
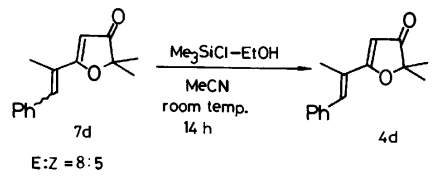
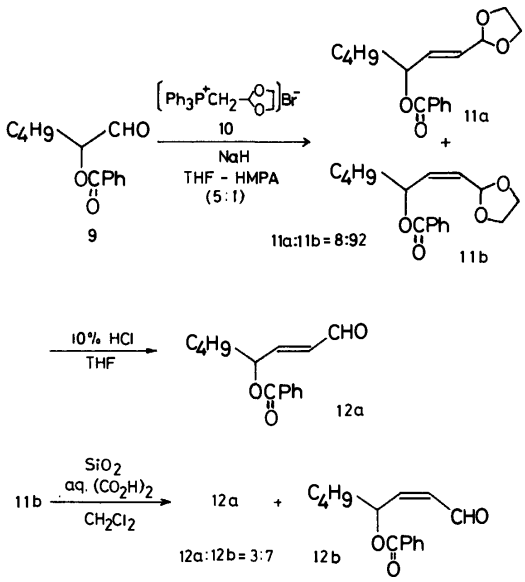


Scheme 3.



Scheme 4.

ratio of **3a—e** and its participation in the geometry of the resulting **4a—e**. We confirmed that **3d** was ca. 1 : 1 diastereomeric mixture according to the ^{1}H NMR signals due to C-4 proton (δ 5.15 and 5.31), while the isomeric ratios of **3a—c** and **3e** were not clear by ^{1}H NMR analysis. Therefore, the initially formed dehydration product **7** should be a E, Z mixture. The (Z)-isomer of **7** would be converted to a thermodinamically more stable **4** at the acidic conditions[9] via the cationic intermediate **8**. The feasibility of the isomerization was exemplified by using a 8 : 5 E,Z mixture of **7d**,[4] which was readily converted to **4d** by the treatment with Me_3SiCl and EtOH in acetonitrile (Scheme 3).

As a preliminaly experiment for the synthetic study of a related natural product, we wished to confirm the applicability of the above reaction sequence to the stereospecific synthesis of 5-[(1*E*, 3*E*)-5-(benzoyloxy)-1-methyl-1,3-nonadienyl]-2,2-dimethyl-3(2*H*)-furanone (**14**) (Scheme 5) and its (1E, 3Z)-isomer **17** (Scheme 6). For the purpose, a stereoselective synthesis of the starting (*E*)- and (*Z*)-4-(benzoyloxy)-2-octenal (**12a** and **12b**) (Scheme 4) and their transformation to **14** and **17** with retention of the geometry are required.

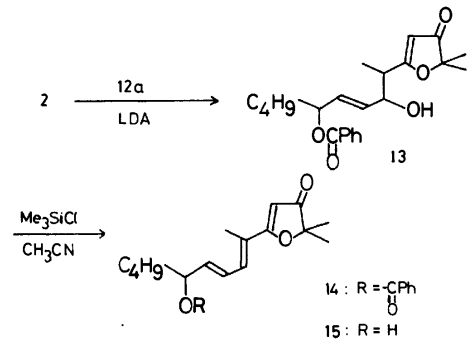
The Wittig reaction of 2-(benzoyloxy)hexanal (**9**)[10] with (1,3-dioxolan-2-ylmethyl)triphenylphosphonium bromide (**10**)[11] in the presence of NaH in THF-HMPA (5 : 1) gave the (Z)-adduct **11b** stereoselctively (E : Z=8 : 92) in 48% yield (Scheme 4). The yield of **11b** was slightly increased to 52% by carring out the reaction in DMF-HMPA (3 : 1), while the yield of the (E)-isomer **11a** was also raised to 19%.

The treatment of the 8 : 92 mixture of **11a** and **11b** with 10% aqueous HCl-THF (1 : 1) afforded the (*E*)-aldehyde **12a** exclusively in 96% yield as a result of the isomerization Z to E. On the other hand, the hydrolysis of the (*Z*)-acetal **11b**, which was isolated by preparative TLC, with silica gel and 5% aqueous oxalic acid[12] in dichloromethane gave the (*Z*)-aldehyde **12b** (57% yield) together with the (E)-isomer **12a** (23% yield). They were separated chromatographycally. Further attempts to increase the ratio of **12b** by using other hydrolytic conditions such as *p*-TsOH[13] or (±)-10-camphorsulfonic acid monohydrate in acetone·H_2O resulted in unfruitfullness.

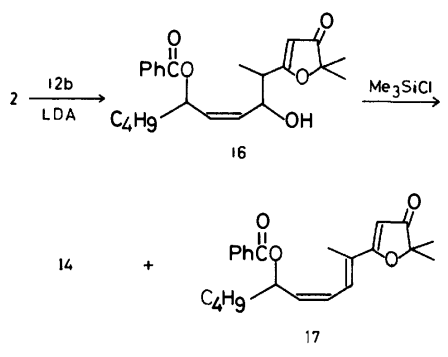
The reaction of lithium enolate of **2** with **12a** gave the aldol product **13** (54% yield). The dehydration with Me_3SiCl afforded **14** (61% yield) and its hydrolyzed product **15** (29% yield) under the acidic conditions (Scheme 5). The geometry of newly formed olefinic double bond of **14** and **15** was assigned to be E by the comparison of their ^{13}C NMR spectral data with those of **3a—e** (Table 2).

A similar aldol reaction of **2** with **12b** gave **16** (54% yield) with retention of the Z geometry (Scheme 6). However, at the subsequent dehydration step, the geomerty was partly inverted to give a 53 : 47 mixture of **14** and **17** (57% yield), which were separated by preparative HPLC. The E or Z geometry of the C-3 and C-4 double bond of the side chain is clearly distinguishable by the analysis of the coupling constants in the ^1H NMR spectra [**14**: $J_{3,4}$=14.5 Hz for E; **17**: $J_{3,4}$=12.0 Hz for Z]. Furthermore, in the ^{13}C NMR spectra (Table 2), the allylic carbon bearing a benzoyloxy group of the (Z)-isomer **17** appeared at 71.3 ppm, which was highly shielded as compared with that of the (E)-isomer **14** (74.7 ppm).

As described above, the present reaction offers a convenient and highly stereoselective synthetic method of 5-[1-(*E*)-alkenyl]-3(2*H*)-furanones and would be useful for other related systems.



Scheme 5.



Scheme 6.

Experimental

IR specra were measured with a JASCO A-102 spectrometer. ^1H NMR spectra (60 MHz) were measured with a JEOL JNM PMX 60 SI spectrometer. Both ^1H NMR (100 MHz) and ^{13}C NMR (25 MHz) spectra were taken on a JEOL FX-100 spectrometer using Me_4Si as an internal standard. GLPC analysis was done by using a Hitachi 163 gas chromatograph. HPLC analysis was carried out by using a Yanagimoto L-2000 high-performance liquid chromatograph. Elemental analyses were performed by Eiichiro Amano of our laboratory with a Yanagimoto MT-3 CHN recorder.

Hydroxy 3(2*H*)-furanones **3a—e**, **13**, and **16** were prepared from **2** and appropriate aldehydes by the procedure similar to that reported by Smith et al.[4] Sectral and analytical data of the new compounds **3c**, **13**, and **16** are shown.

5-(1,3-Dimethyl-2-hydroxybutyl)-2,2-dimethyl-3(2*H*)-furanone (3c): 28% yield; mp 113.5—114 °C (CCl_4); IR (KBr) 3400, 1680, 1580 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.95, 0.98 (each with 3H, d, J=6 Hz), 1.26 (3H, d, J=7 Hz), 1.35 (6H, s), 1.73 (1H, m), 2.30 (1H, br s), 2.79 (1H, m), 3.54 (1H, m), 5.38 (1H, s). Found: C, 67.64; H, 9.42%. Calcd for $C_{12}H_{20}O_3$: C, 67.89; H, 9.50%.

General Procedure for the Dehydration of 5-(2-Hydroxyalkyl)-3(2*H*)-furanone. To a solution of **3** (0.50 mmol) in acetonitrile (1 ml) was added chlorotrimethylsilane (136 mg, 1.25 mmol) through a syringe. The mixture was stirred at room temperature for the time indicated in Table 1. After the reaction was quenched by addition of water, the organic layer was extracted with ether, washed with aqueous sodium hydrogencarbonate and brine, dried ($MgSO_4$), filtered, and then concentrated under reduced pressure. The residual oil was purified by preparative TLC (Merck, Kieselgel PF_{254}, hexane-acetone, 3 : 1) to give **4** in the yield as shown in Table 1. The IR and ^1H NMR spectra of **4a—e** were consistent with those reported.[4,5] The spectral and analytical data of **4c**[5,14] are described below.

5-(1,3-Dimethyl-1-butenyl)-2,2-dimethyl-3(2*H*)-furanone (4c): Mp 68.5—69 °C (hexane); IR (KBr) 1695, 1640, 1560, 1175 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.06 (6H, d, J=7 Hz), 1.39 (6H, s), 1.89 (3H, d, J=1.3 Hz), 2.70 (1H, m), 5.47 (1H, s), 6.40 (1H, dq, J=9 Hz, and 1.3 Hz). Found: C, 74.36; H, 9.25%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%.

Isomerization of 7d to 4d. Chlorotrimethylsilane (33 mg, 0.3 mmol) was added to a mixture of **7d** (E: Z=8 : 5)[4] (29 mg,

0.13 mmol), EtOH (14 mg, 0.3 mmol), and acetonitrile (1 ml). After being stirred for 14 h at room temperature, the mixture was diluted with ether, washed with aqueous sodium hydrogencarbonate and water, dried over $MgSO_4$, and filtered. Removal of the solvent left **4d** (28 mg, 97%) with sufficient purity.

(*Z*)-1-Butyl-3-(1,3-dioxolan-2-yl)-2-propenyl Benzoate (11b). To a cooled mixture (0 °C) of NaH (108 mg, 4.5 mmol), THF (7 ml), and HMPA (2 ml), was added **10**[11] (2.02 g, 4.7 mmol) quickly. The mixture was stirred at room temperature for 40 min, and then cooled to −78 °C. A solution of 2-(benzoyloxy)hexanal **9**[10] (560 mg, 2.55 mmol) in THF (3 ml) was introduced through a syringe. The mixture was allowed to warm to room temperature gradually and stirred for 2 d. After the reaction was quenched by addition of water, the organic layer was extracted with hexane-ether (1 : 1), washed with brine, dried ($MgSO_4$), filtered, and then concentrated. The precipitated Ph_3P=O was removed by filtration with suction. The crude product was separated by preparative TLC (hexane-ether, 4 : 1) to give **11a** (R_f 0.22—0.30, 29 mg, 4% yield) and **11b** (R_f 0.30—0.42, 355 mg, 48% yield). **11a**: IR (neat) 1720, 1660, 1600 cm^{-1}. ^1H NMR (CCl_4) δ=0.7—2.0 (9H, m), 3.85 (4H, m), 5.1—6.1 (4H, m), 7.1—8.1 (5H, m); ^{13}C NMR ($CDCl_3$) δ=13.3 (q), 22.5 (t), 27.3 (t), 34.0 (t), 65.0 (t), 73.5 (d), 103.0 (d), 128.0 (d), 128.4 (d), 129.6 (d), 130.4 (s), 132.9 (d), 134.3 (d), 165.7 (s). Found: C, 70.15; H, 7.62%. Calcd for $C_{17}H_{22}O_4$: C, 70.32; H, 7.64%. **11b**: IR (neat) 1720, 1680, 1600 cm^{-1}; ^1H NMR (CCl_4) δ=0.7—2.0 (9H, m), 3.85 (4H, m), 5.2—6.0 (4H, m), 7.1—8.1 (5H, m); ^{13}C NMR ($CDCl_3$) δ=13.9 (q), 22.5 (t), 27.1 (t), 34.5 (t), 65.0 (t), 70.8 (d), 99.2 (d), 128.9 (d), 129.1 (d), 129.6 (d), 130.5 (s), 132.8 (d), 134.3 (d), 165.8 (s). Found: C, 70.11; H, 7.58%. Calcd for $C_{17}H_{22}O_4$: C, 70.32; H, 7.64%.

The reaction in DMF-HMPA was carried out in a similar way.

(*E*)-4-(Benzoyloxy)-2-octenal (12a). An 8 : 92 mixture of **11a** and **11b** (580 mg, 2 mmol), 10% HCl (3 ml), and THF (3 ml) was stirred for 3 h at room temperature. The organic layer was extracted with ether, washed with aqueous sodium hydrogen carbonate and brine, dried ($MgSO_4$), filtered, and then concentrated. The residual oil was purified by column chromatography (Silica gel 60, Katayama Chemical, Co. Ltd., hexane-acetone, 10 : 1) to give **12a** (470 mg, 96% yield): IR (neat) 1720, 1690, 1640, 1600 cm^{-1}; ^1H NMR (CCl_4) δ=0.8—2.1 (9H, m), 5.65 (1H, m), 6.13 (1H, dd, J=15, 8 Hz), 6.70 (1H, dd, J=15, 5 Hz), 7.3—8.1 (5H, m), 9.42 (1H, d, J=8 Hz); ^{13}C NMR ($CDCl_3$) δ=13.9 (q), 22.5 (t), 27.2 (t), 33.5 (t), 72.8 (d), 128.5 (d), 129.7 (d), 131.5 (d), 133.4 (d), 154.1 (d), 165.6 (s), 193.0 (d). Found: C, 73.25; H, 7.43%. Calcd for $C_{15}H_{18}O_3$: C, 73.15; H, 7.57%.

(*Z*)-4-(Benzoyloxy)-2-octenal (12b). A mixture of silica gel (Merck Kieselgel PF_{254}, 5.0 g), 5% aqueous oxalic acid[11] (0.5 ml), and dichloromethane (8 ml) was stirred vigorously. To this was added a solution of **11b** (542 mg, 1.90 mmol) in dichloromethane (2 ml) and the resulting mixture was stirred for 6 h at room temperature. The mixture was neutralized by addtion of aqueous sodium hydrogencarbonate powder, dried ($MgSO_4$), filtered and then concentrated under reduced pressure. The residue was purified by preparative TLC (hexane-ether, 3 : 1) to give **12b** (R_f 0.57—0.67, 261 mg, 57% yield) and **12a** (R_f 0.38—0.54, 108 mg, 23% yield). **12b**: IR (neat) 1720, 1685, 1615, 1600 cm^{-1}; ^1H NMR (CCl_4) δ=0.7—2.1 (9H, m), 5.74—6.63 (3H, m), 7.1—8.2 (5H, m), 10.08 (1H, d, J=7 Hz); ^{13}C NMR ($CDCl_3$) δ=13.8 (q), 22.4 (t), 27.2 (t), 34.4 (t), 70.4 (d), 128.5 (d), 194.6 (d), 130.0 (s), 130.5 (d), 133.2 (d), 147.5 (d), 165.8 (s), 190.6 (d). Fond: C, 73.23; H, 7.57%. Calcd for $C_{15}H_{18}O_3$: C, 73.15; H, 7.37%.

5-[(*E*)-5-(Benzoyloxy)-2-hydroxy-1-methyl-3-nonenyl]-2,2-dimethyl-3(2*H*)-furanone (13). This compound was prepared in a manner similar to Smith's method[4] in 54% yield. **13**: IR (neat) 3450, 1720, 1700, 1660, 1580 cm^{-1}; ^1H NMR (CCl_4) δ=0.7—2.0 (18H, m), 2.78 (1H, m), 3.70 (1H, br s, OH), 4.36 (1H, m), 5.40 (1H, s), 5.4—5.9 (3H, m), 7.2—8.1 (5H, m). Found: C, 71.29; H, 7.91%. Calcd for $C_{23}H_{30}O_5$: C, 71.48; H, 7.82%.

5-[(1*E*,3*E*)-5-(Benzoyloxy)-1-methyl-1,3-nonadienyl]-3(2*H*)-furanone (14). A similar reaction of **13** (77 mg, 0.20 mmol) with Me_3SiCl (55 mg, 0.50 mmol) was done for 4 h at room temperature. The crude product was separated by preparative TLC (hexane-acetone, 3 : 1, developed twice) gave **14** (R_f 0.34—0.41, 45 mg, 61% yield) and **15** (R_f 0.41—0.46, 15 mg, 29% yield). **14**: IR (neat) 1720, 1695, 1635, 1605, 1550 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.7—2.0 (15H, m), 2.00 (3H, d, J=1.0 Hz), 5.57 (1H, s), 5.60 (1H, m), 6.13 (1H, dd, J=14.5, 6.9 Hz, C-4), 6.68 (1H, dd, J=14.5, 11.3 Hz, C-3), 7.04 (1H, dd, J=11.3 Hz, 1.0 Hz, C-2), 7.3—8.2 (5H, m). Found: C, 74.88; H, 7.79%. Calcd for $C_{23}H_{28}O$: C, 74.79; H, 7.66%. **15**: IR (neat) 3500, 1695, 1630, 1605, 1550 cm^{-1}: ^1H NMR (CCl_4) δ=1.33 (6H, s), 0.8—1.9 (9H, m), 2.01 (3H, s), 4.37 (1H, m), 5.45 (1H, s), 5.8—7.1 (3H, m). Found: C, 72.88; H, 9.32%. Calcd for $C_{16}H_{24}O_3$: C, 72.69; H, 9.15%.

5-[(*Z*)-5-(Benzoyloxy)-2-hydroxy-1-methyl-3-nonenyl]-2,2-dimethyl-3(2*H*)-furanone (16): 54% yield; IR (neat) 3450, 1720, 1700, 1580 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.7—2.0 (18H, m), 2.84 (1H, m), 3.70 (1H, br s, OH), 4.78 (1H, m), 5.46 (1H, s), 5.4—6.0 (3H, m), 7.2—8.1 (5H, m). Found: C, 71.63; H, 7.90%. Calcd for $C_{23}H_{30}O_5$: C, 71.48; H, 7.82%.

Compounds 14 and 17. The dehydration of **16** (72 mg, 0.19 mmol) with Me_3SiCl (51 mg, 0.47 mmol) was done for 2 h at room temperature in the usual way. The crude product was purified by preparative TLC (hexane-acetone, 3 : 1, developed twice) to give a mixture of **14** and **17** (R_f 0.51—0.56, 39 mg, 57% yield). The product ratio of **14** and **17** was determined to be 53 : 47 based on their weights isolated by using preparative HPLC (Yanagimoto column SA-I; 6 mmϕ×250 mm; hexane-ethyl acetate-ethanol, 100 : 2 : 1; 1.0 ml min^{-1}), which showed two peaks due to **14** (retention time: 29.2 min, 19 mg) and **17** (33.5 min, 17 mg). **17**: IR (neat) 1720, 1700, 1635, 1605, 1555 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.7—2.0 (15H, m), 2.0 (3H, s), 5.63 (1H, s), 5.95 (2H, m), 6.28 (1H, dd, J=12.0, 10.1 Hz, C-3), 7.3—8.2 (6H, m, phenyl and C-4). Found: C, 74.85; H, 7.71%. Calcd for $C_{23}H_{28}O_4$: C, 74.97, 7.66%.

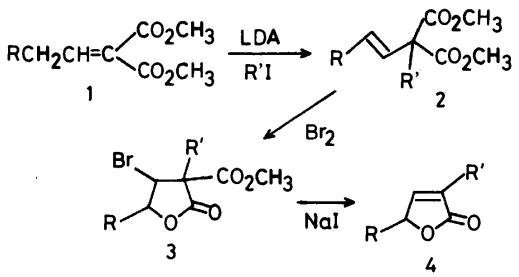
A New Method for the Synthesis of 3,5-Disubstituted 2(5*H*)-Furanones. Synthesis of (±)-Acarenoic Acid

Sadao Tsuboi,* Hiroshi Wada, Koichi Muranaka, and Akira Takeda
Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700
(Received February 26, 1987)

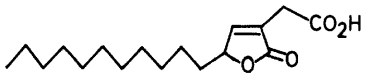
Heating of 3,5-disubstituted 4-bromo-3-methoxycarbonyldihydro-2(3*H*)-furanones with NaI in 3-pentanone gave 3,5-disubstituted 2(5*H*)-furanones in 55.8—93.3% isolated yields. A total synthesis of (±)-acarenoic acid was established in 33% overall yield via 4 steps.

The γ-lactone ring system is a common feature in a wide variety of natural products, and a number of methods are available for its construction.[1] Especially, the synthesis of unsaturated γ-lactones has attracted the attention of organic chemists because of their biological activities and versatile utilization in organic synthesis.[2] In connection with our continuous interest in the chemistry of γ-lactones,[3] we reported a convenient synthesis of enolic δ-lactones with a Wittig reaction.[4]

In a previous paper we reported highly stereo- and regioselective alkylation of alkylidenemalonates **1** giving (3*E*)-2-methoxycarbonyl-2-alkyl-3-alkenoate **2**.[5] Recently, we found that the heating of bromolactonization products **3** with sodium iodide in an appropriate solvent affords 3,5-disubstituted 2(5*H*)-furanones **4** in good yields. This paper describes a new synthesis of **4**



and its application for the synthesis of acarenoic acid **5**.[6]



5

Compound **2** was prepared by the reaction of **1** with alkyl iodide in the presence of lithium diisopropylamide (LDA) as reported previously.[5] Bromolactonization of **2**[5] was carried out in chloroform for 2—3 h at 0 °C and the various alkyl-substituted bromolactones **3** were obtained in 42.3—86.6% yields as shown in Table 1. The stereochemistry of **3** was determined by NOE techniques[7] of ^{1}H NMR. For example, when the 3-methyl protons of **3a** were irradiated, a peak enhancement (5%) was observed for the 4-methine proton, while the irradiation on 5-methine proton did not show any effect for signals due to 3-methyl and 4-methine protons.

Conversion of **3** to 2(5*H*)-furanone **4** was extremely facilitated by heating the 3-pentanone solution of **3** with an excess amount of NaI. Various 3,5-disubstituted 2(5*H*)-furanons **4** were prepared from **3** and the results are tabulated in Table 1. The reaction was completed within 3 days and product **4** was obtained in good isolated yields (55.8—93.3%). Furthermore, the effectiveness of other reagents and solvents for the present reaction was investigated. The conversion of (3*R**, 4*R**, 5*S**)-4-bromo-5-butyl-3-ethoxycarbonylmethyl-3-methoxycarbonyldihydro-2(3*H*)-furanone (**3c**) to **4c** was attempted under various con-

Table 1. Syntheses of Malonates **2**, Bromolactones **3**, and 2(5*H*)-Furanones **4**

ditions and the results are tabulated in Table 2. Sodium chloride, silica-alumina, silica gel, and alumina were not effective, although KI showed a slight effectiveness. Ethanol, as well as 3-pentanone, was a good solvent for this reaction. Although the reaction in benzene resulted in a recovery of the starting material, that in the presence of 15-crown-5[8] gave **4c** in 50% yield.

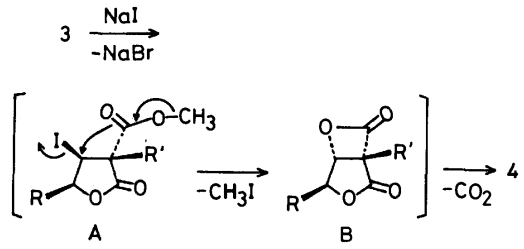
The structure of **4** was elucidated by IR and NMR data and elemental analysis. IR, ^{1}H NMR, and analytical data are given in Table 3. IR absorptions of **4** near 1760 and 1660 cm^{-1} are consistent with the structure of α,β-unsaturated γ-lactone.[3b,9] Signals of olefinic protons appeared at δ 6.8—7.4 as a result of a deshielding effect of the α,β-unsaturated carbonyl system. The ^{13}C NMR spectra of the lactone **4** prepared in this work were measured and tentatively assigned as shown in Table 4. These data afford additional support for assigning the structure of 3,5-disubstituted 2(5*H*)-furanone.

Table 2. Attempts in the Synthesis of **4c** with Various Reagents

Reagent[a]	Reaction condition		Yield/%[b]
	Solvent	Time/d	**4**
NaI	3-Pentanone	2	89
NaI	Ethanol	2	80
NaI	Water	2	0[d]
NaI	Benzene	2	0[d]
NaI	Benzene—15-crown-5[c]	2	50
NaI	Xylene	2	0[d]
KI	3-Pentanone	2	21
NaCl	3-Pentanone	4	0[d]
SiO_2-Al_2O_3	3-Pentanone	4	0[d]
SiO_2	3-Pentanone	2	0[d]
Al_2O_3	3-Pentanone	2	0[d]

a) A solution of **3c** in a solvent was heated at the reflux temperature in the presence of an excess amount (5—10 equiv) of the reagent. b) Estimated by ^{1}H NMR analysis. c) An equimolar amount of 15-crown-5 to NaI was used. d) The starting material **3c** was recovered.

This novel reaction of the 2(5*H*)-furanone formation can be explained by the following mechanism. Initially, the reaction would start to give iodo lactone **A** by the substitution of the bromine with NaI.[10] The elimination of methyl iodide from **A** would yield unstable β-lactone **B**, which would release carbon dioxide to afford the 2(5*H*)-furanone **4**.



The present reaction was applied for the synthesis of (±)-acarenoic acid **5**, a component of *Acarospora chlorophana*,[6] whose total synthesis has never been reported. Our reaction sequence is shown in Scheme 1. A deconjugative alkylation of dimethyl tridecanylidenemalonate (**1g**) with ethyl iodoacetate afforded, exclusively, ethyl (*E*)-3,3-bis(methoxycarbonyl)-4-

Table 3. Physical and Analytical Data of 2(5*H*)-Furanones **4**

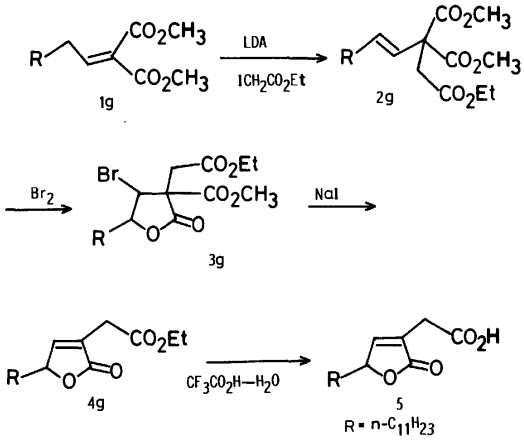

Scheme 1.

hexadecenoate (**2g**) in 68.8% yield; this was subsequently brominated to give (3*R**, 4*R**, 5*S**)-4-bromo-3-ethoxycarbonylmethyl-3-methoxycarbonyl-5-undecyldihydro-2(3*H*)-furanone (**3g**) in 71.0% yield. A treatment of **3g** with 6 equiv of NaI gave (±)-ethyl acarenoate (**4g**) in 93.3% yield and the hydrolysis of **4g** with trifluoroacetic acid-water afforded acarenoic acid **5**[6] in 73% yield.

The present method provides a convenient route to 3,5-disubstituted 2(5*H*)-furanones because of the availability of the starting material, the simplicity of the experiment, and no use of a heavy metal.

Experimental

The melting and boiling points are uncorrected. Infrared (IR) spectra were obtained with a JASCO Model A-102 infrared spectrophotometer. ^1H NMR spectra (60 MHz) were recorded with a JEOL JNM-PMX 60SI apparatus. ^{13}C NMR spectra (25 MHz) were obtained with a JEOL JNM-FX100 apparatus, using $CDCl_3$ as a solvent. NOE experiments were conducted on a deoxygenated sample with a Varian VXR 300 spectrometer. Column chromatography was accomplished with a 100—200 mesh Wakogel C-200. 3-Pentanone was dried over $CaCl_2$ and distilled prior to use. Commercial first-grade aldehydes were distilled prior to use. Ethyl iodoacetate was obtained by a reaction of ethyl bromoacetate with NaI.[10]

Alkylidenemalonates **1** were prepared according to procedures reported in the literature.[11] Compounds, boiling points, and yields are as follows: **1a** (R=C_2H_5), bp 77.5—80 °C/3 Torr (1 Torr=133.322 Pa), **1c** (R=*n*-C_4H_9),[5,11] bp 102 °C/2 Torr, 76%; **1d** (R=*n*-C_6H_{13}), bp 118—120 °C/2 Torr, 80%; **1g** (R=*n*-$C_{11}H_{23}$),[12] 42%.

Compound **2** was prepared according to procedures reported previously.[5] The following exemplifies the synthesis of **2**.

Methyl (*E*)-2-Methoxycarbonyl-2-methyl-3-hexenoate (2a). To a stirred solution of 0.90 ml (6.40 mmol) of diisopropylamine in 6 ml of dry THF was added dropwise 4.1 ml (6.51 mmol) of 1.6 M (1M=1 mol dm^{-3}) butyllithium in hexane at 0 °C. After 20 min, 2.8 ml of HMPA was added, and then the mixture was cooled to −78 °C. Dimethyl butylidenemalonate (1.0 g, 5.38 mmol) was added dropwise and the mixture was stirred for 30 min. After the dropwise addition of methyl iodide (1.43 g, 10.1 mmol), the mixture was allowed to warm up to room temperature for 1 h and was then heated under reflux for 30 min. It was cooled to room temperature, and poured into ice water. The organic material was extracted with ethyl acetate and the combined extracts were washed with dilute HCl and water, and dried over $MgSO_4$. Removal of the solvent gave 0.987 mg of an oil, which was purified by bulb-to-bulb distillation to give 0.682 mg (63.4%) of **2a**: bp 130 °C/7 Torr; IR (neat) 2970 and 1740 cm^{-1}; ^1H NMR (CCl_4) δ=1.02 (3H, t, *J*=7 Hz, $CH_2C\underline{H}_3$), 1.45 (3H, s, CCH_3), 1.87—2.44 (2H, m, $C\underline{H}_2CH_3$), 3.65 (6H, s, $2CO_2CH_3$), 5.40 (1H, dt, *J*=15.5 Hz, $CH_2C\underline{H}$=CH), and 5.81 (1H, d, *J*=16 Hz, CH_2CH=C$\underline{H}$). Found: C, 59.92; H, 7.88%. Calcd for $C_{10}H_{16}O_4$: C, 59.98; H, 8.05%.

Ethyl (*E*)-3,3-Bis(methoxycarbonyl)-4-undecenoate (2f). Dimethyl octylidenemalonate (1.0 g, 4.13 mmol) was treated with LDA and allowed to react with ethyl iodoacetate (1.65 g, 7.77 mmol) as described above. The standard work-up gave 1.57 g of the crude product, which was purified by column chromatography (SiO_2, hexane-ethyl acetate, 30 : 1—5 : 1) to afford 1.17 g (86.4%) of **2f**: TLC (SiO_2; hexane-ethyl acetate, 4 : 1), R_f 0.33; IR (neat) 2950 and 1740 cm^{-1}; ^1H NMR (CCl_4) δ=0.89 (3H, t, *J*=5 Hz), 1.10—1.58 (11H, m, $4CH_2$, $CO_2CH_2C\underline{H}_3$), 1.96—2.36 (2H, m, $C\underline{H}_2CH$=), 3.01 (2H, s, $C\underline{H}_2CO_2Et$), 3.69 (6H, s, $2CO_2CH_3$), 4.04 (2H, q, *J*=8 Hz, $CO_2C\underline{H}_2CH_3$), 5.42 (1H, dt, *J*=15 and 5.5 Hz, $CH_2C\underline{H}$=

and 5.95 (1H, d, J=15 Hz, CH_2CH=C$\underline{H}$).

Other compounds **2** were also prepared by the same procedures as described above.

2b: TLC (SiO_2; hexane-ethyl acetate, 4:1), R_f 0.29; IR (neat) 1740 cm^{-1}. ^1H NMR (CCl_4) δ=1.01 (3H, t, J=7 Hz, C$\underline{H}_3CH_2$), 1.22 (3H, t, J=7 Hz, $CO_2CH_2C\underline{H}_3$), 1.86—2.37 (2H, m, $CH_3C\underline{H}_2$), 3.00 (2H, s, $C\underline{H}_2CO_2Et$), 3.70 (6H, s, $2CO_2CH_3$), 4.05 (2H, q, J=7 Hz, $CO_2C\underline{H}_2CH_3$), 5.47 (1H, dt, J=16 and 6 Hz, $CH_2C\underline{H}$=CH), and 5.95 (1H, d, J=16 Hz, CH_2CH=C$\underline{H}$). Found: C, 57.51; H, 7.40%. Calcd for $C_{13}H_{20}O_6$: C, 57.34; H, 7.40%.

2c: Bp 170 °C/4 Torr (bulb-to-bulb distillation); IR (neat) 2990, 1748, 1735, 1650, and 1438 cm^{-1}; ^1H NMR (CCl_4) δ=0.88 (3H, t, J=6 Hz, $(CH_2)_3C\underline{H}_3$), 1.05—1.53 (4H, m, $2CH_2$), 1.20 (3H, t, J=7 Hz, $CO_2CH_2C\underline{H}_3$), 1.85—2.66 (2H, m, $C\underline{H}_2CH$=), 2.98 (2H, s, $C\underline{H}_2CO_2Et$), 3.66 (6H, s, $2CO_2CH_3$), 4.01 (2H, q, J=7 Hz, $CO_2C\underline{H}_2CH_3$), 5.40 (1H, dt, J=16 and 5.5 Hz, $CH_2C\underline{H}$=CH), and 5.92 (1H, d, J=16 Hz, CH_2CH=C$\underline{H}$).

2e: TLC (SiO_2; hexane-ethyl acetate, 4:1), R_f 0.53; IR (neat) 1742, 1460, 1436, and 1380 cm^{-1}; ^1H NMR (CCl_4) δ=0.89 (3H, t, J=5 Hz, C$\underline{H}_3CH_2$), 1.08—1.70 (12H, m, $6CH_2$), 1.70—2.42 (4H, m, $2CH_2$), 3.65 (6H, s, $2CO_2CH_3$), 5.38 (1H, dt, J=15 and 5.5 Hz, $CH_2C\underline{H}$=CH), and 5.86 (1H, d, J=15 Hz, CH_2CH=C$\underline{H}$). Found: C, 68.14; H, 10.09%. Calcd for $C_{17}H_{30}O_4$: C, 68.42; H, 10.13%.

2g: TLC (SiO_2; hexane-ethyl acetate, 4:1), R_f 0.41; IR (neat) 2950, 1745, 1460, and 1435 cm^{-1}; ^1H NMR (CCl_4) δ=0.88 (3H, t, J=4 Hz, $(CH)_{10}C\underline{H}_3$), 1.03—1.53 (18H, m, $9CH_2$), 1.80—2.25 (2H, m, CH_2), 2.99 (2H, s, $C\underline{H}_2CO_2Et$), 3.68 (6H, s, $2CO_2CH_3$), 4.02 (2H, q, J=7 Hz, $CO_2C\underline{H}_2CH_3$), 5.40 (1H, dt, J=15 and 6 Hz, $CH_2C\underline{H}$=), and 5.92 (1H, d, J=15 Hz, CH_2CH=C$\underline{H}$). Found: C, 66.36; H, 9.57%. Calcd for $C_{22}H_{38}O_6$: C, 66.30; H, 9.61%.

(3*R, 4*R**, 5*S**)-4-Bromo-3-methoxycarbonyl-5-ethyl-3-methyldihydro-2(3*H*)-furanone (3a).** To a solution of **2a** (0.3 g, 1.5 mmol) in chloroform (2.6 ml) was added dropwise bromine (0.264 g, 1.65 mmol) at 0 °C. After the mixture had been stirred for 2.5 h, the solvent was evaporated to give 435 mg of the crude product which crystallized on standing for 1 d. Recrystallization from hexane afforded 0.293 g (73.7%) of **3a**: mp 86.3—87.2 °C; IR (KBr) 2970, 1790, 1742, 1443, and 1428 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.11 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), 1.50 (3H, s, CH_3), 1.39—2.30 (2H, m, $C\underline{H}_2CH_3$), 3.78 (3H, s, CO_2CH_3), 3.83 (1H, d, J=8 Hz, CHBr), and 4.46—4.88 (1H, m, CH-O); ^{13}C NMR ($CDCl_3$) δ=9.7 (q, $CH_2\underline{C}H_3$), 18.1 (q, C_3-$\underline{C}H_3$), 25.1 (t, $\underline{C}H_2CH_3$), 51.7 (d, CHBr), 53.1 (q, $CO_2\underline{C}H_3$), 57.0 (s, C_3), 84.7 (d, C_5), 167.2 (s, $\underline{C}O_2CH_3$), and 172.0 (s, C_2). Found: C, 40.75; H, 4.99%. Calcd for $C_9H_{13}BrO_4$: C, 40.78; H, 4.94%.

(3*R, 4*R**, 5*S**)-4-Bromo-3-ethoxycarbonylmethyl-5-ethyl-3-methoxycarbonyldihydro-2(3*H*)-furanone (3b).** To a solution of **2b** (0.509 g, 1.87 mmol) in chloroform (3 ml) was added dropwise bromine (0.33 g, 2.06 mmol) at 0 °C. The mixture was stirred for 3 h and the solvent was removed in vacuo. The crude product (0.688 g) was chromatographed on SiO_2 (hexane-ethyl acetate, 10:1—5:1) to give 0.401 g (63.6%) of **3b**: TLC (SiO_2; hexane-ethyl acetate, 4:1), R_f 0.31; IR (neat) 3000, 1790, 1750, 1730, 1460, and 1435 cm^{-1}; ^1H NMR (CCl_4) δ=1.24 (3H, t, J=6 Hz, $CH_2C\underline{H}_3$), 1.27 (3H, t, J=7 Hz, $CO_2CH_2C\underline{H}_3$), 1.56—2.19 (2H, m, $C\underline{H}_2CH_3$), 2.79 (1H, d, J=18 Hz, CH_2), 3.81 (3H, s, CO_2CH_3), 4.14 (2H, q, J=7 Hz, $CO_2C\underline{H}_2CH_3$), and 4.46—4.80 (2H, m, BrCHCHO-). Found: C, 42.65; H, 5.04%. Calcd for $C_{12}H_{17}BrO_6$: C, 42.75; H, 5.08%.

Other compounds **3** were prepared by the same procedures as those described for **3b**.

3c: IR (neat) 2975, 1792, 1755, 1731, 1435, and 1402 cm^{-1}; ^1H NMR (CCl_4) δ=0.97 (3H, t, J=5 Hz, $CH_2C\underline{H}_3$), 1.13—2.10 (8H, m, $CH_3(C\underline{H}_2)_3$, $C\underline{H}_2CO_2$), 1.27 (3H, t, J=7 Hz, $CO_2CH_2C\underline{H}_3$), 2.77 (1H, d, J=18 Hz, $C\underline{H}_2CO_2Et$), 3.15 (1H, d, J=18 Hz, $C\underline{H}_2CO_2Et$), 3.76 (3H, s, CO_2CH_3), 4.12 (2H, q, J=7 Hz, $CO_2C\underline{H}_2CH_3$), and 4.40—4.84 (2H, m, CHBrCHO). Found: C, 46.17; H, 5.74%. Calcd for $C_{14}H_{21}BrO_6$: C, 46.04; H, 5.80%.

3d: Mp 76.5—78.0 °C (hexane): IR (KBr) 2940, 1910, 1749, 1209, and 1108 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (3H, t, J=5 Hz, $(CH_2)_5C\underline{H}_3$), 1.10—2.24 (10H, m, $5CH_2$), 1.52 (3H, s, CH_3), 3.69 (3H, s, CO_2CH_3), 3.69 (1H, d, J=10 Hz, CHBr), and 4.42—4.93 (1H, m, CHO-). Found: C, 48.86; H, 6.60%. Calcd for $C_{13}H_{21}BrO_4$: C, 48.61; H, 6.59%.

3e: TLC (SiO_2; hexane-ethyl acetate, 4:1), R_f 0.54; IR (neat) 2950, 1789, 1755, 1460, and 1431 cm^{-1}; ^1H NMR (CCl_4) δ=0.72—1.15 (6H, m, $2CH_3$), 1.15—2.20 (16H, m, $8CH_2$), 3.77 (3H, s, CO_2CH_3), 3.90 (1H, d, J=8 Hz, CHBr), and 4.30—4.75 (1H, m, CHO-). Found: C, 52.89; H, 7.54%. Calcd for $C_{16}H_{27}BrO_4$: C, 52.90; H, 7.49%.

3f: TLC (SiO_2; hexane-ethyl acetate, 4:1), R_f 0.61; IR (neat) 2950, 1788, 1752, 1729, 1460, and 1375 cm^{-1}; ^1H NMR (CCl_4) δ=0.91 (3H, t, J=5 Hz, $(CH_2)_5C\underline{H}_3$), 1.10—2.06 (10H, m, $5CH_2$), 1.27 (3H, t, J=6 Hz, $CO_2CH_2C\underline{H}_3$), 2.79 (1H, d, J=18 Hz, $C\underline{H}_2CO_2Et$), 3.16 (1H, d, J=18 Hz, $C\underline{H}_2CO_2Et$), 3.70 (3H, s, CO_2CH_3), 4.13 (2H, q, J=7 Hz, $CO_2C\underline{H}_2CH_3$), and 4.48—4.70 (2H, m, BrCHCHO-). Found: C, 48.81; H, 6.39%. Calcd for $C_{16}H_{25}BrO_6$: C, 48.87; H, 6.41%.

3g: 71.0% yield; TLC (hexane-ethyl acetate, 4:1), R_f 0.46; IR (neat) 2940, 1781, 1755, and 1735 cm^{-1}; ^1H NMR (CCl_4) δ=0.89 (3H, t, J=5 Hz, CH_3), 1.1—2.0 (25H, m, $(C\underline{H}_2)_{10}CH_3$ and $C\underline{H}_2CO_2Et$), 2.78 (1H, d, J=18 Hz, $C\underline{H}_2CO_2Et$), 3.14 (1H, d, J=18 Hz, $C\underline{H}_2CO_2Et$), 3.78 (3H, s, CO_2CH_3), 4.12 (2H, q, J=7 Hz, $CO_2C\underline{H}_2CH_3$), and 4.46—4.71 (2H, m, CHBrCHO-). Found C, 54.23; H, 7.51%. Calcd for $C_{21}H_{35}BrO_6$: C, 54.43; H, 7.61%.

Some representative syntheses of 2(5*H*)-furanones **4** are shown below.

5-Ethyl-3-methyl-2(5*H*)-furanone (4a). Sodium iodide (275 mg, 1.83 mmol) was charged in a 10 ml two-necked flask and dried in vacuo. A solution of **3a** (81 mg, 0.31 mmol) in 3-pentanone (3 ml) was added and the mixture was heated at the reflux temperature under a nitrogen atmosphere. After 2 d it was poured into ice water and the organic material was extracted with ethyl acetate and the combined extracts were washed with 5% sodium thiosulfate and water, and dried over $MgSO_4$. Removal of the solvent gave 63 mg of the crude product which was chromatographed on SiO_2 (hexane-ethyl acetate, 30:1—5:1). The early fractions gave 15 mg of the starting material **3a**. The later fractions gave 28 mg (72%) (89% based on the consumed **3a**) of **4a**. Spectral and analytical data are shown in Table 3.

3-Ethoxycarbonylmethyl-5-butyl-2(5*H*)-furanone (4c). As shown in **4a**, a stirred mixture of **3c** (200 mg, 0.55 mmol), NaI (495 mg, 3.30 mmol), and 3-pentanone (3 ml) was heated at the reflux temperature under a nitrogen atmosphere for 2.5 d. Column chromatography (SiO_2; hexane-ethyl acetate, 10:1) of the crude product gave 110 mg (88.5%) of **4c**: TLC (SiO_2; hexane-ethyl acetate, 4:1), R_f 0.16. Spectral and analytical data are shown in Table 3.

3-Ethoxycarbonylmethyl-5-undecyl-2(5*H*)-furanone (4g). As shown in **4a**, a mixture of **3g** (200 mg, 0.43 mmol), NaI (387 mg, 2.58 mmol), and 3-pentanone (3 ml) was refluxed with stirring under a nitrogen atmosphere. Column chromatography (SiO_2; hexane-ethyl acetate, 15:1—10:1) gave 130 mg (93.3%) of **4g**: TLC (SiO_2; hexane-ethyl acetate, 4:1), R_f 0.23. Spectral and analytical data are shown in Table 3.

(±)-Acarenoic Acid (5). A mixture of **4g** (45 mg, 0.14 mmol), trifluoroacetic acid (1 ml), and water (2 ml) was stirred for 2 d and then poured into water. The organic material was extracted with dichloromethane, washed with water, and dried over $MgSO_4$. Evaporation of the solvent gave 50 mg of the crude product which was purified by preparative TLC (SiO_2; hexane-ethyl acetate, 4:1). The component of R_f 0.23 gave 12 mg of **4g**. The component of R_f 0—0.13 gave 22 mg (53%) (73% based on the consumed **4g**) of **5**: mp 83.8—84.2 °C (from benzene) (lit,[6] 144—146.5 °C for (−)-**5**); IR (KBr) 2925, 1738, 1708, 1655, 1390, 1298, and 1083 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.88 (3H, t, J=5 Hz, $(CH_2)_{10}CH_3$), 1.04—1.95 (20H, m, $10CH_2$), 3.38 (2H, s, CH_2CO_2H), 4.80—5.11 (1H, m, CHO-), 7.35 (1H, s, CH=C), and 8.94 (1H, br. s, CO_2H); ^{13}C NMR ($CDCl_3$) δ=14.0 (q), 22.6 (t), 25.0 (t), 29.3 (t), 29.5 (t), 31.7 (t), 31.9 (t), 33.2 (t), 82.1 (d), 126.3 (s), 152.0 (d), 173.1 (s), and 184.2 (s).

We thank Mr. Eiichiro Amano of our laboratory for elemental analyses. We also thank Drs. Kazuhiko Kushida and Hajime Kato of Varian Instrument Ltd. for the NOE experiments.

Studies on Hydrogenation by Nickel Complexes. 5. The Selective Hydrogenation of 1,4-Cyclohexadienes to Cyclohexenes Catalyzed by a Nickel Complex

Mutsuji SAKAI,* Nobuo HIRANO, Fumiya HARADA, Yasumasa SAKAKIBARA, and Norito UCHINO
Department of Polymer Science and Engineering, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received March 2, 1987)

1,4-Cyclohexadiene was hydrogenated selectively to cyclohexene with a nickel catalyst generated from bis(acetylacetonato)nickel(II), triethyldialuminium trichloride, and triphenylphosphine at 40 °C under an atmospheric pressure of hydrogen. The hydrogenation of eleven kinds of alkyl-substituted 1,4-cyclohexadienes gave the corresponding cyclohexenes in good yields by the nickel catalyst. The structural factors of the alkyl substituent on the diolefin are shown to affect the hydrogenation rate. The homogeneous nickel catalyst system, in which a nickel hydride complex $NiH(PPh_3)(AlCl_4)$ is supposed to be an active species, was effective for the selective hydrogenation of the diolefin to the olefin. A plausible pathway involving π-allylnickel complexes for the hydrogenation is proposed.

Homogeneous hydrogenation has been extensively investigated.[1-3] Concerning nickel catalysts used for selective hydrogenation of diolefins, nickel-based Ziegler catalysts are known to be effective for the hydrogenation of diolefins[4,5] and unsaturated fats.[6,7] The catalyst systems are complicated (homogeneous and/or heterogeneous system) and poorly understood. Phosphine-coordinated nickel catalysts also are active for the hydrogenation of diolefins.[8,9] In many cases, however, less satisfactory results for selective hydrogenation are obtained. We used a homogeneous nickel catalyst generated from $Ni(acac)_2$, $Et_3Al_2Cl_3$, and PPh_3, and found that diolefins were hydrogenated selectively in good yields with the nickel catalyst in a series of studies reported.[10-13]

In this paper, we examine closely the selective hydrogenation of cyclic diolefins by the nickel catalyst under mild conditions and will complete the aspect of the catalytic hydrogenation.

Experimental

Materials. 1,4-Cyclohexadiene and methylcyclohexenes were commercially available. Alkyl-substituted 1,4-cyclohexadienes were prepared from the corresponding alkylbenzenes by Birch reduction.[14-16] Solvents were distilled over sodium. The other reagents were commercially available and used without purification.

General Procedure. Hydrogenation: To a 200 cm^3 flask fitted with a hydrogen buret, a septum inlet, and a magnetic stirring bar were added $Ni(acac)_2$ (0.11 mmol) and PPh_3 (0.55 mmol) in toluene. After the air was replaced with hydrogen the diolefin (11 mmol) in toluene was added. The hydrogenation was started by the addition of $Et_3Al_2Cl_3$ (1.1 mmol) in toluene. The solution was stirred with a magnetic stirrer and kept in a thermostated bath. An aliquot (2 cm^3) of the solution was taken and treated with a methanol-aqueous hydrochloric acid mixture. The organic layer was separated, washed with water, and subjected to GLC analysis.

Competitive Hydrogenation: The mixture of equimolar amounts of two diolefins was hydrogenated by the same procedure. An aliquot of the solution was worked up similarly. The initial rates for disappearance of diolefin were measured and relative rates were calculated, estimating the disappearance rate of 1,4-cyclohexadiene as 1.0.

Isomerization: Under an atmosphere of nitrogen methylcyclohexene was treated with the nickel catalyst under conditions similar to those of hydrogenation. The same work-up was done.

Analysis. The gas chromatographic analyses were made by a Yanaco G-80 apparatus with a TC detector and herium carrier gas using a 3 m column of bis(2-cyanoethyl) ether. ^1H NMR spectra were recorded on a Varian T-60A spectrometer using tetramethylsilane as an internal standard. The composition of methylcyclohexenes was determined by the NMR analyses, in which the relative areas of the characteristic signals for 3- and 4-methylcyclohexene were calculated.

Results and Discussion

Hydrogenation of 1,4-Cyclohexadienes. Under mild conditions 1,4-cyclohexadiene and alkyl-substituted homologs were hydrogenated selectively to cyclohexenes with a nickel catalyst generated from $Ni(acac)_2$, $Et_3Al_2Cl_3$, and PPh_3. The results are shown in Table 1. 1,4-Cyclohexadiene was hydrogenated selectively to produce cyclohexene in a high yield of 81%. Trace amounts of benzene (disproportionation product)[17] were detected. Cyclohexene was hydrogenated very slowly to cyclohexane with the nickel catalyst. In the case of 1,3-cyclohexadiene polymerization predominated over hydrogenation under the same conditions. However, 1,3-cyclohexadiene also was hydrogenated selectively to cyclohexene by adding the 1,3-diene dropwise to the catalyst system.[12] Mono- and dialkyl-substituted 1,4-cyclohexadienes gave the corresponding cyclohexenes in good yields. However, the compositions of alkyl-substituted cyclohexene isomers, except methylcyclohexenes, could not be determined exactly by GLC and NMR analyses because the isomers overlapped each other on the signals.

GLC analysis showed that methylcyclohexenes formed in the hydrogenation of 1-methyl-1,4-cyclohexadiene consisted of 1-methylcyclohexene (yield, 67%) and the mixture (7%) of 3- and 4-methylcyclohexene.

	180	7.41 (90)	0.82 (10)

a) Reaction conditions: $Ni(acac)_2$ 0.2 mmol; $Ni:Al_2:P=1:10:5$; toluene 100 cm^3; temp 40 °C; under N_2. b) The composition of methylcyclohexene/% by GLC analysis.

At the initial stage of hydrogenation primary products were three kinds of methylcyclohexene, 1-, 3-, and 4-methylcyclohexene, in the ratio of 61 : 17 : 22, as shown in Table 2. After the diolefin was consumed the composition of the products was 90% of 1-methylcyclohexene and 10% of 3- and 4-methyl isomer. The above results suggest a subsequent isomerization occurred.

Isomerization. As shown in Table 3, the treatment of methylcyclohexenes with the nickel catalyst under nitrogen atmosphere resulted in the same composition with that of hydrogenation, 90% of 1-methylcyclohexene and 10% of 3- and 4-methyl isomer. It was found that each of methylcyclohexenes isomerized very rapidly by the nickel catalyst and the reaction mixture attained thermodynamically to equilibrium. The nickel catalyst was an excellent catalyst for the isomerization of the olefins.

On the other hand, 1,4-cyclohexadiene and 1-methyl-

Table 4. Relative Rates for the Competitive Hydrogenation of Substituted 1,4-Cyclohexadienes[a)]

Substituent group on 1,4-cyclohexadiene	Reference diolefin[b)]	Solvent[c)]	Relative rate[d)]
1-Methyl	A	E	0.45
1-Ethyl	B	E	0.36
1-Propyl	C	T	0.32
1-Isopropyl	C	E	0.28
1-Butyl	B	E	0.27
1-Isobutyl	A	T	0.19
1-*t*-Butyl	C	T	0.15
1,2-Dimethyl	B	E	0.28
1,5-Dimethyl	B	E	0.085
1,4-Dimethyl	B	E	0.054

a) Reaction conditions: Each diolefin 5 mmol; $Ni(acac)_2$ 0.1 mmol; $Ni:Al_2:P=1:10:5$; solvent 100 cm^3; temp 60°C; H_2 1 atm. b) Reference diolefin: A 1,4-cyclohexadiene; B 1-methyl-1,4-cyclohexadiene; C 1-ethyl-1,4-cyclohexadiene. c) Solvent: E ethylbenzene; T toluene. d) The disappearance rate of 1,4-cyclohexadiene was estimated as 1.0.

1,4-cyclohexadiene hardly isomerized and the 1,3-dienes were detected in trace amounts.

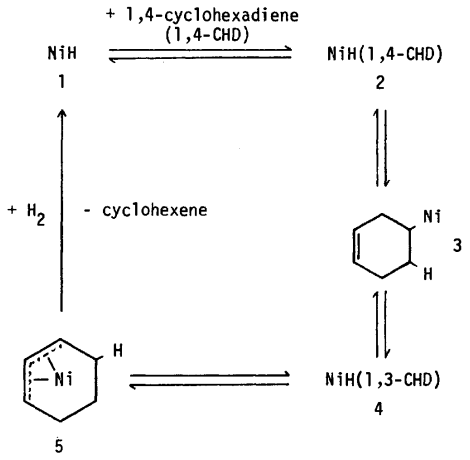
Competitive Hydrogenation. A mixture of equimolar amounts of two diolefins was hydrogenated. The initial rates for disappearance of diolefins were measured and the relative rates were calculated by estimating the disappearance rate of 1,4-cyclohexadiene as 1.0. Table 4 shows that the steric effect of alkyl substituents on the hydrogenation rate. The rate slowed down in the order of the chain length and branching of the alkyl substituent; H(1.0)>Me(0.45)>Et(0.36)>*n*-Pr(0.32)>*n*-Bu(0.27), *n*-Pr(0.32)>*i*-Pr(0.28), and *n*-Bu(0.27)>*i*-Bu(0.19)>*t*-Bu(0.15). Moreover, the number of substituent has a significant influence on the rate, and the order was H(1.0)>1-Me(0.45)>1,2-Me_2(0.28)>1,5-Me_2(0.085)>1,4-Me_2(0.054).

Hydrogenation Pathway. It has been proposed that a nickel hydride complex **1** is the active species for hydrogenation, as represented in the equation.[10,11,18)]

$$Ni(acac)_2 + Et_3Al_2Cl_3 + PPh_3 \longrightarrow \underset{\mathbf{1}}{H(L)Ni(Ph_3P)(Cl\cdot AlCl_3)} \quad (L;\ \text{solvent})$$

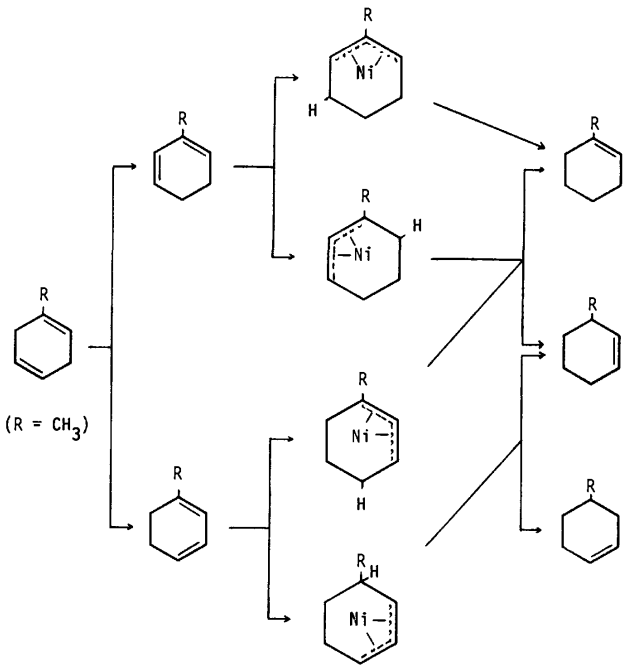
Scheme 1 shows a plausible pathway for the selective hydrogenation of 1,4-cyclohexadiene catalyzed by **1**. 1,4-cyclohexadiene coordinates to **1** and an insertion reaction of coordinated diolefin **2** produces a cyclohexenylnickel complex **3**. Its β-hydrogen elimination leads to the isomerization of 1,4-diene to 1,3-diene and then a π-allylnickel complex **5** is formed via an insertion reaction from the complex **4**. These four steps are reversible. The oxidative addition of hydrogen to **5** and the reductive elimination of cyclohexene regenerate **1**, which continues the catalytic cycle.

It has been reported that complexes such as **1** are most probably planar[19,20)] and the fragment of $AlCl_3$ strengthens the protonic character[21,22)] of hydrogen and promotes a ligand exchange.[23,24)] The use of five equimolar amounts of PPh_3 and a large excess of $Et_3Al_2Cl_3$ was favorable for the hydrogenation of 1,4-



Scheme 1.

cyclohexadiene. It is suggested that appropriate amounts of the phosphine is necessary to form **1** and a second phosphine coordinates to **1** to form NiH-$(PPh_3)_2(AlCl_4)$, an inactive species, in a large excess of the phosphine. The complex **1** would have an excellent catalytic ability for isomerization of olefins and a good catalytic ability for selective hydrogenation of diolefins. Methylcyclohexenes isomerized very rapidly, while, 1,4-cyclohexadiene hardly did. The formation of a π-allylnickel complex[25)] from **4** is suggested by the products in the case of the hydrogenation of 1-methyl-1,4-cyclohexadiene. At the initial stage of the hydrogenation of 1-methyl-1,4-cyclohexadiene primary products were three kinds of cyclohexene,[26)] 1-, 3-, and 4-methylcyclohexene. These cyclohexenes isomerized very rapidly each other in the absence of the diolefin since the strength of coordination of diolefin to **1** is much stronger than that of olefins and the product attained to equilibrium. The formation of three isomers of methylcyclohexene is shown in Scheme 2. 1-Methyl-1,4-cyclohexadiene isomerizes to thermodynamically stable 1,3-isomers. Insertion reactions of coordinated 1,3-diolefin to **1** produce four types of π-allylnickel complex. In these complexes less steric crowding and thermodynamically stable π-allylnickel



Scheme 2.

complexes appear to be preferred.[25] β-Hydrogen eliminations from the complexes formed by oxidative addition of hydrogen to π-allylnickel complexes yield three kinds of methylcyclohexene, 1-, 3-, and 4-methylcyclohexene. It is reported that β-hydrogen eliminations tend to give internal olefins in the hydrogenation of 1,3-diolefins.[11] Thus, it is expected that 1-methylcyclohexene is a major product in the hydrogenation of 1-methyl-1,4-cyclohexadiene. However, little information on the interconversion between π- and σ-allylnickel complexes, and on the direction of β-hydrogen elimination was obtained from the results.

Although the oxidative addition of hydrogen to **5** may be the slow step in the hydrogenation of diolefins,[11] the steric factors of alkyl-substituted 1,4-cyclohexadienes gave a significant effect on hydrogenation rate. The hydrogenation rate slowed down in proportion to the bulkiness of the substrate coordinated (Table 1). This suggests that the equilibrium shown in Scheme 1 lies so far to the left (coordination side). In the isomerization of linear olefins by the nickel catalyst the insertion of olefin into **1** is assumed to be the slow step.[27]

In conclusion, it is presented that the nickel complex generated from $Ni(acac)_2$, $Et_3Al_2Cl_3$, and PPh_3 is a good catalyst for selective hydrogenation of diolefins and the hydrogenation proceeds via π-allylnickel complexes.

(Received March 16, 1987)

6-Formyl- and 6-hydroxymethyl-5,8-dihydroxy-2-methoxy-1,4-naphthoquinones were, respectively, prepared from 2-formyl- and 2-hydroxymethyl-1,4,5,6,8-pentamethoxynaphthalenes which were synthesized as key intermediates of the new antibiotics containing 2-methoxynaphthazarin structure.

Fusarubin (**1**),[2] Erythrostominone (**2**),[2] Purpuromycin (**3**),[3] and Fredericamycin A (**4**)[4] are new antibiotics of naphthoquinone series, and commonly have a 2-methoxynaphthazarin moiety, that is 5,8-dihydroxy-2-methoxy-1,4-naphthoquinone part (Fig. 1). Although there have been some reports[5] concerning the spiro part construction of **4**, no literature was found regarding the naphthoquinone part.

Recently, we have found an efficient methodology for this 2-methoxynaphthazarin system such as 6-formyl- and 6-hydroxymethyl-5,8-dihydroxy-2-methoxy-1,4-naphthoquinones (**10**) and (**13**) from 2-formyl- and 2-hydroxymethyl-1,4,5,6,8-pentamethoxynaphthalenes (**8**) and (**11**). These compounds have been synthesized in our laboratory as key intermediates for the antibiotics described above. The results prompt us to report at this time.

Results and Discussion

Demethylation of 2-formyl-1,4,5,8-tetramethoxynaphthalene (**5**)[6] with ceric(IV) ammonium nitrate (CAN is used as the abbreviation hereafter) gave 6-formyl-5,8-dimethoxy-1,4-naphthoquinone (**6**) in 85% yield. Only two methoxyl groups of 5- and 8-positions of the original **5** had been cleaved by the oxidation. A treatment of **6** with acetic anhydride in the presence of a catalytic amount of sulfuric acid at room temperature gave 1,2,4-triacetoxy-6-diacetoxymethyl-5,8-dimethoxynaphthalene (**7**) in 98% yield. As shown later in this text, it will be proved that one acetoxyl substituent introduced newly among the five acetoxyl groups, occupied the 2-position in **7**; this conclusion is due to an NMR-structural study of **13** (see later). An alkaline hydrolysis of **7**, and methylation with dimethyl sulfate gave **8** in 67% yield. Demethylation of **8** with CAN afforded 6-formyl-2,5,8-trimethoxy-1,4-naphthoquinone (**9**), where only 5- and 8-positional methoxyl groups were cleaved similarly to the demethylation of **5**. A further demethylation of **9** with aluminum chloride at room temperature gave **10**, and the 2-positional methoxyl group remained unchanged (Scheme 1).

Another target **13** was obtained as follows (Scheme 2). A reduction of the aldehyde **8** with lithium aluminum hydride easily gave the correspoding alcohol **11**. Demethylation of **11** with CAN afforded 6-hydroxymethyl-2,5,8-trimethoxy-1,4-naphthoquinone (**12**), which gave **13** (43%) and 5-hydroxy-6-hydroxymethyl-2,8-dimethoxy-1,4-naphthoquinone (**14**) (38%) by further demethylation with aluminum chloride at room temperature. A prolonged reaction time (20 h), however, resulted in the formation of **13** only in 20% yield, with an unidentified product.

The structure of **13** was established on the basis of an NMR-study,[7] of 5,8-dihydroxy-2-methoxy-1,4-naphthoquinone (**15**). The C_8-OH and C_5-OH protons in **15** absorbed at δ 12.17 and 12.63, respectiviely.[7] It is well-

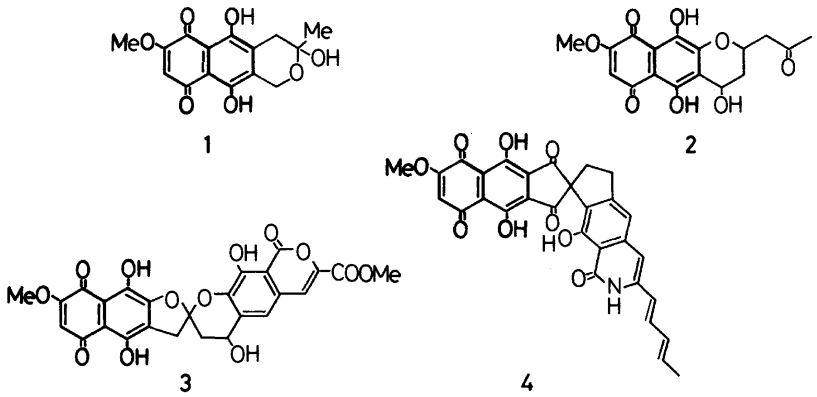

Fig. 1.

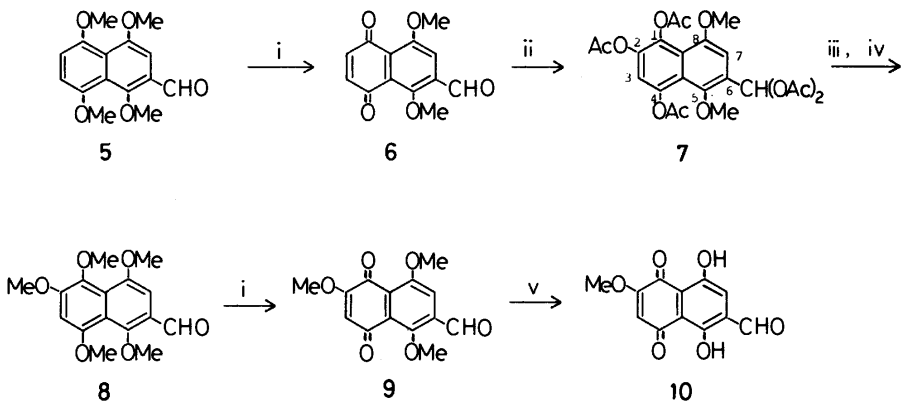
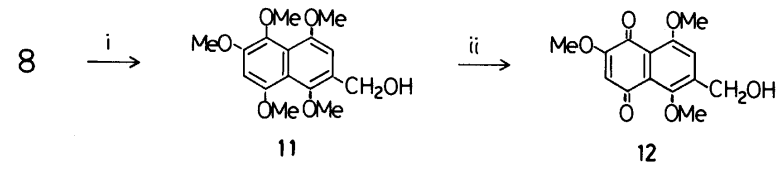
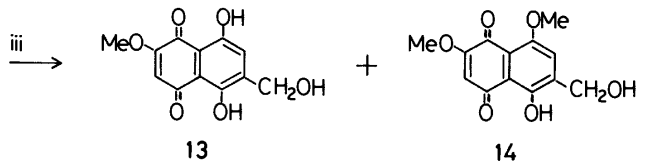


Scheme. 1. i: $(NH_4)_2Ce(NO_3)_6$, H_2O, CH_3CN; ii: Ac_2O, H_2SO_4; iii: OH^-, CH_3OH; iv: OH^-, $(CH_3)_2SO_4$; v: $AlCl_3$, CH_2Cl_2.





Scheme 2. i: $LiAlH_4$, THF; ii: $(NH_4)_2Ce(NO_3)_6$, H_2O, CH_3CN, $CHCl_3$; iii: $AlCl_3$, CH_2Cl_2.

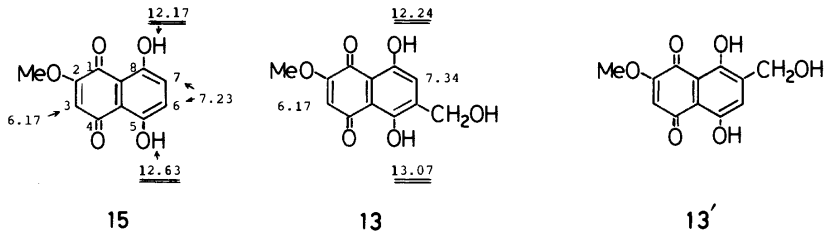


Fig. 2.

known that if **15** has a substituent at either the 6- or 7-position, the chemical shift of the OH proton adjacent to the substituent generally moves in an appreciable extent.[7] In our product **13**, the chemical shift of the C_8-OH proton almost remained unchanged at δ 12.24, whereas that of C_5-OH was found at δ 13.07. As the C_5-OH in our product **13** was observed more downfield than that of **15**, the hydroxymethyl substituent in **13** must be at the 6-position. Therefore, it was concluded that the structure of our product should not be **13'**, but **13**. Then, it could be proved that one of the acetoxyl groups newly introduced by the conversion of **6** to **7**, occupied the 2-position of **7**.

If an aromatic ring has either a formyl or a hydroxymethyl substituent, an ortho-lithiation of the ring is generally possible by the use of butyllithium.[8] Here, the obtained products **8** and **11** have such possibilities to receive new side-chain introductions at their 3-positions; we will be able to apply this to intermediates for syntheses of naphthoquinone antibiotics.

Experimental

^1H NMR spectra were taken on a JEOL JNM-FX60 in $CDCl_3$ and showed in δ values. Mass spectra were obtained with a JEOL DX-300. IR spectra were recorded on a Hitachi 260-30. Column chromatography was carried out on silica gel (Wakogel C-200) with chloroform as an eluent. Melting points were determined with a Yanagimoto micromelting point apparatus and were uncorrected.

6-Formyl-5,8-dimethoxy-1,4-naphthoquinone (6). A solution of CAN (26 g, 47.7 mmol) in water (60 ml) was added to a solution of the aldehyde **5** (5.15 g, 18.7 mmol) in acetonitrile (100 ml) at room temperature, stirred for 30 min, then diluted with water (300 ml). The precipitate was filtered,

washed with water, dried, and gave 3.4 g (74%) of **6** as yellow crystals, mp 175—177 °C. The filtrate was extracted with chloroform. The chloroform solution was washed with brine, dried, and evaporated. Chromatographic purification of the crude product gave 0.51 g (11%) of a sample of **6**. Recrystallization from ligroine-benzene gave an analytical sample, mp 177—178 °C. IR (KBr) 1695 (aldehyde C=O), 1665 (quinone C=O), 1055, and 1020 cm^{-1}; MS *m/z* 246 (M^+), 232, 216, 200, and 189; ^1H NMR δ=4.03 (s, 6H, OCH_3), 6.87 (s, 2H, quinonoid ring H), and 7.77 (s, 1H, benzenoid ring H). Found: C, 63.27; H, 4.06%. Calcd for $C_{13}H_{10}O_5$: C, 63.72; H, 4.09%.

1,2,4-Triacetoxy-6-diacetoxymethyl-5,8-dimethoxynaphthalene (7). A mixture of **6** (8.2 g, 33.4 mmol) in acetic anhydride (50 ml) and concd sulfuric acid (0.5 ml) was allowed to stand at room temperature for 10 d, then poured into ice water and extracted with chloroform. The usual work-up and chromatography gave 16.2 g (98%) of a sample of **7**. Recrystallization from hexane-ethanol gave an analytical sample, mp 174—175 °C. IR (KBr) 1760 (C=O), 1610, 1365, 1200, and 1035 cm^{-1}; MS *m/z* 492 (M^+), 450, 408, 366, and 264; ^1H NMR δ=2.11 (s, 6H, CH_3), 2.32 (s, 3H, CH_3), 2.35 (s, 6H, CH_3), 3.86, 3.93 (each s, 3H, OCH_3), 6.96, 7.08 (each s, 1H, ArH), and 8.15 (s, 1H, CH). Found: C, 56.09; H, 4.94%. Calcd for $C_{23}H_{24}O_{12}$: C, 56.10; H, 4.91%.

2-Formyl-1,4,5,6,8-pentamethoxynaphthalene (8). Sodium hydroxide (12 g, 0.3 mol) dissolved in water (50 ml) was added dropwise to a suspension of **7** (9.93 g, 20 mmol) in methanol (50 ml) under a nitrogen atmosphere and stirred for 1 h. To this was added dimethyl sulfate (76 g, 0.6 mol) and sodium hydroxide (12 g, 0.3 mol) in water (50 ml) alternately and stirred at 40 °C for 5 h. After concentration, the system was extracted with chloroform, worked up as usual, and chromatographed to give 4.14 g (67%) of a sample of **8**. Recrystallization from hexane-ethanol gave yellow crystals, mp 153.5—155.5 °C. IR (KBr) 1660 (C=O), 1595, 1360, 1070, and 1045 cm^{-1}; MS *m/z* 306 (M^+), 291, 276, 263, and 258; ^1H NMR δ=3.81, 3.90, 3.98, 4.01, 4.03 (each s, 3H, OCH_3), 6.78, 7.13 (each s, 1H, ArH), and 10.47 (s, 1H, CHO). Found: C, 62.58; H, 5.92%. Calcd for $C_{16}H_{18}O_6$: C, 62.74; H, 5.92%.

6-Formyl-2,5,8-trimethoxy-1,4-naphthoquinone (9). A solution of CAN (4.0 g, 7.35 mmol) in water (40 ml) was added dropwise to a solution of **8** (0.9 g, 2.94 mmol) in acetonitrile (50 ml), stirred at room temperature for 30 min, then diluted with water and extracted with chloroform. The usual work-up and chromatography gave 0.72 g (89%) of a sample of **9**. Recrystallization from ligroine gave orange crystals, mp 239—241 °C. IR (KBr) 1680 (aldehyde C=O), 1650, 1630 (each quinone C=O), 1585, 1205, 1055, and 1020 cm^{-1}; MS *m/z* 276 (M^+) and 261; ^1H NMR δ=3.88, 3.99, 4.02 (each s, 3H, OCH_3), 6.08 (s, 1H, quinonoid ring H), 7.71 (s, 1H, benzenoid ring H), and 10.50 (s, 1H, CHO). Found: C, 60.83; H, 4.45%. Calcd for $C_{14}H_{14}O_6$: C, 60.87; H, 4.38%.

6-Formyl-5,8-dihydroxy-2-methoxy-1,4-naphthoquinone (10). Anhydrous aluminum chloride (0.48 g, 3.6 mmol) was added to a solution of **9** (0.1 g, 0.36 mmol) in dichloromethane (30 ml), stirred at room temperature for 20 h, decomposed by an addition of 5% aqueous oxalic acid (100 ml), and extracted with chloroform. After the usual work-up, the crude product was chromatographed to give 30 mg (33%) of a sample of **10**, mp 243—244 °C (decomp). IR (KBr) 1690 (aldehyde C=O), 1615 (quinone C=O), 1590, 1560, 1430, 1195, and 1030 cm^{-1}; MS *m/z* 248 (M^+), 220, and 202; ^1H NMR δ=3.98 (s, 3H, OCH_3), 6.25 (s, 1H, quinonoid ring H), 7.75 (s, 1H, benzenoid ring H), 10.55 (s, 1H, CHO), 11.76, and 13.11 (each s, 1H, ArOH). Found: C, 57.70; H, 3.86%. Calcd for $C_{12}H_8O_8$: C, 58.07; H, 3.25%.

2-Hydroxymethyl-1,4,5,6,8-pentamethoxynaphthalene (11). A solution of **8** (0.26 g, 0.86 mmol) in tetrahydrofuran (15 ml) was treated with lithium aluminum hydride (65 mg, 1.7 mmol) under ice cooling, stirred at room temperature for 3 h, then decomposed by an addition of dil hydrochloric acid, and extracted with chloroform. The usual work-up and chromatography gave 0.21 g (78%) of a sample of **11**. Recrystallization from ligroine-benzene gave an analytical sample, mp 138—139 °C. IR (KBr) 3480 (sharp, OH), 1600, 1460, 1370, 1070, and 1050 cm^{-1}; MS *m/z* 308 (M^+), 293 (M^+-CH_3), 265, and 71; ^1H NMR δ=2.33 (s, 1H, OH), 3.77, 3.80, 3.93 (each s, 3H, OCH_3), 3.98 (s, 6H, OCH_3), 4.81 (s, 2H, CH_2), 6.74, and 6.86 (each s, 1H, ArH). Found: C, 62.57; H, 6.59%. Calcd for $C_{16}H_{20}O_6$: C, 62.32; H, 6.54%.

6-Hydroxymethyl-2,5,8-trimethoxy-1,4-naphthoquinone (12). Treatment of **11** (0.57 g, 1.85 mmol) in a mixture of acetonitrile (20 ml) and chloroform (2 ml) with CAN (2.54 g, 4.63 mmol) in water (8 ml) gave a crude product. Chromatography of the crude product gave 0.35 g (68 %) of a sample of **12**. Recrystallization from ethanol gave orange crystals, mp 216.5—217.5 °C. IR (KBr) 3490 (sharp, OH), 1645, 1620 (each C=O), 1585, 1205, 1065, and 1050 cm^{-1}; MS *m/z* 278 (M^+), 248, 234, and 217; ^1H NMR δ=2.21 (t, *J*=5.9 Hz, 1H, OH), 3.84 (s, 6H, OCH_3), 4.00 (s, 3H, OCH_3), 4.85 (d, *J*=5.9 Hz, 2H, CH_2), 6.01 (s, 1H, quinonoid ring H), and 7.43 (s, 1H, benzenoid ring H). Found: C, 60.31; H, 5.18%. Calcd for $C_{14}H_{14}O_6$: C, 60.43; H, 5.07%.

5,8-Dihydroxy-6-hydroxymethyl-2-methoxy-1,4-naphthoquinone (13) and 5-Hydroxy-6-hydroxymethyl-2,8-dimethoxy-1,4-naphthoquinone (14). The reaction of **12** (95 mg, 0.34 mmol) in dichloromethane (30 ml) with anhydrous aluminum chloride (0.46 g, 3.4 mmol) was carried out at room temperature for 2 h. Chromatography of the crude product gave two kinds of crystalline products. One was 37 mg (43%) of a sample of **13**. Recrystallization from ethanol gave reddish brown crystals, mp 218.5—219.5 °C. IR (KBr) 3540 (sharp, OH), 1615 (C=O), 1580, 1430, 1200, and 1080 cm^{-1}; MS *m/z* 250 (M^+), 232, and 221; ^1H NMR δ=2.20 (t, *J*=6.1 Hz, 1H, OH), 3.94 (s, 3H, OCH_3), 4.82 (d, *J*=6.1 Hz, 2H, CH_2), 6.17 (s, 1H, quinonoid ring H), 7.34 (s, 1H, benzenoid ring H), 12.24, and 13.07 (each s, 1H, ArOH). Found: C, 57.96; H, 4.45%. Calcd for $C_{12}H_{10}O_6$: C, 57.61; H, 4.03%.

The other was 34 mg (38%) of a sample of **14**. Recrystallization from ethanol gave reddish orange crystals, mp 222—224 °C. IR (KBr) 3570 (OH), 3470 (OH), 1630 (C=O), 1435, 1215, 1080, and 1050 cm^{-1}; MS *m/z* 264 (M^+), 246, and 203; ^1H NMR δ=2.31 (t, *J*=5.9 Hz, 1H, OH), 3.90, 4.00 (each s, 3H, OCH_3), 4.85 (d, *J*=5.9 Hz, 2H, CH_2), 6.05 (s, 1H, quinonoid ring H), 7.43 (s, 1H, benzenoid ring H), and 13.18 (s, 1H, ArOH). Found: C, 58.68; H, 4.61%. Calcd for $C_{13}H_{12}O_6$: C, 59.09; H, 4.58%.

Synthesis and Spectroscopic Studies of 1,1′-(1,8-Naphthylene)-di-1*H*-1,2,3-triazoles[1)]

Yoshinobu NAGAWA,* Koichi HONDA, and Hiroshi NAKANISHI
National Chemical Laboratory for Industry, 1-1 Higashi, Yatabe, Tsukuba, Ibaraki 305
(Received March 16, 1987)

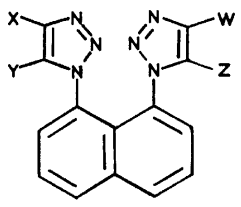
The first 1,8-diheteroaromatic naphthalenes, 1,1′-(1,8-naphthylene)di-1*H*-1,2,3-triazoles (**1**), were synthesized by 1,3-dipolar cycloadditions of 1,8-diazidonaphthalene to acetylenic esters. The spectral properties of these compounds were studied and compared with those of the corresponding 1-(1-naphthyl)-1*H*-1,2,3-triazoles (**2**). The two triazole rings at the peri-positions in **1** are in a face-to-face arrangement according to the results of ^{1}H NMR spectra. The UV spectra of **1** are almost identical with each other and show a red shift from those of corresponding **2**. No significant spectral differences between **1** and **2** were observed in the IR spectra. The fragment ion with two azirine groups at the peri-position in the naphthalene ring was observed in the MS spectra of **1**.

Naphthalenes with substituents in the 1 and 8 positions exhibit unique properties in both structure and reactivity, because the substituents exist in close proximity in these compounds.[2)] Recently, 1,8-diarylnaphthalenes have been synthesized and studied extensively in view of their geometry and inherent strain due to steric overcrowding.[3)] However, heteroaromatic analogues with heterocyclic rings in the peri-position have not yet been studied, presumably because of difficulties in synthesizing them.

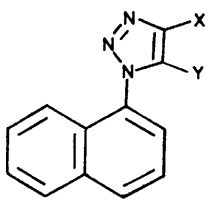
Thus, we have attempted to synthesize the new 1,8-diheteroaromatic naphthalenes, 1,1′-(1,8-naphthylene)-di-1*H*-1,2,3-triazoles (**1a—k**), by the 1,3-dipolar cycloaddition of 1,8-diazidonaphthalene to several acetylenic esters. This paper deals with their syntheses and spectral properties comparing with corresponding 1-(1-naphthyl)-1*H*-1,2,3-triazoles (**2a—h**).

Results and Discussion

The thermal 1,3-dipolar cycloaddition of azides to alkynes is a well-known route to 1*H*-1,2,3-triazoles, and the reaction of various azides have been investigated.[4)]



1a: W=X=Y=Z=CO_2Me
1b: W=X=Y=Z=CO_2Et
1c: W=X=Y=Z=CO_2Pr^i
1d: W=X=Y=Z=CO_2Bu^t
1e: W=X=CO_2Et, Y=Z=H
1f; W=X=H, Y=Z=CO_2Et
1g: W=Y=CO_2Et, X=Z=H
1h: W=X=Z=CO_2Et, Y=H
1i: W=Y=Z=CO_2Et, X=H
1j: W=X=COOH, Y=Z=H
1k: W=X=Y=Z=H

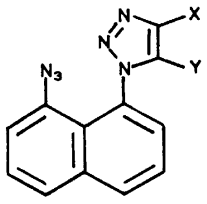


2a: X=Y=CO_2Me
2b: X=Y=CO_2Et
2c: X=Y=CO_2Pr^i
2d: X=Y=CO_2Bu^t
2e: X=CO_2Et, Y=H
2f: X=H, Y=CO_2Et
2g: X=COOH, Y=H
2h: X=Y=H

However, the reactions of 1,8-diazidonaphthalene, as well as 1-azidonaphthalene, have not yet been reported. The reactions of 1,8-diazidonaphthalene with a large excess of acetylenedicarboxylates, RO_2C-C≡CCO_2R (R=Me, Et, Pr^i, and Bu^t), afforded **1a—d** via the formation of dialkyl 1-(8-azido-1-naphthyl)-1*H*-1,2,3-triazole-4,5-dicarboxylate. In order to avoid the decomposition of 1,8-diazidonaphthalene, the reactions were carried out in the dark and at room temperature. The reaction with an unsymmetrical acetylene, ethyl propiolate, gave three isomeric triazoles, **1e—g**. The identification of **1e** and **1f** as shown in the figure was made by comparing the ^{1}H NMR chemical shifts of triazole ring protons in **1e** and **1f** with those in previously reported 1-phenyl-4-methyl-1*H*-1,2,3-triazole and 1-phenyl-5-methyl-1*H*-1,2,3-triazole.[5)] The main product was **1e**, and the most sterically hindered isomer, **1f**, formed very little (**1e**:**1f**:**1g**=26:1:12). The 1:1 addition products of the above reaction, **3a** and **3b**, were employed to synthesize the unsymmetrical triazoles, **1h** and **1i**.

In order to prepare the parent compound, **1k**, following reactions were attempted. Hydrolysis of **1e** in alkaline solution led to carboxylic acid, **1j**. Heating crystals of **1j** up to 180 °C under a nitrogen atmosphere afforded **1k** almost quantitatively. In the similar manner, 1-naphthyltriazoles, **2a—h**, were synthesized from 1-azidonaphthalene.

Spectral properties of **1a—k** and **2a—h** are listed in Tables 1 and 2, respectively. In the ^{1}H NMR spectra of **1k**, the H-4 and H-5 protons appeared at higher field



3a: X=CO_2Et, Y=H
3b: X=H, Y=CO_2Et

Table 1. Spectroscopic Data of 1,1′-(1,8-Naphthylene)di-1*H*-1,2,3-triazoles

Product	^{1}H NMR ($CDCl_3$)[a]	IR(KBr)	UV(CH_3OH)	MS

a) Since **1j** was insoluble in $CDCl_3$, the ^{1}H NMR spectrum of **1j** was measured in DMSO-d_6.

by ca. 0.5 ppm than the corresponding protons in **2h**. Similar high field shifts of H-5 and H-4 were observed between **1e** and **2e** and between **1f** and **2f**, respectively. These high field shifts of each proton at the triazole ring can be explained by the considerable anisotropic effects of the other triazole ring. This suggests that the two triazole rings in **1** are facing to each other. On the other hand, according to the crystal structure of **1k**, which is determined by an X-ray diffraction study, the two triazole rings take a face-to-face arrangement and a trans conformation to each other.[6] Thus, the results obtained by NMR analyses about the conformation of these triazole rings are in well accordance with that by X-ray analyses. The extent of the high field shifts for these compounds are comparable to that for the facing benzene rings in 1,8-diphenylnaphthalene ($\Delta\delta$=0.53).[3]

Two kinds of ^{1}H NMR signal for methyl groups, which were assigned to 4- and 5- ester groups in the triazole ring, were observed in **1a**, **1b**, and **1d**. However, **1c** gave four kinds of methyl group resonance, each splitted by methine proton. This phenomenon shows that the two methyl moiety of the isopropyl group are not equivalent magnetically. Such nonequivalency is, as well as in the case of 1-phenyl-8-[3-(1-hydroxy-1-methylethyl)phenyl]naphthalene,[7] well explained by asymmetric environment of the molecule. Only two kinds of the methyl signals were observed in the isopropyl groups of **2c** at room temperature. These results indicate that the rotation around the pivot bond between triazole ring and naphthalene ring is restricted in **1c**. Probably, the two triazole rings hinder the rotation each other. On the

Table 2. Spectroscopic Data of 1-(1-Naphthylene)-1*H*-1,2,3-triazoles

a) Since **2g** was insoluble in $CDCl_3$, the ^{1}H NMR spectrum of **2g** was measured in DMSO-d_6.

other hand, the racemization may occur in **2c** because the rotation around the bond is so fast.

The ^{1}H NMR signals for the methyl moiety in the ester group of 5-position at the triazole ring are at higher field than those of 4-position in **1a—i**. As the similar relationships were observed in **2a—f**, it may be explained by the anisotropic effect of the naphthalene ring.

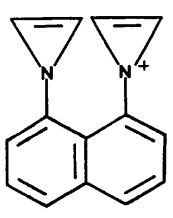
The UV spectra of **1** are almost identical with each other (ca. 221 and 288 nm) and independent of the substituents on the triazole ring, and show a red shift from those of **2**. The extent of the red shift is about 7 nm for the longest wavelength absorption band. Since the absorption band due to the triazole ring exists at ca. 210 nm,[8] the longest wavelength band is assigned to naphthalene ring. The same kind of red shift has been observed between the absorption of 1,8-diphenylnaphthalene and 1-phenylnaphthalene.[9]

In IR spectra, absorptions of C=O (ca. 1700—1750 cm^{-1}) and C-O-C (ca. 1200—1300 cm^{-1}) groups were observed in addition to those of the triazole (ca. 1000—1100 cm^{-1}) and naphthalene rings (ca. 750—850 cm^{-1}) in **1a—j** and **2a—g**. Both **1k** and **2h** show C-H stretching in triazole ring at ca. 3100—3150 cm^{-1}. No significant spectral differences between **1** and **2** were observed in the IR spectra.

In the MS spectra of **1**, molecular ions were observed except for the carboxylic acid, **1j**. The MS spectrum data show that the molecular ion peaks become weaker with the size of the ester groups at the triazole ring become bulkier, as seen in usual carboxyric acid and esters. The fragment ion (m/z=167) of the azirine type, which was generated by the nitrogen elimination from molecular ion, was found in the parent molecules, **2h**. Such fragmentation was reported in the MS spectra of 1-phenyl-1*H*-1,2,3-triazoles.[10] Moreover, the fragment ion (m/z=206) with two azirine groups at peri-position in the naphthalene ring **4** was found in **1k**. The m/z 166 ion, which was produce by the further elimination of one azirine ring from **4**, was also observed in **1k**.

Experimental

Instruments. All melting points were determined on a Mettler FP61 instrument and were uncorrected. ^{1}H NMR spectra were obtained by a JEOL GX-400 spectrometer (399.65 MHz for ^{1}H nuclei) using TMS as an internal standard. IR and UV spectra were measured on a Nicolet 170SX



4

and a Shimadzu MPS-2000 spectrometer, respectively. MS spectra were measured with a JEOL JMS-01SG-2 spectrometer at 75 eV of ionization energy. Elemental analyses were performed on a Yanaco MT-3 CHN micro analyzer.

Materials. 1,8-Diazidonaphthalene and 1-azidonaphthalene were prepared from 1,8-diaminonaphthalene and 1-aminonaphthalene as previously reported, respectively.[11,12] Diisopropyl acetylenedicarboxylate was prepared from acetylenedicarboxyric acid and isopropyl alcohol,[13] and di-*t*-butyl acetylenedicarboxylate was synthesized from acetylenedicarboxylic acid and 1-butene according to the synthetic method of di-*t*-butyl malate.[14] Dimethyl acetylenedicarboxylate, diethyl acetylenedicarboxylate, and ethyl propiolate were commercially available.

Reaction of 1,8-Diazidonaphthalene with Acetylene Carboxylates. To a solution of 1,8-diazidonaphthalene (1.0 g, 4.8 mmol) in diethyl ether (10 ml), a large excess of dimethyl acetylenedicarboxylate (5.0 g, 35.2 mmol) was added and the mixture was allowed to react at room temperature in the dark. It took 14 d until the products with two triazole rings were formed. After the completion of the reaction was checked by TLC (silica gel, diethyl ether), the mixture was purified by chromatographic separation on silica gel (Waco gel C-100) with a diethyl ether–dichloromethane mixture to give **1a**.

Tetramethyl 1,1′-(1,8-naphthylene)di-1*H*-1,2,3-triazole-4,5-dicarboxylate(**1a**): Colorless prisms from methanol; mp 222—223 °C, 2.1 g (89%). Found: C, 53.72; H, 3.66; N, 16.86%. Calcd for $C_{22}H_{18}N_6O_8$: C, 53.44; H, 3.67; N, 17.00%.

Similarly, the reactions of 1,8-diazidonaphthalene (1.0 g, 4.8 mmol) with about 8 times as much excess of diethyl, diisopropyl, and di-*t*-butyl acetylenedicarboxylates gave **1b**, **1c**, and **1d**, respectively.

Tetraethyl 1,1′-(1,8-naphthylene)di-1*H*-1,2,3-triazole-4,5-dicarboxylate (**1b**): Colorless prisms from methanol; mp 138—139 °C, 2.2 g (85%). Found: C, 56.81; H, 4.63; N, 15.14%. Calcd for $C_{26}H_{26}N_6O_8$: C, 56.72; H, 4.76; N, 15.27%.

Tetraisopropyl 1,1′-(1,8-naphthylene)di-1*H*-1,2,3-triazole-4,5-dicarboxylate (**1c**): Colorless needles from methanol; mp 107—108 °C, 2.5 g (86%). Found: C, 59.30; H, 5.50; N, 13.71%. Calcd for $C_{30}H_{34}N_6O_8$: C, 59.40; H, 5.65; N, 13.85%.

Tetra-*t*-butyl 1,1′-(1,8-naphthylene)di-1*H*-1,2,3-triazole-4,5-dicarboxylate(**1d**): Colorless needles from methanol; mp 160—161 °C, 2.5 g (80%). Found: C, 61.83; H, 6.62; N, 12.50%. Calcd for $C_{34}H_{42}N_6O_8$: C, 61.62; H, 6.39; N, 12.68%.

In the similar reaction of the 1,8-diazidonaphthalene (1.0 g, 4.8 mmol) with ethyl propiolate (3.5 g, 35.7 mmol) for 14 d, the following three possible products were all isolated by chromatography on silica gel with a diethyl ether–dichloromethane mixture.

Diethyl 1,1′-(1,8-naphthylene)di-1*H*-1,2,3-triazole-4-carboxylate (**1e**): Colorless needles from methanol; mp 173—174 °C, 1.0 g (52%). Found: C, 58.88; H, 4.22; N, 20.59%. Calcd for $C_{20}H_{18}N_6O_4$: C, 59.11; H, 4.46; N, 20.68%.

Diethyl 1,1′-(1,8-naphthylene)di-1*H*-1,2,3-triazole-5-carboxylate (**1f**): Colorless needles from methanol; mp 175—176 °C, 35 mg (2%). Found: C, 58.80; H, 4.46; N, 20.47%. Calcd for $C_{20}H_{18}N_6O_4$: C, 59.11; H, 4.46; N, 20.68%.

Ethyl 1-[8-(5-ethoxycarbonyl-1*H*-1,2,3-triazol-1-yl)-1-naphthyl]-1*H*-1,2,3-triazole-4-carboxylate (**1g**): Colorless needles from methanol; mp 128—129 °C, 460 mg (24%). Found: C, 59.36; H, 4.26; N, 20.57%. Calcd for $C_{20}H_{18}N_{60}O_4$: C, 59.11; H, 4.46; N, 20.47%.

Identical reaction for 24 h gave the intermediate 1 : 1 adducts, **3a** and **3b**, in the maximum yields, and they were isolated by chromatography on silica gel with a hexane–diethyl ether mixture.

Ethyl 1-(8-azido-1-naphthyl)-1*H*-1,2,3-triazole-4-carboxylate (**3a**): Pale yellow needles from methanol; mp 135—136 °C, 700 mg (48%). ^{1}H NMR ($CDCl_3$) δ=1.48 (t, J=7.2 Hz, 3H, CH_3), 4.51 (q, J=7.2 Hz, 2H, CH_2), 7.31 (d, J=7.5 Hz, 1H, H-7′), 7.47 (d, J=7.3 Hz, 1H, H-2′), 7.58 (dd, J=8.1, 7.5 Hz, 1H, H-6′), 7.60 (dd, J=8.3, 7.3 Hz, 1H, H-3′), 7.77 (d, J=8.1 Hz, 1H, H-5′), 8.06 (d, J=8.3 Hz, 1H, H-4′), 8.34 (s, 1H, H-5). IR (KBr) 2130 (N_3), 1730 (C=O) cm^{-1}. MS m/z (rel intensity, %) 308 (10), 280 (9), 208 (96), 180 (35), 126 (100). Found: C, 58.34; H, 3.88; N, 27.03%. Calcd for $C_{15}H_{12}N_6O_2$: C, 58.44; H, 3.92; N, 27.26%.

Ethyl 1-(8-azido-1-naphthyl)-1*H*-1,2,3-triazole-5-carboxylate (**3b**): Pale yellow needles from methanol; mp 109—110 °C, 250 mg (17%). ^{1}H NMR ($CDCl_3$) δ=1.07 (t, J=7.2 Hz, 3H, CH_3), 4.14 (m, 2H, CH_2), 7.27 (d, J=7.4 Hz, 1H, H-7′), 7.42 (d, J=7.3 Hz, 1H, H-2′), 7.55 (dd, J=8.2, 7.4 Hz, 1H, H-6′), 7.60 (dd, J=8.3, 7.3 Hz, 1H, H-3′), 7.77 (d, J=8.2 Hz, 1H, H-5′), 8.05 (d, J=8.3 Hz, 1H, H-4′), 8.34 (s, 1H, H-4). IR (KBr) 2125 (N_3), 1730 (C=O) cm^{-1}. MS m/z (rel intensity, %) 308 (28), 280 (37), 208 (10), 180 (100), 126 (96). Found: C, 58.27; H, 3.86; N, 27.15%. Calcd for $C_{15}H_{12}N_6O_2$: C, 58.44; H, 3.92; N, 27.26%.

The reaction of **3a** (200 mg, 0.65 mmol) and **3b** (200 mg, 0.65 mmol) with 5 times as much excess of diethyl acetylenedicarboxylate for 14 d at room temperature gave **1h** and **1i**, respectively.

Diethyl 1-[8-(4-ethoxycarbonyl-1*H*-1,2,3-triazol-1-yl)-1-naphthyl]-1*H*-1,2,3-triazole-4,5-dicarboxylate(**1h**): Colorless needles from methanol; mp 130—131 °C, 210 mg (68%). Found: C, 57.74; H, 4.66; N, 17.49%. Calcd for $C_{23}H_{22}N_6O_6$: C, 57.74; H, 4.63; N, 17.56%.

Diethyl 1-[8-(5-ethoxycarbonyl-1*H*-1,2,3-triazol-1-yl)-1-naphthyl]-1*H*-1,2,3-triazole-4,5-dicarboxylate(**1i**): Colorless needles from methanol; mp 170—171 °C, 190 mg (61%). Found: C, 57.58; H, 4.45; N, 17.52%. Calcd for $C_{23}H_{22}N_6O_6$: C, 57.74; H, 4.63; N, 17.56%.

Hydrolysis of 1e. A suspension of **1e** (500 mg, 1.2 mmol) in aqueous NaOH (1.0 g, 25 mmol, 40 ml) was refluxed for 12 h. On adjusting the solution to pH 5 with aqueous HCl, a precipitate was formed immediately. The precipitate was collected by filtration and recrystallized from water to give **1j** as colorless needles.

1,1′-(1,8-Naphthylene)di-1*H*-1,2,3-triazole-4-carboxylic acid (**1j**): mp 253—254 °C, 350 mg (81%). Found: C, 54.99; H, 2.94; N, 24.02%. Calcd for $C_{16}H_{10}N_6O_4$: C, 54.86; H, 2.88; N, 23.99%.

Decarboxylation of 1j. The crystals of **1j** (320 mg, 0.91 mmol) were decarboxylated by heating at 180 °C for 3 h under a nitrogen atmosphere. Sublimation of the crude product gave pure **1k** as colorless needles.

1,1′-(1,8-Naphthylene)di-1*H*-1,2,3-triazole(**1k**): mp>300 °C, 235 mg (92%). Found: C, 63.98; H, 3.78; N, 32.05%. Calcd for $C_{14}H_{10}N_6$: C, 64.11; H, 3.84; N, 32.04%.

Preparation of 1-(1-Naphthyl)-1*H*-1,2,3-triazoles. By the reaction of 1-azidonaphthalene (1 g, 5.92 mmol) with 5 times as much excess of acetylenecarboxylates at room temperature for 72 h, **2a—f** were synthesized and purified by silica-gel chromatography with hexane–diethyl ether.

Dimethyl 1-(1-naphthyl)-1*H*-1,2,3-triazole-4,5-dicarboxylate

(**2a**): Colorless needles from hexane-diethyl ether, mp 122—123 °C, 1.5 g (81%). Found: C, 61.54; H, 4.21; N, 13.39%. Calcd for $C_{16}H_{13}N_3O_4$: C, 61.73; H, 4.21; N, 13.50%.

Diethyl 1-(1-naphthyl)-1*H*-1,2,3-triazole-4,5-dicarboxylate (**2b**): Oil, 1.5 g (75%). Found: C, 63.56; H, 5.16; N, 12.52%. Calcd for $C_{18}H_{17}N_3O_4$: C, 63.71; H, 5.05; N, 12.38%.

Diisopropyl 1-(1-naphthyl)-1*H*-1,2,3-triazole-4,5-dicarboxylate (**2c**): Colorless prisms from hexane-diethyl ether, mp 105—106 °C, 1.9 g (87%). Found: C, 65.22; H, 5.73; N, 11.37%. Calcd for $C_{20}H_{21}N_3O_4$: C, 65.38; H, 5.76; N, 11.44%.

Di-*t*-butyl 1-(1-naphthyl)-1*H*-1,2,3-triazole-4,5-dicarboxylate (**2d**): Colorless prisms from hexane-diethyl ether, mp 142—143 °C, 1.9 g (81%). Found: C, 66.75; H, 6.25; N, 10.48%. Calcd for $C_{22}H_{25}N_3O_4$: C, 66.82; H, 6.37; N, 10.63%.

Ethyl 1-(1-naphthyl)-1*H*-1,2,3-triazole-4-carboxylate (**2e**): Colorless needles from hexane-diethyl ether, mp 101—102 °C, 1.1 g (71%). Found: C, 67.31; H, 4.83; N, 15.64%. Calcd for $C_{15}H_{13}N_3O_2$: C, 67.41; H, 4.90; N, 15.72%.

Ethyl 1-(1-naphthyl)-1*H*-1,2,3-triazole-5-carboxylate (**2f**): Colorless needles from hexane-diethyl ether, mp 102—103 °C, 280 mg (18%). Found: C, 67.50; H, 4.72; N, 15.77%. Calcd for $C_{15}H_{13}N_3O_2$: C, 67.41; H, 4.90; N, 15.72%.

Hydrolysis of **2e** (1 g, 3.7 mmol) as in the case of **1e** gave **2g**.

1-(1-Naphthyl)-1*H*-1,2,3-triazole-4-carboxylic acid (**2g**): Colorless needles from water, mp 147—148 °C, 0.8 g (89%). Found: C, 65.23; H, 3.76; N, 17.56%. Calcd for $C_{13}H_9N_3O_2$: C, 65.27; H, 3.79; N, 17.56%.

Decarboxylation of **2g** (0.5 g, 2.1 mmol) was performed in a similar manner to that of **1j**, and pure **2h** was obtained by sublimation as colorless needles.

1-(1-Naphthyl)-1*H*-1,2,3-triazole (**2h**): mp 102—103 °C, 380 mg (93%). Found: C, 73.77; H, 4.51; N, 21.60%. Calcd for $C_{12}H_9N_3$: C, 73.83; H, 4.65; N, 21.52%.

We wish to thank Dr. Nobuhide Wasada, Dr. Sadao Tamura, and Dr. Akira Nomura, in our Laboratory, for their helpful discussions.

(Received March 19, 1987)

The quantum yields for norbornadiene(N) → quadricyclane(Q) and Q → N isomerization were determined in acetonitrile using several substituted benzophenones (BPs) as triplet sensitizers. For the N → Q isomerization, BPs with electron-donating substituents exhibited higher quantum efficiency (0.4—0.6) than BPs with electron-accepting substituents. The quantum yields for Q → N isomerization increased with electron-accepting ability of the substituents on BPs, but were lower than 0.1. The rate constants for quenching of triplet BPs by N and Q were also determined in acetonitrile by means of laser flash photolysis. The rate constants for N were not dependent on the triplet energies (E_T) of BPs but dependent on electronic properties of the substituents on BPs. On the contrary, those for Q increased with decreasing E_T of BPs and with increasing Hammett's σ constants of the substituents of BPs. Based on these observations an addition-elimination process is proposed for the N → Q isomerization, and an electron transfer process for the Q → N isomerization.

Recently much attention has been paid to isomerization of norbornadiene (N) to quadricyclane (Q) under solar light irradiation to accomplish molecular storage of energy.[1-3] One of the problems of this system is that N absorbs only light in the UV region. In order to utilize solar irradiation efficiently, two ways of approach have been attempted. The first one using N itself, which is readily supplied as a petrochemical product, employs either sensitizers or reagents capable of forming a complex with N to absorb longer-wavelength light than does N.[1-4] The second is to use substituted norbornadienes exhibiting absorption at much longer wavelengths than N.[5-7]

As for the first approach, benzophenones (BPs) and some other aromatic ketones are known to sensitize N → Q isomerization with light longer than 300 or 350 nm.[8] However, there remain some questions regarding the sensitization mechanism. It is still unclear whether the isomerization of N and Q proceeds through energy transfer from sensitizer or not.

Another problem of this system is consumption of the sensitizer ketones during irradiation due to the formation of addition products. It is desirable to find suitable sensitizers which solely bring about the N → Q isomerization but are not seriously consumed by addition to N or Q.

From these viewpoints we have made a mechanistic approach to the sensitizing ability of substituted BPs for N → Q and Q → N photoisomerization.[9] In this paper we report effects of structural factors of sensitizer ketones on the isomerization efficiency, and propose an addition-elimination mechanism for the BP sensitized N → Q isomerization and an electron-transfer interaction in the quenching of triplet BPs by Q, on the basis of the quantum yields, of the quenching rate constants measured in laser flash photolysis, and of the time profile of the isomerization and adduct formation.

Experimental

Norbornadiene (N) and quadricyclane (Q) were purchased from Aldrich Chemical Co., and purified by distillation. Solvent acetonitrile was Luminasol from Dojin Chemical Co. 4-Cyanobenzophenone was prepared according to the literature.[10] Other substituted benzophenones were purchased from Wako or Nakarai Chemical Co. All the benzophenones were crystallized from methanol, ethanol, hexane, or diethyl ether.

The phosphorescence spectra of some sensitizers were measured on a Hitachi MPF-2A fluorescence spectrophotometer and the triplet energies were determined.

The redox potentials of N, Q, and sensitizers were determined by cyclic voltammetry in acetonitrile with respect to an SCE in the presence of 0.1 mol dm^{-3} tetraethylammonium perchlorate as a supporting electrolyte.

Isomerization quantum yields were determined using potassium tris(oxalato)ferrate(III) actinometry. Benzophenone sensitized N → Q isomerization was carried out in Pyrex tubes with 366 nm light through a UVD-36B glass filter from a 400 W high pressure mercury lamp under nitrogen atmosphere. The conversions were determined by gas chromatography, a Shimadzu GC-4CM PF gas chromatograph equipped with an FID.

Laser flash photolyses were performed as described elsewhere.[11] Sample solutions were deaerated by bubbling with nitrogen for 30 min. The first order decay rate constants (k_{obs}) of triplet benzophenones were measured as a function of N or Q concentration by monitoring their T-T absorptions around 530 nm, and the quenching rate constants (k_q^N and k_q^Q) were obtained from linear plots based on the following equation:

$$k_{obs} = \tau_T^{-1} + k_q^S[S], \quad S = N \text{ or } Q.$$

Results

Quantum Yields for N → Q and Q → N Isomerization. The quantum yields for sensitized isomerization of N (0.1 mol dm^{-3}) and Q (0.1 mol dm^{-3}) were determined at low

a) $\Delta G_N^\circ = E_{ox}(N) - (E_{red}+E_T) - 0.06$. b) $\Delta G_Q^\circ = E_{ox}(Q) - (E_{red}+E_T) - 0.06$.

conversion using several BPs and other triplet sensitizers (0.1 $mol\,dm^{-3}$) in deaerated acetonitrile solutions. The results are summarized in Table 1 together with the triplet excitation energies (E_T) of sensitizers employed and Hammett's σ constants ($\sum\sigma$) of the substituents on BPs. Figure 1 plots the quantum yields against E_T of the sensitizers and Fig. 2 plots the quantum yields against Hammett's σ constants of the substituents on BPs. The quantum yield of N → Q isomerization in neat N was also determined on sensitization with benzophenone ($1.12\times10^{-2} mol\,dm^{-3}$) to be 0.9.

Reaction of Triplet Benzophenones with N and Q. To see the consumption of N and Q clearly, benzophenone (BP), 4,4′-dimethoxybenzophenone [$(MeO)_2BP$], and 4,4′-dichlorobenzophenone (Cl_2BP) were used in extremely high initial concentrations, the same concentration as N or Q (0.1 mol dm^{-3}). Figures 3 and 4 depict typical results starting from N and Q, respectively. BPs examined induced the N → Q isomerization with a rate decreasing in a sequence of $(MeO)_2BP$, BP, and Cl_2BP, which is in parallel to their sensitized N → Q isomerization quantum yields in the initial stage (Table 1). Starting from both Q and N, the total amount of Q+N decreased most remarkably in the presence of Cl_2BP and to a least extent in the presence of $(MeO)_2BP$. On irradiation of BP ($1.12\times10^{-2} mol\,dm^{-3}$) in neat N, particular attention was paid to follow the reaction with frequent intervals in the early stage. Figure 5 shows the results.

Quenching Rate Constants of Triplet Sensitizers by N and Q. The quenching rate constants of the BPs triplets by N and Q measured in acetonitrile by means of laser flash photolysis are summarized in Table 2. All the benzophenones examined here have $n\pi^*$ character in the triplet state.[10b] This table also lists redox potentials measured in acetonitrile, and the change in the Gibbs function (ΔG°) for electron transfer from N or Q to BPs triplets estimated according to Eq. 1.

$$\Delta G^\circ/eV = E_{ox} - E_{red} + z_1z_2e^2/\varepsilon r - E_T \quad (1)$$

The redox potentials E_{ox} and E_{red} refer to E ($N^{+\cdot}/N$) or E ($Q^{+\cdot}/Q$) and E ($BP/BP^{-\cdot}$), respectively, and the term $z_1z_2e^2/\varepsilon r$ represents the Coulombic energy associated with bringing separated radical ions of charges z_1 and z_2 at the encounter

Table 3. Triplet Energies of Sensitizers (S) and Energies of Intermediates over the Ground States of the Sensitizers and N (or Q)[a)]

Sensitizer	E_T[b)]	$E(S^{-\cdot}\cdots Q^{+\cdot})$	$E(S^{-\cdot}\cdots N^{+\cdot})$

a) In eV. In parentheses are indicated those for $S^{-\cdot}$ and $N^{+\cdot}$ based on the energies of the sensitizers and Q. b) See footnote in Table 1. c) From Ref. 28.

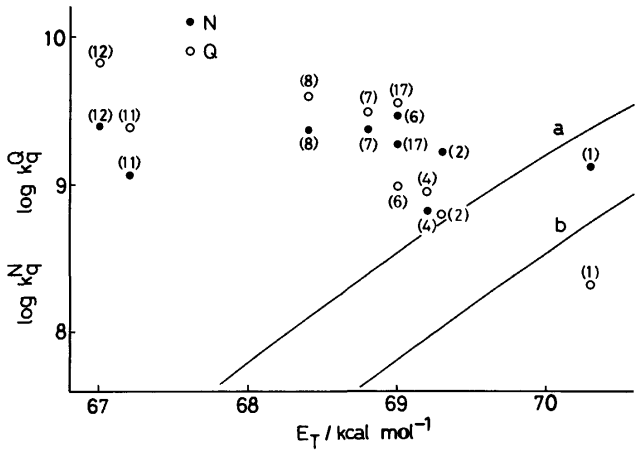

Fig. 6. Plots of quenching rate constants of triplet benzophenones by norbornadiene (k_q^N) and quadricyclane (k_q^Q) vs. triplet energies of benzophenones (E_T). Curves a and b are calculated by Eq. 2 assuming $E_T(N)$=70 and 72 kcal mol^{-1}, respectively.

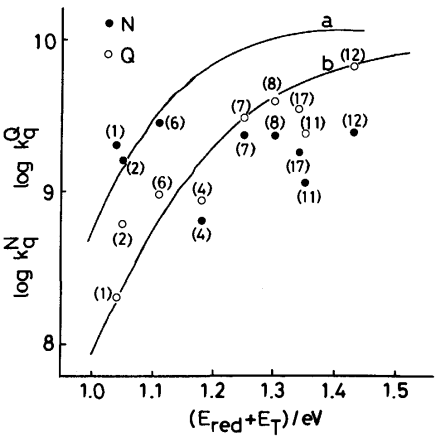

Fig. 8. Plots of quenching rate constants of triplet benzophenones by norbornadiene (k_q^N) and quadricyclane (k_q^Q) vs. $E_{red}+E_T$ of benzophenones. Curves a and b are calculated according to Eq. 3 assuming $\Delta G^{\circ\neq}(0)$=2.4 and 3.5 kcal mol^{-1}, respectively.

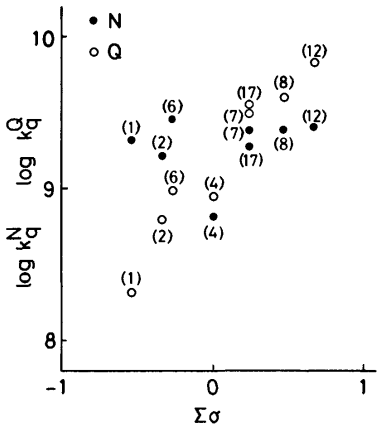

Fig. 7. Plots of quenching rate constants of triplet benzophenones by norbornadiene (k_q^N) and quadricyclane (k_q^Q) vs. Hammett's sigma constants of substituents on benzophenones.

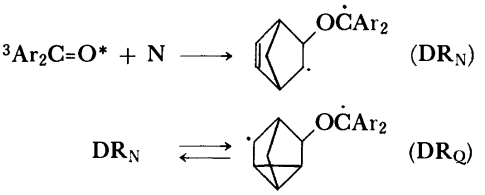

Scheme 1.

distance r in a solvent of dielectric constant ε.[13] The oxidation potentials of Q and N are 1.10 and 1.85 V, respectively, with respect to SCE. The energies of the ion pairs, as calculated as $E_{ox}-E_{red}$ are shown in Table 3. Figures 6 and 7 show logarithmic plots of the quenching rate constants (k_q^N and k_q^Q) against E_T and Hammett's σ constants of BPs, respectively. The plots of log k_q^N and log k_q^Q against the reduction potentials of triplet BPs, as estimated as $E_{red}+E_T$, are illustrated in Fig. 8.

Discussion

Isomerization of N to Q. Three mechanisms are possible for the sensitization of isomerization of N: 1) Triplet energy transfer, 2) electron transfer, and 3) addition-elimination (Scheme 1). As Fig. 1 shows, the efficiency of the N → Q isomerization is not fully governed by the triplet energies of sensitizers. Thus, triphenylene (E_T: 66.5 kcal mol^{-1}, 1 kcal=4.184 kJ) is far less effective than benzophenone (E_T: 69.2 kcal mol^{-1}) and even than 4-phenylbenzophenone with much lower E_T (E_T: 60.7 kcal mol^{-1}). Figure 2 shows that BPs carrying electron-donating substituents act as more effective sensitizers. Accordingly, it is clear that the efficiency of the sensitizer is not fully controlled by its triplet excitation energy, but among BPs some electronic effects of the substituents play an important role in the sensitization.

It is remarkable and consistent with the above results that k_q^N is independent of E_T of the sensitizers and much lower than diffusion controlled limit (Fig. 6). The lack of correlation between k_q^N and E_T suggests that the quenching of triplet BPs by N does not proceed through a simple energy transfer. The curves in Fig. 6 were calculated assuming that the quenching of triplet BPs by N proceeds through energy transfer and obeys Eq. 2,[14] where k_{dif} is the diffusion controlled rate constant, 10^{10} mol^{-1} dm^3 s^{-1}, and ΔE is the triplet energy difference between a BP and N.

$$k_q^N = k_{dif}\exp(-\Delta E/RT)/\{1+\exp(-\Delta E/RT)\} \quad (2)$$

The triplet energy of N was assumed to be 70—72 kcal mol^{-1}.[1,3,15,16] The calculated curves do not fit the plot of the observed rate constants, especially for low energy sensitizers such as 4-cyanobenzophenone, sug-

gesting an important role of quenching processes other than triplet energy transfer.[17]

Electron transfer plays no significant role in the isomerization of N, since the plots of k_q^N against the σ (Fig. 7) and $E_{red}+E_T$ values (Fig. 8) are scattered and seem to have no correlation. From the calculated $\Delta G°$ values in Table 2, the electron transfer from N to triplet BPs is estimated to be more than 0.38 eV endothermic, being in accordance with no correlation in Fig. 6. The rate constant associated with an electron-transfer process usually obeys the Rehm-Weller equation (Eq. 3), where $\Delta G°^{*}(0)$ is the change in the Gibbs function of activation at $\Delta G°=0$ kcal mol^{-1}; $\Delta G°^{*}(0)$ is related to the change in nuclear positions occurring prior to electron transfer, and is 2.4 kcal mol^{-1} for usual electron transfer.[13]

$$k_q = \frac{2\times 10^{10}\ \text{mol}^{-1}\text{dm}^3\text{s}^{-1}}{1+0.25\{\exp(\Delta G°^{*}/RT)+\exp(\Delta G°/RT)\}} \quad (3)$$

$$\Delta G°^{*} = \Delta G°/2+\{(\Delta G°/2)^2+[\Delta G°^{*}(0)]^2\}^{1/2} \quad (4)$$

Because of the large endothermicity (0.38 eV) the rate constant of electron transfer from N to triplet BPs is as low as 2×10^4 mol^{-1} dm^3 s^{-1} according to Eqs. 3 and 4, suggesting less importance of this process.

The addition-elimination mechanism explains reasonably the observed dependence of sensitizing ability of N→Q isomerization on the substituents of BPs[9] and the formation of addition products.[18,19] Comparison of the plot of log k_q^N against E_T with the calculated curve in Fig. 6 suggests that the quenching might proceed mainly through the addition-elimination process for lower energy sensitizers like 4-cyanobenzophenone, while the energy transfer might play a more important role for sensitizers with higher triplet energy like 4,4′-dimethoxybenzophenone.

Shima reported that triplet BP adds to N to give oxetane products.[18] However, later Gorman reported that the formation of the oxetane products is not due to the addition of triplet BP to N but due to the addition to Q resulting from N isomerization.[19] In order to reveal whether the consumption of BP during the irradiation of N is due to its addition to N or to the resulting Q, we carefully reinvestigated irradiation of BP (1.12×10^{-2} mol dm^{-3}) in neat N. Figure 5 clearly shows that the amount of the resulting Q increased linearly with irradiation time and BP decreased even at the very early stage without any induction period.

The present results are in contrast with Gorman's work. Gorman et al. reported that on irradiation of BP in neat N, Q was produced linearly with irradiation time, while the consumption of BP started after an induction period until Q was accumulated in 1.8×10^{-2} mol dm^{-3}.[19] From these results they concluded that the adducts were formed through addition of triplet BP to Q but not to N.[19]

In this concentration of Q, the molar ratio of N (neat: 9.3 mol dm^{-3}) and Q is ca. 520 : 1, and thus by using 6.4×10^8 and 8.8×10^8 mol^{-1} dm^3 s^{-1} as the rate constants for quenching of BP triplets by N and Q, respectively, the fraction of triplet BP to be quenched by Q is estimated to be only 1/380. Inspection of Gorman's data indicates that the relative rate of the Q formation to that of adduct formation is nearly 6—7. This value gives a quantum yield for the adduct formation as strangely high as 49—57 by using 0.9 as the quantum yield for N→Q isomerization determined in the present investigation. Gorman et al. explained their results shortly that the N→Q isomerization must be very inefficient in neat N because of the self quenching of triplet N.[19] However, it is not the case as shown above. The present results are in keeping with the report by Shima which claimed Gorman's arguments and reconfirmed the addition of BP triplets to N.[20]

When the quenching of triplet BPs by N proceeds solely through the addition-elimination mechanism, the observed quenching rate constant (6.4×10^8 mol^{-1} dm^3 s^{-1}) could be supposed to be slightly higher than that expected for the addition of $n\pi^*$ triplet to unsaturated bonds. However, from the analysis of the quantum yields for oxetane formation in the stationary irradiation of benzophenone with furan and for isomerization of *cis*- and *trans*-2-butene induced by benzophenone, the rate constants for the quenching of triplet BP by furan and the cis-alkene mostly by addition are estimated as 4.2×10^7 and 7×10^7 mol^{-1} dm^3 s^{-1}, respectively.[21,22] Also, 4-methoxybenzoyloxyl radical, which has similar electronic configuration to benzophenone triplet carrying an unpaired electron on the oxygen atom, adds to 1,4-cyclohexadiene with a rate constant of ca. 5×10^8 mol^{-1} dm^3 s^{-1} as determined by laser flash photolysis recently.[23] Furthermore, this radical abstracts a hydrogen atom from cyclohexane with ca. 10^6 mol^{-1} dm^3 s^{-1}, nearly the same rate constant for the abstraction of hydrogen atom from 2-propanol by triplet benzophenone.[16] Therefore, it is reasonable to propose that triplet BPs add to N with nearly the same rate constant as that for the addition of 4-methoxybenzoyloxyl radical.

Isomerization of Q to N. As shown in Fig. 6, k_q^Q decreases with increasing E_T of sensitizers. The inverse correlation suggests that E_T of Q is much higher than 58 kcal mol^{-1}, a previously reported value,[15,16] and thus the energy transfer quenching is not important. The fact that the rate constants k_q^Q increases with Hammett's σ of the substituents on BPs indicates that the electron transfer plays an important role in the quenching by Q. The curve a in Fig. 8 was calculated from the Rehm-Weller equation (Eq. 3) using $\Delta G°^{*}(0)=2.4$ kcal mol^{-1} for typical electron transfer.[13] The plot does not fit this curve but fits the curve b calculated by assuming $\Delta G°^{*}(0)=3.5$ kcal mol^{-1}. This means that the electron transfer between BP triplets and Q needs a higher activation energy and thus larger geometrical changes than the usual electron transfer.[24]

The isomerization of Q to N in acetonitrile was not

so efficient as the N→Q isomerization.[8] The quantum yield for Q (0.1 mol dm^{-3})→N isomerization were 0.05, 0.06, and 0.10 in the presence of $(MeO)_2BP$, BP, and 4-cyanobenzophenone, respectively (Table 1). On the other hand, Roth reported that chloranil (CA) sensitized the Q→N isomerization with a high quantum yield, 0.64, and pointed out that the quenching of CA triplets by Q resulted in the production of its radical cations having a geometry close to the transition state of $Q^{+\cdot}\rightarrow N^{+\cdot}$ isomerization.[25] Furthermore, it has been reported that quadricyclane radical cations $Q^{+\cdot}$ generated by γ-irradiation or electrochemical oxidation of Q easily convert into norbornadiene-like radical cations $N^{+\cdot}$ and that the barrier of conversion of $Q^{+\cdot}\rightarrow N^{+\cdot}$ is significantly lower than that for Q→N.[26,27] The low quantum yields observed in the present work could be attributed to the production of N triplets from the radical ion pair consisting of $Q^{+\cdot}$ and $BP^{-\cdot}$. Thus, the isomerization in a radical pair $(BP^{-\cdot}\cdots Q^{+\cdot})\rightarrow(BP^{-\cdot}\cdots N^{+\cdot})$ is exothermic since the ground state of Q is nearly 1 eV higher in energy than that of N.[1] Accordingly, on quenching of triplet BP with Q followed by $Q^{+\cdot}\rightarrow N^{+\cdot}$ isomerization in the pair, the resulting triplet radical pair $^3(BP^{-\cdot}\cdots N^{+\cdot})$ has a higher energy than triplet N (E_T=3.1 eV)[1,3,15,16] as indicated in Table 3, and thus can produce the N triplet effectively. The N triplets deactivate to the ground state to give mainly the starting material Q, therefore leading to low quantum yields of the Q→N isomerization. After the quenching of triplet BP by Q, the resulting radical ion pairs will undergo sequential reactions very quickly since $BP^{-\cdot}$ was not observed after 30 ns of a laser pulse in the nanosecond spectroscopy.

In the case of CA sensitization, however, even if the radical pair $^3(CA^{-\cdot}\cdots N^{+\cdot})$ [triplet energy: 1.84 eV, $E(CA/CA^{-\cdot})$= +0.01 V (SCE)][28] is effectively produced in the quenching of triplet CA by Q, it has a lower energy than has an N triplet (Table 2) and deactivates only to CA+N in the ground state resulting in the higher quantum yield of N.

$$^3BP^* + Q \rightarrow {}^3(BP^{-\cdot}\cdots Q^{+\cdot}) \rightarrow {}^3(BP^{-\cdot}\cdots N^{+\cdot})$$
$$^3(BP^{-\cdot}\cdots N^{+\cdot}) \rightarrow {}^1(BP^{-\cdot}\cdots N^{+\cdot})$$
$$^3(BP^{-\cdot}\cdots N^{+\cdot}) \rightarrow BP + {}^3N^*$$
$$^1(BP^{-\cdot}\cdots N^{+\cdot}) \rightarrow BP + N$$
$$^3N^* \rightarrow Q + N$$

Scheme 2.

In summary, the quenching of triplet BPs by Q proceeds through electron transfer to give norbornadiene-like radical cations, which subsequently recombine with a partner $BP^{-\cdot}$ to generate triplet N reverting to Q finally (Scheme 2). On the other hand, the quenching of triplet BPs by N is proposed to proceed mainly in the addition-elimination fashion which leads finally to effective isomerization to Q (Scheme 1).

(Received March 20, 1987)

1,2-Di-*O*-(2,4-octadecadienoyl)-*sn*-glycero-3-phosphorylcholine is polymerized by radical initiators. An azobisisobutyronitrile (AIBN) and an azobis(2-amidinopropane) dihydrochloride (AAPD) are incorporated into hydrophobic membrane region of the lipid liposomes and an aqueous medium, respectively by sonication. The use of either AIBN or AAPD gives polymerization conversion of about 50% at 60 °C. This is not improved by the elongation of polymerization period at 60 °C or the increase of the amount of these radical initiators. The lyophilized lipids thus polymerized by either AIBN or AAPD are soluble in methanol suggesting the formation of linear polymers. Simultaneous polymerization by both AIBN and AAPD provides almost complete polymerization. AIBN and AAPD have been suggested to initiate radical polymerization of diene groups in 1- and 2-acyl chains, respectively. Potassium peroxodisulfate, another water-soluble radical initiator, yields polymerized liposomes with polymerization conversion of more than 80%. This corresponds to the polymerization of diene groups of not only 2- but also 1-acyl chains due to the hydroxyl radicals which are generated by the radial transfer in an aqueous medium. These different initiation reactions are attributed mainly to the unequivalent chemical environment of diene groups in 1- and 2-acyl chains.

Polymerization of assembled molecules is one of potent techniques to construct highly-ordered polymer structure. UV-irradiation is being used frequently to initiate polymerization of the assembled monomers as liposomes or monolayer membranes because of its convenience.[3-9)] This technique was quite effective to polymerize diacetylenic amphiphiles because of their high reactivity,[4-6)] but some problems raised for the polymerization of diene-containing amphiphiles.[2,10-12)] For example, a strong UV-light irradiation provided an average molecular weight of the diene-containing phospholipids around 5000.[12)] Liposomes with relatively lower degree of polymerization were analyzed to be stabilized only a little.[12)] On the other hand, gamma-ray irradiation is one of potent techniques to initiate in situ polymerization of lipids as liposomes.[11)] However this provides excellent stability of the polymerized liposomes than UV-irradiated ones, it is not commonly-usable method because of less availability of the gamma-ray source and careful treatments. Against this, radical initiators are very common reagents, and those have been found to effectively initiate polymerization of diene containing lipids and to improve membrane stability of the liposomes. This method is quite convenient to prepare polymerized liposomes with excellent stability.[13)] We succeeded the selective polymerization of diene groups of polymerizable amphiphiles as liposomes with water-soluble and -insoluble radical initiators.[12)] This finding may lead to finely regulated polymerization of the assembled molecules. It is therefore getting important to summarize the polymerization profile and characteristics of the selectively polymerized diene-containing lipids.

In this paper, relationship between structural characteristics of radical initiators and polymerization profile of diene-containing amphiphiles is discussed as well as physicochemical characteristics of the obtained polymerized liposomes.

Experimental

1,2-Di-*O*-(2,4-octadecadienoyl)-*sn*-glycero-3-phosphorylcholine (DODPC) was purchased from Nippon Oil & Fats Co. Ltd. and was characterized by thin-layer chromatography (Merck, silica-gel plates) with chloroform–methanol–water (65 : 35 : 5, by vol) as solvent before use.[11)] DODPC showing single spot with R_f value of 0.3 on TLC plate was used for further experiments. Azobisisobutyronitrile (AIBN) and azobis(2-amidinopropane) dihydrochloride (AAPD) were purchased from Tokyo Kasei Co. Ltd. Potassium peroxodisulfate ($K_2S_2O_8$) was purchased from Kanto Chem. Co. Ltd. AIBN was purified twice by recrystallization from dehydrated methanol. AAPD and $K_2S_2O_8$ were recrystallized twice from pure water. Crystals of these radical initiators were dried in vacuo. Triton X-100, polyethylene glycol mono-*p*-octylphenyl ether ($HO(CH_2CH_2O)_{10}C_6H_4C_8H_{17}$), was purchased from Tokyo Kasei Co. Ltd. and was used without further purification. Fluorescent grade 5(6)-carboxyfluorescein (CF) was purchased from Kodak Co. CF was used for the experiments without further purification.

Liposome Preparation. The polymerizable lipids (0.20 g) were dissolved in dehydrated chloroform and slowly evaporated in a rotated sample tube to prepare lipid thin film on the inner surface of the tube. Degassed pure water (20 ml) was then added to the tube. This was sonicated (Tomy Seiko, UR-200P) at 60 W for 10 min in water bath (20 °C) under nitrogen atmosphere to prepare single-walled small liposomes with an average radius of 15—25 nm.

Polymerization. The polymerizable lipids (0.20 g) were dissolved with 2.1 mg of AIBN (5.0 mol% to the polymerizable lipids) in chloroform and was slowly evaporated in a rotated sample tube. Degassed pure water (20 ml) was added to the tube. This was co-sonicated at 60 W for 10 min in water bath at 20 °C to prepare liposome suspension. Lipo-

somes containing different amount of AIBN were also prepared by the same method. Small amount of AIBN was decomposed by 10 min sonication at 60 W. Liposomes were incubated at 8 °C for 3 h to minimize the disordered molecular packing. This procedure provided single-walled liposomes with average radius of 40—70 nm. This liposome dispersion was polymerized under nitrogen atmosphere at 60 °C.

Liposome suspension was prepared and incubated by the same method as mentioned above. AAPD or potassium peroxodisulfate with 0.5—10 mol% to the polymerizable lipids, were then added to the suspensions to avoid decomposition of initiators by the sonication. Liposomes thus prepared were considered to have no AAPD molecule in the inner aqueous phase. Some of liposomes thus prepared were resonicated for 10 s to put AAPD molecules into an inner aqueous phase. Liposomes were polymerized at 60 °C for several hrs under nitrogen atmosphere.

A small amount of DODPC liposome suspension was periodically pipetted out from a sealed sample tube during polymerization. Accurately diluted liposome suspension was analyzed by UV spectrometry to quantitatively determine the polymerization conversion. Calculation of the polymerization conversion was based on the changes of molar extinction coefficient at 255 nm which corresponded to diene groups.[11]

Measurements. Polymerized liposome was stained by uranyl acetate and the suspension was dropped on carbon precoated copper grids and dried carefully to confirm their bilayer structure by TEM (JEOL-100CX). Relatively large liposome suspension (aqueous methanol solution) was dropped on copper sample rest. The liposomal structure was directly analyzed with scanning electron microscopy (JEOL-JSM T20). A laser particle analyzer (Coulter N4D, Coulter Electronics) was used to measure average radius of the polymerized liposomes with a theory of quasielastic light scattering and Stokes-Einstein equation. CF was incorporated into an inner aqueous phase of the liposomes by a similar manner as previously reported.[14] Liposomes containing 0.10 M (1 M=1 mol dm^{-3}) CF were isolated by gel permeation chromatography (Sepharose CL-4B). Diluted liposome suspensions were set into quartz cell for fluorescence measurement at settled temperature. The leakage of CF was followed as the increase of fluorescence intensity at 520 nm by fluorescence spectrometer (Hitachi HPF-4) with excitation beam of 330 nm. A 100% CF leakage was carried out as reference by the sonication of the liposome suspension in the presence of a small excess of Triton X-100.[11] Liposome suspension was prepared with D_2O instead of H_2O by the same manner as mentioned above. Polymerized liposome suspension was put into NMR sample tube with diameter of 5 mm. FT-NMR spectroscopy (JEOL FX-90Q) was used to characterize the segmental motion of the polymerized liposomes at different temperature.

Results and Discussion

Radical Polymerization Profile of DODPC as Liposomes. Polymerization of DODPC liposomes cause the decrease of spectral intensity at 255 nm which is attributed to the diene group.[11] This is essentially applicable to estimate the polymerization conversion. Figure 1 shows the polymerization conversion of

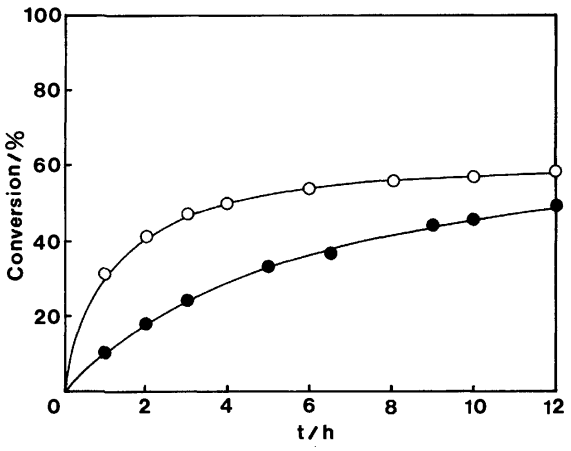

Fig. 1. Polymerization conversion of DODPC as liposomes. DODPC liposomes (10.0 g lipids dm^{-3} H_2O) were polymerized by AIBN (●) or AAPD (○) at 60 °C.

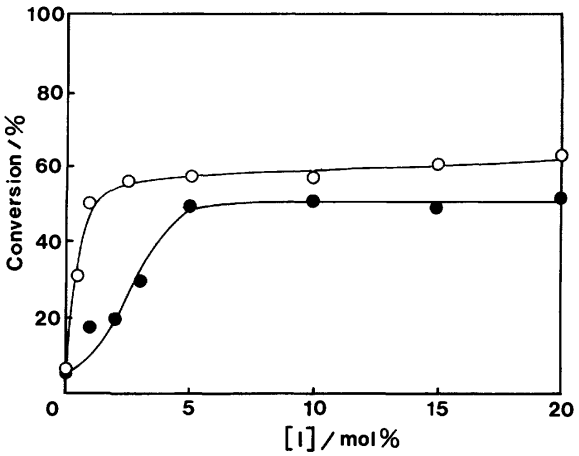

Fig. 2. Relationship between initial concentration of radical initiator and polymerization conversion of DODPC as liposomes (10 h at 60 °C). Liposomes were polymerized by AIBN (●) or AAPD (○).

DODPC lipids initiated by either AIBN or AAPD. The use of either AIBN or AAPD initiated the polymerization with final conversion of about 50% at 60 °C. This conversion was not improved by the elongation of the polymerization time. However certain improvement on the polymerization conversion was observed by further heating, this increase was almost the same as that by thermal polymerization. The increase of the amount of radical initiator did not improve it either as shown in Fig. 2. A thermal polymerization without radical initiator gave about 6—10% polymerization conversion after 12 h heating at 60 °C. AIBN with less than 0.5 mol% to the DODPC lipids was revealed not to participate the initiation of radical polymerization, because such a small amount of AIBN should be decomposed by 10 min sonication at liposome preparation.

The individual radical initiator (AIBN or AAPD) provided only 50% polymerization conversion, which

is important characteristic of DODPC lipids.[12] A 100% polymerization conversion was performed by simultaneous polymerization induced by both of these initiators. This tendency was firstly found by us for the polymerization of DODPC as liposomes.[12] This can be explained by the simple model considering different chemical environment of two diene groups bound to 1- and 2-acyl chains. According to the results of ^{2}D-NMR and X-ray analyses of lipid liposomes or crystals which were reported by Seelig et al.[15,16] and Hitchcock et al.[17] respectively, the glycerol segment was positioned perpendicular to the membrane plane. By applying this result simply to DODPC liposomes, the 2,4-diene group in 2-acyl chain is strongly considered to be faced an aqueous phase.[12] A molecular packing of the polymerizable lipid molecules in the bilayer membrane has already been discussed and the unequivalent characteristics of 1- and 2-acyl chains of the diacetylene-type amphiphiles have already been suggested by O'Brien[18] and Chapman.[19] As in their monomeric lipids, diacetylene groups were located deep in the hydrophobic region, they could not get direct evidence for the unequivalent reactivity of the 1-and 2-acyl chains of monomeric lipid. This unequivalent environment of diene groups was also demonstrated by us with 1-palmitoyl-2-(2,4-octadecadienoyl)-*sn*-glycero-3-phosphorylcholine (POPC).[2] POPC was a model lipid of DODPC and it was easily polymerized as liposomes by water-soluble radical initiator; AAPD, but hardly polymerized by AIBN. Namely, the 2,4-diene group in **2-acyl** chain must be exposed to the aqueous phase. The chemical environment of 2,4-diene groups in 2-acyl chain for POPC should be the same or quite similar to that for DODPC.

The unequivalent chemical environment of the 2,4-diene groups in 1- and 2-acyl chains was also clarified by comparing the polymerization manner with different radical initiators. For example, AAPD could initiate the radical polymerization of the DODPC liposomes which were preliminarily polymerized by AIBN as shown in Fig. 3. This means that the diene groups in 2-acyl chains are not initiated by AIBN radicals but are certainly initiated by AAPD radicals. The simultaneous initiation enabled polymerization with higher conversion than two-step initiation as shown in Fig. 3. This can be explained by the different penetration manner of AAPD through the membranes. The enough amount of AAPD molecules (not radicals) can penetrate the DODPC bilayer to initiate the polymerization of diene groups on 2-acyl chains which were faced the inner surface of the liposome at 60 °C. The penetration of AAPD molecules through bilayer membrane structure was supported by the following results. Some of DODPC liposome solutions containing AAPD in the outer aqueous phase were re-sonicated for 10 s to put AAPD molecules into an inner aqueous phase to compare the polymerization conversion with those for liposomes without re-sonication. There was no difference in the polymerization conversion between systems with and without re-sonication, suggesting that the enough amount of AAPD molecules did penetrate through the membrane at 60 °C. The penetration of radical initiators has already been analyzed to be governed by the temperature and there should be enough penetration to initiate the radical polymerization when temperatures were higher than the phase transition temperature.[12] However, covalent bonds of 1-acyl chains by AIBN-initiated polymerization restricted the permeation of AAPD molecules to cause the initiation less effective.

Similar improvement on the polymerization conversion was found by the addition of other water-soluble radical initiators. Potassium peroxodisulfate also initiated the radical polymerization of DODPC liposomes which were preliminarily polymerized by AIBN

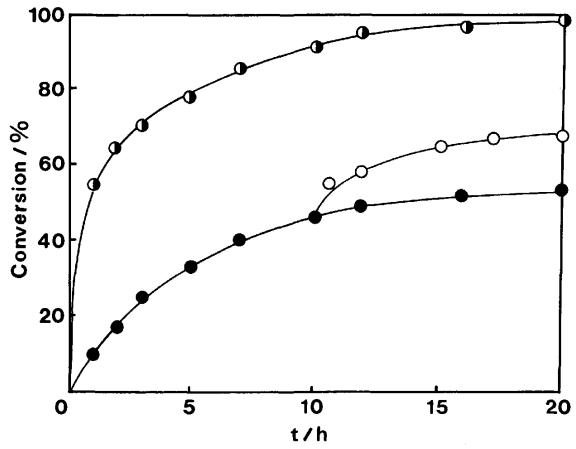

Fig. 3. Polymerization conversion of DODPC as liposomes at 60 °C. DODPC liposomes were polymerized by AIBN and AAPD simultaneously (◑), or by the addition of AAPD (○) to the DODPC liposomes which were pre-polymerized by AIBN (●) at 60 °C.

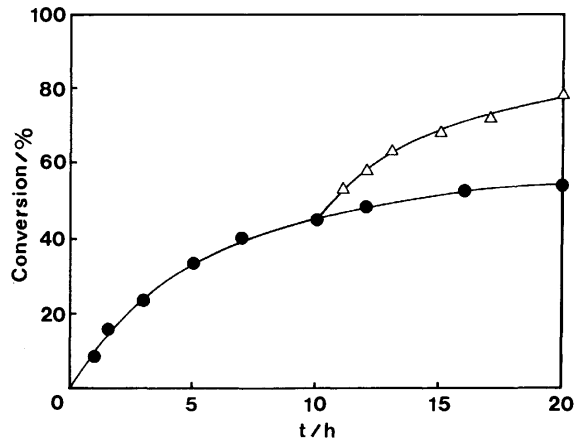

Fig. 4. Polymerization conversion of DODPC as liposomes at 60 °C. Polymerization was newly initiated by the addition of potassium peroxodisulfate (△) to the DODPC liposomes which were pre-polymerized by AIBN (●) at 60 °C.

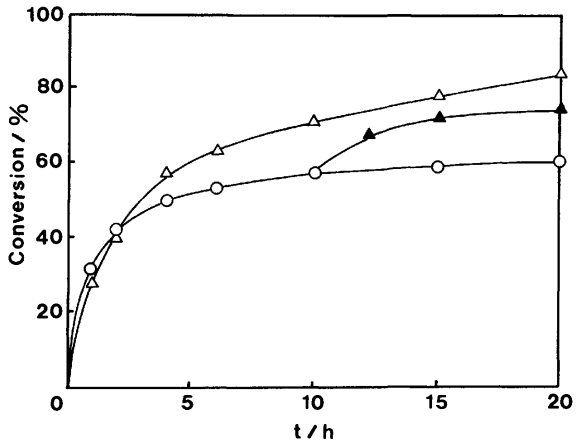

Fig. 5. Polymerization conversion of DODPC as liposomes at 60°C. DODPC liposomes were polymerized by potassium peroxodisulfate (△), or by the addition of potassium peroxodisulfate (▲) to the DODPC liposomes which were prepolymerized by AAPD (○) at 60°C.

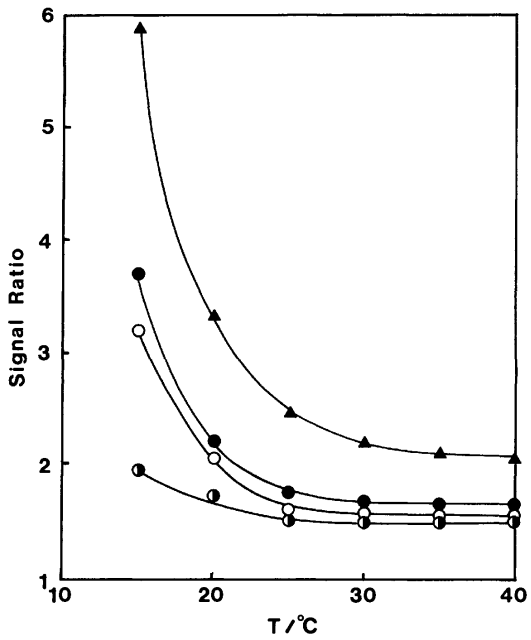

Fig. 6. Effect of temperature on the signal ratio of ^{1}H NMR peak for choline methyl protons to that for terminal methyl protons of polymerized DODPC liposomes. Liposomes were polymerized by; AIBN (●), AAPD (○), or both AIBN and AAPD simultaneously (◑). Data for monomeric DODPC liposomes were also shown as reference (▲).

as shown in Fig. 4. These data suggested that the polymerization reaction of diene groups in 1- and 2-acyl chains were independent with each other and no **intra**molecular polymerization should occur. It should be noted that the polymerization of DODPC liposomes with hydrophilic or hydrophobic radical initiators thus provided direct evidence for the different chemical environment and corresponding selective polymerization of the acyl chains of lipids as liposomes.

A simple addition of potassium peroxodisulfate made the polymerization of DODPC liposomes to reach about 80—90% conversion as shown in Fig. 5. The DODPC liposomes which were prepolymerized by AAPD showed further increase in the polymerization conversion by the addition of potassium peroxodisulfate as also shown in Fig. 5. These results mean that not only diene groups in 2-acyl chains but also those in 1-acyl chains are polymerized by this radical initiator. Potassium peroxodisulfate newly initiated the radical polymerization of DODPC liposomes whereas AAPD did not. The diene groups in 2-acyl chains were considered to be polymerized by AAPD radicals, and no polymerization of other diene groups should be initiated by the further addition of AAPD. The decrease of absorption at 255 nm by the addition of potassium peroxodisulfate should therefore be attributed to the polymerization of diene groups in 1-acyl chains. The possibility for the attack of diene groups in the hydrophobic region could be explained by the size of freshly generated and transferred radicals. Potassium peroxodisulfate radicals were known to generate OH radicals through the radical transfer to water molecules.[20] As OH radicals were much smaller than AAPD radicals, the OH radicals might approach and attack the diene groups in 1-acyl chains.

The different polymerization conversion of DODPC liposomes was certainly observed beyond the experimental error between potassium peroxodisulfate-initiated polymerization (83%) and two-step one (73%) which was polymerized by AAPD first and the initiated by potassium peroxodisulfate as shown in Fig. 5. A simple polymerization of DODPC liposomes which was initiated by the addition of potassium peroxodisulfate made higher polymerization conversion than that for the two-step polymerization. This might be due to the tight covalent bonds on the surface of liposomes provided by the preliminary polymerization of diene groups on 2-acyl chains by AAPD. Some covalent bonds on the surface might restrict the attack of radicals from an aqueous medium to the diene groups in relatively hydrophobic region. A lower segmental motion of hydrophilic region in the DODPC liposomes pre-polymerized by AAPD was actually detected by the ^{1}H NMR measurements as shown in Fig. 6. This data supported the reduction of the radical attack frequency to the hydrophobic region.

A solution polymerization kinetics was applied to the radical polymerization as liposomes. It should be helpful to analyze the polymerization profile of DODPC especially to speculate the polymerization mechanism. Polymerization velocity was calculated from the initial slope of the polymerization conversion profiles as seen in Figs. 1 and 5. Typical polymerization velocity was summarized in Table 1 for each system. A thermal cleavage of AIBN and AAPD to produce radicals has already been analyzed and the

following equations have been empirically presented,[21,22]

$$\text{for AIBN: } k = 1.29 \times 10^{15}\, e^{-30800/RT}, \quad (1)$$

$$\text{for AAPD: } k = 3.77 \times 10^{15}\, e^{-30300/RT} \quad (2)$$

where k, R, and T mean the radical cleavage rate constant (s^{-1}), gas constant and absolute temperature, respectively. A radical cleavage of AAPD is faster than that of AIBN at the same temperature (see Eqs. 1 and 2), but the polymerization in liposome systems can not be compared directly. Because AIBN was dissolved only in the hydrophobic region of the liposomes and the local concentration was about 100 times higher than that for water-soluble one under the present experimental conditions. For example, the local concentration of AIBN in the hydrophobic region of the liposome was calculated to be 5.7×10^{-2} mol dm^{-3} at DODPC concentration of 1.0 wt% and AIBN/DODPC= 1/20 by mol. There was no significant difference in the polymerization velocity for the AIBN-added system at different liposome concentration if DODPC/AIBN mol ratio was set to be constant. The polymerization profile of AIBN-added liposome system was therefore analyzed to be similar to the bulk polymerization. On the other hand, the initial polymerization velocity for the water-soluble radical initiator added system was affected by their initial concentration. The polymerization profile seemed to be analyzable as the emulsion polymerization but these were not the same.

The initial polymerization velocity for AAPD-added system was larger than that for potassium peroxodisulfate-added system as shown in Table 1. This is mainly due to the different radical cleavage rate, and it for AAPD was larger than that for potassium peroxodisulfate. Furthermore peroxodisulfate anions were known to generate radicals and partially transfer them to water molecules to produce hydroxyl radicals.[20] The different polymerization conversion between AAPD- and potassium peroxodisulfate-added system was also explained by the different size of the effective radicals. Namely, small hydroxyl radicals can get in a bilayer membrane structure and initiate polymerization of diene groups in both 1- and 2-acyl chains. This was confirmed by the gamma-ray polymerization of DODPC liposomes.[11] The DODPC lipids provide their diene groups in unequivalent chemical environment due to molecular packing, this strongly suggests possibility of a selective polymerization with the use of suitable radical initiators.

Table 1. Initial Polymerization Velocity of DODPC Liposomes at 60 °C

Initiator	Radical cleavage rate	Polymerization rate
	s^{-1}	mol dm^{-3} s^{-1}
AIBN	8.42×10^{-6}	6.79×10^{-7}
AAPD	5.23×10^{-5}	3.20×10^{-6}
$K_2S_2O_8$	6.89×10^{-6}	1.65×10^{-6}

[DODPC]=1.0 wt%. [Initiator]/[DODPC]=1/20 by mol.

AIBN-initiated polymerization of DODPC was very different from others. One of characteristics of this system is higher local viscosity of the medium, i.e., liquid crystalline state of the hydrophobic region. The AIBN-initiated polymerization of DODPC as liposomes clearly showed the characteristics of the polymerization in viscous liquid-crystalline state. However the radical cleavage rate for AIBN was almost the same as that for potassium peroxodisulfate and local concentration of AIBN was 100 times higher, there was not significant difference in the polymerization velocity as summarized in Table 1. This less efficiency was well explained by the "Cage Effect".[23] The initiation efficiency for AIBN was calculated to be about 0.5—0.7 in ordinary organic solvent where apparent diffusion coefficient of radical pair was around 1×10^{-5} $cm^2 s^{-1}$. In a viscous medium, initiation efficiency of AIBN have already been analyzed by Smets to be getting smaller with increasing viscosity.[24] The liposomal membrane structure provides more viscous matrix, for example the diffusion coefficient of pyrene in dipalmitoylphsophatidylcholine at 60 °C was measured to be 2.0×10^{-7} $cm^2 s^{-1}$ by Sackmann et al.[25] Most of the generated radicals recombined in the matrix and a little radicals could initiate the polymerization of diene groups.

Stability of the Polymerized Liposomes. The leakage of fluorescent probes from an inner aqueous phase of the liposomes has frequently used to evaluate the membrane stability of liposomes. As the carboxyfluorescein (CF) affected the polymerization of DODPC or other monomeric amphiphiles,[26] CF was incorporated into liposomes which had already been polymerized previously.[14] The leakage of CF was extremely suppressed by the DODPC membrane structure which was polymerized by radical initiators as shown in Fig. 7.

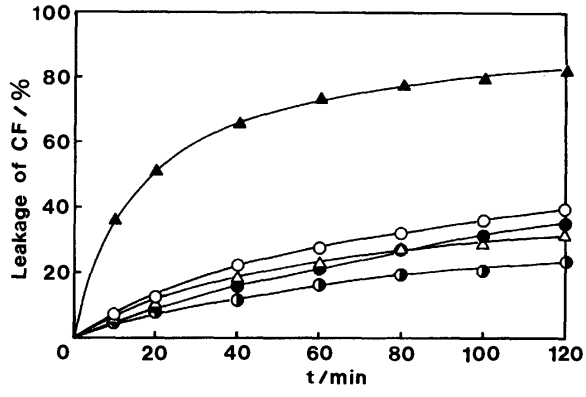

Fig. 7. Leakage of CF from inner aqueous phase of polymerized liposomes at 25 °C. Liposomes were polymerized by; AIBN (●), AAPD (○), potassium peroxodisulfate (△) or both AIBN and AAPD simultaneously (◑). Data for monomeric DODPC liposomes were also shown as reference (▲).

Polymerized liposomes with even 50% polymerization conversion showed excellent membrane stability. The 50% polymerization conversion means the complete polymerization of diene groups in either 1- or 2-acyl chains of lipids as liposome. If certain amount of lipids remained unpolymerized, these liposomes should be in the phase-separated state. For these systems, considerable CF leakage should be observed from the phase boundary.[27] Furthermore, phase separated polymerized liposomes could easily be detected by scanning electron microscopy.[28] These methods might be helpful to analyze the relationship between phase behavior of lipids and membrane stability.

The stability of the liposomes polymerized by both AIBN and AAPD was also examined through the changes of average diameter of the liposomes. The polymerized liposomes were agitated in an aqueous medium at 60 °C, and a small amount of the sample solution was periodically pipetted out and the number-average diameter was determined by a laser particle analyzer. It was confirmed that the polymerized liposomes were actually stable against heat-treating such as 60 °C for over 200 h. The excellent stability should be due to the larger average molecular weight of polymerized DODPC with highly crosslinked state. No diameter change was also found after several temperature cycling between freezing and melting of the polymerized liposomes. The process is well-known as "freeze thaw method" to prepare larger liposomes through liposomal fusion.[29] The polymerized liposomes were revealed to be extremely stable against heating and cooling. Scanning electron microscopy measurements also revealed that the polymerized DODPC liposomes were stable after organic solvent washing. Relatively large DODPC liposomes were polymerized by both AIBN and AAPD, or by potassium peroxodisulfate, and poured into aqueous methanol solution with final methanol content of about 70%. The polymerized liposomes were then characterized by SEM measurements to be stable enough even such a severe conditions. Figure 8 shows stereo-pair of the SEM picture of DODPC liposomes polymerized by potassium peroxodisulfate with polymerization conversion of 80%, and dispersed in an aqueous methanol solution. Spherical liposome structure with no damage was found suggesting that the DODPC liposomes polymerized by radical initiators had excellent membrane stability. Surface of the polymerized DODPC liposomes was smooth but wavy as shown in Fig. 8. For such large polymerized liposomes were generally wavy in surface especially for polymerized DODPC liposomes. This stereo view SEM method is useful to analyze structure for polymerized liposomes especially for the skeletonized ones.[28] The lyophilized DODPC liposomes polymerized by either AIBN or AAPD were stable but soluble in organic solvents such as methanol, ethanol or chloroform under agitation. No liposome structure was seen for these polymeric systems by SEM observation. This fact is the proof of the formation of linear polymers, namely diene groups in 1- and 2-acyl chains can be polymerized selectively.

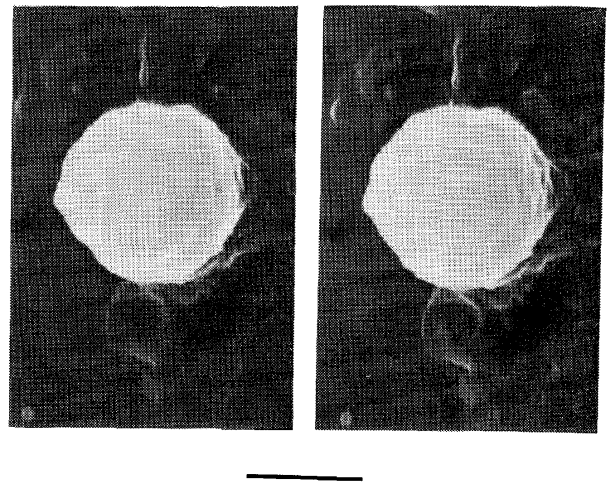

Fig. 8. Stereo pair of scanning electron micrograph of polymerized DODPC liposomes. Space bar indicates 2.0 μm.

It was concluded that radical polymerization behaviors were effectively applied to analyze unequivalent chemical environment of diene groups in both acyl chains. Selective polymerization was also carried out by the suitable selection of the radical initiators.

[2]Metacyclo- and [2]Paracyclo[2](1,3)ferrocenophanes[1)]

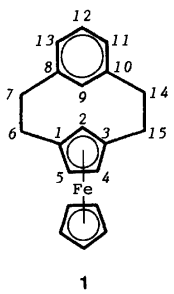
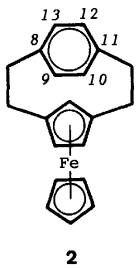
(Received March 26, 1987)

[2]Metacyclo- and [2]paracyclo[2](1,3)ferrocenophanes (**1** and **2**) have been synthesized and characterized by means of X-ray diffraction and spectroscopy. The crystal data of the phanes were determined as follows: **1**, monoclinic, $P2_1$, a=8.851(4), b=15.742(8), c=5.963(3) Å, β=109.76(5)°, Z=2; **2**, orthorhombic, *Pbca*, a=15.308(8), b=24.716(12), c=8.034(4) Å, Z=8. The benzene rings of the both phanes are distorted in a similar manner to [2.2]cyclophanes but the planarities of the cyclopentadienyl (Cp) rings are maintained. The distance between the substituted Cp ring and the iron atom in **1** is considerably extended (1.678(4) Å) in comparison with ferrocene, whereas that of **2** (1.659(3) Å) is not. The 2-hydrogen of the Cp ring and the 9-hydrogen of the benzene ring in **1** are situated right above each other's rings. In the ^{1}H NMR spectrum of 1, the 2- and 9-protons shifted to highfield to a considerable extent (δ 1.18 and 5.34, respectively) due to the diamagnetic anisotropic effects of the benzene and Cp rings. The electronic spectra of both phanes exhibited bathochromic shifts of the d-d absorption band of the iron (**1**, 451 nm, **2**, 447 nm) as compared to [3]metacyclo- and [3]paracyclo[3](1,3)ferrocenophanes (each 442 nm), which were synthesized as reference compounds in this work.

Benzenoid metal π-complexes of cyclophanes have been investigated by many groups in recent years.[2)] On the other hand, there are few reports[3,4)] on intermolecularly bridged (1,3)ferrocenophanes which are ferrocene analogues of the cyclophane π-complexes, although a great number of intramolecular ferrocenophanes and intermolecular (1,1′)ferrocenophanes have been synthesized[5)] since the discovery of ferrocene. One of the reasons why (1,3)ferrocenophanes could not be synthesized until recently would be the difficulty of preparing 1,3-disubstituted ferrocenes, a precursor of the phanes. Since the method obtaining 1,3-disubstituted ferrocene derivatives on a preparative scale was established,[3,4)] it became feasible to synthesize various (1,3)ferrocenophanes by means of conventional methods well-known in preparation of cyclophanes. Incorporation of η^5-C_5H_5 (cyclopentadienyl: Cp) π-complex into [2.2]phane structure is interesting in that it would lead to a more strained system than benzenoid π-complexes. Furthermore, such phanes would enable NMR spectral observation of diamagnetic anisotropy in the upper zone of Cp ring. In this paper we report on the synthesis and characterization of [2]metacyclo- and [2]paracyclo[2](1,3)ferrocenophanes (**1** and **2**),[6,7)]



1

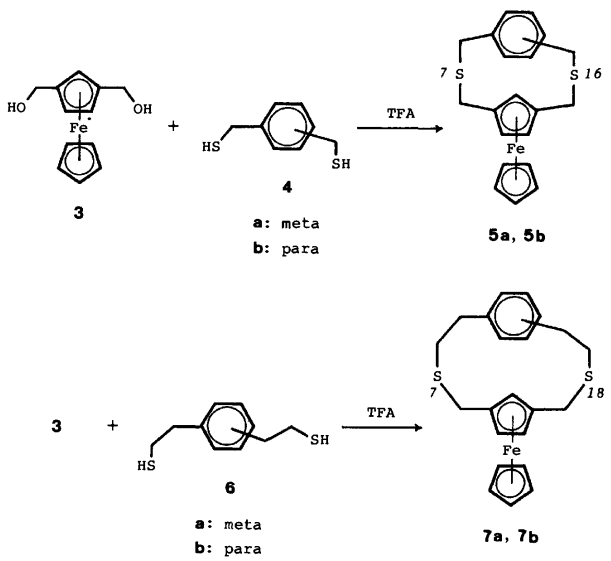


2

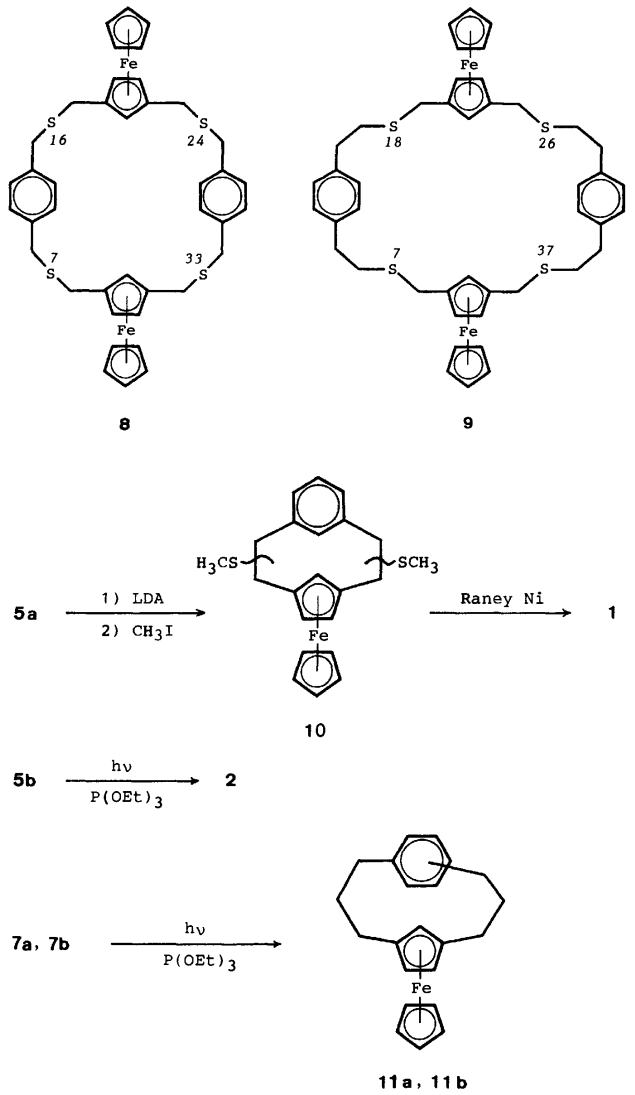
which are the first examples of [2.2](1,3)ferrocenophanes. [3]Metacyclo- and [3]paracyclo[3](1,3)ferrocenophanes (**11a** and **11b**) prepared as reference compounds in spectroscopic study are also described.

Results and Discussion

Synthesis. The route via bridge-rearrangement of dithia[3.3]phanes, which is the most convenient method[8-10)] for synthesis of [2.2]phanes, was applied to this work. Dithia[3.3]phanes are generally prepared by coupling of the corresponding mercaptomethyl and bromomethyl derivatives in the presence of base. However, reaction between 1,3-bis(mercaptomethyl)-ferrocene and bis(bromomethyl)benzenes with NaOH or alkali metal/18-crown-6 gave a complex mixture or only a small amount of product. Czeck and Ratajczak[11)] described a coupling reaction between 1,1′-bis-(hydroxymethyl)ferrocene and dimercaptoalkanes with trifluoroacetic acid (TFA) to afford (1,1′)ferrocenophanes. Consequently, the acid catalyzed reaction was applied to the present system. Diol **3** and dithiol **4a** or **4b** were treated with TFA in dichloromethane under



Scheme 1.



Scheme 2.

high dilution conditions for 15—20 h to give the desired dithia[3.3]ferrocenophanes (**5a**, 55%; **5b**, 21%). In the reaction of **4b** a cyclic dimer **8** containing two benzene rings and two ferrocene moieties was formed in a high yield (67%) besides dithia[3.3]phane **5b**. Macrocyclic dimer **9** was also produced predominantly in the reaction of diol **3** and para-substituted dithiol **6b** (**7b**, 8%, **9**, 62%). The preferential formation of the dimers in the reaction of the para systems is probably due to its thermodynamic stability in comarison with **5b** or **7b**. In fact, treatment of **5b** with TFA gave an equilibrium mixture of **5b** and **8**. The mass spectra of the dimers **8** and **9** by means of the electron impact (EI) ionization showed almost the same spectral patterns as **5b** and **7b**, respectively. The molecular ions of **8** and **9** could be observed only by the field desorption (FD) ionizing technique. The macrocyclic structure of **8** was determined by X-ray crystal analysis.[12]

Methylation of sulfides **5a** and **5b** with Borch reagent[13] to convert these into precursors for Stevens rearrangement[8] afforded only a mixture of unidentifiable products. Wittig rearrangement with lithium diisopropylamide (LDA)/CH_3I was reported by Boekelheide et al.[9] for a convenient synthesis of metacyclophane. An application of the reaction to **5a** gave methylthio[2.2]phane **10** in a good yield (79%). The compound **10** was desulfurized with Raney nickel to give the desired metacyclophane **1**. On the other hand, the Wittig rearrangement of paracycloferrocenophane **5b** afforded only bridge-cleaved compounds in a similar manner as the reaction of paracyclophanes.[9a] Consequently, photochemical extrusion of sulfur bridge[10,14] was attempted. Irradiation of **5b** in triethyl phosphite and benzene with high- or low-pressure

mercury lamp gave [2.2]ferrocenophane **2** in reasonable yields (ca. 50%).

Desulfurization of dithia[4.4]phanes (**7**) was carried out by photochemical method and the corresponding [3.3]phanes **11** were obtained though in low yields.

C(4′)	−0.017(9)	−0.002(5)
C(5′)	0.010(11)	−0.003(5)
Fe	−1.649(6)	−1.652(4)

a) The least-squares planes are shown in *b*—*e*. b) $0.6411X+0.7012Y+0.3119Z=3.3642$. c) $0.6475X+0.7070Y+0.2844Z=6.6805$. d) $-0.7237X+0.4495Y+0.5237Z=-0.3052$. e) $-0.7402X+0.4272Y+0.5193Z=2.9045$.

are shown in Figs. 1—4 and Tables 1—3. The two aromatic moieties of meta-ferrocenophane **1** are in an anti conformation in analogy with [2.2]metacyclophane.[15] The 2-hydrogen of the Cp ring and the 9-hydrogen of the benzene ring are situated right above each other's rings. The distances between the 9-hydrogen and the Cp ring carbons are 2.60(6)—2.65(6) Å and those between the 2-hydrogen and the benzene carbons are 2.80(6)—3.16(7) Å. The benzene and the bridged Cp ring in para-ferrocenophane **2** are more stacked over each other than those of **1**.

The benzene rings of both phanes **1** and **2** are distorted in a similar manner to [2.2]cyclophanes[15-17] and tricarbonylchromium complex of [2.2]paracyclophane.[18] The deformation of the benzene moiety in **2** is somewhat larger than those of [2.2]paracyclophane.[16] and its metal complex.[18] On the other hand, the Cp carbon atoms of both **1** and **2** deviate only slightly from their least-squares planes (Table 3) and the planarities of the bridged Cp rings are almost maintained in spite of their highly strained structures. However, the deviations of the methylene carbons at 6- and 15-positions from the Cp planes are extremely large. The bond of the Cp ring and 6-carbon (or 15-carbon) in **1** is more bent than that of **2** (Fig. 3). This great bending in **1** indicates that its methylene bridges are more strained than that of **2** due to the rigid meta-substituted benzene ring in comparison with the para-substituted ring.

The distance between the iron atom and the bridged Cp ring plane of **1** is considerably extended (1.678(4) Å) as compared to ferrocene (1.66 Å),[19] whereas that of **2** (1.659(3) Å) is almost similar to ferrocene. The distance of **1** is the largest of ferrocene derivatives previously described. These results in X-ray crystal analysis indicate that **1** is an extremely strained compound in comparison with **2** or other [2.2]cyclophanes.

NMR Spectra. In the ^{1}H NMR spectrum of dithia-[3.3]meta-ferrocenophane **5a**, the signals of the 2- and 4,5-protons on the Cp ring appear at δ 3.97 and 3.65, respectively (ferrocene, δ 4.04). The corresponding Cp ring protons of [3.3]meta-ferrocenophane **11a** resonate at δ 3.85 and 3.27. The upfield shifts of the 4,5-protons in comparison with the 2-protons in **5a** and **11a** indicate that these phanes are in syn conformations. The conformational features of the [3.3]meta-ferrocenophanes are similar to those of [3.3]metacyclophane[20] and [3.3](1,3)ferrocenophane.[4]

In contrast to the [3.3]phanes, the signal of the 2-proton of [2.2]meta-ferrocenophane **1** dramatically

shifted to a high field (δ 1.18), whereas the 4,5-proton signal appeared at δ 3.75. The chemical shift difference ($\Delta\delta$) between the 2-protons of **1** and a reference compound (1,3-diethylferrocene) is 2.82 ppm. The value is larger than those of the corresponding aromatic protons in [2.2]metacyclophanes ($\Delta\delta$=2.62 ppm),[21] [2]metacyclo[2](1,3)azulenophane ($\Delta\delta$=2.34 ppm),[22] and [2]metacyclo[2](5,7)azulenophane ($\Delta\delta$= 2.46 ppm).[23] This extremly high field shift of the 2-proton signal in **1** reflects its molecular structural feature revealed by X-ray crystal analysis; the 2-hydrogen is situated right above the benzene ring plane.

On the other hand, the benzenoid 9-proton of **1** resonates at δ 5.34 and the upfield shift difference ($\Delta\delta$) from the coresponding signal of a reference compound (1,3-diethylbenzene) is 1.58 ppm. Despite unusually close proximity of the 9-proton to the Cp ring plane, the upfield shift value is smaller than that of the 2-proton. This shift behavior of the 9-proton indicates that the shielding effect of the above zone of the Cp ring is smaller than that of benzene ring. Muray and Fox[24] determined the magnetic susceptibilities of ferrocene and found the magnetic anisotropy of the molecule. Turbit and Watts[25] presented a map of the shielding and deshielding zone around ferrocene molecule based on the result of the susceptibilities and discussed on the proton chemical shifts of ferrocene derivatives. However, the shielding shift value of the proton situated right above the Cp ring plane has not been detected until recently. Musso et al.[26] reported on the ^{1}HNMR spectra of 1,1′,3,3′-tetramethyl-2,2′-bis(2,4,6-trialkylphenyl)ferrocenes having "*exo*" alkyl groups which are located on the shielding zone of ferrocene nucleus. The upfield shift difference of the alkyl protons from the reference proton shifts are 0.49—0.74 ppm. The shift difference of the 9-proton (1.58 ppm) of **1** is the largest value in the upfield shifts due to the diamagnetic anisotropy of ferrocene nucleus.

The ^{13}CNMR spectra of **1** and **2** show unusual paramagnetic shifts of the inner aromatic carbon signals at 2- and 9-positions (2- and 9-carbons of **1**, δ 72.90 and 139.07; 2-carbon of **2**, δ 72.32). Such downfield shifts of the inner aromatic carbon resonance are generally observed in [2.2]metacyclophanes,[27] but the chemical shift difference of the benzenoid 9-carbon in **1** ($\Delta\delta$=9.0 ppm) from the corresponding signal of *m*-xylene is larger than that of [2.2]metacyclophane ($\Delta\delta$=6.2 ppm). The shift difference of the 2-carbons in **1** and **2** from that of 1,3-diethylferrocene is 5.7 and 5.1 ppm, respectively. The downfield shifts of those carbons of **1** and **2** seem to reflect the proximity of the carbons to the other aromatic rings. The major origin of the shift is attributable to rehybridization due to excessive strain and direct *p*-orbital compression.[27]

Electronic Spectra. The most remarkable difference in the electronic absorption spectra in ethanol between [2.2]phanes (**1**, **2**) and [3.3]phanes (**11a**, **11b**) is seen in the d-d absorption band near 440 nm. The bands of **1** and **2** appear at 451 and 447 nm (ε=150 and 140), respectively, whereas both **11a** and **11b** exhibit the band at wavelength of 442 nm (ε=130 and 110, respectively) similar to that of 1,3-diethylferrocene (439 nm, ε=110). Pronounced difference in absorption coeficient between [2.2]phanes and [3.3]phanes was not seen in these band. The origin of the bathochromic shifts in **1** and **2** would be mainly attributed to the following factors: (i) Some transannular π-electronic interactions between the two aromatic rings, and (ii) a change of the electronic state in the d-orbital of the iron due to excessive strain.

In the study on intramolecularly bridged ferrocenophanes we found that there was a linear relationship between the wavelengths of the d-d absorption and the Cp-Fe-Cp distances in the X-ray crystal structure.[28] This correlation almost holds for **1** although the wavelength of **2** slightly deviates from the straight line.[28] The elongation of the Cp-Fe distance in **1** should result in a change of the d-electronic configuration of the iron and a shift of the d-d absorption. On the other hand, the large bathochromic shift of the band was observed in [3.3](1,3)ferrocenophane (488 nm)[4] having a strainless molecular structure based on the inspection of a molecular model. Kasahara et al.[4] described that the shift was probably due to a transannular π-electronic interaction between the two ferrocene moieties. Transannular intraction between the Cp and benzene rings should be present in [2.2]ferrocenophanes (**1** and **2**), because the two ring planes approach each other. Therefore, it is likely that the bathochromic shifts of the d-d absoption band in **1** and **2** are caused by the two factors mentioned above, although the degree of their contribution cannot be estimated.

The absorption shoulders in the region near 300 nm in [2.2]phanes **1**, **2** and [3.3]phanes **11a**, **11b** are somewhat swollen in comparison with 1,3-diethylferrocene. The swellings possibly arise from some change of electronic configuration in benzene moieties due to charge-transfer intraction with the Cp ring, because the absorption bands based on the interaction between two benzene rings in cyclophanes are observed in this region.

Experimental

All melting points were uncorrected. NMR spectra were measured on a JEOL JNM-FX100 spectrometer relative to tetramethylsilane as an internal standard. The assignments of the signals were made by homo- (^{1}H{^{1}H}) and selective hetero-nuclear (^{13}C{^{1}H}) decoupling technique. Mass spectra were obtained with a Hitachi RMU-7M or a Hitachi M-80 double focusing mass spectrometer by electron impact (EI) ionizing technique at 70 eV unless otherwise stated. Field desorption (FD) ionization was carried out using a carbon or silicon emitter and the FD mass spectra were measured on

the M-80 spectrometer. Empirical formulae of oily or unstable compounds were determined by means of high-resolution mass spectra, which were analyzed on a Hitachi M-003 data processing system. Electronic absorption spectra were recorded on a Hitachi 323 spectrophotometer in ethanol. 1,3-Bis(hydroxymethyl)ferrocene (**3**) (mp 115—117 °C),[3] 1,3-bis(mercaptoethyl)benzene (**6a**) (oil),[29] and 1,4-bis(mercaptoethyl)benzene (**6b**) (oil)[29] were prepared according to the usual procedures.

General Procedures. Coupling reaction between diol **3** and bis(mercaptoalkyl)benzenes **4**, **6** with trifluoroacetic acid (TFA): Dichloromethane freshly distilled from CaH_2 was used as solvent and oxygen in the solvent was removed as much as possible by ultrasonic vibration followed by bubbling dry nitrogen gas immediately before use. Each solution of 1,3-bis(hydroxymethyl)ferrocene (**3**) and the corresponding bis(mercaptoalkyl)benzene (1 mol equiv to **3**) in dichloromethane was added dropwise to a stirring solution of TFA in dichloromethane under a nitrogen atmosphere. The solvent was used in enough volume to keep a high dilution condition (concn of **3**: ca. 10^{-3} mol dm^{-3}) of the reaction system. The reaction mixture was stirred in the dark at room temperature. Saturated aq $NaHCO_3$ was added and the organic layer was phase-separated, washed with saturated aq NaCl, dried over Na_2SO_4 and evaporated. The residue was column-chromatographed to isolate the coupling products.

Photochemical extrusion of sulfur: A solution of sulfide in benzene and triethyl phosphite was placed in a qualtz tube. A stream of argon gas was bubbled through the solution for 30 min. External irradiation was carried out using a 100 W high pressure mercury lamp (Ushio electric Inc. UM-102 type) or eight of 30 W low pressure mercury lamps (The Southern N.E. Ultraviolet Co., Royal type RS Preparative Photochemical Reactor). The temperature of the reaction mixture was maintained below 30 °C with the aid of a water bath throughout irradiation. After evaporating benzene and triethyl phosphite in vacuo, the residue was column-chromatographed over silica gel.

7,16-Dithia[3]metacyclo[3](1,3)ferrocenophane (5a). Each solution of diol **3** (400 mg, 1.6 mmol) and 1,3-bis(mercaptomethyl)benzene (**4a**) (276 mg, 1.6 mmol) in dichloromethane (each 200 ml) was added to a solution of TFA (1.8 g, 16 mmol) in dichloromethane (1200 ml), and the mixture was stirred for 20 h. The product was column-chromatographed over silica gel, and the first band eluted with hexane-dichloromethane (1 : 1) yielded sulfide **5a** (339 mg, 55%), which was recrystallized from hexane-benzene to give yellow needles; mp 136—137 °C. ^{1}H NMR ($CDCl_3$) δ=3.51 and 3.71 (each 2H, an AB system, J=14.5 Hz, 6, 17-H), 3.53 and 3.69 (each 2H, an AB system, J=11.5 Hz, 8, 15-H), 3.65 (2H, d, J=1.4 Hz, 4, 5-H), 3.93 (5H, s, unsubstd. Cp-H), 3.97 (1H, t, J=1.4 Hz, 2-H), 6.79 (1H, bs, 10-H), 6.90—7.00 (3H, m, 12, 13, 14-H); ^{13}C NMR ($CDCl_3$) δ=33.04 (6, 17-C), 37.13 (8, 15-C), 68.37 (4, 5-C), 68.81 (unsubstd. Cp-C), 72.51 (2-C), 84.60 (1, 3-C), 126.31 (12, 14-C), 127.96 (13-C), 131.57 (10-C), 137.95 (9, 11-C); MS m/z (rel intensity) 380 (100, M$^+$), 315 (50), 222 (21), 193 (23), 135 (33), 121 (56), 91 (93); FD-MS m/z 380 (M$^+$).

Found: C, 64.06; H, 5.39; S, 15.99%; M$^+$, m/z 380.0349. Calcd for $C_{20}H_{20}S_2Fe \cdot 1/6C_6H_6$: C, 64.12; H, 5.38; S, 16.30%; M for $C_{20}H_{20}S_2Fe$, 380.0353.

The second band eluted with hexane-dichloromethane (1 : 2) yielded a yellow powder (218 mg), which was possibly a mixture of oligomer and polymers.

7,16-Dithia[3]paracyclo[3](1,3)ferrocenophane (5b). Each solution of diol **3** (200 mg, 0.81 mmol) and 1,4-bis(mercaptomethyl)benzene **4b** (138 mg, 0.81 mmol) in dichloromethane (each 100 ml) was added to a solution of TFA (0.92 g, 8.1 mmol) in dichloromethane (600 ml), and the mixture was stirred for 15 h. The product was column-chromatograghed over silica gel, and the first band eluted with hexane-dichloromethane (1 : 1) yielded sulfide **5b** (66 mg, 21%), which was recrystallized from benzene-ethyl acetate to give yellow needles; mp 172—173 °C (decomp). ^{1}H NMR ($CDCl_3$) δ=2.89 (1H, t, J=1.4 Hz, 2-H), 3.20 and 3.46 (each 2H, an AB system, J=14.5 Hz, 6, 17-H), 3.79 (4H, s, 8, 15-H), 3.84 (5H, s, unsubstd. Cp-H), 3.91 (2H, d, J=1.4 Hz, 4, 5-H), 6.95 and 7.01 (each 2H, an AA'BB' system, Ph-H); ^{13}C NMR ($CDCl_3$) δ=32.02 (6, 17-C), 38.11 (8, 15-C), 67.59 (4, 5-C), 68.71 (unsubstd. Cp-C), 69.49 (2-C), 86.49 (1, 3-C), 128.11 (10, 11-C), 130.45 (13, 14-C), 137.56 (9, 12-C); MS m/z (rel intensity) 380 (100, M$^+$), 315 (12), 244 (10), 212 (8), 185 (9), 121 (12), 91 (20); FD-MS m/z 380 (M$^+$).

Found: C, 62.96; H, 5.29; S, 16.68%; M$^+$, m/z 380.0364. Calcd for $C_{20}H_{20}S_2Fe$: C, 63.16; H, 5.30; S, 16.86%; M, 380.0353.

The second band eluted with hexane-dichloromethane (1 : 2) yielded 7,16,24,33-tetrathia[3]paracyclo[3](1,3)ferroceno-[3]paracyclo[3](1,3)ferrocenophane (**8**) (206 mg, 67%), which was recrystallized from benzene-ethyl acetate to give orange-yellow needles; mp 172—174 °C (decomp). ^{1}H NMR ($CDCl_3$) δ=3.34 and 3.39 (each 2H, an AB system, J=14.5 Hz, $CpCH_2$-), 3.62 (4H, s, $PhCH_2$-), 3.96 (1H, t, J=1.4 Hz, 2-H), 4.02 (5H, s, unsubstd. Cp-H), 4.13 (2H, d, J=1.4 Hz, 4, 5-H), 7.19 (4H, s, Ph-H); ^{13}C NMR ($CDCl_3$) δ=30.82 ($CpCH_2$-), 35.23 ($PhCH_2$-), 68.69 (4, 5-C), 69.45 (unsubstd. Cp-C), 70.28 (2-C), 84.90 (1, 3-C), 129.05 (unsubstd. C of Ph), 136.91 (substd. C of Ph); MS m/z (rel intensity) 760 (0, M$^+$), 380 (100), 315 (13), 244 (12), 212 (5), 185 (8), 121 (16), 91 (23); FD-MS m/z 760 (M$^+$).

Found: C, 63.10; H, 5.28; S, 16.61%. Calcd for $C_{40}H_{40}S_4Fe_2$: C, 63.16; H, 5.30; S, 16.86%.

7,18-Dithia[4]metacyclo[4](1,3)ferrocenophane (7a). Each solution of diol **3** (400 mg, 1.6 mmol) and 1,3-bis(2-mercaptoethyl)benzene **6a** (320 mg, 1.6 mmol) in dichloromethane (each 200 ml) was added to a solution of TFA (1.9 g, 17 mmol) in the same solvent (1200 ml), and the mixture was stirred for 18 h. The product was column-chromatographed over silica gel, and the first band eluted with hexane-dichloromethane (1 : 1) yielded sulfide **7a** (530 mg, 80%), which was recrystallized from hexane-benzene to give yellow plates; mp 148—149 °C. ^{1}H NMR ($CDCl_3$) δ=2.74 (8H, s, 8, 9, 16, 17-H), 3.49 (4H, s, 6, 19-H), 4.06 (5H, s, unsubstd. Cp-H), 4.11 (1H, t, J=1.4 Hz, 2-H), 4.15 (2H, d, J=1.4 Hz, 4, 5-H), 6.65—7.15 (4H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=30.46, 31.43 and 34.45 (methylene-C), 68.90 (4,5-C), 69.49 (unsubstd Cp-C), 70.80 (2-C), 85.23 (1, 3-C), 126.60 (13, 15-C), 127.14 and 127.67 (11, 14-C), 140.04 (10, 12-C); MS m/z (rel intensity) 408 (100, M$^+$), 343 (29), 252 (23), 251 (35), 218 (14), 206 (20), 121 (33), 91 (56); FD-MS m/z 408 (M$^+$).

Found: C, 65.87; H, 6.47; S, 15.05%; M$^+$, m/z 408.0649. Calcd for $C_{22}H_{24}S_2Fe \cdot 1/6C_6H_6$: C, 65.55; H, 5.98; S, 15.22%; M for $C_{22}H_{24}S_2Fe$, 408.0666.

7,18-Dithia[4]paracyclo[4](1,3)ferrocenophane (7b). Each solution of diol **3** (284 mg, 1.2 mmol) and 1,4-bis(2-mercaptoethyl)benzene **6b** (228 mg, 1.2 mmol) in dichlo-

romethane (each 200 ml) was added to a solution of TFA (13.1 g, 1.2 mmol) in dichloromethane (750 ml), and the mixture was stirred for 2 h. The product was column-chromatographed over silica gel. The first band eluted with hexane-dichloromethane (1 : 1) yielded sulfide **7b** (38 mg, 8%), which was recrystallized from hexane-benzene to give yellow needles; mp 163—164 °C (decomp). ^{1}H NMR ($CDCl_3$) δ=2.40—3.00 (8H, m, 8, 9, 16, 17-H), 3.23 (4H, s, 6, 19-H), 3.60 (1H, t, J=1.4 Hz, 2-H,), 3.78 (2H, d, J=1.4 Hz, 4, 5-H), 3.92 (5H, s, unsubstd. Cp-H), 6.88 and 6.94 (4H, an AA'XX' system, Ph-H); ^{13}C NMR ($CDCl_3$) δ=33.72, 35.23 and 35.43 (methylene-C), 68.71 (4, 5-C), 69.49 (unsubstd. Cp-C), 69.70 (2-C), 85.86 (1, 3-C), 128.50 (unsubstd. C of Ph), 137.37 (substd. C of Ph); MS m/z (rel intensity) 408 (100, M^+), 343 (33), 252 (27), 206 (19), 181 (8), 121 (27), 91 (34); FD-MS m/z 408 (M^+).

Found: C, 65.48; H, 6.43; S, 15.27%; M^+, m/z 408.0676. Calcd for $C_{22}H_{24}S_2Fe \cdot 1/6C_6H_6$: C, 65.55; H, 5.98; S, 15.22%; M for $C_{22}H_{24}S_2Fe$, 408.0666.

The second band eluted with hexane-dichloromethane (1 : 2) yielded 7,18,26,37-tetrathia[4]paracyclo[4](1,3)ferroceno-[4]paracyclo[4](1,3)ferrocenophane (**9**) (292 mg, 62%). Recrystallization of **9** from hexane-benzene gave yellow needles; mp 196—197 °C (decomp). ^{1}H NMR ($CDCl_3$) δ=2.40—2.80 (8H, m, $PhCH_2CH_2$-), 3.49 (4H, s, $CpCH_2$-), 4.08 (5H, s, unsubstd. Cp-H), 3.14 (2H, d, J=1.4 Hz, 4, 5-H), 4.22 (1H, t, J=1.4 Hz, 2-H), 6.86 (4H, s, Ph-H); ^{13}C NMR ($CDCl_3$) δ=31.87, 32.80 and 36.01 (methylene-C), 68.71 (4, 5-C), 69.54 (unsubstd. Cp-C), 69.83 (2-C), 85.71 (1, 3-C), 128.35 (unsubstd. C of Ph), 138.49 (substd. C of Ph); FD-MS m/z 816 (M^+).

Found: C, 64.90; H, 6.24; S, 15.65%. Calcd for $C_{44}H_{48}S_4Fe_2$: C, 64.70; H, 5.92; S, 15.70%.

[2]Metacyclo[2](1,3)ferrocenophane (1). A solution of lithium diisopropyl amide (LDA) in hexane-THF (0.81 ml, 0.65 mmol) was added dropwise to a solution of dithia[3]-metacyclo[3]ferrocenophane (**5a**) (100 mg, 0.26 mmol) in THF (2 ml) under an argon atmosphere at room temperature. After stirring for 3 min, iodomethane (0.08 ml, 1.3 mmol) was added to the brownish yellow solution. The resulting pink solution was stirred for 5 min at room temperature and water was added. The mixture was extracted with dichloromethane, and the organic layer was washed with saturated aq NaCl, dried over $CaCl_2$ and evaporated. The residue was column-chromatograghed over silica gel with hexane-dichloromethane (1 : 1) to yield a mixture of rearrangement products **10** (84 mg, 79%) from the first eluted band. Recrystallization of **10** from hexane-benzene gave orange-yellow crystals; mp 178—181 °C (decomp). ^{1}H NMR ($CDCl_3$, only assignable peaks) δ=1.25 (t, 2-H), 1.95 and 2.09 (each s, SCH_3), 3.98 (s, unsubstd. Cp-H), 5.40 and 5.87 (each bt, 9-H), 6.80—7.50 (m, Ph-H).

Found: M^+, m/z 408.0671. Calcd for $C_{22}H_{24}Fe$: M, 408.0666.

A suspension of methyl sulfide **10** (32 mg, 0.08 mmol) and active Raney nickel(W-7) in ethanol (10 ml) was refluxed for 30 min. The mixture was filtered and evaporation of the filtrate left [2]metacyclo[2](1,3)ferrocenophane (**1**) (24 mg, 98%), which was recrystallized from methanol to give orange-yellow needles; mp 131—132 °C. ^{1}H NMR ($CDCl_3$) δ=1.18 (1H, t, J=1.4 Hz, 2-H), 1.82, 2.22, 2.55, and 2.90 (each 2H, m, methylene-H), 3.75 (2H, d, J=1.4 Hz, 4, 5-H), 3.97 (5H, s, unsubstd. Cp-H), 5.34 (1H, m, 9-H), 6.80—7.15 (3H, m, 11, 12, 13-H). ^{13}C NMR ($CDCl_3$) δ=32.21 (6, 15-C), 39.52 (7, 14-C), 64.71 (4, 5-C), 67.35 (unsubstd. Cp-C), 72.90 (2-C), 89.22 (1, 3-C), 125.38 (11, 12, 13-C), 127.87 (12-C), 139.07 (9-C), 140.15 (8, 10-C); MS m/z (rel intensity) 316 (100, M^+), 246 (13), 222 (9), 191 (6), 190 (6), 189 (6), 165 (6), 121 (17).

Found: C, 75.67; H, 6.59%, M^+, m/z 316.0904. Calcd for $C_{20}H_{20}Fe$: C, 75.96; H, 6.37%, M, 316.0912.

[2]Paracyclo[2](1,3)ferrocenophane (2). A solution of dithia[3]paracyclo[3]ferrocenophane **5b** (30 mg, 0.08 mmol) in benzene (24 ml) and triethyl phosphite (48 ml) was irradiated with a high-pressure mercury lamp for 18 h. On column chromatography of the product over silica gel with hexane-ether (1 : 1), the first band yielded [2]paracyclo-[2](1,3)ferrocenophane (**2**) (13 mg, 53%), which was recrystallized from methanol to give orange-yellow needles; mp 106—107 °C. ^{1}H NMR ($CDCl_3$) δ=2.00—3.15 (8H, m, methylene-H), 2.37 (1H, t, J=1.4 Hz, 2-H), 3.37 (2H, d, J=1.4 Hz, 4, 5-H), 3.87 (5H, s, unsubstd. Cp-H), 6.23 and 6.93 (each 2H, an AA'XX' system, Ph-H); ^{13}C NMR ($CDCl_3$) δ=28.26 (6, 15-C), 35.62 (7, 14-C), 64.76 (4, 5-C), 67.20 (unsubstd. Cp-C), 72.32 (2-C), 90.00 (1, 3-C), 129.82 and 131.77 (unsubstd. C of Ph), 139.95 (substd. C of Ph); MS m/z (rel intensity) 316 (97,

M$^+$), 212 (100), 121 (52), 91 (25).

Found. C, 75.85; H, 6.40%; M$^+$, m/z 316.0887. Calcd for $C_{20}H_{20}Fe$: C, 75.96; H, 6.37%; M, 316.0912.

The second band eluted with hexane-ether (10:1) yielded yellow solid (10 mg) whose ^{1}H NMR and mass spectra showed extrusion of one sulfur bridge. The compound was so unstable that cannot be further purified. The third band yielded the starting material (2 mg, 7%).

Irradiation of **5b** with a low pressure mercury lamp also afforded **2** in a comparable yield (54%).

[3]Metacyclo[3](1,3)ferrocenophane (11a). A solution of dithia[4]metacyclo[4]ferrocenophane **11a** (376 mg, 0.92 mmol) in benzene (10 ml) and triethyl phosphite (75 ml) was irradiated with a low-pressure mercury lamp for 85 h. The resulting residue was column-chromatographed over silica gel with hexane-ether (20:1). The solid yielded from the first band was further chromatographed over thin-layered alumina in a preparative scale with hexane-ether (100:1) to separate into three bands. The first band yielded unknown yellow oil (6 mg), and the yellow crystals (3 mg) yielded from the third band was possibly a partially desulfurized compound. The second band in the thin-layered chromatography afforded [3]metacyclo[3](1,3)ferrocenophane (**11a**) (8 mg, 3%), which was recrystallized from methanol to give yellow needles mp 88—89 °C. ^{1}H NMR ($CDCl_3$) δ=1.60—3.00 (12H, m, methylene-H), 3.27 (2H, d, J=1.4 Hz, 4, 5-H), 3.83 (5H, s, unsubstd. Cp-H), 3.85 (1H, t, J=1.4 Hz, 2-H), 6.50—6.90 (4H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=29.87, 31.92,

and 35.91 (methylene-C), 66.71 (4, 5-C), 68.22 (unsubstd. Cp-C), 69.10 (2-C), 87.08 (1,3-C), 124.41 (12, 14-C), 126.89 (13-C), 134.59 (10-C), 140.78 (9, 11-C); MS *m/z* (rel intensity) 344 (100, M^+), 279 (20), 277 (9), 172 (4), 121 (13), 91 (5).

Found: M^+, *m/z* 344.1212. Calcd for $C_{22}H_{24}Fe$: M^+, 344.1225.

The second band in the first column chromatography yielded the starting material **7a** (40 mg, 11%).

[3]Paracyclo[3](1,3)ferrocenophane (11b). A solution of dithia[4]paracyclo[4]ferrocenophane **7b** (17 mg, 0.042 mmol) in benzene (3 ml) and triethyl phosphite (30 ml) was irradiated with a low pressure mercury lamp for 85 h. The resulting product was column-chromatographed over silica gel with hexane-ether (20:1). The first band yielded [3]paracyclo[3](1,3)ferrocenophane (**11b**) (2 mg, 14%), which was recrystallized from methanol to give yellow needles; mp 115—117 °C. ^{1}H NMR ($CDCl_3$) δ=1.65—3.10 (12H, m, methylene-H), 2.77 (1H, t, J=1.4 Hz, 2-H), 3.59 (2H, d, J=1.4 Hz, 4, 5-H), 3.77 (5H, s, unsubstd. Cp-H), 6.54 and 6.88 (each 2H, an AA'XX' system, Ph-H); ^{13}C NMR ($CDCl_3$) δ=28.90, 32.60, and 35.91 (methylene-C), 65.49 (4, 5-C), 68.32 (unsubstd. Cp-C), 70.46 (2-C), 89.32 (1, 3-H), 128.79 and 128.89 (unsubstd. C of Ph), 139.12 (substd. C of Ph); MS *m/z* (rel intensity) 344 (100, M^+), 279 (19), 277 (13), 213 (4), 172 (6), 121 (23), 117 (15), 91 (10).

Found: M^+, *m/z* 344.1204. Calcd for $C_{22}H_{24}Fe$: M, 344.1225.

Crystallographic Measurements. Both crystals of **1** and **2** (yellow plates) used in the X-ray diffraction were grown from methanol solutions. The lattice parameters and intensity data were measured on a Phillips PW-1100 diffractometer by means of the θ—2θ scan method by using graphite-monochromated radiation. For the crystal of **1**, Cu $K\alpha$ radiation was used due to the small size of the crystal but for **2**, Mo $K\alpha$ radiation was used. Crystal data and some conditions for data collection are given in Table 4. Lorentz and polarization corrections were made but no absorption correction was applied.

The structures were solved by the heavy atom method. Both atomic coordinates of Fe atoms in the two compounds were reduced from the Patterson maps, and all carbon atoms were located in the Fourier maps. The refinements were carried out by block-diagonal-matrix least-squares procedure. The final atomic parameters are given in Tables 5 and 6.††

The authors are indepted to Professor Takeo Akiyama in Sophia University for helpful discussion and suggestion on the photochemical reaction in desulfurization. Thanks are also due to Mr. Tohru Harada for the preparation of compounds **7a** and **7b**.

Synthesis of Opically Active 3-Morpholinecarboxylic Acid and Tetrahydro-2*H*-1,4-thiazine-3-carboxylic Acid

Yuji KOGAMI† and Kenji OKAWA*
Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Nishinomiya 662
(Received March 31, 1987)

A convenient synthesis of optically active 3-morpholinecarboxylic acid and its thio analogue, tetrahydro-2*H*-1,4-thiazine-3-carboxylic acid, has been developed. These intermediates were obtained by reaction of benzyl (*S*)-*N*-benzyloxycarbonyl-2-aziridinecarboxylate and its enantiomer with 2-chloroethanol or 2-chloroethanethiol, respectively.

Many *N*-substituted morpholine analogues have been synthesized and widely used for medical purposes, however, only a few papers have been published on the synthesis of 3-morpholinecarboxylic acid (**3**) and its derivatives. In 1981, racemic *N*-acetyl-3-morpholinecarboxylic acid derivatives were first synthesized by Callens from *N*-acetylmorpholine,[1] but the yield was poor. The thio analogue, tetrahydro-2*H*-1,4-thiazine-3-carboxylic acid (**6**) had been already synthesized in 1964 by Wong as an optically active product from L-cysteine in good yield.[2] However, synthesis of the D-form of **6** remained a problem because optically pure D-cysteine is difficult to obtain.

We report here convenient syntheses of opically active **3** and **6** from benzyl (*S*)-*N*-benzyloxycarbonyl-2-aziridinecarboxylate (L-Z-Azy-OBzl) and its enantiomer (D-Z-Azy-OBzl).

Since several trials to synthesize *O*-(2-chloroethyl)-serine (**2**) from the serine derivative by several methods were unsuccessful, therefore we used Z-Azy-OBzl as the starting material. The synthetic routes via the ring-opening reaction of the aziridine derivatives[3,4] are shown in Scheme 1.

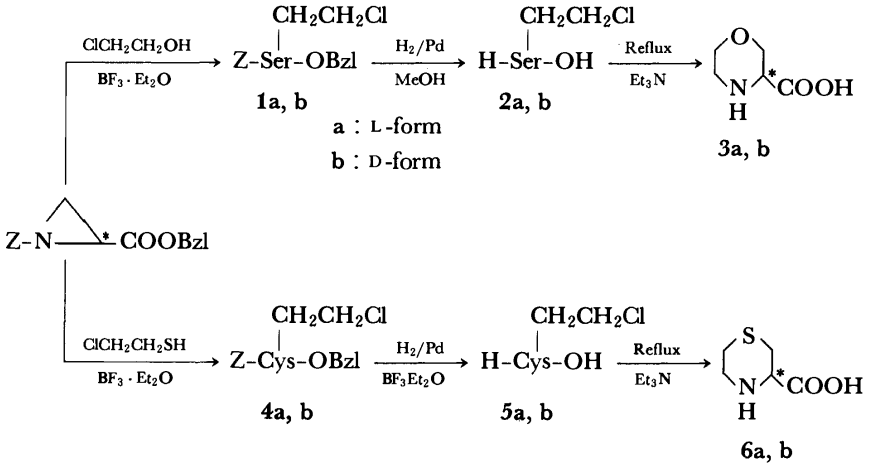
The reaction was carried out between Z-Azy-OBzl (3.0 mmol) and 2-chloroethanol (2 ml) in chloroform containing a catalytic amount of boron trifluoride etherate at room temperature. The expected ring-opening reaction easily occurred, and the intermediate, *N*-benzyloxycarbonyl-*O*-(2-chloroethyl)serine benzyl ester (**1**), of **3** was obtained. The benzyloxycarbonyl and benzyl ester groups were removed by catalytic hydrogenation, followed by cyclization (1.0 mmol in 15 mL of methanol at 64 °C for 7 h) in the presence of triethylamine (0.28 mL) to give **3**. The total yields of **3a** and **3b** from Z-Azy-OBzl were 65.9% and 63.9%, respectively.[5]

The synthesis of **6** is as follows. Z-Azy-OBzl (6.0 mmol) was treated with dichloromethane solution of 2-chloroethanethiol (4.2 g), prepared from thiirane with hydrogen chloride[6] to give **4**. Deprotection was carried out by use of catalytic hydrogenation (H_2/Pd) in the presence of boron trifluoride etherate to give **5** in good yield. This was treated in the same manner as above to give **6**. The total yields of **6a** and **6b** from Z-Azy-OBzl were 27.4 and 9.8%, respectively.

The physical properties of the synthetic products are summarized in Table 1.

Experimental

The melting points are uncorrected. Optical rotations were determined at the D line on a Perkin-Elmer 141 polarimeter. The NMR spectra were obtained with a Hitachi R-20B high-resolution NMR spectrometer, the chemical shifts being obtained using TMS as the internal reference.



Scheme 1. Synthetic routes of **3a, b** and **6a, b.**

†Present address: Research Center, Toyo jozo Co., Ltd., Ohito, Shizuoka 410-23.

Table 1. Physical Properties of 3-Morpholinecarboxylic Acid (**3a, b**) and Tetrahydro-2*H*-1,4-thiazine-3-carboxylic Acid (**6a, b**)

Characteristic	3a	3b	6a	6b
Melting point θ_m/°C	218(decomp)	216—218(decomp)	251(decomp)	250—251(decomp)
Optical rotation[a] $[\alpha]_D^{25}$/°	−14.4	+13.8	−51.7	+52.0
Solubility (g mL^{-1})[b]	1.26	—	—	—

a) **3a**, **b**: c 2.0, 1 M $HCl_{aq.}$, **6a**, **b**: c 2.0, H_2O. b) Solubility in water at 25 °C; Pro 1.63 g mL^{-1}.

The homogeneity of the products was checked by thin-layer chromatogrphy on silica-gel plates.

L-Z-Ser(OCH_2CH_2Cl)-OBzl (1a). L-Z-Azy-OBzl (0.93 g, 3.0 mmol) was dissolved in $CHCl_3$ (10 mL) and $HOCH_2CH_2Cl$ (2 mL), then $BF_3 \cdot OEt_2$ (2 drops) was added at room temperature. The reaction mixture were stirred for 4 h, then washed with water, dried over Na_2SO_4, and concentrated in vacuo. The residue was subjected to silica-gel column chromatography with elution with ethyl acetate-hexane (1 : 3 v/v). The eluent was concentrated in vacuo and 1.04 g (88.0%) of **1a** was obtained as colorless needles. mp 52.0—52.5 °C, $[\alpha]_D^{25}$ +13.4° (*c* 1.0, MeOH). ^1H NMR ($CDCl_3$): δ=3.52 (4H, m), 3.80 (2H, m, $-CH_2-Cl$), 4.41 (1H, α-proton), 5.08, 5.18 (4H, 2s), 7.26 (10H, s). Found: C, 61.15; H, 5.63; N, 3.60%. Calcd for $C_{20}H_{22}O_5NCl$: C, 61.30; H, 5.66; N, 3.58%.

D-Z-Ser(OCH_2CH_2Cl)-OBzl (1b). D-Z-Azy-OBzl (0.93 g, 3.0 mmol) was dissolved in $CHCl_3$ (10 mL) and $HOCH_2CH_2Cl$ (2 mL), then $BF_3 \cdot OEt_2$ (2 drops) was added at room temperature. The reaction mixture was worked up as described above to give **1b**.

L-H-Ser(OCH_2CH_2Cl)-OH (2a). The solution of **1a** (0.78 g, 2.0 mmol) in methanol (10 mL) was hydrogenated over Pd black. After 30 min, the mixture was filtered and the filtrate was concentrated in vacuo. The residue was crystallized from methanol, 258 mg (77.0%), mp 136.0—137.0 °C, $[\alpha]_D^{25}$ +11.0° (*c* 2.0, 1 M HCl (1 M=1 mol dm^{-3})). Found: C, 35.78; H, 6.04; N, 8.49%. Calcd for $C_5H_{10}O_3NCl$: C, 35.79; H, 6.02; N, 8.36%.

D-H-Ser(OCH_2CH_2Cl)-OH (2b). The solution of **1b** (0.78 g, 2.0 mmol) in methanol was worked up as described above to give **2a**.

L-3-Morpholinecarboxylic Acid (3a). To the solution of **2a** (168 mg, 1.00 mmol) in methanol (15 mL) was added Et_3N (0.28 mL, 2.0 mmol) at room temperature. The reaction mixture was refluxed for 7 h at 64 °C, and concentrated in vacuo. Chloroform was added to the residue and an insoluble material was filtered and recrystallized from water and methanol to give **3a**, 128 mg (97.3%), mp 218 °C (decomp), $[\alpha]_D^{25}$ −14.4° (*c* 2.0, 1 M HCl). NMR (D_2O) δ=3.00 (2H, m, $C-CH_2-N$), 3.50, 3.55 (4H, m, $-CH_2-O-CH_2-$), 3.88 (1H, dd, α-proton). Found: C, 45.42; H, 6.94; N, 10.66%. Calcd for $C_5H_9O_3N$: C, 45.79; H, 6.92; N, 10.70%.

D-3-Morpholinecarboxylic Acid (3b). The reaction mixture in methanol was worked up as described above to give **3b**, mp 216.0—218.0 °C (decomp), $[\alpha]_D^{25}$ +13.8° (*c* 1.0, 1 M HCl). Found: C, 45.78; H, 6.91; N, 10.46%. Calcd for $C_5H_9O_3N$: C, 45.79; H, 6.92; N, 10.70%.

L-Z-Cys(SCH_2CH_2Cl)-OBzl (4a). L-Z-Azy-OBzl (1.86 g, 6.0 mmol) was dissolved in CH_2Cl_2 (20 mL) and $HSCH_2CH_2Cl$ (4.2 g, 43.5 mmol), then $BF_3 \cdot OEt_2$ (5 drops) was added at room temperature. The reaction mixture was stirred for 24 h, then washed with water, dried over Na_2SO_4, and concentrated in vacuo. The residue was purified by silica-gel column chromatography with elution by ethyl acetate-hexane (1 : 3 v/v). The effluent was concentrated in vacuo and 1.89 g (77.0%) of **4a** was obtained as colorless needles. mp 69.5—70.0 °C, $[\alpha]_D^{25}$ −14.3° (*c* 1.0, MeOH). ^1H NMR ($CDCl_3$): δ=2.75 (2H, t, $-S-CH_2-$), 3.01 (2H, d, β-protons), 3.50 (2H, t, $-CH_2-Cl$), 4.63 (1H, br, α-proton), 5.10, 5.17 (4H, 2s), 7.33 (10H, s). Found: C, 58.75; H, 5.38; N, 3.29%. Calcd for $C_{20}H_{22}O_4NSCl$: C, 58.89; H, 5.44; N, 3.43%.

D-Z-Cys(SCH_2CH_2Cl)-OBzl (4b). D-Z-Azy-OBzl (0.93 g, 3.0 mmol) was dissolved in CH_2Cl_2 (10 mL) and pure $HSCH_2CH_2Cl$ (2.1 g, 21.7 mmol), then $BF_3 \cdot OEt_2$ (3 drops) were added at room temperature. The reaction mixture was worked up as described above to give **4b**.

L-H-Cys(SCH_2CH_2Cl)-OH (5a). To the solution of **4a** (410 mg, 1.0 mmol) in abs MeOH were added $BF_3 \cdot OEt_2$ (0.37 mL, 3.0 mmol) and 11.8 M HCl/EtOH (0.16 mL, 2.0 mmol). The mixture solution was hydrogenated over Pd black for **1** h, and filtered. The filtrate was neutralized with Et_3N and concentrated in vacuo. The solid residue was washed with $CHCl_3$ and gave **5a**, 161 mg (88.0%), mp 156.5—157.0 °C, $[\alpha]_D^{25}$ −2.0° (*c* 1.0, 1 M HCl). Found: C, 32.54; H, 5.49; N, 7.54%. Calcd for $C_5H_{10}O_2NSCl$: C, 32.69; H, 5.47; N, 7.56%.

D-H-Cys(SCH_2CH_2Cl)-OH (5b). To the solution of **4b** (410 mg, 1.0 mmol) in abs MeOH (10 mL) were added $BF_3 \cdot OEt_2$ (0.37 mL, 3.0 mmol) and 11.8 M HCl/EtOH (0.16 mL, 2.0 mmol). The mixture solution was worked up as described above to give **5b**.

L-Tetrahydro-2*H*-1,4-thiazine-3-carboxylic Acid (6a). To the solution of **5a** (91.8 mg, 0.5 mmol) in DMF (5 mL) was added Et_3N (0.14 mL, 1.0 mmol) at room temperature. The reaction mixture was refluxed for 2 h at 94 °C and concentrated in vacuo. Chloroform was added to the residue and an insoluble material was filtered and recrystallized from water and methanol to give **6a**, 57.5 mg (78.0%), mp 250.0—251.0 °C, (decomp), $[\alpha]_D^{25}$ −51.7° (*c* 1.0, H_2O) [lit,[7] $[\alpha]_D^{13}$ −52.94° (*c* 2.0, H_2O)]. Found: C, 40.49; H, 6.38; N, 9.37%. Calcd for $C_5H_9O_2NS$: C, 40.79; H, 6.17; N, 9.52%.

D-Tetrahydro-2*H*-1,4-thiazine-3-carboxylic Acid (6b). The reaction mixture in DMF was worked up as described above to give **6b**, mp 248.0—249.0 °C (decomp), $[\alpha]_D^{25}$ +50.6° (*c* 1.0, H_2O). Found: C, 40.46; H, 6.17; N, 9.41%. Calcd for $C_5H_9O_2NS$: C, 40.52; H, 6.12; N, 9.45%.

The authors wish to thank the staff of the research laboratory of Toyo Jozo Co. for the elemental analyses, and Messrs. Tatsuya Inui, Yoshiya Matsuoka, and Shuichi Inaya for their kind assistance. This work was partially supported by a Grant-in-Aid for Scientific Research (No. 59340-034) from the Ministry of Education, Science and Culture.

ESR and FT-IR Studies for Coal Structures. Characteristics of Japanese Coals

Osamu Ito,* Hiroyuki Seki, and Masashi Iino
Chemical Research Institute of Nonaqueous Solutions, Tohoku University, Katahira, Sendai, 980
(Received March 10, 1987)

The ESR parameters (spin concentration, line width, g-value, and spin-lattice relaxation time) of various coals mined in Japan and in many foreign countries have been measured. Low spin concentrations, broad line widths, and long spin-lattice relaxation times have been recognized as characteristics of Japanese bituminous coals (e.g., Akabira, Miike, and Shin-yubari coals) compared with the foreign coals having similar carbon contents. The origins of these differences were interpreted by the aid of the FT-IR spectra. Low fractions of aromatic carbon and rich aliphatic groups of Japanese bituminous coals are closely related to the characteristics in the ESR parameters.

Many spectroscopic methods have been used to obtain chemical information about the structures of organic solids such as coals.[1,2] In addition, the magnetic relaxation measurements give an information about the molecular motions; the nuclear spin-spin relaxation times (T_2) measured with NMR have been successfully applied to polymers and coals.[3,4] The measurements of the electron spin-lattice relaxation times (T_1) of carbonaceous materials including various coals were reported in 1950's.[5-9] Smidt and van Krevelen, however, indicated that the T_1-values were strongly affected by the adsorbed oxygen on coals.[8] Therefore, it has been believed for a long time that information about the dynamic behavior of the molecules in coals is hidden behind the interactions with oxygen. Recently, it was reported that the T_1-values for the polymers including polyacetylenes afford useful information.[10,11] Thus, it may be worth reinvestigating the electron-spin relaxation phenomena for coals. For Japanese coals, Toyoda, Sugawara, and Honda reported the various ESR parameters including T_1-values;[12] they found that the line widths of Japanese coals were broader than foreign ones, which is an only characteristic of Japanese coals; the spin concentrations and T_1-values are similar to those of the foreign coals observed by Smidt and van Krevelen.[8] On the basis of well-known properties of Japanese coals such as rich in hydrogen atom and rich in volatile matters,[13,14] it would be anticipated that Japanese coals have low spin concentrations and that the molecular motions of Japanese bituminous coals are flexible because of their high efficiency in liquefaction[15] and high solubility.[16]

In this study, we chose a wide variety of coals including Japanese and foreign coals having carbon contents from 65 to 93%. In order to help the interpretation of the ESR parameters which give a rather physical information about coals, the FT-IR spectra were measured with the diffuse reflectance method to obtain certain chemical information.

Experimental

Samples: Six kinds of Japanese coals having carbon content from 65 to 86.7% were selected. Foreign coals were selected in a wide range of the carbon contents. The ultimate analytical data were summarized in Table 1 with the abbreviation of coals.

These coal samples (under 60 mesh (<250 μm)) were dried at 80 °C in a vacuum oven. For brown coals (lignites), it is reported that the contact with air affected the ESR signals;[17] especially, coexistence of moisture and oxygen molecule strongly affected the intensities of ESR signals.[18,19] Thus, we dried coals samples in vacuum at lower temperature.

Deashing: In a solution containing 15 ml hydrochloric acid, 5 ml hydrofluoric acid, and 15 ml water, 1 g of original coal was suspended and warmed at 95 °C under nitrogen gas for 3 h; then the residues after filtration were washed with distilled water and dried in a vacuum oven at 80 °C.[20]

Maceral Separation: Some deashed coals were separated into maceral-rich groups with float sink method using a mixed solvent consisting of carbon tetrachloride and cyclohexane.[21]

Alkylation and Acetylation: Alkylation was performed by the reflux of coal (2 mg) in butyl alcohol (150 ml) with coexist of p-toluenesulfonic acid as a catalyst.[22] Deashed coal was acetylated with acetic anhydride in dry pyridine with refluxing under nitrogen gas during 12 h.[23]

ESR Measurements: Pulverized coals (under 100 mesh (<150 μm)) in ESR sample tube of 3 mm outer diameter were measured with a JEOL-FE3X and a Varian E-4 spectrometer (X-band/100 kHz field modulation) at room temperature. The effects of the degassing upon the line shape and saturation phenomena were examined from 4 to 10^{-4} Pa. Spin concentrations were calculated by the integration of the ESR differential signals comparing with standard DPPH. When the ESR signal contained two or more components, each curve was separated with the aid of the computer simulation method using the Lorentzian curve shape which is used for the homogeneous spin system.[24] Spin-lattice relaxation times were evaluated by the continuous wave saturation method with varying the microwave powers.[25,26] When the ESR signals were attributed to the mixture of homogeneous and inhomogeneous, some corrections were necessary according to Castner's method.[27]

FT-IR Measurements: The FT-IR spectra were measured by a JEOL JIR-100 spectrometer equipped with a diffuse reflectance apparatus; 3 mg of pulverized coals (under 200 mesh (<75 μm)) were diluted with 200 mg of KBr powder and the intensities of the IR bands were calculated by Kubelka-Munk function ($f(R_\infty)$) after averaging 200 times scan.[28,29]

Evaluation of f_a: The fraction of aromatic carbon (f_a) were calculated by Brown's method using a constant (0.42)

a) Japan. b) America (U.S.A.). c) Australia. d) China (P.R.C.). e) Germany (F.R.D.). f) Canada. g) Vietnam. h) The f_a-values could not be estimated, since the aromatic C–H band at 3030 cm^{-1} was weak.

which is the ratio of the extinction coefficient of the aromatic C–H stretching band at 3030 cm^{-1} to that of the aliphatic C–H stretching band at 2940 cm^{-1}. This ratio was estimated by the comparison of ^1H NMR (Hitachi R-600 ^1H FT-NMR) with FT-IR data of the pyridine-soluble parts of some coals.[30] This value is similar to that reported by Painter et al.[28] The f_a-values are summarized in Table 1. The f_a-values thus calculated are compatible with those evaluated by the solid state CP/MAS ^{13}C NMR.[31–33]

Results and Discussion

Hydrogen Contents. Figure 1 shows the ratios of hydrogen atom contents to carbon atom contents (in atomic unit) for all coals listed in Table 1. Dots between 70 and 85 C% show some scatter, but they seem to stud between two lines—upper line and lower line. A tendency that Japanese coals have higher hydrogen contents is confirmed for coal samples adopted in this study. From proximate analysis data, one can also find that Japanese coals contain much volatile matters.[29] These facts have been already pointed out by many investigators as characteristics to Japanese coals;[13,14] The coal samples adopted here also satisfy our purpose in disclosing how such a characteristic appears in the ESR parameters.

Apparent Characteristics of ESR Signals. Figure 2a shows ESR spectra of two kinds of bituminous coals; one is Japanese bituminous coal (Shin-yubari coal 86.7 %C) and another is Canadian bituminous coal (Vicary Creek 87.8 %C). Shin-yubari coal shows a single symmetric signal (line width (ΔH_{pp})=0.74 mT) which is weak and easily saturated with an increase in a microwave power for evacuated sample. On the other hand, the ESR signal of Vicary Creek coal is composed of two components; one is broad line (ΔH_{pp}=0.53 mT) and another is narrow line

(ΔH_{pp}=0.13 mT). The both lines showed the saturation phenomena at high microwave power. Similar phenomena were reported for American coals.[34] The narrow lines are observed in almost all foreign subbituminous and bituminous coals.[1]

As for the origin of the narrow lines, there have been presented some interpretations. Some investigators attributed to one of the macerals such as inertinite (fusinite) group;[34] other researchers to macromolecular component in coals.[24] In general, the spin concentrations originated from the narrow lines are less than 10—20% of the broad ones, when they were compared before saturations.

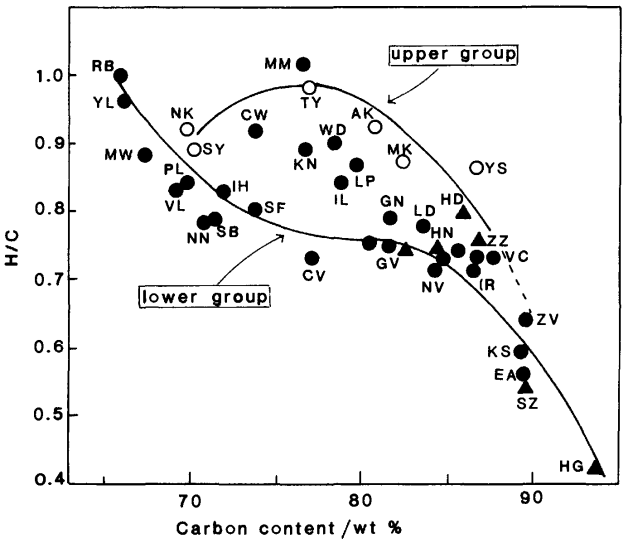

Fig. 1. Hydrogen atom contents (H/C in atomic unit) vs. carbon contents. Abbreviations of coal samples are quoted from Table 1.

Corresponding FT-IR. Figure 2b shows FT-IR spectra of Shin-yubari coal and Vicary Creek coal measured by the diffuse reflectance method. The vibrational band of the aliphatic C-H groups at 2940 cm^{-1} of Shin-yubari coal is stronger than that of Vicary Creek coal. The aromatic C-H groups (at 3030 cm^{-1}) of both coals are approximately equal, but the broad band which increases with wavenumber up to the near-IR region is observed for Vicary Creek. This broad band was not attributed to the scattering of the monitoring light which was frequently observed in the transmittance method using KBr pellet, but to the edge of the real electronic absorption band which is characteristic of the polycondensed aromatic hydrocarbons (the π-π^* transitions) and/or of their layered structures (the intermolecular charge-transfer transitions).[29] Thus, Vicary Creek coal may contain such highly polycondensed aromatic hydrocarbons; the broad band in the near-IR region seems to correspond to the narrow line in the ESR signal. This relation is generalized for other coals.

Spin Concentration. For coal samples showing different saturation phenomena, it is essential to compare the signal intensities before the saturation (at low microwave power). Among the coals investigated in this study, Akabira and Miike coals show the satura-

a) The T_1-values could not be obtained, since the broad lines could not be completely resolved.

tion at the most low microwave power (1 mW in the cavity of JEOL-FE3X and 5 mW in the cavity of Varian E-4). A strict linear relation holds at lower microwave power than about a half of each maximum value; in the linear range, the spin concentrations were evaluated. They are summarized in Table 2.

In Fig. 3, the spin concentrations thus measured for original coals in evacuated system were plotted against the carbon contents of coal samples. One can see that the spin concentrations increase with an increase in carbon contents; some bituminous coals and anthracite have higher spin concentrations than brown coals and subbituminous coals by a factor of 10—50.[1,2,8,12] This tendency, however, shows a band-type correlation; the spin concentrations of the upper-lying coals are greater than the lower-lying ones by a factor of about 5 times. Around the lower group, we can find Japanese subbituminous and bituminous coals; this is one of characteristics of Japanese coals found in the ESR parameters in this study. The proportionality of the spin concentrations with the f_a-values and the inverse proportionality with the H/C-values (from Table 1) suggest the reasons for the low spin concentrations of Japanese bituminous coals.

For deashed coals, a similar correlation to Fig. 3 was found, although some decreases (1/1.5—1/2) in the spin concentrations by the deashing were observed for some coals. Thus, the band-type correlation shifts toward lower in a small extent. For the reason for the decrease in the spin concentration by deashing, one can consider the instabilization of the spin centers by the protonation of aromatic rings or semiquinone type radicals with the action of mineral acids; another interpretation is the spin-pairing by the removal of inorganic matters.[35]

Similar correlations were found for the aerated sample system; although the narrow ESR lines in foreign coals were broadened by the adsorption of oxygen

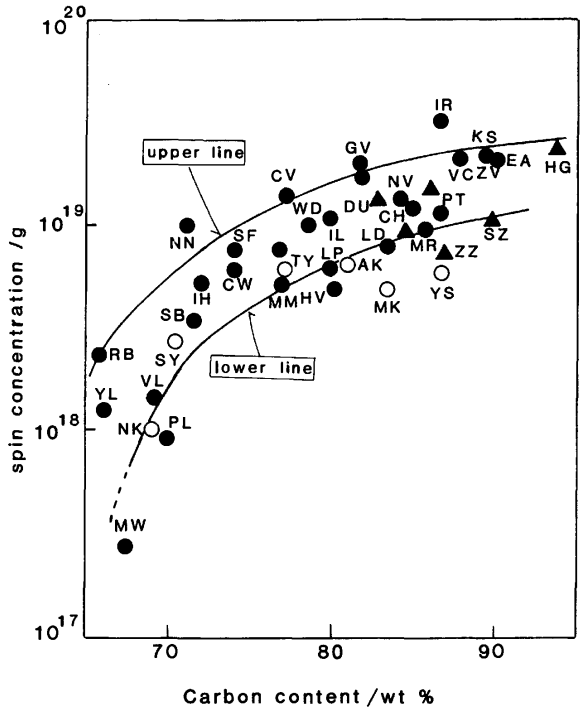

Fig. 3. Dependence of the spin-concentrations for raw coals (measured under vacuum) upon the carbon contents.

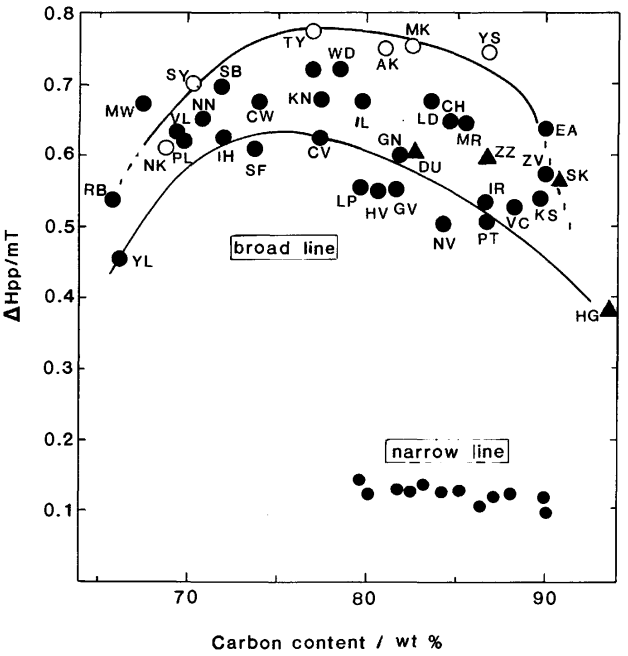

Fig. 4. Line widths (ΔH_{pp}) vs. carbon contents; for coals showing broad and narrow lines, both line widths are shown.

molecules, the integrated intensities were not varied in large extent.[36]

Line Widths. In Fig. 4, the line widths of raw coals observed in evacuated system are plotted against the carbon contents; for foreign coals composed of two lines, the both line widths are shown. It can be seen in this figure that the narrow lines appear for the foreign coals having carbon contents greater than about 78% C. Among the broad lines, the lines for Japanese subbituminous and bituminous coals are wider than the foreign ones by about 0.2 mT. This finding was already indicated by Toyoda, Sugawara, and Honda, who suggested on the basis of the H/C-values that the hydrogen atoms around the spin centers broaden the line width by the hyperfine interactions.[12]

The hydrogen atoms can be divided into two groups by the aid of the IR spectra; one is the hydrogen atoms attached directly to the aromatic rings (the bands at 3030 cm^{-1}) and another is aliphatic C-H groups (the band at 2940 cm^{-1}).[28] In the IR spectra of coals having the same carbon content, the intensities of the aromatic C-H bands of the Japanese bituminous coals are similar to those of foreign coals as shown in Fig. 5. On the other hand, a pronounced increase in the intensities of the aliphatic C-H bands is found for Japanese bituminous coals. It is well-known that the hyperfine coupling constants of the hydrogen atoms at the aliphatic groups in the vicinity of the radical center (α- and β-positions) are generally similar to those by the hydrogen atoms attached directly to aromatic rings.[37] Thus, the finding that the line widths of the Japanese bituminous coals are broad is closely related to their rich aliphatic groups. For the narrow ESR lines observed mainly for the foreign coals, one can interpret similarly by the poor aliphatic C-H groups for these components in coals.

g-Values. It is well-known that the g-values of

Table 3. Observed T_1-Values for Some Coals and Pitches. Changes with Degree of Vacuum and Densities, and Effects by Alkylation and Acetylation

Sample	Treatment	T_1/μs
Shin-yubari	4.0 Pa	70
	0.67 Pa	69
	0.0001 Pa	67
	In air	4
Zao-zhuang	Raw coal	<2
	Soluble part (33 wt%)	140
Gilsonit pitch	85.4% C (f_a=0.33)	80
Ashiland pitch	92.8% C (f_a=0.43)	490
Taiheiyo	Raw coal	9
	Acetylation	29
	Alkylation	55
Moura	Raw coal	<2
	d=1.28	12
	d=1.30	12
	d=1.33	3
	d=1.38	<2

coals decrease with the degree of coalification; the g-values generally increase with the amount of the hetero atoms such as oxygen, sulfur, and nitrogen atoms,[2,34] in which the oxygen content mainly determines the g-values. It would be anticipated that the oxygen atoms near the spin center are mainly the phenolic oxygen. In order to examine this assumption, we show the correlation between the g-values and the amount of the phenolic O-H which can be easily evaluated from the IR band at ca. 3450 cm^{-1}.[28] In Fig. 6, a good linear proportionality can be seen, suggesting that there are the phenolic O-H groups in the vicinity of the spin center. Although the importance of the nitrogen atom in the exinite groups was recently suggested,[34] their roles are not clear in our study because the nitrogen and sulfur atoms are contained only a small amount in coals (Table 1).

Spin-Lattice Relaxation Times. Spin-lattice relaxation times for various coals could be estimated as relative values by the continuous-wave saturation method.[24] The plots of peak-peak heights of the signals against the microwave powers observed for the samples in vacuum system are shown in Fig. 7. The Japanese bituminous coals such as Shin-yubari coal show the saturation at lower microwave power, whereas the foreign bituminous coals show the saturation at high microwave power.[38] The narrow lines show the saturation at the higher microwave power. When one ESR line is composed of both homogeneous and inhomogeneous components, the upward curvature in Fig. 7 deviated from the symmetric curve with respect to the maximum; in such cases, some corrections are necessary to estimate the maximum microwave power (P_{mx}) according to Castner's method.[27]

The T_1 values can be estimated from the following equation as relative values;

$$T_{1x} = T_{1s}(\Delta H_x/\Delta H_s)(P_{ms}/P_{mx}) \quad (1)$$

where, T_{1x} and T_{1s} refer to the spin-lattice relaxation times for unknown and standard samples, respectively; ΔH refers to the line width.[34] By adopting the T_1 values for Miike coals reported by Toyoda, Sugawara, and Honda (59 μs),[12] the relative values can be converted into the absolute values.

By the comparison of the T_1-values observed in low vacuum (10^{-1} Pa during a few hours) with those in high vacuum (10^{-4} Pa during a week), any appreciable difference in the T_1-values was not observable (Table 3). By the introduction of air into the sample, the T_1-value decreases considerably.[6] These findings indicate that the oxygen effect can be easily eliminated even by low evacuation. The T_1-values summarized in Table 2 were observed for the considerably high

vacuum system (about 10^{-2} Pa).

The T_1-values thus estimated are plotted against the carbon contents as shown in Fig. 8. For the low rank coals from 65%C to about 77%C, a monotonous decrease in the T_1-values with an increase in the carbon contents was observed. In the range of carbon contents greater than 77%C, coals can be divided into two groups; upper group contains Japanese bituminous coals and some foreign coals such as Millmerran coal. In the lower group, some foreign bituminous and subbituminous coals belong.

Duber and Wieckowski estimated the T_1- and T_2-values of the broad lines and narrow lines of Polish coals and observed that the T_1-values of the components showing the broad lines were longer than those of the narrow lines. This was interpreted by them on the basis of the two-phonon Raman process which suggests that the T_1-values become short in a phase with larger regions of crystalline lattice ordering strongly bounded to one another by covalent bonds.[24] Thus, it would be expected that the macromolecules with many cross linkages show shorter T_1-values than the macromolecules with less cross linkages. As shown in Table 3, we observed for Zao-zhuang (Chinese bituminous coal) that the soluble part has longer T_1-values than the corresponding original coal. This finding is compatible with the observation by Kevan et al. that the T_1-value of a SRC (solvent refined coal) is longer than the original coal.[39,40] We observed that the petroleum pitches show the long T_1-values (Table 3); this observation is in agreement with Yen's observation even though they measured in aerated system.[41] From these observations, it can be confirmed that the components strongly connected with cross linkages have short T_1-values than the components with less cross linkages or small molecules. Dependence of the T_1-value upon the degree of polymerization was indicated for polyacetylenes.[11]

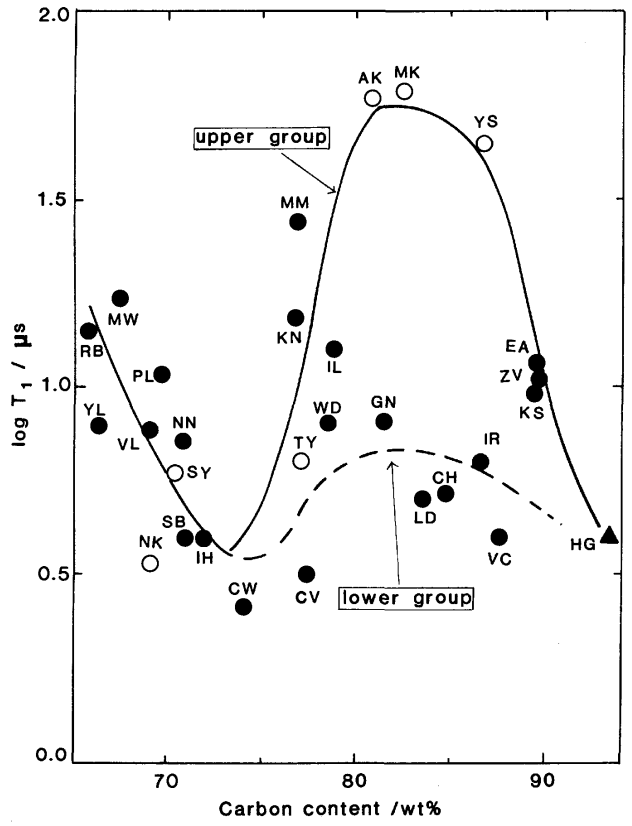

Fig. 8. The T_1-values estimated for raw coals under vacuum vs. carbon contents.

By acetylation of Taiheiyo coal which has rich phenolic O-H groups (Fig. 6), the T_1-values become longer than the original coal (Table 3). This suggests an importance of the interaction via the hydrogen bonds which connect the molecular chains. Alkylation which may occur at the aromatic rings exhibited a strong effect on the T_1-value (Table 3).

It was recently pointed out that the inertinite-rich groups exhibit uneasy saturation.[35] In this connection, we observed the decrease in T_1-values with the increase in the density of Moura coal as shown in Table 3. The inertinite components, in general, have greater f_a-values than the exnite and vitrinite components; thus, an increase in the degree of aromatization tends to decrease the T_1-values.

From these observations, we can interpret Fig. 8; a decrease in the T_1 values from 65 to 77%C may be related to the increase in the cross linkages between the polymer chains with condensation accompanying elimination of small molecules such as water and carbon dioxide as was suggested by van Kreveren's coal band.[42] In the region greater than 77%C, a large splitting was seen; the upper group contains the Japanese coals and some foreign coals which are belonging to the upper group in the H/C-plot (Fig. 1), in the linewidth plot (Fig. 3), and in the aliphatic group-plot (Fig. 5), whereas they are to the lower group in the spin-concentration plot (Fig. 4). In the upper group of Fig. 8, the increase in the T_1-values from 77 to 85%C may be related to the increase in the aliphatic groups, since a similar change was observed in Fig. 5. Decrease in the cross linkages or decrease in the hydrogen bonds would be also expected to occur in this region. Decrease in the T_1-values from 83 to 93%C may be related to the increase in polycondensation of aromatic rings.

As origins of the big difference in the T_1-values between the upper and lower groups, many factors should be taken into the consideration. One is originated from the difference in the f_a-values; the coals belonging to the lower group in Fig. 8 have larger f_a-values than the lower one by a factor of ca. 0.1 (Table 1) which is considerably large difference. A large difference in the amounts of the aliphatic groups may also strongly influence the T_1-values as the result of alkylation suggested.

For deashed coals, a similar figure to raw coals (Fig. 8) was obtained excepting slightly longer T_1-values;

this may suggest that flexibility increase with a loss of the inorganic matters which might connect the coal segments by the coordinations. For the higher degree coals, inorganic matters may hinder the approach of the aromatic rings; i.e., they may destroy the crystalline phase.

It can be pointed out that a similar correlation to the upper group was reported by Yokono and Sanada in the ^1H nuclear spin-lattice relaxation times.[4] The molecular weights between bridges in the crosslinking macromolecules in coals, which were estimated from the swelling measurements in solvents by Sanada and Honda, may also support the longer T_1-values of the coals in the range of 80—86 C%.[43] One of our purposes is to find some relations between the ESR parameters (especially the T_1-value) and the solubility of coals, since it would be anticipated that the coals showing high solubility have less cross linkages or low molecular weights. In pyridine (Soxhlet extraction)[44-46] or in a mixed solvent (pyridine-CS_2 extraction),[47] a tendency that the Japanese bituminous coals are considerably soluble was found. Although such tendency seems to reflect on the T_1-values (Fig. 8), the maximum solubility in the plot against the carbon contents exists at about 86% C; a slight shift from the peak in Fig. 8 was seen. This may be partly attributed to our finding that the T_1-values are influenced not only by the real molecular weights but also by the molecular weights between the cross linkages. Furthermore, physical properties such as maximum fluidity which suggest the high flexibility of Japanese bituminous coals may be related with their observed long T_1-values.[13,14]

Summary

The ESR parameters of various coals were investigated and we found some characteristics of Japanese bituminous coals especially in the electron spin-lattice relaxation times (T_1). These ESR parameters which give a rather physical information were discussed with an aid of the IR data which afford a useful chemical information. In this study, it can be emphasized that the electron spin-lattice relaxation phenomena can be potentially used to estimate the molecular interaction including dynamic behavior of the molecules contained in the carbonized materials. We need further study for the electron spin-relaxation phenomena of the compounds which are appropriate as models for coals.

We thank Professor Masamoto Iwaizumi of Tohoku University for his useful suggestions for the analysis and interpretation of the T_1-values. We are also grateful to Professor Minoru Matsuda of Tohoku University and Dr. Takashi Iwasaki of Tohoku Technical Research Institute for their kindness for the use of ESR spectrometers. Informative discussions with Professors Yoshiyuki Nishiyama, Akira Tomita, and Yasuo Ohtsuka of Tohoku University are gratefully appreciated. Coal samples and their analytical data were kindly presented by Coal Chemistry Laboratory in our Institute.

Nucleotide Sequences of DNA and Their Structural Analysis. Categorical Discrimination of 5′-Splice Site Sequences in mRNA Precursors

Yôichi IIDA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received February 28, 1987)

The signals which direct excision of introns from mRNA precursors in higher eukaryotes' genes are not well-understood. Although a consensus sequence, $^{C}_{A}$AG/GT$^{A}_{G}$AGT, has been proposed with the 5′-splice site, actual 5′-splice site sequences differ from it to a greater or lesser degree. In the present paper, structural analysis of 5′-splice site sequences was done by using quantification theory (class II). Nucleotide sequences were transformed into categorical data, and categorical discriminant analysis was carried out between 5′-splice site sequences and sequences other than 5′-splice site. Relative importance of each position of nucleotide sequence was then estimated by calculating partial correlation coefficient on each position.

Many eukaryotic genes are interrupted by introns, which are removed from mRNA precursors (pre-mRNAs) by the RNA splicing mechanism.[1-5] The splicing of pre-mRNA includes, as a first step, cleavage of the 5′-splice junction and formation of a lariat involving the 5′-end of the intron joined by a 2′—5′ phosphodiester bond to an A residue upstream of the 3′-splice junction. This is then followed by cleavage at the 3′-splice junction together with ligation of the 5′ and 3′ exons. Although both steps are related to several reactions, the machinery for splicing (macromolecular ribonucleoproteins containing small nuclear RNAs) carries out this process in a concerted manner.[3-5] The compilation of sequences surrounding intron boundaries demonstrates consensus sequences at both the 5′ (donor) and the 3′ (acceptor) splice sites.[1,2] The 5′-splice site consensus sequence is described by 5′-(exon)-$^{C}_{A}$AG/GT$^{A}_{G}$AGT-(intron)-3′, where the stroke (/) indicates boundary between exon and intron. Such a sequence plays an important role in defining the 5′-splice site, because a number of naturally occurring and in vitro derived mutations within the consensus regions result in splice site inactivation.[6,7] However, the consensus sequence has been ambiguous in what degree of matching between observed junction sequences and the consensus sequence is necessary to specify the exact splice site. That is, actual splice site sequences differ from the consensus sequence to a greater or lesser degree. It is also impossible for the consensus sequence to account for relative importances of each of the nucleotides in the sequence. In order to study such situation more quantitatively, Staden used the weight matrix method.[8] On the other hand, we applied previously multivariate statistical analysis to 5′-splice site sequences of pre-mRNAs, and performed categorical discriminant analysis, where nucleotide sequences were transformed into categorical data.[9] In the present paper, discriminating 5′-splice site sequences and sequences other than 5′-splice site, we calculate a value for partial correlation coefficient on each position of the sequence. This approach enables us to know relative importance of each position of nucleotide sequence.

Categorical Discriminant Analysis

Categorical Data. The formulation of categorical data was described in the previous paper.[9] In the following, we summarize the procedure briefly. Our data assume two groups of nucleotide sequences. The first group is composed of 5′-splice site sequences as recognized by the machinery for splicing. They are taken from authentic 5′-splice site sequences in various mammalian genes containing introns, such as globin genes, insulin genes, etc.[10] We take into consideration the consensus sequence, $^{C}_{A}$AG/GT$^{A}_{G}$AGT, for 5′-splice site, and take 9-nucleotide sequence composed of three nucleotides at the 3′-end of exon and six nucleotides at the 5′-end of intron. It is assumed that essential pattern to define 5′-splice site may lie within such 9-nucleotide sequence. In this way, we summarized 155 sequences into the first group. Some of the sequence data are shown in Table 1.

The second group is composed of sequences other than 5′-splice site. They are taken from human β-globin gene in the following way. The β-globin gene sequence is separated into three exons by two introns,

Table 1. Some of the 9-Nucleotide Sequences Belonging to Group 1 and Group 2[a)]

No.	Group	Sequence	Gene
1	1	GAGGTGAGG	Human alpha-Globin
2	1	AAGGTGAGC	
3	1	CAGGTTGGT	Human beta-Globin
4	1	AGGGTGAGT	
:	:	:	
155	1	AGGGTGAGC	Dog Insulin
156	2	ACATTTGCT	Human beta-Globin
157	2	CATTTGCTT	
:	:	:	
1751	2	TTTCATTGC	

a) Group 1 is composed of 5′-splice site sequences, while Group 2, of sequences other than 5′-splice sites. For further details, see text.

and there are two positions of 5′-splice junctions.[11] In this gene, we first take the 9-nucleotide sequence at the 5′-cap site. Next, we progress one nucleotide in the 3′ direction, and take the next 9-nucleotide sequence. In this way, we truncate 9-nucleotide sequence at every position of the whole pre-mRNA. In those sequences, however, there lie two sequences of the authentic 5′-splice sites, belonging to the first group. These two are excluded, and the remaining 1596 sequences are summarized into the second group, as shown in Table 1.

