rate for N(⁴S) measured by the absorption of resonance lines around 120 nm was much smaller. Quenching by ground-state atomic nitrogen, N(⁴S), must be a minor process since the atomic concentration was in the order of $3\times10^{-5}\ mol\ m^{-3}$,[7] and the bimolecular rate constant for the deactivation of N(²P) was measured to be less than $4\times10^5\ m^3\ mol^{-1}\ s^{-1}$.[6,10] It is considered that this quenching process is due mainly to a three-body recombination, but Taghipour and Brennen have showed that a two-body process is far more dominant below 1.3 kPa and that the termolecular rate constant is smaller than $7\times10^4\ m^6\ mol^{-2}\ s^{-1}$.[10] Quenching due to impurities in N_2 may also have a minor importance since it must be assumed that N_2 contained more than 10 ppm of O_2 or 1 ppm of unsaturated hydrocarbons in order to explain the present results by impurity quenching.

In the presence of quenchers, the decay rate increased linearly with the partial-pressure of the quencher. Figures 1 and 2 show the partial pressure dependence of the decay rates for several quenchers. From the least-squares slopes of such plots, the bimolecular quenching rate constants could be obtained. The results are summarized in Table 1, together with the results of other investigators. In this table, the rate constants have been converted to cross sections; $\sigma_Q=k_Q(8kT/\pi\mu)^{-1/2}$, where k_Q is the quenching rate constant, k is the Boltzmann constant, T is the absolute temperature, and μ is the reduced mass. The error limits are the standard deviations.

As for the effect of other active species, N(²D) does not play a significant part, since a large amount of N_2 quenches fairly rapidly. By employing the rate constant regarding the deactivation obtained in a previous work, the lifetime can be calculated to be

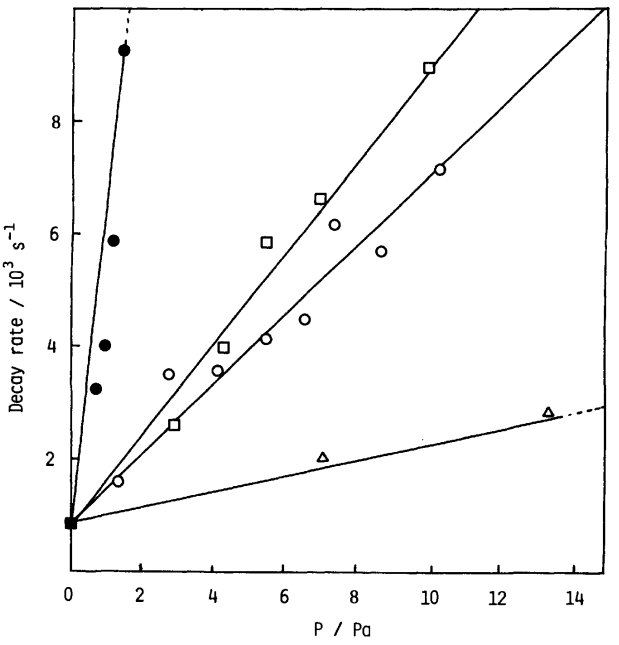

Fig. 1. The decay rates of N(²P) atoms as a function of the C_2H_2(●), *neo*-C_5H_{12}(□), O_2(○), or C_2H_6(△) pressure. As for C_2H_2 and C_2H_6, there are data points which are out of the range of this figure. The symbol ■ represents the average of 25 runs measured in the absence of any quenchers. This point was weighted by a factor of 5 in the calculations of the least squares slopes.

3 μs under the present conditions.[7] The MgF_2 windows used in the experiments involving $N(^2P)$ were exposed to vacuum ultraviolet light for a long time, and did not transmit the resonance triplet lines around 120 nm. Therefore, $N(^4P)$ is not considered to be formed optically from $N(^4S)$. Then, the only active species which could disturb the present measurements would be $N_2(A^3\Sigma_u^+)$. Meyer *et al.* have shown that $N(^4S)$ quenches $N_2(A^3\Sigma_u^+)$ to produce $N(^2P)$.[14] The quenching-rate constant has been measured to be fairly large; $2-3\times10^7$ m^3 mol^{-1} s^{-1}.[14,15] If the quantum efficiency for the production of $N(^2P)$ is large, this reaction can become a cause of errors regarding the present measurements. However, if $N(^2P)$ is formed predominantly in this reaction, the initial concentration of $N(^2P)$ must strongly depend on the partial pressures of the added gases. For instance, the quenching rate of $N_2(A)$ by 1.2×10^{-3} mol m^{-3}(3 Pa) of ethene is two orders of magnitude larger than that by 3×10^{-5} mol m^{-3} of $N(^4S)$,[16] and the initial concentration of $N(^2P)$ in the presence of ethene should be much smaller than that in pure N_2. The present experimental results completely contradict this. The transmittance of 174-nm light shortly after irradiation was almost constant, around 75%, regardless of the pressure of the quencher. This strongly suggests that $N(^2P)$ is formed at the initial stage, probably from ionic species, and that the quantum yield for the production of $N(^2P)$ from $N_2(A)$ and $N(^4S)$ is low. For a further check, we also measured the decay rate of $N(^4S)$ in pure N_2, as well as the ratio of the initial concentration of $N(^2P)$ to that of $N(^4S)$. The ratio was estimated from measurements of the transmittance at 174 nm and at 120 nm, the resonance triplet lines of $N(^4S)$, and the known atomic-transition probabilities.[17] Because of a self-reversal phenomenon, the literature values of the transition probabilities are not good for estimating the relative concentrations, but they may be used in a first approximation. The result is that the ratio is 0.12, while the decay rate of $N(^4S)$ is about 10 s^{-1}. This means that, even if $N(^4S)$ which disappeared from the viewing zone was all converted to $N(^2P)$, there is only a 4% increase in the $N(^2P)$ concentration during a typical time range, 0.5 ms.

In the presence of hydrocarbons, $N_2(A^3\Sigma_u^+)$ is supposed to produce free radicals, since its energy is much higher than C–H bond energies. These free radicals must be very reactive with $N(^2P)$. In order to estimate their effect, we simulated the temporal profiles of the concentrations of the unstable species by the Runge Kutta method, assuming the following reaction mechanism:

$$N_2(A) + RH \rightarrow N_2 + R + H, \quad (1)$$

$$N(^2P) + RH \rightarrow \text{Products}, \quad (2)$$

$$N(^2P) + R \rightarrow \text{Products}, \quad (3)$$

$$N(^4S) + R \rightarrow \text{Products}, \quad (4)$$

$$R + R \rightarrow \text{Products}. \quad (5)$$

The values of the initial concentrations of $N_2(A)$, $N(^2P)$, and $N(^4S)$ were chosen to be 7×10^{-6}, 4×10^{-6}, and 3×10^{-5} mol m^{-3}, respectively. The concentration of $N_2(A)$ was estimated from theoretical calculations of the *G*-values.[18] The rate constants for Reactions 3—5 were assumed to be 2×10^8 m^3 mol^{-1} s^{-1}; *i.e.* those of every collision. The rate constants for the quenching of $N_2(A)$ by a variety of hydrocarbons have been reported by Maruta *et al.*,[16] but the branching ratios for the production of R are not

known. Then, we employed a very severe condition, that the ratios are unity. According to this simulation, the relative errors in the estimation of the rate constants of Reaction 2 were shown to be less than 9%. Therefore, this effect also seems minor.

Discussion

Quenching by Inorganic Compounds. As Table 1 shows, the agreement between the present results and the literature values is fairly good except for H_2, although the values obtained by Young and Dunn seem a little small in every case. The quenching cross section for N_2 obtained by Lin and Kaufman at 400 K is larger than the others by more than two orders of magnitude. Schofield has questioned this value,[2] but this may imply the presence of a large activation energy, more than 60 kJ/mol. The cross section for CO reported by Husain *et al.* seems too large and erroneous. As for H_2 the value of Husain *et al.* is smaller than the present one by a factor of 8, while that of Young and Dunn is still smaller. We think it is hard to explain this discrepancy by impurities in H_2. The possible contaminant in H_2 is O_2. If Husain's value is true, in order to explain the present result, it is necessary to assume that the H_2 that we used contained more than 0.5% of O_2, which sounds unrealistic. One possible explanation is that the rate constant is pressure dependent. Husain *et al.* and Young and Dunn conducted their experiments with total pressures below 6.7 kPa.[4,6] Ours were at 107 kPa. According to the recent work by Berman and Lin, the rate constant for $CH+H_2$ reaction changes by a factor of 6, between 3.3 and 80 kPa.[19] They also found a similar pressure dependence for the $CH+N_2$ reaction.[20] Quenching by D_2 is only slightly inefficient than that by H_2. If this difference between H_2 and D_2 is due to a change in the activation energies, that will be 0.8 kJ/mol, much smaller than the difference in the zero-point energies of H_2 and D_2. This small difference suggests that the vibrational energy of $H_2(D_2)$ is reserved at the transition state, or there is no large activation energy and the small quenching efficiency is due only to a symmetry restriction.

Table 2 shows a comparison of the cross sections for the quenching of N(^{2}P) and N(^{2}D). In every case, without an exception, the cross section of N(^{2}P) is smaller than that of N(^{2}D). The unreactive nature of N(^{2}P) to diatomic and linear triatomic molecules has been satisfactorily explained in terms of the concept of adiabatic correlation.[2,23] In the next section we would like to see if it is possible to extend this concept to nonlinear polyatomic molecules.

Concept of Adiabatic Correlation. An extension of the concept of adiabatic correlation to nonlinear polyatomic molecules has been proposed but has not been generally accepted.[24] It is true, strictly speaking, that correlation diagrams cannot be readily constructed for complex polyatomics. However, the inertness of the upper excited states of C, O, S, and N atoms to simple alkane hydrocarbons compared to their lower excited states implies the presence of some general rule. Table 3 gives a comparison of the ratios of the rate constants for the quenching of the upper and the lower excited states of O, S, N, and P atoms by H_2, CH_4, and C_2H_6. Although the values for CH_4 and C_2H_6 are smaller than those for H_2, they are all larger than unity. Sometimes, united-atoms concept is very useful, but it seems to be an oversimplification in the present

Table 2. Cross sections for the quenching of N(^{2}P, ^{2}D)

cases. For example, a united atom of CH_3 is F and CH_4 should be replaced by HF in this approximation. Meanwhile, it can easily be shown that $N(^2P_u)+HF(X^1\Sigma^+)$ correlates adiabatically to one of the energetically accessible states, $NH(a^1\Delta)+F(^2P_u)$ and it is impossible to explain the inertness of the upper state with this concept. On the other hand, it is possible to account for the large ratios shown in Table 3 for CH_4 by assuming that the reaction proceeds holding C_s or C_{3v} symmetry. For instance, if it is assumed that N atoms approach CH_4 along one of the three-fold axes of CH_4 and that the reaction proceeds on a surface with C_{3v} symmetry (end-on attack), or that they approach along one of the σ planes and reaction proceeds with C_s symmetry (side-on attack), the main features of the correlation diagram for $N+H_2$ would be applicable to the $N+CH_4$ system. A similar discussion might be possible for $N+C_2H_6$, although the symmetry restriction would be less rigorous.

Exit Channels in the Quenching by Hydrocarbons. Relatively efficient quenching by unsaturated hydrocarbons apparently results from interactions with π electrons. The initial step must be an addition reaction to the unsaturated bonds. This is followed by decomposition or stabilization. Fluorine substitution has minor effects on the rate constants except for $CH_2=CF_2$, in which case, the quenching cross section is 1/4 of those for other fluoroethenes.

As for reactions with saturated hydrocarbons, it should be noted that the cross sections divided by the number of the C-H bonds are almost constant from C_3H_8 to *neo*-C_5H_{12} as is shown in Table 4. It should also be pointed out that there is no large isotope effect between C_2H_6 and C_2D_6, and C_3H_8 and C_3D_8. In the reactions of $OH(X^2\Pi)$, $O(^3P)$, and $Hg(^3P)$, the cross sections are much smaller than those for gas kinetic collisions and increase with a decreasing C-H bond energy.[25-27] Meanwhile, the cross sections for $O(^1D)$, $CH(X^2\Pi)$, and $CH(A^2\Delta)$ show minor dependence on the C-H bond strength.[1,28,29] For example, the ratio of the cross section per C-H bond for the reaction of $OH(X^2\Pi)$ with *i*-C_4H_{10} to that with *neo*-C_5H_{12} at room temperature is 3.2, while that for $O(^1D)$ is 1.1.[1,25] Fairly large C-H *vs.* C-D isotope effect has also been observed in the reactions of OH and $Hg(^3P)$.[25,30] It has been considered that, in the cases of $OH(X^2\Pi)$, $O(^3P)$, and $Hg(^3P)$, the reactions proceed *via* H(D)-atom abstraction from the C-H(C-D) bonds; some theoretical interpretations have also been presented.[25,26,31,32] On the other hand, insertion reactions have been postulated to occur predominantly in the cases of $O(^1D)$ and CH radicals.[28,29,33] In other words, the rate constants for the abstraction reactions with energy barriers show great variation with the C-H bond strength, while those for insertion do not. Table 4 shows a comparison of the cross sections for the reactions of excited N atoms, $O(^1D)$, and CH radicals. Although the quenching efficiencies for N atoms are one or two orders of magnitude smaller than those for $O(^1D)$ and CH radicals, they show parallel behavior. This strongly suggests that the quenching of $N(^2D)$ and $N(^2P)$ cannot be characterized by an abstraction of H-atoms. The quenching of $N(^2D)$ to $N(^4S)$ is highly spin-forbidden and it is hard to consider that such a process proceeds so rapidly. Therefore, we conclude that insertion reactions are also dominant for $N(^2D)$. On the other hand, in the case of $N(^2P)$, deactivation to $N(^2D)$ is a spin-allowed process, although this may be non-adiabatic. The small cross sections for CH_4 and C_2H_6 may reflect the low efficiencies of nonadiabatic transitions or the presence of a steric hindrance, which has been postulated in the case of $Hg(^3P)$ quenching.[34] For a further discussion, information regarding the temperature dependence of the reaction rates, as well as the identification of the exit channels, would be useful.

Vapor Phase Carbonylation of Alkyl Chloroacetates

Kiyonori SHINODA* and Kensei YASUDA
Toyama Technical College, 13 Hongo, Toyama 939
(Received April 19, 1985)

The vapor-phase carbonylation of alkyl chloroacetates with rhodium trichloride supported on active carbon was carried out under various conditions. The reaction equation for the preparation of dialkyl malonate from alkyl chloroacetate in the presence of alcohol with carbon monoxide is given as:

$$CH_2ClCOOR + ROH + CO = CH_2(COOR)_2 + HCl$$

The carbonylation proceeded smoothly at 175 °C with an inert solvent as well as with an alkoxide anion donor, such as alcohol, ether, and an ester. The mechanism of the rhodium trichloride-catalyzed carbonylation is probably similar to that of methanol to acetic acid.

The carbonylations of alkyl chloroacetate with carbon monoxide in the presence of alcohol, catalyzed by cobalt carbonyl, have been known for a number of years.[1-7] At present, though, little is known about the vapor-phase carbonylation, since the volatility of metal carbonyl is unavoidable at high temperatures. Consequently, the reaction system has been held under elevated pressure to keep sufficient carbon monoxide in the liquid phase by the use of an autoclave.

Furthermore, alkaline reagents, such as amine,[1,2] sodium alkoxide,[3] alkali metal hydroxide,[4] sodium carbonate[5,6] and alkaline earth metal hydroxide[7], are necessary to remove hydrogen chloride from the reaction field in a large quantity in order to promote the carbonylation. It is said that the effect of the pH of a reaction system on the yield of dialkyl malonate is sensitive and that the exact control of reaction conditions is extremely important.

The present investigation was undertaken in order to examine the vapor-phase carbonylation of alkyl chloroacetate into dialkyl malonate under atmospheric pressure. In accordance with the above views, several searches were made for an effective catalyst and carrier for the carbonylation. Rhodium trichloride was more active when supported on a carrier of a relatively low activity, such as active carbon. Dimethyl malonate was obtained in a good yield in the vapor-phase carbonylation of methyl chloroacetate with rhodium trichloride supported on active carbon.[8] In particular, the present paper is concerned with several alkyl chloroacetates and with several different solvents such as the alkoxide-anion donor at the vapor-phase carbonylation catalyzed by rhodium trichloride supported on active carbon.

Experimental

Materials. The methyl chloroacetate, ethyl chloroacetate, and isopropyl chloroacetate (Tokyo Kasei Kogyo, K.K.) were of a reagent grade and were used without further purification. The active carbon, rhodium trichloride trihydrate, alcohols, ethers, esters, formaldehyde dimethyl acetal, acetic acid, and dichloromethane were purchased from the Wako Pure Chemicals Co. The active carbon was cylindrical in form, 7 mm in length and 4 mm in diameter.

Preparation of Catalyst. The solution was prepared by dissolving 1 g of rhodium trichloride trihydrate in 100 ml of alcohol or water. 10 g of active carbon was impregnated with this solution, and the solution was evaporated to dryness with the oven in the air.

Apparatus. A flow-type system was used.[9] A Pyrex reaction vessel, with a tube 40 cm in length and 2.6 cm in diameter, was heated in a vertical electric furnace. The evaporator, a glass tube, was placed in an electrically wound vertical furnace. The reaction temperature was measured with a Chromel-Alumel thermocouple in a thermowell placed in the catalyst bed.

General Procedure for the Carbonylation of Alkyl Chloroacetates. 11 g of the catalyst (1 g of rhodium trichloride trihydrate supported on 10 g of active carbon) was placed in the middle of the reactor, the bed being supported by necking the reactor tube. While the reaction temperature was regulated, carbon monoxide gas was passed over the catalyst. A mixture of alkyl chloroacetate and the solvent was prepared with the volume ratio of 1:5. Carbon monoxide gas was fed in at the rate of 0.25 mol/h, as measured with a flow meter. The mixture was then fed into the evaporator with a microfeeder at the rate of 20 ml/h in liquid and preheated to 150 °C, the vapor being passed to the reactor. Therefore, carbon monoxide gas was mixed with the vapor of alkyl chloroacetate and the solvent in the evaporator. The product gas stream entered a cooler and was condensed in a water-ice trap. The reaction products were analyzed by means of gas chromatography (PEG 6000, Porapak).

Carbonylation of Methyl Chloroacetate. Methyl chloroacetate was fed into the reactor at the rate of 0.038 mol/h, together with the solvent, and was carbonylated with carbon monoxide over the catalyst. The feed mole ratio of the solvent to methyl chloroacetate was made to vary with the changes in the molecular weight and density of the solvents, because the volume ratio of the solvent to methyl chloroacetate was kept constant. These values are given in Tables 1 and 2. The main reaction products were methyl acetate and dimethyl malonate. The side reaction products were the methyl methoxyacetate and methyl glycolate formed by the direct reaction of methyl chloroacetate with methanol and water. On the other

hand, methanol, formaldehyde dimethyl acetal, and methyl acetate reacted with methyl chloroacetate in an atmosphere of carbon monoxide to form dimethyl malonate and were converted at the same time into hydrogen chloride, chloromethyl ether, and acetyl chloride respectively. Since hydrogen chloride was not detected in the waste gas, the chloride ion in the liquid product was determined by the Volhard method. This was confirmed by titration with a standard solution of a base. Moreover, the effect of water on the product composition was investigated by varying the amount of water added to the methanol.

Carbonylation of Ethyl Chloroacetate. A mixture of ethyl chloroacetate and a solvent was fed into the reactor at the rate of 20 ml/h. Therefore, the feed rate of ethyl chloroacetate was 0.032 mol/h. Ethyl chloroacetate was carbonylated with carbon monoxide in the presence of ethanol, diethyl ether, or ethyl acetate into diethyl malonate. While diethyl ether was transformed into ethyl chloride, ethyl acetate was converted into acetyl chloride.

Carbonylation of Isopropyl Chloroacetate. The feed rate of isopropyl chloroacetate was 0.027 mol/h. The isopropyl chloroacetate was carbonylated in the presence of diisopropyl ether with carbon monoxide into diisopropyl malonate in a good yield, and diisopropyl ether was transformed into isopropyl chloride. Isopropyl chloroacetate reacted with isopropyl acetate to give diisopropyl malonate and acetyl chloride.

Results and Discussion

Carbonylation of Alkyl Chloroacetate in the Presence of Alcohol. Dialkyl malonates are important chemical intermediates for the fine chemicals and are manufactured in the form of various alkyl types.

Hence, the relation of the alkyl group to the reactivity was investigated at 150—175 °C. The product compositions for the carbonylation of methyl chloroacetate in the presence of methanol at 175 °C are given in Table 1. The chlorine liberated from methyl chloroacetate during carbonylation was recovered as hydrogen chloride. Several times as much hydrogen chloride was formed in the steady state as at the initial step of the reaction. It might be assumed that the desorption rate of hydrogen chloride from the surface of active carbon was faster than that of dimethyl malonate. The recovery of hydrogen chloride in the free form was 50—70%. It seemed that hydrogen chloride reacted partly with methanol on the surface of the catalyst at the reaction temperature, as methyl chloride was found in the effluent gas.

The reaction equation for the preparation of dimethyl malonate from methyl chloroacetate in the presence of methanol with carbon monoxide is given as:

$$CH_2ClCOOCH_3 + CH_3OH + CO = CH_2(COOCH_3)_2 + HCl \quad (1)$$

Figure 1 shows the effect of the water content in methanol upon the conversion of methyl chloroacetate into methyl acetate. The formation of methyl acetate increased with an increase in the water content. Methyl chloroacetate may be carbonylated, in the presence of water with carbon monoxide, into methyl hydrogen malonate. However, there was no detectable amount of methyl hydrogen malonate. It has been well-known that malonic acid and methyl hydrogen malonate are thermally unstable compounds. Therefore, methyl acetate might be formed by the thermal decomposition of methyl hydrogen malonate. The carbonylation of methyl chloroacetate catalyzed by rhodium trichloride supported on active carbon is a fairly selective reaction.

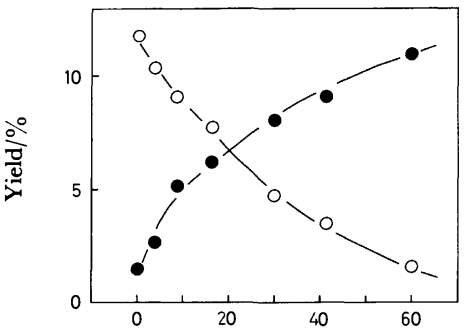

Fig. 1. Effect of the water content in methanol on the formation of methyl acetate at 175°C.
●: CH_3COOCH_3, ○: $CH_2(COOCH_3)_2$

Table 1. Product compositions for the carbonylation of methyl chloroacetate at 175 °C[a)]

Reaction time/h	Product composition/mol × 10^{-3}/h					
	CH_3COOCH_3	$CH_2(OCH_3)COOCH_3$	$CH_2ClCOOCH_3$	$CH_2(OH)COOCH_3$	$CH_2(COOCH_3)_2$	HCl
1	1.20	—	36.17	—	0.52	6.31
3	1.07	0.02	31.71	—	5.09	4.26
6	1.15	0.04	30.98	—	5.72	3.26
11	1.03	0.05	31.26	—	5.55	3.45
16	0.98	0.04	31.34	0.04	5.49	3.35
20	0.89	0.04	31.34	0.03	5.59	3.46

a) The feed mole ratio ($CH_3OH/CH_2ClCOOCH_3$) was 10.9.

Ethyl chloroacetate was carbonylated into diethyl malonate in the presence of ethanol with carbon monoxide on the rhodium trichloride catalyst, while diisopropyl malonate was formed from isopropyl chloroacetate and 2-propanol.

Figure 2 shows the effect of the reaction time on the conversion of alkyl chloroacetates into dialkyl malonates at 150 °C. All curves have a tendency to increase the conversion at the initial reaction step because of the adsorption of dialkyl malonate on active carbon. It has been reported that the elongation of the reaction time led to a decrease in the yield of dimethyl malonate at higher temperatures.[8] However, no indications of the deactivation of the catalyst were recognized at this temperature. It could be anticipated that the durability of catalytic activity was continued for a considerably long time at a moderate temperature. The yield of dialkyl malonate decreased with an increase in the bulkiness of the alkyl group. The carbonylation of alkyl chloroacetate with carbon monoxide in the presence of alcohol is a nucleophilic reaction. The nucleophilicity of higher alcohol is increased by the inductive effect of the alkyl group. The steric hindrance and inductive effect of the alkyl group compensated for each other. Consequently, it was thought that the conversion of ethyl chloroacetate into diethyl malonate was approximately equal to that of isopropyl chloroacetate.

Carbonylation of Alkyl Chloroacetate in the Presence of the Alkoxide Anion Donor. Alkyl chloroacetate was diluted with an inert solvent such as dichloromethane as well as with an ether and an ester as an alkoxide-anion donor. In addition, we tried to carbonylate methyl chloroacetate into dimethyl malonate when such diluents were not used. The method of carbonylation was identical to that described

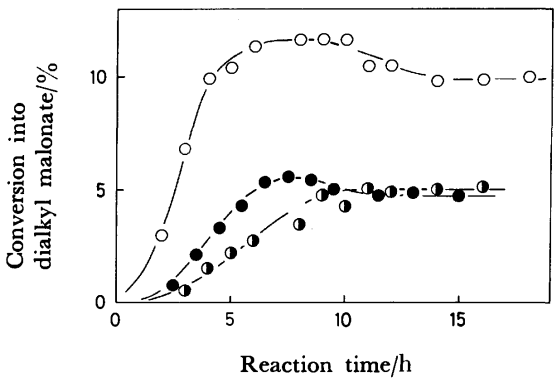

Fig. 2. Variation of catalytic activity with reaction time at 150 °C.

$CH_2ClCOOCH(CH_3)_2$-$CH_3COOCH(CH_3)_2$	5.35		94.6 $CH_2ClCOOCH(CH_3)_2$, 5.4 $CH_2[COOCH(CH_3)_2]_2$	2.0 CH_3COCl

a) The feed rate of $CH_2ClCOOCH_3$ was 0.057 mol/h.

previously in the case of alcohol. The experimental results obtained by the vapor-phase carbonylation of alkyl chloroacetate in the presence of various solvents at 175 °C are given in Table 2.

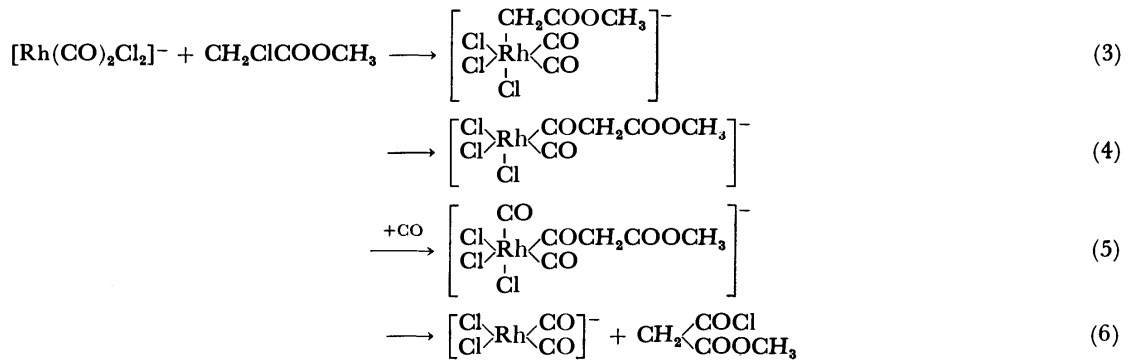
These results are particularly surprising in view of the fact that dimethyl malonate was formed with dichloromethane, which is an inert solvent, and in the absence of a solvent in the vapor-phase carbonylation. It was found that the reaction product contained a small quantity of dimethyl malonate, even when acetic acid was used. On the other hand, dimethyl malonate was obtained in a good yield by the use of methyl acetate instead of dichloromethane. When considered in connection with these experimental results, ester might act as the alkoxide-anion donor. The reason why the formation of dimethyl malonate in the absence of a solvent or in the presence of an inert solvent was found is as follows. Methyl chloroacetate itself has been shown to act as an anion donor. These reactions proceeded according to the following equation:

$$2CH_2ClCOOCH_3 + CO = CH_2(COOCH_3)_2 + CH_2ClCOCl \quad (2)$$

That is to say, the ester was transformed into acid chloride, which was then converted into acid with water and ester with alcohol. Similarly, ether, as the alkoxide-anion donor, reacted with alkyl chloroacetate and carbon monoxide to form alkyl chloride. When acetic acid was used as the starting material, methyl acetate was produced in a significant amount because of the decomposition of methyl hydrogen malonate. Many reports have been published on the mechanism of a rhodium complex-catalyzed carbonylation of methanol to acetic acid.[10-14] Rhodium compounds, in conjunction with various forms of iodide, can be used for the carbonylation of methanol to acetic acid, whereas no direct evidence has been provided as to the chloride forms with a variety of catalysts.

However, it can be assumed that rhodium trichloride acts as a catalyst or catalyst precursor, because the reaction system does not contain any type of iodide.

Taking these previous papers into account, the present reaction scheme may be illustrated as below:



(3) (4) (5) (6)

Since the amount of dialkyl malonate remained unchanged upon the addition of water or alcohol, intermediary acid chloride probably plays an important role in the postulated step. On the basis of the experimental results, the pathways for the formation of dialkyl malonates can be given by the following equations:

$$ClCOCH_2COOR + ROH = CH_2(COOR)_2 + HCl \quad (7)$$
$$+ ROR = CH_2(COOR)_2 + RCl \quad (8)$$
$$+ CH_2(OR)_2 = CH_2(COOR)_2 + CH_2ClOR \quad (9)$$
$$+ CH_3COOR = CH_2(COOR)_2 + CH_3COCl \quad (10)$$
$$+ CH_2ClCOOR = CH_2(COOR)_2 + CH_2ClCOCl \quad (11)$$
$$+ CH_3COOH = [HOOCCH_2COOR] + CH_3COCl \quad (12)$$
$$+ H_2O = [HOOCCH_2COOR] + HCl \quad (13)$$

Methyl hydrogen malonate is unstable and may be decomposed into methyl acetate and carbon dioxide according to Eq. 14:

$$[HOOCCH_2COOR] = CH_3COOR + CO_2 \quad (14)$$

Synthesis of 5-*O*- and 6-*O*-Methyldihydrostreptomycin

Teruo KISHI, Tsutomu TSUCHIYA,* Naokazu KOGA, Yoshihiko KOBAYASHI, and Sumio UMEZAWA

Institute of Bioorganic Chemistry, 1614 Ida, Nakahara-ku, Kawasaki 211

(Received May 10, 1985)

5-*O*- and 6-*O*-Methyldihydrostreptomycin have been prepared from dihydrostreptomycin by a sequence of reactions involving methylation of a selectively protected derivative (**4**) with diazomethane in the presence of tin(II) chloride. The structures of the final products were confirmed by their ^{13}C-NMR spectra and the TACu method.

Streptomycin is inactivated by resistant bacteria[1,2,3] producing inactivating enzymes: AAD(3″) or APH(3″) which adenylylates or phosphorylates the 3″-hydroxyl group, and AAD(6) or APH(6) which adenylylates or phosphorylates the 6-hydroxyl group of streptomycin and dihydrostreptomycin† to give the corresponding *O*-adenylyl or *O*-phosphoryl compounds. To counteract the action of the enzymes AAD(3″) or APH(3″), 3″-deoxydihydrostreptomycin[4,5,6] and 3″-epidihydrostreptomycin[7,8] had been prepared. These compounds showed satisfactory activities against the resistant bacteria owing to the lack of the equatorial 3″-hydroxyl group to be modified. Another device for the enzymes AAD(6) or APH(6), however, was unsuccessful. Chemically prepared 6-deoxydihydrostreptomycin[9] showed only very weak antibacterial activity, suggesting that the 6-hydroxyl group plays an important role in the mechanism of antibacterial action. In connection with our interest in the structure-activity relationships, in this paper, we have described the synthesis of 5-*O*- and 6-*O*-methyldihydrostreptomycin (**9** and **10**). The former derivative (**9**) was prepared to determine the steric influence of the neighboring substituent on the 6-modifying mechanism.

Tris(N^G,N^G,*N*-benzyloxycarbonyl)dihydrostreptomycin (**1**),[10] the starting compound, was treated with *p*-tolualdehyde dimethyl acetal in the presence of acid catalyst under strictly dry conditions. Tris (N^G,N^G,*N*-benzyloxycarbonyl)-5,6:3′,3′a:4″,6″-tris(*O*-*p*-methylbenzylidene)dihydrostreptomycin (**2**) was obtained with slight accompanied mono-, di-, and overacetalated derivatives. Chromatographic separation gave the pure **2**. In this acetal-exchange reaction, formations of N^G,*O*-acetals such as 3,3′a:4″,6″-bis(*O*-*p*-methylbenzylidene)-N^G,*O*-(*p*-methylbenzylidene) derivatives bearing cyclic bridges between 1-N^G,2-*O*, 2-*O*,3-N^G, or 1-N^G,6-*O*, were also suspected. Formation of such type of compounds was found[11] in the reaction of 2-guanidino-1-cyclohexanols with 1,1-dimethoxycyclohexane (in *N*,*N*-dimethylformamide in the presence of *p*-toluenesulfonic acid). In the above case, however, they were successfully removed in the purification step.

† As the name dihydrostreptomycin has been widely used, we have used this trivial name.

Acetylation of **2** with acetic anhydride in pyridine gave the tetraacetate (**3**), the positions of the acetyl groups being estimated 1,3-N^G,N^G and 2,3″-*O*,*O*. Selective deacetalation of **3** in a medium containing acetic acid gave the corresponding 5,6-*O*-deacetalated derivative (**4**) in a moderate yield. Careful methylation of **4** with diazomethane in the presence[12] of tin(II) chloride gave a mixture of 5-*O* and 6-*O*-methyl derivatives (**5** and **6**), which, without purification, deacetylated (to give **7** and **8**). Treatment of the product mixture with sodium in liquid ammonia (to remove the *p*-methylbenzylidene and benzyloxycarbonyl groups) followed by repeated chromatography gave 5-*O*- and 6-*O*-methyldihydrostreptomycin (**9** and **10**).

The structures of the final products were determined by the ^{13}C-NMR spectra (Table 1). Since dihydrostreptomycin gave well-separated signals at pD≈6, the spectra of the minor (**9**) and the major (**10**) products were measured at the same pD. The ^{13}C signals of **9** and **10** except for C-5,6 were both readily assigned on the basis of comparison of the corresponding chemical shifts of dihydrostreptomycin.[13] The remaining resonances of the minor product (**9**) were those at δ 83.8 and 71.9, and of the major (**10**), at δ 73.7 and 82.5. Since C-5 and C-6 of dihydrostreptomycin resonated[13] at δ 74.2 and 72.4 at pD≈6, respectively, the signals at δ 71.9 of **9** and δ 73.7 of **10** were assigned to C-6 and C-5 of the respective compounds. The signals of 80′(δ) of **9** and **10** were, therefore, assigned to the resonances of C-5 and C-6 carrying the OMe groups of the respective compounds, the chemical shifts being typical[14] for the carbons carrying an ether group. Furthermore, as the results of the negative shift effect of *O*-methylation at the neighboring positions,[14] the signals of C-4 and C-6 of **9**, and C-1 and C-5 of **10** were respectively shifted upfield, compared to the chemical shifts of the corresponding carbons of dihydrostreptomycin. Thus, the major (**10**) and the minor (**9**) methylated products were determined 6-*O*- and 5-*O*-methyldihydrostreptomycin, respectively. These results, in turn, supported that **3** had 5,6-*O*- and not N^G,*O*-benzylidene structure, as already described.

a) In ppm downfield from TMS calculated as $\delta^{TMS} = \delta^{dioxane} + 67.4$ ppm. b) Adjusted by addition of DCl.

The structures of **9** and **10** were confirmed by the tetraamminecopper(II) (TACu)§ method[15,16] on their deamidino derivatives (Table 2). Deamidination of **9**, **10** and dihydrostreptomycin according to Polglase[17] gave the corresponding 1,3-diamino derivatives (**11**, **12**, and **13**[17]). 1,3-Di(deamidino)-5-*O*-methyldihydrostreptomycin (**11**) and **13** showed similar $\Delta[M]_{TACu}$ and $\Delta[M]_{TACu\text{-}NH_3}$ values owing to the lack of participation for complexing including the functional groups at C-5, although, in **11**, the proportion of the complexing like B (see Fig. 1) seemed to be slightly less than that in **13**, In 1,3-di(deamidino)-6-*O*-methyldihydrostreptomycin (**12**), the degree of the A-type complex in TACu solution was considered to be essentially the same with the complexings of the other compounds (**11** and **13**). However, after addition of ammonia, complexing could occur both at NH_2(1)-OH(2)(sign−) and OH(2)-NH_2(3)(sign+) competitively, thus showing the value as expected from the apparent complexing formed only at $NHCH_3$(2″)-OH(3″)(see Fig. 2).

The antibacterial spectra of **9** and **10** showed that they had only very slight activities, suggesting that

§ TACu can form complex only with a pair of vicinal amino and hydroxyl groups having relative special orientations of ≈60° dihedral angle and the $\Delta[M]_{TACu}$(= $[M]_{TACu} - [M]_{H_2O}$) shows a value of ±900°, the sign being decided by counterclockwise (positive) or clockwise (negative) orientation in the Newman projection of -(*NH*$_2$)CH-CH(*OH*)-. In the case of **13**, TACu forms complexes mainly at NHMe(2″)-OH(3″)(sign+) and NH_2(1)-OH(2)-(sign−) to give roughly cancelled value (+340[16]), and by slight addition of ammonia to the TACu solution,[16] the latter complex almost disappeared and, instead, two new complexes at OH(2)-NH_2(3)(sign+) and NH_2(1)-OH(6)-(sign+) appeared, to result in giving a large positive value of $\Delta[M]_{TACu\text{-}NH_3}$(+2530[16]). This phenomenon was interpreted by the assumption that TACu made complexes in streptamine portion of **13** in a state of equilibrium as depicted in Fig 1.[16]

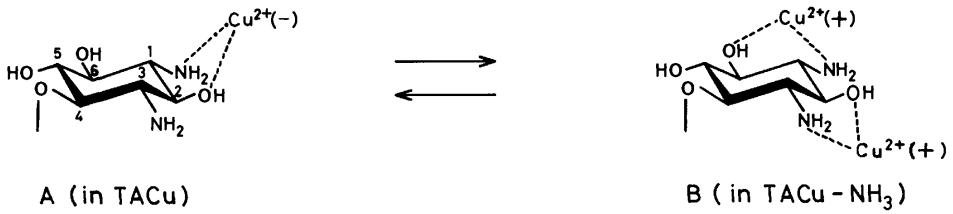

Fig. 1.

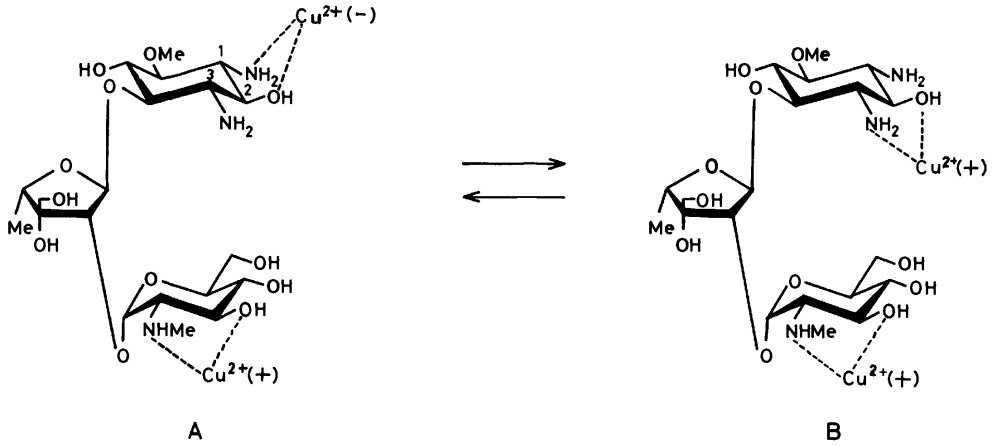

In TACu a mixture of 1,2-(type A, ≈73%) and 2,3-complexes(type B, ≈27%) was expected, and in TACu-NH_3, 1,2-(≈46%) and 2,3-complexes(≈54%).

Fig. 2.

Table 2. $\Delta[M]_{TACu}$ values of **11**, **12**, and **13**[17] before and after addition of ammonia

	$[M]_{H_2O}$	$[M]_{TACu}$[a]	$\Delta[M]_{TACu}$	$[M]_{TACu\text{-}NH_3}$[b]	$\Delta[M]_{TACu\text{-}NH_3}$
11	−1110	−760	+350	+920	+2030
12	−1410	−930	+480	−440	+970
13	−1260	−1000	+260	+1380	+2600

a) 0.01 mmol of each sample (as the hydrogencarbonate) was dissolved in 1.0 ml of 0.16 mmol TACu solution and the rotation of the solution was measured in 0.1 dm tube at 436 nm.[16] b) After measuring the $[M]_{TACu}$, 0.001 ml each of 15 mol dm^{-3} ammonium hydroxide solution was added to the solution (0.55 mol) and the rotation of the solution was again measured. The procedure was repeated until the rotation reached to a constant value.[16]

masking of the hydroxyl at C-5 or C-6 both greatly influences the binding of the antibiotic to the bacterial ribosome.

Experimental

General. ^{1}H-NMR spectra were recorded at 90 MHz with a Varian EM-390 spectrometer except for **9** and **10**, the spectra of which being recorded at 250 MHz in the FT mode with a Bruker WM 250 spectrometer. ^{13}C-NMR spectra were recorded in the FT mode with a Bruker WM 250 spectrometer operating at 62.5 MHz. Thin-Layer chromatography (TLC) was performed on Wakogel B5. For column chromatography, silica gel (Wakogel C-200) was used.

1,3,2″-Tris(N^G,N^G,N-*benzyloxycarbonyl*)-*5,6:3′,3′a:4″,6″-tris*(O-p-*methylbenzylidene*)*dihydrostreptomycin* (**2**). To a solution of **1** (6.0 g) in dry *N,N*-dimethylformamide (120 ml) were added *p*-tolualdehyde dimethyl acetal (24 ml) and molecular sieves 5A (6 g) and, after stirring for 30 min, was added anhydrous *p*-toluenesulfonic acid (3 g), and the mixture was stirred at 60 °C for 5 h under reduced pressure (≈15 Torr (1 Torr=133.322 Pa); to remove the methanol liberated). The solution was poured into a saturated aqueous sodium hydrogencarbonate solution (27 ml) and the precipitates were filtered off with aid of methanol. (If the addition of the reaction mixture to the alkaline solution is reversed, yield of **2** sometimes greatly decreased

owing to removal of the 5,6-acetal group.) The filtrates and washings combined were concentrated to give a syrup, that was extracted with chloroform. The organic solution was washed with saturated aqueous sodium chloride, dried (Na_2SO_4), and concentrated. Addition of hexane to the concentrate gave a solid (≈6 g). Purification of the solid by silica-gel column chromatography with benzene–ethanol–triethylamine (30:1:0.1) as the developer gave an amorphous solid of **2**, 3.18 g (41%), $[\alpha]_D^{25}$ −64° (*c* 1, chloroform). ^{1}H-NMR ($CDCl_3$) δ=1.2—1.4 [3H, CH_3(5′)], 2.3 (9H br s, 3C*H*$_3$C$_6$H$_4$–).

Found: C, 64.12; H, 6.01; N, 7.59%. Calcd for $C_{69}H_{77}N_7O_{18}$: C, 64.19; H, 6.01; N, 7.40%.

*1,3-Di-*N^G*-acetyl-2,3″-di-*O*-acetyl-1,3,2″-tris(*N^G,N^G,N*-benzyloxycarbonyl)-5,6:3′,3′a:4″,6″-*tris(O-p-*methylbenzylidene)dihydrostreptomycin (3).* A mixture of **2** (900 mg) and acetic anhydride (4.8 ml) in pyridine (13.5 ml) was kept at room temperature overnight. Pouring the solution into ice water (100 ml) gave precipitates, that was thoroughly washed with water, then dried to give a solid of **3**, 1.00 g (99%), TLC (benzene–ethanol=15:1): R_f=0.75 (*cf.* **2**: 0.2), $[\alpha]_D^{20}$ −37° (*c* 1, chloroform).

^{1}H-NMR ($CDCl_3$) δ=1.2—1.4 [3H, CH_3(5′)], 1.9—2.2 (12H, mainly 4 singlets with different strength, 4Ac), 2.4 (9H, s, 3C*H*$_3$C$_6$H$_4$–), 2.74 (3H, s, NCH_3).

Found: C, 63.06; H, 5.95; N, 6.46%. Calcd for $C_{77}H_{85}N_7O_{22}$; C, 63.32; H, 5.86; N, 6.71%.

*1,3-Di-*N^G*-acetyl-2,3″-di-*O*-acetyl-1,3,2″-tris(*N^G,N^G,N*-benzyloxycarbonyl)-3′,3′a:4″,6″-bis(*O-p-*methylbenzylidene)dihydrostreptomycin (4).* A solution of **3** (1062 mg) in a mixture of 1,4-dioxane (25 ml) and 50% aqueous acetic acid (25 ml) was allowed to stand at room temperature for 4 h. The solution was poured, with careful agitation, into water (100 ml) containing sodium hydrogencarbonate (20 g) and the mixture extracted with chloroform. The extract, after dried (Na_2SO_4), was concentrated to give a residue, that contained three products, on checking by TLC (benzene–ethanol=15:1), having R_f 0.25 (slight), 0.17 (**4**, major), and 0.12 (slight). Separation with silica-gel column chromatography with benzene–ethanol–triethylamine (30:1:0.05) gave a solid of **4**, 634 mg (64%), $[\alpha]_D^{20}$ −38° (*c* 1, chloroform).

^{1}H-NMR ($CDCl_3$) δ=≈1.3 [3H, CH_3(5′)], 1.9—2.2 (12H, mainly 3 peaks, including unresolved, small strength, 4Ac), 2.4 (6H s, 2C*H*$_3$C$_6$H$_4$–), 2.74 (3H br s, NCH_3).

Found: C, 60.77; H, 6.02; N, 7.06%. Calcd for $C_{69}H_{79}N_7O_{22}$: C, 61.01; H, 5.86; N, 7.22%.

Reaction of 4 with Diazomethane. To an ice-cold solution of **4** (240 mg) in methanol (2.7 ml) containing $SnCl_2 \cdot 2H_2O$ (8 mg, 0.2 mol equiv for **4**) was added diazomethane in ether[18] in small portions, and the reaction was monitored by TLC (benzene–ethanol=7:1). After 20 ml addition of the ether solution, the starting **4** (R_f= 0.37) almost disappeared and the products (**5**, **6**, R_f= 0.43) appeared. Concentration gave a residue, that was extracted with chloroform. The extract was washed thoroughly with water, dried (Na_2SO_4), and concentrated to give a solid (232 mg). The ^{1}H-NMR ($CDCl_3$) spectrum of the products gave a clear peak at δ=3.6 (OMe).

5-O- and 6-O-Methyldihydrostreptomycin (9 and 10). A crude mixture of **5** and **6** (220 mg) dissolved in methanol (22 ml) containing 15 M aqueous ammonia (0.44 ml)(1 M=1 mol dm^{-3}) was kept at room temperature for 1 h. Concentration gave a residue (190 mg), that was purified by silica-gel column chromatography with benzene–ethanol (15:1) to give a mixture of **7** and **8** (125 mg). In the ^{1}H-NMR spectrum, no peak was observed near δ=2 (Ac). A solution of the mixture (115 mg) in oxolane (1.5 ml) was gradually poured into a solution of sodium (≈60 mg) in liquid ammonia (15 ml) maintained at −60 °C, and the blue solution was kept at the temperature for 1.5 h. Addition of methanol until the color disappeared was followed by raising the temperature until 30 °C in order to evaporate the ammonia. The residue was then neutralized with 1 M aqueous hydrochloric acid and charged on a column of Amberlite CG 50 (NH_4^+ form, 20 ml). After washing the column with water, the products were eluted by aqueous ammonium carbonate solution (l→5%, the concentration was gradually changed) and the portion positive for biacetyl color test (indication for the presence of guanidino group) was collected and repeatedly concentrated with several additions of water to remove ammonium carbonate to give a solid (a mixture of **9** and **10**, 32 mg). The mixture was dissolved in 50% aqueous acetic acid (0.6 ml) and separated by column chromatography of microcrystalline cellulose powder (Avicel SF, 15 g, Funakoshi Co., Tokyo) with 1-butanol–pyridine–water–acetic acid (6:4:3:1). Fractions containing **9** and **10** were, respectively, concentrated, and the residue was purified by a column of Amberlite CG 50 (NH_4^+ form) with 5% aqueous ammonium carbonate. The fractions positive for biacetyl were repeatedly concentrated with several additions of water (to remove $(NH_4)_2CO_3$) to give, after drying, solids of **9**, 6.5 mg (5% based on **4**) and **10**, 18.5 mg (15% based on **4**), each as the carbonate.

9: $[\alpha]_D^{20}$ −79° (*c* 0.8, water).

^{1}H-NMR (D_2O, the hydrogencarbonate salt) δ=1.25 [3H d, *J*=7 Hz, CH_3(5′)], 2.43 (3H s, NCH_3), 2.62 (1H dd, H-2″), 3.33 (1H unresolved t, H-5) 3.62 (3H s, OCH_3), 3.83 (1H dd, *J*=4.8 and 12 Hz) and 3.92 (1H dd, *J*=2 and 12 Hz)(H-6,6′), 4.225 (1H d, H-2′), 4.27 (1H q, *J*=7 Hz, H-4′), 5.26 (1H d, H-1″), and 5.29 (1H d, H-1′); $J_{1',2'}$=1, $J_{1'',2''}$=3, and $J_{2'',3''}$=11 Hz.

^{1}H-NMR (D_2O+DCl; pD<1) δ=1.24 [3H d, CH_3(5′)], 2.89 (3H s, NCH_3), 3.32 (1H, H-5), 3.35 (1H dd, H-2″), 3.60 (3H s, OCH_3), 4.25 (1H q, H-4′), 4.305 (1H d, H-2′), 5.28 (1H d, H-1′), and 5.57 (1H d, H-1″); *J* values were the same with those of the hydrogencarbonate.

Found: C, 39.95; H, 6.67; N, 13.55%. Calcd for $C_{22}H_{43}N_{27}O_{12} \cdot 2H_2CO_3$: C, 39.94; H, 6.56; N, 13.59%.

10: $[\alpha]_D^{20}$ −88° (*c* 1, water).

^{1}H-NMR (D_2O, the hydrogencarbonate salt) δ=1.24 [3H d, *J*=7 Hz, CH_3(5′)], 2.41 (3H s, NCH_3), 2.61 (1H dd, H-2″), 3.24 (1H unresolved t, H-6), 3.59 (3H s, OCH_3), 3.83 (1H dd, *J*=4.8 and 12 Hz) and 3.93 (1H dd, *J*=2 and 12 Hz)(H-6,6′), 4.205 (1H d, H-2′), 4.30 (1H q, *J*=7 Hz, H-4′), 5.23 (1H d, H-1″), and 5.29 (1H d, H-1′); $J_{1',2'}$=1, $J_{1'',2''}$=3, and $J_{2'',3''}$=11 Hz.

(Received May 22, 1985)

The reaction of sodium *cyclo*-triphosphate(P_{3m}) with L-α- or β-alanine in an aqueous solution was investigated using anion-exchange chromatography, ^{31}P-NMR spectroscopy, chemical analysis for phosphorus and alanine, IR spectroscopy, and thin-layer chromatography(TLC). 1) P_{3m} readily reacted with L-α-alanine at pH 10 and 12 to form two orthophosphate derivatives of α-alanine: *N*-(1-carboxyethyl)phosphoramidate(P_1-(*N*)ala) and 1,3,2-oxazaphospholidin-2-olate derivative(P_1-(*N,O*)ala) of five-membered ring structure. 2) Only triphosphate derivative, *N*-(2-carboxyethyl)triphosphoramidate(P_3-(*N*)ala), was obtained in the reaction of P_{3m} and β-alanine. 3) The total yield of P_1-(*N*)ala and P_1-(*N,O*)ala was about 75% when P_{3m} was allowed to react with α-alanine at a molar ratio of 1:3 and pH 12, while the yield of P_3-(*N*)ala was about 80% in the reaction of P_{3m} with β-alanine at a molar ratio of 1:1 and pH 12. 4) Oligopeptides such as L-alanylalanine(dimer) and L-alanylalanylalanine(trimer) were formed in the reaction of P_{3m} with α-alanine. 5) Under acidic conditions, P_3-(*N*)ala recyclized to the starting material P_{3m} and β-alanine. 6) The mechanism of the reaction of P_{3m} with α- or β-alanine is discussed.

Phosphorus pentaoxide, polyphosphoric acid, phosphoryl chloride,[1-3] and various organic phosphorus compounds[4-6] have been used as phosphorylating agents for organic and bioorganic compounds. Phosphorylation with these compounds, however, requires special and cumbersome techniques and is usually accompanied by the formation of considerable amounts of by-products.

Feldmann reported in 1965—1967 that phosphorylation of alkylamines,[7] phenols,[8] and alcohols[9] can be effected by the use of *cyclo*-triphosphate(P_{3m}). Following this, Rabinowitz[10-12] reported in 1969—1971 that amino acids (glycine and alanine) condense to form oligopeptides in the presence of polyphosphate or P_{3m}. These facts lead one to imagine that inorganic condensed phosphates such as polyphosphate and P_{3m} might have played an important role in the creation of proteins from amino acids in the prebiotic process which preceded the emergence of life on the earth.[11,13,14] However, little is known about the reaction products and mechanism of P_{3m} with amino acids. As a part of our developmental work on the application of P_{3m} as a phosphorylating agent, the present authors investigated the reaction of P_{3m} with L-α- or β-alanine under various conditions (molar ratio of alanine to P_{3m}, pH, and reaction time) in order to characterize the structure and yields of the reaction products as well as the reaction mechanism.

P_{3m} has many advantages over any other phosphorylating agents; it is a component of metaphosphate, which has been approved for safety as a food additive.[15] Furthermore it is very easy to handle and requires no special technique for phosphorylation. The present authors have already reported that P_{3m} is of great value as a phosphorylating agent for nucleosides.[16]

Experimental

Chemicals. Sodium *cyclo*-triphosphate hexahydrate, $Na_3P_3O_9 \cdot 6H_2O$, was prepared by the procedure described in the previous paper[17] and recrystallized three times from aqueous solution. Reagent-grade L-α- and β-alanine, and potassium acetyl phosphate (Rasa Industries Ltd.) were used without further purification. Unless otherwise stated, guaranteed grade reagents from Wako Chemical Industries Ltd., were used.

Reaction between cyclo-*Triphosphate with* L-α- *or* β-*Alanine.* In the reaction of P_{3m} with L-α-alanine, 50 cm^3 of 0.5 mol dm^{-3} aqueous sodium *cyclo*-triphosphate(P_{3m}) solution was mixed with 50 cm^3 of 0.5—1.5 mol dm^{-3} aqueous L-α-alanine solutions. The pH values of the mixed solutions were about 5.2—5.3. In the reaction of P_{3m} with β-alanine, on the other hand, 50 cm^3 of 0.5 mol dm^{-3} aqueous P_{3m} solution was mixed with 50 cm^3 of 0.5 mol dm^{-3} aqueous β-alanine solution, and the pH value of the mixed solution was about 6.1. These mixed solutions were then adjusted to the predetermined pH value(pH 12, 10, 7, or 4) by use of a sodium hydroxide solution or hydrochloric acid, and the reaction was allowed to stand at room temperatue. Since the pH of each mixed solution decreased as the reaction progressed, the solution was constantly adjusted to the predetermined pH by adding a sodium hydroxide solution.

^{31}P-NMR Measurement. A JEOL FT-NMR Spectrom eter (Model JNN-FX 100) operating at 40.25 MHz for ^{31}P was used. 85% orthophosphoric acid was used as a reference.

TLC Analysis. For analysis of L-α-alanine, L-alanylalanine(dimer), L-alanylalanylalanine(trimer), and β-alanine, TLC was used. A mixed solvent consisting of $CHCl_3$, CH_3OH, and 17% aqueous ammonia (2:2:1) was used, with silica gel plates (made by E. Merck Co. and Wako Chemical Industries Ltd.).

Anion-exchange chromatography, IR spectroscopy, and

the determination of phosphorus and α-alanine were carried out by the methods described in the previous paper.[18]

Results and Discussion

Reaction of cyclo-*Triphosphate with* L-α- *or* β-*Alanine.* After aqueous solutions of P_{3m} and L-α- or β-alanine were mixed, the mixtures were adjusted to a desired pH(12, 10, 7, or 4) with sodium hydroxide or hydrochloric acid, and then allowed to stand at room temperature. Reaction products obtained by the reaction of P_{3m} with α- or β-alanine were separated and determined by anion-exchange chromatography. Figures 1-a and b show the anion-exchange chromatograms of the reaction products of P_{3m} with α- or β-alanine at a molar ratio of 1:1, pH 12, and at room temperature. In the reaction of P_{3m} with α-alanine, two elution peaks of unknown compounds (designated as Compounds I and II) were observed between those of ortho-(P_1) and pyrophosphate(P_2). In the reaction between P_{3m} and β-alanine, on the other hand, a large peak of an unknown compound (Compound III) appeared at 1400 cm^3 of the effluent, other than the peaks of ortho-, pyro-, tri-(P_3), and tetraphosphate(P_4). As can be seen from Fig. 1-a and b, the formation of Compound I and P_2 was predominant in the P_{3m}-α-alanine system, whereas the predominant product in the P_{3m}-β-alanine system was Compound III, with P_1, P_2, P_3, and P_4 being formed only in very small quantities.

Structures of Compounds I, II, and III. The molecular structures of Compounds I, II, and III were determined by means of chemical analysis, IR spectroscopy, and ^{31}P-NMR spectroscopy. In addition, the reaction of Compounds I, II, and III in an acidic solution was investigated in order to determine the structure.

Compound II was fractionated by anion-exchange chromatography according to the method described in the previous paper.[17] The amounts of phosphorus and α-alanine in Compound II were determined by chemical analysis and with an amino acid analyzer.[18] It was found that the ratio of phosphorus to α-alanine in Compound II is 1:0.96, showing that Compound II may be an orthophosphate derivative of α-alanine containing P_1 and α-alanine in the molar ratio of 1:1.

The IR spectrum of compound II is shown in Fig. 2. Characteristic absorptions that can be assigned to α-alanine were noticed at about 2850 ($\nu_{s\,CH_2}$), 1595 ($\nu_{C=O}$), 1450 (ν_{CH_2}), 1412 ($\nu_{C=O}$), and 1358 cm^{-1} (ν_{C-H}).[19] In addition, characteristic absorptions due to the P-O-C(↑) and P-N bonds(⇡) were observed at the vicinity of 1150 and 900 cm^{-1},[20,21] and 710 cm^{-1},[22-24] respectively. These results demonstrate that Compound II is a phosphate derivative of α-alanine having both P-O-C and P-N bonds in its molecule. For reference, the IR spectrum of the raw material, L-α-alanine, is also shown in Fig. 2-(1).

Figure 3 shows the ^{31}P-NMR spectra of the reaction products between P_{3m} and α-alanine. As can be seen in the ^{1}H-decoupling spectrum, singlet peaks corre-

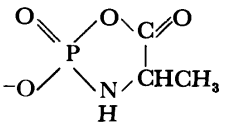
sponding to the two unknown compounds were observed at δ (chemical shift) 9.3 and 8.7 ppm. From the peak heights (amounts) of Compounds I and II on anion-exchange chromatogram (Fig. 1), peaks at δ 9.3 and 8.7 ppm were attributable to Compounds I and II, respectively. It was found from the ^{1}H-decoupling spectrum that these compounds are both orthophosphate derivatives of α-alanine. The fact that each singlet peak split into doublets due to ^{1}H-coupling suggests that Compounds I and II might be two of the following three compounds: *N*-(1-carboxyethyl)phosphoramidate(P_1-(*N*)ala) containing P-N bond in the molecule, $^{-}O-\overset{\overset{O}{\|}}{P}(O^-)-NHCH(CH_3)COO^-$, 2-aminopropionyl phosphate having P-O-C bond, $^{-}O-\overset{\overset{O}{\|}}{P}(O^-)-O-\overset{\overset{O}{\|}}{C}-CH(CH_3)-NH_2$, and 4-methyl-5-oxo-1,3,2-oxazaphospholidin-2-olate 2-oxide (P_1-(*N,O*)ala) of five-membered ring structure,



Since the proton on a nitrogen atom undergoes rapid exchange, the spin-spin coupling to phosphorus atom(P-N-H) has not been observed. Of these, the possibility of the formation of 2-aminopropionyl phosphate was excluded because no ^{1}H-coupling of phosphorus atom was observed in ^{31}P-NMR spectrum of authentic acetyl phosphate, $^{-}O-\overset{\overset{O}{\|}}{P}(O^-)-O-\overset{\overset{O}{\|}}{C}-CH_3$.

Therefore, the two unknown compounds could be P_1-(*N*)ala and P_1-(*N,O*)ala. It may thus be deduced that Compound II(δ 8.7 ppm) would be P_1-(*N,O*)ala, because its IR spectrum (Fig. 2) showed the presence of both P-O-C and P-N bonds in the molecule. On the other hand, when an aqueous solution of Compound II was acidified to pH 4, hydrolysis took place to give P_1 and α-alanine. Based on all the experimental results, Compound II was identified as an orthophosphate derivative of α-alanine, 1,3,2-oxazaphospholidin-2-olate derivative(P_1-(*N,O*)ala).

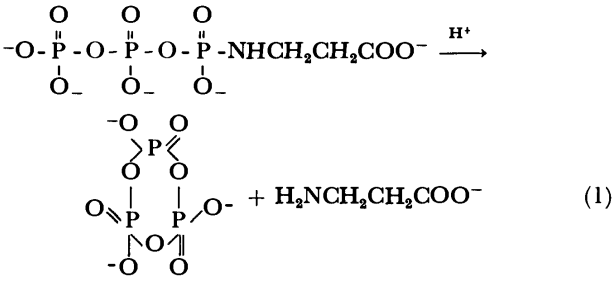
It was difficult to investigate the structure of Compound I by use of IR spectroscopy and chemical analysis, because this compound could not be isolated in a pure form by the chromatographic separation due to its unstability at neutral conditions. However, the result of ^{31}P-NMR spectrum (^{1}H-decoupling) shows that Compound I is an orthophosphate derivative of α-alanine. Since this readily undergoes hydrolysis under neutral and acidic conditions to form P_1 and α-alanine, it is expected that this compound contains P-N bond in its molecule. Based on these facts, we deduced that Compound I may probably be *N*-(1-carboxyethyl)-phosphoramidate(P_1-(*N*)ala).

Figure 4 shows the ^{31}P-NMR spectra of the reaction products of P_{3m} and β-alanine at a molar ratio of 1:1 and pH 12. By comparing with the ^{31}P-NMR spectra of triphosphoramidate in the literature,[25] Compound III was identified as a triphosphate derivative of β-alanine, *N*-(2-carboxyethyl)triphosphoramidate(P_3-(*N*)ala). In the ^{1}H-decoupling spectrum of Fig. 4, the doublets at δ −0.6 and −4.3 ppm were assigned to the end phosphorus atoms, P_α and P_γ, respectively, and the triplet at −19.6 ppm corresponded to the middle phosphorus atom, P_β. Each of the doublets of P_α should in principle split into triplets in ^{1}H-coupling by the influence of the two hydrogen atoms of $-NHCH_2COO^-$, but actually quintet was observed as a result of overlapping.

Table 1. Change of the amounts of phosphorus compounds due to pH

Compound / pH	P_1 (%)	P_2 (%)	P_3 (%)	[III] (%)	P_{3m} (%)
pH 12	0.8	0.6	0.6	69.3	28.6
pH 4	0.8	0.6	0.8	0.0	97.9
pH4-pH12	0.0	0.0	+0.2	−69.3	+69.3

The reaction solution containing a large amount of Compound III was divided into two portions, one being set at pH 12 and the other being controlled to pH 4 by adding dilute hydrochloric acid, and both samples were analyzed by anion-exchange chromatography. The results are shown in Table 1; the amounts of phosphorus compounds at pH 12 in top row, those at pH 4 in middle row, and the difference between the two pH levels in bottom row. Compound III formed in 69.3% yield at pH 12 disappeared completely at pH 4, regenerating the starting material P_{3m}. This result indicates that Compound III recylized to P_{3m} as shown in formula(1) under acidic conditions.



(1)

Quimby[25] and Feldmann[7] have reported in the study of the reaction of P_{3m} with ammonia or various alkylamines that amidotriphosphate or *N*-alkyltriphosphoramidate formed were readily recyclized to produce P_{3m} under acidic conditions.

Amounts of Compounds I, II, and III. Figure 5 shows the changes in the amounts of P_1, P_2, P_3, P_1-(*N*)ala, and P_1-(*N,O*)ala formed by the reaction of P_{3m} with α-alanine at a molar ratio of 1:1, pH 12 and at room temperature. As can be seen from Fig. 1-a, elution peaks of P_1-(*N*)ala and P_1-(*N,O*)ala overlapped with each other, so the amounts of these compounds are shown as total in Fig. 5. The total amount of P_1-(*N*)ala and P_1-(*N,O*)ala gradually increased with the passage of reaction time, reaching about 33.5% after 22 d. P_2 was formed in a considerable quantity at the initial stage of the reaction, while the amounts of P_1 and P_3 gradually increased as the reaction progressed.

Figure 6 shows the changes in the amounts of phosphates formed by the reaction of P_{3m} and α-

alanine at a mixing ratio of 1:1 and pH 10. In this case, the total amount of P_1-(*N*)ala and P_1-(*N,O*)ala was about 6%, which was much lower than that at pH 12. The amount of P_1, on the other hand, increased linearly with the reaction time, amounting to about 39% after 30 d. The formation of P_1 was notable compared with the case of pH 12. No reaction took place between P_{3m} and α-alanine under neutral and acidic conditions. It is clear from these results that P_{3m} readily reacts with α-alanine under alkaline conditions and that the reactivity lowers with decreasing pH, until eventually no reaction occurs when the pH is lowered to 7.

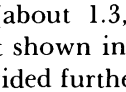
Figure 7 shows the changes in the amounts of various phosphates when the reaction was carried out using 0.5 mol dm^{-3} P_{3m} and 1.5 mol dm^{-3} α-alanine (mixing ratio=1:3) at pH 12. As is apparent from Figs. 5 and 7, the reaction proceeded much faster at a mixing ratio of 1:3 than at that of 1:1. The total amounts of P_1-(*N*)ala and P_1-(*N,O*)ala formed at a reaction ratio of 1:3 were much greater than those formed at 1:1. P_1-(*N*)ala and P_1-(*N,O*)ala began to be formed immediately at the initial stage of the reaction, whose total amount reached about 65% after

3 d. After that, the amount continued to increase slowly until a nearly constant level of about 75% was reached. The slight decrease in the amount of P_2 after 2 d was due to the precipitation of crystals of tetrasodium pyrophosphate decahydrate, $Na_4P_2O_7 \cdot 10H_2O$, which were removed from the solution phase.

Figure 8 shows the changes in the amounts of phosphorus compounds formed by the reaction between P_{3m} and β-alanine (molar ratio=1:1) at pH 12 and room temperature. A rapid formation of P_3-(*N*)ala was observed. This amount reached about 54% in 10 d and increased slowly thereafter. The amount of P_3 increased linearly with the reaction time, which was presumably due to the hydrolysis of P_{3m}. Since P_1, P_2, and P_4 were formed in quite small quantities (about 1.3, 2.5, and 0.4%, respectively), they are not shown in Fig. 8. Such low yields of P_1 and P_2 provided further evidence that Compound III is a triphosphate derivative of β-alanine. The formation of P_4 when the reaction was continued for long periods is considered to be a result of a reaction of free P_1 with P_3-(*N*)ala having a P–N bond.[26]

Formation of Oligopeptides. The reaction products of P_{3m} with α- or β-alanine were analyzed by TLC to investigate the peptide bond formation of alanine in the reaction solutions. As can be seen in Fig. 9, which indicates, other than the spot of monomeric alanine, those of its dimer(L-alanylalanine) and trimer(L-alanylalanylalanine) in the reaction of P_{3m} with α-alanine were formed. On the other hand, no oligopeptide was formed in the reaction of P_{3m} with β-alanine.

Feldmann,[27] Paecht and Katchalsky,[28] and Koshland[29] reported that a compound having a



structure reacts with a free amino acid to form a peptide bond. Based on these results, the authors have postulated a reaction mechanism for the

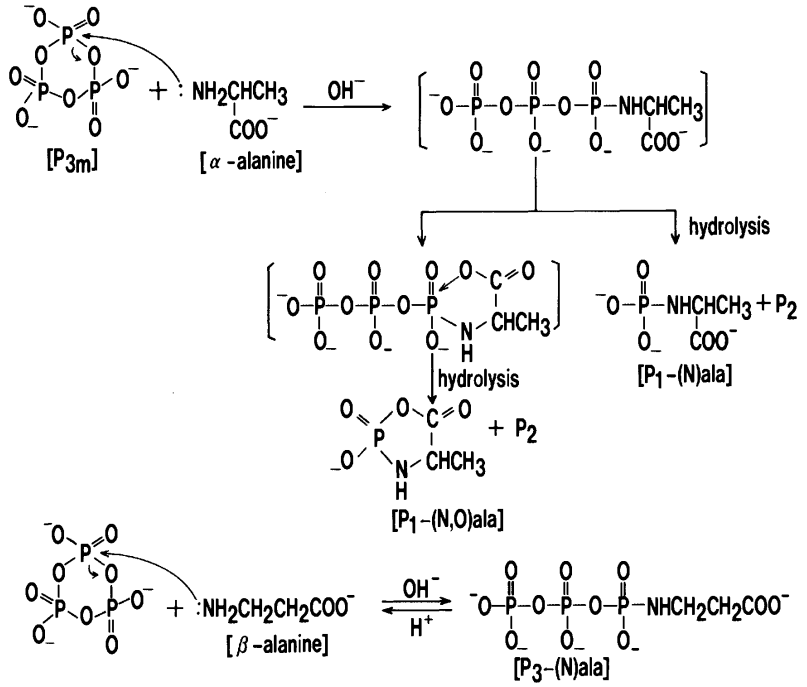

Fig. 11. Mechanism of the reaction of P_{3m} with L-α- alanine or β-alanine.

formation of the dimer and trimer of α-alanine as shown in Fig. 10. A nucleophilic attack by the amino group of free α-alanine on the carboxylate carbon atom of P_1-(*N*,*O*)ala, gives an orthophosphate derivative of alanylalanine as a reaction intermediate, which is unstable and readily undergoes hydrolysis to form alanylalanine and P_1. The dimer then reacts with P_1-(*N*,*O*)ala in a similar manner to afford the trimer. Tetramer and higher oligomers should also be formed through the same mechanism, which, however, could not be detected by TLC probably because of the small amounts present. Such oligopeptide formation has already been observed by our previous investigation on the reaction of P_{3m} with glycine.[18]

On the contrary, oligopeptides were not formed at all in the reaction of P_{3m} with β-alanine, showing that P_3-(*N*)ala formed in this reaction did not react with free β-alanine to produce its oligomers. It may be apparent from the foregoing that the five-membered ring compound, P_1-(*N*,*O*)ala, plays an important role in the formation of oligopeptides in the reaction of P_{3m} with alanine.

