The soybean cyst nematode (*H. glycines* Ichinohe) parasitizes a small group of host plants, including soybean (*Glycine max*), kidney bean (*Phaseolus vulgaris*), and adzuki bean (*P. angularis*), and causes "soybean sickness."[7] The life cycle of this nematode is summarized as follows.[7] The female adult, after copulation, is almost completely filled with the ovary and then with the eggs, and dies. Within a few days, the embryo in the egg molts into the first and second stage larva, and enters a domant stage in the dead female called "cyst." Each cyst usually contains about 250 eggs within the body and, without host plants, persists in the soil for many years. In spring, when temperature, moisture, and other factors become desirable, and also when the host plants are cultivated in the soil, the second stage larvae in the eggs hatch, and the hatched larvae emerge out of the cysts. After invading the roots and causing formation of giant cells, the second stage larvae become large and molt into the male and female adults via the third and fourth stage larvae. These larvae feed on the giant cells and hence infect the host plants. This life cycle is completed within 4 weeks, if all the conditions are satisfied. The most interesting stage in this life cycle is hatching and emergence. Various factors affecting the hatching and emergence have been examined in details.[8-13] Of these factors, the most important one is chemical stimuli secreted by the roots of host plants, since these stimuli are connected with the host-parasite specificity. In 1966 Tsutsumi and Sakurai demonstrated[14] that the hatching and the larval emergence of the soybean cyst nematode were stimulated by root diffusates from the host plants. The present investigation was then commenced in 1967 with the purpose of ecological eradication of the nematode, based on these findings, and resulted recently in successful isolation and structure elucidation of the relevant natural hatching stimuli, designated as glycinoeclepins A, B, and C. These results have been reported in preliminary communications.[15-18] In the present article we describe the isolation procedure of these active principles in details.

Bioassay. The method of bioassay for the hatching, required for efficient isolation of the active principles, was carried out as follows. Usually ca. 100 cysts were obtained from ca. 100 g of the nematode-infested soil, which were collected in October at Memuro, Hokkaido, and stored in a refrigerator at 5 °C. The cysts were soaked at 25 °C for 10 d, then dissected in water and sieved through a 325-mesh sieve. The dissected cyst wall fragments remained on the sieve. The eggs and larvae, which had been hatched, were collected on filter papers and transferred to a beaker with water so that 1 ml of the aqueous suspension contained 150—200 eggs. Then 1 ml of this suspension was transferred to a Syracuse watch glass to which 1 ml of the test solution and 8 ml of distilled water were added. The whole suspension was kept at 25 °C, and the number of larvae hatched was counted after 10 d. The per cent hatching rate was expressed as $P=P_t-P_w$, where P_t and P_w denote the per cent hatching observed in the test solution and in distilled water, respectively. The test solution was said to be active, when the hatching rate, P, exceeded 50%. This bioassay is characterized by using the free eggs instead of the cysts, and also by soaking the cysts in water at 25 °C for 10 d before the test. Compared with the bioassays which had been performed with the cyst by most of the previous workers, this bioassay has been found to be simpler and more reproducible.

Preparation of Hatch-Stimulating Concentrates. A large amount of the concentrates, the active raw materials, were prepared from aqueous extracts of the

roots of two subspecies ("Hon-kintoki" and "Beni-kintoki") of kidney bean rather than those from their root diffusates, because the diffusates were highly active, compared with the aqueous extracts, but too unstable for further purification.[19] The two subspecies were cultivated in 1 hectare of the field at Memuro for 3 months (early May to late July). The roots were collected by cutting just before flowering, air-dried for 1—3 months (August to November), and pulverized. The dried and powdered roots (ca. 100 kg) thus obtained were extracted with water (1.5—3 kl) at a temperature below 10 °C for 1 month (November to December). The aqueous suspensions were filtered and concentrated below 30 °C, acidified with concd hydrochloric acid to pH 3, and extracted again with chloroform repeatedly (January to April). The chloroform solution, after concentration, gave the hatch-stimulating concentrates (ca. 100 g) (Chloroform extracts A), which stimulated the hatching and emergence at 10^{-5} g ml^{-1} in water at 25 °C. The dilute (10^{-5} g ml^{-1}) aqueous solution of the concentrates was called "standard solution" and always used for the bioassay for reference.

Isolation. In 1982 we reported[15] the isolation of a natural hatching stimulus, designated as glycinoeclepin A (GEA), for the soybean cyst nematode, as its bis(*p*-bromophenacyl) ester (p-BPE). In 1977, five years before the isolation, we had obtained one fraction [Fraction L (p-BPE)] after repeated chromatography of the hatch-stimulating concentrates according to the procedure shown in Table 1.[20] The fraction had revealed a single peak by analytical high performance liquid chromatography (HPLC) on a variety of columns and showed high activity (active at 10^{-11}—$^{-12}$ g ml^{-1}) for the hatching. However, with a limited amount (ca. 5 μg from ca. 100 g of the concentrates) of the fraction, it had not been feasible in the year of 1977 to obtain any useful MS and ^{1}H NMR spectral data of the fraction, because of unavoidable contamination by impurities of solvent and column origin. Four years later, in 1981, the fraction could be identified as p-BPE of the active principle in question on the basis of the same chromatographic behavior and FD-MS spectrum as those of GEA p-BPE. It implies that the procedure described in Table 1 has resulted in the first isolation

Table 1. Isolation of GEA as its p-BPE

Dried and powdered roots of kidney bean "Beni-kintoki" [135 kg (1 ha)]	
↓ Extraction with water (2 kl) (<10 °C)	
↓ Evaporation (<30 °C) under reduced pressure

Fraction J (p-BPE)	(0.19 mg, active at 10^{-10} g ml^{-1} after hydrolysis)
↓ Preparative HPLC, MicroPak NH_2-10 (C_6H_{14}-CH_2Cl_2-MeCN, 70:18:12)	
Fraction K (p-BPE)	(≈50 μg, active at 10^{-10}—$^{-11}$ g ml^{-1} after hydrolysis)
↓ Preparative HPLC, Hitachi Gel #3011 (MeOH-CH_2Cl_2, 9:1)	
Fraction L (p-BPE) (=GEA p-BPE)	(≈5 μg, active at 10^{-11}—$^{-12}$ g ml^{-1} after hydrolysis)

of GEA.

The isolation procedure summarized in Table 1 will deserve the following comments. a) The hatch-stimulating concentrates were initially fractionated (Fraction A to H) by various types of column chromatography such as adsorption, reversed-phase partition, and ionic exchange chromatography, in the light of the separation procedure of gibberellins[21] and prostaglandins. A number of inactive aliphatic and aromatic acids and abscisic acid-related compounds were isolated and identified during chromatography over Charcoal-Celite (Fig. 1) and silica gel (see Experimental). Usually several active fractions were separated in each of the steps. Fortunately, any special enhancement in the activity was not observed by combination of such active fractions, and only the most active fraction in each step was submitted to the subsequent separation step. The following points are annotated. i) Chromatography over silica gel (Fraction C to E) did not always give satisfactory results in reproducibility; it sometimes resulted in remarkable decrease of the amount without increase or with loss of the activity.[22] ii) Reversed-phase partition chromatography on a siliconized Hyflo Super Cel column (Fraction E to F) led to efficient concentration of active fractions (Fig. 2) under almost the same conditions as those for effective separation of prostaglandins.[23] However, the column was not expected to be suitable for separation of a large amount of the material. iii) Subsequent separation by chromatography over ionic exchange resins (Fraction F to H), Amberlyst-15 (Ag^+ form) and Amberlyst XN-1005 (Ag^+ form) columns, appeared to have been

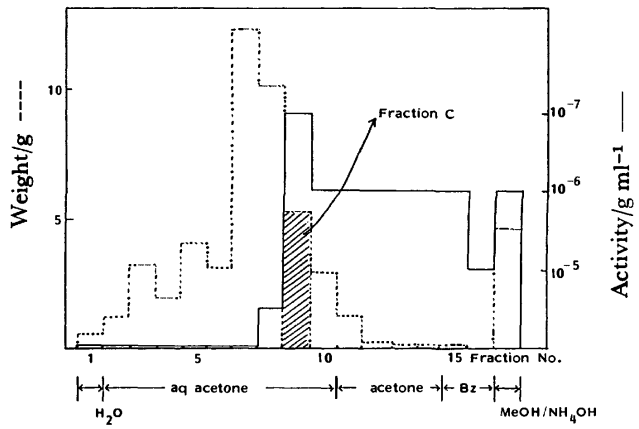

Fig. 1. Column chromatography of Acidic extracts B on the Charcoal-Celite column (Table 1). Eluent: Frs. 1—10, H_2O–acetone (10 : 0, 9 : 1, 8 : 2, 7 : 3, 6 : 4, 3 : 7, 2 : 8, 1 : 9); Frs. 11—14, acetone: Frs. 15—16 (benzene); Fr. 17, (MeOH–concd NH_4OH). The hatching activity was checked with the eggs.

performed efficiently, as had been exemplified by smooth separation of prostaglandins such as PGE_1 and PGE_2.[24,25] However, the silver cations, contaminated in the columns and eluted with solvents, caused serious decrease in the activity of eluates and disturbed the bioassay. It was necessary to wash the columns with distilled water repeatedly (ca. 1 month) in order to remove the silver cations completely and carry out the bioassay in a usual manner. b) *p*-Bromophenacylation of the acid mixture [Fraction H to I (p-BPE)] did not proceed in a satisfactory yield (ca. 30%) by the reported procedure using crown ethers.[26] c) Preparative HPLC on three different types of columns resulted in the effective separation of active fractions, giving only one active fraction in each of the steps without loss of the activity (Figs. 3, 4, and 5). The MicroPak CN-10 column[27] is packed with silica gel (LiChrosorb Si-60) whose surface is bonded chemically with 3-cyanopropylsilyl groups and hence is hydrophobic. The column was found to be superior to silica gel itself (MicroPak Si-10)[20,27] in reproducibility. On the other hand, the MicroPak NH_2-10 column[27] is much polar than the MicroPak CN-10 one, because it is filled up with silica gel (LiChrosorb Si-60) whose surface is modified chemically with 3-aminopropylsilyl groups and interacts with solutes by hydrogen bonding. The Hitachi Gel #3011 column[27b,28] is completely different from these two columns in the separation mode. The packing is a porous polystyrene-divinylbenzene copolymer and the separa-

tion appears to be attributed to a kind of hydrophobic adsorption and/or van der Waals' interaction between the gels and solutes. Examination with p-BPEs of monobasic and dibasic acids suggested that the active principle(s) would probably be dibasic acid(s).[20] All these findings led us to revise the procedure as shown in Table 2 and to obtain a lot of Fraction L (p-BPE) which, if necessary, may be subjected to further purification.

The isolation procedure summarized in Table 2 was improved as follows. a) Initial fractionation of the hatch-stimulating concentrates (Fraction C to F) (Figs. 6 and 7), following the Charcoal-Celite chromatography, proceeded smoothly without loss of the activity and with high recovery of the material by chromatography on columns different from the previous ones; namely, chromatography over silica gel, siliconized Hyflo Super Cel, and ionic exchange resins (Table 1) was replaced by that over Sephadex LH-20 and DEAP-Sephadex LH-20. The Sephadex LH-20 column consists of a kind of methylene-bridged dextran (Sephadex G-25) whose surface (hydroxyl groups) is bonded chemically with 2-hydroxypropyl groups, and is used for gel permeation chromatography as a molecular sieve, including weak interaction (adsorption) between the gels and solutes, and partition chromatography,[29] depending on eluents. The partition chromatography on this column with a 95:5 mixture of dichloromethane and methanol had been used for separation of prostaglandins[29b] as efficiently as that on the siliconized Hyflo Super Cel column. On the other hand, the DEAP-Sephadex LH-20 column[30,31] is packed with Sephadex LH-20 whose surface (hydroxyl groups) is modified chemically by 3-diethylamino-2-hydroxypropyl groups and behaves as a lipophilic anion exchanger. This was effective for group separation of mono-, di-, and polybasic acids as had been shown for separation of fatty acids.[31] b) Efficient *p*-bromophenacylation of the acid mixture [Fraction F to G (p-BPE)] was achieved in the presence of *N,N*-diisopropylethylamine in acetonitrile,[32] giving the corresponding esters in an almost quantitative yield. c) Fractionation of a mixture of the p-BPEs of acids [Fraction G (p-BPE) to I (p-BPE)] was initially performed by preparative HPLC on Hitachi Gel #3019 and then on Bondapak C_{18}/Porasil B columns,[27d] which are recommended for large scale preparative work, because of a large amount (ca. 300 mg) of Fraction G (p-BPE) compared with that (ca. 1 mg) of

the corresponding fraction [Fraction I (p-BPE)] in Table 1. These columns, packed with particles of dp ≒50 μm, are similar to Hitachi Gel #3011[27b,28] and μBondapak C_{18}, columns[27b,27c] (dp≒10 μm), respectively, in the chemical constitution and separation selectivity. Of the latter two columns, the μBondapak C_{18} one is packed with silica gel (μPorasil) whose surface is chemically bonded with octadecylsilyl groups and hence hydrophobic, and is useful for high-efficiency reversed-phase partition chromatography, as shown by effective separation of p-BPEs of a variety of fatty acids differing in the number and geometry of double bonds and hydroxyl groups.[33] Thus Fractions G and H (p-BPEs) were separated roughly into several fractions with somewhat loss of active fractions. d) Subsequent preparative HPLC [Fraction I (p-BPE) to L (p-BPE)] on a μBondapak NH_2 column with three different systems of eluents effected smooth separation of active fraction(s), finally giving the relevant fraction, Fraction L (p-BPE). The column[27,34] is packed with silica gel (μPorasil) whose surface is bonded chemically with 3-aminopropylsilyl groups and is used for normal-phase adsorption chromatography. Examination of

model compounds indicated that the separation sequence or selectivity of a series of p-BPEs of fatty acids and their derivatives was influenced remarkably by delicate change of the eluent systems.[20]

In 1981, after the careful chromatographic purification described above, we could achieve the isolation of ca. 50 μg of Fraction L (p-BPE), which showed a single peak by analytical HPLC on μBondapak NH_2, μBondapak C_{18}, and μBondapak/Phenyl columns,[27] and stimulated the hatching at 10^{-11}—$^{-12}$ g ml^{-1} after hydrolysis. With this sample, we could observe a clear triplet, corresponding to the molecular ion peaks, in the FD-MS spectrum[15] and useful signals in the ^{1}H NMR spectrum.[15] These spectral data led us to assign the molecular formula to GEA and to presume the presence of several oxygen functions.[15] These results, coupled with other evidence discussed later, have led us to believe that Fraction L is the p-BPE of an active principle itself, designated as GEA.[15] However, we could not accomplish the elucidation of the whole structure of GEA, owing to the limited amount (ca. 50 μg) of the isolated GEA p-BPE. It was required to isolate a large amount, at least 500 μg, of GEA p-BPE. Thus the starting hatch-stimulating concentrates (ca. 1 kg) were prepared from dried and powdered roots (ca. 1 ton) of kidney bean, which had been collected in 10 hectares of the field at Memuro, and fractionated, according to the procedure shown in Table 3.

The procedure summarized in Table 3 was practically the same as the previous one (Table 2) in the sequence and efficiency. a) In each of the steps, a dozen or several dozens of chromatographic separations were repeated cautiously and laboriously,

because of a large amount of the material to be fractionated. b) Two previous large-scale separation steps (Table 2), which had not always given satisfactory results, were revised as follows. i) Chromatography on the Hitachi Gel #3019 column [Fraction H (p-BPE) to I (p-BPE)] was carried out more easily at atmospheric pressure (Fig. 8) (not at high pressure in Table 2), and ii) preparative HPLC of Fraction I (p-BPE), corresponding to Fraction H (p-BPE) in Table 2, was performed more efficiently on the μBondapak C_{18} column (expensive !) for preparative scale work (Fig. 9) (not on the Bondapak C_{18}/Porasil B one). c) Subsequent fractionation of Fraction J (p-BPE) on the μBondapak NH_2 column afforded Fraction K (p-BPE) as the major fraction, which was active at 10^{-11} g ml^{-1} after hydrolysis, along with the minor one [Fraction K′ (p-BPE)] (Fig. 10). The latter was further purified by preparative HPLC on the same column to give Fraction K″ (p-BPE) [=glycinoeclepin C (GEC) p-BPE] (1.8 mg). The major fraction was further purified by preparative HPLC on the same column with a different eluent

system to give Fraction L (p-BPE) (=GEA p-BPE) (1.25 mg) and Fraction L′ (p-BPE) (Fig. 11). The latter was purified in the same manner to yield Fraction L″ (p-BPE) [=glycinoeclepin B (GEB) p-BPE] (1.8 mg). The p-BPE of GEA was then hydrolyzed with base under mild conditions to give GEA, which, after purification by HPLC on the μBondapak C_{18} column, showed a single peak (Fig. 12) and high activity (active at 10^{-12} g ml^{-1}) for the hatching in water. Likewise, the p-BPEs of GEB and

Table 4. Hatching and Larval Emergence of the Soybean Cyst Nematode[a] in an Aqueous Solution of GEA[b]

Test soln	Total eggs	Unhatched eggs	Hatched larvae	
			Unemerged	Emerged
GEA[b]	2158 (8 cysts)	505 (23.4%)[c]	136 (6.3%)	1517 (70.3%)[d]
Water	2875 (9 cysts)	2352 (81.8%)	302 (10.5%)[e]	221 (7.7%)[e]

a) The cysts were soaked at 25 °C and, without dissection, kept in the test soln and in water, respectively, at 25 °C for 10 d. b) A highly dilute soln of GEA (10^{-10} g ml^{-1}) was used. c) Most of the eggs were immature or dead. d) These larvae moved actively. e) These larvae did not move actively, and when kept in the test soln, moved actively.

GEC were converted into the corresponding acids GEB and GEC, which were purified by HPLC on a NOVA-PAK cartridge C_{18}[35] and were not active for the hatching at 10^{-8} g ml^{-1} in water.

Identification of Glycinoeclepin A as the Active Principle. Identification of GEA as the active principle was deduced from the following evidence. i) The fraction isolated always showed a single peak by analytical HPLC over a variety of columns (μBondapak NH_2, MicroPak NH_2-10, μBondapak C_{18}, and μBondapak/Phenyl) with different solvent systems. ii) The fraction was divided into ten fractions by HPLC on a Develosil ODS-5 column. The hatching activity of each divided fraction after hydrolysis paralleled the quantity of the respective fraction, estimated by the UV spectra.[19] iii) The activity (10^{-12} g ml^{-1}) of crystalline GEA p-BPE, obtained by recrystallization from hexane and dichloromethane, was slightly higher than that (10^{-11}—$^{-12}$ g ml^{-1}) of GEA p-BPE contained in the mother liquors after hydrolysis. iv) As described in the preceding section, the fraction was hydrolyzed with base (0.1 M† KOH in MeOH), acidified with acid (0.2 M HCl) to pH 2—3, and extracted with ethyl acetate. The extracts were simply separated by HPLC over μBondapak C_{18} with acidic aqueous methanol to give GEA, which showed a single peak on the column and high activity (10^{-12} g ml^{-1}) (Fig. 12). Surprisingly, the IR spectrum [1572 and 1420 cm^{-1} (KBr)] indicated that GEA was not isolated as the acid itself but as its (potassium) salt. All these facts confirmed that GEA is the active principle itself.

Biological Activity of Glycinoeclepin A. Biological activity of GEA for the hatching and emergence was examined, the result (Table 4) being summarized as follows. The cysts were soaked in water at 25 °C for 10 d, and then kept in a highly dilute solution (10^{-10} g ml^{-1}) of GEA in water at 25 °C for 10 d. In the test solution, ca. 80% of the eggs hatched and most of the hatched larvae emerged out of the cysts, while in water more than 80% of the eggs were not hatched, and less than half (8%) of the hatched larvae emerged out of the cysts. The result indicates that GEA stimulates not only hatching but also emergence of the soybean cyst nematode in a highly dilute solution, and is completely consistent with the Sakurai and Tsutsumi result using the root diffusate of kidney bean.[14] Further examination revealed that (i) most of the unhatched eggs in the test solution were found to be dead or immature under a microscope, and were not hatched by additional addition of the test solution, (ii) the larvae which emerged in the test solution moved actively, while those in water did not move, but moved actively on addition of the test solution, and (iii) naturally, the unhatched eggs in water were hatched when kept in the test solution. These observations imply that the hatching may be only a resultant phenomenon of active motion of the second stage larvae, and GEA may stimulate the motor nervous system of the larvae.

† 1 M=1 mol dm^{-3}.

Experimental

The bioassay was carried out according to the procedure described in the text. The melting points were measured in open capillaries or under a microscope, and uncorrected. Preparative TLC was carried out on silica gel (Wakogel B-5F or Merck Kieselgel 60 F254) and spots were detected by a UV lamp or in iodine vapor unless otherwise stated. The IR and ^{1}H NMR spectra were measured in liquid state and in [^{2}H]chloroform, respectively, unless otherwise stated. Analytical and preparative HPLC were performed at 22 °C with a Varian Aerograph 4200 and a Waters Associates 6000A liquid chromatograph, equipped with a UV monitor (JASCO UVDEC-100), and the chromatograms were recorded on a Unicorder Model-22 M or -225 MB (Nippon Denshi Kagaku Co.). All guranteed solvents (Wako Pure Chemical Ind.) were used as carrier solvents without further purification, unless otherwise stated.

(I) Experimentals Summarized in Table 1. Preparation of Chloroform Extracts A and Acidic Extracts B. Roots of "Beni-kintoki," a subspecies of kidney bean, cultivated in 1 hectare of the field at Memuro, Hokkaido, were collected in late July or in early August just before the flowering time, washed roughly with water, air-dried, and crushed. The powdered roots amounted to 135 kg. A part of the roots (ca. 15 kg) was extracted with water (95 l) below 10 °C for 3 d to be prevented from putrefaction. After being squeezed, the roots were again extracted with water (2×60 l). The combined aqueous (aq) muddy suspension was concentrated

to ca. 10 l below 30 °C by a thin film evaporator (Hitachi Kontro). This process (extraction and concentration) was repeated nine times. All the concentrates (ca. 100 l) were combined and made acidic to pH 2—3 with 6 M hydrochloic acid (HCl). A part of the aq suspension (ca. 40 l) was extracted with chloroform (ca. 60 l) continuously for 50 h by a special Soxhlet apparatus (Shibata Chemical Apparatus Mfg. Co.). This extraction procedure was repeated three times. The combined chloroform solution (soln) was evaporated to leave an oily material (223 g), which was distilled under reduced pressure below 50 °C to remove inactive lower fatty acids, giving Chloroform extracts A (115 g).

The fraction (115 g) was dissolved in ethyl acetate (300 ml) and treated with saturated aq sodium hydrogencarbonate ($NaHCO_3$) (600 ml+4×50 ml). The acetate soln was washed with water (50 ml), dried and evaporated to leave neutral and basic substances, which were not further examined. The combined aq soln (ca. 850 ml) was acidified to pH 2 by addition of 6 M HCl (140 ml) and extracted with ethyl acetate (5×200 ml). The combined acetate soln was washed with water (50 ml) and evaporated to give Acidic extracts B (66.5 g), which was active at 10^{-5}—$^{-6}$g ml^{-1} for the hatching. The acidic aq soln was further extracted with 1-butanol (3×300 ml). The butanol soln was evaporated to leave an acidic oil (7.9 g), which was active at 10^{-5} g ml^{-1} and was not further examined.

Chromatography on a Charcoal-Celite Column (B to C). Charcoal (220 g, Tokusei-Shirasagi Brand, Takeda Chemical Ind.) and Celite-545 (440 g, Johns-Manville) were mixed thoroughly with water and packed in a glass column (7×64 cm). A part (22 g) of Acidic extracts B was dissolved in acetone, mixed with Celite (40 g), evaporated, placed on the top of the column, and then eluted successively with water (2.2 l), water-acetone (9:1, 8:2, 7:3, 6:4, 5:5, 4:6, 3:7, 2:8 and 1:9, v/v, each 2.2 l), acetone (4×2.2 l), benzene (2×2.2 l), and methanol-concd aqueous ammonia (NH_4OH) (21:1, v/v, 4.4 l). This procedure was repeated three times. Each fraction, other than that eluted with ammoniacal methanol, was evaporated to give an oily or solid eluate. The methanol fraction was dissolved in water (100 ml), acidified and extracted with 1-butanol, and the butanol soln was likewise evaporated. The amount and biological activity of each eluate is described in Fig. 1. The 80% aq acetone eluate (5.2 g) (Fraction C), showing the highest activity (active at 10^{-7} g ml^{-1}), was submitted to further separation. Each eluate, even if inactive, was examined in somewhat detail.

i) Eluates with 40% Aqueous Acetone. The oily eluate (950 mg) was separated into 6 fractions by preparative TLC with benzene-1-butanol-acetic acid (16:3:1): Fraction (Fr.) 1, (R_f=0.7) 125 mg: 2, (0.4) 337; 3, (0.3) 253; 4, (0.2) 40; 5, (0.15) 36; 6, (0.05) 29 mg. To an ethanol soln (10 ml) of Fr. 2 (305 mg), adjusted to pH 6.8 with 0.1 M aq potassium hydroxide (KOH) and one drop of 0.1 M HCl, was added *p*-bromophenacyl bromide (1 g) in ethanol (25 ml). The mixture was heated under reflux for 1.5 h,[36] cooled and extracted with chloroform (4×10 ml). The chloroform soln was worked up as usual to give orange crystals (1048 mg), which were roughly separated by column chromatography over silica gel (Merck 120—230 mesh, 10 g, 1.8×9.5 cm) with chloroform into 3 fractions. The third eluate gave a crystalline mixture of p-BPEs (577 mg), from which 2-hydroxy-4-methylpentanoic acid p-BPE (90 mg), mp 86.5—88 °C ($CHCl_3$-hexane), $[\alpha]_D$ −5° ($CHCl_3$), and 2-hydroxy-3-methylpentanoic acid p-BPE (125 mg), mp 35—39 °C ($CHCl_3$), $[\alpha]_D$ −12° ($CHCl_3$), were isolated by twice preparative TLC with chloroform-benzene (9:1, double development). The IR and ^1H NMR spectra of these esters were identical with those of the p-BPEs of the authentic samples, respectively.[37,38] Fr. 4 was purified by chromatography over silica gel with ethyl acetate to give crude vomifoliol (9 mg), which will be described later.

ii) Eluates with 50% Aqueous Acetone. A part (2.05 g) of the solid eluate was separated into 6 fractions by preparative TLC with a 1:4 mixture of ethyl acetate and an upper phase of benzene-propionic acid-water (8:3:5): Fr. 1, (R_f=0.8) 600 mg; 2, (0.6) 327; 3, (0.4) 216; 4, (0.25) 130; 5, (0.2) 161; 6, (0.1) 128. Fr. 1 (25 mg) gave 3- furoic acid (10 mg), mp 120—120.5 °C, on recrystallization from water. Fr. 2 (100 mg) was separated into 3 fractions by preparative TLC with an upper phase of benzene-acetic acid-water (3:3:1). The lst fraction (R_f=0.6) gave a crystalline substance (25 mg), which on recrystallization from water afforded suberic acid (3 mg), mp 135—137°C. The mother liquor (18 mg), after sublimation, gave 2-furoic acid (4 mg), mp 128—129 °C. The 2nd fraction (R_f=0.5) gave a crystalline substance (18 mg), which on recrystallization from water yielded maltol (3 mg), mp 158—159 °C.

Fr. 5 (150 mg) was purified by preparative TLC with ethyl acetate to give a crystalline substance (55 mg), which on recrystallization from benzene gave vomifoliol (i) (24 mg), mp 112—113°C; $[\alpha]_D$ +220° ($CHCl_3$); CD, λ_{max}^{MeOH} ($\Delta\varepsilon$) 318 nm (−0.65) and 240 (+11.9); UV (MeOH), 237 nm (ε 13900); IR (Nujol), 3400, 1662, 1617, and 973 cm^{-1}; ^1H NMR, δ=1.01 and 1.07 (each 3H, s), 1.28 (3H, d, J=6 Hz), 1.88 (3H, d, J=1.5 Hz), 2.07 (2H, 2OH, D_2O-exchangeable), 2.23 and 2.42 (each 1H, ABq, J=17 Hz), 4.38 (1H, dq, J=6 and 3.5 Hz), 5.75 (1H, d, J=16 Hz), 5.83 (1H, dd, J=16 and 3.5 Hz), and 5.88 (1H, q, J=1.5 Hz); MS m/z 206 (M^+ −18), 168, and 124 (base). This was identified by direct comparison with (+)-vomifoliol[39—43] (blumenol A) from *Podocarpus blumei* Endl.[41]

Fr. 3 (130 mg) was purified by preparative TLC with ether-benzene (9:1) and then with ethyl acetate to give dehydrovomifoliol (ii) (11 mg), oil; $[\alpha]_D$ +159°($CHCl_3$); CD, λ_{max}^{EtOH} ($\Delta\varepsilon$) 318 nm (−1.95), 240 (+27.6); UV (EtOH), 237 nm (ε 20000); IR ($CHCl_3$), 3400, 1666, 1626, and 982 cm^{-1}; ^1H NMR, δ=1.01 and 1.09 (each 3H, s), 1.87 (3H, d, J=1.5 Hz), 2.29 (3H, s), 2.34 and 2.48 (each 1H, ABq, J=17 Hz), 5.95 (1H, q, J=1.5 Hz), and 6.45 and 6.83 (each 1H, ABq, J=16 Hz); MS, m/z 166 (M^+ −56) and 124 (base). These spectral data indicated the compound (**ii**) to be a dehydro derivative of vomifoliol (**i**). This was confirmed by conversion of **i** into **ii** as follows. To a soln of **i** (23 mg) in acetone (0.5 ml) was added Jones reagent [CrO_3 (10 mg), H_2SO_4 (0.01 ml), and H_2O (0.03 ml)]. The mixture was stirred for 3 min, diluted with water (2 ml), and extracted with ethyl acetate (3×1 ml). The combined acetate soln was evaporated to leave an oil (22 mg), which was purified by preparative TLC with benzene-ethyl acetate (1:1) to yield **ii**. The compound (**ii**), named (+)-dehydrovomifoliol,[42—46] appeared to be a new compound isolated from natural sources, although its racemate had been prepared by two groups.[39,47,48] (+)-Dehydrovomifoliol (**ii**) was converted

into (+)-abscisic acid in the same manner[47] as the synthetic racemate[47,48] as follows. A mixture of **ii** (18 mg) and (ethoxycarbonylmethylene)triphenylphosphorane (29 mg) in toluene (1 ml) was heated under reflux for 4 h and distilled to remove the toluene. The residue was heated at 150—170 °C for 40 min, cooled, and separated by preparative TLC with benzene–ethyl acetate (1:1) to give a mixture (9 mg) of esters. The mixture (8 mg) was hydrolyzed with 2M methanolic KOH (6 ml) at room temperature (temp) for 23 h. The reaction mixture was evaporated, acidified with 1.5 M HCl (4 ml), and extracted with ether (3×2 ml). The ether soln gave a 1:1 mixture[39] of (+)-abscisic acid[49] and its 2-*trans*-isomer:[47,48] CD, $\lambda_{max}^{0.006\,M\,HCl\,in\,EtOH}$ ($\Delta\varepsilon$) 318 nm (−0.92), 265 (+28.2), and 230 (−21.0); UV (0.006 M HCl in EtOH), 262 nm (ε 21000). These spectral values indicated that (+)-dehydrovomifoliol (**ii**) possessed the same absolute configuration at the carbon atoms corresponding to C-6 of abscisic acid.[39]

Fr. 6 (80 mg) was purified by preparative TLC with benzene-1-butanol-acetic acid (14:5:1) to give dihydrophaseic acid (**iii**) (34 mg), amorphous; CD, λ_{max}^{MeOH} ($\Delta\varepsilon$) 265 nm (−2.8); UV (MeOH), 259 nm (ε 15500); ^{1}H NMR (CD_3COCD_3), δ=0.90 and 1.06 (each 3H, s), 1.80 (4H, br), 1.95 (3H, d, J=1.5 Hz), 3.60 (1H, d, J=7.5 Hz), 3.73 (1H, dd, J=7.5 and 1.5 Hz), 4.10 (1H, br), 5.66 (1H, br s), and 6.54 and 8.06 (each 1H, d, J=16 Hz); MS, m/z 282 (M^+) and 264. The acid (**iii**) was converted with ethereal diazomethane into its methyl ester, amorphous; IR ($CHCl_3$), 3420, 1710, 1674, and 1610 cm^{-1}; ^{1}H NMR, δ=0.95 and 1.17 (each 3H, s), 1.80 (4H, br), 2.05 (3H, d, J=1.5 Hz), 3.72 (3H, s), 3.77 (2H, br), 4.26 (1H, m, W_H=20 Hz), 5.73 (1H, q, J=1.5 Hz), 6.40 and 7.98 (each 1H, d, J=16 Hz); MS, m/z 296 (M^+), 278, 264, 247, 246, 154, 125, 122, 94, and 43 (base). The ester was oxidized with Jones reagent as follows. To a soln of the ester (6 mg) in acetone (0.05 ml) was added Jones reagent [CrO_3 (5 mg), H_2SO_4 (0.005 ml), and H_2O (0.02 ml)] for 3 min. The mixture was diluted with water (0.3 ml) and extracted with ethyl acetate (3×0.3 ml). The acetate soln was dried and evaporated to leave an oil (3 mg), which was separated by preparative TLC with benzene–ethyl acetate (1:1) to give the dehydro ester (1 mg), mp 152—155 °C (benzene); CD, λ_{max}^{MeOH} ($\Delta\varepsilon$) 314 nm (−0.55), 262 (+5.2), and 230 (−4.2); ^{1}H NMR,

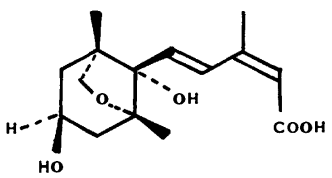
ii R==O



iii

δ=2.50 and 2.64 (each 2H, br s), 3.73 (1H, d, J=8 Hz), and 3.95 (1H, dd, J=8 and 1.5 Hz); MS, m/z 294 (M^+), 276, 121, and 43 (base). The ester was identified as methyl phaseate[49-51] by comparison of the spectral data (MS, IR, and ^{1}H NMR), and hence compound **iii** was named dihydrophaseic acid.[52]

iii) Eluates with 60% Aqueous Acetone. The solid eluate (453 mg) was separated into 6 fractions by preparative TLC with an upper phase of benzene–acetic acid–water (8:3:5): Fr. 1, (R_f=0.4) 178 mg; 2, (0.3) 35; 3, (0.25) 97; 4, (0.15) 28; 5, (0.1) 37; 6, (0.0) 16. Frs. 1 (167 mg) and 2 (30 mg) gave benzoic acid (160 mg) and vanillic acid (19 mg) after sublimation, respectively. Fr. 3 (90 mg) was purified by preparative TLC with ethyl acetate–chloroform–acetic acid (15:5:1) and recrystallized from water to give azelaic acid (46 mg). Fr. 5 (30 mg) was crystallized and recrystallized from chloroform to give *p*-hydroxybenzoic acid (2 mg).

iv) Eluates with 70% Aqueous Acetone. Benzoic, vanillic, and *p*-hydroxybenzoic acids were detected, when the eluate was developed on a silica-gel plate with an upper phase of benzene–acetic acid–water (8:3:5).

v) Eluates with 90% Aqueous Acetone. The solid eluate (2.9 g) was separated by chromatography over silica gel (Merck 120—230 mesh, 300 g, 5×42.5 cm) with ethyl acetate–chloroform–acetic acid (15:5:1). The eluates (each 15 ml) were collected, evaporated and assayed: Frs. 1—36, (537 mg) inactive; 37—41, (506) active at 10^{-6} g ml^{-1}; 42—68, (1033) active at 10^{-7}—$^{-8}$; 69—88, (285) active at 10^{-6}; 89—200, (257), inactive. Fr. 33 (90 mg) was separated into 5 fractions by preparative TLC with an upper phase of benzene–acetic acid–water (8:3:5, developed twice): Fr. 1′, (R_f=0.50) 34 mg; 2′, (0.45) 12; 3′, (0.35), 8; 4′, (0.25) 12; 5′, (0.10) 18. Fr. 1′ (30 mg) gave salicylic acid (8 mg) after sublimation in twice and recrystallization from benzene. Fr. 2′ (10 mg) afforded dodecanedioic acid (4 mg) after recrystallization from chloroform.

vi) Eluates with Acetone, Benzene, and Ammoniacal Methanol. Salicylic acid was detected on a silica-gel plate with ethyl acetate–chloroform–acetic acid (15:5:1).

Chromatography on a Silica-Gel Column (C to D).[53] Fraction C (5.2 g) was separated by chromatography over silica gel (Merck 70—325 mesh, 520 g, 5×66.5 cm) with ethyl acetate–chloroform–acetic acid (15:5:1, v/v/v). The eluates (each 19.5 ml) were collected, evaporated and assayed. The amount and activity of each or collected eluates are summarized as follows: Frs.31—39, (55 mg) inactive; 40—55, (2468) inactive; 56—57, (203) active at 10^{-6} g ml^{-1}; 58—60, (241) active at 10^{-7}; 61—67, (360) active at 10^{-8}; 68—83, (402) active at 10^{-7}; 84—100, (231) active at 10^{-6}; 101—140, (384) active at 10^{-6}; 141—154, (97) inactive; 155—226, (307) inactive. Frs. 61—67 (360 mg) (Fraction D) was the most active and submitted to further separation. Other inactive or less-active fractions were examined in somewhat detail.

i) Fraction 45. The fraction (194 mg) was separated into 5 fractions by preparative TLC with an upper phase of benzene–acetic acid–water (8:3:5): Fr. 1, (R_f=0.45) 53 mg; 2, (0.35) 46; 3, (0.25) 29; 4, (0.10) 28; 5, (0.03) 20. Fr. 2 was treated with ethereal diazomethane and analyzed by GC-MS; column, 5% diethylene glycol adipate polyester on Anakrom Q. Sebacic, undecanedioic acid (ca. 90%), and dodecanedioic acids were identified.

ii) Fraction 53. The fraction (145 mg) was separated into

8 fractions by preparative TLC (twice development) in the same manner as Fr. 45: Fr. 1, (R_f=0.50) 2 mg; 2, (0.45) 2; 3, (0.35) 11; 4, (0.30) 10; 5, (0.25) 35; 6, (0.15) 29; 7, (0.05) 19; 8, (0.00) 19. Fr. 1 gave veratric acid, and Fr. 3 was found to consist of sebacic (trace), undecanedioic (ca. 90%), and dodecanedioic acids by GLC of the trimethylsilyl derivatives (2% OV-17 on Anakrom Q). Fr. 4 gave syringic acid (3 mg) after chromatography over silica gel. Fr. 5, when recrystallized from diisopropyl ether-hexane, gave 4-hydroxydodecanedioic acid γ-lactone (13 mg), mp 48.5—50 °C, which was converted with diazomethane into its methyl ester, mp 20—22 °C: acid, IR ($CHCl_3$), 1760, 1705, and 1170 cm^{-1}: ester, ^1H NMR, δ=1.2—1.9 (14H, br), 2.26 (2H, t, J=7 Hz), 2.5 (2H, m), 3.60 (3H, s), and 4.46 (1H, m, W_H=18 Hz); MS, m/z 242 (M^+), 224, 211, 192, 151, and 85 (base). Frs. 6—8 were found to consist of a mixture of long-chain fatty acids on the basis of their NMR spectra.

iii) Fractions 101—154. The fractions (480 mg) were crystallized from methanol-ethyl acetate and recrystallized from acetic acid to give 9,10,13-trihydroxyoctadecanoic acid (16 mg), mp 139—139.5 °C, which formed its methyl ester, (with diazomethane), mp 117.5—119.5 °C, and trimethylsilyl derivative [with trimethylsilyl *N*-(trimethylsilyl)acetimidate]. The planar structure was elucidated on the basis of the spectral data and chemical reactions.[54] The filtrate (465 mg) was dissolved in ethanol (2 ml). To the soln, adjusted to pH 6.6 with 0.1 M aq KOH and a few drops of 0.1 M HCl, was added *p*-bromophenacyl bromide (607 mg) in ethanol (2 ml). The mixture was heated under reflux for 2.5 h,[36] cooled, concentrated, diluted with water (15 ml), and then extracted with chloroform (2×10 ml). The chloroform soln was worked up as usual to leave an oily residue (1.0 g), which was roughly separated by chromatography over silica gel (Merck 120—230 mesh, 10 g, 2×6.4 cm), with benzene (950 ml), benzene-chloroform (1:1, 600 ml), chloroform (200 ml), and ethyl acetate (200 ml). A fraction eluted with ethyl acetate afforded a mixture of p-BPEs (563 mg), which was further separated into more than 215 fractions [Frs. 1′—137′ (each eluent 9.1 g) and Frs. 138′—215′, (each eluent 14.7 g)] by chromatography over silica gel containing 10% silver nitrate (Merck 120—230 mesh, 70 g, 2×40 cm) with a mixture of chloroform, ethyl acetate, and methanol as eluents.

Frs. 111′—135′ (81 mg), eluted with chloroform-ethyl acetate (2:3), was crystallized and recrystallized from ethyl acetate containing a trace of methanol to give (11*E*)-9,10,13-trihydroxy-11-octadecenoic acid p-BPE (20 mg), mp 127—128 °C. This planar structure was deduced from the following experiment. The ester (7.6 mg) was hydrolyzed with 0.1 M KOH in methanol (2 ml) at room temp for 24 h. The mixture was evaporated, acidified with 3M HCl and extracted with 1-butanol (2×2 ml). The butanol extracts were treated with ethereal diazomethane in methanol to give a mixture of its methyl ester and methyl *p*-bromobenzoate, which was submitted to chromatography over silica gel (Merck 120—230 mesh, 2 g, 1×7 cm) with chloroform and/or ethyl acetate. Eluates with ethyl acetate was evaporated and recrystallized from ethyl acetate to give its methyl ester (3.1 mg), mp 88.5—90.5 °C; IR (KBr), 3270, 1735, and 968 cm^{-1}; ^1H NMR, δ=0.90 (3H, br t, J=7 Hz), 1.2—1.8 (23H, br, 20H on addition of D_2O), 2.30 (2H, t, J=7 Hz), 3.60 (1H, br), 3.66 (3H, s), 4.12 (2H, br), and 5.77 (2H, m, W_H=9 Hz). The methyl ester (0.5 mg) was treated with trimethylsilyl *N*-(trimethylsilyl)acetimidate (40 μl) at 55 °C for 5 min. The mixture was mixed with water (100 μl) and extracted with hexane (2×100 μl). The combined hexane soln was washed with water (30 μl) and evaporated to leave its tris(trimethylsilyl ether), oil, which showed the following MS spectrum: m/z 545 (M^+−15), 460 [$M^+-C_6H_{12}O$ (hexanal)], 455, 439, 399, 387, 301, 297, 259, 227, 173 (base), 155 [$^+O{\equiv}C(CH_2)_7CHO$], 147, 129, 103, 83, 75, and 73.[54] On the other hand, the methyl ester was oxidized with potassium periodate[55] as follows. A soln of the ester (not of the ether) (0.23 mg) in acetic acid (0.5 ml) was combined with 0.02 M aq potassium periodate (0.05 ml) and stirred at room temp for 30 min. To the soln was added ethylene glycol (0.005 ml) in water (0.02 ml) and then 0.4% 2,4-dinitrophenylhydrazine in 4 M HCl (0.5 ml). The mixture was kept at 2 °C for 3 d, and the precipitates (ppts) were collected by filtration, washed with water and dried. The hydrazone mixture was proved to consist of methyl 9-oxononanoate 2,4-dinitrophenylhydrazones by HPLC (TSK-G1000H8) and TLC by comparison of the authentic samples,[56] which were prepared from 9-oxononanoic acid[57] by the known procedure.

Frs. 181′-200′ (65 mg), eluted with chloroform-ethyl acetate (1:4), were crystallized and recrystallized from ethyl acetate to give (15*Z*)-9,10,13-trihydroxy-15-octadecenoic acid p-BPE (21 mg), mp 112—113 °C. ^1H NMR, δ=0.97 (3H, t, J=7 Hz), 1.35—1.64 (16H, br), 2.07 and 2.28 (each 2H, m), 2.48 (2H, t, J=7 Hz), 2.61 (3H, br s, D_2O-exchangeable), 3.62 (3H, br), 5.27 (2H, s), 5.48 (2H, m), and 7.60 and 7.76 (each 2H, d, J=9 Hz). This p-BPE was converted into the corresponding methyl ester, which was further derived into the tris(trimethylsilyl ether): The methyl ester, oil; IR (neat), 3300 and 1735 cm^{-1}: the ether, oil; MS, m/z 529 (M^+−31), 491, 455, 439, 401, 389, 311, 301, 299, 259, 227, 171, 155, 147, 129, 103, 81, 75, and 73 (base).[54]

Fr. 216′ (6 mg), eluted with ethyl acetate, and Fr. 217′ (19 mg), eluted with ethyl acetate and methanol (9:1), were combined, crystallized and recrystallized from ethyl acetate to give (11*E*, 15*Z*)-9,10,13-trihydroxy-11,15-octadecadienoic acid p-BPE (3 mg), mp 114—115 °C; ^1H NMR, δ=0.96 (3H, t, J=7 Hz), 1.35—1.62 (12H, br), 2.07 and 2.28 (each 2H, m), 2.47 (2H, t, J=7 Hz), 2.60 (3H, br, s, D_2O-exchangeable), 3.60 (1H, br), 4.12 (2H, br), 5.27 (2H, s), 5.47 (2H, br), 5.78 (2H, m, W_H=9Hz), and 7.60 and 7.76 (each 2H, d, J=9 Hz). The p-BPE was converted into the corresponding methyl ester, which was further derived into the tris(trimethylsilyl ether): The methyl ester, oil; IR (neat), 3360, 1735, and 973 cm^{-1}; the ether, oil; MS, m/z 543 (M^+−15), 460 [$M^+-C_6H_{10}O$ (hexenal)], 453, 437, 399, 387, 299, 297, 259, 171, 155, 147, 129, 103, 81, 75, and 73 (base).[54]

Chromatography on a Silica-Gel Column (D to E). Fraction D (360 mg) was separated by chromatography over silica gel (Merck 70—325 mesh, 55 g, 2×28.5 cm) with ethyl ether-acetic acid (99:1, v/v). The eluates (each 6 ml) were collected, evaporated, and assayed: Frs. 1—33, (3 mg) inactive; 34—44, (127) inactive; 45—62, (117) active at 10^{-8} g ml^{-1}; 63—74, (28) active at 10^{-7}; 75—120, (12) active at 10^{-6}—$^{-7}$. The fractions 45—62 (Fraction E) was the most active and submitted to further separation.

Reversed-Phase Partition Chromatography on a Siliconized Hyflo Super Cel Column (E to F). Hyflo Super Cel

(Johns-Manville; Nakarai Chemicals) was washed successively with 6 M HCl, distilled water and methanol, dried at 110 °C for 46 h, cooled, and kept in a desiccator containing dimethyldichlorosilane for 10 d. The siliconized Hyflo Super Cel was washed with methanol until the washings became neutral, and dried at 110 °C for 3 h.[58] The hydrophobic Hyflo Super Cel (18 g) thus obtained was mixed with a lower (stationary) phase (16 ml) of methanol-water-acetic acid-chloroform-(2-ethyl-1-hexanol) (150:150:2:15:15, by vol.) for 3 min. To the mixture was added the upper (mobile) phase (50 ml).[59] The slurry mixture was poured into a glass tube (12 mm in diameter), homogenized by rapid up and down movement of a stainless plunger. The resulting fine suspension was then packed in the tube to give a column of 33 cm in length.[58] Fraction E (115 mg) dissolved in the mobile phase (1 ml) was separated by chromatography on the column with the same solvent mixture. The eluates (each 20 ml) were collected, evaporated in vacuo, and assayed. The amount and activity of each or collected eluates are summarized in Fig. 2. As shown in Fig. 2, a large amount of inactive substances were eluted in early fractions (Frs. 1—10), and two groups of active fraction [Frs. 11—22 (23.9 mg) and Frs. 24—28 (4.6 mg)] were then eluted separately. The former active fractions were combined (Fraction F, active at 10^{-8}—$^{-9}$ g ml^{-1}, 23.9 mg) and submitted to further separation. The inactive fractions were examined in somewhat detail.

Fractions 5 and 6. The fractions (16.7 mg) gave a crystalline mixture, which was again purified by chromatography on the hydrophobic Hyflo Super Cel (18 g) under the same conditions described above to yield hydroxy dibasic acid (11.8 mg), mp 149—153 °C. This acid was converted easily into its dimethyl ester, oil; IR ($CHCl_3$), 1726 cm^{-1}; ^{1}H NMR, δ=1.2—1.7 (14H, br), 1.9 (1H, br s, D_2O-exchangeable), 2.32 (2H, t, J=7 Hz), 2.45 (2H, m), 3.69 and 3.73 (each 3H, s), and 3.9 (1H, br); MS, m/z 225 (M^+−31−18), 211 (M^+−31−32), 210 [(OH)CH$(CH_2)_8$COOCH$_3$], 193 (201—18), 172 [$(CH_2)_8$COOCH$_3$+H], 169 (201—32), 151 (193—42), 143, 129, 103 [base, (OH)CHCH_2COOCH$_3$], 87, and 74. The acid was identified as 3-hydroxydodecanedioic acid by comparison with a racemic, synthetic sample,[60] mp 105—107 °C.

Chromatography on an Amberlyst-15 (Ag^+ form) Column (F to G). Amberlyst-15 (Rohm & Haas; Organo Ltd., 9.0 g) was washed with ethanol in a Soxhlet apparatus for 20 h, packed into a glass tube (1.0 cm in diameter), and washed with distilled water. The resin was then converted into the silver form by passing 5% aq silver nitrate ($AgNO_3$), until silver cations were detected in the effluent (ca. 130 ml). The resin was then washed with distilled water thoroughly, when silver ions had not been detected, and then with ethanol.[23] Fraction F (23.1 mg) in ethanol was placed on the column, and eluted with ethanol (total 18 ml) and then with 5% cyclohexene in ethanol (total 50 ml). All eluates were collected in 2 ml portions. The odor of cyclohexene was detected in the fractions after Fr. 19. Frs. 4—10, 11—18, and 19—34 were combined, evaporated and assayed, respectively: Frs. 4—10, (14.4 mg) active at 10^{-8}~$^{-9}$ g ml^{-1}; 11—18, (0.5) active at 10^{-6}; 19—34, (3.0) active at 10^{-6}. The second fraction (Frs. 4—10) (Fraction G) was the most active and submitted to further separation. Less active fractions were examined in somewhat detail.

The Fourth Fraction (Frs. 19—34) gave a crystalline mixture (0.3 mg), which was treated with diazomethane in ether, evaporated, and then treated with trimethylsilyl *N*-(trimethylsilyl)acetimidate (25 μl) for 24 h. The soln was mixed with water (50 μl) and extracted with hexane (2×50 μl). The hexane soln was washed with water (20 μl), evaporated to leave an oily residue, whose MS spectrum [m/z 455 and 453 (M^+−15), 439 and 437 (M^+−31)] indicated that the fraction would contain dihydroxyoctadecadienoic and dihydroxyoctadecatrienoic acids.

Chromatography on an Amberlyst XN-1005 (Ag^+ form) Column (G to H). Amberlyst XN-1005 (Rohm & Haas; Organo Ltd., 100 g) placed in a large column was washed successively with 1 M aq sodium hydroxide (NaOH) (600 ml), distilled water (600 ml), 1 M HCl (1200 ml), distilled water (600 ml), 95% ethanol (600 ml), and distilled water (600 ml). This procedure was repeated three times. The purified resin was converted into the silver form by addition of 5% aq $AgNO_3$ (1200 ml) and washed with distilled water, until silver ions were not detected in the effluent, and then with methanol. The resin thus treated was packed into a long glass column (1.0 cm in diameter) to form a bed of 216 cm in length.[25] Fraction G (14.4 mg) in methanol was placed on the column and eluted with methanol to give 46 fractions (each 5 ml). An aliquot (2 μl) of each fraction was assayed. Active fractions [Frs. 28—33, (0.90 mg) active at 10^{-9}—$^{-10}$ g ml^{-1}, and Frs. 34—39, (0.63) active at 10^{-9}] were combined to amount to 1.53 mg (Fraction H) and submitted to further purification.

***p*-Bromophenacylation [H to I (p-BPE)].** A mixture of Fraction H (1.53 mg), potassium hydrogencarbonate ($KHCO_3$) 2.7 mg, 0.027 mmol), *p*-bromophenacyl bromide (9.4 mg, 0.034 mmol), and dicyclohexano-18-crown-6 (1.31 mg, 0.0035 mmol) in acetonitrile (60 μl) was heated in a sealed tube at 75 °C for 30 min,[26] cooled, and evaporated to remove the acetonitrile. The residue was dissolved in a small volume of benzene, placed on a silica-gel column (Merck 120—230 mesh, 3 g, 1.3×5.5 cm), and then eluted successively with benzene (Fr. 1), chloroform (Fr. 2), chloroform-ethyl acetate (9:1 and 1:1) (Frs. 3 and 4), ethyl acetate (Fr. 5), and ethyl acetate-acetic acid (9:1) (Fr. 6) to give 6 fractions (each 15 ml). An aliquot (3 μg) of each of Frs. 1—5 was hydrolyzed with 0.1 M KOH in methanol (25 μl) at room temp for 15 h, respectively. After removal of the methanol, the reaction mixture was acidified with 0.2 M HCl (25 μl) and extracted with ethyl acetate (3×50 μl). The combined ethyl acetate soln was washed with distilled water (15 μl) and evaporated in vacuo or under flashing argon. The residue and a part (2 μg) of Fr. 6 were dissolved in distilled water (2 ml) and assayed, respectively: Fr. 1, (8.7 mg) inactive; 2, (0.10) active at 10^{-8}—$^{-9}$ g ml^{-1}; 3, (0.91) active at 10^{-10}; 4, (0.55) active at 10^{-9}; 5, (0.11) active at 10^{-8}—$^{-9}$; 6, (0.47) active at 10^{-8}—$^{-9}$. Fr. 3 (0.91 mg) was the most active, named Fraction I (p-BPE), and submitted to further separation.

Preparative HPLC on a MicroPak CN-10 Column [I (p-BPE) to J (p-BPE)]. Fraction I (p-BPE) (0.90 mg) was dissolved in chloroform (100 μl), and the soln was injected in 20 μl portions onto the column (Varian, MicroPak CN-10, 2.2 mm×25 cm)[27c] and separated into 5 fractions, a 45:55 mixture of hexane and diethyl ether being used as an eluent at flow rate of 0.83 ml min^{-1} (Fig. 3). An aliquot (3 μg) of each fraction was hydrolyzed as described above and

assayed, respectively: Fr. 1, (0.225 mg) active at 10^{-8} g ml^{-1}; 2, (0.225), active at 10^{-8}–$^{-9}$; 3, (0.190) active at 10^{-10}–$^{-11}$; 4, (0.170) active at 10^{-7}–$^{-8}$; 5, (0.110) active at 10^{-7}–$^{-8}$. Fr. 3 (0.190 mg) was the most active, named Fraction J (p-BPE), and submitted to further purification.

Preparative HPLC on a MicroPak NH_2-10 Column [J (p-BPE) to K (p-BPE)]. Fraction J (p-BPE) (0.180 mg) was dissolved in chloroform, and the soln was injected onto the column (Varian, MicroPak NH_2-10, 2.0 mm×25 cm),[27c] and separated into 5 fractions, a 70:18:12 mixture of hexane, dichloromethane and acetonitrile being used as an eluent at flow rate of 0.5 ml min^{-1} (Fig. 4). An aliquot (ca. 0.3 μg) of each fraction was hydrolyzed as described above, and then assayed, respectively: Fr. 1, (≈45 μg) inactive; 2, (≈15) inactive; 3, (≈15) inactive; 4, (≈50) active at 10^{-11} g ml^{-1}; 5, (≈55) inactive. Fr. 4 [Fraction K (p-BPE)] (≈50μ g) was the most active and submitted to further purification.

Preparative HPLC on a Hitachi Gel #3011 Column [K (p-BPE) to L (p-BPE) (=GEAp-BPE)]. Fraction K (p-BPE) (≈50 μg) was dissolved in chloroform (5 μl) and separated into 4 fractions by preparative HPLC on a Hitachi Gel #3011 column [Hitachi Ltd., 4 mm×50 cm; eluent, methanol-dichloromethane (9:1); flow rate, 1 ml min^{-1}] (Fig. 5). One-two hundredth of each separated fraction was hydrolyzed as described above, dissolved in water, and assayed. Only Fr. 3 [Fraction L (p-BPE) =GEA p-BPE] 5—10 μg, estimated by the UV intensity of the chromatogram) was active after hydrolysis, and was purified by simple chromatography on the MicroPak NH_2-10 column under the same conditions to remove impurities contaminated from the gels and/or solvents.

The homogeneity of Fraction L (p-BPE) was further checked by analytical HPLC on a MicroPak CH-10 column [Varian, 2.2 mm×25 cm, methanol-water (8:2); flow rate, 0.67 ml min^{-1}], when a single peak (R_t 9 min) was observed on the chromatogram.

(II) Experimentals Summarized in Table 2. Preparation of Chloroform Extracts A and Acidic Extracts B. Roots of "Hon-kintoki," a subspecies of kidney bean, cultivated in 1 hectare of the field at Memuro, were collected in early August, washed roughly with water, dried in the shade and crushed. The dried and powdered roots amounted to 113 kg. A part (41 kg) of the roots was extracted with water (300 l) at 2—8 °C for 4 d. After being squeezed, the roots were further extracted with water (2×200 l). The combined aq muddy suspension (ca. 650 l) was concentrated to 13 l below 30 °C by a thin-film evaporator. This process was repeated three times. All the concentrates (38 l) were combined, made acidic to pH 2—3 with 6 M HCl, and extracted with chloroform (ca. 60 l) continuously for 50 h by a special Soxhlet apparatus. The chloroform soln was evaporated to give an oily material (Chloroform extracts A) (102 g), which was active at 10^{-5} g ml^{-1} for the hatching in water at 25 °C.

The extracts (102 g) was dissolved in ethyl acetate (400 ml) and treated with saturated aq $NaHCO_3$ (500+6×100 ml). The combined aq soln was acidified to pH 2 by addition of 6 M HCl (250 ml) and extracted with ethyl acetate (300+5×200 ml). The combined acetate soln was washed with water (2×50 ml), dried over sodium sulfate, and evaporated to give an acidic oily material (Acidic extracts B) (56.9 g), which was active at 10^{-5}–$^{-6}$ g ml^{-1}.

Chromatography on a Charcoal-Celite Column (B to C). A mixture of Charcoal (500 g) and Celite-545 (1 kg) in water was packed in a glass column (8.4×88 cm). Acidic extracts B (56.5 g) was dissolved in acetone, mixed with Celite (60 g), evaporated, placed on the top of the column, and eluted successively with water (5 l) (Fr. 1), water–acetone (9:1, 8:2, 7:3, 6:4, 5:5, 4:6, 3:7, 2:8, and 1:9, v/v, each 5 l) (Frs. 2—10), and methanol–concd NH_4OH (22:1, v/v, 12 l) (Fr. 11). All the fractions, except the last one, were simply evaporated and assayed, while that (Fr. 11) eluted with ammoniacal methanol, after being evaporated, was dissolved in water (100 ml), acidified with 3 M HCl, and extracted with ethyl acetate (3×100 ml). The acetate solution was then dried, evaporated, and assayed. The hatching activity of each fraction is summarized as follows: Fr. 1, (0.01 g) inactive; 2, (0.07) inactive; 3, (0.53) active at 10^{-6} g ml^{-1}; 4, (0.68) active at 10^{-5}; 5, (2.08) inactive; 6, (5.17) inactive; 7, (7.49) inactive; 8, (8.25) active at 10^{-6}–$^{-7}$ g ml^{-1}; 9, (5.66) active at 10^{-6}; 10, (3.18) active at 10^{-5}; 11, (4.41) active at 10^{-6}. Frs. 8—11 were combined (Fraction C) (21.5 g) and submitted to further separation.

Chromatography on a Sephadex LH-20 Column (C to D). Fraction C (21.5 g) in methanol (50 ml) was separated by chromatography on a Sephadex LH-20 column (Pharmacia, 1013 g) (8.4×74 cm). The column was eluted with methanol (6.5 l), 130 fractions (each 50 ml) being collected. The amount and biological activity of each eluate is summarized in Fig. 6. Fractions 59—78 were active nearly at 10^{-6}–$^{-7}$ g ml^{-1}, combined (Fraction D) (10.1 g), and submitted to further separation.

Chromatography on a DEAP-Sephadex LH-20 Column (D to E). A suspension of DEAP-Sephadex LH-20 (120 g), prepared according to the reported procedure,[30] in 72% aq ethanol was packed in a glass column (3.1×63 cm) and washed successively with 0.5 M aq potassium acetate in 72% aq ethanol (6 l), which had been prepared and adjusted to pH 10 by addition of 1 M aq KOH, 72% aq ethanol (4 l), 0.1 M acetic acid in 72% aq ethanol (4 l), and 72% aq ethanol (4 l), when the packing was converted into the acetate form (3.1×81.5 cm). Fraction D (10.1 g) in 72% aq ethanol (90 ml) was placed on the top of the column and then eluted successively with 72% aq ethanol (4 l) (Fr. 1), 0.1 M acetic acid in 72% aq ethanol (4 l) (Fr. 2), 0.3 M acetic acid in 72% aq ethanol (4 l), which had been adjusted to pH 6.0 by addition of concd NH_4OH (Fr. 3), and 0.3 M acetic acid in 72% aq ethanol (4 l), which had been adjusted to pH 9.0 by addition of concd NH_4OH (Fr. 4).[30,31] Frs. 1 and 2 were evaporated thoroughly to dryness to give inactive oily mixtures (3.18 and 4.87 g) of neutral compounds and monobasic acids, respectively. Fr. 3 was evaporated, dissolved in water (150 ml), acidified with 3 M HCl (130 ml), and extracted with ethyl acetate (4×100 ml). The combined acetate solution was washed with water (3×50 ml), dried, and evaporated to leave an oily mixture of dibasic acids (1.99 g), which was active at 10^{-7} g ml^{-1}. Fr. 4 was treated in the same manner to give an amorphous mixture of polybasic acids (0.17 g) (active at 10^{-6} g ml^{-1}). The mixtures of dibasic and polybasic acid were combined (Fraction E) (2.16 g) and submitted to further separation.

Chromatography on a Sephadex LH-20 Column (E to F). Fraction E (2.12 g) was separated by partition chromatography on a Sephadex LH-20 column (106 g) (2.5×90 cm). The column was eluted with dichloro-

methane–methanol (95:5), 50 fractions (each 30 ml) being collected. The amount and biological activity of each eluate is summarized in Fig. 7. Frs. 25—28 were combined (Fraction F) (135 mg) and submitted to *p*-bromophenacylation.

***p*-Bromophenacylation [F to G (p-BPE)].** A mixture of Fraction F (135 mg), *p*-bromophenacyl bromide (1.70 g), and *N,N*-diisopropylethylamine (0.5 ml) was stirred in dry acetonitrile (15 ml) at room temp for 19 h and then evaporated to leave an oily material. The residue was dissolved in benzene (5 ml) and separated simply by chromatography on a silica-gel column (Wakogel C-200, 20 g) (2.1×21.5 cm) with benzene (Fr. 1), chloroform (Fr. 2), chloroform–ethyl acetate (9:1 and 1:1) (Frs. 3 and 4), ethyl acetate (Fr. 5), and ethyl acetate–acetic acid (99:1) (Fr. 6) (each eluent 100 ml): Fr. 1, (1364 mg); 2, (20.9); 3, (315.7); 4, (27.3); 5, (5.3); 6, (7.7). A part (0.20—0.40 mg) of each eluate was treated with 0.1 M KOH in methanol (50 μl) at room temp for 20 h. The reaction mixture was evaporated, acidified with 0.2 M HCl (50 μl), and extracted with ethyl acetate (3×100μl). The combined acetate solution was washed with water (50 μl) and evaporated under a stream of nitrogen. The residue was dissolved in water (1 ml for 0.02 mg of the initial weight) and assayed: Frs. 1 and 2, both inactive; 3, active at 10^{-8} g ml^{-1}; 4 and 5, both inactive; 6, active at 10^{-6}–$^{-7}$ g ml^{-1}. Fr. 3 [Fraction G (p-BPE)] (315.7 mg) was submitted to further separation.

Preparative HPLC on a Hitachi Gel #3019 Column [G (p-BPE) to H (p-BPE)]. A soln of Fraction G (p-BPE) (316 mg) in chloroform (1.4 ml) was injected in portions of 60—100 μl onto a Hitachi Gel #3019 column (8 mm×50 cm) and separated roughly into 4 fractions, methanol–dichloromethane (7:3) being used as an eluent at flow rate of 4 ml min^{-1}. Each fraction (40 μg) was hydrolyzed as described above and then assayed: Fr. 1, (59.5 mg) inactive; 2, (57.0) active at 10^{-6}–$^{-7}$ g ml^{-1}; 3, (112) active at 10^{-8}–$^{-9}$; 4, (67.7) active at 10^{-8}. Fr. 3 [Fraction H (p-BPE)] (112 mg) was submitted to further separation.

Preparative HPLC on a Bondapak C_{18}/Porasil B Column [H (p-BPE) to I (p-BPE)]. A soln of Fraction H (p-BPE) (112 mg) in a 1:1 mixture (1 ml) of chloroform and methanol was injected onto a Bondapak C_{18}/Porasil B column (7.8 mm×61 cm) and separated into 6 fractions, methanol–water (8:2) being used as an eluent at flow rate of 6 ml min^{-1}. Each fraction (40 μg) was hydrolyzed as described above and assayed: Fr. 1, (9.1 mg) active at 10^{-8} g ml^{-1}; 2, (14.9) active at 10^{-8}; 3, (7.7) active at 10^{-9}; 4, (21.6) active at 10^{-9}; 5, (7.1) active at 10^{-8}; 6, (30.7) active at 10^{-7}–$^{-8}$. Frs. 3 and 4 were combined [Fraction I p-BPE)] (29 mg) and submitted to further separation.

Preparative HPLC on a μBondapak NH_2 Column [I (p-BPE) to J (p-BPE)]. A soln of Fraction I (p-BPE) (29 mg) in chloroform (1.3 ml) was injected in portions of 100—150 μl onto a μBondapak NH_2 column (3.9 mm×30 cm) and separated into 4 fractions, hexane–dichloromethane–acetonitrile (70:18:12) being used as an eluent at flow rate of 1.5 ml min^{-1}. Each fraction (4 μg) was hydrolyzed as described above and then assayed: Fr. 1, (18.18 mg) active at 10^{-6}–$^{-7}$ g ml^{-1}; 2, (0.93) active at 10^{-8}–$^{-9}$; 3, (2.17) active at 10^{-10}; 4, (1.90) active at 10^{-8} g ml^{-1}. Fr. 3 [Fraction J (p-BPE)] (2.17 mg) was submitted to further separation.

Preparative HPLC on a μBondapak NH_2 Column [J (p-BPE) to K (p-BPE)]. A soln of Fraction J (p-BPE) (2.17 mg) in chloroform (0.5 ml) was injected in portions of 100, 200, and 200 μl onto the same column as described above and separated into 4 fractions, hexane–dichloromethane–acetonitrile (80:12:8) being used as an eluent at flow rate of 2.5 ml min^{-1}. Each fraction (0.4 μg) was hydrolyzed and assayed as described before: Fr. 1, (0.28 mg) active at 10^{-8} g ml^{-1}; 2, (0.07) active at 10^{-8}; 3, (0.44) active at 10^{-10}; 4, (0.76) active at 10^{-10}. Frs. 3 and 4 [Fraction K (p-BPE)] (1.20 mg) were submitted to further separation.

Preparative HPLC on a μBondapak NH_2 [K (p-BPE) to L (p-BPE) (=GEA p-BPE)]. A soln of Fraction K (p-BPE) (1.20 mg) in chloroform (120 μl) was injected in portions of 10—25 μl (6 times) onto the aforementioned column and separated into 3 fractions, a 60:36:4 mixture of hexane–dichloromethane–acetonitrile being used as an eluent at flow rate of 1.5 ml min^{-1}. Each fraction (0.4 μg) was hydrolyzed as described above and then assayed: Fr. 1, (0.77 mg) active at 10^{-8}–$^{-9}$ g ml^{-1}; 2, (0.05) active at 10^{-11}–$^{-12}$; 3, (0.07) active at 10^{-10}–$^{-11}$ g ml^{-1}. The second fraction [Fraction L (p-BPE)] showed a single peak by analytical HPLC on the following columns and the highest activity for the hatching after hydrolysis. Analytical HPLC: column, solvent (flow rate), retention time; μBondapak NH_2 (3.9 mm×30 cm), hexane–dichloromethane–acetonitrile (60:36:4) (1.5 ml min^{-1}), 9.5 min; μBondapak C_{18} (3.9 mm×30 cm), methanol–water (8:2) (2.0 ml min^{-1}), 8.5 min; μBondapak/Phenyl (3.9 mm×30 cm), methanol–water (8:2) (2.0 ml min^{-1}), 8.5 min.

(III) Experiments Summarized in Table 3. Preparation of Chloroform Extracts A and Acidic Extracts B. Dried and powdered roots (1058 kg) of "Beni-kintoki" and "Hon-kintoki," subspecies of kidney bean, which had been collected in late July during several years at Memuro (10 hectares) were extracted with water, concentrated and then extracted with chloroform continuously as described above. The total Chloroform extracts A, prepared from all the roots, amounted to 1011 g which stimulated the hatching and emergence at 10^{-5} g ml^{-1} in water at 25 °C.

A part (120 g) of Chloroform extracts A was dissolved in ethyl acetate (500 ml) and treated with saturated aq $NaHCO_3$ (6×200 ml) repeatedly. The aq solns were combined, acidified with 6 M HCl (250 ml) to pH 2—3, and extracted again with ethyl acetate (5×200 ml) and then with chloroform continuously for 18 h. The neutral acetate extracts were dried over anhydrous sodium sulfate and evaporated to leave a dark gum (27.3 g) (inactive), while the acidic acetate extracts were treated in the same manner to give a viscous oil (Acidic extracts B) (84 g) (636 g from total Chloroform extracts A), which was active at 10^{-5}–$^{-6}$ g ml^{-1}. The chloroform extracts also afforded an active oil (4.2 g) (active at 10^{-5}–$^{-6}$ g ml^{-1}).

Chromatography on a Charcoal-Celite Column (B to C). A part (88.2 g) of Acidic extracts B was dissolved in acetone (200 ml) and mixed with Celite-545 (70 g) under vigorous stirring. The mixture, after being evaporated, was placed on the top of a column (11.4×92 cm) prepared from Charcoal (1 kg) and Celite-545 (2 kg) in water, and eluted with water (10 l) (Fr. 1), water–acetone (9:1 to 1:9, each 10 l) (Frs. 2—10), acetone (10 l) (Fr. 11), and methanol–concd NH_4OH (19:1, 20 l) (Fr. 12). The final fraction (Fr. 12) was evaporated, acidified and extracted with ethyl acetate (3×

100 ml), and the acetate extracts were combined with Fr. 11. Frs. 9—11, eluted with 80 and 90% aq acetone and acetone, were more active than other fractions and combined to give a resinous oil (Fraction C) (26.6 g) (197.3 g from total Acidic extracts B), which was active at 10^{-6} g ml^{-1}.

Chromatography on a Sephadex LH-20 Column (C to D). A part (17.57 g) of Fraction C in methanol (40 ml) was separated by chromatography on a Sephadex LH-20 column (1 kg) (8.4×72 cm) in methanol. The column was eluted with methanol (5 l), 180 fractions (each 25—30 ml) being collected. Frs. 76—100 were more active (10^{-6}–$^{-7}$ g ml^{-1}) than those 130—160 (10^{-6} g ml^{-1}), and were combined to give a viscous oil (Fraction D) (7.40 g) (88.9 g from total Fraction C).

Chromatography on a DEAP-Sephadex LH-20 Column (D to E). A part (38.4 g) of Fraction D in 72% aq ethanol (390 ml) was submitted to chromatography on a DEAP-Sephadex LH-20 column[30] (128 g) (3.1×82 cm) packed in 72% aq ethanol (v/v). The column was eluted with 72% aq ethanol (3.9 l) (Fr. 1), 0.1 M acetic acid in 72% aq ethanol (4 l) (pH 4.0) (Fr. 2), and then with 0.3 M acetic acid in 72% aq ethanol (4 l) and concd NH_4OH (127 ml) (pH 9.0) (Fr. 3). Frs. 1 and 2 were evaporated to dryness to give inactive oily residues (20.57 and 9.35 g), respectively. Fr. 3 was evaporated, dissolved in water (100 ml), acidified with 6 M HCl (195 ml) to pH 2, and extracted with ethyl acetate (5×100 ml). The acetate extracts were washed with saturated brine (3×50 ml), dried and evaporated to leave a slightly dark oil (Fraction E) (7.75 g) (18.15 g from total Fraction D), which was active at 10^{-7} g ml^{-1}.

Chromatography on a Sephadex LH-20 Column (E to F and to G). A part (3.21 g) of Fraction E in dichloromethane–methanol (95:5, v/v) (7 ml) was separated by chromatography on a column (2.7×75 cm), which had been packed by Sephadex LH-20 (120 g) with methanol and then with dichloromethane–methanol (95:5). The column was eluted with the same solvent mixture (total 2 l), 60 fractions (each 35 ml) being collected. Most of the fractions were active to some extent. Frs. 19—31 were more active than other fractions and combined to give an oil (Fraction F) (636 mg) (3.59 g from total Fraction E), which was active at 10^{-7}–$^{-8}$ g ml^{-1}.

Fraction F (3.59 g) in dichloromethane–methanol (95:5, v/v) was separated by rechromatography on the same column (2.7×75 cm) packed with Sephadex LH-20 (140 g). The column was eluted with dichloromethane–methanol (97:3) (total 2.5 l), 18 fractions (each ca. 150 ml) being collected. Frs. 9—13 were more active than others and combined to give an oil (Fraction G) (0.95 g), which was active at 10^{-8} g ml^{-1}.

***p*-Bromophenacylation [G to H (p-BPE)].** To a soln of Fraction G (0.95 g) and *p*-bromophenacyl bromide (4.01 g) in acetonitrile (10 ml) was added *N,N*-diisopropylethylamine (2 ml), and the mixture was stirred vigorously at room temp for 19 h, when white ppts appeared. The whole suspension was evaporated to leave a semisolid residue (6.42 g), which was simply purified by chromatography (5.5×26 cm) over silica gel (Wakogel C-200) (250 g). The column was eluted with benzene (1.5 l), chloroform (1 l), chloroform–ethyl acetate (9:1 and 1:1) (each 1 l), ethyl acetate (1 l), and ethyl acetate–methanol (1:1) (1 l). Fracitons eluted with chloroform–ethyl acetate (9:1 and 1:1) were combined to give a gum [Fraction H (p-BPE)] (2.21 g), which was active at 10^{-8} g ml^{-1} after hydrolysis as described below.

A part (0.1 mg) of Fraction H (p-BPE) was treated with 0.1 M KOH in methanol (0.2 ml) at room temp for 4 h. The reaction mixture was evaporated, acidified with 0.2 M HCl (0.4 ml), and extracted with ethyl acetate (3×0.1 ml). The extracts were washed with water (0.1 ml), dried and evaporated to leave a residue, which was dissolved in acetone (one drop) and diluted with water for the bioassay.

Chromatography on a Hitachi Gel #3019 Column [H (p-BPE) to I (p-BPE)]. A part (944 mg) of Fraction H (p-BPE) in dichloromethane–methanol (3:7) (2 ml) was separated by chromatography on a column (2.5×64 cm) packed with Hitachi Gel #3019 (100 g) in dichloromethane–methanol (2:8). The column was eluted with dichloromethane–methanol (2:8) (total 1.6 l), 100 fractions (each 16 ml) being collected (Fig. 8). Frs. 36—50 were more active than others and combined to give a brown oil [Fraction I (p-BPE)] (149 mg) [336 mg from total Fraction H (p-BPE)], which was active at 10^{-9} g ml^{-1} after hydrolysis.

Preparative HPLC on a μBondapak C_{18} Column [I (p-BPE) to J (p-BPE)]. A part (5 mg) of Fraction I (p-BPE) in acetone (0.2 ml) was submitted to preparative HPLC on a μBondapak C_{18} column (7.8 mm×30 cm) and separated into 15 fractions, 80% aq methanol (v/v) (Frs. 1—13) and methanol (Frs. 14 and 15) being used as eluents at flow rate of 2 ml min^{-1} (Fig. 9). The eluents were monitored by the UV spectra and checked by the hatching activity after hydrolysis. Frs. 8 and 9 were more active than others after hydrolysis and combined to give an oil [Fraction J (p-BPE)] (ca. 1.2 mg), which was active at 10^{-9}–$^{-10}$ g ml^{-1} after hydrolysis. This procedure was repeated 70 times to give 79 mg of the Fraction J (p-BPE).

Preparative HPLC on a μBondapak NH_2 Column [J (p-BPE) to K (p-BPE) and K″ (p-BPE)(=GEC p-BPE)]. A part (1.5 mg) of Fraction J (p-BPE) in dichloromethane (0.24 ml) was separated into 6 fractions by preparative HPLC on a μBondapak NH_2 column (7.8 mm×30 cm), hexane–dichloromethane–acetonitrile (76:14:10, v/v/v) being used as an eluent at flow rate of 1.5 ml min^{-1} (Fig. 10). Only Fr. 5 (R_t 13—16 min) was highly active after hydrolysis. This fraction was collected by repeated HPLC (55 times) to amount to 8.8 mg of an oily substance [Fraction K (p-BPE)], which was active at 10^{-10}–$^{-11}$ g ml^{-1} after hydrolysis. On the other hand, Fr. 4 (R_t 11 min) [Fraction K′ (p-BPE)] [4.9 mg from total Fraction J (p-BPE)], showing a practically single peak, was further purified by preparative HPLC on the same column with a mixture of hexane, dichloromethane, and acetonitrile (60:36:4, v/v/v) to give Fraction K″ (p-BPE) (=GEC p-BPE) [1.8 mg from total Fraction J (p-BPE)].