In order to transform sequence data into categorical data, we introduce a dummy variable $x_{i(\alpha)}^{r(\nu)}$ and parameters of r, ν, i, and α. The parameter, r, indicates the groups, where $r=1$ or 2 corresponds to the first or second group, respectively. We denote n_r as sample size of each group, and take $\nu=1, 2, \cdots, n_r$, where $n_1=155$ and $n_2=1596$. Next, we consider item and category. In our case, there are nine items with $i=1, 2, \cdots, 9$. They correspond to the positions of nucleotides in 9-nucleotide sequence, and are defined by the order from the 5′- to 3′-ends of the sequence. Category denotes the kind of nucleotide, where we specify nucleotide A, G, C, or T by $\alpha=1$, 2, 3, or 4 at every item, respectively. Using these parameters, dummy variable of $x_{i(\alpha)}^{r(\nu)}$ is expressed by

$$x_{i(\alpha)}^{r(\nu)} = \begin{cases} 1 : \text{if the sample sequence } (\nu) \text{ of the group } (r) \\ \quad \text{has a nucleotide } (\alpha) \text{ at the position } (i), \\ 0 : \text{otherwise.} \end{cases} \tag{1}$$

In this way, we transformed the sequence data of Table 1 into the categorical data. Here, we note the redundant condition for any sample sequence $r(\nu)$,

$$\sum_{\alpha=1}^{4} x_{i(\alpha)}^{r(\nu)} = 1, \quad (i=1, 2, \cdots, 9). \tag{2}$$

Categorical Discriminant Analysis. It was made according to Hayashi's quantification analysis (class II).[12,13] Quantification of the categorical data leads to the sample score value

$$y^{r(\nu)} = \sum_{i=1}^{9} \sum_{\alpha=1}^{4} x_{i(\alpha)}^{r(\nu)} a_{i(\alpha)}, \tag{3}$$

where $r=1$, 2 and $\nu=1, 2, \cdots, n_r$. Coefficient of $a_{i(\alpha)}$ is the real number and is called category weight. Our analysis estimates the $a_{i(\alpha)}$ and $y^{r(\nu)}$ values in such a way that the two groups of 5′-splice site sequences ($r=1$) and sequences other than 5′-splice site ($r=2$) may be discriminated most distinctly. For this purpose, we calculate the mean value of sample scores within the group r as

$$\bar{y}^r = \frac{1}{n_r} \sum_{\nu=1}^{n_r} y^{r(\nu)} = \sum_{i=1}^{9} \sum_{\alpha=1}^{4} \bar{x}_{i(\alpha)}^{r} a_{i(\alpha)}, \tag{4}$$

where

$$\bar{x}_{i(\alpha)}^{r} = \frac{1}{n_r} \sum_{\nu=1}^{n_r} x_{i(\alpha)}^{r(\nu)}, \quad (r=1, 2). \tag{5}$$

On the other hand, the mean value of the total samples is

$$\bar{y} = \frac{1}{N} \sum_{r=1}^{2} n_r \bar{y}^r, \tag{6}$$

where $N=n_1+n_2=1751$ is the number of total samples. Using these values, variance of the total samples, σ^2, and variance between groups 1 and 2, σ_B^2, are given by

$$\sigma^2 = \frac{1}{N} \sum_{r=1}^{2} \sum_{\nu=1}^{n_r} (y^{r(\nu)} - \bar{y})^2, \tag{7}$$

$$\sigma_B^2 = \frac{1}{N} \sum_{r=1}^{2} n_r (\bar{y}^r - \bar{y})^2. \tag{8}$$

In order to discriminate the groups 1 and 2 most distinctly, we maximize the following η^2 value,

$$\eta^2 = \frac{\sigma_B^2}{\sigma^2}. \tag{9}$$

The procedure to maximize η^2 and to obtain $a_{i(\alpha)}$ values at the optimum condition was briefly summarized in the previous paper.[9]

Partial Correlation Coefficient. Using the optimum values of category weight $\hat{a}_{i(\alpha)}$, ($i=1, 2, \cdots, 9$; $\alpha=1$, 2, 3, 4), we calculate the optimum values of sample scores $\hat{y}^{r(\nu)}$ by Eq 3. Then, we obtain from Eq. 4

$$\hat{y}^r = \frac{1}{n_r} \sum_{\nu=1}^{n_r} \hat{y}^{r(\nu)}, \quad (r=1, 2). \tag{10}$$

We define $x_i^{r(\nu)}$ by

$$x_i^{r(\nu)} = \sum_{\alpha=1}^{4} \hat{a}_{i(\alpha)} x_{i(\alpha)}^{r(\nu)}, \quad (\nu=1, 2, \cdots, n_r;\ i=1, 2, \cdots, 9). \tag{11}$$

Using these parameters, we calculate the following quantities;

$$\sigma_{ij} = \frac{1}{N} \sum_{r=1}^{2} \sum_{\nu=1}^{n_r} (x_i^{r(\nu)} - \bar{x}_i)(x_j^{r(\nu)} - \bar{x}_j), \quad (i, j=1, 2, \cdots, 9), \tag{12}$$

$$\sigma_{iy} = \frac{1}{N} \sum_{r=1}^{2} \sum_{\nu=1}^{n_r} (x_i^{r(\nu)} - \bar{x}_i)(\hat{y}^r - \hat{y}), \quad (i=1, 2, \cdots, 9), \tag{13}$$

$$\sigma_{yy} = \frac{1}{N} \sum_{r=1}^{2} n_r (\hat{y}^r - \hat{y})^2, \tag{14}$$

where

$$\bar{x}_i = \frac{1}{N} \sum_{r=1}^{2} \sum_{\nu=1}^{n_r} x_i^{r(\nu)}, \quad (i=1, 2, \cdots, 9), \tag{15}$$

$$\hat{y} = \frac{1}{N} \sum_{r=1}^{2} n_r \hat{y}^r. \tag{16}$$

Next, we introduce correlation coefficients between

items, r_{ij}, and between item and sample sequence, r_{iy}, by

$$r_{ij} = \frac{\sigma_{ij}}{\sqrt{\sigma_{ii}\sigma_{jj}}}, \quad (i, j = 1, 2, \cdots, 9), \tag{17}$$

$$r_{iy} = \frac{\sigma_{iy}}{\sqrt{\sigma_{ii}\sigma_{yy}}} = r_{yi}, \quad (i = 1, 2, \cdots, 9, y). \tag{18}$$

We construct the 10-dimensional matrix, **R**, composed of those coefficients by

$$\mathbf{R} = \begin{bmatrix} r_{11} & r_{12} & \cdots & r_{19} & r_{1y} \\ r_{21} & r_{22} & \cdots & r_{29} & r_{2y} \\ \vdots & \vdots & & \vdots & \vdots \\ r_{91} & r_{92} & \cdots & r_{99} & r_{9y} \\ r_{y1} & r_{y2} & \cdots & r_{y9} & r_{yy} \end{bmatrix}. \tag{19}$$

This matrix leads to the inverse matrix, $\mathbf{R}^{-1}$, whose matrix elements are

$$\mathbf{R}^{-1} = \begin{bmatrix} r^{11} & r^{12} & \cdots & r^{19} & r^{1y} \\ r^{21} & r^{22} & \cdots & r^{29} & r^{2y} \\ \vdots & \vdots & & \vdots & \vdots \\ r^{91} & r^{92} & \cdots & r^{99} & r^{9y} \\ r^{y1} & r^{y2} & \cdots & r^{y9} & r^{yy} \end{bmatrix}. \tag{20}$$

By the use of these matrix elements, partial correlation coefficient between samples and the i-th item is given by

$$r_{iy \cdot 1,2,\cdots,i-1,i+1,\cdots,9} = \frac{-r^{iy}}{\sqrt{r^{ii}r^{yy}}}, \quad (i = 1, 2, \cdots, 9). \tag{21}$$

where $r_{iy.1,2,\cdots,i-1,i+1,\cdots,9}$ indicates a correlation coefficient between i and y, removing influences of the other items of $1, 2, \cdots, i-1, i+1, \cdots, 9$. The magnitude of this coefficient tells us to what extent the i-th item may contribute to the discrimination of sample sequences between the first and second groups.

Results

We applied the above method to the $N=1751$ sample sequences, and discriminated 5′-splice site sequences ($r=1$) from sequences other than 5′-splice sites ($r=2$) most distinctly. The optimum values for category weights $\hat{a}_{i(\alpha)}$, ($i=1, 2, \cdots, 9$; $\alpha=1, 2, 3, 4$), were estimated as shown in Table 2. Using these values together with Eqs. 10—18, we constructed the **R** matrix. Its matrix elements are symmetrical and the lower half of them is only given in Table 3. After transforming **R** matrix into $\mathbf{R}^{-1}$ matrix, partial correlation coefficients in Eq. 21 are calculated as 0.100, 0.162, 0.264, 0.424, 0.329, 0.175, 0.206, 0.351, and 0.157 for items $i=1, 2, 3, 4, 5, 6, 7, 8$, and 9, respectively.

Discussion

So far, the splice junction signals have been summarized as "consensus" sequences. In the case of 5′-splice site consensus sequence, $^{C}_{A}$AG/GT$^{A}_{G}$AGT has been proposed by Mount.[2] Attempts have been widely made to look for sequences relevant to the consensus sequence in the whole pre-mRNA. However, its technique is rather unsatisfactory, because actual splice site sequences differ from the consensus sequence to a greater or lesser degree. The consensus sequence is also ambiguous in which nucleotides are important to specify the 5′-splice site and which nucleotides are less important. The optimum values of category weight $\hat{a}_{i(\alpha)}$, ($i=1, 2, \cdots, 9$; $\alpha=1, 2, 3, 4$), may answer this problem. In this case, the item, i, corresponds to the position of nucleotide in 9-nucleotide sequence, while the category, α, denotes the kind of nucleotide at the i-th position. Relative importance of the kind of nucleotide at each position was previously discussed in terms of the $\hat{a}_{i(\alpha)}$ value.[9]

Next, we consider relative importance of item (position of nucleotide) in 9-nucleotide sequence. There

Table 2. Optimum Category Weight Values of $\hat{a}_{i(\alpha)}$'s Calculated with Categorical Discriminant Analysis of 5′-Splice Site Sequences[a]

a) The tenth item in this table is read as $i, j=y$. Since $r_{ij}=r_{ji}$, the lower half of the matrix elements is only given.

have been known a few approaches to measure quantitatively contribution of item to the discrimination between two groups of 5′-splice site sequences and sequences other than 5′-splice sites. One approach is to calculate partial correlation coefficient between sample sequences and the i-th item under the optimum condition of discrimination. This was done in the previous sections. Here, the larger the value of such a partial correlation coefficient, the greater the contribution of the i-th item to the discrimination between the two groups. As is shown in Results, the largest value of the partial correlation coefficient was found to be 0.424 at the fourth position. The next largest values range as 0.351 at the eighth position, 0.329 at the fifth position, and 0.264 at the third position, while the smallest values were found to be 0.100 at the first position and 0.157 at the ninth position. Therefore, the fourth, eighth and fifth positions are more important to specify 5′-splice site sequences, whereas the first, ninth and second positions are less important. This prediction is consistent with the experimental results that the GT dinucleotide at the fourth and fifth positions and the G nucleotide at the eighth position are almost invariant in every sequence of 5′-splice junction.[2)] It is also found that nucleotides at the other positions are rather variable, differing from junction to junction. The small values of partial correlation coefficients at the other positions may correspond to this phenomenon.

Another approach to measure relative importance of item (position of nucleotide) is to estimate the range of category weights, R_i, which is defined by

$$R_i = \max_{\alpha}(\hat{a}_{i(\alpha)}) - \min_{\alpha}(\hat{a}_{i(\alpha)}). \quad (22)$$

This parameter implies that the larger the R_i value, the greater the influence of $\hat{a}_{i(\alpha)}$'s at the i-th item on the total sample score $y^{r(\nu)}$. Using the data of $\hat{a}_{i(\alpha)}$ in Table 2, the R_i values are calculated as $R_1=3.3657$, $R_2=5.0741$, $R_3=8.7810$, $R_4=14.7574$, $R_5=10.1131$, $R_6=5.4637$, $R_7=6.0187$, $R_8=11.5297$, and $R_9=5.1414$. These results show that the degree of importance of items aligns in the order of $i=4, 8, 5, 3, 7, 6, 9, 2$, and 1. It appears that this order of importance is in good accordance with that of the previous partial correlation coefficients given in the previous section of Results.

Several other evidences which support our conclusion are provided by experimental results on mutational changes of nucleotides around 5′-splice junctions. One example is the study of Treisman et al.,[6)] who reported three mutants of human β-globin gene. The β-globin gene sequence is separated into three exons by two introns, and there are two positions of 5′-splice junctions.[11)] In the normal gene, the 9-nucleotide sequence at the 5′-splice site of the first intron is ··· CAG/GTTGGT ···. All of the above three mutant genes (i)—(iii) contain single nucleotide changes within the 9-nucleotide sequence, causing β-thalassemia phenotype. The β-thalassemia comprises a group of diseases in which the synthesis of normal β-globin polypeptide is either absent or reduced. In the (i) mutant, a G→A transition took place at the fourth position of the 9-nucleotide sequence, resulting in ··· CAGATTGGT ···. The (ii) mutant underwent a G→C transversion at the eighth position, and has a sequence ··· CAGGTTGCT ···. In the (iii) mutant, a T→C transition took place at the ninth position, resulting in ··· CAGGTTGGC ···. Treisman et al. analyzed the RNA synthesis and expression of the mutant gene after its introduction into cultured mammalian cells on a suitable vector.[6)] In all of the (i)—(iii) genes, the mutational changes inactivated the authentic 5′-splice site signal at the first intron, failing in normal β-globin mRNA synthesis or reducing the synthesis. The mutation at the fourth position completely inactivated the 5′-splice site of the first intron, giving no production of normal β-globin mRNA. On the other hand, the mutation at the eighth position resulted in partial inactivation of the 5′-splice site, while the mutation at the ninth position showed a less dramatic decrease in the production level of normal mRNA. Although the latter two mutations led to β^+-thalassemia, the eighth position mutation caused a more pronounced deficiency of β-globin synthesis than did the ninth position mutation. These experimental results may correspond well to our categorical discriminant analysis. Since the relative importance of items (position of nucleotide) is greatest at the fourth

position, mutation at this position will influence the 5′-splice site signal most strongly. This may be a reason why the G→A change at the fourth position of the (i) mutant inactivated completely the 5′-splice site. According to our discriminant analysis, the next important item corresponds to the eighth position, and the least important item, to the ninth position. In accordance with this view, both of the eighth and ninth position mutations caused partial inactivation of the 5′-splice site, but the deficiency of mRNA synthesis is more severe in the eighth position mutant than in the ninth position mutant.

Another example of mutations which supports our conclusion is the work of Wieringa et al.,[7] who reported mutagenic inactivation of an authentic 5′-splice site of the second intron in rabbit β-globin gene. The 9-nucleotide sequence of the normal gene at this site is ···AGG/GTGAGT···. Six mutant genes were prepared by site-directed mutagenesis involving purine transitions; (i) A→G transition at the first position, (ii) G→A at the second position, (iii) G→A at the third position, (iv) G→A at the fourth position, (v) G→A at the sixth position and (vi) A→G at the seventh position. Expression of these genes in HeLa cells revealed that mutations of (i)—(iii), (v) and (vi) affected neither the quantity nor the structure of correct β-globin mRNA. However, the mutation of (iv) inactivated completely the 5′-splice site, giving no correctly spliced β-globin mRNA. These experimental results seem to be consistent with the previous discriminant analysis, because the 5′-splice site sequence is influenced most strongly by the mutational change at the fourth position, and because the effects of the other positions are much weaker than that of the fourth position.

Crystal Structure and ^{35}Cl NQR of Copper(II) Trichloroacetate Trihydrate

Hideko KIRIYAMA,† Masao HASHIMOTO,* and Nanami OKUNO
Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe 657
(Received March 24,1987)

The crystal structure of the title compound has been determined by means of X-ray diffraction. The crystal data and the final R value are: $Cu(CCl_3COO)_2 \cdot 3H_2O$, monoclinic $C2/c$, $a=23.082(3)$, $b=6.253(1)$, $c=9.726(2)$ Å, $\beta=94.67(1)°$, $Z=4$, $R=0.049$. The structure consists of monomeric $Cu(CCl_3COO)_2(H_2O)_3$ molecules, which are linked together by intermolecular O-H···O hydrogen bonds to form a layer parallel to (100). Each Cu(II) atom is coordinated by five oxygen atoms which form nearly a square pyramid; two oxygen atoms of two carboxylate ions and two water molecules form its basal plane and the remaining water molecule occupies the apical position. The mean basal Cu-O length is 1.961 Å and the apical one 2.183 Å. The Cu(II) atom is displaced from the basal plane by 0.110 Å toward the apical oxygen. Thermal analysis (DSC) disclosed two phase transitions at 163 and 207 K, their estimated molar enthalpies being about 0.4 and 0.7 kJ mol^{-1}, respectively. At 77 K, 24 ^{35}Cl NQR signals are observed in the frequency range 38.7—40.3 MHz. The X-ray diffraction photographs for both low-temperature phases indicate the appearance of superstructures with less symmetrical space groups; the b spacing doubles below 207 K, while both b and c spacings double below 163 K.

One of the present authors studied ^{35}Cl nuclear quadrupole resonance (NQR) on a various salts of trichloroacetic acid with a view to obtaining structural informations.[1] Of these, the NQR spectrum of $Cu(CCl_3COO)_2 \cdot nH_2O$ was not consistent with that reported in the literature.[2] In order to solve this question, we investigated the crystal structure of the title compound. In course of this work, it was found that the ^{35}Cl NQR spectrum expected from the crystal structure determined at room temperature is quite different from that observed at 77 K. In fact, thermal analysis confirmed the occurrence of phase transitions at 163 and 207 K. Fortunately, undergoing of both phase transitions did not damage the crystal, and the structural changes could be followed by X-ray diffraction method at low temperatures. To get further information on the transitions the temperature dependence of the ^{35}Cl NQR frequencies were reinvestigated more accurately than in the earlier work.

The present paper deals with the crystal structures of the compound and the nature of the phase transitions newly found. Furthermore, the conformation of CCl_3COO^- group is discussed in detail especially in comparison with that recently found in $CCl_3COONH_4 \cdot 2.5H_2O$.[3]

Experimental

Material. Addition of dicopper carbonate dihydroxide hydrate to an aqueous solution of trichloroacetic acid in a stoichiometric ratio yielded a light blue precipitate at about 40 °C. The trihydrate crystal was obtained by recrystallization of the precipitate from water as a blue, flat plate characterized by perfect cleavage.

X-Ray Structure Determination. The density was measured by pycnometry with petroleum at 18 °C. The lattice parameters and the space group were first determined with a Weissenberg camera (Rigaku Denki Co.); reflection conditions hkl: $h+k=2n$ and $h0l$: $l=2n$ led to monoclinic $C2/c$ or Cc, the former space group being confirmed by successful refinements. A single crystal 0.2×0.3×0.3 mm in size was mounted with [010] coincident with the goniostat axis of an automated Rigaku four-circle diffractometer AFC-4, graphite-monochromated Mo $K\alpha$ radiation ($\lambda=0.7107$ Å), 40 kV-200 mA used. Unit cell parameters were refined by a least-squares method using 25 2θ values ($25° < 2\theta < 34°$). Intensity measurement in ω—2θ scan mode was made up to $2\theta=55°$ ($-30 \leqq h \leqq 30$, $0 \leqq k \leqq 8$, $-12 \leqq l \leqq 12$), three standard reflections (040, 1604, 915) were monitored every 50 reflections throughout the experiment. A total of 3210 reflections were measured. Lorentz-polarization and absorption effects were corrected, empirical absorption correction-factors on F less than 1.19.[4] Equivalent reflections were merged ($R_{av}=\sum||F_o|-<|F_o|>|/\sum|F_o|=0.017$), and of 1608 reflections remained 1441 with $|F_o|>3\sigma(F_o)$ were used for the structure determination.

The positional coordinates of Cu and Cl atoms were obtained by a direct method with MULTAN78[5] and confirmed by a three-dimensional Patterson synthesis. The other non-hydrogen atoms were located by successive Fourier syntheses. The structure was refined by block-diagonal least-squares with anisotropic thermal parameters for non-hydrogen atoms. All hydrogen atoms were located by a difference Fourier synthesis and refined with isotropic thermal parameters. The quantity $\sum w(|F_o|-|F_c|)^2$ with $w=1/[\sigma^2(F_o)+0.13247|F_o|]$ was minimized for 1441 unique reflections and 96 variables. The final refinement including hydrogen atoms gave $R=\sum(||F_o|-|F_c||)/\sum|F_o|=0.049$, $R_w=[\sum w(|F_o|-|F_c|)^2/\sum wF_o^2]^{1/2}=0.073$ and goodness of fit $S=[\sum w(|F_o|-|F_c|)^2/(m-n)]^{1/2}=1.14$, where m is the number of reflections and n the number of refined parameters. The maximum positive and negative electron densities $(\Delta\rho)_{max}$ and $(\Delta\rho)_{min}$ in the final difference Fourier synthesis were +0.9 and −0.9 e Å^{-3}, respectively. The maximum ratio of parameter shift to e.s.d. for non-hydrogen atoms, $(\Delta/\sigma)_{max}$, was 0.017. Neutral atomic scattering factors were used for all atoms and corrections for anomalous dispersion applied.[6] The computer programs used were MULTAN78, ORTEPII and UNICS-OSAKA.[5,7,8] The final atomic parameters are listed in Table 1.[9]

Crystal Data: $[Cu(CCl_3COO)_2(H_2O)_3]$, $M_r=442.34$, $C2/c$, $a=23.082(3)$, $b=6.253(1)$, $c=9.726(2)$ Å, $\beta=94.67(1)°$, $Z=4$,

Thermal Analyses. Thermal gravimetry (TG), differential thermal analysis (DTA) and differential scanning calorimetry (DSC) were carried out with two pieces of Rigaku "thermoflex" apparatus. The temperature ranges studied were 300—450 K for the former two and 100—300 K for the latter one. A relatively large single crystal (3×3×1 mm, about 16 mg) sealed in an aluminium cell under an atmosphere of nitrogen was used for DSC, because the transition enthalpies are too small to be detected with a powdered sample.

^{35}Cl NQR Experiment. The ^{35}Cl NQR frequencies were measured on a polycrystalline sample by use of a superregenerative spectrometer with an accuracy of ±2kHz.[10]

Low-Temperature X-Ray Experiment. Oscillation and Weissenberg photographs were taken with a Cu $K\alpha$ radiation (40 kV, 150 mA) at 183 and 145 K. The specimen was kept at a desired temperature by controlling the flow rate of cold nitrogen gas and the current of a heater wound around an inner tube in which the gas flows. A flow of nitrogen-gas jetted through an outer tube formed a curtain to avoid formation of frost on the crystal during the experiment. A rather large single crystal (0.5 mm on edge) was chosen for the goniometric use at low temperatures.

Results and Discussion

Crystal Structure. A stereo pair of the crystal structure viewed along [010] and the projection along [100] with the atomic numbering scheme are shown in Figs. 1 and 2, respectively. Selected interatomic distances and angles are listed in Table 2. The structure of copper(II) trichloroacetate hydrate consists of discrete monomeric molecules, $[Cu(CCl_3COO)_2(H_2O)_3]$, in agreement with the prediction from the magnetic susceptibility[11] and ESR spectra.[12] The molecule has a crystallographic C_2 axis passing through the Cu and O(W2) atoms. Each copper(II) atom is coordinated by five oxygen atoms (two from monodentate trichloroacetato groups and three from water molecules) in a nearly square pyramidal arrangement. The four donor atoms, O(1), O(W1), O(1^i), O(W1^i), form a slightly distorted square and the water oxygen O(W2)

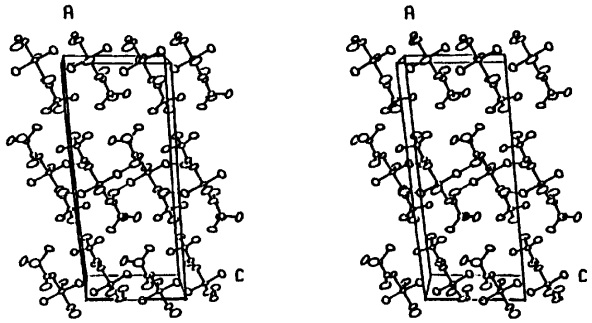

Fig. 1. A stereoscopic view of the crystal structure of $Cu(CCl_3COO)_2\cdot 3H_2O$ along the b axis. Thermal ellipsoids are shown at 50% probability level.

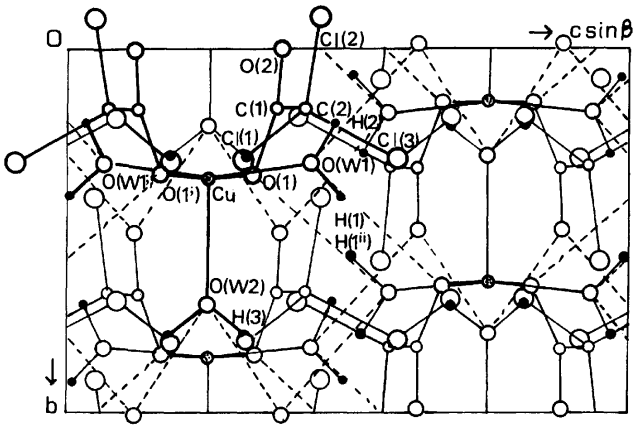

Fig. 2. The projection of crystal structure along the a axis with the atom numbering scheme.

occupies the apical position. The apical Cu-O(W2) distance (R_L=2.183 Å) is significantly longer than the mean basal Cu·O distance (R_s=1.961 Å), the tetragonality T^5(=R_S/R_L) being 0.90.[13] Such lengthening of the apical bond is quite common in copper(II) complexes with coordination numbers of 6 and even 5.[14] The four oxygen atoms in the CuO_5 chromophore is planar within 0.082(6) Å, and the central Cu atom is displaced from this plane by 0.110(2) Å toward O(W2). Although the second oxygen of each carboxylate ion

group is situated at 2.946 Å from the Cu(II) atom, it is not regarded as bonded to Cu(II).

The bond lengths and angles in the trichloroacetato ligand are in agreement with those found in $CCl_3COONH_4 \cdot 2.5H_2O$,[3] except for C-O distances and torsion angles. The lengths of 1.242 Å for C(1)-O(1) and 1.212 Å for C(1)-O(2) are significantly different owing to monodentative coordination of the ligand. More remarkable differences are seen in the torsion angles O-C-C-Cl, which are associated with the conformation of CCl_3COO^- ligand. In the most stable conformation of its free ion, the three torsion angles will be 90, 30, and 150°. In other words, one of the three C-Cl bonds will be perpendicular to the COO plane in the projection along the molecular axis C-C. As given in Table 2, the torsion angles deviate from these ideal values by 12—19° (the mean 15.3°) in contrast to the corresponding values of 0.3—3.0 (the mean 1.4°) for the NH_4 salt.[3] In both compounds, the CCl_3 groups are faced to each other with van der Waals contact and all the carboxylate oxygen atoms are participated in hydrogen bonds as acceptors. However, there exists a serious difference in coordination scheme between the two salts; in the Cu salt, one oxygen atom of the COO group coordinates also to a Cu(II) atom. It was therefore evidenced that the conformation of CCl_3COO moiety is largely affected by the bonding scheme with its surroundings.

As shown in Figs. 1 and 2, the $[Cu(CCl_3COO)_2(H_2O)_3]$ molecules are linked together by intermolecular hydrdogen bonds of O(W1)-H···O(2), O(W1)-H···O(1), and O(W2)-H···O(2), forming a distinct layer parallel to (100). Thus, the terminal CCl_3 groups of trichloroacetato ligands face to each other with van der Waals contact between Cl(1) and Cl(2) (3.659 Å) and between Cl(1) and Cl(3) (3.582 Å) in interlayer space. Such a distinct layer structure is responsible for the perfect cleavage parallel to (100).

Thermal Properties and Phase Transitions. The DTA and TG experiments indicated that the dehydration of $Cu(CCl_3COO)_2 \cdot 3H_2O$ proceeds in two steps; two water molecules were lost at about 338 K and the rest at about 404 K. On the other hand, two faint, but definite endothermic (exothermic) peaks were observed on heating (cooling) runs of DSC, providing a clear evidence for the presence of two phase transitions at 163 and 207 K. The transition enthalpies were estimated to be approximately 0.4 kJ mol^{-1} for the transition at 163 K and 0.7 kJ mol^{-1} for that at 207 K. These values are quite small and suggest very slight structural changes associated with the phase transitions. In fact, the single crystal remained unchanged in appearance after it experienced either phase transition many times. The three phases will be abbreviated as LTP, ITP, and RTP in order of increasing temperature, hereafter.

^{35}Cl NQR in LTP and ITP. The ^{35}Cl NQR frequencies at 77 K (the lowest temperature studied) are

		−6.85	ν_{21}	38.732	−2.87

a) These frequencies coincide with those reported for $Cu(CCl_3COO)_3 \cdot nH_2O$.[2] b) Two ^{35}Cl NQR lines superimpose by accident.

summarized in Table 3. At this temperature, 21 ^{35}Cl NQR lines were apparently observed, but three of them split into two lines at higher temperatures (see below). Therefore, there exist in total 24 NQR lines at 77 K. Twelve of these 24 frequencies coincide well with the 12 frequencies reported for $Cu(CCl_3COO)_2 \cdot nH_2O$.[2] The temperature dependences of the NQR frequencies are shown in Fig. 3. The lines at 39.813, 39.697, and 39.132 MHz at 77 K split into two lines as the temperature was raised. All of the 24 NQR signals faded out in the temperature range 115—170 K. Only a few signals could be observed still above about 160 K, and their frequency vs. T curves showed discontinuities around 163 K, as can be seen in Fig. 3(b). This observation confirms the presence of the phase transition at 163 K found by DSC.

The crystal structure of LTP has not been analyzed, but it is reasonable to expect that the difference in crystal structure between LTP and RTP is very slight. Therefore, one may discuss the ^{35}Cl NQR spectrum of LTP on the basis of the crystal structure of RTP. The ^{35}Cl NQR frequencies of LTP are distributed in a relatively wide frequency range from 38.7 to 40.3 MHz. This frequency splitting (at most 1.6 MHz) is too large to be attributed to mere crystal field effect. The geometry of the CCl_3 group is quite normal: Every C-Cl distance is typical of a single bond length and the angles between the three C-Cl bonds are close to the tetrahedral one. Thus, there seems to be no interaction of intramolecular origin through σ bonds that will be responsible for the frequency splitting. A possibility which could account for the frequency splitting is the rather peculiar configuration of the CCl_3COO group. Because its structure deviates considerably from the ideal one, Cl(2) and O(2) atoms are brought close together (2.863(6) Å) and this contact could contribute to shift the ^{35}Cl NQR frequency of the Cl(2).

Another possibility which could explain the frequency splitting is the interactions between chlorine

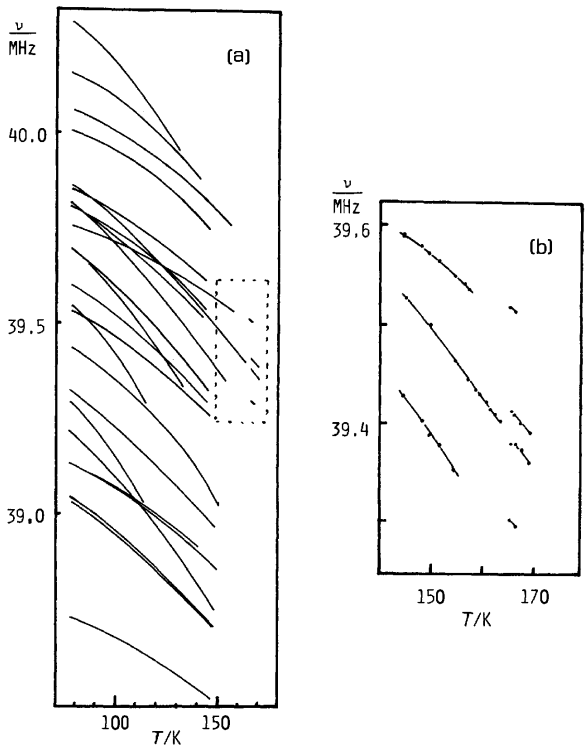

Fig. 3. (a) The temperature dependence of ^{35}Cl NQR frequencies in $Cu(CCl_3COO)_2 \cdot 3H_2O$; (b) enlargement of the region enclosed by dotted line in (a).

and water hydrogen atoms. The Cl(3)···H(1) distance 2.68(8) Å is shorter than the sum of the van der Waals radii (3.0 Å). In addition, H(3) is the second nearest hydrogen atom of the Cl(3) atom (3.6(1) Å), while H(2) and H(1) are the first and second nearest hydrogen atoms of the Cl(2) atom (3.10(8) and 3.36(8) Å). In contrast to these, the Cl(1) atom has no hydrogen neighbor closer than 3.9 Å. In an electrostatic model of hydrdogen bond, it is considered that a net positive charge is produced on the hydrogen atom participated in a hydrogen bond. In the present system, the positive

charge on H(1), H(2), and H(3) can cause excess electric field gradients at the positions of Cl(3) and Cl(2) which could give rise to a shift of ^{35}Cl NQR frequency of about a hundred kHz. Thus, both effects of the hydrogen bonds and the Cl(2)···O(2) contact seem to be responsible for the frequency splitting.

Besides the large frequency splitting mentioned above, the extreme multiplicity is also characteristic of the ^{35}Cl NQR spectrum of LTP. According to the present X-ray analysis, RTP has only one crystallographically independent CCl_3 group in the unit cell. Therefore, the number of the ^{35}Cl NQR lines in RTP, if they were detected, should be three. In contrast, 24 ^{35}Cl NQR lines have been detected for LTP. Because the difference in the crystal structure between RTP and LTP is very slight, one may expect that the 24 NQR lines in LTP can be divided into three frequency groups each of which has 8 lines distributed in a narrow frequency region. However, the 24 lines are distributed almost uniformly and one fails to sort the lines in such a way. This indicates that the change in the crystal structure, though it is very slight, is quite effective to cause the shifts of the NQR frequencies to give a uniform distribution of lines. As shown in Table 3, the values of the temperature coefficients of the NQR frequencies are widely distributed and several of them are extremely large. These facts also suggest that the environment of each chlorine atom in LTP is considerably different from each other.

Structural Changes at Phase Transitions. The X-ray oscillation photographs, and zero- and first-layer Weissenberg photographs around [010] taken at 183 and 145 K provided valuable information on the crystal structures of ITP and LTP. The diffraction patterns of both phases were quite similar to those of RTP, except for extra spots superimposed on them. These additional sets of reflections had the spacings and very weak intensities indicative of the appearance of superstructures. It was therefore evidenced that the structural changes associated with the phase transitions are very slight, but the b spacing in RTP is doubled in ITP and the c spacing is also doubled in LTP. Moreover, the $(h1l)$ Weissenberg photographs for LTP phases suggested the lowering of the crystal symmetry from monoclinic to triclinic with the interaxial angles α' and γ' close to 90°. The observed reflection conditions, hkl: no and $h0l$: $l=2n$, led to monoclinic $P2/c$ or Pc for the superlattice in ITP, while the conditions, hkl: no and $h0l$: no did to triclinic $P\bar{1}$ or $P1$ for the superlattice in LTP.

The crystal data thus obtained are as follows:

$T=183$ K (ITP); $a'(=a)=23.13(5)$, $b'(=2b)=12.42(5)$, $c'(=c)=9.58(2)$ Å, $\beta'=95°$, $P2/c$ or Pc, $Z=8$,

$T=145$ K (LTP); $a'(=a)=23.09(6)$, $b'(=2b)=12.41(9)$, $c'(=2c)=19.04(5)$ Å, $\beta'=95°$, $P\bar{1}$ or $P1$, $Z=16$.

The numbers of ^{35}Cl NQR lines expected from these X-ray results are 12 or 24 for ITP and 48 or 96 for LTP, in contrast with the observations. The fade out of most or all signals in ITP or RTP may be due to rapid reorientation of CCl_3 groups about their threefold axes, in accord with the relatively large thermal parameters of Cl atoms (Table 1). On the other hand, the number of lines observed in LTP is just half of the expected one for more probable space group $P\bar{1}$. The further splitting may be too small to be detected.

In conclusion, the preliminary X-ray studies at low temperatures demonstrated that the positions of the heavy atoms in the three phases are not changed much. However, the appearance of superstructures in both ITP and LTP provided an evidence for some slight changes in geometries of CCl_3COO^- ligand and/or of (4+1) oxygen coordination around the Cu(II) atom, in particular with respect to the arrangements of the light atoms, O, C, and H. Such a mechanism would be supported by the very small enthalpy changes at the phase transitions. If in LTP the torsion angles in CCl_3COO^- groups are modified and consequently the water molecules form several kinds of hydrogen bonds, the interactions between Cl and O atoms and also between Cl and H atoms will be changed and hence the NQR frequencies of these chlorine atoms may shift from those of RTP. As a result, the splitting pattern in LTP will be different from that expected from the crystal structure of RTP.

The authors thank Professor Kazuhide Ogawa, Osaka University for allowing us to use a Weissenberg camera at low temperatures and are grateful also to Dr. Yuriko Yamagata for her help in part of the X-ray work.

Oscillatory Variation near the C-K Edge in the Photon *W*-Value of Ethylene

Isao H. Suzuki* and Norio Saito
Electrotechnical Laboratory, Sakura-mura, Niihari-gun, Ibaraki 305
(Received April 6, 1987)

The dependence of ethylene *W*-value on photon energy has been precisely measured in the region from 269 to 324 eV by using monochromatized synchrotron radiation. The *W*-value showed an oscillatory variation at the $C_{1s} \rightarrow \pi^*$ excited state as well as the C-K edge. A model has been proposed in which the inner-shell excitation gives rise to a change in the energy of the electron ejected from the molecule having absorbed a photon. It has been found that the model can reproduce the oscillatory variation feature of the *W*-value.

The *W* value of ionizing radiation is a fundamental constant regarding interaction between the radiation and a gas; average energy expended by the radiation to produce an ion pair. A variety of measurements have been carried out on the *W*-values of atoms and molecules for different radiation above several keV.[1] It is well known that the *W*-value is constant for that radiation. Recently some group measured the *W*-value of molecules for electrons in the region below 1 keV.[2-6] Those *W*-values increased with decreasing energy. This phenomenon originates from the fact that the fraction of neutral excitations exceeds that of ionizations in electron-molecule collisions as the electron energy decreases. Srdoč and Obelić measured the *W*-values of methane and propane for photons using characteristic X-rays and filtered bremsstrahlung radiation.[5,6] The measured *W*-values showed a slight increase with decreasing energy. By using line spectra in discharge lamps, Samson and Haddad obtained the *W*-value of Xe for photon in the region of 12 to 90 eV.[7] They found distinct increase of the *W*-value at the ionization threshold of the 4d electron. This increase was ascribed to a decrease of the energy of the electron ejected from the 4d orbital in comparison to that of the O-shell.

Studies on the *W*-value of methane and propane for photons were performed in the ultra-soft X-ray region by the present authors.[8-10] A novel variation near the C-K edge was found in the energy dependence of the *W*-value. This variation was interpreted in connection with the transition of the K-shell electron into the Rydberg orbitals and the ionized state. According to the energy loss spectrum using a high energy electron beam, ethylene shows transitions of the K-shell electron into the $1b_{2g}$ orbital (π^*) at 284.7 eV and into the Rydberg orbitals (3s and 3p) at 287.4 and 287.8 eV.[11] Similar results were found by Eberhardt et al., who obtained an electron yield spectrum using monochromatized synchroton radiation.[12] The transitions of the K-shell electron into the Rydberg orbitals and the ionized state in ethylene probably make the *W*-value oscillate in those energies, as well as methane and propane. However, it remains unsolved how the transition into the π^* orbital affect the *W*-value in ethylene, because methane and propane have no π^* orbital. It is interesting to measure the energy dependence of the *W*-value of ethylele in the region near the excited state $(1s)^{-1}(1b_{2g})^1$.

In the present study, the *W*-value of ethylene for photon has been measured precisely from 269 to 324 eV by using a proportional counter.

Experimental

Synchrotron radiation from the storage ring at the Electrotechnical Laboratory was monochromatized by a plane grating monochromator (resolving power: about 150).[10,13,14] The monochromatized photons entered a gas-flow proportional counter (Manson-04) with a thin Al window (thickness: 1500 Å). Ethylene (purity: 99.9%) was supplied to the counter at 5.3×10^3 Pa. Signals from the counter were amplified and accumulated in a multichannel analyzer (MCA: Canberra-40). The resultant pulse height distributions of the signals were transferred to a micro-computer. Using this computer, the pulse height distributions were analyzed to obtain average pulse height.

The pulse height distribution can be approximately expressed by the following,[10,15]

$$f(z) = \frac{z^{x-1} \cdot \exp(-z/z_a)}{z_a^x \cdot \Gamma(x)} . \quad (1)$$

In the above equation, z indicates the number of electrons amplified by the electric field within the counter, z_a denotes the average gas amplification factor, x is the average number of the electrons initially produced by the radiation effect of a photon, and Γ is the gamma function. The distributions calculated using Eq. 1 were fitted to those obtained by observation.[10] The average pulse height distribution P is given by

$$P(E_p) = \int z \cdot f(z) \cdot dz = z_a \cdot x = \frac{z_a \cdot E_p}{W_p(E_p)} , \quad (2)$$

where E_p indicates the energy of a photon and W_p denotes the *W*-value.[5,6,8-10]

Using Eq. 2, relative *W*-values were obtained for photons with energies from 269 to 324 eV. Any change in P owing to a drift in the gas pressure was cancelled by measuring the P several times at the same photon energy in the course of the experiment. There may be photoabsorption by ethylene in which only neutral fragments are produced but in which no ion pair is formed. This process should alter the *W*-value, although the present technique using a proportional counter cannot count up these types of processes. At present,

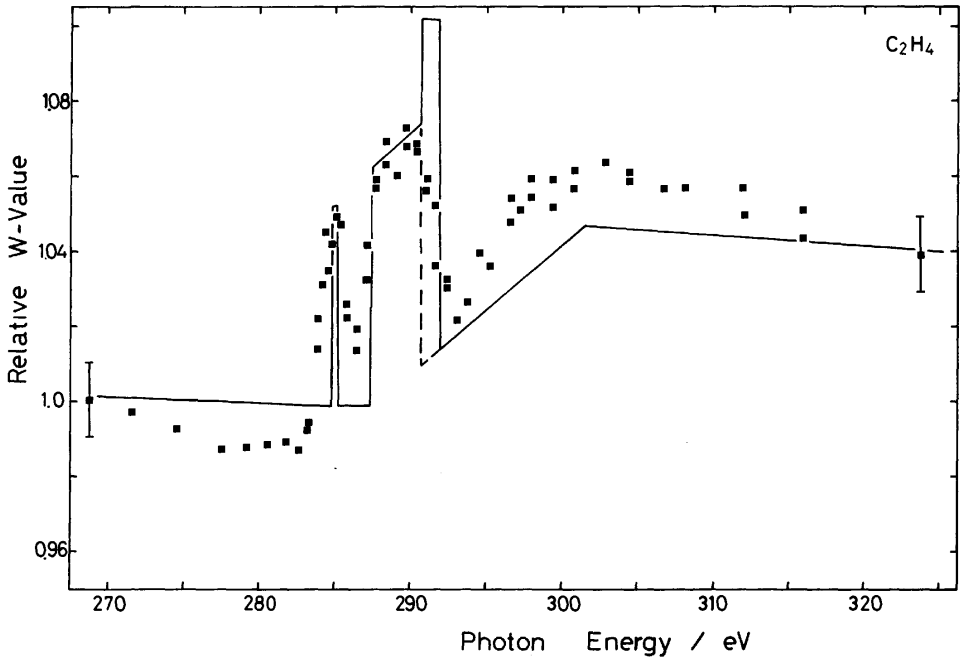

Fig. 1. W-Value of ethylene as a function of photon energy near the C–K edge. Solid squares indicate measured data. Solid curve denotes the calculated profile based on the present model. Bars indicate the error sizes of the measured data. Broken line means the profile when a post-collision interaction does not occur (see text).

Table 1. Energy Values Used in the Calculation of the W-Value (in Units of eV)

W-Value for sufficiently high energy radiation	(W)	25.8
Average energy of subionization electron for an electron with an energy E	(U_1 for $E<30$)	11
	(U_2 for $E>200$)	22
First ionization energy	(E_f)	10.5
Average of ionization energy for valence electron	(E_v)	16.1
Ionization energy of the inner-shell	(E_K)	290.6
Average energy of Auger electron	(E_A)	245.8
Average energy of deexcitation electron from the $(1s)^{-1}(\pi^*)^1$ state	($E_{A\pi}$)	255
Average energy of deexcitation electron from the $(1s)^{-1}(R)^1$ state	(E_{AR})	255
Average energy gain of Auger electron in a post-collision interaction	(a)	E_p-288

π^* and R indicate $1b_{2g}$ and Rydberg orbitals, respectively. E_p denotes photon energy.

these processes are assumed to be negligible, by analogy of the results of ionization yield of methane by Backx and Van der Wiel.[16]

Results and Discussion

The energy dependence of the W-value is shown with solid squares for photon energies from 269 to 324 eV in Fig. 1. The solid curve indicates a calculated profile based on a model described below. The measured W-value gradually decreases from 269 eV to 283 eV as the photon energy increases. The W-value rises to a peak at 285 eV, drops to a sharp valley at 287 eV and again goes up to a broad peak at 290 eV. Above a minimum at 293 eV, the experimental data show a near-linear dependence on the photon energy between 293 and 301 eV. Above the latter energy, the W-value seems to have a slight decreasing trend.

As those of methane and propane, it is important to consider the oscillatory variation of the W-value of ethylene in connection with the excitation transitions of the 1s electron. Hitchcock and Brion observed electron energy loss spectra of ethylene for the 1s electron excitation in the energy resolution of 0.2—0.5 eV.[11] The observed spectra show strongly resonant transitions of the 1s electron to the $1b_{2g}$ orbital at 284.68, 285.04, and 285.50 eV. The transitions into the 3s orbital and the 3p orbital were found to occur at 287.4 and 287.8 eV, respectively. Those to higher Rydberg orbitals and that to the ionized state appeared above 288.3 and 290.6 eV, respectively. They further found shake-up states at 292.6 and 295.2 eV. Eberhardt and coworkers observed an electron yield spectrum of ethylene in the same energy region by use of monochromatized synchrotron radiation.[12] The same transitions were identified although the resolution was lower and the observed energy values deviated slightly (0.3—0.7 eV).

A comparison between the inner-shell excited states and the energy dependence of the W-value gives us a model for interpretation as follows. Table 1 lists

energy values necessary for calculation of the W-value on the basis of the present model. These energies have been estimated from available data in the literature, e.g. Auger electron spectra and photoelectron spectra.

i) Below 284.7 eV: Only a valence electron is ejected by photoabsorption, because the photon cannot excite an inner-shell electron. The average energy of this ejected electron is E_p-E_v, where E_v is the average binding energy of the valence electrons. Ethylene has 6 orbitals for valence electrons, which are $1b_{1u}$, $1b_{1g}$, $1b_{2u}$, $2b_{3u}$, and $2a_g$.[17,18] The value of E_v is assumed to be 16.1 eV. (Adoption of vertical ionization energy is supposed to be appropriate in the present study.) The ejected photoelectrons ionize ambient molecules and produce a number of ion pairs. On the other hand, the W-value of low energy electrons (W_e) can be approximately given by the following equation.[1,19]

$$W_e(E) = \frac{E \cdot W}{E-U} \tag{3}$$

The term W denotes the W-value for radiation with a sufficiently high energy (25.8 eV),[1] U indicates the average energy of sub-ionization electrons, and E is the energy of a primary electron. The sub-ionization electrons mean the electrons which do not contribute to ionization in a system receiving irradiation. In this case, the average number of ion pairs, N_e, is given by

$$N_e = \frac{E}{W_e} = \frac{E-U}{W}. \tag{4}$$

Using Eqs. 3 and 4, the photon W-value is expressed by the following.

$$W_p(E_p) = \frac{E_p}{1+N_e} = \frac{E_p \cdot W}{E_p + W - E_V - U_2}. \tag{5}$$

Where U_2 is assumed to be 22 eV from the data regarding the W-value for low energy electrons.[3] Multiple photoionization of the valence electrons is assumed to occur only at negligibly low probability at present.

ii) Between 284.7 and 285.1 eV: The 1s electrons can be excited to the π^* orbital ($1b_{2g}$) and a hole is formed in the inner-shell. After this excitation, an Auger transition is supposed to occur because fluorescence yield is extremely low in a light element. A variety of Auger transitions have been observed in ethylene.[20,21] The average energy of Auger electrons, E_A, has been estimated to be 245.8 eV, according to the spectrum by Rye et al.[20] However, the average Auger electron energy in the present case is supposed to be somewhat higher than 245.8 eV owing to the existence of that electron in the π^* orbital. This average energy $E_{A\pi}$ is assumed to be 255 eV, by analogy from a resonance-type Auger electron spectrum of CO.[22,23] The W-value is expressed by

$$W_p(E_p) = \frac{E_p}{1+N_e} = \frac{E_p \cdot W}{E_{A\pi} + W - U_2}. \tag{6}$$

When Eq. 6 is compared with Eq. 5, $E_{A\pi}$ (255 eV) is lower than E_p-E_v (e.g., 270.9 eV for the photon with energy of 287 eV). This fact means that the W-value at 287.4 eV becomes higher than that at 287 eV. In the present model, it is assumed that the photoabsorption probability involving the valence electrons can be negligibly low in this photon energy region on account of the spectra of the inner-shell excitation.[11,12] This assumption is also applied for the energy region above 287.4 eV (cases iv) to vii)).

iii) Between 285.1 and 287.4 eV: Photons can excite only valence electrons, because there is no inner-shell excited state in this energy region. Ejected photoelectrons ionize ambient molecules and produce a number of ion pairs. The W_p is expressed by Eq. 5.

iv) Between 287.4 and 290.6 eV: Photons can excite the inner-shell electrons to the Rydberg orbitals and then the formed inner-hole is filled with a valence electron through the subsequent Auger transition. There exists no available report on this type of Auger transition, in which the upper state is a $(1s)^{-1}$ (molecular Rydberg)^1. However, this type of the Auger process is presumed to be very similar to that of the case ii) described above. The average energy of the Auger electrons E_{AR} is assumed to be 255 eV.

v) Between 290.6 and 291.5 eV: The inner-shell electrons can be ejected from the molecule by the photons, but this ejected photoelectron leaves slowly. In the case of CO, the K-shell photoelectron with low energy is retrapped by the molecular ion when a second electron with higher energy is ejected by an Auger transition (post-collision interaction).[24] Since there has been no detailed study in other molecules, the slow photoelectron in the present case is assumed to be retrapped at the instance of the Auger transition. The Auger electron obtains a slightly higher energy owing to the existence of the slow photoelectron than the normal Auger electron. This energy gain of the Auger electron is equal to the energy loss of the trapped electron. The average energy of the Auger electron is here assumed to be $245.8+a$ eV ($a=E_p-288$ eV), because of no available data in molecules. This post-collision interaction is tentatively assumed to occur between 290.6 and 291.5 eV, in consideration of the energy giving a minimum W-value (293 eV) and of the photon energy resolution.

vi) Between 291.5 and 301.1 eV: The inner-shell electrons can be ionized and can promptly escape from the molecular field. This photoelectron ejection is followed by a normal Auger transition. The photoelectron has an energy of $E_p-290.6$ eV. However, this electron can not ionize other ambient molecules because the electron energy is lower than the first ionization energy of the valence electron ($E_f=10.5$ eV). The Auger electron (E_A) has an average energy of 245.8 eV.

vii) Above 301.1 eV: The photoelectron released from the inner-shell has an energy higher than the first ionization energy of ethylene. This electron and the

Auger electron produced subsequently can ionize ambient molecules. The W-value is expressed by the following equation.

$$W_p(E_p) = \frac{E_p}{2+N_{e1}+N_{e2}} = \frac{E_p \cdot W}{E_p+E_A+2W-E_K-U_1-U_2}, \quad (7)$$

where U_1 denotes the average energy of the subionization electrons for the electron with kinetic energy between 11 and 33 eV. The U_1 is assumed to be 11 eV on account of the study by Combecher.[3]

By using the present model, the relative W-value has been calculated and shown with the solid curve in Fig. 1. The resolving power of the monochromator was not included in this calculation. The energy dependence of the calculated W-value is in agreement with the experimental results. Therefore, the present model is essentially correct.

There is a slight discrepancy between the experimental data and the calculated result at a few energies. That at 286 eV is ascribed to the low resolving power of the present monochromator. That between 291 and 293 eV is presumed to originate from the two reasons, except the low resolving power. First, although the energy of the electron may be lowered through a post-collision interaction below 291.5 eV, there is a possibility that some fractions of slow photoelectrons are not retrapped by the molecular ion. If this is the case, the final configuration is that having two holes in the valence orbital. The calculated W-value becomes lower than that shown in Fig. 1 between 290.6 and 291.5 eV. Second, there have been observed slightly distorted pulse height distributions in the proportional counter around 291 eV. The width of the distribution was broader than those in other energies. This phenomenon is supposed to be brought about by a contamination of the used grating, which gave a decrease of output photon intensity near the C-K edge. This should make the effective resolving power lower. From the minimum at 293 eV (not at 290.6 eV), it can be said that the post-collision interaction takes place just above the C-K edge, as well as for methane. However, it is impossible at present to estimate the size of energy region where it occurs. (The broken line between 290.6 eV and 291.5 eV in Fig. 1 shows the calculated result in the case of no occurrence of the post-collision interaction.)

The reason why the experimental data are slightly lower than the calculated curve near 280 eV is not clear at present. The photoabsorption cross section near 280 eV is very low owing to no excitation transition of the inner-shell electrons. The electron cloud induced by photoabsorption is distributed more homogeneously in the proportional counter near 280 eV than other energies. This fact may make a small effect on the average pulse height distribution through a possible change in gas amplification factor.

The shake-up states were reported to exist at 292.6 and 295.2 eV.[11] In contrast to the transition to the π^* orbital, the transition probability to those states was considerably lower than that to the normal continuum state. Thus that transition was not expected to make an appreciable effect on the W-value. The experimental W-value does not show a change at those energies in Fig. 1 within experimental accuracy.

The authors wish to express their sincere thanks to the members of the accelerator group of the Electrotechnical Laboratory for providing synchrotron radiation.

Lanthanoid Chirality as a Tool for Assignment of *f*-*f* Transitions. Tb^{3+} and Tm^{3+} Diglycolate

Bhutnath KARMAKAR, Prabir K. CHATTERJEE, Samita BASU, and Mihir CHOWDHURY*
Department of Physical Chemistry, Indian Association for the Cultivation of Science, Jadavpur, Calcutta 700032, India
(Received April 5, 1986)

Although chiral studies have proved to be handy in the assignment of transitions in biological molecules, organic molecules and transition metal complexes, its potentiality for lanthanoid transition needs to be demonstrated. The paper explores the usefulness of CD studies in the assignment of lanthanoid transitions with two specific chiral single crystals-thulium diglycolate (Tm^{3+}-DG) and terbium diglycolate (Tb^{3+}-DG). It has been shown that chirality can distinguish $\Delta J=0, \pm1$ transition from others. The need for studies under higher resolution has been pointed out.

Identification of weak transitions in the presence of a strong one is a challenging problem for spectroscopists. For example, in heterocyclic organic molecules the $^1(n, \pi^*)$ state often remains undetected as this weak band frequently gets masked by the stronger (π, π^*) transitions. The same is the case with many spin-forbidden transitions. Various techniques, such as, measurement of polarized absorption spectra of single crystals or other orienting medium, measurements of polarized luminescence excitation spectrum by photoselection technique, improving the resolution by using supersonic jet-cooled molecules, application of magnetic or electric field, heavy atom or solvent perturbation, circular dichroism spectroscopy, two-photon spectroscopy etc. have been used to locate hidden transitions. We would like to demonstrate here how chiral studies can help in the assignment of the lanthanoid f^N-f^N transitions in situation where a number of J-states crowd together.

Unlike organic molecules or transition metal complexes, most chiral studies of lanthanoid complexes almost invariably involve chiral centers other than the lanthanoid ion. Although such studies can throw light on the interaction between Ln^{3+}-ion and the chiral center, these systems are hardly appropriate for spectra-environment correlation or assignment of Ln^{3+} transitions. Sen, Bera, and Chowdhury[1] was the first to make detailed study of a system where the chirality is derived from the immediate environment of the Ln^{3+} ion. Since then, extensive studies on three interesting chiral single crystal systems Ln^{3+}-DG (hexagonal; site-symmetry-D_3), lanthanoid double nitrate (Ln^{3+}-DN) (cubic; site symmetry-distorted dodecahedron) and lanthanoid pyrogermanate (Ln^{3+}-PG) (tetragonal; site symmetry-distorted pentagonal bipyramid)—have been made.[2-13] In this paper we would like to report the spectra of chiral single crystals of Tb^{3+}- and Tm^{3+}-DG and discuss the extent they can throw light on the asssignment problem. Crowding of different J-states has caused considerable uncertainty and confusion in the identification of $^1I_6$, $^3P_0$, $^3P_1$ states of Tm^{3+} and those states of Tb^{3+} lying above 25000 cm^{-1}; it is therefore worthwhile to explore the potentiality of other types of spectroscopy.[14-16]

A part of the problem in the case of assignment from one-photon forced electric dipole transition arises from the fact that the selection rules,[17] $\Delta J \leqslant 6$, $\Delta L \leqslant 6$, $\Delta S=0$ are not always valid due to J-mixing and breakdown of L-S coupling, and even when they are valid, they are not restrictive enough to be useful in the J-assignment of states.[14,15] A more restrictive J-selection rule ($\Delta J \leqslant 2$), offered by two-photon transition selection rule, has been used by us and others for assignment of Gd^{3+} and other Ln^{3+} transitions.[18-21] Experimental difficulties, however, have stood in the way of carrying out similar studies on Tm^{3+} and Tb^{3+} crystals. We have therefore tried to exploit $\Delta J=0, \pm1$ selection rule for magnetic dipolar transitions. One way of estimating qualitatively the magnitude of magnetic dipolar transition moment is from the CD/OD strength, as pointed out by us in earlier papers.[6-10] It is expected that the transitions to the $^1I_6$ state of Tm^{3+} and $^5G_{5,6}/^5L_{6,7}$ states of Tb^{3+} will be intense in CD spectrum relative to others, leading to their identification.

Experimental

The single crystals were grown from solution by slow evaporation as described earlier.[10] The optic axis was identified by means of a polarizing microscope and the crystals were thinned by grinding and polishing with diamond paste of different grain sizes. In order to minimize the extent of overlap of transitions (which may cause cancellation of rotation) and identify the crystal-field components, the crystals were cooled to 20 K in an Air-product CS202 closed-cycle cryo-cooler. The absorption spectra were taken in a Cary 17D spectrophotometer and the CD spectra in a JASCO 500 spectrophotometer with minimum possible slit. For some of the transitions, the ultimate resolution is limited by the resolving power of the instrument.

Results and Discussion

Figure 1 shows the molecular structure of the Ln^{3+}-diglycolate complex. Each lanthanoid metal is coordinated to nine oxygen atoms, comprising a trigonal prism. The upper and lower triangles were made of

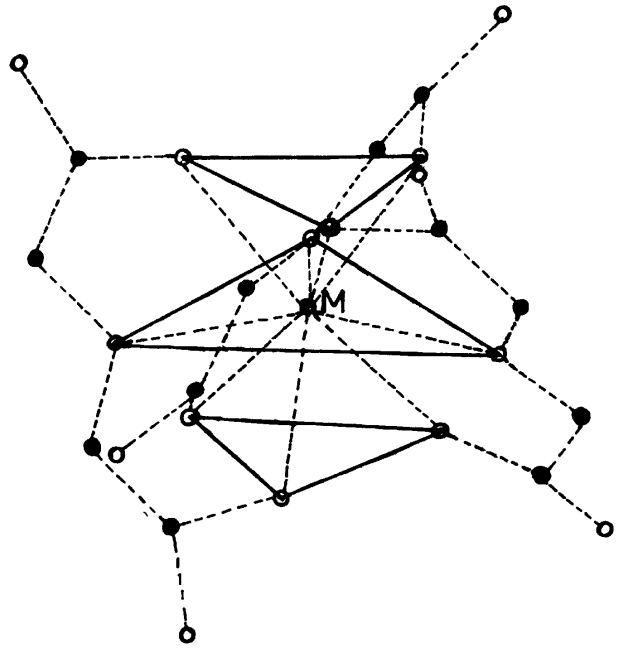

Fig. 1. The molecular structure of $[Ln(OCOCH_2OCH_2OCO)_3]^{3-}$ (Ln^{3+}-DG).

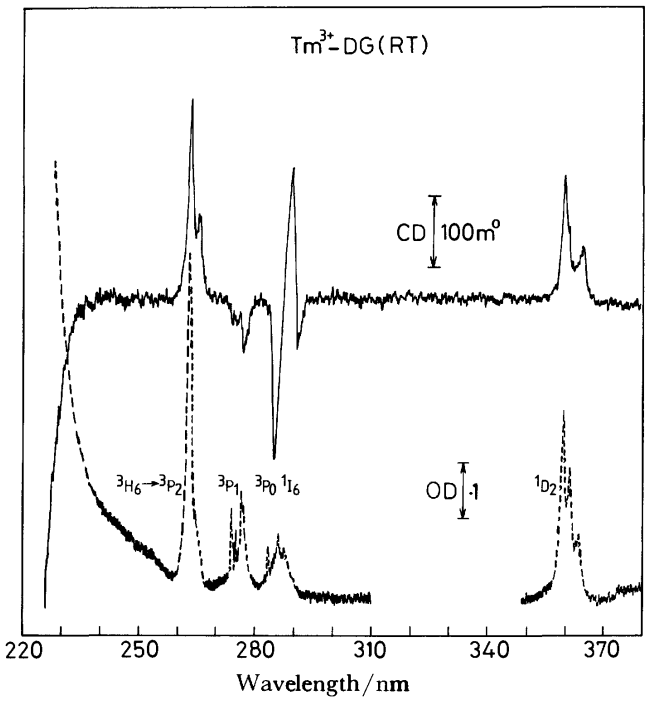

Fig. 2. The low-resolution room temperature absorption (dotted line) and circular dichroism (solid line) spectra of an oriented Tm^{3+}-DG single crystal. Light propagates along the optic axis.

six carboxylate oxygens and they are rotated relative to each other, destroying the plane of symmetry. The middle triangle is formed by the three ethereal oxygens.

Figure 2 shows the CD and absorption spectra of the same single crystal of Tm^{3+}-DG at room temperature. In view of the $\Delta J=0, \pm 1$ selection rule for magnetic dipolar transition, and in view of the fact that circular

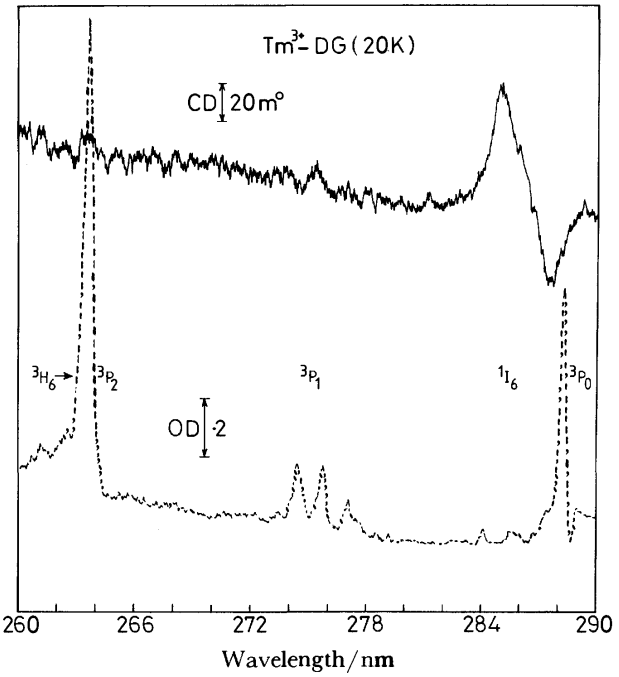

Fig. 3. The resolved absorption (dotted line) and CD (solid line) spectra of Tm^{3+}-DG single crystal at 20 K.

dichroism is a scalar product (imaginary part only) of electric dipolar and magnetic dipolar transition moments while OD depends on the sum of squares (absolute value) of the two moments, the CD/OD ratio is expected to be high for the $^3H_6 \rightarrow {}^1I_6$ transition. The higher CD/OD ratio near 285 nm, the wavelength region for the $^3H_6 \rightarrow {}^1I_6$ transition is apparent from the spectrum. Since the $^3P_0$ state and the components of the $^1I_6$ state overlap, we cooled the crystals to 20 K and carefully scanned the wavelength region 250—300 nm. A phase transition occurs at about 108 K;[7] however, the crystal still remains optically active. In spite of our best effort we have not been able to completely resolve all the components in the commercial CD instruments (Fig. 3). This limitation notwithstanding, the high CD/OD ratio and low OD value leave little doubt that the weak peaks between 283 and 287 nm belong to CF-split components of the $^1I_6$ state. The strong absorption peak at 287.5 nm appears as a weak signal in the slope of the CD band and hence is assigned to the $^3H_6 \rightarrow {}^3P_0$ transition. It is also interesting to note that the $^3P_1$ and $^3P_2$ bands, fairly prominent in absorption spectrum, hardly give any CD signal. Circular dichroism study can therefore be used as a useful tool for identifying the CF components of the spin-forbidden $^3H_6 \rightarrow {}^1I_6$ transition, which are normally masked by spin-allowed $^3H_6 \rightarrow {}^3P_{0,1,2}$ transitions.

In case of Tm^{3+}, neither the crystal field alone nor the spin-orbit coupling alone can cause a mixing, in first order, between the ^3P states and the $^1I_6$ state, although simultaneous application of the two can. It may be expected therefore that $^3P_{0,1,2}$ and $^1I_6$ states will,

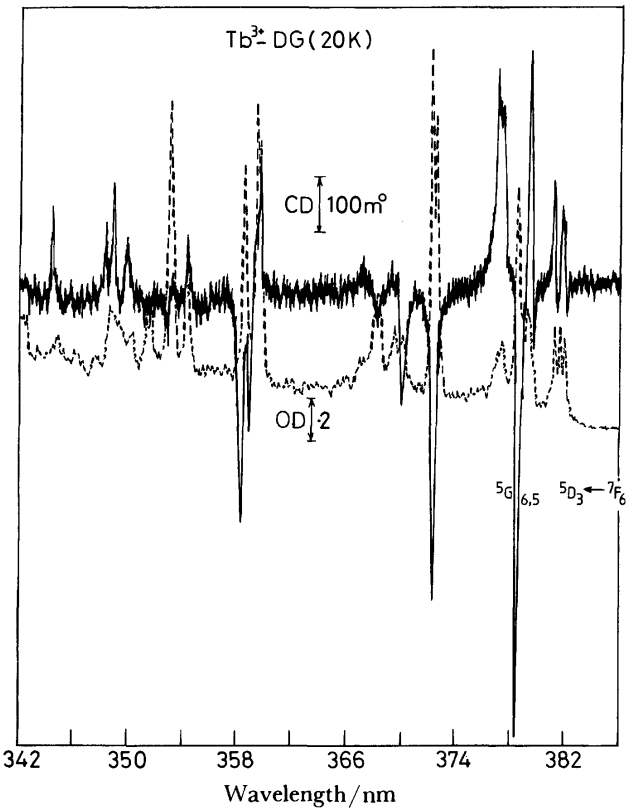

Fig. 4. The absorption (dotted line) and CD (solid line) spectra of a Tb^{3+}-DG single crystal at 20 K.

to a great extent, retain their characteristics regarding magnetic dipolar- or spin-allowedness. The situation is less clear-cut in Tb^{3+}-DG whose spectrum is shown in Fig. 4. In case of Tb^{3+}, the density of levels becomes so high below 348 nm that it becomes virtually impossible to identify the components from the mess of overlapping transitions. However, attempts have been made previously to assign the states in $TbCl_3 \cdot 6H_2O$ and $Tb_2(SO_4)_3 \cdot 6H_2O$. The detailed assignments are given in Dieke's book.[14] In order of increasing energy, the J-states are $^5D_3$, $^5L_{10}$, and $^5G_{5,6}$. In the present case, the first four bands close to 381 nm do not show high CD, although they are more resolved in the CD spectrum than in the normal absorption spectrum. This set of transitions should therefore be ascribed to $^7F_6 \rightarrow {}^5D_3$ transitions. On the other hand, the set of bands between 376 and 381 nm shows very high CD/OD ratio. This agrees with the expected location of the $^5G_{5,6}$ state in this region. However, the resolution of the spectrum is not enough to decide whether only the $^5G_{5,6}$ components appear in the above wavelength region, or there are additional overlapping $^5L_{10}$ components. Other states expected to be CD active are $^5L_{6,7}$. However, they occur at shorter wavelengths where background absorption stands in the way of their identification.

Conclusion

The CD spectrum may be an useful tool for identifying $\Delta J=0, \pm 1$ transitions, specially in situations where J-mixing is expected to be small. However, for unambiguous assignments, all the bands need to be resolved both in absorption and CD spectra. It is also useful for studying the nature of phase transitions.

Interaction of Divalent Metal Acids with Pentyl Alcohol and Isopentyl Acetate

Mirza Aijaz Beg* and Mohd. Shakil Kidwai
Department of Chemistry, Aligarh Muslim University, Aligarh 202 001, (U. P.), India
(Received July 29, 1985)

Extraction of monobasic divalent metal bromo acids in pentyl alcohol-benzene and isopentyl acetate-benzene mixtures was studied at room temperature (25 °C). Three molecules of pentyl alcohol ae well as of isopentyl acetate were associated with each metal acid molecule of cobalt and copper in the organic phase. Zinc, cadmium, and mercury acids take up two molecules of pentyl alcohol and one molecule of isopentyl acetate. Metal acids studied here mostly exist as monomer in the organic phase. In pentyl alcohol, however, copper acid is monomeric only at lower concentrations (4×10^{-5} to 2×10^{-4}M) and dimeric at higher concentrations (3.3×10^{-4} to 1.4×10^{-3}M).

It has long been known that aqueous $HClO_4$, $HReO_4$, and HBr are extracted by tributyl phosphate[1] (TBP) in xylene or CCl_4 as $H_3O^+\cdot 3TBP\cdot yH_2O\cdot X^-$, where $O\leqslant y\leqslant 3$, and X^- is the respective anion. A number of mineral and complex metal acids were later extracted in trioctylphosphine oxide[2] (TOPO) in organic solvents.

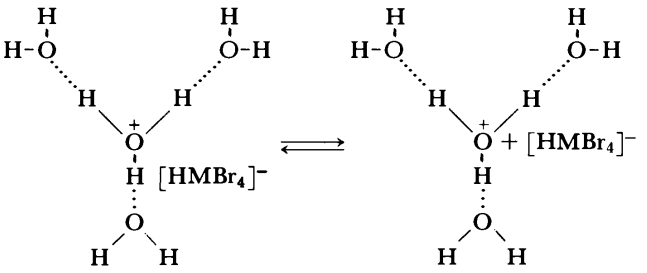
The extraction studies for metal acids made so far, are mostly limited to species of the type HMX_4. Several polyvalent transition[3] and nontransition[4] metal salts have been extracted with various extractants and solvents. It was thus thought worthwhile to study the extraction of dibasic metal acids,[5-9] $H_2[CoBr_4]$, $H_2[CuBr_4]$, $H_2[ZnBr_4]$, $H_2[CdBr_4]$, and $H_2[HgBr_4]$ which are practically monobasic in pentyl alcohol and isopentyl acetate mixture using benzene as diluent and seek a relation between the acidity of extracted acids and basicity of the solvents.

Experimental

For extraction studies, 3.0 ml aqueous metal acid solution obtained by adding the respective metal bromide in concentrated HBr was shaken with 25.0 ml benzene-pentyl alcohol (1—10%) or isopentyl acetate (8 to 15%) mixture for 1 h and there after allowed to stand for about 10 h. Polymerization studies were, however, made in 10% pentyl alcohol (or 10% isopentyl acetate)-benzene mixture. Metal content in either phase was determined by titrating it against EDTA using indicator (Xylenol Orange for cobalt, PAN for copper, and Erichrome Black T for zinc, cadmium, and mercury). Metal content in the organic phase was determined after evaporating off the solvent completely and digesting the residue in distilled water. Aqueous phase was also evaporated and digested in distilled water before titration.

Extraction Equilibria

In concentrated aqueous HBr, bromides of cobalt, copper, zinc, cadmium, and mercury exist[5-9] as H_2MBr_4, M being surrounded tetrahedrally with Br. As in aqueous phase, the proton is further hydrated through hydrogen bonding[10] and the dissociation constant of $[HMBr_4]^+$ species being negligible, the metal acid species in the aqueous phase may be represented[1,2c] as follows:



When aqueous metal acid is shaken with the organic phase, some acid passes into the organic phase. In this process, the hydrogen bonded water of the proton is partly or completely replaced by the organic ligand.[2c] Since, pentyl alcohol as well as isopentyl acetate are less basic than water, they do not interact with the second proton, to which even water is inert. In low dielectric constant solvents like benzene (D=2.3) the metal acid anion, $[HMBr_4]^+$ forms the ion pair $H_3O^+\cdot 3AA\cdot[HMBr_4]^-$.

Assuming that metal acid is extracted into the organic phase as one single species, having J metal ion, the extraction equilibrium will be represented by Eq. 1.

$$J[HMBr_4]_w^- + J\,\overset{+}{H_3O}_w + nAA_o \rightleftharpoons nAA.\ J(\overset{+}{H_3O}[HMBr_4]^-)_o \qquad (1)$$

(secondary solvation of proton is not shown)

AA stands for pentyl alcohol and isopentyl acetate, suffix o and w refer to organic and water phases, respectively. The total metal concentration in the organic phase, $[M^{2+}]_o$, is given by Eq. 2 in terms of metal concentration in the aqueous phase and extraction equilibrium constant, K,

$$[M^{2+}]_o = K J[H(MBr_4)^-]_w^J[AA]_o^n[H_3O^+]_w^J, \qquad (2)$$

$$\log[M^{2+}]_o - J\log[M^{2+}]_w = n\log[AA]_o + K', \qquad (3)$$

where $K'=\log K+\log J+J\log[H_3O^+]_w$ and $[H_3O^+]_w$ is invariant. If J equals unity, Eq. 3 rearranges into Eq. 4.

$$\log D = n\log[AA]_o + K'. \qquad (4)$$

D stands for distribution coefficient of metal acid,

between organic and aqueous phases. According to Eq. 3, the plot of log $[M^{2+}]_o$ against log $[M^{2+}]_w$ at a constant concentration of extractant (pentyl alcohol or isopentyl acetate in C_6H_6) should yield a straight line, whose slope would measure, J, the degree of polymerization in the organic phase. For the determination of the number of extractant molecules incorporated with metal acid in the organic phase, a plot of log D versus log $[AA]_o$ was drawn.

Results and Discussion

The log $[M^{2+}]_o$ −log $[M^{2+}]_w$ plot in pentyl alcohol-benzene mixture (Fig. 1) yields straight line, whose slopes show that metal acids are extracted as monomer in the organic phase. The behavior of Cu^{2+} is, however, unique in the sense that it is monomer at lower concentrations (4×10^{-5} to 2×10^{-4} M (1 M=1 mol dm^{-3})) and dimer at higher concentrations (3.3×10^{-4} to 1.4×10^{-3} M).

In isopentyl acetate-benzene system, the plots of log $[M^{2+}]_o$ against log $[M^{2+}]_w$ are straight lines (Fig. 2) with unit slopes, showing that metal acids are present

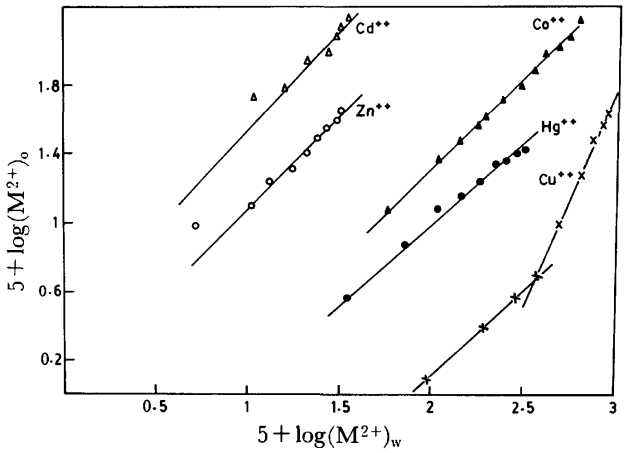


Fig. 1. Log$[M^{2+}]$ versus log$[M^{2+}]_w$ plots, at constant concentration of pentyl alcohol (10% by volume) in benzene at 25°C.

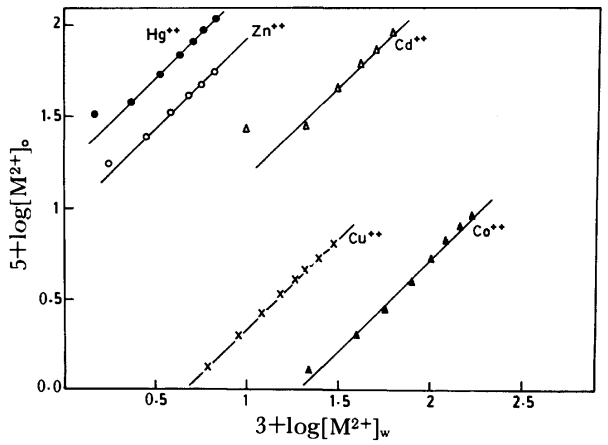

Fig. 2. Log$[M^{2+}]$ versus log$[M^{2+}]_w$ plots, at constant concentration of isopentyl acetate (10% by volume) in benzene at 25°C.

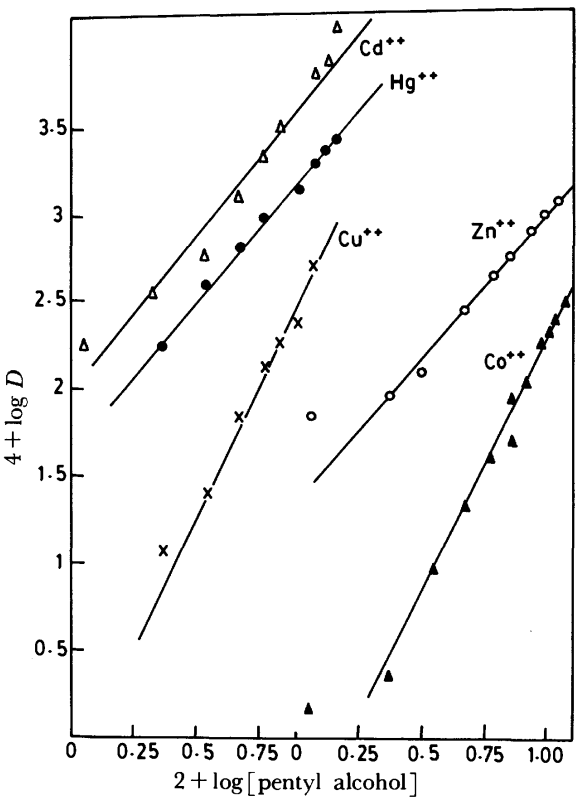

Fig. 3. Log$D$ versus log [pentyl alcohol] plots, for five metal acid. ×: 1.1×10^{-2}, ▲: 1.5×10^{-2}, ○: 5.0×10^{-3}, △: 7.0×10^{-3}, ○: 5.0×10^{-3} mol dm^{-3} at 25°C.

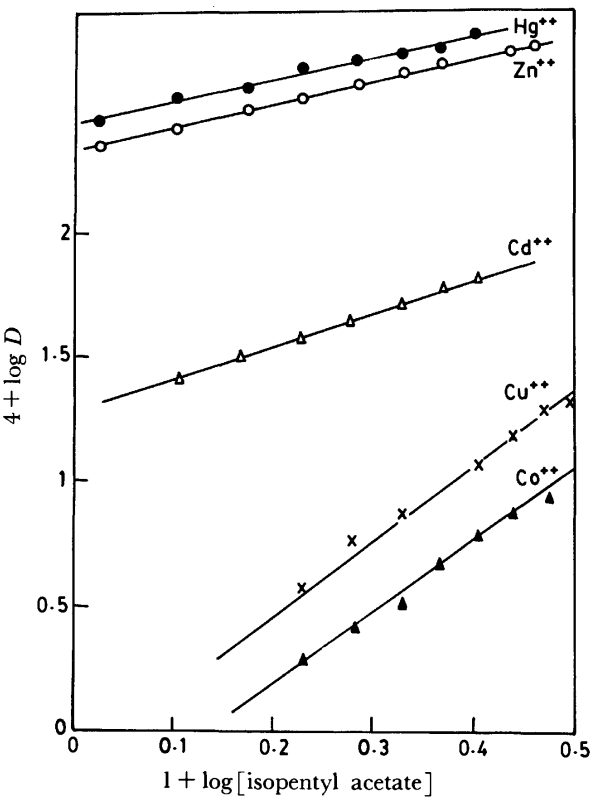

Fig. 4. Log$D$ versus log [isopentyl acetate] plots, for five metal acid. ×: 2.0×10^{-4}, ▲: 3.5×10^{-4}, ○: 1.2×10^{-2}, △: 1.1×10^{-2}, ●: 1.3×10^{-2} mol dm^{-3} at 25°C.

as monomer in the organic phase in this system as well.

Because of proportionately higher transport of HBr from aqueous into the organic phase at lower metal acid concentrations, the slopes (Figs. 1 and 2) become progressively less than unity. As metal acids compete with HBr (present in excess) for coordination with extracts in the organic phase, the extraction of metal acids at their lower metal concentration decreases significantly because excessive flow of HBr into the organic phase reduces the availability of the extracts to metal acids. This becomes distinct in the case of zinc and cadmium. Similar behavior has also been observed[11] in the extraction of tetraalkylammonium hydroxide in different alcohols.

The log plots of distribution coefficient versus concentration of pentyl alcohol in benzene (Fig. 3) at constant metal ion concentration are straight lines for Co^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, and Hg^{2+}, having slopes of 2.8, 2.7, 2.1, 2.3, and 2.3 respectively. Thus, the number of pentyl alcohol molecules, incorporated with metal acids, are assumed to be three for cobalt and copper and two each for the rest.

Again, the log plots of distribution coefficient versus concentration of isopentyl acetate in benzene for the five species of metal ions at constant metal ion concentration are straight lines (Fig. 4) with the slopes showing three incorporated isopentyl acetate molecules each for cobalt and copper and one each for zinc, cadmium, and mercury.

The transition metal (cobalt and copper) acids are comparatively more acidic than those of the zinc family members which have more pronounced covalent character. Hence metal acids of zinc, cadmium, and mercury give more strongly bound ion pairs, whereas those of cobalt and copper give weakly bound ones. Thus in case of cobalt and copper, each cation (hydrated proton) of the ion pair incorporates three extractant molecules (pentyl alcohol or isopentyl acetate) whereas zinc, cadmium, and mercury acid anions being more closely held to the proton accommodate only two pentyl alcohol molecules. Further, due to steric hindrance and crowding, only one isopentyl acetate molecule could be bound with the cation of the ion pair in the zinc family.

Silver-Gelatin Method for the Determination of Trace Amounts of Carbon Monoxide in Air

Tarasankar PAL,* Ashes GANGULY, and Durga S. MAITY
Department of Chemistry, Indian Institute of Technology, Kharagpur 721302, India
(Received April 14, 1986)

The use of silver-gelatin complex was found suitable for the determination of trace amounts of carbon monoxide in air. Silver-gelatin complex is reduced by carbon monoxide to give intensely colored sol. Measurement of the color intensity of the stable silver sol enables the determination of carbon monoxide successful under various environmental conditions. The detection limit is 2—100 ppm. The relative standard deviation for the determination of 10 ppm carbon monoxide is 2.6%.

Carbon monoxide is a man-made pollutant widely distributed in the atmosphere. As the gas is neutral in its character, it is difficult to impinge. It can react with various metals and hence stabilize many low valent metals. Recently with the increased concern about the effects of atmospheric pollution, several methods have been developed for the determination of carbon monoxide in air.

There are many instrumental methods which are often useless for the field evaluation. Though the nondispersive infrared (NDIR) spectroscopy and Robbins[1] photometric methods are suitable for carbon monoxide determination, these methods are of little importance for the routine and continuous determination of carbon monoxide under the environmental conditions. Similarly, gas chromatographic techniques[2,3] are rather sophisticated though the detection limit is about 0.1—1000 ppm. Colorimetric methods for the determination of carbon monoxide date back to more than 50 years but are still gaining ground.[4-8]

The well-known carbon monoxide and iodine pentaoxide reaction can be used for the determination of carbon monoxide by estimating the liberated iodine by various means.[9,10] Gravimetric method[11] converting carbon monoxide into carbon dioxide, color reaction of impregnated silica gel,[12,13] etc. are inexpensive and easy, but the accuracy is not satisfactory. Lambert[14,15] and his coworkers have developed certain reagents for the colorimetric estimation of carbon monoxide, but the sensitivity and instability make the reagents unsuitable for the routine continuous analysis. The use of the less stable silver sol method[16,17] is suitable for the colorimetric estimation of carbon monoxide. The method by Simonescu et al.[16] can be employed in a concentration range of 5—500 ppm and the determination error is less than 3% for carbon monoxide. The last two methods stand on the basis of formation of metallic silver sol from the complex of silver ions with sulfamoyl groups in alkaline medium. Considering the obvious difficulty of impingement of carbon monoxide, West et al.[17] extended the method by Simonescu for the field evaluation just by using a permeation technique.

It was observed that some weak metal-amino acid complexes in alkaline medium were easily reduced by trace amounts of carbon monoxide to form colored metallic sol.[13] But silver sol easily breaks into black precipitates rendering difficulty in color intensity measurements. The present paper describes a simple method for the determination of trace amounts of carbon monoxide using silver-gelatin complex in alkaline medium. The method can be reliably applied to field evaluation without the use of toxic chemicals. Even, no tedious preparation like the recently reported octaethylporphyrinatoruthenium(II)[18] is needed. Moreover, the sol is better stabilized in solution by gelation than by any other previously reported method.

Experimental

Apparatus. A Cary-17D (Varian) spectrophotometer was used to measure all absorbance values.

Impinger. Simple impingers of length 21 cm and internal diameter 2.2 cm were used for gas absorption. The outer wall was covered with black paint to protect the reagent from direct sunlight.

Silver-Gelatin Reagent Solution. The reagent solution was prepared by dissolving 0.5 g gelatin powder (E. Merck) in 100 ml of boiled and warm distilled water with constant stirring. Sixty ml of 10^{-3} M (M=mol dm^{-3}) silver nitrate solution was added. If any turbidity appeared, it was removed by adding a few drops of 2 M sodium hydroxide solution. The solution was heated at 50—60 °C for five minutes. The solution was diluted with 0.5 M sodium hydroxide solution to 250 ml. The reagent solution was stored in an amber-colored bottle and kept in the dark. The solution remained stable for more than 10 weeks.

Reagents. All reagents used were of analytical grade without any further purification.

Results and Discussion

Calibration Curve. Ten ml of silver-gelatin reagent solution was placed in the impinger and exposed to a known concentration of carbon monoxide for a specified period of time, typically 50 ppm for 6 h. Preparation of carbon monoxide-air mixtures was accomplished by successive dilution of a pure carbon monoxide stream with streams of purified air, nitrogen or inert gases; rotameters were used to measure flow rates. Upon completion of the exposure using a flow-rate of 500 ml min^{-1} the solution was kept for 1h and the absorbance was measured at 415 nm against a reagent blank. The concentration of carbon monoxide

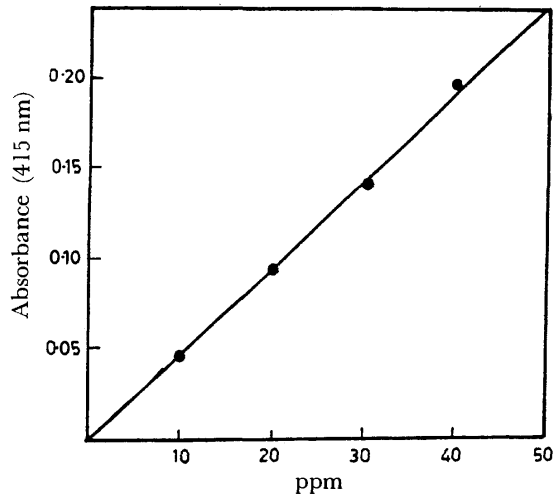

Fig. 1. Calibration curve for CO determination.

was calculated from the equation $A=kCt$; where k is a constant determined experimentally, C is the concentration of carbon monoxide, t is the time of exposure, and A, the absorbance at 415 nm (Fig. 1).

Interferences. The interferents were injected into the carbon monoxide-air stream by using a motor-driven syringe.[19] The accuracy of this syringe technique was checked by controlling the plunger speed by standard methods. Gaseous acetylene, aqueous solutions of formaldehyde (30%), aqueous ammonia (50%), and standard chlorine water were introduced. The results of the interference studies are shown in Table 1.

Data reported for sulfur dioxide, nitrogen dioxide, carbon dioxide, and hydrogen sulfide are based on 24 h exposures to 10 ppm carbon monoxide and interferent species at the level indicated. It was observed that several reducing agents like SO_2 and NO_2 gave unexpected lower absorbance values. This may possibly due to quicker reduction of the silver-gelatin complex and hence aggregation of sol lowers the absorbance values. For maintaining interferent levels of chlorine, ammonia, acetylene, and formaldehyde studies were conducted with 6 h exposures to 40 ppm carbon monoxide and interferent species at four times the level indicated.

The silver-gelatin method has two serious drawbacks. First, the reducing gases like H_2S, SO_2 must be removed by classical means. Secondly, a less serious disadvantage is that the exposed solution is to be taken for the measurement at least after 1 h time.

Numerous techniques for eliminating or reducing interferences were tried without success. It has been reported[19] that potential interferences from hydrogen sulfide for this reagent can be eliminated by passing the air sample through the silver-gelatin complex absorbed on silica gel. The advantage of this method over the conventional methods[16,17] is the stability of the exposed silver sol solution in gelatin.

In conducting the investigations, the concentration levels of possible interferent species were chosen in relation to appropriate Indian standards; the concentration of carbon monoxide chosen was 20 ppm, which corresponds to the typical background level of carbon monoxide found in the laboratory during the study.

Field Evaluation. In order to confirm the usefulness of the proposed method, it was applied to the determination of carbon monoxide in both the laboratory as well as the rural environment. The air sample was sucked after removing the acidic gases like SO_2, CO_2, H_2S using aqueous sodium hydroxide and lead acetate traps. The results are summarized in Table 2, together with the results obtained by the permeation method[17] carried out for comparison.

Precision and Accuracy. The relative standard

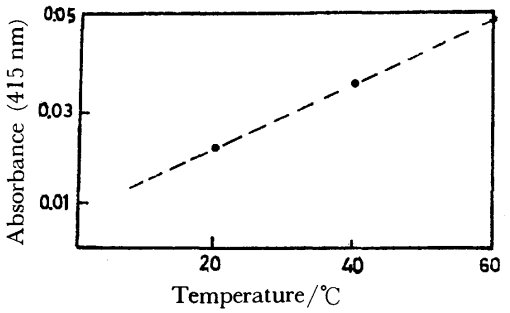

Fig. 2. Temperature effect, flow rate of sample gas 500 ml min^{-1}, standing time after exposure 1 h. CO concentration 8 ppm.

deviation and confidence limits for the determination of carbon monoxide with silver-gelatin complex were calculated and found to be 2.6% and 7.6±0.04 respectively, while the carbon monoxide concentration was 10 ppm and the flow rate of the gas was kept at 500 ml min^{-1}.

Temperature Effect. The reduction of silver-gelatin complex by carbon monoxide is temperature dependent. The effect of temperature was studied by keeping all other factors constant. The same amount of silver-gelatin complex was taken in a different impinger and reduced with the same amount of carbon monoxide at different temperatures. The results are given in Fig. 2, where each point represents an average of six determinations. The data indicate that there may be an error in the determination of carbon monoxide by this method of about 2.3% per degree centigrade, for each degree of temperature difference between the temperature at which a measurement is made and the temperature at which the device was calibrated.

Response of Measurement System. The response of the system as measured by the product Ct (C, Concentration of carbon monoxide; t, time of exposure) must be uniform throughout the useful range of the method. The absorbance value obtained on exposure to 30 ppm for 5 h should be same as that obtained on exposure to 15 ppm for 10 h, for example. It was observed that the absorbance (A) value varies with time (t), and for a sample with a given concentration (C) of carbon monoxide the absorbance is expressed by the equation $A=f(C, S, D, T, t)$, where S stands for gas reagent interface, D for diffusion coefficient, and T for temperature. This observation was made within 1 h time after the disconnection of the gas flow (500 ml min^{-1}) through the absorbing solution (10 ml).

Effect of Light. The diffused sunlight or indoor lighting in the laboratory produces no deterioration in either exposed or unexposed reagent for periods of one week. It was found during the present investigation that placement of exposed and unexposed reagent in direct sunlight results in complete loss of color in about 5 h. As a result of this observed deterioration in the presence of direct sunlight, it was necessary to shield the impinger from light in the shelter used in field evaluations. As a precaution the reagent also was stored in amber-colored bottles and kept in dark place in the Laboratory.

Stability of the Reagent. The present method was developed to determine average concentrations of carbon monoxide over periods of several hours. It was essential, therefore, that the response of the reagent is essentially uniform during the entire exposure period. Any silver sol formed early in the exposure period must be stable during the remainder of the exposure period, and the response of any unexposed reagent must be the same during the last portion of the exposure period as during the early portion.

To determine the stability of both exposed and unexposed reagent, carbon monoxide (400 ppm) was bubbled for 3 h through 50 ml of reagent at a flow rate 500 ml min^{-1}, and the gas flow was then discontinued and sample of exposed and unexposed reagents were placed in constant-temperature baths. The absorbance of each sample was measured at periodic intervals. The results are shown in Table 3. Each absorbance value represents an average of at least three determinations.

The data indicate that the intensity of the color produced by the silver sol is found to decrease with time; the net decrease average is about 1.0% in 6 h and 3.1% in 24 h at 25 °C and the instability increased with temperature.

The blank value at higher temperatures tended to stabilize at an absorbance value of 0.042—0.055 after 48 h. The present method offered the advantage of stabilizing the silver sol over a wide range of concentration of silver and hence silver sol is not precipitated unlike the methods as referenced in literature.

The method developed here is simple, inexpensive and reliable for the determination of average concentrations of carbon monoxide in the ambient atmosphere. The technique requires no electrical or mechanical connections to complex equipment, and

Table 3. Stability of Exposed and Unexposed Silver-Gelatin Reagents

Time/h	Temp 25 °C		Temp 30 °C		Temp 40 °C	
	Blank[a)]	Rgt.[b)]	Blank	Rgt.	Blank	Rgt.
0	0.033	0.193	0.033	0.195	0.033	0.192
6	0.033	0.191	0.035	0.192	0.037	0.189
24	0.034	0.187	0.038	0.189	0.039	0.178

a) Unexposed reagent. b) Reagent exposed to 400 ppm CO.

no tedious sampling technique is required. The method has some limitations, however.

The method is not suitable where high interferent concentrations may be present, nor is it suitable for process stream analysis where very rapid measurement is required and the temperature variation also affect the results.

The reagent is stable at ordinary room temperature up to 10 weeks, and the absorbance value of the blank at 30 °C is less than 0.005; this value varies by less than 0.001.

Coordination Chemistry of New Sulfur-Containing Ligands: Transition Metal Complexes of *N*-Ethoxycarbonyl-1-pyrrolecarbothioamide

Veena CHAUHAN and Sheo Kant DIKSHIT*
Department of Chemistry, Indian Institute of Technology, Kanpur 208016, India
(Received July 10, 1986)

Reaction of *N*-ethoxycarbonyl-1-pyrrolecarbothioamide (Hept) with a variety of transition metal ions leads to the formation of $[M^{II}(ept)_2]$ (M=Ni, Cu, Pd, Pt), $[M^{II}(ept)_2(py)]$ (M=Co, Ni), $[Rh^{I}Cl(Hept)(PPh_3)]_2$, and $[M^{III}Cl(ept)_2(H_2O)]$ (M=Ru, Rh). Reaction of Hept with Ag(I), Cu(II), Pb(II), Hg(II), and Cd(II) under refluxing conditions yields the corresponding sulfides and an oxygenated form of the ligand (Hept), which was characterized as  . All metal complexes have been characterized on the basis of analytical, IR and electronic spectral, and magnetic measurement studies.

Over the past five years, we have been interested in the changes in both chemical reactivity and structural properties of thioamide complexes induced by alterations in the peripheral structure of the coordinated ligand.[1-4] Our work recently has centered on thioamide ligands ($R_1CSNHCOR_2$) derived from R_1=2-pyrrolyl, 2-thienyl, or 4-tolyl and R_2=OC_2H_5, NH_2, NHPh. This effort was motivated by an attempt to establish the relative importance of resonance forms (**1**, **2**, and **3**) of the ligand having terminal substituents R_1

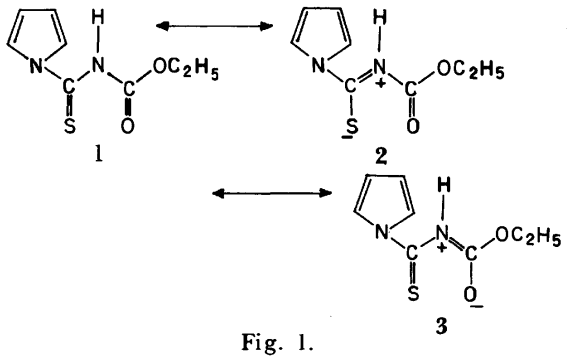

Fig. 1.

and R_2 of wide variety and their contribution to the electronic structure of resulting coordination compounds. With the above objective and as an extension of our work we report here the ligating properties of a new ligand of this class namely *N*-ethoxycarbonyl-1-pyrrolecarbothioamide (Hept). The only report[4] on the complexing behavior of the title ligand is the reaction with $[CuX(MPh_3)_3]$ (M=P or As; X=Cl or Br) in neutral media (benzene solution) resulting in the formation of tetrahedral complexes with the ligand behaving as a monodentate thione-S donor (structure **2**).

Experimental

The chemicals used were either chemically pure or AR grade. The ligand was prepared by the literature method.[5]

Preparation of Complexes. Bis(*N*-ethoxycarbonyl-1-pyrrolecarbothioamidato)copper(II). A cold solution of Hept (0.80 g, 4 mmol) in ethanol (25 ml) was added dropwise to an ice-cold solution of $CuCl_2 \cdot 2H_2O$ (0.34 g, 2 mmol) in water (25 ml). Immediate light brown precipitate results. The precipitate was centrifuged, washed with water, ethanol and ether, and then dried in vacuo.

Bis(*N*-ethoxycarbonyl-1-pyrrolecarbothioamidato)(pyridine)nickel(II). A cold solution of Hept (0.80 g, 4 mmol) in ethanol (10 ml) was added dropwise to an ice-cold solution of $NiCl_2 \cdot 6H_2O$ (0.48 g, 2 mmol) in water (25 ml) containing 10 ml of pyridine, which resulted in the precipitate of green compound. The compound was filtered off, washed with water, and dried in vacuo.

Bis(*N*-ethoxycarbonyl-1-pyrrolecarbothioamidato)nickel(II). This compound was obtained as yellow colored solid by heating the above complex at 90—100 °C.

Bis(*N*-ethoxycarbonyl-1-pyrrolecarbothioamidato)(pyridine)cobalt(II). A cold solution of Hept (0.80 g, 4 mmol) in ethanol (10 ml) was added dropwise to an ice-cold solution of $CoCl_2 \cdot 6H_2O$ (0.48 g, 2 mmol) in water (25 ml) containing 10 ml of pyridine, which resulted in the precipitation of brown compound. The compound was filtered off, washed with water, and dried in vacuo.

(*N*-Ethoxycarbonyl-1-pyrrolecarbothioamidato)silver(I). A solution of Hept (0.40 g, 2 mmol) in ethanol (10 ml) was added to a stirred solution of $AgNO_3$ (0.34 g, 2 mmol) in water (10 ml) at room temperature. The resulted yellow precipitate was filtered off, washed with water, ethanol, ether, and dried in vacuo. This compound decomposes on heating or on standing for more than one day.

Aquachlorobis(*N*-ethoxycarbonyl-1-pyrrolecarboamidato)ruthenium(III). An aqueous solution (25 ml) of hydrated ruthenium trichloride (0.26 g, 1 mmol) was added to an ethanolic solution (25 ml) of Hept (0.40 g, 2 mmol) and the resulting solution refluxed on a water bath for 1—2 h. The black-brown complex which precipitated out was separated by centrifugation, washed successively several times with water, ethanol and ether, and then dried in vacuo.

Aquachlorobis(*N*-ethoxycarbonyl-1-pyrrolecarboamidato)rhodium(III). A solution of Hept (0.40 g, 2 mmol) in ethanol (10 ml) was added to a stirred solution of $RhCl_3 \cdot 3H_2O$ (0.26 g, 1 mmol) in water (50 ml). The resulting orange colloidal solution was digested on a water bath for 2 h and the reddish orange rhodium complex was then filtered off, washed with water, a small quantity of ethanol, and finally with ether, and then dried in vacuo.

Di-μ-chlorobis(*N*-ethoxycarbonyl-1-pyrrolecarboamidato)bis(triphenylphosphine)dirhodium(I). A solution of Hept (0.13 g, 0.6 mmol) in dichloromethane (25 ml) was mixed with a solution of $[RhCl(PPh_3)_3]$ (0.46 g, 0.5 mmol) in dichloromethane (25 ml). The resulting mixture was heated

under reflux for 15 min, the solution was then cooled at room temperature and concentrated to 5 ml at reduced pressure. The addition of petroleum ether (40—60°) to this solution caused precipitation of a yellow complex. It was filtered, washed with petroleum ether, and dried in vacuo.

Bis(*N*-ethoxycarbonyl-1-pyrrolecarbothioamidato)palladium(II). A solution of Hept (0.40 g, 2 mmol) in ethanol (20 ml) was added to a hot solution of $PdCl_2 \cdot 2H_2O$ (0.21 g, 1 mmol) in water (50 ml). Immediately a yellow palladium complex appeared. The precipitate was separated through filtration, washed with water, ethanol and ether, and then dried in vacuo.

Bis(*N*-ethoxycarbonyl-1-pyrrolecarboamidato)platinum(II). A solution of Hept (0.40 g, 2 mmol) in ethanol (25 ml) was added to a solution of H_2PtCl_6 (0.41 g, 1 mmol) in water (25 ml). The mixture was heated under reflux for 1 h. The dark brown precipitate appeared. The precipitate was separated, washed with water, ethanol and ether, and then dried in air.

Sulfur Abstraction from Hept by Soft Metal Ions. An aqueous solution of hydrated metal salts† (ca. 1 mmol) was mixed with an ethanolic solution of Hept (ca. 1.5 mmol). The mixture was heated under reflux for 2—4 h. The respective sulfides Ag_2S (black), CuS (black), PbS (black), Hg_2S (black), and CdS (yellow) were precipitated and characterized after separation. The filtrate obtained was evaporated to dryness and the resulting residue was crystallized from chloroform. The crystals were recrystallized from a mixture of CCl_4 and ethyl acetate (1 : 1 ratio). The resulting crystals were characterized as *N*-ethoxycarbonyl-1-pyrrolecarboamide. Abstraction of sulfur by soft metal ions from similar ligands were also reported from our laboratory.[1,3]

Results and Discussion

All compounds are air stable, insoluble in non-coordinating solvents and soluble in solvents like ethanol, DMF, DMSO, acetone etc. Analytical data (Table 1) are in good agreement with the stoichiometry proposed for the complexes. Metal ions form inner complexes (b—e) rather than simple salts (a). Hept functions both as a mono- and bidentate ligand.

The donor ability of the ligand and the shifts of various IR bands in the spectra of complexes can be best understood in terms of resonance structures (**1**, **2**, and **3**).

The positions of the major bands of interest are shifted in the spectra of complexes. The changes in IR spectra and the inferences drawn regarding site of bonding are summarized below.

The band at 3210 cm^{-1} (ν NH) in the spectrum of ligand disappears in the spectra of the complexes except the Rh(I) complex. This could most probably be explained on the assumption that during the formation of the complexes, the NH group of the ligand is

†$AgNO_3$, $CuCl_2$, $Pb(NO_3)_2$, $HgCl_2$, and $CdSO_4$.

deprotonated with the formation of a metal to nitrogen bond. Two bands at 685 and 630 cm^{-1} assigned to τ(NH) also disappear in the spectra of the complexes, confirming deprotonation of the ligand. In case of $[RhCl(Hept)(PPh_3)]_2$ the band at 3210 cm^{-1} (ν NH) becomes broad, possibly because of hydrogen bonding in the solid state of the compound. The broad bands around 3300—3500 and 1630 cm^{-1} in the spectra of Ru(III) and Rh(III) complexes are tentatively assigned, respectively to stretching (symmetric and asymmetric) and bending modes of water molecule.

For Ni(II), Co(II), Cu(II), and Rh(I) structures **1** and **3** seem to predominate and the band at 1730 cm^{-1} (ν C=O) of Hept shifts towards lower wave numbers (see Table 2). A band at 1125 cm^{-1} of Hept (ν C=S) either remains stationary or goes up and thioamide band IV having major contribution of ν(C=S) (ca. 880 cm^{-1}) undergoes blue shifts in the spectra of complexes. These shifts are indicative of non-involvement of thiocarbonyl sulfur in bond formation, indicating strong interaction of the metal ion with carbonyl oxygen.

For Ag(I), Rh(III), Pt(II), and Pd(II) and Ru(III) complexes structures **1** and **2** of the ligand appear to be operative and the band due to ν(C=O) at 1730 cm^{-1} in the ligand either remains stationary or shifts towards higher wavenumber. This indicates the non-involvement of carbonyl oxygen in the bond formation with the metal ion. The ν(C=S) band of the ligand at 1125 cm^{-1} shifts to lower frequencies whereas in case of $[RuCl(ept)_2(H_2O)]$ the band disappears probably merging with 1095 cm^{-1} band of the ligand. The red shift observed for thioamide band IV further supports the bonding through thiocarbonyl sulfur.

The band at 1500 cm^{-1} in the ligand is assigned to thioamide band I (ν(C-N)+δ(C-H)).[6] In most of the complexes this band shifts to higher wave numbers (see Table 2). Only in the case of $Cu(ept)_2$ the band remains stationary.

A band at 1320 cm^{-1} of Hept assigned to thioamide band II (ν(C=S)+ν(C-N)+δ(C-H)) shifts to lower frequencies (ca. 10—12 cm^{-1}) in the spectra of all the complexes with the exception of $[Rh(Hept)(PPh_3)Cl]_2$ in which Hept is bonded to rhodium(I) through carbonyl oxygen only, as expected, this band shifts to higher wavenumber (1330 cm^{-1}).

Thioamide band III (mainly due to ν(C=S) and ν(C-N) at 1015 cm^{-1} of Hept undergoes red shift on complexation in all the cases.

The new band at 1580 cm^{-1} of $[Cu(ept)_2]$ which has been tentatively assigned to ν(C=N), will have significant contribution of ν(C=O) also as in this complex ν(C=O) of the ligand at 1730 cm^{-1} disappears. Large red shift is indicative of relatively stronger interaction of the Cu(II) ion with carbonyl oxygen. In case of $[Ni(ept)_2(py)]$ band at 1580 cm^{-1} has major contribution of ν(C=N) because there is a band at 1620 cm^{-1} which is assigned as ν(C=O) in the complex. The bands at 1450 and 1490 cm^{-1} for $[Cu(ept)_2]$ and

a) This band has significant contribution from both ν(C=N) and ν(C=O).

[Ni(ept)$_2$(py)], respectively have been assigned to ν(N-C=S).[7] The weak broad band at ca. 3500 cm^{-1} in the spectra of [Ni(ept)$_2$(py)] and [Co(ept)$_2$(py)] are characteristic of pyridine, ca. 80 cm^{-1} towards higher frequency (pyridine band ca. 3420 cm^{-1}). In both the complexes bands in free pyridine at 604 cm^{-1} (in plane ring deformation) and 405 cm^{-1} (out-of-plane ring deformation) shift to higher frequencies (ca. 35 cm^{-1}).[8-10]

The appearance of new medium intensity bands in the region 500—300 cm^{-1} is strong evidence of coordination by both nitrogen and oyxgen or sulphur. They have been tentatively assigned to coupled vibrations of ν(M-N), ν(M-O), and ν(M-S). Bands of a few representative compounds in this region are as given below: 330, 345 cm^{-1} [Cu(ept)$_2$]; 335, 360 cm^{-1} [RuCl(ept)$_2$-H$_2$O]; 340, 450, 490 cm^{-1} [Ni(ept)$_2$]; and 300, 390, 440 cm^{-2} [Co(ept)$_2$(py)].

All compounds except Ni(II), Co(II), and Ru(III) complexes were found diamagnetic at room temperature. The magnetic moment of Ni(II) complex corresponds to two unpaired electrons whereas those of Co(II) and Ru(III) indicate the presence of one unpaired electron in each.

The electronic spectrum of Hept in ethanol exhibits two strong transitions at 300 and 262 nm which are assigned to n→π* and π→π* intraligand transitions, respectively. Usually n→π* transitions involving N and S occur at lower energy and are less intense than π→π*.[11,12] The spectra of almost all the compounds show the presence of these two bands with the hypsochromic blue shift. The high intensity of these bands suggest that they should be charge-transfer or intraligand and not d-d transition bands. The absence of band around 300 nm (n→π*) from the spectra of some complexes may be due to stabilization of the energy of the lone pair of electrons on complex formation,[13] and similarly the hypsochromic shift in bands in the spectra of complexes may be explained as that metal ions are bonded through thiocarbonyl sulfur, carbonyl oxygen, and nitrogen.[14] The bond formations lower the energy of non-bonding orbitals as well as π-levels, thus now more energy will be required to promote the electron from the n or π level to π* orbital hence the observed hypsochromic shift (Fig. 2).

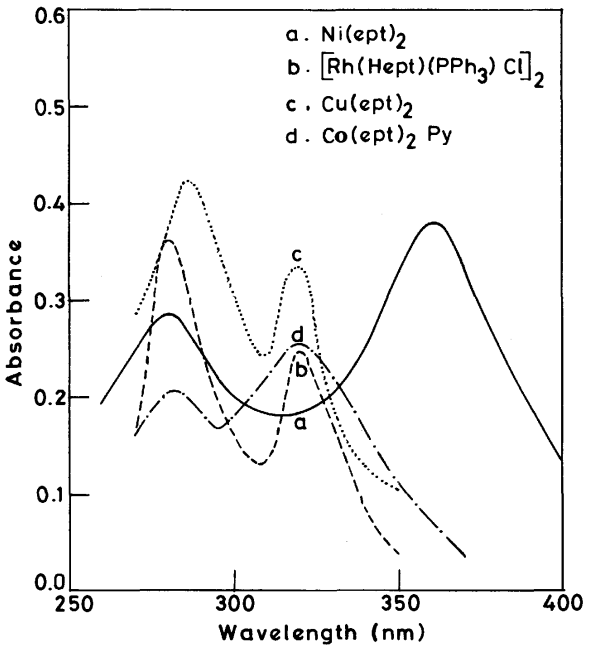

Fig. 2. Electronic spectra.

The IR evidence clearly indicates that the ligand acts as an NO/NS donor in these complexes. Square planar geometry is assigned to Ni(II), Pd(II), Pt(II), Rh(I), and Cu(II) complexes. Ru(III) and Rh(III) complexes are octahedrally coordinated whereas [Ni(ept)$_2$·(py)] and [Co(ept)$_2$(py)] are proposed to have square pyramidal geometry and the Ag(ept) complex is linear one. In case the ligand functions as a bidentate to one metal ion, it will result in a four membered chelate ring (structure b) and this will involve undue strain specially in case when the ligand acts as a NO donor. In view of the above fact and the insolubility of the complexes in most of the non-coordinating solvents the complexes may have open polymeric structures with the nitrogen and oxygen atoms of one ligand being bound to two different metal atoms (structure c).

It is known that OS donor β-thioxoketonates form exclusively cis-complexes with square planar coordinated metal ions and facial complexes with octahedrally coordinated metal ions.[15] Consequently, it is suggested that the Pd(II) and Pt(II) complexes (in which the ligand in NS donor) have the cis square

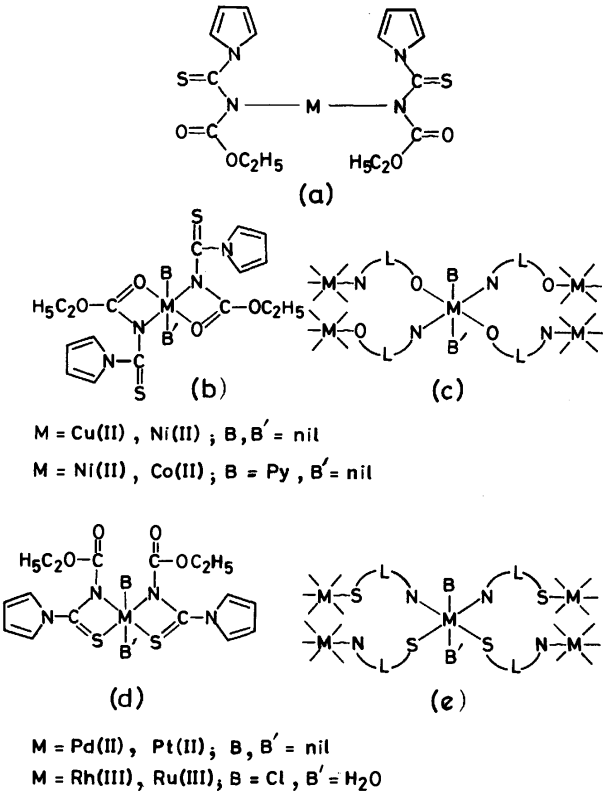

Fig. 3.

planar configuration and those of Ru(III) and Rh(III) are octahedral. Although these structures contain a four membered ring, they do not involve undue strain because of the large size of the sulfur atom. Four membered chelate rings are known with NS ligands.[16] Hence, inspite of insolubility of compounds, in case of NS donor situation, both chelate and open polymeric structures (structures d and e) are equally probable.

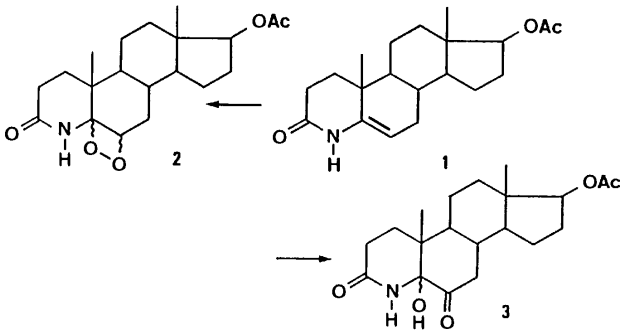
(Received April 8, 1986)

Two steroidal ene lactams, *N*-methyl-4-aza-5-androsten-3,17-dione and *N*-methyl-6-methoxy-4-aza-5-androsten-3,17-dione, and an enamine, *N*-methyl-4-aza-5-androsten-17β-ol, have been synthetized and their sensitized photooxygenations were investigated. The two ene lactams yield fragmentation compounds via the corresponding dioxetanes. Comparison with the previously reported behavior of an analogous *N*-unsubstituted ene lactam, seems to indicate that *N*-substitution is essential for the fragmentation to take place. On the other hand, the enamine yields a ketol. All results are briefly discussed from the mechanistic point of view.

Some years ago we published that the photooxygenation of 17β-acetoxy-4-aza-5-androsten-3-one (**1**) yields, among other products, 17β-acetoxy-5ξ,6ξ-epidioxy-4-azaandrostan-3-one (**2**) and 17β-acetoxy-5ξ-hydroxy-4-azaandrostan-3,6-dione (**3**) (Scheme 1).[3] The dioxetane readily isomerizes to **3**, and was therefore thought to be an intermediate in the transformation **1**→**3**. On the other hand, neither chemiluminescence nor the typical fragmentation to a dicarbonyl compound, were observed when heating **2**. This somewhat anomalous behavior for a 1,2-dioxetane,[4] suggested the necessity of investigating those structural details of the molecule which could be responsible for it. With the purpose of studying their photooxygenation, we decided to synthesize compounds **6**, **9**, and **11** (Scheme 2), which show the following structural modifications:



Scheme 1.

(a) *N*-Substitution
(b) Higher electronic density of the double bond (cf. **9**), and
(c) Suppresion of the carbonyl group at C-3, to an enamine (cf. **11**)

Results

Synthesis of the Heterocyclic Steroids. Starting materials for the synthesis of lactams **6** and **9** were, respectively, 4-androsten-3,17-dione (**4**)[5] and 6β-methoxy-4-androsten-3,17-dione (7).[6] Successive von

Rudloff fragmentation[7] to the seco-carboxylic acids **5** and **8**, and condensation with methylamine, yielded the lactams in 40—70% yield (Scheme 2). An X-ray analysis confirmed the structure of **9**. Lithium aluminium hydride reduction of lactam **10**,[8] gave the enamine **11** in 88% yield.

Crystal Data of 9, Structure Solution and Refinement. Suitable crystals of **9** ($C_{20}H_{29}O_3N$) were obtained by slow evaporation of an acetone-petroleum ether solution. The single crystal was mounted on a four-circle diffractometer (Syntex $P2_1$). Unit cell dimensions were as follows: a=11.466(5); b=11.848 (5); c=13.567(6) Å. Space group $P2_12_12_1$ (Z=4). Intensities were collected with Cu K_α radiation (λ=1.54178 Å) monochromatized by a graphite single crystal, using ω-scan technique.

Of 1443 reflections measured, 1382 were considered significant $I \geqslant 2.5\sigma(I)$. After the Lorentz-polarization corrections were applied, the structure was determined by direct methods (MULTAN program[9]). The atomic parameters were refined using SHELX program[10] (full matrix least-squares). The positions of H-atoms were calculated and floated on the adjacent C-atoms assuming C-H=1.08 Å. The final conventional R value was 0.061. Atomic coordinates and equivalent isotropic temperature factors are listed in Table 1, bond distances and angles in Tables 2 and **3** respectively.** Figure 1[11] is a drawing of the molecule with the numbering scheme.

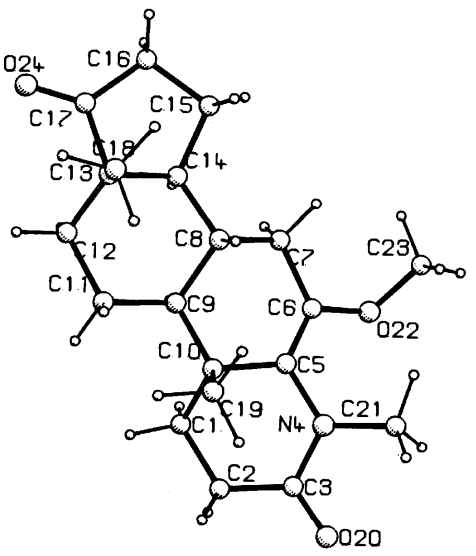

Fig. 1. Perspective view of molecule **9** with numbering scheme.

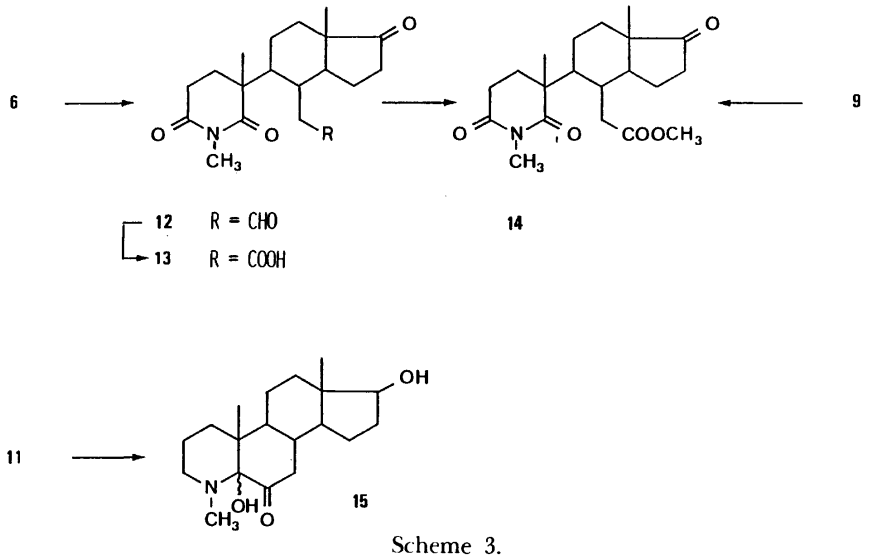

Scheme 3.

Photooxygenation of 6, 9, and 11. The three photooxygenations were carried out in dry benzene solution, with Rose Bengal adsorbed on silica gel as sensitizer[12] (alternatively, polymer-immobilized Rose Bengal, Sensitox,[13] can be used), and a Sylvania 500 watts tungsten-iodine lamp. Lactam **6** yielded one main compound which was identified as the seco-keto aldehyde **12** (46%) (Scheme 3). Jones oxidation of **12** followed by CH_2N_2 treatment, gave the seco-keto ester **14** (**12**→**13**→**14**). This compound was also directly obtained, in 40% yield, by the photosensitized oxygenation of **9**. In this case, a second more polar product was detected by TLC, which with the time evolved towards **14**. The structure of **14** was confirmed by an X-ray analysis.

Crystal Data of 14, Structure Solution and Refinement. A single crystal of **14** was mounted on a Syntex $P2_1$ diffractometer. Cell parameters: a=6.128(2); b=8.929(5); c=35.551(14) Å. Space group $P2_12_12_1$ (Z=4). Intensity data were measured using the same technique as for compound **9**. Of 1576 reflections measured, 1416 ($I \geqslant 2.5\sigma(I)$) were considered reliable and used in the crystal structure analysis. After the Lorentz-polarization corrections were applied the structure was determined by direct methods, (MULTAN program[9]). The atomic parameters were refined by full matrix least-squares calculations (SHELX program[10]). The positions of H-atoms were calculated and floated on the adjacent C-atoms assuming C-H=1.08Å. The final conventional R value was 0.051. Atomic coordinates and equivalent isotropic temperature factors are listed in Table 4, bond distances and angles in Tables 5 and 6 respectively.** Figure 2[11] is a drawing of the molecule with the numbering scheme.

Photooxygenation of **11** yielded the keto alcohol **15** in 22% yield. The structure of **15** is tentatively assigned on the basis of its spectral data: The chemical shift of the 19-methyl group in the ^{1}H NMR spectrum appears at a very high field (δ 0.70) in agreement with the presence of a carbonyl at C(6);[14] on the other hand the IR spectrum exhibits a carbonylic band at 1710 cm^{-1}.

The isolation of the fragmentation compounds **12** and **14** from **6** and **9**, points towards the intermediacy

**The anisotropic thermal parameters of non-hydrogen atoms, the parameters of hydrogen atoms, and the tables of the observed and the calculated structure factors were kept at the Chemical Society of Japan (as Doc. No. 8712).

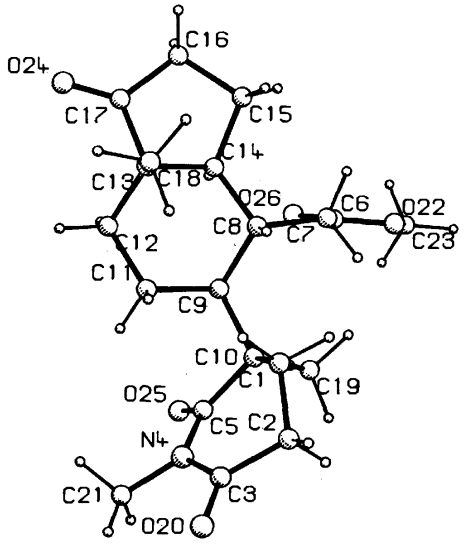

Fig. 2. Perspective view of molecule **14** with numbering scheme.

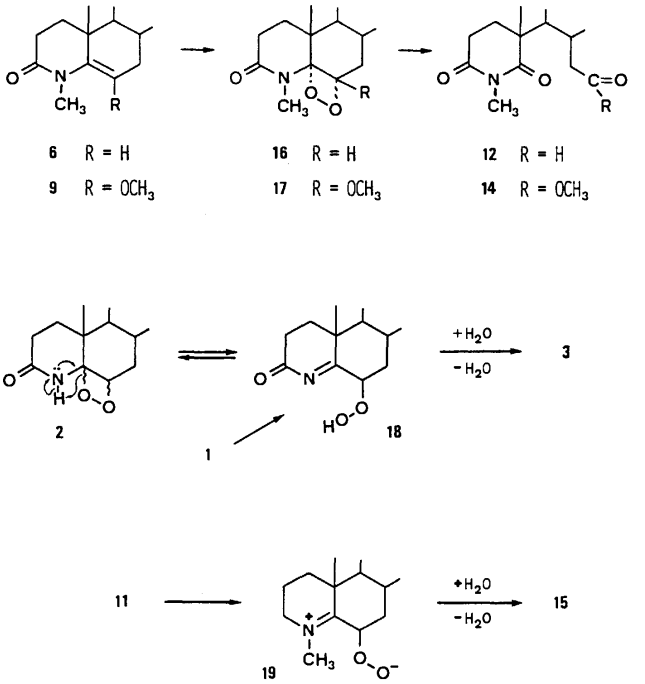
of the 1,2-dioxetanes **16** and **17**, respectively (Scheme 4). In fact, **16** and **17** have been obtained in quantitative yield in low temperature experiments,[15] and characterized by ^{1}H (300 MHz) and ^{13}C NMR and also by their conversion to the cleavage products **12** and **14** upon heating.[16]



Scheme 4.

Concerning the objectives of our work, the results obtained suggest that in the case of the lactams, the evolution of the dioxetanes towards fragmentation compounds or alternatively towards a ketol derivative, depends on the absence or presence of a hydrogen attached to the nitrogen atom. The anomalous behavior of the dioxetane **2** could be explained assuming a preferential isomerization to the ketol **3**, as shown in Scheme 4 (**2**⇄**18**→**3**), which in the absence of the N-H would not take place (no ketol was detected in the crude photooxygenation mixtures of **6** or **9**). Compound **3** could be also directly formed from **1** via the allylic hydroperoxide **18**.

In the case of the enamine **11**, no fragmentation products have been detected and this result is different from those described in the literature: Usually enamines yield fragmentation compounds via dioxetanes.[17] In the case of **11**, a zwitterionic intermediate of type **19** is proposed,[18] although its formation via dioxetane is not excluded. The difference in behavior between the lactams **6** and **9** and the enamine **11** can be explained by means of the availability of the lone pair electron of amine.

Experimental

General Remarks. By extraction in the usual way is meant: Dilution of the reaction mixture with ethyl acetate, washing of the organic phase with concentrated NaCl solution till neutral, drying on anhydrous Na_2SO_4 and evaporation under reduced pressure with a rotatory evaporator.

Silica gel Merck 0.063—0.2 mm, was used for column

chromatography (ratio to substance, 100:1). Thin-layer chromatography was performed using Merck Silica Gel 60F-254 plates. Spots were detected by direct observation under UV light (253.7 nm) or with 50% sulfuric acid spray followed by heating at 150 °C during 1 min.

Crystallizations were carried out in acetone-petroleum ether (bp 50—70 °C). Melting points were determined in an open capillary (Büchi-Tottoli apparatus) and are uncorrected.

Infrared spectra (KBr) were recorded on a Perkin-Elmer 683 spectrophotometer; absorption is given in ν values (cm^{-1}). The ultraviolet spectra (in Merck Ethanol UVASOL solution) were recorded on a Perkin-Elmer 124 spectrophotometer; absorption is given in λ_{max} (nm) values, followed by the ε value in brackets. Perkin-Elmer R-24 or Varian XL-100 spectrometers were used to obtain the ^1H NMR spectra (in $CDCl_3$ solution, unless otherwise specified). Chemical shifts (δ values) are reported relative to TMS as an internal standard. Coupling constants (J) are given in Hz. Multiplicities are expressed as: singlet (s), doublet (d), triplet (t), quartet (qa), multiplet (m), and broad signal (br). Mass spectra were measured on a Hewlett-Packard 5930A or Varian M-44 spectrometers. EI=Electron Impact, CI=Chemical Ionization, DCI=Desorption Chemical Ionization.

For the photosensitized oxygenations, a Sylvania 500T 3Q/Cl/U 200 V lamp and a typical immersion unit were used.

Synthesis of the Heterocyclic Steroids. *N*-Methyl-4-aza-5-androsten-3,17-dione (6). To a solution of **4** (5.853 g, 20 mmol) in *t*-BuOH (1.5 L), an oxidizing von Rudloff solution (24.8 g $NaIO_4$, 5.96 g K_2CO_3, 0.789 g $KMnO_4$, 1.5 L H_2O) was added, and the mixture was stirred for 2 h at r.t. The *t*-BuOH was evaporated in vacuo, HCl (10%, 60 mL) added and the resulting mixture worked up with EtOAc in the usual way. SiO_2 filtration (benzene-EtOAc 1:1) yielded 5.108 g (81.5%) of 5,17-dioxo-A-nor-3,5-secoandrostan-3-oic acid (**5**). IR (film) 3400—2500 (br), 1745, 1725, 1710. ^1H NMR: 0.95 (s, $H_3C(18)$), 1.16 (s, $H_3C(19)$), 9.68 (br, H-OOC(3), disappears on D_2O addition). MS 306 (M^+).

One hundred mL of a 1.5% solution of Na in EtOH, were added to 1.854 g of methylamine hydrochloride in 22 mL EtOH. After filtration, a solution of **5** (1.119 g, 4 mmol) in EtOH (54 mL) was added and the mixture was heated at 140 °C in a sealed tube, for 15 h. After allowing it to cool to r.t. and evaporation in vacuo, it was worked up with chloroform. SiO_2 chromatography (benzene-EtOAc 1:1) yielded 848 mg (80%) of pure **6**. Mp 162—167.5 °C (d) after three crystallizations. IR: 3040, 1730, 1660, 1635. UV: 235 (13800). ^1H NMR: 0.91 (s, $H_3C(18)$), 1.09 (s, $H_3C(19)$), 3.10 (s, H_3C-N(4)), 5.03 (dd, J_1=4.5, J_2=2, H-C(6)). MS 301 (M^+). Found: C; 75.46, H; 9.05; N 4.57%. Calcd for $C_{19}H_{27}NO_2$ (301.43): C 75.71; H 9.03; N 4.65%.

***N*-Methyl-6-methoxy-4-aza-5-androsten-3,17-dione (9).** To a solution of **7** (0.301 g, 0.8 mmol) in *t*-BuOH (120 mL), an oxidizing von Rudloff solution (2.0 g $NaIO_4$, 0.6 g K_2CO_3, 0.02 g $KMnO_4$, 450 mL H_2O) was added, and the mixture was stirred for 3 h at r.t. The *t*-BuOH was evaporated in vacuo, HCl (2M (1 M=1 mol dm^{-3}), till pH 2) was added and the resulting mixture was worked up with EtOAc to yield 0.251 g (79%) of 6β-methoxy-A-nor-3,5-seco-5,17-dioxoandrostan-3-oic acid (**8**). IR (film) 3600—2500 (br), 1750, 1715, 1100. ^1H NMR 0.93 (s, $H_3C(18)$); 1.26 (s, $H_3C(19)$); 3.30 (s, CH_3-O (6)); 3.58 (t, J_1=J_2=2, H-C(6)); 8.65 (br, H-OOC(3), disappears on D_2O addition).

Liquid methylamine was added in excess to a solution of **8** (0.120 g, 0.3 mmol) in THF (50 mL), and the mixture was heated at 140 °C in a sealed tube for 15 h. After allowing it to cool to r.t., it was worked up with chloroform. SiO_2 chromatography (EtOAc-cyclohexane 2:1) yielded 53 mg (51%) of **9**. IR (film) 2840, 1730, 1670—1645 (br). UV 243 (9900). ^1H NMR 0.96 (s, $H_3C(18)$), 1.05 (s, $H_3C(19)$), 3.15 (s, H_3C-N(4)), 3.53 (s, $CH_3O(6)$). MS 331 (M^+). The compound decomposed during the recrystallization procedure, which prevented its elemental analysis.

***N*-Methyl-4-aza-5-androsten-17β-ol (11).** 1.2 g $LiAlH_4$ in 120 mL dry Et_2O were placed in the round-bottom flask of a Soxhlet apparatus, and 0.400 g (1.3 mmol) of **10** were placed in its cartridge. Reflux of ether slowly added **10** on the reducing agent. After 13 h reflux and 6 h at r.t. with stirring, 6 mL of a saturated Na_2SO_4 solution were added dropwise. After filtration it was worked up with ether to yield 0.353 g (93%) of **11**. Mp 161—164 °C after three crystallizations. IR: 3450, 3075, 1645. UV 218 (5400). MS 289 (M^+). Found: C, 78.79; H, 10.82; N, 4.71%. Calcd for $C_{19}H_{31}NO$ (289.47): C, 78.84; H, 10.79; N, 4.84%.

Photooxygenation Reactions. Photooxygenation of 6. A solution of **6** (680 mg, 2.2 mmol) in dry benzene (15 mL), together with Rose Bengal-SiO_2 (701 mg), was irradiated for 20 min at 5 °C under a current of O_2. After filtration, the solution was concentrated to 10 mL with a N_2 current and immediately SiO_2 chromatographed (benzene-EtOAc 3:2) to yield 316 mg (43%) of *N*-methyl-3,5,17-trioxo-4-aza-5,6-secoandrostan-6-al (**12**), as an oil. IR 2740, 1750, 1725, 1670. UV 214 (9600). ^1H NMR 0.95 (s, $H_3C(18)$), 1.32 (s, $H_3C(19)$), 2.61 (d, J=6, H_2-C(7)), 3.11 (s, H_3C-N(4)), 9.66 (br s, HCO(6)), sharpens when irradiating at 2.61). MS 333 (M^+).

Jones Oxidation of 12. To a solution of **12** (84 mg, 0.25 mmol) in acetone (25 mL), 1.5 mL of Jones reagent were added, till persistence of a red color. MeOH was then added (15 mL) till green coloration and, after evaporation in vacuo, the mixture was worked up with EtOAc, to yield 86 mg (98%) of *N*-methyl-3,5,17-trioxo-4-aza-5,6-secoandrostan-6-oic acid (**13**). IR (film) 3600—2500 (br), 1750—1720 (br), 1670. ^1H NMR 0.89 (s, $H_3C(18)$), 1.30 (s, $H_3C(19)$), 2.60 (d, J=5, H_2-C(7)), 3.10 (s, $H_3CN(4)$), 7.27 (br, H-OOC(6), disappears on D_2O addition). MS 349 (M^+).

Esterification of 13. A solution of 80 mg (0.23 mmol) of **13** in 50 mL ether was treated with an ethereal solution of diazomethane. Solvent elimination in vacuo yielded 77 mg (96%) of methyl *N*-methyl-3,5,17-trioxo-4-aza-5,6-secoandrostan-6-oate (**14**). IR (film) 1745—1720 (br), 1670, 1165. ^1H NMR 0.93 (s, $H_3C(18)$), 1.37 (s, $H_3C(19)$); 2.61 (d, J=5, H_2-C(7)), 3.13 (s, H_3C-N(4)), 3.69 (s, H_3C-OOC(6)). MS 363 (M^+). Decomposition during recrystallization prevented its elemental analysis.

Photooxygenation of 9. A solution of **9** (23 mg, 0.07 mmol) in dry benzene (10 mL), together with Rose Bengal-SiO_2 (25 mg), was irradiated for 1 h under a current of O_2. After filtration, it was left at r.t. for 3 d. SiO_2 chromatography (EtOAc-cyclohexane 1:1) yielded 10 mg (39%) of **14** (mixed TLC, IR, ^1H NMR, and MS).

Photooxygenation of 11. A solution of **11** (260 mg, 0.9 mmol) in dry benzene (100 mL) and Sensitox (200 mg), was irradiated for 50 min at 5 °C and under a current of O_2. Filtration, evaporation with a current of N_2 and SiO_2 chro-

matography yielded mostly decomposition products and 58 mg (20%) of assumed *N*-methyl-5ξ,17ξ-dihydroxy-4-aza-androstan-6-one (**15**), as an oil. IR (film) 3500, 1710. ^{1}H NMR 0.65 (s, H_3C(18)), 0.70 (s, H_3C(19)), 1.92 (s, H_3C-N(4)), 2.2 (br, HO-C(17), simplifies after D_2O addition), 2.3—2.6 (m, H_2-C(3)+H_2-C(7)), 3.80 (m, HO-C(5)+HC(17), simplifies after D_2O addition). MS: EI 321 (M^+), 303(M^+ −18); CI 304 (M^++1−18); DCI 322(M^++1).

We are grateful to Prof. Dr. J. Camps (Instituto de Química Bio-Orgánica, C.S.I.C., Barcelona) for elemental analysis, Prof. Dr. C. Pascual (Instituto de Química Orgánica General, C.S.I.C., Madrid) for 100-MHz ^{1}H NMR spectra, Prof. Dr. E. de Hofmann (Université de Louvain) for MS spectra and to Prof. Dr. A. P. Schaap (Department of Chemistry, Wayne State University, Detroit) for valuable mechanistic discussions.

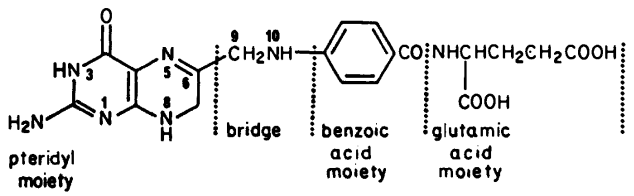
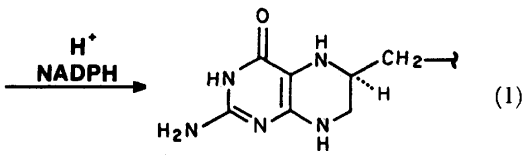
(Received May 6, 1986)

Two site-specific mutations on dihydrofolate reductase from *Escherichia coli* have been carried out at the Phe-31 site. From the crystallographic structure the Phe-31 is located at the dihydrofolate binding site and interacts with both the pteridine ring and the *p*-aminobenzoyl moiety of the substrate. Two mutant enzymes (Phe-31→Tyr and Val) have been purified to homogeneity and characterized by steady-state kinetics. The two mutations are aimed at assessing the hydrophobic interaction between the phenyl ring and the aromatic ring moiety of the substrate. Despite the fact that the first mutation has introduced a polar Tyr-group into a hydrophobic binding site, the Michaelis constant K_{DHF} (K_M with saturating NADPH and varying dihydrofolate) has increased only five-fold. The second mutation (Phe-31→Val-31) results in a 25-fold increase in K_{DHF}. More importantly, the maximum velocity of both mutant enzymes has increased more than 100%, indicating that these are better enzymes under the condition of [substrate]>K_{DHF}. Thus, in both mutant enzymes the decrease in binding has not been translated into a loss of catalytic efficiency.

Site-directed mutagenesis is becoming an increasingly powerful technique for elucidation of the role of specific amino acids in proteins.[1-6] Dihydrofolate reductase (DHFR) catalyzes the reduction of dihydrofolate (H_2-folate) to tetrahydrofolate (H_4-folate) with NADPH as the cofactor. The metabolic importance of



DHF (H_2-folate)



(1)

THF (H_4-folate)

DHFR, which stems from the fact that derivatives of its product, H_4-folate, have coenzyme functions in one-carbon transfer reactions, has inspired extensive research on inhibitors of the enzyme, several of which are widely used as antibacterial or antitumor agents.[7] This enzyme is one of a few proteins whose X-ray crystal structure has been solved to a resolution better than 2 Å.[8,9] It is a single polypeptide chain of 159 amino acids (17800 daltons) and possesses an extensive secondary structure consisting of eight β strands, seven of which are parallel, and four α helices.[8,9] Thus, this richness of structural information enables us to study the relationship between enzyme structure and function in detail by means of site-directed mutagenesis on this enzyme.

The structure of the *E. coli* DHFR-methotrexate binary complex is shown schematically in Fig. 1, with

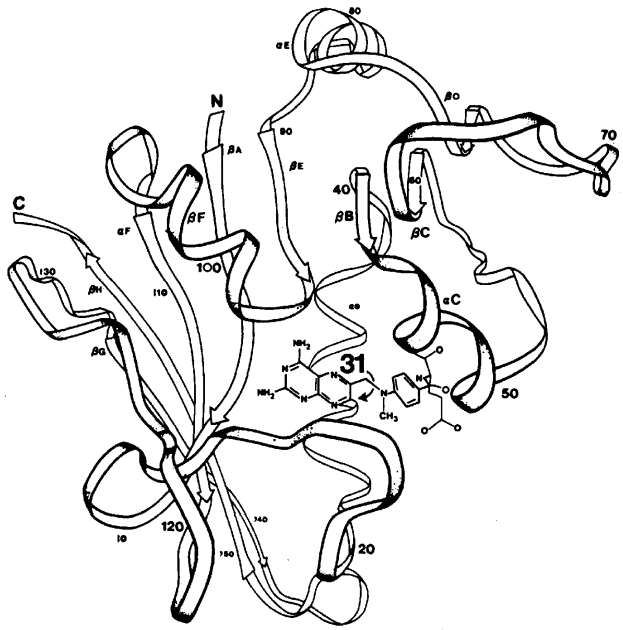


Fig. 1. Backbone ribbon drawing of the *E. coli* DHFR-methotrexate binary complex[8] with the mutation site, Phe-31, indicated by the arrow.

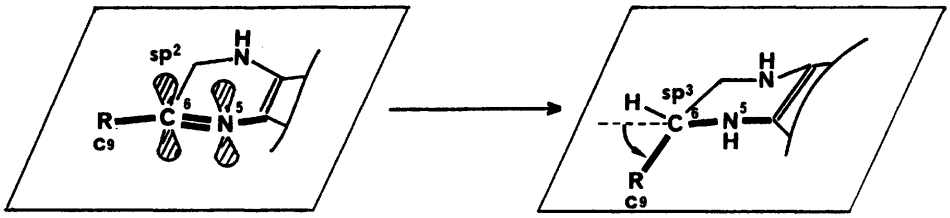
the site of particular interest, Phe-31, indicated by an arrow. This phenylalanine, strictly conserved in all known sequences of DHFR, interacts with both the pteridine ring and the *p*-aminobenzoyl moiety. The *p*-aminobenzoyl moiety is almost perpendicular to the pteridine ring with the Phe-31 being at the corner of the bend providing van der Waals contacts with both aromatic rings. Considering the fact that the hybridization of C6 changes from sp^2 to sp^3 so that C9 swings away from the plane of the pteridine ring upon reduction of the C6=N5 imino bond, it is of interest to inquire whether the interactions with Phe-31 change during product formation.

One might also imagine that the imino double bond



(2)

in H_2-folate may be activated towards reduction through a degree of strain on the imino bond, possibly caused by the bend. By replacing the Phe-31 by a smaller amino acid such as Val, one can assess to what degree reduced substrate-enzyme interactions alter catalysis. In addition we have chosen Tyr for the replacement of Phe-31, which still possesses aromatic character but may be able to facilitate the protonation of N5 prior to reduction since no amino acid exists at the active site that is capable of direct proton transfer.[8]

This approach is made possible through the technique of site-directed mutagenesis. We have successfully created two new proteins (Tyr-31 and Val-31) via site-directed mutagenesis which have been purified to homogeneity and offer significant mechanistic insights which could not be gained merely by studying the wild-type enzyme.

Methods

The method of Dalbadie-McFarland et al. was employed to generate specific mutations using a chemically synthesized oligodeoxynucleotide that directs the mutationl.[1] Figure 2(a) shows the nucleotide sequence of the synthetic 22-mer oligodeoxynucleotide, with asterisks indicating mismatches, together with the corresponding base sequence of the wild-type *E. coli* DHFR. Figure 2(b) illustrates a restriction map of the plasmid DNA, pTY1,[10] in which a 1 Kb fragment containing the DHFR gene (*fol*)[11] is inserted into the *Bam*H I site of a 4.4 Kb pBR322 derivative DNA lacking the *Eco*R I site, as well as the restriction fragments formed upon treatment with *Aha* III and *Bam*H I. The recognition sequence of the *Aha* III is TTTAAA which is found in the wild-type DHFR gene corresponding to Phe-31 and Lys-32 (see Fig. 2(a)). Upon mutation of the Phe-31 the TTT codon is replaced by a corresponding codon for each mutant enzyme, in case of the Tyr-31 mutant, the corresponding codon is TAT. Thus, any successful mutation destroys the *Aha* III recognition site in *fol*, resulting in the resistance of a 1 Kb fragment toward *Aha* III digestion. The isolation of the *Aha* III resistant 1 Kb fragment followed by religation with the 4.4 Kb pBR322

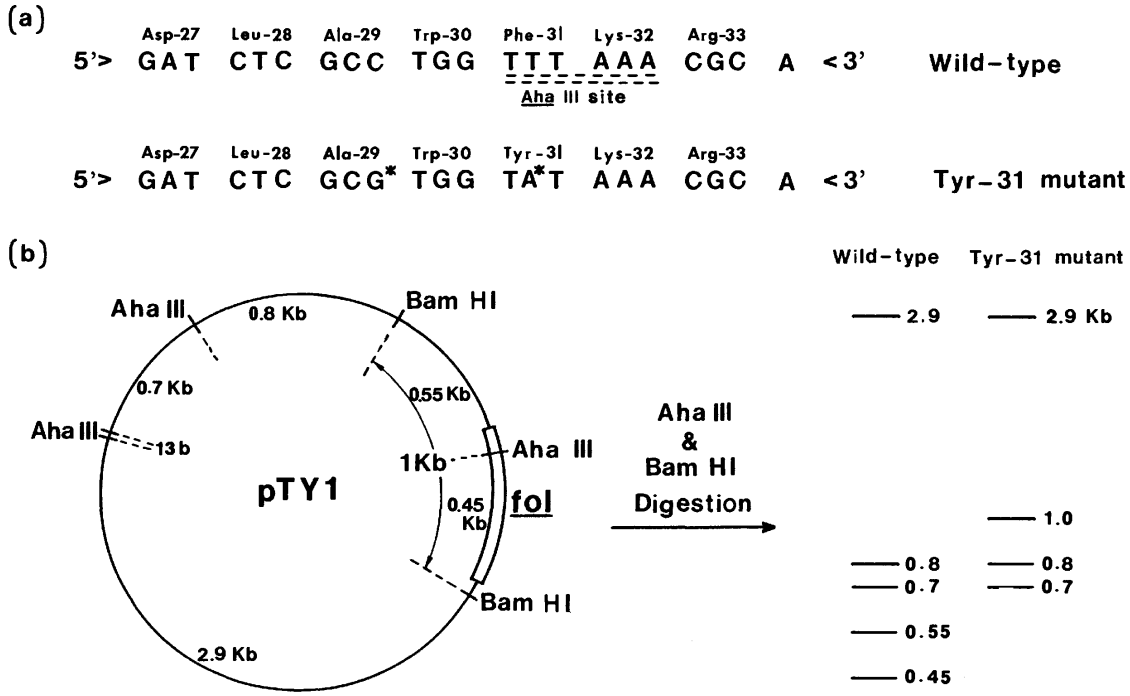


Fig. 2. (a) Nucleotide sequence of the syuthetic oligodeoxynucleotide for Tyr-31 mutant and the corresponding sequence for the wild-type *E. coli* DHFR. The base pair mismatches are indicated by asterisks and the amino acids encoded by both mutant and wild-type sequences are shown. (b) Restriction map of the plasmid DNA, pTY1, showing the location of the DHFR gene (*fol*) by the open box. Gel electrophoresis results of both wild-type and mutant DNAs upon *Aha* III/*Bam*H I digestion are schematically shown.

derivative completes the preparation of mutant plasmid DNA. The exact experimental conditions employed[10-15] are described in the following section.

Experimental

Oligodeoxyribonucleotides. The syntheses of two oligodeoxyribonucleotides were performed on an Applied Biosystems Model 380A DNA synthesizer. Base sequences of the two oligodeoxyribonucleotides were as follows, with asterisks indicating mismatchs.

Tyr (22-mer):
5′>GAT CTC GCG* TGG TA*T AAA CGC A<3′
Val (21-mer):
5′>GAT CTC GCG* TGG G*TT AAA CGC<3′

The oligodeoxyribonucleotides were purified by means of HPLC on a reverse phase μBONDAPAK C18 column employing a 10—30% gradient of CH_3CN in 0.1 M§ triethylammonium acetate (TEAA) pH 7. After detritylation with 3% CH_3COOH at room temperature for 3 min the deblocked oligonucleotides were subject to a second HPLC purification under the above conditions.

Purity of the primers was confirmed by repeating the HPLC procedure as well as running electrophoresis on ^{32}P-end-labelled primers prepared as follows.[12] To an Eppendorf tube were added 4 μl H_2O, 2.5 μl 5X Kinase buffer (0.5 M Tris·HCl, pH 8.0, 0.05 M $MgCl_2$, 0.025 M DTT), 1 μl deoxyribonucleotide (4.0 OD_{260}/ml, ≈12 pmol), 3 μl [γ-^{32}P]-ATP (2500 Ci/mmol, New England Nuclear), and 2 μl T4 Kinase (2 u/μl, New England Biolabs). This solution was incubated at 37 °C for 1 1/4 h, mixed with 10 μl 0.5 M EDTA to stop the reaction, and the solution spin desalted through a G25 fine Sephadex column. The column was washed with 50 μl TE (10 mM Tris·HCl, pH 7.5, 1 mM EDTA). The recovered ^{32}P-end-labelled primer (20×10^3 CPM in 1 μl) was mixed with 9 μl of a sequencing dye and ca. 1 μl of this sample per lane was loaded onto a denaturing 20% polyacrylamide gel calibrated with appropriate standards. This electrophoresis analysis confirmed the purity as well as the length of each primer.

Plasmid pTYl. Two *Hae* III fragments (574 base pairs and 408 base pairs long) containing the DHFR gene were isolated from pCV29 DNA[11] and subcloned by Yaegashi et. al.[10] into the *Bam*H I site of a pBR322 derivative lacking the *Eco*R I site to generate pTYl.

Nicking. Fifty micrograms of supercoiled pTYl DNA and 15 μg of ethidium bromide in 50 μl of 50 mM Tris·HCl, pH 7.5, 50 mM NaCl, 10 mM $MgCl_2$, and 1 mM dithiothreitol (DTT) were treated in the dark at room temperature with 4.0 μl of *Eco*R I (10 units/μl) for 4.5 h.[1] (The reaction was assayed, after stopping the reaction by an addition of 1 μl of 0.5 M EDTA, by electrophoresis on 0.8% agarose gel in 40 mM Tris acetate, pH 8.0, 1 mM EDTA; conditions that separate nicked, linear, and supercoiled DNA molecules.) The solution was extracted once with an equal volume of phenol, which had been equilibrated with TE buffer, once with 1/2 volume of phenol and 1/2 volume of chloroform, twice with equal volumes of chloroform, and then four times with 3—5 times volumes of diethyl ether. The DNA was precipitated by adding 1/10 volume of 3 M sodium acetate, pH 7.1, and 2.5 volumes of absolute ethanol and the mixture maintained at −20 °C for longer than 3 h. After centrifugation, the pellet was washed three times with 70% (vol/vol) ethanol, dried and dissolved in 30 μl of TE, pH 7.5. The concentration of the DNA was calculated to be 1.24 μg/μl, assuming that one OD_{260} equaled 50 μg DNA/ml.

Gapping. Prior to each exonuclease treatment the activity of the enzyme was checked by digesting a linear double-stranded pTYl plasmid and following the formation of two single-stranded fragments by electrophoresis on 0.7% agarose containing 1 μg ethidium bromide per ml. About 5 μg (1.4 pmol) of the nicked DNA was treated for 60 min at room temperature with 100 units of exonuclease III in 50 μl of 66 mM Tris·HCl, pH 8.0, 90 mM NaCl, 5 mM $MgCl_2$, and 10 mM DTT. The reaction was stopped by carrying out phenol extraction followed by ethanol precipitation as described above. This exonuclease III treatment created an approximately 600 bp gap. The gapped DNA was dissolved in 2 μl of TE and stored at −70 °C.

Phosphorylation of Oligonucleotides. Two hundreds pmoles of 5′-OH oligodeoxyribonucleotide (6.7 μM) were treated with 5 units of polynucleotide kinase for 50 min at 37 °C in 30 μl of 100 μM ATP, 100 mM Tris·HCl, pH 8.0, 10 mM $MgCl_2$, and 5 mM DTT.[12] The enzyme was inactivated by heating to 65 °C for 15 min. The final solution was stored at −70 °C.

Annealing of Oligonucleotide, Polymerization, and Ligation. The nicked and exonuclease-treated DNA (1.1 pmol of gapped circular pTY1) was heated to 65 °C for 7 min in the presence of about 44 pmol of the 5′-phosphorylated synthetic oligonucleotide in 40 μl of 40 mM NaCl, 20 mM Tris·HCl, pH 7.5, 10 mM $MgCl_2$, 1 mM DTT, and then the solution was chilled on ice for 4 h.

This oligonucleotide annealed DNA was treated with 7.8 units of Klenow fragment and 2500 units of T4 DNA ligase at 10 °C overnight in 60 μl of 350 μM ATP, 175 μM dATP, 175 μM dCTP, 175 μM dGTP, 175 μM dTTP, 40 mM NaCl, 20 mM Tris·HCl, pH 7.5, 10 mM $MgCl_2$, and 1 mM DTT.[1-5] The resulting heteroduplex containing DNA was isolated as before by phenol extraction followed by ethanol precipitation.

Competent HB101 Cells. Five hundred mls of LB medium (5.0 g of Bacto-trypton, 2.5 g of Bacto-yeast extract, and 5.0 g of NaCl in 500 ml of H_2O) was sterilized and 5.0 ml of this LB medium was transferred to a sterile 16×100 mm Kimble culture tube, inoculated with a single colony of *E. coli* strain HB101, and shaken at 37 °C overnight. Two 250 ml flasks containing 100 ml of LB media with 0.2% glucose were autoclaved, inoculated with 1.0 ml of the overnight culture of HB101, shaken at 250 rpm at 30 °C for 8 h until the OD_{600} had reached 0.65, and then left on ice for 2 h. The intact flask of HB101 (the one not used for the OD measurements) was opened and the cell suspension was centrifuged at 6000 rpm for 5—8 min at 4 °C. After decantation of the supernatant fluid the cells were resuspended in ca. 50 ml of a cold sterile solution of 100 mM $CaCl_2$, 70 mM $MnCl_2$, and 40 mM sodium acetate, pH 5.5, left on ice for 30 min, and centrifuged again at 6000 rpm at 4 °C. The pellet was resuspended in 10 ml of cold 100 mM $CaCl_2$, 70 mM $MnCl_2$, and 40 mM sodium acetate, pH 5.5, and then 1.4 ml of sterile 80% glycerol was added. The competent cells were dispensed as 0.3 ml aliquots into about 34 culture tubes (Kimble, 16×100 mm), and stored at −70 °C.[10,12] These competent cells could

§1 M=1 mol dm^{-3}.

be kept more than 6 months without losing much of the transformation frequency ($\approx 10^5$).

Transformation, Growth of Bacteria, and Amplification of Plasmid. The concentration of the heteroduplex containing circular DNA was adjusted to ca. 0.1 μg DNA per 100 μl TE (pH 7.5). One hundred μl of this solution were incubated with 0.3 ml of competent HB101 cells, kept on ice for 60 min and then heat shocked at 42 °C for 2 min. To this was then added 2.6 ml of LB medium and the solution agitated at 37 °C for 60 min. In order to confirm the transformation, 100 μl of this solution was plated on two agar plates containing 50 μg of ampicillin per ml of medium and the remaining 2.8 ml used to inoculate a one liter LB medium containing the same concentration of ampicillin. The latter was incubated at 37 °C with agitation at 250 rpm until the culture had reached an OD_{650} of 0.5. At this point 4 ml of a solution of chloramphenicol (40 mg/ml in ethanol) was added for amplification of plasmids and the incubation was continued with agitation at 250 rpm at 37 °C for 15 h.[12]

Harvesting, Lysis, and Isolation of Plasmid DNA. Bacterial cells in the one liter culture were harvested, lysed, and the plasmid DNA isolated as in Ref. 12.

***Aha* III and *Bam*H I Digestion of Plasmid DNA and Isolation of Mutant 1 Kb Fragment.** Two hundreds micrograms of the plasmid DNA were digested with both 50 units of *Aha* III and 160 units of *Bam*H I for 16 h at 37 °C in 400 μl of 75 mM NaCl, 10 mM Tris·HCl, pH 8.0, 10 mM $MgCl_2$, and 5 mM DTT. (*Bam*H I digestion produces two fragments: 4.4 Kb fragment of a linear pBR322 derivative lacking the *Eco*R I site and 1 Kb fragment containing the DHFR gene. Of this 1 Kb fragment only a mutated gene at the Phe-31 site is resistant to the *Aha* III digestion because of the destruction of the *Aha* III recognition sequence (see Fig. 2).) The digestion mixture was loaded on a 3.5% polyacrylamide gel and a gel portion containing the 1 Kb fragment was cut out from the gel (the position of the 1 Kb fragment was identified by staining only the control lane containing the 1 Kb fragment with ethidium bromide and the mutant 1 Kb fragment was not exposed to the ethidium bromide). The gel portion containing the mutant 1 Kb fragment was placed in a dialysis bag with 0.1X TBE buffer (5 mM Tris base, 6.6 mM boric acid, 0.1 mM EDTA) and an electroelution[12] was carried out overnight in the same 0.1X TBE buffer at 8 mA at 4 °C. The mutant 1 Kb fragment was absorbed onto 0.1 ml of DE52 which had been prequilibrated in 100 mM NaCl, 50 mM Tris·HCl, pH 7.8, and 1 mM EDTA followed by equilibration with TE, and was eluted from the DE52 by running 300 μl of a high salt solution of 2 M NaCl, 50 mM Tris·HCl, pH 7.8, and 1 mM EDTA. The eluent was dialyzed against 500 ml of 10 mM Tris·HCl, pH 7.5 at 4 °C for 36 h with two changes and concentrated to 250 μl.

Ligation of Mutant 1 Kb Fragment with pBR322 Derivative at *Bam*H I Site. Dephosphorylation of a pBR322 derivative linearized at the *Bam*H I site was carried out, by treating 10 μg of a linear pBR322 derivative with 1.0 unit of alkaline phosphatase for 60 min at 37 °C in 50 μl of 50 mM Tris·HCl, pH 8.0, 1 mM $MgCl_2$, and 0.1 mM $ZnCl_2$, in order to avoid self-ligation and/or polymerization of the linear pBR322 derivative upon ligation with the mutant 1 Kb fragment. The dephosphorylated pBR322 derivative linearized at the *Bam*H I site was purified by phenol extraction followed by ethanol precipitation. One μg of the dephosphorylated 4.4 Kb fragment and 0.2 μg of the mutant 1 Kb fragment were treated with 400 units of T4 DNA ligase at 10 °C for 18 h in 50 μl of 0.5 mM ATP, 50 mM Tris·HCl, pH 7.5, 10 mM $MgCl_2$, and 10 mM DTT. The enzyme was inactivated by phenol extraction and the ligated nicked DNA was purified on a Sephadex G25 fine column. The eluent was used for the second transformation.

Second Transformation and Colony Screening. The second transformation was carried out using the ligated nicked DNA and the same procedure described above. Well-separated single colonies were numbered and seven colonies were arbitrarily chosen. For a rapid isolation of plasmid DNA the transformed HB101 cells were grown on a much smaller scale (15 ml LB medium) without amplification and the isolated DNA was partially purified by a treatment with DNase-free RNase in place of the cesium chloride-ethidium bromide gradients purification. These plasmid DNAs were digested with *Aha* III and *Bam*H I and those 1 Kb DHFR gene fragments which were resistant to the digestion were identified as mutant colonies.

Isolation of Mutant Plasmid DNA and Purification of *Bam*H I 1 Kb Fragment. Five ml of LB medium containing 50 μg of ampicillin per one ml of medium was inoculated with a mutant single bacterial colony. The bacteria were eventually grown in 2 l medium and each mutant plasmid DNA was isolated and purified by the cesium chloride-ethidium bromide gradients as described earlier. The purified mutant plasmid DNA was digested with *Bam*H I and the 1 Kb fragment was isolated as described earlier.

***Dde* I Digestion of 1 Kb Fragment, End-Labelling, and Sequencing.** About 1 μg of the *Bam*H I 1 Kb fragment was treated with 4 units of *Dde* I at 37 °C for 4 h in 20 μl of 100 mM Tris·HCl, pH 7.5, 100 mM NaCl, 5 mM $MgCl_2$, and 6 mM 2-mercaptoethanol. To this were then added 14 μl of H_2O, 4 μl of [α-^{32}P] dTTP (3200 Ci/mmol), and 0.7 μl of reverse transcriptase (16 units/μl), and the solution was kept at room temperature for 6.5 h. The reaction mixture was mixed with a loading dye and two fragments were isolated from a 3.5% polyacrylamide gel (the position of each fragment could be located by an autoradiogram). After both fragments were cut from the gel, they were eluted out (10 mA, 4 °C, overnight), collected on a DE52 column ($\approx$0.05 ml resin). The column was eluted with 400 μl of 2 M NaCl, 50 mM Tris·HCl, PH 7.8, and 1 mM EDTA, the eluent then mixed with 1 μl of *t*-RNA (30 μg/μl), and the DNA fragment precipitated at −20 °C (6 h ethanol precipitation). The pellet was washed with 0.5 ml of cold 70% ethanol three times, dried in a speed vac for 10 min, and dissolved in 50 μl of TE and 5.5 μl of 3 M NaAc, pH 7.1. After an addition of 140 μl of ethanol, the mixture was kept at −20 °C for 1 h and centrifuged. The pellet was washed with 70% ethanol three times, dried in a speed vac, and redissolved in 50 μl of H_2O. The radioactivity of each sample varied from 700 to 3000 cps/5 μl. The DNA sequence of each fragment was determined by the general method[12,13] of Maxam and Gilbert with minor modifications. The DNA sequences were confirmed by autoradiogram.

Isolation of Mutant Enzymes. Five ml of LB medium containing 50 μg of ampicillin per one ml medium were inoculated with a single mutant colony. Cells for each mutant enzyme were grown in 2 l culture containing 50 μg of ampicillin/ml to a final optical density of 1.0 at 650 nm and harvested by centrifugation at 6000 rpm at 4 °C. The cells were suspended in 20 ml of 40 mM Tris·HCl, pH 8.0, 1

mM EDTA and centrifuged at 20000 rpm at 4 °C for 30 min to yield about 6 g of precipitate. All steps for the following cell lysis were conducted at 4 °C. The cells (ca. 6 g) were suspended in 7 ml of buffer (40 mM Tris·HCl, pH 8.0, 1 mM EDTA, 1 mM DTE (dithioerythritol)) with 0.7 μl of PMSF (phenylmethanesulfonyl fluoride) (17.4 mg/ml) and the following additions were made to the suspension: 1) 15 mg of lysozyme in 1 ml of the above buffer and 2.1 ml of EDTA (20 mg/ml in the above buffer) followed by sonication of the mixture for 30 sec then 8 min on ice (this sonication-cooling process was repeated two more times.); 2) 2.1 ml of Brij 58 (5 g/100 ml above buffer) followed by sonication for 30 s then 7 min on ice (this process was repeated two more times.); and 3) 330 μl of $MgCl_2$ (5.1 g/25 ml above buffer) and 500 μl of DNase (6.84 mg/3 ml above buffer) with occasional mixing for 15 min. The suspension was centrifuged at 20000 rpm for 40 min. To the supernatant 1.2 ml of streptomycin sulfate (1 g/10 ml above buffer) was added at 1 min intervals (100 μl/each time) with gentle stirring and the suspension then was centrifuged at 20000 rpm for 40 min. The supernatant (16.5 ml) was made 40% saturated in ammonium sulfate by gradually adding 3.85 g of finely powdered $(NH_4)_2SO_4$ over a period of 15 min with stirring. The stirring was continued for another 15 min. Unwanted protein was removed by centrifugation at 20000 rpm for 1.5 h. The supernatant was then made 90% saturated by gradually adding 5.8 g of $(NH_4)_2SO_4$ over a period of 20 min, and the mixture was gently stirred for additional 15 min and then kept on ice for 1.5 h. Following the centrifugation at 20000 for 30 min, the white pellet was resuspended in 13 ml of 40 mM KH_2PO_4, pH 6.0, 0.2 M KCl, 1 mM EDTA, and 1 mM DTE. To this was then added 2 ml of MTX (methotrexate) resin[14] and the solution gently shook for 20 h. The MTX resin was batch washed each time with 10 ml of 0.2 M KH_2PO_4, pH 6.0, 1 M KCl, 1 mM EDTA, and 1 mM DTE total four times. The MTX resin was transferred to a 10 ml column and washed with the same high salt buffer (0.2 M KH_2PO_4, 1 M KCl, 1 mM EDTA, 1 mM DTE) until the OD_{280} of the eluent was below 0.1. The mutant DHFR was eluted with 0.2 M K_3BO_3, pH 9.0, 1 M KCl, dialyzed against 2 l of 10 mM Tris·HCl, pH 7.4, 1 mM EDTA, and 1 mM DTE for 8 h with two changes, and purified on a column (52×1.1 cm) of DEAE-Sephacel with a linear gradient of 500 ml each of a solution containing 10 mM Tris·HCl, pH 7.4, 1 mM EDTA, 1 mM DTE, and a solution containing 1 M NaCl, 1 mM EDTA, 1 mM DTE. About 1 mg pure mutant DHFR was obtained per 1 g cells. The pure enzyme was made 90% saturated with $(NH_4)_2SO_4$ and stored at −20 °C. Although this DHFR is a Form I (Leu-28) isozyme, it is not necessary to make the eluting buffer 1 mM in folic acid since the mutant enzymes (Tyr-31 and Val-31) bind to the MTX resin less tightly than the wild-type DHFR. This affinity difference for the MTX resin enabled us to separate the mutant DHFR from possible contamination by the wild-type DHFR. The purity of the mutant DHFR was confirmed by the observation of a single band on a 12% polyacrylamide protein gel. There was no contamination by nucleic acids since the OD_{280}/OD_{260} ratio was 1.9 for both mutant enzymes.

Kinetics and Data Analysis. Initial velocities for dihydrofolate reductase were determined at 25 °C following the disappearance of NADPH and DHF at 340 nm (ε=11800 M^{-1} cm^{-1}). The buffer used for the assays contained 50 mM 2-morpholinoethanesulfonic acid (MES), 25 mM tris(hydroxymethyl)aminomethane (Tris), 25 mM 2-aminoethanol, and 100 mM NaCl (MTEN buffer).[15] The concentration of NADPH was maintained constant at 60 μM. The concentrations of DHF and the enzymes are listed in Table 1.

Data obtained at each pH value by varying the concentration of DHF were fitted to Eq. 3 by a nonlinear computer fitting program to yield values for the maximum velocity (V) and the Michaelis constant (K_a) as well as for V/K_a.

$$v = \frac{V[\mathrm{DHF}]}{K_a + [\mathrm{DHF}]} \tag{3}$$

Results

Two mutant plasmid DNAs (Tyr-31 and Val-31) have been constructed by the procedure illustrated in

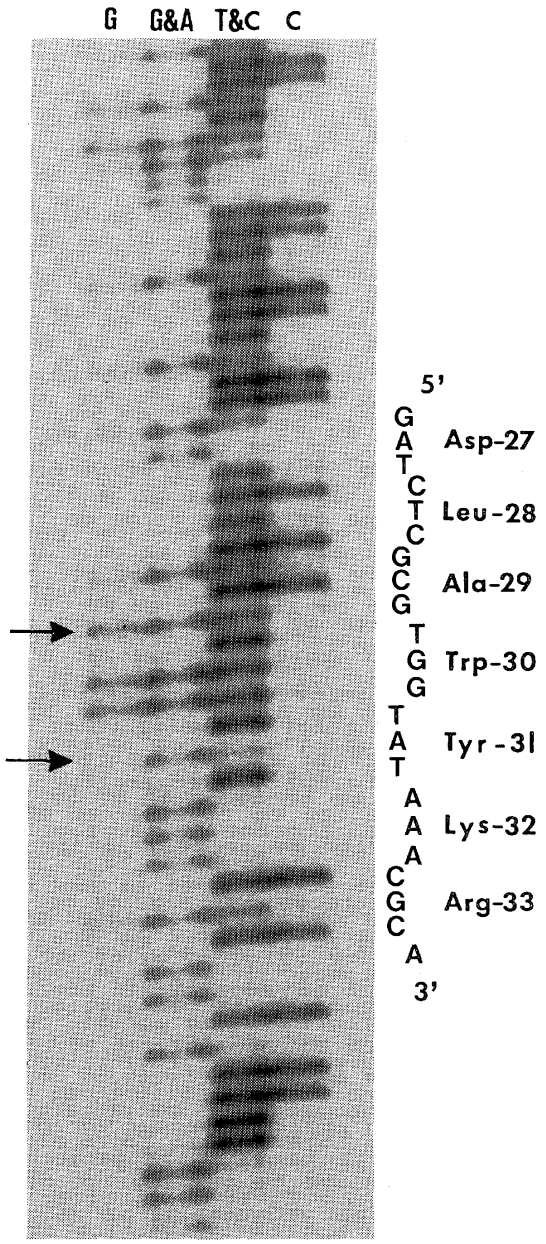

Fig. 3. Maxam-Gilbert sequencing ladder of Tyr-31 plasmid around the mutated *Aha* III site. Two replacements (TA→A and C→G, see Fig. 2(a)) are indicated by arrows.

Table 1. Summary of pH-Independent Values of V, V/K_{DHF}, and K_{DHF}, for Tyr-31 and Val-31[a]

	V/s^{-1}	V/K / $10^{-6}\,M^{-1}\,s^{-1}$	$K_{DHF}/\mu M$
Wild-type	12	11	1.1[b]
Tyr-31	30	5.3	5.7
Val-31	26	0.97	27

a) Conditions: 60 μM NADPH, 3.25—120 μM H_2-folate, 1.1—500 nM (Tyr-31)-DHFR, 6.1—730 nM (Val-31)-DHFR, MTEN buffer, 25 °C, 340 nm. b) Taken from Ref. 15.

Fig. 2. The DHFR coding sequences in these plasmids have been determined by the chemical method of Maxam and Gilbert[12,13] and the sequencing ladder of Tyr-31, as an example, around the mutated *Aha* III site is shown in Fig. 3 with the replacements marked by arrows. The whole structural genes have been completely sequenced and no mutations, other than designed ones, have been detected. The two mutant enzymes were isolated and purified to homogeneity. The purity of the mutant DHFR was confirmed by SDS gel electrophoresis which showed a single band.

Table 1 summarizes the pH independent values of V, V/K, and K_M (see the accompanying paper) determined for the purified mutant enzymes, Tyr-31 and Val-31. The kinetic experiments were performed under conditions similar to those employed by Stone and Morrison.[15] Both of these mutants have V values significantly larger than that of wild-type (wt), while the V/K values are smaller. The Tyr-31 mutant has a 2.5 fold higher V value than that of wt in the pH independent region, indicating that, under saturating DHF conditions, the Tyr-31 mutant is a better catalyst than the wild-type enzyme. The Tyr-31 mutant has a two-fold smaller value for V/K_{DHF} owing to a 5-fold increase in K_{DHF} at low pH. At high pH values, however, the K_{DHF} value increases to 300 μM (pH 9.5), possibly due to the ionization of Tyr, drastically decreasing the hydrophobicity of the side chain. The detailed pH-rate profile will be discussed in the accompanying paper.

The effect of the Val-31 mutation is again a 2.2-fold increase in V and a 25-fold increase in K_{DHF}. This increase in K_{DHF} is probably a reflection of a higher K_D value for H_2-folate, by analogy with a parallel increase in the dissociation constant estimated from its behavior during purification from the methotrexate resin.

Discussion

Site-Directed Mutagenesis. The first controlled modifications of proteins were reported two decades ago using chemical reactions to change the hydroxyl group of a serine residue at the active site of the proteolytic enzyme subtilisin into a mercapto group.[16,17] The problem with chemical modification is that it is harsh and nonspecific. Unless great care is taken, an attempt for example to exchange a serine for a cysteine at the active site may result in exchanging all serines on the surface of the enzyme for cysteines with unpredictable results. Furthermore, many desired changes, as in our Phe-31 → Tyr and Val mutations, cannot be achieved with chemical techniques, beside the fact that many of these residues are in the interior of the enzyme and inaccessible to a reagent. Advances in genetic engineering technology in the last few years, however, have made amino acid substitutions "almost routine."[1-6]

The procedure described in Fig. 2 takes advantage of destroying a restriction site upon successful incorporation of a synthetic oligodeoxynucleotide primer and isolating a new restriction fragment. Even if such a convenient restriction site is not available, the colony hybridization technique,[1,18] with the same oligodeoxynucleotide labeled with ^{32}P as a hybridization probe, allows identification of the desired mutant colony regardless of its phenotype. After the second transformation, the plasmid DNA of each mutant was characterized not only in the region of the mutation but also the entire structural gene and shown to have the desired sequence (see Fig. 3).

DHF Binding Site. Nonpolar interactions between the pteridine ring and the enzyme originate with the side chains of residues Ile-5, Ala-7, Phe-31, and Ile-94 providing most of the van der Waals contacts.[8] Among these residues only Ala-7 and Phe-31 are strictly conserved, although all of them are hydrophobic in all the known sequences. The *p*-aminobenzoyl moiety occupies a hydrophobic pocket formed by the helix αB on one side and by the loop (Gly-51 to Gly-56) connecting αC to βC on the other. In particular, the side chains of Leu-28 and Phe-31 extending from αB interact with the inner face of the *p*-aminobenzoyl group. This Phe-31, but not the Leu-28, is strictly conserved in all known sequences.[8]

A closer examination of the DHF (dihydrofolate) binding site reveals that the *p*-aminobenzoyl moiety is almost perpendicular to the pteridine ring with the Phe-31 at the corner of the bend. We felt that this bend could be important for the catalysis because of the following reasons. The enzyme catalyzes its reaction by having an active site that is complementary in structure to the structure of the transition state of the substrate rather than the substrate itself.[19] During the reduction of H_2-folate to H_4-folate (Eq. 1), the hybridization of C-6 carbon changes from sp^2 to sp^3 accompanying the movement of the C-9 carbon of the side chain from its original in-plane position at sp^2 to the out of plane from the pteridine ring at the sp^3 state (see Eq. 2). If the DHF binding site is designed such that it stabilizes the transition state or product more favorably than the substrate, H_2-folate, some of the intrinsic binding energy is utilized for catalysis.[20] The Phe-31, which is located at the corner of the bend interacting with both the pteridine ring and the *p*-aminobenzoyl moiety, could be a part of an interacting network.[21-25]

Replacement of Phe-31 by a smaller group as in the site-directed mutagenesis experiment of Phe-31 → Val-31, should decrease the affinity of the mutant enzyme for the substrate to some extent depending on the intrinsic binding energy of the mutant enzyme, but the affinity for the transition state would be decreased to a greater extent. This means that the value of K_{DHF} may be increased but the value of k_{cat} will fall. The steady-state kinetic parameters for the Tyr-31 and Val-31 mutants listed in Table 1 are, at first glance, not supportive of the transition state stabilization hypothesis. That the increase in V for the Tyr-31 mutant may result from the facilitated protonation of N5 necessary for reduction is unlikely since a similar increase in V is observed for the Val-31 mutant. However, additional experiments have revealed that the steady-state parameters mask any changes in the hydride transfer step. Pre-steady state stopped-flow measurements convincingly implicate the rate of dissociation of H_4-folate as mainly rate-limiting at this pH.[29] Consequently the increase in V noted in the two mutations arises simply from an increased rate of product dissociation that is reflected in the higher K_D of H_2-folate. Because the hydride transfer step is still not rate-limiting, one cannot readily assess the effect of the mutations in terms of the transition state stabilization hypothesis. The interpretation of the effects of mutations based on steady state parameters is always subject to ambiguities unless one known step in the kinetic sequence is dominant.

Although the mutants we have generated are not necessarily the evolutionary precursors of the present native enzyme, they are possible forms of the enzyme that have been rejected during evolution, since the rate of spontaneous mutation is sufficiently high for them to have arisen and hence been tested. For the sake of the argument, however, let us assume that each of the mutant enzymes, Tyr-31 and Val-31, is an evolutionary precursor of the native Phe-31 enzyme. Various proposals have been made as to how enzymic rate constants should respond to selective pressure in evolution to maximize the overall rate of reaction[30,31] by stabilizing both transition state and substrate-enzyme complexes. This kind of evolutional replacement leads to an increase in rate as long as [S] remains below K_M; other wise ([S]>K_M), stabilization of (ES) and (ES)$^{\neq}$ equally has a neutral effect (no change in rate).[31] Since the concentration of dihydrofolate in vivo is estimated to be below 1 μM, the Tyr-31 and Val-31 mutant enzymes, despite their higher turnover numbers, would be less effective in maintaining H_4-folate levels owing to their greater K_{DHF} values.

In conclusion, the present study has demonstrated that a protein engineering at the level of DNA is a powerful technique for elucidation of the structure-reactivity relationship in an enzyme. Specifically, in both Tyr-31 and Val-31 mutant enzymes the decrease in binding has not been translated into a loss of catalytic efficiency and both the mutant enzymes have generated an improved k_{cat}, most probably by facilitating the product-release step without significantly altering the hydride transfer step.

We thank our colleagues, especially Carol A. Fierke for the helpful discussions and Valerie Mizrahi and Patricia A. Benkovic for their suggestions at various stages of this study.

(Received May 6, 1986)

Site-specific mutations on dihydrofolate reductase from *Escherichia coli* at the Phe-31 site have generated (Try-31)-DHFR and (Val-31)-DHFR mutant enzymes. The pH dependence of log V and log V/K_{DHF} for these enzymes suggests that protonation is important for both the interaction of dihydrofolate and the maximum velocity of the reaction. More importantly, a "hollow" is observed for the Tyr-31 mutant in a log V/K-pH profile, necessitating a modification of the wild-type kinetic scheme. The intrinsic pK_a of 5.8, obtained based on the modified more general kinetic scheme, for the Tyr-31 mutant agrees well with that obtained from inhibition studies by 2,4-diamino-6,7-dimethylpteridine.

During the last two decades the interest and research in enzyme chemistry has expanded so rapidly with applications of physical organic techniques[1] that it now occupies an important position in chemistry as a whole. Moreover, recent recombinant DNA technology has revolutionized our ability to tailor the structure and activity of enzymes by manipulation of their genes.[2-8]

As described in the preceding paper,[8] our interest in the mechanism of dihydrofolate reductase (DHFR), which catalyzes the reduction of dihydrofolate (H_2-folate) to tetrahydrofolate (H_4-folate) with NADPH as the cofactor,[9] has led us to carry out site-specific mutations on this enzyme at the Phe-31 site. From the crystallographic structure[10,11] the Phe-31 is located at the dihydrofolate binding site and interacts with both the pteridine ring and the *p*-aminobenzoyl moiety of the substrate.

The first mutation (Phe-31 → Tyr-31) has resulted in an only five-fold increase in K_{DHF} (K_M with saturating NADPH and varying dihydrofolate), despite the fact that the mutation has introduced a polar Tyr-group into a hydrophobic binding site, and a 2.5-fold increase in the maximum velocity. Similarly, the second mutation (Phe-31 → Val-31) resulted in a 25-fold increase in K_{DHF} with a 2.2-fold increase in the maximum velocity. Thus, in both mutant enzymes the decrease in binding has not been translated into a loss of catalytic efficiency.

We report here the pH dependency of log V and log V/K_{DHF} for these mutant enzymes. Although the pH dependencies of these values for the Val-31 mutant DHFR are clearly half-bell-shaped as they are for the wild-type DHFR,[12] a "hollow"[13] is observed for the Tyr-31 DHFR. The kinetic scheme proposed for the wild-type DHFR[12] is inadequate to explain this "hollow" phenomenon, necessitating a modification of the wild-type kinetic scheme. The modified more general kinetic scheme may also be applicable to explain the wild-type steady-state kinetic data.

Experimental

Mutant Enzymes. Preparation of the mutant enzymes (Tyr-31 and Val-31) has been described.[8]

Kinetics and Data Analysis. Initial velocities for dihydrofolate reductase were determined at 25 °C following the disappearance of NADPH and DHF at 340 nm (ε=11800 M^{-1} cm^{-1} (1 M=1 mol dm^{-3})). The buffer used for the assays contained 50 mM 2-morpholinoethanesulfonic acid (MES), 25 mM tris(hydroxymethyl)aminomethane (Tris), 25 mM 2-aminoethanol, and 100 mM NaCl (MTEN buffer). The concentration of NADPH was maintained constant at 60 μM. The concentrations of DHF and enzymes are listed in Table 1.

Data obtained at each pH value by varying the concentration of DHF were fitted to Eq. 1 by a nonlinear computer fitting program to yield values for the maximum velocity (V) and the Michaelis constant (K_a) as well as for V/K_a.

$$v = \frac{V[\mathrm{DHF}]}{K_a + [\mathrm{DHF}]} \quad (1)$$

The pH-rate profiles were fitted to Eq. 2, and for the special case with a "hollow" phenomenon (Fig. 2(c)) Eq. 3 was used.

Table 1. Summary of pH-Independent Values of V, V/K_{DHF}, K_{DHF}, Apparent p$K_a(V)$, and p$K_a(V/K)$ Values for Tyr-31 and Val-31[a]

	V/s^{-1}	V/K / 10^{-6} M^{-1} s^{-1}	K_{DHF}/μM	pK_a[V]	pK_a[V/K]
Wild-type	12	11	1.1[b]	8.4[b]	8.1[b]
Tyr-31	30	5.3	5.7	7.9	6.8
Val-31	26	0.97	27	7.4	6.9

a) Conditions: 60 μM NADPH, 3.25—120 μM H_2-folate, 1.1—500 nM (Tyr-31)-DHFR, 6.1—730 nM (Val-31)-DHFR, MTEN buffer, 25 °C, 340 nm. b) Taken from Ref. 12.

$$V = \frac{V_{max}}{\left\{1+\frac{K_a}{(H)}\right\}} \quad \text{or} \quad V/K = \frac{(V/K)_{max}}{\left\{1+\frac{K_a}{(H)}\right\}} \tag{2}$$

$$V/K = \frac{C_1\left\{1+\frac{C_2K_1}{(H)}\right\}}{\left\{1+\frac{K_1}{(H)}\right\}\left\{1+\frac{C_3K_1}{(H)}\right\}} \tag{3}$$

Results

Table 1 summarizes the V, V/K, K_M, and pK_a values observed in pH-rate profiles determined for the purified mutant enzymes, Tyr-31 and Val-31. The reported V and V/K terms are pH-independent. The kinetic experiments were performed under conditions similar to those employed by Stone and Morrison.[12] Both of these mutants have V values significantly larger than that of wild-type, while the V/K values are smaller. Also, each mutation results in a pK_a shift to lower pH in both the V and V/K profiles.

The Tyr-31 mutant has a 2.5-times higher V value than that of wild-type in the pH independent region, indicating that, under saturating DHF conditions, the Tyr-31 mutant is a better catalyst than the wild-type enzyme. The increase in V may in one interpretation result from the accelerated product release step which may constitute a significant part of the rate determining step. The Tyr-31 mutant has only a two-fold smaller value for V/K_{DHF} owing to a 5-fold increase in K_{DHF} at low pH. At high pH values, however, the K_{DHF} value increases to 300 μM (pH 9.5), possibly due to the ionization of Tyr, drastically decreasing the hydrophobicity of the side chain.

The effect of the Val-31 mutation is similar; a 25-fold increase in K_{DHF} and a 2.2-fold increase in V. This increase in K_{DHF} is probably a reflection of a higher K_D value for H_2-folate, by analogy with a parallel increase in the dissociation constant for methotrexate resin. The decrease in the apparent pK_a value could be due to the introduction of water in the active site to fill the volume originally occupied by the Phe-31. However, the pK_a value of 8.1 of wild-type in the V/K profile may not reflect the intrinsic pK_a as originally thought.[12] This point will be discussed in more detail in the next section.

In Fig. 1 are shown the pH dependence of log V and log V/K_{DHF} for the reaction catalyzed by the Val-31 mutant DHFR. Values for V and V/K_{DHF} were determined over the pH range 5.0—9.8. The pH dependence of these values suggests that protonation is important for both the interaction of DHF and the maximum velocity of the reaction. The initial velocities, especially at pH values less than 6.0, were corrected for the decomposition of NADPH. Both profiles fit to the theoretical lines calculated from Eq. 2 with the parameters given in Table 1.

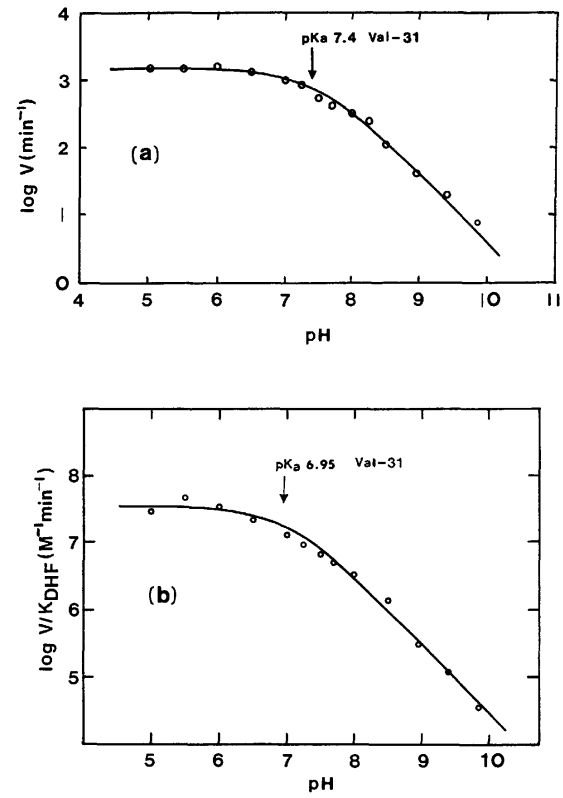

Fig. 1. (a) The pH dependence of log V for the reaction catalyzed by the Val-31 mutant DHFR. (b) The pH dependence of log V/K_{DHF} for the Val-31. The lines represent a best fit to Eq. 2 with the parameters given in Table 1.

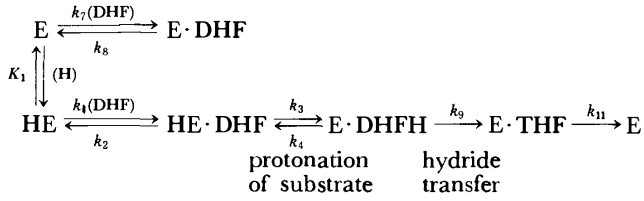
Figure 2 illustrates the analogous pH dependence of log V and log V/K_{DHF} for the Tyr-31 mutant. Again, the overall pH dependence of these values indicates that the protonation is important for both the interaction of DHF and the maximum velocity of the reaction. The theoretical lines for Fig. 2(a) and (b) were drawn according to Eq. 2 with the apparent pK_a's shown in the profiles also given in Table 1. Although the theoretical curve in Fig. 2(a) fits the experimental points satisfactorily,that of Fig. 2(b) is inadequate because of the observed "hollow". The use of Eq. 2 for describing the data in Fig. 2(b), was based on the assumption that the kinetic scheme for Tyr-31 is same as that of the wild-type DHFR proposed by Stone and Morrison:[12]



Scheme 1.

where E denotes the enzyme-NADPH binary complex since the kinetic studies were carried out under the saturation with NADPH. The V/K_{DHF} equation for

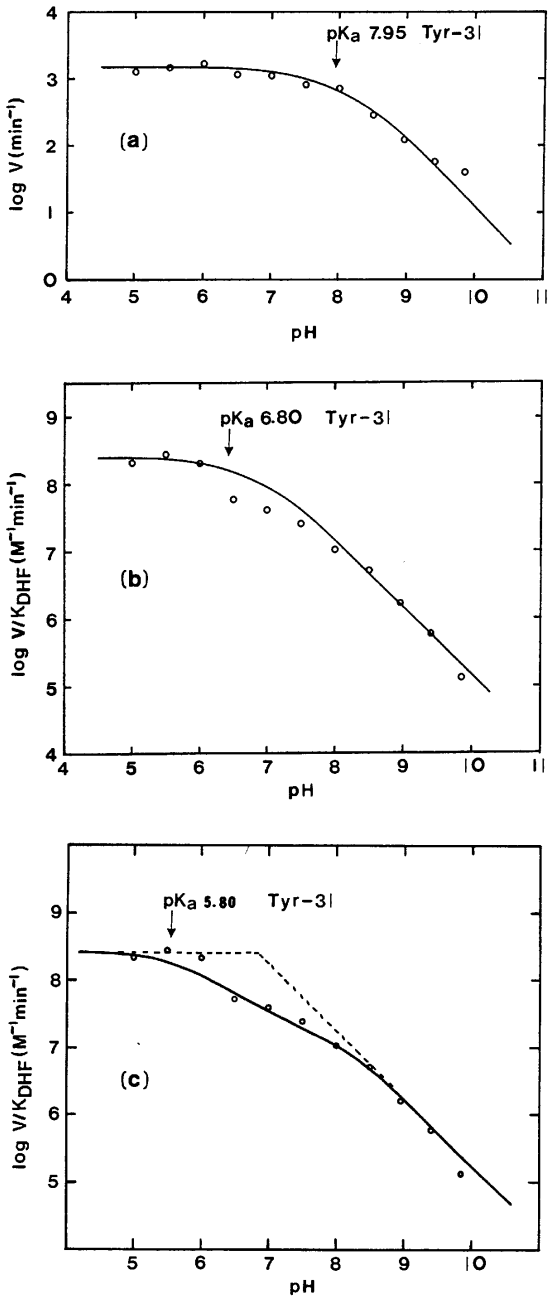


Fig. 2. (a) The pH dependence of $\log V$ for the Tyr-31, where the solid line is the theoretical curve based on Eq. 2. (b) The pH dependence of $\log V/K_{DHF}$ for the Tyr-31, where the theoretical line is based on Eq. 2. (c) The pH dependence of $\log V/K_{DHF}$, same as in (b), for the Tyr-31, where the theoretical line is drawn according to Eq. 7 with the intrinsic pK_a of 5.8 and the conditions of $k_1=10\,k_7$, $k_3=10\,k_6$, $k_6=10\,k_2$, and $k_9=10\,k_4$. The intercept of the dashed line corresponds to the apparent pK_a of 6.8.

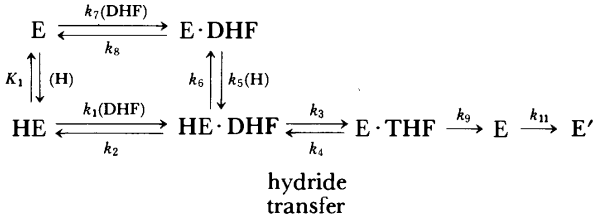
the reaction described by Scheme 1 is given by

$$\frac{V}{K}=\frac{k_1k_3k_9\ (E_T)}{(k_2k_4+k_2k_9+k_3k_9)\left\{1+\dfrac{K_1}{(H)}\right\}} \tag{4}$$

which contains only one pH-dependent term yielding a half-bell-shaped curve of the type illustrated in Fig. 1(b).

Since the Eq. 4 derived on the basis of Scheme 1 cannot adequately describe the "hollow" phenomenon[13] of the Tyr-31 mutant shown in Fig. 2(b), the kinetic scheme proposed by Stone and Morrison was expanded to the following more general case:



Scheme 2.

where E and E′ denote the enzyme-NADPH complex and free enzyme, respectively. The hydride transfer and protonation of DHF were combined into a single, reversible step (k_3, k_4) with k_9 and k_{11} representing rate coefficients associated with product release. The initial velocity equation for the reaction described by Scheme 2 is given by:

$$v=\frac{k_1k_3k_9(k_8+k_5H+\dfrac{k_5k_7K_1}{k_1})(E_T)(DHF)}{\begin{aligned}&(k_3k_7k_9+k_6k_7k_9+k_4k_6k_7+k_2k_4k_7+k_2k_7k_9+k_5Hk_7k_9+\\&k_4k_5Hk_7+k_3k_5Hk_7+k_3k_5Hk_7k_9/k_{11})\cdot\frac{K_1}{(H)}\\&+k_1(k_4k_6+k_6k_9+k_4k_5H+k_5Hk_9+k_4k_8+k_8k_9+\\&k_3k_5H+k_3k_8+k_3k_5Hk_9/k_{11}+k_3k_8k_9/k_{11})\\(DHF)+&\frac{(k_3k_8k_9+k_6k_8k_9+k_4k_6k_8+k_3k_5Hk_9+k_2k_4k_5H}{+k_2k_5Hk_9+k_2k_4k_8+k_2k_8k_9)\cdot\left\{1+\dfrac{K_1}{(H)}\right\}}\\&\frac{(k_3k_7k_9+k_6k_7k_9+k_4k_6k_7+k_2k_4k_7+k_2k_7k_9}{+k_5Hk_7k_9+k_4k_5Hk_7+k_3k_5Hk_7+}\\&k_3k_5Hk_7k_9/k_{11})\cdot\frac{K_1}{(H)}+k_1(k_4k_6+k_6k_9+k_4k_5H+\\&k_5Hk_9+k_4k_8+k_8k_9+k_3k_5H+k_3k_8+\\&k_3k_5Hk_9/k_{11}+k_3k_8k_9/k_{11})\end{aligned}} \tag{5}$$

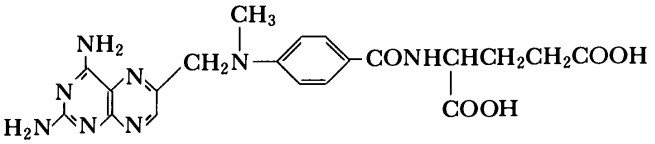
The V and V/K_{DHF} relationships for the mechanism given in Scheme 2 are described by Eqs. 6 and 7.

$$V=\frac{\dfrac{k_3k_9k_{11}(E_T)}{k_3k_9+k_3k_{11}+k_4k_{11}+k_9k_{11}}\left\{1+(1+\dfrac{k_2}{k_6})\dfrac{k_7K_1}{k_1(H)}\right\}}{\begin{aligned}&1+\left\{\frac{k_7}{k_1}+(\frac{k_8}{k_6}+\frac{k_4k_{11}+k_9k_{11}}{k_3k_9+k_3k_{11}+k_4k_{11}+k_9k_{11}})\frac{k_2k_7}{k_1k_8}\right\}\frac{K_1}{(H)}\\&+\left\{\frac{k_7k_{11}(k_2k_4+k_2k_9+k_3k_9+k_4k_6+k_6k_9)}{k_1k_5(k_3k_9+k_3k_{11}+k_4k_{11}+k_9k_{11})}\right\}\frac{K_1}{(H)^2}\end{aligned}} \tag{6}$$

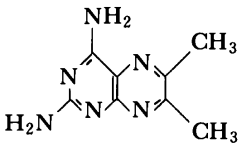
$$\frac{V}{K}=\frac{\dfrac{k_1k_3k_9(E_T)}{k_2k_4+k_9(k_2+k_3)}\left\{1+(1+\dfrac{k_2}{k_6})\dfrac{k_7K_1}{k_1(H)}\right\}}{\left\{1+\dfrac{K_1}{(H)}\right\}\left\{1+(1+\dfrac{k_6}{k_2+\dfrac{k_3}{1+\dfrac{k_4}{k_9}}})\cdot\dfrac{k_2k_7K_1}{k_6k_1(H)}\right\}} \quad (7)$$

The Eq. 7, from which the individual rate constants can be combined to form constants C_1, C_2, and C_3 of Eq. 3, has three pH-dependent terms. Thus, depending on the magnitude of C_2 and C_3 in Eq. 3, a fit for the "hollow" in the pH-log V/K profile can be generated. The theoretical curve for the pH-log V/K_{DHF} profile of the Tyr-31 mutant is drawn in Fig. 2(c) according to Eq. 3 with the following parameters: $C_1=5.3\times10^6$ M^{-1} s^{-1} (pH-independent value of V/K_{DHF} in Table 1); $C_2=0.1$, $C_3=0.01$, and the intrinsic pK_a of 5.8 (pK_1 =5.8). Although the individual rate constants in Eq. 7 are not known, the condition of $C_2=0.1$ and $C_3=0.01$ may be met, as one of several possibilities, when $k_6/k_2=k_3/k_6=k_1/k_7=k_9/k_4=10$ in Eq. 7.

Shown in Fig. 3 is the pH dependence of inhibition for the Tyr-31 mutant by a substrate analogue, 2,4-diamino-6,7-dimethylpteridine, which differs from methotrexate (MTX) by the absence of the side chain. Although the pK_a value determined from a V/K profile may be displaced, the analysis of the pH dependence of

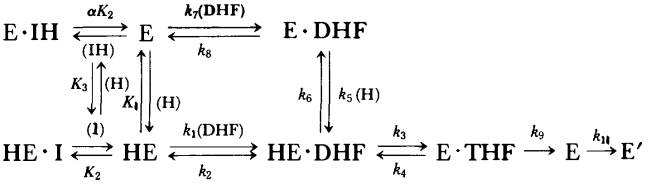


MTX(methotrexate)



2,4-diamino-6,7-dimethylpteridine

the inhibition caused by a substrate analogue will generally[14] yield the correct[12,13] pK_a value. The variation with pH of the inhibition of the wild-type DHFR by 2,4-diamino-6,7-dimethylpteridine yielded a bell-shaped curve with two pK_a values of 5.9 and 7.9.[12] The lower pK_a value corresponds to the value of 5.75 determined for the protonation of the N-1 nitrogen of the pteridine.[12,15] As can be seen from Fig. 3, however, the mutation Phe-31 → Tyr-31 has shifted the higher pK_a value of the wild-type, Phe-31, to a much lower pH region. The solid line in Fig. 3 is drawn according to Eq. 8 based on Scheme 3.



Scheme 3.

In Eq. 8, K_i(app) denotes the apparent inhibition constant which can be obtained by plotting $1/v$ vs. the inhibitor concentration (Dixon plot).[16] K_1, K_2, and K_3 are defined in Scheme 3, of which pK_3, the protonation

$$K_i(\text{app})=\frac{K_2\left\{1+\dfrac{(H)}{K_3}+\dfrac{K_1}{(H)}+\dfrac{K_1}{K_3}\right\}}{1+\dfrac{K_1}{\alpha K_3}}, \quad (8)$$

of the N-1 nitrogen of the pteridine inhibitor, is already reported to be 5.75.[15] Since, at low pH, the inhibition of the Tyr-31 mutant by 2,4-diamino-6,7-dimethylpteridine was comparable to that of the wild-type enzyme, the pH independent value of the inhibition constant, K_2, was assumed to be 13 nM which was the reported value for the wild-type enzyme.[12] Assuming that α equals unity, two theoretical lines are drawn in Fig. 3: The intrinsic pK_a of the enzyme, pK_1, is assumed to be 5.8 for the solid line, and 6.8 for the dashed line. Although the experimental points are limited, the solid line with the intrinsic pK_a of 5.8 better fits to the experimental data. This intrinsic pK_a of 5.8, obtained by the inhibition study, agrees well with the intrinsic pK_a of 5.8 obtained from the "hollow" profile of Fig. 2(c).

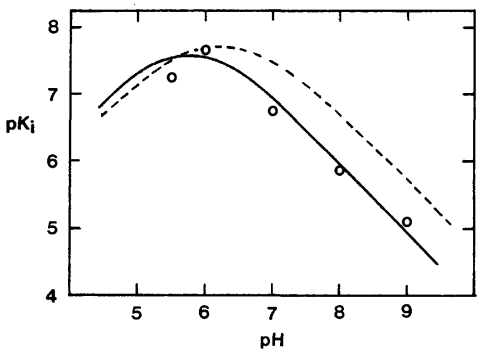


Fig. 3. Variation with pH of the pK_i ($-\log K_i$) value of the Tyr-31 mutant for 2,4-diamino-6,7-dimethylpteridine. The units for K_i are M. The theoretical curves are drawn according to the Eq. 8 with the parameters of pK_3=5.75, K_2=13 nM, α=1, and for the solid curve pK_1=5.80, and for the dashed curve pK_1=6.80.

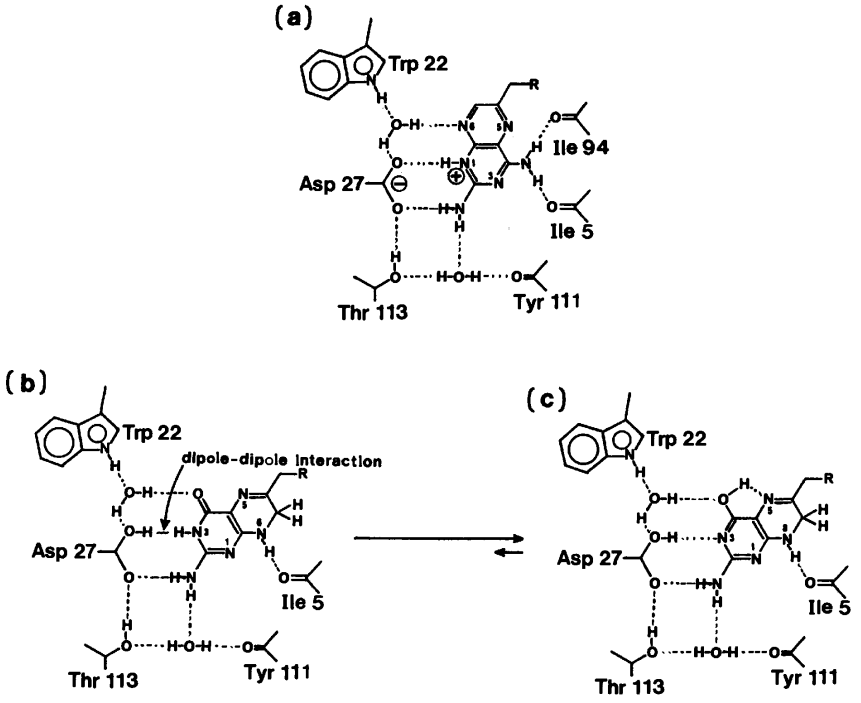

Fig. 4. Schematic representation of hydrogen bonding interaction between dihydrofolate reductase and the pteridine portions of (a) methotrexate and (b), (c) 7,8-dihydrofolate. At neutral pH, the enzyme bound methotrexate is protonated, on the other hand, the enzyme bound dihydrofolate is not protonated.

Discussion

General Kinetic Scheme with Saturating NADPH. From the variation of V and V/K_{DHF} with pH in Figs. 1 and 2, it is apparent that protonation enhances the maximum velocity, V, of the dihydrofolate reductase reaction as well as the flux rate V/K_{DHF}, with the enzyme-NADPH binary complex to yield a productive complex. For the wild-type *E. coli* DHFR, activity is dependent on a group with a pK_{a1} of about 8 that must be protonated, and on another group with a pK_{a2} of about 5 that must be unprotonated.[17] Moreover, it has been suggested that Asp-27 is responsible for the pK_a of 8.[12] In view of the conclusion that DHF is bound to DHFR in an inverted fashion relative to the binding of an inhibitor such as methotrexate and, at neutral pH, productive binding must occur as a result of reaction between unprotonated DHF and protonated enzyme (protonated Asp-27), a modified representation[10] of the hydrogen bonding interaction between DHFR and DHF based on the X-ray crystallographic structure of the methotrexate-DHFR complex is given in Fig. 4(a). One may speculate that tautomerization of the initial complex relieves an unfavorable dipole-dipole interaction and promotes protonation of the N-5 nitrogen, thereby facilitating the following hydride transfer reaction (Figs. 4(b) and (c)).

A general kinetic scheme with saturating NADPH has been proposed[12] as reproduced in Scheme 1. The V/K_{DHF} expression for the reaction described by Scheme 1 is given by Eq. 4. When log V/K_{DHF} is plotted versus pH, the curve described by Eq. 4 is half-bell-shaped with asymptotes given by Eqs. 9 and 10 at low and high pHs, respectively.

$$\log V/K_{DHF} = \log \left(\frac{k_1 k_3 k_9 E_T}{k_2 k_4 + k_2 k_9 + k_3 k_9} \right) \quad (9)$$

$$\log V/K_{DHF} = \log \left(\frac{k_1 k_3 k_9 E_T}{k_2 k_4 + k_2 k_9 + k_3 k_9} \right) - pH + pK_1 \quad (10)$$

It is apparent from these equations that the intersection of the asymptotes with slopes of 0 (Eq. 9) and -1 (Eq. 10) for the plot of log V/K_{DHF} against pH will occur at the point where $pH=pK_1$ and thus yield a true value for the ionizing group on the enzyme. Namely, the pK_a of 8.1 obtained from the log V/K_{DHF}-pH profile of the wild-type enzyme must be the intrinsic pK_a of DHFR.

Although the pK_a of 6.9 for Val-31 mutant obtained from the log V/K_{DHF}-pH profile (Fig. 1(b)) may be considered to be the intrinsic pK_a of the Val-31 mutant presuming that the general kinetic scheme (Scheme 1) still is applicable for this mutant enzyme, the same interpretation cannot be ascribed to the Tyr-31 mutant. In order to accomodate the "hollow" phenome-

nom observed in the log V/K_{DHF}-pH profile for the Tyr-31 mutant, Scheme 1 has been expanded as shown in Scheme 2, where the proton on Asp-27 in the ternary HE-NADPH-DHF complex can now communicate with the solvent. The V/K_{DHF} relationship for the expanded mechanism is described by Eq. 3 or 7. Since there are three pH-dependent terms in these equations, the "hollow" phenomenon can be rationalized. The minimum requirement to observe a hollow in a log V/K_{DHF}-pH profile is that the varied substrate is sticky, that is, the substrate dissociates from the enzyme more slowly than it reacts to yield products ($k_2<k_3$). Otherwise, if $k_2>k_3$, the V/K_{DHF} expression reduces to Eq. 11, with a single dependency on pH.

$$\frac{V}{K} = \frac{k_1k_3k_9(E_T)}{k_2(k_4+k_9)\left\{1+\frac{K_1}{(H)}\right\}} = \frac{C_1'}{\left\{1+\frac{K_1}{(H)}\right\}} \qquad (11)$$

From Eq. 3 the asymptotes of the log V/K_{DHF}-pH profile for the expanded mechanism described by Scheme 2 are calculated to give Eqs. 12 and 13 at low and high pHs, respectively.

$$\log V/K = \log C_1 \qquad (12)$$

$$\log V/K = \log C_1 + \log C_2 - \log C_3 - pH + pK_1 \qquad (13)$$

Thus, a true pK_1 value will not be obtained from the log V/K-pH profile of the expanded mechanism since the intersection will occur at the point where:

$$pH = pK_1 + \log C_2 - \log C_3. \qquad (14)$$

A theoretical line for the hollow of the Tyr-31 mutant is drawn in Fig. 2(c) according to Eq. 3 with the conditions of pK_1=5.8, C_1=5.3×10^6 (M^{-1} s^{-1}), C_2=0.1, and C_3=0.01. This fitting indicates that the apparent pK_a of Tyr-31 is shifted up by one pH unit from its intrinsic pK_1 of 5.8.

In order to confirm this intrinsic pK_a value of 5.8, inhibition studies by 2,4-diamino-6,7-dimethylpteridine were carried out according to Scheme 3. Judging from the two theorectical curves given in Fig. 3, the solid curve with pK_1=5.8 better fits to the experimental points than the dashed curve with pK_1=6.8 which were expected to be the intrinsic pK_a if the original mechanism of Scheme 1 were applicable to the Tyr-31 mutant enzyme. Thus, both the hollow and the inhibition studies are in accord with the intrinsic pK_a of 5.8 for the Tyr-31 mutant.

Conclusion

Examination of the engineered proteins (Tyr-31 DHFR and Val-31 DHFR) has clarified the kinetic sequence for wild-type DHFR. Specifically, the observation of a hollow in the pH-log V/K profile for the Tyr-31 mutant DHFR has necessitated a modification of the wild-type kinetic scheme (Scheme 1) to a more general case (Scheme 2), where the proton on Asp-27 in the ternary complex can now communicate with the solvent. This mechanism can adequately rationalize the kinetic data for both the wild-type and the mutant enzymes. In order to support further our mechanism, more detailed kinetic studies such as deuterium isotope effects and pre-steady state kinetics have been under taken.

We thank our colleagues, especially Ruth J. Mayer for the helpful discussions and Valerie Mizrahi and Patricia A. Benkovic for their suggestions at various stages of this study.

In Situ Trapping of NO: Application of *S*-Nitroso Derivatives for Metal Nitrosyls Synthesis

Daya Shankar PANDEY, S. K. SAINI,† and Umesh Chandra AGARWALA*
Chemistry Department, Indian Institute of Technology, Kanpur-208016, India
†Defence Materials & Stores Research & Development Establishment, P. B. No. 320, Kanpur, India
(Received June 26, 1986)

Several known nitrosyl complexes of Ru, Rh, and Co have been synthesized using *S*-nitroso organic compound (*S*-nitrosocysteine). Physicochemical methods such as IR, magnetic measurements, conductance measurements, and elemental analysis were used for characterization of the reaction products.

In situ trapping of NO as a synthetic procedure for metal-nitrosyls using *N*-nitroso derivatives ($\begin{matrix}R'\\R\end{matrix}$>N-NO) has been exploited in our earlier work[1] and an attempt was made there to generalize the method and to reduce multistep process for nitrosyl synthesis to a single-step one. It was also pointed out that the reactivity of a particular *N*-nitroso derivatives is a function of the substituents R and R′.

Because of our continuing interest in finding new procedures for metal nitrosylation, we looked into the possibility of employing recently synthesized *S*-nitroso derivatives[2] as nitrosylating agents which undergo dissociation reaction (2 RS-NO→R-S-S-R+ 2 NO) at varying temperatures depending upon the organic moiety linked to the sulfur. The temperature dependence of *S*-nitroso derivatives has further added an interest in us because for most of the cases the percentage yield of a particular metal nitrosyl using NO as a nitrosylating agent is temperature dependent. (Some metal nitrosyls can not be synthesized even at room temperature[3]). Thus there exists a possibility of choosing a S-nitroso derivative for a particular metal nitrosyl synthesis. The focus of this short note is to study the nitrosyl group transfer in solution from S-nitrosocysteine to metal centers (Ru, Rh, Co) in presence of other coligands.

Experimental

Chemically pure grade chemicals were used throughout. Microanalytical work has been carried out in the Microanalytical Lab. of the Indian Institute of Technology, Kanpur. Infrared spectra have been recorded on a Perkin-Elmer 580 Spectrophotometer in KBr discs. Magnetic measurements were made on a Guoy balance at room temperature. The results are given in Table 1.

Synthetic Reactions. Following are the procedures for the reactions of *S*-nitrosocysteine with the metal ions and their complexes. *S*-Nitrosocysteine was prepared by the literature method[4,5] (Cystine hereafter is referred as cys-cys).

(A) Reaction of $RuCl_3 \cdot xH_2O$ with *S*-Nitrosocysteine in the Presence of Triphenylphosphine. 40 ml of a solution containing 25 ml of ethanolic solution of $RuCl_3 \cdot xH_2O$ (0.5 mmol), triphenylphosphine (2 mmol), 15 ml of *S*-nitrosocysteine (0.48 mmol) in tris solution was heated under reflux for 40—45 min, whereupon shining yellow crystals of [Ru(cys-cys)$_2$Cl(NO)] were separated on cooling the solution. Crystals were filtered, washed with water, ethanol

Table 1.

Compound	Analysis: Calcd (Found)/%				
	C	H	N	X	S
$[RuCl(NO)(cys\text{-}cys)_2]H_2O$	21.6 (21.8)	3.6 (4.1)	10.5 (10.5)	5.4 (4.8)	19.2 (21.5)
$[RuCl_2(NO)(PPh_3)_2(cys\text{-}cys)]$	52.2 (53.9)	4.3 (4.1)	4.3 4.5)	7.1 (7.7)	6.4 (6.5)
$[RuCl_3(NO)(PPh_3)_2]$	56.9 (55.7)	4.1 (3.0)	2.0 (1.9)	14.3 (14.0)	— —
$[RhCl_2(NO)(PPh_3)_2]$	59.3 (58.7)	4.1 (3.8)	1.9 (2.3)	9.7 (10.4)	— —
$[RhCl_2(NO)(cys\text{-}cys)(PPh_3)]$	—	—	—	—	—
$[CoCl(NO)(bpy)_2]ClO_4$	44.8 (44.8)	3.0 (3.1)	13.0 (12.7)	12.8 (11.8)	— —
$[Co(NO)(NO_2)(bpy)_2]ClO_4$	42.7 (42.9)	2.8 (3.1)	14.9 (14.7)	6.2 6.3)	— —

and dried under vacuum.

(B) Reaction of $[RuCl_2(PPh_3)_3]$ with *S*-Nitrosocysteine. 15 ml of an aqueous solution of *S*-nitrosocysteine (0.48 mmol) was added to 10 ml ethanolic solution of $[RuCl_2(PPh_3)_3]$ (0.05 mmol) and the reaction mixture was heated to reflux for 40—45 min whereby a yellowish orange colored compound $[Ru(NO)Cl_2(cys\text{-}cys)(PPh_3)_2]$ was separated. It was filtered and washed as in (A) and dried in vacuum.

(C) Reaction of $[RuCl_2(PPh_3)_3]$ with S-Nitrosocysteine in Presence of $HgCl_2$. The procedure for carrying out the reaction was the same as that given in "B" except that 0.05 g of $HgCl_2$ was added to the reaction mixture. It resulted in the formation of a compound which was analyzed as $[Ru(NO)Cl_3(PPh_3)_2]$.

(D) Reaction of $[RuCl_2(PPh_3)_4]$ with *S*-Nitrosocysteine. 5 ml of an aqueous solution of *S*-nitrosocysteine was allowed to react with 10 ml of an ethanolic solution of $[RuCl_2(PPh_3)_4]$ by the procedure given in "B" whereupon $[Ru(NO)Cl_2(cys\text{-}cys)(PPh_3)]$ was precipitated out.

(E) Reaction of $[RhCl(PPh_3)_3]$ with *S*-Nitrosocysteine. A solution of $[RhCl(PPh_3)_3]$ (0.1 mmol) in 15 ml of ethanol was allowed to react with 15 ml of an aqueous solution of *S*-nitrosocysteine (0.5 mmol), according to the procedure given in "B" whereby $[Rh(NO)Cl_2(PPh_3)]$cys-cys was separated

The same reaction when carried out in presence of $HgCl_2$ yielded $[Rh(NO)Cl_2(PPh_3)_2]$.

(F) Reaction of $CoCl_2\cdot 6H_2O$ with *S*-Nitrosocysteine in Presence of $LiClO_4$ and 2,2′-Bipyridyl. $CoCl_2\cdot 6H_2O$ (0.25 g) and $LiClO_4$ (0.2 g) were dissolved in 20 ml of absolute ethanol and the solution was deaerated by flushing with nitrogen. A solution of 2,2′-bipyridyl (0.37 g) dissolved in hot ethanol (10 ml) was slowly added to the $CoCl_2$ solution under nitrogen, followed by the addition of *S*-nitrosocysteine (0.25 g) in 15 ml water. The resulting solution was stirred at room temperature for 30 minutes, whereby brown microcrystalline compound $[Co(bpy)_2Cl(NO)]ClO_4$ was separated. It was filtered, washed with ethanol, ether and dried under vacuum.

(G) Reaction of $CoCl_2\cdot 6H_2O$ with *S*-Nitrosocysteine in the Presence of $LiClO_4$, $NaNO_2$, and 2,2′-Bipyridyl. 0.15 g 2,2′-bipyridyl, 0.5 g $LiClO_4$, and 0.04 g $NaNO_2$ were mixed in 10 ml of ethanolic solution of $CoCl_2\cdot 6H_2O$ (0.15 g) and deaerated with N_2 gas, followed by the addition of 15 ml of *S*-nitrosocysteine solution in water. The color of the solution turned brown and finally a yellowish brown solid was separated out. It was filtered, washed with ethanol and ether and dried under vacuum. The compound was analyzed for $[Co(bpy)_2(NO)(NO_2)]ClO_4$.

Results and Discussion

The empirical formulae of the compounds resulting by the interaction of *S*-nitrosocysteine with metal ions are enlisted in Table 1. The bright yellow diamagnetic Ru(II) complex $[RuCl(NO)(cys\text{-}cys)_2]$ exhibited in its IR spectrum a band at 1870 cm^{-1} corresponding to ν(NO) besides the characteristic bands of cystine. The positions of all cystine bands (3500, 2900, 2565, 1742, 1577, 1521, 1231, 1216, and 876 cm^{-1}) except one around 1700 cm^{-1} (assigned to ν(CO) of COO^- group) remained constant. The lowering of 1700 cm^{-1} band position suggested bonding of ruthenium through COO^- moiety. Presuming ruthenium in +2 oxidation state with a formal charge of +1 on NO [ν(NO), 1870 cm^{-1}] the charge balance required cystine to be bonded with ruthenium as uninegative ion (Dipositive ruthenium in the complex is also suggested by its diamagnetic nature). It is therefore, assumed that the binding of cystine with ruthenium occurs through COOH group after deprotonation. Further six being the preferred coordination number of Ru(II) in its complexes[6] each cystine anion should provide two bonding sites to the metal center which could be either another oxygen, sulfur or nitrogen atom. Although it is difficult to decide the second donor site, but since the positions of other IR bands assigned to cystine remained practically unaltered, we tentatively assume oxygen atom of the COO^- group to be another bonding site. It is, however, only tentative.

An orange yellow complex having an empirical formula $[RuCl_2(NO)(PPh_3)_2(cys\text{-}cys)]$ has been obtained by the reaction of $[RuCl_2(PPh_3)_3]$ with *S*-nitrosocysteine. The IR spectrum exhibited the characteristic bands of PPh_3 and cystine. The position of ν(CO) of cystine also shifted to lower wave number suggesting the bonding of ruthenium with carboxyl group after deprotonation because of the charge balance as discussed in the preceding paragraph.

It appears that in both Ru(II) complexes sites above cystine formed during the decomposition of *S*-nitrosocysteine also coordinated to ruthenium along with NO group. In order to inhibit the cystine coordination during the reaction, a strategy of removing the cystine from the reaction site formed after decomposition of *S*-nitroso compound was thought. If the reaction is performed in presence of $HgCl_2$, the latter will not only catalyze the decomposition of *S*-nitroso compound[7] but will also pickup preferentially the formed organothio radical leaving NO radical for coordination with the metal ion in accordance with the following reaction:

Thus, the reaction when carried out in the presence of excess $HgCl_2$ yielded pure $[RuCl_3(NO)(PPh_3)_2]$ in our reactions.

Similar to ruthenium complexes the reaction of $[RhCl(PPh_3)_3]$ with *S*-nitrosocysteine yielded a mixture of $[RhCl_2(NO)(PPh_3)(cys\text{-}cys)]$ and $[RhCl_2(NO)(PPh_3)_2]$. However, the same reaction in presence of $HgCl_2$ yielded pure literature known compound $[RhCl_2(NO)(PPh_3)_2]$.

The reaction of Co(II) salts with the *S*-nitroso compound did not yield a complex having bonded cystine even under varying reaction conditions. These reac-

tions, however, yielded pure literature known complexes (Table 1). Possibly Co(II), being 'a' class metal ions may not bind preferentially with sulfur-containing cystine in presence of a better base, viz 2,2′-bipyridyl. The literature known complexes viz. $[RuCl_3(NO)(PPh_3)_2]$,[8] $[RhCl_2(NO)(PPh_3)_2]$,[9] $[CoCl(NO)(bipy)_2]ClO_4$,[10] $[Co(NO_2)(NO)(bpy)_2]ClO_4$[10] were identified by comparing their mp mixed mp spectral (IR, UV, and visible) and magnetic properties with the authenticated samples prepared by the literature methods.

It is evident from the above discussion that there exists a definite possibility of applying successfully *S*-nitrosococysteine, in particular, and *S*-nitroso derivatives, in general, for metal nitrosylation reactions. It is also obvious that the competitive reaction of the generated organothio radical to link with the metal ion (particularly b-class) along with its dimerization can be inhibited by adding excess $HgCl_2$ which not only assists in removing the thio radical from the reaction but also catalyzes the decomposition of S-nitroso compounds. Further work in this direction is in progress where the application of the method will be utilized for the nitrosylation of other metal ions with other *S*-nitroso derivatives, especially those having stability at low temperature. The latter reactions will be carried out with those metal ions where nitrosyls are obtained only at low temperature.

The Superconductive Compound of the Ba-Y-Cu Oxide

Akira ONO* and Masayuki TSUTSUMI
National Institute for Research in Inorganic Materials, Namiki, Ibaraki 305
(Received March 16, 1987)

Synopsis. Chemical composition of a novel compound in the Ba-Y-Cu-O system is determined. Formulae of the phase is $Ba_4Y_2Cu_7O_{14}$. X-Ray powder pattern can be indexed successfully on the basis of an orthorhombic unit cell. Stability of the phase is preliminary studied by a thermogravimetric method.

Recently, superconductivity of oxide compounds has been reported in the Ba-La-Cu-O and Ba-Y-Cu-O systems.[1-3] In the latter system, the resistivity drop sets in at 95 K, above the stability range of liquid N_2.[3] The phase responsible for the superconductivity is, however, not identified. We have synthesized a novel compound as a nearly pure single phase of which resistivity is zero at 77 K. This paper describes the synthesis, stability, chemical composition, X-ray, and resistivity properties of this novel compound in Ba-Y-Cu-O system.

The compound was prepared by mixing the prescribed amount of powders of Y_2O_3, $BaCO_3$, and CuO followed by reacting the mixture at 900 °C for 10—15 h in air. Re-mixing and re-heating for each run were carried out at least two times during the heat-treatment. The compound prepared was pelletized and sintered at 900—950 °C in air.

The crystalline phases were analyzed on a polished section of the sintered specimen with an electron probe microanalyzer, JXA 5A using standard crystals of a snythetic xenotime (YPO_4), polycrystalline CuO and a synthetic $Ba_{0.75}Al_{11.0}O_{17.25}$.[4] Correction procedure used was the Bence-Albee method.[5] Based on the analytical data of the superconductive material, the mixing ratio of Ba, Y, and Cu of the starting material were determined as 4 : 2 : 7 in the atomic ratio.

The X-ray properties of the material prepared were recorded with a diffractometer JEOL TDX-7F using Cu $K\alpha$ radiation with quartz as internal standard. Thermogravimetric analysis was carried out with an thermogravimetor, ULVAC TA 1500, at a heating rate of 10 K min^{-1}. Surfaces of the powdered specimens were observed with a scanning electron microscope, Akashi, DS 130.

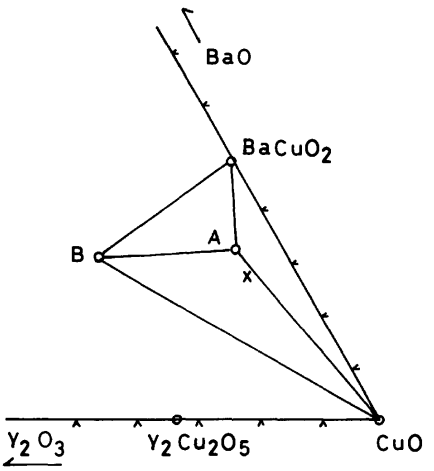

Fig. 1. Phase relations in the BaO-Y_2O_3-CuO system at 900 °C in air. A: $Ba_4Y_2Cu_7O_{14}$. B: $Ba_4Y_8Cu_5O_{21}$.

Figure 1 shows the phase relation in the BaO-Y_2O_3-CuO system at 900 °C in air. Three phases, CuO, $Ba_4Y_2Cu_7O_{14}$, and $BaCuO_2$ exist in the vicinity of the superconduction phase "A". A sintered specimen of the bulk composition X in Fig. 1 consist of CuO, $Ba_4Y_8Cu_5O_{21}$, and the superconductive phase. The chemical compositions of these phases are given in Table 1. These analyses are based on the assumption that the valency of Cu is +2 in these crystals. Y and Ba contents in the crystalline CuO are negligibly small. $Ba_4Y_8Cu_5O_{21}$ has a large and euhedral crystal form. Chemical formula of the superconductive phase may be represented as $Ba_4Y_2Cu_7O_{14}$.

X-Ray powder patterns of the superconductive

Table 1. Chemical Compositions of the Crystalline Phases

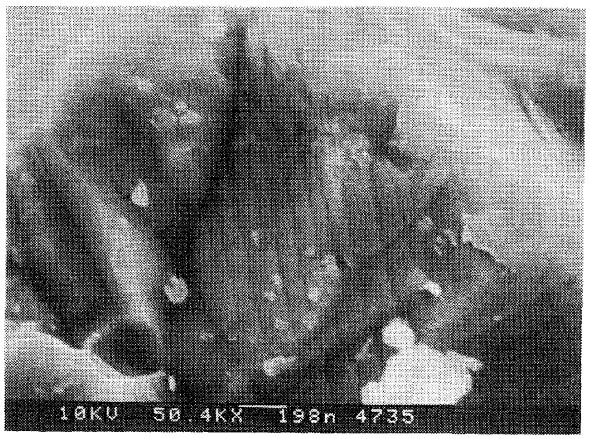

Fig. 3. Scanning electron microscopic image of the superconductive phase. Scale bar: 198 nm.

phase change considerably with heating time. Difference of the lattice parameters a and b become large with increasing heating time. At the same time X-ray peaks of impurity phases decrease its intensities with increasing heating time. An X-ray pattern of well-crystallized material is given in Table 2, which can be indexed on the basis of orthorhombic unit cell with a=3.8857(9) Å, b=3.8267(8) Å, c=11.681(4) Å. Possible space groups are P222, Pmm2, and Pmm. The unit cell dimensions are similar to those of $LaSrVO_4$,[6] and the presence of 001 peak indicates that the crystal symmetry differs from that of La_2CuO_4. The value $c/3$ is similar to those of a and b, so that this crystal is a distorted cubic phase.

Figure 2 illustrates a thermogravimetric curve of powdered superconductive materials synthesized at 900 °C in air. Weight gain takes place near 400 °C with subsequent gradual weight loss. These weight changes may be due to the change of oxygen content in the specimen. However, further study is needed for the confirmation. Considerable weight losses take place in the two different temperature ranges, namely from 900 to 950 and from 950 to 1000 °C. The former loss is due to partial decomposition of the superconductive phase. The latter one may be due to its partial melting.

Our specimens were obtained at 900 °C in air. The heating temperature is slightly above the decomposition temperature of the superconductive phase. This is a reason why small amount of impurity phases (mainly CuO of about 5—10% by volume) were detected in the X-ray diffraction pattern and on the polished section of the sintered material. A study on the compositional change of the superconductive phase as a function of temperature is now in progress.

A scanning electron microscopic image of the fractured surface of the superconductive crystal is shown in Fig. 3. Fine banding structure was observed in most of the crystals. This structure may be transition twin induced during the transformation of high temperature phase with tetragonal or higher symmetry to low temperature orthorhombic phase.

Electrical resistivity of the superconductive phase has been measured from 65 K to room temperature. The methods of the measurements and the results will be described in detail in near future. The resistivity is several m Ω cm at room temperature. Onset temperature of the superconductivity is 103 K, and the final drop is ended at 85 K.

We thanks Dr. Fujio Izumi for re-indexing our initial indexing based on the reduced cell and computing the lattice parameters. Dr. Yoshio Ishizawa was kindly enough to measure electrical resistivity of the specimens.

Synthetic Photochemistry. XXXVIII.[1] The Photorearrangement of the Tropone Endoperoxide, 6,7-Dioxabicyclo-[3.2.2]nona-3,8-dien-2-one

Akira MORI and Hitoshi TAKESHITA*
Research Institute of Industrial Science, 86, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816
(Received March 3, 1987)

Synopsis. The photolysis of 6,7-dioxabicyclo[3.2.2]nona-3,8-dien-2-one produced six photolysates, including a cage γ-lactone which belongs to the same type of product as was characterized in each case of the photolysis of the endoperoxides derived from 2-aryl- and 2,7-diaryltropones by Mukai et al. The new products identified were 2,7-dioxabicyclo-[3.2.2]nona-3,8-dien-6-one, a δ-lactone acetal, and 7-exo-formyl-3-oxabicyclo[4.1.0]hept-4-en-2-one, a δ-lactone.

In 1970's, Mukai et al. discovered a photorearrangement of several 1-aryl-, 3-aryl, and 1,3-diaryl-6,7-dioxabicyclo[3.2.2]nona-3,8-dien-2-ones **1a—c**, and the endoperoxides derived from 2-aryl- and 2,7-diaryltropones, to cage γ-lactones **2a—c**.[2] Then, by means of low-temperature IR spectroscopy, they identified a bicyclic ketene as the intermediate leading to the photolysate.[3] On this basis, they proposed a reaction sequence from the endoperoxides **1** to ketene **A** and cage lactones **2**, and explained the mechanism in terms of a transannular interaction of the enone and the isolated double bond[4] in the molecule.

Although, unfortunately, they failed[2] to isolate or characterize any photolysate other than **2**, it is hardly conceivable that the ketene intermediate results selectively in only one type of product. In addition, recently we ourselves have noticed a transannular interaction of the enone part and the dioxa linkage in related compounds.[5] Furthermore, Mukai et al. have stated[2] that no product could be identified in the photolysis mixture of the parent tropone endoperoxide, 6,7-dioxabicyclo[3.2.2]nona-3,8-dien-2-one (**3**).[6] These findings prompted us to carry out a reinvestigation of Mukai's experiments with a synthetically useful parent compound, **3**.[7] The results, identifying six products **4—9**, will be presented briefly.

The irradiation of a benzene solution of the parent peroxide **3** by means of a high-pressure mercury lamp caused a rapid photolysis. The products could be isolated by means of silica-gel chromatography; the structures were deduced mainly from the NMR spectra,[9] which revealed mutually-coupled methine proton systems, allowing for a first-order analysis.

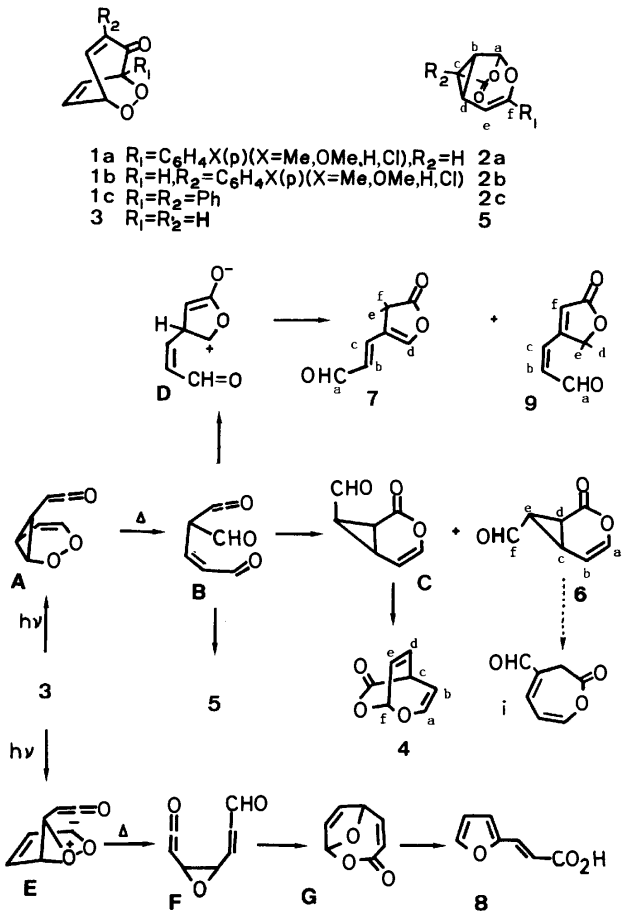
The least polar product **4**, one of the major products, was a bicyclic acetal δ-lactone, showing the carbonyl absorption[9] at 1775 cm^{-1}; an analysis of the whole coupling sequence of protons, four of which were on the sp^2-carbons, by means of an intensive double-irradiation technique,[10] enables us to deduce that **4** was 2,7-dioxabicyclo[3.2.2]nona-3,8-dien-6-one.

Another major product (**5**=**2**; R_1=R_2=H) was shown to be a cyclopropane-containing compound; the characteristic 4-alkoxy-γ-lactone absorption was observed at ν: 1782 cm^{-1}. The well-separated ^1H NMR spectrum of this tricyclic compound, 2,8-dioxatricyclo[4.2.1.$0^{5,9}$]-non-3-en-7-one, showed a close resemblance to those of the reported photolysates **2a—c** from **1a—c**.[2] The third product, an enol δ-lactone aldehyde (**6**) [IR ν: 1760 and 1715 cm^{-1}], was deduced to be 7-exo-formyl-3-oxabicyclo[4.1.0]hept-4-en-2-one on the basis of the spectroscopic data.

The fourth photolysate **7** was an aldehydic enol γ-lactone [IR ν: 1830 and 1807 cm^{-1}]; its structure was deduced by means of detailed ^1H and ^{13}C NMR spectral analyses.

The most polar photolysate **8** was 3-(2-furyl)acrylic acid, as was confirmed by direct comparison with an authentic sample.[11] The remaining photoproduct **9** was obtained in a mixture with the furylacrylic acid **8**. Its ^1H NMR spectral data were compatible with those of 3-(2,5-dihydro-5-oxo-3-furyl)acrylaldehyde.[12]

The present results show a much improved material balance (50% vs. trace to 21%) compared to those of previous studies by Mukai et al.[2] It is now possible to



Scheme 1.

discuss the general features of this photorearrangement. There is no photoproduct with a peroxy group, and the absence of an alcoholic function eliminates the heterolytic cleavage of the peroxy linkage. Consequently, the peroxy group might have been transformed via the electrocyclic processes during the irradiation, but it is difficult to explain the formation of all the new photolysates by means of Mukai's mechanism, that is, via a ketene intermediate **A**. These products can thus be classified into two groups according to the *proto*-photolysates, precursor ketenes: i.e., Type I (**4**—**7** and **9**) and Type II (**8**). All the Type I products carry a branched side chain from the α- or β-carbon to the carboxylic carbon, and all could be derived from ketene **A**. Its cycloreversion should give **B**, with which an intramolecular Diels-Alder reaction should form C and its stereoisomer, **6**.[13] Cage lactone acetals, **4** and **5**, could be derived from **C** and **B** respectively, and the furanones, **7** and **9**, should be formed by cyclization at the ketene and aldehyde moieties of **B** to a precursor cyclisate (**D**), followed by two ways of hydrogen transfer. On the other hand, the formation of the remaining compound, **8**, a free carboxylic acid, of Type II, could be explained in terms of another precursor: The ketene E, with a zwitterionic peroxirane group and resulting from a transannular reaction of the α,β-unsaturated keto group and the peroxide linkage, might be isomerized to a neutral epoxy ketene (**F**), which, via a bicyclic ε-lactone (**G**), should afford **8**.

Consequently, the photolysates isolated and characterized from **3** in this study show that the reaction is not so simple as was reported by Mukai et al.; particularly, the formation of **8** must be explained by another precursor, E, with a peroxirane structure.

Experimental

The UV-Light Irradiation of 6,7-Dioxabicyclo[3.2.2]nona-3,8-dien-2-one. A benzene solution (5 cm^3) of **3** (163 mg) was irradiated by means of a 400-W high-pressure mercury lamp through a Pyrex glass filter at 10—20 °C under an N_2 atmosphere for 2 h. The reaction was monitored by the disappearance of the **3** in high-pressure liquid chromatography. The residual mixture obtained by the evaporation of the solvent was then chromatographed on a silica-gel column and eluted with benzene-ethyl acetate to obtain the respective products:

8) The NMR spectra were measured in $CDCl_3$ solutions, unless otherwise stated, and the chemical shifts were expressed in δ units. The IR spectra were taken as liquid films.

9) The $\nu_{(C=O)}$ of 1,5,5-trimethyl-2,6-dioxabicyclo[2.2.2]-octan-3-one appeared at 1773 cm^{-1}. See I. D. Rae and A. M. Redwood, *Austr. J. Chem.*, **27**, 1143 (1974).

10) This was analyzed by means of the 400-MHz ^{1}H NMR spectrum.

11) B. Capron, C. Paulmier, and P. Pastour, *Bull. Soc. Chim. Fr.*, **1975**, 2575.

12) The carboxylic acid function could not be derived by an auto-oxidation of the aldehydic function; **4**—**7**, and **9** are all on the same oxidation level as **8**.

13) Frequently, an aldehyde **i**, apparently derived from **6**, was identified among the photolysates; its ^{1}H NMR spectrum [δ=3.16 (2H, s), 6.38 (1H, dd, J=12, 6 Hz), 6.98 (1H, d, J=6 Hz), 6.98 (1H, d, J=12 Hz), and 9.48 (1H, s)] indicated the structure depicted.

Fries Rearrangement of 1-Methoxy-4-(4-methyl-2- and -3-pentenoyloxy)benzenes[1)]

Yasuhiro TANOUE and Akira TERADA*
Department of Chemistry, Kyushu Institute of Technology, Tobata, Kitakyushu 804
(Received March 16, 1987)

Synopsis. Not only rearrangement but also cyclization occurred in a Fries rearrangement of 1-methoxy-4-(4-methyl-2- and -3-pentenoyloxy)benzenes and gave 5,8-dihydroxy-4,4-dimethyl-3,4-dihydro-1(2*H*)-naphthalenone. The reduction and oxidation of the dihydronaphthalenone gave 5-hydroxy-8,8-dimethyl-5,6,7,8-tetrahydro-1,4-naphthalenedione and 8,8-dimethyl-7,8-dihydro-1,4,5(6*H*)-naphthalenetrione, respectively.

Naphthoquinone compounds occur widely in nature among plants and fungi.[2)] They have been studied not only with regard to their pigment and structure[3)] but also concerning expectations of physiological activity.[4)] We have recently reported the total synthesis of shikalkin[(±)Shikonin], 5,8-dihydroxy-2-(1-hydroxy-4-methyl-3-pentenyl)-1,4-naphthoquinone.[5)] This paper deals with a result of Fries rearrangements of phenolic esters, 1-methoxy-4-(4-methyl-2- and -3-pentenoyloxy)benzenes, as a model reaction for the introduction of the side chain of shikonin, 1-hydroxy-4-methyl-3-pentenyl moiety, to a phenolic nucleus. The product, 5,8-dihydroxy-4,4-dimethyl-3,4-dihydro-1(2*H*)-naphthalenone(**5**), was derived to 5-hydroxy-8,8-dimethyl-5,6,7,8-tetrahydro-1,4-naphthalenedione(**6**) and 8,8-dimethyl-7,8-dihydro-1,4,5(6*H*)-naphthalenetrione(**7**).

Results and Discussion

Following Caspi's procedure,[6)] a reaction of isobutyraldehyde with malonic acid in pyridine gave *trans*-4-methyl-2-pentenoic acid (**1**). This was then isomerized with alkali to 4-methyl-3-pentenoic acid (**2**). However, this isomerization did not proceed completely and gave an equilibrated isomeric mixture of **1** and **2**. The ^{1}H NMR spectrum of this mixture showed that it contained about 24% acid **1** and 76% of **2**. Since an attempted separation of these isomers was not successful, this acid mixture was used in the next step: treatment with thionyl chloride gave the corresponding acid chlorides, **3a** and **3b**.

p-Methoxyphenol was allowed to react with the acid chlorides to give a mixture of phenolic esters **4a** and **4b** in 68% yield. The ratio of **4a** and **4b** was about 3 : 1 by ^{1}H NMR. The treatment of an ester mixture **4a** and **4b** with a molten mixture of aluminum chloride and sodium chloride prepared at 180 °C, gave a crystalline product in 24% yield. The ^{1}H NMR spectrum showed two signals at δ 12.3 and 8.1 due to the phenolic hydroxyl groups; the former suggested the existence of a strongly hydrogen bonded OH. A single peak at δ 1.5 was due to two methyl groups and the signals of methine groups in the starting materials (**4a**: $-CH=C(CH_3)_2$ and **4b**: $-CH=CHCH(CH_3)_2$) had disappeared. These spectral data could indicate only a cyclic ketone, **5**.

It can be concluded that the Fries rearrangement described here was accompanied with cyclization and demethylation. A Fries rearrangement of pure ester **4b**[7)] also resulted in the formation of cyclic ketone **5** in 16% yield. These results suggested that a rearrangement of the carbon-carbon double bond in the side chain of **4b** had occured. Ketone **5** was also prepared from **4** in 38% yield by using boron trifluoride etherate instead of a molten mixture of $AlCl_3$–NaCl.

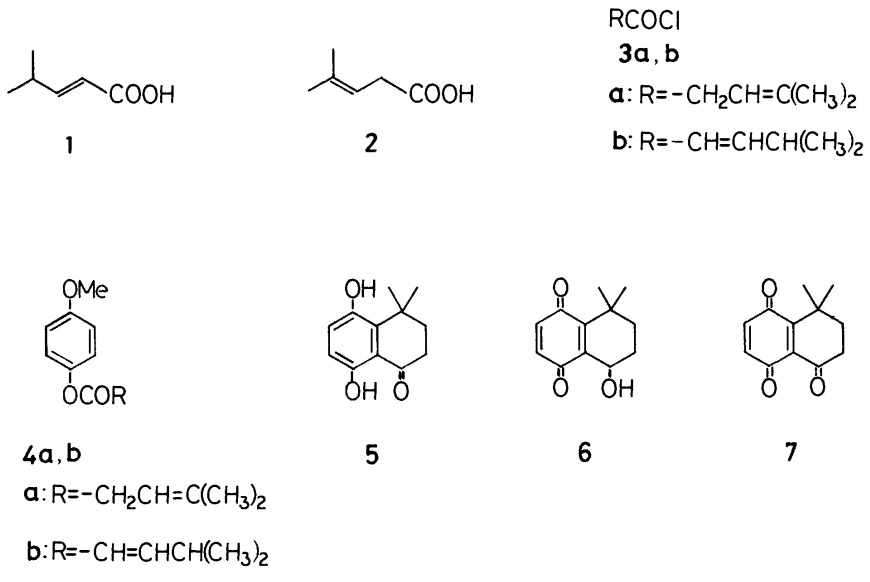

Fig. 1.

A reduction of **5** with lithium aluminum hydride in tetrahydrofuran and subsequent air-oxidation gave **6** in 37% yield.

A oxidation of **5** with ceric (IV) ammonium nitrate gave **7** in 79% yield.

Experimental

^{1}H NMR spectra were taken on a JEOL JNM-FX60 spectrometer using tetramethylsilane as an internal standard; the chemical shifts were reported in δ values. Mass spectral data were obtained with a JEOL DX-300. Infrared spectra were recorded on a Hitachi 260-30 infrared spectrometer and the UV spectra on a Shimadzu recording spectrometer UV-200S. Column chromatography was performed on silica gel (Wakogel C-200). Melting points were determined with a Yanagimoto micromelting point apparatus and were uncorrected.

4-Methyl-3-pentenoyl Chloride (3a) and 4-Methyl-2-pentenoyl Chloride (3b) Mixture. 4-Methyl-3-pentenoic acid **2** (16.8 g, 0.147 mol, containing ca. 24% of **1**) was added dropwise to thionyl chloride (21.0 g, 0.176 mol) under reflux and the mixture was refluxed for another 30 min, then fractionally distilled under reduced pressure to give 14.6 g (75%) of an oil of **3** (**3a**:**3b**=3:1), bp 55—58 °C/22 mmHg (1 mmHg=133.322 Pa). IR (neat) 1795 (C=O), 1755 (C=O), 1625 (C=C), 1030, and 960 cm^{-1}; MS *m/z* 134(M^++2), 132 (M^+), 97, and 69; ^{1}H NMR ($CDCl_3$) **3a**: δ=1.64, 1.74 (6H, $2CH_3$), 3.61 (d, *J*=6.8 Hz, 2H, CH_2), and 5.28 (m, 1H, CH); **3b**: δ=1.04, 1.14 (6H, $2CH_3$), 2.41 (m, 1H, CH), 6.09 (dd, *J*=15.5 and 1.0 Hz, 1H, COCH=CH), and 7.32 (dd, *J*=15.5 and 6.0 Hz, 1H, COCH=CH).