Mechanism of the Reaction of cyclo-*Triphosphate with α- or β-Alanine.* The mechanism of the reaction between P_{3m} and α- or β-alanine in alkaline solutions is shown in Fig. 11. In the reaction of P_{3m} with α-alanine, a nucleophilic attack by the amino group of α-alanine upon the phosphorus atom of P_{3m} causes a ring opening of the latter to form a triphosphate derivative of α-alanine having a P–N bond in the molecule as an intermediate. This intermediate, which is very unstable (as evidenced by the fact that it cannot be detected by either HPLC or anion-exchange chromatography), is considered to undergo hydrolysis through the following two routes: (1) an attack by the carboxyl group upon the phosphorus atom of the intermediate to form propionyl triphosphate with a five-membered ring structure, followed by hydrolysis into P_1-(*N*,*O*)ala and P_2, and (2) a direct hydrolysis of the intermediate to form P_1-(*N*)ala and P_2.

There is no possibility of a direct attack by the carboxyl group of α-alanine upon the phosphorus atom of P_{3m}, because no reaction takes place between CH_3COO^- and P_{3m} under the same conditions. In the reaction between P_{3m} and β-alanine, on the other hand, it is assumed that the ring opening of P_{3m} is caused by a nucleophilic attack of the amino group of β-alanine upon its phosphorus atom, producing P_3-(*N*)ala. This compound is stable in an alkaline solution, but readily recyclizes to P_{3m} under acidic conditions. Thus, the reaction of P_{3m} with β-alanine is reversible, depending on the pH.

The difference in the reaction mechanisms of *cyclo*-triphosphate with α- and β-alanine is outstanding, that is, the formation of a heterocyclic compound takes place with α-alanine but not with β-alanine. A further precise study is necessary in order to clarify any differences in the mechanisms.

We are indebted to Prof. Morifusa Eto and Dr. Eiichi Kuwano at Faculty of Agriculture in Kyushu University for the ^{31}P-NMR measurements.

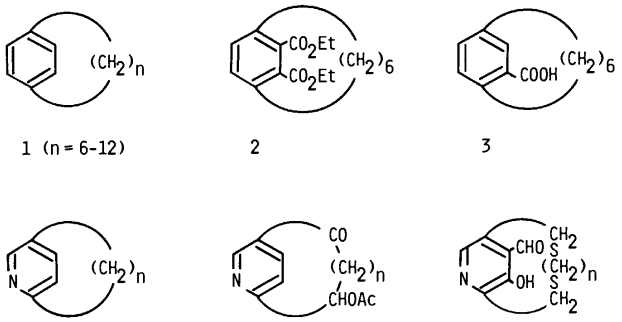
Synthesis and Properties of the [n](2,5)Pyridinophane Ring System[1)]

Tomoshige KOBAYASHI and Makoto NITTA*
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160
(Received June 6, 1985)

The synthesis and properties of a series of [n](2,5)pyridinophane derivatives (**13a—e**) (n=10, 8, 7, and 6) are described. These compounds are prepared in low yields by the [Mo(CO)$_6$]-induced cycloaddition reaction of 3-aryl-4,5-polymethylene-substituted isoxazoles (**11a—e**) with dimethyl acetylenedicarboxylate. The reaction pathways are suggested to involve the inclusion of the acetylenic ester across the C-4–C-5 bond of the N-complexed isoxazoles and the subsequent elimination of the oxygen atom from the resulting isoxazoline ring. The structures of **13a—e** are established on the basis of the ^{1}H-NMR, ^{13}C-NMR, and UV spectra. A significant strain for the pyridine ring in **13a—e** is reflected in the UV spectra. As the [n] decreases in **13—e**, there is a red shift in the absorption spectra. This feature is in good accordance with that observed in a series of [n]paracyclophane ring systems.

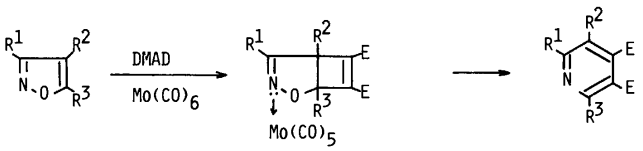
Much interest has been focussed on the chemistry of the cyclophanes.[2)] Especially, the [n]paracyclophane ring system (**1**)(n=6—12) has been one of the simplest models for clarifying the correlation of the aromaticity with the distortion of the benzene ring from planarity.[2)] The synthesis of "more bent" benzene ring than the previous example is though still an intriguing and challenging problem. The [n]paracyclophane ring system **1** has been synthesized for most values of [n], from 16 to 6.[2,3)] The [n]paracyclophane **1** (n=6), which has the smallest methylene chain known for this series, was first reported by Jones *et al.* in 1974.[3c)] However, it is only recently that new efficient routes to the [6]paracyclophane derivatives (**2**)[3g)] and (**3**),[3h)] both of which have substituents on the benzene ring, were developed. Their X-ray studies revealed that the benzene rings are highly deformed (*ca.* 20°) from planarity.[3g,h)]



1 (n = 6-12) 2 3

4 (n = 8-12) 5 (n = 9, 10) 6 (n = 4, 5)

In contrast to these studies, only a few examples of the aza analogue, the [n](2,5)pyridinophane ring system, have been known. The first example of [n](2,5)pyridinophane (**4**) (n=8—12) appeared in 1968.[4)] The functionalization of **4** (n=9 and 10) leading to **5** has also been studied.[5)] With a view toward a model for vitamin B$_6$-dependent enzyme, the chemistry of [n](2,5)pyridinophane (**6**)(n=4 and 5) containing pyridoxal has also been studied.[6)] Thus, the smallest value of [n] for [n](2,5)pyridinophane known so far is [8].[4)]



7 8 9

Scheme 1.

In our previous studies,[7)] [Mo(CO)$_6$] has been shown to effect a novel inclusion of the acetylenic ester across the C-4–C-5 bond of isoxazoles **7** and the subsequent elimination of an oxygen atom to give pyridine derivatives **9** *via* an intermediate **8** (Scheme 1). If this reaction is applicable to some 4,5-polymethylene-substituted isoxazoles (R^2-R^3=-(CH$_2$)$_n$- in **7**), [n](2,5)pyridinophanes can be expected as the products. We wish to describe here on the synthesis of [6](2,5)pyridinophane derivatives (**13d, e**), which might contain one of the most deformed pyridine rings, as well as a series of [10], [8], and [7] homologues, (**13a—c**).

Results and Discussion

The synthetic sequences of the [n](2,5)pyridinophane derivatives **13** are illustrated in Scheme 2. The syntheses of the desired 3-aryl-4,5-polymethylene-substituted isoxazoles (**12**) were achieved by method similar to that used in the preparation of ring-annelated isoxazoles.[8)] The 1,3-dipolar cycloaddition of benzonitrile oxide to 1-(1-pyrrolidinyl)-1-cycloalkenes (**10a—d**) afforded the corresponding cycloadducts, 4,5-polymethlene-subsituted 3-phenyl-5-(1-pyrrloidinyl)isoxazolines (**11a—d**). Similarly, the isoxazoline (**11e**) was obtained from the reaction of 4-chlorobenzonitrile oxide with **10d**. Compounds **11a, b** and **11d, e** were easily purified by recrystallization to give colorless crystals. On the other hand, oily **11c** decomposed on distillation [at *ca.* 120 °C (bath temp)/667 Pa]. Therefore, **11c** was purified by column chromatography on silica gel to give a

colorless oil and then submitted to the next step. On the acid-catalyzed elimination of the pyrrolidine, **11a—e** were converted to the desired 3-aryl-4,5-polymethylene-substituted isoxazoles (**12a—e**). The yields of the 2-isoxazolines **11a—e** and the isoxazoles **12a—e** are listed in Table 1. The structures of **11a—e** and the **12a—e** were unequivocally assigned on the basis of the physical data (see Experimental section). According to the procedure employed in our related studies,[7] the reaction of the isoxazoles **12** (1 mmol) with dimethyl acetylenedicarboxylate (DMAD, 2 mmol) in the presence of $[Mo(CO)_6]$ (1 mmol) afforded [*n*](2,5)pyridinophane derivatives (**13a—e**). Although the yields of **13a—e** are only 5—11% (Table 1), no other product is isolated except for hexamethyl benzenehexacarboxylate (*ca.* a 10% yield based on the DMAD used), which results from the $[Mo(CO)_6]$-induced trimerization of DMAD.[7]

The formation of **13a—e** can be best explained by the reaction pathways shown in Scheme 3.[7] The initial stage of this reaction would be the coordination of $[Mo(CO)_5]$ on the nitrogen atom of the isoxazole **12**, leading to **14**. In **14**, there may be a delocalization of the d-electron from the molybdenum atom to the π^* (LUMO) of the isoxazole moiety.[9] In the presence of DMAD, the C-5-atom of **14** may connect with DMAD to give **15**, the following cyclization would afford the propellane-type[3] intermediate **16**. The facile N-O bond cleavage of the 2-isoxazoline ring has been shown previously.[7,10] Thus, the intermediate **16** undergoes the cleavage of both N-O and C-4-C-5 bonds to give the complexed vinylnitrene **17**.[11] The cyclization of **17** to lead to **18**[7,12] and the subsequent decomplexation eliminating CO_2 and $[Mo(CO)_4]$ result in the formation of the [*n*](2,5)pyridinophane derivatives **13a—e**.

The structures of **13a—e** were determined on the basis of the elemental analyses and the mass, IR, ^{1}H-NMR, ^{13}C-NMR, and UV spectra (see Experimental section). Considering the ^{1}H-NMR spectra, several protons of the methylene chain appear at δ 0.60—0.95 (10H) for **13a**, at δ 0.10—2.10 (12H) for **13b**, at δ 0.20—2.20 (10H) for **13c**, at δ 0.45—0.98 (4H) for **13d**, and at δ 0.40—0.80 (4H) for **13e**. These protons located over the face of the corresponding pyridine ring. The shielding effect can be exactly attributed to the aromatic ring current of the pyridine ring. However, the degree of the shielding effect for the methylene chain in **13a** and **13b** seems to be smaller than that of [*n*](2,5)pyridinopane **4**.[4] In compound **4**, the high-field signals appear at δ 0.2—2.2 (16H) for **4** (n=10) and at δ −0.40—1.85 (12H) for **4** (n=8). Thus, it can be suggested the two methoxycarbonyl groups on the pyridine ring of **13** reduce the ring current. Furthermore, **13d** exhibits a signal at δ 3.30 (1H, J_{jem}=12.0 Hz, J_{vic}=6.0 Hz). The signal could be assigned to the H_α proton (Fig. 1), which is located in the deshielding region of the phenyl group. A similar characteristic is observed in **13e**. This fact suggests that the [6](2,5)pyridinophane derivatives

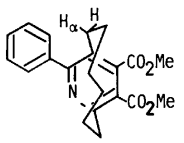

Fig. 1.

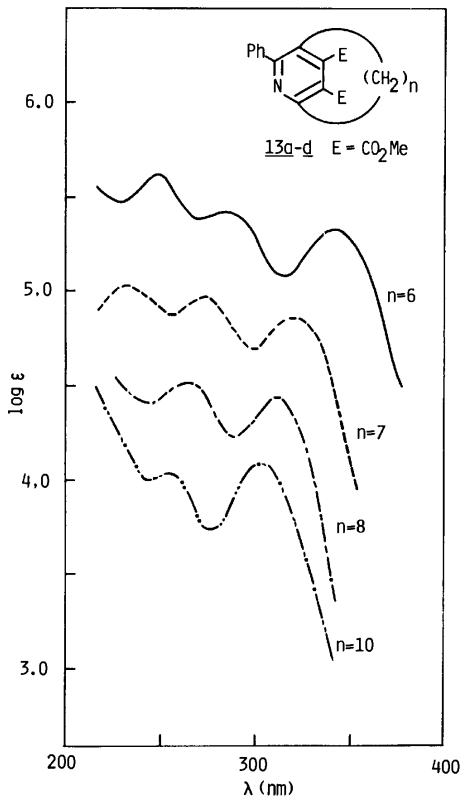

Fig. 2. UV spectra of the [n](2,5)pyridinophanes **13a—d** in absolute ethanol.
The curves are displayed upward successively by 0.5 log unit from the curve immediately below.

13d, **e** have rather rigid structures. The ^{13}C-NMR of the **13a—e** series are similar to each other, and the ring-current effect for the methylene chain seems to be negligibly small. The ring-current effect for the chemical shift of ^{13}C-NMR is not a predominant factor and often overwhelmed by a steric compression.[13]

The UV spectra of **13a—d** in ethanol are depicted in Fig. 2. The absorption maxima of [n](2,5)pyridinophane **13a—d**, **4**, and a series of [n]paracyclophane **1** along with the model compounds, 2-methyl-3,4-bis(methoxycarbonyl)-6-phenylpyridine (**19**)[7] and 1,4-diethylbenzene (**20**),[3c] are also summarized in Table 2. The significant ring strain of the [n](2,5)pyridinophane derivatives **13a—d** is reflected in the UV spectra. An increase in the red shift is observed for **13—d** as the value of [n] decreases. Since the absorption maximum of **13a** is very similar to that of **19**, **13a** seems to contain a planar and less-constrained pyridine ring. In contrast, the longest absorption maxima of **13d** and **13e**, both of which have the smallest value of [n] in the **13** series are exactly shifted to wavelength longer by 40 and 43 nm respectively as compared to **13a**. These features are in good agreement with those observed in the series of the [n]paracyclophanes **1**[3c,d] and the [n](2,5)pyridinophanes **4**.[4] Therefore, these can be no doubt that the [n](2,5)pyridinophanes **13d** and **13e** contain one of the most deformed pyridine ring thus far obtained.

Experimental

The IR spectra were recorded on a Shimadzu IR-400 spectrometer. The ^{1}H-NMR spectra were recorded on a Hitachi R-24 (60 MHz) spectrometer, and the chemical shifts are given in ppm (δ) relative to an internal $SiMe_4$ standard. The ^{13}C-NMR spectra were recorded on a JMN-FX90Q (22.5 MHz) spectrometer. The mass-spectral studies were conducted on a Shimadzu GCMS QP-1000 spectrom-

eter at 70 eV. All of the melting points are uncorrected. The solvents were dried and purified by the standard methods. The enamines, 1-(1-pyrrolidinyl)cyclododecene (**10a**),[14] 1-pyrrolidino-1-cyclodecene (**10b**),[14] 1-pyrrolidino-1-cyclononene (**10c**),[15] and 1-pyrrolidino-1-cyclooctene (**10d**),[15] were prepared by the method described in the literature. Benzohydroximoyl chloride and 4-chlorobenzohydroximoyl chloride were also obtained by the standard method.[16]

General Procedure for the Synthesis of 2-Isoxazolines ***11a—e.*** A solution of enamine **10** (30 mmol) and triethylamine (5 cm^3) in ether (200 cm^3) was cooled at 0 °C. To this solution we then slowly added a solution of benzohydroximoyl chloride (30 mmol) in ether (30 cm^3). The reaction mixture was stirred at 0 °C for 6 h, and then it was poured into water (100 cm^3). The ether layer was separated, washed with water, and dried over $MgSO_4$. The ether was removed *in vacuo* to give the 2-isoxazolines **11a—e**.

Compounds **11a**, **b**, **d**, and **11e** were purified by recrystallization to give colorless crystals. Compound **11c** was obtained as a colorless oil and decomposed on distillation [*ca.* 120 °C (bath temp)/667 Pa]. Therefore, **11c** was purified by column chromatography on silica gel using benzene as the eluent and submitted to the next step. The structures of **11a—e** were determined on the basis of the following physical data. For **11a**: mp 78—79 °C (from hexane); IR ($CHCl_3$), 2920, 1451, 1343, 1130 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.20—2.45 (24H, m), 2.40—3.05 (4H, m), 3.10—3.55 (1H, m), 7.20—7.70 (5H, m). Found: C, 77.98; H, 9.75; N, 7.72%. Calcd for $C_{23}H_{34}N_2O$: C, 77.92; H, 9.67; N, 7.90%. For **11b**: mp 115—116 °C (from hexane); IR ($CHCl_3$), 2923, 1605, 1574, 1492, 1453, 1358, 1134 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.10—2.50 (20H, m), 2.50—3.10 (4H, m), 3.12—3.41 (1H, m), 7.18—7.70 (5H, m). Found: C, 77.05; H, 8.99; N, 8.52%. Calcd for $C_{21}H_{30}N_2O$: C, 77.25; H, 9.26; N, 8.58%. For **11c**: colorless oil; IR ($CHCl_3$), 2923, 1605, 1574, 1492, 1453, 1358, 1132 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.20—2.25 (18H, m), 2.25—3.00 (4H, m), 3.10—3.35 (1H, m), 7.20—7.80 (5H, m). For **11d**: mp 126—128 °C (from hexane); IR ($CHCl_3$), 2928, 2857, 1449, 1349, 1328, 1250 cm^{-1}; ^{1}H-NMR ($CDCl_3$), δ=1.40—2.40 (16H, m), 2.45—2.95 (4H, m), 3.10—3.35 (1H, m), 7.30—7.68 (5H, m). Found: C, 76.53; H, 8.85; N, 9.30%. Calcd for $C_{19}H_{26}N_2O$: C, 76.47; H, 8.78; N, 9.39%. For **11e**: mp 128—129 °C (from hexane); IR ($CHCl_3$), 2923, 2808, 1594, 1494, 1402, 1338, 1090, 1011 cm^{-1}; ^{1}H-NMR ($CDCl_3$), δ=1.10—2.40 (16H, m), 2.40—2.90 (4H, m), 3.10—3.30 (1H, m), 7.32 (2H, d, J=8.6 Hz), 7.60 (2H, d, J=8.6 Hz). Found: C, 68.41; H, 7.49; N, 8.42%. Calcd for $C_{19}H_{25}N_2OCl$: C, 68.56; H, 7.57; N. 8.42%.

General Procedure for the Synthesis of Isoxazoles ***12a—e.*** A solution of the 2-isoxazoline **11** (10 mmol) in methanol (25 cm^3) and concentrated HCl (45 cm^3) was refluxed for 1 h. The solution was then neutralized with aqueous NaOH and extracted with benzene. The benzene extract was washed with water and dried over Na_2SO_4. After the benzene had been evaporated, the residue was purified by recrystallization or distillation to give the isoxazoles **12a—e**. **12a**: mp 38—39 °C (from hexane); IR (CCl_4), 2915, 2865, 1620, 1468, 1445, 1410 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.20—2.10 (16H, m), 2.50—3.00 (4H, m), 7.30—7.80 (5H, m); MS, *m/z* (rel intensity), 283 (M^+, 100). Found: C, 80.28; H, 8.79; N, 4.88%. Calcd for $C_{19}H_{25}NO$: C, 80.52; H, 8.89; N, 4.94%. **12b**: bp 128 °C/132 Pa; IR (film), 2923, 1618, 1582, 1473, 1447, 1414, 1335, 1273, 1131 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.05—2.10 (12H, m), 2.45—3.00 (4H, m), 7.15—7.65 (5H, m); MS, *m/z* (rel intensity), 255 (M^+, 14), 77 (100). Found: C, 79.65; H, 8.38; N, 5.38%. Calcd for $C_{17}H_{21}NO$: C, 79.96; H, 8.29; N, 5.49%. **12c**: bp 120—125 °C/132 Pa; IR ($CHCl_3$), 2911, 1620, 1583, 1465, 1445, 1418, 1353, 1283, 1205 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.18—2.05 (10H, m), 2.40—2.70 (2H, m), 2.73—3.00 (2H, m), 7.30—7.75 (5H, m); MS, *m/z* (rel intensity), 241 (M^+, 53), 77 (100). Found: C, 79.67; H, 7.78; N, 5.52%. Calcd for $C_{16}H_{19}NO$: C, 79.63; H, 7.94; N, 5.80%. **12d**: mp 54—55 °C (from hexane); IR ($CHCl_3$), 2932, 2857, 1594, 1584, 1449, 1418, 1351, 1261, 1126, 1071, 1010 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.35—2.05 (8H, m), 2.40—2.75 (2H, m), 2.75—3.10 (2H, m), 7.22—7.70 (5H, m); MS *m/z* (rel intensity), 227 (M^+, 100). General Procedure for the Synthesis of [n](2,5)Pyridinophanes ***13a—e.*** A solution of the isoxazole **12** (1 mmol), [$Mo(CO)_6$] (1 mmol), and DMAD (2 mmol) in benzene (10 cm^3) was refluxed for 24 h under dry-nitrogen atmosphere. After hexane (10 cm^3) was added to the reaction mixture, it was filtered through Celite to remove insoluble material. The filtrate was concentrated, and the resulting residue was separated by TLC on silica gel using benzene as the developer to give the [*n*](2,5)pyridinophane derivatives **13a—e** and hexamethyl benzenehexacarboxylate (*ca.* 10% yield in each case based on the DMAD used). The UV spectra of **13a—d** are displayed in Fig. 2, while absorption maxima are summarized in Table 3. **13a**: bp 150 °C (bath temp)/66 Pa; IR ($CHCl_3$), 1729 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=0.60—0.95 (10H, m), 1.00—2.06 (6H, m), 2.83—3.35 (4H, m), 3.88 (3H, s), 3.90 (3H, s), 7.30—7.75 (5H, m); ^{13}C-NMR ($CDCl_3$) δ=24.4, 25.9, 26.5, 26.6, 27.2, 27.4, 27.6, 27.7, 28.2, 35.2 (methylene chain), 52.4 (methoxyl groups), 128.4, 128.7, 129.7, 139.8, 142.4, 158.4, 161.3, 167.1, 167.7 (aromatic rings and carbonyls); MS, *m/z* (rel intensity), 409 (M^+, 38), 350 (100). Versatile Synthesis of Dialkyl Cyclopropylphosphonates *via* Reductive Phosphonation

Toshikazu HIRAO,* Masahiko HAGIHARA, and Toshio AGAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, 2-1 Yamadaoka, Suita, Osaka 565
(Received June 10, 1985)

Reductive phosphonation of *gem*-dibromocyclopropanes was accomplished by the reaction with trialkyl phosphites, triethylamine, and water affording dialkyl cyclopropylphosphonates. This unique transformation proceeds by the virtue of trialkyl phosphites and dialkyl phosphonates.

The development of new routes for carbon–phosphorus bond formation is required for the synthetic utility of organophosphorus compounds. From this point of view, we have disclosed the palladium(0)-catalyzed phosphonation[1] as the necessary complement of carbon–phosphorus bond formation because the Arbuzov or Michaelis-Becker reaction is not generally applicable to the synthesis of alkenylphosphonates or arylphosphonates. Cyclopropylphosphonates are known as another class of less readily obtainable compounds due to the difficulty of nucleophilic displacement on a cyclopropane ring. In the course of our investigation[2,3] on reduction with dialkyl phosphonates (commercially named, dialkyl phosphites), we found a novel reductive phosphonation of *gem*-dibromocyclopropanes to give dialkyl cyclopropylphosphonates.[4] The present paper describes details of this methodology.

Results and Discussion

Treatment of the *gem*-dibromocyclopropanes **1** with triethyl phosphite in the presence of triethylamine and water at 90 °C gave mixtures of diethyl *cis*- and *trans*-cyclopropylphosphonates **2**. The

a) Reaction temperature, 90 °C. b) *cis*:*trans*=1. c) *endo*:*exo*=1. d) EtOH (2 equiv.) was used instead of water. e) Diethyl *trans*-3-phenyl-2-propenylphosphonate (**5c**, 11%) and *trans*-3-ethoxy-1-phenyl-1-propene (**6c**, <1%) were produced as by-products. f) **1i** was recovered.

simultaneous reduction took place with phosphonation on a cyclopropane ring (reductive phosphonation). The *gem*-dibromocyclopropanes **1** were recovered almost quantitatively in the reaction without water, indicating that this method differentiates from the Arbuzov phosphonation. The molar ratio of reactants is a dominant factor for the successful results of this reductive phosphonation as shown in Table. The presence of a large quantity of water caused the preferential reduction of the *gem*-dibromocyclopropanes **1** into the corresponding monobromocyclopropanes **3** (runs 3 and 7). The formation of **3** is explained by the reduction of **1** with diethyl phosphonate and triethylamine as reported previously[2] because triethyl phosphite is considered to be hydrolyzed to diethyl phosphonate with water *in situ*. The increase in the amount of triethylamine lowered the yields of **2** (runs 4 and 8). Reductive phosphonation was efficiently performed in case **1**, triethyl phosphite, triethylamine, and water were used in the molar ratio of 1:4:2:2.

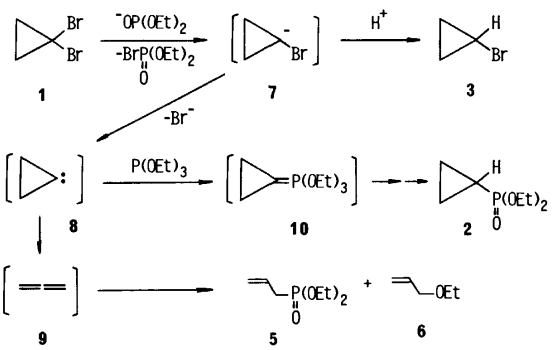
A variety of *gem*-dibromocyclopropanes were converted to **2** (Table). However, starting from *gem*-dibromocyclopropanes with an electron-withdrawing group such as ethoxycarbonyl or cyano group, reduction to the corresponding monobromocyclopropanes occurred exclusively (runs 19 and 20), maybe due to their susceptibility to reduction with diethyl phosphonate and triethylamine even at room temperature.[2] 1,1-Dichloro-2-phenylcyclopropane (**1i**) was not subjected to phosphonation under the conditions employed here (run 21). Use of triisopropyl phosphite yielded the corresponding diisopropyl cyclopropylphosphonate **4**. It should be noted that the formation of by-products (the cinnamylphosphonate and cinnamyl ether derivatives) was extremely depressed as compared to the reaction of **1c** with triethyl phosphite (runs 12 and 17).

The above-mentioned phosphonation seemed curious since diethyl phosphonate present *in situ* can reduce the *gem*-dibromocyclopropanes **1** to the monobromocyclopropanes **3** predominantly. One might consider that **3** intervenes as an intermediate capable of undergoing the Arbuzov phosphonation with triethyl phosphite. The independently prepared 1-bromo-2-phenylcyclopropane (**3c**), however, was not converted to the phosphonate **2c** on treatment with triethyl phosphite (4 equiv.) or with a mixture of triethyl phosphite (4 equiv.), triethylamine (2 equiv.), and water (2 equiv.) at 90 °C for 60 h. On the other hand, the reaction of 7,7-dibromonorcarane (**1b**) with triethyl phosphite, diethyl phosphonate, and triethylamine gave the corresponding cyclopropylphosphonate **2b**. This evidence implies that diethyl phosphonate plays an important role in the phosphonation reaction. Use of ethanol instead of water scarcely caused the present transformation because triethyl phosphite was not hydrolyzed to diethyl phosphonate in the absence of water (run 11).

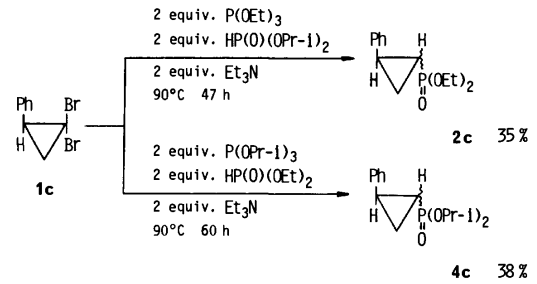
As mentioned above, the cinnamyl derivatives were obtained as by-products (run 12), which are assumed to be resulted from the addition of diethyl phosphonate or ethanol to phenylallene. The allene formation is considered to be derived from 2-phenylcyclopropylidene intermediate. Ring cleavage occurred almost selectively in phosphonation of 1,1-dibromo-2,2-diphenylcyclopropane (**1j**), giving diethyl 3,3-diphenyl-2-propenylphosphonate (**5j**) and 3-ethoxy-1,1-diphenyl-1-propene (**6j**) together with a small amount of the cyclopropylphosphonate **2j**.

The reaction path to the cyclopropylphosphonate **2** might be postulated as depicted in the following scheme. The *gem*-dibromocyclopropane **1** undergoes debromination with the generated anion of diethyl phosphonate giving the carbanion **7**. Diethyl phosphonate is converted to diethyl phosphorobromidate and its degradation accompanies the deposition of $Et_3N \cdot HBr$.[2] Protonation of **7** with diethyl phosphonate or water gives the monobromocyclopropane **3**, which is consistent with reduction with diethyl phosphonate and triethylamine.[2] Elimination of Br^- from **7** results in the generation of the cyclopropylidene **8**. Prior to ring cleavage into the allene **9**, **8** is assumed to interact with triethyl phosphite to afford the ylide **10**. It is conceivable that the degradation of **10** completes the route to the cyclopropylphosphonate **2**.

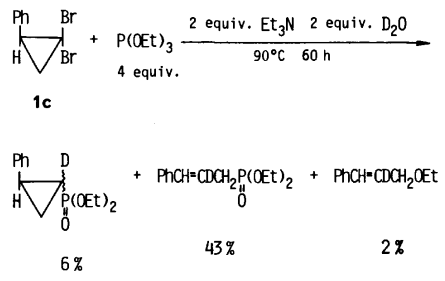
Another possibility is proposed that **8** is subjected to α-addition of diethyl phosphonate, but excluded



by the following observations. Treatment of **1c** with triethyl phosphite, diisopropyl phosphonate, and triethylamine gave the diethyl cyclopropylphosphonate **2c** exclusively. The formation of the diisopropyl cyclopropylphosphonate **4c** was not detected by GLC. The reverse combination of triisopropyl phosphite and diethyl phosphonate led to the exclusive formation of the diisopropyl cyclopropylphosphonate **4c**. These results support that the agent participating in carbon–phosphorus bond formation is trialkyl phosphite.



The α-proton of **2** is essentially derived from water, which was ascertained by the deuterium introduction (>90%) in the reaction of **1b** with deuterium oxide. In the case of **1c**, however, use of deuterium oxide changed the reaction course. Ring-opening phosphonation occurred predominantly producing diethyl 3-phenyl-2-propenyl-2-*d*-phosphonate.



Preparation of cyclopropylphosphonates is not easily accessible because dialkyl diazomethylphosphonates commonly used for their synthesis[5] are potentially carcinogenic and explosive. The present method provides a facile synthesis of dialkyl cyclopropylphosphonates under the mild reaction conditions.

Experimental

IR spectra were taken on a JASCO IRA-1 spectrometer. NMR spectra were obtained on a JEOL JNM FX-90Q spectrometer with tetramethylsilane as an internal standard. Mass spectrometry was performed with Hitachi RMU-6E and JEOL JMS-DX 300 (high resolution) spectrometers.

Materials. *gem*-Dibromocyclopropanes were prepared according to the common method using a phase-transfer catalyst.[6] Trialkyl phosphites and dialkyl phosphonates were purified by distillation.

General Procedure for the Preparation of Dialkyl Cyclopropylphosphonates (2 or 4). To the *gem*-dibromocyclopropane **1** (5.0 mmol) were added trialkyl phosphite (20 mmol), triethylamine (10 mmol), and water (10 mmol) successively. The mixture was stirred at 90 °C for 25—60 h. During the reaction, the white precipitate ($Et_3N \cdot HBr$) separated. After the consumption of **1**, the salt was filtered off and washed with benzene (3×10 mL). The filtrate and washings were evaporated *in vacuo* and the residue was flash column chromatographed to give a mixture of dialkyl *cis*- and *trans*-cyclopropylphosphonates **2** or **4**. Further purification was done by distillation or rechromatography. These results are summarized in Table.

In the preparation of diethyl 2-phenylcyclopropylphosphonate (**2c**), diethyl *trans*-3-phenyl-2-propenylphosphonate (**5c**, 11%) and *trans*-3-ethoxy-1-phenyl-1-propene (**6c**, <1%) were obtained as by-products, which were purified by GLC (conditions: PEG 20 M column, 200 °C) after flash column chromatography.

Phosphonation with Trialkyl Phosphite and Dialkyl Phosphonate. To the *gem*-dibromocyclopropane **1** (5.0 mmol) were added trialkyl phosphite (10 mmol), dialkyl phosphonate (10 mmol), and triethylamine (10 mmol). The mixture was stirred at 90 °C for 47—60 h. Workup was carried out as mentioned above to give **2** or **4**. Yields were shown in the equation or scheme. The selectivity was checked by GLC (conditions: PEG 20 M column, 200 °C).

Phosphonation in the Presence of D_2O. To the *gem*-dibromocyclopropane **1** (5.0 mmol) were added triethyl phosphite (20 mmol), triethylamine (10 mmol), and D_2O (10 mmol). The mixture was stirred at 90 °C for 60 h. Workup and isolation of products were done as mentioned above. Starting from **1b**, the corresponding α-deuteriocyclopropylphosphonate was obtained in 27% yield. Diethyl 2-phenylcyclopropyl-1-*d*-phosphonate (6%), diethyl 3-phenyl-2-propenyl-2-*d*-phosphonate (43%), and 3-ethoxy-1-phenyl-2-*d*-1-propene (2%) were obtained in the phosphonation reaction of **1c**. The olefinic geometry was not determined. In every case, the deuterium content was more than 90%.

This work was partially supported by the Grant-in-Aid for Developmental Scientific Research from the Ministry of Education, Science, and Culture.

Aryliminodimagnesium Reagents. IX. The Reaction with Benzophenones. The Mechanism of Coordination and Electron Transfer Processes Distinct from That of Grignard Reaction

Masao Ōkubo
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840
(Received June 10, 1985)

In the reaction of aryliminodimagnesium reagents(ArN(MgBr)$_2$, Ar=C_6H_5, *p*-MeC_6H_4, and *p*-$MeOC_6H_4$) with some *p*-substituted benzophenones, the arylaminyl radicals(ArṄMgBr) derived from the reagents were detected by ESR in low concentrations and identified by computer simulation. From comparison of all the itemized facts characteristic of the reaction with those of Grignard reaction of the same substrates, the mechanisms of initial coordination and electron transfer of the two reactions were distinguished.

Aryliminodimagnesium reagents(ArN(MgBr)$_2$, aryl-IDMg) condense with diaryl ketones.[1,2] When the reagent has *o*-Me group, diarylmethanol is obtained as the sole abnormal product arising from ketyl radical *via* hydrogen abstraction from solvent.[2] In this paper, the identification of arylaminyl radical produced from IDMg reagent in the reaction with *p*-substituted benzophenones will be described first. On the basis of the fact that electron transfer is involved in both IDMg and Grignard[3] reactions with benzophenones, all the facts characteristic of each reaction will be itemized and compared. The distinctive mechanisms, consistent with the respective facts, for the initial processes of the two reactions will be proposed.

Results and Discussion

Identification of Arylaminyl Radicals. The ESR measurements were carried out at room temperature under the conditions similar to those of preparative reactions.[1,2] The benzophenones used are 4,4′-disubstituted ones, the substituents being Me_2N, MeO, Me, and Cl groups. The concentration of unsubstituted and *p*-substituted phenyl-IDMg reagents was 0.02 M[†] and the molar ratio of reagent to substrate was 2:1. The degassed and sealed solutions of reagent and substrate in tetrahydrofuran(THF) were mixed by breaking the seal.[3] The radical concentrations observed in this study were quite lower compared with those observed in the reactions with ArMgBr;[3] a high microwave power and a large modulation width(2.00 G, G=10^{-3} T) were supplied for obtaining the sufficient intensity of signals. The typical spectra obtained in the reactions of 4,4′-bis(dimethylamino)benzophenone with phenyl- and *p*-methoxyphenyl-IDMg are shown in Figs. 1a_1 and 1b_1, respectively. The spectra are incompletely resolved and slightly anisotropic, and the resolution was unimproved by dilution in the evacuated sample cell.

For the analysis of spectra 1a_1 and 1b_1, computor simulation with half width of 3.5 G was carried out by use of Lorentzian curve. The Mg-ketyl of the ketone was prepared by use of Mg-Hg amalgam; its ESR signal, observed under the same conditions of measurement, was simulated and overlapped with the simulated spectra of arylaminyl π-radicals,[4] $C_6H_5\dot{N}X$ and *p*-$MeOC_6H_4\dot{N}X$: The resultant spectra are shown

† 1 M=1 mol dm^{-3}.

in Figs. $1a_2$ and $1b_2$, respectively. In both cases, the remarkable deviations are observed in two areas: The one at the left near to the center and the other near to the right end of each spectrum. The former deviation is ascribed to the slightly different *g*-factor of IDMg-ketyl from that of Mg-ketyl, since the best fits of $1a_2$ and $1b_2$ with $1a_1$ and $1b_1$, respectively, are obtained when the simulated signal of Mg-ketyl is shifted to the lower field by 3.0 G: The difference of *g*-factor originates from the presence of bromine atom combined to Mg atom of IDMg-ketyl. The latter deviation is ascribed to the decay of radicals during the course of scanning.

The spectrum observed in the reaction of the same ketone with *p*-methylphenyl-IDMg was simulated similarly. The values of splitting constans and *g*-factors given in Table 1 are reasonable as compared to those of various types of arylaminyl π-radicals($Ar\dot{N}X$: Ar=*t*-Bu, O-*t*-Bu, and H) reported previously.[5-7] The attempt to observe triplet state at 77 K was unsuccessful: The observed spectra are assignable to the mixtures of arylaminyl($Ar\dot{N}MgBr$) and ketyl ($Ar'_2\dot{C}OMgBr$) radicals interacting, if any, quite weakly with each other.

When the substituent on reagent is fixed, the shape of spectrum remains almost independent of the substituent on substrate, which, however, causes the gradual decrease in the signal strength according to the order: $Me_2N>MeO>Me>H>Cl$.[8] Since no diarylmethanol was detected, the observation implies that the electron-repelling substituent assists the substrate in rate-determining coordination of carbonyl oxygen to Mg atom of reagent and the resultant acceleration of electron transfer leads to the effective condensation(*vide infra*).[2,9]

Mechanistic Distinction between Grignard and IDMg Reactions. The electron transfer from reagent to substrate is involved in pathways for the formation of normal products in the reactions of benzophenone with both ArMgBr(***C***) and $ArN(MgBr)_2$(***N***): This is revealed not only by ESR measurement but also by use of *o*-Me-substituted reagents, which give rise to the increase in yields of abnormal products.[2,3] The coordination of carbonyl oxygen to Mg atom of reagent (or σ-complex formation, process I) due to the strong affinity of magnesium for oxygen, in addition to the subsequent electron transfer (process II), is also common to the two reactions. Accordingly, the itemized facts characteristic of the reactions observed in the previous and present studies (Table 2,

i) Type A includes the reactions which are hardly controllable due to vigorous electron transfer.[9] ii) Ref. 11). iii) See text. iv) 1,1,2,2-Tetraphenylethan-1,2-diol.

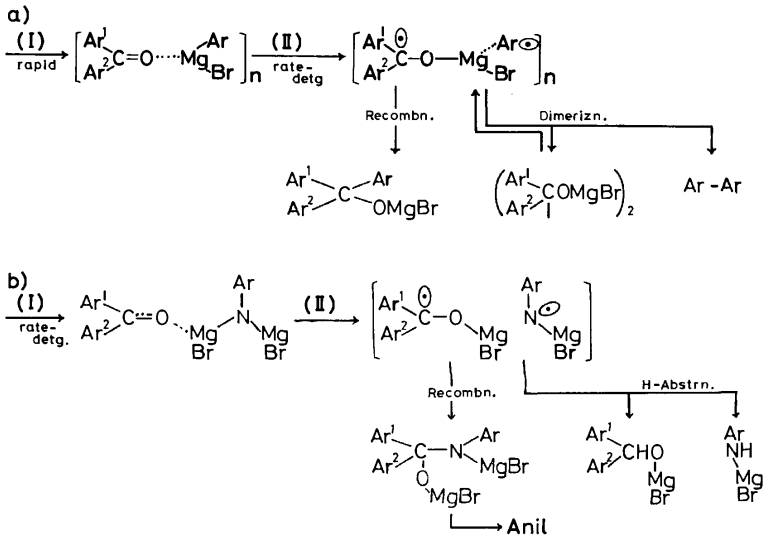
[*a*—*g*]) are helpful in distinguishing the mechanisms from each other.

The fundamental fact for the distinction is that *one of the two initial processes is rate-determining*[g] and the subsequent ones for product formation are not. The rate-determining nature of process II in the reaction of ***C***[g] established by the thermochemical study of Holm[10] was confirmed by acceleration of ketyl formation by *p*-F- and *p*-Cl-substituents on benzophenone[*c*].[3,9] The rate-determining nature of process I in the reaction of ***N***[g] is suggested from the fact that *p*-Me_2N and *p*-MeO substituents on benzophenone favor the formation of products[*c*],[2,9] and is verified by the substituent effect on radical concentration. The rate-determining process moves between I and II depending on the electron-donating abilities(EDA) of reagents:[9] The weaker EDA of ***N*** than that of ***C***[*e*] is estimated by polarographic measurement of oxidation potentials.[11] On this basis, the mechanism of initial processes leading to the *monomeric* diarylmethanol in IDMg reaction is distinguished from that leading to the *dimeric* 1,1,2,2-tetraphenylethan-1,2-diol(TPE-diol) in Grignard reaction[*d*].

Since process II of the reaction of ***C*** is rate-determining, process I proceeds rapidly but incompletely. The "incomplete coordination" is substantiated by considering the two previous observations: The oligomeric aggregation of reagent molecules in the presence of oxygen-containing substances[12] and the presence of equilibrium between Grignard-ketyl and Mg–TPE–diolate[3,13] (Scheme 1a). The aggregation is best ascribed to the prior interaction of benzophenone molecules with ***C*** having strong EDA[*e*], and *the electron transfer from aggregated reagent molecules* give rise to production of Grignard-ketyls in the neighborhood of each other. This favors the formation of Mg–TPE–diolate[*d*], the equilibration with it being responsible for the ESR observation of long-lived Grignard-ketyl in moderately high concentration[*f*]. Aryl radicals, produced inside the reagent aggregate, are hardly observable by ESR[*f*] due to the favorable formation of biaryl[*d*] and also probably due to the delocalization of unpaired electrons in the aggregate.

In the reaction of ***N***, process II proceeds after the rate-determining σ-complex formation (process I) has been at least nearly completed[g]. The complex formation assists the substrate in lowering its HOMO and LUMO energy levels[8,14] and accepting electrons from ***N*** having weak EDA[*e*]. From the "complete σ-complex" surrounded by solvent molecules, both IDMg–ketyl and arylaminyl radicals are produced in monomeric states: They are thus short-lived and detectable in quite low concentration[*f*]. Most part of the two kinds of radicals recombine with each other leading to the formation of anil[1,2] (Scheme 1b), but a part of them abstracts hydrogen from solvent[*d*] especially when the radical recombination is retarded by *o*-Me substituent.[2]

The essential roles of processes I and II in the reactions of ***N*** and ***C***, respectively, are exemplified by the distinctive behaviors of the reagents towards sterically hindered 2,3,5,6-tetramethylbenzophenone. On the treatment with ***N***, neither ESR signal nor coloration of the mixture indicative of σ-complex formation is observed and the ketone is recovered unchanged. On the treatment with ***C***, in contrast, the ketyl accumulates gradually up to a very high concentration.[3] Whereas ***N*** having weak EDA is unable to transfer electrons *because the σ-complex formation is inhibited,* ***C*** having strong EDA transfers electrons *even though the coordination is incomplete.* The previous postulate on the possibility of produc-



Scheme 1.

tion of "benzophenone anion radical" prior to the O–Mg bond formation in the reaction of ***C*** resembles the discussion given above. However, the aggregate formation, supposed in the earliest paper on Grignard-ketyls,[16] is verified to be essential in the reaction of ***C*** due to its strong EDA.

Experimental

Materials and Procedures. Benzophenone and aniline as well as their substituted derivatives were commercially available, and were purified by recrystallization or distillation if necessary. The preparation of stock solutions of reagents[1] and ESR measurements[3,16] were carried out according to the reported procedures.

The author wishes to express his gratitude to Professor Kazuhiko Ishizu, Ehime University, for helpful discussion. He also wishes to thank Dr. Noboru Takisawa and Mr. Toshiki Tsutsumi, Saga University, for computer simulation of ESR spectra.

Isolation and Structures of Euphohelins, New Toxic Diterpenes from *Euphorbia Helioscopia* L.

Seiji KOSEMURA, Yoshikazu SHIZURI, and Shosuke YAMAMURA*
Department of Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
(Received June 12, 1985)

Five new toxic diterpenes, euphohelins A, B, C, D, and E, have been isolated from the plant *Euphorbia helioscopia* L., and their stereostructures have also been elucidated on the basis of their spectral data coupled with some chemical evidence: euphornin, the known toxic diterpene, has been successfully converted into euphohelin A.

In connection with highly-oxygenated diterpenes which have antitumor activity or promote cancer development in tumor formation, we examined toxic substances of the plants *Euphorbiaceae* and could isolate euphoscopin A (**1**),[1,2] euphornin (**2**),[3] euphohelioscopin A (**3**),[2] euphohelionone (**4**),[4] and others from the plant *Euphorbia helioscopia* L. (Todai-Gusa in Japanese), as seen in Fig. 1. Further investigation of toxic compounds in the same plant resulted in the isolation of five new diterpenes, euphohelins A, B, C, D, and E (**5**, **6**, **7**, **8**, and **9**) in addition to the known diterpenes (**1**, **2**, and **3**) and others.[1-3]

Isolation of Euphohelins A, B, C, D, and E. Fresh leaves and roots of the plant *Euphorbia helioscopia* L. collected in Kanagawa Prefecture in the middle of June were immersed in methanol at room temperature, and then the methanol extract was concentrated and shaken with ethyl acetate. The ethyl acetate extract was partitioned between 90% aqueous methanol and "isooctane". The methanol extract was roughly separated by column chromatography [silica gel (Merck 7734)] using a gradient solution of hexane and ethyl acetate. The fraction eluted only with ethyl acetate was further separated by repeating preparative TLC (Kieselgen PF_{254}) using hexane–ethyl acetate

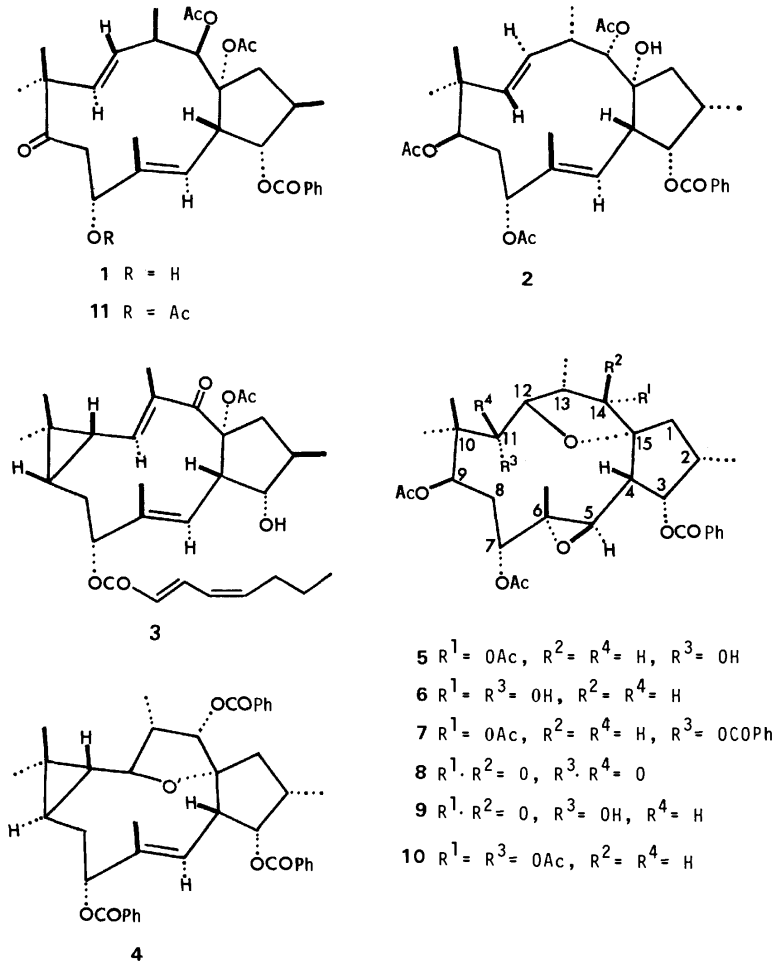

Fig. 1. Toxic diterpenes from *Euphorbia helioscopia* L.

* Overlapped with other signals.

(2:1) to afford euphohelins A, B, C, D, and E (**5**, **6**, **7**, **8**, and **9**) in 0.038, 0.0035, 0.021, 0.061, and 0.0042% yields, based on the weight of the methanol extract, respectively, in addition to the known diterpenes.[1-3] The structure of these newly isolated diterpenes, which are shown in Fig. 1, have been unambiguously determined on the basis of their spectral data coupled with some chemical evidence.

The Structure of Euphohelin A (5). Euphohelin A with a molecular formula $C_{33}H_{44}O_{11}$ has the IR absorption bands at 3500, 1730, 1600, and 1580 cm^{-1}, and its ^1H and ^{13}C NMR spectral data are described in Tables 1 and 2. As seen in Table 1, euphohelin A (**5**) has one benzoyloxyl group [δ 7.41—7.53 (3H), 8.20—8.25 (2H)], three acetoxyl groups [δ 1.42 (C^7-OAc), 2.01 (C^9-OAc), 2.16 (C^{14}-OAc)] and five methyls [δ 0.93 (6H, s), 1.07 (3H, d, J=6.5 Hz), 1.09 (3H, d, J=7.2 Hz), 1.36 (3H, s)]. As judged from Table 2, furthermore, euphohelin A is regarded as a tetracyclic diterpene, because it has no sp^2 carbon atom except for ten sp^2 carbon atoms included in one benzoyloxyl and three acetoxyl groups. In addition, one of the four rings must be a trisubstituted epoxide ring on the basis of a gated decoupling experiment at δ 56.0 together with selected decoupling ones: the doublet at δ 56.0 due to the C^5 carbon atom, which has a characteristically large $^1J_{C\text{-}H}$ (178.8 Hz), is coupled with the proton (C^5-H) (δ 3.66). As seen in Table 1 and Fig. 2, a detailed analysis of the ^1H NMR spectrum of euphohelin A (**5**) by homonuclear spin decoupling experiments indicated the presence of partial structures [A], [B], and [C] and three tertiary methyls. In addition, euphohelin A has one secondary hydroxyl group, which is accommodated in [C] on the basis of the following observation: on acetylation of euphohelin A (**5**) with acetic anhydride–pyridine giving rise to the corresponding acetate (**10**), the doublet at δ 3.30 in **5** was shifted to δ 4.89 in **10**. Another important information about euphohelin A will be obtained from its ^1H NMR spectrum, as follows. One of the methyl singlets due to the three acetoxyl groups in **5** is observed in higher magnetic field (δ 1.42) rather than the remaining ones (δ 2.01

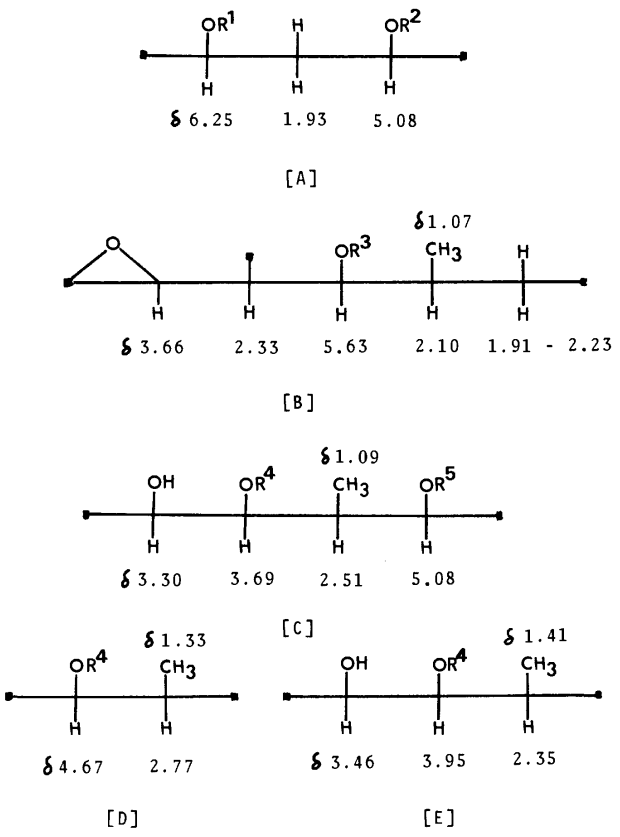
* This signal is assigned tentatively. ** Corresponding to two protons.



■ These are quaternary carbon atoms.

Fig. 2. Partial structures of euphohelins.

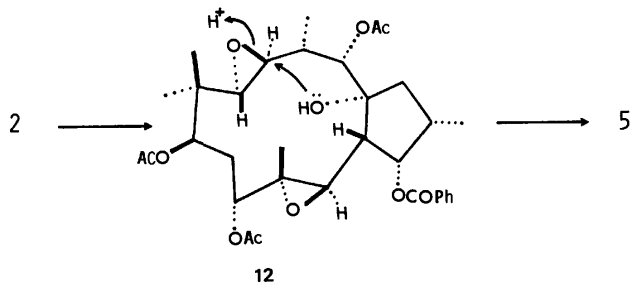


Fig. 3. Chemical conversion of euphornin (**2**) to euphohelin A (**5**).

and 2.16). This may be due to anisotropic effect of the benzoyloxyl group, as seen in the cases of euphornin (**2**)[3] and euphoscopin B (**11**).[1]

In the light of the above-mentioned results together with co-occurrence of euphoscopins A and B (**1** and **11**) and euphornin (**2**) and their ^{1}H NMR spectra, a tentative structure (**5**) is given to euphohelin A except for its stereochemistry (C^2-Me and C^{11}—C^{15}). Finally, the stereostructure of euphohelin A (**5**) was unambiguously determined in connection with euphornin (**2**), as follows.

Fortunately, euphornin (**2**), whose conformation strictly based on an X-ray crystallographic analysis, ^{1}H NMR spectrum, and molecular mechanics calculations,[3] was subjected to epoxidation using *m*-chloroperbenzoic acid in dichloromethane (room temp, 2 d) to give euphohelin A (**5**), 87% yield, through the corresponding diepoxide (**12**), as shown in Fig. 3., wherein one of the two epoxide rings was subsequently attacked by the hydroxyl group at C^{15}-position resulting in the formation of a tetrahydrofuran ring. Thus, the stereostructure of euphohelin A must be depicted as **5**, which is supported by its ^{1}H NMR spectrum: in consideration of the most plausible conformation, in which the acetoxyl group at C^7-position in **5** (δ 1.42) adopts the same situation as that in euphornin (**2**) and related diterpenes (δ 1.27—1.33), the two hydrogen atoms at C^{11}- and C^{12}-positions must be in a trans configuration having dihedral angle of 180° (J=9.0 Hz).

The Structure of Euphohelin B (6). Euphohelin B (**6**) with a molecular formula $C_{31}H_{42}O_{10}$ has the IR absorption bands at 3500, 1720, 1600, and 1580 cm^{-1}, and its ^{1}H NMR spectral data is also cited in Table 1. On a detailed comparison of the ^{1}H NMR spectra between euphohelins A and B, the NMR signal at δ 5.08 due to the proton (AcO-C^{14}-H) in **5** is not found in the latter, but instead a doublet is newly observed at δ 4.06, suggesting that euphohelin B (**6**) is a deacetyl derivative of euphohelin A (**5**) at C^{14}-position. Thus, euphohelin A was subjected to regioselective hydrolysis using one equivalent of KOH in methanol (room temp, 50 min) to afford euphohelin B (**6**) in 90% yield.

The Structure of Euphohelin C (7). Euphohelin C (**7**) has a molecular formula $C_{38}H_{46}O_{11}$ and its ^{1}H NMR spectrum indicates the presence of three acetoxyl and two benzoyloxyl groups. However, the IR spectrum of **7** has no absorption band assignable to a hydroxyl group. As seen in Table 1, the NMR signal at δ 3.30 (HO-C^{11}-H) in euphohelin A (**5**) is also not found in **7**, but instead the corresponding one is observed at δ 5.16, suggesting that euphohelin C has an additional benzoyloxyl group at C^{11}-position because the other corresponding signals are quite similar to one another. Thus, euphohelin A (**5**) was treated with benzoyl chloride in pyridine (room temp, overnight and then 60 °C, 1 h) to afford euphohelin C (**7**) in almost quantitative yield.

The Structure of Euphohelin D (8). The IR and ^{1}H NMR spectra of euphohelin D (**8**) having a molecular formula $C_{31}H_{38}O_{10}$ indicate the presence of one benzoyloxyl group and two acetoxyl groups (see Table 1), and any absorption band due to a hydroxyl group is not found in its IR spectrum. Furthermore, on the basis of detailed proton homonuclear spin decoupling and gated decoupling experiments, euphohelin D (**8**) has a trisubstituted epoxide ring (δ 54.5, $^1J_{C\text{-}H}$=178.8 Hz) and two partial structures [A] and [B], as seen in the case of euphohelin A (**5**). However, euphohelin D (**8**) with two carbonyl groups [δ 208.5 (s) and 217.7 (s)] possesses a partial structure [D] instead of [C] in **5** (see Fig. 2), suggesting that the two carbonyl groups are located at C^{11}- and C^{14}-positions. On Sarett oxidation at room temperature for 6 h, euphohelin B (**6**) was readily converted into euphohelin D (**8**) in 74% yield.

The Structure of Euphohelin E (9). On the basis of the IR and ^{1}H NMR spectra, euphohelin E (**9**) with a molecular formula $C_{31}H_{40}O_{10}$ has one secondary hydroxyl group [IR (film) 3500 cm^{-1}; δ 3.46 (1H, d, J=8.8 Hz)], two acetoxyl groups [δ 1.39 (3H, s) and 2.04 (3H, s)] and one benzoyloxyl group [δ 7.43—7.59 (3H, m) and 8.26—8.31 (2H, m)]. Further detailed proton homonuclear spin decoupling experiments of **9** indicate that it has a partial structure [E] instead of [C] in euphohelin A (**5**), in addition to the known moieties [A] and [B]. Thus, Sarett oxidation of euphohelin B (**6**) was carried out carefully at room temperature for 40 min to give rise to euphohelin E (**9**) in 65% yield, together with euphohelin D (**8**) in 18% yield.

Euphohelins, the highly-oxygenated diterpenes, belong to a small group of jatrophone-type ones,[5] and have been isolated only from the plant *Euphorbia helioscopia* L. collected in the middle of June and not found in April as well as early in May. Finally, from view points of their biogenesis and stereochemistry, it is quite interesting that euphohelins and the known macrocyclic diterpenes (**1**—**4**) co-occur in the same plant.

Experimental

All the melting points were uncorrected. ^1H and ^{13}C NMR spectra were taken on a JEOL JNM-FX 200 (199.5 MHz and 50.1 MHz) spectrometer, using $CDCl_3$ as solvent, unless otherwise stated. Chemical shifts are given in ppm from TMS as an internal standard. Coupling constants are given in Hz (s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet). IR spectra were recorded on a JASCO Model A-202 spectrophotometer. Mass spectra were obtained on a Hitachi M-80 mass spectrometer operating with an ionization energy (70 eV). Optical rotations were taken on a JASCO DIP-360 polarimeter. Preparative and analytical TLC were carried out on Kieselgel 60 PF_{254} (E. Merck A.G. Germany), unless otherwise stated.

Isolation of Euphohelins. Fresh leaves and roots of the plant *Euphorbia helioscopia* L. (*ca.* 5 kg), which were collected at Atsugi in Kanagawa Prefecture in the middle of June, were hashed with a shears and immersed in MeOH (20 L) at room temperature for 2 months, and then filtered. The filtrate was concentrated under reduced pressure below 40 °C to leave a greenish brown oil (*ca.* 110 g) which was partitioned between water and AcOEt. The AcOEt layer was dried over large amounts to anhydrous Na_2SO_4 and then concentrated under reduced pressure to leave a greenish brown oil (28.5 g), which was further partitioned between 90% aq MeOH and isooctane (isooctane layer, *ca.* 8.1 g). The 90% aq MeOH layer was concentrated under reduced pressure to leave a greenish brown oil (*ca.* 20.1 g) which was dissolved in small amounts of MeOH and adsorbed on activated charcoal (*ca.* 30 g), and then eluted with MeOH (1.5 L) and $CHCl_3$ (2.0 L) quickly. The eluate was concentrated under reduced pressure to leave a greenish brown oil (19.5 g) which was roughly separated by column chromatography on silica gel (Merck 7734) (500 g) using a gradient solution of hexane and AcOEt [hexane–AcOEt (5:1) 0.5 L, hexane–AcOEt (3:1) 2 L, AcOEt 2 L] to afford six fractions (Fr. **1**, 400 mg; Fr. **2**, 2200 mg; Fr. **3**, 320 mg; Fr. **4**, 1140 mg; Fr. **5**, 500 mg; Fr. **6**, 420 mg) after removal of the nonpolar fraction containing hydrocarbons using hexane–AcOEt (5:1) (3.5 L). The first fraction was mainly comprised of a lot of hydrocarbons. Analytical TLC of the fraction **2**—**5** using hexane–AcOEt (2:1) showed the spots corresponding to euphoscopins A and B, euphornin, euphohelioscopins A and B, and the related known diterpenes.[1-3] Therefore, further separation of these fractions has not been carried out.

The most polar fraction **6**, which showed several new spots on analytical TLC plate [hexane–AcOEt (2:1)], was separated by preparative TLC using hexane–AcOEt (2:1) to afford euphohelin D (**8**) (97 mg), euphohelin C (**7**) (23 mg), euphohelin E (**9**) (4.6 mg), euphohelin A (**5**) (42 mg), and euphohelin B (**6**) (3.9 mg) in the order of increasing polarity: **8** as a colorless oil: $[\alpha]_D^{27}$ +46.9° (*c* 2.21, $CHCl_3$); IR (film) 1745, 1720, 1600, 1580, and 1245 cm^{-1}; Found: *m/z* 570.2469. Calcd for $C_{31}H_{38}O_{10}$: M, 570.2462. **7** as a colorless oil: $[\alpha]_D^{27}$ +44.6° (*c* 1.24, $CHCl_3$); IR (film) 1740, 1720, 1600, and 1240 cm^{-1}; Found: *m/z* 720.3144. Calcd for $C_{40}H_{48}O_{12}$: M, 720.3143. **9** as a colorless oil: $[\alpha]_D^{27}$ +24.9° (*c* 0.57, $CHCl_3$); IR (film) 3500, 1735, 1720, 1595, 1580, and 1250 cm^{-1}; Found: *m/z* 572.2632. Calcd for $C_{31}H_{40}O_{10}$: M, 572.2619. **5** as a colorless oil: $[\alpha]_D^{27}$ +31.8° (*c* 1.55, $CHCl_3$); IR (film) 3500, 1730, 1600, 1580, and 1240br. cm^{-1}; Found: *m/z* 616.2893. Calcd for $C_{33}H_{44}O_{11}$: M, 616.2880. **6** as a colorless oil: $[\alpha]_D^{27}$ +25.8° (*c* 0.76, $CHCl_3$); IR (film) 3500br., 1720, 1600, 1580, 1275, and 1250 cm^{-1}; Found: *m/z* 574.2752. Calcd for $C_{31}H_{42}O_{10}$: M, 574.2775.

Acetylation of Euphohelin A (5). Euphohelin A (5 mg) was dissolved in Ac_2O (0.3 mL) and pyridine (0.6 mL) at room temperature and allowed to stand at the same temperature overnight. After decomposition of excess Ac_2O with MeOH, the reaction mixture was partitioned between water and AcOEt. The AcOEt layer was dried over anhydrous Na_2SO_4 and then concentrated under reduced pressure to give an oil, which was purified by preparative TLC using hexane–AcOEt (2:1) to afford euphohelin A acetate (**10**) (5.1 mg) as a colorless oil: IR (film) 1740, 1720sh, 1600, 1580. and 1235 cm^{-1}; Found: *m/z* 658.3006. Calcd for $C_{35}H_{46}O_{12}$: M, 658.2987.

Reaction of Euphornin (2) with m-*Chloroperbenzoic Acid.* To a solution of euphornin (11.2 mg) in dry dichloromethane (1 mL) was added, with stirring, *m*-chloroperbenzoic acid (13.1 mg) at room temperature. The reaction mixture was further stirred at room temperature for 2 d, and then diluted with aqueous sodium hydrogensulfite and extracted with AcOEt. The AcOEt extract was dried over anhydrous Na_2SO_4 and concentrated under reduced pressure to leave an oil, which was purified by preparative TLC [hexane–AcOEt (1:1)] to afford euphohelin A (**5**) (10.3 mg) (TLC, IR and ^1H NMR spectra).

Regioselective Hydrolysis of Euphornin A (5). To a solution of euphohelin A (10.5 mg) in MeOH (2 mL) was added, with stirring, a solution of KOH (1 mg) in MeOH (0.1 mL) at room temperature. The reaction solution was further stirred at the same temperature for 50 min. After addition of one drop of AcOH, the reaction solution was partitioned between water and AcOEt. The AcOEt layer was dried over anhydrous Na_2SO_4 and then concentrated under reduced pressure to give a colorless oil which was purified by preparative TLC [hexane–acetone (1:1)] to afford euphohelin B (**6**) (8.8 mg) (TLC, IR, and ^1H NMR spectra).

Reaction of Euphohelin A (5) with Benzoyl Chloride. A solution of euphohelin A (3.1 mg) and benzoyl chloride (1 drop) in pyridine (1 mL) was stirred at room temperature for 24 h, and then at 60 °C for 1 h. After addition of MeOH, the reaction mixture was diluted with water and extracted with AcOEt. The AcOEt solution was dried over anhydrous Na_2SO_4 and concentrated under reduced pressure to leave an oil, which was purified by preparative TLC [hexane–AcOEt (1:1)] to give euphohelin C (**7**) (3.4 mg) (TLC, IR, and ^1H NMR spectra).

Sarett Oxidation of Euphohelin B (6). To a solution of euphohelin B (8.5 mg) in pyridine (0.4 mL) was added, with stirring, excess amounts of CrO_3–pyridine complex. The reaction mixture was further stirred at room temperature for 6 h. The reaction mixture was diluted with small amounts of $CHCl_3$ and chromatographed on silica gel (5 g). Elution with $CHCl_3$ afforded an oil, which was purified by preparative TLC [hexane–AcOEt (1:1)] to give rise to euphohelin D (**8**) as a colorless oil (6.2 mg) (TLC, IR, and ^1H NMR spectra).

Under essentially the same conditions as described above, euphohelin B (8.6 mg) in pyridine (0.6 mL) was also oxi-

dized with excess amounts of CrO_3-pyridine complex at room temperature. However, the oxidation reaction was stopped only in 40 min. According to the above-mentioned procedure, the reaction mixture was chromatographed on silica gel (5 g) and eluted with $CHCl_3$ to give an oil, which was subjected to preparative TLC [hexane–AcOEt (1:1)] to afford euphohelin D (**8**) (1.5 mg) and euphohelin E (**9**) (5.5 mg) [TLC, IR, and ^1H NMR spectra).

This research has been supported in part by grants from the Ministry of Education, Science and Culture as well as from the Foundation for the Promotion of Research on Medicinal Resources, to which grateful acknowledgment is made.

††*Department of Industrial Chemistry, Faculty of Technology, Utsunomiya University, Ishii-cho 2753, Utsunomiya 321*
(Received June 18, 1985)

The pyrolysis of 1,1,2,4,4-pentaphenyl-1,4-butandiol, *trans*-1,2-bis(hydroxydiphenylmethyl)hexane, *trans*-1,2-bis(hydroxydiphenylmethyl)indan, and *cis-endo*- and *trans*-1,2-bis(hydroxydiphenylmethyl)bicyclo[2.2.1]-heptane gave styrene, cyclohexene, indene, and norbornene respectively, accompanied by benzophenone and benzhydrol. The pyrolysis of *trans*-1,2-bis(hydroxydiphenylmethyl)spiro[2.6]nona-4,6,8-triene afforded indene *via* rearrangement to form *trans*-1,2-bis(hydroxydiphenylmethyl)indan. The pyrolysis of *cis*-1,1,4,4-tetraphenyl-2-butene-1,4-diol afforded 2,2,5,5-tetraphenyl-2,5-dihydrofuran. On the other hand, *trans*-1,1,4,4-tetraphenyl-2-butene-1,4-diol afforded 1,2,4,4-tetraphenyl-3-buten-1-one. The mechanisms of these decomposition reactions are discussed.

Generally, vic-dicarboxylic acids (**1**) can be synthesized by Diels-Alder reactions readily and usually in good yields.[1] The introduction of double bonds to such vic-dicarboxylic acids by the elimination of the two carboxyl groups is a useful reaction for the synthesis of many organic compounds. Several types of such reactions have been developed and used as powerful synthetic methods.[2]

It is known that the pyrolysis of benzopinacol (**5**) gives benzophenone (**3**) and benzhydrol (**4**) *via* a disproportionation reaction of the initially formed hydroxydiphenylmethyl radical (**6**).[3] We investigated the application of this decomposition reaction to the preparation of the olefins from **1** in the expectation that 1,1,4,4-tetraphenyl-1,4-butanediol derivatives (**2**), which can be prepared by the Grignard reaction of **1**, would be pyrolyzed to form the olefins eliminating two mole equivalents of **6**, which in turn disproportionates to **3** and **4**. Various types of **2** were synthesized and pyrolyzed. The pyrolysis of several kinds of 1,1,4,4-tetraphenyl-2-butene-1,4-diol derivatives were also investigated. Here, we wish to report on these results.