Preparative HPLC on a μBondapak NH_2 Column [K (p-BPE) to L (p-BPE) (=GEA p-BPE) and L″(p-BPE) (=GEB p-BPE). A part (0.50 mg) of Fraction K (p-BPE) in dichloromethane (0.1 ml) was purified by preparative HPLC on a μBondapak NH_2 column (7.8 mm×30 cm), a 63:33:14 (v/v/v) mixture of hexane, dichloromethane, and acetonitrile being used as an eluent at flow rate of 1.5 ml min^{-1}. The eluents were monitored by the UV spectra, when two major fractions with R_t 10.5 and 14.5 min were separated, as shown in Fig. 11. This procedure was repeated 20 times. The former, which was active at 10^{-11}–$^{-12}$

g ml^{-1} in water after hydrolysis, was crystallized on trituration with hexane and dichloromethane to give GEA p-BPE (1.25 mg). On the other hand, the latter [Fraction K' (p-BPE)] [2.6 mg from total Fraction K (p-BPE)] was much less active after hydrolysis and was further purified by preparative HPLC on the same column with a 68:13.2:8.8 (v/v/v) mixture of hexane, dichloromethane, and acetonitrile (flow rate, 3 ml min^{-1}) to give an oil [Fraction L'' (p-BPE)] (=GEB p-BPE)] [1.80 mg from total Fraction K (p-BPE)].

GEA p-BPE (0.1 mg) was treated with 0.1 M KOH in methanol (0.2 ml) at room temp for 4 h. After being evaporated, the soln was acidified with 0.2 M HCl (0.4 ml) to pH 2—3 and extracted with ethyl acetate (3×0.1 ml). The acetate extracts were washed with water (0.1 ml) and purified by preparative HPLC on a μBondapak C_{18} column (7.8 mm×30 cm), 0.1% aq acetic acid–methanol (35:65, v/v) being used as a solvent at flow rate of 2 ml min^{-1} (Fig. 12). The eluent was monitored by the UV spectrum to give an amorphous substance with R_t 10.1 min, GEA (as its potassium salt), which was active at 10^{-12} g ml^{-1}.

The authors are grateful to Mr. Shizuo Sanae for collection of kidney bean, and also to Drs. Minoru Ichinohe, Kazuo Kegasawa, Haruo Inagaki, Masaaki Tsutsumi, and Toshiaki Okada, Hokkaido National Agricultural Experiment Station, for helpful discussion on the bioassay. The research was supported by a Grant-in-Aid for Special Project Research No. 56104009 and Grant-in-Aid for Scientific Research No. 57470022 provided by the Ministry of Education, Science and Culture of Japan, and many other funds.

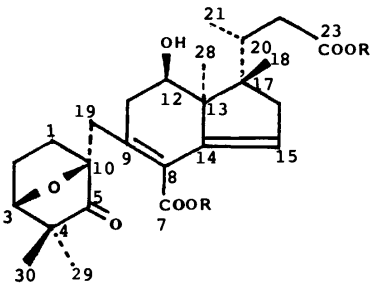
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

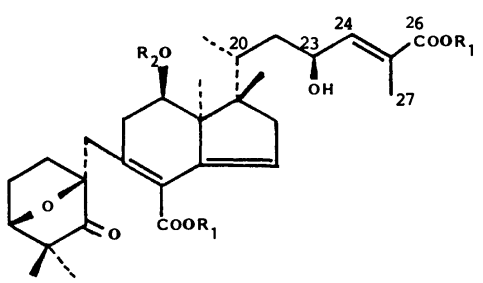
(Received August 7, 1986)

The structures of three new compounds, glycinoeclepins A, B, and C, isolated from the hatch-stimulating extracts of kidney beans for the soybean cyst nematode, have been determined. The structures were resolved by using spectroscopic methods, especially by the difference NOE techniques, and confirmed by the X-ray diffraction analysis. These structures are characterized by (1) migration of two methyl groups in the C and D rings, (2) oxidative cleavage of the B ring with loss of one carbon atom and (3) presence of the 7-oxabicyclo[2.2.1]heptane system in the A ring, compared with those of cycloartanes, and are regarded as pentanor- (GEA) or nortriterpenes (GEB and GEC).

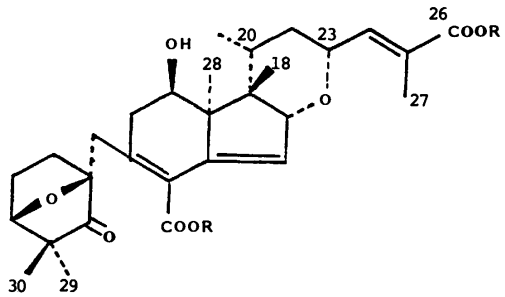
In the preceding paper[1] we described the isolation of natural hatching stimuli, designated as glycinoeclepins A, B, and C (GEA, GEB, and GEC), for the soybean cyst nematode as their *p*-bromophenacyl esters (p-BPEs). Of these compounds, GEA, identified as an active principle, stimulated the hatching at 10^{-11}—$^{-12}$ g ml^{-1} in water at 25 °C.[2] In preliminary communications,[3,4] we reported the structures of these stimuli. However, it has recently been found that the reported (20*R*, 23*S*, 24*E*) configuration[4,5] of the side chain of GEC should be revised to the (20*R*, 23*R*, 24*E*) one. The present paper describes the details of the structural elucidation of GEs including the structural revision of GEC.



GEA (**1**), R=H
GEA p-BPE (**1a**), R=$CH_2COC_6H_4Br$



GEB (**2**), R_1=H, R_2=$COCH_3$
GEB p-BPE (**2a**), R_1=$CH_2COC_6H_4Br$, R_2=$COCH_3$
Deacetyl GEB (**2b**), R_1=H, R_2=H



GEC (**3**), R=H
GEC p-BPE (**3a**), R=$CH_2COC_6H_4Br$

Structural Elucidation of GEA on the Basis of the Spectroscopic Evidence. The molecular formula of GEA (**1**) was determined as $C_{25}H_{34}O_7$ on the basis of the FD-MS [*m/z* 838, 840, and 842 (1:2:1)] and CI(NH_3)-MS spectra [*m/z* 856, 858, and 860 (1:2:1)] of GEA p-BPE (**1a**) as well as the ^{1}H NMR spectra of **1a** [$CDCl_3$ (Fig. 1) and C_6D_6]. The ^{13}C NMR spectra of **1a** ($CDCl_3$ and C_6D_6) under completely decoupled (Table 1) and off-resonance conditions, combined with the INEPT studies, indicated the presence of 5 methyl, 6 methylene, 1 methine, and 3 quaternary (■) carbon atoms, 2 methine and 1 quaternary carbon atoms bearing oxygen atoms, 1 trisubstituted and 1 tetrasubstituted double bonds, and 2 carboxyl and 1 carbonyl carbon atoms. These spectral data, coupled with IR spectrum of **1a** (1758 cm^{-1}, sh), revealed the presence of the following oxygen functions: 2 -COOH, 1 -OH, 1 -O-, and 1 -C(=O)- (ketone). Moreover, the ^{1}H NMR spectra of **1a**, combined with the detailed analysis of the COSY spectra (Fig. 2) and extensive decoupling studies, indicated the presence of structural units (i) to (x) as shown in Table 2. However, confirmatory evidence was required for the presence of the units (iii) and (iv), because the coupling constants between vicinal protons in the units [unit (iii), ■-C(12)H(OH)-C(11)H_2-■, $J_{12\alpha,11\beta}$=

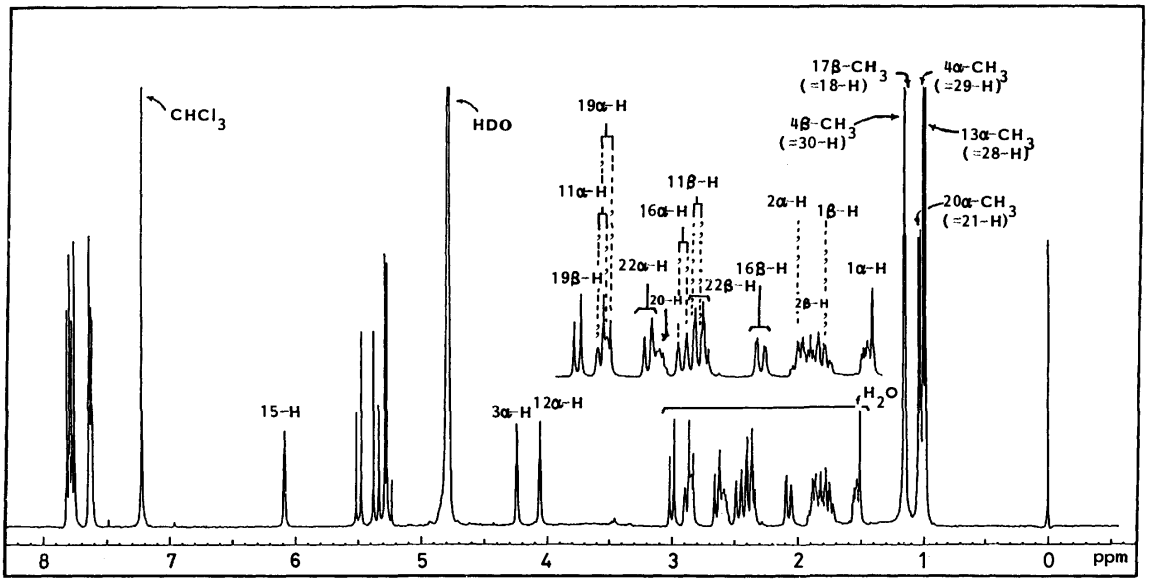


Fig. 1. The ^{1}H NMR spectrum of GEA p-BPE (**1a**) (400 MHz, 0.5 mg in $CDCl_3$ and D_2O).

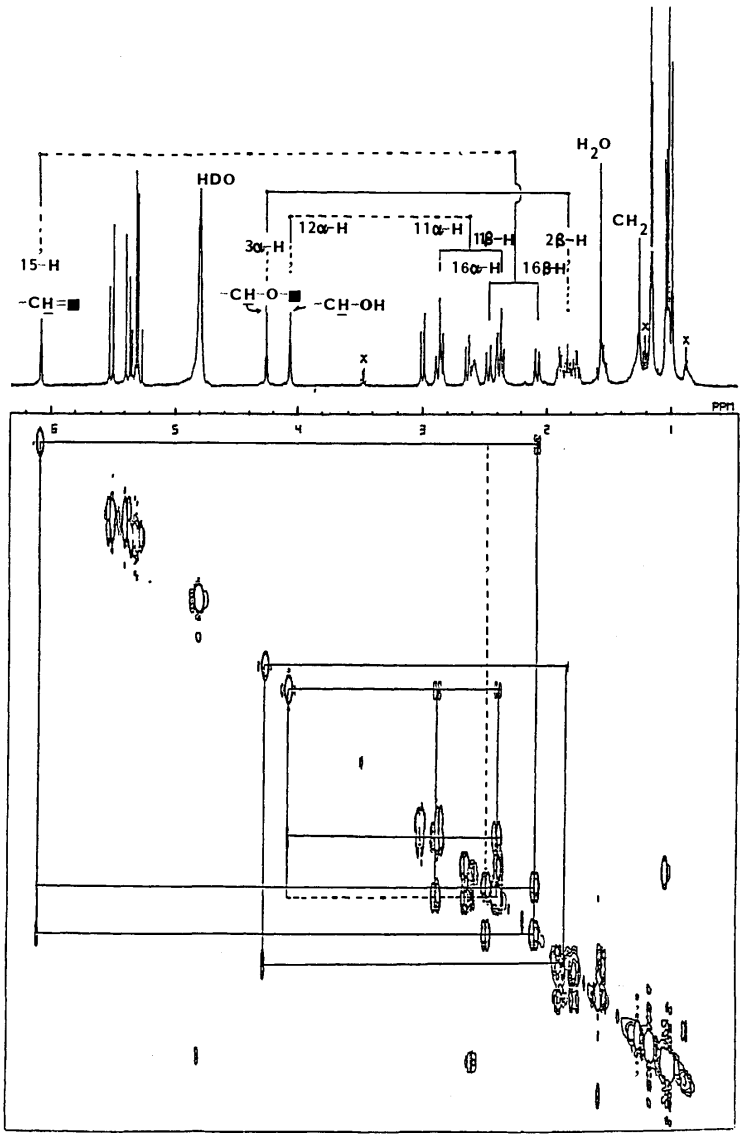

Fig. 2. The COSY spectrum of GEA p-BPE (**1a**) (500 MHz, 1 mg in $CDCl_3$ and D_2O).

1.5 Hz and $J_{12\alpha,11\alpha}$=3 Hz; unit (iv), ■=C(15)H-C(16)H_2-■, $J_{15,16\beta}$=3.5 Hz, $J_{15,16\alpha}$=1.5 Hz] were less than 4 Hz and hence might be attributed to long-range coupling. Thus the NOE difference spectra of these vicinal protons were measured. The result clearly demonstrated that the protons in question in the respective units are situated in a narrow region each other, and the C(11) and C(15) atoms are connected directly to the C(12) and C(16) atoms, respectively.

The following comments are annotated on Tables 1 and 2. (1) The olefinic proton H_{15} in the unit(iv) of **1a** was observed at δ 6.08 (cf., **2a**, δ 6.02; **3a**, δ 6.22), at rather low-field compared with usual olefinic protons. (2) Two *p*-bromophenacyloxycarbonyl carbon atoms in the units(viii) and (ix) of **1a** appeared with clearly different chemical shifts (δ 167.6 and 173.1, $\Delta\delta$ 5—6 ppm) (Table 1), while the corresponding atoms in **2a** and **3a** did at practically the same field (**2a**, δ 167.8 and 167.8; **3a**, δ 167.2 and 167.6) (Table 1). These facts are consistent with that one of the relevant carbon atoms is connected to an sp^3-type carbon atom [unit(ix)] and another to an sp^2-type carbon atom [unit(viii)] in **1**. (3) The chemical shift (δ 216.6) of one carbonyl carbon atom [unit(x)] of **1a** strongly suggested that the carbonyl group would be sterically hindered and/or involved in a strained system (cf., **2a**, δ 216.7; **3a**, 216.3).[6] All these facts will be discussed again.

Now we must connect these structural units(i) to (x), which are disconnected by ten quaternary (■) carbon atoms. The NOE difference spectra[7,8] (Fig. 3) between protons of two geminal methyl groups [unit(vii)] and those in the unit(i) indicated that (1) one [■=C(4)] of the terminal quaternary carbon atoms in the unit(i) must be identical with that of the unit(vii), and (2) another terminal quaternary carbon [■=C(10)] of the unit(i) must be identical with that bearing the ether oxygen atom, because (a) neither of the two protons ($H_{1\beta}$ and $H_{1\alpha}$) at the C(1), attached to C(10), is located close to all other protons involved in the units(ii) to (vi), and (b) if the relevant carbon C(10) were identical with the former C(4), forming a four-membered ring, the coupling constants between geminal protons at C(1) and C(2) would be much smaller than those observed ($J_{1\beta,1\alpha}=J_{2\beta,2\alpha}$=12 Hz). Hence the units(i) and (vii) can be extended to a structural moiety (A), in which the coupling constants between protons at C(3) and C(2) were $J_{3\alpha,2\beta}\fallingdotseq$ 5 Hz and $J_{3\alpha,2\alpha}\fallingdotseq$0 Hz. These constants led us to presume that the moiety (A) must be involved in a 7-oxabicyclo[2.2.1]heptane system. This skeletal system indeed exists as the A ring in acerinol[9] (**4**), a triterpene of natural origin. The coupling con-

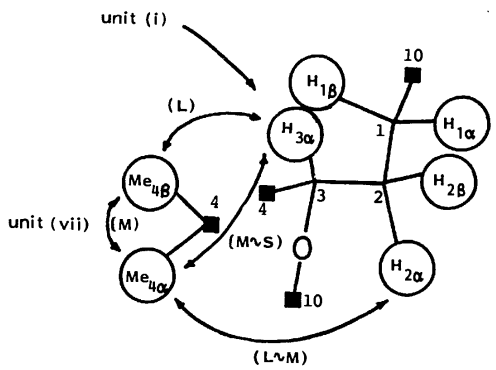

Fig. 3. The difference NOEs (⌒) between the geminal methyl and other protons in GEA p-BPE (**1a**).

stants between protons in the A ring of **4** were readily obtained by measurement of the decoupling difference spectrum (Fig. 4), the result being tabulated in Table 3. Table 3 revealed that these coupling constants were essentially the same as those of the protons in the moiety (A), indicating that the moiety (A) can be extended to a 4,4-dimethyloxabicyclo[2.2.1]heptane moiety[10] (B) with an sp^2-type carbon atom at C-5 (a carbonyl carbon or an olefinic carbon). Then we prepared 1-bromomethyl-3,3-dimethyl-7-oxabicyclo[2.2.1]heptan-2-one (**5**) (Scheme 1) and compared the spectral data with those of **1a**

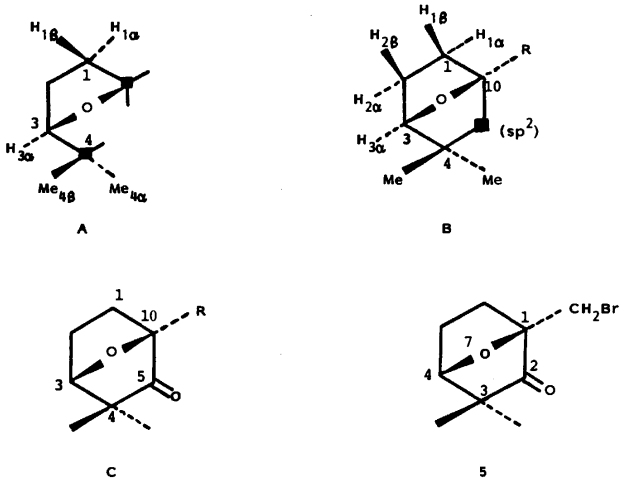
a) The spectra were measured in $CDCl_3$. b) The coupling constants were estimated at the 1st order approximation.

[IR (KBr), **1a**, 1760 cm^{-1} (sh) (**1**, 1757 cm^{-1}) (C=O); **5**, 1757 cm^{-1}: ^{13}C NMR ($CDCl_3$), **1a**, δ 216.9 (C=O); **5**, δ 214.6: ^1H NMR ($CDCl_3$ and C_6D_6), **1a**, δ *1.02 and 0.73* (4α-CH_3), and 1.17 and 1.10 (4β-CH_3); **5**, δ *1.06 and 0.66* (3α-CH_3), and 1.23 and 1.04 (3β-CH_3)]. The absorption peaks due to the carbonyl group in the IR (near 1760 cm^{-1}) and ^{13}C NMR spectra (near δ 215 ppm), coupled with the up-field shift ($\Delta\delta \approx 0.4$ ppm) of α-oriented methyl protons in the ^1H NMR spectrum in hexadeuteriobenzene, have established that a 4,4-dimethyl-3,10-epoxy-5-cyclohexanone moiety[10] (C) is involved in GEA (**1**).



We next discuss on a structural moiety constructed by the units(ii), (iii), (iv), and (vi) in Table 2. The NOE difference spectra[7,8] between the protons of these units of **1a** were measured in details, the result being summarized in Fig. 5. As shown in Fig. 5, the protons of one (17β-CH_3=18-H) of two methyl groups in the unit(vi) were located close to secondary methyl protons (20β-CH_3=21-H)[11] and one proton (22β-H)[11] in the unit(ii), a hydroxyl proton (measured in C_6D_6) in the unit(iii), and two protons (16β-H and 15-H) in the unit(iv), while another methyl protons (13α-CH_3=28-H) were situated close to most of the remaining protons of the units(ii) (20α-H and 22α-H), (iii) (12α-H and 11α-H), and (iv) (16α-H). These findings revealed that (1) three major C–C bonds of the units(ii) to (iv) constitute an almost flat plane, and (2) half (20β-CH_3, 22β-H, OH, and 16β-H) of these protons and one methyl protons (17β-CH_3) are disposed at an upper (or lower) side of the plane, and the remaining protons (20α-H, 22α-H, 12α-H, 11α-H, and 16α-H) and another methyl protons (13α-CH_3) are located at a lower (or upper) side of the plane. It is emphasized that any notable NOE was not observed between these protons of the units(ii), (iii), (iv), and (vi) and other protons of the units(i) and (vii). We had to connect these units so as to form a structural moiety consistent with all the spectral data, although a number of combinations of the units were possible.

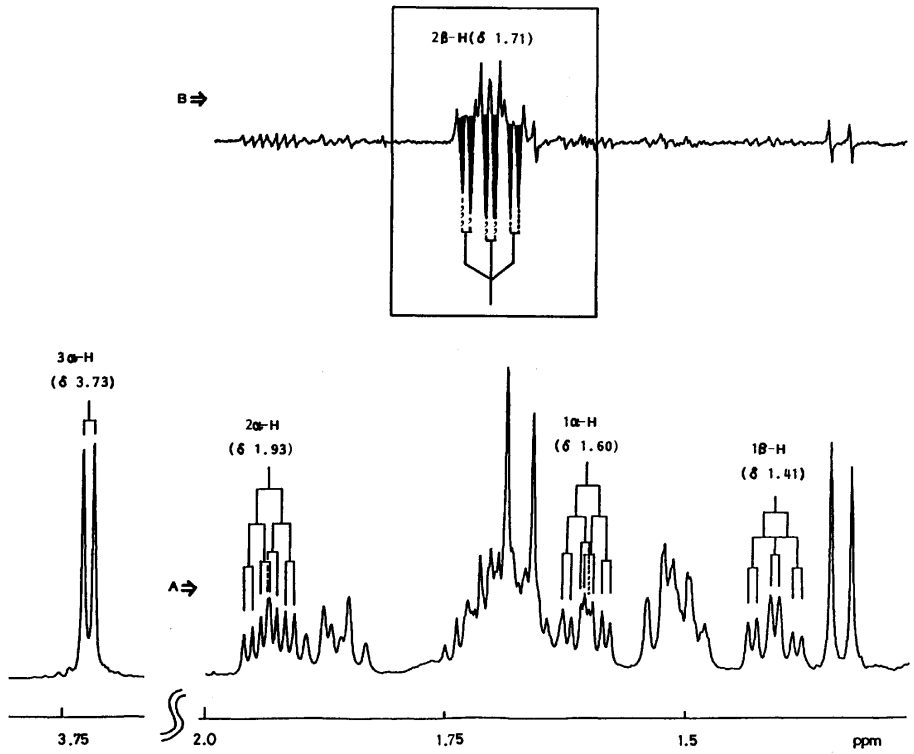


Fig. 4. The ^1H NMR spectrum of the A-ring of acerinol (**4**) (500 MHz, $CDCl_3$).
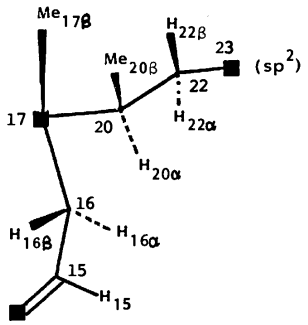
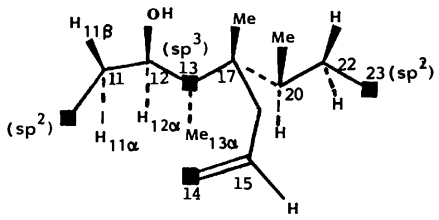
(A) The normal spectrum: (B) The decoupling difference spectrum on irradiation at δ 3.73 (3α-H).

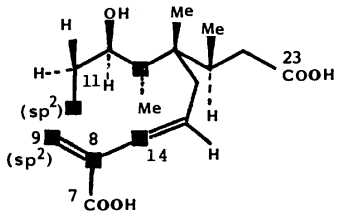
As indicated in Fig. 5, the secondary methyl protons (20β-CH_3)[11] in the unit(ii) were located near to both two geminal protons (16β-H and 16α-H) in the unit(iv) and the methyl protons (17β-CH_3), attached to a quaternary carbon [C(17)] and disposed at the upper side of the plane. The latter protons (17β-CH_3) were also situated close to one proton (22β-H) in the unit(ii) and one proton (16β-H) in the unit(iv). Thus one terminal quaternary carbon atom of the unit(ii) and that of the unit(iv) must be identical with the quaternary carbon atom C(17), forming a structural moiety (D). The same discussion holds for relation between another methyl protons (13α-CH_3), attached to a quaternary carbon atom [C(13)] and located at the lower side of the plane, two protons (12α-H and 11α-H) in the unit(iii), and half (20α-H, 22α-H, and 16α-H) of the protons in the moiety (D). Hence one terminal quaternary carbon atom of the unit(iii) must be identical with that C(13), which must be connected directly to that C(17) in the moiety (D). It follows that the moiety (D) can be extended to a structural moiety (E).



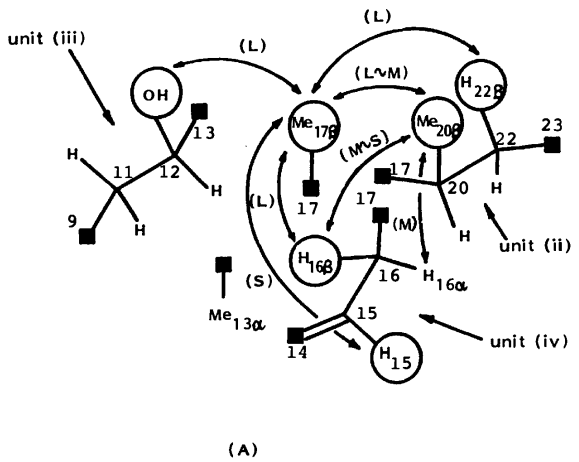
D



E



F



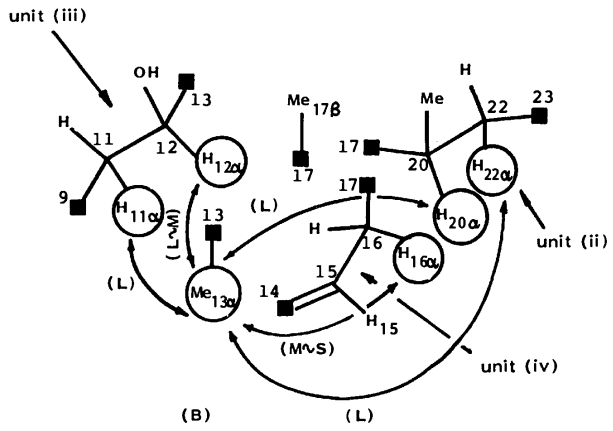


Fig. 5. The difference NOEs (⌒) (A) and (B) between the two methyl (unit vi) and other protons in GEA p-BPE (**1a**).

The moiety (E) is further extended to a structural moiety (F) on the basis of the following reasons. (1) GEA (**1**) showed an absorption maximum at 251.5 nm (ε 8300) in the UV spectrum [cf., **1a**, 254.5 nm (ε 27100)] and a sharp signal (W_H=3 Hz) due to an olefinic proton at δ 5.66 in the ^{1}H NMR spectrum (CD_3OD) [cf., **1a**, δ 6.08 ($CDCl_3$) and 6.54 (C_6D_6)]. These data indicated that two double bonds in the units(iv) [and hence in the moiety (E)] and (viii) are conjugated in a cross-conjugation manner. (2) Two protons (22β-H and 22α-H) in the unit(ii) [hence in the moiety (E)] appeared at δ 2.64 and 2.37 in the ^{1}H NMR spectrum of **1a** ($CDCl_3$) (cf., δ 2.75 and 2.44 in C_6D_6). These chemical shifts indicated that the carbon atom [C(22)] bearing these protons must be attached to an sp^2-type quaternary carbon atom. Examination of Table 2 revealed that the units of **1** seriously differed from those of **2** only in the units(ii) and (ix), indicating the (C_{sp^3}) and (C_{sp^2}) atoms in the unit(ix) of **1** and **2** must be the methylene carbon [C(22)] and methyl-substituted olefinic carbon atoms [C(25)] in the unit(ii) of **1** and **2**, respectively. Thus the moiety (F) can be constructed reasonably by the units(ii), (iii), (iv), (vi), (viii), and (ix). The remaining unit is only that (v).

Careful and repeated measurement of the NOE difference spectra revealed the presence of the small NOEs between one (19β-H)[11] of two geminal protons in the unit(v) and both the protons (1β-H) (Fig. 6) and (11β-H) in the moieties (C) and (F).[12] This finding led us to presume that one of two quaternary carbon atoms of the unit(v) must be identical with the undefined one [C(10)] of the moiety (C), and another with that [C(9)] attached to the carbon bearing the relevant proton (11β-H), respectively. Thus partial structures (C) and (F), and the unit(v) must be connected straightforward as shown in Fig. 7. GEA is therefore represented favorably by formula **1**, in which the absolute configuration remains undetermined.

Structural Elucidation of GEA on the Basis of the X-Ray Diffraction Analysis. A good single crystal of GEA p-BPE (**1a**) was grown by slow evaporation from the solution in hexane and dichloromethane containing a trace amount of methanol. The crystal data follow as: $C_{41}H_{44}O_9Br_2 \cdot 1/2CH_2Cl_2$, monoclinic, space group $P2_1$, a=18.596(6), b=15.010(4), c=16.112(5) Å,

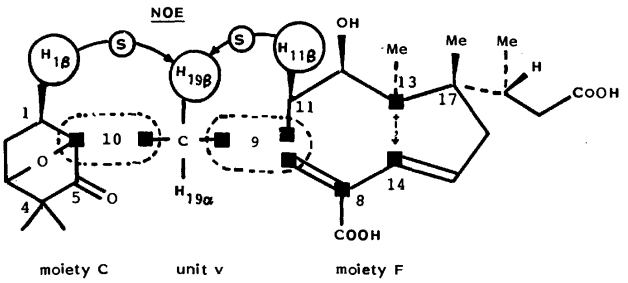

Fig. 7. A combination of the moieties (C) and (F) and the unit (v).

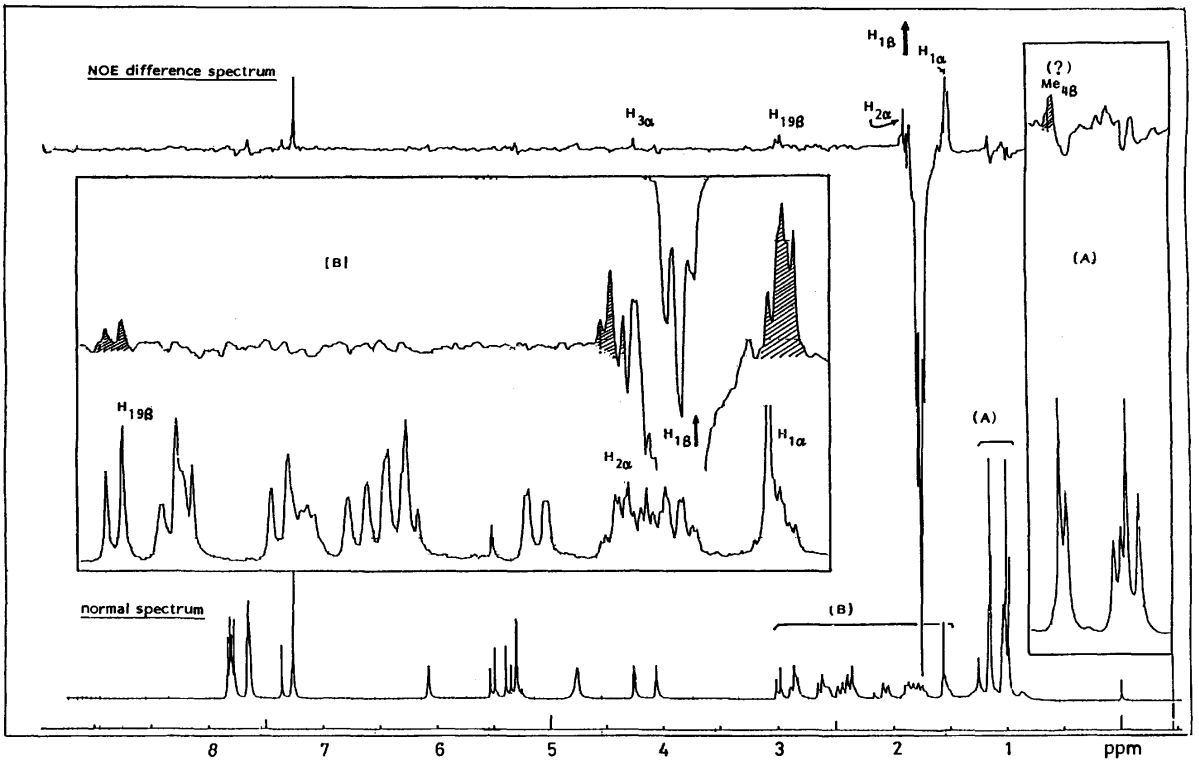

Fig. 6. The NOE difference spectrum of GEA p-BPE (**1a**) on irradiation at δ 1.76 (1β-H) (400 MHz, 0.5 mg in $CDCl_3$ and D_2O).

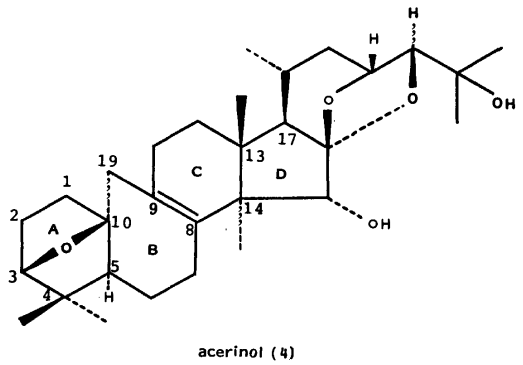
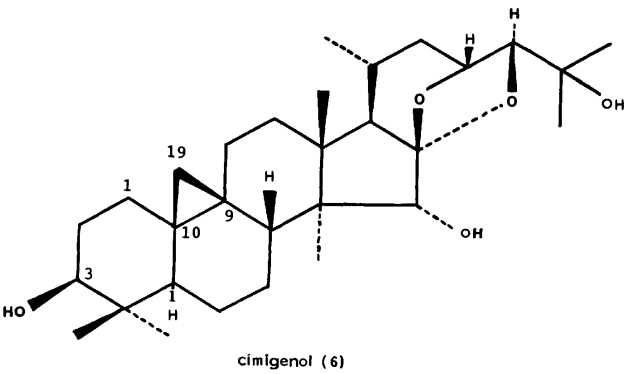
β=114.41(2)°, Z=4, D_C=1.432 g cm^{-3}, μ(Cu-$K\alpha$)=35.6 cm^{-1}. The intensities of 4725 independent reflections with $2\theta<120°$ were collected on an automatic, four-circle diffractometer with graphite-monochromated Cu-$K\alpha$ radiation using the ω—2θ scanning technique.[13] Since three standard reflections showed a gradual decrease in intensity with the course of data collection, the intensities were corrected for this damage to the sample as well as for the Lorenz and polarization factors. The structure was solved by the Monte Carlo direct method,[14] using the 30 strongest reflections as a starting set. An E-map based on the 58th random phase set afforded all the non-hydrogen atoms in the two ester molecules. The dichloromethane molecule was located in a difference Fourier map. After several cycles of the least-squares refinement had been carried out using the carbon atomic scattering factors for all the light atoms, the oxygen atoms were distinguished from the carbon atoms on the basis of the isotropic temperature factors and the bond distances and angles. The structure was then refined by the block-diagonal least-squares method with anisotropic thermal parameters. The absolute configuration was assigned by taking account of the anomalous dispersion of the halogen atoms for Cu-$K\alpha$ radiation. The R-factor for two enantiomeric structures, 1.106, excluded one of them at the 99.5% confidence level.[15] After the 78 hydrogen atoms had been located in a second difference Fourier map, further least-squares refinement were performed including these hydrogen atoms. The final R-value was 7.8%. These two crystallographically-independent molecules of **1a** had almost the same geometries, and one of the two is depicted in Fig. 8. The molecular structure including the absolute configuration of **1a** has thus been determined, and hence the structure of GEA is represented by formula **1**.[16]

On the basis of the assigned structure, we propose the following biogenesis for formation of GEA, shown in Fig. 9. The biogenesis, including a cycloartane, one of naturally occurring triterpenes such as acerinol[9] (**4**) and cimigenol[9] (**6**), as a





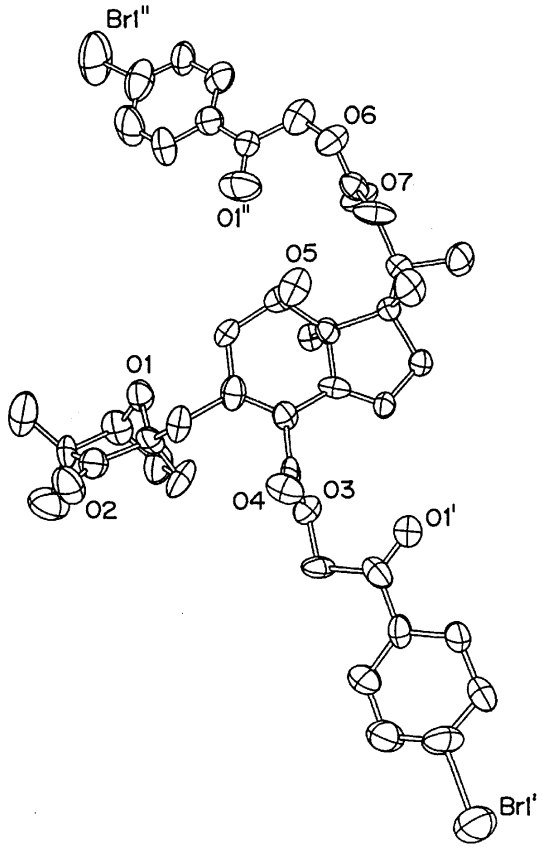


Fig. 8. The X-ray crystal structure of GEA p-BPE (**1a**).

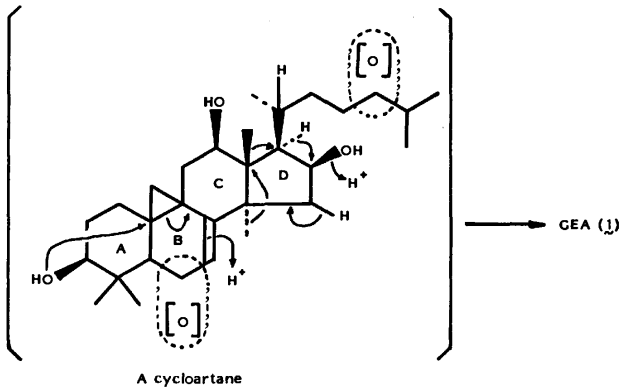

Fig. 9. A plausible biogenesis for formation of GEA (**1**).

precursor, involves (1) migration of two methyl groups in the C and D rings in a back-bone rearrangement manner, (2) cleavage of the C(9)–C(10) bond followed by formation of a 7-oxabicyclo[2.2.1]-heptane system, and (3) oxidative cleavage of the B ring and side chain with loss of one and four carbon atoms. Thus GEA (**1**) is regarded as a pentanortriterpene. These biogenetical characteristics represent the distinctive structural features of GEA. The structure with such characteristics has not been encountered previously. Only recently, isolation of a triterpene, mariesiic acid A, "having a methyl-rearranged skeleton of lanostane" from *Abies mariesii* has been reported by Hasegawa et al.[17]

Structural Elucidation of GEB. The molecular formula of GEB (**2**) was established as $C_{31}H_{42}O_9$ on the basis of the FD-MS spectrum [*m/z* 950, 952, and 954 (1:2:1)] of GEB p-BPE (**2a**) as well as the ^{1}H NMR spectra of **2a** [$CDCl_3$ (Fig. 10) and C_6D_6]. The ^{13}C NMR (Table 1) and ^{1}H NMR spectra of **2a** measured in the same manner as **1a**, indicated the presence of ten structural units(i) to (x) tabulated in Table 2. The ^{1}H NMR spectral properties, especially the difference NOEs[7,8] and coupling constants summarized in Fig. 11, of most of the protons included in these units, were essentially identical with those of the corresponding protons of **1a**. Thus structural moieties (a) including the units(i), (vii), and (x) (**2a**, IR_{max} 1750 cm^{-1}), (b) equivalent to the unit(v), (c) involving the units(iii), (iv), (vi), and (viii) [**2**, UV_{max} 252 nm (ε 9500)], and (d) containing the units(ii) and (ix), must constitute the A, B (cleaved), C and D rings, and the side chain, respectively. In view of the co-occurrence of **1** and **2** in the same plant, GEB

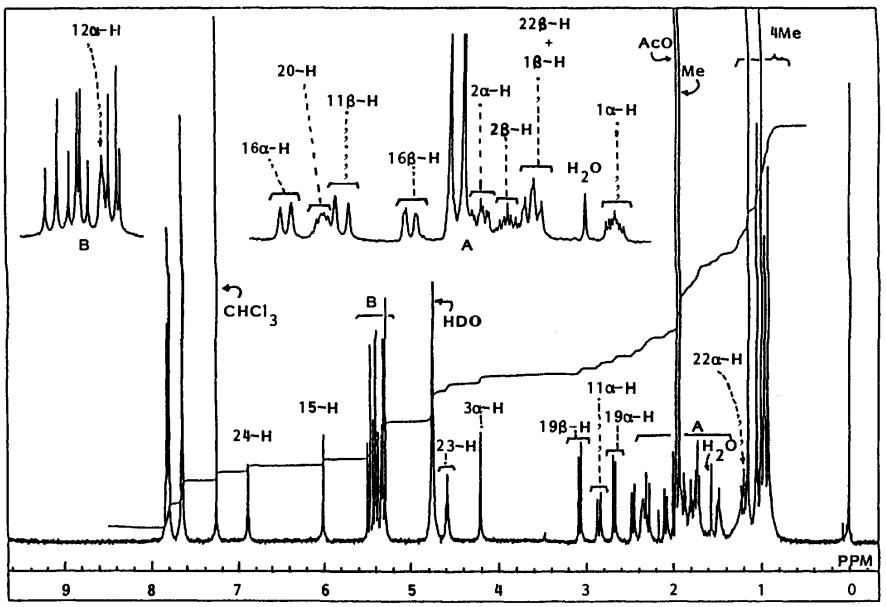

Fig. 10. The ^{1}H NMR spectrum of GEB p-BPE (**2a**) (500 MHz, 1 mg in $CDCl_3$ and D_2O).

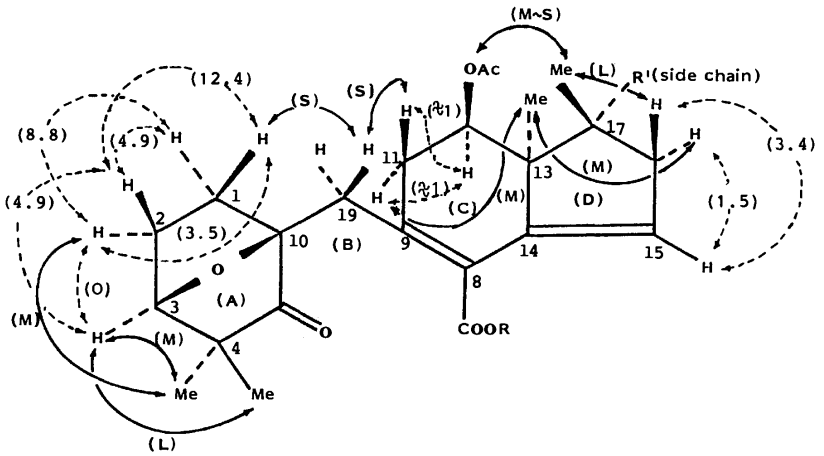

Fig. 11. The NOEs (⌒) and coupling constants (Hz) between the protons in the A→D rings of GEB p-BPE (**2a**) (R=$CH_2COC_6H_4Br$).

must possess the same skeleton and the same absolute configuration as GEA, differing from **1** only in the substituent (OH→OAc) at C(12) and the side chain. The structure of the side chain [the units(ii) and (ix)] was elucidated on the basis of the result of conformational analysis, deduced from the difference NOEs[7,8] (Fig. 12) between the relevant protons. The result was also consistent with the following coupling constants (Hz): $J_{20\alpha,22\beta}$=0 (dihedral angle, $\theta\fallingdotseq$110°); $J_{20\alpha,22\alpha}$=11.1 ($\theta\fallingdotseq$10°); $J_{22\beta,23\alpha}$=12.8 ($\theta\fallingdotseq$160°); $J_{22\alpha,23\alpha}$=2.0 ($\theta\fallingdotseq$80°); $J_{23\alpha,24}$=8.2 ($\theta\fallingdotseq$180°); $J_{24,27}$=1.2. The conformation depicted in Fig. 12 indicates that **2a** possesses the (20*R*, 23*S*, 24*E*) configuration. GEB is therefore represented most favorably by formula **2**.

Structure Elucidation of GEC. The molecular formula of GEC (**3**) was established as $C_{29}H_{38}O_9$ on the basis of the FD-MS spectrum [*m/z* 906, 908, and 910 (1:2:1)] and the ^{1}H NMR spectra of GEC p-BPE (**3a**). The ^{13}C NMR (Table 1) and ^{1}H NMR spectra of **3a** revealed the existence of ten structural units(i) to (x) shown in Table 2. Detailed examination of the NOE difference spectra between the methyl and other protons included in these units indicated that GEC (**3**) must possess the same skeleton as GEA (**1**) with the C(16) atom substituted by an ether oxygen atom, which involves three structural moieties (a) including the units(i), (vii), and (x) (**3a**, IR_{max} 1754 cm^{-1}), (b) the unit(v), and (c) including the units(ii), (iii), (iv), (vi), and (viii) [**3**, UV_{max} 253 nm (ε 9500)], corresponding to the A, B (cleaved), and C and D rings, respectively. The (20*R*, 23*R*, 24*E*) configuration in the D ring and the side chain was deduced mainly from the difference NOEs[7,8] shown in Fig. 13 (cf., Fig. 4 in Ref. 4). The coupling and difference coupling constants (Hz) between the relevant protons were in good accord with the conformation depicted in Fig. 13: $J_{20\beta,22\beta}$=6 (dihedral angle, $\theta\fallingdotseq$35°); $J_{20\beta,22\alpha}$=13 ($\theta\fallingdotseq$155°); $J_{22\beta,22\alpha}$=13; $J_{22\beta,23\beta}$=3 ($\theta\fallingdotseq$40°); $J_{22\alpha,23\beta}$=13 ($\theta\fallingdotseq$160°); $J_{23\beta,24}$=8 ($\theta\fallingdotseq$170°); $J_{24,27}$=1.2. GEC is therefore represented best by formula **3**.

Fig. 13. The difference NOEs (⌒) between the protons in the side chain of GEC p-BPE (**3a**) (R= $CH_2COC_6H_4Br$).

Experimental

The IR spectra were recorded on KBr disks with JASCO model IRA-810 and/or JEOL model JIR-100 spectrometers, and the UV spectra in methanol with a Hitachi model 124 spectrometer. The MS spectra was measured with JEOL model JMS-D300 and/or JMS-OISG-2 spectrometers. The ^{1}H NMR spectra, COSY spectra, and NOE difference spectra, and decoupling difference spectra were measured in [^{2}H]chloroform, (Merck Co., Inc. and Aldrich Chem. Co., Inc.), [$^2H_6$]benzene, and/or [$^2H_4$]methanol with JEOL model PS-100, FX-400, GX-400 and/or GX-500 spectrometers, TMS (Aldrich Chem. Co., Inc.) being used as an internal standard. The ^{13}C NMR spectra were recorded in [^{2}H]chloroform and/or [$^2H_6$]benzene with JEOL model FX-90, FX-100 and/or GX-500 spectrometers.

GEA p-BPE (1a). GEC (3). Compound **3a** (0.5 mg) was hydrolyzed with 0.1 M KOH in methanol at room temp for 10 h. The reaction mixture was worked up as usual to yield an amorphous residue, which was purified by preparative HPLC as described above to give **3** (0.26 mg), amorphous. UV (MeOH), 253 nm (ε 9500): IR (KBr), 3375 (m), 1761 (m), 1572 (vs), 1414 (vs), 1055 (m), 1018 (m), and 654 (w) cm^{-1}: ^{1}H NMR (400 MHz, CD_3OD), δ=0.99 and 1.15 (each 3H, s, 29-H and 30-H=4α-CH_3 and 4β-CH_3), 1.23 and 1.29 (each 3H, br s, 28-H and 18-H=13α-CH_3 and 17β-CH_3), 1.28 (3H, d, J=6.5 Hz, 21-H=20α-CH_3), 1.89 (3H, br s, 27-H=25-CH_3), 2.01 (1H, m, 20β-H), 2.06 (1H, br d, J=18.5 Hz, 11β-H), 2.33 (1H, br d, J=14 Hz, 19α-H), 2.88 (1H, br d, J=18.5 Hz, 11α-H), 3.05 (1H, br d, J=14 Hz, 19β-H), 3.90 (1H, br s, 16β-H), 3.93 (1H, br s, 12α-H), 4.24 (2H, m, 3α-H and 23β-H), 5.75 (1H, br s, 15-H), and 6.37 (1H, m, 24-H).

1-Bromomethyl-3,3-dimethyl-7-oxabicyclo[2.2.1]heptan-2-one (5). (Scheme 1). a) A soln of α-chloroacrylonitrile (18.5 g, 0.22 mol), 2,4-dimethyl-1,3-pentadiene (10.5 g, 0.11 mol), and 2,6-di-*t*-butyl-4-methylphenol (BHT, 500 mg) in benzene (100 ml) was stirred under reflux for 7 h. The reaction mixture was evaporated and then distilled under reduced pressure to give 1-chloro-2,2,4-trimethyl-3-cyclohexene-1-carbonitrile (**5a**) (12.1 g), bp 108—113 °C (12 Torr) (1 Torr=133.322 Pa). The undistilled residue was submitted to chromatography over silica gel with hexane–benzene (10:1) to afford an additional amount (4.0 g) of **5a**. The total yield of **5a** amounted to 80%. **5a**: ^{1}H NMR (100 MHz, CCl_4), δ=1.17, 1.30, and 1.69 (each 3H, s), and 5.11 (1H, br s): MS, m/z 185 and 183 (1:3, M^+), 132 and 96 (base).

b) To a soln of copper(II) sulfate (68.0 g as $5H_2O$, 0.272 mol) in water (250 ml) was added zinc powder at 0 °C. The mixture was stirred at the temp for 10 min and filtered to give zinc-copper couples (Zn–Cu), which were washed with water and ethanol. To a soln of **5a** (25.0 g, 0.136 mol) in 80% aq ethanol (750 ml) were added the couples. The mixture was stirred under reflux for 15 h, when precipitates (ppts) appeared, and were then collected by filtration and washed with methanol and ethyl acetate repeatedly. All the organic solns were combined, evaporated, diluted with saturated brine, and extracted with ethyl acetate. The ethyl acetate soln was washed with water and brine, dried and evaporated to leave an oily residue, which was distilled under reduced pressure to afford 2,2,4-trimethyl-3-cyclohexene-1-carbonitrile (**5b**) (19.6 g, 97%), bp 122—123 °C (15 Torr): IR (neat), 2220 and 1460 cm^{-1}: ^{1}H NMR (100 MHz, CCl_4), δ=1.11 (6H, s), 1.63 (3H, s), and 5.08 (1H, br s): MS, m/z 149 (M^+), 134, 107, and 96 (base).

c) To a soln of diisopropylamine (12.9 ml, 92 mmol) in tetrahydrofuran (THF, 100 ml) was added butyllithium [BuLi, 1.6 M hexane soln (57.5 ml, 92 mmol)] at 0 °C, and the mixture was stirred for 30 min at 0 °C. To the mixture cooled at −78 °C was added **5b** (12.4 g, 83 mmol) in THF (60 ml) during a period of 1 h, and the mixture was then stirred at the temp for 1 h. Into the mixture was bubbled oxygen gas at −78 °C for 1 h, and was then added triethyl phosphite (15 ml, 87 mmol). The whole mixture was stirred at −78 °C for 15 min and then at 0 °C for 1.5 h. The reaction mixture was diluted with water and extracted with diethyl ether. The ether soln was washed with water and brine, dried, and evaporated to leave an oily residue, which was distilled in vacuo to give 2,2,4-trimethyl-3-cyclohexen-1-one (4.1 g). The undistilled residue was separated by chromatography over silica gel (130 g) with hexane–benzene (1:1) to yield an additional amount of the ketone (3.4 g): ^{1}H NMR (100 MHz, CCl_4), δ=1.07 (6H, s), 1.72 (3H, s), and 5.20 (1H, br s). The combined ketone was reduced without further purification.

A soln of the ketone (7.5 g, 54 mmol) in methanol (100 ml) was stirred with sodium borohydride (2.0 g, 54 mmol) at 0 °C for 1 h. After being quenched with acetic acid and neutralized with saturated aq sodium hydrogencarbonate ($NaHCO_3$), the reaction mixture was concentrated, diluted with water, and extracted with ether and then with ethyl acetate. The combined extracts were washed with saturated brine, dried, and evaporated to leave an oily residue, which was purified by distillation to give 2,2,4-trimethyl-3-cyclohexen-1-ol (**5c**) (7.17 g, 95%), bp 48—49 °C (0.35 Torr):

^{1}H NMR (100 MHz, $CDCl_3$), δ=0.95, 1.00, and 1.62 (each 3H, s), 3.53 (1H, dd, J=7 and 4 Hz), and 5.06 (1H, br s).

d) To a soln of **5c** (4.7 g, 33.6 mmol) and bis(acetylacetonato)oxovanadium(IV) [$VO(acac)_2$, 10 mg, 0.035 mmol] in benzene (100 ml) was added dropwise *t*-butyl hydroperoxide (a 70% soln in water, 8.6 g, 67 mmol), which had been dried azeotropically with benzene, in benzene under stirring. The mixture was stirred at room temp for 10 h, and quenched by addition of aq sodium thiosulfate ($Na_2S_2O_3$). The aq soln was separated and extracted with ether. The benzene and ether solns were combined, washed with aq $NaHCO_3$ and brine, dried, and evaporated to leave an oily residue which was purified by chromatography over silica gel (100 g) with benzene to give 2,2,4-trimethyl-*c*-3,*c*-4-epoxy-*r*-1-cyclohexanol (**5d**) (4.85 g, 93%): ^{1}H NMR (100 MHz, $CDCl_3$), δ=1.04, 1.17, and 1.32 (each 3H, s), 2.73 (1 h, br s), and 3.30 (1H, t, J=4 Hz): MS, m/z 156 (M^+), 138, 123, 100, and 44 (base).

e) A soln of **5d** (400 mg, 2.56 mmol) and ethyl vinyl ether (1 ml, 10.5 mmol) in dichloromethane (20 ml) was stirred with pyridinium *p*-toluenesulfonate (PPTS, 64 mg, 0.26 mmol) at room temp for 15 h. The soln was diluted with ether, washed with aq $NaHCO_3$ and brine, dried, and evaported to leave an oily residue, which was purified by chromatography over silica gel (20 g) with benzene–ethyl acetate (10:1) to give 2-ethoxyethyl ether (**5e**) of **5d** (0.55 g, 94%): IR (neat), 1380, 1135, 1100, 1085, 1060, and 1050 cm^{-1}: ^{1}H NMR (100 MHz CCl_4), δ=0.93—1.24 (15H, m), 2.35 (1H, br s), 3.40 (3H, m), and 4.55 (1H, m). Compound **5e** was a diastereoisomeric mixture and showed complex signals in the NMR spectrum.

f) To a soln of diethylamine (0.1 ml, 1.0 mmol) in ether (2 ml) was added BuLi [1.6 M hexane soln (0.65 ml, 1.0 mmol)] at 0 °C, and the mixture was stirred at the temp for 30 min. To this soln was added hexamethylphosphoric triamide (HMPA, 0.17 ml, 1.0 mmol) and then **5e** (114 mg, 0.5 mmol) in ether. The whole mixture was stirred under reflux for 20 h, cooled, poured into aq ammonium chloride (NH_4Cl), and extracted with ether repeatedly. The ether soln was washed with aq $NaHCO_3$ and brine, dried, and evaporated to leave an oily residue, which was separated by chromatography over silica gel (8 g) with benzene–ethyl acetate (10:1) to give a diastereoisomeric mixture (51 mg, 45%) of 2-ethoxyethyl ethers of 2,2-dimethyl-4-methylene-*c*-3,*r*-1-cyclohexanediol and of 2,2,4-trimethyl-4-cyclohexene-*c*-3,*r*-1-diol: IR (neat), 3490, 3040, 1660, 1450, 1380, 1130, 1095, 1025, 990, and 930 cm^{-1}: ^{1}H NMR (100 MHz, $CDCl_3$), δ=1.82 (3/2H, br s), 4.68 (1H, m), 4.82 (2/2H, br s), and 5.24 (1/2H, m). The mixture was used for the next reaction without further separation.

A soln of the mixture of the olefinic alcohols (45 mg, 0.20 mmol) in pyridine (2 ml) was treated with acetic anhydride (0.2 ml, 2.0 mmol) under stirring at room temp for 15 h. The reaction mixture was diluted with ether, washed with dil HCl, aq $NaHCO_3$ and brine, dried, and evaporated to leave an oily mixture of the acetates. This acetate mixture in THF (2 ml) was treated with 2 M HCl (0.3 ml) under stirring at room temp for 1 h. The mixture was worked up as usual to give an oily residue, which was separated by chromatography over silica gel (3 g) with benzene–ethyl acetate (5:1) to afford a mixture (30 mg, 77%) of 2,2-dimethyl-6-methylene-*c*-3-hydroxy-*r*-1-cyclohexyl acetate (**5f**) and 2,2,6-trimethyl-*c*-3-hydroxy-5-cyclohexane-*r*-1-yl acetate (**5f′**): IR (neat), 3490, 3090, 1740, 1660, 1445, 1370, 1260, 1110, 990, and 920 cm^{-1}: ^{1}H NMR (100 MHz, $CDCl_3$), δ=2.09 and 2.12 (total 3H, each s), and 3.50 (1H, m). The mixture was used for the next reaction without further separation.

g) A soln (30 mg, 0.15 mmol) of **5f** and **5f′** in acetonitrile (5 ml) was treated with N-bromosuccinimide (35 mg, 0.20 mmol) under stirring at room temp for 10 h. The mixture was diluted with ether, washed with aq $NaHCO_3$ and brine, dried, and evaporated to leave a residue, which was submitted to chromatography over silica gel (3 g) with benzene–ethyl acetate (5:1) to give 6-bromomethyl-2,2-dimethyl-*c*-3,*c*-6-epoxy-*r*-1-cyclohexyl acetate (**5g**) (14 mg, 33%) and the unreacted olefin (**5f′**) (10 mg, 33%). **5g**, mp 70—71.5 °C: IR ($CHCl_3$), 1740, 1385, 1260, 1060, and 1020 cm^{-1}; ^{1}H NMR (500 MHz, $CDCl_3$), δ=0.95 and 1.15 (each 3H, s), 2.02 (3H, s), 3.55 and 3.69 (each 1H, ABq, J=10.1 Hz), 4.01 (1H, d, J=4.6 Hz), and 4.61 (1H, s): MS, m/z 278, 276 (M^+), 235, 233, 183, and 154. Found: m/z 278.0262 and 276.0398. Calcd for $C_{11}H_{17}O_3Br$: M, 278.0340 and 276.0362. **5f′**, oil: ^{1}H NMR (100 MHz, $CDCl_3$), δ=0.96 and 0.99 (each 3H, s), 1.63 (3H, d, J=2 Hz), 2.12 (3H, s), 3.54 (1H, t, J=5 Hz), 5.48 (1H, br s), and 5.53 (1H, m).

h) A soln of **5g** (11 mg, 0.04 mmol) in an 8:1 mixture of methanol and water was treated with potassium carbonate (10 mg, 0.06 mmol) at 0 to 15 °C for 12 h. The soln was evaporated, mixed with water, and extracted with ether. The ether soln was worked up as usual to give an oily, crude alcohol, which was dissolved in acetone (4 ml). The acetone soln was treated with Jones' reagent (5 drops) at 0 °C under stirring for 30 min. The reaction mixture was quenched with isopropyl alcohol, diluted with water, and extracted with ether. The ether soln was worked up as usual to leave an oily residue, which was purified by chromatography over silica gel (3 g) with hexane–ethyl acetate (9:1) to give **5** (9.2 mg, 99%), oil: IR (neat), 1760, 1470, 1390, 1245, and 1020 cm^{-1}: ^{1}H NMR (400 MHz, $CDCl_3$), δ=1.06 and 1.23 (each 3H, s), 3.66 and 3.78 (each 1H, ABq, J=11.7 Hz), and 4.34 (1H, d, J=3.9 Hz): ^{13}C NMR (25 MHz, $CDCl_3$), δ=19.73 and 22.43 (each q), 25.83, 28.42, and 28.77 (each t), 49.61 (s), 84.01 (d), 87.30 (s), and 214.65 (s): MS, m/z 234, 232 (M^+), 206, 204, 125 (base), and 107. Found: m/z 234.0060 and 232.0067. Calcd for $C_9H_{13}O_2Br$: M, 234.0077 and 232.0097.

The authors wish to express their sincere thanks to many investigators for measurement of the spectra: Drs. Tetsuo Higuchi (JEOL) of FD-MS, CI-MS, and EI-MS, Kenji Watanabe (Hokkaido Univ.) for FD-MS, and Minoru Isobe (Nagoya Univ.) for FD-MS; Drs. Fumiko Kaneuchi (JASCO) for FT-IR and CD, Shun-ichi Ikawa (Hokkaido Univ.) for FT-IR and Akihiro Shibata (Toray) for FT-IR; Drs. Tsutomu Higashijima (The Univ. of Tokyo) for ^{1}H NMR (270 MHz), Tetsu Hinomoto (JEOL) for ^{13}C NMR (22.5 MHz), and Toshio Inubushi (Kyoto Univ.) for ^{1}H NMR (220 MHz). The research was supported by a Grant-in-Aid for Special Project Research No. 56104009 and a Grant-in-Aid for Scientific Research No. 57470022 provided by the Ministry of Education, Science and Culture of Japan, and many other funds.

Concentration Quenching of Fluorescence from Bridged Synthetic Porphyrins

Kazuhiro MARUYAMA,* Soichi MORIKAWA, and Atsuhiro OSUKA
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received August 21, 1986)

Concentration quenching phenomena of singly and doubly bridged porphyrins and their zinc and magnesium complexes were studied. Hypothetical nonfluorescent dimer trap was suggested to be not a coplanarly stacked face-to-face dimer but a loosely interacting pair.

In the primary events of green plant photosynthesis, photons are absorbed by the antenna chlorophyll molecules and the resultant singlet excitation is transfered from molecule to molecule and ultimately trapped to the reaction center, where the efficient one-electron transfer from the special chlorophyll dimer to an appropriate acceptor takes place very rapidly. However, in vitro, chlorophylls and/or synthetic porphyrins exhibit the phenomenon of concentration quenching[1] of the excited singlet state whether in fluid solutions,[2,3] or in organized assemblies such as lipid monolayers,[4] multilayers,[5] lipid bilayer vesicles,[6] and detergent micelles,[7] or in a swollen polyethylene phase in the presence of other amphiphilic substances.[8] Whenever chlorophyll concentration is high enough for being comparable with that (ca. 10^{-1} M†) in the chloroplast, the singlet excited state is efficiently quenched, with complete annihilation of its photochemistry and usually that of the triplet also. Since singlet-singlet energy transfer between chlorophyll (or porphyrin) monomers (Eq. 1) has been well-established as a key step in photosynthesis and does not lead to the consumption of the excitation energy, it is reasonable to assume that dimers or aggregated form of chlorophyll or porphyrin is involved in the nonradiative decaying process of the concentration quenching. A possible molecular mechanism for the quenching process in homogeneous solutions has been suggested to involve capture of excitation energy by a nonfluorescent dimer trap[9] (Eq. 2—4).

$$^1P^* + P \xrightarrow{k_1} P + {}^1P^* \quad (1)$$

$$P + P \xrightarrow{K} P{-}P \quad (2)$$

$$^1P^* + P{-}P \xrightarrow{k_2} P + {}^1P{-}P^* \quad (3)$$

$$^1P{-}P^* \xrightarrow{k_d'} P{-}P \quad (4)$$

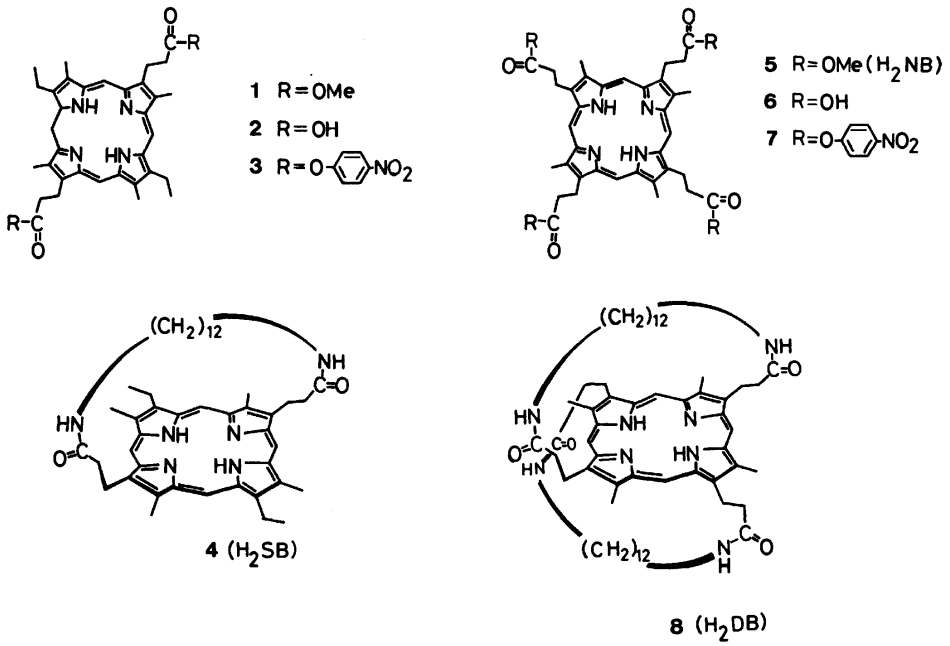
Although a large number of measurements on fluorescence lifetimes and fluorescence quantum yields have been reported in vivo and in vitro, relatively little is known about the steric effects around the porphyrin macrocycle upon the concentration quenching of fluorescence. Singlet energy transfer of chlorophyll and/or porphyrins may proceed via Förster-type inductive resonance-transfer mechanism (dipole-dipole interaction)[10] and thus may be independent of the steric hindrance around the macrocycles. However, one can expect *the steric effects on the formation of the hypothetical non fluorescent dimer* (Eq. 2). In order to obtain a better understanding of the quenching process and to make a model of an antenna chlorophyll function *in solution*, we have undertaken systematic studies on fluorescence properties of bridged porphyrins **H_2SB** and **H_2DB**.

Results and Discussion

Mesoporphyrin-II dimethyl ester (**1**) was prepared according to Chang's modified procedure.[11] Singly bridged porphyrin **4** (**H_2SB**) was synthesized in 45% yield by the reaction of 1,12-dodecamethylenediamine with mesoporphyrin-II bis(4-nitrophenyl) ester **3**,[12] which, in turn, was prepared by the treatment of mesoporphyrin-II dicarboxylic acid **2** with 4-nitrophenyl trifluoroacetate.[12] Coproporphyrin-I tetramethyl ester **5** (**H_2NB**) was hydrolyzed to the corresponding tetracarboxylic acid **6**, which was converted into tetrakis(4-nitrophenyl) ester **7**. The reaction of **7** with 1,12-dodecamethylenediamine in a dilute pyridine solution gave doubly bridged porphyrin **8** (**H_2DB**) in 8% yield. Dodecamethylene bridged structures of **H_2SB** and **H_2DB** were apparent from their 400 MHz ^{1}H NMR spectra; dodecamethylene protons in **H_2SB** appeared at δ −0.26 (4H, m), −0.12 (4H, m), 0.07 (4H, m), 0.14 (4H, m), 0.53 (4H, m), and 2.80 (4H, m) ppm; those in **H_2DB** appeared at δ −0.22 (8H, m), −0.11 (8H, m), 0.06 (8H, m), 0.18 (8H, m), 0.47 (8H, m), and 2.81 (8H, m) ppm. Almost the same chemical shifts of dodecamethylene protons in **H_2SB** and **H_2DB** indicate that a dodecamethylene bridge has a similar conformation in both porphyrins and thus may provide a similar degree of steric hindrance on one porphyrin side.

The optical absorption spectra and the fluorescence emission spectra of **H_2SB** and **H_2DB**, and their zinc and magnesium complexes were not significantly

† 1 M=1 mol dm^{-3}.



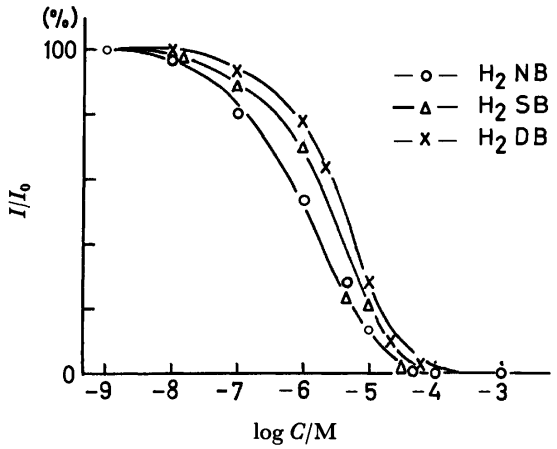


Fig. 1. Relative fluorescence yields of H_2NB, H_2SB, and H_2DB in CH_2Cl_2–CH_3OH (v/v=95/5) at 25 °C as a function of concentration.

altered by introduction of dodecamethylene bridge (Table 1). Relative fluorescence quantum yields were determined in CH_2Cl_2–MeOH (v/v=95/5) or CH_2Cl_2 at various concentration of porphyrins (Figs. 1—4). As shown in Fig. 1, there are small but distinct differences among **H_2NB**, **H_2SB**, and **H_2DB**. Critical concentrations of porphyrins and metalloporphyrins are defined as the concentration where an half of the intrinsic porphyrin fluorescence yields is lost by self-concentration quenching. The critical concentrations of **H_2NB**, **H_2SB**, and **H_2DB** are 1.1×10^{-6} M, 2.8×10^{-6} M, and 5.0×10^{-6} M, respectively (Table 2). Thus, the introduction of a dodecamethylene bridge roughly doubled the critical concentration of free base porphyrins in dichloromethane at room temperature.

Effects of the dodecamethylene bridge were much more pronounced in zinc porphyrins, **ZnNB, ZnSB,** and **ZnDB** (Fig. 2). Fluorescence concentration

Table 1. Absorption and Emission spectra of Nonbridged and Bridged Porphyrins[a)]

Porphyrin	Absorption/nm		Emission/nm	
	Soret band ($\varepsilon\times10^{-5}$)	Q-bands ($\varepsilon\times10^{-3}$)		
H_2NB	398 (1.48)	496 (10.8), 533 (8.8), 570 (5.6), 620 (5.0)	620	686
H_2SB	398 (1.47)	497 (9.7), 534 (7.5), 567 (5.7), 623 (4.7)	622	687
H_2DB	402 (1.48)	500 (11.0), 531 (7.2), 568 (4.3), 622 (3.8)	622	688
ZnNB	406 (4.04)	533 (21), 570 (32)	578	624
ZnSB	404 (3.95)	533 (20), 570 (30)	578	627
ZnDB	404 (4.09)	533 (19), 569 (26)	578	630
MgNB	411 (4.16)	546 (18), 582 (17)	587	627
MgSB	409 (4.17)	545 (19), 582 (23)	587	627
MgDB	408 (4.26)	545 (20), 582 (27)	588	628

a) Measured in CH_2Cl_2 at 10^{-5} M at 25 °C.

quenching of **ZnNB** occurred at more dilute conditions compared with that of **H_2NB** and the critical concentration of **ZnNB** was only 5.2×10^{-8} M. Zinc-complexes of porphyrins have been shown to be five-coordinate in a number of studies,[13] and we expect the same to be true for **ZnNB** and **ZnSB.** Therefore, the concentration quenching of zinc porphyrins may be in part due to the formation of a dimer (or larger aggregate) bridged by coordination of one ester or amide group to other central zinc. The presence of the dodecamethylene bridge over the porphyrin macrocycle must result in retardation of such coordination, thus suppressing the concentration quenching. Accordingly, doubly bridged zinc porphyrin **ZnDB** showed the nearly same critical concentration (2.0×10^{-6} M) as that of the corresponding free base, **H_2DB.**

While effects of the dodecamethylene bridge upon the concentration quenching of Mg-porphyrins were much less than those of Zn-porphyrins in a CH_2Cl_2-MeOH (v/v=95/5) solution (Fig. 3), those became more prominent in an aprotic nonpolar solution (CH_2Cl_2) (Fig. 4). This may be ascribed to a much stronger coordination of methanol to the central magnesium, which leads to monomerization of Mg-porphyrin.

Fluorescence lifetimes of these nonbridged and bridged porphyrins and metalloporphyrins were measured by the time-correlated single-photon-counting technique. For all of the solution studied, the fluorescent decay is a single exponential within experimental error (Table 3). In accordance with the results of the fluorescence quantum yields, fluores-

Table 4. Relative Fluorescence Quantum Yields[a] in Micellar System

Porphyrin	SDS[b]	CTAB[c]	Brij-58
H_2NB	1.0	1.0	1.0
H_2SB	1.5	1.1	1.07
H_2DB	4.5	1.3	1.12

a) Relative fluorescence quantum yields of **H_2SB** and **H_2DB** to that of **H_2NB** measured at 25 °C. b) Porphyrin concentration was 1×10^{-6} M, and detergent concentration was 6×10^{-2} M. b) Sodium dodecyl sulfate. c) Hexadecyltrimethylammonium bromide.

cence lifetime increased in the order of **H_2NB<H_2SB<H_2DB, ZnNB<ZnSB<ZnDB,** and **MgNB<MgSB<MgDB.** At 10^{-5} M, the introduction of a dodecamethylene bridge increased the singlet lifetimes of **H_2NB** and **H_2SB** by ca. 1.5 ns.

Finally, we examined the relative fluorescence quantum yields of porphyrins in micellar systems such as sodium dodecyl sulfate (SDS), hexadecyltrimethylammonium bromide (CTAB), and Brij-58. It is interesting to note that the fluorescence quantum yield of **H_2DB** was retained 4.5 times as much as that of **H_2NB** in a SDS micelle. This result may suggest the steric hindrance around the porphyrin macrocycles becomes increasingly important in the more ordered and highly viscous environment.

In all the cases examined here, the steric hindrance imposed by the dodecamethylene bridge diminished the concentration quenching phenomena of porphyrin and metalloporphyrin to some extent. However, the concentration quenching was still observed even in the doubly bridged system under much more dilute conditions than those of antenna chlorophyll in chloroplast. Since a stacked face-to-face dimer cannot be formed from **H_2DB** and its metal complexes, it seems unnecessary to form such a compact dimer for the self-concentration quenching. In other words, the hypothetical nonfluorescent dimer may have a very loose structure.

Experimental

Melting points were measured on a Yanagimoto micro melting point apparatus and are uncorrected. Infrared spectra were recorded on a JASCO model 402-G spectrometer. 400 MHz ^{1}H NMR spectra were recorded on a JEOL GX-400, and chemical shifts are reported in parts per million on the δ scale from internal tetramethylsilane. Elemental analyses are performed at the Microanalytical Laboratory of Kyoto University. Preparative separations were usually performed by flash column chromatography on silica gel (Merk, Kieselgel 60 H, Art. 7736). Fluorescence spectra and fluorescence quantum yields were measured under aerobic conditions on a Shimadzu model RF 502 fluorometer. Fluorescence lifetimes were measured by the time-correlating single-photon-counting technique on a HORIBA NAES 1100 model.

1,12-Dodecamethylenediamine, 4-nitrophenyl trifluoroacetate (Aldrich), SDS, CTAB, and Brij-58 were commercially available and were used without further purification. Mesoporphyrin-II dimethyl ester (**H_2NB**),[11] mesoporphyrin-II dicarboxylic acid (**1**),[12] mesoporphyrin-II bis-(4-nitrophenyl) ester (**2**),[12] and coproporphyrin-I tetramethyl ester (**5**)[13] were prepared according to the reported procedures. Coproporphyrin-I tetracarboxylic acid (**6**) was prepared by acid-catalyzed hydrolysis of **5**.[12]

Preparation of Singly-Bridged Porphyrin H_2SB. To 400 mL of dry pyridine (maintained at 65—70 °C) were added six equimolar portions of mesoporphyrin-II bis(4-nitrophenyl) ester (**2**) (646 mg, 0.8 mmol) and 1,12-dodecamethylenediamine (169 mg, 0.8 mmol) under argon atmosphere at 2 h intervals. After completion of the last reagent addition, the reaction mixture was left overnight at 65 °C. The pyridine was removed on the rotary evaporator. The residue was dissolved in CH_2Cl_2-MeOH (v/v=5/1) and filtered through alumina short column. Filtrate was concentrated and then separated on flash column chromatography using CH_2Cl_2-MeOH (v/v=20/1) as the eluant. First porphyrin fraction was singly bridged porphyrin , **5 (H_2SB)**, yield 262 mg, 45%; mp> 300 °C. IR (KBr) 2860 and 1640 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=10.11 (s, 2H, meso H), 10.07 (s, 2H, meso H), 4.80 (br., 2H, -CONH-), 4.66 (dd, 2H, -CH_2CH_2CO-), 4.11 (dd, 2H, -CH_2CH_2CO-), 4.10 (q, 4H, -CH_2CH_3), 3.25 (dd, 2H, -CH_2CH_2CO-), 3.07 (dd, 2H, -CH_2CH_2CO-), 1.87 (t, 6H, -CH_2CH_3), and -3.78 (br, 2H, NH). Chemical shifts due to the dodecamethylene bridge were discussed in the text.