1-Methoxy-4-(4-methyl-3-pentenoyloxy)benzene (4a) and 1-Methoxy-4-(4-methyl-2-pentenoyloxy)benzene (4b) Mixture. A mixture of *p*-methoxyphenol (9.2 g, 74.2 mmol) and the acid chloride mixture **3** (10 g, 75 mmol) was refluxed until the evolution of hydrogen chloride ceased. The reaction product was distilled under reduced pressure to give 11.2 g (68%) of an oil, **4** (**4a**:**4b**=3:1), bp 180—186 °C/20 mmHg. IR (neat) 2850 (OCH_3), 1760 (C=O), 1650 (C=C), 1250, 1196, and 1035 cm^{-1}; MS *m/z* 220 (M^+), 124, and 97; ^{1}H NMR ($CDCl_3$) **4a**: δ=1.69, 1.77 (6H, $2CH_3$), 3.23 (d, *J*=7.3 Hz, 2H, CH_2), 3.74 (s, 3H, OCH_3), 5.39 (m, 1H, CH), and 6.9 (m, 4H, ArH); **4b**: δ=1.03, 1.15 (6H, $2CH_3$), 2.58 (m, 1H, CH), 3.74 (s, 3H, OCH_3), 5.93 (dd, *J*=15.6 and 1.0 Hz, COCH=CH), 6.9 (m, 4H, ArH), and 7.1 (dd, *J*=15.6 and 7.2 Hz, 1H, COCH=CH). Found: C, 70.74; H, 7.45%. Calcd for $C_{13}H_{16}O_3$: C, 70.89; H, 7.32%.

5,8-Dihydroxy-4,4-dimethyl-3,4-dihydro-1(2*H*)-naphthalenone (5). A. 5 from 4 (4a and 4b Mixture) by Using Aluminum Chloride and Sodium Chloride Molten Mixture. A mixture of anhydrous aluminum chloride (30 g) and sodium chloride (10 g) was melted at 180 °C, and to this was added dropwise the ester **4** (7.8 g, 35 mmol) under vigorous stirring. After 10 min, the obtained pasty mass was decomposed by the addition of dil. hydrochloric acid and extracted with ether. The ether solution was washed with water, dried, and evaporated. The crude product was recrystallized from hexane-tetrahydrofuran to give 1.70 g (24%) of **5** as yellow crystals, mp 239—240 °C. IR (KBr) 3300 (OH), 2950, 1623 (C=O), 1475, and 1240 cm^{-1} (OH); MS *m/z* 206 (M^+), 191, and 163; ^{1}H NMR ($(CD_3)_2CO$) δ=1.53 (s, 6H, CH_3), 1.91 (m, 2H, CH_2), 2.71 (m, 2H, CH_2), 6.62 (d, *J*=9.2 Hz, 1H, ArH), 7.08 (d, *J*=9.2 Hz, 1H, ArH), 8.11 (s, 1H, OH), and 12.34 (s, 1H, OH); UV (dioxane) 264 (ε 13800) and 368 nm (ε 7900). Found: C, 69.68; H, 6.78%. Calcd for $C_{12}H_{14}O_3$: C, 69.89; H, 6.84%.

B. 5 from 4b by Using Aluminum Chloride and Sodium Chloride Molten Mixture. The reaction of **4b**[7] (5.18 g, 24 mmol) with a molten mixture of aluminum chloride (15 g) and sodium chloride (1.3 g) was carried out by the procedure described above and gave 0.80 g (16%) of **5**, mp 238—240 °C. All the spectral data agreed with those of **5** prepared from method A.

C. 5 from 4 (4a and 4b Mixture) by Boron Trifluoride Etherate. Boron trifluoride etherate (1.2 ml, 9.6 mmol) was added dropwise to the ester **4** (680 mg, 3.2 mmol) at 140 °C, and after 10 min, was decomposed by addition of dil hydrochloric acid and extracted with chloroform. The usual work-up and chromatography on silica gel with chloroform gave 250 mg (38%) of a sample of **5**. Recrystallization from ligroine-benzene gave an analytical sample, mp 239—241 °C. All the spectral data agreed with those of **5** prepared from method A.

5-Hydroxy-8,8-dimethyl-5,6,7,8-tetrahydro-1,4-naphthalenedione (6). Lithium aluminum hydride (36 mg, 0.97 mmol) was added to a solution of the ketone **5** (100 mg, 0.485 mmol) in tetrahydrofuran (2 ml), stirred at room temperature for 1 h, decomposed with ice water, and extracted with chloroform. The usual work-up and chromatography on silica gel with chloroform gave 37 mg (37%) of a sample of **6** as a semisolid, mp 69—73 °C. IR (KBr) 3410 (OH) and 1645 cm^{-1} (C=O); MS *m/z* 206 (M^+), 188, 173, 151, and 123; HRMS *m/z* calcd for $C_{12}H_{14}O_3$ 206.0943, found 206.0945; ^{1}H NMR ($CDCl_3$) δ=1.29 (s, 3H, CH_3), 1.37 (s, 3H, CH_3), 1.6—2.0 (m, 4H, $2CH_2$), 3.18 (d, *J*=2.6 Hz 1H, OH), 4.72 (m, 1H, CH), and 6.67 (s, 2H, quinonoid ring H).

8,8-Dimethyl-7,8-dihydro-1,4,5(6*H*)-naphthalenetrione (7). A solution of ceric(IV) ammonium nitrate (800 mg, 1.46 mmol) in water (5 ml) was added dropwise to a solution of **5** (100 mg, 0.49 mmol) in tetrahydrofuran (5 ml) at room temperature, stirred for 1 h, diluted with water, and extracted with chloroform. The usual work-up and chromatography on silica gel with chloroform gave 78 mg (79%) of a sample of **7**. Recrystallization from hexane gave an analytical sample, mp 120—121 °C. IR (KBr) 1705 (C=O), 1660 (C=O), 1285, and 855 cm^{-1}; MS *m/z* 204 (M^+), 189, 161, and 149; ^{1}H NMR ($CDCl_3$) δ=1.47 (s, 6H, $2CH_3$), 1.94 (m, 2H, CH_2), 2.67 (m, 2H, CH_2), and 6.71 (s, 2H, quinonoid ring H). Found: C, 70.58; H, 5.92%. Calcd for $C_{12}H_{12}O_3$: C, 69.92; H, 6.18%.

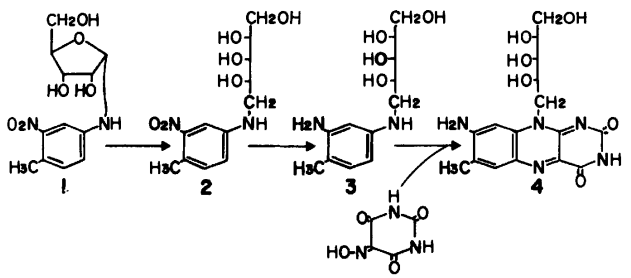
An Improved Synthesis of 8-Amino-8-demethylriboflavin

Sabu KASAI,* Bernhard J. FRITZ, and Kunio MATSUI
Research Institute for Atomic Energy, Osaka City University, Sugimoto, Sumiyoshi-ku, Osaka 558
(Received March 25, 1987)

Synopsis. 8-Amino-8-demethylriboflavin was synthesized from 3-nitro-4-methylaniline *N*-D-riboside by selective reduction of the *N*-glycoside with sodium borohydride, followed by hydrogenation of the nitro group in the presence of Raney's catalyst. The obtained phenylenediamine was condensed with violuric acid to give the flavin in a high yield.

8-Amino-8-demethylriboflavin (**4**) has been used as a riboflavin (RF) analogue to study reaction mechanisms of flavoenzymes,[2] flavin-protein interactions,[3,4] or antimicrobial action.[1,5] **4** has a low redox potential (about 100 mV lower than RF),[1] and both the conjugation system and the stability of the semiquinone differ from those of RF.[1,2,12] Moreover, **4** is a key compound from which many 8-substituted flavins can be derived via diazotization,[9,10] and 8-substituted flavins such as the naturally occuring 8-hydroxy-8-demethylriboflavin,[6-8] have been used widely. It is noteworthy that most flavins used in biochemical studies carry a ribityl group at 10-position of the isoalloxazine ring, whereas in purely chemical research usually lumiflavin derivatives are used.

4 was already synthesized by Berezovskii et al.,[11] but, using their method, we achieved only low yields of 5 to 10%. In the final step, a dark powder was obtained, making the purification tedious. If the reduction of the riboside is carried out in one step as given by Berezovskii et al., there exists the possibility that the nitro group is reduced first, followed by migration of the ribosyl group. Upon condensation with violuric acid, a product of the lumichrome type would be obtained. We figured this to be the main reason for the low yield of above method, and aimed to reduce first the riboside selectively, thus preventing the migration of the ribosyl group. This was achieved by using excess sodium borohydride in refluxing ethanol. The reaction can also be carried out with sodium cyanotrihydroborate, where smaller amounts of the reductant are sufficient. Samples prepared according to our



method gave analytical results and absorption spectra identical to samples prepared by us according to Berezovskii et al.

Experimental

Mass spectrum (field desorption) was taken on a JEOL JMS-01SG-2; IR spectrum was recorded on a JASCO model IRA grating infrared spectrophotometer; UV spectra were recorded on a Hitachi 320 recording spectrophotometer; 400 MHz ^{1}H NMR spectra were taken with a JEOL model JMM GX 400. Melting points were measured with a Yanaco MP micro melting point apparatus.

3-Nitro-4-methyl-*N*-ribitylaniline (2). Two grams of 3-nitro-4-methylaniline *N*-D-riboside (**1**)[11] was dissolved in 20 ml ethanol and sodium borohydride (1.5 g) was added. The reaction mixture was refluxed for 1.5 h under stirring, during which the color of the solution changed from orange to red. After cooling to room temperature, the solution was neutralized with 1 M (mol dm^{-3}) hydrochloric acid and evaporated to dryness. A small amount of methanol was added to the residue. Salt precipitated, which was filtered and washed. Filtrates were combined, evaporated, redissolved in a 8:2 mixture of dichloromethane and methanol, charged on a silica-gel column (Wakogel C-200, Wako Pure Chemical Industries, Ltd., 3 cm×20 cm), and developed with the same solvent. Red fractions were collected and evaporated. Attempts to crystallize the syrup from several solvents were unsuccessful. FD-MS: Found *m/z* 286.0. Calcd for $C_{12}H_{18}O_6N_2$: M, 286.28.; IR (Nujol) 1545 and 1350 cm^{-1} (NO_2).

The syrup obtained above was dissolved in 10 ml ethanol and hydrogen chloride gas was introduced into the solution under cooling, upon which the color of the solution changed from red to light brown. 30 ml of diisopropyl ether were added to the solution and 3-nitro-4-methyl-*N*-ribitylaniline hydrochloride (**2'**) separated as syrup, which was crystalized by adding seed crystals. The crystals were filtered off, washed with diisopropyl ether and dried over calcium chloride in vacuo. Yield 2.0 g (88%): mp 138—140 °C; ^{1}H NMR (D_2O) δ=2.61 (3H, s, CH_3), 3.67 (2H, dd, J=12 and 4 Hz, 5'CH_2), 3.79 (4H, m, 1'CH_a, 2'-4'CH), 4.14 (1H, m, 1'CH_b), 7.65 (1H, d, J=8 Hz, 5CH), 7.74 (1H, dd, J=8 and 2 Hz, 6CH), 8.18 (1H, d, J=2 Hz, 2CH). Found: C, 44.63; H, 5.96; N, 8.67%. Calcd for $C_{12}H_{19}N_2O_6Cl$: C, 44.66; H, 5.93; N, 8.68%.

8-Amino-8-demethylriboflavin (4). One gram of **2'** was suspended in 20 ml methanol and 120 mg powdered NaOH was added. Color of the solution was changed from colorless to red and the solution became turbid with crystals of NaCl, which were filtered off and washed with methanol. The combined filtrates were hydrogenated at 50 °C for 30 min under 50 kg cm^{-2} in the presence of Raney's catalyst, which was prepared from 4.0 g of a 50% alloy with 1 M NaOH. The catalyst was filtered from the colorless solution, washed with methanol, and the combined filtrates were evaporated in vacuo. The diamine obtained was easily oxidized, and therefore was used for the next reaction without isolation. The residue, dissolved in 20 ml methanol, was added to a hot solution of 0.6 g violuric acid in 40 ml of a 1 : 3 (v/v) mixture of methanol and water. Soon after addition, the color of the reaction mixture turned dark, fluorescence developed, and fine orange crystals appeared. After reflux for 4 h the reaction mixture was cooled and allowed to stand at room temperature overnight. Crystals (760 mg) were collected by filtration, washed with methanol and dried over $CaCl_2$. Another 210 mg of the crystals were recovered from the mother liquid. Total yield 970 mg (81%). For elemental analysis, the product was recrystallized from hot water.

^{1}H NMR (DMSO-d_6)(*indicates exchangable H) δ=2.48 (3H, s, CH_3), 3.47 (1H, m, 5'CH_a), 3.58 (1H, m, 5'CH_b), 3.67 (2H, m, 3',4'CH), 4.26 (1H, m, 2'CH), 4.32* (1H, t, J=6 Hz, 5'OH), 4.52 (1H, d, J=14 Hz, 1'CH_a), 4.68 (1H, d, J=4 Hz, 1'CH_b), 4.76* (2H, m, OH), 4.90* (1H, d, J=5 Hz, OH), 6.97 (1H, s, ϕ-H), 6.99* (2H, s, NH_2), 7.63 (1H, s, ϕ-H), 10.73* (1H, s, 3NH) (for assignments, see also[13]). UV (0.2M phosphate buffer pH 7.0) 235nm (ε_{mM} 31.7), 296 (8.9), and 476 (43.9); (6M HCl) 246 (36.5), 308 (18.9), 384 (4.6), and 477 (32.3); (0.1M NaOH) 248 (46.9), 292sh (6.3), and 475 (46.9); mp over 300 °C. Found: C, 50.78; H, 4.96; N, 18.41%. Calcd for $C_{16}H_{19}N_5O_6$: C, 50.92; H, 5.08; N, 18.56%. Literature values[10]; mp over 350 °C; UV (water) 252 (49.0), 296 (8.8), and 490 (42.0).

The authors thank Drs. Tetsuo Shiba and Tadashi Teshima of Osaka University for recording the mass spectrum, and Mr. Junichi Goda for the elemental analysis. B.J.F. is grateful for the financial support by the Japanese Ministry of Education, Mombusho.

Electrooxidative Functionalizations of Dehydroabietic Acid

Kenji UNEYAMA, Tatsuo KATAYAMA, and Sigeru TORII*
Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700
(Received March 26, 1987)

Synopsis. Dehydroabietic acid methyl ester (**1**) was converted into 7-acetoxydehydroabietic acid methyl ester by direct electrooxidation in acetic acid and 7-oxodehydroabietic acid methyl ester by ruthenium dioxide-mediated oxidation. Non-Kolbe type electrodecarboxylation of **1** resulted in the introduction of a double bond into the ring A of **1**.

Dehydroabietic acid[1] (**1a**) is a well-known resin acid of pine tree and usable as a chiral building block for steroid and terpene syntheses.[2] Several oxidative degradations have been attempted to modify the B ring of **1b**,[3] where excess amount of oxidation reagents such as trifluoroperacetic acid, ozone, and hydrogen peroxide have been employed. As one of our research programs on utilization of natural chiral compounds, some of the electrooxidative reactions of **1** have been studied to seek a mild oxidative functionalization of the A and B ring of **1**.

(1) Electro-Acetoxylation on C-7 of 1b. Introduction of acetoxyl group on C-7 of **1b** with cobalt acetate[4] and manganese acetate[5] is unsatisfactory. Meanwhile, electrooxidation of **1b** in an acetic acid-sodium acetate system using carbon electrodes provides **2a** and **2b** in 61 and 13% yields, respectively. The acetate **2a** is a mixture of stereoisomers on C-7 (40:60 by HPLC). To avoid hydrolysis of the acetoxyl group, acetic anhydride was added as a cosolvent, yielding 72% of **2a** along with 3% of **2b**. In contrast to the successful electroacetoxylation using carbon electrodes,[6] the use of platinum electrode was unsuccessful for the present purpose.[7] It is notable that side-chain acetoxylation occurs predominantly on C-7 rather than C-18. A sequence of ECE process, initial one-electron transfer from aromatic ring followed by deprotonation and successive one-electron oxidation leading to a carbenium ion on C-7, would be the most reasonable reaction sequence.[6] Ball-and-stick molecular model reveals that one of the carbon-hydrogen bond orbitals on C-7 overlaps with π-orbital of aromatic ring for the effective deprotonation.

(2) Electrooxidation of Methylene Group on C-7 to Carbonyl Group. Oxidation of methylene group of **1a** and **1b** to carbonyl group has been studied by cobalt acetate-catalyzed oxidation,[3] and chromium trioxide,[8] providing unsatisfactory yield and product-selectivity. Electrooxidation of **1b** in an MeOH-LiClO_4-(C) system (20 mA cm^{-2}, 7 F mol^{-1}) gave **3a** and **3b** in 52 and 27%, respectively along with a trace amount of **2c**. On the other hand, electrolysis at a lower current density (1 mA cm^{-2}) gave 7-methoxy compound **2c** (77:23 mixture of stereoisomers) in 79% yield as a sole product. The predominant formation of **3a** and **3b** reveals that **2c** is further oxidized in the high current density to the corresponding dimethyl acetal which would be converted to **3a** by the electrogenerated acid catalysis. No methoxy compound **1c** was detected, suggesting methylene proton on C-7 is much reactive than methine proton of isopropyl group.

Meanwhile, ruthenium tetraoxide-mediated electrooxidation of **1b** was examined in a CCl_4-H_2O-NaCl-HCl-NaH_2PO_4-(Pt) system, using ruthenium dioxide as an oxidant which could be converted to ruthenium tetraoxide by electrooxidatively generated active chlorine species.[9] This method provides **3a** in 52% yield. No hydroxy compound **2b** was detected suggesting the conversion of hydroxyl group to carbonyl group is facile in this system.

(3) Non-Kolbe Type Electrooxidation of 1a. Pb(IV) acetate is one of the most frequently employed oxidative reagents for decarboxylative olefin synthesis.[10] But the yields of **5** and **6a,b** are unsatisfactory. Pyrolysis of **1a** at 450 °C provided a mixture of **5** and **6a,b**.[11] Non-Kolbe type electrooxidation of carboxylic acid is useful for decarboxylative olefin synthesis.[6] Indeed, electrooxidation of **1a** provided a mixture of **5** and **6a,b**, which would arise from the carbenium ion intermediate **4**. The exo-olefin **5** can be transformed into chiral steroidal compounds by Natsumoto's method.[12]

Experimental

Boiling points are indicated by an air bath temperature and uncorrected. The NMR spectra were obtained with JNM FX-100 spectrometer at 100 MHz in $CDCl_3$ using Me_4Si as an internal standard. Acid **1a** was separated and purified from the resin acid mixture according to the reported method,[1] and its methyl ester **1b** was prepared by esterification with diazomethane.

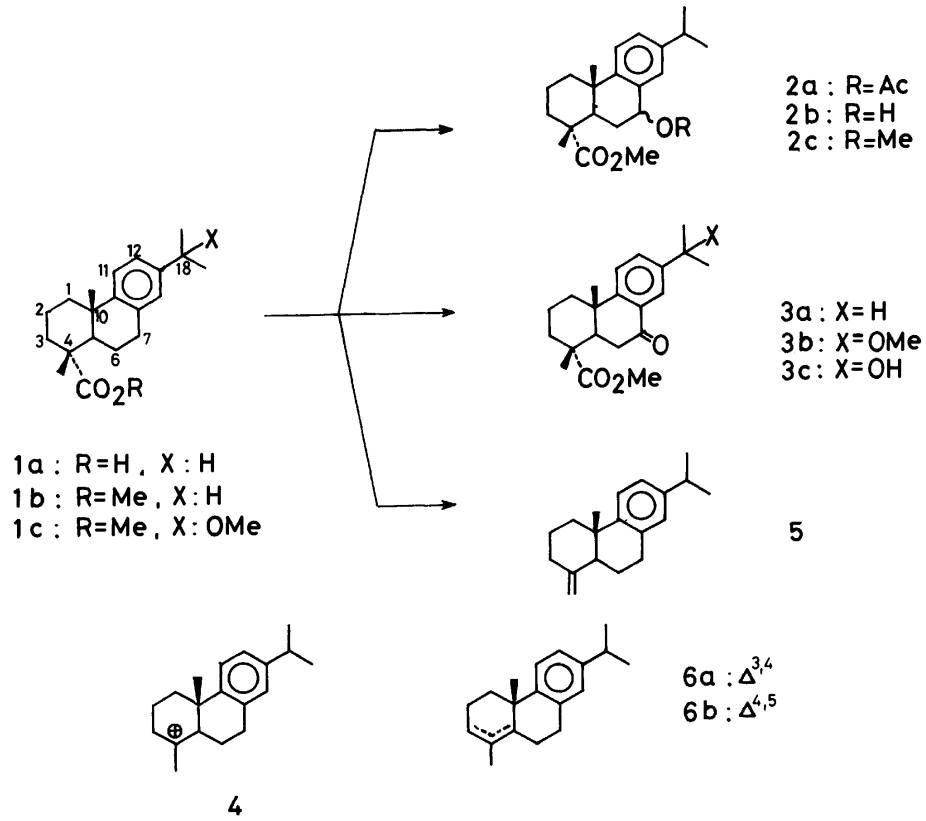
Electrolysis of 1b in Acetic Acid: A mixture of **1b** (100 mg, 0.32 mmol) and AcONa (150 mg, 1.8 mmol) in AcOH (5 ml) and $(Ac)_2O$ (1 ml) was electrolyzed using carbon plate electrodes (3 cm^2) in an undivided cell. After passing 10 F mol^{-1} (1F=96480C, 20 mA cm^{-2}) of electricity, acetic acid was evaporated under reduced pressure and the residue was dissolved in AcOEt. Usual workup and chromatography (SiO_2, hexane-AcOEt=4:1) gave 86 mg (72%) of **3a**, and 3 mg (3%) of **3b**. The structures of **3a** and **3b** were identified by spectroscopic comparison with those of the authentic samples.[5]

Electrolysis of 1b with RuO_2: Two platinum plates (3 cm^2) were settled in a water layer of the reaction mixture which contains **1b** (100 mg, 0.32 mmol) $RuO_2 \cdot 2H_2O$ (22 mg, 0.13 mmol), saturated NaCl containing 0.1 mol dm^{-3}

Table 1. Non-Kolbe Electrooxidation of **1a**

Run	Solv-electrolyte	Yield/%	5:6a:6b[d]
1	MeOH-MeONa	61[a]	58:25:17
2	H_2O-Hexane-KOH	58[b]	55:31:14
3	H_2O-THF-KOH	74[c]	44:38:18

a) 5 mA cm^{-2}, 4 F mol^{-1}. b) 20 mA cm^{-2}, 15 F mol^{-1}. c) 10—1 mA cm^{-2}, 3 F mol^{-1}. d) HPLC analysis.



NaH_2PO_4 (4 ml, pH 4), 10% HCl (0.05 ml), and CCl_4 (2 ml). Constant current (20 mA cm^{-2}, 30 F mol^{-1}) was passed at room temperature in an undivided cell. Carbon tetrachloride layer was separated and the water layer was extracted three times with ether. The combined organic extracts were treated as usual, providing **3a**[4] (54 mg, 52%) and **3c**[12] (6 mg, 6%).

Electrolysis of 1b in MeOH: A mixture of **1b** (60 mg, 0.19 mmol), $LiClO_4$ (40 mg, 0.38 mmol), and MeOH (6 ml) was electrolyzed in an undivided cell using two carbon plate electrodes (3 cm^2) [1 mA cm^{-2}, 14 F mol^{-1}]. The usual workup gave **2c** (54 mg, 79%). Methyl 1, 2, 3, 4, 4a, 9, 10, 10a-octahydro-9-methoxy-1, 4a-dimethyl-7-(1-methylethyl)-1-phenanthrenecarboxylate (**2c**). Bp 145 °C [4 Torr(1 Torr= 133.322 Pa)]; IR ($CHCl_3$) 2940, 2844, 2801, 1720, 1459, 1242, 1080, 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.16 (S, 3H, CH_3), 1.23 (d, J=7 Hz, 6H, CH_3), 1.29 (s, 3H, CH_3), 1.6—2.0 (m, 6H, CH_2), 2.04—3.04 (m, 3H, CH, CH_2), 3.38, 3.41 (S, 3H, CH_3), 3.67 (S, 3H, CH_3), 4.22 (t, J=3 Hz, 1H, $CHOCH_3$ for α-OCH_3 isomer), 4.52 (t, J=8 Hz, 1H, $CHOCH_3$ for β-OCH_3 isomer); Found : C, 76.50; H, 9.56%. Calcd for $C_{22}H_{32}O_3$: C, 76.70 ; H, 9.36 %.

Electrolysis of 1a: A mixture of **1a** (120 mg, 0.4 mmol), 1 mol dm^{-3} KOH (0.4 ml), and THF (6 ml) was electrolyzed in an undivided cell using two carbon plate electrodes (3 cm^2) at a constant terminal voltage (40 V) for 6 hr during which current was dropped from 30 to 3 mA. Silica-gel chromatography of the product gave a mixture of **5**, **6a**, and, **6b**, (76 mg, 74%). Separation of **5**, **6a**, and **6b** was performed by HPLC (μ-porasil, hexane) and the structures were identified spectroscopically.[11,13,14]

Effect of Polymer Matrices on Oxygen-Binding of a Cobalt Porphyrin Complex

Manshi OHYANAGI, Hiroyuki NISHIDE, Koichi SUENAGA, Takehiko NAKAMURA, and Eishun TSUCHIDA*
Department of Polymer Chemistry, Waseda University, Tokyo 160
(Received March 20, 1987)

Synopsis. Oxygen-binding of the (1-methylimidazole)-[α,α′,α″, α‴-5,10,15,20-tetrakis(*o*-pivalamidophenyl)porphinato]cobalt(II) complex fixed in polymer membranes, poly(dimethylsiloxane), poly(butyl methacrylate), and poly(methyl methacrylate), was studied spectroscopically. The apparent oxygen-binding affinity increased with oxygen solubility in the polymer matrix, which was corrected with the solubility coefficient of oxygen in the polymer.

A polymer membrane containing a carrier which interacts specifically and reversibly with oxygen is of great interest as a facilitated transport membrane of oxygen. The authors have recently reported[1] that oxygen transport through a polymeric membrane was augmented by the addition of a (1-methylimidazole)-[α,α′,α″,α‴-5,10,15,20-tetrakis(*o*-pivalamidophenyl)-porphinato]cobalt(II) (CoPIm) complex or a (*N*,*N*′-disalicylideneethylenediamine)cobalt(II) complex, which form oxygen adducts rapidly and reversibly, even in the solid state. One important point in a discussion of the facilitated transport mechanism is to quantitatively elucidate the oxygen-binding property of the carrier, i.e. the cobalt complex, fixed in a membrane.

In this work, the effect of polymer matrices on the oxygen-binding equilibrium of a CoPIm complex was studied spectroscopically by embedding the complex in three polymer membranes with greatly different T_g: poly(dimethylsiloxane) (PDMS), poly(butyl methacrylate) (PBMA), and poly(methyl methacrylate) (PMMA). This situation is discussed in connection with the oxygen solubility in these polymers.

Experimental

Preparation of the Membranes. Toluene solutions of the CoPIm complex and PBMA (Mw=320000) or PMMA (Mw=540000) were mixed, carefully cast on a Teflon plate under an atmosphere free of oxygen, then dried in vacuo to yield a transparent membrane with a thickness of about 60 μm containing 2.5 wt% CoPIm. A PDMS membrane with a thickness of 200 μm was prepared by using a room-temperature vulcanizing silicone rubber (KE-103, Shinetsu Silicone Inc.). The membrane became swollen in a toluene solution containing a large amount of CoPIm; the solvent was carefully evaporated under an atmosphere free of oxygen. The content of the CoPIm, thus prepared, PDMS membrane was also adjusted to 2.5 wt%.

Spectroscopic Measurements. Reversible oxygen-binding to the CoPIm complex fixed in the membranes was observed through the spectral change in the visible absorption using a highly sensitive spectrophotometer Shimazu UV-2000 with a kinetic data processor according to a previously reported method.[1] The spectrophotometer was equipped with a cell having a gas inlet and outlet tube. A membrane sample was attached to the cell wall. A gaseous mixture of oxygen and nitrogen was introduced into the cell through a gas inlet and outlet tube with a standing pressure such that the total pressure in the cell became 1 atm.

Determination of the Solubility Coefficient. The solubility coefficient (k_D) of oxygen in the rubbery PDMS and PBMA membranes and the apparent solubility coefficient of the glassy PMMA membrane were calculated from the results of the following permeation experiment. The oxygen permeation coefficient (P_{O_2}) was measured with a low-vacuum permeation apparatus in a chamber with stable thermostating (Rika Seiki Inc. gas permeation apparatus K-315 N-03). The diffusion coefficient (D) was calculated from time-lag (θ) of the permeation curve ($D=L^2/6\theta$, L; thickness of the membrane), and the division of P_{O_2} by D yields k_D ($P=K_DD$).

Results and Discussion

Oxygen-Binding Equilibrium The visible absorption spectrum of the deoxy CoPIm complex (λ_{max}=528 nm) fixed in the transparent membranes was changed to a spectrum with λ_{max}=545 nm, assigned to the oxy CoPIm complex (O_2/Co=1/1 adduct, Eq 1) immediately after the exposure to oxygen. The oxy-deoxy spectral change was rapid and reversible with isosbestic points at 480, 538, and 667 nm. These visible absorption spectra agreed with those for the corresponding complex in a toluene solution.[2]

$$\text{CoPIm} + O_2 \underset{}{\overset{K}{\rightleftarrows}} \text{CoPIm–}O_2 \qquad (1)$$

Oxygen-binding isotherms of the CoPIm complex fixed in the membranes are shown in Fig. 1; these were drawn by analyzing the spectral changes in response to the exposed oxygen pressure with Drago's equation.[3] The apparent oxygen-binding equilibrium constant (K_{app}) of the CoPIm in the membranes was determined from Fig. 1 and is given in Table 1. The K_{app} value for the CoPIm in the PDMS membrane is larger than those for the CoPIm in the methacrylate polymers. It is considered that a larger amount of oxygen dissolves in the PDMS matrix with a larger k_D (Table 2, mentioned later) and brings about the larger K_{app}.

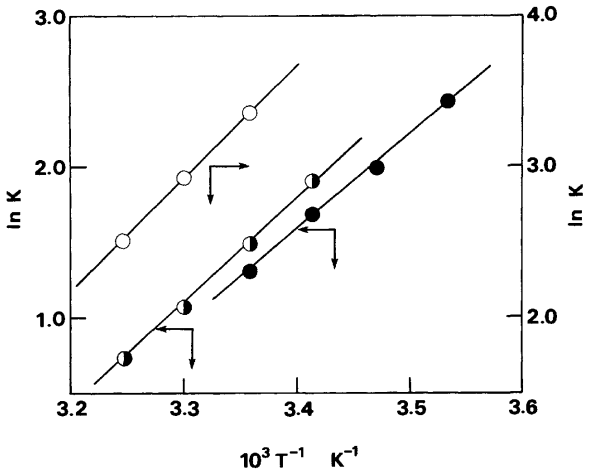

Fig. 2. Van't Hoff plots of the oxygen-binding equilibrium constants for the CoPIm membranes. (○; PDMS, ◑; PBMA, ●; PMMA) [CoPIm]=2.5 wt%.

The apparent thermodynamic parameters for the oxygen-binding were estimated from the temperature dependence of K_{app} (in atm^{-1} in Fig. 2) and are also given in Table 1. The apparent enthalpy change (ΔH_{app}) becomes more negative with a decrease in Tg of the polymer matrix. These apparent thermodynamic parameters for the oxygen-binding equilibrium are corrected with those for oxygen dissolution in the polymer matrix, as follows;

$$K=[\text{CoPIm-O}_2]/[\text{CoPIm}][\text{O}_2] \quad (2)$$

and

$$[\text{O}_2]=k_D p(\text{O}_2), \quad (3)$$

where $[O_2]$ is the oxygen concentration around the CoPIm complex and $p(O_2)$ is atmospheric oxygen pressure to which the membrane is exposed. When $[CoPIm\text{-}O_2]/[CoPIm]$ is 1, K can be written as

$$K=K_{app}/k_D. \quad (4)$$

Accordingly, the thermodynamic parameters from van't Hoff plots of K_{app} ($=k_DK$) are just affected by the k_D values and its heat of dissolution (ΔH_d) as shown in Eq. 7.

$$k_D=ke^{-\Delta H_d/RT} \quad (5)$$

$$\ln K=-\Delta H_{app}/RT+\Delta S_{app}/R \quad (6)$$

$$\Delta H=\Delta H_{app}-\Delta H_d,\ \Delta S/R=\Delta S_{app}/R-\ln k \quad (7)$$

Here, ΔH and ΔS is the thermodynamic parameters in which the effect of the polymer matrix is reduced. ΔH and ΔS are calculated with Eq. 7 by using ΔH_{app}, ΔH_d, and k in Tables 1 and 2 and is shown in Table 2. Both the values of ΔH and ΔS in the PDMS membrane are equal to the ones in the PBMA membrane. Although the apparent equilibrium and thermodynamic parameters of the oxygen-binding reaction of the CoPIm complex fixed in polymer membranes are found to be fairly affected by the oxygen solubility in the polymer matrices, the parameters corresponding to the oxygen-binding reaction to the CoPIm complex are not essentially dependent on the species of the polymer matrix.

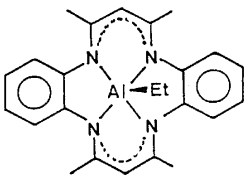
Synopsis. Homolytic photocleavage of an aluminum carbon bond in ethyl(1,8-dehydro-5,7,12,14-tetramethyldibenzo[*b*,*i*][1,4,8,11]tetraazacyclotetradecinato)aluminum was confirmed by using EPR technique. The photochemistry of this aluminum carbon bond was also studied by NMR and emission spectroscopic experiments.

Photoreactivity of metal-alkyl bonds has been an increasing interest.[1-5] In this note, we report some photochemical behaviors of $Al(C_{22}H_{22}N_4)(C_2H_5)$ (**1**) which has known to be remarkably stable to Al-ethyl dissociation in the dark and resistant to demetallation.[6]



1

Figure 1 shows the electronic spectrum of compound **1**. This compound has a strong absorption band at 358 nm (ε=7.0×10⁴) and a shoulder at about 410 nm ($\varepsilon\simeq10^4$). This spectrum is similar to that of $Ni(C_{22}H_{22}N_4)$,[7] though the bands of **1** lie at shorter wavelengths than those of the Ni complex. Structual study of **1** showed that the in-plane ligand is not planar but take the suddle shape structure.[6] Previous semi-empirical Pariser-Par-Pople MO calculation[8] implied that the visible absorption bands of **1** are predominantly due to the $\pi\pi^*$ transition of deformed macrocyclic ligand.

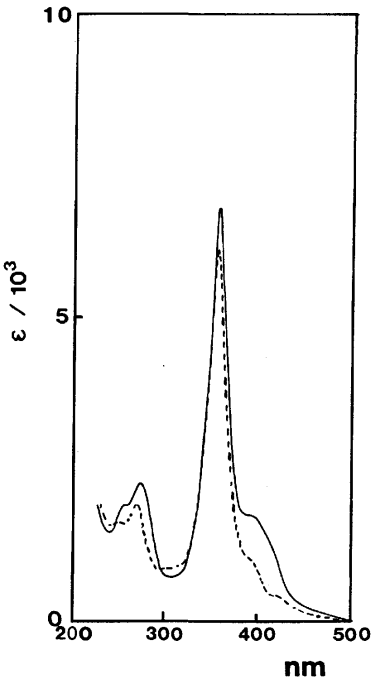


Fig. 1. Electronic spectra of compound **1** (——) and $Al(C_{22}H_{22}N_4)Cl$ (----) in methanol.

Figure 2(A) shows a ^1H NMR spectrum of **1** in $CDCl_3$ at 20 °C. When the solution was irradiated with visible light (λ>450 nm), the spectrum changed with irradiation time (Fig. 2(B—D)). The signal intensities due to the ethyl group at δ 0.18 (t, CH_3) and −0.92 (q, $-CH_2-$) decreased as a new peak of ethane appeared at δ 0.85. Simple spectral change was also observed at lower magnetic field region. Three hours irradiation brought the reaction to completion under the experimental conditions. The main product was identified as $Al(C_{22}H_{22}N_4)Cl$ by means of mass spectrometry of the product (m/z=404). The absorption spectrum of

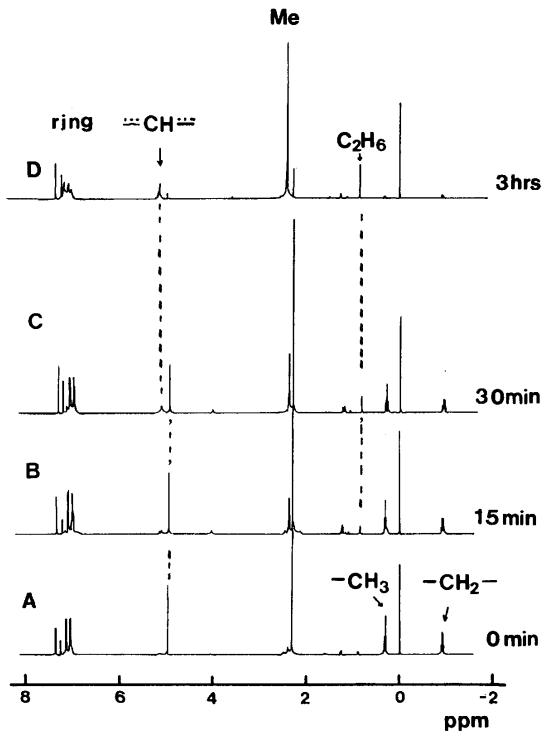

Fig. 2. 400 MHz NMR spectral changes upon photolysis of $CDCl_3$ solution of $Al(C_{22}H_{22}N_4)(C_2H_5)\cdot 1/2C_6H_6$ at 20 °C. A: Before irradiation, B, C, and D: after 15, 30 minutes, and 3 hours irradiations, respectively.

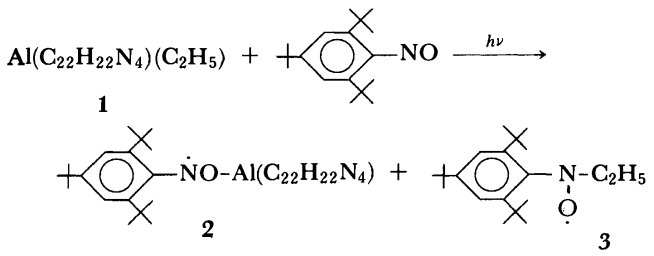
the chloro complex isolated by passing through Al_2O_3 column is also depicted in Fig. 1. The simple spectral change in Fig. 2 indicates that the reaction proceeds rather simply and smoothly at 20 °C. However, prolonged irradiation at room temperature caused the solution dark and turbid, possibly due to the simultaneous side reactions of the radicals arising from the solvent. An attempt to determine the quantum yield of the photo-induced chlorination by the spectrophotometric method[4] was unsuccessful because of the small spectral change during the reaction (see Fig. 1). However, it was roughly estimated to be in the order of 10^{-3} from the initial absorbance change of the reaction at 400 nm. The value was in the same order of magnitude as reported for photolysis of [Al(tpp)Et] in $CHCl_3$.[4]

Figure 3(A) shows an EPR spectrum obtained upon irradiation of a degassed benzene solution of **1** with visible light ($\lambda > 450$ nm) in the presence of ten-fold excess of spin trapping agent, 2,4,6-tri-*t*-butylnitrosobenzene (TBN). Though the spectral pattern is rather complicated, the spectrum can be unequivocally assigned as an overlap of signals due to two spin adducts, **2** and **3** in Eq. 1.



(1)

Figures 3(B) and 3(C) show the simulation spectra of **3** and **2**. EPR parameters obtained were: for **2**, a^N=1.06, a^{Al}=0.14, a_m^H=0.17[9] mT, and g=2.0048; for **3**, a^N=1.34, a^H=1.78, and a_m^H=0.08[9] mT, and g=2.0061. These values are almost identical with those previously reported for TBN spin adducts obtained upon photolysis of [Al(tpp)(Et)].[4] Spin adduct **2** is the anilino radical bonded through O to Al, while **3** is the nitroxyl radical bonded through N to Et. The EPR intensity ratio for spin adducts **3** and **2** was found to be approximately 1 : 1.5. This ratio is likely to depend on trapping rate. In the absence of TBN, no EPR signal was observed under the same conditions. The recombination of radicals may be too fast to detect the EPR signals.

Emission behavior from photoexcited state of **1** and its free ligand $H_2(C_{22}H_{22}N_4)$ has been also studied in 2-methyltetrahydrofuran (MTHF).[10] Complex **1** showed emission with a maximum peak at 580 nm and the lifetime was found to be 50 ms at 77 K. Excitation spectrum was in accord with its absorption. These results indicate that the emitting state is attributable to the excited triplet state of the ligand π-conjugated system. Recently we observed the triplet signal for compound **1** using time resolved EPR technique.[8] It should be noted that the phosphoresence was not observed at 290 K when the oxygenated solution was used, while it was observed at both 77 and 290 K when the solution was degassed. That is, the triplet state was quenched by oxygen at room temperature.

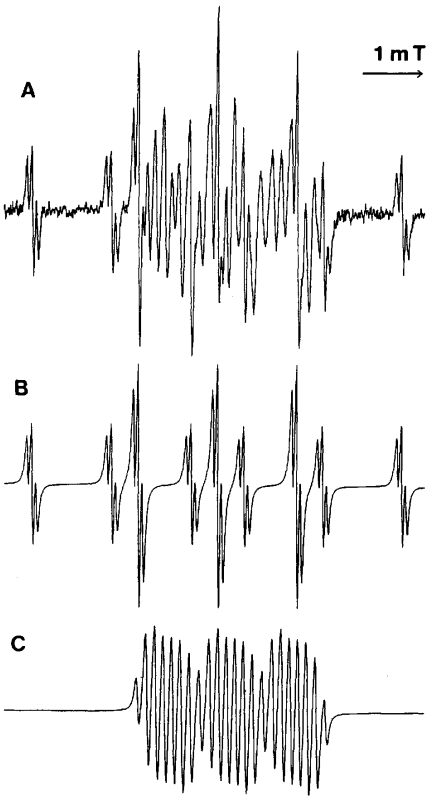


Fig. 3. A: EPR spectrum of a benzene solution of $Al(C_{22}H_{22}N_4)(C_2H_5)$ with TBN upon light irradiation ($\lambda > 450$ nm). B and C: EPR simulation spectra of TBN-C_2H_5 and TBN-$Al(C_{22}H_{22}N_4)$, respectively.

This work clearly indicates that the homolytic cleavage of Al-C bond of the present complex is induced by visible light, that is mainly by the in-plane ligand absorption. However, when the reaction was carried out in non-reactive solvent such as benzene or in the absence of spin traps, neither EPR signal nor NMR spectral change was observed under the irradiation. In order to clarify whether the photochemically reacting species is singlet or triplet, further detailed studies are necessary.

Experimental

Sample Preparation. $Al(C_{22}H_{22}N_4)(C_2H_5)$ was prepared by the method reported in the literature.[6]

NMR Measurement and Visible-Light Irradiation. ^1H NMR spectra were recorded on a JEOL GX-400 spectrometer. An Ushio ultra-high pressure 500 W mercury lamp and Toshiba glass filter ($\lambda > 450$ nm) were used for irradiation of visible light at 20 °C.

EPR Measurement. EPR spectra were recorded on a JEOL FE2XG spectrometer (100 kHz modulation) at room temperature. Visible light irradiation was carried out with the use of the same mercury lamp and glass filter as those in the NMR measurements.

Emission Experiment. Fluoresence and phosphoresence spectra were recorded on a Spex Fluorolog 2 fluorimeter quipped with a Xenon lamp.

9) a_m^H denotes hyperfine coupling constants with benzene ring proton at meta position.
10) The emission from the free ligand was disclosed to be fluoresence. The free ligand showed an emission spectrum with maximum at 560 nm, but its excited state decayed very rapidly after the pulsed excitation. It is suggested that the presence of Al makes the intersystem crossing from S_1 or S_2 to T_1 easier.

The Thermal Decomposition of Lithium Hydrogenphosphoramidate Trihydrate

Choichiro SHIMASAKI,* Hiroki SUZUKI, and Hiroshi TODA
Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Gofuku, Toyama 930
(Received December 17, 1986)

Synopsis. The thermal decomposition of lithium hydrogenphosphoramidate trihydrate $LiHPO_3NH_2 \cdot 3H_2O$ was investigated by means of DTA-TG, X-ray diffraction analysis, IR, ^{31}P NMR, and compositional analysis. The decomposition proceeds via an anhydrous phase, a newly found intermediate phase, and polyphosphates to lithium metaphosphate. The activation energies of the dehydration of the water of crystallization and of the polymerization reaction for the thermal decomposition were estimated to be 96.2 and 105.4 kJ mol^{-1} respectively.

The reaction products[1,2] between urea (or its nitrogen derivatives) and phosphoric acid have been used as a flameproofing and fire-retardant (glow-retardent) agent. The derivatives of phosphoramidates have been investigated systematically for these purposes: The thermal decomposition of ammonium, sodium, and potassium hydrogenphosphoramidate (anhydrous salts) was previously reported by the present authors.[3,4] The decomposition study was been extended to lithium hydrogenphosphoramidate trihydrate $LiHPO_3NH_2 \cdot 3H_2O$ in the present work.

Experimental

Preparation Methods. No anhydrous salt was synthetically obtained. The sample (trihydrated salt, yield; 65—70%) was prepared as follows: Ammonium hydrogenphosphoramidate[5] (4.6 g 0.04 mol) was dissolved in 40 ml of a 2.0 M (1M=1 mol dm^{-3}) lithium hydroxide solution. This solution was then cooled (to 5—10 °C), neutralized (to pH 6) with glacial acetic acid, and precipitated with 300 ml of ethanol. The salt filtered out with suction was recrystallized repeatedly from a water-ethanol solution, washed with ethanol and ether, and air-dreid.

Measurements. The chemical analysis was made by the method reported by Watanabe et al.[6] The DTA-TG (Rigakudenki Co., Ltd., Japan) was performed in air. The dehydrated samples were hygroscopic, so that the X-ray diffraction was measured at high temperatures with nickel-filtered Cu $K\alpha$ radiation with a X-ray diffractometer XD-3A (Shimazu Co., Ltd., Japan). The IR spectra (KBr disc method) of a sample (quenched and preserved in a desiccator) were measured with an IR-810 spectrometer (JASCO, Japan). The ^{31}P NMR spectra of the solutions were measured with a JNM-FX-900FT-NMR spectrometer (JEOL, Japan); the quenched sample (50 mg) was dropped into a 6% EDTA deuterated-water solution and stirred for several minutes.

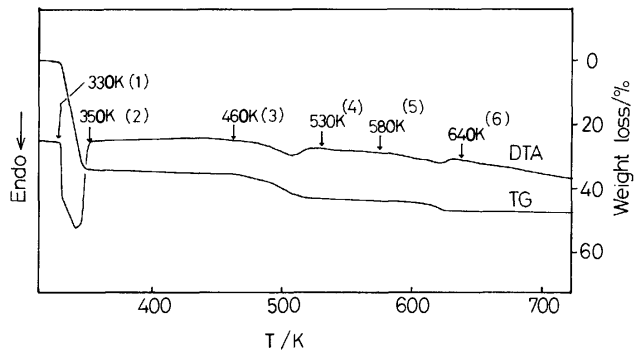

Fig. 1. DTA and TG curves of $LiHPO_3NH_2 \cdot 3H_2O$. Heating rate: 1 K min^{-1}.

Results and Discussion

A typical DTA-TG curve of $LiHPO_3NH_2 \cdot 3H_2O$ is shown in Fig. 1. In this figure, the temperatures for analyzing the samples are indicated; the results of the compositional analysis, the IR spectra, the ^{31}P NMR spectra, and the X-ray diffraction are shown in Table 1, and Figs. 2, 3, and 4 respectively. In Fig. 1, three endothermic peaks and the corresponding weight losses are shown: the first stage (330—350 K), the second stage (slight change, 460—530 K), and the third stage (slight change, 580—640 K).

The first stage of the decomposition is assumed to be the dehydration of the crystalline water as follows:

$$LiHPO_3NH_2 \cdot 3H_2O \rightarrow LiHPO_3NH_2 + 3H_2O. \quad (1)$$

The results of the compositional analysis and the weight loss (Sample No. 2 in Table 1) support this hypothesis. The X-ray diffraction in Fig. 4 has changed from that of $LiHPO_3NH_2 \cdot 3H_2O$ (Sample No. 1) to a new pattern (Sample No. 2) which should be assigned to the anhydrous phase. A splitting of the

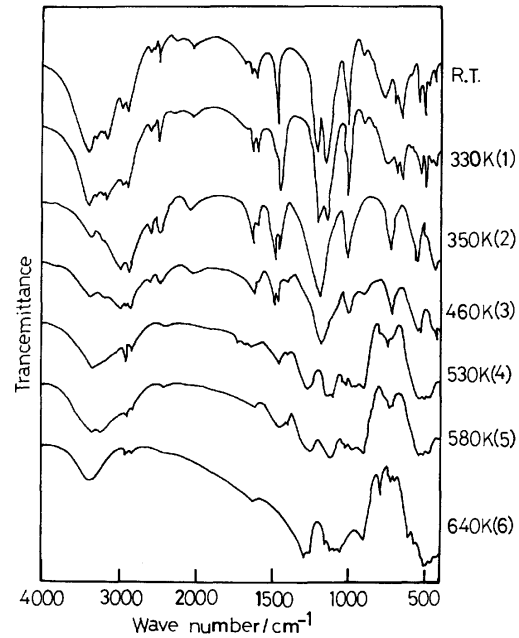

Fig. 2. IR spectra of the thermal decomposition products of $LiHPO_3NH_2 \cdot 3H_2O$.

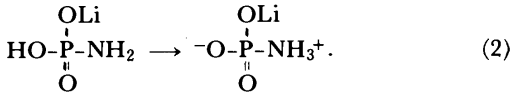
DTA peak was observed when it was heated rapidly (e.g., 9 or 11 K min^{-1}).

The anhydrous hydrogen phosphoramidate is considered to become zwitterion as follows at 330—350 K, since the IR absorption due to the zwitterion reported by Corbrige et al.[7] were observed at 1460 and 1595 cm^{-1} in Sample Nos. 2 and 3 in Fig. 2. In Fig. 4 (the X-ray diffraction pattern of Sample Nos. 2 and 3), a decrease in the peak intensity of the anhydrous phase and a very weak trace of a different diffraction pattern (detailed analysis impossible) was apparently observed.

Therefore, lithium hydrogen phosphoramidate is considered to become zwitterion when transformed as follows:



$$HO\text{-}P(=O)(OLi)\text{-}NH_2 \longrightarrow {}^{-}O\text{-}P(=O)(OLi)\text{-}NH_3^{+}. \quad (2)$$

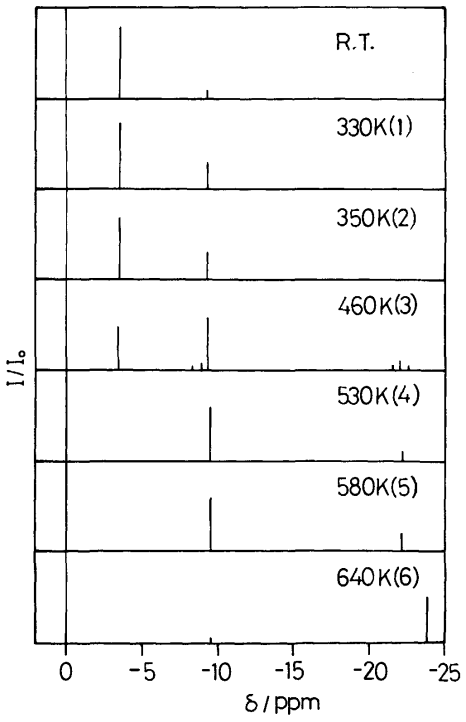


Fig. 3. ^{31}P NMR spectra and of the thermal decomposition products of $LiHPO_3NH_2 \cdot 3H_2O$.

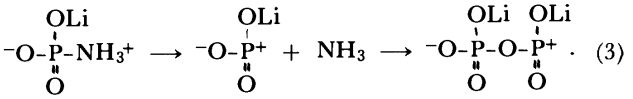
The second stage of the decomposition is assumed to be the following reaction:



$$HO\text{-}P(=O)(OLi)\text{-}NH_3^{+} \longrightarrow {}^{-}O\text{-}P^{+}(=O)\text{-}OLi + NH_3 \longrightarrow {}^{-}O\text{-}P(=O)(OLi)\text{-}O\text{-}P^{+}(=O)\text{-}OLi \cdot \quad (3)$$

The results of the compositional analysis (Sample No. 4 in Table 1), show the apparent disappearance of the IR absorption, and the X-ray diffraction pattern due to the zwitterion mentioned above (Sample No. 4 in Figs. 2 and 4), and a pungent odor of ammonia.

Concomitantly, the water in Eq. 1 is held by adsorption on the surface of the sample; therefore, the following (dimerization) reaction is assumed to occur simul-

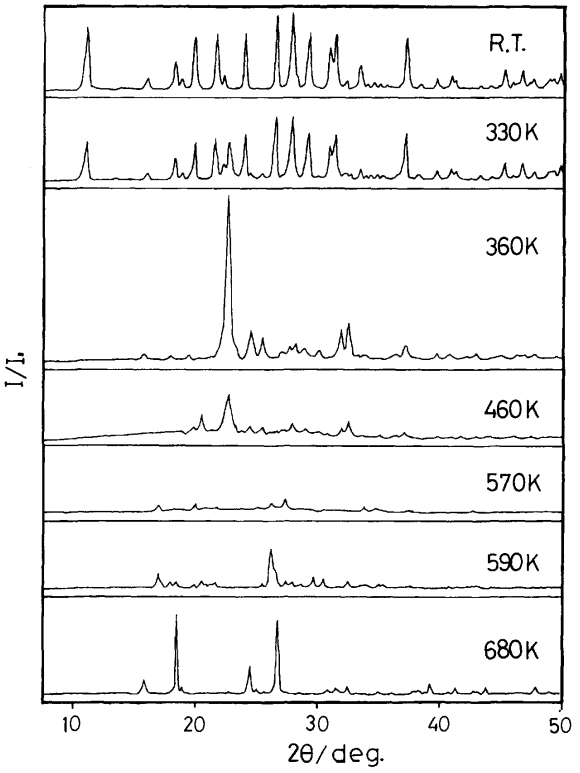


Fig. 4. X-Ray diffraction diagrams of the thermal decomposition products of $LiHPO_3NH_2 \cdot 3H_2O$. Heating rate: 2 K min^{-1}.

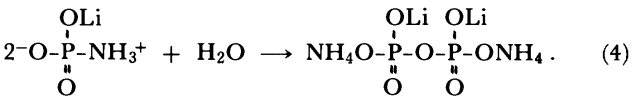
taneously with the second stage of the decomposition:

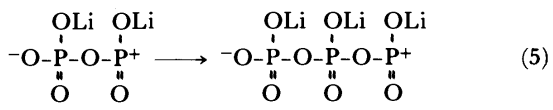


(4)

The ^{31}P NMR spectrum of Sample No. 3 indicated small peaks of middle-PO_4 groups and small peaks of an end-PO_4 group. The product was metastable at room temperature, therefore, the ^{31}P NMR spectrum of the product indicated peaks due to phosphoramidate and an end-PO_4 group, and hardly changed in comparison with Sample No. 2. The IR absorption of a NH_4^+ was observed for Sample No. 3. It may be estimated that any indications of the polymerization reaction could be recognized by means of these results.

The ^{31}P NMR spectrum of Sample No. 6 indicated a small peak of an end-PO_4 group and a peak of a middle-PO_4 group. Sample No. 6 contained no nitrogen and hydrogen. The X-ray diffractions of the resultant thermal product at a given isothermal temperature are shown in Fig. 3. The three strongest lines of $LiPO_3NH_2 \cdot 3H_2O$ disappeared at 360 K, and the three new lines which appeared from 330 K became strong at 360 K. The diffraction lines at 360 K are considered to be those of the anhydrous product. The thermal product at 570 K was found to be amorphous by the use of an X-ray diffractor, while the product at 590 K showed weak, unknown X-ray diffraction peaks. The thermal product at 680 K showed X-ray diffraction peaks of lithium metaphosphate.[8]

The third stage of the decomposition is assumed to be the following reaction:



(5)

The activation energies of the first and second stages for the thermal decomposition for $LiHPO_3NH_2 \cdot 3H_2O$ were determined tentatively from the DTA curves (Kissinger method[9]) and the TG curves (Ozawa method[10,11]) with the heating rate of 1, 3, 5, 7, 9, and 11 K min^{-1}: 95.3 and 97.1 kJ mol^{-1} for the first stage (average; 96.2 kJ mol^{-1}) and 103.9 and 106.8 kJ mol^{-1} for the second stage (average; 105.4 kJ mol^{-1}) respectively.

We wish to thank Prof. Ikuya Matsuura for the X-ray diffraction analysis, Mr. Kiyoshi Terayama for the DTA-TG and Mr. Yoshiharu Yoneyama for the NMR spectra.

(Received December 24, 1986)

Synopsis. A simple procedure for the determination of mercury(II) by graphite furnace atomic absorption spectrometry is described. Mercury(II) was extracted as tetradecyldimethylbenzylammonium (Zephiramine) thiocyanatomercurate(II) into diisobutyl ketone (DIBK) by using a 10-cm^3 centrifuge tube, and an aliquot of the organic extract was directly pipetted out from the upper layer in the centrifuge tube and injected into the graphite furnace. The heating temperature program by ramp mode and the background correction by means of a 2-channel type atomic absorption spectrometer gave satisfactory results.

In the determination of volatile elements such as mercury by graphite furnace atomic absorption spectrometry (GF-AAS), losses of the analytes may occur during the ashing stage in the thermal cycle. Recently, a number of publications have described matrix modification or stabilization procedures by which analyte losses before atomization stage may be minimized or eliminated.[1-5] For example, the absorbance of mercury can be increased by addition of ammonium sulfide to the sample solution; this effect has been attributed to the formation of stable mercury(II) sulfide at the ashing temperature.[1] Kirkbright et al. have recommended a procedure in which the addition of potassium dichromate to the mercury sample in nitric acid solution allowed the use of ashing temperatures up to 250 °C without significant loss of mercury.[2] Filippelli reported a method for determining low levels of mercury by GF-AAS with preliminary preconcentration using ammonium 1-pyrolidinecarbodithioate (APDC)-chloroform extraction system.[3]

In this paper a method for the determination of mercury by GF-AAS combined with a small scale solvent extraction technique is described; mercury(II) was converted to thiocyanatomercurate and extracted into diisobutyl ketone (DIBK) as the ion-pair with tetradecyldimethylbenzylammonium (Zephiramine), and the extract was injected into graphite tube to measure the atomic absorption of mercury. This method is convenient and rapid, as the extraction is carried out by using a centrifuge tube and an aliquot of the organic phase in the upper layer can be directly pipetted out of the tube. This enables us to use much smaller amounts of samples and reagents compared with those in the conventional extraction, which serves to reduce laboratory-used mercury waste.

Experimental

Apparatus. A Nippon Jarrell-Ash Model AA-8200 two-channel atomic absorption spectrometer equipped with a Model FLA-100 graphite furnace atomizer was used. Background correction was accomplished by using a deuterium lamp. A Rikadenki Model B-381 strip chart recorder was used to monitor both the background-corrected atomic absorption and the background signals. Digital micropipettes of Gilson Model Pipetman P-20, P-200, P-1000, and P-5000 were used. The shaking for the extraction was carried out with a Taiyo Model SR-II shaker, where 10-cm^3 centrifuge tubes with ground stoppers were used instead of separatory funnels.

Reagents. Pure water from an Organo Miniclear Model DC-610 system was used. All chemicals were of analytical-reagent grade and were used without further purification. A 1000 μg cm^{-3} of mercury(II) standard stock solution was prepared by dissolving mercury(II) nitrate in dilute nitric acid. Solutions of suitable concentration were prepared by dilution with 0.1 mol dm^{-3} nitric acid before use. A 5.0×10^{-2} mol dm^{-3} Zephiramine solution was prepared by dissolving 2.02 g of Zephiramine chloride dihydrates (Wako Pure Chemicals) to 100 cm^3 with water. A 2.0 mol dm^{-3} potassium thiocyanate solution was prepared by dissolving 19.4 g of potassium thiocyanate (Wako Pure Chemicals) to 100 cm^3 with water.

Standard Procedure. Transfer an aliquot of the mercury(II) solution containing not more than 80 ng mercury(II) into the centrifuge tube. Add 200 mm^3 of the potassium thiocyanate solution and 80 mm^3 of the Zephiramine solution, and dilute the mixture to 5 cm^3 with water. Then, add 1 cm^3 of DIBK. Shake the centrifuge tube for ca. 5 min by means of the mechanical shaker. After standing for ca. 15 min, inject an aliquot of 20 mm^3 of the upper organic phase into the graphite furnace and measure the atomic absorption peak signal of mercury. The instrument operating conditions are listed in Table 1.

Results and Discussion

Optimization of Instrument Operating Conditions. In order to avoid the loss of mercury before the atomization stage and to separate the atomic absorption peak signal from the background signal, a moderate elevation of temperature throughout the heating cycle was very essential. Experiments were carried out to determine the loss of mercury during the drying and ashing stages of the heating program by recording signals from 20-mm^3 aliquots containing 1.6 ng mercury(II). A setting of 60 °C-50 s for the drying stage was suitable. No appreciable loss of mercury from the furnace was observed at the ashing temperature of up to ca. 300 °C with the ramp mode which avoided abrupt vaporization. The background signal decreased significantly with increase in the ashing temperature. The

Table 1. Instrument Operating Conditions

Atomizer (FLA-100)

results are shown in Fig. 1. Therefore, the ashing condition of 300 °C-120 s was selected for the standard procedure. The effects of atomization temperature with the maximum ramp mode on the atomic absorption and background peak signals are shown in Fig. 2. The atomic absorption peak signal was maximum and constant over the temperature range of 1200—2200 °C, whereas the background signal increased as the temperature increased. So that, the atomization

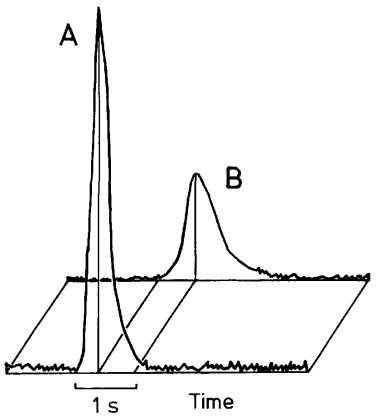

Fig. 3. Signal vs. time profiles. Mercury(II): 1.6 ng. A: Mercury atomic absorption, B: background. See Table 1 for conditions.

temperature of 1300 °C was chosen. Under the conditions, the atomic absorption signal of mercury appeared first, followed by the background peak signal ca. 0.6 s later. The signal vs. time profiles obtained for both the atomic absorption and background are shown in Fig. 3.

Optimization of Conditions of Solvent Extraction. In liquid-liquid extraction, the organic solvent should have a high distribution coefficient for the analyte and be insoluble in water. Moreover, it is preferable for the organic solvent to float on the aqueous phase so that the organic extract can be directly pipetted out of the centrifuge tube without separating the organic layer. DIBK was confirmed to be a favorable solvent in these respects.

The effect of pH on the extraction was investigated by extracting mercury(II) from a series of aqueous solutions containing 400 ng mercury(II) buffered at various pH values, while other variables in the standard procedure were kept constant. The maximum extraction of the ion-pair of Zephiramine thiocyanatomercurate(II) was obtained, when the acidity of the aqueous phase lay within the range of 1 mol dm^{-3} in nitric acid to pH 7.

The effects of the concentration of potassium thiocyanate and Zephiramine in the aqueous phase on the extraction were also examined according to the standard procedure. When the concentration of mercury(II)

Table 2. Analytical Results of Mercury in Several Waste Water Samples

Sample	Mercury found/ng cm^{-3}	
	Calibration curve method	Standard addition method
Raw sewage water A[a)]	1.8±0.2	2.0±0.3
Raw sewage water B[a)]	N.D.[b)]	N.D.[b)]
Raw mercury waste water A	14.3±0.3	14.7±0.3
Raw mercury waste water B	28.6±0.4	28.8±0.3
Raw mercury waste water C	9.8±0.3	12.0±0.2

a) Acid digestion sample.[6] b) N.D.: Not detected.

in the aqueous phase was kept at 80 ng cm^{-3}, it was necessary for the maximum and constant extraction that the concentrations of potassium thiocyanate and Zephiramine were at least 1×10^{-2} and 2×10^{-4} mol dm^{-3}, respectively. In order to minimize the background peak signal which was mainly caused by an excess Zephiramine extracted with the ion-pair, we selected 8×10^{-2} and 8×10^{-4} mol dm^{-3} as the initial concentrations of potassium thiocyanate and Zephiramine in the aqueous phase, respectively.

Extraction Percentage. The extraction efficiency was estimated to be 99% from the results obtained by the successive extraction of mercury(II) in the aqueous phase according to the standard procedure in which the initial concentration of mercury(II) in the aqueous phase was kept at 80 ng cm^{-3}.

Detection Limit and Working Curve. The detection limit was 0.5 ng cm^{-3} on the basis of the above results. The detection limit was defined as the concentration in the aqueous phase required to give a signal three-fold greater than the standard deviation of the base line fluctuation. The calibration curve was linear up to 80 ng cm^{-3} mercury(II) initially present in the aqueous phase. The relative standard deviation for 10 replicate determinations was 1.0% for 40 ng mercury(II). As to the stability of the extract, no appreciable change in the absorbance was observed over the period of 48 h, even when the organic phase was kept standing with the aqueous phase.

Application to Determination of Mercury in Waste Water Samples. Some waste water samples were analyzed for mercury contents by the standard procedure. As a check, the samples were also analyzed by standard addition method. As can be seen from the results given in Table 2, both data are in satisfactory agreement.

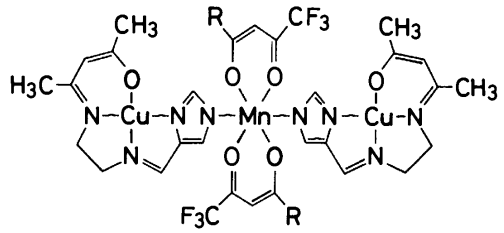
Synopsis. Imidazolate-bridged trinuclear(copper(II)-manganese(II)-copper(II)) complexes [CuLMn(tfa)$_2$LCu]-2H$_2$O **1** and [CuLMn(hfa)$_2$LCu]3H$_2$O **2** have been prepared and characterized, where tfa=trifluoroacetylacetonate, hfa=hexafluoroacetylacetonate, H$_2$L=unsymmetrical quadridentate Schiff base derived from the condensation reaction of acetylacetone, ethylenediamine, and 4-formylimidazole with the mole ratio of 1:1:1. The magnetic susceptibility data were represented by a spin-only interaction model(1/2-5/2-1/2) with J_{Mn-Cu} value of -13 cm^{-1} for **1** and -8 cm^{-1} for **2**.

Hetero-polynuclear complexes which contain magnetic centers with different spin-multiplicities are of current interest from the point of view of the development of ferromagnets[1] and models of active sites of some metal enzymes such as bovine erythrocyte superoxide dismutase and cytochrome c oxidase.[2,3] In the previous paper,[4] we reported the synthesis and characterization of imidazolate-bridged binuclear copper(II) complexes in which two coordination spheres of copper(II) ions are not identical. These complexes have been prepared by the reaction of the copper(II) complex with unsymmetrical quadridentate ligand containing an imidazole moiety (a-site component complex) and the copper(Il) complex exhibiting an unsaturated coordination site (b-site component complex) under the presence of one equivalent of alkali. This synthetic method can be easily extended to the synthesis of hetero-metal polynuclear complexes by using another metal complex instead of the copper(II) complex as the b-site complex. In this study, we report the synthesis and characterization of imidazolate-bridged trinuclear copper(II)-manganese(II)-copper(II) complexes **1** and **2** whose schematic structures are shown in the drawing as an example of the complexes containing magnetic centers with different spin-multiplicities.



1 (R = CH_3); 2 (R = CF_3)

Experimental

Physical Measurements. Elemental analyses for C, H, and N were performed by Mr. Shinichi Miyazaki at the Technical Service Center of Kumamoto University. Elemental analyses for Mn and Cu were carried out on a Hitachi 508 atomic absorption spectrophotometer. Melting points were measured on a Yanagimoto micro-melting point apparatus and were uncorrected. Electrical conductivity measurements were carried out on a Denki Kagaku Keiki AOC-10 on ca. 10^{-3} mol dm^{-3} solutions in chloroform. Thermogravimetric analyses were carried out on a Shimadzu TGC 20 type microthermobalance at a heating rate of 5 °C min^{-1}, using ca. 10 mg samples for each run. Infrared spectra were recorded on KBr discs with a JASCO A-702 spectrophotometer. Magnetic susceptibilities were obtained by the Faraday method from the temperature of liquid nitrogen to the ambient temperature, according to the procedure reported previously. The susceptibilities were corrected for the diamagnetism of the component atoms by the use of Pascal's constants. The molar effective magnetic moment was calculated by the equation $\mu_{eff}=2.828(\chi_M T)^{1/2}$.

Syntheses. The starting complexes [Mn(tfa)$_2$]2H$_2$O and [Mn(hfa)$_2$]2H$_2$O were prepared by mixing manganese(II) acetate tetrahydrate and each of trifluoroacetylacetone and hexafluoroacetylacetone with the mole ratio of 1:2 in water according to the modified method in the literature.[5] The complex [CuHL](ClO$_4$) was prepared by the method described elsewhere.[6]

Hetero-Metal Trinuclear Complex [CuLMn(tfa)$_2$LCu]2H$_2$O 1. A suspension of [CuHL](ClO$_4$) (382 mg, 1 mmol) and [Mn(tfa)$_2$]2H$_2$O (397 mg, 1 mmol) in 150 cm^3 of chloroform was refluxed for 10 min. To this was slowly added a solution of triethylamine (1 mmol) in 10 cm^3 of chloroform. During the addition of triethylamine, the complex [CuHL](ClO$_4$) was gradually dissolved. After the completion of the addition, the solution was further refluxed for 30 min and then filtered. The filtrate was evaporated to dryness, the residue was dissolved in 50 cm^3 of diethyl ether, and the ether solution was filtered and kept overnight in a refrigerator. During that time, reddish pink microcrystalline materials precipitated. They were collected by suction filtration, washed with a small amount of diethyl ether, and dried in vacuo. Attempts at recrystallization were unsuccessful. Found: C, 39.93; H, 4.46; N, 11.60; Mn, 5.7; Cu, 12.7%. Calcd for $Cu_2MnF_6O_6N_8C_{32}H_{36}\cdot 2H_2O$: C, 39.99; H, 4.17; N, 11.67; Mn, 5.9; Cu, 13.7%. Mp 203—205 °C (decomp), Λ_M 0.4 S mol^{-1} cm^2 (chloroform), TGA: mass loss, 3.2 wt% (95—155 °C); Calcd for 2H$_2$O, 3.7 wt%.

Hetero-Metal Trinuclear Complex [CuLMn(hfa)$_2$LCu]·3H$_2$O 2. This complex was prepared by a similar method except that [Mn(hfa)$_2$]2H$_2$O instead of [Mn(tfa)$_2$]2H$_2$O was used. Attempts at recrystallization were unsuccessful. Found: C, 35.30; H, 3.40; N, 10.29; Mn, 4.7; Cu, 11.6%. Calcd for $Cu_2MnF_{12}O_6N_8C_{32}H_{30}\cdot 3H_2O$: C, 35.37; H, 3.34; N, 10.31; Mn, 5.1; Cu, 11.7%. Mp. 238—241 °C, Λ_M 0.1 S mol^{-1}cm^2 (chloroform), TGA: mass loss, 4.5 wt% (80—140 °C); Calcd for 3H$_2$O, 5.0 wt%.

Results and Discussion

The complexes **1** and **2** assume the chemical formulations [CuLMn(tfa)$_2$LCu]2H$_2$O and [CuLMn(hfa)$_2$-LCu]3H$_2$O, respectively, though the starting materials [CuHL](ClO$_4$) and each of [Mn(tfa)$_2$]2H$_2$O and [Mn-(hfa)$_2$]2H$_2$O were mixed in the mole ratio of 1 : 1 as described in the experimental section. The configuration around the manganese(II) ion in the present complexes **1** and **2** is presumed to be of six-coordination with four oxygen atoms of two β-diketonato ligands and two imidazolate nitrogen atoms of the a-site component complexes. The elemental analyses for Mn and Cu by atomic absorption verified the 1 : 2 ratio of Mn and Cu. The complexes **1** and **2** crystallize as hydrates. The water of crystal was detected by thermogravimetric analyses. The molar electrical conductances measured in chloroform solutions revealed that both complexes **1** and **2** are nonelectrolytes. This suggests that the imidazole-proton of [CuHL]$^+$ is deprotonated and the imidazolate nitrogen of [CuL] thus formed functions as the bridging group to the manganese(II) ion. The deprotonation of the imidazole-proton is supported by infrared spectra: The IR bands due to the imidazole-proton stretching vibration (3350 cm^{-1}) and the perchlorate anion (around 1080 cm^{-1}) of the starting material [CuHL](ClO$_4$] disappear in the spectrum of the complexes **1** and **2**.

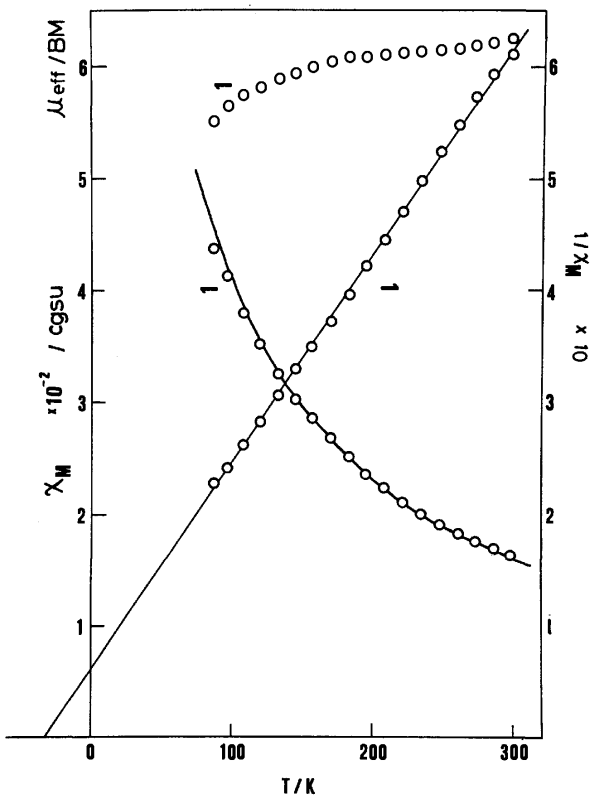


Fig. 1. Plots of the temperature dependence of the molar magnetic susceptibility, of the reciprocal molar magnetic susceptibility, and of the effective magnetic moment for the complex [CuLMn(hfa)$_2$LCu]3H$_2$O, **2**, where the solid curve of χ_M vs. T plot represents the theoretical curve of Eq. 1 with the parameters of g=2.00 and J=−8cm^{-1}.

The complexes **1** and **2** show qualitatively a similar magnetic behavior. Plots of the temperature dependence of the molar magnetic susceptibility, reciprocal molar magnetic susceptibility, and effective magnetic moment for the complex **2** are shown in Fig. 1, where χ_M, $1/\chi_M$, and μ_{eff} is given as the values per trinuclear complex in this text. The $1/\chi_M$ vs. T plots for the complexes **1** and **2** are nearly linear in the temperature range measured (80—300 K) and obey the Curie-Weiss law ($\chi_M=C(T+\theta)$) with the Weiss constants of θ=60 K for **1** and θ=33 K for **2**, where the Weiss constants were obtained by a least-squares method and the maximum deviation of the observed $1/\chi_M$ values from the calculated values is 2.8% for **1** and 3.5% for **2**, respectively. This suggests that there operates intra- or/and intermolecular antiferromagnetic interaction. The molar effective magnetic moment gradually increased from 5.3 BM for **1** and 5.5 BM for **2** at 87 K to 6.2 BM for **1** and 6.2 BM for **2** at 300 K. It is therefore apparent that the manganese(II) ion in the present complexes are high-spin(S=5/2). The temperature dependence of the effective magnetic moments also suggests that there are several spin states derived from Cu(II)-Mn(II)-Cu(II) spin system such as S=7/2, 5/2, and 3/2, where the spin-only values for S=7/2, 5/2, and 3/2 states are 7.94, 5.92, and 3.87 BM, respectively. The magnetic susceptibility data were analyzed on the basis of the spin-only expression for a symmetrical three-spin system (1/2-5/2-1/2). The molar magnetic susceptibility expression is given in Eq. 1.[7]

$$\chi_M = \frac{Ng^2\beta^2}{kT}\left[\frac{5x^{-7}+35(x^{-2}+1)/2+42x^5}{4x^{-7}+6(x^{-2}+1)+8x^5}\right] \quad (1)$$

In Eq. 1, x=exp(J/kT) and the other symbols have their usual meanings, where J is the Cu-Mn coupling constant, the Cu-Cu coupling constant is set to zero, and g is fixed 2.00. The observed susceptibility data for both complexes were closely represented by Eq. 1. For the complex **1**, the best-fit was obtained as J=−13 cm^{-1}. The generalized R factor, $R=[\sum[\chi_M(\text{obsd})-\chi_M(\text{calcd})]^2/\sum\chi_M(\text{obsd})^2]^{1/2}$, using as a convenient statistical indicator of the quality of fit is 0.020. For the complex **2**, the best-fit was obtained as J=−8 cm^{-1} and R=0.022. A theoretical χ_M vs. T curve using the J value obtained above is represented as a solid line in Fig. 1.

The antiferromagnetic parameters of the present complexes are relatively small, in comparison with the J values reported for bis(nitroxyl radical) adducts of bis(hexafluoroacetylacetonato)manganese(II) (J=−79, −105 cm^{-1})[7] and the J values for phenolic oxygen bridged complexes CuFe(fsaR)Cl·nH$_2$O (H$_4$fsaR=*N*,*N*′-bis(3-carboxysalicylidene)alkanediamine) (J=−50 cm^{-1}) which are the largest ones for hetero-metal polynuclear complexes with spin-system (S=5/2-1/2) reported so far.[3] The J values of the present complexes are compatible with that of [Cu(prp)$_2$enMn(hfa)$_2$] ((prp)$_2$en=quadridentate Schiff base ligand derived from 2′-hydroxy-propiophenone and ethylenediamine) (J=−13.2 cm^{-1}).[8]

The present complexes provide a synthetic route for hetero-metal polynuclear complexes with different spin-multiplicities and with unidentical coordination environments which are of current interest because of applications in biological systems. The study of the related hetero-metal binuclear complexes is in progress in our laboratory.

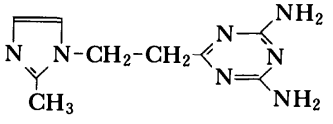
Enantiotropy of 2,4-Diamino-6-[2-(2-methyl-1-imidazolyl)ethyl]-1,3,5-triazine

Kazuo KAMAGATA* and Shuuji YOSHIDA
Research and Development Center, Shikoku Chemicals Corp., 25-1 Miyako, Namegawa, Hiki-gun, Saitama 355
(Received August 28, 1986)

Synopsis. Measurements using elementary analysis, differential thermal analysis, IR spectroscopy, and X-ray diffractometry have revealed that the title triazine assumes two crystalline forms α and β. The conversion from α to β proceeds rapidly at 230 °C, whereas the reversal takes place slowly at 60 °C and 95% RH.

2,4-Diamino-6-[2-(2-methyl-1-imidazolyl)ethyl]-1,3,5-triazine (**1**) is widely used as a curing agent for epoxy resin, because it provides good electric and mechanical properties to cured resin.[1] Compound **1** is synthesized from 2-methylimidazole, acrylonitrile, and dicyanodiamide.[2] It consists of a triazine ring, which is π-defficient, and an imidazole ring, which is π-excessive:[3]



1

Compound **1** is decomposed into 2,4-diamino-6-vinyl-1,3,5-triazine and 2-methylimidazole at elevated temperature.[4] This paper reports of differential thermal analyses (DTA) on **1** and **1** heat-treated at 230 °C for 25 min which detected different curves, their X-ray powder diffractions which also detected entirely different patterns, and DTA examination of chemical reactivities of **1** and heat-treated **1** to diglycidyl ether of bisphenol A (DGEBA).

Experimental

Materials. Compound **1** was purified before use by repeated recrystallization from methanol solution and dried at 60 °C for 8 h under vacuum. Its high-performance liquid chromatogram registered 99.9% purity. Heat treatment on **1** was carried out at 230 °C for 25 min in an oven (heat-treated **1**). Heat-treated **1** was treated under various conditions (samples *a*, *b*, and *c*). Pure DGEBA was kindly supplied from Yuka Shell Epoxy Co., Preliminary mixtures of **1** or heat-treated **1** with DGEBA were prepared at a temperature slightly higher than the melting point of DGEBA (46 °C) and mixed well at room temperature.

Apparatus and Precedures. IR spectra were taken with KBr pellets on a Hitachi 260-10 Spectrophotometer. A Shimadzu Thermal Analyzer DT-20B was used for DTA. In each run of DTA, 5 mg of sample was loaded and the same amount of Al_2O_3 was used as a reference. The temperature was raised from room temperature to 300 °C at a rate of 5 °C min^{-1}. The apparent activation energy of the reaction of **1** or heat-treated **1** with DGEBA was obtained by the Kissinger method[5] using heating rates ranging from 1 to 20 °C min^{-1}. X-Ray powder diffraction was conducted with a Rigaku X-ray powder diffractometer using graphite monochromatized Cu $K\alpha$ radiation (λ=1.5405 Å).

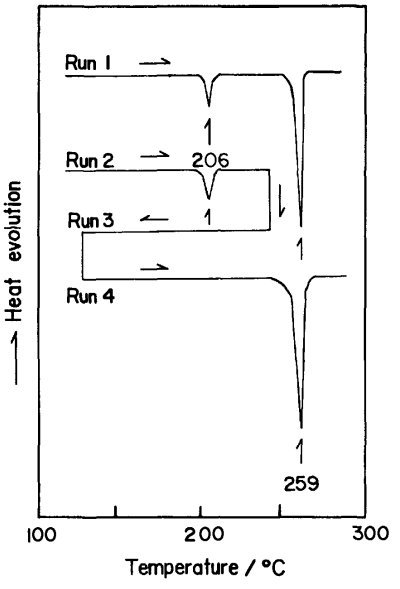


Fig. 1. DTA curves of 2,4-diamino-6-[2-(2-methyl-1-imidazolyl)ethyl]-1,3,5-triazine.

Results and Discussion

Polymorphic Behavior of 1. The DTA curves of **1** are given in Fig. 1. A small endothermic peak appears at 206 °C and a sharp endothermic peak due to fusion

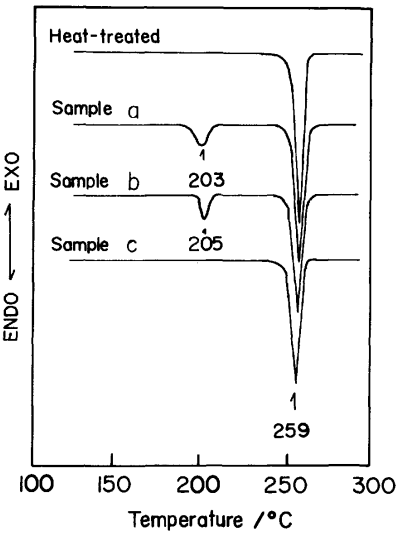

Fig. 2. DTA curves of 2,4-diamino-6-[2-(2-methyl-1-imidazolyl)ethyl]-1,3,5-triazine treated by various conditions after the heat treatment of 230 °C for 25 min. Heat-treated: heat-treated at 230 °C for 25 min.
Sample *a*; Kept at 60 °C, 95% RH for 48 h after the heat treatment. Sample *b*; Recrystallized from a methanol solution after the heat treatment. Sample *c*; Kept at room temperature for 30 d after the heat treatment.

Table 1. Elementary Analysis Data of **1** and Heat-Treated **1**

	C/%	H/%	N/%
Found for **1**	49.21	5.92	44.89
Found for heat-treated **1**	49.25	5.96	45.01
Calcd for $C_9H_{13}N_9$	49.30	5.98	44.72

Table 2. ^{1}H NMR of **1** and Mass Spectral Data of **1** and Heat-Treated **1**

^{1}H NMR (D_2O, 40 °C) (δ/ppm)	MS (75 eV, 140 °C) (m/z)
6.95 (d, H, J=1.5 Hz)	219(M^+), 204, 191
6.82 (d, H, J=1.5 Hz)	177, 149, 138, 125,
4.27 (t, 2H, J=6.8 Hz, -N-CH_2-CH_2-<)	111, 109, 95, 82, 81
2.87 (t, 2H. J=6.8 Hz, -N-CH_2-CH_2-<)	
2.25 (s, 3H, -CH_3)	

appears at 259 °C (run 1). The same heating process as run 1 was applied above the lower endothermic peak (run 2) and was followed by cooling down to room temperature (run 3). Subsequent heating gave no endothermic peak at 206 °C, but reproduced the sharp endothermic peak at 259 °C (run 4).

In order to interpret the above phenomena, **1** was heated at 230 °C for 25 min. The DTA curve (heat-treated **1** in Fig. 2) shows no endothermic peak at about 206 °C. On the other hand, sample *a* (equal to a heat-treated **1** which was kept at 60 °C and 95% RH for 48 h and dried at 60 °C for 8 h under vacuum) and sample *b* (equal to a heat-treated **1** which was dissolved and recrystallized from methanol solution and dried at 60 °C for 8 h under vacuum) gave a small endothermic peak at 203—205 °C in their DTA curves. The IR spectrum of sample *b* is identical with that of **1**. The small endothermic peak was absent in the DTA curve of sample *c* (equal to a heat-treated **1** which was kept at room temperature for 30 d).

The results of elementary analysis of **1** and heat-treated **1** were idential with the calculated value for $C_9H_{13}N_7$ as indicated in Table 1. In Table 2 are given the ^{1}H NMR data of **1** and the mass spectral data of **1** and heat-treated **1**, which are also identical with each other.

Part of the IR spectra of **1** and heat-treated **1** are given in Fig. 3. In Fig. 3, curve **A** represents the spectrum of **1**, which is essentially the same as those of samples *a* and *b*. Curve **B** represents the spectra of heat-treated **1** and sample *c*. The pronounced difference between curves **A** and **B** consists in the absorptions for the NH_2 stretching and bending. The NH_2 stretching bands appear at 3320 and 3100 cm^{-1} (curve **A**) and at 3475, 3320, and 3100 cm^{-1} (curve B). The absorption at 3475 cm^{-1} is possibility due to the stretching of NH_2 in free state.[6] The bending gives rise to the absorption at 1660 cm^{-1} in curve **A** and at 1630 and 1680 cm^{-1} in curve **B**.

Yuki et al. reported[7] an IR spectrum of 2-amino-4-(*N*-methyl-anilino)-6-isopropenyl-1,3,5-triazine (**2**) similar to that of **1** and attributed the difference in

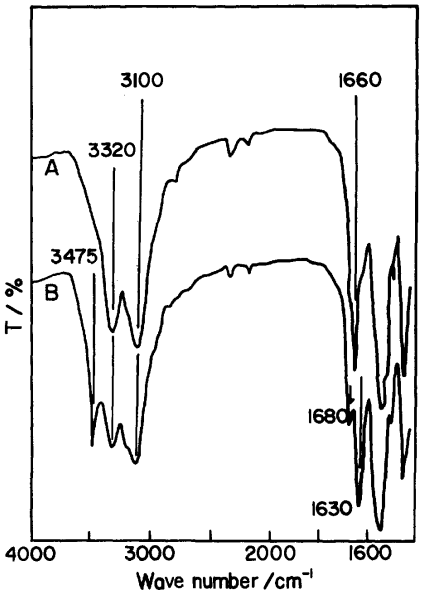

Fig. 3. IR Spectra of 2,4-diamino-6-[2-(2-methyl-1-imidazolyl)ethyl]-1,3,5-triazine (**A**) and heat-treated one at 230 °C for 25 min (**B**).

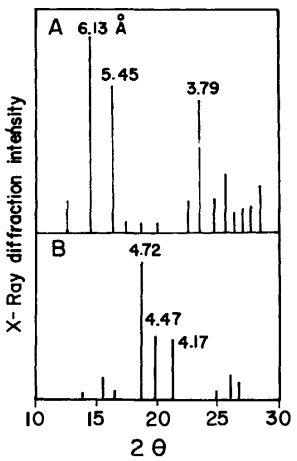

Fig. 4. X-Ray powder diffraction patterns of 2,4-diamino-6-[2-(2-methyl-1-imidazolyl)ethyl]-1,3,5-triazine (**A**) and heat-treated one at 230 °C for 25 min (**B**).

NH_2 absorption to different interactions between the proton of amino group and the π electron of isopropenyl group.

The results so far described are summarized with some inference as follows:

1. Compound **1** and heat-treated **1** give different DTA curves.
2. The measured elementary compositions of **1** and heat-treated **1** are the same as the calculated for $C_9H_{13}N_9$, and the mass spectral data of **1** and heat-treated **1** also are the same with each other.
3. The IR spectra of **1** and heat-treated **1** are different from each other in the absorptions due to NH_2 stretching and bending, suggesting different angles between the imidazole and triazine rings.

In order to investigate the existence of polymorphic forms of **1**, X-ray powder diffraction patterns of **1** and

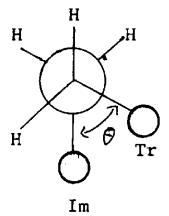
heat-treated **1** were examined. Both the patterns are entirely different as shown in Fig. 4. A very strong and two strong peaks corresponding to the spacings of 6.13, 5.45, and 3.79 Å, respectively, are observed for **1**, whereas a strong and two medium strong peaks corresponding to the spacings of 4.72, 4.47, and 4.17 Å, respectively, for heat-treated **1**. Samples *a* and *b* gave diffraction patterns similar to **1**, whereas sample *c* gave patterns to similar heat-treated **1**. We refer to the former as the α-form and the latter as the β-form.

Polymorphic phenomenon of triazine compound was previously reported with reference to dimorphic forms of **2** by Yuki et al.[7] Compound **2**, recrystallized from methanol solution, had two different crystalline forms. They referred to the **2** immediately crystallized from methanol solution as the α-form and the **2** slowly crystallized from methanol solution as the β-form. The β-form melts at 104 °C and immediately solidifies into a crystal that melts at 118 °C, while the α-form melts at 118 °C. The X-ray powder diffraction patterns of the α- and β-forms are entirely different. The IR spectrum of **2** that was heated at 115 °C is identical with that of the α-form. From the above results, they concluded that the α-form is a thermodynamically less stable crystal form than the β-form.

The polymorphic phenomena of organic crystals are classified into monotropic and enantiotropic.[8] Compound **2** is polymerized immediately after fusion of its stable form, but **1** is changed gradually from its crystalline form when heated under high humidity as folows:

$$\alpha \underset{60\,^{\circ}C,\ 95\%\ RH,\ 48\ h}{\overset{230\,^{\circ}C,\ 25\ min}{\rightleftharpoons}} \beta$$

The α-form is transformed into the β-form by beeing heated at 230 °C for 25 min, and the β-form into the α-form by beeing kept at 60 °C under 95% RH for 48 h. Since the α- and β-forms gave exactly the same elementary compositions and mass spectra but different DTA curves, IR spectra, and X-ray diffraction patterns, the α- and β-forms may be considered to be conformationally isomeric with respect to the imidazole and triazine rings connected by the ethylene bridge. On the basis of the wavenumber 3475 cm^{-1} at which the absortion due to the stretching of freestate NH_2 appears,[6] the α- and β-forms are taken to be antiperiplaner to each other with different angles θ between the imidazole and triazine rings connected by the ethylene bridge. The conformational isomeric situation is illustrated diagramatically below:



Their conformations are supported by chemical reactivities of **1** and heat-treated **1** to DGEBA described in the following section.

Chemical Reactivity of 1 to DGEBA. Compound **1** is widely used as a curing agent for epoxy resin as mentioned before. The reaction of imidazole compound with epoxy resin consists of two steps.[9] The first step is the addition to epoxide of group NH at the 1-position of the imidazole ring. The second step is the ring opening of epoxide by the catalyst produced in the first step. Since in **1** the hydrogen at the 1-position of the imidazole ring is already substituted, the reaction of **1** or heat-treated **1** with DGEBA essentially starts with the second step. The chemical reactivity of **1** and heat-treated **1** to DGEBA was studied by measuring activation energies of the reaction. Apparent activation energies were obtained by the Kissinger equation:[5]

$$\frac{d(\ln \phi/T_m^2)}{d(1/T_m)} = -\frac{E}{R} \quad (1)$$

where ϕ is the heating rate in °C min^{-1}, T_m is the absolute temperature of the exothermic peak in DTA curves, and R is the gas constant. The exothermic temperature was measured by changing the heating rate from 1 to 20 °C min^{-1}. The activation energies calculated according to Eq. 1 are 38.3 kcal mol^{-1} for the mixture of **1** and DGEBA and 25.3 kcal mol^{-1} for that of heat-treated **1** and DGEBA. It is considered that the difference in activation energy results from the difference in the crystalline forms of **1** and heat-treated **1**.

The authors wish to express their profound thanks to Assistant Professor Yoshio Shibasaki, Saitama University for providing them with the X-ray diffraction patterns and useful discussion. They also wish to express their sincere thanks to Dr. Natsuo Sawa, Excutive Director and Mr. Atsushi Saeki, Shikoku Chemicals Corp. for furnishing them with some of the ^1H NMR and mass spectral data and helpful discussion.

Nonacarbonyldiiron-Induced Reaction of 3-Azido-1,2,3-triphenylcyclopropene and 4,5,6-Triphenyl-1,2,3-triazine

Tomoshige KOBAYASHI, Naoki MURATA, and Makoto NITTA*
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160
(Received January 6, 1987)

Synopsis. The $[Fe_2(CO)_9]$-induced reaction of 3-azido-1,2,3-triphenylcyclopropene (**1**) undergoes elimination of a nitrogen molecule and C-C bond cleavage to result in the formation of benzonitrile, diphenylacetylene, 2,3-diphenylinden-1-one, and 1,2,3-triphenylpropen-1-one. The similar reaction of 4,5,6-triphenyl-1,2,3-triazine, which is an isomer of **1**, undergoes reductive N-N bond cleavage to give 3,4,5-triphenylpyrazole in good yield.

Previously, we have found that $[Mo(CO)_6]$, $[Fe(CO)_5]$, and $[Fe_2(CO)_9]$ can induce the reductive N-O bond cleavage of isoxazoles in protic media to give β-amino enones in good yields.[1] Application of this method for the synthesis of geiparvarin has been demonstrated.[2] Furthermore, our group[3] and other groups[4-10] have investigated the generation and chemical behaviors of the complexed nitrene intermediates which are derived from the reaction of organic azides with iron carbonyl. A series of these studies then raise the question whether the complexed nitrene intermediate, which is derived from 3-azido-1,2,3-triphenylcyclopropene (**1**) and $[Fe_2(CO)_9]$, undergoes ring expansion to give azete (azacyclobutadiene) or complexed azete derivative or not. Thermal reaction of **1** has been reported to give 4,5,6-triphenyl-1,2,3-triazine (**2**).[11] The photochemical reaction of **2** has also been reported to give benzonitrile, diphenylacetylene, 2,3-diphenylquinoline, and 2,3,5,6,7,8-hexaphenyl-1,4-diazocine via postulated azete intermediate.[11,12] However, up to now, three azete derivatives, tris(dimethylamino)-,[13] tri-*t*-butylazete,[14] and 2-arylbenzazete,[15] have been isolated as the products of the thermal decomposition of the corresponding triazines. We report here the results for the $[Fe_2(CO)_9]$-induced reaction of **1** and **2**.

The reaction of **1** with $[Fe_2(CO)_9]$ at ambient temperature in anhydrous benzene, acetonitrile, and aqueous acetonitrile afforded benzonitrile (**3**), diphenylacetylene (**4**), 2,3-diphenyl-1*H*-inden-1-one (**5**), and 1,2,3-triphenylpropen-1-one (**6**) as shown in Scheme 1. The product **3** was detected by GLC and IR, and the isolation was not carried out. The reaction conditions and the yields of the products except **3** are summarized in Table 1 (Entries 1—3). In contrast, the reaction of **1** and $[Fe_2(CO)_9]$ in methanol gave mainly **6** and the complex **7** in addition to **3**, **4**, and **5** (Table 1, Entry 4).

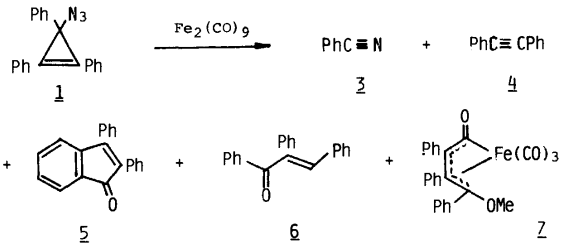
Table 1. Results of the Reaction of **1** with $[Fe_2(CO)_9]$[a]

Entry	Solvent	Product (yield/%)				
		3	**4**	**5**	**6**	**7**
1	PhH	b)	8	6	8	—
2	MeCN	b)	5	15	9	—
3	MeCN-H_2O[c]	b)	3	4	10	—
4	MeOH	b)	1	1	67	13

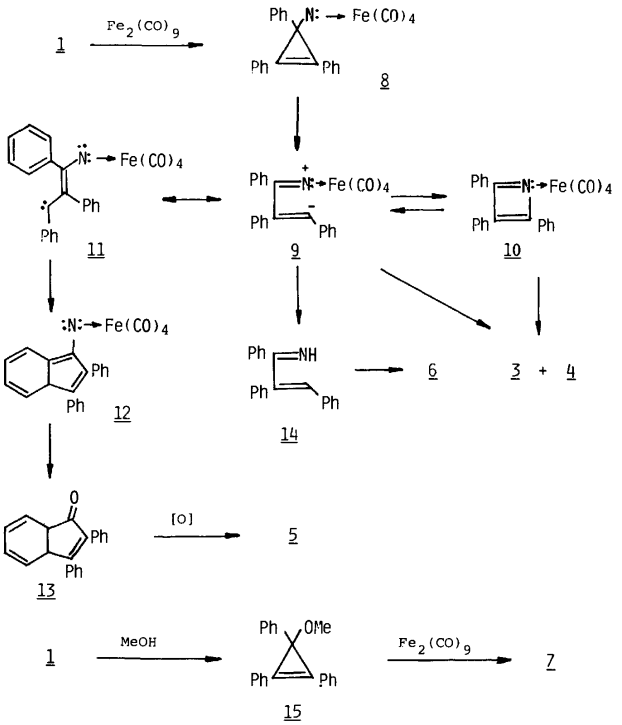
a) Reactions were carried out at ambient temperature for 24 h. b) Isolation was not carried out. c) 5.0 Molar equivalent amounts of water was added.

The postulated mechanistic pathways for the reaction are shown in Scheme 2. The reaction of **1** with $[Fe_2(CO)_9]$ initially gives the complexed nitrene intermediate **8**.[3-10] Then, the C-C bond cleavage of **8** seems to occur to give **9**. The direct decomposition of **9** can give **3** and **4**. An alternative route involving an azete intermediate **10**, which can give **3** and **4**, might not be ruled out. However, no evidence has been obtained at this stage.

On the other hand, compound **9** would cyclize to **12**,



Scheme 1.

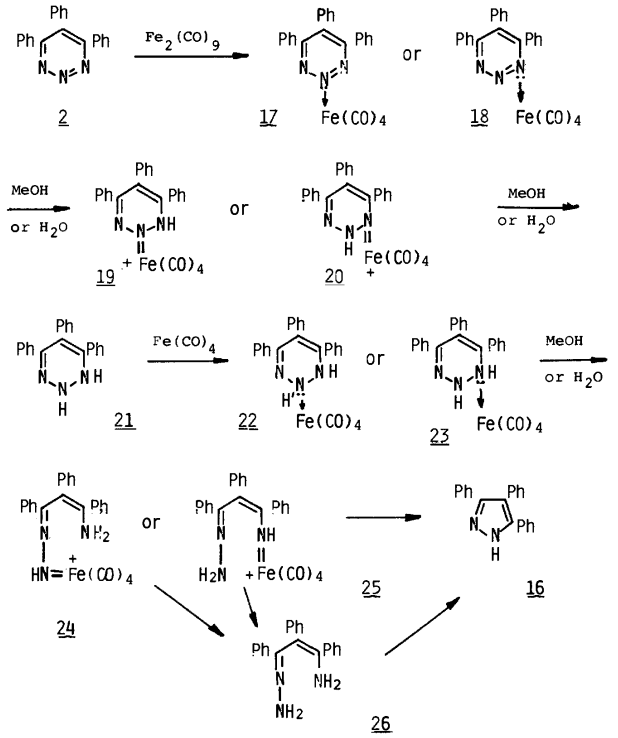


Scheme 2.

probably through intermediarily formed **11**. The reduction of the nitrene moiety of **12** to enamine followed by hydrolysis under workup conditions would give **13**.[1,3] The oxidation of **13** seems to occur easily to give **5**. Furthermore, the protonation and reduction of the nitrogen moiety of **9** giving **14** followed by hydrolysis would give **6**.[16] The compound **6** was obtained even in anhydrous solvents (Table 1, Entries 1 and 2). Even in the reaction in anhydrous solvents, the possibility of stray water can not be ruled out. The compound **6** was obtained in good yield in methanol (Table 1, Entry 4). This fact would be attributable to the effective reduction and protonation of **9** in methanol.[16] The complex **7** has already been isolated in the reaction of iron carbonyls with 3-methoxy-1,2,3-triphenylcyclopropene (**15**).[17] Actually, the reaction of **1** with methanol afforded **15** in a quantitative yield, therefore the formation of **7** would be rationalized. Thus, the complexed cyclopropenylnitrene **8** was demonstrated to undergo easy cleavage of the bent C-C bond. The intervention of the complexed azete **10** is not supported by experimental evidence.

On the other hand, the reaction of **2** with $[Fe_2(CO)_9]$ in methanol or in aqueous acetonitrile under reflux afforded 3,4,5-triphenylpyrazole (**16**) in 80 or 77% yield, respectively.

The reaction is formally explained by the pathways shown in Scheme 3. The initial step should be an n-donor complexation of **2** to the $[Fe(CO)_4]$ species[1] to give **17** [or **18**]. The peroxy acid oxidation of 1,2,3-triazine derivatives gives 1-oxides and/or 2-oxides.[18] No evidence is available to distinguish between the N1 and N2 complexation to give **18** and **17** at the present reaction. The back donation of the d-electron from the iron to the complexed 1,2,3-triazine **17** [or **18**] and subsequent protonation gives **19** [or **20**] and then **21** in protic media. The further complexation of **21** with another $[Fe(CO)_4]$ species giving **22** [or **23**] followed by reductive ring opening gives **24** [or **25**], cyclization of which then affords the pyrazole **16**. The reduction-protonation sequences of **24** [or **25**] seems also possible to give **26** which would give **16**.[11] Although the catalytic hydrogenation of **2** has been known to give **16** in good yield,[11] the present reaction could provide the first example of $[Fe_2(CO)_9]$-induced reductive cleavage of the triazine ring system.



Scheme 3.

Experimental

The IR spectra were recorded on a Shimadzu IR-400 spectrometer. The NMR spectra were recorded on a Hitachi R-24 spectrometer and the chemical shifts are given in ppm (δ) relative to the internal $SiMe_4$ standard. The mass spectral studies were conducted using Shimadzu GCMS QP-1000 spectrometer. $[Fe_2(CO)_9]$ was prepared by the standard method.[19] All of the $[Fe_2(CO)_9]$-induced reactions were carried out under a nitrogen atmosphere. The desired compounds, 3-azido-1,2,3-triphenylcyclopropene (**1**)[11] and 4,5,6-triphenyl-1,2,3-triazine,[20] were prepared according to the literatures. All of the melting points are uncorrected.

General Procedure for the Reaction of 1 with $[Fe_2(CO)_9]$. A solution of **1** (309 mg, 1 mmol) and $[Fe_2(CO)_9]$ (728 mg, 2 mmol) in a solvent (20 cm^3) was stirred for 24 h at ambient temperature. Then, the solution was filtered through Celite to remove insoluble materials, and the filtrate was concentrated in vacuo. The residue contained benzonitrile **3** which was detected by GLC and IR. The residue was separated by column chromatography on silica gel. The fractions eluted with hexane afforded **4**, the mixture of **5** and **6**, and **7**. The mixture was further separated by TLC on silica gel using CCl_4 as a developer to give **5** and **6**. The reaction conditions and the yields of the products are summarized in Table 1. For **5**: mp 145—146 °C (from MeOH) (lit,[21] 149—151 °C); IR ($CHCl_3$) 1709, 1604 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.19—7.63 (14H, m). For **6**: mp 96—97 °C (from benzene-hexane) (lit,[21] 96.5—97.5 °C). For **7**: mp 131—133 °C (decomp) (from benzene-hexane) (lit,[17] 133—135 °C); IR ($CHCl_3$) 3075, 3033, 2961, 2065, 1998, 1731 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.79 (3H, s), 6.77—7.36 (15H, m); *m/z* (rel intensity), 466 (M^+−28, 3), 105 (100).

Formation of 15 in Methanol. A solution of **1** (160 mg, 0.5 mmol) in anhydrous methanol (5 cm^3) was stirred for 24 h at ambient temperature. After the methanol was evaporated, the residue was extracted with ether. The organic layer was dried over Na_2SO_4, and evaporated to give 90% of **15**: mp 67—68 °C (lit,[22] 69—70 °C); IR ($CHCl_3$) 1812 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.40 (3H, s), 7.18—7.59 (10H, m), 7.63—7.89 (5H, m).

General Procedure for the Reaction of 2 with $[Fe_2(CO)_9]$. A solution of **2** (309 mg, 1 mmol) and $[Fe_2(CO)_9]$ (728 mg, 2 mmol) in methanol (20 cm^3) was refluxed for 2 h. The solution was filtered through Celite to remove insoluble materials. The filtrate was concentrated and the residue was purified by column chromatography on Florisil using benzene as the eluant to give **16** in an 80% yield. The reaction carried out in moist acetonitrile containing 5 molar equivalent amounts of water also afforded **16** in a 77% yield. The structure of **16** was confirmed by comparison of the spectral data with those of authentic specimen.[11,23]

ESR Spectroscopic Study of Triphenylmethyl-Substituted Thioaminyl Radicals: *N*-(Triphenylmethylthio)alkylaminyls and -arylaminyls[1)]

Yozo Miura,* Mamoru Isogai, and Masayoshi Kinoshita
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received February 4, 1987)

Synopsis. The title radicals, generated by hydrogen-atom abstraction from the corresponding *N*-(triphenylmethylthio)-alkylamines and -arylamines, have been studied by means of ESR spectroscopy. The alkylaminyls were transient in solution at room temperature, while the arylaminyls persisted for a long period under the same conditions. The ESR parameters are discussed by comparing them with those for structurally related aminyls.

Thioaminyl radicals (RṄSR′) have an interesting structure in which a divalent sulfur atom attaches directly to the radical center. In our ESR studies of a variety of thioaminyl radicals, we have found that, in the radicals, the unpaired electron is delocalized considerably onto the adjacent sulfur and that some thioaminyls can be isolated as hydrazine-like dimers or pure radical crystals.[2,3)] In the present paper we wish to report an ESR spectroscopic study of *N*-(triphenylmethylthio)alkylaminyls and -arylaminyls (**2**), which have never appeared in the literature.[4)]

Results and Discussion

Thioaminyls **2** were generated by the phtolysis of *N*-(triphenylmethylthio)alkylamines or -arylamines (**1**) in benzene in the presence of di-*t*-butyl peroxide. Additionally, the arylaminyls **2d** and **2e** were also generated by treating the corresponding amines with (*t*-BuOOCO-)$_2$. Some typical ESR spectra are illustrated in Figs. 1 and 2, while the ESR parameters are summarized in Table 1.

Although the radical generation was performed at room temperature with a low-power mercury lamp (100 W), all the ESR spectra were relatively strong, as may be found in Fig. 1. However, upon the interruption of UV-irradiation, the ESR signals due to the alkylaminyls **2a—c** disappeared immediately at room temperature. On the other hand, the arylaminyls **2d** and **2e** survived for a long period under the same conditions; in particular, **2e** was quite long-lived; the lifetime shown by a brief kinetic study was more than a week.

In most spectra, an impure radical with a *g* value of 2.003 appeared in the signals of **2**, as is shown in Fig. 1. The low *g* value and its extremely persistent property suggested that the impure radical was the triphenylmethyl radical. This was confirmed by comparing its ESR spectrum with that of an authentic triphenylmethyl radical obtained from a solution of PhN=NCPh$_3$. This impure radical was not observed from the pho-

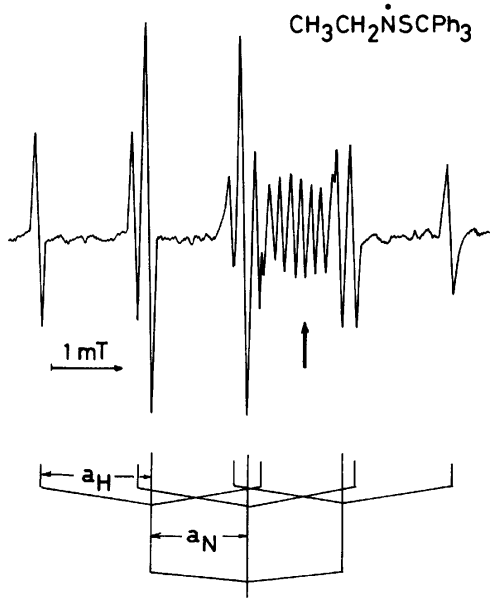

Fig. 1. ESR spectrum of **2b** recorded during photolysis of a solution of **1b** in 1:4 (v/v) di-*t*-butyl peroxide–benzene at 17°C. The impure radical indicated by a bold arrow is the triphenylmethyl radical.

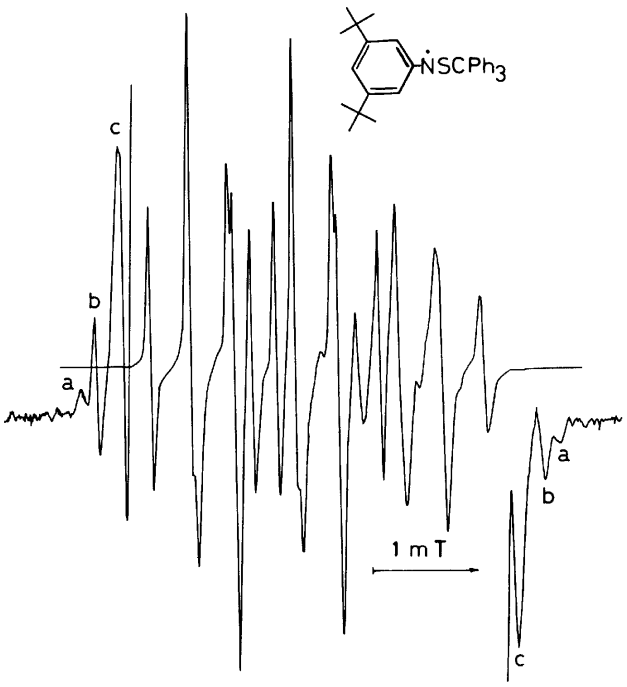

Fig. 2. ESR spectrum of **2e** generated by treating **1e** with (*t*-BuOOCO-)$_2$ in degassed benzene at 17°C. Both wings of the parent signal are shown at high gain (100 times). Assignment of the satellite lines are as follows: a, ^{33}S; b, ^{13}C (1C); c, ^{13}C (3C).

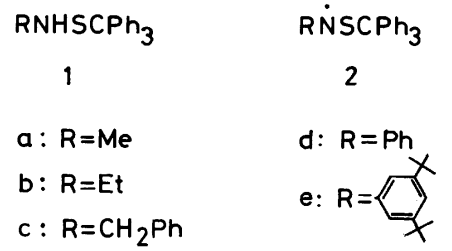
Table 1. ESR Parameters for *N*-(Triphenylmethylthio)alkylaminyls and -arylaminyls[a-c]

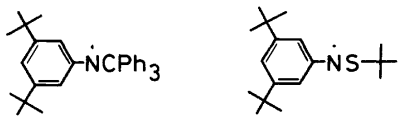
Radical	a_N	a_H[d]	g
2a	1.26	1.66 (3)	2.0074
2b	1.25	1.42 (2)	2.0073
2c	1.23	1.48 (2)	2.0073
2d[e]	0.995	0.381 (2),[f] 0.128 (2),[g] 0.426 (1)[h]	2.0062
2e[e,i]	0.988	0.385 (2),[f] 0.443 (1)[h]	2.0062

a) Hyperfine splitting constants are given in mT. b) Solvent: benzene or 1:4 (v/v) di-*t*-butyl peroxide–benzene. c) Temperature: 17±2°C. d) Numbers in parentheses refer to the number of equivalent protons. e) Hyperfine splitting constants have been determined by computer simulation. f) Ortho protons on the anilino benzene ring. g) Meta protons on the anilino benzene ring. h) Para proton on the anilino benzene ring. i) $a_{^{13}C}$=0.55 (3C), 1.03 mT (1C), $a_{^{33}S}$=0.43 mT.



Scheme 1.

Scheme 2.



Scheme 3.

tolysis of a solution of **1** alone. Thus, we thought that it was derived from **2**, probably through the homolytic C-S bond cleavage, as is shown in Scheme 2. A similar decomposition reaction of radicals has been reported to occur in aryl triphenylmethyl nitroxide radicals.[5]

Because of its considerably persistent property, the thioaminyl **2e** permitted us to measure some satellite lines due to ^{13}C and ^{33}S atoms at natural abundance (^{13}C 1.11%, ^{33}S 0.76%). As is shown in Fig. 2, three satellite lines were found in each wing of the parent spectrum recorded at a high gain (100 times). From the intensity ratios to the parent spectrum the a peak (<0.2%)[6] was assigned to the satellite lines due to ^{33}S, while the b (0.5%) and c peaks (1.3%) were assigned to those due to one and three magnetically almost equivalent ^{13}C atoms.

Furthermore, *N*-(triphenylmethyl)-3,5-di-*t*-butylphenylaminyl (**3**) was generated, for a comparison of the ESR parameters, by the oxidation of *N*-(triphenylmethyl)-3,5-di-*t*-butylaniline (**4**) with PbO_2. The ESR parameters thus obtained (in benzene at 17 °C) were a_N=0.931, $a_{o\text{-}H}$=0.563 (2H), $a_{p\text{-}H}$=0.727 mT (1H), and g=2.0038. This aminyl was relatively persistent and gave a strong ESR signal.

ESR Parameters. The aminyls **2** give ESR parameters very similar to those for the radicals of the RṄSBu^t[2] and ArṄSBu^t[7] types (R=alkyl, Ar=aryl). For instance, the hyperfine splitting (hfs) constants for **2a** are very close to those for MeṄSBu^t (a_N=1.25, a_β=1.64 mT).[2] Similarly, those for **2e** are very similar to those for **5** (a_N=0.993, $a_{o\text{-}H}$=0.368, $a_{p\text{-}H}$=0.420, $a_{^{33}S}$=0.466 mT).[2,7] Accordingly, we can say that the thioaminyls **2** adopt the same, or almost the same, configuration as the RṄSBu^t or ArṄSBu^t radicals (probably planar around the nitrogen).[2]

In contrast, the ESR parameters are quite different from those of the radicals of the RṄR′ or ArṄR type radicals.[8] A typical example is given by **3**, whose $a_{o\text{-}H}$ and $a_{p\text{-}H}$ values are substantially higher than those for **2e**. The reduction in a_H found in going from **3** to **2e** is obviously a consequence of the conjugative delocalization of the unpaired electron from the nitrogen to the sulfur in **2** (-Ṅ-Ṡ- ↔ -Ṅ⁻-Ṡ⁺-), as is suggested by the relatively high $a_{^{33}S}$ value and the higher g value. Here, the π-orbital spin density (ρ_S^π) on the sulfur in **2e** was estimated from the $a_{^{33}S}$ value by using Equation 1, which had been previously established through an investigation of the ^{33}S hfs constants of a variety of RṄSR′ radicals.[2] The ρ_S^π value thus obtained is 0.18;

$$\rho_S^\pi = a_{^{33}S}/Q_S = a_{^{33}S}/2.3 \text{ mT} \quad (1)$$

this magnitude strongly suggests that the thioaminyls **2** are electronically substantially stabilized by this conjugation. However, because of the relatively weak C-S bonds, the thioaminyls **2** were less persistent than had been anticipated, and no **2** could be isolated as the radical or dimer substance.

Experimental

The melting points and the IR and ^1H NMR spectra were taken as previously reported.[9] Triphenylmethanesulfenyl chloride[10] (Ph_3CSCl), phenylazotriphenylmethane,[11] and 3,5-di-*t*-butylaniline[12] were prepared by the previously reported methods.

The *N*-(triphenylmethylthio)amines (**1**) were prepared by either method, A or B. Method A: a solution of 1.12 g (3.60 mmol) of Ph_3CSCl in 15 ml of CH_2Cl_2 was added dropwise to an aqueous RNH_2 solution (with a large excess of RNH_2) with vigorous stirring at 0 °C. After being stirred for 0.5 h at the same temperature, the organic layer was separated and dried over $MgSO_4$. After filtration, the solvent was evaporated, and the residue was chromatographed on silica gel (Wako gel C-200; column size 4×20 cm) using 1:2 (v/v) benzene–hexane as the eluant and was crystallized from methanol.

Method B: a solution of 1.12 g (3.60 mmol) of Ph_3CSCl in 15 ml of CH_2Cl_2 was added dropwise to a solution of 10 mmol of RNH_2 (or 4.5 mmol of RNH_2 and 7.2 mmol of Et_3N) in 10 ml of CH_2Cl_2 with stirring at 0 °C. After being stirred for 1 h at the same temperature, the reaction mixture was washed with water (30 ml×3), saturated K_2CO_3 (30 ml), and brine (30 ml), and dried over $MgSO_4$. After filtration, the solvent was evaporated, and the residue was chromatographed as above and crystallized from methanol.

N-(Triphenylmethylthio)methylamine (**1a**) [mp 109—111 °C (lit,[13] 119—120 °C)] and *N*-(triphenylmethylthio)ethylamine (**1b**) were obtained by Method A, while *N*-(triphenylmethylthio)benzylamine (**1c**), *N*-(triphenylmethylthio)aniline (**1d**) [mp 96—98 °C (lit,[13] 103 °C)], and *N*-(triphenylmethylthio)-3,5-di-*t*-butylaniline (**1e**) were prepared by Method B.

Thioamine 1b: Colorless prisms; mp 88—90 °C yield 47% (0.54 g, 1.7 mmol); IR (KBr) 3260 cm^{-1} (NH); ^1H NMR ($CDCl_3$) δ=0.82 (t, J=7 Hz, 3H, CH_3), 2.40 (s, 1H, NH), 2.52 (q, J=7 Hz, 2H, CH_2), 7.12—7.42 (m, 15H, aromatic). Found: C, 79.26; H, 6.64; N, 4.44%. Calcd for $C_{21}H_{21}NS$: C, 78.95; H, 6.63; N, 4.38%.

Thioamine 1c: Colorless needles; mp 97—98 °C; yield 61% (0.82 g, 2.2 mmol); IR (KBr) 3300 cm^{-1} (NH); ^1H NMR ($CDCl_3$) δ=2.72 (t, J=5.9 Hz, 1H, NH), 3.62 (d, J=5.9 Hz, 2H, CH_2), 6.92—7.48 (m, 20H, aromatic). Found: C, 81.91; H, 6.13; N, 3.56%. Calcd for $C_{26}H_{23}NS$: C, 81.85; H, 6.08; N, 3.67%.

Thioaniline 1e: Pale yellow prisms; mp 117—119 °C yield 26% (0.45 g, 0.93 mmol); IR (KBr) 3350 cm^{-1} (NH); ^1H NMR ($CDCl_3$) δ=1.19 (s, 18H, *t*-Bu), 4.78 (s, 1H, NH), 6.49—7.42 (m, 18H, aromatic). Found: C, 82.24; H, 7.72; N, 2.82; S, 6.90%. Calcd for $C_{33}H_{37}NS$: C, 82.62; H, 7.77; N, 2.92; S, 6.68%.

***N*-(Triphenylmethyl)-3,5-di-*t*-butylaniline (4).** A mixture of 0.80 g (3.9 mmol) of 3,5-di-*t*-butylaniline, 1.0 g (3.6 mmol) of triphenylmethyl chloride, and 1.5 ml of Et_3N in 50 ml of dry ether was stirred at room temperature for 24 h. After the reaction mixture was filtered and evaporated, the residue was crystallized from methanol to give pale yellow prisms in a 39% yield (0.62 g, 1.4 mmol). Mp 172.5—173.5 °C; IR (KBr) 3410 cm^{-1} (NH); ^1H NMR ($CDCl_3$) δ=1.06 (s, 18H, *t*-Bu), 4.85 (s, 1H, NH), 6.14—7.39 (m, 18H, aromatic). Found: C, 88.81; H, 8.42; N, 2.88%. Calcd for $C_{33}H_{37}N$: C, 88.54; H, 8.33; N, 3.13%.

ESR Measurements. Aminyls **2** were generated by the photolysis or **1** in degassed 1 : 4 di-*t*-butyl peroxide-benzene with a high-pressure mercury lamp. Aminyls **2d** and **2e** were also generated by treating the corresponding **1** with (*t*-BuOOCO-)$_2$ in degassed benzene. Radical **3** was prepared by the oxidation of **4** with PbO_2 in benzene. All the ESR spectra were recorded at 17±2 °C on a JEOL JES-ME-3X spectrometer. The hyperfine splitting constants and g values were determined by comparison with Fremy's salt in a K_2CO_3 aqueous solution (a_N=1.309 mT, g=2.0057).

Ion Selectivity of 14-Crown-4 Derivative Possessing Two Potential Anionic Sites on Extraction of Alkali and Alkaline-Earth Metal Ions

Keiichi KIMURA,* Mutsuo TANAKA, and Toshiyuki SHONO*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-Oka, Suita, Osaka 565
(Received March 18, 1987)

Synopsis. A lipophilic 14-crown-4 derivative bearing two dinitrophenol moieties was synthesized and its ion selectivity was elucidated on cation extraction from a basic aqueous phase into an organic phase. The crown ether derivative was found to possess preferences for Ca^{2+} and Sr^{2+} as well as Li^+.

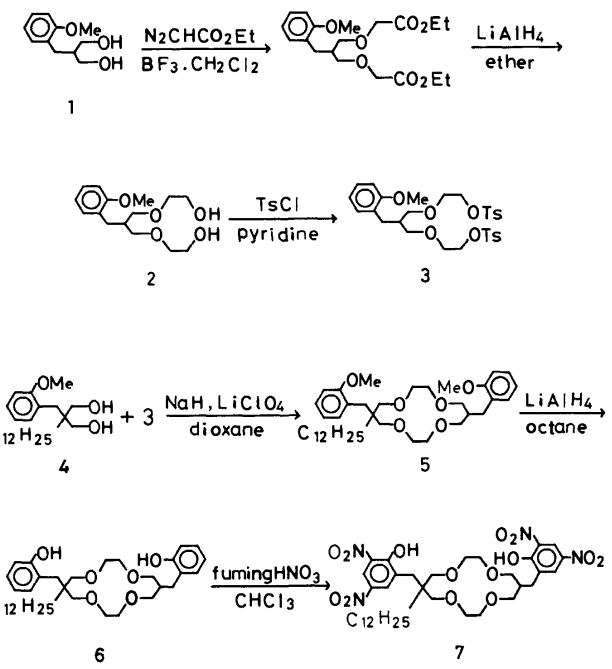
One of the highly selective ligands for Li^+ is 14-crown-4 (1,4,8,11-tetraoxacyclotetradecane) derivatives.[1,2] Such high Li^+ selectivity has also been realized in 14-crown-4 derivatives carrying an proton-dissociable moiety in the side chain, which extract Li^+ selectively from basic aqueous solutions containing alkali and alkaline-earth metal ions by the proton-cation exchange mechanism.[3-6] If a chromogen is included in the proton-dissociable moiety,[6] the ionizable 14-crown-4 derivatives also serve as spectrophotometric reagents after the selective cation extraction.[3,5] In addition, the ionizable 14-crown-4 derivatives carry out proton-driven membrane transport of Li^+ with excellent selectivities.[7] In the Li^+ complexes of 14-crown-4 derivatives bearing a proton-dissociated moiety, the positive charge of the cation is counterbalanced intramolecularly by the monovalent anion. The electroneutrality of the resulted complexes, combined with the fitness of Li^+ into the 14-crown-4 ring, contributes remarkably to the Li^+ selectivity of the crown ethers bearing a potential monovalent anion, especially against multivalent cations like alkaline-earth metal ions. It occurred to us that 14-crown-4 derivatives incorporating two proton-dissociable substituents might exhibit some selectivities for divalent small cations like Mg^{2+} and Ca^{2+} on the cation extraction and the membrane cation transport. This paper reports synthesis of a 14-crown-4 bearing two dinitrophenol moieties and its ion selectivity on the cation extraction.

Experimental

Synthesis of 14-Crown-4 Bis(dinitrophenol) 7 or 6,13-Bis(2-hydroxy-3,5-dinitrobenzyl)-6-dodecyl-1,4,8,11-tetraoxacyclotetradecane The synthetic route is given in Scheme 1. The synthesis of 1,3-propanediol derivatives **1** and **4** has been described elsewhere.[5] The reaction of **1** (77 mmol) with ethyl diazoacetate (230 mmol) in dry dichloromethane (700 cm^3) in the presence of $BF_3 \cdot OEt_2$ (1 cm^3, dropwise addition under a nitrogen atmosphere while cooling in an ice bath) for 1 h at room temperature and then for 2 h at the refluxing temperature gave diethyl 5-(2-methoxybenzyl)-3,7-dioxanonane-1,9-dioate (72%), which (55 mmol) was reduced with $LiAlH_4$ (84 mmol) in diethyl ether (150 cm^3) to yield 5-(2-methoxybenzyl)-3,7-dioxanonane-1,9-diol (**2**, ≈100%). The diol was then converted to corresponding ditosylate **3** in a usual fashion.

The procedures for the cyclization to **5**, demethylation, and nitration are as follows. In a dioxane solution (125 cm^3) of **4** (1.9 mmol), NaH (20 mmol), and $LiClO_4$ (2.5 mmol) were suspended and the mixture refluxed for 0.5 h. To the refluxing suspension was added a dioxane (25 cm^3) solution of **3** (1.9 mmol) dropwise in 1 h. The reflux was continued for 3 d. Preparative reversed-phase liquid chromatography (octadecylsilanized silica(ODS), MeOH-$CHCl_3$(10/1)) afforded colorless liquid of **5** (17%). The demethylation was performed by treating **5** (0.82 mmol) with $LiAlH_4$ (16 mmol) in refluxing octane (100 cm^3) for 8 h to yield colorless liquid of crown bisphenol **6** (50%). The crown bisphenol was nitrated by fuming HNO_3. To a chloroform (200 cm^3) solution of **6** (0.34 mmol) was added fuming HNO_3 (50 cm^3). The mixture was then stirred for 5 min at room temperature. After the reaction, water (200 cm^3) was added to the mixture. The chloroform phase was separated and washed with water. Evaporation of the chloroform gave crude product of **7**, which was purified by the reversed-phase chromatography (MeOH) to yield yellow liquid of **7** (50%): UV-VIS ($ClCH_2CH_2Cl$) 268 (ε 2.64×10^4) and ca. 350 nm (sh, ε 6.14×10^3); IR (neat) 3180 and 1260 (O-H), 1540 (N=O), and 1120 and 1100 cm^{-1} (C-O); ^1H NMR (CCl_4) δ=0.88 (3H, t, J=6 Hz, CH_3), 1.1—1.5 (22H, m, $(CH_2)_{11}CH_3$), 1.9—2.1 (1H, m, $(OCH_2)_2CH$), 2.7—2.9 (4H, m, CH_2Ph), 3.2—3.7 (16H, m, OCH_2), 8.2—9.0 (4H, m, aromatic H), 11.4—11.6 (2H, m, OH). Found: C, 56.83; H, 6.87; N, 7.03%; M^+ 764. Calcd for $C_{36}H_{52}O_{14}N_4$: C, 56.53; H, 6.85; N, 7.33%; M, 764.

Cation Extraction. The metal salts employed here were



Scheme 1.

of analytical grade. Water and 1,2-dichloroethane were purified by distillation and deionization. The extraction was undertaken at room temperature for the qualitative comparison of cation extractability. Equal volumes (5 cm^3) of a 1,2-dichloroethane solution of 3.5×10^{-5} mol dm^{-3} crown ether and a buffered aqueous solution of 1 mol dm^{-3} metal chloride were placed in a stoppered centrifuge tube (10 cm height×1.5 cm diameter). The pH in the aqueous phase was adjusted to pH 7.23 by using 3-morpholino-1-propanesulfonic acid (MOPS)-tetramethylammonium hydroxide (TMAOH) buffer. The tube was shaken vigorously for 30 s. After the centrifugation, 4 cm^3 of the organic phase solution was taken up for the spectrophotometry.

For the determination of the extraction equilibrium constant, the extraction was carried out at 25 °C by varying the metal ion concentration (0.1—1 mol dm^{-3}) and keeping the crown ether concentration constant (3.5×10^{-5} for Li^+ and Sr^{2+}, 7×10^{-5} for Ca^{2+}, and 1.4×10^{-4} mol dm^{-3} for Ba^{2+}). The pH in the aqueous phase was 7.60 with a MOPS-TMAOH buffer. A stoppered tube connected with 1-cm quartz cell containing the 1,2-dichloroethane and aqueous solutions (3 cm^3 each) was shaken vigorously and was then allowed to stand for 12 h in a thermostated bath of 25 °C. Visible spectra of the organic phase were in situ measured in a cell holder thermostated at the same temperature.

Extraction Equilibrium Constant.[5,6] On the assumption that the crown ether (H_2L) forms only 1:1 cation (M^+)-crown (HL^- or L^{2-}) complexes (MHL or ML), the constants (K_{ex}) are defined as Eq. 1 for monovalent cations and as Eq. 2 for divalent cations, where subscript "a" and "o" denote the aqueous and organic phases, respectively.

$$K_{ex}=([MHL]_o[H^+]_a)/([H_2L]_o[M^+]_a) \quad (1)$$

$$K_{ex}=([ML]_o[H^+]_a^2)/([H_2L]_o[M^{2+}]_a) \quad (2)$$

Since the crown ether is highly lipophilic, its undissociated, proton-dissociated, and complexed species are hardly partitioned to the aqueous phase, i.e., $[H_2L]_a\simeq0$, $[HL^-]_a$ (or $[L^{2-}]_a)\simeq0$, and $[MHL]_a$ (or $[ML]_a)\simeq0$. If the following assumptions are also made, i.e., $[H_2L]_t$ ("t" is "total".)$\simeq$ $[H_2L]_o+[MHL]_o$ (or $[ML]_o$) and $[M^+]_t$ (or $[M^{2+}]_t)\simeq[M^+]_a$ (or $[M^{2+}]_a$), Eqs. 1 and 2 can be transformed to Eqs. 3 and 4, respectively.

$$[H^+]_a/[M^+]_t=(K_{ex}\varepsilon_{MHL}[H_2L]_t/A_o)-K_{ex} \quad (3)$$

$$[H^+]_a^2/[M^{2+}]_t=(K_{ex}\varepsilon_{ML}[H_2L]_t/A_o)-K_{ex} \quad (4)$$

Here, ε_{MHL} (or ε_{ML}) and A_o stand for molar absorptivity and absorbance for MHL (or ML) in the organic phase at a wavelength where H_2L does not absorb at all. Thus the K_{ex} values were determined from the intercepts of the plots of $[H^+]_a/[M^+]_t$ (or $[H^+]_a^2/[M^{2+}]_t$) vs. $1/A_o$.

Results and Discussion

Since 14-crown-4 bearing two dinitrophenol moieties **7** are easily proton-dissociable (the average pK_a: 5.20 in dioxane-water(1/1)), extractions of metal ions that have affinity to the crown ring, based on the H^+-M^+ exchange mechanism, should occur even under mild pH conditions of the aqueous phase, being accompanied by significant spectral changes of the chromogen in the organic phase. Figure 1 depicts typical spectral changes on the cation extraction of alkali and alkaline-earth metal ions. Definitely, increasing absorption in the visible region on the cation extraction is derived from the complex formation between the metal ions and the proton-dissociated species of **7** in the organic phase, inasmuch as any spectral change was not attained without metal ions in the initial aqueous phase under the identical pH conditions. The monovalent metal ion is different from the divalent ones in the wavelength of the visible absorption for the complexes (Table 1). Also, the monovalent cation complex possesses about one half the molar absorptivity for the divalent ones, which in turn is close to that for the ion pair between the dianionic species of **7** and two tetramethylammonium ions (ε 2.68×10^4 at 376 nm). The spectral data suggest that the monovalent and divalent ions (M^+ and M^{2+}) interact with mono- and dianionic species of **7** (HL^- and L^{2-}), respectively, to form electrically-neutral complexes (MHL and ML). In the group of alkali metal ions, Li^+ is extracted most effectively by the crown ether. Slight and practically no extractions were found with Na^+ and the other alkali metal ions, respectively. The high Li^+ selectivity of **7** against other alkali metal ions is quite similar to that of a corresponding 14-crown-4 derivative with only one dinitrophenol moiety, 6-dodecyl-6-(2-hydroxy-3,5-dinitrobenzyl)-1,4,8,11-tetraoxacyclotetradecane.[5] As anticipated from the easy charge compensation for divalent cations, **7** is able to extract alkaline-earth metal ions. This was not the case with the derivative possessing only one dinitrophenol moiety, which hardly extracted any alkaline-earth metal ions under the identical pH conditions.

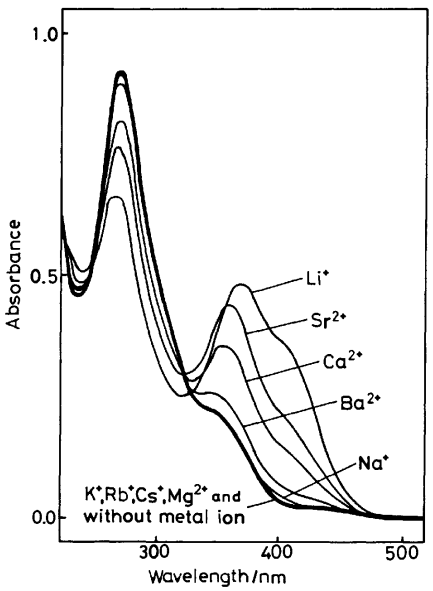


Fig. 1. Spectral change in organic phase on cation extraction with 14-crown-4 bis(dinitrophenol) **7**.

Table 1. Extraction Equilibrium Constants and Spectral Data for Cation Complexes of **7**

Complexed cation	pK_{ex} [a]	ε_{MHL} or ε_{ML} [b] (λ_{max}) [c]
Li^+	7.36	1.62×10^4 (368)
Ca^{2+}	15.61	2.75×10^4 (359)
Sr^{2+}	15.56	2.78×10^4 (359)
Ba^{2+}	16.43	2.92×10^4 (359)

a) In $ClCH_2CH_2Cl$-H_2O system, at 25°C. $pK_{ex}=-\log K_{ex}$. b) In $dm^3\,mol^{-1}\,cm^{-1}$. c) In nm.

Interestingly, **7** exhibited good extractabilities for the medium-size alkaline-earth metal ions, but hardly did any extractability for Mg^{2+} that resembles Li^+ in size. The poor extractability for Ba^{2+} may be ascribable to the fact that the 14-crown-4 ring is too small to form stable complexes with the large cation.

An attempt was made to determine the extraction equilibrium constants of **7** for the electrically-neutral 1 : 1 cation-crown ether complexes. The plots of $[H^+]_a/[M^+]_t$ (for monovalent cations) or $[H^+]_a^2/[M^{2+}]_t$ (for divalent ones) vs. $1/A_o$ gave straight lines with coefficients of correlation of better than 0.999 for Li^+, Ca^{2+}, Sr^{2+}, and Ba^{2+}, thus affording their K_{ex} values (Table 1). The K_{ex} values for the other metal ions could not be obtained because of the poor extractabilities towards them.

In conclusion, the 14-crown-4 derivative bearing two dinitrophenol moieties **7** is still highly Li^+-selective against other alkali metal ions on the cation extraction. In addition, good affinity for some alkaline-earth metal ions, although not very drastic, was attained with the crown ether.

Syntheses and Biological Activities of Neurokinin A Analogs Substituted with Glycine

Tadashi HASHIMOTO,* Katsuro KUROSAWA, and Yoshiki UCHIDA
School of Pharmacy, Hokuriku University, Ho-3, Kanagawa-machi, Kanazawa 920-11
(Received March 28, 1987)

Synopsis. Five neurokinin A (NKA) analogs substituted with glycine at position 3, 4, 5, 6, or 7 were synthesized by Merrifield's solid phase method. The contractile activities of the synthetic analogs were assayed on isolated guinea pig ileum and rat vas deferens. The results suggest that Asp[4], Phe[6], and Val[7] residues of NKA may be essential for the intrinsic activity on guinea pig ileum and on rat vas deferens, respectively.

Neurokinin A (NKA, also called neuromedin L or substance K) and neurokinin B (NKB, also called neuromedin K) are novel neuropeptides isolated from porcine spinal cord. Structure elucidation[1] revealed that NKA and NKB have close structural homologies with tachykinin such as substance P (SP), kassinin and physalaemin (Fig. 1). Decapeptide amides, NKA and NKB, have the same sequence between Phe[6] and Met[10] and are very similar to the mammalian tachykinin SP, particularly in the sequence of C-terminal region.

Our study[3] on the structure activity relationship of NKB provides clear indication on the location of the active site, that is, the replacement of Phe[6] or Val[7] residue with Gly moiety brings drastic decrease of the contractile activities on isolated guinea pig ileum (GPI) and rat vas deferens (RVD), while the substitution of Gly for Phe[5] enhances their activities. In other words, NKB related octapeptide analogs [Gly[6]]-NKB (3-10) and [Gly[7]]-NKB (3-10) have no intrinsic activity on GPI and RVD. Furthermore, it has been revealed that the replacement of Phe[6] in NKB with Gly moiety changes the pharmacological spectrum of NKB from that of an agonist to that of an antagonist.[4] The knowledge has been utilized in the design of NKB analogs, and we have succeeded in the development of several specific antagonists against NKB.[5] Therefore glycine substitution seems to be useful tool for the study of the structure activity relationship of NKA.

In the present investigation, in order to examine the biological effect of the substitution of Gly moiety for Thr[3], Asp[4], Ser[5], Phe[6], and Val[7] residues of NKA and the amino acid residues for recognition of SP-P and SP-E type receptors, we synthesized [Gly[3]]-, [Gly[4]]-, [Gly[5]]-, [Gly[6]]-, and [Gly[7]]-NKA (Fig. 2), and submitted them for biological assay.

Synthesis of NKA analogs used in this study was performed on an automated peptide synthesizer by standard solid phase method[6] starting from *t*-butoxycarbonyl (Boc)-Met benzhydrylamine-resin. Boc protection was used for α-amino function. The side-chain protective groups used were cyclohexyl for Asp, tosyl for His, benzyloxycarbonyl for Lys and benzyl for Ser and Thr. Deprotection and dicyclohexylcarbodiimide (DCC) coupling were programed as given in Table 1.

The second coupling was repeated with additive of one equivalent of 1-hydroxybenzotriazole (HOBt) according to a program without step 1—4. A 2.5 fold excess of amino acid derivatives was used for all couplings. The coupling reaction was monitored by the ninhydrin color test procedure of Kaiser et al.[7] A trace of unreacted amino group was acetylated with acetic anhydride and pyridine. After the completion of the

a) Condition of analytical HPLC: column, NOVA-PAK C_{18}; flow rate, 1 ml min^{-1}; Detection, 210 nm; eluent system, linear gradient from 14% [b) 4.2%] to 35% CH_3CN (15 min) in 20 mM phosphate buffer (pH 3.0).

chain elongations, the peptide resin was treated with liquid hydrogen fluoride (HF)[8] in the presence of anisole for 30 min at −20 °C and then 30 min at 0 °C to cleave the peptide from the resin with simultaneous removal of the protecting groups and formation of the carboxyl terminal amide. The excess HF was removed in vacuo, and the resulting material was washed with ethyl acetate prior to extraction of the peptide with aq acetic acid (50%). The crude product was purified by preparative reverse-phase high-performance liquid chromatography (HPLC) using aq trifluoroacetic acid (0.1%) in acetonitrile as eluent. The desired fractions were collected and desalted on a column of Sephadex LH-20 eluted with aq *N*,*N*-dimethylformamide (90%) containing 0.02% 1,2-ethanedithiol, giving pure peptide. The yield was sacrificed for the purity test of the fractions selected. Acid hydrolysates of the peptides contained the constituent amino acids in the ratios predicted by theory (Table 2). Homogeneity of the peptides was demonstrated by analytical HPLC and thin-layer chromatography (TLC) (Table 3). When single peaks and single spots were observed for a peptide in all chromatographic systems, the sample was considered appropriately pure for bioassay.

Biological properties of the synthetic NKA analogs were examined on GPI having SP-P type receptor and RVD having SP-E type receptor. The contractile activities of the analogs were compared with that of our synthetic NKA. The results are shown in Table 4.

On GPI assay, analog **1**, **2**, **3**, and **5** possessed about 25, 10, 20, and 10%, respectively, of the contractile activity of NKA, while analog **4** had little activity. The potency of analog **1** was as high as the intrinsic activity of NKA itself and analog **3** possessed about 80% of the activity on RVD assay, but analogs **2**, **4**, and **5** showed no agonistic activity. Analogs **4** on GPI, and **2**, **4**, and **5** on RVD, were tested for their antagonistic effects against NKA respectively. None of the analogs **2**, **4**, and **5** was found to act as an antagonist of NKA on both assays. These data suggest that the Phe^6 of NKA as well as NKB is essential for binding or stimulation of SP receptors in the two smooth muscle preparations. In contrast to the results obtained in NKB, whereby the substitution of Gly for Phe^6 changes the pharmacological spectrum of NKB from that of an agonist to that of an antagonist, the Gly^6 analog of NKA shows no antagonism to NKA. In comparison with the results that the Gly analogs of NKB provided consistent indications of the active sites, Phe^6 and Val^7, in GPI and RVD,[3] the Gly analogs of NKA indicated the location of the additional active site of Asp^4 in RVD. In other words, Asp^4 moiety as well as Phe^6 and Val^7 in NKA seems to be important for the recognition of SP-E type receptors. The results well agrees with the observation of Osakada et al.,[9] Asp^4 and Val^7 moieties being important for the recognition of SP-E type receptors.

a) Relative contractile activity to NKA=1. b) Antagonistic activity against NKA. c) Not tested. d) No antagonistic activity.

Experimental

Amino acid derivatives were purchased from Peptide Institute, Inc., Osaka, and benzhydrylamine (BHA) resin (available amine of the resin: 0.6 mmol g^{-1} of support) from Beckman Inc. The solid phase synthesis was carried out using a Beckman System 990C Peptide Synthesizer. Optical rota-

tions were measured in a Nipponbunkoh DIP-4 Polarimeter. Amino acid analyses on samples previously hydrolyzed with 6 M HCl (1 M=1 mol dm^{-3}) (110 °C, 24 h) were performed on a Beckman System 7300 Amino Acid Analyzer. TLC were carried out on silica-gel plates (Merck). The following solvent systems were used and allowed to ascend for 10 cm: R_f^1, *n*-BuOH-AcOH-H_2O (4:1:5, upper phase); R_f^2, *n*-BuOH-pyridine-AcOH-H_2O (30:20:6:24). Analytical HPLC were effected on the following systems: column, NOVA-PAK C_{18} (3.9×150 mm); flow rate, 1 ml min^{-1}, detection, 210 nm; eluent system, linear gradient of CH_3CN in 20 mM phosphate buffer (pH 3.0).

General Procedure for the Preparation of Analog. The first Boc-amino acid was coupled to the BHA-resin (0.60 meq. N g^{-1}) as follows. A half gram of the BHA-resin hydrochloride was neutralized with a solution of 10% (by volume) triethylamine (TEA) in dichloromethane (10 ml). Then the resin was washed with 10 ml of dichloromethane, and was mixed with 2.5 equiv of Boc-Met-OH and DCC in dichloromethane. The quantitation of coupling reaction was carried out by a negative ninhydrin color test. The unreacted amino groups were blocked by acetylation using Ac_2O (5 equiv) and pyridine (1 equiv) in dichloromethane for 20 min. For the coupling reactions after second Boc-amino acids, deprotection and DCC coupling were programed as given in Table 1. For second coupling, a programed without steps 1—4 was used. A 2.5 fold excess of DCC and the amino acid derivative dissolved in dichloromethane were used for all couplings. One equivalent of HOBt was used only for the second DCC-coupling. The protected peptide resin was simultaneously cleaved and deblocked with anhydrous liquid HF containing 10% anisole. Approximately 5 ml of liquid HF was used for 0.25 g resin, and the reaction mixture was kept at −20 °C for 30 min and then 0 °C for 30 min to prevent the succinimide formation in Asp-Gly sequence. After evaporation of HF in vacuo with ice-cooling, the peptide-resin mixture was washed with AcOEt. The peptide was extracted with three portions of 50% AcOH and the extracts combined were lyophilized.

Purification of the Peptides. The crude peptide was subjected to HPLC which is composed of a model 590 pump and an U6K injector (Waters) connecting with a column (20×300 mm) of Chemcosorb ODS (Chemco). The eluates were monitored with an UV detector S-310A model-II (Soma) at 210 nm wavelength. CH_3CN-0.1% TFA solvent system was used as eluent at flow rate 10 ml min^{-1}. Each peptide was emerged at 40—60 min by isocratical elution with 14—20% CH_3CN contents of the solvent system. The desired fraction was desalted on a Sephadex LH-20 column (15×500 mm) eluted with DMF-H_2O (9:1) containing 0.02% 1,2-ethanedithiol and the product was lyophilized. Homogeneity of the peptides was analyzed by analytical HPLC on a column of NOVA-PAK C_{18} (3.9×150 mm) with gradient elution using 20 mM phosphate buffer (pH 3.0)/CH_3CN and by TLC on silica-gel plate. The peptides on silica-gel plate were detected with ninhydrin and chlorine-*o*-tolidine reagents. When single peaks and single spots were observed for a peptide in all chromatographic systems and amino acid composition after hydrolysis of the peptides were consistent with the calculated values, the sample was submitted for bioassay.

Bioassay. The biological activities of NKA analogs were measured on GPI and RVD. Male guinea pig (weighing 200—250 g) and male rat (weighing 250—300 g) were stunned by a blow to the neck and exsanguinated. Ileum and vas deferens were rapidly isolated and kept for dissection in Tyrode's solution (137 mM NaCl, 2.7 mM KCl, 1.8 mM $CaCl_2$, 1.1 mM $MgCl_2$, 0.4 mM NaH_2PO_4, 12 mM $NaHCO_3$, 5.6 mM glucose) at room temperature. Both organs were suspended in a 30 ml organ bath containing Tyrode's solution thermostated at 30 °C and bubbled with 95% O_2 and 5% CO_2 gas for 1 h. The contraction was recorded by means of an isotonic transducer (Nippon Kohden, TD-111T) with load of 2 or 1 g (for ileum and vas deferens respectively) on a Servocorder (Watanabe Instruments, SR6204). Concentration-response curves were obtained using a cumulative dose-assay, the time between two consecutive dose-response curves was longer than 10 min. In the tests for antagonistic activity on GPI and RVD, analog was added 10 min before NKA was added. The cumulative dose-response curve of NKA in the presence or the absence of the analog was obtained. In the presence of analogs at concentration 2×10^{-6} M, the maximal response induced by NKA was almost the same response without analogs.

Synopsis. The determination of ozone decomposition rate by flow injection analysis (FIA) was investigated. Under the conditions studied a sampling rate was about 43 samples/h, and the pseudo-first-order kinetic plot of the obtained data showed a good linearity. This FIA method seems to be useful for kinetic measurement of ozone decomposition in water.

Ozone is known as a powerful oxidant, and widely applied to the treatment of drinking water and waste water. In routine water-disinfection application of ozone, residual ozone at 5 minutes after ozone injection is maintained at sub-mg dm^{-3} levels. In order to obtain these residuals, in general, the initial ozone concentration in water is known to be between 0.5 and 4.0 mg dm^{-3}. The decomposition rate of ozone is very important for the achievement of the treatment. The rapid determination of the rate is, therefore, desired.

Ozone in water is commonly determined by iodometry or by photometric detection at 254 nm.[1] The former is a standard analytical method for ozone, but it is disadvantageously time-consuming, and requires a large sample volume. The latter is convenient for continuous measurement of ozone, but the sensitivity is not high enough because of the small molar extinction coefficient of ozone in water, and large interference from coexisting substances in sample solutions is unavoidable. Straka et al.[2] reported the flow injection analysis (FIA) of residual ozone by employing indigo as a reagent. But this method has a disadvantage of evaluating a negative peak caused by ozone decoloration of the dye, and the background absorption level is very high. In ozone measurement, an automated technique based on iodometry is desirable in order to achieve a continuity between the data obtained by a new method and the known data determined by the standard iodometric method. In this paper, the automated iodometric measurement of ozone by FIA and its application to the rapid determination of the ozone decomposition rate were investigated.

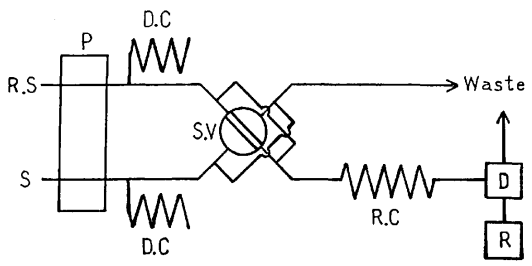

Fig. 1. Schematic flow diagram for ozone analysis. R.S: KI aqueous solution, S: sample solution, P: peristaltic pump (MP-3, Tokyo Rikakikai Co., Ltd.), D.C: damper coil, S.V: sample injection valve (46 μl), R.C: reaction coil (1 mm i.d.), D: detector (Absorbance at 354 nm, UVIDEC-100, Nihon Bunko Co., Ltd.), R: recorder (D2R2M, Ohkura Co., Ltd.).

Experimental

The flow diagram of FIA is shown in Fig. 1. A sample solution was pumped through a flow line by a micro pump. The sample solution(46 μl) was periodically injected into the flow of a reagent solution by rotating a sample injection valve, followed by mixing in a reaction coil, and liberated I_2 was directly measured by photometry at the maximum wavelength 354 nm. The reaction of ozone with I^- is shown as follows: $O_3+2I^-+2H^+ \rightarrow O_2+H_2O+I_2$. The stoichiometry of the ozone-iodide reaction is known to be 1.0 over a wide pH range.[3]

Results and Discussion

Effect of the Reaction Coil Length. The result is presented in Fig. 2. In this case, the peak width of the FIA signal increased with increasing length of the coil, and therefore the sampling rate decreased from 55 samples/h (40 cm coil) to 45 (300). If the coil was shorter than 40 cm, the reproducibility of the FIA signal was not good. Under these experimental conditions, the coil length was shown to be most suitable in the range of about 40—100 cm.

Effect of the KI Concentration of the Reagent Solution. The experimental conditions such as the rea-

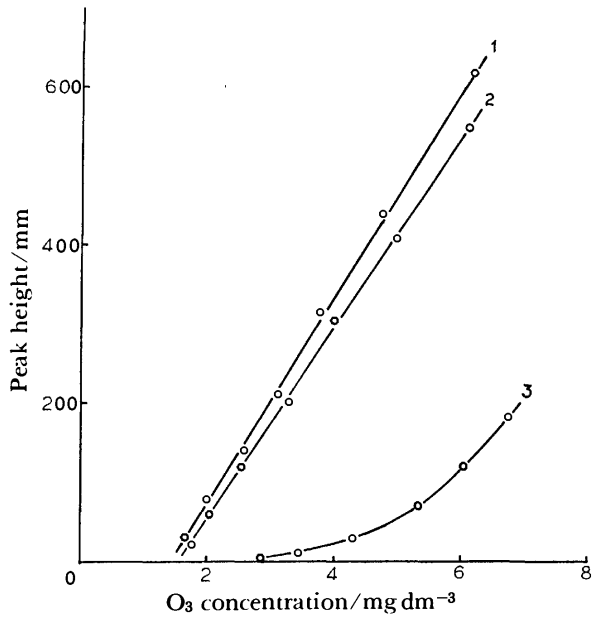

Fig. 2. Effect of reaction coil length on FIA of O_3 at 25 °C. Reagent solution: 5% KI Aqueous solution, reagent flow rate: 1.45 $cm^3 min^{-1}$, 1: 40 cm, 2: 100 cm, 3: 300 cm.

gent flow rate, the temperature of the reagent solution and the reaction coil length were 1.45 $cm^3 min^{-1}$, 25 °C and 100 cm respectively. The detection limit (S/N=2.5) and the sampling rate were as follows: 0.1% KI solution, 0.3 mg dm^{-3} (30 samples/h); 1, 0.7 (43); 5, 1.6 (50); 10, 2.5 (60). A suitable KI concentration should be selected by considering the levels of ozone in sample solutions.

Effect of the Reagent Flow Rate. The effect of the flow rate was investigated in the range 1.70—0.55 $cm^3 min^{-1}$. The experimental conditions such as the reagent solution, its temperature and the reaction coil length were 5% KI, 25 °C and 100 cm, respectively. The peak width increased with decreasing flow rate, and hence the sampling rate decreased from 64 samples/h (1.70 $cm^3 min^{-1}$) to 26 (0.55). A desirable flow rate of the reagent solution was shown to be near 1.45 $cm^3 min^{-1}$ or above.

Conditions of FIA. From experimental results, the conditions of the FIA were decided as follows: Reagent solution, 1% KI; reaction coil, 100 cm; reagent flow rate, 1.45 $cm^3 min^{-1}$; temperature of the reagent solution, 25 °C. Under these conditions, dispersion of sample zone was investigated, and a dispersion coefficient (D) was shown to be 30. The obtained calibration curve was confirmed to be linear up to 11.3 mg dm^{-3} O_3, but the upper limit of the linear range could not be evaluated because of the low power of a ozone generator used. When the sample (2.92 mg dm^{-3} O_3) was injected five times, the precision (C.V.) was 0.67%.

Effect of Coexisting Substances. Tap water (2000 cm^3) was aerated at a constant flow rate of 2.8 $dm^3 min^{-1}$ using a G-2 sintered glass filter for 5 h at 50 °C, and residual chlorine was purged. A sample solution was prepared by using 500 cm^3 of chlorine-free tap water, followed by measurement of dissolved ozone by the standard iodometric method and by this FIA. Typical data are shown in Table 1. Minerals, the levels of which were suitable for drinking water, were shown not to interfere the measurement of O_3 by this FIA. Ozone attacks many organic compounds containing carbon-carbon double bonds to result in oxalic acid as a main final oxidation product.[4] Therefore, in the measurement of residual ozone, the effect of oxalic acid should be examined. Experimental data in Table 1 show that the interference of oxalic acid with the O_3 measurement by this FIA is small.

Application to the Determination of Ozone Decomposition Rate. The decomposition rate of ozone in chlorine-free tap water was measured by this FIA. A sample solution was prepared using 500 cm^3 chlorine-free tap water obtained in the same way as described above. Immediately after the completion of ozone injection, the measurement of ozone by this FIA was started. Typical FIA signals obtained in the experiment are presented in Fig. 3. The pseudo-first-order kinetic plot of the obtained data shows a good linearity (n, 6; γ, −0.994; α, 0.001). Therefore, the decomposition of O_3 in this experiment was shown to be first order with respect to O_3. The kinetic plots are shown in Fig. 4. In these cases, the first half-lives of O_3 were 8.7 and 5.8 min, when the initial concentrations of O_3

Table 1. Determination of Ozone in Water

	4.16	4.19
	5.10	4.90

a) Ozone was injected into chlorine-free tap water. b) Ozone was injected into 361 mg dm^{-3} oxalic acid-water.

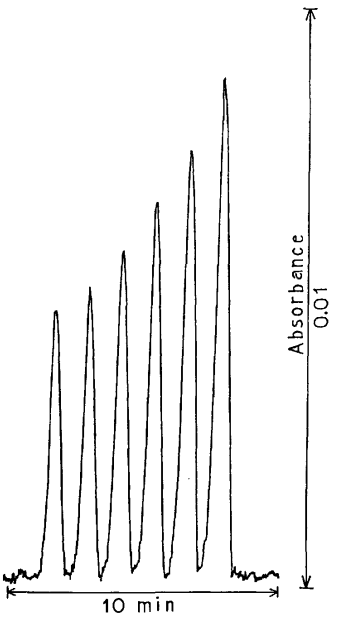

Fig. 3. Typical FIA signals obtained for measurement of O_3 in chlorine-free tap water. Initial concn of O_3: 2.5 mg dm^{-3}, pH of the sample solution: 7.9.

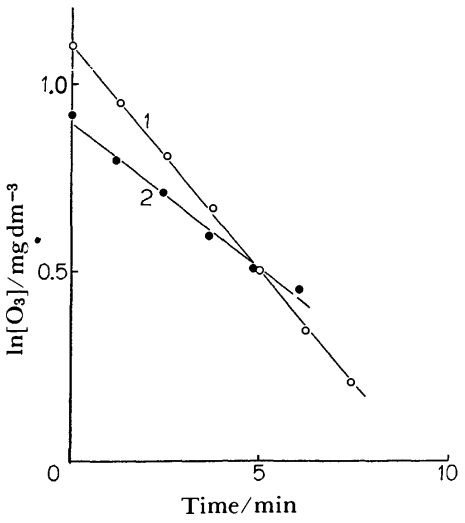

Fig. 4. Pseud-first-order plot for decomposition of ozone in chlorine-free tap water at 25°C. 1, Initial concn of O_3: 3.0 mg dm^{-3}, $\log[O_3]=1.10-0.119 \cdot t$ (n:7, γ:−0.999, α:0.001). 2, Initial concn of O_3: 2.5 mg dm^{-3}, $\log[O_3]=0.895-0.0774 \cdot t$ (n:6, γ:−0.994, α:0.001).

were 2.5 and 3.0 mg dm^{-3}, respectively. Horie and coworkers[5] reported on the half-life of O_3 in water which was processed by coagulation and filtration without chlorine treatment, where the half-lives were 8, 15, and 30 min at 20 °C for the initial concentrations of 2.0, 1.0, and 0.5 mg dm^{-3}, respectively. Half-life measured in this experiment was a reasonable value compared with these results. From these results, this FIA can be applied to the automated measurement of the decomposition rate of O_3 in water. If necessary, the sampling rate and the sensitivity of this FIA can be controlled by slight modifications of the KI concentration and reaction coil.

Improved Spectrophotometric Determinations of Cobalt(II) and Nickel(II) with Zincon in the Surfactants Micellar

Itsuo MORI,* Yoshikazu FUJITA, Kinuko FUJITA, Takeshi TANAKA, Yukari YANO, and Makiko ASADA
Osaka University of Pharmaceutical Sciences, 2-10-65 Kawai, Matsubara, Osaka 580
(Received December 13, 1986)

Synopsis. Reactions between Zincon and cobalt(II) in the presence of *N*-hexadecylpyridinium chloride (cationic surfactant), and between Zincon and nickel(II) in the presence of poly(vinyl alcohol) (nonionic surfactant) are discussed in terms of the development of simple, sensitive and improved spectrophotometric determinations of cobalt(II) and nickel(II). The calibration graphs were rectilinear in the ranges 0—2.2 μg 10 cm^{-3} cobalt(II) with a Sandell sensitivity of 0.00015 μg cm^{-2} at 550 nm and 0—42.0 μg 10 cm^3 nickel(II) with that of 0.0047 μg cm^{-2} nickel(II) at 470 nm. The proposed methods were relatively sensitive in comparison with the methods in the absence of surfactants with apparent molar extinctions of 4.6×10^5 for cobalt(II) and 2.4×10^4 dm^3 mol^{-1} cm^{-1} for nickel (II). Separative assays of cobalt(II) and various metals (nickel(II), zinc(II), copper(II), and iron(III)) were possible by selections of analytical wavelengths, respectively.

The spectrophotometry of micro amounts of cobalt(II) or nickel(II) has recently attracted much attention regarding heavy metal pollution in enviromental areas. For cobalt(II) or nickel(II), various spectrophotometric determinations using Dithizone,[1] 4-(2-pyridylazo)resorcinol(PAR),[2] nitroso R salt,[3] dimethylglyoxime.[4] Chrome Azurol S,[5] etc., have already been reported. However, most methods are relatively complicated and therefore organic solvent extractions are necessary using a toxic organic solvent such as chloroform. Although determinations of cobalt(II) and nickel(II) using Zincon are comparatively sensitive,[6-9] these methods lack selectivity, stability and reproducibility. On the other hand, we found that the reaction systems between cobalt(II) and Zincon in the presence of a cationic surfactant micellar(such as *N*-hexadecylpyridinium chloride (HPC)) and between nickel(II) and Zincon in the presence of a nonionic surfactant micellar(such as poly(vinyl alcohol) (PVA)) posessed many advantages over these reaction systems (binary complex) in the absence of surfactants: highly sensitive, stability and a wide coloring pH ranges under these experimental conditions.

In this paper, simple, sensitive and improved spectrophotometric determinations of cobalt(II) using Zincon in the presence of HPC, and of nickel (II) using Zincon in the presence of PVA are, respectively, discussed and proposed in water-soluble surfactants micellar media.

Experimental

Reagents and Apparatus. Standard cobalt(II) and nickel(II) solutions, a stock solution containing 1.0×10^{-2} M (1 M≒1 mol dm^{-3}) of cobalt(II) or nickel (II), were prepared by dissolving cobalt nitrate or nickel nitrate in water. The concentrations of these stock solutions were determined by chelatometric titration.[10] A working solution (5.0×10^{-4} M) was prepared by a suitable dilution of this stock solution. A 1.0×10^{-3} M Zincon solution was prepared by dissolving Zincon(Merck Chemical Co., Ltd.) in methanol according to a previous report.[11] A 1.0×10^{-2} M solution of HPC was prepared by dissolving HPC in water. A 1.0% PVA, solution was prepared by dissolving PVA (n≒2000) in water. A Sörensen phosphate buffer solution was used for the pH adjustments.

All the other reagents and materials were of analytical grade and were used without further purification. Twice-distilled water was used throughout this work.

Shimadzu Model UV-200, recording spectrophotometer with 1.0-cm^3 quartz cells was used for the absorption spectra and absorbance measurements. A Hitachi-Horiba Model F-7AD glass electrode pH meter was used for the pH measurements.

Operating Procedure. Determination of Cobalt(II): A standard solution containing up to 2.2 μg of cobalt(II) was placed in a 10-cm^3 volumetric flask; then, 1.0 cm^3 of a 1.0×10^{-2} M HPC solution, 2.0 cm^3 of a Sörensen phosphate buffer solution (pH 8.5), and 2.0 cm^3 of 1.0×10^{-3} M Zincon solution were added. The solution was diluted to the mark with water, mixed well, kept at 60 °C for 30 min, and then cooled in water at room temperature for 10 min. The difference of absorbance at 550 nm between the Zincon-cobalt(II) solution (Solution A) and the Zincon solution (Solution B) was measured against water.

Determination of Nickel(II): A standard solution (0—42.0 μg of nickel (II)) was placed in a 10-cm^3 volumetric flask; 1.0 cm^3 of a 1.0% PVA solution, 2.0 cm^3 of a Sörensen buffer solution (pH7.0), and then 2.0 cm^3 of a 1.0×10^{-3} M Zincon solution were added. The solution was diluted to the mark with water, mixed well (Solution A′), kept at room temperature for 20 min together with Zincon solution (Solution B′). The absorbance difference at 470 nm between Solutions A′ and B′ was measured against water. The concentrations of cobalt(II) or nickel(II) were determined by using a calibration graph.

Results and Discussion

Reaction between Zincon and Cobalt(II) or Nickel(II). The reaction systems between cobalt(II) or nickel(II) and Zincon in the presence or absence of a surfactant (cationic—HPC, anionic—sodium dodecyl sulfate, nonionic—PVA, amphoteric—sodium *N*-lauroylsarcosine) were studied at room temperature or by heating at 60 °C. The reaction systems in the absence were unstable, inconvenient and insensitive in comparison with the reaction systems in the presence of a surfactant. The absorption spectra of Zincon-cobalt(II) and Zincon solutions in the presence of HPC (Solutions A and B), and Zincon-nickel(II) and Zincon solutions in the presence of PVA (Solutions A′ and B′) are shown in Figs. 1 and 2. The Zincon-cobalt(II) solution in the presence of a cationic surfactant such as HPC was more easily decomposed by heating at 60 °C

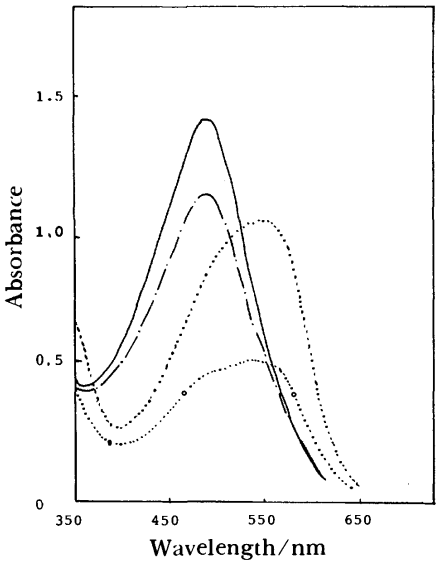

Fig. 1. Absorption spectra of Zincon-cobalt(II) and Zincon solutions in the presence of HPC or in the presence of Tween (0.1%) under the operating procedure. Cobalt(II), 2.0×10^{-6} M; Reference, water. ---o---: Zincon-cobalt(II)-HPC (Solution A); ------: Zincon-HPC solution (Solution B); -·-·-: Zincon-cobalt(II)-Tween 20; ——: Zincon-Tween 20.

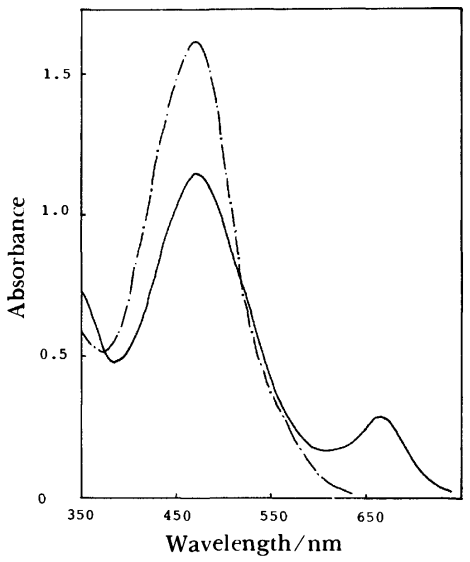

Fig. 2. Absorption spectra of Zincon-nickel(II) and Zincon solutions in the presence of PVA under the operating procedure. Ni(II), 2.5×10^{-5} M; PVA, 0.1%; Reference, water.
——: Zincon-nickel(II) (Solution A'); -·-·-: Zincon (Solution B').

than the Zincon-cobalt(II) solution in the absence of surfactant. There was a large distinct difference of absorbance between Solutions A and B at 550 nm. The difference of absorbances at 470 and 665 nm between Solutions A' and B' in the presence of a nonionic surfactant (such as PVA) at room temperature was stable and abundant in reproducibility compared with reaction systems in the absence of a surfactant. Consequently, the later measurements were carried out by measuring the absorbance of 550 and 470 nm.

A maximum and constant absorbance was obtained in the pH range of 8.0—9.0 for a determination of cobalt(II), and 6.0—8.3 for a determination of nickel(II), by using 2.0 cm^3 of a Sörensen phosphate buffer solution. Later measurements were carried out at pH 8.5 for the assay of cobalt(II) and at pH 7.0 for the assay of nickel(II).

For the determinations of these metal ions, the effects of various surfactants(cationic—HPC, hexadecyltrimethylammonium chloride, zephiramine, benzylhexadecylmethylammonium chloride, nonionic—PVA, poly(oxyethylene) 6-methylheptyl ether, poly(oxyethylene) sorbitan monolaurate(Tween 20), poly(oxyethylene) dodecyl ether, and poly(*N*-vinylpyrrolidone) were studied. The uses of HPC for cobalt(II), and PVA for nickel (II) were best regarding sensitivity and stability. A maximum and constant absorbance could be obtained by the addition of 0.5—2.0 cm^3 of a 1.0×10^{-2} M HPC solution for the determination of cobalt(II), and 0.5—3.0 cm^3 of a 1.0% PVA solution for a determination of nickel(II), at final volume of 10 cm^3.

The effect of the amount of Zincon on the operating procedure was studied while keeping the amounts of cobalt(II) or nickel(II) constant. Though the molar ratio of nickel(II) to Zincon regarding the reaction system was found to be 2:1 by the molar ratio and continuous variation methods, the maximum and almost constant difference of the absorbance was obtained by using 0.5—2.0 cm^3 for the assay of nickel(II), and 1.25—2.5 cm^3 of a 1.0×10^{-3} M Zincon solution for the assay of cobalt(II) in the final 10 cm^3. Although a further investigation is necessary, the molar ratio of Zincon to cobalt(II) could not be explicitly defined.

Effect of Temperature and Time. A study of the influence of temperature on the reaction system was performed at 15—80 °C. The reaction rate (for times between 0 and 60 min) increased with the temperature, and a reproducible absorbance was obtained at 60 °C for 30 min. On the other hand, the reaction system between Zincon and nickel(II) was the best regarding stability and reproducibility at room temperature. From these results, the conditions of 60 °C for 30 min for cobalt(II) and at room temperature for 20 min for nickel(II) were chosen.

Calibration Graphs and Reproducibilities. Calibration graphs for the determinations of cobalt(I) and nickel(II) were obtained by the operating procedure. Beer's laws were followed up to 0—2.2 μg 10 cm^{-3} of cobalt(II), and 0—42.0 μg 10 cm^{-3} of nickel(II). Sandell sensitivities were 0.00015 μg, cm^{-2} cobalt(II) and 0.0047 μg cm^{-2} nickel(II). This proposed method for cobalt(II) was especially about 20 times as sensitive as the method[7] using Zincon alone. Also, the relative standard deviations for cobalt(II) and nickel(II) (n=5) were to be 0.33 and 0.95%, respectively (relatively good values).

Effects of Foreign Ions. Effects of various foreign ions were examined regarding interference. As described in Table 1, the coexistence of such elements as iron(III), copper(II), and zinc(II) showed positive errors owing to the reaction with Zincon. The coexist-

Table 1. Effect of Foreign Ions Under the Operating Procedure

Foreign ion	Added		Difference of absorbance	
	as	μg 10 cm^{-3}	Co(II) at 550 nm	Ni(II) at 470 nm
—	—	—	0.587	0.610

NO_2^-	Sodium	57.5	0.481	0.609
I^-	Potassium	79.3	0.587	0.610
F^-	Sodium	238.0	0.587	0.610
$S_2O_3^{2-}$	Sodium	14.0	0.405	0.600
Citrate	Sodium	31.0	0.661	0.605
CN^-	Potassium	1.3	0.540	0.605

Ni(II) taken, 14.7 μg 10 cm^{-3}, Co(II) taken 0.9 μg 10 cm^{-3}.

ence of bismuth(III) or tin(IV) up to 2.5×10^{-5}—1.0×10^{-6} M over cobalt(II) or nickel(II) did not interfere. The coexsitence of such anions as sulfate, chloride, iodide, bromide, and nitrate ions did not entirely interfere. The coexistence of cyanide, thiosulfate or nitrite ions, excess over cobalt(II) or nickel(II) 1/2—5 molar ratios gave negative errors. Citrate or oxalate ion gave a positive error for cobalt(II), and a negative error for nickel(II), respectively.

Assay of Cobalt(II) in the Coexistence of Nickel(II) or Some Metal Ions. Although the absorbance at 615 nm of Zincon-cobalt(II) solution was relatively small, its value was not affected by the coexistence of nickel(II). The amounts of cobalt(II) in the coexistence of nickel(II) up to about 25-fold over cobalt(II) could be determined by measuring the absorbance differences at 615 nm between Solution A involving nickel(II) and Solution B prepared according to the operating procedure. On the other hand, the amounts of nickel(II) were calculated using the nickel(II)-calibration graph previously prepared in the coexistence of this assayed cobalt(II) concentrations. Moreover, the separative assay of cobalt(II) in the coexistence of some metal ions(zinc(II), copper(II), iron(III), etc.) was possible by measuring the absorbance on the cobalt(II)-mixed solution involving these each metal ion up to about 10—25-fold over cobalt(II) at proper wavelength; the absorbance difference at 595 nm in the coexsitence of zinc(II), at 580 nm in the coexistence of copper(II) and at 582 nm in the coexistence of iron(III), respectively.

In conclusion, reactions between Zincon and cobalt(II) in the presence of a cationic surfactant, and between Zincon and nickel(II) in the presence of a nonionic surfactant were the best concerning sensitivity and reproducibility. Accordingly, simple, sensitive and improved spectrophotometric determinations of cobalt(II) and nickel(II) were obtained, respectively, by using reaction of Zincon-cobalt(II) in the presence of HPC and Zincon-nickel(II) in the presence of PVA established at basic media. The sensitivity for cobalt(II) was about 20-times larger than that reported method by Gomez et al.[9] Also, the sensitivities on these proposed methods were about 8—10-times larger than the methods using nitrosonaphthol derivatives, etc.[3,8,12] Moreover, the separative assay of cobalt(II) in the coexistence of some metal ions-nickel(II), zinc(II), copper(II), or iron(III), etc. was possible by measuring at indivdual analytical wavelength.

Trace Determination of Indium by Electrolytic Preconcentration and Open Circuit Stripping via Localized Galvanic Cells

Sambamoorthy JAYA, Talasila Prasada RAO,† and Gollakota Prabhakara RAO*
Central Electrochemical Research Institute, Karaikudi, India
†Regional Research Laboratory, Industrial Estate P. O., Trivandrum 695019, India
(Received July 10, 1986)

Synopsis. A galvanic stripping analysis procedure is described for the trace determination of indium(III). The determination involves the reoxidation of predeposited indium on the mercury-film-coated glassy carbon electrode in open circuit position (in the absence of external potential or current input or oxidant in solution). The reoxidation of indium was shown to occur due to the formation of localized galvanic cells. The time of reoxidation (stripping) was found to be proportional to the concentration of indium present in the solution (1 to 100 ppb). The details of the development of such a procedure and its possible application to determination of indium in zinc deposits and aluminium alloys are discussed.

Electroanalytical techniques were widely used for the trace determination of indium. These include phase selective[1] and second harmonic[2] a.c. Polarographic, differential pulse polarographic[3] and anodic stripping voltammetric techniques.[4-10] Stripping voltammetric techniques are preferred over polarographic techniques in view of the simplicity, rapidity, and higher sensitivity of these procedures. Most of the researchers utilize halide medium in anodic stripping voltammetric studies as they offer higher sensitivity arising out of the fast reactions of indium in these media. A few of these stripping voltammetric procedures find application in the determination of 1.8 ppm of indium in zinc[6] or 0.2 to 0.7 ppm of indium in aluminium.[7] Recently, we have described a novel electroanalytical technique namely galvanic stripping analysis (GSA) which was successfully utilized for trace determination of cadmium,[11] chromium,[12] and lead.[13] This paper describes the development of galvanic stripping analysis procedure for the determination of traces of indium and its possible application to determination of indium in zinc deposits and aluminium alloys.

Experimental

Reagents. Indium(III) Solution: This solution was prepared by dissolving 0.2212 g of indium(III) chloride in 100 ml of conductivity water (0.01 mol dm^{-3}). A working solution containing 10 ng cm^{-3} of indium was prepared by suitably diluting the stock solution with conductivity water.

Acetate Buffer: This solution was prepared by dissolving 13.608 g of sodium acetate in water and adding 6 ml of glacial acetic acid, adjusting the pH to 3.5 with dilute HCl and diluting the solution to 100 cm^3.

Apparatus: A Wenking potentiostat (Model LB 75 M) coupled with a Wenking scan generator (Model VSG 72) was used for controlling the potential during preconcentration step. A Ricadenki xy/t recorder was used for obtaining galvanic stripping E-t profiles. A conventional three electrode cell consisting of mercury film coated glassy carbon working electrode (MFGCE) prepared as described elsewhere[14] (Tokai & Co., 3 mm dia.), a platinum foil counter and a normal calomel electrode (NCE) as reference was used. All the potentials were expressed with respect to NCE and measurements were made at room temperature.

Porcedure: Transfer a suitable aliquot (upto 40 cm^3) of sample solution containing ≤100 ppb of indium(III) into a 50 cm^3 volumetric flask. Add 5 cm^3 of acetate buffer solution and dilute to volume with conductivity water. Transfer the solution to electrochemical cell and deaerate with N_2 for 15 min. After preconcentrating electrolytically for 4 min at −1.4 V vs. NCE, the galvanic stripping E-t profiles were drawn after keeping the potentiostat in open circuit position (i.e. where the counter electrode is disconnected from the three electrode assembly) and in the absence of any external oxidant or electrical input. The E-t profiles thus obtained represent the variations of the MFGCE working electrode potential with respect to NCE. The time taken for stripping forms the analytical signal of GSA. Prepare a calibration graph for the determination of 1—100 ppb of indium(III) by the above procedure.

Results and Discussion

Figure 1 shows the stripping E-t profiles obtained after preconcentrating 0, 10, 30, and 50 ppb of indium-(III) (curves A, B, C, and D respectively) onto MFGCE at −1.4 V vs. NCE for 4 min. These E-t profiles were drawn by keeping the potentiostat in open circuit mode immediately after preconcentration step and in the absence of any imposed stripping conditions viz. external electrical input (potential or current) or addition of chemical oxidants. On the other hand, when the potentiostat is kept in open circuit position after

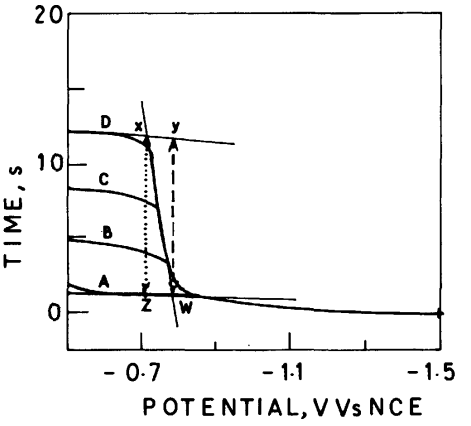

Fig. 1. Galvanic stripping E-t profiles recorded for 0, 10^{-7}, 3×10^{-7}, and 5×10^{-7} M of indium(III) between MFGCE working and normal calomel reference electrode, 0.1 M acetate buffer (pH 3.5); total volume=50 ml; deposition potential (E_d)=−1.4 V vs. NCE; deposition time (t_d)=4 min.

Table 1. Effect of Supporting Electrolyte

Sample No.	Supporting electrolyte (concentration)	Stripping time s
1	KI (0.2 M) or KBr (0.2 M) or NaCl (0.2 M)	Not resolved
2	Chloroacetate buffer (0.1 M)	0.0
3	KNO_3 (0.1 M)	0.60
4	Acetate buffer, pH 3 (0.1 M)	2.00
5	KNO_3 (0.1 M)+Acetate buffer, pH 3 (0.1 M)	0.65
6	Acetate buffer, pH 3 (0.1 M)+KSCN (0.2 M)	0.70
7	Acetate buffer, pH 3 (0.1 M)+KI (0.2 M)	0.60
8	Acetate buffer, pH 3 (0.1 M)+KBr (0.2 M)	1.60
9	Acetate buffer, pH 3 (0.1 M)+NaCl (0.2 M)	2.00

Concentration of indium=10 ppm. Deposition potential (E_d)=−1.4 V vs. NCE. Time of deposition (t_d)=4 min.

depositing for 4 min at −1.4 V vs. NCE, the potential of hanging mercury drop and glassy carbon with respect to NCE drop to −0.8 and 0.1 V vs. NCE respectively. Thus in case of MFGCE, the potential difference between In (Hg) film electrode and uncovered portions of GCE (as mercury film is known to present as fine droplets) is ≈0.9 V. Hence, the stripping profiles of Fig. 1 can be thought of as due to the formation of localized galvanic cells between indium amalgam and uncovered portions of glassy carbon electrode (GCE). Experiments were then carried out to confirm the formation of localized galvanic cells as described elsewhere.[11-13] These include a) observing the flow of current from Pt foil to MFGCE, when Pt foil and MFGCE were connected externally by placing zero resistance ammeter in between (during this experiment potentiostat is kept in open circuit position) b) stability of indium amalgam on hanging mercury drop electrode and c) unaltered GSA stripping profiles with different stirring rates. Further, the time of stripping measured as indicated for curve D in Fig. 1 (xz or yw) is proportional to indium present in solution.

Effect of Supporting Electrolyte. The effect of supporting electrolyte on the galvanic stripping analysis (GSA) signal of 10 ppb of indium using MFGCE was investigated by drawing E-t profiles in open circuit selection mode after preconcentrating for 4 min at −1.4 V vs. NCE. The results obtained are shown in Table 1, from which it is clear that the stripping signal is maximum in acetate or acetate-chloride medium compared to other media.

Effect of pH. The effect of pH in the range 2.5 to 6.0 on the GSA determination of 10 ppb of indium on MFGCE was then studied by employing 0.1 M (1M=1 mol dm^{-3}) acetate buffer as supporting electrolyte. The results obtained are shown in curve A of Fig. 2 from which it is clear that the optimum pH range is 3.0 to 3.8. pH 3.5 acetate buffered medium was chosen in further studies.

Effect of Deposition Potential. In order to ascertain optimum deposition potential, the deposition potential during 4 min preconcentration of 10 ppb of indium was varied in the range −0.8 to −1.5 V vs. NCE in steps of 0.1 V onto MFGCE. Curve B in Fig. 2 shows the time of stripping obtained from E-t profiles drawn during stripping of indium deposited at various deposition potentials. The maximum GSA stripping signal is obtained at potentials more negative to −1.4 V vs. NCE as seen from curve B of Fig. 2.

Effect of Time of Deposition. The effect of deposition time (1 to 16 min) on GSA stripping signal of 10 ppb of indium was next investigated by depositing at −1.4 V vs. NCE onto MFGCE. The results thus obtained revealed that the stripping signal is directly proportional to the time of deposition.

Calibration Graph and Precision. Linear calibration graph passing through the origin was obtained for 1—100 ppb of indium (cf. Fig. 3) with 4 min of deposition time. The relative standard deviation for 5 replicate determinations of 10 ppb of indium(III) was calculated to be 3.8%.

Analysis of Synthetic Samples. The results of the analysis of aluminium and zinc metal samples spiked with known amounts of indium are shown in Table 2. Aluminium do not interfere at all concentrations in the present procedure. But zinc do interfere by codepositing with indium which can be avoided by maintaining deposition potential at −1.05 V vs. NCE. Under these conditions the sensitivity of the procedure decreases by ≈6%. However, the calibration range

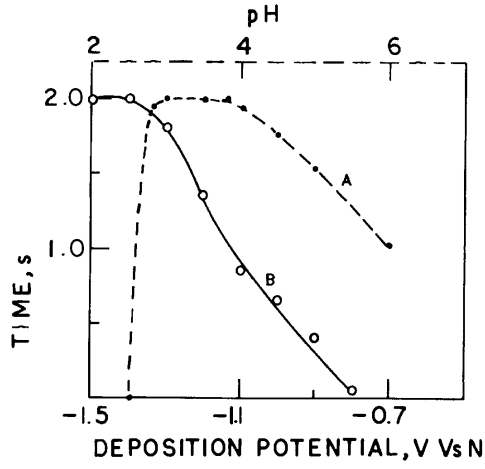

Fig. 2. Effect of pH (curve A) and deposition potential (curve B) on the galvanic stripping signal of 10 ppb of indium; 0.1 M acetate buffer, pH 3.5; t_d=4 min.

Table 2. Analysis of Synthetic Samples

Sample solution	Amount of indium(III) added	Aliquot taken	Indium(III) found	Recovery
	μg/g	ml	μg/g	%
1. Aluminium Metal	—	40	0.0	—
(5 g per 50 ml)	0.5	40	0.49	98.0
	1.0	40	1.01	101.0
2. Zinc metal[a)]	—	40	0.0	—
(5 g per 50 ml)	0.4	40	0.39	97.5
	0.8	40	0.80	100.0
	1.2	25	1.18	98.3

a) By depositing at −1.05 V vs. NCE for 4 min.

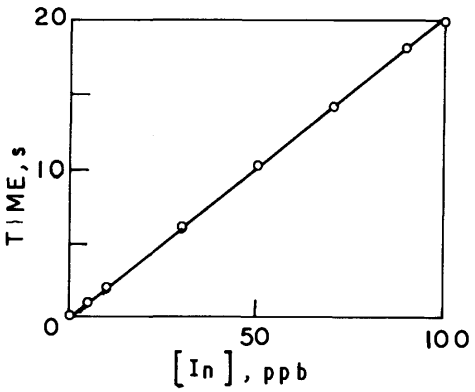

Fig. 3. Calibration graph.

remains unaffected. As the recoveries obtained were quantitative, the developed (cf. Table 3) procedure is expected to find application in ascertaining the concentration of indium in zinc deposits and aluminium alloys.

Polymers as Reagents and Catalysts. XI. Stereospecific Iodofluorination of Alkenes in the Presence of Polymer Supported Hydrogen Fluoride[1)]

Ana GREGORČIČ and Marko ZUPAN*
"Jožef Stefan" Institute and Department of Chemistry, "E. Kardelj" University, Ljubljana, Yugoslavia
(Received March 18, 1986)

Synopsis. *N*-Iodosuccinimide reacted with phenyl substituted alkenes in the presence of insoluble polymer supported hydrogen fluoride, which was prepared by reaction of hydrogen fluoride with crosslinked poly(styrene-co-4-vinylpyridine) containing 40—45 mol% of 4-vinylpyridine, thus forming vicinal iodofluorides in high yields. Reactions proceeded with Markovnikov type regioselectivity, and in the case of (*Z*)- and (*E*)-stilbene, (*Z*)- and (*E*)-1-phenylpropene and indene anti stereospecificity was also observed. Iodofluorinations of phenyl substituted acetylenes occurred regio and stereospecifically, forming (*Z*)-1-fluoro-2-iodo-1-phenylalkenes, with lower yields than those observed in the case of alkenes.

Polymeric resins can be chemically transformed so that they can act as reagents or catalyst, and besides offering simpler experimental techniques, the chemical reactivity can also be changed when the reagent is attached to a polymer backbone.[2)] Our continued interest in methods for mild introduction of fluorine into organic molecules stimulated us to search further for new reagents. It is now known that appropriate synthesis of a polymer supported reagent is one of the most important factors influencing its effectiveness. We have already demonstrated that polymer-supported (difluoroiodo) arene could be prepared by reaction of xenon difluoride[3,4)] with polymer supported iodobenzene, while Patrick and coworkers[5)] have shown that a similar reagent cannot be prepared by reaction of HgO-HF with polymer supported (dichloroiodo)-arene. Banks and coworkers[6)] have also very nicely demonstrated how important is the appropriate synthesis of a polymer supported reagent which should be able to convert alcohols into fluorides.

Hydrogen fluoride has been often used for the preparation of fluorine containing molecules, its great disadvantage being its toxicity to living beings and the fact that usually pressure equipment and low temperatures must be used in order to prevent decomposition of some organic molecules. Some of the experimental difficulties can be avoided by use of a mixture of hydrogen fluoride and pyridine which was extensively employed by Olah and coworkers.[7)]

We have found that crosslinked poly(styrene-co-4-vinylpyridine), containing 40—45 mol% of 4-vinylpyridine, reacted with hydrogen fluoride thus forming an easily handled reagent.[8)] We have recently showed that polymer-supported hydrogen fluoride could be used for chloro- and bromofluorination of alkenes at room temperatures, and that reaction proceed with Markovnikov type regioselectivity.[9)]

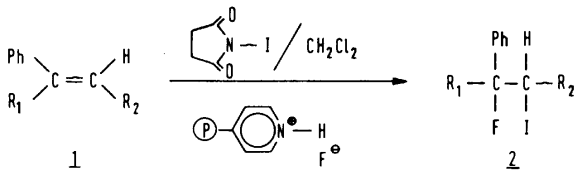
Results and Discussion

Vicinal iodo fluoro compounds are very unstable compounds and could be prepared with varying degrees of success from a mixture of *N*-iodosuccinimide and hydrogen fluoride. On the other hand, we found that the reactivity of difluoro iodosubstituted compounds strongly depends on the nature of the substituent. Reactions of (difluoroiodo)arenes with olefins usually resulted in rearranged geminal difluorides,[10)] while reactions of (difluoroiodo)methane with various alkenes gave vicinal iodofluorides at room temperature. Reactions follow Markovnikov type regioselectivity and are in most cases stereospecifically anti.[11-15)] Vicinal iodo fluoro compounds are usually accompanied by vicinal difluoro compounds, which are formed by further reaction with fluoride anion or by rearrangement of products. However, this reaction pathway is diminished when (difluoroiodo)methane is used as reagent, but its greatest disadvantage is the high price of xenon difluoride which is used for its room-temperature preparation.

We first studied the reactions of *N*-iodosuccinimide in dichloro methane in the presence of insoluble polymer supported hydrogen fluoride with 1,1-diphenylethene, and found that after 2.5 hours it was quantitatively converted to 1-fluoro-1,1-diphenyl-2-iodoethane. Further, we studied the effect of the structure of the olefin on iodofluorination, and for this reason all the reactions were run for only one hour. Crude reaction mixtures were analyzed by ^{1}H and ^{19}F NMR spectra using octafluoronaphthalene as internal reference.

The effect of the structure of the olefin on iodofluorination is presented in Scheme 1. It is evident that 1,1-diphenylethene is the most reactive olefin, while the introduction of an electron withdrawing group in to the phenyl ring, i.e. 1-(4-chlorophenyl)-1-phenylethene or the introduction of a halogen atom on the double bond, e.g. 2-fluoro-1,1-diphenylethene, diminished the reactivity. All the reactions follow the Markovnikov type regioselectivity and vicinal iodo fluoro compounds were not accompanied by difluorides or rearranged products.

Further, we studied the stereochemistry of iodofluorination of various phenyl substituted alkenes. In all cases, i.e. (*E*)- or (*Z*)-1-phenylpropene, (*E*)- or (*Z*)-stilbene, and indene the formation of only one product was observed. The structures of the products were determined on the basis of their spectroscopic data and their comparison to those of independently synthesized compounds. Iodofluorination of all five olefins followed Markovnikov type regioselectivity and proceeded stereospecifically anti. In order to get information about the effect of the structure of the olefin on the course of the reaction, all the reactions were performed at room temperature for one hour and the



THE EFFECT OF SUBSTITUENTS ON CONVERSION OF ALKENES TO IODO FLUORO COMPOUNDS[a]

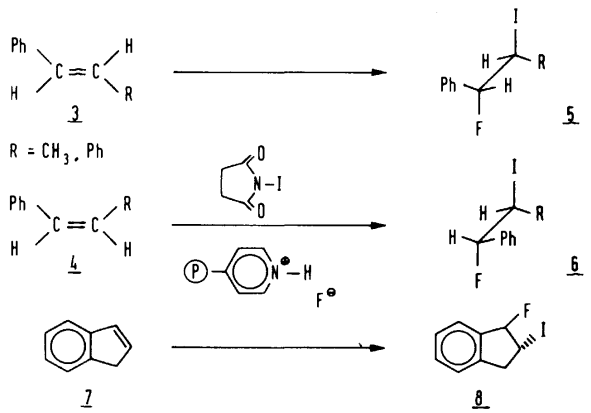
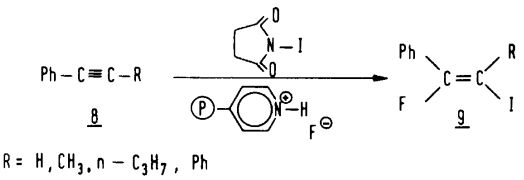
Scheme 1.



Scheme 2.

amounts of vicinal iodo fluoro compounds determined in the crude reaction mixtures were as follows: 61% from (*E*)-1-phenylpropene, 45% from (*Z*)-1-phenylpropene, 40% from (*E*)-stilbene, 38% from (*Z*)-stilbene, and 56% from indene.

Further, we studied iodofluorination of acetylenes and found that reactions occurred regiospecifically, thus forming (*Z*)-1-fluoro-2-iodo-1-phenylethenes. The substituent R influenced the conversion of acetylene. After a 1.5 h reaction the following amounts of iodo fluoro compounds were determined: 16% from phenylacetylene, 25% 1-phenylpropyne, 31% from 1-phenyl-1-pentyne, while reaction with 1,2-diphenylacetylene failed. Prolongation of the reaction time to 2.5 hours resulted in enhanced reaction and the following amounts were observed: 18, 30, 28, and 5% (data correspond to the same order of substrates as above). However, further prolongation of reaction time did not enlarge the yields of iodofluorides, and after 7 hours even smaller amounts of products than those observed after 2.5 hour reactions were found, which could be explained by decomposition of the products. The structures of the products were determined on the basis of their spectroscopic data and comparison to



Scheme 3.

those of the independently synthesized ones.[16] It is known that the solvent plays an important role in the transformation of organic molecules with polymer-supported reagents, and for this reason we tried to increase the amount of iodo fluoro compounds from acetylenes by varying the solvent. However it was found that reactions did not occur in tetrahydrofuran and acetonitrile.

The polymer resins could be easily recovered after reaction, and reused several times.

Experimental

IR spectra were recorded using a Perkin Elmer 727 B instrument and ^1H and ^{19}F NMR spectra with a Jeol JNM PS-100 spectrometer with Me_4Si or CCl_3F as internal reference. For determination of the amounts of products formed, octafluoronaphthalene was used as internal standard. Mass spectra and high resolution measurements were taken with a CEC-21-110 spectrometer. GLC was carried out on a Varian Aerograph 1800 instrument and TLC on Merck silica gel F-254. Crosslinked poly(styrene-co-4-vinylpyridine) and polymer supported hydrogen fluoride were prepared according to previously published procedures,[8,17] while *N*-iodosuccinimide of Fluka Purum Quality was used without further purification.

Addition and Isolation Procedures. 0.15 g of polymer supported hydrogen fluoride was mixed with 2 ml of dichloro methane and 1 mmol of *N*-iodosuccinimide was added at 0 °C and stirred until complete dissolution of *N*-iodosuccinimide occured. Further, 0.5 mmol of olefin or acetylene was added and the reaction mixture was stirred for various times (1—7 h), depending on the reactivity of the alkene or acetylene. Polymer beads were filtered off and

washed with 5 ml of dichloro methane, the filtrate was washed with water (10 ml, twice), dried over anhydrous sodium sulfate, and the solvent evaporated in vacuo. The crude reaction mixtures were analyzed by ^{19}F NMR spectroscopy (amounts of products were determined by the use of octafluoronaphthalene in ^{19}F NMR as internal standard). Pure products were isolated as described previously[12-16] and their structures determined by comparison of spectroscopic data to the literature ones. The yields of pure products formed after reactions of olefins and acetylenes were: 1-Fluoro-2-iodo-1-phenylethane (reaction time: 1h, yield of pure product 56%) 2-fluoro-1-iodo-2-phenylpropane (r.t.: 1h, 58%), 1,1-diphenyl-1-fluoro-2-iodoethane (r.t.: 1h, 61%), 1-fluoro-2-iodo-1-phenyl-1-(4'-chlorophenyl)ethane (r.t.: 1h, 16%), 1,2-difluoro-1,1-diphenyl-2-iodoethane (r.t.: 1h, 11%), 1,1-diphenyl-1-fluoro-2-iodopropane (r.t.: 1h, 54%), *erythro*-1-fluoro-2-iodo-1-phenylpropane (r.t.: 1h, 55%), *threo*-1-fluoro-2-iodo-1-phenylpropane (r.t.: 1h, 38%), *erythro*-1,2-diphenyl-1-fluoro-2-iodoethane (r.t.: 1h, 34%), *threo*-1,2-diphenyl-1-fluoro-2-iodoethane (r.t.: 1h, 33%), *trans*-1-fluoro-2-iodoindane (r.t.: 1h, 49%), (*Z*)-1-fluoro-2-iodo-1-phenylethylene (r.t.: 2.5h, 15%), (*Z*)-1-fluoro-2-iodo-1-phenylpropene (r.t.: 2.5h, 26%), (*Z*)-1-fluoro-2-iodo-1-phenyl-1-pentene (r.t.: 2.5h, 24%), (*Z*)-1,2-diphenyl-1-fluoro-2-iodoethylene (r.t.: 2.5h, 4%).

Regenerations of Resins. Beads were washed with methanol, dichloro methane, and chloroform, and dried in air. 5 g of polymer beads were suspended in 5 ml of chloroform and under stirring hydrogen fluoride (1.5 g) was introduced for 0.5 h at 0 °C. The beads were filtered off, washed with chloroform and dried to constant weight at room temperature. Polymer beads can be reused at least ten time for fluorination.

Bleaching of Bis[1-(4-dimethylaminophenyl)-2-phenylethanedithione]-nickel(0) in Polymer Solution and Polymer Matrix

Koe Enmanji
The Materials Engineering Laboratory of Mitsubishi Electric Co.,
Tsukaguchi-Honmachi, Amagasaki 661
(Received January 23, 1987)

Bis[1-(4-dimethylaminophenyl)-2-phenylethanedithione]nickel(0) (BDN), a Q-switch dye for neodymium lasers, bleached in polymer matrix such as poly(butyl methacrylate). To elucidate the bleaching mechanism, the effect of water-soluble polymer added to dimethyl sulfoxide (DMSO) solution of BDN on the bleaching rate was investigated. BDN was reduced by a water-soluble polymer such as poly(vinyl alcohol) (PVA), starch, and cyclodextrin (CD) in DMSO. BDN bleached in DMSO solution with PVA and bleaching rate depended on the saponification number of PVA. BDN was also bleached by adding CD to DMSO solution. From the concentration dependence of CD on BDN bleaching rate, it was presumed that the vicinity of Ni of BDN is not included in β- and γ-CD, but is included in α-CD. For avoiding reduction of BDN by CD, 2,4,5-tri-*O*-methoxy-β-cyclodextrin (T-β-CD) was examined. BDN was not reduced by an inclusion complex of BDN with T-β-CD. The storage life of Q-switch with matrices of poly(butyl methacrylate) and polystyrene was determined. The Q-switch with polystyrene matrix having transmittance of 70.0% is expected to have transmittance of 70.4% after strage for 10 years at 25 °C.

The toluene solution of bis[1-(4-dimethylaminophenyl)-2-phenylethanedithione]nickel(0) (BDN) in glass cell has been used for a Q-switch of neodymium laser, because BDN has absorption peak at 1060 nm, that is the oscillation wavelength of neodymium laser. A solid state Q-switch is desirable for making it small and its life longer. BDN bleaches so remarkably in vinyl polymers that the solid state Q-switch is impracticable. The bleaching of BDN in solution was studied from various points of view[1-4] and it was found that there are two types of bleaching mechanism of BDN: (1) Oxidative bleaching by attacking of radicals[1-3] and (2) reductive bleaching by coordination of solvent to Ni.[4] The oxidative bleaching could be decreased by removing radicals or by inclusion of BDN with cyclodextrin (CD).[3] The author wishes to elucidate the mechanism of bleaching of BDN in polymer matrix. It seems that reduction of BDN by coordination of oxygen in polymer to Ni of BDN is a cause of the bleaching. In order to confirm this assumption, the correlation between the amount of OH group and the bleaching rate was studied with addition of water-soluble polymers containing plenty oxygen such as poly(vinyl alcohol) (PVA), starch, and CD[3] to a dimethylsulfoxide (DMSO) solution of BDN. The storage time and resistance to oscillation of a solid state Q-switch using polystyrene (PS) matrix will also be reported.

Experimental

Materials. BDN was purchased from Kodak Co. and CD from Tokyo Chemical Co. 2,4,5-Tri-*O*-methoxy-β-cyclodextrin (T-β-CD) was presented by Dr. H. Yamaguchi (Colledge of Technology, Ibaraki University). Low molecular weight PVA samples from Unichika Chemical Co. were used after precipitation three times from methanol solution in toluene. Their saponification number was 81.7 (UMR-20H®), 63.8 (UMR-20M®), and 35.0 (UMR-20L®). Starch 2-hydroxypropyl ether of Matsutani Chemical Co. (Stacodex®) was used as starch which was purified by precipitation three times from toluene–methanol system. Butyl methacrylate (PBMA) polymerized in xylene was purified by precipitation three times from methanol–xylene system. A high impact polystyrene from Denki Kagaku Co. (TPUSH®) was purified by precipitation three times from toluene–methanol system. Benzoin ethyl ether (BEE) was purchased from Nakarai Chemical Co. DMSO and petroleum ether of reagent grade by Nakarai Chemical Co. and toluene of Spectral grade by Wako Junyaku Co. were used.

The inclusion complex of BDN with T-β-CD was prepared by the following procedure: BDN (10 mg) and T-β-CD (100 mg) were dissolved in toluene (100 ml) and the solution was stirred for 10 min at 60 °C. Toluene was evaporated with a rotaryevaporator, and the inclusion complex in residue was dissolved into petroleum ether. The liquid was centrifuged at 1000 g for 10 min to remove excess BDN.

Measurement. UV-visible spectra and IR spectra were measured by Shimadzu MPS-5000 spectrophotometer and Shimadzu 430 infrared spectroscope, respectively. The light source for bleaching experiments was Ushio 500 high-pressure marcury lamp with an output of 150 mW cm^{-2}.

Results and Discussion

The effect of polymer on bleaching rate of BDN in solution. The toluene solution of BDN was not bleached in the experiment for a day. A commercial poly(methyl methacrylate) (PMMA) added to the solution caused bleaching as to decrease the absorption peak at 1100 nm. Because the logarithm optical density (OD) at 1100 nm decreased linearly with time at 25 °C, the bleaching reaction is of the first order BDN. But purified PMMA, which was precipitated

three times from methanol-toluene system, showed no bleaching effect. When 1 ml of aqueous potassium iodide solution (10%) was added to 10 ml of a toluene solution of commercial PMMA (10%), and the mixture was shaken vigorously and made to stand for 30 min, the color of water layer changed to yellow. This phenomenon suggests the existence of peroxide in the commercial PMMA. It was also shown that benzoin peroxide bleached BDN.[3] It is likely that the remaining peroxide in the commercial PMMA used for polymerization bleached BDN. A peroxide must be removed from polymer by reprecipitation when the polymer is used for matrix of Q-switch. On the other hand, BDN was bleached reductively in a DMSO solution and the absorption peak at 1100 nm shifted to 1030 nm. The rate constant of bleaching reaction was 5.24×10^{-4} min^{-1} at 25 °C. The author proposed a previous paper,[4] that two DMSO molecules coordinate to BDN and the coordinated DMSO molecules reduce BDN to an anion radical in the similar manner as *N*,*N*-dimethylformamide (DMF), and that the following equation holds:

$$\mathrm{BDN} + 2(\mathrm{DMSO}) \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} \mathrm{BDN(DMSO)_2} \xrightarrow{k_2} \mathrm{BDN}\cdot^{\ominus}. \quad (1)$$

Equation 2 can be obtained from Eq. 1.

$$\frac{d[\mathrm{BDN}]}{dt} = -k_2 \frac{k_{+1}}{k_2+k_{-1}}[\mathrm{BDN}][\mathrm{DMSO}]^2 \quad (2)$$

Addition of commercial PVA to DMSO solution of BDN made the bleaching rate of BDN to increase. The mechanism of this reaction is thought that DMSO coordinating to BDN takes up proton from OH of PVA and reduces BDN with this proton. A similar reaction mechanism was preveously reported for α-tocopherol.[4] The mechanism can be expressed by the following equation.

$$\mathrm{BDN} + 2(\mathrm{DMSO}) \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} \mathrm{BDN(DMSO)_2}, \text{ and} \quad (3)$$

$$\mathrm{BDN(DMSO)_2} + \mathrm{PVA} \xrightarrow{k_2} \mathrm{BDN}\cdot^{\ominus}. \quad (4)$$

Equation 5 can be derived from Eqs. 3 and 4.

$$\frac{d[\mathrm{BDN}]}{dt} = -\frac{k_{+1}k_2[\mathrm{PVA}]}{k_{-1}+k_2[\mathrm{PVA}]}[\mathrm{BDN}][\mathrm{DMSO}]^2, \quad (5)$$

where [PVA] is the concentration of monomer unit of PVA. By changing k_{+1}, k_{-1}, and k_2 purposely, the inclination of the plot between [PVA] and bleaching rate varies. For confirming this relation, the experiments were carried out by using PVA with different sapponification numbers. The effect of UMR-20H, -M, and -L in DMSO solution of BDN on the bleaching rate is shown in Fig. 2. Figure 2 shows that the larger the saponification number is, the larger the apparent bleaching rate constant as well as the smaller the slope of plot become. It appears therefore, that the bleaching rate correlates with the number of OH group.

BDN was also reduced by starch. The effect of hydroxypropyl starch (Stacodex®) on the bleaching rate of BDN in DMSO solution is shown in Fig. 3. The hydroxypropyl starch has the following chemical structure.[6]

Starch-O-CH_2-CH(OH)-CH_3.

The inclination of relationship between the concentration of the starch and the bleaching rate of

—O—: UMR-20L®, —X—: UMR-20M®, —Δ—: UMR-20H®. Concentration of BDN is 5.13×10^{-5} mol dm^{-3}

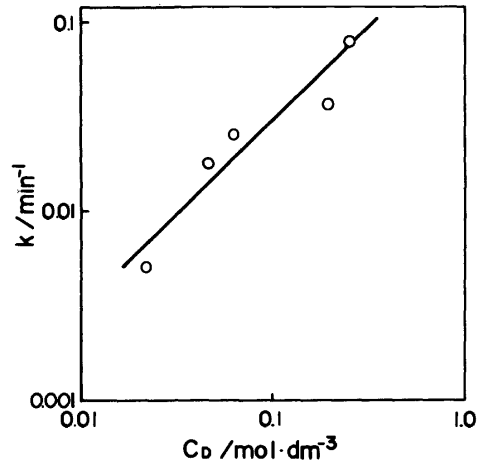

Fig. 3. Dependence of bleaching rate of BDN on the concentration of starch. Concentration of BDN is 5.13×10^{-5} mol dm^{-3}.

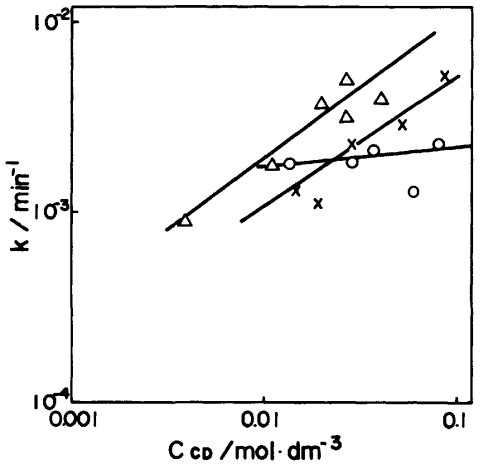

Fig. 4. Dependence of bleaching rate of BDN on the concentration of cyclodextrin.
—O—: α-Cyclodextrin, —X—: β-cyclodextrin, —△—: γ-cyclodextrin. Concentration of BDN is 5.13 $\times10^{-5}$ mol dm^{-3}

BDN is unity from Fig. 3. We was recognized in the previous paper[3] that we must reexamine the behavior of BDN in CD. From the following experiment, it was found that BDN is reduced by CD in DMSO solution. The effect of CD on the reduction rate of BDN is shown in Fig. 4 which shows that the bleaching rate of BDN with γ-CD (glucose number, 8) is larger than that with α-CD (glucose number, 6) and β-CD (glucose number, 7). This result will be due to the fact that γ-CD has more OH groups than α-CD and β-CD. The inclination of the plot between concentration of CD and bleaching rate was 0.6—0.7 for β-CD and γ-CD and that was 0.1 for α-CD. Since the CD concentration exceeds that of BDN, it seems that all BDN molecules are included in CD. The fact that BDN was bleached even by β-CD and γ-CD of

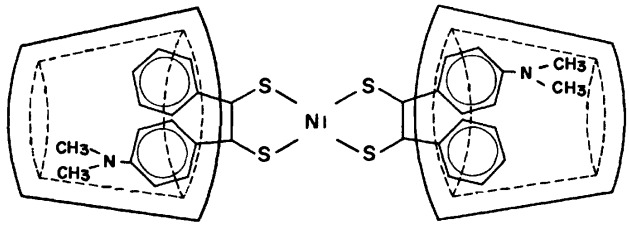

Fig. 5. Assumed structure of the inclusion complex of BDN with β- or γ-cyclodexrin

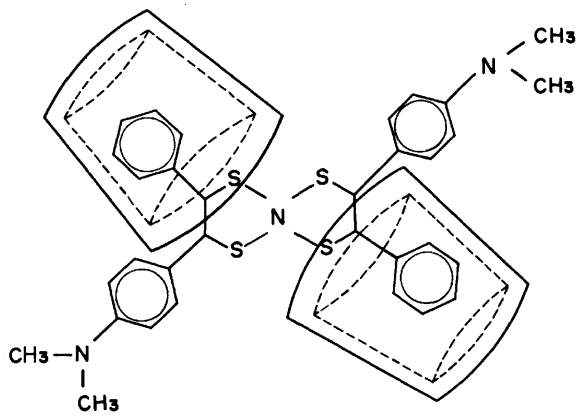

Fig. 6. Assumed structure of the inclusion complex of BDN with α-cyclodextrin.

which have spacious hydrophobic pores indicates that the central Ni of BDN is not included in CD as shown in Fig. 5. Because α-CD has less OH groups than other CD species, it is expected that the slope of plot between concentration of α-CD and bleaching rate must be unity. From the facts that the slope was 0.1, and that α-CD has small hydrophobic pore, a vicinity of Ni of BDN molecule may clog the pore as shown in Fig. 6.

From the above discussion, BDN included in CD seems to be reduced to a product, possibly an anion radical. The material which does not reduce BDN would be considered. T-β-CD with methoxyl instead of OH groups in a toluene solution of BDN did not change the spectrum even after a long time of standing. The optical spectrum of petroleum ether solution of BDN with T-β-CD is shown in Fig. 7. The spectrum differs from that of BDN toluene solution in a point that near-infrared absorption peak at 1100 nm shifts to 960 nm. Because the d-d transition appears at visible region, this compound must not be a reduced product of BDN. A stable inclusion complex was formed, because bleaching rate constant of BDN in petroleum ether with T-β-CD was larger (k=0.151 min^{-1}) than that in toluene solution (k=0.088 min^{-1}), UV light was irradiated after BEE (1%) was added to the solution. IR spectra of BDN included in T-β-CD, BDN, and T-β-CD are compared in Fig. 8. The assignment and absorbance of each peak and the ratios

of optical density for other peaks to that for $\nu(N(CH_3)_2)$ are shown on Table 1. As seen in Table 1, the absorbance of ν(C–S) peak of BDN in T-β-CD decreased by about 20 percent from that of BDN itself. The structure illusteated in Fig. 9 deloneated that $N(CH_3)_2$ group is projected in solvent and benzene ring and C–S are included in CD pores. It will be that BDN is occluded by T-β-CD more shallowly than by α-CD. From this reason, the resistance to attack by radicals of BEE disappears. Storage life of solid state dye Q-switch and resistance to repeating oscillation.

A solid-state dye Q-switch of wich PBMA matrix was prepared. The absorbance was determined with time(days) kept in an electric oven at 69, 83, and 103 °C. Because logarithm absorbance at 1100 nm decreased linearly with the storage time, the rate constant was estimated from tangent of the linear relations. The Arrhenius plot for decay of solid-state dye Q-switch is shown in Fig. 10. Extrapolation of the plot gives the assumed storage life at each temperature (Table 2). The storage time at 30 °C is assumed to be about 2 months. Because PBMA was purified by careful reprecipitation, bleaching of BDN will not occur by residual peroxide, but by reduction with butoxyl group. The Arrhenius plot of bleaching rate of BDN in toluene which contains a small amount of peroxide is also shown in Fig. 10 for comparison.

The author considered that the storage life would be improved by dispersing BDN in a polymer as low-T_g-polystyrene with no N and O atoms, because styrene with lower T_g will decrease damage induced by

a) The year for increasing transmittance from 70 to 75%.

laser.[7,8] A mixed solution of BDN and polystyrene in toluene was coated in 10 μm thickness on a PMMA plate of 1 mm thickness and dried at room temperature. The sample was stored in an oven at 88, 100, and 130 °C. Absorbance at 1100 nm plotted against storage time revealed that logalithm OD decreases linearly with storage time. The Arrhenius plot of bleaching rate constant is shown in Fig. 11. The bleaching rate at each temperature and the storage life assumed by rate constant are given in Table 3. The bleaching rate constant k at 25 °C was estimated from Fig. 11 to be 5×10^{-6}d^{-1}. The result indicated that the transmittance of improved solid-state Q-switch of 70.0% will change to 70.4% after 10 years storage.

The resistance to repeating oscillation of the Q-switch was measured. The Q-switch with BDN dispersed in PBMA withstood against oscilation of 20000 times by 200 J YAG laser for one day, while that dispersed in low-T_g-polystyrene withstood 100 times' oscillation by the similar experiment for 2 hours. The solid Q-switch is believed to be useful for practical use.

Metal Colloids Produced by Means of Gas Evaporation Technique. IV. Size Distribution of Small Mg and In Particles

Keisaku KIMURA
Instrument Center, Institute for Molecular Science, Myodaiji, Okazaki 444
(Received February 4, 1987)

Ultrafine metal particles with different sizes have been obtained by several preparation methods. The smallest Mg particles (the average diameter D_m of about 2 nm) were obtained by the matrix isolation method in He and the largest (D_m, 100 nm) by the conventional gas evaporation method in Ar. By changing the pressure and the kind of gas, particles with an intermediate diameter have been obtained. The size distribution of small In particles was discussed.

There are many reports on the preparation of fine metal particles with the diameter of less than 1 μm by the evaporation of metals in an inert gas.[1-5] However, it is not easy to obtain particles with the diameter of less than 10 nm by the conventional gas evaporation method, because particles become larger by coalescence when they contact with each other on the walls of preparation chamber. To prevent particles from contacting, a liquid is used for intervening between particles. Two approaches have been proposed. Yatsuya et al. reported the VEROS (vacuum evaporation on running oil substrate) method, in which a metal is evaporated in vacuum onto surface of running oil.[6-8] This method yields particles with a size of 3 nm, although there are severe restrictions on the selection of oil. The matrix isolation method combining the gas evaporation technique was also used by several researchers.[9-11] Furthermore, the gas flow-solution trap method and the gas flow-cold trap method were developed in the previous studies by the present author using organic liquids as substrate.[11,12] The particle diameter at the maximum distribution reached the range of 1 nm. Several kinds of well dispersed ultrafine metal particles were obtained such as Ni, Ag, Cu, Au, Sb, and Al by Wada[9] and Ag, Au, Cu, In, Al, Ca, Sn, and Pb by the present author.[11] The reaction of metal particles with liquids and the change in particle diameter due to the reaction were examined in a previous work.[12]

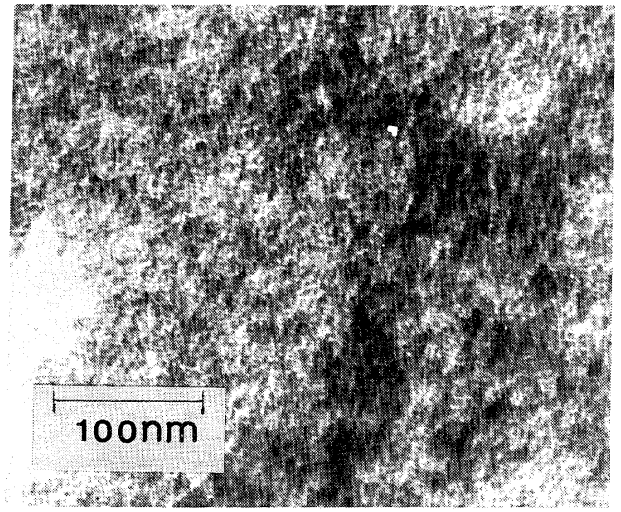
A wide difference of particle diameter between the conventional gas evaporation method (several tens nm) and the liquid substrate method (several nm) suggests difference in particle growth mechanism. The mechanism of nucleation growth from gaseous atoms was studied by analyzing size distribution of the particles produced. As is usually seen in many physical processes, the normal distribution results from a random process. Granqvist[13,14] proposed the log-normal distribution for the metal particles produced by the gas evaporation method. His proposal was confirmed for extremely small particles prepared by the VEROS method[15] irrespective of large difference in particle diameter between two methods. Since no study was performed on the nucleation mechanism of small particles produced by the matrix isolation method, the gas flow-solution trap method, and the gas flow-cold trap method, this paper describes the size distribution by differnt preparation methods in the case of Mg particles in tetrahydrofuran (THF) and In particles in acetone.

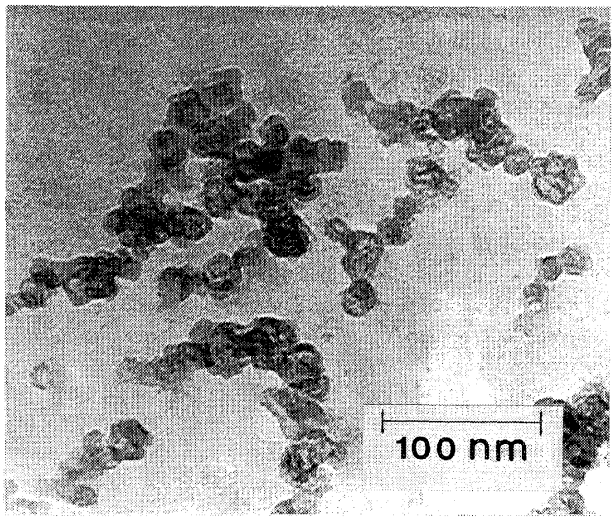
Experimental

Small metal particles were prepared by the matrix isolation method, the gas flow-solution trap method, and the gas flow-cold trap method similarly as described in the previous paper.[11] Several kinds of gas atmosphere were examined: He and Ar for the matrix isolation method, and a He/Ar mixture as well for the gas flow method were used. The metals used were 99.999% In, 99.99% Mg, and 99.5% Au. Acetone was purified with CaH_2 and THF was distilled from its Na-benzophenone solution. The size distribution of particles was determined by electron microscopy. A colloidal solution was dropped on a Cu mesh coated with evaporated carbon film of 10 nm in thickness. Hitachi H-500H electron microscope of the Laboratory of Electron Microscopy, the National Institute for Physiological Sciences at Okazaki was used with a 100 kV high resolution mode. The histograms of size distribution were obtained by an Image Analyser, Kontron IBAS-1, of the Center for Analytical Instrument, the National Institute for Basic Biology at Okazaki.

Results and Discussion

Size Distribution of Mg Particles. Figure 1 shows micrographs of Mg particles produced by different methods. The finest particles in Fig. 1a were prepared by the matrix isolation method in He gas atmosphere. Figure 1b shows Mg particles prepared by the same method but in Ar atmosphere. The largest particles in Fig. 1c[16] were obtained by the conventional gas evaporation method in Ar atmosphere, in which hexagonal crystal habit characteristic of hcp structure is seen. The size distributions curves f(d) in Fig. 2 were obtained from Figs. 1a, 1b, and 1c, respectively. It is evident that the average diameter widely varies from 2 to 100 nm with the preparation





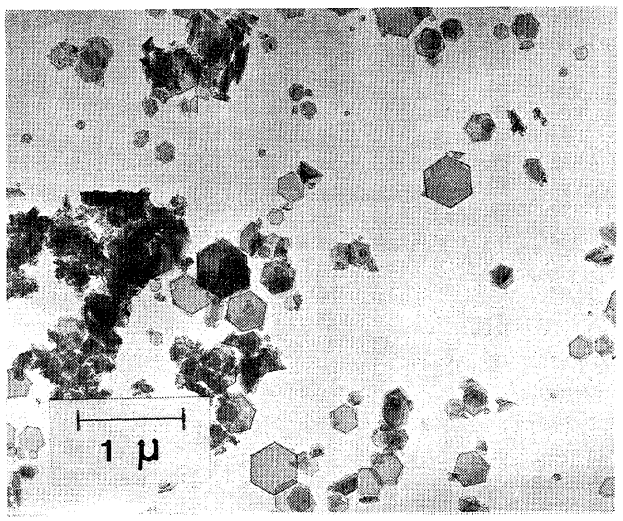


Fig. 1. Electron microscope images of Mg small particles of different sizes.

method and conditions. The number of atoms in a single particle accordingly varies from 10^2 to 10^7. This result differs from that of giant clusters produced by the supersonic nozzle beam method, in which the size distribution is a monotonously decreasing function of the size modulated by small cusps at the position of magic numbers.[17,18] It is also noteworthy that the half-value width of distribution is a function of the average diameter. The smaller the particle diameter is, the narrower the width of distribution becomes. This tendency was also reported for Al particles produced in He gas.[19]

The effect of mass and pressure of inert gas on the particle size was reported by Wada on the conventional gas evaporation method.[20] The particle size increases in the order of He, Ar, and Xe. The size also increases with increasing ambient gas pressure. In this experiment, larger particles (Fig. 1b) were obtained in Ar than in He (Fig. 1a). The distribution in Fig. 1b (the diameter at the maximum distribution D_m of 19 nm) is close to that by the gas evaporation method in He (D_m, 21 nm). This shows that the gas evaporation method in a gas with small molecular weight yields the particles of size equivalent to that by the matrix isolation method in a gas with large molecular weight. It seems evident that the matrix isolation method is superior to the gas evaporation technique in order to obtain ultrafine particles when we expect the quantum size effect. For Mg metal, a particle of 2.1 nm (Fig. 1a) is composed of 210 atoms and, therefore, the average electron level spacing near the Fermi level is about 130 K, which is far above the normal cryogenic temperature.[21] Hence, it is easy to observe the quantum size effect for these particles.[22,23]

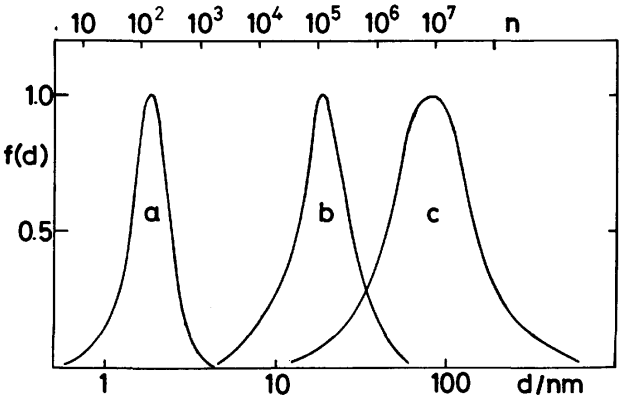

Fig. 2. Size distribution of Mg small particles produced by different method.
Curves, a, b, and c are from those in Fig. 1. The distribution maxima locate at the diameter (D_m) of 2.1 nm for a, 19 nm for b, and 100 nm for c. Numbers in the top abscissa are the number of Mg atoms in a particle whose diameter is designated in the bottom abscissa.

Analysis of Size Distribution of In Particles. Particle size distribution strongly depends on its growth process. Two main processes have been proposed:[24] One is the absorption growth process where particle nuclei grow up with absorption of metal atoms. This gives the normal distribution of particle size. Another is the coalescence growth process where particles grow up by collision of particle nuclei to give a log-normal size distribution. This distribution is derived from the assumption that the change in volume (mass) at each step is a random fraction of the volume after coalescence. The normalized distribution for logarithm of volume is given by

$$f_{LN}(v) = \frac{1}{\sqrt{2\pi}\ln\sigma_v}\exp\left\{-\frac{1}{2}\left[\frac{\ln(v/\bar{v})}{\ln\sigma_v}\right]^2\right\}, \quad (1)$$

where $\bar{v}$ is the mean volume and σ_v is the standard deviation of volume. The number of particles Δn per logarithmic volume interval is, therefore, given by $\Delta n = f_{LN}(v)\Delta(\ln v)\cdot n$. For a sphere particle, one obtains the so-called log-normal distribution function for particle diameter, d, as

$$f_{LN}(d) = \frac{1}{\sqrt{2\pi}\ln\sigma}\exp\left\{-\frac{1}{2}\left[\frac{\ln(d/\bar{d})}{\ln\sigma}\right]^2\right\}. \quad (2)$$

The fraction of the number of particles per diameter interval can be written as $\Delta n/n = f_{LN}(d)\cdot\Delta d/d$.[14] For the log-normal distribution, the mean diameter d is related to the peak diameter D_m as $\bar{d} = D_m\cdot\exp[\ln\sigma]^2$.

Figure 3 shows a typical size histogram of In particles produced by the gas flow-cold trap method in acetone. The best fit with the log-normal distribution is shown by a broken line in Fig. 3. The features of fitting are wholly good. Since it is difficult to achieve the best fit only from the appearance of fitting to the distribution curve, a better technique will be found with reference to graphical "normal-probability" and "log-probability" analyses as stated below. If the size distribution is a linear normal distribution, cumulation of the number of particles of a certain size follows the error function and plotting of the points on normal probability paper will give a straight line. Figure 4a shows the normal-probability plot of the sample shown in Fig. 3. It is clear that the size distribution does not fit with the normal distribution. On the other hand, the log-probability plot of the same sample gives a good straight line as shown in Fig. 4b, indicating that the size distribution of this sample is of a log-normal. The fitting was also checked by the χ^2-test with sample number 250 and the number of classes 29. The best fitting was obtained with σ of 2.13 and $\bar{d}$ of 20 nm and shown in Fig. 3 by a broken line. The significance level is over 75%

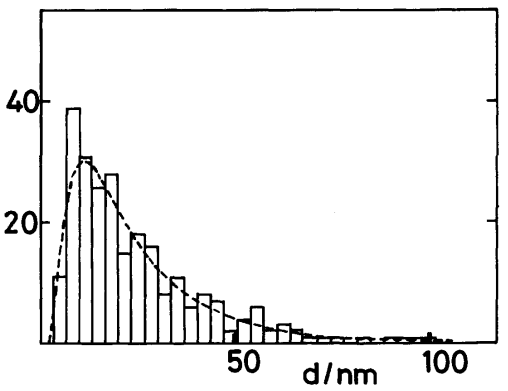

Fig. 3. Size histogram for In samll particles produced by the gas flow-cold trap method in acetone. The pressure of He+Ar mixed gas was 1.3 kPa. Broken line is a calculated curve from the log-normal distribution with fitted parameters σ=2.13 and $\bar{d}$=20 nm. The ordinate represents the number of particles at a given size interval.

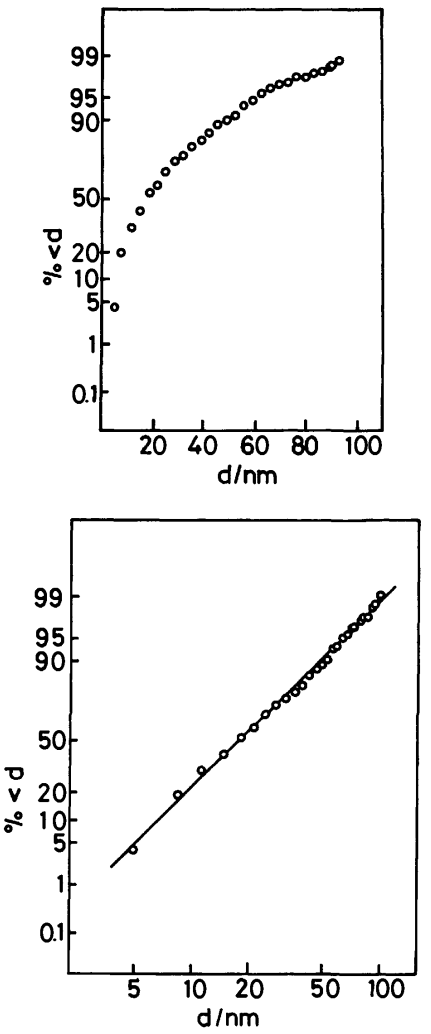

Fig. 4. a) Normal-probability plot and b) log-probability plot for In small particles. The ordinate stands the cumulative percent of particles with diameters smaller than d.

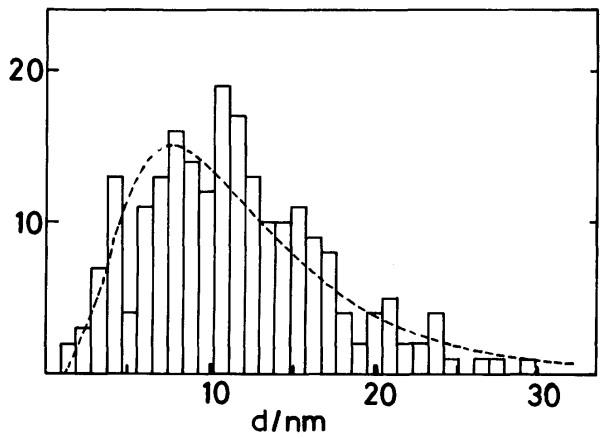

Fig. 5. Size histogram for In small particles produced by the matrix isolation method in acetone. The N_2 gas pressure was 1.3 kPa. Broken line is a calculated curve from the log-normal distribution with fitted parameters σ=1.8 and $\bar{d}$=10.8 nm. The ordinate represents the number of particles at a given size interval.

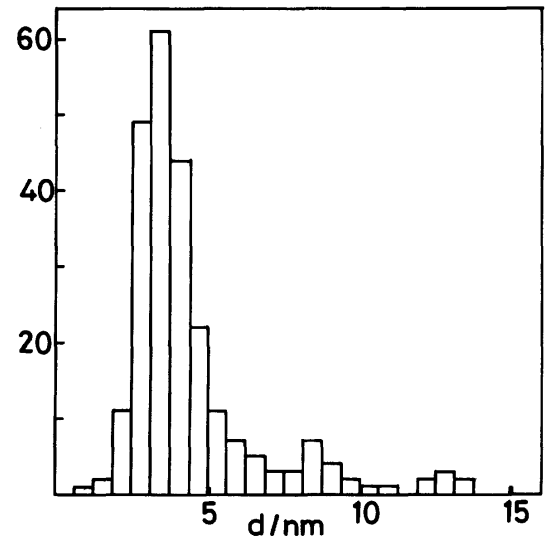

Fig. 6. Size histogram for In small particles produced by the gas flow-solution trap method in acetone.
The He gas pressure was 1.3 kPa. The peak diameter D_m=3 nm. No fitting was obtained for normal-probability and log-probability plots. The ordinate represents the number of particles at a given size interval.

showing the strong reliability of this fit, because the rejection level is normally set at 1 or 5%.

Figure 5 shows the size histogram of In particles produced by the matrix isolation method in acetone under N_2 atmosphere. The fitting of size distribution with the log-normal distribution was also checked by the χ^2-test with a significance level of 30%. This result seems to confirm that the log-normal distribution is applicable to this sample. The technique of the matrix isolation method is similar to that of the conventional gas evaporation method only except for the substrate of low temperature organic matrix.

Figure 6 shows the size histogram of small In particles produced by the gas flow-solution trap method in acetone under He atmosphere. In this preparation, the diameter of maximum distribution is about 3 nm. It was confirmed that the smallest particles are formed in low pressure He as in the case of Mg shown in Fig. 2. The histogram in Fig. 6 fits with neither the normal-distribution nor the log-normal distribution. The size distribution of Au particles in acetone produced by the same method (D_m=1.1 nm) fits with neither of two distribution curves. These distribution functions are derived on the assumption that the system is in thermodynamical equilibrium during particle growth. This is the case for a closed chamber atmosphere such as the conventional gas evaporation method and the matrix isolation method but not for the gas flow method, in which a constant flow of inert gas turbulates the nucleus growth process. The size distribution in Fig. 6, therefore, shows the distribution at the beginning of particle growth. Narrow size distribution of particles supports this assumption. Nevertheless, we need to know why the log-normal distribution is observed in the gas flow-cold trap method as shown in Fig. 3. In this method, the particles co-deposit with organic vapor on the walls of glass reaction vessel and are embedded in the matrix. The volume fraction of metal is so high in the matrix that particles tend to coagulate in the matrix. Large particles of 20 nm produced by the gas flow-cold trap method probably reflect the coagulation process, because the size of particles in a gas stream is believed to be of the order of 3 nm. It will be suggested that the size of small metal particles could be widely and easily changed from 2 to 100 nm in any suitable organic liquid, although only tetrahydrofuran and acetone were examined in the present study.

The author expresses his gratitude to Prof. Sanshiro Sako for presenting the photograph of Mg particles produced by the conventional gas evaporation method.

The Liquid-Junction Potential at the Contact of Two Immiscible Electrolyte Solutions in the Absence of Supporting Electrolytes Reference Electrodes Reversible to Alkylammonium Ions and Tetraphenylborate Ion in Nitrobenzene

Takashi KAKIUCHI and Mitsugi SENDA*
Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606
(Received March 4, 1987)

The liquid-junction potentials between two immiscible electrolyte solutions have been studied for the interface: $R_4^+TPB^-$(nitrobenzene)/$R_4^+X^-$(water) and $R_4^+TPB^-$ (nitrobenzene)/Li^+TPB^-(water), where R_4^+ is a tetraalkylammonium ion, TPB^- is tetraphenylborate ion, and X^- is a halide ion. These interfaces may be seen as a simplest form of either a liquid ion-exchange membrane ion-selective electrode sensing the activity of the ion in the aqueous phase or a reference electrode of a liquid membrane type reversible to the ion in the nonaqueous phase. The effects of the cationic species(R_4^+), the anionic species(X^-) and the concentration of the electrolytes on the electrical potential difference developed at the interface have been studied. These properties of the interfaces were compared with a simplified theoretical treatment of the liquid-junction potential between the two immiscible solutions. The theory can predict the basic features of the system by knowing the standard ion-transfer potentials and the diffusion coefficients of the relevant ions as well as its concentration. In the concentration range where a significant deviation from the Nernstian response of the liquid-junction potential occurred, the diffusion potential has been demonstrated to contribute significantly to the liquid-junction potential.

In the study of the double layer structure of the interface between two immiscible electrolyte solutions(ITIES) and the electrochemistry of charge transfer at the interface, large hydrophobic ions such as tetrabutylammonium ion(TBA^+) and tetraphenylborate ion(TPB^-) are used for a supporting electrolyte in the nonaqueous phase.[1a,b] In order that the electrical potential difference across the interface be well defined, it is desirable to use a reference electrode which is reversible to one of such organic ions in the nonaqueous phase. For this purpose, an aqueous solution containing the ion which is the same as one of the ions in the nonaqueous phase has been usually employed;[1a,b] the aqueous phase and the nonaqueous phase in contact form a nonpolarized interface through which the common ion works as a potential-determining ion. When all other ions are not transferable across the interface, there exists a so called contact equilibrium[2] between the two phases and there is no net flow of ions through the interface. The potential difference between the two phases is then represented by the Nernst equation with respect to the common ion. When an ion other than the potential determining ion, e.g., a counter ion of the potential-determining ion, is also appreciably transferable between the two phases, a net flow of the ions across the interface generally occurs even at zero-current condition until the final distribution equilibrium is attained.

The potential difference between two immiscible electrolyte solutions has been analyzed in detail by Hung[3] in the case where the distribution equilibrium of the ions between the two phases is established. He derived the equations which predict the distribution potential by knowing the initial concentrations and the standard ion-transfer potentials of the ions as well as the volumes of the two phases. However, in practice, the reference electrodes with ITIES are not always used under the condition of ultimate distribution equilibrium throughout the phases, and the potential difference across the interface is yet quite stable irrespective of the volumes of the two solutions shortly after the initial contact of these solutions. Therefore, it is necessary to study experimentally as well as theoretically the electrical potential difference between two immiscible electrolyte solutions without resorting to the assumption of the distribution equilibrium over the two phases in contact. This is the purpose of this study. We have previously presented the theory of the mixed ion-transfer potential at the ITIES in the presence of the supporting electrolytes in both phases.[4] We report here the theoretical treatment as well as the experimental study of the liquid-junction potential (l.j.p.) of the type: R^+TPB^-(nitrobenzene)/R^+X^-(water) and R^+TPB^-(nitrobenzene)/Li^+TPB^-(water), where R^+ is a tetraalkylammonium ion, TPB^- is tetraphenylborate ion, and X^- is a halide ion. The interfaces of these systems may also be seen as the interface between a liquid membrane and a sample solution in the liquid-membrane ion-selective electrode. Accordingly, this study will also provide us with insight into the basic properities of ion-selective electrodes.

Theoretical

Let us consider the electrical potential difference that develops across a plane interface when we bring into contact a semi-infinite aqueous phase containing 1:1 electrolyte K_1A_1 with a semi-infinite nonaqueous (oil) phase containing 1:1 electrolyte K_1A_2, where K and A denote a cation and an anion, respectively. In most of the cases encountered in practice, the ion transfer of one of these three ionic species can be neglected.[3] In the following, we consider only the case where only two ionic species K_1 and A_1 are transferable across the interface. The K_1 and A_1 may then be considered as a primary ion and an interfering ion, respectively. For the sake of simplicity, we assume the complete dissociations of K_1A_2 in the oil phase and of K_1A_1 in both phases and neglect the activity coefficients of the relevant ions. Let the x-axis be chosen normal to the interface, where $x=0$, and be directed from the oil toward the aqueous phase. The flux of an ion in each phase may be represented by the Nernst-Planck equation:

$$f_i^\alpha = -D_i^\alpha \frac{\partial c_i^\alpha}{\partial x} - \frac{z_i F}{RT} D_i^\alpha c_i^\alpha \frac{\partial \varphi^\alpha}{\partial x}, \tag{1}$$

where f is the flux, D is the diffusion coefficient, c is the concentration of the ion i, φ is the electrical potential(inner potential), x is the distance normal to the plane, z_i is the charge number of ion, and F, R, and T have the usual meanings. The superscript α(α=O or W) denotes the phase, whereas the subscript i(i=K_1, A_1, or A_2) the ionic species. Since there are three ionic species in the oil phase when the ion transfer of the ion A_1 takes place, the diffusion-migration problem in the oil phase is not solved analytically. We treat here the case where the concentration of the interfering ion(A_1) in the oil phase is so small that the migration of A_1 in the oil phase is negligible. This approximation holds as long as the deviation from the Nernstian response is small.

When the condition

$$D_{K1}^O c_{K1}^O + D_{A2}^O c_{A2}^O \gg D_{A1}^O c_{A1}^O \tag{2}$$

is fulfilled, we obtain the following equations for the mass transfer of the ions in the oil phase(See Appendix 1):

$$\frac{\partial c_{K1}^O}{\partial t} = \mathscr{D}_1^O \frac{\partial^2 c_{K1}^O}{\partial x^2} + \mathscr{D}_2^O \frac{\partial^2 c_{A1}^O}{\partial x^2} \tag{3}$$

and

$$\frac{\partial c_{A1}^O}{\partial t} = D_{A1}^O \frac{\partial^2 c_{A1}^O}{\partial x^2} \tag{4}$$

where

$$\mathscr{D}_1^O = \frac{2D_{K1}^O D_{A2}^O}{D_{K1}^O + D_{A2}^O} \tag{5}$$

and

$$\mathscr{D}_2^O = \frac{D_{K1}^O (D_{A1}^O - D_{A2}^O)}{D_{K1}^O + D_{A2}^O} \tag{6}$$

Similarly, for the aqueous phase we may write

$$\frac{\partial c_{K1}^W}{\partial t} = \mathscr{D}^W \frac{\partial^2 c_{K1}^W}{\partial x^2} \tag{7}$$

where

$$\mathscr{D}^W = \frac{2D_{K1}^W D_{A1}^W}{D_{K1}^W + D_{A1}^W} \tag{8}$$

The initial and boundary conditions for the differential Eqs. 3,4, and 7 are:

$$c_{K1}^O = {}^b c_{K1A2}^O \qquad (t=0,\ x<0) \tag{9}$$
$$c_{A1}^O = 0$$

$$c_{K1}^W = {}^b c_{K1A1}^W \qquad (t=0,\ x>0) \tag{10}$$

$$c_{K1}^O = {}^b c_{K1A2}^O \qquad (t>0,\ x=-\infty) \tag{11}$$
$$c_{A1}^O = 0$$

$$c_{K1}^W = {}^b c_{K1A1}^W \qquad (t>0,\ x=+\infty) \tag{12}$$

Here, ${}^b c_{K1A2}^O$ and ${}^b c_{K1A1}^W$ are the bulk concentrations of the electrolyte K_1A_2 in the oil phase and K_1A_1 in the aqueous phase.