Preparations of Glycols

The reaction of a cyclohexane derivative (**7**) with phenyllithium afforded the corresponding diketone (**8**) in a 53% yield; this diketone gave *trans*-1,2-bis(hydroxydiphenylmethyl)hexane (**9**) in a 52% yield in a reaction with phenyllithium. *trans*-1,2-Bis(hydroxydiphenylmethyl)indan (**11**) was prepared in a 62% yield by reaction of phenyllithium with indane derivative (**10**).[4] *cis-endo*- and *trans*-5,6-Bis(hydroxydiphenylmethyl)bicyclo[2.2.1]hept-2-ene (**13a** and **13b**) were synthesized in 71 and 87% yields respectively, by reactions of the corresponding diesters (**12a** and **12b**) with phenyllithium. *cis-endo*- and *trans*-1,2-Bis(hydroxydiphenylmethyl)bicyclo[2.2.1]heptane (**14a** and **14b**) were obtained almost quantitatively by catalytic hydrogenations of **13a** and **13b** respectively. *cis-endo*-8,9-Bis(hydroxydiphenylmethyl)tricyclo[3.2.2.$0^{2,4}$]non-2-ene (**17**) was synthesized in a overall yield of 77% from a corresponding diester (**15**) by reaction with phenyllithium *via* the dicarbonyl compound (**16**). *cis*- and *trans*-1,1,4,4-

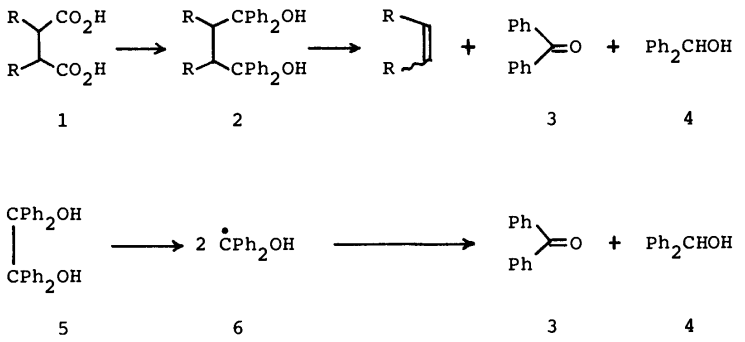

Fig. 1.

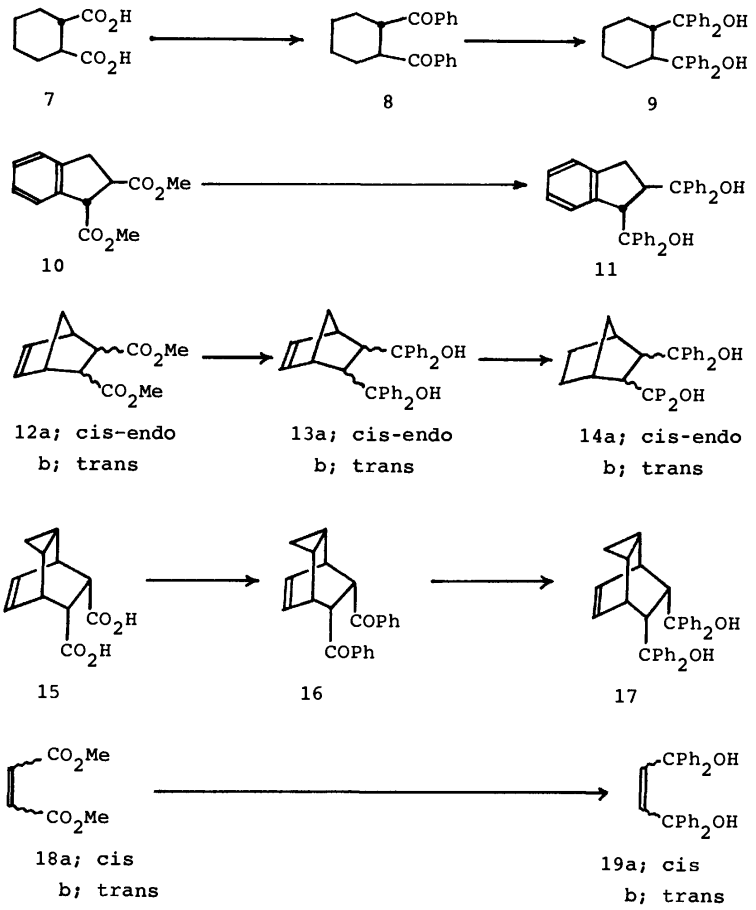

Fig. 2.

Tetraphenyl-2-butene-1,4-diol (**19a** and **19b**) were obtained in 25 and 31% yields respectively by reactions of the corresponding diesters (**18a** and **18b**) with phenyllithium.

1,1,2,4,4-Pentaphenyl-1,4-butandiol (**20**),[5] *trans*-1,2-bis(hydroxydiphenylmethyl)spiro[2.6]nona-4,6,8-triene (**30**),[6] and 1,2-bis(hydroxydiphenylmethyl)benzene (**35**)[7] were synthesized according to the literature.

Pyrolyses

Glycol **20** was pyrolyzed at 250 °C for 2 h to afford styrene (**21**, 40%), together with 1,1,3-triphenyl-1-propane (**22**, 11%), a cyclic ether (**23**, 46%), benzophenone (**3**, 60%), and benzhydrol (**4**, 10%). The pyrolysis of **9** under analogous conditions gave cyclohexene (**24**, 30%) accompanied by a cyclic ether (**25**, 35%), **3** (25%), and **4** (68%). The pyrolysis of **11** gave indene (**26**, 75%), **3** (99%), and **4** (60%). Pyrolysis of *cis-endo*-glycol **14a** afforded norbornene (**27**, 30%), along with a diphenylmethylene derivative (**28**, 37%), a cyclic ether (**29**, 9%), **3** (75%), and **4** (20%); on the other hand, the pyrolysis of *trans*-glycol **14b** gave **27** (27%), **28** (64%), **3** (95%), and **4** (15%). The cyclic ether **29** was not detected. The heating of **30** at 250 °C for 1 h afforded **26** (34%) and **11** (59%),[8] accompanied by **3** (44%) and **4** (26%).

The pyrolysis of *cis-endo*-glycol **13a** yielded cyclopentadiene (**31**, 55%), a cyclic ether **32** (68%), and **19a** (21%); on the other hand, *trans*-glycol **13b** afforded **31** (45%) and a diphenylmethylene derivative (**33**, 44%).[9] The pyrolysis of *cis-endo*-glycol **17** afforded tropylidene (**34**, 80%) and **32** (88%). The pyrolysis of *cis*-glyco **19a** afforded a cyclic ether **32** (53%) and **3** (58%), but *trans*-glycol **19b** gave **33** (45%). The pyrolysis of **35** was carried out at 350 °C in an autoclave, with *t*-butyl alcohol as the solvent, in order to trap benzyne, which was expected to be formed, but resulted in a quantitative formation of a cyclic ether **36**.[7]

Discussion

The mechanism of the formation of the olefins **21**, **24**, **26**, and **27** is considered to be as follows. A bond cleavage of the glycol **2** to form one mole equivalent of **6** gives a radical intermediate **37**, which affords the olefins by eliminating the other mole equivalent of **6**. On the other hand, the dehydration reaction of **2** forms **38**, which gives the diphenylmethylene deriva-

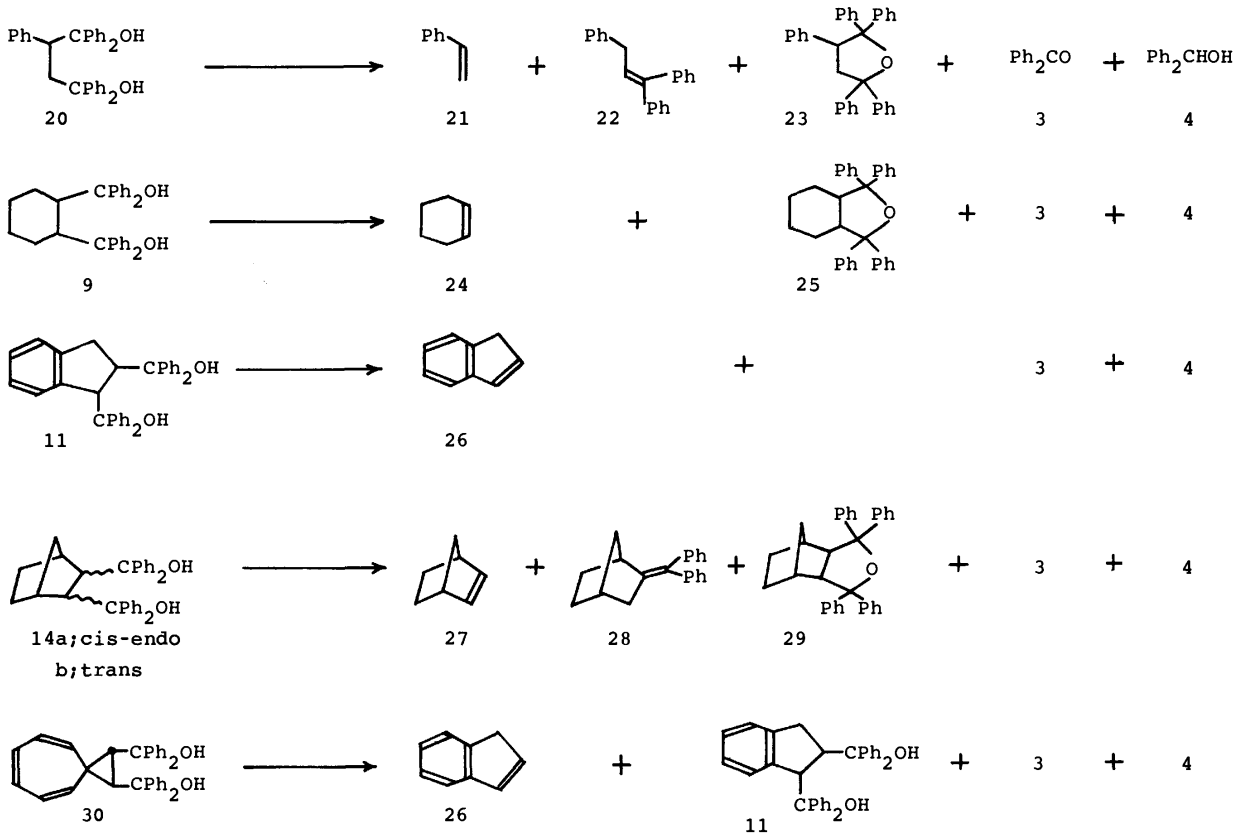

Fig. 3.

tive **39** by eliminating one mole equivalent of **6**.[10]

The formation mechanism of **33** can be considered to be as follows. An O–H bond fission of **19b**, followed by a 1,2-shift of the phenyl group, forms **40**, which gives **33** *via* a dehydration reaction.

The above-mentioned pyrolysis of the 1,2-bis(hydroxydiphenylmethyl) substituted hydrocarbons can be considered to be useful for the synthesis of olefinic compounds, because the desired olefins, styrene (**21**), cyclohexene (**24**), indene (**26**), and norbornene (**27**) are obtained. However, the other desired olefins, spiro[2.6]nonatetraene (**41**),[11] norbornadiene (**42**), and tricyclo[3.2.2.$0^{2,4}$]nonadiene (**43**) could not be obtained from the pyrolysis of **30**, **13**, and **17** respectively.

The spiro compound **30** is considered to have rearranged to **11** before the pyrolysis to afford **41** because of the high temperature.[8] The temperature needed by the pyrolysis seems also to be high enough to cause retro-Diels-Alder reactions in such compounds as **13** and **17**, which have double bonds at positions suitable for retro-Diels-Alder reactions. In order to cause the pyrolysis at lower temperature, pyrolyses of the glycols were also carried out in the presence of several kinds of radical initiators, however, no improvement was observed.

Experimental

All the melting and boiling points are uncorrected. The NMR spectra were measured with a Varian HA-100 or a Hitachi R-20B spectrometer with tetramethylsilane as the internal standard. The mass and IR spectra were recorded with Hitachi M-52 and DS-701G spectrometers respectively. Wako gel C-200 and Wako gel B-5F were used for column and thin-layer chromatography respectively.

All the pyrolysis reactions were carried out under a nitrogen stream without any solvent in a flask connected with three combined traps. The first trap was cooled with an ice-water bath while the second and last ones were cooled with a Dry Ice–acetone bath. Water formed by the dehydration reactions was swept away from the flask by a nitrogen stream and condensed in the first trap. The olefins formed were collected mainly in the second trap.

Preparations of Glycols

Preparation of **9**. A solution of **7** (6.88 g, 40 mmol) in anhydrous tetrahydrofuran (200 ml) was stirred with a solution of phenyllithium (320 mmol) in anhydrous ether (140 ml) at room temperature over a 1 h period. After further stirring at room temperature for 16 h, the reaction mixture was decomposed with water and extracted with ethyl acetate. The organic layer was washed with water and brine, and dried over anhydrous sodium sulfate. After

filtering, the solvent was removed on a rotary evaporator. The colorless residue was chromatographed on silica gel to give colorless crystals **8** (6.19 g, 53%) by the use of pet ether–benzene (3:7). Recrystallization from cyclohexane gave pure crystals of **8**.

8: Mp 115—116 °C. Found: C, 82.05; H, 6.86%. Calcd for $C_{20}H_{20}O_2$: C, 82.16; H, 6.89%. IR (KBr): 3100, 2950, 1670, 1600 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.43 (m, 8H), 3.82 (m, 2H), 7.0—7.5 (m, 10H). Mass *m/z* (rel intensity) 292 (M^+, 6.6), 105 (100), 77 (65).

A solution of **8** (7.70 g, 26 mmol) in anhydrous tetrahydrofuran (180 ml) was added to a solution of phenyllithium (204 mmol) in anhydrous ether (120 ml) at room temperature over a 1 h period and then further stirred for 20 h. The usual workup afforded a colorless tarry material, which was chromatographed on silica gel to give colorless crystals **9** (6.09 g, 52%) by the use of benzene–ether (9:1). Recrystallization from benzene gave pure crystals of **9**.

9: Mp 201—203 °C. Found: C, 84.57; H, 7.25%. Calcd for $C_{32}H_{32}O_2$: H, 85.67; H, 7.18%. IR (KBr): 3400, 3050, 1600 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.41 (m, 8H), 3.43 (m, 2H), 3.60 (bs, 2H), 7.1—7.5 (m, 20H). MS *m/z* (rel intensity) 430 (M^+, 25), 353 (100), 248 (71).

Preparation of ***11***. A solution of **10** (234 mg, 1 mmol) in anhydrous ether (10 ml) was added to a solution of phenyllithium (8 mmol) in anhydrous ether (10 ml) at room temperature, after which the mixture was stirred for 16 h. The usual workup gave a yellow oil, which was chromatographed on silica gel to give colorless crystals **11** (277 mg, 62%) by the use of benzene–ether (4:1). Recrystallization from ethyl acetate gave pure **11**.

11: Mp 189—190 °C. Found: C, 86.75; H, 6.23%. Calcd for $C_{35}H_{30}O_2$: C, 87.10; H, 6.27%. IR (KBr): 3570, 3070, 1600 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.05 (bs, 2H, OH), 2.65 (m, 1H), 2.95 (m, 1H), 3.46 (m, 1H), 4.42 (m, 1H), 6.28 (m, 1H), 6.75 (m, 1H), 6.93 (m, 1H), 7.0—7.4 (m, 21H). MS *m/z* (rel intensity) 446 (M^+), 282 (100), 191 (35), 183 (70), 167 (90).

Preparation of ***13a***. A solution of **12a** (420 mg, 2 mmol) in anhydrous ether (50 ml) was added to a solution of phenyllithium (16 mmol) in anhydrous ether (50 ml) at room temperature. After stirring at the boiling temperature for 4 h, the reaction mixture was treated as usual to give colorless crystals **13a** (650 mg, 71%), which were recrystallized from ethyl acetate.

13a: Mp 262—263 °C. Found: C, 86.44; H, 6.59%. Calcd for $C_{33}H_{30}O_2$: C, 86.43; H, 6.59%. IR (KBr): 3470, 3360, 1600 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.32 (m, 2H), 2.58 (bs, 2H), 4.24 (bs, 2H), 6.49 (m, 2H), 6.8—7.6 (m, 20H). MS *m/z* (rel intensity) 440 (M^+−18, 51), 381 (36), 258 (82), 183 (100), 167 (58).

Preparation of ***13b***. The same procedure as above, but using **12b** (420 mg, 2 mmol) and phenyllithium (16 mmol), gave colorless crystals **13b** (795 mg, 87%), which were then recrystallized from ethyl acetate.

13b: Mp 179—180 °C. Found: C, 86.38; H, 6.68%. Calcd for $C_{33}H_{30}O_2$: C, 86.43; H, 6.59%. IR (KBr): 3470, 3360, 1600 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.20 (m, 1H), 0.78 (m, 1H), 2.75 (bs, 2H), 3.07 (m, 1H), 3.52 (m, 1H), 3.80 (m, 1H), 5.20 (m, 1H), 6.28 (m, 1H), 6.83 (m, 1H). MS *m/z* (rel intensity) 458 (M^+, 5), 440 (8), 258 (45), 183 (100), 167 (28).

Preparation of ***14a***. A solution of **13a** (1.50 g, 3.1 mmol) in benzene (150 ml) was hydrogenated over palladium charcoal (10%, 150 mg) to absorb the hydrogen (70 ml, 3.1 mmol). After the subsequent removal of the palladium charcoal by filtration, the solvent was evaporated on a rotary evaporator to give colorless crystals **14a** (1.5 g, *ca.* 100%), which were then recrystallized from ethyl acetate.

14a: Mp 269—270 °C. Found: C, 86.09; H, 6.72%. Calcd for $C_{33}H_{32}O_2$: C, 86.05; H, 7.00%. IR (KBr): 3550, 3250, 1598 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.8—1.6 (m, 6H), 2.11 (m, 2H), 2.54 (m, 2H), 3.47 (bs, 2H), 7.1—7.5 (m, 20H). MS *m/z* (rel intensity) 442 (M^+−18, 8), 365 (6), 260 (100), 183 (44).

Preparation of ***14b***. A solution of **13b** (3.00 g, 6.2 mmol) in benzene (250 ml) was hydrogenated with palladium charcoal (10%, 200 mg) to absorb the hydrogen (145 ml, 6.2 mmol). The usual work-up afforded colorless crystals **14b** (3.00 g, *ca.* 100%), which were then recrystallized from ethyl acetate.

14b: Mp 191—193 °C. Found: C, 85.81; H, 6.90%. Calcd for $C_{33}H_{32}O_2$: C, 86.05; H, 7.00%. IR (KBr): 3550, 3240, 1600 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.7—1.5 (m, 6H), 2.32 (m, 3H), 2.59 (m, 1H), 3.22 (bs, 2H), 6.8—7.5 (m, 20H). MS *m/z* (rel intensity) 442 (M^+−18, 10), 424 (22), 365 (36),

260 (100), 183 (61).

Preparation of 17. A solution of **15** (6.50 g, 30 mmol) in anhydrous tetrahydrofuran (100 ml) was added to a solution of phenyllithium (240 mmol) in anhydrous ether (70 ml) at room temperature, after which the mixture was stirred for 17 h. The usual workup gave colorless crystals **16** (8.86 g, 90%), which were then recrystallized from benzene.

16: Mp 164—165 °C. Found: C, 83.85; H, 6.14%; M^+, 328. Calcd for $C_{23}H_{20}O_2$: C, 84.12; H, 6.14%; M^+, 328.

A solution of **16** (4.00 g, 12 mmol) in anhydrous tetrahydrofuran (100 ml) was added to a solution of phenyllithium (60 mmol) in anhydrous ether (200 ml) at room temperature, after which the mixture was stirred for 20 h. The usual workup gave colorless crystals **17** (5.00 g, 86%), which were then recrystallized from ethyl acetate.

17: Mp 284—285 °C. Found: C, 87.00; H, 6.66%. Calcd for $C_{35}H_{32}O_2$: C, 86.74; H, 6.66%. IR (KBr): 3470, 3060, 1600 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.5—1.2 (m, 4H), 2.65 (m, 2H), 3.91 (bs, 2H), 5.18 (bs, 2H), 6.04 (m, 2H), 6.9—7.6 (m, 20H). MS *m/z* (rel intensity) 466 (M^+−18, 38), 375 (16), 284 (64), 183 (100), 167 (47).

Preparation of 19a. A solution of **18a** (2.88 g, 20 mmol) in anhydrous ether (150 ml) was added to a solution of phenyllithium (160 mmol) in anhydrous ether (100 ml) at room temperature, after which the mixture was stirred for 19 h. After the usual workup, the brown tarry material was chromatographed on silica gel to yield colorless crystals **19a** (1.96 g, 25%), which were then recrystallized from benzene.

19a: Mp 215—217 °C. Found: C, 85.70; H, 6.10%. Calcd for $C_{28}H_{24}O_2$: C, 85.68; H, 6.16%. IR (KBr): 3550, 3050, 1670 cm^{-1}. ^1H NMR ($CDCl_3$) δ=4.80 (s, 2H), 6.17 (s, 2H), 7.2 (m, 20H). MS *m/z* (rel intensity) 374 (M^+−18, 19), 270 (100), 192 (26).

Preparation of 19b. The same procedure as above, but using **18b** (2.88 g, 20 mmol) and phenyllithium (160 mmol), afforded colorless crystals **19b** (2.43 g, 31%), which were then recrystallized from cyclohexane.

19b: Mp 219—221 °C. Found: C, 85.98; H, 6.13%. Calcd for $C_{28}H_{24}O_2$: C, 85.68; H, 6.16%. IR (KBr): 3550, 3050, 1670 cm^{-1}. ^1H NMR ($CDCl_3$) δ=4.71 (s, 2H), 6.38 (s, 2H), 7.3 (m, 20H). MS *m/z* (rel intensity) 374 (M^+−18, 13), 270 (100), 192 (24).

Pyrolyses of Glycols

Pyrolysis of 20. Glycol **20** (940 mg, 2 mmol) was pyrolyzed at 250 °C for 2 h to give **21** (84 mg, 40%). The residual resinous material was chromatographed on alumina to give a colorless oil (120 mg) and colorless crystals **23** (410 mg, 46%) using pet ether, **3** (210 mg, 60%) using pet ether-benzene (4:1), and **4** (30 mg, 10%) using ether. The colorless oil was distilled under reduced pressure to give a colorless oil **22** (62 mg, 11%).

22: Bp 0.1 Torr (1 Torr=133.322 Pa), 130 °C (bath temperature). Found: C, 92.96; H, 6.98%. Calcd for $C_{21}H_{18}$: C, 93.29; H, 6.71%. IR (neat): 3070, 2920, 1600 cm^{-1}. ^1H NMR ($CDCl_3$) δ=3.46 (d, 2H, J=7 Hz), 6.38 (t, 1H, J=7 Hz), 7.3 (bs, 15H). MS *m/z* (rel intensity) 270 (M^+, 61), 193 (100), 167 (36).

Pyrolysis of 9. Glycol **9** (3.00 g, 6.6 mmol) was pyrolyzed at 250 °C for 1.5 h to give **24** (165 mg, 30%). The residue was chromatographed on silica gel to give colorless crystals **25** (1.05 g, 35%), using pet ether-benzene (7:3), **3** (306 mg, 25%) using pet ether-benzene (1:4), and **4** (820 mg, 68%) using ether. The crystals **25** were purified by recrystallization from ethyl acetate.

25: Mp 199—201 °C. Found: C, 89.49; H, 7.09%. Calcd for $C_{32}H_{30}O$: C, 89.26; H, 7.02%. IR (KBr) 3070, 2920, 1600 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.5 (m, 8H), 3.3 (m, 2H), 7.0—7.4 (m, 20H). MS *m/z* (rel intensity) 353 (M^+−C_6H_5, 10), 246 (100), 168 (32).

Pyrolysis of 11. Glycol **11** (482 mg, 1 mmol) was pyrolyzed at 290 °C for 3 h to yield 26 (87 mg, 75%). The residue was chromatographed on alumina to give **3** (180 mg, 99%) using pet ether-benzene (4:1) and **4** (110 mg, 60%) using ether.

Pyrolysis of 14a. Glycol **14a** (500 mg, 1.1 mmol) was pyrolyzed at 290 °C for 3 h to yield **27** (32 mg, 30%). The residue was chromatographed on alumina to give colorless crystals **28** (105 mg, 37%) using pet ether, colorless crystals **29** (45 mg, 9%) and **3** (153 mg, 75%) using pet ether-benzene (4:1), and **4** (33 mg, 20%) using ether. The crystals **28** and **29** were recrystallized from benzene and ethanol respectively.

28: Mp 68—69 °C. Found: C, 92.26; H, 7.83%. Calcd for $C_{20}H_{20}$: C, 92.26; H, 7.74%. IR (KBr): 3030, 2960, 1600 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.3—1.9 (m, 6H), 2.05 (m, 1H), 3.01 (bs, 1H), 7.3 (bs, 10H). MS *m/z* (rel intensity) 260 (M^+, 100), 231 (80), 205 (14), 191 (27), 167 (36).

29: Mp 279—280 °C. Found: C, 89.54; H, 7.00%. Calcd for $C_{33}H_{30}O$: C, 89.55; H, 6.83%. IR (KBr): 3060, 2950, 1600 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.8—1.7 (m, 6H), 2.44 (bs, 2H), 4.01 (bs, 2H), 6.9—7.4 (m, 20H). MS *m/z* (rel intensity) 442 (M^+, 6), 366 (31), 289 (100), 260 (12), 194 (10).

Pyrolysis of 14b. Glycol **14b** (500 mg, 1.1 mmol) was pyrolyzed at 290 °C for 3 h to yield **27** (29 mg, 27%). The same procedure as above gave **28** (183 mg, 64%), **3** (170 mg, 95%), and **4** (20 mg, 15%).

Pyrolysis of 30. Glycol **30** (1.00 g, 2.1 mmol) was pyrolyzed at 250 °C for 1 h to yield **26** (80 mg, 34%). The residue was chromatographed on alumina to give **3** (169 mg, 44%), using pet ether-benzene (4:1), colorless crystals of **11** (585 mg, 59%) using benzene-ether (4:1), and **4** (100 mg, 26%) using ether.

Pyrolysis of 13a. Glycol **13a** (500 mg, 1.1 mmol) was pyrolyzed at 270 °C for 2 h to give **31** (40 mg, 55%). The residue was chromatographed on alumina to give colorless crystals **32** (284 mg, 68%) using pet ether and **19a** (88 mg, 21%) using benzene-ether (1:1). The crystals **32** were recrystallized from ethyl acetate.

32: Mp 184—185 °C. Found: C, 89.85; H, 5.83%. Calcd for $C_{28}H_{22}O$: C, 89.80; H, 5.92%. IR (KBr): 3050, 1590 cm^{-1}. ^1H NMR ($CDCl_3$) δ=6.42 (s, 2H), 7.2 (bs, 20H). MS *m/z* (rel intensity) 374 (M^+, 46), 297 (100), 269 (82), 220 (59).

Pyrolysis of 13b. Glycol **13b** was pyrolyzed at 250 °C for 2 h to give **31** (65 mg, 45%). The residue was submitted to thin-layer chromatography on silica gel, using pet ether-benzene (1:1) as the developing solvent to give colorless crystals **33** (370 mg, 44%, R_f=0.45). The structure of **33** was determined by comparison of its physical properties with the literature.[9]

Pyrolysis of 17. Glycol **17** (500 mg, 1 mmol) was pyrolyzed at 290 °C for 3 h to give **34** (75 mg, 80%). The residue was chromatographed on alumina to give **32** (322 mg, 83%) using pet ether.

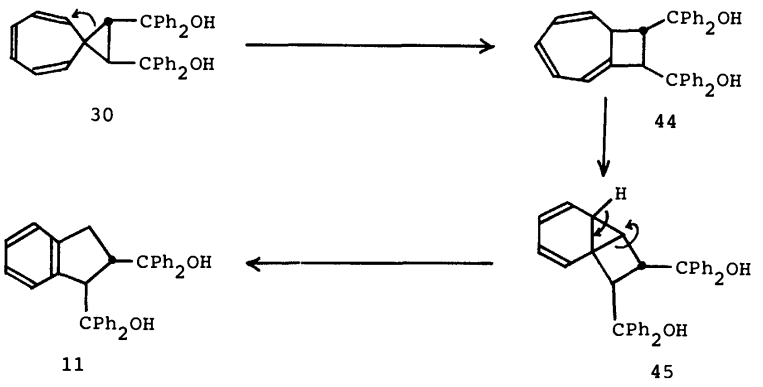

Fig. 8.

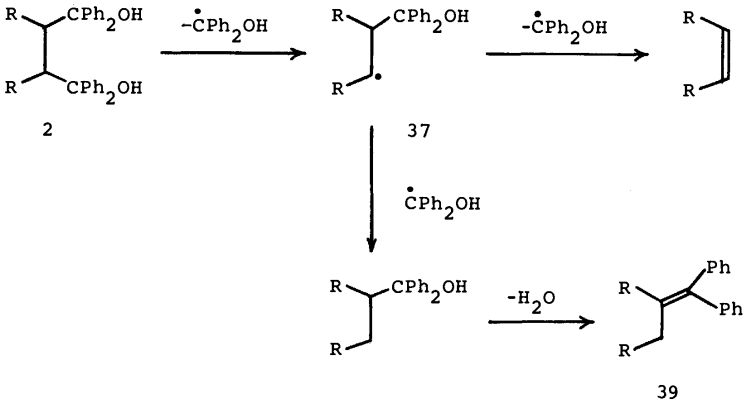

Fig. 9.

Pyrolysis of 19a. Glycol **19a** (1.00 g, 2.6 mmol) was pyrolyzed at 250 °C for 2 h. The residue was chromatographed on silica gel to yield colorless crystals **32** (506 mg, 53%) using pet ether and **3** (272 mg, 58%) using pet ether–benzene (4:1).

Pyrolysis of 19b. Glycol **19b** (1.00 g, 2.6 mmol) was pyrolyzed at 250 °C for 2 h. The residue was submitted to thin-layer chromatography on silica gel, using pet ether–benzene (1:1) as the developing solvent to give colorless crystals **33** (382 mg, 40%, R_f=0.45).

Pyrolysis of 35 A solution of **35** (1.00 g, 2.3 mmol) in *t*-butyl alcohol (40 ml) was heated at 330 °C for 5 h in an autoclave. The subsequent evaporation of the solvent gave colorless crystals **36** (950 mg, *ca.* 100%, mp 174—175 °C, lit,[7] 174—175 °C).

(Received May 24, 1985)

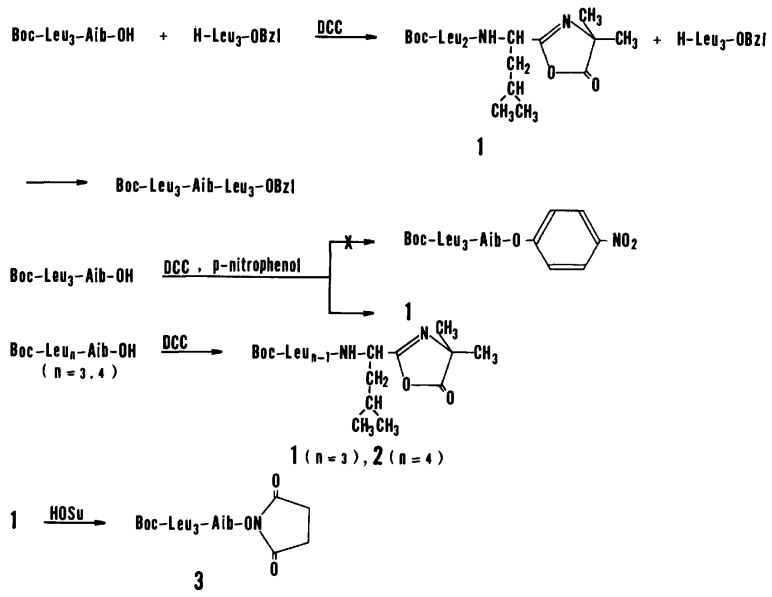
The reaction of Boc-Leu$_3$-Aib-OH with H-Leu$_3$-OBzl using DCC as a coupling reagent proceeded *via* the exclusive 2-substituted 4,4-dimethyl-5(4*H*)-oxazolone formation followed by a slow aminolysis. Similar treatment of Boc-Leu$_3$-Aib-OH with DCC in the presence of *p*-nitrophenol did not produce a *p*-nitrophenyl ester, but produced the 2-substituted 4,4-dimethyl-5(4*H*)-oxazolone (**1**) in a high yield within 20 min. The high potential for the oxazolone formation of Boc-Leu$_n$-Aib-OH (n=3 and 4) is apparently attributed to the conformational effect of C-terminal Aib residues, namely, the restriction of the backbone dihedral angles ϕ and ψ of Aib residues. Ring-opening reactions of oxazolones with hydroxy compounds were easily monitored by following the disappearance of the intense oxazolone peak at 1820 cm^{-1}. The oxazolone (**1**) reacted faster with HOSu than H-Leu$_3$-OBzl, followed by the slow aminolysis of the succinimide ester produced. In contrast, HOBt did not react with the oxazolones derived from Boc-Leu$_n$-Aib-OH (n=3 and 4), but strongly catalyzed the aminolysis of the oxazolones in dichloromethane to form peptide bonds in nearly quantitative yields. A little catalytic effect of acetic acid on the oxazolone aminolysis indicated that the oxazolone aminolysis in the presence of HOBt did not proceed through a simple acid catalytic pathway, but proceeded through a biphilic (electrophilic-nucleophilic) pathway.

The most common route to racemization during peptide bond formation involves a 5(4*H*)-oxazolone-mediated mechanism and, in many circumstances, a 5(4*H*)-oxazolone can be detected directly when an acylamino acid or peptide acid is converted to an activated derivative. Thus, the racemization and ring-opening reactions of 5(4*H*)-oxazolones with nucleophiles have been widely studied by many workers.[2] The role of 5(4*H*)-oxazolones in peptide synthesis has been reviewed by Kemp[3] and Benoiton[4] and, in their reviews, they considered the following issues: (a) the evidence for the intermediacy of 5(4*H*)-oxazolones in peptide coupling reactions, (b) the nature of the catalysis for the rate-determining ring closure, (c) the chemical behaviors of 5(4*H*)-oxazolones, and (d) the effect of substituents on the ease of 5(4*H*)-oxazolone formation. However, little attempt has been made concerning the possibility of using 5(4*H*)-oxazolones derived from peptides as coupling reagents because of lability of C$^\alpha$ hydrogen atoms.[2]

Recently we have demonstrated the usefulness of a novel strategy for solubility improvement in helical oligopeptides based on the restriction of the values of the backbone dihedral angles ϕ and ψ of Aib residues,[5] and the implication of the new findings for the study of artificial proteins containing Aib residues was discussed on the basis of the stabilizing efficacy of Aib residues on helical regions of proteins.[5–7] In the study of Aib-containing peptides,[5–7] we also found that the peptide containing an Aib residue at a C-terminal had high potential for the formation of 2-substituted 4,4-dimethyl-5(4*H*)-oxazolone and the oxazolone had low reactivity. Aib-containing peptides such as alamethicin, suzukacillin, and their peptide fragments have widely been studied mainly on their conformation.[8,9] But little information of the reactivity of an Aib residue is available.[8] Our attempts in this paper are directed towards elucidating the reactivity of a 2-substituted 4,4-dimethyl-5(4*H*)-oxazolone and exploring the possibility of using the 5(4*H*)-oxazolone as a coupling reagent, where the 5(4*H*)-oxazolone is free from racemization due to having a structure in which a labile C$^\alpha$ hydrogen atom of Ala is substituted with a methyl group.

Results

C-Terminal Aib residues are highly hindered[8] and the reaction of Boc-Leu$_3$-Aib-OH with H-Leu$_3$-OBzl using DCC as a coupling reagent proceeds *via* the exclusive 5(4*H*)-oxazolone formation followed by a slow aminolysis (Scheme 1). The characteristic IR absorption at 1820 cm^{-1} allows sensitive detection of the 5(4*H*)-oxazolone species. The IR spectrum of the reaction mixture in dichloromethane is shown in Fig. 1a. Similar treatment of Boc-Leu$_3$-Aib-OH with DCC in the presence of *p*-nitrophenol does not produce the *p*-nitrophenyl ester, but produces the oxazolone (**1**) in a high yield within 20 min (Scheme 1, Fig. 1b). The intense oxazolone peak at 1820 cm^{-1} indicates that the reaction is almost completed within 20 min, while the absence of the carbonyl band of *p*-nitrophenyl ester at about 1760 cm^{-1} indicates that the mixture does not contain the *p*-nitrophenyl ester (Fig. 1b). This is in remarkable contrast with the result that the same treatment of usual peptide acids produces exclusively corresponding *p*-nitrophenyl



Scheme 1.

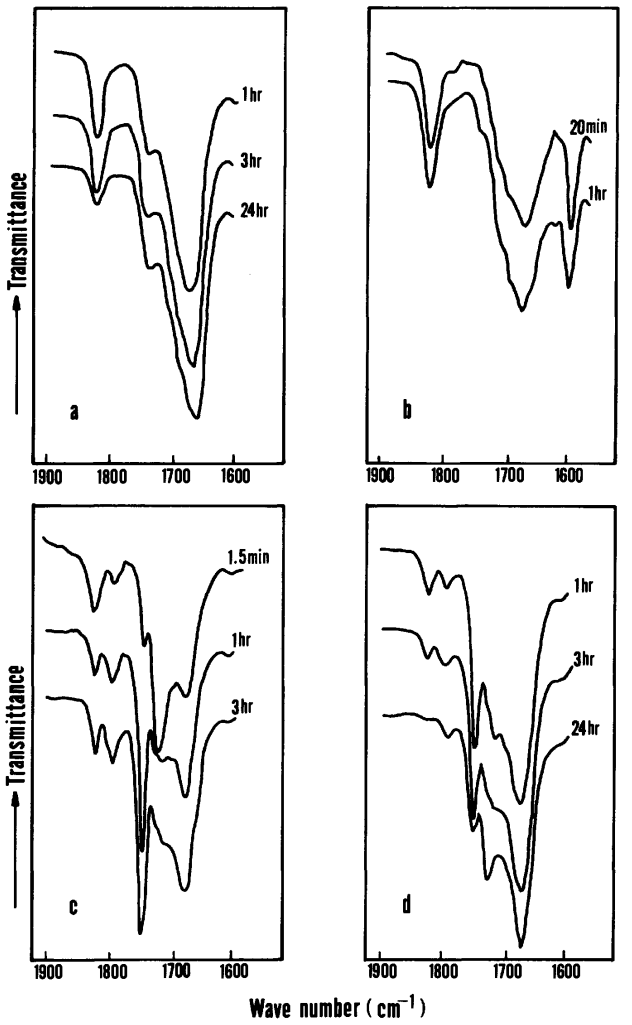


Fig. 1. Monitoring of the 5(4*H*)-oxazolone formation and the reaction of 5(4*H*)-oxazolone (**1**) with various nucleophiles by IR absorption spectra. The nucleophiles used are in the following: a, H–Leu_3–OBzl; b, *p*-nitrophenol; c, HOSu; d, HOSu, and H–Leu_3–OBzl.

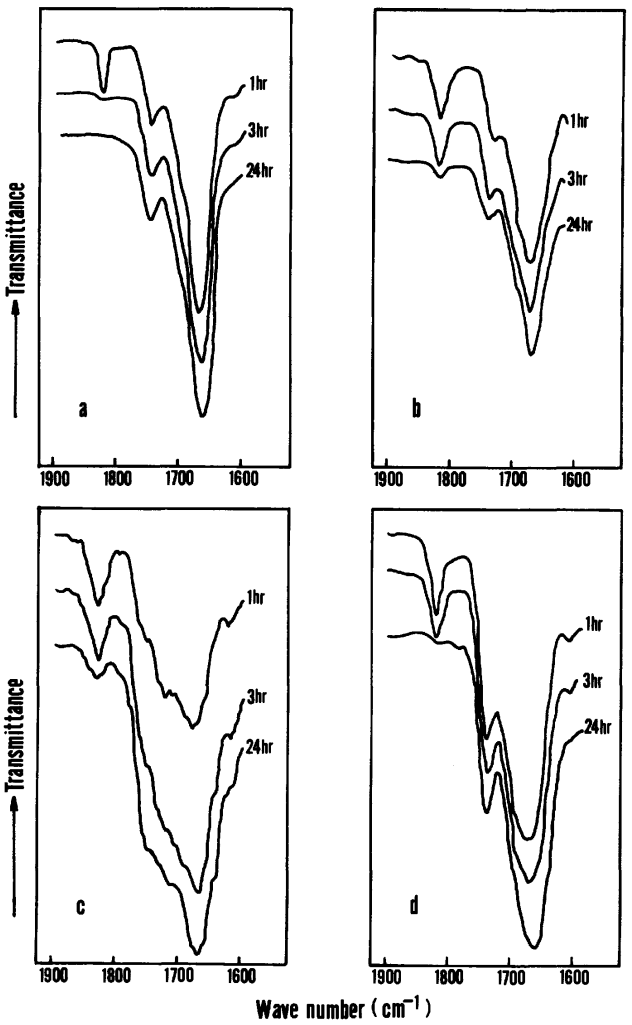

Fig. 2. Monitoring of the catalytic aminolysis of the oxazolone (**1**) with H–Leu_3–OBzl by IR absorption spectra. The catalysts used are in the following: a, HOBt; b, *p*-nitrophenol; c, acetic acid; d, imidazole.

esters of peptides. Treatment of Boc-Leu$_n$-Aib-OH (n=3 and 4) with DCC in the absence of nucleophiles begins to precipitate *N,N'*-dicyclohexylurea almost immediately and produces the corresponding 5(4*H*)-oxazolones in high yields (Scheme 1). Treatment of Boc-Leu$_3$-Aib-OH with acetic anhydride also produced the oxazolone (**1**). Ring-opening reactions of oxazolones with hydroxy compounds were easily monitored by following the disappearance of the intense oxazolone peak at 1820 cm^{-1}. The hydroxy compounds examined were in the following: *p*-nitrophenol, *o*-nitrophenol, pentachlorophenol, 2,4,6-trichlorophenol, 8-quinolinol, HOBt, and HOSu. For the hydroxy compounds, only HOSu reacted with the oxazolones at room temperature in dichloromethane to produce the succinimide ester (**3**) (Scheme 1, Fig. 1c). Even in the presence of amino component peptides such as H-Leu$_3$-OBzl and H-Leu$_n$-Aib-OBzl (n=3 and 4), the oxazolone (**1**) reacted faster with HOSu than the amino component peptides, followed by the slow aminolysis of the ester (**3**) (Fig. 1d). In contrast, HOBt does not react with the oxazolone under the same conditions, but strongly catalyzes the aminolysis of the oxazolone (**1**) in dichloromethane to form a peptide bond in a nearly quantitative yield. The catalytic effect of HOBt on the aminolysis were easily monitored by following the disappearance of the intense oxazolone peak at 1820 cm^{-1} (Fig. 2a). The reaction was also monitored by HPLC on a gel filtration column (Fig. 3). Other hydroxy compounds showed a little

Table 1. The coupling yields of the catalytic aminolysis of the oxazolones (**1**) and (**2**) with various amino component peptides in the presence of HOBt

Oxazolone	Product	Yield/%
1	Boc-Leu$_3$-Aib-Leu$_3$-OBzl	98
1	Boc-(Leu$_3$-Aib)$_2$-OBzl	97
1	Boc-(Leu$_3$-Aib)$_3$-OBzl	97
2	Boc-Leu$_4$-Aib-Leu$_4$-OBzl	95
2	Boc-(Leu$_4$-Aib)$_2$-OBzl	95
2	Boc-(Leu$_4$-Aib)$_3$-OBzl	93

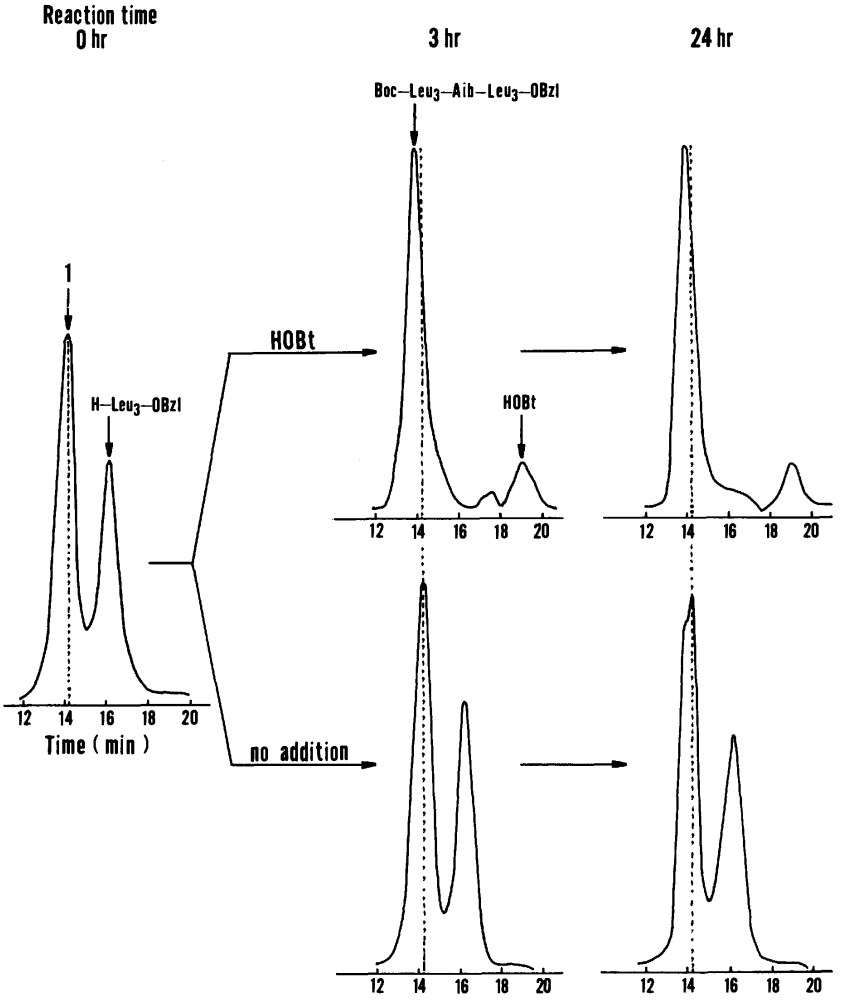

Fig. 3. Monitoring by HPLC of catalytic aminolysis of the oxazolone (**1**) with H-Leu$_3$-OBzl in the presence of HOBt.

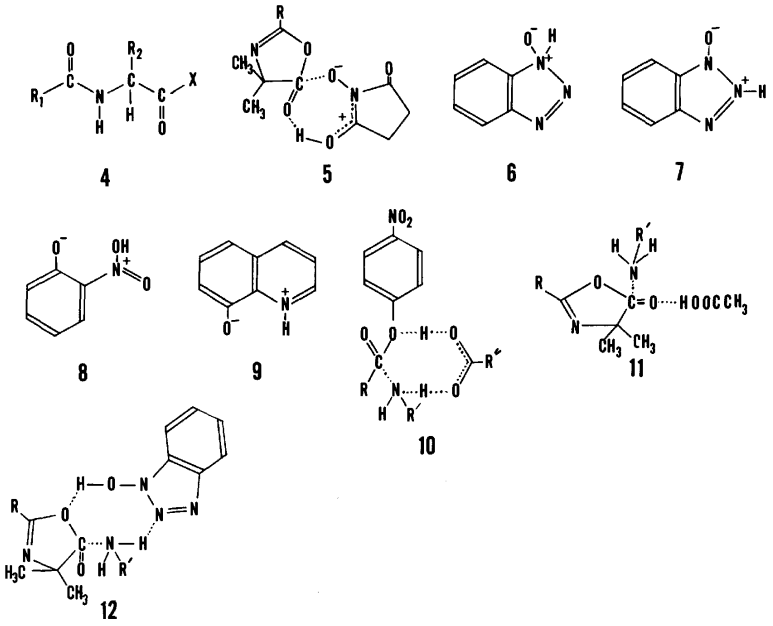
catalytic effect on the aminolysis of the oxazolone (**1**) with H-Leu$_3$-OBzl (Fig. 2b). Acetic acid and imidazole also catalyze the aminolysis of the oxazolone (**1**) (Fig. 2c and 2d). The catalytic effect was in the following order: HOBt $\gg$ imidazole>acetic acid, *p*-nitrophenol, pentachlorophenol, *o*-nitrophenol, 2,4,6-trichlorophenol>8-quinolinol. The aminolysis of the oxazolones (**1**) and (**2**) with various amino component peptides is practically catalyzed by HOBt in dichloromethane to form peptide bonds in nearly quantitative yields. (Table 1).

Discussion

In the reaction of Boc-Leu$_n$-Aib-OH with DCC in the presence of nucleophiles except for HOSu, the exclusive formation of 5(4*H*)-oxazolones is very surprising. In a series of C-terminal-activated derivatives of peptides (the structure **4** in Scheme 2), the effect of substituents R_1 and R_2 on the ease of 5(4*H*)-oxazolone formation has been reported by Young.[10] If one assumes that 5(4*H*)-oxazolone formation occurs by a base-catalyzed path, then one expects the acidity of the amide at R_1 to be the major determinant, in accord with the simple acyl order, $CF_3CO>C_6H_5CO>CH_3CO$. The effect of R_2 on the ease of 5(4*H*)-oxazolone formation is difficult to rationalize due to the complexity of the situation. In the case of the reaction of Boc-Leu$_n$-Aib-OH with DCC, the ease of the 2-substituted 4,4-dimethyl-5(4*H*)-oxazolone formation is apparently attributed to the conformational effect of C-terminal Aib residues, namely, the extreme restriction of the backbone dihedral angles ϕ and ψ of Aib residues.[9a,9f,11] In term of activation entropy, the conformational restriction is clearly favorable for the intramolecular cyclization, the oxazolone formation. On the other hand, the low reactivity of the oxazolone with nucleophiles results from steric hindrance of both methyl groups on the oxazolone.

In the ring-opening reactions of (4S)-2-phenyl-4-benzyloxazolone with α nucleophiles (species containing two adjacent nucleophilic centers), biphilic (electrophilic-nucleophilic) pathways have been estimated.[12] HOSu has also been viewed as proceeding by a concerted mechanism involving nucleophilic-electrophilic attack of an anionic form (the transition state **5** in Scheme 2).[12] The high reactivity of HOSu with the oxazolone (**1**) derived from Boc-Leu$_3$-Aib-OH can be understood as involving a biphilic pathway through the transition state **5** (Scheme 2). No reaction of HOBt with the oxazolone (**1**) may be attributed to no contribution of the zwitterionic structures **6** and **7** (Scheme 2) due to weak basicity of the nitrogen atoms. No reaction of 8-quinolinol and *o*-nitrophenol with the oxazolone (**1**) may also be attributed to no contribution of the zwitterionic structures **8** and **9** (Scheme 2).

Catalytic effects of HOBt on the oxazolone aminolysis is quite significant. The pK_a value of HOBt (pK_a=4.00) is close to that of acetic acid (pK_a=4.05) and HOSu (pK_a=4.05). In the detailed studies on the acid catalysis of *p*-nitrophenyl ester aminolysis, Nakamizo proposed a bifunctional concerted mechanism that involves the 8-membered transition state **10** (Scheme 2).[13] A different transition state was also visualized by Muzalewski.[14] A little catalytic effect of acetic acid on the oxazolone aminolysis indicates that the oxazolone aminolysis in the presence of HOBt does not proceed through the



Scheme 2.

simple acid catalytic pathway (the transition state **11** in Scheme 2), but proceed through the biphilic pathway (the transition state **12** in Scheme 2).

Peptides having an α,α-disubstituted α-amino acid residue at C-terminal are expected to have high potential for the oxazolone formation due to the restriction of the backbone dihedral angles ϕ and ψ of the amino acid residue. The study for the reactivity of α,α-disubstituted α-amino acid residues will be in progress.

Experimental

General. The uncorrected capillary melting points will be reported. Analytical HPLC of the peptides was performed on a column packed with an acrylonitrile-divinylbenzene-styrene copolymer (7.5×500 mm) using a mini micro pump NSP-800-5DX (Nihon Seimitsu Kagaku) and a refractive index detector model RI-3H (Japan Analytical Industry). The operating conditions of HPLC were the following: Column with exclusion limit of 5000; solvent, DMF; flow rate, 1 ml/min; chart speed, 0.5 cm/min; temperature, room temperature. The IR spectra in the solid state were recorded for nujor mulls with a JASCO model DS-701G spectrometer. Those in solution were recorded employing 0.025 mm pathlength cells with potassium bromide windows. The concentration of the solution was kept near 4.0×10^{-2} M†.

Preparation of Oxazolones from Boc-Leu$_n$-Aib-OH (n=3 and 4) Using DCC as a Dehydration Reagent. Boc-Leu$_n$-Aib-OH (5 mmol) divided to five portions was added at 30 min intervals to an ice-chilled stirred solution of DCC (5 mmol) in 20 ml of dichloromethane. Precipitation of *N,N'*-dicyclohexylurea began almost immediately. After 1 h the solution was filtered and the dichloromethane was removed at room temperature under reduced pressure to give a solid material. The solid product was recrystallized from the appropriate solvents. The oxazolone (**1**), from ethyl acetate/hexane (1/5); yield, 80%; mp 161—163 °C.

Found: C, 60.91; H, 9.26; N, 10.63%. Calcd for $C_{27}H_{48}N_4O_6$ $0.5H_2O$: C, 60.76; H, 9.25; N, 10.50%.

The oxazolone (**2**), from tetrahydrofuran/hexane (1/3); yield, 83%; mp 205—207 °C.

Found: C, 62.05; H, 9.75; N, 11.09%. Calcd for $C_{33}H_{59}N_5O_7$ $0.5H_2O$: C, 61.98; H, 9.18; N, 10.62%.

Preparation of Oxazolones from Boc-Leu$_n$-Aib-OH (n=3 and 4) Using Acetic Anhydride as a Dehydration Reagent. A solution of a peptide (5 mmol) in acetic anhydride (20 ml) was heated at 110—120 °C for 15 min and then evaporated under reduced pressure. Last traces of acetic anhydride were removed by addition of toluene (10 ml) and evaporation, and the residual oxazolone recrystallized from the appropriate solvents. The yields of the oxazolones (**1**) and (**2**) were 95 and 78%, respectively.

IR Absorption Monitoring of the 5(4H)-Oxazolone Formation by the Reaction of Boc-Leu$_3$-Aib-OH with DCC in the Presence of Nucleophiles (H-Leu$_3$-OBzl, p-Nitrophenol, HOSu, and HOSu + H-Leu$_3$-OBzl). The formation of the 2-substituted 4,4-dimethyl-5(4*H*)-oxazolone (**1**) by the reaction of Boc-Leu$_3$-Aib-OH with DCC in the presence of nucleophiles were monitored by following the appearance of the intense oxazolone peak at 1820 cm^{-1}. The concentrations of Boc-Leu$_3$-Aib-OH, DCC, and nucleophiles were 4.0×10^{-1} M, respectively. The results were shown in Fig. 1.

Reactions of Oxazolones with Hydroxy Compounds. Ring-opening reactions of oxazolones with hydroxy compounds were carried out at room temperature in dichloromethane and monitored by following the disappearance of the intense oxazolone peak at 1820 cm^{-1}. The concentrations of the oxazolone and hydroxy compounds were 4.0×10^{-2} M, respectively, in the ring-opening studies.

Preparation of Boc-Leu$_3$-Aib-OH N-Hydroxysuccinimide Ester. To a solution of the oxazolone (**1**) from Boc-Leu$_3$-Aib-OH (1 mmol) in 10 ml of dichloromethane, *N*-hydroxysuccinimide (127 mg, 1.1 mmol) was added in one portion and the reaction was allowed to stir for 8 h at room temperature. The solvent was evaporated at room temperature under reduced pressure and 50 ml of water was added to dissolved unreacted *N*-hydroxysuccinimide. Crude product (530 mg, 73%), showing a single peak on HPLC, was obtained after filtration and washing with cold ether (to remove oxazolone). The product was recrystallized from ethyl acetate/hexane (1/2); yield, 87%; mp 133—137 °C.

Found: C, 56.16; H, 8.43; N, 10.40%. Calcd for $C_{31}H_{53}N_5O_9$ H_2O: C, 56.60; H, 8.43; N, 10.65%.

Peptide Bond Formation by the Reactions of the Oxazolone (1) with Amino Component Peptides. Ring-opening reactions of the oxazolone (**1**) with amino component peptides were carried out at room temperature in dichloromethane and monitored by following the disappearance of the intense oxazolone peak at 1820 cm^{-1}. The reactions were also monitored by HPLC on a gel filtration column. The concentrations of the oxazolone and amino component peptides were 4.0×10^{-2} M, respectively, in the ring-opening studies.

Catalytic Effects of Hydroxy Compounds on Peptide Bond Formation by the Reactions of the Oxazolone (1) with Amino Component Peptides. Accelerating effects of hydroxy compounds on the aminolysis of the oxazolone (**1**) were studied at room temperature in dichloromethane and monitored by following the disappearance of the intense oxazolone peak at 1820 cm^{-1}. The concentrations of the oxazolone, amino component peptide, and hydroxy compounds were 4.0×10^{-2} M, respectively, in the aminolysis. The reaction was also monitored by HPLC on a gel filtration column.

Preparation of Aib-containing Peptides Using the Oxazolones (1) and (2) as Coupling Reagents. A oxazolone (1.0 mmol) was added to a stirred mixture of an amino component peptide hydrochloride salt (1.0 mmol), *N*-methylmorpholine (1.0 mmol), and HOBt (1.0 mmol) in dichloromethane (20 ml). The reaction mixture was allowed to stir for 12 h at room temperature and then washed with water, 10% citric acid, and 5% sodium hydrogencarbonate, dried over sodium sulfate, and concentrated under reduced pressure. IR absorption spectra of crude products were free from the absorption band at 1820 cm^{-1} and in good agreement with those of authentic samples.[5,6]

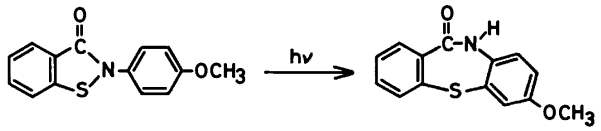
(Received May 25, 1985)

The photochemical reaction of a series of 2-aryl-1,2-benzisothiazol-3(2*H*)-ones (**1**) under deaerated conditions was found to give dibenzo[*b*,*f*][1,4]thiazepin-11(10*H*)-ones (**2**). A mechanism through a biradical species is proposed for the photoreaction. When the photolysis of **1** was carried out in the presence of oxygen, 2-aryl-1,2-benzisothiazol-3(2*H*)-one 1-oxides (**11**) were formed together with compounds **2**.

In recent years much attention has been focused on the photochemistry of five-membered heterocyclic ring systems. These studies have dealt with the synthetic usefulness of the photochemistry of heterocyclic compounds as well as their reaction modes.[1-4] In earlier communications we reported that the photochemical reaction of 2-substituted 1,2-benzisothiazol-3(2*H*)-one 1,1-dioxides in benzene gave rise to *N*-substituted *o*-phenylbenzamides with the extrusion of sulfur dioxide,[5] whereas, the photolysis of 2-aryl-1,2-benzisothiazol-3(2*H*)-one, which corresponds to reduced derivatives of *N*-substituted 1,2-benzisothiazol-3(2*H*)-one 1,1-dioxides in benzene, gave dibenzothiazepinones.[6] We give here a full account for the photochemical behavior of a series of 2-aryl-1,2-benzisothiazol-3(2*H*)-ones (**1**).

Results and Discussion

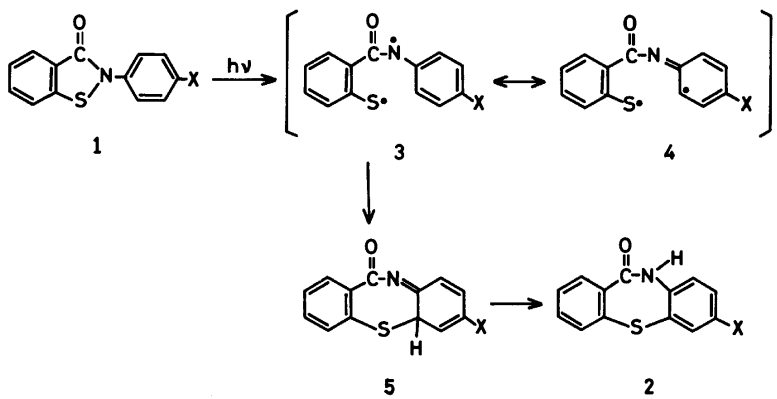
When a deaerated solution of 2-(4-methoxyphenyl)-1,2-benzisothiazol-3(2*H*)-one (**1a**) in benzene was irradiated with 340-nm wavelength light, a single photoproduct was obtained. An assignment of this material as 7-methoxydibenzo[*b*,*f*][1,4]thiazepin-11-(10*H*)-one (**2a**) was made on the basis of its spectral data, especially its 400-MHz ^{1}H NMR spectrum.



1a **2a**

Several related 2-aryl-1,2-benzisothiazol-3(2*H*)-ones (**1**) were also irradiated under similar conditions to give dibenzo[*b*,*f*][1,4]thiazepin-11(10*H*)-ones (**2**) as the only isolable photoproducts. The results are summarized in Table 1. A reaction mechanism which explains the phototransformation is outlined in Scheme 1. The photoexcited **1** undergoes homolytic cleavage of the weakest bond (S–N) in the molecule to give biradical (**3**). The initially-formed biradical attacks the ortho-position of the *N*-aryl group to give the cyclized product **5**. A subsequent 1,7-hydrogen shift of intermediate **5** leads to the final product. The last step of the sequence can proceed by either a thermal or photochemical hydrogen shift.

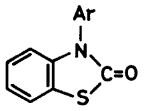
Recently, Rokach and Hammel reported that a small amount of a photo-ring expansion product was formed together with 3-phenylthiazol-2(3*H*)-one upon irradiation of 2-phenylisothiazol-3(2*H*)-one.[7] However, we could not detect the corresponding 3-aryl-2(3*H*)-benzothiazolone (**6**) in the reaction mixture.



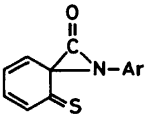
1 **3** **4** **5** **2**

Scheme 1.

According to the mechanism proposed,[7] a ring-contracted intermediate such as **7** would seem reasonable. The absence of compound **6** among the products suggests that this intermediate (*i.e.* **7**) is not formed in the photoreaction of **1**. The absence of **7**

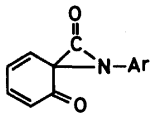


6



7

can be accounted for in terms of the high energy required to interrupt the aromaticity of the benzene ring. The photo-transposition reaction of the related 2-alkyl-1,2-benzisoxazol-3(2*H*)-one system to 3-alkyl-1,2-benzoxazol-2(3*H*)-one *via* the ring-contracted intermediate **8** was reported by Kinstle and co-workers.[8] Therefore, the absence of **7** can be also attributed to the instability of the C=S group (2pπ—3pπ) compared with the C=O group (2pπ—2pπ).



8

Recently, Kulyk and Neckers have reported the intermolecular photoaddition of the benzisothiazole system to alkenes and alkynes and demonstrated the synthetic usefulness of benzothiazepines.[9] Our present reaction is of interest from both mechanistic and synthetic points of view since medium-size seven-membered ring compounds are generally very difficult to prepare. Unfortunately, the yield of **2** is low as is shown in Table 1. This can be attributed to the fact that biradical **3** gives rise to polymeric compounds at a faster rate than an intramolecular reaction to give **2**. If this postulate is correct, the yield of **2** would be expected to improve with the use of a more viscous solvent. The irradiation of **1b** was carried out in *t*-butyl alcohol using a Tungsten filter. However, no difference in the yield of **2b** was observed. Then, **1b** was irradiated in *t*-butyl alcohol using a Pyrex, Corex or Vycor filter to determine whether the wavelength of light would affect the yield of **2**. A considerable improvement was observed with the latter two filters. When compound **1b** was irradiated through a Corex filter in either *t*-butyl alcohol, benzene or methanol, the yield of **2b** was low in the latter two solvents. The results are summarized in Table 2. These results imply that both the wavelength of the light and the solvent are important in the photoreaction of compound **1** to obtain the photoproduct **2** in a good yield. Since the yield of compound **2b** was improved upon irradiation through a Corex filter in *t*-butyl alcohol, several related compounds were irradiated under similar conditions (Table 3). We found that an improvement in the yield occurred only when the *N*-phenyl group of **1** possesses an electron-donating substituent.

We also studied the photoreaction of (*E*)-2-styryl-1,2-benzisothiazol-3(2*H*)-one (**9**) expecting the formation of a photoexpansion product (**10**). However,

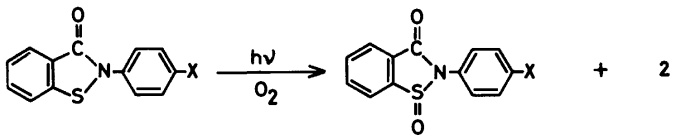
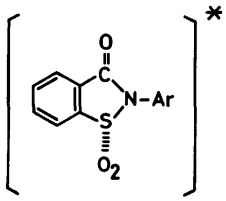
no photochemical transformation was observed upon irradiation for long periods of time (≈30 h) and all of the starting material **9** was recovered.

Irradiation of **1a** was also carried out in benzene using light of wavelength >340 nm in the presence of oxygen. Under these conditions, 2-(4-methoxyphenyl)-1,2-benzisothiazol-3(2*H*)-one 1-oxide (**11a**) was formed in 8% yield in addition to compound **2a**. The structure of **11a** was verified by a comparison with an authentic sample which was prepared by a treatment of **1a** with *N*-chlorosuccinimide, followed by a reaction with aqueous potassium hydrogencarbonate. Several related 2-aryl-1,2-benzisothiazol-3(2*H*)-ones **1** were also irradiated under similar conditions and were found to give the corresponding photo-oxidized product (**11**) together with compound **2**. The results are summarized in Table 4.

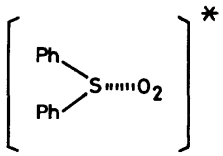


1 11

The mechanism of the photo-oxidation reaction is of considerable interest. We believe that compound **1** does not act as a sensitizer to form singlet oxygen since the triplet energy of **1** is estimated to be greater than 250 KJ per mol.[10] Therefore, the formation of singlet oxygen as the oxidant can be ruled out. Moreover, singlet oxygen is known not to oxidize diphenyl sulfide in benzene.[11] An alternate possibility involves the formation of an excited complex (**12**) resulting from the interaction of compound **1** and oxygen. Unfortunately, all attempts to detect such an intermediate by spectroscopic methods failed. Tezuka and co-workers have reported that a related complex, such as **13**, could indeed be detected spectroscopically in the photoreaction of diphenyl sulfide[12] with oxygen and they ruled out a mechanism which involves singlet oxygen as an intermediate.[13]



12



13

Table 4. Photochemical reaction of **1** in the presence of oxygen[a]

X in **1**		Solvent	Product	Yield[b]		
1a	OCH_3	Benzene	**12a**	8%	**2a**	12%

a) Irradiation with a medium-pressure 450 W mercury lamp (Hanovia) through a Tungsten filter (>340 nm) under bubbling oxygen. In case of **1e**, a Molybdenum filter (>320 nm) was used. b) Yields (isolated) are based on the starting materials consumed.

Experimental

Measurement. Melting points are uncorrected. The infrared absorption spectra were determined on a Hitachi Model 260—10 spectrophotometer using KBr disks. The electronic spectra were determined on a Hitachi Model 220A spectrophotometer. The NMR spectra were recorded at 60 and 400 MHz using a Hitachi R20B and a JEOL JNM-GX400 spectrometer, respectively, with Me_4Si as an internal standard. Mass spectra were determined with a JEOL JMS-DX300 mass spectrometer with a JEOL JMA 5000 mass-data system at an ionizing voltage of 20—70 eV. Elemental analyses were carried out using a Perkin Elmer 240 elemental analyzer.

Preparation of 2-Aryl-1,2-benzisothiazol-3(2H)-ones (1). An improved method of Reissert and Manns[14] was employed for the syntheses of **1**. A solution containing 2,2′-dithiobis[benzoyl chloride] (2.0 g, 5.0 mmol) in dry dichloromethane (100 cm^3) was added dropwise at the ambient temperature to a well stirred solution of substituted aniline (29 mmol) in dry dichloromethane (50 cm^3) over a period of 15 min. The resulting mixture was stirred at room temperature for 3 h; then, the solvent was evaporated under reduced pressure. The residue was stirred with 1 M† hydrochloric acid (100 cm^3) for 30 min at room temperature to remove any excess aniline. The solid product, *N,N′*-diaryl-2,2′-dithiobis[benzamide], was collected, washed with water, and dried in a desiccator. A solution of bromine (1.4 g, 8.7 mmol) in dichloromethane was added dropwise at ambient temperature to a well stirred suspension of the *N,N′*-diaryl-2,2′-dithiobis[benzamide] (5.8 mmol) in dichloromethane (150 cm^3) over a period of 3—5 min. Stirring was continued at room temperature overnight. Activated basic alumina (Wako Pure Chemical, 300 mesh, 20 g) was added to the reaction mixture and stirring was continued for an additional 3 h. Removal of the solvent left a pale-yellow residue which was chromatographed over an activated alumina column (300 mesh, 40 g) and eluted with chloroform to give pure **1**. The following compounds were prepared using the above procedure.

2-(4-Methoxyphenyl)-1,2-benzisothiazol-3(2H)-one (1a): Yield, 96%; mp 148—149 °C (lit[15], mp 147—149 °C); ^1H NMR (Me_2SO-d_6) 400 MHz, δ=3.819 (3H, s, OCH_3), 7.085 and 7.569 (2H and 2H, A_2B_2 quartet, J_{AB}=8.9 Hz, 3′- and 2′-H), 7.509 (1H, m, J_{5-4}=8 Hz, J_{5-6}=7.0 Hz, 5-H), 7.764 (1H, m, J_{6-5}=7 Hz, J_{6-7}=8 Hz, 6-H), 7.951 (1H, d, J_{7-6}=8 Hz, 7-H),

*Preparation of (E)-2-Styryl-1,2-benzisothiazol-3(2H)-one (**9**).* To a mixture of 60 cm^3 of 25% aqueous ammonia and 60 cm^3 of THF was added 12.9 g of 2,2′-dithiobis[benzoyl chloride] in 150 cm^3 of THF at −15 °C over period of

30 min and the solution was stirred for additional 2 h. The solution was concentrated under reduced pressure. The remaining solid was washed with water, cold acetone, and then ether and dried in a desiccator to give 11.4 g of 2,2′-dithiobis[benzamide]: mp 239 °C (dec.); IR (KBr) 3400, 3200, 1640, and 1400 cm^{-1}. To a suspension of 3.8 g of the above compound in 15 cm^3 of carbon tetrachloride was added 2.5 g of bromine in 15 cm^3 of carbon tetrachloride over a period of 10 min. The mixture was stirred overnight, the solvent was evaporated under a reduced pressure and 3 g of sodium hydrogencarbonate in 50 cm^3 of water and 10 cm^3 of THF was added to the resulting residue and the mixture was stirred for 1 h. The solution was concentrated under reduced pressure to give 3.5 g of 1,2-benzisothiazol-3(2*H*)-one: mp 160—161 °C; IR (KBr) 3050, 2900, 2680, 1745, 1635, 1440, and 1325 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.2—8.2 (m); UV (methanol) 203 (ε=1.1×10⁴), 226 (1.6×10⁴), and 316 nm (4.4×10³).