Coproporphyrin-I Tetrakis(4-nitrophenyl) Ester (7). Coproporphyrin-I tetracarboxylic acid (**6**) (654 mg, 1 mmol) was dissolved in dry pyridine (300 mL) under nitrogen atmosphere. 4-Nitrophenyl trifluoroacetate (3.3 g, 14 mmol) was added to the above solution and the resulting solution was stirred at 50—55 °C for 3 h, and then at 10 °C for 12 h. Microcrystalline solids were precipitated, which were collected and washed with pyridine and hexane, and dried under vacuum to give **7**, (1.49 g, 88%): mp, 204—206 °C; IR (KBr) 1770 (ester C=O), 1500 and 1350 (NO_2) cm^{-1}. ^{1}H NMR δ=10.22 (s, 8H, meso H), 7.94 (d, 8H), 6.88 (d, 8H), 4.62 (t, 8H, CH_2-CH_2CO-), 3.68 (t, 8H, CH_2CH_2CO-), 3.62 (s, 12H, CH_3), 3.65 (br, 2H, NH).

Doubly Bridged Porphyrin, 8 (H_2DB). Doubly bridged porphyrin **8 (H_2DB)** was synthesized in the same fashion with 5 by the reaction of **7** (890 mg, 0.8 mmol) with 1,12-dodecamethylenediamine (320 mg, 1.6 mmol). Separation by flash column chromatography over silica gel using CH_2Cl_2-MeOH (v/v=5/1) gave **8**, (63 mg, 8%) as the first fraction. **8 (H_2DB)**; mp >300 °C; IR (KBr) 2860 and 1640 (amide C=O) cm^{-1}; ^{1}H NMR ($CDCl_3$-CD_3OD, v/v=20/1) δ=10.7 (s, 4H, meso), 4.87 (br., 4H, -CONH-), 4.65 (dd, 4H, -CH_2CH_2CO-), 4.15 (dd, 4H, -CH_2CH_2CO-), 3.62 (s, 12H, -CH_3), 3.19 (dd, 4H, -CH_2CH_2CO-), 3.00 (dd, 4H, -CH_2CH_2CO-), and −3.75 (br, 2H, NH). Chemical shifts due to the dodecamethylene bridge was discussed in the text.

Photochemistry of Epoxynaphthoquinones. 8. Endo-Stereoselective Photocycloaddition of 2,3-Epoxy-2,3-dihydro-2,3-dimethyl-1,4-naphthoquinone to Olefins Containing Amide Group

Kazuhiro MARUYAMA,* Atsuhiro OSUKA, and Katsuhiko NAKAGAWA†
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
†Department of Industrial Chemistry, Niihama National College of Technology, Niihama 792
(Received August 25, 1986)

Irradiation of a benzene solution of 2,3-epoxy-2,3-dihydro-2,3-dimethyl-1,4-naphthoquinone with olefins containing amide group, i.e., *N*-substituted acrylamides and *N*-allylcarboxamides predominantly gave the endo-cycloadducts. Upon further irradiation, the cycloadducts underwent photorearrangement to give spirophthalides and alkylidenephthalides.

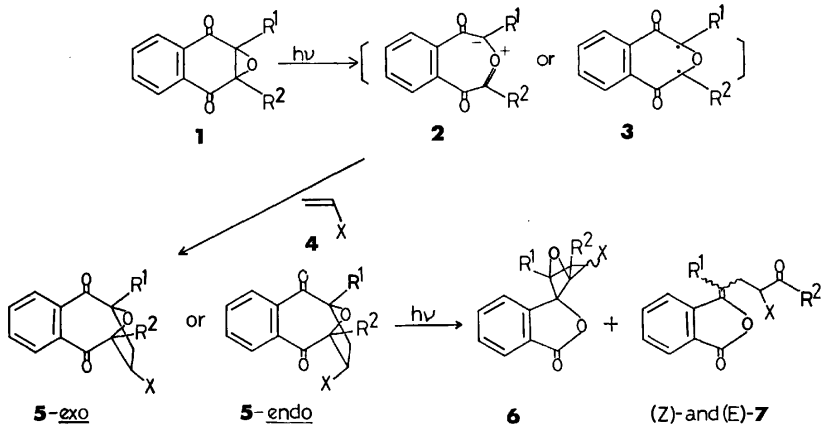
Recently, we reported the photochemical generation of the carbonyl ylide **2** or the 1,3-biradical **3** from several epoxynaphthoquinones **1**.[1] These intermediates were trapped by a variety of reagents including olefins,[2] ketones, aldehydes, singlet oxygen, and alcohol.[3] Reaction of **2** or **3** with olefin gave the tricyclic diketone **5**, which, upon further irradiation, underwent the secondary photorearrangement to produce the spirophthalide **6** and the alkylidenephthalides (*Z*)-**7** and (*E*)-**7**. (Scheme 1) The endo-exo stereoselectivity in the formation of the primary adduct **5** has been extensively studied in the photoreaction of 2,3-epoxy-2,3-dihydro-2,3-dimethyl-1,4-naphthoquinone (**1a**; R^1=R^2=Me) with a variety of functionalized olefins, whereby electron-releasing substituents show a endo-orientating tendency and electron-attracting substituents show a exo-orientating tendency.

Among these, cyano group has been found to be quite unique, since it shows remarkable high endo-orientating tendency in spite of its electron-attracting nature. In connection with these studies, we have studied the photoreaction of **1a** with olefins containing amide group, such as acrylamides and *N*-allylcarboxamides, so as to see the effect of nitrogen atom on the endo-exo stereoselectivity of the cycloaddition of **2** or **3**.

Results and Discussion

Photochemical Cycloaddition of 1a with *N*-Substituted Acrylamides. When a benzene solution of **1a** (0.04 M†) containing a high concentration (0.16 M) of *N*-phenylacrylamide (**4a**) was irradiated for 10 h, **1a** was mostly recovered and substantial amounts of polymeric materials derived from **4a** were formed. On the other hand, irradiation of a benzene solution of **1a** (0.04 M) containing a much less concentration (0.048 M) of **4a** for 10 h resulted in a smooth conversion of **1a**, giving the endo cyclodduct **5a**-*endo* (55%) along with the spirophthalide **6a** (25%) and the alkylidenephthalides (*Z*)-**7a** (6%) and (*E*)-**7a** (6%). In the latter photolysate, the amounts of polymeric materials derived from **4a** were greatly reduced.

These photoproducts were separated by column chromatography on silica gel, and their structures were determined on the basis of their spectroscopic properties (see Tables 5 and 6). The endo-



Scheme 1.

† 1 M=1 mol dm^{-3}.

stereochemistry of phenylcarbamoyl group in **5a**-*endo* was unambiguously determined by its independent synthesis from the tetracyclic adducts **8**, whose stereochemistry is apparently endo because of the hemiacetal structure.[2] Jones' oxidation of **8** afforded the corresponding carboxylic acid **5q**-*endo*, which, after treatment with oxalyl dichloride in dichloromethane, was reacted with aniline to give **5a**-*endo* in a 45% overall yield. In order to investigate the substituent effect of *N*-substituted acrylamides on the stereochemistry of the photocycloaddition of **1a**, we examined the photochemical reactions of **1a** with *N*-substituted acrylamides **4b—f**. The results are summarized in Table 1.

In the reaction with *N*-monosubstituted acrylamides **4a—d**, the stereochemistry of the primary adduct **5** is exclusively endo, regardless of the steric hindrance of *N*-substituents in olefins. Under identical conditions, isolated yields of **5c** and **5d** were lower than those of **5a** and **5b**, indicating that the secondary photorearrangements of **5c** and **5d** are faster than **5a** and **5b**. Since the secondary photorearrangement of **5** to **6** or **7** can be considered to proceed via a reversible α-cleavage (Eq. 1), more efficient secondary photoreaction of **5c**-*endo* and **5d**-*endo* may be ascribed to the buttressing effect of bulky substituents st the nitrogen, which may suppress the recombination of biradical **10** to **5**.

In sharp contrast to **4a—d**, the photochemical reaction of **1a** with *N*,*N*-disubstituted acrylamides **4e** and **4f** gave substantial amounts of **5e**-*exo* and **5f**-*exo*, along with **5e**-*endo* and **5f**-*endo*, **6e** and **6f**, and **7e** and **7f**, respectively. Structure determinations of the primary cycloadducts **5e**-*endo* and **5f**-*endo* were based on the independent synthesis of these compounds from **8**. Similary, the isomeric adducts **5e**-*exo* and **5f**-*exo* were independently synthesized from the tricyclic compounds **9**, whose structure had previously been well-established.[2]

Next, we have investigated the photochemical

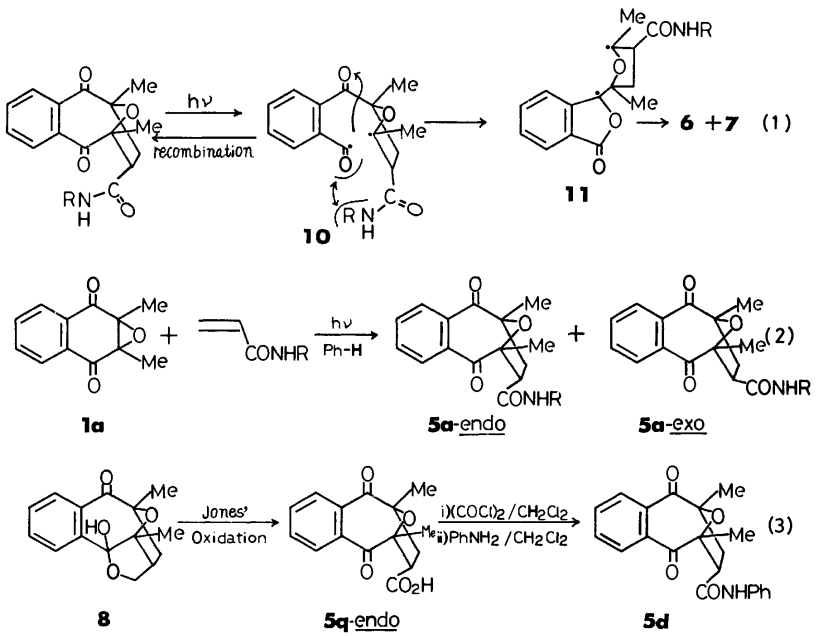


Table 1. Photoinduced Cycloaddition of Epoxynaphthoquinone **1a** to *N*-Substituted Acrylamides[a]

Run	Olefin		Irrad. time/h	Conversion %	Isolated yield[b]/%			
					5		6	7
					endo	exo		(Z)- (E)-

a) A benzene solution of **1a** (0.04 M) and acrylamides (0.048 M) were used. b) Isolated yield based on the consumed amounts of **1a**.

cycloaddition reactions of **1a** with *N*-allylcarboxamides **4g—k**, which can be regarded as electron-rich olefin. Photoreaction of **1a** with **4g—k** proceeded well similarly with **4a—f**, giving **5g—k**-*endo*, **5g—j**-*exo*, **6g—k**, and **7g—k** in moderate to good yields. Isolated yields and physical properties of these photoproducts are listed in Tables 2, 5, and 6.

Photoinduced cycloaddition of **1a** to olefin consists primarily of two processes, namely photochemical oxirane ring opening leading to the formation of **2a** or **3a** and subsequent (presumably thermal) 1,3-dipolar cycloaddition of olefin to **2a** or **3a**. The first step has been well-shown to occur from the lowest triplet state of **1a**. In the previous studies on the photoreaction of **1a** with olefins, there has been also shown to exist a deactivating process for ^{3}(**1a**)* by charge transfer interactions with olefin.

Quantum yields for the disappearance of **1a** (0.04 M) in benzene containing various concentrations of olefins were determined at 313 nm by using valerophenone as the chemical actinometer[4] (Table 3). Quantum yields for the disappearance of **1a** in the reaction with acrylamide **4a**, **4d**, *N*-allylpropion-

amide (**4h**), *N*-allylbenzamide (**4j**) were one or two orders of magnitude lower compared with other functionalized olefins. Upon increasing the concentration of olefins, quantum yields for the formation of primary cycloadduct **5** decreased, whereas those for the disappearance of the olefin increased. Typically, irradiation of **1a** in the presence of high concentration of **4b** or **4j** (<ca. 0.2 M) merely resulted in the polymerization of the olefin, leaving **1a** almost intact in the reaction mixture. These facts clearly indicate the quenching of ^{3}(**1a**)* by olefins, presumably through the chrarge-transfer interactions.[5]

Since the primary cycloadducts **5** underwent the secondary photoreaction with different efficiencies depending upon their structures, the endo/exo ratios were determined at low conversions (<5%)(Table 4[5]). Results with allyl alcohol were included in Table 4 for the purpose of comparison. The cycloaddition with *N*-monosubstituted acrylamide **4a, 4b,** and **4c** proceeds exclusively with endo stereoselectivity, while *exo*-cycloaddition was favored in the reaction with *N,N*-disubstituted acrylamide. The reaction with *N*-allylpropinamide (**4h**) and *N*-allylbenzamide (**4j**) proceeded also with endo-stereoselectivity, but the selectivity of **4h** was much less than in the reaction with *N*-monosubstituted acrylamide and **4j**. However, as in the reaction with acrylamides, endo-stereoselectivity was inverted from endo to exo in the reaction with *N*-allyl-*N*-methylacetamide (**4k**); the endo/exo=0.3. Remarkably high endo-stereoselectivity observed with **4a—c, 4i,** and **4j** and inversed exo-stereoselectivity with **4e, f,** and **k** suggest the favorable

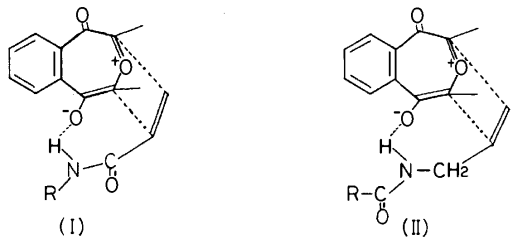

Fig. 2. Photochemical cycloaddition of **1a** with acrylamides and *N*-allylcarboxamides.

hydrogen-bonding interaction by amide N-H bond in the transition state of the cycloaddition such as I and II in Fig. 2. Similar interaction may explain a relatively high endo-selectivity of allyl alcohol.

Thus, we examined the effects of hydrogen-bond donating or accepting solvent upon the endo-exo stereoselectivity in the formation of **5** (Table 4). Exclusive endo-selective stereochemistry observed with **4a**—**c** and **4j** was not affected by addition of *t*-BuOH or *N*,*N*-dimethylformamide (DMF). However, the endo/exo ratio in the reaction with **4h** decreased by addition of *t*-BuOH and DMF (Run 6, in Table 4). Much more prominent solvent effects are observed in the reaction of **1a** with allyl alcohol (Run 9, in Table 4), indicating that the hydrogen-bonding interaction plays an important role in determination of 1,3-dipolar cycloaddition stereochemistry.

High endo-selective stereoselectivity in the reaction of **1a** with **4a**—**c** and **4j** may be accounted for in terms of the interplay of the strong hydrogen bond and the secondary orbital overlap between the carbonyl ylide and the amide nitrogen lone pair in the olefins. Although we have not succeeded in a quantitative assessment of these interactions, it may be considered that amide N-H bond at an appropriate position can control the stereochemistry of cycloaddition of epoxynaphthoquinone (**1a**).

Experimental

Apparatus. Melting points were measured on Yanagimoto micro-melting points apparatus and are uncorrected. Infrared spectra were taken on a JASCO-IR-1A spectrometer. ^{1}H NMR spectra were recorded on a JEOL GX-400 (400 MHz) and a JEOL FX-90Q (90 MHz) spectrometer with use of tetramethylsilane as an internal standard and the chemical shifts are expressed in δ values. UV spectra were taken by using a Shimadzu UV-200 spectrometer. Elemental analyses were performed at the Microanalytical Laboratory of Kyoto University. Mass spectra were recorded on a JEOL JNM DX-300 spectrometer. High pressure liquid chromatography (HPLC) analyses were performed on a Yanaco LC-2000 equipped with an UV detector (Yanaco M-315). The separations were made on a 250×4 mm stainless-steel column packed with Shodex ODS pack F-411 with a mixture of methanol and water (80/20) as the eluent. GC analyses were performed on a Hitachi Model 163, using a 3 mm i.d., ×2 M stainless-steel column packed with 10% SE-30 on celite 545 AM. Preparative separations were performed by column chromatography over silica gel (Wakogel C-200). UV irradiations were carried out in a Pyrex vessel (Fuji glass) under a nitrogen atmosphere with a Fuji glass 300-W high-pressure mercury lamp.

Materials. 2,3-Epoxy-2,3-dihydro-2,3-dimethyl-1,4-naphthoquinone[2] (**1a**) was prepared by the epoxidation of 2,3-dimethyl-1,4-naphthoquinone with 10% aqueous sodium hypochlorite in pyridine. *N*-Substituted acrylamides **4a**—**f** were prepared by the condensation of acryloyl chloride with the corresponding amines at temperature below 5 °C.[6] *N*-Allyl-carboxamides **4g**—**k** were prepared by condensation of allyl amine with the corresponding acyl chlorides at temperature below 5 °C. *N*,*N*-Dimethylacrylamide **4e** and *N*-Allyl-*N*-methyl-acetamide **4k** were prepared by the alkylation of the corresponding amides with methyl iodide in dimethyl sulfoxide.

General Procedure for the Photochemical Reaction of 1a with Acrylamides and *N*-Allylcarboxamides. A degassed solution of **1a** (1 mmol) and acrylamides or *N*-allylcarboxamides (1.2 mmol) in 25 ml of benzene in a Pyrex tube, using a 300-w high-pressure mercury lamp from outside. The progress of the reaction was followed by thin-layer chromatography (TLC), HPLC or GC. After removal of solvent, the residual oil was separated by chromatography on silica gel with ethyl acetate / hexane as an eluent. Final purification was usually accomplished by preparative TLC and recrystallization. Physical properties of the photoproducts were summarized in Table 5 and 6.

Transformation of 9 into the Primary Adduct (5e-*exo*). A mixture of **9** (100 m), 10 ml of 5% aqueous NaOH, and 10 ml of isopropyl alcohol was heated at 50 °C under a nitrogen atmosphere for 4 h. Then the reaction mixture was acidified with 5% aqueous HCl. The resulting mixture was extracted twice with ether, and the combined extracts were washed with water and dried over Na_2SO_4. Removal of the solvent on a rotary evaporator afforded crude acid (**5q**-*exo*). This was treated with oxalyl dichloride in dry dichloromethane, giving the acid chloride. After dimethylamine hydrochloride was added to the acyl chloride under a nitrogen atmosphere, the reaction mixture was stirred at room temperature for 12 h. Removal of the solvent on a rotar evaporator afforded the crude amide, which was chromatographed on silica gel to yield the primary adduct (**5e**-*exo*) (47 mg, 45%) (mp 128—129 °C).

Measurement of Quantum Yields. Valerophenone actinometry was used for quantum yield determination. The 313-nm line was isolated with a filter solution containing 0.002 M K_2CrO_4 in a 1% aqueous solution of K_2CO_3. The degree of the reaction was determined by HPLC analyses relative to a known concentration of internal standard (naphthalene) in the case of acrylamides and *N*-allylcarboxamides. The standard naphthalene was added after the photoreaction. And in the case of allyl alcohol the degree of the reaction was determined by GC analysis relative to a known concentration of internal standard (dodecane).

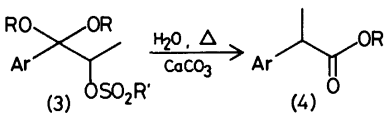
A General Synthetic Method of Chiral 2-Arylalkanoic Esters via Thermal 1,2-Rearrangement[1)]

Yutaka HONDA,* Aiichiro ORI, and Gen-ichi TSUCHIHASHI*
Department of Chemistry, Faculty of Science and Technology, Keio University,
3-14-1, Hiyoshi, Kohoku-ku, Yokohama 223
(Received August 27, 1986)

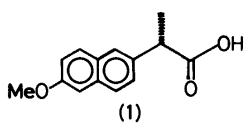
(*S*)-1-Aryl-2-sulfonyloxy-1-alkanone acetals, prepared from natural ethyl (*S*)-lactate or (*S*)-valine (chiral sources) by the use of a Grignard reaction, were rearranged under hydrolytic conditions in the presence of a base to give (*S*)-2-arylalkanoic esters which, in general, showed much higher pharmacological activities than their antipodes.

2-Arylalkanoic acids constitute a group which involves many biologically active compounds. Especially, 2-arylpropanoic acids, such as 2-(6-methoxy-2-naphthyl)propanoic acid (Naproxen, **1**), show potent antiinflammatory activity,[2)] and 2-aryl-3-methylbutanoic acid is known as the acid-moiety of pyrethroid-type insecticides (**2**) (Fig. 1).[3)] These acids have an asymmetric center at C-2, and each (*S*)-enantiomer shows much higher pharmacological activity than its antipode.[4,5)] A typical conventional process for preparing the chiral acid includes an optical resolution of the corresponding racemic derivative using a resolving reagent such as cinchonidine.[6)] However, the optical resolution is disadvantageous from an economical standpoint, since one half of the racemic acid is an unnecessary isomer and complicated racemization steps are required to reuse the antipode.[7)] On the other hand, the process starting from a chiral compound does not require optical resolution as the final step, and is economical compared with the conventional processes.

In these seven years, many investigators have reported syntheses of the racemic 2-arylalkanoic esters by a 1,2-aryl shift. Recently, a general commentary was written by C. Giordano et al.[8)] Previously, we reported that hydrolysis of 1-aryl-2-sulfonyloxy-1-propanone acetals (**3**) afforded 2-arylpropanoic esters (**4**) via 1,2-rearrengement of the aryl group (Eq. 1).[9,10)]



(1)



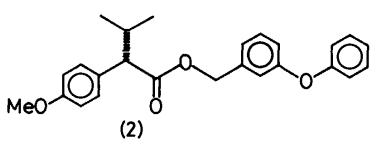


Fig. 1.

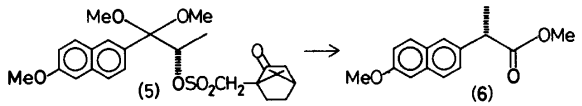
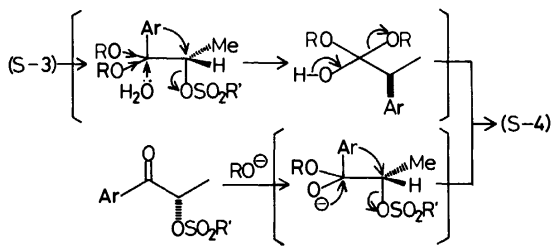
Next, optically active (*S*)-sulfonate (**5**), prepared using the optical resolution of (−)-10-camphorsulfonate, afforded (*S*)-2-arylpropanoic esters (**6**) with 100% inversion on the C-2 chiral center (Eq. 2).[11,12)]



(2)

We assume that this rearrangement proceeds through a concerted process which involves a concominant attack of H_2O, a 1,2-aryl shift, and an elimination of the sulfonyloxy group. Thus, it is regarded as a substitution-type rearrangement (Eq. 3),[13-15)] in contrast to the elimination-type (Eq. 4),[16)]



(3)
(4)

such as pinacol, Favorskii, and quasi-Favorskii rearrangements. In the former, one of the driving forces is a push effect by the electron pairs of the oxygen of an acetal oriented antiperiplanar to the migrating group and the attacking nucleophile;[17)] in the latter, an electron pair of oxygen anions plays the role.

Next, we developed a route involving a Friedel-Crafts reaction[1b,13g)] using chiral acyl chlorides (**7**)[18)] and (**8**) derived from (*S*)-lactic acid and ethyl (*S*)-lactate respectively (Fig. 2). In the case of the derivatives which have the aryl group substituted by the alkyl group, (*R*)-α-halogeno ketone (**9**) and (*S*)-α-sulfonyloxy ketone (**10**) were obtained in high yields. However, the regioselectivity of *o*- and *p*-orientation was reduced by electron-donating substituents on the aryl group.[19)] Resulting ketone (**9**) was rearranged by a treatment with silver carbonate and boron trifluoride diethyl etherate in methanol to afford (*R*)-**4**.[13a,k)] On the other hand, ketone (**9**) was treated with sodium

methoxide,[9,20] followed by sulfonylation to afford the partially racemic sulfonate (**3**). Ketone (**10**) was acetalized by a treatment with trimethoxymethane and sulfonic acid, followed by hydrolysis to afford (*S*)-**4**. However, in the case when the β-carbon atom to acetal was secondary, the reaction rate of acetalization was small.[17] Acetalization using trimethylsilyl trifluoromethanesulfonate and 2,2-dimethyl-1,3-bis(trimethylsilyloxy)propane in dichloromethane[21] was accompanied by a little racemization (98% ee).[14b]

Now, we report a general procedure for the synthesis of chiral 2-arylalkanoic esters which overcomes these faults.

Results and Discussion

At first, the synthesis of chiral α-hydroxy ketone was examined by reactions between chiral α-hydroxyalkanoic acid derivatives and organometallic reagents.[22-24] α-Amino acid can be transformed quantitatively into α-hydroxy acid by the Van-Slyke procedure.[25] *O*-Protected alkanamides,[26] for example (*S*)-2-*O*-methoxymethyl- or 2-*O*-(1-ethoxyethyl)-*N*,*N*-dimethyllactamide (**11** or **12**) and (*S*)-2-(1-ethoxyethoxy)-*N*,*N*,3-trimethylbutanamide (**13**), were readily prepared; these were suitable for reactions with organometallic reagents to give the protected α-hydroxy ketones (**14**) in high yields (Fig. 3, Table 1).

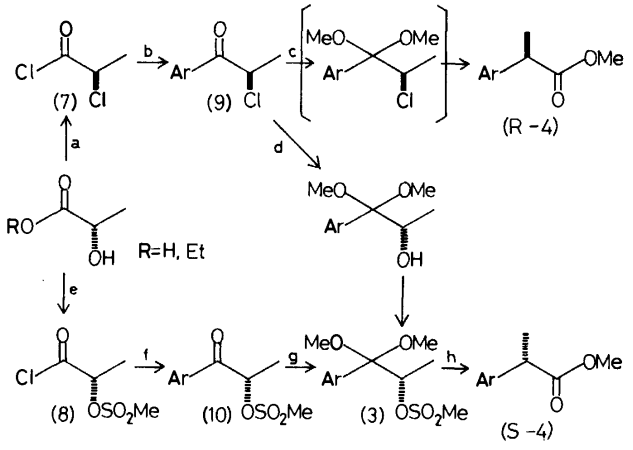


Fig. 2. Friedel-Crafts procedure.
a: 1; $SOCl_2$, pyridine, 2; PhCOCl. b: ArH, $AlCl_3$ in CS_2. c: Ag_2CO_3, BF_3–OEt_2 in MeOH. d: MeONa in MeOH. e: 1; MsCl in pyridine, 2; aq KOH, 3; SO_2Cl_2, pyridine. f: $FeCl_3$ or $FeSO_4$ in $MeNO_2$. h: $CaCO_3$ in MeOH–H_2O.

The ketone (**14**, R=1-ethoxyethyl=EE) was easily deprotected by the treatment with pyridinium *p*-toluenesulfonate (PPTS)[27] in ethanol to give the chiral α-hydroxy ketone (**15**) in a high yield. In the case of the hydrolysis of **14** (R=methoxymethyl=MOM) it was necessary to heat at 60 °C in dilute hydrochloric acid (Fig. 3, Table 1).

The sulfonylation of α-hydroxy ketone (**15**) was easily achieved by the use of methanesulfonyl chloride (MsCl) and triethylamine (Et_3N) at −42 °C[28] to give α-sulfonyloxy ketone (**16**) quantitatively, but the acetalization of **16** was accompanied with the various difficulties described above. Among the number of methods, four procedures were successfully applied

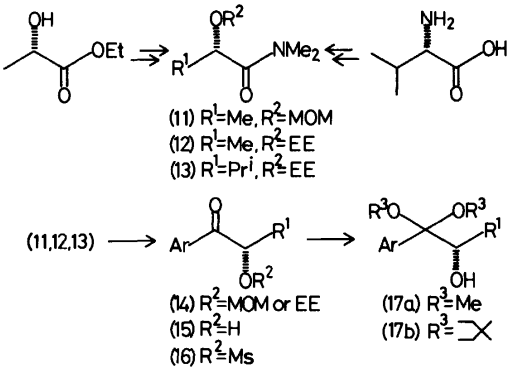

Fig. 3. Synthesis of α-hydroxy acetal (**17**).

for the acetalization of **15** without racemization. The α-hydroxy ketone (**15**) was treated with trimethoxymethane (5 equiv) and methanesulfonic acid (1 equiv) in anhydrous methanol[29] at 0 °C to give dimethyl acetal (**17a**) (Procedure A). On the other hand, the ketone (**14**, R=MOM) was treated with the same reagent as in procedure A at 50 °C to give dimethyl acetal (**17a**) in a moderate yield (Procedure B). The α-hydroxy ketone (**15**) was treated with 2,2-dimethyl-1,3-propanediol (10 equiv) and trimethylsilyl chloride (1.5 equiv) in anhydrous methanol[30] to give cyclic acetal (**17b**) in a good yield (Procedure C). Under acidic and dilute conditions in methanol, the reaction proceeded smoothly via internal epoxidation without racemization. Under high-concentration conditions or at high temperature, the dimer (**18** or **18'**) of the epoxide was the major product (Fig. 4). In the presence of a catalytic amount of *p*-toluenesulfonic acid, the reaction using 2,2-dimethyl-1,3-propanediol proceeded with an azeotropic removal of water with benzene under reflux at 50 °C to give cyclic acetal (**17b**) in a high yield (Procedure D). However, in the case when the β-carbon atom to carbonyl was secondary, an elimination of water easily occurred (Table 1, Run 4).

The resulting α-hydroxy acetal (**17**) was sulfonylated by the usual method to give α-sulfonyloxy acetal (**19**) (Fig. 5, Table 2). Since this sulfonate is relatively unstable, it was purified by using short silica-gel column chromatography (dichloromethane).

Sulfonate (**19**) was hydrolyzed by heating in the presence of a base to yield the desired ester (**20**) (Fig. 5, Table 2). The aryl group migrates more preferentially than the alkoxyl group. The cyclic acetal derivative gave a half ester (**20b**) in high yield without any migration of the oxygen of the acetal as the side reaction. This was because the intermediate in migration of the alkoxyl group has a seven-membered ring. The use of sodium acetate increased the reaction rate as compared with the case using calcium carbonate,[8] and enabled the lowering the reaction temperature. As the results, the formation of the by-product, α-methoxy ketone (**21**),[8] decreased in the case of the dimethyl acetal (Table 2, **20a**). The optical purity of the obtained ester was determined to be over 98% by an ^{1}H NMR measurement of methyl ester (**20a**) in the presence of a chiral shift reagent.[31] Half ester (**20b**) was transformed to methyl ester (**20a**) by the acidic ester exchange without racemization.

Consequently, it is concluded that the optical purity of the starting, *N*,*N*-dimethyl amide remained throughout the rearrangement and the following derivation. If ethyl (*S*)-lactate contained a trace amount of (*R*)-isomer,[32] the optical purity can be increased to 100% by the recrystallization of α-hydroxy ketones (**15**) or sulfonates (**19**). In practice, methyl ester (**20a**) and half ester (**20b**) of Naproxen (Table 2, Run 5) were obtained as a pure form by the recrystallization of α-hydroxy ketone (**15**). In our

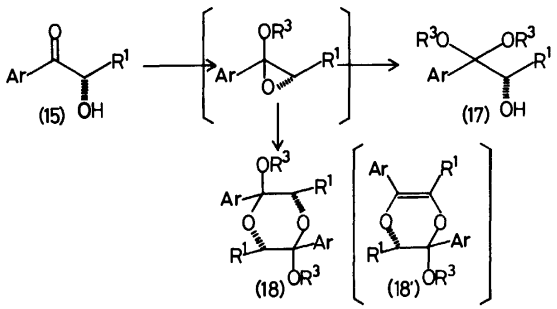

Fig. 4. Acetalization of α-hydroxy ketone (**15**).

a) $CaCO_3$ (2.0 equiv), 110 °C in $MeOH/H_2O=7/3$. b) $CaCO_3$ (2.0 equiv), 130 °C in $DMF/H_2O=4/1$.

laboratory, methods for obtaining the other chiral sources that are difficult to be derived from natural sources have been studied. For example, an asymmetric hydrolysis by using microorganisms to afford the chiral α-hydroxy ketones has been demonstrated.[33]

Experimental

General. Optical rotation was measured with a Japan Spectroscopic DIS-SL Polarimeter. The ^{1}H NMR spectra were recorded with a Varian EM 390 spectrometer at 90 MHz, the peak position being given in δ values. The IR spectra were recorded with a Japan Spectroscopic A-202 spectrophotometer. Kieselgel F_{254} (Merck), Wakogel C-300 (Wako), and Wacogel B-5F (Wako) were used for TLC, column chromatography, and preparative TLC, respectively.

(*S*)-*N*,*N*-Dimethyllactamide. According to the literature,[26] a 150-ml Pyrex heavy-walled pressure bottle was charged with ethyl (*S*)-lactate (Aldrich, 20.0 g, 0.169 mmol) and anhydrous dimethylamine (Kodack, 23.0 g, 0.510 mmol) under ice-salt cooling. The bottle was tightly sealed with a steel cap and heated at 70 °C for 60 h with stirring. After cooling, the reaction mixture was concentrated, followed by distillation under reduced pressure to yield 18.5 g (93%) of (*S*)-*N*,*N*-dimethyllactamide, bp 71—74 °C/0.7 mmHg (1 mmHg=133.322 Pa), $[\alpha]_D^{24}$ +0.85° (*c* 1.01, MeOH), IR (film) 3400, 1660, 1640 cm^{-1}, ^{1}H NMR ($CDCl_3$) δ=1.33 (3H, d, *J*=6.6 Hz, H-3), 3.01 (6H, s, -NMe), 3.8 (1H, broad s, -OH), 4.47 (1H, q, *J*=6.6 Hz, H-2) ppm.

(*S*)-2-*O*-Methoxymethyl-*N*,*N*-dimethyllactamide (11). Into a suspension of sodium hydride (60% oily, 1.02 g, 25.5 mmol) in THF (30 ml) was added a solution of (*S*)-*N*,*N*-dimethyllactamide (2.00 g, 17.1 mmol) in THF (7 ml) at 0 °C. The mixture was stirred for 30 min, and then chloromethyl methyl ether (1.67 ml, 22.2 mmol) was added. After 2 h stirring, water (2 ml) was added to form the precipitate. The pH of the decanted supernatant was adjusted 6.5—7.0 by using Na_2CO_3–aqueous $NaHCO_3$. The mixture was dried over Na_2SO_4, concentrated and distilled to give 3.07 g of **11** (82%), bp 102—103 °C/15 mmHg, $[\alpha]_D^{21}$ −95.3° (*c* 1.03, MeOH), IR (film) 1650 cm^{-1}, ^{1}H NMR ($CDCl_3$) δ=1.39 (3H, d, *J*=6.6 Hz, H-3), 2.97 (3H, s, -NMe), 3.07 (3H, s, -NMe), 3.38 (3H, s, -OMe), 4.55 (1H, q, *J*=6.6 Hz, H-2), 4.63 (2H, s, -OCH_2O-) ppm.

HRMS; Found: *m*/*z* 161.1022. Calcd for $C_7H_{15}O_3N$: M$^+$, *m*/*z* 161.1050.

(*S*)-2-*O*-(1-Ethoxyethyl)-*N*,*N*-dimethyllactamide (12). Into the mixture of (*S*)-*N*,*N*-dimethyllactamide (10.0 g, 85.4 mmol) and ethyl vinyl ether (8.2 ml, 128 mmol) in anhydrous dichloromethane (50 ml) was added PPTS (2.15 g, 8.6 mmol) at 0 °C. The mixture was allowed to warm to room temperature. After stirring overnight, solid $NaHCO_3$ (1.1 g) was added, and the mixture was vigorously stirred for 1 h. The reaction mixture was evaporated and the obtained residual syrup that contained salts was purified by flash column chromatography (Wacogel C-300, 50 g, hexane/ethyl acetate=3/1) to give crude **12** (15.8 g). It was distilled to yield pure **12** (15.3 g, 95%); bp 78—80 °C/0.7 mmHg; IR (film) 1660 cm^{-1}, ^{1}H NMR ($CDCl_3$) δ=1.1—1.5 (9H, m, -CMe), 2.96 (s), 3.09 (s), 3.12 (s) (total 6H, -NMe), 3.3—3.9 (2H, m, -OCH_2C-), 4.4—4.9 (2H, m, -OCHO- and -CHCO-) ppm.

HRMS; Found: *m*/*z* 189.1351. Calcd for $C_9H_{19}O_3N$: M$^+$, *m*/*z* 189.1363.

Methyl (*S*)-2-Hydroxyisovalerate. According to the literature,[25] a solution of sodium nitrite (30 g, 435 mmol) in H_2O (40 ml) was added into a solution of L-valine (25.8 g, 220 mmol) in 2 M† H_2SO_4 (250 ml) over 6 h under ice-cooling. The mixture was stirred for 6 h at 0 °C, and then for 12 h at rt. Furthermore, it was treated with H_2SO_4 (10.6 g, 108 mmol) and sodium nitrite (15 g, 217 mmol) by the above procedure. The reaction mixture was saturated by NaCl, followed by extraction with diethyl ether (100 ml×12). The organic layer was dried over $MgSO_4$ and then concentrated to yield crude (*S*)-2-hydroxyisovaleric acid (25.7 g, 99%) as an oily residue: IR (film) 1730 cm^{-1}, ^{1}H NMR ($CDCl_3$) δ=0.92 (3H, d, *J*=6.9 Hz, H-4), 1.05 (3H, d, *J*=6.9 Hz, H-4′), 1.9—2.3 (1H, m, H-3), 4.11 (1H, d, *J*=3.6 Hz, H-2), 5.77 (2H, broad s, -COOH and -OH) ppm.

The solution of the crude acid (5.00 g, 42.3 mmol) in diethyl ether (10 ml) was treated with diazomethane under ice-cooling to yield methyl (*S*)-2-hydroxyisovalerate (4.50 g, 81%); bp 90—92 °C/70 mmHg, $[\alpha]_D^{32}$ +18.2° (*c* 1.0, $CHCl_3$), IR (film) 3500, 1735 cm^{-1}, ^{1}H NMR ($CDCl_3$) δ=0.86 (3H, d, *J*=6.6 Hz, H-4), 1.01 (3H, d, *J*=6.6 Hz, H-4′), 1.8—2.2 (1H, m, H-3), 2.06 (1H, s, -OH), 3.76 (3H, s, -COOMe), 4.03 (1H, d, *J*=3.6 Hz, H-2) ppm.

HRMS; Found: *m*/*z* 132.0754. Calcd for $C_6H_{12}O_3$: M$^+$, *m*/*z* 132.0758.

(*S*)-2-Hydroxy-*N*,*N*,3-trimethylbutanamide. A 150 ml Pyrex heavy-walled pressure bottle was charged with methyl (*S*)-2-hydroxyisovalerate (4.43 g, 33.5 mmol), 4-dimethylaminopyridine (0.49 g, 3.35 mmol), and anhydrous dimethylamine (6.6 ml, ab. 100 mmol) under ice-salt cooling. The bottle was heated at 70 °C for 110 h, followed by distillation to give (*S*)-2-hydroxy-*N*,*N*,3-trimethlbutanamide (3.87 g, 80%): bp 59—61 °C/2 mmHg, $[\alpha]_D^{25}$ +38.4° (*c* 0.97, MeOH). ^{1}H NMR ($CDCl_3$) δ=0.73 (3H, d, *J*=6.8 Hz, H-4), 0.94 (3H, d, *J*=6.8 Hz, H-4′), 1.6—1.9 (1H, m, H-3), 2.86 (6H, s, -NMe), 3.19 (1H, d, *J*=7.5 Hz, -OH), 3.93 (1H, dd, *J*=7.5 Hz, *J*=2.9 Hz, H-2) ppm.

HRMS; Found: *m*/*z* 128.1098. Calcd for $C_7H_{14}ON$: M$^+$−OH, *m*/*z* 128.1074.

General Synthetic Procedure of (*S*)-1-Aryl-2-hydroxy-1-alkanone Dimethyl Acetal (17a): 1) Procedure A [from **14** (R′=MOM)]; Into a solution of **14** (10 mmol) in anhydrous methanol (150 ml) were added trimethoxymethane (5.53 ml, 50 mmol) and methanesulfonic acid (0.65 ml, 10 mmol) under an argon atmosphere. The mixture was heated at 50 °C for 1 h and allowed to cool to rt. The reaction mixture was poured into the vigorously stirred $NaHCO_3$ solution at 0 °C, and then extracted with diethyl ether (100 ml×3). The organic layer was washed with water (50 ml), dried over $MgSO_4$ in the presence of pyridine (1 ml), concentrated, and then purified by column chromatography (Florisil, Waco, hexane-diethyl ether) to give **17a** as a colorless oil.

2) Procedure B (from **15**); Into a solution of **15** (10 mmol) and trimethoxymethane (5.53 g, 50 mmol) in anhydrous methanol (150 ml), cooled in an ice bath, was added methanesulfonic acid (0.65 g, 10 mmol). The reaction mixture was treated by the above procedure to give **17a** (procedure B).

(*S*)-2-Hydroxy-1-phenyl-1-propanone Dimethyl Acetal (93% from **14**, 85% from **15**); $[\alpha]_D^{28}$ −17.7° (*c* 1.11, MeOH); IR (film) 3500 cm^{-1}; ^1H NMR (CCl_4) δ=0.88 (3H, d, *J*=6.9 Hz, H-3), 2.41 (1H, s, -OH), 3.16 (3H, s, -OMe), 3.38 (3H, s, -OMe), 3.98 (1H, q, *J*=6.9 Hz, H-2), 7.2—7.6 (5H, m, -Ph) ppm.

General Synthetic Procedure of (*S*)-1-Aryl-2-hydroxy-1-alkanone 2,2-Dimethyltrimethylene Acetal (17b): 1) Procedure C (from **15**); Into a solution of **15** (10 mmol) and 2,2-dimethyl-1,3-propanediol (10.42 g, 100 mmol) in anhydrous methanol (150 ml), cooled in an ice bath, was added trimethylchlorosilane (27.16 g, 25 mmol). The mixture was stirred in an ice bath for 2 h. The reaction mixture was poured into the vigorously stirred $NaHCO_3$ solution at 0 °C, and then extracted with ethyl acetate (100 ml×3). The organic layer was dried over magnesium sulfate, concentrated, and then purified by silica-gel column chromatography (hexane/ethyl acetate) to give **17b** as a colorless oil.

2) Procedure D (from **15**); Into a 500 ml flask equipped with a Soxlet's extractor packed by molecular sieves 4A 1/16 was charged **15** (10 mmol), 2,2-dimethyl-1,3-propanediol (1.56 g, 15 mmol), *p*-toluenesulfonic acid (0.34 g, 2 mmol), and benzene (200 ml). The resulting mixture was heated at 50 °C and a vacuum was applied in order to maintain a smooth reflux. After completion, the reaction mixture was cooled and poured into the stirred aqueous $NaHCO_3$, and then extracted with diethyl ether (50 ml×3). The organic layer was treated by the above procedure to give **17b** as a colorless oil.

(*S*)-2-Hydroxy-1-phenyl-1-propanone 2,2-Dimethyl-trimethylene Acetal [89% from **15** (Procedure C)]; $[\alpha]_D^{28}$ −0.7° (*c* 1.12 MeOH); IR (film) 3510 cm^{-1}; ^1H NMR (CCl_4) δ=0.60 (3H, s, -CMe), 0.93 (3H, d, *J*=6.6 Hz, H-3), 1.25 (3H, s, -CMe), 2.24 (1H, d, *J*=3.6 Hz, H-3), 3.39 (4H, s, $-CCH_2C-$), 3.62 (1H, dq, *J*=3.6 Hz, *J*=6.6 Hz, H-2), 7.2—7.5 (5H, m, -Ph) ppm.

General Synthetic Procedure of Methyl (*S*)-Alkanoate (20a) or 3-Hydroxy-2,2-dimethylpropyl (*S*)-Alkanoate (20b): A Pyrex pressure bottle was charged with **19** (10 mmol), sodium acetate (984 mg, 12 mmol), and methanol-water (7:3 v/v, 50 ml). The bottle was tightly closed with a cap and heated at 100—110 °C for 6—18 h with stirring. After cooling, the reaction mixture was poured into a stirred ice water (100 ml), which was then extracted with diethyl ether (50 ml×3). The organic layer was dried over $MgSO_4$, concentrated, and purified by silica-gel column chromatography (hexane-ethyl acetate) to give **20**.

Methyl (*S*)-2-Phenylpropionate (72% from **19a**); colorless oil; $[\alpha]_D^{28}$ +93.3° (*c* 0.96, EtOH); IR (film) 1735 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.10 (3H, d, *J*=7.2 Hz, H-3), 3.57 (3H, s, -COOMe), 3.58 (1H, q, *J*=7.2 Hz, H-2), 7.20 (5H, s, -Ph) ppm.

HRMS; Found: *m/z* 164.0838. Calcd for $C_{10}H_{12}O_2$: M$^+$, *m/z* 164.0836.

3-Hydroxy-2,2-dimethylpropyl (*S*)-2-Phenylpropionate (93% from **19b**); colorless oil; $[\alpha]_D^{25}$ +38.3° (*c* 1.00, $CHCl_3$); IR (film) 3470, 1735 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.82 (6H, s, -CMe), 1.52 (3H, d, *J*=7.2 Hz, H-3), 1.99 (1H, broad s, -OH), 3.13 (2H, s, $-OCH_2C-$), 3.74 (1H, q, *J*=7.2 Hz, H-2), 3.82 (1H, d, *J*=11.4 Hz, $-COOCH_2-$), 4.00 (1H, d, *J*=11.4 Hz, $-COOCH_2-$), 7.32 (5H, s, -Ph) ppm.

HRMS; Found: *m/z* 219.1354. Calcd for $C_{14}H_{19}O_2$: M$^+$−OH, *m/z* 219.1383.

Methyl (*S*)-2-(4-Methylphenyl)propionate (85% from **19a**); colorless oil; $[\alpha]_D^{20}$ +84.4° (*c* 0.98, $CHCl_3$); IR (film) 1740 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.39 (3H, d, *J*=7.2 Hz, H-3), 2.26 (3H, s, $-C_6H_4-$Me), 3.53 (1H, q, *J*=7.2 Hz, H-2), 3.55 (3H, s, -COOMe), 6.9—7.2 (4H, m, $-C_6H_4-$) ppm.

HRMS; Found: *m/z* 177.0891. Calcd for $C_{11}H_{13}O_2$: M$^+$−1, *m/z* 177.0914.

3-Hydroxy-2,2-dimethylpropyl (*S*)-2-(4-Methylphenyl)propionate (93% from **19b**); colorless oil; $[\alpha]_D^{20}$ +35.8° (*c* 1.03, $CHCl_3$); IR (film) 3460, 1730 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.83 (6H, s, -CMe-), 1.49 (3H, d, *J*=7.2 Hz, H-3), 2.31 (3H, s, $-C_6H_4-$Me), 2.46 (1H, broad s, -OH), 3.13 (2H, s, $-OCH_2C-$), 3.70 (1H, q, *J*=7.2 Hz, H-2), 3.81 (1H, d, *J*=12.0 Hz, $-COOCH_2-$), 3.99 (1H, d, *J*=12.0 Hz, $-COOCH_2-$), 7.17 (4H, s, $-C_6H_4-$) ppm.

HRMS; Found: *m/z* 250.1554. Calcd for $C_{15}H_{22}O_3$: M$^+$, *m/z* 250.1567.

Methyl (*S*)-2-(4-Methoxyphenyl)propionate (97% from **19a**); colorless oil; $[\alpha]_D^{21}$ +75.3° (*c* 1.02, $CHCl_3$); IR (film) 1735 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.39 (3H, d, *J*=7.2 Hz, H-3), 3.52 (1H, q, *J*=7.2 Hz, H-2), 3.56 (3H, s, -COOMe), 3.70 (3H, s, -OMe), 6.71 (2H, d, *J*=8.7 Hz, $-C_6H_4-$), 7.09 (2H, d, *J*=8.7 Hz, $-C_6H_4-$) ppm.

HRMS; Found: *m/z* 194.0954. Calcd for $C_{11}H_{14}O_3$: M$^+$, *m/z* 194.0942.

3-Hydroxy-2,2-dimethylpropyl (*S*)-2-(4-Methoxyphenyl)-propionate (92% from **19b**); colorless oil; $[\alpha]_D^{30}$ +30.2° (*c* 1.00, $CHCl_3$); IR (film) 3500, 1730 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.47 (3H, d, *J*=7.2 Hz, H-3), 3.67 (2H, s, $-OCH_2C-$), 3.68 (1H, q, *J*=7.2 Hz, H-2), 3.80 (3H, s, -OMe), 6.87 (2H, d, *J*=8.7 Hz, $-C_6H_4-$), 7.24 (2H, d, *J*=8.7 Hz, $-C_6H_4-$) ppm.

HRMS; Found: *m/z* 266.1524. Calcd for $C_{15}H_{22}O_4$: M$^+$, *m/z* 266.1517.

Methyl (*S*)-2-(4-Methoxyphenyl)-3-methylbutanoate (90% from **19a**); colorless oil; $[\alpha]_D^{23}$ +61.6° (*c* 1.01, MeOH); IR (film) 1735 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.70 (3H, d, *J*=6.6 Hz, H-4), 1.00 (3H, d, *J*=6.6 Hz, H-4′), 2.28 (1H, m, *J*=10.5 Hz, *J*=6.6 Hz, H-3), 3.07 (1H, d, *J*=10.5 Hz, H-2), 3.65 (3H, s, -COOMe), 3.79 (3H, s, -OMe), 6.83 (2H, d, *J*=9.0 Hz, $-C_6H_4-$), 7.24 (2H, d, *J*=9.0 Hz, $-C_6H_4-$) ppm.

HRMS; Found: *m/z* 222.1253. Calcd for $C_{13}H_{18}O_3$: M$^+$, *m/z* 222.1254.

3-Hydroxy-2,2-dimethylpropyl (*S*)-2-(4-Methoxyphenyl)-3-methylbutanoate (96% from **19b**); colorless oil; $[\alpha]_D^{24}$ +24.9° (*c* 1.00, $CHCl_3$); IR (film) 3510, 1730 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.71 (3H, d, *J*=6.6 Hz, H-4), 0.85 (6H, s, $-CMe_2C-$), 1.03 (3H, d, *J*=6.6 Hz, H-4′), 2.1—2.5 (2H, m, H-2), 3.0—3.3 (3H, m, $-CCH_2OH$ and -OH), 3.77 (3H, s, -OMe), 3.90 (2H, s, $-COOCH_2C-$), 6.84 (2H, d, *J*=9.0 Hz, $-C_6H_4-$), 7.22 (2H, d, *J*=9.0 Hz, $-C_6H_4-$) ppm.

HRMS; Found: *m/z* 294.1844. Calcd for $C_{17}H_{26}O_4$: M$^+$, *m/z* 294.1830.

Methyl (*S*)-2-(6-Methoxy-2-naphthyl)propionate (97% from **19a**); colorless crystals from hexane-diethyl ether; mp 91.0—92.0 °C; $[\alpha]_D^{21}$ +78.4° (*c* 1.05, $CHCl_3$); IR (film) 1735 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.57 (3H, d, *J*=7.2 Hz, H-3), 3.68 (3H, s, -COOMe), 3.90 (1H, q, *J*=7.2 Hz, H-2), 3.91 (3H, s, -OMe), 7.13 (1H, s), 7.1—7.2 (1H, s), 7.43 (1H, dd, *J*=1.8 Hz, *J*=8.4 Hz), 7.70 (2H, s), 7.79 (1H, s) (total 6H, $-C_{10}H_6-$) ppm.

HRMS; Found: *m/z* 244.1109. Calcd for $C_{15}H_{16}O_3$: M$^+$, *m/z* 244.1099.

3-Hydroxy-2,2-dimethylpropyl (*S*)-2-(6-Methoxy-2-naphthyl)propionate (95% from **19b**); colorless crystals from hexane-diethyl ether; mp 59.0—60.0 °C; $[\alpha]_D^{21}$ +31.2°C (*c* 0.92, $CHCl_3$); IR (film) 3500, 1730 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.84 (6H, s, $-CMe_2C-$), 1.58 (3H, d, *J*=7.2 Hz), 2.17 (1H, s, -OH), 3.12 (2H, s, $-OCH_2C-$), 3.84 (1H, d, *J*=10.5 Hz, $-COOCH_2C-$), 3.87 (1H, q, *J*=7.2 Hz, H-2), 3.91 (3H, s, -OMe), 4.01 (1H, d, *J*=10.5 Hz, $-COOCH_2C-$), 7.12 (1H, s), 7.1—7.3 (1H, m), 7.42 (1H, dd, *J*=1.8 Hz, *J*=8.4 Hz), 7.6—7.8 (3H, m) (total 6H, $-C_{10}H_6-$) ppm.

HRMS; Found: *m/z* 316.1676. Calcd for $C_{19}H_{24}O_4$: M$^+$, *m/z* 316.1656.

Transformation of 3-Hydroxy-2,2-dimethylpropyl Ester

(20b) to Methyl Ester (20a): A Pyrex pressure bottle was charged with **19b** (1 mmol), anhydrous methanol (15 ml), and sulfuric acid (41 mg, 0.7 mmol). The bottle was tightly closed with a cap and heated at 110 °C for 1 d. After cooling in an ice bath, the reaction mixture was powered into a stirred aqueous $NaHCO_3$ solution (100 ml), and extracted with diethyl ether (30 ml×3). The organic layer was concentrated and purified by silica-gel column chromatography to give the corresponding methyl ester (**20a**) quantitatively. Enantiomeric excess was determined to be over 98% by ^1H NMR measurement using $Eu(tfc)_3$.

A part of this research was financially supported by the Asahi Glass Foundation for Industrial Technology.

13) Some substitution-type rearrangements which afforded the 2-arylalkanoic esters have been reported in these seven years: a) 1-Aryl-2-halogeno-1-alkanone acetal was treated with silver salts: C. Giordano, G. Castaldi, F. Casagrade, and A. Belli, IT(Italian Patent) 20187 (1980); *J. Chem. Soc., Perkin Trans. 1*, **1982**, 2575; b) 1-Aryl-1-alkanone acetal was treated with iodine monochloride: A. Goosen and C. W. McCleland, *J. Chem. Soc., Chem. Commun.*, **1982**, 1311; c) 1-Aryl-2-halogeno-1-alkanone acetal was treated with zinc alkanoate: J. A. Walker and S. I. Amin, U. S. Patent 396967 (1982); DE 3322459 (1984); d) 1-Aryl-2-halogeno-1-alkanone acetal was treated with Lewis acid: G. Castaldi, A. Belli, F. Vaggeri, and C. Giordano, *J. Org. Chem.*, **48**, 4658 (1983); C. Giordano, G. Castaldi, F. Uggeri, and F. Gurzoni, *Synthesis*, **1985**, 436; e) 1-Aryl-2-iodo-1-alkanone acetal was treated with peroxy acid, chlorine, or iodine–chlorine, and 1-aryl-2-amino-1-alkanone acetal was treated with nitrous acid: S. D. Higgins and C. B. Thomas, *J. Chem. Soc., Perkin Trans. 1*, **1983**, 1483; f) Chiral 1-aryl-2-sulfonyloxy-1-alkanone acetal, which was prepared by Friedel-Crafts reaction, was treated with trimethoxymethane and sulfonic acid: G. Tsuchihashi, K. Kitajima, and S. Mitamura, JP 90978 (1981); EP 67698 (1982); G. Tsuchihashi, S. Mitamura, K. Kitajima, and K. Kobayashi, the 47th National Meeting of the Chemical Society of Japan, April 1, 1983, Abstr. II, 958, 959; U. S. Patent 4539420 (1985); g) Chiral 1-aryl-2-sulfonyloxy-1-alkanone acetal, which was prepared by the use of coupling of α-sulfonyloxypropanoyl chloride (**8**) with organometallic reagent, was treated with potassium acetate (92% ee): G. C. Schloemer, U. S. Patent 329672 (1981); EP 81993 (1983); JP 135833 (1983); h) Chiral 1-aryl-2-amino-1-alkanone acetal was treated with nitrous acid and 1-aryl-2-disulfonamido-1-alkanone acetal was treated with calcium carbonate under reflux: G. Tsuchihashi, S. Mitamura, K. Kitajima, and K. Kobayashi, EP 91575 (1983); i) 1-Aryl-2-hydroxy-1-alkanone acetal was treated with base (or amide) and SO_nXX' (or SO_2–X_2, n=0—1, X, X'=halogen): T. Yamauchi, K. Hattori, S. Ikeda, K. Nakano, and K. Tamaki, JP 75551 (1984); EP 160241 (1985); j) 2-Alkyl-1-aryl-2-halogeno-1-alkanone was treated with trialkoxymethane and methanesulfonic acid in methanol: S. Numata and K. Kitajima, JP 137442 (1985); 50th National Meeting of the Chemical Society of Japan, April 3, 1985, Abstr. II, 1047; k) 1-Aryl-2-phenylseleno- or 2-phenyltelluro-1-alkanone acetal was treated with peracid: S. Umemura, S. Fukuzawa, T. Yamauchi, K. Hattori, S. Mizutani, and K. Tamaki, *J. Chem. Soc., Chem. Commun.*, **1984**, 426; l) 1-Aryl-1-alkanone was treated with $PhI(OAc)_2$, trimethoxymethane in the presence of sulfuric acid: Y. Tamura, Y. Shirouchi, and J. Haruta, *Synthesis*, **1984**, 231; in the presence of $HClO_4$: Y. Tamura, T. Yakura, Y. Shirouchi, and J. Haruta, *Chem. Pharm. Bull.*, **33**, 1097 (1985); m) 1-Aryl-2-halogeno-1-alkanone acetal was treated with base: G. Castaldi, C. Giordano, and F. Uggeri, *Synthesis*, **1985**, 505; G. Castardi and C. Giordano, EP 151817 (1985); C. Giordano, F. Uggeri, and F. Minisci, EP 152003 (1985); n) 1-Aryl-2-halogeno-1-alkanone was treated with Broensted acid: IT 19434 (1984); EP 152004 (1985); o) Chiral 1-aryl-2-halogeno-1-alkanone acetal was treated with base: C. Graziano, V. Fulvio, and C. Giordano, IT 19782 (1984); EP 153701 (1985); G. Castaldi, F. Uggeri, and C. Giordano, IT 19783 (1984); EP 154853 (1985); p) 1-Aryl-1-alkanone was treated with iodine and trimethoxymethane in toluene under reflux: A. Citterio, L. Tinucci, L. Filippin, and A. Belli, IT 21883 (1984); EP 171840 (1986).

14) Some synthetic approach of the chiral 2-arylalkanoic esters by the use of asymmetric syntheses of the intermediates for rearrangement has been reported. a) The acetal of

racemic 2-chloro-1-(6-methoxy-2-naphtyl)-1-propanone with (+)-dimethyl (*R,R*)-tartrate was treated with KH_2PO_4–NaOH to afford (*S*)-Naproxen ester (diastereo selective rearrangement, 62% ee): C. Giordano, G. Castaldi, F. Uggeri, and S. Cavicchioli, EP 158255 (1985); b) Asymmetric bromination of the acetal of 1-(6-methoxy-2-naphtyl)-1-alkanone with (+)-dimethyl (*R,R*)-tartrate, followed by rearrangement, afforded the ester of 5′-bromo-(*S*)-naproxen (97% ee): C. Giordano, G. Castaldi, and F. Uggeri, EP 158913 (1985); c) Asymmetric reduction of 1-aryl-1,1-dimethoxy-2-alkanone with $LiAlH_4$ and the chiral ligand, (*S*)-(+)-2-(anilinomethyl)pyrrolidine[34] or (*S*)-(−)-2,2′-dihydroxy-1,1′-binaphtyl,[35] followed by sulfonylation and rearrangement, afforded (*S*)-2-arylalkanoic ester (69—79% ee): Y. Honda and G. Tsuchihashi, Ref. 1b.

15) On this basis, substitution-type rearrangements accompanied by the introduction of some anions, for example hydride,[a] alkyl, alkynyl,[b] and cyano anion,[c] have been developed. a) Y. Honda, M. Sakai, and G. Tsuchihashi, *Chem. Lett.*, **1985**, 1153; b) Y. Honda, E. Morita, and G. Tsuchihashi, *ibid*, **1986**, 277; c) Y. Honda, M. Sakai, and G. Tsuchihashi, 50th National Meeting of the Chemical Society of Japan, April 2, 1985, Abstr. II, 1023.

16) Some elimination-type rearrangements which afforded 2-arylalkanoic esters have been reported in these seven years; a) Aryl methyl ketone was treated with lead(IV) acetate in the presence of methanol and boron trifluoride diethyl etherate: B. Myrboth, H. Ila, and H. Junjappa, *Synthesis*, **1981**, 126; b) Aryl ethyl ketone was treated with lead acetate in the presence of trialkoxymethane and perchloric acid: K. Fujii, K. Nakao, and T. Yamauchi, *Synthesis*, **1982**, 456; *ibid*, **1983**, 444; c) Chiral 1-aryl-2-sulfonyloxy-1-alkanone acetal was treated with iodotrimethylsilane and Lewis acid, for example aluminum trichloride and titanium tetrachloride: K. Kitajima, S. Mitamura, Y. Honda, and G. Tsuchihashi, unpublished data; G. C. Shloemer, Ref. 13g.

17) P. Deslongchamps, "Stereoelectronic Effects in Organic Chemistry," Pergamon Press (1983), Series Vol. 1.

18) S.-C. J. Fu, S. M. Birnbaum, and J. P. Greenstein, *J. Am. Chem. Soc.*, **76**, 6054 (1954).

19) When isobutylbenzene was treated with (*S*)-2-(methylsulfonyloxy)alkanoyl chloride in the presence of iron(III) chloride in nitromethane, 1-(*p*-isobutylphenyl)-1-propanone was mainly obtained (*p*-/*o*-=37). But when methoxybenzene was treated by the same procedure, 1-(*o*-methoxyphenyl)-1-alkanone was obtained in a half yield of the 1-(*p*-methoxyphenyl)-1-alkanone.[1b,13f]

20) C. L. Stevens, W. Malik, and R. Pratt, *J. Am. Chem. Soc.*, **72**, 4758 (1950).

21) T. Tsunoda, M. Suzuki, and R. Noyori, *Tetrahedron Lett.*, **21**, 1357 (1980).

22) α-Hydroxy amide was reacted with 3 equivalents of Grignard reagent to yield α-hydroxy ketone: S. S. Jenkins, *J. Am. Chem. Soc.*, **56**, 682 (1934).

23) a) Magnesium bromide 2-bromopropionate was treated with arylmagnesium bromide to yield the 2-arylpropanoic acid: G. J. Matthews and R. A. Arnold, U. S. Patent 769070 (1977); JP 111018 (1978); b) Asymmetric coupling of α-metalated propanoic acid derivatives with aryl halide in the presence of the organotransition metal catalyst has been reported: G. W. Erickson, JP 112735 (1985).

24) a) D. Enders and H. Lotter, *Angew. Chem., Int. Ed. Engl.*, **20**, 795 (1981); b) T. F. Buckley and H. Rapoport, *J. Am. Chem. Soc.*, **103**, 6157 (1981).

25) a) A. H. Cook, S. F. Cox, T. H. Farmer, *J. Chem. Soc.*, **1949**, 1022; b) E. Fisher and H. Scheibler, *Chem. Ber.*, **41**, 2897 (1908).

26) K. Feudenberg, W. Kuhn, and I. Bumann, *Chem. Ber.*, **63**, 2380 (1930).

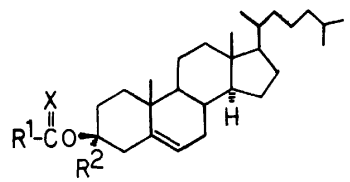
O-Cholesteryl chalcogenoformates-*d*, DC(=X)(OR) (**2**: X=O; **3**: X=S; **4**: X=Se; R=3β-cholesteryl), were synthesized and allowed to react with 2,4,6-tri-*t*-butylphenyllithium. 1,3,5-Tri-*t*-butylbenzene was a main product in each reaction. The other products were 2,4,6-tri-*t*-butylbenzaldehyde-*d* (**9**) for **2**, 2,4,6-tri-*t*-butylthiobenzaldehyde-*d* for **3**, and **9**, 6,8-di-*t*-butyl-1-deuterio-3,4-dihydro-4,4-dimethyl-1*H*-2-benzoselenin, bis(2,4,6-tri-*t*-butyl-α-deuteriobenzyl) diselenide, and bis(2,4,6-tri-*t*-butyl-α-deuteriobenzyl) triselenide for **4**. The mechanisms for these reactions have been discussed.

We have previously reported[1] that 2,4,6-tri-*t*-butylphenyllithium (**1**) reacts with selenoformates at three different sites (i.e. the selenoformyl hydrogen, the selenoformyl carbon, and the selenium atoms). We became interested in the hydrogen abstraction from the selenoformyl group and studied similar abstraction reactions of a series of chalcogen analogs **2**—**4** having a deuterated formyl group in order to elucidate the effect of these heteroatoms on the reactivity and the mechanism of these reactions.



2 X=O; R^1=D, R^2=H
3 X=S; R^1=D, R^2=H
4 X=Se; R^1=D, R^2=H
5 X=Se; R^1=H, R^2=H
6 X=Se; R^1=H, R^2=D

Syntheses of Formate 2 and Thioformate 3. Deuterated compounds **2** and **3** were synthesized by the reaction of iminium salt **7**,[2] prepared from *N*,*N*-dimethylformamide-d_7, with cholesterol followed by treatment with water and hydrogen sulfide, respectively.

$$D\text{-}\overset{Cl}{\overset{|}{C}}{=}\overset{+}{N}(CD_3)_2 \quad \mathbf{7} + ROH \longrightarrow D\text{-}\overset{OR}{\overset{|}{C}}{=}\overset{+}{N}(CD_3)_2 \longrightarrow D\text{-}\overset{OR}{\overset{|}{C}}{=}X$$

3: X=S 33%
R=3β-cholesteryl

Reactions with 2,4,6,-Tri-*t*-butylphenyllithium (1). The esters **2**—**4** were allowed to react with **1**, prepared from 1-bromo-2,4,6-tri-*t*-butylbenzene with 2 equiv of *t*-butyllithium, at −78 °C in tetrahydrofuran (THF). The reaction mixtures were allowed to warm to room temperature in the reactions of **2** and **3** or to 60 °C in the reaction with **4**. The results are listed in Table 1.#

The formate **2** afforded mostly 1,3,5-tri-*t*-butylbenzene (**8**) along with a small amount of deuterated 2,4,6-tri-*t*-butylbenzaldehyde (**9**). The thioformate **3** gave rise to similar products (**8** and **10**), but the yield of **8** was decreased when compared with the reaction of **2**. The reaction of **4** resulted in an even smaller amount of **8**; **9** and other four products **11**—**13**, and $(ArSe)_2$[1] being also formed. It has been reported that **11** and **9** are formed by cyclization of 2,4,6-tri-*t*-butylselenobenzaldehyde-*d* (**14**) and hydrolysis of the initial adduct **15** (X=Se), respectively.[1] The mechanism for the formation of **12** and **13** will be discussed later.

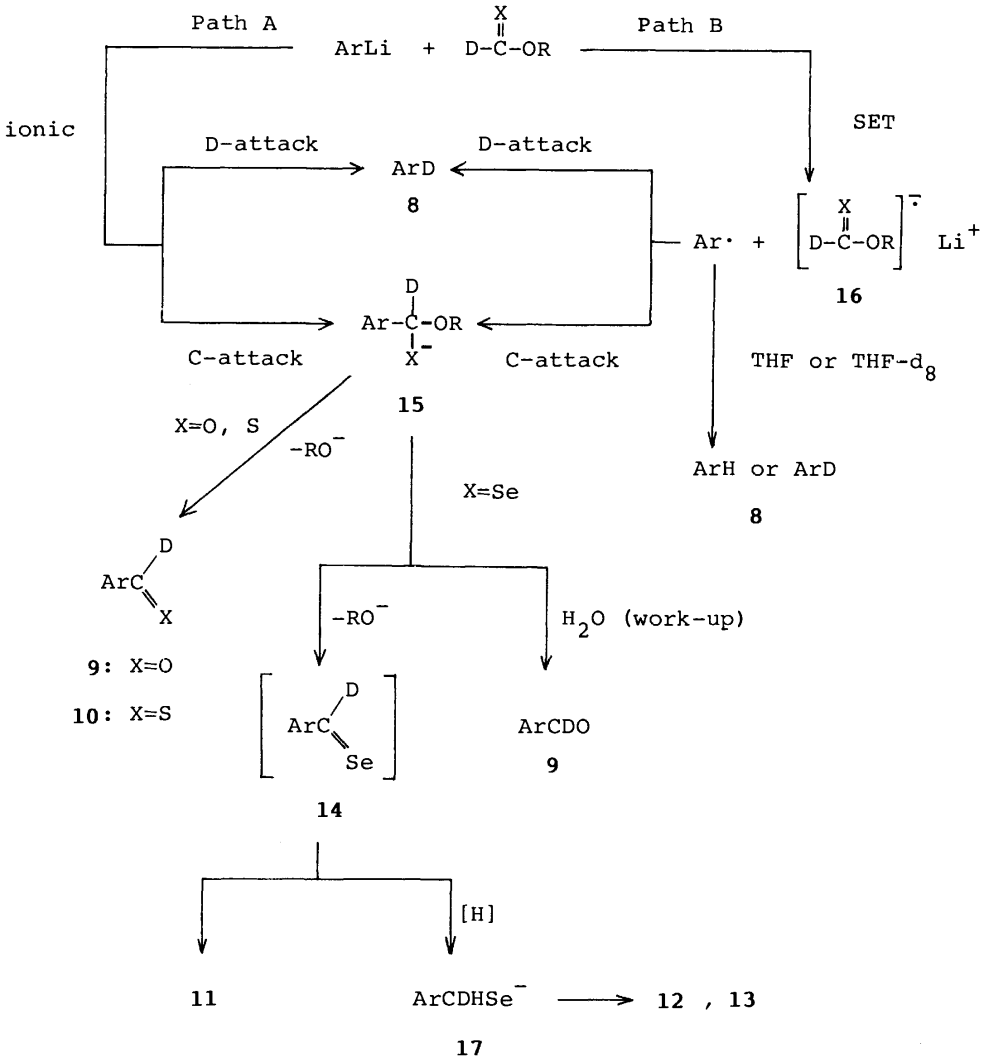
Reaction Mechanism. There are two conceivable mechanisms for the reaction of ArLi with the formates **2**—**4** (Scheme 1); one is an ionic mechanism (Path A) and the other is a homolytic one involving single electron transfer (SET) from ArLi to the formates (Path B)(Scheme 1).[3] The following experiments using THF-d_8 as a solvent clearly show that Path B involving Ar· is operative in these reactions. Thus, the quenching of a THF-d_8 solution of ArLi after 35 min of the preparation gave ArH (88% yield) with no deuterium (by MS), while a similar experiment with the selenoformate **5** (having a HC(=Se) group) added soon after the preparation of ArLi gave ArH (37%) containing 2.6±0.4% deuterium (by MS). The formation of ArD in the latter reaction can be explained only in terms of the abstraction of deuterium from THF-d_8 by 2,4,6-tri-*t*-butylphenyl radical Ar· which is formed by SET from ArLi to **5**, since the former reaction shows that ArLi itself is stable under the reaction conditions and can not react

Throughout this paper, Ar denotes 2,4,6-tri-*t*-butylphenyl.

with THF-d_8 to give ArD. Although the possibility that Path A and Path B are both operative in these reactions can not be excluded, we consider that the formation of all the reaction products can be accounted for in terms of Path B as shown in Scheme 1.

As can be seen from Table 1, the yield and deuterium content of 1,3,5-tri-*t*-butylbenzene show an interesting and systematic change depending on the heteroatoms in the formates **2**—**4**. The results suggest that the relative rate of the reaction of Ar· with anion radical **16** is in the order of O>S>Se for D-attack and O<S<Se for C-attack. This is probably related to the spin density on the duterium and the carbon of the anion radical **16**. ArH is most probably formed from the reactions of Ar· and unreacted ArLi with THF. Actually ArLi was found to react with THF to give ArH at room temperature.



Scheme 1.

Table 1. Products and Yields of the Reactions of **1** with Esters **2**—**4**

Ester	Product Yield/%			
	ArH + ArD(%d) (**8**)	ArCDO (**9**)	ArCDS (**10**)	Others
2	86 (41.0±0.2)	3		
3	51 (21.5±0.9)		37	
4	35 (5.8±0.1)	16		**11**(2), **12**(8) **13**(14), $(ArSe)_2$(trace)

Selenides **12** and **13** are considered to be formed during work-up procedure by the oxidative coupling of selenide ion **17** with another molecule of **17** and $ArCHDSe_2^-$ which is formed from **17** and selenium, respectively. Since **17** is a reduced form of **14**, some attempts to clarify the formation mechanism of **17** were carried out. Since it has been reported that an alkoxide ion derived from an alcohol having α-hydrogen atom can reduce thioketones,[4] one possible reducing agent of selenoaldehyde **14** is a cholesteryloxide anion formed from **15**. To check this possibility, selenoformate **6** was synthesized from the corresponding 3α-deuteriocholesterol and was allowed to react with ArLi under the conditions identical with those for **4**. The products were ArH (38%), ArCHO (2%), 6,8-di-*t*-butyl-3,4-dihydro-4,4-dimethyl-1*H*-2-benzoselenin (9%), and $ArCH_2Se_nCH_2$-Ar (**18**, n=2, 9%; n=3, 9%). Since **18** thus formed contained no deuterium, the above possibility was excluded. The mechanism for the formation of **12** and **13** is not clear at present.

The formation of **8** in a high yield in the reactions with the formate **2** suggests a possibility of the existence of anion $^-C(=O)(OR)$ **19** in solution. The anion **19** is an interesting species since it is an umpolung species of chloroformate ClC(=O)(OR) and enables the synthetically useful process, HC(=O)-(OR)→R′C(=O)(OR), if it is quenched with electrophiles such as aldehydes and alkyl halides.[5] To check this possibility, the reactions of ArLi with some formates HC(=O)(OR) (**20**, R=cholesteryl, *i*-Pr, *t*-Bu) were carried out at low temperatures (−78—−98 °C) and quenched with benzaldehyde, benzophenone, and benzyl chloride. The products, however, were **8** and ArCHO, no trapping of **19** being observed. This is probably due to high instability of **19**, which decomposes into carbon monoxide and an alkoxide ion.[6]

Table 2. Attempted Trapping Experiments of Anion **19**

R of **20**/equiv	Temp/°C	Quencher/equiv
i-Pr (5)	−78	$PhCH_2Cl$ (2)
cholesteryl (1)	−78	$PhCH_2Cl$ (1)
i-Pr (1.6)	−78	PhCHO (1.5)
i-Pr (1.6)	−98	PhCHO (1.5)
i-Pr (1.5)	−78	PhCHO (1.5)[a]
i-Pr (1.5)	−98	PhCHO (1.5)[a]
t-Bu (1.2)	−98	PhCHO (1.5)

Experimental

Melting points are uncorrected. ^1H NMR spectra were measured in $CDCl_3$ with a JEOL FX-90Q spectrometer at 90 MHz using tetramethylsilane as an internal standard. The mass spectra were recorded with a JEOL JMS-D300 mass spectrometer. Preparative liquid chromatography (PLC) was carried out using JAI Gel 1H column (Japan Analytical Industry) with chloroform as solvent. All reactions were carried out under argon.

The "usual work-up" refers to quenching with aqueous ammonium chloride, extraction with ether, washing with water, drying over anhydrous magnesium sulfate, and evaporation. The "chromatographic purification" refers to separation by column chromatography (silica gel, hexane) and subsequent purification of each fraction by PLC.

***O*-Cholesteryl Chalcogenoformate-*d*.** *O*-Cholesteryl formate-*d* (**2**): Colorless needles (ethanol-methanol), mp 98.3—98.8 °C (lit,[7] mp 97 °C for its protium analog); ^1H NMR δ=0.68—2.46 (43H, m), 4.48—4.96 (1H, m), 5.31—5.48 (1H, br d), and 8.02 (trace, HC(=O)); *O*-cholesteryl thioformate-*d* (**3**): Pale yellow needles (ethanol), mp 132.5—133.5 °C (lit,[2] mp 124—126 °C for its protium analog); ^1H NMR δ=0.69—2.58 (43H, m), and 4.99—5.75 (2H, m); *O*-3α-deuteriocholesteryl selenoformate (**6**) was prepared using 3α-deuteriocholesterol[8,9] by the Barton's method[2]: Orange crystals (hexane), mp 129.5—131.5 °C (lit,[2] mp 126—128 °C for its protium analog).