The continuity of the flux for K_1 at the interface, $f_{K1}^O|_{x=0} = f_{K1}^W|_{x=0}$, leads to

$$[-D_{A1}^O + t_{A1}^W (D_{K1}^O + D_{A1}^O)] \left.\frac{\partial c_{A1}^O}{\partial x}\right|_{x=0} = -\mathscr{D}^W \left.\frac{\partial c_{A1}^W}{\partial x}\right|_{x=0} + 2t_{A1}^W D_{K1}^O \left.\frac{\partial c_{K1}^O}{\partial x}\right|_{x=0} \tag{13}$$

where

$$t_{A1}^W = \frac{D_{A1}^W}{D_{K1}^W + D_{A1}^W} \tag{14}$$

Furthermore, since the ion-transfer reaction at the oil-water interface is usually a fast process,[5] the surface concentrations of the K_1 in both phases are related through the Nernst equation:

$$p = \frac{c_{K1}^O(0,t)}{c_{K1}^W(0,t)} = \exp\left[\frac{F}{RT}(\Delta_O^W \varphi - \Delta_O^W \varphi_{K1}^0)\right] \tag{15}$$

Similarly, for the anion A_1,

$$q = \frac{c_{A1}^O(0,t)}{c_{A1}^W(0,t)} = \exp\left[-\frac{F}{RT}(\Delta_O^W \varphi - \Delta_O^W \varphi_{A1}^0)\right] \tag{16}$$

In Eqs. 15 and 16, $\Delta_O^W \varphi$ is the inner potential of the aqueous phase with respect to that in the oil phase. It is the quantity usually called the interfacial potential or phase-boundary potential.[4] $\Delta_O^W \varphi_{K1}^0$ and $\Delta_O^W \varphi_{A1}^0$ are the standard ion-transfer potentials for K_1 and A_1.[1]

Solving the Eqs. 3, 4, and 7 under these initial and boundary conditions, Eqs. 9—16, we finally obtain for the interfacial potential at zero current, $\Delta_O^W\varphi_{\text{interfacial},i=0}$ (See Appendix 2):

$$\Delta_O^W\varphi_{\text{interfacial},\,i=0} = \Delta_O^W\varphi_{K1}^W + \frac{RT}{F}\ln\left\{\frac{1}{2}\left[\frac{{}^bc_{K1A2}^O}{{}^bc_{K1A1}^W} + \left\{\left(\frac{{}^bc_{K1A2}^O}{{}^bc_{K1A1}^W}\right)^2 + 4\alpha\xi\right\}^{1/2}\right]\right\} \quad (17)$$

where

$$\alpha = \left(\frac{D_{A1}^O}{\mathscr{D}^W}\right)^{1/2}\frac{{}^bc_{K1A2}^O}{{}^bc_{K1A1}^W} + \frac{1}{2}\left(\frac{\mathscr{D}_1^O}{D_{A1}^O}\right)^{1/2}\left(1+\frac{D_{A1}^O}{D_{K1}^O}\right) + \frac{\mathscr{D}_2^O}{D_{A1}^O+(D_{A1}^O\mathscr{D}_1^O)^{1/2}} \quad (18)$$

and

$$\xi = \exp\left[\frac{F}{RT}(\Delta_O^W\varphi_{A1}^0 - \Delta_O^W\varphi_{K1}^0)\right] \quad (19)$$

The interfacial potential depends on the concentration ratio ${}^bc_{K1A2}^O/{}^bc_{K1A1}^W$, the difference in the values of the standard ion-transfer potentials, and the diffusion coefficients of the relevant ions in both phases, which actually enter into Eq. 17 through the ratio D_{K1}^O/D_{K1}^W, D_{A1}^O/D_{A1}^W, D_{A2}^O/D_{A1}^O, and D_{A1}^O/D_{K1}^O. When the condition

$$\left(\frac{{}^bc_{K1A2}^O}{{}^bc_{K1A1}^W}\right)^2 \gg 4\alpha\xi \quad (20)$$

is fulfilled, Eq. 17 reduces to

$$\Delta_O^W\varphi_{\text{interfacial},i=0} = \Delta_O^W\varphi_{K1}^0 + \frac{F}{RT}\ln\frac{{}^bc_{K1A2}^O}{{}^bc_{K1A1}^W} \quad (21)$$

Namely, as long as the ${}^bc_{K1A1}^W$ is sufficiently small, the ITIES reveals the Nernstian response with respect to the concentraton of the ion K_1, even when ξ is appreciably large, i.e., A_1 is relatively hydrophobic.

Equation 17 has a form similar to the equation derived by Hung(Eq. 34 in Ref. 3) assuming that the distribution equilibrium is established throughout the two phases and the volumes of the two phases are equal. In Hung's equation, α is given by

$$\alpha = 1 + \frac{c_{K1A2}^O}{c_{K1A1}^W} \quad (22)$$

where c_{K1A1}^O and c_{K1A1}^W are the initial concentrations of electrolytes. When all the diffusion constants of the ions are equal in both phases, Eq. 18 reduces to Eq. 22. However, its physical meanings are different from those of Eq. 17. Equation 17 contains the terms involving the diffusion coefficients of the relevant ions, reflecting the importance of the transport processes of the ions. The advantage of Eq. 17 over Hung's equation is that one need not assume any size of the volume for the two solutions nor the establishment of the distribution equilibrium throughout the two phases, which may rarely occur in practical cases.

In addition to the interfacial potential, there exists the diffusion potential on each side of the interface insofar as the system is not at equilibrium. This diffusion potential becomes significant when the transfer of K_1A_1 from the aqueous phase to the oil phase becomes discernable. The diffusion potential in the oil phase, φ_{diff}^O, and that in the aqueous phase, φ_{diff}^W, may be written as (See Appendix 2):

$$\varphi_{\text{diff}}^O = \frac{RT}{F}(1-2t_{K1}^O)\ln\frac{Ap'}{{}^bc_{K1A2}^O} \quad (23)$$

and

$$\varphi_{\text{diff}}^W = \frac{RT}{F}(1-2t_{A1}^W)\ln\frac{A}{{}^bc_{K1A1}^W} \quad (24)$$

where

$$A = \frac{N{}^bc_{K1A2}^O + (\mathscr{D}^W)^{1/2}{}^bc_{K1A1}^W}{Mq'+Np'+(\mathscr{D}^W)^{1/2}} \quad (25)$$

$$M = (D_{A1}^O)^{1/2} - t_{A1}^W\left[\frac{D_{K1}^O+D_{A1}^O}{(D_{A1}^O)^{1/2}} + \frac{2D_{K1}^O\mathscr{D}_2^O}{D_{A1}^O(\mathscr{D}_1^O)^{1/2}+\mathscr{D}_1^O(D_{A1}^O)^{1/2}}\right] \quad (26)$$

$$N = 2t_{A1}^W D_{K1}^O/(\mathscr{D}_1^O)^{1/2} \quad (27)$$

$$t_{K1}^O = D_{K1}^O/(D_{K1}^O+D_{A2}^O)$$

and p' and q' are p and q at zero current. The total potential difference between the two phases at zero current, i.e., the l.j.p. at zero current, $\Delta_O^W\varphi_{i=0}$, is generally given by

$$\Delta_O^W\varphi_{i=0} = \varphi_{\text{diff}}^O + \Delta_O^W\varphi_{\text{interfacial},\,i=0} + \varphi_{\text{diff}}^W \quad (28)$$

It is noted that if we take account of the migration of A_1 ion in the oil phase, the diffusion potential could be much larger than expected from Eq. 23.

Experimental

Reagent-grade nitrobenzene was treated with active alumina and then equilibrated with twice distilled water. Tetraphenylborate salts of tetrahexyl-(THA^+), tetrapentyl-($TPnA^+$), tetrabutyl-, and tetrapropylammonium($TPrA^+$) ions were prepared from sodium tetraphenylborate(Dojin Lab., Japan) and corresponding alkylammonium halides of reagent grade as described previously.[6] Reagent grade tetrabutylammonium chloride and tetrapropylammonium chloride were recrystallized from acetone-ether mixture. The aqueous solutions of these salts were stirred in the presence of AgCl powder to remove a trace amount of bromide and/or iodide ions. Lithium tetraphenylborate (LiTPB) was prepared from sodium tetraphenylborate.[7] The stock solution of 0.0705 mol dm^{-3} LiTPB contained 0.001 mol dm^{-3} lithium hydroxide to prevent the decomposition of LiTPB. The concentration of LiTPB was determined by titration of the solution with zephiramine.[8]

The electromotive force of the cell was measured with a Keithley 616 electrometer. The cell was made in a U-shaped

poly(tetrafluoroethylene) tubing of 9 mm inner diameter and 10 cm tall. About 8 ml of a nitrobenzene solution was first put into the tubing and then a few milliliter of aqueous solution were added onto the nitrobenzene solution in each leg of the cell. Appropriate reference electrodes were then immersed into the aqueous solutions. The liquid-liquid contact in a reference electrode, if necessary, was made via a glass frit when the solvent is water, or a poly(vinyl chloride) gel of nitrobenzene solution when the solvent is nitrobenzene. The cell was immersed in a water bath at 25 ±0.1°C. The emf measurements were started immediately after the contact of the aqueous and nitrobenzene solutions.

Results and Discussion

Nitrobenzene-Water Interface Reversible to Large Tetraalkylammonium Ions. Effect of Cationic Species: The emf response of the interface, RCl(W)/RTPB(NB), to c^{W}_{RCl} was measured at c^{o}_{RTPB}=const. for R=TPrA$^+$, TBA$^+$, TPnA$^+$, and THA$^+$. The following two types of the cell were used;

I	II	III	IV	V	VI	VII
Ag	AgCl	*a* M† RCl (W)	*b* M RTPB (NB)	*c* M RX (W)	AgX	Ag

(I)

and

I	II	III	IV	V	VI	VII	VIII
Ag	AgCl	*a* M LiCl (W)	*a* M LiTBP (W)	*b* M RTPB (NB)	*c* M RCl (W)	AgCl	Ag

(II)

The interface between the phases IV and V in the cell (I) and that between V and VI in the cell (II) are the nonpolarized interfaces at which the l.j.p. we are concerned with resides. The cell (I) was used for R=TPrA$^+$(*a*=1, *b*=1, and *c*=1—500 mmol dm^{-3}) and TBA$^+$(*a*=10, *b*=50, and *c*=0.1—200 mmol dm^{-3}), and the cell(II) for R=TPnA$^+$(a=1, *b*=100, and *c*=0.1—100 mmol dm^{-3}) and THA$^+$(*a*=1, *b*=40, and *c*=0.02—2 mmol dm^{-3}). Since the nitrobenzene phase was thick, the potential between the phases III and IV in the cell (I) and that between IV and V in the cell(II) remain unchanged with the change of c^{W}_{RCl}. The l.j.p. across the phases III and IV in the cell(II) is also constant. The change in the potential difference between phases V and VI in (I) and that between phases VI and VII in the cell(II) with the change of $^{b}c^{W}_{RCl}$ were calculated assuming the Nernstian response of the Ag/AgCl electrodes to the Cl$^-$ ion. The activity coefficients of RCl's were estimated by using the Davies equation.[9] These calculated values were added to the corresponding emf values to obtain the change of the l.j.p. at the interface. The resultant variation of the l.j.p. values was plotted against the logarithm of the concentration ratio, $\log(^{b}c^{W}_{RCl}/^{b}c^{NB}_{RTPB})$. These curves were shifted vertically so that their linear portions were superimposed upon each other, eliminating the difference in the emf values due to the different reference electrode included in each cell. Figure 1 indicates that TPrA$^+$ has the largest concentration range of the Nernstian response. With the increase of the alkyl-chain length, the Nernstian region becomes narrower, as is expected from the theoretical treatment given above, because the increase in the hydrophobicity of the cation gives rise to the increase in ξ in Eq. 17 (see also Eq. 19). The arrows in Fig. 1 indicate the predicted points, where the curves deviate by 1 mV from the Nernstian slope, calculated using Eq. 17 and the values for the diffusion coefficients and the standard ion-transfer potentials given in Table 1. The values of diffusion coefficients for TPnA$^+$ and THA$^+$ are assumed to be the same as that for TBA$^+$. The diffusion coefficient of each ion in the nitrobenzene was taken as a half of the one in aqueous solution.[6]

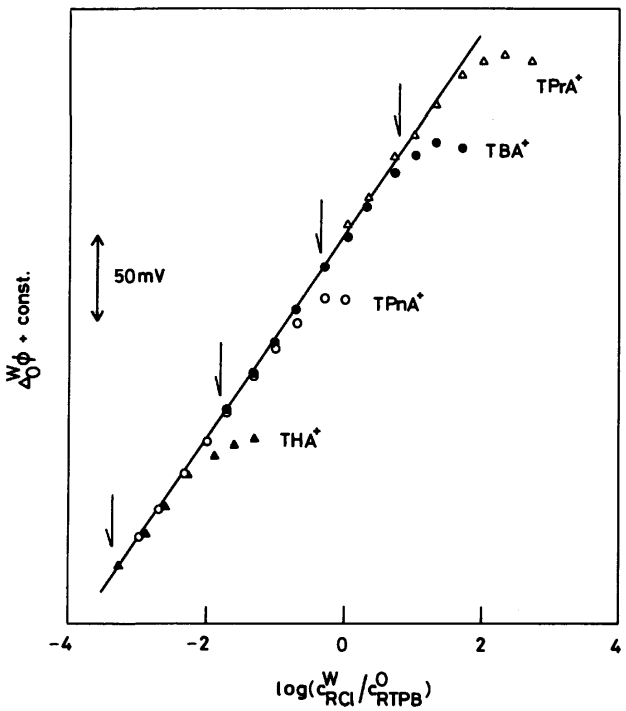

Fig. 1. Change of the liquid junction potentials for the system: RTPB(nitrobenzene)/RCl(water), where R=tetrapropylammonium(TPrA$^+$), tetrabutylammonium(TBA$^+$), tetrapentylammonium(TPnA$^+$), or tetrahexylammonium ion(THA$^+$).

Effect of the Anionic Species: The effect of the counter ionic species was studied for the interface, TBAX(W)/TBATPB(NB) using the cell(I) for X$^-$= Cl$^-$(*a*=1, *b*=50, and *c*=0.1—200 mmol dm^{-3}) and

† 1 M=1 mol dm^{-3}.

Br^-(a=1, b=10, and c=0.01—100 mmol dm^{-3}) and also using the following cell:

I	II	III	IV	V	VI	VII	VIII
Ag	AgCl	1 mM TBACl (W)	0.1 M TBATPB (NB)	0.02—5 mM TBAI (W)	satd. KCl	AgCl	Ag

(III)

for X^-=I^-. The change in l.j.p. values from the measured emf values was obtained as described above for X^-=Cl^- and Br^-, while the l.j.p. at the interface between phases V and VI was neglected in the cell(II). The results were plotted against $\log(c^{W}_{TBAX}/c^{o}_{TBATPB})$ in Fig. 2.

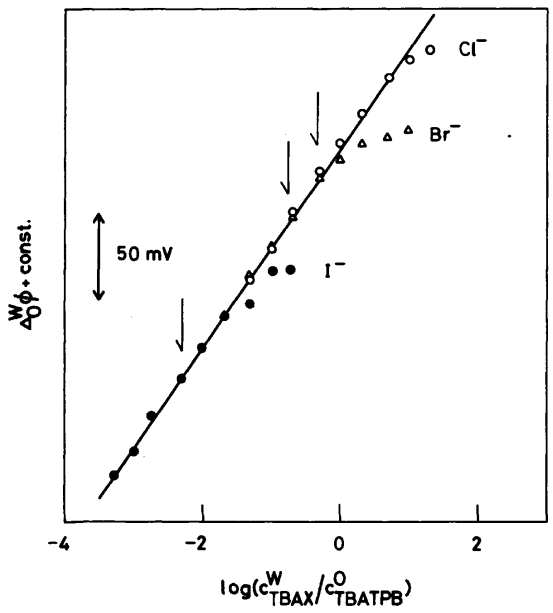

Fig. 2. Change of the liquid-junction potentials for the system: TBATPB(nitrobenzene)/TBAX(water), where R=chloride, bromide, or iodide ion.

Table 1. Standard Ion-Transfer Potentrials of Ion Transfer from Water to Nitrobenzene and Diffusion Coefficients of Ions in Water

Ion	$\Delta^{W}_{NB}\varphi^0$/V[a]	D/cm^2s^{-1}[c]
Li^+	0.395	—
$TPrA^+$	−0.154[b]	6.24×10^{-6}
TBA^+	−0.248	5.21×10^{-6}
$TPnA^+$	−0.343[b]	—
TUA^+	−0.438[b]	—
Cl^-	−0.324	2.0×10^{-5}
Br^-	−0.295	2.1×10^{-5}
I^-	−0.195	2.1×10^{-5}
TBP^-	0.372	—

a) Data in Ref. 3. b) Calculated from the data in Ref. 3. c) Calculated from the limiting equivalent conductances given in Ref. 10.

These curves were shifted vertically to superimpose the linear portions of the curves upon each other. As the radius of the counter ion increases, the curves start to deviate from the Nernstian response at the lower value of the concentration ratio, i.e., the more hydrophobic the counter ion is, the greater is the degree of interference. This is also the behavior expected from Eq. 17. The arrows in Fig. 2 indicate the points where the curves deviate by 1 mV from the Nernstian slope, calculated with Eq. 17 and the values in Table 1.

Effect of the Concentration of the Electrolyte: Equation 17 indicates that when the system K_1A_1(W)/ K_1A_2(O) functions as a liquid-membrane ion-selective electrode at a constant concentration of K_1A_2, the concentration level of K_1A_2 influences the concentration range of K_1A_1 where the system shows Nernstian response. Similarly, when the system works as a reference electrode reversible to the K_1 ion in the oil phase at a constant concentration, the concentration level of K_1A_1 in the aqueous phase limits the range of the Nernstian region. Such a concentration effect has great practical importance to determine the suitable conditions in designing reference electrodes and ion-selective electrodes of a liquid-membrane type.

The change of the l.j.p. for the system TBATPB (NB)/ TBACl(W) was estimated from the emf values of the cell (I) for the various concentrations(a=b/10, b=0.5,1,2,5,10,20,50, and 100, and c=0.1—500 mmol dm^{-3}) of TBATPB and TBACl. Figure 3 shows the response of the system with respect to the concentra-

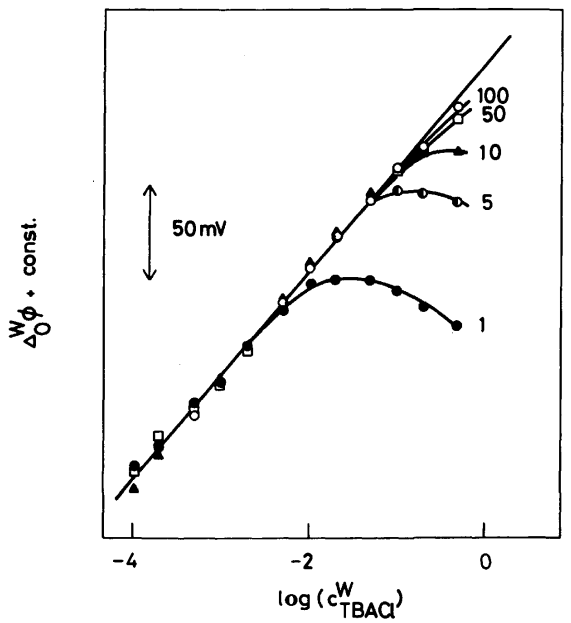

Fig. 3. Effect of the concentration of TBATPB in nitrobenzene on the change of the liquid-junction potential. Labels indicate the concentration of TBATPB in nitrobenzene in mmol dm^{-3}.

tion of TBACl at five different concentrations of TBATPB in the nitrobenzene phase. As the concentrations of TBATPB increases, the Nernstian region becomes wider. In terms of the liquid-membrane ion-selective electrodes, this means that the concentration of the "ion-exchanger"(TPB$^-$ ion in the present system) in the membrane must be high in order to obtain the wider concentration range of the Nernstian response for TBACl. The curve for ${}^{b}c^{O}_{TBATPB}$=1 mmol dm^{-3} in Fig. 3 has a maximum and, in the higher concentration region, the l.j.p. changes in opposite direction with increasing concentration of TBACl. Similar tendency was found also in the curve at ${}^{b}c^{O}_{TBATPB}$=5 mmol dm^{-3}. Such a tendency can be ascribed to the l.j.p. in the nitrobenzene phase caused by the migration of Cl$^-$ ion in the nitrobenzene phase, as will be shown below.

Figure 4 shows the change of the l.j.p. with the mean ionic activity of TBATPB in the nitrobenzene phase, $a^{\pm,NB}_{TBATPB}$, at the three different concentrations of TBACl. The activity instead of the concentration was used in Fig. 4 to check if this system responds thermodynamically to the activity of the TBA$^+$ ion. The activity coefficients of TBA$^+$ and TPB$^-$ ions were calculated by using the Debye-Hückel theory allowing for the finite size of the ions.[11] At ${}^{b}c^{W}_{TBACl}$=1 mmol dm^{-3}, the change of the l.j.p vs. $\log(a^{\pm,NB}_{TBATPB})$

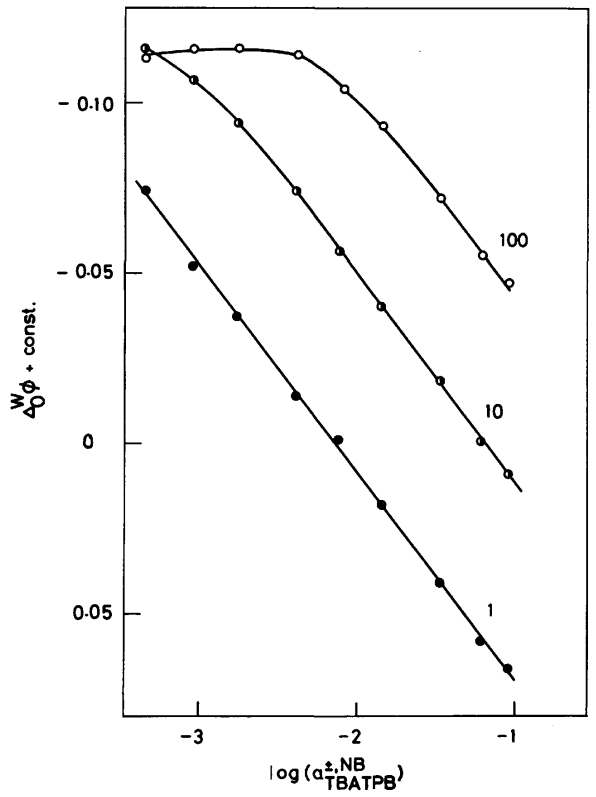

Fig. 4. Effect of the concentration of TBACl in aqueous solution on the change of the liquid-junction potential. Labels indicate the concentration of TBACl in aqueous phase in mmol dm^{-3}.

plot was linear with the slope of 60 mV per decade change of $a^{\pm,NB}_{TBATPB}$ in the whole concentration range studied(0.5—100 mmol dm^{-3}). This indicates that the present system can be employed as a reference electrode reversible to the TBA$^+$ ion in the nitrobenzene phase in this concentration range. At ${}^{b}c^{W}_{TBACl}$=10 mmol dm^{-3} the curve in Fig. 4 deviated from the Nernstian slope in the lower concentration (activity) region of TBA$^+$ ion. The deviation occured at much higher concentration(activity) region when ${}^{b}c^{W}_{TBACl}$=100 mmol dm^{-3}. These results indicate that the concentration of TBACl must be kept as small as possible to obtain a wider range of Nernstian response. This type of the interface has been successfully used at ${}^{b}c^{W}_{TBACl}$=5 mmol dm^{-3} as a reference electrode in studying the specific adsorption of TBA$^+$ and TPB$^-$ ions at the nitrobenzene-water interface by using electrocapillary measurements.[12]

Nitrobenzene-Water Interface Reversible to Tetraphenylborate Ion. It is sometimes convenient to use a reference electrode reversible to an anion instead of a cation dissolved in organic phase. For example, to study thermodynamically the specific adsorption of cations in the nitrobenzene, one must use a reference electrode reversible to the anion in the nitrobenzene phase. In addition, when a cation in the oil phase is very hydrophobic, i.e., in the case $\Delta^{W}_{O}\varphi^{0}_{K1} \leqq \Delta^{W}_{O}\varphi^{0}_{A1}$, one has to keep the ratio ${}^{b}c^{O}_{K1A2}/{}^{b}c^{W}_{K1A1}$ large enough to ensure the Nernstian response of the interface if one uses a cation reversible reference electrode. In such cases, the anion reversible reference electrode is promising. We examined the possibility of the nitrobenzene-water interfaces reversible to the TPB$^-$ ion by measuring the emf of the following cells:

I	II	III	IV	V		
Ag	AgCl	1 mM LiCl (W)	1 mM LiTPB (W)	a M TPnATPB (NB)		
		VI	VII	VIII	IX	
		a/10 M LiTPB (W)	a/10 M LiCl (W)	AgCl	Ag	(IV)

for TPnA$^+$ (a=5—200 mmol dm^{-3}) and

I	II	III	IV	V		
Ag	AgCl	0.5 mM LiCl (W)	0.5 mM LiTPB (W)	a M THATPB (NB)		
		VI	VII	VIII	IX	
		a M TPrATPB (NB)	a M TPrACl (W)	AgCl	Ag	(V)

for THA^+(a=5—40 mmol dm^{-3}).

Since in the cell (IV) the ratio ${}^{b}c^{NB}_{TPnATPB}/{}^{b}c^{W}_{LiTPB}$ was kept constant during the change of ${}^{b}c^{NB}_{TPnATPB}$, the change of the potential difference between the phases V and VI with ${}^{b}c^{NB}_{TPnATPB}$ can be considered negligible. Similarly, the change in the potential difference between the phases VI and VII is also negligible. The changes in the potential falls between phases VII and VIII in the cells (IV) and (V) with ${}^{b}c^{W}_{RCl}$ (R=Li^+ or $TPrA^+$) were allowed for as described above. The changes of the l.j.p.'s which reside between the phases VI and VII in the cell (IV) and between the phases V and VI in the cell (V) were neglected, because the change of the ratio of the equivalent conductances for THATPB and TPrATPB in the nitrobenzene phase with the change of the electrolyte concentration and also that for LiTPB and LiCl in the aqueous phase seem negligibly small. The changes of the l.j.p.'s across the phases IV and V in the cell (IV) and (V) thus estimated are plotted against $\log(a^{\pm,NB}_{RTPB})$ in Fig. 5. Both interfaces respond linearly with the slopw of 58 mV($TPnA^+$) and 60 mV(THA^+) within the concentration range studied. Thus, the system LiTPB (W)/RTPB(NB) can be used as a reference electrode reversible to the TPB^- ion in the nitrobenzene phase. This type of reference electrode has been applied in studying the specific adsorption of cationic surfactants at the nitrobenzene-water interface by using the mixed electrolyte method.[13]

Significance of the Diffusion Potential. Figure 3 shows that the curves at ${}^{b}c^{O}_{TBATPB}$=1 and 5 mmol dm^{-3} have maxima. The approximate theoretical treatment of the l.j.p. described above can predict the concentration at which the l.j.p. starts to deviate from the Nernstian response, but cannot explain the inversion of the slope. In fact, Eq. 17 gives a constant value of $\Delta^{W}_{O}\varphi_{interfacial,i=0}$ when ${}^{b}c^{O}_{K1A2}/{}^{b}c^{W}_{K1A1}\to\infty$. The approximation introduced previously is obviously not adequate in such a high concentration region, since a significant amount of Cl^- ion enters into the nitrobenzene phase, so that its amount is no longer negligible in the vicinity of the interface. The diffusion coefficient of Cl^- ion is probably much larger than those of TBA^+ and TPB^- ions in the nitrobenzene phase (cf. Table 1). Therefore, the positive diffusion potential(the potential is referred to that at the infinity of the nitrobenzene phase), which is opposite in sign to that of the interfacial potential, will develop in the vicinity of the interface.

If this diffusion potential is responsible to the inversion of the potential, the addition of a supporting electrolyte in the nitrobenzene phase should suppress the l.j.p. in that phase, resulting in the disappearance of the maximum. The emf of the following cell was measured with and without 40 mmol dm^{-3} THATPB.

I	II	III		IV	
Ag	AgCl	1 mM TBACl (W)	1 mM TBATPB	+	40 mM THATPB (NB)

V	VI	VII	
a M TBABr (W)	AgBr	Ag	(VI)

The change in the potential drop between the phases V and Vl was allowed for as described above.

Figure 6 shows the change of the l.j.p. vs. $\log({}^{b}c^{W}_{TBABr}/{}^{b}c^{O}_{TBATPB})$ curves. The curve for the cell without THATPB (Curve 1 in Fig. 6) exhibited a maximum at $\log({}^{b}c^{O}_{TBATPB}/{}^{b}c^{W}_{TBABr})\fallingdotseq 1$ and decreased with the further increase of ${}^{b}c^{W}_{TBABr}$. This inverted change of the l.j.p. was almost eliminated by adding 40 mmol dm^{-3} THATPB to the nitrobenzene phase, as is shown in Curve 2 in Fig 6. The slight decrease at the highest concentration is probably due to an insufficient concentration of THATPB to eliminate fully the migration of the Cl^- ion. This experiment clearly indicates the significant contribution of the diffusion potential in the nitrobenzene phase to the inversion of the slope shown in Curve 1 in Fig. 6. To confirm further the effect of the diffusion potential, the diffusion-migration equations were solved numerically using a finite difference method[14] without introducing the assumption given by Eq. 2. The values given in Table 1 were used for the calculation. The result for the system TBABr(W)/TBATPB(NB) is

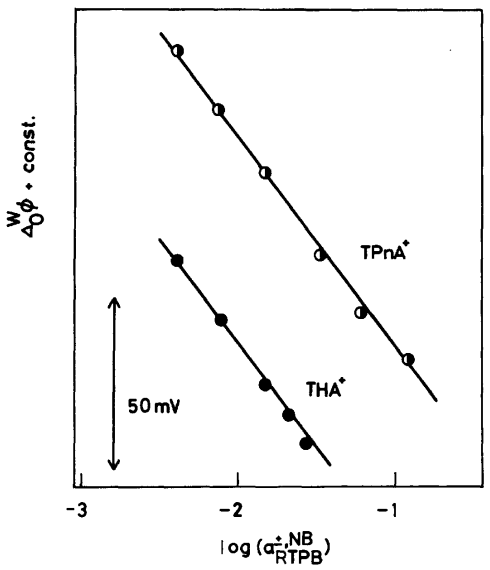

Fig. 5. Change of the liquid-junction potentials for the system: RTPB(nitrobenzene), LiTPB(water), where R=$TPnA^+$ or THA^+ ion.

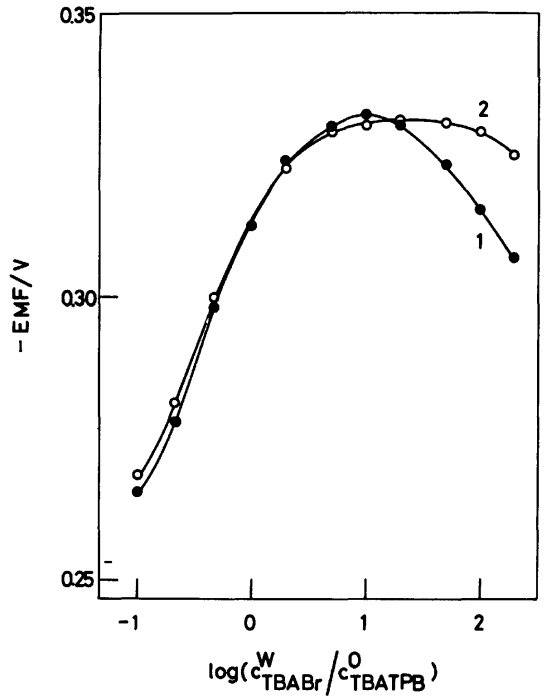

Fig. 6. Change of the liquid-junction potential for the system: TBATPB(nitrobenzene)/TBABr(water), in the presence of (Curve 2) and the absence of (Curve 1) 40 mmol dm^{-3} THATPB in nitrobenzene as a supporting electrolyte.

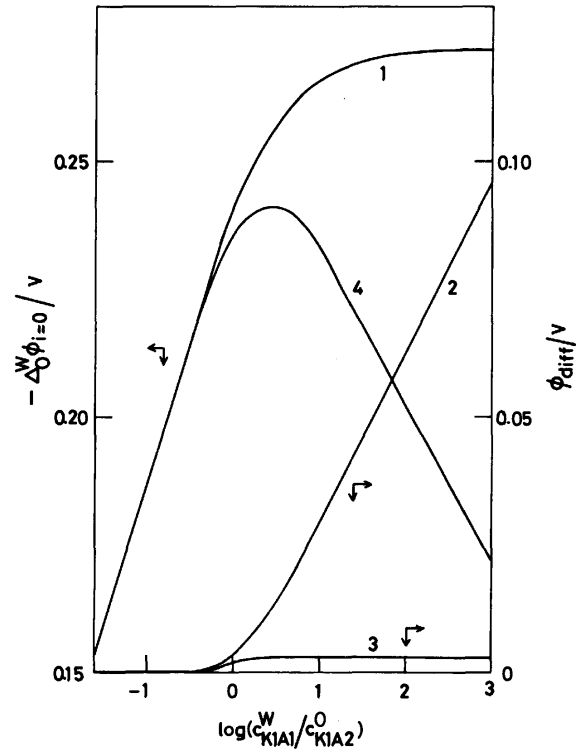

Fig. 7. Calculated values of the interfacial potential(Curve 1), the diffusion potential in nitrobenzene phase(Curve 2), the diffusion potential in aqueous phase(Curve 3), and the total liquid-junction potential(Curve 4) for the system: TBATPB-(nitrobenzene)/TBABr(water).

given in Fig. 7.

In the higher concentration region, the interfacial potential (Curve 1) reached a limiting value. Simultaneously, the diffusion potential in the nitrobenzene phase(Curve 2) increases linearly with the logarithm of the concentration ratio, while the diffusion potential in the aqueous phase(Curve 3) stays at a nominal value. Accordingly, the total liquid-junction potential(Curve 4) possesses a maximum and beyond this point the potential in turn decreases linearly with the concentration. Thus, although the contribution of the diffusion potential seems smaller in the actual system if one compares Fig. 6 with Fig. 7, the numerical calculation essentially reproduces the experimental trend, indicating the importance of the diffusion potential in the concentration range far from the Nernstian response.

Such a contribution of the diffusion potential to the measured emf value may have a practical importance. Liquid-ion exchange membrane ion-selective electrodes have been used to determine the critical micelle concentration of ionic surfactants by making use of the intersection point of the two linear portion of the emf vs. logarithm of the surfactant concentration curve.[15,16] The results in Figs. 6 and 7 indicate that such a method for determining the critical micelle concentration(cmc) may lead to a spurious conclusion. Disagreement has been reported between the cmc value determined from another method and the value from the concentration of the intersection point in the emf vs. the logarithm of the surfactant concentration curve.[17,18]

Appendix 1

From Eq. 1, we may write for the flux of the ions in oil phase

$$f^{o}_{K1} = -D^{o}_{K1}\frac{\partial c^{o}_{K1}}{\partial x} - \frac{F}{RT}D^{o}_{K1}c^{o}_{K1}\frac{\partial \varphi^{o}}{\partial x}, \tag{A1}$$

$$f^{o}_{A1} = -D^{o}_{A1}\frac{\partial c^{o}_{A1}}{\partial x} + \frac{F}{RT}D^{o}_{A1}c^{o}_{A1}\frac{\partial \varphi^{o}}{\partial x}, \tag{A2}$$

$$f^{o}_{A2} = -D^{o}_{A2}\frac{\partial c^{o}_{A2}}{\partial x} + \frac{F}{RT}D^{o}_{A2}c^{o}_{A2}\frac{\partial \varphi^{o}}{\partial x}. \tag{A3}$$

On the other hand, the current density I in oil phase is represented by

$$I = F(f^{o}_{A1}+f^{o}_{A2}-f^{o}_{A1}). \tag{A4}$$

Substituting (A1), (A2), and (A3) into (A4), $\partial\varphi^{o}/\partial_x$ can be represented by

$$\frac{\partial \varphi^{o}}{\partial x} = -\frac{RT}{F}Z, \tag{A5}$$

where

$$Z = (D^{o}_{K1}\frac{\partial c^{o}_{K1}}{\partial x} - D^{o}_{A1}\frac{\partial c^{o}_{A1}}{\partial x} - D^{o}_{A2}\frac{\partial c^{o}_{A2}}{\partial x} + \frac{I}{F})/\beta$$

and

$$\beta = D^{o}_{K1}c^{o}_{K1}+D^{o}_{A1}c^{o}_{A1}+D^{o}_{A2}c^{o}_{A2}.$$

When $D^{o}_{K1}+c^{o}_{K1}+D^{o}_{A2}c^{o}_{A2} \gg D^{o}_{A1}c^{o}_{A1}$, after substituting Eq. A5 into A1, A2, and A3, we obtain

$$f^{o}_{K1} = -\mathscr{D}^{o}_{1}\frac{\partial c^{o}_{K1}}{\partial x} - \mathscr{D}^{o}_{2}\frac{\partial c^{o}_{A1}}{\partial x} + t^{o}_{K1}\frac{I}{F} \tag{A6}$$

and

$$f^{o}_{A1} = -D^{o}_{A1}\frac{\partial c^{o}_{A1}}{\partial x}, \tag{A7}$$

where $\mathscr{D}^{o}_{1}$ and $\mathscr{D}^{o}_{2}$ are given by Eqs. 5 and 6.

Appendix 2

Solving the differential equations, Eqs. 7—9, under the initial and boundary conditions, Eqs. 10—16, we obtain, when $D^{o}_{A1} \neq \mathscr{D}^{o}_{1}$

$$c^{o}_{K1}(x, t) = {}^{b}c^{o}_{K1A2} + \left(pA - \frac{\mathscr{D}^{o}_{2}}{D^{o}_{A1}-\mathscr{D}^{o}_{1}}qA - {}^{b}c^{o}_{K1A2}\right)\mathrm{erfc}\left[-\frac{x}{2(\mathscr{D}^{o}_{1}t)^{1/2}}\right] + \frac{\mathscr{D}^{o}_{2}}{D^{o}_{A1}-\mathscr{D}^{o}_{1}}qA\ \mathrm{erfc}\left[-\frac{x}{2(D^{o}_{A1}t)^{1/2}}\right] \tag{A8a}$$

and

$$c^{o}_{A1}(x, t) = qA\ \mathrm{erfc}\left[-\frac{x}{2(D^{o}_{A1}t)^{1/2}}\right], \tag{A9}$$

where p, q, and A are given by Eqs. 15, 16, and 24, respectively. When $D^{o}_{A1}=\mathscr{D}^{o}_{1}$, instead of Eq. A1, we have

$$c^{o}_{K1}(x, t) = {}^{b}c^{o}_{K1A2} - \frac{\mathscr{D}^{o}_{2}}{2(\mathscr{D}^{o}_{1})^{3/2}}qAx\frac{1}{(\pi t)^{1/2}}\exp\left(-\frac{x^2}{4t\mathscr{D}^{o}_{1}}\right) + (pA-{}^{b}c^{o}_{K1A2})\ \mathrm{erfc}\left[-\frac{x}{2(\mathscr{D}^{o}_{1}t)^{1/2}}\right]. \tag{A8b}$$

On the oher hand, for $c^{w}_{K1}(x, t)$ we have

$$c^{w}_{K1}(x, t) = {}^{b}c^{w}_{K1A1} + A\ \mathrm{erfc}\left[\frac{x}{2(\mathscr{D}^{w}t)^{1/2}}\right]. \tag{A10}$$

From Eqs. A4, A8, A9, and A10, the current-potential relationship can be written as:

$$\frac{I}{F} = -\frac{1}{(\pi t)^{1/2}}\frac{1}{t^{w}_{A1}}A[Np+(M-(D^{o}_{A1})^{1/2})q]-N{}^{b}c^{o}_{K1A2}, \tag{A11}$$

where M and N are given by Eqs. 26 and 27. This equation is valid irrespective of the magnitude of D^{o}_{A1} and $\mathscr{D}^{o}_{1}$. Setting $I=0$ in Eq. A11, we obtain Eq. 17.

Under the conditions of Eq. 2 and at $I=0$ we may write from Eq. 1,

$$\frac{\partial\varphi}{\partial x} = \frac{RT}{F}\frac{D^{o}_{A2}-D^{o}_{K1}}{D^{o}_{K1}+D^{o}_{A2}}\frac{\partial \ln c^{o}_{K1}}{\partial x}. \tag{A12}$$

Integrating this equation from $x=-\infty$ to $x=-0$, we have

$$\varphi(x=0) - \varphi(x=-\infty) = \frac{RT}{F}(1-2t^{o}_{K1})\ln\frac{c^{o}_{K1}(0, t)}{{}^{b}c^{o}_{K1A2}} \tag{A13}$$

Substituting Eq. A8 at $x=-0$, we obtain Eq 23. Eq. 24 can be derived similarly.

The Effect of the Electrical Potential Difference on the Adsorption of the Hexadecyltrimethylammonium Ion at the Polarized Nitrobenzene-Water Interface

Takashi KAKIUCHI, Miki KOBAYASHI, and Mitsugi SENDA*
Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606
(Received March 4, 1987)

The adsorption of the hexadecyltrimethylammonium ion(HTMA$^+$) at the polarized nitrobenzene-water interface has been studied using electrocapillary measurements. The adsorption of HTMA$^+$ was found to be markedly dependent on the potential drop across the interface. HTMA$^+$ exhibited no specific adsorption in the potential range where the aqueous phase is positive, whereas a strong adsorption occurred in the potential range where the electric potential in the aqueous phase is negative with respect to that in the nitrobenzene. The adsorption free energy depends linearly on the potential difference across the interface. The specific adsorption of HTMA$^+$ significantly alters the double-layer structure. The outer Helmholtz potential in the nitrobenzene phase was inverted from negative to positive due to the adsorption of HTMA$^+$ ions.

The electrical aspects of the adsorption of molecules and ions at metal-solution interfaces have been studied extensively, and now the double-layer structure and the adsorption mechanism have been elucidated in detail.[1] In contrast, much fewer studies have appeared for oil-water interfaces, and even fewer for air-water interfaces, mainly because of the difficulty of controlling the electrical potential difference between the phases.

Guastalla[1] first reported the change in the interfacial tension with an externally applied potential for the interface between nitrobenzene and water in the presence of the HTMA$^+$ ion. He suggested the "electroadsorption" model for the interpretation of the phenomena. Since then, the adsorption phenomena of ionic surfactants at oil-water interfaces under the influence of an externally applied electric field have been studied by Blank et al.,[3,4] Watanabe et al.,[5,6] Dupeyrat et al.,[7,8] Gavach et al.,[9-11] and Joos et al.[12,13] In the study of the adsorption of various ionic surfactants at the methyl isobutyl ketone-water interface, Watanabe et al. adopted the concept of electrocapillarity,[5] thereby introducing a thermodynamic point of view for the interpretation of electrosorption phenomena at oil-water interfaces. However, in most of the preceding studies of the adsorption phenomena at oil-water interfaces, the electrical state of the interface has not been well-defined, making an unambiguous interpretation of the results difficult. This is partly because of the uncertainty concerning the polarizability of the interfaces employed and partly because of the lack of suitable reference electrodes to define the electrical potential.

It has been shown recently that the polarizability of oil-water interfaces can be characterized in terms of the transfer free energy of ions dissolved in the two neighboring phases,[14] and experimentally[15] we can make the interface virtually ideally polarized by suitably choosing the ions dissolved in the phases. The rigorous thermodynamics of the electrocapillarity of oil-water interfaces[16] and the experimental study of the double layer structure of polarized nitrobenzene-water interfaces[17] have also been presented recently. By using such polarized interfaces, we are now able to study the adsorption of surfactants and ions at the oil-water interfaces in depth as cases of the electrosorption studies at metal-solution interfaces.[1] Only through this polarized type of interface can the electrical aspects of surfactants adsorption in equilibrium be fully explored. The electrocapillarity of nonpolarized oil-water interfaces has also been studied.[18-22] The advantage of an ideal polarized interface over a nonpolarized one in studying the adsorption behavior of surfactants is that it has an additional degree of freedom for the electrical parameter: Electrostatic potential difference or excess surface-charge density. This enables us to estimate the charge due to specifically adsorbed ions separately from the total excess-charge density.[16] The aim of this study is to establish such a new experimental approach for studying the electrochemical aspects of surface phenomena at oil-water interfaces. This paper will report the adsorption properties of the hexadecyltrimethylammonium ion, HTMA$^+$, at the polarized nitrobenzene-water interface, across which the potential difference is regulated externally.

Experimental

The interfacial tension of the nitrobenzene-water interface was measured by means of the drop-time method using a drop-by-drop ascending electrolyte solution electrode.[15] The potential drop across the interface was controlled using a four-electrode potentiostat with a positive feed back circuit for *iR* compensation. The details of the measurements and the conversion of the drop time to interfacial tension have been reported elsewhere.[23] All the measurements were made at 25.00±0.05 °C.

The hexadecyltrimethylammonium tetraphenylborate

(HTMATPB) was prepared from hexadecyltrimethylammonium chloride and sodium tetraphenylborate and was recrystallized twice from acetone. The tetrapentylammonium tetraphenylborate(TPnATPB) and lithium tetraphenylborate were prepared as has been described previously.[24] The nitrobenzene was distilled under reduced pressure, and the middle portion of the distillate was used for preparing the solution. The water was triply distilled.

Results

We used the mixed electrolyte method,[25,26] in which the sum of the concentrations of TPnATPB and HTMATPB in nitrobenzene is held constant at 0.1 mol dm^{-3}, while the concentration of HTMA$^+$ is varied. The TPnA$^+$ ion shows no specific adsorption at the nitrobenzene-water interface.[27] The TPB$^-$ ion is also known to show no specific adsorption.[17] Accordingly, this mixed-electrolyte-solution method allows us to obtain the specifically adsorbed amount of HTMA$^+$ directly from the electrocapillary data.[25,26] An additional advantage of this method here is that it enables us to avoid the undesirable decrease in the conductivity in the nitrobenzene phase in the lower concentration range of HTMATPB.

The electrochemical cell employed in this study may be represented thus;

I	II	III	IV	V	VI	VII	VIII	
Ag	AgCl	1 mM LiCl (W)	1 mM LiTPB (W)	$(0.1-x)$ M TPnATPB + x M HTMATPB (NB)	0.05M LiCl (W)	AgCl	Ag	(I)

where M designates mol dm^{-3} and where x was varied between 0 and 0.1. The nitrobenzene phase V contains TPnATPB and HTMATPB, such that the sum of the concentrations of these salts is 0.1 mol dm^{-3}. The HTMA$^+$ ion was thus dissolved in the nitrobenzene phase as a TPB salt. This is a key point for the study of the adsorption of the HTMA$^+$ ion when the interface is polarized. If we add the HTMA$^+$ ion to the aqueous phase, then the HTMA$^+$ ion will immediately commence transferring across the interface to dissolve into the nitrobenzene phase anywhere in the potential range studied; hence, it will be impossible to achieve the polarization condition of the interface. This is because the standard ion-transfer potential of the HTMA$^+$ ion is greatly negative; i.e., HTMA$^+$ as a whole is a very hydrophobic ion, as will be described below. The aqueous phase VI contains 0.05 mol dm^{-3} LiCl, while Phases III and IV contain 1 mmol dm^{-3} LiCl, and 1 mmol dm^{-3} LiTPB respectively. The interface between Phases V and VI is a polarized interface. The other nitrobenzene-water interface between Phases IV and V is a nonpolarized one, across which the potential drop is determined by the activities of the TPB$^-$ ions in the two adjacent phases,[24] i.e., the interface reversible to the TPB$^-$ ion. The reference electrode reversible to TPB$^-$ ion is essential in detecting the specific adsorption of cations in the nitrobenzene phase.[25,26] Since the concentrations of the TPB$^-$ ion in Phase IV and in Phase V are constant, the potential across the interface between Phases IV and V may be taken as constant, even when the concentration of HTMA$^+$ ion is varied. The liquid junction potential at the interface between Phases III and IV is also unaltered. Consequently, the change in the potential difference between the terminals of Cell (I) is directly related to the change in the potential difference across the polarized nitrobenzene-water interface. We denote the potential of the right-hand side of Cell (I), referred to that of the left, as E_{0-}^{w-}, where the super- and subscripts indicate that the reference electrodes in the aqueous and nitrobenzene phases are both reversible to the anions.

Figure 1 shows the current-potential curves for Cell (I) when the concentration of the HTMA$^+$ ion in Phase V, c, equals 0 (Curve 1) and 0.1 (Curve 2) mol dm^{-3}. The polarized potential range where the current passing through the interface is negligible is between -0.55 and -0.2 V for c=0; i.e., the interface has a potential window of 0.35 V voltage span. The current-potential curve for c=0.1 mol dm^{-3} also has almost the same polarized potential range, demonstrating that the adsorption of HTMA$^+$ as well as the double layer structure of the interface can be studied under a polarized condition. This sugests that

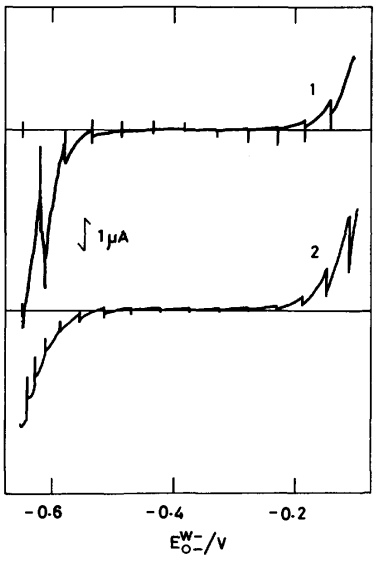

Fig. 1. Current-potential curves recorded using dropwise ascending electrolyte solution electrode for 0.05 mol dm^{-3} LiCl in water and 0.1 mol dm^{-3} TPnATPB(Curve 1) or 0.1 mol dm^{-3} HTMATPB-(Curve 2) in nitrobenzene.

the standard ion-transfer potential of the $HTMA^+$ ion is at least not more positive than those of the Cl^- and $TPnA^+$ ions.

The electrocapillary equation for Cell (I) at a constant temperature and pressure is given by:[16,26]

$$-d\gamma = q^W dE_{o-}^{w-} + \Gamma_{TPnA^+} RT d\ln(1-m) + \Gamma_{HTMA^+} RT d\ln m \quad (1)$$

where γ is the interfacial tension, q^W is the excess surface-charge density in the aqueous phase, E_{o-}^{w-} is the potential of the terminal of the right hand side of Cell (I) with respect to the left, Γ_j is the relative surface excess of the j ion (j=$TPnA^+$ and $HTMA^+$), and $m=x/0.1$. R and the T are the gas constant and the absolute temperature respectively. In deriving Eq. 1, the activity coefficients of the ions in Phase V are assumed to be constant when the composition of this phase is changed. This assumption will not introduce any serious error, because the ionic strength in Phase V is kept constant. If we assume that Γ_{TPnA^+} and the nonspecifically adsorbed portion of Γ_{HTMA^+} follow the Gouy-Chapman diffuse layer theory, Eq. 1 may be rewritten as:[25,26]

$$-d\gamma = q^W dE_{o-}^{w-} + \Gamma^1_{HTMA^+} RT d\ln m + RTm\left[\int_{x_1}^{x_2}\left\{\exp\left(-\frac{F\varphi}{RT}\right)-1\right\}dx\right]d\ln m \quad (2)$$

where $\Gamma^1_{HTMA^+}$ is the specifically adsorbed amount of the $HTMA^+$ ion, φ is the the electrostatic potential, F is the Faraday constant, and x_1 and x_2 are the positions of the outer Helmholtz planes in the nitrobenzene phase for the $HTMA^+$ and $TPnA^+$ ions respectively. The last term in the r.h.s. of Eq. 2 represents the contribution that arises from the difference in the size of the ions. In the following, we will neglect this last term. Therefore, the change in γ due to the change of m may be considered to be a direct measure of the specific adsorption of the $HTMA^+$ ions. (The term *specific adsorption* refers to the part of the adsorption which cannot be explained by the Gouy-Chapman theory.)

Figure 2 shows the electrocapillary cruves for a given cocentration of HTMATPB. The interfacial tension decreases with the increase in the concentration of $HTMA^+$ in the potential range negative to the electrocapillary maximum (ecm), which we will hereafter call "the negative branch," while the interfacial tension remaines unchanged in the potential range positive to the ecm, "the positive branch." Obviously, the $HTMA^+$ ion specifically adsorbs only in the potential range where the potential of the aqueous phase is negative with respect to that of the nitrobenzene phase. At the potential in the neighborhood of the ecm, the change in the interfacial tension with $HTMA^+$ concentration is very small, indicating that the adsorption at the ecm is almost negligible. The specifically adsorbed amount of $HTMA^+$ was calculated from the electrocapillary curves through Eq. 2 by using numerical differentiation with a third-order B-spline function.[28] The results are plotted in electrical units, $q^*=F\Gamma^1_{HTMA^+}$, in Fig. 3 as a function of E_{o-}^{w-}. As is to be expected from the electrocapillary curves, the specific adsorption of the $HTMA^+$ ion in the negative branch increases with the concentration and with the decrease in the potential.

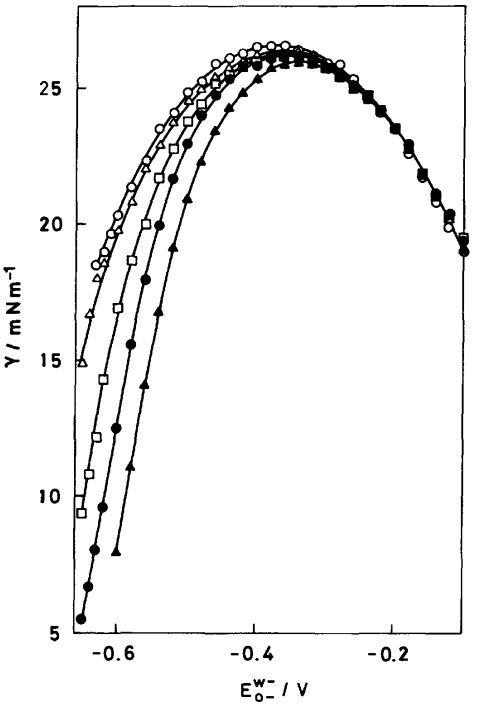

Fig. 2. Electrocapillary curves for the interface between 0.05 mol dm^{-3} LiCl aqueous solution and (0.1−x) mol dm^{-3} TPnATPB+x mol dm^{-3} HTMATPB nitrobenzene solution at 25 °C: x=0(○), 0.005(△), 0.02(□), 0.05(●), and 0.1(▲).

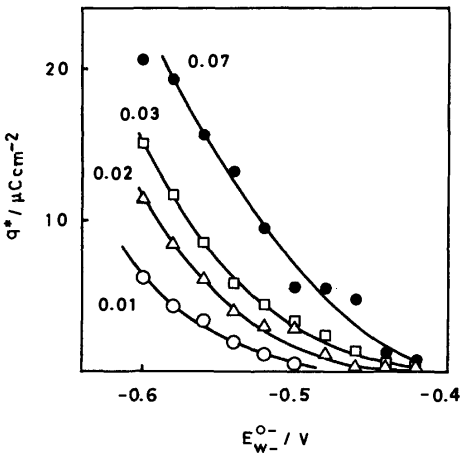

Fig. 3. Specifically absorbed change $q^*=F\Gamma^1_{HTMA^+}$ of $HTMA^+$ for c=0.01(○), 0.02(△), 0.03(□), and 0.07(●) mol dm^{-3}.

Figure 4 shows the adsorption isotherms for $HTMA^+$ for different values of E_{0-}^{W-}. These isotherms were analyzed with a virial isotherm of the form:

$$\ln\left(\frac{c}{q^*}\right)=\frac{\Delta G_a^0}{RT}+2vq^* \quad (3)$$

where ΔG_a° is the adsorption free energy and where v is the second virial coefficient. This isotherm at a given electrode potential was recently proposed by Vorotyntsev;[29,30] it is suitable for describing the adsorption of ions at the metal-solution interface, especially when the discreteness-of-charge effect previals at a lower surface coverage. The $\ln(c/q^*)$ vs. q^* plots at a given value of E_{0-}^{W-} were found to be straight lines (Fig. 5), indicating that Eq. 3 well describes the present experimental isotherms. We also tested the isotherm based on the Grahame-Parsons model of the inner layer at a constant q^W[31,32] and obtained a less satisfactory fitting of the experimental data. In particular, the ΔG_a° value thus obtained increased with the decrease in E_{0-}^{W-}, which seems physically unreasonable.

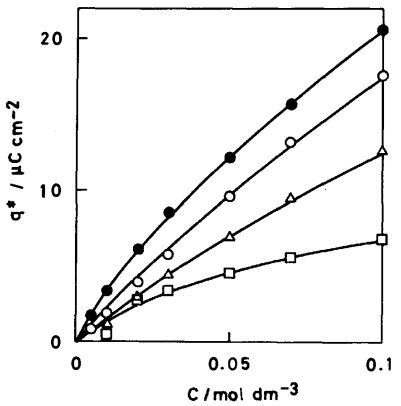

Fig. 4. Adsorption isotherms for specifically adsorbed $HTMA^+$ ions at E_{0-}^{W-}=−0.50(□), −0.52(△), −0.54(○), and −0.56(●)) V.

Discussion

The results clearly indicate that the adsorption of the $HTMA^+$ ion at the nitrobenzene-water interface has a remarkable dependence on E_{0-}^{W-} and, hence, on the potential drop across the interface. This is in marked contrast with the case of the nonionic surfactant adsorption at oil-water interfaces; e.g., Span 60 showed a positive adsorption throughout the polarized potential range at the nitrobenzene-water interface.[33] The fact that the $HTMA^+$ ion does not adsorb in the positive branch means that even a surfactant may not exhibit any surface activity, depending on the electrical potential drop across the interface. In the negative branch, the apparent surface activity of $HTMA^+$ increases with the increase in the potential difference. A similar asymmetric adsorption has previously been reported by Watanabe et al. for various ionic surfactants, but they used less polarized and, hence, electrochemically less characterized, methyl isobutyl ketone-water interfaces.[5]

The adsorption free energy for $HTMA^+$ was evaluated from the intercepts of the plots in Fig. 5. The ΔG_a° value thus obtained refers to the reference states of infinite dilution for both nitrobenzene and adsorption layers and to the standard states of 1 mol dm^{-3} for the nitrobenzene solution and of 1 μC cm^{-2} for the adsorption layer. ΔG_a° values are plotted in Fig. 6 against E_{0-}^{W-} (Curve 1). ΔG_a° was linearly dependent of E_{0-}^{W-}. The slope of this plot gave 5.0×10^4 C mol^{-1}. In general, various factors contribute to the dependence of ΔG_a° on the potential difference across the interface. The change in the applied potential causes not only the change in the inner-layer structure, but also the change in the diffuse-layer structure in the aqueous phase. The effect of the diffuse layer on the aqueous side of the

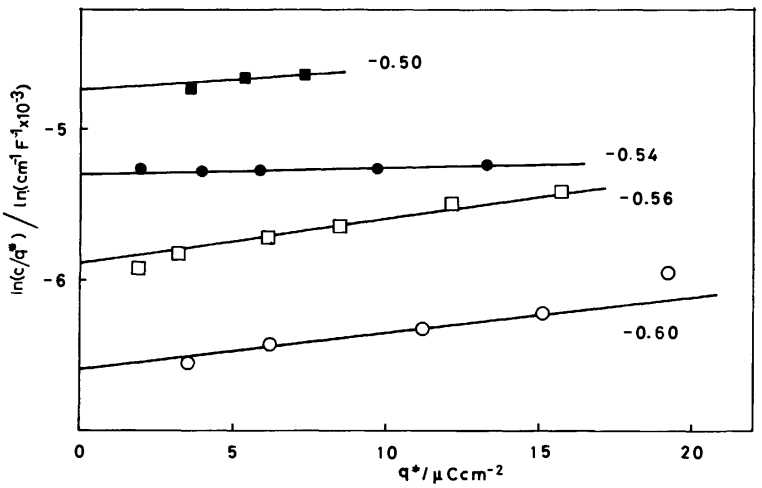

Fig. 5. Plots of $\ln(c/q^*)$ against q^* at E_{0-}^{W-}=−0.50(■), −0.54(●), −0.56(□), and −0.06(○) V.

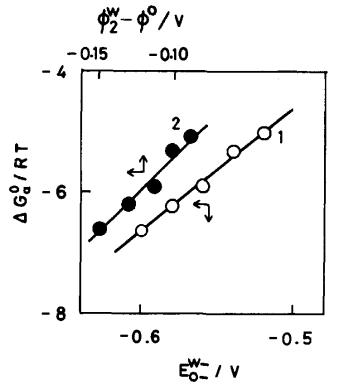

Fig. 6. Absorption free energy of HTMA+, $\Delta G_a°$, as a function of E_{0-}^{W-} (Curve 1) and of φ_2^W-φ^0 (Curve 2).

interface on $\Delta G_a°$ is appreciable, especially when the head group of the HTMA+ ion in its adsorption state is exposed to the aqueous phase. If the head group protrudes into the aqueous phase while leaving the hydrocarbon chain in the aqueous phase,[6] we may expect that the electrical work required to bring the charged head group of a HTMA+ ion from a bulk nitrobenzene phase to a certain point in the aqueous phase, e.g., the outer Helmholtz plane (OHP), constitutes a significant part of $\Delta G_a°$. Then, the change in the potential difference between the bulk of the nitrobenzene phase and the adsorption site caused by the change in E_{0-}^{W-} must contribute greatly to the dependence of $\Delta G_a°$ on E_{0-}^{W-} shown in Fig. 6. If we assume that the head group of an adsorbed HTMA+ ion is located at the OHP in the aqueous phase, then the effective potential difference for the electrical work in the adsorption process will be $\varphi_2^W-\varphi^0$, where φ_2^W and φ^0 are the potentials at the OHP in the aqueous phase and in the bulk of the nitrobenzene phase. $\Delta G_a°$ is replotted in Fig. 6 as a function of $\varphi_2^W-\varphi^0$ on the rational potential scale (Curve 2).[34] The slope was 6.8×10^4 C mol^{-1}. On the other hand, the electrical work for the transfer of 1 mol of monovalent ions across the potential difference of 1 V is 9.6×10^4 J mol^{-1}, and the change in this work with the potential difference is 9.6×10^4 C mol^{-1}. This is of the same order of magnitude as the experimental result, suggesting a large contribution of this electrical work to $\Delta G_a°$. The difference between the two values can be interpreted by assuming that the location of the adsorption site of the head group is on the nitrobenzene side of the OHP in the aqueous phase. In this case, the head group would not be fully exposed to the aqueous phase, and the effective potential difference should be smaller than $\varphi_2^W-\varphi^0$. However, our preliminary findings about the effect of the counterion in the aqueous phase on the adsorption of HTMA+[35] strongly suggest that the head group resides within the aqueous phase. Hence, the numerical difference between these two values seems to indicate the presence of other contributions including those opposing the electrostatic work. One such possible contribution is the work to replace the solvent molecules in the interfacial region with the head group and the hydrocarbon tail of the HTMA+ ion. Since the dielectric constant of the interfacial region is probably higher than that of the hydrocarbon part of the HTMA+ ion, this replacement gives rise to a positive contribution to the adsorption free energy.[36] According to Frumkin's two-parallel-plate condenser model for the adsorption of organic compounds on electrodes, this part of the adsorption free energy depends quadratically on the electrode potential. The range of E_{0-}^{W-} studied is perhaps not enough to detect such a quadratic dependence. It is also probable that there exists another factor which counteracts this quadratic term, leading to an apparent linear dependence. For example, the increase in the concentration of Cl^- at the OHP in the aqueous phase with the negative increase in E_{0-}^{W-} can increase the adsorption of HTMA+ not only by screening the repulsion between the adsorbed HTMA+ ions, but also by enhancing the salting-in effect for the head group of HTMA+.

The change in $\Delta G_a°$ with E_{0-}^{W-} is thermodynamically related to the change in q^W accompanied by the adsorption:[37]

$$\left(\frac{\partial q^W}{\partial \Gamma^1_{HTMA^+}}\right)_{E_{0-}^{W-}} = -\frac{d\Delta G_a^0}{dE_{0-}^{W-}} \quad (4)$$

Thus, the linear variation in $\Delta G_a°$ in Fig. 6 implies that q^W should also vary linearly with $\Gamma^1_{HTMA^+}$. Figure 7 shows the plots of q^W as a function of q^* at different values of E_{0-}^{W-}. All q^W vs. q^* curves gave straight lines whose slopes are very close to each other. The slope at $E_{0-}^{W-}=-0.54$ V was 4.1×10^4 C mol^{-1}, which is very close to the value obtained from Fig. 6. This agreement ensures the internal consistency of the data analysis. It should be noted that the positive value of

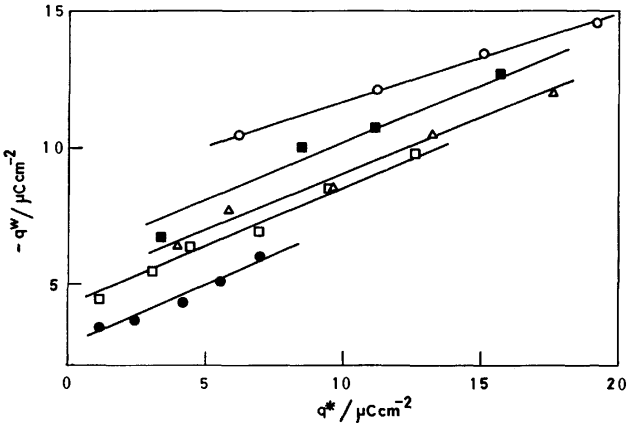

Fig. 7. Change of q^W as a function of q^* at a given value of E_{0-}^{W-}: $E_{0-}^{W-}=-0.48$(●), -0.52(□), -0.54(△), 0.56(●), and -0.60(○) V.

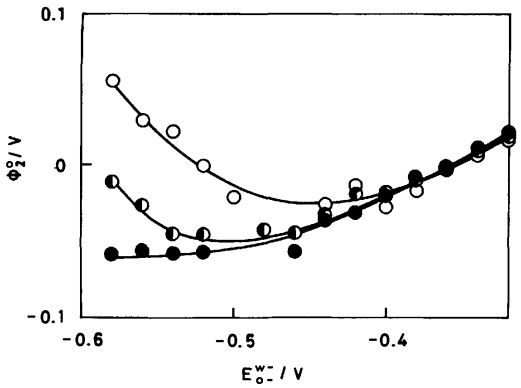

Fig. 8. Change of the potential at the outer Helmholtz plane in the nitrobenzene phase φ_2^0 with the change of E_{0-}^{W-} for the concentrations: c=0.01 (●), 0.02(○), and 0.05(○) mol dm^{-3}.

$(\partial q^W/\partial \Gamma^1_{HTMA^+})E_{0-}^{W-}$ means that the double layer capacity should increase with the adsorption of the $HTMA^+$ ion, because q^W at a constant E_{0-}^{W-} increased with the increase in $\Gamma^1_{HTMA^+}$.

The values of the interaction parameter v obtained from Fig. 5 were in the range from 0.002 to 0.015 cm^2 C^{-1}. These values are considerably lower than those estimated in the adsorption of inorganic ions at a metal-solution interface.[29] Since the intermolecular interaction between the hydrocarbon chains of adsorbed surfactants is usually small at oil-water interfaces,[38] the present results suggest that the repulsive interaction between the charged head groups is very weak.

The double-layer structure of the nitrobenzene-water interface is significantly altered by the adsorption of $HTMA^+$ ions. Figure 8 shows the φ_2^0 potential plotted against E_{0-}^{W-} for a given value of the concentration of the $HTMA^+$ ion. In the negative potential range, the sign of the φ_2^0 potential is inverted from negative to positive, that is, the specifically adsorbed charge q^* exceeds the excess charge density in the aqueous phase, q^W. The double layer structure in the presence of $HTMA^+$ adsorption in the negative branch is illustrated in Fig. 9. Thus, the adsorption of the $HTMA^+$ ion drastically affects the double layer structure especially, resulting in a change in the distribution of the potential across the interface. One important consequence of such an inversion of the φ_2^0 potential is that, by introducing ionic surfactants at the interface, one can modify the electric field sensed by ions participating in ion-transfer reaction through the interface. It may be noted that the φ_2^0 potential thus obtained is of average character and that the *micro potential*[39] could be less affected by the $HTMA^+$ adsorption, since the surface coverage of $HTMA^+$ achieved in the present study was at most 0.4, where the discreteness of the charge is certainly not negligible.

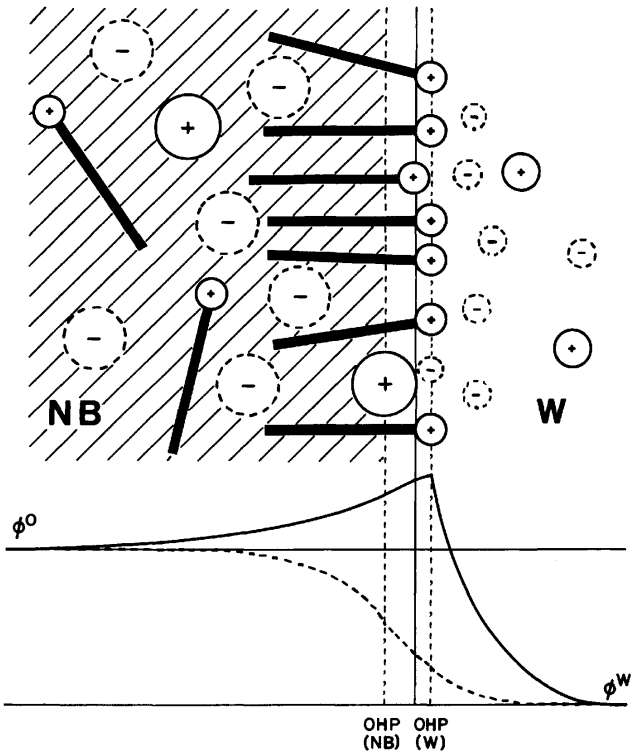

Fig. 9. Schematic representation of the double layer structure of the interface between nitrobenzene and aqueous solutions in the negative branch in the presence of the specific adsorption of $HTMA^+$ ions.

In conclusion, the adsorption of the $HTMA^+$ ion showed marked asymmetry with respect to the electrical potential applied across the interface. Such a dependence of the adsorption on the electrical potential difference is of great importance for the physical chemistry of emulsions, liposomes, micelles, and artificial and biological membranes. This potential dependence provides us with the possibility of regulating the surface activity of surfactants by applying the electrical potential difference across the interface. In the present study, the composition of the aqueous phase was held constant. If we change the composition of the aqueous phase while keeping that of the oil phase constant, then the change in the adsorption characteristics of the ions in the aquous phase due to the presence of surfactant adsorption can be investigated thermodynamically. This approach seems particularly useful in studying counterion effects in surfactant adsorption. Along this line, subsequent papers will deal with the effect of counter-ions in the aqueous phase on the adsorption properties of ionic surfactants.

Effect of Molybdenum Codeposition on the Thermal Properties of Electroless Ni-B Alloy Plating Films

Tetsuya OSAKA,* Ichiro KOIWA, Keizo YAMADA, Masao NISHIKAWA, and Masahiko USUDA
Department of Applied Chemistry, School of Science and Engineering, Waseda University, Okubo, Shinjuku-ku, Tokyo 160
(Received March 12, 1987)

Electroless Ni-Mo-B alloy films from a bath using dimethylamine-borane(1/1) (DMAB) as a reducing agent were investigated. Only a small amount of Mo-complex addition to the bath decreased the boron content and increased the molybdenum content drastically. The maximum molybdenum content and maximum resistivity under as-plated conditions were obtained as 22.1 wt% and 322 μΩ cm respectively. Such a high resistivity is characteristic of Ni-Mo-B alloy films. Both crystallized and amorphous states of Ni-Mo-B alloy films, whose Mo contents were above 20 wt% with a small amount of boron, were prepared by controlling the Mo-complex concentration in the bath. The heat change properties of Ni-Mo-B alloy films were quite different from those of the electroless Ni alloy films reported previously. The resistivity of Ni-Mo-B alloy films after heat treatment at 500 or 600 °C became higher than that of those created under as-plated conditions. The structure transformation of Ni-Mo-B alloy films after heat treatment was quite different from that of ordinary electroless Ni alloy films. The Ni-Mo-B alloy film after heat treatment was confirmed by TEM observation to show a mosaic-like structure. Therefore, it was thought that such a high resistivity and such thermal properties of Ni-Mo-B alloy films are caused by such a mosaic-like structure.

In general, electroless nickel deposits contain P or B as impurities from reducing agents, and the properties of electroless alloy films depend strongly on the kind of reducing agent used.[1] It is also well known that a higher impurity content makes a film amorphous.[2-6] Since amorphous alloy films usually possess high resistivity and low temperature coefficient,[7] amorphous electroless Ni alloy films have a high possibility for use as thin film resistors. The amorphous films, however, are unstable because of these easy crystallization upon heat treatment. The high-melting-point element, molybdenum, has been reported to codeposit into electroless Ni films,[8-12] and the codeposition of Mo into the Ni films has the possibility of overcoming the demerit of its less stable thermal property. The present authors have previously attempted the Mo codeposition into Ni-P films on the basis of this point of view and have confirmed that the electroless plated Ni-Mo-P alloy film of a crystallized state has a thermal stability superior to that of amorphous and crystallized Ni-P film.[12]

In this paper, the present authors will report amorphous or crystallized electroless Ni-Mo-B alloy films of a high thermal stability, plated from a bath using dimethylamine-borane(1/1) (DMAB) as the reducing agent.

Experimental

Electroless Ni-Mo-B alloy films were plated from a caustic alkaline bath using dimethylamine-borane(1/1) (DMAB) as the reducing agent. The basic bath compositions and operating conditions are listed in Table 1. Molybdenum was easily codeposited by complexing sodium molybdate with sodium gluconate before constructing the bath by analogy to the method by Mallory.[10] The film thickness was adjusted to 2 μm by controlling the deposition time; however, in the case of transmission electron microscopy (TEM) measurement, the film thickness was adjusted to about 500 Å. Therefore, the initial deposition films were observed by means of TEM. Ninety six wt% alpha-alumina ceramics were used as a plating substrate except for the TEM measurement. For the TEM measurement, polyimide film (25KA, Toray Co. Ltd.) was used as a substrate, and the plated films were separated from the substrate by dipping the specimen in a hydrazine-ethylenediamine solution. The repeated two step process for catalyzation was used (sensitizer:$SnCl_2 \cdot 2H_2O$, 1 g dm^{-3}; 37% HCl, 1.0 ml dm^{-3}; activator:$PdCl_2$, 0.1 g dm^{-3}; 37% HCl, 0.1 ml dm^{-3}).[13] The contents of molybdenum and boron were determined by means of atomic absorption spectroscopy and the use of an inductively coupled argon plasma emission spectrophotometer (ICAP-575 markII, Nippon Jarrell-Ash). For the amorphous Ni-Mo-B alloy film, auger electron spectrometry (15-110A, PHI Co. Ltd.) was used to investigate such impurities as carbon and oxygen. The resistivity of deposits on the alumina substrate was measured by the four-probe method (MODEL K-705RD, Kyowa Riken Co. Ltd.). The structures of the deposits were determined by the use of an X-ray diffractometer (RAD-IIA,

Rigaku Denki Co., Ltd.) and TEM measurement (100 kV, HU-12A, Hitachi Seisakusho Co., Ltd.). In the case of the heat treatment of deposits, the samples were heated under 2×10^{-3} Pa from room temperature to the setting temperature at a constant heating rate of 10 °C min^{-1}. The samples were heated for one hour at the setting temperature and were then left to cool spontaneously.

Results and Discussion

Film Composition and Resistivity of Electroless Plated Ni-Mo-B Alloy Films. The film composition and the resistivity as function of the Mo-complex concentration are listed in Table 2. The data of Ni-Mo-P alloy films were quoted from the previous paper[12] so as to compare them with those of Ni-Mo-B alloy films. In the case of Ni-Mo-B alloy films, the maximum Mo content and the highest resistivity value, 22.1 wt% and 322 μΩ cm respectively, were obtained at Mo-complex concentration of 0.0025 mol dm^{-3}. The highest resistivity value is about twice the value of a usual amorphous Ni-P alloy film. Moreover, the Mo content was almost independent of the Mo-complex concentration. This tendency was different from the case of Ni-Mo-P alloy films in the higher Mo-complex concentration region. On the other hand, the boron content was drastically decreased from 6.3 to 0.63 wt% by adding 0.0025 mol dm^{-3} Mo-complex. Moreover, the boron content gradually decreased with an increase in the Mo-complex concentration, and films with a very small 0.10 wt% B content were obtained at the region of a Mo-complex concentration of more than 0.0100 mol dm^{-3}. At the same Mo-complex concentration, the resistivity of Ni-Mo-B alloy film was always higher than that of Ni-Mo-P alloy film.

From the above results, there appears to be a difference between Ni-Mo-P alloy film and Ni-Mo-B alloy film under as-plated conditions. Especially, the Ni-Mo-B alloy film has the characteristics of a higher Mo content and a higher resistivity. In this paper, we mainly discuss the resistivity of Ni-Mo-B alloy film and its heat change properties, in particular, for the film at a Mo-complex concentration of 0.0025 mol dm^{-3}.

Heat Treatment Effect of Electroless Ni-Mo-B Alloy Film on Specific Resistance. Figure 1 demonstrates the effect of heat treatment on the specific resistance of Ni-Mo-B alloy films at Mo-complex concentrations of 0.0025 and 0.0125 mol dm^{-3}. The ρ value of Ni-B alloy film usually decreases with an increase in the heat treatment temperature as just as has been reported previously.[11] This tendency is generally found in Ni-P alloy films.[14]

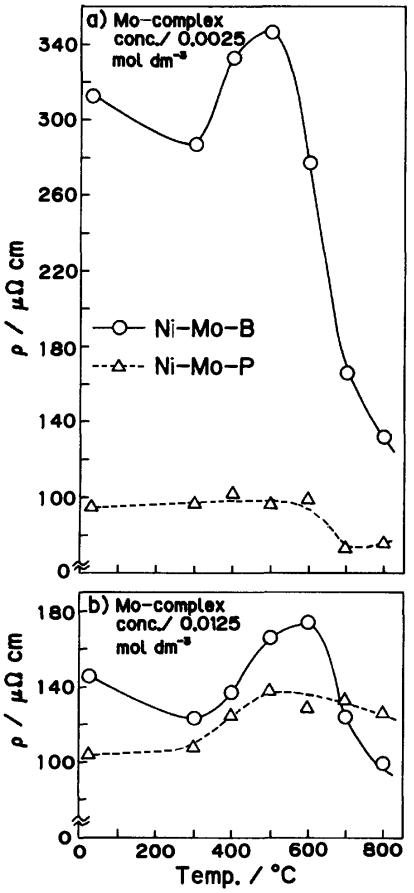

Fig. 1. Effect of heat treatment temperature on specific resistance, ρ. Solid line (circles): Ni-Mo-B. Dashed line (triangle): Ni-Mo-P.[12] a) 0.0025 mol dm^{-3} Mo-complex concentration, b) 0.0125 mol dm^{-3} Mo-complex concentration.

Table 2. Film Composition and Resistivity of Ni-Mo Alloy Films

Mo-complex conc. /mol dm^{-3}	Ni-Mo-B			Ni-Mo-P[12]		
	Mo/wt%	B/wt%	ρ/μΩ cm	Mo/wt%	P/wt%	ρ/μΩ cm
0	0	6.3	120	0	10.2	127
0.0025	22.1	0.63	322	10.0	2.0	95
0.0050	19.8	0.17	138	14.1	1.1	105
0.0075	21.5	0.12	130	14.8	0.98	101
0.0100	22.0	0.10	126	16.5	0.94	99
0.0125	21.1	0.10	146	16.5	0.95	104

The dashed lines are the data of Ni-Mo-P alloy films, quoted from a previous paper[12] for the sake of comparison. The ρ values of Ni-Mo-B alloy film at an Mo-complex concentration of 0.0025 mol dm^{-3} are always higher than those of Ni-Mo-P alloy films at any temperature. In Fig. 1a, the ρ value of Ni-Mo-B alloy film at a Mo-complex concentration of 0.0025 mol dm^{-3} after 300 °C heat treatment becomes a little lower than that of the as-plated conditions. In the heat treatment region from 300 until 500 °C, the ρ value increases with an increase in the heat treatment temperature; the maximum value of 347 $\mu\Omega$ cm was obtained after heat treatment at 500 °C. In the region higher than 500 °C, the ρ value drastically decreases with an increase in the heat treatment temperature. Even after heat treatment at 700 °C, however, the ρ value of Ni-Mo-B alloy film at the Mo-complex concentration of 0.0025 mol dm^{-3} is still higher than the maximum (150 $\mu\Omega$ cm) of electroless binary Ni alloy films. In the case of binary Ni alloy films, the maximum resistivity can be obtained only for the as-plated conditions. Therefore, the amorphous Ni-Mo-B alloy films showed a higher thermal stability of resistivity than did the previously reported binary Ni alloy films.

Moreover, the ρ value tendency of Ni-Mo-B at Mo-complex concentration of 0.0125 mol dm^{-3} is almost the same as that of Ni-Mo-B at the Mo-complex concentration of 0.0025 mol dm^{-3}, as is shown in Fig. 1b. From the above results, the ρ value behavior of amorphous and crystallized Ni-Mo-B alloy films after heat treatment is as follows: i.e., first there appears a little decrease at a low temperature heat treatment; then the ρ value increases in the region of medium-temperature heat treatment before decreasing abruptly at higher heat treatment temperatures.

The characteristics of three typical films are listed in Table 3. In general, a high resistivity film of the electroless plated one is obtained only for the films controlling high impurity. Though the boron contents of both Ni-Mo-B alloy films were very small, $\rho_{\text{as-plated}}$ and ρ_{maximum} values of the Ni-Mo-B alloy film

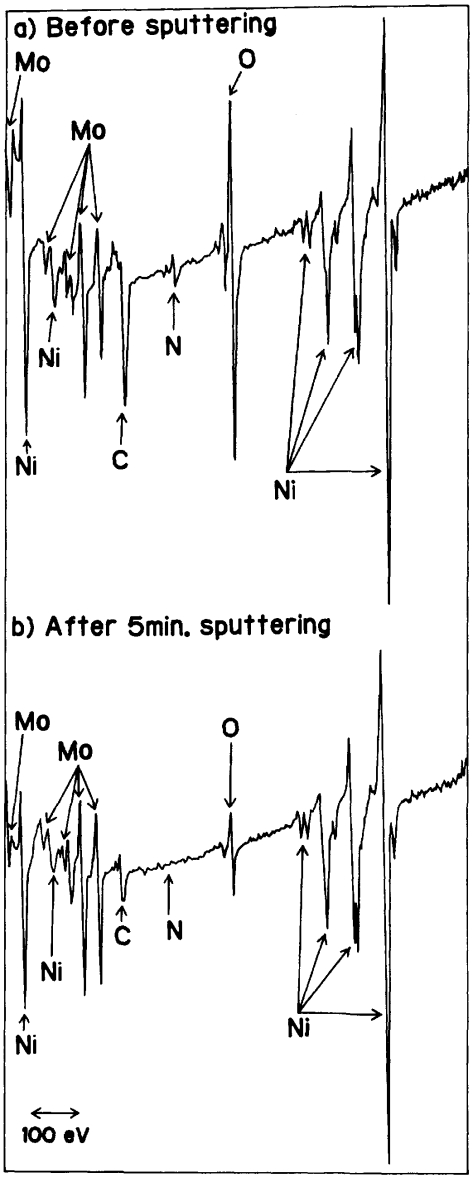

Fig. 2. Auger electron spectroscopy of amorphous Ni-Mo-B alloy films at 0.0025 mol dm^{-3} Mo-complex concentration. a) Before sputtering, b) after 5 min. sputtering.

Table 3. Characteristics of Typical Ni Alloy Films

Mo-complex conc. /mol dm^{-3}	$\rho_{\text{as-plated}}/\mu\Omega$ cm Structure	$\rho_{\text{maximum}}/\mu\Omega$ cm Their condition and structure
0	120 Amorphous	120 Under as-plated conditions Amorphous
0.0025	322 Amorphous	347 After 500°C treatment Almost amorphous
0.0125	146 Crystallized	176 After 600°C treatment Crystallized

are higher than those of the Ni-B alloy film. In particular, the maximum $\rho_{as\text{-}plated}$ value, 322 μΩ cm, is attained at the Mo-complex concentration of 0.0025 mol dm^{-3}. Moreover, the maximum ρ value, 347 μΩ cm, of electroless Ni-Mo-B alloy film was obtained by heat treatment at 500 °C. The heat treatment behavior of the ρ value of Ni-Mo-B alloy films is quite unique and can not be simply explained by the explanation given in the case of binary electroless plated film.[14]

Auger Electron Spectroscopy (AES) Analysis of the Ni-Mo-B Alloy Film. Figure 2 demonstrates the AES spectra of the Ni-Mo-B alloy film at the Mo-complex concentration of 0.0025 mol dm^{-3}. Before sputtering, the peaks corresponding to Ni, Mo, C, N, and O were detected. However, after 5 mins' sputtering, the peaks corresponding to C, N, and O remarkably decreased. The peak intensities of C and O after 5 mins' sputtering are almost the same as those of the other alloy, which means they come from the impurity. Thus, such a highly specific resistance of the Ni-Mo-B alloy film at the Mo-complex concentration of 0.0025 mol dm^{-3} is confirmed not to be the result of its containing an insulator composed of C and O atoms. The origin of such unique characteristics is assumed to come from a structure containing Mo atoms. Below, the structure of electroless Ni-Mo-B alloy films will be discussed.

The Effect of Heat Treatment on the Structure of Electroless Ni-Mo-B Film. Figure 3 demonstrates the X-ray diffraction patterns of Ni alloy films at Mo-complex concentrations of 0, 0.0025 and 0.0125 mol dm^{-3}. Under as-plated conditions, only the two peaks due to the substrate are detected for Ni-B and Ni-Mo-B alloy films at 0.0025 mol dm^{-3}, and they both show an amorphous structure. Amorphous binary alloy films, such as Ni-P and Ni-B alloy films, are usually obtained only in the case of films containing high P or B impurities. In fact, the Ni-B alloy film shows high boron content (6.3 wt%). On the other hand, Ni-Mo-B alloy film at the Mo-complex concentration of 0.0025 mol dm^{-3} shows the same X-ray pattern in spite of its quite low boron content (0.63 wt%). In contrast to the above two alloys, the Ni-Mo-B alloy film at the Mo-complex concentration of 0.0125 mol dm^{-3} shows a highly crystallized structure under as-plated conditions, since the peaks of the Ni matrix were detected, as is shown in Fig. 3c. Moreover, the peaks of the Ni(111) and Ni(200) plane shift to the lower angle side as compared with those of pure Ni; the interplanar spacing of the Ni-Mo-B film was widened by the codeposited Mo atoms. The molybdenum in the deposit may form a solid solution in the nickel matrix. The shift behavior of the Ni(111) plane peak is almost the same as that of Ni-Mo-P alloy film, but the amount of the shift is larger than that of Ni-Mo-P alloy film.[12] This large shift could be caused by the higher Mo content, as is shown in Table 2.

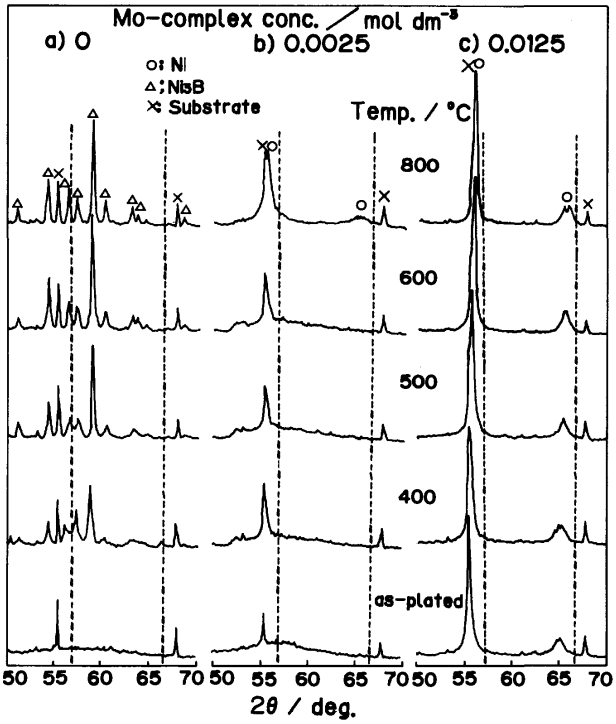

Fig. 3. X-Ray diffraction patterns of Ni-B and Ni-Mo-B alloy films at various annealing temperature using Fe target. The dashed lines represent the peak positions of pure Ni.
a) Ni-B alloy films, b) Ni-Mo-B alloy films plated from 0.0025 mol dm^{-3} Mo-complex concentration bath, c) Ni-Mo-B alloy films plated from 0.0125 mol dm^{-3} Mo-complex concentration bath.

Based upon the above results, we will now discuss the characteristics of electroless Ni-Mo-B alloy films under as-plated conditions in comparison with the results of the previous investigation. First, we will discuss the structures of electroless Ni-Mo-B alloy films. According to our previous investigation of electroless Ni-W-P alloy films, both amorphous and crystallized Ni-W-P alloy films with low P content could be prepared.[15,16] Therefore, the codeposited tungsten causes an amorphous state of the film. Since the boron content of amorphous Ni-Mo-B was extremely small, i.e., 0.63 wt%, the effect of the codeposited Mo atom in the Ni-B film is much greater than that of the codeposited W atom in the Ni-P film. In the case of highly crystallized Ni alloy films under as-plated conditions, the phenomenon of the d value shift, which may mean the formation of the solid solution between the codeposited atom and Ni matrix, can not be observed in the case of Ni-W-P alloy film,[15,16] but it can be observed in the case of Ni-Mo-P alloy film.[12] Therefore, the codeposited molybdenum can form a solid solution.

Next, we will discuss the resistivity of electroless

Ni-Mo-B alloy films. The amorphous Ni-P and Ni-W-P alloy films showed almost the same resistivity, i.e., about 150 μΩ cm, the highly crystallized Ni-P and Ni-W-P alloy films also show almost the same resistivity, i.e., about 50 μΩ cm. Therefore, the resistivities of the Ni-P and Ni-W-P alloy films depend strongly on the film structure. In the case of electroless Ni-Mo-B alloy films, the resistivities are much higher than those of Ni-P and Ni-W-P alloy films under the same structure conditions. Therefore, the resistivity of Ni-Mo-B alloy films can not be explained only by the structure. In general, amorphous alloys between transition metals, such as Zr-Ni[17] and Nb-Ni,[18] show a high resistivity above 200 μΩ cm. Therefore, in the case of amorphous Ni-Mo-B alloy film prepared by the electroless plating method, an effect similar to those of Zr-Ni and Nb-Ni is a possibility.

Based upon the above discussion, the amorphous and crystallized Ni-Mo-B alloy films are considered to be quite different from the amorphous and crystallized Ni-W-P alloy films. Therefore, the codeposited molybdenum is an important factor in determining the structure and resistivity. Moreover, the effect of codeposited molybdenum on film properties is different from that of codeposited tungsten.

In this investigation, three typical alloy films are obtained, i.e., the amorphous Ni-B, the amorphous Ni-Mo-B (plated from a 0.0025 mol dm^{-3} Mo-complex concentration bath), and the crystallized Ni-Mo-B (plated from a 0.0125 mol dm^{-3} Mo-complex concentration bath). These three typical alloy films will now be considered.

In the case of Ni-B alloy, only the peaks due to Ni_3B appear after heat treatment at 400 °C, as is shown in Fig. 3a, where the boron content of this amorphous Ni-B alloy film is almost the same as in the stoichiometric Ni_3B compound (6.3 wt%, i.e., 26.9 at%, see Table 2). The peak intensities gradually increase with an increase in the heat treatment temperature; indicates that the crystallinity of the Ni_3B compound progresses with heat treatment.

On the other hand, for the amorphous Ni-Mo-B alloy film, there is no structure change until 500 °C under heat treatment, as is shown in Fig. 3b, though an obvious structure change is observed after heat

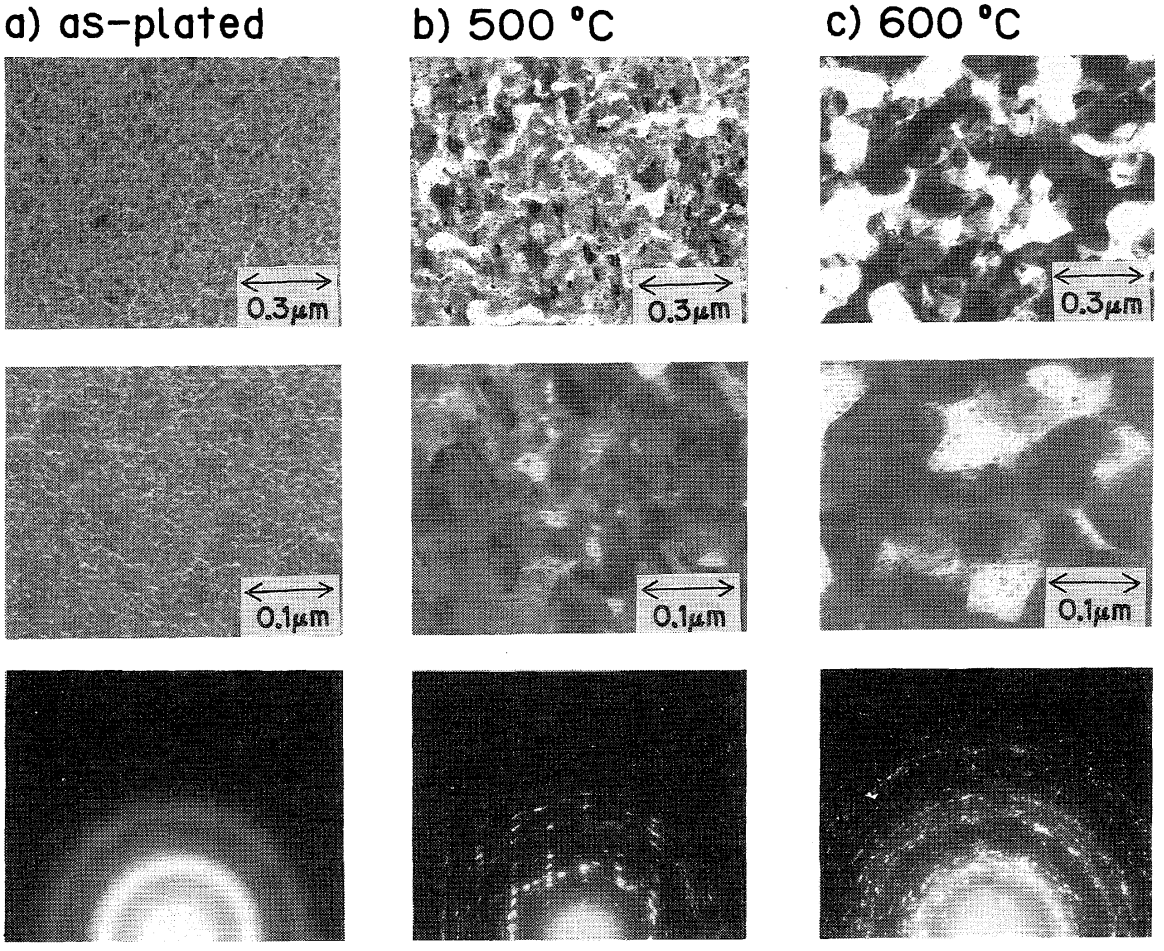

Fig. 4. Transmission electron micrographs (TEM) and transmission high energy electron diffraction (THEED) patterns of Ni-B alloy films. a) As-plated conditions, b) after 500 °C treatment, c) after 600 °C treatment.

treatment at 700 °C. In general, an amorphous alloy is very unstable against heat treatment; however, the thermal stability of this amorphous film has been improved by the codeposition of the Mo atom, much as in the case of Fe-Ni-Mo-B[19,20] and Cr-Mo[21] amorphous alloys. By considering the previous reported facts, such an excellent thermal stability of amorphous Ni-Mo-B alloy film may be assumed to be due to the codeposition of the Mo atom into Ni-B film.

For the crystallized Ni-Mo-B alloy film, the structure shows almost no change until heat treatment at 500 °C as is shown in Fig. 3c. The peak intensities gradually increase with an increase in the heat treatment temperature above 500 °C.

In the cases of both amorphous and crystallized Ni-Mo-B alloy films, the peaks of the Ni(111) and Ni(200) planes are shifted to a lower angle side than those of pure Ni. Thus, there is a stable solid solution between Mo and Ni.

Transmission Electron Microscopy (TEM) and Transmission High Energy Electron Diffraction (THEED) Measurement. Figures 4—6 demonstrate the TEM and THEED patterns for the films at the Mo-complex concentrations of 0, 0.0025, and 0.0125 mol dm^{-3}, respectively. Figure 4a demonstrates the TEM and THEED patterns of Ni-B alloy film under as-plated conditions. The TEM micrographs show an Ni-B alloy film consisting of very small grains, while the THEED pattern gives halo diffraction rings due to the Ni phase. After heat treatment at 500 °C, the film comes to consist of large grains, while the THEED pattern shows the formation of the Ni_3B compound, as is shown in Fig. 4b. After heat treatment at 600 °C, the contrast and the grain size become clearer and larger respectively. These results coincide well with results of the X-ray diffraction measurement. Therefore, a drastic structural transformation is produced by the heat treatment.

Figure 5 demonstrates the TEM and THEED patterns of amorphous Ni-Mo-B alloy film with the same arrangement as is shown in Fig. 4. The results of the TEM and THEED of amorphous Ni-Mo-B alloy film under as-plated conditions are almost the same as those of Ni-B alloy film, as is shown in Fig. 4a. Broad

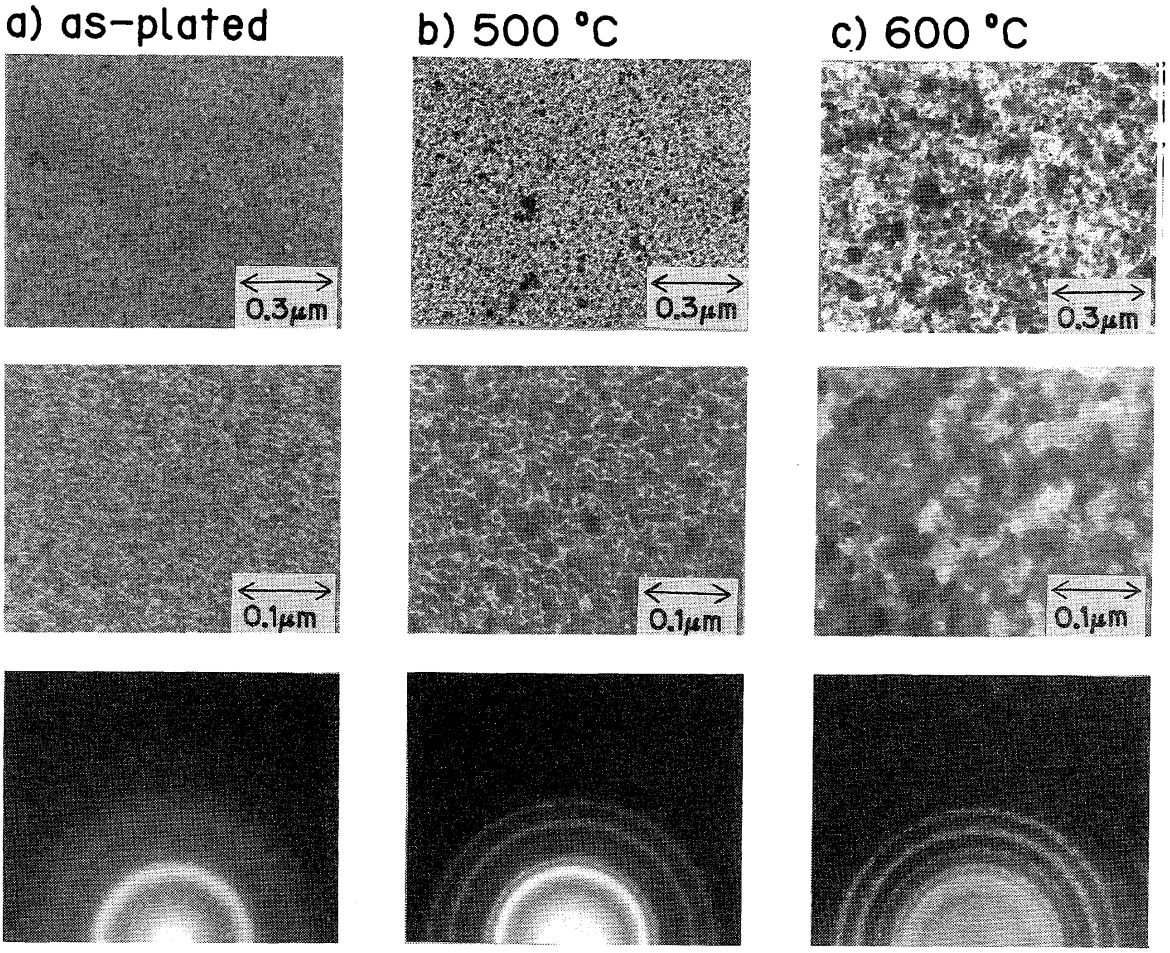

Fig. 5. Transmission electron micrographs (TEM) and transmission high energy electron diffraction (THEED) patterns of Ni-Mo-B alloy films at 0.0025 mol dm^{-3} Mo-complex concentration. a) As-plated conditions, b) after 500 °C treatment, c) after 600 °C treatment.

diffraction rings due to the Ni-Mo alloy are observed under as-plated conditions, and the grain sizes become a little larger after heat treatment at 500 °C treatment. The crystallinity after treatment at 500 °C is not so high, judging from the wider width of the diffraction rings. After heat treatment at 600 °C, the contrast and the grain sizes increase, and there appears a mosaic-like structure; however, the width of the diffraction rings is still wider.

Figure 6 demonstrates the TEM and THEED patterns of crystallized Ni-Mo-B alloy film in the same manner as in Figs. 4 and 5. The same tendency as that in Fig. 5 is observed. As is also seen in the X-ray diffraction measurement results in Fig. 3c, the crystallization proceeds gradually with an increase in the heat treatment temperature. The diffraction rings became sharper after heat treatment at 500 °C. The grain sizes after heat treatment at 600 °C are almost the same as those after heat treatment at 500 °C, only the contrast between 500 and 600 °C becomes clearer.

In general, the crystallized film after heat treatment shows large grown-grains and sharp diffraction rings. In contrast with the usual case, the heat change behavior of electroless Ni-Mo-B alloy films is quite different. Such a mosaic-morphology and broad diffraction rings after heat treatment are characteristic of the Ni-Mo-B alloy film. The usual crystallization process is accompanied by an increase in grain size, and finally the grown-grains combine with each other, thus making possible a free path of electrons.[14] Therefore, the resistivity is usually decreased by the normal crystallization process after heat treatment. In contrast with such a usual crystallized film, the crystallized Ni-Mo-B alloy is crystallized by heat treatment, without any accompanying increase in grain size. The grains are still clearly separated, even after treatment at 600 °C, and such a formation of a grain matrix does not permit a free path for electrons. Thus, the characteristics of such a mosaic-like structure are assumed to be the origin of the high resistivity and high thermal stability. Moreover, in the case of amorphous Ni-Mo-B alloy films, these characteristics are enhanced.

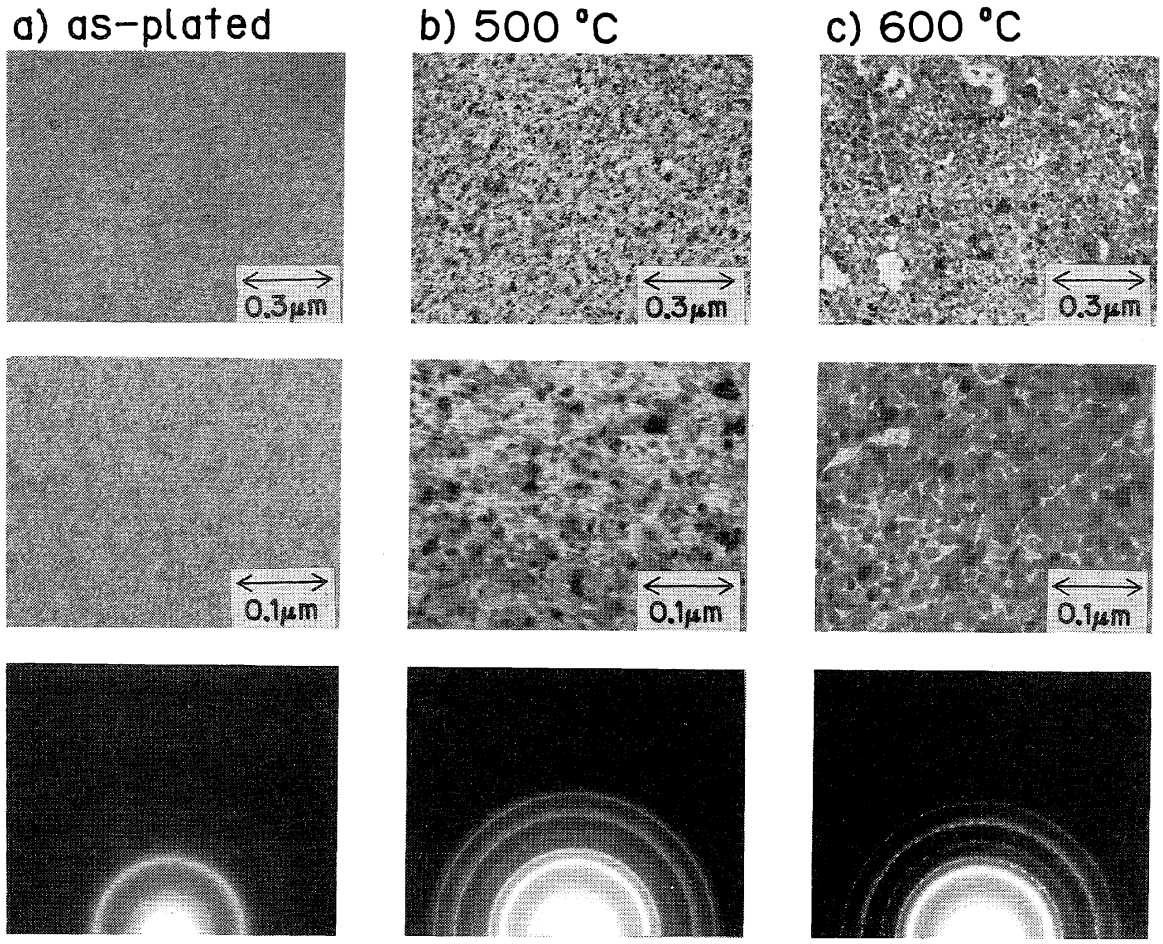

Fig. 6. Transmission electron micrographs (TEM) and transmission high energy electron diffraction (THEED) patterns of Ni-Mo-B alloy films at 0.0125 mol dm^{-3} Mo-complex concentration. a) As-plated conditions, b) after 500 °C treatment, c) after 600 °C treatment.

Conclusion

Electroless Ni-Mo-B alloy films, which had been prepared from a bath using dimethylamine-borane (1/1) (DMAB) as the reducing agent, were studied from the viewpoint of forming thermally stable film. The following results were obtained:

1) Amorphous and crystallized Ni-Mo-B alloy films with Mo contents of more than 20 wt% were obtained from an electroless plating bath.

2) The maximum molybdenum content and the very high resistivity value of Ni-Mo-P film were 22.1 wt% and 322 μΩ cm respectively under as-plated conditions. The origins of such a high resistivity value of Ni-Mo-B alloy film were assumed to be the formation of a solid solution and the unique microstructure.

3) The maximum resistivity of electroless Ni-Mo-B alloy films was obtained after heat treatment. After heat treatment at 500 °C, the maximum resistivity of 347 μΩcm was obtained for the film plated from a 0.0025 mol dm^{-3} Mo-complex concentration bath.

4) The microstructure of Ni-Mo-B alloy film, with a high resistivity, after heat treatments at 500 and 600 °C was due to an unique mosaic-like structure.

(Received March 17, 1987)

The ^{29}Si chemical shifts of silicon hydrides and fluorosilanes were calculated by means of the FPT method within the CNDO/2 framework. It was found that, by a small revision of the formula for the off-diagonal elements of the core Hamiltonian matrix in the CNDO/2 method, the calculated results agree well with the gross trend of the experimental values of the ^{29}Si chemical shifts in the literature. Further, the relationship between the ^{29}Si chemical shift and the electronic structure was discussed.

The widespread interest in ^{13}C NMR has ensured that the chemical shift of this nucleus has received much attention at both the semiempirical MO- and ab initio MO-level approaches, and the comparison of the calculated and experimental ^{13}C chemical shifts has provided useful information on the electronic distribution and molecular structure.[1,2] On the other hand, in spite of the fact that ^{29}Si NMR spectroscopy is widely used for investigating molecular structures and electronic distributions in organosilicon compounds, theoretical investigation has been carried out only by using such a rough approximate theory as the averaged excitation energy (ΔE) method.[3,4] This method has an ambiguity in the estimation of the value of ΔE as parameter in the paramagnetic term by which ^{29}Si chemical shift is predominantly governed. According to our best knowledge, there have been few ^{29}Si chemical-shift calculations using sophisticated methods.

In this work, therefore, we aim to calculate the ^{29}Si chemical shifts of several organic compounds containing a silicon atom by the use of the finite-perturbation theory (FPT)[5] within the CNDO/2 framework, which reproduces well the experimental trend for the ^{13}C chemical-shift values;[6] we will also discuss the relationship between the ^{29}Si chemical shift and the electronic structure through a comparison of the calculated and experimental chemical-shift values.

Theoretical

In the FPT method,[5] the ^{29}Si shielding tensor of a nucleus A, $\sigma_{\alpha\beta}(A)$, is expressed as a sum of the diamagnetic term, $\sigma^{d}_{\alpha\beta}(A)$, and the paramagnetic term, $\sigma^{p}_{\alpha\beta}(A)$ as follows:

$$\sigma_{\alpha\beta}(A) = \sigma^{d}_{\alpha\beta}(A) + \sigma^{p}_{\alpha\beta}(A), \qquad [1]$$

$$\sigma^{d}_{\alpha\beta}(A) = \frac{e^2}{2mc}\sum_{\mu}\sum_{\nu} \boldsymbol{P}_{\mu\nu}(0) < \chi_{\mu} \left| \frac{\delta_{\alpha\beta}\boldsymbol{r}_{\nu}\cdot\boldsymbol{r}_{A} - r_{\nu\alpha}r_{A\beta}}{|\boldsymbol{r}_{A}|^3} \right| \chi_{\nu} >, \qquad [2]$$

$$\sigma^{p}_{\alpha\beta}(A) = -\frac{e\hbar}{mc} i \sum_{\mu}\sum_{\nu} \left(\frac{\partial P_{\mu\nu}(\boldsymbol{H}_{\alpha})}{\partial \boldsymbol{H}_{\alpha}} \right)_{\mathbf{H}=0} < \chi_{\mu} \left| \frac{(\boldsymbol{r}\times\nabla)_{\beta}}{|\boldsymbol{r}_{A}|^3} \right| \chi_{\nu} > \quad (\alpha, \beta = x, y, z), \qquad [3]$$

where the gauge origin of the vector potential is set at the position of the nucleus A. The $\mathbf{r}_{\nu}$ and $\mathbf{r}_{A}$ vectors are the position vectors of an electron considered from the point of view of a nucleus of the atom containing the $\mathbf{AO}_{\chi_{\nu}}$ and from that of nucleus A respectively. $\boldsymbol{P}_{\mu\nu}(\boldsymbol{H}_{\alpha})$ and $\boldsymbol{P}_{\mu\nu}(0)$ are the elements of the density matrix with and without the perturbation due to the magnetic field $\boldsymbol{H}$ respectively; they are obtained by solving the Roothaan equation[7] with the Hartree-Fock matrix, $\boldsymbol{F}_{\mu\nu}(\boldsymbol{H}_{\alpha})$, containing the perturbation terms:

$$\boldsymbol{F}_{\mu\nu}(\boldsymbol{H}_{\alpha}) = \boldsymbol{H}^{\mathrm{core}}_{\mu\nu} + \sum_{\lambda}\sum_{\sigma} \boldsymbol{P}_{\mu\nu}(\boldsymbol{H}_{\alpha})[(\mu\nu|\lambda\sigma) - \frac{1}{2}(\mu\sigma|\lambda\nu)] - i(e\hbar/2mc)\sum_{\alpha} \boldsymbol{H}_{\alpha} < \chi_{\mu}|(\boldsymbol{r}\times\nabla)_{\alpha}|\chi_{\nu} >, \qquad [4]$$

where $\boldsymbol{H}^{\mathrm{core}}_{\mu\nu}$, $(\mu\nu|\lambda\sigma)$, and $(\mu\sigma|\lambda\nu)$ are the unperturbed core Hamiltonian, the Coulomb integral, and the exchange integral respectively; these are estimated by means of the parameters in the INDO method. In the present calculation, we shall adopt Pole's parameters[8] except for the off-diagonal element of the core Hamiltonian, which is estimated from this expression:

$$\boldsymbol{H}^{\mathrm{core}}_{\mu\nu} = (\kappa_{\pi}/2)(\beta^{0}_{\mathrm{A}} + \beta^{0}_{\mathrm{B}})S_{\mu\nu} \qquad (\mu \neq \nu), \qquad [5]$$

in which κ_{π} denotes a correction factor for the π-π interaction. κ_{π}=0.85 was used in this work according to the previous proposal.[5] β^{0}_{A} is the bonding parameter for the atom A, and $S_{\mu\nu}$, the overlap integral. The density matrix is allowed to be complex

to accommodate the purely imagniary nature of the perturbation, while $\mathbf{Im}[\boldsymbol{P}_{\mu\nu}(\boldsymbol{H}_\alpha)]$ represents the imaginary part. The derivative in Eq. 3 is evaluated numerically using the finite-difference technique, in which it is approximated by a single difference:

$$(\partial \boldsymbol{P}_{\mu\nu}(\boldsymbol{H}_\alpha)/\partial \boldsymbol{H}_\alpha)_{\mathbf{H}=0} = \mathbf{Im}[\boldsymbol{P}_{\mu\nu}(\boldsymbol{H}_\alpha)]/\boldsymbol{H}_\alpha. \quad [6]$$

In this calculation, the bond lengths and bond angles used were taken from the X-ray-diffraction data[9] and also from the standard values proposed by Pople and Gordon.[10] All the calculations were carried out by means of a HITAC M-280H computer of the Tokyo Institute of Technology and a S-810 computer at the Computer Center of Tokyo University.

Results and Discussion

Since the ^{29}Si chemical shift is considered to be governed predominantly by the paramagnetic term as well as by the ^{13}C chemical shift, we will evaluate mainly the contribution from this terms using the FPT CNDO/2 method. In such a semiempirical MO calculation, we sometimes encounter the question of whether or not, the CNDO parameters proposed by Pople et al.[11] are appropriate to give a satisfactory agreement between the calculated and experimental chemical shifts. Ando et al.[6] and Ellis et al.[12] showed that the MO parameters proposed by Pople et al. did not give a satisfactory agreement between the calculated and experimental ^{13}C chemical-shift values in hydrocarbons. They therefore altered the bonding parameters for carbon and hydrogen atoms to improve their results. For our experiment, we will use a set of Ando's bonding parameters,[6] β_C=−15 eV and β_H=−13 eV, for the carbond and hydrogen atoms respectively contained in organosilicon compounds; these parameters reproduce reasonably well the gross trends of the observed values of the ^{13}C chemical shifts and the shielding tensor. However, as for the Si atom considered here, the optimized value of the bonding parameter, which reproduces reasonably well the experimental values of the ^{29}Si chemical shifts is not known. Therefore, the optimized value of the β parameter for the silicon atom will be examined.

First, we will consider the ^{29}Si chemical shift of silicon hydride derivatives, which consist of silicon, carbon, and hydrogen atoms. As is shown in Table 1, the experimental ^{29}Si chemical-shift data indicate that, as the degree of hydrogen substitution is increased, the chemical shifts are displaced upfield; the range of the chemical-shift displacement is about 90 ppm. In spite of such a simple structural change, the range of the chemical-shift displacement is quite large. This means that silicon-hydride derivatives are excellent for use in a theoretical study of the ^{29}Si chemical shift.

We will now examine the ^{29}Si chemical-shift behaviour of silicon-hydride derivatives calculated by using a set of Pople's bond parameters[11] (β_H=−9 eV, β_C=−21 eV, and β_{Si}=−13.065 eV) for hydrogen, carbon, and silicon atoms respectively. A plot of the experimental chemical shifts versus the calculated values is shown in Fig. 1a. The dashed line is a theoretical line with the slope of 1. This means that the experimental and calculated values agree with each other exactly. As may be seen from Fig. 1a, the data points greatly deviate from the theoretical line, and the calculated chemical-shift range is quite small compared with the experimental data. This means that the set of Pople's bonding parameters are not appropriate in the ^{29}Si chemical-shift calculation.

As is to be expected from the previous results[6] for the ^{13}C chemical shift, the lowering of the absolute value for β_{Si} leads to a wide expansion of the calculated

Table 1. Calculated ^{29}Si Chemical Shifts of Silicon Hydrides[a]

Compound	d	σ^d	σ^p	σ^T	δ_{calcd} [b]	$\delta_{exp.}$ [c]
1) SiH_4	3.4578	66.78	−321.64	−254.86	−63.87	−92.5

4) SiH_3Bz	3.5175	67.60	−341.22	−273.62	−45.11	−56.0
5) SiH_2Me_2	3.5376	67.88	−348.38	−280.50	−38.23	−40.0
6) SiH_2MePh	3.5546	68.11	−346.13	−278.02	−40.71	−36.9
7) SiH_2Ph_2	3.5874	68.56	−341.51	−272.95	−45.78	−33.6
8) $SiHMePh_2$	3.6058	68.80	−358.63	−289.82	−28.91	−19.5
9) $SiHPh_3$	3.6286	69.11	−352.99	−283.88	−34.85	−17.8
10) $SiHMe_2Ph$	3.5715	68.34	−367.09	−298.75	−19.98	−17.6
11) $SiHMe_3$	3.5577	68.15	−360.83	−292.67	−26.06	−16.3
12) $SiHPr_3$	3.5918	68.62	−375.43	−306.82	−11.91	−8.5
13) $SiHEt_3$	3.5798	68.45	−372.51	−304.05	−14.68	0.2

a) The bonding parameters used are β_H=−13 eV, β_C=−15 eV, and β_{Si}=−12 eV. b) Values given in ppm. Chemical shifts calculated with respect to TMS. The negative sign means an upfield shift from TMS. c) Data taken from Ref. 14. The negative sign means an upfield shift from TMS.

^{29}Si chemical-shift range. Thus, the value of β_{Si} which yields the best agreement between the experimental and calculated values for all chemical shifts was determined. This examination leads to the selection of the value of −12 eV for β_{Si}. As was mentioned above, a set of Ando's β_C and β_H bonding parameters (β_C=−15 eV and β_H=−13 eV) for carbon and hydrogen atoms was fixedly used. A plot of the experiment chemical shifts versus the calculated ones is shown in Fig. 1b. It may be seen that data points line on the theoretical line. The fit to the least-squares line has a correlation coefficient of 0.933. This means that the calculation reproduces well the experiment.

The diamagnetic, paramagnetic, and total contributions for the ^{29}Si chemical shift calculated using the "new" value of β_{Si}(=−12 eV), together with the experimental values, are listed in Table 1. Note that the calculated chemical shift (σ) is a nuclear shielding constant, and so the negative sign means deshielding.

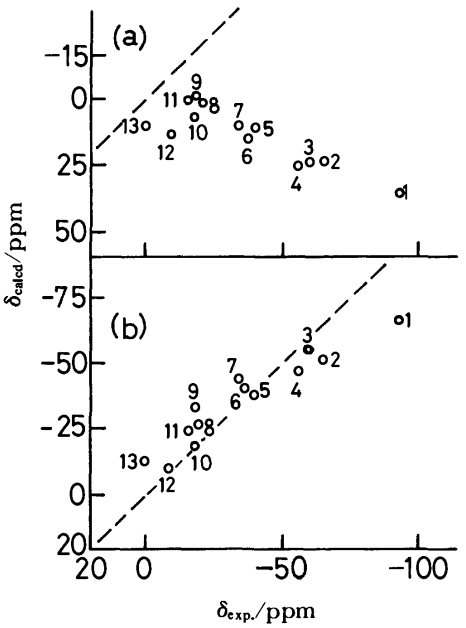

Fig. 1. The plot of the calculated ^{29}Si chemical shifts versus the experimental ones in silicon hydrides.
(a): Pople's β parameters (β_H=−9 eV, β_C=−21 eV, and β_{Si}=−13.065 eV). (b): β parameters proposed in this work (β_H=−13 eV, β_C=−15 eV, and β_{Si}=−12 eV).
The negative sign means upfield shift relative to TMS.
The numbers refer to the following compounds: 1: SiH_4; 2: SiH_3Me; 3: SiH_3Ph; 4: SiH_3Bz; 5: SiH_2Me_2; 6: SiH_2MePh; 7: SiH_2Ph_2; 8: $SiHMePh_2$; 9: $SiHPh_3$; 10: $SiHMe_2Ph$; 11: $SiHMe_3$; 12: $SiHPr_3$; 13: $SiHEt_3$.
The abbreviations used are as follows: Me, methyl; Ph, phenyl; Bz, benzyl; Pr, *n*-propyl; Et, ethyl.
The dashed line is the theoretical one with the slope of 1.0. This means that the experimental and calculated values completely agree with each other.

On the other hand, the negative sign of the experimental chemical shift (δ) means shielding. Therefore, tetramethylsilane was used as the standard reference. As may be seen from Table 1, the diamagnetic term, σ^d, moves upfield by about 2 ppm in going from SiH_4 to $SiHEt_3$. This variation is quite small, and the chemical-shift displacement is in the opposite direction compared with the experimental one. On the other hand, the paramagnetic term, σ^p, moves downfield by about 50—60 ppm. This means that the ^{29}Si chemical shift is predominantly governed by the paramagnetic term.

Next, we will consider the ^{29}Si chemical-shift behavior of organic silicon compounds containing the fluorine atom. The fluorine atom is known to be the most electronegative of all the atoms. This may be attributed to the effect of the higher electron unbalance in the Si-F bond and may lead to a wider range of ^{29}Si chemical shifts compared with the case of silicon-hydride compounds.

In the ^{29}Si chemical-shift calculation, the value of β_{Si} determined above in silicon-hydride compounds was used; also, as the β_F parameter for the fluorine atom, we adopted the value of −20 eV obtained by Ando et al.,[13] by the use of which the ^{19}F chemical-shift calculation reproduces the experiment reasonably well. The diamagnetic, paramagnetic, and total contributions calculated using these β parameters are listed, together with the experimental chemical-shift values, in Table 2. It may be seen that the chemical-shift range is more greatly expanded than in the case of silicon-hydride compounds. It may also be found that the relative chemical shift is

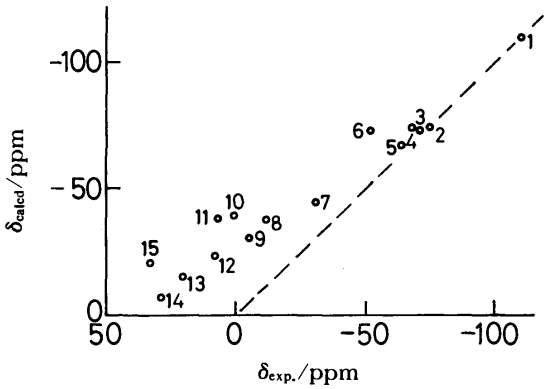

Fig. 2. The plot of the calculated ^{29}Si chemical shifts versus the experimental ones in fluorosilanes.
β bonding parameters (β_H=−13 eV, β_C=−15 eV, β_{Si}=−12 eV, and β_F=−20 eV). The negative sign means upfield shift relative to TMS.
The numbers refer to the following compounds: 1: SiF_4; 2: SiF_3Ph; 3: SiF_3PhMe; 4: SiF_3PhOMe; 5: SiF_3Bz; 6: SiF_3Me; 7: SiF_2Ph_2; 8: SiF_2MePh; 9: $SiFPh_3$; 10: SiF_2Et_2; 11: SiF_2Me_2; 12: $SiFMePh_2$; 13: $SiFMe_2Ph$; 14: $SiFPr_3$; 15: $SiFMe_3$.

predominantly governed by the paramagnetic term, although the diamagnetic term is more greatly varied by the degree of fluorine substitution than in the case of silicon-hydride compounds. A plot of the experimental chemical shifts versus the calculated ones is shown in Fig. 2. It may be seen that data points deviate slightly from the theoretical line with the slope of 1.0, but the overall trend of the experimental data is reproduced by the calculation. In particular, it can be said that it has been established that the ^{29}Si chemical shift in SiR_nF_{4-n} (R means the substitution group, and n, the substitution number) moves upfield as the degree of fluorine substitution is increased. (It is noticeable that the upfield shift with an increase in the degree of fluorine substitution is opposite to the case of the ^{13}C chemical shift in CR_nF_{4-n}.)

Finally, we will consider the relationship between the ^{29}Si chemical shift and the electron density. It has been reported that the ^{13}C chemical shift is closely related to the electron density on the carbon atom. The larger electron density on the carbon leads to the upfield shift. The calculated electron densities on the silicon atoms considered here are listed in Tables 1 and 2. It may be seen that the electron densities on silicon atoms in silicon-hydride compounds decrease as the degree of hydrogen substitution is increased, while those in SiR_nF_{4-n} decrease as the degree of electronegative fluorine substitution is increased. From Tables 1 and 2 it may also be seen that σ^d moves linearly upfield with an increase in the electron density on the silicon atom, as is to be expected from Eq. 2. The direction of such a shift is opposite to that of the experimental chemial shift. On the other hand, σ^p and σ^T move downfield, with a great scatter, with an increase in the electron density. Further, a plot of the experimental chemical shift versus the electron density on the silicon atom is shown in Fig. 3. The experimental chemical shifts move downfield, with a great scatter, with an increase in the electron density. The direction of such a shift is opposite to the general consideration that an increase in the electron density leads to an upfield shift. Therefore, it seems that it is difficult to explain the ^{29}Si chemical shift obtained experimentally only in terms of the electron density.

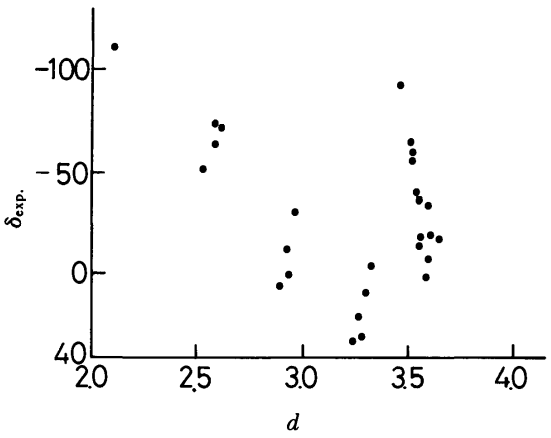

Fig. 3. The plot of the experimental ^{29}Si chemical shift $\delta_{exp.}$ against the calculated electron density d in organosilicon compounds.

From the above-mentioned results, it can be concluded that the experimental overall trend of ^{29}Si chemical shifts in sililcon hydrides and fluorine-containing organic compounds can be fairly reproduced by the FPT CNDO/2 method, with a small improvement of the β-bonding parameter.

(Received March 18, 1987)

The reaction of hydrogen atoms with trifluoroethylene has been studied at room temperature by using the mercury photosensitized decomposition of hydrogen as the source of hydrogen atoms. Product analyses using gas chromatography and ^1H and ^{19}F NMR spectroscopy confirmed the 1,2-migration of a fluorine atom in the CH_2FCF_2 radical produced by the addition of a hydrogen atom to trifluoroethylene. The rate constant of the migration was estimated to be 2×10^{10} s^{-1} from the pressure dependence of the five kinds of hexafluorobutanes produced. NMR parameters for these fluorinated compounds were determined.

When we consider the addition reaction of a free atom to the olefinic double bond of an organic compound in the gas phase, there arise two naive questions: One is which side of the double bond is attacked by the free atom, and the other is how the radical produced behaves before being thermalized.

In the case of a hydrogen atom-addition reaction to olefinic hydrocarbons, it has been established that a hydrogen atom is added to the less substituted carbon atom in the double bond and that no 1,2-migration of a hydrogen atom occurs in the radical produced.[1,2]

For the last few years, Rowland and his colaborators studied the reactions of radioactive ^{38}Cl atoms with a series of halogenated olefines,[3-5] and found that chlorine and bromine atoms in the produced radical often undergo a 1,2-migration in the radical produced by the addition of a ^{38}Cl atom to the olefin. In fact, the 1,2-migration of chlorine and bromine atoms has been reported even in the liquid phase reaction of complex organic compounds.[6]

In the case of a fluorine atom, however, no 1,2-migration has been reported in liquid phase reactions as far as we are aware. Siefert et al. have recently studied the reactions of recoiled tritium atoms with fluorinated olefins, using $^3He(n,p)T$ as the source of tritium atoms.[7] In a reaction with 1,2-difluoroethylene they found the formation of tritiated 1,1-difluoroethylene as one of the main products and suggested that the 1,2-migration of a fluorine atom occurs in the 1,2-difluoroethyl radical produced by the addition of a tritium atom to 1,2-difluoroethylene. Very recently, our laboratory has also studied the reactions of hot tritium atoms with fluorinated ethylenes ($CFH=CH_2$, $CF_2=CH_2$, and $CF_2=CFH$)[8] and found evidence for the 1,2-migration of a fluorine atom; however, in hot tritium atom reactions so many fragmental products were formed that evidence for the 1,2-migration could not be obtained straightforwardly. We, therefore, looked for a precise method to establish the 1,2-migration of a fluorine atom.

The reaction of hydrogen atoms with hydrocarbon olefins is a prototype subject for chemical kinetics and has been extensively studied.[9] The reaction with fluorinated olefins, however, has not been fully investigated, probably because of the difficulty to identify multi-fluorinated hydrocarbons. Most of these compounds are not commercially available. Scott and Jennings studied the reactions of hydrogen atoms with fluoroethylenes using the mercury photosensitized decomposition of hydrogen as the source of hydrogen atoms.[10] They used gas chromatography and mass spectroscopy for the analysis of products; however, the identification of several fluorinated hydrocarbons was not successful. Consequently, they did not propose a reaction mechanism for the formation of products in the reaction of hydrogen atoms with trifluoroethylene. They derived only the relative rate constants for the addition reactions.

Using this old technique, the mercury photosensitized decomposition of hydrogen as the source of hydrogen atoms, we have reinvestigated the reactions of hydrogen atoms with trifluoroethylene. For an analysis of products, ^1H and ^{19}F NMR spectroscopy were used along with gas chromatography and mass spectroscopy. As a result, we could confirm the 1,2-migration of fluorine atoms in a 1,1,2-trifluoroethyl radical as well as various interesting results.

Experimental

Trifluoroethylene was kindly supplied by Professor Ishikawa of this Institute and was used as received. Other fluorinated compounds used for the identification of products were CH_2FCHF_2 (PCR) and CF_3CH_3 supplied by Central Glass Co. Bottled hydrogen (Showa Denko Co.) and helium (Japan Helium Center), used as a reactant and a carrier gas in a gas chromatograph, respectively, were passed through liquid nitrogen traps before use.

One Torr (133.322 Pa) of trifluoroethylene and about 100 to 750 Torr of hydrogen were introduced into a reaction vessel (359 ml) made of fused quartz, into which a drop of mercury was present, and mixed by means of a glass-covered magnetic fan which could be rotated from outside using a magnet. This reactant mixture was irradiated by a mercury lamp (Sankyo GL6) for a certain time interval. The light intensity absorbed by mercury atoms was found to be 4.8×10^{15} photons/s (estimated by the mercury photosensitized decomposition of N_2O (110 Torr) in the presence of a small amount of butene-1 (5 Torr) on the assumption that the quantum yield of nitrogen is unity).[10] Irradiated samples were slowly pumped out through two long spiral glass traps cooled with liquid nitrogen. Condensed compounds were analyzed with a gas chromatograph equipped with a thermal conductivity detector (Shimadzu GC-6AM) using two columns (one contained dibutyl phthalate (8 m), and the other Porapak-S (4 m)) as well as a temperature-programed operation during chromatography (30 to 80 °C with the dibutyl phthalate column and 70 to 150 °C with Porapak-S column). Reaction products of eleven compounds were found, out of which seven could be identified by using ^1H and ^{19}F NMR spectra obtained with a JEOL FX-90Q spectrometer. Each sample analyzed was the accumulation of 10 to 20 runs of the photochemical reaction.

Results

Identification of Products. The eleven peaks observed with a gas chromatograph of dibutyl phthalate column were named alphabetically from A to K in the order of their retention times (Fig. 1a). When using a Porapak-S column (Fig. 1b), peak A was clearly separated into two peaks; the one named T was a reactant, trifluoroethylene, and the other named A′ was later identified as CF_3CH_3. Since with this column compounds D, F, H, I, J, and K (later identified as mainly fluorinated C_4 compounds with retention times longer than 15 min) were clearly separated from compounds T, A′, B, C, and E (with retention times shorter than 15 min), quantitative gas chromatograms could be obtained by increasing the column temperature from 70 to 150 °C between these two groups of compounds. No authentic samples, except for A′ and E, were available. The relative response of the peak area against the absolute amount was assumed to be 1 to 2 for the C_2 compounds group to the C_4 compounds group, since with this column, the relative sensitivities of C_2—C_4 hydrocarbons for the thermal conductivity detector were found to be proportional to the molecular weight.[11]

Table 1 summarizes the identified products. In the Appendix, their experimental NMR parameters are described. Peaks B and C were too small to be identified. Two compounds corresponding to F and G were also too small and were found to be secondary products (as shown later).

Irradiation Time and Pressure Dependence of Products. Figure 2 shows the irradiation time dependence of the products. The relative yield of 1.0 corresponds to 0.20 μmol. All products, except F and G, were found to be linearly dependent upon the irradiation time. Table 2 summarizes the relative amounts of each product obtained as a function of the hydrogen pressure. The pressure of trifluoroethylene was 1 Torr and the irradiation time was 6 min.

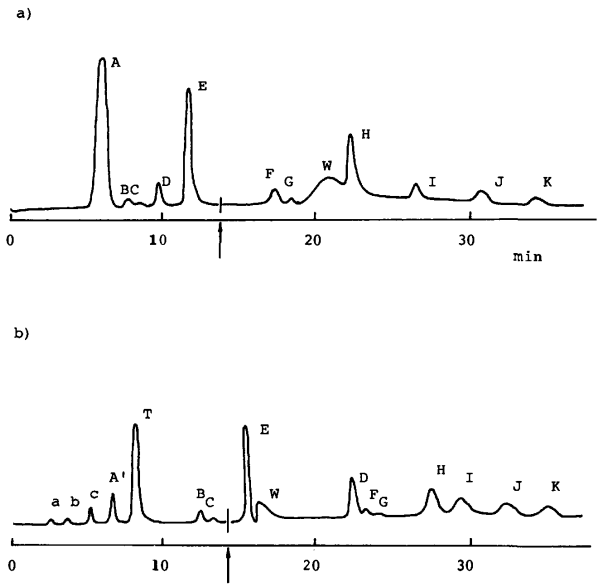

Fig. 1. (a) A typical gas chromatogram obtained with the dibutyl phthalate column. The arrow indicates the start of temperature programed operation from 30 to 80 °C with the rate of 15° min^{-1}. W: Water trapped from the carrier gas. (b) A gas chromatogram obtained with the Porapak S column. The arrow indicates the start of temperature programed operation from 70 to 150 °C with the rate of 5° min^{-1}. a—c were not identified.

Table 1. Identification of Reaction Products

A′	CF_3CH_3
E	CH_2FCHF_2

H	$CF_3CH_2CF_2CH_2F$
I	$CF_3CH_2CHFCHF_2$
J	$CH_2FCF_2CF_2CH_2F$
K	$CH_2FCF_2CHFCHF_2$

Discussion

At very low hydrogen pressures (lower than 50 Torr), the formation of fragmental products such as $CF_2{=}CH_2$ and probably $CF{\equiv}CH$ has been found; however, we ignore them in the present discussion because it is well-known that most of the 253.7-nm resonance line is absorbed within a zone of 1 cm from the window of the reaction vessel and the radicals primarily produced, including hydrogen atoms,

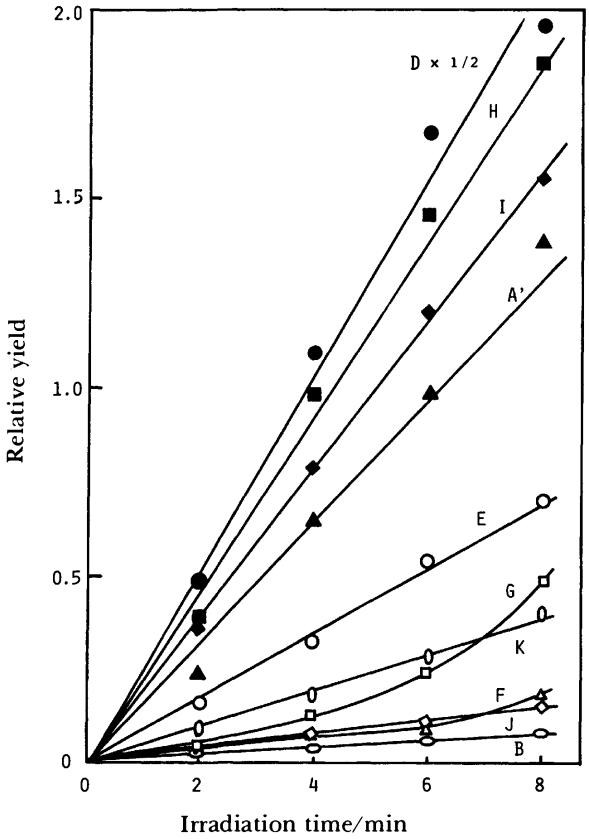

Fig. 2. Irradiation time dependence of the amounts of products. Initial hydrogen pressure is 109.5 Torr and trifluoroethylene is 1 Torr. Relative yield 1.0 corresponds to 0.20 μmol.

Table 2. Hydrogen Pressure Dependence of the Relative Amounts of Products.[a] Trifluoroethylene Pressure is 1 Torr and Irradiation Time is 6 min.

Hydrogen pressure (Torr) Product	19.1	59.1	109.5	516.0	754.9
A′	0.484	0.840	0.976	1.264	1.200
D	2.18	3.23	3.36	1.44	1.14
E	n.d.[b]	0.464	0.524	0.984	1.12
H	1.37	1.59	1.46	1.88	1.98
I	0.808	1.14	1.20	0.624	0.592
J	0.020	0.032	0.113	0.380	0.722
K	0.086	0.130	0.288	0.396	0.596

a) Relative yield 1.0 corresponds to 0.20 μmol. b) Not determined.

diffuse to the quartz surface and react differently from a gas-phase reaction.

Initial reactions may be described as follows:

$$Hg(^1S_0) + h\nu \longrightarrow Hg(^3P_1) \quad (1)$$

$$Hg(^3P_1) + H_2 \longrightarrow Hg(^1S_0) + 2H \quad (2)$$

$$H + CF_2=CFH \longrightarrow \dot{C}F_2CFH_2 \quad \alpha \quad (3)$$

$$\longrightarrow CF_2H\dot{C}FH \quad 1-\alpha. \quad (4)$$

Here, α and $1-\alpha$ denote the fractions of the Markovnikov and anti-Markovnikov additions, respectively. No other reactions such as the formation of HF are considered, since the formation of fragmental products has not been observed at hydrogen pressures higher than 50 Torr.

From two kinds of radicals, $\dot{C}F_2CFH_2$ and $CF_2H\dot{C}FH$, we can expect the formation of following products as the result of radical reactions, if no 1,2-migration of F or H atom is considered.

$$\dot{C}F_2CFH_2 + \dot{C}F_2CFH_2 \longrightarrow CFH_2CF_2CF_2CFH_2 \text{ (J)} \quad (5)$$
$$\longrightarrow CF_2=CFH \text{ (T)} + CF_2HCFH_2 \text{ (E)}$$

$$\dot{C}F_2CFH_2 + CF_2H\dot{C}FH \longrightarrow CFH_2CF_2CFHCF_2H \text{ (K)} \quad (6)$$
$$\longrightarrow CF_2=CFH \text{ (T)} + CF_2HCFH_2 \text{ (E)}$$

$$CF_2H\dot{C}FH + CF_2H\dot{C}FH \longrightarrow CF_2HCFHCFHCF_2H \text{ (L)} \quad (7)$$
$$\longrightarrow CF_2=CFH \text{ (T)} + CF_2HCFH_2 \text{ (E)}$$

Here, the disproportionation reaction accompanied by a fluorine-atom transfer is not taken into consideration, since the expected products have not been observed. Compound L appearing in Reaction 7 has not been observed in the experiments. Judging from the retention times of other products, Compound L probably has a very long retention time and the amount produced may be smaller than other C_4 compounds (discussed later).

Obviously, Reactions 5 to 7 cannot explain the formation of products A′, D, H, and I. We, thus, propose the following 1,2-migration of a fluorine atom in the 1,1,2-trifluoroethyl radical:

$$\underset{1-\beta}{\dot{C}F_2CFH_2} \longrightarrow \underset{\beta}{CF_3\dot{C}H_2}. \quad (8)$$

Here, β denotes the fraction of the radicals which undergo a 1,2-migration and proceed to the following radical reactions:

$$CF_3\dot{C}H_2 + CF_3\dot{C}H_2 \longrightarrow CF_3CH_2CH_2CF_3 \text{ (D)} \quad (9)$$

$$CF_3\dot{C}H_2 + \dot{C}F_2CFH_2 \longrightarrow CF_3CH_2CF_2CFH_2 \text{ (H)} \quad (10)$$
$$\longrightarrow CF_3CH_3\text{(A′)} + CF_2=CFH \text{ (T)}$$

$$CF_3\dot{C}H_2 + CF_2H\dot{C}FH \longrightarrow CF_3CH_2CFHCF_2H \text{ (I)} \quad (11)$$
$$\longrightarrow CF_3CH_3\text{(A′)} + CF_2=CFH \text{ (T)}.$$

In order to estimate α and β, we assume that all radical Reactions 5—7 and 9—11 occur proportionally to the collision number of radicals and let R1, R2, and R3 denote $\dot{C}F_2CFH_2$, $CF_3\dot{C}H_2$ and $CF_2H\dot{C}FH$ radicals, respectively; then, we can obtain the following equations:

$$[R1] : [R2] : [R3] = \alpha(1-\beta) : \alpha\beta : 1-\alpha, \quad \text{(I)}$$

$$a \times [R1] = 2[J] + [H] + [K] + 2N_1[E] + M_1[A'], \quad \text{(II)}$$

$$a \times [R2] = [H] + 2[D] + [I] + [A'], \quad \text{(III)}$$

$$a \times [R3] = [K] + [I] + 2[L] + 2N_2[E] + M_2[A'], \quad \text{(IV)}$$

and $N_1 + N_2 = 1$ and $M_1 + M_2 = 1$.

Here a is a proportional constant. N_1 and N_2 are the relative amounts of product E produced through Reactions 6 and 7, respectively. Similarly, M_1 and M_2 are the relative amounts of product A' produced through Reactions 10 and 11, respectively. These relative values may be expressed as follows:

$$N_1/N_2 = (1-\beta)/(1-\alpha)[\alpha^2(1-\beta) + 4\alpha(1-\alpha)]/[1-\alpha+4(1-\beta)], \text{ and} \quad \text{(V)}$$

$$M_1/M_2 = \alpha(1-\beta)/(1-\alpha). \quad \text{(VI)}$$

When two radicals, X and Y, are recombined at random, the relative amounts of products X_2, XY, and Y_2 can be expressed as $[XY]^2=4[X_2][Y_2]$. The amount of Compound L may be estimated by using the following equation from the amounts of Compounds J and K:

$$[L] = [K]^2/4[J]. \quad \text{(VII)}$$

Figure 3 shows the values of α and β calculated by using Eqs. I to VII as a function of the hydrogen pressure. Obviously, the α value was found to be 0.84, independent of the pressure (as it should be), while the β value was found to be pressure dependent (0.79 at 50 Torr and 0.50 at 750 Torr). This dependence may be explained by the competition between 1,2-fluorine-atom migration in the energy rich radical produced by a hydrogen atom addition reaction and a deactivation of this radical by a collision with a third body, mainly hydrogen molecules in the present system. Reactions 3 and 8 may be rewritten as follows:

$$H + CF_2{=}CFH \longrightarrow \dot{C}F_2CFH_2^*, \quad (3')$$

$$\dot{C}F_2CFH_2^* \underset{k_b}{\overset{k_f}{\rightleftharpoons}} CF_3\dot{C}H_2^*, \quad (8')$$

$$\dot{C}F_2CFH_2^* \xrightarrow{+M} \dot{C}F_2CFH_2, \quad (12)$$

$$\text{and } CF_3\dot{C}H_2^* \xrightarrow{+M} CF_3\dot{C}H_2. \quad (13)$$

Here, k_f and k_b are the rate constants of the forward and reverse isomerization reactions, and M denotes the third body.

A steady state treatment gives

$$(1-\beta)/\beta = k_f/k_b + (z/k_f)[M]. \quad \text{(VIII)}$$

Here, z is the collision number between a radical and a third body; $z=k_{12}=k_{13}$ is assumed. The value of z can be calculated from the collision diameters of the radical and a hydrogen molecule; σ(radical)$\approx\sigma$(ethane)=3.54 A and (H_2)=2.57 A.[12] Figure 4 shows plots of $(1-\beta)/\beta$ as a function of the hydrogen pressure. Although the expected linearity is not so good, we can estimate $k_f=2\times10^{10}$ s^{-1} from the slope and k_b/k_f to be 0.2 from the intercept; this corresponds to the equilibrium constant between two energy rich radicals, $\dot{C}F_2CFH_2^*$ and $CF_3\dot{C}H_2^*$.

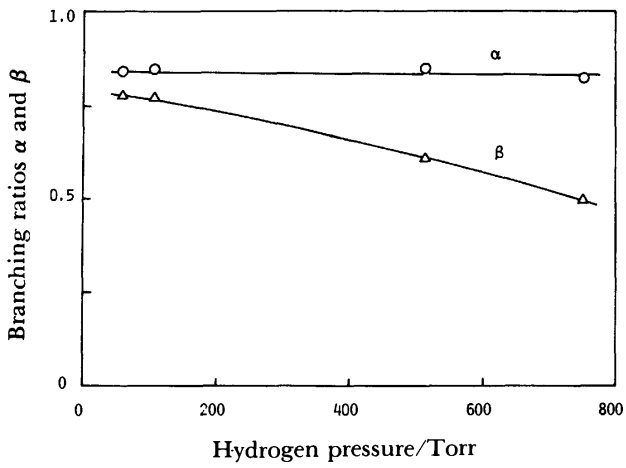

Fig. 3. The branching ratios α and β as functions of hydrogen pressure.

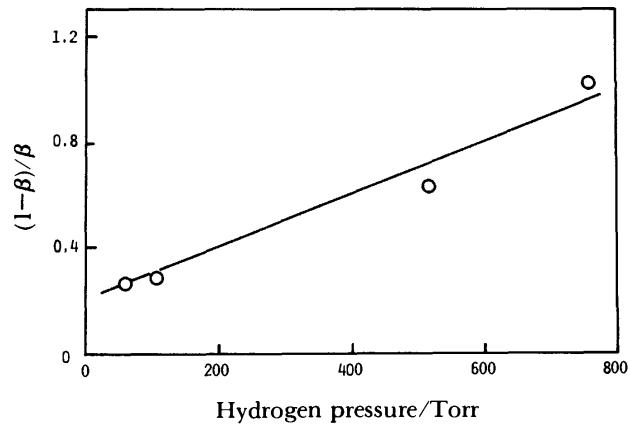

Fig. 4. The plots of $(1-\beta)/\beta$ as a function of hydrogen pressure.

In the above treatment, we ignored the reactions between radicals and the reactant olefin since if R1, R2, and R3 radicals have the same reactivity to the olefin, the above treatment for obtaining the relative ratios, α and β, are not affected by these reactions. Moreover, in this series of experiments, we did not observe the deposition of polymers on the wall of the reaction vessel. This suggests that the reactions leading to the formation of C_6 and/or heavier compounds may be ignored in the present system.

In this report, the 1,2-migration of a fluorine atom in the energy rich trifluoroethyl radical has been phenomenologically proved; however, as described in the Introduction, it is known that the 1,2-migration of a hydrogen atom in an ethyl radical does not occur under similar conditions, in spite of the fact that the binding energy of the C-F bond is usually larger than that of the C-H bond. We, therefore, carried out INDO molecular orbital calculations for these 1,2-migrations. The preliminary results showed that the

fluorine atom migration is much easier than the hydrogen atom migration in partially fluorinated ethyl radicals.[8] More extensive calculations are being undertaken.

Influence of Br^- Concentration on $(Br)^+$-Mediated Indirect Electrooxidation of Alcohols to the Corresponding Carbonyl Compounds

Tsuyoshi TAKIGUCHI and Tsutomu NONAKA*
Department of Electronic Chemistry, Tokyo Institute of Technology,
4259 Nagatsuta, Midoriku, Yokohama 227
(Received March 19, 1987)

Current efficiency for the $(Br)^+$(positive bromine species)-mediated indirect electrooxidation of alcohols to the corresponding carbonyl compounds decreased with increase in Br^- concentration in dichloromethane and aqueous acidic solutions, while no concentration dependence was observed in an aqueous neutral solution. These facts suggested a general and practical guideline for the indirect electrooxidation, i.e. low Br^- concentration is favorable in an electrolytic solution of low nucleophilicity. It was also found that the kind of $(Br)^+$ species formed anodically in the absence of the alcohols in dichloromethane clearly depended on charge(Q) passed as follows: Br_3^- at $Q \leqslant 2/3$ F mol^{-1} (1F=96480 C), Br_n^- ($n>3$) at $2/3<Q<1$ F mol^{-1}, and Br_2 at $Q=1$ F mol^{-1}. Among these species, Br_3^- and Br_2 seemed to be the weakest and strongest oxidizing agents, respectively. Lower efficiency for the indirect electrooxidation in higher Br^- concentration was rationalized as due to more predominant formation of Br_3^- and/or Br_n^- with smaller n values.

It is well-known that indirect electrolysis using redox couples as mediators for electron transfer between electrodes and substrates is one of very useful methods in electroorganic synthesis.[1,2] Among the redox couples, halide(X^-)/positive halogen species-[$(X)^+$] couples have been often used in the indirect electrooxidation of organic compounds.[2]

Recently an interesting phenomenon has been found in the $(X)^+$-mediated indirect electrooxidation: Increase in X^- concentration results in decrease in current efficiency and/or yield.[3-5] In this work, some additional examples of this kind of phenomenon were also found in the $(Br)^+$-mediated oxidation of alcohols to the corresponding carbonyl compounds. This fact seems to indicate that the phenomenon is considerably universal. Since the $X^-/(X)^+$ mediators can be regarded as electrocatalysts, an apparently paradoxical theorem, the smaller amounts of catalyst used, the more smoothly the reaction proceeds, may be induced from the phenomenon.

Although it has been postulated that the $(X)^+$-mediated oxidation involves X^+, X_3^-, X_2, and/or XO^- as the oxidizing agents, their formation and behavior during electrolysis have not been clarified so far. In this work, the formation and behavior of some kinds of $(Br)^+$ species in dichloromethane were investigated by means of electrochemistry and UV-spectroscopy, and also the above strange phenomenon was rationalized as due to low oxidizing power of Br_3^- species which is formed preferentially in high Br^- concentration or at small amounts of charge passed under indirect electrolysis conditions.

Results and Discussion

Influence of Br^- Concentration on $(Br)^+$-Mediated Indirect Electrooxidation of Alcohols. It is known that benzyl alcohol[6] and 2,3-butanediol[7] can be efficiently oxidized to benzaldehyde and acetoin, respectively, by using a $Br^-/(Br)^+$ redox mediatory system. In this work, first the influence of Br^- concentration on current efficiencies for the products was examined in dichloromethane and aqueous solutions. The current efficiencies were determined by analyzing the anodic solutions in which unreacted $(Br)^+$ species were quenched with $NaHSO_3$ just after the electrolyses finished. As shown in Fig. 1, the current efficiencies decreased with increase in Br^- concentration in the oxidation of either benzyl alcohol or 2,3-butanediol at a platinum anode in n-Bu_4NBr-0.2 M (1 M=1 mol dm^{-3}) n-Bu_4NClO_4/dichloromethane containing 3 equiv 2,6-lutidine. Shorter electrolysis time was required in higher Br^- concentration because of larger electrolytic current. However, no dependence of the electrolysis time on the efficiency was observed when a smaller anode, which

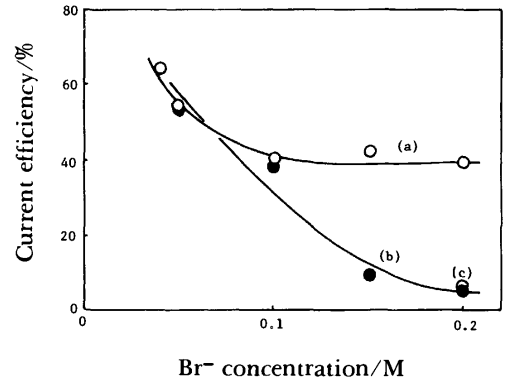

Fig. 1. Influence of Br^- concentration on current efficiency for products in the $(Br)^+$-mediated indirect electrooxidation of alcohols at a platinum anode (5.5 cm^2) in 0.2 M n-Bu_4NClO_4/CH_2Cl_2 containing n-Bu_4NBr and 2,6-lutidine. (a) Oxidation of benzyl alcohol to benzaldehyde at 1.7 F mol^{-1} of charge passed at 1.4 V vs. SCE. (b) Oxidation of 2,3-butanediol to acetoin at 2.0 F mol^{-1} at 1.3 V. (c) Electrolysis similar to (b) using a smaller anode (1.5 cm^2).

required longer electrolysis time, was used (See Fig. 1(c)). This fact indicates that the concentration dependence results directly from concentration effects of Br^- in the anodic solution. A cyclic voltammogram of Br^- gave two oxidation peaks at 0.8 and 1.0 V vs. SCE (See Fig. 3(b)). The oxidation of 2,3-butanediol in a first peak potential region could scarecely proceed even in low Br^- concentration (0.05 M).

A similar concentration dependence was also found in the oxidation of 2,3-butanediol in an acidic aqueous solution (0.2 M H_2SO_4), while no dependence in a neutral solution (0.3 M KH_2PO_4–0.3 M Na_2HPO_4) (See Fig. 2).

The above results may give general guidelines for synthetic use of the $(Br)^+$-mediated indirect electrooxidation: (a) To choose reaction media taking into account their nucleophilicity, (b) to electrolyze at potentials more positive than the second oxidation peak potential of Br^-, and (c) to use auxiliary supporting electrolytes when low Br^- concentration is inevitably required.

An Synthetic Application of the $(Br)^+$-Mediated Indirect Electrooxidation of Benzyl Alcohols with Electron-Withdrawing Groups to the Corresponding Benzaldehydes. Benzaldehydes are very important starting compounds for production of a variety of useful organic chemicals and one of the most common synthetic methods is either chemical or electrochemical oxidation of the corresponding toluenes. However, any practical synthetic method of pentafluorobenzaldehyde, which must be an important compound as a building block for synthesis of useful aromatic fluorine compounds, has not been established, because 2,3,4,5,6-pentafluorotoluene can be prepared only with great difficulty. We have recently reported an efficient conversion method of commercially-available pentafluorobenzoic acid into 2,3,4,5,6-pentafluorobenzyl alcohol.[8] In this work, it was also found that pentafluorobenzyl alcohol could be oxidized by the $(Br)^+$-mediated electrolysis to give pentafluorobenzaldehyde as a sole product without any further oxidation to pentafluorobenzoic acid. These facts suggest a possibility of the conversion of pentafluorobenzoic acid into pentafluorobenzaldehyde via pentafluorobenzyl alcohol.

In addition, a nitro-substituted benzyl alcohol, which is hardly oxidized due to the electron-withdrawing effect of nitro group, could be oxidized in a similar manner.

Electrolytic results obtained are summarized in Table 1.

Cyclic Voltammetric Behavior of Br^- and $(Br)^+$ Species. Anodic behavior of Br^- in organic solvents may be generally characterized by two oxidation waves which indicate the occurrence of the following reactions from wave height ratio:[9,10]

$$3Br^- \longrightarrow Br_3^- + 2e \text{ at the lst wave} \quad (1)$$

$$Br_3^- \longrightarrow \frac{3}{2}Br_2 + e \text{ at the 2nd wave} \quad (2)$$

Figures 3(b) and (c) show cyclic voltammograms of Br^- measured at a platinum electrode in dichloromethane. The above reactions seem to be responsible for two oxidation peaks (P_{a2} and P_{a1}) observed. In the curve(c) which was returned at 1.4 V, a small cathodic peak (P_{c1}) was observed. This may be responsible for the reduction of Br_2 to Br_3^-. When benzyl alcohol was added (See the curve (e)), any change of the two peaks (P_{a2} and P_{a1}) was not observed. In addition, the oxidation peak of benzyl alcohol, which appeared in a potential range more positive than 1.8 V, did not significantly decrease. These facts suggest that the oxidation of the alcohol by $(Br)^+$ species formed at P_{a2} is not fast.

Br_3^- may be formed by the reaction of Br^- with Br_2 generated at an anode.[10]

$$Br_2 + Br^- \rightleftharpoons Br_3^- \quad (3)$$

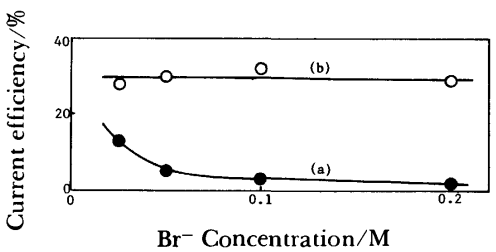

Fig. 2. Influence of Br^- concentration on current efficiency for acetoin in the $(Br)^+$-mediated indirect electrooxidation of 2,3-butanediol at a graphite anode (5.5 cm^2) in aqueous solutions. (a) Electrolysis at 1.5 F mol^{-1} of charge passed at 1.4 V vs. SCE in 0.2 M H_2SO_4. (b) Electrolysis at 2.0 F mol^{-1} at 1.2 V in 0.3 M KH_2PO_4–0.3 M Na_2HPO_4.

Table 1. The $(Br)^+$-Mediated Indirect Electrooxidation of Benzyl Alcohols to the Corresponding Benzaldehydes

Benzyl alcohol	Anode potential[a] V vs. SCE	Conversion %	Yield[b] of benzaldehyde %	Current efficiency %
Benzyl alcohol	1.4	89	83	46
p-Nitro-benzyl alcohol	2.0	79	65	31
Penta-fluoro-benzyl alcohol	2.0	57	67	22

a) 3.3 F mol^{-1} of charge were passed at potentials less positive than those for oxidation of the starting benzyl alcohols themselves in the presence of Br^- (0.05 M). b) Based on benzyl alcohols consumed.

It is well-known that Br_3^- is much less active than Br_2 as a oxidizing agent.[11-13] Therefore, lower current efficiency for the $(Br)^+$-mediated indirect electrooxidation in higher Br^- concentration (See Fig. 1) can be rationalized as due to more smooth formation of Br_3^-. In the neutral aqueous solution which has a higher nucleophilicity than the acidic aqueous and dichloromethane solutions, no dependence of Br^- concentration was observed as shown in Fig. 2(b). This may be rationalized as due to the formation of another active $(Br)^+$ species as shown below:[11]

$$Br_2 + H_2O \longrightarrow HBrO + HBr \quad (4)$$

At the next stage of investigation, cyclic voltammetric behavior of Br_2 was examined in dichloromethane. As shown in Figs. 4(a)—(c), Br_2 showed many reduction and oxidation peaks, among which P_{c1}, P_{c2}, P_{a2}, and P_{a1} seemed to be responsible for the following reactions:

$$Br_2 + \frac{2}{3}e \underset{P_{a1}}{\overset{P_{c1}}{\rightleftharpoons}} \frac{2}{3}Br_3^- \quad (5)$$

$$\frac{2}{3}Br_3^- + \frac{4}{3}e \underset{P_{a2}}{\overset{P_{c2}}{\rightleftharpoons}} 2Br^- \quad (6)$$

However, any reactions responsible for the other peaks (P_{c3}, P_{a4}, and P_{a3}) could not be reasonably thought out.

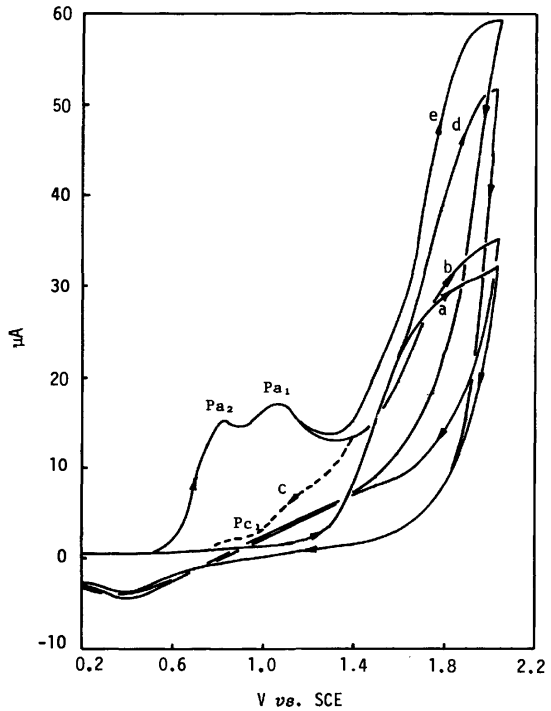

Fig. 3. Cyclic voltammograms of Br^- at a platinum electrode (1.3 mm^2) in the presence of benzyl alcohol. (a) Background solution, 0.1 M n-Bu_4NClO_4/CH_2Cl_2. (b) 5 mM n-Bu_4NBr. (c) 5 mM n-Bu_4NBr (returned at 1.4 V vs. SCE). (d) 10 mM benzyl alcohol. (e) 5 mM n-Bu_4NBr-10 mM benzyl alcohol. Scan rate: 0.1 V s^{-1}.

As shown in Fig. 4(d), the addition of 1 equiv Br^- resulted in a decrease of P_{c1} and increases of P_{a2} and P_{a1}. However, P_{c2} disappeared unexpectedly, while a new peak (P_{c4}) appeared in a negative potential range around −1.8 V but a reaction responsible for this peak also could not be thought out.

UV-Spectroscopic Study of $(Br)^+$ Species Formed Chemically and Electrochemically. Considerable ambiguity has been ramained in the above analysis of the cyclic voltammetric behavior of Br^- and Br_2. Therefore, next it was attempted to identify $(Br)^+$ species by UV-spectroscopy.

Figures 5(a) and (b) show the spectra of Br_2(λ_{max} 230 nm) and Br^-(λ_{max} 231 nm), respectively. A mixture of 2 mM Br_2 and 0.03 mM Br^- gave the spectrum(c) consisting of an absorption peak for Br_2 with an almost equal height to that in the spectrum(a) and a new peak at λ_{max} 271 nm. The height of this new peak increased in proportion to Br^- concentration (See spectra(c)—(e)), while the Br_2 peak decreased gradually (spectra(c), (d)) and disappeared in the concentration equivalent to Br_2(spectrum(e)). As shown in the spectrum(f), the presence of excess Br^- resulted in no change in height of the new peak and in appearance of the Br^- peak as a shoulder. Formation constants of Br_3^- on the basis of Eq. 3 are as extremely large as 10^7—10^9 in aprotic solvents.[14] Gabes and Stufkens[15] reported the λ_{max} and ε_{max} of Br_3^-

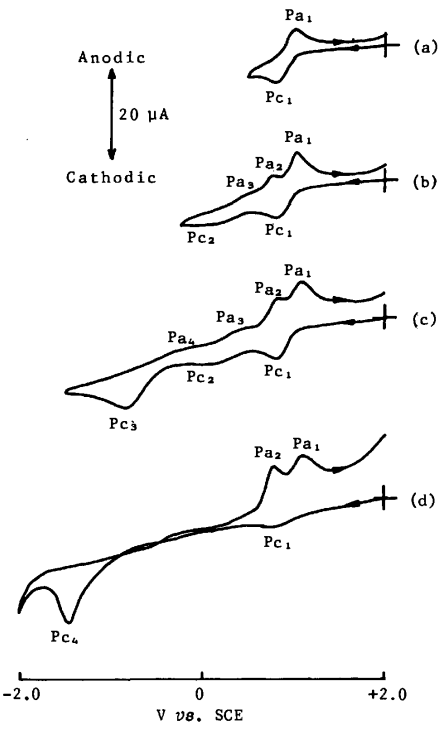

Fig. 4. Cyclic voltammograms of Br_2 at a platinum electrode (1.3 mm^2) in 0.1 M n-Bu_4NClO_4/CH_2Cl_2. (a)—(c) 2 mM Br_2. (d) 2 mM Br_2+2 mM n-Bu_4NBr. Scan rate: 0.1 v s^{-1}.

(a) 2 mM Br_2. (b) 2 mM n-Bu_4NBr. (c) 2 mM Br_2+0.03 mM n-Bu_4NBr. (d) 1 mM Br_2+2 mM n-Bu_4NBr. (e) 2 mM Br_2+2 mM n-Bu_4NBr. (f) 2 mM Br_2+1 mM n-Bu_4NBr.

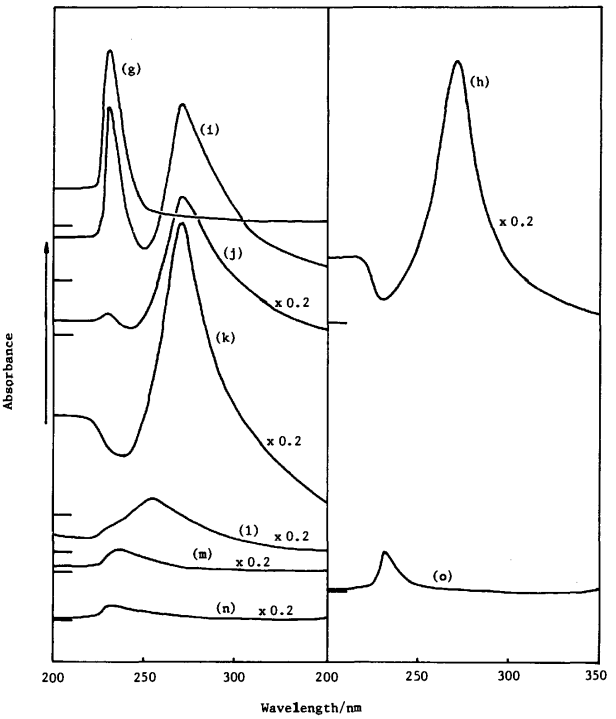

Fig. 6. Changes in UV-spectra of 50 mM n-Bu_4NBr/CH_2Cl_2 with increase in charge passed at a platinum anode (5.5 cm^2). The spectra were measured after diluted fifty times. (g) 50 mM n-Bu_4NBr. (h) 0.70 F mol^{-1} at 1.0 V vs. SCE. (i) 0.06 F mol^{-1} at 1.7 V. (j) 0.28 F mol^{-1} at 1.7 V. (k) 0.67 F mol^{-1} at 1.7 V. (l) 1.00 F mol^{-1} at 1.7 V. (m) 1.10 F mol^{-1} at 1.7 V. (n) 1.13 F mol^{-1} at 1.7 V. (o) 1.10 F mol^{-1} at 2.0 V.

in dichloromethane to be 272 nm and 46600, respectively. Based on these facts observed in this work and reported in the literatures, the new peak was assigned to Br_3^- and its ε_{max} was estimated to be ca. 47000. It is hereby confirmed that Br_3^- is formed almost quantitatively through the reaction shown in Eq. 3 and any $(Br)^+$ species can not be formed in dichloromethane even if excess Br_2 were used.

Figure 6 shows spectra of anodic solutions (50 mM n-Bu_4NBr/CH_2Cl_2) which were electrolyzed by passing various amounts of charge at various potentials using a platinum anode in a divided cell. The spectrum(g) was measured before the electrolysis. When the solution was electrolyzed coulometrically at 1.0 V, the electrolytic current diminished to a residual current level at 0.70 F mol^{-1} (1 F=96480C) of charge passed. Spectrum(h) of the solution after the electrolysis showed a Br_3^- peak, of which height corresponded to 15 mM of Br_3^- concentration, and no Br^- peak. This fact indicates the almost complete occurrence of the reaction shown in Eq, 1, if the reaction mechanism is left out of consideration, since the theoretical Br_3^- concentration is calculated to be 17 mM.

Larger amounts of charge could be passed at more positive potentials. Figures 6(i)—(n) are spectra of the solutions electrolyzed at 1.7 V. When 0.06—0.67 F mol^{-1} were passed, the concentrations of Br_3^- and Br^- were estimated from their peak heights (spectra(i)—(k)) as follows: 1.9 mM Br_3^- (theoretical, 1.5 mM) and 49 mM Br^-(theoretical, 46 mM) at 0.06 F mol^{-1}; 8 mM Br_3^-(theoretical, 7 mM) and 31 mM Br^-(theoretical, 29 mM) at 0.28 F mol^{-1}; 17 mM Br_3^-(theoretical, 17 mM) and 0 mM Br^-(theoretical, 0 mM) at 0.67 F mol^{-1}. These aqreements of found values of the concentrations with the theoretical ones indicate the predominant occurrence of the reaction shown in Eq. 1. However, a strange phenomenon was observed at charge more than 0.67 F mol^{-1} which is the theoretical amount based on Eq. 1.

As shown in Fig. 6(l) and (m), a new peak appeared, while the Br_3^- peak disappeared. Moreover, the λ_{max} and height of this new peak shifted to shorter wavelengths and decreased, respectively, though the Br_3^- and Br_2 peak heights should decrease and increase, respectively, with increase in charge passed if the Eq. 2 reaction occurred following Eq. 1.[9,10] A small Br_2 peak could be observed only as a shoulder in the spectrum(l). When a slightly larger amount of

charge than 1 F mol^{-1}, which is the theoretical amount based on the combination of Eqs. 1 and 2, was passed, the electrolytic current diminished to the residual current level and the new peak apparently overlapped the Br_2 peak. However, Br_2 concentration calculated from the overlapped peak was as much higher as 60 mM than the theoretical value (25 mM). This fact means the peak contains a contribution of another component which has a larger ε_{max} than that of Br_2. The electrolysis at a more positive potential such as 2.0 V resulted in the formation of Br_2(found, 23 mM; theoretical, 25 mM) (See spectrum(o)).

It was also confirmed by iodometry using $Na_2S_2O_3$ that the anodic solutions always had oxidizing capacities equivalent to amounts of charge passed at all the potentials used.

From the results obtained above, it is likely that the peaks observed in the spectra(l)—(n) are assigned to polybromides(Br_n^-, $n>3$) of which the possible preparation as the corresponding quaternary ammonium salts (n=5, 7, 8, 9, 11, and 33) by the direct reaction of bromide salts with liquid or gaseous Br_2 has been reported,[16-18] though only an uncertain evidence for the formation of Br_5^- in solutions has been reported.[19] It is noticeable that a possibility for the formation of Br_n^- ($n>3$) by the anodic oxidation of Br^- in solutions was suggested in this work.

Conclusion

(a) The formation of Br_3^- depends not on potential(E) as indicated by Eqs. 1 and 2 but on charge(Q) passed as shown below.

$$Q \leqslant \frac{2}{3}\text{F mol}^{-1};\ E\text{, independent:}$$

$$2Br^- \xrightarrow{-2e} [Br_2] \xrightarrow{Br^-} Br_3^- \qquad (7)$$

(b) The formation of Br_n^- ($n>3$) occurs by a cascade type of reactions shown below. The reactions depend on both E and Q, in other words n is a function of E and Q.

$$\frac{2}{3}<Q<1\ \text{F mol}^{-1};\ 1<E<2\ \text{V vs. SCE:}$$

$$Br_3^- \longrightarrow \frac{3}{4}Br_4^- + \frac{1}{4}e$$

$$Br_4^- \longrightarrow \frac{4}{5}Br_5^- + \frac{1}{5}e$$

$$\cdots\cdots\cdots\cdots\cdots\cdots$$

$$Br_{n-1}^- \longrightarrow \frac{n-1}{n}Br_n^- + \frac{1}{n}e \qquad (8)$$

Remarkably sensitive changes observed in the spectra of Br_n^- with increase in Q can be reasonably rationalized as due to the occurrence of this type of reactions.

(c) The formation of Br_2 as a final product occurs when 1 F mol^{-1} is completely passed at potentials more positive than 2 V. $\lim_{n\to\infty} Br_n^-$ actually corresponds to Br_2.

(d) The order of oxidizing powers of $(Br)^+$ species is speculated as below.

$$Br_3^- < Br_4^- < \cdots\cdots < Br_n^- < \cdots\cdots < Br_2$$

(e) Low current efficiency for the $(Br)^+$-mediated indirect electrooxidation in high Br^- concentration is explained on the basis of the above items(a)—(d). Therefore, it is recommended for efficient $(Br)^+$-mediated indirect electrooxidation to use low Br^- concentration and positive potential as possible: It is undesirable to make bromide salts serve a double purpose for the mediator and supporting electrolyte, since their concentration must be so high that electroconductivity of the electrolytic solutions is high enough. It is also recommended to use large amounts of other salts, which can play a role as the supporting electrolytes, in addition to small amounts of bromides, in order to perform the electrolysis at a satisfactorily low cell voltage.

Experimental

Materials. All the chemicals were commercially supplied and were used, if necessary, after purification by common methods. Platinum electrodes, which were used as the working electrodes, were polished with alumina powder and washed with acetone before used. Graphite electrodes were also polished with an emery paper (No. 1200), washed with water, polished again with the emery paper, and then washed with acetone. Platinum counter electrodes were used after treatment with diluted nitric acid.

Controlled-Potential Electrolysis. All the macro electrolyses of the alcohols were carried out using 40 cm^3 of anodic solutions in a divided cell at room temperature. The electrolyses of Br^- were also carried out in a similar manner.

Product Analysis. Anodic solutions were subjected to gas chromatography (on PEG 20 M column at 120—160 °C) for analysis of products of electrolyses of the alcohols after quenched with aqueous $NaHSO_3$.

Cyclic Voltammetry. All the measurements were carried out at room temperature in an ordinary procedure.

UV-Spectroscopic Measurement. All the spectra were measured in a 1 cm cell, if necessary after dilution of the sample solutions, using a spectrometer (Hitachi Degital Spectrophotometer Model 624).

Photochemical Stability of Polycyclic Aromatic Hydrocarbons in the Interstellar Medium

Jun-ichi AIHARA
Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422
(Received March 20, 1987)

The astronomical IR spectra of molecular origin have been attributed to compact polycyclic aromatic hydrocarbons. This interpretation can be rationalized in terms of the percent resonance energies of the excited-state species. In general, large compact polycyclic aromatic hydrocarbons are not only thermodynamically stable but also photochemically stable. These hydrocarbons have large percent resonance energies in the excited state, and are expected to survive the rough conditions in space. In contrast, relatively small aromatic hydrocarbons are greatly destabilized when they are excited electronically or deprived of two π electrons.

The infrared astronomical satellite (IRAS) launched in 1983 initiated a new era of interstellar chemistry.[1] Surprisingly, the IRAS satellite found that a series of discrete infrared (IR) bands are emitted from the interstellar medium (ISM). The emission maxima are located at 3.3, 6.2, 7.7, 8.6, and 11.3 μm, all of which are always observed as a set.[1] They are observed in a wide variety of astronomical objects: reflection nebulae, bipolar nebulae, planetary nebulae, and the whole regions of active galaxies.[1] The five IR bands are obviously of molecular origin. Fundamental molecular vibrations must be responsible for these bands.

It was in 1984 that Léger and Puget reported that a similar set of bands appears in the IR absorption spectrum of coronene (**8**).[2,3] They proposed that a mixture of various polycyclic aromatic hydrocarbons (PAHs) is responsible for the astronomical IR spectra. Allamandola et al. supported this view by showing the good agreement between the wavelengths of the astronomical IR bands and the Raman spectrum of automobile soot (a mixture of PAHs and small carbon particles).[4-6]

The five discrete IR bands can really be assigned to fundamental vibrations of PAHs.[1-8] The 3.3 μm band is assignable to an aromatic C–H stretch. The 6.2 μm band is assignable to a C=C stretch in an aromatic ring. The 7.7 μm band is not found in benzene (**1**) and naphthalene (**3**), and may be specific to large PAHs such as coronene.[3,8] The 8.6 μm band is assignable to an in-plane aromatic C–H bend. Finally, the 11.3 μm band is assignable to an out-of-plane aromatic C–H bend.

The wavelength position of the out-of-plane C–H bending mode is very sensitive to the number of adjacent hydrogen atoms on a ring.[3,5,6] The more hydrogens which are adjacent on the same ring, the longer the wavelength of this bending mode becomes. The predominance of the 11.3 μm emission in the 11—13 μm region implies that most interstellar PAHs have many solo hydrogens (see Fig. 1).[3] The emission observed in the 11.5—13 μm region might indicate the presence of PAHs with duo and trio hydrogens (see Fig. 1).

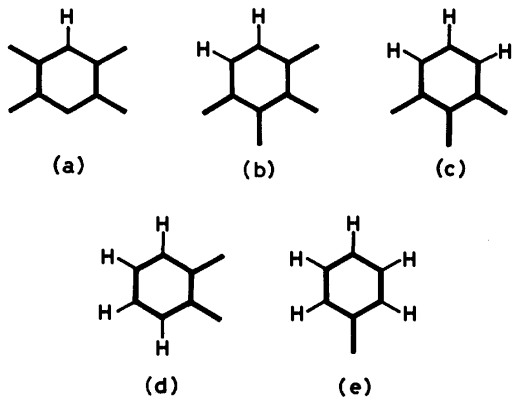

Fig. 1. Classification of hydrogens in PAHs: (a) solo hydrogen, (b) duo hydrogens, (c) trio hydrogens, (d) quartet hydrogens, and (e) quintet hydrogens.

These observations imply that rather compact PAHs with many solo hydrogens dominate the interstellar PAH mixture.[1-6] Typical compact PAHs have only solo and duo hydrogens. Léger and d'Hendecourt then found that the astronomical IR spectra resemble the IR spectra of compact PAHs very closely.[3] The fit with the IR spectra of non-compact PAHs is very poor. PAHs with quartet or quintet hydrogens (see Fig. 1) can be excluded because the emission bands concerned are very weak in the astronomical IR spectra.

Léger et al. further noticed that the extinction coefficient per solo hydrogen is much larger than that per duo hydrogen in the two measured PAHs ovalene (**28**) and dicoronene,[9] which have both solo and duo hydrogens.[3] The large extinction coefficient of a solo hydrogen is commonly found in many smaller PAHs.[8] Therefore, it is reasonable to assume that PAHs in the ISM can have some duo or trio hydrogens in addition to not a few solo hydrogens. This feature is consistent with the molecular structure of large compact PAHs, in which there must be some duo and/or trio hydrogens.

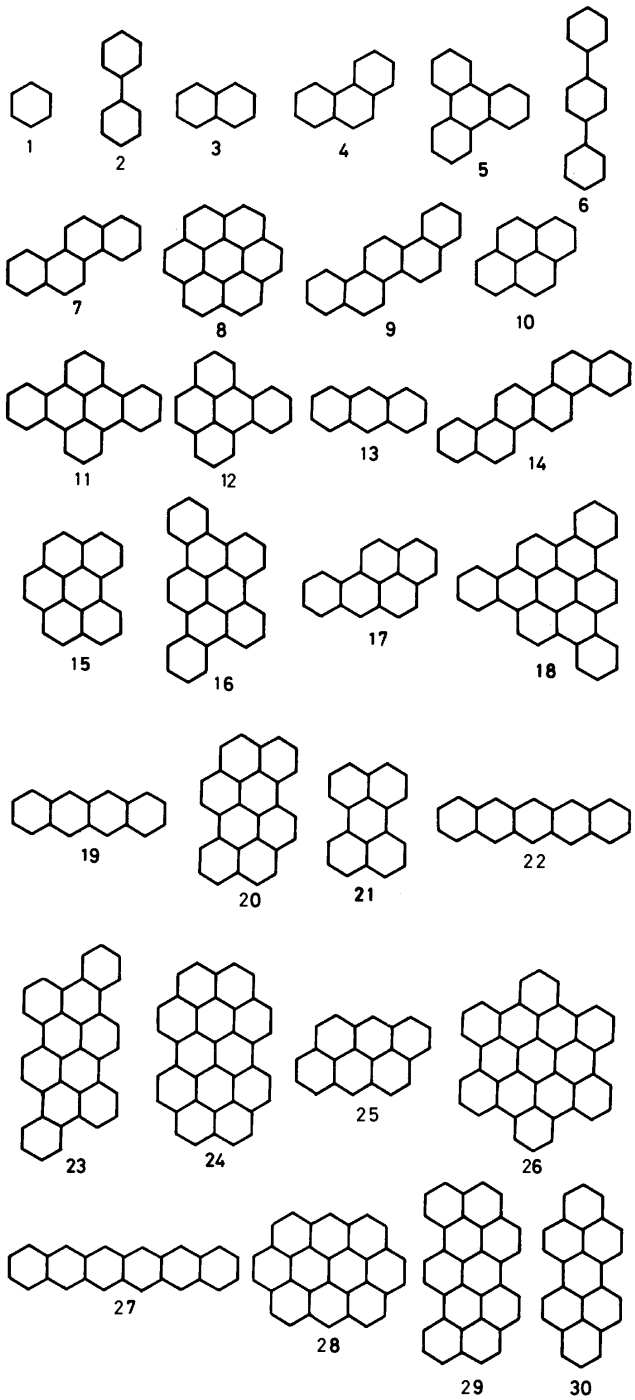
It is now fairly clear that interstellar PAHs, if any, must be limited to a large compact type. If so, we must seek for the reason why such PAHs are dominant

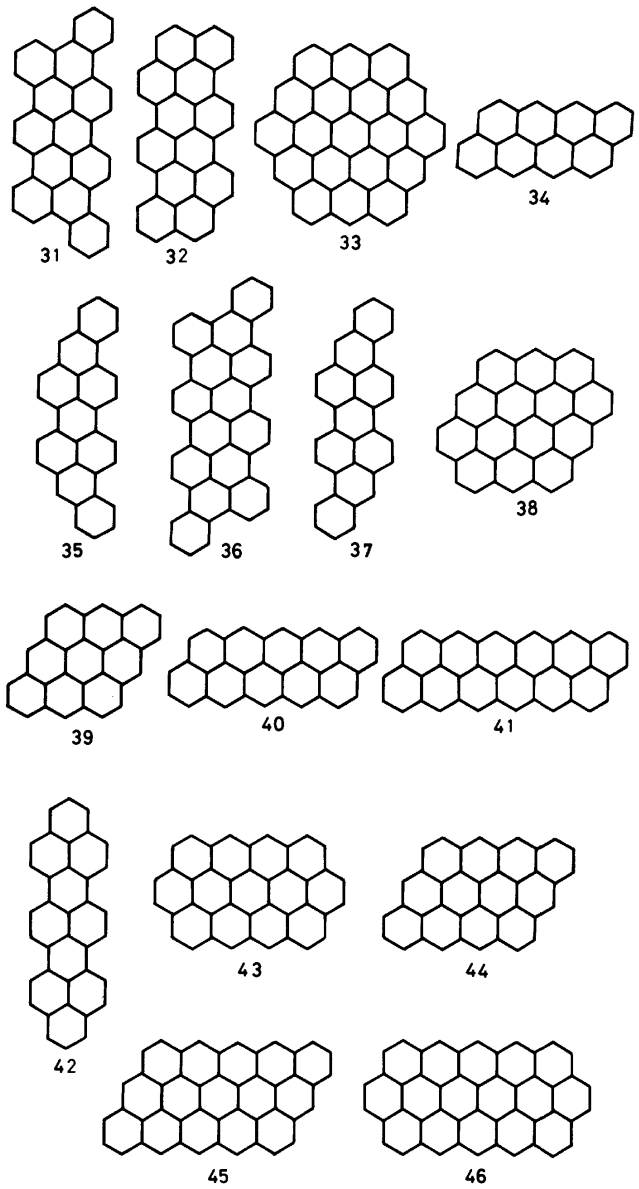
in space. Are these PAHs really stable enough to survive the rough conditions in the ISM? In order to find a clue to this problem, our graph theory of aromaticity[10-13] was applied to a variety of PAHs including those which have so far been the candidates for explaining astronomical IR data.

Results and Discussion

We have developed the graph theory of aromaticity since 1975.[10-13] We defined a new type of resonance energy in graph-theoretical terms. The percent resonance energy (%RE) of a given molecule is then defined as 100 times the resonance energy, divided by the total π-electron energy of its olefinic reference structure.[11,12] The %RE has been recognized as an excellent index for determining the degree of thermodynamic stability of a cyclic conjugated molecule. The %RE is approximately proportional to the resonance energy per π electron.[14,15] A PAH with a large %RE is considered to be thermodynamically stable and typically aromatic in nature.[11,12]

We calculated the %REs of a variety of PAHs (**1—46**) to test the above interpretation of the astronomical IR spectra. The obtained %REs are listed in Table 1. The %REs of relatively small PAHs have already been published.[11,12] As shown by the %REs, most PAHs are stable in our chemical sense. Here, we tentatively assume that a PAH with a %RE larger than 2.15 is very stable. This means that PAHs which are thermo-





dynamically more stable than pentacene (**22**) must be very stable.

First of all, there are a group of very stable PAHs called fully benzenoid hydrocarbons (or fully benzenoid PAHs).[16-18] They are PAHs whose Clar structures consist of aromatic sextets alone.[16] PAHs **1**, **5**, **11**, **16**, **18**, **23**, **26**, **31**, and **36** are such PAHs. Since double bond character is scarcely localized anywhere in each of these PAHs, they provide the ultimate in stability which synthetic chemistry can offer.[15] The energy of the highest occupied molecular orbital (HOMO) in these PAHs is very low in energy, indicating that the HOMO contributes much to the thermodynamic stability of the entire molecule.[11,15] The %REs are all larger than 2.80.

Table 1. Percent Resonance Energies of PAHs

45	2.309	2.316
46	2.515	2.383

Accordingly, it is quite natural that Schmidt et al. regarded such fully benzenoid PAHs as attractive candidates to account for the astrophysical IR data.[16,17] The PAHs chosen by them are highly symmetric hexa-*peri*-benzocoronene (**26**) and tribenzocoronene (**18**). However, there is one serious difficulty with these PAHs. They have no solo hydrogens. Compact fully benzenoid PAHs have only duo and quartet hydrogens, and exhibit no 11.3 μm emission line. Therefore, they are not a major molecular component of the ISM although they are thermodynamically very stable. Benzene (**1**) is the most stable PAH with the largest %RE conceivable. However, there is no evidence for the existence of this molecule in the ISM. These facts strongly suggest that the ground-state stability is not a sufficient condition of the interstellar PAHs.

In this context, it may be worth noting that all IR-emitting PAHs must be placed in the strong radiation field since they must first be excited electronically to emit IR lines.[1-6] In other words, we can observe only PAHs in the emission zone. If a given PAH is fragile in the excited state, it cannot survive the severe radiation field in the ISM. Therefore, the stability of the excited-state species or the photochemical stability must be the most important factor in the present interstellar chemistry. In order to see the photochemical stability, we then calculated the %REs of all PAHs in the first excited state.[19] They are listed in Table 1.

Furthermore, it is very probable that the radiation field in the emission zone is intense enough to ionize many of the PAHs.[3,5,21] The PAHs were estimated to exist in cationic forms to more than 50% in extent.[4,20] The importance of double ionization was stressed by Leach.[22] d'Hendecourt pointed out in Ref. 23 that the radiation field in reflection nebulae is so high that most of the PAHs are probably ionized. From this point of view, the stability of the dications, as well as that of the excited-state species, must be taken into account when the type of interstellar PAHs is sought.

All PAHs are alternant hydrocarbons. Therefore, the energy of the lowest unoccupied molecular orbital (LUMO) is equal to the negative of the energy of the HOMO. Then, the %RE of the dianion of any PAH is equal to that of the dication. The %RE of a given PAH in the first excited state is also equal to that of the dication. Accordingly, we do not need to calculate

the %REs of the dications. The %REs of the excited-state species in Table 1 automatically represent the %REs of the dications. The %RE of the monocation or the monanion can readily be obtained by averaging the %REs of the ground-state species and the dication.

As can be seen from Table 1, fully benzenoid hydrocarbons are unable to form stable dications. The %REs of tribenzocoronene (**18**) and hexa-*peri*-benzocoronene (**26**) decrease much when they are excited electronically or doubly ionized. The same is fairly true for other fully benzenoid hydrocarbons. This is possibly the primary reason why such fully benzenoid PAHs do not contribute appreciably to the astronomical IR spectra. Polyphenyls, such as biphenyl (**2**) and terphenyl (**6**), are a kind of fully benzenoid PAHs. They are also supposed to be photochemically unstable.

There are many solo hydrogens in large linear polyacenes. However, none of them are thermodynamically very stable in the ground state.[11,15] Pentacene (**22**) and hexacene (**27**) must be handled under nitrogen since they are very oxidizable.[16] Higher members of this series are not isolable. Angulated polyacenes, such as phenanthrene (**4**), chrysene (**7**), picene (**9**), and fulminene (**14**), are very stable in the ground state. However, both linear and angulated polyacenes are unstable in the excited state. Therefore, they are not qualified for the PAHs in the ISM. All polyacenes have quartet hydrogens, the presence of which are also inconsistent with the astronomical IR spectra. Angulated polyacene do not have solo hydrogens.

Léger and Puget[2] and Allamandola et al.[5] estimated the carbon content of the interstellar PAHs to lie in the range of 20—50 carbon atoms. PAHs having less than 20 carbons must be much less abundant in the ISM. As shown in Table 1, this suggestion corresponds to the fact that dications derived from relatively small PAHs are not stable. For small PAHs the contribution of the HOMO to the RE is very large. Therefore, they become fairly unstable by losing two π electrons in the HOMO. Among the PAHs in Table 1 those having 30 or less carbon atoms behave in this manner. Dications of PAHs **1**—**5** are antiaromatic with negative %REs. Many of small PAHs do not have solo hydrogens.

Finally, large compact PAHs with solo hydrogens constitute the group of PAHs which have large %REs both in the ground and excited states. They are best exemplified by circumnaphthacene (**46**), dibenzocircumanthracene (**45**), dibenzovalene (**44**), circumanthracene (**43**), and circumpyrene (**38**). The %REs of these PAHs are all larger than 2.15 both in the ground state and in the excited or doubly ionized states. Accordingly, they must be fairly stable not only at high temperature but also in the strong radiation field. Since these PAHs have not a few solo hydrogens, they presumably match the pattern of the astronomical IR spectra. The large compact PAHs can be considered as the best candidates for the interstellar PAHs. The abundance of large compact PAHs has thus been explained satisfactorily.

It should be noted that large compact PAHs are not always qualified for the interstellar PAHs. Only those having large %REs in the excited state are eligible for them. Many compact PAHs do not have solo hydrogens, and their dications have small %REs. PAHs **8**, **20**, **24**, and **28** are all large and compact in shape. However, they are greatly destabilized in the excited state. As stated above, all fully benzenoid PAHs are not stable in the excited or doubly ionized states. Although hexa-*peri*-benzocoronene (**26**) is a large compact PAH, it is not an exception. All fully benzenoid PAHs investigated have no solo hydrogens.

Tielens et al. inferred that hexagonally symmetric PAHs, such as coronene (**8**) and circumcoronene (**33**), might dominate the interstellar PAH mixture.[24] This type of PAHs have doubly degenerate HOMOs. Benzene (**1**) also belongs to this type of PAHs. Dianions of such PAHs necessarily have much smaller %REs than those of other PAHs of similar size. Therefore, the compact PAHs responsible for the astronomical IR spectra must be less symmetric than coronene and circumcoronene. Coronene forms one of the most unstable dications among the PAHs investigated.

PAHs in Table 1 are numbered in such a manner that the excited-state species are arranged in order of increasing %RE. It is evident that rather large compact PAHs come later. Many PAHs with large %REs have not a few solo hydrogens. Circumnaphthacene (**46**) and circumanthracene (**43**) appear to be excellent candidates conceivable at present. These two PAHs are thermodynamically very stable as indicated by the large %REs of the ground-state species. They are also photochemically very stable as indicated by the large %REs of the dianions or the excited-state species.

As shown in Table 1, there are some non-compact PAHs which are photochemically as stable as large compact ones. PAHs **40**—**42** are examples of this kind. PAH **42** does not have solo hydrogens. If there are synthetic routes to these PAHs in the ISM, they must also contribute more or less to the interstellar IR emission.

Concluding Remarks

In general, benzene and fully benzenoid hydrocarbons constitute the most stable group of PAHs. The absence of this group in the ISM suggests that there must be another criterion for determining the type of interstellar PAHs. Fully benzenoid hydrocarbons and most of relatively small PAHs were found to be photochemically unstable. Considering that the IR-emission zone are situated in the strong radiation

field, these photochemically unstable PAHs can be excluded. Then, large compact PAHs remained.

Fortunately, large compact PAHs have many solo hydrogens, and can be considered as excellent candidates for explaining the astronomical IR spectra taken by the IRAS satellite. Thus, it is photochemical stability that determines the type of PAHs in the ISM. The ground-state stability is of course important. However, almost all PAHs satisfy this condition. We believe that the existence of large compact PAHs in the interstellar IR-emission zone[1] has thus been rationalized.

Helpful discussions with Professor Kunio Fukushima are gratefully acknowledged.

A New Type of Tetradentate Square-Planar N_2O_2 Ligands. Copper(II) Complexes of 6,6′-Bis(acylamino)-2,2′-bipyridines

Masaki YAMADA, Koji ARAKI,* and Shinsaku SHIRAISHI*
Institute of Industrial Science, The University of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo 106
(Received March 20, 1987)

A new type of N_2O_2 tetradentate ligands, 6,6′-bis(acylamino)-2,2′-bipyridines, was synthesized and their complex formations with copper(II) were investigated. They form two types of 1:1 complexes; one is the non-deprotonated type having external counter anions and the other is the deprotonated type having no external counter anions. They serve as square planar N_2O_2 tetradentate ligands in either case and the structures of the complexes are very similar to salen complexes. The structures and properties of these complexes were investigated and discussed.

The complexes of tetradentate square-planar N_2O_2 ligands, *N,N′*-di(salicylidene)ethylenediamine (salen) and its derivatives, have been the subject of intense studies because of their ability to activate various molecules, especially, molecular oxygen coordinated to the axial positions of the complexes.[1] Property-control (tuning) by modification of diimine moiety and/or ring substitution of salen is limited in versatility, and exploitation of the complexes of analogous structure has been demanded.

We have been investigating chemistry of 6,6′-diamino-2,2′-bipyridine (dabp).[2,3] The amino groups of dabp are easily modifiable, and, in previous papers, we reported alkylation of the amino groups of dabp and application of these alkyl-substituted derivatives to metal-ion transport.[3] Here, we wish to report another type of derivatives, 6,6′-bis(acylamino)-2,2′-bipyridines, obtained by acylation of the amino groups of dabp, which are found to serve as a new type of N_2O_2 ligands.

The coordination sites in these ligands are expected to be ring-nitrogens and amide-oxygens serving as N_2O_2 tetradentate planar ligands. Dissociation of amide protons upon complex formation may afford the complexes analogous to the salen complexes. Furthermore, the complexes are expected to be more stable than the salen complexes, especially in an acidic solution, because the easily hydrolyzable Schiff base moieties of the salen complexes are replaced by the bipyridine moiety. Two ligands, 6,6′-bis(benzoylamino)-2,2′-bipyridine ($babpH_2$) and 6,6′-bis(hexanoylamino)-2,2′-bipyridine ($habpH_2$) were prepared, and their complexations with copper(II) were investigated. The results were discussed in comparison with the coordination chemistry of salen and its derivatives, and also with that of analogous ligands, 2-(benzoylamino)pyridine (bapH) and 2-(acetylamino)-pyridine (aapH) reported by Nonoyama et al.[4-7]

Results

Syntheses. 6,6′-Bis(acylamino)-2,2′-bipyridines ($babpH_2$ and $habpH_2$) were prepared by acylation of amino groups of dabp with the corresponding acyl chlorides (Scheme 1). 2,9-Bis(benzoylamino)-1,10-phenanthroline ($baptH_2$) was also prepared from 2,9-diamino-1,10-phenanthroline.[8] Elemental analyses agreed well with the calculated values within a permitted experimental error (<±0.3%, Table 1). Chemical shifts in ^{13}C and ^1H NMR spectra of the ligands in dimethyl-d_6 sulfoxide (DMSO-d_6) (Tables 2 and 3, respectively) confirmed their structures, most of which were quite similar to those of corresponding 2-(acylamino)pyridines.[9]

Complexation of $babpH_2$ with copper(II) nitrate and acetate gave different types of complexes, i.e., the non-deprotonated complex **1a** and the deprotonated one **2a** respectively (Table 1). A blue complex $Cu(babpH_2)(H_2O)_2(NO_3)_2$, **1a** was obtained by complexation with copper(II) nitrate in methanol (Scheme 1). The IR spectrum of complex **1a** showed the presence of amide carbonyl and N-H stretching bands (Table 4). The change in IR spectrum upon complexation was quite similar to those of 2-(acylamino)-pyridines.[4-6] On the other hand, a green complex [Cu(babp)], **2a** was obtained by complexation with copper(II) acetate (Scheme 1). This showed neither amide carbonyl nor N-H stretching bands in its IR spectrum (Table 4), indicating the deprotonation of both of the two amide protons. The characteristic IR

bands of **2a** at 1555 and 1366 cm^{-1} were quite similar to those of the palladium complex of 2-(acetylamino)-pyridine [Pd(aap)] (1568 and 1393 cm^{-1}).[4] The ligand $habpH_2$ also gave a blue complex **1b** of similar structure to **1a** by complexation with copper(II) nitrate (Tables 1 and 4). Furthermore, $habpH_2$ gave a green complex **2b** with copper(II) acetate which showed a similar IR bands to **2a** (1554 and 1380 cm^{-1}), suggesting the formation of the deprotonated complex. However, the complex **2b** could not be isolated in a pure form (from elemental analysis).

The ESR spectra of the complexes obtained were also measured (Fig. 1). The spectrum of **1b** was quite similar to that of **1a** (Fig. 1-A).

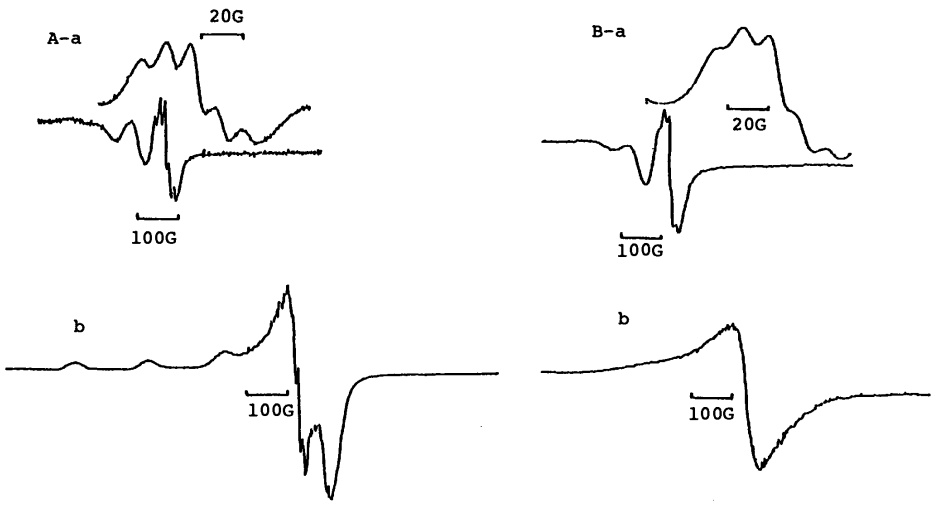

Fig. 1. ESR spectra of copper(II) complexes (1×10^{-3} mol dm^{-3}). A: **1a** in methanol (a) at room temperature (g=2.15) and (b) at 77 K ($g_{//}$=2.26, $g_{\perp}$=2.10), B: **2a** in DMSO (a) at room temperature (g=2.12) and (b) at 77 K (g=2.07).

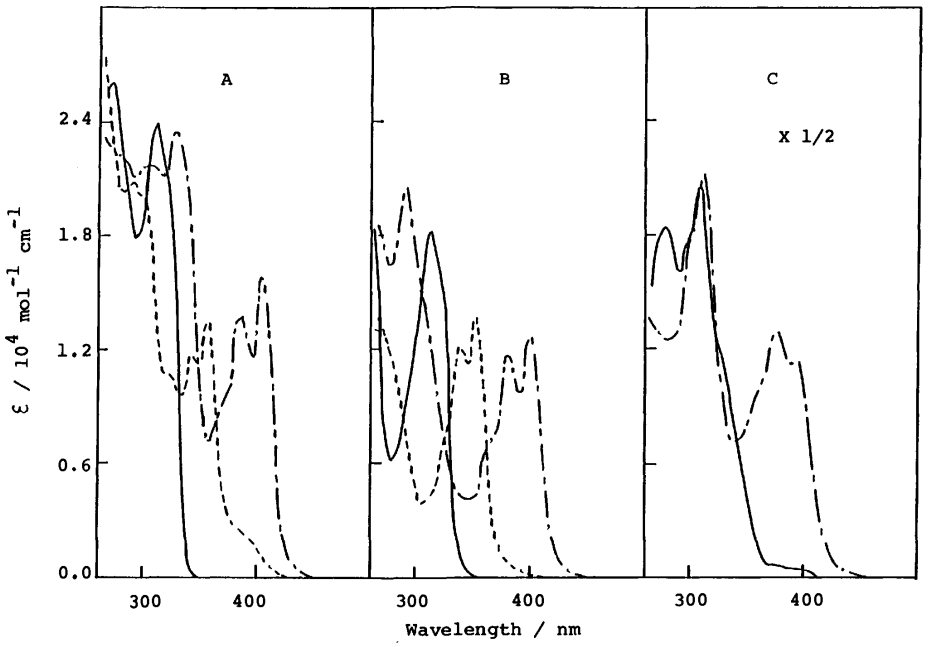

Fig. 2. The electronic spectra of (A) babpH$_2$, (B) habpH$_2$, and (C) baptH$_2$ and their copper(II) complexes in DMSO (6.67×10^{-5} mol dm^{-3}) at 20 °C; (——): metal-free ligands, (------): non-deprotonated complexes in the presence of HNO_3, and (—·—): fully-deprotonated complexes. The spectra of the fully-deprotonated complexes for habpH$_2$ (B) and baptH$_2$ (C) are those of the 1:1 mixture of Cu(OAc)$_2$ with corresponding ligands.

Properties. The electronic spectra of metal-free ligands and their copper(II) complexes are shown in Fig. 2. The spectral changes of the metal-free ligands in DMSO (6.67×10^{-5}mol dm^{-3}) by addition of various amounts of copper(II) acetate indicated the quantitative formation of the 1:1 complexes. The spectra of the equimolar solutions of the ligands and copper(II) acetate in DMSO were quite similar to that of **2a**, indicating the formation of deprotonated complexes, [Cu(babp)], [Cu(habp)], and [Cu(bapt)], in a DMSO solution. The spectra of the equimolar solutions of the ligands and copper(II) nitrate with an excess amount of HNO_3 in DMSO were also almost the same as those of the complexes **1a** and **1b**. The apparent complex-formation constants were too large to measure by the Rose-Drago's method[10] (concentration of ligads; ca. 10^{-5} mol dm^{-3}), and the complexations proceeded completely in the presence of an excess amount of HNO_3 (non-deprotonated complexes) and in the presence of acetic acid produced upon deprotonation (deprotonated complexes) (Scheme 1).

The spectra at 260—500 nm region of the copper(II) complexes of babpH$_2$ and habpH$_2$ in DMSO were sensitive to their concentrations or presence of an acid or a base (Fig. 3). The spectral changes indicated that the two types of the complexes **1** and **2** were in equilibrium. In the course of transformation between the two types of the complexes, two different set of isosbestic points appeared successively, i.e., one is the

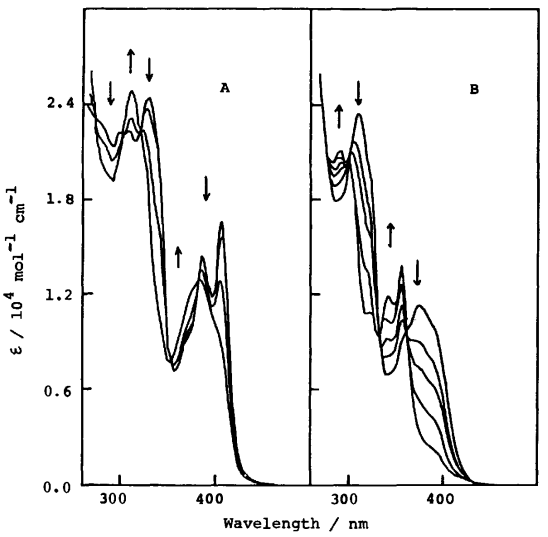

Fig. 3. The changes of electronic spectra of the copper(II) complex **2a** by addition of HNO_3 in DMSO. Concentration of complex **2a**: 6.67×10^{-5} mol dm^{-3}, molar ratio of added nitric acid were as follows; A: 0.0, 0.4, 0.8, and 1.2, and B: 2.0, 4.0, 6.0, 10.0, and 22.0.

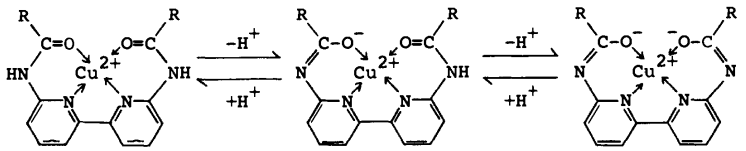
set at 382, 352, 322, and 303 nm (Fig. 3-A) and the other at 363, 332, and 300 nm (Fig. 3-B). This indicates the intervention of monodeprotonated species, i.e., one of the amide protons dissociated (Scheme 2). The spectral changes due to the interconversion of the three types of the complexes were also observed in an aqueous medium, though the



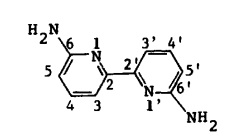
Scheme 2.

fully-deprotonated complex precipitated out in this case. The equilibrium was dependent on the pH of the solution. As the result of the spectrometric titration with concd HNO_3 or KOH (6.67×10^{-5} mol dm^{-3} of the complex), first dissociation of the amide proton in **1b** occured at pH 6.7, and second at pH 9.5. While, the complex **1a** dissociated both of the amide protons almost simultaneously at pH 5.1 in aqueous medium. The complexes themselves were stable during such treatment and neither decomplexation of metal ion nor hydrolysis of the ligands occured even in the presence of an acid or a base.

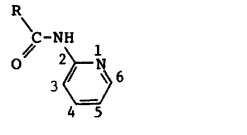
The copper(II) complexes showed additional bands due to d-d transition in their electronic spectra. The absorption maxima of **1a** and **1b** were 640 nm either in DMSO (ε=110) or in methanol (ε=121). On the other hand, a large solvent effect was observed for **2a**, the absorption maximum of which was 595 nm in DMSO (ε=167), 550 nm in chloroform (ε=227), 585 nm in tetrahydrofuran (ε=180), and 605 nm in pyridine (ε=173).

Discussion

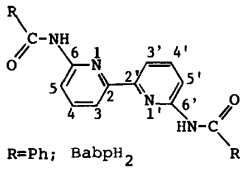
Conformation of the Metal-Free Ligands. The conformation of the metal-free ligands was confirmed to have planar structure by the ^1H NMR spectrometry (Table 3). Chemical shifts of 3,3′-protons are sensitive to the conformation of the two pyridine rings of bipyridine.[11] The large lower-field shift (ca. 0.8-1 ppm) of 3,3′-protons of the bipyridine moiety compared with that of 5-proton of 2-(acylamino)pyridines (bapH and aapH) indicates that the two pyridine rings of the bipyridine moiety are in the plane in "*transoid*" conformation.[11] The chemical shifts of the other ring-protons of $babpH_2$ and $habpH_2$ were almost the same as those of the corresponding protons of 2-(acylamino)pyridines. The large lower-field shift of 5,5′-protons (ca. 1.8 ppm) of 6,6′-bis(acylamino)-2,2′-bipyridines compared with those of dabp[2] is due to the strong deshielding effect by the amide oxygen, suggesting that the amide groups and the pyridine rings are in the plane in "*trans-cis*" conformation as reported for 2-(acylamino)pyridines.[9] Thus, it was concluded that the metal-free ligands have a planar structure as shown below.



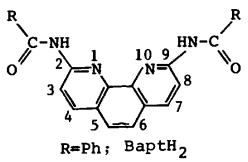
"*transoid*" Conformation of Dabp



"*trans·cis*" Conformation of 2-(Acylamino)pyridine



R=Ph; $BabpH_2$
R=C_5H_{11}; $HabpH_2$



R=Ph; $BaptH_2$

Complex Formation with Copper(II). 2-(Acetylamino)pyridine (aapH) has been reported to form two types of complexes with palladium(II), i.e., $[Pd(aapH)_2]_2^+$ gave deprotonated one, $[Pd(aap)_2]$[4] in alkaline condition. However, $[Cu(aapH)_2]^{2+}$ was decomposed in alkaline solution to give $Cu(OH)_2$ instead of $[Cu(aap)_2]$.[4] In the present case, $babpH_2$ and $habpH_2$ formed both types of copper(II) complexes as described in the previous section.

Structure of the Copper(II) Complexes. 2-(Acylamino)pyridines has been shown unambiguously to coordinate to metal ions as planar NO bidentate ligands from their spectral data[4-7] and X-ray crystal structure analysis.[7] Aap (deprotonated aapH) also serves as a planar NO bidentate ligand.[4,7] Usually deprotonated amide group is known to coordinate at its nitrogen atom,[12] but in the cases of (2-acylamino)pyridine derivatives described here the oxygen is shown to act as the coordination site to form more stable 6-membered ring structure. The shifts of the amide bands of $babpH_2$ and $habpH_2$ in IR spectra upon formation of the complexes **1** (Table 4) are similar to those of the corresponding 2-(acylamino)-pyridines, suggesting the coordination at the amide oxygens[12] (i.e., amide I; red shift, amide II and III; blue shift). The characteristic IR bands of **2** are also similar to those of the deprotonated complex of 2-(acylamino)pyridine, $[Pd(aap)_2]$.[4] Thus, the similarities of IR bands of copper(II) complexes **1a**, **1b**, and **2a** to the corresponding complexes of 2-(acylamino)-pyridines indicate that 6,6′-bis(acylamino)-2,2′-bipyridines act as the square-planar N_2O_2 tetradentate ligands.

The ESR spectra of **1a** and **2a** at room temperature (Fig. 1) were quite similar to each other. They showed the usual four-line pattern due to coupling of electron to the spin 3/2 copper nucleus, and showed five

superhyperfine splitting due to the two nitrogens in the copper coordination sphere. These pattern were almost the same as that of salen derivatives.[13] The ESR spectra at 77 K (Fig. 1), however, were quite different from each other. The complex **2a** showed no fine structure probably due to an intermolecular interaction between copper(II) ions under the measured conditions. The complex **1a** and **1b** showed a typical axial-type spectrum, confirming the structure of a square-planar symmetry. The electronic spectrum of **2a** in 260—500 nm region was similar to that of [Cu(bapt)] (Fig. 2). The ligand baptH$_2$ is regarded as a babpH$_2$ analogue and the conformation of the bipyridine moiety in baptH$_2$ is rigidly fixed in plane. The spectral similarities of the two complexes support the planar structures of the complex **2a**. The complexes **1a**, **1b**, and **2a** have the absorption maxima due to d-d transition appeared at 550—640 nm, similar to that observed in a variety of square-planar copper(II) complexes hitherto reported. The absorption maximum of **2a** in chloroform (550 nm) is similar to that of d-d transition band of copper(II) complex of *N,N'*-bis(1-methyl-3-oxobutylidene)ethylenediamine rather than that of salen (570 nm),[14] suggesting the presence of strong square-planar ligand field around copper(II) ion in the deprotonated complexes. Therefore, these spectral data indicate the square-planar structure of the complexes of 6,6'-bis(acylamino)-2,2'-bipyridine.

The absorption maximum of *d-d* transition band of **2a** in DMSO (Fig. 3) was markedly red-shifted (45 nm) compared with that in chloroform, while that of copper(II) complex of salen or acen showed only a small solvent effect (max. 20 nm).[14] This larger solvent effect may be interpreted in terms of coordination of the solvent molecules at the axial positions of **2a**.

In conclusion, 6,6'-bis(acylamino)-2,2'-bipyridines have been shown to form two different types of 1:1 complexes with copper(II) salt depending on the counter anions of the salts. The deprotonated complexes are similar to salen complexes in their N_2O_2 tetradentate coordination sites, square-planar structure, and the anionic sites on oxygens. Furthermore, in the ligands obtained here, the Schiff base moieties in salen complexes are replaced by bipyridine moieties which have higher chemical stability.

Experimental

Materials 6,6'-Diamino-2,2'-bipyridine was prepared from 2,6-dibromopyridine according to the method previously reported.[3] 2,9-Diamino-1,10-phenanthroline was prepared from 1,10-phenanthroline by the literature method.[8] Other chemicals were obtained commercially, and some of them were purified by conventional methods prior to use.

Spectral Measurements. ^{1}H and ^{13}C NMR spectra were measured with a JEOL JNM-GX270 Spectrometer at 27 °C. ESR spectra were measured with a JEOL JES-FE3X spectrometer operated at X band. Electronic and IR spectra were recorded on a JASCO UVIDEC-505 spectrophotometer at 20 °C and a IRA-1 spectrophotometer, respectively.

6,6'-Bis(benzoylamino)-2,2'-bipyridine (babpH$_2$): Into a solution of dabp (186 mg, 1 mmol) in 10 cm^3 of dry pyridine was added dropwise a solution of benzoyl chloride (1.41 g, 10 mmol) in 10 cm^3 of dry pyridine at 0 °C with stirring. The mixture was stirred for another 15 min at the temperature. Then 100 cm^3 of methanol was added to the mixture in order to precipitate a white solid, which was collected by filtration, washed successively with diluted hydroohloric acid, acetone, diluted aqueous ammonia, and methanol. Recrystallization from benzene yielded 294 mg (75%).

6,6'-Bis(hexanoylamino)-2,2'-bipyridine (habpH$_2$): This was prepared from 186 mg (1 mmol) of dabp and 1.34 g (10 mmol) of hexanoyl chloride in a similar manner to that of babpH$_2$. Yield 298 mg (78%).

2,9-Bis(benzoylamino)-1,10-phenanthroline (baptH$_2$): Into a solution of 2,9-diamino-1,10-phenanthroline (100 mg, 0.47 mmol) in 5 cm^3 of dry pyridine was added dropwise a solution of benzoyl chloride (0.66 g, 4.7 mmol) in 5 cm^3 of dry pyridine at 0 °C with stirring and the mixture was stirred for 15 min at the temperature. Then, 100 cm^3 of ether was added to the mixture to precipitate pale yellow solid, which was collected by filtration and subjected to column chromatography (Wakogel C-200–chloroform). The fraction obtained was washed with diluted aqueous ammonia. Evaporation of chloroform and recrystallization from methanol gave pale yellow needles which was dried at 80 °C under reduced pressure. Yield 84 mg (39%).

Copper(II) Complex 1a: A mixture of babpH$_2$ (78 mg, 0.2 mmol) and Cu(NO$_3$)$_2$·3H$_2$O (48 mg, 0.2 mmol) in 10 cm^3 of methanol was stirred at room temperature until the mixture became a homogeneous blue solution. Then methanol was removed by evaporation. The residual blue solid was recrystallized from water to give light blue plates of Cu(babpH$_2$)(H$_2$O)$_2$(NO$_3$)$_2$, yield 71 mg (58%).

Copper(II) Complex 2a: A mixture of babpH$_2$ (78 mg, 0.2 mmol) and Cu(OAc)$_2$·H$_2$O (40 mg, 0.2 mmol) in 100 cm^3 of chloroform was stirred at room temperature until the mixture became a homogeneous purple solution. Then chloroform was removed by evaporation. The residual green solid was washed by methanol containing KOH, and recrystallized from benzene, yielding 70 mg (76%) of [Cu(babp)].

Copper(II) Complex 1b: This was obtained from 76 mg (0.2 mmol) of habpH$_2$ and 48 mg (0.2 mmol) of Cu(NO$_3$)$_2$·3H$_2$O in a similar manner to the preparation of **1a**. Recrystallization from water gave blue plate of Cu(habpH$_2$)(H$_2$O)(NO$_3$)$_2$, yield 26 mg (18%).

Mixed Alcohol Synthesis from CO-H_2 by Use of KCl-Promoted Mo/SiO_2 Catalysts

Atsushi MURAMATSU, Takashi TATSUMI,* and Hiro-o TOMINAGA
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received March 23, 1987)

Highly active Mo catalysts for mixed alcohol synthesis were prepared using Fuji Davison ID silica gel as a carrier. KCl promoted the selectivity to alcohols but reduced CO conversions in particular to hydrocarbons. Productivity of alcohols was largely affected by the reaction conditions. High pressure and short contact time enhanced space-time yield of alcohols, i.e. 420 g (kg-catalyst)$^{-1}$ h^{-1} at 5.0 MPa, 573 K, and W/F≈ 1.4 g-catalyst h mol^{-1}. The presence of K effectively prevented the complete reduction of Mo to metal, resulting in the increase in the production of alcohols. The study on addition of ethene and ethanol to synthesis gas revealed that the other roles of K are to retard dehydration of alcohols to alkenes and their hydrogenation to alkanes.

The development of a selective catalyst for co-production of methanol and C_2+ higher alcohols remains as one of the main goals of C_1 chemistry. The principal use of the alcohol mixtures is for blending in automotive fuel to meet the octane requirement raised by the global trend to lead phase-down. Blending methanol with gasoline requires the addition of cosolvent to mitigate the problems due to phase separation and high volatility. The C_2+ higher alcohols have proved effective as cosolvent.

It is well-known that appropriate modifications of the methanol synthesis catalyst and also of the reaction conditions result in the production of higher alcohols together with methanol.[1,2] The conventional Fischer-Tropsch catalysts based on iron, ruthenium, and cobalt have been also reported to give long chain alcohols. Institut Francias du Petrole patented catalysts for the synthesis of mixed alcohols, consisting of methanol synthesis catalysts (Cu) and Fischer-Tropsch catalysts (Co).[3]

Molybdenum catalysts have long been recognized as being effective for the Fischer-Tropsch synthesis of light hydrocarbons.[4,5] In our previous study, however, the supported molybdenum catalysts were found to be active in the synthesis of mixed alcohols, which was significantly influenced by support and additive.[6] Moreover, the successive impregnation method, in which addition of K to silica gel was followed by impregnation with molybdenum solution, was found to give higher activity and selectivity for alcohol formation.[7] Dow and Union Carbide have claimed a number of patents of the catalysts based on MoS_2, promoted by CoS and alkali metal salts for higher alcohol synthesis.[8-10]

Here we report the improved design of catalyst and reaction conditions for the production of mixed alcohols. High activity and selectivity for alcohols were attained on the KCl-promoted, ID silica-gel-supported Mo catalyst at high pressure and short contact time; alcohol yield exceeded 420 g (kg-catalyst)$^{-1}$ h^{-1} with 68 C-atom% selectivity.

Experimental

Catalysts were prepared by impregnating various silica gels (Fuji Davison ID, RD, and B) with an aqueous solution of KCl first, followed by air calcination at 673 K for 1 h and impregnation with $(NH_4)_6Mo_7O_{24}$ solution. The Mo metal loading was 10 and 20 wt% and the K/Mo ratio was varied in the range of 0—0.4. The impregnates were dried overnight at 393 K and treated in the He stream at 673 K for 1 h and then reduced by H_2 773 K for 12 h.

The synthesis reaction was carried out in a flow reactor made of stainless steel tube with 0.6 cm inside diameter, containing 1.0 g catalyst. The synthesis gas (H_2/CO=1) was supplied to the reactor through the stainless-steel tube heated at 473 K for decomposition of carbonyl impurities. Hydrogen was purified to remove oxygen by passage through a DEOXO unit (Engelhard), followed by a molecular sieve trap. Activity and selectivity of the catalyst were observed over a reaction period of 50—130 h until their steady states were attained. Products were analyzed by gas chromatographs. Concentrations of CO, CO_2, and CH_4 in the off-gas were determined by a TCD gas chromatograph with an active carbon separation column at 323 K using H_2 as a carrier gas. The organic compounds were analyzed by an FID gas chromatograph with the following separation column using N_2 as a carrier gas; 2 m Porapak Q for C_1—C_5 hydrocarbons, 2 m polyethylene glycol 1500 for oxygenates, 2 m Silicone SE-30 for C_6+ hydrocarbons, and 8 m VZ-7 for isomers of C_3, C_4, and C_5.

The catalytic surface areas of reduced Mo catalysts were measured by O_2 adsorption at 195 K. X-Ray powder diffraction measurements were performed using a Rigaku Denki diffractometer RU-200A with Cu $K\alpha$ radiation.

Results and Discussion

As previously reported, excellent activity for alcohol synthesis activity was obtained by the use of KCl as a promoter in preparing silica-supported Mo catalysts. Three kinds of silica gel were investigated as a carrier for Mo-KCl catalyst and the results are summarized in Table 1. With all of the catalysts, both alcohol selectivity and CO conversion gradually increased with time on stream and therefore the data were

obtained after 50—130 h on stream when the catalytic activity reached the nearly steady state. As is expected from the shift activity of the molybdenum catalysts,[4,5] these catalysts yielded CO_2, instead of water, almost exclusively. Hence the product selectivities (carbon atom%) in this work are given on a CO_2-free basis. Alcohol synthesis activity is represented by space-time yield of alcohols, STY, which stands for the total weight of alcohols produced per unit weight of catalyst per unit time on stream.

The alcohol formation activity over the KCl-promoted silica-supported Mo catalysts increased in the following order; B<RD<ID. Apparent average oxidation number, estimated from O_2 consumption from 195 to 773 K, increased in the order; B<RD<ID. This sequence conforms to the order of alcohol formation activity. This suggests that Mo species with a relatively high oxidation state participates in the key step of alcohol formation.

Alcohols/hydrocarbons ratio in space-time yield increased in the order; RD<B<ID. This order is in accordance with the sequence of pore diameter of support. The silica-supported Mo catalysts have moderate activity for alcohol dehydration as described below. Therefore, if the pores are smaller, product alcohols would have more chance to be readsorbed and dehydrated to hydrocarbons before leaving the catalysts. RD-silica-supported catalyst gave the highest C_2+ alcohol/methanol ratio. The C_2+ hydrocarbons/methane ratio was in the same order but less dependent on the kind of silica gel than C_2+ alcohols/methanol ratio.

Total activities increased in the order; B<ID<RD. This order is not consistent with the order of O_2 uptake.[11] Na_2O impurity (0.25 wt%) in B-silica gel might have the effect of poison on CO hydrogenation activity.[1] ID-silica-supported Mo catalysts were employed for further investigation.

Table 2 shows the influence of Mo loading on the activity for alcohol synthesis, with the K/Mo ratio kept constant at 0.4. The selectivity for alcohols increased with increasing Mo loading. The C_2+ alcohols/methanol ratio and the olefin content also increased. Total activities, however, increased in the order: 5% Mo<20% Mo<10% Mo. In view of the effect of K content on catalyst performance as is described below, this change in activity and selectivity could be accounted for by the K content proportional to the Mo content.

The influence of K content on activities of 20 wt% Mo catalysts is shown in Fig. 1. The addition of KCl reduced CO conversion and also hydrocarbon yield in particular. The selectivity for alcohols increased with KCl content and reached 70 C-atom% at K/Mo=0.4. The yield of alcohols, however, reached a maximum at K/Mo=0.2. With the increase in K/Mo ratio the C_2+ alcohols/methanol ratio largely increased. It

should be noted that C_2+ hydrocarbons/methane ratio remained almost unchanged.

Table 3 represents the O_2 uptakes for the 20 wt% Mo catalysts. Without KCl addition, O_2 uptake for the fresh (reduced) Mo catalyst amounted to 532 μmol g^{-1}. O_2 uptake was significantly reduced by addition of KCl and was at virtually constant level beyond K/Mo $\geqslant$0.2. The decrease in CO conversion by addition of K should be partly due to the decrease in O_2 uptake. Concha and Bartholomew reported a linear correlation between CO hydrogenation activity and O_2 uptake for unsupported MoS_2.[11]

Figure 2 shows X-ray diffractograms of reduced Mo (20 wt%) catalysts with K/Mo ratio changed. Lines corresponding to metallic Mo and MoO_2 appeared on all the catalyst. With increase in K/Mo ratio, the intensity of MoO_2 lines increased at the expense of metallic Mo.[12] The productivity of alcohols is supposed to depend significantly upon the oxidation state of Mo; MoO_2-like species are responsible for alcohol synthesis while metallic Mo is associated with carbon chain growth and hydrocarbon formation.[13] Thus the presence of K could retard the reduction of Mo, resulting in increase in the production of alcohols.

The influence of the time factor (W/F) on CO conversion, the yields of alcohols and hydrocarbons, the selectivity to alcohols and C_2+ alcohols/methanol ratio over Mo(20 wt%)+KCl(K=1.63 wt%)/SiO_2(ID) at 573 K and 1.6 MPa are illustrated in Figs. 3 and 4.

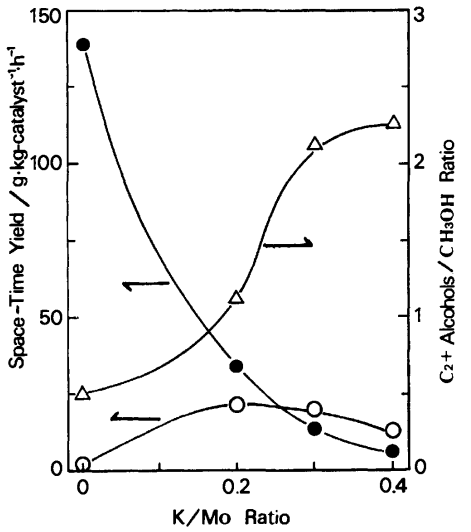

Fig. 1. Effect of K content (K/Mo ratio) on space-time yields of alcohols (O) and hydrocarbons (●), and C_2+OH/CH_3OH ratio (△) over Mo(20 wt%)+KCl/SiO_2(ID) at W/F=10 g-catalyst h mol^{-1}, 573 K, and 1.6 MPa.

Table 3. O_2 Uptake of Mo(20 wt%)+KCl/SiO_2(ID) Catalysts

K/Mo molar ratio	CO conv. %	CO_2 yield %	Net O_2 uptake before use μmol g^{-1}
0	38.3	18.2	532
0.2	10.7	4.8	144
0.3	5.8	2.5	163
0.4	3.4	1.4	126

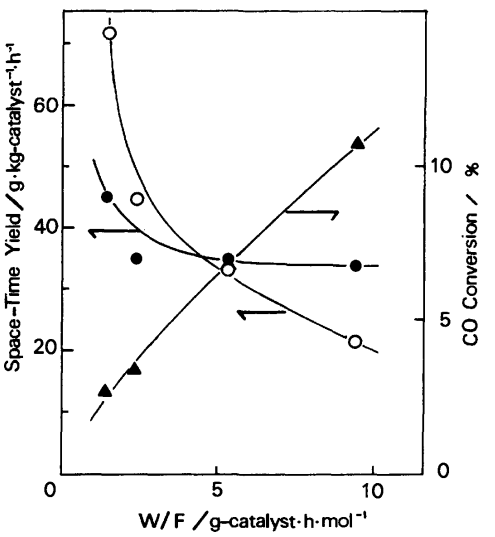

Fig. 3. Effect of time factor on CO conversion (▲) and space-time yields of alcohols (O) and hydrocarbons (●) over Mo(20 wt%)+KCl(K=1.63 wt%)/SiO_2(ID) catalyst at 573 K and 1.6 MPa.

Short contact time enhanced the selectivity for alcohols. The CO conversion vs. W/F plot displayed a convex curvature, which might suggest that the rate of intrinsic surface reaction is not the rate controlling step. At short contact time, the selectivity for alcohols was markedly improved. C_2+ alcohols/methanol ratio was independent of the time factor, ruling out the significant contribution of alcohol homologation, e.g., methanol conversion to ethanol. The alcohol yield tended to be more influenced by W/F with lower K/Mo ratios, indicating that there is a route from alcohols to hydrocarbons promoted by acid sites of the catalysts.

The influence of the addition of ethanol and ethene to CO-H_2 feedstock was investigated on unpromoted and KCl-promoted Mo catalysts. Pertinent data are given in Table 4. Over the unpromoted catalyst, added ethanol momentarily converted to ethene and ethane. This alcohol dehydration activity of Mo/SiO_2 indicates that Mo/SiO_2 has significant acidity, in agreement with the observation by Maruyama et al.[14]

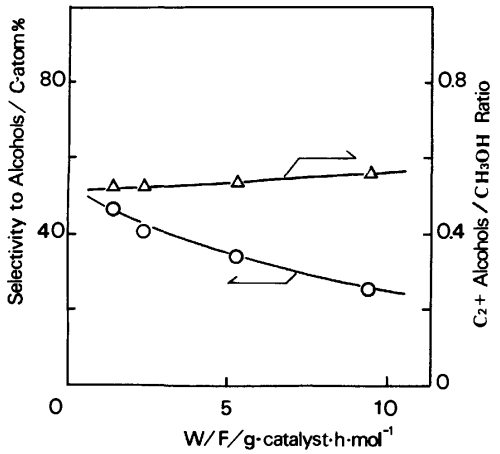

Fig. 4. Effect of time factor on alcohol selectivity (O) and C_2+alcohols/methanol ratio (△) over Mo(20 wt%)+KCl(K=1.63 wt%)/SiO_2(ID) catalyst at 573 K and 1.6 MPa.

Table 4. Addition of Ethanol and Ethene to CO-H_2 over Mo(20 wt%) + KCl/SiO_2(ID)[a]

KCl content	Ethanol conversion rate to ethene and ethane[b]	Ethene conversion rate to ethane[c]
wt%	mmol (kg-catalyst)$^{-1}$ h^{-1}	
0	352	410
1.63	12	105

a) Increase in ethene and/or ethane on addition of ethanol and ethene to synthesis gas. b) Reaction conditions; 523 K, 1.6 MPa, W/F= 10 g·catalyst h mol^{-1} C_2H_5OH= 1.0 mol(kg·catalyst)$^{-1}$h^{-1}. c) Reaction conditions; 473 K, 1.6 MPa, W/F= 10 g·catalyst h mol^{-1}, C_2H_4= 1.3 mol(kg-catalyst)$^{-1}$ h^{-1}.

The addition of KCl led to the considerable decrease in ethene and ethane. This is supposed to be due to the K-induced decrease in acidity. It can be seen in Table 4 that addition of KCl to Mo/SiO_2(ID) remarkably suppressed the ethene conversion rate to ethane. Thus the additional role of K in improving alcohol selectivity is to retard dehydration of alcohol to alkenes and to slow hydrogenation of the alkenes to alkanes.

The yield of alcohols was considerably influenced by raising the total pressure. The effect of total pressure on the product distribution over Mo(20 wt%)+KCl(K=1.63 wt%)/SiO_2(ID) at 573 K and W/F= 1.4 g-catalyst h mol^{-1} was indicated in Fig. 5 and Table 5. Raising the pressure, the yield of alcohols was greatly improved. The C_2+/C_1 ratios of hydrocarbons and alcohols were independent of the pressure. It should be noted that at 5.0 MPa STY of alcohols as large as 420 g (kg-catalyst)$^{-1}$ h^{-1} was obtained in 68 C-atom% selectivity. This STY is comparable with those reported so far with Cu-Co based catalyst[15] and MoS_2-Co-K_2CO_3 catalyst.[11] At 6.5 MPa the selectivity for alcohol formation was deteriorated, while the yield of hydrocarbons was greatly increased. This would also result from the successive reaction of alcohols to hydrocarbons owing to the increase in the contact time under the high pressure. Xie et al. recently claimed that alcohol

yields were very sensitive to total pressure over MoS_2 based catalysts.[16)]

Figure 6 and Table 6 show the effect of reaction temperature on the product distribution over Mo(10 wt%)+KCl(K=1.63 wt%)/SiO_2(ID) at 1.6 MPa and W/F=10 g-catalyst h mol^{-1}. With the decrease in temperature, the selectivity to alcohols was greatly improved. At 513 K, 76 C-atom% of the alcohol selectivity was obtained. A maximum yield of alcohols was attained at 573 K. At temperatures above 573 K, the yield of alcohols was decreased while that of hydrocarbons was strongly promoted. C_2+ alcohols/methanol ratio gradually increased with the increase in temperature.

In the Mo catalyst system, water, the primary product, is rapidly converted to CO_2. This makes the alcohol separation simple and less energy consuming as there is no problem due to azeotrope formation.[17)] Moreover, it is feasible to utilize a synthesis gas with a low H_2/CO ratio produced from coal gasifiers without a separate shift converter.[18)]

(Received April 10, 1987)

Electrical conductivities have been measured for TTC_n-TTF and $TTeC_n$-TTF. In the case of TTC_n-TTF, the compounds with short alkyl chains (n=1—3) show the high resistivities above 10^{10} Ω cm, while the resistivities of the compounds with long alkyl chains ($n\geq4$) decrease to 10^5—10^7 Ω cm. The relatively low resistivities of the compounds with long alkyl chains are attributed to the considerable reduction in intermolecular distance between adjacent TTF skeletons caused by intermolecular interactions through alkyl chain groups taking into account the results of their crystal structures, thermal properties and densities. As for $TTeC_n$-TTF compounds, the carbon number dependence of resistivity is almost similar to that of TTC_n-TTF in the range of large n ($n\geq8$). Exceptionally, $TTeC_1$-TTF exhibits noticeably low resistivity of 6.9×10^4 Ω cm. X-Ray diffraction study confirms that the high conductivity of $TTeC_1$-TTF is caused by the formation of zigzag Te chains due to the presence of strong intermolecular Te-Te atomic contacts.

Since the discovery of a metallic conductivity in TTF-TCNQ, many interests have been devoted to organic conductors with TTF derivative donors. A large number of organic metals are found in charge-transfer complexes with TTF derivative donors such as TMTTF (tetramethyl-TTF), HMTTF (hexamethylene-TTF), and BEDT-TTF (bis(ethylenedithio)-TTF)) complexes. Tetrakis(alkylthio)tetrathiafulvalene (abbreviated as TTC_n-TTF) used in this work is one of these derivatives, which is obtained by the introduction of four alkylthio substitutional groups to a TTF skeleton, as shown in Fig. 1. Some of charge-transfer complexes with TTC_1-TTF have been investigated[1] and an iodine complex with a composition of $(TTC_1\text{-TTF})(I_3)_{0.823}$ shows a metallic conductivity.[2,3] Besides the studies related to CT complexes, TTC_n-TTF attracts interests in anomalous electrical property as a single component organic solid which does not belong to charge-transfer complexes, because of its good electrical conduction.[4] TTC_n-TTF consists of a conjugated part of tetrathio-TTF (C_6S_8) moiety and an aliphatic part of four alkyl chain groups. It is interesting to investigate systematically how the conjugated and the aliphatic parts affect the physical properties of TTC_n-TTF's by changing the carbon number of alkyl group. Moreover, it is easy to extend our system by replacing sulfur atoms with other chalcogen atoms such as selenium or tellurium having bigger van der Waals radius. This strategy will enable to increase the magnitudes of intermolecular interactions and enhance the conductivity. We have reported the novel crystal structure, high electrical conductivity and low ionization energy of TTC_9-TTF compound,[4,5] which are supposed to be associated with the reduction in intermolecular distance between TTF skeletons caused by the function of intermolecular interactions between alkyl chains. In this work, we present the experimental results of electrical conductivities of TTC_n-TTF and tetrakis(alkyltelluro)tetrathiafulvalene (abbreviated as $TTeC_n$-TTF). The origins of relatively low resistivities for the compounds with long alkyl chains are discussed in connection with crystal structures and the other physical properties such as thermal properties, densities, and ionization energies. Furthermore, the differences of electrical properties between TTC_n-TTF and $TTeC_n$-TTF are also discussed according to intermolecular interactions.

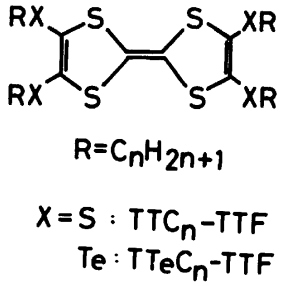

Fig. 1. The molecular structure of TTC_n-TTF and $TTeC_n$-TTF.

Experimental

The synthetic procedures of TTC_n-TTF and $TTeC_n$-TTF compounds (n=1—18) were reported in the previous papers.[1,6] The purification of these compounds was performed by column chromatography with silica gel and recrystallization. The purity was checked by thin-layer chromatography. Single crystals of TTC_n-TTF with n=1—11 were prepared by recrystallization in a mixed solution of hexane and methanol or acetone and methanol. Crystals of

a) Single crystals for the compounds with $n=1$—11 and compaction pellets for the compounds with $n=12$—18. The measurements for the crystals were performed along the long axis of the crystal.

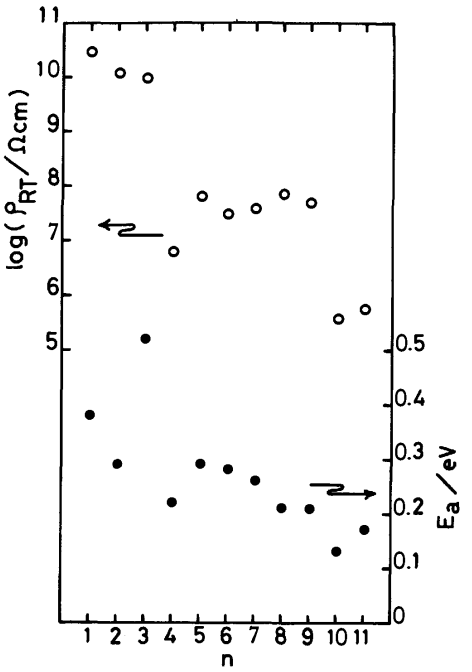

Fig. 2. The correlation between the carbon number n of alkyl group and $\log\rho_{RT}$ or E_a for the single crystals of TTC_n-TTF (n=1—11).

TTC_n-TTF were mainly grown as needle-like crystals except thick plates of n=1, 2, and 9. The colors of the samples were yellow for n=1, 3, and 18 and orange for the other compounds. Single crystals of $TTeC_n$-TTF with n=1, 2, 8, and 9 were obtained as needle-like crystals with dark orange color. Electrical conductivity was measured by a two-probe method between room temperature and a temperature just above a melting point under a vacuum of $\approx10^{-4}$ Pa to avoid an oxidation effect. In the case of the compounds with n=12—18 for TTC_n-TTF and the compounds with n=13—18 for $TTeC_n$-TTF which are difficult to be crystallized as single crystals, conductivity was measured with compaction pellets.

Results and Discussion

TTC_n-TTF. The results of resistivities at room temperature ρ_{RT} and activation energies E_a for semiconductive TTC_n-TTF compounds are summarized in Table 1. Figure 2 shows the correlation between the carbon number n of alkyl group and $\log\rho_{RT}$ or E_a for the single crystal samples with n=1—11. The resistivities of the compounds with n=1—3 are very high (above 10^{10} Ω cm), while those of the compounds with $n\geq4$ decrease to 10^5—10^7 Ω cm except n=18 with $\approx10^{10}$ Ω cm. Especially, the resistivity values of 3.7×10^5 and 5.6×10^5 Ω cm for TTC_{10}-TTF and TTC_{11}-TTF, respectively, are remarkably low among single component organic solids ever observed (TTT (tetrathiotetracene) single crystal was reported to have the lowest resistivity 1.5×10^5 Ω cm among the organic solids including sulfur atoms though there have been arguments against the result because of the possibility of extrinsic features associated with the complex formation with oxygen[7]). The n dependence of the activation energies is correlated to that of room temperature resistivities as seen in Fig. 2, where TTC_{10}-TTF with a minimum resistivity corresponds to a minimum activation energy E_a=0.13 eV.

Up to now the crystal structures are presented for the compounds with n=1, 2, 4, 5, 9, and 10.[8,9] The central C_6S_8 moieties of n=1 and 2 are nonplanar and the molecular structure has a boat form. The intermolecular interactions between adjacent C_6S_8 moieties are weak and can be described in terms of the van der Waals interactions because of the absence of discernible intermolecular overlaps between adjacent π systems. Therefore, the high resistivities of n=1 and 2 can be understood taking account of this fact. On the contrary, C_6S_8 moieties of n=4, 5, 9, and 10 are planar and the molecular structure has a chair form. The intermolecular overlaps between adjacent π systems are effectively large because there exists columnar stacking structures consisting of the conjugated π systems which are not found in TTC_1-TTF and TTC_2-TTF. Thus the compounds with $n\geq4$ show the relatively low resistivities due to the crystal structures which are favorable for electron transport. The remarkable enhancement of the conductivity with increasing n can be explained by the fact that TTC_9-TTF and TTC_{10}-TTF have the short interplanar distance of 3.49 Å between adjacent C_6S_8

Table 2. Anisotropies of Resistivities of TTC_n-TTF

Compound	ρ_x[a]/Ω cm	ρ_y[b]/Ω cm	ρ_z[c]/Ω cm

a) Single crystals for the compounds with $n=1$—9 and compaction pellets for the compounds with $n=13$—18. The measurements for the crystals were performed along the long axis of the crystal.

moieties which is considerably reduced in comparison with 3.73 Å in TTC_5-TTF (The difference in the observed resistivities between TTC_9-TTF and TTC_{10}-TTF with the same interplanar distance of 3.49 Å is considered to be caused by the difference in the magnitude of the transfer integrals between adjacent molecules which are easily changed by subtle difference in crystal structures.) These facts concerning crystal structures confirm that the remarkably low resistivities in the compounds with long alkyl chains are accomplished by strong intermolecular interactions due to the reduction in the intermolecular distance between adjacent C_6S_8 moieties.

The anisotropies of resistivities at room temperature for the compounds with n=1, 2, and 9 are summarized in Table 2. According to the structure analysis, TTC_9-TTF shows a large anisotropy $\rho_b/\rho_c\approx10^6$ as shown in Table 2 and the easy axis for electrical conduction (ρ_c) corresponds to the stacking direction of C_6S_8 moiety parallel to the c-axis, while the hard axis corresponds to the b-axis, in which direction adjacent TTC_9-TTF molecules face to each other through long alkyl chains elongated parallel to the b-axis. Along the a-axis, there exist strong S-S contacts which give rise to about the same magnitude of ρ_a to ρ_c. The investigation of resistivity just above the melting point (T_m=57 °C) shows that ρ_c increases to $\approx10^{12}$ Ω cm which is nearly equal to ρ_b in the crystal around T_m. This fact gives evidence that the regular stacks of the conjugated π systems parallel to the c-axis favorable to the good conduction is destroyed in liquid state. These results suggest the presence of the electrical conduction path associated with the large intermolecular overlaps and the short S-S contacts between adjacent π systems. On the other hand, TTC_1-TTF and TTC_2-TTF show a relatively small anisotropy (10^2—10^4) because of the absence of a special direction for easy electrical conduction.