A mixture containing 1.5 g of the above isothiazolone, 1.8 g of phenylacetaldehyde dimethyl acetal, and 10 mg of *p*-toluenesulfonyl chloride was heated at 100 °C for 20 h. The mixture was solidified on cooling to room temperature and the crude solid was purified by chromatography on a silica gel column using benzene as the eluent. The major fraction (2.1 g) obtained was identified as (*E*)-2-styryl-1,2-benzisothiazol-3(2*H*)-one (**9**) on the basis of the following data: mp 145—146 °C; IR (KBr) 1670, 1640, 1450, 1350, 1300, 1265, 1200, 935, and 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.31 (1H, d, J=14.0 Hz), 8.00 (1H, d, J=14.0 Hz) and 7.0—8.2 (9H, m); UV (methanol) 219 (ε=2.3×10⁴), 298 (1.4×10⁴), and 346 nm (1.6×10⁴). Anal. Calcd for $C_{15}H_{11}NOS$: C, 71.12; H, 4.38; N, 5.53. Found: C, 71.45; H, 4.28; N, 5.65.

Photolysis of (E)-2-Styryl-1,2-benzisothiazol-3(2H)-one (9). A solution containing 112 mg (0.44 mmol) of (*E*)-2-styryl-1,2-benzisothiazol-3(2*H*)-one (**9**) in 220 cm^3 of benzene or *t*-butyl alcohol was irradiated using a 450-W Hanovia medium-pressure mercury lamp through a Corex filter sleeve for 30 h. No photoconversion of the starting material was observed by HPLC or TLC. After removing the solvent under reduced pressure to give a solid, the ^1H NMR spectra was identical with that of the starting material **9**.

Photolysis of 2-Aryl-1,2-benzisothiazol-3(2H)-one (1) in the Presence of Oxygen. A solution containing 0.44 mmol of **1** in 220 cm^3 of benzene or methanol with bubbling of oxygen was irradiated through a filter sleeve using a 450-W Hanovia medium-pressure mercury lamp for 2 h. The removal of the solvent under reduced pressure left a light-brown residue which was purified by silica gel chromatography using dichloromethane–hexane as the eluent. Photo-oxidized product **11** was isolated with **2**.

Preparation of 2-Aryl-1,2-benzisothiazol-3(2H)-one 1-Oxide (11). To a solution containing 301 mg (2.25 mmol) of *N*-chlorosuccinimide in 40 cm^3 of dichloromethane was added 2.2 mmol of 2-aryl-1,2-benzisothiazol-3(2*H*)-one in 20 cm^3 of dichloromethane over a period 20 min at 0 °C. The mixture was then stirred for 1 h at room temperature. A solution containing 7 g of potassium hydrogencarbonate in 20 cm^3 of water was added to the reaction mixture and stirred for an additional 1 h. The organic layer was washed with water, dried over anhydrous magnesium sulfate, and concentrated under reduced pressure. The residual solid was purified by chromatography on silica gel using hexane–ethyl acetate as the eluent. 2-Aryl-1,2-benzisothiazol-3(2*H*)-one 1-oxides (**11a—e**) were obtained in 70—80% yield. The physical and spectral data are as follows:

2-(4-Methoxyphenyl)-1,2-benzisothiazol-3(2H)-one 1-Oxide (11a). Mp 147—148 °C; IR (KBr) 1715 (s, C=O), 1515 (s), 1260 (s, C-O-C, as), and 1100 cm^{-1} (s, S=O); ^1H NMR ($CDCl_3$) δ=3.84 (3H, s, OCH_3), 6.9—8.2 (4H, m), 7.02 and 7.41 (2H and 2H, A_2B_2 quartet, J_{AB}=8.9 Hz); ^{13}C NMR ($CDCl_3$) δ=164.7 (C=O), 128.2 and 145.6 (3a- and 7a-C), 125.1, 126.6, 133.2, and 134.4 (4-, 5-, 6-, and 7-C), 160.0 (1′-C), 129.2 (2′-C), 115.0 (3′-C), 126.1 (4′-C), and 55.5 (OCH_3); UV (methanol) 204 (ε=4.3×10⁴), 226 (1.8×10⁴), and 275 nm (5.8×10³); MS *m/z* 273 (M^+). Anal. Calcd for $C_{14}H_{11}NO_3S$: C, 61.53; H, 4.06; N, 5.13. Found: C, 61.06; H, 3.90; N, 5.03.

2-(4-Methylphenyl)-1,2-benzisothiazol-3(2H)-one 1-Oxide (11b). Mp 167.5—168.5 °C: IR (KBr) 1170 (s, C=O), 1315 (s), and 1100 cm^{-1} (s, S=O); ^1H NMR ($CDCl_3$) δ=2.28 (3H, s. CH_3), and 7.0—8.2 (8H, m); ^{13}C NMR ($CDCl_3$) δ=164.4 (C=O), 128.1 and 145.4 (3a- and 7a-C), 125.0, 126.5, 133.2, and 134.3 (4-, 5-, 6-, and 7-C), 131.0 (1′-C), 127.2 (2′-C), 130.2 (3′-C), 138.8 (4′-C), and 21.1 (CH_3); UV (methanol) 206 (ε=4.3×10⁴), 220 (s), 255 (s), and 275 nm (s); MS, *m/z* 257 (M^+). Anal. Calcd for $C_{14}H_{11}NO_2S$: C, 65.35; H, 4.31; N, 5.44. Found: C, 64.80; H, 4.08; N; 5.29.

2-Phenyl-1,2-benzisothiazol-3(2H)-one 1-Oxide (11c). Mp 136—137 °C; IR (KBr) 1685 (s, aromatic amide C=O) and 1100 (s, S=O); ^1H NMR ($CDCl_3$) δ=7.0—8.2 (m, aromatic-H); ^{13}C NMR ($CDCl_3$) δ=164.3 (C=O), 128.2 and 145.4 (3a- and 7a-C), 125.1, 126.6, 133.3, and 134.5 (4-, 5-, 6-, and 7-C), 133.9 (1′-C), 127.2 (2′-C), 129.6 (3′-C), and 128.8 (4′-C); UV (methanol) 204 (ε=4.29×10⁴) and 270 nm (s); MS, *m/z* 243 (M^+). Anal. Calcd for $C_{13}H_9NO_2S$: C, 64.18; H, 3.73; N, 5.76. Found: C, 63.85; H, 3.56; N, 5.85.

2-(4-Chlorophenyl)-1,2-benzisothiazol-3(2H)-one 1-Oxide (11d). Mp 139—140 °C; IR (KBr) 1720 (s, C=O), 1495 (s), 1310 (s), and 1195 cm^{-1} (s, S=O); ^1H NMR (acetone-d_6) 400 MHz, δ=7.595 and 7.616 (2H and 2H, A_2B_2 quartet J_{AB}=9.2 Hz, 2′- and 3′-H), 7.952 (1H, dt, J_{6-5}=J_{6-7}=8 Hz, J_{6-4}=1.2 Hz, 6-H), 8.024 (1H, dt, J_{5-4}=J_{5-6}=8 Hz, J_{5-7}=1.2 Hz, 5-H), 8.066 (1H, dd, J_{7-6}=8 Hz, J_{7-5}=1.2 Hz, 7-H), and 8.171 (1H, dd, J_{4-5}=8 Hz, J_{4-6}=1.2 Hz, 4-H); ^{13}C NMR (acetone-d_6) δ=164.4 (C=O), 128.1, 145.6 (3a- and 7a-C), 125.3, 126.9, 133.5, and 134.7 (4-, 5-, 6-, and 7-C), 132.7 (1′-C), 128.5 (2′-C), 129.9 (3′-C), and 134.7 (4′-C); UV (methanol) 205 (ε=4.4×10⁴), 225 (s), and 260 (s); MS, *m/z* 277 and 279 (M^+). Stereochemical Study on 1,3-Dipolar Cycloaddition Reactions of Heteroaromatic *N*-Ylides with Symmetrically Substituted cis and trans Olefins

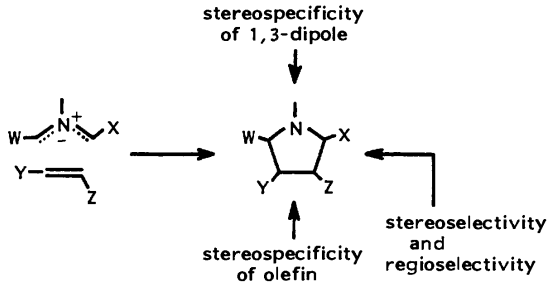
Otohiko TSUGE,* Shuji KANEMASA, and Shigeori TAKENAKA
Research Institute of Industrial Science, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816
(Received July 8, 1985)

Stereochemistry of the cycloadditions of twenty-four heteroaromatic *N*-ylides with several symmetrically substituted cis and trans olefins has been investigated. Cyclic and acyclic cis olefins cycloadd to the anti form of the ylides in a highly *endo*-selective manner giving almost quantitative yields of stereospecific endo 3+2 cycloadducts. *N*-Ylides stabilized with a substituent of carbonyl type react with trans olefins to form mostly two stereoisomeric 3+2 cycloadducts to the anti form of the ylides. In most cases, they undergo the stereospecific interconversion through a retro cycloaddition process, the isomer ratios and the easiness of transformation depending upon the nature and size of substituents on the five-membered ring which has been built up in the cycloaddition step. On the other hand, *N*-ylides stabilized with a substituent of noncarbonyl type react with trans olefins to give stereospecific and stereoselective 3+2 cycloadducts as single isomers which are assigned as the cycloadducts to the syn form of the ylides.

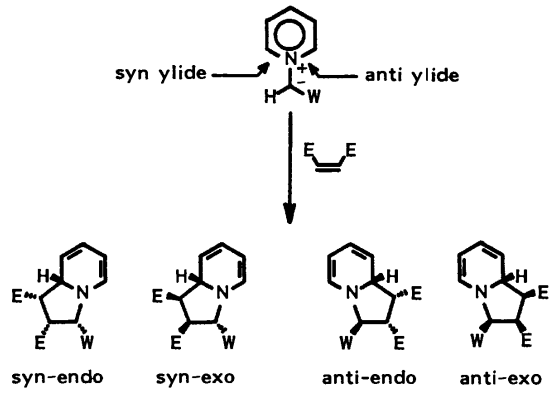
1,3-Dipolar cycloaddition reaction is a process by which heterocyclic five-membered ring systems can be prepared. As exemplified below by the reaction between an azomethine ylide 1,3-dipole and an olefinic dipolarophile, this reaction involves several stereochemical and regiochemical aspects: the regioselectivity (the orientation between both an unsymmetrical 1,3-dipole and an olefin), the stereospecificity of a 1,3-dipole and an olefin (whether the stereochemistry of a 1,3-dipole and an olefin can be faithfully transmitted to the cycloadduct or not), and the stereoselectivity (the endo or exo approach between a 1,3-dipole and an olefin). Sixteen stereoisomers are possible for the cycloadduct of this reaction. Therefore, stereochemical and regiochemical control of this reaction is necessary for the wide applications of 1,3-dipolar cycloaddition reactions to organic synthesis as a useful process, especially the application to natural product synthesis.



Among the above stereo- and regiochemical aspects, it has been well documented that 1,3-dipolar cycloadditions usually take place in a highly regioselective manner with the preservation of stereochemistry of olefins.[1-7] Some stereospecific cycloadditions have been also demonstrated by the use of highly reactive dipolarophiles and anti and syn, or trans and cis, azomethine ylides which can be selectively accessible by the thermal conrotatory ring opening of cis and trans aziridines, respectively.[8-15] In most cases, the selectivity between the endo and exo approaches is awfully poor.[8-12] Only when the azomethine ylide is substituted with an acyl group at the terminal carbon, stereoselective cycloadducts have been obtained.[13,14] However, the kind of approach (endo or exo) and the origin of stereoselectivity have not been solved since two geometrical isomers are possible for each isomer of the ylide and because it was hardly able to specify the species that was actually concerned in the cycloaddition.

Heteroaromatic *N*-ylides as reactive azomethine ylide 1,3-dipoles, readily available from nitrogen-containing aromatic heterocycles by the sequence of alkylation at the nitrogen and deprotonation, have been long applied to the cycloadditions with acetylenic dipolarophiles yielding fused heterocycles with a nitrogen at the point of fusion.[16-19] It is only quite recent that several reports on the stereochemical study of 1,3-dipolar cycloadditions of heteroaromatic *N*-ylides have started to appear, most of them being not inclusive but fragmentary.[20-28]

As shown below, the pyridinium methylide with a ylide-stabilizing substituent, as a representative of heteroaromatic *N*-ylides, contains both anti and syn azomethine ylide 1,3-dipolar structures. Unlike the open-chained systems derived from aziridines, there is no isomeric structure possible for both the anti and syn ylide. Accordingly, the simple structural analysis of cycloadducts formed in the reaction with an olefinic dipolarophile will give us answers to the following questions: 1) Which is more reactive, anti or syn ylide? 2) How is this cycloaddition stereospecific with respect to the ylide? 3) Is this reaction *endo*-selective or *exo*-selective?



In the present paper, the 1,3-dipolar cycloaddition reactions of a variety of heteroaromatic *N*-ylides with symmetrically substituted cis and trans olefinic dipolarophiles were investigated, and it was attempted to figure out the stereochemical feature of 1,3-dipolar cycloaddition of heteroaromatic *N*-ylides on the basis of structural analysis of the cycloadducts.

Results and Discussion

In the present research were employed twenty-four heteroaromatic *N*-ylides involving six different heterocyclic ring systems (Scheme 1): Pyridinium methylides **1a—g** with several ylide-stabilizing substituents, pyridinium phenacylides **1h—n** substituted on the pyridine nucleus, isoquinolinium methylides **2a—d** also substituted at the ylide carbon, isoquinolinium 1-benzoylethylide **3**, quinolinium phenacylide **4**, pyridazinium phenacylide **5**, thiazolium methylides **6a** and **6b**, and benzothiazolium phenacylide **7**.

As these heteroaromatic *N*-ylides are all labile, they were generated *in situ* from the corresponding quaternary salts and triethylamine, and used without isolation for the cycloadditions to olefinic dipolarophiles.

Cycloadditions to Cyclic cis Olefins. The suspension of *N*-phenacylpyridinium bromide in dry chloroform containing an equivalent of *N*-methylmaleimide **8a** was treated with triethylamine at 0 °C. In a few minutes at room temperature, the suspension dissolved into a clean orange solution. After the reaction was completed (10 min), triethylamine hydrobromide was removed off by washing the reaction mixture with sufficient water. Dryness and evaporation of the chloroform under vacuum below room temperature gave a quantitative yield of the 1:1 adduct **9** as a single isomer (Scheme 2 and Table 2).

Other pyridinium methylides **1b—f** as well as **1a** readily reacted with several *N*-substituted maleimides **8a—d**, under similar conditions, to afford almost quantitative yields of the corresponding cycloadducts **10—18** as single isomers. Although the reaction of pyridinium *p*-nitrobenzylide **1g** with **8c** in chloroform was so sluggish that only 59% of the cycloadduct **19** was obtained after 24 h at room temperature with the recovery of *N*-(*p*-nitrobenzyl)pyridinium bromide (40%), the same reaction in dimethyl sulfoxide (12 h at room temperature) afforded a quantitative yield of **19** also as a single product.

A ^{1}H-NMR spectroscopic observation of the reaction of *N*-(2-furoylmethyl)pyridinium bromide with **8a** in the presence of triethylamine at 0 °C in deuteriochloroform showed that the cycloaddition was completed in a few minutes and that the only products formed in this solution were the cyclo-

a) All the ylides were generated *in situ* from the corresponding precursors and triethyamine. b) Isolated yields. The isomer ratios were determined by a ^{1}H-NMR spectroscopy. c) CF: chloroform; DM: dichloromethane; DMSO: dimethyl sulfoxide. d) Not separated. e) The melting points for the mixtures.

adduct **13** and triethylamine hydrobromide, no other product being formed. This indicates that **13** is the cycloadduct from a kinetically controlled reaction. The cycloadduct **13** was found too labile to be purified by crystallization. In deuteriochloroform **13** gradually decomposed even at room temperature and in 24 h at the same temperature it completely changed into a complex mixture of the secondary products. In deuteriobenzene the decomposition was suppressed, but when warmed at 50—60 °C the complete decomposition of **13** was observed in a few hours.

The other cycloadducts **9**—**19** showed comparable instability, their purification providing authentic samples for elemental analyses being unsuccessful. However, their structures were confirmed on the basis of the spectral data as well as the molecular weight measurement.

The ^{1}H-NMR spectra were most informative to determine the stereostructures of cycloadducts **9**—**19** (Table 2). Very small coupling constants between 4-H and 3a-H (0—0.8 Hz) confirm a trans relationship of these hydrogens. As the only possible manner of ring fusion at the 3a- and 9b-positions is cis geometry, 3a-H and 9b-H are cis each other. A structural inspection using molecular models shows that the coupling constants of 7.7—8.0 Hz are only possible for the cis configuration between 9b-H and 9a-H. Thus, all the cycloadducts **9**—**19** were assigned as the endo 3+2 cycloadducts to the anti ylides of **1a**—**g**. An additional evidence for the assigned structures is the extraordinarily big difference of chemical shifts between 7-H and 9-H. Since the difference of the corresponding hydrogens of 1-phenyl-1,2-dihydropyridine[29] is only 0.27 ppm (3-H: 5.21 ppm and 5-H: 4.94 ppm), this big differences which are more than 1.3 ppm must be because of the unusual low field shifts of 9-Hs. In the endo cycloadducts, these hydrogens are so closely located to a carbonyl of fused maleimide ring that they are suffering from its anisotropy showing unusual low chemical shifts.

When a substituent is introduced at the 2- or 3-position of pyridine nucleus of **1**, two unidentical ylide forms are possible. As each of them contains two 1,3-dipolar systems, anti and syn azomethine ylides, in the same molecule, there are four stereoisomers possible to form for the endo cycloadducts to a maleimide.

The reactions of pyridinium phenacylides **1h**—**n** bearing a variety of substituents on the pyridine ring with **8c** under similar conditions gave, in all cases, the endo 3+2 cycloadducts **20**—**29** to the corresponding anti ylides (Scheme 2, Table 1, and 2). When the 2-position of ylide is substituted by a methyl group, the cycloaddition occurred only at the 6-position of **1h** to give **20**, steric hindrance around the reaction sites being the major factor which determined the periselectivity of cycloaddition. In fact, the reaction of 2,6-dimethylpyridinium phenacylide with **8c** gave no cycloadduct under various reaction conditions. On the other hand, in the reactions of 3-substituted pyridinium ylides **1i**, **1m**, and **1n**, regioisomeric mixtures of endo 3+2 cycloadducts to the anti ylides, **21**+**22**, **26**+**27**, and **28**+**29** were obtained. On the basis of these results, it is easily indicated that two ylide forms of the 3-substituted pyridinium phenacylides actually exist and only the anti ylides of them preferentially participate in the cycloaddition to a cyclic dipolarophile. These regioisomers could not be separated each other because of their instability which will be discussed later.

Similar reactions of other heteroaromatic *N*-ylides

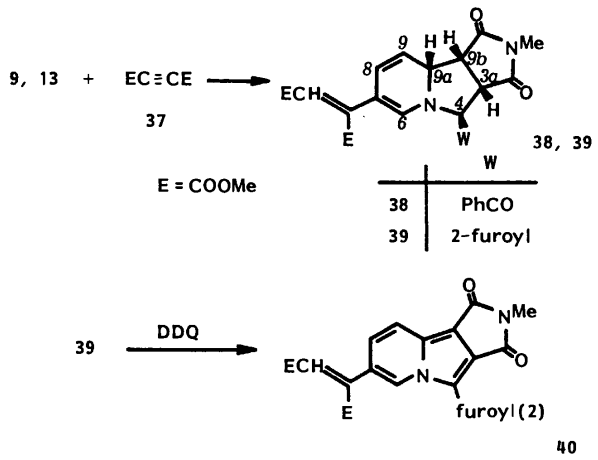
a) ^{13}C-NMR spectrum is available in Experimental Section. b) Measured as a mixture with its stereoisomer. c) Satisfactory elemental analysis is available in Experimental Section.

3, **4**, **6**, and **7** with *N*-substituted maleimides **8** gave each single isomers of the 3+2 cycloadducts **30—34** in quantitative yields (Scheme 3 and Table 1). Their structures were assigned as the endo cycloadducts to the anti ylides on the basis of the spectral data shown in Table 2, especially of the close resemblance of coupling patterns of the methine hydrogens on the newly formed five-membered rings between **9—29** and **30—34**. The configuration at the 8-position of **30** was confirmed by the low field shift of 8-Me (1.96 ppm) owing to an anisotropy from the adjacent maleimide carbonyl, and by the comparison of chemical shifts of 8a-, 11a-, and 11b-H (4.44, 3.43, and 4.64 ppm, respectively) with those of the corresponding methine hydrogens in the endo 3+2 cycloadduct between the anti form of isoquinolinium *p*-nitrophenacylide and *N*-phenylmaleimide (8a-H: 4.11, 10a-H: 3.63, and 10b-H: 4.78 ppm).[30] The low field shift of 6-H of **31** is consistent with the assigned endo structure (6-H: 6.43 and 5-H: 6.03 ppm). A similar 3+2 cycloadduct **36** was obtained in the reaction of **7** with maleic anhydride **35**.

The heteroaromatic ring which has been incorporated from the heteroaromatic *N*-ylides into cycloadducts as a dihydro form tends to recover its aromaticity. This tendency induces the C–C bond cleavage into a betain intermediary and brings about further decomposition with the elimination of heteroaromatic ring.[31,32] Instability of these cycloadducts will be reduced if the remaining unsaturation on the incorporated heterocycles is consumed in another reaction.

With the aim of the formation of Diels-Alder cycloadducts, reactions of the 3+2 cycloadducts **9** and **13** with dimethyl acetylenedicarboxylate **37** were carried out. However, the 1:1 adducts **38** and **39** obtained were not the expected Diels-Alder cycloadducts but the Michael type adducts at the 7-position as shown in Scheme 4. Although **38** was found stable enough to be purified without serious decomposition, **39** was still unstable. So it was dehydrogenated with DDQ into the indolizine derivative **40**.



Scheme 4.

As described above, the cycloaddition reactions of heteroaromatic *N*-ylides to cyclic cis olefins proceed in a highly stereoselective manner giving quantitative yields of the endo 3+2 cycloadducts to the anti form of ylides. The reaction of a pyridinium methylide **1** carrying W as a ylide-stabilizing substituent with a maleimide is illustrated in Fig. 1 as an example. There is an attractive interaction working between the π conjugation on the pyridine nucleus and the additional unsaturations (carbonyls) of maleimide, only the endo approach of these reagents being preferred. The exclusive participation of the anti form of **1** may be partly because the endo approach toward the anti ylide **A** leads to a sterically less hindered transition state than that toward the syn ylide **B**. If the anti and syn forms of heteroaromatic *N*-ylides are energetically unidentical, unlike the pyridinium methylides such as **1a—g**, there should be some difference of stability between these two ylidic forms. It will be discussed later that the anti form of ylide is more stabilized than the syn form when the ylide is carrying a ylide-stabilizing substituent of carbonyl type.

Cycloaddition to Acyclic cis Olefins. In the reactions of the pyridinium phenacylide **1a** with such acyclic cis olefins as (*Z*)-1,2-dibenzoylethene **41b** and dimethyl maleate **41c**, the corresponding 3+2 cycloadducts could not be isolated because of their instability, only the pyridine-eliminated products being obtained.[32] However, maleonitrile **41a** produced a fairly stable cycloadduct **42** as a single stereoisomer in a quantitative yield as shown in Scheme 5 and Table 3.

It is clear that the cis geometry of the olefin **41a** has been retained in the cycloadduct **42**, for a similar stereospecific reaction of **1a** with fumaronitrile **55a**, the trans isomer of **41a**, provides two stereoisomeric 3+2 cycloadducts neither of which is identical with **42** as discussed later. The structure of **42** was independently assigned to be the endo 3+2 cycloadduct to the anti form of **1a** on the basis of the spectral data shown in Table 4, especially of a small

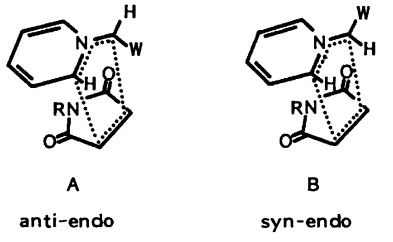


Fig. 1. Two endo approaches between **1** and a maleimide.

coupling constant between 2-H and 3-H (3.2 Hz).

Expecting the formation of stable 3+2 cycloadducts to acyclic cis olefins, several isoquinolinium methylides **2a—c** were allowed to react with **41a—d**, at room temperature in chloroform for less than an hour, to give only the endo cycloadducts **43—48** to the anti forms of **2** (Scheme 5 and Table 3). Similarly the thiazolium **6b** and benzothiazolium methylides **7** afforded the endo cycloadducts **50—52** in the stereoselective and stereospecific reactions with **41**.

The cycloadducts derived from the esteric dipolarophiles **41c** and **41d** are usually sensitive to dehydrogenation at one of the bonds newly formed in a cycloaddition step. In these cases, it is not easy to purify the crude cycloadducts since they undergo ready dehydrogenation during the purification by chromatography over silica gel or when warmed for a while in solution. Thus, the chromatographic treatment of **47** gave *trans*-2,3-dihydro-1,2,3-tris(methoxycarbonyl)pyrrolo[2,1-*a*]isoquinoline **53** in a fair yield. When isoquinolinium *p*-nitrobenzylide **2d** which was found not so highly reactive toward **41c** at room temperature in chloroform was allowed to react with **41c** under reflux in acetonitrile for 1 h, was obtained none of the cycloadduct **49** but the dehydrogenated product **54** as a single isomer.

a) The only exception is **43** which was measured in acetonitrile-d_3 (the upper column) or in dimethyl-d_6 sulfoxide (the lower). b) Satisfactory elemental analysis is available in Experimental Section. c) No clear coupling was given because of the signal overlapping. d) Satisfactory high mass spectrum is available in Experimental Section. e) No parent ion peak was observed.

collected in Table 4. The assignment of signals in the ^{1}H-NMR spectra was based upon the decoupling of coupled signals by irradiation or deuterium labeling. The use of the monodeuterated derivative of **2a** in the reaction with **41c** succeeded in the introduction of a deuterium at the 3-position of **45**. The cycloadducts **45—48** are carrying two endo ester groups introduced from the esteric dipolarophiles **41c** and **41d**. The ones at the 1-position (3.30—3.33 ppm for COOMe and 1.12 ppm for COOBu^t) are more extensively shielded by the fused benzene ring than the others at the 2-position (3.65—3.75 ppm for COOMe and 1.39 ppm for COOBu^t), the assigned endo structures being confirmed.

As described above, the endo cycloadducts **9—36** to maleimides showed very small vicinal couplings (0—1.0 Hz) from a terminal methine hydrogen of ylidic origin. Although the cycloadducts **42—52** possess the same configuration to **9—36**, their coupling patterns are quite different. The corresponding vicinal couplings are varying in some wide range (3.2 to 8.0 Hz).

Figure 2 illustrates the conformations of pyrrolidine rings included as a part of the endo 3+2 cycloadducts to cyclic and acyclic cis olefins. A molecular model inspection indicates that the cycloadduct **C** to a maleimide is conformationally rigid. The cycloadduct **D** which carries such sterically small substituents as cyano moiety (E=CN) may take a conformation of close resemblance to **C**, since the gausch repulsion among substituents seems not critical. In these cases (cycloadducts **42**, **43**, and **51**), small coupling constants (3.2—3.5 Hz) were observed between 2-H and 3-H. When the substituents in **D** are bulky and therefore the gausch conformation becomes unstable, a rotation around C–C bonds takes place in a way to minimize the steric repulsion leading to **E**. The coupling constant between 2-H and 3-H becomes larger (6.4—8.0 Hz) and that between 1-H and 2-H slightly smaller (7.0—8.0 Hz) in the cycloadducts derived from the olefins **41b—d**.

The exclusive formation of endo cycloadducts to the anti forms of ylides in the reactions with acyclic cis olefins shows that the attractive interaction between the heteroaromatic plane of ylides and the additional unsaturations of olefins has overwhelmed the steric repulsion of all sorts. It is quite surprising that no any exo cycloadduct was formed in the reaction with **41d** which bears two bulky ester groups (COOBu^t).

The thermal stability for some of these cycloadducts will be discussed in the following section.

Cycloaddition to Acyclic trans Olefins. The reaction of **1a** with fumaronitrile **55a** in chloroform

Scheme 6.

at 0 °C for 5 min furnished a mixture of two stereoisomeric cycloadducts **56** and **57** (7:3), and for 1 h at the same temperature only **57**, both in quantitative yields (Scheme 6 and Table 5). On standing in solution (chloroform) at room temperature, **56** gradually changed into **57** and this clean isomerization was completed in 1 h, indicating that **56** and **57** are kinetically and thermodynamically controlled products, respectively. Although chromatographic separation of the kinetical cycloadduct **56** from the mixture with **57** was unsuccessful, the reaction of **1a** with **55a** in dimethyl sulfoxide under similar conditions precipitated almost pure **56** out of the solution.

Based upon the spectral data listed in Table 6, the structures of **56** and **57** were assigned to be the 1-endo-2-exo and 1-exo-2-endo cycloadducts to the anti form of **1a**, respectively. The isomer **57** shows a small coupling constant (2.8 Hz) between 2-H and 3-H which are in a trans relationship. This cycloaddition is highly stereospecific, so neither **56** nor **57** is identical with the cycloadduct **42** which was obtained as a single isomer from the cis olefin **41a** (Scheme 5). The stereospecific isomerization of **56** into **57** proceeds through a retro cycloaddition pathway as evidenced below. These facts were also helpful for the structural determination of **56** and **57**.

A similar reaction of isoquinolinium phenacylide **2a** with **55a** in dimethyl sulfoxide precipitated out the kinetically controlled cycloadduct **58** in a pure form together with **58**+**59** as a solution, and in chloroform the thermodynamically controlled 1-exo-2-endo isomer **59** was a major product in an equilibrium with **58** (Table 5). This equilibration can be achieved within a few minutes at room temperature in chloroform.

It was found that the isomerization of the 1-endo-2-exo cycloadducts into the 1-exo-2-endo cycloadducts was deeply related with thermal instability of these cycloadducts. They have a tendency of going back to the starting components, the heteroaromatic *N*-ylide and the dipolarophile, when heated or dissolved in solvent. This retro cycloaddition proceeds in a highly stereospecific fashion and is facilitated if both of the ylide and dipolarophile are carrying strongly electron-withdrawing substituents such as cyano and benzoyl moieties. Thus, the isomerization of **56** into **57** has taken place in the following way: The kinetic cycloadduct **56** is cleaved into **1a** and **55a** even at room temperature and then the dissociated species are

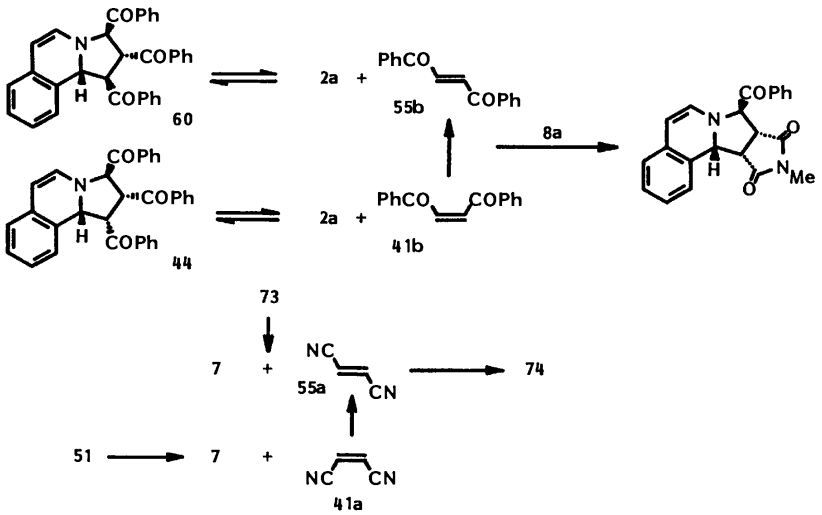
a) All the ylides were generated *in situ* from the corresponding precursors and triethyamine. b) Isolated yields as single cycloadducts or mixtures of stereoisomeric cycloadducts. The isomer ratios were determined on the basis of the ^{1}H-NMR spectra of crude products. c) CF: chloroform; DMSO: dimethyl sulfoxide; AN: acetonitrile; DM: dichloromethane. d) Tentatively assigned as a cycloadduct to the syn form of **2d**. e) Containing 17% of the 1,10b-dehydrogenated derivative of **37**.

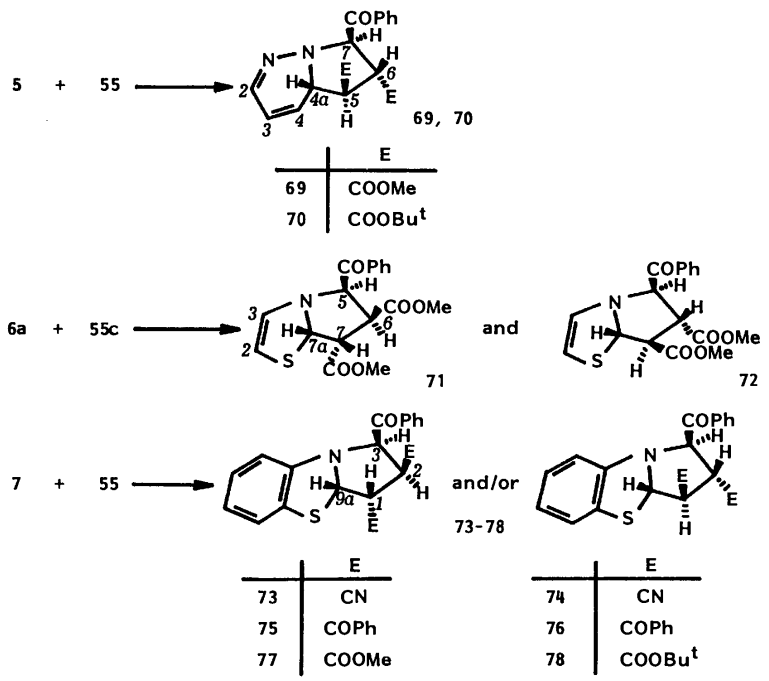
recombined into the thermodynamic isomer **57**, both processes being highly stereospecific.

When the 1-exo-2-endo cycloadduct **60**, the only product in the reaction of **2a** with (*E*)-1,2-dibenzoylethene **55b** at room temperature for 10 min, was warmed at 50—60 °C in dimethyl sulfoxide in the presence of *N*-methylmaleimide **8a**, the endo 3+2 cycloadduct of **8a** to the anti form of **2a** was formed in an excellent yield (Scheme 7). This result as an evidence for the retro cycloaddition process indicates that even the thermodynamically controlled cycloadducts may be readily dissociated into the starting ylide and olefin. An unusual isomerization of **44**, the cycloadduct of **2a** to (*Z*)-1,2-dibenzoylethene **41b**, occurred leading to **60** when warmed in dimethyl sulfoxide at 50—60 °C for 1 h. This reaction is also stereospecific, but with the complete inversion of stereochemistry of olefin part (from Z to E). As **41b** was found to isomerize into **55b** with comparable easiness under the reaction conditions, it can be concluded that this isomerization has been caused through the similar retro cycloaddition pathway and the additional olefin isomerization.

The cycloadducts carrying at least one esteric substituent, which were obtained in the reactions of **2b** or **55c** and **55d** as shown in Scheme 6 and Table 5, resist their dissociation into the starting ylides and olefins. Neither the incorporation of maleimide nor



Scheme 7.



Scheme 8.

the change of isomer ratio was observed on their heating in the presence or absence of a maleimide. It was found, however, that the isomerization was catalyzed by palladium on charcoal. Thus, the mixture between **61** and **62** or among **67**, **68**, and their isomer[33] could isomerize into **62** or **68** in almost quantitative yield, respectively, when heated under reflux in benzene in the presence of palladium on charcoal.

Similar cycloadditions of other heteroaromatic *N*-ylides **5**, **6a**, and **7** with symmetrically substituted olefins **55** are shown in Scheme 8, the results in Table 5, and the spectral data of cycloadducts obtained in Table 6.

The first nine cycloadducts in Table 6 (compounds **55** to **77**) as kinetical products have the same stereochemistry as to the newly formed five-membered rings whose four consecutive methine hydrogens are in a cis-trans-cis relationship. The small trans coupling constants of **58**, **61**, **65**, and **67** (3.5—4.8 Hz) and the upfield shift of COOMe in **61** (3.14 ppm) and COOBu^t in **67** (1.08 ppm) at the 1-endo position are consistent with the proposed structures. On the other hand, the large trans couplings of **56**, **71**, **73**, **75**, and **77** will be because of the increase of dihedral angle by the rotation around the corresponding bonds. In the kinetic cycloadducts to **2**, for example **61**, such rotation is inhibited by the growing steric repulsion between the substituent at the 1-position and the extruding hydrogen at the 10-position.

The other fourteen cycloadducts (compounds **57** to **78**) as thermodynamic products have another stereochemistry on the five-membered rings whose four methine hydrogens are in a trans-trans-trans relationship that is thermodynamically more stable than the above cis-trans-cis succession. All the cycloadducts of this category show a similar coupling pattern. The trans couplings from the ylide hydrogen are generally small (2.8—5.8 ppm) and no strong shielding towards the substituents of olefins from the fused heterocyclic rings has been observed, the proposed structures being again confirmed.

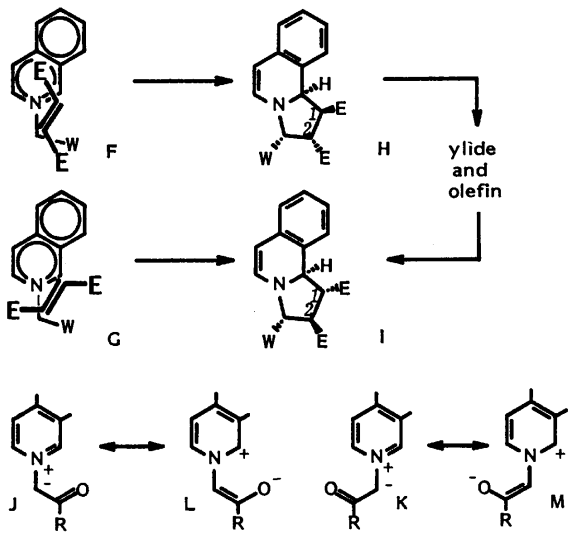


Fig. 3. Approaches of trans olefins to the anti form of heteroaromatic *N*-ylides.

As described above, the attractive interaction between the heteroaromatic ring of ylides and the substituents of olefins have determined the structures of cycloadducts in the 1,3-dipolar cycloadditions of heteroaromatic *N*-ylides to both cyclic and acyclic cis olefins. With trans olefins, the similar interaction also plays an important role as shown in Fig. 3 which illustrates the reaction of an isoquinolinium ylide as an example. One of the electron-withdrawing substituents E of trans olefin positively interacts with the heteroaromatic plane of the anti form of ylide, through the approach **F**, leading to the 1-endo-2-exo cycloadduct **H** as a kinetically controlled product. When both E and W are strongly electron-withdrawing, **H** is readily dissociated into the starting ylide and olefin, which are then recombined giving the thermodynamically more favored cycloadduct **I**, both in a highly stereospecific manner. Such dissociation of cycloadduct is inhibited under the conditions of cycloaddition reaction if it carries at least one esteric substituent. In this case, the formation of **H** and/or **I** is a result from the competition between the 1-endo-2-exo **F** and 1-exo-2-endo approach **G**, and hence from a cycloaddition path of kinetically controlled type. When E is small in size, the attractive interaction of E toward the ring in **F** is predominant, the cycloadduct **H** being the major product. However, when E is bulky, such interaction in **F** is reduced and instead the repulsion between the other E and W is increased. In the other approach **G**, an attractive interaction works between E and the edge of heteroaromatic plane, so that steric repulsion is not critical. This is the reason why the 1-exo-2-endo cycloadduct **I** was the only cycloadduct formed when both E and W are sterically crowded.

It is surprising that, in the approach **F**, the substituent W from the ylide has been sitting in such a direction as it causes some steric repulsion toward E. As shown by the exclusive participation of the anti form of ylide in the cycloadditions to cis olefins, there is no important attractive interaction working between E and W. Accordingly a reasonable explanation is that the anti ylide **J** is better stabilized than the syn ylide **K** so as to get a chance of participating to the cycloadditions. This stabilization may be caused by a proximate interaction of the both poles of 1,5-dipole **L** which arises from an extended conjugation of 1,3-dipole with the carbonyl. It is not confirmed so far, however, whether cyano moiety can act in the same manner or not.

Isoquinolinium *p*-nitrobenzylide **2d** might exist

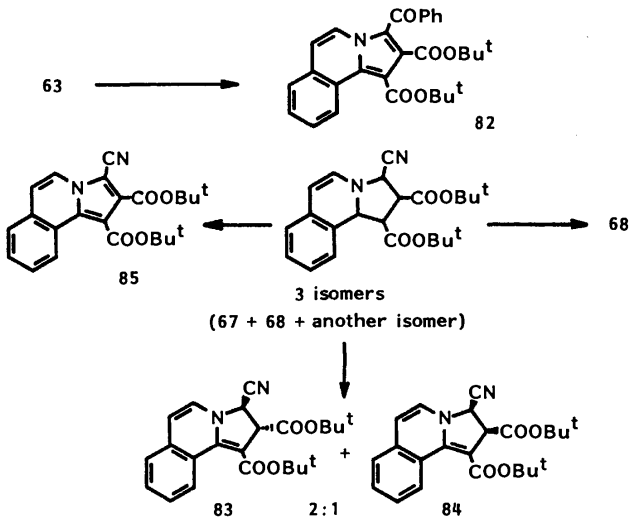
Scheme 9.



Scheme 10.

both as the anti and syn forms since no stabilization of anti ylide is expected in this case. Therefore, its cycloadditions to trans olefins will lead to the 1-endo-2-exo cycloadducts to the syn form, which are the most feasible products from the analysis of all possible attractive interactions and steric repulsions. As expected, the corresponding cycloadducts **79—81** were obtained as single stereoisomers (Scheme 9) and assigned as the 1-endo-2-exo cycloadducts to the syn form of **2d** on the basis of the spectral data shown in Table 6 and of the reaction mode of **2d** toward unsymmetrically substituted trans olefins.[34]

As shown in Scheme 10, some of the cycloadducts to trans olefinic esters undergo dehydrogenation reactions. The cycloadduct **63** was dehydrogenated into a pyrrolo[2,1-*a*]isoquinoline **82** when heated under reflux in benzene in the presence of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ). A mixture of three isomers formed from **2c** and **55d**, which was found to isomerize into the thermodynamically most stable cycloadduct **68** on heating in benzene in the presence of palladium on charcoal, was similarly dehydrogenated into the pyrrolo[2,1-*a*]isoquinoline **85** or the 2:1 mixture of stereoisomeric dihydropyrrolo[2,1-*a*]isoquinolines **83**+**84** when heated in ethanol or chromatographed over silica gel using benzene as an eluent, respectively.

Experimental

General. Melting points were determined on a Yanagimoto micro melting point apparatus and uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^{1}H-NMR spectra were recorded on a Hitachi R-40 or a JEOL FX-100 instrument and ^{13}C-NMR spectra on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane. Mass spectra were measured with a JEOL JMS-01SG-2 spectrometer at 70 eV of ionization energy. Elementary analyses were performed on a Hitachi 026 CHN analyzer. Thin-layer chromatography (TLC) was accompolished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck) or of aluminum oxide 60 F-254 type-E (Merck). Visualization was with ultraviolet light (254 and 365 nm) and iodine. Wakogel C200 and C300 (Wako) and Silicagel 60 (Merck) were used for preparative column chromatography. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silicagel 60 (Merck, size: 0.04—0.063 mm). Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type V.

Materials. The following olefins are commercially available and were used without further purification: *N*-methylmaleimide **8a**, maleic anhydride **35**, dimethyl maleate **41c**, fumalonitrile **55a**, and dimethyl fumarate **55c**. *N*-Substituted maleimides such as *N*-phenyl- **8b** (mp 89—90 °C), *N*-(*p*-methylphenyl)- **8c** (mp 152—153 °C), *N*-(2-propenyl)- **8d** (mp 52—53 °C), and *N*-(*p*-methoxyphenyl)-maleimide **8e** (mp 149—150 °C) were all prepared according to the reported method[35] which involves the aminolysis of **35** with the corresponding primary amines in ether at room temperature and the followed cyclization of the maleamic acids with acetic anhydride at 110—120 °C. *trans*-1,2-Dibenzoylethene **55b** was obtained by the Friedel-Crafts reaction of fumaroyl dichloride with benzene in the presence of aluminum chloride (**55b**: mp 108—110 °C).[36] Di-*t*-butyl fumarate **55d** was synthesized by the reaction of fumaroyl dichloride with 2 equivalents of *t*-butyl alcohol under reflux in ether for 2 h in the presence of *N*,*N*-dimethylaniline (**55d**: bp 113—115 °C/400 Pa; mp 59—60 °C; ^{1}H-NMR ($CDCl_3$) δ=1.50 (18H, s, $COOBu^t$) and 6.63 ppm (2H, s, =CH)). Maleonitrile **41** (bp 105—110 °C/2260 Pa) was prepared from the trans isomer **55a** according to the known method.[37] *cis*-1,2-Dibenzoylethene **41b** (mp 128—129 °C)[38] was given by a phothochemical isomerization from **55b**, and similarly di-*t*-butyl maleate **41d** from **55d** (**41d**: mp 64—65 °C; ^{1}H-NMR ($CDCl_3$) δ=1.50 (18H, s, $COOBu^t$) and 6.03 ppm (2H, s, =CH)).

Preparation of Quaternary Salts as the Precursors of Heteroaromatic N-*Ylides.* A mixture of heteroaromatic compound and slightly excess of alkylating reagent in dry ether was allowed to stir at room temperature for a few hours to a day precipitating the corresponding quaternary salt which was collected on a filter and washed with ether. The filtrate was again stirred at the same temperature

giving another portion of the precipitate of quaternary salt. The precursors of heteroaromatic *N*-ylides thus synthesized are as follows: *N*-phenacylpyridinium bromide:[39,40] mp 204—206 °C. *N*-(2-furoylmethyl)pyridinium bromide: mp 208—209 °C (IR (KBr) 1692 cm^{-1}; ^{1}H-NMR (DMSO-d_6) δ=6.38 (2H, s, CH_2), 6.87, 7.72, 8.20 (each 1H, dd, furoyl-H), 8.30 (2H), 8.72 (1H), and 9.07 ppm (2H, each dd, pyridyl-H); Found: C, 49.14; H, 3.84; N, 5.25%. Calcd for $C_{11}H_{10}O_2NBr$: C, 49.25; H, 3.73; N, 5.22%). *N*-acetonylpyridinium bromide:[39,40,41] hygroscopic solid (no melting point was measured). *N*-(methoxycarbonylmethyl)pyridinium chloride:[42] mp 170—173 °C. *N*-(ethoxycarbonylmethyl)pyridinium bromide:[40,43,44] mp 120—123 °C. *N*-(cyanomethyl)pyridinium bromide: mp 166—167 °C (Found: C, 42.07; H, 3.56; N, 14.26%. Calcd for $C_7H_7N_2Br$: C, 42.21; H, 3.52; N, 14.07%). *N*-(*p*-nitrobenzyl)pyridinium bromide:[44,45] mp 224—225 °C. *N*-phenacyl-2-methylpyridinium bromide:[46] mp 229—231 °C (dec). *N*-phenacyl-3-methylpyridinium bromide:[47] mp 185—187 °C. *N*-phenacyl-4-methylpyridinium bromide:[48] mp 274—276 °C (dec). *N*-phenacyl-3,5-dimethylpyridinium bromide: mp 200—203 °C (Found: C, 58.56; H, 5.33; N, 4.54%. Calcd for $C_{15}H_{16}ONBr$: C, 58.82; H, 5.23; N, 4.58%). *N*-phenacyl-4-cyanopyridinium bromide: mp 224—227 °C (dec) (Found: C, 55.22; H, 3.71; N, 9.42%. Calcd for $C_{14}H_{11}ON_2Br$: C, 55.43; H, 3.63; N, 9.24%). *N*-phenacyl-3-(trifluoromethyl)-pyridinium bromide: mp 197—198 °C (Found: C, 48.39; H, 3.25; N, 4.18%. Calcd for $C_{14}H_{11}ONF_3$: C, 48.55; H, 3.18; N, 4.05%). *N*-phenacyl-3-(methoxycarbonyl)pyridinium bromide:[49] mp 183—185 °C. *N*-phenacylisoquinolinium bromide:[39] mp 209—210 °C. *N*-(methoxycarbonylmethyl)-isoquinolinium bromide:[50] mp 159—160 °C (dec). *N*-(cyanomethyl)isoquinolinium bromide: mp 215—218 °C (dec) (Found: C, 52.64; H, 3.75; N, 11.39%. Calcd for $C_{11}H_9N_2Br$: C, 52.82; H, 3.63; N, 11.29%). *N*-(*p*-nitrobenzyl)isoquinolinium bromide:[39,40,51] mp 207—208 °C. *N*-(1-benzoylethyl)isoquinolinium bromide: mp 183—184 °C (Found: C, 63.30; H, 4.72; N, 4.07%. Calcd for $C_{18}H_{16}ONBr$: C, 63.16; H, 4.68; N, 4.09%). *N*-phenacylquinolinium bromide:[39,40] mp 173—175 °C (dec). *N*-phenacylpyridazinium bromide: mp 227—228 °C (dec) (Found: C, 51.42; H, 4.04; N, 10.04%. Calcd for $C_{12}H_{11}ON_2Br$: C, 51.61; H, 3.94; N, 10.04%). *N*-phenacylthiazolium bromide: mp 215—216 °C (Found: C, 46.39; H, 3.67; N, 5.20%. Calcd for $C_{11}H_{14}ONSBr$: C, 46.48; H, 3.52; N, 4.93%). *N*-(2-furoylmethyl)thiazolium bromide: mp 204—205 °C (IR (KBr) 1690 cm^{-1}; ^{1}H-NMR (DMSO-d_6) δ=6.37 (2H, s, CH_2), 6.88, 7.72, 8.20 (each 1H, dd, furyl-H), 8.44, 8.61, and 10.34 ppm (each 1H, dd, thiazolium-H); ^{13}C-NMR (DMSO-d_6) δ=59.36, 113.13, 120.41, 126.40, 138.14, 148.95, 161.68, 178.77, and 203.61 ppm; MS (rel intensity) *m/z* 190 (23), 95 (base peak), and 81 (8); Found: C, 39.43; H, 3.17; N, 5.04%. Calcd for $C_9H_8O_2NBr$: C, 39.43; H, 2.94; N, 5.11%). *N*-phenacylbenzothiazolium bromide:[53] mp 249—250 °C (dec).

General Procedure for the Cycloadditions to Cyclic cis Olefins. To the suspension of a quaternary salt was added an equivalent of cis olefin and then slowly a slight excess (1.1—1.2 equivalent) of triethylamine at 0 °C or room temperature. The resulting mixture was stirred at room temperature until all the salt dissolved into a clear solution. The solvent and time for each reaction are listed in Table 1. After the completion of reaction, the solution was poured into ice water and extracted with dichloromethane or chloroform. The extract was dried over $MgSO_4$ and evaporated under vacuum at or below room temperature. Mostly the residue solidified on the trituration with ether or petr. ether or their mixture. If the product is an oily material, the residue was subjected to an opperation for the complete elimination of reaction and extraction solvents under high vacuum at or below room temperature for at least a few hours. The yield as well as the melting point of each cycloadduct is given in Table 1. In most cases the purification of cycloadduct was unsuccessful affording no analytical samples of authentic purity because of their lability. Therefore the unpurified products were subjected to the spectral measurement whose results are listed in Table 2. Other data for the cycloadducts are given as follows: **9**: ^{13}C-NMR ($CDCl_3$) δ=25.41 (q, *N*-Me), 45.47, 51.30 (each d, 3a- and 9b-C), 59.24 (d, 9a-C), 70.59 (d, 4-C), 98.24 (d, 7-C), 114.13 (d, 9-C), 124.01, 128.95, 129.13, 129.30, 134.18 (each d), 134.07 (s), 176.07, 178.19 (each s, CON), and 194.19 ppm (COPh). **14**: ^{13}C-NMR ($CDCl_3$) δ=21.25 (*p*-Me), 44.56, 52.49 (3a- and 9b-C), 59.53 (9a-C), 71.86 (4-C), 97.69 (7-C), 112.78, 114.42, 119.71, 123.70, 125.99, 129.28, 129.81, 134.39, 147.54, 174.72 (CON), 176.89 (CON), and 177.71 ppm (furyl-CO). **26+27**: F-NMR ($CDCl_3$) δ=31.28 (7-CF_3) and 34.39 ppm (9-CF_3) with the ratio of 1:2. **33**: ^{13}C-NMR ($CDCl_3$) δ=24.78 (*N*-Me), 46.91, 51.25 (5a- and 8a-C), 67.52 (5-C), 70.98 (8b-C), 97.16, 112.72, 121.06, 132.92, 148.83, 149.42, 174.37 (CON), 176.80 (CON), and 183.06 ppm (furyl-CO). **34**: ^{13}C-NMR ($CDCl_3$) δ=47.60, 50.59 (each d, 3a- and 10a-C), 55.27 (q, OMe), 68.43 (d, 3b-C), 71.89 (d, 10-C), 173.30, 176.48 (each s, CON), and 194.02 ppm (s, COPh); Found: C, 68.54; H, 4.39; N, 6.15%. Calcd for $C_{26}H_{20}O_4N_2S$: C, 68.41; H, 4.42; N, 6.14%. **36**: ^{13}C-NMR ($CDCl_3$) δ=47.88, 51.09 (each d, 3a- and 10a-C), 69.32 (d, 3b-C), 71.93 (d, 10-C), 167.64, 172.08 (each d, CON), and 193.22 ppm (s, COPh); Found: C, 65.02; H, 3.68; N, 3.96%. Calcd for $C_{19}H_{13}O_4NS$: C, 64.96; H, 3.73; N, 3.99%.

Reaction of 9 with 37 Leading to 38. A mixture of each equivalents of the cycloadduct **9** and dimethyl acetylenedicarboxylate **37** in dichloromethane was refluxed for 10 min and the solvent was removed under vacuum. The residue was chromatographed over silica gel using hexane/ethyl acetate (3:1) to give 67% of **38**: pale yellow prisms; mp 200 °C; IR (KBr) 1780, 1720—1700, 1620, 1600, and 1580 cm^{-1}; ^{1}H-NMR (CD_3CN) δ=2.95, 3.47, 3.68 (each 3H, s, *N*-Me and COOMe), 3.54 (1H, dd, J_{9b-9a}=9.8 and J_{9b-3a}=7.4 Hz, 9b-H), 3.63 (1H, dd, J_{3a-9b}=7.4 and J_{3a-4}=0.5 Hz, 3a-H), 5.63 (1H, dd, J_{9a-9b}=9.8 and J_{9a-9}=8.0 Hz, 9a-H), 5.73 (1H, d, J_{4-3a}=0.5 Hz, 4-H), 5.79 (1H, ddd, J_{9-8}=9.8, J_{9-9a}=8.0, and J_{9-6}=1.0 Hz, 9-H), 6.57 (1H, dd, J_{8-9}=9.8 and J_{8-6}=3.4 Hz, 8-H), 6.84 (1H, dd, J_{6-8}=3.4 and J_{6-9}=1.0 Hz, 6-H), 7.36 (1H, br. s, HC=), 7.40—7.80, and 8.05—8.25 ppm (5H, m, COPh); ^{13}C-NMR ($CDCl_3$) δ=25.25 (q, *N*-Me), 51.31, 52.19 (each q, COO<u>Me</u>), 47.79 (d, 2×C, 3a- and 9b-C), 57.59 (d, 9a-C), 67.75 (d, 4-C), 102.04 (s, 7-C), 129.05 (d), 130.57 (d), 132.62 (d), 132.74 (s), 134.33 (d), 134.92 (d), 135.39 (d), 144.48 (d, CH=), 167.85 (s, 2×C, <u>C</u>OOMe), 174.60, 176.07 (each s, CON), and 194.92 ppm (s, <u>C</u>OPh); MS (rel intensity) *m/z* 450 (M^+, 22), 105 (base peak), and 77 (79).

Found: C, 63.85; H, 5.01; N, 6.34%. Calcd for $C_{24}H_{22}O_7N_2$: C, 63.99; H, 4.92; N, 6.22%.

Reaction of ***13*** *with* ***37*** *Leading to* ***39***. The similar procedure described above gave 70% of **39**: yellow solid; mp 117—118 °C; IR (KBr) 1770, 1720, and 1690 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=3.07, 3.58, 3.72 (each 3H, s, *N*-Me and COOMe), 3.48 (1H, dd, J_{3a-9b}=8.7 and J_{3a-4}=2.0 Hz, 3a-H), 3.76 (1H, t, J_{9b-9a}=J_{9b-3a}=8.7 Hz, 9b-H), 5.22 (1H, d, J_{4-3a}=2.0 Hz, 4-H), 5.25—5.80 (2H, m, 9- and 9a-H), 6.60 (1H, dd, J_{8-9}=9.4 and J_{8-6}=3.5 Hz, 8-H), 6.63 (1H, dd, J=3.8 and 1.7 Hz, 4-H of furyl), 6.93 (1H, dd, J_{6-8}=3.5 and J_{6-9}=0.8 Hz, 6-H), 7.34 (1H, br. s, CH=), 7.50 (1H, dd, J=3.8 and 0.8 Hz, 5-H of furyl), and 7.72 ppm (1H, dd, J=1.7 and 0.8 Hz, 2-H of furyl); ^{1}H-NMR (CD_3CN) δ=2.96, 3.48, 3.67 (each 3H, s, *N*-Me and COOMe), 3.53 (1H, dd, J_{3a-9b}=8.5 and J_{3a-4}=2.4 Hz, 3a-H), 3.77 (1H, dd, J_{9b-9a}=9.5 and J_{9b-3a}=8.5 Hz, 9b-H), 5.36 (1H, d, J_{4-3a}=2.4 Hz, 4-H), 5.63 (1H, dd, J_{9a-9b}=9.5 and J_{9a-9}=8.5 Hz, 9a-H), 5.80 (1H, ddd, J_{9-8}=10.4, J_{9-9a}=8.5, and J_{9-6}=1.0 Hz, 9-H), 6.58 (1H, J_{8-9}=10.4 and J_{8-6}=3.4 Hz, 8-H), 6.69 (1H, dd, J=4.0 and 1.7 Hz, 4-H of furyl), 6.83 (1H, dd, J_{6-8}=3.4 and J_{6-9}=1.0 Hz, 6-H), 7.33 (1H, br. s, CH=), 7.64 (1H, dd, J=1.7 and 0.8 Hz, 5-H of furyl), and 7.83 ppm (1H, dd, J=4.0 and 0.8 Hz, 3-H of furyl); ^{13}C-NMR ($CDCl_3$) δ=25.19 (q, *N*-Me), 51.31, 52.13 (each q, COOMe), 47.79, 48.08 (each d, 3a- and 9b-C), 57.65 (d, 9a-C), 67.05 (d, 4-C), 102.56 (s, 7-C), 112.96 (d), 120.59 (d), 130.39 (d), 132.45 (s), 135.15 (d), 135.38 (d), 144.07 (d), 149.30 (s), 148.30 (d, CH=), 167.73 (s, 2×C, COOMe), 174.72, 175.83 (each s, CON), and 184.05 ppm (s, furyl-CO).

Purification of **39** in order to get the authentic sample failed due to its instability.

Dehydrogenation of ***39*** *into* ***40***. An equimolar mixture of **39** (347 mg, 0.79 mmol) and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ, 179 mg, 0.79 mmol) in 10 ml of dry benzene was heated under reflux for 21 h. The solvent was evaporated *in vacuo* and the residue was chromatographed over silica gel using ethyl acetate/hexane (1:1) giving 211 mg (61%) of **40**: pale yellow needles from ethyl acetate/hexane; mp 204 °C; IR (KBr) 1780, 1730, 1710, 1670, 1640, and 1270 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=3.03, 3.72, 3.78 (each 3H, s, *N*-Me and COOMe), 6.54 (1H, dd, J_{7-8}=12.0 and J_{7-5}=3.3 Hz, 7-H), 6.62 (1H, dd, J=3.8 and 2.0 Hz, 4-H of furyl), 6.70 (1H, d, J_{8-7}=12.0 Hz, 8-H), 7.38 (1H, d, J_{5-7}=3.3 Hz, 5-H), 7.39 (1H, dd, J=3.8 and 0.9 Hz, 5-H of furyl), 7.67 (1H, dd, J=2.0 and 0.9 Hz, 3-H of furyl), and 7.98 ppm (1H, s, CH=); ^{13}C-NMR ($CDCl_3$) δ=24.35 (q, *N*-Me), 52.71 (q, 2×C, COOMe), 113.01 (d), 121.16 (d), 121.60 (d), 126.07 (s), 127.07 (s), 127.77 (s), 129.20 (s), 132.30 (s), 135.71 (d), 138.25 (d), 141.07 (d), 148.54 (d), 151.54 (s), 162.36, 163.07, 164.60, 164.78 (each s, CON and COOMe), and 170.48 ppm (s, furyl-CO); MS (rel intensity) *m/z* 436 (M^+, base peak), 320 (75), and 95 (76); Found: C, 60.55; H, 3.81; N, 6.56%. Calcd for $C_{22}H_{16}O_8N_2$: C, 60.55; H, 3.70; N, 6.42%.

General Procedure for the Cycloadditions to Acyclic cis Olefins. To the suspension of a quaternary salt in dry chloroform was added an equivalent of acyclic cis olefin and then slowly a slight excess (1.1—1.2 equivalent) of triethylamine at 0 °C. The cooling bath was removed and the reaction mixture was stirred at room temperature until all the suspension disappeared. After the reaction was complete, the mixture was poured into ice water and extracted with dichloromethane (twice). The combined extract was evaporated *in vacuo* below room temperature. The residue, in most cases, solidified on the trituration with ether, petr. ether, or their mixture. If the product is an oily material, the residue was evacuated below room temperature for a few hours. The yield and melting point of each cycloadduct is given in Table 3. The crude cycloadducts were all submitted for the ^{1}H-NMR spectral measurement from which the isomer formation was judged. Although some of the cycloadducts were successfully purified by crystallization below room temperature (down to −78 °C), the purification of the other failed because of their instability. The IR, ^{1}H-NMR, and mass spectra of each cycloadduct are listed in Table 4. Other data for the cycloadducts are given as follows: **43**: yellow needles from $CHCl_3$; Found: C, 77.28; H, 4.62; N, 12.85%. Calcd for $C_{21}H_{15}ON_3$: 77.52; H, 4.65; N, 12.92%. **44**: yellow grains from ether; Found: C, 81.90; H, 5.19; N, 3.15%. Calcd for $C_{33}H_{25}O_3N$: C, 81.96; H, 5.21; N, 2.90%. **45**: yellow prisms from ether; Found: *m/z* 391.1412. Calcd for $C_{23}H_{21}O_5N$: M, 391.1418. **47**: yellow needles from ether-petr. ether; Found: C, 62.33; H, 5.55; N, 4.09%. Calcd for $C_{18}H_{19}O_6N$: C, 62.60; H, 5.55; N, 4.06%; Found: *m/z* 345.1220. Calcd for $C_{18}H_{19}O_6N$: C, 345.1211. **48**: Found: *m/z* 312.1108. Calcd for $C_{17}H_{16}O_4N_2$: M, 312.1108. **51**: colorless plates from ethanol; Found: C, 68.71; H, 3.81; N, 12.51%. Calcd for $C_{19}H_{13}ON_3S$: C, 68.86; H, 3.95; N, 12.68%. **52**: pale yellow needles from benzene-hexane; Found: C, 63.47; H, 4.82; N, 3.53%. Calcd for $C_{21}H_{19}O_5NS$: C, 63.37; H, 4.79; N, 3.67%.

The crude cycloadduct **47** was dehydrogenated when chromatographed over silica gel using benzene as an eluent to give **53** in 36% yield: **53**: colorless needles from ether; mp 156 °C (lit.[54] mp 156—157 °C).

The reaction between each equivalent amounts of **2d** and **41c** in chloroform at room temperature for 10 h was carried out and the crude product which showed no clean formation of the cycloadduct **49** in its ^{1}H-NMR spectrum was subjected to a chromatography over silica gel using benzene as an eluent. The product **54** obtained in 40% yield was colored viscous oil whose purification by the repeated chromatography failed. **54**: IR (neat) 1760 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=3.64, 3.78 (each 3H, s, COOMe), 3.97 (1H, d, J_{3-2}=4.7 Hz, 3-H), 5.38 (1H, d, J_{2-3}=4.7 Hz, 2-H), 6.23 (1H, d, J_{6-5}=6.9 Hz, 6-H), 6.57 (1H, d, J_{5-6}=6.9 Hz, 5-H), 7.20-8.30 (7H, m, ArH), and 9.89 ppm (1H, br. d, J_{10-9}=8.0 Hz, 10-H).

General Procedure for the Cycloadditions to Acyclic trans Olefins. To the suspension of a quaternary salt was added an equivalent of trans olefin and then slowly a slight excess (1.1—1.2 equivalent) of triethylamine at 0 °C. The resulting mixture was stirred at 0 °C or room temperature until all the salt dissapeared. The solvent and time for each reaction are listed in Table 5. After the completion of reaction, the mixture was poured into ice water and extracted with dichloromethane (twice). The extract was dried over $MgSO_4$ and evaporated under vacuum at or below room temperature. The crude product was submitted, after the complete elimination of the reaction and extraction solvents *in vacuo* below room temperature, for the ^{1}H-NMR measurement. The ^{1}H-NMR spectrum was inspected in order to know the isomer formation and

isomer ratio. The yield as well as the isomer ratio of each reaction is given in Table 5 and the IR, ^{1}H-NMR, and mass spectra in Table 6. Sometimes the crude cycloadducts solidified when triturated with ether, petr. ether, or their mixture. They were purified by crystallization below room temperature (down to −78 °C). However, in most cases not only the purification but the separation of isomers was unsuccessful because the cycloadducts were too labile against heating and chromatographic treatment. The unstable cycloadducts or the unseparable mixture of isomeric cycloadducts were assigned only on the basis of the spectral data. Other data and exceptional procedures for the cycloadducts are given as follows:

The reaction between **1a** and **55a**, 1 mmol each, in 10 ml of chloroform or dimethyl sulfoxide at 0 °C for 5 min precipitated almost pure **56**, whereas the same reaction in 50 ml of chloroform for 1 h gave a clean solution of **57**. **56**: pale yellow needles from chloroform; mp 120—121 °C (dec); Found: *m/z* 275.1034. Calcd for $C_{17}H_{13}ON_3$: M, 275.1058. **57**: yelow viscous oil.

The reaction between **2a** and **55a**, 1 mmol each, in 10 ml of dimethyl sulfoxide at room temperature for 5 min precipitated almost pure **58** which was collected on a filter and washed with ether, whereas the same reaction in 50 ml of chloroform gave a clean solution of **59** which was contaminated with a small amount of **58**. **58**: colorless prisms from acetonitrile; mp 179—182 °C (dec); Found: *m/z* 325.1210. Calcd for $C_{21}H_{15}ON_3$: M, 325.1214. **59**: yellow needles from chloroform–ether; mp 127 °C.

Other data are shown as follows: **60**: yellow needles from ether; mp 173 °C (dec); Found: C, 81.96; H, 5.21; N, 2.90%. Calcd for $C_{33}H_{25}O_3N$: C, 81.75; H, 5.15; N, 3.18%. **61+62**: viscous yellow oil. **63**: yellow prisms from ether; mp 84—86 °C (dec); Found: *m/z* 475.2373. Calcd for $C_{29}H_{33}O_5N$: M, 475.2357. **64**: viscous yellow oil. **65+66**: yellow solid from ether; mp 138—142 °C; Found: C, 80.18; H, 4.98; N, 6.92%. Calcd for $C_{27}H_{20}O_2N_2$: C, 79.90; H, 4.98; N, 6.92%. **67+68**+another isomer: yellow solid from ether; mp 67—70 °C; Found: C, 69.39; H, 7.06; N, 6.99%. Calcd for $C_{23}H_{28}O_4N_2$: C, 69.67; H, 7.12; N, 7.07%. **69**: colorless plates from ether; mp 130—132 °C (dec); Found: C, 62.98; H, 5.33; N, 8.29%. Calcd for $C_{18}H_{18}O_5N_2$: 63.15; H, 5.30; N, 8.18%. **70**: yellow viscous oil; Found: C, 67.36; H, 7.02; N, 6.50%. Calcd for $C_{24}H_{30}O_5N_2$: C, 67.58; H, 7.09; N, 6.59%. **71+72**: orange viscous oil. **73**: colorless needles from ethanol–hexane; mp 190—191 °C; Found: C, 69.05; H, 3.90; N, 12.44%. Calcd for $C_{19}H_{13}ON_3S$: C, 68.87; H, 3.96; N, 12.68%. **74**: colorless prisms from ethanol–hexane; mp 133—135 °C (dec); Found: C, 68.82; H, 4.09; N, 12.60%. Calcd for $C_{19}H_{13}ON_3S$: C, 68.87; H, 3.96; N, 12.68%. **75+76**: yellow prisms from ether; mp 64 °C; Found: C, 75.77; H, 5.00; N, 3.15%. Calcd for $C_{31}H_{23}O_3NS$: C, 76.07; H, 4.70; N, 2.86%. **77**: colorless needles from carbon tetrachloride; mp 104—105 °C (dec); Found: C, 63.14; H, 4.74; N, 3.50%. Calcd for $C_{21}H_{19}O_5NS$: C, 63.47; H, 4.82; N, 3.53%. **78**: pale yellow prisms from ether; mp 50 °C; Found: C, 67.66; H, 6.25; N, 3.26%. Calcd for $C_{27}H_{31}O_5NS$: C, 67.36; H, 6.44; N, 2.91%. **79**: pale yellow grains from ether; mp 93 °C; Found: *m/z* 496.1462. Calcd for $C_{32}H_{20}O_4N_2$: M, 496.1421. **80**: yellow solid; mp 80—82 °C. **81**: pale yellow grains from ether; mp 75—77 °C; Found: *m/z* 492.2258. Calcd for $C_{28}H_{32}O_6N_2$: M, 492.2258.