Reaction of *O*-Cholesteryl Formate-*d* (2) with 2,4,6-Tri-*t*-butylphenyllithium (ArLi). ArLi was prepared from 1-bromo-2,4,6-tri-*t*-butylbenzene[13] (151.4 mg, 0.465 mmol) by treatment with *t*-BuLi (2 equiv) in THF (5 ml) at −78 °C. To this ArLi was added **2** (0.232 g, 0.557 mmol) in THF (2 ml) at −78 °C. The mixture was allowed to warm to room temperature. The usual work-up and chromatographic purification gave ArCDO (**9**, 3.6 mg, 3%) and a mixture of ArD and ArH (98.4 mg, 86%). The ratio of ArD/ArH was (41.0±0.2)/(59.0±0.2) (n=7) as determined by its mass spectra (20 eV). **9**: Colorless crystals (methanol), mp 195.2—197.0 °C; ^1H NMR δ=1.33 (9H, s, *p*-*t*-Bu), 1.37 (18H, s, *o*-*t*-Bu), 7.37 (2H, s, arom.), and 11.13 (trace, CHO); MS m/z (rel intensity) 275 (M^+, 24), 260 (100), 242 (46), 218 (30), and 57 (83).[14]

Reaction of *O*-Cholesteryl Thioformate-*d* (3) with ArLi. ArLi was prepared from ArBr (172.6 mg, 0.531 mmol) by treatment with *t*-BuLi (2 equiv) in THF (5 ml) at −78 °C. To this ArLi was added **3** (273 mg, 0.632 mmol) in THF (2 ml) at −78 °C. The mixture was stirred for 10 min at −78 °C and allowed to warm to room temperature. The usual work-up and chromatographic purification gave ArCDS (**10**, 56.8 mg, 37%) and a mixture of ArD and ArH (66.8 mg, 51%). The ratio of ArD/ArH was (21.5±0.9)/(78.5±0.9) (n=9) by its mass spectra (20 ev). **10**: Purple crystals (methanol under N_2), mp 154.7—155.0 °C; ^1H NMR δ=1.33 (9H, s, *p*-*t*-Bu), 1.37 (18H, s, *o*-*t*-Bu), and 7.38 (2H, s,

arom); MS *m/z* (rel intensity) 291 (M^+, 34), 276 (10), 258 (19), 235 (40), 234 (44), 220 (30), 202 (15), 179 (15), 87 (25), and 57 (100).[15]

Reaction of *O*-Cholesteryl Selenoformate-*d* (4) with ArLi. ArLi was prepared from ArBr (201.4 mg, 0.619 mmol) and *t*-BuLi (2 equiv) at −78 °C. To this ArLi was added **4**[1] in THF (3 ml) at −78 °C. The mixture was allowed to warm to 60 °C and stirred at this temperature for 20 h. The usual work-up and chromatographic purification afforded 6,8-di-*t*-butyl-1-deuterio-3,4-dihydro-4,4-dimethyl-1*H*-2-benzoselenin (**11**, 4.4 mg, 2%), ArCDO (26.5 mg, 16%), $ArCDHSe_nCDHAr$[14] (48.6 mg; **12**, 8% and **13**, 14% from ^1H NMR), $(ArSe)_2$[1] (trace), and a mixture of ArD and ArH (53.7 mg, 35%). The ratio of ArD/ArH was (5.8±0.1)/(94.2±0.1) (n=5) by its mass spectra (20 ev). **11**: ^1H NMR δ=1.32 (9H, s, *t*-Bu), 1.47 (9H, s, *t*-Bu), 1.53 (6H, s, $SeCH_2C(C\underline{H}_3)_2$), 2.76 (2H, s, $SeC\underline{H}_2C(CH_3)_2$), 4.01 (1H, br s, benzyl), and 7.35 (2H, s, arom); MS *m/z* (rel intensity) 339 (M^+, 37), 324 (18), 282 (19), 245 (10), 230 (20), and 57 (100). Found: *m/z* 339.1570. Calcd for $C_{19}H_{29}D^{80}Se$: M, 339.1573.[14]

Reaction of *O*-Cholesteryl Selenoformate (5) with ArLi in THF-d_8. THF-d_8 (Merck, 99%) was dried over sodium-potassium alloy[16] before use. ArLi was prepared from ArBr (81.4 mg, 0.250 mmol) and *n*-BuLi (1.2 equiv.) in THF-d_8 (2 ml) at −78 °C. To this ArLi was added **5**[2] (147.1 mg, 0.308 mmol) at −78 °C. After stirring for 30 min, methanol was added for quenching to the reaction mixture at −78 °C. The usual work-up and chromatographic purification gave a mixture of ArD and ArH (22.7 mg, 37%). The ratio of ArD/ArH was (2.6±0.4)/(97.4±0.4) (n=8) by its mass spectra (20 ev).

Reaction of *O*-3α-Deuteriocholesteryl Selenoformate (6) with ArLi. ArLi was prepared from ArBr (256.6 mg, 0.789 mmol) and *t*-BuLi (2 equiv) in THF (13 ml) at −78° C. To this ArLi was added **6** (413.8 mg, 0.865 mmol) in THF (4 ml) at −78 °C. The mixture was allowed to warm to 60 °C and stirred at this temperature for 20 h. The usual work-up and chromatographic purification gave ArH (73.4 mg, 38%), 2,6-di-*t*-butyl-3,4-dihydro-4,4-dimethyl-1*H*-2-benzoselenin (23.8 mg, 9%),[1] $ArCH_2Se_nCH_2Ar$ (70.0 mg; n=2, 9% and n=3, 9% from ^1H NMR)[1] and ArCHO (4.8 mg, 2%). No deuterium was introduced to the products by their mass and/or ^1H NMR spectra.

Attempted Trapping of Anion 19. ArLi was prepared from ArBr (1 mmol) and *n*-BuLi (1.2 equiv) in THF at −78 °C. To this ArLi was added formate **20** and a quencher under the conditions described in Table 2. The usual work-up gave only a mixture of ArCHO and ArH by its ^1H NMR spectra.

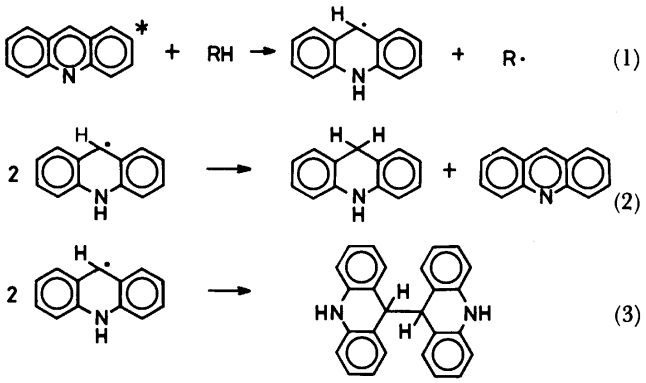
The Photoreduction Mechanism of 10-Methylacridinium Chloride in Methanol. The Formation of 9,10-Dihydro-9-methoxy-10-methylacridine and Hydride Transfer

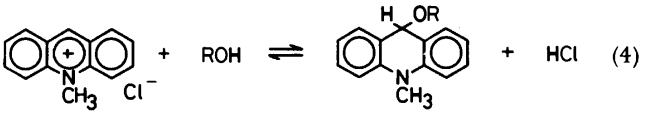
Koji KANO,* Bin ZHOU, and Shizunobu HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto 602
(Received September 8, 1986)

The photolysis of 9,10-dihydro-9-methoxy-10-methylacridine (MeOA), which is a product of the nucleophilic addition of methanol to 10-methylacridinium chloride, yielded 9,10-dihydro-10-methylacridine (AH_2) and 10,10′-dimethyl-9,9′,10,10′-tetrahydro-9,9′-biacridinyl ($(AH)_2$) in various solvents. The quenching experiment using 1,3-pentadiene indicates that AH_2 and $(AH)_2$ are produced from the photoexcited singlet and triplet states of MeOA respectively. The results on the solvent effects and the photolyses in solvent matrices at 77 K suggest that the photochemical reaction of MeOA yielding AH_2 occurs via hydride transfer from the methoxide anion to the 10-methylacridinium cation, these ions being generated from the heterolysis of MeOA in the photoexcited singlet state.

The photochemical reduction of acridine in alcohols has been a well-studied subject.[1–15] 9,10-Dihydroacridine is a major photoproduct of the dilute alcoholic solutions of acridine ($<10^{-3}$ M, 1 M=1 mol dm^{-3}), while 9,9′,10,10′-tetrahydro-9,9′-biacridinyl is also produced at higher acridine concentrations ($<10^{-1}$ M).[2] Photoexcited acridine (n, π* singlet or triplet states) abstracts a hydrogen atom from a solvent to yield the 9,10-dihydroacridinyl radical, which subsequently gives 9,10-dihydroacridine and 9,9′,10,10′-tetrahydro-9,9′-biacridinyl through disproportionation and coupling reactions respectively (Eqs. 1—3).[16] The photochemical reactions of the 10-methylacridinium ion (A^+) in alcohols are somewhat similar to those of acridine.[2,3,6,17] For example, the photolysis of 1.2×10^{-3} M 10-methylacridinium chloride (A^+Cl^-) in methanol containing trimethylamine gives 9,10-dihydro-10-methylacridine (AH_2) and 9,10-dihydro-9-hydroxymethyl-10-methylacridine in 11 and 28% yields respectively.[6] At higher concentration of A^+Cl^- (2.2×10^{-2} M) in ethanol, 10,10′-dimethyl-9,9′10,10′-tetrahydro-9,9′-biacridinyl ($(AH)_2$, 17%) is formed, together with AH_2 (12.7%) and 9,10-dihydro-9-(1-hydroxyethyl)-10-methylacridine (12.6%). Although the photoreduction mechanism of acridine has been studied in detail,[16] that for the acridinium ion is still unresolved. Zanker et al. have postulated a mechanism for the formation of $(AH)_2$ involving hydrogen abstraction by the photoexcited acridinium ion from ethanol.[17] Such hydrogen abstraction by the photoexcited acridinium ion, however, is hard to accept because the 10-alkylacridinium ion has no odd electrons which can participate in the n–π* transition.



In the present paper, we demonstrate a mechanism of the photoreduction of A^+Cl^- in a methanolic solution which is quite different from those for acridine. In a previous communication, we reported a nucleophilic addition of primary and secondary alcohols to the 9-position of A^+Cl^- in dilute solutions ($[A^+Cl^-]=1\times10^{-5}$ M):[18]



The mechanisms presented herein involve the photoreactions of 9-methoxy-9,10-dihydro-10-methylacridine, a methanol adduct of A^+Cl^-.

Experimental

A^+Cl^- was prepared by passing an aqueous solution of 10-methylacridinium iodide through an ion-exchange column (Dowex-1- X8), the crude A^+Cl^- thus obtained was recrystallized from acetonitrile. 9,10-Dihydro-9-methoxy-10-methylacridine (MeOA),[19] AH_2,[20] and $(AH)_2$[6] were prepared according to the procedures described in the literature. 1,3-Pentadiene was distilled. The analysis by means of HPLC indicated that distilled 1,3-pentadiene was still a mixture of cis and trans isomers. Spectral grades of methanol, ethanol, and 2-propanol were refluxed in the presence of K_2CO_3 and distilled. The other solvents (reagent grades) were used without further purification. All the solvents were dried using molecular sieves. Water was distilled and passed through an ion-exchange column.

The absorption spectra were taken on a Shimadzu UV-200S spectrophotometer. The fluorescence and phosphorescence spectra were measured by means of a Hitachi 650-60

spectrofluorometer. Photolyses were carried out by using an Ushio USH-5000 super-high-pressure Hg lamp (500 W) as the point-light source. The sample, in a Pyrex tube (ϕ=4 mm) or in a quartz cell (1-cm optical length), was placed at a distance of 60 cm from the light source. The deaeration of the sample was performed by five freeze-pump-thaw cycles. For photolyses and/or spectroscopic measurements at 77 K, the sample in the glass tube was placed in a Dewar vessel equipped with a quartz cell. The identification and the quantitative analyses of photoproducts were performed by a Shimadzu LC-5A HPLC apparatus equipped with a column of Shimadzu ZORBAX ODS (46×250 mm). AH_2, $(AH)_2$, and 10-methyl-9(10*H*)-acridinone (A=O) could be analyzed by means of HPLC but not A^+Cl^- and MeOA.

Results and Discussion

Nucleophilic Addition of Alcohols to A^+Cl^-. The absorption spectra of A^+Cl^- in water and alcohols are shown in Figs. 1 and 2. The assignments of the absorption bands of acridinium compounds blended in polymer films have been done by linearly-polarized absorption spectroscopy.[21,22] The shape of the absorption spectrum of A^+Cl^- (1×10^{-5} M) in water (pH 5.5) is essentially the same as that in polymer film. As is shown in Fig. 1, however, the spectrum in methanol is completely different from that in water; i.e., the ^1L_a (440, 415, and 395 nm), ^1L_b (358 and 343 nm) and ^1B_b (258 and 242 nm) bands observed in water disappear in methanol, while new absorption bands appear at 320 and 280 nm. This spectral change of A^+Cl^- in methanol has been ascribed to the formation of MeOA, which is a product of the nucleophilic addition of methanol to A^+Cl^- (Eq. 1).[18] MeOA was not formed in methanol containing small amounts of HCl. Figure 3 shows the absorption spectra of various concentrations of A^+Cl^- in methanol. An increase in the initial concentration of A^+Cl^- causes a decrease in the conversion of A^+Cl^- into MeOA. The addition of triethylamine to the system, containing both MeOA and A^+Cl^-, caused the disappearance of A^+Cl^- and an enhancement of the MeOA formation. These results clearly indicate the equilibrium shown in Eq. 4. Although it is expected that the equilibrium constant (K) can be determined spectroscopically, the poor reproducibility did not allow us to get an accurate K value. The determination of K is now in progress.

As is shown in Fig. 2, ethanol also converts A^+Cl^- to 9,10-dihydro-9-ethoxy-10-methylacridine. The nucleophilic addition of primary alcohols to A^+Cl^- occurs in 1-propanol, 1-butanol, and 1-octanol, but not in grycerol. *t*-Butyl alcohol does not give an alcohol adduct (Fig. 2). In the case of a secondary alcohol, 2-propanol, small amounts of unreacted A^+Cl^- coexist with the corresponding 9-alkoxy-9,10-

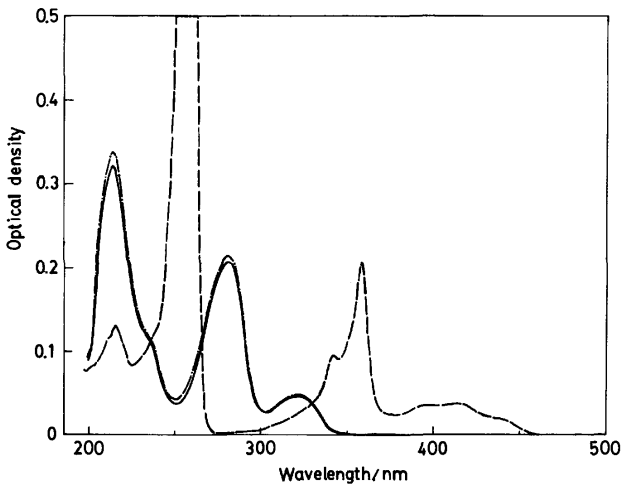


Fig. 1. Absorption spectra of A^+Cl^- (1×10^{-5} M) in water (----) and methanol (——) and authentic MeOA (1×10^{-5} M) in methanol (—·—) at 25 °C.

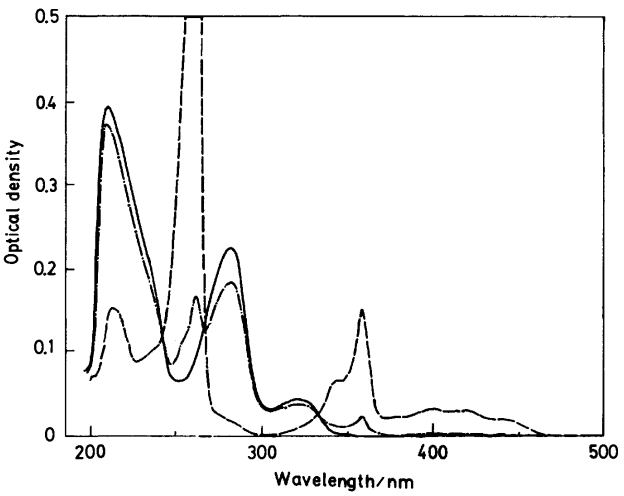

Fig. 2. Absorption spectra of A^+Cl^- (1×10^{-5} M) in ethanol (——), 2-propanol (—·—), and *t*-butyl alcohol (----) at 25 °C.

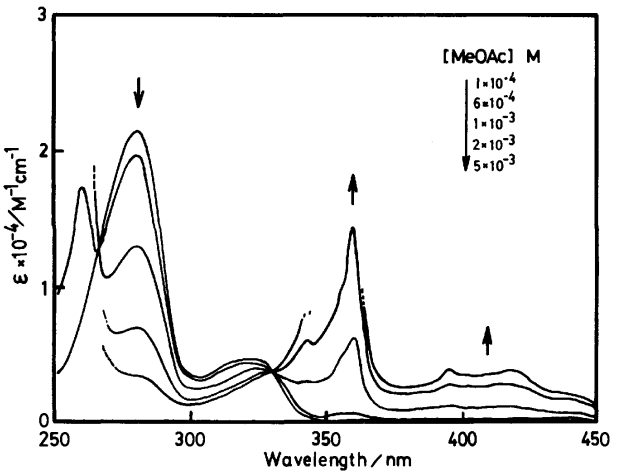

Fig. 3. Concentration effect on the absorption spectrum of A^+Cl^- in methanol at 25 °C.

dihydro-10-methylacridine. These findings reveal that the formation of 9-alkoxy-9,10-dihydro-10- methylacridine is sensitively affected by steric factor(s). Steric hindrance due to the hydrogen atoms at the 1- and 8-positions of the acridinium ring and the thermodynamically unstable structures of the alcohol adducts may inhibit the formation of 9-alkoxy-9,10-dihydro-10-methylacridines in 2-propanol, *t*-butyl alcohol, and glycerol.

It has been known that the 9-position of the 10-methylacridinuim ion (A^+) is so electrophilic that such nucleophiles as hydroxide[20,23-27] and methoxide anions[19,28,29] attack this position, thus yielding 9-hydroxy- and 9-methoxy-9,10-dihydro-10-methylacridines respectively. Our present observation reveals that weaker nucleophiles, the alcohols, also attack the 9-position of A^+. A^+Cl^- acts as a pseudo acid in the primary and secondary alcohols, such as methanol, ethanol, 1-propanol, 1-butanol, 1-octanol, and 2-propanol (Eq. 4).

Photolysis of MeOA. It is reasonable to assume that the primary step in the photoreaction of a dilute methanolic solution of A^+Cl^- is the photoexcitation of MeOA. Therefore, we studied the photochemical reaction of MeOA under various conditions.

Figure 4 shows the progressive absorption spectral changes of MeOA (5×10^{-5} M) in deaerated ethanol upon irradiation at room temperature. The photolyzed solution was analyzed by means of HPLC. $(AH)_2$ was produced as a major photoproduct, along with small amounts of AH_2 and A=O. $(AH)_2$ was isolated from the photolyzed solution of MeOA (5×10^{-4} M) and identified by means of ^1H NMR and elementary analysis. The results of the fluorescence spectral measurment of the photolyzed solution (λ_{ex}=298 nm) support the formation of AH_2 (λ_{em}=360 nm).

The yields of AH_2, $(AH)_2$ and A=O for the photolyses of MeOA in methanol, ethanol, 2-propanol, and acetonitrile under anaerobic and aerobic conditions are summarized in Table 1. Under anaerobic conditions, AH_2, $(AH)_2$, and A=O are formed, and the yields of $(AH)_2$ are higher than those of AH_2 in all the solvents used herein. In air-saturated solutions, however, the formation of $(AH)_2$ was almost completely depressed, and the yields of AH_2 increased remarkably. Prolonged irradiation in aerated solvents, especially in 2-propanol, led to an enhancement of the A=O formation (Fig. 5). In 2-propanol, the rapid formation of AH_2 was followed by the decomposition of AH_2, while the yield of A=O gradually increased. The reaction profile for the photolysis in acetonitrile

Table 1. Photochemical Reactions of MeOA in Deaerated and Aerated Solvents[a]

Solvent	Yield/%[b]		
	A=O	AH_2	$(AH)_2$
Methanol	6 (1)	14 (32)	19 (0)
Ethanol	4 (5)	7 (35)	40 (0)
2-Propanol	2 (31)	5 (20)	19 (1)
Acetonitrile	3 (21)	5 (21)	24 (0)

a) MeOA (5×10^{-5} M) in a solvent was irradiated with a 500 W super-high pressure Hg lamp for 2 min at room temperature. The yields of the photoproducts were determined by means of HPLC. b) The values in parentheses are the yields for the photolyses in air-saturated solvents.

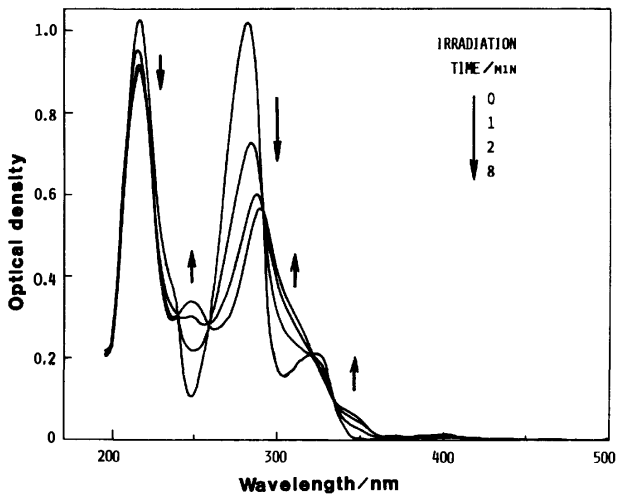

Fig. 4. Progressive absorption spectral changes of MeOA (5×10^{-5} M) in deaerated ethanol upon full irradiation with a 500 W super-high pressure Hg lamp at room temperature.

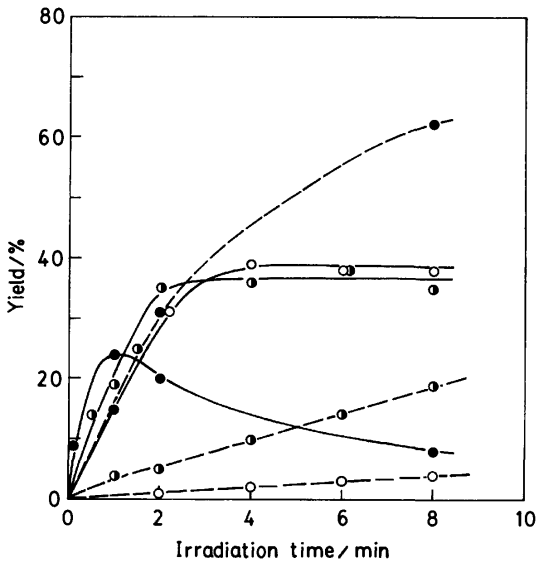

Fig. 5. Plots of the yields of AH_2 (——) and A=O (----) against the irradiation time when MeOA (5×10^{-5} M) in air-saturated methanol (○), ethanol (◑), and 2-propanol (●) was irradiated with a 500 W super-high pressure Hg lamp at room temperature.

was similar to that in 2-propanol (the data are not shown). In the cases of methanol and ethanol, the formation of A=O continued even after the rate of the AH_2 formation has become a plateau. These findings suggest that A=O is formed by the photooxidation of AH_2. Figure 6 shows the progressive absorption-spectral changes, which show the time course of the photoreaction of AH_2 (5×10^{-5} M) in air-saturated acetonitrile. The isosbestic points were observed at 325, 276, and 216 nm. The spectrum of the final photoproduct is completely in agreement with that of authentic A=O. Rapid photooxidation giving A=O was also found for $(AH)_2$ in aerated acetonitrile and 2-propanol (Fig. 7). It can be concluded, therefore, that A=O is produced by the photooxidation of AH_2 and/or $(AH)_2$ in these solvents. In methanol and ethanol, however, there was a very slow photooxidation of AH_2. A 70-min irradiation in methanol gave A=O in only a 30% yield. The reaction profiles for the photolyses of MeOA in methanol and ethanol shown in Fig. 5 can be explained by saying that the rate of AH_2 formation competes with that of the photooxidation of AH_2 to A=O at a longer irradiation time. The photolysis of $(AH)_2$ in methanol did not produce A=O at an initial stage, but a photoproduct with an absorption maximum at 280 nm was formed upon irradiation for 1 min. The HPLC analysis indicated the photoproduct to be AH_2 (40% yield). Under anaerobic conditions, however, no photoinduced conversion of $(AH)_2$ to AH_2 occurred. At the present stage, the solvent effects on the photooxidation of AH_2 and $(AH)_2$ and the effects of oxygen on the photoreaction of $(AH)_2$ are not understood.

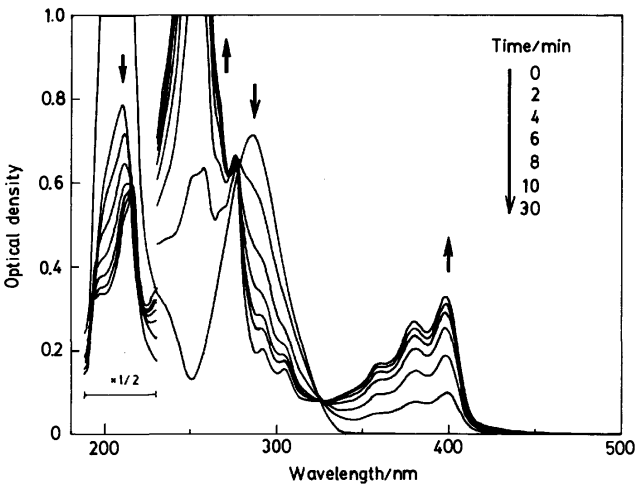

Fig. 6. Progressive absorption spectral changes of AH_2 (5×10^{-5} M) in air-saturated acetonitrile upon irradiation with a 500 W super-high pressure Hg lamp at room temperature.

Effects of 1,3-Pentadiene. The photochemical reaction of MeOA is very sensitive toward oxygen dissolving in solutions (vide supra). Oxygen can be expected to be a triplet-quencher for the photoreactions of MeOA. The photochemical reactions of MeOA under aerobic conditions, however, were so complex that the role of oxygen as a triplet quencher

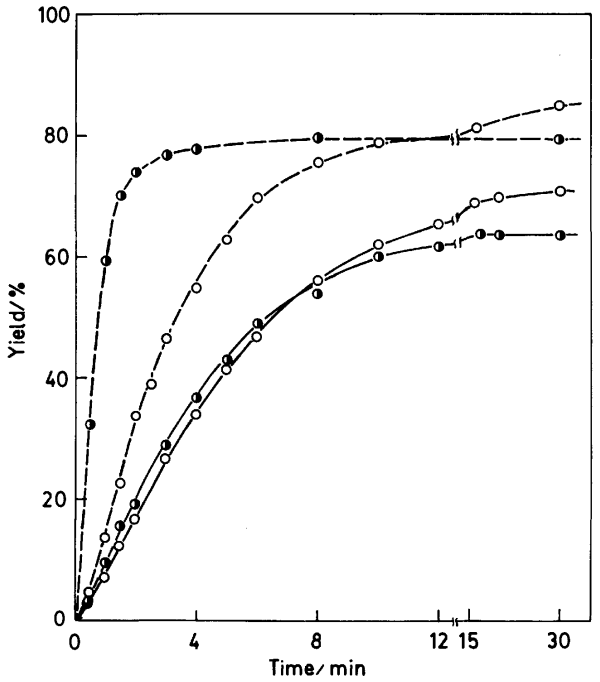

Fig. 7. Plots of the yields of A=O against the irradiation time when AH_2 (——) and $(AH)_2$ (----) in air-saturated 2-propanol (○) and acetonitrile (◑) were irradiated with a 500 W super-high pressure Hg lamp at room temperature.

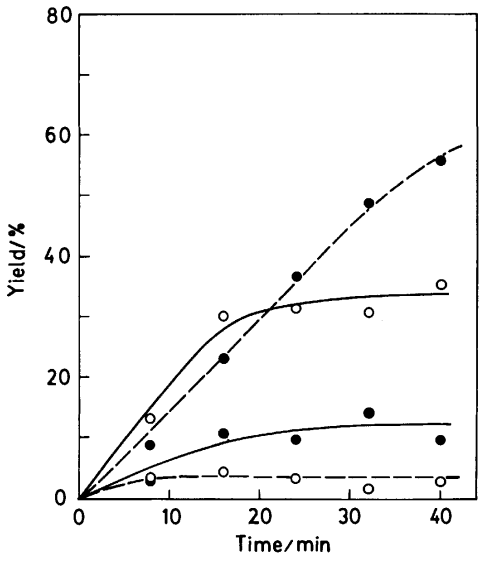

Fig. 8. Plots of the yields of AH_2 (○) and $(AH)_2$ (●) against the irradiation time when MeOA (5×10^{-5} M) in deaerated ethanol was irradiated with a 500 W super high-pressure Hg lamp (>300 nm) in the absence (----) and the presence (——) of 1,3-pentadiene (1×10^{-2} M) at room temperature.

could not be verified from the results presented above. Therefore, we examined the photolysis of MeOA (5×10^{-5} M) in degassed ethanol containing 1,3-pentadiene, which is well-known as an effective triplet quencher.[30]

The effects of 1,3-pentadiene (1×10^{-2} M) on the yields of AH_2 and $(AH)_2$ are shown in Fig. 8. The samples were irradiated by light with wavelengths above 300 nm (glass filter) in order to avoid the excitation of the 1,3-pentadiene. As Fig. 8 clearly shows, 1,3-pentadiene inhibited the formation of $(AH)_2$ and enhanced the yield of AH_2. The effects of 1,3-pentadiene are similar to those of oxygen. $(AH)_2$ did not decompose at all upon irradiation (>300 nm). Judging from these results, it can be concluded that AH_2 and $(AH)_2$ are produced via the lowest excited singlet and triplet states of MeOA respectively.

Photolyses of MeOA in Rigid Matrices and Reaction Mechanisms. In order to detect the reaction intermediate(s) for the photoreaction of MeOA, MeOA (5×10^{-5} M) in ethanol was irradiated at 77 K. In a glassy ethanol matrix, MeOA showed an absorption spectrum similar to that in the liquid phase except for the bands at around 320 nm, a broad absorption band at 320 nm in the fluid medium being split into two bands in the ethanol matrix (Fig. 9). Photoirradiation caused a rapid disappearance of the absorption bands of MeOA and the appearance of the characteristic absorption bands attributable to the 10-methylacridinium cation (A^+) (Fig. 9). The photoproduct should be 10-methylacridinium methoxide (A^+MeO^-). The emission spectra of the photolyzed solution were also measured (Fig. 10). Although MeOA does not fluoresce in ethanol at room temperature, it emits fluorescence with a maximum intensity at 337 nm (λ_{ex}=288 nm) in glassy ethanol at 77 K. Upon irradiation, the fluorescence intensity due to MeOA decreased, while new fluorescence and phosphorescnce bands appeared at 512, 481, and 472 nm (λ_{ex}=358 nm) and 418 nm (λ_{ex}=300 nm). The fluorescence excitation spectrum of the photolyzed solution followed at 481 nm corresponds to the absorption spectrum of A^+MeO^- shown in Fig. 9. The phosphorescence spectrum was completely in agreement with that of the authentic sample of AH_2. After a 13-min irradiation at 77 K, the sample was thawed at room temperature and analyzed by means of HPLC. The formation of AH_2 (ca. 10% yield) was detected. No $(AH)_2$ was measured by means of HPLC.

In place of ethanol, methanol, 1-propanol, and 1-butanol were also useful for the solvents in which MeOA was photoionized to yield A^+MeO^- at 77 K. Meanwhile, the formation of A^+MeO^- was not detectable in the photolyses in 1-octanol, *t*-butyl alcohol, methylcyclohexane, and acetonitrile at 77 K. In smaller alcohols without bulky group(s), the methoxide anion generated photochemically as a counter anion of A^+ may interact with the surrounding alcohol molecules through hydrogen bonding, resulting in the stabilization of the methoxide anion. Since alcohols with long or bulky alkyl chains as well as aprotic solvents could not interact with the methoxide anion at 77 K, a rapid recombination reaction of A^+ and MeO^- may occur to yield original MeOA. In all the media used herein, small amounts of AH_2 (<10%) were formed in the photolyses of MeOA at 77 K.

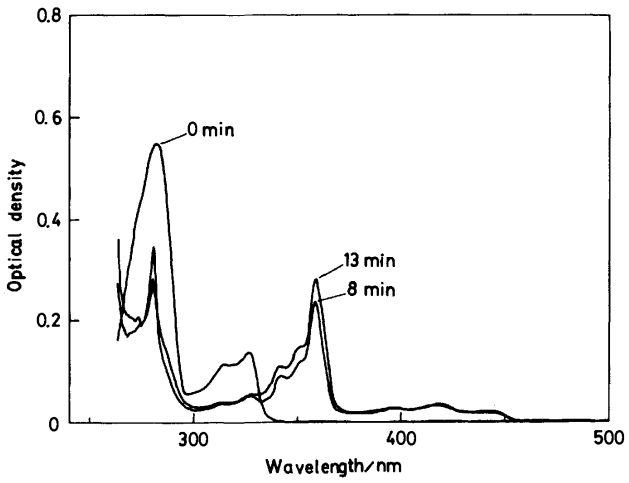

Fig. 9. Progressive absorption spectral changes of MeOA (5×10^{-5} M) in glassy ethanol upon irradiation with a 500 W super-high pressure Hg lamp at 77 K.

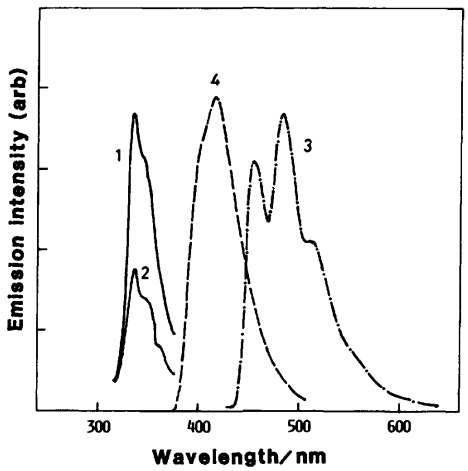

Fig. 10. Emission spectra of MeOA (5×10^{-5} M) and the photolyzed sample of MeOA in glassy ethanol at 77 K: 1 : MeOA before irradiation (λ_{ex}=288 nm), 2: MeOA after irradiation for 13 min (λ_{ex}=288 nm), 3: fluorescence of A^+MeO^- generated by the photolysis of MeOA (λ_{ex}=358 nm), 4: phosphorescence of AH_2 generated by the photolysis of MeOA (λ_{ex}=300 nm).

We can use the information obtained for the photolyses in rigid matrices to elucidate the reaction mechanisms of MeOA in fluid solutions. The heterolysis of MeOA may occur via the photoexcited singlet state of MeOA to give A^+MeO^-. Two competing reactions, the hydride transfer from MeO^- to A^+ forming AH_2 and formaldehyde (a most plausible product from MeO^-), and the recombination of A^+ and MeO^- regenerating MeOA, seem to proceed in fluid solutions:

$$MeOA + h\nu \longrightarrow {}^1MeOA^* \quad (5)$$

$${}^1MeOA^* \longrightarrow A^+ + MeO^- \quad (6)$$

$$A^+ + MeO^- \longrightarrow AH_2 + HCHO \quad (7)$$

$$A^+ + MeO^- \longrightarrow MeOA \quad (8)$$

This mechanism for forming AH_2 can account for the formation of AH_2 in the photolysis of MeOA in acetonitrile (see Table 1). Of course, a two-step mechanism involving electron transfer, followed by hydrogen transfer, may account for the formation of AH_2 from A^+MeO^-:

$$A^+ + MeO^- \longrightarrow AH\cdot + MeO\cdot \quad (9)$$

$$AH\cdot + MeO\cdot \longrightarrow AH_2 + HCHO \quad (10)$$

This mechanism, however, seems inadequate for the reasons to be presentd below.

In the absence of oxygen, the photochemical reaction via the triplet state of MeOA becomes predominant. The major photoproduct of this case is $(AH)_2$. The most plausible precursor of $(AH)_2$ is the 9,10-dihydro-10-methylacridinyl radical (AH·). If the coupling reaction of these radicals provides $(AH)_2$ in the photolysis of MeOA, AH· should have a low ability to abstract a hydrogen atom from MeO· and/or the surrounding solvent molecule. The yield of $(AH)_2$ in 2-propanol is similar to those in methanol and acetonitrile, and no significant difference in the yield of AH_2 was observed between the hydrogen-donative alcohols and acetonitrile (see Table 1). The low ability of the acridinyl radical to abstract a hydrogen atom has also been found in the photolysis of acridine.[11,16] In the case of the photoreduction of acridine in hydrogen donative alcohols, a disproportionation of the 9,10-dihydroacridinyl radicals has been assumed for the mechanism of the 9,10-dihydroacridine formation (Eq. 2).[16] A possible mechanism for the $(AH)_2$ formation can be represented as:

$${}^3MeOA^* \longrightarrow AH\cdot + MeO\cdot \quad (11)$$

$$2AH\cdot \longrightarrow (AH)_2 \quad (12)$$

$$2MeO\cdot \longrightarrow MeOH + HCHO \quad (13)$$

The two-step mechanism, however, may still remain if a contact radical pair of AH· and MeO· is produced by the electron transfer from MeO^- to A^+ (Eq. 9) and if a subsequent hydrogen abstraction by AH· from MeO· (Eq. 10) occurs instantaneously. At the present stage, we cannot distinguish this two-step mechanism (a total hydride transfer mechanism) from the hydride transfer mechanism.

Conclusion

We have pesented mechanisms for the photochemical reactions of MeOA yielding AH_2 and $(AH)_2$. There is no doubt that the photolysis of a dilute methanolic solution of A^+Cl^- occurs via MeOA. The reaction mechanisms can be represented as Eqs. 5—8 and 11—13. At higher concentration of A^+Cl^-, the direct photoreaction of A^+Cl^- with methanol cannot be excluded because A^+Cl^- and MeOA coexist in the system. We found, however, that A^+Cl^- (5×10^{-5} M) in methanol containing 2×10^{-4} M HCl does not show any photochemical reaction. This indicates the absence of any reactivity of the 10-methylacridinium cation toward photolysis in the hydrogen-donative alcohol. The mechanism involving MeOA as an intermediate seems to be reasonable, even for the photolysis of A^+Cl^- at higher concentrations.

Free Radical Addition of 2-Bromoalkanoic Acids to Alkenes

Taichi NAKANO,* Mikio KAYAMA,† and Yoichiro NAGAI*
Department of Chemistry, Faculty of Technology, Gunma University, Tenjin-cho, Kiryu 376
(Received September 9, 1986)

The benzoyl peroxide-catalyzed reaction of 2-bromoalkanoic acids such as bromoacetic, 2-bromopropionic, and 2-bromobutyric acid with 1-alkenes was found to proceed through the addition of the C-Br bond across the double bond followed by cyclization affording 4-alkanolides in good yields.

There has been considerable interest in the construction of γ-butyrolactone skeleton, since γ-butyrolactones act as precursors for biologically active α,β-butenolides[1] or 2-methylene-4-alkanolides,[2] and are sometimes used for flavor and additive for foods.[3]

Although a variety of synthetic methods for the construction of γ-butyrolactone skeleton have been reported,[4] we present in this paper a convenient method for the construction of γ-butyrolactone structure which is easily accomplished by the reaction of a 2-bromoalkanoic acid with simple alkenes in the presence of benzoyl peroxide.[5]

Experimental

Boiling points are uncorrected. GLC analysis was performed on an Ohkura Model 802 instrument equipped with a thermal conductivity detector and 6 mmϕ×1—2 m columns packed with Celite 545AW (60—80 mesh) coated with Silicone DCQF-1 (20%). The yields determined by GLC were corrected with thermal conductivity coefficients. IR spectra were recorded on a Jasco A 102 spectrophotometer, and ^{1}H NMR spectra were obtained on a Varian Associate Model EM-360 spectrometer. Chemical shifts(δ) are given in ppm relative to tetramethylsilane as an internal standard. Abbreviations for multiplicity are t; triplet and m; multiplet. Di-*t*-butyl peroxide[6] and the ruthenium(II) complex[7] were prepared according to literature directions. Benzoyl peroxide (BPO), 2,2′-azobisisobutyronitrile (AIBN), copper(I) chloride, bromoacetic acid, 2-bromopropionic acid, and 2-bromobutyric acid were commercially available and used without further purification. Alkenes were purchased commercially and distilled from calcium hydride prior to use. Known 4-alkanolides obtained in the present work were identified by comparing their physical properties with those of an authentic sample, and for the new compounds, structural determination was made by elementary analysis as well as spectral analysis. All of the physical data for the new compounds are compiled in Table 3.

BPO-, DTBP-, and AIBN-Catalyzed Reactions Were Carried Out as Follows. To a refluxing mixture of bromoacetic acid (12 mmol), 1-octene (10 mmol), and benzene (15 ml) was added with stirring a solution of a catalyst (1—2 mmol) in benzene (15 ml) during 1 h under nitrogen. After the addition was completed, the resulting mixture was refluxed for additional 5—15 h and then subjected to GLC analysis.

CuCl-Catalyzed Reaction. A mixture of bromoacetic acid (12 mmol), 1-octene (10 mmol), acetonitrile (4 ml), and copper(I) chloride (0.6 mmol) was introduced into a glass ampoule. The mixture was degassed through several freeze-evacuate-thaw cycles prior to sealing in vacuo. Then, the sealed ampoule was kept at 80 °C for 12 h. GLC analysis of the resulting mixture disclosed that the expected γ-butyrolactone (**3**) was not produced at all. The starting materials were recovered.

$RuCl_2(PPh_3)_3$-Catalyzed Reaction. A mixture of bromoacetic acid (12 mmol), 1-octene (10 mmol), and the ruthenium(II) complex (0.18 mmol) was heated at reflux for 10 h under argon. GLC analysis of the resulting mixture showed that the alkene was consumed in 41% and the lactone (**3**) was formed in 30% yield.

A Typical Example for the Synthesis of 4-Alkanolides. 2-Methyl-4-nonanolide (7): To a refluxing mixture of 2-bromopropionic acid (19.6 g, 128 mmol), 1-heptene (9.8 g, 100 mmol), and benzene (30 ml) was added with stirring a solution of BPO (3.6 g, 15 mmol) in benzene (45 ml) during 1 h under nitrogen. The reflux was further continued for additional 9 h. The resulting mixture was washed with water and dried with magnesium sulfate. Distillation of the mixture gave 13.0 g (78% yield) of **7**.

Results and Discussion

Initially, catalytic activity of several catalysts such as benzoyl peroxide, di-*t*-butyl peroxide, azobisiso-

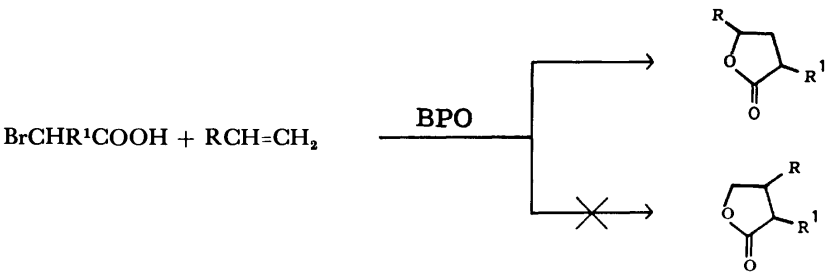
butyronitrile, copper(I) chloride, and dichlorotris-(triphenylphosphine)ruthenium(II) complex toward the reaction of bromoacetic acid with 1-octene was investigated. The results are summarized in Table 1 which shows that benzoyl peroxide is the most favorable catalyst. BPO-catalyzed reactions of 2-bromoalkanoic acids (bromoacetic, 2-bromopropionic, and 2-bromobutyric acid) with some 1-alkenes were carried out, the results being shown in Table 2. As is clearly seen from the Table, the reaction of bromoacetic acid with 1-alkenes afforded the corresponding γ-butyrolactones in 65—77% yields. In each reaction, a small amount of debrominated carboxylic acid (2—3% yield) was produced as a by-product, but γ-butyrolactones could be readily isolated by means of simple fractional distillation. Similarly, the reactions of 2-bromopropionic and 2-bromobutyric acid with 1-alkenes gave the corresponding 2-methyl- or 2-ethyl-4-alkanolides in 50—80% yields.

In these reactions, the Markownikoff-type products, $RCH(OOCHBrR^1)CH_3$, were not detected to any appreciable extent. In all cases the γ-butyrolactones thus obtained possess an alkyl group in the γ-position only (Eq. 1).



(1)

The observed regioselectivity is in accord with the finding of Kharasch et al. that carbon–carbon bond formation in the reaction of bromoacetic acid with 1-hexene takes place exclusively on the terminal carbon atom of the alkene under free radical conditions (vide post, Eq. 9).[8] In the reaction of 2-bromopropionic and 2-bromobutyric acid with 1-alkenes, the formation of two geometrical isomers (cis

a) To a refluxing 1.2 : 1 benzene solution of a 2-bromoalkanoic acid and an alkene was added with stirring a solution of BPO(0.1 equiv) in benzene during 1 h. Then, the mixture was heated for 5—9 h. b) Determined by GLC. In parentheses are shown isolated yields. c) See Ref. 10). d) See Ref. 11). e) See Ref. 12). f) See Ref. 13). g) See Ref. 14). h) See Ref. 15). i) See Ref. 16).

Table 3. Physical Properties of New γ-Butyrolactones

Lactone No.	IR($\nu_{C=O}$)	^{1}H NMR (δ, ppm)	Elemental Analysis[a] C	H
[9]	1775	4.26(m, 1H, -O-C-H), 2.33(m, 3H, =CHH, -COC<u>H</u>(CH_3)-), 1.15(m, 15H, -$(CH_2)_6$-, -COCH(C<u>H</u>$_3$)-), 0.92(t, 3H, -CH_3)	73.11 (72.68	11.29 11.18)
[11]	1770	4.22(m, 1H, -O-C-H), 2.27(m, 3H, =CHH, -COC<u>H</u>(CH_2-CH_3)-), 1.57(m, 8H, -$(CH_2)_3$-, -COCH(C<u>H</u>$_2$$CH_3$)-), 0.87(m, 6H, -$CH_3$, -COCH($CH_2$C<u>H</u>$_3$)-)	70.55 (70.55	10.66 10.66)
[12]	1770	4.17(m, 1H, -O-C-H), 2.25(m, 3H, =CHH, -COC<u>H</u>(CH_2-CH_3)-), 1.54(m, 10H, -$(CH_2)_4$-, -COCH(C<u>H</u>$_2$$CH_3$)-), 0.93(m, 6H, -COCH($CH_2$C<u>H</u>$_3$), -$CH_3$)	71.36 (71.70	11.01 10.94)
[14]	1770	4.34(m, 1H, -O-C-H), 2.33(m, 3H, =CHH, -COC<u>H</u>(CH_2-CH_3)-), 1.62(m, 14H, -$(CH_2)_6$-, -COCH(C<u>H</u>$_2$$CH_3$)-), 1.00(m, 6H, -COCH($CH_2$C<u>H</u>$_3$)-, -$CH_3$)	73.75 (73.54	11.34 11.39)
[15]	1770	4.23(m, 1H, -O-C-H), 2.27(m, 3H, =CHH, -COC<u>H</u>(CH_2-CH_3)-), 1.57(m, 16H, -$(CH_2)_7$-, -COCH(C<u>H</u>$_2$$CH_3$)-), 0.91(m, 6H, -COCH($CH_2$C<u>H</u>$_3$)-, -$CH_3$)	74.05 (74.29	11.54 11.58)

a) In parentheses are shown calculated values.

and trans) is possible. For example, ^{13}C NMR analysis revealed 2-methyl-4-octanolide (**6**) thus obtained to be a mixture of two geometrical isomers,[9] although isomer ratio was not ultimately determined.

A plausible pathway leading to γ-butyrolactone involves the free radical addition of a 2-bromoalkanoic acid to an alkene through the rupture of the C-Br bond to give the expected 1 : 1 adduct followed by subsequent cyclization. Thus, the formation of the 4-bromoalkanoic acid [**C**] is simply explained in terms of a free-radical chain process, involving the two chain-carrying species [**A**] and [**B**] (Eqs. 5 and 6).

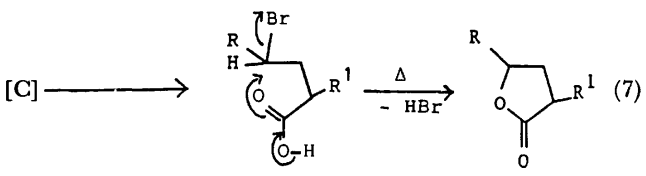
$$\text{BPO} \longrightarrow 2\,\text{PhCOO}\cdot \quad (2)$$

$$\text{PhCOO}\cdot \longrightarrow \text{Ph}\cdot + CO_2 \quad (3)$$

$$\text{Ph}\cdot + \text{BrCHR}^1\text{COOH} \longrightarrow \underset{[\mathbf{A}]}{\text{PhBr} + \cdot\text{CHR}^1\text{COOH}} \quad (4)$$

$$[\mathbf{A}] + \text{RCH=CH}_2 \longrightarrow \underset{[\mathbf{B}]}{\text{RCHCH}_2\text{CHR}^1\text{COOH}} \quad (5)$$

$$[\mathbf{B}] + \text{BrCHR}^1\text{COOH} \longrightarrow \underset{[\mathbf{C}]}{\text{RCHBrCH}_2\text{CHR}^1\text{COOH}} + [\mathbf{A}] \quad (6)$$



(7)

Ring closure of the adduct [**C**] with liberation of hydrogen bromide can be most conveniently interpreted by the intramolecular nucleophilic substitution (Eq. 7). Formation of the debrominated adducts is elucidated in terms of the attack of [**B**] on the labile allylic hydrogens in 1-alkenes, HS, (Eq. 8).

$$[\mathbf{B}] + \text{HS} \longrightarrow \underset{\text{H}}{\text{RCHCH}_2\text{CHR}^1\text{COOH}} + \cdot\text{S} \quad (8)$$

In fact, Kharasch et al.[8] reported that the photolysis of bromoacetic acid in excess 1-hexene yielded octanoic acid in 80% yield (Eq. 9).

$$\text{BrCH}_2\text{COOH} + \text{C}_4\text{H}_9\text{CH=CH}_2 \xrightarrow{h\nu} \text{C}_7\text{H}_{15}\text{COOH} \quad (9)$$

Syntheses and Some Reactions of 4*H*-Cyclohepta[4,5]-pyrrolo[1,2-*a*]pyrimidin-4-ones

Noritaka Abe
Department of Chemistry, Faculty of Sciences, Yamaguchi University, Yamaguchi 753
(Received September 10, 1986)

The reaction of 2-aminocyclohepta[*b*]pyrroles with ethyl acetoacetate in phoshoryl chloride–polyphosphoric acid gives 2-methyl-4*H*-cyclohepta[4,5]pyrrolo[1,2-*a*]pyrimidin-4-ones. A ring closure of diethyl *N*-(cyclohepta[*b*]pyrrol-2-yl)aminomethylenemalonates gives 4-oxo-4*H*-cyclohepta[4,5]pyrrolo[1,2-*a*]pyrimidine-3-carboxylates (**2**) in phosphoryl chloride–polyphosphoric acid or in hot *t*-butylbenzene, which are deesterified by the treatment with hot hydrobromic acid. Compounds **2** undergo replacement reactions towards some electrophiles at positions C-3, C-11, and C-7 (in that order).

Hetero-annulated azaazulenes are interesting compounds for their physical and chemical properties as well as physiolosical activities. Although some synthetic studies on hetero-annulated azaazulenes are known,[1–4] investigations on azaazulenes fused with a pyrimidine ring are rare,[5,6] in spite of the attractive attention on hetero-annulated pyrimidines.[7,8] In this paper, I wish to report on the syntheses of 4*H*-cyclohepta[4,5]pyrrolo[1,2-*a*]pyrimidin-4-ones by means of the annulation of 2-aminocyclohepta[*b*]-pyrroles (2-amino-1-azaazulenes) in a phosphoryl chloride–polyphosphoric acid mixture ($POCl_3$–PPA), a useful condensing agent.[9]

The treatment of ethyl 2-aminocyclohepta[*b*]pyrrole-3-carboxylate[2,6] (**1a**) with ethyl acetoacetate (EAA) in $POCl_3$–PPA for 1 h at 115 °C yielded ethyl 2-methyl-4-oxo-4*H*-cyclohepta[4,5]pyrrolo[1,2-*a*]pyrimidine-11-carboxylate (**2a**) in 81% yield (which was stimulative). Deesterification of **2a** with hot 48% hydrobromic acid (HBr) gave 2-methyl-4*H*-cyclohepta-[4,5]pyrrolo[1,2-*a*]pyrimidin-4-one (**2b**) in 80% yield together with cyclohepta[*b*]pyrrol-2(1*H*)-one[10] (2%). The structure of **2b** was confirmed from observing the deshielding effects produced by tris(dipivaloylmethanato)europium shift reagent [Eu(dpm)$_3$] on the ^{1}H NMR spectrum. The ^{1}H NMR spectrum of **2b** shows protons at δ 2.45 (s, Me), 6.18 (s, H-3), 6.71 (s, H-11), 6.90—7.35 (m, H-7, 8, and 9), 7.55—7.85 (m, H-10), and 9.50—9.75 (m, H-6). The addition of Eu(dpm)$_3$ produced progressive down-field chemical shifts, and protons were observed at δ 3.47 (s, Me), 7.10—7.60 (m, H-7, 8, and 9), 7.68 (s, H-11), 8.15—8.45 (m, H-10), 9.43 (s, H-3), and 13.85—14.10 (m, H-6). Protons at C-3 and C-6 are most affected, to the extent of 3.25 and 4.35 ppm, respectively; these are much larger than those of H-11 and H-10, 0.97 and 0.60 ppm, respectively. These show that the complexing of the Eu(dpm)$_3$ with amide oxygen at C-4, not at C-2 of **3**, gives rise to a predominant deshilding effect positions C-3 and C-6. If the carbonyl group is present at C-2 as **3**, only the proton of C-3 should be deshilded predominantly.

When 2-aminocyclohepta[*b*]pyrrole[4,11] (**1b**) was treated in a similar manner as for **1a**, the reaction was rather complex and compound **2b** could be isolated only in low yield.

In a similar treatment of **1a** with ethyl benzoate (EBA) in $POCl_3$–PPA, **2c** and **2d** were obtained in moderate yields.

Unsubstituted 4*H*-cyclohepta[4,5]pyrrolo[1,2-*a*]pyrimidin-4-one (**2h**) was synthesized by the reaction of 2-aminocyclohepta[*b*]pyrroles (**1**) with diethyl ethoxymethylenemalonate (DEEM) and a subsequent cyclization and deesterification.

The treatment of **1a—c** with DEEM in hot ethanol or hot 1-butanol gave diethyl *N*-(cyclohepta[*b*]pyrrol-2-yl)aminomethylenemalonates (**4a—c**), respectively, in excellent yields. The ^{1}H NMR spectra of **4a—c** shows low-field resonated olefinic protons at δ 9.1—9.2 which couple (J=13 Hz) with amine protons at δ 11.3—12.5. By adding of D_2O, latter signals were disappeared and former changed to singlets. The results show that the substitution occurred on the amino group at C-2 of **1**, not on the N-1 position. Regarding the reaction of **1b** with DEEM, thermal cyclization partly occurred, and small amount of **2f** was obtained. In the ^{1}H NMR spectrum of **2f**, two signals of singlets can be seen at δ 7.00 (H-11) and 8.97 (H-2), and seven-menbered ring protons at δ 7.25—7.70 (3H, m, H-7, 8, and 9), 7.85—8.20 (1H, m, H-10), and 10.05—10.40 (1H, m, H-6), besides an ethyl ester group. The low-field appearance of the H-6 proton may be due to a shielding effect by the carbonyl group.

Compound **2f** was easily deesterified by the treatment with a hot 48% HBr–PPA mixture to give **2h** in 75% yield. The ^{1}H NMR spectrum of **2h** shows two 1H doublets (J=6.5 Hz) at δ 6.35 (H-3) and 8.15 (H-2) and low-field resonated 1H multiplet at δ 9.60—9.85 (H-6). The results agree with the report that H-2 protons resonate at δ ca. 8.1 and H-6 protons at lowest field in ^{1}H NMR spectra of 4-oxopyrimido[2,1-*b*]-benzazoles.[12]

The treatment of **2e** with 48% HBr or 48%HBr–PPA gave **2h** in low yields together with cyclohepta[*b*]-pyrrol-2(1*H*)-one[10] and **1b** which should be hydrolyzed products.

Cyclizations of **4a—c** were achieved by heating in xylene, *t*-butylbenzene, or tetralin, and yielded **2e—g**,

in moderate to excellent yields. Treatment of **4a** with $POCl_3$–PPA at 120 °C for 1h yielded **2e** in 95% yield. Similar treatment of **4b** with $POCl_3$–PPA resulted in complex mixture. From the mixture, **2f** was isolated in 17% yield together with yellow prisms **5** (48%). Compound **5** was assigned as ethyl 1,4-dihydro-4-oxocyclohepta[4,5]pyrrolo[2,3-*b*]pyridine-3-carboxylate. The IR spectra of **5** exhibits a signal at 3370 cm^{-1} assignable to NH. In its ^1H NMR, no signals are seen around δ 7.0; it does exhibit the signals of seven-membered ring protons at δ 7.75—8.15 (3H, m, H-6, 7, and 8), 8.45—8.75 (1H, m, H-9), and 9.75—10.00 (1H, m, H-9). It is known that ethyl 6-methyl-4-oxo-4*H*-pyrido[1,2-*a*]pyrimidine-3-carboxylate transformed thermally to ethyl 7-methyl-1,4-dihydro-4-oxo-1,8-naphthyridine-3-carboxylate.[13] However, an interconversion of **2f** and **5** was not observed under the conditions of boiling *t*-butylbenzene or hot $POCl_3$–PPA. Therefore, **5** would be directly produced from **4b**.

Electrophilic Replacement of 2. Compound **2h** was deuteriated by a treatment with D_3PO_4 or CF_3CO_2D to give 3,11-dideuteriated product **2i**. Bromination of **2h** gave 3,11-dibrominated compound **2j** in excellent yield. Bromination of **2f** gave **2k** in 82% yield. When the positions (C-3 and 11) were blocked, bromination occurred at C-7 position; thus the brominatin of **2e** afforded **21** in 15% yield. When Vilsmeier-Haak reaction of **2h** was carried out at 65 °C, a 3-formylated product **2m** (24%) and a 3,11-diformylated product **2n** (18%) were obtained. Compound **2f** was formylated at C-11 position to give **2o** in 44% yield, but **2e** was not formylated at all. These results show that compounds **2** were reactive towards some electrophiles at the positions of C-3, C-11, and C-7, in the order.

Experimental

Melting points were uncorrected. ^1H NMR spectra were recorded on a Hitachi R-24B spectrometer and ^{13}C NMR spectra on a JEOL FX-100 spectrometer using deuteriochloroform as a solvent with tetramethylsilane as an internal standard, unless otherwise stated. IR spectra were recorded on a JASCO IR-G spectrometer for Nujol mulls and electronic spectra on a Hitachi 220A spectrophotometer for ethanol solutions. Kieselgel 60 was used for column chromatography.

Reaction of 1 with EAA. A mixture of **1a** (1.729 g, 8.00 mmol), EAA (4.16 g, 32.0 mmol), $POCl_3$ (4.90 g, 32.0 mmol), and PPA (3.0 g) was stirred for 1 h at 115 °C. After hydrogen chloride evolution has ceased, ethanol (10 ml) was added, and the mixture was heated for 10 min at 100 °C. The reaction mixture was poured into ice-water (200 ml), neutralized with Na_2CO_3, extracted with chloroform, dried (Na_2SO_4), and evaporated to dryness. Chromatography of the residue with chloroform gave **2a** (1.826 g, 81%), which, was crystallized from cyclohexane-dichloromethane to give reddish violet prisms (1.170 g, 52%), mp 176—178 °C; λ_{max} 217 nm (log ε 4.40), 236 (4.38), 268 (4.52), 288 (4.29), 297 (4.28, sh), 431 (4.07), and 490 (3.77, sh); ν_{max} 1675 (ester C=O) and 1665 cm^{-1} (amido C=O); ^1H NMR δ=1.48 (3H, t, J=7 Hz, Me), 2.53 (3H, s, Me), 4.48 (2H, q, J=7 Hz, OCH_2), 6.25 (1H, s, H-3), 7.35—7.70 (3H, m, H-7, 8, and 9), 8.95—9.30 (1H, m, H-10), and 10.05—10.30 (1H, m, H-6). Anal. ($C_{16}H_{14}N_2O_3$) C, H, N. Elution with ethyl acetate gave **1a** (0.178 g, 10%).

In a similar manner, **1b** gave **2b** (14%).

2b: Dark violet needles (from cyclohexane-dichloromethane), mp 196—198 °C; λ_{max} 260 nm (log ε 4.54), 289 (4.14), 299 (4.13, sh), 400 (3.99), 425 (4.01), 479 (3.71), 510 (3.67, sh), 545 (3.50, sh); ν_{max} 1675 (amido C=O); ^1H NMR δ=2.45 (3H, s, Me), 6.18 (1H, s, H-3), 6.71 (1H, s, H-11), 6.90—7.35 (3H, m, H-7, 8, and 9), 7.55—7.85 (1H, m, H-10), and 9.50 (1H, m, H-6), δ[$CDCl_3$-Eu(dpm)$_3$]= 3.47 (3H, s, Me), 7.10—7.60 (3H, m, H-7, 8, and 9), 7.68 (1H, s H-11), 8.15—8.45 (1H, m, H-10), 9.43 (1H, s, H-3), and 13.85—14.10 (1H, m, H-6), δ (CF_3CO_2D)=2.68 (3H, s, Me), 6.48 (1H, s, H-3, exch.), 7.33 (1H, s, H-11, exch.), 8.10—8.50 (3H, m, H-7, 8, and 9), 8.65—8.90 (1H, m, H-10), and 10.35—10.70 (1H, m, H-6). Anal. ($C_{13}H_{10}N_2O$) C, H, N.

Deesterification of 2a. a) A solution of **2a** (0.800 g, 2.83 mmol) in 48% HBr (10 ml) was heated under reflux for 2 h, and poured into water (200 ml). The mixture was neutralized with $NaHCO_3$, extracted with chloroform, dried

(Na_2SO_4), and evaporated to dryness. Chromatography of the residue with chloroform gave **2b** (0.481 g, 80%). Elution with ethyl acetate gave cyclohepta[*b*]pyrrol-2(1*H*)-one[10] (0.010 g, 2%).

b) A mixture of **2a** (0.200 g, 0.71 mmol) and PPA (5.0 g) was heated at 150 °C for 3 h, and worked up as above. Chromatography of the residue with chloroform gave **2a** (0.060 g, 30%) and **2b** (0.084 g, 56%), successively.

Reaction of 1a with EBA. a) A mixture of **1a** (0.432 g, 2.00 mmol), EBA (1.54 g, 8.00 mmol), $POCl_3$ (2.46 g, 16.0 mmol), and PPA (3.0 g) was stirred at 120 °C for 3 h. The reaction mixture was treated as for **1a** with EAA. Chromatography of the residue with chloroform gave **2c** (0.347 g, 50%), which was crystallized from cyclohexane-dichloromethane to give reddish violet needles (0.180 g, 26%), mp 201—203 °C; λ_{max} 212 nm (log ε 4.39), 258 (4.48), 273 (4.42, sh), 297 (4.38), 315 (4.36, sh), 353 (3.87, sh), 435 (3.97), and 495 (3.69, sh); ν_{max} 1675 (ester C=O) and 1655 (amido C=O); ^{1}H NMR δ=1.55 (3H, t, J=7 Hz, Me), 4.49 (2H, q, J=7 Hz, OCH_2), 6.82 (1H, s, H-3), 7.10—7.65 (6H, m, H-7, 8, 9, and *m,p*-phenyl), 8.00—8.25 (2H, m, H-*o*-phenyl), 9.00—9.40 (1H, m, H-10), and 10.00—10.25 (1H, m, H-6). Anal. ($C_{21}H_{16}N_2O_3$) C, H, N.

b) When the above reaction was carried out under reflux for 1 h and worked up, compound **2d** (0.055 g, 10%) was isolated by chromatography with chloroform; this was crystallized from cyclohexane-dichloromethane to give brown needles (0.030 g, 5%), mp 201—203 °C; λ_{max} 261 nm (log ε 4.50), 288 (4.50), 300 (4.44, sh), 345 (3.88, sh), 403 (3.93), 428 (3.99), 486 (3.72), 510 (3.71, sh), 550 (3.56, sh), and 605 (3.09, sh); ν_{max} 1660 cm^{-1} (amido C=O); ^{1}H NMR δ=6.82 (1H, s, H-3), 6.92 (1H, s, H-11), 7.00—7.30 (3H, m, H-7, 8, and 9), 7.35—7.55 (3H, m, H-*m,p*-phenyl), 7.60—7.95 (1H, m, H-10), 8.00-8.20 (2H, m, H-*o*-phenyl), and 9.65—9.90 (1H, m, H-6). Anal. ($C_{18}H_{12}N_2O$), C, H, N.

Reaction of 1 with DEEM. a) A mixture of **1a** (2.60 g, 12.0 mmol) and DEEM (7.80 g, 36.1 mmol) in abs ethanol (100 ml) was heated under reflux for 48 h, then evaporated. Chromatography of the residue with chloroform gave **4a** (4.197 g, 90%), which was crystallized from cyclohexane-dichloromethane to give yellow needles (3.601 g, 77%), mp 158—160 °C; λ_{max} 266 nm (3.96), 311 (4.37), 317 (4.36, sh), 330 (4.31), 386 (4.40), 443 (3.54); ν_{max} 3200 (NH), 1685, 1670, and 1650 cm^{-1} (ester C=O); ^{1}H NMR δ=1.38, 1.41, and 1.53 (each 3H, t, J=7 Hz, Me), 4.28, 4.40, and 4.53 (each 2H, q, J=7 Hz, OCH_2), 7.60—7.95 (3H, m, H-5, 6, and 7), 8.25—8.50 (1H, m, H-8), 9.00—9.30 (1H, m, H-4), 9.20 (1H, d, J=13 Hz, NHC<u>H</u>), 12.53 (1H, bd, J=13 Hz, NH, exch.). Anal. ($C_{20}H_{22}N_2O_6$) C, H, N. Elution with ethyl acetate gave 1a (0.075 g, 3%).

In a similar manner, **1b** gave **4b** (95%) and **2f** (4%).

4b: Reddish orange prisms (from cyclohexane-dichloromethane), mp 129—131 °C; λ_{max} 239 nm (log ε 4.21, sh), 246 (4.22), 253 (4.21), 286 (4.33, sh), 295 (4.41), 328 (4.55), 381 (4.50), 455 (3.89); ν_{max} 3250 (NH), 1690 and 1675 cm^{-1} (ester C=O); ^{1}H NMR δ=1.34 and 1.38 (each 3H, t, J=7 Hz, Me), 4.28 and 4.34 (each 2H, q, J=7 Hz, OCH_2), 6.83 (1H, s, H-3), 7.3—7.85 (3H, m, H-5, 6, and 7), 8.05—8.50 (2H, m, H-4 and 8), 9.10 (1H, d, J=13 Hz, NHC<u>H</u>), 11.35 (1H, bd, J=13 Hz, NH, exch.). Anal. ($C_{17}H_{18}N_2O_4$) C, H, N.

2f: Red needles (from cyclohexane-dichloromethane), mp 179—181 °C; λ_{max} 237 nm (log ε 4.32), 263 (4.48), 305 (4.06), 403 (3.90, sh), 428 (4.04), 480 (3.95, sh), 495 (3.97); ν_{max} 1735 (ester C=O) and 1655 cm^{-1} (amido C=O); ^{1}H NMR δ=1.42 (3H, t, J=7 Hz, Me), 4.40 (2H, q, J=7 Hz, OCH_2), 7.00 (1H, s, H-11), 7.25—7.70 (3H, m, H-7, 8, and 9), 7.85—8.20 (1H, m, H-10), 8.97 (1H, s, H-2), and 10.05—10.40 (1H, m, H-6). Anal. ($C_{15}H_{12}N_2O_3$) C, H, N.

b) When above reaction was carried out in hot 1-butanol, **1a** and **1c** gave **4a** (95%) and **4c** (96%), respectively.

4c: Yellow needles (from cyclohexane-dichloromethane), mp 210—212 °C; λ_{max} 242 nm (log ε 3.94, sh), 262 (4.12), 305 (4.48), 329 (4.48), 382 (4.45), 445 (3.66); ν_{max} 3190 (NH), 2210 (CN), 1700, and 1660 cm^{-1} (ester C=O); ^{1}H NMR δ=1.37 and 1.40 (each 3H, t, J=7 Hz, Me), 4.31 and 4.40 (each 2H, q, J=7 Hz, OCH_2), 7.75—7.95 (3H, m, H-5, 6, and 7), 8.27—8.53 (2H, m, H-4 and 8), 9.10 (1H, d, J=13 Hz, NHC<u>H</u>), and 11.62 (1H, bd, J=13 Hz, exch.). Anal. ($C_{18}H_{17}N_3O_4$) C, H, N.

Cyclization of 4. a) A mixture of **4a** (4.910 g, 12.7 mmol), $POCl_3$(18.0 g), and PPA (4.0 g) was stirred for 1 h at 120 °C. To the mixture, ethanol (20 ml) was added, and the mixture was heated for 10 min at 100 °C. The reaction mixture was poured into ice-water (200 ml), neutralized with Na_2CO_3, extracted with chloroform, dried (Na_2SO_4), and evaporated. Chromatography of the residue with chloroform gave **2e** (4.110 g, 95%), which was crystallized from cyclohexane-dichloromethane to give red needles (3.910 g, 90%), mp 213—215°C; λ_{max} 233 nm (log ε 4.34), 266 (4.50), 299 (4.22), 310 (4.18, sh), 431 (3.98), 475 (4.00); ν_{max} 1725 and 1670 (ester C=O), and 1655 cm^{-1} (amido C=O); ^{1}H NMR δ=1.43, 1.50 (each 3H, t, J=7 Hz, Me) 4.42, 4.55 (each 2H, q, J=7 Hz, OCH_2), 7.65—8.00 (3H, m, H-7, 8, and 9), 9.07(1H, s, H-2), 9.25—9.55 (1H, m, H-10), and 10.35—10.65 (1H, m, H-6). Anal. ($C_{18}H_{16}N_2O_5$) C, H, N.

In a similar treatment, **4b** gave **2f** (17%) and **5** (48%).

5: Yellow prisms (from methanol-ethyl acetate), mp 234—236 °C; λ_{max} 260 nm (log ε 4.12, sh), 282 (4.40), 315 (4.47), 388 (3.89), 435 (2.98, sh); ν_{max}3370 (NH), 1715 (ester C=O), and 1705 (C=O); ^{1}H NMR δ=1.41 (3H, t, J=7 Hz, Me), 4.42 (2H, q, J=7 Hz, OCH_2), 7.75—8.15 (3H, m, H-6, 7, and 8), 8.45—8.75 (1H, m, H-9), 8.4—9.0 (1H, broad, NH), 8.83 (1H, s, H-2), and 9.75—10.00 (1H, m, H-5); MS (70 eV) *m/z* (rel intensity) 268 (M^+; 50), 222 (61), 196 (34), 194 (100), 166 (29), 140 (47), 139 (54), and 113 (21). Anal. ($C_{15}H_{12}N_2O_3$) C, H, N.

b) Solutions of **4a** and **4b** (0.795 mmol) in tetralin (3 ml) were heated under reflux for 1 h and evapolated. Chromatography of the residue with chloroform gave **2e** (46%), and **2f** (46%), respectively.

c) A solution of **4b** (0.300 g, 0.954 mmol) in *t*-butylbenzene (5 ml) was heated under reflux for 12 h and evaporated. Chromatography of the residue with chloroform gave **2f** (0.266 g, 88%).

d) A solution of **4c** (0.150 g, 0.442 mmol) in dry xylene (30 ml) was heated under reflux for 48 h and evaporated. The residue was chromatographed. Elution with chloroform gave **4c** (0.014 g, 9%). Further elution gave **2g** (0.117 g, 90%), mp 240—242 °C (dec); λ_{max} 232 nm (log δ 4.40), 267 (4.57), 297 (4.24), 305 (4.21, sh), 435 (4.06), 475 (4.03); ν_{max} 2230 (CN), 1730 (ester C=O), and 1670 cm^{-1} (amido C=O); ^{1}H NMR δ=1.43, (3H, t, J=7 Hz, Me), 4.38 (2H, q, J=7 Hz, OCH_2), 7.70—8.00 (3H, m, H-7, 8, and 9), 8.30—8.60 (1H, m, H-10), 9.00 (1H, s, H-2), 10.40—10.60 (1H, m, H-6). Anal. ($C_{16}H_{11}N_3O_3$) C, H, N.

Deesterifications of 2. A mixture **2f** (0.300 g, 1.19 mmol), PPA (4.0 g), and 48% HBr (15 ml) was heated under reflux for 1 h, then poured into ice-water (200 ml). The mixture was neutralized with Na_2CO_3, extracted with chloroform, dried (Na_2SO_4), and evaporated. The residue was chromatographed with chloroform to give **2h** (0.210 g, 96%), which was crystallized from cyclohexane-dichloromethane to give dark violet needles (0.167 g, 76%), mp 160—162 °C; λ_{max} 225 nm (log ε 4.19), 256 (4.42), 288 (4.03, sh), 397 (3.93), 425 (3.92), 482 (3.64), 505 (3.62); ν_{max} 1660 (amido C=O); ^{1}H NMR δ=6.35 (1H, d, J=6.5 Hz, H-3), 6.83 (1H, s, H-11), 6.95—7.45 (3H, m, H-7, 8, and 9), 7.55—7.90 (1H, m, H-6), 8.15 (1H, d, J=6.5 Hz, H-2), 9.60—9.85 (1H, m, H-10); ^{13}C NMR δ=106.3 (C-11), 108.2 (C-3), 125.9 (C-9), 131.7 (C-7), 132.0 (C-8), 133.8 (C-10), 135.9 (C-6), 141.9 (C-10a), 144.0 (C-5a), 153.4 (C-2), 157.8 (C-11a), 162.2 (C-4). Anal. ($C_{12}H_8N_2O$) C, H, N.

In a similar manner, **2e** gave **2h** (16%) and cyclohepta[*b*]-pyrrol-2(1*H*)-one[10] (5%).

Deutriation of 2h. Compound **2h** (0.090 g, 0.46 mmol) was dissolved in D_3PO_4(1.0 g) and set for 7 d at ambient temperature. The solution was diluted with water (100 ml), neutralized with $NaHCO_3$, extracted with chloroform, and dried (Na_2SO_4). Evaporation of the solution gave **2i** (0.089 g, 98%), which was crystallized from cyclohexane-dichloromethane to give violet needles (0.060 g, 73%), mp 160—161 °C; ^{1}H NMR δ=6.90—7.35 (3H, m, H-7, 8, and 9), 7.55—7.85 (1H, m, H-10), 8.14 (1H, s, H-2), 9.55—9.75 (1H, m, H-6); MS (70 eV) *m/z* (rel intensity) 198 (M^+; 100), 170 (67) 115 (12).

Bromination of 2. A solution of **2h** (0.150 g, 0.76 mmol) and bromine (0.30 g, 1.87 mmol) in acetic acid (4 ml) was stirred for 24 h at ambient temperature. The reaction mixture was diluted with water (100 ml) and neutralized with $NaHCO_3$. The precipitate formed were collected by filtration and washed with water to give **2j** (0.265 g, 98%), which was crystallized from cyclohexane-dichloromethane to give brown needles, (0.176 g, 65%), mp 223 °C (decomp); λ_{max} 221 nm (log ε 4.43), 270 (4.47), 300 (4.06, sh), 418 (4.09), 445 (4.11), 505 (3.74) 534 (3.71), 575 (3.55, sh); ν_{max} 1680 cm^{-1} (amido C=O); ^{1}H NMR δ=7.20—7.50 (3H, m, H-7, 8, and 9), 7.75—8.00 (1H, m, H-10), 8.52 (1H, s, H-2), 9.70—9.85 (1H, m, H-6). Anal. ($C_{12}H_6Br_2N_2O$) C, H, N.

In a similar manner, **2f** and **2e** gave **2k** (82%) and **21** (15%), respectively.

2k: Violet prisms (from cyclohexane-dichloromethane), mp 204—206 °C; λ_{max} 220 nm (log ε 4.43) 238 (4.35), 269 (4.46), 297 (4.04), 303 (4.03), 420 (3.96), 444 (4.11), 490 (3.90), 513 (3.90); ν_{max} 1735 (ester C=O) and 1660 cm^{-1} (amido C=O); ^{1}H NMR δ=1.43 (3H, t, J=7 Hz, Me), 4.43 (2H, q, J=7 Hz, OCH_2), 7.35—7.70 (3H, m, H-7, 8, and 9), 7.95—8.25 (1H, m, H-10), 9.00 (1H, s, H-2), 10.00—10.25 (1H, m, H-6). Anal. ($C_{15}H_{11}BrN_2O_3$) C, H, N.

21: Red needles (from cyclohexane-dichloromethane), mp 210—212 °C; λ_{max} 222 nm (log ε 4.17), 271 (4.46), 299 (4.15), 309 (4.14), 440 (3.93), 485 (3.84); ν_{max} 1735, 1690 (ester C=O), and 1660 cm^{-1} (amido C=O); ^{1}H NMR δ=1.43, 1.48 (each 3H, t, J=7 Hz, Me), 4.42, 4.53 (each 2H, q, OCH_2), 7.48 (1H, dd, J=10 and 9 Hz, H-9), 8.13 (1H, dd, J=9 and 2 Hz, H-8), 9.06 (1H, s, H-2), 9.25 (1H, d, J=10 Hz, H-10), 10.88 (1H, d, J=2 Hz, H-6). Anal. ($C_{18}H_{15}BrN_2O_5$) C, H, N.

Formylation of 2. To a solution of **2h** (0.150 g, 0.76 mmol) in *N,N*-dimethylformamide (DMF) (2 ml), a mixture of DMF (3 ml) and $POCl_3$ (0.5 g) was added drop by drop. The mixture was stirred for 24 h at 65 °C. After addition of NaOAc (0.300 g), the mixture was stirred for 1 h at 65 °C, then poured into water (100 ml), neutralized with $NaHCO_3$, and extracted with chloroform. The extract was dried (Na_2SO_4) and evaporated. Chromatography of the residue with chroloform gave **2h** (0.015 g 10%), **2n** (0.035 g, 18%), and **2m** (0.041 g, 24%), successively. [**2m:** violet needles from cyclohexane-dichloromethane, mp 230 °C (dec); λ_{max} 219 nm (log ε 4.00), 237 (4.08), 264 (4.32), 305 (3.82), 312 (3.82), 405 (3.66, sh), 433 (3.84), 497 (3.89); ν_{max} 1670 cm^{-1} (C=O); ^{1}H NMR δ=7.12 (1H, s, H-11), 7.45—7.85 (3H, m, H-7, 8, and 9), 8.05—8.40 (1H, m, H-10), 8.85 (1H, s, H-2), 10.10—10.35 (1H, m, H-6), 10.42 (1H, s, CHO). Anal. ($C_{13}H_8N_2O_2$) C, H, N. **2n:** red needles (from cyclohxane-dichloromethane), mp >300 °C; λ_{max} 218 nm (log ε 4.26), 237 (4.33), 265 (4.54), 305 (4.07), 314 (4.07), 407 (3.93, sh), 433 (4.08), and 498 (4.13); ν_{max} 1675 and 1660 cm^{-1} (C=O); ^{1}H NMR (DMSO-d_6) δ=8.30—8.55 (3H, m, H-7 , 8, and 9), 8.76 (1H, s, H-2), 9.60—9.80 (1H, m, H-10), 10.23 and 10.58 (each 1H, s, CHO), 10.50-10.65 (1H, m, H-6). Anal. ($C_{14}H_8N_2O_3$) C, H, N. MS *m/z* 252 (M^+)].