Ultraviolet photoelectron spectroscopic studies presented that the compounds with long alkyl chains showed extraordinarily low ionization energies of 4.7—4.85 eV.[5] Such low values can be explained by the enhancement of polarization energy through large intermolecular interactions due to the small intermolecular distance. The studies of the thermal property suggest that intermolecular interactions are dominated mainly by the van der Waals interaction of C_6S_8 moieties in the range of small n ($n\leqslant7$), while they are dominated mainly by alkyl chain groups in the range of large n.[10] Taking into consideration of the results of crystal structures, the short interplanar distance for the compounds with large n is caused by these intermolecular interactions between alkyl chain groups, which is consistent with the following result of the density. The density measurements showed that the ratio of effective volumes of C_6S_8 moieties to those of alkyl chain groups for the compounds with $n\geqslant8$ decreased obviously as compared with the ratio of the compounds with $n<8$.[10] This fact means that effective volumes of C_6S_8 moieties for the compounds with $n\geqslant8$ are effectively depressed by intermolecular interactions caused by long alkyl chains. These results suggest that intermolecular interactions through alkyl chain groups work to reduce the interplanar distance between adjacent C_6S_8 moieties, which leads to remarkably high conductivities of the compounds with long alkyl chains.

$TTeC_n$-TTF. $TTeC_n$-TTF compounds also have semiconductive characters and the results of their electrical resistivities at room temperature ρ_{RT} and activation energies E_a are summarized in Table 3. Single crystals were employed only in n=1, 2, 8, and 9 for the present resistivity measurement. The magnitude of the resistivity of 6.9×10^4 Ω cm for $TTeC_1$-TTF, which is the lowest in the series of $TTeC_n$-TTF, is lower than the minimum resistivity in the TTC_n-TTF system. Crystal structure analysis gives the knowledge to understand noticeably low resistivity of this compound.[11] The central $C_6S_4Te_4$ moiety of $TTeC_1$-TTF is planar unlike TTC_1-TTF. $TTeC_1$-TTF molecules are stacked to form a column

structure with the interplanar distance of 3.76 Å. Tellurium atoms between neighbouring columns form zigzag chains along the stacking axis of $TTeC_1$-TTF molecules. The shortest Te-Te distance between neighbouring columns is 3.64 Å, which is significantly smaller than the van der Waals distance 4.12 Å of Te atom. The network of the zigzag Te chains in this material is reminiscent of the crystal structure of inorganic pristine Te where strong interatomic interactions associated with a short Te-Te distance (2.84 Å) bring about high conductivity (1 Ω cm). Therefore, the strong Te-Te interactions of $TTeC_1$-TTF compound is considered to give noticeably high conductivity. The short Te-Te contact has been observed also in the crystal of HMTTeF (bis(trimethylene)tetratellurafulvalene),[12] where HMTTeF molecules form columns stacked alternately with Te-Te distances of 3.583 and 3.743 Å. The dimerization effect of HMTTeF may be unfavorable to realize good electrical conduction.[13] On the contrary, for $TTeC_1$-TTF, the uniform zigzag Te interchains network can contribute to accomplish noticeably high conductivity. $TTeC_1$-TTF reveals the well-conductive character even just above melting point (T_m=170 °C) with the resistivity of $\approx 10^7$ Ω cm. This fact means that the short range ordering of molecular stacking associated with intermolecular interactions still remain in the molten state because of strong interatomic interactions between tellurium atoms. $TTeC_2$-TTF is found to have higher resistivity than $TTeC_1$-TTF. The high resistivity of $TTeC_2$-TTF can be easily understood by crystal structure analysis,[11] which suggests that the shortest Te-Te distance 3.99 Å in $TTeC_2$-TTF is considerably large as compared with 3.64 Å in $TTeC_1$-TTF and the interplanar distance between $C_6S_4Te_4$ moieties is very large (4.2 Å). For the compounds with $n \geq 8$, the resistivity is in the similar range to that for TTC_n-TTF with $n \geq 8$. According to the results of thermal properties, the series of $TTeC_n$-TTF is divided into two subgroups depending on the length of alkyl chain, which are different from the series of TTC_n-TTF.[14] For the compounds with long alkyl chains ($n \geq 7$), similar to TTC_n-TTF, intermolecular interactions associated with long alkyl chains predominate molecular packing, leading to the reduction in the distance between the $C_6S_4Te_4$ π systems which can act to enhance electrical conduction. The behavior of the resistivity for the compounds with $n \geq 7$ can be explained along this line. For the compounds with $n < 7$, which belong to the other subgroup, competition among three kinds of intermolecular interactions originating from alkyl chains, tellurium atoms and TTF π systems gives peculiar crystal structures depending on n. In the case of $TTeC_1$-TTF which has the shortest alkyl chains, strong intermolecular interaction between tellurium atoms plays an important role to determine a crystal structure and works to realize good electrical conduction as well as pristine tellurium.

Summary

The solid state properties of TTC_n-TTF and $TTeC_n$-TTF have been investigated by electrical conductivity measurement. In the case of TTC_n-TTF, the compounds with small n (n=1—3) show the high resistivities of above 10^{10} Ω cm, while those with large n ($n \geq 4$) show relatively low resistivities of 10^5—10^7 Ω cm. Especially, TTC_{10}-TTF and TTC_{11}-TTF show the remarkably low resistivities of 3.7×10^5 and 5.6×10^5 Ω cm, respectively. These values are exceptionally low among organic conductors which do not belong to charge-transfer complexes. The fairly good conductivities of the compounds with long alkyl chains are caused by the reduction in the distance between π systems of adjacent C_6S_8 moieties parallel to the stacking axis, which is accomplished by intermolecular van der Waals interactions through alkyl chain groups. The function of long alkyl chains for the reduction in the distance between the adjacent π systems can be called as "a molecular fastener effect". The optical band gaps are ≈2 eV for TTC_n-TTF compounds.[15] Thus the small activation energies of 0.1—0.3 eV from conductivity cannot be explained by a simple band picture for semiconducting materials. Electrical properties of $TTeC_n$-TTF are qualitatively same to those of TTC_n-TTF for the long alkyl chain compounds ($n \geq 8$). $TTeC_1$-TTF shows the lowest resistivity of 6.9×10^4 Ω cm among a series of TXC_n-TTF (X=S and Te). The noticeably high conductivity of this compound is considered to be caused by strong intermolecular interactions due to the presence of uniform zigzag Te chains similar to inorganic pristine Te.

The authors wish to thank Prof. Tadaoki Mitani of Institute for Molecular Science for his helpful discussion. This work was supported by a Grant-in-Aid for Scientific Research No. 61133008 from the Ministry of Education, Science and Culture.

Photo-Excitable Membranes. Photoinduced Potential Changes across Poly(vinyl chloride)/Spirobenzopyran Membranes Doped with Valinomycin and Nonactin

Jun-ichi Anzai, Yasushi Hasebe, Akihiko Ueno, and Tetsuo Osa*
Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980
(Received April 27, 1987)

Poly(vinyl chloride)/spirobenzopyran membranes doped with valinomycin or nonactin were prepared to study the photoresponse of the membrane potential in the presence of K^+ or NH_4^+ ion. Ultraviolet (UV) light irradiation induced more than 100 mV of potential change across the membrane doped with valinomycin in the presence of 10^{-8}—10^{-6} M† KCl, whereas the potential change was extremely suppressed in the presence of higher KCl concentration (>10^{-3} M). The photoresponse of the membrane potential depended upon the direction from which the membrane was irradiated. The nonactin-doped membranes showed a similar tendency in photoresponse in the presence of NH_4Cl to that observed for the valinomycin-doped membrane in the presence of KCl. The results were explained in terms of surface potential changes at the irradiated surface of the membrane, associated with the photochemical reaction of spirobenzopyran and the specific adsorption of cations to the surface of the membrane.

Several reports have described efforts to photochemically regulate the membrane potential across the polymer membranes doped with spiropyran derivatives. Suzuki et al. have reported that 20—30 mV of membrane potential can be induced by photoirradiating a cellulose/phosphatidylcholine composite membrane doped with 1′,3′,3′-trimethyl-6-nitrospiro-[2*H*-1-benzopyran-2,2′-indoline].[1,2] The results have been explained in terms of photochemically-induced changes in the fixed charge density in the membrane arising from the photochemical reaction of the spiropyran derivative. They have also prepared asymmetric membrane which contains spiropyran derivative at the surface of one side of the membrane.[3] Bellobono et al. have prepared cellulose membranes incorporating five kinds of spiropyran compounds to examine their photoresponse in membrane potential, with the intention of applying the membrane in constructing photoresponsive devices used in the field of optical data storage.[4,5] Synthetic polymers which contain spiropyran side chains have also been used to study photoresponse of the membrane. Irie et al. have prepared polymer membranes composed of poly(methacrylate) having spiropyran pendant groups and measured membrane potential under irradiation.[6] They have suggested the importance of the conformational changes of the polymer chains as well as the charge density in the membrane.

In all cases cited above, the magnitude of photoinduced potential was 20—30 mV and the response was somewhat slow. We have succeeded in highly improving the photoresponse in membrane potential across the spiropyran-contaning membrane, by the use of plasticized poly(vinyl chloride) (PVC) as a membrane matrix.[7-14] In the course of our study on the PVC/spiropyran membranes, the followings were found; (1) UV irradiation induces membrane potential changes of more than 100 mV with a response time of 1—2 min, (2) the photoinduced potential changes arise from the change in charge density on the membrane surface (i.e., surface potential change), which, in turn, stems from the photo-generated open form of spiropyran, (3) the content of open form of spiropyran is higher on the UV-irradiated surface than that on the nonirradiated surface (i.e., formation of asymmetric membrane). The present paper describes the photoresponse in membrane potential across the PVC/1′-hexadecyl-3′,3′-dimethyl-6-nitrospiro[2*H*-1-benzopyran-2,2′-indoline] (**1**) membranes doped with nonactin and valinomycin. These systems are useful for studying the effects of specific adsorption of ions on the membrane surface upon the photoresponse of the membrane, because valinomycin and nonactin are ionophores which bind K^+ and NH_4^+ ions, respectively.

Experimental

Materials. PVC (molecular weight of ca. 70000) was purchased from Wako Chemical Co. and used without further purification. Dibutyl phthalate (DBP), tetrahydrofuran (THF), ammonium chloride (NH_4Cl), potassium chloride (KCl), nonactin, and valinomycin are of extra pure reagent grade. The synthetic procedure and analytical data of **1** were reported elsewhere.[12]

Membrane Preparation. PVC/**1**/nonactin membrane was prepared by pouring the mixture of 250 mg of PVC, 0.5 ml of DBP, 30 mg of 1, 5 mg of nonactin, and 20 ml of THF onto a flat Petri dish (8.5 cm diameter), and allowing the solvent to evaporate at room temperature. PVC/**1**/valinomycin membrane was prepared in the same manner

† 1 M=1 mol dm^{-3}.

using 5 mg of valinomycin in place of nonactin. The thickness of the membranes thus prepared was ca. 0.15 mm.

Measurements. Membrane potential measurements were conducted at 25 °C using a U-shaped glass cell illustrated in Fig. 1. The composition of the electrochemical cell for the membrane potential measurements was as follows; Ag/AgCl |0.1 M $(CH_3)_4NCl$|electrolyte solution (c_1)|PVC/**1**/nonactin or PVC/**1**/valinomycin membrane|electrolyte solution (c_2) |0.1 M $(CH_3)_4NCl$|Ag/AgCl. The electrode in the c_1 compartment was earthed. Photoirradiation was carried out from the c_1 or c_2 side with a 500 W xenon lamp using cut-off filters Toshiba UVD-35S and O-55 to isolate UV (320 nm$<\lambda<$400 nm) and visible ($\lambda>$490 nm) light, respectively. Noise level in the potential was within 1 mV under the present experimental conditions. Absorption spectra of the membrane were recorded on a Shimadzu UV-visible spectrophotometer (Type UV-250).

Results and Discussion

We have already reported that the membrane potential across the PVC/**1** membrane changes upon photoirradiation, associated with the photochemical interconversion of **1** between closed form and open form.[7-14] The photoinduced membrane potential was ascribed to changes in charge density at the UV-irradiated surface of the membrane, arising from the photochemically-generated open form of **1**.

Figure 2 depicts a typical photoresponse of the membrane potential across the PVC/**1**/valinomycin membrane. When the membrane was exposed to UV light from c_2 side, the membrane potential shifted in the negative direction and, subsequently, the membrane potential was restored to the original value upon visible light irradiation. The photoresponsive behavior of the PVC/**1**/valinomycin membrane was essentially comparable to those previously observed for valinomycin-free PVC/**1** membrane.[12] This was also the case for photoresponse of the PVC/**1**/nonactin membrane. These results suggest that valinomycin and nonactin have scarcely any influence on the photochemical reaction of **1** in the membrane.

PVC/1/Valinomycin Membrane. In general, the potential difference across a charged membrane (membrane potential, $\Delta\phi$) is given as an algebraic sum of the diffusion potential in the membrane and the surface potential difference at membrane-solution interfaces.[15-18] In the case of plasticized PVC membranes, the contribution from the diffusion potential is considered small due to the depressed ionic permeability in the highly hydrophobic membrane interior, as was discussed for PVC/crown ether membranes in the previous paper.[19] For the PVC/**1**/valinomycin membrane, it is reasonable to assume that the surface potentials at the membrane-solution interfaces depend on the density of the ions which are adsorbed to the membrane surface by forming complexes with valinomycin, as well as on the content of open-**1**.

We therefore measured the membrane potential across the PVC/**1**/valinomycin membrane under visible and UV light in the presence of 10^{-8}—10^{-1} M KCl in the c_2 side solution (Fig. 3). In the dark or under visible light, where **1** assumes wholly closed form (noncharged form), the $\Delta\phi$ values increased linearly with increasing concentration of K^+ ion over the range of 10^{-5}—10^{-1} M. This should be caused by adsorption of K^+ ions on the membrane surface as a result of complexation between K^+ ions and valinomycin. This means that the charge density on the membrane surface reflects the concentration of K^+ ion in the aqueous solution adjacent to the membrane surface. The $\Delta\phi$ values measured under UV light irradiation from c_1 or c_2 side were also affected by the concentration of K^+ ion. UV irradiation from the c_1 side induced positive shift of the membrane potential, while the potential shifted in the negative direction upon UV irradiation from c_2 side. The polarity of the potential shift was reasonably explained based on the

asymmetric membrane formation under UV light irradiation.[12]

Figure 4 shows the $\Delta(\Delta\phi)$ values, the difference between the $\Delta\phi$ value under UV light irradiation and that in the dark or under visible light, observed upon UV irradiation from c_1 or c_2 side. When the membrane was irradiated from c_2 side, an approximately linear relationship existed between the $\Delta(\Delta\phi)$ values and the concentration of K^+ ion over the range of 10^{-6}—10^{-3} M. The magnitude of $\Delta(\Delta\phi)$ value was enhanced in the lower concentration region of K^+ ion, whereas, over 10^{-2} M KCl, the photoresponse was suppressed, being 5 mV or less. On the contrary, the $\Delta(\Delta\phi)$ values were always about 100 mV when the membrane surface facing the c_1 solution, where K^+ ion was absent, was exposed to UV light. These observations imply that the higher charge density on the irradiated surface of the membrane is not favorable for the enhanced photoresponse.

Figure 5 shows the $\Delta\phi$ values across the membrane under the conditions that KCl concentrations in both sides are equal with each other. The membrane potential was always near to zero under visible light or in the dark. UV light irradiation from c_1 or c_2 side induced shifts in membrane potential in the positive or negative direction, respectively, in spite of the conditions of $c_1=c_2$. This can be ascribed to asymmetric membrane formation under UV light irradiation,[20-22] i.e., the photochemical reaction of **1** from closed form to open form proceeds more efficiently on the irradiated surface of the membrane than on the opposite surface. Therefore, the content of open-**1** on the irradiated surface is higher than that on the nonirradiated surface. This is the reason why photoinduced potential changes were observed even for $c_1=c_2$. The $\Delta(\Delta\phi)$ values were dependent on the KCl concentration, in both cases when irradiated from c_1 and c_2 sides. These results can be also explained based on the idea that the higher charge density on the irradiated surface of the membrane suppresses the photoresponse in membrane potential.

We also checked the photoresponse of PVC/**1** membrane without valinomycin in the presence of KCl, and found that the $\Delta(\Delta\phi)$ values were always about 100 mV irrespective of KCl concentration. This means that valinomycin is essentially required for binding K^+ ions to regulate the charge density on the membrane surface.

In previous papers,[7-14] we have explained the photoresponse of **1**-doped PVC membranes in terms of the formation of asymmetric membrane under UV irradiation. To obtain a further evidence for this, we

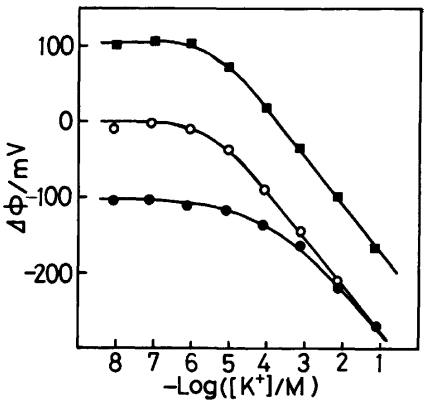

Fig. 3. The membrane potential across the PVC/1/valinomycin membrane under UV light irradiation from c_1 side (—■—) and c_2 side (—●—) and visible light (—○—) from c_2 side as a function of KCl in the c_2 solution. The concentration of KCl in the c_1 side solution was zero.

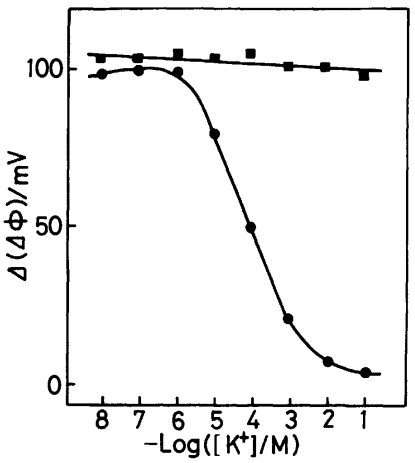

Fig. 4. The effects of KCl concentration on the $\Delta(\Delta\phi)$ value. The membrane was irradiated from c_1 side (—■—) and c_2 side (—●—). The concentration of KCl in the c_1 side solution was zero.

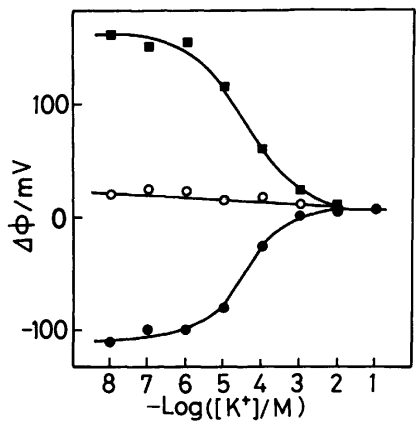

Fig. 5. The asymmetric membrane potential across the PVC/1/valinomycin membrane in the presence of KCl under UV light irradiation from c_1 side (—■—) and c_2 side (—●—) and under visible light from c_2 side (—○—). The concentration of KCl in both solutions was equal with each other.

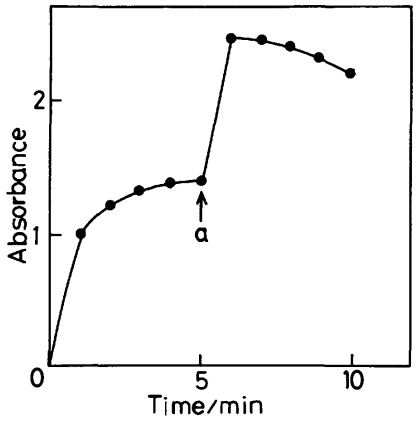

Fig. 6. Change of absorbance of the membrane at 565 nm under UV light irradiation. After 5 min-irradiation from one side of the membrane, the opposite surface of the membrane was exposed to UV light at (a).

measured absorption spectra of the membrane. As depicted in Fig. 6, the absorbance of the membrane at 565 nm, which is absorption maximum of open-**1**, increased rapidly at the initial stage of UV irradiation and declined to reach a steady-state value after about 5 min. The absorbance no longer increased even after prolonged irradiation from the same direction. When the membrane, after the steady-state value of absorbance had been attained by UV irradiation from one side of the membrane, was exposed to UV light, in turn, from the opposite direction, a further increase of the absorbance was observed. This is a clear evidence for the formation of asymmetric membrane under UV light irradiation.

PVC/1/Nonactin Membrane. Photoresponse of PVC/**1**/nonactin membrane was also examined in the presence of NH_4^+ ions. We have already reported some results concerning photoresponse of the PVC/**1**/nonactin membrane.[14] Figure 7 shows the dependence of $\Delta\phi$ values on the NH_4Cl concentration in the aqueous solution. The basic profiles of the membrane potentials under visible and UV light were essentially the same as those observed for PVC/**1**/valinomycin membrane in the presence of KCl.

The $\Delta(\Delta\phi)$ values were shown in Fig. 8. When the membrane surface facing c_1 solution was exposed to UV light, the $\Delta(\Delta\phi)$ values measured 180—190 mV irrespective of the concentration of NH_4Cl in c_2 solution. The $\Delta(\Delta\phi)$ values, in contrast, depended remarkably on the NH_4Cl concentration when irradiated from c_2 side. This behavior can be explained based on the same idea which explicated the photoresponse of PVC/**1**/valinomycin membrane in the presence of KCl. Namely, the specific adsorption of NH_4^+ ions on the membrane surface facing c_2 solution affected the magnitude of the $\Delta(\Delta\phi)$ values.

Figure 9 shows the $\Delta\phi$ values across the PVC/**1**/

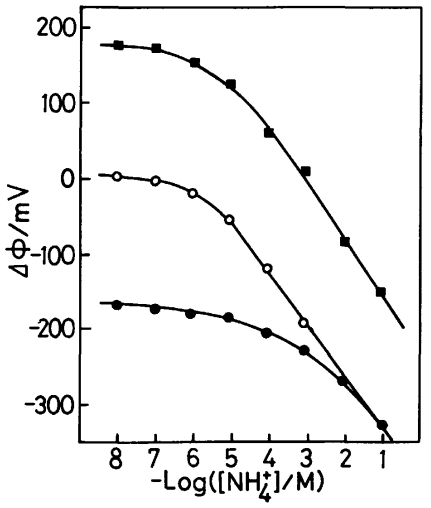

Fig. 7. The membrane potential across the PVC/**1**/nonactin membrane in the presence of NH_4Cl under UV light irradiation from c_1 side (—■—) and c_2 side (—●—) and under visible light from c_2 side (—○—). The concentration of NH_4Cl in the c_1 side solution was zero.

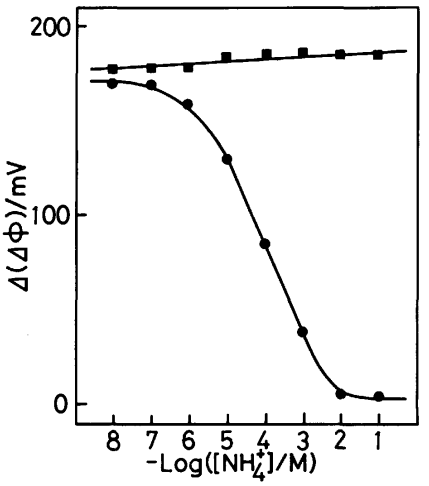

Fig. 8. The effects of NH_4Cl concentration on the $\Delta(\Delta\phi)$ value. The membrane was irradiated from c_1 side (—■—) and c_2 side (—●—). The concentration of NH_4Cl in the c_1 side solution was zero.

nonactin membrane under the conditions that the concentrations of NH_4Cl in c_1 and c_2 solutions are equal with each other. The membrane potentials under visible light or in the dark were always near to zero. UV irradiation from c_1 or c_2 side induced positive or negative shift of the membrane potential, respectively. The $\Delta\phi$ values observed under UV light irradiation drastically depended on the NH_4Cl concentration in the aqueous phase.

We elucidated the effects of nonactin concentration in the membrane on the magnitude of $\Delta(\Delta\phi)$ values in the presence of 10^{-4} M NH_4Cl (Fig. 10). When the nonactin-free membrane was irradiated, more than

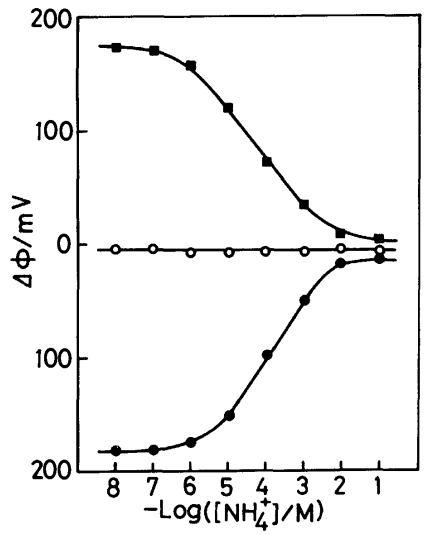

Fig. 9. The asymmetric membrane potential across the PVC/1/nonactin membrane in the presence of NH_4Cl under UV light irradiation from c_1 side (—■—) and c_2 side (—●—) and under visible light (—○—). The concentration of NH_4Cl in both side solutions was equal with each other.

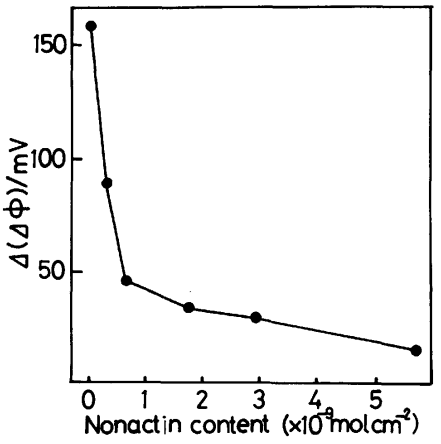

Fig. 10. Effects of nonactin content in the membrane on the photoresponse of the PVC/**1**/nonactin membrane. The concentration of NH_4Cl in both side solutions was 10^{-4} M.

150 mV of photoinduced potential was observed. On the other hand, the $\Delta(\Delta\phi)$ values lowered to 50 mV or less in the presence of 1×10^{-9}—5×10^{-9} mol cm^{-2} of nonactin in the membrane. This clearly indicates that the formation of nonactin/NH_4^+ ion complexes on the membrane surface has a serious influence on the $\Delta(\Delta\phi)$ values.

In conclusion, the photoresponse in membrane potential across the PVC/**1** membranes doped with valinomycin and nonactin drastically depended on the concentration of K^+ and NH_4^+ ions, respectively, in the aqueous solution adjacent to the UV-irradiated surface of the membrane. These membranes may be applicable to the sensitive layer of a novel class of ion sensors which change the $\Delta(\Delta\phi)$ value in response to the concentration of ions such as K^+ and NH_4^+ in the solution.

Multi-Ionic Potential and Membrane Permeability Matrix. II. Na^+-Ca^{2+} Bi-Ionic System with a Cation-Exchange Membrane and Effects of Cl^- on Cation Transport

Kozue KAIBARA,* Hiroyoshi INOUE, and Hideo KIMIZUKA
Department of Chemistry, Faculty of Science, Kyushu University,
Hakozaki, Higashi-ku, Fukuoka 812
(Received April 18, 1987)

Transport characteristics of Na^+-Ca^{2+} bi-ionic system with a highly selective cation-exchange membrane were investigated on the basis of nonequilibrium thermodynamic theory. As a principal transport parameter, the membrane permeability matrix or membrane conductance matrix can be estimated from the membrane potential, conductance, and ion flux data. Significances of diffusional and electroconductive processes of ion transport across membrane were systematically discussed in terms of these matrix elements. Partial contributions of inter-cationic (Na^+-Na^+, Na^+-Ca^{2+}, and Ca^{2+}-Ca^{2+}) correlations to the membrane transport process of ions were examined by means of comparing the estimated values of corresponding matrix elements. It was suggested that Ca^{2+} ions, of which membrane concentrations are kept at high level independently of the Na^+/Ca^{2+} concentration ratio of external aqueous solutions, play a critical role in the membrane transport phenomena. Participations of Cl^- transport in the cation-exchange processes were also discussed on the basis of membrane conductance matrix theory.

Characterization of the ion-transport processes across membrane is a fundamental and important subject in wide varieties of artificial and biological systems, such as ion exchange membranes, lipid bilayers, and biological cellular membranes. Phenomenological analyses on the membrane-transport processes are performed generally utilizing linear formulations relating the thermodynamic driving forces with fluxes across membrane based on the nonequilibrium thermodynamics.[1,2] An appropriate set of the linear phenomenological equations formulating the coupling of driving forces and fluxes can be derived for various transport phenomena arising across membranes.[3]

In case of the ionic membrane transport processes, detailed descriptions of the electrochemical properties, by means of estimating the appropriate phenomenological coefficient as a membrane transport parameter of permselectivity index, are essential procedures to characterize the membrane systems. In this context, the membrane permeability matrix and the membrane conductance matrix were introduced as a principal membrane transport parameter in an earlier paper to describe membrane permselectivities to ions based on the electrochemical and ion flux measurements.[4] By utilizing these membrane permeability parameters in a matrix form, the membrane transport processes of ions can be characterized in terms of the correlations between permeating ions. Furthermore, fundamental aspects of the diffusional and electroconductive movements of ions within membrane phase can be discussed based on these transport parameters.[5,6]

The present investigations were designed to systematically analyze the ion permselectivities and electrochemical properties of $NaCl$-$CaCl_2$ aqueous systems with a cation-exchange membrane on the basis of nonequilibrium thermodynamics. Effects of Ca^{2+} as a bivalent cation on the ion transport across cation-exchange membrane and effects of Cl^- on the cation transport were examined and compared with the results obtained in the NaCl-CsCl systems reported in the preceding paper.[6] Detailed analyses on the correlations between ion fluxes across charged membranes would contribute toward an improvement of efficiencies in the membrane process operations. Recently, it was clarified that a part of K^+ flux across excitable cell membrane, Ca^{2+}-dependent K^+ flux, is strongly affected and triggered by the entry of Ca^{2+} into the cell.[7] Quantitative descriptions of the coupling between permeating ions are also important in biological systems, since the Ca^{2+}-dependent K^+ movement has become established and important physiological concept and Ca^{2+}, which plays a crucial role in many biological reactions, is considered to be a mediator for the ion transport across cellular membranes.

Experimental

Experimental systems consisted of a "CK-1, 1.0t" cation-exchange membrane (Asahi Chemical Industry, Co., Ltd.)[6] with aqueous solution phases I and II separated by the membrane, one of which contains NaCl and the other, $CaCl_2$. Transport numbers of the CK-1, 1.0t membrane to Na^+ and Ca^{2+} were estimated at 0.97—0.99 and 0.95—0.98 from the membrane potential measurements on concentration cell systems with electrolyte concentration ranges of 10^{-1}—10^{-3} mol dm^{-3}. In this study, electrochemical and ion flux measurements were carried out on the systems where concentrations of NaCl or $CaCl_2$ in phase I were varied from 10^{-1} to 10^{-3} mol dm^{-3} and those of the other electrolyte in phase II were kept constant at 10^{-1}, 10^{-2}, or 10^{-3} mol dm^{-3}. Electrolyte solutions were prepared from extra pure salts with conductivity water.

Experimental arrangements for the membrane potential

and conductance measurements were the same as reported earlier.[6] Cation fluxes were measured by the tracer flux method. ^{22}Na and ^{45}Ca in chloride form as a radioactive tracer were purchased from the Japan Radioisotope Association. Radioactive NaCl or $CaCl_2$ aqueous solution with an appropriate specific activity was set in the solution chamber on one side of the membrane, then, the time courses of increases in radioactivity of solution on the other side were detected by the γ-ray scintillation counter or liquid scintillation counter to estimate the steady cation fluxes across membrane. Cl^- fluxes were estimated from Na^+ and Ca^{2+} flux data under the experimental conditions where the total electric membrane currents were zero. Cl^- flux was also checked in some systems by measuring the tracer flux using ^{36}Cl as a tracer ion.

All the measurements were carried out at regulated room temperature, 25 ± 1 °C.

Results and Discussion

General Formulations. A set of the phenomenological equations characterizes well the ion transport processes by formulating the relationships of ion fluxes across membrane with coupled thermodynamic forces, gradients of electrochemical potentials of ions. For the present system studied, the linear phenomenological equations can be written as:[4,6]

$$\begin{bmatrix} J_{Na} \\ J_{Ca} \\ J_{Cl} \end{bmatrix} = -\begin{bmatrix} P_{Na\cdot Na} & P_{Na\cdot Ca} & P_{Na\cdot Cl} \\ P_{Ca\cdot Na} & P_{Ca\cdot Ca} & P_{Ca\cdot Cl} \\ P_{Cl\cdot Na} & P_{Cl\cdot Ca} & P_{Cl\cdot Cl} \end{bmatrix} \times \begin{bmatrix} a^{II}_{Na}\exp(FV/2RT) - a^{I}_{Na}\exp(-FV/2RT) \\ a^{II}_{Ca}\exp(FV/RT) - a^{I}_{Ca}\exp(-FV/RT) \\ a^{II}_{Cl}\exp(-FV/2RT) - a^{I}_{Cl}\exp(FV/2RT) \end{bmatrix} \quad (1)$$

or

$$\begin{bmatrix} i_{Na} \\ i_{Ca} \\ i_{Cl} \end{bmatrix} = -\begin{bmatrix} g_{Na\cdot Na} & g_{Na\cdot Ca} & g_{Na\cdot Cl} \\ g_{Ca\cdot Na} & g_{Ca\cdot Ca} & g_{Ca\cdot Cl} \\ g_{Cl\cdot Na} & g_{Cl\cdot Ca} & g_{Cl\cdot Cl} \end{bmatrix} \begin{bmatrix} V-V_{Na} \\ V-V_{Ca} \\ V-V_{Cl} \end{bmatrix} \quad (2)$$

In these formulations, solvent fluxes are neglected, since the effects of solvent transport across membrane on the interactions of permeant ions are fairly small in the highly charged membrane system.[8] Here, J is the ion flux across membrane, a is the activity, V is the membrane potential, and i is the ionic membrane current; the subscripts Na, Ca, and Cl identify permeant ions; the superscripts I and II refer to the solution phases I and II separated by the membrane; F, R, and T are the Faraday constant, gas constant, and absolute temperature, respectively. V_{Na}, V_{Ca}, and V_{Cl} are the equilibrium membrane potentials to Na^+, Ca^{2+}, and Cl^- calculated by the Nernst equations for the respective ions. The 3×3 matrices in Eqs. 1 and 2 are the membrane permeability matrix and membrane conductance matrix, respectively. Elements of these matrices correspond to modified phenomenological coefficients indicating the participations of interactions between permeant ions specified by the subscript indices to the membrane transport processes. Only the membrane conductance elements satisfy the reciprocal relations, since, in Eq. 1, the permeability matrix element is recognized as a phenomenological coefficient relating the ion flux with electrochemical activity difference between solution phases I and II as a substituted conjugated thermodynamic force.[4,6] The conductance matrix element is defined as a coefficient describing the ohmic relation between ionic membrane current with effective membrane potential difference.

The membrane permeability parameters, which indicate the permselectivities to ions by means of referring the permeating speed of ions across membrane, are expressed as a function of the permeability matrix elements:[4]

$$\begin{aligned} P_{Na} &= P_{Na\cdot Na} + 2P_{Ca\cdot Na} - P_{Cl\cdot Na} \\ P_{Ca} &= \tfrac{1}{2}P_{Na\cdot Ca} + P_{Ca\cdot Ca} - \tfrac{1}{2}P_{Cl\cdot Ca} \\ P_{Cl} &= -P_{Na\cdot Cl} - 2P_{Ca\cdot Cl} + P_{Cl\cdot Cl} \end{aligned} \quad (3)$$

where P_{Na}, P_{Ca}, and P_{Cl} are the electroconductive permeabilities to Na^+, Ca^{2+}, and Cl^-, respectively. Similarly, the membrane conductance, G_m, and ionic membrane conductances, g_{Na}, g_{Ca}, and g_{Cl}, are expressed as a function of the conductance matrix elements:

$$\begin{aligned} G_m &= g_{Na} + g_{Ca} + g_{Cl} \\ &= (g_{Na\cdot Na} + g_{Ca\cdot Na} + g_{Cl\cdot Na}) \\ &\quad + (g_{Na\cdot Ca} + g_{Ca\cdot Ca} + g_{Cl\cdot Ca}) \\ &\quad + (g_{Na\cdot Cl} + g_{Ca\cdot Cl} + g_{Cl\cdot Cl}) \end{aligned} \quad (4)$$

Therefore, the ohmic relations for the total membrane electric current, I, are expressed as:

$$\begin{aligned} I &= -F\{P_{Na}[a^{II}_{Na}\exp(FV/2RT) - a^{I}_{Na}\exp(-FV/2RT)] \\ &\quad + 2P_{Ca}[a^{II}_{Ca}\exp(FV/RT) - a^{I}_{Ca}\exp(-FV/RT) \\ &\quad - P_{Cl}[a^{II}_{Cl}\exp(-FV/2RT) - a^{I}_{Cl}\exp(FV/2RT)]\} \\ &= -g_{Na}(V-V_{Na}) - g_{Ca}(V-V_{Ca}) - g_{Cl}(V-V_{Cl}) \\ &= -G_m(V-V_0) \end{aligned} \quad (5)$$

where V_0 is the membrane potential in the absence of membrane electric current and the following relation is satisfied:

$$\begin{aligned} &2P_{Ca}a^{II}_{Ca}\exp(2FV_0/RT) + (P_{Na}a^{II}_{Na} + P_{Cl}a^{I}_{Cl})\exp(3FV_0/2RT) \\ &\quad - (P_{Na}a^{I}_{Na} + P_{Cl}a^{II}_{Cl})\exp(FV_0/2RT) - 2P_{Ca}a^{I}_{Ca} = 0 \end{aligned} \quad (6)$$

Electrochemical and Flux Data. Figure 1 summarizes the membrane potential, membrane conductance, and cationic flux data. The NaCl-$CaCl_2$ bi-ionic systems with a highly selective cation-exchange membrane studied here can be classified into two large groups: the systems in which Cl^- fluxes are negligible order and the membrane processes are characterized only by Na^+ and Ca^{2+} transports, and the systems in

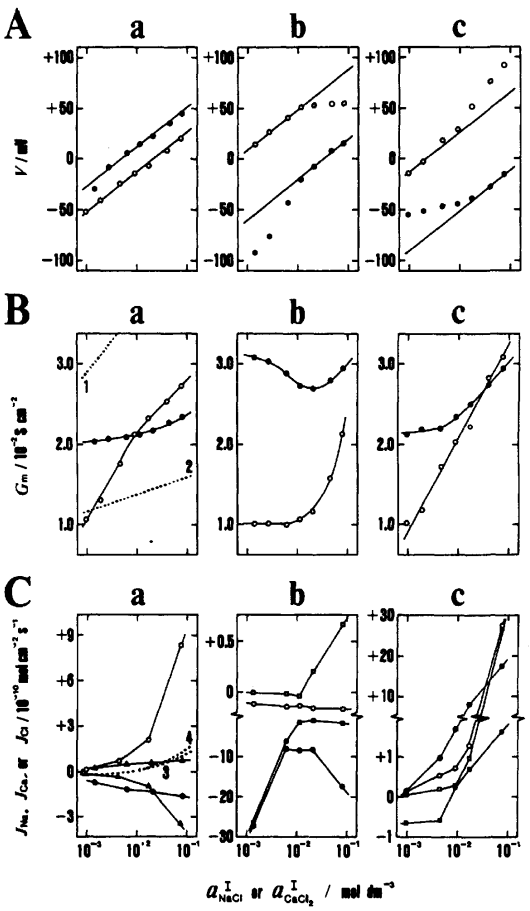

Fig. 1. Membrane potential (A), membrane conductance (B), and ionic flux (C) data as a function of mean electrolyte activity of phase I. Closed and open symbols refer to: a, $CaCl_2$(I)-10^{-2} mol dm^{-3} NaCl(II) and NaCl(I)-10^{-2} mol dm^{-3} $CaCl_2$(II); b, $CaCl_2$(I)-10^{-1} mol dm^{-3}NaCl(II) and $CaCl_2$(I)-10^{-3} mol dm^{-3} NaCl(II); c, NaCl(I)-10^{-1} mol dm^{-3} $CaCl_2$-(II) and NaCl(I)-10^{-3} mol dm^{-3} $CaCl_2$(II). In A, the solid lines refer to the ideal Na^+-Ca^{2+} bi-ionic potential responses estimated by Eq. 7 with a constant P_{Na}/P_{Ca} assumption. In C, ●, ○: J_{Na}; ▲, △: J_{Ca}; ■, □: J_{Cl}. The broken lines 1 and 3 refer to membrane conductance data and J_{Na} data in NaCl(I)-10^{-2} mol dm^{-3} NaCl(II) system; the broken lines 2 and 4 refer to membrane conductance data and J_{Ca} data in $CaCl_2$(I)-10^{-2} mol dm^{-3} $CaCl_2$ (II) systems.

which Cl^- fluxes comparable to cationic fluxes are observed and, accordingly, the cation transport is affected considerably by Cl^- transport.

As illustrated in Fig. 1-C-a, Cl^- fluxes are negligible order as compared with Na^+ and Ca^{2+} fluxes in the $CaCl_2$(I)-10^{-2} mol dm^{-3} NaCl(II) and NaCl(I)-10^{-2} mol dm^{-3} $CaCl_2$(II) systems. When the membrane processes in these systems are characterized only by the cation transport, the next equation can be derived from Eq. 6:

$$V_0 = -(2RT/3F)\ln(P_{Na}a_{Na}^{II}/2P_{Ca}a_{Ca}^{I}) \text{ or } -(2RT/3F)\ln(2P_{Ca}a_{Ca}^{II}/P_{Na}a_{Na}^{I}) = V_{Na\text{-}Ca} \quad (7)$$

The membrane potential expressed by Eq. 7 can be recognized as a cationic equilibrium potential for bi-ionic system being equivalent to the Nernst potential in concentration cell systems. In the present cases, observed membrane potentials correspond to the equilibrium potentials for Na^+ and Ca^{2+}, $V_{Na\text{-}Ca}$. Equation 7 deduces that the constant Na^+/Ca^{2+} permeability ratio is realized for the system in which the linear membrane potential responses of 39.44 mV/(logarithmic electrolyte activity of phase I) at 25 °C are observed.[9-11] Figure 1-A-a indicates that the 10^{-2}mol dm^{-3} NaCl(II) and 10^{-2}mol dm^{-3} $CaCl_2$ (II) systems realize these situations.

On the contrary, non-linear potential responses were observed in the systems where the NaCl or $CaCl_2$ concentrations in phase II were fixed at 10^{-1} or 10^{-3}mol dm^{-3} as can be seen in Figs. 1-A-b and A-c. The ideal slope of the Na^+-Ca^{2+} bi-ionic membrane potential plots mentioned above, 39.44 mV/logarithmic activity of phase I, shifted to increase as relative NaCl concentrations increased and to decrease as relative $CaCl_2$ concentrations increased. In these systems, definite amounts of Cl^- are transported simultaneously with two cations as shown in Figs. 1-C-b and C-c, and it is expected that the Na^+/Ca^{2+} permeability ratio is no longer constant with the external electrolyte concentration changes.

Membrane conductances of the present systems changed within the limits of the conductance values lower than those of NaCl concentration cell system and higher than those of $CaCl_2$ concentration cell system. Accordingly, it is suggested to occur a competitive sharing of available ion-exchange sites by Na^+ and Ca^{2+}.

In the following part of this section, membrane transport characteristics of the present systems are discussed firstly for the case in which only cations, Na^+ and Ca^{2+}, are permeable with a constant membrane permselectivity ratio, and secondly for the case in which the transport of Cl^- has significant effects on the membrane selectivity to these cations.

System with a Constant Na^+/Ca^{2+} Permeability Ratio. The membrane processes in the 10^{-2} mol dm^{-3} NaCl(II) or 10^{-2} mol dm^{-3} $CaCl_2$(II) systems are characterized by the cation transport alone and, consequently, by four membrane permeability matrix elements, $P_{Na\cdot Na}$, $P_{Ca\cdot Na}$, $P_{Na\cdot Ca}$, and $P_{Ca\cdot Ca}$. Including these matrix elements, all the membrane transport parameters can be evaluated from the available experimental data, the membrane potential, conductance, and ion flux, by the same manner as reported earlier based on the following relationships, Eqs. 8—11, with Eqs. 3, 5, and 7.[4,6] The membrane conduct-

ance is expressed as:

$$G_m = (F^2/RT)[P_{Na}a^I_{Na}\exp(-FV_0/2RT) + 2P_{Ca}a^I_{Ca}\exp(-FV_0/RT)] = (F^2/RT)[P_{Na}a^{II}_{Na}\exp(FV_0/2RT) + 2P_{Ca}a^{II}_{Ca}\exp(FV_0/RT)] \quad (8)$$

When the membrane electric current is absent, Na^+ and Ca^{2+} fluxes are characterized by diffusional membrane permeabilities, P^0_{Na} and P^0_{Ca}:

$$J_{Na} = -P^0_{Na}[a^{II}_{Na}\exp(FV_0/2RT) - a^I_{Na}\exp(-FV_0/2RT)] = 2P^0_{Ca}[a^{II}_{Ca}\exp(FV_0/RT) - a^I_{Ca}\exp(-FV_0/RT)] = -2J_{Ca} \quad (9)$$

The diffusional permeability to electroconductive permeability ratio is expressed as:

$$P^0_{Na}/P_{Na} = P^0_{Ca}/P_{Ca} = 1-(2P_{Ca\cdot Na}/P_{Na}) - (P_{Na\cdot Ca}/2P_{Ca}) \quad (10)$$

The cross coefficients of membrane permeability matrix, $P_{Na\cdot Ca}$ and $P_{Ca\cdot Na}$, are related each other as:

$$\frac{P_{Na\cdot Ca}}{P_{Ca\cdot Na}} = \frac{(a^I_{Na}a^{II}_{Na})^{1/2}}{(a^I_{Ca}a^{II}_{Ca})^{1/2}} \times \frac{\sinh[F(V_O-V_{Na})/2RT]/[F(V_O-V_{Na})/2RT]}{\sinh[F(V_O-V_{Ca})/RT]/[F(V_O-V_{Ca})/RT]} \quad (11)$$

The diffusional membrane permeabilities to Na^+ and to Ca^{2+}, P^0_{Na} and P^0_{Ca}, are expressed as a function of the permeability matrix elements.

$$P^0_{Na} = (P_{Na\cdot Na}P_{Ca\cdot Ca} - P_{Na\cdot Ca}P_{Ca\cdot Na})/P_{Ca}$$
$$P^0_{Ca} = (P_{Na\cdot Na}P_{Ca\cdot Ca} - P_{Na\cdot Ca}P_{Ca\cdot Na})/P_{Na} \quad (12)$$

The diffusional permeabilities, P^0_{Na} and P^0_{Ca}, which should be discriminated from the electroconductive permeabilities, P_{Na} and P_{Ca}, satisfy the following phenomenological equation in the absence of membrane electric current:

$$\begin{bmatrix} J_{Na} \\ J_{Ca} \end{bmatrix}_{I=0} = -\begin{bmatrix} P^0_{Na} & 0 \\ 0 & P^0_{Ca} \end{bmatrix} \times \begin{bmatrix} a^{II}_{Na}\exp(FV_0/2RT) - a^I_{Na}\exp(-FV_0/2RT) \\ a^{II}_{Ca}\exp(FV_0/RT) - a^I_{Ca}\exp(-FV_0/RT) \end{bmatrix} \quad (13)$$

The electroconductive permeability represents conductive process of ions across membrane, while the diffusional permeability represents diffusion process of ions, and accordingly, the former is related to the mobility of permeant ion and the latter, to the diffusion coefficient.[5,6]

Evaluated membrane transport parameters are summarized in Fig. 2. As illustrated in Figs. 2-A-a and A-b, the CK-1, 1.0t membrane is more permselective to Ca^{2+} than to Na^+ in these systems. Since the CK-1, 1.0t membrane is developed so as to be more permeable to

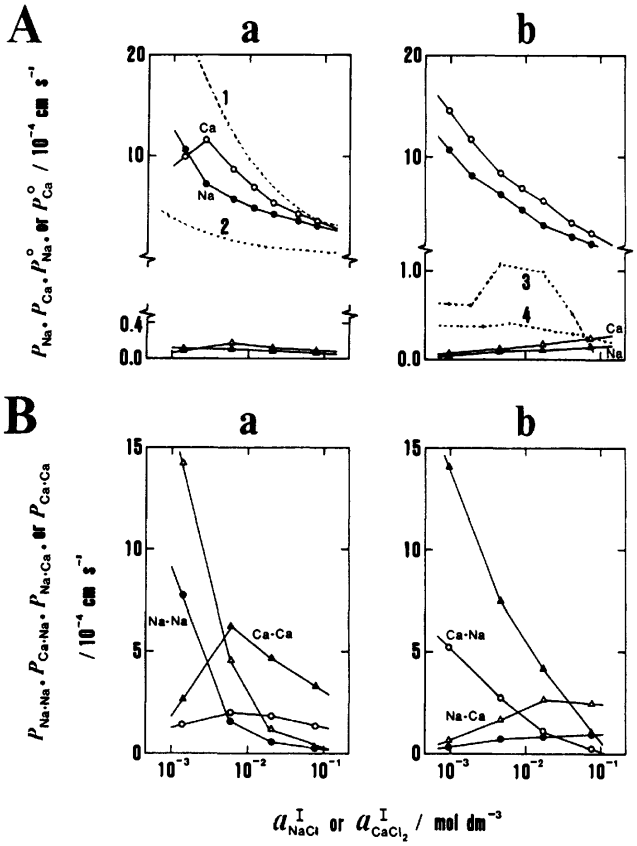

Fig. 2. Electroconductive and diffusional membrane permeabilities (A) and permeability matrix elements (B) as a function of mean electrolyte activity of phase I. a: $CaCl_2$(I)-10^{-2} mol dm^{-3} NaCl(II). b: NaCl(I)-10^{-2} mol dm^{-3} $CaCl_2$(II). In A, ●: P_{Na}; ○: P_{Ca}; ▲: P^0_{Na}; △: P^0_{Ca}. The broken lines 1 and 3 refer to P_{Na} and P^0_{Na} in NaCl(I)-10^{-2} mol dm^{-3} NaCl(II) system; the broken lines 2 and 4 refer to P_{Ca} and P^0_{Ca} in $CaCl_2$(II)-10^{-2} mol dm^{-3} $CaCl_2$(II) systems. In B, ●: $P_{Na\cdot Na}$; ○: $P_{Ca\cdot Na}$; △: $P_{Na\cdot Ca}$; ▲: $P_{Ca\cdot Ca}$.

univalent cations than to bivalent cations for the desalination process applications, the membrane permeability to Na^+ in concentration cell system is almost 10 times larger than that to Ca^{2+}. Furthermore, Figs. 2-B-a and B-b indicate that the calculated values of the membrane permeability matrix element conjugated with an electrochemical activity difference of Ca^{2+} between phases I and II are larger than those conjugated with an electrochemical activity difference of Na^+, namely, $P_{Ca\cdot Na} > P_{Na\cdot Na}$ and $P_{Ca\cdot Ca} > P_{Na\cdot Ca}$. These influential contributions of Ca^{2+} to the membrane transport processes seem to be due to the fact that membrane concentrations of Ca^{2+} relative to those of Na^+ are kept at high level within a wide range of external Na^+/Ca^{2+} concentration ratio. In the present 10^{-2} mol dm^{-3} NaCl(II) and 10^{-2} mol dm^{-3} $CaCl_2$(II) systems, measurements of the cation concentrations in the CK-1, 1.0t membrane phase indicated that 90—99% of cations in the membrane

phase are site-bound and that more than 80% of cations are Ca^{2+} in the membrane (unpublished observations). In general both the membrane/solution partition of ions and the migration speed of ions across membrane are dominant factors to control the membrane permselectivity to ions. The Ca^{2+} controlled membrane processes in the present systems are due to the facts that the greater part of fixed cation-exchange sites are occupied by Ca^{2+} and the Donnan adsorption of electrolyte is suppressed at quite low level.

Figure 3 shows Na^+/Ca^{2+} membrane permeability ratios and diffusional/electroconductive membrane permeability ratios, as well as comparisons with these ratios evaluated in concentration cell systems. The P_{Na}/P_{Ca} values in the present bi-ionic systems changed drastically from those in the concentration cell systems so as to reverse the cationic permselectivity sequences. As expected from the linear membrane potential responses and Eq. 7, almost constant P_{Na}/P_{Ca} vslues were obtained. P^0_{Na}/P_{Na} $(=P^0_{Ca}/P_{Ca})$ values less than 0.1 indicate that electroconductive movements of cations progress much more efficiently than diffusion of cations. These situations were more remarkable in the bi-ionic systems than in the concentration cell systems. Furthermore as indicated by Eq. 10, deviations of the diffusional/conductive permeability ratio from unity denote the order of participations of the correlative or cooperative effects between different permeant ions, namely the Na^+-Ca^{2+} correlations in the present bi-ionic systems and Na^+-Cl^- or Ca^{2+}-Cl^- correlations in the respective concentration cell systems, to the membrane processes.[5]

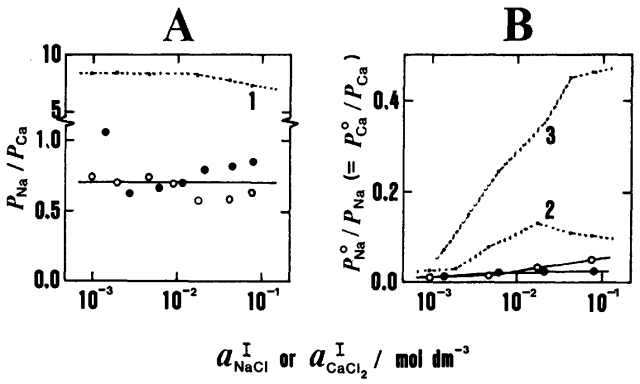

Fig. 3. Cationic membrane permeability ratio ($P_{Na}/P_{Ca}=P^0_{Na}/P^0_{Ca}$) (A) and diffusional/electroconductive permeability ratio ($P^0_{Na}/P_{Na}=P^0_{Ca}/P_{Ca}$) (B) as a function of mean electrolyte activity of phase I. Closed and open circles indicate $CaCl_2$(I)-10^{-2} mol dm^{-3} NaCl(II) and NaCl(I)-10^{-2} mol dm^{-3} $CaCl_2$(II) systems, respectively. The broken lines 1, 2, and 3 refer to P_{Na}/P_{Ca}, P^0_{Na}/P_{Na}, and P^0_{Ca}/P_{Ca} values estimated in NaCl(I)-10^{-2} mol dm^{-3}NaCl(II) and $CaCl_2$(I)-10^{-2} mol dm^{-3} $CaCl_2$(II) systems.

System with a Varying Na^+/Ca^{2+} Permeability Ratio and Effect of Cl^- Permeation. Estimations for the transport parameters relating Cl^- are required for the systems where NaCl or $CaCl_2$ concentrations of phase II are fixed constant at 10^{-1} or 10^{-3} mol dm^{-3}, since definite amounts of Cl^- are transported across the membrane as can be seen in Figs. 1-C-b and C-c. Within the limits of approximately 10-fold concentration difference between the external NaCl and $CaCl_2$ solutions, almost all the Cl^- fluxes were suppressed and only Na^+ and Ca^{2+} permeated across the membrane holding the relationship, $J_{Na}=-2J_{Ca}$. However, as the external NaCl concentrations increased, Na^+-Ca^{2+} bi-cationic transport processes shifted gradually to NaCl transport processes ($J_{Na}=J_{Cl}$) and, as the $CaCl_2$ concentrations increased, to $CaCl_2$ transport processes ($J_{Ca}=1/2J_{Cl}$). These experimental facts seem to indicate redistribution processes of Na^+ and Ca^{2+} within membrane, in which the one cation species tend to occupy entirely the negatively charged fixed sites and simultaneously to exclude the other cation species from the membrane phase depending upon the external cation concentrations.

Equation 5 can be modified to the following form in which the membrane electric current is expressed as the sum of two terms describing currents carried by cations, Na^+ and Ca^{2+}, and Cl^-:

$$\begin{aligned} I &= -2FP_{Na\text{-}Ca}a_{Na\text{-}Ca}\sinh[3F(V-V_{Na\text{-}Ca})/4RT] \\ &\quad -2FP_{Cl}(a^I_{Cl}a^{II}_{Cl})^{1/2}\sinh[F(V-V_{Cl})/2RT] \\ &= -g_{Na\text{-}Ca}(V-V_{Na\text{-}Ca})-g_{Cl}(V-V_{Cl}) \end{aligned} \quad (14)$$

where $P_{Na\text{-}Ca}$ is the membrane permeability to whole cations refer to P_{Cl} defined as:

$$P_{Na\text{-}Ca} = (2P_{Na}P_{Ca})^{1/2}\exp(\pm FV/4RT) \quad (15)$$

The signs in the exponential term in Eq. 15 refer to + for NaCl (I)-$CaCl_2$(II) system and to − for $CaCl_2$(I)-NaCl(II) system. $a_{Na\text{-}Ca}$ $(=(a^I_{Na}a^{II}_{Ca})^{1/2}$ or $(a^I_{Ca}a^{II}_{Na})^{1/2})$ is the averaged concentration of external cations. $g_{Na\text{-}Ca}$ is the cationic membrane conductance dependent upon Na^+ and Ca^{2+} refer to g_{Cl}:

$$\begin{aligned} g_{Na\text{-}Cl} &= \frac{3F^2}{2RT}P_{Na\text{-}Ca}a_{Na\text{-}Ca}\frac{\sinh[3F(V-V_{Na\text{-}Ca})/4RT]}{3F(V-V_{Na\text{-}Ca})/4RT} \\ g_{Cl} &= \frac{F^2}{2RT}P_{Cl}(a^I_{Cl}a^{II}_{Cl})^{1/2}\frac{\sinh[-F(V-V_{Cl})/2RT]}{-F(V-V_{Cl})/2RT} \end{aligned} \quad (16)$$

The membrane conductance, G_m, and potential, V_0 for these systems are expressed as:

$$\begin{aligned} G_m &= g_{Na\text{-}Ca} + g_{Cl} \\ &= (F^2/RT)\exp(-FV_0/2RT) \\ &\quad \times[P_{Na}a^I_{Na}+2P_{Ca}a^I_{Ca}\exp(-FV_0/2RT)+P_{Cl}a^{II}_{Cl}] \\ &= (F^2/RT)\exp(FV_0/2RT) \\ &\quad \times[P_{Na}a^{II}_{Na}+2P_{Ca}a^{II}_{Ca}\exp(FV_0/2RT)+P_{Cl}a^I_{Cl}] \end{aligned} \quad (17)$$

$$V_0 = (g_{Na-Ca}/G_m)V_{Na-Ca} + (g_{Cl}/G_m)V_{Cl} = t_{Na-Ca}V_{Na-Ca} + t_{Cl}V_{Cl} \quad (18)$$

where t_{Na-Ca} and t_{Cl} are the transport number to whole cations and to Cl^-, respectiely.

On the basis of assumptions where permeability ratios are constant within the limits of narrow concentration range of the external electrolyte solution, P_{Na}/P_{Ca} values can be evaluated by utilizing Eq. 6 to a pair of membrane potential values. Then, at given electrolyte concentrations, V_{Na-Ca} values are determined by Eq. 7, and consequently, P_{Na}, P_{Ca}, and P_{Cl} values can be calculated using the above equations and electrochemical data. Figure 4 shows t_{Na-Ca} values with P_{Na}/P_{Ca} and P_{Cl}/P_{Na} ratios; the plotted membrane permeability ratios were calculated from the respective permeability values to Na^+, Ca^{2+}, and Cl^- estimated as described above. Furthermore, in this figure, the P_{Na}/P_{Ca} values were compared with those calculated by Eq. 7 assuming that Cl^- permeations can be ignored, namely, that the relation, $V_0=V_{Na-Ca}$, is satisfied. For the case where relative NaCl concentrations are high (see Fig. 4-a: 10^{-1} mol dm^{-3} NaCl(II) system and Fig. 4-d: 10^{-3} mol dm^{-3} $CaCl_2$(II) system), P_{Na}/P_{Ca} values increase rapidly as relative Na^+ concentration increases, while P_{Cl}/P_{Na} and t_{Cl} values are kept at almost constant and low levels. On the contrary, when relative $CaCl_2$ concentrations are high (see Fig. 4-b: 10^{-3} mol dm^{-3} NaCl(II) system and Fig. 4-c: 10^{-1} mol dm^{-3} $CaCl_2$(II) system), t_{Na-Ca} values decrease gradually as relative Ca^{2+} concentrations increase, while P_{Na}/P_{Ca} values are kept at almost constant levels similarly to those in the system with a negligible Cl^- permeation discussed in earlier parts of this section. So it is suggested that the positive deviations from the linear relationships of ideal Na^+-Ca^{2+} bi-ionic potential responses are due to a rise in the Na^+ permeation and that the negative deviations are due to a rise in the Cl^- permeatins.

When three ionic species, Na^+, Ca^{2+}, and Cl^-, are involved in the transport processes, the membrane system is characterized by the 3×3 permeability matrix or conductance matrix as shown in Eqs. 1 and 2. Accordingly, detailed phenomenological analyses on membrane permselectivity are required to estimate nine elements of the permeability matrix or six elements of the conductance matrix from available experimental data. However, estimations of the complete sets of these phenomenological coefficients are required to carry out complicated measurements with extreme cares under various experimental conditions. In the present study, only the effects of Cl^- permeation on the entire cation transport are discussed according to the following simplified formulations based on the potential, conductance, and flux data:

$$\begin{bmatrix} i_{Na-Ca} \\ i_{Cl} \end{bmatrix} = -\begin{bmatrix} g_{Na-Ca\cdot Na-Ca} & g_{Na-Ca\cdot Cl} \\ g_{Cl\cdot Na-Ca} & g_{Cl\cdot Cl} \end{bmatrix} \begin{bmatrix} V-V_{Na-Ca} \\ V-V_{Cl} \end{bmatrix} \quad (19)$$

where i_{Na-Ca} ($=i_{Na}+i_{Ca}$) is the cationic membrane current. By means of evaluating three matrix elements, such as $g_{Na-Ca\cdot Na-Ca}$ depending only upon cations, $g_{Na-Ca\cdot Cl}$ ($=g_{Cl\cdot Na-Ca}$) describing the correlations between whole cation and Cl^-, and $g_{Cl\cdot Cl}$, the effects of Cl^- permeations on the permselectivities to cations are characterized quantitatively on the basis of nonequilibrium thermodynamics. Results are given in Fig. 5. It can be seen in these figures that the changes in $g_{Na-Ca\cdot Na-Ca}$ and $g_{Na-Ca\cdot Cl}$ with external electrolyte concentration are relatively small, whereas $g_{Cl\cdot Cl}$ increases rapidly as the concentration differences between NaCl and $CaCl_2$ solutions separated by the

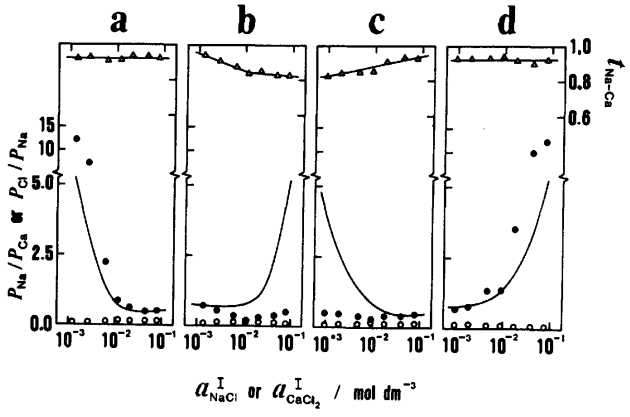

Fig. 4. Transport number to whole cations, t_{Na-Ca} (△), and permeability ratios, P_{Na}/P_{Ca}(●) and P_{Cl}/P_{Na} (○), as a function of mean electrolyte activity of phase I. a: $CaCl_2$(I)-10^{-1} mol dm^{-3} NaCl(II). b: $CaCl_2$(I)-10^{-3} mol dm^{-3} NaCl(II). c: NaCl(I)-10^{-1} mol dm^{-3} $CaCl_2$(II). d: NaCl(I)-10^{-3} mol dm^{-3} $CaCl_2$(II). The solid lines refer to P_{Na}/P_{Ca} values calculated by Eq. 7 from membrane potential data assuming $P_{Cl}=0$.

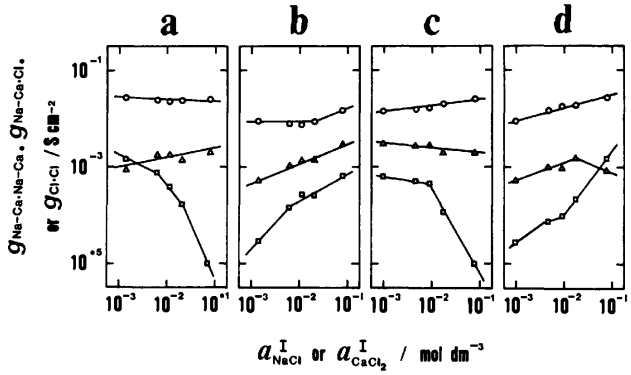

Fig. 5. Membrane conductance matrix elements, $g_{Na-Ca\cdot Na-Ca}$(○), $g_{Na-Ca\cdot Cl}$($=g_{Cl\cdot Na-Ca}$)(△), and $g_{Cl\cdot Cl}$(□), as a function of mean electrolyte activity of phase I. a, b, c, and d denote the same systems as in Fig. 4.

membrane increase. By referring Fig. 5 with Figs. 1-A-b, A-c, and 4, it is seen that the conductance matrix element as a linear phenomenological coefficient in Eq. 19 can describe well the deviation from ideal Na^+-Ca^{2+} bi-ionic potential response and the mode of ionic permselectivity in the CK-1, 1.0t membrane sytem.

Na^+-Cs^+ and Na^+-Ca^{2+} Bi-Ionic Systems. As reported earlier for the NaCl-CsCl system,[6] Na^+ and Cs^+ contributed equally to the transport processes across highly selective cation-exchange membrane, CK-1, 1.0t. The extents of participations of Na^+ and Cs^+ to the membrane processes depended simply on the rates of external concentrations of respective cations, which should be parallel to the rates of membrane concentrations of cations. In case of the Na^+-Cs^+ bi-ionic systems, effects of Cl^- permeations were almost perfectly excluded within the limits of wide ranges of external electrolyte concentrations.

On the contrary in the present NaCl-$CaCl_2$ system, Ca^{2+} contributions to the membrane processes are dominant and the permselectivity to Ca^{2+} is improved to reverse the sequences to Na^+ compared with those in the respective concentration cell systems. These Ca^{2+} effects originate in the high membrane concentrations of Ca^{2+}. Cation-exchange membranes developed for the applications in desalination processes are usually performed the membrane surface treatments to prevent from penetrations of multivalent cations, especially Ca^{2+}, into the membrane phase. However, Ca^{2+}, once penetrating into the membrane due to the high external $CaCl_2$ concentrations, plays a dominant role in the membrane transport processes according to the high concentrations and tight interactions with negatively charged sites within the membrane phase. It was also suggested that increases in Cl^- permeations are closely related to the increase in external Ca^{2+} concentrations. The present studies served as a quantitative representations of these cooperative interactions between permeating ions and of Ca^{2+} effects on the basis of nonequilibrium thermodynamic theory.

The authors wish to thank the Ministry of Education, Science and Culture for a Grant-in-Aid for Scientific Research (No. 61540332) and the Asahi Chemical Industry Co. Ltd. for providing the ion exchange membranes used in this work. One of the authors (K. K) is also grateful to the Kurata Foundation for supporting the research grant.

Clogging and Gel-Layer Formation during Membrane Filtration and Its Effect on Analytical Data

Manabu IGAWA,* Takeshi YOSHIDA, Chiaki OHTAKE, and Takashi HAYASHITA
Department of Applied Chemistry, Faculty of Engineering, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221
(Received September 25, 1986)

Clogging and gel-layer formation during membrane filtration affect the concentration of ions in the filtrate as well as the concentration of suspended solids. The flow rate analysis and the observation of the filter surface with a scanning electron microscope show that a gel-layer is formed subsequently after the clogging. Humic acids, fulvic acids, metal hydroxides, and soft particles dispersed in natural waters cause the clogging and hence the gel-layer formation. Cross-flow filtration decreases the rate of the clogging and the gel-layer formation and gives little rise to the filtration effects on analytical results.

Membrane filters have been commonly used to separate suspended solids from natural waters.[1,2] However, it is known that the filtration by membrane filters seriously affect the analytical results in the following ways; contamination from and/or adsorption on a membrane filter; sieve effect, that is, partial permeation of the solute depending on the ratio of the pore diameter to the particle diameter; clogging and gel-layer formation on the filter.

The amounts of impurities in membrane filters,[3-5] variation of impurity levels[6] and elutions of total organic carbon(TOC), chemical oxygen demand (COD), NO_3^- from membrane filters[7] have been studied in detail. Furthermore the physical and physicochemical properties of the membrane, such as the sieve effect and the gel-layer formation on the filter, are important in relevance to filtration,[8,9] ultrafiltration,[10] and reverse osmosis.[11] However, little attention has been paid to the latter problems until now.

Seldon has reported on the size separation of marine seston by membrane filters.[12] Danielsson has studied the influence of filtration on the determined values of the colloid contents in a natural sample as a function of the sample volumes treated,[13] and Laxen et al. have reported that screen filters provide accurate size fractionation, as long as the filter is not allowed to clog.[14] Errede et al. have studied the effect of the surface modification on the flow rate of water.[15]

In this paper, the mechanism of the clogging and the gel-layer formation were studied on filtration of natural waters by various membrane filters. The possible materials which may cause the clogging and then form the gel-layer are also discussed. Cross-flow filtration was tried to minimize the influence of the membrane filtration on the analytical results.

Experimental

General Procedure for Filtration. The filters used in this study were Nuclepore 47 mm diameter filters of 0.10, 0.40, and 1.0 μm pore size (N010CPR04700, N040CPR04700, and N100CPR04700, respectively, Nuclepore Corp.) and Millipore 47 mm diameter filters of 0.45 μm pore size (HAWP04700, Millipore Corp.). A membrane filter set in a holder (FH047PL001101, Nuclepore Corp.) was washed with 200 cm^3 of deionized water and then a certain volume of sample solution was filtered under a reduced pressure of 60 cm Hg (1 cm Hg=1333.22 Pa) using a handy aspirator (WP-45, Yamato Sci., Corp.). An apparatus used for cross-flow filtration is shown in Fig. 1. It was handmade using acrylic resin boards and 3 mm-thick silicone rubber sheets. For trace analysis, Teflon sheets should be used instead of the silicone rubber sheets. The sample solution was circulated and flowed on the membrane filter with a pump at a rate of 15 $dm^3\ min^{-1}$.

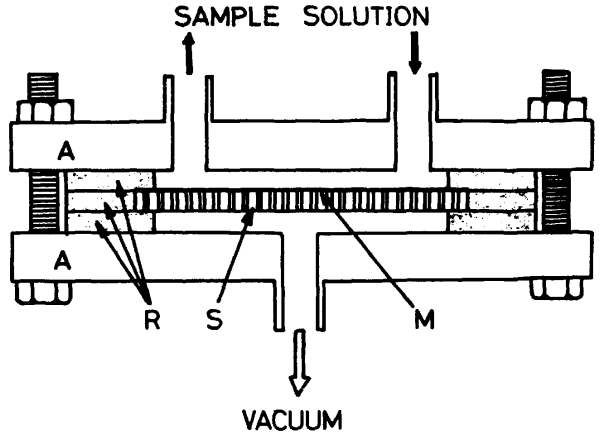

Fig. 1. Apparatus of cross-flow filtration: A, acrylic resin frame; M, membrane filter; R, silicone rubber sheet; S, membrane filter support.

Samples. The sample solutions used in this filtration experiment were river waters, a carbon black dispersion, a humic acid solution, a fulvic acid solution, and a sulfuric acid extract from a river sediment.

The river waters were sampled in 1984 and 1985 at the Kawamukoh bridge on the Tsurumi river† in Yokohama.

The carbon black used was Thermax (Thermatomic Carbon Company), whose particle size ranges from 0.1 to 1.0 μm and the maximum was between 0.4 to 0.5 μm. The

† The Tsurumi river flows through urban regions of both Yokohama city and Kawasaki city; the total length of the river is 42.3 km, and much domestic sewage discharges into it.

surface of the carbon black particles was oxidized by H_2O_2 and a definite amount was dispersed in water by shaking in a ultrasonic bath just before the filtration.

The sediment was collected at the same sampling location. It was dried in an oven 110 °C and milled to pass through a 40 mesh screen. A 14 g sample of the dried sediment was boiled with 600 cm^3 of 0.5% NaOH solution for 30 min and centrifuged at 2000 min^{-1} for 20 min. To a 500 cm^3 portion of the supernatant, 5.0 cm^3 of concentrated H_2SO_4 was added. The solution was stirred vigorously and filtered through a Whatman glass filter GC/D. The filtrate was diluted 2-fold with pure water and used as a fulvic acid solution.[16] The precipitate on the filter was dissolved throughly with 500 cm^3 of 0.1% NaOH and the filtrate diluted 2-fold and used as a humic acid solution.[16] Another 14 g of the dried sediment was dispersed in 600 cm^3 of 0.5 mol dm^{-3} H_2SO_4 and boiled for 30 min. When cooled, the sample was centrifuged at 2000 min^{-1} for 20 min. The supernatant was diluted 2-fold and used as a sulfuric acid extract, containing much metal ions, for example, ca. 100 ppm of iron.

Detemination of Metal Ion Concentrations and Suspended Solids Contents. The metal ions in the filtrate were determined by a flame and/or flameless atomic absorption spectrophotometer (Varian AA-1275). The contents of suspended solids were determined from the difference of the weights of the membrane filter dried at 60 °C for 2 h before and after the filtration.

Observation of Membrane Surface. The surface were observed by a scanning electron microscope (JSM-35C SEM, Japan Electron Optics Laboratory Corp.) before and after the filtration. The samples were imaged with gold in vacuo.

Results and Discussion

Effect of Filtration on Analytical Results. The concentrations of metal ions in the river water sample were measured by varying the sample volume treated on one filter. It was reported by Danielsson[13] that the concentrations of heavy metal ions such as iron decreased with the increase of the volume. While, the concentrations of alkaline and alkaline earth metal ions such as sodium and calcium did not change with the increase of the volume.

By using the sample solutions, the concentration of suspended solids was examined similarly, and it was found that the amount of solids trapped on the filter varied depending on the properties of the suspended solids. Figure 2 shows the change of the suspended solids concentration against the sample volume treated. The concentrations of suspended solids in a river water sample apparently increase with the volume, but that of a carbon black dispersion in pure water remains constant as would normally be expected. The values determined by Millipore filters were different from those determined by Nuclepore filters because of the difference of the filter structures between Millipore and Nuclepore filters.[14]

Variation of Rate of Filtration. The membrane filtration influences the values of metal ions and

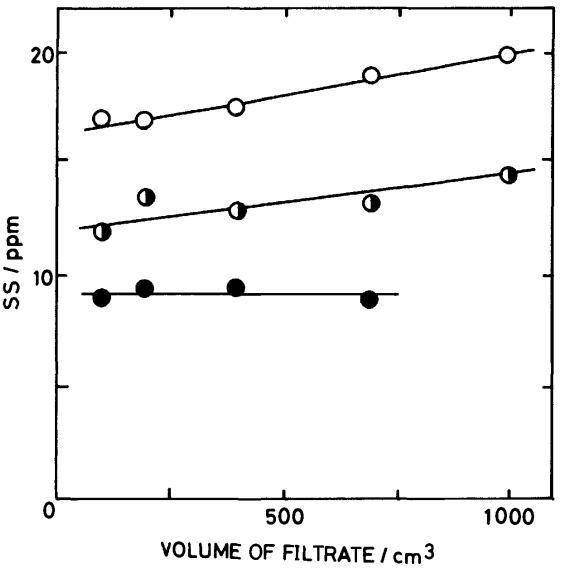

Fig. 2. Effect of volume of filtrate on measured value of suspended solids concentration: membrane filter, Nuclepore filter (0.40 μm, ●, ◑) and Millipore filter (0.45 μm, ○); sample, river water (◑, ○) and carbon black dispersion (●).

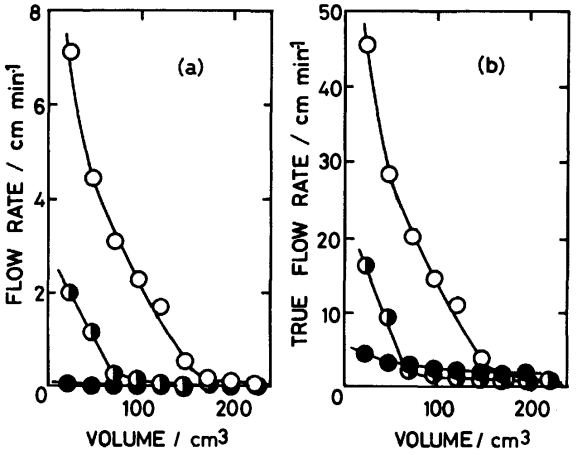

Fig. 3. (a) Flow rate vs. volume of filtrate and (b) true flow rate vs. volume of filtrate: membrane filter, Nuclepore filter; ○, 1.0 μm pore size; ◑, 0.40 μm pore size; ●, 0.10 μm pore size; sample, river water.

suspended solids determines because of clogging and gel-layer formation. To clarify the mechanism of the clogging and the gel-layer formation, the following experiments were carried out: The filtration rates were measured on various types of membrane filters, the electron microscopic images of the membrane surface were compared before and after the filtration, and the permeation properties of natural waters through the filters were compared with those of the synthesized solutions containing certain components of natural waters.

A flow rate through a filter decreases on increasing the volume of the filtrate as is shown in Figs. 3(a) and

3(b). "Flow rates" here are defined as the volumes of filtrate obtained in unit time through unit filter area, and "true flow rates" are those obtained in unit time through unit pore area on the filter. Based on the pore density of the filter:[17] 2×10^7, 1×10^8, and 3×10^8 cm^{-2} for 1.0, 0.4, and 0.1 μm pore size filter, respectively, the ratios of the pore area to the filter area are calculated to be 16, 13, and 2.4%, respectively. In the initial period, "true flow rates" through the larger pores were faster than those through the smaller pores and this was parallel with the case of the "flow rates." As the volume of the filtrate increased, the former rate became slower than the latter. That is, at an early stage of filtration the total area of the filter pores controlled the rate, but later, the pore area remaining unclogged or unshielded by the gel-layer began to control the rate. This can be described quantitatively as follows.

It has been known that in the cake filtration process a linear relationship exists between the ratio of the filtration time to the volume of filtrate, t/V, and the volume, V.

In the standard blocking process a linear relationship also holds between t/V and the filtration time, t.[18-19] These relations can be expressed in Eqs. 1 and 2 for a given constant pressure,

$$t/V = K_c/2 \times V + 1/Q_c \quad (1)$$

$$t/V = K_s/2 \times t + 1/Q_s \quad (2)$$

where K_c, K_s, Q_c, and Q_s are constants dependent on the filter structure and the solution properties. In Fig. 4, the plots of t/V vs. V and t/V vs. t are shown for membrane filters having different pore sizes. It can be seen from the Figure that there are two processes in the filtration. The one, cooresponding to the linear relation of t/V–t, is observed in the early stage of filtration and is due to the development of clogging. The other corresponding to the linear relation of t/V–V, is due to a gel-layer formation on the surface of the membrane filter, which occurs subsequently after the clogging. As shown by curves in Fig. 4, the smaller the pore size, the earlier the gel-layer formation begins. Comparing this result with that of the filtration effect on determined values, the filtration does not have much affect on the values during the clogging process.

SEM Images of Filter Surface. The clogging and the formation of gel-layer can be visualized by the SEM technique. Figure 5(a) shows the surface of a Nuclepore filter (0.4 μm) washed with pure water running through it at 25 cm min^{-1}, and Fig. 5(b) shows the surface of the same membrane filter but filtrated with 20 cm^3 river water. The flow rate of the river water was calculated as 2.5 cm min^{-1}, the clogging of pores is clearly observed but not the gel-layer. Figure 5(c) is the surface of the membrane filter

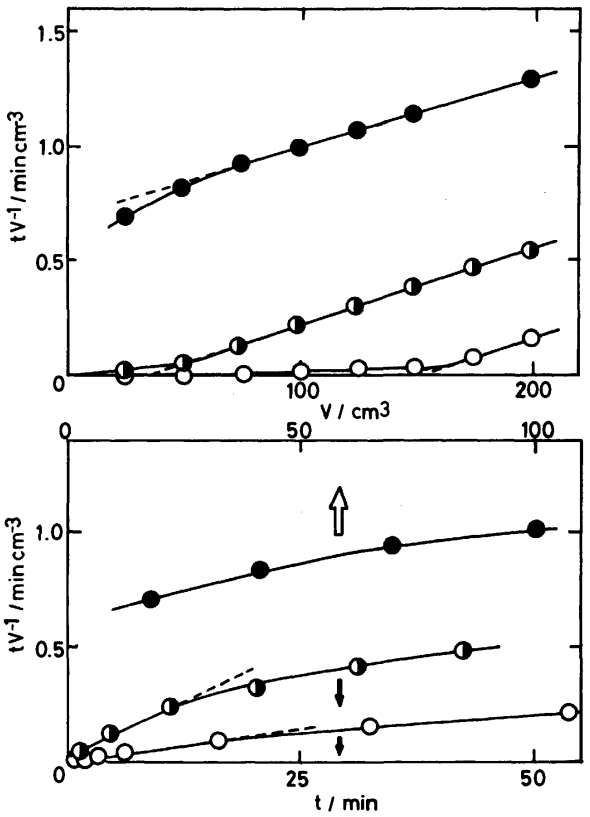

Fig. 4. t/V vs. volume of filtrate, V and t/V vs. filtration time, t: membrane filter, Nuclepore filter; ○, 1.0 μm pore size; ◑, 0.40 μm pore size; ●, 0.10 μm pore size; sample, river water.

after the filtration of 40 cm^3 river water with the rate of 0.41 cm min^{-1}, the whole surface of the filter is seen to be covered with a gel-layer, and no pores are observed.

Comparison of Permeabilities of Some Components in Natural Waters. In river waters, there are many kinds of colloids and particles which may cause clogging and gel-layer formation, such as humic acids, fulvic acids, metal hydroxides, bacteria suspended sediments, and so on. For the investigation of the materials which caused the clogging and the gel-layer on filters, the river water samples and the solutions of some major components of river waters, a fulvic acid, a humic acid, and surfuric acid extract were filterd at various pH and their filtration rates and suspended solids contents were compared. The pH of the samples was adjusted with HNO_3 and NaOH, and 100 cm^3 aliquots were filtered. The mean flow rates and the concentrations of suspended solids are shown in Fig. 6.

In the case of the river water, the flow rate was high when the pH was over 10 or under 2 and minimum in the range of pH 2 to 3. On the other hand, the suspended solids concentration was high when the pH was over 10 and low when the pH was under 2. The pH dependence of flow rate and the suspended solids

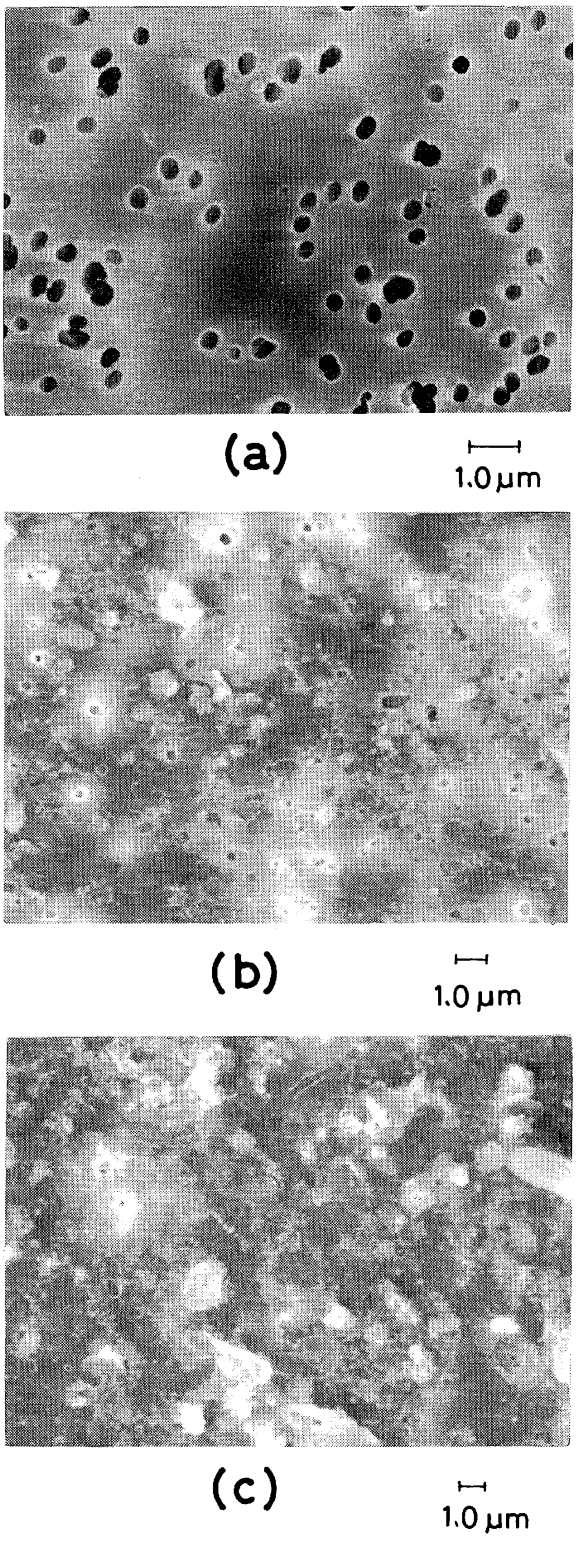

Fig. 5. Observation by scanning electron microscope on surface of Nuclepore filter. (a) Before filtration. (b) After filtration of 20 cm^3 river water. (c) After filtration of 40 cm^3 river water: membrane filter, Nuclepore filter (0.4 μm).

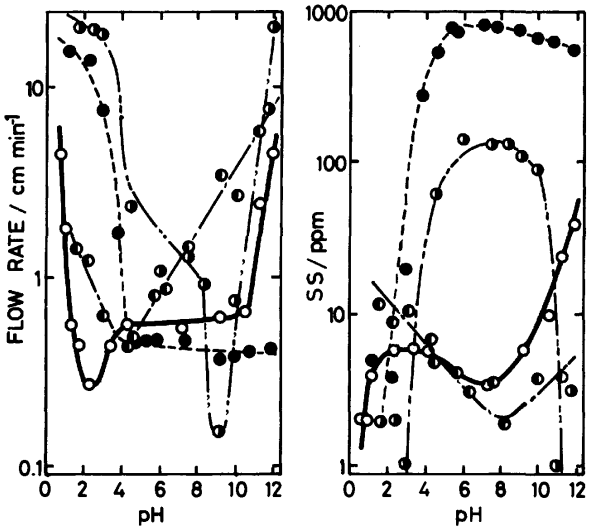

Fig. 6. Flow rate and suspended solids concentration, SS vs. pH: membrane filter, Nuclepore filter (0.40 μm); ○, river water; ◐, humic acid solution; ◑, fulvic acid solution; ●, acid extracted solution; volume of each solution, 100 cm^3.

concentration of the river water were not the same as those of the solutions of the fulvic acid, the humic acid, and the sulfuric acid extract. However some points were commonly observed in them; the minimum flow rate and minimum suspended solids concentration in intermediated pH range for the humic acid; the high flow late and the low suspended solids concentration in low pH range for the fulvic acid and the sulfuric acid extract.

These pH dependences are due to the change of the surface charge of the colloids in the solutions.[20] In a high pH range, they are negatively charged, whereas they are positively charged in a low pH range. The filtration rates are high at low or high pH, because the causing materials in the river water are highly charged and repel each other at the pH and a gel-layer with loose structure is formed on the filter. The high concentration of suspended solids at high pH is due to the precipitation of metal hydroxide. In the intermediate pH range, the charge on the colloids became low and they coagulate at their isoelectric points. Then, a layer with high density was formed on the filter as a result of van der Waals forces of attraction and the filtration rate was low.[21] The flow rate was constant in a wide pH range, because there are many kinds of materials causing the clogging and the gel-layer and their isoelectric points vary widely. It is also reported that humic acids and fulvic acids are coagulated with polyvalent metal ions in a neutral pH range,[22] while iron by itself is coagulated mostly at pH 6.5.[11]

Consequently, in the filtration of river waters, humic acids, fulvic acids, and metal ions or

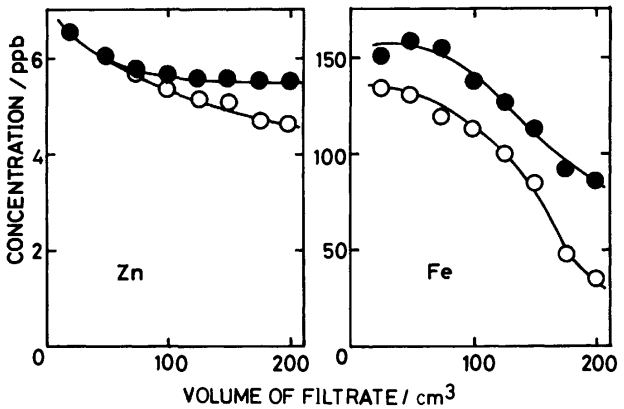

Fig. 7. Concentration change with volume of filtrate: Membrane filter, Nuclepore filter (0.40 μm); ○, usual filtration; ●, cross-flow filtration; sample, river water.

hydroxides cause the clogging and the gel-layer formation independently or in combination with each other. Furthermore, as it is known that soft particles readily plug the pores of the membrane filter,[23] soft and fine particles dispersed in river waters such as bacteria also cause clogging and gel-layer formation. The pH range of 2 to 3 where the flow rate of the river water was minimum may be related to the isoelectric points of most of the bacteria and colloidal silica particles (pH 2 to 3 and pH 2, respectively[20]) which are also major components of river waters.

The effect of the ionic strength on the filtration behavior was also studied by adding NaCl to river waters. The flow rate decreased and the suspended solids concentration increased gradually with NaCl concentration.

Cross-Flow Filtration. Cross-flow filtration is commonly applied to prevent gel-layer formation in reverse osmosis and ultrafiltration. For the improvement of the filtration behaviors, the cross-flow filtration was developed. The apparent changes of solute concentration with the volume of filtrate was observed on cross-flow filtration, and the results were compared with those of the usual filtration. As shown in Fig. 7, the decrease of the concentrations in the cross-flow filtration was less significant than in the usual filtration.

Figure 8 shows the plots of t/V vs. t and V observed in the cross-flow filtration. As is obvious from the comparison with those of the usual filtration, the filtration is much facilitated in the cross-flow filtration because the clogging and the gel-layer formation grows much more slowly. By cross-flow filtration, a large quantity of sample solution can be treated without a significant decrease of the filtration rate and a large deposition of metal hydroxides on the filter. To further improve filtration, more filter material is necessary to weaken the interaction between the colloidal particles and the filter matrix.

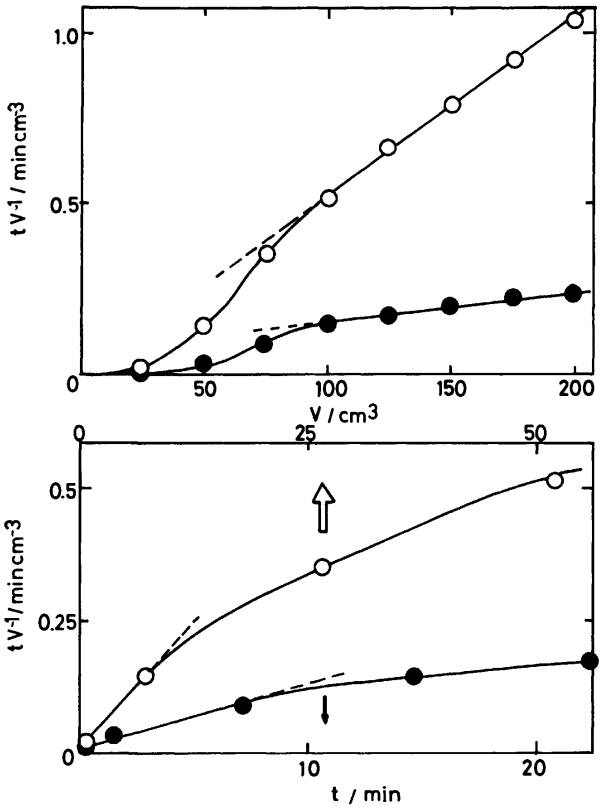

Fig. 8. Relationships between t/V and V, and t/V and t in usual filtration and in cross-flow filtration: Membrane filter, Nuclepore filter (0.40 μm); ○, usual filtration; ●, cross-flow filtration; sample, river water.

The authors thank Mr. Shigeyoshi Hagiwara for helpful suggestion on carbon black, Mr. Yūki Abe for taking the scanning electron microscope photographs, and Miss Tomoko Hiyori and Mr. Tsuyoshi Ohashi for conducting parts of the experiment.

Preparation and Characterization of $U_2O_2F_7$

Kameo ASADA,† Keiko EMA,* and Takashi IWAI††
Radiation Laboratory, Department of Nuclear Engineering, Kyoto University,
Uji, Kyoto 611
(Received January 22, 1987)

Reaction of UO_2F_2 with UF_5 at 400 °C under UF_6-pressure of 3 atm followed by evaporation of excess UF_5 has yielded a greenish white residue. Its X-ray diffraction pattern and infrared spectrum are sufficiently unique to establish that this material is a true compound. Its chemical formula has been shown to be $U_2O_2F_7$, on the grounds of chemical analysis and thermal decomposition. The oxygen content was determined directly by means of ^{18}O isotopic dilution method based on the combustion of the samples with BrF_5.

In our article on the studies of the physical properties of liquid UF_5,[1] a brief mention was made of our encounter with a possibly new fluoride oxide of uranium which was definitely lower than hexavalent. This article describes the results of the closer investigation into this compound.

Preparation and Isolation

(1) Encounter with the New Compound.[1] UF_5 melts at 348 °C.[2] Physical properties of liquid UF_5 were measured with an alumina tube of high purity (>99.5%) as the container. Sufficient pressure of UF_6 (e.g., 3 atm at 400 °C) was maintained over the melt, to prevent the disproportionation of UF_5.[3]

Examination of the solidified UF_5 after measurements revealed that the bottom part of the sample was occasionally very hard and whitish in color, in contrast with the upper main mass which was easy to be raked out and saphire-blue in color. X-Ray diffraction pattern of this whitish material contained a series of characteristic reflections (Table 1) together with those assigned to α-UF_5.[3] The substance identifiable with these reflections as the fingerprint will be named tentatively the phase *X*.

The phase *X* is presumably insoluble in liquid UF_5. And its density is between that of liquid UF_5 (4.50 g cm^{-3} [1]) and U_2F_9 (7.60 g cm^{-3}, at room temperature[3]), because they were found in this order in the alumina container when they coexisted.

Volatility of UF_5 (vapor pressure: 65 mmHg (1 mmHg=133.322 Pa) at 400 °C[2]) gives a means to purify UF_5. An impure sample of UF_5 contained in an alumina tube was put into a bigger alumina tube and heated to 400 °C under UF_6-pressure of 3 atm. Evaporated UF_5 condensed on the upper (cooler) wall of the outer tube in the form of ice-blue needles. The residue in the inner tube was white with a tinge of green and its X-ray diffraction pattern contained no reflection other than those assigned to the phase *X*. Chemical analysis made on a small sample gave a value, 5.39, for the mean valence of uranium in that material.

(2) Preparation. Since UF_5 is very hygroscopic, it was natural to assume that the phase *X* had its origin in the hydrolysis of UF_5, though the latter was handled always in a dry box. On exposure to moist air, α-UF_5 changed rapidly into a yellow-green mouldy mass, which proved to be amorphous by X-ray diffraction. A mixture of this intentionally hydrolyzed UF_5 and ordinary UF_5 was subjected to the isolation process described in the above, and the solid residue showed again the X-ray diffraction pattern characteristic of the phase *X*.

Though the above-stated procedure certainly gives a synthetic route to the phase *X*, it is impossible to incorporate oxygen in a quantitative manner. This

† Present address: Japan Storage Battery Co.

†† Present address: Japan Atomic Energy Research Institute.

difficulty has been overcome by replacement of hydrolyzed UF_5 with well-crystallized UO_2F_2. (The latter was prepared as follows. UF_6 was hydrolyzed by water in a Kel-F tube. The pasty product was dried under vacuum at 180 °C, transferred into an alumina tube and heated at 600 °C in an equimolar mixture of HF and O_2 at about 1 atm.[4] To our surprise, alumina was inert to this atmosphere.) A typical synthetic result was as follows; treatment of 1.0 g of UO_2F_2 and 1.6 g of α-UF_5 at 370 °C for 16 h yielded about 2 g of product free from α-UF_5 and UO_2F_2.

The phase *X* was very hygroscopic, too.

Identification

(1) X-Ray Powder Diffraction. All the uranium compounds appearing in this article are more or less sensitive to moisture, so we have designed an air-tight sample holder which can be handled in a dry box and mounted on the goniometer of an X-ray diffractometer. The windows of the holder are equipped with aluminum foils 30 μm in thickness; a pair of these foils reduces the intensity of Cu $K\alpha$ X-ray to about one half.

Diffraction patterns of more than ten samples from different preparations are put in order as shown in the left column of Table 1. The values of *d* have been corrected with those of α-UF_5 as the internal standard. This pattern is unique; definitely different from those of UO_2F_2,[5] $U_3O_5F_8$,[6] α-UOF_4,[7] and β-UOF_4[8] and also dissimilar to those of Pa_2OF_8[9] and $NpOF_3$.[10]

A comparison of diffraction patterns (Table 1) shows a close similarity between the phase *X* and the phase ϕ reported by Rude et al.[11] Their work will be referred to later in the Discussion section.

(2) Infrared Spectrum. Infrared spectra of good quality were recorded by Jacob and his coworkers in their studies on some hygroscopic compounds of uranium.[7,12] They resorted to the Nujol method with CsI disks as the windows, using a vacuum kneader. Instead, we added CaH_2 powder into Nujol to prevent hydrolysis of samples[13] and could thus obtain spectra comparable to theirs.

The infrared spectrum of the phase *X* is shown in Fig. 1. It is definitely different from those of UO_2F_2,[14] α- and β-UF_5,[12] and UOF_4,[7] and could be used for identification purposes.

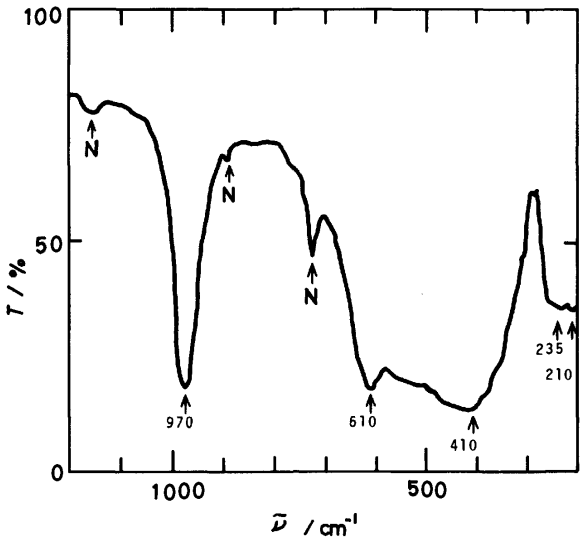

Fig. 1. Infrared spectrum of the phase *X*. (Absorption bands denoted by N are those due to Nujol.)

Determination of Oxygen

In the determination of chemical formula of uranium oxyfluorides, it has been a common practice that the uranium and fluorine content are obtained by actual analyses and the oxygen content by difference. Since the weight fraction of oxygen in those fluoride oxides is generally small (10% or less) the accuracy of the oxygen content thus obtained is open to question, though measured values of the valence of uranium serve as a check.

Jacob et al.[7] determined the oxygen content in UOF_4 by reacting the samples with carbon at 2000 °C and analyzing CO by infrared spectroscopy. On the other hand, Otey et al.[6] burned their sample of $U_3O_5F_8$ with ClF_3, put the gaseous product to gas chromatography and obtained the O/U ratio from the peaks of O_2, ClO_2F, and UF_6. At first we followed Otey's method, with BrF_5 replacing ClF_3. This modification was made, first because BrO_2F is far less stable than ClO_2F[15,16] and hence no oxygen-containing compound other than elemental oxygen would be formed; and secondly because a Br-compound has generally longer retention time than the corresponding Cl-compound, leading to better separation. This approach was, however, abandoned because the retention time of BrF_3, a by-product, was found nearly equal to that of UF_6. Thereupon, we made a shift to an ^{18}O isotopic dilution method, as described below.

An unknown sample and ^{18}O-labelled U_3O_8 (spike), each containing 5—10 mg of oxygen, were weighed in turn into a nickel crucible. The crucible was put into a monel reaction tube and the valve on the latter was closed. The reaction tube was taken out of the dry box and connected to a vacuum manifold. After evacuation, BrF_5 (pre-purified by distillation) was collected into the tube with liquid nitrogen to Br/U ratio of about 5. (By the way, IF_7 was found inadequate as the fluorinating agent; it seemed not to decompose water completely into elemental oxygen at room temperature. IF_7 was tried, because it was known to clean apparatus contaminated with uranium-bearing deposits at 20 °C or above.[17]) The tube was then held at 300 °C for about 1 h, to convert the sample and the spike together completely into a gaseous product.

With the tube immersed in liquid nitrogen, part of the elemental oxygen liberated was expanded into a pair of glass samplers through a liquid nitrogen trap, and subsequently analyzed for ^{18}O atom-fraction by mass spectrometry (Atlas, model CH 4). The ^{18}O atom-fraction in the spike (U_3O_8) was obtained in the same manner. Thus, oxygen content of the unknown sample was estimated by the conventional isotope dilution method.

The chemical form U_3O_8 was chosen as that of the spike, because it is a weighing form in gravimetry of uranium, in spite of the existence of some solid solution ranges.[3] Ammonium diuranate formed on introduction of UF_6 into aqueous ammonia (about 28 wt%) was filtered, dried at 130 °C and ignited at 800—900 °C in open atmosphere to constant weight. Next, a portion of thus prepared U_3O_8 was brought to contact with ^{18}O-enriched oxygen (0.2 atm) at 700 °C, with the gaseous phase renewed every 10—15 h. (The enriched oxygen used (The British Oxygen Co.) was found to be a synthetic mixture of nearly pure $^{18}O_2$ and $^{16}O_2$ in the ratio of 1:4. Since the ^{17}O atom-fraction of this gas was as small as 0.045 atom% and the natural abundance of ^{17}O is 0.0374 atom%, no correction was required for the contribution of $^{17}O_2$ to the MS peak, m/z=34.) The ^{18}O atom-fraction of the spike measured repeatedly over a period extending for a few months ranged at random between 13.86 to 14.06 atom% with the mean value at 14.01±0.03 atom%. This seemed to form a strong evidence for the absence of any exchange reaction between U_3O_8 and atmospheric oxygen at room temperature, as well as the absence of water adsorbed within the reaction system which should have interfered the analysis.

The accuracy of this analytical method was tested with the U_3O_8 sample of isotopically natural composition, which had been prepared as described in the foregoing paragraph. The mean value of six determinations of the oxygen content was 15.24±0.11 wt% (theor.: 15.20 wt%) and the O/U ratio was calculated to be 2.68±0.02 (theor.: 2.67) on the assumption that the sample contained no element other than uranium and oxygen.

It may be worthwhile to refer to the isotopic equilibrium in the oxygen gas evolved on combustion of U_3O_8. Equilibrium was always attained in the case of the spike only, but not in the case of the mixture of the spike and natural U_3O_8. The ratio of MS peaks, m/z=32, 34, and 36, was away from the binominal distribution, but closer to it than in the hypothetical case that oxygen was liberated separately from the enriched and natural U_3O_8 and then mixed together. Since no isotopic exchange was observed between $^{18}O_2$ and $^{16}O_2$ at 300 °C, it is safely presumed that some oxygen-bearing compound, such as U_3O_8, some fluoride oxide or OF_2, should have taken part in the exchange.

The analytical method was tested further with the crystallized UO_2F_2 mentioned before. Satisfactory results were obtained again, with the mean value of two determinations being 10.39±0.13 wt% (theor.: 10.39 wt%).

In the following a brief mention is to be made of some articles related to the analytical method developed in the present work. Trace of oxygen in metals was determined by ^{18}O isotopic dilution, with the oxygen extracted as CO and CO_2.[18] Oxygen contents in metal oxides were determined gasometrically, by burning the oxides with either BrF_3 or $KBrF_4$ and collecting elemental oxygen with a Toepler pump.[19,20]

Determination of Chemical Formula

(1) Chemical Analysis. Determination of U(IV) was made by oxidation with $K_2Cr_2O_7$ followed by back titration with Fe(II). The total uranium content was obtained as follows; the sample was dissolved in an alkaline H_2O_2 solution, evaporated to dryness as sulfate, passed through a Jones Reductor and after addition of $K_2Cr_2O_7$ back-titrated with Fe(II).

Fluorine was determined by the method of Combs and Grove.[21] The sample was brought to solution as in the total uranium analysis. Fluorine was precipitated by $SmCl_3$ at pH 3.0—3.5 and the excess Sm(III) was titrated with EDTA. Under carefully controlled conditions, no interference by uranium was observed; for example, a weighed sample of UF_6 was hydrolyzed in a NaOH solution and after neutralization with H_2SO_4 six aliquots were subjected to analysis, with the result of 32.53±0.09 wt% (theor.: 32.38 wt%).

Results of analysis of the phase *X* are summarized in Table 2. Main conclusions deduced from this table are as follows.

a) The mean valence of uranium calculated from data of U(IV) and Total U is 5.51±0.02, while that from data of Total U, O, and F is 5.47±0.07. These values are very close to $5\,1/2$.

b) The O/U ratio calculated from the data of Total U and O is equal to 1.04±0.02, a value very close to unity. The simplest formula in agreement with these two findings is $U_2O_2F_7$.

Table 2. Composition of the Phase *X* (wt%)

	Phase *X*	$U_2O_2F_7$ (Theoretical)
U (IV)	17.82±0.04 (2) [a]	18.57
Total U	72.15±0.87 (2) [a]	74.27
O	5.05±0.06 (5) [a]	4.99
F	19.55±0.22 (6) [a]	20.74
Total	96.75±0.90	100

a) Number of determinations.

(2) Thermal Decomposition. Composition of the fluoride oxide can be estimated by the weight loss on thermal decomposition, referring to the method reported by Wilson.[22,23] That is, the following experimental results can be explained by assuming the decomposition reaction:

$$2U_2O_2F_7=2UO_2F_2+UF_4+UF_6\uparrow$$

In a dry box, about 200 mg of the sample was weighed into a platinum crucible equipped with a lid and the crucible was put into a monel reaction tube. The tube was connected to a vacuum manifold and was heated for 24 h at 300 °C under continuous evacuation through a liquid nitrogen trap. The residue was whitish green and was composed of UO_2F_2 and UF_4 by X-ray analysis. The O/U and F/U ratio of the original sample calculated from the weight loss (30.3%) and the mean valence of uranium in the original sample (5.51) were 0.96 and 3.60, respectively, while those calculated from the weight loss and the valence in the residue (5.45) were 1.05 and 3.50, respectively. Though the relative errors of these ratios might be as large as 5%, this decomposition experiment was regarded as a corroboration of our conclusion based on chemical analyses.

$U_2O_2F_7$ does not decompose at 400 °C under UF_6 pressure of 3 atm, though it decomposes at 300 °C in vacuum, as detailed in the earlier section. It would be of value to measure its dissociation pressure at different temperatures, as in the work of Agron on intermediate fluorides of uranium.[3]

Discussion

The chemical formula $U_2O_2F_7$ can be found in the report by Rude et al. published in 1971.[11] They reacted UF_4 with ClO_3F or OF_2 at 200—300 °C, to produce UF_6. The solid residue was diversified in color, ranging from white to green. Its X-ray diffraction pattern contained a series of reflections, together with those of UO_2F_2 and/or UF_4. They named the substance identified with these reflections the phase ϕ. As shown in Table 1, there is certainly a close similarity between *their* phase ϕ and *our* phase X, though the synthetic routes are entirely different from each other.

They assigned the chemical formula $U_2O_2F_7$ to this phase ϕ; but without well-grounded evidence, as summarized in the following. First, their samples were more or less contaminated with UO_2F_2 and/or UF_4, because they had no means to isolate their phase ϕ. Secondly, their analytical data were too much scattered to allow any quantitative deduction (for example, their data for U(IV) content on seven preparations ranged from 9.7 to 28 wt%). So, we claim this work as the first confirmation of the compound, $U_2O_2F_7$.

Appendix

In conjunction with the present work, some other attempts to prepare fluoride oxides of uranium in lower oxidation states were made, but were terminated without great success, as described below.

(1) Reaction of UF_4 with Oxygen. This reaction has attracted much attention as a method for the production of UF_6 without the use of elemental fluorine.[3,24,25] The work of Kirslis et al.[26] has a distinctive feature, in that the reaction was carried out with alternating oxygen pressure and vacuum. A cloud of white particles was blown out of the reactor into a filter chamber. The chemical formula, U_2OF_8, was assigned to this white material, on the ground of chemical analysis (wt% Found U, 72±2; U(IV), 36±1; F, 21±2). Assignment of this formula is, however, not convincing, since straightforward calculation from their analytical data (mean valence of U: 5.00±0.04 and F/U: 3.65±0.36) gives a value, 0.67±0.18, for the O/U ratio. They claimed that thermal decomposition of the material at 300 °C yielded UF_6, UO_2F_2 and UF_4 in the proportion 1:1:2 in agreement with the formula, U_2OF_8, but no analytical data were shown. Its X-ray diffraction pattern was reported to be similar to that of U_4F_{17}.[3]

Our experimental procedure was nearly identical with Kirslis's. A platinum boat containing UF_4 was placed in a monel tubular reactor lined with a platinum plate. After evacuation and introduction of HF to about 0.5 atm, the reactor was heated to 500 °C. Then HF was replaced by oxygen at 1 atm, and the temperature was raised to, typically, 685 °C. As observed by Kirslis, the lower the temperature and the shorter the period of alternating evacuation and pressurization with O_2, the greater was the yield of the white material collected on a sintered nickel filter placed 30 cm downstream of the reactor. Out best result was as follows. Starting with 1.3$_5$ g of UF_4, the reaction was carried out for 150 min, with the cycle of 0.5 min for evacuation and 0.5 min for pressurization. The residue on the boat weighed 0.7 g and was composed mainly of UO_2F_2, together with some unreacted UF_4 (X-ray analysis). (A few thin leaves, transparent and amber-colored, were found attached to the rim of the boat. The X-ray diffraction pattern of this material had reflections *only* at d=5.20, 2.60, and 1.74 Å. These reflections correspond to those of UO_2F_2 with the hexagonal Miller indices, $h=k=0$ and $l=3n$ (n=1, 2, ···).[5]) Over the downstream half of the platinum plate was found about 0.2 g of UF_4. A cold trap at the farmost downstream collected 0.11 g of UF_6. About 0.1 g of the white material had deposited on the filter.

The X-ray diffraction pattern of the white material revealed that it was amorphous, excepting a trace of UO_2F_2 and/or UF_4. Its infrared spectrum as shown in Fig. 2 is unique. Values of the mean valence of uranium determined for three preparations were 5.1$_4$, 5.1$_3$, and 4.9$_5$. We have thus reconfirmed the main features of the experiments by Kirslis et al. And it was established that *our* $U_2O_2F_7$ is different from *their* U_2OF_8.

(2) Hot Filament Reduction of UF_6. In 1970 Schröder and Grewe[27] claimed the first synthesis of WF_5, by reducing WF_6 with a hot tungsten filament and collecting WF_5 on the wall of a cooled glass container. Later, Falconer et al.[28] synthesized some metal fluorides by use of a less

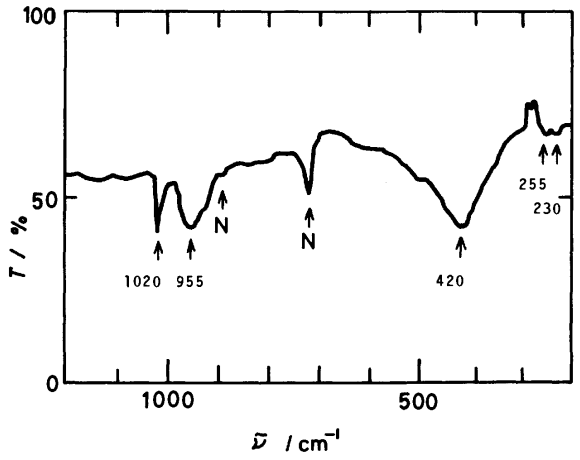

Fig. 2. Infrared spectrum of the white material deposited on the filter. (Absorption bands denoted by N are those due to Nujol.)

sophisticated apparatus.

After successfully reproducing the results of Falconer's on MoF_5, we tried reduction of UF_6 with a nickel filament. Three nickel wires, 0.5ϕ×1200 mm, were coiled to the length of 300 mm, connected in parallel, rinsed with HNO_3 and suspended in a Pyrex tube, 31ID×370 mm. After evacuation, UF_6 was introduced and purified until its vapor pressure was reduced to 25 mmHg or less at 0 °C. (The pressure was measured by a bellows gauge.[29]) With the tube immersed in ice water to the neck, the filaments were heated electrically to dull red (800 °C). The inner wall of the tube was gradually covered with a white material. After 3 h of lighting, 0.15 g of the white material was recovered, which proved to be β-UF_5 by X-ray analysis and determination of mean valence of uranium. No contamination with nickel fluoride was detected.

Next, we repeated the experiment with 80 mmHg of elemental oxygen added into the system, with the intention of preparing some fluoride oxide. But the product was again β-UF_5. Experiments with the nickel filaments covered with platinum black could not alter the result.

The authors thank Mr. Keiichi Hayashi, now with Sumitomo Atomic Industries, who took charge of the earlier stages of the determination of the oxygen content.

The Iodine Content of Atmospheric Aerosols as Determined by the Use of a Fluoropore Filter® for Collection

Hirofumi TSUKADA,*,† Hiroshi HARA, Kiyoshi IWASHIMA, and Noboru YAMAGATA†
Institute of Public Health, 4-6-1 Shirokanedai, Minato-ku, Tokyo 108
(Received February 7, 1987)

Atmospheric aerosols were collected onto a Fluoropore filter in order to determine the iodine by means of instrumental neutron activation analysis. The collection filter was found to be the best material among the nine filters examined, for it has the lowest blank values for iodine as well as for other halogens and sodium. The iodine concentrations in Tokyo were found to be 1.7—12.7 ng m^{-3}. Of the soluble iodine, 10% or less was in the form of IO_3^-.

Among the radionuclides released from nuclear fuel reprocessing plants, radioiodine is of special concern because of its high fission yield, its volatility, and its accumulation in the human thyroid. An extraordinary long half-life of ^{129}I (1.6×10^7 y) necessitates the knowledge of the geochemical cycle of stable iodine in order to assess the behavior of ^{129}I in the environment and to estimate internal exposure through food ingestion.

The concentrations of aerosol iodine have been reported to be from several to several tens ng m^{-3}.[1-8] However, in most of the reported cases, the filter blank of iodine was not sufficiently low as compared with the amount of iodine collected on the filter, suggesting the potential inaccuracy of the reported values of the iodine concentration. This paper deals with the choice of an appropriate collection filter and the determination of stable iodine in atmospheric aerosols.

The present study examined nine filters for the blank iodine by means of instrumental neutron activation analysis; it demonstrated that the Fluoropore AF07P filter had the lowest iodine blank values. This filter was employed as the collection material for atmospheric aerosol in Tokyo. The aerosol was analyzed for iodine and some other elements, such as bromine, sodium, and aluminum, in order to obtain information regarding the environmental behavior of iodine.

Experimental

Three kinds of filters were analyzed by means of the instrumental neutron activation method: (a) filters prepared for standards, (b) filters for blank contents, and (c) filters with collected aerosols on them.

Standard Samples. Standard solutions of iodine, bromine, and chlorine were prepared by dissolving the respective potassium salts in twice-distilled water. For the iodine solution, the pH was adjusted to 8 with lithium hydroxide so as to prevent any iodine from being lost from the solution. Each of the solutions was impregnated uniformly onto a cellulose filter (Toyo 7) of the same size and shape as the other samples. For the standard of sodium and aluminum, powder of Standard Rock JG-1 (Porphyrite biotite granodiorite: Na, 2.51; Al, 7.53%), prepared by the Geological Survey of Japan, was caused to adhere onto a cellulose filter (Toyo 7) in the way described above.

† Present address: Japan Chemical Analysis Center, 295-3, Sanno-cho, Chiba-shi, Chiba 281.

Filter Blanks. Table 1 covers the analyzed nine filters. The filters were subjected to the analysis without any particular treatment.

Filters with Collected Aerosols on Them. A Fluoropore AF07P filter (Sumitomo Electric Industries, 22.8×17.7 cm) was employed as the aerosol-collection material (aerosol collection efficiency: 99.9%).[9] Atmospheric aerosol was collected for from three to ten hours by means of a high-volume air sampler set on the rooftop of the Institute of Public Health, Tokyo (about 15 m above the ground).

Instrumental Neutron Activation Analysis. The filters were sealed in polyethylene bags previously washed with nitric acid. A number of bags were put into a polyethylene capsule and irradiated in the Rikkyo University TRIGA II Reactor at a flux rate of 1.5×10^{12} n cm^{-2} s^{-1} for 10 minutes. The samples were cooled for five minutes after irradiation and then counted by means of a Ge(Li) detector (volume: 55 cm^3) for five minutes.

Results and Discussion

Concentrations of Blank Filters. The blank contents of iodine and the other elements are listed in Table 1, which shows that Fluoropore AF07P (polytetrafluoroethylene) has the lowest blank iodine, 0.04 ng cm^{-2}, one or two orders of magnitude lower than any other filters analyzed. The same thing goes for the other determined elements. In addition, this filter is designed for air filtration and so it designed to have a small pressure drop (0.69 Pa s m^{-1}), as small as that of the commonly used quartz-fiber filter. All of these findings establish the appropriateness of this filter for collecting aerosol iodine.

S/N Ratio of Iodine Concentrations. The accuracy of the observed iodine concentrations is directly affected by the blank value of iodine for the filter employed. The accuracy is quantified as the S/N ratio, where signal and noise correspond to the iodine content per unit of area of the filter with collected aerosol on it and to the blank value of iodine for the filter itself. This ratio was applied to the present results and the previously reported data. When the blank value was not reported by the original authors, it was replaced in this work by the corresponding blank values.

The S/N ratios are listed in Table 2. The present work is characterized by a high S/N ratio, around 100, whereas most of the other works have had smaller ratios, 1—10. It follows that our measured iodine concentrations are exceedingly reliable.

Evaluation of Iodine Volatilization in the Neutron Irradiation Process. Iodine loss by means of volatilization might be suspected in the process of neutron irradiation. In order to examine this problem, the iodine content was compared between two pieces of filters with collected aerosol. A filter with collected aerosol was cut into two pieces of equal size. One piece was impregnated with a lithium hydroxide solution before irradiation to prevent the iodine from volatalizing, while the other was not treated thus. Two samples, S2 and S3, were thus compared. The respective iodine contents for the treated and not-treated filter pieces were as follows: S2: 7.4±0.4 and 6.6±0.4; S3: 11.5±0.5 and 11.9±0.5 ng cm^{-2}. No significant difference between the treated and untreated pieces was noted, indicating that no such treatment was necessary to apply the samples in this study.

a) Determined by this work.

Atmospheric Concentration of Iodine in Aerosols. Table 3 shows the atmospheric concentrations of iodine in the aerosol collected in Tokyo. The iodine concentrations ranged between 1.7 and 12.7 ng m^{-3}. For the other elements, the factors of air to air fluctuation were one order, about the same as that of iodine. In the present work, samples were analyzed for several tens of cubic meters.

The obtained iodine concentrations are in the range of reported values not only for Tokyo but also for various sites in the world (ng m^{-3}): 3.2—15.4 (Tokyo),[8] 1.32—>24.6 (Hawaii),[1] 1.5—5.2 (Hawaii),[2] 0.3—9.4 (Alaska),[3] 4.7—10 (San Francisco),[4] 2—10 (Massachusetts),[5] and 2.2—5.1 (New York).[6]

Different Mechanisms of Iodine and Chloride in Aerosols. The principal source of iodine in the atmosphere has been reported to be marine.[13,14] However, soil-derived iodine and surface soil particles in air are collected together with airborne particles. For that reason, their iodine content can be calculated on the basis of the aluminum concentrations listed in Table 3, which range from 56 to 338 ng m^{-3}, assuming that the average contents of aluminum and iodine in

a) The ± values indicate the counting errors.

soil are 71 g kg^{-1} and 5 mg kg^{-1} respectively.[15] The calculated values are 0.024 (S2), 0.019 (S3), and 0.004 (S4) ng m^{-3} respectively. Thus, the contribution of soil particles to the total iodine content of aerosols is negligibly small. Most of the iodine in aerosols may thus be of marine origin.

The principal source of chloride in the atmosphere has been also considered to be marine, but recently there was appeared an anthropogenic supply of chloride, formed from the hydrogen chloride emitted from incinerating plants. At the same site over a period from June, 1979, to July, 1982, one of the present authors determined the particle-size distributions for chloride and other components in order to ascertain the seasonal variation of the chloride distribution.[16] On a monthly averaged basis, the chloride in the coarse-particle region was 78, 61, and 27% of the total chloride for July, October, and November respectively. On the basis of these values, the chloride concentration in aerosols of marine origin can be postulated. The calculated values of I/Cl (by weight) in marine-origin aerosols are $0.38—2.2\times10^{-2}$, but the I/Cl (by weight) in sea water is 3.2×10^{-6}.

If the behavior of iodine through transport is the same as that of chloride, the same order of magnitude of I/Cl in aerosols should be expected as in sea water, but the result indicates an extraordinarily high ratio (by a factor of about 10^3). This is in accord with similar observations of the total I/Cl ratios in aerosols and precipitation reported by many researchers[1,3,5,13] and strongly suggests a different behavior of iodine through transport from that of chloride.

A Simple Fractionation of Iodine Species. Atmospheric aerosol probably contains various sorts of iodine compounds. Aerosol iodine was tentatively fractionated into water-soluble and insoluble residues, and iodate was collected so as to be determined for the former fraction.

Two equivalent pieces were cut out of a sample filter in the manner described before. One piece was analyzed for total iodine (T_I). The other was subjected to ultrasonic extraction with water: iodine was determined for the water extract (S_I) and for the insoluble residue (R_I). This measurement was applied to three samples.

The extraction was satisfactory because no appreciable chlorine, all of which could be regarded water-soluble, was observed for the insoluble residue. The water-soluble fraction was further passed over the

anion-exchange resin (Dowex 2-X8) to separate the iodate fraction (S_{IO_3}), which was them analyzed for iodate.[17,18]

Table 4 indicates that the recovery was almost satisfactory, that only 42—73% of the iodine was water-soluble, and that 10% or less of the soluble iodine was iodate, IO_3^-.

The existence of the IO_3^- form in aerosols was established in the present work, although there could be various kinds of iodine compounds in the atmosphere.

We are grateful to Mr. Hiroyuki Takagi for his help in the Gamma-ray measurements.

Chromatographic Study of Optical Resolution. XIV.[1] Optical Resolution of Amine Complex Cations of the Type $[Co(N)_6]^{3+}$ by Reversed-Phase Ion-Pair Chromatography Using Bis(μ-*d*-tartrato)diantimonate(III) and Arsenic Analog as an Ion-Pairing Reagent

Shinji Izumoto,† Katsuhiko Miyoshi, and Hayami Yoneda*
Department of Chemistry, Faculty of Science, Hiroshima University,
Higashi-senda-machi, Naka-ku, Hiroshima 730
(Received February 24, 1987)

Reversed-phase ion-pair chromatography (RPIPC) was applied to the optical resolution of amine complex cations of the type $[Co(N)_6]^{3+}$ using either bis(μ-*d*-tartrato)diantimonate(III) ion, $[Sb_2(d\text{-tart})_2]^{2-}$ or its arsenic analog, $[As_2(d\text{-tart})_2]^{2-}$ as an ion-pairing reagent. With either reagent, efficient optical resolution was attained for $[Co(en)_3]^{3+}$, $[Co(tn)_3]^{3+}$, [Co(sen)]$^{3+}$, [Co(sep)]$^{3+}$, and [Co(diNOsar)]$^{3+}$ (en=ethylenediamine, tn=trimethylenediamine, sen=1,1,1-tris[[(2-aminoethyl)amino]methyl]ethane, sep=1,3,6,8,10,13,16,19-octaazabicyclo[6.6.6]icosane, and diNOsar=1,8-dinitro-3,6,10,13,16,19-hexaazabicyclo[6.6.6]icosane). Dependence of retention volumes and separation factors of these complexes on the concentration and the counterion of the ion-pairing reagents was examined with Na^+, Me_4N^+, and Et_4N^+ employed as counterions. Experimental results were discussed with reference to those obtained by means of normal-phase ion-exchange chromatography (NPIEC) using the same eluents. It was concluded that $[As_2(d\text{-tart})_2]^{2-}$ serves as a more effective eluent in both RPIPC and NPIEC than $[Sb_2(d\text{-tart})_2]^{2-}$, and that RPIPC is a much more useful tool for the optical resolution of the $[Co(N)_6]^{3+}$-type complex cations than NPIEC.

In a previous work,[2] optical resolution of some *cis*(N)-$[Co(O)_4(N)_2]^-$-type complex anions was accomplished by means of reversed-phase ion-pair chromatography (abbreviated as RPIPC hereafter) using cinchona alkaloid cations as an ion-pairing reagent. In the present study, optical resolution of some amine complex cations of the type $[Co(N)_6]^{3+}$ was attempted by the same technique. The key factor here is to find out a suitable chiral anion capable of functioning as an ion-pairing reagent. The two chiral anions, *d*-tartrate (*d*-tart^{2-}) and bis(μ-*d*-tartrato)diantimonate(III) ($[Sb_2(d\text{-tart})_2]^{2-}$) ions have been successfully utilized as a chiral eluent to resolve a variety of complex cations by normal-phase ion-exchange chromatography[3] (abbreviated as NPIEC). The former anion is found to be too hydrophilic to be distributed to the stationary phase composed of linear-chain alkyl moieties in RPIPC. The latter anion, $[Sb_2(d\text{-tart})_2]^{2-}$ does not contain any alkyl chains nor aromatic rings and it carries a high electric charge compared with commonly used ion-pairing reagents such as tetraalkylammonium and alkanesulfonate ions. However, it is regarded as rather hydrophobic, since its charged groups are all coordinated to Sb(III) ions and it is fairly large in size. Therefore, this chiral anion is expected to serve as a potential ion-pairing reagent in RPIPC.[4a] $[As_2(d\text{-tart})_2]^{2-}$ ion, an As analog of $[Sb_2(d\text{-tart})_2]^{2-}$, has seen limited use as a chiral eluent, since it is not commercially available. Thus, it seems attractive to compare the two anions with respect to their ability as an eluent in chromatography.

In RPIPC, structural characteristics of ion-pairing reagents have been examined in detail, since they have a profound influence on the retention volumes as well as on the separation factors.[4] By contrast, the functions of the counterions M^+ of the ion-pairing reagents have been hardly taken into consideration. In the present study, however, the electric charge of the tervalent complex cation is not completely neutralized in the 1 : 1 association with $[Sb_2(d\text{-tart})_2]^{2-}$, and thus the complex cation is distributed to the stationary phase probably in the form of $M[Co(N)_6]][Sb_2(d\text{-tart})_2]_2$ rather than $[Co(N)_6]_2[Sb_2(d\text{-tart})_2]_3$ if the counterion M^+ is more hydrophobic than $[Sb_2(d\text{-tart})_2]^{2-}$. Consequently, a hydrophobic counterion M^+ is expected to promote cooperatively the retention of the complex cation to a considerable extent, since $[Sb_2(d\text{-tart})_2]^{2-}$ is less hydrophobic than usual ion-pairing reagents.

Experimental

Materials. The $[Co(N)_6]^{3+}$-type complexes used were $[Co(en)_3]^{3+}$,[5] $[Co(tn)_3]^{3+}$,[6] [Co(sen)]$^{3+}$,[7] [Co(sep)]$^{3+}$,[8] *lel*$_3$-$[Co(chxn)_3]^{3+}$,[9] and [Co(diNOsar)]$^{3+}$[10] (en=ethylenediamine, tn=trimethylenediamine, sen=1,1,1-tris[[(2-aminoethyl)amino]methyl]ethane, sep=1,3,6,8,10,13,16,19-octaazabicyclo[6.6.6]icosane, chxn=*trans*-1,2-cyclohexanediamine, and diNOsar=1,8-dinitro-3,6,10,13,16,19-hexaazabicyclo[6.6.6]icosane). For comparison, $[Co(gly)(en)_2]^{2+}$[11] was also used (gly=glycinate anion). Figure 1 illustrates schematic structures of some of these complexes, which were prepared as chloride salts by the literature methods. Absolute configurations have been already assigned to all of them.

† Present address: Daicel Chemical Industries, Ltd., Research Center, Shinzaike, Aboshi-ku, Himeji 761-12.

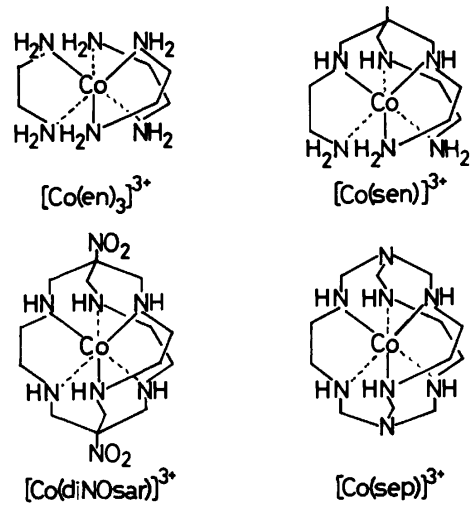

Fig. 1. Structures of Δ-enantiomers of the $[Co(N)_6]^{3+}$-type complexes investigated in the present study.

$K[Co(edta)]\cdot 2H_2O$ (edta=ethylenediaminetetraacetate anion), used as a marker for the void volume measurement, was prepared by a well-established method.[12]

Following salts of $[Sb_2(d\text{-tart})_2]^{2-}$ or $[As_2(d\text{-tart})_2]^{2-}$ were used as ion-pairing reagents; $Na_2[Sb_2(d\text{-tart})_2]\cdot 5H_2O$, $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$, $(NH_4)_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$, $(Me_4N)_2[Sb_2(d\text{-tart})_2]\cdot 3.5H_2O$, $(Et_4N)_2[Sb_2(d\text{-tart})_2]\cdot 1.5H_2O$, and $Na_2[As_2(d\text{-tart})_2]\cdot 5H_2O$. The potassium salt was obtained commercially and was used without purification. The sodium salt was prepared by the literature method.[3b] The ammonium salt was similarly prepared using ammonium hydrogen *d*-tartrate in place of sodium hydrogen *d*-tartrate. Found: C, 15.43; H, 2.94; N, 4.40%. Calcd for $C_8H_{12}N_2O_{12}Sb_2\cdot 3H_2O$: C, 15.35; H, 2.91; N, 4.48%. The tetramethylammonium and tetraethylammonium salts were prepared in a following way. An equivalent amount of antimony(III) oxide was added to an aqueous solution of *d*-tartaric acid. After heating just to the boiling point, an equivalent amount of aqueous MOH ($M^+=Me_4N^+$ or Et_4N^+) was carefully added dropwise with stirring. The suspension was concentrated and undissolved substances were filtered off. The filtrate was evaporated to dryness to obtain a glassy material. Its purity was checked by elemental analysis. Found: C, 25.69; H, 4.71; N, 3.70%. Calcd for $C_{16}H_{28}N_2O_{12}Sb_2\cdot 3.5H_2O$: C, 25.72; H, 4.73; N, 3.75%. Found: C, 34.89; H, 5.65; N, 3.37%. Calcd for $C_{24}H_{44}N_2O_{12}Sb_2\cdot 1.5H_2O$: C, 35.01; H, 5.77; N, 3.40%. $Na_2[As_2(d\text{-tart})_2]\cdot 5H_2O$ was easily prepared according to well-established procedures[13] followed by recrystallization from water. Found: C, 16.47; H, 2.42%. Calcd for $C_8H_4As_2Na_2O_{12}\cdot 5H_2O$: C, 16.62; H, 2.45%.

The column packings used in the present study were TSK gel ODS-120A (Toyo Soda Manufacturing Co., Ltd.), which carries linear-chain alkyl moieties (octadecyl groups) covalently bonded to the surface of silica gel (for RPIPC), and TSK gel SP-2SW (Toyo Soda Manufacturing Co., Ltd.), which carries sulfopropyl groups covalently bonded to the surface of silica gel (for NPIEC).

Chromatographic Experiments. A stainless steel column (4×300 mm) packed with TSK gel ODS-120A or a similar column (7.5×75 mm) packed with TSK gel SP-2SW was equilibrated with an aqueous eluent solution. A mixture of 20 μl of an aqueous solution of a racemic complex (0.1 mol dm^{-3}) with 10 μl of an aqueous solution of a marker (0.01 mol dm^{-3}), was injected by a syringe on the top of the column and was eluted at an elution rate of 0.25 $cm^3\ min^{-1}$. The effluents were fractionally collected and their absorption and circular dichroism (CD) spectra were measured to obtain elution curves and to determine elution orders. The chromatographic apparatus used here consisted of a JASCO BIP-1 pump for HPLC, a JASCO variable loop injector VL-613, and a Shimadzu UV-140 double beam spectrophotometer. The CD spectra were recorded on a JASCO J-40CS recording spectropolarimeter.

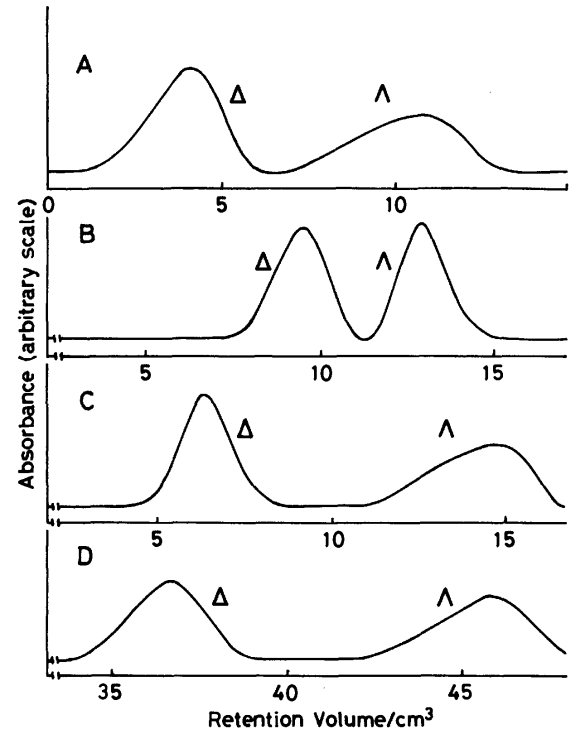

Fig. 2. Elution curves of $[Co(en)_3]^{3+}$ (A), $[Co(tn)_3]^{3+}$ (B), $[Co(sen)]^{3+}$ (C), and $[Co(sep)]^{3+}$ (D) obtained by RPIPC. Eluent: aqueous $K_2[Sb_2(d\text{-tart})_2]$ (0.1 mol dm^{-3}).

Results and Discussion

Reversed-Phase Ion-Pair Chromatography (RPIPC). Typical elution curves obtained for the $[Co(N)_6]^{3+}$-type complexes with $K_2[Sb_2(d\text{-tart})_2]$ employed as an eluent in RPIPC are shown in Fig. 2. Though the curves are rather broad, base-line resolution is assured for each complex. It is noteworthy that complete resolution is accomplished easily even for $[Co(tn)_3]^{3+}$, complete resolution of which has been barely attained with resort to time-consuming recycling chromatography.[14] Experimental data obtained with $M_2[Sb_2(d\text{-tart})_2]$ ($M^+=Na^+$, K^+, NH_4^+, Me_4N^+, and Et_4N^+) used

Table 1. Effect of Counterion M^+ on Retention Volume V_R and Separation Factor α Obtained by RPIPC with Aqueous M_2 $[Sb_2(d\text{-tart})_2]$ (0.1 mol dm^{-3})

a) Retention volume of the later-eluted Λ-enantiomer.

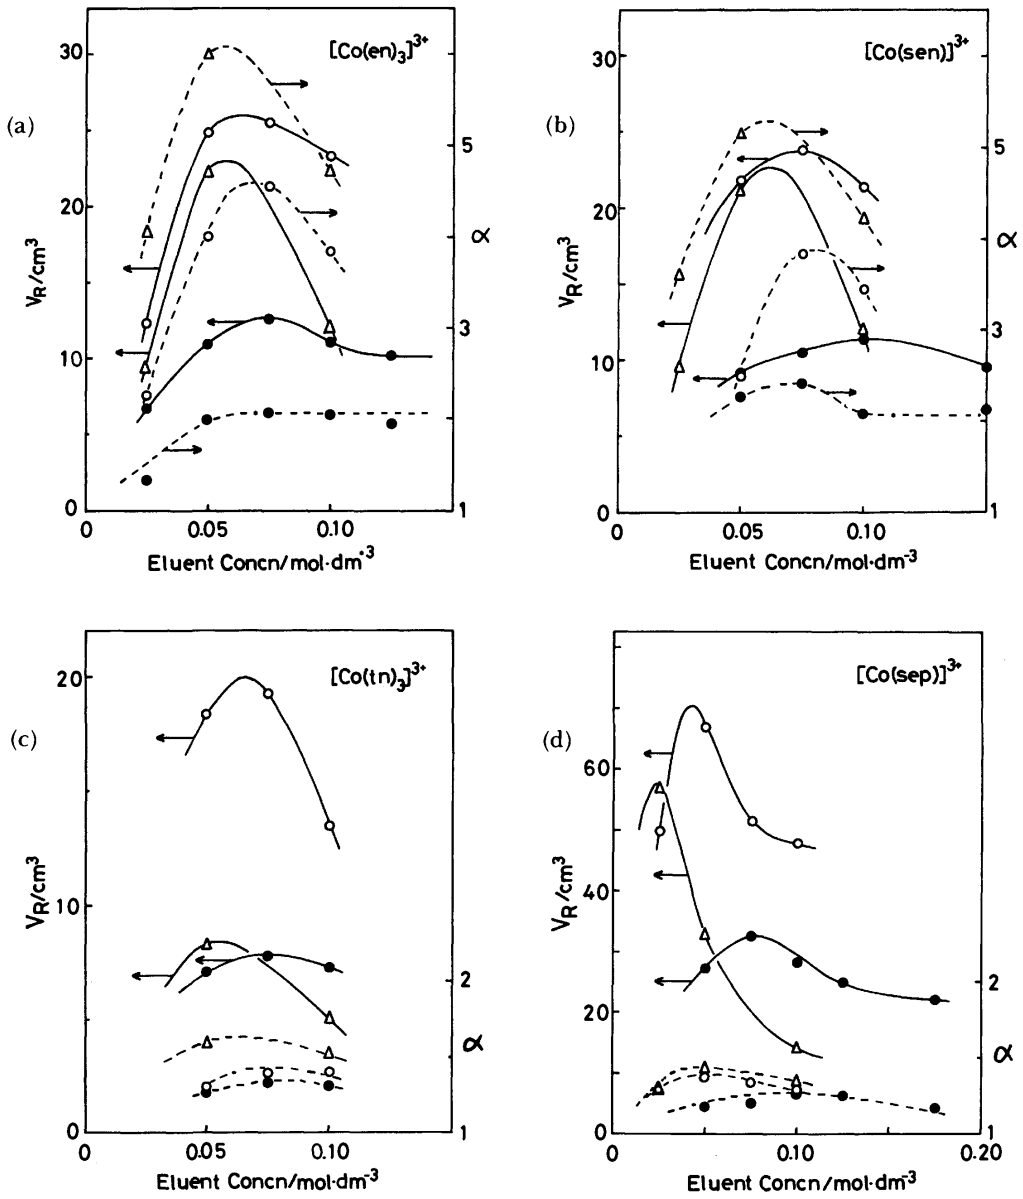

Fig. 3. Plots of retention volumes V_R (——) of the later-eluted enantiomer and of separation factors α (------) obtained by RPIPC against the eluent concentration. Eluent: $Na_2[Sb_2(d\text{-tart})_2]$ (●), $(Me_4N)_2[Sb_2(d\text{-tart})_2]$ (○), and $(Et_4N)_2[Sb_2(d\text{-tart})_2]$ (Δ).

as an ion-pairing reagent are summarized in Table 1.[15] For all the complexes, the Λ-enantiomers are eluted later. This means that $[Sb_2(d\text{-tart})_2]^{2-}$ gets associated more readily with the Λ- than with the Δ-enantiomer, in keeping with the association constants estimated for these complex cations with $[Sb_2(d\text{-tart})_2]^{2-}$ in aqueous solution.[16] Furthermore, this observation does not contradict with the elution orders predicted from the chiral discrimination mechanism established earlier between $[Sb_2(d\text{-tart})_2]^{2-}$ and $[Co(N)_6]^{3+}$-type complexes.[17] One different elution order is noted between RPIPC and NPIEC. The complex cation, $[Co(tn)_3]^{3+}$, when eluted from either an SP-Sephadex C-25 or Dowex 50W-X2 cation-exchange column with aqueous $Na_2[Sb_2(d\text{-tart})_2]$, was partially resolved with the Δ-enantiomer eluted slightly faster unlike other $[Co(N)_6]^{3+}$-type complexes.[18] This suggests that $[Sb_2(d\text{-tart})_2]^{2-}$ favors the Δ- over the Λ-enantiomer for $[Co(tn)_3]^{3+}$ in NPIEC. In RPIPC, on the contrary, $[Sb_2(d\text{-tart})_2]^{2-}$ always exhibits a greater affinity toward the Λ-enantiomer for all the complexes including $[Co(tn)_3]^{3+}$. The anomalous behavior of $[Co(tn)_3]^{3+}$ will be discussed later.

Data in Table 1 reveal that different counterions M^+ of $[Sb_2(d\text{-tart})_2]^{2-}$ give different retention volumes V_R and separation factors α for each $[Co(N)_6]^{3+}$-type complex. In general, the larger the size of M^+, i.e., the more hydrophobic nature M^+ bears, the greater the retention volume of each complex. However, when M^+ is as large as Et_4N^+, the retention volume starts to decrease. Then, in Figs. 3-a to 3-d are plotted the V_R and α values of $[Co(en)_3]^{3+}$, $[Co(sen)]^{3+}$, $[Co(tn)_3]^{3+}$, and $[Co(sep)]^{3+}$, in this order, as a function of the concentration of ion-pairing reagents with $M^+=Na^+$, Me_4N^+, and Et_4N^+. For each complex, V_R shows a clear maximum with $M^+=Me_4N^+$ and Et_4N^+, the latter exhibiting it at lower eluent concentrations and the former giving a higher maximum at least in the concentration range covered. On the contrary, the V_R curve with $M^+=Na^+$ shows a less clear maximum. Appearance of such maxima in V_R may be explained as follows. Since Me_4N^+ and Et_4N^+ are much more hydrophobic than Na^+, they are more easily distributed together with $[Sb_2(d\text{-tart})_2]^{2-}$ to the stationary phase composed of linear-chain alkyl moieties,[19] generating more cation-exchange sites on the stationary phase.[4b] This will lead to remarkably increased retention volumes. On the other hand, the effect of expelling the complex cation already distributed to the stationary phase by the counterion M^+ present in the moving phase, viz., the exclusion effect of M^+, becomes more and more dominant with increasing concentration of the eluent and with increasing hydrophobic nature of M^+. Thus, a maximum in V_R appears at a lower eluent concentration for $M^+=Et_4N^+$ than for $M^+=Me_4N^+$, since the former counterion is more hydrophobic and thus has a greater exclusion effect. A lower maximum in V_R observed for the former is similarly interpreted, and the absence of a clear V_R maximum for $M^+=Na^+$ may be due to its hydrophilic nature which leads to a small retention volume and to a weak exclusion effect. These interpretations are indirectly supported by the observation that $[Co(sep)]^{3+}$, regarded as the most hydrophobic of the four complexes, exhibits the V_R maxima at the lowest eluent concentrations, and that it always gives greater retention volumes than $[Co(en)_3]^{3+}$ regardless of the kind of M^+.[20]

Let us next look into the separation factors α obtained by RPIPC. It is seen in Table 1 and Fig. 2 that fairly high separation factors are obtained to such an extent that complete resolution is attained with ease for each complex. In a previous study, for example, optical resolution of $[Co(en)_3]^{3+}$ resulted in a separation factor of 1.45[21] on an SP-Sephadex C-25 column with an aqueous $K_2[Sb_2(d\text{-tart})_2]$ solution (0.1 mol dm^{-3}) employed as an eluent. The α value of 2.63 obtained in the present RPIPC under a similar set of conditions (Table 1) demonstrates a remarkable improvement in the resolution efficiency. As noted above, $[Co(tn)_3]^{3+}$ can also be resolved completely with a separation factor of 1.33 under the same conditions as above, though NPIEC gives a separation factor of 1.00 for this complex, as seen later in Table 3.

It is noticeable in Fig. 3 that surprisingly high α values are obtained for $[Co(en)_3]^{3+}$, $[Co(sen)]^{3+}$, and $[Co(tn)_3]^{3+}$,[22] particularly when their retention volumes are increased with Me_4N^+ or Et_4N^+. On the contrary, $[Co(sep)]^{3+}$ gives an almost constant separation factor even if its retention volume is increased appreciably. Structural characteristics of these complexes (Fig. 1) indicate that the former three complexes allow the hydrogen-bonding association of $[Sb_2(d\text{-tart})_2]^{2-}$ from the direction of the C_3 axis (C_3 association) or the C_2 axis (C_2 association), while only the C_2 association is allowed for $[Co(sep)]^{3+}$ because it has alkyl caps along the C_3 axis. These characteristics seem to be responsible for the chromatographic behavior mentioned above, which will be discussed more closely in the last section.

Now, a comparison is made between $[Sb_2(d\text{-tart})_2]^{2-}$ and its As analog, $[As_2(d\text{-tart})_2]^{2-}$ with respect to their ability as an ion-pairing reagent in RPIEC. Table 2 compares the experimental data obtained with the two ion-pairing reagents. It is evident that first, $[As_2(d\text{-tart})_2]^{2-}$ gives much greater retention volumes than $[Sb_2(d\text{-tart})_2]^{2-}$ for all the complexes, second, the former gives correspondingly somewhat higher separation factors, and finally, the Λ-enantiomers are eluted later with either of the two eluents. These results lead us to conclude that $[As_2(d\text{-tart})_2]^{2-}$ interacts more strongly with these amine complex cations of the type $[Co(N)_6]^{3+}$ than does $[Sb_2(d\text{-tart})_2]^{2-}$ and thus can be

Table 2. Comparison of Retention Volumes V_R and Separation Factors α Obtained by RPIPC with $Na_2[As_2(d\text{-tart})_2]$ and with $Na_2[Sb_2(d\text{-tart})_2]$ (0.1 mol dm^{-3})

	$[As_2(d\text{-tart})_2]^{2-}$		$[Sb_2(d\text{-tart})_2]^{2-}$

used more preferably as an ion-pairing reagent for the optical resolution of these complex cations in RPIPC, and that the chiral discrimination mechanisms are essentially the same for the two ion-pairing reagents.

[Co(diNOsar)]$^{3+}$ behaves somewhat anomalously in that it gives smaller V_R values and considerably greater α values than the analogous cage complex, [Co(sep)]$^{3+}$ with either ion-pairing reagent (Table 2). Highly efficient optical resolution attained for [Co(diNOsar)]$^{3+}$ has been already interpreted in terms of the severe steric repulsion expected stereoselectively between the nitro group of the Δ-enantiomer and the distal carboxylato group of $[Sb_2(d\text{-tart})_2]^{2-}$.[17b] The smaller retention volumes obtained for this complex may be attributed to the presence of the polar nitro groups which render this complex less hydrophobic than the parent complex [Co(sep)]$^{3+}$.[23]

Normal-Phase Ion-Exchange Chromatography (NPIEC). For the purpose of elucidating why $[As_2(d\text{-tart})_2]^{2-}$ gives greater V_R values than $[Sb_2(d\text{-tart})_2]^{2-}$ in RPIPC, NPIEC was applied to the optical resolution of the $[Co(N)_6]^{3+}$-type complexes with the two chiral anions employed as an eluent. The results are listed in Table 3. For each of these complexes, $[As_2(d\text{-tart})_2]^{2-}$ and $[Sb_2(d\text{-tart})_2]^{2-}$ give comparable separation factors, but the former gives smaller retention volumes, indicative of the stronger affinity of the former anion for these complexes. This is in complete conformity with the results obtained by RPIPC. In other words, $[As_2(d\text{-tart})_2]^{2-}$ has inherently a stronger association tendency toward these complexes than $[Sb_2(d\text{-tart})_2]^{2-}$.

An X-ray crystallographic analysis has revealed that $[As_2(d\text{-tart})_2]^{2-}$ is somewhat smaller in size than $[Sb_2(d\text{-tart})_2]^{2-}$. If the two oxygen atoms coordinated to the same Sb or As atom, i.e., the alcoholic oxygen atom of one *d*-tartrate moiety and the carboxylic oxygen atom of the other *d*-tartrate moiety are used for the double hydrogen bonding to the two axial NH protons of the complex directed along either the C_3 or the C_2 axis, as assumed before,[17] the matching of the O-O and H-H distances is of prime importance to the interaction. The O-O distance actually estimated is 2.561 Å[24] for $[As_2(d\text{-tart})_2]^{2-}$ and 2.692 Å[25] for $[Sb_2(d\text{-tart})_2]^{2-}$. The H-H distance of $[Co(en)_3]^{3+}$ is 2.283 and 2.270 Å for the C_3 and C_2 axial protons, respectively.[26] It will then follow that $[As_2(d\text{-tart})_2]^{2-}$ is more susceptible to intimate hydrogen bonds to $[Co(en)_3]^{3+}$ and other related complexes than $[Sb_2(d\text{-tart})_2]^{2-}$ is. In this way, smaller and greater V_R values obtained with $[As_2(d\text{-tart})_2]^{2-}$ in NPIEC and RPIPC, respectively, are interpreted reasonably within the framework of the C_3 and C_2 association modes proposed previously.[17]

Comparison between RPIPC and NPIEC. A comparison of the experimental results obtained between RPIPC and NPIEC (Tables 2 and 3) reveals very interesting facts as follows. For such complexes as $[Co(en)_3]^{3+}$, [Co(sen)]$^{3+}$, and $[Co(tn)_3]^{3+}$ for which both of the C_3 and C_2 association modes are possible, the application of RPIPC leads to a remarkable improvement in the separation factor. For example, $[Co(tn)_3]^{3+}$ gives a single elution curve in NPIEC, while base-line resolution is attained for this complex in RPIPC. By contrast, no such drastic improvement is detected for [Co(sep)]$^{3+}$, [Co(diNOsar)]$^{3+}$, and *lel*$_3$-$[Co(chxn)_3]^{3+}$ (chxn=*trans*-1,2-cyclohexanediamine) (Table 4)[27] for which only the C_2 or the C_3 association mode is possible owing to the presence of alkyl caps along the C_3 axis or bulky substituents along the C_2 axis (Fig. 1).

Several reasons are conceivable why RPIPC offers highly improved resolution efficiency for the former three complexes. The sample retention in NPIEC depends on the sample-ion-exchange resin interaction which is not related to chiral discrimination as well as on the sample-resolving reagent interaction, and the contribution of the former is unfortunately dominant generally in NPIEC. For example, for *lel*$_3$-$[Co(chxn)_3]^{3+}$ having presumably a very strong affinity for the resin, the α value is as high as 1.09 (Table 4). In other words, NPIEC appears unable to take full advantage of the chiral discrimination ability of the resolving reagent. On the other hand, the sample

Table 4. Comparison of Retention Volumes V_R and Separation Factors α Obtained with $Na_2[Sb_2(d\text{-tart})_2]$ by NPIEC and by RPIPC

	NPIEC			RPIPC

a) Retention volume of the faster-eluted Λ-enantiomer. b) Retention volume of the later-eluted Λ-enantiomer.

retention in RPIPC is governed mainly by the sample-resolving reagent interaction which is directly associated with chiral discrimination. Consequently, RPIPC has a general possibility to afford a higher separation factor than NPIEC for a particular sample. However, it is hard to accept that the improvement in α detected in the present study has been brought about simply by the above-mentioned reason, because α is greatly improved only for those complexes which adopt both the C_3 and the C_2 modes.

The chiral discrimination mechanism of $[Sb_2(d\text{-tart})_2]^{2-}$ proposed previously can be summarized as follows.[17] $[Sb_2(d\text{-tart})_2]^{2-}$ comes into interaction with the complex cation from the direction of either the C_3 or the C_2 axis to form hydrogen bonds to the axial NH protons directed along the C_3 or the C_2 axis, respectively. When the C_3 association mode is adopted, the chiral anion favors the Λ- over the Δ-enantiomer, whereas the Δ-enantiomer is favored in the C_2 association mode.[28] As a result, the chiral discrimination efficiency is in general low for those complexes which can adopt both association modes. A typical example is provided by $[Co(tn)_3]^{3+}$ for which so low resolution is attained in NPIEC that its elution order is reversed even when the eluent employed is changed from $[Sb_2(d\text{-tart})_2]^{2-}$ to $[As_2(d\text{-tart})_2]^{2-}$ (Table 3). This means that the elution order of $[Co(tn)_3]^{3+}$ is determined by a delicate balance of the two comparable association modes prevailing in NPIEC. However, in the stationary phase of RPIPC where the effective dielectric constant is probably very low, the second-step association forming an ion triplet $[Co(N)_6][Sb_2(d\text{-tart})_2]_2^-$, the electric charge of which is finally neutralized by the counterion M^+,[19] will take place, because the tervalent charge of the complex cation is not completely neutralized in the ion pair $[Co(N)_6][Sb_2(d\text{-tart})_2]^+$ formed in the first-step association. In the ion triplet where the electrostatic repulsion is inevitable between the two anions, the C_3 association mode should be much more favored than in the ion pair, since the electrostatic repulsion is the least when the two anions approach the complex cation along the C_3 axis from the opposite side. Consequently, the relative fraction of the C_3 mode will be increased and thus the discrimination efficiency will be greatly improved, when RPIPC is applied to the tervalent complex cations for which both of the C_3 and C_2 modes are possible. In fact, the α value of the divalent complex $[Co(gly)(en)_2]^{2+}$ for which the two modes are similarly possible, is not appreciably improved in RPIPC (Table 4). This is because the electric charge of $[Co(gly)(en)_2]^{2+}$ has been completely neutralized in the first-step association and thus the ion triplet is not formed even in RPIPC.

It should be noted here that the α value of $[Co(sen)]^{3+}$ is greatly improved in RPIPC, though both of the two ion-pairing anions cannot adopt the C_3 mode in the ion triplet $[Co(sen)][Sb_2(d\text{-tart})_2]_2^-$ owing to the steric demand of $[Co(sen)]^{3+}$ (Fig. 1). It is certain that the C_3 mode favors the Λ-enantiomer, while the C_2 mode favors the Δ-enantiomer for $[Co(sen)]^{3+}$ like for $[Co(en)_3]^{3+}$, as far as the first-step association is concerned.[17] In the ion triplet of $[Co(sen)]^{3+}$, however, both the C_3 and the C_2 modes favor the Λ-enantiomer, since the chiral ion-pairing anion adopting the C_2 mode is disposed so as to escape the electrostatic repulsion from the other ion-pairing anion adopting the C_3 mode, imposing a severe steric repulsion stereoselectively on the alkyl cap of the Δ-enantiomer.[17b] As a result, an improved α value is also expected for $[Co(sen)]^{3+}$ in RPIPC, though one chiral anion adopts the C_3 mode and the other anion adopts the C_2 mode in the ion triplet $[Co(sen)][Sb_2(d\text{-tart})_2]_2^-$.

For those complexes which adopt either the C_3 or the C_2 mode only, on the other hand, no appreciable improvement in α is expected,[27] since the relative fraction of the C_3 or the C_2 mode adopted by them is always unity even if the ion triplet is formed in RPIPC. The above interpretations are highly speculative, but they seem quite attractive.

19) In other words, these tervalent complex cations are distributed to the stationary phase in the form of $M[Co(N)_6][Sb_2(d\text{-tart})_2]_2$ which carries no net electric charge. Therefore, the retention of the complex cation $[Co(N)_6]^{3+}$ should be directly affected by the nature of the counter ion M^+, as is actually the case.

20) Greater retention volumes obtained for $[Co(sep)]^{3+}$ than for $[Co(en)_3]^{3+}$ are attributed not only to the greater hydrophobic nature of the former complex, but also to its greater hydrogen-bonding ability to the ion-pairing reagent. See, Refs. 16 and 23.

22) A glance of Fig. 3-c might indicate that the α value is not appreciably increased for $[Co(tn)_3]^{3+}$ with $M^+=Me_4N^+$ or Et_4N^+. However, the optical resolution efficiency of this complex is actually improved to a considerable extent in RPIPC, since NPIEC gives a separation factor of 1.00 for this complex. See, Table 3.

27) For *lel*$_3$-$[Co(chxn)_4]^{3+}$ which adopts the C_3 mode only, a somewhat higher α is obtained in RPIPC than in NPIEC. This is what is expected, because the two C_3 modes in the ion triplet contribute additively to the chiral discrimination with some inevitable electrostatic repulsion between them in RPIPC, while only one C_3 mode contributes in NPIEC. Similar additive contribution of the two association modes is expected more or less for other $[Co(N)_6]^{3+}$-type complexes in RPIPC.

28) Why the C_2 association mode favors the Λ-enantiomer but not the Δ-enantiomer for the cage complexes, has been discussed in detail in Ref. 17b.

Synthesis, and Crystal and Molecular Structure of Bis[2-(2-benzoxazolyl)-phenolato]nitratoiron(III), $Fe(C_{13}H_8O_2N)_2(NO_3)$

(Received March 17, 1987)

The title complex was newly synthesized and its crystal and molecular structure was determined by the single-crystal X-ray diffraction technique. The crystal is monoclinic, space group $C2/c$, a=16.005(4), b=10.520(2), c=15.338(4) Å, β=114.68(2)°, and Z=4. In the complex, the central metal atom is hexa-coordinated being in a deformed octahedral geometry: Two 2-(2-benzoxazolyl)phenolato ligands form six-membered chelate rings being coordinated with their oxazolyl nitrogen and phenolato oxygen atoms, while the nitrate ion acts as a bidentate with its two oxygen atoms. As the benzoxazolyl ring is parallel and overlapped with that of the neighboring complex along the c-axis, where the interplane distance is 3.557 Å, some interaction between the rings is expected. As this complex in solid state is deep violet, almost black, in color, some charge-transfer bands are expected to exist in its electronic spectra. The bis[2-(2-benzothiazolyl)phenolato]-nitratoiron(III) was found to be isomorphous to the title complex.

The 2-(2-benzoxazolyl)phenol (Hbxp) is known as a chelating reagent for many bivalent metals. Analyses of zinc(II), cadmium(II), palladium(II), and copper(II) using Hbxp as the colorimetric reagent, have been reported in several literatures.[1-4] The crystal structures of copper(II) and cadmium(II) salts of Hbxp ($M(bxp)_2$, M=Cu, Cd) were already determined by the single-crystal X-ray diffraction method.[5] The 2-(2-benzothiazolyl)phenol (Hbtp) is also a good analytical reagent which forms stable complexes with bivalent metals. An analytical chemistry study of its metal complexes had been presented by Charles and Freiser[6] and the authors have investigated the solvent-extraction of some metals using Hbtp.[7]

However, there have been yet very few studies about the tervalent metal complexes of bxp and btp, nor any reports of their structure.

This time, we could obtain the iron(III) salts of both Hbxp and Hbtp, $Fe(bxp)_2(NO_3)$ (**1**) and $Fe(btp)_2(NO_3)$ (**2**), though the FeL_3 type complex was not obtained. Both salts resemble each other in color (deep violet, almost black), in their solubilities in various solvents, as well as in their crystal forms. As **1** and **2** were found to be isomorphous, the crystal and molecular structure of **1** was determined by the single-crystal X-ray diffraction technique.

Experimental

Synthesis of Bis[2-(2-benzoxazolyl)phenolato]nitratoiron-(III) (1). The solutions of iron(III) nitrate enneahydrate (0.81 g, 2.0 mmol in 30 cm^3 of ethanol), and of Hbxp (1.69 g, 8 mmol in 200 cm^3 of ethanol) were mixed and stirred. After left standing the mixed solution overnight, the precipitate was filtered off, washed with a small portion of ethanol, and dried in vacuo over silica gel. Yield, 0.54 g (50%). Found; Fe, 10.44; C, 58.09; H, 2.99; N, 7.78%. Calcd for ($FeC_{26}H_{16}O_7N_3$); Fe, 10.38; C, 58.02; H, 3.00; N, 7.81%.

Synthesis of Bis[2-(2-benzothiazolyl)phenolato]nitratoiron-(III) (2). The solutions of iron(III) nitrate enneahydrate (0.81 g, 2.0 mmol in 30 cm^3 of ethanol), and of Hbtp (1.82 g, 8 mmol in 300 cm^3 of hot ethanol) were mixed and stirred. The product began to precipitate soon, and the reaction was completed in several hours. The product was filtered off, washed with ethanol, and dried in vacuo over silica gel. Yield, 0.65 g (57%). Found; Fe, 9.63; C, 54.75; H, 2.87; N, 7.40; S, 11.22%. Calcd for ($FeC_{26}H_{16}O_5N_3S_2$); Fe, 9.79; C, 54.75; H, 2.83; N, 7.37; S, 11.24%.

The recrystallization of the products have been unsuccessful so far. From the solution of the complex in the solvents such as chloroform, ethanol, and others, only decomposition products were obtained when a part of the solvent was evaporated off.

Single-Crystal X-Ray Analysis. A crystal of **1** used for the X-ray analysis was chosen from the synthesized product. The crystallographic data and some experimental conditions used to obtain the intensity data are tabulated in Table 1. The reflections were collected on a Rigaku AFC-6A automated four-circle X-ray diffractometer with graphite monochromated Mo $K\alpha$ radiation (λ=0.71073 Å) (scan speed: 4° $min^{-1}(\theta)$) using the ω—2θ scan technique.

was solved by the heavy-atom method. The positions of the iron and some nitrogen and oxygen atoms were deduced from a three dimensional Patterson map, and the other non-hydrogen atoms were successively located by the repeated Fourier syntheses. Their positional, isotropic and then anisotropic thermal parameters were refined by a block-diagonal least-squares method. At the final cycle of the refinement with anisotropic temperature factors for all non-hydrogen atoms, all the parameter shifts were less than one-third of the corresponding standard deviations.

All the calculations were carried out on a HITAC-680H at the Computer Center of the University of Tokyo, using a local version of the UNICS program.[8] The atomic scattering factors were taken from Ref. 9.

Other Measurements. The X-ray powder patterns of the complexes were obtained by a diffractometer of Model DX-GO-F JEOL, using Cu $K\alpha$ radiation in the range of 4° to 35° in 2θ. Infrared spectra were measured with a JASCO IRA-1 type infrared spectrophotometer using KBr disk technique. The electronic spectra in chloroform solutions (immediately after dissolving the complexes) were obtained with a Shimadzu UV-240 spectrophotometer. Magnetic moments of the complexes were measured using a Gouy balance at ambient temperature.

Results and Discussion

The final atomic parameters and their equivalent thermal parameters of the complex are listed in Table 2, while the bond lengths and bond angles are tabulated in Table 3.[10] A perspective drawing of the complex around the metal atom including the overlapping benzoxazole ring of the neighboring complex are shown in Fig. 1, while the projection of a unit cell to the ac-plane in Fig. 2.

Key to the symmetry operations: i, $1-x$, y, $0.5-z$.

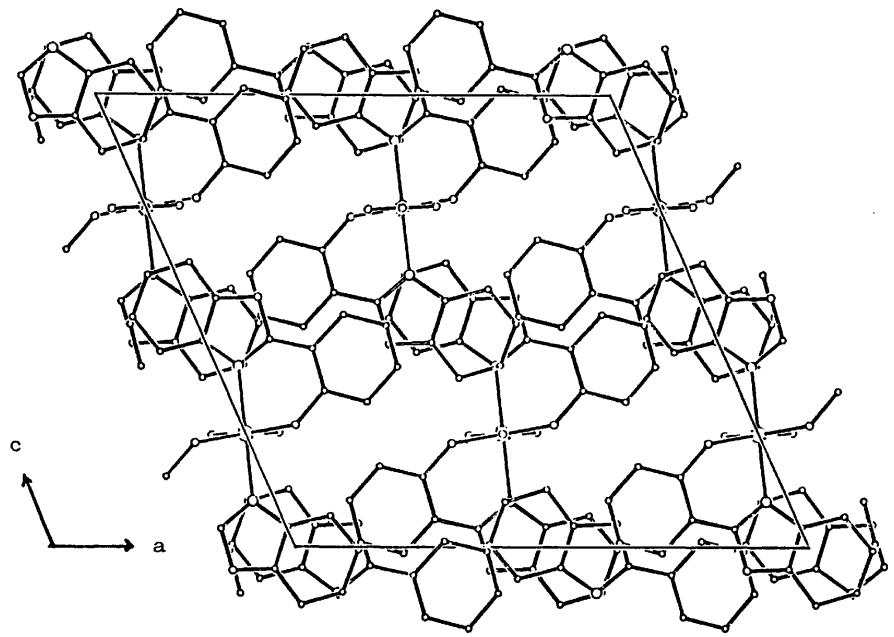

Fig. 2. A projection of the unit cell to the ac-plane.

O(N1) atoms of the nitrate ion are at the respective special positions: 0.5, y, 0.25. The metal atom is 2*N*4*O*-hexa-coordinated being in a deformed octahedral geometry. From both ends of an axis, two oxazole nitrogen atoms of the respective ligands, N(1) and N(1^{i})[11] are ligated. On the equatorial plane, two oxygen atoms of the phenolato groups of the ligands, O(2) and O(2^{i})[11], as well as two nitrato oxygen atoms of an ion O(N2) and O(N2^{i})[11] are coordinated to the metal atom. The oxazolyl oxygen atom, O(1), is not ligated to the metal atom. Thus the bxp anion forms a six-membered chelate ring, while the nitrate ion makes a four-membered ring.

The least-squares plane of O(2), O(2^{i}), O(N2), O(N2^{i}), and Fe atoms[12] (average of the positional deviations of the atoms from the plane is 0.070 Å) is approximately perpendicular to Fe–N(1) (88.4°), and the angle N(1)–Fe–N(1^{i}) is 178.1(5)°. However, on the equatorial plane, the angles O(2)–Fe–O(2^{i}) and O(N2)–Fe–O(N2^{i}) are 117.8(2), and 59.1(2)°, respectively: They deviate greatly from the right angle. The bond lengths Fe–N(1) and Fe–O(2) are 2.084(12) and 1.875 Å, respectively. As the sum of Shannon's ionic radii[13] are Fe–N, 2.11 and Fe–O, 2.00 Å, both of the observed values are shorter than the expected values. On the other hand, as Fe–O(N2) was found to be 2.154(7) Å, which is much longer than the sum of the ionic radii, the bond is thought to be weak. The two such weakly bonding oxygen atoms, O(N2) and O(N2^{i}), are regarded as cooperating with each other and occupying one equatorial position of the trigonal-bipyramidal penta-coordination geometry.

The benzoxazole ring (A), the phenyl ring of the phenolato group (B), and the six-membered chelate ring (C) are about on the respective planes. The average deviations of the atoms from the respective ring planes are: (A) 0.011; (B) 0.011; and (C) 0.113 Å. The dihedral angles between the planes are: (A–B) 9.22; (A–C) 7.45; (B–C) 10.79°. As shown in Table 3, all the bond lengths of C–C, C–N, and C–O in the ligand bxp, including C(9)–O(2), are intermediate of the single and double bonding ones (according to Pauling's presentation; the single bonding and double bonding C–C, C–N, and C–O are: 1.544 and 1.334; 1.47 and 1.29; and 1.51 and 1.29° Å respectively[14]). Almost all C–C–C bond angles of the phenylene and phenyl rings of the ligand are about 120°. The angles of C(1)–C(6)–C(5) and C(2)–C(3)–C(4) are a little smaller, but these deviations were also found in those of the free ligand.[15] Consequently, the conjugated double bond system is likely extended all over the bxp ligand, probably including the chelate ring, too. The N(N)–O(N1) and N(N)–O(N2) lengths of the nitrate ion are 1.199(15) and 1.273(11) Å, respectively. Therefore, the N=O double bonding is a little localized in the former bond, although both of them are shorter than the single bonding N–O expected from the sum of the covalent bonding radii.[14]

As shown in Fig. 2, the benzoxazole ring of the ligand is parallel and overlapped with the ring of the complex molecule next to the c-axis direction, although its phenylene ring side of the overlapping ligand is above the oxazole side of the original ligand ring, and vice versa. The interplane distance of both ring planes is 3.557 Å. As the thickness of an aromatic ring is about 3.5 Å, these rings are likely in contact with each other. Therefore, some interaction, such as charge transfer, is expected to occur between them. Although there are no coordination bridgings between the complexes, they are thought to be connected in this way, and they are laid in the c-axis direction. As shown in Fig. 2, there is no overlapping of the ligands in the part of the phenolato group as well as the chelate ring; the interatomic distances between the carbon atoms of these parts and of the neighboring ligand are more than 3.5 Å. The central matl parts are lined along the a-axis, although no ligand bridgings exist between them. The barrier of the nonpolar ligand skeleton part is intercalated between the lines of the metal part; thus in the crystal, the polar part and nonpolar part (both of them are parallel to the ab plane) appear alternately.

As shown in Table 2, the equivalent isotropic temperature factor of O(N1) is relatively large. This is probably due to the fact that no atoms approach near to the atom in the crystal: There is a vacancy near the atom, and the atom is not tightly fixed.

As there was no good crystal of the btp complex, **2** to use for X-ray analysis, the single-crystal study has not yet been completed on **2**. But as the powder X-ray pattern of **1** and **2** closely resemble each other, a similar type of structure is expected for the complex **2**.

In their IR spectra, the peaks observed at 1634 cm^{-1} for Hbxp and 1625 cm^{-1} for Hbtp are lowered on chelation to 1612 and 1598 cm^{-1}, respectively. These bands are assigned to the C=N stretching vibration primarily.[16-17] These facts indicate that the coordination takes place through the unsaturated nitrogen atom on the oxazole or thiazole ring. The peaks at 1532, 1318, and 1015 cm^{-1} in the bxp complex and at 1522, 1300, and 1010 cm^{-1} in the btp complex are regarded as the bands of the bidentate nitrate ion. In general, the separation of the two highest frequency bands for the bidentate nitrato complex appears in the range 350—200 cm^{-1},[18] and the separations in **1** and **2** spectra are found to be 214 and 222 cm^{-1} respectively.

The maximum wavenumberes of electronic absorption spectra together with the absorption coefficients (in log ε) of their chloroform solutions are shown in Table 4.

The strong violet color may be caused by a charge-transfer band at 18600 cm^{-1} for the bxp complex and at 18200 cm^{-1} for the btp complex which may occur between very closely overlapped aromatic or pseudo-

aromatic rings.[19] Such strong CT bands are also recognized in the salts of tetrahalogenoferate(III) with 3,5-dialkyl-1,2-dithiolium cation.[20,21]

When the violet color solutions of both bxp and btp complexes were left standing for several hours, the color faded away gradually and a brown precipitate was formed.

Magnetic moments were 6.11 BM for the bxp complex and 6.10 BM for the btp complex. Although these values are a little higher than those of the common Fe(III) complexes, there are some other complexes with such high values.[22]

†Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received March 17, 1987)

The ligand-field spectra for the cobalt complexes in the single crystals of $K_3H_2[Co^{III}W_{12}O_{40}]\cdot 16H_2O$ and $K_4H_2[(Co^{II}, Zn^{II})W_{12}O_{40}]\cdot nH_2O$ have been observed at several temperatures above 1.4 K and assigned under D_2 site symmetry. In the spectrum of the elongated $Co^{III}O_4$ complex, two absorption bands of 8250 and 8953 cm^{-1} strengthen with increasing temperature by vibronic mechanism. The X-band ESR spectra of both complexes have also been measured at 77 K. The signal from the Co(III) complex is not observed. The signal of the high-spin Co(II) complex of tetrahedral symmetry is unequivocally observed even at relatively high temperature of 77 K. From the analysis of the ESR spectrum, it is concluded that the $Co^{II}O_4$ tetrahedron of D_2 symmetry is flattened and deviated slightly from axial symmetry.

The tetrahedral high-spin complexes of both Co(III) and Co(II) are known to exist in the heteropolyanions of Keggin type as $[Co^{III}W_{12}O_{40}]^{5-}$ and $[Co^{II}W_{12}O_{40}]^{6-}$, respectively. The high-spin complex of Co(III) ($3d^6$, $S=2$) is very few. Another example is found only in Co(III)-doped garnets.[1,2] The high-spin Co(II) complex ($3d^7$, $S=3/2$) is also interesting especially from the viewpoint of ESR study because ESR data of high-spin complexes are relatively few compared with those of low-spin complexes.[3-6] It would be of great interest, therefore, to study these Co(III) and Co(II) complexes by means of the optical and ESR spectra.

Concerning the low-temperature properties of these complexes, there have been some reports on the magnetic susceptibility of powder samples[7,8] and the brief report on the ESR frozen spectrum of the Co(II) complex.[9] In the previous paper,[10] we have first reported the single-crystal absorption spectra of the pure Co(III) and Co(II) complexes at 77 K.

Yanonni[11] has reported that the crystal of Co(III) complex belongs to hexagonal system ($P6_222$, $Z=3$) at room temperature and the tetrahedron of $Co^{III}O_4$ is elongated, having three pairs of oxygen-oxygen distance of 2.69, 3.20, and 3.31 Å. From these data, Simmons[7] has concluded that the symmetry of this tetrahedron is D_2 which is nearly S_4. Unfortunately, the exact orientation of the tetrahedron with respect to the crystal axes has not been shown in the reports.[11,12] The crystals of both complexes of Co(III) and Co(II) are known to be isomorphous, but the exact symmetry of the $Co^{II}O_4$ tetrahedron is unknown.

In this report, we will discuss the single-crystal optical spectra at various temperatures above 1.4 K and the ESR spectra at 77 K both of the pure Co(III) complex and of the pure and diluted Co(II) complexes in the potassium salts of the Keggin-structure heteropolyanions.

Experimental

The potassium salts were prepared and crystallized by the method in the literature.[10,13] For comparison, $(K,H)_5[Ga^{III}W_{12}O_{40}]\cdot mH_2O$[14] and $K_2\{(C_4H_9)_4N\}_4[Co^{II}W_{12}O_{40}]\cdot lCH_3CN$[15] were also crystallized from aqueous and CH_3CN solutions, respectively. Mixed crystal of Co(III) with Ga(III) could not be obtained.

For the spectroscopic measurements, a JASCO CT-100 grating spectrometer was used with a HTV-R376 photomultiplier for the visible range or with a HTV-P819 PbS detector in the near-infrared range. Photoelectric signals were amplified and converted into logarithmic scale. A Glan-Taylor prism served as a polarizer. The samples were immersed in liquid helium for measurements at 1.4 and 4.2 K. For measurements at higher temperatures, the method in the literature[16] was used. That is, the samples were placed in a glass vessel immersed in liquid helium, and cooled by exchange helium gas inserted into the vessel or heated with an electric heater on the copper sample holder. The temperatures were measured with a Ge resistor and a thermocouple of Chromel vs. Au-Fe.

X-Band ESR spectra were recorded on a JEOL-FE2XG spectrometer equipped with a liquid-nitrogen-insertion Dewar. DPPH served as a magnetic field calibrant.

Results and Discussion

Co(III) Complex. The spectra of the Co(III) complex are shown in Figs. 1—3 and listed in Table 1. The relative intensities among the Figures are not shown, but the spectra in Fig. 3 are very weak compared with those in Figs. 1 and 2, as reported in the previous paper.[10] In Fig. 1, the D-band is assigned, as described previously,[10] to the spin-forbidden transition of $^5A \rightarrow {}^3T_1$. This transition may gain intensity by mixing of the $^3T_1$ state with the nearby $^5T_2$ state. The actual intensity of the A-band is larger for $E//c$ than for $E\perp c$, but the reverse of that is found for the B- and C-bands. The B- and C-bands

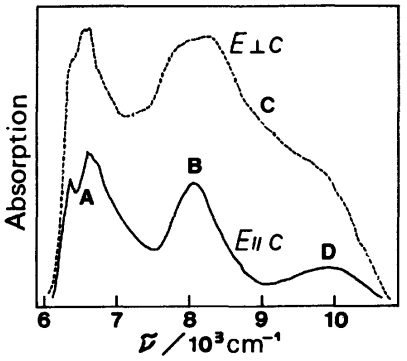

Fig. 1. Absorption spectra of the $^5E\rightarrow{}^5T_2$ transition of $K_3H_2[Co^{III}W_{12}O_{40}]\cdot 16H_2O$ at 4.2 K. E denotes the electric vector of the incident light. c denotes the crystal c-axis.

extremely strengthen with increasing temperature; the spectrum at 200 K becomes comparable to that of the complex soluted in CH_3CN (Fig. 2).

To interpret these spectra, the energy levels for Co(III) in the complex of D_2 site symmetry are considered (Fig. 4). The energy-level order in the ligand field of an elongated tetrahedron of S_4 symmetry ($^5E>{}^5B>{}^5A>{}^5B$) has been determined for yttrium iron garnet[17] and adopted for the interpretation of the spectrum of Co(III) in yttrium gallium garnet.[2] Simmons[7] has discussed the order of the magnitude for these energy levels in the ligand field of S_4 or D_2 symmetry. Defining the elongated axis of the $Co^{III}O_4$ tetrahedron as the z-axis and taking the z-axis parallel to the c-axis of the crystal, then, for electric

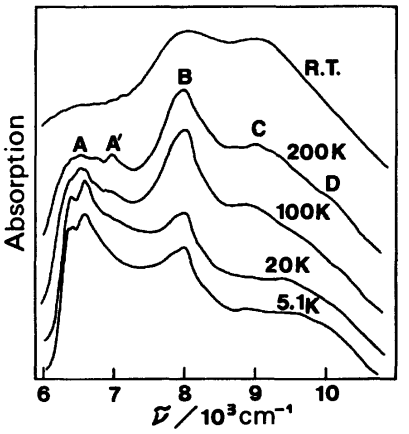

Fig. 2. Temperature dependence of the $^5E\rightarrow{}^5T_2$ transition of $K_3H_2[Co^{III}W_{12}O_{40}]\cdot 16H_2O$ (unpolarized). For comparison, the spectrum of $[Co^{III}W_{12}O_{40}]^{5-}$ in CH_3CN solution at room temperature is also shown uppermost. In aqueous solution, the spectrum is almost unchanged.

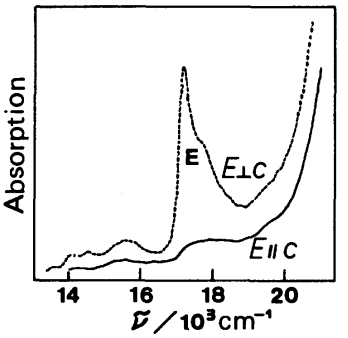

Fig. 3. Absorption spectra of the spin-forbidden transitions of $K_3H_2[Co^{III}W_{12}O_{40}]\cdot 16H_2O$ at 1.4 K. Note that the ordinate is enlarged compared with that in Fig. 1.

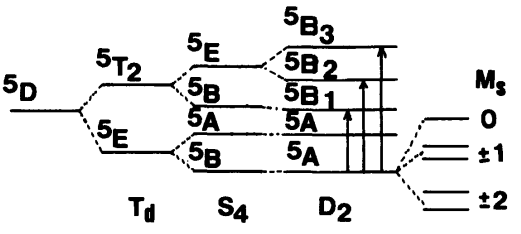

Fig. 4. Schematic energy levels of the ^5D state.

dipole radiation, the $^5A\rightarrow{}^5B_1$ transition is expected to be allowed in z-polarization ($E//c$) and the transitions of $^5A\rightarrow{}^5B_2$ and $^5A\rightarrow{}^5B_3$ allowed in y- and in x-polarization ($E\perp c$), respectively. Moreover, considering the contribution of a internal vibration of B_1-type either to the ground state or to each excited state, then the $^5A\rightarrow{}^5B_2$ and $^5A\rightarrow{}^5B_3$ transitions are allowed

vibronically also in x- and in y-polarization, respectively. Some vibrations of the $Co^{III}O_4$ tetrahedron have been reported.[18]

From these results, it seems most reasonable that the A-, B-, and C-bands are assigned as the $^5A \rightarrow {}^5B_1$, $^5A \rightarrow {}^5B_2$, and $^5A \rightarrow {}^5B_3$ transitions, respectively. The B-and C-bands may strengthen by the vibronic mechanism at higher temperatures. Note that the alternate interpretation of the $^5B_2$ and $^5B_3$ levels is possible in the present study.

The A-band is composed of the two peaks (6361.9, 6587.0 cm^{-1}) in the $E//c$ spectrum. There are two possibilities of the assignment of these peaks. One is that the lower-energy peak is the zero-phonon line of the $^5A \rightarrow {}^5B_1$ transition and the higher-energy peak is the one-phonon line, and the other is that the peaks are derived from the splitting of the $^5B_1$ state by the spin-orbit interaction

The A'-band which strengthens with increasing temperature may be a phonon band associated with the A-band.

The E-band in Fig. 3 which is very weak compared with the A- and B-bands as described in the previous paper[10] is allowed in the $E \perp c$ spectrum. The spectra at 4.2 K are almost the same as those at 1.4 K (not shown). This band has been assigned to the transitions to the $^3A_2$, $^3A_1$, and ^1E states only on the basis of the energy-level fitting in T_d symmetry.[10] However, the intensities of the spin-forbidden transitions to the $^3T_1$ and $^3T_2$ states will be larger than those to the $^3A_2$, $^3A_1$, and ^1E states because of the strong spin-orbit interaction between the $^5T_2$ state and the $^3T_1$ and $^3T_2$ states. Moreover, the positions of the $^3T_1$ and $^3T_2$ states can not be determined only from the energy-level fitting in T_d symmetry because of the splitting of these states in D_2 symmetry as observed in the $^5T_2$ state. Therefore, the E-band seems to be ascribed to the splitting components of the higher excited levels of $^3T_1$ and $^3T_2$ in T_d symmetry.

From the results described above, it is concluded that the spectra of the Co(III) complex are explained in the ligand field of the elongated tetrahedron of D_2 symmetry.

ESR signal from Co(III) is not observed at 77 K. The preliminary measurement at 5.5 K shows also no signal. Sturge et al.[2] have suggested that the ^5B ground state in S_4 symmetry would have the $M_s=\pm 2$ states the lowest. This holds also in D_2 symmetry (Fig. 4). In the Co(III)-doped garnets, Sturge et al.[2] have observed the forbidden transition of $\Delta M_s=4$ between the two states of $M_s=\pm 2$ using 24 GHz (K-band) and 56 GHz frequencies, but Chiba et al.[4] have not observed using $\approx$9.5 GHz (X-band). Therefore, the possible explanation for no signal observed from Co(III) in the present study is that the energy separation between the two states of $M_s=\pm 2$ is too large for X-band frequencies.

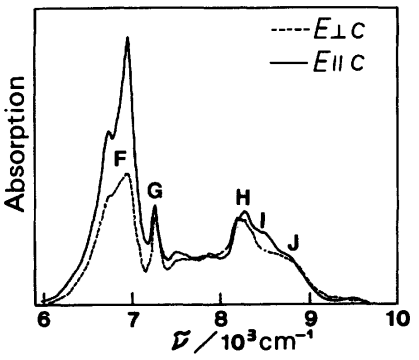

Fig. 5. Absorption spectra of the $^4A_2 \rightarrow {}^4T_1(F)$ transition of $K_4H_2[(Co^{II}, Zn^{II})W_{12}O_{40}]\cdot nH_2O$ at 4.2 K.

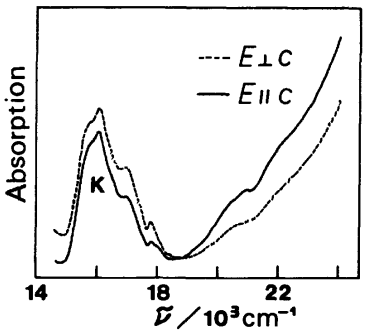

Fig. 6. Absorption spectra of the $^4A_2 \rightarrow {}^4T_1(P)$ transition of $K_4H_2[(Co^{II}, Zn^{II})W_{12}O_{40}]\cdot nH_2O$ at 1.4 K. Note that the ordinate is shortened compared with that in Fig. 5.

Co(II) Complex. The spectra are shown in Figs. 5 and 6 and listed in Table 2. The ESR spectra are shown in Fig. 7. The F-band in Fig. 5 is attributed to the vibrational band of the water of crystallization, because the corresponding band is also observed for $(K,H)_5[Ga^{III}W_{12}O_{40}]\cdot mH_2O$ but not observed for $K_2\{(C_4H_9)_4N\}_4[Co^{II}W_{12}O_{40}]\cdot lCH_3CN$.

As is found in Figs. 5 and 6, the crystal of Co(II) diluted with Zn(II) shows hardly any poralization anisotropy. Its ESR spectrum shows nonaxial symmetry with three effective g-values (a in Fig 7). The angular dependence is hardly found for $H//c$ or for $H \perp c$ (not shown). That is, ESR spectrum similar to a in Fig. 7 is always observed independent of the direction of magnetic field. Contrary to the mixed crystal, the significant angular dependence is observed in the preliminary ESR measurement for the single crystal of pure Co(II) complex. From these observations, the $Co^{II}O_4$ tetrahedron may have nonaxial symmetry and oriented fairly irregurally in the crystals doped with Zn(II).

By assuming D_2 symmetry as nonaxial symmetry of the $Co^{II}O_4$ tetrahedron, the splitting of energy levels could be shown in Fig. 8. On the basis of these energy

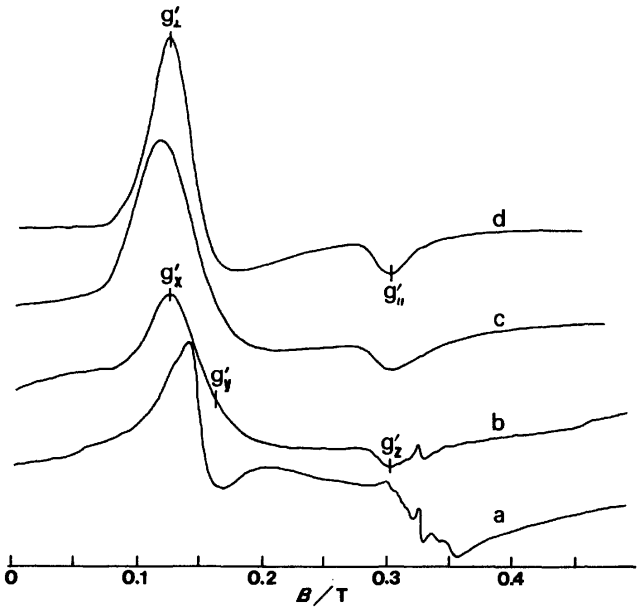

Fig. 7. ESR spectra of Co(II) complexes at 77 K. a: $K_4H_2[(Co^{II},Zn^{II})W_{12}O_{40}]\cdot nH_2O$ (single crystal), b: powder pattern of a, c: $K_4H_2[Co^{II}W_{12}O_{40}]\cdot 17H_2O$ (powder), d: $K_2\{(C_4H_9)_4N\}_4[Co^{II}W_{12}O_{40}]\cdot lCH_3CN$ (powder).

levels, the absorption bands in the $^4A_2\rightarrow{}^4T_1(F)$ region shown in Fig. 5 may be assigned to the transitions all of which are allowed for electric dipole radiation as follows: The G-band is due to the $^4B_1\rightarrow{}^4A$ transition, and the H-band is assigned to the lower branch splitted from the ^4E state in S_4 symmetry ($^4B_2$ or $^4B_3$) and the I- or J-shoulder to the upper branch ($^4B_2$ or $^4B_3$).

In Fig. 6, the spectral shape of the K-band which is mainly due to the $^4A_2\rightarrow{}^4T_1(P)$ transition is very similar to that of the solution spectrum.[10] In this visible region there may be many spin-forbidden transitions which gain intensity by interaction with spin-allowed bands, therefore, it is not possible to discuss the details of the K-band in the present study.

The ESR spectrum of the Zn-doped complex, $K_4H_2[(Co^{II},Zn^{II})W_{12}O_{40}]\cdot nH_2O$, shows a nonaxial pattern with $g'_x=5.20$, $g'_y=4.02$, and $g'_z=2.15$ (**b** in Fig. 7). On the other hand, the tetrabutylammonium salt of the pure Co(II) complex, $K_2\{(C_4H_9)_4N\}_4[Co^{II}W_{12}O_{40}]\cdot lCH_3CN$, shows an axial pattern with $g'_\perp=5.09$ and $g'_{//}=2.17$ (**d** in Fig 7). Similar spectrum with $g'_\perp=5.02$ and $g'_{//}=2.14$ is observed in the preliminary experiment at 5.5 K (not shown). It is interesting that the ESR spectrum of the high-spin Co(II) complex is unequivocally observed even at relatively high temperature of 77 K. It seems that the spin-lattice relaxation time of Co(II) in this complex is rather long. The powder pattern of the pure Co(II) complex in $K_4H_2[Co^{II}W_{12}O_{40}]\cdot 17H_2O$ crystallized from aqueous solution is intermediate between **b** and **d** (**c** in Fig. 7).

In the same manner as the halo complexes,[3,5] the resonances in Fig. 7 can be assigned as the transition between the lowest $M_s=\pm 1/2$ states (Fig. 8). By the method of Drulis et al.[5] using the g'_x, g'_y, and g'_z values observed, the parameters can be calculated in the spin Hamiltonian, $H=D\{S_z^2-1/3S(S+1)\}+E(S_x^2-S_y^2)+\beta(g_xS_xH_x+g_yS_yH_y+g_zS_zH_z)$, for the Zn-doped Co(II) complex (**b** in Fig. 7). On the assumption of $g_x=g_y=g_\perp$ and $g_z=g_{//}$, the parameters can be estimatd as follows: $g_\perp=2.32$, $g_{//}=2.20$, and $E/D=0.0858$. Similar result is obtained from the equations of Fukui et al.[6]

From the facts that $g_\perp$ is larger than $g_{//}$ and that the $M_s=\pm 1/2$ states may be the lowest, the $Co^{II}O_4$

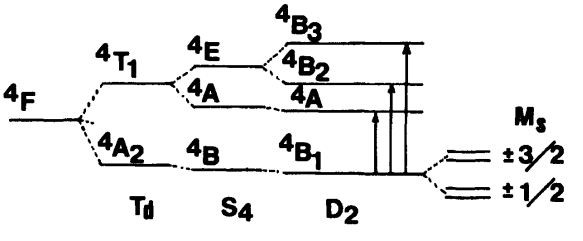

Fig. 8. Schematic energy levels of the ^4F state.

tetrahedron may be flattened.[5,19] This is in contrast with the $Co^{III}O_4$ tetrahedron described above. The nonaxiality parameter (E/D) of 0.0858 is one of the smallest among the reported values.[5,6] Therefore, the $Co^{II}O_4$ tetrahedron in the Zn-doped complex may be only slightly deviated from axial symmetry.

The $g_\perp$ and $g_{//}$ values give g_{eff}=2.28 and μ_{eff}=4.41. Simmons[7] has obtained the values of g_{eff}=2.20 and μ_{eff}=4.27—4.28 from the magnetic susceptibility.

From the equation of $g_{eff}=2.001-(8\lambda)/10D_q$, where D_q=460 cm^{-1},[10] the spin-orbit coupling constant λ is estimated to be $-160\ cm^{-1}$. The fact that the $|\lambda|$ value is smaller than the free-ion value of $178cm^{-1}$ is consistent with the result that the Racah parameter B of $650cm^{-1}$ for the Co(II) complex[10] is smaller than the free-ion value B_0 of $971cm^{-1}$. Considering the magnitude of $|\lambda|$, there is also possibility that the absorption bands ranging from the H-band to the J-shouder in Fig. 5 are accounted for the spin-orbit splitting of the ^4E state in nearly S_4 symmetry.

For comparison, the values of $g_\perp$=2.55, $g_{//}$=2.17, g_{eff}=2.43, and μ_{eff}=4.71 are obtained for $K_2\{(C_4H_9)_4N\}_4[Co^{II}W_{12}O_{40}]\cdot 1CH_3CN$ (**d** in Fig. 7).

Comparison between Co(III) and Co(II) Complexes. By lowering of symmetry from T_d to S_4, the $^5T_2$ state for Co(III) complex and the $^4T_1$(F) state for Co(II) complex are estimated to split by ≈2100 and $\approx 1300cm^{-1}$, respectively.[20] This larger splitting for Co(III) complex may be due to the Jahn-Teller effect in the ^5E ground state or in the $^5T_2$ excited state. As described above, the $Co^{III}O_4$ tetrahedron is elongated and shows D_2 symmetry, but the $Co^{II}O_4$ tetrahedron is probably flattened and shows D_2 symmetry which is nearly S_4.

Thanks are due to Professor Hiroaki Ohya of Kyoto University for helpful discussions of the ESR spectra and to Dr. Masahiro Khono of JEOL Ltd. for measurements of the ESR spectra at 5.5 K. This work was partially supported by a Grant-in-Aid for Scientific Research No. 61740356 from the Ministry of Education, Science and Culture.

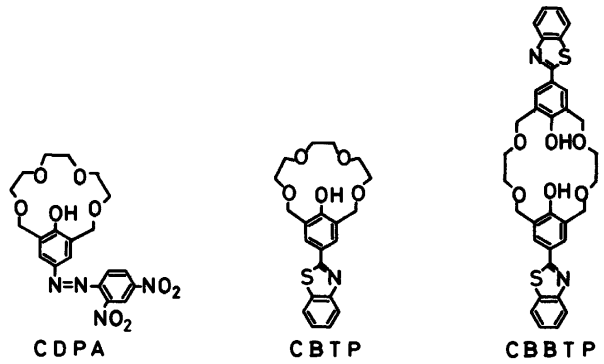
(Received April 2, 1987)

The fluorescence behavior by a complexation of "crowned" benzothiazolylphenols (CBTP and CBBTP) with alkali and alkaline earth metal ions in the presence of triethylamine was examined in various organic solvents. The fluorescence spectra of these CBTP- and CBBTP-metal ion complexes were measured in order to compare mutually both their excitation and emission maxima together with the relative fluorescence intensities (RFI). Both the Li-CBTP and Li-CBBTP complexes showed considerably higher RFI than the other metal complexes. The stability of the fluorescence intensity and various conditions for the determination of Li^+ or Ca^{2+} were fully examined. On the basis of these experiments, fluorometric methods were developed for a sensitive determination of trace amounts of Li or Ca by using the crown compounds (CBTP and/or CBBTP). Moreover, a thin-layer chromatographic method for the separation of Li from other metal ions was examined in order to selectively determine Li by using CBBTP.

New applications of crown compounds as reagents for chemical analyses are becoming of interest in analytical chemistry.[1] A great many improvements and further applications in this field have been extensively carried out. For example, several crown compounds have been studied for their usefulness as neutral carriers of Li^+-selective electrodes.[2] However, it seems that their sensitivity is as yet quite unsatisfactory for applications to the determination of lithium, as compared with atomic and light absorption spectrometry. Recently, a new method has been proposed[3] for the spectrophotometric determination of Li^+ in the concentration range of 25—250 ng ml^{-1} with a "crowned" dinitrophenylazophenol (CDPA) in chloroform–dimethyl sulfoxide–triethylamine (TEA). This was the first example of a colorimetric determination of Li^+ with a crown ether. Succeedingly, a complexation of CDPA with alkali and alkaline earth metal ions in chloroform–MeOH–TEA was studied by means of their absorption spectra; two kinds of linear relationships were found between the ionic radii of these ions, both with the wavenumbers of the absorption maxima and with the molar absorption coefficients of the resulting complexes except for Be^{2+}.[4,5] Moreover, a new sensitive and simple method for the spectrophotometric determination of alkylamine with a CDPA–Ba^{2+} complex in MeOH was developed.[6]

The incorporation of a fluorescent moiety in the place of the dinitrophenylazo group of CDPA should greatly improve the sensitivity in the determination of Li^+. The new fluorescent "crowned" benzothiazolylphenols (CBTP and its bis-type compound, CBBTP) have now been synthesized and show characteristic fluorescence with alkali and alkaline earth metal ions.[7] In this paper, we report the fluorescence reactions of CBTP and CBBTP with alkali and alkaline earth metal ions, and a highly sensitive fluorometric determination of Li^+ or Ca^{2+}. This is based on a complex formation with CBTP and/or CBBTP, followed by a measurement of the fluorescence of the phenolate of the complex obtained by a treatment with TEA. Attempts to improve the selectivity for lithium were made and then fluorometry of Li^+ combined with a thin-layer silica-gel chromatography (TLC) was proposed.



Experimental

Reagents. Metal chlorides and TEA were of analytical grade. Organic solvents (MeOH, EtOH, benzene, and CH_2Cl_2) were used after distillation. Commercially available silica-gel plates (Kieselgel 60, Merck) were used.

Apparatus. The fluorescence spectra and intensities were measured with a Shimadzu RF-540 spectrofluorometer in 10×10 mm quartz cells.

General Procedures. a)[8] Determination of Li^+ by CBTP: To a 50-μl portion of a LiCl solution in MeOH in a 10-ml standard volumetric flask, 5.0 ml of 10^{-4} M (1 M=1 mol dm^{-3}) CBTP in benzene were added and mixed. After the addition of TEA (50 μl) the mixture was diluted to the mark with benzene and mixed well; then the relative fluorescence intensity (RFI) was measured at 410 nm

(emission, λ_{em}) with excitation (λ_{ex}) at 375 nm (cf. Fig. 2).

b) Determination of Li^+ by CBBTP: To a 50-μl portion of LiCl solution in MeOH, 5 ml of CH_2Cl_2 and a solution of CBBTP in CH_2Cl_2 (2×10^{-4} M, 100 μl) were added successively and mixed. Then TEA (20 μl) was added and the whole was finally adjusted to 10 ml with CH_2Cl_2 and mixed well. RFI was measured at 410 nm (λ_{em}) with λ_{ex} at 360 nm.

c) Determination of Ca^{2+} by CBBTP: For a 100-μl portion of a $CaCl_2$ solution in MeOH, the same operation as b) was carried out and then RFI was measured at 400 nm with λ_{ex} at 360 nm.

TLC Method. a) Procedure: A 1 wt% aq solution (10 μl) of metal ion (Li, Na, K, Rb, Cs, Be, Mg, Ca, Sr, or Ba) was spotted on a TLC plate. The plate spotted was developed up to 12 cm by using EtOH–acetic acid (100:1), and dried at room temperature. After being sprayed with violuric acid (1.5 wt%, in EtOH), the plate was dried for 20 min at 110 °C. b) Li^+-determination: The spot for Li^+ developed according to the above procedure was thoroughly scratched and transferred into a 10-ml glass-stoppered tube, to which MeOH (2 ml) was added, vortexed for 2 min, and then centrifuged at 2000 g for 10 min. The supernatant (100 μl) was taken into a 10-ml volumetric flask; to this, CH_2Cl_2 (5 ml) and a solution of CBBTP in CH_2Cl_2 (10.8×10^{-4} M, 250 μl), and then TEA (20 μl) were added successively. The mixture was diluted to the mark with CH_2Cl_2 and mixed well; the RFI was measured at λ_{ex} and λ_{em}. For the blank, the methanol eluate of the part of the corresponding Li-spot on the TLC, which was free from Li salt, was used.

Results and Discussion

Fluorescence Reactions of CBTP and CBBTP with Alkali and Alkaline Earth Metal Ions. The crown rings of CBTP and CBBTP easily form complexes with alkali and alkaline earth metal ions in various solvents such as benzene, chloroform, and dichloromethane. Their fluorescence spectra have been shown to be almost identical with those of the corresponding ligands. By an addition of TEA, the spectra exhibited red shifts as well as the enhanced relative fluorescence intensities (RFI) due to the formation of phenolates. It has been demonstrated that neither CBTP nor CBBTP dissociates in the aprotic solvents, even in the presence of excess TEA.[7] In the present experiments, since MeOH, even in small amounts, should be used for the preparation of a standard solution (homogeneous) of metal salts, a dissociation of the phenols is, more or less, unavoidable. However, the spectra of the phenolates complexed with metal ions have been clearly shown to be different from those derived from the corresponding ligands themselves (Table 1 and cf. Figs. 2 and 3). Thus, it was interestingly observed on the complexes that both excitation and emission maxima were shifted to the longer wavelengths with

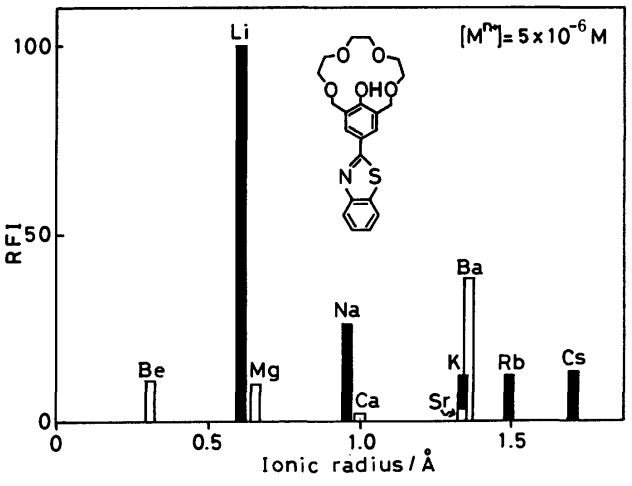

Fig. 2. RFI of the CBTP complexes vs. ionic radius.

an accompanying increase of RFI.

a) CBTP. The fluorescence reaction of CBTP with alkali and alkaline earth metal ions was examined in benzene. The fluorescence of the Li^+-complex is fairly unstable in the light, even though it is the most stable among all the complexes examined in the dark. The fluorescence spectral data are listed in Table 1. Figure 1 shows the excitation spectra of the CBTP-Li^+ complex (a) and a reagent blank (c) and the emission spectra of the complex (b) and the reagent blank (d) excited at 375 nm. The excitation maximum for the reagent blank is at 330 nm, and the emission intensity of the reagent blank is negligible compared with that of the complex when an excitation wavelength (λ_{ex}) of 375 nm is used. The emission maximum of the blank is at 382 nm if λ_{ex} is 330 nm. This choice of λ_{ex} in the above measurement is important for a determination of Li^+ stated later. The relation of the CBTP-M^{n+} complex (M^{n+}=alkali or alkaline earth metal ion) between RFI and ionic radius is shown in Fig. 2 (RFI=100 to the CBTP-Li^+ complex). The order of decreasing RFI is as follows:

$Li^+ > Ba^{2+} > (Na^+, Sr^{2+}) \gg (K^+, Rb^+, Cs^+, Be^{2+}, Mg^{2+}, Ca^{2+})$.

In this series the intensity of Li^+ was extremely high and its ratios of Li^+ to Ba^{2+}, Na^+, and K^+ were about 2, 4, and 10, respectively. It is interesting to note that the RFI of the Na^+, Be^{2+}, Ba^{2+}, and Sr^{2+} complexes, which would interfere in the determination of Li^+, decrease remarkably within 30 min, even in the dark. In the experiment carried out on the Ba^{2+}-complex, it was observed that the RFI decreased promptly and then recovered temporarily, upon adding the standard Ba^{2+} methanolic solution. However, the addition of barium chloride powder into the resulting solution caused an increased RFI which persisted even in the light. We have no idea yet of how to account for this anomalous behavior, which seems to be related to changes in the composition of the host to the guest ion in the complexes yielded in the presence of trace amounts of metal ions.

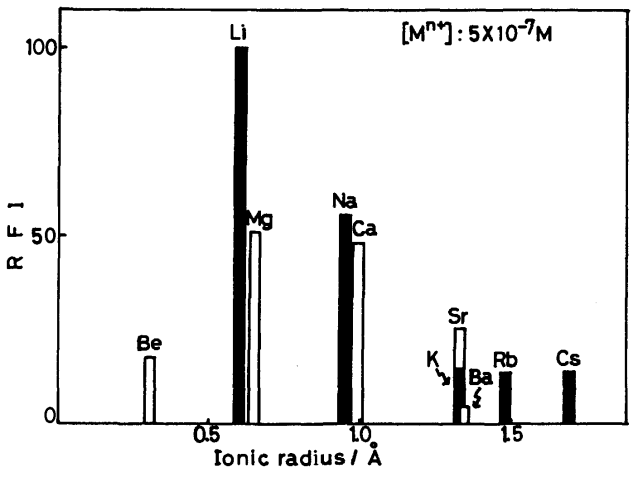

Fig. 3. RFI of the CBBTP complexes vs. ionic radius.

b) CBBTP. In the case of the fluorescence reaction of CBBTP with the metal ions, dichloromethane was particularly chosen as a solvent in order to obtain optimum conditions (Table 1). It is noted that the fluorescence resulting from complexation in the presence of TEA is quite stable relative to the CBTP-complexes, even in the light. In a correlation with the

Table 2. The Mole Ratio of Metal Ion to CBBTP[a)]

Ion	Mole ratio
Li^+	2 : 1
Na^+	2 : 1
K^+	2 : 1

ionic radii of the metals, Fig. 3 shows the RFI (the Li^+-complex, 100) of the CBBTP complexes, with a decreasing order of:

$$Li^+ \gg Na^+ > (Mg^{2+}, Ca^{2+}) \gg Sr^{2+} > (Be^{2+}, K^+, Rb^+, Cs^+) \gg Ba^{2+}.$$

In this connection, it is interesting to examine the composition ratios of the complexes. The mole ratio of metal to CBBTP were examined spectrofluorometrically by the continuous variation method (Table 2). The anomalous behavior of Be^{2+} seems to be largely caused by its extremely small ionic size. As typical representative spectra, the case of the CBBTP-Li^+ complex is shown with the blank (CBBTP free from Li^+) in Fig. 4, in which the selection of 360 nm as the λ_{ex} can minimize the influence of the blank. This selection is very important for a highly sensitive determination of Li^+.

Determination of Li^+ or Ca^{2+}. Before establishing a procedure for the determination of Li^+ using CBTP, the CBTP, TEA, and MeOH concentrations were examined. It was shown that at least a 10-fold molar excess of reagent was necessary in the final concentration. The maximal RFI of the complex was obtained with final concentrations of 0.5—1.1 vol% TEA and 0.3—0.5 vol% MeOH. The fluorescence developed immediately and its RFI was constant for at least 120 min or more when the solution was kept in the dark. The calibration curve obtained by the standard method passed through the origin and was linear from 0.39 to 39 ng ml^{-1}. The relative standard deviation (RSD) for five replicates at the 24-ng ml^{-1} was 2.2%. The use of CBBTP instead of CBTP resulted in about a three-fold increase in the sensitivity for Li. The calibration graph obtained by the established standard procedure was linear from 0.14—7.0 ng ml^{-1} [RSD, 2.7% at 2.1-ng ml^{-1} (n=8)].

Moreover, in connection with an assay of Ca^{2+} in biological products, CBBTP was examined and was found to be useful for a sensitive determination of trace amounts of Ca^{2+}. After examining the fluorometric conditions, the maximal FRI of the Ca-complex was obtained with a final concentration of 0.2 vol% TEA and 2×10^{-6} M CBBTP. The calibration curve for Ca^{2+} was obtained in the concentration range 0.8—20.0 ng ml^{-1} [RSD, 3.8% at 22-ng ml^{-1} (n=4)].

Separation and Determination of Lithium by TLC. Lithium-selective reagents should be very important for monitoring the Li^+ activity in biological systems. The realization of a simple and sensitive Li^+-determination method is expected for the therapy of maniacal psychosis.[9] In our present studies, it has become apparent that an improvement in the selectivity is inevitable for a Li^+-determination. We preliminarily examined the separation and determination of Li^+ by a TLC method.[10] According to the chromatographic conditions described in Experimental, the spots due to metal salts can first be clearly visualized by drying at 110 °C after spraying a solution of violuric acid in EtOH as a potential color-producing reagent:[11] Li^+, reddish pink; Na^+, reddish orange; K^+, bluish violet; Rb^+, reddish violet; Cs^+, blue; Be^{2+}, pale blue; Mg^{2+}, yellowish orange; Ca^{2+}, orange; Sr^{2+}, reddish violet; Ba^{2+}, reddish violet. Li^+, Be^{2+}, and Mg^{2+} showed their R_f-values at 0.35, 0.17, and 0.15 respectively, and other metal spots stayed at the origins. For a determination the Li^+-spot colored was completely scratched and eluted with MeOH. The eluate was treated according to b) in Experimental. The fluorometric measurements of the Li^+-CBBTP complex showed that the calibration graph was linear from 3.3 to 16.5 μg/10 ml. The lower limit of the determination was 0.82 μg/10 ml (S/N>2). Aoyama reported that the range of the effective content of Li in normal human blood is generally 0.6—1.2 mEq l^{-1}.[12] Since 0.6 mEq of Li corresponds to 0.1 μg/0.1 ml blood, the TLC method examined here cannot be applicable to the determination of Li in normal blood. This TLC method, which has preliminarily been carried out, may prove to be useful in both its simplicity and selectivity. However, regarding sensitivity, the development of stronger color-producing reagents than violuric acid for trace amounts of Li should intensively be carried out next.

Synthesis and Chromogenic Properties of Some Phthalazinylhydrazones and Extractive Spectrophotometric and Analogue-Derivative Spectrophotometric Determination of Trace Amounts of Nickel with Di-2-pyridylmethanone 1-Phthalazinylhydrazone

Tsugikatsu ODASHIMA, Minoru YAMADA, Naoki YONEMORI, and Hajime ISHII*
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai, Miyagi 980
(Received April 3, 1987)

Four kinds of 1-phthalazinylhydrazones have been synthesized and their chromogenic properties and reactivities with metal ions investigated. Of the synthesized hydrazones, di-2-pyridylmethanone 1-phthalazinylhydrazone (DPPhH) proved to be the best chromogenic reagent for nickel. It reacts with nickel(II) at pH above 2.5 to form a 1:2 (nickel-ligand) complex extractable into various organic solvents. The extracted species into benzene has an absorption maximum at 500 nm and gives a maximum and constant absorbance in the pH range 4.3—10.7. Beer's law is obeyed over the range 0.1—1.0 μg cm^{-3} of nickel. The molar absorptivity (ε) and the sensitivity for an absorbance of 0.001 are 5.4×10^4 dm^3 mol^{-1} cm^{-1} and 1.08 ng cm^{-2} at 500 nm, respectively. A sensitive and selective extraction-spectrophotometric method for the determination of nickel at μg cm^{-3} levels is proposed and has been applied successfully to the analysis of iron and steel samples. The proposed method can be made more sensitive by the introduction of an analogue-derivative spectrophotometric technique.

Since Lions et al.[1,2] first reported the preparation of hydrazones derived from 2-pyridylhydrazine and the properties of their metal complexes, a lot of nitrogen-containing heterocyclic hydrazones[3-6] have been synthesized and proposed as analytical reagents. On the other hand, we have prepared, over the period of more than 10 years, a series of hydrazones derived mainly from 2-benzothiazolylhydrazine[7-10] and proposed them as sensitive and useful reagents for metals. As for the phthalazinylhydrazone, however, only a few compounds[11,12] were prepared to date, since furfural 1-phthalazinylhydrazone and its analogue[13] were first synthesized and proposed as sensitive chromogenic reagents by us.

In the work presented here, 4 new hydrazones derived from 1-phthalazinylhydrazine, 2-pyridinecarbaldehyde 1-phthalazinylhydrazone (PAPhH), 1-(2-pyridyl)ethanone 1-phthalazinylhydrazone (MPPhH), phenyl(2-pyridyl)methanone 1-phthalazinylhydrazone (PPPhH), and di-2-pyridylmethanone 1-phthalazinylhydrazone (DPPhH) were synthesized and their chromogenic properties and reactivities with metal ions investigated and compared, as part of our continuing studies on the analytical application of hydrazones. Of the synthesized hydrazones, DPPhH was superior to the others as a spectrophotometric reagent for nickel(II) in terms of both sensitivity and selectivity. A sensitive and practical extraction-spectrophotometric method for the determination of trace amounts of nickel with DPPhH has been developed and successfully applied to the analysis of iron and steel samples. Further sensitization of the method by employing an analogue-derivative technique was feasible.

Experimental

Synthesis of Hydrazones. In 40 cm^3 of 5% hydrochloric acid dissolve 0.01 mol of 1-phthalazinylhydrazine, then add 20 cm^3 of ethanol solution containing 0.01 mol of the corresponding aldehyde or ketone. Heat the solution under reflux for 3 h. After cooling to room temperature, neutralize the solution with dilute aqueous ammonia. Filter off the resultant crystalline product with suction, recrystallize twice from ethanol and dry in vacuo.

Reagents. All reagents were of analytical-reagent grade and all solutions were prepared with distilled, deionized water, unless stated otherwise.

Hydrazone solutions, 2.5×10^{-3} M (1 M=1 mol dm^{-3}). Prepared by dissolving the required mass of each synthesized hydrazone in ethanol. These solutions were stable for at least several months when stored in an amber bottle.

Standard nickel(II) solution. Prepared by dissolving 2.5 g of nickel nitrate [$Ni(NO_3)_2\cdot6H_2O$] in about 100 cm^3 of water, adding 10 cm^3 of nitric acid (1+1) and diluting to 500 cm^3 with water. This solution was standardized by EDTA titration with copper 1-(2-pyridylazo)-2-naphtholate (Cu-PAN) as an indicator. Working solutions were prepared by diluting this solution with water.

Buffer solutions. Buffers consisting of 1 M chloroacetic acid–1 M sodium chloroacetate, 1 M acetic acid–1 M sodium acetate, M/15 potassium dihydrogenphosphate–M/15 disodium hydrogenphosphate, (0.2 M boric acid+0.05 M sodium chloride)–0.05 M sodium borate, and 1 M aqueous ammonia–1 M ammonium chloride systems were used according to the pH values required.

Apparatus. For measurements of the absorbance and the absorption spectrum, a Hitachi 139 and a Hitachi 200-10 spectrophotometer, respectively, were used. To obtain the derivative spectrum, a modified Hitachi 200-0576 derivative unit composed of two analogue differentiation circuits (each having six different time constants from 0.07 to 2.0 s) was

connected in series between the output of a Hitachi 556 dual-wavelength spectrophotometer and the input of a Hitachi 057 X-Y recorder, the former being used as an ordinary double-beam spectrophotometer. The details of this apparatus and the principle and characteristics of analogue-derivative spectrophotometry have already been described.[14,15]

Procedures. Ordinary Spectrophotometry: Place a sample or standard solution containing up to 10 μg of nickel(II) in a 50-cm³ separating funnel and add suitable masking agents if necessary, 2 cm³ of 2.5×10^{-3} M DPPhH solution, followed by 2 cm³ of 1 M acetate buffer (pH 5.0) and dilute to approximately 20 cm³ with water. Extract the nickel complex into 10 cm³ of benzene by shaking mechanically for a few minutes. Allow the phases to separate and transfer the organic phase into a flask containing about 1 g of anhydrous sodium sulfate in order to dehydrate it. Measure the absorbance of the extract at 500 nm against a reagent blank prepared under the same conditions using 1-cm cells.

Second-Derivative Spectrophotometry: When the nickel content of the extract prepared by the procedure described above is too low to give a measurable absorbance, record the second-derivative spectrum from 550 to 380 nm against a reagent blank by using a combination of both first- and second-order differentiation circuits of No. 6 and a scan speed of 150 nm min^{-1} and measure the second-derivative value (the vertical distance from a peak to a trough or that from the base line to a trough of the peak).

Dissolution and Pretreatment of Iron and Steel Samples: Prepare 100 cm³ of the sample solution by decomposing about 0.1 g of the sample with aqua regia and perchloric acid and then removing iron by extraction with 4-methyl-2-pentanone, by the same way as described earlier.[13] Use 2 cm³ or other appropriate aliquot of the resultant solution for the determination.

Results and Discussion

Identification of the Hydrazones. The infrared spectra of the synthesized hydrazones, PAPhH, MPPhH, PPPhH, and DPPhH, were measured with potassium bromide tablets in order to confirm their structures. The spectra had absorption peaks assigned to the stretching vibration of an azomethine bond (-N=C<) around 1600 cm^{-1}.[16] On the basis of these results and those of the elemental analysis shown in Table 1, the synthesized hydrazones are presumed to have the structures shown in Table 1.

Table 1. Structures and Physical Properties of Hydrazones

			(69.9)	(4.3)	(25.8)

a) Results in parentheses indicate calculated values.

Properties and Characteristics of the Hydrazones. PAPhH, MPPhH, PPPhH, and DPPhH are insoluble in water but soluble in organic solvents such as benzene, chloroform, and 4-methyl-2-pentanone.

As is evident from the structures of these hydrazones, at least 4 species, H_3L^{2+}, H_2L^+, HL, and L^-, are involved in their acid dissociation equilibria, depending on the pH:

$$H_3L^{2+} \overset{K_{a3}}{\rightleftharpoons} H_2L^+ \overset{K_{a2}}{\rightleftharpoons} HL \overset{K_{a1}}{\rightleftharpoons} L^-$$

Where L denotes the undissociable part of the hydrazone and K_{a1}, K_{a2}, and K_{a3} are the acid dissociation constants. The pK_a values were determined by extraporating the linear ethanol concentration (10—40%) versus apparent pK_a plot to the intercept. The apparent pK_a values were determined spectrophoto-

Table 2. Acid Dissociation Constants of the Hydrazones. Ionic Strength = 0.2; and Temperature = 25±0.1 °C

Hydrazone	pK_{a_1}[a] (Imino group)	pK_{a_2} (Pyridine nitrogen)	pK_{a_3} (Phthalazino nitrogen)
MPPhH	14.6_6	5.4_4	2.4_9
PAPhH	14.6_0	4.9_8	2.5_4
PPPhH	14.6_1	5.0_6	2.4_1
DPPhH	14.4_5	5.0_5	1.8_7

a) Ionic strength = 3.0, calculated by simplex method with a personal computer.

metrically at an ionic strength of 0.2, at 25±0.1 °C and at various ethanol concentrations. As an example, typical plots of apparent pK_{a2} of the 4 synthesized hydrazones versus ethanol concentration are shown in Fig. 1. The pK_a values of all the hydrazones thus obtained are summarized in Table 2. The pK_{a1} corresponds to the deprotonation of the secondary amino group, whereas the pK_{a2} and pK_{a3} correspond to that of the protonated pyridine-nitrogen and phthalazine-nitrogen, respectively.

Reactivities of the Hydrazones with Metal Ions. The reactivities of the synthesized hydrazones with metal ions and the extractabilities of the resultant complexes into benzene from aqueous media of pH 4,

7, and 10 were investigated. The results are summarized in Table 3—6. Every hydrazone is found to react with cadmium(II), copper(II), iron(II), nickel(II), zinc(II), etc. to give colored complexes having large molar absorptivities. Of these, the reaction of DPPhH with nickel(II) proceeds over the wide pH region from weakly acidic to alkaline media to give a complex having large molar absorptivity (ε) and in addition, one can expect not only high sensitivity but also high selectivity when this complexation reaction in the weakly acidic medium is utilized to the determination of nickel, so the conditions for this complexation were examined in detail in subsequent experiments.

Spectrophotometric Studies for the Determination of Nickel with DPPhH. Extraction Solvent, Effect of pH and Absorption Spectra: Nickel(II) reacts rapidly with DPPhH to form a red complex in weakly acidic to alkaline media. The complex is insoluble in water but soluble in organic solvents such as benzene, chloroform, 4-methyl-2-pentanone, and 1,2-dichloroethane. Of these, benzene was the most preferred extraction solvent, because the benzene extract gave the highest molar absorptivity. As shown in Fig. 2, the complex gave a constant, maximum absorbance when extracted from aqueous media of pH 4.3—10.7. Thus a pH of 5.0 is recommended. Figure 3 illustrates the absorption spectra of DPPhH and its nickel complex in benzene, together with the corresponding second-derivative spectrum. The complex has an absorption maximum at 500 nm, whereas the absorption of DPPhH at this wavelength is almost negligible.

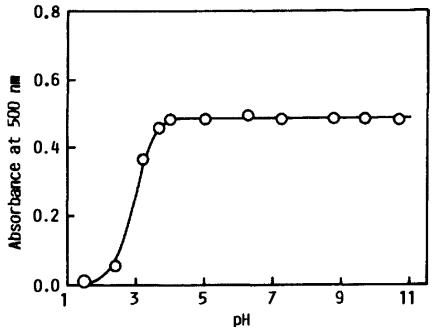

Fig. 2. Effect of pH. Ni(II): 5.1 μg/10 cm³, DPPhH: 2.5×10^{-4} M, reference: reagent blank.

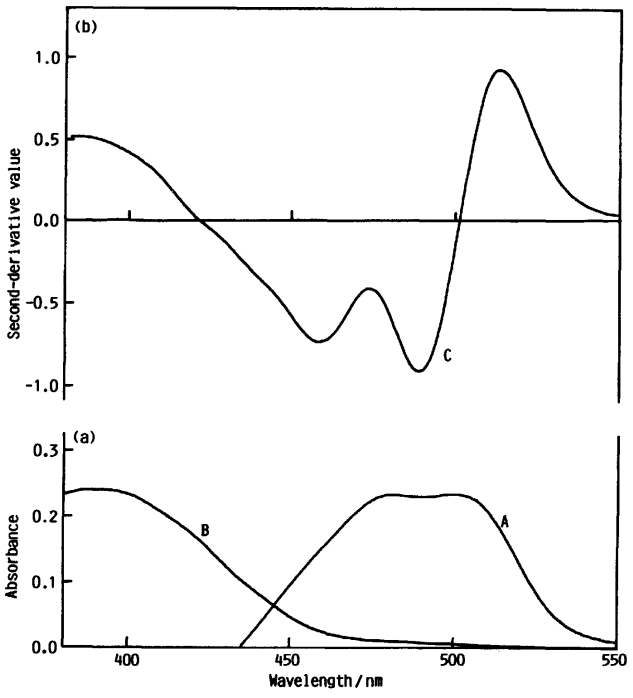

Fig. 3. (a) Absorption spectra of DPPhH and its nickel complex and (b) second-derivative spectrum of nickel-DPPhH complex in benzene. Ni(II): 2.53 μg/10 cm³, DPPhH: 1.25×10^{-5} M, pH: 5.0, A, C: complex against reagent blank, B: reagent blank against benzene. Second-derivative spectrum was measured with scan speed 150 nm min^{-1} and circuits all No. 6.

Effects of DPPhH Concentration and Shaking Time: A 3-fold molar excess of DPPhH was the minimum required for obtaining constant absorbance, and excess of DPPhH did not interfere. Shaking for a few minutes was sufficient for quantitative extraction of the complex.

Effect of Other Variations in Extraction: Variations in temperature from 15 to 30 °C, the ethanol concentration up to 15% in aqueous phase and the organic to aqueous phase ratio from 1:1 to 1:5 did not affect the absorbance. The absorbance of the extract remained constant even after several hours, which suggests that the extracted complex is very stable.

Composition of the Complex: The composition of the extracted complex was determined by the continuous variation method. The result, which is shown in Fig. 4, revealed that the metal to ligand ratio of the complex was 1:2. So DPPhH is considered to act presumably as a tridentate ligand, but no further detailed experiments to confirm this were carried out.

Calibration Graph, Sensitivity, and Precision: The calibration graph obtained by the recommended procedure was linear over the range 1—10 μg of nickel and passed through the origin. The equation for the line obtained by least-squares treatment was

$$\mathrm{Ni}(\mu g) = 10.8A \qquad (1)$$

where A is the absorbance. The molar absorptivity and the sensitivity for an absorbance of 0.001 calculated from Eq. 1 were 5.4×10^{4} dm³ mol^{-1} cm^{-1}

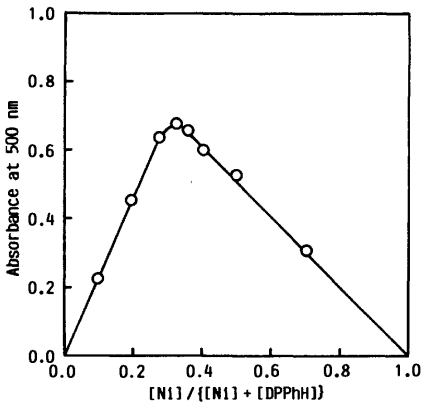

Fig. 4. Continuous variation graph for the nickel-DPPhH system. [Ni]+[DPPhH]=1.72×10^{-4} M, pH: 5.0.

and 1.08 ng cm^{-2}, respectively. These values indicate that the proposed method is extremely superior in sensitivity to that with 5-methylfurfural 1-phthalazinylhydrazone reported previously by us.[13] The relative standard deviation for 5.1 μg of nickel was 0.7%.

Effect of Diverse Ions: In order to study the effect of other ions on the determination of nickel, a fixed amount (5.1 μg) of nickel(II) was taken with various amounts of foreign ions and the recommended procedure was followed. An error of ±3% in the absorbance reading was considered tolerable. Tolerances for various foreign ions are shown in Table 7. Copper(II), iron(II,III), mercury(II), vanadium(IV,V), and zinc(II) interfere when no masking agent is added, whereas the other ions do not interfere. These interferences except that by iron(II) can be removed by the addition of masking agents noted in Table 7. Interference from iron(II) can be eliminated by masking with fluoride after oxidizing it to iron(III). Interference from a large amount of iron(III) can easily be removed by extracting it with 4-methyl-2-pentanone prior to the nickel determination, as mentioned already. On the other hand, most anions do not interfere, although the tolerance limit for iodide is somewhat low in comparison with those for other anions. The proposed method, therefore, may be regarded as very selective as well as sensitive for nickel.

Application to Actual Samples: In order to confirm the usefulness of the proposed method, it was applied to the determination of nickel in standard iron and steel samples. The results, shown in Table 8, are in good agreement with certified values.

Sensitization by Employing Analogue-Derivative Spectrophotometry. As described in earlier papers[14,15] the determination limit of ordinary spectrophotometry can remarkably be lowered by the introduction of a derivative spectrophotometric technique using the analogue differentiation circuit. As an example of sensitization, the second-derivative spectrophotomet-

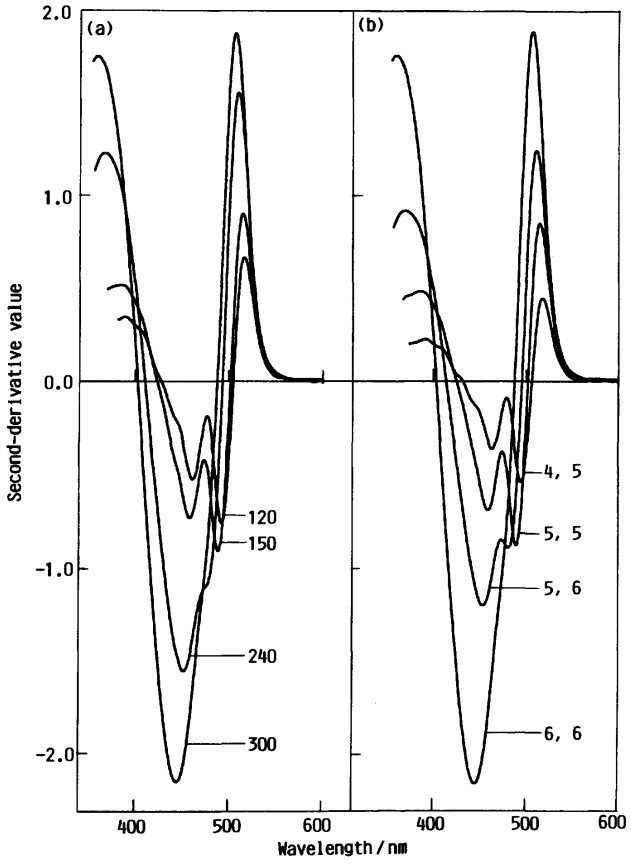

Fig. 5. Influence of (a) scan speed (with circuits all No. 6) and (b) circuit number (with scan speed 300 nm min^{-1}) on second-derivative spectra of the complex in benzene. Ni(II): 2.53 μg/10 cm^3, DPPhH: 1.25×10^{-5} M. pH: 5.0, slit width: 1 nm; recorder sensitivity: ×1/4, reference: reagent blank. Numerical values indicate scan speeds in (a) and first- and second-differentiation circuits in (b).

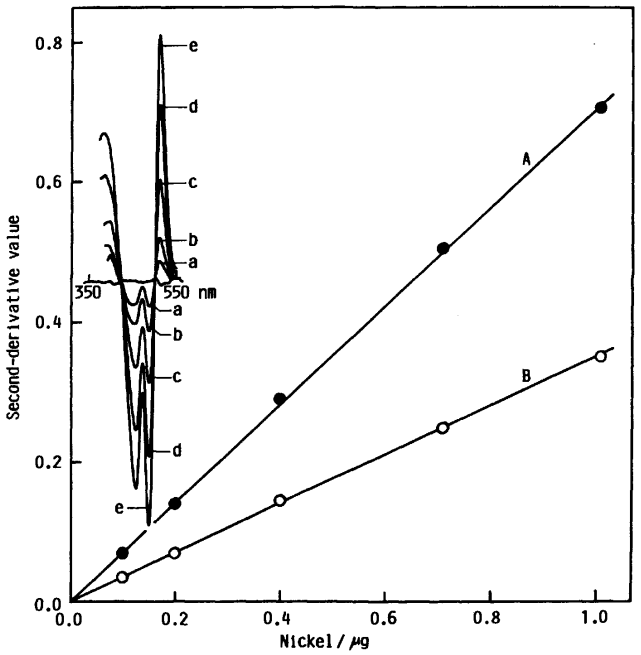

Fig. 6. Calibration graph for nickel in second-derivative spectrophotometry. Circuits: All No. 6, Scan speed: 150 nm min^{-1}, slit width: 1 nm, recorder sensitivity: ×1, reference: reagent blank. A: Peak-to-trough values are plotted, B: base line-to-trough values are plotted. Nickel (μg)—a: 0.10, b: 0.20, c: 0.40, d: 0.71, e: 1.01.

ric determination of nickel is described here.

Selection of Conditions for Merasurements: As the second-derivative value (the vertical distance from a peak to trough or that from the base line to a trough of the spectrum) depends on both the time constant of the analogue differentiation circuit and the scan speed of the spectrophotometer in second-derivative spectrophotometry, these need to be optimized to give a well resolved large peak (to give good selectivity and higher sensitivity). Figure 5 shows the second-derivative spectra of the nickel-DPPhH complex solution measured with varying circuit number or scan speed. A combination of circuit No. 6 (which has the largest time constant, 2.0 s, the time constant increasing with increasing circuit number in our apparatus) and a scan speed of 300 nm min^{-1} gives the highest sensitivity, but the resolution (i.e., selectivity) is poor in this combination. Taking both the sensitivity and selectivity into consideration, a combination of circuit No. 6 and a scan speed of 150 nm min^{-1} or that of No. 5 and 300 nm min^{-1} is recommended for the nickel determination.

Calibration Graph, Sensitivity, and Precision: The calibration graph prepared by plotting the second-derivative value versus the nickel concentration, an example of which is shown in Fig. 6, is linear and passes through the origin when either the peak-to-trough values or the base line-to-trough values were plotted. The equation for each line measured with a combination of circuit No. 6 and a scan speed of 150 nm min^{-1} was

$$\text{Ni}(\mu\text{g}) = 1.42\,D \quad (2)$$

$$\text{Ni}(\mu\text{g}) = 2.86\,D \quad (3)$$

respectively, where D is the second-derivative value represented by the conversion of the value into absorbance. It will be seen that as little at 100 ng or less of nickel can easily be determined in this way. Twelve standard solutions containing 400 ng of nickel(II) were analyzed. The results gave a relative standard deviation of 1.3%.

(Received April 13, 1987)

The ion product of water at 298.15 K was evaluated according to the Pitzer ionic interaction theory in LiCl, NaCl, KCl, KNO_3, $LiClO_4$, and $NaClO_4$ media of different concentrations (0.1—5 mol kg^{-1}) and in artificial seawaters at different salinities (20—44‰). The Pitzer approach was also applied to the estimation of the ion products of water in NaCl media at temperatures (288—373 K) different from 298.15 K. The theoretically evaluated values showed reasonable agreement with experimental ones.

In studying ionic equilibria over an alkaline range in an aqueous solution, a knowledge of the ion product of water in that solution is indispensable. By inspection of the ion products of water available (see Tables 1—9),[1-3] it is apparent that they are influenced in diverse manners by the type and concentration of the electrolyte as well as by the temperature. Thus, the theoretical evaluation of the ion product of water in an aqueous electrolyte solution at a desired composition and temperature, where the experimental information is absent or difficult to be obtained, is of crucial importance.

In a previous paper[4] the enthalpy changes for ionization of water were determined at 298.15 K in

concentrated aqueous single electrolyte solutions of several kinds, and compared with those predicted in terms of the Pitzer ionic interaction model.[5,6] The observed and estimated values agreed fairly well. It was also found that the free energy and enthalpy changes for dissociation of ammonium ion determined at 298.15 K in concentrated single electrolyte solutions and in artificial seawaters[7-9] showed good agreement with those estimated via the Pitzer approach.

In the present work, the free energy changes for ionization of water (ion products of water) at 298.15 K were evaluated according to the Pitzer approach in LiCl, NaCl, KCl, KNO_3, $LiClO_4$, and $NaClO_4$ media with different concentrations (0.1—5 mol kg^{-1}) and in artificial seawaters at various salinities (20—44‰). The Pitzer approach was also applied to the estimation of the ion products of water in NaCl media at temperatures (288—373 K) different from 298.15 K. The theoretical values thus evaluated were compared with the experimental ones available in the literature.

The experimental values of the ion products, which are subjected to the comparison with the predicted values, are given in Tables 1—9. The ion products of water at 298.15 K in $LiClO_4$ media, which have not been reported, were experimentally determined in a usual way by acid-base titrations with hydrogen

electrodes.[10)] The pK_w values originally expressed in molar concentration units were converted to the values with the molality scale by the use of the densities of the salt solutions. The densities of electrolyte solutions, when not available in the literature, were measured pycnometrically.

Procedures for Theoretical Estimation of Ion Product. The autoprotolytic reaction of water is denoted by Eq. 1,

$$H_2O = H^+ + OH^-. \quad (1)$$

The relation of the ion product, $K_w(I,T)$, with the activity coefficients of the relevant ionic species, γ, and the water activity, a_{H_2O}, in solution at ionic strength I mol kg^{-1} and temperature T K is represented by Eq. 2,

$$pK_w(I,T) = pK_w(0,T) + (\ln \gamma_H + \ln \gamma_{OH} - \ln a_{H_2O})/\ln 10, \quad (2)$$

where $pK_w(0,T)$ denotes the ion product in a salt-free solution. Since the $pK_w(0,T)$ value is usually available in the literature, the present problem is reduced to estimating the γ values of H^+ and OH^- ions and the a_{H_2O} in the solution at ionic strength I and temperature T. The accepted $pK_w(0,T)$ values at temperatures of interest are given in Table 10.[3)]

According to Pitzer's approach,[11)] the trace activity coefficients of the ionic components of unit charge, H^+ and OH^-, and the water activity in the solution containing cations c's and anions a's of ionic strength I can be determined from Eqs. 3, 4, and 5, respectively.

$$\ln \gamma_H = F + \sum_{a=1}^{N_a} m_a(2B_{Ha} + ZC_{Ha}) + \sum_{c=1}^{N_c} m_c(2\theta_{Hc} + \sum_{a=1}^{N_a} m_a\Psi_{Hca}) + \sum_{a=1}^{N_a-1}\sum_{a'=a-1}^{N_a} m_a m_{a'}\Psi_{aa'H} + \sum_{c=1}^{N_c}\sum_{a=1}^{N_a} m_c m_a C_{ca}, \quad (3)$$

$$\ln \gamma_{OH} = F + \sum_{a=1}^{N_c} m_c(2B_{cOH} + ZC_{cOH}) + \sum_{a=1}^{N_a} m_a(2\theta_{OHa} + \sum_{c=1}^{N_c} m_c\Psi_{OHac}) + \sum_{c=1}^{N_c-1}\sum_{c'=c-1}^{N_c} m_c m_{c'}\Psi_{cc'OH} + \sum_{c=1}^{N_c}\sum_{a=1}^{N_a} m_c m_a C_{ca}, \quad (4)$$

$$\ln a_{H_2O} = -0.0180\phi \sum_i m_i. \quad (5)$$

For use in Eqs. 3—5 the following terms are defined.

$$F = -A^\phi[I^{1/2}/(1+1.2I^{1/2}) + (2/1.2)\ln(1+1.2I^{1/2})] + \sum_{c=1}^{N_c}\sum_{a=1}^{N_a} m_c m_a B'_{ca} + \sum_{c=1}^{N_c-1}\sum_{c'=c+1}^{N_c-1} m_c m_{c'}\theta'_{cc'} + \sum_{a=1}^{N_a-1}\sum_{a'=a+1}^{N_a} m_a m_{a'}\theta'_{aa'}, \quad (6)$$

$$C_{ca} = C^\phi_{ca}/2|z_c z_a|1/2 \quad (7)$$

$$Z = \sum_i z_i m_i \quad (8)$$

$$\sum_i m_i(\phi - 1) = 2(-A^\phi I^{3/2}/(1+1.2I^{1/2}) + \sum_{c=1}^{N_c}\sum_{a=1}^{N_a} m_c m_a(B^\phi_{ca} + ZC_{ca}) + \sum_{c=1}^{N_c-1}\sum_{c'=c+1}^{N_c} m_c m_{c'}(\theta^\phi_{cc'} + \sum_{a=1}^{N_a} m_a\Psi_{cc'a}) + \sum_{a=1}^{N_a-1}\sum_{a'=a+1}^{N_a} m_a m_{a'}(\theta^\phi_{aa'} + \sum_{c=1}^{N_c} m_c\Psi_{aa'c}) \quad (9)$$

In Eq. 3 m_c is the molality of cation c, and N_c the total number of cations. Similar definitions apply for anions a's. A^ϕ in Eqs. 6 and 9 is the Pitzer-Debye-Hückel limiting slope given by Eq. 10,

$$A^\phi = (1/3)(2\pi N_0 d_w/1000)^{1/2}(e^2/DkT)^{3/2}, \quad (10)$$

where N_0 is Avogadro's number, d_w and D are the density and dielectric constant of water, respectively. The second virial coefficients B in Eqs. 3, 4, 6, and 9 are given by the following ionic strength dependence.

$$B^{\phi}_{ca} = \beta^{(0)}_{ca} + \beta^{(1)}_{ca} \exp(-\alpha_{ca} I^{1/2}) + \beta^{(2)}_{ca} \exp(-12 I^{1/2}) \quad (11)$$
$$B_{ca} = \beta^{(0)}_{ca} + \beta^{(1)}_{ca} g(\alpha_{ca} I^{1/2}) + \beta^{(2)}_{ca} g(12 I^{1/2}) \quad (12)$$
$$B'_{ca} = \beta^{(1)}_{ca} g'(\alpha_{ca} I^{1/2})/I + \beta^{(2)}_{ca} g'(12 I^{1/2})/I \quad (13)$$

The functions, g and g', are defined by the equations.

$$g(x) = 2(1-(1+x)\exp(-x))/x^2 \quad (14)$$
$$g'(x) = -2(1-(1+x+x^2/2)\exp(-x))/x^2 \quad (15)$$

with $x=\alpha_{ca}/I^{1/2}$ or $12I^{1/2}$. When either cation c or anion a is univalent, $\alpha_{ca}=2$. For 2:2 or higher valence pairs $\alpha_{ca}=1.4$. The second virial coefficients θ, which depend on the ionic strength, are given in the following form.

$$\theta^{\phi}_{ij} = \theta_{ij} + {}^{E}\theta_{ij}(I) + I\,{}^{E}\theta'_{ij}(I) \quad (16)$$
$$\theta_{ij} = \theta_{ij} + {}^{E}\theta_{ij}(I) \quad (17)$$
$$\theta'_{ij} = {}^{E}\theta_{ij}(I) \quad (18)$$

When the ions i and j are of the same charge, ${}^{E}\theta_{ij}(I)$ and ${}^{E}\theta'_{ij}(I)$ are set equal to zero. The third virial coefficients, C^{ϕ}_{ca} and ψ_{ijk} are assumed to be independent of the ionic strength.[6] Usually, the contributions of the higher order terms θ and ψ are small, and significant only at high ionic strength.

The values for $\beta^{(0)}$, $\beta^{(1)}$, $\beta^{(2)}$, and C^{ϕ} at 298.15 K have been calculated from the activity coefficient and osmotic coefficient data of single electrolytes, and the values for θ and ψ at 298.15 K from the data of mixed electrolytes.[12-14] The relevant parameter values used in the calculations by means of Eqs. 3—5 are collected in Tables 11 and 12.

Since the parameter values for the Mg^{2+}-OH^- interactions, which are needed for the theoretical calculations in artificial seawaters, are not available, they were estimated on the basis of hydrolysis data for Mg^{2+} and Ca^{2+} ions. The equilibrium constant for the reaction $M^{2+}(M=Mg \text{ or } Ca)+OH^-=MOH^+$ has been reported to be ca. 360 for Mg^{2+} and 14 for Ca^{2+} at 298.15 K in a salt-free solution,[15] while no data for their enthalpy changes having been reported. Thus, the $\beta^{(0)}$, $\beta^{(1)}$, $\beta^{(2)}$, and C^{ϕ} for the Mg^{2+}-OH^- interactions were estimated simply on the assumption that they were 360/14 times the corresponding values for the Ca^{2+}-OH^- interactions. These parameter values are given in Table 11.