*Isomerization of **44** into **60** and of **41b** into **55b**.* The cycloadduct **44** was dissolved in dimethyl-d_6 sulfoxide in an NMR sample tube. The ^{1}H-NMR spectrum of the solution after 1 h at 50—60 °C showed the quantitative formation of **60**. Under the same conditions, **41b** was found to isomerize into **55b**.

*The Retro Cycloaddition of **60**.* The solution of each equivalent amounts of **60** and **8a** in dimethyl-d_6 sulfoxide was warmed at 50—60 °C for 24 h in an NMR tube. The quantitative formation of the endo cycloadduct of **8a** to the anti form of **2a** and the eliminated olefin **55b** was confirmed in the ^{1}H-NMR spectrum.

*Isomerization of **73** and **51** into **74** and of **41a** into **55a**.* The cycloadduct **73** or **51** was dissolved in acetonitrile-d_3 in an NMR tube. The ^{1}H-NMR spectrum of the solution after 24 h at room temperature showed the clean isomerization into **74**. Under the same conditions **41a** was found to isomerize completely into **55a**.

*Dehydrogenation of **63** Leading to **82**.* A mixture of each equivalent amounts of **63** and DDQ in benzene was heated under reflux for 23 h. The residue obtained by the removal of the benzene *in vacuo* was chromatographed over silica gel using benzene as an eluent giving 31% of **82**: pale yellow prisms from hexane; mp 153—154 °C; IR (KBr) 1720, 1710, and 1630 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.05, 1.67 (each 9H, s, COOBu^t), 6.98 (1H, d, J=8.0 Hz, 6-H) 7.30—7.93 (8H, m, ArH), and 8.52 ppm (2H, m, 5- and 10-H); MS (rel intensity) *m/z* 471 (M^+, 34) and 359 (base peak).

Found: C, 73.68; H, 6.27; N, 2.99%. Calcd for $C_{29}H_{29}O_5N$: C, 73.86; H, 6.20; N, 2.97%.

*Isomerization of a Mixture of **67**, **68**, and Another Isomer into **68**.* The solution of 1.0 mmol of the mixture among **67**, **68**, and another isomer in 20 ml of dry benzene was heated under reflux in the presence of palladium on charcoal (10 mg) for 24 h. The benzene was evaporated *in vacuo* leaving the residue whose ^{1}H-NMR in $CDCl_3$ was identical with that of **68**.

*Dehydrogenation of a Mixture of **67**, **68**, and Another Isomer into the Dihydropyrrolo[2,1-a]isoquinolines **83+84** or the Pyrrolo[2,1-a]isoquinoline **85**.* The mixture of three isomers was heated under reflux in ethanol for 48 h and the residue after the evaporation of the ethanol *in vacuo* was chromatographed over silica gel using benzene as an eluent giving 40% of **85**: colorless needles from ether; mp 212 °C (dec); IR (KBr) 2220 and 1720 cm^{-1}; ^{1}H-NMR ($CDCl_3$) δ=1.63, 1.66 (each 9H, s, COOBu^t), 7.13 (1H, br. d, J=7.5 Hz, 6-H), 7.44—7.73 (3H, m, ArH), 8.39 (1H, m, 10-H), and 8.88 ppm (1H, d, J=7.5 Hz, 5-H); MS (rel intensity) *m/z* 347 (M^+, base peak).

Found: C, 70.68; H, 6.33; N, 6.87%. Calcd for $C_{23}H_{24}O_4N_2$: C, 70.39; H, 6.16; N, 7.14%.

The above mixture was subjected to a column chromatography over silica gel using benzene affording the eluent containing 2:1 mixture of **83** and **84** in 25% yield. Their separation by repeated chromatography failed. **83+84**: yellow oil; IR (neat) 2210, 1710, and 1680 cm^{-1}; ^{1}H-NMR $CDCl_3$) **83**: δ=1.48, 1.52 (each 9H, s, COOBu^t), 4.20 (1H, d, J_{2-3}=4.0 Hz, 2-H), 5.02 (1H, d, J_{3-2}=4.0 Hz, 3-H), 6.16 (1H, d, J_{6-5}=7.4 Hz, 6-H), and 6.70 ppm (1H, d, J_{5-6}=7.4 Hz, 5-H); **84**: δ=1.48, 1.51 (each 9H, s, COOBu^t), 4.10 (1H, d, J_{2-3}=11.8 Hz, 2-H), 5.13 (1H, d, J_{3-2}=11.8 Hz, 3-H), 6.13 (1H, d, J_{6-5}=7.4 Hz, 6-H), and 6.72 ppm (1H, d, J_{5-6}=7.4

Hz, 5-H).

The Crystal and Molecular Structure of Two Triple-layered Metaparacyclophanes

Yosuke KOIZUMI, Toshihiro TOYODA, Nobutami KASAI,†* and Soichi MISUMI*
The Institute of Scientific and Industrial Research, Osaka University, Mihogaoka, Ibaraki, Osaka 567
†*Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565*
(Received July 18, 1985)

Molecular structures of triple-layered metaparacyclophanes containing two and one para-bridged, outside benzene rings([2.2]paracyclo(4,6)[2.2]metaparacyclophane (PMP) and [2.2]metacyclo(4,6)[2.2]metaparacyclophane (MMP), respectively) have been determined by means of X-ray diffraction. PMP: monoclinic, space group $P2_1/a$, a=15.989(1), b=9.932(1), c=5.991(1) Å, β=100.61(1)°, Z=2. MMP: monoclinic, space group $P2_1/c$, a=8.969(2), b=22.774(4), c=10.339(2) Å, β=119.32(1)°, Z=4. The structure of PMP was solved by the vector search method and that of MMP by the direct method. They are refined anisotropically by the least-squares procedure, final R values are 0.066 for PMP and 0.096 for MMP. Of the two possible conformers PMP has a centrosymmetric staircase structure(anti-form) whereas MMP takes a platform shape(syn-form).

Previously, a variety of triple-layered metaparacyclophanes has been synthesized by desulfurization of the corresponding dithiacyclophanes.[1] There have been discussed the assignment of their structures in detail and the conformational flipping of the meta-bridged benzene ring at the high temperature based on the NMR studies, and also the transannular electronic interactions between benzene rings.[2] In this paper, the crystal structure analysis of triple-layered metaparacyclophanes containing two and one para-bridged, outside benzene rings(PMP and MMP, respectively) is reported. A brief account of these metaparacyclophane structures has been given to prove the assigned structure in NMR studies.[2]

Experimental

Crystal Data. PMP. $C_{26}H_{26}$, M 338.5, monoclinic, space group $P2_1/a$(No. 14, absent reflections, $h0l$: $h=2n+1$, $0k0$: $k=2n+1$), a=15.989(1), b=9.932(1), c=5.991(1) Å, β=100.61(1)°, V=935.14(6) Å^3, D_m=1.20 g cm^{-3}, D_c=1.202 g cm^{-3} for Z=2. MMP. $C_{26}H_{26}$, M 338.5, monoclinic, space group $P2_1/c$(No. 14, absent reflections, $h0l$: $l=2n+1$, $0k0$: $k=2n+1$), a=8.969(2), b=22.774(4), c=10.339(2) Å, β=119.32(1)°, V=1841.2 Å^3, D_m=1.23 g cm^{-3}, D_c=1.221 g cm^{-3} for Z=4.

Both crystals were recrystallized from toluene. A colorless, platelet crystal of PMP with approximate dimensions of 0.3×0.4×0.4 mm and a colorless, hexagonal crystal of MMP with 0.4×0.2×0.4 mm were selected for the X-ray experiment. A Rigaku automated, four-circle diffractometer was used for the determination of unit-cell dimensions and the measurement of integrated intensities.

Intensity data were collected by the θ—2θ scan technique at a 2θ rate of 4° min^{-1}. The scan range for PMP was from $\{2\theta(\alpha_1)-1.0\}$° to $\{2\theta(\alpha_2)+1.0\}$° for Zr-filtered Mo $K\alpha$ radiation and that for MMP from $\{2\theta(\alpha_1)-0.8\}$° to $\{2\theta(\alpha_2)+0.8\}$° for graphite monochromatized Mo $K\alpha$ radiation (λ= 0.71069 Å). Backgrounds were counted for 10 s at both ends of a scan. Five standard reflections measured after every 50 reflections to monitor the stability and orientation of the crystals showed no significant decay throughout the data collection of both crystals. In total, 1864 non-zero reflections out of 2908 and 3152 out of 4499 were obtained for PMP and MMP, respectively($\sin\theta/\lambda<0.7$). Usual Lorentz and polarization corrections were made but absorption correction was ignored for both sets of data [μ(Mo)=0.72 cm^{-1} for PMP and MMP].

Structure Solution and Refinement

PMP. In order to obtain a clue to solve the structure, the benzene ring which is a main component of the molecule has been assumed as a rigid body, and the central benzene ring of the PMP molecule could be found by the vector search method(*XRICS*).[3] Successive Fourier synthesis phased by the six carbon atoms of the benzene ring could locate the remaining carbon atoms. The structure was refined anisotropically by the block-diagonal least-squares procedure(*HBLS* V).[4] The function minimized was $\sum w(\Delta F)^2$, where w=1. Hydrogen atoms were located on a difference Fourier map, which were included in the refinement with isotropic temperature factors. The R value converged to 0.066 for 1864 non-zero reflections. Final atomic parameters of carbon atoms are listed in Table 1a.††

MMP. The structure was solved by the direct method (*MULTAN*),[6] and refined by using the *HBLS* V program with anisotropic temperature factors and unit weight for all reflections. Hydrogen atoms were located on the calculated positions, which were confirmed on a difference Fourier map. They were refined isotropically. The final R value was 0.096 for 3152 non-zero reflections. Atomic parameters are given in Table 1b.††

Atomic scattering factors were taken from International Tables for X-Ray Crystallography.[7] Computations were done mainly on a NEAC 2200-500

†† Tables of anisotropic temperature factors, atomic parameters of hydrogen atoms, and observed and calculated structure factors are kept at the Chemical Society of Japan, Document No. 8550.

Table 1. Atomic parameters of carbon atoms in PMP and MMP with estimated standard deviations in parentheses

Results and Discussion

Molecular Structure. PMP. The molecule has a centrosymmetric staircase structure, which is depicted in Fig. 1a(*ORTEP*).[8] Bond distances and bond angles are given in Fig. 2a.

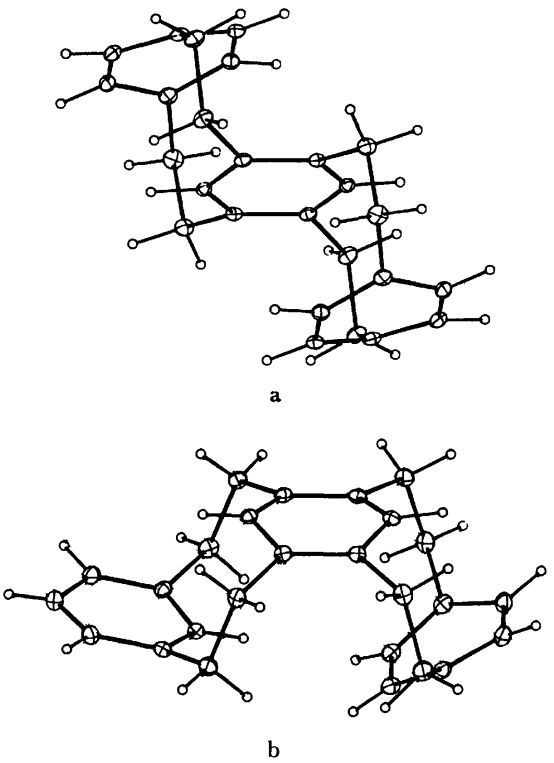

Fig. 1. A perspective view[8] of PMP (a) and MMP (b) molecules. Carbon atoms are represented by thermal ellipsoids with 10% probability level, hydrogen atoms as spheres with $B=1.0$ Å^2.

The outside para-bridged benzene ring is in a boat form as is found usually, the deformation angle p_1 at the C(3) atom(the dihedral angle between the plane defined by the C(4), C(5), C(7), and C(8) (Plane 1) and that by the C(3), C(4), and C(8) (Plane 2)) is 13.6° and that at the C(6), p_2 is 12.8°. The angle q_1 at the C(3) atom made by the C(2)–C(3) bond and the plane 2 is 15.4° and the corresponding angle q_2 at the C(6) is 15.2°, which are much larger than those in [2.2]paracyclophane.[9] The inner angles, C(4)–C(3)–C(8) and C(5)–C(6)–C(7) [117.4(3) and 117.5(3)°, respectively] in the benzene ring are smaller than 120°.

The center of the inside four-bridged benzene ring lies on a crystallographic center of symmetry, and this ring takes a chairform (Fig. 3a). The bending angle at the C(12) atom is 4.3°. The C(11)–C(12)–C(13) and C(11′)–C(12′)–C(13′) angles [both 123.9(3)°] are larger, and the other four angles [117.9(3) and 118.0(3)°] are smaller, than 120°.

In the ethylene bridges between the inside and outside benzene rings, the central C_{sp^3}–C_{sp^3} bonds are equal in length [1.579(4) and 1.572(4) Å]. Different from the corresponding angles in [2.2]paracyclophane and those of related compounds, the C(1)–C(2)–C(3) and C(6)–C(9)–C(10) angles[both 108.7(3)°] are smaller than the C(2)–C(1)–C(13) and C(9)–

b

Fig. 2. Bond distances and bond angles in PMP (a) and MMP (b). Estimated standard deviations in parentheses.

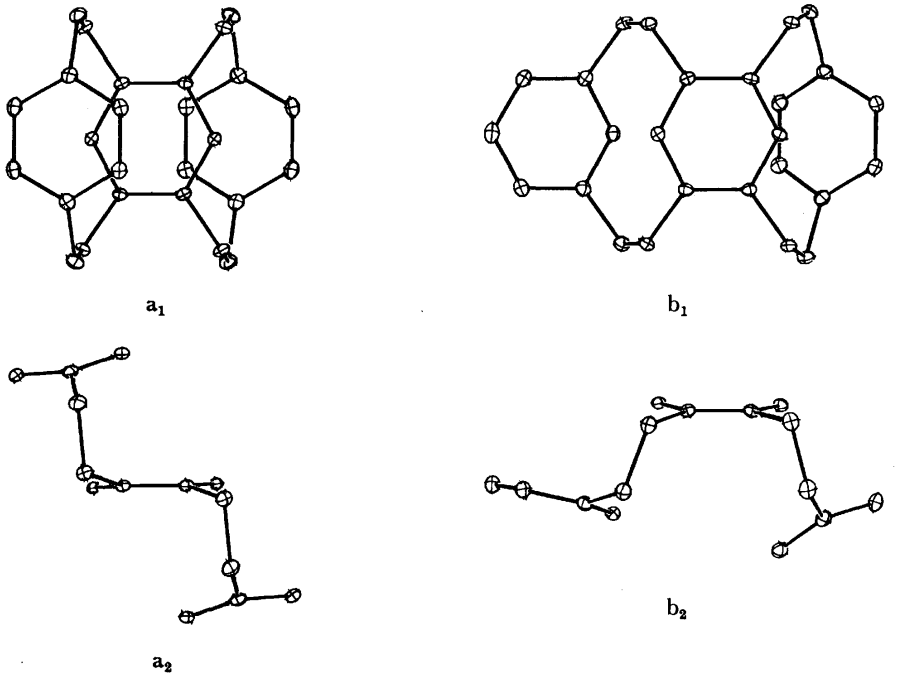

Fig. 3. Projections of molecules.
a_1: PMP molecule projected onto the plane defined by the C(11), C(13), C(11'), and C(13') atoms.
a_2: PMP molecule projected along the vector passing through the midpoints of the C(11)–C(13') and C(11')–C(13) bonds.
b_1: MMP molecule projected onto the plane defined by the C(11), C(13), C(14), and C(16) atoms.
b_2: MMP molecule projected along the vector passing through the midpoints of the C(13)–C(14) and C(11)–C(16) bonds.

C(10)–C(11) angles [111.7(3) and 111.4(3)°, respectively]. This fact is one of the features of [2.2]metaparacyclophane and the similar compounds.

The overlapping of three benzene rings is small: Between the outside and inside benzene rings the Plane 1 and the plane defined by the C(11), C(13), C(11'), and C(13') atoms makes an angle of 11.6°. Short nonbonded distances between atoms in the outside and inside benzene rings are given in Table 2, the closest distance, C(6)···C(11), is 2.780(4) Å.

MMP. A perspective view(*ORTEP*) of the molecule is drawn in Fig. 1b. The molecule has a platform shape(syn-form). Bond distances and bond angles are given in Fig. 2b. The projection of the molecule onto the least-squares plane of the C(11), C(13), C(14), and C(16) atoms and that along the vector passing through the midpoints of the C(13)–C(14) and C(11)–C(16) bonds are presented in Fig. 3b.

The outside meta-bridged benzene ring takes a boatform, the deformation angle p_1 at the C(5) atom is 4.9° and p_2 at the C(8) 9.2°. The C(4)–C(3)–C(8) [117.7(6)°] and C(6)–C(7)–C(8)[118.1(5)°] angles are smaller than 120°.

The central four-bridged benzene ring is also in a boatform, the deformation angle at the C(12) atom[14.8°] is larger than that at the C(15)[12.6°].

C(3)···C(12)	2.981(4)	C(8)···C(12)	2.649(7)
C(4)···C(12)	3.111(4)	C(3)···C(13)	3.051(7)
C(5)···C(12)	3.103(4)	C(8)···C(13)	3.068(7)
C(6)···C(12)	2.970(4)	C(14)···C(21)	3.441(7)
C(7)···C(12)	3.117(4)	C(14)···C(22)	2.871(7)
C(8)···C(12)	3.126(4)	C(14)···C(23)	3.193(7)
C(3)···C(13)	2.793(4)	C(15)···C(19)	3.042(7)
C(4)···C(13)	3.451(4)	C(15)···C(20)	3.081(7)
C(7)···C(13)	3.497(4)	C(15)···C(21)	3.084(7)
C(8)···C(13)	2.982(4)	C(15)···C(22)	3.034(7)
		C(15)···C(23)	3.288(7)
		C(15)···C(24)	3.292(7)
		C(16)···C(19)	2.885(7)
		C(16)···C(20)	3.447(7)
		C(16)···C(24)	3.188(7)

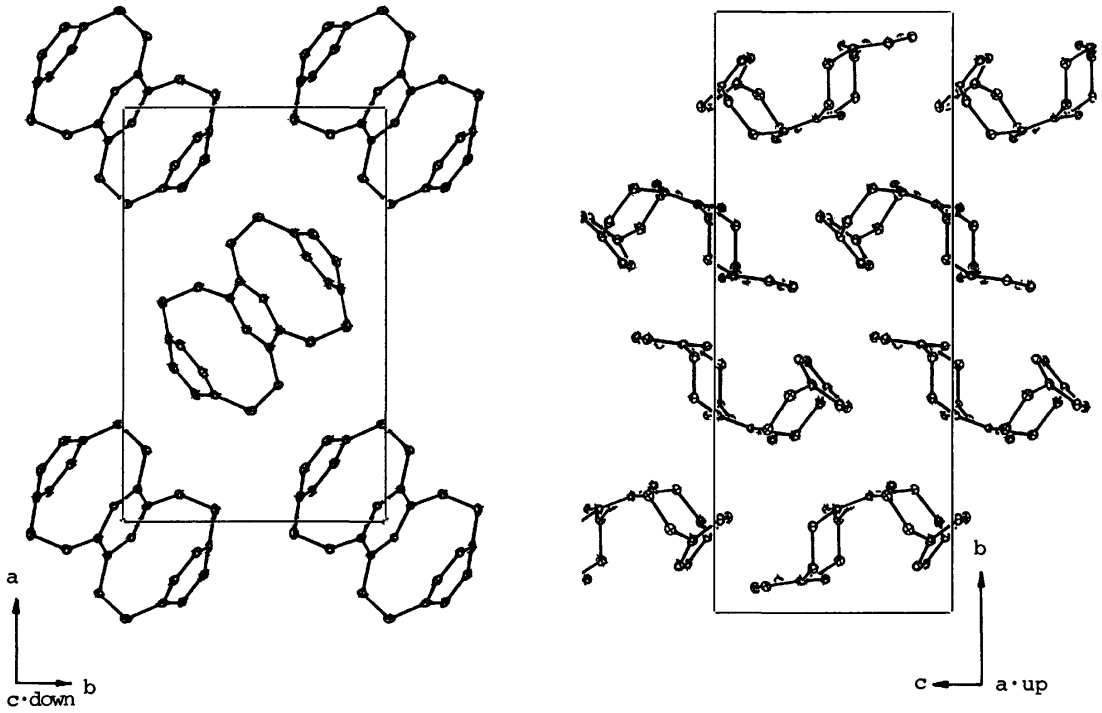

Fig. 4. Crystal structure[8] of PMP (a) and MMP (b) projected along an axis of the unit-cell. Carbon atoms are drawn as thermal ellipsoids with an arbitrary probability level.

The C(11)-C(12)-C(13) and C(14)-C(15)-C(16) angles are 123.4(5) and 123.6(5)°, respectively (Fig. 2b), which are larger than 120°. The other four inner angles [117.1(4) to 117.5(5)°] are smaller than 120°.

As a whole, the structure of the [2.2]metacyclophane moiety, consisting of the meta-bridged benzene and central benzene rings mentioned above and two ethylene bridges (Fig. 3b), is very similar to that of the two-third of the triple-layered metacyclophane-(*ud* isomer).[10,11] The closest intramolecular atomic contact is C(8)···C(12)[2.649(7) Å] (Table 2).

The third para-bridged benzene ring is also in a boatform. The deformation angles p_1 and q_1 at the C(19) atom are 13.9 and 14.9°, respectively, and those at the C(22) are p_2=14.8° and q_2=14.4°. These values of q's are larger than the corresponding angles in [2.2]paracyclophane.

Ethylene bridges in the [2.2]metaparacyclophane moiety, *i.e.* those between the central and third para-bridged benzene rings, have similar structure to those in the [2.2]metaparacyclophane moiety in PMP but slightly different structure from those in [2.2]paracyclophane moiety. The C(14)-C(26)[1.535(7) Å] and C(16)-C(17)[1.545(7) Å] bonds are longer, and the C(14)-C(26)-C(25)[114.5(5)°] and C(16)-C(17)-C(18) [114.7(4)°] angles are larger than the corresponding bond distances and bond angles in many [2.2]paracyclophanes, respectively. The torsion angles around the C(17)-C(18) and C(25)-C(26) bonds are equal[40.6 and 42.9°, respectively] but they are smaller than those around the C(1)-C(2)[59.8°] and C(9)-C(10) bonds[60.5°] in the [2.2]metacyclophane moiety of the present molecule.

The overlapping of the central and third para-bridged benzene rings are small. These two rings make an angle of 27.4°, which is much larger than the corresponding angle in the PMP molecule. Short nonbonded interatomic distances in the [2.2]metaparacyclophane moiety are C(14)···C(22) [2.871(7) Å] and C(16)···C(19)[2.885(7) Å].

Crystal Structure. The packing of PMP and MMP molecules in the crystal is shown in Fig. 4. In these two crystals molecules are packed rather loosely, and no short intermolecular contact less than 3.6 Å is found between non-hydrogen atoms.

The authors are grateful to Miss Nobuko Kanehisa who helped them at the final stage of the computation and for *ORTEP* drawing.

Activity and Selectivity Regulation of Synthesis Gas Reaction over Supported Ruthenium Catalysts

Kaoru FUJIMOTO,* Tatsuya NOBUSAWA, Takakazu FUKUSHIMA, and Hiro-o TOMINAGA
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received February 15, 1985)

The catalytic activities of supported ruthenium for synthesis-gas conversion to hydrocarbons was found to be in the following order:

$$TiO_2 > Nb_2O_3 > ZrO_2 > SiO_2 > Ta_2O_5 > Al_2O_3 > V_2O_5 > Mo_3 > WO_3 > MnO_2 > ZnO$$

Turnover frequencies of the supported ruthenium increased with decrease in dispersion of the metal particles for every carrier material. Even the activities per unit weight of metals were higher for low-dispersion ruthenium on Al_2O_3, TiO_2, and ZrO_2. The chain-growth probability of a hydrocarbon product, which is characterized by the Schulz-Flory distribution, increased markedly with decrease in the metal dispersion irrespective of the carrier material. The catalytic activity of ruthenium particles with a dispersion level of 0.7 or higher reached a ceiling level at about 0.5 MPa, whereas that of low dispersed ruthenium increased almost linearly with an increase in reaction pressure (up to at least 2.0 MPa).

A supported ruthenium catalyst is one of the most active and promising catalysts for producing liquid hydrocarbons from synthesis gas.[1-3] Hydrocarbon products of Fischer-Tropsch (F-T) synthesis on supported ruthenium catalysts have been known to follow the Schluz-Flory distribution.[4,5] One of the most important targets regarding catalyst preparation for producing a liquid hydrocarbon by F-T synthesis is to control the probability of hydrocarbon chain growth. A maximization of the formation of C_5 to C_{20} hydrocarbons is especially important. Vannice *et al.*[3] and Kikuchi *et al.*[6] have reported that activities of supported ruthenium catalysts are markedly influenced by carrier materials and that, especially, Ru/TiO_2 is one of the most active and chain-growing catalysts. The activity and selectivity of a ruthenium catalyst are also influenced by the sizes of supported metals.[4-6] King has claimed that although the turnover frequency (TOF) of a synthesis-gas reaction increases with a decrease in the metal dispersion, no consistent relationship between the chain-growth probability of the product hydrocarbon and the dispersion exists.[7] Kellner and Bell have reported that the turnover frequency of a reaction on alumina-supported ruthenium catalysts under atmospheric conditions decreases moderately with an increasing dispersion (up to 0.7). The decrease is above 0.7, but neither the chain-growth probability nor the olefin-to-paraffin ratio is affected.[4]

The activity and selectivity of ruthenium catalysts should be determined under pressurized conditions using a synthesis gas of normal composition in order to determine the real performances of the F-T reaction, since they are very sensitive to these conditions.[1,2] In both of the studies mentioned above, the dispersions of supported ruthenium were controlled by regulating the ruthenium loading. This method is quite powerful for controlling metal dispersion; however, it has a disadvantages that the particle sizes are widely distributed.[8] Also, the range of the dispersion controlled by this method is not wide enough.

The present authors have developed a simple method for regulating the dispersion level of a supported ruthenium catalyst with constant loading and with the same source material and have shown that both activity and selectivity are influenced by either the carrier materials or the dispersion level of ruthenium.[5]

In the present work, the effects of carriers and the sizes of metal particles of supported ruthenium catalysts on the activity, selectivity, and other catalytic features (characterized by the CO conversion rate per weight of a catalyst, turn-over frequency, chain-growth probability, methane selectivity and pressure dependence) were studied under conditions normally utilized for F-T synthesis.

Experimental

Catalyst Preparation and Dispersion Measurements. All catalysts used in the present study contained 2 wt% of ruthenium. TiO_2 was obtained by the hydrolysis of titanium isopropoxide ($[(CH_3)_2CHO]_4Ti$), followed by calcining at 723 K for 3 h. This gave anatase type TiO_2. WO_3 and MoO_3 were prepared through the calcination (in air at 773 K for 7 h) of ammonium tungstate ($(NH_4)_2WO_4$) and ammonium molybdate ($(NH_4)_2\ MoO_4$), respectively. Alumina-magnesia(Al_2O_3-6MgO) was prepared by the calcination (in air at 723 K for 1 h) of a commercially available Al-Mg hydroxycabonate ($Mg_6Al_2(OH)_{16}CO_3$). Other metal oxides were used as received after calcining in air at 723 K for 1 h. SiO_2 (Aerosil-380) was obtained from Japan Aerosil Co. (380 m^2/g). A γ-Al_2O_3 (220 m^2/g) was prepared by hydrolyzing aluminium isopropoxide and calcining in air at 873 K for 3 h. Supported ruthenium catalysts were prepared by impregnating the carriers with $RuCl_3 \cdot 3H_2O$ from its aqueons solutions, drying at 353 K and then drying overnight at 393 K in an air oven. These catalysts were represented as H-(Highly-dispersed) catalysts.

Another group of catalysts represented as L-(Low-dispersed) catalysts were prepared by calcining H catalysts in air at 673 K for 3 h before reduction. The catalyst precursors were molded to granules (20—40 mesh) under pressure. The catalysts were activated in situ by reducing in flowing hydrogen at 453 K for 1 hr and then at 673 K for 2 h.

The chemisorption of CO was measured at room temperature using a flow-through cell connected to a glass vacuum system. A catalyst sample was first activated *in situ* as described above and then evacuated at 723 K for 3 h. The amount of desorped CO was determined as the difference between the first isotherm and the second isotherm which was measured following to evacuation for 30 min at room temperature after the first isotherm measurement. Metal dispersion was calculated assuming that one CO molecule was chemisorbed by one surface ruthenium atom.

Synthesis Gas Reaction and Product Analysis. Synthesis gas reactions were conducted in a flow-type fixed-bed reaction apparatus under pressurized conditions. A stainless-steel tube (inner diameter 8 mm, outer diameter 10 mm) was used as a reactor. The details of this apparatus has been described elswhere.[9] When highly active catalysts were used, they were diluted by α-Al_2O_3 (surface area<2 m^2/g) granules with the same size (20/40 mesh) in order to produce an even temperature profile over the catalyst bed (within 2K).

Activities and selectivities of the ruthenium catalysts were measured under the following reaction conditions: 503 K, 2.03 MPa, $H_2/CO=2$. The time factor (W/F) was adjusted to produce about 10% CO conversion.

Synthesis gas ($H_2/CO=2$) was introduced into the reactor after being purified by being passed through a series of silica-gel and activated charcoal columns. All products effluted from the catalyst bed were withdrawn in gaseous states from the high-pressure zone and were analyzed on-line by gas chromatographs. Hydrocarbons trapped in the catalyst bed during the reaction were extracted *in situ* with hot toluene for 1 h after a reaction was completed to be analyzed. CO, CH_4, and CO_2 were analyzed using an activated charcoal column. C_1–C_5 hydrocarbons were analyzed with a Porapak Q column, C_4–C_{20} hydrocarbons were analyzed with a Silicone SE-30/Chromosorb 101 column and C_{10}–C_{45} hydrocarbons were analyzed with a Dexil 300 GC column, respectively.

In all that follows, catalyst activity is defined by the equation:

Activity$=(CO_{in}-CO_{out})/W$ where CO_{in} and CO_{out} are the flow rates of carbon monoxide which enter and exit the reactor (moles/hour), respectively and W is the catalyst weight (gram).

Results and Discussion

Metal Dispersion. Table 1 shows the amount of CO chemisorption, metal dispersion, catalyst activities and turn-over frequencies. The dispersion level of supported ruthenium prepared without air calcination is distributed between 10 and 90%. Obviously, the dispersions of ruthenium on each of the four carriers (ZrO_2, SiO_2, Al_2O_3, TiO_2) were lowered due to air calcination prior to reduction.

Table 1. CO Chemisorption, dispersion and specific activity of supported ruthenium catalyst[a)]

Carrier	CO_{ch}[b)] μ-mol/g-cat	D_{Ru}[c)] %	N_{CO}[d)] $10^{-3}/s$	α[e)]

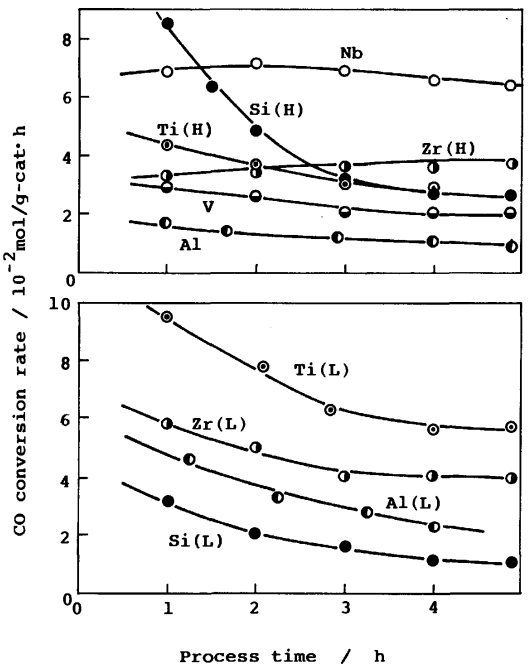

Fig. 1. Change in catalytic activity of supported ruthenium catalysts. Temperature: 503 K, Pressure: 2.03 MPa, H_2/CO: 2/1 mole ratio.

Since ruthenium chloride has been proven by our experiment to be converted to ruthenium oxide during air calcination, it can move easily on the carrier and aggregate into large particles as expected due to its high sublimation characteristics.

Characteristic Features of Synthesis-gas Reaction. As demonstrated in Fig. 1, the activities of most catalysts, expressed by CO conversion rates, decreased

with the processing time. Since deactivated catalysts restored their activities upon being treated with hydrogen at 673 K, the deactivation can be attributed to carbon deposition or an accumulation of wax on the catalysts. The activities and selectivities were expressed by average values which were measured between 4 and 5 h after starting.

The product hydrocarbon, eluted from the catalyst bed in a gaseous state, was characterized by the fact that hydrocabons higher than C_{15} are quite small, as demonstrated in Fig. 8. This was the same even with the L-catalysts whose chain-growth ability was high. It was caused by a trapping of high-boiling-point hydrocarbons in the catalyst bed.[5] A large amount of waxy hydrocarbon was extracted with hot toluene after the synthesis-gas reaction. By combining the extracted products with the gaseous products, the ratio of the amount of recovered hydrocarbons to the amount of consumed carbon monoxide (on carbon base) increased from 35 to 88% (for Ti-L-catalyst) and from 63 to 91% (Ti-H catalyst), respectively. The total hydrocarbon distributions, thus obtained, showed smooth profiles distributed from C_1 to C_{40}, or higher (Figs. 2 and 3). The distributions fit the Schulz-Flory equation very well as demonstrated by Figs. 4 and 5. It is clear from

the data in Fig. 3 that the chain-growth probability (α value), which is determined from the distribution of gaseous hydrocarbons, agrees well with that obtained from the combined product. The α values of other catalysts were determined from the distribution of gaseous products. It is also worth while to note that the Schulz-Flory plot for a Ti–H catalyst can be expressed by two straight lines, whereas that of a Ti–L catalyst can be expressed by one straight line. This phenomenon will be discussed in the later chapter.

Controlling Factors of Catalyst Activity. The conversion levels, catalytic activities, methane selectivities, olefin content of products and chain-growth probabilities are shown in Tables 1 and 2. Although metal loadings are the same for all catalysts, metal dispersions are distributed from 5 to 89% and the activity per unit weight of catalysts are distrubued over a range of about 60 by factor. Figure 6 shows the relationship between ruthenium disperion and the turnover frequency (TOF). It is clear that the TOF is controlled not only by carrier materials, but also by the ruthenium dispersion. Catalysts can be classified into 3 groups: (1) Low dispersion-high TOF, (2) high dispersion-low TOF, and (3) low dispersion-low TOF. It is also demonstrated that a decrease in the dispersion by air calcination causes an increase in the TOF without exception. Similar facts have already been pointed out by King regarding methane synthesis.[7] or by Kikuchi *et al.*[6] for CO

hydrogenation and by Kellner *et al.*[4] for the atomospheric Fischer-Tropsch synthesis. Not only the TOF but also activities per unit weight of ruthenium are higher for L-catalysts than for H-catalysts (Table 2). Thus, the fairly poor dispersion (less than 30%) of ruthenium is favored for the high activity of F-T synthesis. The reason for the high activity of the low-dispersed ruthenium has been discussed by Kellner *et al.*[4] however, the real reason has not been made clear yet. The L-catalyst exhibits, as will be shown in the later chapter, high activity under high reaction pressures.

On a similar dispersion basis, ruthenium showed a high activity when it was supported on Nb_2O_5, TiO_2, ZrO_2, SiO_2, or Ta_2O_5. ZnO, MnO_2, WO_3, and Al–Mg oxide showed poor abilities as carriers of ruthenium. Thus, it can be concluded that the selection of a carrier is also one of the essential factors in effecting catalytic activity. The effect of carrier materials on catalytic activity may be ascribed not only to the difference in metal dispersion, but also to some interaction between the carrier and the metal. In fact, by using carriers such as Nb_2O_5, TiO_2, Ta_2O_5, and V_2O_3, known to exhibit a SMSI effect,[10–12] highly active catalysts could be prepared.

Pressure Characteristics. It was also found that the degree of ruthenium dispersion affects the pressure characteristics of catalytic activity. It is very clear from Fig. 7 that the catalytic activity of a TiO_2-supported H-catalyst (Ti–H catalyst) increases markedly with an increase in pressure from 0.1 MPa to 0.51 MPa. However, above this the increase in the activity is quite small. The activity of a Ti–L catalyst increases almost linearly up to a pressure of 2.03 MPa. Thus, the activity of a H-catalyst is higher than that of a L-catalyst under atmospheric pressure, the reverse is true above 1.01 MPa. Not only the TiO_2 supported catalyst, but also the Ru/Al_2O_3 catalysts exhibit the same characteristics.

As can be seen in Fig. 7, the average reaction orders with respect to the total pressure at H_2/CO=2/1 were determined to be about 1 for both Ti–L and Al–L catalysts while those of Ti–H and Al–H catalysts are 0.4 and 0.6, respectively. It has been reported that the reaction order of the F-T reaction over Ru/Al_2O_3 catalysts are close to or higher than 1.0 with respect to hydrogen, whereas it is zero or negative with respect to carbon monoxide.[13,14] As the reaction order with respect to the total pressure is the sum of the orders with respect to the partial pressures of carbon monoxide and hydrogen, the low reaction order of an H-catalyst may due to a negative reaction order with respect to carbon monoxide. However, the details must be determined in further studies.

Controlling Factors of Product Selectivity.

a. Chain Growth. Figure 8 shows carbon number distributions of gaseous products under a standard condition with the above-mentioned 4 types of H- and L-catalysts. It is obvious that the distribution is less steep for L-catalysts than for H-catalysts, without exception. This indicates that the chain-growth probability is higher for L-catalysts. Figure 9 exhibits a clear inverse relationship between the dispersion and the growth probability, irrespec-

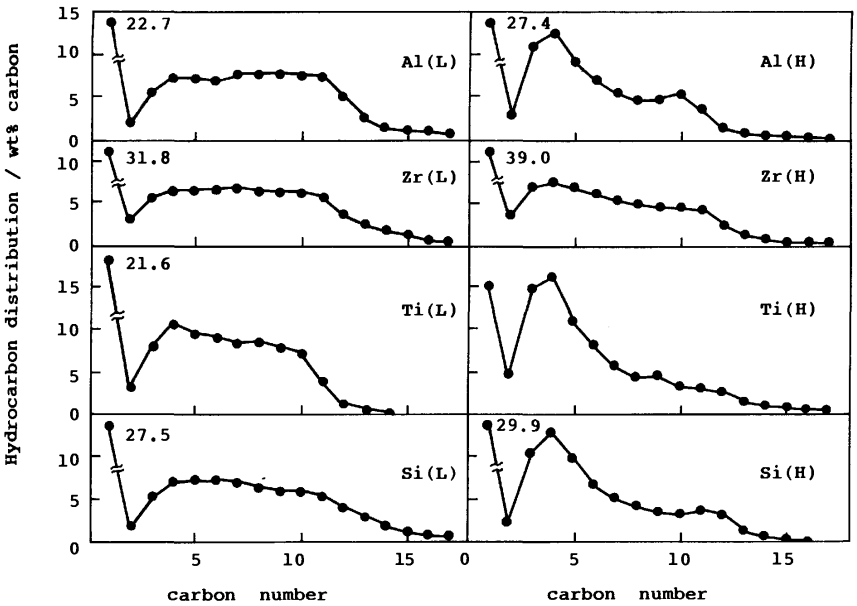

Fig. 8. Carbon number distribution of gaseous produts on L and H type ruthenium catalysts. Temperature: 503 K, Pressure: 2.03 MPa, H_2/CO : 2/1 mole ratio.

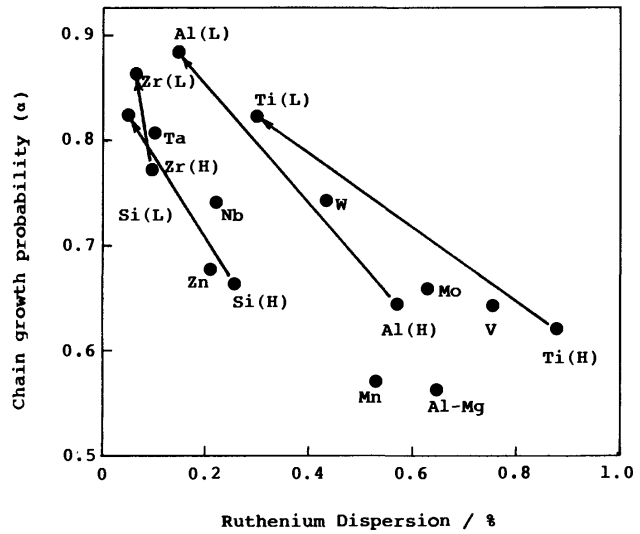

Fig. 9. Chain growth probability *vs.* ruthenium dispersion of supported ruthenium catalysts. Temperature: 503 K, Pressure: 2.03 MPa, H_2/CO : 2/1 mole ratio.

tive of carrier materials. It is also apparent that the calcination of the supported ruthenium chloride in air prior to hydrogen reduction caused the growth of ruthenium particles as well as the increase in the chain-growth probability. The results coincide well with that of Jacobs *et al.*[21], namely the values of α are mostly higher than 0.8 when the dispersion level is lower than 0.3. Thus, the regulating the dispersion level of ruthenium is one of the most effective methods for controlling the activity and the chain-growth ability of a catalyst.

Carrier material is also an important factor for regulating the α value. Ruthenium metals supported on TiO_2, Al_2O_3, or WO_3 exhibit high α values for a similar dispersion level. Among them, TiO_2 is an excellent carrier for a ruthenium catalyst with either CO conversion or carbon–carbon bond formation, as has already been shown.[16,17] However, supported ruthenium particles with the dispersion levels of 10% or lower exhibit high chain-growth probabilities irrespective of the carrier materials. This fact suggests that the carrier effect is reduced at low dispersion since there is a small contact area between ruthenium particle and the carrier surface.

b. Deviation from Schulz-Flory Distribution. Several examples have been reported where products on supported ruthenium catalysts do not follow the S-F distribution.[18–20] Jacobs *et al.* suggested that the unique distributions can be well simulated by assuming that the maximum carbon number of product hydrocarbon depends upon the sizes of metal particles.[21] In the present work, the S-F plots (Figs. 4 and 5) of products show that the distribution for an H-catalyst can be expressed by two straight lines, wheares that for an L-catalyst is well approximated by one straight line. The values of α obtained from the slopes of the plots are 0.87 for the Ti-L-catalyst, while 0.65 and 0.8 for the Ti-H-catalyst, respectively. The approximation using two staight lines had been also reported.[22]

The present authors explain the phenomenon as follows: It is common that a supported metal catalyst has a wide distribution regarding the size of metal particles when it is prepared by the impregnation method.[8] Thus, an H-catalyst should have particles with both "high" and "low" dispersions. The critical dispersion level of "high" and "low" is

estimated to be about 30%, as described above. This classification is based on our finding that the chain-growth ability of a supported ruthenium catalyst is definitely divided at 30% of the dispersion.[23)] The products on the high- and low- dispersion particles supported on TiO_2 should have the α values of 0.65 and 0.87, respectively, under the conditions adopted. On the other hand, all metal particles on the Ti-L-catalyst should have a dispersion lower than 30%. Since smaller particles can easily aggregate to become large particles, due to sintering during air calcination,[8)] all products on these particles must have a chain-growth probability of 0.87.

c. Methane Selectivity. Points on plots of CH_4 selectivity *vs.* dispersion are scattered widely (Fig. 10). This suggests that the relationship between them is poor. However, for each set of the four carriers (TiO_2, Al_2O_3, ZrO_2, SiO_2) a decrease in the dispersion is necessarily accompanied by a decrease in the CH_4 selectivity. So long as the decrease in the dispersion brings about an increase in the chain-growth probabbility, as pointed out in the present paper, a decrease in the CH_4 selectivity can be expected due to the S-F equation. However, since the drastic decrease in the CH_4 selectivity (about 50%) for Ru/SiO_2 and the Ru/ZrO_2 catalysts is unable to be explained by the S-F theory, some unknown dispersion effect remains to be accounted for. Also, carrier materials, themselves, are the controlling factors of CH_4 selectivity. SiO_2, ZrO_2, Al-MgO_x, and Nb_2O_5 are favored for CH_4 formation whereas V_2O_5, TiO_2, Al_2O_3, and ZnO are effective for suppressing CH_4 formation. Thus, it is concluded a low-dispersion ruthenium catalyst supported on Al_2O_3 or TiO_2 is favored for selectively producing liquid hydrocarbons.

d. Isoparaffin Formation. It is interesting to note that with the MoO_3- and the WO_3- supported catalysts, methane selectivities are fairly low in spite of the low olefin contents in the products. Also, the high selectivities of isoparaffins are obtained, which are scarcely observed in products with other catalysts. These phenomena were especially marked in the case of the WO_3 carrier. As shown in Table 3, the ratio of branched paraffins to normal paraffins (i/n ratio) in hydrocarbons from C_4 to C_{10} is higher than 20 (in total). Isoparaffin formation was also observed (to some extent) when a mixed catalyst consisting of 2 wt% Ru/TiO_2 and WO_3 was subjected to a synthesis-gas reaction. The i/n ratio increased with an increased reaction temperature as demonstrated in Table 3. Isoparaffin formation could be attributed to the acidic character of MoO_3 and WO_3,[7)] which isomerize n-olefins produced on the ruthenium metal to isoolefins which are then hydrogenated to isoparaffins on the carriers or on the ruthenium.

Conclusion

It has been found that the specific activity of supported ruthenium for a synthesis-gas reaction is determined by both carrier materials and ruthenium dispersion, and the selectivity (carbon number distribution of product hydrocarbon) is essentially determined by the dispersion or particle-size distribution, but rather independent of the carrier.

Carrier materials affect both ruthenium dispersion and its catalytic activity. In more detail,

1) Carrier materials which are effective for giving small metal particles are V_2O_5, TiO_2, and Al_2O_3.

2) ZrO_2, SiO_2, TiO_2, and Nb_2O_3 promote the catalytic activity of ruthenium on them.

Effects of ruthenium dispersion on its catalysis are summarized as:

1) The specific activities of supported ruthenium catalysts increase markedly as the dispersion decreases, irrespective of the carrier materials.

2) Low-dispersion ruthenium exhibits a higher chain-growth probability, which is little affected by carrier materials.

3) The chain-growth probability is not uniform for a highly dispersed catalyst, which is suggested to be attributed to the wide distribution of particle sizes.

4) Catalytic activities of low-dispersion catalysts increase almost linearly up to a pressure at about 2.03 MPa. However, those of highly dispersed catalysts level off at around 1.01 MPa.

5) Isoparaffins are formed with high selectivities on MoO_3 and WO_3 supported catalysts. It is suggested that this is caused by their acid character.

The Thermodynamic Behaviour of Nickel in a Molten LiF-KF-O^{2-} System

Yasuhiko ITO,* Hidetaka HAYASHI,† Yasuhiko ITOH,† and Shiro YOSHIZAWA†

Department of Nuclear Engineering, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

†*Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606*

(Received May 20, 1985)

The thermodynamic behaviour of nickel in a molten LiF-KF-O^{2-} system was investigated by using $Pt(O_2)$/stabilized zirconia electrode as an oxide-ion-concentration indicator. The potentials of the $Pt(O_2)$/stabilized zirconia/LiF-KF-O^{2-} electrode and the Ni/NiO/LiF-KF-O^{2-} electrode at 550 °C were measured as :

$$E = 2.25 - \frac{RT}{2F} \ln X_{O^{2-}} \quad \text{(V. } vs. \text{ Li-K/Li}^+, \text{ K}^+\text{)}$$

and:

$$E = 1.42 - \frac{RT}{2F} \ln X_{O^{2-}} \quad \text{(V. } vs. \text{ Li-K/Li}^+, \text{ K}^+\text{)}$$

respectively. The solubility product of NiO in the melt was thus determined to be $K_{sp}=1.3\times10^{-6}$ at 550 °C. With these results, a potential-pO^{2-} diagram of the nickel in the system was presented.

Molten fluoride is a useful material for use in many energy processes, such as the Molten Salt Breeder Reactor and heat-storage systems.[1] To use this melt for such purposes, however, it is necessary to protect the metal container from the corrosion caused by any oxidizing agents as contaminated water and oxygen. The corrosion behaviour of metals in a fluoride melt is strongly dependent on the oxide film formed on the metal surface, the stability of which is influenced by the redox potential and the oxide-ion concentration in a melt system.

In this paper, an LiF-KF eutectic melt containing oxide ions has been selected as an example of a fluoride melt, and the oxide concentration and solubility product of NiO in this melt have been determined by the use of a stabilized zirconia electrode. Finally, a potential-pO^{2-} diagram of nickel has been constructed on the basis of a thermochemical analysis of this system. Recently it has been shown that a stabilized zirconia solid electrolyte can be used as an oxide-ion-concentration indicator in melt systems, especially molten chloride systems. Also, the solubility product of metal oxide,[2-4] and the chemical equilibrium associated with oxide ion[5] have been investigated by using this electrode. However, in molten fluoride systems, the solubility products of oxide were mainly determined by a chemical analysis method[6,7] that may derive higher solubility product values caused by colloidal metal oxide; this type of electrode has not been used as an oxide-ion indicator. By the use of a stabilized zirconia oxide indicator, not only a rigorous value of the solubility product, but also direct thermodynamic information about the oxide ion in the melt can be obtained.

Thermodynamic Description

By means of a constant-current electrolysis of a molten LiF-KF-O^{2-} system, the Li-K alloy is formed on the cathode; its composition is almost constant (Li:K=2:1) independent of the current densities.[8] That is, the single-electrode potential of the Li-K/Li^+, K^+ couple can be chosen as a common reference electrode in this system. In this paper, as will be described later, the potentials were measured with respect to a quasi-reference electrode, such as the Ni/NiO or Ni/NiF_2 electrode, but the data obtained were converted to the potential against the Li-K/Li^+, K^+ couple.

The emf of the electrochemical cell:

$$\text{Li-K/LiF-KF-O}^{2-}\text{/stabilized } ZrO_2/O_2(Pt) \qquad (1)$$

will obey the following Eq. 2 if the stabilized zirconia acts as an oxide-ion-concentration indicator:

$$E = E^\circ_{O_2/O^{2-}} - \frac{RT}{2F} \ln X_{O^{2-}} \qquad (2)$$

$X_{O^{2-}}$ represents the anionic mole fraction of the oxide ion in the melt. By the use of Eq. 2, the thermodynamic behaviour of nickel in this system can be described as below. To simplify the situation, only three chemical species are considered in this paper: Ni(s), the Ni(II) ion, and NiO(s). Among these three species, there exist the following three electrochemical or chemical equilibria:

$$\text{Ni(II)} + 2e^- = \text{Ni(s)} \qquad (3)$$

$$\text{NiO(s)} + 2e^- = \text{Ni(s)} + O^{2-} \qquad (4)$$

$$\text{NiO(s)} = \text{Ni(II)} + O^{2-} \qquad (5)$$

The equilibria involving the trivalent nickel ion, *e.g.* Ni(III) and Ni_2O_3(s), are not considered in this paper, since their existence has not been reported in the literature.[9]

The Nernst equation corresponding to the electrochemical equilibria 3 and 4 are expressed as Eqs. 6 and 7 respectively, while the equilibrium constant of Eq. 5 is expressed as Eq. 8 with the use of the solubility product of NiO, K_{sp}:

$$E_{Ni/Ni(II)} = E^\circ_{Ni/Ni(II)} + \frac{RT}{2F} \ln X_{Ni(II)} \quad (6)$$

$$E_{Ni/NiO} = E^\circ_{Ni/NiO} - \frac{RT}{2F} \ln X_{O^{2-}} \quad (7)$$

$$K_{sp} = X_{Ni(II)} \cdot X_{O^{2-}} \quad (8)$$

(when the melt is saturated with NiO(s))

When the melt is saturated with NiO, $E_{Ni/Ni(II)}$ is equal to $E_{Ni/NiO}$; hence, from Eqs. 6, 7, and 8, Eq. 9 can be derived:

$$E^\circ_{Ni/NiO} = E^\circ_{Ni/Ni(II)} + \frac{RT}{2F} \ln K_{sp} \quad (9)$$

For the drawing of the Potential-pO^{2-} diagram, the determination of the values of $E^\circ_{Ni/Ni(II)}$, $E^\circ_{Ni/NiO}$, and K_{sp} would seem to be necessary, but, as Eq. 9 is valid, it is sufficient to measure the values of K_{sp} and $E^\circ_{Ni/NiO}$. The K_{sp} value can be obtained from the emf response of the cell (1) to the amount of metal oxide (NiO in this case) added to the melt. That is, when the amount of NiO added to the melt is small, free oxide ions are produced corresponding to the amount of NiO added, and the potential shifts to the negative side according to the Nernst Eq. 2. However, once the melt is saturated with NiO, the added NiO does not dissociate any more and the emf remains constant. Hence, the intersection of the two lines gives the solubility of NiO, from which the solubility product, K_{sp} can be calculated by means of Eq. 10:

$$K_{sp} = [X^\circ_{NiO(added)}]^2 = [X^\circ_{Ni(II)(added)}][X^\circ_{O^{2-}(added)}] \quad (10)$$

where X°_{NiO} is the solubility of NiO.

Concerning the value of $E^\circ_{Ni/NiO}$, it can be calculated from the standard electrode potential, $E^\circ_{O_2/O^{2-}}$, of the reaction:

$$1/2\,O_2 + 2e^- = O^{2-} \quad (11)$$

and the difference ($E^\circ_{O_2/O^{2-}} - E^\circ_{Ni/NiO}$) which can be calculated from the standard free-energy change of the reaction:

$$NiO(s) = Ni(s) + 1/2O_2$$

Experimental Method and Apparatus

The experimental cell is shown in Fig. 1.

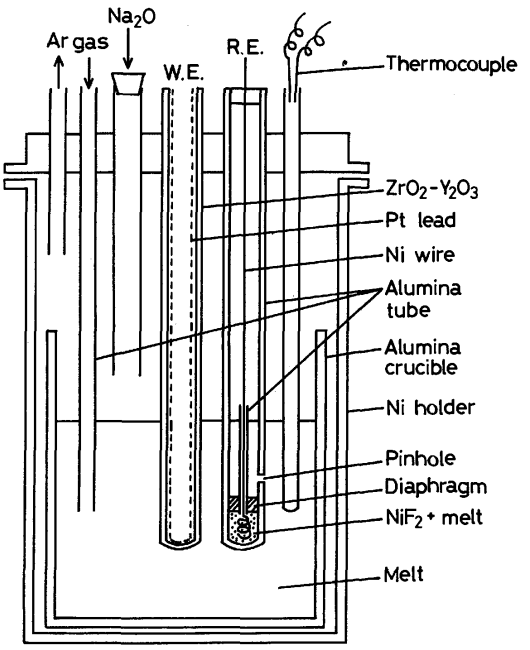

Fig. 1. Experimental cell.

Commercial LiF and KF (Reagent Grade, Wako Chemicals Co., Ltd.) were mixed, and the eutectic mixture was dried under a vacuum for a week at 200 °C, after which it was placed in a high-purity alumina crucible (Nippon Kagaku Togyo Co., Ltd., SSA-S) and melted under an argon (water content<10 ppm) atmosphere at 550 °C. By this procedure, the oxide-ion-concentration level could be reduced to the order of 10^{-4} mole fraction.[10] For an oxide ion indicating electrode, an yttria- or magnesia-stabilized zirconia tube (Nippon Kagaku Togyo Co., Ltd.) was used. The inside of the tube was coated with a platinum powder layer which acted as an air electrode. The measured emf was converted to the potential of the oxygen (Pt)/stabilized zirconia electrode, taking into account the partial pressure of oxygen in air. Several types of electrodes, for example, NiF_2/Ni and NiO/Ni electrodes, were used as quasi-reference electrodes, according to the experimental conditions. The potential of the quasi-reference electrode was calibrated *versus* the Li-K/Li^+, K^+ electrode potential before use. By means of a constant-current electrolysis between the graphite anode and the stainless-steel cathode, Li-K alloy of a finite composition (Li:K=2:1)[8] was deposited on the cathode. The cathode potential measured against the quasi-reference electrode was kept constant for several tens of minutes after the current interruption. From this constant potential value, the potential of the quasi-reference electrode against the Li-K/Li^+, K^+ electrode was determined. The oxide-ion concentration in the melt was controlled by adding the appropriate amount of dry Na_2O (Aldrich Co., Ltd.). For the solubility-product measurement of NiO(s), commercial NiO(s) (Wako

Chemicals Co., Ltd.) was added to the melt. The Ni/NiO electrode could be prepared by baking nickel wire for several tens of minutes in air at around 900 °C.

Results and Discussion

The relation between emf of the cell(1) and the oxide-ion concentration is shown in Fig. 2. A clear Nernst relation can be observed in the figure. From this straight line, obtained experimentally, the potential of the $Pt(O_2)$/stabilized zirconia/LiF-KF-O^{2-} electrode can be written as:

$$E = 2.25 - \frac{RT}{2F} \ln X_{O^{2-}} \text{ (V. vs. Li-K/Li}^+, \text{K}^+) \qquad (2')$$

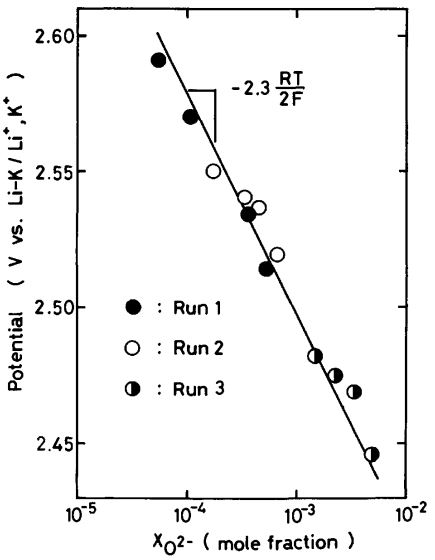

Fig. 2. Relation between emf of the cell: Li-K/LiF-KF-O^{2-}/stabilized zirconia/$Pt(O_2)$ and oxide-ion concentration.

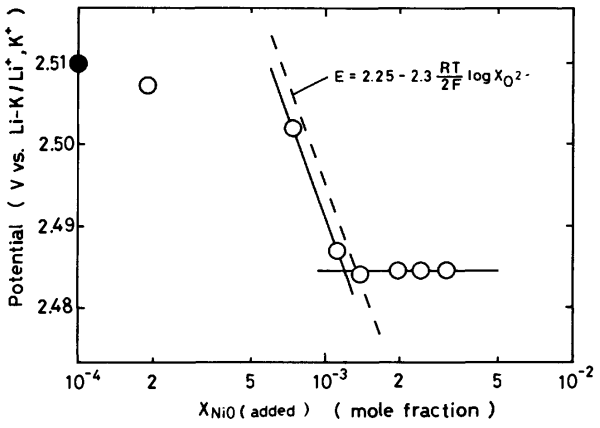

Fig. 3. Relation between $Pt(O_2)$/stabilized zirconia/LiF-KF-O^{2-} electrode potential and the added cmount of NiO (mole fraction).

Figure 3 shows the relation between the $Pt(O_2)$/stabilized zirconia/LiF-KF-O^{2-} electrode potential and the added NiO (expressed as a mole fraction). In the figure, the closed circle represents the potential before the addition of the NiO. This potential is determined by the concentration of the oxide ion contaminating the melt. In an early stage of the increase in the amount of NiO added, the potential response is not so quantitative because of the contaminating oxide ion, but when the amount of added NiO exceeds the contamination level, the potential shifts towards the negative side, obeying the Nernst equation. When the NiO in the melt is saturated, the potential remains constant at any amount of added NiO. From the intersection of the two lines, the K_{sp} values can be calculated by the use of Eq. 10.

In a practical calculation, however, the oxide-ion concentration, $X^\circ_{O^{2-}}$, due to the contamination before the experiment should also be taken into account. That is, the Ni(II)-ion concentration in the NiO-saturated melt is the difference between the measured oxide-ion concentrations, $X_{O^{2-}}$, and $X^\circ_{O^{2-}}$, thus, Eq. 10 is rewritten as:

$$K_{sp} = X_{Ni(II)} \cdot X_{O^{2-}} = [X_{O^{2-}} - X^\circ_{O^{2-}}] \cdot X_{O^{2-}} \qquad (10')$$

From Eq. 10′ and Fig. 3, and several other similar experimental results like Fig. 3 which are not given in this paper, the averaged K_{sp} value was determined to be 1.3×10^{-6} at 550 °C.

By the method described above, $E^\circ_{Ni/NiO}$ can be calculated from the standard free-energy change of reaction (12) and the $E^\circ_{O_2/O^{2-}}$ value of 2.25 V appearing in Eq. 2′ to be 1.42 V. That is, Eq. 7 is rewritten as:

$$E_{Ni/NiO} = 1.42 - \frac{RT}{2F} \ln X_{O^{2-}} \qquad (7')$$

The validity of Eq. 7′ was confirmed experimentally by using a cell similar to that in Fig. 1 and measuring the emf of the cell:

$$\text{Ni/NiO/LiF-KF-O}^{2-}\text{/stabilized zirconia/O}_2\text{(Pt)} \qquad (13)$$

The emf change of this cell with the time is shown in Fig. 4. About 2 h after the immersion of the Ni/NiO electrode in the melt, the emf remains almost constant at around 830 mV. This value exactly coincides with the value calculated from the difference between Eqs. 2′ and 7′.

From the data obtained above, the potential-pO^{2-} diagram of Ni-LiF-KF-O^{2-} system can be drawn as in Fig. 5.

After the experiment, the stabilized zirconia tube was examined carefully by visual observation; no mechanical damage nor chemical corrosion could be

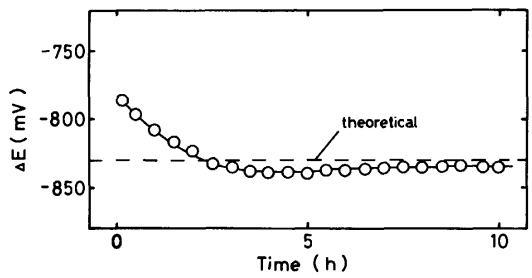

Fig. 4. Emf change of the cell: Ni/NiO/LiF–KF–O^{2-}/stabilized zirconia/Pt(O_2) with immersion time.

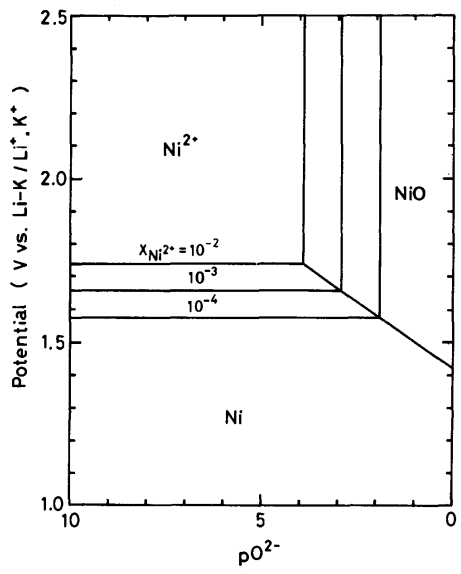

Fig. 5. Potential-pO^{2-} diagram of Ni–LiF–KF–O^{2-} system at 550 °C.

observed. During the whole experiment, reproducible measurements were possible. From these facts, it seems that stabilized zirconia can be used for an oxide-ion-concentration measurement in a fluoride melt at 550 °C.

Conclusion

The thermodynamic behaviour of nickel in a molten LiF–KF–O^{2-} system was investigated, and a potential-pO^{2-} diagram of the nickel in the system was presented, in which stabilized zirconia played an important role in measuring the oxide-ion concentration in the melt. The potential of the Pt(O_2)/stabilized zirconia/LiF–KF–O^{2-} electrode and the potential of the Ni/NiO/LiF–KF–O^{2-} electrode can be written as:

$$E = 2.25 - \frac{RT}{2F} \ln X_{O^{2-}} \quad \text{(V. } vs. \text{ Li-K/Li}^+, \text{ K}^+\text{: 550 °C)}$$

and:

$$E = 1.42 - \frac{RT}{2F} \ln X_{O^{2-}} \quad \text{(V. } vs. \text{ Li-K/Li}^+, \text{ K}^+\text{: 550 °C)}$$

respectively.

The solubility product of NiO in the melt was determined to be $K_{sp}=1.3\times10^{-6}$ at 550 °C.

Further refinement of the experimental technique might be necessary to get more rigorous and wider information. Especially, the improvement of the melt-purification technique and improvement of zirconia solid electrolyte might help us to get more reliable data. At least, though, this paper has shown that our method of using stabilized zirconia can offer useful information about the behaviour of metals in an oxide-ion-containing fluoride melt.

Use of Propagators in the Hückel Model. VII. Thermochemical and Photochemical Rearrangement in Cycloheptatriene, Tropone, and Related Compounds

Masaaki YAMAMOTO, Kiyoshi NISHIKAWA, and Shigeyuki AONO*
Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa 920
(Received March 4, 1985)

Hückel propagator theory has been applied to the analysis of photochemical and thermochemical rearrangement reactions, such as [1,3] sigmatropy, valence isomerization of norcaradiene, Cope rearrangement *et al.* In treatments employing the frontier orbital theory, the molecule is sometimes separated into two parts, and the orbital interaction between specified orbitals of two fragments is taken into account. In the propagator theory, the molecule is always considered as a whole, assuming a resonable transition state. In this transition state, the bond order between sites responsible for the reactions under consideration is estimated, and then the perturbing interaction between these sites is introduced. Then we can evaluate the extra energy to determine whether the reaction occures or not.

In the Hückel model the propagator is expressed in the M.O. basis set $\{|n>\}$ as[1)]

$$G(z) = \sum_n \frac{|n><n|}{z-\varepsilon_n}, \tag{1}$$

where ε_n and z are the energy eigenvalue and the complex variable, respectively. Using this propagator, we can easily obtain the bond order q_{rs} between sites r and s, and total energy as[1)]

$$q_{rs} = \frac{1}{2\pi i}\int_c G(r,s;z)\mathrm{d}z, \tag{2}$$

$$E = Tr\frac{1}{2\pi i}\int_c G(z)z\mathrm{d}z, \tag{3}$$

where integration is carried out along the Coulson contour which encloses poles of propagator corresponding to the occupied energy levels, and is assumed to include the spin summation.

In the previous papers, we have presented the perturbation theory[1)] to treat the chemical stability and reactivity,[2)] and the reactivity in the radiation field.[3)] Here we restrict ourselves to take into account the first order term with respect to the perturbation V. This is enough to the following analysis. The first order energy ΔE and that in the radiation field ΔE_f are given as follows:

$$\Delta E = \sum_{r,s} V_{rs}\frac{1}{2\pi i}\int_c G(s,r;z)\mathrm{d}z = \sum_{r,s} V_{rs}q_{sr}, \tag{4}$$

$$\Delta E_f = \frac{n|f_{\mathrm{HL}}|^2}{(\varepsilon_{\mathrm{LH}}-\omega)^2}\sum_{r,s} V_{rs}(q_{sr}^{\mathrm{L}}-q_{sr}^{\mathrm{H}}) \propto \sum_{r,s} V_{rs}(q_{sr}^{\mathrm{L}}-q_{sr}^{\mathrm{H}}). \tag{5}$$

The former is responsible for the thermochemical reaction, while the latter for the photochemical reaction. In the aboves, q_{rs} and q_{rs}^{P} are, respectively, the bond order and the partial bond order between r and s sites. f_{HL} is the interaction matrix element between electron and radiation field, and n and w are photon number and angular frequency. L and H represent LUMO and HOMO, respectively, and $\varepsilon_{\mathrm{LH}}=\varepsilon_{\mathrm{L}}-\varepsilon_{\mathrm{H}}$. In considering chemical reactivity for possible reaction pathes more over two, we can select, as a preferable reaction path. one with the lowest ΔE or ΔE_f. If the interaction is introduced only between r and s sites, Eqs. 4 and 5 simply become as

$$\Delta E \fallingdotseq 2Vq_{rs}, \tag{6}$$

$$\Delta E_f \propto Vq_{rs}^{\mathrm{LH}}, \tag{7}$$

where note that $V=V_{rs}=V_{sr}$, $q_{rs}=q_{sr}$, and $q_{rs}^{\mathrm{LH}}=q_{sr}^{\mathrm{LH}}$. The condition that $\Delta E<0$, which indicates the chemical bond being formed, holds for the following two cases:

$$q_{rs}<0,\ V>0 \quad \text{or} \quad q_{rs}>0,\ V<0. \tag{8}$$

The treatment of photochemical reaction is the same as that of thermochemical reaction except that we are using the partial bond order, and the condition that $\Delta E_f<0$ holds for the following two cases:

$$q_{rs}^{\mathrm{LH}}<0,\ V>0 \quad \text{or} \quad q_{rs}^{\mathrm{LH}}>0,\ V<0. \tag{9}$$

Accordingly, we have only to know the bond order or the partial bond order of molecule in question.

The sign of V_{rs} depends on phases of basis sets $|r>$ and $|s>$. Usually the direction of the basis set $\{|r>\}$ is determined so that the resonance integral β should be negative. In the case of π-electron system, and the sign of V_{rs} is negative when $|r>$ and $|s>$ have a facial symmetry, and positive when $|r>$ and $|s>$ have a point symmetry (see Fig. 1(a)).