In a similar manner, **2f** gave **2o** (44%).

2o: Red needles (from cyclohexane-dichloromethane), mp 229—231 °C; λ_{max} 223 nm (log ε 4.16), 235 (4.09, sh), 269 (4.22), 303 (4.05, sh), 320 (4.09), 450 (3.87), and 465 (3.87); ν_{max} 1735 (ester C=O) and 1660 cm^{-1} (C=O); ^{1}H NMR δ=1.42 (3H, t, J=7 Hz, Me), 4.40 (2H, q, J=7 Hz, OCH_2), 7.80—8.20 (3H, m, H-7, 8, and 9), 9.00 (1H, s, H-2), 9.60—9.85 (1H, m, H-10), 10.73 (1H, s, CHO), 10.55—10.80 (1H, m, H-6). Anal. ($C_{16}H_{12}N_2O_4$) C, H, N.

I am grateful to Dr. Akira Mori, Kyushu University, for the ^{13}C NMR and Mass spectra.

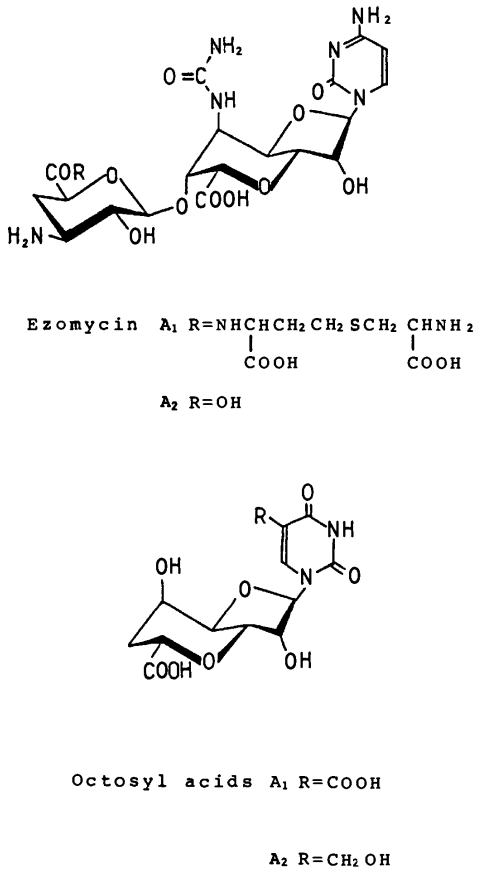
Synthetic Approach toward Antibiotic Ezomycins. III. Synthesis of a Protected Derivative of the Octose Moiety

Osamu SAKANAKA, Takashi OHMORI, Shuji KOZAKI, and Tetsuo SUAMI*
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Yokohama 223
(Received September 13, 1986)

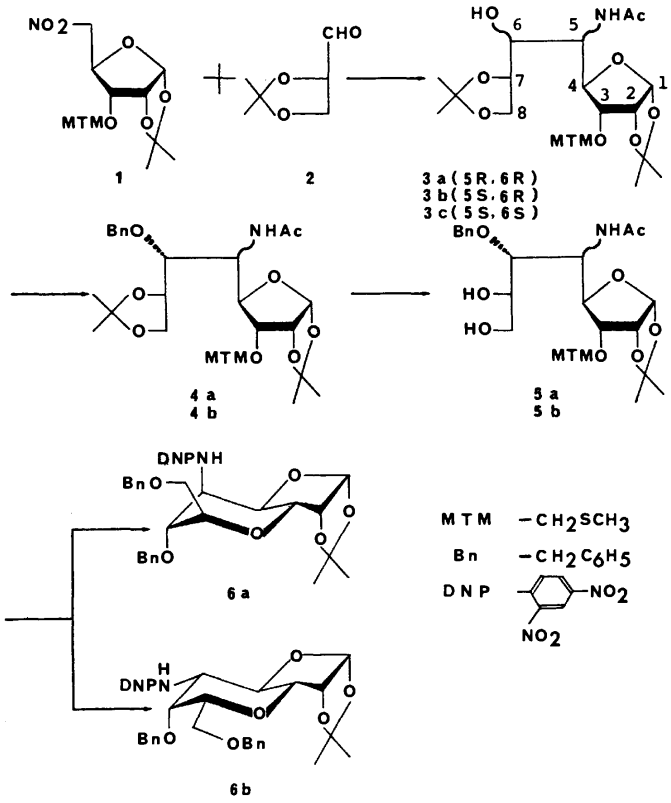
A protected derivative of the octose moiety of antibiotic ezomycins A_1 and A_2, 4-*N*-benzoyl-1-[methyl 3,7-anhydro-2-*O*-benzoyl-5-(3-*N*-benzoylureido)-6-*O*-benzyl-5-deoxy-β-D-*threo*-D-allooctofuranos-(1,4)-yluronate]-cytosine, has been synthesized from 5-acetamido-6-*O*-benzyl-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methylthiomethyll-β-L-*erythro*-D-allooctofuranose-(1,4) by a series of reactions involving 23 steps.

Antibiotic ezomycins are produced by a fermentation of a very similar strain of Streptomyces Kitazawaensis.[1] They exhibit antimicrobial activity against limited species of phytopathogenic fungi, such as Sclerotinia and Botritis. Their structures were established by a degradation study and a spectroscopic analysis as shown in Scheme 1.[2-4] The unique bicyclic trans-fused 3,7-anhydrooctofuranose-(1,4) skeleton was also found in octosyl acids.[5] Several synthetic approaches toward 3,7-anhydrooctofuranose-(1,4) derivatives have been reported,[6-8] and total syntheses of octosyl acid A_1 were recently published by two groups.[9,10] However, so far any synthesis of the octose moiety of ezomycins has not appeared in the literature.

In the preceding papers,[11,12] a preliminary investigation on the synthesis of 5-acetamido-5-deoxyoctofuranose-(1,4) derivatives and their conversion into 3,7-anhydrides has been described. A potassium fluoride-catalyzed Henry reaction between 5-nitro-D-ribose derivative (**1**) and L-glyceraldehyde derivative (**2**) and a successive hydrogenation followed by *N*-acetylation afforded three diastereomeric isomers (**3a**, **3b** and **3c**). Also their absolute configurations of the newly introduced chiral centers on C-5 and C-6 have been established. The configurations of the major product **3a** were found to be identical with those of the octose moiety of ezomycins. Furthermore, from **3a** and **3b** 3,7-anhydride (**6a** and **6b**) could be successfully synthesized by a series of reactions involving ten and



Scheme 1.



Scheme 2.

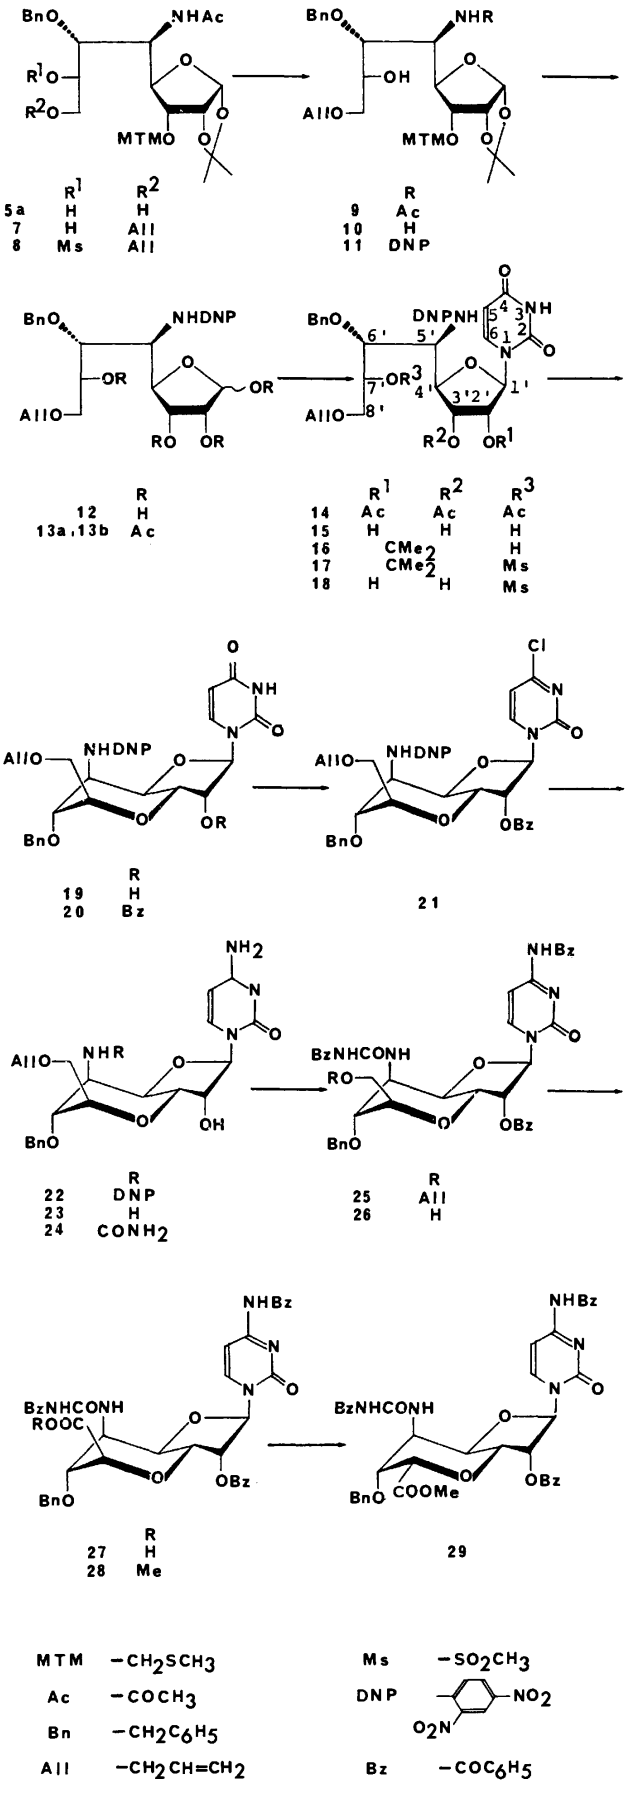
eight steps, respectively.

In the present paper, we wish to report a synthesis of the octose moiety of ezomycins A_1 and A_2 as a protected form.

Results

A preparation of **5a** was previously described.[11] *O*-Benzylation of an intact mixture (67% yield from **1**) of **3a** and **3b**, which could not be separated chromatographically, with benzyl bromide and sodium hydride in *N*,*N*-dimethylformamide (DMF) gave the corresponding benzyl ethers (**4a** and **4b**), which could be isolated readily in 49 and 30% yield, respectively. Selective removal of 7,8-*O*-isopropylidene group in **4a** with aqueous acetic acid afforded a diol (**5a**) in 91% yield.

Preferential protection of a primary alcoholic group of **5a** with allyl bromide and sodium hydride in tetrahydrofuran (THF) gave an allyl ether (**7**) in 65% yield. *O*-Mesylation of **7** with methanesulfonyl chloride in pyridine and successive treatment of the resultant mesylate (**8**) with sodium hydride in DMF followed by an acidic workup with silica gel afforded an epimer (**9**) at C-7 in a high yield. An alkaline hydrolysis of **9** with sodium hydroxide in aqueous 2-methoxyethanol and successive treatment of the free amine (**10**) with 2,4-dinitrofluorobenzene and triethylamine in THF gave a reprotected compound **11** in a high yield. Simultaneous removal of 1,2-*O*-isopropylidene and 3-*O*-methylthiomethyl groups of **11** with aqueous trifluoroacetic acid followed by a conventional *O*-acetylation produced an anomeric mixture of tetra-*O*-acetates (**13a** and **13b** 1/2.8) in 82% yield. A glycosidation of the intact mixture with bis(trimethylsilyl)uracil in the presence of trimethylsilyl trifluoromethanesulfonate in acetonitrile[13] afforded only the aimed β-glycoside (**14**) in a high yield. De-*O*-acetylation with methanolic sodium methoxide, *O*-isopropylidenation with 2,2-dimethoxypropane in the presence of *p*-toluenesulfonic acid in DMF, *O*-mesylation with methanesulfonyl chloride in pyridine and removal of isopropylidene group with aqueous trifluoroacetic acid were successively carried out to give a mesylate (**18**) in 82% yield from **14**. Treatment of **18** with sodium hydride in dimethyl sulfoxide (DMSO) afforded the desired 3,7-anhydride (**19**) in 87% yield. *O*-Benzoylation of **19** with benzoyl chloride in pyridine yielded a benzoate (**20**) almost quantitatively. Treatment of **20** with oxalyl dichloride in 1,2-dichloroethane containing a small amount of DMF and successive ammonolysis of the resultant chloropyrimidinone (**21**) with methanolic ammonia gave a cytosine derivative (**22**) in 80% yield. De-*N*-protection of **22** with Amberlite IRA-400 (OH^-) in a mixture of acetone, methanol and water[14] and successive *N*-carbamoylation of the resultant amine (**23**) with



Scheme 3.

sodium cyanate in aqueous acetic acid[15] afforded an ureido derivative (**24**) in 31% yield. Benzoylation of **24** with benzoyl chloride in pyridine gave a tribenzoyl compound **25** in 62% yield. Oxidative cleavage of allyl group of **25** with selenium dioxide in dioxane containing acetic acid[16] afforded a primary alcohol (**26**) in 73% yield. Oxidation of **26** with chromium trioxide in acetone containing sulfuric acid yielded an uronic acid (**27**), which was successively esterified with methanolic hydrogen chloride to give a methyl ester (**28**) in 47% yield. Treatment of **28** with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in DMF resulted in an epimerization at C-7′ as expected to afford an epimer (**29**) in 60% yield. It was confirmed by comparison with the ^{1}H NMR data of the derivatives from natural product that the uronate (**29**) had the identical configurations with those of the octose moiety of ezomycins.[2]

Experimental

Melting points were determined on a Büchi 510 capillary apparatus and are uncorrected. Optical rotations were measured with a Jasco DIP-4 polarimeter. IR spectra were recorded on a Hitachi 225 spectrometer. ^{1}H NMR spectra were recorded on a Varian EM-390 (90 MHz) or a JEOL FX-200 (200 MHz) spectrometer with a reference to tetramethylsilane as an internal standard. Mass spectra were recorded on a Hitachi M-80A or a Hitachi M-80B spectrometer. Solutions were dried over anhydrous sodium sulfate and concentrated under reduced pressure below 40 °C. Column chromatography was performed using Merck Kieselgel 60 F_{254} (Art. 7734) or Wakogel C-200. Preparative TLC was performed on glass plates coated with Merck Kieselgel 60 F_{254} (Art. 5715).

5-Acetamido-8-*O*-allyl-6-*O*-benzyl-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methylthiomethyl-β-L-*erythro*-D-allooctofuranose-(1,4) (7). To a solution of **5a** (2.80 g) in anhydrous THF (28 ml) were added allyl bromide (0.67 ml) and sodium hydride (60% dispersion in mineral oil, 475 mg) under ice cooling, and the mixture was allowed to stand for 40 h in the refrigerator. After addition of cold water (100 ml), the mixture was repeatedly extracted with dichloromethane. The combined extract was dried and concentrated to dryness. The residue was chromatographed on a silica-gel column (toluene–ethyl acetate (v/v) 1:2) to afford 1.96 g (64.5%) of **7** as crystals and 0.35 g (12.5%) of the starting material. Recrystallization from cyclohexane–toluene (2:1 v/v) yielded an analytical sample: Mp 130—131 °C; $[\alpha]_D^{27}$ +8.5° (*c* 1.09, $CHCl_3$); IR (KBr) 3240, 3080, 1635 cm^{-1}; ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.36, 1.54 (3H×2, s×2, CMe_2), 1.99 (3H, s, NHAc), 2.18 (3H, s, SMe), 5.25 (2H, m, $OCH_2CH=C\underline{H}_2$), 5.81 (1H, d, *J*=5 Hz, H-1), 5.69—6.18 (2H, NH and $OCH_2C\underline{H}=CH_2$), 7.35 (5H, s, Ph).

Found: C, 58.77; H, 7.18; N, 2.71%. Calcd for $C_{25}H_{37}O_8NS$: C, 58.69; H, 7.29; N, 2.74%.

5-Acetamido-8-*O*-allyl-6-*O*-benzyl-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methylthiomethyl-α-D-*threo*-D-allooctofuranose-(1,4) (9). To a solution of **7** (2.34 g) in dry pyridine (24 ml) was added methanesulfonyl chloride (1.06 ml) under ice cooling, and the mixture was allowed to stand for 14 h in the refrigerator. After addition of cold water (2 ml) the mixture was concentrated, and the residue was dissolved in ethyl acetate, and the solution was washed with aqueous sodium hydrogencarbonate and water successively, dried and concentrated to dryness. The residue was dissolved in anhydrous DMF (24 ml), and under ice cooling to the solution was added sodium hydride (732 mg). After 90 min at room temperature, the reaction mixture was partitioned between cold water and ethyl acetate. The organic layer was repeatedly washed with water, dried and concentrated to dryness. The residue was dissolved in a small amount of toluene, and a silica-gel column was charged with the solution. After 2 h, elution (toluene–ethyl acetate (v/v) 1:2) gave 2.28 g (97.2%) of **9** as crystals: Mp 91—92 °C; $[\alpha]_D^{25}$ +30.5° (*c* 1.11, $CHCl_3$); IR (KBr) 3410, 3290, 1655 cm^{-1}; ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.34, 1.53 (3H×2, s×2, CMe_2), 1.93 (3H, s, NHAc), 2.19 (3H, s, SMe), 2.59 (1H, d, *J*=4 Hz, OH), 5.24 (2H, m, $OCH_2CH=C\underline{H}_2$), 5.67—6.13 (3H, H-1, NH and $OCH_2C\underline{H}=CH_2$), 7.35 (5H, s, Ph).

8-*O*-Allyl-6-*O*-benzyl-5-deoxy-5-(2,4-dinitrophenylamino)-1,2-*O*-isopropylidene-3-*O*-methylthiomethyl-α-D-*threo*-D-allooctofuranose-(1,4) (11). A mixture of **9** (1.38 g), 2-methoxyethanol (19 ml), water (1 ml) and sodium hydroxide (1.6 g) was heated for 90 min under reflux. The mixture was partitioned between cold water and ethyl acetate. The organic layer was repeatedly washed with water, dried and concentrated to dryness. The residue was dissolved in THF (14 ml), and to the solution were added triethylamine (1.13 ml) and 2,4-dinitrofluorobenzene (1.0 g). After 90 min at room temperature, the reaction solution was diluted with ethyl acetate. The mixture was washed with water, dried and concentrated to dryness. The residue was chromatographed on a silica-gel column (toluene–ethyl acetate (v/v) 5:1) to give 1.64 g (95.9%) of **11** as amorphous solids: $[\alpha]_D^{24}$ +17.4° (*c* 1.70, $CHCl_3$); IR (KBr) 3430, 3330, 1525 cm^{-1}; ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.34, 1.53 (3H×2, s×2, CMe_2), 2.09 (3H, s, SMe), 2.55 (1H, d, *J*=5 Hz, OH), 5.16 (2H, m, $OCH_2CH=C\underline{H}_2$), 5.75 (1H, d, *J*=5 Hz, H-1), 5.78 (1H, m, $OCH_2C\underline{H}=CH_2$), 7.16 (1H, d, *J*=10 Hz, H-6′), 7.32 (5H, s, Ph), 8.02 (1H, dd, *J*=3, 10 Hz, H-5′), 9.06—9.28 (2H, NH and H-3′).

1,2,3,7-Tetra-*O*-acetyl-8-*O*-allyl-6-*O*-benzyl-5-deoxy-5-(2,4-dinitrophenylamino)-β(and α)-D-*threo*-D-allooctofuranose-(1,4) (13a and 13b). Compound **11** (2.25 g) was dissolved in 90% aqueous trifluoroacetic acid (45 ml), and the solution was allowed to stand for 75 min at room temperature. After coevaporation with toluene, the residue was dissolved in a mixture of dry pyridine (55 ml) and acetic anhydride (5.4 ml). After 1 h at room temperature, the mixture was coevaporated with toluene to dryness. The residue was chromatographed on a silica-gel column (toluene–ethyl acetate (v/v) 5:1) to afford 0.54 g of **13a** and 1.50 g of **13b** (total 81.9%) as amorphous solids, respectively.

13a: $[\alpha]_D^{24}$ −137° (*c* 1.34, $CHCl_3$); IR (KBr) 3320, 1750, 1535 cm^{-1}; ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.78, 1.93, 1.98, 2.09 (3H×4, s×4, OAc×4), 4.75 (1H, d, *J*=12 Hz, CH_2Ph), 4.92 (1H, d, *J*=12 Hz, CH_2Ph), 5.79 (1H, m, OCH_2-

CH=CH_2), 6.10 (1H, s, H-1), 7.09 (1H, d, J=10 Hz, H-6′), 7.38 (5H, s, Ph), 8.26 (1H, dd, J=3, 10 Hz, H-5′), 8.89—9.26 (2H, NH and H-3′).

1-[2,3,7-Tri-*O*-acetyl-8-*O*-allyl-6-*O*-benzyl-5-deoxy-5-(2,4-dinitrophenylamino)-β-D-*threo*-D-allooctofuranos-(1,4)-yl]-uracil (14). A suspension of uracil (1.4 g) in 1,1,1,3,3,3-hexamethyldisilazane (14 ml) was heated for 90 min under reflux to become a clear solution, which was concentrated to give 2,4-*O*-bis(trimethylsilyl)uracil quantitatively as a syrup. Without any purification the product was dissolved in dry acetonitrile (5 ml) containing trimethylsilyl trifluoromethanesulfonate (1.04 ml), and the solution was added to a solution of an intact mixture of **13a** and **13b** (2.04 g) in dry acetonitrile (21 ml). The total mixture was heated for 45 min under reflux. The mixture was partitioned between aqueous sodium hydrogencarbonate and ethyl acetate. The organic layer was washed with water, dried and concentrated to dryness. The residue was chromatographed on a silica-gel column (toluene–ethyl acetate (v/v) 2:3) to give 2.01 g (91.8%) of **14** as amorphous solids: $[\alpha]_D^{23}$ −235° (c 3.52, $CHCl_3$); IR (KBr) 3330, 1750, 1700, 1525 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=1.86, 1.92, 2.07 (3H×3, s×3, OAc×3), 4.71 (1H, d, J=13 Hz, CH_2Ph), 4.92 (1H, d, J=13 Hz, CH_2Ph), 7.36 (5H, s, Ph), 8.29 (1H, dd, J=3, 9 Hz, H-5″), 8.99 (1H, d, J=9 Hz, NHDNP), 9.11 (1H, d, J=3 Hz, H-3″), 9.74 (1H, s, H-3).

1-[8-*O*-Allyl-6-*O*-benzyl-5-deoxy-5-(2,4-dinitrophenylamino)-7-*O*-methylsulfonyl-β-D-*threo*-D-allooctofuranos-(1,4)-yl]uracil (18). A solution of **14** (1.08 g) in 0.1 M methanolic sodium methoxide (20 ml) was stirred for 3 h under ice cooling. The solution was neutralized with Amberlite IR-120 (H^+), and the resin was filtered off. The filtrate was concentrated to dryness, and the residue was dissolved in dry DMF (9 ml). To the solution were added 2,2-dimethoxypropane (3.5 ml) and p-toluenesulfonic acid monohydrate (55 mg), and the mixture was stirred for 10 h at room temperature. The reaction mixture was partitioned between aqueous sodium hydrogencarbonate and ethyl acetate. The organic layer was repeatedly washed with water, dried and concentrated to dryness. The residue was dissolved in dry pyridine (9 ml), and to the solution was added methanesulfonyl chloride (0.33 ml) under ice cooling. The mixture was stirred for 90 min at room temperature, and partitioned between aqueous sodium hydrogencarbonate and ethyl acetate. The organic layer was washed with water, dried and concentrated to dryness. The residue was dissolved in ice-cooled 90% aqueous trifluoroacetic acid (10 ml). After 3 h under ice cooling the solution was concentrated to dryness. The residue was chromatographed on a silica-gel column (toluene–ethyl acetate (v/v) 1:3) to afford 824 mg (81.6% from **14**) of **18** as crystals: Mp 166—167 °C; $[\alpha]_D^{24}$ −134° (c 3.16, $CHCl_3$); IR (KBr) 3280, 1675, 1515, 1175 cm^{-1}; ^1H NMR (90 MHz, CD_3COCD_3) δ=2.98 (3H, s, SO_2Me), 8.30 (1H, dd, J=3, 9 Hz, H-5″), 9.02 (1H, d, J=3 Hz, H-3″), 9.29 (1H, d, J=11 Hz, NHDNP), 10.20 (1H, bs, H-3).

1-[8-*O*-Allyl-3,7-anhydro-2-*O*-benzoyl-6-*O*-benzyl-5-deoxy-5-(2,4-dinitrophenylamino)-α-L-*erythro*-D-allooctofuranos-(1,4)-yl]uracil (20). To a solution of **19** (531 mg) in dry pyridine (5.3 ml) was added benzoyl chloride (0.18 ml), and the mixture was stirred for 1 h under ice cooling. After addition of water (1 ml) the mixture was concentrated. The residue was dissolved in ethyl acetate, and the solution was washed with aqueous sodium hydrogencarbonate and water successively, dried and concentrated to dryness. The residue was chromatographed on a silica-gel column (toluene–ethyl acetate (v/v) 2:1) to afford 610 mg (98.2%) of **20** as amorphous solids: $[\alpha]_D^{22}$ +114° (c 1.20, $CHCl_3$); IR (KBr) 3330, 1720, 1520, 1515 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=5.56 (1H, s, H-1′), 6.30 (1H, d, J=10 Hz, H-6″), 7.14 (1H, d, J=8 Hz, H-6), 7.46 (5H, s, CH_2Ph), 7.93 (1H, dd, J=2, 9 Hz, H-5″), 8,77 (1H, d, J=5 Hz, NHDNP), 8.99 (1H, d, J=2 Hz, H-3″), 9.34 (1H, bs, H-3); MS (FD) 716 (M+1).

1-[8-*O*-Allyl-3,7-anhydro-6-*O*-benzyl-5-deoxy-5-(2,4-dinitrophenylamino)-α-L-*erythro*-D-allooctofuranos-(1,4)-yl]cytosine (22). To a solution of **20** (463 mg) in dry 1,2-dichloroethane (25 ml) were added oxalyl dichloride (0.42 ml) and dry DMF (1 drop) under ice cooling, and the mixture was stirred for 36 h at room temperature. The mixture was poured into cold 1% aqueous sodium hydrogencarbonate, and the mixture was extracted with ethyl acetate. The extract was repeatedly washed with water, dried and concentrated to dryness. The residue was dissolved in saturated methanolic ammonia (60 ml), and the solution was allowed to stand for 5 d at ambient temperature. The reaction mixture was concentrated to dryness, and the residue was chromatographed on a silica-gel column (dichloromethane–methanol (v/v) 10:1) to afford 316 mg (80.0%) of **22** as amorphous solids: $[\alpha]_D^{22}$ +173° (c 1.05, MeOH); IR (KBr) 3390, 1650 cm^{-1}; ^1H NMR (90 MHz, CD_3OD) δ=5.65 (1H, d, J=9 Hz, H-5), 5.70 (1H, s, H-1′), 6.84 (1H, d, J=11 Hz, H-6″), 7.40 (5H, s, Ph), 8.08 (1H, dd, J=2, 9 Hz, H-5″), 8.95 (1H, d, J=2 Hz, H-3″); MS (SIMS) 611 (M+1).

1-[8-*O*-Allyl-3,7-anhydro-6-*O*-benzyl-5-deoxy-5-ureido-α-L-*erythro*-D-allooctofuranos-(1,4)-yl]cytosine (24). A mixture of **22** (267 mg), Amberlite IRA-400 (OH^-) (ca. 3 ml), acetone (14 ml), methanol (7 ml) and water (7 ml) was heated for 3 h under reflux. After the resin was filtered off, the filtrate was concentrated to dryness. To a solution of the residue in 30% aqueous acetic acid (15 ml) was added sodium cyanate (270 mg), and the mixture was allowed to stand for 10 h at 50 °C. The reaction mixture was coevaporated with ethanol, and the residue was roughly chromatographed on a silica-gel column (dichloromethane–methanol (v/v) 5:1). Crystallization of the crude product from ethanol gave 66 mg (31%) of **24**: Mp 158—159 °C; $[\alpha]_D^{25}$ +21° (*c* 0.76, $CHCl_3$–MeOH (v/v) 1:1) IR (KBr) 3400, 1670 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$–CD_3OD (v/v) 1:1) δ=5.30 (1H, s, H-1′), 5.84 (1H, d, *J*=8 Hz, H-5), 7.32 (5H, s, Ph), 7.51 (1H, d, *J*=8 Hz, H-6); MS (SIMS) 488 (M+1).

1-[8-*O*-Allyl-3,7-anhydro-2-*O*-benzoyl-5-(3-benzoylureido)-6-*O*-benzyl-5-deoxy-α-L-*erythro*-D-allooctofuranos-(1,4)-yl]-4-*N*-benzoylcytosine (25). To a solution of **24** (66 mg) in dry pyridine (2 ml) was added benzoyl chloride (145 mg) at −20 °C, and the mixture was stirred for 1 h under ice cooling. The reaction mixture was diluted with ethyl acetate, and the solution was washed with aqueous sodium hydrogencarbonate and water successively, dried and concentrated to dryness. The residue was chromatographed on a silica-gel column (toluene–ethyl acetate (v/v) 2:3) to afford 68 mg (62%) of **25** as crystals. Recrystallization from toluene yielded an analytical sample: mp 200—201 °C (decomp); $[\alpha]_D^{25}$ +42° (*c* 0.65, $CHCl_3$); IR (KBr) 3400, 3250, 1680 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ=3.65 (1H, dd, *J*=6, 10 Hz, H-8′), 3.76 (1H, dd, *J*=5, 10 Hz, H-8′), 4.60 (1H, d, *J*=12 Hz, CH_2Ph), 4.74 (1H, d, *J*=12 Hz, CH_2Ph), 5.08—5.20 (3H, H-5′ and $OCH_2CH{=}CH_2$), 5.77 (1H, d, *J*=6 Hz, H-2′), 5.80 (1H, m, $OCH_2CH{=}CH_2$), 6.18 (1H, s, H-1′), 7.30 (5H, s, $CH_2\underline{Ph}$).

Found: C, 66.05; H, 5.17; N, 8.60%. Calcd for $C_{44}H_{41}O_{10}N_5$: C, 66.07; H, 5.17; N, 8.76%.

1-[3,7-Anhydro-2-*O*-benzoyl-5-(3-benzoylureido)-6-*O*-benzyl-5-deoxy-α-L-*erythro*-D-allooctofuranos-(1,4)-yl]-4-*N*-benzoylcytosine (26). To a solution of **25** (45 mg) in anhydrous dioxane (4.5 ml) were added selenium dioxide (7.5 mg) and acetic acid (5 μl), and the mixture was vigorously stirred for 45 min under reflux. The reaction mixture was concentrated to dryness, and the residue was chromatographed on a silica-gel column (ethyl acetate) to give 31 mg (73%) of **26** as amorphous solids: $[\alpha]_D^{25}$ +32° (*c* 0.69, $CHCl_3$); IR (chloroform) 3270, 1695 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ=4.41 (1H, dd, *J*=6, 10 Hz, H-3′), 4.55 (1H, d, *J*=12 Hz, CH_2Ph), 4.67 (1H, d, *J*=12 Hz, CH_2Ph), 4.92 (1H, m, H-5′), 5.95 (1H, d, *J*=6 Hz, H-2′), 6.10 (1H, s, H-1′), 7.25 (5H, s, Ph); MS (FD) 760 (M+1).

4-*N*-Benzoyl-1-[methyl 3,7-anhydro-2-*O*-benzoyl-5-(3-benzoylureido)-6-*O*-benzyl-5-deoxy-α-L-*erythro*-D-allooctofuranos-(1,4)-yluronate]cytosine (28). To a solution of **26** (31 mg) in acetone (4 ml) was added Jones' reagent (0.3 ml, a solution of chromic trioxide (2.67 g) in sulfuric acid (2.3 ml) diluted with water to a volume of 10 ml) under ice cooling, and the mixture was stirred for 1 h under ice cooling. After the reaction mixture was diluted with ethyl acetate the solution was repeatedly washed with water, dried and concentrated to dryness. The residue was dissolved in 5% methanolic hydrogen chloride, and the solution was refluxed for 1 h. The reaction solution was concentrated to dryness, and the residue was dissolved in pyridine (2 ml). To the solution was added benzoyl chloride (30 mg) under ice cooling, and the mixture was stirred for 15 min under ice cooling. The mixture was partitioned between aqueous sodium hydrogencarbonate and ethyl acetate. The organic layer was washed with water, dried and concentrated to dryness. The residue was chromatographed on a silica-gel column (toluene–ethyl acetate (v/v) 1:2) to give 16 mg (47%) of **28** of amorphous solids: $[\alpha]_D^{25}$ +27° (*c* 1.05, $CHCl_3$); IR (KBr) 3400, 1690 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ=3.70 (3H, s, COOMe), 4.52 (1H, dd, *J*=5, 11 Hz, H-3′), 4.88 (1H, m, H-5′), 5.87 (1H, d, *J*=5 Hz, H-2′), 6.24 (1H, s, H-1′), 7.26 (5H, s, CH_2Ph); MS (FD) 788 (M+1).

4-*N*-Benzoyl-1-[methyl-3,7-anhydro-2-*O*-benzoyl-5-(3-*N*-benzoylureido)-6-*O*-benzyl-5-deoxy-β-D-*threo*-D-allooctofuranos-(1,4)-yluronate]cytosine (29). To a solution of **28** (11.3 mg) in dry DMF (0.5 ml) was added 1,8-diazabicyclo-[5.4.0]undec-7-ene (20 mg), and the mixture was stirred for 2 h at room temperature. After addition of acetic acid (20 mg) the mixture was diluted with ethyl acetate, and the solution was repeatedly washed with water, dried and concentrated to dryness. The residue was chromatographed on a silica-gel preparative plate (toluene–ethyl acetate (v/v) 2:3) to afford 6.8 mg (60%) of **29** as amorphous solids: $[\alpha]_D^{25}$ +5.2° (*c* 0.58, $CHCl_3$); IR ($CHCl_3$) 1695 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ=3.55 (3H, s, COOMe), 4.33 (1H, dd, *J*=5.5, 11 Hz, H-3′), 4.42 (1H, dd, *J*=2.5, 5.5 Hz, H-6′), 4.61 (1H, d, *J*=2.5 Hz, H-7′), 4.62 (1H, d, *J*=12 Hz, CH_2Ph), 4.66 (1H, dd, *J*=4.5, 11 Hz, H-4′), 4.82 (1H, d, *J*=12 Hz, CH_2Ph), 4.90 (1H, m, H-5′), 5.81 (1H, d, *J*=5.5 Hz, H-2′), 5.95 (1H, s, H-1′), 7.32 (5H, s, CH_2Ph); MS (FD) 788 (M+1).

The authors express their sincere thanks to Miss Shigeko Miki and Mr. Masayuki Ito, Meiji Seika Kaisha, Ltd., for recording the mass spectrum, and to Mr. Akio Takahashi for his elemental analyses.

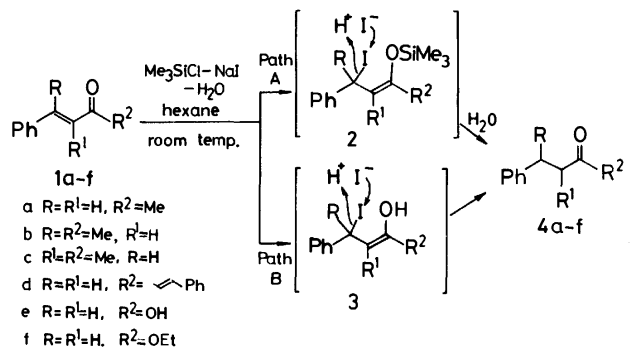
A Convenient Reduction Method of β-Phenyl α,β-Unsaturated Carbonyl Compounds with Me_3SiCl-NaI-ROH Reagent

Takashi SAKAI, Kazuyoshi MIYATA, Masanori UTAKA, and Akira TAKEDA*
Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700
(Received July 23, 1986)

Treatment of β-phenyl α,β-unsaturated ketones, cinnamic acid and its ester with Me_3SiCl-NaI-ROH reagent in hexane at room temperature gave the corresponding saturated carbonyl compounds in good yields. A similar reaction of 2,4-hexadienoic acid afforded 4-hexanolide.

A Me_3SiCl–NaI reagent has been applied to a variety of organic syntheses as a Me_3SiI equivalent,[1] where beside the application to cleavage of ether, ester and amide,[2] it can be used effectively in the deoxygenation of sulfoxide,[3] alcohol,[4] epoxide,[5] and vicinal diol[6] as well as in the dehalogenation of α-halo ketone.[7] The reagent is also effective for the conversion of α,β-unsaturated carbonyl compounds to β-iodo carbonyl compounds. Thus, the reaction of conjugated enones with Me_3SiI gives β-iodo ketones,[8] and a similar treatment of 2-alkenoic acids affords trimethylsilyl 3-iodoalkanoates.[9] Recently, Larson et al.[10] have reported that acrylaldehyde and methyl vinyl ketone were transformed into ethylene acetals of 3-iodopropanal and 4-iodo-2-butanone, respectively, by the action of Me_3SiCl-NaI–ethylene glycol reagent in CH_3CN. However, reduction of carbon-carbon (C-C) double bond of α,β-unsaturated carbonyl compounds with the reagent has not been reported.

In relation to our continuing investigations[11,12] to extend the applicability of the Me_3SiCl-NaI reagent in organic synthesis, we have found that β-phenyl α,β-unsaturated ketones, ester, and acid (**1a—f**) can be reduced to the corresponding saturated carbonyl compounds (**4a—f**) in good yields by using an excess of Me_3SiCl–NaI–ROH reagent in hexane at room temperature (Scheme 1 and Table 1). It is interesting that water or poly alcoholic compounds such as 2,3-butanediol, (*R,R*)-diethyl tartrate, and cellulose are used for ROH as hydrogen sources.



Scheme 1.

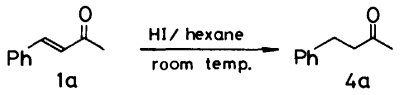
Although such transformation can be done by using several known methods, for example, alkali metals in liquid ammonia,[13] amalgamated zinc in hydrochloric acid,[14] Me_3SiH in CF_3CO_2H,[15] combination of $LiAlH_4$ and CuI,[16] 2-phenylbenzothiazoline,[17] Hantzsch ester-silica gel,[18] and so on, the present method offers the significant advantages that the reagent is inexpensive and the reaction can be done conveniently under mild conditions. Furthermore, products obtained after washing with aqueous $Na_2S_2O_3$ have sufficient purity, as checked by using ^1H NMR.

The present reaction was usually carried out by adding Me_3SiCl (6—10 mmol) with stirring to a mixture of substrate 1 (1 mmol), NaI (6—10 mmol), H_2O (6—10 mmol), and hexane (2 ml) as shown in Table 1. Since the amount of water added was equimolar with those of Me_3SiCl and NaI, it would completely be consumed to produce HI. The reaction was retarded by using a large excess of water. When 10 mmol of water and 6 mmol of Me_3SiCl–NaI were used in the reduction of 1 mmol of **1a**, **4a** was obtained still in an 80% yield. However, an increase in the amount of water to 30 mmol (five equivalents of Me_3SiCl-NaI) decreased the yield of **4a** to 23% accompanied by unidentified impurities. A further increase in the amount of water to 60 mmol resulted merely in recovery of **1a**.

Scheme 1 shows a possible mechanism for the reduction which involves two pathways. In path A, the reaction is initiated by 1,4-addition of Me_3SiI generated in situ to **1** to produce β-iodo enol silyl ether intermediate **2**, whose allylic and benzylic iodo substituent would be extremely labile and attacked by an iodide anion existing in excess to generate iodine molecule in parallel with hydrogenation. The compound having the same functionality as that of **2** has been isolated by Miller[8] in the reaction of α,β-unsaturated ketone with Me_3SiI under anhydrous conditions, and identified by using ^1H NMR. In the present reaction, however, the intermediate **2** seems to make relatively small contribution because, as described above, the reaction in the presence of 1.67 equivalent of water to Me_3SiCl-NaI gave **4a** in 80% yield in spite of the fact that Me_3SiCl and Me_3SiI are

readily hydrolysed by water.[19] In path B, HI generated in situ adds to the C-C double bond of **1** to give β-iodo ketone intermediate **3** as reported in the literatures.[9,10] Subsequent reduction of **3** with HI leads to **4** in a manner similar to path A. Path B is supported on the basis of two facts: a) addition of **1a** to a stirred mixture of Me_3SiCl, NaI, H_2O, and hexane also gave **4a** in an 80% yield, and b) the reaction of **1a** with dry HI, generated by adding 55% aqueous HI to phosphorus pentoxide, also afforded **4a** in a 57% yield (Scheme 2). Comparison of the yield between the two methods indicates the obvious advantage of the present method using Me_3SiCl-NaI-H_2O.

Table 1 shows several examples of the reactions by using olefins whose C-C double bond is conjugated with phenyl group and carbonyl moiety. When 2,3-butanediol was employed instead of water for the reduction of **1a**, cyclic acetal **5** was obtained predominantly. The work-up procedure becomes more convenient by using cellulose (absorbent cotton), which is easily removable from the reaction mixture. It is worthy to note here that asymmetric induction



Scheme 2.

Table 1. Reduction of β-Phenyl α,β-Unsaturated Carbonyl Compounds **1a—f** with Me_3SiCl-NaI-ROH Reagent

Substrate[a]	ROH[b] (Molar ratio vs. 1)	Reaction time/h	Product[c] (Yield/%)[d]
 **1a**	A (6)	30	 **3a** (86)
1a	A (6)[e]	30	**4a** (95)[f]
1a	B (10)	38	**4a** (29) +  **5** (51)
1a	C[g]	20	**4a** (60)
 **1b**	A (10)	22	 **4b** (52)
1b	C[g]	22	**4b** (70)[h]
1b	D (3)	7	**4b** (81)[i]
 **1c**	A (10)	31	 **4c** (42) **6** (31)
 **1d**	A (10)	100	 **4d** (75)
 **1e**	A (10)	100	 **4e** (90)
 **1f**	A (10)	108	 + **4e** (27) **4f** (66)

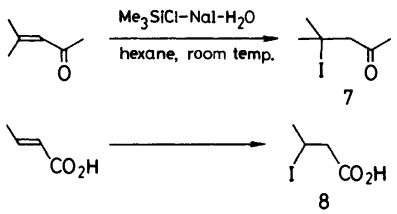
a) 1 mmol of substrate was generally used. b) A: H_2O; B: 2,3-butanediol; C: cellulose (absorbent cotton); D: (*R,R*)-diethyl tartrate. c) Products obtained are known compounds excepting 5. d) Isolated yield by preparative TLC. e) 10 mmol of substrate was used. f) After purification by distillation. g) Against 1 mmol of **1a** or **1c**, 1.8 g of cellulose (absorbent cotton) was used. h) $[\alpha]_D^{25}$ −1.2° (*c* 3.06, C_6H_6) [maximun rotation, $[\alpha]_D$ −75.5° (*c* 1, C_6H_6) for *R*-(−)-**4b**: F. Leyendercker, F. Jesser, and B. Ruhland, *Tetrahedron Lett.*, **22**, 3601 (1981)]. i) $[\alpha]_D^{21}$ −1.8° (*c* 4.1, C_6H_6).

was observed, though very slight, in the reduction of **1b** by using (*R,R*)-diethyl tartrate or cellulose. Reaction of **1c** with Me_3SiCl–NaI–H_2O reagent afforded **4c** and oxidation product **6**, which may be formed via addition of generated iodine to **1c** and subsequent hydrolysis. The methyl group at C-3 would retard 1,4-addition of iodide anion by the electron donating effect.[20]

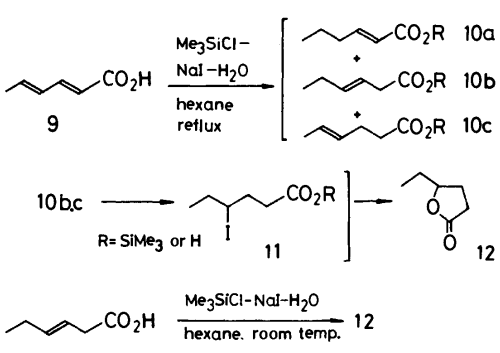
Unfortunately, the present reduction method is not applicable to β-alkyl α,β-unsaturated ketone and acid. For example, the reactions with mesityl oxide and crotonic acid gave merely 4-iodo-4-methyl-2-pentanone (**7**) (70% yield) and 3-iodobutanoic acid (**8**) (94% yield), respectively, as expected[8,9,10] (Scheme 3).

The reactions listed in Table 1 were generally done in a small scale by using 1 mmol of substrates. The crude products obtained were therefore purified by preparative TLC. The preparative scale of 10 mmol order was exemplified by employing typical enone **1a**. In this case, vacuum distillation of the crude product gave **4a** with 98% purity (GLPC and ^1H NMR analysis) in a 95% yield.

The Me_3SiCl–NaI–H_2O reagent was also found to be effective for the transformation of 2,4-hexadienoic acid (**9**) to 4-hexanolide (**12**) (54% yield), although it required refluxing. The formation of **12** suggests the occurrence of the reduction of **9** to a mixture of regioisomers of hexenoic acids and/or their trimethylsilyl esters (**10a—c**), addition of HI to **10b, c** to give 4-iodohexanoic acid and/or its trimethylsilyl ester (**11**), and lactonization to **12** in a successive way (Scheme 4). We confirmed that the treatment of 3-hexenoic acid with the reagent at room temperature also gave **12** in a 66% yield.



Scheme 3.



Scheme 4.

Experimental

General. IR spectra were taken on a JASCO Model A-102 spectrometer. ^1H NMR spectra (60 MHz) were measured with a JEOL Model JNM-60 SI spectrometer using Me_4Si as an internal standard. Optical rotation was recorded with a JASCO Model DIP-4 apparatus. GLPC analysis was done with a Hitachi Model 163 gas chromatograph. The preparative TLC was carried out on silica gel (Kieselgel 60 PF_{254}, Merck A. G. Darmstadt). Elemental analysis was performed by Eiichiro Amano of our laboratory. Starting materials **1b**,[21] **1c**,[22] and **1d**[23] were prepared according to the methods reported and **1a**, **1e**, and **1f** are commercially available.

General Procedure for the Reaction of 1a—f with Me_3SiCl–NaI–H_2O Reagent. To a mixture of NaI (1.5 g, 10 mmol), olefin **1** (1 mmol), water (0.18 ml, 10 mmol) and hexane (2 ml), was added Me_3SiCl (1.28 ml, 10 mmol) dropwise with stirring. Then, stirring was continued at room temperature for the time indicated in Table 1. During the course of the reaction, the mixture was colored dark purple gradually due to liberated iodine. After addition of water (3 ml), the ether extract was washed with aqueous $Na_2S_2O_3$ and brine, dried over $MgSO_4$, and concentrated. Purification of the residue by preparative TLC (hexane–ether 3:1) gave product, whose IR and ^1H NMR spectral data were identical with those reported (compounds **4a**,[24] **4b**,[25] **4c**,[24] **4d**,[26] **6**,[27] **7**,[28] and **8**[29]) or with those of authentic samples commercially available (**4e** and **4f**).

Reactions by using 2,3-butanediol, (*R,R*)-diethyl tartrate, or cellulose for ROH were done in a similar way to that described above and the quantities of ROH used are indicated in Table 1.

Reaction of 1a with Me_3SiCl–NaI–2,3-Butanediol. Crude products were fractionated by preparative TLC (hexane–ether, 3:1) to give **4a** (R_f 0.45, 29% yield) and **5** (R_f 0.67, 51% yield). **5**: IR (neat) 1583, 1604 cm^{-1}; ^1H NMR (CCl_4) δ=1.18 (6H, d, *J*=6 Hz), 1.30 (3H, s), 1.84 (2H, m), 2.66 (2H, m), 3.53 (2H, m), 7.08 (5H, s). Anal. ($C_{14}H_{20}O_2$)C, H.

Effects of the Amount of Water on the Yield of 4a. The reaction of **1a** (146 mg, 1 mmol) with Me_3SiCl (0.77 ml, 6 mmol), NaI (900 mg, 6 mmol) and water (0.18 ml, 10 mmol) in hexane (4 ml) was carried out in a manner similar to that described above. The crude product was distilled [bp 105—110 °C (5 mmHg) (1 mmHg=133.322 Pa)] to give **4a** (119 mg, 80% yield).

A similar reaction with an increased amount of water (540 mg, 30 mmol) gave a 88:12 (by ^1H NMR) mixture (38 mg) of **4a** (23% yield) and **1a** (3% recovered) after distillation [bp 110 °C (5 mmHg)]. A considerable amount of tarry material remained as a still residue.

The reaction with a large excess of water (1.1 g, 60 mmol) was done in a similar way and the recovery of the most of **1a** with a small amount of unidentified material was confirmed by using ^1H NMR.

Reduction of 1a by Addition to a Mixture of Me_3SiCl–NaI–H_2O. A mixture of Me_3SiCl (0.77 ml, 6 mmol), NaI (900 mg, 6 mmol), water (0.108 ml, 6 mmol) and hexane (4 ml) was stirred for 1 h at room temperature and then **1a** (146 mg, 1 mmol) was added. The mixture was stirred for

additional 24 h at room temperature and treated in a usual way to give **4a** (120 mg, 80% yield) after distillation.

Reduction of 1a in a Preparative Scale. A similar reaction using **1a** (1.46 g, 10 mmol) and Me_3SiCl-NaI-H_2O each with 60 mmol gave **4a** (1.40 g, 95% yield) after distillation [bp 100—110 °C (5 mmHg)]. GLPC analysis (SE-30, 1.0 m×5 mm o.d., N_2 27 ml min^{-1}, oven temperature 100 °C) of the product showed a peak at the retention time of 4.5 min with an relative intensity of 98%.

Reduction of 1a with Dry HI. To a mixture of **1a** (292 mg, 2 mmol) and hexane (5 ml) was introduced dry HI, which was generated by dropping 55% aqueous HI solution (5 ml, 37 mmol) to phosphorus pentoxide (13 g, 92 mmol).[30] The mixture was stirred for 24 h at room temperature and then poured into aqueous $NaHCO_3$. The organic layer was extracted with ethyl acetate and treated in a usual way to give **4a** (167 mg, 57% yield) after distillation. A tarry material was remained as a still residue.

4-Hexanolide (12) from 2,4-Hexadienoic Acid (9). To a mixture of acid **9** (224 mg, 2 mmol), NaI (3.0 g, 20 mmol), water (0.36 ml, 20 mmol) and hexane (4 ml), was added Me_3SiCl (2.56 ml, 20 mmol) at room temperature. After being stirred under reflux for 18 h, the mixture was washed with aqueous $NaHCO_3$ and treated in a usual way. Kugelrohr distillation [bp 120—130 °C (18 mmHg)] of the residual oil gave **12** (123 mg, 54% yield), whose IR and ^1H NMR spectra were identical with those reported.[31] The aqueous $NaHCO_3$ layer was acidified and the ether extract was treated in a similar way to give 189 mg of a mixture of acidic materials, whose separation and structual identification were unsuccessful.

Lactone 12 from 3-Hexenoic Acid. A mixture of 3-hexenoic acid[32] (228 mg, 2 mmol), Me_3SiCl (2.56 ml, 20 mmol), NaI (3.0 g, 20 mmol), water (360 mmol), and hexane (4 ml) was allowed to react for 44 h at room temperature and treated in a usual way to give **12** (152 mg, 66% yield) after distillation. Attempts to purify the acidic material (87 mg) by preparative TLC was failed.

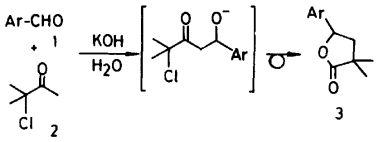
(Received October 9, 1986)

Reaction of Aromatic aldehydes or hetero-aromatic aldehydes with 3-chloro-3-methyl-2-butanone in ethanolic KOH at room temperature gave 3,3-dimethyl-5-aryltetrahydro-2-furanone as a major product. The reaction can be tentatively explained by the combination of Favorskii rearrangement and aldol reaction.

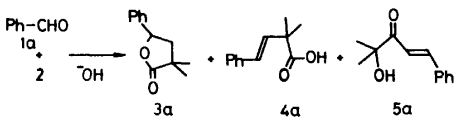
The Favorskii rearrangement has been known as a useful synthetic method of carboxylic acids or their derivatives by the skeletal rearrangement of α-halo ketones with nucleophilic bases.[1] This paper describes a novel type of the Favorskii rearrangement which involves an aldol reaction (KOH/EtOH) of aromatic aldehyde (**1**) with the enolate of 3-chloro-3-methyl-2-butanone (**2**), giving γ-butyrolactone derivative (**3**) as a major product in one-pot reaction (Scheme 1). In order to estimate the synthetic utility of the present reaction, the scope of reaction and the possible mechanism are discussed.

The reaction conditions and the product distribution were examined by the use of typical reaction of benzaldehyde (**1a**) wirh α-halo ketone (**2**) (Table 1). It is well-known that the Favorskii rearrangement is affected by many factors such as base, solvent, halogen, and so on.[1] For example, treatment of **2** with 40% aqueous NaOH gives pivalic acid, while



Scheme 1.

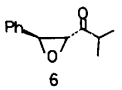
Table 1. Reaction of Benzaldehyde (**1a**) with Halo Ketone (**2**)



Reaction conditions	Yields/%		
	3a	**4a**	**5a**
40% $NaOH/H_2O$	32[a]	14	3
40% KOH/H_2O	25[a]	14	5
14% KOH/EtOH	50	14	5
14% $NaOH/H_2O$	0	0	80

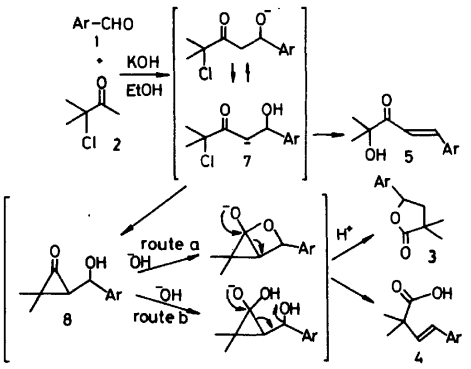
a) The decreased yield is due to the formation of pivalic acid, which was checked by ^1H NMR.

treatment with weak base such as 20% aqueous Na_2CO_3 affords 3-hydroxy-3-methyl-2-butanone, exclusively.[2] We also confirmed that the reaction of **2** with 14% aqueous or ethanolic KOH also yielded the hydroxy ketone. Thus, a mixture of compounds **1a** and **2** were treated with 40% aqueous NaOH (**1a**:**2**:NaOH=1:3.5:7)[3] at room temperature for 3 h to give 3,3-dimethyl-5-phenyltetrahydro-2-furanone (**3a**)[4] (32% yield), accompanied by 2,2-dimethyl-4-phenyl-3-butenoic acid (**4a**) (14% yield) and 4-hydroxy-4-methyl-1-phenyl-1-penten-3-one (**5a**)[5] (3% yield). It is quite interesting that the yield of lactone **3a** was improved up to 50% in the reaction with 14% ethanolic KOH, in spite of the fact that it is the hydrolytic conditions of **2**.[6] On the contrary, when the reaction was done in 14% aqueous NaOH, **5a**[7] was obtained exclusively in an excellent yield. In aqueous media with weak base, hydrolysis of **2** may occur readily in competition with the aldol reaction. Furthermore, the analogous reaction carried out with NaOEt in ether was found to give a mixture of **3a** (11% yield), **4a** (23% yield), and 1,2-epoxy-4-methyl-1-phenyl-3-pentanone (**6**) (28% yield).

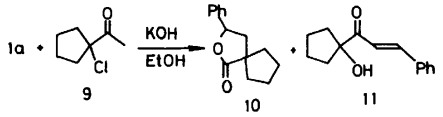


A conceivable mechanism of the present reaction (KOH/EtOH) is shown in Scheme 2, which involves the Favorskii rearrangement of initially formed aldol product **7**. It is possible that the cyclopropanone intermediate **8**[8] is cleaved either by the intramolecular alkoxide ion[9] (route a) or by hydroxide ion (route b). The by-product **5** may be formed either by hydrolysis of **7** or by the Claisen-Schmidt condensation of **1** with 3-hydroxy-3-methyl-2-butanone, which is formed initially in competition with the reaction of **1** with **2**. The present reaction is the first example of the Favorskii rearrangement which undergoes in combination with an aldol reaction.

Table 2 shows that this reaction (KOH/EtOH) can be adapted to a variety of aromatic aldehydes and hetero-aromatic aldehydes,[10] giving γ-butyrolactone derivatives **3b**—**g** as the major product. In addition, a



Scheme 2.



Scheme 3.

Aldehyde **1** Ar		Products (Yields/%)					
		3		**4**		**5**	
1b	2-Chlorophenyl-	**3b**	(52)			**5b**	(27)
1c	4-Chlorophenyl-	**3c**	(54)	**4c**	(33)		
1d	2,4-Dichlorophenyl-	**3d**	(47)				
1e	3-Nitrophenyl-	**3e**	(42)	**4e**	(20)		
1f	3-Pyridyl-	**3f**	(29)				
1g	2-Furyl-	**3g**	(31)	**4g**	(16)		

a) In the reaction with 14% ethanolic KOH.

similar reaction of 1-(1-chlorocyclopentyl)ethanone (**9**)[11] with **1a** gave 3-phenyl-2-oxaspiro[4.4]nonan-1-one (**10**) (23% yield) and 1-(1-hydroxycyclopentyl)-3-phenyl-2-propen-1-one (**11**) (13% yield) (Scheme 3). Although the yields of the lactones **3a—g** and **10** were moderate to low and they were accompanied by the by-products such as **4**, **5**, or **11**, the present method has the advantage that the reaction can be done in one-pot in a very simple way.

Experimental

Melting points were measured on a Yamato Model MP-21 melting point apparatus and are uncorrected. Evaporative bulb-to-bulb distillation was done using a Büchi Kügelrohrofen. IR spectra were taken on a JASCO Model A-102 spectrometer. ^{1}H NMR spectra (60 MHz) were measured with a JEOL Model JNM-60 SI spectrometer and ^{13}C NMR spectra (25 MHz) were taken on a JEOL Model FX-100 spectrometer using Me_4Si as an internal standard. Analysis and preparative isolation by GLC were done with Hitachi Model 163 (SE-30 5 mmϕ×1.2 m, N_2 27 ml min^{-1}, oven temperature 130 °C) and Yanagimoto Model G-80 (Apiezone Glease L on 10% Chromosorb, N_2 50 ml min^{-1}, oven temperature 200 °C) gas chromatographs, respectively. The preparative TLC was carried out on silica gel (Kieselgel 60 PF_{254}, Merck A. G. Darmstadt). Elemental analysis was performed by Eiichiro Amano of our laboratory.

Typical Reaction of α-Halo Ketones with Aromatic Aldehydes in Ethanolic KOH. 3,3-Dimethyl-5-phenyltetrahydro-2-furanone (3a). To a solution of benzaldehyde (**1a**) (0.53 g, 5.0 mmol) and 3-chloro-3-methyl-2-butanone (**2**)[12] (2.11 g, 17.5 mmol) in ethanol (10 ml), was added a solution of KOH (1.96 g, 35 mmol) in ethanol (10 ml) over a period of 30 min at room temperature. After being stirred for 3 h at room temperature, ethanol was removed under reduced pressure. The residue was acidified with 10% HCl and then stirred for 30 min for completion of lactonization. The resulting organic layer was extracted with ether, washed with aqueous $NaHCO_3$ and then with water, dried ($MgSO_4$), and concentrated under reduced pressure. The residual oil was subjected to vacuum distillation [bp 125—145 °C (2 mmHg) (1 mmHg=133.322 Pa)] to give 504 mg of a mixture of **3a**[4] (50%)[13] and **5a**[5,6] (5%)[13] which were separated by preparative GLC. Structural identification was done by comparison of their spectral data with those reported in the literature. The aqueous $NaHCO_3$ layer was acidified and the ether extract was treated in a similar way as described above to give 2,2-dimethyl-4-phenyl-3-butenoic acid (**4a**) (133 mg, 14%) after purification by preparative TLC (hexane–acetone, 3:1). **4a**: IR (neat) 3600—2300, 1685, 1600, 1580 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.40 (6H, s), 6.40 (2H, s), 7.30 (5H, br s), 10.80 (1H, br s); ^{13}C NMR ($CDCl_3$) δ=24.9 (q), 44.4 (s), 126.6 (d), 127.7 (d), 128.7 (d), 130.3 (d), 133.8 (d), 137.1 (s), 182.7 (s). Anal. ($C_{12}H_{14}O_2$) C, H.

Reaction of 1a with 2 in the Presence of NaOEt in Ether. To a solution of **1a** (382 mg, 3.6 mmol) and **2** (434 mg, 3.6 mmol) in ether (20 ml), was added NaOEt (294 mg, 4.3 mmol) at room temperature. After being stirred for 20 h at room temperature, the mixture was acidified with 10% HCl. The resulting mixture was treated in a manner similar to that described above and the crude products were firstly divided into neutral and acidic portions. The former was fractionated by column chromatography (hexane–ether, 20:1) to give **3a** (76 mg, 11%) and 1,2-epoxy-4-methyl-1-phenyl-3-pentanone (**6**) (192 mg, 28%): IR (neat) 1715 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.10 (3H, d, J=7 Hz), 1.13 (3H, d, J=7 Hz), 2.74 (1H, m), 3.37 (1H, d, J=2 Hz, trans[14]), 3.85 (1H, d, J=2 Hz, trans[14]), 7.27 (5H, br s); ^{13}C NMR ($CDCl_3$) δ=17.3 (q), 18.1 (q), 37.0 (d), 58.4 (d), 61.9 (d), 125.6 (d), 128.6 (d), 128.9 (d), 135.3 (s). Anal. ($C_{12}H_{14}O_2$) C, H. The acidic portion was purified by TLC to give **4a** (156 mg, 23%).

γ-Butyrolactones **3b—g** and **10** were synthesized in the similar way to the typical reaction described above. Procedure for purification of the poroducts, their yields and physical properties are as follows.

5-(2-Chlorophenyl)-3,3-dimethyltetrahydro-2-furanone (3b). A neutral portion was subjected to vacuum distillation [bp 148—152 °C (2 mmHg)] and further purified by preparative TLC (hexane–acetone, 3:1) to give **3b** (R_f 0.50—0.58, 52% yield) and 1-(2-chlorophenyl)-4-hydroxy-4-methyl-1-penten-3-one (**5b**)[5] (R_f 0.25—0.40, 27% yield). **3b**: IR (neat) 1780, 1595, 1577 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.21 (3H, s), 1.33 (3H, s), 1.82 (1H, dd, J=10 Hz and 14 Hz), 2.66 (1H, dd, J=7 Hz and 14 Hz), 5.52 (1H, dd, J=7 Hz and 10 Hz), 7.6—

7.9 (4H, m). Anal. ($C_{12}H_{13}O_2Cl$) C, H.

5-(4-Chlorophenyl)-3,3-dimethyltetrahydro-3-furanone (3c). A neutral portion was purified by vacuum distillation [bp 148—150 °C (3 mmHg)] followed by preparative TLC (hexane-acetone, 3:1, R_f 0.1—0.26) to give **3c**: 54% yield, mp 56—57 °C (hexane-ether, 3:1); IR (KBr) 1780, 1605 cm^{-1}; ^1H NMR (CCl_4) δ=1.24 (3H, s), 1.30 (3H, s), 1.88 (1H, dd, J=7 Hz and 14 Hz), 2.42 (1H, dd, J=7 Hz and 14 Hz), 5.32 (1H, dd, J=7 Hz and 10 Hz), 7.27 (4H, br s). Anal. ($C_{12}H_{13}O_2Cl$) C, H. An acidic portion was purified by TLC (hexane-acetone, 3:1, R_f 0.26—0.37) to obtain 4-(4-chlorophenyl)-2,2-dimethyl-3-butenoic acid (**4c**): 33% yield, mp 145—147 °C (hexane-ether, 3:1); IR (KBr) 1690, 1602 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.45 (6H, s), 6.42 (2H, s), 7.30 (4H, br s). Anal. ($C_{12}H_{13}O_2Cl$) C, H.

5-(2,4-Dichlorophenyl)-3,3-dimethyltetrahydro-2-furanone (3d). A neutral portion was purified by vacuum distillation [bp 180—200 °C (0.2 mmHg)] and preparative TLC (hexane-acetone, 3:1) to give **3d**: 47% yield, IR (neat) 1785, 1592, 1561 cm^{-1}; ^1H NMR (CCl_4) δ=1.27 (3H, s), 1.32 (3H, s), 1.82 (1H, dd, J=10 Hz and 13 Hz), 2.59 (1H, dd, J=6 Hz and 13 Hz), 5.60 (1 H, dd, J=6 Hz and 10 Hz), 7.1—7.6 (3H, m). Anal. ($C_{12}H_{12}O_2Cl_2$) C, H.

3,3-Dimethyl-5-(3-nitrophenyl)tetrahydro-2-furanone (3e). A neutral portion was purified by preaparative TLC (hexane-acetone, 2:1) to give **3e**: 42% yield; mp 82—84 °C (CCl_4); IR (KBr) 1768, 1535 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.33 (3H, s), 1.60 (3H, s), 2.05 (1 H, dd, J=10 Hz and 13 Hz), 2.62 (1H, dd, J=6 Hz and 13 Hz), 5.54 (1H, dd, J=6 Hz and 10 Hz), 7.3—8.4 (4 H, m). Anal. ($C_{12}H_{13}O_4N$) C, H. An acidic portion was refined in a similar way to afford **4e**: 20% yield; mp 105—106 °C (hexane-ether, 1:1); IR (KBr) 3720—2300, 1708, 1615, 1528 cm^{-1}; ^1H NMR (CCl_4) δ=1.45 (6H, s), 6.53 (2H, s), 6.7—8.5 (4H, m), 10.10 (1H, br s). Anal. ($C_{12}H_{13}O_4N$) C, H.

3,3-Dimethyl-5-(3-pyridyl)tetrahydro-2-furanone (3f). A neutral portion was purified by vacuum distillation [bp 160-170 °C (2 mmHg)] and preparative TLC (hexane-acetone, 1:1) to give **3f**: 29% yield; mp 78—79 °C (hexane-ether, 2:1); IR (neat) 1770, 1620, 1615 cm^{-1}; ^1H NMR (CCl_4) δ=1.26 (3H, s), 1.8—2.8 (2H, m), 5.40 (1H, dd, J=6 Hz and 9 Hz), 7.1—8.8 (4H, m). Anal. ($C_{11}H_{13}O_2N$) C, H.

5-(2-Furyl)-3,3-dimethyltetrahydro-2-furanone (3g). A neutral portion was distilled under vacuum [bp 130—135 °C (4 mmHg)] and separated by preparative TLC (hexane-acetone, 3:1) to give **3g** (R_f 0.57, 31% yield) and 1-(2-furyl)-4-hydroxy-4-methyl-1-penten-3-one (**5g**)[5] (R_f 0.50, 16% yield). **3g**: IR (neat) 1768, 1604 cm^{-1}; ^1H NMR (CCl_4) δ=1.29 (6H, s), 2.30 (2H, d, J=8 Hz), 5.29 (1H, t, J=8 Hz), 6.33 (2H, br s), 7.35 (1H, br s); ^{13}C NMR ($CDCl_3$) δ=24.4 (q), 24.9 (q), 40.3 (s), 41.2 (t), 71.0 (d), 110.0 (d), 110.7 (d), 143.7 (d), 150.8 (s), 181.1 (s). Anal. ($C_{10}H_{12}O_3$) C, H.

3-Phenyl-2-oxaspiro[4.4]nonan-1-one (10). A neutral portion was fractionated by preparative TLC (hexane-acetone, 3:1, three times developments) to afford **10** (R_f 0.38—0.44, 23% yield) and 1-(1-hydroxycyclopentyl)-3-phenyl-2-penten-1-one (**11**) (R_f 0.44—0.51, 13% yield). **10**: IR (neat) 1770, 1650, 1610 cm^{-1}; ^1H NMR (CCl_4) δ=1.1—1.9 (8 H, m), 1.9—2.7 (2H, m), 5.27 (1H, dd, J=7 Hz and 9 Hz), 7.25 (5H, s). Anal. ($C_{14}H_{16}O_2$) C, H. **11**: IR (neat) 3480, 1680, 1640, 1610, 1575, 1555 cm^{-1}; ^1H NMR (CCl_4) δ=1.3—2.2 (8H, m), 3.7 (1H, br s), 6.87 (1H, d, J=16 Hz), 7.1—7.8 (5H, m), 7.76 (1H, d, J=16 Hz). Anal. ($C_{14}H_{16}O_2$) C, H.

The Transformation of Cyclic Alcohols into Cyclic Acetals through a New Oxygen Atom Insertion by Photolysis in the Presence of Lead Tetraacetate and Iodine[1)]

Hiroshi SUGINOME,* Haruka WASHIYAMA, and Shinji YAMADA
Organic Synthesis Division, Department of Chemical Process Engineering,
Faculty of Engineering, Hokkaido University, Sapporo 060
(Received October 15, 1986)

Photolysis of the hypoiodites of steroidal cyclic homoallyl alcohols such as cholesterol and of cyclic alcohols such as 5α-androstan-17β-ol generated in situ in benzene with three molar equivalents each of lead tetraacetate and iodine was found generally to result in the unprecedented formation of corresponding lactol acetates in yields up to 66%. The lactol acetates are readily hydrolysed to lactols in most cases during their isolation and lactols are isolated products. Thus, cholesterol gave 4-oxa-*A*-homocholest-5-en-3-ol and its acetate in a 53% yield. The products differ considerably from those reported by us after the photolysis of the hypoiodites by using mercury(II) oxide and iodine as the reagents for generating the hypoiodites; they also differ from those in the oxidation of the steroidal alcohols with lead tetraacetate alone. The photolysis of the hypoiodite of 2,2-dimethyl-5β-cholestan-3-ol was found to lead to the formation of an anomalous lactol, 2α-iodomethyl-2β-methyl-4-oxa-*A*-homo-5α-cholestan-4ξ-ol together with normal lactol. We discuss the paths of the formation of the lactol acetates involving β-scission of the alkoxyl radicals. A new process was found in the photolysis of 2-indanol hypoiodite in the presence of lead tetraacetate and iodine. Our previously suggested pathways to the formation of 3α,5-epoxy-6-iodo-4-oxa-*A*-homo-5α-cholestanes and 3-formyloxy-2-iodo-2,3-seco-*A*-norcholest-5-ene in the photolysis of cholesterol hypoiodite in the presence of mercury(II) oxide and iodine were supported by the results of the photolysis of 4-oxa-*A*-homocholest-5-en-3-ol hypoiodite in the presence of mercury(II) oxide and iodine.

In our previous papers,[2)] we have reported that the photo-induced reaction of the hypoiodites of steroidal cyclic homoallyl alcohols such as cholesterol (**1**) and several methyl-substituted cholest-5-en-3-ols generated in situ in benzene by an excess of mercury(II) oxide and iodine resulted in several typical products arising from the allyl radical intermediates generated by β-scission of the alkoxyl radicals. Typically, the hypoiodite of cholesterol (**1**) in benzene containing an excess of mercury(II) oxide and iodine underwent photoinduced rearrangement to give 3α,5-epoxy-6β- and 6α-iodo-4-oxa-*A*-homo-5α-cholestanes (**2**) and (**3**) together with 3- formyloxy-2-iodo-2,3-seco-*A*-norcholest-5-ene (**4**).[2a)]

^{18}O Labeling studies using $Hg^{18}O$ disclosed that the products such as **2**, **3**, and **4** are formed via new multi-step processes involving the intra- and intermolecular reactions of intermediary allyl radicals, generated by β-scission of the corresponding alkoxyl radicals, with I_2O, as outlined in Scheme 1.[3)]

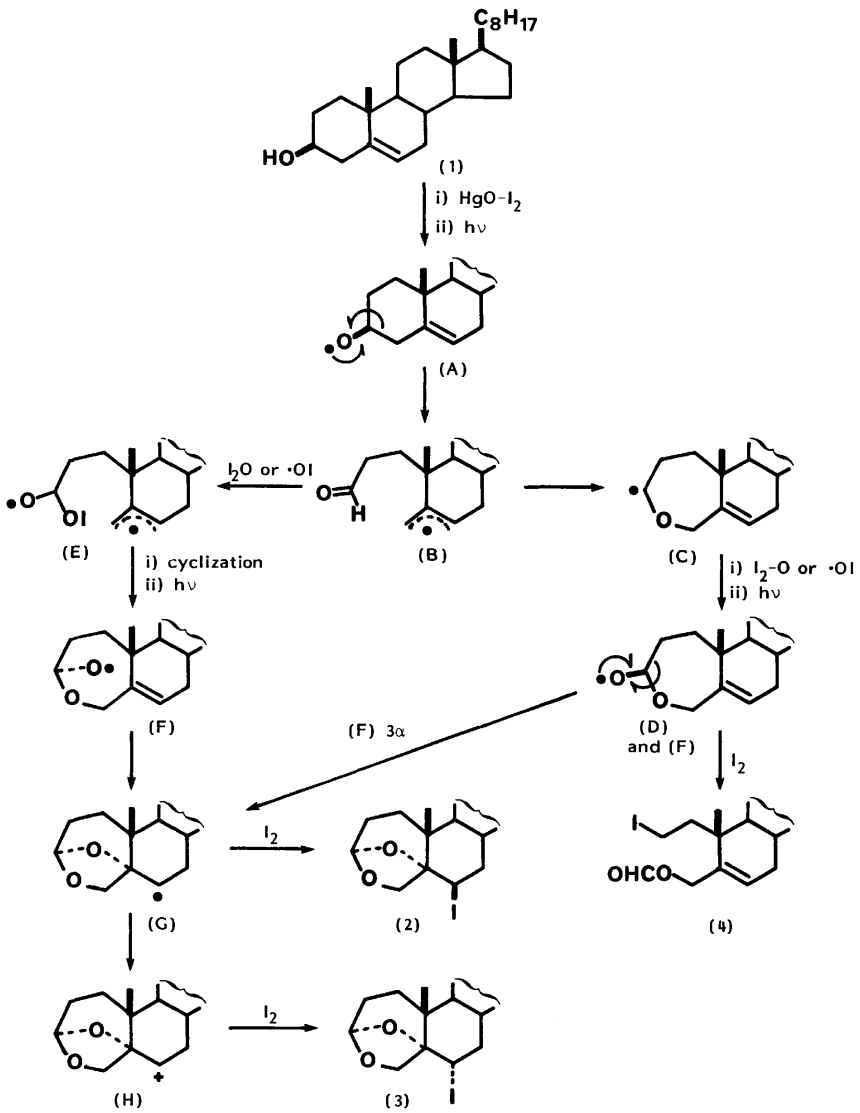
All alkyl hypoiodites used in these photoinduced reaction were prepared by the reaction of cyclic alcohols with iodine oxide (I_2O) generated in situ from mercury(II) oxide and iodine.[4)] Another reagent which has been proved to be useful for generating alkyl hypoiodites from alcohols is a combination of lead tetraacetate and iodine.[5)] This reagent has been extensively used for the intramolecular functionalization of nonactivated carbons, particularly in the steroid field by a Swiss group.[5,6)]

In this paper, we describe the results of photo-induced reactions of the hypoiodites of steroidal cyclic homoallyl alcohols and cyclic alcohols such as cholesterol (**1**) and 5α-androstan-17β-ol (**40**) generated by lead tetraacetate–iodine reagent. The investigation was aimed at comparing a mercury(II) oxide–iodine reagent and a lead tetraacetate–iodine reagent in the photo-induced reactions of the hypoiodites of cyclic alcohols. These comparisons were thought likely to shed further light on the roles of these reagents in the hypoiodite photolysis.

As we describe below, the products of the photoinduced reactions of the hypoiodites generated by lead tetraacetate–iodine are lactol acetates which are formed in fair to good yields by the hydroxyl oxygen insertion and thus differ considerably from those obtained by using mercury(II) oxide–iodine. The reaction is a new version of the reactions which are performed by the lead tetraacetate–iodine reagent.