The parameter values $\beta^{(0)}$, $\beta^{(1)}$, and C^{ϕ} for HCl,

a) Estimated from observed pK_w values.

NaCl, and NaOH required to predict the pK_w values in NaCl media at temperatures higher than 298.15 K were estimated in the following.

Recently, Pitzer and coauthors[16,17] have estimated the ion-interaction parameters $\beta^{(0)}$, $\beta^{(1)}$, and C^ϕ for several 1:1 electrolytes including HCl and NaCl as a function of temperature on the basis of the apparent molar heat capacities above 298.15 K, and represented the temperature dependence of the parameter values by simple empirical equations. The parameter values for $\beta^{(0)}$, $\beta^{(1)}$, and C at T K and 1.01×10^5 Pa are expressed by the following equations,

$$\begin{aligned}\beta^{(0)} = {} & A^c_\beta(T/2+298^2/2T-298) \\ & + B^c_\beta(T^2/6+298^3/3T-298^2/2) \\ & + C^c_\beta(T^3/12+298^4/4T-298^3/3) \\ & + (298-298^2/T)(\partial\beta^{(0)}(298)/\partial T) \\ & + \beta^{(0)}(298), \end{aligned} \quad (19)$$

$$\beta^{(1)} = (298-298^2/T)(\partial\beta^{(1)}(298)/\partial T) + \beta^{(1)}(298), \quad (20)$$

$$C = (298-298^2/T)(\partial C(298)/\partial T) + C(298), \quad (21)$$

where A^c_β, B^c_β, and C^c_β are the fitting parameters independent of temperature. The temperature derivatives of the parameter values at 298.15 K have been obtained from the heat of dilution data for the electrolytes.[6] The parameter values $\beta^{(0)}$, $\beta^{(1)}$, and C^ϕ for HCl at temperatures of interest were calculated with the values for A^c_β, B^c_β, and C^c_β and those for the temperature derivatives of $\beta^{(0)}$, $\beta^{(1)}$, and C. The values for NaCl were taken from Ref. 16. They are collected in Table 13. Since the three A^c_β, B^c_β, and C^c_β values for NaOH are not available, they were estimated on the basis of the observed pK_w data at three temperatures; i.e., Eqs. 19—21 were introduced into Eqs. 3—5, and the rearranged Eqs. 3—5 into Eq. 2. The observed pK_w values in 1.019 mol kg^{-1} NaCl medium at 353, 363, and 373 K in Table 8 and the $pK_w(0,T)$ values at the corresponding temperatures in Table 10 were then introduced into Eq. 2 to solve the three resultant equations for the A^c_β, B^c_β, and C^c_β values. In these calculations was made no introduction of the higher order terms θ and ψ, because their contributions are expected to be small at this level of concentration. The A^c_β, B^c_β, and C^c_β values for NaOH were estimated to be 21.6, −0.132, and 2.01×10^{-4}, respectively. In Table 13 are also shown the parameter values $\beta^{(0)}$, $\beta^{(1)}$, and C^ϕ for NaOH at temperatures in question calculated according to Eqs. 19—21 with the relevant parameter values.

The ion-interaction parameter values $\beta^{(0)}$, $\beta^{(1)}$, and C^ϕ for HCl, NaOH, and NaCl at 308.15 K were calculated according to Eq. 22[6] on the basis of their activity coefficients at that temperature available in the literature.[18]

$$\ln\gamma_{ca} = f^\gamma + m_{ca}B^\gamma_{ca} + m^2_{ca}C^\gamma_{ca}, \quad (22)$$

where

$$\begin{aligned} f^\gamma = {} & -A^\phi[I^{1/2}/(1+1.2I^{1/2}) \\ & + (2/1.2)\ln(1+1.2I^{1/2})], \end{aligned} \quad (23)$$

$$\begin{aligned} B^\gamma_{ca} = {} & 2\beta^{(0)} + (\beta^{(1)}_{ca}/2I)[1 \\ & - \exp(-2I^{1/2})(1+2I^{1/2}-2I)], \end{aligned} \quad (24)$$

$$C^\gamma_{ca} = (3/2)C^\phi_{ca}. \quad (25)$$

The calculated ion-interaction parameter values at

Table 14. Single Electrolyte Parameters in Pitzer's Equations at 288.15 and 308.15 K

	$\beta^{(0)}$			$\beta^{(1)}$			$C^\phi\times10^3$		
Temperature/K	HCl	NaOH	NaCl	HCl	NaOH	NaCl	HCl	NaOH	NaCl
288.15	0.1782	0.0833	0.0675	0.2940	0.2434	0.2615	2.2	3.8	3.1
308.15	0.1746	0.0971	0.0790	0.2913	0.2507	0.2882	−0.6	0.1	1.7

308.15 K are given in Table 14. The observed pK_w values in NaCl media at 308.15 K (Table 9) were compared with both of the values predicted with the parameter values in Table 13 and with those in Table 14.

The parameter values for HCl, NaOH, and NaCl given in Table 13, which have been estimated by the use of the heat capacities at temperatures above 298 K, are not applicable to the prediction of pK_w values at temperatures below 298 K. Thus, for the prediction of pK_w values in NaCl media at 288.15 K (observed pK_w values in Table 9) the ion-interaction parameter values for HCl, NaOH, and NaCl were calculated in the same manner as for the case at 308.15 K according to Eq. 22 by using their activity coefficients at 288.15 K available in the literature.[18] The calculated parameter values are given in Table 14.

Results and Discussion

Evaluation of pK_w Values in Single Electrolyte Solutions at 298.15 K. In Tables 1—6 there are quantitative comparisons between the observed and predicted pK_w values in single electrolyte solutions at 298.15 K. The calculations were made with and without the higher order terms θ and ψ so that the need for considering the terms was examined. All the θ and ψ values required for the calculations are known only in NaCl and KCl media. As for the NaCl and KCl media it is apparent from Tables 2 and 3 that the values calculated with the higher order terms in Table 12 are in agreement with the observed ones within the experimental uncertainties, while the differences are fairly large, especially at high molalities in the calculations without them. These results point out the need to use θ and ψ values at high ionic strengths when they are available. The agreement between the values observed and those predicted with the higher order terms in the NaCl and KCl media demonstrates the validity of the Pitzer approach, and thus, suggests that unknown θ and ψ values are determinable from the observed pK_w values. With the other electrolyte solutions (Tables 1, 4—6), where all the higher order terms are not always available, it is seen that rather large discrepancies between the values observed and those calculated without the higher order terms occur at higher ionic strengths. The introduction of a partial set of the higher order terms leads to worse agreement between the observed and predicted values (an exception being the LiCl system). The higher order terms should be included when a full set of them are known. However, the omission of unknown θ and ψ values is unlikely to have a serious effect at low ionic strengths. Unknown θ and ψ values were estimated according to Eqs. 2—5 on the basis of the observed pK_w values in Tables 1 and 4—6. In Table 12 are also given the θ and ψ values thus estimated, which may be employed for the theoretical calculations of equilibrium constants in other systems where H^+ and/or OH^- ions participate.

Evaluation of pK_w Values in Artificial Seawaters at 298.15 K. The values observed and predicted with the parameter values in Tables 11 and 12 are compared each other in Table 7. Although the deviations are seen to exceed the experimental uncertainties, the agreement may be reasonable in view of the fact that the parameter values for the Mg^{2+}–OH^- interactions were estimated with the simple assumption (360/14 times the parameter values for the Ca^{2+}–OH^- interactions) and that the composition for each seawater, which was not given in Ref. 19, was deduced on the basis of the description about its preparation procedures. From a comparison of the pK_w values in Tables 2 and 7 it is apparent that the pK_w values in the seawaters are much smaller than the values in the NaCl solutions at the corresponding ionic strengths. An attempt was made to calculate the pK_w values in the seawaters on the assumption that the parameter values for the Mg^{2+}–OH^- interactions were the same as those for the Ca^{2+}–OH^- interactions. It was found that the calculated pK_w values were around 13.7-(19.90‰)—13.5(44‰), which are much higher by 0.4 than the observed values. This result indicates that the main difference between the pK_w values in the seawaters and those in the NaCl media results from the Mg^{2+}–OH^- interactions in the seawaters.

Evaluation of pK_w Values in NaCl Media at Temperatures Different from 298.15 K. a) pK_w Values in 1.019 mol kg^{-1} NaCl Medium at Temperatures above 298.15 K. It is seen from Table 8 that the observed values are in reasonable agreement with the predicted ones in consideration of the fact that the activity coefficients of NaOH have been estimated by using the A_β, B_β, and C_β values calculated from a limited number of pK_w values for lack of the apparent heat capacity data for NaOH.

b) pK_w Values at 308.15 K. The observed values are compared in Table 9 with both the values estimated with the parameter values in Table 13 and with those in Table 14. The observed values yield better agreement with the values estimated with the data in Table 14, which is reasonable, if one considers some uncertainties introduced in the calculations of the parameter values for NaOH in Table 13. The rather large discrepancy at 2.08 mol kg^{-1} may be due to the neglect of the higher order terms which are not available.

c) pK_w Values at 288.15 K. The observed and calculated values in Table 9 are seen to show good agreement each other.

In the light of the above results, it may be said that although the deviations between the observed and estimated values exceed in some cases by far the experimental uncertainties probably due to approximations made in the calculations and the unavail-

ableness of higher order terms, the present results demonstrate the reliability of the ionic interaction model by Pitzer and co-workers to estimate free energy changes in concentrated salt solutions over a wide range of temperature. It is necessary to determine higher order terms by e.g., isopiestic measurements in mixed electrolyte solutions so that free energy changes at high ionic strengths should be predicted more accurately.

The work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (No. 61540444).

Mössbauer Study of Iron Oxide Surface Layers Formed on Fine Iron Particles

Yonezo MAEDA,* Masaaki ARAMAKI, Yoshimasa TAKASHIMA, Michiharu OOGAI,† and Takeshi GOTO†
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812

(Received February 19, 1987)

Mössbauer studies of iron oxides formed on the surface of fine iron particles (acicular type about 15 nm in diameter and 100 nm long) and of an oxidation process in air have been done in the temperature range from 4.2 to 298 K. The Mössbauer spectra indicate that the main component of the oxide layers 2.1—5.6 nm thick, except for a few oxide layers from the iron surface, is composed of fine particles of γ-Fe_2O_3, and that fine iron oxide particles are produced freshly during the oxidation process at 110 °C in air with the growth of iron oxide particles. It is concluded that an oxide layer 2.1 nm thick is formed on the iron surface if a fresh iron surface is exposed to air at room temperature.

The oxidation or corrosion behavior of iron has yielded a number of interesting results concerning the magnetic properties[1-5] and the corrosion process and products,[6-12] and it has been studied by a number of investigators because iron is an important material in our daily life. However, our knowledge about the corrosion process is far from being sufficient, and the chemical species of the corrosion products formed on the iron surface have not been fully elucidated because the amount of products directly in contact with the metal surface is less that of the corrosion products of relatively thick oxide layers. Sewell and Cohen[13] and van Diepen et al.[14] indicated that the oxides formed up to 175 °C on the surface of iron are cubic Fe_3O_4 and γ-Fe_2O_3. Haneda and Morrish[15] indicated that the oxide layer is a mixture of Fe_3O_4 and γ-Fe_2O_3. Shinjo et al.[16] suggested that the oxide layer is γ-Fe_2O_3. Various methods of preparation (by the evaporation of iron, electrochemical deposition, and chemical reduction from α-FeOOH) for metallic iron were used in these studies, each method produced characteristic result regarding particle size, shape, and micropores in the metal. Furthermore, the corrosive conditions were different, and there has been disagreement as to which part of the oxide layer is actually detected.

Conversion electron Mössbauer spectroscopy (CEMS) is known to be suitable for the study of a surface. However, CEMS gives information of the surface range at a depth 60 nm from the particle surface. Therefore, the information obtained by CEMS is not related to the products directly in contact with the metal surface.[17] Fine samples with a large surface area are needed for a study of the oxide formed on iron. In the present study, corrosion products with a thickness of the order of 2—5 nm on the iron surface have been examined using fine particles of metallic iron.

Experimental

Iron powder was prepared by the reduction of α-FeOOH (doped with aluminium of 1.8 wt%) and stocked in a toluene solution until use because fine particles of iron are very easily oxidized in air at room temperature and are strongly pyrophoric because of their high surface area. The average particle dimensions of the acicular iron powder used here were determined, by means of an analytical electron microscope JEM-2000FX of HVEM Laboratory, Kyushu University, to be 15 nm in diameter and 100 nm in length. The specific surface area was determined by the BET nitrogen adsorption method to be 46.5 $m^2 g^{-1}$. This value is slightly larger than that of 39.2 $m^2 g^{-1}$ estimated on the base

Fig. 1. Electron micrograph of the original iron powder (×15000).

of the geometrical values. An electron micrograph for original iron powder is shown in Fig. 1. The particle size is estimated to be uniformly distributed in diameter, but to vary widely in length. The particle forms a single crystal of metallic iron covered with fine oxides, and no micropore was observed in the iron particles. The electron-diffraction patterns for these samples indicated that the sample was composed of metallic α-iron and iron oxide with a spinel structure.

X-Ray diffraction patterns were taken using Cu $K\alpha$ radiations. The data indicate that the iron powder contains a spinel iron oxide phase besides an iron phase. Line broadening for the spinel lines was observed because of the ultrafine particles of iron oxide formed on the surface of the iron particles.

Mössbauer spectroscopy was effected by using a constant-acceleration spectrometer described elsewhere.[18] The spectra were corrected for the curvature of the baseline due to the geometry of the measurement system and then fitted to the Lorentzian line shape, by using a least-squares method, at the Computer Center, Kyushu University. Isomer shifts are reported with respect to the centroid of the spectrum of an iron foil enriched with ^{57}Fe.

Results and Discussion

Oxidation/annealing of the iron powder was done at 110 °C in an air bath. The Mössbauer spectra of samples which has been oxidized/annealed at 110 °C in air for 2, 8, 26, 76, and 220 h were taken at 298 and 78 K; some of them are shown in Figs. 2 and 3. The Mössbauer parameters estimated for the samples are listed in Table 1. The spectrum of the original iron powder at 298 K consists of a superposition of a sextet with a magnetic hyperfine structure of metallic iron and a paramagnetic doublet of iron oxide. Broad lines are added in the spectra for the annealed samples, and the intensities of the broad lines and paramagnetic lines increase at the expense of that for metallic iron with an increase in the annealing time. The full width at a half maximum (fwhm) for metallic iron is narrow, and the hyperfine field coincides with the standard α-Fe value.

The Mössbauer spectra for the samples at 78 K consist of a superposition of the sextets with a magnetic hyperfine structure of both metallic iron and iron oxide. The fwhm for the iron oxide having a larger hyperfine field is wider than that of bulk γ-Fe_2O_3 or Fe_3O_4. A large value of fwhm for iron oxide is usually observed in the case of fine particles.[15] The average hyperfine fields for the iron oxide part were estimated to be 488—492 kOe at 78 K. These values are

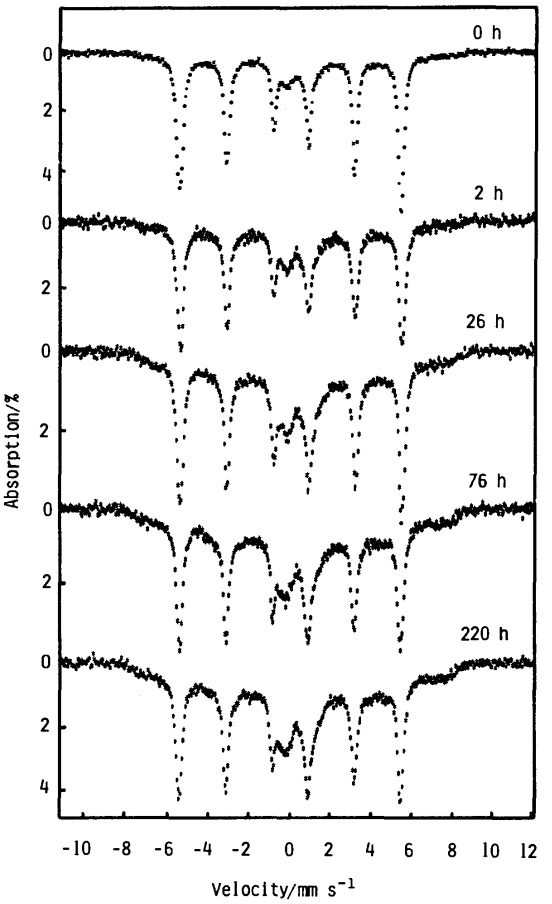

Fig. 2. Mössbauer spectra for the representative samples at 298 K.

a) Fwhm for the lowest energy line. b) Fwhm for the highest energy line. c) The ratio of absorption area for the oxide species to the total absorption area. d) The diameter of the metallic iron part remaining in the sample.

close to 494 kOe (the average of those for A and B sites at room temperature) for bulk γ-Fe_2O_3[19] and less than the value of 527 kOe (78 K) for 18 nm α-Fe_2O_3.[20] That for bulk Fe_3O_4 is known to be 492 kOe for Site A (tetra) and 461 kOe for Site B (octa) above the Verwey temperature (T_v=119 K for bulk).[21] The fields for Fe_3O_4 below the Verwey temperature are reported to be 511 and 499 kOe(at 4.2 K);[22] the line positions of their spectra approach each other, and it becomes difficult to distinguish clearly between γ-Fe_2O_3 and Fe_3O_4 except for a small shoulder in the lowest energy line. The Verwey temperature is reported to lie between 101 and 87 K for 10 nm Fe_3O_4.[23] The spectra show the existence of no Verwey transition above 78 K and no existence of absorption due to iron in the B sites. These facts support the idea that the iron oxides are not Fe_3O_4.

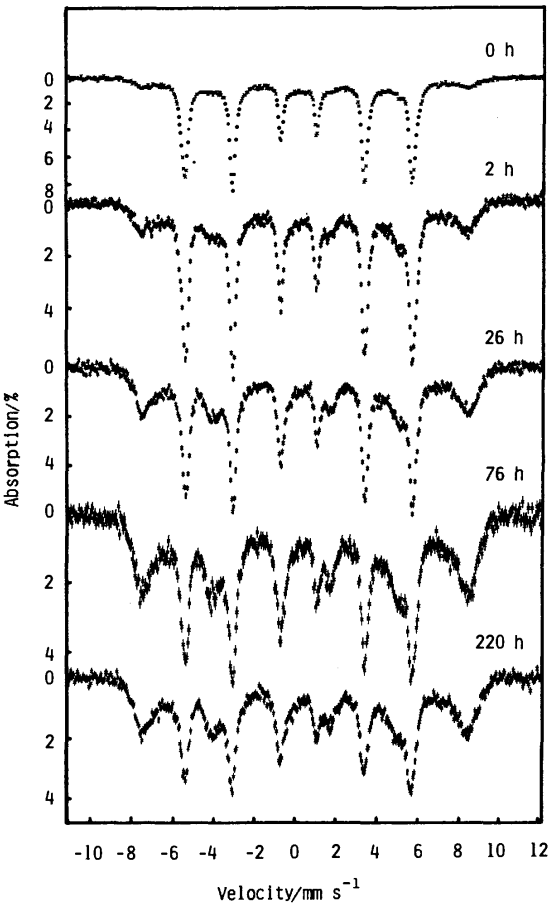

Fig. 3. Mössbauer spectra for the representative samples at 78 K.

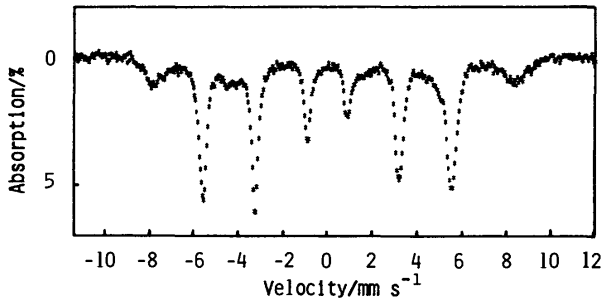

Fig. 4. Mössbauer spectrum for the original iron powder at 4.2 K.

A Mössbauer spectrum for the original sample was measured at 4.2 K; the spectrum is shown in Fig. 4. The spectrum consisted of two simple sextet patterns due to iron oxide and metallic iron, and the hyperfine field for the oxide was estimated to be 498 kOe, close to the value of 500 kOe (at 4.2 K) reported for 0.4 nm thick iron film (actually, this sample was oxidized) by Shinjo et al.[16] The lowest energy line does not split into a doublet, as is observed in the spectra of Fe_3O_4. Our spectra(δ=0.451 mm s^{-1}, ΔE=0.0 mm s^{-1} for the oxide) are in accord with those for γ-Fe_2O_3 and do not resemble the superparamagnetic behavior for Fe_3O_4 observed by Aharoni and Litt,[24] who reported larger isomer-shift values (δ=0.59 mm s^{-1} at 77 K and δ= 0.89 mm s^{-1} at 4.2 K).

The Mössbauer spectra for iron oxides in the original sample are similar to those for the annealed samples. Therefore the chemical structure of iron oxides in the original sample seems to be the same as that for the annealed sample. It is assumed that a minor component (less than 10—20% of the total absorption area in the spectra) can not be detected/resolved because the line positions for γ-Fe_2O_3 are close to those for Fe_3O_4 at 78 K or below. On the other hand, the surface of Fe_3O_4 undergoes a transformation from Fe_3O_4 to γ-Fe_2O_3 which is prominent on fine particles.[25] The thickness of the oxide layer for the original sample is estimated to be 5 monolayers, as will be described later. Therefore, the pattern observed supports the conclusion that the oxide consists of γ-Fe_2O_3. However, it is not possible to reach even a tentative conclusion concerning the mean 1—2 layers from the iron surface, which occupy 10—20% of the total ^{57}Fe in the original sample.

The intensity ratio of the six line patterns at 298 K for metallic iron is close to 3 : 2 : 1 : 1 : 2 : 3, which indicates that the magnetization is orientated at random. The intensity ratio for the spectra at 78 K is different from this ratio. The reason for this is derived from the facts that the samples prepared for low-temperature measurement were pressed to make a disk and that the shape anisotropy of the samples prefers to orientate.

The six lines for the metallic species are clearly observed, and the metallic absorption can be drawn unambiguously. The spectra of Fig. 5 were obtained by the subtraction of the metallic iron peaks from the spectra at 298 K shown in Fig. 2. These spectra show the characteristics of relaxation due to fine iron oxide particles; the superparamagnetic relaxation should

also be taken into account. The spectra are symmetric, and the FeO or Fe^{2+} absorptions observed in the spectra of ultrathin Fe_3O_4 film by Terashima and Bando[26] were not visible. A spectrum of the finest iron oxide particle is shown in Fig. 5(a), while a sextet of the magnetic hyperfine structure of iron oxide begins to appear in Figs. 5(c)—(f). However, a strong doublet in the center of the spectra is observed, even in Fig. 5(f), the sample of which was annealed at 110 °C for 220 h.

Interesting variations are found for the line positions. If the lines of the magnetic hyperfine pattern are denoted from low to high energy by the indices from $p1$ to $p6$, the parameter;

$$\Delta E' = p6 - p5 - (p2 - p1),$$

relates to the quadrupole interaction by means of this relationship;

$$\Delta E' = \frac{e^2qQ}{2} \times \frac{3\cos^2\theta - 1}{2}.$$

The parameter $\Delta E'$ for the iron oxide is approximately zero at 78 K. However, the quadrupole splitting ($\Delta E = e^2qQ/2$) for the paramagnetic components at 298 K is about 1.10 mm s^{-1}. The difference between $\Delta E'$ and ΔE is caused by the angle θ, which specifies the orientation of the V_{zz} axis with respect to the direction of the magnetic hyperfine field. It has been established that the spin structure is canted at temperatures below 300 K in the surface layer and/or in particles smaller than about 10 nm.[15,20,23]

Figure 6 shows a spectrum simulated for Fig. 5(e) using the motional narrowing formula derived by Wickman et al.[27] although fitting a theoretical curve is quite difficult and it is impossible to get a unique solution. The relaxation time of $3\tau_L$ (τ_L is the Larmor precession time 2×10^{-8} s) was obtained, the other parameters (positions, intensity ratio, and fwhm of the sextet of the magnetic hyperfine structure) used for the fitting were determined with reference to the spectra at 78 K. The fit is not good because of the reasons described above and because of the distribution of the particle size of the iron oxide. It should be noted that the paramagnetic components are observed in the spectra of samples annealed for a long time and that their intensities do not decrease with the annealing time, although the absorption lines with the magnetic hyperfine structure due to larger particles of the iron oxides do increase in intensity. These facts imply that very fine particles are always produced newly on iron surface during the annealing process. The oxide of the first monolayer on the iron surface is different from that of other layers, and an increase in the mole volume upon further chemical transformation leads to a disruption of the next first oxide layer into fine particles which grow over the iron surface. The following simple model of corrosion is considered (Fig. 7): I. In a first step, oxygen is adsorbed on the metal surface. The metal is now covered by one or two monolayers (these layers are considered to consist of Fe^{2+} and O^{2-}, but there has not yet been experimental proof of this.) II. Further oxidation leads to the formation of layers of γ-Fe_2O_3 up to about 5 nm. New fine iron oxides are formed on iron during the progress of the corrosion.

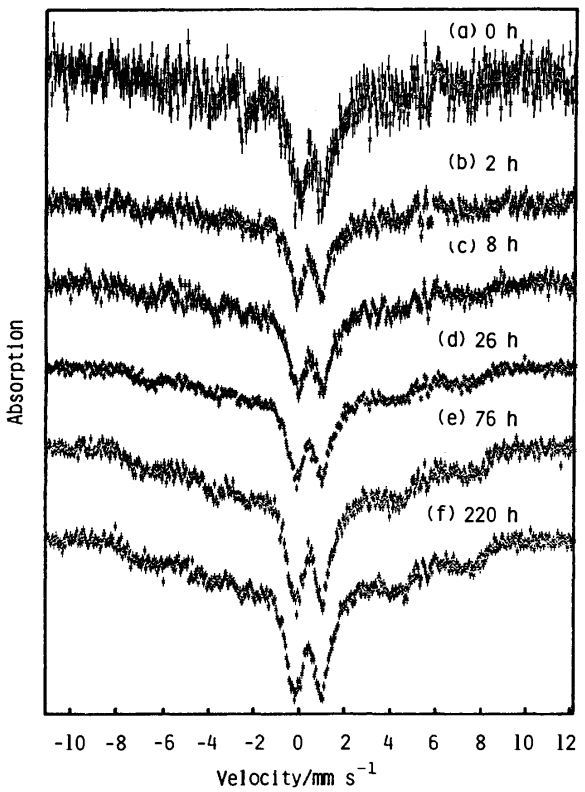

Fig. 5. Mössbauer spectra subtracted metallic iron peaks from the spectra at 298 K.

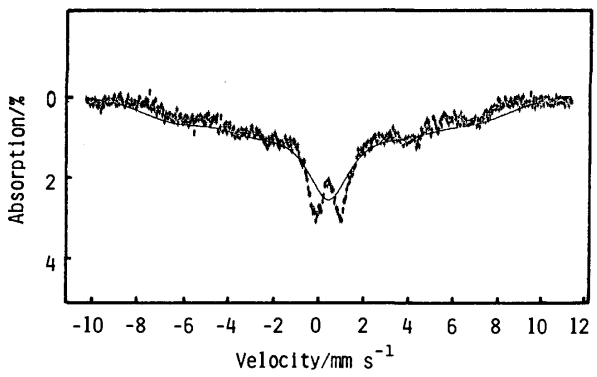

Fig. 6. Mössbauer spectrum for oxide species in the sample annealed at 110 °C for 220 h. The experimental spectrum is compared with a theoretical curve calculated on the basis of a simple model discussed in the text.

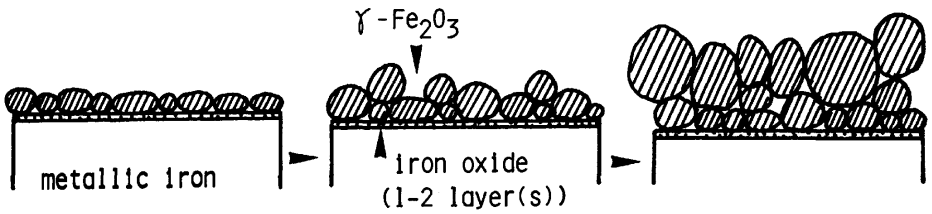

Fig. 7. A model proposed for corrosion of iron.

The recoilless fraction (f) of fine particles is of great interest. The Mössbauer spectrum of the original iron powder was measured at 4.2K in order to evaluate the fraction of metallic iron or iron oxide in the sample, for the recoilless fraction of iron oxide can be supposed to be equal to that of metallic iron at 4.2K. The metallic iron components in the original sample were estimated to be 86% of the total ^{57}Fe. From the relation of this value to the absorption area for individual chemical species at 78K, the ratios of residual metallic iron part to the total ^{57}Fe were evaluated for all the samples; they are shown in Table 1. The recoilless fraction of our sample is not very small; the f(78 K)/f(4.2 K) ratio for iron oxide was 0.78. It has been reported that f(300 K)/f(4.2 K) is 0.43 for very fine oxide (corresponding to 0.4 nm thick iron) and 0.78 for the oxide on 2.0 nm thick iron film.[16] Our datum supports the idea that recoilless fraction for very fine oxides is not so small as was suggested by Belozerskii et al.[28]

Taking a model that iron is oxidized uniformly from the surface of metallic iron and that metallic iron forms a continuous solid without micropores, the thickness of the metallic iron is estimated to be as listed in Table 1. The thickness of the oxide layer for the original sample is evaluated to be 2.1 nm. This thickness corresponds to the case formed if 1.4 nm of an iron layer (corresponding to 5 monolayers) is oxidized. Haneda and Morrish[15] have reported, from the line-broadening observed in the X-ray diffraction pattern using the Scherrer relation, that the average size of oxide is 2.7 nm. However, the Mössbauer spectrum reported by Haneda is similar to that for the sample annealed at 110 °C for 76 h in our experiment. Shinjo et al.[16] have reported that the oxide part is 59% of the total ^{57}Fe in 2.0 nm-thick iron film (corresponding to the thickness of 1.2 nm of metallic iron for a very thin layer of iron). From the kinetic study of oxygen absorption into iron metal, Quinn and Roberts[29] reported that oxidation to 6 layers occurs at 78 K. Fromm[30] and Fromm and Mayer[31] investigated the kinetics of oxygen absorption on evaporated metal film and reported that sorption-layer formation plus molecular chemisorption take place in the O_2/Fe system, that the initial sticking probability is not dependent on the temperature, and that layer formation is thermally activated at a higher coverage sorption. Although the sample treatment was not described in detail in these papers, our value (2.1 nm of iron oxide) is in accordance with the values they reported. This layer may be the thinnest one necessary to prepare metallic iron without severe autoxidation at room temperature in air.

Chemical Behavior of an Oxygen Ligand in the Reaction between Oxo Complex of Ru^{IV} and Alcohols to Give Both Hydroxo and Alkoxo Complexes of Ru^{III}

Hirotaka NAGAO, Kimitake AOYAGI, Yasuhiko YUKAWA,† F. Scott HOWELL, Masao MUKAIDA,* and Hidetake KAKIHANA
Department of Chemistry, Faculty of Science and Technology, Sophia University, 7-1 Kioi-cho, Chiyoda-ku, Tokyo 102
(Received March 9, 1987)

Under mild conditions, *trans*-$[RuCl(O)(py)_4]^+$ in alcohols changes to an alkoxo complex, *trans*-$[RuCl(OR)(py)_4]^+$, The hydroxo complex, *trans*-$[RuCl(OH)(py)_4]^+$, which retains the reactive oxygen of the oxo complex, was found to exist as a precursor in the formation of the alkoxo complex. The reaction progress was traced by spectrometrical and ^{18}O-labelling experiments.

There has been growing interest in high-valence ruthenium complexes with a reactive oxygen ligand ($Ru^{IV}=O^{2-}$). This interest centers mainly on the chemical and electrochemical generation of the oxo ligand,[1-5] on structural and spectrochemical characterization of the moiety,[6-8] and on its reactivity, in particular as an oxygen-transfer agent.[9-13] We have reported a new synthetic route for an oxo complex of Ru^{IV}, *trans*-$[RuCl(O)(py)_4]^+$, which was prepared by the oxidation of a nitrosyl complex of Ru^{II}.[5,6] As an extension of this study, the chemical behavior of the ($Ru^{IV}=O^{2-}$) unit in the oxo complex toward alcohols (MeOH, EtOH, and *n*- and *i*-PrOH) was investigated. Such a study has not yet been reported, although Meyer et al. investigated a reaction of *cis*-$[Ru(O)(bpy)(trpy)]^{2+}$ (trpy: 2,2′:6′,2″-terpyridine) with *i*-PrOH containing large amounts of water from kinetic and mechanistic viewpoints.[10] They concluded that the reaction is initiated by a formation of the corresponding hydroxo complex of Ru^{III}, as an intermediate, which is the one-electron reduced species of the oxo complex of Ru^{IV}. Here, we report on synthetic evidence which proves the existence of the hydroxo complex of Ru^{III} as a precursor in the reaction of the oxo complex of Ru^{IV} with alcohols. Also reported is evidence that the reactivity of the ($Ru^{IV}=O^{2-}$) unit, as an oxidant toward alcohols, depends on the property of the oxo complex used for the reaction. Five new complexes were isolated as the reaction products between *trans*-$[RuCl(O)(py)_4]^+$ and the alcohols. Among the alkoxo complexes obtained here, the methoxo complex of Ru^{III} has already been reported in part.[5]

Experimental

Instruments and Reagents. IR spectra were measured on a Hitachi EPI G2 spectrometer. UV-vis spectra were recorded on a Hitachi 200-20 spectrometer. Magnetic moments were measured by the Gouy method. Elemental analyses were performed by the Sophia University Analytical Facility. Cyclic voltammetry and normal pulse voltammetry were carried out by using a Fuso Polarograph Model 321 with a stationary platinum disk electrode. $RuCl_3 \cdot nH_2O$ was purchased from Nippon Engelhardt. MeOH(Spectrosol), used for both synthetic and spectrometric studies was purchased from Wako Chemical Co. The CH_3CN, used for the electrochemical experiment, was purified by a procedure described in the literature.[5] All other chemicals were obtained as reagent grade and used without further purification. $H_2{}^{18}O$ (99.0%) was purchased from the Japan Radioisotope Association. Oxo complexes, *trans*-$[RuX(O)(py)_4]Y$ (X=Cl, Br; Y=ClO_4, PF_6), were prepared as starting materials of the present reactions by procedures described elsewhere.[5,13]

Isolation of Reaction Products. Chloro(hydroxo)tetrakis(pyridine)ruthenium(III) Hexafluorophosphate, [RuCl(OH)(py)$_4$]PF$_6$ (1A): $[RuCl(O)(py)_4]PF_6$ (100 mg) was dissolved in the mixed solution of MeOH–H_2O (15–15 cm^3). It was refluxed for 15 min., until the color changed from green to yellow. The solution was kept standing for 1—2 d at room temperature. The yellow crystals which appeared were collected, washed with ether, and dried in vacuo. Yield 70%. Found: C, 38.8; N, 9.0; H, 3.4%. Calcd for $C_{20}H_{21}ON_4ClPF_6Ru$: C, 39.1; N, 9.1; H, 3.4%.

Chloro(hydroxo)tetrakis(pyridine)ruthenium(III) Perchlorate, [RuCl(OH)(py)$_4$]ClO$_4$ (1B): This was prepared by the same procedure, using the corresponding oxo complex of perchlorate salt. Yield 60%. Found: C, 42.1; N, 9.8; H, 3.7%. Calcd for $C_{20}H_{21}N_4O_5Cl_2Ru$: C, 42.2; N, 9.8; H, 3.7%.

Chloro(methoxo)tetrakis(pyridine)ruthenium(III) Hexafluorophosphate, [RuCl(OMe)(py)$_4$]PF$_6$ (2A): Oxo complex (PF_6 salt 50 mg) was dissolved in methanol (25 cm^3), using a Erlenmeyer flask, and kept at room temperature for 2 d in the dark, until the solution color changed to greenish yellow. The volume of the solution was reduced to 5 cm^3 using a rotary evaporator to produce a red crystalline material. The product was filtered out, washed with acetone and then ether, and dried in vacuo. Yield 60%. Found: C, 40.0; H, 3.6; N, 8.8%. Calcd for $C_{21}H_{23}N_4OClPF_6Ru$: C, 40.1; H, 3.7; N, 8.9%.

Chloro(methoxo)tetrakis(pyridine)ruthenium(III) Perchlorate [RuCl(OMe)(py)$_4$]ClO$_4$ (2B): This was prepared by almost the same procedure as in **2A**, using the corresponding perchlorate salt of the oxo complex. Found: C, 43.4; H,

† Present address: Division of Chemistry, General Education Department, Niigata University, 8050 Ikarashi, Ninocho, Niigata 950-21.

4.0; N, 9.6%. Calcd for $C_{21}H_{23}N_4O_5ClRu$: C, 43.4; H, 4.0; N, 9.6%. The corresponding bromo complex, $[RuBr(OMe)(py)_4]PF_6$, was obtained by the same procedure, using the bromo complex as a starting material. Found: C, 40.1; H, 3.6; N, 8.9%. Calcd for $C_{21}H_{23}N_4OBrPF_6Ru$: C, 40.2; H, 3.7; N, 8.9%.

Chloro(ethoxo)tetrakis(pyridine)ruthenium(III) Hexafluorophosphate $[RuCl(OEt)(py)_4]PF_6$ (3A): Oxo complex (PF_6 salt, 80 mg) was dissolved in EtOH (100 cm^3), using a Erlenmeyer flask, and kept at room temperature for 5—6 d in the dark. When the solution color changed from green to pale yellow, the volume of the solution was quickly reduced using a rotary evaporator. A small amount of red crystals deposited. Excess ether was added to the solution (total volume 80—100 cm^3); this was then kept in a refrigerator overnight. The product was filtered out, washed with a mixed solvent (EtOH–ether) and then ether, and dried in vacuo. Yield 50%. Found: C, 40.8; H, 3.9; N, 8.5%. Calcd for $C_{22}H_{25}N_4OPF_6ClRu$: C, 41.1; H, 3.9; N, 8.7%. The corresponding bromo complex, $[RuBr(OEt)(py)_4]PF_6$, was obtained by the procedure described above, using $[RuBr(O)(py)_4]PF_6$. Found: C, 38.3; H, 3.7; N, 8.2%. Calcd for $C_{22}H_{25}ON_4BrPF_6Ru$: C, 38.4; H, 3.7; N, 8.2%.

Chloro(propoxo)tetrakis(pyridine)ruthenium(III) Hexafluorophosphate, $[RuCl(OPr^n)(py)_4]PF_6$ (4): Oxo complex (PF_6 salt, 35 mg) was suspended in *n*-PrOH (50 cm^3) using a Erlenmeyer flask (50 cm^3). The suspension was stirred for one week at room temperature in the dark, until a homogeneous pale yellow solution was obtained. After the solution was filtered out, the filtrate was concentrated using a rotary evaporator. When a small amount of red crystals deposited, ether was added to the solution (total volume 50 cm^3); this was then kept in a refrigerator overnight. The red crystals were collected, washed with ether–EtOH and then ether, and dried in vacuo. Found: C, 42.4; H, 4.3; N, 8.3%. Calcd for $C_{23}H_{27}ON_4ClPF_6Ru$: C, 42.0; H, 4.1; N, 8.5%. Yield 40%. The corresponding bromo complex, $[RuBr(OPr^n)(py)_4]PF_6$, could be obtained by the same procedure, using the PF_6 salt of the bromo oxo complex. Found: C, 39.2; H, 4.0; N, 7.9%. Calcd for $C_{23}H_{27}ON_4BrPF_6Ru$: C, 39.4; H, 3.9; N, 8.0%.

Chloro(isopropoxo)tetrakis(pyridine)ruthenium(III) Hexafluorophosphate, $[RuCl(OPr^i)(py)_4]PF_6$ (5): The complex was prepared by almost the same procedure as that for **4**. Yield 40%. Found: C, 41.8; H, 4.1; N, 8.3%. Calcd for $C_{23}H_{27}ON_4ClPF_6Ru$: C, 42.0; H, 4.1; N, 8.5%. All the alkoxo complexes were stored under argon to avoid hydrolysis (described later).

^{18}O Labelling. Complex **4** (8 mg) was dissolved in $H_2{}^{18}O$ (1 cm^3) containing a small amount of HPF_6; the solution was heated until a pale green solid ($[RuCl(^{18}OH)(py)_4]PF_6$) deposited. After removal of the solid, $(NH_4)_2Ce(NO_3)_6$ was added to the mother liquor, and the solution was gently warmed until its color changed to green (2—3 min), and then cooled down to room temperature. NH_4PF_6 (6 mg) was added until a green product ($[RuCl(^{18}O)(py)_4]PF_6$) appeared. Both products were collected by sintered-glass filters and washed by a mixed solvent of EtOH and ether and then by ether. The ^{18}O incorporation was found to be achieved almost completely, based on the relative intensity of the $\nu(^{18}OH)$ and $\nu(^{16}OH)$ in the hydroxo complex.

X-Ray Data Collection. Crystals (**1A** and **2B**) were used for the measurements without shaping. Crystal data are as follows. For **1A**: tetragonal, with space group $P4/ncc$, a=25.937(4) Å, c=14.469(1) Å, V=9733(2) Å^3, μ(Mo $K\alpha$)=8.78 cm^{-1}, F.W.=614.9, Z=16, D_m=1.67 g cm^{-3}, D_x=1.68 g cm^{-3}. For **2B**: monoclinic, $P2_1/n$, a=22.311(3) Å, b=13.546(2) Å, c=8.091(1) Å, β=95.89°, V=2432.4(6) Å^3, μ=8.91 cm^{-1}, F.W.=583.4, Z=4, D_m=1.58 g cm^{-3}, D_x=1.59 g cm^{-3}. The reflections were collected by ω-scan technique ($2\theta<55°$ for **1A**, $2\theta<50°$ for **2B**) on a Rigaku AFC-6A automated four-circle diffractometer, with graphite monochromated Mo $K\alpha$ radiation (0.7107 Å). The 3123 (for **1A**) and 6154 (for **2B**) independent reflections with $|F_o|>3\sigma(|F_o|)$ were used for a structure refinement. The intensities were corrected for Lorentz and polarization factors, but no correction was made for the absorption. All the calculations were carried out in a HITAC M-200H computer at the Computer Center of the University of Tokyo, using a local version of UNICS.[14] The atomic scattering factors were taken from the Tables.[15]

Structure Determination. The structures were solved by a heavy-atom method. The positions of Ru and Cl atoms were obtained from a three-dimensional Patterson function, while the positions of all the non-hydrogen atoms were successively located by Fourier syntheses. In case of **2B**, all hydrogen atoms of both pyridine and methoxyl groups were found at reasonable positions on the final difference Fourier map; they were then included in the calculation, while those of **1A** were calculated and fixed, since only a few positions of hydrogen atoms were obtained.

Positions and thermal parameters of all other atoms were refined by a repeated block-diagonal least-squares method. The weighting scheme was $W=1/[\{\sigma(|F_o|)\}^2+(0.02\times|F_o|)^2]$. In the last cycle of the refinement with anisotropic temperature factors for all non-hydrogen atoms, all the parameter shifts were less than one-third of the corresponding standard deviations. The final R values ($R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$) were 0.083 for **1A** and 0.040 for **2B**. The F_o-F_c data and the anisotropic temperature parameters are deposited as Document No. 8752 at the Office of the Editor of the Bulletin of the Chemicai Society of Japan.

Results and Discussion

Spectral Change Observed for *trans*-$[RuCl(O)(py)_4]^+$ in MeOH. A green methanol solution of *trans*-$[RuCl(O)(py)_4]PF_6$ changes gradually to yellow-orange while standing at room temperature. The reaction which gave the hydroxo complex of Ru^{III} was monitored by spectrophotometry; its progress can be conveniently divided into three steps (in Fig. 1). A freshly prepared methanol solution of the oxo complex exhibits a strong absorption band at 265 nm and a weak band at 690 nm. In the first stage of the reaction ([A] in Fig. 1), the intensity of the band at 265 nm slowly decreased as a new band appeared at 285 nm. The intensity of this new band developed as it moved to 296 nm (this took about 50 h). The weak band at 690 nm also decreased in intensity and was replaced by a weak band at 640 nm, which remained without remarkable changes in either wave length or intensity until the solution color changed to yellow.

In the second stage ([B]), the band at 296 nm shifted slightly to 300 nm, while its intensity decreased (60—70 h). Later (dotted line in [B]), two new bands appeared near 245 and 375 nm, with further decreasing of the intensity of the two bands at 265 and 300 nm. The presence of an isosbestic point could not be observed in any stage. When the experiment was attempted in a preparative scale, using the PF_6 salt of the oxo complex, the solution obtained in the first stage of the reaction gave a yellow product when the solution volume is reduced, while that of the second step gives red crystals. The yellow crystalline product could be isolated when the intensities of the two absorption bands at 265 and 296 nm became almost the same.

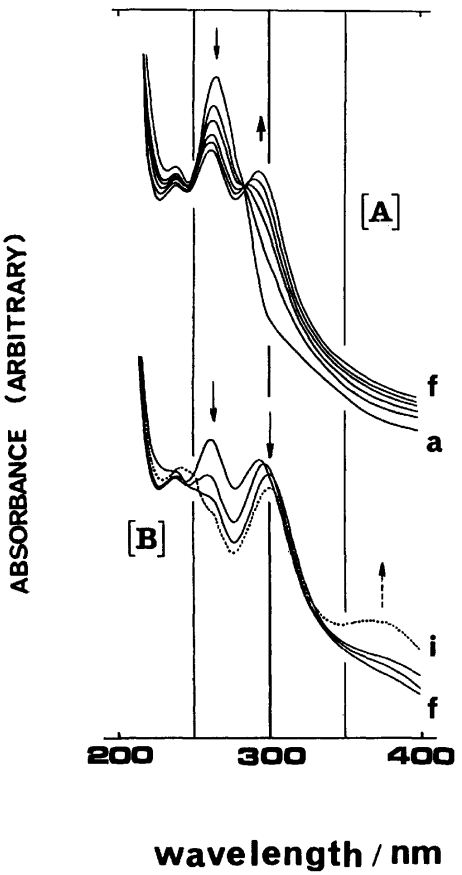

Fig. 1. UV spectral Change of $[RuCl(O)(py)_4]PF_6$ (6.5×10^{-5} mol dm^{-3}) in MeOH at room temperature (22 °C).
[A]: 1st step of the reaction, (a) immediately after, (b) 10 h, (c) 25 h, (d) 37 h, (e) 45 h, (f) 51 h. [B]: 2nd and 3rd (dotted line) steps, (f) 51 h, (g) 61 h, (h) 68 h, (i) 75 h. Arrows illustrate the direction of change of the peaks on subsequent scans.

The experimental conditions for the isolation of the yellow crystals are rigid, since it appears to be short-lived relative to the red one. The experimental data (analyses, CV, UV-vis, and IR) observed for both yellow and red crystals are the same as those of **1A** and **2A** prepared as authentic samples. The spectrometric experiment showed that the addition of a small amount of water (1—3 cm^3) to the methanol solution served to slow down the progress of the reaction, where the same products can be observed to form. No spectral evidence which suggested the formation of the aqua complex of Ru^{II}, $[RuCl(H_2O)(py)_4]^+$, as the two-electron reduced species of the original oxo complex, could be observed. The aqua complex of Ru^{II} could only be formed when the oxo complex was reduced in an acidic aqueous solution by a strong reductant such as Zn-Hg amalgam.[16]

Characterization of Reaction Products between the Oxo Complex and Alcohols. The reaction products were formulated as the hydroxo and alkoxo complex of Ru^{III}, **1** and **2—5** (Table 1), based on analyses, magnetic measurements, cyclic voltammetry, IR spectra, and X-ray structure determination (for **1A** and **2B**). The effective magnetic moments for **1A** and **2B** were found to be 2.05 and 2.15 B.M., respectively. These values are almost the same as that observed for $[RuCl_2(py)_4]PF_6$ and are close to spin-only values for one-unpaired spin.[17]

The cyclic voltammograms of all these complexes in CH_3CN exhibit reversible reduction waves at −0.7——0.8 V (vs. $Ag|AgClO_4$ (0.1 mol dm^{-3} in CH_3CN) at 25 °C), which is a reasonable potential

Table 1. Products and Their Properties

Complex		μ_{eff}/μ_B[a]	$E_{1/2}$/V[b]	$E_{pc(ox)}$/V	$\lambda(\varepsilon)$[c]

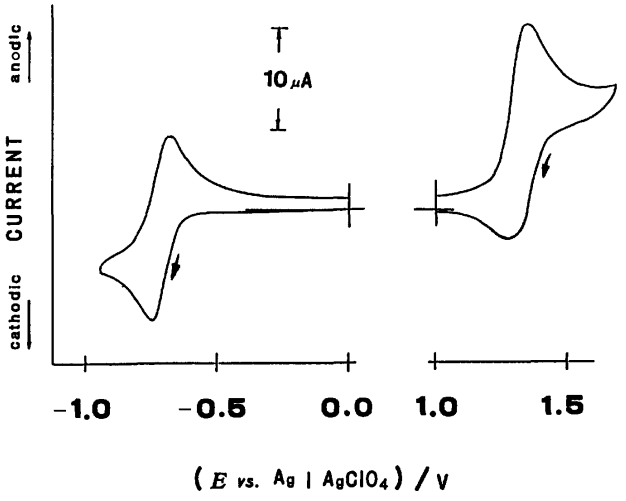

Fig. 2. Cyclic voltammograms of $[RuCl(OH)(py)_4]^+$ **1A** at a stationary platinum electrode in 0.1 mol dm^{-3} TEAP-CH_3CN at 25 °C (scan rate 200 mV s^{-1}).

region for $Ru^{III/II}$ reduction. A typical cyclic voltammogram of **1A** is shown in Fig. 2. The results are summarized in Table 1. The current heights, observed by the normal pulse voltammetry at the same experimental conditions, of the reduction waves of these complexes were almost the same as that of $[RuCl_2(py)_4]PF_6$, which has been well characterized in our laboratory.[17] At the oxidative scan the cyclic voltammogram of **1A** exhibits an irreversible one-electron oxidation wave at 1.39 V. The oxidation potential of **1A** appeared at almost the same potential region as that of $[RuCl_2(py)_4]PF_6$, which indicates a

reversible couple of $Ru^{III/IV}$.[17] The smallness of the cathodic response in **1A** indicates that the facile deprotonation occurs in (Ru^{III}-OH^{-}) group to give ($Ru^{IV}=O^{2-}$).[5] In the methoxo complex **2B**, two irreversible oxidation waves were observed at 1.0 and 1.4 V regions. A ligand oxidation reaction in MeO ligand is expected to occur in these potential regions.

The IR spectra of **1A** are essentially the same as those of $[RuCl_2(py)_4]PF_6$, except for the absorption bands observed at 3544, 938, and 599 cm^{-1}, which are assignable to ν(OH), δ(RuOH), and ν(RuO) respectively, as are shown in Table 2. ^2H- and ^{18}O- labelling experiments using $[RuCl(OD)(py)_4]^+$ and $[RuCl(^{18}OH)(py)_4]^+$ support these assignments. The IR spectra of **2** could also be reasonably assigned by a comparison with those for its deuterated complex, $[RuCl(OCD_3)(py)_4]^+$. Several IR studies on the assignment of the methoxyl ligand have been reported.[18] Upon the deuteration, the methoxyl CH stretching vibration bands at 2860 and 2786 cm^{-1} shifted to 2172 and 2040 cm^{-1}, respectively. The methoxyl CH bending vibration band at 1422 cm^{-1} disappeared; it is thought to have shifted over to near the 1100 cm^{-1} region, where a strong absorption band due to ClO_4^- was observed. The band at 1035 cm^{-1} which is believed to be due to methoxyl CO stretching vibration, shifted to 1004 cm^{-1}. The Ru-O stretching vibration at 549 cm^{-1} shifted to 526 cm^{-1} in its deuterated complex. These shifts found in C-O and Ru-O stretching vibrations are regarded as being reasonable for the deuteration of a methoxyl group coordinated to metals.[18]

The structure of both **1A** and **2B** were determined to confirm the above characterization. The final atomic parameters are listed in Tables 3 and 4. The perspective drawings of **1A** and **2B**, and the numbering schemes of the atoms are given in Figs. 3 and 4. Selected interatomic distances and angles are given in Tables 5 and 6. The cations are a hydroxo complex ion and a methoxo complex ion of Ru^{III}. They have the expected trans octahedral geometry, with pyridine nitrogen atoms approximately in a plane containing the ruthenium atom. As can be seen in Figs. 3 and 4, **1A** and **2B** have a propeller-like structure similar to those of both oxo and nitrosyl complexes,[5,19] used as starting material for the present reaction. No remarkable difference between the

structures of **1A** and of **2B** could be observed, except that the CH_3 group of the methoxyl ligand was directed to bisect the N(1)-Ru-N(4) angle, with Ru-O-C angle of 127.1.(2)°. A similar structure of the CH_3O moiety has been found in $[Mn^{IV}(TPP)(OCH_3)_2]$.[18] The hydroxyl or the methoxyl oxygen and the chlorine atoms are almost on the line including the Ru atom: 175°. The Ru-O bond distances, 1.957(9) Å (for **1A**) and 1.937(2) Å (for **2B**) are shorter than the sum of the single bond radii for Ru^{III}-O^{2-} 2.03 Å),[20] but they are significantly longer than the value of 1.862(8) Å observed for the oxo complex, the starting material. Its bond length is consistent with the bond order of two. The Ru-Cl distances, trans to the oxygen atom, are 2.377(3) Å (for **1A**) and 2.376(1) Å (for **2B**). These distances are comparable to the values reported for various Ru^{III} complexes, and they are considerably longer than those of the original nitrosyl or the oxo complexes, where the shortening of the Ru-Cl distance trans to NO^+ or O^{2-} has been expected due to their ability to act as strong acceptor ligands.[2,21] The Ru-N distances vary from 2.081(9) Å to 2.104(2) Å. These values are almost the same as those of the original oxo complex, though less shortening was observed than in the cases of $[RuCl(NO)(py)_4]^{2+}$ or $[Ru(py)_6]^{2+}$.[19,22] The crystal data of **1A**, as well as its crystal packing, are almost the same as those of the original oxo complex.[5,23] The existence of the hydrogen atom in the OH moiety appears to be an unimportant factor in determining their crystal structures.

Reactivity of (Ru^{IV}=O^{2-}) Unit. Under mild conditions, *trans*-$[RuCl(O)(py)_4]^+$ in neat MeOH gave two complexes: The hydroxo and the methoxo complex. A formulation of the latter as a complex which involves a methanol molecule as a ligand or a solvent of crystallization can be ruled out. The spectral and synthetic investigations mentioned earlier proved that the hydroxo complex was a precursor in the formation of the methoxo complex. This appears to be the first example to be synthetically confirmed. It had also become apparent that the reactivity of the (Ru^{IV}=O^{2-}) unit depends on the oxo complex used for the reaction. As described above, the hydroxo complex of Ru^{III}, *trans*-$[RuCl(OH)(py)_4]^+$, and the methoxo complex of Ru^{III}, *trans*-$[RuCl(OMe)(py)_4]^+$, were confirmed to be the first and the

second products obtained. Although the first product of the present reaction was the same as that reported by Meyer et al. in the mechanistic study of *cis*-$[Ru(O)(bpy)(trpy)]^{2+}$ in 2-propanol containing water,[10] the second product was different; the second product in their work was an aqua complex of Ru^{II}, while that found in the present work was the alkoxo complex of Ru^{III}. Their reaction progress where 2-propanol is oxidized to acetone has been reported as follows (Eqs. 1—4):[10]

$$2(Ru^{IV}=O^{2-})^{2+} + (CH_3)_2CHOH \longrightarrow 2(Ru^{III}-OH^{-})^{2+} + (CH_3)_2CO\cdot \quad (1)$$

This reaction (Eq. 1) has been believed to occur via the following reactions (Eqs. 2 and 3):

$$(Ru^{IV}=O^{2-})^{2+} + (CH_3)_2CHOH \longrightarrow (Ru^{II}-OH_2)^{2+} + (CH_3)_2CO \quad (2)$$

$$(Ru^{IV}=O^{2-})^{2+} + (Ru^{II}-OH_2)^{2+} \longrightarrow 2(Ru^{III}-OH^{-})^{2+}. \quad (3)$$

In the final step, the hydroxo complex produced in Eq. 1 undergoes a further reduction to an aqua complex of Ru^{II}:

$$2(Ru^{III}-OH^{-})^{2+} + (CH_3)_2CHOH \longrightarrow 2(Ru^{II}-OH_2)^{2+} + (CH_3)_2CO\cdot \quad (4)$$

It should be emphasized that, under our experimental conditions, no evidence indicating any formation of the aqua complex of Ru^{II}($[RuCl(OH_2)(Py)_4]^+$), which corresponds to the final product in Eq. 4, could be observed by spectral monitoring.

The origin of the hydroxyl hydrogen atom in **1** could no be clarified. Meyer et al., have stated that the reduction of *cis*-$[Ru(O)(bpy)(trpy)]^{2+}$ to the corresponding hydroxo complex (Eq. 1) is initiated by a hydride transfer from the α-C-H bond of the 2-propanol to ($Ru^{IV}=O^{2-}$) unit.[10] A direct application of their mechanism to the present reaction appears to be difficult, owing to a disagreement in the spectral observations. They found isosbestic points due to the formation of first the hydroxo complex of Ru^{III} (Eq. 1) and then the aqua complex of Ru^{II} (Eq. 4), whereas the present reaction does not exhibit those points. Although a hydride-transfer mechanism can be acceptable if the aqua complex of Ru^{II} is confirmed to exist before the hydroxo complex formation occurs (Eq. 2), such an aqua complex as the intermediate species is not detectable, because it appears that the intermediate species is not built up to appreciable concentrations or is too short-lived to be seen spectrophotometrically.[10]

The alkoxo complex **3**—**5** undergo a facile hydrolysis to give the hydroxo complex, while the hydrolysis of **2** is extremely slow. Treatment of the hydrolysis solution with Ce^{4+}, used as an oxidant in acidic conditions, gave the original oxo complex quantitatively. By the same procedure using $H_2{}^{18}O$ (99%) $[RuCl(^{18}O)(py)_4]PF_6$ could be obtained from the alkoxo complex **4**. Upon ^{18}O substitution, the IR absorption band due to ν(RuO), observed at 804 cm^{-1} for the original oxo complex, disappeared. This finding suggests the existence of an ^{18}O atom in the product, although the IR absorption band ($\nu(Ru^{18}O)$) could not be confirmed, since the region where this would be expected (780—760 cm^{-1}) was hidden by the strong absorption band from the pyridine moiety. $[RuCl(^{18}OH)(py)_4]PF_6$ could also be isolated in this stage before the formation of the ^{18}O-labelled oxo complex occurs, without addition of any oxidant. The labelling experiment can be illustrated by the following scheme:

$$[Ru^{III}Cl(OR)(py)_4]^+ + H\text{-}\overset{*}{O}\text{-}H \longrightarrow [Ru^{III}Cl(\overset{*}{O}H)(py)_4]^+ + ROH \quad (5)$$

$$[Ru^{III}Cl(\overset{*}{O}H)(py)_4]^+ \longrightarrow [Ru^{IV}Cl(\overset{*}{O})(py)_4]^+ + e^- + H^+. \quad (6)$$

If we assume that the alkoxo complex formation occurs by a water-condensation reaction between alcohol and the hydroxo complex, the reverse reaction of the schemes (Eqs. 5 and 6) may be indicative of the behavior of the ($Ru^{IV}=O^{2-}$) unit in *trans*-$[RuCl(O)(py)_4]^+$ toward alcohols; the alkoxo complex does not retain the oxygen atom in the ($Ru^{IV}=O^{2-}$) unit, whereas the hydroxo complex can be considered to retain it.

At room temperature, *trans*-$[RuCl(OMe)(py)_4]^+$ **2B** dissolved in methanol changed from yellow-orange to red after long standing. The absorption spectra of the solution was scanned repeatedly between 230—500 nm for 20 d. As shown in the dotted line of [B] (Fig. 1), decreasing of intensities of the bands at 265 and 300 nm and developing of the bands at 245 and 375 nm were observed, with isosbestic points forming at 237, 255, and 327 nm. A methoxo complex of Ru^{II}, $[RuCl(OMe)(py)_4]$, appears to from at this stage of the reaction. The electrochemical experiment described above showed that the methoxo complex **2** underwent a reversible one-electron reduction. Attempts to isolate the species were unsuccesful. In place of the methoxo complex of Ru^{II}, small amounts of red crystals, which could easily be identified as $[RuCl_2(py)_4]$,[25] deposited after further standing of the solution.

The authors wish to express their thanks to Professor Akira Ouchi, the University of Tokyo, and Associate Professor Mamoru Shimoi, Tohoku University, for the X-ray diffraction measurements and for their helpful discussions. Thanks are also due to Mariko Ogura and Akito Kuwayama for their technical assistance. The present work was partially supported by Grant-in-Aid for Science Research No. 61540454 from the Ministry of Education, Science and Culture.

Infrared Absorption Study of Human Hemoglobin α-Chain (123-136) Fragments in Dichloromethane[1)]

Mitsuaki NARITA,* Masamitsu DOI, and Takao NAKAI
Department of Industrial Chemistry, Faculty of Technology,
Tokyo University of Agriculture and Technology, Koganei 184
(Received February 3, 1987)

In connection with the relationship between the conformation and solubility of peptide intermediates having polar side chains, IR spectroscopic conformational analysis of peptide fragments of human hemoglobin α-chain (123-136) was performed in dichloromethane. In dichloromethane, the conformational behavior of the peptide fragments was, in essence, dependent on their amino acid sequences, and Boc-Ser(Bzl)-Thr(Bzl)-Val-Leu-OPac through Boc-Ala-Ser(Bzl)-Val-Ser(Bzl)-Thr(Bzl)-Val-Leu-OPac had predominantly unordered structures including some intramolecular hydrogen bonds, while Boc-Ala-Ser(Bzl)-Leu-Asp(OBzl)-Lys(Z)-Phe-Leu-OPac had successive intramolecular hydrogen bonds, probably corresponding to an α-helical structure. On the other hand, in carbon tetrachloride, the conformation of Boc-Val-Ser(Bzl)-Thr(Bzl)-Val-Leu-OPac and Boc-Ser(Bzl)-Val-Ser(Bzl)-Thr(Bzl)-Val-Leu-OPac had a typical β-sheet structure. These results are discussed on the basis of the amino acid sequences of the peptide fragments.

One of the serious problems in protein synthesis by the classical solution method is the low yields of the fragment condensation reactions, along with the decrease in the solubility of peptide intermediates with the increase in peptide chain length. In fact, Hofmann and coworkers[2)] reported that the azide condensation of tetraeicosapeptide with heptapentacontapeptide gave ribonuclease T_1 (24-104) only in 5% yield. The extreme decline in coupling yields with increasing peptide chain length was presumed to be caused by conformational factors. The reactive ends of the peptides may become sterically hindered because of folding into the peptide chain. Since conformational stability can be expected to increase with increasing chain length, conformation may become the overriding factor influencing the coupling yields. In synthetic studies of peptides and proteins, however, conformational analysis in solution has seldom been performed,[3-5)] since the role of the polar amino acid residues in the conformational behavior of peptide fragments is complicated. This is in contrast with the fact that conformational analyses of homo- and sequential peptides have been widely carried out.[6-8)]

In relation to the problem of the extreme decrease in the solubility and reactivity of peptide intermediates with increasing peptide chain length, we have developed the solubility-improvement[9,10)] and solubility-prediction methods[11)] and proposed the design method of the synthetic route for peptides and proteins based on the solubility prediction method.[12)] In connection with the relationship between the conformation and solubility of peptide intermediates having polar side chains, we here report IR spectroscopic conformational analysis of peptide fragments of human hemoglobin α-chain (123-136) in dichloromethane, which is most commonly used in solid phase peptide synthesis and is the best solvent for coupling reactions when peptide intermediates are soluble. Our concern in this paper is to elucidate the role of polar amino acid residues in the conformational behavior of peptide fragments.

Fig. 1. The amino acid sequence of human hemoglobin α-chain (123-136) and the peptides **1**—**7** used in this study.

The amino acid sequence of human hemoglobin α-chain (123-136) corresponds to the partial sequence of the helical H region (Fig. 1).[13,14] Figure 1 also illustrates the protected peptide fragments **1—7** used in this study.

Experimental

Materials. The preparation of the samples of human hemoglobin α-chain (123-136) fragments will be reported elsewhere. The purity of the peptides was confirmed by amino acid and elemental analyses. The peptides also gave a single peak on HPLC.

IR Measurements. The IR absorption spectra of the samples in dichloromethane were recorded at room temperature with a JEOL Model JIR-100 FT-IR spectrometer by employing 0.5 mm- and 5 mm-path length cells with potassium bromide windows.

Results

IR Absorption Spectra of the Tripeptide 1, the Tetrapeptides 2 and 4, and the Pentapeptide 5 in Dichloromethane. The peptides **1**, **2**, **4**, and **5** are easily soluble in dichloromethane, and their IR absorption spectra were obtained over a wide range of concentration (0.10—10 mM (1 M=1 mol dm^{-3})). In Fig. 2, we show the N-H stretching bands of the peptides **1**, **2**, **4**, and **5** in dichloromethane and clearly see two distinct bands around 3425 and 3360 cm^{-1} over the entire concentration range. The 3425-cm^{-1} band is clearly due to the free N-H stretching vibration, while the 3360-cm^{-1} band is due to a hydrogen-bonded species.[3,4,6-8,15] Since the intensities of these two bands show little dependence on concentrations, the 3360-cm^{-1} band is mainly attributed to the intramolecular hydrogen-bonded species. The band around 3440 cm^{-1} of the peptide **2** is assigned to the free N-H stretching band of the side chain urethane group of the Lys residue. The IR absorption spectra in the amide I region of the peptides **1**, **2**, **4**, and **5** are also illustrated in Fig. 3. Their IR spectra measured over the wide range of concentration show the bands around 1755—1740, 1711—1707, and 1678—1670 cm^{-1}, corresponding to the Pac and Bzl ester carbonyl, Boc urethane carbonyl, and amide carbonyl groups, respectively. The absorption band around 1690 cm^{-1} of the peptide **1** may be attributed to the Pac ketone carbonyl group. The band around 1718 cm^{-1} of the peptide **2** is also assigned to Z urethane carbonyl group free from hydrogen bonding. The amide carbonyl bands of the peptides **1**, **2**, **4**, and **5** also showed little dependence on concentration (0.10—10 mM).

IR Absorption Study of the Hexapeptide 6 in Dichloromethane. The IR absorption spectra in the N-H stretching region of the peptide **6** in dichloromethane (0.10—10 mM) are shown in Fig. 4A. Those in the amide I region are also shown in Fig. 4B. At lower concentrations, the spectral patterns of the peptide **6** are essentially the same as those of the

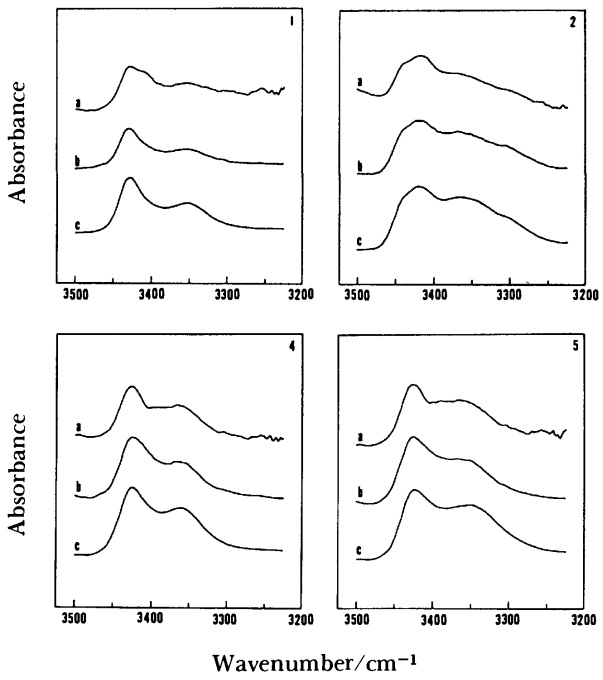

Fig. 2. IR absorption spectra in the amide A region of the tripeptide **1**, the tetrapeptides **2** and **4**, and the pentapeptide **5** in dichloromethane over the wide range of concentrations (0.10—10 mM). **a**: 0.10 mM, **b**: 1.0 mM, **c**: 10 mM.

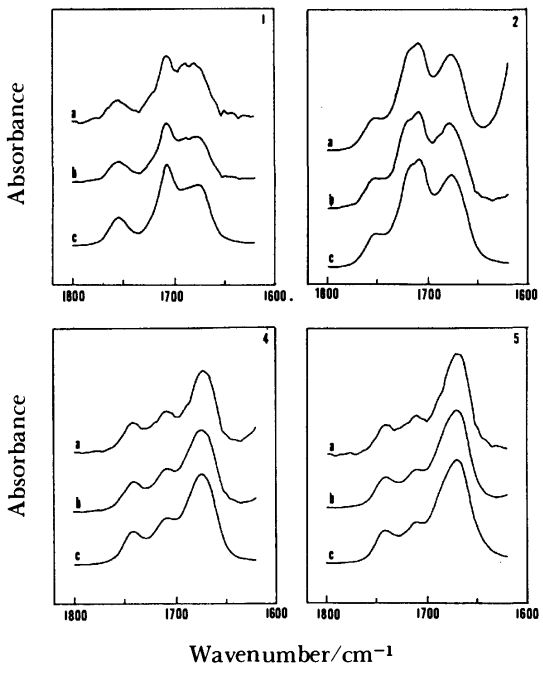

Fig. 3. IR absorption spectra in the amide I region of the tripeptide **1**, the tetrapeptides **2** and **4**, and the pentapeptide **5** in dichloromethane over the wide range of concentrations (0.10—10 mM). **a**: 0.10 mM, **b**: 1.0 mM, **c**: 10 mM.

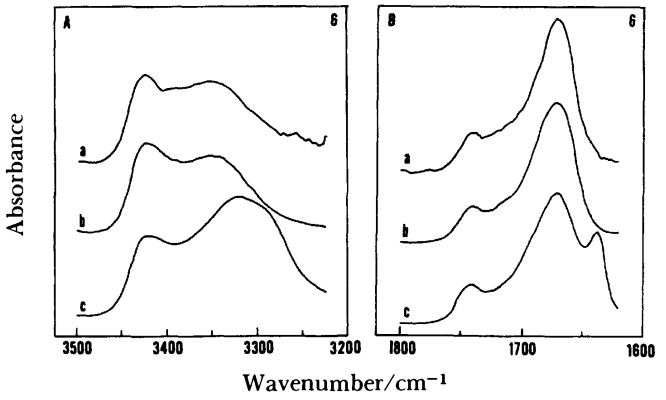

Fig. 4. IR absorption spectra of the hexapeptide **6** in dichloromethane over the wide range of concentrations (0.10—10 mM). A: The amide A region, B: the amide I region. **a**: 0.10 mM, **b**: 1.0 mM, **c**: 10 mM.

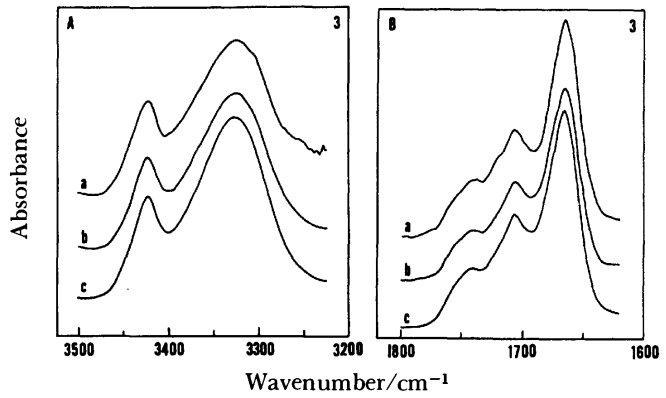

Fig. 5. IR absorption spectra of the heptapeptide **3** in dichloromethane over the wide range of concentrations (0.10—10 mM). A: The amide A region, B: the amide I region. **a**: 0.10 mM, **b**: 1.0 mM, **c**: 10 mM.

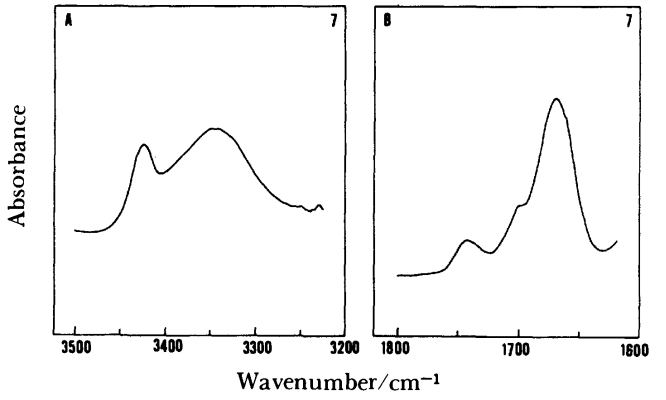

Fig. 6. IR absorption spectra of the heptapeptide **7** in dichloromethane (below 0.1 mM, saturated concentration). A: The amide A region, B: the amide I region.

peptides **4** and **5**, while at the high concentration, the concentration-depending absorption bands appear around 3300 cm^{-1} and at 1637 cm^{-1}, suggesting the onset of a β-sheet structure.[3,4,6-8,15] In fact, the IR absorption spectra of the peptides **5** and **6** in carbon tetrachloride (**5**: 2 mM, **6**: ca. 0.1 mM, saturated concentration) have the bands at 3280—3278, 1695, and 1635—1631 cm^{-1}, indicating an antiparallel β-sheet structure.[3,4,6-8,15,16]

IR Absorption Spectra of the Heptapeptides 3 and 7 in Dichloromethane. The IR absorption spectra in the N-H stretching region of the peptide **3** in dichloromethane (0.10—10 mM) are shown in Fig. 5A. We also see two distinct bands at 3425 cm^{-1} and around 3325 cm^{-1} over the entire concentration range. Again, the 3425-cm^{-1} band is due to the free N-H stretching vibration, while the band around 3325 cm^{-1} is due to a hydrogen-bonded species. The intensity of the hydrogen-bonded band (Fig. 5A) is little dependent on concentration, indicating it is nearly free from intermolecular hydrogen bonding. The positions and intensity ratios of the carbonyl bands (Fig. 5B) are also independent of concentration (0.10—10 mM). Assignment of each band at 1743, 1707, and 1666 cm^{-1} is essentially the same as that of the peptides **1**, **2**, **4**, and **5**. Figures 6A and 6B show the IR absorption spectra in the amide A and amide I regions of the peptide **7** in dichloromethane (below 0.1 mM, saturated concentration), respectively. The free N-H stretching band also appears at 3425 cm^{-1}, while the hydrogen-bonded band of the peptide **7** shifts to a higher frequency (3344 cm^{-1}) than that of the peptide **3** (3325 cm^{-1}). The absorption bands in the amide I region appear at 1743, 1701, and 1670 cm^{-1}.

Discussion

With respect to conformational analysis of Boc-Leu_4-OBzl and Boc-Leu_5-OBzl in dichloromethane, in a previous paper,[17] we showed that the positions and intensity ratios of the bands at 3430—3420 and 3350—3320 cm^{-1} are nearly independent of concentration and that the absorptions of the three free N-H groups in Boc-Leu_4-OBzl and Boc-Leu_5-OBzl are almost clearly comparable with similar absorption in Boc-Leu_3-OBzl. On the basis of these results, we suggested the occurrence of successive intramolecular hydrogen bonds like incipient α-helical structures in Boc-Leu_4-OBzl and Boc-Leu_5-OBzl. In Fig. 2, the positions and intensity ratios of the bands around 3425 and 3360 cm^{-1} are also nearly independent of concentrations, and the 3360-cm^{-1} band is thus to be attributed to intramolecular hydrogen-bonded species. Compared to the intensity ratios of the hydrogen-bonded N-H absorption to the free N-H absorption (A_H/A_F) for Boc-Leu_4-OBzl and Boc-Leu_5-OBzl, however, those for the peptides **2**, **4**, and **5** are relatively small, indicating that the hydrogen-bonded

species of the latter are different from those of the former. The same conformational behavior is also observed in the hexapeptide **6** at lower concentrations (Fig. 4A), being in contrast to the fact that Boc-Leu-Pro-Leu$_4$-OBzl develops successive intramolecular hydrogen bonds in dichloromethane.[17] This different conformational behavior is clearly attributed to the low potential of the peptides **2** and **4**—**6** for the formation of an α-helical structure. The helical structure of the peptides **5** and **6** in dichloromethane may be unstable due to repulsion among C^{β}-branched Val and Thr(Bzl) residues, although the sequence of -Ser-Val-Ser-Thr-Val-Leu- is included in the helical H region of human hemoglobin α-chain.[14] Furthermore, interactions among protected polar side chains and peptide bonds disturb the formation of an α-helix or β-sheet structure, leading to an unordered structure. Thus, the conformations of the peptides **1**, **2**, and **4**—**6** are inferred to be unordered structures including intramolecular hydrogen bonds among protected polar side chains and peptide bonds. At the high concentration (10 mM), the peptide **6** in dichloromethane indicates the onset of a β-sheet structure, and the conformations of the peptides **5** and **6** in carbon tetrachloride of low polar solvent are indeed typical β-sheet structures. The results in carbon tetrachloride exhibit that the structures of the peptides **5** and **6** in carbon tetrachloride are the same as those in the solid state.[18] Further development of interpeptide-chain interactions through hydrogen bonds with increase in peptide chain length gives rise to the severe insolubility of peptides in carbon tetrachloride.

On the other hand, the conformational behavior of the heptapeptide **3** in dichloromethane is in contrast to that of the hexapeptide **6** and the heptapeptide **7**. Over the entire range of concentrations, the positions and spectral patterns of the N-H and C=O absorption bands are independent of concentrations and resemble those of Boc-Leu$_2$-Pro-Leu$_4$-OBzl in dichloromethane,[17] which is inferred to have a large contribution of α-helical structure. For the purpose of elucidating the intramolecularly hydrogen-bonded species, the IR difference spectra between the peptides **3** and **1** and between the peptides **3** and **2** were examined in the amide A and amide I regions (Figs. 7A and 7B). In the difference spectrum between the peptides **3** and **1**, the shoulder band around 3440 cm^{-1} is also assigned to the free N-H stretching band of the side chain urethane group of the Lys residue, and the band around 1720 cm^{-1} to the corresponding urethane carbonyl group. On the other hand, the IR difference spectrum between the peptides **3** and **2** shows a negative band at 1720 cm^{-1}, indicating that the Z urethane carbonyl group of the peptide **3** is subjected to hydrogen bonding more than that of the peptide **2**. Although both IR difference spectra in the amide A region still show the existence of a small amount of the free N-H stretching vibration, the bands at 3323—3321 and 1664—1662 cm^{-1} strongly suggest a large contribution of successive intramolecular hydrogen bonds similar to an α-helical structure.[17] With respect to the conformational behavior of the peptide **7**, the spectrum in the amide A region indicates an increase of hydrogen-bonded species, compared to the peptides **5** and **6**. Since the spectrum in the amide I region shows no band around 1635 cm^{-1}, the increase in the band at 3344 cm^{-1} probably corresponds to the increase in the intramolecular hydrogen-bonded species, suggesting the onset of an α-helical structure around N-terminal portions. The conformational behavior of the peptides **3** and **5**—**7**, which are equal

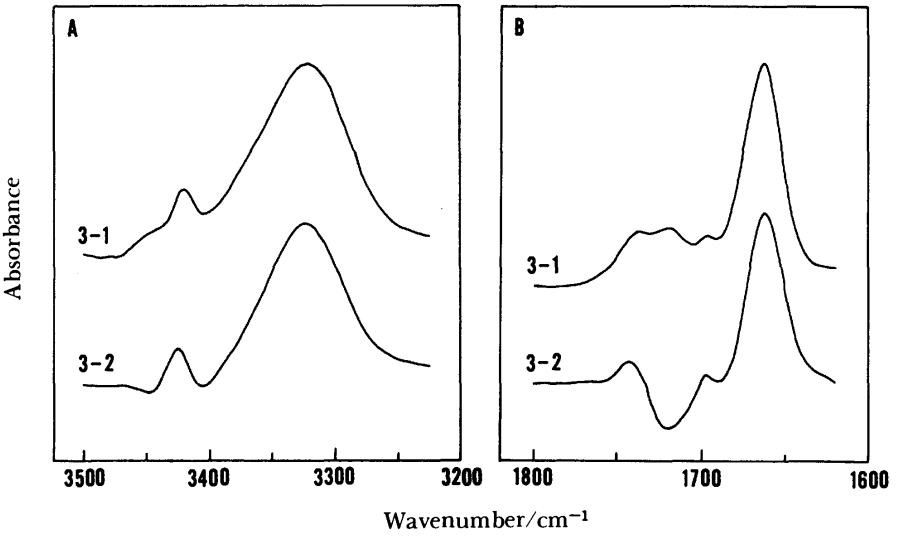

Fig. 7. IR difference spectra between the peptides **3** and **1** and between the peptides **3** and **2** (1.0 mM). A: The amide A region, B: the amide I region.

to or larger than a pentapeptide, clearly reflects their potential for the formation of an α-helical structure and are estimated using the average helix conformation $\langle P_\alpha \rangle$ values[19] of each peptide as discussed for the effect of shear stress on conformational behaviors of the peptides **3** and **5—7** in the solid state.[18]

Regio- and Stereoselective Introduction of Functional Groups into 1-Isoindolinone and 1(2*H*)-Isoquinolone Systems[1)]

Michihiko NOGUCHI,* Manabu YOSHIOKA, Shinji KAKIMOTO, and Shoji KAJIGAESHI
Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755
(Received February 4, 1987)

The oxidation of 3*a*,4-dihydro-1-isoindolinone derivatives with MCPBA was carried out regio- and stereoselectively to afford the 5,6-epoxide products **2**. The ring opening reaction of **2** with amines, alcohols, and sodium azide gave homoallyl alcohol type of products, derived from the ring opening at C-5 of **2**. Lithium (cyano-*C*)methylcuprate reacted with **2** to give homoallyl and/or allyl alcohol, which is due to the conjugate addition to the C-7a position. This approach for selective introduction of functional groups into the heterocycles was extended for 3,4,4*a*,5-tetrahydro-1(2*H*)-isoquinolone system.

Recently, we reported the preparation of 3*a*,4-dihydro-1-isoindolinone and 3,4,4*a*,5-tetrahydro-1(2*H*)-isoquinolone derivatives, **1** and **17**, via an intramolecular "diene-regenerable" Diels-Alder reaction of 2-pyrone-6-carboxamides.[1b)] Compounds **1** and **17** were regarded as cyclo-1,3-diene systems fused by lactam rings, and the lactam rings seemed to control the stereochemistry of the succeeding intermolecular Diels-Alder reaction.[1b)]

A stereoselective formation of oxiranes[2)] and successive ring-opening reactions[3)] with various nucleophiles are recognized as a promising pathway for selective functionalization in molecules.

If the stereochemistry of the epoxidation of **1** and **17** is also controlled by their lactam moieties and the selective ring-opening reaction of the resulting oxiranes is possible, the selective introduction of functional groups into the above heterocyclic systems would be achieved. Thus, we investigated the epoxidation of **1** and **17** followed by ring opening reaction with several nucleophiles. The sequence of these two reactions proceeded regio- and stereoselectively and revealed to be suitable for our purpose. The regiochemistry for the ring opening reactions is also discussed.

Results and Discussion

Regio- and Stereoselective Oxidation of 3*a*,4-Dihydro-1-isoindolinones 1. The oxidation of 2-phenyl- (**1a**), 2-benzyl-4-methyl- (**1b**), and 2-benzyl-4-phenyl-3*a*,4-dihydro-1-isoindolinone (**1c**) with *m*-chloroperbenzoic acid (MCPBA) in dichloromethane-water at room temperature resulted in epoxidation of the 5,6-double bond of **1a—c**, and the oxiranes **2a—c** were isolated in almost quantitative yields as single isomers (Scheme 1). The configuration between the oxirane and lactam rings of **2** was assigned to be syn on the basis of the values of the coupling constants among the protons and the 3a-, 4-, 5-, and 6-positions of **2a—c** (Table 1). For **2a** the vicinal coupling constants J_{3a-4} (7.5 and 11.7 Hz) between methine (3a-position) and methylene (4-position) were assignable as cis and trans[1b)] and J_{4-5} (2.8 and ca. 0 Hz) to be also cis and trans,[4)] respectively. The values of J_{3a-4} (ca. 10.5 Hz) and J_{4-5} (less than 1 Hz) for **2b** or **2c** are deduced to be trans and trans configurations among the three protons.

Therefore, the oxygen is introduced to the C–C double bond on the same side as the lactam ring with high stereoselectivity regardless of the kind of substituent at the 4-position. The syn-directing effect of allylic hydroxyl[5)] or allylic amido group[6)] is well-known in the stereoselective epoxidation of the cyclohexene system by peracids. Interestingly, the lactam ring of **1** causes an excellent syn-directing effect, nevertheless it is located far from the oxidized double bond in this case.

Ring Opening Reaction of Oxiranes 2 with Nucleophiles. The oxiranes **2a—c** have four reaction sites for nucleophiles as demonstrated in Fig. 1. In order to establish the regioselectivity of the nucleophilic attack, we examined for the first time the reaction with hard bases[7)] such as heteroatomic

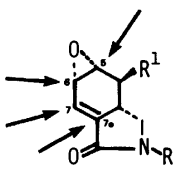

Fig. 1. Reaction sites of oxiranes **2** for nucleophiles.

nucleophiles. Recently, Posner et al. reported that the ring opening of oxiranes with nucleophiles proceeded smoothly in the presence of commercially available neutral alumina.[8]

In a similar manner to Posner's method, **2a—c** were allowed to react with benzylamine (**3**) and pyrrolidine (**4**) to afford homoallyl alcohols, **5a—c** and **6a—c**, derived from the ring opening at the C-5 of **2**. No products derived from that of C-6 were observed. The structural assignment for the homoallyl alcohols was accomplished on the basis of their spectral data. Especially, in their mass spectra the fragment ion peaks due to the elimination of aldehydes from the molecular ion, $M^+-R^1CH_2CHO$, were observed. The stereochemical relationships between the functional groups carrying oxygen and nitrogen atoms could not be determined only from the coupling constants because of the complexity of the signal patterns. However, these were tentatively assigned to be trans according to the reaction pathway[9] reported heretofore.

The analogous reaction of **2b** with methanol (**7**) and 1-pentanol (**8**) gave the same type of adducts **9** and **10** together with diol **11**, respectively. Under similar conditions the ring opening of **2b** with water afforded **11** in only 19% yield with the recovery of **2b** (64%). Therefore, the formation of **11** in the reaction with alcohol would be attributable to the secondary reaction via **9** or **10**.

The ring opening of **2** using azide ion as a softer base was examined. The reaction of **2a—c** with sodium azide (**12**) in aqueous THF gave homoallyl alcohols **13a—c** in good yields.

These results are shown in Schemes 2 and 3. The regio- and stereochemistries of these adducts were confirmed on the basis of the similarities of the spectral data to those of the adducts with amines.

The introduction of an alkyl group into the 1-oxoisoindoline system was finally investigated. The reaction of **2** with Grignard reagents or alkyllithiums afforded only disappointing results. So, the reaction

Scheme 2.

of **2** with lithium (cyano-*C*)methylcuprate (**14**) was examined, which is widely used as an effective reagent for opening oxiranes.[10] Oxirane **2a** reacted with **14** in THF at −30 °C to give homoallyl alcohol **15a** and allyl alcohol **16a**, which was derived from the conjugate addition of methyl anion onto the C-7a. However, in a similar reaction of **2b** or **2c** with **14**, only homoallyl alcohol **15b** or **15c** was obtained (Scheme 4).

The structure of **16a** was elucidated on the basis of its spectral data. In its ^{1}H NMR spectrum, two olefinic proton signals at δ=6.44(doublet) and 5.72 (double doublet) were observed. Its mass spectrum showed a fragment ion peak due to (M^+-CH_3), but the peak characteristic of a homoallyl alcohol type of product, M^+-CH_3CHO, was not observed.

The relationship between the methyl group at the 7a-position and the hydroxyl at the 5-position is tentatively assigned to be trans because the conjugate addition of lithium alkyl(cyano-*C*)cuprates to 1,3-diene monooxides have been shown to proceed in a highly selective manner.[11] This assignment is also supported by the findings that the conjugate addition of **14** only occurs at the reaction with **2a**, which bears the least hindered substituent (R^1=H) at the 4-position among oxiranes **2**.

The hard and soft acid–base concept[7] appears to be useful in considering the regioselectivities of these ring-opening reactions. According to the concept, the 5- and 6-positions are hard and the 7- and 7a-position are soft reaction sites,[12] respectively. The reaction with hard nucleophiles as well as with azide ion occurred exclusively at the 6-position, which is more reactive than the 5-position owing to it being an allylic position. Methyl anion prefers to react with the softer acid site, e.g., C-7a position. However, the regiochemistry of the addition was eventually determined on the balance between the affinity and the steric hinderance, which becomes serious for attack at the 7a-position when the substituent at the 4-position is bulky.

Regio- and Stereoselective Oxirane Formation of 3,4,4*a*,5-Tetrahydro-1(2*H*)-isoquinolone System and Its Ring Opening Reaction. The regio- and stereoselective oxidation of **1** to **2** followed by the regioselective ring opening allowed to the introduction of functional groups into the 3*a*,4-dihydro-1-isoindolinone system. Accordingly, we investigated the oxidation of 2-benzyl-3,4,4*a*,5-tetrahydro-1(2*H*)-isoquinolone (**17**), a higher homolog of **1**, and the successive introduction of functional groups into the 1(2*H*)-isoquinolone system.

The oxidation of **17** with MCPBA in dichloromethane–water below 0 °C[13] and treatment by column chromatography on silica gel gave an oxirane **18**, resulting in oxidizing of the 6,7-double bond of **17**, in 84% yield (Scheme 5).

The structure of **18** was confirmed on the basis of spectral data and, especially, the configuration between the oxirane and lactam rings was also syn. Therefore, the fused lactam moiety in **17** as well as **1** caused the directing effect in the oxidation with MCPBA.

The ring opening reaction of **18** with pyrrolidine (**4**) and sodium azide (**12**) gave homoallyl alcohol type of products **19** and **20**. On one hand, oxirane **18** reacted with lithium (cyano-*C*)methylcuprate (**14**) to afford homoallyl alcohol **21** and allyl alcohol **22** in 60 and 21% yields, respectively (Scheme 6).

Experimental

General. All melting points are uncorrected. The IR spectra were measured on a JASCO IRA-1 spectrometer. The ^{1}H NMR spectra were obtained on JEOL FX-200, FX-100, and/or JMN-MH-100 spectrometers. The chemical shifts are expressed in parts per million downfield from internal tetramethylsilane. Splitting patterns are indicated as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; ov, overlapped with each other. The mass spectra were determined with a JEOL JMS-012G-2 or JMS-D spectrometer and at an ionization energy of 75 eV. The elemental analyses were performed on a Hitachi 026 CHN analyzer. The progress of most reactions was monitored by thin-layer chromatography (Silica gel 60F-254, Merck). The visualization was made with ultraviolet light (254 and 365 nm). Wakogel C-200 and C-300 were used for the preparative chromatography. As catalysts for the ring opening of the oxiranes, Woelm-200 neutral alumina (activity grade I) was used.

Epoxidation of 3*a*,4-Dihydro-1-isoindolinones 1 with MCPBA. Typical Procedure: A mixture of 0.50 g (2.4 mmol) of **1a** and 0.57 g (3.3 mmol) of MCPBA in dichloromethane–water (60—20 mL) was stirred for 12 h at room temperature. After destroying the excess MCPBA with sodium hydrogensulfite, the organic layer was collected and evaporated to dryness. The residue was subjected to a short column chromatography on silica gel (chloroform) to afford 0.51 g (96%) of oxirane **2a**.

2a: Colorless plates (benzene); mp 168—169 °C; IR (KBr) cm^{-1}: 1670 (CO); MS *m/z* (rel intensity) 227 (M^+, base peak) and 77 (77).

Found: C, 73.97; H. 5.76; N, 6.26%. Calcd for $C_{14}H_{13}NO_2$: C, 73.99; H, 5.77; N, 6.16%.

2b: Yield 100%; colorless plates (benzene); mp 139—140 °C; IR (KBr) cm^{-1}: 1660 (CO); MS *m/z* (rel intensity) 255 (M^+, 40) and 91 ($C_7H_7^+$, base peak).

Found: C, 75.25; H, 6.66; N, 5.60%. Calcd for $C_{16}H_{17}NO_2$: C, 75.27; H, 6.71; N, 5.49%.

2c: Yield 99%; colorless prisms (benzene); mp 139—140 °C; IR (KBr) cm^{-1}: 1660 (CO); MS *m/z* (rel intensity) 317 (M^+, 48) and 91 ($C_7H_7^+$, base peak).

Found: C, 79.44; H, 6.05; N, 4.55%. Calcd for $C_{21}H_{19}NO_2$: C, 79.47; H, 6.03; N, 4.41%.

The ^{1}H NMR spectral data for **2** are demonstrated in Table 1.

Reaction of Oxiranes 2 with Amines. Typical Procedure: A mixture of 300 mg (1.32 mmol) of **2a** and 710 mg (6.64 mmol) of benzylamine (**3**) in dry THF (10 mL) was stirred in the presence of 10 g of the neutral alumina for 6 h at room temperature. The alumina was filtered off and washed with methanol. The filtrate was collected and evaporated to dryness. The residue was subjected to column chromatography on silica gel (chloroform) to give 280 mg (63%) of **5a**.

5a: Colorless needles (ethanol); mp 186—188 °C; IR (KBr) cm^{-1}: 3320 (OH), 3280 (NH), and 1650 (CO); ^{1}H NMR ($CDCl_3$) δ=1.56 (1H, m, 4-Hb), 2.16 (1H, m, 3a-H), 2.4—3.2 (3H, ov, 4-Ha, OH, and NH), 3.24 (1H, m, 6-H), 3.45 (1H, t, 3-Hb, $J_{gem}=J_{3-3a}$=9.5 Hz), 3.84 (1H, m, 3-Ha), 3.92 (2H, s, $-CH_2-$Ph), 4.05 (1H, m, 5-H), 6.55 (1H, br s, 7-H), and 7.0—7.8 (10H, m, phenyl); MS *m/z* (rel intensity) 334 (M^+, 6), 290 (M^+-CH_3CHO, base peak), 199 (290—CH_2Ph, 46), and 77 (92).

Found: 75.61; H, 6.70; N, 8.37%. Calcd for $C_{21}H_{22}N_2O_2$: C, 75.42; H, 6.63; N, 8.38%.

5b: Yield 73%; colorless needles (ethanol); mp 197—199 °C; IR (KBr) cm^{-1}: 3320 (OH), 3270 (NH), and 1640 (CO); ^{1}H NMR ($CDCl_3$) δ=1.04 (3H, d, CH_3, J=8.5 Hz), 1.54 (1H, m, 4-H), 2.4—2.9 (3H, ov, 3a-H, NH, and OH), 2.90

Found: *m/z* 343.2147. Calcd for $C_{21}H_{29}NO_3$: M, 343.2146.

11: Colorless plates (ethanol); mp 180—182 °C; IR (KBr) cm^{-1}: 3380—3320 (OH) and 1660 (CO); ^1H NMR ($CDCl_3$) δ=1.06 (3H, d, CH_3, J=7.1 Hz), 1.70 (1H, m, 4-H), 2.6—3.1 (2H, ov, 3a-H and OH), 2.97, 3.49 (1H each, 2t, 3-Hb and -Ha, $J_{gem}=J_{3-3a}=7.7$ Hz), 3.8 (1H, m, 5-H), 4.14 (1H, br d, OH, J=4.9 Hz), 4.24 (1H, m, 6-H), 4.58 (2H, s, $-CH_2-Ph$), 6.52 (1H, br s, 7-H), and 7.35 (5H, m, phenyl); MS *m/z* (rel intensity) 273 (M^+, 23), 215 ($M^+-CH_3CH_2CHO$, 23), 124 (215—CH_2Ph, 11), and 91 ($C_7H_7^+$, base peak).

Found: C, 70.50; H, 7.08; N, 5.20%. Calcd for $C_{16}H_{19}NO_3$: C, 70.31; H, 7.01; N, 5.13%.

Reaction of 2 with Sodium Azide (12). Typical Procedure: A mixture of 500 mg (2.20 mmol) of **2a** and 160 mg (2.46 mmol) of **12** in aqueous THF (20 mL) was stirred for 5 h at room temperature. The reaction mixture was extracted with chloroform (20 mL×3) and the organic layer was evaporated to dryness. The residue was subjected to column chromatography on silica gel with chloroform–ethyl acetate (3/1) elution to give 400 mg (67%) of **13a**.

13a: Colorless prisms (chloroform); mp 132—133 °C; IR (KBr) cm^{-1}: 3370 (OH), 2080 (N_3), and 1660 (CO); ^1H NMR ($CDCl_3$) δ=1.5 (1H, m, 4-Hb), 2.12 (1H, m, 3a-H), 3.1—3.6 (2H, ov, 4-Ha and OH), 3.63, 4.08 (1H each, 2t, 3-Hb and -Ha, $J_{gem}=J_{3-3a}=8.3$ Hz), 4.03 (1H, br s, 5-H), 4.28 (1H, br s, 6-H), 6.65 (1H, br s, 7-H), and 7.2—7.9 (5H, m, phenyl); MS *m/z* (rel intensity) 270 (M^+, 69), 229 (31), 228 (M^+-N_3, 28), and 77 (base peak).

Found: C, 62.00; H, 5.28; N, 20.68%. Calcd for $C_{14}H_{14}N_4O_2$: C, 62.21; H, 5.22; N; 20.73%.

13b: Yield 74%; colorless prisms (ethanol); mp 74—76 °C; IR (KBr) cm^{-1}: 3230 (NH), 2050 (N_3), and 1640 (CO); ^1H NMR ($CDCl_3$) δ=1.08 (3H, d, CH_3, J=9.0 Hz), 1.56 (1H, br dq, 4-H, $J_{3a-4}=11.8$ and $J_{4-Me}=9.0$ Hz), 2.89 (1H, m, 3a-H), 2.96, 3.49 (1H each, 2t, 3-Hb and -Ha, $J_{gem}=J_{3-3a}=10.7$ Hz), 3.07 (1H, br s, OH), 3.89 (1H, br s, 5-H), 4.07 (1H, br s, 6-H), 4.47, 4.70 (1H each, 2d, $-CH_2-Ph$, $J_{gem}=16.9$ Hz), 6.50 (1H, br s, 7-H), and 7.2—7.5 (5H, m, phenyl); MS *m/z* (rel intensity) 298 (M^+, 21), 256 (M^+-N_3, 98), and 91 ($C_7H_7^+$, base peak).

Found: C, 64.51; H, 6.08; N, 18.85%. Calcd for $C_{16}H_{18}N_4O_2$: C, 64.41; H, 6.08; N, 18.78%.

13c: Yield 65%; colorless prisms (ethanol); mp 160—162 °C; IR (KBr) cm^{-1}: 3290 (OH), 2090 (N_3), and 1660 (CO); ^1H NMR ($CDCl_3$) δ=2.70 (1H, m, 4-H), 2.90, 3.40 (1H each, 2t, 3-Hb and -Ha, $J_{gem}=J_{3-3a}=9.2$ Hz), 3.0—3.8 (2H, ov, 3a-H and OH), 4.10 (1H, br s, 5-H), 4.24 (1H, br s, 6-H), 4.45, 4.68 (1H each, 2d, $-CH_2-Ph$, $J_{gem}=16.0$ Hz), 6.62 (1H, br s, 7-H), and 7.2—7.6 (10H, m, phenyl); MS *m/z* (rel intensity) 360 (M^+, 18), 318 (M^+-N_3, 89) and 91 ($C_7H_7^+$, base peak).

Found: C, 69.81; H, 5.66; N, 15.68%. Calcd for $C_{21}H_{20}N_4O_2$: C, 69.98; H, 5.59; N, 15.55%.

Reaction of 2 with Lithium (Cyano-*C*)methylcuprate (14). Typical Procedure: To a mixture of 580 mg (6.5 mmol) of cuprous cyanide and 10 mL of THF, 6.4 mmol of methyllithium was added under nitrogen atmosphere at −78 °C. The temperature was slowly raised to −30 °C, and 500 mg (2.2 mmol) of **2a** in THF (2 mL) was injected into the reaction mixture. The mixture was stirred at the same temperature for an additional one hour, then warmed up to 0 °C and kept at that temperature for 6 h. The mixture was made acidic with conc. hydrochloric acid and extracted with dichloromethane (20 mL×3). The organic layer was collected and evaporated to dryness. The residue was subjected to column chromatography on silica gel (chloroform–ethyl acetate: 4/1) to give 180 mg (32%) of **15a** and 50 mg (9%) of **16a**.

15a: Colorless needles (ethanol); mp 163—164 °C; IR (KBr) cm^{-1}: 3400 (OH) and 1670 (CO); ^1H NMR ($CDCl_3$) δ=1.05 (3H, d, CH_3, J=8.0 Hz), 1.40 (1H, ddd, 4-Hb, J_{gem}=12.6, J_{3a-4}=11.2, and J_{4-5}=2.0 Hz), 2.16 (1H, ddd, 4-Ha, J_{gem}=12.6, J_{3a-4}=5.7, and J_{4-5}=4.8 Hz), 2.45 (1H, m, 6-H), 2.67 (1H, br d, OH, J=4.0 Hz), 3.18 (1H, m, 3a-H), 3.49, 3.95 (1H each, 2t, 3-Hb, and -Ha, J_{gem}=J_{3-3a}=8.8 Hz), 3.98 (1H, m, 5-H), 6.49 (1H, t, 7-H, J_{3a-7}=J_{6-7}=2.8 Hz), and 7.1—7.5 (5H, m, phenyl); MS *m/z* (rel intensty) 243 (M^+, base peak), 200 (24), 199 (M^+−CH_3CHO, 71), and 77 (52).

Found: C, 73.88; H, 7.16; N, 5.86%. Calcd for $C_{15}H_{17}NO_2$: C, 74.05; H, 7.04; N, 5.76%.

16a: Colorless oil; IR (Neat) cm^{-1}: 3380 (OH) and 1680 (CO); ^1H NMR ($CDCl_3$) δ=1.10 (3H, s, CH_3), 2.02 (1H, m, 4-Hb), 2.13 (1H, dd, 4-Ha, J_{gem}=15.7 and J_{3a-4}=7.0 Hz), 2.2—2.7 (2H, ov, 3a-H and OH), 3.5—3.6 (2H, ov, 3-Ha and -Hb), 4.36 (1H, br s, 5-H), 5.72 (1H, dd, 6-H, J_{5-6}=5.0 and J_{6-7}=11.7 Hz), 6.44 (1H, d, 7-H, J_{6-7}=11.7 Hz), and 7.0—7.7 (5H, m, phenyl); MS *m/z* (rel intensity) 243 (M^+, base peak), 228 (M^+−CH_3, 7), 106 (62), and 77 (44).

Found: *m/z* 243.1254. Calcd for $C_{15}H_{17}NO_2$: M, 243.1258.

15b: Colorless oil; IR (Neat) cm^{-1}: 3400 (OH) and 1660 (CO); ^1H NMR ($CDCl_3$) δ=1.06 (3H, d, CH_3, J=7.1 Hz), 1.39 (1H, m, 4-H), 2.4—3.1 (4H, ov, 3-Hb and -Ha, 3a-H, and 6-H), 3.50 (1H, br s, OH), 3.66 (1H, m, 5-H), 4.44, 4.74 (1H each, 2d, $-CH_2$-Ph, J_{gem}=15.4 Hz), 6.47 (1H, br s, 7-H), and 7.2—7.6 (5H, m, phenyl); MS *m/z* (rel intensity) 271 (M^+, 84), 214 (57), 213 (M^+−CH_3CH_2CHO, 25), 122 (11), and 91 ($C_7H_7^+$, base peak).

Found: *m/z* 271.1573. Calcd for $C_{17}H_{21}NO_2$: M, 271.1571.

15c: Colorless prisms (ethanol); mp 176—177 °C; IR (KBr) cm^{-1}: 3310 (OH) and 1660 (CO); ^1H NMR ($CDCl_3$) δ=1.19 (3H, d, CH_3, J=7.7 Hz), 2.23 (1H, m, 4-H), 2.5—2.8 (2H, ov, 6-H and 3a-H), 2.83, 3.38 (1H each, 2t, 3-Hb and -Ha, J_{gem}=J_{3-3a}=9.2 Hz), 3.58 (1H, br s, OH), 3.83 (1H, m, 5-H), 4.45, 4.67 (1H each, 2d, $-CH_2$-Ph, J_{gem}=15.7 Hz), 6.58 (1H, t, J_{3a-7}=J_{6-7}=3.0 Hz), and 7.2—7.5 (10H, m, phenyl); MS *m/z* (rel intensity) 333 (M^+, 47), 214 (73), 213 (M^+−$PhCH_2CHO$, 10), and 91 ($C_7H_7^+$, base peak).

Found: C, 79.45; H, 6.98; H, 4.51%. Calcd for $C_{22}H_{23}NO_2$: C, 79.25; H, 6.95; N, 4.20%.

Formation of Oxirane 18 and Its Ring Opening Reaction with Nucleophiles 4, 12, and 14. The oxidation of **17** with MCPBA was performed in a similar manner to that of **1** with the exception of reaction temperature (below 0 °C).[13]

18: Colorless oil; IR (Neat) cm^{-1}: 1600 (CO); ^1H NMR ($CDCl_3$) δ=1.42 (1H, m, 5-Hb), 1.55 (1H, m, 4-Hb), 1.86 (1H, m, 4-Ha), 2.40 (1H, ddd, 5-Ha, J_{gem}=14.2, J_{4-5}=8.4, and J_{5-6}=3.3 Hz), 2.55 (1H, m, 4a-H), 3.21 (1H, ddd, 3-Hb, J_{gem}=13.9, J_{3-4}=5.7, and J_{3-4}=3.2 Hz), 3.33 (1H, ddd, 3-Ha, J_{gem}=13.9. J_{3-4}=12.6, and J_{3-4}=3.7 Hz), 3.48 (1H, t, 7-H, J_{6-7}=J_{7-8}=4.5 Hz), 3.59 (1H, dd, 6-H, J_{5-6}=3.3 and J_{6-7}=4.5 Hz), 4.55, 4.76 (1H each, 2d, $-CH_2$-Ph, J_{gem}=16.2 Hz), and 7.2—7.4 (6H, ov, 8-H and phenyl); MS *m/z* (rel intensity) 255 (M^+, 45), 164 (M^+−CH_2Ph, 8), and 91 ($C_7H_7^+$, base peak).

Found: *m/z* 255.1264. Calcd for $C_{16}H_{17}NO_2$: M, 255.1258.

The ring opening reactions of **18** with **4**, **12**, and **14** were performed in similar manners to those of the corresponding reactions of oxirane **2**.

19: Colorless prisms (ethanol); mp 156—158 °C; IR (KBr) cm^{-1}: 3390 (OH) and 1610 (CO); ^1H NMR ($CDCl_3$) δ=1.25 (1H, m, 5-Hb), 1.5—2.1 (7H, ov, 4-Ha and -Hb, 5-Ha, and pyrrolidinyl), 2.5—2.9 (5H, ov, 4a-H and pyrrolidinyl), 3.18 (1H, m, 3-Hb), 3.2—3.6 (3H, ov, 3-Ha, 7-H, and OH), 4.02 (1H, m, 6-H), 4.76 (2H, s, $-CH_2$-Ph), 7.15 (1H, br s, 8-H), and 7.3—7.6 (5H, m, phenyl); MS *m/z* (rel intensity) 326 (M^+, 41), 282 (M^+−CH_3CHO, base peak), 191 (282−CH_2Ph, 76), and 91 ($C_7H_7^+$, 89).

Found: C, 73.49; H, 8.21; N, 8.30%. Calcd for $C_{20}H_{26}N_2O_2$: C, 73.59; H, 8.03; N, 8.58%.

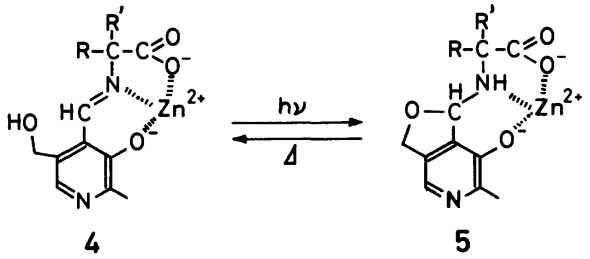
Photochromic Behavior of Pyridoxal-α-Amino Acid-Zn(II) Complexes in Methanol

Kazuya OHGA* and Yoshiaki KURAUCHI
Department of Environmental Chemistry and Engineering, Oita University,
Dannoharu, Oita 870-11
(Received March 13, 1987)

Zn(II) complexes of pyridoxal-α-amino acid Schiff bases showed photochromic behavior in methanol. Spectral studies revealed that intramolecular nucleophilic attack of 5′-hydroxyl group on imine linkage forms cyclic α-amino ether intermediates which thermally return to the original complexes. The photochromism was characteristic of complexes having a 1:1 ligand-metal ratio. Analogous photochromism was also observed with the Cd(II) complex of *N*-pyridoxylidenevaline having a fully occupied d-orbital like the Zn(II) complexes, whereas no photochromism was observed with other transition metal complexes such as Ni(II), Cu(II), Mn(II), and Co(II) complexes.

We have previously reported that Zn(II) complexes of Schiff bases derived from pyridoxal-5′-phosphate and α-amino acids exhibit photochromism in an aqueous solution.[1] The photochromism is caused by photoinduced hydrolysis of the Schiff base ligands, as delineated in Scheme 1. This nucleophilic attack of water on imine carbon made us presume that an intramolecular nucleophilic attack will occur in 5′-hydroxyl group of pyridoxal-α-amino acid-Zn(II) complexes (Scheme 2).

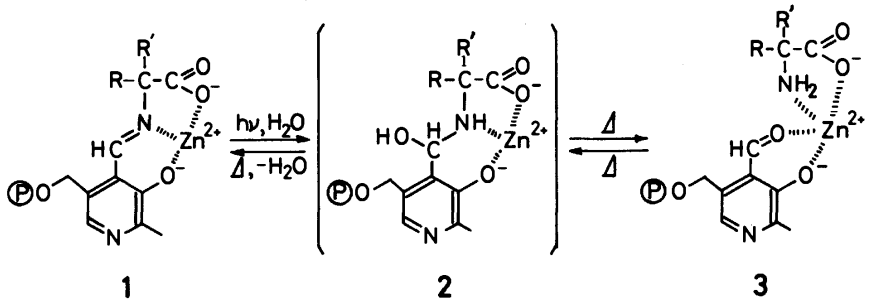
The best-known cyclic ether analogous to the cyclization product **5** is the hemiacetal form of pyridoxal (PL) which is in equilibrium with the aldehyde form in solution and predominant in acidic and neutral methanol solutions.[2] Most metal complexes of PL-α-amino acid Schiff bases, on the other hand, exist exclusively in the imine form.[3] Cyclic isomer **5** is assumed to be thermally unstable so as to return to the original isomer **4**. This report describes spectral examination to confirm the photochromic mechanism. We will further discuss the difference in photochemical behavior between 1:1 (ligand-metal ratio) and 2:1 complexes. The effect of acid on the photochromism will also be examined.



Scheme 2.

Experimental

PL hydrochloride (Sigma Chem. Co.) was converted to free base in the same manner as described by Christensen.[4] Bis(*N*-pyridoxylidenevalinato)zinc(II) (bis[*N*-(3-hydroxy-5-hydroxymethyl-2-methyl-4-pyridylmethylene)valinato]zinc-(II)) was prepared according to the procedure of Christensen[4] except for the use of zinc perchlorate and KOH instead of chloride and NaOH. 5′-Deoxypyridoxal (3-hydroxy-2,5-dimethyl-4-pyridinecarbaldehyde; 5′-DPL) was prepared by a five-step synthesis[5] starting from pyridoxine hydrochloride (3-hydroxy-4,5-dihydroxymethyl-2-methylpyridine hydrochloride) and was purified by sublimation at 80 °C (mp 108—109 °C). α-Amino acids (Wako Pure Chem. Co.)[6] and metal perchlorates (Kishida Chem. Co.) of the reagent grade or better were used without further purification. Acetonitrile and methanol (Dojin Chem. Co.) of the spectral grade were used as received. UV absorption and fluorescence spectra were recorded on a Shimadzu UV 202 or a JASCO UVIDEC-610A spectrophotometer and a Shimadzu RF-510 spectrometer, respectively. ^{1}H NMR spectra were obtained by a Hitachi R-24B spectrometer with tetramethylsilane as an internal standard. IR spectra were obtained by a Hitachi 285S spectrophotometer using KBr disk method.



Scheme 1.

UV Spectral Studies. Metal complexes of PL-α-amino acid Schiff bases for UV studies were prepared in situ unless otherwise noted. A methanolic solution of the PL free base was mixed with α-amino acids dissolved in methanol with an equimolar KOH. After 1 h, a solution of a given metal perchlorate in methanol was added to the yellow Schiff base solution. The concentration of amino acids and metal perchlorates was 5 and 10 times as high as that of PL (1.0×10^{-4} M (1 M=1 mol dm^{-3})), respectively. The use of excess amino acids and metal ions was required to complete the complex formation promptly. Methanolic solutions of the Zn(II) complexes of 5'-DPL-α-amino acid Schiff bases were also prepared in situ in the similar manner. The solutions showed almost the same UV spectra as those of the PL complexes.

The metal complex solutions thus obtained were deaerated by repeated evacuation and flushing with argon three or more times, placed in a 1-cm quartz spectrophotometric cell, and then irradiated with a 500-W super high-pressure mercury lamp (Ushio USH-500D) at room temperature through a filter system composed of a glass filter (Toshiba UV-39) and water in a 5-cm cylindrical cell with quartz windows. After the irradiation, the UV absorption spectra were recorded at appropriate time intervals.

Desired acid or base species of the Zn(II) complexes, when necessary, were obtained by adding standard methanolic solutions of $HClO_4$ or KOH.

^{1}H NMR Spectral Studies of PL-Valine-Zn(II) System. A weighed amount of $Zn(ClO_4)_2\cdot6H_2O$ was dissolved in D_2O and the D_2O solution was evaporated to dryness. After this procedure was repeated several times, the residue was dissolved in CD_3OD. CD_3OD solution of zinc perchlorate thus obtained (1.0 M, 0.1 cm^3) was added to a suspension of 63 mg of bis(*N*-pyridoxylidenevalinato)zinc(II) in 0.5 cm^3 CD_3OD, and the complex was dissolved completely. The complete dissolution of 2:1 complex by the addition of Zn^{2+} implies that 1:1 complex is more soluble in methanol than 2:1 complex. To the clear solution was added 0.08 cm^3 of a CD_3OD solution of KOD (1.0 M) in order to slow down a thermal back reaction; the retardation will be mentioned later. At this time, a small amount of pale yellow precipitate was separated out.[7] After standing for 30 min, the precipitate was filtered out. The resulting clear solution was devided into two parts, and each part was transferred to a Pyrex tube (18 mm diameter) and deaerated by the method described above. The tubes were then dipped in water (20.0±0.5 °C) and irradiated separately with the same Hg lamp as used in the UV studies without any glass filters. In order to ensure efficient mixing, the sample tubes were slanted and rotated while being irradiated. After the irradiation, the photolysates were transferred quickly to NMR sample tubes and NMR spectra were taken at ambient temperature at appropriate time intervals. The spectral changes of two samples in lower and higher magnetic fields were examined. This procedure was required to obtain more unambiguous signals of a photochemically produced intermediate and to follow their momentary changes.

Isolation of Intermediate. When the above sample for the NMR measurement was not efficiently agitated during the irradiation, a small amount of precipitate was deposited on the inner wall of Pyrex tube. The precipitate, which is an intermediate formed in the photochromic change as will be described later, disappeared within 10 min on standing at room temperature. In order to isolate it, an analogous CH_3OH solution of the Zn(II) complex was irradiated without agitation at a low temperature (ca. 0 °C) and the photolysate was quickly centrifuged. The precipitate clinging to the bottom of the centrifuge glass tube was dried in vacuo and used for IR measurement in that condition. No attempt to isolate the intermediate was successful.

Determination of Quantum Yield. The quantum yield for the disappearance of the starting complex **4** determined by means of an optical-bench system equipped with Ushio USH-500D lamp at 25±1 °C. A beam of 365 nm band isolated with a monochromator (Shimadzu, Baush & Lomb, Grating 1350 grooves/mm) was devided into two beams by a beam splitter, one of which was used to monitor the intensity of incident light. Another beam was used to irradiate the same sample solutions as UV studies in a cylindrical quartz cell of 20×10 mm. The number of photons (2.2×10^{15} quanta s^{-1}) absorbed by the sample solutions was evaluated by subtracting the intensity of transmitted light from that of incident light. The light intensity was determined by the trioxalatoferrate(III) actinometry using 0.006 M potassium trioxalatoferrate(III).[8] The thermal recovery of absorbance at λ_{max} (382—384 nm) obeyed the first-order kinetics. The amount of **4** regenerated during the irradiation was ignored, because it was less than 5% of the amount of **4** reduced by the irradiation.

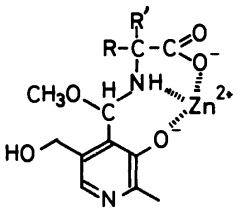
Relative Fluorescence Intensity. The relative fluorescence intensity at 465 nm of the Zn(II) complex of *N*-pyridoxylidenevaline ([PL]=1.0×10^{-4} M) was measured at 25±1 °C with an excitation wavelength of 385 nm.

Results and Discussion

UV Spectral Studies. Irradiation of a methanolic solution of the Zn(II) complex of *N*-pyridoxylidenevaline with light of wavelengths longer than 390 nm led to an immediate decrease in intensity of absorption bands at 384 and 271 nm and a new absorption band with the maximum wavelength at 314 nm appeared (Fig. 1). When the photolysate was kept in the dark, the UV spectrum returned more than 98% of its initial figure within 60 min at room temperature and showed two isosbestic points at 287 and 333 nm. Almost the same spectral changes were observed with other α-amino acids. The spectral data are summarized in Table 1 together with the quantum yield for photoinduced disappearance of the starting complexes.[9] It is noted that glycine, phenylalanine, homoserine, and serine, in common, gave a weak but discernible shoulder at about 250 nm. In the cases of alanine, valine, α-aminoisobutyric acid, and methionine, this absorption band seems to be buried in an intense band at a shorter wavelength of about 230 nm.

The divalent metal complexes of Schiff bases derived from PL and α-amino acids usually have two characteristic absorption bands in UV region; the longer wavelength band at about 390 nm has been

called the π_1 band and the shorter one at about 270 nm the π_2 band.[2a] These bands are assigned as π-π^* transitions of the extended conjugated system formed from pyridine ring, phenolic oxygen and imine linkage. The lack of the conjugated imine linkage, on the other hand, causes shift of these absorption bands to a shorter wavelength. For example, the π_1 and π_2 bands of the Zn(II) complex of pyridoxamine (4-aminomethyl-3-hydroxy-5-hydroxymethyl-2-methylpyridine) appear at 301 and 240 nm, respectively;[2a] those of the Zn(II) complex of an α-hydroxy amine derived from PL and *N*-methylglycine appear at 316 and 248 nm, respectively.[3c] Thus, the appearance of new absorption bands at about 315 and 250 nm suggests the transformation of imine linkage to a saturated C-N bond. This result seems to agree with the prediction outlined in Scheme 2; however, the formation of an α-amino ether **6** by nucleophilic addition of solvent molecule to imine carbon can also be envisaged.



6

Table 1. Photochromism of the Zn(II) Complexes of PL-α-Amino Acid Schiff Bases **4** in Methanol[a]

α-Amino acid	λ_{max}/nm		Isosbestic points/nm	Quantum yield[b]
	Before irradiation	Just after irradiation		
Glycine	384, 270	316, ca. 250[c]	336, 287	0.22
Alanine	383, 269	314	334, 285	0.17
Valine	384, 271	314	333, 287	0.19
Phenylalanine	384, 273	316, ca. 250[c]	337, 290	0.23
AIB[d]	382, 270	310	332, 284	0.18
Methionine	383, 278	315	335, 290	0.05
Homoserine	382, 281	316, ca. 250[c]	335, 290	0.17
Serine	382, 279	315, ca. 250[c]	336, 292	0.20

a) The initial concentrations of PL, α-amino acids, Zn^{2+}, and KOH were 1.0×10^{-4}, 5.0×10^{-4}, 1.0×10^{-3}, and 5.0×10^{-4} M, respectively. b) Quantum yield for the disappearance of **4**.[9] c) Shoulder. d) α-Amino-isobutyric acid.

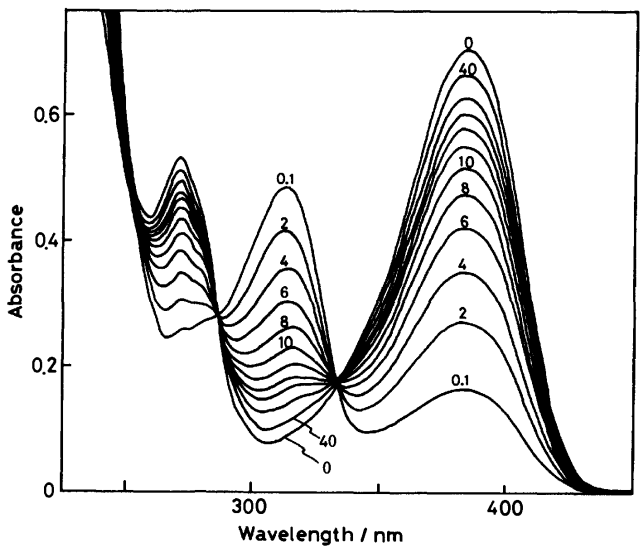


Fig. 1. UV spectral changes of the Zn(II) complex of *N*-pyridoxylidenevaline in methanol. The numeral 0 gives the spectrum before irradiation, and other numerals give the time in minutes after 1-min irradiation at the start of each scan.

IR Spectral Studies. A small amount of precipitate was obtained by irradiating more concentrated solution of the Zn(II) complex of *N*-pyridoxylidenevaline at a low temperature (see Experimental section). When the precipitate was dissolved in methanol again, almost the same thermal UV spectral changes as those in Fig. 1 were observed. This fact suggests that the precipitate is an intermediate of the photochromism.

As shown in Fig. 2(a), the IR spectrum of the intermediate showed a band at 1085 cm^{-1} which can be assigned to the C-O-C stretching vibration. In addition, the intensity of the bands due to the

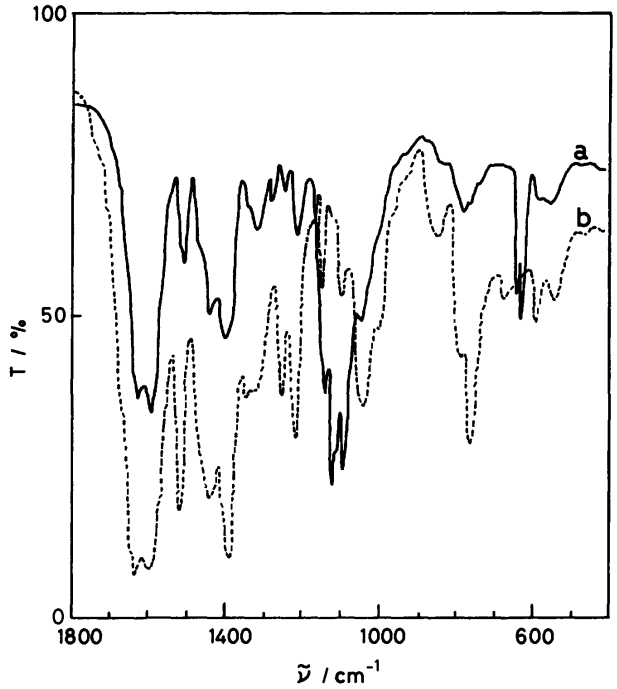

Fig. 2. Comparison of the infrared spectrum of a precipitate obtained through irradiation (a) with that of bis(*N*-pyridoxylidenevalinato)zinc(II) (b).

alcoholic 5′-OH group of bis(*N*-pyridoxylidenevalinato)zinc(II) at 1248, 1045, and 760 cm^{-1} (Fig. 2(b)) decreased remarkably.[10] These facts suggest that the formation of **5** by the intramolecular addition of 5′-OH is predominant over the formation of solvent adduct **6**. This is also supported by the following two facts from UV spectral studies: (1) The Zn(II) complexes of 5′-DPL-α-amino acid Schiff bases without 5′-OH group showed an irreversible slow photoreaction instead of photochromism; (2) almost the same photochromic spectral changes were observed in acetonitrile with low nucleophilicity.[11]

^{1}H NMR Spectral Studies. The ^{1}H NMR spectrum of the Zn(II) complex of *N*-pyridoxylidenevaline in slightly alkaline CD_3OD showed five prominent signals (Fig. 3, 0: before irradiation), which were readily assigned on the basis of data reported for several Schiff base metal complexes:[3b,7b,12] δ 8.80 (1H, s, HC=N-), 7.50 (1H, s, 6-H), 3.82 (1H, d, α-H of valine moiety), 2.55 (3H, s, 2-CH_3), and 1.08 and 0.99 (6H, d and d, CH_3 of isopropyl group). The signal of methylene proton of 5-hydroxymethyl group is probably obscured by the solvent absorption.

Figure 3 also shows that new signals appeared on irradiation and then disappeared within 10 min at ambient temperature. The UV spectral changes simultaneously observed were almost the same as those in Fig. 1.

NMR spectra by imine proton showed a marked shift with irradiation from δ 8.80 to a higher magnetic field at δ 5.85. It has been reported[13] that the imine proton resonance of *N*-pyridoxylidenehistidine at δ 8.33 shifts to a higher magnetic field at δ 5.81 by cyclization forming a tetrahydropyridine derivative. Moreover, the 4-CH signal of an α-hydroxy amine formed from PL and *N*-methylglycine appears at δ 6.09,[14] and the signals of methine protons at 2 position of various 2-phenyloxazolidine compounds appear at about δ 5.8.[15] Thus, the photocyclization to **5** described above was further confirmed by the singlet signal induced at δ 5.85 as well as by other newly-induced signals which can be readily assigned to pyridine ring proton (δ 7.62, s), the valine moiety α-proton (δ 3.48, d), the 2-methyl protons (δ 2.53, s), and the methyl protons of the isopropyl group (δ 1.12—0.94, m) of **5**.

Effects of Acid and Base on Photochromism. UV spectra of the metal complexes of PL-α-amino acid Schiff bases have two characteristic bands, i.e., the π_1 and π_2 bands described above. These bands were affected by the addition of $HClO_4$ or KOH. For example, the π_1 band (382 nm) of the Zn(II) complex of *N*-pyridoxylidenevaline in an acidic solution shifted to a longer wavelength (385 nm) with a decrease in absorbance by the addition of KOH,

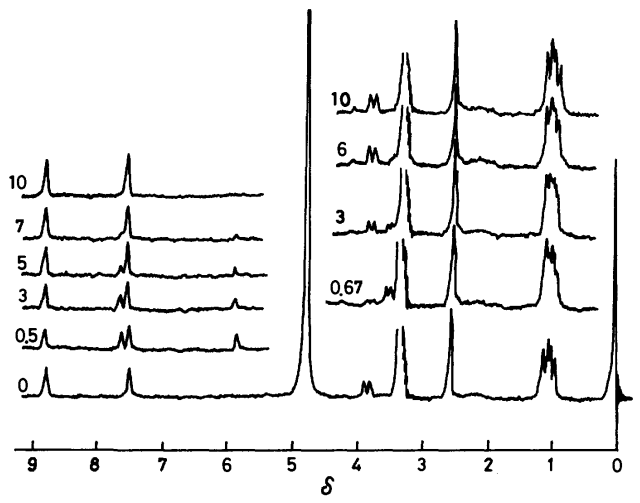

Fig. 3. ^{1}H NMR spectra of a CD_3OD solution of the Zn(II) complex of *N*-pyridoxylidenevaline. The numeral 0 gives the spectrum before irradiation and other numerals give the time in minutes after irradiation at the start of each scan. The spectra in lower and higher magnetic fields were separately taken using two samples.

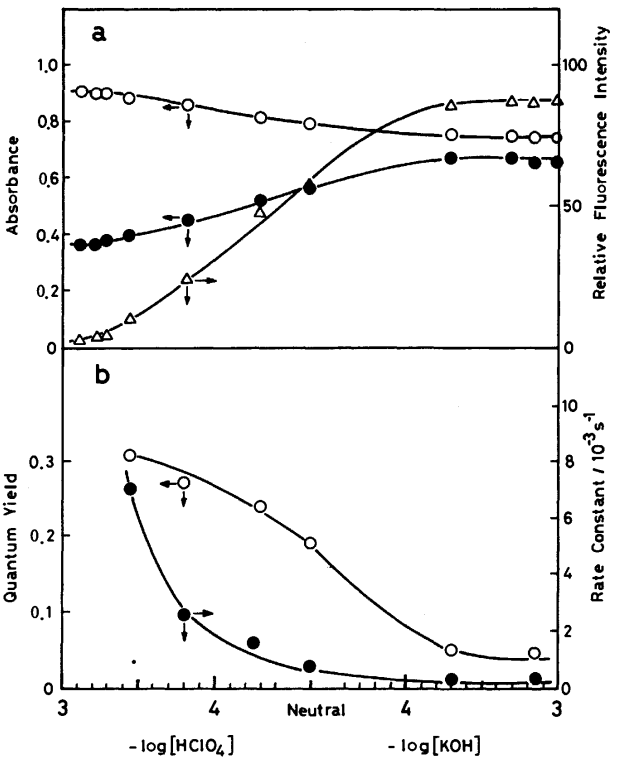

Fig. 4. (a) UV absorbance changes at 385 nm (○) and 272 nm (●) and fluorescence intensity changes (△) of the Zn(II) complex of *N*-pyridoxylidenevaline as a function of $HClO_4$ or KOH concentration in methanol. (b) Quantum yields for the disappearance of the Zn(II) complex of *N*-pyridoxylidenevaline (○) and rates of the thermal back reaction (●) as a function of $HClO_4$ or KOH concentration.

whereas the π_2 band at 280 nm shifted to a shorter wavelength (272 nm) with an increase in absorbance. Plots of the absorbances at 272 and 385 nm vs. the negative common logarithm of concentration of the added $HClO_4$ or KOH (Fig. 4(a)) gave titration curves similar to those in H_2O,[16] and can be well explained by the proton equilibrium on pyridine nitrogen. The relative fluorescence intensity also varied with adding $HClO_4$ or KOH and the resulting titration curve had an inflection point similar to that of UV absorbance (Fig. 4(a)).[17] This fact indicates that the pK value for the proton equilibrium of pyridine nitrogen in the excited singlet state is nearly equal to that in the ground state.

All solutions used for preparing the titration curves in Fig. 4(a) showed photochromic spectral changes, and the π_1 band of the intermediate occurred at 300 nm in a slightly alkaline solution (the concentration of KOH added, 5.0×10^{-5} M), whereas the band in solutions acidified with $HClO_4$ occurred at 314 nm. This difference can also be explained by the proton equilibrium on pyridine ring of the intermediate. A similar proton equilibrium has been reported for the Cu(II) complex of *N*-(3-hydroxy-5-hydroxymethyl-2-methyl-4-pyridylmethyl)valine:[18] The deprotonation of the complex causes a blue shift of the absorption maximum from 315 to 300 nm.

The quantum yield for disappearance of the Zn(II) complex of *N*-pyridoxylidenevaline became greater with an increase in the concentration of $HClO_4$ and the titration curve (Fig. 4(b)) showed an inflection point similar to those observed in UV and fluorescence spectral studies. The photocyclization seems, therefore, to be accelerated by protonation of pyridine nitrogen in the excited singlet state or in the ground state. The rate of thermal back reaction increased with an increase in the amount of $HClO_4$ added, and inversely decreased as the amount of KOH added increased (Fig. 4(b)). The rate change can be interpreted in terms of proton catalysis in a ring cleavage reaction of **5**.

Difference in Photochemical Behavior between 2:1 and 1:1 Complex. Addition of much larger amount of KOH (e.g., 1.05×10^{-2} M) caused the disappearance of photochromism, and instead, a slow irreversible spectral change took place to give a band of product with λ_{max} at 322 nm. The irreversible change was also observed in systems containing less than equimolar amount of Zn^{2+}: for example, in a system containing Zn^{2+} of 0.6×10^{-4} M and PL, valine, and KOH of 1.0×10^{-4} M.

The Zn(II) complexes of PL-α-amino acid Schiff bases exist as 2:1 form in solid state.[4,7b,15b] Gansow and Holm,[7b] on the other hand, showed by NMR analyses that 2:1 and 1:1 species co-exist in an aqueous PL-alanine-Zn(II) system and that the extent of formation of 2:1 species increases with an increase in pH. The 2:1 species is also formed in aqueous solutions containing appreciably smaller amounts of Zn^{2+} (0.016—0.05 M) than those of PL and alanine (0.1 M). These facts made us infer that the irreversible change is induced by excitation of 2:1 species, whereas the photochromism is induced by excitation of 1:1 species.

In order to ascertain this idea, the influence of Zn^{2+} on ^1H NMR spectra of the Zn(II) complex of *N*-pyridoxylidenevaline was investigated and the results are depicted in Fig. 5. A saturated solution of the Zn(II) complex in alkaline CD_3OD (0.12 M KOD) prepared by dissolving 2:1 complex showed, as a whole, upfield-shifted signals compared to those of solutions containing extraneous Zn^{2+}, indicating that the signals of 2:1 species appear in higher magnetic fields than 1:1 species. It seems important that the solution without extraneous Zn^{2+} failed to show the photochromic spectral changes as observed in a solution containing excess Zn^{2+} (Fig. 3). These results support the idea that the presence of 1:1 species is a prerequisite for the photochromism.

Irradiation of Other Metal Complexes. Photochemical behavior of *N*-pyridoxylidenevaline complexes with other divalent metal ions such as Cu^{2+}, Ni^{2+}, Co^{2+}, Mn^{2+}, and Cd^{2+} was investigated in

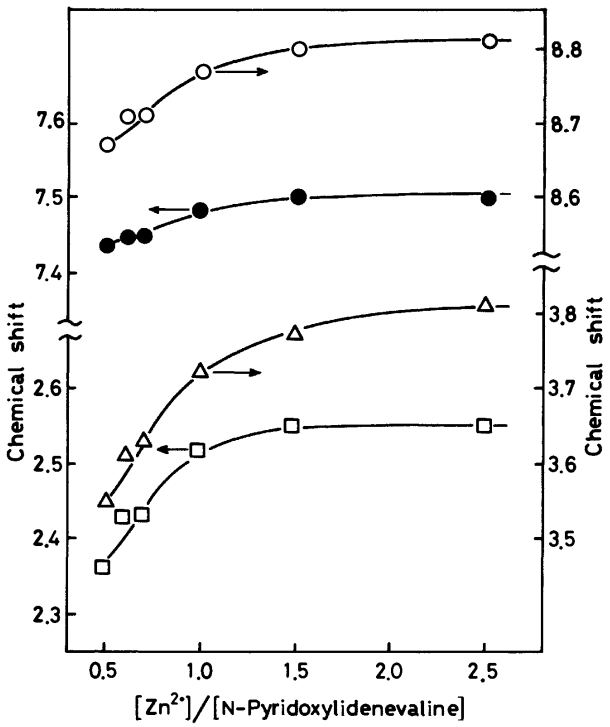

Fig. 5. ^1H NMR chemical shifts as a function of the concentration of Zn^{2+} in a methanolic solution of the Zn(II) complex of *N*-pyridoxylidenevaline ([*N*-pyridoxylidenevaline]=4.0×10^{-2} M, [KOH]=0.12 M): ○; -CH=N-, ●; ArH, △; α-H of valine moiety, □; Ar-CH_3.

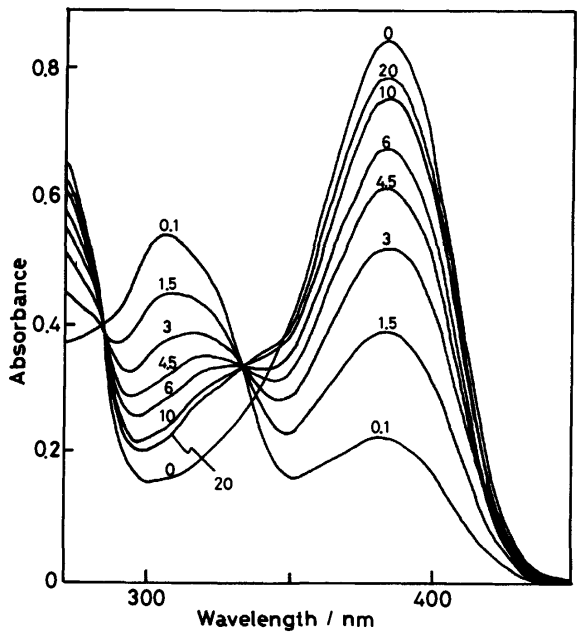

Fig. 6. UV spectral changes of the Cd(II) complex of *N*-pyridoxylidenevaline in methanol. The numeral 0 gives the spectrum before irradiation, and other numerals give the time in minutes after 3-min irradiation at the start of each scan.

methanol containing excess metal ions. The Cd(II) complex having the d^{10} electronic structure like the Zn(II) complexes showed photochromism (Fig. 6), whereas the Cu(II) and Ni(II) complexes were exceedingly photostable. For the Co(II) and Mn(II) complexes, only a slight irreversible decrease was observed in the absorbance of intraligand π–π^* bands at about 385 nm: less than 5% decrease after irradiation for 3 min. In addition, fluorescence intensity of the complexes showing no photochromism was negligibly weak in comparison with those of the photochromic Zn(II) and Cd(II) complexes. Thus, lack of photochromism in the transition-metal complexes with unfilled d-shells appears to be attributed to the presence of nonradiative processes from the intraligand π–π^* singlet state to d-d or charge-transfer excited state, although it is not yet clear whether the singlet state is photoreactive or not in the cases of the Zn(II) and Cd(II) complexes.

6) Optically-active amino acids were of L-configuration.

7) a) The precipitate appears to be a mixture of 2:1 complex, $Zn(OD)_2$, and $KClO_4$, because the IR spectrum of the precipitate was similar to that of 2:1 complex and because the addition of KOD possibly leads to deposition of $Zn(OD)_2$ and $KClO_4$. The precipitation of the complex is in harmony with the formation of a 2:1 complex at high pH in an aqueous PL–alanine–Zn(II) system,[7b] as will be discussed later in detail; b) O. A. Gansow and R. H. Holm, *J. Am. Chem. Soc.*, **90**, 5629 (1968); *ibid.*, **91**, 573 (1969).

9) As will be described later, the Zn(II) complex of *N*-pyridoxylidenevaline existed as the 1:1 form rather than 2:1 form when the concentration of Zn^{2+} was 1.5 times or above as high as that of the Schiff base ligand (see Fig. 5). Since the solutions used here contained excess Zn^{2+} ($[Zn^{2+}]/[\text{ligand}]=10$, see Experimental section), all the starting complexes probably exist as 1:1 forms.

10) Careful inspection of IR spectrum of the precipitate (Fig. 2(a)) revealed that the intermediate was contaminated with a small amount of starting complex and $Zn(ClO_4)_2$. A new band at 1110 cm^{-1} is attributed to the stretching vibration of a perchlorate anion which was added to the sample solution as zinc perchlorate.

11) a) Acetonitrile solution was prepared by mixing the crystalline 2:1 complex and zinc perchlorate at a 1:5 molar ratio. At this time, the addition of a small amount of water (2%) was required to dissolve two components. The direct participation of water in the photochromism, if any, would give an α-hydroxy amine analogous to **2** which has a UV spectrum similar to those of the cyclic ethers **5**. However, this type of α-hydroxy amine has not yet been detected,[11b] and thus is expected to be readily transformed into a mixed complex analogous to **3**.[1] Careful inspection of the spectrum just after the irradiation revealed the absence of the mixed complex which probably has a similar spectrum to that of PL, dismissing the possibility of the photohydrolysis; b) D. Hopgood and D. L. Leussing, *J. Am. Chem. Soc.*, **91**, 3740 (1969); D. L. Leussing and C. K. Stanfield, *J. Am. Chem. Soc.*, **88**, 5726 (1966).

15) H. Aoyama, M. Sakamoto, K. Kuwabara, K. Yoshida, and Y. Omote, *J. Am. Chem. Soc.*, **105**, 1958 (1983).

16) a) Davis et al.[16b] reported an increase in the absorbance of the π_1 band and a decrease in the π_2 band in H_2O by lowering pH, and obtained the pK_a value of 6.5 for the proton dissociation on the pyridine nitrogen. b) L. Davis, F. Roddy, and D. E. Metzler, *J. Am. Chem. Soc.*, **83**, 127 (1961).

17) Although the absorbances at the excitation wavelength (385 nm) decreased with a decrease in the $HClO_4$ concentration and an increase in the KOH concentration (Fig. 4(a)), the fluorescence intensity inversely increased. Thus the acid and base effects on the fluorescence intensity are somewhat underestimated.

Optical Resolution by Preferential Crystallization of DL-Thiazolidine-4-carboxylic Acid

Tadashi SHIRAIWA,* Yujin SADO, Masamitsu KOMURE, and Hidemoto KUROKAWA
Faculty of Engineering, Kansai University, Yamate-cho, Suita, Osaka 564
(Received March 19, 1987)

Infrared spectrum, solubility, and ternary solubility diagram indicated that DL-thiazolidine-4-carboxylic acid (DL-THC) is a conglomerate at room temperature. The free energy of critical nucleation in supersaturated solutions for the crystallization of D- and L-THC was examined to resolve DL-THC efficiently by preferential crystallization. Successive preferential crystallization of DL-THC was experimented at 20 °C for an aqueous racemic solution with a supersaturation of 150%, and D- and L-THC with optical purity of 96—100% were obtained in the range of resolution of 58—76%. The optical resolution was more successfully done in 1 mol dm^{-3} aqueous glycine to give D- and L-THC with optical purity of 93—99% in the degree of resolution of 77—87%. Recrystallization of D- and L-THC obtained with a succeeding treatment with hydroxylamine hydrochloride gave D- and L-cysteine with 100% optical purity.

L-Cysteine (abbreviated as L-Cys) as a useful material for medicines, food additives, and cosmetics has been obtained mainly from hair. Although D-Cys was also noted, recently, as a pharmaceutical material,[1] it is difficult to find D-Cys in natural products. An efficient synthesis of DL-Cys has been known,[2] and DL-Cys can be optically resolved by the diastereomeric procedure.[3,4] The optical resolution by a preferential crystallization seems to be more useful for an industrial purpose than the diastereomeric procedure. However, the optical resolution by preferential crystallization of DL-Cys was tried only for DL-cysteine hydrochloride monohydrate.[1] This paper describes an attempt to obtain D- and L-Cys efficiently by the preferential crystallization.

DL-Thiazolidine-4-carboxylic acid (DL-THC) was easily obtained by the reaction of DL-cysteine hydrochloride monohydrate with formaldehyde.[5] By infrared spectrum, solubility, and ternary solubility diagram, DL-THC seemed to be a conglomerate. DL-THC was subjected to optical resolution in water at 20 °C. The free energy of critical nucleation in supersaturated solutions of D- and L-THC was examined to find the appropriate conditions for optical resolution by preferential crystallization of DL-THC.[6-8] The optical resolution in 1 mol dm^{-3} aqueous glycine was also examined to obtain D- and L-THC more efficiently than in water.

Experimental

Materials. DL- and L-Cysteine hydrochloride monohydrate were purchased from Sigma Chemicals Co. and Wako Pure Chemicals Ind., respectively, and formaldehyde, hydroxylamine hydrochloride, and triethylamine from Wako Pure Chemicals Ind.

Synthesis of Thiazolidine-4-carboxylic Acid. DL- and L-Thiazolidine-4-carboxylic acid were prepared by the reaction of each cysteine hydrochloride monohydrate with formaldehyde.[5] DL-THC: Mp 195—198 °C (decomp) (lit,[9] mp 183—184 °C, 195 °C (decomp)). L-THC: Mp 202—204 °C (decomp) (lit,[9] mp 196—197 °C, 205—209 °C (decomp)); $[\alpha]_D^{20}$ −141° (*c* 1.00, water) (lit,[9] $[\alpha]_D^{20}$ −141° (water)).

D-THC of 37.5% optical purity was obtained from the mother liquor in optical resolution of DL-THC. After dissolving 26.64 g of D-THC in 280 cm^3 of water at an elevated temperature, and the solution was stirred for 1 h at 20 °C. The precipitated D-THC was collected by filtration, washed with a small amount of cold water and ethanol successively, and dried to give 9.88 g of optically pure D-THC; mp 202—204 °C (decomp); $[\alpha]_D^{20}$ +141° (*c* 1.00, water).

Optical Resolution. Preferential Crystallization: DL-THC was dissolved in 50 cm^3 of water at 40 °C to give racemic solutions with different degrees of supersaturation from 120 to 170% (20 °C) as shown in Table 1. The solution was slowly cooled to 20 °C and seeded with 0.050 g of L-THC. After stirring the mixture at 100 rpm and 20 °C, the precipitated L-THC was collected by filtration, washed with a small amount of ethanol, and dried. The optical purity, yield of optically pure modification (YOPM/g), degree of resolution of L-THC, and amounts of crystallization of D- and L-THC (W_D and W_L/g) were determined by

$$\text{Optical purity}/\% = (\text{Specific rotation of obtained THC}/^\circ \times 100)/(-141), \quad (1)$$

$$\text{YOPM/g} = (\text{Yield/g} \times \text{Optical purity}/\%)/100 - 0.050, \quad (2)$$

Table 1. Preparation of Supersaturated Solution in Water[a]

Degree of supersaturation[b]/%	Amount of DL-THC[c]/g
120	3.586
130	3.885
140	4.184
145	4.333
150	4.483
155	4.632
160	4.782
170	5.080

a) Water: 50 cm^3. b) Temperature: 20 °C. c) DL-THC: DL-Thiazolidine-4-carboxylic acid.

$$\text{Degree of resolution}/\% = (\text{YOPM/g} \times 100)/(1/2)(\text{Amount of consumed DL-THC/g} - 2.989), \quad (3)$$

$$W_D/\text{g} = (1/2)(\text{Yield/g} - \text{YOPM/g} - 0.050), \quad (4)$$

$$W_L/\text{g} = \text{YOPM/g} + W_D/\text{g}. \quad (5)$$

Successive Preferential Crystallization: DL-THC was dissolved in 50 cm^3 of water or 1 mol dm^{-3} aqueous glycine at 40 °C; 4.483 g in water (150% supersaturation) and 4.710 g in 1 mol dm^{-3} aqueous glycine (155% supersaturation). The solution was cooled to 20 °C and seeded with 0.050 g of L-THC. After stirring the mixture at 100 rpm and 20 °C, the precipitated L-THC was collected by filtration. DL-THC was dissolved in the filtrate at 40 °C; the amount was equal to that of crystallized THC. After seeding the solution with 0.050 g of D-THC at 20 °C, the mixture was treated similarly as above. The degree of resolution of D- and L-THC was calculated by

$$\text{Degree of resolution}/\% = (\text{YOPM/g} \times 100)/(\text{Operation amount of D- or L-THC/g} - M), \quad (6)$$

where M is 1.494 g in water, and 1.520 g in 1 mol dm^{-3} aqueous glycine.

The optical resolution was also performed for a solution containing 26.892 g of DL-THC in 300 cm^3 of water using 0.300 g of D- or L-THC as seed crystals; the supersaturation of the initial solution was 150%.

Preparation of Optically Active Cysteine. A mixture of D- or L-THC recrystallized from water (1.332 g, 0.010 mol) and 0.732 g (0.010 mol) of hydroxylamine hydrochloride in 50 cm^3 of methanol was refluxed for 60 min. After adding 0.366 g (0.005 mol) of hydroxylamine hydrochloride to the mixture and refluxing for 60 min, the solution was stirred in an ice bath for 60 min. The formed formaldehyde oxime was removed by filtration, and pH of the filtrate was adjusted to 5—6 with triethylamine. Precipitated crude Cys (0.02 g) was filtered out; $[\alpha]_D^{20}$ +18.7 or −18.0° (water). After drying the filtrate under reduced pressure at 30 °C, the residue was added to 50 cm^3 of methanol. The mixture was stirred for 1 h at 40 °C and insoluble Cys was filtered, washed with methanol, and dried. D-Cys: Yield 0.989 g; $[\alpha]_D^{20}$ +16.5° (*c* 2.00, water). L-Cys: Yield 0.995 g; $[\alpha]_D^{20}$ −16.5° (*c* 2.00, water) (lit,[10] $[\alpha]_D$ −16.5° (water)).

Measurements. The specific rotation was measured by a Union Giken PM-101 digital polarimeter with a quartz cell of 0.5 dm path length. The infrared spectra were obtained in the range 4000—400 cm^{-1} by a JASCO A-102 infrared spectrophotometer using the KBr disk method.

Results and Discussion

Racemic Structure. DL-THC shows identical infrared spectrum with that of L-THC and is more soluble than L-THC as described in Table 2. The ternary solubility diagram is shown in Fig. 1.

The above results infer that DL-THC is a conglomerate at room temperature.[11]

Preferential Crystallization. Since DL-THC was optically resolved by preferential crystallization in 50 cm^3 of water at 20 °C in the presence of 0.050 g of L-THC seed crystals, as shown in Table 3, DL-THC was confirmed to be a conglomerate at room temperature. Relationships between the amounts of crystallization of D- and L-THC and the resolution

time are shown in Fig. 2 for the solutions of supersaturation of 130, 140, and 160%, where the solvent is 50 cm^3 of water.

After a rapid crystallization in extremely short time, L-THC appears to crystallize at a constant speed with respect to the increase in resolution time. The speed of crystallization of L-THC (R_L/g min^{-1}) and the amount of crystallization extrapolated to zero resolution time (W_0/g) were calculated from linear plots in Fig. 2 for different degrees of supersaturation; the correlation coefficient of the linear relationships ranges from 0.989 to 0.997. The retardation time for crystallization of D-THC (Θ_D/min), defined as the resolution time until D-THC begins to crystallize rapidly, was estimated from Fig. 2. Although Fig. 2 indicates that D-THC co-exists in L-THC crystallized in shorter resolution time than Θ_D, DL-THC adhered on precipitates should have been considered in the estimation. These factors on crystallization of D- and L-THC are given in Table 4.

Optical Resolution by Preferential Crystallization. Relationship between Factors Controlling Crystallization and Free Energy of Critical Nucleation: In our previous paper,[8] it was reported that the

appropriate conditions for the optical resolution by preferential crystallization is predictable by the free energy of critical nucleation (Δg_{max}/J nucleus^{-1}) in supersaturated solutions. The values of Δg_{max} were calculated for aqueous solutions of DL-THC with various degrees of supersaturation,[6-8,12)] and given in Table 5. The relationship between R_L and Δg_{max} for different degrees of supersaturation of 130, 140, and 160% and that between Θ_D and Δg_{max} were obtained by Eqs. 7 and 8,[8)] respectively,

$$\ln R_L = -1.766 \ln \Delta g_{max} - 74.19, \quad (7)$$

$$\ln \theta_D = 1.707 \ln \Delta g_{max} + 70.64, \quad (8)$$

where the correlation coefficients for Eqs. 7 and 8 were 0.995 and 0.997, respectively. The relationship between W_0 and Δg_{max} is expressed by Eq. 9

$$\ln W_0 = -0.3543 \ln \Delta g_{max} - 15.59, \quad (9)$$

where the correlation coefficient was 0.993. The amount of crystallization of L-THC at Θ_D can be estimated by Eqs. 7—9 for various degrees of supersaturation.

The values of R_L, W_0, and Θ_D for an aqueous solution with 120% supersaturation were calculated to be 4.01×10^{-4} g min^{-1}, 0.102 g, and 660 min, respectively; the solvent was 50 cm^3 of water. The value of Θ_D suggests that D-THC does not crystallize rapidly within 660 min. The optical resolution at 360 min gave L-THC with 100% optical purity in 0.284 g yield as shown in Table 3. The amount of crystallized L-THC was 0.234 g and agreed well with the calculated value at 360 min by Eqs. 7 and 9 (0.247 g). The calculated values of R_L and W_0 suggest that the theoretical amount of L-THC (0.299 g) crystallizes after 490 min. The optical resolution at 490 min gave L-THC with 94.7% optical purity in 0.319 g yield; the amount of crystallization of L-THC was 0.261 g. The relatively large difference between the experimental result and calculated value suggests that the crystallization of L-THC is inhibited after a long resolution time, because the supersaturation of L-THC in the solution decreases considerably with crystallization of L-THC. However, for the solutions with supersaturation of 130—160%, L-THC seems to crystallize at a rate proportional to the resolution time until at least Θ_D min as demonstrated in Fig. 2 and indicated by Eq. 7.

Appropriate Conditions of Optical Resolution: Although the optical resolution at Θ_D will give the maximum yield of L-THC with high optical purity, the optical resolution at Θ_D—5 min seems to be more suitable to stable operation than that at Θ_D, because D-THC begins to crystallize rapidly after Θ_D. The amount of L-THC produced at Θ_D—5 min ($W_{(-5)}$/g) is expressed by Eq. 10

$$W_{(-5)} = R_L(\theta_D - 5) + W_0. \quad (10)$$

The values of R_L, W_0, Θ_D, and $W_{(-5)}$ for various degrees of supersaturation were calculated by Eqs. 7—10. The relationship between $W_{(-5)}$ and the degree of

supersaturation is shown in Fig. 3.

The calculated $W_{(-5)}$ values showed an identical tendency with that of experimental data in supersaturation between 130 and 170%. Figure 3 suggests that the optical resolution at 150% supersaturation gives the muximum amount of L-THC. This optical resolution was performed at resolution time in the range 20—50 min as given in Table 3, because Θ_D is 33.4 min calculated by Eq. 8. The experimental amounts of crystallization of L-THC are compared with those calculated by Eqs. 7 and 9 in Fig. 4.

The value of Θ_D is 35 min in Fig. 4 and agrees well with the calculated value of 33.4 min. The optical resolution at 30 min, namely at Θ_D−5 min, gave L-THC with 96.3% optical purity of 61.3% degree of resolution. The amount of crystallization of L-THC is 0.468 g; the amount calculated is 0.440 g at 28.4 min by

4	0.877	2.632	2.077	50	D 1.031	95.0	0.929	83.5

a) Solvent: 50 cm^3 of 1 mol dm^{-3} aqueous glycine. Seed crystals: 0.050 g of D- or L-THC. Temperature: 20 °C. Degree of supersaturation of initial solution: 155%. b) The operation amounts of D- and L-THC in Runs 2—4 were calculated on the basis of the analyses of the obtained THC in Runs 1—3. c) YOPM: See note b) in Table 3.

Eqs. 7 and 9. The maximum yield of optically pure modification (YOPM/g) in Table 3 appears at θ_D−5 min for each degree of supersaturation (cf. also Table 4). The optical resolution at 30 min with 150% supersaturation is most favorable to obtain efficiently L-THC with high optical purity.

These results revealed that appropriate conditions can be estimated by Δg_{max} in the optical resolution by preferential crystallization.

Successive Preferential Crystallization: Based on the above results, the successive preferential crystallization was carried out in 50 cm^3 of water at 20 °C for 30 min using a solution with 150% initial supersaturation, as listed in Table 6. The procedure gave D- and L-THC with optical purity of 96—100% and resolution of 58—77%.

The optical resolution under the same conditions was scaled up 6 times as described in Table 6. The optical purity of L-THC fell to 80.1%, and hence the degree of resolution was 47.3%. This low optical purity will be due to a change of stirring condition by the scale up. However, the optical resolution in runs 2—11 was satisfactory for producing D- and L-THC with optical purity of 92—100% and resolution of 62—79%.

Optical Resolution in Aqueous Glycine Solution. D- and L-THC with high optical purity were efficiently obtained by the successive preferential crystallization in water under appropriate conditions estimated by Δg_{max}, but the values of YOPM were only 10—14% of the amount of DL-THC dissolved in the initial solution; YOPM denotes the theoretical amount of optically pure THC obtained by recrystallization.

Since the solubility of DL- and L-THC is slightly higher in 1 mol dm^{-3} aqueous glycine than in water, as shown in Table 2, an attractive interaction may exist between glycine and THC molecules. This suggests that the value of θ_D is larger in the glycine solution than in water, because the growth of critical nuclei of THC is inhibited by glycine molecules.[7] Since the crystallization of L-THC will also be inhibited by glycine, the successive preferential crystallization was attempted in 1 mol dm^{-3} aqueous glycine for a solution with 155% supersaturation. This result was listed in Table 7.

L-THC with 93.6% optical purity was obtained in degree of resolution of 77.0% by the procedure for 60 min; YOPM was 13.7% of the amount of DL-THC dissolved in the initial solution. THC in aqueous glycine may crystallize as a molecular compound with glycine,[13] but the elemental analyses show that only L-THC crystallizes.[14] This result is supported by the fact that D-THC does not crystallize for at least 60 min.

The D- and L-THC with optical purity of 95—99% were obtained in degree of resolution of 82—87% in runs 2—4, and YOPM were approxymately 20% of the amount of DL-THC dissolved in the initial solution.

The recrystallization of obtained D- and L-THC from water, followed by treatment with hydroxylamine hydrochloride, gave optically pure D- and L-Cys in 82% yield.

12) In order to calculate Δg_{max}, the molecular volume of THC (1.320×10^{-28} m^3) was measured in water at 20 °C. The molecular radius was calculated to be 3.159×10^{-10} m on the assumption of spherical molecule. The average values of the radius (4.027×10^{-10} m) and interfacial energy (1.807 J m^{-2}) of embryo in the saturated aqueous solution at 20 °C were calculated on the basis of the solubility of DL-THC according to the procedure reported in Ref. 6; the average number of THC molecule forming the embryo in the solution was 2.072.

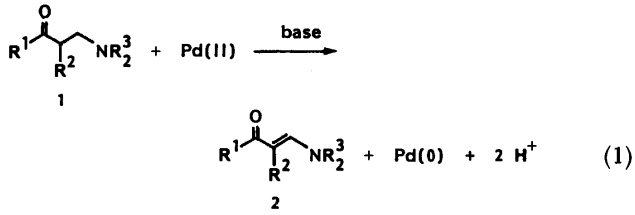
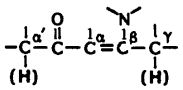
The reaction of β-amino ketones with bis(acetonitrile)dichloropalladium(II) in the presence of triethylamine gives the corresponding enaminones regioselectively. The cyclic β-amino ketones can be converted into the corresponding exocyclic enaminones. The enaminones thus obtained are versatile synthetic intermediates. The reaction of (E)-enaminones with organocuprates gave the corresponding (E)-α,β-unsaturated ketones.

Transition metals insert into the carbon–hydrogen bond α to the nitrogen of tertiary amines to give iminium ion hydride complexes.[1] In relation to the study of these intermediates, we have found that palladium-promoted transformation of β-amino ketones **1** to enaminones **2** proceeds efficiently as depicted in Eq. 1.

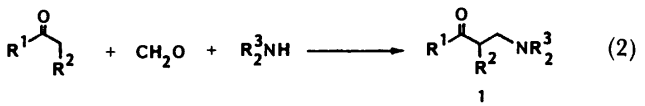


(1)

Enaminones are versatile synthetic intermediates because of their regioselective reactions with either nucleophiles or electrophiles[2] Nucleophiles attack at the carbonyl carbon and the β-carbon of carbonyl groups,[3] while electrophiles attack at the carbonyl oxygen[4] and the α-carbon of carbonyl groups. In the presence of bases, electrophiles attack at the α′ and γ-carbons of carbonyl groups selectively.[5] Enaminones have been prepared by the limited methods,



which include condensation of 1,3-diketones with amines,[6] reaction of enamines with ketenes,[7] addition of amines to ethynyl ketones,[8] oxidative amination of α,β-unsaturated ketones,[9] reaction of ketones with formamide acetals,[10] and condensation of silyl enol ethers with oxime mesylates.[11] The present palladium-induced reaction of β-amino ketones provides a new strategy, since the starting substrates, β-amino ketones are readily available by Mannich reaction of carbonyl compounds[12] as depicted in Eq. 2.



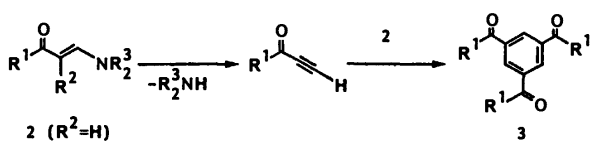
(2)

Described herein are the preparation of enaminones, mechanistic aspects, and synthetic applications.[13]

Results and Discussion

Treatment of 4-diethylamino-2-butanone (**1a**) with $PdCl_2(MeCN)_2$ in the presence of two equivalents of triethylamine in acetonitrile gave (*E*)-4-diethylamino-3-buten-2-one (**2a**) in 95% yield. The HCl salt of β-amino ketone can be also utilized as substrates by adding three equivalents of bases. Generally, the reaction is strongly affected by the solvent used as shown in Table 1.

Although a polar aprotic solvent, such as acetonitrile gives enaminones in high yields, using a nonpolar solvent, such as benzene, the reaction rates become slow. Ethanol is a poor solvent because the reduction of the Pd(II) complex with ethanol proceeds fast. The reaction of β-amino ketones (R^2=H) with $PdCl_2(MeCN)_2$ in the absence of bases gave 1,3,5-triacylbenzenes and none of enaminones was detected. The reaction can be rationalized by assuming the reaction pathway shown in Eq. 3.[14] Apparently, the



(3)

enaminones derived from β-amino ketones are the precursor. Deamination of enaminones gives acetylenic ketones, which undergo acid catalyzed condensation, with **2** to give 1,3,5-triacylbenzenes **3**. Indeed, the treatment of (*E*)-3-dimethylamino-1-phenyl-2-

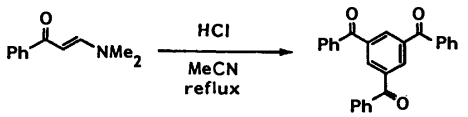
Entry	Solvent	(ε[b])	Yield[c]/%
1	MeCN	(37.5)	95
2	Acetone	(20.7)	47
3	THF	(7.58)	37
4	Benzene	(2.28)	26
5	EtOH	(24.6)	15

a) All reactions were carried out using 1 molar equivalent of $PdCl_2(MeCN)_2$ and 2 molar equivalents of Et_3N in a solvent at reflux for 0.5 h. b) Dielectric constant at 20 °C, and at 25 °C for MeCN. c) Determined by GLC.

propen-1-one (**2b**) with hydrochloric acid in acetonitrile gave 1,3,5-tribenzoylbenzene (**3b**) in 95% yield. This reaction is highly efficient for the preparation of 1,3,5-triacylbenzenes.



2b 3b

The formation of enaminones is strongly affected by the bases added as shown in Table 2. When a weaker base such as Na_2CO_3 was used for the palladium-promoted reaction of **1b**, both enaminones and triacylbenzenes were obtained. For these reactions $Pd(OAc)_2$ is more reactive than $PdCl_2(MeCN)_2$, although the yields with $Pd(OAc)_2$ are lower. The conversion of 1-dimethylamino-4,4-dimethyl-3-pentanone (**1c**) is low because of the steric effect of *t*-butyl group. Therefore, we examined the effect of bases on the $Pd(OAc)_2$-promoted reaction of **1c**. As shown in Table 3 the conversion of **1c** in the presence of

Table 2. The Effect of Bases on the Pd(II)-Induced Reaction of β-Amino Ketones[a]

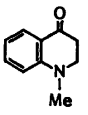
8		(**1h**)	0.25		(**2h**)	95

a) All reactions were carried out using β-amino ketone (0.8 mmol) and $PdCl_2(MeCN)_2$ (0.8 mmol) in the presence of Et_3N (1.6 mmol) in MeCN (10 mL) at reflux unless otherwise noted. b) Isolated yields and GLC yields in the parentheses. c) β-Amino ketone hydrochloride was used. d) $Pd(OAc)_2$ and Na_2CO_3 were used.

triethylamine is 50% and the yield of **2c** is quite low. However, Na_2CO_3 was found to be an excellent base for the conversion of **1c**.

The present reaction is generally applicable for the conversion of various β-amino ketones as shown in Table 4. Various enaminones are obtained in moderate to very good yields. The structures of the enaminones were established by IR, NMR, and mass spectral data and elemental analyses. The stereochemistry was established to be trans by the NMR spectra.[15] The cyclic β-amino ketones can be converted into the corresponding exocyclic enaminones, which are important synthetic intermediates, such as dihydrojasmones and others.[16] Cyclic amino ketones such as **1i** and **1j** do not undergo dehydrogenation.

1i

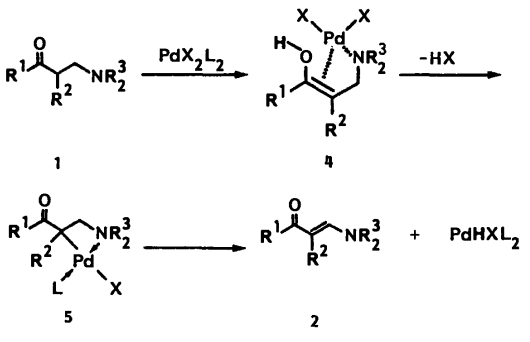


1j

Low-valent palladiums such as Pd black and $Pd(PPh_3)_4$, which are excellent catalysts for the activation of amines to give iminium ion complexes,[1] are almost inert to the present reaction.

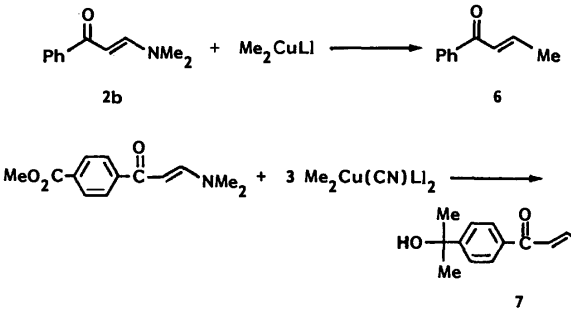
Ketones generally undergo dehydrogenation by either direct[17] or indirect methods[18] to give α,β-unsaturated ketones. In these reactions, β-carbonyl palladium intermediates or oxo(π-allyl)palladium complexes have been postulated. The present reaction proceeds similarly as shown in Scheme 1.

The coordination of Pd(II) complex to the enol of β-amino ketones gives π-complex **4** which undergoes insertion to give HX and β-carbonyl palladium complex **5**.[19] Further elimination of $PdHXL_n$ gives enaminone **2**. The stable conformer of **5**, where the carbonyl group may occupy the trans position to the amino group, undergoes cis-elimination of PdH species to give (E)-enaminones **2**. The present reaction shows different reactivity in comparison with the direct palladium-promoted transformation of ketones to α,β-unsaturated ketones. In contrast to the poor regioselectivity of the direct palladium-induced dehydrogenation, the present reaction gives enaminones regioselectively. Further the direct dehydrogenation of α-alkylated cyclic ketones can be converted into endocyclic olefins, while the present reaction gives exocyclic ketones. The regioselectivity seems to be determined at the stage of the coordination of palladium to the nitrogen of β-amino ketones. Actually, cyclic keto amines such as **1i** and **1j** do not undergo dehydrogenation, because the coordination of palladium to the nitrogen and the enol of cyclic amino ketones at the same time is difficult.



Scheme 1.

Although various synthetic application of enaminones have been demonstrated,[2-5,20] the nucleophilic reactions of enaminones with organocuprates provide a new strategy for the stereoselective synthesis of α,β-unsaturated ketones. Combining Eq. 2, ketones can be converted into (E)-substituted α,β-unsaturated ketones via enaminones by the substitution of the dialkylamino group with the alkyl group of organocuprates. Thus, the treatment of (*E*)-3-dimethylamino-1-phenyl-2-propen-1-one (**2b**) with dimethylcuprate gave (*E*)-1-phenyl-2-buten-1-one (**6**) stereoselectively in 86% yield. Further the reaction of methyl 4-(1-oxo-3-dimethylamino-2-propenyl)benzoate with excess amounts of cyanodimethylcuprate gave (*E*)-1-[4-(1-hydroxy-1-methylethyl)phenyl]-2-buten-1-one (**7**) in 66% yield. Again, the alkylation of dimethylamino group of enaminones proceeds selectively. These reactions are compatible to the stereo-selective synthesis of α,β-unsaturated ketones by the reaction of organocuprates with β-alkylthio α,β-enones.[21]



This study describes the palladium(II)-promoted, regioselective transformation of β-amino ketones to enaminones, which are versatile synthetic intermediates.

Experimental

General. ^1H NMR spectra were run as $CDCl_3$ and CCl_4 solutions on a 60 MHz JNM-PMX-60 SI (JEOL) and a 100 MHz JNM-FX-100 (JEOL) spectrometer; chemical shifts (δ) were expressed in parts per million downfield from Me_4Si. IR spectra were taken in a NaCl cell on a Hitachi 215

spectrometer. Analytical GLC evaluations of product mixtures were performed on a JEOL JGC-20-KFP or Shimadzu GC-8A gas chromatograph equipped with a flame ionization detector, while preparative GLC was performed on a JEOL JGC-20KT equipped with a thermal conductive detector. Mass spectra were obtained on a Hitachi RMS-4 mass spectrometer. Elemental analyses were obtained on a Yanagimoto MT-2 CHN recorder.

Materials. Bis(acetonitrile)dichloropalladium(II) was prepared by stirring $PdCl_2$ in acetonitrile at room temperature overnight followed by recrystallization from acetonitrile. Palladium(II) acetate was prepared according to the reported method.[22] Triethylamine was distilled over calcium hydride under nitrogen. Acetonitrile was dried over phosphorus pentoxide and distilled over calcium hydride under nitrogen. Methyl-4-piperidinone (**1i**) was purchased from Tokyo Kasei Co. 4-Diethylamino-2-butanone (**1a**),[23] 3-dimethylamino-1-phenyl-1-propanone (**1b**) hydrochloride,[24] 1-dimethylamino-4,4-dimethyl-3-pentanone (**1c**) hydrochloride,[25] and 2,3-dihydro-1-methyl-4(1*H*)-quinolinone (**1j**)[26] were prepared according to the reported procedures. 1-Dimethylamino-3-hexanone (**1d**),[24] 4-dimethylamino-2-butanone (**1e**),[23] 2-(dimethylaminomethyl)cyclopentanone (**1f**),[27] 2-(dimethylaminomethyl)cyclohexanone (**1g**),[27] and 5,5-dimethyl-2-(dimethylaminomethyl)cyclohexanone (**1h**)[27] were prepared by modification of the reported procedures.

Palladium-Induced Dehydrogenation of β-Amino Ketones to Enaminones: The following procedure for the preparation of (*E*)-4-diethylamino-3-buten-2-one (**2a**) is typical. To a suspension of $PdCl_2(MeCN)_2$ (0.208 g, 0.80 mmol) in acetonitrile (10 mL) were added 4-diethylamino-2-butanone (**1a**, 0.114 g, 0.80 mmol) and triethylamine (0.162 g, 1.6 mmol). The mixture was heated at reflux for 0.5 h under nitrogen. The palladium metal precipitated was filtered off. The filtrate was concentrated in vacuo, poured into water (10 mL), and extracted with ether (10 mL×3). The combined extracts were dried over Na_2SO_4. After the solvent was removed in vacuo, Kugelrohr distillation gave **2a** (0.078 g, 70%): bp 101—110 °C/1.6 mmHg (1 mmHg=133.3 Pa); IR (neat) 2990, 2950, 2892, 1654 (C=O), 1563, 1367, 1257, 1203, 1128, 986, 771 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.20 (6H, t, J=7.2 Hz, $-CH_3$), 2.07 (3H, s, $CO-CH_3$), 3.22 (4H, q, J=7.2 Hz, $-CH_2-$), 5.07 (1H, d, J=13.0 Hz, CO-CH=C), 7.41 (1H, d, J=13.0 Hz, N-CH=C). Found: C, 67.73; H, 10.58; N, 9.48%. Calcd for $C_8H_{15}NO$: C, 68.04; H, 10.71; N, 9.92%.

Enaminones **2b**, **2d**—**2h** were prepared in a similar manner that used for **2a** and the purification was achieved by Kugelrohr distillation, preparative TLC (SiO_2), or chromatographic separation (Al_2O_3) as indicated respectively. The IR and ^1H NMR spectra of these products were identical with those of the authentic materials prepared by the reported procedure.[10]

(*E*)-3-Dimethylamino-1-phenyl-2-propen-1-one (2b): Preparative TLC (SiO_2, THF–hexane=95/5, R_f=0.65); mp 95—100 °C; IR ($CHCl_3$) 3010, 1646 (C=O), 1588, 1551, 1435, 1423, 1364, 1248, 1121, 1056, 903 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.01 (6H, s, $N(CH_3)_2$), 5.73 (1H, d, J=12.2 Hz, CO-CH=C), 7.34—8.05 (6H, m, ArH, N-CH=C). Found: C, 75.10; H, 7.37; N, 8.05%. Calcd for $C_{11}H_{13}NO$: C, 75.40; H, 7.48; N, 7.89%.

(*E*)-1-Dimethylamino-1-hexen-3-one (2d): Chromatographic separation (Al_2O_3, eluent=benzene–ether); IR (neat) 2963, 1658 (C=O), 1569, 1437, 1362, 1283, 1112, 1054, 767 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.96 (3H, t, J=6.8 Hz, $-CH_3$), 1.65 (2H, tq, J=7.0 Hz and 6.8 Hz, $-CH_2-$), 2.33 (2H, t, J=7.0 Hz, $CO-CH_2-$), 2.92 (6H, s, $N(CH_3)_2$), 5.04 (1H, d, J=12.8 Hz, CO-CH=C), 7.49 (1H, d, J=12.8 Hz, N-CH=C). Found: C, 67.56; H, 10.48; N, 9.79%. Calcd for $C_8H_{15}NO$: C, 68.04; H, 10.71; N, 9.92%.

(*E*)-4-Dimethylamino-3-buten-2-one (2e): Kugelrohr distillation; bp 123—128 °C/6.0 mmHg; IR (neat) 2920, 1655 (C=O), 1568, 1430, 1356, 1261, 1192, 1110, 958, 847, 798, 760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.08 (3H, s, $C-CH_3$), 2.92 (6H, s, $N(CH_3)_2$), 5.01 (1H, d, J=12.6 Hz, CO-CH=C), 7.40 (1H, d, J=12.6 Hz, N-CH=C). Found: C, 63.49; H, 9.66; N, 12.36%. Calcd for $C_6H_{11}NO$: C, 63.68; H, 9.80; N, 12.38%.

(*E*)-2-(Dimethylaminomethylene)cyclopentanone (2f): Preparative TLC (SiO_2, THF, R_f=0.49); mp 40—42.5 °C; IR (neat) 2950, 1677 (C=O), 1573, 1437, 1380, 1307, 1273, 1208, 1116, 1002, 849, 787 cm^{-1}; ^1H NMR (CCl_4) δ=1.39—2.98 (6H, m, $-CH_2-$), 3.06 (6H, s, $N(CH_3)_2$), 6.90—7.01 (1H, m, N-CH=C).

(*E*)-2-(Dimethylaminomethylene)cyclohexanone (2g): Kugelrohr distillation; bp 99—104 °C/0.7 mmHg; IR (neat) 2942, 1648 (C=O), 1547, 1428, 1326, 1299, 1158, 1130, 1037, 926, 827 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.54—2.87 (8H, m, $-CH_2-$), 3.07 (6H, s, $N(CH_3)_2$), 7.44—7.59 (1H, m, -CH=C).

(*E*)-5,5-Dimethyl-2-(dimethylaminomethylene)cyclohexanone (2h): Kugelrohr distillation; bp 110—115 °C/1.4 mmHg; mp 75.5—76.0 °C; IR (KBr) 2912, 1635 (C=O), 1428, 1299, 1223, 1122, 1058, 960 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.96 (6H, s, $C(CH_3)_2$), 1.49 (2H, t, J=6.6 Hz, $-CH_2-$), 2.12 (2H, s, $CO-CH_2-$), 2.71 (2H, t, J=6.6 Hz, $CH_2C=C$), 3.08 (6H, s, $N(CH_3)_2$), 7.48 (1H, br, N-CH=C). Found: C, 72.22; H, 10.36; N, 7.68%. Calcd for $C_{11}H_{19}NO$: C, 72.88; H, 10.57; N, 7.73%.

(*E*)-4,4-Dimethyl-1-dimethylamino-1-penten-3-one (2c): A suspension of $Pd(OAc)_2$ (0.225 g, 1.0 mmol), Na_2CO_3 0.319 g, 3.0 mmol), and 4,4-dimethyl-1-dimethylamino-3-pentanone (**1c**) hydrochloride (0.194 g, 1.0 mmol) in acetonitrile (10 mL) was heated at reflux for 0.5 h under nitrogen. The reaction mixture was worked up as described above. Kugelrohr distillation gave **2c** (0.115 g, 74%) as a colourless solid: bp 96—101 °C/3.2 mmHg; mp 37.4—37.8 °C; IR (KBr) 2957, 1650 (C=O), 1554, 1429, 1356, 1288, 1085, 1014, 917, 767 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.13 (9H, s, $C(CH_3)_3$), 2.91 (6H, s, $N(CH_3)_2$), 5.21 (1H, d, J=12.4 Hz, CO-CH=C), 7.56 (1H, d, J=12.4 Hz, N-CH=C). Found: C, 69.27; H, 10.10; N, 8.96%. Calcd for $C_9H_{17}NO$: C, 69.63; H, 11.04; N, 9.04%

1,3,5-Triacetylbenzene (3): A mixture of 4-diethylamino-2-butanone (**1a**, 0.217 g, 1.5 mmol), $PdCl_2(MeCN)_2$ (0.395 g, 1.5 mmol), and acetonitrile (5 mL) was heated at reflux for 5 h. The reaction mixture was worked up as described above. Preparative TLC (SiO_2, THF–hexane=4/6, R_f=0.48) gave 1,3,5-triacetylbenzene (**3a**, 0.033 g, 32%): mp 159—162 °C; IR ($CHCl_3$) 2965, 2933, 1695 (C=O), 1365, 1233, 785 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.78 (9H, s, $-CH_3$), 8.95 (3H, s, ArH). The IR and ^1H NMR spectra of the product were identical with those of the authentic sample.

In a similar manner, 1,3,5-tribenzoylbenzene (**3b**) was obtained in 35% yield by the reaction of 3-dimethylamino-1-phenyl-1-propanone (**1b**) and $PdCl_2(MeCN)_2$: Preparative TLC (SiO_2, ether–hexane=4/5, R_f=0.36); mp 119—121 °C;

IR ($CHCl_3$) 3019, 1655 (C=O), 1599, 1451, 1318, 1255, 1180, 1130, 1005, 907 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.58—8.01 (15H, m, $-C_6H_5$), 8.55 (3H, s); MS *m/z* (rel intensity) 390 (M^+, 100), 313 (66), 285 (42). Found: C, 82.92; H, 4.60%. Calcd for $C_{27}H_{18}O_3$: C, 83.06; H, 4.65%.

Conversion of Enaminone 2b to Triacylbenzene 3b: To a solution of enaminone **2b** (0.300 g, 1.71 mmol) in acetonitrile (5 mL) was added a mixture of H_2O (0.300 g, 16.7 mmol) and three drops of concentrated HCl solution. After heating at reflux for 4 h, the reaction mixture was extracted with CH_2Cl_2 (30 mL) The extract was washed with water (10 mL×3) and dried over $MgSO_4$. Evaporation of the solvent gave **3b** (0.210 g, 95%).

Reaction of (*E*)-3-Dimethylamino-1-phenyl-2-propen-1-one (2b) with Dimethylcuprate: To a suspension of CuI (0.419 g, 2.20 mmol) in dry ether (5 mL) was added a solution of 1.32 M (1M=1 mol dm^{-3}) of methyllithium (3.3 mL, 4.40 mmol) in ether at 0 °C. The mixture was stirred at room temperature for 15 min. The $LiCuMe_2$ solution in ether was added to a solution of (*E*)-3-dimethylamino-1-phenyl-2-propen-1-one (**2b**, 0.351g, 2.00 mmol) in dry ether (8 mL) with stirring at room temperature. The reaction mixture was allowed to stand overnight and quenched with water (5 mL) and extracted with ether. The organic layer was washed and dried over Na_2SO_4. Evaporation of the solvent gave the residue, which was subjected to column chromatography (Al_2O_3). Elution with benzene–ether (9:1) gave (*E*)-1-phenyl-2-buten-1-one (**6**, 0.253g, 86%): IR (neat) 1672, 1626, 1452, 1298, 1226cm^{-1}; ^1HNMR ($CDCl_3$) δ=1.98 (3H, d, *J*=5.0Hz, CH_3), 6.60—7.13 (2H, m, CH=CH), 7.30—7.57 (3H, m, ArH), 7.80—8.13 (2H, m, ArH); MS *m/z* 146 (M^+). The structure was established by comparing the spectral data with those of the authentic sample.

Reaction of Methyl 4-(1-Oxo-3-dimethylamino-2-propenyl)benzoate with Cyanodimethylcuprate: To a slurry of CuCN (0.806 g 9.0 mmol) in ether (10 mL) was added a solution of 1.32 M methyllithium (18 mmol) in ether with stirring at −78°C under argon, and the mixture was stirred at 0°C. To a suspension of methyl 4-(1-oxo-3-dimethylamino-2-propenyl)benzoate (0.467 g, 2.0 mmol) which was prepared from ethyl 4-acetylbenzoate and *N,N*-dimethylformamide dimethyl acetal, mp 177 °C; ^1H NMR ($CDCl_3$) δ=3.01 (6H, s, $N(CH_3)_2$), 3.88 (3H, s, OCH_3), 5.67 (1H, d, *J*=6.2 Hz, COCHC=), 7.75 (1H, d, *J*=6.2 Hz, COCH=CH), 7.75—8.15 (4H, m, ArH), in ether (5.0 mL), was added the above $Li_2CuCN(Me)_2$ solution with stirring at −78 °C for 5 min. After stirring at room temperature for 6 h, the mixture was quenched with water and extracted with ether (10 mL×5). The ether extracts were dried over Na_2SO_4 and concentrated. Chromatography on silica gel gave pure (*E*)-1-[4-(1-hydroxy-1-methlethyl)phenyl]-2-buten-1-one (**7**) (0.272 g, 66%): IR (neat) 3430, 2980, 1670, 1620, 1302, 1232 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.58 (6H, s, CH_3), 1.96 (3H, d, *J*=5.0 Hz, CH_3), 2.43 (1H, br, OH), 6.65—7.09 (2H, m, CH=CH), 7.42—7.97 (4H, m, ArH). Found: C, 76.24; H, 7.86%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90%.

We wish to thank Mr. Kazuo Ike for the experimental assistance.

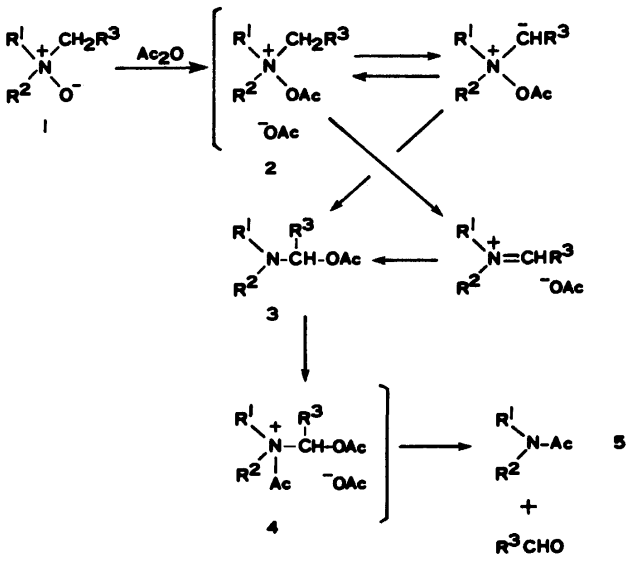
Silicon Polonovski Reaction. Formation and Synthetic Application of α-Siloxy Amines

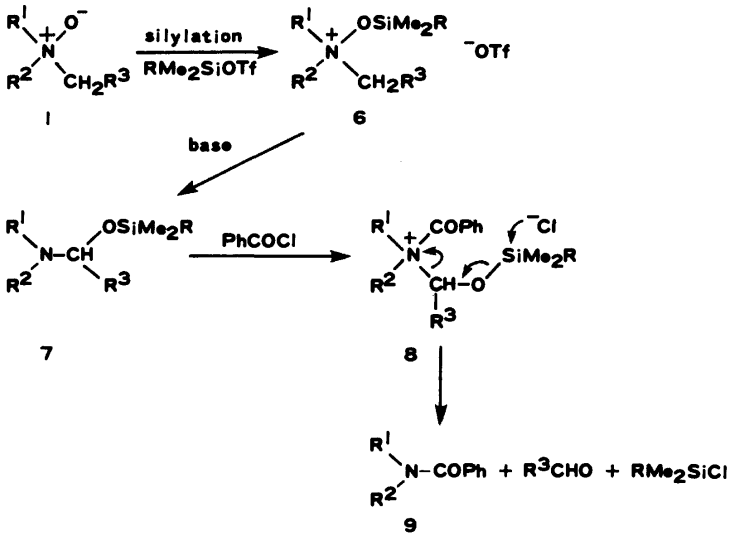
Norihiro Tokitoh† and Renji Okazaki*
Department of Chemistry, Faculty of Science, The University of Tokyo,
Hongo, Bunkyo-ku, Tokyo 113
(Received March 20, 1987)

A new and versatile synthetic intermediate, α-siloxy amine was prepared in situ by the base-promoted rearrangement of a siloxyammonium salt obtained by treatment of a tertiary amine *N*-oxide with trialkylsilyl trifluoromethanesulfonate. The best combination of the base and silylating reagent was found to be methyllithium and *t*-butyldimethylsilyl trifluoromethanesulfonate. The reactions of α-siloxy amines with acyl halides and haloformates gave the corresponding amides and carbamates in moderate to good yields, respectively. Treatment of α-siloxy amines with acetic acid resulted in a direct dealkylation to free secondary amines. Fluoride induced alkylation of α-siloxy amines using alkyl halides as electrophiles leading to tertiary amines was also examined and demonstrated to be a new transalkylation method of amines.

Amine *N*-oxides are readily available compounds by oxidation of tertiary amines and the functionalization of the amines taking advantage of the oxidation state of the nitrogen atom seems potentially useful. Actually, the reaction of tertiary amine *N*-oxides with some acid anhydrides is well-known as the Polonovski reaction[1] and is used as a useful dealkylation method for tertiary amines to afford the corresponding amides. The Polonovski reaction is considered to proceed via α-acetoxyamine intermediate **3** which reacts again with the anhydride to give the dealkylated product **5** via ammonium salt **4** (Scheme 1). The use of acid anhydrides necessarily results in the formation of amide **5** as a final product although, in some limited cases, the formation of enamines or Mannich bases have been reported.[2] It occurred to us that the use of siloxyammonium ions **6** instead of acyloxyammonium ions **2** would lead to α-siloxy amine **7** by an appropriate base (Scheme 2). Since **7** can be expected



Scheme 1.



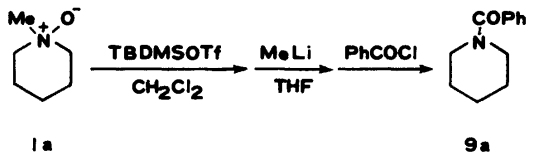
Scheme 2.

† Present address: Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305.

to react with various electrophiles, it would become a useful intermediate in functionalization of tertiary amines. In this article we report that this expectation was indeed fulfilled and tertiary amines could be converted into various types of secondary amine derivatives by this methodology.[3]

Results and Discussion

Rearrangement of Siloxyammonium Salts; Formation of α-Siloxy Amines. Siloxyammonium salts were prepared from the tertiary amine *N*-oxides and trialkylsilyl trifluoromethanesulfonate and subjected to a base-promoted rearrangement leading to α-siloxy amines (Scheme 2). The formation of the siloxy amines was confirmed by trapping with acyl halides to give the corresponding amides. For example, *N*-methylpiperidine *N*-oxide (**1a**) was allowed to react with *t*-butyldimethylsilyl trifluoromethanesulfonate (TBDMSOTf) in dichloromethane at 0 °C to give the corresponding siloxyammonium salt **6a**, the quantitative formation of which was confirmed by NMR spectroscopy.[4] After replacement of the solvent by tetrahydrofuran (THF), **6a** was treated with methyllithium at 0 °C and then with benzoyl chloride at room temperature to afford the expected amide **9a** in 76% yield (Eq. 1). The effects of silylating agents and



(1)

1a 9a

bases on the yields were studied by using the reaction of Eq. 1 and the results are shown in Table 1.[5]

Although alkyllithiums, lithium amides, lithium phenoxide, and potassium *t*-butoxide were effective as a base, methyllithium gave the best result. Tertiary amines such as triethylamine, *N*,*N*-diisopropylethylamine (Hünig base), and 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU), which were often used as a base in the Polonovski reaction, were of no use in the present case probably because their basicity is not high enough to cause rearrangement because of low leaving ability of the siloxyl group. As for a silylating reagent, TBDMSOTf was more effective than TMSOTf.[6] This is most likely due to the steric protection of the silicon atom by the *t*-butyl group which makes the expected deprotonation preferable to the undesirable nucleophilic attack to the silicon atom by the base. Since the best combination of the reagents was found to be TBDMSOTf and methyllithium, this combination is used in the following reactions.

Table 1. Yields of *N*-Benzoylpiperidine (**9a**)

Base	Me_3SiOTf	*t*-$BuMe_2SiOTf$
n-BuLi	50	70
s-BuLi	c)	66
t-BuLi	65	73

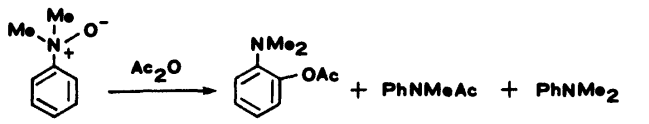
g		**1g**		**9a**	33
h		**1h**		**9a**	45

a) Used reagents were TBDMSOTf, methyllithium, and benzoyl chloride. b) Isolated yield. c) Benzaldehyde (56%) was also obtained. d) $R^1=R^2=Me$ **9e** 52%; $R^1=Me$, $R^2=PhCH_2$ **9e'** 29%.

Dealkylation of Tertiary Amines. a) Amide Formation. The conversion of several amine *N*-oxides into the corresponding benzamide with TBDMSOTf and methyllithium was carried out, and the results are summarized in Table 2. Since tertiary amines can be oxidized to the corresponding *N*-oxides almost quantitatively, this reaction provides a new general method for the dealkylation of tertiary amines to secondary amine derivatives. Although, as mentioned above, a similar conversion of tertiary amine *N*-oxides into amides of secondary amines can be achieved by the Polonovski reaction using acid anhydrides, the present method has the advantage of affording a dealkylated product selectively in some cases, since the Polonovski reaction of aromatic amine *N*-oxides such as *N*,*N*-dimethylaniline oxide (**1c**) is reported to give a rearranged product, *o*-acetoxy-*N*,*N*-dimethylaniline (**10**), as a main product (Eq. 2).[8] In the case of

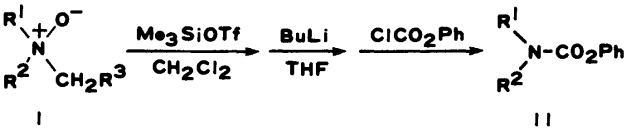


1c 10 (2)

tribenzylamine oxide (**1b**), benzaldehyde, an expected product, was isolated in 56% yield in addition to amide **9b**. The formation of the aldehyde was also confirmed by the isolation of its 2,4-dinitrophenylhydrazone in 56% yield. Furthermore, it is also noteworthy that the product was a benzaldehyde derivative **9f** in the case of 2-methyl-1,2,3,4-tetrahydroisoquinoline *N*-oxide (**1f**), since it suggests that the rearrangement took place regioselectively at the benzyl position.

The results listed in Table 2 suggest that the regioselectivity of this dealkylation is controlled by the acidity of α-hydrogen in the siloxyammonium salts **6** to be deprotonated by the base, and in the cases of **1a** and **1f** the dealkylation proceeded regioselectively to give the amides **9a** and **9f**, respectively.

b) Carbamate Formation. When phenyl chloroformate was used as an electrophile in the reaction with α-siloxy amines, the final product was the corresponding carbamate **11**. The results obtained for the reactions of several tertiary amine *N*-oxides are given in Table 3.



I II

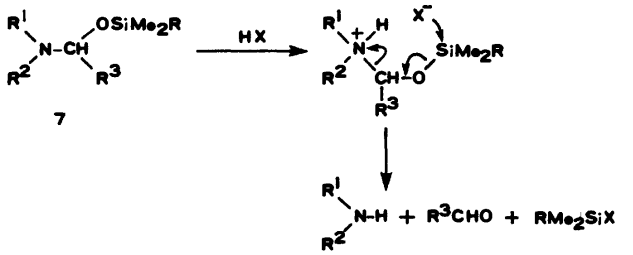
Since the combination of TBDMSOTf and methyllithium was not used in these reactions, the yields of the carbamates have not been optimized.

c) Direct Dealkylation into Secondary Amines. We next examined the direct dealkylation of tertiary amines via α-siloxy amines. If an appropriate protic acid is used as an electrophile, α-siloxy amine **7** is expected to be converted into the corresponding secondary amine (Scheme 3).

As expected, sequential treatment of tribenzylamine oxide (**1b**) with TBDMSOTf, methyllithium, and acetic acid afforded dibenzylamine in 67% yield.

Furthermore, when treatment with acetic acid was carried out in the presence of isopentyl nitrite, *N*-nitrosodibenzylamine was obtained in 85% yield. A similar result was obtained in the case of *N*-methylpiperidine *N*-oxide (**1a**) to give *N*-nitrosopiperidine in 41% yield.

Transalkylation of Tertiary Amines. Although transalkylation reactions (i.e., the replacement of a substituent on the nitrogen atom by other groups) are useful for the introduction of a new functional group



Scheme 3.

a) TMSOTf, butyllithium, and phenyl chloroformate were used.

into amines, there have been very few reports on direct transalkylation[9] and the conventional methods involve some steps, i.e., dealkylation to free secondary amines and their realkylation.[10] We have found that the use of alkyl halides as an electrophile in the reaction of α-siloxy amines in the presence of fluoride ion results in transalkylation of tertiary amines (Scheme 4). Thus, treatment of α-siloxy amines **7** (obtained in situ from amine *N*-oxides **1**) with alkyl halides followed by desilylation with fluoride ion (*n*-$Bu_4N^+F^-$/THF) in a sealed tube at 110 °C afforded the corresponding transalkylation products **12** in moderate yields.[11] Results obtained from the reactions of *N*-methylpiperidine *N*-oxide (**1a**) and triethylamine oxide (**1d**) with several alkyl halides are summarized in Table 4. In contrast to the dealkylation reaction by acyl halide or haloformate, this transalkylation proceeds only in the presence of fluoride ion and with heating perhaps due to poor reactivity of alkyl halides in quaternization and to low activating facility of the alkyl group in desilylation step. Of particular note among these results is the introduction of carbonyl functionality into new alkyl groups (entries 4, 5, and 8), which provides a route not only for the prolongation of alkyl chains but for the modification of *N*-alkyl groups, i.e., the formal functionalization of α-position of tertiary amines.

In summary, we have established a new method for a facile formation of α-siloxy amines by "silicon Polonovski reaction," and some successful applications of this versatile synthetic intermediate to the functionalization of amines by the reactions with electrophiles. Although dealkylation of tertiary amines to secondary amine derivatives can be achieved by several methods such as the Polonovski reaction[2] and the von Braun reaction,[12] the present method has the following advantages. (1) Various derivatives of secondary amines including free amines can be obtained directly using appropriate electrophiles. (2) Facile transalkylation reactions of tertiary amines are feasible using fluoride induced desilylation of α-siloxy amines. In view of ready availability of tertiary amine *N*-oxides and a variety of electrophiles and of the achievement of the direct dealkylation and transalkylation of tertiary amines, we believe that the "silicon Polonovski reaction" described here will provide a new convenient synthetic method for nitrogen containing compounds including natural products.

Experimental

All the melting points and boiling points were not corrected. ^1H NMR spectra were measured with Hitachi R-

24B, Hitachi R-20B (60 MHz), and JEOL JNM-FX90Q (90 MHz) spectrometers using tetramethylsilane as an internal standard. ^{13}C NMR spectra were measured with JEOL JNM-FX90Q. The NMR spectra were measured in deuteriochloroform at room temperature unless otherwise noted. MS spectra were measured with JEOL JMS-D300 mass spectrometer. All the experiments were carried out in argon or nitrogen atmosphere.

Materials. Amine *N*-oxides were prepared by oxidation of the corresponding amines by either 30% hydrogen peroxide or *m*-chloroperbenzoic acid. 2-Methyl-1,2,3,4-tetrahydroisoquinoline[13] and *N*-benzylpiperidine[14] were prepared by the reported method. The other amines used were commercial products.

Formation of Amides. The procedure with *N*-methylpiperidine *N*-oxide (**1a**) is typical.

General Procedure. Transformation of *N*-Methylpiperidine *N*-Oxide (1a) into *N*-Benzoylpiperidine (9a). To a solution of *N*-methylpiperidine *N*-oxide (**1a**) (140.4 mg, 1.22 mmol) in 10 ml of dichloromethane was added *t*-butyldimethylsilyl trifluoromethanesulfonate (TBDMSOTf) (355 mg, 1.1 equiv) at 0 °C and the mixture was stirred for 30 min at this temperature. After the replacement of the solvent into 10 ml of THF, to this solution was added methyllithium (1.59 mmol, 1.3 equiv) at 0 °C, during which time an evolution of gas was observed. After stirring for 1 h, to this solution was added 0.21 ml (1.81 mmol, 1.5 equiv) of benzoyl chloride at 0 °C, and the mixture was stirred overnight at room temperature. The solvent was evaporated and the resulting oil was submitted to chromatography (Al_2O_3, hexane–ether 3:1) to afford *N*-benzoylpiperidine (**9a**) (175.3 mg, 76%, oil). The structure of the product was confirmed by the following spectral data and by comparison with an authentic sample. **9a**: ^1H NMR δ=1.6 (brs, 6H), 3.5 (brs, 4H), and 7.35 (s, 5H); MS *m/z* (rel, intensity) 189 (M^+, 16%), 188 (34), 122 (29), 105 (100), and 77 (86).

The amide formation from other *N*-oxides listed in Table 2 were carried out in a similar way. The spectral data of the products were as follows. **9b—e** were identified by comparison of these spectral data with those of anthentic samples prepared by benzoylation of the amines. **9b**: White solid; ^1H NMR δ=4.5 (brs, 4H) and 6.7—7.6 (m, 15H); MS *m/z* 301 (M^+, 3%), 211 (18), 210 (34), 149 (12), 105 (100), 98 (8), 91 (19), 84 (30), and 77 (36). **9c**: Pale yellow oil; ^1H NMR δ=3.48 (s, 3H) and 6.7—7.6 (m, 10H); MS *m/z* 211 (M^+, 21%), 122 (22), 105 (100), and 77 (92). **9d**: Colorless oil; ^1H NMR δ=1.1 (brt, *J*=7 Hz, 6H), 3.0—3.7 (m, 4H), and 7.3 (s, 5H); MS *m/z* 177 (M^+, 18), 176 (25), 105 (100), and 77 (42). **9e**: Colorless oil; ^1H NMR δ=2.93 (s, 6H) and 7.25 (s, 5H). **9e'**: Pale yellow oil; ^1H NMR δ=2.87 (s, 3H), 4.53 (brs, 2H), and 7.27 (s, 5H). **9f**: White paste; ^1H NMR δ=1.9—4.1 (m, 7H), 6.9—7.6 (m, 9H), and 9.81, 10.24 (brd, 1H); ^{13}C NMR (−50 °C) δ=193.75, 193.40, 172.03, 171.13, 140.80, 139.33, 135.84, 135.73, 135.49, 134.49, 133.86, 133.37, 133.21, 131.94, 129.50, 129.01, 128.23, 128.07, 127.36, 126.77, 126.01, 51.46, 48.67, 38.17, 33.15, 31.96, and 30.45; MS *m/z* 267 (M^+, 1%), 161 (22), 149 (11), 148 (29), 136 (12), 132 (5), 119 (5), 118 (39), 106 (9), 105 (100), 91 (6), 90 (16), 77 (31), and 57 (10); High-MS, Found: *m/z* 267.1258. Calcd for $C_{17}H_{17}NO_2$: M, 267.1258.

Trapping of Benzaldehyde. To a solution of tribenzylamine oxide (147.5 mg, 0.49 mmol) in dichloromethane (10 ml) was added TBDMSOTf (142.3 mg, 1.1 equiv). After the solvent exchange into 5 ml of THF, MeLi (0.59 mmol, 1.2 equiv) was added at 0 °C and the mixture was stirred for 30 min. To this yellow solution was added an excess of acidic solution of 2,4-dinitrophenylhydrazine (0.25 g, 1.25 mmol/concd H_2SO_4 1.9 ml/EtOH 19 ml/H_2O 65 ml) and the mixture was stirred vigorously. The red brown precipitates were collected by filtration and dried to give benzaldehyde hydrazone (77.6 mg, 56%), mp 237 °C.[15]

Formation of Carbamates. As a typical example, the procedure with *N*-methylpiperidine *N*-oxide (**1a**) is described.

Transformation of 1a to 11a. To a solution of **1a** (226 mg, 1.97 mmol) in 12 ml of dichloromethane was added TMSOTf (656 mg, 1.5 equiv) and after the replacement of the solvent into THF (15 ml) was added *n*-BuLi (2.96 mmol, 1.5 equiv). To this solution was added 0.37 ml of phenyl chloroformate (462 mg, 1.5 equiv) at 0 °C and the mixture was stirred overnight at room temperature. After the removal of the solvent the residual oil was subjected to chromatography (Al_2O_3, hexane–ether 3:1) to afford the corresponding carbamate **11a** (264.3 mg, 65%) as a white solid.[16] **11a**: ^1H NMR δ=1.5—1.8 (m, 6H), 3.2—3.8 (m, 4H), and 6.8—7.5 (m, 5H); ^{13}C NMR δ=153.68, 151.67, 129.11, 124.97, 121.72, 45.30, 25.74, and 24.30; MS *m/z* 205 (M^+, 10%), 112 (100), 94 (45), 77 (16), and 72 (29).

Other *N*-oxides listed in Table 3 (**1c**, **1d**, and **1i**) were converted into the corresponding carbamates **11c**, **11d**, and **11i** in a similar way to **1a** in 40, 41, and 23% yields, respectively.[17] **11c**: Colorless oil; ^1H NMR δ=3.33 (s, 3H) and 6.5—7.4 (m, 10H); MS *m/z* 227 (M^+, 20%), 134 (100), 106 (34), 94 (42), and 77 (45). **11d**: Pale yellow oil; ^1H NMR δ=1.20 (t, *J*=7.5 Hz, 6H), 4.63 (q, *J*=7.5 Hz, 4H), and 6.8—7.5 (m, 5H); MS *m/z* 193 (M^+, 9%), 100 (100), 98 (15), 94 (12), 77 (7), and 72 (64). **11i**: Colorless oil; ^1H NMR δ=0.9—2.1 (m, 10H), 2.90 (s, 3H), 4.0 (brs, 1H), and 6.7—7.6 (m, 5H); MS *m/z* 233 (M^+, 7%), 140 (50), 94 (100), 83 (73), and 77 (10).

Dealkylation of Tribenzylamine via Its *N*-Oxide. To a solution of tribenzylamine oxide (**1b**) (172 mg, 0.57 mmol) in 10 ml of dichloromethane was added TBDMSOTf (180.6 mg, 1.2 equiv) and after the solvent exchange into THF (10 ml) was added MeLi (0.74 mmol, 1.3 equiv) at 0 °C. After stirring for 1 h at room temperature 0.32 ml (5.6 mmol, 9.8 equiv) of acetic acid was added to the reaction mixture at room temperature and then the mixture was refluxed for 2 h. After removal of the solvent the mixture was shaken with 30 ml of dichloromethane and 5% aq. NaOH solution. The aqueous layer was extracted with dichloromethane (20 ml×2) and the extracts were combined with the organic layer, dried over $MgSO_4$, and concentrated. The resulting oil was subjected to chromatography on alumina (hexane–ether) to give dibenzylamine (75.0 mg, 67%). The ^1H NMR spectrum of the product was consistent with that of an authentic sample.

***N*-Nitrosation Reactions. a) Dibenzylamine.** To a solution of tribenzylamine oxide (**1b**) (213 mg, 0.7 mmol) in 7.5 ml of dichloromethane was added TBDMSOTf (240 mg, 1.3 equiv) and MeLi (0.91 mmol, 1.3 equiv) as described above and after the addition of acetic acid (0.4 ml, 10 equiv) the mixture was refluxed for 1 h. To this mixture was added isopentyl nitrite (0.47 ml, 5 equiv) at room temperature and

then the mixture was refluxed for 1 h. After evaporation of the solvent the residual oil was treated with 50 ml of 5% aq. NaOH solution and 50 ml of dichloromethane. The aqueous layer was extracted with dichloromethane (30 ml×3), and the extracts were combined with the organic layer, dried over $MgSO_4$, and concentrated. The residual oil was submitted to chromatography (Al_2O_3, hexane-CH_2Cl_2 6:1) to give *N*-nitrosodibenzylamine (135.3 mg, 85%) as a white solid; ^{1}H NMR δ=4.61 (s, 2H), 5.14 (s, 2H), and 6.7—7.8 (m, 10H); ^{13}C NMR δ=135.46, 134.81, 129.78, 129.56, 129.26, 129.11, 128.61, 55.76, and 45.85; MS *m/z* 226 (M^+, 11%), 181 (5), 149 (3), 118 (3), 105 (4), 92 (11), 91 (100), and 65 (13); white solid mp 57—8 °C (lit,[18] mp 58 °C).

b) Piperidine. To a solution of **1a** (192.7 mg, 1.68 mmol) in 10 ml of dichloromethane was added TBDMSOTf (532 mg, 1.2 equiv) at 0 °C, and after the solvent exchange into THF (15 ml) was added MeLi (2.1 mmol, 1.25 equiv). To this mixture was added 1 ml (10 equiv) of acetic acid and subsequently 15% ethanol solution of ethyl nitrite (2.5 ml, 3 equiv) and then the mixture was refluxed overnight. The solvent was evaporated and chromatography (Al_2O_3, hexane–ether 3:1) of the residual oil gave *N*-nitrosopiperidine (78.9 mg, 41%); colorless oil; ^{1}H NMR δ=1.2—1.9 (m, 6H), 3.6—3.9 (m, 2H), and 4.1—4.3 (m, 2H); ^{13}C NMR δ=50.84, 39.84, 26.49, 24.78, and 24.22. The properties of the product were identical with those of an authentic sample.[19]

Transalkylation. The procedure with **1a** and benzyl chloride is typical.

a) Transformation of 1a into *N*-Benzylpiperidine. To a solution of **1a** (115.0 mg, 1 mmol) in 10 ml of dichloromethane was added TBDMSOTf (290 mg, 1.1 equiv) and after the solvent exchange into THF (15 ml) was added MeLi (1.2 mmol, 1.2 equiv) at 0 °C. After stirring for 1 h at room temperature, to this solution was added benzyl chloride (0.17 ml, 189 mg, 1.5 equiv) and tetrabutylammonium fluoride (n-$Bu_4N^+F^-$) (THF solution, 1.1 mmol, 1.1 equiv) at room temperature. The mixture was then heated in a sealed tube at 110 °C for 10 h. After the evaporation of the solvent the resulting oil was subjected to chromatography (Al_2O_3, hexane–ether 3:1) to afford *N*-benzylpiperidine (**12a**; R=CH_2Ph) (101.7 mg, 58%). **12a** (R=CH_2Ph):[20] Colorless oil; ^{1}H NMR δ=1.1—1.8 (m, 6H), 2.1—2.5 (m, 4H), 3.5 (s, 2H), and 7.3 (s, 5H); MS *m/z* 175 (M^+, 46%), 174 (49), 98 (53), 92 (16), 91 (100), and 84 (56).

The other transalkylation reactions listed in Table 4 were carried out silimarly. In the case of benzoylmethylation, solid phenacyl bromide was added in one portion. **12a** (R=$(CH_2)_4CH_3$):[21] colorless oil; ^{1}H NMR δ=0.8—1.8 (m, 14H) and 1.9—2.5 (m, 6H); MS *m/z* 155 (M^+, 5%), 100 (8), 99 (9), 98 (100), 70 (6), and 57 (11). **12a**: (R=$(CH_2)_7CH_3$):[22] Colorless oil; ^{1}H NMR δ=0.6—1.8 (m, 21H), and 2.0—2.6 (m, 6H). **12a** (R=$CH_2CO_2CH_2CH_3$):[23] Pale yellow oil; ^{1}H NMR δ=1.27 (t, J=8 Hz, 3H), 1.2—2.0 (m, 6H), 2.4—2.7 (m, 4H), 3.21 (s, 2H), and 4.24 (q, J=8 Hz, 2H); MS *m/z* 171 (M^+, 5%), 157 (2), 127 (2), 114 (3), 99 (12), 98 (100), 86 (21), 84 (34), 71 (16), and 57 (21). **12a** (R=CH_2COPh):[24] Pale yellow oil; ^{1}H NMR δ=1.1—1.9 (m, 6H), 2.2—2.6 (m, 4H), 3.70 (s, 2H), 7.2—7.7 (m, 3H), and 7.9—8.3 (m, 2H). **12d** (R=CH_2Ph):[25] Pale yellow oil; ^{1}H NMR δ=1.00 (t, J=8 Hz, 6H), 2.53 (q, J=8 Hz, 4H), 3.64 (s, 2H), and 7.53 (s, 5H); MS *m/z* 163 (M^+, 5%), 162 (4), 148 (23), 142 (3), 105 (3), 92 (16), 91 (100), 86 (5), 77 (3), and 65 (8). **12d** (R=$(CH_2)_7CH_3$):[26] Colorless oil; ^{1}H NMR δ=0.7—1.9 (m, 15H), 0.89 (t, J=7.5 Hz, 6H), 2.0—2.5 (m, 2H), and 2.40 (q, J=7.5 Hz, 4H); MS *m/z* 185 (M^+, 15%), 170 (4), 142 (42), 100 (15), 91 (100), 58 (10), and 57 (15). **12d** (R=$CH_2CO_2CH_2CH_3$):[27] Pale yellow oil; ^{1}H NMR δ=1.00 (t, J=7.5 Hz, 3H), 1.16 (t, J=7.5 Hz, 6H), 2.57 (q, J=7.5 Hz, 4H), 3.54 (s, 2H), and 4.10 (q, J=7.5 Hz, 2H); MS *m/z* 159 (M^+, 5%), 145 (8), 144 (91), 130 (4), 116 (18), 88 (12), 86 (100), 72 (20), and 58 (25).

The authors are grateful to Shin-etsu Chemical Co. Ltd. for the generous gift of chlorosilanes.

4) The quantitative formation of siloxyammonium salts **6** was confirmed by the following experiment. To a deuteriochloroform solution (0.5 ml) of **1a** (40 mg, 0.35 mmol) was added TMSOTf (93 mg, 1.2 equiv) under argon at 0 °C in an NMR sample tube. In the ^{1}H NMR spectrum of the mixture a singlet at δ 3.67 due to the *N*-methyl protons of siloxyammonium salts **6a** appeared at the expense of a singlet at δ 3.19 due to the *N*-methyl protons of **1a**. Furthermore, the *N*-α protons of the piperidine ring of **6a** appeared as a multiplet at about δ 3.6, while those of **1a** were observed as a multiplet at about δ 3.2, and the protons of trimethylsilyl group of **6a** were observed at δ 0.48 as a singlet peak. The low-field shift of the *N*-methyl and *N*-α protons suggested the formation of siloxyammonium salt **6a** and the absence of the *N*-methyl signal of **1a** at δ 3.19 showed the almost quantitative conversion into **6a**.

5) Any change in reaction time, temperature, stoichiometry of reactants, and additives did not improve the yield of the amide.

6) Trimethylsilyl chloride can also be used as a silylating agent, but much less effectively as expected from its low silylation ability.[7] The reaction using **1a**, trimethylsilyl chloride, butyllithium and phenyl chloroformate gave the corresponding carbamate in 24%, while the use of TMSOTf under otherwise identical conditions resulted in the yield of 65% (see Table 3).

Reactions of Trialkylstannane Anions R_3Sn^- with Arylstannanes $ArSnR'_3$

Kunio MOCHIDA
Department of Chemistry, Faculty of Sciences, Gakushuin University,
1-5-1 Mejiro, Tokyo 171
(Received March 24, 1987)

The reactions of trialkylstannane anions R_3Sn^- with arylstannanes $ArSnR'_3$ have been investigated; trialkylstannane anions with arylstannanes at 50 °C gave substitution products $ArSnR_3$ in good yields. Most of these substitution products are diverted to reduction products ArH when *t*-butylamine for trapping free anionoids is present in the reaction mixture. These results are consistent with an initial tin-alkali metal exchange or an electron-transfer forming aryl anions and distannanes which subsequently react to the substitution products. Aryl radical intermediates by an electron-transfer process are also important in the reactions of trialkylstannane anions with electron-withdrawing groups-substituted arylstannanes, 1-naphthylstannanes, diphenylstannanes, and triphenylmethylstannane as good electron acceptor substrates.

The displacement of halides and other groups from alkyl and aryl substrates by alkali metal derivatives of organometal anions represents one of the most important methods for the formation of carbon–metal σ bonds.[1] This approach to the formation of carbon–metal σ bonds has been particularly useful in group 4B chemistry.

Arylstannanes can be synthesized by the reactions of triorganostannane anions with aryl halides.[2-12] This formal nucleophilic aromatic substitution by triorganostannane anions is of considerable interest both in synthetic chemistry and regarding reaction mechanisms. Recently, Kuivila and co-workers,[11] and Pereyre and co-workers[12] have reported on the reactions of trialkylstannane anions with aryl halides and discussed on the mechanism involving alkali metal exchange, electron-transfer, and benzyne process in detail. However, a study of nucleophilic aromatic substitution by triorganostannane anions has been limited to aryl halides as substrates.

In this paper, we describe other nucleophilic aromatic substitutions by trialkylstannane anions: that is, reactions of trialkylstannane anions with arylstannanes.

Results

Reactions of Trimethylstannane Anions with Phenyltrialkylsilane, -germane, and -stannane. Reactions of sodium, lithium, and potassium trimethylstannate, prepared from chlorotrimethylstannane or hexamethyldistannane and alkali metals with phenyltrialkylsilane, -germane, and -stannane were examined under various conditions. These results are

a) A: at 24 °C for 1 h; B: at 50 °C for 30 min. b) Based on the concentration of Me_3SnM'. c) Yields of products could not be determined by GLC.

summarized in Table 1.

The reaction of lithium trimethylstannate with phenyltriethylstannane in tetrahydrofuran (THF) at 24 °C for 1 h gave no substitution products. Hexamethyldistannane was formed quantitatively and phenyltriethylstannane was nearly recovered. Lithium trimethylstannate reacted with phenyltriethylstanane at 50 °C for 30 min to give phenyltrimethylstannane, hexamethyldistannane, and trimethylstannane (No. 4). The reaction time and temperature effected the yields of products. At a constant temperature of 50 °C, the yield of phenyltrimethylstannane reached a maximum (ca. 30%) in 40—50 min and, then, gradually decreased. On the other hand, the yield of the product rose to ca. 40% as the temperature was increased to 60 °C for 30 min. However, it is known that lithium trimethylstannate reacts with THF to give ring-opening products at high temperatures and for a long reaction time.[13] Under the reaction conditions (50 °C and 30 min) employed here, the yield of phenyltrimethylstannane is better and side reactions occur only slightly.

The stability of lithium trimethylstannate was stable at 50 °C for 30 min (Fig. 1). A part of lithium trimethylstannate changed to hexamethyldistannane.

As shown in Table 1, a substitution product was also produced in the reactions of lithium trimethylstannate with phenyltriethylstannane in 1,2-dimethoxyethane (DME), tetraglyme (TG), and hexamethylphosphoric triamide (HMPA) (Nos. 5—7). The product was produced even at 24 °C in HMPA. The yield of a substitution product by lithium trimethylstannate in various solvents (Table 1) was variable and depended upon the polarity of the solvents employed.

Sodium and potassium trimethylstannate in THF also reacted with phenyltriethylstannane at 50 °C (Nos. 8 and 9). The yields of the substitution products were almost constant with experimental errors, despite counter ions.

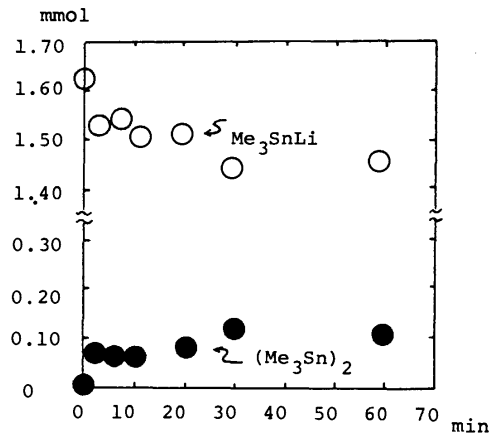

Fig. 1. The stability of lithium trimethylstannate (1.63 mmol) at 50 °C.

Through reactions of lithium trimethylstannate with phenyltrimethylsilane and -germane, the corresponding substitution products were not produced. Only hexamethyldistannane was formed (Nos. 1 and 2).

Reactions of Lithium Trimethylstannate with Arylstannanes. Reactions of lithium trimethylstannate with various arylstannanes in THF were examined. The results are summarized in Table 2.

Table 2 shows the effects of substituents of aryl groups on the yields of the substitution and reduction products in the reactions of lithium trimethylstannate and aryltriethylstannanes. The yields of substitution and reduction products increased as the substituents of aryl groups became electron-withdrawing: *m*-CF_3≫*H*>*p*-CH_3≳*p*-OCH_3 (Nos. 4, 10, 11, and 12). With [*m*-(trifluoromethyl)phenyl]triethylstannane, α,α,α-trifluorotoluene was produced in 9% yield. Furthermore, the color of the solution of [*m*-(trifluoromethyl)phenyl]triethylstannane and lithium trimethylstannate changed to red, unlike other solutions. These facts probably suggest that the reaction of lithium trimethylstannate with [*m*-(trifluoromethyl)-phenyl]triethylstannane involves an electron transfer

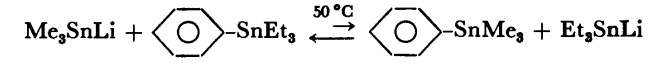
followed by a free radical process, rather than a simple bimolecular nucleophilic reaction.

Table 2 also shows the effects of aryl groups on the yields of substitution and reduction products in the reactions of lithium trimethylstannate with arylstannanes. Lithium trimethylstannate reacted with phenyltripropylstannane and phenyltributylstannane with difficulty to produce phenyltrimethylstannane, (Nos. 13 and 14, respectively). However, with diphenyldibutylstannane, triphenylmethylstannane, and 1-naphthyltriethylstannane, lithium trimethylstannate reacted at 24 °C to give substitution products, although the yields of the products were very low. Especially, triphenylmethylstannane was very reactive toward lithium trimethylstannate and the substitution product by the reaction of lithium trimethylstannate with triphenylmethylstannane at 50 °C was formed quantitatively (No. 18).

The formation of reduction products was fairly well observed in the reactions of lithium trimethylstannate with [*m*-(trifluoromethyl)phenyl]triethylstannane, diphenyldibutylstannane, and 1-naphthyltriethylstannane. These arylstannanes are known to be good electron acceptor substrates.

Reactions of Lithium Trialkylstannates with Phenyltrimethylstannane. The effect of modest changes in the steric bulk at the tin atom were estimated by examining the reactions of lithium triethylstannate, tripropylstannate, and tributylstannate with respect to the yields of substitution products. These results are summarized in Table 3. The reaction of lithium triethylstannate with phenyltrimethylstannane occurred with great facility to give a substitution product, phenyltriethylstannane, in high yield. Benzene was formed in low yield (No. 21). However, lithium tripropylstannate or tributylstannate did not react with phenyltrimethylstannane. Hexaalkyldistannanes were detected in both reactions. It is clear that the difference of reactivities of lithium trialkylstannates may be due to either the steric bulk at the tin atom or the degree of associations of lithium trialkylstannates.

By taking the results in Tables 1 and 3 into consideration, the reaction of lithium trimethylstannate with phenyltriethylstannane at 50 °C is reversible. Equilibrium of this reaction leans to the reverse direction.



On the other hand, the reactions of lithium trimethylstannate with phenyltripropylstannane and phenyltributylstannane are irreversible.

Reactions of Lithium Trimethylstannate with Aryltriethylstannanes in the Presence of Trapping Reagents. Recently, Kuivila and co-workers have reported that *t*-butylamine is a very effective trapping reagent for free anionoids.[14] In order to obtain further information on the mechanism of the reactions of trialkylstannane anions with arylstannanes, the reactions of lithium trimethylstannate with phenyltriethylstannane, [*m*-(trifluoromethyl)phenyl]triethylstannane, and 1-naphthyltriethylstannane in the presence of *t*-butylamine for aryl anions and cumene

for free aryl radicals were examined. These results are summarized in Table 4.

t-Butylamine reacted more rapidly with the carbanion intermediates to give the corresponding alkanes than with lithium trimethylstannate under these conditions. The stability of lithium trimethylstannate in the presence of *t*-butylamine was examined at 50 °C. Lithium trimethylstannate is susceptible to form hexamethyldistannane. However, the concentration of lithium trimethylstannate is sufficiently large to react with aryltriethylstannanes under these conditions (Fig 2).

Lithium trimethylstannate reacted with phenyltriethylstannane in THF at 50 °C to produce <1% benzene, 24% phenyltrimethylstannane, 16% hexamethyldistannane, and 17% 1,1,1-trimethyl-2,2,2-triethyldistannane (No. 4). When *t*-butylamine was present in the initial reaction mixture, the yields of benzene, hexamethyldistannane, and 1,1,1-trimethyl-2,2,2-triethyldistannane increased upon increasing the concentration of *t*-butylamine, and that of phenyltrimethylstannane deccreased correspondingly (Fig. 3). Lithium trimethylstannate reacted with phenyltriethylstannane at higher *t*-butylamine concentrations to give 10% benzene, 2% phenyltrimethylstannane, 44% hexamethyldistannane, and 19% 1,1,1-trimethyl-2,2,2-triethyldistannane. Similarly, the effects of the *t*-butylamine concentration on the yields of products in the reactions of lithium trimethylstannate with [*m*-(trifluoromethyl)phenyl]triethylstannane and 1-naphthyltriethylstannane were examined. The yields of reduction products, hexamethyldistannane, and 1,1,1-trimethyl-2,2,2-triethyldistannane increased with the concentration of *t*-butylamine, and the substitution products decreased correspondingly. The yields of substitution products at the higher *t*-butylamine concentrations decreased in order: [*m*-(trifluoromethyl)phenyl]triethylstannane>1-naphthyltriethylstannane>phenyltriethylstannane. In contrast with the results of [*m*-(trifluoromethyl)phenyl]triethylstannane (Nos. 12 and 26) and 1-naphthyltriethylstannane (Nos. 20 and 28), a total amount of increased reduction product and decreased substitution product in the reaction of lithium trimethylstannate with phenyltriethylstannane in the presence of *t*-butylamine is not consistent with that of reduction and substitution products in the initial reaction (Nos. 4 and 24). This inconsistency may be explained by the fact that lithium trimethylstannate in part changes to hexamethyldistannane before a nucleophilic reaction by trimethylstannane anion in the presence of *t*-butylamine; then, the concentration of lithium trimethylstannate decreases.

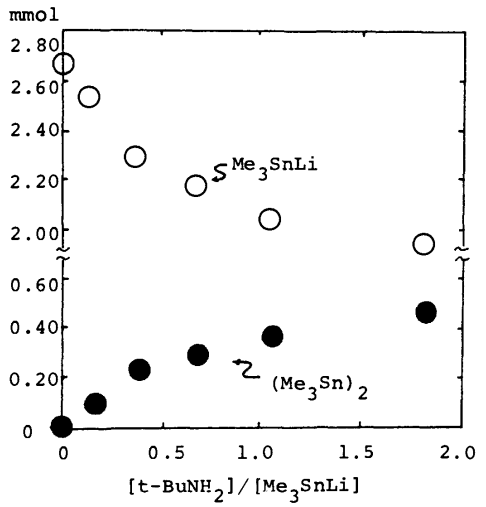

Fig. 2. The stability of lithium trimethylstannate (2.66 mmol) in the presence of *t*-butylamine at 50 °C for 30 min.

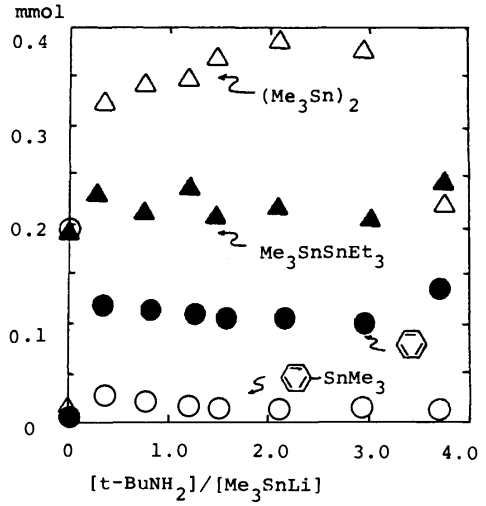

Fig. 3. Effects of TBA concentration on yields of products in the reaction of lithium trimethylstannate (1.28 mmol) with phenyltrimethylstannane (1.12 mmol) at 50 °C for 30 min.

Cumene is known to be an effective reagent for trapping free aryl radicals. Lithium trimethylstannate reacted with phenyltriethylstannane in the presence of cumene to produce <1% benzene, 12% phenyltrimethylstannane, 42% hexamethyldistannane, and 1,1,1-trimethyl-2,2,2-triethyldistannane (No. 25). Similarly, the effects of cumene on the yields of products in the reactions of lithium trimethylstannate with [*m*-(trifluoromethyl)phenyl]triethylstannane and 1-naphthyltriethylstannane were also examined. The yields of the reduction products, substitution products, 1,1,1-trimethyl-2,2,2-triethyldistannane, and hexaethyldistannane decreased, and hexamethyldistannane increased in both reactions in the presence of cumene (Nos. 27 and 29). By taking into consideration that lithium trimethylstannate is susceptible to form hexamethyldistannane in the presence of cumene at 50 °C, the decreased yields of products,

except for hexamethyldistannane, may be due to the low concentration of lithium trimethylstannate. Thus, cumene may not be an effective trapping reagent for free aryl radical intermediates under these reaction conditions. The results of reactions of lithium trimethylstannate with arylstannanes in the presence of trapping reagents are summarized in Table 4.

ESR Studies. In addition to the chemical evidence, ESR studies on the reactions of lithium trimethylstannate with phenyltriethylstannane and [*m*-(trifluoromethyl)phenyl]triethylstannane were examined. No ESR signals in the reaction of lithium trimethylstannate with phenyltriethylstannane in THF were observed. On the other hand, a very complexed ESR spectra attributed to carbon centered radicals (judging from the *g* factor) were observed in the case of [*m*-(trifluoromethyl)phenyl]triethylstannane. However, the ESR spectra could not be analyzed.

Discussion

The results summarized in Tables 1—3 demonstrate that trimethylstannane and triethylstannane anions react with arylstannanes to give substitution products, aryltrimethylstannane and aryltriethylstannane, respectively. The reactions of trialkylstannane anions with aryltriethylstannanes are endothermic. The yields of reduction and substitution products are highly variable, depending on the arylstannanes employed. In general, the yields of reduction products increased in the reactions of trialkylstannane anions with electron-withdrawing groups-substituted aryltriethylstannanes, 1-naphthyltriethylstannane, diphenyldibutylstannane, and triphenylmethylstannane as good electron acceptor substrates.

Recently, Kuivila and co-workers have demonstrated that *t*-butylamine is an effective reagent for trapping free anionoids.[14] The results in Table 4 show that the yields of reduction products increase in the presence of *t*-butylamine. These facts strongly imply that aryl anions are imporatnt intermediates in these reactions by trialkylstannyl anions. The formation of aryl anions can be explained by tin–alkali metal exchange or electron-transfer process. By the results of tin–alkali metal exchange in the reactions of trialkylstannyl anions with arylstannanes, aryl anions and distannanes are formed in the cage. Continuously, aryl anions react with distannanes to form substitution products (arylstannanes) and the corresponding stannane anions. Furthermore, the reactions of stannane anions, thus prepared, with the substitution products (arylstannanes) occur if circumstance requires. When *t*-butylamine is present in the reaction mixture, escaped aryl anions from the cage are trapped to give reduction products. As a result, the yields of reduction products and unattacked distannanes by aryl anions increase and those of substitution products decrease.

On the other hand, in light of trialkylstannane anions to act as one electron reducing reagents toward suitable substrates, the formation of aryl anions may also be explained by an electron-transfer process.[15] The first step is an electron-transfer from trialkylstannane anions to arylstannanes that leads to arylstannane anion radicals and trialkylstannane radicals in a cage. Subsequently, aryl anions and stannane radicals are formed from unstable arylstannane anion radicals. Distannanes are formed by a cage combination of stannane radicals from unstable arylstannane anion radicals and trialkylstannane radicals. The property of the formation of aryl anions by electron-transfer is discussed later. The attack on either tin atoms of the formed distannanes by aryl anions depends on the nature of the aryl anions and the stannane compounds. The mechansim for aryl anion intermediates in the reactions of trialkylstannane anions with arylstannanes is proposed in the following (Scheme 1).

The reaction of lithium trimethylstannate with phenyltriethylstannane at 50 °C is reversible. Equilibrium of this reaction shifts to the reverse direction. This shift may be due to either the difference of nucleophilicity or the degree of association of trimethylstannane and triethylstannane anions. On the other hand, the reactions of lithium trimethylstannate with phenyltripropylstannane and phenyltributylstannane at 50 °C are irreversible, respectively. This irreversibility of the reaction may result from either the steric hindrance or degree of association of tributylstannane and tripropylstannane anions.

However, by judging from the results of the formation of reduction products at the higher *t*-butylamine concentrations, aryl radical intermediates are also formed in the reactions of trialkylstannane anions with arylstannanes. The formation of aryl radicals may be explained by an electron-transfer process. The first step is an electron-transfer from trialkylstannane anions to arylstannanes that leads to

$$R_3Sn^-M^+ + ArSnR_3' \longrightarrow \begin{cases} \overline{Ar^-M^+\ R_3SnSnR_3'} \\ \text{or} \\ \overline{R_3Sn\cdot\ M^+\ [ArSnR_3']^{\pm}} \longrightarrow \overline{Ar^-M^+\ R_3Sn\cdot\ \cdot SnR_3'} \end{cases} \longrightarrow \text{products}$$

Scheme 1. The mechanism for aryl anion intermediates.

$$R_3Sn\text{-}M^+ + ArSnR_3' \longrightarrow \overline{R_3Sn\cdot\ M^+\ [ArSnR_3']^{\pm}}$$
$$\longrightarrow \overline{R_3Sn\cdot\ \cdot Ar\ M^+SnR_3'^-}$$
$$\longrightarrow \text{products}$$

Scheme 2. The mechanism for aryl radical intermediates.

arylstannane anion radicals and trialkylstannane radicals in the cage. Subsequent dissociation of aryl radicals produced from unstable arylstannane anion radicals followed by cage combination with trialkylstannane radicals and by proton abstraction from solvents employed would provide substitution products, aryltrialkylstannanes, and reduction products, respectively. According to this scheme, the formations of reduction and substitution products can be observed despite of *t*-butylamine (Scheme 2).

In fact, the formation of reduction products in the absence of *t*-butylamine and substitution products at the higher *t*-butylamine concentrations were observed in the reactions of trialkylstannane anions with [*m*-(trifluoromethyl)phenyl]triethylstannane, 1-napthyltriethylstannane, diphenyldibutylstannane, and triphenylmethylstannane. These facts imply that aryl radical intermediates are also involved in the reactions of trialkylstannane anions with good electron acceptors such as the above arylstannanes.

A pattern of cleavage of the aryl–tin bond for arylstannane anion radicals may be shown in the following.

$$[ArSnR_3]^{\pm} \begin{cases} \longrightarrow Ar^- + \cdot SnR_3 \\ \longrightarrow Ar\cdot + {}^-SnR_3 \end{cases}$$

A pattern of cleavage of the aryl–tin bond for arylstannane anion radicals may depend on the nature of the aryl group (Ar) and the alkyl group (R).

In conclusion, the reactions of trialkylstannane anions with arylstannanes proceed via two different key intermediates: aryl anions and aryl radicals. Aryl anion intermediates formed by tin–alkali metal exchange or electron-transfer are most important in the reactions of trialkylstannane anions with arylstannanes. However, aryl radical intermediates formed by an electron-transfer is also important in the reactions of trialkylstannane anions with [*m*-(trifluoromethyl)phenyl]triethylstannene, 1-naphthyltriethylstannane, diphenyldibutylstannane, and triphenylmethylstannane as good electron acceptor substrates.

Experimental

^{1}H NMR spectra were recorded on a Varian FT 80A, with tetramethylsilane as internal standard. GC-Mass spectra were obtained with JEOL JMS-DX 303 mass spectrometer. Infrared spectra were recorded on a Hitachi 260-10 spectrometer. Gas chromatography was performed on a Shimadzu GC-6A and -8A with 2 m 20% SE-30 and 2 m 30% Apiezon L columns.

Materials. *t*-$BuNH_2$ and cumene are commercially available and purified prior to use. Me_3SnCl, bp 152—154 °C,[16] Et_3SnCl, bp 109—110 °C/20 mmHg†,[17] Pr_3SnCl, bp 123 °C/13 mmHg,[18] Bu_3SnCl, bp 145—147 °C/5 mmHg,[19] $Me_3SnSnMe_3$, bp 182 °C,[20] $Et_3SnSnEt_3$, bp 160 °C/23 mmHg,[20] $Pr_3SnSnPr_3$, bp 142 °C/15 mmHg,[21] $Bu_3SnSnBu_3$, bp 156—160 °C/0.03 mmHg,[20] $Me_3SnSnEt_3$, bp 105 °C/6 mmHg,[20] Me_3SnH, bp 59 °C,[22] Et_3SnH, bp 79—81 °C/92 mmHg,[23] $PhSiMe_3$, bp 72 °C/27 mmHg,[24] $PhGeMe_3$, bp 80 °C/27 mmHg,[25] $PhSnMe_3$, bp 91 °C/30 mmHg,[27] *p*-$MeC_6H_4SnMe_3$, bp 105 °C/3 mmHg,[27] *p*-$MeOC_6H_4SnMe_3$, bp 115 °C/3 mmHg,[28] *m*-$CF_3C_6H_4SnMe_3$, bp 78—81 °C/14 mmHg,[28] 1-$NpSnMe_3$, bp 120 °C/1 mmHg,[27] $PhSnEt_3$, bp 113—114 °C/6 mmHg,[29] *p*-$MeC_6H_4SnEt_3$, bp 91 °C/1 mmHg,[29] *p*-$MeOC_6H_4SnEt_3$, bp 138 °C/5 mmHg,[29] *m*-$CF_3C_6H_4SnEt_3$, bp 105 °C/3 mmHg,[30] $PhSnPr_3$, bp 150 °C/15 mmHg,[31] $PhSnBu_3$, bp 139 °C/0.6 mmHg,[31] Ph_2SnBu_2, bp 137 °C/0.2 mmHg,[31] and Ph_3SnMe, mp 61 °C were prepared as cited literatures.

Preparation of 1-Naphthyltriethylstannane. A Grignard reagent was prepared from 1-bromonaphthalene (11.0 g, 0.05 mol) and magnesium (1.2 g, 0.05 g atom) in a mixture solvent of THF (50 cm^3), benzene (30 cm^3), and ether (20 cm^3). To this Grignard reagent was added chlorotriethylstannane (12.0 g, 0.05 mol) in a mixture solvent of THF (20 cm^3), benzene (10 cm^3), and ether (5 cm^3). The reaction mixture was stirred with reflux for 5 h. After hydrolysis with water, the organic layer was extracted with ether and dried over sodium sulfate. The solvent was removed and then fractional distillation gave 1-naphthyltriethylstannane (10 g, 0.03 mol, 60% yield), bp 142—145 °C/3 mmHg; ^{1}H NMR ($CDCl_3$) δ=1.30 (s, 15H), 7.25—8.00 (m, 7H); n^{20} 1.5957. Found: C, 57.48; H, 6.72%. Calcd for $C_{16}H_{22}Sn$: C, 57.70; H, 6.66%.

Preparation of Lithium Trimethylstannate. Lithium trimethylstannate was prepared from hexamethyldistannane or chlorotrimethylstannane and lithium metal in THF, DME, TG, or HMPA in an atmosphere of nitrogen for 4—5 h. Yields were determined by treatment with bromobenzene or *p*-tolyl bromide and the amounts of phenyltrimethylstannane or *p*-tolyltrimethylstannane produced, respectively, by GLC with an internal standard method. Yields were 80—85%.

Preparation of Sodium Trimethylstannate. Sodium trimethylstannate was prepared from hexamethyldistannane and sodium metal as described above for lithium trimethylstannate. Yields were 80—90%.

Preparation of Potassium Trimethylstannate. Potassium trimethylstannate was prepared as described above lithium trimethylstannate. Yields were 85—90%.

Preparation of Lithium Triethylstannate, Tripropylstannate, and Tributylstannate. Lithium triethylstannate, tripropylstannate, and tributylstannate were prepared from the corresponding chlorides and lithium metal in THF in an atmosphere of nitrogen for 4—5 h. Yields were determined by treatment with an excess of bromobenzene or *p*-tolyl bromide and by the amounts of the corresponding tin compounds formed.

Stability of Lithium Trimethylstannate at 50 °C. Li-

† 1 mmHg=133.322 Pa.

thium trimethylstannate in THF was heated at 50 °C. Yields of lithium trimethylstannate were determined by the reaction of excess of bromobenzene or *p*-tolyl bromide at constant time and the amounts of phenyltrimethylstannane or *p*-tolyltrimethylstannane, respectively, and hexamethyldistannane produced.

Stability of Lithium Trimethylstannate in the Presence of *t*-Butylamine at 50 °C. A mixture of lithium trimethylstannate and *t*-butylamine in THF was heated at 50 °C. Yields of lithium trimethylstannate were determined as described above for the stability of lithium trimethylstannate at 50 °C.

Stability of Lithium Trimethylstannate in the Presence of Cumene. A mixture of lithium trimethylstannate and cumene in THF was heated at 50 °C. Yields of lithium trimethylstannate were determined as described above of the stability of lithium trimethylstannate at 50 °C.

Reaction of Lithium Trimethylstannate with Phenyltrimethylsilane. Lithium trimethylstannate (1.67 mmol) was added to phenyltrimethylsilane (1.74 mol) in THF (2 cm^3) and stirred at 24 °C for 1 h or 50 °C for 30 min. After hydrolysis with water, the organic layer was extracted with ether. The ether solution was dried over sodium sulfate. Phenyltrimethylsilane (1.74 mmol) and hexamethyldistannane (0.86 mmol) were determined by an internal standard method by GLC. Each product was isolated by preparative GLC and structures were verified by comparing their GC-Mass, IR, and NMR retention times on GLC of authentic samples.

Reaction of Lithium Trimethylstannate with Phenyltrimethylgermane. Lithium trimethylstannate (1.12 mmol) was added to phenyltrimethylgermane (1.22 mmol) in THF (2 cm^3) and stirred at 24 °C for 1 h or at 50 °C for 30 min. After hydrolysis with water, the organic layer was extracted with ether. The ether solution was dried over sodium sulfate. Phenyltrimethylgermane (1.20 mmol) was recovered and hexamethyldistannane (0.53 mmol) was produced. Each product was isolated by preparative GLC and the structures were identified by comparing their GC-Mass, IR, and NMR spectra, and retention times on GLC with those of authentic samples.

Reaction of Lithium Trimethylstannate with Phenyltriethylstannane at 24 °C. Lithium trimethylstannate (1.67 mmol) was added to phenyltriethylstannane (1.2 mmol) in THF (2 cm^3) and stirred at 24 °C for 1 h. After hydrolysis with water, the organic layer was dried over sodium sulfate. Phenyltriethylstannane (1.18 mmol) was recovered and hexamethyldistannane (0.61 mmol), and 1,1,1-trimethyl-2,2,2-triethyldistannane (0.01 mmol) were formed. Each product was isolated by preparative GLC and the structures were identified by comparing their GC-Mass, IR, NMR, and retention times on GLC with those of authentic samples.

Reaction of Lithium Trimethylstannate with Phenyltriethylstannane at 50 °C. Lithium trimethylstannate (1.67 mmol) was added to phenyltriethylstannane (1.12 mmol) in THF (2 cm^3) and stirred at 50 °C for 30 min. After hydrolysis with water, the solution was extracted with ether. The organic layer was dried over sodium sulfate. Yields of benzene (trace), phenyltrimethylstannane (0.40 mmol), phenyltriethylstannane (0.68 mmol), hexamethyldistannane (0.27 mmol), 1,1,1-trimethyl-2,2,2-triethyldistannane (0.30 mmol), and hexaethyldistannane (trace) were determined by an internal standard method by GLC.

Reactions of Trialkylstannane Anions with Arylstannanes. Reactions of trialkylstannane anions with arylstannanes were carried out as described above for the reaction of lithium trimethylstannate with phenyltriethylstannane. Yields of the reaction products were determined in the same manner as those of the reaction of lithium trimethylstannate with phenyltriethylstannane.