However, V_{rs} generally has π- and σ-components. The former is perpendicular to the bond axes and the latter parallel. Interaction with the basis set of no direction, for example, the 1s orbital, has only the σ-component (see Fig. 1(b)). These considerations

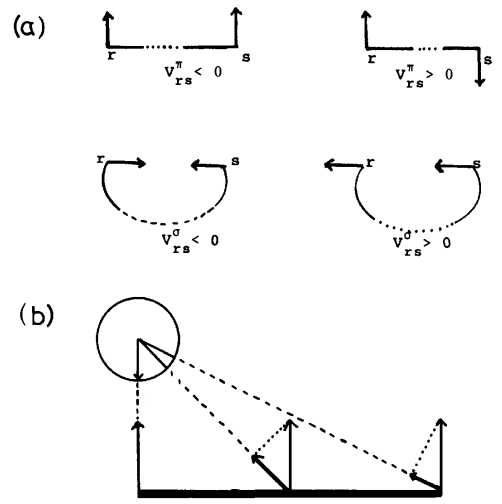

Fig. 1. Example of sign of V_{rs}.
(a) interactions between p orbitals, (b) interactions between s and p orbitals.

play a important role in the sigmatropic and ring closure reactions. For the ring closure reaction, there are two modes named conrotatory and disrotatory. If the π-orbitals are concerned with this, the relationship between the sign of V_{rs} and the mode are as follows ($V^{\sigma}_{rs}=V^{\sigma}_{sr}=V$):

$$V > 0 \text{ ; conrotatory,}$$
$$V < 0 \text{ ; disrotatory.} \qquad (10)$$

In treating reactivity, the frontier orbital theory and the Woodward-Hoffmann rule are sometimes used. These essence are the orbital interaction between specified orbitals and the conservation of orbital symmetry, respectively. They have made brilliant achievements[4,6] in explaining chemical reactions *e.g.* electrocyclic and sigmatropic reactions. However the former has a tendency of taking into account only for specified orbitals, and in the latter it is difficult to draw the correlation diagram for sigmatropic reaction which does not conserve the orbital symmetry. In the propagator method, the effect of all electrons are counted and we need not take care of the conservation of orbital symmetry at all.

Applications, Comparing with the Frontier Orbital Theory

In this section, We deal with the [1,3] sigmatropy, [1,5] prototropy, [1,3] prototropy, and ring closure reaction of *cis*-butadiene and compare the propagator method with the frontier orbital theory.[4]

Thermochemical [1,3] Sigmatropic Reaction.[6] A few thermal uncatalyzed [1,3] shifts are known. Berson and Nerson made a dramatic observation that

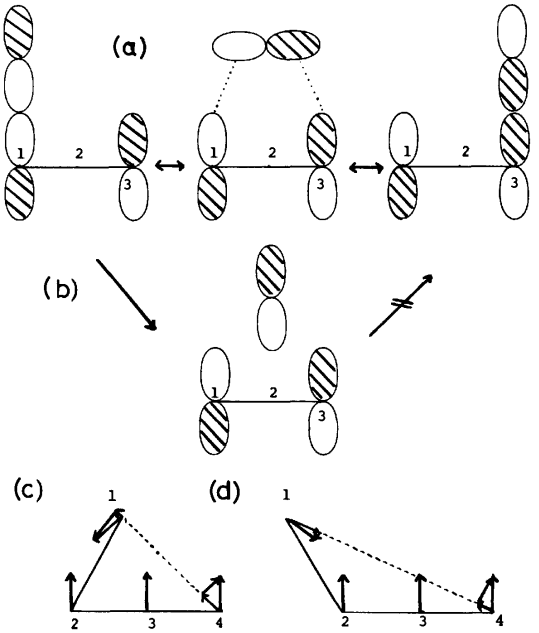

Fig. 2. (a), (b) The reaction path of the [1,3] sigmatropic reaction explained by the frontier orbital theory. (c), (d) The transition state in the [1,3] sigmatropic reaction in our treatment.

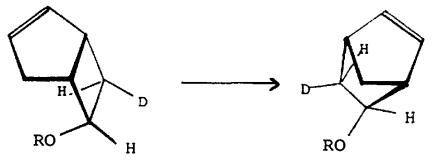
the system (a) undergoes a symmetry allowed suprafacial [1,3] shift with inversion at the migrating center, to give (b), at 307 °C.



(a) (b)

In view of orbital interaction, this reaction is caused by the interaction between SOMO of the allyl radical and the $2p_z$ of carbon. Thus the frontier orbital theory predicts the reaction path shown in Fig. 2(a) rather than Fig. 2(b).

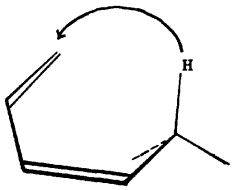
In our treatment of the [1,3] sigmatropy, this reaction is explained as follows: At first, considering the model for the transition state of the sigmatropic reaction as shown in Fig. 2(c), we calculate bond orders and determine signs of π and σ components of V_{rs} as

Site (r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 2	0.8944	−	−	−	
1 , 3	0.0000	+	−		
1 , 4	−0.4472	+(−)	0	−(+)	YES(NO)

On the other hand, if we assume the transition state as shown in Fig. 2(d), the calculated results are shown in braces. In this case, it is impossible for the [1,3]-σ tropy to occur. So we conclude that the

transition state of the [1,3]-σ tropy is as shown in Fig. 2(c). In the above calculation, for simplicity, all resonance integrals are approximately equal to β and the coulomb integral is put 0.

Thermochemical [1,5]-Prototropy. Now, we deal with the [1,5] prototropy.[4] The treatment is the same as that of the [1,3]-σ tropy.



According to the frontier orbital theory, we consider the interaction between the H-1s orbital and SOMO of pentadienyl radical as shown in Fig. 3(a). In the present method, we assume the transition state as shown in Fig. 3(b) which is also schematically displayed in Fig. 3(c), and proceeds as same as in the case of the [1,3]-σ tropic reaction except for the sign of V_{rs}. In this case, the π-components of V_{1r} are 0 and the σ-component is negative. The result is shown as

Site(r , s)	q_{rs}	V_{rs}^{π}	V_{rs}^{σ}	ΔE	reaction
1 , 2	0.8711	0	−	−	YES
1 , 3	0.0000	0	−		
1 , 4	−0.3877	0	−	+	
1 , 5	0.0000	0	−		
1 , 6	0.3014	0	−	−	YES

When $q_{rs}V_{rs}$ is negative, the shorter R_{rs} is, the more the reaction will occur. Therefore, the hydrogen designated by 1 is most probably transfered to the site 6 ([1,5] sigmatropic reaction). It is noted that the most probable transition state of the [1,5] prototropic reaction is a cis type as shown in Fig. 3(c).

Photochemical [1,3]-Prototropy. The photochemical [1,3] prototropic reaction[6] as

$$CH_3\text{-}CH{=}CH_2 \rightleftharpoons CH_2{=}CH\text{-}CH_3$$

is easily understood by symmetry characters of orbitals. According to the frontier orbital theory, the reaction is explained by the interaction between LUMO of the allyl radical and the 1s of hydrogen as shown in Fig. 4(a).

While, in our theory this is explained as follows: At first, we assume the transition state shown in Fig. 4(b), and then evaluate the partial bond orders and signs of interaction matrix elements. The results are tabulated in the following:

Site(r , s)	q_{rs}^{LH}	V_{rs}^{π}	V_{rs}^{σ}	ΔE	reaction
1 , 2	−0.4472	0	−	+	
1 , 3	0.0000	0	−		
1 , 4	0.7236	0	−	−	YES

It is quite possible that the photochemical [1,3] prototropic reaction will occur.

Photochemical and Thermochemical Reactions of the Ring Closure of Butadiene. It is well known that in the case of photochemical reaction or thermochemical reaction, the mode of ring closure of butadiene[4] is disrotatory or conrotatory, respectively. According to the frontier orbital theory, the former is explained by the LUMO-LUMO interaction of two

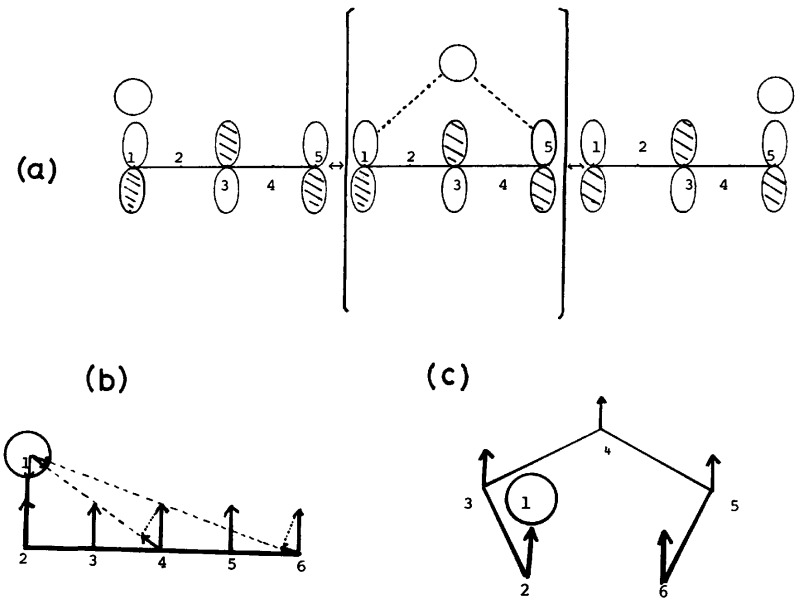


Fig. 3. (a) The reaction path in an example of [1,5] prototropic reaction explained by the frontier orbital theory. (b) The transition state in an example of the [1,5] prototropic reactionin our treatment. (c) The schematic representation of the transition state.

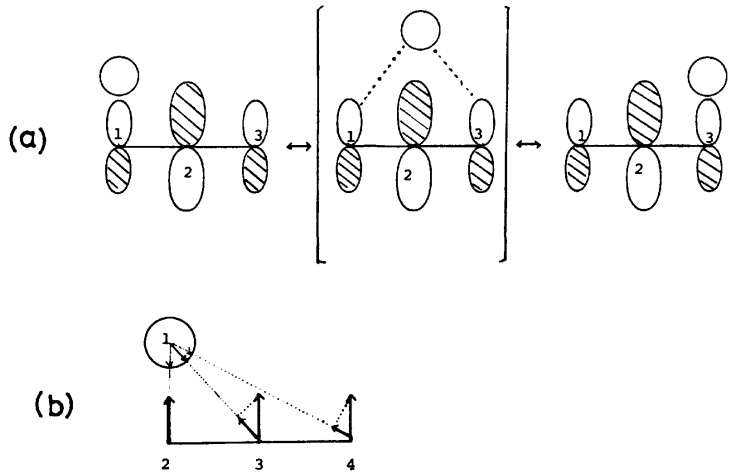

Fig. 4. (a) The reaction path of the photo-[1,3] prototropic reaction explained by the frontier orbital theory. (b) The transition state adopted in our treatment.

ethylene, and the latter by the HOMO-LUMO of two ethylene. (see Fig. 5(a), (b)). This consideration results that the modes of photochemical and thermochemical ring closure are disrotatory and conrotatory mode, respectively.

In view of the propagator method, the treatment is same as previous example, and it is natural to guess the transition state that all the carbons lie on the plane so that V_{14}^{π} and V_{14}^{σ} are negative (see Fig. 5(c)). In the case of photochemical reaction, since $q_{1,4}^{LH}$ is positive, this reaction occurs with the disrotatory mode. The result is shown as

Site (r , s)	q_{rs}^{LH}	V_{rs}^{π}	V_{rs}^{σ}	ΔE	reaction
1 , 2	−0.4472	−	0		
1 , 3	0.0000	−	0		
1 , 4	0.7236	−	−	−	YES

On the other hand, the thermochemical reaction of this is explained as follows: If the transition state is as same as that of photochemical reaction, this reaction will not occur, because $q_{14}<0$ and $V_{14}<0$. If we consider the transition state where the 2pπ orbitals at sites 1 and 4 twist considerably to the same direction as shown in Fig. 5(d), a positive V_{14}^{σ} shown in brace will produce a slight possibility of the conrotatoty ring closure. However, since V_{14}^{π} is still negative, we can assert this reaction hardly occurs.

Site (r , s)	q_{rs}	V_{rs}^{π}	V_{rs}^{σ}	ΔE	reaction
1 , 2	0.8944	−	0	−	
1 , 3	0.0000	−	0		
1 , 4	−0.4472	−	−(+)	+	NO

According to the Woodward-Hoffmann rule, the reactions are explained by the correlation diagrams.[6]

We have compared the propagator method with the frontier orbital theory or the Woodward-Hoffmann rule in these simple thermochemical and photochemical reactions, and get the same results. From now on, we are going to investigate the chemical reaction by the use of the propagator method and, if necessary, compare with the frontier orbital theory or the Woodward-Hoffmann rule.

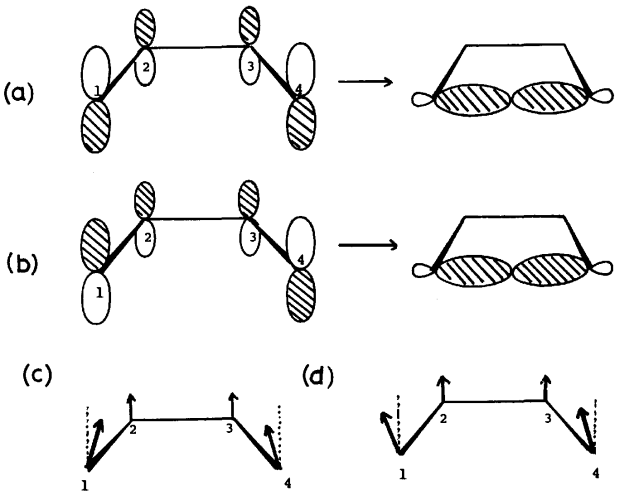

Fig. 5. (a), (b) The ring closure reaction of butadiene in photochemical and thermochemical reactions explained by the frontier orbital theory, respectively. (c), (d) The disrotatory and conrotatory modes of the transition state in the ring closure reacton of butadiene, respectively.

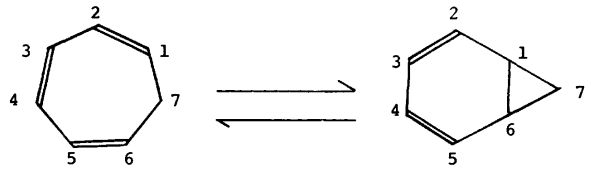
Thermochemical and Photochemical Reactions Cycloheptatriene and Norcaradiene Series

Cycloheptatriene and Norcaradiene.[5] Cycloheptatriene is the valence isomer of norcaradiene and this series undergo many queer rearrangements. We will try to predict these reaction pathes and sometimes compare with treatments with the frontier orbital

theory.

It is well known that cycloheptatriene and norcaradiene are with each other in thermal equilibrium.



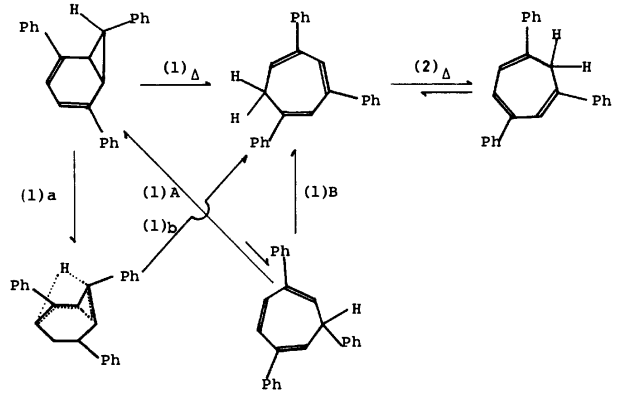
Cycloheptatriene Norcaradiene

It is natural to assume that in the transition state all the carbon atoms numbered from 1 to 7 lie on the molecular plane, but the interactions between sites 1 and 7 and between sites 6 and 7 are neglected because of σ-bond character (see Fig. 6(a)). Thus the treatment is nearly equal that for hexatriene. The result is shown as,

Site(r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 4	−0.3877	−	0	+	
1 , 5	0.0000	−	0	+	
1 , 6	0.3014	−	0	−	YES

Therefore it is quite natural that a new bond is formed between sites 1 and 6. By the way, it is mentioned that the ring opening reaction is considerd as the reverse reaction of the ring closure, since all the elementary reactions are supposed to be reversible. According to the frontier orbital theory, this reaction is explained as the interaction of HOMO of heptatriene(see Fig. 6(b)), and the sites 1 and 6 will bind with the conrotatory mode.

Thermoisomerization of 2,5,7-Triphenylnorcaradiene.[5,8] In this section, we try to predict the mechanism of thermal isomerizations of 2,5,7-triphenylnorcaradiene. First we investigate the step(1)A.



We begin with considering this reaction from the right side to the left side, assuming the transition state as shown in Fig. 7(a) for 2,5,7-triphenylcycloheptatriene. Namely this transition state is the same to that of hexatriene in the ring closure reaction except for three substituting phenyl radicals. The calculated parameters are given as

Site(r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 4	−0.3681	−	0	+	
1 , 6	0.2716	−	−	−	YES
2 , 5	−0.0694	−	0	+	

Thus it is probable that between sites 1 and 6 a new σ-bond forms. If it is assumed that the reverse reaction proceeds along the same reaction path, the answer is given.

Next, we deal with the [1,5] prototropy in the step(1)B. It is natural to guess the transition state of 2,5,7-triphenylcycloheptatriene in this reaction is as shown in Fig. 7(b). That is to say, the carbon orbitals at site 7 rehybridizes from three sp^3 orbitals to two sp^2 and a $2p_z$, and then the carbon $2p_z$ binds not only with the H 1s, but also with π-orbitals of the substituting phenyl group and of the cycloheptatriene. Now we assume that for simplicity the resonance integral between H 1s and $2p_z$ at site 7 is nearly equal to β. The result is:

Site(r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 8	−0.1489	0	−	+	
2 , 8	−0.2713	0	−	+	
3 , 8	0.1953	0	−	−	YES

Therefore, it is quite possible that H transfers from the carbon site 7 to the carbon site 3 or 4, and our prediction is agree with the experimental result.

In the next reaction(2), only the substituting positions of phenyl groups are different from the previous one. Thus the transition state shown in Fig. 7(c) yields the result:

Site(r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 8	−0.1488	0	−	+	
2 , 8	−0.2799	0	−	+	
3 , 8	0.1863	0	−	−	YES
4 , 8	0.1786	0	−	−	YES
5 , 8	−0.2834	0	−	+	
6 , 8	−0.1353	0	−	+	

From these calculations the [1,5] prototropy (in our notation between 3 and 8, or 4 and 8) is quite probable.

According to the frontier orbital theory, the above two reactions are expressed as the orbital interaction between SOMO of cycloheptatrienyl radical and the H 1s (see Fig. 7(d)), but the position of H is not so clear. On the other hand, the position of H is almost fixed in our treatment, because we assume the transition state such that the H 1s binds with the carbon $2p_z$ at site 7.

Then, we try to predict the reaction path (1)a and (1)b. It is natural to assume the transition state as shown in Fig. 7(e). The mutual interaction energy

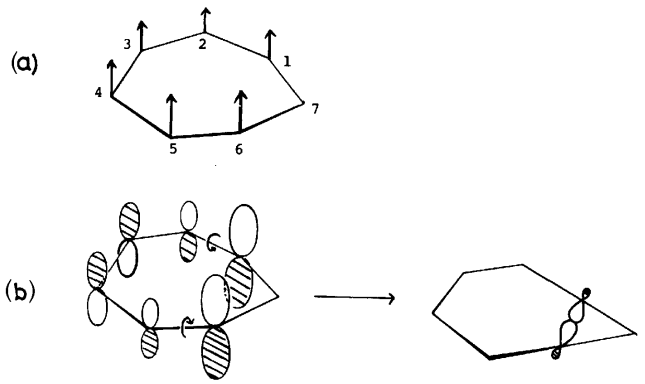


Fig. 6. (a) The transition state of cycloheptatriene in the ring closure reaction. (b) The reaction path from cycloheptatriene to norcaradiene explained by the Woodward-Hoffmann rule.

among three sp^3 hybridized orbitals are approximately, equal to β, because it is nearly equal to be $(\varepsilon_{2s}-\varepsilon_{2p})/4 \fallingdotseq -2\text{eV}$ (ε_{2s}, for example, the orbital energy of the carbon 2s), and the interactions between sites 1 and 7, between 6 and 8, and between 9 and 10 are approximately equal to 2β, because $\beta^{\sigma}_{rs} \fallingdotseq 2\beta^{\pi}_{rs}$. We have the result:

Site (r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 10	−0.2326	0	−	+	
2 , 10	−0.0421	0	−	+	
3 , 10	0.0962	0	−	−	YES

Accordingly we may expect that the reaction will occur along this reaction path. But it seems considerably difficult to occur, because $q_{3,10}$ is not so

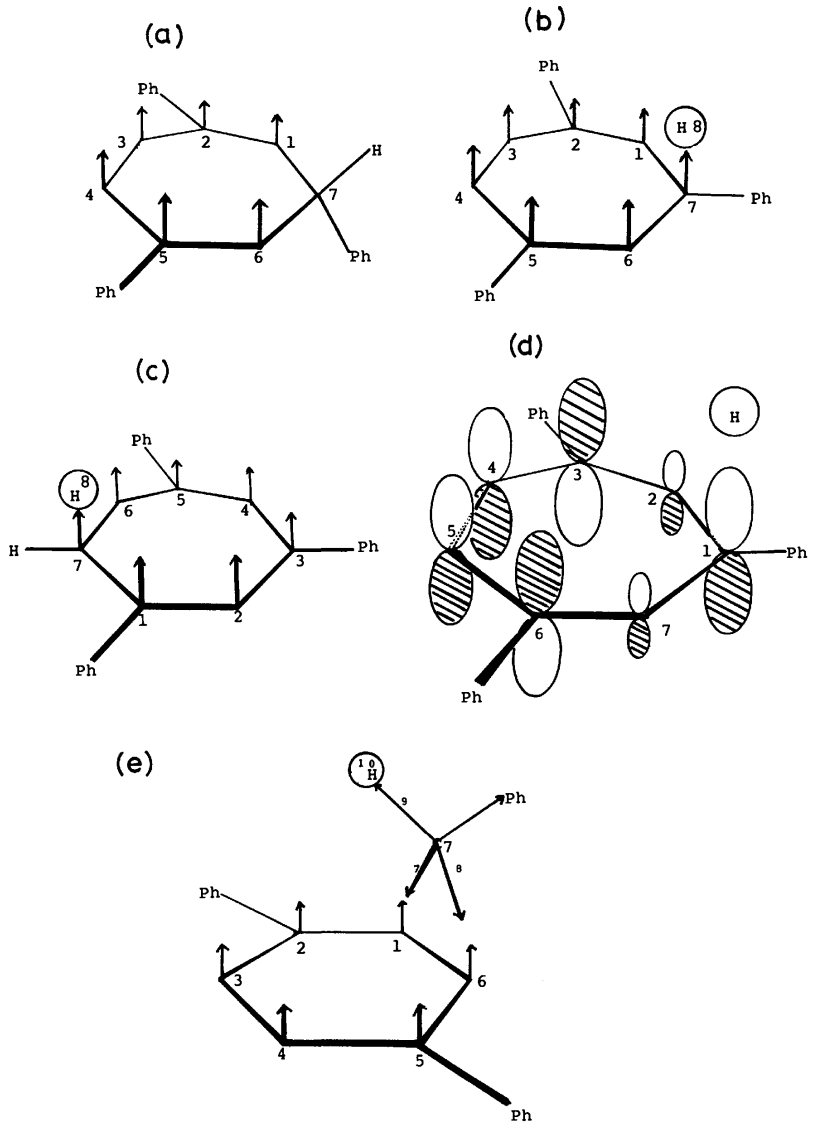

Fig. 7. (a), (b) The transition state of 2,5,7-triphenylcycloheptatriene in the ring closure reaction and the H-transfer, respectively. (c) The transition state of 1,3,5-triphenylcycloheptatriene in the H-transfer. (d) The reaction of 2,5,7-triphenylcycloheptatriene explained by the frontier orbital theory. large.

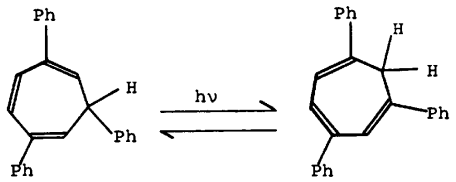
Photoisomerization of 2,5,7-Triphenylcycloheptatriene. In this section we deal with the photochemical reaction of 2,5,7-triphenylcycloheptatriene.[5,9] It is shown as



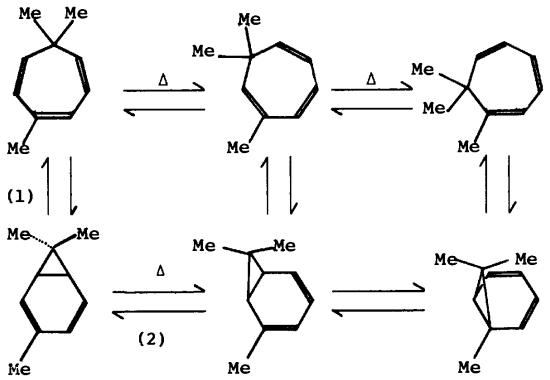
Then assuming the transition state shown in Fig. 7(b), we obtain the result:

Site (r , s)	q_{rs}^{LH}	V_{rs}^{π}	V_{rs}^{σ}	ΔE	reaction
1 , 8	0.2238	0	−	−	YES
2 , 8	0.1399	0	−	−	YES
3 , 8	−0.1745	0	−	+	

Therefore, the hydrogen will transfer from the carbon site 7 to the carbon site 1 or 2, the former being a little more probable. In this case, the former refers [1,7] prototropy and the latter gives the starting material. The same treatment for 1,4-diphenylcycloheptatriene gives the result that perfectly agrees with the experimental one.

BERSON-WILLCOTT Rearrangement

In this section, we deal with the thermoisomerization of methyl-substituted cycloheptatriene,[5] and compare the photoisomerization of triphenylnorcaradiene,[5] because these two reactions are similar in mechanism in spite of their difference in reaction characters.



Berson and Willcott have observed a remarkable serise of the isomerization of methyl-substituted cycloheptatriene[10] as shown above. Woodward and Hoffmann expected that this [1,5] sigmatropic shift had to proceed with retention at the migrating carbon atom[6] as shown in Fig. 8(a). This condition implies that each group substituting the shifting carbon pivots 180° above the cyclohexatriene ring. However we have obtained a different result as will be mentioned below.

The structure of 3,7,7-trimethylcycloheptatriene is the same as that of cycloheptatriene except for the methyl groups at sites 3 and 7. If the carbons designated by 1~6 lying on the molecular plane have $2p_z$ orbitals, the interactions between these are negative, while the effect of two methyl groups at the site 7 are disregarded due to the σ-bond character. Assuming the transition state as shown in Fig. 9(a), we calculate bond orders and determine signs of π- and σ- components of interaction matrix elements:

Site (r , s)	$q_{rs}^{(1)}$	$q_{rs}^{(2)}$	$q_{rs}^{(3)}$	V_{rs}^{π}	V_{rs}^{σ}	ΔE	reaction
1 , 3	0.0661	0.0512	0.0856	−	0	−	
1 , 4	−0.3738	−0.3809	−0.3612	−	0	+	
1 , 5	−0.0231	−0.0168	−0.0307	−	0	+	
1 , 6	0.2913	0.2970	0.2814	−	0	−	YES

Therefore, it is quite possible that the sites 1 and 6 will bind with disrotatory mode (step(1)). This trend is also hold for cases(2; 2,7,7-trimethyl compound) and (3; 1,7,7-trimethyl compound). As is the case of

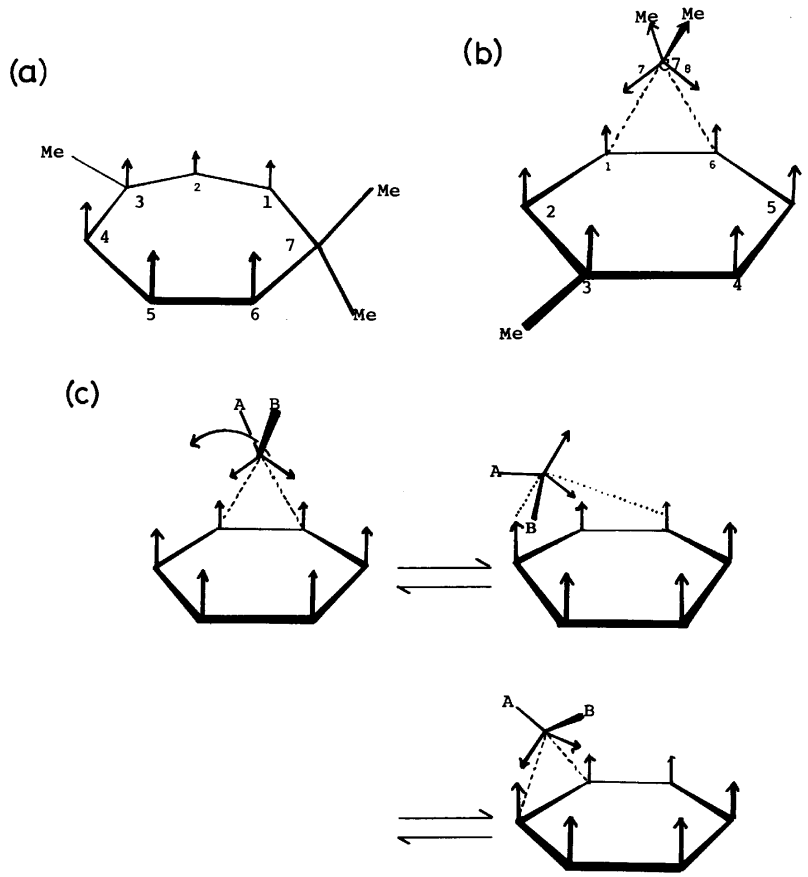


Fig. 9. (a) The transition state of 3,7,7-trimethylcycloheptatriene in the ring closure. (b) The transition state of 3,7,7-trimethylnorcaradiene in the sigmatropic reaction. (c) The reaction path of trimethylnorcaradiene series predicted in our treatment.

cycloheptatriene, we treat the ring opening reaction from norcaradiene to cyclohexatriene as a reverse reaction of the above.

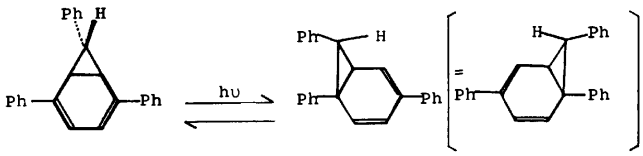
Next we deal with the sigmatropic reaction of step(2). It is natural to guess the transition state shown in Fig. 9(b). Namely, the carbon which would transfer is in the sp^3 character, and the triangle formed by carbons numbered 1,6 and 7 is perpendicular to the molecular plane, and the six carbons lying on the molecular plane are conjugated like in benzene. The effect of two methyl groups is neglected. The interactions are put, $\beta_{17}=\beta_{68}\fallingdotseq\beta_{78}\fallingdotseq\beta$, for simplicity. Calculated bond orders and signs of V_{rs}^{π} and V_{rs}^{σ} are shown as

Site (r , s)	$q_{rs}^{(1)}$	$q_{rs}^{(2)}$	V_{rs}^{π}	V_{rs}^{σ}	ΔE	reaction
2 , 7	0.0119	0.0443	+	−		
3 , 7	0.1610	0.1713	+	−	+	
4 , 7	0.0673	−0.0204	+	+	+	
5 , 7	−0.3446	−0.3505	+	+	−	YES
6 , 7	−0.0638	0.0100	+	−		
1 , 8	0.0301	−0.0968	+	−		
2 , 8	−0.3541	−0.3386	+	+	−	YES
3 , 8	−0.0502	−0.0323	+	+		
4 , 8	0.1543	0.1612	+	−	+	
5 , 8	0.0237	0.0190	+	−		

It is quite possible that the sigmatropic reaction will occur without retention at the shifting center shown in Fig. 9(c). Our result is opposite to the prediction by Woodward and Hoffmann. However, the experimental proof has not yet given. The treatment of reactions for the 2-methyl compound is the same as the previous one, and the result is in the above table(2).

According to the frontier orbital theory, the transition state is assumed such that the three menbered ring of norcaradiene is cut at the carbon 7, and the sp^3 orbitals rehybridize to two sp^2 and a $2p_z$. The $2p_z$ and SOMO of cycloheptatrienyl radical interact with each other, so that this reaction occurs with retention at the resting center. Figure 9(c) might help to understand the difference of the reaction mode predicted by the propagator method and the frontier orbital theory.

Next we deal with the photochemical reaction which is similar to the Berson-Willcott rearrangement:[9]



We begin with assuming the transition state of 2,5,7-triphenylnorcaradiene shown in Fig. 7(e) and evaluate the partial bond orders and signs of interaction matrix elements. The result is as follows:

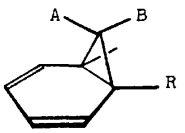
Site (r , s)	q_{rs}^{LH}	V_{rs}^{π}	V_{rs}^{σ}	ΔE	reaction
2 , 7	0.1951	+	+	+	NO
4 , 7	−0.2534	+	−		
6 , 7	0.3373	−	−	−	

Thus we conclude that photoisomerization of 2,5,7-triphenylnorcaradiene which is similar to the Berson-Willcott rearrangement will not occur under the condition that the shifting carbon is in the sp^3-like state. This suggests that the present model of transition state is not adequate. Then we consider a new model that the shifting carbon is in sp^2 and $2p_z$ due to the effect of phenyl group substituting this carbon. It is noticed that there are interaction matrix elements among sp^3 orbitals, but between the sp^2 and $2p_z$ not. Under these considerations, we evaluate partial bond orders and signs of interaction matrix elements. The result is in the following:

Site (r , s)	q_{rs}^{LH}	V_{rs}^{π}	V_{rs}^{σ}	ΔE	reaction
2 , 7	−0.3642	+	+	−	YES
4 , 7	0.2813	+	−		

Conclusively, the phenyl group attached to the migrating carbon has a great influence on the photochemical [1,5] sigmatropy, and the shifting carbon may transfer without retention. This result is also explained by the frontier orbital theory, namely, by the interaction between the $2p_z$ of the shifting carbon and LUMO of cyclohexadienyl radical as shown in Fig. 8(b). We show the difference between the reaction mode predicted by the propagator method and that by the frontier orbital theory in Fig. 10.[6]

If in the molecule written as



the similar reactions as mentioned in this section proceed with the retention at the migrating center, the slither mechanism is available not to loose the optical activity. However, if we employ the frontier orbital theory, the migrating center pivots in the thermal reaction resulting racemerization. On the other hand, in the optical reaction both treatments give the same results keeping the optical activity.

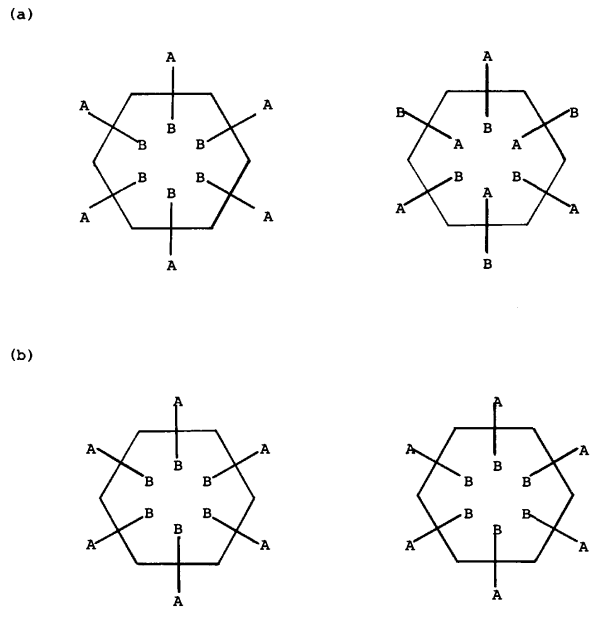


Fig. 10. The reaction modes of the Berson-Willcott rearrangement and photo-isomerization of 2,5,7-triphenylnorcaradiene predicted by the propagator method and the frontier orbital theory.
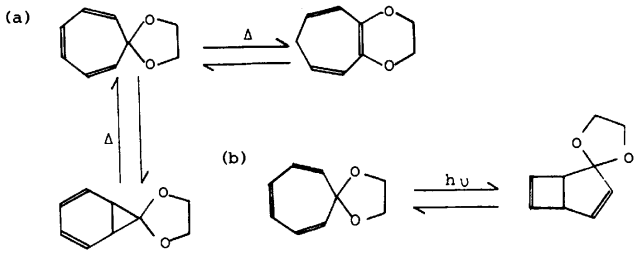
(a) Thermochemical reaction, (b) photochemical reaction.

Photochemical and Thermochemical Rearrangements of Tropone Ethylene Acetal

In this section, we deal with the photochemical and thermochemical rearrangement of tropone ethylene acetal.[5,11]



First we deal with the photoisomerization. It is natural to assume the transition state as shown in Fig. 11(a), where the effect of oxygen can be disregarded because of its σ-bond character. The calculated results are:

Site (r , s)	q_{rs}^{LH}	V_{rs}^{π}	V_{rs}^{σ}	ΔE	reaction
1 , 4	0.4356	−	0	−	YES
1 , 6	−0.5431	−	0	+	
2 , 5	−0.1076	−	0	+	

Therefore, this reaction will occur with disrotatory mode.

Next we consider the thermochemical reaction for two alternative pathes. A and B as shown in the following. We predict which path is suitable.

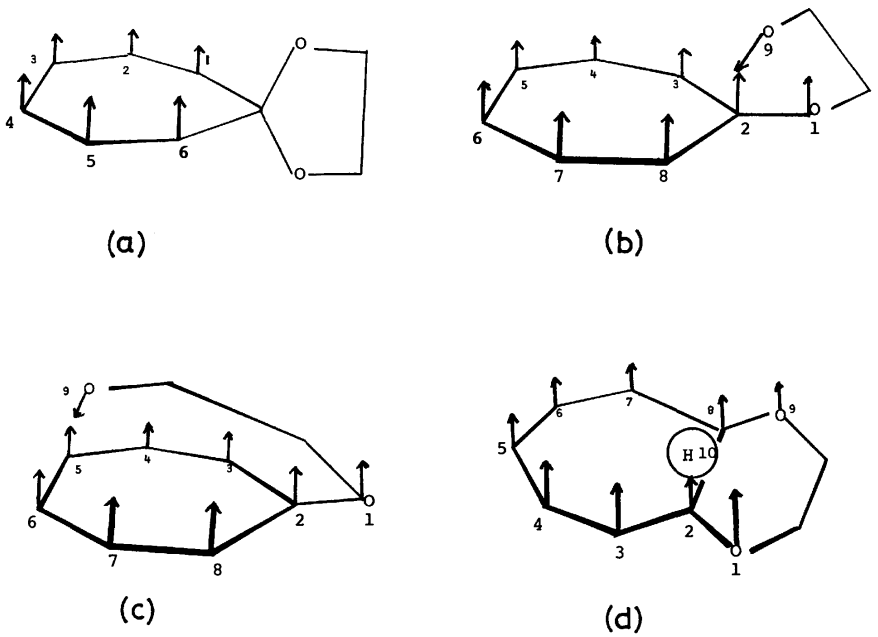


Fig. 11. (a), (b) The transition state of tropone ethylene acetal in the ring closure and O-transfer, respectively. (c), (d) The transition state of intermediate product of tropone ethylene acetal in the O-transfer and H-transfer, respectively.

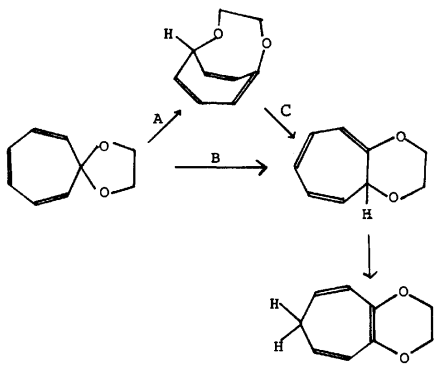


In the case of the first sigmatropy, we assume the transition state as shown in Fig. 11(b) and obtain the result as

Site (r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 9	−0.1965	+ <	−	+	
2 , 9	0.7639	−	−	−	
3 , 9	−0.1498	+ <	−	+	NO
4 , 9	−0.1952	+ <	−	+	
5 , 9	0.1310	+ <	−	−	YES

Therefore it is quite possible that the [1,5] sigmatropy occurs. This implies the reaction path A to be preferable, and the "NO" for the 3,9 and 8,9 shifts mean the reaction path B is not acceptable. In order to predict the next step reaction, we assume the transition state as shown in Fig. 11(c) to get the results:

Site (r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 9	−0.0438	+	−		
2 , 9	0.1217	−	−	−	YES
3 , 9	−0.2005	+ <	−	+	
4 , 9	−0.1563	+ <	−	+	
5 , 9	0.7960	+ <	−	−	
6 , 9	−0.2004	+ <	−	+	
7 , 9	−0.1976	+ <	−	+	
8 , 9	0.1749	+ <	−	−	YES

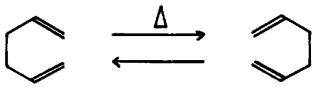
Therefore the reaction will occur on path C. In the above table, the latter "YES" refers to get the product and the former the reverse reaction. What reaction will follow the previous one? We assume the transition state as shown in Fig. 11(d) and calculate as follows:

Site (r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 10	−0.1759	0	−	+	
3 , 10	−0.1766	0	−	+	
4 , 10	−0.2808	0	−	+	
5 , 10	0.2220	0	−	−	YES
6 , 10	0.1716	0	−	−	YES
7 , 10	−0.3133	0	−	+	
8 , 10	−0.1020	0	−	+	
9 , 10	0.0052	0	−	+	

It is expected that H will shift from the carbon site 2 to 5 or 6. Here we note that even for complicated reactions mentioned above the propagator method gives nice ways to predict the reaction path correctly.

Cope Rearrangement

Chair, Boat and Quasi-boat Model. The Cope rearrangement[7] is a kind of the [3,3] sigmatropic reaction as



In view of the frontier orbital theory,[4] this reaction is explained as the interaction between two SOMO's of allyl radical. Therefore, the transition state of the Cope rearrangement, as is shown in Fig. 12(a)~(c) has three types named chair, boat and quasi-boat type referring to the relative positions of two allyl radicals.

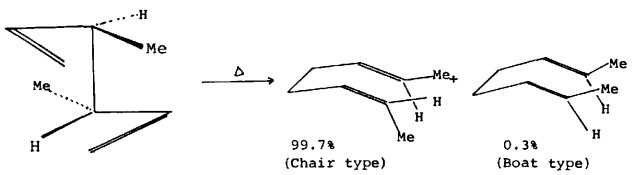
Usually, the Cope rearrangement occurs through the transition state of chair type at low temperature, and the higher the temperature is, the more increasing the product through the boat type is. It is impossible for the simple frontier orbital theory to explain this experimental result, because SOMO of the allyl radical has no amplitude at site 2 so that there is no difference between chair and boat types. Fukui[4] explained this result by taking account of the interaction between LUMO and HOMO of the allyl radical.

In our treatment of the Cope rearrangement, we begin with assuming the transition state of 1,5-hexadiene as shown in Fig. 12(d) and (e), where at carbon sites 3 and 4 rehybridizations arise from three sp^3 to two sp^2 and a $2p_z$, so that sites 3 and 4 are coupled through $2p_z$'s. The resonance integral $\beta_{3,4}$ is approximated to be β for simplicity. Under these conditions calculations are carried out to give

Site (r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 4	−0.3877	+	−	?	
1 , 6	0.3014	−	−	−	YES
2 , 5	−0.0867	+(−)	−	?(+)	(hinderance)

In the above, the results for the boat type are shown in braces. Because of the difference of V_{25}, the transition state of chair type is more stable than that of boat type.

The same treatment explains the following reaction



Thus we understand that the chair type is generally more stable than the boat type.

On the other hand for tropone, the experiment[13] suggests the quasi-boat rearrangement.

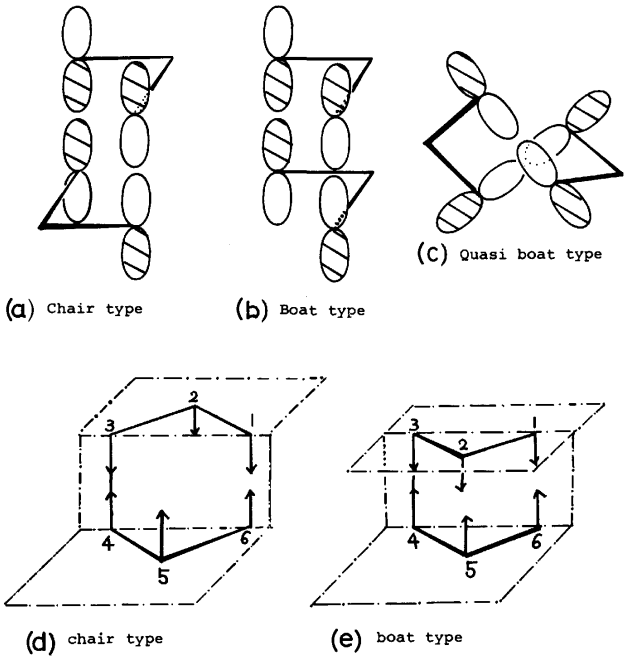


Fig. 12. (a), (b), (c) The possible transition states of the Cope rearrangement in the frontier orbital theory. (d), (e) The transition states of the Cope rearrangement in our treatmemt.

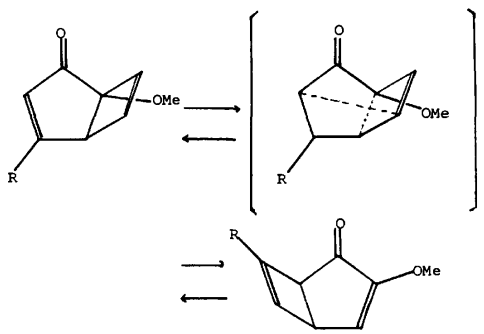


At sight, there be no interaction between two double bonds of molecular ends. If we make a model that carbons at sites 2, 4, 5, 7, and 8 are in sp^2-like state and the carbons at sites 3 and 6 are sp^3-like state, we can find that the σ-bond between sites 3 and 6 has a strain as shown in Fig. 13(a), and the resultant π-components are perpendicular to the left and right planes. So it is natural to imagine two double bond of molecular ends are conjugated with each other through the π-components at sites 3 and 6. As to the coupling parameteres, we put $\beta_{36} \fallingdotseq 2\beta$, $\beta_{23}=\beta_{34}=\beta_{56}=\beta_{67}=\alpha\beta$ ($\alpha>0$). We have tried two type parameters which are $\alpha=1.0$ and $\alpha=0.5$. The calculated results are shown as (a) and (b), respectively:

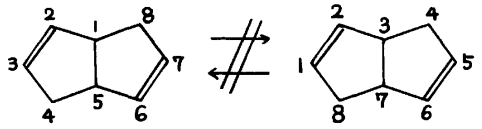
Site (r , s)	$q^{(a)}_{rs}$	$q^{(b)}_{rs}$	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
2 , 4	−0.0580	−0.0080	−	−	+	
2 , 5	−0.1245	−0.0182	−	−	+	
4 , 7	−0.1127	−0.0295	−	−	+	
4 , 8	−0.0285	0.0079	−	−	+(−)	
5 , 7	0.0496	−0.0026	−	−	−(+)	
5 , 8	0.1273	0.0313	−	−	−	YES

These two treatments give the qualitatively same results. Therefore, it is likely that a bond between sites 5 and 8 may be formed in the transition state in Fig. 13(a) and the reaction path should be such as shown above. Organic chemists[5,7] and R. Hoffmann[6] regard this reaction as a quasi-boat Cope rearrangement, as it is a [3,3] sigmatropic reaction. But this reaction is understood in a little different manner from the Cope rearrangement of 1,5-hexadiene series in the following sense:

(1) Due to π-components of the 3—6 bond, the double bonds at molecular ends do interact so that the resultant phase of bond order makes the reaction under consideration possible, together with the corresponding interaction matrix elements.

(2) It is also pointed out that in our treatment of the tight-binding approximation, the σ-character of the 3—6 interaction matrix element is fairly large to amount nearly 2β, and this effect is profoundly important in the present result.

Now, we turn to the experimental results. First we concern with the following reaction[14] which actually does not occur.



If this reaction would occur, it would be a pure Cope rearrangement through the transition state of the quasi-boat type. In view of our treatment, since the 1—5 σ bond is almost on plane, there is no π conjugation between two double bonds of molecular ends, namely these double double bonds are almost independent with each other. Therefore this molecule has no potential to make the rearrangement possible. Also a discussion has been given that, in the Dewar benzene series[15] having similar species of tropone series, the Cope rearrangement will occur through the quasi-boat type. If the reaction would occur, it would be shown schematically as

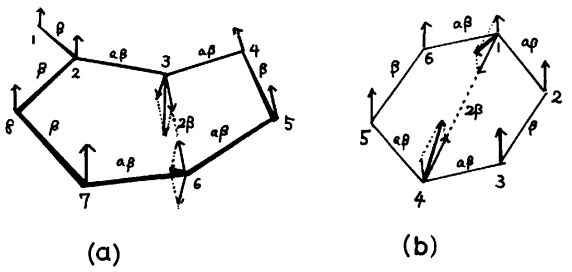


Fig. 13. (a) The transition state of the Cope rearrangement, through the quasi-boat. (b) The transition state of the Dewer benzene.

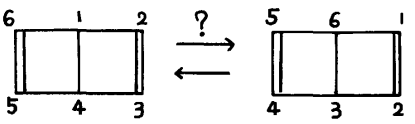


In view of our treatment, it does not occur. The reason is as follows: First, we assume the transition state of the Dewar benzene series as shown in Fig. 13(b), and calculate as useal. We can find there is no reaction mode in which ΔE is negative.

Site (r , s)	q_{rs}	V_{rs}^{π}	V_{rs}^{σ}	ΔE	reaction
2 , 5	−0.3333	−	0	+	NO
2 , 6	0.0000	−	0		

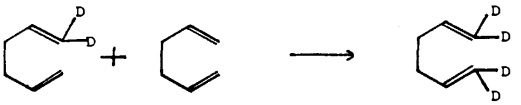
Untill now, we have considered the transition states of the Cope rearrangement: (1) chair type, (2) boat type, (3) quasi-boat type. However in literatures[5,7] we found four type states more than shown as

(4) allyl radical type (5) 1,4-biradical type

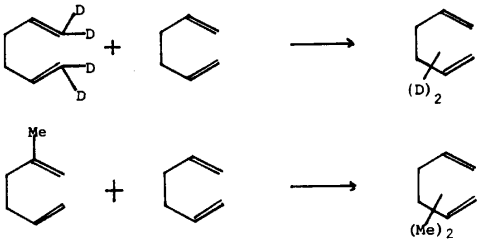
(6) ion-pair type (7) 1,4-dipole type

These concepts except (4) can be reinterpretended by our method in the following.

Cope Rearrangement Through the Allyl Radical. It was said that 1,5-hexadiene was cleaved to two allyl radicals, and each of them had a great concern with the Cope rearrangement at the beginning of reaction, but it was turned out to be uncorrect.[16] Doering[17] reported the next experimental result.

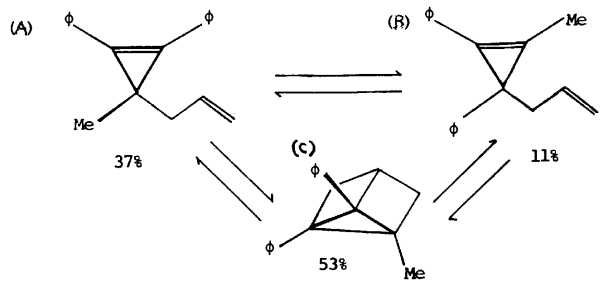


and then Wigfield[18] reported as,



Observing these, it can be asserted that these reactions are of intermolecular character and do not concern with any intramolecular reaction (cleaving into two allyl radicals). We do not discuss these any longer.

Cope Rearrangement Through the 1,4-Biradical.
The reaction said to be a Cope rearrangement through the 1,4-biradical[19] is shown as



It is natural for our treatment to guess the transition state of (A) as shown in Fig. 14(a). Then we get calculated parameters as

Site (r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 3	−0.0913	+	−		
1 , 6	0.1312	−	−	−	YES
2 , 5	−0.0913	+(−)	−	(+)	(hinderance)
2 , 6	0.1312	+	−		

In the above, the results for the boat type are in braces. Therefore, we find that the chair type is more stable than the boat type, because $q_{25}V_{25}$ is positive in the latter. In spite of the advantage of the chair type, why does the reaction which seems through the boat type occurs? If we choose the transition state of the intermediate product as shown in Fig. 14(b), the calculated parameters are:

Site (r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 5	−0.0460	+	−		
2 , 5	−0.2833	+	0	−	YES
3 , 5	−0.0172	+	−	+	

Therefore, it is possible that this reaction will occur through the boat type.

In addition, we point out the [1,3] sigmatropy could occur, if groups or fragments inside the molecule could prevent sites 1 and 6 from approaching.

The reaction(B) presented at the beginning of this section is treated by the same method, considering effect of the different substituting group. The calculated parameters are:

Site (r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 5	−0.0946	+	−		
1 , 6	0.2175	−	−	−	YES
2 , 5	−0.0932	+(−)	−	(+)	(hinderance)
2 , 6	0.1149	+	−		

In the above, the results for the boat type are shown in braces. Therefore, it is quite possible that this reaction from (B) to (C) will occur through the chair type. Then comparing the value of q_{16} between (A) and (B), we find that this is larger in (B) than in (A), implying that the transition state of (B) is perhaps preferable to that of (A). So the equilibrium probably tends to (A). Our prediction resultantly agrees with the experimental result.

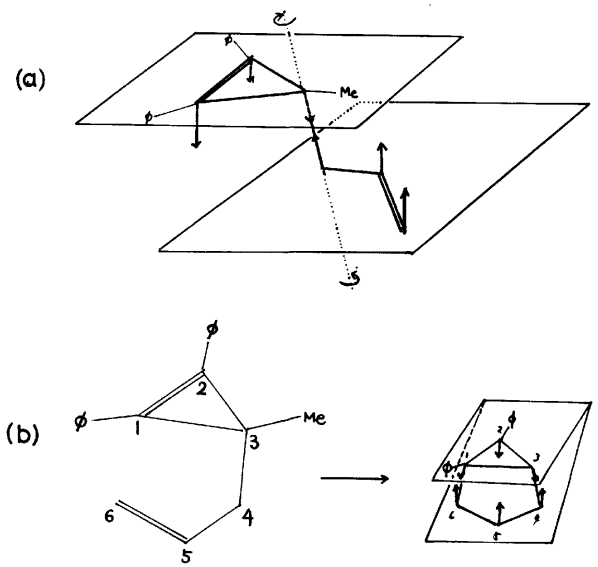


Fig. 14. The transition state of the Cope rearrangement, through the 1,4-biradical.

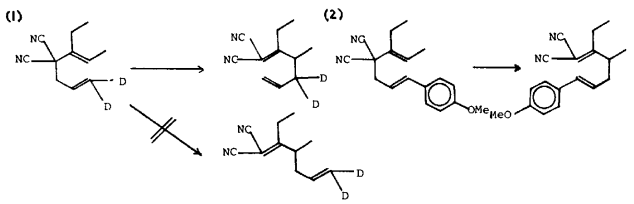
Cope Rearrangement Through the Ion Pair.
The ion pair or dipole models is rather a classical model. It is not acceptable from our viewpoint that the chemical reaction is genereated by quantum mechanical characters of electron, *i.e.* wavefunction or bond order. Employing our method, we can deal with reactions which have been explained by the ion pair model:[20]



The difference between the above two reactions lies in environments, *i.e.*, sites 1 and 6 can easily approach with each other or not. We proceed under the following considerations:

(1) If sites 1 and 6 easily approach, the Cope rearrangenent will occur.

(2) If not, a possibility of the [1,3] sigmatropy increases.

Assuming the transition state for the first reaction as in Fig. 15(a), we calculate necessary parameters as

Site (r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 5	−0.0946	+	−		
1 , 6	0.2175	−	−	−	YES
2 , 5	−0.0932	+	−		
2 , 6	0.1149	+	−		

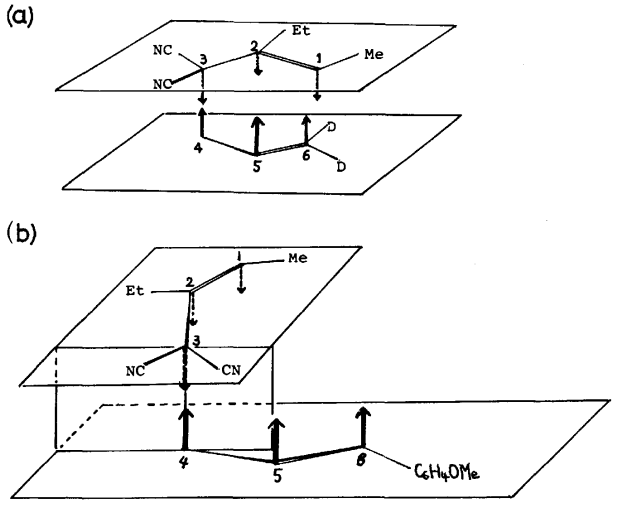


Fig. 15. The transition state of the Cope rearrangement (a) and the [1,3] sigmatropy (b), through the ion pair.

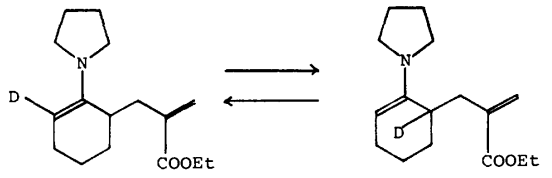
Thus, we can easily explain this reaction as a normal Cope rearrangement through the chair type corresponding to the case (1).

Next, we assume the transition state of the latter reaction as shown in Fig. 15(b), considering steric hinderance similar in the [1,3] sigmatropic reaction. Then we get the results:

Site (r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 4	−0.2581	+	≒0	−	YES
1 , 6	0.1897	+	−		
2 , 5	−0.0620	+	−		
3 , 6	−0.2413	+	≒0	−	YES

The possibility of the 1—4 binding ([1,3] sigmatropy) is consistent with the experimental result. While the 3—6 binding is considered to be fairly difficult due to steric hinderance.

Cope Rearrangement Though the 1,4-Dipole Model. We deal with the reaction,



which has been explained to be a Cope rearrangement by the 1,4-dipole model.[21] In this case, either the Cope rearrangement and the [1,3] sigmatropy give the same product. As the steric effects scarcely hinder sites 1 and 6 approaching, we deal with this reaction as a Cope rearrangement. The chair type is sterically less hindered than the boat type is, as shown in Fig. 16. The required calculations are:

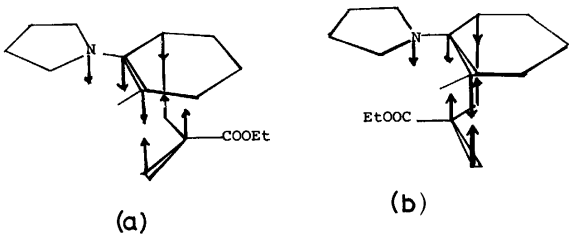


Fig. 16. The transition state of the Cope rearrangement, through the 1,4-dipole. (a) chair type, (b) boat type.

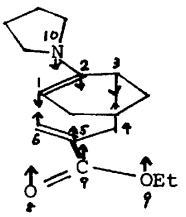
(Chair type)

Site (r , s)	q_{rs}	V^{π}_{rs}	V^{σ}_{rs}	ΔE	reaction
1 , 6	0.2070	−	−	−	YES
2 , 5	−0.0705	+	−		

It is noted here that there is little posibility of the [1,3] sigmatropic reaction because of a vanishingly small steric hinderance.

By the way, we examine why the 1,4-dipole model is not adequate. Assuming the structure,



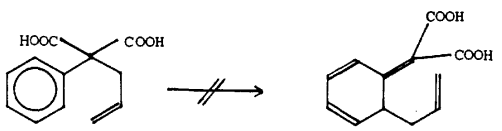
we can easily calculate the π-electron densities in the tight-binding approximation:

Site	r	q_r	Site	r	q_r
1	1.1347	$\delta-$	2	0.9526	$\delta+$
3	1.0202	$\delta-$	4	0.9823	$\delta+$
5	1.0290	$\delta-$	6	0.8256	$\delta+$
7	0.6489	$\delta+$	8	1.5926	$\delta-$
9	1.8964	$\delta+$	10	1.9172	$\delta+$

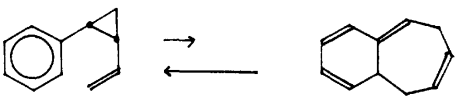
The net charge densitiy at site 7 is qualitatively positive ($\delta+$ in the above table), which is opposite to the transition state proposed in the reference.[7]

Claisen Rearrangement. The Cope rearrangement in which the double bond of the phenyl radical concerns with rearrangement is called the Claisen rearrangement. We present experimental examples below:[22,23]

(A)



(B)



According to our treatment, we assume a transition state for the reactant of (A) as shown in Fig. 17(a), and evaluate bond orders and signs of interactions as

Site (r , s)	$q_{rs}^{(a)}$	$q_{rs}^{(b)}$	V_{rs}^{π}	V_{rs}^{σ}	ΔE	reaction
1 , 4	−0.2901	−0.2351	+	−		
1 , 6	0.1194	0.1706	+	−	−	YES
2 , 5	−0.0512	−0.1020	−	−	+	
3 , 6	−0.1597	−0.2103	+	−		

Then for the product (the right hand), assuming a transition state as in Fig. 17(b), we get bond orders and signs of interactions as in the above table(b).

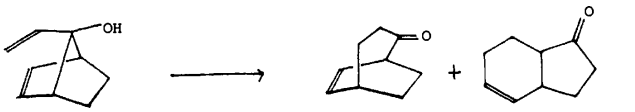
In the aboves we find a considerbly larger values of q_{16} in the latter than in the former. It suggests the reverse reaction is easier to occur than the forward one does, and then the equilibrium tends strongly to the left. This consideration qualitatively explains the experimental result.

In order to predict the reaction(B), we assume transition states for reactant and product as in Fig. 17(c) and (d), respectively. Evaluated parameters are:

Site (r , s)	$q_{rs}^{(c)}$	$q_{rs}^{(d)}$	V_{rs}^{π}	V_{rs}^{σ}	ΔE	reaction
1 , 4	−0.3986	−0.3068	+	−		
1 , 6	0.1628	0.3805	+	−	−	YES
2 , 5	−0.0730	−0.0698	−	−	+	
3 , 6	−0.2195	−0.4503	+	−		

The value of q_{16} being considerably larger in the latter than in the former, the equilibrium seems to lean to the left side. It agrees with the experimental result, too.

Oxy-Cope Rearrangement. This and the related reactions have been classified by Berson[24] as the oxy-Cope rearrangement and the [1,3] sigmatropy systematically. First, we deal with the famous reaction



(1,3-σ tropy) (88%) (3,3-Cope) (7%)

Remembering the basic considerations previously given about the Cope rearrangement and the [1,3] sigmatropy, we assume the transition state as shown in Fig. 18(a). As to interaction matrix elements, $V_{16}^{\sigma}$is negative, V_{14}^{π}positive and V_{14}^{σ}vanishingly small. Due to the molecular shape, the distance between sites 1 and 6 is rather larger than that between sites 1 and 4. Under these considerations, calculations are carried

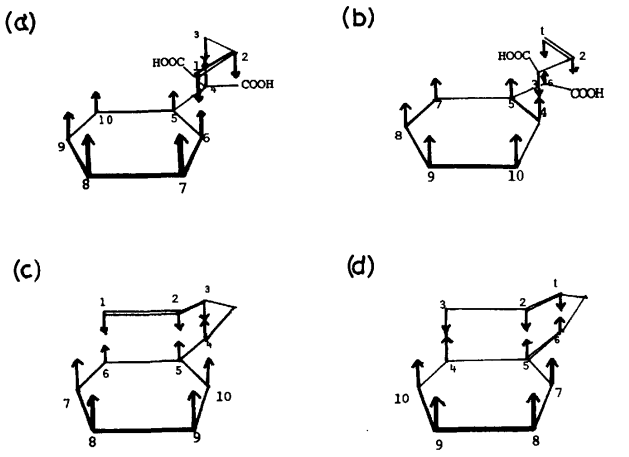


Fig. 17. The transition state of the Claisen rearrangement.

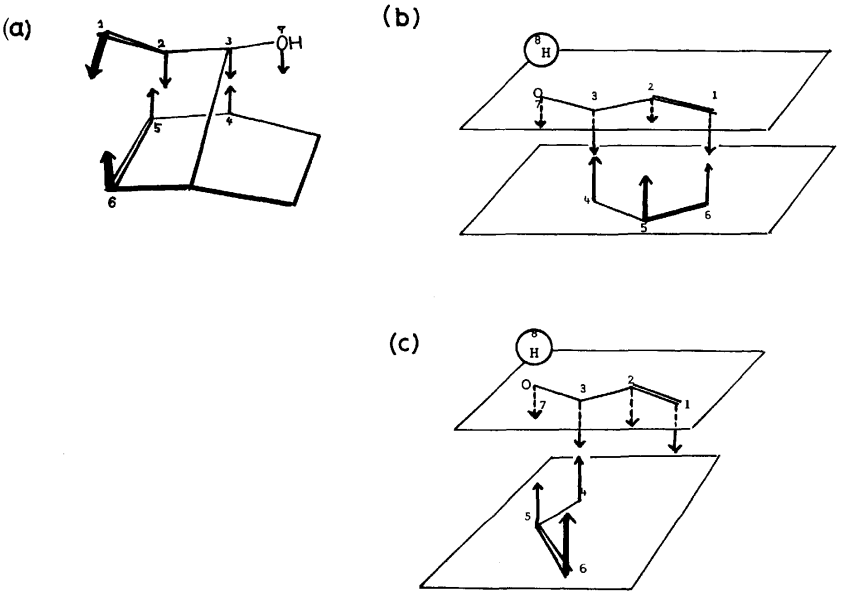

Fig. 18. The oxy-Cope rearrangement.

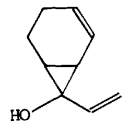
out as:

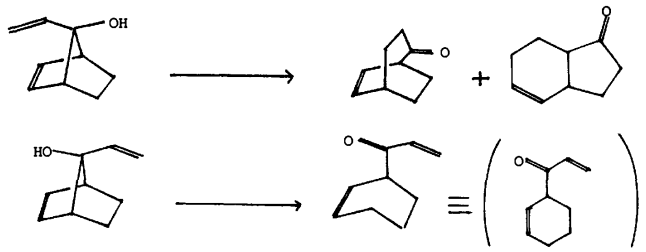
Site (r , s)	$q_{r,s}$	$V^{\pi}_{r,s}$	$V^{\sigma}_{r,s}$	ΔE	reaction
1 , 4	−0.3393	+	0	−	YES
1 , 6	0.2012	−	−	−	YES
2 , 5	−0.0748	−	−	+	
3 , 6	−0.3393	≒0	0	−	YES

Therefore, it is quite possible that the [1,3] sigmatropy occurs. In our notation, either the 1,4-transfer and the 1,6-transfer give products shown above, while the 3,6-transfer gives a queer material as



and it will be unstable.

Next, we deal with the competitive reactions, the Cope rearrangement *versus* prototropy shown as



The transition state of this reaction is assumed as shown in Fig. 18(b), and the calculated parameters are:

Site (r , s)	$q_{r,s}$	$V^{\pi}_{r,s}$	$V^{\sigma}_{r,s}$	ΔE	reaction
1 , 6	0.2801	−(+)	0(−)	−(?)	YES
1 , 8	−0.2153	0	0		
2 , 8	−0.0674	0	+		
3 , 8	0.2278	0	+	+	
4 , 8	0.1661	0	−	−	YES
5 , 8	0.0169	0	−	+(−)	
6 , 8	−0.1227	0	−		

An other possile transition state is shown in Fig. 18(c). The results derived from this are the values in braces of the above table. These data suggest that only prototropy is possible.

The related reactions are reported by Thies[25] and by Mukai *et al.*[26] in other systems.

We expect that the Cope rearrangement will occur when the sites 1 and 6 can easily approach with each other, while the [1,3] sigmatropy takes place when sites 1 and 6 hardly approach due to some steric effect.

Concluding Remarks

From the preceding treatments, we can understand some advantages of our method:

(1) Our treatment is based on a reasonable assumption that the reaction will occur through a transition state in which the perturbing interaction makes energy lowering

(2) Considering the rearrangement reaction by use of the frontier orbital theory, we have to cut some bonds of molecule and take into account the interactions between the specified orbitals(*e.g.* HOMO, SOMO, or LUMO) of fragments. In our method, we need not such unnatural treatments but deal with the system always as a whole, taking into account the effect of all electrons in the molecule. We have only to assume the transition state of molecule in order to evaluate bond orders and interaction matrix elements.

(3) We need not to take care of the conservation of the orbital symmetry which is important in the Woodward-Hoffmann rule. Instead, the mutural phase of bond order at the place where the perturbing interaction takes place plays a important role, together with the sign of the interaction matrix element.

Conclusively we can say our treatment takes a step forward beyond the Woodward-Hoffmann rule or the frontier orbital theory.

Tungstic Acid-Tributyltin Chloride on a Charcoal Catalyst in the Epoxidation of Alkenes with Hydrogen Peroxide

Yasushi Itoi, Masami Inoue,* and Saburo Enomoto
Faculty of Pharmaceutical Sciences, Toyama Medical and Pharmaceutical University, 2630 Sugitani, Toyama 930-01
(Received May 10, 1985)

Several alkenes, such as cyclopentene, cyclohexene, 1-octene, 2-octene, 1-decene, styrene, and 1-methyl-1-cyclohexene, were epoxidized with aqueous (30%) hydrogen peroxide. *n*-Bu_3SuCl was a good co-catalyst of H_2WO_4 for the selective epoxidation. The conversion was improved by modifying charcoal as the carrier with such alkylating or alkylsilylating agents as *N,N*-dimethylformamide dibutyl acetal (DMFBA) or *N,O*-bis(trimethylsilyl)acetamide. Cyclopentene oxide, cyclohexene oxide, and 2-octene oxide were obtained from the corresponding olefins in the good yields of 74, 64, and 76% respectively by using DMFBA-modified charcoal as the support. The epoxidation was first-order with respect to both cyclohexene and H_2O_2. The apparent activation energy of the epoxidation of cyclohexene was 11.2 kcal/mol.