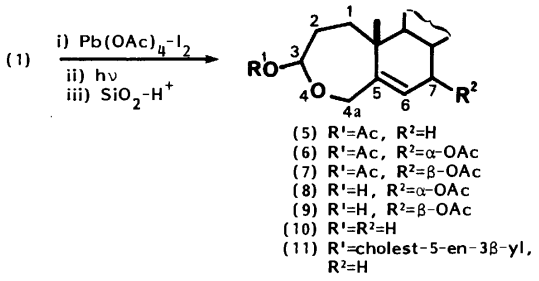
Results

Products of the Photoinduced Reactions of Hypoiodites of Steroidal Cyclic Homoallyl Alcohols. We have chosen cholesterol (**1**) and 4,4-dimethylcholesterol (**19**)[7)] as steroidal cyclic homoallyl alcohols. The photoinduced reaction of cholesterol hypoiodite in benzene in the presence of an excess of lead tetraacetate and iodine has already been reported to give a novel ether, cholest-5-en-3β-yl 4-oxa-*A*-homocholest-5-en-3α-yl ether (**11**) in a 23% yield.[8)] We then went on to investigate the reaction in more detail and found that the products of the reaction hinge on the amounts of the lead tetraacetate and iodine used. Irradiation of cholesterol (**1**) in dry benzene containing 3 mol equiv each of lead tetraacetate and



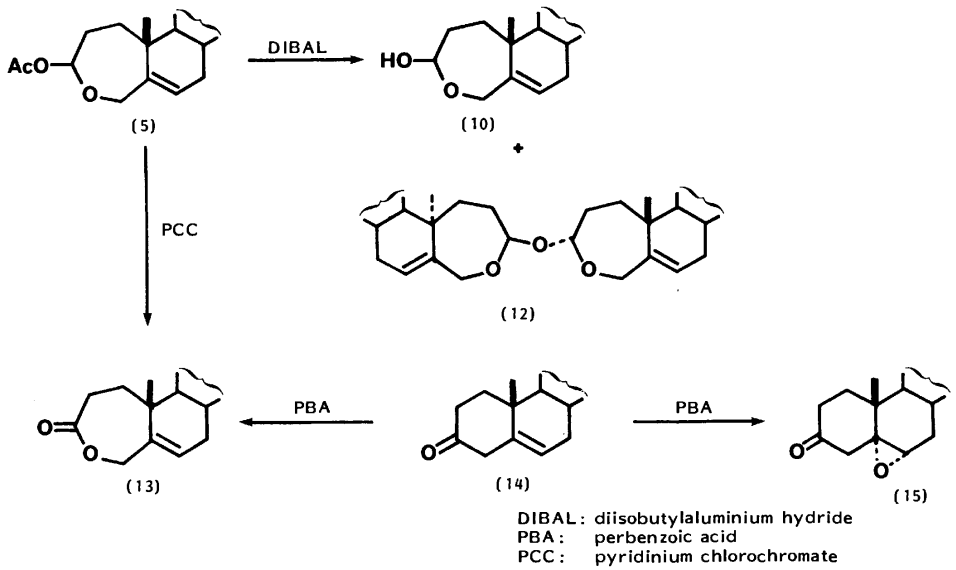
Scheme 1.

iodine in a Pyrex vessel with a light generated by a 100-W high pressure Hg arc lamp for 4.5 h gave a product mixture. Isolation of the products by preparative TLC gave four products [1], [2], [3], and [4] in an order of increasing polarity. The product [1], $C_{29}H_{48}O_3$ (high-resolution mass spectrometry), obtained in a 47% yield showed a band due to an acetoxyl group in the IR spectrum. The ^1H NMR spectrum showed a 3H singlet at δ 2.07, a pair of doublets (2H) at δ 3.70 and 4.41 (J=12.5 Hz), a 1H broad doublet at δ 5.64 and a doublet of doublet (1H) (J=6.84 and 4.41 Hz) at δ 6.00. These signals are assigned to the acetoxyl protons, an isolated methylene group having an oxygen atom, an olefin proton, and a proton attached to the carbon atom carrying two oxygen substituents. Its EIMS showed an ion at m/z 384 as the base peak, a peak derived by the elimination of acetic acid from the molecular ion. These spectral results enabled us to assign the structure of the



Scheme 2.

product [1] to 4-oxa-*A*-homocholest-5-en-3ξ-ol acetate (**5**) (Scheme 2). This structure was subsequently confirmed by transforming it into the compounds recorded in the literature. Thus, the reduction of acetate **5** with DIBAL (diisobutylaluminium hydride) in toluene afforded two compounds **10** and **12**. The major and more polar product **10** (56%) was identified



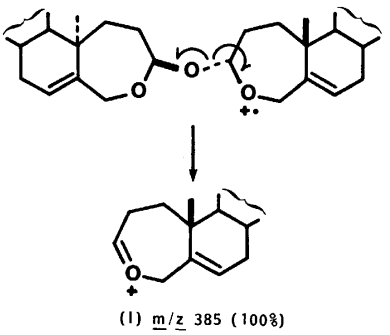
Scheme 3.

as a mixture of 4-oxa-*A*-homocholest-5-en-3α- and 3β-ol,† a product of the acidic hydrolysis[2a] of cholest-5-en-3β-yl 4-oxa-*A*-homocholest-5-en-3α-yl ether (**11**) previously obtained in this photolysis[8] and in the thermolysis of cholesterol hypoiodite in the presence of mercury(II) oxide and iodine in benzene.[2a]

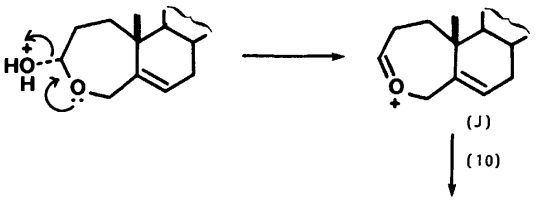
The less polar minor product **12** (8%) proved to be a dimeric acetal. FIMS (field ionization mass spectrometry) showed that the molecular ion at *m/z* 786 corresponded to the molecular formula $C_{54}H_{90}O_3$. The IR spectrum proved the absence of hydroxyl and carbonyl groups. The ^{1}H NMR spectrum was very similar to that of 4-oxa-*A*-homocholest-5-en-3-ol (**10**). These spectral results strongly suggested that product **12** is a dimer of lactol **10**. The assigned structure is also consistent with the spectrum of the EIMS (electron impact mass spectrometry) which showed the base peak at *m/z* 385, attributable to an ion (I) in Scheme 4. A probable genesis of this dimeric acetal involving the reaction of an intermediary oxonium ion (*J*)[9] with lactol **10** is outlined in Scheme 5.

Oxidation of acetate **5** with PCC (pyridinium chlorochromate) gave 4-oxa-*A*-homocholest-5-en-3-one (**13**) which has been obtained together with an epoxide **15** by the oxidation of cholest-5-en-3-one (**14**) with perbenzoic acid[10] (Scheme 3).

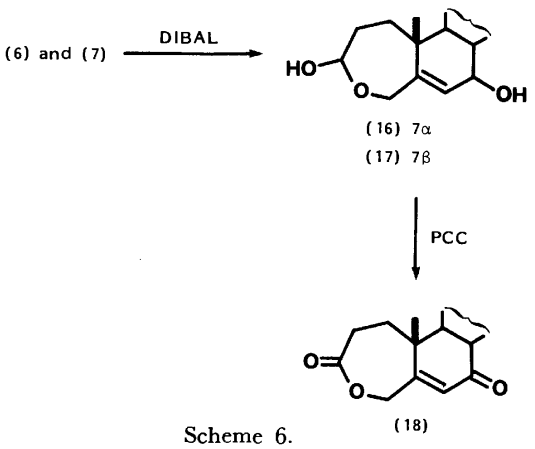
† 4-Oxa-*A*-homocholest-5-en-3α-ol reported in the previous paper[2a] may also be a mixture of 3α- and 3β-isomers. Its ^{1}H NMR spectrum (270 MHz) (see Experimental) proved that the chemical shifts of the 3-H, 4a-H, 5-H, and 18-H of 3α- and 3β-isomers are nearly identical but the 19-H of 3α-isomer differs from that of 3β-isomer. The spectrum also proved the presence of a trace of the corresponding ring-opened aldehyde. It is very likely that in solution the 3α- and 3β-isomers and the ring-opened aldehyde are in an equilibrium.



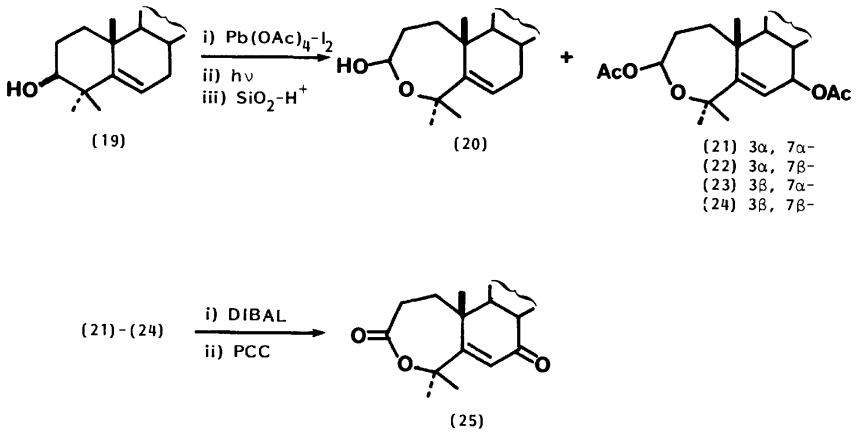
Scheme 4.



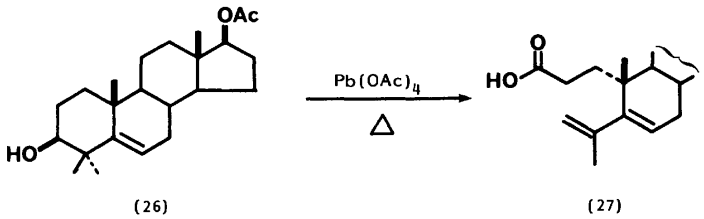
Scheme 5.



Scheme 6.



Scheme 7.



Scheme 8.

The ^{1}H NMR spectrum of the product [2], $C_{31}H_{51}O_5$ (high-resolution mass spectrometry) indicates that it is a stereoisomeric mixture of 4-oxa-*A*-homocholest-5-en-3ξ,7α- (**6**) and 3ξ,7β-diol diacetate (**7**); the IR spectrum indicated a band at 1728 cm^{-1} (OAc). The details of the analysis of the signals in the ^{1}H NMR spectrum of product [2] are recorded in the experimental section. The ratio of diacetates **6** and **7** was found to be 4:1 on the basis of the ratio of the area of the signals due to 7β-H and 7α-H of diacetates **6** and **7**. Their structures were confirmed by further transformations of the mixture. Reduction of the mixture with DIBAL gave a 3:1 mixture of 7α- **16** and 7β-hydroxylactol **17** which was then oxidized with PCC to give a crystalline 4-oxa-*A*-homocholest-5-en-3,7-dione **18** (Scheme 6). The spectroscopic results of dione **18** was fully consistent with the assigned structure (see Experimental).

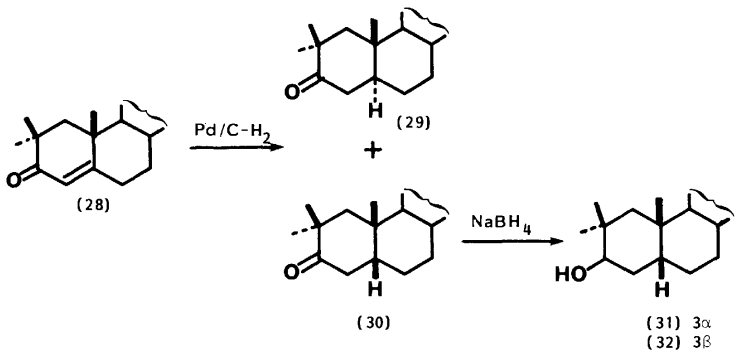
The product [3] (7% yield) was 4-oxa-*A*-homocholest-5-en-3ξ,7α-diol 7-acetate (**8**) contaminated with its 7β-isomer **9** and their ring-opened aldehydes. The results of the analysis of the ^{1}H NMR spectrum is described in the experimental section.

The product [4] (6%) was identical with the 4-oxa-*A*-homocholest-5-en-3-ols (**10**) obtained by the reduction of lactol acetate **5** with DIBAL. Not a trace of cholest-5-en-3β-yl 4-oxa-*A*-homocholest-5-en-3α-yl ether (**11**), which was reported to be the product in this photoinduced reaction,[8] was found in the products in this experiment.

We then found that cholest-5-en-3β-yl ether **11** is formed at the expense of lactols **5**—**10** if a smaller amount of lead tetraacetate and iodine is used in this reaction. Thus the photolysis of cholesterol hypoiodite prepared by 2 mol equiv of lead tetraacetate and iodine instead of 3 mol. equiv gave cholestenyl ether **11**[2a,8],†† in a 13% yield together with 4-oxa-*A*-homocholest-5-en-3ξ-ol acetate (**5**) (12%), a stereoisomeric mixture of 4-oxa-*A*-homocholest-5-en-3ξ,7β-(**6**) and 3ξ,7β-diol diacetate (**7**) (8%), 4-oxa-*A*-homocholest-5-en-3-ols (**10**)[2a] (11%), and a recovered cholesterol (13%).

A photoinduced reaction of 4,4-dimethylcholest-5-en-3β-ol hypoiodite prepared in situ by the treatment of the 3β-ol **19**,[7] with 3 mol equiv each of lead tetraacetate and iodine was then studied in order to examine the generality of the new reaction found for cholesterol hypoiodite. The irradiation of the hypoiodite in benzene under the conditions as described for the photoreaction of cholesterol gave a mixture of products which were separated by preparative TLC to give products [5] and [6]. The less polar product [5] (4%) was found to be 4a,4a-dimethyl-

†† The formation of cholestenyl ether **11** by using 3 mol equiv each of lead tetraacetate and iodine has been reported in the previous paper.[8] An explanation for this is that while a commercial lead tetraacetate was used in the present experiment, a freshly prepared lead tetraacetate used in the previous experiment was contaminated by some acetic acid.



Scheme 9.

4-oxa-*A*-homocholest-5-en-3ξ-ol (**20**) on the basis of the analysis of the ^{1}H NMR which is described in the experimental section. The more polar product [6] was found to be a mixture of the four possible stereoisomers of 4a,4a-dimethyl-4-oxa-*A*-homocholest-5-en-3,7-diol diacetate **21**—**24** by the analysis of the ^{1}H NMR spectrum (see Experimental) (Scheme 7). The assigned structure was further ascertained by transforming it into a crystalline 4a,4a-dimethyl-4-oxa-*A*-homocholest-5-ene-3,7-dione (**25**) by its reduction with DIBAL to 7-hydroxylactols followed by the oxidation with PCC.

The oxidation of 4,4-dimethylandrost-5-ene-3β,17β-diol 17-acetate (**26**) with lead tetraacetate alone has been reported by Amorosa et al.,[11] to give a seco aldehyde **27** in a 28% yield, as outlined in Scheme 8. The different results obtained by the two reagents may thus be apparent.

Products of the Photoinduced Reactions of the Hypoiodites of Steroidal Cyclic Alcohols and 2-Indanol. As was expected, the irradiation of cyclic alcohol hypoiodites under the foregoing conditions similarly gives lactol acetates in better yields in one step if the alkoxyl radicals generated from the hypoiodites are susceptible to β-scission.

We describe the results with steroidal alcohols, i.e. 2,2-dimethyl-5β-cholestan-3α- (**31**) and 3β-ol (**32**), 2,2-dimethyl-5α-cholestan-3β-ol (**33**),[12] 5α-androstan-17β-ol (**40**),[12] and 2-indanol (**45**) below. A mixture of 3-alcohols **31** and **32**, and 3β-alcohol **33** were prepared by reduction of the corresponding ketones with $NaBH_4$ (Scheme 9). Thus, 2,2-dimethylcholest-4-en-3-one (**28**)[13] was hydrogenated in the presence of palladium-charcoal as a catalyst to afford 2,2-dimethyl-5α-cholestan-3-one (**29**) identical with the authentic specimen and its isomer, 2,2-dmethyl-5β-cholestan-3-one (**30**) in a 3:17 ratio. The structure of the latter was apparent from its spectroscopic data (see Experimental). Reduction of 5β-isomer **30** with $NaBH_4$ gave approximately a 1:1 mixture of 2,2-dimethyl-5β-cholestan-3α-ol (**31**) and 3β-ol **32** (Scheme 9). The separatioh of the isomeric alcohols by means of preparative TLC was unsuccessful.

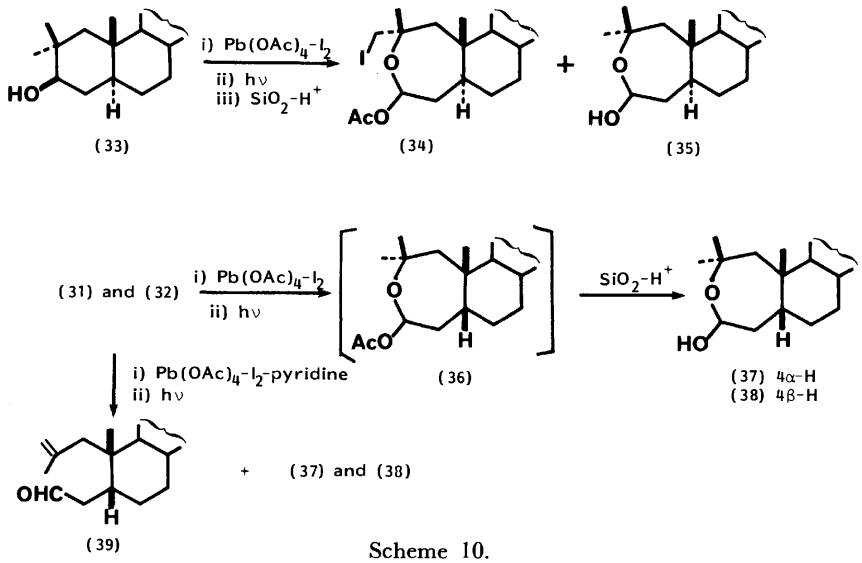
The preparation of the hypoiodite of 3β-alcohol **33** by the reaction with 3 mol equiv each of lead tetraacetate and iodine and irradiation of the solution under the conditions above gave two products **34** and **35**. The molecular formula of the less polar product **34**, which carries an iodine atom, was established to be $C_{28}H_{49}OI$ by an exact mass measurement of the ion due to $(M-CH_3COOH)^+$. The IR spectrum indicated the presence of an acetoxyl group. The ^{1}H NMR spectrum proved that the one of the *gem*-dimethyl of the starting 3β-ol was lost and exhibited only one 3H singlet at δ 1.44 attributable to Me group beside the two singlets due to the 18- and 19-H. It also showed a 3H singlet attributable to an acetoxyl group, and a 2H broad singlet at δ 3.40 assignable to a methylene group having an iodine. Thus, the structure of product **34** should be 2α-iodomethyl-2β-methyl-4-oxa-*A*-homo-5α-cholestan-4ξ-ol which can accommodate all the foregoing spectral results. The iodomethyl group attached to the C-2 of this lactol acetate **34** should be α-oriented since the chemical shift of the signal due to the 19-H (δ 1.03) does not differ appreciably from that of the signal due to the 19-H (δ 1.02) of product **35** for which the structure, 2,2-dimethyl-3-oxa-*A*-homo-5α-cholestan-4ξ-ol, was deduced on the basis of the mass spectrum together with the spectroscopic data (see Experimental).

Similar irradiation of the hypoiodites of 3α- and 3β-ols **31** and **32** in benzene under the conditions as for 3β-ol **33** and the separation of the product by means of preparative TLC gave a 1:1 mixture of 2,2-dimethyl-3-oxa-5β-cholestan-4α-(**37**) and 4β-ols (**38**) in a 66% yield. The structures were deduced by means of the IR, ^{1}H NMR and mass spectra (see Experimental). When this photolysis was carried out by adding a small amount of pyridne, an appreciable amount of a seco-aldehyde **39** (27%) was formed as an accompanying product at the expense of the yields of the lactols.

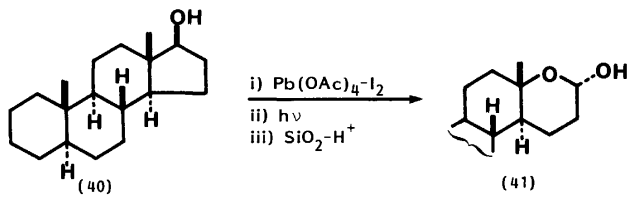
The irradiation of the hypoiodite of 5α-androstan-17β-ol (**40**),[12] a typical steroidal five-membered cyclic

alcohol, in benzene under the conditions as described above, gave 17a-oxa-D-homo-5α-androstan-17α-ol (**41**) in a 24% yield. The product **41** was identical with the specimen prepared by Baeyer–Villiger oxidation of 5α-androstan-17-one followed by its reduction with DIBAL.[15] The difference in the product **41** with those reported for the oxidation of steroidal 17β-ol **42** with lead tetraacetate alone by Amorosa et al,[11] which is outlined in Scheme 12, is again apparent.

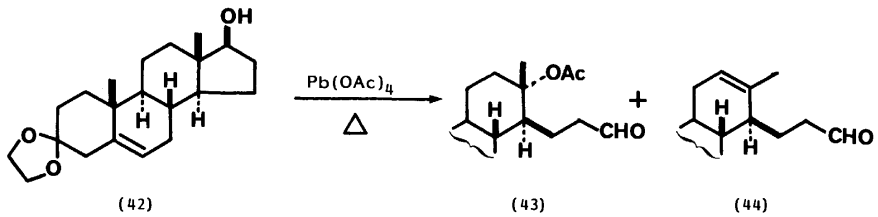
Finally, we undertook the photolysis of 2-indanol hypoiodite which should generate a stabilized benzyl radical by a β-scission of the corresponding alkoxyl radicals. We found that the major product was 2,3-dihydro-1*H*-2-benzopyran-3-ol acetate (**46**) (23% yield),



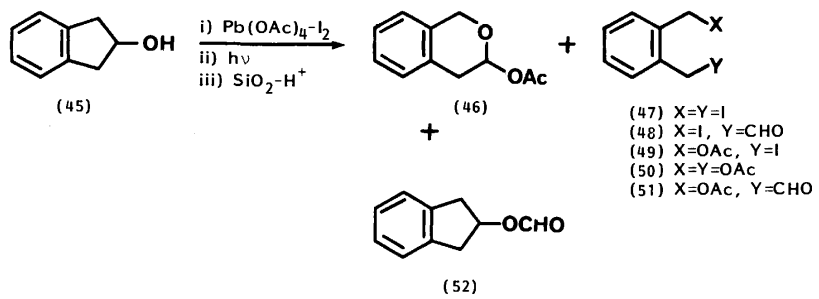
Scheme 10.



Scheme 11.



Scheme 12.

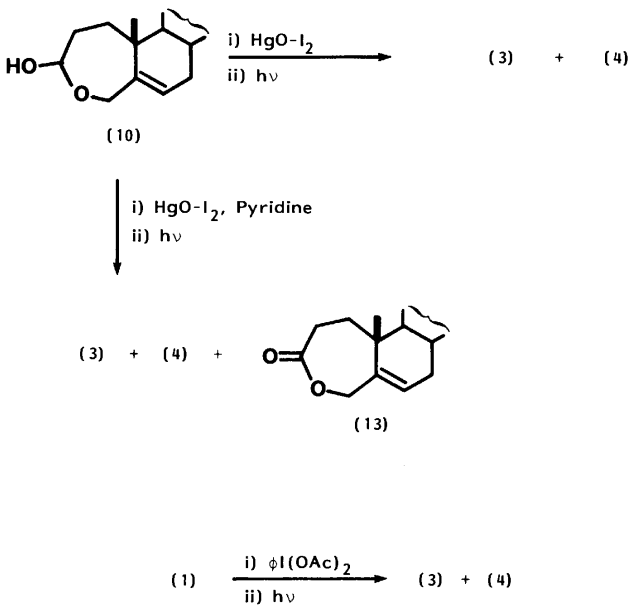


Scheme 13.

while several minor products **47**—**51**, arising from the combinations between the benzyl radical or cation and ·OAc, $^-$OAc, or iodine, as well as 2-indanol formate (**52**), were obtained in low yields (Scheme 13).

Products of the Photoinduced reaction of the Hypoiodite of 4-Oxa-A-homocholest-5-en-3-ols (10) in the Presence of Mercury(II) Oxide and Iodine. As we mentioned at the outset of this paper, the photolysis of hypoiodite of cholesterol (**1**) in benzene containing an excess of mercury(II) oxide and iodine gives 3α,5-epoxy-6β- and 6α-iodo-4-oxa-*A*-homo-5α-cholestanes (**2**) and (**3**) together with iodo formate **4**.[2a,3] It has recently been reported that (diacetoxyiodo) benzene is a good reagent for the production of hypoiodite from alcohols.[16] We therefore prepared cholesterol hypoiodite from (diacetoxyiodo)benzene and cholesterol and subjected it to photolysis. It was found that 3α,5-epoxy-6α-iodo-4-oxa-*A*-homo-5α-cholestane (**3**) and iodo formate **4** are the major products and that no 6β-iodooxasteroid **2** was found in the product. The difference in the products when mercury(II) oxide–iodine and (diacetoxyiodo)benzene are used to generate hypoiodites is interesting.

As outlined in Scheme 1, the paths leading to these products should involve the intermediacy of alkoxyl radicals such as (D) or (F). These species can be generated by the irradiation of the hypoiodites of 3α- and 3β-lactols **10**. In order to ascertain the proposed paths outlined in Scheme 1, the products of the photolysis of the hypoiodites of lactols **10** were studied. Irradiation of lactols **10** in benzene containing 3 mol equiv each of mercury(II) oxide and iodine was found to give oxasteroid **3** (17%) and iodo formate **4** (56%), as otulined in Scheme 14. This photolysis was also carried out in the presence of pyridine. We found



Scheme 14.

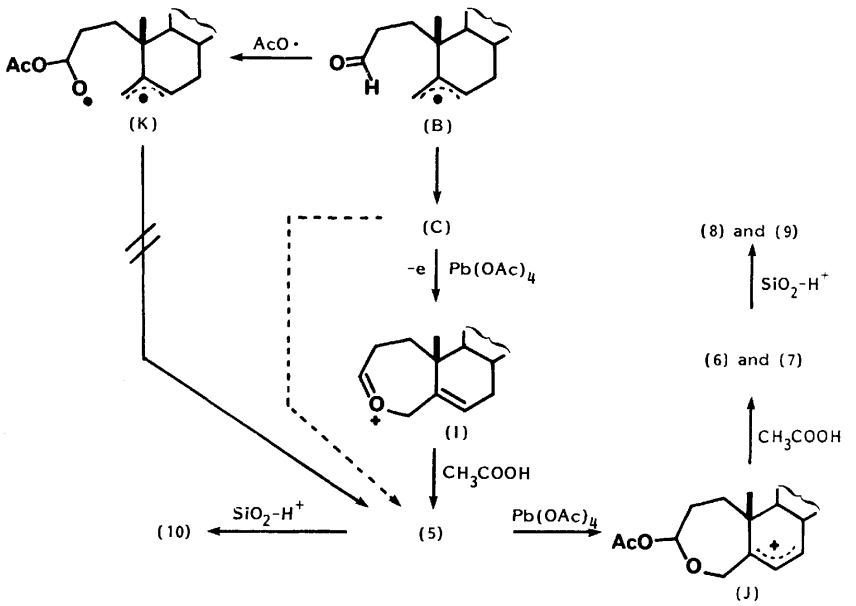
that besides oxasteroid **3** (11%) and iodo formate **4** (39%), lactone **13**[10] is formed in a 25% yield. The results can be taken as a further evidence that the immediate forerunners of 3α,5-epoxy-4-oxa-*A*-homosteroids such as **3** and iodo formate **4** in the steroid-5-en-3-ol hypoiodite photolysis are alkoxyl radicals (D) and (F). Pyridine accelerates the formation of lactone **13**. No further experiments have been carried out to clear up the problem as to why radical (G) is more readily oxidized to give cation (H), from which 6α-iodo compound **3** is believed to be formed, in the case of the photolysis of lactol hypoiodite.

Discussion

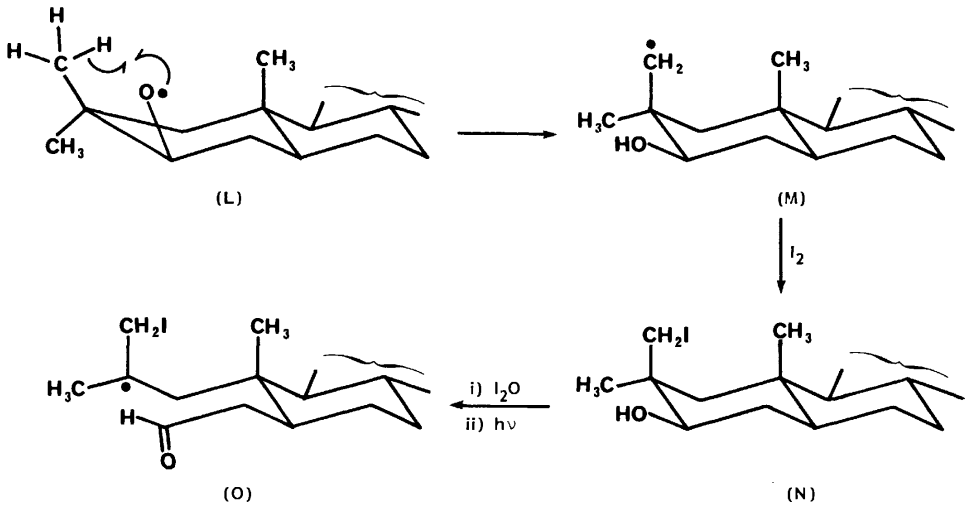
The foregoing experiments clearly show that the products in the photolysis of the hypoiodites of cyclic alcohols generated in situ in benzene with three molar equivalents each of lead tetraacetate and iodine differ considerably from those in a photolysis using mercury(II) oxide and iodine[2] as the reagent for generating the hypoiodites; the photolysis generally results in the formation of the lactols or their acetates by an oxygen insertion and no 3α,5-epoxy-4-oxa-*A*-homo-5α-cholestanes such as **2** and **3** and iodo formate **4**[2a,3] are formed. The formation of the lactols from the cyclic alcohols in one step is unprecedented.

We confirmed that no reaction took place when the above cyclic alcohols in benzene containing lead tetraacetate alone were irradiated and an intractable mixture resulted when cholesterol in benzene containing lead tetraacetate was heated under reflux.

The probable paths for the formation of the lactols and their acetates in the present study are outlined in Scheme 15. The cyclic alcohols are transformed into the corresponding hypoiodites with CH_3COOI generated in situ by the reaction of lead tetraacetate with iodine.[5,6] The excited hypoiodites generate the corresponding alkoxyl radicals which rearrange to the allyl radicals (B) by β-scission. Its intramolecular combination with the carbonyl oxygen then generates the radicals (C). Thus, the formation of lactol acetates may well follow the same path as that in the photoinduced reaction by using mercury(II) oxide and iodine up to the formation of the intermediate (C). The one-electron oxidation of the radical (C) with lead tetraacetate generates an oxonium ion (I) which traps acetic acid to give lactol acetates (**5**). An alternative formation of lactol **5**, although less likely, by a radical combination between radical (C) and an acetoxyl radical may also be possible. The formation of **5** via a biradical (K) is very unlikely since a β-scission may precede from species (K). The parent cyclic alcohols such as cholesterol can apparently compete with acetic acid in the reaction with the oxonium ion (I) to form an ether such as **11**[8] when a concentration of the lead tetraacetate-iodine reagent is lower. Lactol



Scheme 15.

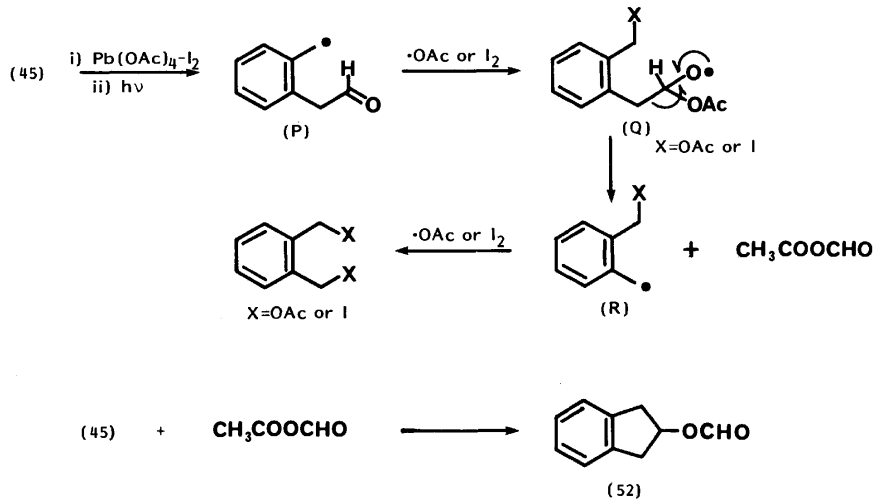


Scheme 16.

acetates **6** and **7** are formed by oxidation of acetates **5** with lead tetraacetate or through a hydrogen abstraction of the allylic hydrogen with acetoxyl radical to form an allyl radical followed by its oxidation to an allyl cation which traps acetic acid. The formation of the lactols alone or with the corresponding acetates have been observed for all the photolysis of the present hypoiodite photolysis. It is clear that these lactols are not the primary products but that they are formed by hydrolysis with silica gel in preparative TLC. The formation of these lactols by preparative TLC of the lactol acetates was in fact confirmed for some of the lactol acetates. It is interesting to note that no lactols corresponding to the lactol acetates **21**—**24** and **34** were found after the treatment with silica gel (preparative TLC), nor were lactol acetates corresponding to lactols **5**, **35**, **37**, **38**, and **41** isolated in preparative TLC with silica gel. These different patterns of behavior of the initially formed lactol acetates are apparently ascribable to hindrance by nearby substituents.

The formation of anomalous lactol acetate **34** which carries an iodine atom (Scheme 10) is interesting. Scheme 16 outlines its formation from the alkoxyl radical (L). The ring A should adopt a somewhat flattened chair conformation owing to the 1,3-diaxial interaction between 2β- and 10β-Me groups. The alkoxyl radical (L), therefore, can abstract a hydrogen of the 2β-Me via a normally incapable five-membered transition state to form a carbon-centred radical (M) which then abstracts an iodine atom to give a new intermediate (N). The path from the intermediate (N) to the lactol acetate **34** via (O) is straightforward.

Finally, all the products with the exception of formate **52** formed in the photolysis of 2-indanol hypoiodite should be derived by a radical (P) arising



Scheme 17.

from a β-scission of 2-indanyloxy radical as outlined in Scheme 17. The simultaneous formation of formate **52** and products **47**, **49**, and **50** strongly suggests the involvement of an intermediate (Q) which can be generated by the attack of an acetoxyl radical on a formyl group of an intermediary aldehyde. The β-scission of the alkoxyl radical (Q) may give acetic formic anhydride and a new benzyl radical (R). The former then reacts with 2-indanol to give formate **52**[17] while the reaction of the latter with iodine or an acetoxyl radical leads to products **47**, **49**, and **50**.

The present photoinduced reaction can be useful in synthesis since the lactols can be obtained in yields as high as 66% in one step from cyclic alcohols provided the alkoxyl radicals generated from them are susceptible to β-scission. Even the unsaturated lactols such as **5** and **20** which are not easily obtainable by other methods can be obtained in one step from cyclic homoallyl alcohols.

Experimental

Mps were determined with a Yanagimoto micro mp apparatus. IR spectra were determined for Nujol mulls by a Hitachi Model 285 infrared spectrometer unless stated otherwise. ^{1}H NMR spectra was determined by a Hitachi-R-90H spectrometer (90 MHz) or JEOL-JMS-GX-270 spectrometer (270 MHz) (solvent $CDCl_3$: $SiMe_4$ as internal standard). Mass spectra were taken by JEOL JMS-D300 spectrometer (70 eV) (Faculty of Pharmaceutical Sciences of this University). TLC was carried out on Merck Kiesel gel 60 PF_{254}. Elemental analyses were performed by the staff of the Faculty of Pharmaceutical Sciences.

Lead Tetraacetate. A quality of lead tetraacetate was found to affect considerably to the yields of each product. Throughout the present work, a commercial lead tetraacetate was used.

The Photolysis of Cholesterol Hypoiodite in the Presence of Lead Tetraacetate and Iodine. (a) Cholesterol (**1**) (1 g, 2.59 mmol) in benzene (120 mg) containing lead tetraacetate (3.44 g, 7.77 mmol) and iodine (1.97 g, 7.74 mmol) was irradiated under an atmosphere of a nitrogen for 4.5 h. TLC indicated that no starting material remained unchanged. After the removal of the precipitates by filtration, the solution was washed with 5% sodium thiosulfate solution, 5% sodium hydrogencarbonate solution, water and saturated brine successively and dried (Na_2SO_4). After the usual work-up the residue (1.464 g) was subjected to preparative TLC with a benzene–diethyl ether (10:1) to give three fractions. The most mobile fraction (551 mg, 47%) was an oily lactol acetate (**5**). ^{1}H NMR (200 MHz) 0.69 (3H, s, 18-H), 0.98 (3H, s, 19-H), 2.07 (3H, s, OAc), 3.70 (1H, d, J=12.5 Hz, 4a-H), 4.41 (1H, d, J=12.5 Hz, 4a-H), 5.64 (1H, br.d, 6-H), and 6.00 (1H, dd, J=6.84 and 4.41 Hz, 3-H); IR (neat) 1733 (OAc), 1222 (C–O), and 1005 (C–O); MS (70 eV) m/z (rel intensity) 444 (M^+, 0.3), 384 ([M−CH_3COOH]$^+$, 100), 328 (39.9), 247 (36.8), and 215 (42.8). Found: (M−CH_3COOH)$^+$ 384. 33626. Calcd for $C_{27}H_{44}O$: M−CH_3COOH, 384.33916.

The second mobile fraction (233 mg) was a mixture of lactols **8** and **9** and their acetates **6** and **7**. This was again subjected to preparative TLC with benzene and diethyl ether (2:1)to give two fractions A (181 mg) and B (79 mg, 6.6%). The more mobile fraction A was again subjected to preparative TLC with hexane and diethyl ether (1:1) to give an oily mixture of two epimers of lactol acetate **6** and **7** (49 mg, 3.8%). ^{1}H NMR (200 MHz) 0.68 (3H, s, 18-H of two C-7 epimers), 0.98 (3H, s, 19-H) of C-7 epimers), 2.03 (3H, s, Ac), 2.08 (3H, s, Ac), 3.74 (1H, d, J=13.19 Hz, 4a-H of two epimers), 4.40 (0.2H, d, J=13.19 Hz, 4a-H of 7β-acetoxy epimer), 4.44 (0.8H, d, J=13.19 Hz, 4a-H of 7α-acetoxy epimer), 5.00 (0.8H, br.t, J=4.4 Hz, 7β-H of 7α-acetoxy epimer), 5.12 (0.2H, dd, J=2 and 8.6 Hz, 7α-H of 7β-acetoxy epimer), 5.47 (0.8H, d, J=2 Hz, 6-H of 7β-epimer), 5.77 (0.2H, d, J=4.88 Hz, 6-H of 7α-epimer), 6.01—6.41 (1H, m, 3-H of 7α- and 7β-epimers); MS (70 eV) m/z (rel intensity) 502 (M^+, 0.2), 442 ([M−CH_3COOH]$^+$, 23), 400 (30), and 43 (100); IR (neat) 1728 (OAc), 1243 (C–O), and 1020 (C–O). Found: M^+ 502.36289. Calcd for $C_{31}H_{50}O_5$: M, 502.37569. The less mobile fraction B was a gummy 7α-acetoxylactol **8** contaminated with 7β-acetoxylactol **9** and the corresponding ring-opened aldehydes. ^{1}H NMR (90 MHz) 0.66 (s, 18-H

of 7α-acetoxylactol), 0.69 (s, 18-H of 7β-acetoxylactol), 0.94 (s, 19-H of 7α-acetoxylactol), 1.01 (s, 19-H of 7β-acetoxylactol), 2.00 (s, OAc of 7β-acetoxylactol), 2.02 (s, OAc of 7β-acetoxylactol), 3.60 (br.d, J=12 Hz, 4a-H of 7α- and 7β-acetoxylactols), 4.51 (br.d, J=12 Hz, 4a-H of 7α- and 7β-acetoxylactols), 4.06 (br.s, 4a-methylene group of ring-opened aldehyde), 4.95—5.05 (m, 7-H of 7α- and 7β-acetoxylactols and their ring-opened aldehydes), 5.09—5.15 (m, 3-H of 7α- and 7β-acetoxylactols), 5.42 (d, J=2 Hz, 6-H of 7β-acetoxylactol), 5.74 (d, J=5.6 Hz, 6-H of 7α-acetoxylactol), and 9.72 (br.s, CHO of the ring-opened aldehydes); IR 3400 cm^{-1} (OH), 1718 (OAc), 1237 (C-O), and 1020 (C-O); MS (70 eV) m/z (rel intensity) 442 ($[M-H_2O]^+$ of lactols, 3.6%), 400 ($[M-AcOH]^+$ of lactols 47), and 43 (100).

The third fraction (19 mg) was 4-oxa-*A*-homocholest-5-en-3-ol (**10**) which was identical with the authentic specimen.

(b) Cholesterol (100 mg, 0.26 mmol) in benzene (15 ml) containing lead tetraacetate (228 mg, 0.52 mmol) and iodine (131 mg, 0.52 mmol) was irradiated under an atmosphere of a nitrogen for 4 h. TLC of the reaction mixture indicated the presence of some cholesterol. The reaction mixture was worked up as described above. The crude product (153 mg) was subjected to preparative TLC with a benzene–diethyl ether (10:1) to give five fractions a to e. The most mobile fraction a was a mixture and therefore subjected again to preparative TLC with a benzene–hexane (1:1) to give a dimeric acetal **11** (27 mg, 14%) which was identical with the authentic specimen. The next mobile fraction b (14 mg, 12%) was lactol acetate **5**. The fraction c (11 mg, 8%) was a mixture of lactol acetates **6** and **7** judged from the ^1H NMR spectrum. Fraction d (13 mg) was cholesterol. Fraction e was lactols **10**.

Reduction of Lactol Acetate 5 with DIBAL. The lactol acetate **5** (81 mg) in dry toluene (8 ml) was cooled by Dry Ice–methanol. To this solution DIBAL (1 M hexane solution, Ventron) (0.22 ml) was added by means of micro syringe. After the solution was stirred for 2 h, water was added and the reaction mixture was stirred for half an hour. After the precipitates were removed by filtration, the organic layer was washed with brine and dried over anhydrous sodium sulfate. Usual work-up of the solution gave a residue which showed two spots on TLC plate. The product was subjected to preparative TLC with benzene–diethyl ether (5:1) to give two products. The more mobile compound (11 mg, 7.6%) was a dimeric acetal **12** which was recrystallized from dichloromethane. Mp 225—231 °C. FDMS (rel intensity) m/z 786 (M^+, 77%), 768 (40), 385 (100, the ion I in the text). ^1H NMR (200 MHz) 0.68 (6H, s, 18 and 18'-H), 0.89 (6H, s, 19 and 19'-H), 4.30 (2H, d, J=13.3 Hz, 4a- and 4a'-H), 4.95—5.20 (2H, m, 3 and 3'-H), 5.50—5.62 (2H, m, 6- and 6'-H); IR 1257 and 1020 cm^{-1} (C-O). The less mobile compound (41 mg, 56%) was a mixture of 3α- and 3β-lactols **10**. ^1H NMR 0.69 (s, 18-H of 3α- and 3β-isomers), 0.97 (s, 19-H of 3α-isomer), 0.93 (s, 19-H of 3β-isomer), 3.58 (br.d, J=13 Hz, 4a-H of 3α- and 3β-isomers), 4.48 (d, J=13 Hz, 4a-H of 3α- and 3β-isomers), 5.17 (br.t, 3β- and 3α-H of 3α- and 3β-isomers), 5.62 (br.dd, J=2 and 5 Hz; 5-H of 3α- and 3β-isomers), 9.75 (br.t, CHO of the ring opened aldehyde).

Oxidation of Lactol Acetate 5 with Pyridinium Chlorochromate (PCC). To the lactol acetate **5** (41 mg) in dichloromethane (7 ml) containing some Celites, PCC (30 mg) was added and the solution was stirred for 2 h. After the solution was filtered, the filtrate was washed with water and then a brine successively and dried over anhydrous sodium sulfate After the usual work-up, the crude product was purified by means of preparative TLC to give a pure 4-oxa-*A*-homocholest-5-en-3-one (**13**) (30 mg, 70%). Analytical specimen was obtained by recrystallization from methanol. Mp 200—202 °C (lit,[10] 202 °C). ^1H NMR (90 MHz) 0.69 (3H, s, 18-H), 1.07 (3H, s, 19-H), 4.20 (1H, d, J=13.2 Hz, 4a-H), 4.78 (1H, d, J=13.2 Hz, 4a-H), and 5.84 (1H, br.dd, J=6.2 and 2.2 Hz); IR 1733 cm^{-1} (lactonic C=O), 1288, 1155, and 1035; MS (70 eV) m/z (rel intensity) 400 (M^+, 51.6), 385 ($[M-15]^+$, 22.1), 287 (82.3), and 43 (100).

Reduction of Lactol Acetates 6 and 7 with DIBAL. The lactol acetates (63 mg) in dry toluene (6 ml) was reduced with DIBAL (0.26 ml) as described for the reduction of lactol acetate **5**. The product (47 mg) was subjected to preparative TLC with diethyl ether to give a 3:1 mixture of gummy lactols **16** and **17** (24 mg, 61%). ^1H NMR (90 MHz) 0.69 (3H, s, 18-H), 0.96 (3H, s, 19-H), 3.60 (1H, br.d, J=13 Hz, 4a-H), 4.52 (1H, br.d, J=13 Hz, 4a-H), 3.87 (1H, br.s, 7-H), 5.08—5.23 (1H, m, 3-H), 5.53 [0.24H, br.d, J=2 Hz, 6-H of (**14**)], 5.78 (0.75H, br.d, J=5.3 Hz, 6-H of (**13**)]; IR 3340 cm^{-1} (OH) and 1027 (C-O); MS (70 eV) m/z (rel intensity) 418 (M^+, 6.7), 400 ($[M-H_2O]^+$, 23), 353 (57), and 55 (100). Found: M^+ 418.34219. Calcd for $C_{27}H_{46}O_3$: M, 418.34459.

Oxidation of Lactols 16 and 17 with PCC. To the lactols (21 mg) in dichloromethane (5 ml) containing Celite, PCC (33 mg) was added. The reaction mixture was stirred for 4 h and worked up as described for the oxidation of lactol acetate **5**. The curde product (18 mg) was subjected to preparative TLC with a 5:1 benzene–diethyl ether to give a crystalline lactone **18** (7 mg, 34%). The lactone was recrystallized from acetone–methanol. Mp 267—272 °C. ^1H NMR (90 MHz) 0.70 (3H, s, 18-H), 1.28 (3H, s, 19-H), 4.37 (1H, d, J=13.3 Hz, 4a-H), 4.92 (1H, d, J=13.3 Hz, 4a-H), 5.91 (1H, s, 6-H); MS (70 eV) m/z (rel intensity) 414 (M^+, 100), 355 (29.9), and 341 (19.3) and 206 (74.3). Found: m/z 414.31295. Calcd for $C_{27}H_{42}O_3$: M, 414.31335. IR 1719 cm^{-1} (lactonic C=O), and 1652 (α, β-unsaturated C=O).

The Photolysis of the Hypoiodite of 4,4-Dimethylcholest-5-en-3α-ol (19) in the Presence of Lead Tetraacetate and Iodine. The 3β-ol **19** (100 mg, 0.24 mmol) in benzene (15 ml) containing lead tetraacetate (321 mg, 0.73 mmol) and iodine (194 mg, 0.73 mmol) was irradiated for 3.5 h as described above for cholesterol. The reaction mixture was worked up as usual. The product was subjected to preparative TLC with 10:1 benzene–diethyl ether to give two fractions. The more mobile fraction (21 mg) was again subjected to preparative TLC to give a gummy lactol **20** (4 mg). ^1H NMR (90 MHz) 0.69 (3H, s, 18-H), 0.93 (3H, s, 19-H), 1.26 and 1.52 (3H, s, 4a *gem*-dimethyl), 4.87 (1H, br.s, 3-H), 5.39 (1H, m, 6-H); IR 3340 cm^{-1} (OH), and 1042; MS (70 eV) m/z (rel intensity) 412 ($[M-H_2O]^+$, 100), 394 (32.5), and 379 (20.8). Found: m/z 412.36934 $(M-H_2O)^+$. Calcd for $C_{29}H_{48}O$: M, 412.37044.

The less mobile fraction (44 mg) was a mixture of gummy lactol acetates **21—24** which were found to be actually a mixture of four possible stereoisomers by its ^1H NMR spectrum. ^1H NMR (270 MHz) 0.67 an 0.70 (each s, 18-H of

the stereoisomers), 1.20 (s, 19-H), 2.49 and 1.58 (each s, 4a *gem*-dimethyl), 2.038, 2.045, 2.048, 2.065, 2.273, 2.098 (each s, OAc attached to C-3 and C-7 of the stereoisomers), 4.95—5.29 (m, 6-H and 7-H of the stereoisomers), 5.66—6.02 (m, 3-H of the stereoisomers); IR 1733 cm^{-1} (OAc), 1237 and 1011 (-O); MS (70 eV) *m/z* (rel intensity) 515 ($[M-Me]^+$, 1.6), 470 ($[M-AcOH]^+$, 14.7), 428 (33.0), 370 (34.5), and 43 (100).

The Transformation of Lactol Acetates 21—24 into Lactone 25. To lactol acetates (30 mg) in toluene (4 ml) cooled by Dry Ice, DIBAL solution (1 M solution, 0.11 ml, Ventron) was added through micro syringe. The solution was stirred for 2 h and worked up in a usual manner. The crude lactols were dissolved in dichloromethane containing Celite and to this solution PCC (15 mg) was added. The solution was stirred for 2 h at room temperature and filtered. The filtrate was washed with water and then brine and dried over anhydrous sodium sulfate. The usual work-up gave a crude lactone which was purified by means of preparative TLC with 1:1 benzene–diethyl ether to give 4 mg of lactone **25**.

Catalytic Reduction of 2,2-Dimethylcholest-4-en-3-one 28. Enone **28** (280 mg) in ethanol (15 ml) containing Pd-C (30 mg) was placed in a round-bottomed flask and was stirred in an atmosphere of hydrogen for 6 h at room temperature. After the removal of the catalyst and the solvent the residue was recrystallized from methanol–acetone to yield 2,2-dimethyl-5β-cholestan-3-one (**30**), mp 79.5—81.0 °C. ^{1}H NMR (90 MHz) 0.68 (3H, s, 18-H), 0.99 (3H, s, 19-H), 1.05 and 1.19 each 3H, each s, *gem*-dimethyl), 1.97 (1H, dd, J=3.6 and 15.7 Hz, 4β-H), and 2.93 (1H, dd, J=14.3 and 15.7 Hz, 4α-H); IR 1706 cm^{-1} (C=O); MS (70 eV) *m/z* (rel intensity) 414 (M^+, 100), 396 (55.4), 381 (51.4), and 259 (54.0). Found: C, 83.96; H, 12.22%. Calcd for $C_{29}H_{50}O$: C, 83.99; H, 12.15%.

The combined filtrates from the recrystallization was collected and after the removal of the solvent the residue was subjected to preparative TLC to give an isomeric ketone **29** identical with the authentic specimen.[12] The ratio of the yields of ketones **29** and **30** in this catalytic hydrogenation was 3:17.

Reduction of 2,2-Dimethyl-5β-cholestan-3-one (30) with Sodium Borohydride. The 3-ketone **30** (200 mg) in ethanol (20 ml) containing $NaBH_4$ (200 ml) was stirred for 2 h at room temperature. After the addition of water, the solution was extracted with dichloromethane. The solution was washed with water and then brine, and dried over anhydrous sodium sulfate. After the usual work-up, the crude 3-ols **31** and **32** were recrystallized from methanol. Mp 97.5—98.5 °C. ^{1}H NMR (270 MHz) 0.64 (3H, s, 18-H), 0.89 and 0.91 (each s, 19-H of 3α-ol and 3β-ol), 0.95 and 0.99 (each 3H, each s, *gem*-dimethyl), and 3.35—3.41 (1H, m, 3α- and 3β-H); IR 3300 cm^{-1} (OH), 1070, and 1022 cm^{-1}; MS (70 eV) *m/z* (rel intensity) 416 (M^+, 12), 398 ($[M-H_2O]^+$, 100), 383 (41.9), 328 (86.6), 316 (32.5), 243 (50.3), and 95 (15.1). Found: (C, 83.83; H, 12.42%).

The Photolysis of the Hypoiodite of 2,2-Dimethyl-5α-cholestan-3β-ol (32) in the Presence of Lead Tetraacetate and Iodine. The 3β-alcohol (100 mg, 0.24 mmol) in benzene (15 ml) containing lead tetraacetate (321 mg, 0.73 mmol) and iodine (184 mg, 0.73 mmol) was irradiated for 2.5 h as described for the photolysis of cholesterol. After the usual work-up, the product was subjected to preparative TLC with a 10:1 benzene–diethyl ether to give two fractions. The more mobile fraction (31 mg) was gummy lactol acetate **34**. ^{1}H NMR (90 MHz) 0.66 (3H, s, 18-H), 1.03 (3H, s, 19-H), 1.44 (3H, s, 2-Me), 2.06 (3H, s, OAc), 3.40 (2H, br. s, CH_2I), and 5.88 (1H, br.d, J=9.7 Hz, 4-H); MS (70 eV) *m/z* (rel intensity) ($[M-CH_3COOH]^+$, 0.7), 525 ($[M-CH_3COOH-Me]^+$, 1.7), 459 ($[M-CH_2I]^+$, 11), 413 (29.9), 399 (39.4), and 83 (100). Found: *m/z* 540.28212 $(M-CH_3COOH)^+$. Calcd for $C_{29}H_{49}OI$: M, 540.28292.

The less mobile fraction (31 mg) was a gummy lactol **35** which was recrystallized from acetonitrile. Mp 117—119 °C. ^{1}H NMR (90 MHz) 0.65 (3H, s, 18-H), 1.02 (3H, s, 19-H), 1.23 and 1.29 (each 3H, each s, *gem*-dimethyl), and 5.01 (1H, dd, 4-H); IR 3412 cm^{-1}, 1103, 1030, and 1001; MS (70 eV) *m/z* (rel intensity) 414 ($[M-H_2O]^+$, 39), 399 (25.0), 359 (45.2), 314 (44.8), 201 (41.7), and 83 (100). Found: *m/z* 414.38753 $(M-H_2O)^+$. Calcd for $C_{29}H_{50}O$: M, 414.38613.

The Photolysis of the Hypoiodite of 2,2-Dimethyl-5β-cholestan-3α- (31) and 3β-ol (32) in the Presence of Lead Tetraacetate and Iodine. (a) The mixture of 3α- and 3β-alcohols, **31** and **32** (77 mg, 0.19 mmol) in benzene (15 ml) containing lead tetraacetate (245 mg, 0.56 mmol) and iodine (141 mg, 0.56 mmol) was irradiated for 2 h as described for an isomeric 5α-ol hypoiodite above. After the usual work-up the product was subjected to preparative TLC with 5:1 benzene–diethyl ether to give three fractions. The most mobile fraction (18 mg) was an intractable mixture. The second (15 mg) and the third fractions (39 mg) were found to be identical and was a mixture of two lactols **37** and **38**. The second fraction was most probably the corresponding acetate **36** but it was probably hydrolyzed during its extraction from the TLC plates. The mixture of **37** and **38**. ^{1}H NMR (270 MHz) 0.65 (s, 18-H), 0.67 (s, 18-H of C-4 isomer), 0.91 (s, 19-H), 1.02 (s, 19-H of C-4 isomer), 1.15, 1.19, 1.32 and 1.37 (each s, *gem*-dmethyl of two C-4 isomers), 5.11 (dd, J=2.2 and 8.5 Hz, 4-H), 5.21 (dd, J=5.5 and 5.7 Hz, 4-H of C-4 isomer); 414 ($[M-H_2O]^+$, 40.2), 399 (60.3) 314 (41.6), 259 (45.9), and 43 (100); IR 3390 cm^{-1} (OH) and 1042. Found: *m/z* 414.38450 $(M-H_2O)^+$. Calcd for $C_{29}H_{50}O$: M, 414.38610.

(b) In the Presence of Pyridine. The mixture of 3α- and 3β-alcohols, **31** and **32** (112 mg, 0.27 mmol) in benzene (17 ml) containing lead tetraacetate (357 mg, 0.81 mmol), iodine (205 mg, 0.81 mmol) and pyridine (0.1 ml) was irradiated for 4 h as described above. After the work-up of the reaction mixture by the usual method, the product was subjected to preparative TLC to give three fractions. The most mobile fraction was a gummy secoaldehyde **39** (30 mg). ^{1}H NMR (270 MHz), 0.66 (3H, s, 18-H), 1.16 (3H, s, 19-H), 1.80 (3H, s, 2-Me), 2.52—2.81 (2H, m, 4-H), 4.70 and 4.86 (each 1H, each s, 2-methylene), and 9.64 (1H, dd, J=3.3 and 0.7 CHO); IR 2705 cm^{-1} (aldehydic CH), 1720 (CHO), and 890 (C=CH_2); MS (70 eV) *m/z* (rel intensity) 414 (M^+, 4), 399 ($[M-Me]^+$, 4), 359 (51), 341 (44.9), 315 (76.2), and 57 (100). Found: 414.38752 (M^+). Calcd for $C_{29}H_{51}O$: M, 414.38612.

The second fraction (29 mg) was an intractable mixture. The third fraction (27 mg) was lactols **37** and **38**.

The Photolysis of the Hypoiodite of 5α-Androstan-17β-ol (40). The 17β-ol (100 mg, 0.36 mmol) in benzene (20 ml) containing lead tetraacetate (482 mg, 1.09 mmol) and iodine (276 mg, 1.09 mmol) was irradiated under the conditions as

described for cholesterol hypoiodite. The work-up as usual gave a product which was subjected to preparative TLC with a 5:1 benzene–diethyl ether to give three fractions. The most and next mobile fractions were an intractable mixture. The least mobile fraction (25 mg) was lactol **41** which was identical with the authentic specimen.[15]

The Photolysis of the Hypoiodite of Cholesterol in the Presence of (Diacetoxyiodo)benzene. Cholesterol (100 mg) in dry benzene (15 ml) containing (diacetoxyiodo)benzene (166 mg) and iodine (131 mg) was flushed with a nitrogen and irradiated with mercury arc for 4 h. The solution was washed with a 5% aq sodium thiosulfate, aq sodium hydrogencarbonate and water and dried. Evaporation of the solution left a residue which was subjected to preparative TLC with a 4:1 benzene–diethyl ether to give a less polar iodo formate (25 mg, 18%) and a more polar cyclic ether **3** (14 mg, 10%).

Photolysis of the Hypoiodite of 4-Oxa-A-homocholest-5-en-3-ol (10) in the Presence of Mercury(II) Oxide and Iodine. (a) The lactol (238 mg) in dry benzene (35 ml) containing mercury(II) oxide (257 mg), iodine (300 mg) and pyridine (0.3 ml) in a Pyrex vessel was irradiated with a 100-W high pressure mercury arc in an atmosphere of nitrogen for 4.5 h. The photolyzed solution was worked up as described for the photolysis of cholesterol hypoiodite. The crude product (327 mg) was subjected to preparative TLC with 3:1 benzene–hexane to give three fractions. The most mobile fraction (122 mg) was an iodo formate **4** identical with the authentic specimen. The second fraction (35 mg) was identified to be a cyclic ether **3**[2a] by a comparison with the authentic specimen. The third fraction (77 mg) was once purified by preparative TLC to give a pure lactone **13** (60 mg) which was identical with the authentic specimen.

(b) The lactol **10** (41 mg) in dry benzene (5 ml) containing mercury(II) oxide (44 mg) and iodine (52 mg) was subjected to the photolysis under the conditions as described above. The work-up as described above gave iodo formate (30 mg, 56%) and cyclic ether (9 mg, 17%). No lactone **13** was detected in the crude product by TLC.

The Photolysis of the Hypoiodite of 2-Indanol (45) in the Presence of Lead Tetraacetate and Iodine. 2-Indanol **45** (150 mg, 1.11 mmol) in benzene (20 ml) containing lead tetraacetate (1.49 g, 3.35 mmol) and iodine (853 mg, 3.35 mmol) was irradiated for 1.5 h as described for cholesterol. The reaction mixture was worked up as usual. The product was subjected to preparative TLC with 10:1 benzene–diethyl ether to give four fractions. The most mobile fraction (24 mg, 6%) was 1,2-bis[iodomethyl]benzene (**47**) which was recrystallized from hexane. Mp 111—112 °C. IR 1147 and 766 cm^{-1}; ^1H NMR (90 MHz) 4.56 (4H, s, CH_2I) and 7.24 (4H, m, aromatic H); MS (70 eV) *m/z* (rel intensity) 358 (M^+, 3.4%), 231 ($[M-I]^+$ 100), and 104 ($[M-2I]^+$, 85.9).

The next mobile oily fraction (64 mg) was a mixture of 1:5:5 mixture of iodo aldehyde **48**, 2-indanol formate (**52**) and 2-(iodomethyl)benzylacetate (**49**) judged from the ^1H NMR. ^1H NMR (90 MHz) Iodo aldehyde **48**: 3.80 (2H d, *J*=1.8 Hz, CH_2CHO), 4.38 (2H, s, $-CH_2I$), and 9.77 (1H, t, *J*=1.8 Hz, CHO); formate **52**: 3.01 (2H, dd, *J*=6 and 17 Hz, benzylic H), 3.36 (2H, dd, *J*=6 and 17 Hz, benzylic H), 5.5—5.8 (1H, m, CHOCHO), and 7.98 (1H, s, OCHO); Iodide **49**: 2.12 (3H, s, OAc), 4.52 (2H, s, CH_2I), 5.21 (2H, s, CH_2–OAc), and 7.31 (4H, m, aromatic H). This mixture was again subjected to preparative TLC with 5:5:1 mixture of benzene–hexane–diethyl ether to give a 1:1 mixture of 2-indanol formate and 2-(iodomethyl)benzylacetate (4 mg). Further separation could not be achieved.

The next fraction (50 mg, 23%) was an oily 3,4-dihydro-2-benzopyran-3-ol acetate (**46**). ^1H NMR (90 MHz) 2.05 (3H, s, OAc), 2.83 (1H, dd, *J*=4.2 and 16.5 Hz, benzylic H), 3.19 (1H, dd, *J*=3.5 and 16.5 Hz, benzylic H), 4.83 (2H, d, *J*=2.2 Hz), 6.33 (1H, t, *J*=3.5 and 4.2 Hz, acetal-H); IR 1733 cm^{-1} (OAc) and [1220, 1196 and 1131 cm^{-1} (C–O)]; MS (70 eV) *m/z* (rel intensity) ($[M-CH_3COOH]^+$. 93%), and 104 (100 (CH_2-ϕ-CH_2)$^+$). Found: *m/z* 132.05632 ($M-CH_3COOH$)$^+$. Calcd for C_9H_8O: 132.05722.

The most polar fraction (58 mg) was a mixture which was subjected to preparative TLC with a 5:5:1 mixture of ethyl acetate–hexane–diethyl ether to give two fractions. The less polar fraction (11 mg, 4%) was a thick liquid 1,2-bis[acetoxymethyl]benzene **50**.[19]

The more polar fraction (25 mg, 12%) was an aldehyde **51**. IR (neat) 2723 cm^{-1} (CHO), 1724 (CHO), 1222 (OAc), and 1027 (C–O); ^1H NMR (90 MHz) 2.04 (3H, s, OAc), 3.77 (2H, d, *J*=1.8 Hz, CH_2CHO), 5.08 (2H, s, CH_2OAc), 3.35 (4H, m, aromatic H), and 9.72 (1H, t, *J*=1.8 Hz, CHO); *m/z* 191 ($[M-1]^+$, 0.2), 104 ($[M-OAc-CHO]^+$, 100) (Found: C, 68.92; H, 6.35. Calcd for $C_{11}H_{12}O_3$; C, 68.74; H, 6.29).

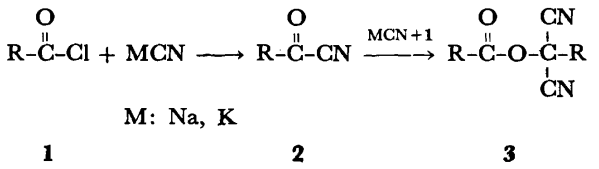
Reaction of Aromatic Acyl Chlorides with Potassium or Sodium Cyanide Impregnated onto Amberlite XAD Resins. Efficient Synthesis of Aromatic Acyl Cyanides

Kazuaki SUKATA
Nihon Tokushu Kagaku Kogyo Co., Ltd., 1, Takijiri-aza-hashimoto, Izumi-cho, Iwaki, Fukushima 970-04
(Received October 16, 1986)

The effects of alkali metal cyanide impregnated on Amberlite XAD resins (KCN/XAD, NaCN/XAD) have been examined using the cyanation of benzoyl chloride. In benzene, benzoyl cyanide was obtained in a very high yield with high selectivity under mild conditions. It is proposed that the reaction occurs on the surface of the resin. On the basis of the result obtained in the absence of any solvent, the reactivity of KCN/XAD toward dimerization of benzoyl cyanide has been found to be much poorer than that of KCN in solution. Although the reaction of acyl chlorides with KCN/XAD or NaCN/XAD in benzene gave various acyl cyanides in good to excellent yields, no aliphatic acyl cyanide could be obtained.

Acyl cyanides are versatile and important synthetic intermediates and have classically been prepared by the reaction of acyl chloride (**1**) with mercury(II) cyanide, silver cyanide, or copper(I) cyanide.[1] Subsequently, improved methods have been developed using thallium(I) cyanide,[2] trimethylsilyl cyanide,[3] tributyltin cyanide,[4] or acyl iodide.[5] Although these procedures give good results, the use of them are limited in view of the availability and cost of cyanating agents. Also the liquid–liquid two phase reaction of **1** with NaCN has been reported.[6] This reaction, however, gives substantial quantities of the acyl cyanide dimer (**3**) as well as the acyl cyanide (**2**).



1 **2** **3**

Recently, it has been reported that the reaction of **1** with KCN is remarkably promoted by the addition of a trace amount of water[7] and irradiation with ultrasound[8] giving **2** in good yields. However, the former requires a high reaction temperature and the addition of a crown ether in the case of less reactive *p*-methoxybenzoyl chloride. In the latter, the yield of **3** is still high.

On the other hand, in a previous paper,[9] it has been reported that substitution reactions are accelerated by a simple impregnation of reagents on macroporous polymer resins such as Amberlite XAD-2, XAD-4, and XAD-7. These polymer resins have no ion-exchange capabilities and no phase-transfer catalysis functions. This paper reports that the reaction of aromatic acyl chloride with NaCN or KCN impregnated on XAD-2 or XAD-4 (NaCN/XAD-2,4 or KCN/XAD-2,4) gives **2** in good yields with high selectivities under mild conditions.

Results and Discussion

In order to ascertain the effect of solvents, the reaction of benzoyl chloride (**4**) with KCN/XAD-2 was carried out in various solvents. Table 1 shows the results. The coversion rate of **4** was in the order of acetonitrile $\gg$ benzene$>CH_2Cl_2$, hexane, tetrahydrofuran (THF), dioxane$\approx$no solvent. Although the reaction was extremely fast in acetonitrile, the benzoyl cyanide dimer (**5**) was obtained in very high yield (24%) even for the molar ratio KCN/**4**=1.0. For the molar ratio KCN/**4**=4.0, a large amount of unidentified product was produced. This result contrasts with that of the reaction of **1** with KCN using a trace amount of water or ultrasound in which acetonitrile was effective.[7,8] The yields of benzoyl cyanide (**6**) and **5** in acetonitrile were very similar to those obtained by phase-transfer catalysis.[6] Surprisingly, in the absence of any solvent, the yield of dimer (**5**) was extremely low. This fact indicates that the reactivity of the KCN impregnated on XAD-2 toward the dimerization of **6** is much poorer than that in solution. The yields of **5** in other solvents were very low and quite similar to that in the absence of any solvent. These facts indicate that in acetonitrile the reaction occurs substantially in the bulk organic phase, while in the other solvents, it occurs predominantly on the surface of the resin. Contrary to expectations, the reaction rates in THF and dioxane were similar to those in CH_2Cl_2 and hexane or in the absence of any solvent. Interestingly, when benzene was used as a solvent, **6** was produced in substantial quantities with high selectivity. Also, the reaction rate with benzene was faster than those in other solvents with the exception of acetonitrile.

On the other hand, the importance of a trace amount of water to attack the crystal lattice of the solid in solid-liquid two phase systems is well-known.[7,9,10,11] The same effect was also observed in the present reaction. In the case of THF, CH_2Cl_2, benzene, and hexane, the effect was examined. It was

observed that the addition of a trace amount of water substantially completed the conversion of **4** in 1—2 h. In THF or CH_2Cl_2, however, substantial quantities of benzoic anhydride (**7**) were produced along with **5** as by-products, and in hexane, **5** was produced in a substantial yield as a by-product. On the contrary, in benzene, the yield of by-products such as **5** and **7** was extremely low and was similar to that obtained in the absence of water.

Mass transfer strongly influences the reaction rate in heterogeneous systems.[12] In the present reaction, the mass transfer of substrate **4** from the bulk organic phase to the surface of the resin and the mass transfer of product **6** from the surface of the resin to the bulk organic phase will strongly affect the reaction rate. In the reaction without water, the rates of reaction in the solvents, except benzene and acetonitrile, were quite similar to that in the absence of any solvent. This fact indicates that the mass transfer of **4** from the bulk organic phase to the surface of the resin minimally affects the reaction rate.

At present, although I have no explanation why benzene is the best solvent, I suggest the following interpretation for the specific solvent effect of benzene: It is well-known that XAD-2 and XAD-4 resins can efficiently extract most organic compounds from

Table 1. Reaction of PhCOCl (**4**) with KCN/XAD-2 in Several Solvents[a]

Solvent	H_2O / μl	Time / h	Yield/%[b]			
			4	PhCOCN(**6**),	Dimer(**5**),	$(PhCO)_2O$(**7**)
None	—	2	34	51	1	≈0

XAD-4	10	30	2	≈0	90	3	<1
h)	10	30	2	≈0	86	3	<1

a) Unless otherwise noted, reactions were carried out with KCN (30 mmol)/support (7.5 g), **4** (7.5 mmol), and benzene (40 ml). b) Yields were determined by GLC using internal standards. c) KCN (30 mmol)/Al_2O_3 (12.0 g) was used. d) No solvent was used. e) KCN (10 mmol)/Al_2O_3 (4.0 g), **4** (10 mmol), and benzene (20 ml) were used. f) KCN (10 mmol)/silica gel (2.5 g), **4** (10 mmol), and benzene (20 ml) were used. g) Granular activated charcoal was ground in a mortar. KCN (30 mmol)/activated C (12.0 g) was used. h) NaCN was used.

water.[13] Nonpolar compounds are more strongly adsorbed on these resins than polar compounds, and furthermore, aromatic compounds are much more strongly adsorbed on the resin than low-molecular-weight aliphatic compounds.[13] Similarly, in the present system, the XAD resin has such properties as previously described. Since product **6** is an aromatic and relatively polar compound, it must have a stronger affinity to the XAD resin than the solvent with the exception of benzene. Therefore, only in benzene, the cyanide (**6**) produced on the surface migrates much more effectively from the surface of the resin to the bulk organic phase. Consequently, the reaction of **4** with KCN is accelerated and the formation of by-products such as **5** and **7** is suppressed.

Table 2 summarizes the results of cyanation of **4** using several other supports. In the case of alumina, which is effective in the cyanation of alkyl halides,[14] for the molar ratio KCN/**4**=4.0, the conversion of **4** was very fast in the presence of a trace amount of water. The yield of **6**, however, was very poor and a large amount of tarry material was obtained. For the molar ratio KCN/**4**=1.0, the coversion was slow, and the main product was benzoic anhydride (**7**) in both the presence and absence of water. When silica gel was used, for the molar ratio KCN/**4**=1.0, the reaction was faster than that using alumina and gave mainly **7**. A substantial amount of water appeared to remain after drying. For the molar ratio KCN/**4**=4.0, although the conversion of **4** was fast, almost no product was isolated. In the impregnation of KCN onto the silica gel, the evolution of a substantial amount of HCN gas was observed when silica gel was added to an aqueous KCN solution. This HCN must be produced through the reaction of KCN with acidic silica ≡Si–OH.[15]

$$KCN + \equiv Si\text{–}OH \longrightarrow \equiv Si\text{–}OK + HCN$$

For the molar ratio KCN/**4**=4.0, most of **4** would react with ≡SiOK, being trapped on the silica-gel surface as ≡SiOCOPh. When activated charcoal was used as a support, almost all of **4** was recovered. The effect of XAD-4 was similar to that of XAD-2. The reaction using KCN/XAD was slightly faster than that using NaCN/XAD.

Table 3 summarizes the results of the cyanation of the other acyl chlorides using KCN/XAD in benzene. XAD-4 was superior to XAD-2 in reaction rate. This fact may be due to the difference in the surface area.[16] When R in **1** was a strong electron-attracting group such as *p*-chloro- or *p*-bromophenyl, the addition of water increased the yield of by-products such as the acyl cyanide dimer (**3**) and the acid anhydride. In the reaction of **4** in benzene, the increase in the reaction rate by the addition of water was small, though substantially no increase in the yield of by-products was observed (Table 1). These findings suggest that the merit of the addition of water is small with respect to the yield and selectivity.

Table 3. Preparation of Acyl Cyanides Using KCN/XAD in Benzene[a]

a) All reactions were carried out with KCN (30 mmol)/XAD (7.5 g), acyl chloride (7.5 mmol) at 30 °C in benzene (40 ml). b) A: XAD-2; B: XAD-4. c) Isolated yields. Values in parentheses are the yields determined by GLC. d) Conversion percentage of acyl chloride determined by GLC.

Experimental

Materials. Acetonitrile, benzene, and hexane were dried with molecular sieves 3A or 4A. THF and dioxane were passed through an alumina column, distilled, and then dried with molecular sieves 4A. Dichloromethane was washed with aqueous Na_2CO_3, distilled, and then dried with molecular sieves 3A. Benzoyl chloride (**4**) was distilled prior to use. The other acyl chlorides were used as obtained (Tokyo Kasei Kogyo Co.). Authentic samples (benzoyl cyanide (**6**) and benzoyl cyanide dimer (**5**)) were prepared by the literature method,[6] and benzoic anhydride (**7**) was purchased from Wako Chemicals Co. Amberlite XAD resins were purchased from Organo Co., thoroughly washed with methanol, benzene–methanol (1:2 vol), and methanol, and then dried under vacuum. Alumina (Merck 90, neutral, 70—230 mesh, activity I, Art 1077) and silica gel (Merck 60, 70—230 mesh, Art 7734) were used as obtained. Activated charcoal was pulverized in a mortar. KCN/XAD and NaCN/XAD were prepared according to the method previously reported,[9] dried at 90 °C and 0.1 mmHg (1 mmHg=133.322 Pa).

Typical Procedure for the Reaction of Acyl Chloride (1) with KCN or NaCN/Support. In all reactions, **1** was directly added to the flask in which the KCN or NaCN/Support was made and dried. All the products were known compounds.

The Reaction of Benzoyl Chloride (4) with KCN/XAD-2 in Various Solvents. A mixture of KCN/XAD-2 made from KCN (1.95 g, 30 mmol) and XAD-2 (7.5 g) and a solvent (30 ml) with or without water (10 μl) was stirred for 1—2 min. To the mixture was added **4** (1.05 g, 7.5 mmol) in benzene (10 ml) and the resulting mixture was stirred for 2 h at 30 °C. The solid material was filtered off and eluted with benzene (70 ml) and CH_2Cl_2 (30 ml). After removal of most of the solvent under reduced pressure at room temperature, the yields of **4**, **5**, **6**, and **7** were determined by GLC (Silicone OV-17, 10%, 3 m×3 mm, 140 °C for **4** and **6**: Silicone OV-17, 3%, 0.5 m×3 mm, 200 °C for **5** and **7**). Internal standards for **4** and **6**, and **5** and **7** were dodecane and dibenzyl ether, respectively.

Benzoyl Cyanide (6): A solution of **4** (1.05 g, 7.5 mmol) in benzene (10 ml) was added to a mixture of KCN/XAD-4 made from KCN (1.95 g, 30 mmol) and XAD-4 (7.5 g), benzene (30 ml), and water (10 μl). The mixture was stirred for 2 h at 30 °C. The solid material was filtered through Celite and eluted with benzene (70 ml) and CH_2Cl_2 (30 ml). After removal of the solvent, the residue, which solidified immediately at room temperature, was recrystallized from hexane to give 0.81 g (83%) of **6**, mp 30—32 °C (lit,[6] mp 30—32 °C).

***p*-Methylbenzoyl Cyanide:** The reaction was performed with KCN (30 mmol)/XAD-4 (7.5 g), *p*-methylbenzoyl chloride (1.16 g, 7.5 mmol), water (10 μl), and benzene (40 ml) as a solvent for 3 h at 30 °C according to the same method as **6**. Removing the solvent gave 1.04 g (95%) of the cyanide, mp 49—51 °C (lit,[7] mp 49.5—50.0 °C) which was recrystallized from CH_2Cl_2–hexane to give pure *p*-methylbenzoyl cyanide, mp 50—51 °C.

***p*-Chlorobenzoyl Cyanide:** The reaction was performed with KCN (1.95 g, 30 mmol)/XAD-4 (7.5 g), *p*-chlorobenzoyl chloride (1.31 g, 7.5 mmol), and benzene (40 ml) as a solvent for 4 h at 30 °C according to the same method as **6**. Removal of the solvent gave 1.13 g of the crude product. To this product was added CH_2Cl_2 (1 ml) and the insoluble solid was filtered off. The filtrate was passed through a silica-gel column (10 cm) with CH_2Cl_2–hexane (1:4) as an eluent. Removing the solvent gave 0.93 g (75%) of *p*-chlorobenzoyl cyanide, mp 40.0—41.5 °C (lit,[8] mp 41.4—42.1 °C).

***p*-Bromobenzoyl Cyanide:** The reaction was performed with KCN (1.95 g, 30 mmol)/XAD-4 (7.5 g), *p*-bromobenzoyl chloride (1.65 g, 7.5 mmol) and benzene (40 ml) as a solvent for 4 h at 30 °C according to the same method as **6**. Removal of the solvent gave 1.32 g (84%) of *p*-bromobenzoyl cyanide, mp 60.5—62.0 °C (lit,[7] mp 62.5—64.0 °C), recrystallization of which from CH_2Cl_2–hexane gave the pure compound, mp 61.5—62.5 °C.

Cinnamoyl Cyanide: The reaction was performed with KCN (1.95 g, 30 mmol)/XAD-4 (7.5 g), cinnamoyl chloride (1.25 g, 7.5 mmol), and benzene (40 ml) as a solvent at 30 °C for 4 h according to the same method as **6**. Removal of the solvent gave 1.15 g of the residue, which was purified by silica-gel column chromatography (CH_2Cl_2–hexane, 1:3) to give 0.48 g (41%) of cinnamoyl cyanide, mp 111—113 °C (lit,[7] 114.5—115.2 °C).

2-Furoyl Cyanide: The reaction was performed with KCN (1.95 g, 30 mmol)/XAD-4 (7.5 g), 2-furoyl chloride (0.98 g, 7.5 mmol), and benzene (40 ml) as a solvent at 30 °C for 2 h according to the same method as **6**. Removal of the solvent gave 0.81 g (89% yield, 96% purity GLC) of the product, distillation of which gave 0.66 g (73%) of 2-furoyl cyanide, bp 86—87 °C/15 mmHg (lit,[8] bp 86—88 °C/15 mmHg).