Reaction of Lithium Trimethylstannate with Aryltriethylstannanes in the Presence of *t*-Butylamine. A typical example for the reactions of lithium trimethylstannate with aryltriethylstannanes in the presence of *t*-butylamine is described. Lithium trimethylstannate (1.28 mmol) was added to a mixture of phenyltriethylstannane (1.12 mmol) and *t*-butylamine (1.43 mmol) in THF (2 cm^3) and stirred at 50 °C for 30 min. After hydrolysis with water, the solution was extracted with ether. The organic layer was dried over sodium sulfate. Yields of benzene (0.12 mmol), phenyltrimethylstannane (0.03 mmol), hexamethyldistannane (0.56 mmol), and 1,1,1-trimethyl-2,2,2-triethyldistannane (0.24 mmol) were formed.

Reactions of Lithium Trimethylstannate with Aryltriethylstannanes in the Presence of Cumene. A typical example for the reactions of lithium trimethylstannate with aryltriethylstannanes in the presence of cumene is described. Lithium trimethylstannate (1.28 mmol) was added to a mixture of phenyltriethylstannane (1.12 mmol) and cumene (1.44 mmol) in THF (2 cm^3) and stirred at 50 °C for 30 min. After hydrolysis with water, the solution was extracted with ether. The organic layer was dried over sodium sulfate. Yields of phenyltrimethylstannane (0.15 mmol), hexamethyldistannane (0.53 mmol), and 1,1,1-trimethyl-2,2,2-triethyldistannane (0.14 mmol) were formed.

ESR Studies on the Reactions of Lithium Trimethylstannate with Aryltriethylstannanes. In a typical example, a solution of lithium trimethylstannate in THF was added using a hypodermic syringe to a small amount of phenyltriethylstannane contained THF in a glass tube constructed with a 6×60 mm upper portion and 2×80 mm lower portion. The tube was then sealed off after freeze-pump-thaw cycles on a vacuum line.

Synthesis, Properties, and Reactivity of (1*H*,1*H*-Perfluoroalkyl)- and (1*H*-Perfluoro-1-alkenyl)aryliodonium Triflates and Their Analogs

Teruo UMEMOTO* and Yoshihiko GOTOH
Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229
(Received March 26, 1987)

(1*H*,1*H*-Perfluoroalkyl)phenyl- and -(*p*-fluorophenyl)iodonium triflates, fluorosulfate, sulfate (**3**)—(**7**) were synthesized in good yields by the oxidation of 1-iodo-1*H*,1*H*-perfluoroalkanes ($RfCH_2I$) with trifluoroperacetic acid followed by treatment with triflic acid and benzene or fluorobenzene. (1*H*,1*H*,5*H*,5*H*-Perfluoropentane-1,5-diyl)bisphenylbisiodonium triflate was synthesized similarly. (*trans*-1*H*-Perfluoro-1-alkenyl)phenyliodonium triflates (**11**) were synthesized by dehydrofluorination of **3** with a base in good yields. Thermolysis of **3** produced 1*H*,1*H*-perfluoroalkyl triflate and iodobenzene, while **11** gave (*Z*)-1-iodo-1*H*-perfluoro-1-alkene and phenyl triflate. The thermolysis experiment, including (perfluoroalkyl)phenyliodonium triflate (**17**), demonstrated that the C–I bond strength of the trivalent iodine compounds increased in the order of $RfCH_2$–I, Rf–I<Ph–I<RfCF=CH–I. The ionic mechanism containing $RfCH_2^+$, Ph^+, and Rf^+ for the thermal decomposition of **3**, **11**, and **17**, respectively, was proposed. The reactivities of **3** and **11** to such nucleophiles as phenoxide, alkoxide, and alkanethiolate anions were studied and compared with that of **17**. Remarkable changes in the reactivity were found depending on the nature of the fluoro-alkyl and -alkenyl groups. The reaction of **11** with the oxide anions yielded (2-phenoxy- and -alkoxy-1*H*-perfluoro-1-alkenyl)phenyliodonium triflates.

Hypervalent iodine compounds have been of increasing importance from the viewpoint of the consideration of their bonding and structures, or of the organic synthesis as useful reagents or reactive intermediates.[1] Many kinds of hypervalent iodine compounds were synthesized and their properties or reactivities were studied.[1] The hypervalent iodines carrying fluoro-alkyl or -alkenyl groups have been expected to have interesting properties because of the high electronegativity of the fluoro groups.[2]

We have already synthesized a series of (perfluoroalkyl)aryliodonium triflates and their analogs, and have demonstrated that they act as reactive electrophilic perfluoroalkylating agents.[3] In this connection, it is of great interest to study the syntheses and reactivities of (1*H*,1*H*-perfluoroalkyl)- and (polyfluoroalkenyl)-aryliodonium salts where the trivalent iodine atom is separated from the electronegative perfluoroalkyl group by a methylene and a vinyl unit, respectively. It was reported that (1*H*,1*H*,ω*H*-perfluoropentyl or heptyl)-*p*-tolyliodonium halides and (1*H*,1*H*,6*H*,6*H*-perfluorohaxane-1,6-diyl)bis(*p*-tolyl)bisiodonium halides were unstable and only the bromides could be isolated in pure form in low yields.[4] The hypervalent iodines possessing fluorinated alkenyl groups have never been synthesized.

This paper describes the syntheses, properties, and reactivities of a series of (1*H*,1*H*-perfluoroalkyl)- and (1*H*-perfluoro-1-alkenyl)aryliodonium triflates and their analogs.

Results and Discussion

1-[Bis(trifluoroacetoxy)iodo]-1*H*,1*H*-perfluoroalkanes **2** were prepared almost quantitatively by treating 1-iodo-1*H*,1*H*-perfluoroalkanes **1** with trifluoroperacetic acid by the modified Yagupol'skii's procedure.[4] **2a—e** were allowed to react with benzene and triflic acid in 1,1,2-trichloro-1,2,2-trifluoroethane at 0 °C for 1 day to give (1*H*,1*H*-perfluoroalkyl)phenyliodonium triflates **3a—e** with different carbon numbers of the perfluoroalkyl (Rf) groups in good yields. ^1H NMR spectra of **3** exhibited the characteristic peaks of methylene groups which appeared at δ ca. 4.8 downfield compared to that of **1** (δ ca. 3.7), as triplets or quartets due to coupling with the vicinal fluorine atoms.

$$\underset{\textbf{1a—e}}{RfCH_2I} \xrightarrow{[O]} \underset{\textbf{2a—e}}{RfCH_2I(OCOCF_3)_2} \xrightarrow{PhH,\ TfOH} RfCH_2\text{-}\underset{\underset{Ph}{|}}{I}\text{-}OTf^{5)} \quad (1)$$

3a (Rf=CF_3, 88%)
3b (Rf=C_2F_5, 72%)
3c (Rf=*n*-C_3F_7, 70%)
3d (Rf=*i*-C_3F_7, 77%)
3e (Rf=*n*-C_7F_{15}, 89%)

The use of fluorobenzene instead of benzene gave *p*-fluorophenyl isomer **4** exclusively. Fluorosulfuric acid and sulfuric acid, instead of triflic acid, gave fluorosulfate **5** and sulfate **6**, respectively. Similarly, 1-iodo-1*H*,1*H*, ω*H*-perfluorododecane gave **7**.

$$2 \xrightarrow{ArH,\ RSO_3H} RfCH_2\text{-}\underset{\underset{Ar}{|}}{I}\text{-}OSO_2R \quad (2)$$

4 (Ar=*p*-FC_6H_4, R=CF_3, Rf=CF_3, 72%)
5 (Ar=Ph, R=F, Rf=*n*-C_7F_{15}, 95%)
6 (Ar=Ph, R=OH, Rf=*n*-C_7F_{15}, 49%)
7 (Ar=Ph, R=CF_3, Rf=$(CF_2)_{10}H$, 85%)

Bis(iodonium) triflate **9** was similarly synthesized from diiodide **8** in high yield.

$$\underset{\mathbf{8}}{ICH_2(CF_2)_3CH_2I} \xrightarrow[2,\ PhH,\ TfOH]{1,\ [O]} \underset{\mathbf{9}\quad 96\%}{TfO\text{-}I(Ph)\text{-}CH_2(CF_2)_3CH_2\text{-}I(Ph)\text{-}OTf} \qquad (3)$$

We found that triflates **3b**, **3c**, and **3e** underwent easy dehydrofluorination by treatment with sodium hydride in acetonitrile at 0 °C to give (*trans*-1*H*-perfluoro-1-alkenyl)phenyliodonium triflates **11b**, **11c**, and **11e** in good yields. The treatment of **3e** with a

$$\mathbf{3b,\ c,\ e} \xrightarrow{NaH} \underset{F}{\overset{Rf'}{\diagdown\!=\!\diagup}}\!\!\underset{Ph}{I\text{-}OTf} \qquad (4)$$

11b ($Rf' = CF_3$, 80%)
11c ($Rf' = C_2F_5$, 86%)
11e ($Rf' = n\text{-}C_6F_{13}$, 87%)

$$\left[\ Rf'CF_2\bar{C}H\text{-}\overset{+}{I}(Ph)\ \right]$$

10

weak base, 2,4,6-collidine, at room temperature gave **11e** in a 40% yield. This indicates that the methylene protons of **3** are considerably acidic. **11** were assigned as trans isomers from the coupling constant (33 Hz) between the olefinic proton and the fluorine atom. The NMR resonance (δ ca. 8.2) of the olefinic protons of **11** appeared at a very low magnetic field. The corresponding proton of iodide **15** appeared at δ 6.63. On the other hand, it is interesting that **3a** and **3d** did not afford the expected (2,2-difluorovinyl)- and (2-trifluoromethyl-3,3,3-trifluoro-1-propenyl)-phenyliodonium triflates, **11a** and **11d**, respectively, by

$$\mathbf{3a,\ d} \xrightarrow{//} \underset{Rf_2}{\overset{Rf_1}{\diagdown\!=\!\diagup}}\!\!\underset{Ph}{I\text{-}OTf} \qquad (5)$$

11a ($Rf_1 = Rf_2 = F$)
11d ($Rf_1 = Rf_2 = CF_3$)

the same procedure, but, rather, the decomposition of **3a** and **3d** occurred. We isolated sodium triflate in the latter case. This might be due to the instability or high reactivity of **11a** and **11d** compared to **11b**, **11c**, or **11e**. It is known that the 2,2-difluorovinyl moiety is sensitive to a nucleophilic attack at the C–F carbon site, while the 2,2-bis(trifluormethyl)vinyl moiety is sensitive at the C-1 site.[6]

We failed in synthesizing the fluoroalkynyl analogs **12** from **11** by the action of sodium hydride in acetonitrile. The decomposition of **11** occurred and sodium triflate was isolated.

$$\mathbf{11} \xrightarrow{NaH} Rf'\text{-}C{\equiv}C\text{-}\underset{Ph}{I}\text{-}OTf \qquad (6)$$

12

The dehydrofluorination of **3** should occur via interesting halogen ylides **10**. An attempt to react the intermediate **10e** with such an electrophile as benzaldehyde was unsuccessful.

Salts **3** are apparently nonhygroscopic, stable crystals; the stability increases as the chain of a Rf group is lengthened. In general, they are soluble in acetonitrile and almost insoluble in diethyl ether, tetrahydrofuran, or haloalkanes such as dichloromethane. **3e** is satisfactorily stable, but **3a** decomposed very slowly and almost completely in about 3 weeks at room temperature (ca. 25—31 °C). **3a** is stable enough to be handled at room temperature and can be stored for long time in a refrigerator or a freezer. *p*-Fluorophenyl analog **4** is more stable than **3a**, judging from their decomposition points. **4** decomposed completely in 2—3 days in a moist acetonitrile-d_3 solution at room temperature.

Fluoroalkenyl analogs **11** are apparently nonhygroscopic crystals and have a high stability compared to **3**. While **3** decomposed at their melting points, **11** melted without decomposition near the decomposition points of **3**.

Salts **3** appeared to us to be less stable than (perfluoroalkyl)phenyliodonium triflates **17**. This suggests that the stability of the trivalent iodine compounds decreases as the electronegativity of the alkyl groups decreases, and makes it very clear to us that nobody can succeed in the isolation of the hydrocarbon analogs,[1a,7] alkyl(aryl)iodonium salts, because of the instability arising from the low electronegativity of the hydrocarbon alkyl group.

The I···O bonds of **3—7**, **9**, and **11** appear to be highly ionic, but not completely polarized, on the

$$R\text{-}\overset{\delta+}{I}(Ph)\cdots\overset{\delta-}{O}SO_2R'$$

(R = Rf, $RfCH_2$, RfCF=CH)

basis of the fact that the ^{19}F NMR analysis of analogous iodine compounds **17** and their derivatives has demonstrated that the I···OSO_2R' bonds are not completely polarized and that the degree of polarization varies depending on the electronegativity of R'.[3a] Therefore, we can express the bonds as $>I\text{-}OSO_2R'$, but not as $>I^+\ ^-OSO_2R'$.

The thermolysis of **3** and **11** gave very interesting results: **3e** decomposed at 140—145 °C to produce 1*H*,1*H*-perfluroalkyl triflate **13** and iodobenzene **14** in good yields, while **11e** remained intact at 140 °C and decomposed at 200 °C to give (*Z*)-1-iodo-1*H*-perfluoro-1-alkene **15** and phenyl triflate **16** in good yields. As reported previously, the thermolysis of **17a**

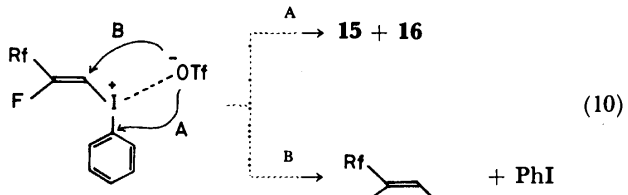
$$\mathbf{3e}\ (Rf=n\text{-}C_7F_{15}) \xrightarrow{140-145\,^\circ C} RfCH_2OTf + PhI \quad (7)$$
$$\mathbf{13}\ (90\%) \quad \mathbf{14}\ (89\%)$$

$$\mathbf{11e}\ (Rf=n\text{-}C_8F_{13}) \xrightarrow{200\,^\circ C} \begin{matrix} Rf \\ F \end{matrix}\!\!\diagdown\!\!\diagup\!\!\begin{matrix} \\ I \end{matrix} + PhOTf \quad (8)$$
$$\mathbf{15}\ (79\%) \quad \mathbf{16}\ (76\%)$$

$$Rf\text{-}I(Ph)\text{-}OTf \xrightarrow{145-151\,^\circ C} RfOTf + \mathbf{14} + I\text{-}C_6H_4\text{-}Rf \quad (9)$$
$$\mathbf{17a}\ (Rf=n\text{-}C_8F_{17}) \quad \mathbf{18}\ (73\%) \quad (63\%) \quad \mathbf{19}\ (25\%)$$

at 145—151 °C produced perfluorooctyl triflate **18**, **14**, and (perfluorooctyl)iodobenzene **19**.[3a] It is worth noting that the cleavage of CH_2–I and Rf–I bonds occurred in **3** and **17**, while the Ph–I bond was broken in **11**. **11** and **3** or **17** differ much from each other regarding the fission pattern. The above results clearly demonstrate that the C–I bond strength increases in the order of $RfCH_2$–I, Rf–I<Ph–I<RfCF=CH–I. It is noticeable that the C–I bond of RCF=CH–I is much stronger than that of Ph–I. Furthermore, the thermolysis of **11** is in sharp contrast to that of a hydrocarbon analog, vinyl(phenyl)iodonium bromide, which revealed that the bond fission between the vinyl carbon and the iodine atom occurred exclusively.[1b,8] The vinyl(phenyl)iodonium salts have been shown to be useful vinylating agents.[1b,9] They are based on a weak bonding between the vinyl carbon and the iodine atom compared to the Ph–I bond. The strong bonding between the fluorinated vinyl carbon and the iodine atom of **11** would be due to the high electronegativity of a Rf group and a fluorine atom binding to the vinyl moiety.

The cleavage of the bond between the sp^3 carbon and the iodine of **3** probably proceeds by an ionic mechanism, which is in agreement with the fact that **3** acts as a very useful source of a $RfCH_2$ cation.[10] **15** and **16** should also be formed from **11e** by the ionic mechanism, since the free-radical mechanism containing the homolytic cleavage of the C–I bond should require the improbable formation of the extremely high-energy trifluoromethanesulfonyloxyl radical for the production of **16**. The following two routes for **15** and **16** can be thought as the possible ionic mechanism: (1) The addition of TfO^- to a phenyl nucleus followed by the elimination of the positive iodine atom, and (2) the combination of a phenyl cation generated and TfO^-. Since TfO^- is one of the strongest leaving groups, the nucleophilicity is extremely low.[11] Furthermore, if the mechanism of (1) is real, why doesn't process B that gives **20** and **14** occur rather than A which gives **15** and **16**? The reason is because a Rf group has a strong stabilizing effect on the intermediate anion at the α-position. Neither **20** nor **14** was produced. Accordingly, we



(10)

$$\mathbf{11} \longrightarrow \underset{\mathbf{15}}{RfCF{=}CHI} + \underbrace{[Ph^+] + {}^-OTf}_{\downarrow\ PhOTf\ \ \mathbf{16}} \quad (11)$$

propose the phenyl cation mechanism (2) (Eq. 11). The relatively easy formation of a phenyl cation compared to the fluorinated vinyl cation is surprising in view of the fact that a phenyl cation is much less stable than a nonfluorinated vinyl cation.[12] It would reflect the strong electronegative effect of a Rf group and a fluorine atom bonding to the vinyl moiety.

18 and **14** would also be formed from **17** by an ionic mechanism containing a Rf cation. However, it is unclear by which mechanism **19** was formed, ionic or free radical. Since such a compound as **19** was not produced in the case of **3**, the formation of **19** from **17** appears to be closely related to the difference in the electronegativity between Rf and $RfCH_2$ or in the easiness in the formation between their cations, Rf^+ and $RfCH_2^+$. Rf is more electronegative than $RfCH_2$[2] and, thus, Rf^+ is more difficult to generate than $RfCH_2^+$.

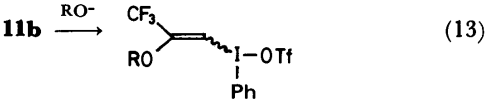
The mass spectra of **3** and **11** well reflected the strength of the bonds around the trivalent iodine atoms. All of **3** showed neither peaks corresponding to $[RfCH_2(Ph)I]^+$ nor ones corresponding to $[RfCH_2I]^+$, but base peaks or strong peaks of $[PhI]^+$. The peaks of $[RfCH_2OTf]^+$ were not observed in **3** and **7**. **5** and **6** showed small peaks of $[RfCH_2I]^+$ in addition to the base peak of $[PhI]^+$. On the other hand, all of **11** showed the strong peaks of $[RfCF{=}CHI]^+$ and $[PhOTf]^+$, and **11c** and **11e** exhibited the small peaks of $[RfCF{=}CHI(Ph)]^+$. The mass spectrum of **17** ($Rf=n\text{-}C_3F_7$) showed a strong peak of $[PhI]^+$ and a small peak of $[RfI(Ph)]^+$, but no peak of $[RfI]^+$. In this way, the fission pattern of the iodonium salts in the mass spectra is closely related to the bond strength order mentioned before. Since the mass spectra were measured at 100 °C, the spectrum of **3a** with a decomposition point of less than 100 °C may almost or partly consist of the decomposition products.

As expected from the thermolysis experiment, **3**, **11**, and **17** are very different from each other regarding reactivity. As reported, **3** reacted with phenoxide, alkoxide, and alkanethiolate anions to give *1H,1H*-perfluoroalkyl phenyl ether **21a**, alkyl ether **21b**, and alkyl sulfide **21c** in good yields, respectively,[10]

indicating an easy heterolytic fission of the C–I bonds of **3**. However, the treatment of **11b** with phenoxide and 2-phenylethoxide anions gave [[2-phenoxy- and 2-phenylethoxy-2-trifluoromethyl]vinyl]phenyliodonium triflates, **22** and **23**, in 42 and 32% yields, respectively. This should be due to a strong C–I bonding around the iodine atom of **11**. **22** was one

$$\mathbf{3} \xrightarrow{RX^-} RXCH_2Rf \qquad (12)$$

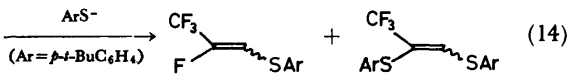
21a (X=O, R=Ph)
21b (X=O, R=CH_2CH_2Ph)
21c (X=S, R=n-$C_{12}H_{25}$)



(13)

22 (42%, R=Ph)
23 (32%, R=CH_2CH_2Ph)

isomer and **23** was a 12:88 mixture of two isomers. The structures could not be determined. On the other hand, it is interesting that **11b** reacted with an arenethiolate anion to afford monosulfide **24** and disulfide **25** in 16 and 32% yields, respectively, as a

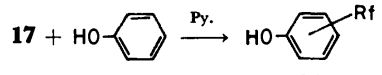


(14)

24(16%, E/Z=1/4) **25**(32%, E/Z or Z/E=1/6)

mixture of each two structural isomers. Although the detailed reaction mechanism is unclear, the difference between the oxide and the thiolate anions may be attributed to the high nucleophilicity of the thiolate anion since **11** has a double bond activated with two leaving groups, a fluorine atom and the polarized iodine atom.

3 are quite different from **17** in their reactivities. The treatment of **17** with an alkoxide produced no perfluoroalkyl ether, but a decomposition of **17** occurred.[3b] However, **17** reacted with arenethiols and alkanethiols in the presence of a base in dichloromethane to give perfluoroalkyl aryl and alkyl sulfides in good yields.[3b,13] **17** smoothly reacted with phenol in the presence of a base to afford a mixture of *o*-, *m*-, and *p*-Rf-phenyls **25** in a 55% yield with a ratio of 4.1:1:4.6, but not an ether, RfOPh[3b,14] (Eq. 15). With phenols having bulky substituents, **17** gave the



(15)

25

perfluoroalkyl ethers along with the *C*-perfluoroalkylated phenols.[15] As mentioned above, **3** reacted only at the oxygen site of the phenoxide anion, but **3** reacted with the anion of phenol having an electron-donating substituent to give a small amount of *C*-$RfCH_2$-phenol in addition to *O*-$RfCH_2$-phenol.[16] Whereas **3** reacted with aniline derivatives at the nitrogen sites to give *N*-$RfCH_2$-anilines or *N*-$RfCH_2$-anilinium triflates,[10] **17** underwent a displacement at the aromatic ring to give a mixture of *o*- and *p*-Rf-aniline derivatives.[3b,14] **17** showed a higher reactivity than **3** as follows: **3** did not react with alkenes such as styrene and butadiene, while **17** reacted smoothly with them to give Rf-alkenes in good yields, and **17** reacted much more smoothly with aromatic compounds than **3**.[3b,10,14]

As a whole, the reaction pattern of **3**, **11**, and **17** agrees with the bond strength order mentioned before. Namely, $RfCH_2$–I and Rf–I bonds of **3** and **17** are easily broken and the cleavage of the corresponding bonds of **11** is difficult. The above results also reveal that the pattern depends not only on the nature of the iodine compounds but also on the reactants. The remarkable difference between **3** and **17** might finally be attributed to the easy formation of $RfCH_2^+$ compared to Rf^+ cations, or to the high electron deficiency at the iodine sites of **17** due to the high electronegativity of the Rf groups, compared to that of **3**.

The predominant fluoroalkylation of **3** at the O- and N-sites of phenols and anilines and the preferential reaction of **17** at the C-sites may suggest that, while **3** could be directly attacked by nucleophiles at highly positively polarized CH_2 carbon sites, the reactions of **17** might be initiated preferably by a one-electron transfer[17] from the nucleophiles to the iodine sites, resulting in the homolytic fission of Rf–I bonds, because of the difficulty in the formation of Rf^+ species.

In conclusion, the presented results show that the properties and reactivity of the trivalent iodine compounds vary to a remarkable degree depending on the static or dynamic properties of the fluoro-alkyl or -alkenyl groups bonding to the iodine atoms.

Experimental

General. Melting points were uncorrected. ^1H NMR spectra were recorded with a Varian XL-100 NMR spectrometer, a Varian EM 390 NMR spectrometer, or a Bruker AM-400 NMR spectrometer with tetramethylsilane as an internal standard. ^{19}F NMR spectra were measured with a Varian XL-100 NMR spectrometer or a Hitachi R-20B NMR spectrometer. ^{19}F NMR chemical shifts were reported in ppm upfield from trichlorofluoromethane as an internal standard. IR spectra were measured on a Jasco A-202 diffraction grating infrared spectrometer. Mass spectra were recorded on a Hitachi RMU-6MG spectrometer at 70 eV and 100 °C.

Materials. 1,1,1-Trifluoro-2-iodoethane is commercially available. Other 1-iodo-1*H*,1*H*-perfluoroalkanes and 1-iodo-1*H*,1*H*,ωH-perfluorododecane were prepared from 1*H*,1*H*- and 1*H*,1*H*,ωH-perfluoro-1-alkanols, respectively, according to the reported method.[18] Diiodide **8** was

similarly prepared from the corresponding diol. 2,3,3,3-Tetrafluoro-2-trifluoromethyl-1-propanol was prepared by the reduction with lithium aluminium hydride from perfluoroisobutyric acid which was prepared from 2-iodoperfluoropropane according to the reported method.[19]

(Polyfluoroalkyl)aryliodonium salts 3, 4, 5, 6, and 7. General Procedure; Into a mixture of 82 ml of trifluoroacetic anhydride and 0.7 ml of trifluoroacetic acid was dropwise added 6.45 ml of 60% aq hydrogen peroxide with stirring under cooling on an ice bath. After stirring for additional 10 min, 1-iodopolyfluoroalkane (143 mmol) was added into the mixture. The reaction mixture was stirred for 1 day at 0 °C to room temperature, and evaporated up to dryness to give almost quantitatively 1-[bis(trifluoroacetoxy)iodo]polyfluoroalkane **2** as a white solid. An arene (189 mmol) and a sulfonic acid (122 mmol) were added into a mixture of 122 mmol of **2** in 150 ml of 1,1,2-trichloro-1,2,2-trifluoroethane at 0 °C and it was stirred for 1 day at 0 °C. The reaction mixture was evaporated up to dryness and the resulting solid was washed with chloroform to give pure crystals of an iodonium salt. For further purification the crystals were recrystallized from acetonitrile or acetonitrile–ether at room temperature. **3a**: 88% yield; mp 88—89 °C (decomp); ^{1}H NMR (CD_3CN) δ=4.80 (2H, q, J=10 Hz, CH_2), 7.40—7.90 (3H, m, ArH), 8.00—8.30 (2H, m, ArH); ^{19}F NMR (CD_3CN) 61.5 (3F, t, J=10 Hz, CF_3), 77.9 (3F, s, CF_3S); IR (KBr), 3060, 3040, 2970, 1565, 1470, 1440, 1400, 1280, 1240, 1195, 1170, 1120, 1040, 985, 840, 760, 730, 680, 650, 620 cm^{-1}; MS m/z 204 (PhI^+, 100%). Found: C, 25.03; H, 1.51%. Calcd for $C_9H_7F_6IO_3S$: C, 24.79; H, 1.62%. **3b**: 72% yield; mp 130 °C (decomp); ^{1}H NMR (acetone-d_6) δ=5.20 (2H, t, J=18 Hz, CH_2), 7.46—7.96 (3H, m, ArH), 8.26—8.50 (2H, m, ArH); ^{19}F NMR (acetone-d_6) 77.3 (3F, s, CF_3S), 82.7 (3F, m, CF_3), 106.5 (2F, t, J=18 Hz, CF_2); IR (KBr), 3040, 2980, 1570, 1480, 1445, 1410, 1340, 1220, 1180, 1050, 1015, 995, 920, 790, 735, 710, 680, 650, 630, 575, 520 cm^{-1}; MS m/z 204 (PhI^+, 100%). Found: C, 24.78; H, 1.19%. Calcd for $C_{11}H_6F_9IO_3S$: C, 25.60; H, 1.17%. **11e**: 87% yield; mp 128—130 °C; ^{1}H NMR (acetone-d_6) δ=7.50—7.96 (3H, m, ArH), 8.32 (1H, d, J=33 Hz, vinyl proton), 8.30—8.50 (2H, m, ArH); ^{19}F NMR (acetone-d_6) 78.0 (3F, s, CF_3S), 80.5 (3F, m, CF_3), 95.0 (1F, m, vinyl F), 116.0 (2F, m, CF_2), 121.3 (2F, m, CF_2), 122.1 (4F, m, CF_2), 125.6 (2F, m, CF_2); IR (neat) 3130, 3080, 1670, 1590, 1570, 1475, 1450, 1370, 1250, 1200, 1180, 1145, 1090, 1030, 990, 950, 920, 850, 800, 790, 760, 740, 720, 680, 650, 640 cm^{-1}; MS m/z 567 ($C_6F_{13}CF$=$CHIPh^+$, 10%), 490 ($C_6F_{13}CF$=CHI^+, 32%), 226 ($PhOTf^+$, 100%), 204 (PhI^+, 40%). Found: C, 24.97; H, 0.75%. Calcd for $C_{15}H_6F_{17}IO_3S$: C, 25.16; H, 0.84%.

Thermolysis of 3e. The crystals of **3e** was heated at 140—145 °C for 10 min under atmospheric pressure. The decomposition products were separated by column chromatography on silica gel with pentane as an eluent. The structural assignment of the products **13** and **14** was carried out by the comparison with authentic samples.

Thermolysis of 11e. The crystals of **11e** was heated at 200 °C under pressure of 180 mmHg (1 mmHg=133.322 Pa) by using a glass tube oven. The decomposition products **15** and **16** condensed at the cooled part of the glass tube and their yields were determined by ^{19}F NMR technique. Each of the products was isolated by the usual method. **15**: 79% yield, oil, ^{1}H NMR ($CDCl_3$) δ=6.63 (1H, J=31 Hz, vinyl proton); ^{19}F NMR ($CDCl_3$) 81.6 (3F, s, CF_3), 103.3 (1F, m, CF), 116.7 (2F, m, CF_2), 122.7 (2F, m, CF_2), 123.4 (4F, m, CF_2), 126.9 (2F, m, CF_2); IR (neat) 3120, 1670, 1370, 1320, 1300, 1240, 1200, 1150, 1125, 1090, 1040, 1020, 840, 795, 735, 710, 655 cm^{-1}; MS m/z 490 (M^+). **16**: 76% yield, oil, ^{1}H NMR ($CDCl_3$) δ=7.10—7.70 (5H, m); ^{19}F NMR ($CDCl_3$) 73.1 (s, CF_3); IR (neat) 3080, 1605, 1590, 1490, 1420, 1250, 1210, 1140, 1070, 1020, 910, 880, 780, 760, 730, 680, 620, 600 cm^{-1}; MS m/z 226 (M^+).

Reaction of 11b with Sodium Phenoxide. Under argon atmosphere, 0.667 mmol of sodium hydride (50% in oil) was added into a solution of 0.667 mmol of phenol in 2 ml of dichloromethane and the mixture was stirred for 5 min. **11b** (0.606 mmol) was added and the mixture was stirred for 30 min at 0 °C. Then the reaction mixture was filtered with celite and evaporated up to dryness. The resulting solid was recrystallized from dichloromethane–diethyl ether–pentane to give **22** in a 42% yield. **22**: mp 86—87 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ=6.94—7.00 (2H, m, ArH), 7.20—7.63 (6H, m, ArH), 7.43 (1H, s, vinyl proton), 7.90—7.96 (2H, m, ArH); ^{19}F NMR ($CDCl_3$) 66.8 (3F, s, CF_3), 78.8 (3F, s, CF_3S); IR (KBr) 3100, 1640, 1590, 1490, 1440, 1320, 1280, 1250, 1210, 1160, 1060, 1030, 990, 860, 790, 730, 635 cm^{-1}; MS m/z 314 [$CF_3(PhO)C$=CHI^+]. Found: C, 35.35; H, 1.95%. Calcd for $C_{16}H_{11}F_6IO_4S$: C, 35.58; H, 2.05%.

Reaction of 11b with Sodium 2-Phenylethoxide. The procedure was similar to the above case. The crude product was recrystallized from ethyl acetate–pentane to give **23** as a mixture of E- and Z-isomers in a 32% yield. **23**: mp 62—63 °C (a 88:12 or 12:88 mixture of E- and Z-isomers); ^{1}H NMR (400 MHz, $CDCl_3$) A:B component=88:12, A component; δ=3.07 (2H, t, J=6.7 Hz, benzyl protons), 4.44 (2H, td, J=6.8, 0.7 Hz, allyl protons), 6.91 (1H, s, vinyl proton), 7.74—7.80 (2H, m, ArH), B component; δ=3.06 (2H, t, J=6.4 Hz, benzyl protons), 4.23 (2H, t, J=6.5 Hz, allyl protons), 6.74 (1H, s, vinyl proton), 7.98—8.02 (2H, m, ArH), A+B component; δ=7.15—7.62 (m, ArH); ^{19}F NMR ($CDCl_3$) A:B component=88:12, A component; 66.0 (3F, s, CF_3), 78.8 (3F, s, CF_3S), B component; 65.2 (3F, s, CF_3), 78.8 (3F, s, CF_3S); IR (KBr) 3080, 1620, 1560, 1500, 1470, 1440, 1325, 1270, 1250, 1190, 1160, 1090, 1050, 1030, 990, 730, 700, 660, 630 cm^{-1}. Found: C, 37.93; H, 2.65%. Calcd for $C_{18}H_{15}F_6IO_4S$: C, 38.04; H, 2.66%.

Reaction of 11b with Sodium *p*-*t*-Butylbenzenethiolate. In analogy with that described above, **11b** was treated with sodium *p*-*t*-butylbenzenethiolate in dichloromethane at 0 °C for 1 h, which was prepared in situ from *p*-*t*-butylbenzenethiol and sodium hydride. The usual post-treatment and then thin-layer chromatography gave **24** and **25** in 16 and 32% yields, respectively. **24**: A 78:22 mixture of Z- and E-isomers; oil, ^{1}H NMR ($CDCl_3$) Z-isomer; δ=1.40 (9H, s, *t*-Bu), 6.38 (1H, d, J=31.5 Hz, vinyl proton), 6.85—7.30 (3H, m, ArH), 7.56—7.75 (2H, m, ArH), E-isomer; δ=1.40 (9H, s. *t*-Bu), 6.48 (1H, d, J=19.5 Hz, vinyl proton), 6.85—7.35 (3H, m, ArH), 7.56—7.75 (2H, m, ArH); ^{19}F NMR ($CDCl_3$) Z-isomer; 72.1 (3F, d, J=13 Hz, CF_3), 131.6 (1F, dq, J=31.5, 13 Hz, vinyl F), E-isomer; 68.7 (3F, d, J=10 Hz, CF_3), 128.2 (1F, dq, J=19.5, 10 Hz, vinyl F); IR (KBr) 3090, 2980, 2880, 1500, 1350, 1240, 1190, 1140, 1060, 1010, 840 cm^{-1}; MS m/z 278 (M^+). Found: C, 56.01; H, 5.15%. Calcd for $C_{13}H_{14}F_4S$: C, 56.10; H, 5.07%. **25**: A 86:14 mixture of two isomers A and B; bp 230 °C/5 mmHg (using a glass tube oven); ^{1}H NMR ($CDCl_3$) δ=1.31 (18H, s, *t*-Bu), 7.20—7.50 (8H, m, ArH), 7.78 (1H, bs, vinyl proton); ^{19}F NMR ($CDCl_3$) A isomer; 64.1 (s, CF_3), B isomer; 56.6 (s, CF_3); IR (KBr) 3100, 2980, 2920, 2890, 1570, 1495, 1460, 1400, 1365, 1270, 1250, 1200, 1160, 1130, 1010, 960, 840, 825, 710, 650 cm^{-1}; MS m/z 424 (M^+). Found: C, 66.00; H, 6.78%. Calcd for $C_{23}H_{27}F_3S_2$: C, 65.05; H, 6.41%.

Electrochemical Synthesis of Poly(amino acid)s, Poly(amino acid)-Urethane Copolymers, and Electroconductive Poly(amino acid)-Polypyrrole Complex Films

Tetsuo KOMORI, Tsutomu NONAKA,* Toshio FUCHIGAMI, and Kunmao ZHANG†

(Received March 28, 1987)

When amino acid *N*-carboxy anhydrides (NCA's) were polymerized with various electrogenerated base (EGB) catalysts, the yield of poly(amino acid)s remarkably increased and the reaction time was extremely shortened compared with the conventional method using triethylamine catalyst. This novel polymerization method was successfully applied to the copolymerization of different kinds of NCA's and to the preparation of poly(amino acid)-urethane copolymers. NCA's were also polymerized with the EGB's in the matrix of polypyrrole simultaneously formed by the anodic polymerization of pyrrole to provide electroconductive poly(amino acid)-polypyrrole complex films which were stable in the air and flexible.

Poly(amino acid)s and their related polymers are widely used as synthetic leathers, medicines, medical materials, fibers, surfactants, and piezodevices. Poly(amino acid)s are commercially produced by the *N*-carboxy anhydride(NCA) method,[1] in which NCA's are polymerized with base catalysts such as primary and tertiary amines. It is well-known that the yield and quality of poly(amino acid)s are greatly affected by impurities in NCA's and kind of the base catalysts.[2] Since NCA's are usually prepared from amino acids and phosgene or trichloromethyl chloroformate(phosgene dimer), enormous efforts must be made to remove chlorine-contaminants from the NCA's, especially in the case of amino acid such as L-valine which is polymerized with difficulty.[2]

Recently, cathodically-generated anionic species, so-called electrogenerated bases(EGB's), have been widely used as reducing reagents, nucleophiles, and bases.[3] In our previous work,[4] it was found that the EGB catalysts polymerized valine NCA's much more efficiently than conventional catalyst such as triethylamine, though both catalysts would induce the polymerization in similar of reaction mechanism in which an initiation step is the abstraction of amido hydrogen of NCA's.[2] In this work, this cathodic polymerization was successfully extended to the preparation of a variety of homopoly (amino acid)s, copoly(amino acid)s, poly(amino acid)-urethane copolymers, and electroconductive poly(amino acid)-polypyrrole complex films.

Results and Discussion

EGB's are generated by the one-electron reduction of acidic hydrogen compounds (PB's) such as amides, carboxylic acids, phenols, alcohols, and carbon acids in general as shown below.[3].

$$\mathrm{XH} \xrightarrow[\mathrm{M^+Y^-}]{\mathrm{e}} \mathrm{X^-M^+} + \frac{1}{2}\mathrm{H_2} + \mathrm{Y^-}$$

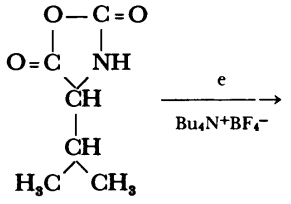
(PB) (Supporting electrolyte) (EGB)
(X: N, O, C)

The reactivity of the EGB's thus formed is affected by their counter cations (M^+) coming from supporting electrolytes (M^+Y^-) used.[5,6] In this work, two methods for the polymerization of amino acid NCA's with EGB's were employed. In the first method (Method A), amides such as α-pyrrolidone,[7] ε-caprolactam, acetanilide and *N*-methylacetamide and a phenol such as 2,6-di-*t*-butyl-*p*-cresol[10] were cathodically reduced in dry THF solutions and then EGB solutions thus prepared were added to THF solutions of NCA's. In Method B, NCA's, themselves were used as probases (PB's) without any other PB's, since they have molecular structures of amides. No contamination of poly(amino acid)s by the catalysts used was expected in this case where the self-catalyzed polymerization should proceed. The polymerization seemed to proceed not only on the surface of cathode but also in the whole cathodic solution (divided cell). In addition to these methods,a conventional one was examined by using triethylamine as the catalyst under the similar conditions (Method C). In all these methods, 0.05 mol/mol-NCA of the EGB and amine catalysts were used. Amounts of EGB's used were controlled by the amounts of charge passed.

Electrochemical and Chemical Syntheses of Homopoly(amino acid)s. As shown in Fig. 1, L-valine NCA was reduced in a potential range less negative than the background solution. Therefore, the EGB catalyst in Method B seemed to be anion (**1**) generated by the reduction of the NCA itself rather than the supporting electrolyte.

Results of the polymerization of L-valine NCA using EGB catalysts generated from various PB's in

Method A are shown in Table 1. Among the PB's used, α-pyrrolidone gave the best result in either reaction time or yield, optical rotating power([α]D)



L-Valine NCA

(a) 3.8 mmol dm^{-3} L-valine NCA. (b) Background.

and molecular weight (kinematic viscosity) of poly(L-valine) obtained. The largest value of $[\alpha]_D^{20}$ is 155° (in CF_3COOH).[11] The molecular weight could not be directly measured because of insolubility of poly(L-valine) in solvents other than CF_3COOH. A standard sample of poly(L-valine) (MW, 7200) which was commercially supplied from Sigma Chemical Co. showed 0.616×10^{-6} m^2 s^{-1} of kinematic viscosity in 0.5 w/v% CF_3COOH solution at 25°C. However, estimation of the molecular weight from the viscosity could not be performed for lack of a standard sample with a different MW. The secondary structure of poly(L-valine) obtained was confirmed to be β-coil form from IR-spectrum (an amido carbonyl band observed at 1630 cm^{-1}).[12]

As shown in Table 2, the EGB catalysts with Na^+ as their counter cations did not induced the polymerization of L-valine NCA. This fact is rationalized as due to low basicity of the EGB's with hard counter cations such as Na^+ of high Lewis acidity.[5] Inferior results obtained with the catalysts with *n*-Oct_4N^+ counter cation to those with *n*-Bu_4N^+ may be due to steric hindrance effect.

Results of the polymerization of various NCA's by the electrochemical (Methods A and B using α-pyrrolidone as PB and *n*-Bu_4N^+ as counter cation) and

Table 2. Influence of Counter Cations of EGB Catalysts on the Polymerization of L-Valine NCA by Methods A and B

Method	PB	Counter cation	Reaction time/h	Poly(L-valine)		
				Yield/%	$[\alpha]_D^{20}$/°	Kinematic viscosity /10^{-6} m^2 s^{-1}
A	α-Pyrrolidone	Na^+	2	7	−82	—[a]
A[b]	α-Pyrrolidone	*n*-Bu_4N^+	0.02	98	−110	0.708
A	α-Pyrrolidone	*n*-Oct_4N^+	2	50	−95	0.681
B	L-Valine NCA	Na^+	2	4	−101	—[a]
B	L-Valine NCA	*n*-Bu_4N^+	2	59	−120	0.670
B	L-Valine NCA	*n*-Oct_4N^+	2	55	−100	0.639

a) Not measured. b) Charge required to generate 0.02 mol/mol-NCA of EGB was passed.

chemical (Method C using triethylamine as base catalyst) methods are summarized in Table 3 for comparison. The Methods A and B were clearly superior to Method C in terms of reaction time and yield, while Method C gave poly(L-valine) and poly(L-leucine) with somewhat larger values of $[\alpha]_D^{20}$ than other methods. It is noticeable that *N*-methylglycine NCA without any acidic amido hydrogen atom could be polymerized by Method B. This NCA can not be polymerized with tertiary amine catalysts.[2] These facts may suggest possible cathodic formation of unknown effective catalyst other than *n*-Bu_3N which can be generated by electroreductive decomposition of *n*-Bu_4N^+. Therefore, polymerization mechanism in this case would be quite different from that in cases of other amino acid NCA's.

The molecular weight($\bar{M}n$) of poly(γ-benzyl L-glutamate) soluble in THF was estimated to be 1730

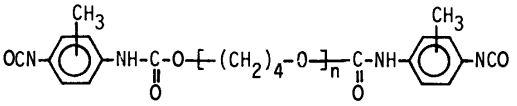
a) Reaction time, 2 h. b) {[(a+b)(wt.) in copoly(amino acid)]/[(a+b)(wt.) in starting NCA's]}×100(%). c) Approximately estimated from ^{1}H-NMR. d) Not determined.

(polystyrene standard) by GPC. The secondary structures of poly(D-valine), poly(L-leucine) and poly(L-tryptophan) were confirmed to be β-, α helix- and α-forms, respectively, from IR spectra.[12]

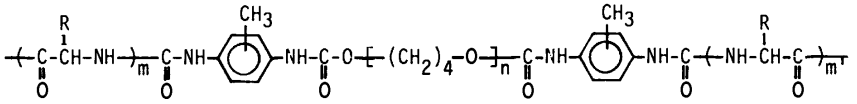
Electrochemical and Chemical Syntheses of Copoly (amino acid)s. The coplymerization of mixtures of amino acid NCA's was carried out in a manner similar to the homopolymerization in Table 3. As shown in Table 4, Methods A an B gave higher yields of copoly(amino acid)s than Method C. Properties of copoly(amino acid)s can be varied by changing either the combination or composition ratio, or both amino acid components. The composition ratio in copoly(amino acid)s formed was approximately equal to those of the starting mixtures of NCA's. It was confirmed that the copoly(amino acid)s with γ-benzyl L-glutamate could be cast from their benzene solutions to provide flexible transparent films, though their molecular weights and secondary structures were not determined. It has been also remained unknown whether the copoly(amino acid)s are homogeneous or block copolymers.

Electrochemical and Chemical Syntheses of Poly(amino acid)–Urethane Block Copolymers. Improvement of properties of poly(amino acid)s can also be achieved by the block copolymerization of amino acid NCA's with urethane prepolymers (**2**).[2,13] The copolymerization was carried out in the presence of **2**(n, ca. 28) in a manner similar to the homopolymerization in Table 3 and the corresponding poly(amino acid)-urethane block copolymers(**3**) were obtained.



Urethane prepolymer (**2**)

As shown in Table 5, Methods A and/or B gave higher yields of the block copolymers than Method C. Molar ratios of amino acid components to the urethane prepolymer in the block copolymers thus obtained were almost equal to those in the starting mixtures in all the methods. The copolymers with γ-benzyl L-glutamate were able to cast from their THF solutions to provide flexible films. The molecular weight of a poly(γ-benzyl L-glutamate)–urethane copolymer with 17 of molar ratio of γ-benzyl L-glutamate to the urethane prepolymer was determined to be $\bar{M}$n 7900 and $\bar{M}$w 21100 (polystyrene standard) by GPC.



Poly(amino acid)-urethane block copolymer (**3**)

Table 5. Electrochemical and Chemical Block Copolymerization of Amino Acid NCA's with an Urethane Prepolymer (2; n, ca. 28) with EGB and Triethylamine Catalysts, Respectively

Poly(γ-benzyl L-glutamate)	0.5	43	4	5
Poly(γ-benzyl L-glutamate)-urethane block copolymer	1.2	35	0.04	1

Electrochemical Preparation of Flexible Electroconductive Poly(amino acid)-Polypyrrole Complex Films. It is well-known that the anodic oxidative polymerization of pyrrole forms electroconductive polypyrrole coatings on anodes but they are not so flexible to be peeled off as films from the anodes.[14] It may be the way to get the electroconductive polypyrrole films to make blend polymers with other flexible polymers, but it is not so easy because of insolubility of polypyrrole in most solvents.

Efforts have been made to prepare flexible polypyrrole films. It has recently been reported that flexible polypyrrole films can be prepared by anodically polymerizing pyrrole using electrodes coated with a variety of nonconductive polymers such as poly(vinyl chloride), polystyrene, and poly(methyl methacrylate).[14-17] The films thus prepared show good thermal and mechanical properties.[14]

In this work, poly(amino acid)-polypyrrole complex films were prepared by anodically polymerizing pyrrole on platinum anode in the presence of amino acid NCA's in an undivided cell. It is noted that the polymerization of NCA's proceeds in the whole area of the cell, as described previously. Therefore, poly(amino acid)s formed in the vicinity of the anode during the electrolysis might be incorporated into polypyrrole films deposited on the anode surface. The films were easily peeled off from the anode. As shown in Table 6, there were not any great differences in conductivity between the surface and back sides. The films are also expected to have hydrophilic nature and affinity for biomaterials: This may suggest possibility of their in vivo use.

Experimental

Materials. Amino acid NCA's were prepared from amino acid and trichloromethyl chloroformate (phosgene dimer).[18] The urethane prepolymer(**2**) was kindly supplied by Mitsubishi Kasei Co. All the other chemicals were commercially available.

Syntheses of Homopoly(amino acid)s, Copoly(amino acid)s, and Poly(amino acid)-Polyurethane Copolymers. In Method A, PB's (0.7 mmol) were electrolyzed at a platinum cathode (12 cm^2) in 60 cm^3 of dry THF containing n-Bu_4NBF_4 (0.1 mol dm^{-3}). The electrolysis was carried out by passing 0.05 F/mol-NCA of charge under galvanostatic conditions (at 0.08 A dm^{-2} of current dencity) in a divided cell and then the resulting cathodic solution was added to an NCA solution. Electrolysis in Method B was also carried similarly in the absence of PB's.

After the electrolysis, precipitating poly(amino acid) was filtered and washed with THF. IR and ^{1}H NMR spectra were measured in KBr and CF_3COOH, respectively. Kinematic viscosity of poly(amino acid) (0.5 w/v% in CF_3COOH) was also measured using an Ubbelohde's viscometer at room temperature.

Preparation of Poly(amino acid)-Polypyrrole Complex Films. Amino acid NCA (1 g) was electrolyzed using platinum electrodes (12 cm^2) in 0.1 mol dm^{-3} n-Bu_4NBF_4/CH_3CN(200 cm^3) containing pyrrole (0.01 mol) for 1 h under galvanostatic conditions(20 mA) in an undivided cell. After the electrolysis, the film deposited on the anode surface was peeled off and its conductivity was measured under dry conditions by the two probe method. Poly(amino acid) content in the films was determined from UV-spectra of solutions which were prepared by extracting the films with CF_3COOH or benzene under ultrasonic irradiation.

(Received March 30, 1987)

The decay processes of aryldiazenyl radicals were studied by using a time-resolved ESR method. The first order rate constants of decomposition were determined at −117—−48 °C in cyclopropane solutions in the presence or absence of olefins. Aryldiazenyl radicals were relatively persistent and the k_1 of phenyldiazenyl-d_5 at −96 °C in cyclopropane was 34 s^{-1}. The k_1 of 20 aryldiazenyl radicals at −96 °C afforded a ρ value of +1.53 (r=0.91) in a Hammett plot. Activation energies ranged from 46.2 to 25.2 kJ mol^{-1} and the frequency factors, log A, from 13.2 to 8.2 s^{-1}. The second-order decay rates were measured at the initial period of the decay process at lower temperatures, in a batch system (cyclopropane) and in a flow system (isohexane). The rate constant of phenyldiazenyl-d_5 in cyclopropane was $9.2 \cdot 10^5$ M^{-1} s^{-1} at −93 °C and the Arrhenius parameters were E_a=23.5 kJ mol^{-1} and log A=12.77 M^{-1} s^{-1}, respectively.

Aryldiazenyl radicals have been studied as transient radicals in organic syntheses such as the Gomberg-Bachmann reaction,[1] and from theoretical interests in thermolysis of acylarylnitrosamines[2] and of aryl(triphenylmethyl)diazenes.[3] Informations concerning the lifetime of the radicals were reported in a trapping experiment of the radicals by using triphenylmethyl radicals[4] and in CIDNP experiment using diazenes or nitrosamine.[4-6] These investigations suggested a very rapid decay nature of aryldiazenyl radicals. Another estimation of a rather slow decay rate of phenyldiazenyl radicals was reported from a study of activation free energy of azo compounds.[7] We could observe aryldiazenyl radicals in solutions by an ESR technique and this fact supported a rather persistent nature of the radicals.[8] We will here report the rate constants of decomposition of aryldiazenyl radicals in solutions, obtained in a time-resolved ESR study.

Experimental

(1) Time-Resolved ESR Spectroscopy a) Apparatus. The measurement of the decay rates of aryldiazenyl radicals was carried out on a Varian E-109E spectrometer with 100 kHz modulation for the first order decay rate, after insertion of a 100 kOhm resistance in the receiver to attain a faster responce of about 0.3 ms. For determination of second order rate constant, we constructed a 1 MHz modulation amplifier and a coherent receiver by the method of Smith and coworkers,[9] thereby a pair of hair-pin type modulation coil was set around the Dewar tube in the cavity.

To follow the decay of aryldiazenyl radicals, we measured one line of the ESR spectrum of aryldiazenyl radical at a specified resonance magnetic field under a rather high modulation amplitude. The signal intensities were transferred via a transient memory, Biomation 805, into a microcomputer, Multi-16, accumulating up to 2^{16} transients. The microcomputer output decay curves, signal intensity-time plots for the first and second order rate analyses, and the calculated rate constants.

For flash photolysis we used a 1 kW Xe lamp with a rotating sector (flash duration 30 to 50 ms) for k_1 measurements and a Nitrogen Laser, Molectron UV-14 for k_2 measurements. The block diagram of the system was shown in Fig. 1.

b) Reaction Cell. For determination of k_1 and k_2 using a higher concentration of aryl(arylthio)diazenes, $\geqslant 2 \cdot 10^{-2}$ M††, we used a sample tube as that used in a previous study.[8] (We call this a batch method.) For measurements of k_2 using a solution of low concentration, $4 \cdot 10^{-4}$ M, we adopted a flow method, using a sample tube (quartz, ϕ 4 mm), closed by a screw cap, through which a concentric inlet tube (Pyrex, ϕ 2 mm), a teflon outlet tube (ϕ 2 mm), and a copper-constantan thermocouple were introduced.

In the flow system an air-free sample solution under Ar, 300—500 ml, cooled in Dry Ice-methanol bath, was forced to flow into the sample tube by Ar pressure, via a cold thermostat (ca. −130 °C) and a cold path (teflon, ca. −100 °C),

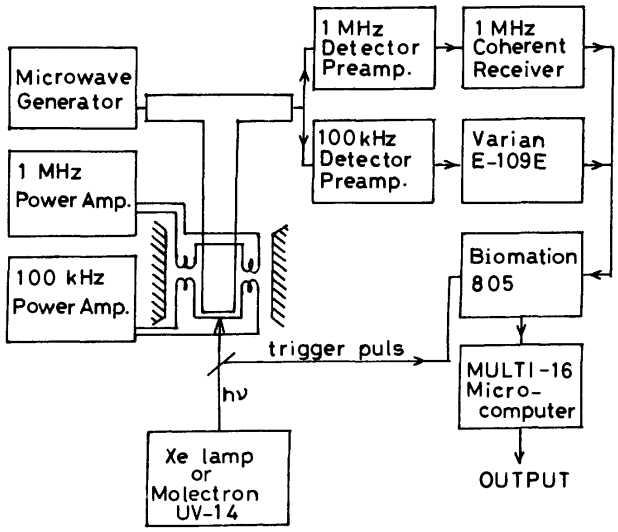

Fig. 1. Block diagram of time-resolved ESR spectrometer.

†† 1 M=1 mol dm^{-3}.

both regulated by cold nitrogen tream and monitored by copper-constantan thermocouple. About 10 m teflon tube in the thermostat was sufficient to attain a desired low temperature. The sample tube was placed in the Dewar tube in the ESR cavity. (Ref. Fig. 6 and the description on it.)

(2) Materials. a) Aryl(arylthio)diazenes. Aryl(arylthio)-diazenes were prepared as described in a previous paper.[8] Additional diazenes used in this kinetic study were listed in Table 1.

For the measurement of second order rate constants we used perdeuteriophenyl-, 4-methoxy-3,5-dideuteriophenyl-, and 4-chloro-3,5-dideuteriophenyldiazenyl radicals to eliminate the hfs of ESR spectrum due to 3,5-hydrogens. The preparation of 4-substituted 3,5-dideuterioanilines was performed as follows: 1) 4-nitrophenol was deuterated by heating with D_2O–D_2SO_4, then methylated by diazomethane and then reduced by $SnCl_2$–HCl, ii) 4-nitroaniline was deutetrated by heating with D_2O–DCl, and then transformed into 4-chloro-3,5-dideuterionitrobenzene by the Sandmeyer reaction and then reduced to aniline.

The deuterium exchange was monitored by ^1H NMR method.

b) Solvents. Cyclopropane, methylcyclopentane, toluene, 1-butene, *cis*-2-butene, ethoxyethene, propene, bromoethene, 1-chloropropene, were used after they have been degassed by repeated freeze and thaw in vacuum and distilled from bulb into sample tube. Isohexane for the flow method was purified by wasing with concd. H_2SO_4, boiled over sodium wire, followed by distillation over lithium tetrahydridoaluminate under Ar. The purity of isohexane was monitored by determining peroxyl radical during photolysis by ESR measurement.

(3) Kinetic Analysis. a) First Order Reaction Rate. Decay curves obtained by using time-resolved ESR technique were examined by plotting, 1) $1/(R\cdot)_t$ against time for second order decay reaction, and 2) $\ln[(R\cdot)_0/(R\cdot)_t]$ against time for first order reaction, here $(R\cdot)_0$ and $(R\cdot)_t$ stand for the concentrations of aryldiazenyl radicals at time 0 and t, respectively (Figs. 2 and 3).

b) Second Order Reaction Rate. In a batch method we

used solutions of aryl(arylthio)diazenes of a higher concentration, $2.0 \cdot 10^{-2}$ M. In this case the light introduced in the solution was completely absorbed and the radicals formed in the solution were not distributed homogenously in the solution but the radical concentration decreased exponentially from the front surface of the sample tube into the inner part of solution. On this problem H. Fischer and his coworkers have discussed and estimated the accuracy of the experimental values of k_2.[10] We have analyzed the decay curves by taking account of this exponential distribution of the radicals in the following way.

In our experiments we assumed a front area of the light path to be half of the surface of the sample tube of inner diameter 0.253 cm, multiplied by 1.20 cm height, and devided by 2 because of the lattice of the cavity window.

The distibution of aryldiazenyl radicals in solution at time 0 was assumed to be the exponential curve A as depicted in Fig. 4.

The bimolecular decay reaction of aryldiazenyl radicals proceeds in a small volume section at l_i of the solution, thereby we assumed no diffusion of the radicals out of or into the section l_i.[11]

For the second order reaction in section l_i we can apply the equations

$$-d(R\cdot_i)/dt = 2\cdot k_2\cdot(R\cdot_i)^2 \quad (1)$$

and

$$1/(R\cdot_i)_t - 1/(R\cdot_i)_0 = 2\cdot k_2\cdot t, \quad (2)$$

where $(R\cdot_i)_0$ and $(R\cdot_i)_t$ stand for radical concentrations in the section l_i at time 0 and t, respectively.

On summation of $(R\cdot_i)$ over all sections at l_i, we get total radical concentration $(R\cdot)_0$ and $(R\cdot)_t$ at time 0 and t, respectively, i.e.,

$$(R\cdot)_0 = \sum_{l_i} (R\cdot_i)_0$$

and

$$(R\cdot)_t = \sum_{l_i} (R\cdot_i)_t \quad (3)$$

We observed experimentally the decay process of $(R\cdot)_0$ from time 0 to ∞, as illustrated in Fig. 5.

The initial radical distribution, $(R\cdot_i)_0$, can be expressed by Eq. 4, assuming that the aryldiazenyl radicals were produced from diazene by photolysis:

$$(R\cdot_i)_0 = (R\cdot_0)_0\cdot\exp(-2.30\cdot\varepsilon\cdot c\cdot l_i), \quad (4)$$

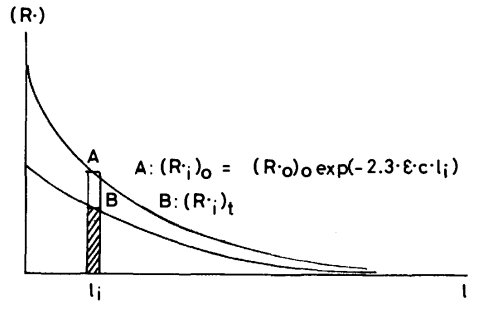

Fig. 4. Exponential distribution of concentration of aryldiazenyl radicals in solution.

where $(R\cdot_0)_0$ denotes the initial radical concentration at time 0 in the section at l_0, ε the molar absortion coefficient of the starting compound aryl(arylthio)diazene at wavelength 337 nm, $6.5 \cdot 10^3$ M cm^{-1} for (4-*t*-butylphenylthio)-phenyldiazene, and c the concentration of the diazene.

The radical concentration at time t, $(R\cdot)_t$, can be expressed in terms of $(R\cdot_i)_0$, by using Eqs. 2 and 3 as follows:

$$(R\cdot)_t = \sum_{l_i} (R\cdot_i)_t = \sum_{l_i} [1/\{1/(R\cdot_i)_0 + 2\cdot k_2\cdot t\}]. \quad (5)$$

Equation 5 was transformed by integration into Eq. 6,

$$(R\cdot)_t = \frac{\ln\{1+2\cdot(R\cdot_0)_0\cdot k_2\cdot t\}}{2\cdot 30\cdot 2\cdot\varepsilon\cdot c\cdot k_2\cdot t}, \quad (6)$$

which was changed by approximation using the first 3 terms of the Maclaurin Expansion into

$$(R\cdot)_t = \frac{(R\cdot_0)_0}{2.30\cdot\varepsilon\cdot c\cdot\{1+(R\cdot_0)_0\cdot k_2\cdot t\}}, \quad (7)$$

or into Eq. 8,

$$1/(R\cdot)_t = 2.30\cdot\varepsilon\cdot c/(R\cdot_0)_0 + 2.30\cdot\varepsilon\cdot c\cdot k_2\cdot t, \quad (8)$$

when $1 \gg 2\cdot(R\cdot_0)_0\cdot k_2\cdot t$.[12] On plotting $1/(R\cdot)_t$ against time, we can obtain k_2.

In the flow method using a $4 \cdot 10^{-4}$ M solution of diazene we assumed a homogenous distribution of radicals throughout the irradiated solution and the volume of the solution was taken as one half of the outer sphere in the sample tube (Fig. 6).

The rate constants were calculated by using Eq. 9 of the second order decay reaction.

$$1/(R\cdot)_t - 1/(R\cdot)_0 = 2\cdot k_2\cdot t \quad (9)$$

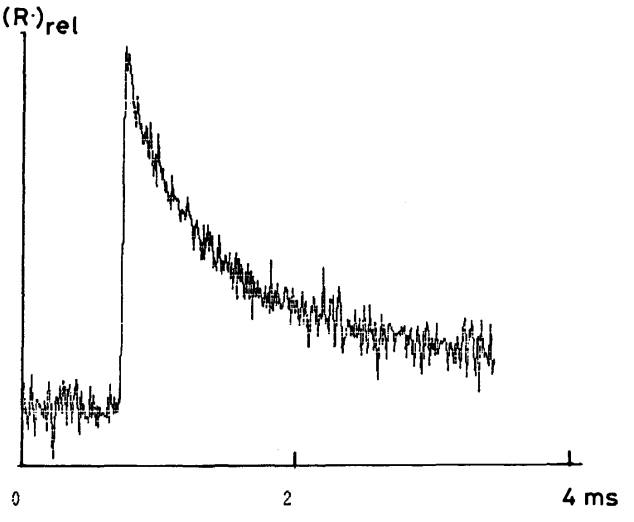

Fig. 5. Second-order decay curve of phenyldiazenyl-d_5 radicals, at −102 °C in $2 \cdot 10^{-2}$ molar diazene in cyclopropane. Batch method.

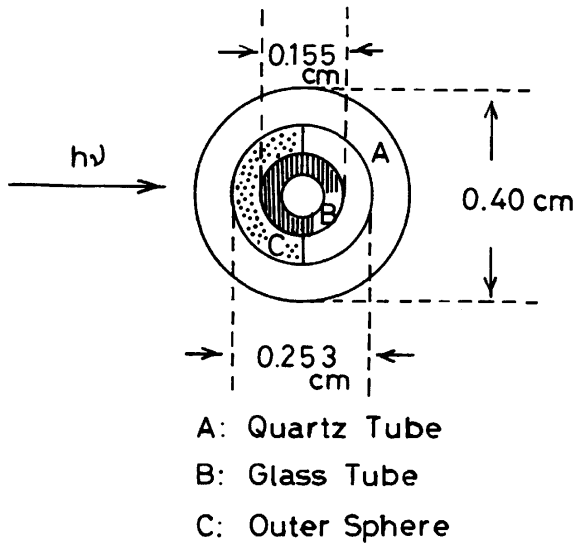

Fig. 6. Aryldiazenyl radicals formed in the outer sphere of sample tube.

It was determined that the effect of k_1 was negligible in the calculation of k_2.

c) Calibration Curve for Determination of the Radical Concentration. As a standard solution of known concentration of free radicals we used solutions of pure nitrosodisulfonate in slightly ammoniacal aq. solution. It was thereby assumed that the line shape of the ESR spectrum of aryldiazenyl radicals was the same as that of nitrosodisulfonate and that the sensitivity of the ESR apparatus was kept constant for free radicals even though the solvent for the radicals was changed from water (nitrosodisulfonate) to a variant of organic solvent (aryldiazenyls).

One line of the triplet of ESR spectrum of nitrosodisulfonate of $0.4\cdot10^{-9}$ to $1.6\cdot10^{-9}$ mol was determined by averaging 20 runs at 25 °C and then double-integrated digitally. A linear correlation of the spectrum peak height to the integrated value was obtained. The conditions of ESR spectrometer for the measurement of calibration curve were set to those for the time-resolved ESR experiment in microwave power, modulation amplitude, and receiver gain.

The kinetic studies were performed at low temperatures and so it was necessary to correct the signal intensity. The increase in intensity was assumed to be proportional to $1/T$ and the signal heights were corrected by multiplying $T/298$.

Results and Discussion

To understand the decay kinetics of aryldiazenyl radicals, it is plausible to describe the following Scheme 1: Aryl(arylthio)diazene was decomposed photochemically to yield aryldiazenyl–arylthiyl radical pair, and then proceeded two reactions, k_{comb} and k_{diff}, in competition. Thereafter occured bimolecular and unimolecular reactions in the solution.

$$\text{Ar-N=N-S-Ar}' \xrightarrow{h\nu} \overline{\text{Ar-N=N}\cdot\ \cdot\text{S-Ar}'} \quad (10)$$

$$\overline{\text{Ar-N=N}\cdot\ \cdot\text{S-Ar}'} \xrightarrow{k_{comb}} \text{Ar-N=N-S-Ar}' \quad (11)$$

$$\text{or Ar-S-Ar}' + \text{N}_2 \quad (12)$$

$$\xrightarrow{k_{diff}} \text{Ar-N=N}\cdot + \cdot\text{S-Ar}' \quad (13)$$

$$2\ \text{A-N=N}\cdot \xrightarrow{k_2} \text{Ar-N=N-Ar} + \text{N}_2$$

$$\text{or Ar-Ar} + 2\text{N}_2 \quad (14)$$

$$\text{Ar-N=N}\cdot + \cdot\text{S-Ar}' \xrightarrow{k_{term}^1} \text{Ar-S-Ar}' + \text{N}_2 \quad (15)$$

$$2\ \text{Ar}'\text{-S}\cdot \xrightarrow{k_{term}^2} \text{Ar}'\text{-S-S-Ar}' \quad (16)$$

$$\text{Ar-N=N}\cdot \xrightarrow{k_1} \text{Ar}\cdot + \text{N}_2 \quad (17)$$

Scheme 1.

Aryl radicals formed in Reaction 17 react with solvent molecules, affording stable products and secondary radicals.

The bimolecular reactions of aryldiazenyl radicals, Reactions 14 and 15, became measurable at the initial period of decay process, when the radical concentrations were high enough or on occasions of slow unimolecular decay of aryldiazenyl radicals by lowering the reaction temperature.

Arylthiyl radicals formed photochemically in 10^{-2} molar diazene solution disappeared in a half-life of several microseconds at −100 °C, which we could follow by measuring the transient UV absorption around 450 to 550 nm of arylthiyl radicals.[13] We can therefore neglect Reaction 15 in calculation of the second order reaction rate of aryldiazenyl radicals. In dilute solutions of 10^{-4} molar aryldiazenes the reaction 15 may cause an effect in k_2 measurements.

(1) First Order Reaction Rate. a) Rate Constant of Phenyldiazenyl-d_5 Radicals. The first order decay rates of aryldiazenyl radicals were obtained by using a 100 kHz modulation ESR spectrometer. The decay curves were analyzed by plotting $\ln\{(\text{R}\cdot)_0/(\text{R}\cdot)_t\}$–time and $1/(\text{R}\cdot)_t$–time to separate the first order reaction from the second-order decay process. The first order rate constants so obtained are listed in Table 2 and Arrhenius Plot of k_1 of some aryldiazenyl radicals is reproduced in Fig. 7.

Aryldiazenyl radicals are relatively persistent and the first order rate constant of phenyldiazenyl-d_5 radical was $34\ \text{s}^{-1}$ at −96 °C. Porter and his coworkers[4] have estimated the rate of decomposition of the order of 10^7 to $10^9\ \text{s}^{-1}$ at 40 °C for phenyldiazenyl radical from the analysis of CIDNP experiment of phenyl(1-methyl-1-phenylethyl)diazene. Another estimation from CIDNP of the half-life of phenyldiazenyl was reported by Kasukhin and colaborators[5] as $t_{1/2}=10^{-7}$ s ($k_1\fallingdotseq 7\cdot10^6\ \text{s}^{-1}$) at 60 °C.

Our rate constant of phenyldiazenyl-d_5 was extrapolated to +60°C to afford $k_1 = 4.8 \cdot 10^5\ s^{-1}$. This value was by far lower than the values estimated from CIDNP experiments.

At lower temperatures when the unimolecular decay became slower, bimolecular decay reactions proceeded at the initial period of the decay: The bimolecular reactions were observed at −87 °C for 4-methoxyphenyldiazenyl radicals, at −96 °C for 4-methylphenyldiazenyl radicals, and even at −73 °C for 4-dimethylaminophenyldiazenyl radicals, which were the most persistent radicals among those we studied.

b) Substituent Effect on the First Order Reaction Rate of Aryldiazenyl Radicals. The first order rate constants of 20 aryldiazenyl radicals at −96 °C were plotted against the Hammett sigma constants for 3- and 4-substituted phenyldiazenyl radicals and against the values equivalent to sigma value for 2-substituted phenyldiazenyl radicals. The latter "ortho sigma values" were derived from the acid dissociation constants of 2-substituted benzoic acid[14] based on the definition of the Hammett sigma constant.

For 2-methylthio substituent, the "sigma value" was calculated from σ_p by means of Eq. 18, presented by

Yoshida and Hojo[15]

$$\sigma_o = 0.72 + 1.91 \cdot \sigma_p \quad (18)$$

The rate constants of aryldiazenyl radicals correlated linearly to sigma values with ρ=+1.53 (r=0.91). We did not find any evidence for the extra stabilization effect of 2- and 4-substituents nor extra acceleration effect by the 2-substituents on the decomposition reaction. The fairly linear nature of the Hammett plot is a characteristic feature of aryldiazenyl radicals and stands in a clear contradictory to those of aryldiazonium ions.[16] In the diazonium ions the mesomeric effect of substituents at 2-and 4-positions of the benzene ring, regardless of electron-releasing and electron-withdrawing natures, retarded the decompositions.

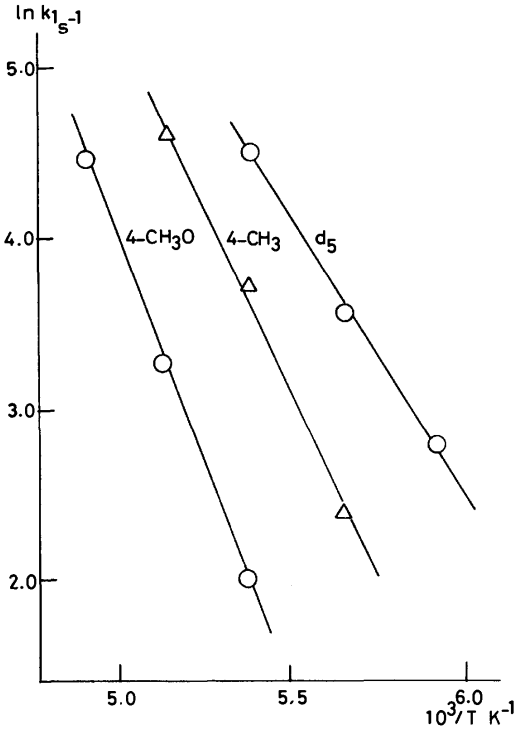

Fig. 7. Arrhenius plot of k_1 for substituted phenyldiazenyl radicals in cyclopropane.

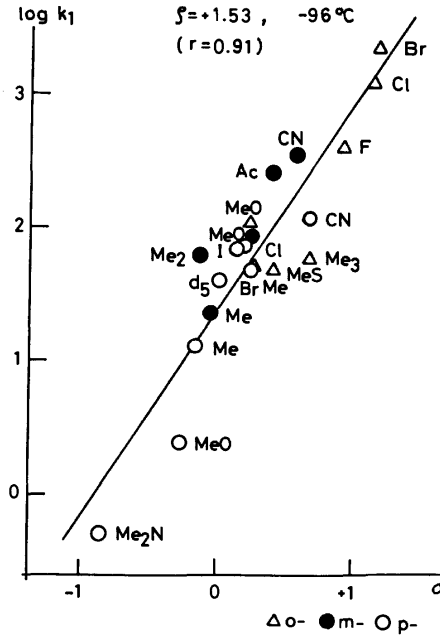

Fig. 8. Hammett plot of k_1 for substituted phenyldiazenyl radicals at −96 °C in cyclopropane.

The positive reaction constant, +1.53, implies a stabilization effect of electron-releasing substituent groups of aryldiazenyl radicals, polarizing thereby negatively at the -N=N group. The INDO calculation[8] suggested also a polar nature of the radicals with a dipole moment of ca. 2.8.

The negatively polarized -N=N group evokes an electrophilic property of aryldiazenyl radicals in their unimolecular decomposition in a variant of solvents. This became true in the determination of rate constants in olefinic solvents.

c) Solvent Effect on the First Order Reaction Rate. The effect of solvent on the rate of the unimolecular decomposition of 4-methoxyphenyldiazenyl radical was studied at −87 °C by using, i) inert hydrocarbon solvents, and ii) olefinic solvents, both in neat or in a 1 : 1 (volume) mixture of cyclopropane.

i) Inert Hydrocarbon Solvent. In inert hydrocarbon of higher molecular weight, such as 2,2,4-trimethylpentane, methylcyclopentane, and toluene in a 1 : 1 mixture of cyclopropane, the unimolecular decay rate of 4-methoxyphenyldiazenyl radical increased by a factor of 2 to 3, independent of the aliphatic or aromatic nature of the solvents. The increase in rate, effected by 2,2,4-trimethylpentane, must be due to viscosity of the solvent, and the effect caused by the trimethylpentane exceeded that of

Table 3. First Order Rate Constant of 4-Methoxyphenyldiazenyl Radical in 1 : 1 Mixture with Cyclopropane at −87 °C

Solvent added	k_1/s^{-1}	E_a/kJ mol^{-1}	$\log A$ / s^{-1}

Bromoethene	35	—	—
1-Chloropropene	26	—	—

toluene, i.e., hydrogen abstraction reaction by 4-methoxyphenyldiazenyl radical from the methyl group of toluene was probably not important at these low temperatures.

ii) Olefinic Solvents. Olefinic solvents on the other hand accelerated the decay rate of 4-methoxyphenyldiazenyl radicals remarkably. An effect other than that of viscosity must be important. The rate constants in olefinic solvents are listed together with those in hydrocarbon solvents in Table 3.

In 1-butene or *cis*-2-butene neat, we could observe the same ESR spectrum of 4-methoxyphenyldiazenyl radical as that in cyclopropane solution (Fig. 9). This result supports strongly that we are studying the primary radicals formed by photolysis of aryl(arylthio)diazenes and not the radical derived secondarily by some addition reaction of a radical to the starting diazenes.

The increase in rate effected by olefinic solvents is probably caused by a reaction between aryldiazenyl radical and the olefin molecule in a manner such as π-complexing, but not by addition reaction of aryldiazenyl radicals to olefinic double bond.

The minor roll of this addition reaction was deduced from a product study of photolysis of (4-*t*-butylphenylthio)(4-methoxyphenyl)diazene in propene at −78 °C. The reaction products were analyzed by using GC, HPLC, TLC, and NMR techniques, and identified as **a**: anisole (15%), **b**: 4-methoxyphenylpropane (6%), **c**: 4-*t*-butylphenyl 4-methoxyphenyl sulfide (in a small yield), **d**: 4,4′-di-t-butyldiphenyl disulfide (in an appreciable yield), and **e**: probably 2-(4-*t*-butylphenylthio)-1-(4-methoxyphenyl)propane (in a high yield). The compounds **d** and **e** decomposed seriously under the GC conditions. Aryldiazenyl radicals were transformed into dediazoniated products in the main routes of the reactions and this suggested that the dediazoniation was the first step of the reaction of aryldiazenyl radicals.

The mechanism of dediazoniation of aryldiazenyl radicals in olefinic solvents resembles the molecular mechanism of perbenzoic acid in methyl methacrylate[17] and proceeds probably through a formation of complex between aryldiazenyl radical and olefinic linkage under charge transfer from olefinic double bond to diazenyl nitrogen, followed by dediazoniation. The Hammett correlation of the decay rate of 4-methoxyphenyldiazenyl radical to the substituent constants of olefins, $\rho \fallingdotseq -1.0$, although of a poor linearity, and the decrease in activation energy in olefinic solvents, both support a mechanism of dediazoniation accelerated by charge transfer, and this is parallel to the substituent effect in the unimolecular rate constant of aryldiazenyl radicals in cyclopropane: Aryldiazenyl radicals are the more labile, the more neutral the −N=N groups in the radicals are (Fig. 10).

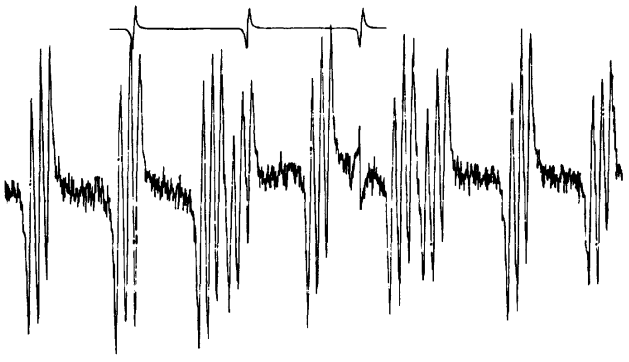

Fig. 9. ESR spectrum of 4-methoxyphenyldiazenyl radicals in 1-butene neat.

d) Possible Reaction Sequence of Unimolecuar Decomposition of Aryldiazenyl Radicals. The characteristic feature of k_1 of aryldiazenyl radicals is the very low frequency factor and the low activation energy, log A=12.8 to 8.3 s^{-1} and E_a=46 to 25 kJ mol^{-1}, respectively. The nature of this is not clear as yet, but can be probably explained by collision activation: aryldiazenyl radicals are activated by collision in a specific configuration, followed by decomposition. The sequence of the processes may be expressed as Eq. 19,

$$\mathrm{d} + \mathrm{m} \underset{k_r}{\overset{k_f}{\rightleftharpoons}} \mathrm{a} + \mathrm{m} \xrightarrow{k_{\text{spontan.}}} \text{products} \qquad (19)$$

where a denotes aryldiazenyl radicals in activated state and d those in the ground state. The symbol m stands for the second molecule of collision, usually solvent molecule. When k_f is rate-determining, then k_1 can be expressed as

$$k_1 = k_f \cdot (\mathrm{m})$$

and the rate should be of low frequency factor and dependent on solvent properties. Depolarization of aryldiazenyl radical would be the key step in the decomposition of the radical.

(2) Second Order Reaction Rate. a) Second Order Rate Constant of Phenyldiazenyl-d_5 by Batch Method. In the batch method a cyclopropane solution (2 ml) of $2 \cdot 10^{-2}$ M of aryl(arylthio)diazene was sealed in sample tube in vacuum. After 300 pulse irradiations the irradiated solution in the quartz cell-tube was refreshed by mixing with that of the reservoir, keeping

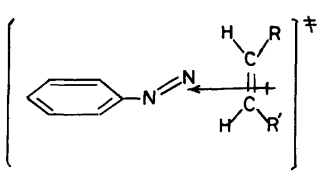

Fig. 10. Charge transfer in the dediazoniation step.

thus the concentration of solution at that of the initial one during the experiment. The rate constants were calculated by using Eq. 8.

The second order decay rates were determined by using 1 MHz modulation technique. A typical decay curve of phenyldiazenyl-d_5 in cyclopropane at $-102\,^{\circ}C$ is reproduced in Fig. 5. The rate constants, k_2, and the Arrhenius parameters are listed in Table 4 and plotted in Fig. 11, respectively.

b) Second Order Rate Constants by Flow Method. In order to examine the rate constants obtained by the batch method using Eq. 8, we measured the rate constant by using more dilute solutions of aryl-(arylthio)diazenes $4\cdot10^{-4}$ M in a flow system. In this experiment we used isohexane as solvent instead of cyclopropane because of the low boiling point of cyclopropane and of the low melting point of isohexane.

The concentration of the diazene of $4\cdot10^{-4}$ M, and the depth of the cell solution, 0.048 cm gave an estimation that about 70% of the light intensity irradiated into the solution would pass through unabsorbed and the aryldiazenyl radicals formed were assumed to be homogeneously distributed in the solution. In the calculation of the rate constant we used Eq. 9. The rate constants k_2 of phenyldiazenyl-d_5 in isohexane are listed in Table 5.

The rate constants obtained by the flow method in isohexane were ca. 30 times as high as those obtained by the batch method in cyclopropane, showing the same activation energy. The reason for this difference can be devided in two: 1) the difference of the properties of solvents used, and 2) the conditions for determination of rate constants.

The manuals in the flow method were established as was confirmed by the same rate data by the batch method using isohexane as solvent for $2\cdot10^{-2}$ molar diazene solution as those obtained by the flow method using the isohexane solution of $2\cdot10^{-2}$ M, calculating the rate constant by Eq. 8 for both. The results are shown in Table 6 and in Fig. 11.

The about 3 times higher rate constants by the flow method in isohexane of Table 5 than those by the batch and flow methods in isohexane of Table 6 may arise from the unknown bimolecular side reactions occurring in the more dilute solutions. We believe that the true rate constants are those of the Table 6, judging from 3 points:

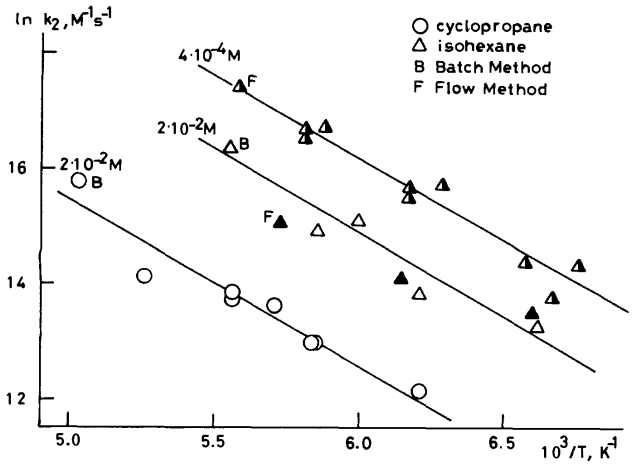

Fig. 11. Arrhenius plots of k_2 for phenyldiazenyl-d_5 radicals. O: Cyclopropane; Δ: isohexane; B: batch method; F: flow method.

Method	Temp/°C	k_2/M^{-1}s^{-1}	E_a/kJ mol^{-1}	log A/M^{-1}s^{-1}
Batch	−93	$1.3\cdot10^7$	24.3	14.02
	−103	$3.1\cdot10^6$		
	−107	$3.5\cdot10^6$		
	−112	$9.9\cdot10^5$		
	−122	$5.9\cdot10^5$		
Flow	−99	$3.4\cdot10^6$		
	−111	$1.3\cdot10^6$		
	−122	$7.4\cdot10^5$		

1) the approximation Eq. 8 of the batch method gives a correct rate constant when the condition, $1 \gg 2 \cdot (R\cdot_o)_o \cdot k_2 \cdot t$, is satisfied.[12] If not, the equation could give a rate constant about 50% lower than the correct one, and the condition was fulfilled in our experiments. The neglect of the fourth term in the derivation of Eq. 7 can cause only ca. 10% lowering of the rate constant.

2) The estimation of the surface and the volume of the reaction cell in the batch and the flow methods would be too high, may be ca. 2 times. This could give an overestimation of k_2 of ca. 2 times for the both cases.

3) In the flow method using a more dilute radical solution, the apparent rate constant could become higher owing to concurrent radical reactions of aryldiazenyl radicals with other radicals such as arylthiyl radicals, Reaction 15, and with alkylperoxyl radicals formed from peroxide of the solvent molecule when the exclusion of air from the diazene solution was not perfect. We have eliminated the rate data when we have observed traces of peroxyl radicals in the ESR spectrum of aryldiazenyls in the flow method. The accurate amount of the contribution of these concurrent reactions was not clear.

The rate constants in isohexane were about 10 times higher than those in cyclopropane. The accelerating effect of hydrocarbon solvents of higher molecular weight in k_1 is shown in Table 3. We measured k_2 of phenyldiazenyl-d_5 radicals in propane solution at $-102\,^\circ C$ to be $9.71 \cdot 10^5\ M^{-1}\,s^{-1}$ by the batch method. This value was ca. twice as high as that in cyclopropane, $4.3 \cdot 10^5\ M^{-1}\,s^{-1}$ at the same temperature. Viscosity of the solvent could affect the bimolecular decay rate of aryldiazenyl radicals. The exact nature of the accelerating effect of propane and isohexane was not clear.

The extrapolation of k_2 in cyclopropane by the batch method to $60\,^\circ C$ afforded a value $1.1 \cdot 10^9\ M^{-1}\,s^{-1}$ which was rather high. We are not in the position to discuss on it now.

c) Substituent Effect in the Second-Order Rate Constants of Phenyldiazenyl Radicals. The second-order rate constants of 4-methoxy-3,5-dideuteriophenyldiazenyl and 4-chloro-3,5-dideuteriophenyldiazenyl radicals were measured by the flow method in isohexane and the results are listed in Table 7.

We found a little increase in activation energy from 21.3 (4-methoxy-3,5-dideuteriophenyldiazenyl) to 24.3 (perdeuteriophenyldiazenyl) to 25.9 (4-chloro-3,5-dideuteriophenyldiazenyl) kJ mol^{-1} but the effect of increase in frequency factors was dominant. The increase in the frequency factor log A, from 13.23 to 14.58 to 15.83 $M^{-1}\,s^{-1}$ was supposed to be due to the increase in the degree of freedom in the activation collision, because the aryldiazenyl radicals are more and more neutral in the -N=N group in the order 4-methoxy- to hydrogen to 4-chloro-substituted phenyldiazenyls and the interaction leading to dediazoniation would be possible from a longer distance in this order.

Table 7. Substituent Effect in the Second-Order Rate Constants of Substituted Phenyldiazenyl Radicals, Flow Method, $4 \cdot 10^{-4}$ M

Substit. in phenyldiazenyl	Temp °C	k_2 $M^{-1}\,s^{-1}$	E_a kJ mol^{-1}	log A $M^{-1}\,s^{-1}$
4-CH_3O-3,5-d_2	−86	$1.9 \cdot 10^7$	21.3	13.23
	−97	$8.6 \cdot 10^6$		
	−107	$3.0 \cdot 10^6$		
	−117	$1.3 \cdot 10^6$		
4-Cl-3,5-d_2	−100	$1.1 \cdot 10^8$	25.9	15.83
	−113	$2.0 \cdot 10^7$		
	−113	$2.2 \cdot 10^7$		
	−124	$5.4 \cdot 10^6$		

For the chemical processes we propose reactions of Eq. 14 for the bimolecular reaction of aryldiazenyl radicals. In accordance with this an emission signal of azoarene was reported in the CIDNP studies of azo compounds.[18]

We are very greateful to Prof. Masahiro Kotani of Gakushuin University for his kind advices and suggestions for our research work.

Photochemical Reactions of Contact Charge-Transfer Pairs of 1-Arylcyclohexenes and Oxygen

Masanobu KOJIMA,* Hirochika SAKURAGI,† and Katsumi TOKUMARU†,*
Department of Chemistry, Faculty of Liberal Arts, Shinshu University, Asahi, Matsumoto 390
†Department of Chemistry, University of Tsukuba, Sakura-mura, Ibaraki 305
(Received April 7, 1987)

Photoexcitation of contact charge-transfer (CCT) pairs of 1-arylcyclohexenes **1** (aryl: phenyl, 4-methylphenyl, and 4-methoxyphenyl) and oxygen in acetonitrile and benzene gave 1,2-epoxy-1-arylcyclohexanes **2** as major products together with 2-aryl-2-cyclohexen-1-ols and acetophenones **4**. Similar irradiation of the CCT pairs in methanol/acetonitrile afforded mainly 2-aryl-2-methoxycyclohexanols instead of **2** and small amounts of 1-aryl-1-methoxycyclohexanes, 2-aryl-2-cyclohexen-1-ones, and **4**. The formation of these products can be explained by photoinduced electron transfer in the excited CCT pairs generating radical cations of **1** and superoxide anions.

Dye-sensitized oxygenation of organic substrates has been extensively investigated.[1,2] However, photochemistry of contact charge-transfer (CCT) pairs of the organic substrates and oxygen has not been so well investigated,[3-5] though spectral evidence for the CCT pairs has been documented.[6-8] Recently, we have reported selective photoexcitation of the CCT pairs of some organic compounds and molecular oxygen leading to specific reactions, in which their radical cations and superoxide anions play important roles. These reactive intermediates, after generation through electron transfer in the excited CCT pairs, can produce other reactive intermediates, for example, a) neutral free radicals through deprotonation of the radical cations, b) carbocations through electron transfer of the free radicals, and c) singlet oxygen through back electron transfer between the radical cations and superoxide anions.[9-12] The CCT pairs of olefins, such as 4-methoxy- and 4-methylstyrene, and oxygen in acetonitrile afforded, on excitation, their dimers accompanied by small amounts of their oxygenated products.[10,12] The reaction proceeds through their radical cations, which undergo addition to the ground-state olefin to give dimeric radical cations followed by electron transfer probably from superoxide anions. We now report structure dependence of the reaction course of excited CCT pairs of aromatic olefins and oxygen; 1-arylcyclohexenes (aryl: phenyl, 4-methylphenyl, and 4-methoxyphenyl) give mainly the corresponding epoxides or their derivatives in contrast to the above styrene derivatives.

Experimental

^{13}C NMR spectra were recorded on a JEOL FX-90Q spectrometer with TMS as an internal standard. Infrared and UV spectra were measured on a Hitachi 260-10 and a Shimadzu UV-300 spectrophotometer, respectively. Mass spectra were determined on a Shimadzu QP-1000 mass spectrometer.

Materials. 1-Phenylcyclohexene (**1a**),[13] 1-(4-methylphenyl)cyclohexene (**1b**),[13] and 1-(4-methoxyphenyl)cyclohexene (**1c**)[14] were prepared by the reaction of cyclohexanone with the corresponding 4-substituted phenylmagnesium bromide followed by treatment with 4-methylbenzenesulfonic acid in benzene.

1,2-Epoxy-1-phenylcyclohexane (**2a**)[15] was prepared from 2-bromo-1-phenylcyclohexanol by treatment with an aqueous potassium hydroxide solution;[16] bp 94 °C/5 Torr (1 Torr=133.322 Pa).

1-Methoxy-1-phenylcyclohexane (**6a**)[17] and 2-phenyl-2-cyclohexen-1-one (**7a**)[18] were prepared as previously described.

Acetonitrile, methanol, and benzene (guaranteed reagents) were purchased from Wako Pure Chemical Industries, and distilled before use.

Absorption Spectra of CCT Pairs. Samples of **1** (neat or 1 mol dm^{-3} in benzene) were placed in a sample cell and a reference cell, and a stream of oxygen was passed for several minutes through the sample in the sample cell, and a stream of argon through the sample in the reference cell. Immediately after a spectrum was measured, argon was passed through the sample cell and a spectrum was again recorded. The band observed under oxygen atmosphere disappeared completely by argon bubbling.

Measurements of Oxidation Potentials. Oxidation potentials of olefins **1**'s were determined by cyclic voltammetry using a three-electrode cell with a Nikko Keisoku NPG-501 potentiogalvanostat and a Nikko Keisoku NFG-3 function generator. The working electrode was a platinum wire (diameter, 1 mm) sealed into glass and a counter electrode was a platinum gauze. A saturated caromel electrode (SCE) was used as a reference electrode and tetraethylammonium perchlorate (0.1 mol dm^{-3}) as a supporting electrolyte. The current-potential curves were recorded directly from the output of the potentiogalvanostat on a Watanabe WX-1000 X-Y recorder. The oxidation potentials were 1.59, 1.51, and 1.28 V (vs. SCE) for **1a**, **1b**, and **1c**, respectively.

Irradiations. Photochemical reactions were carried out with a 400 W high-pressure mercury lamp (Riko UVL-400HA) and a 160 W low-pressure mercury lamp (Riko UVL-160LA). The irradiation mixtures were analyzed on a Shimadzu GC-8A gas chromatograph equipped with a flame ionization detector using 3.2 mm×2 m glass columns

packed with Silicone OV-17 (2%, Chromosorb W AW-DCMS, 60—80 mesh) and FON (10%, Chromosorb W AW-DCMS, 80—100 mesh). An internal standard (1,2-diphenylethane) was used to determine composition of the reaction mixtures.

Irradiation of 1-Arylcyclohexenes (1). In Acetonitrile: A solution (3 cm^3) of **1a** (0.1 mol dm^{-3}) in acetonitrile was irradiated under oxygen atmosphere for 9 h at 20 °C in a Pyrex tube with a 400 W high-pressure mercury lamp. GLPC analysis of the sample revealed the formation of 1,2-epoxy-1-phenylcyclohexane (**2a**, 22%), 2-phenyl-2-cyclohexen-1-ol (**3a**, 6%), and acetophenone (**4a**, 4%) at 68% consumption of **1a**.

Cyclohexene **1a** (3.16 g, 20 mmol) was irradiated in acetonitrile (200 cm^3) under oxygen with the high-pressure mercury lamp for 3.5 h. The reaction mixture was concentrated and chromatographed on silica gel under pressure. Epoxide **2a** was isolated and the structure was determined by comparing its ^{13}C NMR spectra with those of an authentic sample.

In Benzene: A solution (3 cm^3) of **1a** (0.1 mol dm^{-3}) in benzene was irradiated for 9 h in a similar way to that in acetonitrile. The yields of **2a** (22%), **3a** (8%), and **4a** (3%) were determined by GLPC.

In Methanol/Acetonitrile: A solution (3 cm^3) of **1a** (0.1 mol dm^{-3}) in a mixture of methanol and acetonitrile (1:2 by volume) in a Pyrex tube was irradiated under oxygen atmosphere with a 400 W high-pressure mercury lamp for 20 h at 20 °C. GLPC analysis of the reaction mixture showed almost complete consumption of **1a** and the formation of **4a** (9%), 2-methoxy-2-phenylcyclohexanol (**5a**, 30%), 1-methoxy-1-phenylcyclohexane (**6a**, 2%), and 2-phenyl-2-cyclohexen-1-one (**7a**, 5%).

A solution of **1a** (0.1 mol dm^{-3}) was similarly irradiated in the mixed solvent under argon atmosphere. No reaction products were detected in the irradiation mixture by GLPC analysis.

Cyclohexene **1a** (3.96 g, 25 mmol) was irradiated under oxygen in a 1:2 methanol–acetonitrile mixture (250 cm^3) with the high-pressure mercury lamp for 21 h. The reaction mixture was concentrated and chromatographed on silica gel under pressure. Cyclohexanol **5a** was isolated together with **4a**, **6a**, and **7a**. GLPC and ^{13}C NMR spectra showed that **5a** consisted of two stereoisomers.

2-Methoxy-2-phenylcyclohexanol (**5a**).[19] Isomer **5a**-A: ^{13}C NMR($CDCl_3$) δ=141.0 (s), 127.3 (d), 126.5 (d), 126.3 (d), 79.6 (s), 74.8 (d), 48.9 (q), 29.6 (t), 23.0 (t), and 20.6 (t); MS (70 eV) *m/z* (rel intensity) 206 (M^+, 34), 147 (100), 121 (75), 105 (44), 91 (49), and 77 (40); isomer **5a**-B: ^{13}C NMR($CDCl_3$) δ=142.6 (s), 128.0 (d), 127.2 (d), 127.0 (d), 79.5 (s), 73.2 (d), 49.0 (q), 28.1 (t), 24.0 (t), 20.5 (t), and 18.9 (t); MS (70 eV) *m/z* (rel intensity) 206 (M^+, 29), 147 (100), 121 (51), 105 (40), 91 (37), and 77 (32).

A solution (3 cm^3) of epoxide **2a** (0.069 mol dm^{-3}) in a 1:2 methanol–acetonitrile mixture was irradiated in a Pyrex tube with a 400 W high-pressure mercury lamp for 9 h. GLPC analysis showed that **5a** was produced in 65% yield at 24% conversion of **2a**.

Cyclohexene **1b** (3.5 g, 20 mmol) was irradiated in a 1:2 methanol–acetonitrile mixture (200 cm^3) under oxygen with a 400 W high-pressure mercury lamp for 16 h. The reaction mixture was concentrated and chromatographed on silica gel under pressure. 2-Methoxy-2-(4-methylphenyl)cyclohexanol (**5b**), 1-methoxy-1-(4-methylphenyl)cyclohexane (**6b**), and 2-(4-methylphenyl)-2-cyclohexen-1-one (**7b**) were isolated (Table 1).

Similarly, when **1c** (0.1 mol dm^{-3}) was irradiated in a 2:3 methanol–acetonitrile mixture (50 cm^3) under oxygen in a uranium glass tube with a 400 W high-pressure mercury lamp for 39 h. 2-Methoxy-2-(4-methoxyphenyl)cyclohexanol (**5c**) and 1-methoxy-1-(4-methoxyphenyl)cyclohexane (**6c**) were isolated from the irradiation mixture (Table 1).

2-Methoxy-2-(4-methylphenyl)cyclohexanol (**5b**). Isomer **5b**-A: ^{13}C NMR ($CDCl_3$) δ=138.0 (s), 135.9 (s), 128.2 (d), 126.6 (d), 79.6 (s), 74.9 (d), 48.9 (q), 29.6 (t), 23.1 (t), 20.9 (t), and 20.3 (q); MS (70 eV) *m/z* (rel intensity) 220 (M^+, 30), 161 (100), 135 (74), 105 (43), and 91 (36); isomer **5b**-B: ^{13}C NMR($CDCl_3$) δ=139.6 (s), 136.4 (s), 128.6 (d), 126.8 (d), 79.2 (s), 72.9 (d), 48.7 (q), 28.0 (t), 23.8 (t), 20.4 (t and q), and 18.8 (t); MS (70 eV) *m/z* (rel intensity) 220 (M^+, 28), 161 (100), 159 (43), 135 (74), 105 (72), and 91 (49). Found (for mixture of the isomers): C, 76.09; H, 8.85%. Calcd for $C_{14}H_{20}O_2$: C, 76.33; H, 9.15%.

1-Methoxy-1-(4-methylphenyl)cyclohexane (**6b**): bp 102—103 °C/5 Torr; ^{13}C NMR($CDCl_3$) δ=142.8 (s), 136.0 (s), 128.7 (d), 125.9 (d), 76.9 (s), 49.1 (q), 35.4 (t), 25.6 (t), 21.9 (t), and 20.8 (q); MS (70 eV) *m/z* (rel intensity) 204 (M^+, 33), 161 (100), 129 (17), and 105 (27). Found: C, 82.57; H, 10.06%. Calcd for $C_{14}H_{20}O$: C, 82.30, H, 9.87%.

2-(4-Methylphenyl)-2-cyclohexen-1-one (**7b**):[20] ^{13}C NMR ($CDCl_3$) δ=197.9 (s), 147.2 (d), 140.1 (s), 137.0 (s), 133.5 (s), 128.5 (d), 128.3 (d), 38.9 (t), 26.4 (t), 22.8 (t), and 20.9 (q); MS (70 eV) *m/z* (rel intensity) 186 (M^+, 100), 130 (51), 129 (43), and 115 (49).

2-Methoxy-2-(4-methoxyphenyl)cyclohexanol (**5c**). Isomer **5c**-A: ^{13}C NMR ($CDCl_3$) δ=158.6 (s), 133.3 (s), 128.2 (d), 113.5 (d), 79.7 (s), 75.4 (d), 55.1 (q), 49.4 (q), 30.0 (t), 23.3 (t), and 21.4 (t); MS (70 eV) *m/z* (rel intensity) 236 (M^+, 39), 177 (100), 151 (90), and 121 (30); isomer **5c**-B: ^{13}C NMR($CDCl_3$) δ=159.2 (s), 134.6 (s), 128.6 (d), 114.0 (d), 79.5 (s), 73.7 (d), 55.3 (q), 49.3 (q), 28.2 (t), 24.4 (t), 20.9 (t), and 19.3 (t); MS (70 eV) *m/z* (rel intensity) 236 (M^+, 36), 177 (100), 151 (84), and 121 (30). Found (for mixture of the isomers): C, 70.89; H, 8.73%. Calcd for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53%.

1-Methoxy-1-(4-methoxyphenyl)cyclohexane (**6c**): bp 123 °C/6 Torr; ^{13}C NMR ($CDCl_3$) δ=158.5 (s), 137.9 (s), 127.3 (d), 113.6 (d), 55.1 (q), 49.3 (q), 35.5 (t), 25.7 (t), and 22.1 (t); MS (70 eV) *m/z* (rel intensity) 220 (M^+, 72), 189 (62), 177 (100), and 121 (73). Found: C, 76.53; H, 9.30%. Calcd for $C_{14}H_{20}O_2$: C, 76.33; H, 9.15%.

Dye-Sensitized Oxygenation of 1a. A solution (50 cm^3) of **1a** (1g, 6.32 mmol) in a 1:2 methanol–acetonitrile mixture containing Methylene Blue (50 mg, 0.134 mmol) was put in five uranium glass tubes (10 cm^3 each), and irradiated for 40 h under oxygen atmosphere through a filter solution of K_2CrO_4 (0.27 g dm^{-3}) and Na_2CO_3 (1 g dm^{-3}). The combined reaction mixture was evaporated in vacuo and 2-phenyl-2-cyclohexenyl hydroperoxide was isolated from the residue by flash-column chromatography[21] using a 1:3 hexane–benzene as an eluent. This compound was decomposed into cyclohexenol **3a** and cyclohexenone **7a** (**3a**/**7a**=1/1) in the GLPC column (240 °C). Reduction of the hydroperoxide by $NaBH_4$ gave cyclohexenol **3a** as a sole product. The yield of the peroxide was determined by

GLPC analysis after treatment with $NaBH_4$.

2-Phenyl-2-cyclohexenyl hydroperoxide (**8a**):[22] ^{13}C NMR ($CDCl_3$) δ=140.3 (s), 133.5 (s), 132.3 (d), 127.9 (d), 126.5 (d), 125.4 (d), 78.6 (d), 25.9 (t), 25.8 (t), and 16.2 (t).

2-Phenyl-2-cyclohexen-1-ol (**3a**):[23] ^{13}C NMR($CDCl_3$) δ=140.3 (s), 139.1 (s), 128.2 (d), 126.8 (d), 125.9 (d), 65.2 (d), 31.6 (t), 26.0 (t), and 17.2 (t); MS (70 eV) *m/z* (rel intensity) 174 (M^+, 68), 117 (53), 115 (56), and 91 (100).

Photooxidation of 1a in the Presence of 2,3-Dimethyl-2-butene (TME) and 1,4-Diazabicyclo[2.2.2]octane (DABCO). A solution (3 cm^3) of **1a** (0.1 mol dm^{-3}) in a 1:2 methanol–acetonitrile mixture containing TME (0.1 mol dm^{-3}) in a Pyrex tube was irradiated under oxygen atmosphere with a 400 W high-pressure mercury lamp for 20 h at 20 °C. GLPC analysis of the irradiation mixture showed that the yields and distribution of the products are quite similar to those in the photooxidation of **1a** in the absence of TME. The results are shown in Table 2.

Under similar conditions, **1a** (0.1 mol dm^{-3}) was irradiated with DABCO (0.1 mol dm^{-3}) for 20 h. The olefin was recovered almost quantitatively and trace amounts of **2a** and **4a** were detected by GLPC analysis.

Autoxidation of 1a. A solution (10 cm^3) of **1a** (0.1 mol dm^{-3}) in a 1:2 methanol–acetonitrile mixture containing AIBN (30 mg, 0.22 mmol) was heated at 65 °C for 20 h in an oxygen stream in the dark. The yields of the products, **2a**, **3a**, and **5a**, were determined by GLPC, and are shown in Table 1. **4a** and **6a** were not detected at all.

Results and Discussion

Absorption Spectra of the CCT Pairs of 1-Arylcyclohexenes and Oxygen. Under oxygen atmosphere, 1-phenylcyclohexene (**1a**) (neat or in benzene solution) exhibited a new weak absorption in the range of 320—400 nm. 1-(4-Methylphenyl)- (**1b**) and 1-(4-methoxyphenyl)cyclohexene (**1c**) also showed new absorptions at 320—410 and 325—450 nm, respectively, under similar conditions. These bands disappeared reversibly on introduction of argon to their solutions to exclude oxygen. These bands can be reasonably assigned to the CCT pairs of **1** and oxygen.[10,12]

Irradiation of the CCT Pairs of 1-Arylcyclohexenes and Oxygen. Selective irradiation into the CCT band of **1a** and oxygen in acetonitrile (effective wavelength of light: 313 nm) afforded 1,2-epoxy-1-phenylcyclohexane (**2a**, 22% based on **1a** consumed) together with 2-phenyl-2-cyclohexen-1-ol (**3a**, 6%), and acetophenone (**4a**, 4%). Similar irradiation of **1a** in benzene gave nearly the same distribution of the products (Table 1). However, in a mixture of methanol and acetonitrile (1:2 by volume) 2-methoxy-2-phenylcyclohexanol (**5a**, 30%) instead of epoxide **2a** was a main product, accompanying 1-methoxy-1-phenylcyclohexane (**6a**, 2%), 2-phenyl-2-cyclohexen-1-one (**7a**, 5%), and **4a** (9%). The formation of **5a** is assumed to be due to (photochemical) methanolysis of **2a** as a primary product since, in a control experiment, irradiation of **2a** with 313 nm light gave **5a** (a mixture of the cis- and trans-isomers) in a methanol–acetonitrile mixture.

However, on irradiation of **1a** under argon with 313 nm light in a methanol–acetonitrile mixture, no reaction products were detected by GLPC analyses. Also, on direct excitation of **1a** with 254 nm light, no products were obtained and the starting **1a** was recovered quantitatively both under argon and under oxygen. From these results it is reasonably concluded that all the products result from a sequence of reaction of the excited CCT pairs.

Table 1. Yields of Products on Irradiation and Autoxidation of 1-Arylcyclohexenes **1** under Oxygen in Solvents

Substrate	Additive	Solvent	Atmosphere	Irrad. wavelength /nm[b]	React. time /h	Conv. /%	Yield[a]/%

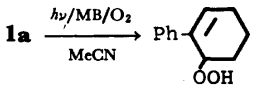
	—	MeOH/MeCN	Ar	254	15	0	—	—	—	—	—
	—	MeOH/MeCN	O_2	313	20	95	Trace	6	9	30	2
	—	MeOH/MeCN	Ar	313	20	0	—	—	—	—	—
	AIBN/65 °C[d]	MeOH/MeCN	O_2	—	20	53	8	4	—	46	—
	AIBN/65 °C	PhH	O_2	—	20	60	43	6	—	—	—
1b	—	MeOH/MeCN	O_2	313	15	96	—	3[e]	2	23	8
	—	MeOH/MeCN	Ar	313	15	0	—	—	—	—	—
1c	—	MeOH/MeCN	O_2	366	20	98	—	—	Trace	59	13
	—	MeOH/MeCN	Ar	366	20	6	—	—	—	—	Trace

a) Yields of products: [(moles of products)/(moles of **1** consumed)] × 100. The conversions of olefins **1** and the yields of the products were determined by GLPC analyses. b) Effective excitation wavelength. c) The sum of cyclohexenol **3** and cyclohexenone **7**. d) AIBN: azobisisobutyronitrile. e) The yield of cyclohexenone **7b**.

Irradiation into the CCT bands of 1-(4-methylphenyl)- (**1b**) and 1-(4-methoxyphenyl)cyclohexene (**1c**) under oxygen in a methanol–acetonitrile mixture led to similar results to the case of **1a** as shown in Table 1; **1b** afforded 2-methoxy-2-(4-methylphenyl)cyclohexanol (**5b**), 1-methoxy-1-(4-methylphenyl)cyclohexane (**6b**), 2-(4-methylphenyl)-2-cyclohexen-1-one (**7b**), and 1-(4-methylphenyl)ethanone (**4b**), and **1c** gave 2-methoxy-2-(4-methoxyphenyl)cyclohexanol (**5c**), 1-methoxy-1-(4-methoxyphenyl)cyclohexane (**6c**), and 1-(4-methoxyphenyl)ethanone (**4c**).

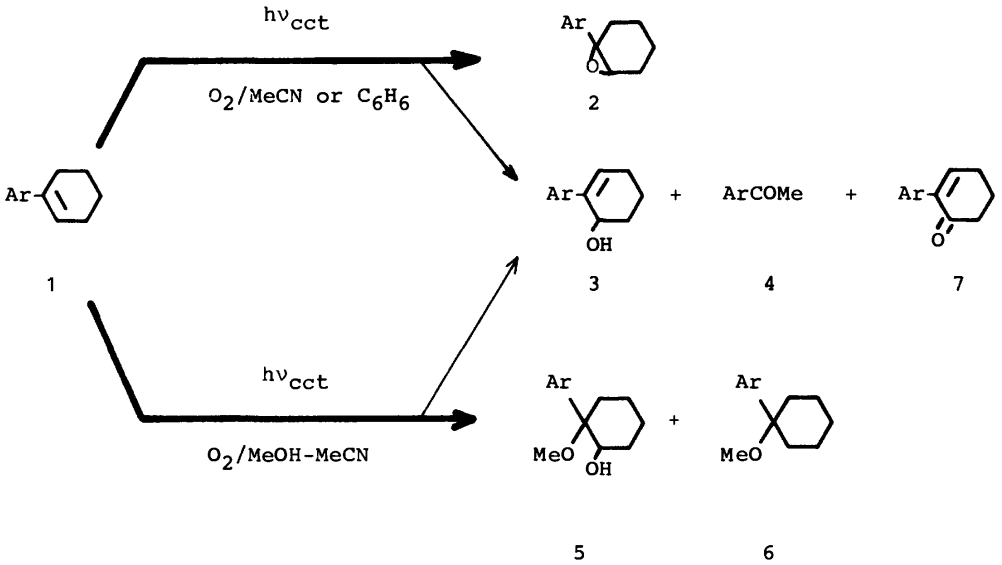
Some control experiments were carried out to examine oxygen species involved in the present oxygenation. In Methylene Blue(MB)-sensitized photooxygenation of **1a**, 2-phenyl-2-cyclohexenyl hydroperoxide (**8a**), which is known as a product in singlet oxygen oxygenation of **1a**,[22] was solely isolated (45%), but none of the products obtained from the CCT pair excitation was detected. Accordingly, it can be concluded that singlet oxygen is not associated with the reactions induced by CCT pair excitation of **1**.[10,11]



8a

Furthermore, addition of 2,3-dimethyl-2-butene (TME), a highly reactive singlet oxygen trap, brought about no effects on the product distribution in the CCT pair excitation of **1a** in a methanol–acetonitrile mixture (Table 2).

When **1a** was irradiated under oxygen in a methanol–acetonitrile mixture in the presence of 1,4-diazabicyclo[2.2.2]octane (DABCO), only trace amounts of **2a** and **6a** were formed (Table 2). DABCO works not only as a singlet oxygen quencher but also



Scheme 1. **1a**: Ar=Ph; **1b**: Ar=4-MeC$_6$H$_4$; **1c**: Ar=4-MeOC$_6$H$_4$.

Table 2. Effects of 2,3-Dimethyl-2-butene (TME) and 1,4-Diazabicyclo[2.2.2]octane (DABCO) on Irradiation of 1-Arylcyclohexenes (**1**) under Oxygen in MeOH/MeCN

Substrate	Additive	Irrad. wavelength /nm[b]	Conversion /%	Yield[a]/%

a) Yields of products: [(moles of products)/(moles of **1** consumed)] × 100. b) Effective excitation wavelength. c) The sum of cyclohexenol **3** and cyclohexenone **7**. d) Methylene Blue(MB)-sensitized oxygenation. e) The yield of hydroperoxide **8a**, which was determined by GLPC analysis after treatment with sodium borohydride.

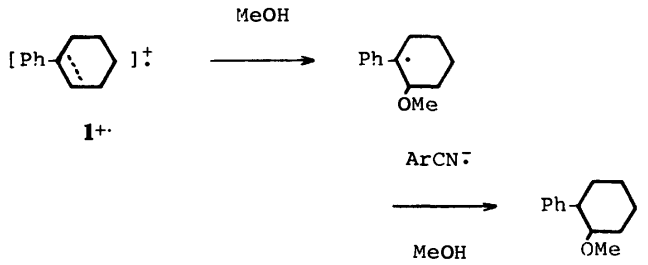
as an electron-donating quencher. Since the oxidation potential of DABCO (E_{ox}: 0.68 V vs. SCE) is by ca. 0.9 V lower than that of **1a** (1.59 V) and, as mentioned above, TME does not affect the photoreaction of the CCT pairs of **1a**, it is reasonably supposed that **1a** radical cations generated from the excited CCT pairs were reduced by DABCO, thus recovering **1a**.

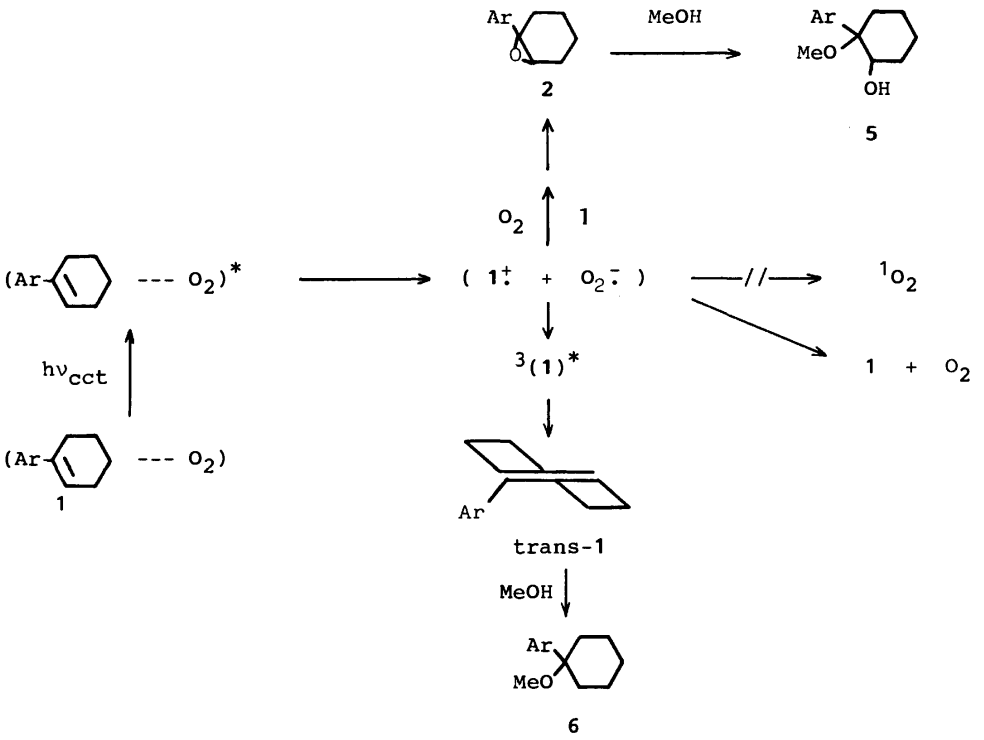
Reaction Course of Excited CCT Pairs. The above product study shows that the photochemical reactions take place only when the CCT pairs of **1** and oxygen were excited. The main product is epoxide **2** in acetonitrile and benzene; however, in the presence of methanol **2** is converted into methoxyalcohol **5**.

Azobisisobutyronitrile(AIBN)-initiated autoxidation of **1a** also gave **2a** as a main product (Table 1). As already reported, β-alkoxystyrenes give, on excitation of their CCT pairs with oxygen, the corresponding epoxides through an olefin–oxygen copolymerization process together with carbonyl compounds resulting from oxidative cleavage of the double bond.[24,25] Therefore, similar processes may be operative in the present oxygenation of **1** (Scheme 2).

More remarkable is the formation of 1-methoxy-1-arylcyclohexanes **6**, Markownikoff adducts of methanol to **1**. It is well-known that *trans*-cyclohexenes react with methanol to give addition products such as **6a**.[26–31] The adducts **6** were formed on excitation of the CCT pairs with oxygen, but not on direct excitation of the olefins under argon. Therefore, it is probable that excitation of the CCT pair leads to the formation of the triplet state of **1** [triplet energy (E_T) of **1a**: 56±3 kcal mol^{-1}],[32,33] which is deactivated from its twisted geometry to the *trans*-cyclohexene in the ground state. The cyclohexene triplets may be generated by back electron transfer between the olefin radical cations and superoxide anions, the energy of these pairs being 57 kcal mol^{-1} over the ground state as estimated from their electrochemical potentials.[34] The yields of ethers **6** were increased by introduction of an electron-donating group on the aromatic ring of **1a** (**6a**, 2%; **6b**, 8%; **6c**, 13%), probably because of increase in electron density on the double bond of *trans*-arylcyclohexene with increasing electron-donating ability of the substituent.[36]

Another possibility for **6** formation might be a reaction of the **1** radical cation with methanol followed by electron transfer and protonation. However, this possibility can be ruled out since addition of methanol to the **1** radical cation is assumed to take place at the 2-position of **1** on the basis of cyanoaromatics-sensitized addition of methanol to **1a**.[37] The present results indicate that the **1** radical





Scheme 2.

cations react probably with superoxide anions to give either some radical intermediates initiating autoxidation of **1** affording the epoxides or the triplet **1** decaying to *trans*-**1** (Scheme 2).

Photochemical behavior of CCT pairs of arylcyclohexenes **1** is in contrast with that of 4-methoxystyrene which gives a dimeric product as reported previously.[10,12] The difference in the reaction course between these CCT pairs may be associated with reactivity of the olefins towards their radical cations. Generally, trisubstituted and 1,2-disubstituted olefins are less reactive than monosubstituted olefins in free radical addition reactions,[38] whereas **1a** undergoes photodimerization in the excited state.[31,39] Therefore, it is reasonably supposed that arylcyclohexenes **1** are not so reactive with their radical cations as 4-methoxystyrene with its radical cation. As a result, the radical cations of **1** react with superoxide anion or oxygen rather than with **1**.

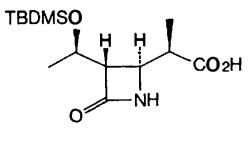
Nitrone Cycloaddition Route to the 1β-Methylcarbapenem Key Intermediate[1,2]

Yoshio Ito, Yoshikazu Kimura, and Shiro Terashima*
Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229
(Received April 11, 1987)

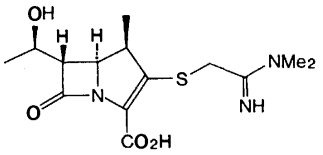
The 1β-methylcarbapenem key intermediate, (3*S*,4*S*)-3-[(*R*)-1-(*t*-butyldimethylsilyloxy)ethyl]-4-[(*R*)-1-carboxyethyl]-2-azetidinone, was prepared from (*S*)-methyl 3-hydroxy-2-methylpropionate by employing 1,3-dipolar cycloaddition of the chiral nitrone with benzyl crotonate as a key reaction.

Since its development first by Kametani[3,4] and later by Stevens,[5] the nitrone cycloaddition route has been recognized as one of the most reliable methods of preparing several structural types of carbapenem key intermediates.[4] The preparation of optically active carbapenem key intermediates has been also accomplished by the same methodology which utilizes the chiral nitrones derived from (*R*)-(+)-*N*-(α-phenylethyl)hydroxylamine[6] or (−)-menthyl glyoxylate hydrate.[7]

Based on these successful results so far reported,[3-7] we examined to explore the nitrone cycloaddition route for preparing the optically active 1β-methylcarbapenem key intermediate (**1**). The novel nitrone (**2**) obtainable from commercially available (*S*)-methyl 3-hydroxy-2-methylpropionate (**3**), was employed as a dipole by expecting that the chiral center involved in **2** may control the steric course of addition reaction in a



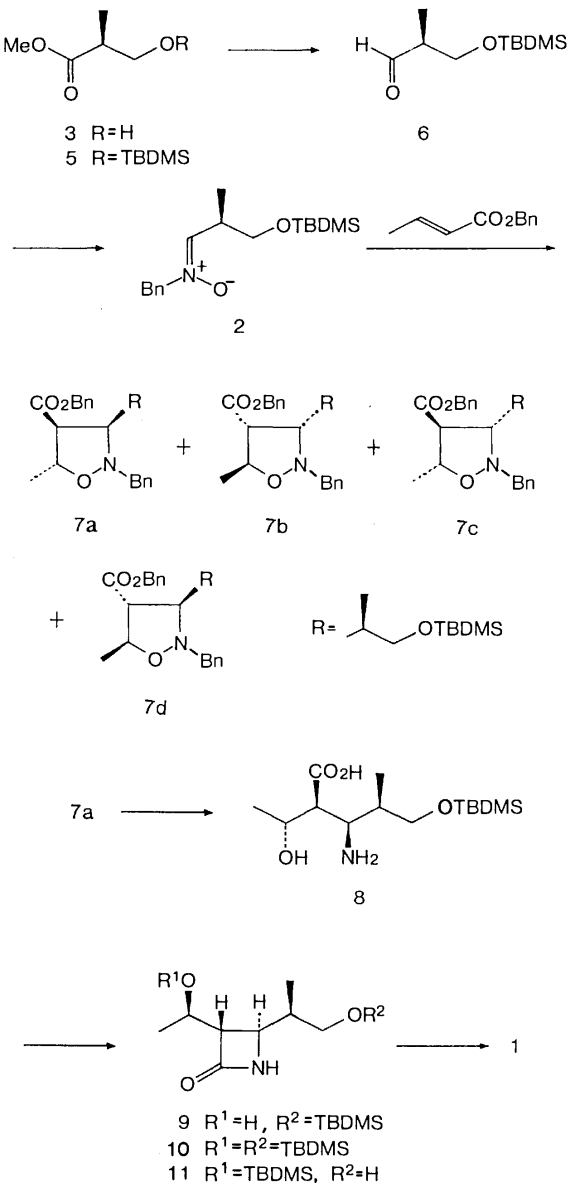
1



4

desired sence. The 1β-methylcarbapenem such as **4** is currently well-known as the synthetic carbapenem antibiotic showing excellent antibacterial activity, chemical stability, and insensitivity to renal dipeptidase-I.[8] We wish to report here that, while the control of steric course of cycloaddition reaction is not realized contrary to our expectation, the synthetic scheme can really produce optically pure **1** starting from **3**.

As shown in Scheme 1, sequential silylation of **3** and reduction of the methyl ester (**5**) gave the chiral aldehyde (**6**) in a good combined yield. Treatment of **6** with benzylhydroxylamine[9] produced a 64% yield of the optically active nitrone (**2**). The cycloaddition of **2** with benzyl crotonate was effected by heating 80 °C in toluene, producing the adduct (**7**) in 80% yield. Disappointingly, the 400 MHz NMR spectrum of **7** clearly disclosed that it consisted of almost the same amounts of four possible diastereomers (**7a—d**) in a ratio of 21:29:23:27. This represents that the endo- and exo-additions occur in an almost equal probability and the chiral center of **2** originating from **3** can not control the steric course of addition reaction. The diastereoselectivity could not be improved in favor of the desired diastereomer (**7a**) even by employing various crotonic acid esters and amides and



several solvent systems. Accordingly, the selective hydrolysis of **7a—d** was next examined by expecting that the ester groups of the useless $C_{3,4}$-trans adducts (**7c,d**) should be more rapidly saponified than those of the sterically congested $C_{3,4}$-cis isomers (**7a,b**). As expected, when the mixture of **7a—d** was treated with aq barium hydroxide in tetrahydrofuran[10] and the ester mixture (**7a—d**) obtained in 55% recovery was analyzed by 400 MHz NMR spectrum, the ratio of **7a—d** was found to be improved to 34:20:5:41. These results definitely suggest that the orginal reaction product (**7a—d**) contains the $C_{3,4}$-cis- and the $C_{3,4}$-trans-isomers (**7a,b** and **7c,d**) in a ratio of 48(21+27):52(29+23) and the partial saponification increases the ratio of **7a,b** to **7c,d** to 75(34+41):25(20+5).

Since the separation of **7a—d** turned out to be fruitless, the preparation of the optically active β-amino acid (**8**) was attempted by using the ester mixture in which the fraction of **7a** had been enriched. Treatment of **7a—d** under hydrogenolysis conditions followed by careful separation with column chromatography gave **8** from the major fraction in 21% yield,[11] mp 178—179 °C (decomp) and $[\alpha]_D^{20}$ −2.0° (methanol). Although it was quite ambiguous whether the isolated β-amino acid involves the desired stereochemistry, **8** was rigorously verified by obtaining the alcohol (**11**) from this compound.

The optically active β-amino acid (**8**) was lactamized by the Mukaiyama-Ohno method,[12] giving the lactam (**9**) in a quantitative yield, mp 105—106 °C and $[\alpha]_D^{20}$ −8.6° (chloroform). Studies on the ^{1}H NMR spectrum measured in the presence of the chiral shift reagent (Eu(hfc)$_3$) clearly disclosed that each synthetic step to the stage of **9** can proceed without substantial racemization (see Experimental.) Introduction of a *t*-butyldimethylsilyl group into the secondary alcohol of **9**, followed by selective acidic removal of the *t*-butyldimethylsilyl group which protects the primary alcohol of **10**, produced the optically pure alcohol (**11**) in 79% overall yield, mp 89—90 °C and $[\alpha]_D^{20}$ −20.9° (chloroform). This was identified with the authentic sample[13] by spectral comparisons. It has already been established that oxidation of **11** with pyridinium dichromate can produce **1** in 91% yield.[13]

As described above, we have succeeded in developing the new synthetic route to optically pure **1** by featuring the nitrone cycloaddition as a key reaction. The overall scheme may have a practical value if the diastereoselectivity of the addition reaction could be much more improved.

Experimental

General. All melting points were determined with a Yamato MP-21 melting point apparatus and were uncorrected. IR spectral measurements were carried out with a JASCO A-202 diffraction grating infrared spectrometer. ^{1}H NMR spectra were recorded with a Hitachi R-90H spectrometer (90 MHz) and a Bruker AM-400 spectrometer (400 MHz). All signals were expressed as ppm downfield from TMS used as an internal standard (δ value). Mass spectra were taken with a Hitachi RMU-6MG mass spectrometer. Measurements of optical rotations were performed with a Horiba SEPA-200 automatic digital polarimeter. Wakogel C-200 was used as an adsorbent for column chromatography.

(*S*)-(+)-Methyl 3-(*t*-Butyldimethylsilyloxy)-2-methylpropionate (5). *t*-Butyldimethylchlorosilane (1.30 g, 8.6 mmol) was added to a solution of commercially available **3** (1.00 g, 8.5 mmol) and imidazole (1.15 g, 17 mmol) in DMF (10 mL) at rt and the mixture was stirred there for 1.5 h. After H_2O (10 mL) and hexane (20 mL) were added to the reaction mixture, the organic layer was separated and the aqueous layer was extracted with hexane. The combined organic layers were washed with water and dried over anhyd $MgSO_4$. Filtration and concentration in vacuo gave **5** as a colorless oil (1.91 g, 97%). Bulb-to-bulb distillation (120 °C, 14 mmHg†) afforded an analytical sample of **5**. $[\alpha]_D^{20}$ +18.9° (*c* 1.00, $CHCl_3$). IR (neat) 2950, 2860, 1740, 1460, 1255, 1196, 1173, 1096, 833, 775 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=0.03 (6H, s, Me_2Si), 0.87 (9H, s, Me_3CSi), 1.13 (3H, d, *J*=7.0 Hz, MeCH), 2.64 (1H, m, MeCH), 3.66 (3H, s, COOMe), 3.60—3.80 (2H, m, CH_2O). MS *m/z* 217 $[M-Me]^+$, 201 $[M-MeO]^+$, 175 $[M-t\text{-}Bu]^+$.

(*S*)-(+)-3-(*t*-Butyldimethylsilyloxy)-2-methylpropanal (6). A one mol dm^{-3} solution (8.4 mL) of diisobutylaluminium hydride in hexane was added to a stirred solution of **5** (1.31 g, 5.6 mmol) in Et_2O (18.5 mL) over 5 min at −78 °C. After the stirring was continued at the same temperature for 30 min, the reaction mixture was diluted successively with MeOH (0.09 mL) and H_2O (0.84 mL). The resulting gelatinous mixture was filtered and washed with Et_2O. The filtrate was dried over anhyd $MgSO_4$, concentrated in vacuo, then purified with column chromatography (SiO_2: hexane–EtOAc 9:1), giving **6** as a colorless oil (0.890 g, 78%). Bulb-to-bulb distillation (110 °C, 14 mmHg) gave an analytical sample of **6**. $[\alpha]_D^{20}$ +37.8° (*c* 1.20, $CHCl_3$). IR (neat) 2950, 2860, 1735, 1470, 1256, 1100, 1029, 835, 777 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=0.00 (6H, s, Me_2Si), 0.82 (9H, s, Me_3CSi), 1.04 (3H, d, *J*=7.0 Hz, MeCH), 2.50 (1H, m, MeCH), 3.78 (2H, d, *J*=5.9 Hz, CH_2O), 9.74 (1H, d, *J*=1.5 Hz, CHO).

(*R*)-(−)-*N*-(3-*t*-Butyldimethylsilyloxy-2-methylpropylidene)benzylamine *N*-Oxide (2). The aldehyde (**6**) (0.600 g, 3.0 mmol) was added dropwise to a mixture of *N*-benzylhydroxylamine[9] (0.368 g, 3.0 mmol) and $CaCl_2$ (0.330 g, 3.0 mmol) in Et_2O (30 mL) at 0 °C. The stirring was continued there for 1 h and at rt for 2 h. After being filtered, the reaction mixture was concentrated in vacuo. The concentration residue was purified with column chromatography (SiO_2: hexane–EtOAc 1:1—0:1) to give **2** as a colorless oil (0.658 g, 64%). $[\alpha]_D^{20}$ −37.7° (*c* 0.89, $CHCl_3$). IR (neat) 2950, 2870, 1595, 1460, 1256, 1098, 840, 780, 702 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=−0.02, 0.00 (6H, two s, Me_2Si), 0.84 (9H, s, Me_3CSi), 1.10 (3H, d, *J*=6.8 Hz, MeCH), 3.10—3.40 (1H, m, MeCH), 3.63 (2H, m, CH_2O), 4.87 (2H, s, $PhCH_2$), 6.59 (1H, d, *J*=7.0 Hz, CH=N), 7.37 (5H, s, C_6H_5). MS *m/z* 307 $[M]^+$, 292 $[M-Me]^+$, 290 $[M-OH]^+$, 250 $[M-t\text{-}Bu]^+$. Found:

† 1 mmHg=133.322 Pa.

C, 65.86; H, 9.25; N, 4.46%. Calcd for $C_{17}H_{29}NO_2Si$: C, 66.40; H, 9.51; N, 4.55%.

Cycloaddition of (*R*)-(−)-*N*-(3-*t*-Butyldimethylsilyloxy-2-methylpropylidene)benzylamine *N*-Oxide (6) with Benzyl Crotonate. Preparation of a Mixture of the Four Diastereomers of 2-benzyl-4-benzyloxycarbonyl-3-[(*R*)-2-*t*-butyldimethylsilyloxy-1-methylethyl]-5-methylisoxazolidine (**7a**—d). Benzyl crotonate (0.89 g, 5.6 mmol) was added to a solution of **5** (0.86 g, 2.8 mmol) in anhyd toluene (2.8 mL) and the mixture was stirred at 80 °C for 24 h. After toluene and excess benzyl crotonate were distilled off at 110 °C in vacuo, the oily residue was purified with column chromatography (SiO_2: hexane–EtOAc 19:1), giving a mixture of **7a**—d as a colorless oil (1.03 g, 80%). IR (neat) 2950, 2880, 1738, 1454, 1255, 1178, 1090, 837, 777, 698 cm^{-1}. ^1H NMR ($CDCl_3$, 400 MHz) δ=−0.053, −0.046, −0.036, −0.029, −0.021, 0.005, 0.014 (6H, seven s, Me_2Si, intensity ratio: 12:23:14:12:14:14:11), 0.836, 0.839, 0.873 (9H, three s, Me_3CSi intensity ratio: 22:52:26), 1.33, 1.34, 1.35, 1.36 (3H, four d, *J*=6.07, 5.86, 5.81, and 6.03 Hz, MeCHCH$_2$O intensity ratio: 21:29:23:27), 1.65—2.05 (1H, m, MeCH CH$_2$O), 2.70—4.42 (6H, other protons) 4.40—4.66 (1H, m, MeCHO), 5.10—5.50 (2H, m, PhCH$_2$O), 7.20—7.42 (10H, m, aromatic protons). Based on the NMR spectrum, the formation ratio of **7a**—d could be estimated as 21:29:23:27. Since several attempts to separate **7a**—d turned out to be fruitless, the assignment of NMR signals and the determination of chemical yield for each diastereomer could not be achieved. However, comparison of the NMR spectra of the mixture of **7a**—d before and after saponification rigorously uncovered the formation ratio of the $C_{3,4}$-cis isomers (**7a,b**) to the $C_{3,4}$-trans ones (**7c,d**) as 48(21+27):52-(29+23). MS *m/z* 483 $[M]^+$, 468 $[M-Me]^+$, 426 $[M-t\text{-}Bu]^+$.

Selective Saponification of the Mixture of the Four Diastereomers of 2-Benzyl-4-benzyloxycarbonyl-3-[(*R*)-2-*t*-butyldimethylsilyloxy-1-methylethyl]-5-methylisoxazolidine (7a—d). Satd aq $Ba(OH)_2$ (50 mL) was added to a solution of the four diastereomers mixture of **7** (5.50 g) in THF (50 mL) and the mixture was stirred vigorously at the same temperature for 24 h. After an insoluble material was removed by filtration, the filtrate was diluted with hexane (150 mL). The upper organic layer was separated, washed successively with satd aq $NaHCO_3$, satd NaCl, then dried over anhyd $MgSO_4$. Filtration and concentration in vacuo gave an oily residue which was purified with column chromatography (SiO_2, hexane–EtOAc 1:0→19:1) to give a mixture of **7a**—d (3.00 g, 55% recovery). ^1H NMR ($CDCl_3$, 400 MHz) δ=−0.053, −0.046, −0.036, −0.029, −0.021, 0.005, 0.014 (6H, seven s, Me_2Si, intensity ratio: 17:11:20:4:8:23:17), 1.33, 1.34, 1.35, 1.36 (3H, four d, *J*=6.07, 5.86, 5.81, and 6.03 Hz, intensity ratio: 34:20:5:41). Since the $C_{3,4}$-trans isomers (**7c,d**) was expected to be saponified more preferencially than the $C_{3,4}$-cis ones (**7a,b**), this selective saponification could improve the ratio of the latter isomers to the former ones (**7a,b**:**7c,d**) from 48:52 to 75:25.

(2*S*,3*R*,4*R*)-3-Amino-5-*t*-butyldimethylsilyloxy-2-[(*R*)-1-hydroxyethyl]-4-methylpentanoic Acid (8). 10% Palladium on carbon (1.00 g) was added to a methanolic solution (50 mL) containing **7a—d** (10.0 g, 20.7 mmol) directly obtained by the above selective saponification, and the whole mixture was stirred under a hydrogen atmosphere (5 atm) for 7 h. The catalyst was filtered off and the filtrate was concentrated in vacuo. The concentration residue was purified by column chromatography (SiO_2: $CHCl_3$–MeOH 10:1→8:1) to give **8** as a colorless solid (1.30 g, 21%)[11] from the major fraction. Recrystallization of **8** from EtOH–H_2O (1:2) gave an analytical sample of **8** as colorless needles, mp 178—179 °C (decomp.) and $[\alpha]_D^{20}$ −2.0° (*c* 1.18, MeOH). IR (KBr) 3500, 2900, 2120, 1640, 1540, 1480, 1405, 1340, 1284, 1258, 1198, 1126, 1100, 1080, 1055, 1005, 960, 840, 813, 782, 728, 680, 620, 594, 557, 474 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.06 (6H, s, Me_2Si), 0.89 (9H, s, Me_3CSi), 1.12 (3H, d, *J*=7.0 Hz, MeCHCH$_2$O), 1.23 (3H, d, *J*=6.4 Hz, MeCHO), 1.95 (1H, m, MeCHCH$_2$O), 2.51 (1H, m, CHCOOH), 3.69 (3H, m, MeCHCH$_2$ and CHNH$_2$), 4.21 (1H, m, MeCHO). MS *m/z* 290 $[M-Me]^+$, 260 $[M-COOH]^+$, 248 $[M-t\text{-}Bu]^+$. Found: C, 54.81; H, 10.26; N, 4.48%. Calcd for $C_{14}H_{31}NO_4Si$: C, 55.04; H, 10.23; N, 4.59%.

(3*S*,4*R*)-4-[(*R*)-1-(*t*-Butyldimethylsilyloxymethyl)ethyl]-3-[(*R*)-1-hydroxyethyl]-2-azetidinone (9). A solution of triphenylphosphine (1.01 g, 3.9 mmol) in acetonitrile (62 mL) was added dropwise to a solution of recrystallized **8** (0.980 g, 3.2 mmol) and di-2-pyridyl disulfide (0.850 g, 3.9 mmol) in acetonitrile (300 mL) under reflux. After the heating at reflux was continued for 3 h, the mixture was concentrated in vacuo and the residue was dissolved in ether (40 mL). The ethereal solution was washed successively with 1 mol dm^{-3} NaOH and satd NaCl, then dried over anhyd Na_2SO_4. After filtration and concentration in vacuo, the residue was dissolved in EtOAc (3.7 mL). The ethyl acetate solution was diluted with hexane (8.9 mL) to crystallize triphenylphosphine oxide. After filtration, the filtrate was concentrated in vacuo to give almost pure **9** as a colorless solid (0.970 g, quantitative yield). A part of the residue was purified with TLC (SiO_2: hexane–EtOAc 3:7) and recrystallized from benzene, affording an analytical sample as colorless crystals, mp 105—106 °C and $[\alpha]_D^{20}$ −8.6° (*c* 1.08, $CHCl_3$). IR (KBr) 3370, 3230, 2950, 2870, 1722, 1475, 1363, 1314, 1255, 1154, 1089, 997, 840, 777, 708, 684 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.09 (6H, s, Me_2Si), 0.91 (9H, s, Me_3CSi), 0.96 (3H, d, *J*=6.8 Hz, MeCHO), 1.34 (3H, d, *J*=6.4 Hz, MeCHCH$_2$O), 1.77 (1H, m), 2.73 (1H, d, *J*=4.6 Hz, MeCHOH), 3.01 (1H, dd, *J*=7.8, 2.0 Hz, CHNH), 3.51 (1H, dd, *J*=7.8, 2.0 Hz, CHCO), 3.62 (2H, m, MeCHCH$_2$O), 4.14 (1H, m, MeCHO), 5.95 (1H, bs, NH). MS *m/z* 272 $[M-Me]^+$, 270 $[M-OH]^+$, 259 $[M-Me-OH]^+$, 230 $[M-t\text{-}Bu]^+$. Found: C, 58.71; H, 10.00; N, 4.87%. Calcd for $C_{14}H_{29}NO_3Si$: C, 58.49; H, 10.17; N, 4.87%. In order to examine an extent of racemization to the stage of **9** in the synthetic scheme, another lot of **9** (21.0 mg, 20%) was prepared from the mixture of **7a—d** (175 mg, 0.36 mmol) without any recrystallizations according to the reaction steps described above. Measurement of the ^1H NMR spectrum carried out with this sample in the presence of the chiral shift reagent [Eu(hfc)$_3$] clearly showed the methyl group of MeCHCH$_2$O moiety in an intensity ratio of 97.5:2.5 as two doublets at 1.82 and 1.79 ppm. Since the racemic β-lactam (*dl*-**9**)[14] exhibited the same methyl group as two sets of doublets of equal intensity at 1.79 and 1.82 ppm, the optical purity of **9** was estimated 95%ee. Accordingly, it became evident that each synthetic step to the stage of **9** could proceed without substantial racemization.

(3*S*,4*R*)-4-[(*R*)-1-(*t*-Butyldimethylsilyloxymethyl)ethyl]-3-[(*R*)-1-(*t*-butyldimethylsilyloxy)ethyl]-2-azetidinone (10). *t*-

Butyldimethylchlorosilane (35.0 mg, 0.23 mmol) was added to a solution of **9** (22.4 mg, 0.078 mmol) and imidazole (32.0 mg, 0.47 mmol) in DMF (0.5 mL) and the mixture was stirred at rt for 1.5 h. After the reaction was quenched by adding H_2O (0.5 mL), the mixture was extracted with EtOAc. The combined extracts were washed with H_2O, dried over anhyd $MgSO_4$, filtered, then concentrated in vacuo. The residue was purified with column chromatography (SiO_2: hexane–EtOAc 9:1→17:3) to give **10** as colorless crystals (31.1 mg, 99%). Recrystallization from MeOH–H_2O gave an analytical sample of **10** as colorless crystals, mp 97—99 °C and $[\alpha]_D^{20}$ −6.7° (*c* 0.95, $CHCl_3$). IR (KBr) 3470, 3180, 3120, 2950, 2880, 1760, 1717, 1480, 1258, 1140, 1101, 968, 840, 780 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.04, 0.07 (12H, two s, Me_2Six2), 0.87, 0.89 (18H, two s, Me_3CSix2), 0.96 (3H, d, *J*=6.8 Hz, MeCHCH$_2$O) 1.22 (3H, d, *J*=6.4 Hz, MeCHO), 1.79 (1H, m, MeCHCH$_2$), 2.88 (1H, m, CHNH), 3.55 (2H, d, *J*=4.8 Hz, MeCHCH$_2$), 3.70 (1H, dd, *J*=5.4, 2.3 Hz, CHCO), 4.17 (1H, dq, *J*=6.4, 5.4 Hz, MeCHO), 5.74 (1H, bs, NH). MS *m/z* 386 $[M-Me]^+$, 344 $[M-t\text{-}Bu]^+$. Found: C, 59.84; H, 10.71; N, 3.41%. Calcd for $C_{20}H_{43}NO_3Si_2$: C, 59.80; H, 10.79; N, 3.49%.

(3*S*,4*R*)-3-[(*R*)-1-(*t*-Butyldimethylsilyloxy)ethyl]-4-[(*R*)-1-(hydroxymethyl)ethyl]-2-azetidinone (11). One mol dm^{-3} hydrochloric acid (4.0 μL) was added to a solution of **10** (10.7 mg, 0.027 mmol) in MeOH (1.0 mL) and H_2O (0.2 mL) at 0 °C and the mixture was stirred there for 2 d. After satd aq $NaHCO_3$ (0.5 mL) and satd NaCl (1.0 mL) were added, the mixture was extracted with EtOAc. The combined organic extracts were washed with satd NaCl, dried over anhyd $MgSO_4$, filtered, then concentrated in vacuo. The residual solid was purified with column chromatography (SiO_2: hexane–EtOAc 1:1) to give **11** (6.1 mg, 80%) as colorless crystals, mp 89—90 °C and $[\alpha]_D^{20}$ −20.9° (*c* 0.37, $CHCl_3$) (lit.,[11] mp 90—91 °C and $[\alpha]_D^{20}$ −21.7° (*c* 0.46, $CHCl_3$)). IR (KBr) 3450, 3180, 3100, 2950, 1755, 1713, 1373, 1255, 1140, 1098, 1062, 1050, 1027, 984, 963, 838, 810, 780 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.13 (6H, s, Me_2Si), 0.90 (3H, d, *J*=6.8 Hz, MeCHCH$_2$O), 0.92 (9H, s, Me_3CSi), 1.35 (3H, d, *J*=6.0 Hz, MeCHO), 1.86 (1H, m, MeCHCH$_2$O), 2.96 (1H, dd, *J*=8.3, 4.9 Hz, OH), 3.15 (1H, ddd, *J*=9.0, 2.2, 1.0 Hz, CHN), 3.30 (1H, dd, *J*=8.8, 2.2 Hz, CHCO), 3.53 (2H, m, CH$_2$OH), 4.13 (1H, dq, *J*=8.8, 6.0 Hz, MeCHO), 5.99 (1H, bs, NH). MS *m/z* 272 $[M-Me]^+$, 230 $[M-t\text{-}Bu]^+$. These spectral properties were identical with those of the authentic sample independently prepared by our hands.[13] Found: C, 58.30; H, 10.15; N, 4.75%. Calcd for $C_{14}H_{29}NO_3Si$: C, 58.49; H, 10.17; N, 4.87%.

The authors are indebted to Dr. M. Sunagawa, Research Laboratories, Research and Development Division, Sumitomo Pharmaceuticals Co. Ltd., for valuable suggestions.

10) When aq sodium hydroxide or aq potassium hydroxide solution was employed in place of aq barium hydroxide solution and alcoholic solvents were used as the reaction medium, significant epimerization of the C_4 esters of the $C_{3,4}$-cis-adducts (**7a,b**) was observed.

11) In another hydrogenolysis carried out in a small scale, we have succeeded in obtaining the other two diastereomers of **8** in pure states by TLC separation (SiO_2, $CHCl_3$–MeOH 6:1) although their yields could not be specified. When being treated under the Mukaiyama–Ohno conditions,[12] these two compounds were found to produce the *trans*- and the *cis*-β-lactams whose stereochemistry could be definitely determined by NMR analyses. Accordingly, the diastereomers of **7** which gave the *trans*-β-lactam was identified as **7b** and the other producing the *cis*-β-lactam as **7c** or d (Y. Ito, Y. Kimura, and S. Terashima, unpublished results).

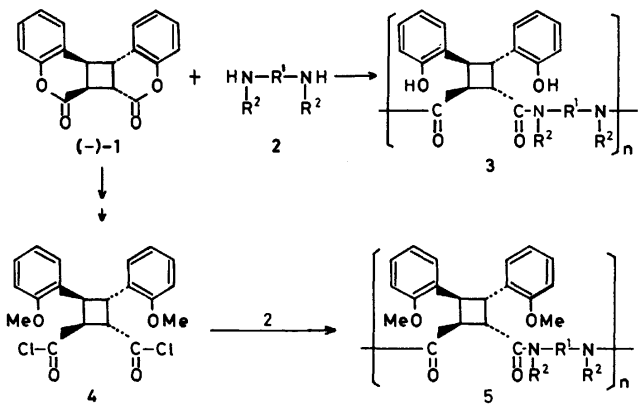
Optically Active Polyamides Having (−)-Anti Head-to-Head Coumarin Dimer Component. 3. Chiral Recognition Ability

Yun CHEN, Kazuhiko SAIGO,* Noriyuki YONEZAWA, Kouzou TACHIBANA, and Masaki HASEGAWA
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received April 21, 1987)

Optically active polyamides (**3a—f**) and *O*-methylated polyamides (**5a,d,e**), derived from (−)-anti head-to-head coumarin dimer [(−)-**1**], were absorbed on macroporous silica gel particles and used as chiral stationary phases for direct resolution of racemates (**6—13**) having aromatic moiety by high-performance liquid chromatography. Polyamide **3a** and **3e** could resolve **6—10** and **9—13**, respectively (separation factor $\alpha>1.03$), and **3d** showed especially high selective recognition ability to **7** ($\alpha=1.63$). However, **3c,f** and **5a** showed no resolution ability to all of the racemates. The high recognition ability of **3a** is attributed mainly to the difference in stability between the diastereomeric complexes formed by the simultaneous interaction of **3a** with the racemates. The recognition ability of polyamides derived from piperazine (**3d**, **5d**) and 1,4-phenylenediamine (**3e**, **5e**) seems to be attributed not only to the simultaneous interaction but also to their ordered conformations in the film state.

A variety of optically active polymers have been synthesized,[1] but only a few of them have been found to be applicable as chiral packing materials in high-performance liquid chromatography (HPLC).[2-5] In most polymeric chiral stationary phases such as isotactic (+)-poly(triphenylmethyl methacrylate),[6-10] poly(amino acid)s,[11,12] microcrystalline cellulose triacetate,[13,14] and phenylcarbamates of polysaccharides,[15] high chiral recognition ability depends strongly on their secondary or higher ordered structures. The chiral recognition by crosslinked polyacrylamides with chiral pendant group is known to be due to the contribution of hydrogen-bonding.[2,16] For low-molecular-weight chiral stationary phases, chiral recognition requires at least three simultaneous interactions between the chiral stationary phase and one of the enantiomer of racemate.[17-23]



Polyamide	R^1	R^2	η_{inh}
3a	$-(CH_2)_6-$	H	0.88
3b	$-(CH_2)_6-$	CH_3	0.35
3c	$-CH_2-C_6H_4-CH_2-$	H	0.63
3d	$-N\langle\rangle N-$		0.51
3e	$-C_6H_4-$	H	0.36
3f	$-C_6H_4-O-C_6H_4-$	H	0.31
5a	$-(CH_2)_6-$	H	1.01
5d	$-N\langle\rangle N-$		1.00
5e	$-C_6H_4-$	H	0.50

Previously, we reported the synthesis of a series of optically active polyamides (**3a—f**), composed of (−)-anti head-to-head coumarin dimer component [(−)-**1**] subunit, and showed that by varying the rigidity of diamine component the ordered conformations of these polyamides in solutions can also be controlled to some extent.[24,25] Moreover, we reported briefly that some of polyamide **3a—f**, depending on the structure of diamine component, are applicable as chiral packing materials for direct HPLC resolution of racemates.[26] But the different chiral recognition behavior of **3a—f** could not be explained merely by the simultaneous interactions between the racemates and the interaction sites in the polyamides, i.e. phenolic hydroxyl group, aromatic group, and amide linkage, and/or the ordered conformation in solutions. In order to elucidate the recognition mechanism, we also synthesized *O*-methylated polyamides **5** and investigated the chiroptical properties of **3** and **5** in the film state,[27] which is considered to be analogous to the coated state for recognition process. Similar to the results obtained in solutions,[25] the conformations in the film state also depended strongly on the structure of diamine components. Polyamides derived from piperazine (**3d**, **5d**) and aromatic diamines (**3e,f** and **5e**) formed ordered conformation, while other polyamides existed in random conformation in the film state. In this paper we wish to report in detail the chiral recognition ability of **3** and **5**, and possible correlation between the chiral recognition ability and the simultaneous interaction or ordered conformation in the film state.

Experimental

General. Synthesis, characterization, and chiroptical properties of optically active polyamides **3** and **5**, derived from (−)-anti head-to-head coumarin dimer, were described in previous papers.[25,26] Racemates **6**—**13** and diphenylsilane coupler were of commercial origins.

Chromatographic Resolution of Racemates. Direct chromatographic separation of racemates was accomplished on a Shimadzu LC-5A HPLC system equipped with a Toyo Soda UV-8-II detector and, in some cases, a Jasco DIP-181 polarimeter detector at room temperature. The eluent was a mixture of hexane and 2-propanol, but in some cases methanol or ethanol only was used. The flow rate was 0.5 ml min^{-1}.

Macroporous silica gel particles (4.0 g) (Merck LiChrospher SI 1000),[28] pretreated with diphenylsilane coupler, were coated with about 25 wt% of polyamides in DMAc solution (ca. 0.85 g/8 ml) and then dried in vacuo at 60 °C for 5 h. The polyamide-coated silica gel thus obtained was packed in a stainless steel column [25×0.46 (i.d.) cm] by the slurry method. Theoretical plate number of the columns bearing **3a**—**f** for benzene were 2600, 2800, 4200, 2100, and 2200, respectively. Theoretical plate number of the columns bearing *O*-methylated polyamide **5a**, **5d**, and **5e** were 1600, 2200, and 1150, respectively. The void volume was estimated to be about 3.0 ml with a trace amount of water in methanol.

Results and Discussion

It is well-known that one of the driving forces for chiral recognition is a simultaneous interaction between the functional groups in a stationary phase and a solute.[3] Optically active polyamides **3** and **5** possess possible interaction sites for chiral recognition, i.e. phenolic hydroxyl (methoxyl) group, aromatic group, and amide linkage. Then, we expected that racemates **6**—**13**, having an aromatic group and a site for hydrogen-bonding, would be resolved by these polyamide-coated silica gel columns.

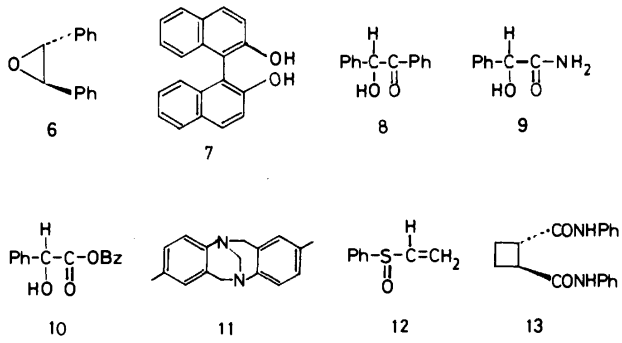


Figure 1 shows the chromatograms of 2,2′-dihydroxy-1,1′-binaphthyl (**7**), benzoin (**8**), and *trans*-1,2-cyclobutanedicarboxanilide (**13**) on the columns bearing **3d**, **3a**, and **3e**, respectively. The chromatographic parameters for the resolution of **6**—**13** using the polyamide-coated silica gel columns are summarized in Table 1.

Contrary to the expectation, it was shown clearly that the chiral recognition by these chiral stationary phases was diverse and strongly depended on the structure of diamine component in the main chain.

Polyamide **3a** resolved **6**—**10** efficiently (α is larger than 1.10), which all contain an aromatic group and a site for hydrogen-bonding. This suggests that the chiral discrimination of **3a** would involve the simultaneous interactions of aromatic stacking and hydrogen-bonding with the racemates. The separation factor of **3a** has tendency to decrease as the inherent viscosity increases (Table 2). More importantly, **3a** with higher theoretical plate number for benzene (η_{inh} 0.68 and 0.98 dl g^{-1}) showed smaller separation factors than those with lower theoretical plate number (η_{inh} 0.43 and 0.53 dl g^{-1}). This phenomenon would be explained as follow; with

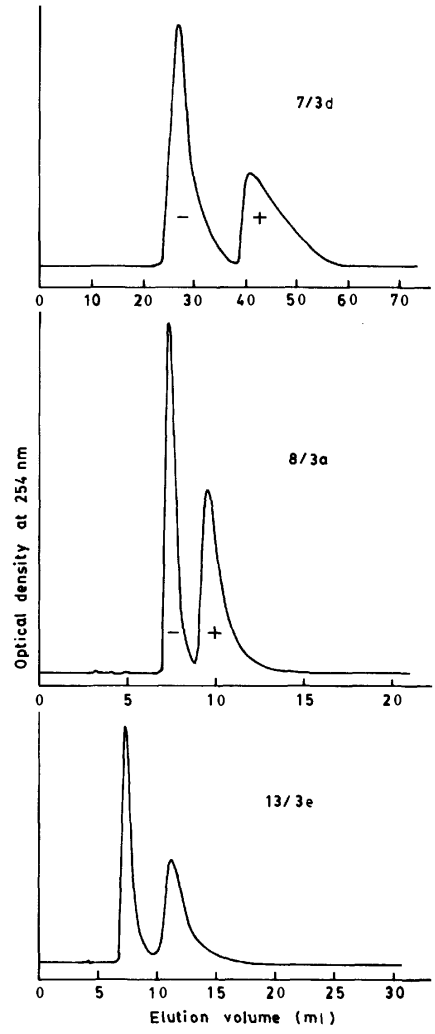

Fig. 1. Chromatograms of **7**, **8**, and **13** on the columns bearing 3d, **3a**, and **3e**, respectively. Columns, 25×0.46 (i.d.) cm; eluent, hexane/2-propanol (v/v=9/1); flow rate, 0.50 ml min^{-1} at room temperature.

0.98	2900	1.37	1.18	1.38	1.17	1.09

a) Resolution conditions are the same as those in Table 1. b) 0.30 g dl^{-1} in DMAc at 30 °C. c) For benzene.

increasing π–π interaction ability of **3a**, which contributes to the theoretical plate number of the column, the π–π interaction between phenyl groups in **3a** and the racemates surpasses the polar interaction and the difference in stability between diasteriomeric complexes decreases. Moreover, **3b** and **5a** having no amide hydrogen or phenolic hydrogen showed no resolution ability to racemates **6**—**13**. These results indicate that hydrogen-bonding plays more important role than π–π interaction in the chiral recognition process by **3a**.

On the other hand, **3c** shows no resolving ability to all of the racemates, although it also possess the same interaction sites as **3a**. This can be caused by the interference of aromatic moiety in diamine residue during recognition process.

The influence of the eluent with different amount of 2-propanol was also investigated. As shown in Table 3, the racemates resolved by polyamide **3a** can be divided into two groups. Racemates **8**—**10** can form an intramolecular hydrogen-bonding, and the other racemates **6**, **7**, and **13** don't possess this possibility due to the lack of hydrogen-bonding pair for **6** or the trans orientation of the possible interaction sites for **7** and **13**. With increasing the content of protic solvent in the eluent from 10% 2-propanol (IPA) to ethanol only, the separation factor (α) of **8**—**10** all increased at first and then decreased. This phenomena would be caused by the equilibrium between the inter- and intramolecular hydrogen-bonding, which changes depending on the content of protic solvent in the eluent. At low content of protic solvent, the chiral recognition is lower due to the dominance of intramolecular hydrogen-bonding within the racemate, which is disadvantageous to the chiral discrimination. With increasing the ratio of 2-propanol, the racemate would be solvated and the interaction between the racemate and polyamide **3a** surpasses the intramolecular interaction within the racemate, resulting in better recognition. However, at very high content of protic solvent the interaction between the racemate and the eluent becomes major, and the interaction between the racemate and polyamide **3a** is diminished, resulting in low separation factor. For racemates **6**, **7**, and **13**, separation factor decreased harmoniously with increasing the content of protic solvent in the eluent. This would arise from the decrease of the interaction between the racemates and polyamide **3a** by solvation. These results also support the simultaneous interaction mechanism of chiral recognition by **3a**.

Polyamide **3e** resolved **9**—**13**, which is partially different from those resolved by **3a**. Especially, **13** with propeller-like phenyl groups was resolved with a high separation factor (α=1.81). Moreover, contrary to **5a**, *O*-methylated polyamide **5e** still showed resolution ability to **8**—**10** although it has no phenolic hydroxyl group, which exists in polyamide **3e**. From these results, it seems that the driving force for chiral recognition by **3e** is different from that by **3a**. Since

Table 3. Chromatographic Resolution of Racemates **6**—**13** by **3a** or **3e**-Coated Silica Gel Column Using Different Eluents[a)]

Racemates	Parameter[c)]	Column bearing **3a**				Column bearing **3e**[b)]	
		10% IPA[c)]	20% IPA	30% IPA	EtOH	10% IPA	30% IPA
6	k_1'	0.35	0.30	0.23	0.15	0.41	0.18
	α	2.51	2.27	2.29	15.1	1	1

	α	1.34	1.25	1	1	1	1
8	k_1'	2.53	1.50	1.03	0.13	2.16	1.11
	α	1.65	1.79	1.75	1.45	1	1
9	k_1'	9.33	2.70	1.57	0.20	8.04	1.43
	α	1.29	1.40	1.43	1	1.03	1
10	k_1'	2.13	1.13	0.74	0.11	1.68	0.72
	α	1.11	1.15	1.16	1	1.05	1
11	k_1'	0.71	0.47	0.37	0.29	0.89	0.47
	α	1	1	1	1	1.12	1
12	k_1'	2.12	1.40	0.87	0.13	5.64	2.17
	α	1	1	1	1	1.04	1
13	k_1'	1.41	0.63	0.48	0.12	2.00	0.60
	α	1.28	1.24	1	1	1.81	1.59

a) The resolution conditions and the definition of parameters are the same as those in Table 1; polyamide **3a** with $\eta_{inh}=0.53$ dl g^{-1} was used. b) It showed no resolution ability to all of the recemates when methanol was used as an eluent. c) Eluent used is a mixture of hexane and 2-propanol (IPA).

both **3e** and **5e** form an ordered conformation of macromolecular asymmetry in the film state,[27] it is reasonable to say that this ordered conformation plays an important role in chiral recognition process. As shown in Table 3, with increasing the content of 2-propanol in eluent from 10 to 30%, **3e** showed no recognition to the racemates except for **13** (α=1.59). This is also quite different from the observed for **3a** which showed no resolution ability to **13** when an eluent containing 30% 2-propanol is used. From these facts, the chiral discrimination ability of **3e** can be attributed to its ordered conformation in the film state. The ordered conformation makes the difference in stability between diasteriomeric complexes large, which arises from the interaction of hydroxyphenyl groups of **3e** with aromatic groups of the racemates.

However, **3f** showed no resolution ability to all of the racemates, although it possesses polymer main chain structure with mesomeric aromatic residue similar to **3e**. This can be ascribed to its incompleteness of the ordered conformation[27] or to longer and more flexible diphenyl ether linkage in comparison with 1,4-phenylene linkage in **3e**.

Polyamide **3d** resolved atropisomeric compound **7** with a high separation factor (α=1.63). *O*-methylated polyamide **5d** resolved **6** with trans phenyl groups. This high selective resolution ability of **3c** to **7** and **5d** to **6** would be attributed to their rigid and fixed structure,[25,27] which makes the aromatic packing with racemates more stable for one of the enantiomer than the other.

The present results show that optically active polyamides **3** and **5**, derived from (−)-anti head-to-head coumarin dimer, are useful as chiral stationary phases for direct resolution of racemates having aromatic groups by HPLC. Polyamide **3a** derived from 1,6-hexanediamine shows the best results, and its recognition ability is mainly attributed to the simultaneous interactions with the solutes. The chiral discrimination ability of polyamides **3e** and **5e**, derived from 1,4-phenylenediamine, may be attributed to their ordered conformation in the film state as well as the simultaneous interaction with the racemates. The selective recognition ability of **3d** to **7** and **5d** to **6** seems due to their rigid and fixed conformation in the film state. The ordered conformation of the polyamides derived from piperazine and 1,4-phenylenediamine are less effective for chiral recognition than the simultaneous interaction with polar groups in **3a** unless the ordered conformation is fully-developed.[6-10]

Michael Addition and Alkylation of 2-Azaallyl Anions Derived from *N*-(1-Cyanoalkyl)imines, and Stereoselective Cyclization of Imine Esters or Ketones Leading to 1-Pyrrolines

Otohiko Tsuge,* Kazunori Ueno, Shuji Kanemasa, and Kiyotaka Yorozu
Institute of Advanced Material Study, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816
(Received April 30, 1987)

The 2-azaallyl anions derived from *N*-(1-cyanoalkyl)imines and DBU undergo Michael addition or alkylation to produce *N*-(1-alkylated 1-cyanoalkyl)imines. The Michael addition of some aryl-substituted imines are highly diastereoselective. The alkylated Michael adducts are converted into lactams through a hydrolysis and recyclization sequence. Base-induced cyclization furnishes 1-pyrrolines through a cyclization and HCN elimination sequence. In the latter reaction, 4,5-*cis*-1-pyrrolines are selectively produced when the adducts are treated with LDA in the presence of lithium iodide.

Deprotonation of imines adjacent to the nitrogen generates 2-azaallyl anions, while prior *N*-protonation or *N*-alkylation leads to azomethine ylides. These two anionic species are conplementary in organic synthesis: 2-Azaallyl anions undergo either nucleophilic addition to electrophilic multiple bonds or cycloaddition with nonactivated olefins,[1] while azomethine ylides react only with electron-poor activated olefins affording cycloadducts.[2] Recently both azomethine ylide and 2-azaallyl anion species have been generated by a separated procedure using a common precursor and their reactions with electron-poor olefins showed reverse regioselectivity, synthetic value of the precursor being increased.[3]

Deprotonation of the imines of 2-amino esters occurs readily to generate ester-stabilized 2-azaallyl anions. Reaction of the anions with Michael acceptors or alkylating agents followed by hydrolysis is one of the most important preparation method of 2-alkylated 2-amino acids.[4] Compared to the broad applications of the imines of 2-amino esters, synthetic utilization of the imines of 2-amino nitriles is quite limited.[5]

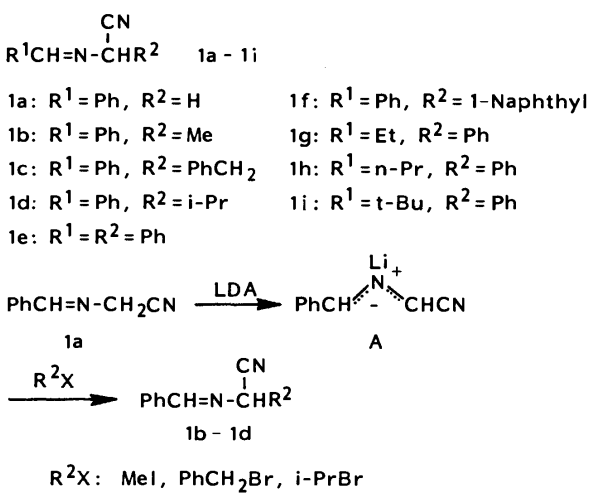
We have continued to study on the synthetic utility of the imines of 2-amino nitriles. The most important reaction on these imines must be its thermal tautomerization generating *N*-protonated azomethine ylides of cyano-stabilized types.[6] These ylides are found to be useful synthetic equivalents of non-stabilized nitrile ylides through a cycloaddition and HCN elimination sequence.

The present article deals with the chemistry of 2-azaallyl anions which can be generated by deprotonation of *N*-(1-cyanoalkyl)imines. Michael additions as well as alkylation reactions using these anions are investigated. Cyclization reactions of the Michael adducts and alkylated products lead to a variety of nitrogen heterocycles. Some of these conversions can be carried out in a stereoselective fashion.

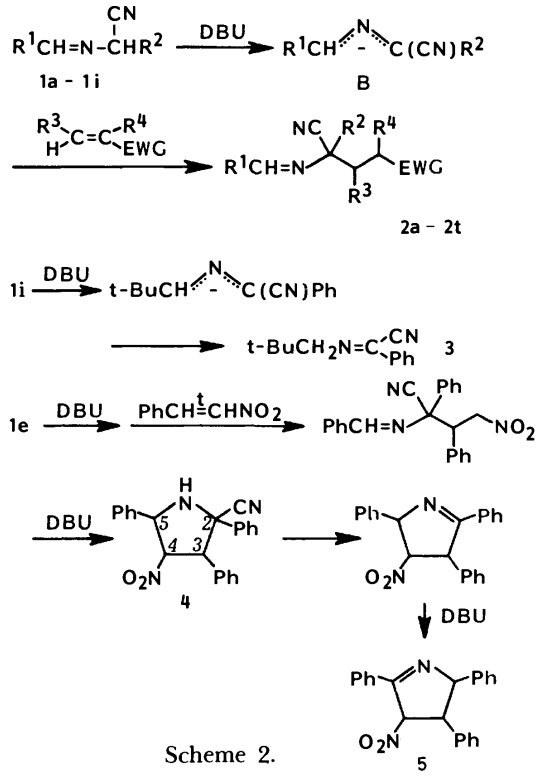
Results and Discussion

Michael Addition and Alkylation of *N*-(1-Cyanoalkyl)imines. *N*-(1-Cyanoalkyl)imines **1** are available by condensation of 2-amino nitriles with carbonyl compounds (Scheme 1). Among these imines **1a** is most easily accessible from aminoacetonitrile and benzaldehyde. Treating **1a** with LDA in THF at −78 °C forms the anion **A** and it can be smoothly alkylated with methyl iodide, benzyl bromide, or isopropyl bromide all in excellent yields. Accordingly the alkylation of **1a** is the most easy access to the alkylated derivatives **1b—1d**. Other imines **1e—1i** were prepared by the reactions of α-aminophenylacetonitrile or α-amino-(1-naphthyl)acetonitrile with the corresponding aldehydes.

N-(1-Cyanoalkyl)imines **1a—1i** generate the corresponding 2-azaallyl anions **B** when treated with DBU in THF at −78 °C and undergo Michael additions to a variety of electron-deficient olefins such



Scheme 1.



Scheme 2.

as methyl and *t*-butyl acrylates, 3-buten-2-one, acrylonitrile, methyl crotonate, and methyl α-silylacrylate, and (*E*)-β-nitrostyrene (Scheme 2 and Table 1). Acrylates, 3-buten-2-one, and acrylonitrile which carry a sterically less hindered β-carbon smoothly reacted with the anions **B** (R^1=Ph, R^2=$PhCH_2$ or *i*-Pr) derived from imines **1c** and **1d** bearing a bulky alkyl moiety on the carbon. However, these anions showed only decreased reactivity toward methyl crotonate even under harder conditions probably due to a steric hindrance.

The anion **B** (R^1=Ph, R^2=H) from **1a** is very reactive to methyl acrylate to furnish a Michael adduct. This adduct can be again deprotonated to form the anion **B** (R^2=CH_2CH_2COOMe) which can react with the second molecule of the acrylate, frequently yielding a mixture of 1:1 and 1:2 Michael adducts.

Though 2-azaallyl anions **B** have two nucleophilic sites, all the Michael additions took place regioselectively at the carbon substituted by CN. These high selectivity presumably resulted from the anion-stabilizing ability of sterically small CN group.

The anion **B** (R^1=*t*-Bu, R^2=Ph) from **1i** was found

a) All reactions were carried out in THF by using each one equivalent amount of **1** and an olefin. b) Yield of isolated products. c) Isomer ratio was determined by ^{1}H NMR spectrum. d) The starting imine was recovered intact.

inactive. It was quenched to form quantitatively a double bond-migrated imine **3** (Scheme 2). Cyclization products **4** and **5** of the Michael adducts were produced (**4**: 11%, **5**: 83%), both as single stereoisomers, in the reaction of the anion **B** (R^1=R^2=Ph) derived from **1e** with (*E*)-β-nitrostyrene. Elimination of HCN and subsequent double bond migration of pyrrolidine **4** would be a route leading to 1-pyrroline **5**. Strong electron-withdrawing property of the nitro group should be responsible for the instability of the Michael adduct.

It was surprising that the anions **B** bearing an aryl group as R^2 underwent stereoselective Michael additions to methyl crotonate to produce single diastereomers **2o—2r**, while reactions of other anions bearing an aliphatic R^2 are nonregioselective (Table 1).

These stereoselective adducts **2o**, **2q**, and **2r** were converted into the same 2-pyrrolidinone **6** as a single stereoisomer through hydrolytic cyclization (Scheme 3). This compound **6** was assigned to be an isomer in which 4-Me and 5-Ph are cis to each other on the basis of spectral data. For instance irradiation at the 4-Me (δ=1.24) resulted in a 13% of NOE enhancement of the 5-Ph. A similar hydrolytic cyclocondensation of **2p** produced **7** also as a single isomer.

On the other hand diastereomeric mixtures **21** (1:1) and **2m** (3:1) gave stereoisomeric mixtures of 2-pyrrolines **8** (1:1) and **9** (2.8:1), respectively. The major isomer of **9** was assigned to be cis, and minor one trans, on the basis of the ^{1}H chemical shifts of 4-Me and 5-Me (cis: δ=1.13 and 1.51; trans: 1.30 and 1.63) as well as the ^{13}C chemical shifts of 4-Me, 5-Me, 4-C, 5-C, and CN (cis: δ=14.30q, 21.24q, 38.94d, 55.89s, and 121.54s; trans: 15.00q, 24.76q, 41.36d, 59.06s, and 119.36s).

Stereoselectivity in the Michael addition of 2-azaallyl anions **B** is most likely to depend upon the electronic nature of R^2 substituent; Steric effect of R^2 is not important. We believe that there exists an attractive interaction between the aryl of 2-azaallyl anions **B** and the ester of methyl crotonate in the transition state.[7] As shown in Fig. 1, there are two possible approaches **C** and **C′** in which the ester is effectively overlapping with the aryl plane. The approach **C′** is more crowded between the methyl and the imine part so that the approach **C** leading to **2o—2r** becomes more favored. When R^2 is alkyl group no such attractive interaction exists. Neither of the two

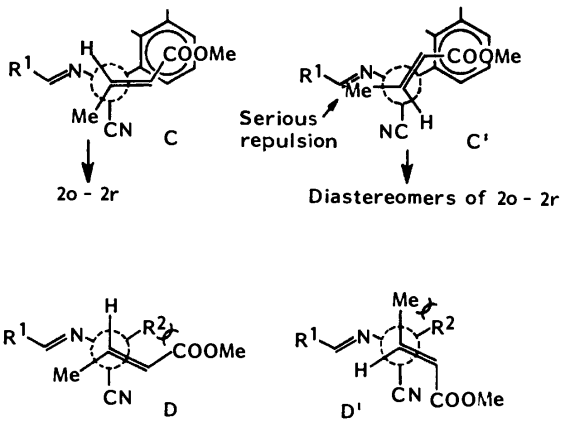

Fig. 1. Stereoselective Michael additions of aryl-substituted imines **1e—1g** with methyl crotonate.

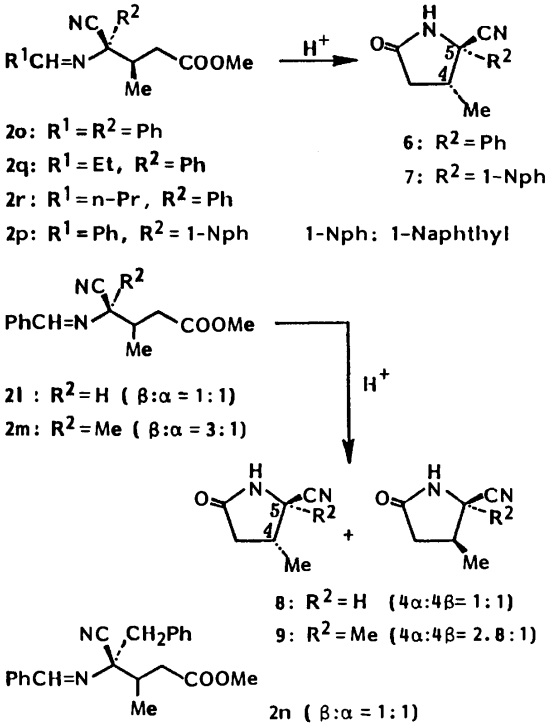
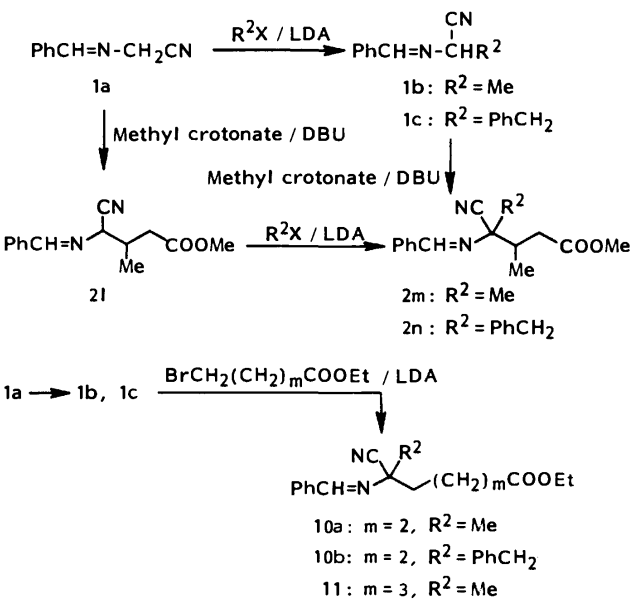


Scheme 3.



Scheme 4.

most likely approaches **D** and **D'** can find sterical predominance over the other. Accordingly the Michael additions become non-stereoselective, two diastereomers of Michael adducts being formed.

As described above two alkyl substituents can be introduced to α-(benzylideneamino)acetonitrile (**1a**) by two sequential alkylations using an alkyl halide/LDA and then a Michael acceptor/DBU (Scheme 4, **1a**, **1b**, **1c**, **2m**, **2n**). On the other hand the Michael addition of **1a** can be followed by the alkylation with an alkyl halide. For example **1a** was first allowed to react with methyl crotonate to afford a Michael adduct **21** which was then alkylated with methyl iodide or benzyl bromide to give the same dialkylated products **2m** and **2n** (Table 2).

Alkylation of **1** by the Michael addition route using α,β-unsaturated esters leads to 4-amino esters **2**. 6-Amino as well as 5-amino esters are also available when imines **1** are alkylated with ω-halo esters as alkylating agents (Scheme 4). Thus **1a** was first methylated or benzylated into **1b** or **1c**, and then alkylated with ethyl 4-bromobutanoate or 5-bromopentanoate to produce **10a**, **10b**, or **11**.

A quantitative conversion of the Michael adducts **21**—**2m** into γ-lactams **6**—**9** through a hydrolytic cyclization process was above mentioned in Scheme 3. The imine **10** bearing a longer framework by one carbon could undergo a similar hydrolytic cyclization to produce δ-lactams, 2-piperidinones **12a** and **12b** (Scheme 5). However the hydrolysis of **11** under comparable conditions gave methyl 6-aminoheptanoate **13**, no further cyclization being observed.

Base-Induced Cyclization of 2-(Alkylideneamino) Esters Leading to 1-Pyrrolines. Grigg and his coworkers have demonstrated the base-induced Michael additions between the imines of 2-amino esters and α,β-unsaturated esters.[8] These Michael adducts were converted into pyrrolidines by treatment with potassium *t*-butoxide or benzyltrimethylammonium methoxide in benzene. Stereoselectivity of these cyclizations was not high.

We first employed his cyclization procedure to *N*-(1-cyanoalkyl)imines **2** (Scheme 6 and Table 3). The cyclization of imines **2** was exclusively accompanied by a spontaneous elimination of CN group giving 1-pyrrolines **14** and/or **14'**. As shown with Entries 1, 6, 8, 13, 14, 24 (KOBu-*t*) and Entries 11 and 23 (BTAM) in Table 3, the cyclization of **2** under these conditions

a) Carried out in THF in the presence of LDA or DBU (1 equiv). b) Yield of isolated products. c) The reaction conditions are listed in Table 1. d) Isomer ratio : 4:1 (^{1}H NMR). e) Isomer ratio : 1.5:1 (^{1}H NMR).

is very poor in stereoselectivity. Either mixtures of two 4,5-stereoisomers **14**+**14′** were obtained or the only isomers were 4,5-*trans*-1-pyrrolines **14′** when the cyclization was stereoselective (Entries 11 and 13). Stereochemistry at the 3-position is not important since this position is known to isomerize into a thermodynamically more stable 3,4-trans configuration through an imine/enamine tautomerization.[9]

To our great surprise methylation of the Michael adduct **2l** with LDA and methyl iodide provided 4,5-*cis*-1-pyrroline **14l** as a single isomer (Scheme 6 and Entry 17 in Table 3). Although it was easily understood that **2l** was first methylated leading to **2m**, why the cyclization of **2m** under the methylation conditions was so fast and cis-selective? Both **2l** and **2m** were completely recovered intact on treatment with LDA at −78 °C (Entries 16 and 18), but a 1:1 stereoisometric mixture of cyclized products **14l**+**14l′** was obtained at an elevated temperature (Entry 19). In the presence of methyl iodide the cyclization was again cis-selective to give **14l** as a single product (Entry 20). In the end we noticed that lithium iodide would play an important role in the cis-selective cyclization reactions. Actually only cis isomer **14l** was given in an excellent yield in the reaction of **2m** with LDA in the presence of lithium iodide (Entry 21).

Thus cyclizations of other imines **2** were carried out under the cyclization conditions using LDA and lithium iodide, and 4,5-*cis*-1-pyrrolines **14** were the only products in most cases (Table 3). Lithium iodide probably worked as a Lewis acid to activate the C=N bond of imines **2** so that the intramolecular cyclization was considerablly facilitated. The high stereoselectivity would be discussed later.

Cyclization of imines **2g**—**2i** which bear an acetyl moiety as EWG was found also stereoselective but 4,5-*trans*-1-pyrrolines **14′** were the only or major products (Entries 10—13). As 4,5-*cis*-1-pyrroline **14i** readily epimerizes into 4,5-trans isomer **14i′** under the cyclization conditions, the predominant formation of **14g′**—**14i′** would be a result of facile epimerization at the carbon which is substituted with EWG (Scheme 6).

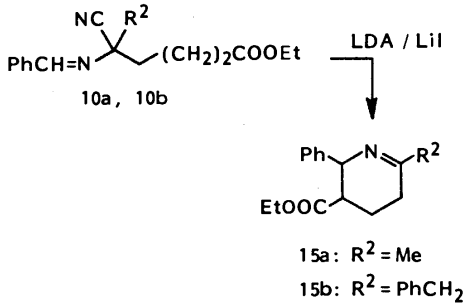
E: TBAF (0.1 equiv) in THF. F: TBAF (0.1 equiv) in HMPA. b) Yield of isolated products. c) Recovered **2c**: 31%. d) Inseparable mixture. Isomer ratio was determined by ^1H NMR or ^{13}C NMR spectrum. e) Recovered **2d**: 14%. f) Recovered **2o**: 11%. g) Yield determined by ^1H NMR spectrum (recovered **2t**: 60%). h) Isomer ratio is uncertain.

When 4-H of 4,5-cis isomers **14** is highly acidic, this position epimerizes presumably via an enol intermediate to lead to thermodynamically more stable 4,5-trans relationship. Quick isomerization at the 3-position is followed through an imine/enamine tautomerization to give **14'**.[9]

In other base-induced cyclizations of imines **2**, 4,5-*cis*-1-pyrrolines **14** would be formed exclusively or predominantly as the initial products. They undergo a similar epimerization both at the 3- and 4-positions leading to 4,5-*trans*-1-pyrrolines **14'**. It is apparent that isomer ratios **14**:**14'** depend upon the cyclization conditions (base, temperature, time etc.). As LDA/LiI-induced cyclization occurs more rapidly than the other cyclizations, one can conduct this reaction at a low temperature in a short period. As a result the subsequent epimerization is suppressed.



Scheme 7.

The alkylated imines **10a** and **10b** with one more carbon also underwent a similar cyclization under the influence of LDA and lithium iodide to give tetrahydropyridines **15a** and **15b** both as mixtures of two stereoisomers, respectively (Scheme 7). Contrary to this the cyclization of **11** under comparable conditions was entirely unsuccessful, **11** being quantitatively recovered.

The above 4,5-*cis*-selective cyclizations of Michael adducts **2** is explained with an example of cyclization of **2m** (Fig. 2). One possible transition model is called Cyclic Model which implies a seven-menbered ring of lithium chelate **F** and **F'** The other one called Open Chain Model involves a chair-like enolate geometry **G** and **G'**. The LDA/LiI-induced cyclization of **2m** which is a 1:1 mixture of two diastereomers (*ul*-**2m** and *lk*-**2m**) at −78 °C allowed the selective consumption of one isomer *ul*-**2m** forming **14** l. The other isomer *lk*-**2m** was recovered intact. In the both models the enolate intermediates **F** and **G** derived from *ul*-**2m** are sterically more favored than their isomeric intermediates **F'** and **G'** making possible the kinetical separation.

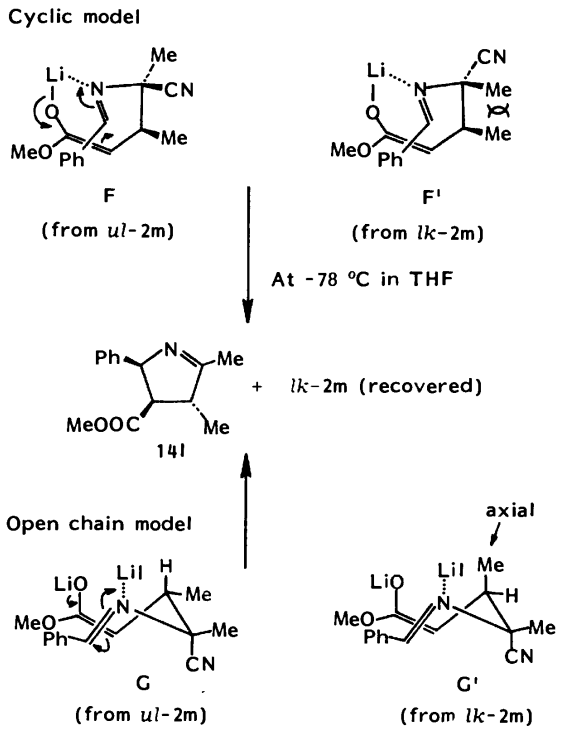


Fig. 2. Two possible transition models for the stereoselective cyclization of **2m** leading to **14**l.

Experimental

General. Melting points were determined on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-40 (90 MHz) or a JEOL FX-100 instrument (100 MHz) and ^{13}C NMR on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra as well as high resolution mass spectra were measured with a JEOL-01SG-2 spectrometer at 70 eV of ionization energy. Elemental analyses were performed on a Hitachi 026 CHN analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck). For preparative column chromatography Wakogel C-200, C-300 (Wako), and Silicagel 60 (Merck) were employed. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silicagel 60 (Merck, size: 0.04—0.063 mm). Micro vacuum distillation was made on a Sibata GTO-250R Kugelrohr distilling apparatus. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type-V.

General Procedure for Preparation of *N*-(1-Cyanoalkyl)-imines 1a—1i. Imines **1a** and **1e—1i** were prepared by the condensation of 2-aminoalkanenitriles with carbonyl compounds: Equimolar mixture of a 2-aminoalkanenitrile and a carbonyl compound was heated under reflux in the solvent described below (2—5 ml for 1 mmol of the substrate). The solution was dried over anhydrous magnesium sulfate and evaporated in vacuo to give imines **1** in an almost quantitative yield. Imines **1a**, **1e**, and **1g** are known.[6d] The reaction solvent and time are as follows: **1f**: In benzene for 1 h; **1h**: in chloroform for 2 h; **1i**: in benzene for 2 h. Imines **1b—1d** were prepared by the alkylations of **1a**: To a solution

of LDA (3 mmol in THF (3 ml)) freshly prepared from butyllithium and diisopropylamine was added imine **1a** (0.43 g, 3 mmol in THF (5 ml)) at −78 °C. After 5 min an alkylating agent (methyl iodide, benzyl bromide, or isopropyl bromide, each 3.3 mmol in THF (2—3 ml)) was added. The mixture was stirred under the following conditions: **1b**: at −78 °C for 2 h; **1c** and **1d**: at −78 °C for 1 h and then at room temperature for 1 h. The reaction was quenched by treating with ice water and the products were extracted with diethyl ether (30 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using chloroform to give **1b** (0.4 g, 85%), **1c** (0.614 g, 88%), or **1d** (0.48 g, 52%).

1b: Pale yellow liquid; bp 150 °C (133 Pa, bulb-to-bulb); IR (neat) 2225 and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.63 (3H, d, J=6.0 Hz, Me), 4.64 (1H, dq, J=6.0 and 2.0 Hz, CH), 7.2—7.6 (3H, m, Ph), 7.7—7.9 (2H, m, Ph), and 8.42 (1H, d, J=2.0 Hz, CH=N); ^{13}C NMR ($CDCl_3$) δ=21.06 (q, Me), 53.24 (d, CH), 118.89 (s, CN), 128.89, 131.83 (each d), 135.07 (s), and 162.66 (d, CH=N); MS m/z (rel intensity, %) 158 (M^+, 62), 143 (64), 131 (19), 130 (14), 117 (base peak), 105 (26), 104 (49), 103 (17), 90 (16), 89 (33), and 77 (88). HRMS Found: m/z 158.0840. Calcd for $C_{10}H_{10}N_2$: M, 158.0839.

1c: Pale yellow liquid; IR (neat) 2250, 1740, and 1645 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.17, 3.22 (each 1H, dd, J=13.0 and 8.0 Hz, CH_2Ph), 4.77 (1H, dt, J=8.0 and 2.0 Hz, NCH), 7.2—7.9 (10H, m, Ph), and 8.20 (1H, d, J=2.0 Hz, CH=N); MS m/z (rel intensity, %) 234 (M^+, 37), 143 (54), 118 (17), 117 (18), 116 (29), 107 (43), 91 (base peak), and 77 (30). HRMS Found: m/z 234.1165. Calcd for $C_{16}H_{14}N_2$: M, 234.1157.

1d: Pale yellow liquid; IR (neat) 2240 and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.05, 1.13 (3H, d, J=8.0 Hz, *i*-Pr), 2.23 (1H, m, *i*-Pr), 4.44 (1H, dd, J=6.0 and 2.0 Hz, NCH), 7.3—7.5 (3H, m, Ph), 7.70 (2H, m Ph), and 8.35 (1H, d, J=2.0 Hz, CH=N); ^{13}C NMR ($CDCl_3$) δ=17.94, 19.18 (each q, *i*-Pr), 32.88 (d, *i*-Pr), 65.06 (d, NCH), 117.24 (s, CN), 128.95, 129.19, 131.83, 134.66, and 163.00 (d, CH=N); MS m/z (rel intensity, %) 186 (M^+, 11), 144 (50), 143 (68), 116 (base peak), 104 (16), 91 (12), 90 (36), and 89 (54). HRMS Found: m/z 186.1158. Calcd for $C_{12}H_{14}N_2$: M, 186.1157.

1f: Yellow liquid; IR (neat) 2240 and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.33 (1H, d, J=2.0 Hz, CH), 7.2—8.2 (12H, m, Ar), and 8.52 (1H, d, J=2.0 Hz, CH=N); MS m/z (rel intensity, %) 270 (M^+, 45), 166 (base peak), 140 (11), and 127 (4). HRMS Found: m/z 270.1168. Calcd for $C_{19}H_{14}N_2$: M, 270.1168.

1h: Pale yellow liquid; bp 150 °C (133 Pa, bulb-to-bulb); IR (neat) 2430 and 1660 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.95 (3H, t, J=7.0 Hz, *n*-Pr), 1.60 (2H, m, *n*-Pr), 2.34 (2H, m, *n*-Pr), 5.46 (1H, s, CH), 7.36 (5H, s, Ph), and 8.00 (1H, t, CH=N); ^{13}C NMR ($CDCl_3$) δ=13.69 (t, *n*-Pr), 19.01, 37.79 (each t, *n*-Pr), 61.90 (d, CH), 117.20 (s, CN), 127.30, 129.00, 129.12 (each d), 134.97 (s), and 168.55 (d, CH=N); MS m/z (rel intensity, %) 186 (M^+, 8), 181 (16), 158 (39), 157 (18), 132 (22), 118 (22), 116 (base peak), 89 (21), and 58 (11). HRMS Found: m/z 186.1160. Calcd for $C_{12}H_{14}N_2$: M, 186.1157.

1i: Pale yellow liquid; bp 130 °C (133 Pa, bulb-to-bulb); IR (neat) 2250 and 1660 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.10 (9H, s, *t*-Bu), 5.46 (1H, d, J=2.0 Hz, CH), 7.30 (5H, s, Ph), and 7.85 (1H, d, J=2.0 Hz, CH=N); ^{13}C NMR ($CDCl_3$) δ=26.65 (q, *t*-Bu), 36.94 (s, *t*-Bu), 61.36 (d, CH), 117.30 (s, CN), 127.24, 128.48, 129.01 (each d), 135.19 (s), and 175.19 (d, CH=N); MS m/z (rel intensity, %) 200 (M^+, 26), 185 (33), 117 (39), 116 (base peak), 89 (18), and 58 (39). HRMS Found: m/z 200.1310. Calcd for $C_{13}H_{16}N_2$: M, 200.1991.

General Procedure for Michael Additions of *N*-(1-Cyanoalkyl)imines 1a—1i to Olefins Leading to 2a—2t. To a solution of imine **1** (1 mmol) in dry THF (5 ml) was added at −78 °C DBU (0.167 to 0.015 g, 1.1 to 0.1 mmol in 1 ml of THF). After 5 min, an olefin (1.1 mmol in 1 ml of THF) was added to the resulting red solution. This mixture was allowed to react under the conditions listed in Table 1 in an atmosphere of nitrogen, poured into ice water, and then extracted with diethyl ether (25 ml×2). The combined extracts were dried over anhydrous magnesium sulfate and evaporated in vacuo. The residue was chromatographed through a short column packed with silica gel by using chloroform as an eluent. The results are listed in Table 1.

2a: Pale yellow liquid; IR (neat) 2225, 1740, and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.62 (3H, s, Me), 2.2—2.4 (4H, m, 2×CH_2), 3.56 (3H, s, COOMe), 7.2—7.6 (3H, m, Ph), 7.7—7.9 (2H, m, Ph), and 8.46 (1H, s, CH=N); ^{13}C NMR ($CDCl_3$) δ=27.65 (q, Me), 29.41, 36.18 (each t, CH_2), 51.59 (q, COOMe), 62.59 (s, q-C), 119.36 (s, CN), 128.83, 131.77 (each d), 135.07 (s), 160.36 (d, CH=N), and 172.42 (s, COOMe); MS m/z (rel intensity, %) 244 (M^+, 2), 213 (38), 158 (39), 157 (base peak), 141 (82), and 104 (34). HRMS Found: m/z 244.1209. Calcd for $C_{14}H_{16}N_2O_2$: M, 244.1209.

2b: Pale yellow liquid; IR (neat) 2240, 1740, and 1645 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.37 (4H, m, 2×CH_2), 3.12 (2H, s, CH_2Ph), 3.52 (3H, s, COOMe), 7.1—7.4 (8H, s and m, Ph), 7.60 (2H, m, Ph), and 7.97 (1H, s, CH=N); ^{13}C NMR ($CDCl_3$) δ=29.47, 35.12, 46.18 (each t, CH_2), 51.65 (q, COOMe), 68.06 (s, q-C), 118.07 (s, CN), 127.60, 128.30, 128.83, 131.00, 131.77, 134.07, 134.83, 161.66 (d, CH=N), and 172.65 (s, COOMe); MS m/z (rel intensity, %) 320 (M^+, 15), 230 (16), 229 (base peak), 197 (12), 169 (56), and 104 (17). HRMS Found: m/z 320.1546. Calcd for $C_{20}H_{20}N_2O_2$: M, 320.1567.

2c: Pale yellow liquid; IR (neat) 2250, 1740, and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.95, 1.15 (each 3H, d, J=7.0 Hz, *i*-Pr), 2.0—2.4 (4H, m, CH_2), 3.55 (3H, s, COOMe), 7.3—7.5 (3H, m, Ph), 7.78 (2H, m, Ph), and 8.42 (1H, s, CH=N); ^{13}C NMR ($CDCl_3$) δ=17.53, 17.71 (each q, *i*-Pr), 29.53, 32.59 (each t, CH_2), 36.65 (d, *i*-Pr), 51.77 (q, COOMe), 61.06 (s, q-C), 117.89 (s, CN), 128.95, 131.80 (each d), 135.00 (s), 160.89 (d, CH=N), and 173.07 (s, COOMe); MS m/z (rel intensity, %) 272 (M^+, 14), 241 (26), 230 (32), 229 (93), 186 (32), 185 (36), 144 (67), and 143 (base peak). HRMS Found: m/z 272.1533. Calcd for $C_{16}H_{20}N_2O_2$: M, 272.1541.

2d: Colorless liquid; IR (neat) 2220, 1715, and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.3—2.7 (4H, m, CH_2), 3.50 (3H, s, COOMe), 7.2—7.8 (10H, m, Ph), and 8.50 (1H, s, CH=N); MS m/z (rel intensity, %), 306 (M^+, 26), 220 (22), 219 (base peak), 142 (60), and 115 (39). HRMS Found: m/z 306.1363. Calcd for $C_{19}H_{18}N_2O_2$: M, 306.1360.

2e: Pale yellow liquid; IR (neat) 2220, 1740, and 1665 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.15 (3H, t, J=7.0 Hz, Et), 1.7—2.0 (2H, m, Et), 2.2—2.6 (4H, m, CH_2), 3.60 (3H, s, COOMe), 7.2—7.7 (5H, m, Ph), and 8.07 (1H, t, J=5.0 Hz, CH=N); ^{13}C NMR ($CDCl_3$) δ=9.59 (q, Et), 29.12, 29.41 (each t, Et and CH_2), 38.77 (t, CH_2), 51.65 (q, COOMe), 70.01 (s,

q-C), 118.36 (s, CN), 126.07, 128.83, 129.01 (each d), 139.66 (s), 166.66 (d, CH=N), and 172.42 (s, COOMe); MS *m/z* (rel intensity, %) 258 (M^+, 4), 203 (16), 171 (24), 143 (23), 142 (base peak), 116 (39), 115 (57), 104 (36), 91 (29), 77 (32), and 41 (31). HRMS Found: *m/z* 258.1361. Calcd for $C_{15}H_{18}N_2O_2$: M, 258.1367.

2f: Yellow liquid; IR (neat) 2240, 1725, and 1645 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.40 (9H, s, *t*-Bu), 1.63 (3H, s, Me), 2.1—2.5 (4H, m, CH_2), 7.3—7.5 (3H, m, Ph), 7.6—7.8 (2H, m, Ph), and 8.41 (1H, s, CH=N); ^{13}C NMR ($CDCl_3$) δ=27.77 (q, Me), 28.00 (q, *t*-Bu), 30.77, 36.24 (each t, CH_2), 62.65 (s, *t*-Bu), 80.48 (s, q-C), 119.36 (s, CN), 128.83, 128.95, 131.77 (each d), 135.07 (s), 160.18 (d, CH=N), and 171.24 (s, COOBu-*t*); MS *m/z* (rel intensity, %) 286 (M^+, 1), 230 (15), 213 (98), 203 (28), 183 (34), 158 (42), 127 (65), 104 (52), and 57 (base peak). HRMS Found: *m/z* 286.1680. Calcd for $C_{17}H_{22}N_2O_2$: M, 286.1680.

2g: Pale yellow liquid; IR (neat) 2200, 1720, and 1645 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.04 (3H, s, COMe), 2.2—2.6 (4H, m, CH_2), 3.10 (2H, s, CH_2Ph), 7.07 (5H, s, Ph), 7.20 (3H, m, Ph), 7.60 (2H, m, Ph), and 7.93 (1H, s, CH=N); ^{13}C NMR ($CDCl_3$) δ=25.94 (q, COMe), 30.06, 34.06, 38.77 (each t, CH_2), 68.12 (s, q-C) 118.12 (s, CN), 127.66, 128.36, 128.89, 131.13, 131.89, 134.13, 134.89, 161.66 (d, CH=N), and 206.72 (s, COMe); MS *m/z* (rel intensity, %) 304 (M^+, 19), 213 (58), 198 (16), 171 (23), 105 (27), 91 (base peak), and 77 (28). HRMS Found: *m/z* 304.1596. Calcd for $C_{20}H_{20}N_2O$: M, 304.1616.

2h: Colorless liquid; IR (neat) 2220, 1715, and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.03 (3H, s, COMe), 2.50 (4H, m, CH_2), 7.2—7.9 (10H, m, Ph), and 8.49 (1H, s, CH=N); MS *m/z* (rel intensity, %) 290 (M^+, 46), 220 (25), 219 (base peak), 186 (25), 116 (16), and 89 (16). HRMS Found: *m/z* 290.1417. Calcd for $C_{19}H_{18}N_2O_2$: M, 290.1417.

2i: Pale yellow liquid; IR (neat) 2220, 1715, and 1665 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.15 (3H, t, *J*=7.0 Hz, Et), 1.7—1.9 (2H, m, Et), 2.10 (3H, s, COMe), 2.2—2.6 (4H, m, CH_2), 7.2—7.7 (5H, m, Ph), and 8.08 (1H, t, *J*=5.0 Hz, CH=N); ^{13}C NMR ($CDCl_3$) δ=9.65 (q, Et), 29.06 (t, Et), 29.88 (q, COMe), 37.53, 38.47 (each t, CH_2), 69.83 (s, q-C), 118.54 (s, CN), 126.01, 128.72, 128.95 (each d), 139.71 (s), 166.37 (d, CH=N), and 206.30 (s, COMe); MS *m/z* (rel intensity, %) 242 (M^+, 36), 187 (24), 186 (98), 171 (50), 168 (30), 144 (69), 115 (30), and 43 (base peak). HRMS Found: *m/z* 242.1424. Calcd for $C_{15}H_{18}N_2O$: M, 242.1418.

2j: Colorless liquid; IR (neat) 2450, 2390, and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.3—2.7 (4H, m, CH_2), 7.3—7.6 (8H, m, Ph), 7.85 (2H, m, Ph), and 8.60 (1H, s, CH=N); MS *m/z* (rel intensity, %) 273 (M^+, 2), 219 (17), 169 (12), 142 (26), 129 (34), 116 (25), 115 (33), 105 (36), and 77 (base peak). HRMS Found: *m/z* 273.1266. Calcd for $C_{18}H_{15}N_3$: M, 273.1266.

2k: Colorless liquid; IR (neat) 2240, 2190, and 1670 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.14 (3H, t, *J*=7.0 Hz, Et), 1.6—2.1 (2H, m, Et), 2.2—2.5 (4H, m, CH_2), 7.2—7.6 (5H, m, Ph), and 8.07 (1H, t, *J*=5.0 Hz, CH=N); MS *m/z* (rel intensity, %) 225 (M^+, 1), 210 (3), 198 (59), 172 (28), 169 (69), 145 (93), 144 (36), 143 (41), 132 (27), 131 (48), 130 (base peak), 116 (44), 104 (66), 103 (23), 96 (24), 91 (28), 77 (37), and 52 (21). HRMS Found: *m/z* 225.1263. Calcd for $C_{14}H_{15}N_3$: M, 225.1263.

2l (a 1:1 mixture of diastereomers): Yellow liquid; IR (neat) 2240, 2200, 1740, and 1645 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.15 (3H, d, J=7.0 Hz, Me), 2.2—2.8 (3H, m, CH_2 and CH), 3.63, 3.66 (each 1/2×3H, s, COOMe), 4.72 (1H, m, CHN), 7.2—7.5 (3H, m, Ph), 7.6—7.8 (2H, m, Ph), and 8.40 (1H, d, *J*=2.0 Hz, CH=N); ^{13}C NMR ($CDCl_3$) δ=16.06, 16.30 (each q, Me), 34.59, 34.88 (each d, CH), 36.77, 37.71 (each t, CH_2), 51.77 (q, COOMe), 62.36, 62.95 (each d, CHN), 116.95 (s, CN), 129.01, 132.01 (each d), 135.07 (s), 163.65, 163.89 (each d, CH=N), 172.36, and 172.60 (each s, COOMe); MS *m/z* (rel intensity, %) 244 (M^+, 37), 213 (25), 171 (base peak), 144 (20), 143 (36), 117 (16), 116 (41), 89 (20), and 76 (15). HRMS Found: *m/z* 244.1204. Calcd for $C_{14}H_{16}N_2O_2$: M, 244.1209.

2m (a 3:2 mixture of diastereomers): Pale yellow liquid; IR (neat) 2225, 1735, and 1645 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.0—1.3 (3H, m, Me), 1.60 (3H, s, Me), 2.0—2.8 (3H, m, CH_2 and CH), 3.53 (2/5×3H, s, COOMe), 3.62 (3/5×3H, s, COOMe), 7.2—7.6 (3H, m, Ph), 7.7—7.9 (2H, m, Ph), and 8.48 (1H, s, CH=N); ^{13}C NMR ($CDCl_3$) δ=15.30, 15.71 (each q, Me), 24.77, 26.24 (each q, Me), 36.77 (t, CH_2), 39.53 (d, CH), 51.71, 51.83 (each q, COOMe), 67.00, 67.59 (each s, q-C), 118.89, 119.42 (each s, CN), 125.66, 128.95, 129.95, 131.83 (each d), 135.24 (s), 160.13, 160.54 (each d, CH=N), and 172.72 (s, COOMe); MS *m/z* (rel intensity, %) 258 (M^+, 2), 158 (77), 157 (base peak), 155 (26), 143 (48), 131 (23), 121 (23), 116 (49), 105 (37), 104 (36), 77 (52), and 52 (28). HRMS Found: *m/z* 258.1368. Calcd for $C_{15}H_{18}N_2O_2$: M, 258.1368.

2n (a 1:1 mixture of diastereomers): Pale yellow liquid; IR (neat) 2210, 1730, and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.18, 1.27 (each 1/2×3H, d, *J*=7.0 Hz, Me), 2.2—3.0 (3H, m, CH_2 and CH), 3.12 (2H, s, CH_2Ph), 3.52, 3.62 (each 1/2×3H, s, COOMe), 7.04 (5H, s, Ph), 7.30 (3H, m, Ph), 7.55 (2H, m, Ph), 7.76, and 7.79 (each 1/2H, s, CH=N); ^{13}C NMR ($CDCl_3$) δ=15.30, 16.00 (each q, Me), 37.18, 39.06 (each t, CH_2), 39.24 (d, CH), 42.53, 43.77 (each t, CH_2Ph), 51.65, 51.89 (each q, COOMe), 72.36, 72.95 (each s, q-C), 117.42, 117.95 (each s, CN), 127.54, 128.18, 128.83, 131.24, 131.71, 134.30, 134.95 135.07, 141.83, 161.48 (d, CH=N), 161.89 (d, CH=N), 172.65, and 172.78 (each s, COOMe); MS *m/z* (rel intensity, %) 334 (M^+, 9), 244 (10), 243 (61), 183 (base peak), 116 (18), 104 (24), and 91 (86). HRMS Found: *m/z* 334.1983. Calcd for $C_{21}H_{22}N_2O_2$: M, 334.1683.

2o: Colorless liquid; IR (neat) 2220, 1740, and 1645 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.02 (3H, d, *J*=7.0 Hz, Me), 2.23 (1H, dd, *J*=15.0 and 9.0 Hz, one of CH_2), 2.55 (1H, dd, *J*=15.0 and 5.0 Hz, the other of CH_2), 3.00 (1H, m, CH), 3.50 (3H, s, COOMe), 7.2—7.8 (10H, m, Ph), and 8.54 (1H, s, CH=N); MS *m/z* (rel intensity, %) 320 (M^+, 6), 219 (base peak), 115 (55), 91 (26), 90 (22), 89 (54), and 77 (46). HRMS Found: *m/z* 320.1516. Calcd for $C_{20}H_{20}N_2O_2$: M, 320.1510.

2p: Pale yellow liquid; IR (neat) 2235, 1740, and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00 (3H, d, *J*=7.0 Hz, Me), 2.36 (1H, dd, *J*=16.0 and 9.0 Hz, one of CH_2), 2.75 (1H, dd, *J*=16.0 and 6.0 Hz, the other of CH_2), 3.46 (3H, s, COOMe), 3.76 (1H, ddq, *J*=9.0, 6.0, and 7.0 Hz, CH), 7.2—7.9 (11H, m, Ar), 8.55 (1H, s, CH=N), and 8.82 (1H, d, ArH); ^{13}C NMR ($CDCl_3$) δ=16.47 (q, Me), 37.30 (t, CH_2), 38.53 (d, CH), 51.53 (q, COOMe), 77.47 (s, q-C), 117.77 (s, CN), 124.72, 126.13, 126.24 126.48, 126.60, 126.89, 128.13, 128.95, 129.19, 129.42, 129.60, 130.53, 132.07, 134.18, 135.19, 162.71 (d, CH=N), and 172.83 (s, COOMe); MS *m/z* (rel intensity, %) 370 (M^+, 20), 270 (25), 269 (base peak), 192 (10), and 191 (18). HRMS Found: *m/z* 370.1684. Calcd for $C_{24}H_{22}N_2O_2$: M, 370.1684.

2q: Pale yellow liquid; IR (neat) 2230, 1740, and

1670 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.9—1.3 (6H, m, Et and Me), 1.6—2.0 (2H, m, Et), 2.1—3.0 (3H, m, CH_2 and CH), 3.56 (3H, s, COOMe), 7.2—7.6 (5H, m, Ph), and 7.96 (1H, t, J=5.0 Hz, CH=N); ^{13}C NMR ($CDCl_3$) δ=9.18 (q, Et), 15.00 (q, Me), 28.77 (t, Et), 35.88 (t, CH_2), 41.00 (d, CH), 51.18 (q, COOMe), 74.71 (s), 117.19 (CN), 126.13, 128.48 (each d), 138.89 (s), 166.66 (d, CH=N), and 172.18 (COOMe). MS m/z (rel intensity, %) 272 (M^+, 11), 172 (59), 171 (base peak), 144 (50), 143 (87), 104 (36), 91 (49), 77 (22), 59 (20), 41 (31), and 39 (23). HRMS Found: m/z 272.1525. Calcd for $C_{16}H_{20}N_2O_2$: M, 272.1525.

2r: Colorless liquid; IR (neat) 2230, 1740, and 1665 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.8—1.0 (6H, m, Me and n-Pr), 1.3—1.7 (2H, m, n-Pr), 2.0—2.6 (4H, m, CH_2 and n-Pr), 2.80 (1H, m, CH), 3.60 (3H, s, COOMe), 7.2—7.6 (5H, m, Ph), and 8.00 (1H, t, J=5.0 Hz, CH=N); ^{13}C NMR ($CDCl_3$) δ=13.82, 15.47 (each q, Me and n-Pr), 18.94 (t, n-Pr), 36.36, 37.82 (each t, CH_2 and n-Pr), 41.36 (d, CH), 51.71 (q, COOMe), 75.24 (s, q-C), 117.71 (s, CN), 126.60, 128.83, 129.53 (each d), 139.24 (s), 166.60 (d, CH=N), and 172.83 (s, COOMe); MS m/z (rel intensity, %) 286 (M^+, 1), 258 (16), 255 (7), 186 (30), 185 (58), 158 (22), 144 (23), 143 (63), 116 (51), 104 (55), 103 (31), 91 (base peak), and 76 (41). Elemental analysis by HRMS could not be achieved because of the weak parent ion peak.

2s: Colorless liquid; IR (neat) 2200, 1740, 1645, 1250, and 845 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.85 (9H, s, Me_3Si), 1.92 (1H, d, J=12.0 Hz, one of CH_2), 2.08 (1H, d, J=15.0 Hz, the other of CH_2), 2.81 (1H, dd, J=15.0 and 12.0 Hz, CH), 3.31 (3H, s, COOMe), 7.1—7.7 (10H, m, Ph), and 8.43 (1H, s, CH=N); ^{13}C NMR ($CDCl_3$) δ=−3.12 (q, Me_3Si), 32.94 (d, CH), 41.83 (t, CH_2), 51.24 (q, COOMe), 71.06 (s, q-C), 118.65 (s, CN), 126.48, 128.83, 128.95, 129.19, 131.95, 135.24, 139.54, 160.95 (d, CH=N), and 174.71 (s, COOMe); MS m/z (rel intensity, %) 378 (M^+, 12), 363 (3), 306 (26), 219 (base peak), and 159 (40). HRMS Found: m/z 378.1779. Calcd for $C_{22}H_{26}N_2O_2Si$: M, 378.1795.

2t (mixture of two diastereomers): Pale yellow liquid; IR (neat) 2220, 1715, 1250, and 840 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.00 (9H, s, Me_3Si), 1.15 (3H, t, J=7.0 Hz, Et), 1.7—3.0 (5H, m, Et, CH_2, and CH), 3.50 (3H, s, COOMe), 7.2—7.6 (5H, m, Ph), and 8.08 (1H, t, J=5.0 Hz, CH=N); ^{13}C NMR ($CDCl_3$) δ=0.00 (q, Me_3Si), 9.47 (q, Et), 29.12 (t, Et), 32.77 (d, CH), 41.41 (t, CH_2), 51.06, 51.65 (each q, COOMe), 70.89 (s, q-C), 118.30, 118.54 (each s, CN), 125.95, 126.13, 126.36, 127.36, 128.65, 128.89 (each d), 139.24, 139.54 (each s), 165.30, 166.42 (each d, CH=N), and 174.60 (s, COOMe); MS m/z (rel intensity, %) 330 (M^+, 1), 115 (42), 104 (33), 89 (33), 73 (base peak), 59 (29), 55 (40), and 44 (32). Elemental analysis based on HRMS was unsuccessful because of the parent ion peak with a low intensity.

3: Pale yellow liquid; IR (neat) 2250 and 1660 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.00 (9H, s, t-Bu), 3.65 (2H, s, CH_2), 7.39 (3H, m, Ph), and 7.90 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=27.88 (q, t-Bu), 33.30 (s, t-Bu), 70.53 (t, CH_2), 109.71 (s, CN), 127.60, 128.95 (each d), 132.07 (s). The imine carbon can not be observed.

4: Pale yellow needles (chloroform–hexane); mp 190—192 °C; IR (KBr) 3340, 2430, and 1550 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.96 (1H, br, NH), 4.40 (1H, d, J=8.0 Hz, 3-H), 5.36 (1H, d, J=8.0 Hz, 5-H), 5.78 (1H, t, J=8.0 Hz, 4-H), and 7.0—7.7 (15H, m, Ph); MS m/z (rel intensity, %) 369 (M^+, 1), 296 (2), 220 (8), 193 (base peak), 178 (18), 116 (17), and 115 (79). Found: C, 74.69; H, 5.27; N, 11.36%. Calcd for $C_{23}H_{19}N_3O_2$: C, 74.78; H, 5.18; N, 11.38%.

5: Yellow liquid; IR (neat) 1620 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.95 (1H, t, J=8.0 Hz, 4-H), 5.37 (1H, dd, J=8.0 and 2.0 Hz, 5-H), 6.22 (1H, dd, J=8.0 and 2.0 Hz, 3-H), 7.0—7.5 (8H, m, Ph), and 7.85 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=61.06 (d, 4-C), 78.42 (d, 5-C), 99.36 (d, 3-C), 126.89, 127.54, 127.83, 128.06, 128.30, 128.48, 128.95, 129.19, 129.54, 131.30, 131.54, 132.07, 138.42, 141.01, and 164.89 (s, 2-C); MS m/z (rel intensity, %) 296 (M^+−46, 2), 218 (10), 165 (19), 115 (26), 105 (12), 104 (66), and 77 (base peak). Elemental analysis based on HRMS failed because of the absence of the parent ion peak.

General Procedure for Hydrolytic Cyclization of Michael Adducts 2 Leading to 2-Pyrrolidinones 6—9. A solution of the Michael adduct **2** in MeOH (5 ml for 1 mmol of **2**) was heated under reflux in the presence of p-toluenesulfonic acid (PTSA, 30 mg) or concentrated hydrochloric acid (HCl, a few drops). The mixture was poured into ice water and extracted with dichloromethane (25 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using chloroform to give **6—9**.

6: Obtained in 96% from **2o**, 79% from **2q**, and 95% from **2r** in the reactions with PTSA for 2h each as a single isomer: Colorless prisms (chloroform–hexane); mp 126—127 °C; IR (KBr) 3380, 2250, 1755 and 1720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.24 (3H, d, J=7.0 Hz, 4-Me), 2.3—2.7 (3H, m, 3- and 4-H), 6.84 (1H, s, NH), and 7.3—7.6 (6H, m, Ph and NH); ^{13}C NMR ($CDCl_3$) δ=14.18 (q, 4-Me), 37.77 (t, 3-C), 45.54 (d, 4-C), 66.77 (s, 5-C), 117.95 (s, CN), 125.24, 129.48, 129.77 (each d), 136.54 (s), and 176.89 (s, 2-C). Found: C, 72.04; H, 6.08; N, 13.84%. Calcd for $C_{12}H_{12}N_2O$: C, 71.98; H, 6.04; N, 13.99%.

7: Obtained as a single isomer in 89% yield in the reaction with HCl for 3 h: Colorless prisms (chloroform–hexane); mp 205—206 °C; IR (KBr) 3200—2800, 2240, and 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.42 (3H, d, J=7.0 Hz, 4-Me), 2.05 (1H, dd, J=17.0 and 6.0 Hz, one of 3-H), 2.46 (1H, dd, J=17.0 and 8.0 Hz, the other of 3-H), 3.00 (1H, ddq, J=8.0, 6.0, 3×7.0 Hz, 4-H), 7.4—8.2 (7H, m, Ar), and 9.40 (1H, s, NH); ^{13}C NMR ($CDCl_3$+DMSO-d_6) δ=17.59 (q, 4-Me), 36.65 (t, 3-C), 39.83 (d, 4-C), 65.18 (s, 5-C), 118.89 (s, CN), 123.83, 124.42 125.00, 126.24, 126.89, 129.00, 129.91, 130.65, 132.13, 134.66, and 175.42 (s, 2-C); Found: C, 76.63; H, 5.59; N, 10.97%. Calcd for $C_{16}H_{14}N_2O$: C, 76.78; H, 5.64; N, 11.19%.

8: Obtained in 79% yield as a 1:1 mixture of 4,5-trans and 4,5-cis isomers (^{1}H NMR) in the reaction with PTSA for 2 h. These isomers were separated from each other through column chromatography over silica gel by using chloroform (4,5-trans: 36%, 4,5-cis: 32%). 4,5-trans-**8:** Pale yellow liquid; IR (neat) 3200, 2250, and 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.26 (3H, d, J=7.0 Hz, 4-Me), 1.9—3.0 (3H, m, 3- and 4-H), 3.98 (1H, d, J=5.0 Hz, 5-H), and 7.35 (1H, br, NH); ^{13}C NMR ($CDCl_3$) δ=18.94 (q, 4-Me), 35.59 (d, 4-C), 37.12 (t, 3-C), 50.42 (d, 5-C), 118.48 (s, CN), and 177.50 (s, 2-C); MS m/z (rel intensity, %) 124 (M^+, 50), 70 (12), 55 (26), and 42 (base peak). HRMS Found: m/z 124.0629. Calcd for $C_6H_8N_2O$: M, 124.0624. 4,5-cis-**8:** Colorless prisms (diethyl ether–hexane); mp 92—94 °C; IR (KBr) 3200, 2440, and 1660 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.25 (3H, d, J=7.0Hz, 4-Me),

2.14 (1H, dd, J=16.0 and 10.0 Hz, one of 3-H), 2.20 (1H, dd, J=16.0 and 8.0 Hz, the other of 3-H), 2.80 (1H, m, 4-H), 4.44 (1H, d, J=8.0 Hz, 5-H), and 6.80 (1H, br, NH). Found: C, 58.19; H, 6.54; N, 22.47%. Calcd for $C_6H_8N_2O$: C, 58.05; H, 6.50; N, 22.57%.

9: Obtained in 95% yield as an inseparable mixture of 4,5-cis and 4,5-trans isomers (2.8:1) in the reaction with PTSA for 2 h: Colorless solid; IR (KBr) 2250 and 1670 cm^{-1}, ^1H NMR ($CDCl_3$) 4,5-cis: δ=1.13 (3H, d, J=7.0 Hz, 4-Me), 1.51 (3H, s, 5-Me), 2.0—3.0 (3H, m, 3- and 4-H), and 7.75 (1H, br, NH); 4,5-trans: δ=1.30 (3H, d, J=7.0 Hz, 4-Me), 1.63 (3H, s, 5-Me), 2.0—3.0 (3H, m, 3- and 4-H), and 7.75 (1H, br, NH); ^{13}C NMR ($CDCl_3$) 4,5-cis: δ=14.30 (q, 4-Me), 21.24 (q, 5-Me), 37.30 (t, 3-C), 38.94 (d, 4-C), 55.89 (s, 5-C), 121.54 (s, CN), and 176.85 (s, 2-C); 4,5-trans: δ=15.00 (q, 4-Me), 24.76 (q, 5-Me), 38.00 (t, 3-C), 41.36 (d, 4-C), 59.06 (s, 5-C), 119.36 (s, CN), and 177.01 (s, 2-C). Found: C, 60.70; H, 7.27; N, 20.00%. Calcd for $C_7H_{10}N_2O$: C, 60.85; H, 7.30; N, 20.28%.

General Procedure for Alkylation of 2 l Leading to 2m—2n and of 1b—1c Leading to 10 and 11. An imine **2 l**, **1b**, or **1c** (1 mmol in THF (1 ml)) was added to a solution of LDA (1.1 mmol in THF (2 ml)) at −78 °C. After 5 min, methyl iodide or benzyl bromide (1 mmol) was added and the mixture was allowed to stir under the conditions listed in Table 2. The mixture was poured into ice water and extracted with diethyl ether (20 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using chloroform as an eluent. The results are summarized in Table 2.

10a: Colorless liquid; bp 180 °C (133 Pa, bulb-to-bulb); IR (neat) 2200, 1730 and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.25 (3H, t, J=7.0 Hz, Et), 1.5—2.5 (6H, m, CH_2), 1.64 (3H, s, Me), 4.07 (2H, q. J=7.0 Hz, Et), 7.3—7.4 (3H, m, Ph), 7.7 (2H, m, Ph), and 8.40 (1H, s, CH=N); ^{13}C NMR ($CDCl_3$) δ=14.24 (q, Et), 20.18 (q, Me), 27.94, 33.71, 40.59 (each t, CH_2), 60.42 (t, Et), 63.36 (s, q-C), 119.83 (s, CN), 128.89, 131.71 (each d), 135.24 (s), 159.94 (d, CH=N), and 172.95 (s, COOEt); MS m/z (rel intensity, %) 272 (M^+, 21), 227 (54), 169 (90), 158 (83), 157 (base peak), 123 (36), and 104 (26). HRMS Found: m/z 272.1522. Calcd for $C_{16}H_{20}N_2O_2$: M, 272.1522.

10b: Colorless liquid; IR (neat) 2240, 1725, and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.20 (3H, t, J=7.0 Hz, Et), 1.5—2.4 (6H, m, CH_2), 3.12 (2H, s, CH_2Ph), 4.05 (2H, q, J=7.0 Hz, Et), 7.1—7.6 (10H, m, Ph), and 7.97 (1H, s, CH=N); ^{13}C NMR ($CDCl_3$) δ=14.30 (q, Et), 20.18, 33.88, 39.53, 46.47 (each t, CH_2), 60.53 (t, Et), 68.83 (s, q-C), 118.65 (s, CN), 127.66, 128.36, 128.95, 131.19, 131.71 (each d), 134.42, 135.19 (each s), 161.30 (d, CH=N), and 173.07 (s, COOEt); MS m/z (rel intensity, %) 254 (M^+−94, 11), 253 (62), 233 (50), 143 (68), 116 (30), 91 (base peak), 88 (17), 85 (30), 83 (43), and 77 (16). Elemental analysis based on HRMS could not be performed because of the absence of the parent ion peak.

11: Colorless liquid; IR (neat) 2260, 1735, and 1645 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.20 (3H, t, J=7.0 Hz, Et), 1.3—2.3 (8H, m, CH_2), 1.60 (3H, s, Me), 4.03 (2H, q, J=7.0 Hz, Et), 7.2—7.4 (3H, m, Ph), 7.30 (2H, m, Ph), and 8.40 (1H, s, CH=N); MS m/z (rel intensity, %) 286 (M^+, 6), 172 (17), 158 (59), 157 (base peak), 143 (57), 130 (29), 116 (70), and 77 (88). HRMS Found: m/z 286.1686. Calcd for $C_{17}H_{22}N_2O_2$: M, 286.1681.

General Procedure for Hydrolytic Cyclization of 10 Leading to 12 and Hydrolysis of 11 into 13. A solution of **10a**, **10b**, or **11** (1 mmol) in methanol (3 ml) was heated under reflux in the presence of a catalytic amount of concentrated hydrochloric acid. The mixture was poured into water and extracted with dichloromethane (15 ml×2). The combined extracts were washed with water, dried over magnesium sulfate, and evaporated in vacuo. Evaporation of the solvent gave solid of **12** which was purified by crystallization. The residue containing **13** was purified by column chromatography over silica gel by using chloroform as an eluent. The reaction time and yield were as follows: **12a**: 7.5 h, 78%; **12b**: 6 h, 58%; **13**: 6 h, 78%.

12a: Colorless prisms (chloroform–hexane); mp 175—176 °C; IR (KBr) 3220, 2460, and 1660 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.66 (3H, s, Me), 1.8—2.6 (6H, m, CH_2), and 7.65 (1H, br, NH); MS m/z (rel intensity, %) 138 (M^+, 42), 123 (89), 82 (10), 70 (35), 55 (base peak), and 43 (74). Found: C, 60.95; H, 7.32; N, 20.08%. Calcd for $C_7H_{10}N_2O$: C, 60.85; H, 7.30; N, 20.28%.

12b: Colorless prisms (chloroform–hexane); mp 215—216 °C; IR (KBr) 3200 2430, and 1665 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.8—2.5 (6H, m, CH_2), 2.95, 3.15 (each 1H, d, J=15.0 Hz, CH_2Ph), 6.40 (1H, br, NH), and 7.25 (5H, s, Ph); ^{13}C NMR ($CDCl_3$) δ=18.30, 30.88, 33.24, 46.77 (each t, CH_2), 56.30 (s, q-C), 120.36 (s, CN), 128.60, 129.30, 130.65 (each d), 132.18 (s), and 171.36 (s, CO); MS m/z (rel intensity, %) 214 (M^+, 12), 123 (28), 91 (base peak), 65 (46), 55 (43), and 43 (26). Found: C, 72.69; H, 6.49; N, 12.79%. Calcd for $C_{13}H_{14}N_2O$: C, 72.87; H, 6.59; N, 13.08%.

13: Colorless liquid; IR (neat) 3500, 3400, 3200, 2250, and 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.22 (3H, t, J=7.0 Hz, Et), 1.5—1.7 (4H, m, CH_2), 2.10 (3H, s, Me), 2.2—2.5 (4H, m, CH_2), 4.05 (2H, q, J=7.0 Hz, Et), and 7.35 (2H, br, NH_2); MS m/z (rel intensity, %) 172 (M^+−26, 17), 127 (31), 126 (17), 116 (27), 112 (11), 101 (22), 87 (11), 84 (14), 81 (23), 73 (14), and 43 (base peak). Elemental analysis by HRMS was not available because of the absence of the parent ion.

General Procedure for Base-Induced Cyclization of Alkylated Imines 2 Leading to 14. To a solution of appropriate base was added an imine **2** (1 mmol) at −78 °C: Method A: Imine **2** (in 2 ml of THF) was added to t-BuOK (1.1 mmol in THF (2 ml)); Method B: Imine **2** (in 2 ml of THF) was added to LDA (1 mmol) freshly prepared in THF (3 ml); Method B (MeI): Imine **2** (in 4 ml of THF) and then MeI (1.1 mmol in THF (0.6 ml)) were added to LDA (1.5 mmol in 7 ml); Method C: Lithium iodide (1 mmol) and then imine **2** (in 2 ml of THF) was added to LDA (1 mmol in THF (3 ml)); Method D: Imine **2** (in 5 ml of THF) was added to benzyltrimethylammonium methoxide (BTAM, 1 mmol in THF (1 ml)); Method E: Tetrabutylammonium fluoride (TBAF, 1M† solution in THF, 0.1 ml, 0.1 mmol) was added to imine **2** (in 5 ml of THF); Method F: TBAF (0.1 ml, 0.1 mmol) was added at 0 °C to imine **2** (in 5 ml of HMPA). The resulting mixture was stirred under the conditions listed in Table 3 and poured into ice water. The products were collected in dichloromethane (15 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using chloroform or chloroform–diethyl

† 1 M=1 mol dm^{-3}.

ether as an eluent to give **14**. Pyrrolines **14a**, **14d**, **14d'**, **14e**, **14k**, **14l**, **14n**, and **14o** are all known.[10]

14b: Pale yellow liquid; IR (neat) 1735 and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.55 (1H, dd, J=18.0 and 9.0 Hz, one of 3-H), 3.03 (3H, s, COOMe), 3.3—3.7 (2H, m, 4-H and the other of 3-H), 3.80 (2H, s, CH_2Ph), 5.43 (1H, d, J=9.0 Hz, 5-H), and 6.9—7.3 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=39.23, 40.65 (each t, 3-C and CH_2Ph), 48.18 (d, 4-C), 51.18 (q, COOMe), 78.24 (d, 5-C), 127.07, 127.65, 128.13, 128.95, 129.30 (each d), 136.54, 138.77 (each s), 172.59 (s, 2-C), and 177.48 (s, COOMe); MS m/z (rel intensity, %) 293 (M^+, 51), 234 (57), 207 (36), 206 (22), 115 (18), 105 (23), and 91 (base peak). HRMS Found: m/z 293.1391. Calcd for $C_{19}H_{19}NO$: M, 293.1413.

14c+14c' (a 2:1 mixture): Yellow liquid; IR (neat) 1730 and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.20 (1/3×6H, d, J=7.0 Hz, *i*-Pr), 1.25 (2/3×6H, d, J=7.0 Hz, *i*-Pr), 2.5—3.0 (3H, m, *i*-Pr and 3-H), 3.07 (2/3×3H, s, COOMe), 3.2—3.6 (1H, m, 4-H), 3.66 (1/3×3H, s, COOMe), 5.22 (1/3H, t, J=3.0 Hz, 5-H), 5.40 (2/3H, d, J=9.0 Hz, 5-H), and 6.9—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=20.24 (q, *i*-Pr), 32.65 (d, *i*-Pr), 38.01, 39.30 (each t, 2:1, 3-C), 48.06, 50.94 (each d, 2:1, 4-C), 51.24, 52.18 (each q, 2:1, COOMe), 77.82, 78.95 (each d, 2:1, 5-C), 126.48, 127.54, 128.07, 128.65 (each d), 138.89, 143.31 (each s), 172.83, 174.89 (each s, 2:1, COOMe), 181.95, and 183.60 (each s, 1:2, 2-C); MS m/z (rel intensity, %) 245 (M^+, 63), 214 (15), 186 (57), 159 (base peak), 117 (79), 91 (19), and 90 (34). HRMS Found: m/z 245.1368. Calcd for $C_{15}H_{19}NO_2$: M, 245.1413.

14e+14e' (a 4:1 mixture): Pale yellow liquid; IR (neat) 1735 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.10 (3H, m, Et), 1.4—1.9 (2H, m, Et), 2.5—3.7 (3H, m, 3- and 4-H), 3.70 (3H, s, COOMe), 4.45 (1H, m, 5-H), 7.2—7.6 (3H, m, Ph), and 7.7—7.9 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) **14e**: δ=11.59 (q, Et), 25.41 (t, Et), 38.06 (t, 3-C), 45.83 (d, 4-C), 51.65 (q, COOMe), 75.65 (d, 5-C), 127.89, 128.60, 130.77 (each d), 134.30 (s), 171.01 (s, 2-C), and 173.72 (s, COOMe); **14e'**: δ=10.41 (q, Et), 25.41 (t, Et), 38.06 (t, 3-C), 45.83 (d, 4-C), 51.65 (q, COOMe), 75.95 (d, 5-C), 127.89, 128.60, 130.77 (each d), 134.30 (s), 171.01 (s, 2-C), and 173.72 (s, COOMe); MS m/z (rel intensity, %) 231 (M^+, 33), 216 (24), 202 (36), 172 (72), 145 (42), 144 (42), 143 (38), 130 (base peak), 117 (24), 115 (41), 104 (70), and 77 (45). HRMS Found: m/z 231.1262. Calcd for $C_{14}H_{17}NO_2$: M, 231.1258.

14f+14f' (a 3:2 mixture): Pale yellow liquid; IR (neat) 1725 and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00 (3/5×9H, s *t*-BuOOC), 1.46 (2/5×9H, s, *t*-BuOOC), 2.17 (6H, d, J=2.0 Hz, Me), 2.5—3.7 (3H, m, 3- and 4-H), 5.25 (2/5H, br s, 5-H), 5.45 (3/5H, d, J=10.0 Hz, 5-H), and 7.1—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=19.60 (q, *t*-Bu), 27.44, 28.08 (each q, 2-Me), 42.36, 42.94 (each t, 3-C), 49.73, 52.36 (each d, 4-C), 78.34 (s, *t*-Bu), 79.62, 80.44 (each d, 5-C), 126.37, 127.13, 128.00, 128.47 (each d), 139.12, 143.27 (each s), 171.18, 173.23, 173.93, and 174.98 (each s, 2-C and COOBu-*t*); MS m/z (rel intensity, %) 259 (M^+, 7), 227 (15), 222 (18), 204 (22), 203 (base peak), 201 (53), 158 (53), and 157 (40). HRMS Found: m/z 259.0771. Calcd for $C_{21}H_{16}NO_2$: M, 259.0774.

14g': Colorless liquid; IR (neat) 1710 and 1640 cm^{-1}: ^1H NMR ($CDCl_3$) δ=2.10 (3H, s, COMe), 2.6—3.3 (3H, m, 3- and 4-H), 3.80 (2H, br s, $PhCH_2$), 5.25 (1H, br d, J=6.0 Hz, 5-H), and 7.2—7.4 (10H, m, Ph); MS m/z (rel intensity, %) 277 (M^+, 1), 249 (5), 248 (22), 234 (26), 186 (32), and 105 (base peak). Elemental analysis by HRMS could not be achieved because of the weak parent ion peak.

14h': Yellow liquid; IR (neat) 1710 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.10 (3H, s, COMe), 3.28 (3H, m, 3- and 4-H), 5.33 (1H, ddd, J=5.0, 3.2, and 2.0 Hz, 5-H), 7.1—7.5 (8H, m, Ph), and 7.85 (2H, m, Ph); MS m/z (rel intensity, %) 263 (M^+, 14), 221 (17), 220 (base peak), 193 (41), 117 (11), and 115 (16). HRMS Found: m/z 263.1303. Calcd for $C_{18}H_{17}NO$: M, 263.1308.

14i': Pale yellow liquid; IR (neat) 1710 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.04 (3H, t, J=7.0 Hz, Et), 1.5—2.0 (2H, m, Et), 2.16 (3H, s, COMe), 2.9—3.4 (3H, m, 3- and 4-H), 4.29 (1H, m, 5-H), 7.2—7.6 (3H, m Ph), and 7.7—7.9 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=10.35 (q, Et), 28.65 (q, COMe), 29.47 (t, Et), 37.30 (t, 3-C), 54.42 (d, 4-C), 77.30 (d, 5-C), 127.71, 128.42, 130.60 (each d), 133.95 (s), 170.19 (s, 2-C), and 207.89 (s, COMe); MS m/z (rel intensity, %) 215 (M^+, 4), 172 (22), 144 (43), 143 (61), 130 (42), 117 (24), 116 (33), 115 (base peak), 104 (73), 103 (41), 89 (24), 77 (50), 76 (24), 63 (22), and 55 (32). HRMS Found: m/z 215.1331. Calcd for $C_{14}H_{17}NO$: M, 215.1309.

14i+14i': This mixture (1:2) was identified on the basis of ^1H NMR in $CDCl_3$: δ=1.04 (3H, J=7.0 Hz, Et), 1.60 (1/3×2H, q, J=7.0 Hz, Et), 1.80 (2/3×2H, q, J=7.0 Hz, Et), 2.10 (3H, s, MeCO), 2.8—3.6 (3H, m, 3- and 4-H), 4.30 (2/3H, m, 5-H), 4.56 (1/3H, m, 5-H), 7.3—7.4 (3H, m, Ph), and 7.8—7.9 (2H, m, Ph). The signal at 4.30 ppm (5-H of **14i'**) showed a 15% of NOE enhancement when the acetyl signal at 2.10 ppm was irradiated, confirming the 4,5-trans structure of **14i'**.

14j+14j' (a 10:1 mixture): Pale yellow liquid; IR (neat) 2240 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.13 (3H, t, J=7.0 Hz, Et), 1.7—2.2 (2H, m, Et), 2.6—2.9 (2H, m, 3-H), 3.40 (1H, m, 4-H), 4.30 (1H, m, 5-H), 7.3—7.6 (3H, m, Ph), and 7.7—7.9 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=11.29 (q, Et), 26.71 (t, Et), 31.00 (d, 4-C), 40.30 (t, 3-C), 74.77 (d, 5-C), 116.77 (s, CN), 127.95, 128.89, 129.07, 129.42 (each d), 131.42, 133.36 (each s), and 169.77 (s, 2-C); MS m/z (rel intensity, %) 198 (M^+, 3), 130 (60), 115 (25), 105 (26), 104 (58), 103 (44), 77 (base peak), 76 (30), and 63 (24). HRMS Found: m/z 198.1161. Calcd for $C_{13}H_{14}N_2$: M, 198.1159.

14l+14l': All data of **14l** were presented in Ref. 10. Formation of **14l'** was deduced on the basis of ^1H NMR ($CDCl_3$) of the mixture with **14l**: δ=1.30 (3H, d, J=7.0 Hz, 3-Me), 2.05 (3H, d, J=2.0 Hz, 2-Me), 3.65 (3H, s, COOMe) and 5.10 (1H, m, 5-H). The other signals are overlapping with those of **14l**.

14m: Pale yellow liquid; IR (neat) 1735 and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.16 (3H, d, J=7.0 Hz, Me), 3.0—4.0 (4H, m, CH_2Ph, 3-H, and 4-H), 3.07 (3H, s, COOMe), 5.45 (1H, d, J=9.0 Hz, 5-H), and 7.0—7.4 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=16.53 (q, Me), 38.36 (t, CH_2Ph), 46.27 (d, 3-C), 51.18 (q, COOMe), 57.04 (d, 4-C), 75.71 (d, 5-C), 126.60, 128.13, 128.65, 128.89, 129.36, 131.30 (each d), 136.36, 138.21 (each s), 172.18 (s, COOMe), and 180.60 (s, 2-C); MS m/z (rel intensity, %) 307 (M^+, 15), 248 (20), 207 (29), 206 (19), 131 (19), 130 (16), 115 (14), 105 (32), 91 (base peak), and 76 (31). HRMS Found: m/z 307.1569. Calcd for $C_{20}H_{21}NO_2$: M, 307.1570.

14n+14n' (a 1:3 mixture): All data of **14n** were presented in Ref. 10. ^1H NMR ($CDCl_3$) of **14n'** was abstracted from that of the mixture with **14n**: δ=1.30 (3H, d, J=7.0 Hz, Me),

2.80 (1H, t, J=6.2 Hz, 4-H), 3.76 (3H, s, COOMe), 3.85 (1H, m, 3-H), 5.53 (1H, dd, J=6.2 and 1.5 Hz, 5-H), 7.2—7.5 (8H, m, Ph), and 7.85 (2H, m, Ph).

14o+14o′ (a 3:2 mixture): Pale yellow liquid; IR (neat) 1730 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.9—1.4 (6H, m, Et and Me), 1.5—2.0 (2H, m, Et), 2.50 (2/5H, t, J=6.0 Hz, 4-H), 2.96 (3/5H, dd, J=8.0 and 4.2 Hz, 4-H), 3.63 (2/5×3H, s, COOMe), 3.68 (3/5×3H, s, COOMe), 3.6—4.0 (1H, m, 3-H), 4.27 (1H, m, 5-H), 7.2—7.6 (3H, m, Ph), and 7.7—7.9 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=10.71, 11.88 (each q, 2:3, Et), 17.53, 19.71 (each q, 3:2, Me), 25.41, 29.94 (each t, 3:2, Et), 45.89, 47.06 (each d, 2:3, 3-C), 51.59, 52.12 (each q, 3:2 COOMe), 54.89, 55.89 (each d, 3:2, 4-C), 74.12, 76.77 (each d, 2:3 5-C), 128.25, 128.65, 130.48 (each d), 133.71, 133.95 (each s), 173.83, 174.60, and 175.66 (each s, 2-C and COOMe); MS m/z (rel intensity, %) 245 (M^+, 77), 216 (22), 186 (94), 158 (21), 145 (base peak), 131 (24), 130 (95), 127 (24), and 104 (41). HRMS Found: m/z 245.1414. Calcd for $C_{15}H_{19}NO_2$: M, 245.1415.

General Procedure for LDA-Induced Cyclization of 10 Leading to 15. To a solution of LDA (in THF 3 ml) freshly prepared from butyllithium and diisopropylamine (each 1 mmol) was added at −78 °C **10a** or **10b** (1 mmol) in THF (2 ml). After 30 min at −78 °C the mixture was stirred under nitrogen at room temperature for 6 h. The reaction was quenched with saturated aqueous ammonium chloride and extracted with diethyl ether (20 ml×2). The combined extracts were dried over anhydrous magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel to give **15a** or **15b** (**15a**: 37%; **15b**: 25%).

15a (a 2:1 mixture of stereoisomers): Yellow liquid; IR (neat) 1730, 1660, and 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.04 (3H, t, J=7.0 Hz, Et), 1.5—3.0 (5H, m, CH_2 and 5-H), 2.02 (1/3×3H, d, J=2.0 Hz, Me), 2.06 (2/3×3H, d, J=2.0 Hz, Me), 3.90 (2H, m, Et), 4.67 (1/3H, br d, J=9.0 Hz, 6-H), 5.10 (2/3H, br d, J=5.0 Hz, 6-H), and 6.9—7.5 (5H, m, Ph); MS m/z (rel intensity, %) 245 (M^+, 96), 172 (60), 145 (40), 144 (28), and 104 (base peak). HRMS Found: m/z 245.1406. Calcd for $C_{15}H_{19}NO_2$: M, 245.1413.

15b Yellow liquid; IR (neat) 1725 and 1650 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.03 (3H, t, J=7.0 Hz, Et), 1.6—3.0 (5H, m, CH_2 and 5-H), 3.60 (2H, br s, CH_2Ph), 4.80 (1H, br d, J=10.0 Hz, 6-H), and 7.25 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.00 (q, Et), 22.29 (d, 4-C), 27.12 (d, CH_2Ph), 46.89 (t, 3-C), 48.06 (d, 5-C), 60.53 (t, Et), 64.06 (d, 6-C), 126.95, 127.36, 127.60, 128.30, 128.60, 128.89, 129.24, 131.13, 137.71, 143.07, 170.30 (s, 2-C), and 174.42 (s, COOEt); MS m/z (rel intensity, %) 321 (M^+, 46), 248 (56), 220 (19), 130 (35), 116 (29), 91 (base peak), and 77 (32). HRMS Found: m/z 321.1724. Calcd for $C_{21}H_{23}NO_2$: M, 321.1727.