In the last decade much interest has been directed to the epoxidation of olefins for the synthesis of valuable key intermediates in the chemical industry. Also, attention has been paid to several kinds of hormones and mutagens involving an oxirane moiety in their structure. For the selective epoxidation of simple olefins, molybdenum complexes[1] are well known to catalyze under mild reaction conditions. Various complexes of Ti[2], Cr[3], and Pt[4] have also been used as catalysts for the epoxidation of allyl alcohols, alkenes, and terminal olefins respectively. However, among VIA-group metal oxides, tungstic acid (H_2WO_4) has not yet been found to catalyze the epoxidation of alkenes with *t*-butyl hydroperoxide. The use of H_2O_2 as an oxidizing agent has given diol exclusively.[5] Recently, however, it has been claimed that the addition of Me_3SnOH to tungstic acid catalyzes the epoxidation of cyclohexene with concentrated (70—90%) H_2O_2 to give cyclohexene oxide,[6] though the yields are not sufficiently high. Under the presence of phase-transfer agents, olefins have also been epoxidized with diluted aqueous H_2O_2 in the presence of Na_2WO_4-Na_3PO_4-H_3PO_4 at pH=9.[7] However, the use of a heterogenized tungstic acid catalyst in the epoxidation of olefins has not been proposed. Previously, authors have found that molybdenum oxide fixed on charcoal epoxidized olefins selectively with 30% H_2O_2 in the presence of *n*-Bu_3SnCl.[8] The yields were improved by using chemically modified charcoals as support.[9] When this catalyst system was applied to H_2WO_4, several alkenes, especially inner olefins, were epoxidized in good yields. In this report, the properties of tungsten catalysts will be studied in comparison with those of molybdenum catalysts.

Experimental

Materials. The cyclohexene, 30% aqueous hydrogen peroxide (Hayashi Pure Chemicals), *N,O*-bis(trimethylsilyl)acetamide, *N,N*-dimethylformamide dibutyl acetal, tungstic acid (Wako Pure Chemicals), organotin compounds (Kyodo Yakuhin), and charcoal (palm DC-5200) (Dia Catalysts & Chemicals) were purchased. The cyclohexene and other olefins were distilled before use.

Preparation of Catalyst. The H_2WO_4-charcoal catalyst was prepared by fixing H_2WO_4 on charcoal (65 mesh) by stirring it overnight with a H_2WO_4 solution dissolved with a small amount of 30% H_2O_2 in 2-propanol. The catalyst was then filtered off, washed with 2-propanol, and dried.

Pretreatment of Catalyst. Acid or Base Treatment of Charcoal. Charcoal powder (1 g) was dispersed in 25 mL of distilled water. The pH value of the charcoal-dispersed solution was adjusted at 2 to 12 by the addition of 0.1 M† HCl or 0.1 M NaOH. The solution, once heated, was left to stand at room temperature and the pH of the solution was readjusted. *Butylation or Trimethylsilylation of Charcoal.* Charcoal powder (1 g) was treated with *N,O*-bis(trimethylsilyl)acetamide or *N,N*-dimethylformamide dibutyl acetal in 20 mL of hexane by stirring at 50 °C. After 2 h, the charcoal was filtered off, washed with hexane, and dried.

Epoxidation Procedure. The tungstic acid–charcoal catalyst (0.4 g) was dispersed in 2-propanol (2 mL), and *n*-Bu_3SnCl (50 mg) was added. After the catalyst had stood at room temperature for 30 min, 2-propanol (4 mL), cyclohexene (1.5 g), and 30% hydrogen peroxide (1 to 2 mL) were added. The reaction was started at 50 °C±1° in an oil bath under magnetic stirring.

Analyses of Products. The reaction products were analyzed by means of gas-liquid chromatography (Shimadzu GC-8A), using OV-17 (3 mm i.d.×2 m in length) as the column-packing material and helium as the carrier gas (12.5 mL/min). The column temperature was programmed from 30° to 150 °C at a rate of 3°/min. The retention times were 1.4 min for cyclohexene, 6.0 min for cyclohexene oxide, 17.1 min for *trans*-1,2-cyclohexanediol monoisopropyl ether, and 17.6 min for *trans*-1,2-cyclohexanediol.

Results and Discussion

Epoxidation of Alkenes in the Presence of Tungsten Catalysts.

The oxidation of cyclohexene with aqueous (30%)

† 1 M=1 mol dm^{-3}.

Table 1. Oxidation of cyclohexene with 30% H_2O_2 in the presence of several tungstic catalysts

Catalyst	Conversion %	Yield/%		
		Epoxide[a]	Ether[b]	Diol[c]
H_2WO_4 (10 mg)	87.5	1.6	10.7	75.2
H_2WO_4-charcoal	34.8	5.5	6.6	22.7
H_2WO_4-*n*-Bu_3SnCl-charcoal	41.1	41.1	0	0
n-Bu_3SnCl-charcoal	0	0	0	0
Charcoal	0	0	0	0

Cyclohexene (1.6 M), H_2O_2 (1.6 M), 1.8% H_2WO_4-charcoal (0.4 g), *n*-Bu_3SnCl (1.58×10^{-2} M), and 2-propanol as the solvent were used. The reaction was carried out at 50 °C for 15 h. a) Cyclohexene oxide. b) *trans*-1,2-Cyclohexanediol monoisoporpyl ether. c) *trans*-1,2-Cyclohexanediol.

Table 2. Epoxidation of various olefins with 30% H_2O_2 on the H_2WO_4-*n*-Bu_3SnCl-charcoal catalyst

Olefin	Molar ratio of olefin to H_2O_2	Epoxide yield/%	By-product/%
Cyclopentene	1	74.4[a]	0
	2	81.0[b]	0
Cyclohexene	1	63.7[a]	0
	2	60.5[b]	0
1-Methyl-1-cyclohexene	2	53.7[b]	0
1-Octene	2	17.5[b]	0
2-Octene	1	76.3[a]	0
	2	56.0[b]	0
Styrene	2	30.3[b]	11.1[c]
1-Decene	2	16.5[b]	0

Olefin (1.6 M), H_2O_2 (0.8 or 1.6 M), 1.8%-H_2WO_4-charcoal (0.4 g), *n*-Bu_3SnCl (1.58×10^{-2} M), and 2-propanol as the solvent were used. Reaction was carried out at 50 °C for 15 h. a) Charcoal was pretreated with DMFBA. b) Charcoal was pretreated with BSA. c) Benzaldehyde.

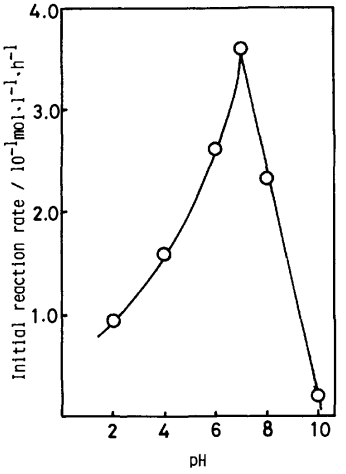

Fig. 1. Effect of pH of charcoal as support in the epoxidation of cyclohexene with 30% H_2O_2 on H_2WO_4-Bu_3SnCl-charcoal catalyst.
Cyclohexene 4.43 M, H_2O_2 8.02×10^{-1} M, 1.8%-H_2WO_4-charcoal 0.4 g, Bu_3SnCl 1.59×10^{-2} M, and solvent 2-propanol were used. Reaction was carried out at 50 °C.

H_2O_2 in the presence of H_2WO_4 catalysts was carried out in 2-propanol at 50 °C. The results are shown in Table 1. H_2WO_4 gave 1,2-cyclohexanediol, a hydrolysate of cyclohexene oxide, as the major product. Similar results were obtained in H_2WO_4-charcoal catalysts. However, the addition of *n*-Bu_3SnCl, as the best choice of the co-catalysts, prevented the hydrolysis and thus gave cyclohexene oxide selectively in a low yield (41%). The yield was not improved by changing the reaction conditions such as the solvent, the temperature, or the reaction time, since charcoal itself decomposed H_2O_2 considerably. By shaking the 2-propanol solution of H_2O_2 in the presence of a catalytic amount of charcoal (0.4g/5 mL) at 50 °C for 15 h, about three-tenths of the H_2O_2 was decomposed. We have observed that a chemically-modified charcoal supressed the decomposition of H_2O_2 to improve the yields of epoxides.[9] Therefore, charcoal was treated with DMFBA or BSA and several alkenes were epoxidized in the presence of H_2WO_4-*n*-Bu_3SnCl-charcoal catalysts. As is shown in Table 2, cyclic olefins of C_5–C_6 and inner olefins of 2-octene gave epoxides in 70—80% yields (based on H_2O_2), with a 1:2 ratio of olefins to H_2O_2. However, rather weak activity was observed in such terminal olefins as 1-octene and 1-decene. The order of yields closely resembled that obtained with the molybdenum oxide-*n*-Bu_3SnCl-charcoal (DMFBA) catalyst.[9]

Effect of the Pretreatment of Charcoal. In the oxidation of alkenes with aqueous H_2O_2, the pretreatment of charcoal drastically affected the conversion and the selectivity. Figure 1 shows the change in the conversions and selectivities when the epoxidation of cyclohexene was carried out in the presence of H_2WO_4 catalysts, using as supports charcoals which had been treated with solutions of various pH values. The oxidation rate for cyclohexene decreased according to the increase in the treated pH, though the selectivity was high. On the other hand, both the conversion and the selectivity

became poor on the acidic side. The best result was obtained by treating charcoal with a solution of pH 7. However, when equivalent amount of cyclohexene and H_2O_2 were used, the yield was as low as 40% by the decomposition of H_2O_2 on charcoal.

The suppression of the decomposition of H_2O_2 was examined by treating charcoal with various agents. The presence of such substituents as amino, carboxyl, and hydroxyl groups on the surface of charcoal is well known. We supposed that the decomposition of H_2O_2 was accelerated by those hydrophilic substituents on charcoal which concentrate H_2O_2 on the surface of charcoal. Therefore, the functional groups were blocked by alkylating or alkylsilylating agents, such as DMFBA, BSA, or diazomethane. Among those compounds, DMFBA is a good surface-modifier. The decomposition of H_2O_2 was suppressed by treating the charcoal with DMFBA; the decomposition rate of 50% in raw charcoal was decreased to 30% under heating for 15 h at 50 °C in a 2-propanol solution.

Effect of the Concentrations of Cyclohexene, H_2O_2 and H_2O on the Epoxidation. In the epoxidation of cyclohexene on H_2WO_4-*n*-Bu_3SnCl-charcoal catalysts, the concentrations of the olefins affected the rates. The initial rates of the oxidation of cyclohexene were first-order with respect to cyclohexene. Usually we used 4.43 M of cyclohexene in 2-propanol to keep a solution homogeneous by mixing in aqueous H_2O_2, cyclohexene, and 2-propanol. The reaction order with respect to the concentration of H_2O_2 was also unity. In the molybdenum oxide-*n*-Bu_3SnCl-charcoal catalyst, the initial rates of the oxidation of cyclohexene were zero-order for both cyclohexene and H_2O_2.[8] These results suggest that the affinity of cyclohexene or H_2O_2 to H_2WO_4 is weaker than that of the Mo catalyst. Though the presence of H_2O decreased the reaction rate in proportion to the amount added to the system, the selectivity to epoxide was excellent. Therefore, it was considered that a moderately hydrophobic surface was formed by the treatment of charcoal.

On the Arrhenius plot of the epoxidation of cyclohexene with H_2O_2 in the presence of the tungstic acid catalyst, an apparent activation energy of 11.2 kcal/mol (1 cal=4.184 J) was obtained. This value is smaller than those of molybdenum oxide-*n*-Bu_3SnCl-charcoal (13.5 kcal/mol),[8] or bis(dimethyldithiocarbamato)molybdenum(VI) oxide (19.0 kcal/mol).[10] Among the oxides of the VIA elements of the periodic table, Mo and W showed similar properties of giving epoxides selectively in the presence of alkyltin compounds. On the other hand, no epoxide was obtained with chromium(VI) oxide, not even in the presence of *n*-Bu_3SnCl, except for the use of $O_2Cr(NO_3)_2$ under mild reaction conditions (−78 °C).[3]

Effect of Organotin Compounds in the Selective Epoxidation. The effect of the co-catalyst of organotin compounds for H_2WO_4 was studied in the epoxidation of cyclohexene with aqueous (30%) H_2O_2. Different conversions and selectivities were obtained according to the kinds of substituents and alkyl groups of organotin chlorides, oxides, or acetates. Among these co-catalysts, *n*-Bu_3SnCl gave the highest yield (Table 3); the butyl group was more effective than the methyl or phenyl group. Furthermore, di or tributyltin compounds gave higher yields than monobutyltin compounds. These results

Table 3. Effects of various organotin compounds used as co-catalysts on the epoxidation of cyclohexene with 30% H_2O_2 on H_2WO_4-charcoal

Organotin compound	Conversion %	Yield/%		
		Epoxide[a]	Ether[b]	Diol[c]
Me_3SnCl	30.3	30.3	0	0
n-Bu_3SnCl	68.0	68.0	0	0
Ph_3SnCl	55.8	51.5	4.3	0
Me_3SnOH	30.4	30.4	0	0
$(n\text{-BuSnO})_2O$	42.8	35.6	7.2	0
n-Bu_2SnO	59.2	59.2	0	0
$(n\text{-}Bu_3Sn)_2O$	59.2	59.2	0	0
n-$Bu_2Sn(OCOCH_3)_2$	61.3	58.6	0	2.7
n-$BuSn(OCOCH_3)_3$	53.2	51.6	0	1.6
$Ph_3SnOCOCH_3$	58.0	52.5	5.5	0
$(Cyclohexyl)_3SnOH$	48.6	48.6	0	0
n-Bu_4Sn	64.6	38.5	26.0	0.1
Ph_4Sn	35.2	24.9	10.3	0

Cyclohexene (4.43 M), H_2O_2 (8.02×10^{-1} M), 1.8% H_2WO_4-charcoal (0.4 g), organotin compound (50 mg), and 2-propanol as the solvent were used. The reaction was carried out at 50 °C for 15 h. a) Cyclohexene oxide. b) *trans*-1,2-Cyclohexanediol monoisopropyl ether. c) *trans*-1,2-Cyclohexanediol.

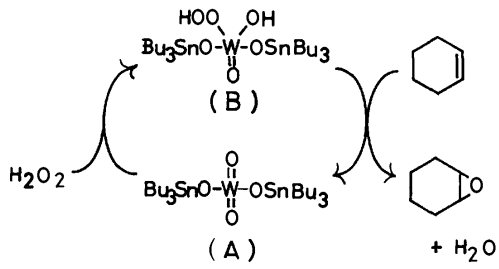

Chart 1.

suggest that the hydrophobic effect increases the yield of cyclohexene oxide. However, such tetraalkyltin as *n*-Bu_4Sn or Ph_4Sn gave lower selectivities for cyclohexene oxide. Therefore, the formation of tightly-bonded complexes between H_2WO_4 and such trialkyltin compounds of chloro, hydroxyl, oxy, or acetoxyl groups are considered to be an element for the selective epoxidation.

$$(HO)_2WO_2 + 2n\text{-}Bu_3SnCl \longrightarrow (n\text{-}Bu_3SnO)_2WO_2 + 2HCl$$

When cyclohexene and H_2O_2 were reacted in the presence of H_2WO_4 and *n*-Bu_3SnCl in 2-propanol at 50 °C for 15 h, white precipitates involving tungsten were obtained. These precipitates separated from the system and then catalyzed the selective epoxidation again. From these results, we considered the precipitates to be pre-active species with the (A) structure in Chart 1. The elemental analyses (C and H) of the precipitates were reasonable for (*n*-$Bu_3SnO)_2WO_2$. The treatment of Complex (A) with H_2O_2 gave an oxidized products. The IR spectra of this peroxy complex showed a remarkable decrease in the broad band at 800—900 cm^{-1}, probably because of the W=O bond observable in the IR spectra of H_2WO_4. Also, the absorption bands of Mo=O have been observed at 800—1000 cm^{-1}[11] in $(NH_4)_2[MoO_3F_2]$.

On the other hand, the band of the hydroxyl groups at 3400 cm^{-1} increased remarkably. Therefore, in our tungsten catalyst, a μ-peroxo-type[12] complex was suggested as an active species for the oxidation, as is shown in Chart 1 (B).

Then, the effect of the amount of *n*-Bu_3SnCl relative to that of H_2WO_4 in the epoxidation of cyclohexene was examined for the initial rate of the epoxidation. As is shown in Fig. 2, both the selectivity and the yield increased linearly with an increase in the amount of *n*-Bu_3SnCl and reached the saturation point at a molar ratio of 1:4 of H_2WO_4 to *n*-Bu_3SnCl. This fact supports a complex formation

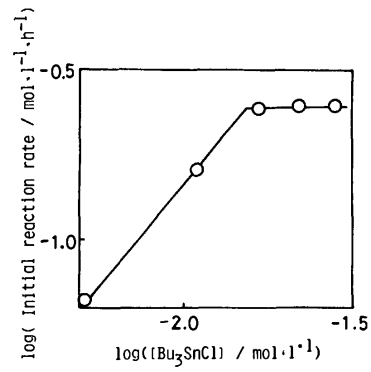

Fig. 2. Effect of the concentration of Bu_3SnCl as co-catalyst in the epoxidation of cyclohexene with 30% H_2O_2 on H_2WO_4–charcoal catalyst.
Cyclohexene 4.43 M, H_2O_2 8.02×10^{-1} M, 1.8%-H_2WO_4–charcoal 0.4 g, and solvent 2-propanol were used. Reaction was carried out at 50 °C.

between H_2WO_4 and *n*-Bu_3SnCl until the molar ratio of 1:4. Therefore, the organotin compounds bound on the acid groups of H_2WO_4 effectively prevent the hydrolysis of epoxides.

Effects of Alkyl Chains of Thiacarbocyanine as the Sensitizer for the Photoreduction of Methylviologen in Micellar Phase

Masayuki NAKAGAKI, Hiroaki KOMATSU,* and Tetsurou HANDA†
Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida-shimoadachi, Sakyo-ku, Kyoto 606
†*Gifu Pharmaceutical University, Mitahorahigashi, Gifu 502*
(Received May 23, 1985)

Photoinduced reduction of methylviologen (MV^{2+}) by ethylenediaminetetraacetate was investigated with 3,3′-dialkylthiacarbocyanines as a sensitizer in the micellar solution of a nonionic surfactant, heptaethylene glycol monododecyl ether. The alkyl chains of the dyes were found to have considerable effects on the reaction rate. The fluorescence yield of a dye having two long alkyl chains, 3,3′-dioctadecylthiacarbocyanine (C_{18-18}) in the micellar phase was larger than that of the dye having only one long alkyl chain, 3-methyl-3′-octadecylthiacarbocyanine (C_{1-18}). This result was discussed in terms of the large effective volume associated with the intramolecular twisting motion in the excited state of C_{18-18}. Also, from the fluorescence quenching experiments, it was found that MV^{2+} was of easier access to C_{18-18} than C_{1-18} in the micellar phase. Thus, the relatively higher stability of the excited state of C_{18-18} and the easier access of MV^{2+} to C_{18-18} were considered to be responsible for the faster reaction rate achieved by C_{18-18} than by C_{1-18} in the micellar solution.

Molecular organization plays important roles in complex biochemical processes. Components of metabolic pathways are compartmentalized in membranes which provide suitable microenvironments and which control the flow of reactants, transients and products. Micelles, monolayers and vesicles (liposomes) have been exploited as membrane mimetic agents.[1-6] Micelles have been extensively used to mimic membrane mediated processes in relatively simple systems.[6-8] To explain the enhancement of enzyme reactions in micelles, the involvements of hydrophobic interaction of the enzyme with the micelles, steric effects of the micelles and specific physical states of the substrates in the micelles have been suggested.[9-11]

For photoinduced reactions, micellar effects on the charge separation in exciplexes and on the prevention of the recombination of the photoproducts have been demonstrated.[12-14] On the other hand, the stability of the excited states of sensitizers and also the accessibility of substances to the sensitizers could be important factors in determining the efficiency of photoinduced reaction. The former would be closely correlated with the microenvironment around the sensitizer, that is, with the local effective polarity and viscosity in the vicinity of the sensitizers.[15] If an amphiphatic dye molecule having distinct hydrophobic and hydrophilic portions is used as a sensitizer, it can be expected that the sensitizer is provided with a different microenvironment in the micelle by changing the hydrophobic-hydrophilic balance, that is, by changing the numbers and/or length of the alkyl chains of the sensitizer. In this study, we investigate the photoinduced reduction of methylviologen by ethylenediaminetetraacetate, sensitized in aqueous solution by 3,3′-dialkylthiacarbocyanine incorporated in the nonionic micelle, heptaethylene glycol monododecyl ether. The effects of the alkyl chains of the sensitizers on the reaction are examined. The results obtained are discussed in relation to the stabilization of the excited state of the sensitizers in the micellar microenvironment and the accessibility of substrates from the aqueous phase to sensitizers in the micellar phase.

Experimental

3-Methyl-3′-octadecyl-2,2′-thiacarbocyanine (C_{1-18}) and 3,3′-dioctadecyl-2,2′-thiacarbocyanine (C_{18-18})(their structures are shown in Fig. 1) were purchased from the Japan Research Institute for Photosensitizing Dye Co., Ltd and used without further purification. Methylviologen (1,1′-dimethyl-4,4′-bipyridinium, MV^{2+}) dichloride (Sigma) and disodium ethylenediaminetetraacetate (EDTA) (Dojindo Laboratories) were used as received. The nonionic surfactant, heptaethylene glycol monododecyl ether (HED) was obtained from Nikko Chemicals Co., Ltd. The surface tension *versus* concentration curve for the aqueous HED solution gave no minimum around the critical micelle concentration (cmc), and the value of cmc agreed with the reported value,[16] 8×10^{-5} M.†† Sodium dodecyl sulfate (SDS) supplied from Nakarai Chemicals Co., Ltd was recrystallized twice from ethanol. Tris(hydroxymethyl)-aminomethane (Tris) of analytical grade was used as recieved. Water was doubly distilled from a quartz still and other solvents were distilled once.

For sample preparations, chloroform solutions of the cyanine dyes and HED were mixed and the solvent evaporated. The residue was dried overnight in a vacuum desiccator and then solubilized with 2×10^{-3} M MV^{2+} solution which was buffered with 2×10^{-3} M Tris and 2×10^{-3} M $EDTA^{3-}$ at pH 7.0, where EDTA (pK_a=2.0, 2.8, 6.1, 10.2)[17] is present as the trivalent anion. C_{1-18} and C_{18-18} are insoluble in water, and therefore, all of the dye is incorporated in the micellar phase. The sample solution was placed in a quartz cell (1×1×4 cm) fitted with a stopcock and was freed of oxygen by bubbling nitrogen gas and then degassed by aspiration at 2700 Pa (20 mmHg) prior to irradiation. The cell was immersed in a water bath (25.0 °C) with a quartz window.

Irradiations were carried out using a Kondo Sylvania

†† 1 M=1 mol dm^{-3}.

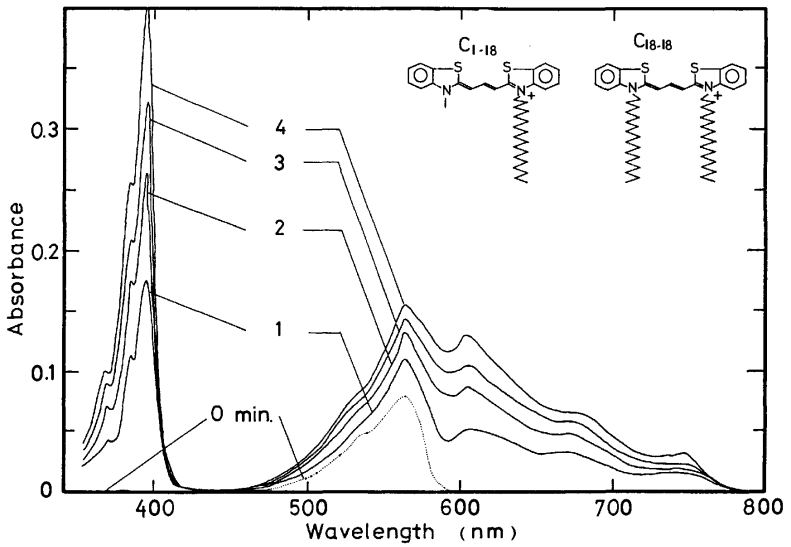

Fig. 1. Structures of sensitizers (C_{1-18} and C_{18-18}) and spectral changes of the solution due to the photoreduction of MV^{2+} using C_{18-18} as a sensitizer at 25.0 °C. 5×10^{-7} M of C_{18-18} is solubilized in 2×10^{-2} M HED micellar solution (2×10^{-3} M $EDTA^{3-}$, 2×10^{-3} M MV^{2+}, and 2×10^{-3} M Tris at pH 7.0). The solution is irradiated by a visible light ($\lambda>460$ nm) for 0, 1, 2, 3, and 4 min. The absorption band at 395 and 603 nm are contributed from MV^{+} formed by the reaction, and the band at 563 nm is attributed to C_{18-18} in the HED micellar phase.

1 kW tungsten halogen lamp. A Toshiba Y-46 cut-off filter was used to eliminate light of $\lambda<460$ nm. The distance from the irradiation source to the center of the cell containing sample solution was 10 cm. The sensitizer dyes had an absorption band around 560 nm in the micellar solution. On the other hand, reduced methylviologen (MV^{+}) formed by irradiation had an absorption maximum at about 603 nm. The latter band, however, resulted in faint reduction of the irradiation intensity (in this study, the reduction after 30 min's irradiation was at most 8% of the initial intensity).

The production of MV^{+} after intervals of irradiation was monitored by the absorption spectra on Shimadzu UV-180 spectrophotometer. The concentration of MV^{+} was calculated from the absorbance of the solution at 395 nm by taking $\varepsilon_{395nm}=3.8\times10^{4}$ M^{-1} cm.[18]

The measurement of the fluorescence yield was carried out for the dyes solubilized by HED in the buffer solution (2×10^{-3} M $EDTA^{3-}$ and 2×10^{-3} M Tris at pH 7.0) without MV^{2+}. The fluorescence spectra (excited at 530 nm) were observed with a Jasco FB-550 spectrofluorometer. The temperature was regulated at 25.0 °C by circulating water through the cuvette holders.

In order to determine the wavelength of the absorption maxima of the dyes in various solvents and micellar solutions, the first derivative absorption spectra were measured with a Hitachi-220 spectrophotometer.

The measurement of the viscosity of the various solvents has been described elsewhere.[19]

Results

Photoreduction of MV^{2+}. The deoxygenated solution containing a sensitizer dye in HED micellar phase and MV^{2+} in aqueous phase was irradiated with visible light. As a result, a blue color was developed in the presence of $EDTA^{3-}$. In Fig. 1, the changes of the absorption spectra are shown at varying irradiation times using C_{18-18} as a sensitizer. The development of absorption maxima at about 395 and 603 nm is charactaristic of the formation of MV^{+}.[20] Then, introduction of air into the cuvette resulted in the prompt reoxidation of MV^{+} to MV^{2+}

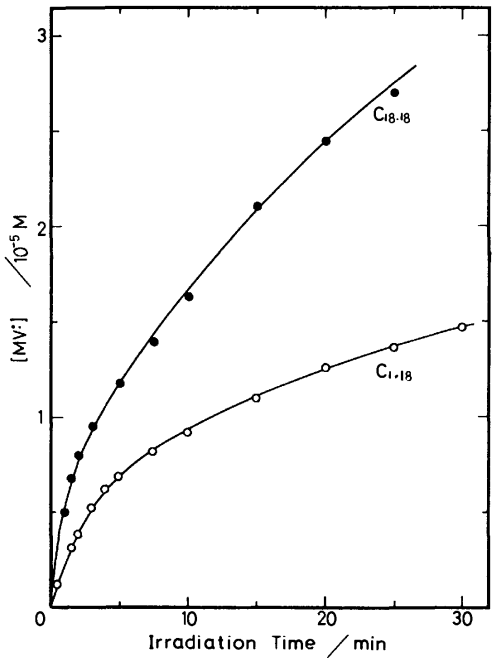

Fig. 2. Built-up of MV^{+} as a function of irradiation time.

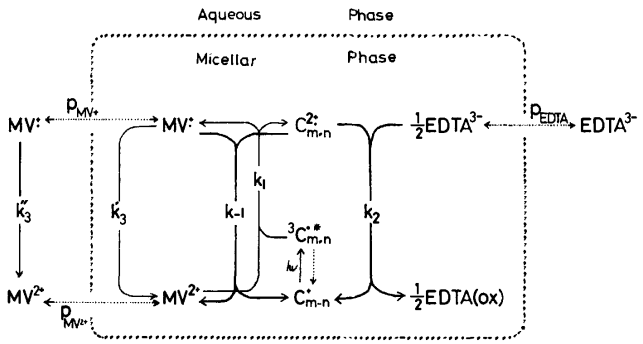

Fig. 3. The proposed mechanism of the photoreduction of MV^{2+} by $EDTA^{3-}$. C^{+}_{m-n} and $^3C^{+*}_{m+n}$ ($m=1$ or 18, $n=18$): sensitizer in the ground and the triplet exited state in the micellar phase, $C^{2+\cdot}_{m-n}$: sensitizer cation radical, EDTA(ox): the oxidized form of $EDTA^{3-}$, P_{MV2+}, P_{MV+}, and P_{EDTA}: the partition coefficient of MV^{2+}, MV^{+}, and $EDTA^{3-}$ from the aqueous to the micellar phase, and k_1, k_{-1}, k_2, and k_3: the rate constant of each reaction, respectively.

as manifested by decolorization.[20] The reduction of the concentration of the sensitizer dye after 30 min's irradiation was less than 5% of that before irradiation. Therefore, the contribution of the decrease of sensitizer to the formation rate of MV^{+} was not taken into account. In the dark or in the absence of $EDTA^{3-}$, no MV^{+} was produced.

In Fig. 2, the concentrations of MV^{+} formed are plotted against the irradiation time. The sensitizer dye having two long alkyl chains, C_{18-18}, exhibited faster formation of MV^{+} than C_{1-18} having only one long alkyl chain. In both cases, the formation rate of MV^{+} decreased with increase of the irradiation time. After removal of the light, the concentration of MV^{+} gradually decreased with increasing time owing to the reoxidation of MV^{+} to MV^{2+} by the small amount of dissolved oxygen in the solution. This reoxidation in the dark followed pseudo first-order kinetics, and the rate constant, k_3, had the same value in both sensitizers, being 5.4×10^{-5} s^{-1}. Such a reoxidation of MV^{+} to MV^{2+} may be considered to proceed not only after removal of the light but also during irradiation with light.

The proposed mechanism of the reaction is depicted in Fig. 3. Assuming that the concentration of the sensitizer cation radical ($C^{2+\cdot}_{m-n}$, $m=1$ or 18, $n=18$) is in the stationary state, and that mole of MV^{2+}, MV^{+}, and $EDTA^{3-}$ in the micellar phase is much smaller than the total mole in the micellar solution, the observed formation rate of MV^{+} can be written as

$$\frac{d[MV^+]_t}{dt} = \frac{k_1 k_2 [^3C^{+*}_{m-n}]_m [MV^{2+}]_m [EDTA^{3-}]_m^{1/2}}{k_{-1}(P_{MV+}[MV^+]_t) + k_2[EDTA^{3-}]_m^{1/2}} - k_3[MV^+]_t, \quad (1)$$

where $k_3=k_3'P_{MV+}+k_3''$. Here, $^3C^{+*}_{m-n}$ represents the sensitizer in the triplet excited state and P_{MV+} stands for the partition coefficient of MV^{+} from the aqueous to the micellar phases, $P_{MV+}=[MV^+]_m/[MV^+]_a$. The subscripts a, m, and t denote the concentration at the aqueous and the micellar phases and the total concentration in the micellar solution, respectively. For the case that $[MV^+]_t$ is small and $[MV^{2+}]_m$ is nearly equal to its initial value, $[MV^{2+}]_m^0$, and that $k_{-1}(P_{MV+}[MV^+]_t) \ll k_2[EDTA^{3-}]_m^{1/2}$, Eq. 1 reduces to

$$\frac{d[MV^+]_t}{dt} = k_1[^3C^{+*}_{m-n}]_m[MV^{2+}]_m^0, \quad (2)$$

which is the initial rate of formation of MV^{+} (V_{init}),

$$V_{Init} = k_1[^3C^{+*}_{m-n}]_m[MV^{2+}]_m^0. \quad (3)$$

Since $[MV^{2+}]_t \gg [MV^+]_t$ and $[MV^{2+}]_m$ in Eq. 1 is, in this experiment, nearly equal to $[MV^{2+}]_m^0$ which is constant, Eq. 1 becomes

$$\frac{d[MV^+]_t}{dt} = \frac{V_{Init}k_2[EDTA^{3-}]_m^{1/2}}{k_{-1}(P_{MV+}[MV^+]_t) + k_2[EDTA^{3-}]_m^{1/2}} - k_3[MV^+]_t, \quad (4)$$

which may be written as

$$\frac{1}{\frac{d[MV^+]_t}{dt} + k_3[MV^+]_t} = \frac{k_{-1}P_{MV+}}{V_{Init}k_2[EDTA^{3-}]_m^{1/2}}[MV^+]_t + \frac{1}{V_{Init}}. \quad (5)$$

Plots of $1/(d[MV^+]_t/dt+k_3[MV^+]_t)$ *versus* $[MV^+]_t$ according to Eq. 5 are shown in Fig. 4. Here, the observed values evaluated from Eqs. 6 and 7 were substituted for the values of $d[MV^+]_t/dt$ and $[MV^+]_t$, respectively.

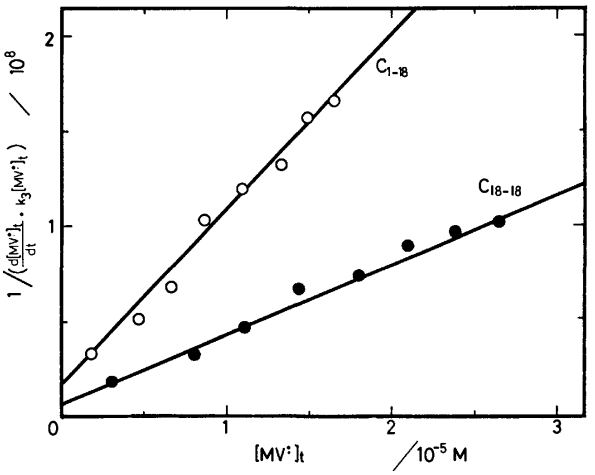

Fig. 4. Variation of $1/(d[MV^+]_t/dt+k_3[MV^+]_t)$ as a function of $[MV^+]_t$ according to Eq. 5.

$$\frac{d[MV^+]_t}{dt} = \frac{[MV^+]_{t(n+1)} - [MV^+]_{t(n)}}{t(n+1) - t(n)} \quad (6)$$

and

$$[MV^+]_t = \frac{[MV^+]_{t(n)} + [MV^+]_{t(n+1)}}{2} \quad (7)$$

where $[MV^+]_{t(n)}$ and $[MV^+]_{t(n+1)}$ are $[MV^+]_t$ at measuring time $t=t(n)$ and $t(n+1)$, respectively. These plots give straight lines and its intercept leads to values for V_{init} of 6.1×10^{-8} and 1.3×10^{-7} M·s^{-1} and $k_{-1}P_{MV+}/k_2[EDTA^{3-}]_m^{1/2}$ of 5.2×10^5 and 5.3×10^5 M^{-1} for C_{1-18} and C_{18-18}, respectively.

Absorption Maxima of Sensitizer Dyes in Various Solvents. In our previous studies,[19] it was found that C_{18-18} showed a marked dependence of its absorption maximum on the solvent polarity (solvatchroism). The solvatchroism for C_{1-18} was measured. C_{1-18} also showed considerably large shifts in its absorption maximum in various aliphatic alcohols as solvents. Figure 5 shows the relationship between the wave number at the absorption maximum ($\tilde{\nu}_{max}$) and the dielectric constant (D) of alcohols. In both dyes, the values of $\tilde{\nu}_{max}$ of sensitizer dyes increased linearly with increasing of D. The values of $\tilde{\nu}_{max}$ of sensitizer dyes in the HED micellar phase are shown by the arrows in Fig. 5. The D in the vicinity of dye molecules in the miceller phase, which is defined as the effective dielectric constant (D_{eff}) in this study, was estimated using the values of $\tilde{\nu}_{max}$ and D for alcohols. These procedures lead to values for D_{eff} of 18.5 and 20.0 for C_{1-18} and C_{18-18}, respectively. These results indicate that effective micropolarity in the vicinity of the chromophore of the dye in the micellar phase corresponds to that of 1-propanol or 1-butanol.

Fluorescence Quantum Yield of the Sensitizer Dyes. The fluorescence yields of the sensitizer dyes in the micellar phases and aliphatic alcohols were evaluated as the fluorescence intensities integrated over the spectra and divided by the absorbance at the excited wavelength (530 nm). Their results are presented in Fig. 6 as the value (ϕ_f^R) relative to that of 3,3'-diethyl-2,2'-thiacarbocyanine (C_{2-2}) in the aqueous phase (2×10^{-3} M EDTA-Tris buffered solution, pH 7.0) at 25.0 °C. Both C_{1-18} and C_{18-18} showed larger yields in the solvent of lower polarity, *e.g.* C_{1-18} had the yield of about 2.5 times larger in 1-octanol than in methanol. Furthermore, C_{18-18}, which has two long alkyl chains, has greater fluorescence yields than C_{1-18} in all solvents studied here. The fluorescence yields in the micellar phases are larger than that in the solvents where dyes are provided with the same dielectric constant in the micellar phases.

Fluorescence Quenching of Sensitizer Dyes in Micellar Phase by MV^{2+} in Aqueous Phase. Fluorescence quenchings of sensitizers solubilized in HED and HED-SDS mixed micellar phases by MV^{2+} as a quencher were measured. In the HED micellar solution, the quenching was slight, while in the mixed micellar solution, intense quenching was observed. If the Langmuir adsorption isotherm is applied to adsorption on the micellar surface of the quencher, MV^{2+}, the Stern-Volmer equation[21] can be written as

$$\frac{\phi_f^R}{\phi_f^{R(MV)}} = k_q\tau\frac{[MV^{2+}]_\infty P[MV^{2+}]}{1+P[MV^{2+}]}. \quad (8)$$

Here, $\phi_f^R/\phi_f^{R(MV)}$ is the ratio of relative fluorescence quantum yields with and without the quencher, k_q is the rate constant of quenching, τ is the lifetime of the excited state of the sensitizer, $[MV^{2+}]_\infty$ is the concentration of saturated adsorption of MV^{2+} on the micellar surface, and P is a constant giving the strength of adsorption of MV^{2+}. Equation 8 is rewritten as

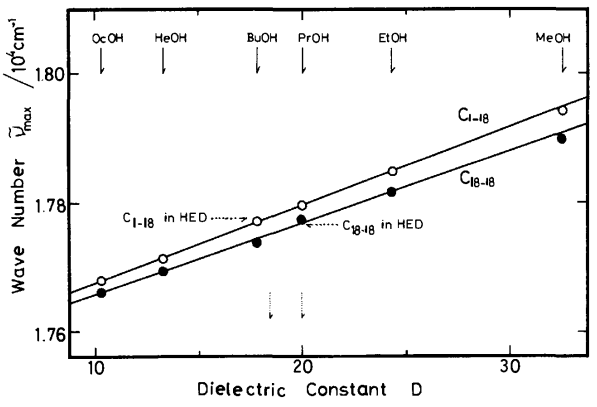

Fig. 5. Relationship of the wave number of absorption maxima ($\tilde{\nu}_{max}$) for C_{1-18} and C_{18-18} with dielectric constant D of solvent. MeOH: methanol, EtOH: ethanol, PrOH: 1-propanol, BuOH: 1-butanol, HeOH: 1-hexanol and OcOH: 1-octanol.

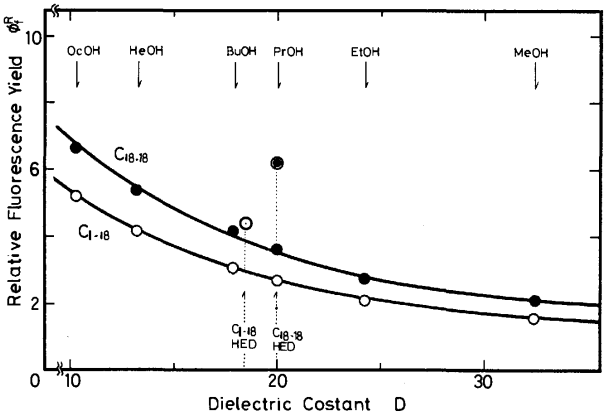

Fig. 6. Relationship of the relative fluorescence yield (ϕ_f^R) for C_{1-18} and C_{18-18} with dielectric constant D of solvent. ϕ_f^R is relative to the value for 3,3'-diethyl-2,2'-thiacarbocyanine (C_{2-2}) in the aqueous phase at 25.0 °C. (○) and (●): C_{1-18} and C_{18-18} in solvents, (⊙) and (◉): C_{1-18} and C_{18-18} in HED micellar phase.

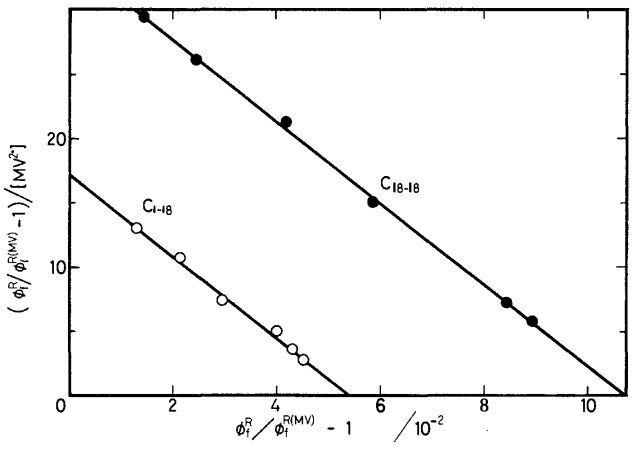

Fig. 7. Plots for fluorescence quenching of C_{1-18} and C_{18-18} in HED-SDS mixed micellar phase by MV^{2+} as a quencher, according to Eq. 9. The mole fraction of SDS in the mixed micelle is 0.1 (the total concentration of surfactants is 2×10^{-2} M). $\phi_f^R/\phi_f^{R(MV)}$ is the ratio of relative fluorescence yields without and with MV^{2+}

$$\left(\frac{\phi_f^R}{\phi_f^{R(MV)}}-1\right)\frac{1}{[MV^{2+}]} = P\left\{k_q\tau[MV^{2+}]_\infty-\left(\frac{\phi_f^R}{\phi_f^{R(MV)}}-1\right)\right\}. \quad (9)$$

In Fig. 7, the experimental values of $(\phi_f^R/\phi_f^{R(MV)}-1)/[MV^{2+}]$ for various amounts of MV^{2+} are plotted against the values of $(\phi_f^R/\phi_f^{R(MV)}-1)$ for the mole fraction of SDS in the mixed micelle of 0.1 (the total concentration of surfactants is 2×10^{-2} M). These plots yield straight lines, giving the same slope, P, in both dyes, with a value of P of 3.2×10^2. The intercept on the $(\phi_f^R/\phi_f^{R(MV)}-1)$ axis gives values for $k_q\tau[MV^{2+}]_\infty$ of 5.4×10^{-2} and 1.1×10^{-1} for C_{1-18} and C_{18-18}, respectively. These results indicate that C_{18-18} is more easily quenched by MV^{2+} than C_{1-18} in the micellar solution.

Discussion

Photoinduced reduction of MV^{2+} by EDTA was first observed with tris-(2,2′-bipyridine)ruthenium as a sensitizer by M. Calvin *et al.*[22] In our study, 3,3′-dialkylthiacarbocyanines in a nonionic micelle were adopted as a sensitizer. With increase of irradiation time, the concentration of MV^+ increased but the formation rate of MV^+ decreased. Equation 1, which represents the formation rate of MV^+, indicates that the decrease in the rate with irradiation time arises from the increase of $[MV^+]_t$. After removal of the light, the rate of disappearance of MV^+ due to reoxidation to MV^{2+} is equal to the second term, $k_3[MV^+]_t^2$ on the right-hand side of Eq. 1.

The initial rate of formation of MV^+, V_{init}, presented by Eq. 3 is proportional to the product of k_1 and $[^3C_{m-n}^{+*}]_m$, because $[MV^{2+}]_m$ is constant independent of a sensitizer. Therefore, the difference in V_{init} is estimated from the differences in k_1 and $[^3C_{m-n}^{+*}]_m$ for C_{1-18} and C_{18-18}.

Effects of Microenvironment on Fluorescence Yield. According to the proposed mechanism shown in Fig. 3, it is clear that the concentration of the sensitizer in the triplet excited state ($^3C_{m-n}^{+*}$) generated from the sensitizer in the singlet excited state ($^1C_{m-n}^{+*}$) plays an important role in the reaction. The relative yield of the intersystem crossing from the singlet excited state (ϕ_{isc}^R) is given by

$$\phi_{isc}^R = \alpha\frac{k_{isc}}{k_{rl}+k_f+k_{isc}}. \quad (10)$$

On the other hand, the relative fluorescence yield of the sensitizer (ϕ_f^R) is

$$\phi_f^R = \alpha'\frac{k_f}{k_{rl}+k_f+k_{isc}}, \quad (11)$$

and therefore, their ratio is

$$\frac{\phi_{isc}^R}{\phi_f^R} = \alpha''\frac{k_{isc}}{k_f}. \quad (12)$$

Here, k_{rl}, k_f, and k_{isc} are the rate constants for radiationless relaxation, radiative (fluorescence) relaxation and intersystem crossing of the excited state, $^1C_{m-n}^{+*}$, and α, α', and α'' are proportionality constants. Since k_f and k_{isc} are considered to be less dependent on the environmental properties,[23-25] the increase in ϕ_f^R is accompanied by the increase in ϕ_{isc}^R as shown in Eq. 12. Since $[^3C_{m-n}^{+*}]_m$ is proportional to ϕ_{isc}^R, $[^3C_{m-n}^{+*}]_m$ can be estimated using ϕ_f^R.

The increase in ϕ_f^R would result from the decrease of the rate constant of radiationless process, k_{rl}. It has been suggested that k_{rl} largely depends on the interaction of the excited dye molecule and the environment around it,[23] that is, the microenvironment in the vicinity of the dye molecule. The microenvironment would actually mean the local effective micropolarity and microviscosity around the dye molecule.

In order to evaluate the micropolarity, the wave number at the absorption maxima of dyes solubilized in the micellar phases were compared with their dependencies on solvent polarity. The reason for employing aliphatic alcohols to calibrate the micropolarity in the micellar phase have already been discussed in detail.[26-28] As seen from Fig. 5, the chromophores of C_{1-18} and C_{18-18} accommodated in the micellar phases are provided with a remarkably less polar environment in comparison with that in the aqueous phase, but they seem to be in a more polar environment than in a liquid hydrocarbon. These results indicate that the chromophores are

located in the surface region of the micelle. The chromophore having two long alkyl chains, C_{18-18}, seems to be located in a somewhat more polar environment than C_{1-18}.

As shown in Fig. 6, the fluorescence yields of both dyes are larger in the micellar phases than in the solvents where dyes are provided with the same dielectric constant in the micellar phases. The microenvironmental effects on the fluorescence yield of dyes would contain polarity and also viscosity factors. These are usually associated with each other in a complex way and can not be investigated separately.

Carbocyanine dyes have been known to exhibit intense twisting modes along the polymethine chain in the electronically excited state.[29-31] This is because in the excited state, the conjugated π electronic structure is broken; this allows twisting modes of the substituents at each end and a destruction of the initial planar structure. The ability of such an intramolecular twisting, which may be strongly affected from the viscosity in the vicinity of the dye molecule, is associated with the internal conversion process of the singlet excited state to the ground state and therefore, with the fluorescence yield.

The radiationless relaxation process of the excited state is divided as

$$k_{rl} = k_a + k_b. \tag{13}$$

Here, k_a is the rate constant of the usual internal conversion which is independent of the viscosity in the vicinity of the dye molecule but dependent on the polarity around the dye molecule. The quantity k_b is the rate constant for relaxation *via* a twisting mode which is influenced by the microscopic viscosity around the dye molecule. Using the Stokes equation, k_b is given as[32,33]

$$k_b = \beta\left(\frac{T}{\eta}\right). \tag{14}$$

Here, β is a function of the effective volume associated with the intramolecular twisting, η is the viscosity of the medium and T is absolute temperature. From Eqs. 11, 13, and 14, the following equation is derived[33]

$$\frac{1}{\phi_f^R} = \frac{1}{\phi_f^{0R}} + \left(\frac{A}{k_f}\right)\left(\frac{T}{\eta}\right). \tag{15}$$

Here, $A=\beta/\alpha'$ and ϕ_f^{0R} is the relative fluorescence yield when the relaxation via twisting mode is absent as $\phi_f^{0R}=\alpha' k_f/(k_a+k_{isc}+k_f)$. It is already known that the relation between the fluorescence yield of Auramine O and the viscosity of the mixed solvent is well described by Eq. 15.[32,38] Equation 15 was examined for C_{1-18} and C_{18-18} in aliphatic alcohols at 25 °C. In these cases, however, no simple correlation, as expected from Eq. 15, was obtained and this is explained by the effective polarity in these solvents. Eq. 15 was, therefore, examined for the viscosity change of a single solvent with change of temperature. Plots of the reciplocal of ϕ_f^R for C_{1-18} and C_{18-18} in ethanol, 1-propanol and 1-butanol *versus* T/η gave straight lines as expected from Eq. 15 (its figure[19] is not shown). The slope and the intercept of the lines allow k_f/A and ϕ_f^{0R} to be evaluated. Figure 8 shows plots of k_f/A and ϕ_f^{0R} as functions of D for C_{1-18} and C_{18-18}. It is seen from Fig. 8 that the greater the polarity of the solvent, the smaller is ϕ_f^{0R} and the larger is k_f/A. The k_f/A is the value which increases with increase of the effective volume associated with the twisting, because $A=\beta/\alpha'$. The larger value of k_f/A in a polar solvent is ascribed to the solvation of the dye molecule. In the same solvent, the value of k_f/A for C_{18-18} is about twice as large as that for C_{1-18}. This indicates that the twisting of the dye molecule affects the radiationless relaxation process of the electronic excited state remarkably and that long alkyl chains such as octadecyl groups have an important effect upon the twisting of the dye molecules and make a great contribution to the effective volume associated with

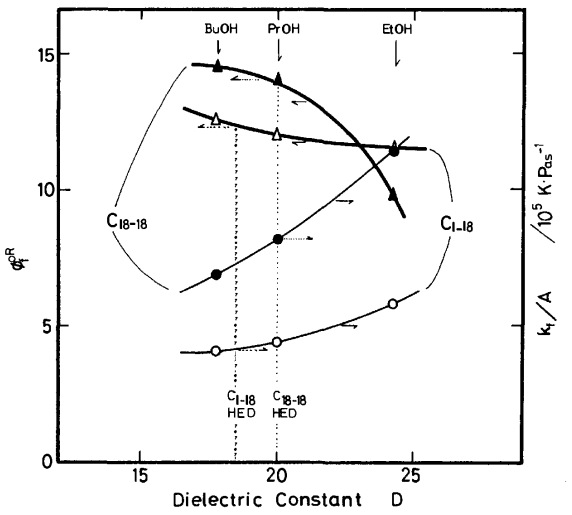

Fig. 8. ϕ_f^{0R} and k_f/A shown as functions of dielectric constant (D). ϕ_f^{0R}: the relative fluorescence yield when the relaxation via intrarotational mode is absent, k_f/A: the value increasing with increase of the effective volume associated with the twisting.

Table 1. Experimental results of C_{1-18} and C_{18-18} in micellar phase

Sensitizer Dye	ϕ_f^R	ϕ_f^{0R}	k_f/A / 10^5 K·Pa·s^{-1}	η_{eff} / 10^{-3} Pa·s
C_{1-18}	4.1	12.3	4.2	4.4
C_{18-18}	6.2	14.0	7.4	4.5

ϕ_f^R: Relative fluorescence yield, η_{eff}: effective microviscosity, ϕ_f^{0R} and k_f/A: see Eq. 15.

Table 2. Experimental values of C_{1-18} and C_{18-18} in micellar solution

Sensitizer dye	$\frac{V_{init}}{M \cdot s^{-1}}$	$\frac{\left(\frac{k_{-1}P_{MV^+}}{k_2[EDTA^{3-}]_m^{1/2}}\right)}{M^{-1}}$	$k_q \cdot \tau \cdot [MV^{2+}]_\infty$	k_q^R
C_{1-18}	6.1×10^{-8} (1)	5.2×10^{5}	5.4×10^{-2} (1)	1
C_{18-18}	1.3×10^{-7} (2.1)	5.3×10^{5}	1.1×10^{-1} (2.0)	1.3

V_{init}: The initial rate of formation of MV^+, τ: the life time of the excited state of sensitizer dye, k_q^R: the relative value of the rate constant of quenching.

the twisting.

If the polarity of the solvent is constant, Eq. 1 gives a straight line as mentioned before. Rearrangement of Eq. 15 leads to

$$\eta = \frac{T\phi_f^{0R}\phi_f^R}{(\phi_f^{0R}-\phi_f^R)\frac{k_f}{A}}. \quad (16)$$

When Eq. 16 is applied to micellar systems, the values in the solvent where dyes are provided with the same effective polarity in the micellar phase should be used. Therefore, the values of ϕ_f^{0R} and k_f/A of dye in alcohols of D, 18.5 for C_{1-18} and 20.0 for C_{18-18}, are assigned to those in the micellar phase (See Fig. 8). Substituting the value of ϕ_f^R in the micellar phase for ϕ_f^R in Eq. 16 yields values for the effective microviscosity in the micellar phase (η_{eff}). Table 1 shows the values of η_{eff} together with ϕ_f^R and k_f/A in the micellar phase. The η_{eff} has about the same value in both dyes, being 4.5×10^{-3}—4.6×10^{-3} Pas (4.5—4.6 cP).

As seen from Table 1, the difference in the values of ϕ_f^{0R} between both dyes is slight. Therefore, the large ϕ_f^R of C_{18-18} in the micellar phase compared with C_{1-18} can be ascribed to the relatively large effective volume ($1/A$) associated with the twisting. This indicates that the two long alkyl chains of C_{18-18} play an important role in the enhancement of the fluorescence yields. On the basis of an estimation of the fluorescence yield, it is suggested that the concentration of the sensitizer dye in the triplet excited state for C_{18-18} having two long alkyl chains is larger than that for C_{1-18} having only one long alkyl chain.

Access of MV^{2+} to Sensitizer Dye in Micellar Phase. As shown in Eq. 3, the initial rate of photoinduced reduction studied here is subject to the reaction between the sensitizer dye in the triplet state and MV^{2+} approching from aqueous to micellar phases. The D of dyes in the micelle indicated that the chromophore of C_{18-18} is located nearer to the micellar surface than that of C_{1-18}, and that C_{18-18} is more easily attacked by MV^{2+} at the miceller surface than C_{1-18}.

In order to obtain additional information about the accesibility of MV^{2+} to the excited sensitizer dye in the micellar phase, measurements of the quenching efficiency of fluorescence of the dye by MV^{2+} were carried out. From the experimental results, it was found that the value of P in Eq. 8 was the same for both dyes, indicating that the adsorption on the micellar surface of the quencher is not influenced by dyes in the micellar phase, and that the value of $k_q\tau[MV^{2+}]_\infty$ evaluated from experimental results was about 2.0 times larger for C_{18-18} than C_{1-18}. On the assumption that $(\tau)_{C(18-18)}/(\tau)_{C(1-18)} \approx (\phi_f^R)_{C(18-18)}/(\phi_f^R)_{C(1-18)}$, the following relation is obtained,

$$\frac{(k_q\tau[MV^{2+}]_\infty)_{C(18-18)}}{(k_q\tau[MV^{2+}]_\infty)_{C(1-18)}} = \frac{(k_q\tau)_{C(18-18)}}{(k_q\tau)_{C(1-18)}} \approx \frac{(k_q\phi_f^R)_{C(18-18)}}{(k_q\phi_f^R)_{C(1-18)}}, \quad (17)$$

because $[MV^{2+}]_\infty$ has the same value for both sensitizer dyes. Here, the parentheses show the terms for C_{1-18} and C_{18-18}, respectively. By using Eq. 17 and the values of ϕ_f^R and $k_q\tau[MV^{2+}]_\infty$ for C_{1-18} and C_{18-18}, the values of $(k_q)_{C(18-18)}/(k_q)_{C(1-18)}$ were evaluated. The results are presented in Table 2 as the value (k_q^R) relative to that of C_{1-18}. The value of k_q^R for C_{18-18} is 1.3 times larger than C_{1-18}. This difference in k_q^R may probably be ascribed to the difference in the location of the chromophores of these dyes in the micellar surface. Thus, it is also indicated from the data for the fluorescence quenching that C_{18-18} is more easily attacked by MV^{2+} than C_{1-18} at the micellar surface.

As shown in Table 2, the product of ϕ_f^R in the micellar phase and k_q^R, that is, $k_q\tau[MV^{2+}]_\infty$ is 2.0 times larger for C_{18-18} and agrees with the ratio of V_{init}, being 2.1. This indicates that the difference in V_{init} of C_{1-18} and C_{18-18} may be explained in terms of the difference in the fluorescence yield of the sensitizer dye in the micellar phase and in the accessibility of MV^{2+} to excited sensitizer dyes in the micellar phase.

Ultralow Interfacial Tension in the Vicinity of the Upper Critical Solution Temperature of the Mixture of Water and Isobutyric Acid

Makoto ARATONO* and Kinsi MOTOMURA
Department of Chemistry, Faculty of Science, Kyushu University, 33, Fukuoka 812
(Received May 24, 1985)

The ultralow interfacial tension of the binary liquid mixture of water and isobutyric acid has been measured as a function of temperature under atmospheric pressure in the vicinity of the upper critical solution temperature. It has been observed that the interfacial tension decreases monotonously as the temperature increases and is reduced to zero at the critical solution temperature. The results have been analyzed on the basis of the thermodynamics of interfaces. It has been found that the formation of interface is accompanied by increases in entropy and energy, which vanish at the critical solution temperature. This behavior has been considered in terms of the partial molar thermodynamic quantities of components. The brief discussion of the critical exponent has been also given for the present system.

The interfacial tension between two phases of a binary liquid mixture has been found to be reduced to zero as temperature approaches the critical solution temperature. In connection with the critical phenomena, therefore, it seems to be great interest to clarify the interfacial behavior in the vicinity of the critical solution temperature. However, the thermodynamic investigations of the interface are scarcely undertaken at temperatures near the critical solution temperature,[1-6] which is probably due to the difficulty of the precise measurement of ultralow interfacial tension. In our previous paper,[7] a new apparatus adopting a sessile drop technique was designed and the ultralow interfacial tension was measured accurately up to the value of 0.02 $\mu N\ m^{-1}$. Further it has been proved that the thermodynamic analysis of the interfacial tension measured as a function of thermodynamic variables is useful to shed light on the properties and structures of interfaces.[8-10] In the present paper, as a part of our thermodynamic studies of interfaces, the interfacial tension of the water–isobutyric acid mixture, of which the upper critical solution temperature is close to room temperature, was measured at temperatures near the upper critical solution temperature and analyzed on the basis of the thermodynamics of interfaces. The comment is also made on the critical exponent of this system.

Experimental

The purification of materials and the purity of isobutyric acid have been described previously.[7] The mutual solubility curve was drawn by using the phase separation temperature and phase mixing temperature determined visually according to the following procedure. The mixture of about 20 cm^3 was weighed and the sample tube was placed in a water bath having a volume of about 65 dm^3. The bath was thermostated by employing a mercury-toluene regulator; the temperature measured by a Beckmann thermometer was found to be constant within ±0.002 K. First, the temperature of the bath was set to a temperature about 0.1 K below or above the phase separation temperature expected. After the mixture was stirred by a magnetic rotor for about 10 min, the temperature was raised by about 0.01 K when the mixture was turbid and the temperature lowered when the mixture transparent. By repeating this procedure, the phase separation temperature and the phase mixing temperature were determined. Both temperatures were found to agree with each other within 0.01 K.

The sessile drop method was adopted to measure the interfacial tension between the two phases at temperatures near the upper critical solution temperature under atmospheric pressure. The apparatus and procedure of the measurement were described in detail in the previous paper.[7]

Results and Discussion

The phase separation and the phase mixing temperature were determined at about 70 different concentrations of the water–isobutyric acid mixture in the relatively narrow temperature range under atmospheric pressure. The mutual solubility curve is shown in Fig. 1 in the form of temperature T *vs.*

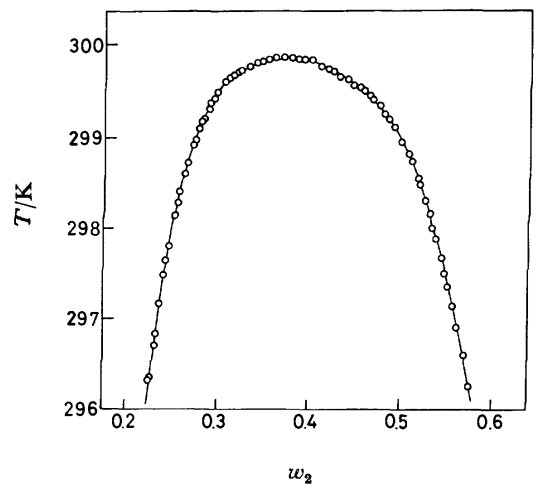

Fig. 1. Phase separation temperature *vs.* mass fraction curve under atmospheric pressure.

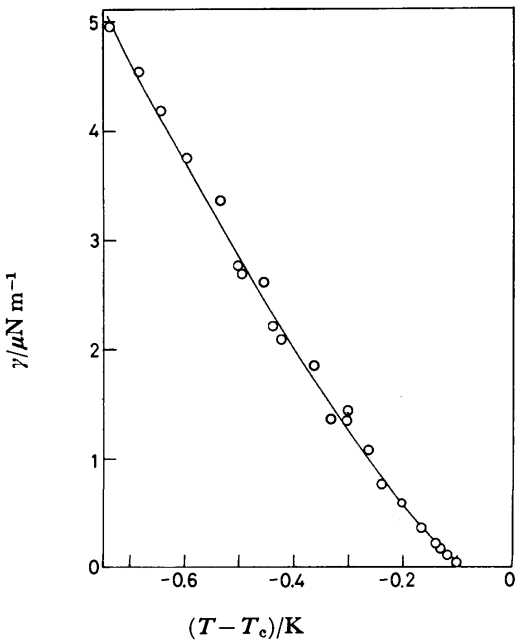

Fig. 3(b). Interfacial tension *vs.* temperature curve under atmospheric pressure.

mass fraction of isobutyric acid w_2 curve. The mass fraction at which the value of $\partial T/\partial w_2$ is zero was regarded as the critical composition w_c and the temperature corresponding to w_c as the upper critical solution temperature T_c. The $\partial T/\partial w_2$ *vs.* w_2 curve is shown in Fig. 2; the values of T_c and w_c were determined to be 299.88 K and 0.370, respectively.[11,12] At temperatures just below T_c, deep brown critical opalescence was observed. However, the determination of the phase separation and the phase mixing temperature was little affected by the opalescence.

The equilibrium interfacial tension γ was measured on critical mixtures at about 80 different temperatures in the vicinity of the critical solution temperature under atmospheric pressure. The γ *vs.* $T-T_c$ curve is drawn in Fig. 3(a) and the magnification of the curve very close to T_c is given in Fig. 3(b). It can be seen that the interfacial tension decreases monotonously from 35 to 0.02 μN m^{-1} with rising temperature in the narrow range of temperature. Further the γ value seems to approach zero at the critical solution temperature. This is the behavior expected for binary liquid mixtures having the upper critical solution temperature.[1-6] It is important to recognize that the slope of the curve is closely related to the entropy of interface formation.

By making use of Fig. 1, the interfacial tension shown in Fig. 3 can be plotted against the composition of the coexisting phases. The result is shown in Fig. 4 in the form of γ *vs.* w_2-w_c plot; the left and right parts of the curve correspond to the water-rich and acid-rich phases, respectively. It is seen that the interfacial tension decreases with decreasing the difference in composition between the conjugate phases and approaches zero at the critical composition. This is in harmony with the observation that an increase in mutual solubilities is responsible for a decrease in interfacial tension.[13,14] It is also seen that the curve is slightly unsymmetrical about the line parallel to the ordinate at the critical composition, which reflects the unsymmetry of the mutual solubility curve given in Fig. 1.

It has been well known that the temperature dependence of the interfacial tension in the vicinity of the critical solution temperature is described by the power law given by

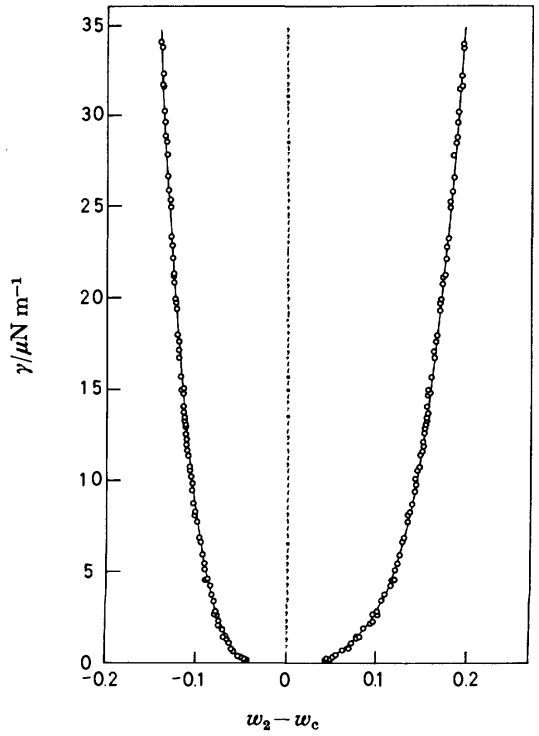

Fig. 4. Interfacial tension *vs.* mass fraction curve under atmospheric pressure.

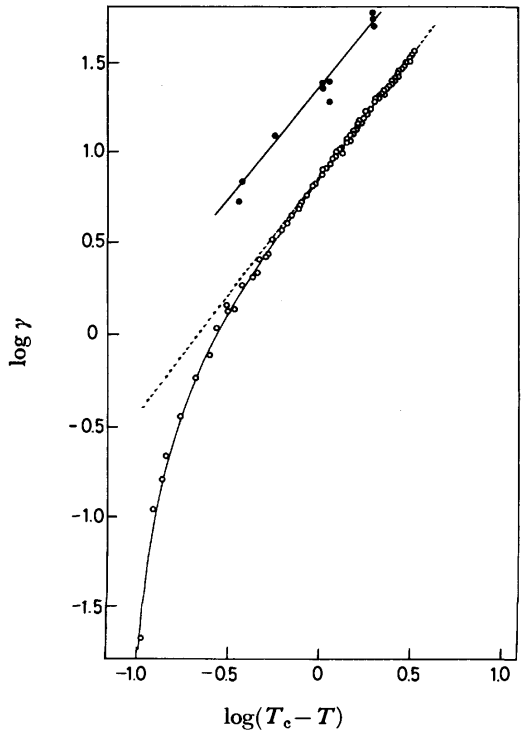

Fig. 5. log γ *vs.* log (T_c-T) curves under atmospheric pressure: (○) present study, (●) data from reference (6).

$$\gamma = k|T_c-T|^{\mu}, \tag{1}$$

where k is a proportionality constant and μ the critical exponent. Further, the temperature range where experimental results obey Eq. 1 has been discussed.[4] To examine the applicability of Eq. 1 to the present system, the value of log γ is plotted against log(T_c-T) in Fig. 5. It is seen that the curve follows the power law only in a limited temperature range and deviates from it at temperatures very close to T_c. The slope of the straight line was found to give $\mu=1.33$ in the range $0.003<(T_c-T)/T_c<0.01$. Also included in this figure for comparison are the results of Howland *et al.*;[6] they obtained $\mu=1.23\pm0.09$ by the unweighted least-squares analysis. It should be noted, however, the γ values of Howland *et al.* are higher than those of the present study and show considerable scatter. Furthermore, the lowest γ value measured is seen to be significantly high compared to that of the present study. Therefore, there seems to be some doubt as to whether Eq. 1 expresses the temperature dependence of the interfacial tension in the vicinity of T_c over a wide range of temperature.

To clarify the properties and structure of liquid/liquid interface, it is of great importance to examine the thermodynamic quantities of interface formation evaluated from experimental results by applying the thermodynamics of interfaces.[8-10] Immediately we notice that the temperature dependence of interfacial tension at constant pressure shown in Fig. 3 is closely related to the entropy of interface formation. The degree of freedom is two since the system under consideration is composed of two components and has two bulk phases separated by a plane interface. From the experimental point of view, therefore, it is convenient to choose temperature T and pressure p of the system as the independent variables. From Eqs. [8], [37], and [39] of Ref. (8), the interfacial tension is expressed in the differential form as

$$d\gamma = -\Delta s dT + \Delta v dp, \tag{2}$$

where Δs and Δv are the entropy and volume of interface formation, respectively. Thus we can estimate the value of Δs by applying Eq. 3 to the results given in Fig. 3:

$$\Delta s = -(\partial\gamma/\partial T)_p. \tag{3}$$

Figure 6 shows the change of the Δs value with temperature. It can be said that the interface formation of the binary mixture having upper critical solution temperature is accompanied by the increase in entropy. However, the value of Δs seems to decrease rapidly as the temperature approaches T_c and to be reduced to zero at T_c. Taking into account that the Δs values obtained for the systems of virtually immiscible oil and water are fairly larger than the above one and closely related to the mutual solubility between them,[10] it is also understandable

from Figs. 1 and 6 that the rapid decrease of the difference between the compositions of the two phases is responsible for the rapid decrease of the entropy of interface formation in the close vicinity of the critical solution temperature.