Substituent Effects. XVI.[1] Acetolysis of 2-Phenylethyl Tosylates[2]

Mizue Fujio, Kimito Funatsu, Mutsuo Goto, Yoji Seki, Masaaki Mishima, and Yuho Tsuno*
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received October 16, 1986)

The acetolysis rates of 2-arylethyl tosylates were determined for a series of aryl substituents. The nonlinear substituent effect was reasonably accounted for on the basis of two linear LArSR relationships; one for the aryl-assisted (Fk_Δ) and one for the unassisted (k_s) processes, respectively. A precise dissection of the apparent substituent effect into individual effects for both processes was achieved in this manner. The substituent effect on the k_s process can be described as a linear function of σ° with a small ρ_s of -0.19, and that on the Fk_Δ process in terms of the LArSR Eq., with a $\rho_\Delta=-3.87$ and an $r_\Delta=0.631$. The use of σ^+ for the Fk_Δ process failed to give any reasonable dissection. The r value for this Fk_Δ process is essentially identical to that for the neophyl solvolysis. The unique r value of 0.6 is concluded to be characteristic of β-aryl-assisted ionization processes in general.

Anchimeric assistance in solvolyses has been the subject of a number of investigations.[3] The importance of neighboring phenyl participation can be estimated from the effects of aryl substituents, which have therefore been an important tool for analyzing the exact mechanism.[2-5] Solvolysis of neophyl brosylates (2-methyl-2-phenylpropyl *p*-bromobenzenesulfonates) has often been used as a reference set for the substituent effects on aryl-assisted solvolyses,[4b,6,7] and we have recently reported[8] that the substituent effect on the neophyl acetolysis can be described by a unique r value of 0.56 in our LArSR Eq.[9]

$$\log (k/k_o) = \rho(\sigma^\circ + r\Delta\bar{\sigma}^+_R) \quad (1)$$

This appreciably exalted r value was taken as evidence for a direct π-delocalization interaction between the aryl π-system and the β-carbocation center, i.e., a bridged structure, in the rate-determining transition state.[9,10] The most important conclusion from general LArSR analysis is that the r value can be a unique parameter characteristic of the structure of the transition state.[9] While the r parameter is a sensitive measure of the resonance demands of varying systems, it usually shows little or no variation within a family of essentially the same mechanism. It is therefore expected that the substituent effect for β-aryl-assisted solvolyses can be characterized by such a unique r value, in contrast to the traditional σ^+ characterization.[5] Accordingly, this investigation was undertaken in an attempt to define more precisely the substituent effect for the anchimerically assisted processes of 2-arylalkyl solvolysis systems.

In the acetolysis of 2-arylethyl tosylates chosen for the present study as well as in most such 2-arylalkyl solvolyses, the precise analysis of substituent effects on the rate suffers from the mechanistic complexity caused by the concurring solvent-assisted process.[2-5] The observed solvolysis rate k_t corresponds to a sum of rates, k_s+Fk_Δ, of two competing processes, aryl-assisted (Fk_Δ) and unassisted (k_s) ones. A useful way for the direct analysis of the two substituent effects has been exploited by Schleyer et al.,[4] on the basis of the assumption of a Hammett-type substituent effect correlation for the respective processes. Although this treatment achieved reasonable dissection into k_s and Fk_Δ processes, their data set involving only a few strongly activating substituents is insufficient to define precisely the substituent effect for the anchimerically assisted process. In the present study, we have extended the range of substituents of 2-arylethyl tosylates and analyzed the respective substituent effects on the k_s and Fk_Δ processes, in terms of the LArSR Eq. 1.

Results and Discussion

Rate constants of acetolysis of 2-arylethyl tosylates were determined at 115.00 °C in glacial acetic acid with initial concentrations (0.02 mol dm^{-3}) of tosylates. All runs gave good first order kinetics over more than two half-lives. The rate constants were reproducible to better than ±1% for repeated runs in a single batch of solvent, while they differed sometimes by 5—10% in different solvent batches; thus, the rate data were normalized each time to the rate of a reference substrate. The results are summarized in Table 1. As Schleyer's k_t values were found to be consistently lower than the present data by a factor of 10%, the k_t values for *m*-F, *m*-CF_3, *p*-CF_3, and 3,5-$(CF_3)_2$ derivatives calibrated by this factor were included in the present analysis.

Logarithms of relative rates are plotted against σ° and σ^+ in Fig. 1. The nonlinear behavior of the substituent effect with either set of substituent constants was pointed out earlier for this acetolysis,[3] and was accounted for by varying competition of the two non-crossover processes with the change of aryl

Table 1. Acetolysis Rate Constants of 2-Phenylethyl Tosylates

substituent.[3] When the substituents are sufficiently deactivating, no participation by aryl is observed, and the compounds react exclusively by the unassisted (k_s) process. On the other hand, sufficiently electron-releasing substituents facilitate participation and such compounds react predominantly by the aryl-assisted (Fk_Δ) process.

The substituent effect on k_t ($=Fk_\Delta+k_s$) is given by

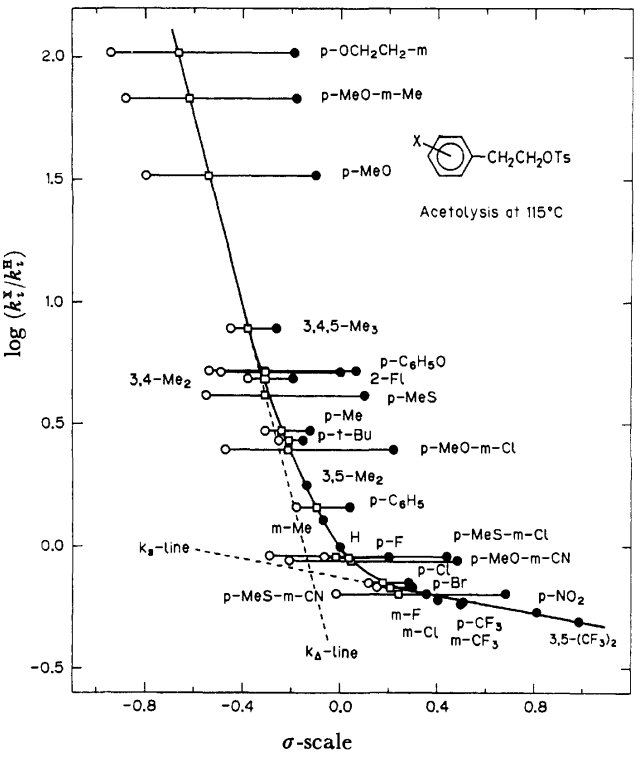

Fig. 1. Plots of log (k_t^X/k_t^H) against σ^+ (open circles), σ° (closed circles), and $\bar{\sigma}$ for $r=0.63$ (squares).

$$\log (k_t^X/k_t^H) = \log (k_s^X/k_s^H) + \log (1+Fk_\Delta^X/k_s^X) + C_s$$

or

$$= \log (Fk_\Delta^X/Fk_\Delta^H) + \log (1+k_s^X/Fk_\Delta^X) + C_\Delta$$

where C_s and C_Δ are constants referred to $\log (k_s^H/k_t^H)$ and $\log (Fk_\Delta^H/k_t^H)$, respectively. When the second terms on the right hand side are neglected, simple Hammett-type relations may be obtained with appropriate sets of substituent constants, $\bar{\sigma}_s$ and $\bar{\sigma}_\Delta$, for the k_s and Fk_Δ processes, respectively,

$$\log (k_t^X/k_t^H) = \rho_s\bar{\sigma}_s + C_s \quad \text{for extreme case of } k_s \gg Fk_\Delta$$

and

$$= \rho_\Delta\bar{\sigma}_\Delta + C_\Delta \quad \text{for the other extreme } Fk_\Delta \gg k_s.$$

The substituent effect on the k_s process may be treated simply with σ°, since the process involves no direct π-interaction between the aryl group and the reaction center. This permits the evaluation of the Fk_Δ values as the residues k_t-k_s for respective substituents and then the Fk_Δ substituent effect may be analyzed in terms of an appropriate $\bar{\sigma}_\Delta$. This is essentially the basis of Schleyer's treatment.[4] The aryl-assisted process is thought to involve a significant direct π-interaction between the aryl and reaction center, and the substituent effect should be described by a set of substituent constants of the σ^+ type. Thus, Schleyer employed σ^+ as an appropriate $\bar{\sigma}_\Delta$ in his original

analysis[4a] but later reported an appreciably improved result by use of the $\bar{\sigma}_\Delta$ from neophyl acetolysis.[4b] Such an appropriate $\bar{\sigma}_\Delta$ set would be described reasonably by the LArSR Eq. 1. Our analysis has therefore been carried out based on the explicit assumption that the LArSR Eq. 1 applies to both the k_Δ and k_s processes of this solvolysis. The best-fit Fk_Δ correlation was given by ρ_Δ=−3.87 and r_Δ=0.631, and the k_s correlation, ρ_s=−0.186 with σ^o (r=0.00).[11] The combined correlation reproduces the $\log(k_t^X/k_t^H)$ values with excellent precision (SD=±0.027), and the fit is distinctly better than the dissection based on σ^+ as the reference $\bar{\sigma}_\Delta$ (SD=±0.10). While a precise LArSR analysis has been achieved statistically,[11] direct graphical analysis in terms of the LArSR Eq. 1 appears to be important in order to verify the LArSR analysis and to understand the nature of the Fk_Δ substituent effects.

Figure 1 is the ordinary LArSR plot for the present system. The line segments between σ^+ and σ^o for the para π-donors represent resonance capabilities, i.e., $\Delta\bar{\sigma}_R^+$ values, of the respective substituents. The LArSR correlation should in general be represented by a single straight line for all substituents, and especially for para π-donors, the line divides all resonance segments at a constant internal ratio corresponding to the r value. For the present system, however, no single straight line correlation was obtained. The nonlinear correlation is of course inevitable because of the mechanistic complexity as described above.

The key principle of this graphical analysis is that only with appropriate $\bar{\sigma}_s$ and $\bar{\sigma}_\Delta$ sets, will the apparent k_t plot result in a single monotonic curvature converging to the theoretical correlation lines at either the activating or deactivating end. All meta substituents as well as para π-acceptors can unequivocally define the k_t correlation, even if nonlinear, in terms of standard σ^o constants, since they are not susceptible to resonance demands (i.e., $\bar{\sigma}_\Delta=\bar{\sigma}_s=\sigma^o$). Such a correlation curve (solid line) ranging from 3,5-Me_2 to 3,5-$(CF_3)_2$ in Fig. 1 should be a rigid reference for analyzing the behavior of the para π-donor substituents susceptible to resonance demands. Clearly the k_t correlation curve can be extrapolated almost linearly toward the activating substrates so as to intersect the resonance segments all at a single point giving a constant ratio of 2:3. This unique ratio refers to the r value of the $\bar{\sigma}_\Delta$ set. Although the plots (squares) in Fig. 1 are shown against the statistically best-fit $\bar{\sigma}_\Delta$ set of r=0.63, there is essentially no difficulty in defining such an intersecting correlation line for p-π-donors even without the aid of the known r value. The LArSR $\bar{\sigma}_\Delta$ plots (squares) all collapse into a single smooth curve determined by r-independent groups. The plot for the activating substrates is sufficiently linear to accurately define the converging Fk_Δ correlation line with a ρ_Δ value of −3.87. The k_s correlation line can also be defined as the tangent line for the k_t curve at the deactivating end, giving a ρ_s value of −0.19. Both correlation (dotted) lines cross at 0.30 log-units below the k_t curve, as required for $k_s=Fk_\Delta=k_t/2$. While the k_t curve intersects the line segments of π-donors at points in between their $\bar{\sigma}_\Delta$ and σ^o values in the crossover section, this is just what is expected for the effective contribution from concurrent k_s process of σ^o-dependence.

On the other hand, neither the σ^o nor the σ^+ plot gives any reasonable single Fk_Δ correlation line connecting smoothly to the k_t-curve. The σ^+ plot splits into three separate curves one each for strong para π-donors, weak ones (alkyl and halogen groups), and resonance-invariant substituents. The σ^+ and LArSR $\bar{\sigma}_\Delta$ correlations are contrasted most sharply by the behavior of the less activating strong π-donors, especially, m-substituted p-MeO and p-MeS derivatives.[12] These disubstituted derivatives have been shown to satisfy the LArSR relationship as united substituents having net $\Delta\bar{\sigma}_R^+$ values comparable to their parent para π-donors.[12] A series of p-π-donors with the same $\Delta\bar{\sigma}_R^+$ should provide a linear plot against σ^+ value with a slope identical to the true ρ value, regardless of the r of the system, since the $r\Delta\bar{\sigma}_R^+$ term in Eq. 1 remains constant for these groups. In fact, the σ^+ plots of strong π-donors with $\Delta\bar{\sigma}_R^+$=−0.6—−0.7 fall on a single line slightly curved at the bottom, covering a reactivity of over 10^2, with an identical slope to the LArSR ρ_Δ value. Similarly, the weak π-donors with $\Delta\bar{\sigma}_R^+$ of −0.15—−0.2 fall on another line with nearly the same slope, lying rather close to reference k_t curve. Note that neither line collapses into the reference k_t correlation curve, and the gap between the lines which should correspond to the $(1-r)\Delta\bar{\sigma}_R^+$ term in LArSR Eq. can be eliminated to coalesce to a single line, by use of $\bar{\sigma}_\Delta$ with an appropriate r value. While there is controversy concerning the real merit of r parameter,[13] it is evident that an intermediate r value is the inevitable requirement in order to account for the substituent effect on the Fk_Δ process of the present reaction.

The above LArSR results are all consistent with the presently accepted mechanism. The complete dissection attained with the k_t substituent effect provides strong support for the accepted competition mechanism, consisting of a non-crossover k_s and a k_Δ processes. The small ρ_s value for the k_s process may be attributed primarily to the relatively long distance between the substituents and the reaction center, as well as the intrinsic S_N2 character of the transition state involving less effective charge separation. The exalted r_Δ value for the assisted process provides evidence for a direct π-delocalization interaction between the aryl π-system and the β-carbocation center in the rate-determining transition state, and further

suggests that the charge delocalization in this aryl-assisted transition state should not be as effective as the benzylic π-delocalization in the 1-methyl-1-phenylethyl solvolysis. The large ρ_Δ value compared with those for the ordinary unassisted β-solvolyses[3] of structurally equivalent systems is also in line with the bridged transition state.

Finally, it should be emphasized that the ρ_Δ and r_Δ values for the present Fk_Δ process are nearly identical with those for the neophyl solvolysis.[8] Furthermore, similar ρ_Δ and r_Δ values have also been obtained for other aryl-assisted processes. It therefore appears likely that the substituent effect for the β-aryl-assisted process can be characterized by this unique r value. An important criticism against our LArSR concept is that the deviation of r from unity or zero may be caused by the mechanistic complexity of the system.[13] The aryl-assisted process of 2-phenylethyl tosylates is indeed a complex one involving significant internal return.[14] On the other hand, neophyl brosylate is thought to solvolyze via a rate-determining aryl-assisted transition state uncomplicated by either internal return or nucleophilic solvent assistance. The essential identity of r_Δ values for both β-aryl-assisted processes indicates that the r value should be determined only by the common rate-determining step, aryl-assisted ionization without return. This fact strongly argues against the interpretation of an intermediate r value in terms of the mechanistic complexity of the reaction.[2,8] As a conclusion, the r value of 0.6 must be characteristic of aryl-assisted ionization process, and the resonance demand of the Fk_Δ process differs intrinsically from the demand r=1.00 defined by the 1-methyl-1-phenylethyl solvolysis. Further discussion will require comparative studies on related systems which involve varying degrees of mechanistic complexity, and also a detailed examination of the results of the statistical analysis.

Experimental

Material. Most of the phenylacetic acids were prepared by the Willgerodt reaction of the appropriate acetophenones. 2-Phenylethyl alcohols were obtained by $LiAlH_4$ reduction of the corresponding acids or esters, as described previously.[2]

2-(3-Cyano-4-methoxyphenyl)ethanol was prepared from *p*-methoxyphenylacetic acid. Bromination of *p*-methoxyphenylacetic acid with Br_2 in acetic acid at 40—45 °C gave 4-MeO-3-Br-phenylacetic acid, mp 116—117 °C, recrystallized from ethanol-water. 4-MeO-3-Br-phenylacetic acid was treated with $LiAlH_4$ and immediately decomposed, since prolonged reaction caused a considerable loss of the bromo group. The crude alcohol, bp 149—151 °C/3 mmHg (1 mmHg=133.322 Pa), containing 5% 2-(*p*-methoxyphenyl)ethanol, was treated with CuCN in DMF and decomposed with $FeCl_3$–HCl, according to the Friedman and Shechter procedure,[15] to give 2-(4-MeO-3-CN-phenyl)ethanol, bp 179—180 °C/3 mmHg, after purification through SiO_2 column.

2-(3-Cyano-4-methylthiophenyl)ethanol was prepared in a similar way as the *p*-MeO derivative. Quick bromination with 2 equiv bromine at 45 °C gave crude acid contaminated with methylsulfoxide derivative which was purified by SiO_2 chromatography, mp 102—103 °C. 2-(4-MeS-3-Br-phenyl)-ethanol and 3-cyano-4-methylthio derivative were purified by chromatography, mp 58—59 °C and mp 40—41 °C.

2-(*p*-Bromophenyl)ethanol was prepared in the usual manner from *p*-bromoacetophenone, via methyl phenylacetate (bp 89—90 °C/0.25 mmHg); bp 103—104.5 °C/2.5 mmHg.

2-(Substituted phenyl)ethyl *p*-toluenesulfonates were synthesized from the corresponding alcohols and tosyl chloride by the Tipson procedure[16] and purified by recrystallization from appropriate solvents. Physical constants of most esters were reported in a previous paper,[2] or are described below.

2-(3-Cyano-4-methoxyphenyl)ethyl tosylate, mp 109.7—110.5 °C. Found: C, 61.57; H, 5.26; N, 4.31%. Calcd for $C_{17}H_{17}NO_4S$: C, 61.61; H, 5.17; N, 4.23%. 4-MeS-3-CN derivative, mp 77—77.5 °C. Found: C, 58.87; H, 4.72; N, 4.19%. Calcd for $C_{17}H_{17}NO_3S_2$: C, 58.77; H, 4.93; N, 4.02%. *p*-Br derivative, mp 91 °C. Found: C, 50.92; H, 4.34%. Calcd for $C_{15}H_{15}O_3SBr$: C, 50.71; H, 4.26%.

Kinetic Measurement. The acetolysis rates were measured by the titrimetric method using the usual ampoule technique. Ten cm^3 (0.02 mol dm^{-3}) aliquots were pipetted into 25 cm^3 of cold acetic acid containing sodium acetate (0.0088 mol dm^{-3}) and titrated with perchloric acid (ca. 0.025 mol dm^{-3}) in acetic acid. The mixture of crystal violet and α-naphtholbenzein was used as indicator.

11) Both the iterative least-squares method used by Schleyer[4] and nonlinear least-squares method (Newton method) were applied to the analysis. Identical result was obtained by assuming fixed r_s value at 0, 0.27 for reducing a variable. Use of $\bar{\sigma}_\Delta$ from neophyl solvolysis (r_Δ=0.58 a fixed) gave closely the same correlation; ρ_Δ=−4.04, ρ_s=−0.16 (r_s=0) with a good precision (SD=±0.036). Use of σ^+ for $\bar{\sigma}_\Delta$ (r_Δ=1.00 a fixed) gave a correlation; ρ_Δ=−3.55, ρ_s=−0.58 (r_s=0) with a lower precision (SD=±0.10); unreasonable ρ_s value and the position (k_s^H) may be noticed.

12) The σ^+ used were primarily based on the experimental values for *m,p*-disubstituted derivatives (M. Fujio, T. Adachi, Y. Shibuya, A. Murata, and Y. Tsuno, *Tetrahedron Lett.*, **25**, 4557 (1984)) and the $\Delta\bar{\sigma}_R^+$ values were given to be equal to those of *p*-substituents.

(Received October 16, 1986)

The label scrambling within the ethylene chain of the final acetolysis products was determined for a series of α-D_2 labeled 2-arylethyl tosylates by using proton NMR spectroscopy and the k_Δ/k_s values were derived from the scrambling ratios. For both buffered and unbuffered acetolysis runs $\log(k_\Delta/k_s)$ were not correlated linearly with σ° or σ^+. Application of the LArSR Eq. results in linear correlations with excellent precision, $\log(k_\Delta/k_s)=-3.70\ (\sigma^\circ+0.63\Delta\bar{\sigma}^+_R)+0.152$ for the unbuffered run and $\log(k_\Delta/k_s)=-3.97\ (\sigma^\circ+0.60\Delta\bar{\sigma}^+_R)-0.207$ for the buffered run. The ρ_Δ and r_Δ values for the aryl-assisted pathway are estimated from the above apparent values based on the reasonable assumption of small ρ_s values for the k_s pathway.

The foregoing papers[1,3] described the dissection of the substituent effect on the acetolysis of 2-arylethyl tosylates into the effects on solvent-assisted (k_s) and anchimerically assisted (Fk_Δ) processes.[4] The dissection was based upon an assumption of the LArSR relationship (1)[5]

$$\log(k/k_o) = \rho(\sigma^\circ + r\Delta\bar{\sigma}^+_R) \quad (1)$$

for the respective substituent effects on the two competing processes. While the validity of the individual correlation was supported by the agreement with other experimental facts,[6] convincing evidence would be provided by a direct application of the LArSR relationship to the substituent effect on each process having been separated by a technique independent of the substituent effect analysis.

A kinetic analysis of the respective processes of the acetolysis of 2-arylethyl tosylates was accomplished by using ^{13}C tracer method for typical substituted derivatives.[2,7] Unfortunately, however, the substituents studied are inevitably limited and insufficient to attain a detailed correlation analysis of the substituent effects.

Among the pertinent quantities obtained in these tracer studies, the aryl rearrangement ratio in the product at $t=\infty$ is the useful quantity which can be determined most easily by using the α- or β-methylene-labeled compounds. This can be related directly to the rate ratio k_Δ/k_s by Eq. 2, based on the Winstein-Coke scheme of this reaction,[8a,9] as

$$k_\Delta/k_s = \frac{[\%\text{Rearrangement ROAc } (t=\infty)]}{50-[\%\text{Rearrangement ROAc } (t=\infty)]} \quad (2)$$

The substituent effect on the k_Δ/k_s value may be simply given as the difference of two linear Hammett relations for the k_Δ and k_s processes.

$$\log(k_\Delta/k_s)_X - \log(k_\Delta/k_s)_H = \log(k_X/k_H)_\Delta - \log(k_X/k_H)_s = \rho_\Delta\bar{\sigma}_\Delta - \rho_s\bar{\sigma}_s$$

where $\bar{\sigma}_\Delta$ and $\bar{\sigma}_s$ are the substituent constants appropriate for k_Δ and k_s processes, respectively. Furthermore, from the additivity of the LArSR correlations, the overall substituent effect on the k_Δ/k_s quantity will be treated totally as a single linear LArSR correlation. Thus the k_Δ/k_s substituent effect is quite different from the nonlinear behavior of the k_t substituent effect in the foregoing analysis.[1,3] Nevertheless, both quantities are only different functions of the same rate parameters, and hence a comparative analysis will give further information concerning the intrinsic substituent effect on respective processes.

Results

The label scrambling in the product 2-arylethyl acetate was determined for a series of α-D_2 labeled 2-arylethyl tosylates, by using proton NMR spectroscopy. k_Δ/k_s values were derived from the scrambling ratios based on Eq. 2. The results are listed in Table 1, and compared with the results of previous ^{13}C-tracer studies.[2] The k_Δ/k_s values were determined over a range of 10^4 ranging from the *p*-MeO derivative solvolyzing exclusively through a k_Δ process to the *m*-Cl one reacting primarily through a k_s process. At both extremes of nearly complete and no scrambling, the k_Δ/k_s value should rapidly become less accurate. Thus further extention of the range of substituents was not attempted in this study, but instead, in the present set were included deactivated strong π-donors, such as 3-Cl- or 3-CN-substituted 4-methoxyphenyl and 4-(methylthio)phenyl derivatives, which were found to be particularly effective for defining the *r* value.[10] The addition of sodium acetate lowered the rearrangement ratio for all substrates. The k_s process rather than k_Δ process may be effectively accelerated by the addition of acetate anion, while the substituent change of the ratio remains approximately the same in both buffered and unbuffered acetolyses.

The type of change of k_Δ/k_s with substituents differs

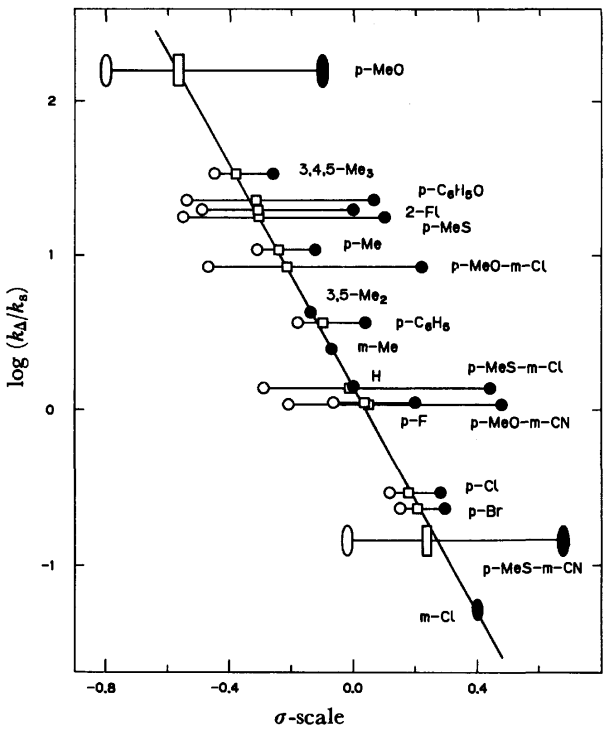

Fig. 1. The LArSR plot of log (k_Δ/k_s) for unbuffered run against σ^+ (open circles), σ° (closed circles), and $\bar{\sigma}$ for $r=0.63$ (squares).

clearly from that of k_t value. There is no simple linear logarithmic relationship between k_Δ/k_s ratios and k_t values. Figure 1 illustrates the substituent effect on log (k_Δ/k_s) quantity for the unbuffered run. Log (k_Δ/k_s) can not be correlated linearly with σ° nor with σ^+, but are linearly described in terms of the LArSR relationship. The line segments between σ° and σ^+ for para π-donors correspond to their $\Delta\bar{\sigma}_R^+$ values, and the LArSR $\bar{\sigma}$ values are represented by the points dividing these resonance segments at a unique internal ratio, which corresponds to the r value. Clearly, we see that such points (squares) with $r=0.63$ all fall on a straight line of a ρ value of -3.70 including m-substituents.

A least-squares application of LArSR Eq. 1 to the unbuffered k_Δ/k_s set results in a linear correlation (Fig. 1),

$$\log (k_\Delta/k_s)_X = -(3.70\pm0.05)(\sigma^\circ + (0.63\pm0.02)\Delta\bar{\sigma}_R^+) + 0.152 \quad (3)$$

with an excellent precision with an R=0.9990 and a SD=±0.042. The substituent parameters used are those employed for the previous analysis.[1] Similarly, the buffered set can also be correlated by (3′)

a) Initial concn of α,α-D$_2$-labeled tosylates, 0.02 mol dm^{-3}; determined by ^{1}H NMR. b) Rearrangement in solvolysis products at complete reaction: 100×[Rearranged acetate]/[Total acetates]. c) Derived from %Rearrangement by Eq. 2. d) Values in the bracket were determined from α-^{13}C labeled tosylates by ^{13}C NMR; Ref. 2. e) At 90 °C. f) At 75 °C.

$$\log (k_\Delta/k_s)_{AcO^-} = (-3.97\pm0.05)(\sigma^\circ + (0.60\pm0.02)\Delta\bar{\sigma}_R^+) - 0.207 \quad (3')$$

with an excellent precision with an R=0.9988 and a SD=±0.045. Both r_Δ values are quite close to the r_Δ obtained for neophyl acetolysis.[10] Both buffered and unbuffered log (k_Δ/k_s) sets in fact give linear plots against log (k_X/k_H) of acetolysis of neophyl brosylates (2-methyl-2-phenylpropyl *p*-bromobenzenesulfonate) with comparable slopes of approximately unity.

Discussion

The linear LArSR correlation with k_Δ/k_s quantities for the entire range of substituents contrasts sharply with the nonlinear behavior observed for the total solvolysis rate of the same reaction. The substituent effects on electrophilic reactions are generally described by the LArSR Eq. 1,[5] in which any sets of apparent substituent constants can be given in a unified manner in terms of varying r characteristic of systems. This unified description of general substituent constants leads to a unique additivity relationship of substituent effects,

$$\Sigma \log (k/k_o)_j = \Sigma \rho_j(\sigma^\circ + r_j\Delta\bar{\sigma}_R^+) = \rho'(\sigma^\circ + r'\Delta\bar{\sigma}_R^+) \quad (4)$$

where $\rho'=\Sigma\rho_j$ and $r'=\Sigma\rho_j r_j/\Sigma\rho_j$. It should be noted that the overall substituent effect can be represented totally as a single linear LArSR correlation with an apparent r'. Mathematically, there is no direct way of differentiating between Eqs. 1 and 4, and of course, the apparent r' for a combined set in itself should have no direct theoretical significance. This is often an important cause of disagreement concerning the real merit of the r parameter,[11-14] as discussed further. The present quantity k_Δ/k_s can be treated, in a similar way, as the difference of the two LArSR correlations again resulting in a single linear LArSR correlation,

$$\log (k_\Delta/k_s)_X - \log (k_\Delta/k_s)_H = \rho_\Delta\bar{\sigma}_\Delta - \rho_s\bar{\sigma}_s = (\rho_\Delta-\rho_s)(\sigma^\circ + ((\rho_\Delta r_\Delta-\rho_s r_s)/(\rho_\Delta-\rho_s))\Delta\bar{\sigma}_R^+) \quad (5)$$

The apparent ρ' and r' values of the correlation (3) should therefore be only the combined values corresponding to $\rho_\Delta-\rho_s$ and $(\rho_\Delta r_\Delta-\rho_s r_s)/(\rho_\Delta-\rho_s)$, respectively. An important key to achieving a reasonable dissection will be provided by the characteristic feature of the k_s substituent effect. From the nature of the k_s reaction, the ρ_s should be small in absolute value and the r_s to be practically unexalted (r=0). A ρ_s value of −0.19±0.04 has been estimated from the k_t effects of sufficiently deactivated derivatives.[1,3] This permits estimation of the ρ_Δ value for the aryl-assisted process to be −3.89, as $\rho_\Delta=\rho'+\rho_s$. Furthermore, because of the small ρ_s value, any conceivable exaltation in r_s does not contribute effectively to the apparent r' value. Thus setting $\rho_s r_s\rightarrow 0$ in Eq. 5 as a reasonable approximation, the r_Δ value can be estimated to be 0.60±0.03. This is essentially the same as the r_Δ value for the Fk_Δ quantity obtained from the k_t analysis.

For the buffered run, acetate ion is known to exert a significant accelerating effect on k_s pathway but no important effect on the rate of aryl-assisted ionization of typical substituted derivatives. Assuming the same ρ_Δ value as for the unbuffered run, the ρ_s can be estimated to be a small positive value of +0.08, and subsequently the r_Δ value is determined to be 0.61±0.02. In fact, a small but positive ρ_s value was observed for the acetolysis rates (k_t) of electron-attracting derivatives in the presence of sodium acetate.[15]

The inherent additivity of LArSR Eq. inevitably causes serious difficulty in dissection of the apparent LArSR correlation (3 or 3'). It should however be noted that the linear analysis applied to the k_Δ/k_s quantity would generally accomplish a correlational result of much higher precision than the nonlinear method applied to the k_t analysis. A precise linear free energy relationship is generally indicative of a fixed mechanism for the reaction. Consequently, the precise conformity to Eqs. 4 or 5 implies that both processes satisfy each individual LArSR correlation for the entire substituent range, providing evidence for the absence of any mechanistic change-over in either process.

The validity of this dissection relies essentially upon the reasonableness of requirement $|\rho_\Delta| \gg |\rho_s|$. As far as this assumption is valid, the apparent r' value of 0.63 in Eq. 3 should not significantly differ from the intrinsic r value for the k_Δ process. Thus the present k_Δ correlation will permit quantitative discussion concerning the substituent effect on the k_Δ quantity as well as on the solvolytic aryl-assisted rate.

The aryl-assisted process of this solvolysis involves significant return from the intermediate, so that the apparent rate constant for this pathway is given as Fk_Δ using a fractionating factor F.[7-9] On the other hand, the present k_Δ quantity based on the product rearrangement is only concerned with the process by which the reactant experiences at least once a symmetrical phenonium intermediate, if any, along the aryl-assisted pathway. It should be emphasized that the k_Δ refers to the relative rate of formation of the first symmetrical intermediate and should be absolutely free from return or any subsequent processes. The identity of both r_Δ values derived from the present k_Δ/k_s and previous k_t analyses evidently indicates that the return process does not cause any significant effect on the ρ and r values for the aryl-assisted pathway. There is independent evidence for the F value of this system being essentially unchanged with substitu-

ents.[7-9] The observed r_Δ value should therefore be characteristic of the aryl-assisted ionization step for the phenonium ion intermediate.

Our results from the present study strongly argue against the contrary view that the deviation of the r value from unity or zero should be attributed for most cases to the complexity of mechanism.[11,12] This view is based exclusively on the use of σ^+ of constant resonance exaltation, termed as $1.00\Delta\bar{\sigma}_R^+$, for conjugative carbocation reactions. According to this traditional treatment, the substituent effect on k_Δ should be described by σ^+ and the effect on k_s by σ° (or σ),[12] and the overall effect on (k_Δ/k_s) quantity can be given as the difference of both effects. The situation is merely a special case $r_\Delta=1.0$ and $r_s=0.0$ of Eq. 5. While the r and ρ are mathematically indefinite in Eqs. 4 or 5, this specification of r enables us to give an unequivocal dissection. From the requirement, $r'=0.63\pm0.02=\rho_\Delta r_\Delta/(\rho_\Delta-\rho_s)$ and $\rho'=-3.70=\rho_\Delta-\rho_s$, this treatment should lead to a definite solution, $\rho_\Delta=-2.3$ and $\rho_s=1.4$. However, this ρ_s value is in serious disagreement with the ρ_s value of -0.19 derived from the k_t dissection. Use of σ (i.e., $r=0.27$) instead of σ° results in an even higher ρ_s value of 1.9. The ρ_s is not negative nor much lower than ρ_Δ in the absolute value when σ^+ is used for $\bar{\sigma}_\Delta$. If the k_s process has such a high, positive ρ_s value, the k_t substituent effect will have to exhibit a curved Hammett plot of significant V shape, which is evidently not the case in the present reaction. While the specification of r values, either 0 or 1, greatly simplifies the way of analysis for any complicated systems apparently satisfying Eq. 1, its definite dissection may not be a reasonable one but often an artifact of the treatment. This obvious conflict invalidates the traditional assumption of a constant resonance demand of $r=1$ generally for electrophilic resonance-exalted processes.

Experimental

Material. Deuterated Compounds. Substituted 2-phenylethan-1,1-d_2-ols were prepared in the usual manner from the corresponding substituted phenylacetic acids by reduction with $LiAlD_4$ (99%D) in ether and were converted into the *p*-toluenesulfonates using the Tipson procedure,[16] followed by recrystallization from appropriate solvents. Physical constants of the deuterated derivatives were generally identical with those of their protio derivatives.

Glacial Acetic Acid. Special grade acetic acid was distilled through a 40 cm glass helixes-packed column and a constant boiling fraction of 0.5 °C range (bp 117—117.5 °C) was collected.

Sodium acetate (special reagent grade) was dried on heating in vacuo immediately before use.

Acetolysis. Acetic acid solution 0.02 mol dm^{-3} of 2-arylethyl-1,1-d_2 tosylates in the absence or the presence of NaOAc (0.06 mol dm^{-3}) were allowed to react for more than 10 half-lives in sealed tubes at 115±0.02 °C. The reaction mixture was concentrated under vacuum at room temperature and extracted with chloroform. The extract was treated with cold water and dil. $NaHCO_3$ solution, and dried over anhydrous magnesium sulfate. The chloroform was removed in vacuo at room temperature and the residue was dissolved in carbon tetrachloride or deuteriochloroform to an appropriate concentration of ca. 1 mol dm^{-3} and was subjected to NMR determination.

Proton NMR Measurement. The ^1H NMR spectrum was obtained at 90 MHz using a Hitachi Perkin-Elmer R-22 Spectrometer. The accumulation method in CW mode was devised to share the data points most effectively into two peak areas of methylene ($\delta \approx 3$ ppm and ≈ 4 ppm) using a Hitac 10 II computer; only two narrow peak areas of the spectrum were accumulated for 100 times or more, sharing 4000 data points for each peak area (sweep width 40 Hz) of α and β-CH_2 signals. These spectral data were further reconfirmed using Brucker AM 360 Spectrometer which was interfaced with an ASPECT 2000 computer (operating at 360.13 MHz, digital resolution of 0.03 Hz/point).

The % rearrangement was calculated as

$$\frac{100\times[\mathrm{ArCD_2CH_2OAc}]}{[\mathrm{ArCH_2CD_2OAc}]+[\mathrm{ArCD_2CH_2OAc}]}$$

from relative peak intensities of α- and β-methylene protons. The NMR intensity determination was repeated more than three times for each run. The reproducibility of % rearrangement value was generally within ±0.3; the *m*-chloro and 4-MeS-3-CN derivatives showed slightly larger deviation of ±0.5. Average % rearrangement values are given in Table 1. In the NMR analysis, any characteristic peak of solvolysis product other than acetate was not detected, especially in the olefin region, for all derivatives.

Stereoselective Synthesis of Octadecapolyenoic Esters as an Insecticide

Sadao Tsuboi, Xue Han Wu,† Seiji Maeda, Shinichiro Ono, Akihisa Kuroda, Kazuyoshi Kawazu, †† and Akira Takeda*

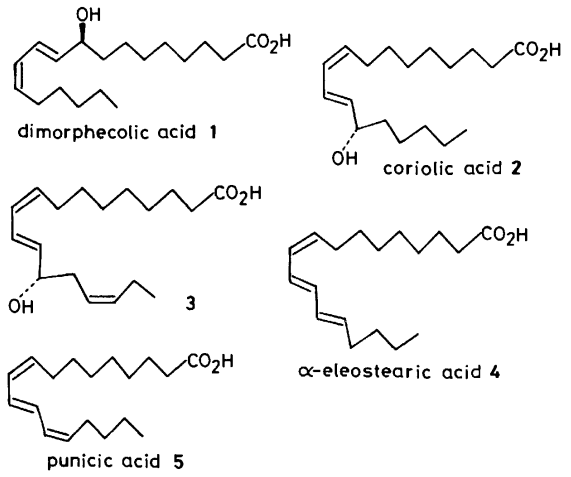
Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

††Faculty of Agriculture, Okayama University, Tsushima, Okayama 700

(Received October 24, 1986)

Octadecapolyenoic acid derivatives such as (±)-*t*-butyl coriolate, α-eleostearic acid, *t*-butyl punicate, and *t*-butyl (9*Z*,11*E*)-13-hydroxy-9,11-octadecadien-15-ynoate were synthesized starting from oleic acid with high stereoselectivity and their insecticidal activity was examined.

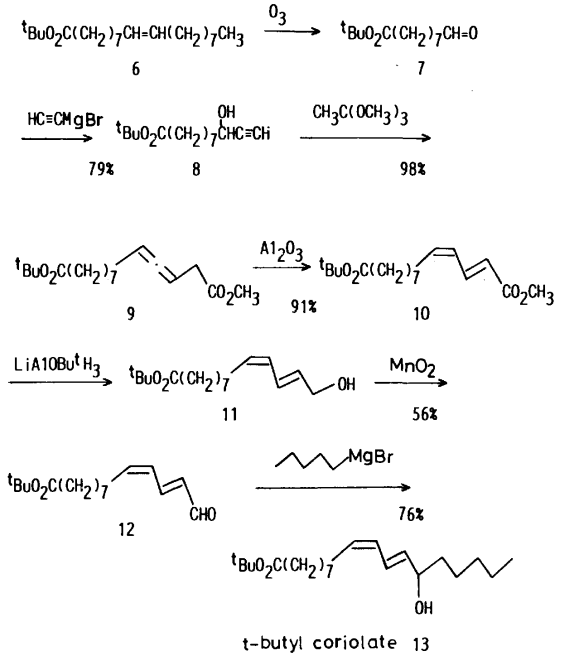
Hydroxyoctadecapolyenoic acids such as dimorphecolic acid (**1**), coriolic acid (**2**), and (13*S*,9*Z*,11*E*,15*Z*)-13-hydroxy-9,11,15-octadecatrienoic acid (**3**) are self defensive substances in rice plant against rice blast disease, which were isolated by Kato et al.[1] α-Eleostearic acid [(9*Z*,11*E*,13*E*)-9,11,13-octadecatrienoic acid] (**4**) and punicic acid [(9*Z*,11*E*,13*Z*)-9,11,13-octadecatrienoic acid] (**5**) are components in some seed oils,[2] and methyl α-eleostearate is a feeding deterrent for the boll weevil on cotton.[3] Kawazu[4] found that esters of octadecapolyenoic acids such as linoleic acid and linolenic acid possess insecticide activity by preliminary experiments. Recently, we reported the



synthesis of **1** and its analogs.[5] As an extention of the previous work,[5] here we report the synthesis of (±)-*t*-butyl coriolate, *t*-butyl punicate, **4**, and an analog of **3**. Furthermore, insecticidal activity of these products was examined.

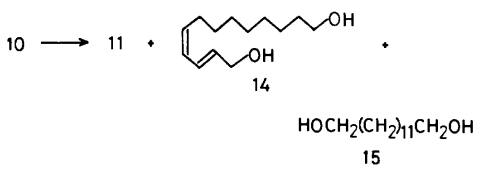
Coriolic acid (**2**) is a component of plant seed oils[6] and also a self defensive substance in rice plant against rice blast disease.[1] Syntheses of **2** have been reported by some groups.[7] Our synthetic sequence is shown in Scheme 1. Readily available oleic acid was used as a starting material. Ozonolysis of *t*-butyl oleate (**6**) at −20—−30 °C gave *t*-butyl 9-oxononanoate (**7**) in a fair yield. Ethynylation of **7** with ethynylmagnesium bromide yielded *t*-butyl 9-hydroxy-10-undecynoate (**8**) in 79% yield. Ortho-Claisen rearrangement of **8** with an excess of trimethyl orthoacetate gave β-allenic ester **9** quantitatively. Conversion of **9** to 1-methyl 13-*t*-butyl (2*E*,4*Z*)-2,4-tridecadiene-1,13-dioate (**10**) was established by the economical and convenient method which was developed by two of us.[8] Treatment of **9** with alumina at the reflux temperature of benzene gave (2*E*,4*Z*)-dienoic diester **10** in 91% yield with high stereoselectivity. Both proton and carbon-13 NMR analyses showed no presence of stereoisomers.

Regioselective reduction of **10** with various reducing agent was attempted and the results were summarized in Table 1. Reduction of **10** with diisobutylaluminum hydride (DIBAL) gave diol **14** as a major product. Reduction with lithium aluminum hydride (LAH) yielded a mixture of the desired product **11** and diol **14**. Prolonged reaction with LAH



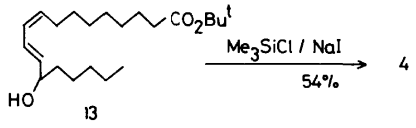
Scheme 1.

† Present address: Institute of Photographic Chemistry, Academia Sinica, Beijing, China.

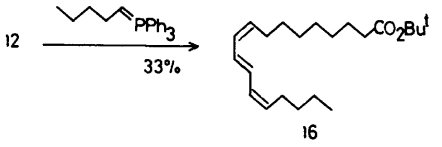


gave a hydrogenated product, 1,13-tridecanediol (**15**) in addition to the reduced products, **11** and **14**. Reduction of **10** with lithium di- or tri-*t*-butoxyaluminum hydride resulted in the formation of *t*-butyl (9*Z*)-13-hydroxy-9-tridecenoate or in the recovery of the starting material. The best result was obtained by the reduction of **10** with lithium *t*-butoxyaluminum hydride at −50 °C to give **11** in 60% yield. Oxidation of the alcohol **11** with active manganese dioxide at room temperature gave *t*-butyl (9*Z*,11*E*)-13-oxo-9,11-tridecadienoate (**12**) in an excellent yield, which is pure by ^{1}H NMR analysis. Reaction of **12** with pentylmagnesium bromide at −15 °C proceeded regioselectively to give (±)-*t*-butyl coriolate **13** in 84% yield as a sole product. The ^{1}H NMR spectrum was identical with that of methyl coriolate[9] except the signal of the ester group. Any 1,4- or 1,6-addition products could not be detected.

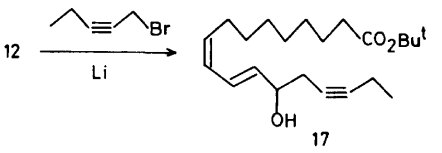
Conversion of (±)-*t*-butyl coriolate **13** to naturally occuring carboxylic acid **2** was attempted. However, the hydrolysis of **13** with chlorotrimethylsilane-sodium iodide[10a] at 25 °C afforded α-eleostearic acid (**4**)[11] in 54% yield with simultaneous dehydration. Synthesis of 1,3-diene from cyclic allylic alcohols and from allylic vicinal diols with Me_3SiCl–NaI is known.[10b] However, to our knowledge this type of dehydration for acyclic allylic alcohols has never reported before, and the general applicability is now under an investigation. On the other hand, acid-catalyzed hydrolyses resulted in the formation of polymerized products.



Punicic acid (**5**) is a component of plant seed oils.[2] Conacher and Gunstone[12] reported the synthesis of **5** from linoleic acid. We prepared *t*-butyl ester **16** of **5** by the Wittig reaction of **12** with pentylidenetriphenylphosphorane.



Shimura et al.[13,14] have reported the isolation and structural elucidation of anti-conidial germination substance, (9*Z*,11*E*,15*Z*)-13-hydroxy-9,11,15-octadecatrienoic acid (**3**). The absolute configuration of **3** was determined to be S-configuration by Kato et al.[1] We attempted the synthesis of (±)-**3**. Although it is reported that lithiation of 1-bromo-2-pentyne and the following reaction with a carbonyl compound gave acetylenic alcohol as a major product,[15,16] our attempts on the reaction of 2-pentynyllithium with aldehyde **12** afforded *t*-butyl (9*Z*,11*E*)-13-hydroxy-9,11-octadecadien-15-ynoate (**17**) in low yield along with an allenic compound. Conversion of **17** to *t*-butyl ester of (±)-**3** with stereoselective hydrogenation resulted in the formation of polymerized products.



Insecticidal activity of polyenoic esters prepared in the present synthesis and also in the previous paper was examined and the results were shown in Table 2. All of compounds showed fair insecticidal activity (LD_{50}=ca. 25—50 μg/fly) against adults of the fruitfly, *Drosophila melanogaster*. No notable relationship between the molecular structure and the activity was observed.

a) Dry film method. b) The number after 24 h. The number in parenthesis is after 48 h. c) The synthesis is reported in the previous paper. See Ref. 5.

Experimental

The melting and boiling points are uncorrected. Infrared (IR) spectra were obtained with a JASCO Model A-102 infrared spectrophotometer. ^{1}H NMR spectra (60 MHz) were recorded with a JEOL JNM-FX100 apparatus, with $CDCl_3$ as a solvent. All chemical shifts are reported in δ units downfield from internal Me_4Si, and J values are given in hertz. Column chromatography was accomplished with 100—200 mesh Wakogel C-200.

Petroleum ether was distilled (bp 40—60 °C) and dried over sodium wire. Tetrahydrofuran (THF) and diethyl ether were dried over sodium benzophenone ketyl and distilled under an atmosphere of nitrogen prior to use. Activated manganese dioxide was prepared according to the procedures in the literature.[17)]

t-Butyl oleate (**6**) was prepared by the reaction of oleoyl chloride with *t*-butyl alcohol in the presence of 2 equivalents of pyridine at 60—80 °C for 3 h: 88% yield.

t-Butyl 9-oxononanoate (**7**) was obtained by the ozonolysis of *t*-butyl oleate according to the procedure of the literature;[18)] bp 85—90 °C/0.08 mmHg (1 mmHg=133.322 Pa); 52.1% yield.

t-Butyl 9-hydroxy-10-undecynoate (**8**) was prepared by following the method described in the preparation of the methyl ester:[19)] 79% yield; IR (neat) 3500, 3300, 2100, 1730 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.30 (m, 10H, $(CH_2)_5$), 1.43 (s, 9H, $C(CH_3)_3$), 2.22 (m, 4H, CH_2CO, $>CHCH_2$), 2.40 (d, 1H, J=2 Hz, HC≡C), 4.35 (m, 1H, >CHOH).

13-*t*-Butyl 1-Methyl 3,4-Tridecadiene-1,13-dioate (9). A mixture of **8** (6.33 g, 0.0249 mol), trimethyl orthoacetate (20.9 g, 0.174 mol), and propionic acid (0.1 g) was heated to the reflux temperature for 24 h with removal of methanol produced by distillation. Removal of volatile materials under reduced pressure gave 7.58 g (98%) of **9**: IR (neat) 1960 (C=C=C), 1730 cm^{-1} (ester C=O); ^{1}H NMR ($CDCl_3$) δ=1.30 (m, 10H, $(CH_2)_5$), 1.45 (s, 9H, $C(CH_3)_3$), 2.12 (m, 4H, $=CHC\underline{H}_2(CH_2)_5$, $C\underline{H}_2CO_2Bu^t$), 3.02 (m, 2H, $C\underline{H}_2CO_2CH_3$), 3.64 (s, 3H, CO_2CH_3), 5.14 (m, 2H, CH=C=CH). Analytical sample was purified by column chromatography (SiO_2, hexane/ethyl acetate (10:1)). Found: C, 69.47; H, 9.50%. Calcd for $C_{18}H_{30}O_4$: C, 69.64; H, 9.74%.

1-Methyl 13-*t*-Butyl (2*E*,4*Z*)-2,4-Tridecadiene-1,13-dioate (10). A mixture of **9** (7.53 g, 0.0243 mol), alumina[8)] (12.4 g), and dry benzene (40 ml) was heated at the reflux temperature for 11 h. After filtration, removal of the solvent gave 6.85 g (91%) of **10** as a clean oil: IR (neat) 1720 (C=O), 1640, 1610 cm^{-1} (C=C); ^{1}H NMR ($CDCl_3$) δ=1.32 (m, 10H, $(CH_2)_5$), 1.41 (s, 9H, $C(CH_3)_3$), 2.17 (m, 4H, $=CHC\underline{H}_2$, $C\underline{H}_2CO_2Bu^t$), 3.66 (s, 3H, CO_2CH_3), 5.50—6.33 (m, 3H, $C\underline{H}$=$C\underline{H}C\underline{H}$=$C\underline{H}CO$), 7.45 (dd, 1H, J=10 and 15.0 Hz, $C\underline{H}$=CHCO). ^{13}C NMR ($CDCl_3$) δ=25.1 (t), 28.1 (s), 29.0 (t), 29.3 (t), 29.5 (t), 29.7 (t), 35.5 (t), 51.4 (q), 79.8 (s), 118.3 (d), 126.5 (d), 139.7 (d), 141.6 (d), 167.6 (s), 173.1 (s). Analytical sample was purified by column chromatography (SiO_2, hexane/ethyl acetate (10:1)). Found: C, 69.41; H, 9.51%. Calcd for $C_{18}H_{30}O_4$: C, 69.64; H, 9.74%.

***t*-Butyl (9*Z*,11*E*)-13-Hydroxy-9,11-tridecadienoate (11).** Lithium aluminum hydride (250 mg, 6.59 mmol) and 10 ml of THF was charged in 60 ml two-necked, round-bottomed flask under an atmosphere of nitrogen. To a stirred mixture was added 0.62 ml (49 mg, 6.58 mmol) of *t*-butyl alcohol at 0 °C. After 10 min, a solution of 2.04 g (6.57 mmol) of **10** in 10 ml of THF was added dropwise at −50 °C. The mixture was stirred for 3 h and then quenched with 1 ml of ethyl acetate and 2.5 ml of 10% HCl. After the mixture was poured into cold water, the organic layer was extracted with

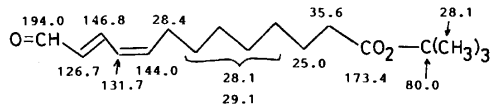
ether. The combined extracts were washed with water and dried over $MgSO_4$. Removal of the solvent gave 1.90 g of a crude product which was purified by column chromatography (SiO_2, hexane/ethyl acetate (9:1—1:1)) to give 1.13 g (60%) of **11** as a clean oil: IR (neat) 3425 (OH), 1735 (ester C=O), 1455, 1365, 1255 cm^{-1}; ^1H NMR δ=1.15—1.75 (m, 10H, $(CH_2)_5$), 1.40 (s, 9H, $C(CH_3)_3$), 1.75—2.40 (m, 4H, $CH_2CH=CH$, $CH_2CO_2Bu^t$), 3.96 (br d, 2H, J=5.6 Hz, CH_2OH), 5.05—6.63 (m, 4H, CH=CHCH=CH). Found: C, 72.32; H, 10.70%. Calcd for $C_{17}H_{30}O_3$: C, 72.30; H, 10.71%. The last fraction gave 110 mg (8%) of **14**: ^1H NMR ($CDCl_3$) δ=1.32 (m, 12H, J=6 Hz, CH_2OH), 4.19 (d, 2H, J=5.5 Hz, $HOCH_2CH=$), 5.17—6.33 (m, 3H, $CH=CHCH=CH$), 6.54 (dd, 1H, J=10 and 15.5 Hz, $HOCH_2CH=CH$). Found: C, 73.67; H, 11.52%. Calcd for $C_{13}H_{24}O_2$: C, 73.54; H, 11.39%.

Reduction of 10 with LiAl(OBu^t)$_3$H. To a stirred mixture of $LiAlH_4$ (120 mg, 3.16 mmol) and THF (3 ml) was added t-butyl alcohol (0.89 ml, 9.44 mmol) at 0 °C. After 10 min a solution of **10** (162 mg, 0.499 mmol) in 5 ml of THF was added dropwise at 15 °C, and the mixture was stirred for 42 h. The work up as described above gave a clean oil (148 mg) or t-butyl (9Z)-13-hydroxy-9-tridecenoate (supposed structure): ^1H NMR (CCl_4) δ=1.03—1.81 (m, 12H), 1.40 (s, 9H), 1.9—2.36 (m, 6H), 2.51 (br s, 1H), 3.50 (t, 2H, J=6 Hz), 5.11—5.52 (m, 2H).

Reduction of 10 with Diisobutylaluminum Hydride (DIBAL). Compound **10** (325 mg, 1 mmol) was reduced in 2 ml of ether with DIBAL (1.0 M in hexane) under the conditions described in Table 1 and worked up as above, giving 63.9 mg of **10**, 30.3 mg (14%) of 1,13-tridecanediol (**15**)[20]: ^1H NMR (CCl_4) δ=1.28 (s, 22H), 1.65 (br s, 2H), 3.40 (t, 4H), 5.9 mg (2%) of **11**, and 110 mg (52%) of **14**.

***t*-Butyl (9*Z*,11*E*)-13-Oxo-9,11-tridecadienoate (12).** (a) To a mixture of 11.0 g of activated manganese dioxide[17] and 100 ml of petroleum ether was added a solution of 1.13 g (4.01 mmol) of **11** in 20 ml of petroleum ether at 5 °C with stirring. The mixture was stirred for 3 h at 25 °C and then filtered off. Concentration of the filtrate gave 0.887 g of an oil which was chromatographed on 10 g of silica gel eluting with hexane/ethyl acetate (10:1) to give 0.624 g (56%) of **12** as a clean oil: IR (neat) 2950, 1725 (ester C=O), 1680 (aldehyde C=O), 1630 (C=C), 1365, 1155, 850 cm^{-1}; ^1H NMR (CCl_4) δ=1.05—1.91 (m, 10H, $(CH_2)_5$), 1.95—2.55 (m, 4H, $CH_2CO_2Bu^t$, $CH_2CH=CH$), 5.69—6.45 (m, 3H, $CH=CHCH=CHCHO$), 7.29 (dd, 1H, J=11 and 15 Hz, $CH=CHCHO$), 9.50 (d, 1H, J=7 Hz, CHO). Found:C, 72.72; H, 10.30%. Calcd for $C_{17}H_{28}O_3$: C, 72.82; H, 10.06%.

^{13}C NMR ($CDCl_3$, δ)

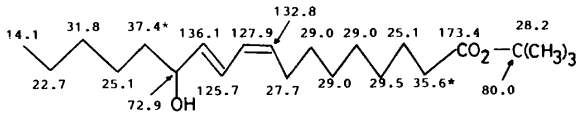


The last fraction eluted with ethyl acetate gave 100 mg of polymerized products.[21]

(b) To a mixture of 0.130 g (1.5 mmol) of activated manganese dioxide and 2 ml of petroleum ether was added a solution of 27 mg (0.096 mmol) of **11** in 0.5 ml of petroleum ether at 25 °C with stirring. The mixture was stirred for 2 h and then filtered off. Concentration of the filtrate gave 25 mg (93%) of **12** as a clean oil. TLC analysis (SiO_2, hexane/ethyl acetate (2:1)) showed one spot at R_f 0.75. IR and ^1H NMR data were identical with those of the authentic sample.

(±)-*t*-Butyl (9*Z*,11*E*)-13-Hydroxy-9,11-octadecadienoate ((±)-*t*-Butyl Coriolate) (13). To a mixture of 18.9 mg (0.778 mmol) of magnesium and 0.3 ml of THF was added dropwise 122 mg (0.808 mmol) of pentyl bromide with stirring. After 2 h, a solution of 96.8 mg (0.345 mmol) of **12** in 3 ml of THF was added dropwise at −15 °C, and then the mixture was stirred for 2 h. The mixture was poured into ice water, and the organic layer was extracted with ether. The combined extracts were washed with water, dried over $MgSO_4$, and concentrated. The resulting residue was chromatographed on 8 g of silica gel eluting with hexane/ethyl acetate (10:1) to give 63.3 mg (76%) of **13**: IR (neat) 3350 (OH), 1730 (C=O); ^1H NMR (CCl_4) δ=0.85 (t, 3H, CH_3), 1.30 (m, 18H, $(CH_2)_5$, $(CH_2)_4$), 1.38 (s, 9H, $C(CH_3)_3$), 2.10 (m, 4H, CH_2CO, $=CHCH_2$), 4.00 (m, 1H, >CHOH), 5.03—6.53 (m, 4H, $(CH=CH)_2$). Found: C, 74.62; H, 11.20%. Calcd for $C_{22}H_{40}O_3$: C, 74.95; H, 11.44%.

^{13}C NMR ($CDCl_3$, δ)



* May be interchangeable.

(9*Z*,11*E*,13*E*)-9,11,13-Octadecatrienoic Acid (α-Eleostearic Acid) (4). To a mixture of 66.3 mg (0.442 mmol) of sodium iodide and 0.5 ml of acetonitrile was added a solution of 82.1 mg (0.233 mmol) of **13** in 1 ml of acetonitrile under an atmosphere of nitrogen. Chlorotrimethylsilane (0.056 ml, 0.44 mmol) was added at 0 °C with stirring and the mixture was stirred for 3 h at 25 °C, and then poured into ice water. The organic layer was extracted with ether, washed with water, dried over $MgSO_4$. After removal of the solvent, the residual oil was chromatographed on silica gel eluting with hexane/ethyl acetate (20:1) to give 35 mg (54%) of **4**. Spectral data were identical with those of the authentic sample.[11]

***t*-Butyl (9*Z*,11*E*,13*Z*)-9,11,13-Octadecatrienoate (*t*-Butyl Punicate) (16).** To a stirred mixture of 143 mg (0.346 mmol) of pentyltriphenylphosphonium bromide and 2 ml of dry THF was added 0.23 ml (0.346 mmol) of 1.65 M butyllithium (1 M=1 mol dm^{-3}) in hexane at −20 °C. After 20 min, a solution of 47 mg (0.168 mmol) of **12** in 1 ml of dry THF was added dropwise. The mixture was stirred for 15 min at −78 °C, then poured into ice water, and neutralized with dilute HCl. The organic materials were extracted with ether, washed with water, and dried over $MgSO_4$. Removal of the solvent gave 71.8 mg of an oil, which was chromatographed (SiO_2, 2.8 g; eluent: hexane/ethyl acetate, 30:1—10:1) to afford 18.6 mg (33%) of **16** as an oil: TLC (hexane/ethyl acetate (1:1)), R_f 0.87. Spectral data were identical with those of the authentic sample[22] except signals due to the ester group. IR (neat) 2950, 1730 (C=O), 1460, 1365, 1255, 1150, 995 cm^{-1}; ^1H NMR (CCl_4) δ=0.90 (br t, 3H, J=6 Hz, CH_3), 1.30 (m, 14H, $7CH_2$), 1.38 (s, 9H, $C(CH_3)_3$), 2.11 (m, 6H, $2CH_2CH=$), 5.00—6.45 (m, 6H, 3CH=CH). ^{13}C NMR ($CDCl_3$) δ=13.9 (q), 22.3 (t), 25.1 (t), 27.8 (t), 28.1 (q), 29.1 (t), 31.8 (t), 35.6 (t), 79.9 (q), 127.9 (d), 128.8 (d), 130.0 (d), 132.7 (d), 173.3 (s). Found: C, 78.83; H,

11.67%. Calcd for $C_{22}H_{38}O_2$: C, 78.99; H, 11.45%.

***t*-Butyl (9*Z*,11*E*)-13-Hydroxy-9,11-octadecadien-15-ynoate (17).** To a stirred mixture of 10 mg (1.44 mmol) of lithium and 1.0 ml of THF was added a solution of 73.5 mg (0.542 mmol) of 1-bromo-2-pentyne and 160 mg (0.571 mmol) of **12** in 1 ml of THF at −40 °C over 1.5 h. Additionally, 73.5 mg (0.542 mmol) of 1-bromo-2-pentyne was added. After being stirred for 4 h at −40 °C, the mixture was poured into ice water. The organic layer was extracted with ether. The combined extracts were washed with water, dried over $MgSO_4$, and concentrated. The residue (178 mg) was purified by column chromatography (SiO_2, hexane/ethyl acetate/methanol (80:9:1), developed twice) to give 47 mg (24%) of **17**: TLC (SiO_2, hexane/ethyl acetate (4:1)), R_f 0.76—0.63; IR (neat) 3450, 2940, 2100 (C≡C), 1730: ^{1}H NMR (CCl_4) δ=0.85—1.86 (m, 13H, $(CH_2)_5$, CH_3), 1.91—2.61 (m, 8H, $CH_2C{\equiv}CCH_2$, $CH_2CH{=}CH$, CH_2CO), 4.20 (br d, 1H, J=5 Hz, CHOH), 5.03—6.89 (m, 4H, olefinic protons); ^{13}C NMR ($CDCl_3$) δ=12.3 (t), 14.0 (q), 24.9 (t), 27.5 (t), 27.9 (t), 27.9 (q), 28.8 (t), 29.3 (t), 35.4 (t), 70.6 (d), 75.0 (s), 79.7 (s), 84.6 (s), 126.3 (d), 217.4 (d), 133.1 (d), 133.4 (d), 173.2 (s). Found: C, 75.55; H, 10.38%. Calcd for $C_{22}H_{36}O_3$: C, 75.82; H, 10.41%. The second fraction gave 35 mg of unidentified compound as an oil. IR (neat) 3450 (OH), 2950, 1950 (C=C=C), 1734 (C=O); ^{1}H NMR (CCl_4) δ=1.0 (t, J=6 Hz), 1.1—1.75 (m), 1.75—2.55 (m), 4.16 (q, 1H, J=6 Hz), 4.80 (t, J=4 Hz), 5.1—6.17 (m), 6.45 (q, J=10 and 15 Hz). The last fraction gave 62 mg of polymerized compounds.

Insecticidal Test (dry film method). The fruitfly, *Drosophila melanogaster*, was reared in the medium described in the literature.[23] An ethyl acetate solution of the test compounds was added to a Petri-dish (ϕ 3 cm). After spontaneous evaporation of the solvent, ten adults of the fruitfly were introduced to the dish and kept at 25 °C for 48 hours. The survivors after 24 or 48 hours were counted and the numbers were shown in Table 2.

We appreciate Dr. Shuhei Nakajima of Department of Agricultural Chemistry, Okayama University for preliminary insecticidal activity test. We also thank Mr. Eiichiro Amano of our laboratory for elemental analysis. The present work was partially supported by a Grant-in-Aid for Developmental Scientific Research No 59850144 from the Ministry of Education, Science and Culture.

Hydrothermal Growth of Calcite Single Crystal in NaCl Solution

Shin-ichi HIRANO* and Kō-ichi KIKUTA
Department of Applied Chemistry, Faculty of Engineering, Nagoya University,
Furo-cho, Chikusa-ku, Nagoya 464
(Received August 23, 1986)

The hydrothermal synthesis of calcite single crystal was studied by using a NaCl solution as a mineralizer. The solubility of calcite in a 3 mol kg^{-1} NaCl solution was measured by a weight-loss technique to be around 2 g l^{-1} at 500 °C and 100 MPa. An optically clear rhombohedral crystal of up to 1.0 mm could be grown in a hydrothermal NaCl solution. The growth of a homogeneous layer of calcite could be observed on the calcite seed at 400 °C.

A calcite single crystal called Iceland spar has been used for such optical meterials as a Nicol prism. Recently, the demand for the growth of optically clear calcite crystals has been increasing due to a depletion of natural resources.

Many artificial techniques have been employed to grow calcite single crystal.[1-3] The flux method was recognized as being acceptable for growing calcite boule. It, however, encounters some difficulties in producing a high-quality single crystal of calcite owing to CO_2 dissociation, impurity contamination and a large thermal stress.

The hydrothermal method is one of the promissing techniques for growing unstable crystals such as a carbonate compound. The authors had preliminarily reported that calcite single crystals of a euhedral form, bounded by {10$\bar{1}$1}, could be grown spontaneously in hydrothermal NaCl and KCl solutions as the solvent; the kind of anion in the solvent was the most significant factor for controlling the coexisting phase as well as the morphology of the grown crystals.[4] Chloride solutions as a hydrothermal solvent, were first used by N. Yu. Ikornikova and have been examined by some authors.[5,6] Experimental details, however, have not been reported.

In the present work, the solubility of calcite in a 3 mol kg^{-1} hydrothermal NaCl solution was studied as a function of the temperature under 100 MPa; the most appropriate conditions for the growth of a calcite single crystal were elucidated as basic data for the large scale production of calcite single crystals.

Experimental

In this work, highly pure natural Iceland spar was used as a starting material. The hydrothermal run was carried out in a hydrothermal pressure vessel of the cold-seal type (1/4" I. D). The temperature was controlled with a calibrated chromel-alumel thermocouple set in the pressure vessel. The pressure was measured with a calibrated Heise gauge.

The calcite solubility was determined by the weight loss method with a hermetically sealed gold capsule (5.0 mm O. D, 4.7 mm I. D, 50 mm in length) containing cleaved Iceland spar crystals of about 3 mm in size. Crystals and the 3 mol kg^{-1} NaCl solvent solution were sealed in the gold capsule by welding and then set in a pressure vessel.

Solubility measurements were carried out under various conditions for a duration of 3 d; this was previously confirmed to be sufficiently long to achieve equilibrium. After a run, the pressure vessel was quenched into cold water. A stainless filler rod was placed in the space above the capsule so as to suppress any convection and to achieve thermal uniformity along the capsule.

The experimental growth conditions are a temperature of 350—500 °C, a pressure of 100 MPa and a duration of 3—14 d. The morphologies of the grown crystals were observed by optical microscopy. The grown crystals were also characterized by infrared spectroscopy and a back-reflection Laue method.

Results and Discussion

Solubility of Calcite in 3 mol kg^{-1} Hydrothermal NaCl Solution. The solubility of calcite in a 3 mol kg^{-1} hydrothermal NaCl solution was measured as a function of the temperature at 100 MPa by the weight-loss method. The solubility in the 3 mol kg^{-1} NaCl solution increased remarkably with increasing temperature above 400 °C and amounted to 2.0 g l^{-1} at 500 °C (Fig. 1). The value of the solubility is

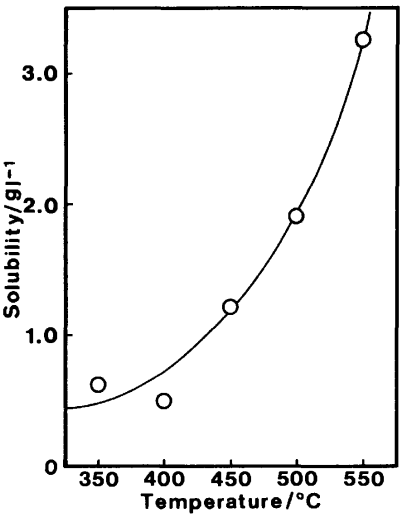

Fig. 1. Solubility of calcite in 3 mol kg^{-1} NaCl solution as a function of temperature.

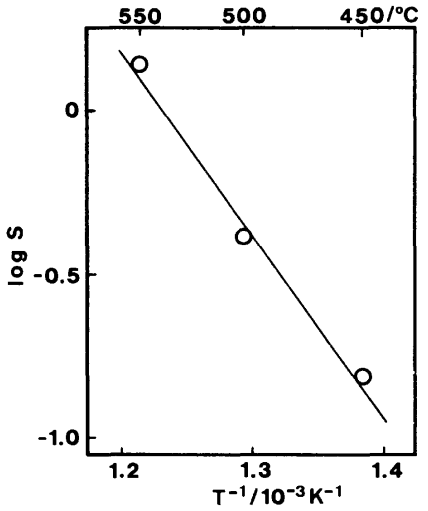

Fig. 2. Log S (solubility) of $CaCO_3$ as a function of $1/T$ in 3 mol kg^{-1} NaCl.

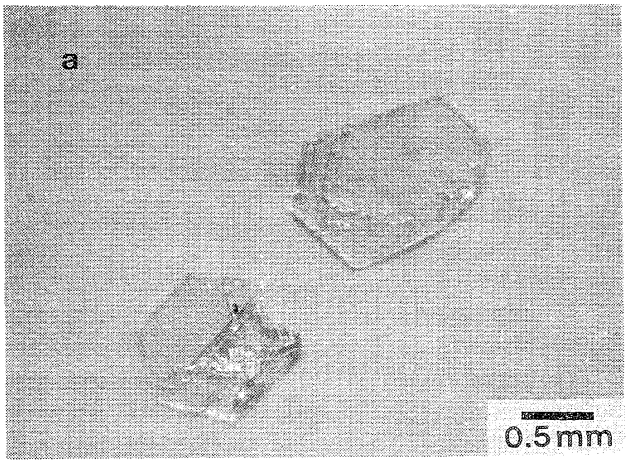

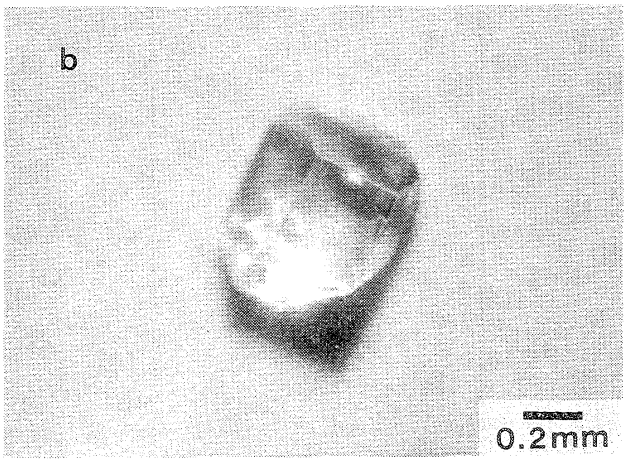

Fig. 3. Photomicrographs of calcite crystals grown in 3 mol kg^{-1} NaCl solution at 500 °C and 100 MPa for 10 d.

acceptable eventually for hydrothermal growth. Thus, all the growth experiments were carried out above 400 °C.

Figure 2 shows a plot of log S (Solubility) vs. $1/T$ in order to investigate the dissolution behavior of calcite in a 3 mol kg^{-1} NaCl solution at 100 MPa. The van't Hoff relation was confirmed to hold. The enthalpy of the solution, ΔH, was calculated to be about 46 kJ mol^{-1}, much larger than $\Delta H°=-12$ kJ mol^{-1} in a $CaCO_3$-H_2O system under ordinal conditions.[7] This fact indicated that the state of dissolved species under hydrothermal conditions was quite different from that under ordinary conditions at atmospheric pressure.

Morphology of Grown Calcite Single Crystal. A few growth runs were carried out with cleaved pure Iceland spar as a starting material of nutrient. Calcite single crystals of sizes up to 1.0 mm were grown spontaneously on the inner wall of the capsule at 500 °C under 100 MPa for 10 d. There were two kinds of crystal habits (Fig. 3). The morphologies of grown crystals were found to be strongly influenced by the growth temperature. Plate-like calcite crystals bounded by well developed {0001} faces could be formed mainly at elevated temperatures (above 500 °C). Associated with the crystals (Fig. 3a), a few polyhedral crystal were grown as shown in Fig. 3b. An identification of the plane is now in progress. The variation of crystal habits showed a good agreement with the occurence of Iceland spar in nature.[8] Euhedral crystals bounded by {10$\bar{1}$1} faces were also prepared at 450 °C and 100 MPa for 10 d (Fig. 4). This fact suggests that the Iceland spar in nature might occur in a hydrothermal solution at a relatively lower temperature.

Figure 5 shows the characteristic IR spectra of a

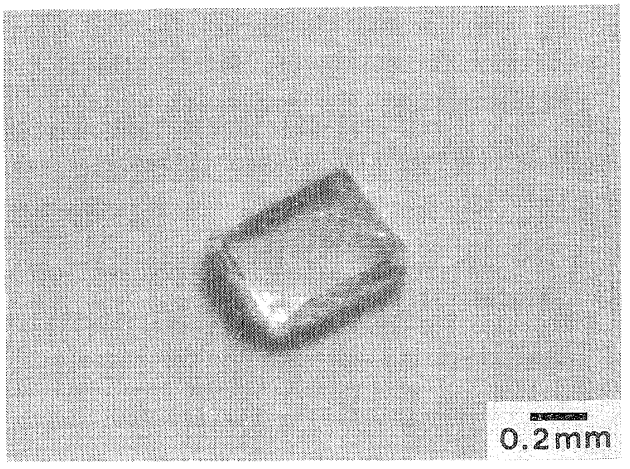

Fig. 4. Photomicrograph of calcite crystal grown in 3 mol kg^{-1} NaCl solution at 450 °C and 100 MPa for 10 d.

grown single crystal of calcite; it is identical to a high-quality natural calcite crystal, even though the crystal includes a stretching vibration due to OH^- around 3500 cm^{-1}. It ensures that the uptake of OH^- in this crystal is comparable to that in a well qualified optical grade of Iceland spar that is used for optical devices.

Growth Experiment with Seed Crystal. On the basis of the preliminary experiments, further growth runs with seed crystals were attempted by using a large pressure vessel (1/2″ I. D) in order to investigate the effect of seed orientation. A gold specimen container was prepared with a lid (10 mm O. D, 9.7 mm I. D, 17 cm in length) instead of a gold capsule. A short stainless filler rod was also placed above a gold container in order to adjust the thermal gradient.

Both spherical and rhombohedral seeds were suspended in the upper portion of the container. The pressure vessel was filled with a 3 mol kg^{-1} NaCl solution, brought up to 400 °C and 100 MPa and maintained for 2 weeks. After a run, it was cooled at a constant rate of 25 °C/hr.

The thickness of the rhombohedral seed increased by 0.087 mm while keeping its appearance. On the other hand, spherical seeds were observed to be completely covered with flat smooth surfaces and the steps of a grown calcite crystal (Fig. 6). The flat plane was identified to be $(10\bar{1}1)$ faces, of which symmetry was confirmed to be two fold by back-reflection Laue photographs. This result revealed that it would be possible to accelerate the growth rate on the seed by a proper selection of the seed orientation, such as $(11\bar{2}0)$.

Conclusion

It is found that the solubility of calcite in a 3 mol kg^{-1} hydrothermal NaCl solution increased remarkably upon increasing the temperature above 400 °C; the enthalpy of the solution, ΔH, was around 46 kJ mol^{-1} at 100 MPa.

Euhedral crystals of calcite could be grown spontaneously in a 3 mol kg^{-1} hydrothermal NaCl solution above 400 °C on the basis of solubility data.

The IR spectra of grown single crystals were found to be identical to high-quality natural Iceland spar with traces of OH^-.

Calcite single crystals could be successfully grown on seed crystals at 400 °C. This result indicates that the growth rate on the $\{10\bar{1}1\}$ plane is too slow for growing a large single crystal; thus, it is necessary to use a seed crystal with the proper orientation for a suitable facet, such as the $(11\bar{2}0)$ face.