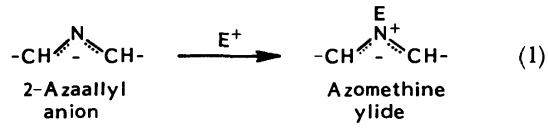
(Received April 30, 1987)

Lithiation of *N*-(1-cyanoalkyl)imines with LDA generates new *N*-lithiated azomethine ylide 1,3-dipoles which show enhanced reactivity toward dipolarophiles. They undergo exclusively regio- and stereoselective 3+2 cycloaddition reaction with α,β-unsaturated esters to give 1-pyrrolines after the elimination of LiCN. Metallic bases other than LDA can be also effective. Such high regio- and stereoselectivity is explained by the involvement of *N*-metalated azomethine ylides.

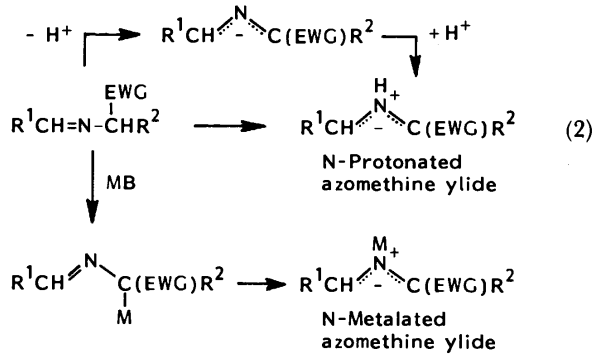
A 1,3-anionic cycloaddition of 2-azaallyl anions leading to five-membered nitrogen heterocycles was pioneered by Kauffmann.[1] Though this reaction with olefins looked promising as a method for the preparation of pyrrolidine skeletons, the difficulty of structural modification of 2-azaallyl anions[2] and the serious limitation of anionophiles employable[3,4] have discouraged its wide applications to heterocyclic synthesis. If an anion-stabilizing substituent is attached on the 1- and/or 3-carbon of 2-azaallyl anionic system, the anion generation by deprotonation of imines becomes easy.[5] However, such highly stabilized 2-azaallyl anions are known to undergo Michael addition rather than cycloaddition.[6,7]



(1)

Though complementary in a synthetic use, 2-azaallyl anions and azomethine ylides are isoelectronic, both carrying 4 pai conjugation along a carbon–nitrogen–carbon framework. The only difference is the presence of a pair of nonbonding electrons on the nitrogen of the anions. Accordingly, 2-azaallyl anions as hard nucleophiles can be converted into azomethine ylides as soft species if this electron pair is utilized to make a bond with an electrophile (E^+).

In the previous articles we have presented some



(2)

examples in which both an azomethine ylide and a 2-azaallyl anion species can be generated from the common precursor.[8,9] Reactions of these anionic species with electron-deficient olefins frequently show reverse regioselectivity.

Imines of 2-amino esters[10] and 2-amino nitriles[9,11] are known to undergo a ready thermal tautomerization into rare *N*-protonated azomethine ylides. This tautomerization formally involves the deprotonation forming 2-azaallyl anions and the reprotonation at the imine nitrogen. Accordingly, metalation of imines with a metallic base (MB) would offer a new and general route to *N*-metalated azomethine ylides because the metal countercation (M^+) in the resulting 2-azaallyl anions is most likely to sit on the nitrogen rather than to stay on the carbon.[12]

The present article describes the first successful example for the generation of *N*-lithiated azomethine ylides by reaction of imines with LDA and their highly regio- and stereoselective cycloaddition with electron-deficient olefins. Use of metallic bases other than LDA is also discussed.

Results and Discussion

α-(Benzylideneamino)acetonitrile (**1a**) was treated with LDA (1 equiv) in dry THF at −78 °C turning bright red. This color faded away as immediately as dimethyl maleate was added. After 6 h at −78 °C the reaction was quenched with aqueous ammonium chloride to give dimethyl *cis*-5-phenyl-2-pyrroline-3,4-dicarboxylate (**2a**) in 71% yield as a single isomer (Scheme 1 and Table 1). As will be discussed later, this reaction involves the initial generation of *N*-lithiated azomethine ylide **Aa**, its stereoselective cycloaddition to dimethyl maleate forming cycloadduct **B**, and the quick elimination of LiCN leading to dimethyl *c*-5-phenyl-1-pyrroline-*r*-3,*c*-4-dicarboxylate (**C**). Ready double bond migration through an imine–enamine tautomerization[13] produced the isolated 2-pyrroline **2a**.

The same 2-pyrroline-3,4-dicarboxylate **2a** is also

available in 66% yield by a stereoselective cycloaddition of *N*-protonated azomethine ylide **Da** which can be generated more simply through a thermal tautomerization of **1a** (Scheme 1).[14] The advantage is that this LDA-induced cycloaddition can be performed at a low temperature (−78 °C), indicating the enhanced reactivity of *N*-lithiated azomethine ylide **Aa** compared to **Da**. We already know that only highly activated olefins such as maleimides, maleates, and fumarates are reactive with the *N*-protonated azomethine ylide **D**. The reaction with an acrylate does proceed, but only under harsh conditions and with a poor stereoselectivity.[14] Therefore it must be interesting to test the reactivity of *N*-lithiated azomethine ylide **Aa** toward such olefin esters as crotonates, cinnamates, and methacrylates which are known to be all inactive toward *N*-protonated ylide **Da**.

The ylide **Aa** was found to show an enhanced reactivity toward methyl acrylate, crotonate, cinnamate, and methacrylate (Scheme 2 and Table 1). The products isolated in high yields were either 1-pyrrolines **2b—2d** or pyrrolidines **3a** and **3b**. They are apparently the results from highly regio- and stereoselective cycloadditions of **Aa** with these olefins: 1-Pyrrolines **2b—2d** were produced by the elimination of LiCN and pyrrolidines **3a**, **3b** were derived by the protonation, both from the initial cycloadducts **E** in which 5-phenyl and 4-methoxycarbonyl are cis. High stereoselectivity with respect to the 2-position of **3a** as

well as **3b** is surprising. This indicates the exclusive participation of one of two possible ylide isomers.[15]

Such high reactivity as well as excellent selectivity was maintained when alkylated imines, *N*-(1-cyanoethyl)imine **1b** and *N*-(1-cyano-2-methylpropyl)imine **1c**, were employed instead of **1a** (Scheme 2 and Table 1). The successful LDA-induced cycloaddition of **1c** indicates that even a bulky alkyl group may be introduced at the 2-position of 1-pyrrolines or pyrrolidines. Alkylated imines can be readily accessible from **1a** and alkyl halides in the presence of LDA.[9b]

Although α-(propylideneamino)phenylacetonitrile (**1d**) bears highly acidic α-hydrogens of imine ($MeC\underline{H}_2CH{=}N-$), its lithiation with LDA took place smoothly at the carbon substituted by a cyano moiety to generate *N*-lithiated azomethine ylide **Ad**, indicating that the stability of *N*-lithiated azomethine ylide may be higher than that of *N*-lithio enamine. Similar cycloadditions of **Ad** with olefins produced **2i**—**2k** in excellent yields (Scheme 2 and Table 1).

The advantages of LDA-induced cycloaddition of *N*-(1-cyanoalkyl)imines **1** are summarized below (Scheme 3).

1) *N*-Lithiated azomethine ylide **Aa** is highly reactive to the olefin esters which can not react with *N*-protonated azomethine ylides **D**.

2) Alkylated ylides **Ab** and **Ac** are similarly reactive, while *N*-protonated counterparts **Db** and **Dc** are absolutely inactive even to maleimides as the most reactive dipolarophiles.

3) Smooth generation of ylide **Ad** is also possible.

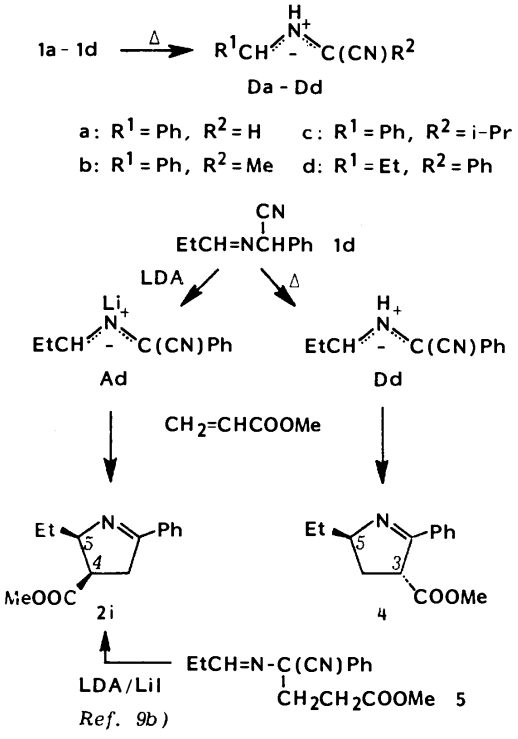
4) Cycloaddition of **A** takes place in a highly regio- and stereoselective manner.

5) In cycloadditions with methyl acrylate, both *N*-lithiated **Ad** and *N*-protonated azomethine ylides **Dd** show high regioselectivity, but their regiochemistry is opposite. Ylide **Ad** gave 4,5-disubstituted 1-pyrroline **2i** whose regiochemistry was assigned by an alternative synthesis from **5**,[9b] while 3,5-disubstituted 1-pyrroline **4** was obtained in the reaction of **Dd**.

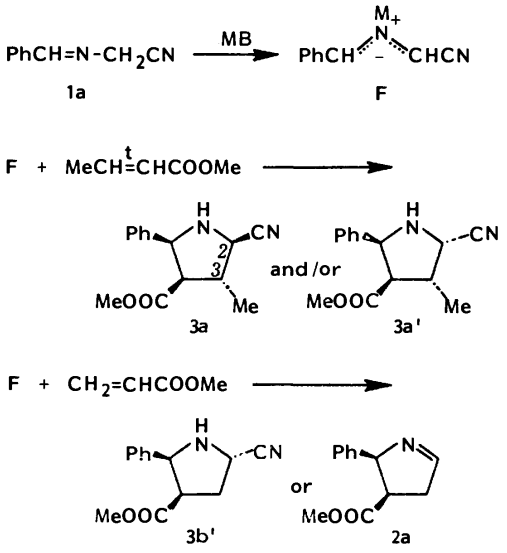
On the other hand, these LDA-induced cycloaddition route involves a disadvantage that the reaction has to be carried out under strongly basic conditions. The reactions of **Aa** with such olefins as maleimides, acrylonitrile, 3-buten-2-one, and phenyl vinyl sulfone led to the formation of polymeric products of olefins, warning that the olefinic dipolarophiles which are susceptible to bases may not be employed.

Metalation of *N*-(1-cyanoalkyl)imines **1** can be accomplished with other metallic bases. For example the reaction of **1a** with ethylmagnesium bromide generated *N*-magnesio azomethine ylide **F** (M=MgBr) which underwent cycloaddition with methyl acrylate or crotonate (Scheme 4 and Table 2). The products isolated as single isomers were pyrrolidines **3a′** and **3b′**, stereoisomers at the 2-position of **3**. The exclusive formation of **3′** indicates the selective participation of the anti form of ylide **F**. This makes a striking contrast with the exclusive participation of the syn form of *N*-lithio azomethine ylide **Aa** (see Scheme 2 and Table 1). Structures of **3a** and **3a′** were based upon the ^{13}C chemical shifts of 2-, 3-C, 2-CN, 3-Me as well as no NOE enhancement between 3-Me and 2-H of **3a′**.[16]

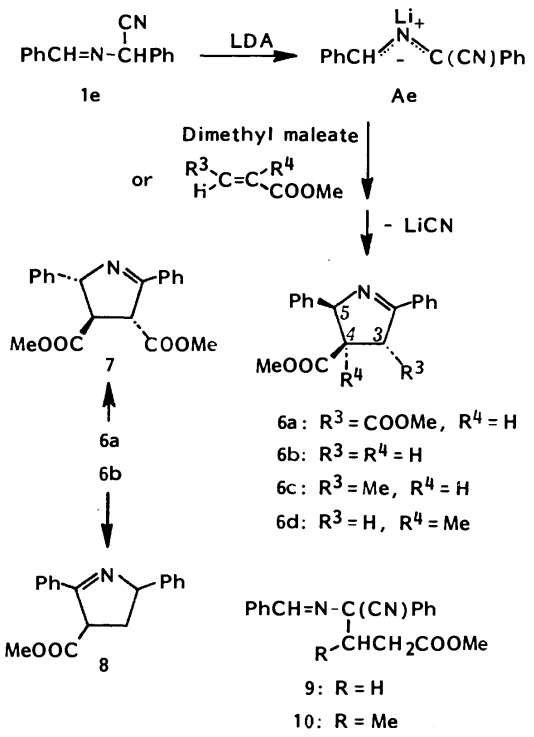
Treatment of ethylmagnesium bromide with an



Scheme 3.



Scheme 4.



Scheme 5.

equimolar amount of diisopropylamine forms magnesium bromide diisopropylamide.[17] This magnesium amide was also effective as a metallic base. *N*-Metalated azomethine ylide **F** (M=MgBr·HN(*i*-Pr)$_2$) was generated from **1a** and reacted with methyl acrylate to give 1-pyrroline **2a**. It is likely that the presence of diisopropylamine facilitated the elimination of MCN as observed in this case and also in the reactions of **A**. Accordingly generation of diisopropylamine-free *N*-lithiated azomethine ylides **F** (M=Li) was next examined.

Thus **1a** was first treated with butyllithium and then with methyl crotonate to produce a mixture of two stereoisomeric pyrrolidines **3a** and **3a'**. Further such other bases as *n*-BuLi/LiI, *n*-BuLi/NEt$_3$, and *n*-BuLi/Ti(OPr^i)$_4$ were employed. Isomer ratio **3a** : **3a'** depends upon the nature and amount of additives, and the highest selectivity for **3a'** was obtained (**3a**:**3a'**= 8 : 92) when triethylamine was used as an additive (Table 2).

N-Lithiated azomethine ylide **Ae** was generated from imine **1e** which bears two phenyl groups. Subsequent cycloadditions with dimethyl maleate, methyl acrylate, crotonate, and methacrylate produced 4,5-*cis*-1-pyrrolines **6a**—**6d** as the initial or isolated products (Scheme 5 and Table 3). The 5-H of 1-pyrrolines **6** is highly acidic because both the 2- and 5-positions are substituted by anion-stabilizing

Table 2. Reaction of α-(Benzylideneamino)acetonitrile (**1a**) with Metallic Bases Other than LDA

	− 78 °C, 0.5 h then rt, 1 h	**6b** (59) + **8** (39)
MeCH=CHCOOMe	− 78 °C, 3 h	**6c** (46) + **10** (23)
CH_2=C(Me)COOMe	− 78 °C, 3 h	**6d** (61)

a) All reactions were performed in THF by using LDA (1 equiv). b) Yield of isolated products. c) Inseparable mixture. The product ratio was determined by ^{1}H NMR spectrum.

phenyl groups. Therefore **6a** experienced a ready epimerization at the 5-position into 4,5-*trans*-1-pyrroline **7** in the presence of LDA, presumably via a 2-azaallyl anion intermediate. Formation of **8**, a regioisomer of **6b**, as a side product in the reaction between **Ae** and methyl acrylate may have arisen from a similar 2-azaallyl anion intermediate. Some cycloadditions were accompanied by Michael adducts, for instance **9** and **10**.

It is clear that *N*-lithiated anionic species are involved in these LDA-induced cycloaddition reactions. These species should be refered to as *N*-lithiated azomethine ylides **A** because the nonbonding electron pair on the imine nitrogen has been utilized to make a nitrogen-lithium bond. The involvement of *N*-lithiated azomethine ylide **A** is confirmed on the ground of the following facts: a) High regio- and stereoselectivity can be well-interpreted by a chelation between the lithium metal on the imine nitrogen and the carbonyl oxygen; b) DBU-Induced Michael addition of **la** with methyl acrylate gives not only the 1:1 adduct but also 1:2 adduct;[9b] c) DBU-Induced Michael addition of imine **1b** with methyl crotonate is poor in stereoselectivity, and of imine **1b** is sterically too hindered;[18] d) Michael adduct of **1b** to methyl crotonae does not cyclize leading to **2f** on treatment with LDA at −78 °C.[19]

Thus it is concluded that the LDA-induced cycloadditions of *N*-(1-cyanoalkyl)imines **1** proceed through a chelated transition state (Fig. 1). There are two possible paths, but we can not so far discriminate the following two routes: Path a: A concerted endo cycloaddition promoted by an attractive interaction between the ester carbonyl of the crotonate and the lithium metal of **A** (**G**→**J**); Path b: A sequence of Michael addition and intramolecular imine addition where the lithium metal migrates from the imine nitrogen to the ester oxygen so that high stereoselectivity may result (**H**→**I**→**J**). These two paths are virtually identical since the synchronousness of bond formations is only slightly different. The discrimination seems to be trivial.

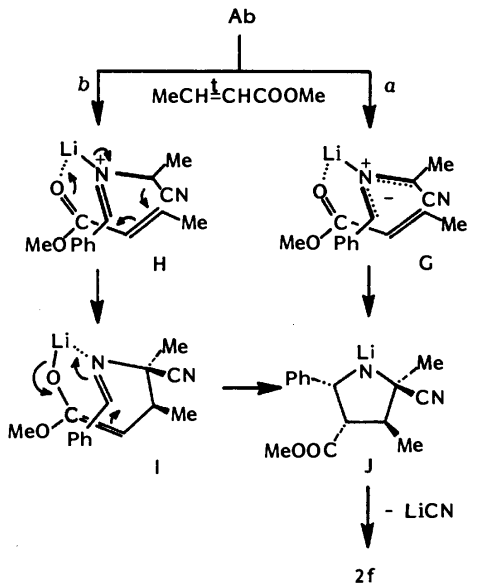

Fig. 1. Two possible mechanisms for the LDA-induced cycloaddition of **1b** to methyl crotonate.

Experimental

General. Melting points were determined on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-40 (90 Hz) or a JEOL FX-100 instrument (100 MHz) and ^{13}C NMR on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra were measured with a JEOL-01SG-2 spectrometer at 70 eV of ionization energy. High resolution mass spectra were obtained on the same instrument. Elemental analyses were performed on a Hitachi 026 CHN analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck). Visualization was made with ultraviolet light (254 and 365 nm), iodine, molybdophosphoric acid (5% in ethanol), or *p*-anisaldehyde (5% in ethanol containing 5% of sulfuric acid). For preparative column chromatography, Wakogel C-200, C-300 (Wako), and Silicagel 60 (Merck) were employed. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type-V at about 50 °C unless otherwise stated.

Imine **1a** or **1d** was prepared from the reaction of aminoacetonitrile or α-aminophenylacetonitrile with the corresponding aldehyde;[9a] **1b** and **1c** were available by alkylation of **1a**.[9b] Tetrahydrofuran (THF) was dried over sodium and distilled on sodium wire immediately before use.

General Procedure for LDA-Induced Cycloaddition of *N*-(1-Cyanoalkyl)imines 1a—1d with Electron-Deficient Olefins Leading to 2b—2k and/or 3a—3c. The reaction of α-(benzylideneamino)acetonitrile **1a** with dimethyl maleate is described as a typical example: To a solution of lithium diisopropylamide (LDA, 2.2 mmol) freshly prepared from butyllithium and diisopropylamine in dry THF (10 ml) was added slowly imine **1a** (0.29 g, 2.01 mmol in THF (2 ml)) at −78 °C. After 5 min at the same temperature, dimethyl maleate (0.316 g, 2.19 mmol in THF (0.5 ml)) was added. The mixture was allowed to stir at −78 °C under nitrogen for 6 h, poured into saturated ammonium chloride, and extracted with diethyl ether (30 ml×3). The combined extracts were dried over anhydrous mgnesium sulfate and evaporated in vacuo. The residue (0.433 g) was chromatographed over silica gel by using chloroform–diethyl ether (5 : 1) to give 2-pyrroline **2a** (0.372 g, 71%).

Other LDA-induced cycloadditions of **1a—1d** with olefins were carried out under the reaction conditions listed in Table 1 in which the results are also summarized.

2a: Colorless prisms (benzene–hexane); mp 120—122 °C; IR (KBr) 3300, 1720, and 1670 cm^{-1}; ^{1}H NMR ($CDCl_3$)

δ=3.08 (3H, s, 4-COOMe), 3.61 (3H, s, 3-COOMe), 4.12 (1H, dd, J=12.3 and 1.0 Hz, 4-H), 4.84 (1H, br, NH), 5.30 (1H, dd, J=12.3 and 1.6 Hz, 5-H), 7.2—7.4 (5H, m, Ph), and 7.46 (1H, dd, J=3.0 and 1.0 Hz, 2-H); ^{13}C NMR ($CDCl_3$) δ=50.48, 51.12 (each q, COOMe), 52.14 (d, 4-C), 66.08 (d, 5-C), 100.29 (s, 3-C), 127.14, 127.96 (each d), 137.66 (s), 150.62 (d, 2-C), 166.07, and 171.24 (each s, COOMe); MS m/z (rel intensity, %) 261 (M^+, 35), 202 (base peak), 170 (45), 143 (50), 117 (21), and 115 (34). Found: C, 64.38; H, 5.84; N, 5.57%. Calcd for $C_{14}H_{15}NO_4$: C, 64.36; H, 5.79; N, 5.36%.

2b: Pale yellow liquid; IR (neat) 1730 and 1625 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.80 (2H, m, 3-H), 3.08 (3H, s, COOMe), 3.50 (1H, ddd, J=9.6, 9.2, and 6.0 Hz, 4-H), 5.52 (1H, ddd, J=9.2, 4.0, and 2.0 Hz, 5-H), 7.0—7.4 (5H, m, Ph), and 7.80 (1H, dt, J=2.0, 1.0, and 1.0 Hz, 2-H); ^{13}C NMR ($CDCl_3$) δ=40.24 (t, 3-C), 46.30 (d, 4-C), 51.36 (q, COOMe), 78.83 (d, 5-C), 127.66, 128.13 (each d), 138.07 (s), 167.24 (d, 2-C), and 172.65 (s, COOMe); MS m/z (rel intensity, %) 203 (M^+, 15), 144 (34), 143 (20), 117 (42), 90 (23), and 43 (base peak). HRMS Found: m/z 203.0932. Calcd for $C_{12}H_{13}NO_2$: M, 203.0945.

2c: Pale yellow liquid; IR (neat) 1740 and 1625 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.22 (3H, d, J=7.1 Hz, Me), 3.06 (1H, dd, J=9.5 and 7.0 Hz, 4-H), 3.15 (3H, s, COOMe), 3.4—3.7 (1H, m, 3-H), 5.60 (1H, dt, J=9.5, 2.0, and 2.0 Hz, 5-H), 7.0—7.4 (5H, m, Ph), and 7.66 (1H, br s, 2-H); ^{13}C NMR ($CDCl_3$) δ=16.06 (q, Me), 46.77 (d, 3-C), 51.24 (q, COOMe), 55.24 (d, 4-C), 78.42 (d, 5-C), 127.54, 127.71, 128.13 (each d), 137.60 (s), and 172.01 (d and s, 2-C and COOMe); MS m/z (rel intensity, %) 217 (M^+, 11), 158 (44), 157 (21), 130 (20), 129 (23), 128 (25), 117 (91), 116 (40), 115 (46), 104 (29), 103 (23), 91 (54), 90 (base peak), 89 (78), 77 (51), 69 (78), 63 (44), 59 (58), 54 (26), 52 (48), 42 (55), and 40 (56). HRMS Found: m/z 217.1097. Calcd for $C_{13}H_{15}NO_2$: M, 217.1100.

2d: Pale yellow liquid; IR (neat) 1740 and 1620 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.14 (3H, s, COOMe), 3.44 (1H, dd, J=9.5 and 7.8 Hz, 4-H), 4.67 (1H, ddd, J=7.8, 3.0, and 2.0 Hz, 3-H), 5.75 (1H, dt, J=9.5, 2.0, and 2.0 Hz, 5-H), 6.9—7.6 (10H, m, Ph), and 7.76 (1H, dd, J=3.0 and 2.0 Hz, 2-H); ^{13}C NMR ($CDCl_3$) δ=51.36 (q, COOMe), 56.83 (d, 4-C), 57.71 (d, 3-C), 78.83 (d, 5-C), 127.54, 127.66, 127.77, 128.18, 128.83, 129.19 (each d), 136.95, 138.77 (each s), 169.19 (d, 2-C), and 171.48 (s, COOMe); MS m/z (rel intensity, %) 279 (M^+, 13), 220 (23), 163 (25), 158 (22), 131 (29), 117 (83), 115 (30), 105 (53), 90 (31), 85 (67), 83 (base peak), 77 (41), and 47 (25). Stability of this compound was not enough for the molecular weight measurement by HRMS.

2e: Pale yellow liquid; IR (neat) 1730 and 1650 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.19 (3H, d, J=2.0 Hz, Me), 2.68 (1H, dd, J=17.5 and 9.5 Hz, one of 3-H), 3.0—3.3 (1H, m, the other of 3-H), 3.08 (3H, s, COOMe), 3.56 (1H, dt, J=9.5 and 6.0 Hz, 4-H), 5.44 (1H, dd, J=9.5 and 2.0 Hz, 5-H), and 7.0—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=19.47 (q, Me), 41.94 (t, 3-C), 48.36 (d, 4-C), 51.24 (q, COOMe), 78.30 (d, 5-C), 127.54, 128.07 (each d), 138.77 (s), 172.76 (s, COOMe), and 175.83 (s, 2-C); MS m/z (rel intensity, %) 217 (M^+, 11), 158 (38), 157 (29), 131 (61), 130 (67), 116 (29), 115 (61), 104 (36), 103 (24), 91 (31), 90 (base peak), 89 (85), 77 (40), 63 (40), 59 (20), 55 (81), 51 (44), and 38 (46). HRMS Found: m/z 217.1068. Calcd for $C_{13}H_{15}NO_2$: M, 217.1084.

2f: Pale yellow liquid; IR (neat) 1735 and 1645 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.18 (3H, d, J=7.0 Hz, 3-Me), 2.30 (3H, s, 2-Me), 3.13 (3H, s, COOMe), 3.1—3.5 (1H, m, 4-H), 3.6—3.7 (1H, m, 3-H), 5.36 (1H, d, J=9.5 Hz, 5-H), and 7.0—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=16.53, 17.59 (each q, Me), 30.94 (d, 4-C), 47.89 (d, 3-C), 51.36 (q, COOMe), 57.00 (d, 5-C), 127.54, 127.71, 128.18 (each d), 138.48 (s), 172.42 (s, COOMe), and 179.42 (s, 2-C); MS m/z (rel intensity, %) 231 (M^+, 45), 172 (13), 131 (base peak), 130 (39), and 90 (26). HRMS Found: m/z 231.1255. Calcd for $C_{14}H_{17}NO_2$: M, 231.1257.

2g: Pale yellow liquid; IR (neat) 1730 and 1650 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.48 (3H, s, 4-Me), 2.17 (3H, d, J=1.8 Hz, 2-Me), 2.19 (1H, d, J=17.8 Hz, one of 3-H), 3.04 (3H, s, COOMe), 3.42 (1H, dd, J=17.8 and 1.1 Hz, the other of 3-H), 4.95 (1H, br s, 5-H), and 7.0—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=19.30 (q, 3-Me), 24.65 (q, 2-Me), 49.65 (t, 3-C), 50.89 (q, COOMe), 54.65 (s, 4-C), 85.89 (d, 5-C), 126.89, 127.19, 127.54 (each d), 138.54 (s), 174.01, and 174.89 (each s, 2-C and COOMe); MS m/z (rel intensity, %) 231 (M^+, 12), 131 (base peak), 130 (46), 90 (50), 89 (33), and 41 (22). HRMS Found: m/z 231.1265. Calcd for $C_{14}H_{17}NO_2$: M, 231.1270.

2h: Yellow liquid; IR (neat) 1740 and 1640 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.2—1.3 (9H, m, Me and *i*-Pr), 2.6—2.9 (1H, m, *i*-Pr), 3.12 (1H, dd, J=9.5 and 7.2 Hz, 4-H), 3.16 (3H, s, COOMe), 3.3—3.7 (1H, d, J=9.5 Hz, 5-H), and 7.0—7.5 (5H, m, Ph); MS m/z (rel intensity, %) 259 (M^+, 58), 159 (base peak), 131 (28) 117 (70), 91 (21), and 90 (21). HRMS Found: m/z 259.1609. Calcd for $C_{16}H_{21}NO_2$: M, 259.1645.

2i: Pale yellow liquid; IR (neat) 1735 and 1625 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.12 (3H, q, J=7.0 Hz, Et), 1.4—1.8 (2H, m, Et), 3.0—3.6 (3H, m, 3- and 4-H), 3.68 (3H, s, COOMe), 4.3—4.4 (1H, m, 5-H), 7.3—7.5 (3H, m, Ph), and 7.7—7.9 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=11.65 (q, Et), 25.41 (t, Et), 38.12 (t, 3-C), 45.83 (d, 4-C), 51.65 (q, COOMe), 75.95 (d, 5-C), 127.95, 128.65, 130.83 (each d), 134.30 (s), 171.13, and 173.77 (each s, 2-C and COOMe); MS m/z (rel intensity, %) 231 (M^+, 4), 172 (24), 144 (27), 143 (47), 130 (base peak), 117 (24), 116 (33), 115 (92), 104 (97), 77 (62), and 51 (37). HRMS Found: m/z 231.1250. Calcd for $C_{14}H_{17}NO_2$: M, 231.1244.

2j: Pale yellow liquid; IR (neat) 1735 and 1620 cm^{-1}; ^{1}HNMR ($CDCl_3$) δ=1.14 (3H, q, J=7.0 Hz, Et), 1.22 (3H, d, J=7.0 Hz, Me), 1.4—1.8 (2H, m, Et), 3.00 (1H, dd, J=8.0 and 4.2 Hz, 4-H), 3.6—4.0 (1H, m, 3-H), 3.64 (3H, s, COOMe), 4.32 (1H, q, J=8.0 Hz, 5-H), 7.2—7.5 (3H, m, Ph), and 7.6—7.9 (2H, m, Ph); ^{13}C NMR($CDCl_3$) δ=11.82 (q, Et), 17.41 (q, Me), 25.35 (t, Et), 45.83 (d, 4-C), 51.47 (q, COOMe), 54.77 (d, 3-C), 74.01 (d, 5-C), 128.18, 128.60, 130.42 (each d), 133.60 (s), 173.72, and 175.66 (each s, 2-C and COOMe); MS m/z (rel intensity, %) 245 (M^+, 8), 156 (31), 145 (23), 130 (79), 115 (30), 104 (base peak), 103 (30), 91 (36), 77 (64), 51 (46), and 41 (55). HRMS Found: m/z 245.1413. Calcd for $C_{15}H_{19}NO_2$: M, 245.1143.

2k: Pale yellow liquid; IR (neat) 1730 and 1625 cm^{-1}; ^{1}HNMR ($CDCl_3$) δ=1.10 (3H, q, J=7.5 Hz, Et), 1.38 (3H, s, Me), 1.3—1.8 (2H, m, Et), 2.76 (1H, d, J=17.0 Hz, one of 3-H), 3.64 (1H, dd, J=17.0 and 2.0 Hz, the other of 3-H), 3.66 (3H, s COOMe), 3.8—4.1 (1H, m, 5-H), 7.3—7.5 (3H, m, Ph), and 7.7—7.9 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=11.77 (q, Et), 25.12 (t, Et), 25.59 (q, Me), 46.00 (t, 3-C), 52.00 (q, COOMe), 83.77 (d, 5-C), 127.83, 128.60, 130.72 (each d), 134.54 (s), 170.84 (s, COOMe), and 175.66 (s, 2-C); MS m/z (rel intensity, %) 245 (M^+, 9), 186 (20), 157 (23), 156 (32), 130 (base peak), 104 (95), 77 (60), and 41 (49). HRMS Found: m/z

245.1422. Calcd for $C_{15}H_{19}NO_2$: M, 245.1428.

3a: Pale yellow liquid; IR (neat) 3360, 2230, and 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.22 (3H, d, J=7.0 Hz, Me), 2.0—2.4 (1H, br, NH), 2.94 (1H, ddd, J=9.0, 7.0, and 5.5 Hz, 3-H), 3.10 (1H, dd, J=8.7 and 5.5 Hz, 4-H), 3.21 (3H, s, COOMe), 3.66 (1H, d, J=9.0 Hz, 2-H), 4.63 (1H, d, J=8.7 Hz, 5-H), and 7.1—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=15.94 (q, Me), 40.89 (d, 3-C), 51.47 (q, COOMe), 54.24 (d, 4-C), 56.59 (d, 2-C), 63.24 (d, 5-C), 120.24 (s, CN), 127.36, 127.89, 128.18 (each d), 140.18 (s), and 171.13 (s, COOMe); MS m/z (rel intensity, %) 244 (M^+, 5), 144 (56), 143 (76), 117 (32), 116 (36), 115 (32), 104 (29), 91 (45), 90 (26), 89 (35), 78 (24), 77 (50), 69 (base peak), 59 (53), 58 (24), 56 (20), 52 (33), 44 (25), 42 (77), and 40 (49). HRMS Found: m/z 244.1212. Calcd for $C_{14}H_{16}N_2O_2$: M, 244.1212.

3b: Colorless liquid; IR (neat) 3350, 2240, and 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.45 (3H, s, Me), 2.02 (1H, dd, J=13.4 and 4.5 Hz, one of 3-H), 2.54 (1H, br s, NH), 3.04 (1H, dd, J=13.4 and 8.5 Hz, the other of 3-H), 3.17 (3H, s, COOMe), 4.22 (1H, s, 5-H), 4.45 (1H, dd, J=8.5 and 4.5 Hz, 2-H), and 7.0—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=21.94 (q, Me), 41.41 (t, 3-C), 45.94 (d, 2-C), 51.06 (q, COOMe), 53.83 (s, 4-C), 72.12 (d, 5-C), 121.66 (s, CN), 126.54, 127.83 (each d), 137.48 (s), and 173.90 (s, COOMe); MS m/z (rel intensity, %) 244 (M^+, 7), 144 (base peak), 143(86), 117 (26), and 116 (24). HRMS Found: m/z 244.1200. Calcd for $C_{14}H_{16}N_2O_2$: M, 244.1190.

3c: Formation of this compound **3c** was only observed in the ^1H NMR spectrum of crude reaction mixture obtained from **1c** and methyl crotonate. When chromatographed over silica gel by using chloroform-diethyl ether (10 : 1 vol/vol), ready elimination of HCN took place and 72% yield of **2h** was isolated. The ratio between **2h** and **3c** was determined by the ^1H NMR of the crude mixture. ^1HNMR ($CDCl_3$) δ=3.03 (s, COOMe) and 4.65 (dd, J=10.0 and 5.5 Hz, 5-H).

Cycloaddition of 1a Induced by Metallic Bases Other than LDA. Preparation procedure for the *N*-metalated species from **1a** is as follows. All the procedures were conducted under dry nitrogen at −78 °C:

EtMgBr: To EtMgBr (2.2 mmol) freshly prepared in THF (7 ml) was added **1a** (0.295 g, 2.05 mmol in THF (2 ml)). An olefin (2.2 mmol) was added after 15 min.

EtMgBr/HN(*i*-Pr)$_2$: To EtMgBr (2.2 mmol in THF (8 ml)) was added diisopropylamine (2.2 mmol in THF (10 ml)) and then **1a** (0.29 g, 2.01 mmol in THF (2 ml)). After 14 min, methyl acrylate (0.19 g, 2.21 mmol) was added.

***n*-BuLi**: To *n*-BuLi (1 M† solution in hexane, 2.2 ml, 2.2 mmol) in THF (5 ml) was added **1a** (0.151 g, 1.05 mmol). After 5 min, methyl crotonate (0.123 g, 1.23 mmol in THF (1 ml)) was added.

***n*-BuLi/LiI, *n*-BuLi/NEt$_3$, or *n*-BuLi/Ti(OPr^i)$_4$**: To LiI (1 mmol or 1.5 mmol), NEt_3 (1.11 mmol), or $Ti(OPr^i)_4$ (1 mmol) in THF (5 ml) was added *n*-BuLi (1.1 mmol). Imine **1a** (0.147 g, 1.02 mmol) was added after 10 min and then the mixture was stirred for an additional 10 min before methyl crotonate (0.115 g, 1.15 mmol) was introduced.

Subsequent cycloadditions were conducted under the conditions listed in Table 2 and the results are shown in the same table. The data for **2a** and **3a** were already presented above.

3a′: Colorless prisms (benzene-hexane); mp 96—97 °C; IR (KBr) 3350, 2230, and 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.26 (3H, d, J=6.5 Hz, Me), 2.40 (br s, NH), 2.9—3.2 (2H, m, 3-and 4-H), 3.10 (3H, s, COOMe), 4.36 (1H, d, J=6.0 Hz, 2-H), 4.81 (1H, d, J=9.1 Hz, 5-H), and 7.1—7.3 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=15.18 (q, Me), 38.30 (d, 3-C), 51.47 (q, COOMe), 54.18 (d, 4-C), 55.24 (d, 2-C), 62.77 (d, 5-C), 119.30 (s, CN), 127.71, 128.18 (each d), 139.83 (s), and 171.78 (s, COOMe); MS m/z (rel intensity, %) 244 (M^+, 16), 163 (39), 145 (base peak), and 144 (77). Found: C, 68.99; H, 6.72; N, 11.42%. Calcd for $C_{14}H_{16}N_2O_2$: C, 68.83; H, 6.60; N, 11.47%.

3b′: Colorless needles (diethyl ether-hexane); mp 78.5—79 °C; IR (KBr) 3330, 2230, and 1730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.00 (1H, br s, NH), 2.32 (1H, ddd, J=13.0, 8.5, and 3.0 Hz, one of 3-H), 2.72 (1H, ddd, J=13.0, 8.0, and 7.0 Hz, the other of 3-H), 3.13 (3H, s, COOMe), 3.41 (1H, dt, J=8.5, 8.5, and 7.0 Hz, 4-H), 4.44 (1H, dd, J=8.0 and 3.0 Hz, 2-H), 4.72 (1H, d, J=8.5 Hz, 5-H), and 7.23 (5H, s, Ph); MS m/z (rel intensity, %) 230 (M^+, 2), 144 (88), 143 (base peak), 142 (23), 117 (61), 116 (51), 115 (63), 104 (49), 91 (33), 90 (45), 89 (66), 78 (22), 77 (68), 66 (24), 65 (25), 63 (27), 55 (67), 51 (51), 50 (20), and 38 (44). Found: C, 67.72; H, 6.13; N, 12.05%. Calcd for $C_{13}H_{14}N_2O_2$: C, 67.81; H, 6.13; N, 12.17%.

General Procedure for LDA-Induced Cycloddition of 1e Leading to 6—10. To a solution of LDA freshly prepared from butyllithium (1.5 mmol) and diisopropylamine in THF (3 ml) was added imine **1e** (0.33 g, 1.5 mmol) at −78 °C in a period of 2 min. After 5 min, an olefin (1.6 mmol) was added to this red solution and the mixture was stirred under the conditions shown in Table 3. The reaction mixture was poured into ice water and extracted with diethyl ether (25 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel. All the results are listed in Table 3. Products **6a**, **6b**, **7**, and **8** have been already prepared from the reactions of *N*-protonated azomethine ylide derived from **1e**,[9a] and Michael adducts **9** and **10** are also known.[9b]

6c: Colorless prisms (hexane); mp 152—153 °C; IR (KBr) 1730 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.26 (3H, d, J=7.0 Hz, Me), 3.06 (3H, s, COOMe), 3.25 (1H, dd, J=9.0 and 4.0 Hz, 4-H), 4.00 (1H, ddd, J=7.0, 4.0, and 2.0 Hz, 3-H), 5.56 (1H, dd, J=9.0 and 2.0 Hz, 5-H), 7.0—7.4 (8H, m, Ph), and 7.7—7.9 (2H, m, Ph); MS m/z (rel intensity, %) 293 (M^+, 28), 234 (41), 193 (base peak), 115 (26), 91 (43), and 77 (27). Found: C, 77.78; H, 6.54; N, 5.01%. Calcd for $C_{19}H_{19}NO_2$: C, 77.79; H, 6.53; N, 4.77%.

6d: Colorless liquid; IR (neat) 1730 and 1620 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.60 (3H, s, Me), 2.80 (1H, d, J=18.0 Hz, one of 3-H), 3.13 (3H, s, COOMe), 3.90 (1H, dd, J=18.0 and 2.0 Hz, the other of 3-H), 5.23 (1H, d, J=2.0 Hz, 5-H), 7.0—7.5 (8H, m, Ph), and 7.95 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=25.59 (q, Me), 46.18 (t, 3-C), 51.47 (q, COOMe), 54.71 (s, 4-C), 86.59 (d, 5-C), 127.54, 127.83, 128.13, 128.77, 131.24 (each d), 134.07, 138.72 (each s), 173.72, and 174.54 (each s, 2-C and COOMe); MS m/z (rel intensity, %) 293 (M^+, 21), 234 (26), 193 (base peak), 165 (21), 103 (29), 90 (49), and 89 (57). HRMS Found: m/z 293.1415. Calcd for $C_{19}H_{19}NO_2$: M, 293.1425.

† 1M=1 mol dm^{-3}.

Electrochemical Redox Intercalation of Copper(I) Cation for $Cu_xMo_6S_8$ Superconductor Accompanied with a Reversible Structure Change

Tooru INOUE* and Toshihiro YAMASE
Research Laboratory of Resources Utilization, Tokyo Institute of Technology,
4259 Nagatsuta-cho, Midori-ku, Yokohama 227
(Received November 18, 1986)

Ternary compounds (Chevrel phase compounds) of molybdenum $Cu_xMo_6S_8$ were prepared by sintering mixed powders of MoS_2, Mo, and CuS and employed as electrodes in aqueous solutions. Electrochemical polarization of the electrodes gives rise to intercalation and deintercalation processes of Cu^+, resulting in deformative change in crystal structure of the compounds. The lattice constants of rhombohedral unit cells of the compounds are a_r=6.66 Å, α_r=96°, and V_r=290 Å^3 for the intercalated compound $Cu_4Mo_6S_{7.8}$, and a_r= 6.43 Å, α_r=91.2°, and V_r=267 Å^3 for the fully deintercalated $Mo_6S_{7.8}$. Both the copper(I) composition and the crystal structure of $Cu_xMo_6S_{7.8}$ can be controlled by the electric quantity in electrochemical redox treatment. Structure deformation results from change in electronic distribution of crystal, as well as in charge density of a Mo octahedral cluster, due to electrolysis.

Ternary compounds of molybdenum designated by $M'_xMo_6S_8$ (M′ is a metal such as Cu, Pb, Sn, or Fe) have been known as one group of atractive superconducting materials since Chevrel reported relevantly the synthetic methods and basic structures of compounds of this group.[1-5] With respect to critical temperature (T_c) and critical magnetic field (H_c) as characteristic properties of superconductors, $PbMo_6S_8$ possesses the highest T_c (16 K) and H_c (600 kG) values of the members of this group, although Mo_6S_8 which has no metal M′ does not show any superconducting property. The T_c value of $Cu_xMo_6S_8$ (x=0—4) changes from 0 to 11 K with increasing value of x. Recent studies have been carried out with their focus on phase digrams, effects of variation in components, and developments of applications such as the construction of secondary batteries and the fabrication of superconducting wires. The crystal structure of the compounds of this group is rhombohedral with a sulfur quasi-cubic cell containing an octahedral molybdenum Mo_6 cluster and metal intercalants. Critical superconducting properties of various Chevrel phase compounds have been reported.[8-10]

Chemical and electrochemical intercalations have been reported for transition metal dichalcogenides (MX_2 where M=Mo, W, Ti, Ta; X=S, Se, Te). Molecules and ions can enter interlayer spaces of these compounds, and it is expected that their electrical conductivities, especially superconductivity, can be enhanced by anisotropic change in electronic charge distribution and crystal structure.[11,12] Chevrel phase compounds may also contain metallic intercalants along the channel space, i.e., a kind of tunnel, of crystal. It is suggested that composition shift of intercalants can affect the superconductive property of compounds. Therefore, study on the relationship between crystal structure and intercalation processes has significance from the standpoint of physical and chemical characterizations and development of applications.

In a previous report, we have described that the redox behavior of $Cu_xMo_6S_{7.8}$ is reversible with respect to both intercalation process and crystal structure change.[13] In this study, redox processes of various copper Chevrel compounds are investigated with particular reference to the deformation of crystal structure in course of redox charge transfer. Anodic and cathodic polarizations of electrode materials lead to reversible redox processes, that is, intercalation and deintercalation of copper(I) cation Cu^+ and result in reversible change in crystal structure. It will be shown that the intercalant composition of $Cu_xMo_6S_{7.8}$ can be controlled by electrolytic charges.

Experimental

Stoichiometric mixtures of powders of CuS, MoS_2, and Mo were ground in acetone. The powder sample was put in a quartz tube, evacuated and dried at ca. 200 °C. The evacuated tube was sealed and set in an electric furnance, and then heated so gradually to 500 °C as to avoid explosion of the tube due to rapid vaporization of the sulfur. The temperature was raised up to 1000 °C, and held there for as long as 100 h for complete equilibration. The sample was then quickly quenched in cold water. A dark gray powder was obtained as a Chevrel phase material. If the sample contained unreacted powder as revealed by powder X-ray diffraction analysis, the above heating procedure was repeated on the sample. The host compound $Mo_6S_{7.8}$, without Cu, was obtained by shaking a 5 M (1 M= 1 mol dm^{-3}) HCl solution with suspended $Cu_2Mo_6S_{7.8}$ in an ultrasonic bath for 1 week. The number of Cu^+ ions which were dissolved into the solution from 1 g of sample powder was ca. 1.25×10^{21} as estimated by a polarographic analysis on the suspended HCl solution. The copper(I) compositions (x) of the other sample compounds were determined, within 3% error, similarly by polarographic analysis on HCl solutions with suspended $Cu_xMo_6S_{7.8}$ powders after shaking. In order to prepare electrodes, the sample powder of 0.3 g was pressed at 300 kg cm^{-2} into a disk with a diameter of

1 cm and a thickness of 1 mm. One face of the disk was connected to a Cu lead wire with conductive silver epoxy resin and covered with insulative epoxy resin.

For electrochemical measurement, three electrodes, i.e., a sample electrode, a Pt counter electrode, and a saturated colomel electrode (SCE), were set in a flask-type glass cell and controlled by a potentiogalvanostat (HD-301, Hokuto Denko Co.). The supporting electrolyte was 0.1 M KNO_3 or 1 M KCl. The intercalant was supplied in the form of CuCl or $Cu(NO_3)_2$. Prior to running electrolyses the aqueous solution was deaerated by N_2 bubbling. In order to detect deintercalated species, the rotating ring-disk electrode (RRDE) method was adopted which used a sample disk of 5 mm diameter and a Pt ring of 7 mm inner 9 mm outer diameter. The measuring technique was described elsewhere.[14,15]

The crystal structures of the samples before and after electrolysis were determined with a powder X-ray diffrometer from Rigaku Denki Co. using Cu $K\alpha$.

Results and Discussion

The behavior of sample electrodes was first investigated in course of redox electrolysis in 0.1 M KNO_3 solutions. Figure 1 shows four cyclic voltammograms of $Cu_xMo_6S_{7.8}$ (x=0, 2, 3, and 4). The oxidation and reduction currents were obtained under anodic and cathodic polarizations. Broad redox waves appear in the potential range [A] between −1.0—0.3 V vs. SCE. These waves have high current densities (>ca. 10 mA cm^{-2} at 0 V vs. SCE) and show good reversibility. The magnitude of redox currents decreases with decrease in the copper composition (x), that is, these currents depend on the composition (x). In the potential range [B] above 0.3 V vs. SCE, another oxidation wave also appears with a remarkably large curent density. When an oxidation current appears at a sample electrode under anodic polarization, a part of solution near the sample electrode turns greenish yellow, with evolution of gas (probably hydrogen) and deposition of Cu on the Pt counter electrode. Although no exact processes occurring on the sample electrode can be determined only from the above potential cycling experiments, it may be estimated that copper cation participates in the redox processes of $Cu_xMo_6S_{7.8}$.

In order to clarify the redox processes for $Cu_xMo_6S_{7.8}$, the rotating ring disk electrode technique was used with application of a $Cu_xMo_6S_{7.8}$ disk and a Pt ring electrode. Figure 2 shows the analytical current–potential curves for the $Cu^{+/2+}$ couple on the Pt ring electrode when oxidation occurs on the $Cu_4Mo_6S_{7.8}$ disk electrode. When oxidation proceeds on the disk at a potential of −0.2 V vs. SCE in the range [A], a large oxidation current from Cu^+ to Cu^{2+} is observed above 0.2 V at the Pt ring electrode. This phenomenon indicates that dissolution of Cu^+ occurs on the sample disk electrode. Then, when an oxidation current appears on the disk at a potential of 0.35 V in the range [B], the oxidation current from Cu^+ to Cu^{2+} decreases and the reduction current from Cu^{2+} to Cu^+ increases on the Pt ring. This phenomenon means that production of Cu^{2+} instead of Cu^+ increases on the disk electrode in this potential

(1) E_{disk}=−0.2 V, I_{disk}=2.5 mA, (2) E_{disk}=0.35 V, I_{disk}=5.2 mA.

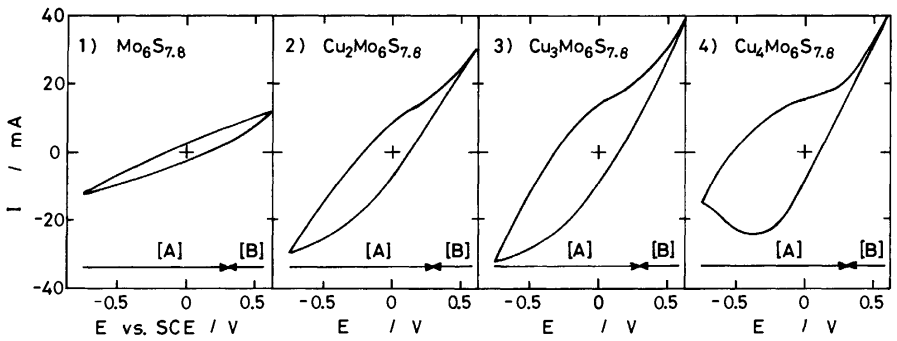

Fig. 1. Cyclic voltammograms of $Cu_xMo_6S_{7.8}$ (x=0, 2, 3, and 4) in 0.1 M KNO_3 solution. Potential scan rate is 30 s V^{-1}.

range, where Cu^{2+} is stabler than Cu^{+} because the standard redox potential of $Cu^{+/2+}$ is ca. 0.3 V vs. SCE in aqueous chloride solution.[14] From these results it is derived that products due to oxidation on $Cu_4Mo_6S_{7.8}$ are Cu^{+} in the potential range [A] and Cu^{2+} in the potential range [B]. The same products were obtained from redox electrolyses on $Cu_2Mo_6S_{7.8}$ and $Cu_3Mo_6S_{7.8}$. For the reduction processes on the $Cu_xMo_6S_{7.8}$ electrodes, similar RRDE techniques were employed on solutions saturated with CuCl. From the RRDE measurements it is derived that the reduction process on $Cu_xMo_6S_{7.8}$ is a consumption process of Cu^{+} in solution. However, no deposition of metallic copper on $Cu_xMo_6S_{7.8}$ disk surface was observed. When we employed Cu^{2+} instead of Cu^{+} in solution for reductive electrolysis, it was recognized through an X-ray diffraction analysis, as mentioned later, that intercalation with Cu^{2+} also occurred on $Cu_xMo_6S_{7.8}$, on the basis of the result of identification that the intercalated sample had the same crystal structure as in the case of Cu^{+}. Therefore, a reduction process of $Cu_xMo_6S_{7.8}$ leads to intercalation of copper(I) cation. From these results, the redox processes can be formulated as;

for oxidation below 0.3 V

$$Cu_xMo_6S_{7.8} \longrightarrow Cu_{x-1}Mo_6S_{7.8} + Cu^{+} + e^{-}, \quad (1)$$

for oxidation above 0.3 V

$$Cu_xMo_6S_{7.8} \longrightarrow Cu_{x-1}Mo_6S_{7.8} + Cu^{2+} + 2e^{-}, \quad (2)$$

for reduction in a solution with Cu^{+}

$$Cu_{x-1}Mo_6S_{7.8} + Cu^{+} + e^{-} \longrightarrow Cu_xMo_6S_{7.8}, \quad (3)$$

and for reduction in a solution with Cu^{2+}

$$Cu_{x-1}Mo_6S_{7.8} + Cu^{2+} + 2e^{-} \longrightarrow Cu_xMo_6S_{7.8}. \quad (4)$$

The redox waves in Fig. 1 correspond to the above reversible intercalations of copper to $Cu_xMo_6S_{7.8}$.

Figure 3 shows a chronopotentiogram of $Cu_3Mo_6S_{7.8}$ under galvanostatic conditions with an oxidation current I=1 mA. This chronopotentiogram shows a positive shift of potential due to deintercalation of Cu^{+}. The Cu composition (x) of the compound decreases with increase in electric quantity (Q) due to oxidative deintercalation. The rest potential of the electrode varies from −0.1 to 0.3 V vs. SCE with oxidation. This electrode potential change which results from stoichiometric variation of $Cu_xMo_6S_{7.8}$ means a shift of the Fermi energy of the compound, which is reflected by variation in electronic distribution within a crystal due to composition change.

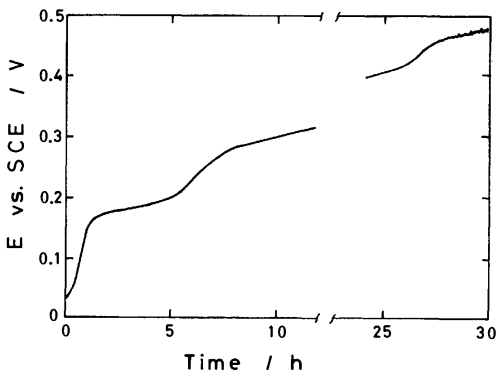

Fig. 3. Chronopotentiogram of a potential of $Cu_3Mo_6S_{7.8}$ under a galvanostatic oxidation with 1 mA in a 0.1 M KNO_3 solution.

It is reported that group compounds with a rhombohedral Chevrel phase contain a variety of metal cation intercalants and that their widely varying superconducting properties depend on both their stoichiometry and crystal structure.[9,10] From the results shown in Figs. 1 and 2, the conformation change of Chevrel phase compounds is expected to be associated with the composition change resulting from the copper cation transfer across the electrode-solution interface. The electric quantity (Q) which is consumed in the course of electrochemical intercalation and deintercalation can affect the stoichiometry of compounds. The relationship between crystal structure of compounds and redox electrolysis was investigated. Powder X-ray diffraction analyses were carried out for compounds $Cu_xMo_6S_{7.8}$ after redox treatment under in galvanostatic conditions with +/− 5 mA. Figure 4 shows the powder X-ray diffraction patterns which were obtained for $Cu_2Mo_6S_{7.8}$ after oxidations with Q=0, 6, and 12 C. The phenomenon that the diffraction patterns change with the degree of oxidation indicates conformation change in crystal. These patterns were analyzed by the Hull-Davey method. Lattice constants for hexagonal unit cell were calculated and converted into those for rhom-

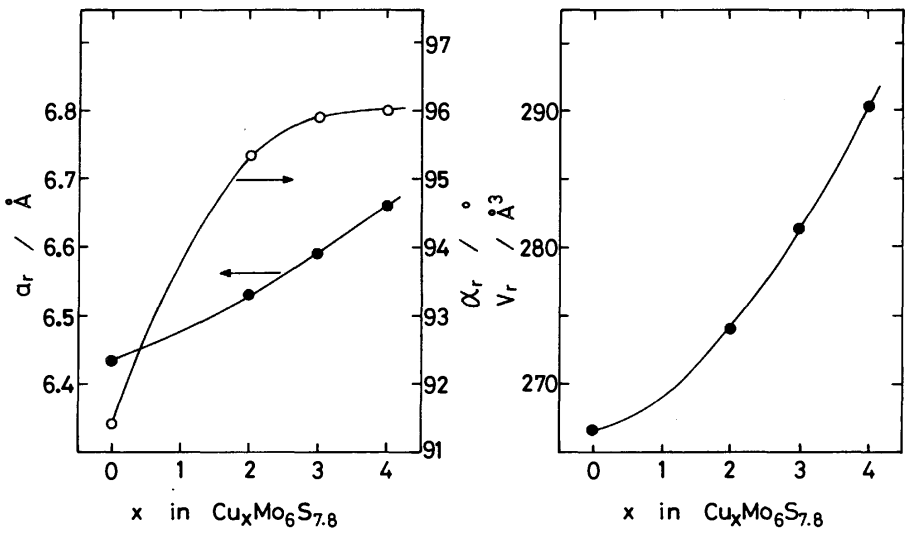

Fig. 5. Lattice constants of $Cu_xMo_6S_{7.8}$ compounds as a function of Cu composition (x).

bohedral unit cell.[16] The rhombohedral crystal structure of $Cu_2Mo_6S_{7.8}$ changes with the electric quantity in oxidation processes.

For the Chevrel phase compounds $Cu_xMo_6S_{7.8}$ (x=0, 2, 3, and 4) which were synthesized with stoichiometric ratios, their rhombohedral structures were also analyzed before redox electrolysis. Figure 5 shows the rhombohedral lattice constants (a_r and α_r) and unit cell volumes (V_r) as a function of Cu composition (x) as determined by the quantitative analysis of dissolved Cu^+ described in the experimental section. This relationship shows a clear dependence of the Chevrel phase structure on Cu composition (x), as described in detail elsewhere.[17] The compounds with various Cu compositions are employed for redox electrolysis, and their structure changes are analyzed as a function of the electric quantity (Q) consumed during the electrolysis.

Figure 6 shows the relationship between rhombohedral lattice constants (a_r, α_r) and oxidative electric quantity (Q_{ox}) for $Cu_4Mo_6S_{7.8}$. Before oxidation, the sample has a rhombohedral structure with a_r=6.65 Å, α_r=96.5°, and V_r=287.5 Å^3. In the course of oxidation, the lattice constants drastically decrease in proportion to the oxidative Q_{ox} to a_r=6.5 Å, α_r=94°, and V_r=273 Å.[3] For $Cu_3Mo_6S_{7.8}$ and $Cu_2Mo_6S_{7.8}$, phenomena similar to that of $Cu_4Mo_6S_{7.8}$ were observed with respect to the relationship between oxidative Q_{ox} and lattice constants, as shown in Figs. 7 and 8. Both a_r and α_r decrease with the degree of oxidation. Especially, the change in lattice angle α_r is characteristic of distorted contraction of crystal. The volume difference (ΔV_r) between $Cu_4Mo_6S_{7.8}$ and $Mo_6S_{7.8}$ is ca. 25 Å^3, which is ca. 10% of the unit cell volume and larger than the ionic volume (14.8 Å^3) as calculated for 4 Cu^+ by using the Cu^+ ionic radius of 0.96 Å.[18] These anisotropic changes in lattice

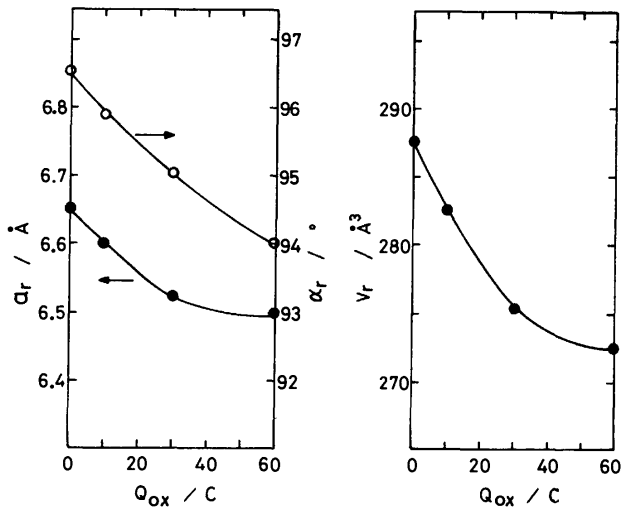

Fig. 6. Dependence of lattice constants on Q_{ox} for an oxidative deintercalation of $Cu_4Mo_6S_{7.8}$.

constants as a function of Q_{ox} claim that the deintercalation process gives rise to a series of changes from $Cu_4Mo_6S_{7.8}$ through $Cu_3Mo_6S_{7.8}$ and $Cu_2Mo_6S_{7.8}$ to the copper-free $Mo_6S_{7.8}$. As seen from a comparison of the crystal parameters in Figs. 6—8 with that in Fig. 5, the copper composition (x) decreases by 1 for each Q_{ox}=ca. 27 C for these compounds:

$$Cu_4Mo_6S_{7.8} \xrightarrow[-e^-]{-Cu^+} Cu_3Mo_6S_{7.8} \xrightarrow[-e^-]{-Cu^+} Cu_2Mo_6S_{7.8} \xrightarrow[-e^-]{-Cu^+} CuMo_6S_{7.8} \xrightarrow[-e^-]{-Cu^+} Mo_6S_{7.8}. \quad (5)$$

When the compound was oxidized at a potential (>0.35 V) in the rane [B], a change in crystal structure similar to that occurring in the range [A] was observed. However, a constant change in lattice

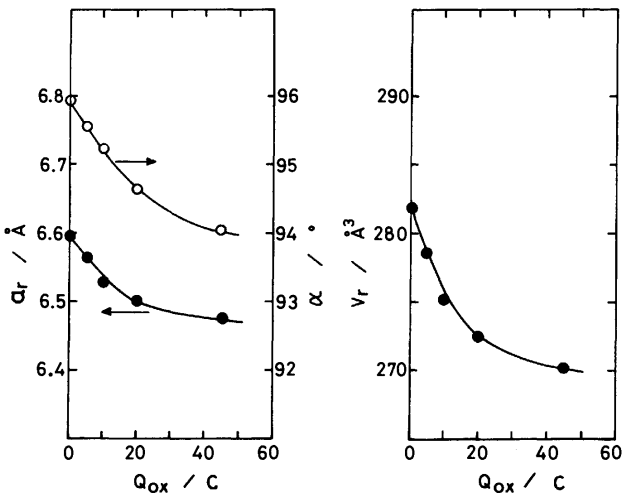

Fig. 7. Dependence of lattice constants on Q_{ox} for an oxidative deintercalation of $Cu_3Mo_6S_{7.8}$.

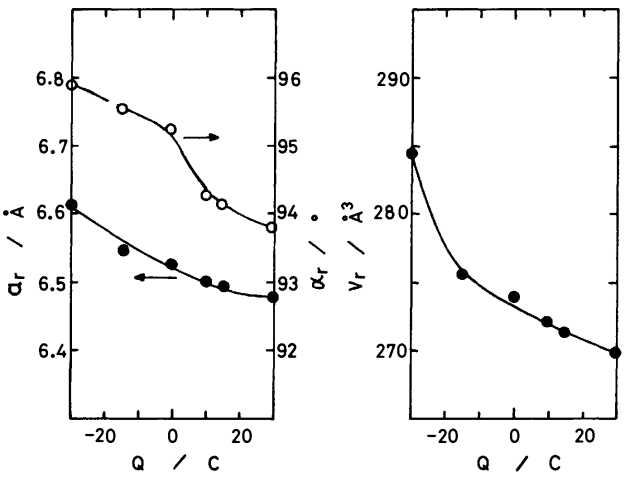

Fig. 8. Dependence of lattice constants on Q for redox intercalation and deintercalation of $Cu_2Mo_6S_{7.8}$.

constant required nearly twice Q_{ox} for the case in the potential range [A]. This means that the deintercalation process according to Eq. 2 involves an oxidation process from Cu^+ to Cu^{2+} at the surface of electrode.

On the other hand, when the sample is reduced, that is, intercalated with Cu^+, it is expected that reverse change in crystal structure will occur in proportion to the reductive electric quantity (Q_{red}), because the cyclic voltammogram of the compound is reversible as shown in Fig. 1. When $Cu_2Mo_6S_{7.8}$ is reduced in a saturated CuCl solution, the crystal structure changes as shown in Fig. 8. In the range of negative Q, the lattice constants increase as intercalation proceeds. Figure 9 shows the relationship between lattice constant and reductive Q_{red} in the course of intercalation for $Mo_6S_{7.8}$. Cu^+ intercalation into a host compound results in increase in the lattice

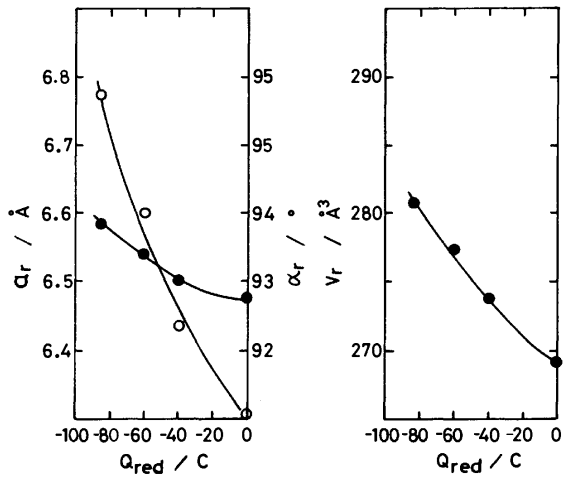

Fig. 9. Dependence of lattice constants on Q_{red} for a reductive intercalation of $Mo_6S_{7.8}$ in a saturated CuCl solution.

constants, that is, expansion of the crystal unit cell.

When an $Mo_6S_{7.8}$ electrolde was reduced in a solution with 0.1 M Cu^{2+}, similar increases in the lattice constants were observed. However, a certain constant degree of intercalation required nearly twice the Q_{red} for the case with Cu^+, that is, the crystal structure at Q_{red}=40 °C with Cu^+ was almost the same as that at Q_{red}=80 °C with Cu^{2+}. This phenomenon suggests that the intercalation reaction according to Eq. 4 involves a reduction process of Cu^{2+} to Cu^+. This result is consistent with the state of copper(I) cation in crystal disclosed by a crystallographic analysis.[9] Therefore, the intercalation and deintercalation of the compound are transfer processes of copper(I) cation across the compound-solution interface.

As seen from the results of Figs. 6—9, the structures of the rhombohedral crystals undergo reversible and continuous change during the redox intercalation and deintercalation processes of Cu^+. The unit cell of the compound expands due to intercalation and contracts due to deintercalation of Cu^+, accompanying structure distortions due to change in lattice angle.

Figure 10 shows the schematic view of a basic rhombohedral Chevrel phase compound. The copper which is surrounded by the S quasi cubics can be deintercalated by oxidation and intercalated reduction. The crystal deformation results from the effect that the Cu^+ intercalation gives rise to change in the relative distances among the S quasi cubics as well as among the Mo_6 octahedra. Moreover, in the course of the redox processes, if the ionic condition is kept as Cu(+1) and S(2−) in $Cu_xMo_6S_{7.8}$ crystal, the valency Z of Mo shifts from 2.6 to 1.93 due to intercalation. That is, the electron density of a Mo_6 cluster also increases due to intercalation. As electronic structure is generally correlated to crystal structure, the electronic

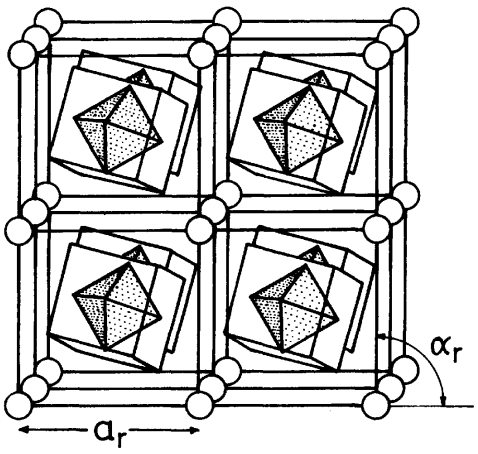

Fig. 10. Schematic illustration of a rhombohedral Chevrel phase compound. Circles denote the Cu Sites. A sulfur cubic contains an octahedral molybdenum Mo_6 cluster.

distribution as well as the density of states of the compound should be affected by the metal cation intercalation and deintercalation. This can explain the observation that the deintercalation of a Cu^+ intercalant from the compound results in a shift of electrode potential which is equivalent to a Fermi energy level, as discussed in connection with the result shown in Fig. 3. The phenomenon that critical temperature T_c of $Cu_xMo_6S_8$ associated with superconducting phenomena varies with Cu composition,[9,10] is evidence for the intercalation effect which leads to change in both the d-electron density of Mo and the crystal structure. Therefore, electrochemical intercalation is useful for studies on superconducting properties of these compounds.

An Efficient Regeneration of Singlet Oxygen from 2,5-Diphenylfuran Endoperoxide Produced by a Dye-Sensitized Oxygenation

Yoshiharu Usui,* Hiroshi Koike, and Yoshimi Kurimura
Department of Chemistry, Faculty of Science, Ibaraki University, Mito 310
(Received March 4, 1987)

The maximum quantum yield of 4.5 was evaluated from the kinetic analysis for the Methylene Blue-sensitized oxygenation of 2,5-diphenylfuran, and the contribution of a chain process to produce the furan endoperoxide was suggested. After the photoreaction, the thermolysis of the endoperoxide occurred to regenerate 2,5-diphenylfuran and singlet oxygen and to produce *cis*-1,2-dibenzoylethylene simultaneously. The activation energy of singlet oxygen recovery was estimated to be 18.5 kcal mol^{-1}. The reversible conversion of singlet oxygen took place efficiently with thiazine and xanthene dyes. A concerted dissociation of singlet oxygen from the endoperoxide was supposed from the negative value of activation enthropy (−9.8 e.u.) for the reaction.

Singlet oxygen($^1O_2$) is one of the active oxygen species which are utilized for synthetic chemistry with oxidative reactions and which affect the photodynamic action in the field of photobiology and photomedecine.[1] Since these active species of $^1O_2$, $O_2^-\cdot$, $OH\cdot$, H_2O_2, etc., are of a high-energy compound thermodynamically and are interconvertible with each other through the respective oxidation and reduction processes, the photochemical formation of $^1O_2$ is significant in the performance on various reactions of the up-hill type upon free energy change.

Provided that the $^1O_2$ formed with a photosensitized reaction is once trapped and stored, and is then regenerated in the dark, such a phenomena of $^1O_2$ formation will show a fascinating feature of the reversible conversion with light energy; visible light can be efficiently used for $^1O_2$ formation by means of an energy transfer from the triplet organic dyes without the decomposition of sensitizers. Choosing 2,5-diphenylfuran (DPF) as an efficient acceptor for the $^1O_2$ formed photochemically, we found the quantum yields on the DPF oxygenation which exceeded the intersystem crossing probability of the triplet sensitizers.

In the present paper, the reaction mechanism of the efficient oxygenation of DPF has been discussed. Then, the decomposition of the product of DPF endoperoxide, resulting in the regeneration of $^1O_2$ has been kinetically investigated.

Experimental

Materials. All the organic dyes (G.R. grade) of Methylene Blue ($C_{16}H_{18}N_3SCl$; MB), Thionine ($C_{12}H_{20}N_3SCl$; Th), Eosine Y ($C_{20}H_6O_5Br_4Na_2$; EY), Erythrosine B ($C_{20}H_6O_5I_4Na_2$; Ery), and Rose Bengal ($C_{20}H_2O_5I_4Cl_4Na_2$; RB) were recrystallized twice from ethanol. The 2,5-diphenylfuran(Tokyo Kasei Co., G.R.) and 1,3-diphenylisobenzofuran(Aldrich Co., G.R; DPBF) and all the solvents (Kanto Kagaku Co., G.R.) of acetonitrile, methanol, chloroform, 1,1,2,2-tetrachloroethane, etc. were used as received.

Procedures. An iodometry reported for the similar compounds was used to determine the amount of DPF-peroxide.[2,3] The extinction coefficient of I_3^- in acetonitrile was 2.55×10^4 M^{-1} cm^{-1} (1 M=1 mol dm^{-3}) at the peak of 363 nm. The sensitized oxidation of DPF and DPBF was monitored with an usual cross-illumination apparatus, as has been reported previously.[4] After the irradiation within a few minutes, the recovery of DPF was also monitored by means of the same apparatus for several tens of minutes in the dark. The photobleaching of MB in an air-saturated aqueous solution was used as a chemical actinometer (the quantum yield: 4.5×10^{-5}) to obtain the light intensity from a 300W tungsten lamp and to estimate the quantum yield of DPF oxidation (Φ).[5] For the spectral and kinetical analyses of the reactions, a system composed of a spectrophotometer (Hitachi, 200-10), a microcomputer(NEC, PC8801), and a digitizer(Mitablet) was used.

In the kinetical analysis of the present photochemical reaction, the rapid irradiation with a higher intensity has to be performed at low temperatures in order to avoid the influence of the thermal decomposition during irradiation.

Results and Discussion

DPF Concentration Effect on the Quantum Yield, Φ. The singlet oxygen($^1O_2$) which is produced by the energy transfer from the triplet sensitizer(^{3}Sens) decays to the ground state molecule($^3O_2$) in a solution or reacts with the added DPF to produce the endoperoxide($DPFO_2$) competetively. The scheme for such reactions has already been reported to be as follows:[4,6-10]

$$^3\text{Sens} \longrightarrow {}^1\text{Sens} \quad (1)$$

$$^3\text{Sens} + {}^3O_2 \longrightarrow {}^1\text{Sens} + {}^1O_2 \quad (2)$$

$$^1O_2 \longrightarrow {}^3O_2 \quad k_d \quad (3)$$

$$^1O_2 + \text{DPF} \longrightarrow DPFO_2 \quad k_q \quad (4)$$

Scheme 1.

According to the above essential scheme, the initial quantum yield of DPF oxygenation(Φ) is expressed as Eq. 5:

$$\Phi = \Phi_{so}\frac{[DPF]}{\beta_{DPF}+[DPF]} \quad (5)$$

where Φ_{so} and β_{DPF} stand for the $^1O_2$ formation yield from ^{3}Sens and the rate parameter of k_d/k_q respectively. From the linear relationship between $1/\Phi$ and 1/[DPF], the reactivity index, β_{DPF}, can be estimated.[4,6] The experimental results for the DPF concentration effect on Φ is shown in Fig. 1. Although the Φ_{so} value for the sensitizer of MB is 0.52, the Φ value at higher concentrations of DPF exceeds Φ_{so}, and its limitation goes up to about eight times of the Φ_{so} value.[11] The amounts of peroxide produced photochemically were determined by means of iodometry; they are listed in Table 1. Although the thermal decomposition of the unstable endoperoxide occurred during irradiation, and thus the amounts of the peroxide decreased at higher temperatures (>25 °C), it was shown that the added DPF changed completely to the peroxide, as is shown in Fig. 1. These results suggest that Eq. 5 cannot be adopted and that DPF might be oxygenated through a chain-reaction process. Since the effect of temperature (0—55 °C) on Φ values was not observed under the present experimental conditions, it seems that the chain cycles for DPF oxygenation proceed rapidly without an activation energy and that the thermal decomposition of the product can also be neglected at the initial stage of irradiation.

Thus we can tentatively introduce a mechanism in which the thermically activated state or intermediate ($DPFO_2$*) reacts with DPF, competing with its own deactivation. The activated state, DPF*, is oxygenated by dissolved oxygen via Eqs. 7—9. This chain mechanism is shown as Scheme 2:

$$^3\text{Sens} \longrightarrow {}^1\text{Sens} \quad (1)$$
$$^3\text{Sens} + {}^3O_2 \longrightarrow {}^1\text{Sens} + {}^1O_2 \quad \Phi_{so} \quad (2)$$
$$^1O_2 \longrightarrow {}^3O_2 \quad k_d \quad (3)$$
$$^1O_2 + \text{DPF} \longrightarrow DPFO_2^* \quad k_q \quad (4)$$
$$DPFO_2^* \longrightarrow DPFO_2 \quad k_1 \quad (6)$$
$$DPFO_2^* + \text{DPF} \longrightarrow DPFO_2' + \text{DPF}^* \quad k_2 \quad (7)$$
$$\text{DPF}^* \longrightarrow \text{DPF} \quad k_3 \quad (8)$$
$$\text{DPF}^* + {}^3O_2 \longrightarrow DPFO_2^* \quad k_4 \quad (9)$$

Scheme 2.

The activated intermediates of $DPFO_2$* and DPF* act as chain carriers, and the chain cycle is involved by means of Eqs. 7 and 9 as long as sufficient DPF exists. $DPFO_2$* produces the endoperoxide($DPFO_2$), competing with the reverse reaction of Eq. 4. $DPFO_2'$ is tentatively assumed to be the peroxide which produces *cis*-1,2-dibenzoylethylene(DBE) via a thermal decomposition as will be described below. In the studies of the reactivity of $^1O_2$ for endoperoxide formation, the existence of such intermediates as an addition complex or a π complex between $^1O_2$ and an acceptor was frequently assumed.[6,12,13] These complexes can be assigned to the $DPFO_2$* and $DPFO_2'$ in Scheme 2. Although $DPFO_2$ regenerated $^1O_2$ and DPF thermically after the irradiation, the degree of DBE formation against the thermal recovery of DPF became small, after irradiation when the initial concentration of DPF was low ([DPF]<20 μM). When the irradiation procedures after the thermal recovery of DPF from $DPFO_2$ were repeated, the added DPF changed to DBE quantitatively. These results are consistent with Scheme 2.

Table 1. Temperature Effect on the Amounts of DPF-Peroxide

Temperature °C	Concentration(/10^{-4} M) of	
	reacted DPF	produced $DPFO_2$
55	1.18	0.344
35	1.18	0.639
25	1.06	0.831
15	1.18	1.01
5	1.18	1.05
−2	1.06	0.92
−7	1.06	1.03
−11	1.06	1.03

[MB]=10 μM, $[DPF]_0$=120 μM, in CH_3CN.

The quantum yield of DPF disappearance, Φ_C, which is derived by applying the stationary-state method to ^{3}Sens, $^1O_2$, and these activated intermediates in Scheme 2, can be expressed as in Eq. 10:

$$\Phi_C = \Phi_{so}\frac{[DPF]}{\beta_{DPF}+[DPF]}\left(1+(1-r)\frac{k_2[DPF]}{k_1+rk_2[DPF]}\right) \quad (10)$$

where $r=k_3/(k_3+k_4[O_2])$; i.e., r means the degree of DPF* deactivation of Eq. 8 in competition with the process of Eq. 9. Under the conditions of $k_1/k_2 \gg$[DPF], the expression of Φ_C coincides with Eq. 5, which is the equation of Φ without the chain process. Further, the rate of the photochemical oxygenation of DPF was analyzed as a first-order reaction under the approximate condition of $\beta_{DPF} \gg$[DPF], and the rate constant was found to be inversely proportional to β_{DPF}. In the case of the DPBF oxygenation, β_{BF} in acetonitrile, which stands for the rate parameter of k_d/k_q' for the reactions, was similarly obtained as 1.26×10^{-5} M at 20 °C. From the comparison of the rate constants for the DPF and DPBF oxygenations, the β_{DPF} value for DPF in acetonitrile (8.3×10^{-5} M) can be estimated.[4] By substituting the k_d value ($=3\times10^4$ s^{-1} in acetonitrile) into the β_{DPF}, k_q was obtained as 3.7×10^8 M^{-1} s^{-1}.[4,6,9,14]

On the other hand, at the higher concentration of DPF ([DPF]$\gg k_1/k_2$), Φ_C can be approximately written as in the following equation:

$$\Phi_C = \Phi_{so}\frac{[DPF]}{\beta_{DPF}+[DPF]}\frac{1}{r}$$
$$= \Phi_{so}\frac{1}{r} = \Phi_{max} \quad (\beta_{DPF} \ll [DPF]) \qquad (11)$$

Therefore, a linear relationship between $1/\Phi$ and 1/[DPBF] was derived from Eq. 11 over the DPF concentration of 20 μM, as is shown in Fig. 1: i.e, the reciprocal plot holds approximately with Eq. 11, but with Eq. 5. From the interception in Fig. 1 a maximum value of $\Phi_C(\Phi_{max})$ was obtained as 4.5. The β_{DPF} value of 6.9×10^{-5} M was obtained from the interception and the slope. By substituting the Φ_{max} value into Eq. 11, the r value of 0.116 is obtained. This suggests that DPF* reacts with $^3O_2$ as an efficient chain carrier in Eq. 9.

Incidentally, the following numerical equation is shown as a dotted line in Fig. 1:

$$\Phi_C(calcd) = \frac{0.52[DPF]}{6.9\times10^{-5}+[DPF]} \times\left(1+\frac{0.884[DPF]}{1.7\times10^{-6}+0.116[DPF]}\right) \qquad (12)$$

From this equation, which is drawn to coincide with the experimental data, the ratio of the rate constants ($k_1/k_2=1.67\times10^{-6}$ M^{-1}) was obtaind using the r value of 0.116. Thus, at the higher concentrations of DPF$\gg k_1/k_2(=1.67\times10^{-6}$ M), it seems that $DPFO_2$* reacts with DPF predominantly and that the chain reaction occurs efficiently.

Recovery Process of DPF from the Endoperoxide. It has been reported that the endoperoxides are unstable and that the thermal decomposition occurs easily.[2,15,16] In order to clarify the reaction mechanism of the decomposition from the point of view of $^1O_2$ regeneration, a kinetic investigation was carried out. By measuring the UV-spectral change of the sample immediately after irradiation, it was confirmed that the regeneration of DPF occurred by means of the $DPFO_2$ decomposition in the dark. Simultaneously, *cis*-1,2-dibenzoylethylene(DBE) with the absorption maximum at 265 nm was produced as is shown in Fig. 2.[2] After irradiation at a higher concentration of DPF (10—300 μM) and at a lower temperature (0—20 °C), the percentage recoveries of DPF and DBE to the added DPF concentration were 55 and 40% in acetonitrile respectively. At lower concentrations of DPF(<10 μM), the percentage recovery of DPF increased, but that of DBE decreased to some extent.

The rate of DPF recovery could be apparently analyzed as first-order with the peroxide concentration, which was estimated as the value of $[DPF]_{max}-[DPF]$ from the maximal recovery of DPF, ($[DPF]_{max}$):

$$\ln([DPF]_{max}-[DPF]) = \ln[DPF]_{max}-k_r t \qquad (13)$$

Similarly, the DBE formation was also analyzed as a first-order reaction. The rate constants were $7.0(\pm0.2)\times10^{-4}$ s^{-1} for DPF (k_r) and $6.9(\pm0.2)\times10^{-4}$ s^{-1} for DBE respectively at 25 °C. The initial rates for the recovery were not influenced by the DPF concentration. Provided that the back reaction of Eq. 14 occurred, the kinetic treatment on DPF should deviate from the first order analysis of Eq. 13:

$$DPFO_2 \longrightarrow DPF + {}^1O_2 \qquad k_r \qquad (14)$$
$$^1O_2 \longrightarrow {}^3O_2 \qquad (15)$$

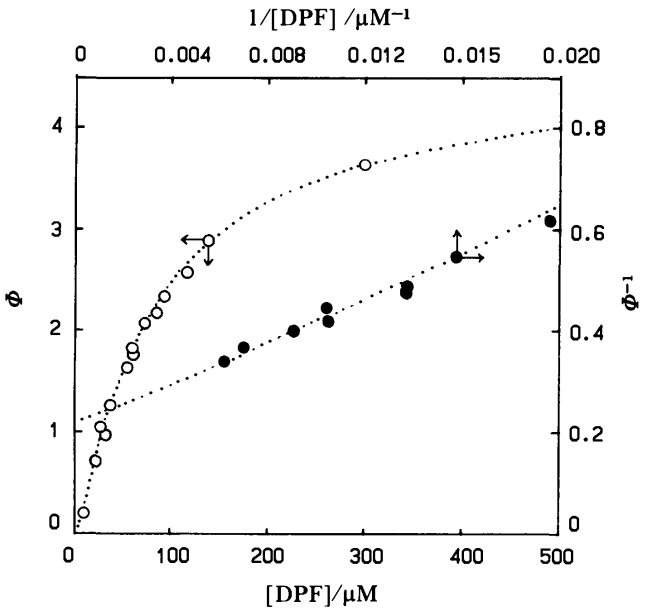

Fig. 1. DPF concentration effect on the oxidation yield, Φ in acetonitrile. (Dotted line: Eq. 12 in text) [MB]: 5 μM; 5 °C.

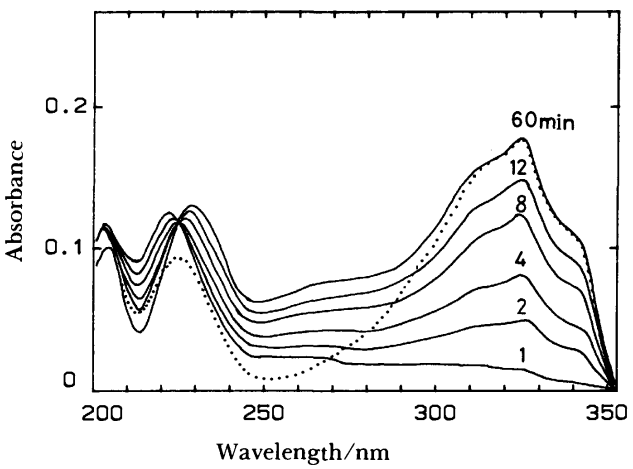

Fig. 2. UV-spectral change for DPF-recovery and DBE formation processes after irradiation in acetonitrile. (Dotted line: Spectrum of DPF in which the absorption was normalized at a peak after 60 min-recovery) [MB]: 5 μM; [DPF]: 10 μM; 50 °C.

However, when the stationary concentration of $^1O_2$ is low (about 30% for the $DPFO_2$ concentration), Eq. 13 approximately holds in a computer simulation for the concentration change in each component, even if both the equilibrium for Eq. 14 and the competitive reactions of Eq. 15 are involved. Since $^1O_2$ is deactivated by acetonitrile, it seems that a first order reaction of Eq. 13 was practically observed under the present conditions.

From the temperature effect on the rate constants of DPF recovery and DBE formation, the apparent activation energies (E_A) were obtained as 18.5± 0.5 kcal mol^{-1}(DPF) and 17.0±0.5 kcal mol^{-1}(DBE) respectively. These values are smaller than those in the cases of the endoperoxides of anthracene derivatives(for example; 9,10-diphenylanthracene endoperoxide: 27.8 kcal mol^{-1}, rubrene endoperoxide: 32.6 kcal mol^{-1}).[17-19] By reference to the behavior of the endoperoxide of 3-(4-methyl-1-naphthyl)propionic acid, which has been reported to have the E_A value of 17 kcal mol^{-1}, DPF recovery was actually observed even at room temperature.[20]

It has been reported that the decomposition mechanism of the furan endoperoxides was dependent on the solvent.[16] In alcohol, the addition of a solvent to $DPFO_2$ produces the hydroperoxide. Hardly no DPF recovery was observed in methanol, ethanol, and 1-propanol, etc. In the mixture of acetonitrile and heptane or ethyl acetate, a good DPF recovery was observed, since the reaction of Eq. 14 occurs successively as a result of the rapid deactivation of $^1O_2$ in these solvents. However, in the solvent mixture of acetonitrile and 1,1,2,2-tetrachloroethane, though the rate of DPF recovery was increased to some extent, the amount of recovery was decreased, as is shown in Table 2. This means that the back reaction in Eq. 14 was not neglected during the recovery, since the lifetime of $^1O_2$ is longer in 1,1,2,2-tetrachloroethane or carbon tetrachloride.[8,21-23]

Regeneration of Singlet Oxygen. DPBF reacts rapidly and specifically with $^1O_2$, without being complicated by any side reactions. In order to check experimentally whether or not $^1O_2$ was produced in the DPF recovery process, DPBF was added to the sample immediately after the irradiation. For the kinetical treatment to $^1O_2$ and the DPBF reaction, the following scheme can be introduced:

$$DPFO_2 \longrightarrow DPF + {}^1O_2 \qquad k_r \qquad (14)$$

$$^1O_2 \longrightarrow {}^3O_2 \text{ (in } CH_3CN) \qquad k_d \qquad (15)$$

$$^1O_2 + DPBF \longrightarrow DPBFO_2 \qquad k_q' \qquad (16)$$

Scheme 3.

Since $^1O_2$ is easily deactivated in acetonitrile, and also since DPBF traps $^1O_2$ in competition with the deactivation, the reaction rate of DPBF in Scheme 3 can be analyzed as in Eqs. 17 and 18 under the assumption of the stationary state method for $[^1O_2]$, using the relation of $[DPFO_2]=[DPFO_2]_0\exp(-k_rt)$. The reaction probability between DPBF and $^1O_2$ was assumed to be unity.[8,9] The β_{BF} value($=k_d/k'_q$) and the k_r value for the DPF recovery reaction in acetonitrile were used in Eq. 18, which was the integrated equation to Eq. 17:

$$-\frac{d[DPBF]}{dt} = k'_q[^1O_2][DPBF] \qquad (17)$$

$$\beta_{BF}\ln[DPBF] + [DPBF] = \beta_{BF}\ln[DPBF]_0 + [DPBF]_0 - [DPFO_2]_0(1-\exp(-k_rt)) \qquad (18)$$

The linear relationship in Eq. 18 is shown in Fig. 3. Since the slope in Fig. 3 was equal to $[DPFO_2]_0$, the initial concentration of $DPFO_2$ which produced $^1O_2$ was calculated to be 60 μM under the present conditions; the amount was approximately equal to the recovered DPF concentration. Accordingly, it can be suggested that the $^1O_2$ regenerated in Eq. 14 was

Table 2. Solvent Effect on the Recovery Rate and Amounts of DPF (25°C)[a]

Solvent χ_{TeCE}[b]	$k_r/10^{-4}$ s^{-1}	Recovered [DPF]/μM (percent recovery)
0	7.01	15.3 (54.9)
0.048	6.5	13.7 (49.0)
0.13	10.1	10.6 (37.1)
0.20	10.4	10.0 (36.0)
0.30	12.0	7.6 (27.1)

a) [MB]=5 μM, [DPF]=27.9 μM. b) Molar fraction of 1,1,2,2-tetrachloroethane.

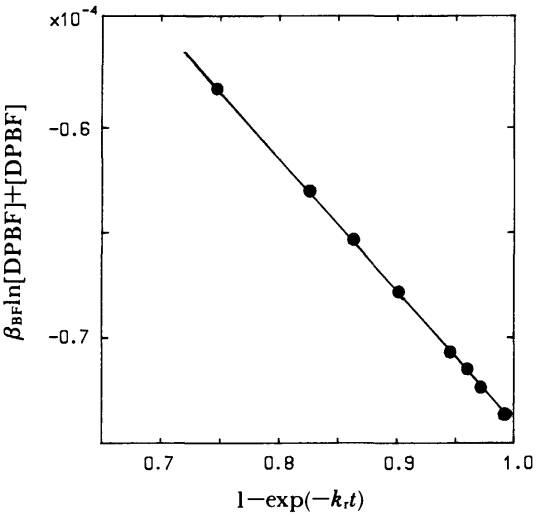

Fig. 3. Kinetic treatment for oxygenation of DPBF with $^1O_2$ regenerated by the thermal decomposition of $DPFO_2$ at 45 °C. (The values for k_r of 1.59×10^{-2} and for β_{BF} of 1.99×10^{-5} are used in Eq. 18.) [MB]: 5 μM; [DPF]: 68 μM; [DPBF]: 49 μM.

reacted with DPBF as is shown in Scheme 3. Provided that DPF and DBE were simultaneously produced from $DPFO_2$, the k_r value in Eq. 18 must be a sum of the rate constants of the formations of DPF and DBE. Putting the sum value into k_r, the plot in Fig. 3 is not expressed as a linear relationship. Thus, as is shown in Scheme 2, it may be supposed that the peroxide which leads to DPF and $^1O_2$ regeneration is not the same as that in the DBE formation.

The possibility of the direct reaction of DPBF with $DPFO_2$ might be considered instead of Eqs. 14—16:

$$DPFO_2 + DPBF \longrightarrow DPF + DPBFO_2 \quad (19)$$

However, the above reaction was obviated by the facts that the DPF recovery rate was not analyzed as exemplifying the second order kinetics in the case of DPBF addition, and that the reaction rate of DPBF becomes faster in the solvents mixed with the 1,1,2,2-tetrachloroethane or carbon tetrachloride, where the lifetime of $^1O_2$ is longer and where the reaction of Eq. 16 predominates.

Confirming that $^1O_2$ was regenerated as an equivalent molar with DPF, the molar ratio of the reacted DPBF against the recovered DPF was calculated under a higher concentration of DPBF (260 μM). The ratio was 0.65 at 20 °C, but became 0.99 at a temperature higher than 50 °C, where an equimolar production of DPF and $^1O_2$ was confirmed, as is shown in Scheme 3.

A detailed mechanism for the release of $^1O_2$ by the thermal decomposition of the endoperoxides of anthracene derivatives was discussed by Turro et al. They checked the temperature effect on the first-order rate constants, k_r for the recoveries of anthracence derivatives. From the analysis of the Eyring plots for the reaction rate, the activation enthropy, ΔS^*, and the activation enthalpy, ΔH^*, were calculated (k: Boltzmann's constant; h: Planck's constant):[24]

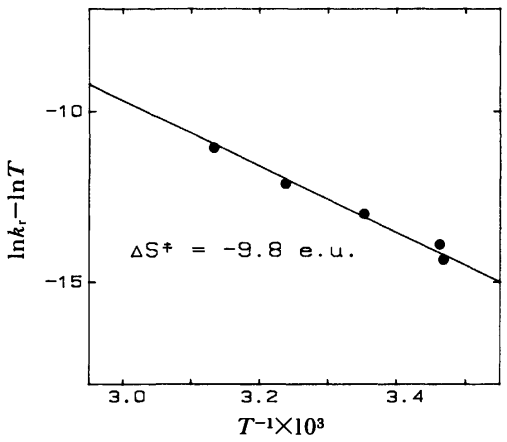

Fig. 4. Estimation of activation entropy for $^1O_2$ formation from $DPFO_2$ in acetonitrile. (Eyring plots) [MB]: 5 μM; [DPF]: 28 μM.

$$\ln k_r - \ln T = \ln(k/h) + (\Delta S^*/R) + (\Delta H^*/RT) \quad (20)$$

Since the ΔS^* values obtained for the endoperoxides of 1,4-dimethyl-9,10-diphenylanthracene and of 1,4-dimethoxy-9,10-diphenylanthracene were comparatively small(i.e., zero or negative), they reported that the $^1O_2$ production from these endoperoxide occurs in the manner of the concerted dissociation of the coupled C–O bonds. For such anthracene endoperoxides as 9,10-diphenylanthracene, which provided the positive values of ΔS^*, C–O bonds dissociate in a step-by-step fashion, and the peroxide radicals are produced. If the parallel spin-state is involved in the process of the positive ΔS^*, $^3O_2$ will be produced, and then the yield of $^1O_2$ will decrease.

In the present case of DPF formation, the kinetical results were similar to these for anthracene endoperoxides with a negative ΔS^*. The ΔS^* and ΔH^* values from the Eyring plots for the reaction were −9.8 e.u. and 18.9 kcal mol^{-1} respectively, as is shown in Fig. 4. According to Turro's model, it may be considered that the following concerted dissociation on $DPFO_2$ operates for the $^1O_2$ formation:

Quantum Efficiency for Single Oxygen Conversion. At higher concentrations of DPF, about 55 percent of the DPF was recovered and an equimolar amount of $^1O_2$ was regenerated at 50 °C in the dark. If significant reactions with regenerated $^1O_2$ occur successively, the recovery reaction can be utilized as a chemical storage of $^1O_2$ from the sensitization by the use of solar-light energy, since $DPFO_2$ is stable at a lower temperature-(<0 °C). In order to increase the efficiency of $^1O_2$-trapping and the conversion of light energy, the following conditions are required practically: (1) The initital concentration of DPF must be larger than the β value in order to trap the $^1O_2$ completely at the photochemical stage. (2) The sensitized reaction should be performed at a lower temperature (<0 °C) and with a higher light intensity to avoid the decomposition of the $DPFO_2$ produced during irradiation.

The conversion efficiency, γ, of $^1O_2$ reproduced in the dark can be defined as the ratio of the total amount of the $^1O_2$ reproduced, $[^1O_2]_\infty$, estimated by means of the amount of recovered DPF, to the total light quantities absorbed in the sample($I_{ab}t$), i.e., $\gamma=[^1O_2]_\infty/I_{ab}t$. In Table 3, the γ values which were obtained by the use of various sensitizers are listed at a constant DPF concentration (150 μM). Higher values were obtained for the sensitizers of MB and Th, which did not bleach durring the irradiation and which were usefully utilized at longer wavelengths. The lower values for xanthene dyes were obtained in spite of the large intersystem crossing probability. Although

a) [DPF]=150 μM. b) Absorption maximum of sensitizer. c) Quantum yield for $^1O_2$ formation. d) $\gamma=[^1O_2]/I_{ab}t$.

these results might be due to the quenching of the dye triplet by DPF, the detailed reason will be investigated in further works.

The Interaction of Pigment with Polystyrene Latex Particles Prepared Using an Amino-Acid-Type Amphoteric Emulsifier

Kazufumi KATO, Kouichiro KANDA, Harumi KONDO, Kunio ESUMI,* and Kenjiro MEGURO

Department of Applied Chemistry and Institute of Colloid and Interface Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received March 24, 1987)

An emulsion polymerization of styrene in the presence of an amino-acid type amphoteric emulsifier (N^{ε}-lauroyl-N^{α},N^{α}-dimethyllysine (DMLL)) was carried out at pH 7.0. The stability of mixed dispersions containing the latex particles prepared with DMLL and titanium dioxide (TiO_2) was then discussed as a function of the pH in a mixed dispersed solution. The zeta-potential of the synthesized latex particles was significantly dependent on the pH and showed the existence of an isoelectric point (IEP) at pH 4.5. On the other hand, TiO_2 particles had their IEP at pH 8.5. Below pH 4.5 and above pH 8.5, the mixed dispersions of the synthesized latex particles and TiO_2 particles were well-dispersed because of their electric repulsion. In the range of pH 4.5—8.5, where the latices were negatively charged, while the TiO_2 were positively charged, at low concentrations of the latex particles the mixed suspension was dispersed, but with an increase in the number of latex they heterocoagulated and were then redispersed at high concentrations of the latex particles. The mechanisms of these processes are discussed.

Latices are added to various pigments in order to achieve many industrial objectives, for example, increases in weatherability, storage stability, and pigment compatibility, and good resistance against alkaline reagents and water. Further, latices play two important roles as film formers and binders. Therefore, it has become a very important problem to study the interaction of pigments with latices.

There have been many reports on mixed dispersion systems containing latices and inorganic pigments by measuring the turbidity, the sedimentation velocity, the sedimentation volume, the viscosity, the particle size, and the surface potential.[1-7] In general, the surface charge of the latex particles prepared using a conventional anionic emulsifier is hardly dependent at all on the pH of their suspended solution, and they have a negative charge everywhere over the pH. On the other hand, normal pigments which are used for coating or painting are almost all dependent on the pH, since H^+ or OH^- acts as a potential determining ion. The pigment particles have a positive charge below the isoelectric point (IEP) and have a negative charge above the IEP. Therefore, in the pH range below the IEP, the mixed aqueous suspension of the latex particles and pigment particles is composed of a loose three-dimensional network structure with an electric force of attraction between the positively charged inorganic pigment and the negatively charged latex particles.

We have previously reported the surface properties of styrene latex prepared by emulsion polymerization in the presence of N^{ε}-lauroyl-N^{α},N^{α}-dimethyllysine (DMLL) as an amphoteric emulsifier, and have found that the latex particles exhibit characteristic properties: they change their surface potential with their pH, and they have an isoelectric point, since the ionic form of the DMLL molecules adsorbed onto the latex surfaces alters with the pH.[8] However, there have been only a few reports relating to the interaction of inorganic pigments with latices prepared by using amphoteric surfactants.

In this work, the effect of the addition of latex particles prepared with DMLL to inorganic pigments on mixed dispersion systems was investigated in respect with the pH of their suspended solutions.

Experimental

Materials. $C_{11}H_{23}CONH(CH_2)_4CH[N(CH_3)_2]COOH$ (DMLL) supplied by the Ajinomoto Co., Ltd., was purified by repeated recrystallization from mixture of hexane and 2-propanol (7:3) and then carefully dried in vacuo before use. The purity of the sample was confirmed by the absence of a minimum in its surface tension vs. concentration curve.

The styrene monomer (Wako Pure Industries, Ltd.) was distilled under a nitrogen atmosphere and was stored in a refrigerator under nitrogen. The potassium peroxodisulfate ($K_2S_2O_8$) used as an initiator was of an analytical grade, supplied by Wako Pure Industries, Ltd.

Titanium dioxide (TiO_2 (rutile)), with a surface treated by Al_2O_3 and supplied by Teikoku Kako Co., Ltd., was used. The characteristics of this pigment are indicated in Table 1. The specific surface area of the pigments was measured using a Shimadzu GAS CHROMATOGRAPH GC-7A connected with a Shimadzu SORPTOGRAPH ADS-1B and was determined by applying the BET theory to the nitrogen adsorption at the temperature of liquid nitrogen.

Table 1. Characteristics of TiO_2 Particles

Pigment	Density / g cm^{-3}	Particle size / nm	Specific surface area / m^2 g^{-1}
TiO_2 (rutile)	4.2	326.8	19.1

Procedure. An isoelectric region of the DMLL solution has been determined using the method described in a previous paper.[8]

Preparation of Latex Particles. The emulsion polymerization was performed in a one-liter glass reactor, fitted with a metal screw and a thermometer. The emulsion polymerization recipe is shown in Table 2. First, water and emulsifier (DMLL) were added to the reactor at room temperature, and then styrene monomer was added to them. The reaction flask was immersed in a constant-temperature bath adjusted to 60±1 °C under a nitrogen atmosphere, and the mixture was stirred at 250 rpm. After the temperature had risen to 60 °C, an aqueous solution of $K_2S_2O_8$ (0.1 g/50 cm^3) was added to the contents of the reactor, resulting in the final initiator concentration (0.1 g/300 g of the mixture). The polymerization time was taken as 3 h. The particle diameter of the synthesized latex particles was determined by means of Transmission Electron Microscopy and by the use of a particle sizer. The molecular weight distribution of polystyrene in the latices was determined by use of a GPC. The number of latex particles per cubic decimeter of the aqueous solution (N) was calculated by means of the particle size and the conversion, which was estimated by means of the (polystyrene latex/styrene monomer) ratio.

Interaction of Pigment with the Latex. The mixed systems of polystyrene latex and TiO_2 were prepared by the following method: First, a known weight of TiO_2 was put into 27 cm^3 of a 10^{-3} mol dm^{-3} sodium chloride aqueous solution in a sedimentation tube. This suspension was dispersed by the use of supersonic waves for an hour, and then 3 cm^3 of a styrene latex suspension was added to it. The mixed suspensions were adjusted to various pH values. After 48 h of standing, the turbidity of the suspension collected from the top portion of the sedimentation tube was measured with a turbidimeter (SEP-PT 501, Nippon Precision Optical Instrument Co., Ltd.).

The zeta-potentials (Zp) of the latex particles and TiO_2 were measured at 25 °C by means of an electrophoresis apparatus [Laser Zee TM Model-500 (PEN-KEM, Inc.)]. The amounts of latex particles adsorbed onto the surface of the TiO_2 particles were determined by means of the difference between the weight of the latices before and after the adsorption.

All of the suspensions for measuring the particle size, the electrophoresis, and the turbidity were prepared with a 10^{-3} mol dm^{-3} sodium chloride aqueous solution in order to keep the ionic strength as constant as possible. The pH of the suspension was adjusted by the addition of sodium hydroxide or hydrochloric acid.

Table 2. Emulsion Polymerization Recipe

Ingredient	Gram
Styrene	50
Water	250
Potassium peroxodisulfate	0.2
N^{ϵ}-Lauroyl-N^{α},N^{α}-dimethyllysine(DMLL)	6.0

Results and Discussion

Characterization of DMLL. DMLL has both acidic and basic groups in the same molecule, and can change its ionic form depending on the pH value of its aqueous solution. DMLL aqueous solutions have a wide isoelectric region ranging from pH 4 to 9: the cationic structure predominates below pH 4, and the zwitterionic one occurs in the range of pH 4—9, whereas the anionic one exists mainly above pH 9.[8-11]

Characterization of the Latex. In the emulsion polymerization of styrene in the presence of DMLL at pH 7.0, it was confirmed that the final latices were stable. The number-average particle diameter (D_n) and its polydispersity (D_w/D_n), as measured by Transmission Electron Microscopy, the z-average particle diameter (D_z) and its polydispersity (Q fac.), as measured by a particle sizer, and the weight-average molecular weight (M_w) and the distribution of the synthesized latex (M_w/M_n) are summarized in Table 3. From the two polydispersities, which give an indication of the breadth of the particle size distributions, it can be seen that the particle size of latex formed with DMLL has a relatively narrow distribution and that the latex consists of rather monodispersed microspheres.

Zeta-Potentials of the Latex and TiO_2. The

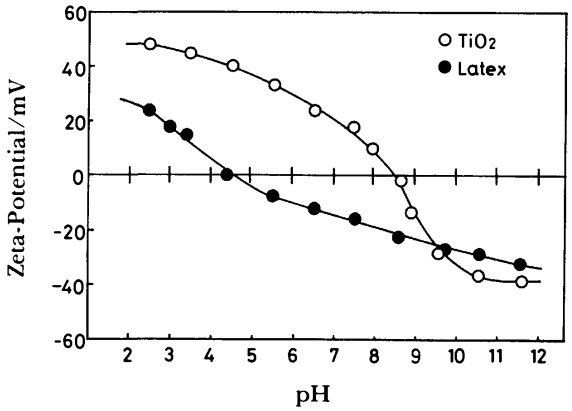

Fig. 1 The change in zeta-potentials of latex particles synthesized with DMLL and TiO_2 particles.

Table 3. Characteristics of the Latex Particles Prepared in a DMLL Solution

1.94		5.24	

change in the zeta-potentials of the latex particles and TiO_2 as a function of the pH is shown in Fig. 1. All the curves had an extended S shape, and the zeta-potentials were largely dependent on the pH.

The latex particles had an isoelectric point (IEP) at pH 4.5. They were positively charged below IEP, while they were negatively charged above it. This variation in the zeta-potential of the latex particles with the change in the pH of the solution is attributable to DMLL molecules adsorbing onto the surface of the latex particles.

TiO_2 had a positive charge below pH 8.5, and its zeta-potential became negative with an increase in the pH. TiO_2 had an isoelectric point at pH 8.5.[12]

The Mixed System of Polystyrene Latex and TiO_2. The change in the turbidity of the mixed suspension with the particle number (N) of the latices at a constant pH (3.0, 5.0, 11.0) is shown in Fig. 2. Here, the amount of TiO_2 added was 10.0 mg. In this figure, a high turbidity means a good titania dispersion and a low one for flocculation. On the measurement of the turbidity, TiO_2 particles were clearly detected, but hardly any latex particles were detected.

At pH 3.0, the turbidity even slightly increased upon the addition of a number of the latex particles, indicating that the mixture of TiO_2 and the latex particles is well-dispersed throughout the range of the number of latex particles (N). At pH 11.0, since the turbidity was constant throughout the range of N values, the mixed suspension was also well-dispersed.

Figure 3 shows the zeta-potentials of TiO_2 particles in the mixed suspension as a function of the N. At pH 2.5 and 3.0, Zp was constantly positive. At pH 10.0 and 11.0, Zp was constantly negative. Since the latex particles and TiO_2 particles are both positively charged below pH 4.5, the good dispersion of their mixed suspension occurs by means of the positive mutual electric repulsion between hetero particles.[13-15] Similarly, above pH 8.5 it is understood that the mixtures are well-dispersed as a result of the mutual electric repulsion between these negatively charged particles.

At pH 5.0, as may be found from Fig. 2, at a low concentration of the latex particles the mixed suspensions are in the dispersed state, but with an increase in the number of latices they are heterocoagulated until they redisperse at a high concentration of the latex particles. At this pH, the polystyrene latex particles have a negative charge, while TiO_2 particles are positively charged.

In order to evaluate in more detail the interaction between the latex and TiO_2 with a different charge, the changes in the turbidity of the mixed suspension with N were measured at the constant pH values of 5.0, 6.0, and 7.0: These results are also shown in Fig. 2. At these pH values (pH 5.0, 6.0, and 7.0), the flocculation and the redispersion of the mixed suspensions were also observed. In the pH range of 4.5—8.5, the mixed aqueous suspensions of the latex particles and pigment particles were composed of a loose three-dimensional network structure. It may be found from Fig. 3 that the particle number of the latex at which the flocculation occurs shifts toward lower numbers of latex particles (N) with an increase in the pH.

The changes in the zeta-potential of the mixed suspension at a constant pH (5.0, 6.0, 7.0) with log N are shown in Fig. 4. The zeta-potential of TiO_2 altered from positive to negative with the increase in N and showed a zero point of charge. The particle number of the latex (N) at the zero point of the charge shifted toward a lower N with an increase in the pH. It was confirmed that the particle number of the latex at the zero point of charge was in good agreement with that at the flocculation of the mixed suspension.

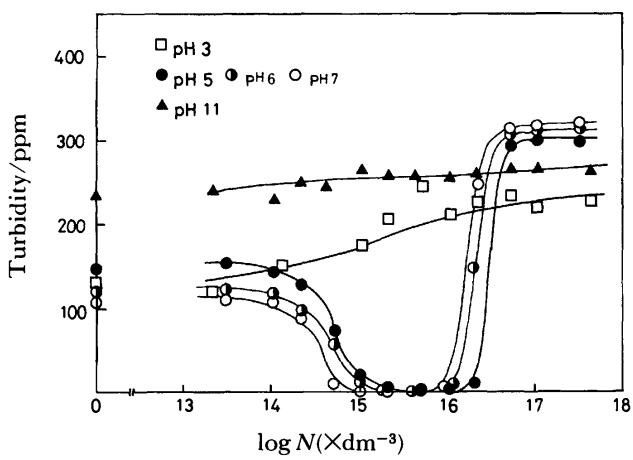

Fig. 2. The change in turbidities of mixed suspensions of latex particles and TiO_2 particles with number of latex particles added at various pH.

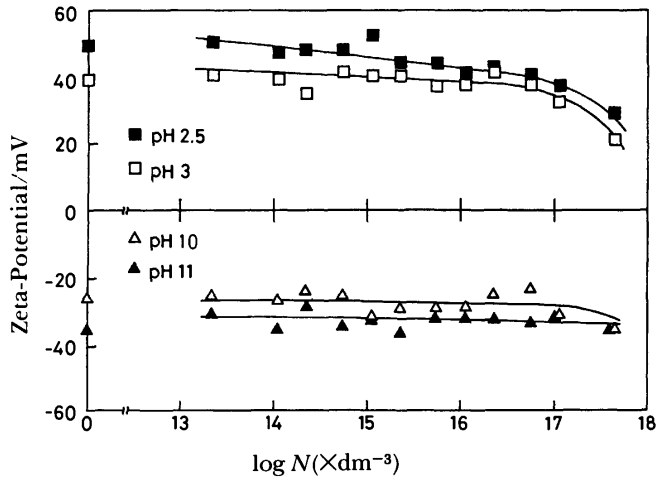

Fig. 3 The change in zeta-potentials of mixed suspension with number of latex particles added at pH 2.5, 3.0, 10.0, 11.0.

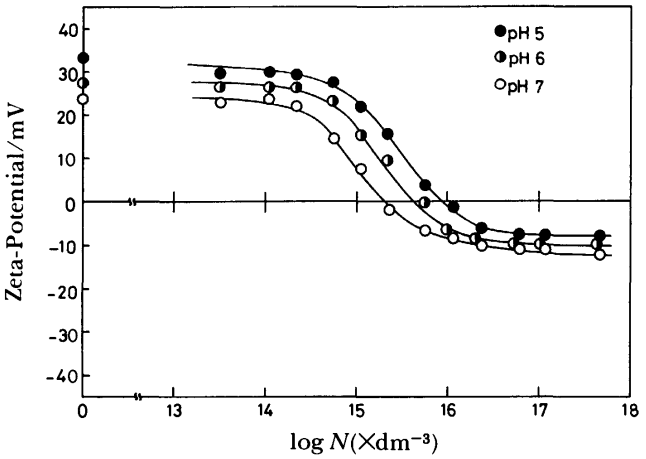

Fig. 4. The change in zeta-potentials of mixed suspensions with number of latex particles added at pH 5.0, 6.0, 7.0.

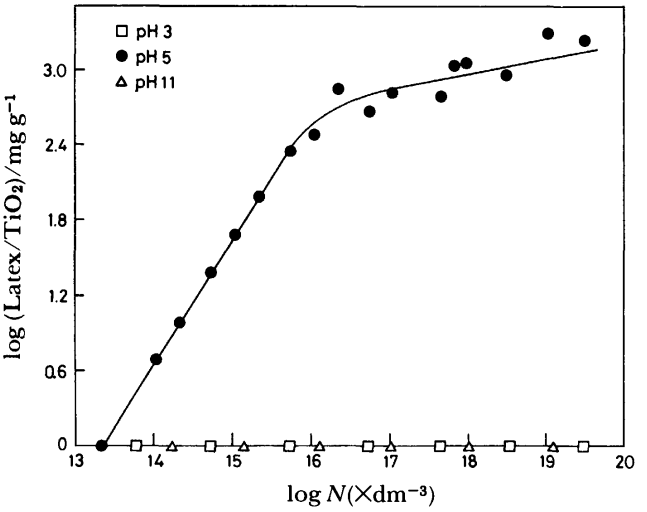

Fig. 5. The amount of latices adsorbed on surface of TiO_2 particles at various pH of suspended solution at 25 °C.

Figure 5 shows the amount of latices adsorbed onto the surface of TiO_2 particles. At pH 3 and 11 of the mixed suspended solutions, hardly any latex particles adsorbed onto TiO_2. This was because of the electric repulsion between the latex particles and the TiO_2 particles. On the other hand, at pH 5 the amounts of latices adsorbed increased in proportion to the number of latex particles added until they were approximately constant. These results indicate that the latex particles surely adsorb onto the surface of TiO_2 particles in the range of the opposite charge between these particles.

Accordingly, the flocculation and the redispersion phenomena in the mixed suspension can be explained by the adsorption of the latex particles onto the TiO_2 particles. A model for the mechanism of these phenomena is shown in Fig. 6:

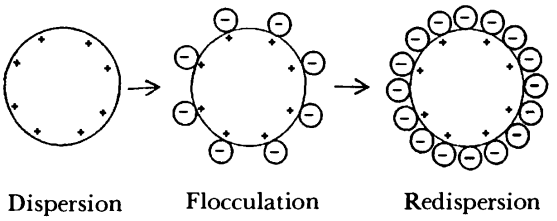

Fig. 6. A model for mechanism of flocculation and redispersion.

(a) At the initial state, without the addition of any latex, TiO_2 particles disperse in the aqueous solution because of the electric repulsion of their own surface's negative charge.

(b) With an increase in the number of the latex particles which have a negative charge, the latex particles are adsorbing on the TiO_2 particles which have a positive charge, and the zeta-potential of the TiO_2 particles covered with latex particles alters from positive to zero. As a result, the flocculation of the mixed suspension occurs at a point of zero charge of the mixed suspension, a result mainly of the electric force of attraction. The results are also supported by the good agreement between the number of latex particles (N) at flocculation (shown in Fig. 2) and that at the point of zero charge of the mixed suspension (shown in Fig. 4).

(c) At a high concentration of the latex particles, as more of the latex particles adsorb on TiO_2, the mixed suspension redisperses, a result of the electric repulsion among latices which have a negative charge. As a result, the TiO_2 particles have a negative charge in the redispersed state. These results are supported by the agreement between the values of the zeta-potential of the single latex and that of the zeta-potential of TiO_2 in the redispersed state (pH 5.0, 6.0, and 7.0).

Furthermore, with an increase in the pH from 5 to 7, since the negative charge of the latex particles increases and the positive charge of TiO_2 particles decreases, the particle number of the latex (N) required for the flocculation of the TiO_2 particles is shifted to a low concentration with the pH.

A Stopped-Flow Kinetic Study on the Binding of Phenylbutazone to Human Serum Albumin Using Absorption and Circular Dichroism Techniques

Kiyofumi MURAKAMI, Yasuo FUJISAKI, and Takayuki SANO*,†
Department of Chemistry, Faculty of Science, Yamaguchi University, Yoshida 1677-1, Yamaguchi 753
†Department of Materials Science, Faculty of Science, Hiroshima University, Higashisenda-Machi, Hiroshima 730
(Received April 3, 1987)

The mechanism of the binding of phenylbutazone(4-butyl-1,2-diphenyl-3,5-pyrazolidinedione) to human serum albumin has been investigated by kinetic experiments using both optical absorption and circular dichroism (CD) stopped-flow methods. Three distinct processes were found to exist by the absorption technique; one of these was within the dead time of the apparatus and other two slow processes were at around 10^{-2} and 1 s, of which the relaxation times were determined. On the other hand, only two processes, which correspond in time range to the first and third processes seen by optical absorption, were found using CD technique. By examining the concentration dependence of the reciprocal relaxation time of each process and by taking account of the binding isotherm, a binding mechanism has been proposed. According to the elucidated reaction scheme, successive binding of two molecules of phenylbutazone is followed by a conformational change which destabilizes one of the bound species. The detailed nature is discussed in the light of the circular dichroism change of each process.

The anti-inflammatry agent phenylbutazone has a high affinity for albumin, and is present predominantly in the bound state in serum.[1] Therefore, the binding of phenylbutazone to albumin plays an important role in the activity, metabolism and excretion of this agent in the body. In connection with these physiological significances, the binding characteristics have been investigated by many static methods such as equilibrium dialysis,[2] spectrophotometric titration,[3] fluorescence titration,[3,4] circular dichroism (CD) titration,[2,5] and spin labeling.[6] From these studies, it has been suggested that hydrophobic interactions play an important role in the binding of phenylbutazone to albumin. Furthermore, from the view point of pharmacology, competitive or cooperative binding of phenylbutazone, fatty acids and other drugs with albumin have also been studied.[7-9]

In contrast to the large amount of static information available, there has been no kinetic study on phenylbutazone binding to albumin, which is necessary in order to gain a profound understanding of these interesting phenomena.

In the present study, the binding mechanism between phenylbutazone and human serum albumin was investigated by the stopped-flow method using absorption as well as CD detection in order to obtain a detailed picture of the binding mechanism from different optical properties.

Experimental

Materials. Human serum albumin (HSA, essentially fatty acid free: less than 0.005%) was purchased from Sigma Chemical Company, and used without further purification. The molar concentration of the protein was determined by spectrophotometrically[10] Phenylbutazone(4-butyl-1,2-diphenyl-3,5-pyrazolidinedione) was also purchased from Sigma Chemical Company. A stock solution was prepared by dissolving the agent in a small quantity of 0.1 M†† NaOH solution, and then mixing with a 0.1 M phosphate buffer of pH=7.4. The concentration of phenylbutazone was determined using the molar extinction coefficient $\varepsilon_{267}=2.0\times10^4\ \mathrm{cm^{-1}\,M^{-1}}$.[3] The concentration of HSA was 3×10^{-5} M for all measurements. (In the stopped flow experiments, this concentration corresponds to the final one).

Equilibrium Dialysis. An Oxford type dialysis cell made of acryl resin was used. The volume of each compartment was 4.5 ml and it was separated by a semipermeable cellulose membrane, purchased from Visking Company. The contact area was 9.6 $\mathrm{cm^2}$. One compartment was filled with HSA solution, and the other with phenylbutazone solution. The cell was continuously rotated at 15 rpm in thermostated water at 20 °C. After 36 h, the concentration of the phenylbutazone solution was measured spectrophotometrically.

Apparatus. The absorption and CD spectra were measured with a spectrophotometer (Union Giken SM 401) and a dichrograph (Jobin-Yvon Mark III-J), respectively. The kinetic measurements were carried out using a stopped-flow apparatus (Union Giken RA 401 and RA 1100) of which dead time is 3 ms. The CD detection in the stopped experiments has been performed by combining the stopped flow apparatus with the CD spectrometer.[11] All the measurements were carried out at 20±1.2 °C.

Results and Discussion

Kinetic Data. The binding of phenylbutazone to HSA generates positive change in absorbance and CD around 285 nm;[2,5] which are, respectively, considered to be due to hydrophobic environment around phenyl

†† 1 M=1 mol $\mathrm{dm^{-3}}$.

rings of phenylbutazone at the binding site[2] and perturbation of the carbonyl chromophore of the drug by an asymmetrical locus at the site.[2,5] The present measurements were performed at 285 nm and results were similar to those in literature.[2,5]

Two distinct reaction processes were observed by optical absorption detection; typical time courses of them are shown in Fig. 1. By comparing the magnitude of the corresponding absorbance change after the dead time with that found under static conditions, another very rapid process was found to be exist within the dead time of the apparatus. In all, three phases of the kinetic processes were accompanied by a decrease in transmittance. These processes were named, in increasing order of relaxation time (τ), as the first (unobserved one within the dead time; $\tau_1<3$ ms), the second ($\tau_2\approx10$ ms) and the third ($\tau_3\approx1$ s) process. In the case of CD detection, however, only one process with a negative CD change was observed (Fig. 2). This process corresponds in time to the third one observed by absorption detection. But no relaxation corresponding to the second process was observed even by accumulating 1000 sets of data. Instead, another very rapid process with a "large positive" CD change was found to exist also within the dead time by the similar method as in the absorption detection experiments. From these observations, it can be seen that in the absorbtion detection, three kinetic processes comparably contribute to the static absorption change, but in the CD detection the unobservable first process within the dead time of apparatus dominates the static CD

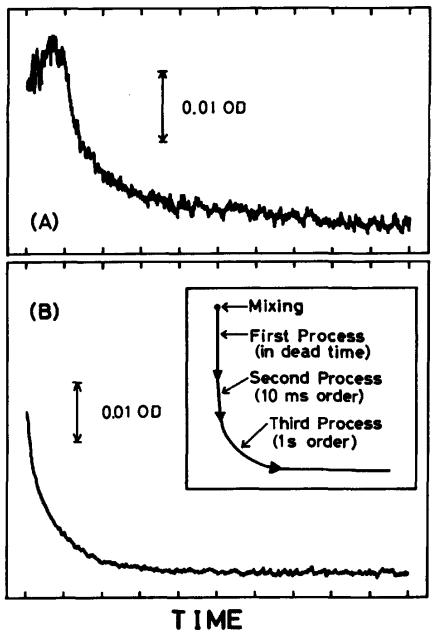

Fig. 1. Typical traces of the transmittance change at 285 nm after the mixing of phenylbutazone (1.5×10^{-5} M) and HSA (6×10^{-5} M). (A) 40 ms/div., (B) 4 s/div. The insert shows a schematic illustration of the relative scale of the transmittance change due to each process.

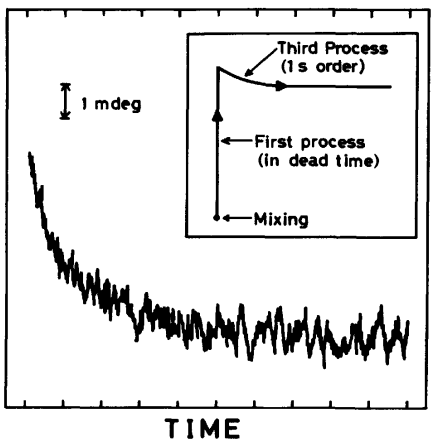

Fig. 2. A typical trace of the CD change at 285 nm after the mixing of phenylbutazone (1.5×10^{-5} M) and HSA (6×10^{-5} M). The horizontal scale is 4 s/div. The data was obtained by averaging over 40 experiments. The insert represents a schematic illustration of the relative CD change due to each process.

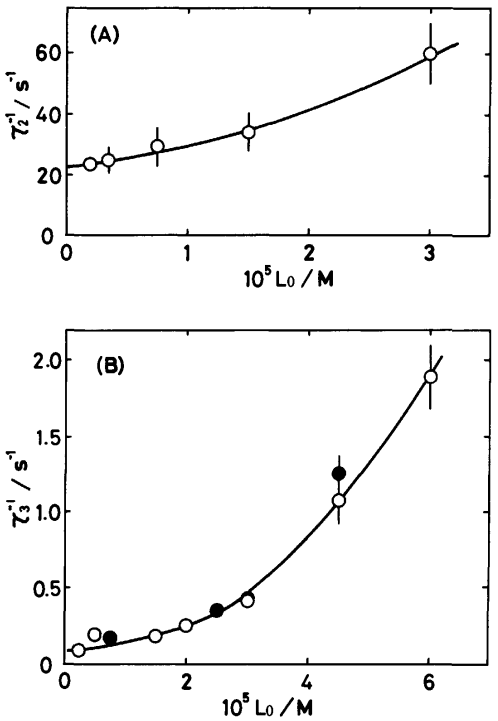

Fig. 3. The total ligand concentration (L_0) dependence of the reciprocal relaxation times of the second and third processes. (A) The second process, and (B) the third processes. (○): Determined from the change in transmittance, (●): determined from the change in CD. The solid lines are drawn to emphasize the tendencies.

change. The inserts in Figs. 1 and 2 show schematic illustrations of the relative size of the transmittance and CD changes due to these processes. The ligand concentration dependence of τ for the second and third processes is shown in Fig. 3. As can be seen in Fig. 3(B), the relaxation times of the third process obtained by the absorption and CD measurements agree well with each other.

The Binding Isotherm. A plot of $\nu/[L]$ versus ν, according to the conventional Scatchard equation; $\nu/[L]=K(n-\nu)$ where ν is the moles of ligand bound per mole of macromolecule, [L] the concentration of free ligand, K the binding constant and n the number of binding site, provides information about binding ability of the macromolecules.[12] A Scatchard plot for the present system was curved (Fig. 4), indicating that there are at least two kinds of binding site. On the conventional assumption that these binding sites are independent of each other and have an integral number of binding sites, a least squares fit analysis according to next equation; $\nu/[L]=\sum K_i(n_i-\nu_i)$ yields the binding parameters: $n_1=1$, $K_1=1.7\times10^6\ M^{-1}$, $n_2=3$, and $K_2=2.0\times10^4\ M^{-1}$, where the subscripts 1 and 2 refer to the primary and secondary binding sites. The values of the binding parameters given in the literature[2-4] differ from each other depending on the method and conditions used to obtain them. The present results are compatible with those obtained by Chignell and Starkweather[2] except for a somewhat larger value of K_1 for the present case, which is probably due to a difference in temperature and/or fatty acid content of the sample.

Analyses of the Kinetic Data. (i) The First and Second Processes: In the analyses of the stopped flow data, each kinetic process must be analyzed in increasing order of time range of the observed process because the law of mass conservation is hold at each step. Here, the second process will be analyzed taking into consideration the unobserved first process in the dead time of apparatus. For the present analysis, considering the existence of at least two kinds of binding site as suggested from the Scatchard plot, analyses were limited to models which involve more than one binding step. The following three models were examined,

$$\text{Model 1:}\quad \mathrm{L + P} \underset{\text{first}}{\overset{K_1}{\rightleftharpoons}} \mathrm{C_1} \underset{k_{-2}\ \text{second}}{\overset{K_2\ k_2}{\rightleftharpoons}} \mathrm{C_2} \qquad (1)$$

$$\mathrm{L + P'} \underset{\text{first}}{\overset{K_1'}{\rightleftharpoons}} \mathrm{C_1'}$$

where L, P, and $C_i(i=1,2)$ denote free ligand, free primary binding site and complex species, respectively, and K_i, k_i and k_{-i} are the equilibrium constant, the forward and backward rate constant of the i-th step, respectively, and superscript "′" denotes the reaction on the secondary binding site of HSA. This mechanism implies the fast competitive binding of phenylbutazone to the primary and secondary sites as the first process within the dead time of apparatus and the conformational change of the complex on the primary site as the second process. Further, this model satisfies the independency of binding sites adopted in the conventional analysis of binding isotherm.

$$\text{Model 2:}\quad \mathrm{L + P} \underset{\text{first}}{\overset{K_1}{\rightleftharpoons}} \mathrm{C_1} \underset{k_{-2}\ \text{second}}{\overset{K_2\ k_2}{\rightleftharpoons}} \mathrm{C_2} \overset{\mathrm{L}\ K_3}{\longrightarrow}_{\text{very fast}} \mathrm{C_3} \qquad (2)$$

This is a cooperative binding mechanism in which a conformational change of the first complex induces a new binding site for phenylbutazone. The third step of above scheme is not observable because of the very fast establishment of its equilibrium.

$$\text{Model 3:}\quad \mathrm{L + P} \underset{\text{first}}{\overset{K_1}{\rightleftharpoons}} \mathrm{C_1} \overset{\mathrm{L}\ K_2\ k_2}{\rightleftharpoons}_{k_{-2}\ \text{second}} \mathrm{C_2} \qquad (3)$$

This is also a cooperative binding mechanism, but without any step of conformational change. In each of Eqs. 1—3, the second step is regarded as the observed second process. Of these models, the former two models (Model 1 and Model 2) gave the minus value for the rate constant k_{-2}, and only Model 3 was found to give acceptable results. Under the condition of rapid formation of C_1, reciprocal relaxation time of the second step in Eq. 3 can be expressed by

$$\tau_2^{-1} = k_2\frac{K_1[L]([L]+4[P]+K_1[L][P])}{1+K_1([L]+[P])} + k_{-2} \qquad (4)$$

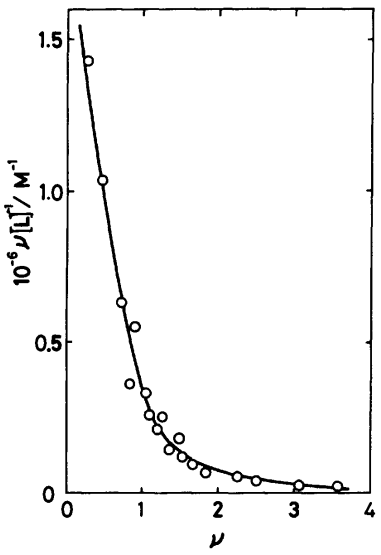

Fig. 4. The binding isotherm obtained from the equilibrium dialysis(O) and its comparison with that reconstructed from the values of the parameters associated with Model 7 (——) (see text).

where [L] and [P] are the concentration of free ligand and free binding site, respectively. This equation shows linear dependence of τ_2^{-1} on $\{K_1[L]([L]+4[P]+K_1[L][P])\}/\{1+K_1([L]+[P])\}$. [L] and [P] can be calculated by assuming values for K_1 and K_2. The plot of τ_2^{-1} versus the concentration term in Eq. 4 provides k_2 and k_{-2} as the slope and the intercept, respectively. With the guidance of linearity of the plot and self-consistent relation between parameters, the model was examined for many different values of K_1 and K_2. Figure 5 shows the plot for $K_1=(1.2\pm0.4)\times10^6\ M^{-1}$, and $K_2=(1.8\pm0.6)\times10^5\ M^{-1}$. The rate constants were determined as $k_2=(4.3\pm1.1)\times10^6\ M^{-1}$ and $k_{-2}=(23\pm6)\ s^{-1}$. The high degree of linearity suggests that Model 3 may be applied to the first and second processes. The fact that Model 1 could not satisfied the kinetic data, gives rise to question on the conventional assumption of independency of binding site which has been adopted in the binding isotherm analysis.

(ii) The Third Process: For the third process, the following models incorporated with the above Model 3 satisfing the first and second processes were examined.

Model 4:

$$L + P \underset{}{\overset{K_1}{\rightleftharpoons}} C_1 \overset{L,\ K_2}{\rightleftharpoons} C_2 \underset{k_{-3}}{\overset{K_3,\ k_3}{\rightleftharpoons}} C_3 \quad (5)$$

first second third

Model 5:

$$L + P \underset{}{\overset{K_1}{\rightleftharpoons}} C_1 \overset{L,\ K_2}{\rightleftharpoons} C_2 \overset{L,\ K_3}{\underset{k_{-3}}{\rightleftharpoons}} C_3 \quad (6)$$

first second third

Model 6:

$$L + P \overset{K_1}{\rightleftharpoons} C_1 \overset{L,\ K_2}{\rightleftharpoons} C_2 \underset{k_{-3}}{\overset{K_3,\ k_3}{\rightleftharpoons}} C_3 \overset{L,\ K_4}{\rightleftharpoons} C_4 \quad (7)$$

first second third very fast

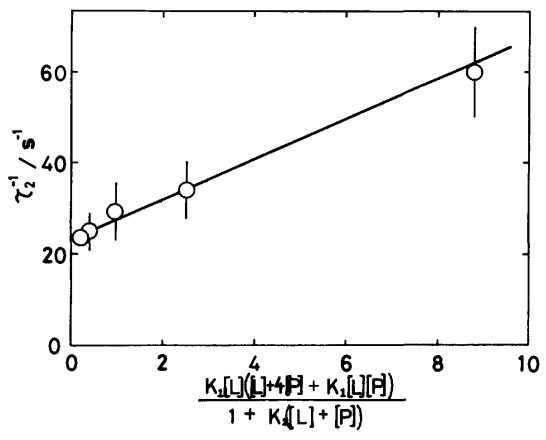

Fig. 5. Plot of τ_2^{-1} versus $K_1[L]([L]+4[P]+K_1[L][P])/(1+K_1([L]+[P]))$ for Model 3. The values on the horizontal axis were calculated using the values of the parameters cited in the text.

Model 7:

$$L + P \overset{K_1}{\rightleftharpoons} C_1 \overset{L,\ K_2}{\rightleftharpoons} C_2 \overset{K_3,\ k_3}{\underset{k_{-3}}{\rightleftharpoons}} C_3 \overset{L,\ K_4}{\rightleftharpoons} C_4 \quad (8)$$

first second third very fast

In these models, the each of third steps implies i) a conformational change of the second complex C_2 (Model 4), ii) further ligand binding to the complex C_2 (Model 5), iii) a conformational change of the complex C_2 which induces further ligand binding (Model 6), and iv) a conformational change of C_2 by which a ligand is released from the complex (Model 7). Using the values of K_1 and K_2 determined from the analysis of the second process, for each model, the concentration dependence of the reciprocal relaxation time of the third process τ_3^{-1} was examined using many sets of values of K_3 and K_4. Of these models, the first three failed from the view points of (i) the linear relationship between the observed τ_3^{-1} and the concentration dependent factor in its theoretical expression and (ii) the self-consistent relationship between the parameters. Finally, it was found that Model 7 is the only possible model for the present system. If the forth binding process in the model is very rapid, the reciprocal relaxation time for the third step in Model 7 can be expressed as

$$\tau_3^{-1} = k_3E + k_{-3}F = k_{-3}(K_3E+F) \quad (9)$$

where

$$E = (K_1K_2[L](1+K_4[L](1+K_4[L](2+K_1[L]))([L]+4[P]+K_1[L][P])+K_1K_2[L]^2(1+K_1([L]+[P])+K_1K_2K_3[L][P](2+K_1[L]))/((1+K_1[L])((1+K_4([L]+[P])+K_1K_2[L]([L]+4[P]+K_1[L][P]))+K_1K_2K_3[L][P](1+K_1[L]+K_1K_2[L]^2)),$$

$$F = (K_4[L](1+K_1([L]+[P])+K_1K_2[L]([L]+4[P]+K_1[L][P]))+K_1K_2K_3[L][P](K_1K_2[L]^2-1))/((1+K_4[L])(1+K_4[L])(1+K_1+K_1([L]+[P])+K_1K_2[L]([L]+4[P]+K_1[L][P]))+K_1K_2K_3[L][P](1+K_1[L]+K_1K_2[L]^2)).$$

Here, K_4 is defined as the association constant: $K_4=[C_3]/[L]\cdot[C_4]$. Equation 9 shows that a plot of τ_3^{-1} versus K_3E+F must be a straight line which goes through the origin, the slope of which provides the value of k_{-3}.[13] Since the linear dependency has been satisfied for some set of K_3 and K_4, all the parameters are determined so as to satisfy both the kinetic and static experimental data. The results are shown in Figs. 4 and 6. These figures demonstrate that Model 7 is full expression applicable to the present system from a kinetic and static point of view. The values of the parameters were evaluated as $K_3=(1.3\pm0.4)$, $k_3=(4.3\pm1.3)\ s^{-1}$, $k_{-3}=(14\pm4)\ s^{-1}$, and $K_4=(1.0\pm0.3)\times10^5\ M^{-1}$. These values and those associated with the

faster processes are summarized in Table 1. From the persent analysis of the kinetic data as well as the static one, it was clarified that the binding of phenylbutazone to HSA is cooperative binding but not the isolated binding which has been reported so far on the basis of only the static experiments.

The Binding Mechanism. From the location of the ellipticity band (287 nm), the CD change for the present system has been interpreted by asymmetrically perturbed carbonyl chromophore of phenylbutazone at the binding site.[2,5] The large positive CD change associated with the first process suggests that phenylbutazone in C_1 is already in highly asymmetrical enviroment. The binding of the secondary ligand to C_1 without any distinct conformational change suggests that the primarily bound phenylbutazone together with its environment may form a site advantageous for the secondary binding. The failure to detect any CD change associated with the second process seems to show that the secondarily bound phenylbutazone exists in a symmetrical environment. The complex C_2 thus formed, then, is converted into C_3 by rearranging of the bound ligands showing small negative CD change and thereby destabilizing one of the two bound states.

In general, and extrinsic Cotton effect reflects the state of an asymmetrically perturbed chromophore. Particularly, a close and rigid contact with an asymmetric center, which exerts an electrostatic force on the chromophore, is effective.[2,14] For the present system, the complex, C_1, which has a predominant contribution to the static CD change, may be formed by such an electrostatic interaction as well as a hydrophobic interaction.[2,3] The relatively large value of K_1 ($1.2\times10^6\ M^{-1}$) could be realized by such a dual nature of interaction.

In recent years, the extrinsic Cotton effect has frequently been used in studies of ligand binding properties of albumin.[16-22] Sometimes, a binding isotherm constructed from the CD data has been compared with that obtained from other methods.[20,21] In some cases, a relatively good agreement has been obtained through the crude assumption that all bound species give the same Cotton effect. At other times, drug interactions with albumin molecule have also been investigated using the extrinsic Cotton effect.[17,21] However, as shown by the present study as well as the kinetic studies which have been performed previously[15,23-27], the mechanism of binding between albumin and ligand is not simple but complicated involving several conformational changes. Hence, it should be noted that a deep understanding of the mechanism of complex phenomena such as drug interactions with albumin is difficult without intensive works. In this connection, kinetic studies like the present one may provide important information. Especially, the use of CD may be informative about the bound states of ligands.

The authors wish to express their thanks to Professor Tatsuya Yasunaga of Kinki University for his helpful discussions. This work was partly supported by Grant-in-Aid for Science Research (No. 6078029) from the Ministry of Education, Science and Culture.

Peroxy Acid Oxidations. I. A Kinetic and Mechanistic Study of Oxidation of Acetylacetone by Peroxomonophosphoric Acid and Hydrogen Peroxide in Alkaline Medium

Chakrapani P. PATNAIK, Surendra Nath MOHAPATRO, Akhil Krishna PANIGRAHI, and Radhasyam S. PANDA*
Department of Chemistry, Khallikote College, Berhampur 760 001, Orissa, India
(Received December 17, 1985)

The kinetics of oxidation of acetylacetone by peroxomonophosphoric acid and hydrogen peroxide have been investigated in the pH range 8—13.7. The oxidations by peroxomonophosphoric acid at 308 K and I= 0.6 mol dm^{-3} follow the rate expressions,

$$\text{(i)}\quad -\frac{d[PMPA]_T}{dt} = \{k_1[A]+k_2[A^-]\}[HPO_5^{2-}]$$

in the pH range 8—10.63, where k_1=1.96 dm^3 mol^{-1} s^{-1} and k_2=0.177 dm^3 mol^{-1} s^{-1}, and

$$\text{(ii)}\quad -\frac{d[PMPA]_T}{dt} = \{k_3[A]+k_4[A^-]\}[HPO_5^{2-}]+\{k_5[A]+k_6[A^-]\}[PO_5^{3-}]$$

in the pH range 11.5—13.7, where k_3=30.4 dm^3 mol^{-1} s^{-1} and $k_6\approx 0$. The rate law for hydrogen peroxide oxidations in the pH range 9.2—13 at 308 K and I=0.1 mol dm^{-3} is given by,

$$-\frac{d[\text{Hydrogen peroxide}]_T}{dt} = \{k_7[A]+k_8[A^-]\}[H_2O_2]+\{k_9[A]+k_{10}[A^-]\}[HO_2^-]$$

the k_7 and k_{10} values being 0.393 dm^3 mol^{-1} s^{-1} and 0.143×10^{-2} dm^3 mol^{-1} s^{-1} respectively. A and A$^-$ represent the diketo and enol form of acetylacetone respectively. The kinetic data and activation parameters are consistent with nucleophilic attack by peroxo species on both diketo and enol form of acetylacetone followed by oxygen-oxygen bond fission.

Studies[1-4] on oxidation of β-diketones by various peroxy compounds, e.g. peroxy acetic acid, peroxy benzoic acid and diperoxy phthalic acid have shown that enolizable β-dicarbonyl compound first reacted with the peroxy acid forming α-hydroxy diketone which on further reaction with peroxy acid or on hydrolytic cleavage afforded the observed products. Epoxidation of the enol form of the diketone was considered to be the reasonable path for the formation of hydroxy ketone.

Payne examined[5] oxidation of a series of β-diketones with hydrogen peroxide in t-butyl alcohol in presence of a mineral acid catalyst and reported that the reaction involved the formation of an intermediate cyclic peroxide which underwent acid-catalyzed decomposition to yield products.

The oxidation of β-diketones ($R^1CO\cdot CR^2R^3COR^4$) with alkaline hydrogen peroxide[6] afforded two types of carboxylic acids depending upon the nature of R^2 and R^3. The unsubstituted β-diketone (in which both R^2 and R^3 are H) suffered an oxidative cleavage producing formic acid (from the central carbon atom) and the acid corresponding to the acyl group involved. The 2-monosubstituted 1,3-diketones underwent two types of reactions (i) an oxidative rearrangement involving migration of R^1 or R^4 from C_1 or C_3 to C_2, yielding the corresponding carboxylic acids, and (ii) an oxidative cleavage similar to that suffered by the unsubstituted β-diketones. The 2,2-disubstituted 1,3-diketones underwent only oxidative rearrangement. The oxidation mechanisms have been discussed on the basis of product studies.

The present study concerns with the kinetics and mechanism of oxidation of acetylacetone by peroxomonophosphoric acid (PMPA) and by hydrogen peroxide in aqueous alkaline medium. The oxidations have been studied in the pH range 8—14 and the reactivities of various peroxo species are discussed.

Experimental

All the chemicals used were of reagent grade or of certified purity. Doubly distilled water was used in preparing solutions. Acetylacetone was distilled just before use and the fractions distilling at 139—140 °C were collected rejecting the large head and tail portions. Peroxomonophosphoric acid was prepared[7-10] by the acid hydrolysis of potassium peroxodiphosphate. For each experiment, PMPA was prepared afresh with care so that further hydrolysis of PMPA to hydrogen peroxide was suppressed. Perchloric acid (Baker analyzed, 70%), used for hydrolysis, was neutralized by addition of requisite amount of carbonate-free sodium hydroxide. The ionic strength of the medium was maintained with sodium perchlorate which was prepared in situ in the oxidation flask by neutralizing $HClO_4$ with NaOH. The pH of the solution, adjusted with standard buffers or carbonate-free NaOH, was determined using a Systronics digital pH meter Model 335. Reactions were followed by measuring the rate of disappearance of PMPA which was estimated by iodometry at pH 4—5 with a drop of ammonium molybdate solution. In case of hydrogen peroxide oxidations, the kinetics was followed by

measuring the rate of disappearance of H_2O_2 by the usual iodometric procedure.[11] Due allowance was given to the self decomposition of peroxide while computing the oxidation rates. In case of H_2O_2 the reaction could not be followed at pH>13 in view of slowness of the reaction and high decomposition of the oxidant. The agreement between replicate runs was within ±5%.

Results and Discussion

The kinetics of oxidation of acetylacetone (diketone) by peroxomonophosphoric acid and by hydrogen peroxide have been investigated in aqueous alkaline medium at 308 K.

Plots of log titer versus time are linear for well over three half-lives showing the first order nature of the oxidation with respect to the peroxo compound. The first order disappearance of peroxide is further supported by the fact that the pseudo first order rate constant (k_1') does not change with the variation of initial peroxide concentration.

The oxidation (by both PMPA and H_2O_2) also exhibits a first order dependence on [diketone], as shown by the constancy of the second order rate constants $k_2'(=k_1'/[\text{diketone}])$ for varying initial diketone concentrations (Tables 1 and 4).

Ionic strength (I) of the medium was varied with $NaClO_4$. For PMPA oxidations, I was varied in the range 0.2—0.8 mol dm^{-3}, and for H_2O_2 oxidations in the range 0.1—0.4 mol dm^{-3}. The rate increased with increase of ionic strength (Tables 1 and 4).

a) [OH$^-$]=0.1 mol dm^{-3}, I=0.4 mol dm^{-3}, aqueous medium, 308 K. b) Observed second order rate constant. c) I=0.2 mol dm^{-3}. d) I=0.6 mol dm^{-3}. e) I=0.8 mol dm^{-3}. f) [Acrylamide]=5×10^{-3} mol dm^{-3}. g) [EDTA]=5×10^{-4} mol dm^{-3}. h) At 298 K. i) At 303 K. j) At 313 K.

The oxidation rate is insensitive to the addition of acrylamide indicating absence of radicals in the reaction system. Addition of EDTA also does not affect the oxidation rate (Table 1).

For both the oxidations, the second order rate constants at four different temperatures are recorded in Tables 1 and 4. Activation parameters have been determined from the linear Arrhenius plots of log k_2' vs. T^{-1}, and are recorded in Table 3.

The energy of activation (E_a), for both the oxidations, lie in the range 46—71 kJ mol^{-1}. Homolytic cleavage of the peroxide bond requires[12] an energy of activation of ≈138 kJ mol^{-1}. Further, (a) bimolecular kinetics (b) negative entropy of activation and (c) insensitivity to radical trapping agents, show that both PMPA and H_2O_2 oxidations involve polar mechanisms.[13]

The study of effect of pH on oxidation rate constitutes a significant part of the oxidation studies. The kinetics of the PMPA oxidation were explored over the pH range 8.3—13.7 (Table 2), and that of H_2O_2 oxidation over the pH range 9.25—13.0 (Table 4). Plots of pH versus log k_2' for both the oxidations are shown in Fig. 1. The sigmoid nature of the plot for PMPA oxidation suggests the participation of various species of PMPA, arising out of the following equilibria (Eqs. 1—3), in the oxidation. In case of H_2O_2, the plot of pH versus log k_2' is a straight line

Various equilibria[7)] involving PMPA, in aqueous solution, are

$$H_3PO_5 \overset{K_1}{\rightleftharpoons} H_2PO_5^- + H^+, \quad (1)$$

$$H_2PO_5^- \overset{K_2}{\rightleftharpoons} HPO_5^{2-} + H^+, \quad (2)$$

$$HPO_5^{2-} \overset{K_3}{\rightleftharpoons} PO_5^{3-} + H^+, \quad (3)$$

where K_1=8.0×10⁻², K_2=4.2×10⁻⁶, and K_3=1.6×10⁻¹³, at 298 K and I=0.2 mol dm⁻³.

The dissociation equilibrium[14)] for acetylacetone in aqueous solution is

$$CH_3COCH_2COCH_3 \overset{K_a}{\rightleftharpoons} CH_3\bar{C}OCHCOCH_3 + H^+, \quad (4)$$

where $K_a = 1 \times 10^{-9}$.

In the pH region of 8.3—13.7 PMPA exists[7,15)] mainly as HPO_5^{2-} and PO_5^{3-}. As the pK_a of acetylacetone[16)] is 8.95, in this pH region it is present both as a neutral diketone and as an anion.

$$CH_3COCH_2COCH_3 + OH^- \overset{K_4}{\rightleftharpoons}$$

(A)

$$(CH_3\bar{C}OCHCOCH_3 \leftrightarrow CH_3COCH{=}\overset{O^-}{\overset{|}{C}}CH_3) + H_2O \quad (5)$$

(A⁻)

A and A⁻ represent the diketo form and the enol form of acetylacetone.

In the alkaline hydrolysis of β-diketones, it was the neutral diketone which cleaved rather than the carbanion or the enol form. The reaction was initiated by the attack of OH^- at the carbonyl carbon; k_{obsd} was reported to be 0.573×10⁻³ min⁻¹ at 308 K and [$Ba(OH)_2$]=0.355 mol dm⁻³.

The reaction of β-diketones with alkaline hydrogen peroxide has been shown[6)] to occur by the attack of

hydrogen peroxide ion on carbonyl group. The oxidative cleavage was routed through the formation of an enol epoxide resulting in the formation of acidic products.

The reactions of enol ethers[18] and enol esters[19] with peroxy acid have been shown to form epoxides as well. Kinetic studies relating to epoxidation using alkaline hydrogen peroxide was reported to involve a nucleophilic attack by hydrogen peroxide ion on the alkene double bond.[20]

It can thus be assumed that in the oxidation of acetylacetone by PMPA and hydrogen peroxide both diketo form and enol form of the diketone are reactive.

In the pH range 8—10.6, PMPA exists[7,13] only as HPO_5^{2-}. The reaction steps in this pH range can, therefore, be presented as

$$HPO_5^{2-} + A \xrightarrow{k_1} \text{Products}, \quad (6)$$

$$HPO_5^{2-} + A^- \xrightarrow{k_2} \text{Products}. \quad (7)$$

The rate law is,

$$\text{Rate} = -\frac{d[PMPA]_T}{dt} = k_1[HPO_5^{2-}][A] + k_2[HPO_5^{2-}][A^-]. \quad (8)$$

$$\text{But} \quad [PMPA]_T = [HPO_5^{2-}] \quad (9)$$

$$\text{and} \quad [\text{diketone}]_T = [A] + [A^-] \quad (10)$$

$[PMPA]_T$ and $[\text{diketone}]_T$ represent the total stoichiometric concentration of PMPA and acetylacetone respectively.

From Eqs. 5 and 10,

$$[A] = \frac{K_h[\text{diketone}]_T}{K_h + [OH^-]} \quad (11)$$

$$\text{and} \quad [A^-] = \frac{[\text{diketone}]_T[OH^-]}{K_h + [OH^-]}, \quad (12)$$

$$\text{where} \quad K_h = \frac{[H_2O]}{K_4} \quad (13)$$

Eq. 8, therefore, takes the form,

$$-\frac{d[PMPA]_T}{dt} = \left\{\frac{k_1K_h + k_2[OH^-]}{K_h + [OH^-]}\right\}[PMPA]_T[\text{diketone}]_T \quad (14)$$

$$\text{where} \quad k_2' = \frac{k_1K_h + k_2[OH^-]}{K_h + [OH^-]}. \quad (15)$$

Plot of $k_2'(K_h+[OH^-])$ versus $[OH^-]$ (using $K_h=K_w/K_a$), in the pH range 8—10.6, is found to be linear (r=1.00). From the intercept and slope of this plot the values of k_1 and k_2 are calculated to be 1.96 $dm^3\ mol^{-1}\ s^{-1}$ and 0.177 $dm^3\ mol^{-1}\ s^{-1}$ respectively, indicating the diketo form of acetylacetone is more reactive than the enol form. The second order rate constants k_2'(calcd), calculated from Eq. 15 using these kinetically estimated values of k_1 and k_2, are collected in Table 2.

In the pH range 11.5—13.7, the major oxidant species[7] are HPO_5^{2-} and PO_5^{3-}; the concentration of PO_5^{3-} increasing with increase of pH.

The steps of the oxidation in pH region 11.5—13.7 can be written as,

$$HPO_5^{2-} + OH^- \overset{K_5}{\rightleftharpoons} PO_5^{3-} + H_2O, \quad (16)$$

$$HPO_5^{2-} + A \xrightarrow{k_3} \text{Products}, \quad (17)$$

$$HPO_5^{2-} + A^- \xrightarrow{k_4} \text{Products}, \quad (18)$$

$$PO_5^{3-} + A \xrightarrow{k_5} \text{Products}, \quad (19)$$

$$PO_5^{3-} + A^- \xrightarrow{k_6} \text{Products}. \quad (20)$$

The reaction sequence leads to the rate expression,

$$-\frac{d[PMPA]_T}{dt} = k_3[HPO_5^{2-}][A] + k_4[HPO_5^{2-}][A^-] + k_5[PO_5^{3-}][A] + k_6[PO_5^{3-}][A^-] \quad (21)$$

From Eq. 16, we have

$$[HPO_5^{2-}] = \frac{[PMPA]_TK_h'}{K_h' + [OH^-]}, \quad (22)$$

$$\text{and} \quad [PO_5^{3-}] = \frac{[PMPA]_T[OH^-]}{K_h' + [OH^-]}, \quad (23)$$

$$\text{where} \quad [PMPA]_T = [HPO_5^{2-}] + [PO_5^{3-}] \quad (24)$$

$$\text{and} \quad K_h' = \frac{[H_2O]}{K_5} \quad (25)$$

Now using Eqs. 11, 12, 22, and 23 in Eq. 21, we get,

$$-\frac{d[PMPA]_T}{dt} = \left\{\frac{k_3K_h'K_h + (k_5K_h + k_4K_h')[OH^-] + k_6[OH^-]^2}{(K_h' + [OH^-])(K_h + [OH^-])}\right\} \times [PMPA]_T[\text{diketone}]_T \quad (26)$$

$$\text{or} \quad k_2' = \frac{k_3K_h'K_h + (k_5K_h + k_4K_h')[OH^-] + k_6[OH^-]^2}{(K_h' + [OH^-])(K_h + [OH^-])}. \quad (27)$$

A least-squares analysis of Eq. 27 was done (using $K_h'=K_w/K_3$) and the values of k_3, $(k_5K_h/K_h'+k_4)$ and k_6 were obtained as 30.4 $dm^3\ mol^{-1}\ s^{-1}$, 0.0144 and $\approx$0 respectively. These values were used to obtain k_2' (calcd) which showed excellent agreement with observed k_2' (Table 2).

Oxidation of acetylacetone by alkaline PMPA resulted in the formation of formic acid and acetic acid. Formic acid could be detected[6] from its reaction with ammoniacal silver nitrate. Acetic acid in presence of formic acid was detected[21] by the color reaction with a solution of sodium nitroprusside containing morpholine. In the reaction of unsubstituted β-diketones with alkaline hydrogen peroxide Cocker and Grayson too have reported[6] the formation of formic acid and acetic acid as oxidation products.

In the present study the formation of formic acid,

even under kinetic experimental conditions, suggests that the α-hydroxy-β-diketone produced undergoes hydrolysis and further reaction with the peroxy acid in a fast step forming the products. The formation of hydroxy diketone is presumed to occur by the intermediate formation of epoxy alcohol. The epoxy alcohol supposedly results from the rate-limiting nucleophilic attack of the peroxo species on carbonyl carbon of the diketo form or alkene double bond of the enol form of acetylacetone followed by the oxygen-oxygen bond fission.

The kinetics of oxidation of acetylacetone by hydrogen peroxide have been studied over the pH range 9.2—13.

In dilute aqueous solution hydrogen peroxide is more acidic than water.[22]

$$H_2O_2 \overset{K_6}{\rightleftharpoons} H^+ + HO_2^- \quad (K_6 = 2.24\times10^{-12},\ 25\ ^\circ C). \tag{28}$$

In the pH region under study since hydrogen peroxide exists as H_2O_2 and HO_2^-, the reaction in this pH range would involve the interaction of these species with both the diketo form and enol form of acetylacetone.

$$H_2O_2 + OH^- \overset{K_7}{\rightleftharpoons} HO_2^- + H_2O, \tag{29}$$

$$H_2O_2 + A \xrightarrow{k_7} \text{Products}, \tag{30}$$

$$H_2O_2 + A^- \xrightarrow{k_8} \text{Products}, \tag{31}$$

$$HO_2^- + A \xrightarrow{k_9} \text{Products}, \tag{32}$$

$$HO_2^- + A^- \xrightarrow{k_{10}} \text{Products}. \tag{33}$$

The above reaction steps would lead to the rate law (Eq. 34)

$$-\frac{d[\text{Hydrogen peroxide}]_T}{dt} = k_7[H_2O_2][A] + k_8[H_2O_2][A^-] + k_9[HO_2^-][A] + k_{10}[HO_2^-][A^-]. \tag{34}$$

$$\text{But } [\text{Hydrogen peroxide}]_T = [H_2O_2] + [HO_2^-] \tag{35}$$

From Eqs. 29 and 35,

$$[H_2O_2] = \frac{[\text{Peroxide}]_T K_h''}{K_h'' + [OH^-]} \tag{36}$$

$$\text{and } [HO_2^-] = \frac{[\text{Peroxide}]_T [OH^-]}{K_h'' + [OH^-]}, \tag{37}$$

$$\text{where } K_h'' = \frac{[H_2O]}{K_7} \tag{38}$$

Using Eqs. 11, 12, 36, and 37 in Eq. 34, we get,

$$-\frac{d[\text{Peroxide}]_T}{dt} = \left\{\frac{k_7K_h''K_h + (k_9K_h + k_8K_h'')[OH^-] + k_{10}[OH^-]^2}{(K_h'' + [OH^-])(K_h + [OH^-])}\right\} \times [\text{Peroxide}]_T[\text{Diketone}]_T, \tag{39}$$

$$\text{where } k_2' = \frac{k_7K_h''K_h + (k_9K_h + k_8K_h'')[OH^-] + k_{10}[OH^-]^2}{(K_h'' + [OH^-])(K_h + [OH^-])}. \tag{40}$$

The values of k_7, k_{10}, and $(k_9K_h/K_h'' + k_8)$ were obtained by least-squares analysis of Eq. 40, and were found to be 0.393 $dm^3\,mol^{-1}\,s^{-1}$, 0.143×10^{-2} $dm^3\,mol^{-1}\,s^{-1}$ and 0.494×10^{-3} respectively. Using these values second order rate constants calculated (k_2' calcd) from Eq. 40 are collected in Table 4.

The authors are thankful to Professor G. P. Panigrahi, Department of Chemistry, Berhampur University for helpful discussions and encouragement.

Kinetics of Oxidation of Amino Acids by Chloramine-T. A Reinvestigation on the Oxidation of Alanine, 2-Aminobutyric Acid, Valine, Serine, and Threonine

M. Shanmugam RAMACHANDRAN* and T. Subburamiyer VIVEKANANDAM
School of Chemistry, Madurai Kamaraj University, Madurai-625 021, India
(Received January 16, 1986)

The kinetics of oxidation of amino acids in aqueous medium were reinvestigated. The rate of oxidation follows second order with respect to chloramine-T (CAT) and an inverse dependence on [*p*-toluenesulfonamide] (RNH_2). At constant [RNH_2] the rate of the reaction can be represented as (in the absence of chloride ion)

$$\frac{-d[CAT]}{dt} = k_a[CAT]^2 + k_b\frac{[\text{Amino Acid}][CAT]^2}{[H^+]} + k_c\frac{[\text{Amino Acid}]^2[CAT]^2}{[H^+]^2}.$$

A linear relationship exists between pK_1 and the rate constants. This shows the electrophilic attack of the oxidant at the carboxylato group of the amino acid. The effect of chloride ion on k_{obsd} is catalytic. The mechanisms of the reactions are discussed in terms of the kinetic results.

The kinetics of oxidations of amino acids by sodium *N*-chloro-*p*-toluenesulfonamidate, generally known as chloramine-T (CAT) have been studied extensively.[1] The mechanism proposed by the earlier workers could not explain some of the observed facts and this leads us to reinvestigate the kinetics of oxidation of amino acids by CAT in acid medium. The results on the oxidation of threonine by CAT were reported in our earlier paper[2] wherein we observed that the active species of the oxidant (CAT) is the dichloramine-T and not the acid chloramine-T as observed by the earlier workers. The main object in this report is to extend the reinvestigation to other amino acids and to elucidate suitable mechanisms and put forward rate laws consistent with the experimental data with a view to shedding more light on the mechanisms of oxidation. CAT was considered once as a quantitative decarboxylating agent for the measurement of amino acid concentration[3] but this expectation fell shortly into disrepute because of reports reflecting on its reliability.[4] Therefore a careful study on the mechanism may give some idea about the analytical use of this reaction. With these views, we discuss here the results obtained on the oxidation of alanine, 2-aminobutyric acid (butryne), valine, and serine by CAT in aqueous perchloric acid medium. The results seem to be different from the oxidation of threonine by CAT reported earlier and hence a careful reexamination on the oxidation of threonine is also made and the results are included.

Experimental

The materials used and experimental methods were discussed in detail in our previous report.[2]

Different ratios of [amino acid] to [CAT], always with [CAT]>[amino acid], were mixed in the absence of acid† at room temperature. Estimation of unreacted [CAT] after 48 h showed that one mole of amino acid consumed more than two moles of CAT as in the following equations.

Alanine + 2.6 CAT ⟶ Products
Butryne + 2.8 CAT ⟶ Products
Valine + 2.7 CAT ⟶ Products
Threonine + 2.8 CAT ⟶ Products
Serine + 2.8 CAT ⟶ Products

The products were identified as a mixture of nitrile, aldehyde and traces of ammonia. Nitrile was identified by the color reaction with hydroxylamine and iron(III) chloride as suggested by Soloway and Lipschietz.[5] Presence of aldehyde was also confirmed by Schiff's reagent. Ammonia was detected by Nessler's reagent. The consumption of more than two moles of CAT per mole of amino acid may be due to the reaction of ammonia with CAT as observed by the earlier workers[6] and may also be due to the further oxidation of aldehyde.

Results and Discussion

The kinetics of oxidations by CAT were followed by observing the disappearance of [CAT] at different time intervals and from the rate of disappearance of [CAT], pseudo first-order rate constants, k_{obsd}, were calculated. All the kinetic runs were carried out with the concentrations of amino acids always, at least five times, in excess of [CAT]. All the reactions were studied in the presence of known amount of *p*-toluenesulfonamide, one of the reaction product obtained from CAT, denoted as RNH_2 where R=*p*-$MeC_6H_4SO_2$-.

Careful analysis of the results, as shown in Fig. 1, indicates that the disappearance of [CAT] does not obey either the integrated first order plot or the integrated second order plot. The plots of log V_t versus time, where V_t is the volume of thiosulfate consumed at time (t), as well as 1/[CAT] versus time show a curvature/deviation in the latter part of the

† At this [CAT] (0.072 M) precipitation occurs in the presence of H^+ and the product analysis were carried out in the absence of H^+ and RNH_2.

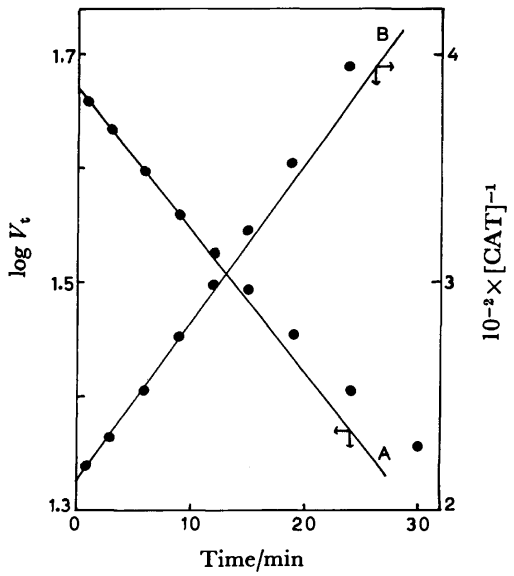

Fig. 1. Rate of disappearance of [CAT] at 30 °C.
A : First order plot, B : Second order plot. [Alanine]= 0.05 M; [RNH_2]=0.01 M; [H^+]=0.10 M; [CAT]= 4.6×10^{-3} M; μ=0.15. 1 M=1 mol dm^{-3}.

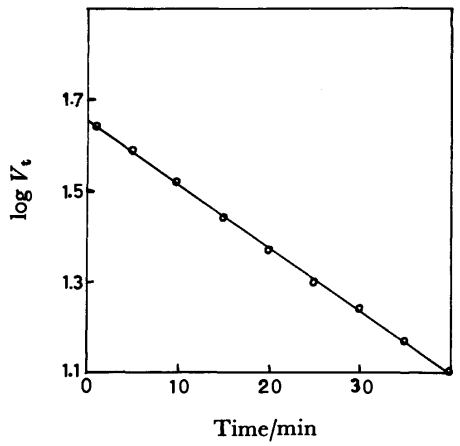

Fig. 2. Rate of disappearance of [CAT] in presence of Cl^- ion at 30 °C.

reaction (Fig. 1). This behavior is observed even in the presence of chloride ion also when [Cl^-]<[CAT]. But when [Cl^-]>[CAT], the reaction is a perfect first order even up to 70% conversion of [CAT] (Fig. 2). Therefore in all the kinetics the rates were followed only up to 25% conversion of [CAT] and the rate constants thus calculated (k_{obsd}) were only the initial rate constants. Examination of k_{obsd} values reveals that the increase in the concentration of CAT causes a proportional increase in the rate constant k_{obsd}. A plot of k_{obsd} versus [CAT] is a straight line passing through the origin (Fig. 3). This clearly proves that the rates of oxidations follow second order with respect to [CAT]. In the presence of chloride ion (0.025 M) (1 M=1 mol dm^{-3}) the plot of k_{obsd} versus [CAT] result in a definite

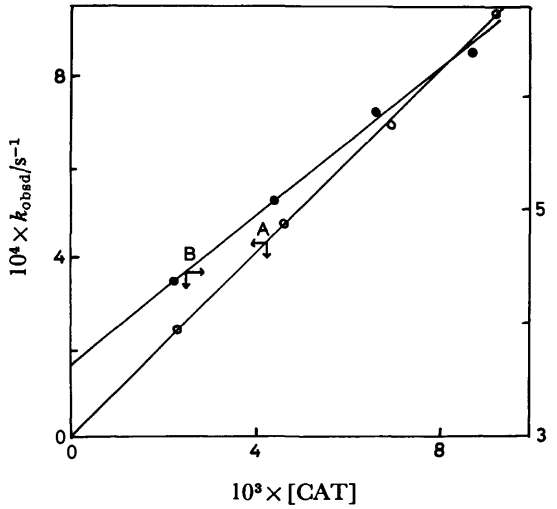

Fig. 3. Plot of k_{obsd} versus [CAT] at 30 °C.

positive intercept (Fig. 3).

The effect of [amino acids] (AA) on the rates of oxidation was studied at constant [H^+] and [RNH_2]. The plots of k_{obsd} versus [amino acids] are parabolic curves with positive intercept ($k_{intercept}$)†† (Fig. 4) and subsequently the plots of k_{obsd}'/[amino acid] versus [amino acid], where k_{obsd}' denotes ($k_{obsd}-k_{intercept}$), are linear at higher concentrations of amino acids (Fig. 5). The initial part of the above plots are parallel to the abscissa. This clearly shows that at lower concentrations of amino acids the reaction follows only first order with respect to [amino acid] whereas at higher

†† Intercept was obtained by linear extrapolation.

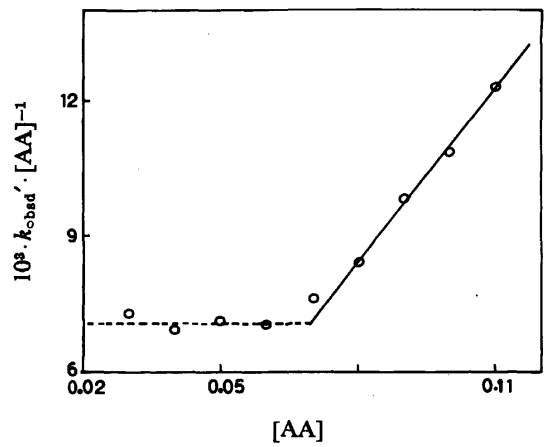

Fig. 5. Plot of k_{obsd}'[Amino Acid]$^{-1}$ versus [Amino Acid] at 30 °C.
Alanine: [CAT]$=4.6\times10^{-3}$ M; [RNH_2]$=0.01$ M; [H^+]$=0.10$ M; $\mu=0.15$.

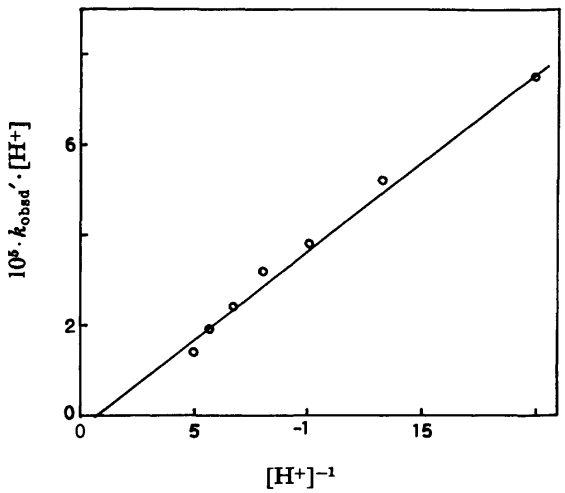

Fig. 6. Plot of k_{obsd}'[H^+] versus $[H^+]^{-1}$ at 30 °C.
[Butryne]$=0.05$ M; [CAT]$=4.6\times10^{-3}$ M; [RNH_2]$=0.01$ M; $\mu=0.25$.

concentration the oxidation obeys second order too.

The values of k_{obsd} decrease with increase in H^+ concentration at constant [amino acid], [CAT], and [RNH_2]. The plots of k_{obsd}' versus $1/[H^+]$ are curves whereas $k_{obsd}'[H^+]$ versus $1/[H^+]$ are straight lines (Fig. 6) with a small negative intercepts in alanine and butryne which can be considered as zero within the experimental error. In all other cases (a small) positive intercept is obtained.

The values of k_{obsd} decrease with increase in [RNH_2] at constant [amino acid], [CAT], and [H^+]. The effect of [Cl^-] on the rate of oxidations is a catalytic one. The influence of ionic strength on the reaction is negligible. The reactions were studied, without Cl^- ion, at four different temperatures (30—45 °C) and from the temperature dependence of k_{obsd} the values of $\Delta H^{\neq}$ for the overall reactions are calculated and tabulated in Table 1.

The oxidation reactions involving CAT are very complex because various species derived/formed from the oxidant are more reactive than CAT itself.

Chloramine-T (RNNaCl where R=*p*-$MeC_6H_4SO_2$-) behaves like a strong electrolyte[7] in aqueous solution as

$$RNNaCl \rightleftharpoons RNCl^- + Na^+.$$

The anion reacts with a proton in acid solution to give free acid monochloramine-T, RNHCl.[8]

$$RNCl^- + H^+ \rightleftharpoons RNHCl \quad K=3.5\times10^4 \text{ at } 25\,^\circ C$$

The formation of free acid RNHCl in acid solution is confirmed by experimental evidence.[7] The free acid RNHCl disproportionates giving rise to *p*-toluenesulfonamide (RNH_2) and dichloramine-T ($RNCl_2$).[9]

$$2RNHCl \overset{K_d}{\rightleftharpoons} RNH_2 + RNCl_2 \quad K_d=6.1\times10^{-2} \text{ at } 25\,^\circ C$$

The free acid RNHCl and dichloramine-T hydrolyze[10] as

Table 1. Kinetic Parameters of Oxidation of Amino Acids by CAT at 30 °C

Amino acid	pK_1[a]	$10^3\times k_1'$ / s^{-1}	k_2 / $dm^3\,mol^{-1}\,s^{-1}$	$10^{-3}\times k_3$ / $dm^6\,mol^{-2}\,s^{-1}$	K_2 / $dm^3\,mol^{-1}$	$10^4\times k_4$ / s^{-1}	$\Delta H^{\neq}$ / kJ mol^{-1}
Alanine	2.35	4.7[b]	6.4	2.4 (3.1)	75	3.6	56.9

a) Ref. 14. b) [H^+]$=0.1$ M. c) [H^+]$=0.15$ M. d) [H^+]$=0.20$ M. Values of k_3 given in the parentheses are calculated from [H^+] variation. e) 2-Aminobutyric acid.

$$RNCl_2 + H_2O \overset{K_h}{\rightleftharpoons} RNHCl + HOCl$$
$$K_h = 8.0 \times 10^{-7} \text{ at } 25\,^\circ C,$$
$$RNHCl + H_2O \overset{K_h'}{\rightleftharpoons} RNH_2 + HOCl$$
$$K_h' = 4.88 \times 10^{-8} \text{ at } 25\,^\circ C.$$

Free chlorine has also been detected by Rao et al.[11] in acid medium in the presence of Cl^- ion. Therefore the possible oxidizing species in acidified CAT solution are RNHCl, $RNCl_2$, HOCl, Cl_2, and probably H_2OCl^+.

Bishop and Jennings[7] have calculated the order of the concentration of the various species at different pH. First approximation calculations by Bishop and Jennings on 0.1 M solution of CAT have shown that the concentrations of RNHCl and HOCl are ca. 10^{-2} M and 10^{-7} M respectively at pH ca. 0—3. Soper et al.[10,12,13] have stated that the direct interaction of RNHCl with the substrate could be slow while HOCl formed by the hydrolysis of RNHCl and $RNCl_2$ would attack at a faster rate. This has been recently disproved by Swain and Crist[14] who have shown that HOCl is relatively unreactive and Cl_2, H_2OCl^+, and possibly Cl^+ formed from HOCl are relatively more reactive species. So, under our experimental conditions, the interaction of HOCl with amino acids can be eliminated.

Bishop and Jennings[7] have also shown that an acidified solution of 0.05 M CAT contains 9.6×10^{-5} M of $RNCl^-$, 4.01×10^{-2} M of RNHCl and 9.9×10^{-3} M of $RNCl_2$ in the pH<1.5 or $[H^+]>0.03$ M and the concentration of these species were insensitive to increase in $[H^+]$, generally greater than 0.03 M. Ruff and Kucksman[15] have shown that the reactivities of various species due to CAT in acid solution are in the order $RNCl_2 > RNHCl > OCl^- > RNNaCl$. So under these experimental conditions it is quite likely that $RNCl_2$ and RNHCl would be the reactive species. The observed experimental facts namely the second order dependence of CAT and inhibitory effect of $[RNH_2]$ suggest that $RNCl_2$ would be the more probable active species. Since the concentrations of RNHCl and $RNCl_2$ are constant and independent of $[H^+]$ when $[H^+]>0.03$ M, the present kinetics were studied with $[H^+]=0.1$ M or >0.1 M (even in the $[H^+]$ variation the lowest concentration we used was 0.05 M). Therefore observed inverse hydrogen ion effect would have come from the substrate side.

It is interesting to note that the rate constants for all the five amino acids are almost of the same order of magnitude. This is not surprising as all amino acids have almost same pK_1 values.[16] This shows that the active species is the same for all the amino acids studied. Amino acids exist as dipolar ions (zwitter ions) in aqueous solution as

$$R'\text{-}\underset{\underset{NH_2}{|}}{CH}\text{-}COOH \rightleftharpoons R'\text{-}\underset{\underset{+NH_3}{|}}{CH}\text{-}COO^-.$$

The dissociation of the amino acids depends on the pH of the medium. In acid solutions, amino acids exist as the mixture of cationic and zwitterionic forms

$$R'\text{-}\underset{\underset{+NH_3}{|}}{CH}\text{-}COO^- + H^+ \overset{K_1}{\rightleftharpoons} R'\text{-}\underset{\underset{+NH_3}{|}}{CH}\text{-}COOH.$$

The observed inverse hydrogen ion effect and the experimental conditions employed suggest that the amino acids in the zwitterionic form would be the more probable reactive species.

Based on the experimental conditions, the more probable mechanistic pathway will be (in the absence of Cl^- ion)

$$RNCl^- + H^+ \overset{k}{\rightleftharpoons} RNHCl, \quad (1)$$
$$2RNHCl \overset{K_d}{\rightleftharpoons} RNCl_2 + RNH_2, \quad (2)$$
$$RNCl_2 + H_2O \overset{k_1}{\longrightarrow} RNCl^- + H_2OCl^+, \quad (3)$$
$$R'\text{-}CH(\overset{+}{N}H_3)COO^- + H^+ \overset{K_1}{\rightleftharpoons} R'\text{-}CH(\overset{+}{N}H_3)COOH, \quad (4)$$
$$R'\text{-}CH(\overset{+}{N}H_3)COO^- + RNCl_2 \overset{k_2}{\longrightarrow} \text{Products}, \quad (5)$$
$$2R'\text{-}CH(\overset{+}{N}H_3)COO^- + RNCl_2 \overset{k_3}{\longrightarrow} \text{Products}, \quad (6)$$
$$R'\text{-}CH(\overset{+}{N}H_3)COO^- + H_2OCl^+ \overset{fast}{\longrightarrow} \text{Products}. \quad (7)$$

In the presence of Cl^- ion, in addition to the reaction steps 1—7, the following reactions may also occur

$$RNHCl + Cl^- \overset{K_2}{\rightleftharpoons} \text{Complex}, \quad (8)$$
$$\text{Complex} \overset{k_4}{\longrightarrow} Cl_2 + RNH_2, \quad (9)$$
$$R'\text{-}CH(\overset{+}{N}H_3)COO^- + Cl_2 \overset{fast}{\longrightarrow} \text{Products}. \quad (10)$$

Dakin[3] employed chloramine-T as the oxidizing agent for a variety of amino acids and the products formed were found to be aldehyde, NH_3, and CO_2. In the presence of excess of [CAT] the corresponding nitrile was formed at the expense of aldehyde and ammonia.[3] This observed fact clearly shows that two different reactions are taking place to give the entirely different products, namely nitrile and aldehyde. The present experimental observations, namely the plots k_{obsd}'/[amino acid] versus [amino acid] and $k_{obsd}'[H^+]$ versus $1/[H^+]$, show that both first order and second order reactions with respect to amino acid concentrations as shown in Eqs. 5 and 6, are equally probable and this may be the reason for getting two different products. The final products obtained in our study, namely nitrile and aldehyde, also give evidence for the above fact.

Since the value of the equilibrium constant K is very high[8] (3.6×10^4 at 25 °C), under the experimental conditions all the [CAT] will be in the protonated form, [RNHCl]. Using this approximation and based on the above reaction schemes the rate equation can be written as

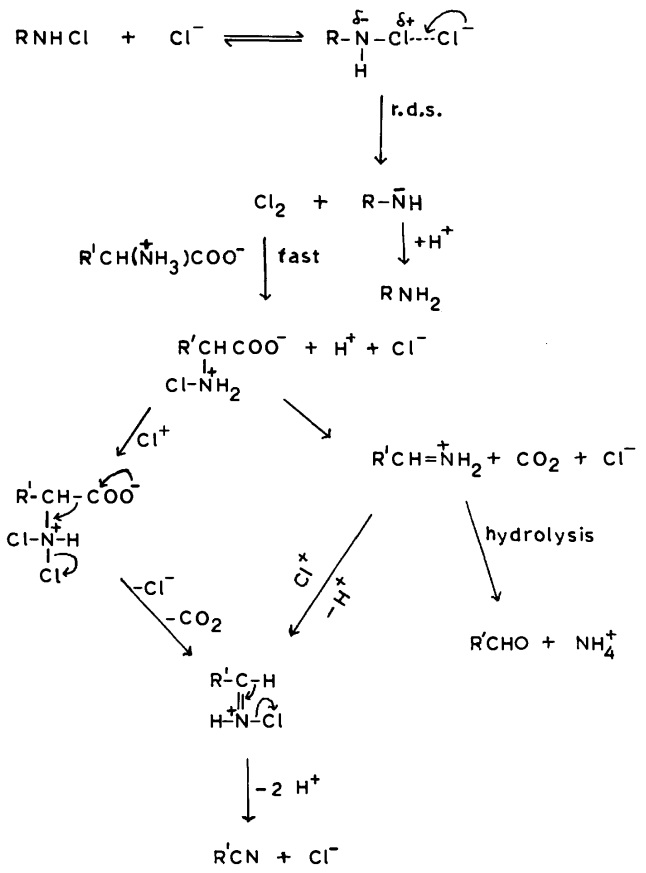
$$\frac{-d[CAT]}{dt} = k_1[RNCl_2][H_2O] + k_2[RNCl_2][R'\text{-}CH(\overset{+}{N}H_3)COO^-] + k_3[RNCl_2][R'\text{-}CH(\overset{+}{N}H_3)COO^-]^2. \quad (11)$$

In the presence of Cl^- ion Eq. 11 becomes

$$\frac{-d[CAT]}{dt} = k_1[RNCl_2][H_2O] + k_2[RNCl_2][R'\text{-}CH(\overset{+}{N}H_2)COO^-] + k_3[RNCl_2][R'\text{-}CH(\overset{+}{N}H_3)COO^-]^2 + k_4[\text{complex}]. \quad (12)$$

Substituting the concentrations of $RNCl_2$, $R'\text{-}CH(NH_3)\text{-}COO^-$ and complex from Eqs. 2, 4, and 8 we get

$$\frac{-d[CAT]}{dt} = \frac{K_d[RNHCl]^2}{4K_d[RNHCl]+[RNH_2]}\left\{k_1[H_2O] + \frac{k_2[\text{amino acid}]}{K_1[H^+]} + \frac{k_3[\text{amino acid}]^2}{K_1^2[H^+]^2}\right\} + \frac{k_4K_2[RNHCl][Cl^-]}{1+K_2[RNHCl]+K_2[Cl^-]}, \quad (13)$$



Scheme 1. The catalytic cycle of the reaction in the presence of chloride ion.

$$k_{obsd} = \frac{K_d[RNHCl]}{4K_d[RNHCl]+[RNH_2]}\left\{k_1' + \frac{k_2[\text{amino acid}]}{K_1[H^+]} + \frac{k_3[\text{amino acid}]^2}{K_1^2[H^+]^2}\right\} + \frac{k_4K_2[Cl^-]}{1+K_2[RNHCl]+K_2[Cl^-]} \quad (14)$$

where $k_1' = k_1[H_2O]$.

In the absence of Cl^- ion the last term in Eq. 14 is neglected and k_{obsd} becomes

$$k_{obsd} = \frac{K_d[RNHCl]}{4K_d[RNHCl]+[RNH_2]} \times \left\{k_1' + \frac{k_2[\text{amino acid}]}{K_1[H^+]} + \frac{k_3[\text{amino acid}]^2}{K_1^2[H^+]^2}\right\}. \quad (15)$$

This Eq. 15 explains all the observed experimental facts. At $[CAT]=4.6\times10^{-3}$ M, $[RNH_2]=1.0\times10^{-2}$ M, and $K_d=6.1\times10^{-2}$ the value of the term $4K_d[RNHCl]=0.11\times10^{-2}$ which is only 10% of the magnitude of $[RNH_2]$. Therefore over the range of CAT varied, the term $4K_d[RNHCl]+[RNH_2]$ will be more or less constant and hence a plot of k_{obsd} versus [CAT] will be a straight line passing through the origin.

According to the reaction mechanism if the hydrolysis of $RNCl_2$ to give H_2OCl^+ is the rate-limiting step, then the values of k_1' obtained from the different substrate and at different $[H^+]$ should be identical in magnitude. The value of k_1' can be calculated from the intercept obtained in the plot of k_{obsd} versus [amino acid] where

$$k_{intercept} = \frac{K_d[RNHCl]k_1'}{4K_d[RNHCl]+[RNH_2]}.$$

Using the literature value of K_d as 6.1×10^{-2}, the values obtained for k_1' at different conditions are tabulated in Table 1. The agreement between these values proves our assumption.

The Eq. 15 can be rearranged as

$$k_{obsd} - k_{intercept} = k_{obsd}' = \frac{K_d[RNHCl]}{4K_d[RNHCl]+[RNH_2]}\left\{\frac{k_2[\text{amino acid}]}{K_1[H^+]} + \frac{k_3[\text{amino acid}]^2}{K_1^2[H^+]^2}\right\}, \quad (16)$$

and this Eq. 16 explains the effect of [amino acid] and $[H^+]$ on k_{obsd}. At low concentration of amino acid the second term in the bracket can be neglected so that k_{obsd}' is directly proportional to [amino acid]. Hence the plots k_{obsd}'/[amino acid] versus [amino acid] are parallel to the abscissa at lower concentration. At higher concentration of amino acids, the contribution from the second term is also appreciable and hence k_{obsd}'/[amino acid] versus [amino acid] are straight lines. Similarly at high $[H^+]$, k_{obsd}' may become proportional to $1/[H^+]$ and probably this may be the reason for getting a small negative intercepts in the plots $k_{obsd}'[H^+]$ versus $1/[H^+]$. The values of k_1', k_2, and k_3 are tabulated in Table 1.

Alexander and Gough[17] reported that the oxida-

tions of amino acids, with the exception of glycine, by chlorine are rapid at pH 2 and 10. Results from this laboratory also show that chloride ion shows no effect on the oxidation of glycine by CAT in acid medium[18] whereas with all other amino acids the effect of chloride ion is found to be a catalytic one. This catalytic effect of Cl^- ion shows that CAT may react with Cl^- ion in the rate-determining step to give Cl_2 which reacts rapidly with amino acids as shown in Eqs. 8—10. Free chlorine, in acidified CAT solution in the presence of Cl^-, has been detected.[11] Jayaraman and Mayanna[19] have proved that, in the oxidation of pyridoxine by *N*-chlorobenzenesulfonamidate in HCl medium, the active species is Cl_2.

The plots of k_{obsd} versus [CAT] in the presence of Cl^- ion which result in a positive intercept clearly shows that the reaction proceeds through two independent steps: (i) second order and (ii) first order with respect to [CAT]. At these reaction conditions almost 75% of [CAT] remains as monochloramine-T (RNHCl).[7] This fact together with the assumption, namely the complex formation between RNHCl and Cl^-, will explain why the reaction follows a perfect first order even up to 70% conversion when $[Cl^-] \gg [CAT]$.

The above discussion clearly shows that Cl^- forms complex only with RNHCl. Similar observations were also made in the oxidation reactions by *N*-chlorobenzenesulfonamidate.[20] The formation constant K_2 for the complex (Eq. 8) can be calculated by considering the effect of Cl^- ion on k_{obsd}. The first term in Eq. 14 represents the value of k_{obsd} in the absence of Cl^- ion and this can be represented as k_a. A plot of $(k_{obsd}-k_a)^{-1}$ i.e. $k_{obsd}''^{-1}$ versus $1/[Cl^-]$ should be a straight line with $1/K_2k_4+[RNHCl]/k_4$ as slope and $1/k_4$ as intercept (Fig. 7). The values for k_4 and K_2 are also given in Table 1 and these values also bring out the fact that the values of k_4 and K_2 are independent of the amino acids used.

We can consider the structure of the complex formed between CAT and Cl^- as, similar to that reported by Jayaraman et al.[20] in *N*-chlorobenzenesulfonamidate-Cl^- system,

$$\text{R-N(H)-Cl} + Cl^- \underset{}{\overset{K_2}{\rightleftharpoons}} \text{R-N(H)-Cl}^{\delta-} \cdots\cdots Cl^-.$$

Apart from the difference in the substituents of the phenyl group, both CAT (*N*-chloro-*p*-toluenesulfonamidate) and CAB (*N*-chlorobenzenesulfonamidate) are structurally similar. Hence the difference in the magnitude of K_2 of CAB-Cl^- and CAT-Cl^- should depend on the electron-releasing/withdrawing nature of the substituent in the phenyl ring. Since the interaction of RNHCl with Cl^- is electrophilic in nature, one would expect a positive value of ρ (susceptibility constant). Therefore the ratio of K_2s, $K_{2(CAT)}/K_{2(CAB)}$, should be less than unity since Hammett substituent constants,[21] σ, for $CH_3=-0.17$ and $H=0.0$. Using the literature value[20] of $K_{2(CAB)}$ as 1.2×10^2 the value obtained for $K_{2(CAT)}/K_{2(CAB)}$ is $\simeq 0.45$. This shows that the values of K_2 obtained for CAT-Cl^- system are of the right order of magnitude.

According to Eq. 14 the values of k_{obsd} should be approximately proportional to CAT as, after neglecting the second part, $k_{obsd}=k[RNHCl]$. Therefore, as the reaction proceeds the concentration of RNHCl depletes. Hence the initial value of k_{obsd} will be entirely different from the values at the latter part of

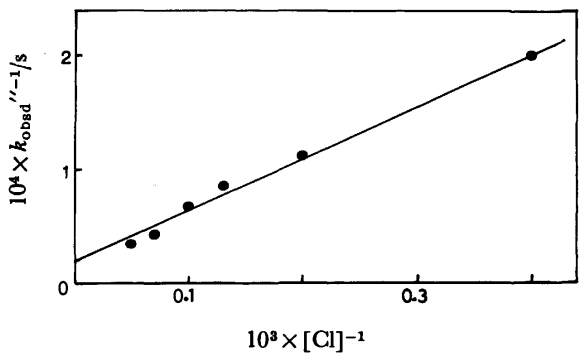


Fig. 7. Plot of $1/k_{obsd}''$ versus $1/[Cl^-]$ at 30 °C. [Butryne]=0.05 M; [CAT]=4.6×10^{-3} M; [NH_2]=0.01 M; [H^+]=0.15 M; μ=0.15.

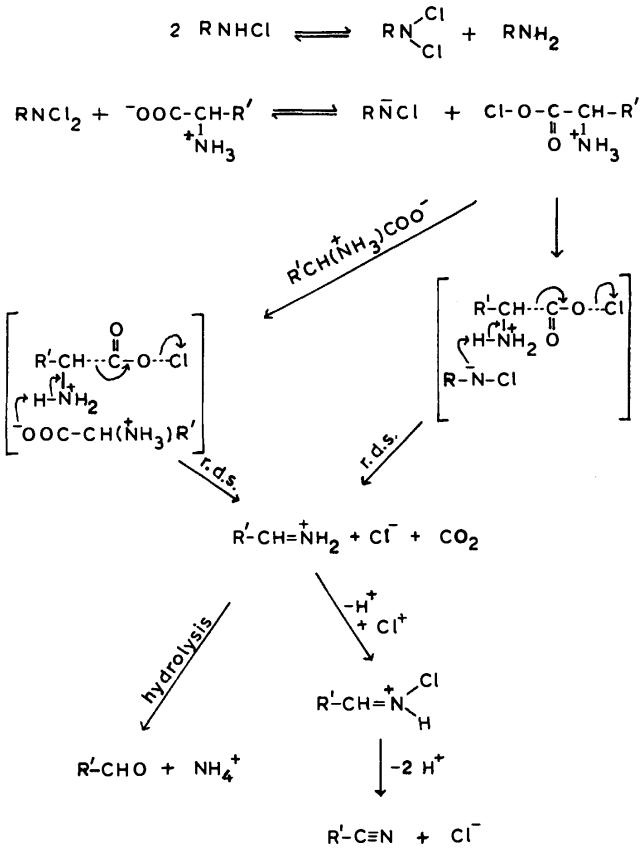

Scheme 2. Reaction scheme.

the reaction. This may be the reason for the curvature in the first order plots.

The accuracy of k_1', k_2, k_3, k_4, and K_2 can be verified by calculating the k_{obsd} using the Eqs. 15 and 16. The results are given only for serine–CAT system. k_{obsd} are calculated using the two independent values of k_3 derived from substrate and [H+] variation. The results are given in Table 2. Perusal of the values shows that the k_{calcd} values calculated using the k_3 derived from the [H+] variation is always higher than k_{obsd}. This is because that k_3 value from the [H+] effect on k_{obsd} is always greater than the k_3 value from [substrate] variation (Table 1). Since the [H+] term occur in the denominator, even a small change in [H+] will show a large effect on k_{obsd}. Moreover, at low [H+] some other side reactions may also occur so that k_{obsd} obtained would be greater than what would be its actual value if no such side reactions. That is why we get a straight line almost passing through origin when we plot k_{obsd}'[H+] versus 1/[H+], but according to Eq. 16 we should get a definite positive intercept.

Based on the experimental results we can propose the following mechanism (Scheme 2) for the reaction of CAT with amino acids.

If the electrophilic substitution takes place at the COO^- group, then the observed reactivity should depend upon the nucleophilicity of the carboxylato group. Any change in the structure of R′ group in the amino acid R′-CH(NH_2)COOH will change the nucleophilicity of the COO^- group which will be reflected on the magnitude of pK_a. According to the pK_1's of the amino acids (Table 1) the order of nucleophilicity should be as alanine>butryne= valine>serine>threonine. Therefore we can expect that the values of k_2 and k_3 should also be in the same order and this expectation is found to be true from the values of k_2 and k_3 (Table 1). A plot of log k_2 or log k_3 with pK_1 of the amino acids is a straight line with positive slope. This clearly proves that the reactions proceed through the electrophilic substitution of CAT at the COO^- group of the amino acid.

This reaction scheme also explains why Dakin observed that in the presence of excess of chloramine-T, the corresponding nitrile was formed at the expense of aldehyde. At higher concentration of CAT, oxidation of imine R′-CH=$\overset{+}{N}H_2$ to give R′CN may also compete with the hydrolysis of R′-CH=$\overset{+}{N}H_2$ to R′CHO.

Reports on the action of chlorine and hypochlorite on amino acids has been reported.[17,22,23] However no adequate explanation has been given for the reactions of these compounds with chlorine. Cl_2 is an effective

a) Values of k_{obsd} and k_{calcd} given for [Cl−] variation corresponds to $(k_{obsd}-k_a)=k_{obsd}''$ as given in Fig. 7. b) k_I corresponds to the values calculated using k_3 obtained from [H+] variation and k_{II} corresponds to the values calculated using k_3 from [AA] variation.

chlorinating agent.[24] It attacks the substrate in a fast step as shown in the catalytic cycle of the reaction in the presence of Cl^- ion. Had the reaction between substrate and Cl_2 been via the formation of $R'\text{-}CH(\overset{+}{N}H_3)COOCl$ as in the case of CAT, the rate constant for the Cl^- catalysed reaction (k_4) would have a dependence upon the structure of substrate. The results given in Table 1 clearly shows that the rate is almost independent of the structure of the substrate. This clearly shows that the reaction proceeds through the *N*-chloro derivative as shown in the Scheme. Many investigators have observed or proposed the formation of *N*-chloro derivatives as intermediates. Kantouch and Abdel-Fattah[23] have observed the formation of such chloro derivatives as intermediates on the oxidation of amino acids with sodium hypochlorite at pH 2 or 8. By investigating the role of the free amino group in the reaction with chlorine they showed that only substitution of the hydrogen atoms of the amino group takes place. Haberfield and Paul[25] have shown the existence of *N*-chloro intermediate in the chlorination of anilines. *N*-chloro derivatives were proposed as the intermediates to explain the mechanism of chlorination of anilines and related compounds.[26]

In our previous report[2] on the oxidation of threonine by CAT, we have observed

$$\frac{-d[CAT]}{dt} = (\text{const})\frac{[\text{amino acid}][CAT]^2}{[H^+]},$$

in the absence of Cl^- ion and at constant RNH_2. This observation is due to a slip in the experimental set up and hence this erroneous observation of $k_{obsd.}$ However a careful study on the oxidation of threonine by CAT shows that this system also behaves similar to the other amino acids.

The encouragement and laboratory facilities from Professor Dr. N. R. Subbaratnam is gratefully acknowledged with pleasure. Acyclic *C*-Nucleoside Analogs of the Type of 5-*C*-Polyhydroxyalkyl-1,3,4-thiadiazoles[1)]

Elsayed S. H. El Ashry,* Mahmoud A. Nassr, Yeldez El Kilany, and Ahmed Mousaad
Chemistry Department, Faculty of Science, Alexandria University, Alexandria, Egypt
(Received March 10, 1986)

The synthesis of some acyclic *C*-nucleoside analogs possessing thiadiazole rings was achieved by the heterocyclization of the 4-arylthiosemicarbazones of D-galactose, D-glucose, D-mannose, D-arabinose, and lactose, Acetylation of the thiadiazoles afforded the corresponding 2-(*N*-acetylarylamino)-5-polyacetoxyalkyl-1,3,4-thiadiazoles and periodate oxidation gave the corresponding 5-(arylamino)-1,3,4-thiadiazole-2-carbaldehyde.

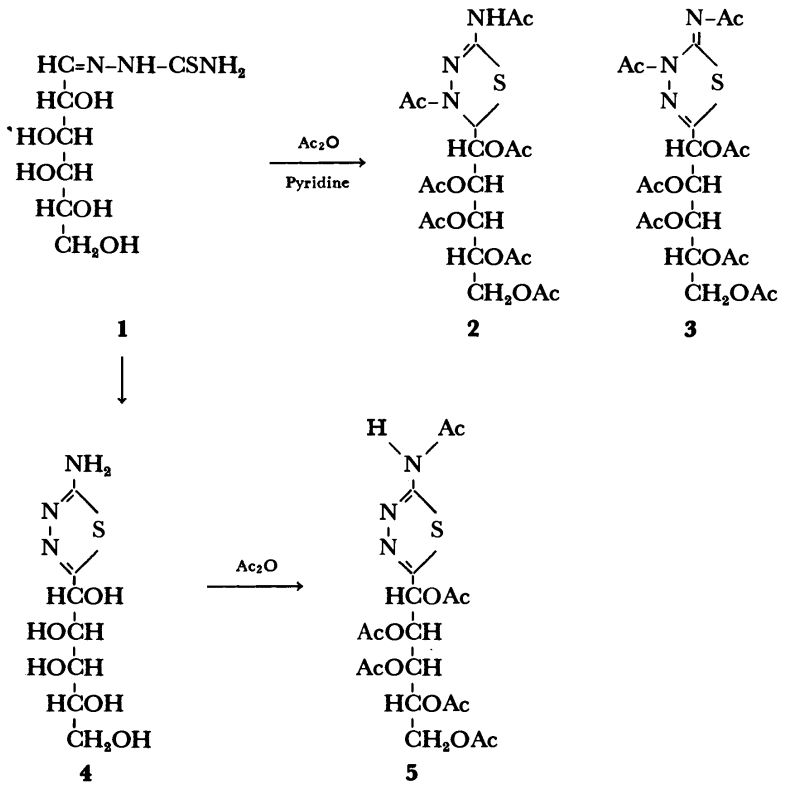
As a consequence of the biological significance of the naturally occurring *C*-nucleosides, various approaches have been explored for their synthesis. One of the main goals in this laboratory is the synthesis of the acylic *C*-nucleoside analogs,[2)] particularly via the heterocyclization of the nitrogen derivatives of sugars.

Thiadiazoles are interesting targets due to their chemotherapeutic value.[3-5)] Consequently, we report in this paper the synthesis of some corresponding acyclic *C*-nucleosides as a continuation of our interest[2,6)] in this work.

Results and Discussion

Acetylation of sugar hydrazones was found to be dependent upon the structure of the hydrazone residue as well as the acylating agent.[7-13)] Saccharide arylhydrazones gave *O*-acetylated derivatives upon reaction with acetic anhydride in pyridine, whereas boiling acetic anhydride caused further acetylation of the hydrazone residue to give *O*,*N*-acetylated derivatives.[7-9)] On the other hand, sugar aroylhydrazones showed a similar behavior to the arylhydrazones upon reaction with acetic anhydride in pyridine under mild conditions whereas boiling acetic anhydride caused cyclization of the aroylhydrazones residue to the corresponding 1,3,4-oxadiazoline derivatives.[10-12)] Reaction of D-galactose thiosemicarbazone (**1**) with hot acetic anhydride in pyridine gave 5-acetylamino-3-acetyl-2-(D-*galacto*-1,2,3,4,5-pentaacetoxypentyl)-2,3-dihydro-1,3,4-thiadiazole (**2**).[13)]

When the thiadiazole **4** was acetylated, a product **5** was obtained whose ^{1}H NMR spectrum showed a singlet at δ 13.2 indicating the presence of only one NH. This as well as the presence of six singlets corresponding to six acetyl groups confirmed the acetylation of the amino group in addition to the hydroxyl groups. The spectrum did not show a



Scheme 1.

doublet at δ 5.83 which appeared in the ^{1}H NMR spectrum of the dihydrothiadiazole derivative (**2**) and attributed to the H-2 of the heterocyclic ring. Moreover, the spectrum showed a doubled at δ 6.37 due to H-1 of the polyacetoxyalkyl side chain. The pronounced downfield shift of H-1 of **5** compared with that of **2** can be attributed to the difference in hybridization of the heterocyclic carbon attached to C-1 of the acetoxyalkyl side chain. These data agreed with structure **5** rather than **2** or **3**.

To explore the scope of heterocyclization of thiosemicarbazones, the 4-substituted thiosemicarbazones were prepared by the condensation of equimolar equivalents of the sugars with 4-substituted thiosemicarbazides. Two variants have been changed; the substituents on the 4-position of the thiosemicarbazide as well as the saccharides, whereby monosaccharides such as D-galactose, D-glucose, D-mannose, and D-arabinose as well as the oligosaccharide lactose were used. Thus the saccharide 4-arylthiosemicarbazones (**6**—**21**) were prepared, and most of them are crystalline compounds (see Table 1). The infrared (IR) spectra of the sugar 4-arylthiosemicarbazones (**6**—**21**) showed NH absorption at 3120—3210 cm^{-1} in addition to the OH band at 3300—3450 cm^{-1}.

Reaction of D-galactose 4-phenylthiosemicarbazone (**6**) with iron(III) chloride, in a similar manner to that reported[14] for thiosemicarbazones and thiobenzoylhydrazones, gave the colorless crystalline product **22**, whose elemental analysis agreed with the structure, 2-anilino-5-(D-*galacto*-1,2,3,4,5-pentahydroxypentyl)-1, 3,4-thiadiazole (**22**), indicating the loss of two hydrogen atoms. This oxidative cyclization could be extended to the whole series of the prepared thiosemicarbazones to give the corresponding thiadiazoles **22**—**34**. As the nitrogen heterocycles derived

from oligosaccharides may have the tendency to be more soluble than the corresponding monosaccharides, a behavior of great advantage in preparing a chemotherapeutic agent, the thiadiazoles **35** and **36** were prepared from the corresponding thiosemicarbazones of lactose.

Acetylation of the thiadiazoles **22—27** and **30—36** gave **37—47**, whose elemental analysis agreed with the molecular formulas having six acetyl groups, indicating that acetylation of the amino groups has occurred in addition to the per-*O*-acetylation of the hydroxyl groups. The IR spectra of the acetates showed the absorptions due to the *O*-Ac groups at 1755—1780 cm^{-1} and the *N*-Ac groups at 1670—1695 cm^{-1}.

Periodate oxidation of the 2-(substituted anilino)-5-(D-*galacto*-1,2,3,4,5-pentahydroxypentyl)-1,3,4-thiadiazoles, afforded the anticipated aldehydes 5-(substituted anilino)-1,3,4-thiadiazole-2-carbaldehyde **48—50**, whose IR spectra showed bands due to the formyl group (1685 cm^{-1}) and the NH group (3200 cm^{-1})

Experimental

General. Melting points were determined with a Kofler block apparatus and are uncorrected. Infrared spectra were recorded in Nujol film, with a Pye Unicam SP-1025 spectrophotometer. ^1H NMR spectra were carried out, in deuteriochloroform solutions containing tetramethylsilane as the internal standard, with a Jeol-100 spectrometer. Chemical shifts are given on the δ scale. Microanalyses were performed in the Chemistry Department, Faculty of Science, Cairo University, Cairo, Egypt.

5-Acetylamino-3-acetyl-2-(D-*galacto*-1,2,3,4,5,-pentaacetoxypentyl)-1,2-dihydro-1,3,4-thiadiazole (2). Acetic anhydride (7 ml) was added to a suspension of D-galactose thiosemicarbazone (**1**) (1 g) in dry pyridine (10 ml). This mixture was heated under reflux at 110 °C for 1.5 h, cooled, and then poured onto crushed ice, and the separated solid was collected by filtration, washed with water, and dried, mp 215 °C (lit,[13] mp 217 °C).

2-Acetylamino-5-(D-*galacto*-1,2,3,4,5-pentaacetoxypentyl)-1,3,4-thiadiazole (5). A solution of **4**[14] (2 g) in pyridine (10 ml) was treated with acetic anhydride (15 ml) and the mixture was kept overnight at room temperature. The reaction mixture was poured onto crushed ice, and the product that separated out was filtered off, washed repeatedly with water and sodium hydrogencarbonate solution, and dried. It was crystallized from ethanol in colorless needles, (yield: 60%), mp 165 °C; ν_{max}^{Nujol} 1750 (OAc) and 1670 cm^{-1} (NCO); ^1H NMR ($CDCl_3$) δ=2.00, 2.03, 2.04, 2.13, 2.17, 2.43 (6s, 18H, 6Ac), 3.09 (q, 1H, $J_{5,5'}$=12.0, $J_{4,5'}$=6.0 Hz, H-5'), 4.30 (q, 1H, $J_{5,5'}$=12.0, $J_{4,5}$=5.0 Hz, H-5), 5.30 and 5.38 (2 m, 3H, H-2, -3, -4), 6.37 (d, 1H, $J_{1,2}$=2.0 Hz, H-1), and 13.2 (s, 1H, NH).

Found: C, 45.6; H, 5.3: N, 7.9%. Calcd for $C_{19}H_{25}N_3O_{11}S$: C, 45.3; H, 5.0; N, 8.3%.

Saccharide 4-Arylthiosemicarbazones (6—21). A solution of the sugar (0.01 mol) in water (5 ml) was treated with a solution of 4-substituted thiosemicarbazide (0.01 mole) in ethanol (50 ml) and the mixture was heated under reflux for 1 h. The resulting solution was concentrated, and the product that separated out upon cooling, was filtered off, washed with ethanol, and dried. It was crystallized from ethanol, giving colorless needles. The noncrystalline thiosemicarbazones were directly transformed into the corresponding thiadiazoles, (yield ≈75%). (see Table 1).

2-Arylamino-5-polyhydroxyalkyl-1,3,4-thiadiazoles (22—36). A 2 M iron(III) chloride solution in ethanol (5 ml) was

added dropwise to a boiling solution of the saccharide 4-substituted thiosemicarbazone (1 g) in ethanol (100 ml). Boiling was continued for further 10 min, and the mixture was then concentrated. The product which separated out on cooling, was filtered off, washed with ethanol, dried and crystallized from ethenol in colorless needles, (yield ≈80%), (see Table 2).

2-(*N*-Acetylarylamino)-5-polyacetoxyalkyl-1,3,4-thiadiazoles (37—47). A solution of saccharide 4-arylthiosemicarbazone (1 g) in a mixture of *N*,*N*-dimethylformamide (10 ml) and dry pyridine (7 ml) was treated with acetic anhydride (10 ml) and the mixture was kept overnight at room temperature. The reaction mixture was poured onto crushed ice, and the product that separated out was filtered off, washed repeatedly with water, and sodium hydrogencarbonate solution and dried. The product was recrystallized from ethanol in colorless needles, (yield ≈ 60%), (see Table 3).

5-(Substituted Anilino)-1,3,4-thiadiazole-2-carbaldehyde (48—50). A suspension of compounds **7,9,10** (0.01 mol) in water (100 ml) was treated with a solution of sodium periodate (0.05 mol) in water (50 ml). The mixture was stirred at room temperature for 2 h, and kept overnight in the dark. The product was filtered off, washed with water, dried and crystallized from ethanol in yellow needles, (yield ≈70%), (see Table 4).

Reaction of Nitrosyl Chloride Gas with Unsaturated Steroids

Shafiullah,* Ansari M. Rafiuddin, and Shakir Husain
Department of Chemistry, Aligarh Muslim University, Aligarh-202001, U.P. India
(Received April 14, 1986)

Reaction of nitrosyl chloride gas at 0 °C with 3,5-cholestadiene (**1**) provided 3,6β-dinitro-5-chloro-5α-cholest-3-ene (**4**) and with 3α,5-cyclo-5α-cholestan-6-one (**2**) afforded 3β-chloro-5-nitro-5α-cholestan-6-one (**7**) and 3β-chloro-6-nitrato-5-cholestene (**8**). Similar reaction with 6-hydroxylimino 3α,5-cyclo-5α-cholestane (**3**) gave 3β,6-dichloro-5-cholestene (**10**), 3β-chloro-6-nitratoimino-5α-cholestane (**11**) and 3β,5-dichloro-6-nitroimino-5β-cholestane (**12**). Compound **12** upon hydrolysis furnished 3β,5-dichloro-5β-cholestan-6-one (**14**). The structures of these compounds were established on the basis of their spectral properties, and some pertinent chemical transformations. Mechanisms for the formation of some unusual products are discussed.

One of the remarkable features of nitrosyl chloride gas is that with the help of it nitro and chloro groups can simultaneously be introduced with ease at unsaturated regions of an organic molecule. Taking advantage of this ability of nitrosyl chloride, nitro and chloro groups were successfully incorporated on adjacent carbon atoms in steroidal olefins.[1-4] For this purpose we have selected, 3,5-cholestadiene (**1**), 3α,5-cyclo-5α-cholestan-6-one (**2**) and its oxime (**3**) to study the chemical behavior of nitrosyl chloride on the unsaturated functionalities in steroids. Interesting results were envisaged because nitrosyl chloride has been used, exiguously in the advancements of steroid chemistry.

Results and Discussion

Reaction of nitrosyl chloride with **1** in CCl_4 at 0 °C afforded a crystalline product **4** which in its IR spectrum showed an absorption band at 1640 for (C=C), two sets of strong bands at 1570, 1385 and at 1530, 1355 cm^{-1}, clearly indicated the presence of two nitro groups, former being a saturated and latter the unsaturated one.[5] Its proton NMR spectrum displayed a singlet at δ 6.35 for C-4 vinylic proton and a triplet at δ 4.80 (J=3 Hz) for C6-αH (equatorial).[6] Compound (**4**) gave 3,6-dinitro-3,5-cholestadiene (**5**) on heating in pyridine and on reducing with Zn-acetic acid, it gave 5α-cholestane-3,6-dione (**6**). These observations helped in concluding that the compound **4** is 5-chloro-3,6β-dinitro-5α-cholest-3-ene: The formation of which follows the same mechanism as given earlier.[4]

Compound **2** when treated with nitrosyl chloride in the similar fashion afforded 3β-chloro-5-nitro-5α-cholestan-6-one (**7**) and 3β-chloro-6-nitrato-5-cholestene (**8**). The position of nitro group at C-5 in **7** was established by the fact that the signal of the methine proton (>C<u>H</u>-NO_2) was absent in its proton NMR

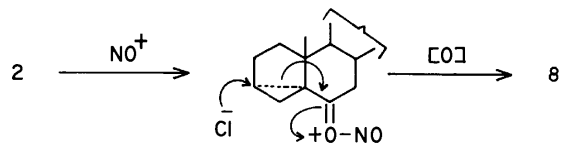
spectrum and the presence of the absorption bands at 1578 and 1380 cm^{-1} in its IR spectrum supported the saturated and tertiary nature of the nitro group.[5]

The IR spectrum of **8** exhibited characteristic absorption bands for nitrato group[5,7] at 1645, 1285, 875, and 770 cm^{-1} and a weak band at 1630 cm^{-1} for (C=C). Moreover, Zn–acetic acid reduction is known to convert the nitrato group into hydroxyl group.[8] When **8** was subjected to this reduction it gave 3β-chloro-5α-cholestan-6-one (**9**): Presumably the enol formed in the reaction tautomerized to **9** owing to the acidic conditions of the reaction medium. Mechanism for the formation of **8** is given in Scheme 1.

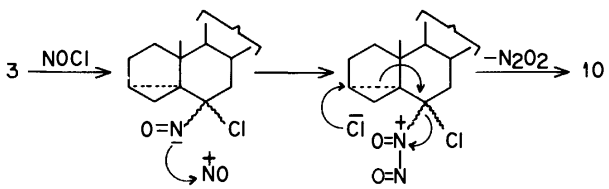
Treatment of **3** with nitrosyl chloride as described earlier provided 3β,6-dichloro-5-cholestene (**10**), 3β-chloro-6-nitratoimino-5α-cholestane (**11**) and 3β,5-dichloro-6-nitroimino-5β-cholestane (**12**).

Formation of *gem*-chloronitroso derivatives from the reaction of nitrosyl chloride and oximes is known.[9] Further nitrosation of *gem*-chloronitro derivative may lead to the elimination of N_2O_2 from the molecule. In view of this aspect the mechanism for the formation of **10** is proposed as in Scheme 2.

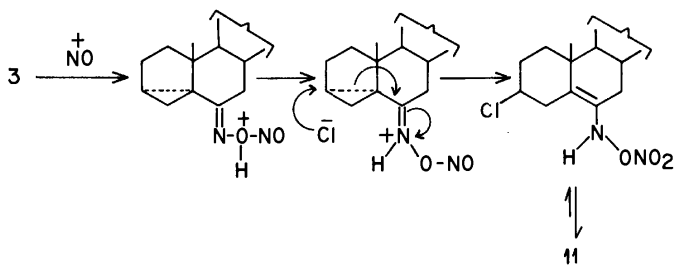
The compound **11** showed four intense bands at 1630, 1275, 875, and 770 cm^{-1} for nitrate function besides a medium band at 1650 cm^{-1} for (C=N) in its IR spectrum. The notching observed in the band at 875 was perhaps due to the N–O–N bonding, hence accounts for the presence of *N*-nitrate grouping. Zn–acetic acid reduction of **11** provided the ketone **9**



Scheme 1.



Scheme 2.



Scheme 3.

and its oxime **13**. The formation of **11** involves enamine–imine tautomerism which is depicted in Scheme 3.

As far as the formation of **12** is concerned, it is assumed that the cyclopropane ring is opened by the attack of chlorine generated as a result of the dissociation of nitrosyl chloride gas. The conversion of hydroxylimino group into nitroimino group by nitrosyl chloride[10,11] involves the formation of *N*-nitrosonitrone species as intermediate which spontaneously rearranges to nitroimine.[12]

In the proton NMR spectrum of **12** the C-3 proton resonated at relatively downfield and showed half band width (≈6.5 Hz) indicating its equatorial nature and cis geometry of A/B ring junction.[6] Chemical justification for this fact was obtained by the hydrolysis of nitroimine **12** to obtain 3β,5-dichloro-5β-cholestan-6-one (**14**) which was found different from its 5α-epimer.[13] The ketone **14** was converted into its oxime **15** which in turn gave the parent nitroimine **12** when treated with nitrosyl chloride. Dehydrochlorination of **14** provided 2,4-cholestadien-6-one (**16**) and 3β-chloro-4-cholesten-6-one (**17**).

Experimental

Melting points were determined on a Koffler hot stage apparatus and are uncorrected. Infrared spectra were recorded on a Pye-Unicam SP3-100 spectrophotometer. Proton nuclear magnetic resonance spectra were taken on a Varian A 60 instrument with $(CH_3)_4Si$ as internal reference, and mass spectra were recorded on a JEOL JMS-D 300 spectrometer. Elemental analyses were performed by Instrumentation Centre at our University. Compounds **1**,[14] **2**,[15] and **3**[16] were prepared according to the literature. Nitrosyl chloride gas was prepared according to Morton and Wilcox's method.[17]

Reaction of 1 with NOCl. The solution of **1** (2 g) in CCl_4 (100 mL) was cooled to 0 °C and dried NOCl was bubbled into it for 2 h. The reaction mixture was kept overnight at 0 °C and the solvent was evaporated under reduced pressure and the residue was taken in ether, washed with water, and dried (Na_2SO_4). After removal of the solvent, the oily residue was subjected to the column chromatography over silica gel (40 g). Elution with light petroleum (bp 60—80 °C):ether (25:1) gave **4**, recrystallized from methanol (1.4 g, 70%); mp 156 °C (positive Beilstein test); IR (KBr) 1640, 1570, 1530, 1385, 1355, 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.72 (3H, s, 18-CH_3), 1.05 (3H, s, 19-CH_3), 4.80 (1H, t, J=3 Hz, 6α-H), 6.35 (1H, s, 4-H); MS, *m/z* (relative intensity) 496/494 (0.20/0.60, M^+), 413 (5), 396 (12), 383 (6), 382 (14), 107 (25), 105 (25). Found: C, 65.56; H, 8.67; N, 5.60%. Calcd for $C_{27}H_{43}N_2O_4Cl$: C, 65.52; H, 8.69; N, 5.66%.

Dehydrochlorination of 4. In pyridine (200 mL), **4** (500 mg) was refluxed for 2 h. The reaction mixture was diluted with water and organic mass was extracted with ether and ethereal layer was washed with dil HCl (5%), $NaHCO_3$ solution (5%) and water and dried (Na_2SO_4). Removal of the solvent gave **5** as an oil, crystallized from methanol (400 mg, 80%); mp 113 °C (lit,[4] 113 °C) (negative Beilstein test); IR (KBr) 1651, 1515, 1380 cm^{-1}; ^1H NMR

($CDCl_3$) δ=0.71 (3H, s, 18-CH_3), 1.10 (3H, s, 19-CH_3), 7.7 (1H, s, 4-H).

Zinc-Acetic Acid Reduction of 4. In 50 mL of warm acetic acid, **4** (500 mg) was dissolved and zinc dust (2 g) was added gradually over a period of 10 min. The mixture was heated under reflux for 4 h, water (5 mL) was added with regular intervals. It was diluted with water and organic mass was extracted with ether. The ethereal layer was worked up, dried (Na_2SO_4) and the solvent was evaporated to get **6** as an oil, crystallized from acetone (300 mg, 60%); mp 167 °C (lit,[18] mp 169 °C) (negative Beilstein test); IR (nujol) 1710 cm^{-1}.

Reaction of 2 with NOCl. The reaction of **2** (5 g) in CCl_4 (250 mL) with NOCl was performed as earlier. After usual work up an oily mass was obtained which was chromatographed over a column of silica gel (80 g). Elution with light petroleum (bp 60—80 °C) afforded **7**, recrystallized from methanol (1.8 g, 36%): mp 92 °C (positive Beilstein test), IR (nujol) 1718, 1578, 1390, 740 cm^{-1}; ^1H NMR (CCl_4) δ=0.75 (3H, s, 18-CH_3), 1.18 (3H, s, 19-CH_3), 1.7 (2H, d, 4-H_2), 3.4 (1H, m, $W_{1/2}$=16 Hz, 3α-H, A/B ring junction trans;[6] MS, *m/z* (relative intensity) 421/419 (2/6, M-NO_2), 418 (20), 416 (61), 318 (45), 306 (3), 304 (9), 270 (35). Found: C, 69.61; H, 9.49; H, 3.02%. Calcd for $C_{27}H_{44}NO_3Cl$; C, 69.60; H, 9.45; N, 3.01%. Further elution with light petroleum (bp 60—80 °C):ether (25:1) afforded **8**, recrystallized from methanol (2.5 g, 50%); mp 124 °C (positive Beilstein test); IR (KBr) 1645, 1630, 1285, 875, 770, 725 cm^{-1}; ^1H NMR (CCl_4) δ=0.77 (3H, s, 18-CH_3), 1.20 (3H, s, 19-CH_3), 3.80 (1H, m, $W_{1/2}$=17 Hz, 3α-H); MS, *m/z* (relative intensity) 467/465 (0.50/1.50 M^+), 416 (1), 414 (2), 398 (45), 370 (15).

Zinc-Acetic Acid Reduction of 8. In warm acetic acid (100 mL), **8** (1 g) was dissolved and zinc dust (5 g) was added portionwise during 15 min. The mixture was stirred for 1 h at 30 °C. It was concentrated to half volume and diluted with saturated brine (300 mL) and filtered, and then worked up as usual to obtaine crude **9**, crystallized from methanol (600 mg, 60%); mp 127 °C (lit,[19] 128—129 °C); IR (nujol) 1705, 740 cm^{-1}.

Reaction of 3 with NOCl. Reaction of NOCl with **3** (5 g) in CCl_4 (250 mL) was carried out worked up in the similar fashion. An orange-colored oily mass thus obtained was chromatographed over a column of silica gel (80 g). Elution with light petroleum (bp 60—80 °C) furnished **10**, recrystallized from light petroleum (bp 40—60 °C) (1.1 g, 22%); mp 95 °C (positive Beilstein test); IR (nujol) 1650, 770, 760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.65 (3H, s, 18-CH_3), 1.28 (3H, s, 19-CH_3), 3.68 (1H, m, $W_{1/2}$=17 Hz, 3α-H); MS, *m/z* (rel intensity) 440/438 (2/6, M^+), 437 (3), 435 (9), 424 (6), 422 (17), 405 (16), 403 (47). Found: C, 73.88; H, 10.00%. Calcd for $C_{27}H_{44}Cl_2$: C, 73.80; H, 10.02%. Further elution with light petroleum (bp 60—80 °C):ether (85:1) afforded **11**, recrystallized from acetone (2.3 g, 46%); mp 114 °C (positive Beilstein test); IR (KBr) 1650, 1630, 1275, 865, 770, 760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.72 (3H, s, 18-CH_3), 1.19 (3H, s, 19-CH_3), 4.7 (1H, m, $W_{1/2}$=18 Hz, 3α-H, A/B ring junction trans);[6] MS, *m/z* (rel intensity) 467/465 (1/3, M-CH_3), 440 (12), 438 (35), 405 (4), 403 (3), 403 (7). Found: C, 67.47; H, 9.31; N, 5.85%. Calcd for $C_{27}H_{45}N_2O_3Cl$: C, 67.43; H, 9.37; N, 5.83%. Continued elution with light petroleum (bp 60—80 °C):ether (80:1) provided **12**, recrystallized from methanol (1.3 g, 26%); mp 124—126 °C (positive Beilstein test); IR (KBr) 1638, 1557, 1362, 760, 680 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.72 (3H, s, 18-CH_3), 1.12 (3H, s, 19-CH_3), 2.8 (2H, d, J=4.5 Hz, 4-Hz), 4.82 (1H, m, $W_{1/2}$=6.5 Hz, 3β-H, A/B ring junction cis);[6] MS, *m/z* (rel intensity) 464/462 (3/9, M-HCl), 431 (5), 404 (13), 402 (40), 386 (4), 384 (12). Found: C, 65.00; H, 8.86; N, 5.58%. Calcd for $C_{27}H_{44}N_2O_2Cl_2$: C, 64.93; H, 8.82; N, 5.61%.

Zinc-Acetic Acid Reduction of 11. In warm acetic acid (100 ml), **11** (1 g) was dissolved and zinc dust (10 g) was added portionwise in 15 min. The mixture was stirred for 30 min at 30 °C. Acetic acid was evaporated to its half volume and saturated brine (300 mL) was added. After working up in usual fashion and oil was obtained which was chromatographed over silica gel (40 g) column. Elution with light petroleum (bp 60—80 °C): ether (40:1) gave **9** (500 mg, 50%). Further elution with light petroleum (bp 60—80 °C): ether (10:1) furnished **13**, recrystallized from methanol (100 mg, 10%); mp 172 °C (lit,[20] mp 175 °C); IR (nujol) 1653, 730 cm^{-1}.

Hydrolysis of 12. A mixture of **12** (2 g), methanol (250 mL) and HCl (10 mL) was heated under reflux for 1 h and was diluted with excess of water, and worked up in usual fashion which fetched **14** as yellowish sticky semisolid (1.7 g, 85%), (positive Beilstein test); IR (nujol) 1720, 760, 675 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.80 (3H, s, 18-CH_3), 1.15 (3H, s, 19-CH_3), 1.9 (2H, d, J=4 Hz, 4-Hz), 4.0 (1H, m, $W_{1/2}$= 8 Hz, 3β-H, A/B ring junction cis);[6] MS *m/z* (rel intensity) 456/454 (5/15, M^+), 452 (26), 418 (20), 416 (62), 398 (4), 382 (10), 353 (13). Found: C, 71.29; H, 9.62%. Calcd for $C_{27}H_{44}OCl_2$: C, 71.21; H, 9.67%.

Oximation of 14. A mixture of **14** (500 mg), hydroxylamine hydrochloride (1 g) and sodium acetate trihydrate (1.5 g) in ethanol (60 mL) was heated under reflux for 1.5 h. The excess of ethanol was evaporated and cold water was poured in. The crude oxime was filtered, washed with water and air dried. Recrystallization from ethanol yielded **15** (350 mg, 70%); mp 153 ° (lit,[21] mp 155 °C): IR (KBr) 3450, 1668, 750, 695 cm^{-1}; ^1H NMR (CCl_4) δ=0.65 (3H, s, 18-CH_3), 1.18 (3H, s, 19-CH_3), 4.50 (1H, m, $W_{1/2}$=8 Hz, 3β-H, A/B ring junction cis),[6] 7.90 (1H, s, 6=N-OH).

Reaction of 15 with NOCl. In CCl_4 (20 mL), 15 (250 mg) was dissolved and cooled to 0 °C. NOCl gas was passed through the solution for 1 h. The solvent was evaporated and taken in ether and worked as usual. Removal of the solvent gave crude **12**, crystallized from methanol (150 mg, 60%); mp 123—126 °C.

Dehydrochlorination of 14. **14** (1 g) was refluxed in pyridine (20 mL) for 2 h. The reaction mixture after work up provided an oil which was chromatographed over silica gel (25 g). Elution with light petroleum (bp 60—80 °C): ether (20:1) afforded **16**, recrystallized from acetone (200 mg, 20%); mp 127—128 °C (lit,[22] mp 128 °C) (negative Beilstein test); IR (KBr) 1673, 1625 cm^{-1} continued elution with light petroleum (bp 60—80 °C):ether (15:1) furnished **17**, recrystallized from light petroleum (bp 40—60 °C) (350 mg, 35%); mp 165 °C (lit,[21] mp 165 °C) (positive Beilstein test); IR (KBr) 1685, 1620, 740 cm^{-1}.

We are grateful to Professor M. S. Ahmad for provision of facilities and useful discussion.

Hydrogenation of Aromatic Nitro Compounds with A Pt/SiO_2-$AlPO_4$ Catalyst

M. Angeles Aramendía Lopidana, Victoriano Borau Bolos, Cesar Jiménez Sanchídrían, J. María Marinas Rubio,* and Francisco Rodero Luque
Department of Organic Chemistry, Faculty of Sciences, Córdoba University, Córdoba, Spain
(Received April 28, 1986)

In this work we have carried out the reduction of aromatic nitro compounds bearing different substituents with gaseous hydrogen, over a Pt catalyst (3% by weight) supported on a SiO_2-$AlPO_4$ system. The catalyst was obtained by impregnation, the impregnating metal salt being reduced with α-phellandrene. The kinetic data found allow us to describe the reduction of nitrobenzene as a Langmuir-Hinslwood kinetic. The sequence of reaction rates for the different nitro compounds assayed conforms to the Hammett-Taft equation, which allows relating the electron density of the aromatic ring to the reduction rate of the nitro group. Finally, we propose mechanism for the process, characterized by the absence of intermediates with net charges.

The reduction of nitro compounds has been comprehensively studied by many authors with the aid of the metal-acid system,[1] using gaseous hydrogen,[2,3] or by hydrogen transfer[4-6] over Fe, Ni, or Pd catalysts supported on silica or alumina,[7,8] as well as in homogeneous phase.[9,10] In spite of being a well-known process, its remarkable industrial applications are responsible for the interest which it still arises among researchers. The solids most frequently used as supports are silica, alumina, carbon, and zeolites.

Aluminum orthophosphates, either pure or mixed with SiO_2 or Al_2O_3, are stable solids whose texture properties and acidity may be controlled in the synthetic procedure[11,12] and which have proved to be excellent as supports for Pd and Pt catalysts in some reduction processes.[13,14] These systems have also been used as supports for nickel (both by our team[15-17] and by Marcelin et al.[18,19]) and rhodium.[20,21] Recently, some authors have begun to prepare catalysts prereduced under reflux with olefinic[22] or hydroaromatic compounds or even other substances which decompose to simple products.[23]

The mechanism through which the reduction of nitro compounds takes place is quite well understood when the reduction is carried out with the metal-acid system; this process begins with the attack of a hydrogen atom:

$$C_6H_5NO_2 \xrightarrow[\text{slow}]{H\cdot} C_6H_5\text{-}\overset{\oplus\cdot}{N}\begin{matrix}\diagup O\text{-}H \\ \\ \diagdown \ddot{O}:^{\ominus}\end{matrix} \rightarrow \rightarrow \rightarrow C_6H_5NH_2 \quad (1)$$

(fast)

However, when the reduction is performed with supported metals, the nature of the support may result in the formation of protons and hydride ions on the metal surface, these species becoming the actors of the reduction process.

On the other hand, in the hydrogenation of nitro compounds with supported palladium catalysts, Carturan et al.[24] found that the rate-determining step in the reduction of a nitro compound with a metal catalyst may be the hydrogenation of the metal surface oxidized by the sorbed nitro compound.

In this work we have carried out the reduction of aromatic nitro compounds with different substituents over Pt catalysts supported on SiO_2-$AlPO_4$. The results obtained seem to indicate that the reduction of the nitro group is not an isolated process of the molecular rest, and that the electron density of the neighboring aromatic ring influences the reduction rate.

Experimental

Support. We have used a support made of SiO_2-$AlPO_4$ (80:20% by weight) named F72, the synthesis and properties of which were described elsewhere.[11,12] Summarized, its texture properties are described as follows: S_{BET}=247 m^2g^{-1}; average pore radius=32 Å; cumulative pore volume= 0.59 mLg^{-1}.

Catalyst. We have used a Pt catalyst (3% by weight) deposited on support F72. It was prepared by impregnation from an aqueous solution of K_2PtCl_6.

The supported metal salt was reduced by keeping the solid under reflux with α-phellandrene at 453 K for 2 h. The resulting catalyst was washed several times with methanol and vacuum-dried prior to use.

The catalyst nomenclature includes the symbol of the metal deposited, the percent loading and the name of the support (F72 in this case).

Apparatus. The reduction of nitrobenzene with gaseous hydrogen was accomplished in a low pressure Gerhardt reactor fitted with a pressure gauge which measured the evolution of the hydrogen pressure in the reaction vessel. All reactions were carried out at 300 K, using methanol as solvent (V_{total}= 20 mL) and 3×10^{-3} g of metal. The reaction temperature was controlled by means of a thermostatic bath.

The reaction rate was calculated from the slope of the straight line obtained by plotting the consumption (in moles of hydrogen) as a function of time.

All reagents used were high-purity commercial chemicals.

Product Analysis. The reaction products were analyzed by gas chromatography, using high-purity standards in their characterization. Their presence was confirmed by mass spectrometry using GC-MS systems.

The products obtained were the corresponding anilines; no by-products or reaction intermediates were detected in

any case. *m*-Dinitrobenzene was reduced selectively to *m*-nitroaniline.

Determination of Metal Particle Size. The metal particle size was determined by X-ray diffraction. The X-ray diffractogram was recorded on a Philips 1130/00/60 apparatus, using the Co $K\alpha$ radiation, with λ=1.7889 Å. The half-peak width was measured graphically at an angle 2θ=46.52° corresponding to plane (1 1 1) of Pt, assuming a value of 0.89 for the Debye-Scherrer constant.

The metal surface, $S(m^2g_{Pt}^{-1})$ was obtained from the mean particle diameter, D (Å), using the relation: $S=6\times10^{-4}/\rho D$, where ρ is the density of platinum (g cm^{-3}).

The metal surface was determined by assuming the spherical particle model. The mean diameter of the metal cristallites was 55 Å and the metal surface 51 $m^2g_{Pt}^{-1}$ for the synthesized catalyst.

Results and Discussion

Influence of the Solvent. Table 1 shows the results obtained in the hydrogenation of nitrobenzene in various solvents. As can be observed, methanol provided the best results and was therefore chosen for all subsequents experiments.

Reaction Kinetic. We have carried out blank test at 300 K in order to confirm the absence of phenomena extraneous to the catalytic process. Neither the support nor any other part of the reactor was found to be active in the nitro compound reduction. Neither did we observe any diffusion phenomena when shaking the reaction mixture at 200 shakes min^{-1} nor intraparticular diffusion in the catalyst studied.

We have checked that the transfer hydrogen from the gas phase to the reaction medium is not the rate-limiting step of the process. Figure 1 shows the straight line obtained by plotting the reciprocal of the reaction rate (in mol of nitrobenzene s^{-1}) obtained at 300 K as a function of the reciprocal of the amount of catalyst used.

The rate of transfer of hydrogen from the gas phase to the catalyst, calculated from the intercept, is much higher than any of the reaction rates found in our experiments. Thus, we can state that the process is not governed by the diffusion of hydrogen to the catalyst surface through the liquid phase.

Hydrogen pressures in the range 3.1—6.2 bar and nitrobenzene concentrations between 0.1—1.0 M (1 M=1 mol dm^{-3}) were used in the determination of the kinetic parameters. The reaction kinetic was studied using methanol as solvent.

We have observed that, under the reaction conditions used, the reaction order with respect to nitrobenzene changes in the manner illustrated in Fig. 2. This order which has a value of 0.48 for nitrobenzene concentrations between 0.1—0.25 M, begins to decrease above this range until eventually becoming zero at a concentration of 0.4 M. The dependence of the reaction order on the concentration may be attributed to the sensitivity of adsorption equilibria to changes in the concentration of a liquid phase reactant.[25,26]

In the range wherein the order in nitrobenzene is zero, the reaction order with respect to hydrogen is 0.92. Under these conditions, the kinetic rate law found was:

$$V = K|P_{H_2}|^{0.92}, \quad (2)$$

where K is the pseudo rate constant.

Table 1. Influence of the Solvent on the Reduction of Nitrobenzene with Gaseous Hydrogen Catalyst Pt 3 F72

Solvent	V_0/mol s^{-1} $m_{Pt}^{-2}\times10^6$	ε
Methanol	48.4	32.6
Tetrahydrofuran	15.7	
N,*N*-Dimethylformamide	14.4	38.0
Dioxane	11.1	2.2
Chloroform	3.6	4.8

* Hydrogen pressure: 5.06 bar; nitrobenzene concentration: 0.5 M; total volume: 20 mL; reaction temperature: 300 K. ε: dielectric constant at 298 K.

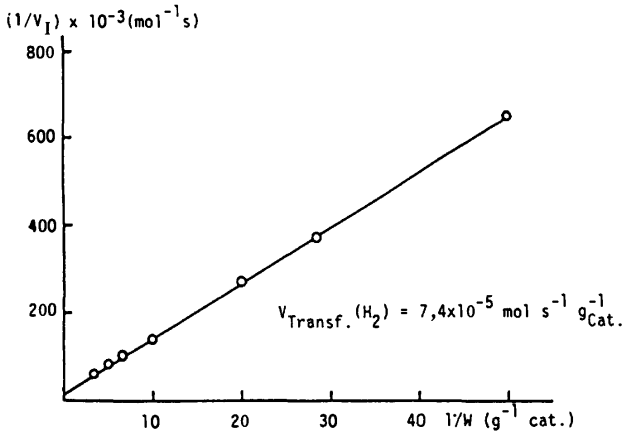

Fig. 1. Plot of $1/V_1$ vs. $1/W$ for the reduction of nitrobenzene with H_2 gaseous.

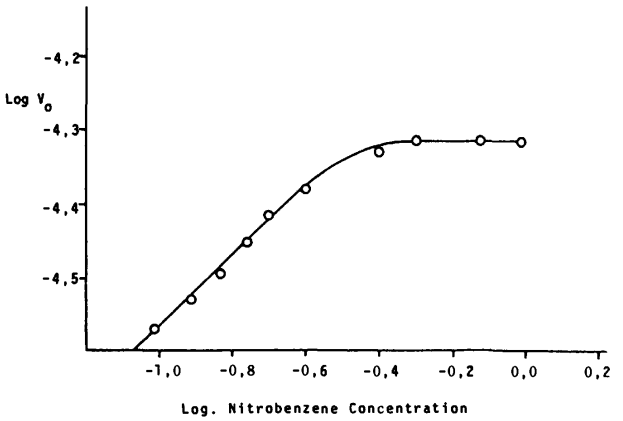

Fig. 2. Logarithmic plot of V_0 as a Function of the nitrobenzene concentration.

The results found are consistent with a Langmuir-Hinselwood type mechanism for which several expressions may be formulated.[27] Our experimental results comform the expression:

$$r_1 = K_0 \frac{KP_{H_2}}{1+KP_{H_2}}, \quad (3)$$

with a correlation coefficient better than 0.99 and with a positive intercept for all temperatures studied. These results are in favor of a noncompetitive adsorption Langmuir-Hinselwood mechanism.

Hydrogenation of Various Nitro Compounds. Table 1 lists the rates of nitrobenzene reduction obtained by using different solvents. There is no correlation between the dielectric constant of the solvent and the reaction rate obtained, which indicates that no net charges (which would result in the formation of carbonium ions or carbanions) develop along the process. Similar results were obtained by using Pd catalysts supported on the same solid in the reaction of nitro compounds with dihydrogen.[28] However, the process is essentially different when the nitro compound reduction is carried out by hydrogen transfer.[29] In that case, the solvent polarity has a strong influence on the reduction rate of the nitro compound, and the determining step of the process may be assumed to involve the attack of a hydride ion or a proton, depending on the electron-withdrawing or electron-releasing nature of the substituent borne by the aromatic ring.[30,31]

Figure 3 illustrates how the results obtained in the reduction of various nitrocompounds in different solvents conform to the Hammett equation in the form: Log $V_1/V_{1o}=\sigma\rho$, where V_1 and V_{1o} are the reduction rate of the substitued nitrobenzene and nitrobenzene respectively.

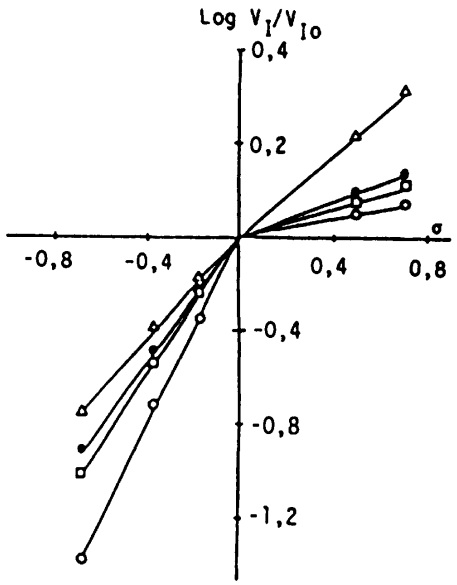

Fig. 3. Correlation between $\log(V_1/V_{10})$ and for various nitro compounds.

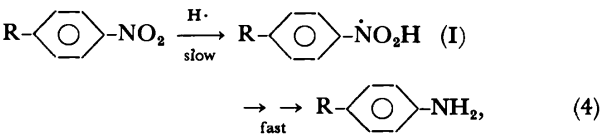
○ Methanol; □ DMF; ● THF; △ $CHCl_3$.

The straight line obtained show a different behavior of the nitro compounds according to whether the substituent is an electron-releasing of electron-withdrawing one. The substituents present only seem to participate through their electric effects. A worse fitting of the experimental results is observed by plotting the corresponding σ^+ or σ^- of the substituents, assuming the involvement of mesomeric effects which would stabilize charged intermediates. The electric effect of the substituent is transmitted through the aromatic ring, either increasing or decreasing the electron density on the nitro group to be reduced. The value of ρ (specific reaction constant), calculated from the slope of the straight lines shown in Fig. 3, provides information on the mechanism through which the process takes place. The value of ρ depends on the particular solvent used, as well as on the electron-releasing or electron-withdrawing nature of the substituents.

As can be observed, the slope changes at the origin, which is indicative of a change either in the mechanism proper or in the sensitivity of the process to the electron-releasing or electron-withdrawing effect of the substituents. The small absolute values of ρ show the slow step of the process to involve a transfer of charge or electron density rather than an appreciable mass transfer.

The results obtained can be accounted for in two ways:

a) According to the following scheme:



(4)

in which the stability of intermediate I is affected by the electron-releasing or electron-withdrawing nature of group R. The mechanism involved in the reduction of nitro compounds is basically the same as that described for the reduction with metal-acid systems,[1] and differs from the one proposed for the reduction of aromatic nitro compounds by hydrogen transfer using Pd supported catalysts in that the rate-determining step of these is supposed to be the transfer of a hydride ion.[28] Other authors have proposed mechanism for the reduction of nitro compounds with metal hydrides[32] or by transfer[9] in which the process starts with the attack of a hydride ion. Recently, it has been observed that the attack of the hydride species can be regarded as the result of three successive stages; an electron, a proton and a new electron.[33] Our results do not seem to indicate the presence of species with net charges in the rate-determining step. The nature of substituent may facilitate or hinder the adsorption of the nitro compound, since it modifies the electron

density on the aromatic ring. Taft et al.[34-36] have studied the variation of the electron density on the carbon atom to which the nitro group is linked as a function of the substituent borne by the ring in different aromatic nitro compounds. Such electron density varies in much the same way as the reaction rates found in this work and in several others.[28,32] For electron-withdrawing substituents, the slope of the straight line obtained is 0.1, whereas for electron-releasing groups, the slope is 2.0, the line corresponding to the reference compound (nitrobenzene) showing an inflection point. Therefore, the aromatic ring seems to inequivocally cooperate in the reduction of the nitro group. Electron withdrawing substituents favor the adsorption of the nitro compound and contribute to stabilize the intermediate generated, which bears unpaired electrons.

In view of the results obtained, the catalyst must have a metal surface with a high electron density which favors the adsorption of the nitro compound. By assuming the possible interaction between the aromatic ring and the metal surface, the ease of adsorption of the nitro compound will increase with decreasing electron density on the aromatic ring as a result of the electron withdrawing effect of the substituent. Table 2 shows the initial rates of hydrogenation of various nitro compounds. The electron configuration of platinum, $5d^9\ 6s^1$, suggests the possibility of an electron flux from the support to the metal, which would result in the filling of the vacant upper levels and hence in increased surface electron density.

b) On the other hand, the mechanism of the process may involve nitrenes according to the scheme proposed by Carturan et al.[24] for the hydrogenation of aliphatic and aromatic nitro compounds by use of supported palladium catalysts:

$$ArNO_2 + \text{metal} \xrightarrow[(1')]{} \text{oxidized metal surface} + ArN\text{:}\ (ads)$$

$$\xrightarrow[(2')]{ArNO_2} R\text{-}\overset{|}{N}\text{-}O\text{-}\ (\text{dimeric or oligomeric intermediates})$$

$$\xrightarrow{H_2} R\text{-}NH_2 + \text{metal} + H_2O\,. \qquad (5)$$

Table 2. Initial Rates of Hydrogenation of Various Nitro Compounds. Catalyst: Pt 3 F72

Nitro compound	σ	V_I/mol s^{-1} $m_{Pt}^{-3} \times 10^6$
p-Aminonitrobenzene	−0.66	2.0
p-Nitrophenol	−0.37	9.0
p-Nitrotoluene	−0.17	21.6
Nitrobenzene	0.00	48.4
p-Nitroacetophenone	0.50	54.3
m-Dinitrobenzene	0.71	56.8