Now let us consider the contributions of components to the entropy of interface formation in some detail. According to the quasithermodynamics, the entropy of interface formation of two-component system can be expressed by use of the partial molar entropy changes of the components in the form[8]

$$\Delta s = \Gamma_1^I \Delta s_1 + \Gamma_2^I \Delta s_2, \tag{4}$$

where Γ_i^I is the number of moles of component i participating in the interface per unit area and Δs_i the partial molar entropy change of component i caused by the interface formation. In case that the two component are practically immiscible with each other, the two terms on the right side of Eq. 4 can be written as

$$\Gamma_i^I \Delta s_i = \Gamma_i^I (\bar{s}_i^I - s_i), \quad i=1, 2, \tag{5}$$

where $\bar{s}_i^I$ is the mean partial molar entropy in the interfacial region and s_i the partial molar entropy in the pure bulk phase. In the case of the present system where the two components are partly miscible with each other, on the other hand, $\Gamma_i^I \Delta s_i$ consists of two terms, *i.e.*, the one resulted from the transfer of component i from the component 1-rich phase α to the interfacial region and the other from the component 2-rich phase β; correspondingly, Γ_i^I is divided into the two parts $\Gamma_i^{I,\alpha}$ and $\Gamma_i^{I,\beta}$ which are attributable to the phases α and β, respectively. Therefore, it can be written as

$$\Gamma_i^I \Delta s_i = \Gamma_i^{I,\alpha}(\bar{s}_i^I - s_i^\alpha) + \Gamma_i^{I,\beta}(\bar{s}_i^I - s_i^\beta), \quad i=1, 2. \tag{6}$$

In the result, we have

$$\Delta s = [\Gamma_1^{I,\alpha}(\bar{s}_1^I - s_1^\alpha) + \Gamma_1^{I,\beta}(\bar{s}_1^I - s_1^\beta)] + [\Gamma_2^{I,\alpha}(\bar{s}_2^I - s_2^\alpha) + \Gamma_2^{I,\beta}(\bar{s}_2^I - s_2^\beta)]. \tag{7}$$

Comparing Eq. 7 with the positive value of Δs shown in Fig. 6, we may conclude, that the entropy of transfer of components from the two phases to the interfacial region, as a whole is positive. Accordingly, the contact of two different molecules which form a mixture with the upper critical solution temperature is said to be accompanied by an increase in entropy. Further, since the physical properties of the conjugate phases become identical as the temperature approaches the critical solution temperature, the partial molar entropies in the bulk phases and the interfacial region turn out to have the same values at T_c.

Now we can calculate the energy of interface formation Δu by applying the following equation to the above results;

$$\Delta u = \gamma + T\Delta s - p\Delta v. \tag{8}$$

The Δu *vs.* $T-T_c$ curve is shown in Fig. 7, where the value of $p\Delta v$ has been assumed to be negligibly small under atmospheric pressure when compared with the values of γ and $T\Delta s$ terms.[15-17] It is seen that the value of Δu is positive and reduced to zero at the critical solution temperature in a similar manner to that of Δs. The analog of Eq. 7 holds for Δu:

$$\Delta u = [\Gamma_1^{I,\alpha}(\bar{u}_1^I - u_1^\alpha) + \Gamma_1^{I,\beta}(\bar{u}_1^I - u_1^\beta)] + [\Gamma_2^{I,\alpha}(\bar{u}_2^I - u_2^\alpha) + \Gamma_2^{I,\beta}(\bar{u}_2^I - u_2^\beta)], \tag{9}$$

where $\bar{u}_i^I$ and u_i are the mean partial molar energy of component i in the interfacial region and the corresponding partial molar energy in the bulk phase, respectively. Therefore, we can say that the overall value of energy of transfer is positive and the differences among $\bar{u}_i^I$, u_i^α, and u_i^β disappear at the critical solution temperature. These facts lead us to the conclusion that the interface formation from the

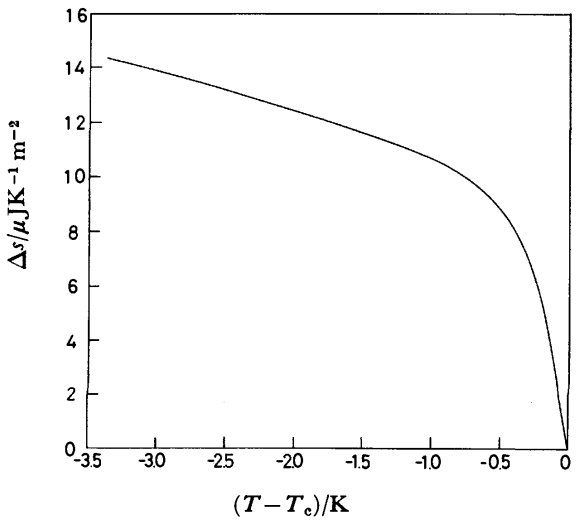

Fig. 6. Entropy of interface formation *vs.* temperature curve under atmospheric pressure.

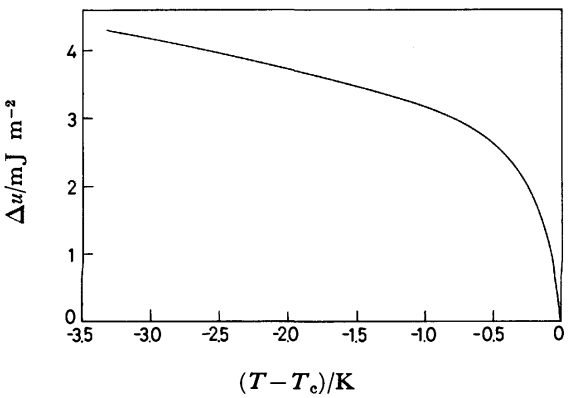

Fig. 7. Energy of interface formation *vs.* temperature curve under atmospheric pressure.

two conjugate phases of a binary system in the vicinity of the upper critical solution temperature is an unfavorable process from the viewpoint of energy, but favorable process from the viewpoint of entropy. Further information regarding the interfacial behavior of molecules will be provided by investigating a binary liquid mixture having the lower critical solution temperature.

Effect of Inner-shell Excitations on the *W*-Value of Propane

Isao H. Suzuki* and Norio Saito
Electrotechnical Laboratory, Sakura-mura, Niihari-gun, Ibaraki 305
(Received June 5, 1985)

The dependence of the propane *W*-value on photon energy has been precisely measured near inner-shell excited states using monochromatized synchrotron radiation. The *W*-value showed an oscillatory variation in this energy region. A model has been proposed in which inner-shell excitation is assumed to give rise to a change in the energy of the electron ejected from the molecule having absorbed a photon. It has been found that the model can reproduce the oscillatory variation feature of the *W*-value. A post-collision interaction is suggested to take place just above the C-K edge of propane.

The *W*-value of ionizing radiation represents the mean energy expended by the radiation to produce an ion pair. A variety of studies were carried out regarding the *W*-values of gases (including propane) in a region higher than several keV.[1] However, a limited number of studies were performed for low energy radiation, although information on the *W*-values in this region is important for calculations regarding the radiation-transport phenomena.[2-7] Recently, Combecher reported on the electron *W*-value for propane in the energy region below 260 eV.[2] The *W*-value showed an increase with decreasing energy. This increase probably originated from the fact that the fraction of neutral excitations exceeded that of ionizations in electron-molecule collisions as the electron energy decreased. Srdoč measured the *W*-value of propane for photons from 90 eV to 280 eV using characteristic X-rays and filtered bremsstrahlung radiation.[3] The obtained data showed a slight increase with decreasing energy.

Samson and Haddad obtained the *W*-value of Xe for photons with energies from 12 eV to 90 eV.[4] Their results showed a distinct variation of the *W*-value over the energy region. This variation was ascribed to a change in the ejected electron energy which was caused by transitions to excited states of the Xe ion. Work on the *W*-value of methane for photons was performed in the ultra-soft X-ray region by the present authors.[5] An oscillatory variation near the C-K edge was found in the energy dependence of the *W*-value. Propane has the K-shell ionization energy of 290.6 eV.[8] Transitions of the K-electrons to unoccupied orbitals are supposed to take place slightly below the ionization threshold although there is no available data on the K-shell excitation spectrum.[9-11] These types of excitations and ionizations probably cause molecules to change into different types of states of the molecular ion. The *W*-value is expected to be affected by these ion states near the K-edge.

The present paper reports precise measurements of the *W*-value of propane for photons from 260 eV to 360 eV. The fine structure of the *W*-value found in this energy region is discussed in connection with the transitions of C-1s electrons.

Experimental and Analysis Method

Synchrotron radiation from the storage ring (electron energy: 400 MeV) at the Electrotechnical Laboratory was monochromatized by a plane grating monochromator.[12,13] The resolving power of the monochromator was about 150. The monochromatized photons entered a gas-flow proportional counter (Manson-04) with a thin film window. The window material was VYNS (thickness: 25 μg/cm²) or Al (1500 Å). Propane (purity: 99.99%) was introduced into the counter. The gas pressure was set to be 40 Torr for the Al window and 100 Torr for the VYNS window.

Signals from the counter were amplified and accumulated in a multichannel analyzer (MCA: Canberra-40). The resultant pulse height distributions of the signals were transferred to a micro-computer. Using this computer, the pulse height distributions were analyzed to obtain average pulse heights. The pulse height distribution can be approximately expressed by the following,[14,15]

$$f(z) = \frac{z^{x-1}\cdot\exp(-z/z_a)}{z_a^x\cdot\Gamma(x)}. \quad (1)$$

In the above equation, z indicates the number of electrons amplified by the electric field within the counter, z_a denotes the average gas amplification factor, x is the average number of the electrons initially generated by the radiation effect of a photon, and Γ is the gamma function. The distributions calculated using Eq. 1 were fitted to those obtained by observation.[14] This fitting procedure served to remove any interference due to contamination of the photon beam when the correct pulse height distributions were determined from the experimental data. The average pulse height distribution P is given by

$$P(E_p) = \int z\cdot f(z)\cdot dz = z_a\cdot x = \frac{z_a\cdot E_p}{W_p(E_p)}, \quad (2)$$

where E_p indicates the energy of a photon and W_p denotes the *W*-value.[3,5,14]

Using Eq. 2, relative *W*-values were obtained for photons with energies from 260 eV to 360 eV. Any nonlinearity of electric circuits (*e.g.*, preamp and MCA) was corrected for. Also, any change in P owing to a drift in the gas pressure was cancelled by performing several measurements at the same photon energy in the course of the experiment. There may be photoabsorption by propane in which only neutral fragments are produced but in which no ion pair are

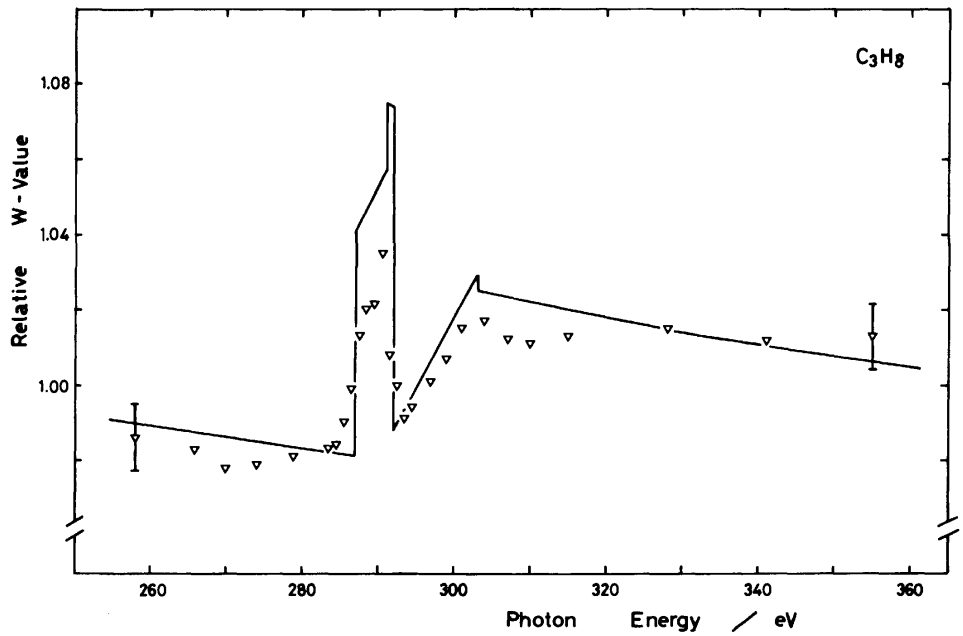

Fig. 1. Dependences of the propane W-value on the photon energy in the region from 260 eV to 360 eV. Open triangles indicate measured results. Solid curve denotes the calculated profile based on the present model. Bars indicate the error sizes of the measured data.

formed. This process should alter the W-value, although the present technique using a proportional counter can not count up these types of processes. At present, these processes are assumed to be negligible, by analogy of the results of ionization yield of methane by Backx and Van der Wiel.[16]

The photoabsorption spectrum was measured using a gas cell (length: 200 mm, inner diameter: 14 mm) with thin VYNS windows (for the entranee and exit of photon beams) and the proportional counter. The counter served to discriminate signals from the noise owing to a contamination of the photon beam, *e.g.*, higher order photons and stray photons with longer wavelengths.

Results and Discussion

The relative W-values derived from the measurements are shown with open triangles for photon energies from 260 eV to 360 eV in Fig. 1. The solid curve indicates a calculated profile based on the model described below. The measured W-value slightly decreases with increasing energy from 260 eV to 280 eV. The W-value shows a sharp rise at 286 eV, goes to a maximum at 291 eV and again decreases to a minimum at 294 eV. A linear dependence of the W-value data on the photon energy is seen from 294 eV to 304 eV. The W-value is essentially constant above 304 eV.

In order to clarify the origin of the variation in the W-value shown in Fig. 1, the present authors observed the photoabsorption spectrum of propane around the C-K edge (Fig. 2). Although the inner-shell excited states are not separated from one another (Fig. 2) owing to the low resolving power of

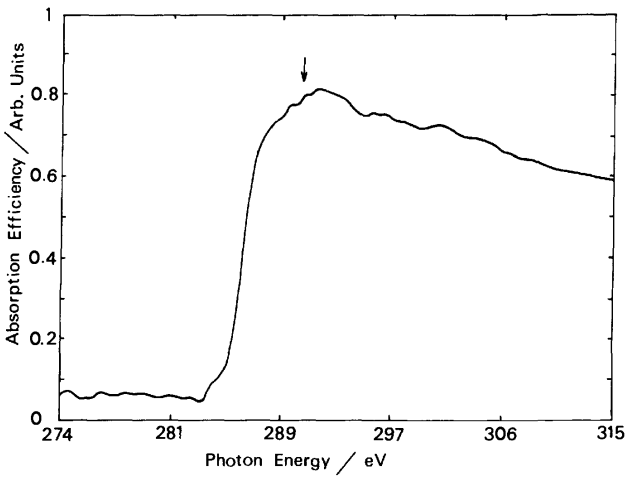

Fig. 2. Photoabsorption spectrum of propane in the region from 274 eV to 315 eV. Arrow indicates the threshold energy of the K-shell ionization (Ref. 8).

the present monochromator, the following items are possibly discernible in the figure. The absorption efficiency is low below 285 eV, becomes high at about 287 eV and has a maximum at around 291 eV. Above 291 eV, this efficiency gradually decreases with increasing photon energy. Judging from the inner-shell excitation spectra of methane and ethane,[9,10] the high efficiency at 287 eV can probably be ascribed to a transition of C-atomic orbitals, 1s→3s. In the cases of methane and ethane, the transition (1s→3s) is low in intensity. This type of transition is supposed to occur with a higher probability because of the poorer symmetry of propane relative to methane and

ethane. It is seen in Fig. 2 that this transition is followed by transitions to higher excited states (*e.g.*, 1s→3p) and to the ionized state.

As a result a comparison between the absorption spectrum and the energy dependence of the *W*-value for propane, a model is here proposed as follows.

i) Below 287 eV: Photons can only excite the valence electrons of propane, which occupy 10 molecular orbitals (composed of C-2s, C-2p, and H-1s orbitals) in the ground state. Ejected photoelectrons ionize ambient molecules and produce a number of ion pairs. On the other hand, the *W*-value of low energy electrons (W_e) can be approximately represented by the following expression.[1-4]

$$W_e(E) = \frac{E \cdot W}{E-U} \tag{3}$$

W denotes the *W*-value for radiation with a sufficiently high energy (24.0 eV),[1] U indicates the average energy of sub-ionization electrons, and *E* is the energy of an electron. Using Eq. 3, the photon *W*-value is given by

$$W_p(E_p) = \frac{E_p}{1+n_e} = \frac{E_p \cdot W}{E_p+W-E_v-U_2}, \tag{4}$$

where E_v is the average binding energy the valence electrons and n_e denotes the average number of ion pairs produced by the ejected photoelectrons. In the derivation of Eq. 4, the following relation was utilized.

$$n_e(E) = \frac{E}{W_e} = \frac{E_p-E_v-U_2}{W} \tag{5}$$

The term E_v is assumed to be 17.9 eV.[8] The average subionization energy, U_2, is assumed to be 25 eV from data regarding the *W*-value for low energy electrons.[2] Multiple ionizations of the valence electrons are at present assumed to be negligible because there is no available data for this type of process.

ii) Between 287 eV and 290.6 eV: Photons can excite the inner-shell electrons to the Rydberg orbitals and a hole can be formed in the inner-shell. (Unoccupied orbitals in the ground state are called Rydberg orbitals in the present study.) After this excitation, an Auger transition is supposed to occur since fluorescence yield is extremely low in a light element. Several types of Auger transitions have been reported in propane. The average energy of those Auger electrons has been estimated to be 248 eV from the work by Rye *et al.*[17] The average energy of the Auger electrons in the present case is supposed to be slightly different from 248 eV due to the existence of that electron in the Rydberg orbital. This average energy E_{RA} is assumed to be 255 eV, by analogy from a resonance-type Auger electron spectrum of CO.[18] The *W*-value is given by

$$W_p(E_p) = \frac{E_p}{1+n_e} = \frac{E_p \cdot W}{E_{RA}+W-U_2}. \tag{6}$$

In a comparison of Eq. 6 with Eq. 4, E_{RA} (255 eV) is lower than E_p-E_v (*e.g.*, 267.1 eV for the photon with energy of 285 eV). Thus, the *W*-value at 287 eV becomes higher than that at 285 eV. In the present model, it is assumed that the photoabsorption probability involving the valence electrons can be negligibly low above 287 eV on account of the spectrum shown in Fig. 2.

iii) Between 290.6 eV and 292 eV: The inner-shell electrons can be ejected from the molecule by the photons. The energy of this ejected photoelectron is very low. This electron is supposed to be retrapped through a post-collision interaction by that propane molecular ion when a second high-energy electron is ejected through an Auger transition, as seen in the case of CO.[19] The Auger electron obtains a somewhat higher energy owing to the existence of the slow photoelectron, compared to a normal Auger electron. The energy gain of the Auger electron is equal to the energy which the trapped electron loses. The average energy of the Auger electrons is here assumed to be (248 eV+E_p−288 eV).

iv) Between 292 eV and 302.6 eV: The inner-shell electrons can be ionized and can quickly escape from the molecular field. An Auger transition follows this photoelectron ejection. The photoelectron has an energy of E_p-E_k (E_k: the ionization energy of the inner-shell, 290.6 eV[8]), and the Auger electron has an average energy of 248 eV (E_A). The former electron can not ionize other ambient molecules because the electron energy is lower than the first ionization energy of the valence electron. (The vertical ionization energy 12.0 eV is considered here.[8])

v) Above 302.6 eV: The photoelectron ejected from the inner-shell has an energy higher than the first ionization energy of propane. This electron, as well as the Auger electron formed subsequently, can ionize other molecules. The *W*-value is expressed by

$$W_p(E_p) = \frac{E_p}{2+n_{e1}+n_{e2}} = \frac{E_p}{E_p+E_A+2W-E_k-U_1-U_2}, \tag{7}$$

where U_1 indicates the average energy of the sub-ionization electrons for the electron with kinetic energy between 12 eV and 60 eV. The U_1 value is assumed to be 11 eV on account of Combecher's study.[2]

The present model is summarized in Fig. 3. Initial and final configurations in the figure denote the configuration of the relevant electrons just after photoabsorption and that after the Auger transition if it happens, respectively. Based on the present model, the relative *W*-value has been calculated and drawn with the solid curve in Fig. 1. In this

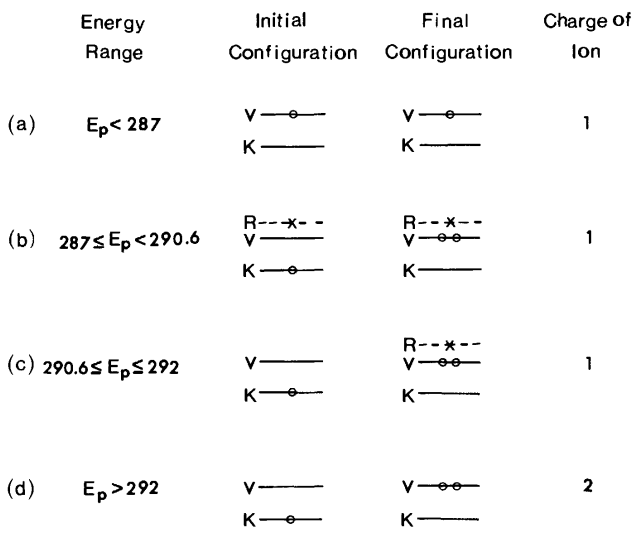

Fig. 3. Illustration of change in the electron configuration. Initial and final configurations indicate the electron configuration just after photoabsorption and that after the Auger transition if it happens, respectively. Charge of ion denotes the final charge state of the residual propane ion. E_p is the photon energy. V, K, and R mean the valence orbitals, the inner-shells and Rydberg orbitals, respectively. O and × represent a hole and an occupation by an electron, respectively.

calculation, the resolving power of the monochromator was not considered. The calculated curve reproduces the characteristics of the experimental results. Therefore, the present model is essentially correct.

There is a slight discrepancy between the experimental data and the calculated result around 290 eV. This discrepancy is probably caused by the low resolving power of the monochromator. However, the following can not be ruled out with respect to the reason for the discrepancy. Between 287 eV and 290.6 eV, the final configuration of the related electrons is not only one. One part of the final configuration may be the final configuration shown in Fig. 3(a); the configuration with one hole in the valence orbital, which is generated through the ejection of the electron promoted into the Rydberg orbital. From 290.6 eV to 292 eV, there is a possibility that some fractions of the slow photoelectrons are not retrapped by that molecular ion, although the energy of the electron may be lowered through a post-collision interaction. If this is the case, the final configuration is as shown in Fig. 3(d), with two holes in the valence orbitals. The two additional final states mentioned above should make the W-value lower than in a model neglecting these states. The calculated result derived from the above consideration is expected to be closer to the experimental data than that in Fig. 1.

If a post-collision interaction does not occur in the region from 290.6 eV to 292 eV, the minimum at 294 eV in the experimental results, shown in Fig. 1, should approach the threshold energy of the K-shell, 290.6 eV. The difference of about 3.5 eV can not be explained by the low resolving power of the monochromator. Thus, it is reasonably expected that the post-collision interaction takes place just above the C–K edge, as well as for CO and methane.[14,19] In methane, a minimum has appeared at 295 eV regarding the energy dependence of the W-value derived from measurements similar to those in the present work.[14] The inner-shell ionization energy of methane is 290.8 eV.[8] This type of post-collision interaction is limited to a narrower energy range in propane than in methane. This fact suggests the following. The more electrons exist in molecular orbitals, the more effectively the field of a doubly charged ion is shielded. This may result in there being no occurrence of a post-collision interaction of the photoelectron in propane at an electron energy lower than that in methane by about 1 eV.

The gap at 303 eV in the calculated curve originates from the adoption of the present values on U_1 and the vertical ionization energy. This gap could probably be removed if we could obtain a more reliable U_1 value and could utilize the adiabatic first ionization energy.

Summary

The energy dependence of the photon W-value for propane has been precisely determined in the region from 260 eV to 360 eV. An oscillatory structure has been found in the W-value near the C–K edge. This structure can essentially be explained by a plain model. In this model, transitions from the ground state to the inner-shell excited states and inner-shell ionization give rise to a change in the energy distribution of the ejected electrons. The Auger transitions are considered to represent the only processes for the re-occupation of the resultant hole in the inner-shell. This change in the energy distribution brings about the oscillatory structure regarding the W-value near the K-edge. The following, however, is necessary for a rigorous confirmation of the present model. The energy distribution of ejected electrons and the charge state of residual ions must be accurately determined as a function of photon energy. This type of information will be obtained soon since studies using synchrotron radiation are being vigorously advanced.

The authors wish to express their sincere thanks to the members of the accelerator group of the Electrotechnical Laboratory for providing synchrotron radiation.

A High-resolution ^{13}C NMR Study of Some Ethylene Oxide Oligomers, Cryptands and Crown Ethers Complexed with a Variety of Metal Ions in the Solid State. Conformational Change of Ligand Molecules as Viewed from the Conformation-dependent Displacements of ^{13}C Chemical Shifts

Ryoko TABETA and Hazime SAITÔ*
Biophysics Division, National Cancer Center Research Institute, Tsukiji 5-Chome, Chuo-ku, Tokyo 104
(Received July 11, 1985)

We recorded high-resolution solid-state ^{13}C NMR spectra of ethylene oxide oligomers, cryptands, and crown ethers complexed with metal ions, determined by cross polarization-magic angle spinning (CP-MAS) NMR method. It is found that peak-intensities of these complexes are significantly enhanced by the presence of metal ions which act toward conformational fixation of flexible ligand molecules. The ^{13}C chemical shifts of ethylene oxide oligomers complexed with $HgCl_2$ or $CdCl_2$ as open-chain analogues of crown ethers were successfully related with a pair of torsion angles of nearby single bonds. ^{13}C Chemical shifts of cyclic ionophores were displaced (up to 6 ppm) together with conformational changes of ligand molecules. In addition, the ^{13}C chemical shifts of the carbons neighbored with nitrogen atoms of cryptands [2.2.2] and [2.2.1] were well related with a pair of torsion angles of neaby bonds. Further, we found that several kinds of metal complexes with *cis-syn-cis* and *cis-anti-cis* isomers of dicyclohexano-18-crown-6 gave rise to substantially different spectral profiles, resulting in the occurrence of significant conformational changes of these ligand molecules as a result of complex formation.

It is well known that synthetic macrocyclic ionophores such as crown ethers and cryptands show a marked ability to form metal complexes with a variety of alkaline and alkaline earth metal ions[1–9] like naturally occurring ionophores such as valinomycin, nonactin, monensin, *etc.* These ionophores have gained much interest in relation to their models of naturally occurring antibiotics as carriers of cations through biological and model membranes, phase-transfer catalysis for salt solubility enhancement and anion activation in synthesis.[1–9] In many instances, these ligand molecules undergo marked conformational changes during ion-binding to achieve stability and ion-selectivity of complexes. Accordingly, it is very important to analyze these conformational changes of ligand molecules both in the solid

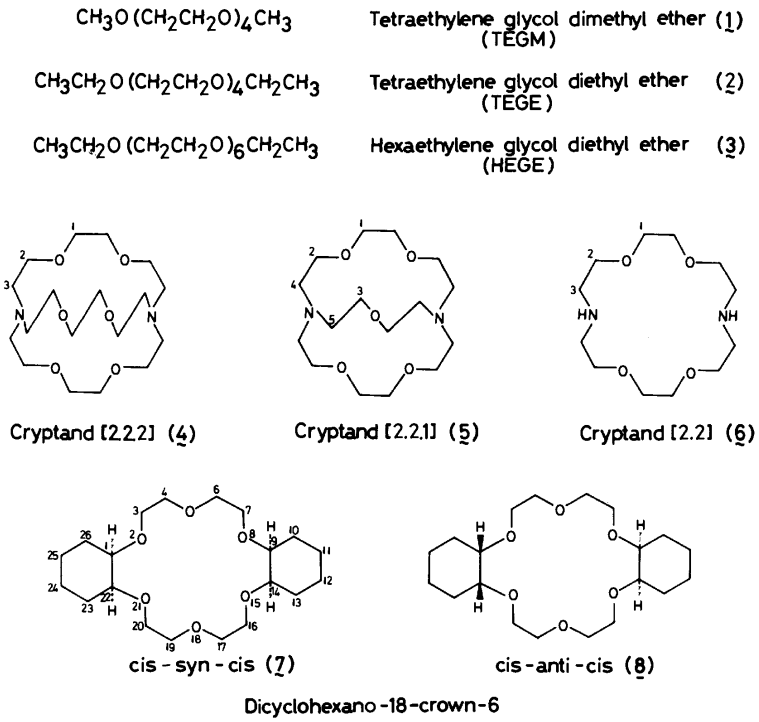

Fig. 1. Chemical structures of ethylene oxide oligomers, dicyclohexano-18-crown-6, and cryptands.

and solution, in order to gain insight of the manner of metal-ligand interaction in the complexes.

As a convenient complementary means to X-ray diffraction, we previously showed that the manner of such conformational changes in the ligand molecules in the solid state is conveniently examined when sizable amounts of displacements of the conformation-dependent ^{13}C chemical shifts, as determined by cross polarization-magic angle spinning (CP-MAS) technique, are seen for any carbons of backbones.[10-19] The major advantage of the present approach is to provide reference data to examine whether particular conformation observed in the solid state is retained in solution or not.

In order to gain insight how ^{13}C chemical shifts of these ligand molecules are varied with conformational changes associated with complexation, we recorded ^{13}C CP-MAS NMR spectra of ethylene oxide oligomers [tetraethylene glycol dimethyl ether (TEGM), tetraethylene glycol diethyl ether (TEGE), hexaethylene glycol diethyl ether (HEGE)], cryptands ([2.2.2], [2.2.1], and [2.2]), and *cis-syn-cis* and *cis-anti-cis* isomers of dicyclohexano-18-crown-6 (see Fig. 1 for chemical structure) complexed with a variety of metal ions. We studied ethylene oxide oligomers as open-chain analogues of cyclic ionophores, because conformations of the former resembles those of the latter and detailed X-ray diffraction data[20-23] are available for the former. We found that the ^{13}C chemical shifts were significantly varied among a variety of complexes, reflecting the conformational changes of ligand molecules. We also attempted to relate these displacements of shifts with a pair of torsion angles of the nearby single bonds. Finally, we compared ^{13}C chemical shifts between the solid and solution in order to evaluate whether or not the conformations achieved in the solid state are retained in solution.

Experimental

Materials. Tetraethylene glycol dimethyl ether (TEGM) and tetraethylene glycol diethyl ether (TEGE) were purchased from Tokyo Kasei Kogyo Co., Ltd., Tokyo and Aldrich Chemical Company, USA, respectively. Hexaethylene glycol diethyl ether (HEGE) was prepared by the reaction of hexaethylene glycol (Aldrich) and ethyl iodide over NaH dissolved in anhydrous dimethyl sulfoxide. $HgCl_2$ or $CdCl_2$ complexes were prepared by the procedure described by Iwamoto.[20-23]

Cryptands [2.2.2], [2.2.1], and [2.2] were purchased from Merck Chemical Company, West Germany. Colorless plate-shaped crystal of cryptand [2.2] with NaSCN was formed by dissolving these two chemicals in methanol-1-butanol solution. KSCN complex with cryptand [2.2] (colorless prism) was grown from benzene containing small amount of water.[24] $Pb(SCN)_2$ complex with cryptand [2.2](prism) was obtained by methanol-1-butanol solvent.[25] NaSCN and KSCN complexes with [2.2.1] were obtained from methanol-1-butanol solution.[26] $CaBr_2$,[27] $TlHCOO$,[28] NaSCN and KSCN complexes with cryptand [2.2.2] were obtained from methanol-ethyl acetate solvent, whereas $Ba(SCN)_2$ complex was obtained from methanol-1-butanol solvent.[29]

Cis-syn-cis and *cis-anti-cis* isomers of dicyclohexano-18-crown-6 (Aldrich Chemical Company, USA) were isolated by the procedure of Izatt *et al.*[30] utilizing OH_3ClO_4 and $Pb(ClO_4)_2$, respectively, as agents for complex formation. Plate-shaped. NaBr-complexes with both isomers were obtained from a solution of equimolecular quantity of individual *cis-syn-cis* or *cis-anti-cis* isomers and sodium bromide (5% excess) in ethanol-acetone which was allowed to evaporate in air.[31] In a similar manner, complexes with $La(NO_3)_3$,[32] KI_3,[33] $CsSCN$,[33] $Pb(ClO_4)_2$,[30] OH_3ClO_4,[30] KI,[34] NH_4SCN,[34] and $Ba(SCN)_2$[34] were prepared by the procedure published already.

^{13}C CP-MAS NMR Spectra. Single-contact ^{13}C CP-MAS NMR spectra were recorded on a Bruker CXP-300 spectrometer at 75.46 MHz, equipped with a CP-MAS NMR accessory. Samples were placed in an Andrew-Beams type rotor machined from perdeuterated poly(methylmethacrylate) and spun by compressed air. A contact time used was usually 800 μs, although several spectra were obtained by varying contact time from 500 μs to 5 ms. Repetition times were 2—4 s and spectral width and data points were 30 kHz and 8 K data points, respectively. Resolution-enhancement was made by a gaussian multiplication.[35] Spectra were accumulated more than 2000 times. Chemical shifts were calibrated through external benzene and converted to the values from tetramethylsilane (TMS).

High Resolution ^{13}C NMR. High resolution ^{13}C NMR spectra were recorded in deuterated chloroform and methanol on a Bruker CXP-300 spectrometer. Chemical shifts were calibrated with respect to external tetramethylsilane in a capillary.

Results

Figure 2 shows 75.46 MHz ^{13}C CP-MAS NMR spectra of ethylene oxide oligomers complexed with $HgCl_2$ or $CdCl_2$ in the solid state. The ^{13}C NMR signals of the terminal methoxyl or ethoxyl groups were readily assigned in view of the data of uncomplexed samples in chloroform solution (see Table 1). Several peaks were well resolved for the internal methylene carbons of polyether moiety and peak-positions and relative peak-intensities are summarized in Table 1. These ^{13}C NMR signals are also split into several peaks even in the uncomplexed molecules in solution state (Table 1). Such a splitting of peaks in the random-coil state is not necessarily caused by variations of local conformers among methylene groups but simply by substituent effects of the terminal methoxyl or ethoxyl groups. In particular, the peaks marked by **a** in the solid and solution states are assigned to the carbons which are neighbored with the terminal methoxyl or ethoxyl groups, in view of the relative peak-intensities and displacements of peaks (Table 1).

Table 1. ^{13}C Chemical shifts of oligomers of ethylene oxide complexed with $HgCl_2$ or $CdCl_2$ in the solid state[a] (ppm from TMS)

	Internal CH_2		Terminal	
	I[b]	II	CH_3	CH_2
TEGM-$HgCl_2$	72.1[c] (2), 71.2*(3), 69.2 (3)	—	58.9 (1) 58.2 (1)	
TEGM (soln)[d]	71.9[c] (2), 70.5*(4), 70.4 (2)	—	58.9 (2)	
TEGM-$CdCl_2$	71.9[c] (1), 70.5*(3), 69.5 (1), 68.2[c] (1)	67.1 (1) 67.9 (1)	60.5 (2)	
HEGE-$HgCl_2$	72.0[c] (2), 71.6 (2), 70.4*(6), 68.9 (2)	67.6 (1) 66.8 (1)	15.3 (2)	67[e] (2)
HEGE (soln)[d]	70.5*(10), 69.7[c] (2)		15.1 (2)	66.5 (2)
TEGE-$HgCl_2$	69.5*(8)		15.1 (2)	65.8 (2)
TEGE (soln)[d]	70.5*(6), 69.8[c] (2)		15.1 (2)	66.5 (2)

a) Numbers in parenthesis denote relative peak-intensities normalized to the total number of carbons. b) Peaks asterisked stand for the most intense signals. c) CH_2O group neighbored with the terminal CH_3 or CH_2CH_3 groups. d) In chloroform solution (uncomplexed). e) Superimposed on the internal CH_2 signals (peak II).

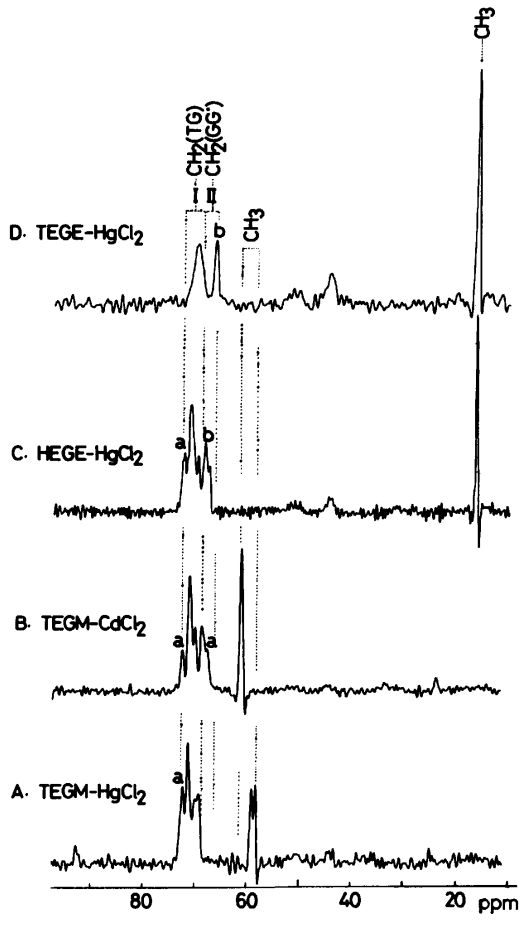

Fig. 2. 75.46 MHz ^{13}C CP-MAS NMR spectra of $HgCl_2$ or $CdCl_2$ complexes with ethylene oxide oligomers in the solid state. The peaks **a** and **b** stand for the peak of carbons neighbored with the terminal methoxyl (or ethoxyl) groups and methylene signal of the terminal ethoxyl groups, respectively.

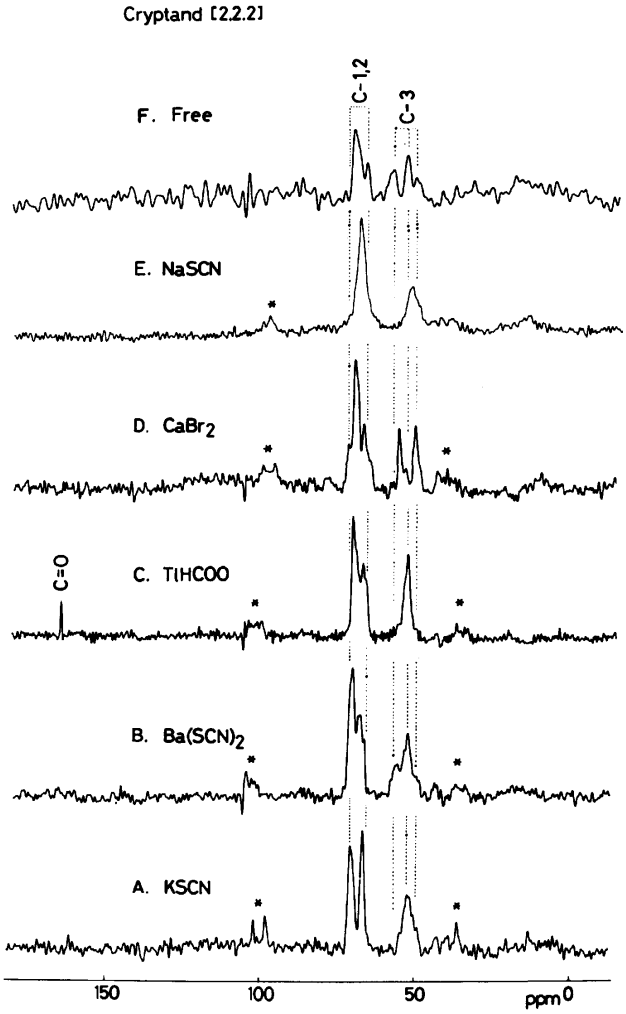

Fig. 3. 75.46 MHz ^{13}C CP-MAS NMR spectra of cryptand [2.2.2] complexed with a variety of metal ions in the solid state. The peaks asterisked are spinning side-bands of the central intense signals.

Figure 3 shows the ^{13}C CP-MAS NMR spectra of cryptand [2.2.2] complexed with a variety of metal ions. Interestingly, the peak-intensities of uncomplexed molecules are very weak as compared with those of the complexed molecules. The assignment of peaks was made on the basis of the solution NMR data. Spectral features are substantially different among complexes. Similarly, the splitting of the C-4,5 signals of cryptand [2.2.1] is quite different between the Na^+ and K^+ complexes, reflecting differences in the molecular conformations as revealed by X-ray diffraction[26] (Fig. 4). By contrast, very little change was observed among NaSCN, $Pb(SCN)_2$, and KSCN complexes with cryptand [2.2] (Table 2). The ^{13}C NMR spectra of uncomplexed [2.2] and [2.2.1] in the solid state turned out to be very difficult to observe, because molecular motion prevents from building up of ^{13}C NMR signals for the former and free molecule is in liquid state for the latter. These ^{13}C chemical shifts in the solid state are summarized in Table 2.

Figures 5 and 6 illustrate the ^{13}C CP-MAS NMR spectra of *cis-syn-cis* and *cis-anti-cis* isomers of dicyclohexano-18-crown-6, respectively, complexed with a variety of metal ions. Again, the peak-intensities of uncomplexed molecules are considerably suppressed as compared with those of the complexed molecules. It is expected that the ^{13}C NMR peaks of the C-1, C-9, C-14, and C-22 carbons of cyclohexane moiety in the solid state are split into a pair of doublet caused by the presence of the ether substituents at the axial (O_{ax}) and equatorial (O_{eq}) positions. The doublet peaks can be readily identified, because the center of the doublet should be very close to the ^{13}C NMR peaks observed in solution state (Table 3). The observation of the doublet peak was possible in solution state upon cooling (−75°)[36] and the magnitude of the separation of peaks (5—7 ppm) is similar to the data observed in the crystalline state (see Table 4). (Note that these doublet peaks are seen for the *cis-syn-cis* and *cis-anti-cis* isomers complexed with $La(NO_3)_3$ even at ambient

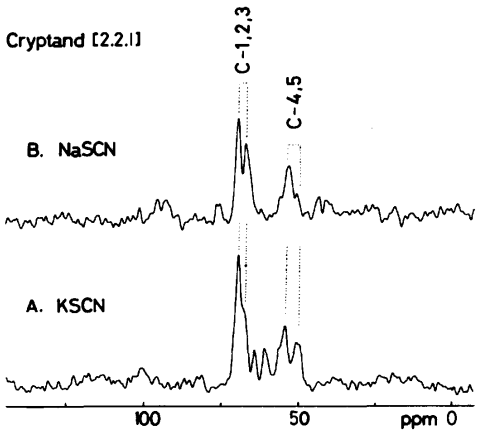

Fig. 4. 75.46 MHz ^{13}C CP-MAS NMR spectra of cryptand [2.2.1] complexed with KSCN (A) or NaSCN (B) in the solid state.

temperature, see Table 3.) For NaBr complex with *cis-anti-cis* isomer,[31] the C-1 and C-14 carbons are ascribed to the O_{eq}, while the C-9 and C-22 are ascribed to the O_{ax} peak. The remaining ^{13}C NMR peaks resonating between 71 and 61 ppm are undoubtedly ascribed to the eight polyether carbons, C-3, 4, 6, 7, 16, 17, 19, 20.

Discussion

Peak-intensities. We found that the peak-intensities of the ^{13}C NMR spectra of uncomplexed cryptands and crown ethers in the solid state are generally weak or suppressed as compared with those of the complexed samples (Figures 3F, 5H, and 6H). In addition, no ^{13}C CP-MAS NMR data are available for uncomplexed cryptands [2.2.1] and [2.2] and ethylene oxide oligomers, because these samples except for cryptand [2.2] complex are in liquid state. The reason why the peak-intensities in the solid state are in many instances suppressed is undoubtedly caused by the presence of plausible molecular motion even in the solid state which might prevent from building up of the ^{13}C NMR signals through cross polarization.[37] In this connection, we were unable to observe ^{13}C CP-MAS NMR spectra of NaI complex with cryptand [2.2.2]. Further, the recording of the ^{13}C CP-MAS NMR spectra of 18-crown-6 complexed with a variety of metal ions was unsuccessful at room temperature because of the reason mentioned above (unpublished finding), although observation of the solid-state high-resolution ^{23}Na NMR signals of sodium complex by a single pulse experiment was not difficult.[38] Therefore, it is probable that the

recording of the ^{13}C CP-MAS NMR spectra at lower temperature is very useful for the samples whose peak-intensities are suppressed at ambient temperature.

Ethylene Oxide Oligomers. Iwamoto[20-23] previously analyzed detailed molecular conformation of TEGM, HEGE, and TEGE complexed with $HgCl_2$ or $CdCl_2$ by X-ray diffraction method. The local conformations of these complexes are summarized in Fig. 7, as defined by sets of torsion angles. Our view is that the ^{13}C NMR signals of particular carbons are primarily influenced by the local conformations

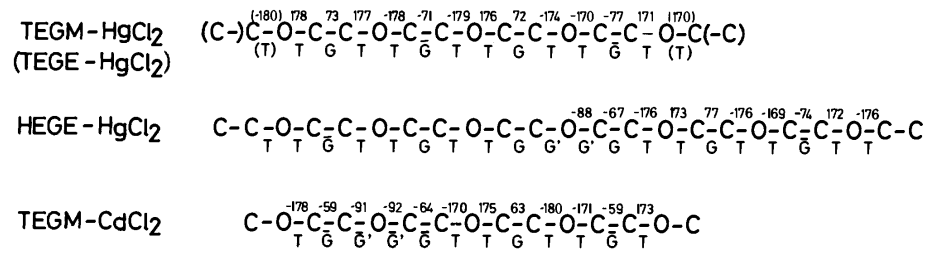

Fig. 7. Conformations of TEGM, TEGE, HEGE complexed with $HgCl_2$ or $CdCl_2$ in the solid state (Data taken from Refs. 20—23). The symbols T, G ($\bar{G}$), and G′ ($\bar{G}'$) stand for the *trans*, *gauche* (minus *gauche*), and torsion angle of about 90°, respectively.

defined by a pair of torsion angles of nearby single bonds. This view has been proven correct for a number of peptides, proteins, carbohydrates, and polysaccharides.[10—19] Accordingly, it is expected that the presence of the following two types of local TG and GG′ conformers in the complexes (Fig. 7) give rise to different types of signals:

$$-O-\overset{T}{\underset{}{C}}H_2-\overset{G}{\underset{}{C}}H_2-O \quad :TG \text{ conformer}$$

$$-O-\overset{G'}{\underset{}{C}}H_2-\overset{G}{\underset{}{C}}H_2-O \quad :GG' \text{ conformer}$$

where the symbols T and G stand for *trans* and *gauche* conformations, respectively, and G′ stands for the torsion angles of about 90°. It is expected from Figure 7 that the relative peak-intensity of the conformer TG with respect to that of the conformer GG′ is 8:0, 8:0, 10:2, and 6:2 for TEGM–$HgCl_2$, TEGE–$HgCl_2$, HEGE–$HgCl_2$ and TEGM–$CdCl_2$, respectively. Therefore, the peaks in regions I and II of the internal CH_2 group in Fig. 2 are ascribed to the TG and GG′ conformers, respectively, as substantiated from the relative peak-intensities of the individual peaks in Table 1 and the population of the TG and GG′ conformers in Fig. 7. Note that the peaks marked by **b** should be ascribed to the methylene carbons of the terminal ethoxyl groups in TEGE and HEGE, although they are within the region II of CH_2 (GG′). In particular, there exists no GG′ conformer in TEGE–$HgCl_2$ complex, as seen from Fig. 7. It is also mentioned that the TG and $T\bar{G}$ conformers gave the identical ^{13}C chemical shifts.

Torsion angles of the |T|, |G|, and |G′| rotamers are 174°±3°, 70°±3°, 90°±2°, respectively (Fig. 7) and the peaks of the TG and GG′ conformers should be observed as two separate single peaks. On the contrary, the TG signals are split into two or three signals as shown in Fig. 2, although the most intense with relative peak-intensity larger than 3 should be ascribed to the carbons at the central core of these oligomers which are not influenced by the presence of the terminal methoxyl or ethoxyl groups. Displacement of peaks from the most intense signals within the peaks of the TG conformers (region I) is less than 1.5 ppm and the positions of the TG conformers are well separated from those of the GG′ conformers which are resonated at higher field by 2 ppm. It is probable that direct effect of metal coordination over the carbon chemical shifts might have some contribution to the splittings of peaks. Such an effect, however, is not larger than 1.5 ppm, if it exists.

Cryptands. The individual assignment of peaks to the C-1 and C-2 in cryptands [2.2] and [2.2.2] and to the C-1, C-2, and C-3 in [2.2.1] in the solid state is difficult,[39] if one considers the maximum separation of the peaks is about 4 ppm which is in the range of the conformation-dependent ^{13}C chemical shifts of single carbon. However, we attempted to relate the ^{13}C chemical shifts of the C-4 plus C-5 and C-3 chemical shifts of cryptands [2.2.1] and [2.2.2], respectively, with the pairs of torsion angles, namely, rotation about N-C-4 and C-4-C-2, and N-C-5 and C-5-C-3 for cryptand [2.2.1] and rotation about N-C-3 and C-3-C-2 for cryptand [2.2.2]. It is now possible to plot the ^{13}C chemical shifts of the C-3 (for cryptand [2.2.2]), and C-4 plus C-5 (for cryptand [2.2,1]) against the torsion angles about N-C-4 and N-C-5 (cryptand [2.2.1]) and N-C-3 (cryptand [2.2.2]),[26—29,40] because the torsion angles C-4-C-2 and C-5-C-3

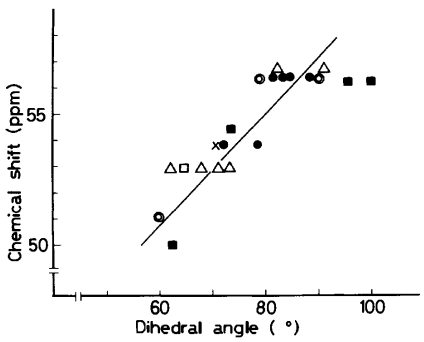

Fig. 8. A plot of C-3 (cryptand [2.2.2]), C-4 plus C-5 (cryptand [2.2.1]) ^{13}C chemical shifts of cryptands [2.2.2] and [2.2.1] against the N-C-3 ([2.2.2]) and N-C-4 and N-C-5 ([2.2.1]) torsion angles. □, K-[2.2.2]; △, Ba-[2.2.2]; ◎, Ca-[2.2.2]; ×, Tl-[2.2.2]; ●, Na-[2.2.1]; ■, K-[2.2.1].

(cryptand [2.2.1]) and C-3-C-2 (cryptand [2.2.2]) do not depart from the standard value (60°±10°) irrespective of the variety of complexes (Fig. 8).[41] Accordingly, it is found that the manner of peak-splittings in the C-3, C-4, and C-5 carbons of cryptands [2.2.2] and [2.2.1] can be well explained in terms of the variation of torsion angles characteristic of nearby local conformations.

Crown Ethers. Dalley *et al.*[42] showed by X-ray diffraction that in the both isomers the cavity surrounded by the six oxygen atoms is elliptical in shape with the two axial oxygen atoms O-21 and O-8 pointing out of the cavity. Consistent with this, the ^{13}C NMR spectra of free *cis-syn-cis* (Fig. 5H) and *cis-anti-cis* (Fig. 6H) are very similar (except for the doubling of the O_{eq} peak in the latter).[43] When NaBr or $Ba(SCN)_2$ salts[44] are complexed with *cis-anti-cis* or *cis-syn-cis* isomers, respectively, macrocyclic conformations are changed either to possess C_i symmetry[31] or to have C_2 symmetry.[44]

Interestingly, the ^{13}C chemical shifts of the O_{ax} and O_{eq} peaks of *cis-anti-cis* isomer are very similar among the eight kinds of complexes, suggesting the presence of similar conformation for cyclohexane moiety as observed for the NaBr complex. However, the conformations of the two cyclohexane moieties are not identical for the complexes with NH_4SCN, KI, $La(NO_3)_3$, and CsSCN, as manifested from the observation of the two pairs of doublets ascribable to the C-1, C-9, C-14, and C-22 carbons, probably reflecting the presence of some steric strain in the ligands. Conformation of two cyclohexane moieties becomes identical when KI_3 is coordinated to *cis-anti-cis* isomer in place of KI, although the ^{13}C NMR profile of polyether moiety remains unchanged. By contrast, the O_{eq} peaks are significantly displaced upfield for *cis-syn-cis* isomer complexed with KI, NaBr, and NH_4SCN (Fig. 5E-G). This finding is readily rationalized by the presence of strong ring strain in cyclohexane rings as a result of coordination at the polyether moiety.

The ^{13}C NMR peaks of the polyether carbons are in many instances split into two peaks, the intensity of which being 3:1 in spite of the presence of eight kinds of carbons. These doublet patterns are modified to yield three peaks (the intensity of which being 2:1:1) for *cis-syn-cis* isomer-$Ba(SCN)_2$ (Fig. 5A), four peaks for *cis-syn-cis* isomer-$La(NO_3)_3$ (Fig. 5B) or seven peaks for *cis-anti-cis* isomer-NH_4SCN complex (Fig, 6D). These observations are consistent with a possibility that local conformation of polyether moiety is C_2 or C_i symmetry, except for *cis-anti-cis* isomer-NH_4SCN complex whose arrangement of polyether moiety is highly distorted. It is interesting to note that the ^{13}C chemical shifts of the highest peak-intensity at 69-71 ppm in the solid state are not strongly varied among complexes with a variety of metal ions and are very close to those observed in solution state (70.8±0.4 ppm) (Table 3). Obviously, these peaks are straightforwardly ascribed to the carbons of the TG conformers in view of their chemical shifts as compared with those of ethylene oxide oligomers. This view is supported by X-ray diffraction study of *cis-anti-cis* isomer of NaBr complexes which is the only available detailed data of dicyclohexano-18-crown-6 complex: all of the torsion angles about the polyether moiety are within the typical TG conformer.[31]

Nevertheless, the upper peak of NaBr-*cis-anti-cis* isomer at 66.3 ppm should be ascribed to the TG conformer, although this position is rather high as compared with that of ethylene oxide oligomers. This may be caused by that the C-3, C-7, C-16, and C-20 peaks are not completely free from the substituent effect of cyclohexane rings. It is emphasized that the ^{13}C chemical shifts of peaks with lower peak-intensities vary with variety of metal ions, depending also on the conformation of the polyether moiety. In particular, the largest upfield displacement of peaks is 7.0 ppm for $La(NO_3)_3$-*cis-anti-cis* isomer. The observation of peaks at such a higher field region (>67 ppm) could be ascribed to the presence of the GG and TT conformers as seen for NaSCN-18-crown-6[45] or uncomplexed 18-crown-6.[46] Further study, however, is required to prove this view.

Conformation in Solution State. It is now possible to examine whether or not the conformations achieved in the solid state are also retained in solution by comparing the ^{13}C chemical shifts of solution with those of the solid state. This kind of information is closely related with stability of complexes in solution, because any conformational change of ligand molecules would lead to decomposition of complexes. It is worthwhile to note that metal complexes with cryptands are generally many orders of magnitude more stable than those with crown ethers.[8,9] In particular, the association constant of the potassium ion both in aqueous or methanol solutions decreases in the following order: [2.2.2]>[2.2.1]>*cis-syn-cis*>*cis-anti-cis*>[2.2]. In the case of the sodium ion, [2.2.1]>[2.2.2]. Consistent with this, [2.2.2] and [2.2.1] complexed with a variety of metal ions maintain their overall conformations achieved in the solid even in solution state, although conformational fluctuation about the N-C-3, N-C-4 or N-C-5 is evident as seen from the time-averaging process in the ^{13}C NMR signals, as judged from the similarity of the ^{13}C chemical shifts between the solid and solution. On the contrary, the presence of ring-puckering in two cyclohexane rings of the crown ethers as seen in solution state is responsible for reduction of stability and selectivity of complexes. Nevertheless, it appears that no drastic conforma-

tional change occurs between the solid and solution for [2.2] as inferred from Table 2, although association constant of this molecule is usually lower than crown ethers.[8,9] Obviously, consideration of steric requirement of ligand molecules in adapting to different metal ions is also very important to explain relative stability of complexes.

Concluding Remarks

We have showed that the ^{13}C NMR peaks of backbone carbons of ethylene oxide oligomers, crown ethers and cryptands exhibit substantial amounts of displacement of peaks (up to 6 ppm) upon complex formation with a variety of metal ions, as determined by cross polarization-magic angle spinning method. These changes of the ^{13}C chemical shifts are mainly ascribed to conformational changes induced by metal-binding as revealed by X-ray diffraction and can be utilized as intrinsic indicators of conformational changes. Analysis of ^{13}C NMR spectra in the solid state can be conveniently performed, when conformational features by X-ray diffraction studies are available. This approach is also suitable for comparative study of conformational changes of these ionophores induced by complexation with a variety of metal ions, even if detailed X-ray diffraction data are unavailable. Further, it is easily evaluated on the basis of the conformation-dependent ^{13}C chemical shifts whether or not the conformations of these ionophores achieved in the crystalline state is retained in solution state.

39) The ^{13}C NMR peaks of cryptand [2.2.1] in solution were already assigned individually (E. Schmidt, J.-M. Tremillon, J.-P. Kintzinger, and A. I. Popov, *J. Am. Chem. Soc.*, **105**, 7563 (1983).

40) D. Moras, B. Metz, and R. Weiss, *Acta Cryst.*, **B29**, 383 (1973).

41) In this treatment, we utilized X-ray diffraction data of the KI complex instead of the KSCN complex whose X-ray diffraction data are unavailable, although some of anions would alter the conformation of host molecules as seen in the case of KI and KI_3 complexes with *cis-anti-cis* isomer (Fig. 6E and 6B). It is probable, however, that the anion does not affect the conformation of host molecule as far as it is well separated from and not directly coordinated to the metal ion

as in the present situation (K^+-[2.2.2] complex).

Studies of the Hydrous Niobium(V) Oxide Ion Exchanger. III. The Effect of Heat Treatment

Yasushi INOUE,* Hiromichi YAMAZAKI, and Yuzo MATSUDA
Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980
(Received March 18, 1985)

The effects of heat treatments in air have been studied regarding the properties of a hydrous niobium(V) oxide ion exchanger in H^+ form. The exchanger lost 17 per cent of the initial ion-exchange capacity when it was heat-treated at 110 °C; thereafter the exchange capacity decreased progressively with temperature until 400 °C, at which point it retained about a half of the initial value. The exchanger began to crystallize into γ-phase at a temperature between 450 to 500 °C where the capacity disappeared. The γ-phase transformed to α-phase at a temperature above 800 °C. An examination of the uptake curves showed that less-acidic exchange sites were more resistant than more-acidic sites to heat treatment. The existence of three kinds of water in the exchanger (adherent, zeolitic, and bound) has been suggested on the basis of the ion-exchange capacity, the thermal-analysis curves, and water recovery brought about by humidifying.

Previous papers in this series described detailed studies regarding the synthesis, the acid-base properties, and the ion-exchange selectivity for various cations of a hydrous niobium(V) oxide ion exchanger.[1,2] The study on the effect of heat treatment regarding ion-exchange properties is also important, since most inorganic ion exchangers are expected to be superior to ion-exchange resins regarding thermal stability. As the hydrous niobium(V) oxide has an amorphous structure, this investigation may be helpful in considering the structure of the compounds by adding some strong circumstantial evidence: The relation between the ion-exchange capacity and the thermal behavior of water in the compound. As to the effect of thermal treatment, there have been many studies regarding the composition and the physical properties,[3-8] while there have been few reports on the ion-exchange properties.

The present paper describes the effect of heat treatment in air with regards to the composition and the ion-exchange properties of hydrous niobium(V) oxide. Furthermore, a classification of various water forms present in the exchanger is discussed, and the thermal stability of the material is compared with other hydrous oxides.

Experimental

Reagents and Apparatus. The hydrous niobium(V) oxide ion exchanger was prepared by pyrohydrolyzing a $NbCl_5$ solution, as has been previously described.[1,2] A thermal analysis was undertaken using a Shimadzu micro thermal analyzer, Model DT-20 B, connected to a thermal balance, Model TGC-20 H, for thermogravimetric analysis (TGA), and a high-temperature sample holder, Model MDH-20, for differential thermal analysis (DTA). The reference material for DTA was α-alumina. The measurement was performed in air at a heating rate of 10 °C min^{-1}.

X-Ray diffraction patterns were obtained by means of a Shimadzu X-ray diffraction unit, Model XD-3A, using Ni-filtered Cu $K\alpha$-radiation. The diffraction angle was calibrated using silicon powder.

Heat Treatment. About 8 g of the exchanger in H^+ form was heated in air to a constant weight at a constant temperature, which was controlled within an accuracy of 1% using an automatic temperature controller (Chino Workers, Ltd.). After cooling, the sample was immersed in water overnight, followed by the humidifying operation described previously.[1,2]

The other experimental procedures were the same as those described in the preceeding papers.

Results and Discussion

Effect of Heat Treatment on the Composition of Hydrous Niobium(V) Oxide. Figure 1 shows the relation between the water content immediately after the heat treatment (open mark) and that of the exchanger subjected to the humidifying operation

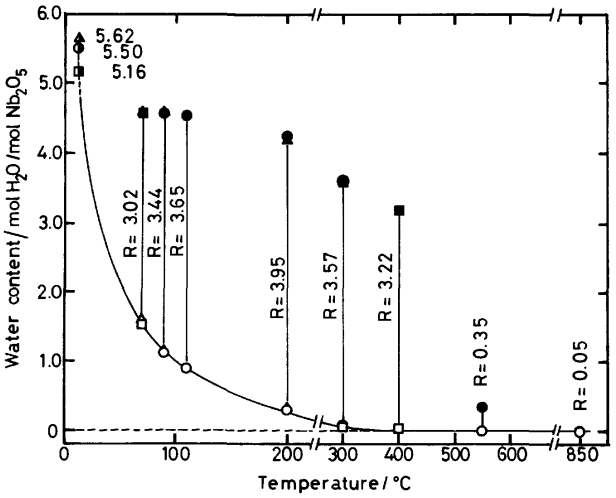

Fig. 1. Change in composition.
▲◑■: Sample R.T. Open marks: Immediately after heat treatment. Filled marks: Immersed in water, dried over saturated NaCl solution. R: Water recovery.

(filled mark). It should be noted that the water content was normalized to the number of moles of water per 1 mole of Nb_2O_5. In the case of the exchanger without heat treatment (designated as sample R.T.), there existed a fluctuation in the water content by an amount of 0.5 mol H_2O/mol Nb_2O_5. This fluctuation is insignificant in considering the effect of the heat treatment since the heat treatment, even at a temperature as low as 70 °C, led to the same composition irrespective of the original values. The amount of water contained in the exchanger immediately after the heat treatment at 70 °C was reduced to about 30% of the original value; then, it gradually decreased with temperature, and finally reached zero at 400 °C. This result is compatible with Lapitskii's observation that the water content of 6.93 mol H_2O/mol Nb_2O_5 at room temperature decreased to 1.79 mol H_2O/mol Nb_2O_5 at 110 °C and to almost zero at 400 °C, in spite of the difference in the experimental conditions.[4]

The following relation holds between the water content immediately after the heat treatment and that of the exchanger subjected to the humidifying operation. For the exchangers heated up to 400 °C, 3 to 4 mol of water per 1 mol of Nb_2O_5 were recovered, while for the samples heated over 550 °C, water was only slightly recovered by humidifying. Figure 2 shows the X-ray diffraction patterns of the samples subjected to the humidifying operation. The samples heated up to 400 °C, together with the sample R.T., have poor crystallinity. Over the range of 450—500 °C many peaks characteristic of γ-niobium(V) oxide, the low temperature phase of the compound reported by Brauer[3] and by Holtzberg *et al.*,[5] appeared and sharpened with increasing temperature, indicating an enhanced crystallization; the material crystallized completely in the γ-phase at a temperature between 600 to 650 °C. When the crystals were heated at a temperature above 800 °C, they were transformed to the α-phase. Therefore, the sudden decrease of water recovery at a temperature above 400 °C may be associated with the crystallization of the exchanger; this brings about a decrease in the space which can accommodate water molecules.

Change in the Ion-exchange Capacity. In order to examine the effect of the heat treatment on the acid-base property of the exchanger, the uptake curves for Na^+ were measured as a function of the pH. The results are shown in Fig. 3. In the case of the exchangers heated up to 400 °C, the dissolution of a part of the exchanger in strong basic solutions limits the maximum cation-exchange capacity to the value at around pH 10.5. For the samples heated up to 110 °C, the decreases in the ion-exchange capacity were 0.06 and 0.13 mol Na^+/mol Nb_2O_5, respectively, at pH 7.6 (breaking point in the curve) and at pH 10; hence, nearly the same amount of exchange sites was destroyed in the pH ranges of either side of the breaking point. When the exchangers were heat-treated at 200 °C or higher, the capacity in a pH range lower than the breaking point decreased with

Table 1. Changes in ion-exchange capacity and water content

Temp of treatment °C	Difference in A[1] exchange capacity mol Na^+/mol Nb_2O_5	Difference in A/2[2] water content mol H_2O/mol Nb_2O_5	Difference in B[3] water content mol H_2O/mol Nb_2O_5	2B/A
70	0.14±0.01	0.07 ±0.01	0.60±0.04	9±2
200	0.24±0.01	0.12 ±0.01	1.27±0.04	11±1
300	0.34±0.01	0.17 ±0.01	1.58±0.04	9±1
400	0.39±0.01	0.19_5±0.01	1.93±0.04	9±1

1) Ion-exchange capacity at pH 10.0; difference between sample R.T. and sample thermally treated. 2) Difference in capacity was converted into that in water content. 3) Difference in water content between sample R.T. and heat-treated sample subjected to the humidifying operation.

the temperature, while in a pH range higher than that point, the curves were parallel to those for the samples heated at a temperature lower than 110 °C; the main part of the exchange sites, destroyed by the heat treatment at a temperature higher than 110 °C, was in the pH region lower than the breaking point. The exchange sites were completely destroyed at 550 °C. The sample heated at 850 °C exhibited no uptake of Na^+ throughout the pH region examined. From the above observations it is considered that the resistance to thermal decomposition is greater for less-acidic than for more-acidic ion-exchange sites.

Table 1 shows the relation between the decrease in ion-exchange capacity at pH 10 and that in the water content of the heat-treated samples subjected to the humidifying operation. Symbols A and B, respectively, are referred to the difference in the exchange capacity and in the water content between the sample R.T. and the heat-treated exchanger. As one mole of water should be liberated by a condensation of two moles of the OH groups which may act as ion-exchange sites, half of the difference in the ion-exchange capacity (A) is equivalent to a decrease of the water content due to the condensation of the exchange sites (A/2). As is shown in the right column in Table 1, the ratio of the loss of total water to the loss of water that originated from the exchange sites (OH groups), by heat treatment, 2B/A, did not change up to 400 °C. Hence, a constant amount of water molecules is considered to be fixed in the exchanger by OH groups through some kind of interaction such as a hydrogen bond (bound water); the irreversible condensation of the OH groups, which cannot be recovered by the humidifying operation, is accompanied by the irreversible release of water.

Thermal Analysis of the Samples. Figure 4 shows the TGA and DTA curves for the samples subjected to the humidifying operation. The TGA curves of the samples heat-treated up to 400 °C are similar to those of the sample R.T.; the sample lost weight abruptly up to around 100 °C and then,

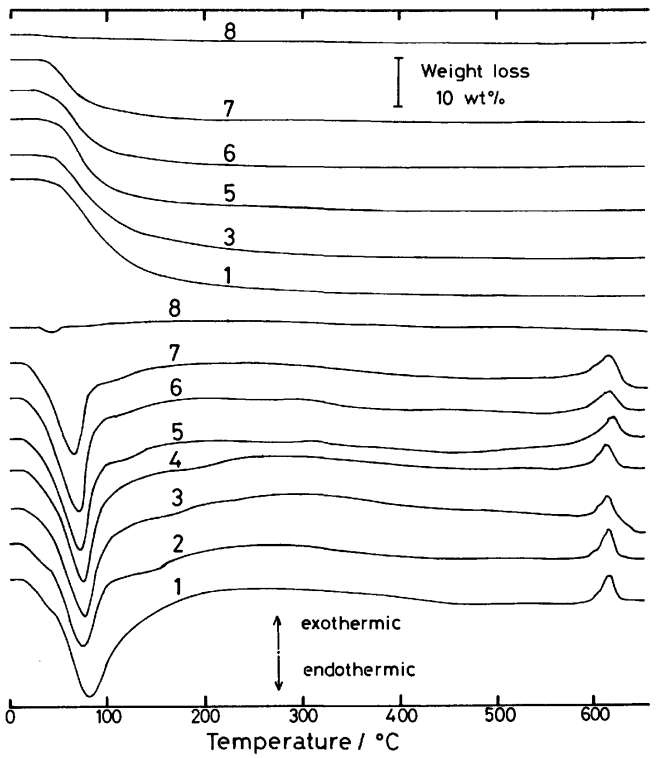

Fig. 4. TGA and DTA curves (Heat treatment, followed by humidiation).
Temperature of treatment; 1: R.T., 2: 70 °C, 3: 90 °C, 4: 110 °C, 5: 200 °C, 6: 300 °C, 7: 400 °C, 8: 550 °C.

gradually, up to about 600 °C, where the weight became constant. In contrast, the sample heated at 550 °C showed little weight loss up to 600 °C. In the DTA curves, large endothermic peaks appearing in the range lower than 200 °C sharpened as the temperature for heat treatment became higher. The position of the peak, observed at 70 to 80 °C for the samples heated below 400 °C, shifted to 45 °C and its area became very small when the sample was heated at 550 °C. Apparently, this observation is compatible with the changes in both the exchange capacity and

Table 2. Effect of heating time on the composition of sample

Heat treatment		Composition	
Temperature	Time	A	B
°C	h	mol H_2O/mol Nb_2O_5	
200	12	0.28±0.01	4.23±0.03
	72	0.26±0.01	4.15±0.03
400	12	0.02±0.01	3.22±0.03
	72	0.02±0.01	3.19±0.03

the degree of the recovery of water, with the temperature for heat treatment, if the peak is considered to correspond mainly to the release of water recoverable by humidifying, that is, a certain kind of zeolitic water. The shoulders observed at the high- and the low temperature sides, respectively, of the peak for the samples heat-treated at temperatures below 200 °C are attributable to the bound water liberated by the condensation of the hydroxyl groups and to the adherent water in the exchanger matrix. For the samples heat-treated below 400 °C, a small exothermic peak was observed at 605 °C; this peak can be assigned to crystallization. This temperature for crystallization is higher, by 100 °C, than that expected from the results in Fig. 2. This may be due to thermally non-equilibrium conditions in DTA measurements; incidentally, the exothermic peak shifted from 610 °C to 574 °C when the heating rate was decreased from 15 °C/min to 2 °C/min. Two exothermic peaks were observed at 375 °C and 545 °C by Sathyanarayana and Patel[6] and at 470 °C and 609 °C by Lapitskii.[4] In the present experiment, however, no exothermic peak was observed in the temperature region below 500 °C.

It is considered from above observations that the samples heated at temperatures up to 400 °C, keep the network structure essentially unchanged and, thereby, recover nearly a constant amount of the zeolitic water and some amount of the bound water, when humidified. When the exchanger is heat-treated at 550 °C or higher, the crystallization proceeds to an extreme and thereby almost all the water is not recovered by humidifying.