A Fast Kinetic Study of Formation and Decay of 2,2′-Azinobis(3-ethylbenzothiazole-6-sulfonate) Radical Cation in Aqueous Solution

Pichai MARUTHAMUTHU,* Lakshmanan VENKATASUBRAMANIAN, and Periasamy DHARMALINGAM
Department of Energy, University of Madras, A. C. College Campus, Madras 600 025, India
(Received November 28, 1985)

The kinetics of oxidation of 2,2′-azinobis(3-ethylbenzothiazole-6-sulfonate) (ABTS) to the radical cation, $ABTS^{\cdot+}$ by $S_2O_8^{2-}$, HSO_5^-, MnO_4^-, $Cr_2O_7^{2-}$, Ce(IV), and molecular Cl_2, Br_2, and I_2 and further oxidation to the dication, $ABTS^{2+}$ by the above oxidants except HSO_5^-, Br_2, and I_2 have been carried out by the stopped-flow spectrophotometric technique. The first-stage oxidation was followed by monitoring the absorption of $ABTS^{\cdot+}$ at 417 nm and the second-stage oxidation, by following the disappearance of $ABTS^{\cdot+}$ or the appearance of $ABTS^{2+}$ at 513 nm. Both the reactions, formation and decay of $ABTS^{\cdot+}$ were found to obey a total second-order kinetics, first-order each with respect to [ABTS] or [$ABTS^{\cdot+}$] and [oxidant]. With I_2, ABTS underwent reversible reaction, the stoichiometry of which being,

$$I_2 + 2ABTS \rightleftharpoons 2ABTS^{\cdot+} + 2I^- \text{ with } K = 142.8,$$

whereas Br_2 generated only the radical cation and Cl_2 gave a decomposed product via radical cation and dication intermediates. $ABTS^{2+}$ formed in presence of excess MnO_4^-, $Cr_2O_7^{2-}$, and Ce(IV) decayed as in the case of Cl_2 reaction but in presence of $S_2O_8^{2-}$ the dication was stable for more than three days. In the absence of excess $S_2O_8^{2-}$, $ABTS^{2+}$ went back to $ABTS^{\cdot+}$, possibly via oxidation of water. The radical cation was converted back to the parent compound ABTS by reducing agents such as dithionite and sulfite ions.

Recently much attention has been focussed on the reactions of radical cations in an aqueous solution to explore the possibility of using them in solar energy conversion processes.[1,2] Würster's salt (TMPD) which forms $TMPD^{\cdot+}$ on one-electron oxidation and Weitz's salt (Methylviologen) which forms a radical cation on one-electron reduction are assessed to be electron-relays in chemical routes to solar energy conversion. We have already reported on the fast kinetics of the formation and decay of *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine raical cation ($TMPD^{\cdot+}$) in aqueous solution by several oxidizing agents.[3] Previous studies on the polarographic oxidation[4,5] of 2,2′-azinobis(3-ethylbenzothiazole) have revealed the formation of a radical cation and a dication. The utility of ABTS as an analytical reagent for colorimetric determination of periodic acid has also been reported.[6] However no kinetic measurements were carried out. Here we present the results of fast kinetics of formation and decay of radical cation, $ABTS^{\cdot+}$ by one-electron as well as multielectron oxidizing agents.

Experimental

All kinetic measurements were made with Applied Photophysics Model-1705 stopped-flow-spectrophotometer. Absorption output was digitised with a Datalab Model-902 Transient recorder equipped with variable input sensitivity and variable sampling interval, and was monitored by Trio Model-CS-1562A Oscilloscope. About 500—700 points were collected for each kinetic measurement and at least six kinetic runs were made for each rate constant measurement. The data were stored and analyzed by CBM-3032 Personal Computer. The kinetic plots were plotted on a Hewlett-Packard graphics plotter. All the measurements were carried out at room temperature (25 °C), with the reagent solutions prepared using doubly distilled water. Cyclic voltammogram studies were carried out with a PAR Model 173/175 electrochemical setup using a platinum wire as the working electrode and KCl as the supporting electrolyte. The chemicals used were of the best research grade commercially available. ABTS was from Boehringer, Mannheim (West Germany) in the form of diammonium salt and was used as such. Peroxomonosulfate (PMS) in the form of a triple salt ($2KHSO_5$–$KHSO_4$–K_2SO_4) with the trade name "OXONE" was obtained from Dupont de Nemours & Co (USA). Other chemicals such as peroxodisulfate (PDS), $KMnO_4$, $K_2Cr_2O_7$, $Ce(NH_4)_2(SO_4)_3$, and molecular I_2, Br_2, and Cl_2 were obtained from Sarabhai M. Chemicals. The reagent solutions were thoroughly degassed by purified nitrogen or argon. The extent of formation and decay of radical cation ($ABTS^{\cdot+}$) were monitored at 417 nm which

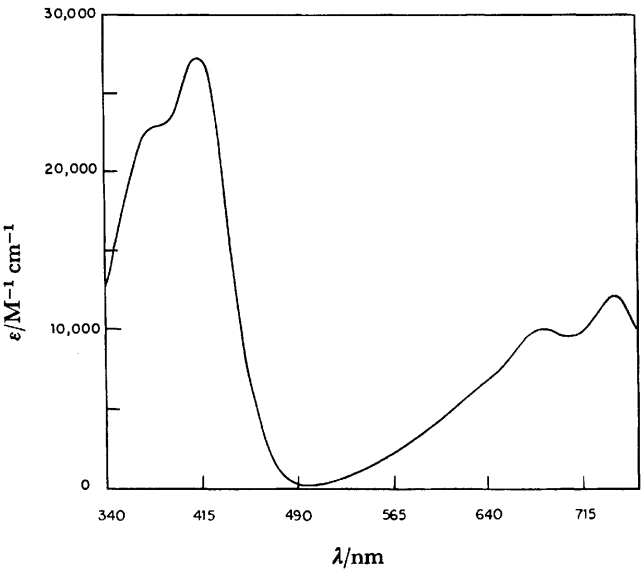

Fig. 1. Molar absorption spectrum of $ABTS^{\cdot+}$.

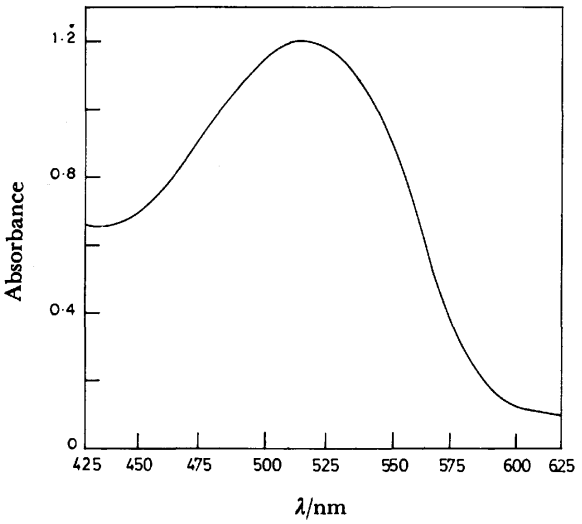

Fig. 2. Transient spectrum of $ABTS^{2+}$.

corresponds to its maximum absorbance ($\varepsilon_{417}=2.70\times10^4\ M^{-1}\ cm^{-1}$ -Fig. 1) (1 M=1 mol dm^{-3}). Formation of dication $ABTS^{2+}$ was monitored by its absorbance maximum at 513 nm (Fig. 2). The radical cation ($ABTS^{\cdot+}$) used was prepared by the reaction of ABTS with PMS (HSO_5^-) in the ratio of 2:1 respectively in deaerated water. The radical cation formed was found to be stable for more than a week.

Results and Discussion

All the kinetic measurements were carried out under pseudo-first order conditions, with the concentration of the oxidant in at least ten times excess over that of ABTS. The changes in the concentration of the transient with time were followed at different time scales depending on the reactivity of the oxidant. Plots of log (absorbance) against time were found to be linear up to ≈70% of the reaction with the correlation coefficient ≥0.99, showing that the reaction is first order with respect to ABTS. Plots of the pseudo first order rate constants k'/s^{-1} against concentrations of oxidant at fixed [ABTS] were found to be linear passing through the origin (Fig. 3), showing the first-order dependence of the rate on the oxidant. From the slopes of the above plots, the second-order rate constants $k_f/M^{-1}\,s^{-1}$ were calculated to be presented in Table 1. The proposed rate law for the formation of radical cation is

$$\frac{d[ABTS^{\cdot+}]}{dt} = k_f[ABTS][Oxidant]. \quad (1)$$

For the determination of the rate constants of the decay of the radical cation either to the dication ($ABTS^{2+}$) or back to ABTS, experiments were carried out with the $ABTS^{\cdot+}$ preprepared as mentioned above. The kinetics were spectrophotometrically followed either at 417 or 513 nm, by varying [$ABTS^{\cdot+}$] as well as [Oxidant] under pseudo-first-order conditions. Rate law analysis similar to the above (Fig. 4)

Table 1. Kinetic Data for the Formation and Decay of $ABTS^{\cdot+}$ at 25 °C

Oxidant	$k_f/M^{-1}\,s^{-1}$	$k_d/M^{-1}\,s^{-1}$
PMS	11.16	—
PDS	0.63	0.20
MnO_4^-	2.50×10^4	1.50×10^3
$Cr_2O_7^{2-}$/0.2 M H^+	1.01×10^3	4.00×10^2
Ce(IV)/0.2 M H^+	3.01×10^2	3.00×10^1
I_2	6.28×10^2	—
Br_2	1.00×10^5	—
Cl_2	—	2.40

gave the kinetic rate law for the decay process to be

$$\text{Rate} = -\frac{d[ABTS^{\cdot+}]}{dt} = \frac{d[ABTS^{2+}]}{dt}$$
$$= k_d[ABTS^{\cdot+}][Oxidant]. \quad (2)$$

The calculated rate constants k_d are shown in Table 1.

Reaction with Peroxodisulfate (PDS) and Peroxomonosulfate (PMS). The kinetics of reactions of these two peroxosalts of sulfur with ABTS were found to be first-order each with respect to the oxidant and ABTS. Although these two oxidants are two-electron transferring agents, they behave like a one-electron oxidant in forming the radical cation, $ABTS^{\cdot+}$. On short time scales, (5—20 ms), PDS (1—5×10^{-2} M) and ABTS (1—5×10^{-5} M) generated only the radical cation ($ABTS^{\cdot+}$). However at longer time scales (20—50 ms)

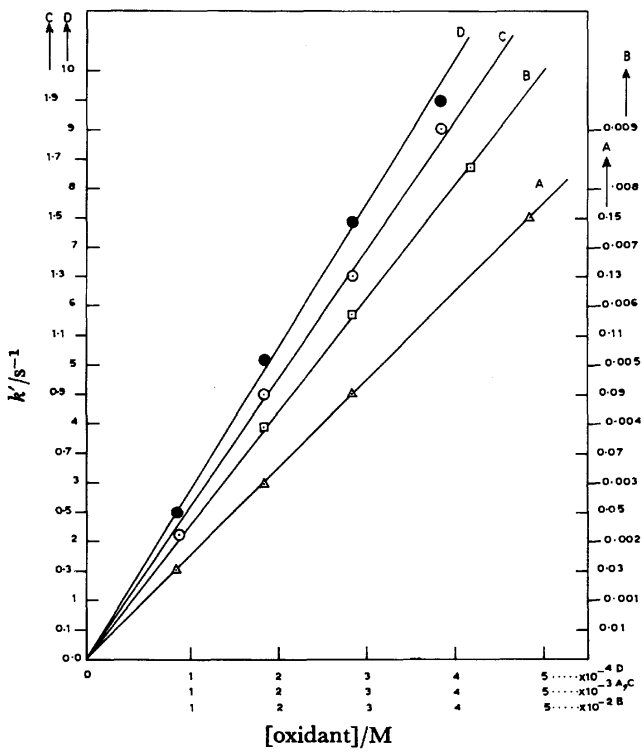

Fig. 4. Evaluation of k_d.
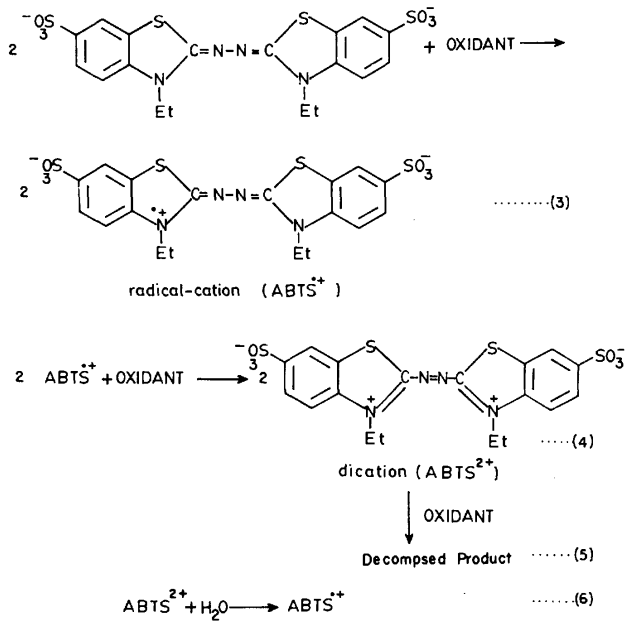
k' vs. [Oxidant]; T=25 °C; A: Ce(IV); B: PDS; C: $Cr_2O_7^{2-}$; D: MnO_4^-.

the radical cation formed decayed to the dication, $ABTS^{2+}$. The rate constant determined for the reaction (3), formation of ABTS$^{\cdot+}$, was 0.63 M^{-1} s^{-1} and that for the second-stage oxidation (4) was 0.20 M^{-1} s^{-1}.



From the magnitudes of the rate constants, it is seen that the oxidation of ABTS$^{\cdot+}$ to $ABTS^{2+}$ is approximately three times slower than that of ABTS to ABTS$^{\cdot+}$. The dication which is pink-red brittle precipitate is stable for more than three days in the presence of excess $S_2O_8^{2-}$. The precipitate, separated and free from $S_2O_8^{2-}$, when dissolved in water turned back into ABTS$^{\cdot+}$ (6). On the other hand, the reaction of HSO_5^- with ABTS, whatever be the concentrations of both of them, stopped with the formation of ABTS$^{\cdot+}$. This unusual stability of the radical cation is explained by strong delocalization of the odd electron into the π-cloud, thus causing a high stability and long wavelength absorption. The rate constant determined for the oxidation of ABTS by PMS is 11.16 M^{-1} s^{-1}. Even though the oxidation potential for PMS (1.81 V) is less than that of PDS (2.01 V), the rate constant for PMS with ABTS is approximately 18 times higher than that of PDS. This observation is similar to the one encountered in many thermal reactions[7] wherein the rate constants for the oxidation by PMS were higher than those of PDS. In some cases, such as oxidation of methoxybenzenes[8] the reaction of PMS took place at measurable rates at 25 °C, whereas PDS reacted only in presence of Ag^+ catalyst. Hence, even though the thermodynamic factor (oxidation potential) is favorable for PDS to react with many substrates, the reactions are kinetically inhibited. This might be true in the present investigation also. However, PMS does not react further with the radical cation unlike $S_2O_8^{2-}$.

Reactions of Halogens. Molecular iodine oxidised ABTS to ABTS$^{\cdot+}$ instantaneously, but I_2 in excess KI (5%) did not bring the reaction instantaneously, suggesting the equilibrium reaction (7),

$$2ABTS + I_2 \underset{k_r}{\overset{k_f}{\rightleftharpoons}} 2ABTS^{\cdot+} + 2I^- \qquad (7)$$

The forward reaction was measured by following the formation of radical cation for various concentrations of ABTS with different amounts of I_2 in water at natural pH (pH=6.9) in 2—10 ms time scale. The second-order rate constant, k_f was calculated to be 628.1 M^{-1} s^{-1}. The reverse process was monitored by following the disappearance of ABTS$^{\cdot+}$ for various concentrations of ABTS$^{\cdot+}$ ($1—5\times10^{-5}$ M) and I^- ($2—8\times10^{-2}$ M). The rate constant for the reverse reaction was, k_r=4.40 M^{-1} s^{-1}, then the equilibrium constant being $K=k_f/k_r$=142.8. The rate constants measured at pH 3—6 did not show any difference from those measured at the near neutral and natural pH. From the equilibrium constant, the change in the Gibbs free energy, $\Delta G°$ at 25 °C for the reaction (7) is calculated to be, $\Delta G°=-RT\ln K$

$$\Delta G° = -8.314 \times 298 \times 2.303 \times 2.155$$
$$\Delta G° = -1.23 \times 10^4 \text{ J mol}^{-1}.$$

The difference in the standard redox potentials between the two one-electron redox couples is $\Delta E° = \Delta G°/F$=−0.127 V. The standard redox potential

$E°$, for $ABTS^{\cdot+}$/ABTS measured in aqueous medium by cyclic voltammetric technique was +0.43 V. Since the $E°$ for I_2/I^- is +0.54 V, theoretical value of the standard electrode potential for the reaction (7) should be −0.11 V which is in good agreement with the one estimated from the equilibrium constant. In the case of the reactions of Br_2 and Cl_2 with ABTS, such equilibrium was not observed. Molecular Br_2 in water or aqueous Br_2/KBr oxidized ABTS to $ABTS^{\cdot+}$ in 0.5—2.0 ms time scale and the rate constant for the reaction (8),

$$ABTS + Br_2 \longrightarrow ABTS^{\cdot+} + Br_2^{\cdot-} \quad (8)$$

was $1.00\times10^5\ M^{-1}\ s^{-1}$. There was no detectable reaction of $ABTS^{\cdot+}$ either with Br_2 or Br^-. No attempt was made to investigate the fate of $Br_2^{\cdot-}$ in the present work since it was postulated to decay by the bimolecular reaction at diffusion controlled rate,[9]

$$2Br_2^{\cdot-} \longrightarrow Br^- + Br_3^- . \quad (9)$$

In the case of Cl_2, the first stage oxidation (3) was very fast and took place within the mixing time of the instrument (dead time 2 ms). The second-stage oxidation resulted in a decomposed product via the dication as the transient even for the lowest concentrations of the reactants $ABTS^{\cdot+}$ and Cl_2. The kinetics of the decay process was also found to be total second-order, first-order each with respect to $[ABTS^{\cdot+}]$ and $[Cl_2]$ and the rate constant was calculated to be $2.40\ M^{-1}\ s^{-1}$.

$$ABTS^{\cdot+} + Cl_2 \longrightarrow ABTS^{2+} \longrightarrow \text{decomposed product} \quad (10)$$

The decomposed product formed in the reaction (10) could not be reverted back to any one of the species, $ABTS^{2+}$, $ABTS^{\cdot+}$, or ABTS by the addition of strong reducing agents such as sulfite or dithionite. Since our interest in this study is centered around the formation and reactivity of radical cations from ABTS, not much attention was paid on the complete identification of the decomposed product. However, IR and UV spectral investigation showed the formation of substituted thiophenol and disulfide depending upon the concentration of Cl_2 used. From the magnitudes of the rate constants (Table 1), the reactivity trend of the halogens with ABTS, $Cl_2>Br_2>I_2$ is similar to the trend of their oxidation potentials and the latter two halogens give only the one-electron oxidation product, $ABTS^{\cdot+}$. In the case of oxidation of $ABTS^{\cdot+}$ to $ABTS^{2+}$, judging from the magnitudes of the oxidation potentials of Cl_2 (1.35 V) and $ABTS^{\cdot+}/ABTS^{2+}$ (0.83 V) and the magnitude of the rate constant for the reaction (10), it is not surprising that Br_2 (oxidation potential 1.06 V) hardly react with $ABTS^{\cdot+}$.

Reaction of MnO_4^-, $Cr_2O_7^{2-}$, and Ce(IV). At low concentrations of the oxidants, ([ABTS]=1—4×10^{-5} M; [oxidant]=1—4×10^{-4} M), both MnO_4^- and $Cr_2O_7^{2-}$ (in 0.2 M H^+) were found to generate only the radical cation. However at higher concentrations of the oxidants and on longer time scales, the radical cation was found to decay at a measurable rate to pink-red dication and then to a decomposed product. In the case of Ce(IV) in 0.2 M H^+, at any concentrations of the reactants, ABTS was oxidized to the dication via the radical cation as a transient. The observed rate constant for both the processes are presented in Table 1. From the magnitudes of the rate constants the reactivity of these oxidants with ABTS as well as $ABTS^{\cdot+}$ is found to be $MnO_4^->Cr_2O_7^{2-}>Ce(IV)$, the second-stage oxidation being one order of magnitude less than that for the radical cation formation in the case of MnO_4^- and Ce(IV). The rate constants estimated are in line with the oxidation potentials[10] of MnO_4^- (1.695 V) and $Cr_2O_7^{2-}$ (1.44 V). In the case of Ce(IV) (1.44 V) on thermodynamic grounds, the reactivity should be comparable to that of $Cr_2O_7^{2-}$. However, it is less reactive than $Cr_2O_7^{2-}$ probably due to its high ability of complexing[11] with groups containing electron donors.

Reduction of Radical Cation. The possibility of the reduction of the radical cation, $ABTS^{\cdot+}$ was tested by using dithionite and sulfite ions as reducing agents. The reaction (11) was brought about, producing the parent compound ABTS,

$$ABTS^{\cdot+} + \text{reductant} \longrightarrow ABTS \cdot \quad (11)$$

The kinetics of the reaction gave the second-order rate constants shown below:

$$ABTS^{\cdot+} + SO_3^{2-} \longrightarrow ABTS,\ k_2 = 1.06\times10^3\ M^{-1}\ s^{-1},$$
$$ABTS^{\cdot+} + S_2O_4^{2-} \longrightarrow ABTS,\ k_2 = 6.30\times10^2\ M^{-1}\ s^{-1}.$$

Other preliminary tests show that the radical cation $ABTS^{\cdot+}$ is capable of oxidizing many organic and inorganic substrates.[12]

Ultraviolet Studies and Fluorescence Quenching of Some Aromatic Primary Amines

Samaresh MUKHERJEE
Department of Physical Chemistry, Indian Association for the Cultivation of Science, Jadavpur, Calcutta 700 032, India
(Received January 25, 1986)

The fluorescence quenching of *o*-aminobenzoic acid, 1-naphthylamine, aniline, *p*-toluidine, *m*-toluidine, and *N,N*-dimethylaniline by 2-hydroxy-5-methyl-1,3-benzenedicarbaldehyde (**VII**) was studied. The equilibrium constant of hydrogen bonding in the ground state was evaluated from the absorption spectral change for various donor-acceptor (D-A) pairs. The rate constants of hydrogen-bond formation as well as decomposition in the excited state were evaluated in the case of several donor-acceptor pairs from fluorescence intensity measurements. In addition, the mechanism of fluorescence quenching and absorption spectral shift when **VII** acted as a quencher/proton donor (D) was discussed on the basis of charge-transfer and hydrogen-bond interaction.

Light absorption brings out rather strong change in some molecular properties in the excited state and the proton dissociation, energy transfer or hydrogen-bond formation of aromatic hydroxy and amino compounds occurs far easily in the excited state than in the ground state.[1-5] Apart from spectral shift, hydrogen bonding also causes fluorescence enhancement or quenching. The phenomenon of fluorescence quenching particularly has received wide attention.[6-15] It is known that aromatic amines experience a large change in the excited state[16-18] consequently it will be of interest to investigate the effect of various influences on the ground vis-a-vis excited state properties of aromatic amines. The present investigation dealing with interaction of some aromatic primary amines, viz. *o*-aminobenzoic acid (**I**), 1-naphthylamine (**II**), aniline (**III**), *p*-toluidine (**IV**), *m*-toluidine (**V**), and *N,N*-dimethylaniline (**VI**) with a proton donor (D), viz. 2-hydroxy-5-methyl-1,3-benzenedicarbaldehyde (**VII**) in cyclohexane at 300 K was undertaken with the object to study the spectral changes in relation to hydrogen-bonding properties of the molecules in the ground and excited state and probable reaction processes leading to fluorescence quenching.

Experimental

1-Naphthylamine, *o*-aminobenzoic acid, and *p*/*m*-toluidines were purified by recrystallization followed by vacuum sublimation. Aniline and *N,N*-dimethylaniline were first dried over solid KOH and then distilled over zinc dust. Cyclohexane (Merck, spectroscopic grade) was dried over metallic sodium and distilled fractionally. Proton donor **VII**[19] was received as a gift from department of inorganic chemistry of this institute. All the absorption spectra were recorded with freshly prepared solutions in a Cary 17D spectrophotometer. The fluorescence spectra were recorded in a Perkin-Elmer fluorescence spectrophotometer (Model MP F-44B) using 1 cm stoppered quartz cell at 300 K. Blank runs were made with solvent alone which showed no fluorescence emission at the maximum sensitivity of the instrument in the spectral region of interest.

The fluorescence quantum yield of amines are measured from the corrected area under fluorescence curve relative to that of anthracene[20] in identical conditions. Radiative lifetimes are estimated from integrated absorption spectra using Eq. 1

$$\tau_N = \frac{1.5}{(\bar{\nu}_{max})^2 \times f}, \quad (1)$$

where $f=4.33\times10^{-9}\int\varepsilon\bar{\nu}d\bar{\nu}$, is the oscillator strength of the lowest electronic transition.

Results and Discussion

The change of absorption spectrum caused by hydrogen bonding is shown in Fig. 1 in the case of *o*-aminobenzoic acid (**I**)+2-hydroxy-5-methyl-1,3-benzenedicarbaldehyde (**VII**) system in cyclohexane. Frequency maxima (ν_E in cm^{-1}) and frequency shifts ($\Delta\nu_E$ in cm^{-1}) for the proton acceptor molecules **I** and **II** are given in Table 1. From the observed spectral change, the equilibrium constant K_g of hydrogen-bond formation with proton acceptor molecules for the case **I** and **II** in the ground state can be evaluated by the Ketelaar's method[21] using the Eq. 2.

$$\frac{1}{A_o - A_f} = \frac{1}{[D]} \cdot \frac{1}{A_b - A_f} \cdot \frac{1}{K_g} + \frac{1}{A_b - A_f} \quad (2)$$

In Eq. 2, A_f and A_b denotes the absorbance of free acceptor and the hydrogen-bonded complex respectively and A_o that of a solution of acceptor where the concentration D is [D]. On extrapolating the straightline obtained from $1/(A_o-A_f)$ vs. $1/[D]$ plot to the point where $1/(A_o-A_f)=0$, K is obtained as $K=-1/[D]$. The association equilibrium constants (K_g) evaluated by linear regression analysis are given in Table 2. It is observed that with gradual increase of [D] the position of the absorption maximum shifts gradually (Fig. 1) and then tends to a constant value above a certain concentration indicating that intermolecular hydrogen bond formation is almost complete as such concentration. Another significant observation is that the oscillator strength (f_b) for

bonded molecules is always greater than that (f_f) for free molecules in the case of both **I** and **II**. Thus we see from Table 1 that there is a correlation between the hydrogen-bond formation and the increase in f-values of transition.

The change of fluorescence spectrum caused by hydrogen bonding of the proton donor (**VII**) with aniline (**III**) and *N*,*N*-dimethylaniline (**VI**) in cyclohexane is shown in Fig. 2 and the relevant spectral data are set out in Table 1. At low concentration the quenching of fluorescence by a proton donor in solution follows the classic Stern-Volmer relationship (3)

$$f^0/f = 1 + K_Q[D], \quad (3)$$

where K_Q is called the quenching constant, f is the intensity of fluorescence at the proton donor **VII** concentration, [D], and f^0 is its value without D. The K_Q values evaluated graphically (Fig. 3) using the relation (3) are given in Table 3. By equating the bimolecular rate constant for the quenching reaction (K_1) against the rate of emission it can be shown[22] that $K_Q = K_1\tau$ where τ is the actual mean life of the fluorescence i.e., quantum efficiency (ϕ) × radiative life (τ_N) (see Table 3). Detailed quantitative study of the relative fluorescence yield and life time measurements were also carried out for all the systems. The wave number shifts $\Delta\nu_F$ and $\Delta\nu_E$ of the fluorescence

and excitation spectrum respectively due to hydrogen-bond formation are given in Table 1. Of all the proton acceptor studied the spectral shift on hydrogen-bond formation in the excited state $\Delta\nu_f=\nu_b-\nu_f$ (b and f referring to bonded and free molecules respectively) is found to be towards longer wavelength for **I** and **II** (i.e., $\Delta\nu<0$) for **IV** to **VI** towards shorter wavelength. For **III**, however, $\Delta\nu=0$.

While K_g is evaluated by Eq. 2 from the absorption spectral change, the corresponding quantity in the excited state, K_e (for **I** and **II**) can be estimated approximately by Eq. 4 assuming the same entropy change due to hydrogen-bond formation in the excited state as well as in the ground state[5]

$$\log K_e = \log K_g + \frac{0.625}{T}\cdot\Delta\nu_a . \quad (4)$$

In Eq. 4 $\Delta\nu_a$ is the limiting wave number shift of the absorption spectrum caused by hydrogen bonding and T is the absolute temperature. The values of K_g and K_e estimated in this way at ≈300 K are given in Table 2. It is important to point out here that in all of the systems under consideration quenching occurred, but the spectral shift observed in the ground state and excited state did not occur in the same way. When **I** and **II** were used as acceptor molecules, spectral shift occurred both in the ground and excited states. On the other hand, in the cases of **IV** and **VI**, spectral shift was observed only in the excited state. However, for **III** no

spectral shift occurred both in ground as well as excited state.

Qualitatively speaking, the observed difference between the hydrogen-bonding effect on the fluorescence and absorption spectrum may indicate that, the equilibrium shifts more or less to the side of hydrogen-bond formation during the life time of fluorescence state. To treat quantitatively the very rapid reaction which occurs during the life time of excited state Mataga et al.[5] has derived the general equation considering the probable reaction scheme and from the general equation they have derived several special cases also assuming the stationary state. For simplicity two approximate relationship can be used here

$$(f_0/f)(I_{abs}/I^0_{abs})\cdot\delta = 1 + K_1\tau[D], \quad (5)$$

$$(f/f_0-1)/[D] = K_f'\tau' K_1/K_f(1+K_2\tau') - [\tau K_1/(1+K_2\tau')]f/f_0 . \quad (6)$$

In these expressions I_{abs} is the total light quanta absorbed by solution when D is present, δ is the fraction of A* and is given by $\delta=1/\{1+(\varepsilon_c/\varepsilon_A)K_g[D]\}$, ε_A and ε_c are the molar extinction coefficients of acceptor (A) and donor acceptor complex (DA) respectively, at the wavelength of exciting light. K_1 is the bimolecular rate constant of hydrogen-bonding reaction and K_2 is the unimolecular rate constant of dissociation of DA*. I^0_{abs} is the total light quanta absorbed by the solution when D is absent and f_0 is the fluorescence intensity in that case. Using Eqs. 5 and 6 one can evaluate $K_1\tau$ and $\tau K_1/(1+K_2\tau')$. Figures 4 and 5 shows that for **I** and **II** these equations are approximately satisfied. The values of τK_1 and $\tau K_1/(1+\tau' K_2)$ obtained in this way are collected in Table 2. Using the values of given in Table 3, K_1 can be easily estimated. From the K_1 values and by means of the relation $K_2=K_1/K_e$, K_2 values may be estimated, if K_e values obtained by Eq. 3 are used. Practically, when no hydrogen-bonded complex exists in the ground state, $\delta=1$. The change of molar extinction coefficient caused by hydrogen-bonding is very small at the wavelengths of exciting light (288, 292, 286, and 298 nm for **III** to **VI** respectively) used, which mean I_{abs} is practically equal to I^0_{abs}. Moreover, because the fluorescence quenching was almost complete in the concentration range studied here, but practically no change in the absorption spectrum was observed, Eq. 6 therefore reduces to $f^0/f=1+K_1\tau[D]$, which incidentally is the simple Stern-Volmer Eq. 3.

One point to note here is that the values of the bimolecular quenching rate constant K_1 given in Tables 2 and 3 are rather high in comparison to diffusion controlled rate constant. A possible explanation may be presumed as follows. As the singlet energy level of **VII** lies below that of the primary aromatic amine, it is quite logical that the observed quenching rate constant K_1 may be composed of two rate constant: viz. (i) for strong hydrogen bond formation by which CT state is produced which may be somewhere below the S_1 state of aromatic amines, and internal conversion (IC) rate from this CT state to the ground state of aromatic amines may be enhanced due to lowering of energy gap between these two states (CT and ground state); (ii) for intermolecular energy transfer from singlet of aromatic amine to singlet of electron acceptor **VII**.

The fluorescence spectral shifts of aniline (**III**), *p*-toluidine (**IV**), *m*-toluidine (**V**), and *N*,*N*-dimethyl-aniline (**VI**) on interaction with **VII** are given in Table 1. It may be noted that in the case of aniline no spectral shift occurs, but the following decreased order of band shift takes place with the other amines: **VI**>**V**>**IV**. This trend is rather expected because the electron density on the nitrogen atom of the substituted anilines have increased by the electron releasing methyl group attached to the nitrogen atom itself or to the aromatic ring. The ionization potentials (I_P) (Table 1) of these compounds (**VI**>**V**>**III**) also clearly indicate that hydrogen bonding of **VII** will occur most easily with **VI** and least readily with **III**. The considerable blue shift of **IV**, **V**, and **VI** in the excited state (Table 1) can be related to the more basic character of these amines in the excited state. This can

be appreciated by taking into consideration the I_P of these molecules in the excited state (Table 1). It may also be noted in Table 2 that $K_e \gg K_g$ which indicates stronger proton acceptor ability (that is more basic character) of the molecules in their electronically excited state. The fluorescence quenching observed in the present study may be interpreted as due to the charge-transfer interaction via hydrogen bonding and seems to be followed by a very rapid nonradiative vibronic interaction process.

Another significant observation is that for certain proton acceptor molecules (**III** to **V**) quenching reaction appears as positive curvature in Stern-Volmer plots at high quencher concentrations.[27-29] Deviations from the Stern-Volmer equation in certain quenching reaction may be explained by a compound formation. In fact it has been observed that proton donor **VII** from Schiff's bases with aniline of the types **VIII** and **IX** at higher concentration of aniline at an elevated temperature.[30]

A Molecular Orbital Study of the Electronic Structure of Some 6-Substituted Uracils

Paul George Abdul-Ahad and Graham Alan Webb†,*
Scientific Research Council, Petroleum Research Center, P.O. Box 10039, Baghdad, Iraq
†Department of Chemistry, University of Surrey, Guildford, Surrey, U.K.
(Received March 19, 1986)

Semiempirical molecular orbital calculations are performed on a series of 28 6-[2-(substituted phenyl)-hydrazino]uracils. Approximate ground state electronic properties are obtained for each molecule studied as well as the electrostatic potentials. First and second order interaction energies are calculated for some selected point charges in the vicinity of the parent molecule. The best correlations obtained between the biological activity and the electronic and steric indicies are considered in a mechanistic context.

A number of 6-substituted uracils are reported to be potent inhibitors of *E. coli* thymidine phosphorylase.[1] Some of the 6-[2-(substituted phenyl)hydrazino]uracils are found to inhibit the replication of the specific enzyme DNA polymerase III of *Bacillus subtilis* by forming strong reversible complexes with the template primer DNA and the enzyme. *Bacillus subtilis* has three DNA polymerases. Of these polymerase I is involved in DNA repair, while polymerase III is necessary for DNA replication.[2]

The activity of the 6-(2-Phenylhydrazino)uracils indicates that most of the enzyme-inhibitor binding energy results from an interaction of the enzyme with the phenyl ring.[3] The phenyl ring-enzyme binding may involve van der Waals or possibly charge-transfer interactions with the amino acid. The mechanism of complex formation appears to involve hydrogen bonding of the uracil and its NH moiety with cytosine in the DNA template and binding of the phenyl group with a hydrophobic site on the enzyme.[4]

a) pK_{50} is the negative logarithm of the molar concentration required to achieve 50% inhibition of enzyme activity.

The rotation of the phenyl N and hydrazino N-N bons are the basis for the formation of an active inhibitory conformation of the drug molecules. With a view to clarifying some of these assumptions the present work employs semiempirical molecular orbital (MO) methods in an attempt to interpret the mechanism of the action of 6-substituted uracils.

Method

The atom numbering scheme used in the present study is given in Structure I. The series of 28 6-[2-(substituted phenyl)hydrazino]uracils presently considered are given in Table 1 together with their calculated MO indices and observed activity data.[4] They are potent inhibitors of *Bacillus subtilis* DNA polymerase III. The inhibitory activities have been reported elsewhere[4] and are expressed as pK_{50}, which is the negative logarithm of the molar concentration required to achieve 50% inhibition of enzyme activity. Inactive compounds are excluded from the present study.

Two possible rotations about the phenyl N and N-N bonds are expected in the formation of an active inhibitory conformation of the drug molecule. The starting point geometry is obtained from reference.[5] This geometry is optimized using the program "GEOMIN" (QCPE 312), with the CNDO/2 option, to obtain a more reliable estimate of conformation in solution. Standard bond lengths and bond angles[6] are used for the substituent groups in the phenyl ring. The optimized bond lengths and angles are reported in Table 2.

The electrostatic potential (e.p.) of the drug molecule is calculated from the CNDO/2 wave functions using method III of reference,[7] in which monocentric differential overlap is retained. To assist in determining the most favorable binding position in the vicinity of the substrate an in-plane electrostatic contour map is plotted for the 6-(2-Phenylhydrazine)-uracils and given in Fig. 1. The lower the e.p. at a given position, the more energetically favorable is the placement of an electropositive reagent group at that position. The map is obtained using the simple plot program package of the University of Manchester.

First the second order interaction energies with each of five hypothetical point charges, placed at different positions in the molecular plane, are calculated. Positions P_1 and P_2 are chosen to coincide with the e.p. minima at -130 and -124 kcal mol^{-1} in the vicinity of O_7 and O_8, respectively, of the pyrimidine ring as shown in Fig. 1. P_3, P_4, and P_5 are positions which would be occupied by the O_2, N_3, and N_4-H atoms of a receptor cytosine group, assuming that these atoms become linked by hydrogen bonds to

N_{12}–H_{13}, N_1–H_{10}, and O_7, respectively, of the substrate. These hypothetical hydrogen bonds between substrate and pyrimidine template are shown in Fig. 1 of Ref. 4.

The first order interaction energy, with a point charge of unit magnitude, is simply the electrostatic potential. The second order interaction energy is calculated using uncoupled Hartree-Fock perturbation theory, with retention of monocentric differential overlap.[8]

Experimental

The calculations are performed on the CDC 7600 computer of the University of Manchester, using the "CNDO/2-3R" MO program (QCPE 261). The conformational analyses were performed on an ICL 2903 computer of the Iraqi Science Research Council.

The CNDO/2 wavefunctions are used to calculate all electronic reactivity indices. As well as the first and second order interaction energies, various simple indices are calculated. These may be calculated with a single atomic center, a pair of centers, or the whole molecule.

The first category is represented by the energy of binding of atom A to the rest of the molecule, $E_A^{BIND}=\sum_{B\neq A} E_{A-B}$, where E_{A-B} is the bond energy between centers A and B, calculated using the energy breakdown procedure.[9] E_{A-B} itself is used as an index of bond strength, this being a representative of the second category mentioned above.

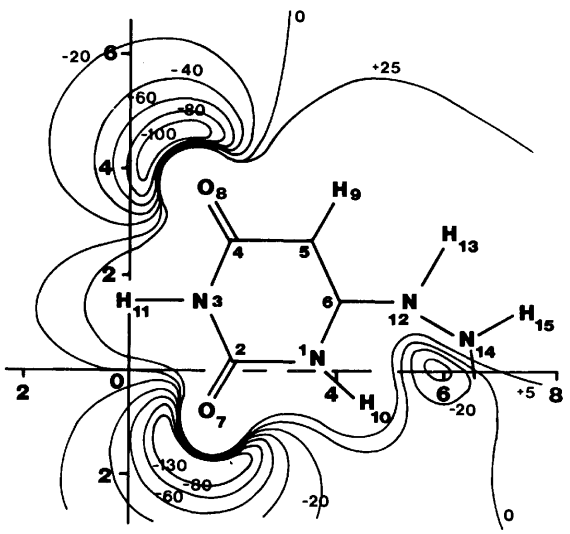

Fig. 1. The CNDO/2 e.p. contour map for 6-(2-phenylhydrazino)uracils (all values are in kcal mol^{-1}).

The following properties of the molecule as a whole are used as indices. The binding energy, B.E. defined as the difference between the CNDO/2 total energy of the molecule and the summed valance electronic energies of the isolated component atoms; the molecular volume, m.v., calculated by numerical integration of the solid produced by centering a sphere of the appropriate van der Waals radius[10] on each atomic center in the molecule. In calculating m.v., a rectangular solid is defined such that all of its faces touch the molecular profile. The solid is segmented into cubes of side 0.1 Å. It is then determined which of these cubes lie within the molecular profile, and a simple counting procedure is used to obtain the molecular volume.

Results and Discussion

The electronic and molecular indices relevant to the best regressions are given in Table 1. The most significant relationships, given in Table 3, have been obtained by searching the regression of inhibitive potency on each single and all pair contributions for eight parameters. The likelihood of random correlation increases with the number of regressions searched, therefore, caution is exercised in the interpretation of the statistical parameters.[11]

The positive coefficient associated with B.E. in regression (1), indicates that the less stable the molecule the higher the drug activity. The negative coefficient of the m.v. indicates that as the molecular size increase, it becomes less active. Since B.E. and m.v. have a substantial negative intercorrelation, it is difficult to decide which, if either, of these is a causal quantity.

The two-variable regressions (3) and (4) each contain an electronic index, as well as a size index. The appearance of the electronic properties of C_{17} tends to confirm the importance of the electronic structure of the phenyl ring. It is possible that there may be a receptor fragment located in this vicinity, in

Table 3. The Best Simple and Two-Variable Regressions Obtained for 6-(2-Phenylhydrazino)uracils

No.	Best simple regressions				No.	Best two variable regressions			
	pK_{50}[a] =	r[b]	s[c]	p[d]/%		pK_{50}[a] =	r[b]	s[c]	p[d]/%
1	0.022(±0.004)B.E. +14.48(±2.01)	0.672	0.85	99.9	3	0.233(±0.05)$E_{C_{17}}^{BIND}$ −0.0541(±0.009)m.v. +39.1(±5.9)	0.807	0.69	>99.9
2	−0.048(±0.01)m.v. +15.41(±2.4)	0.641	0.88	99.9	4	0.190(±0.05)$E_{C_{17}}^{BIND}$ +0.023(±0.004)B.E. +32.95(±5.8)	0.785	0.72	>99.9

a) Negative logarithm of the molar concentration required to achieve 50% inhibition of enzyme activity. b) Correlation coefficient. c) Standard error of estimate. d) Statistical significance determined from an F test.

the drug receptor complex. The positive coefficient associated with $E_{C_{17}}^{BIND}$ which is the only one of the calculated binding energies to enter the regressions, indicates that the more reactive this position the higher the drug activity. It appears that none of the first and second order interaction energies, for the chosen points in the molecular environment, show statistically significant correlations with pK_{50}. Consequently doubt is cast on the possible role of these energies in determining possible receptor binding sites at the chosen positions. Perhaps the electronic structure of the phenyl ring is critical in determining the biological activity of the 6-(2-phenylhydrazino)-uracils studied.

We conclude that, in order to design a more potent compound, with the same basic structure, it is apparently necessary to reduce the substituted molecular size as much as possible, whilst maximizing the reactivity of C_{17}.

Some Properties of Iron(III) Selenite and Its Applications for the Determination of Thorium

Pritam Singh THIND and Jatinder Singh GANDHI*
Department of Chemistry, Guru Nanak Dev University, Amritsar 143 005, India
(Received July 15, 1985)

A new inorganic ion exchanger, iron(III) selenite has been synthesized having an Fe:Se ratio of 2:3 and cation exchange capacity of 0.40 meq g^{-1}. It is fairly stable in water and dilute solutions of acids, bases, and salts. Ion distribution studies on twenty one metal ions have been done in water. Iron(III) selenite granules in H^+-form have also been used as indicators in the determination of thorium in presence of some rare earth cations using hexacyanoferrate(II) as titrant. On the basis of chemical analysis, pH titrations, thermal and infrared analyses the following scheme for the decomposition of iron(III) selenite has been proposed:

$$2Fe_2O_3\cdot 3H_2SeO_3\cdot 2H_2O \xrightarrow{140\,^\circ C} 2Fe_2O_3\cdot 3H_2SeO_3 \xrightarrow{500\,^\circ C} 2Fe_2O_3 .$$

The analytical importance of synthetic inorganic ion exchangers is now firmly established due to their high selectivity, thermal stability and resistance to radiations. There are, however, two fundamental problems which still lack a solution: The ion exchangers, unless crystalline, do not have reproducible properties and they are not chemically stable. It was found that phosphate,[1] arsenate,[2] antimonate,[3] tungstate,[4] and molybdate[5] of iron(III) show interesting properties. Selenites of zirconium,[6] tin,[7] and titanium[8] have been synthesized and used for various separations. A search of literature showed that no such studies have so far been reported on iron(III) selenite. Therefore, a new inorganic ion exchanger, iron(III) selenite has been investigated. The present work describes the synthesis, ion-exchange properties, and analytical applications of iron(III) selenite.

Experimental

Reagents. Sodium selenite (Loba Chemie) and iron(III) nitrate (BDH) were used for the synthesis. All other chemicals used were of AnalaR grade.

Potassium hexacyanoferrate(II): Standard solution of potassium hexacyanoferrate(II) solution (0.025 M)† was prepared by exact weighing and 1.0 g of sodium carbonate was added per liter.

Nitrates of thorium and other metal ions standardized with EDTA were used.

Synthesis of Iron(III) Selenite. The conditions of synthesis are given in Table 1. The iron(III) nitrate solution (0.05 M) was added to a solution of sodium selenite (0.05 M) with constant stirring. The pH of the mother liquor was adjusted to 1.5 (Table 1) by adding either 0.1 M HNO_3 or 0.1 M NaOH. The precipitate so obtained was heated at 60 °C for half an hour and it was allowed to settle for 24 h. Then it was filtered and washed with distilled water till free from nitrate ion. It was heat-treated at 40 °C, converted to H^+-form using 0.1 M HNO_3 and finally washed with demineralized water to remove excess of the acid. Finally it was heat-treated at 40 °C in an electric oven.

Analysis of Metals. Analysis of iron(III) has been done volumetrically using iodometric technique[9] and selenium has been precipitated as selenium metal[10] by passing sulfur dioxide through acidic solution of the material. The red selenium metal separates out. It is then filtered and weighed after heat-treating at 120 °C in an oven to constant weight.

The various cations used for the distribution coefficients determination have been determined by volumetric methods using metal indicators such as Eriochrome Black-T, Xylenol Orange, and PAN and titrating them against standard EDTA solution.

Table 1. Conditions of Synthesis and Properties of Iron(III) Selenites (H^+-form)

VII	0.10 : 0.10	1 : 2	Brown	0.40

† 1 M=1 mol dm^{-3}.

Instrumentation. The solubility of the meterial has been determined colorimetrically using spectrophoto-colorimeter (DDR). The pH of the solutions during potentiometric titrations was measured using a Toshniwal pH meter (CL-46, India). X-Ray diffractograms were obtained by using a PW 1720 X-ray generator with a Debye-Scherrer camera. Infrared studies were made using a Pye Unicam, SP 300 Philips (England) spectrophotometer.

Adsorption Studies. Adsorption studies were carried out by keeping cation solution in contact with the exchanger. Two hundred mg of the exchanger is added in each container containing cation solution and the volume is made to 20 ml by using the demineralized water. After 24 h cation solution is separated from the exchanger and cation is estimated using standard EDTA solution.

Chemical Composition. One hundred mg of iron(III) selenite sample was dissolved in 10 ml of hydrochloric acid. Iron was determined volumetrically[9] while selenium was determined by reducing it to red metal with sulfur dioxide.[10]

Ion-Exchange Capacity. The ion exchange capacity of the different samples of iron(III) selenite was determined by the column method. One g sample of the exchanger in the H^+-form was placed in the column with glass wool support. Alkali or alkaline earth metal nitrate solution (1.0 M) was used as the eluent. The effluent collected in each case, at the rate of 5—10 drops per min, was about 400 ml. The H^+-ions thus eluted from the column were titrimetrically determined against a 0.1 M standard solution of sodium hydroxide.

Distribution Coefficients. Distribution coefficients (K_d) for some inorganic ions have been determined in water. The K_d values were calculated using the equation

$$K_d = \frac{C_0 - C}{C} \cdot \frac{L}{m} (\text{ml g}^{-1}) ,$$

where C_0 and C are initial and residual concentrations of metal ion solution respectively. L is a solution volume (ml) and m is the amount of ion-exchanger sample taken (g). The cation solution was kept in contact with the exchanger for 24 h.

Effect of Temperature on Ion Exchange Capacity. Sample II in the H^+-form was dried at different temperatures in a muffle furnace for 2 h and the ion exchange capacity for Na^+ (1.0 M) was determined by the column method.

Chemical Stability. Fifty mg of the sample II was shaken with 20 ml of different solvents for 24 h. The supernatant liquid was analysed colorimetrically for selenium[11] and iron.[12]

Potentiometric Titrations. The pH titrations of iron(III) selenite sample II were performed using 0.1 M standard solution of different bases like lithium, sodium, and potassium hydroxide by the method of Topp and Pepper.[13] Five hundred mg of the exchanger was added in each flask and the total volume of the solution was made 50 ml (MOH+MCl).

X-Ray Studies. X-Ray diffraction studies were made on iron(III) selenite by the powder method. The powdered sample was filled in a quartz capillary of 0.5 mm diameter. It was then exposed to X-rays for few hours and its pattern was recorded.

Thermal Analysis and Infrared Studies. Thermal studies were performed on a Paulik Erdey MCM derivatograph (Hungary). The infrared spectra of iron(III) selenite (H^+-form) were obtained in KBr pellet.

Determination of Thorium. To the thorium nitrate solution (3 to 12 mg as thorium) were added 5 ml of 0.1 M HNO_3 so that the pH of the solution becomes 2—3. To this 3—4 granules (<0.1 mg) of iron(III) selenite in H^+-form were added and the titration was conducted by adding potassium hexacyanoferrate(II) (0.025 M) dropwise with vigorous shaking till the granules turn blue in color.

Results and Discussion

The results of the study of synthesis and ion exchange capacity of different samples of iron(III) selenite in H^+-form are presented in Table 1. These results show that ion-exchange capacity is independent of the concentration of reactants. Out of the seven samples prepared, one prepared by mixing 0.05 M solution of iron(III) nitrate and sodium selenite in the volume ratio of 1:2 at pH 1.5 (Table 1) was found to be quite chemically stable and having reasonable ion-exchange capacity. Therefore sample II was selected for detailed studies. Five batches of sample II were prepared under similar conditions and the material was found to be reproducible. A typical analysis for the product heat-treated at 40 °C shows 43% Fe_2O_3, 44.9% SeO_2, and 12.1% H_2O, indicating an empirical fomula $2Fe_2O_3 \cdot 3H_2SeO_3 \cdot 5H_2O$, $2Fe_2O_3 \cdot 3SeO_2 \cdot 5H_2O$. The distribution coefficients of Ce^{3+}, Ba^{2+}, Sr^{2+}, and Pb^{2+} were determined with each sample so as to check its reproducibility.

In order to determine the working capacity of

Table 2. Ion-Exchange Capacity of Iron(III) Selenite (Sample II) for Some Uni- and Bivalent Cations

Metal ion	Salt solution used	Concentration of salt/M	Ion-exchange capacity/meq g^{-1}	Hybrated ionic radii/Å
Li^+	$LiNO_3$	1.0	0.32	3.40
Na^+	$NaNO_3$	1.0	0.32	2.76
K^+	KNO_3	1.0	0.42	2.32
Mg^{2+}	$Mg(NO_3)_2$	0.5	0.25	7.00
Ca^{2+}	$Ca(NO_3)_2$	0.5	0.27	6.30
Sr^{2+}	$Sr(NO_3)_2$	0.5	0.29	—
Ba^{2+}	$Ba(NO_3)_2$	0.5	0.40	5.90

iron(III) selenite (H^+-form) as an ion-exchanger, the ion exchange capacity for sample II was determined for some uni- and bivalent cations (Table 2). The order of exchange capacities for alkali and alkaline earth metal ions respectively is: $K^+>Na^+=Li^+$ and $Ba^{2+}>Sr^{2+}>Ca^{2+}>Mg^{2+}$. These results suggest that the ion exchange capacity decreases from 0.42 to 0.32 and 0.40 to 0.25 meq g^{-1} on going from K^+ to Li^+ and Ba^{2+} to Mg^{2+} respectively. On the basis of the radii of the hydrated ions one would expect the same order.

The analytical significance of iron(III) selenite (H^+-form) can be evaluated from the results of K_d values given in Table 3. These results show that this material has high selectivity to Pb^{2+} in water. This makes it possible to separate Pb^{2+} from a large number of other cations. Sample II was heat-treated at different temperatures for 2 h and the ion exchange capacity for Na^+ was determined (Table 4). These results indicate that as temperature is raised from 40 to 200 °C, a slow decrease in ion exchange capacity is observed. On further raising the temperature there is abrupt decrease in the exchange capacity due to loss of selenium. The results of chemical stability of iron(III) selenite in H^+-form showed that the material was considerably stable in water, acids, bases, and organic solvents (Table 5).

The pH-titration curves of lithium, sodium, and potassium hydroxide for air-dried iron(III) selenite in H^+-form (Fig. 1) show two plateaux each one at pH 7 and the other at pH 9. This bifunctional behavior is similar to both crystalline zirconium phosphate[14] and arsenate[15,16] which also exhibit two pH titration plateaux. All the three curves are very much similar. The initial cation exchange selectivity sequence was $Na^+>K^+>Li^+$. At the first pH plateau, the selectivity was $Na^+>Li^+>K^+$. As exchange progressed the position of Li^+ shifted to give the sequence $Li^+>Na^+>K^+$. The exchange capacity for K^+ changes on heat treatment and it is reduced to about half when heated to 300 °C. When iron(III) selenite in H^+-form is treated at 500 °C to constant weight, the cation exchange capacity is completely lost. The titration

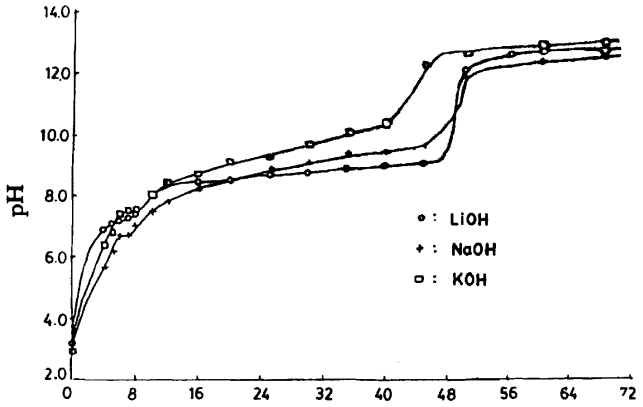
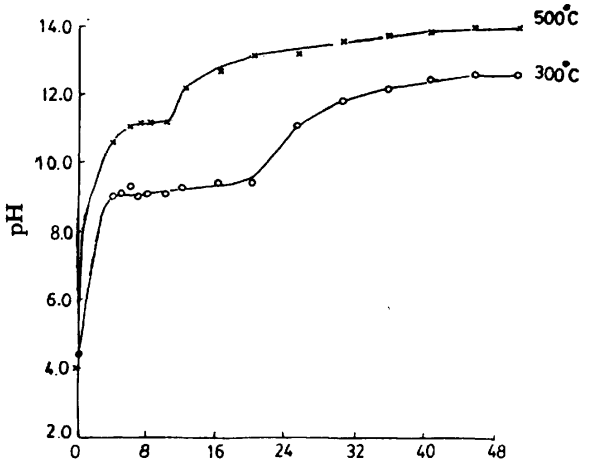
a) $Fe(OH)_3$ dried at 500 °C.



Vol. of 0.1 M standard base added (ml/0.5 g)

Fig. 1. pH-Titrations of iron(III) selenite (H^+-form).



Vol. of 0.1 M standard base added (ml/0.5 g)

Fig. 2. pH-Titrations of iron(III) selenite (H^+-form) heat-treated at different temperatures.

curves obtained for the materials dried at 300 and 500 °C give support to this observation. That is to say, of the most acidic exchange group, the titration curve of iron(III) selenite in H^+-form heat-treated at 300 °C shows a considerable decrease in cation-exchange capacity. At 500 °C, the inflection point originating from the most acidic hydrogen ions completely disappears (Fig. 2).

X-Ray powder diffraction pattern shows that as the drying temperature is increased to 40, 300, and 600 °C, a number of d lines appear. This clearly shows that the material is crystalline at 40 °C as well as at 500 °C.

The infrared studies of iron(III) selenite (Fig. 3) show five absorption peaks with maxima at 3360, 1625, 1390, 710, and 500 cm^{-1}. The band at 3360 cm^{-1} is due to OH stretch of interstitial water, and the band at 1625 cm^{-1} is due to its bending mode. The bands at 1390 and 710 cm^{-1} are due to Se–OH stretching vibrations. The stretching vibration of Fe–O appears at 500 cm^{-1}.

The DTA curve of iron(III) selenite in H^+-form (Fig. 4) shows that there are three endothermic effects (140, 470, and 500 °C). The first endothermic effect (at 140 °C) may be due to the loss of two molecules of water and this is confirmed by analysis and the thermogravimetric analysis. The second endothermic effect (at 470 °C) is accompanied by simultaneous loss of three molecules of water and selenium dioxide (SeO_2). The composition of the product after this endothermic effect at 500 °C corresponds to the formula Fe_2O_3. The infrared spectra show no bands corresponding to stretching or deformation vibration of –OH or $-OH_2$ groups or Se–O groups. A weak band at 3360 cm^{-1} is evidently due to the absorption of moisture on the specimen at the time of recording infrared spectrum. The infrared spectrum of iron(III) selenite dried at 500 °C is very much similar to the

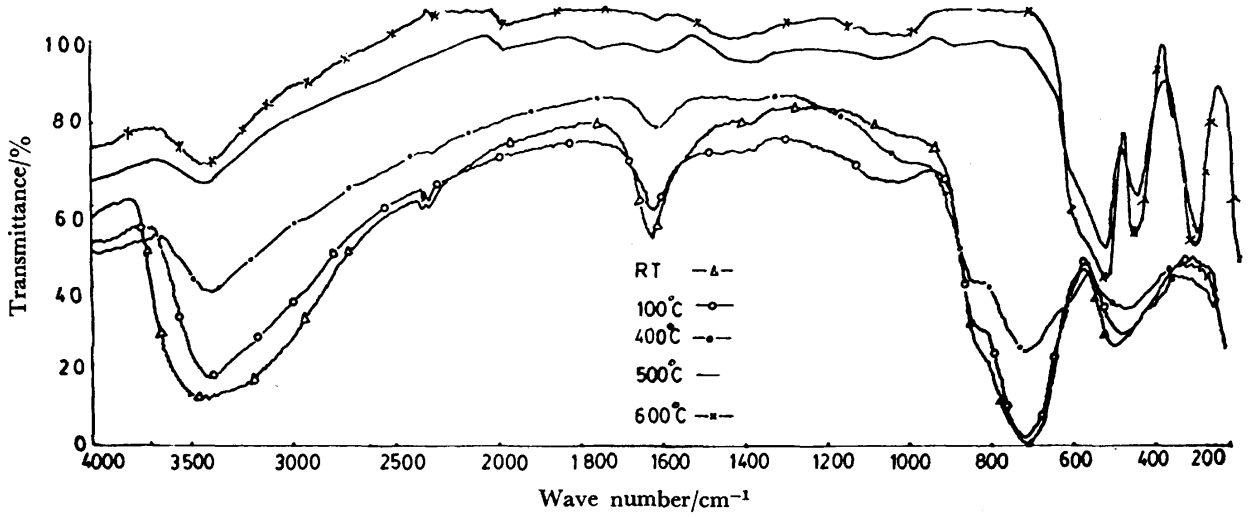


Fig. 3. Infrared spectra of iorn(III) selenite in H^+-form heated to different temperatures.

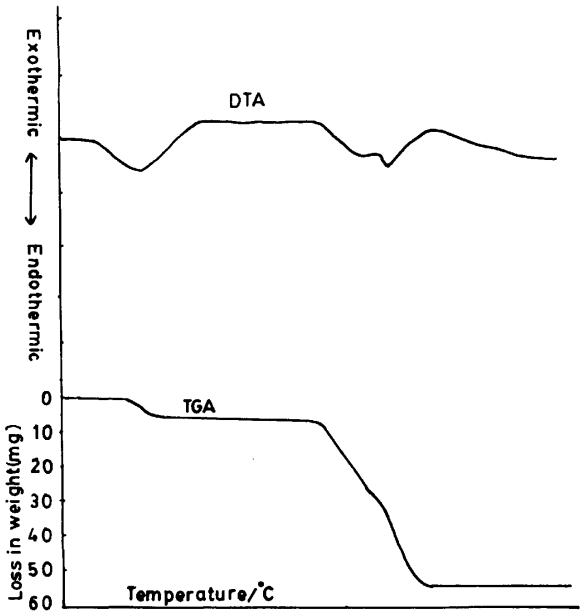

Fig. 4. Simultaneous TGA and DTA of 100 mg of iron-(III) selenite in H^+-form.
Heating rate : 6° min^{-1}.

spectra of iron(III) oxide at 500 °C, indicating that at this temperature the dominant species present is Fe_2O_3.

The following scheme was obtained for the decomposition of iron(III) selenite in H^+-form when it is heated under the conditions for recording DTA curve:

$$2Fe_2O_3 \cdot 3H_2SeO_3 \cdot 2H_2O \xrightarrow{140\,^\circ C} 2Fe_2O_3 \cdot 3H_2SeO_3 \xrightarrow{500\,^\circ C} 2Fe_2O_3$$

Iron(III) selenite granules in H^+-form can also be used as an indicator for the determination of thorium using hexacyanoferrate(II) as titrant. By proposed method 3.02 to 12.06 mg of thorium without and with rare earths can be determined within the conventional error (0.5—1%) for single observation. The amount of the rare earths added as impurities varies from 4.35 to 15.37 mg. This method is superior to other methods involving Th-EDTA. The method is based on the fact that when all the Th(IV) ions are precipitated as $ThFe(CN)_6$ a slight excess of hexacyanoferrate(II) gives a sharp color change to the granules from brown to blue due to the formation of Prussian Blue. As the rare earths used do not form insoluble ferrocyanides under these conditions, they do not interfere.

The method is particularly useful in dilute solution, where the precipitates are not so dense and the color change on the granules can easily be detected at the equivalence point. In more concentrated solutions, the granules are not visible through the thick precipitate, but the color on the solid phase can be seen by raising the beaker above eye level and viewing the granules at the bottom. The titrant solution should not come into direct contact with the indicator granules.

Spectrophotometric Determination of Palladium(II), Osmium(VIII), and Iridium(III) with 2-Methyl-1,4-naphthoquinone 4-Oxime

Kamini SHRAVAH and Sharwan Kumar SINDHWANI*
Department of Chemistry, University of Delhi, Delhi 110 007, India
(Received January 9, 1986)

2-Methyl-1,4-naphthoquinone monoxime (MNQM) forms yellow-colored 1:1 (M:L) complex with palladium(II) and brown-colored 1:2 complex with osmium(VIII) and iridium(III). The complexes are insoluble in water but soluble in 1-butanol. The reagent has been used for the spectrophotometric determination of Pd(II), Os(VIII), and Ir(III). The palladium, osmium, and iridium complexes have maximum absorption at 460, 460, and 450 nm respectively with the sensitivity of 0.012 μg Pd/cm², 0.025 μg Os/cm², and 0.014 μg Ir/cm² for log I_o/I=0.001. The optimum concentration ranges for the determination of Pd(II), Os(VIII), and Ir(III) are 1.58—10.47, 3.02—23.99, and 1.6—11.5 ppm over the pH range 6.5—7.8, 6.5—7.7, and 5.9—7.3 respectively. The determinations have also been carried out in the presence of foreign ions. MNQM reacts with palladium(II) or osmium(VIII) or iridium(III) to form yellow- or brown-colored precipitates which are extractable in 1-butanol. These systems have been studied spectrophotometrically to determine the composition and other physical constants of the complexes. The possibility of determining Pd(II) or Os(VIII) or Ir(III) in presence of diverse ions has also been investigated. Palladium(II) and osmium(VIII) have been successfully determined in synthetic solutions corresponding to the alloys.

Experimental

Reagents and Apparatus. 2-Methyl-1,4-naphthoquinone monoxime (MNQM) was prepared by the method of Veldstra and Wiardi.[1] A 1×10^{-2} M (1 M=1 mol dm^{-3}) solution of the reagent was prepared in ethanol (95%).

1-Butanol (AnalaR) was distilled before use. Buffer solutions were prepared by mixing 0.2 M sodium acetate and 0.2 M acetic acid in requisite proportions. For higher pH, sodium hydroxide was added. Buffer solutions of potassium hydrogen phthalate–sodium hydroxide were prepared from solutions of the corresponding chemicals of reagent grade in doubly distilled water.

Palladium(II) Solution. Standard solution of palladium(II) was prepared by dissolving palladium dichloride (Johnson-Matthey) in dilute hydrochloric acid. The solution was standardized gravimetrically by precipitation with dimethylglyoxime.

Osmium(VIII) Solution. A 1 g ampouls of osmium tetraoxide (Johnson-Matthey) was dissolved in about 100 ml of 0.2 M sodium hydroxide in a glass stoppered flask as described by Ayres and Wells,[2] which was further standardized by the method of Klobbie.[3] Working solutions were prepared by diluting this stock solution, whenever required.

Iridium(III) Solution. A stock solution of iridium was prepared by dissolving iridium(III) chloride (Johnson-Matthey) in doubly distilled water containing 1 M hydrochloric acid. The iridium solution was standardized gravimetrically by precipitating iridium as the hydrated oxide, followed by careful ignition in air and then reduction to the metal in presence of hydrogen and cooling in air atmosphere of carbon dioxide. Subsequent dilutions were made by diluting the stock solution and keeping the acidity at 1 M.

Reagent grade chemicals were used in the study of interferences. Doubly distilled water was used throughout the work.

A Unicam SP 600 spectrophotometer was used for measuring absorbance and an ECIL expanded scale pH meter pH 821A was used for pH measurements.

Absorption Spectra and Effect of pH. Palladium, osmium, and iridium complexes show the maximum absorption at 460, 460, and 450 nm respectively (Figs. 1a, b, and c). This wavelength was chosen for subsequent measurements. A plot of absorbance vs. pH shows that the absorbances remain constant in the pH range 6.5—7.8, 6.5—7.7, and 5.9—7.3 for Pd(II), Os(VIII), and Ir(III), respectively. In subsequent studies the pH of the solutions was adjusted to 7.0, 6.9, and 6.7 for palladium, osmium, and iridium, respectively.

Rate of Color Development and Stability of the Complexes. Complex formation takes place instantaneously after the addition of the reagent to the palladium(II) or osmium(VIII) solution. With iridium(III) it was observed that rate of color development is slow at room temperature, but is accelerated by heating on a water bath. Solutions containing a fixed amount of iridium(III), reagent and buffer was heated on a water bath for different intervals of time and absorbances were measured at 450 nm. Results of this study show that full color development takes place on heating the contents for about 2 h.

The Pd-MNQM, Os-MNQM, and Ir-MNQM complexes were found to be quite stable and absorbances were found to remain unchanged upto 24, 72, and 48 h, respectively after which a slow decrease in absorbance take place.

Effect of Reagent Concentration. A plot of absorbance vs. moles of ligand shows that at least 10, 60, and 30 times molar excess of the reagent is required for maximum complexation for palladium, osmium, and iridium, respectively. In subsequent studies 20, 70, and 40 times molar excess of the reagent was used for Pd, Os, and Ir, respectively.

Adherence to Beer's Law, Optimum Range and Sensitivity. Beer's law is obeyed upto 11.91, 29.48, and 13.7 ppm (1 ppm=1 μg cm^{-1}) and the optimum concentration ranges for accurate determination, as determined from Ringbom plot (Fig. 2), are 1.58—10.47, 3.02—23.99, and 1.6—11.5 ppm for palladium, osmium, and iridium, respectively. The sensitivity, in terms of Sandell's definition, is 0.012 μg Pd/cm², 0.025 μg Os/cm², and 0.014 μg Ir/cm² for log I_o/I= 0.001 with molar absorptivity 8.6×10^3, 7.6×10^3, and 1.26×10^4 l mol^{-1} cm^{-1}, respectively.

I: Pd(II)–MNQM complex.
II: Os(VIII)–MNQM complex.
III: Ir(III)–MNQM complex.

Recommended Procedure. Palladium and Osmium. A suitable aliquot containing 15.8—104.7 μg of palladium(II) or 30.2—239.9 μg of osmium(VIII) is taken and an excess of reagent in ethanol is added. pH is adjusted in the range 6.5—7.8 for palladium with potassium hydrogen phthalate-sodium hydroxide or 6.5—7.7 for osmium with sodium acetate-sodium hydroxide. The volume is made upto 10 ml with doubly distilled water. 10 ml of 1-butanol is added, the contents are shaken on a shaking machine and set aside for equilibration. The nonaqueous layer is separated, centrifuged to remove water droplets and the absorbance is measured against a reagent blank prepared under identical conditions. Knowing the absorbance, the amount of palladium is deduced from the calibration curve.

Iridium(III). To the solution containing 16—115 μg of iridium is added an excess of reagent and pH of the solution is adjusted in the range 5.9—7.3 with acetate buffer and dilute solution of sodium hydroxide. The total volume is made upto 10 ml with doubly distilled water. The contents are heated on a boiling water bath for about 2 h, then cooled to room temperature (30±5 °C) and extracted in 10 ml of 1-butanol. The mixture is shaken on a shaking machine and kept aside for equilibration. The nonaqueous layer is separated, centrifuged and the absorbance is measured at 450 nm. The iridium concentration is then deduced from the calibration curve.

Molar Composition of the Complexes. The composition of the complexes were determined by Job's method of continuous variations,[4,5] which shows that the stoichiometric ratio of metal to MNQM in the complex is 1:1 (Pd:MNQM) or 1:2 (Ir:MNQM) (Figs. 3a and b).

The ratio of osmium to MNQM was determined by logarithmic method of Bent and French,[6] which shows that molar ratio of metal to ligand in the complex is 1:2 (Fig. 3c).

Absorbance Deviations. Measured under optimum conditions, the solutions containing 5.32 ppm of Pd(II) gave absorbance readings with average relative deviation of ±0.46%. The standard deviation was found to be 0.003. 9.51 ppm of Os(VIII) gave an average relative deviation of ±0.44% with standard deviation of 0.0024. 6.4 ppm of iridium the standard deviation comes out to be 0.0024 with an average absorbance of 0.42.

Effect of Diverse Ions. The effect of diverse ions was studied in the determination of palladium, osmium, and iridium following the recommended procedure. The amounts (in ppm) of ions which do not cause any interference with 5.32 ppm of palladium, are given below in parentheses. Masking agents, wherever used, have been mentioned against each:

Chloride or citrate or tartrate (800), bromide or fluoride or

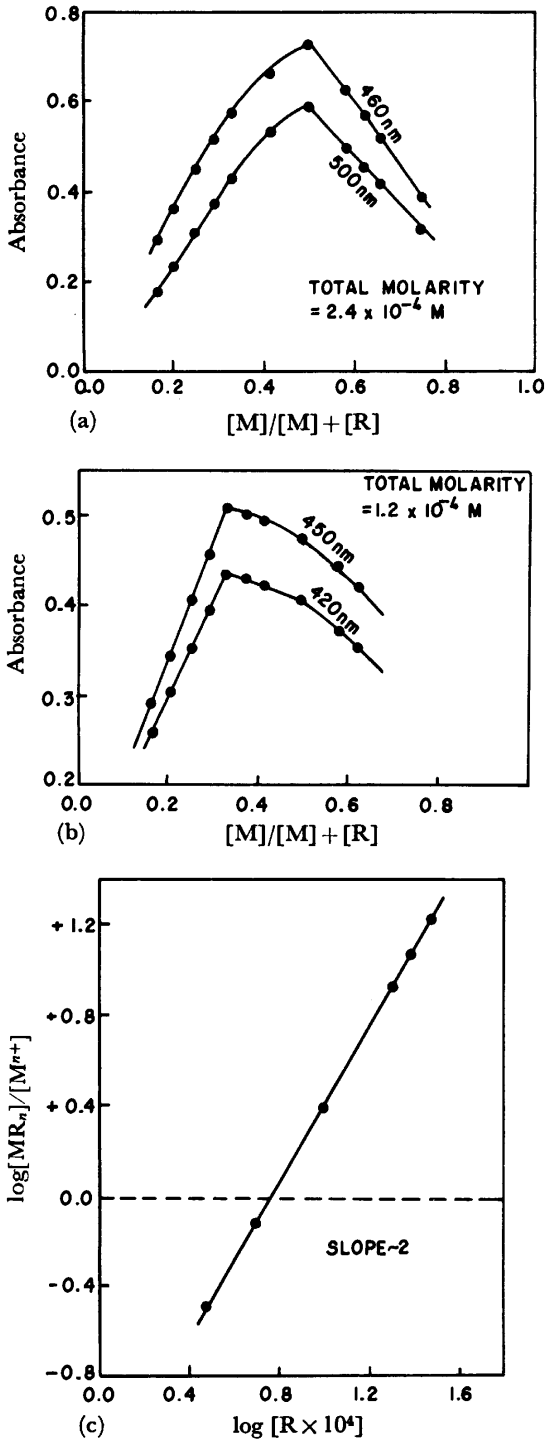

Fig. 3(a). Composition of Pd-MNQM complex by Job's method.
(b): Composition of Ir-MNQM complex by Job's method.
(c): Composition of Os-MNQM complex by Bent and French method.

nitrite (100), nitrate (1500), sulfate or oxalate or phosphate (2500), Ca(II) or Ba(II) or Sr(II) or Cd(II) or La(III) (200), Mg(II) or Ir(III) (20), Al(III) or Sn(II) or Th(IV) (100, F^-), Zn(II) or Hg(II) or Cu(II) or Mo(VI) or U(VI) or V(IV) or Zr(IV) or Li(I) or Y(III) or Pb(II) (100), Fe(II) or Ru(III) (10), Co(II) or Mn(II) (50), Ni(II) or As(III) (70), Cr(III) (50, tar), Ag(I) (70), Rh(III) (8), Pt(IV) (25).

For 9.51 ppm of osmium(VIII), the limits of tolerance are: chloride or bromide or fluoride (250), nitrate (150), nitrite or citrate or sulfide or borate (50), oxalate or thiocyanate (100), phosphate (300), sulfate or sulfite (400), Ca(II) or Hg(II) (100), Ba(II) or Sr(II) or Ni(II) (70), Mg(II) or V(IV) or Pb(II) (40), Al(III) (20, F^-), Mn(II) (10, F^-), Ag*(I) (30, Cl^-), Co(II) or As(III) or Pt(IV) (20), Fe(II) (30), Cu(II) or Ir(III) (10), U(VI) (100, PO_4^{3-}), Ru(III) or Rh(III) (20). Thiosulfate, iodide, and palladium(II) interfere in the determination.

For 6.4 ppm of iridium(III), the limits of tolerance are: chloride (450), bromide or iodide or sulfate or oxalate or tartrate or phosphate (500), nitrate (2500), nitrite or borate or thiocyanate (100), sulfite (1500), citrate (250), fluoride (1000), Ca(II) or Ba(II) (200), Sr(II) (150), Fe(II) or Zn(II) (10), As(III) (70), Mo(VI) (50), Sn(II) (10, F^-), Os(VIII) or Pd(II) (20) (extracted in cold), U(VI) (20, $C_2O_4^{2-}$), Hg(II) (5, I^-), Th(IV) (20, F^-), Cu(II) (5, SCN^-), Al(III) (50, F^-), Mg(II) (20), Ag*(I) (100, Cl^-), Co(II) or Ni(II) (50), Mn(II) (30), V(IV) (60), Pb(II) (80). Ru(III), Rh(III), and Pt(IV) interfere and attempts to mask these cations were unsuccessful.

Table 1. Determination of Pd(II) in Synthetic Solutions

Alloy	Pd present / ppm	Amount of foreign ion taken / ppm	Pd found / ppm	Error/%
1. Pd-Cu (40% Cu, 60% Pd)	6.0	4.0	6.02	+0.33
	6.0	4.0	6.01	+0.16
	6.0	4.0	6.02	+0.33
2. Pd-Ag (40% Ag, 60% Pd)	6.0	4.0	6.01	+0.16
	6.0	4.0	5.99	−0.16
	6.0	4.0	6.03	+0.5
3. Pd-Au (50% Au, 50% Pd)	6.0	6.0	6.0	0.00
	6.0	6.0	6.03	+0.5
	6.0	6.0	6.0	0.00
4. Pd-Ru (Jewellary alloy) (4.5% Ru, 95.5% Pd)	2.00	0.09	1.98	−1.0
	4.24	0.20	4.24	0.00
	3.00	0.14	3.01	+0.33

Determination of Palladium in Synthetic Solutions. To ascertain the selectivity of the reagent the method was successfully used for the determination of palladium in alloys. Synthetic solutions similar to those of the alloys of palladium were prepared and the amount determined following the recommended procedure. Results obtained are summarised in Table 1.

Determination of Osmium in Osmiridium. Osmiridium can be analyzed successfully after decomposition by attack with chlorine and dissolution of platinum metal salts in hydrochloric acid. No distillation is required unless the amounts of interfering elements are above the tolerance

* Removed by centrifugation.

limit. For a synthetic sample of osmiridium results obtained are shown in Table 2.

Discussion

Various chromogenic reagents used for the determination of palladium have been reviewed.[7,8] *N,N*-Dimethyl-*p*-nitrosoaniline[8,9] and *p*-nitrosodiphenylamine[9] have been extensively used for the spectrophotometric determination of palladium. The disadvantage is that both of them cannot be used in presence of large amount of natural salts such as sodium chloride and other platinum metals and several base metals interfere. MNQM is more selective than these methods. As compared to dimethylglyoxime.[8] MNQM is more selective and sensitive. Absorption maximum does not lie in the UV region as in the case of phenyl 2-pyridylketone oxime[10] (340 nm) and triphenylphosphine[11] (346 nm). Methylglyoxime and salicylaldehyde oxime[12] have also been used, but sensitivity of both is low. Palladiazo[13] is less selective than MNQM, since most of the base metals and noble metals interfere. Tropolone[14] method is sensitive but suffers from interference due to many metals. The sensitivity of 2-hydroxy-1-naphthaldehyde oxime[15] is also high but molybdenum(IV) and osmium(III) interfere seriously. The chief advantage of the present method is that palladium can be determined successfully in presence of other metals, especially eighth group metals and platinum metals except osmium.

Out of the several reagents suggested for spectrophotometric determination of osmium, thiourea[16] is one of the most useful and recommended reagent for osmium. Despite the lack of sensitivity, the chief disadvantage is that the quantity of thiourea required for a fixed amount of osmium depends on the volume of the solution. 1,5-Diphenylcarbohydrazide[17,18] is an extremely sensitive reagent for osmium, but the associated platinum metals and base metals (iron, cobalt, nickel, copper) interfere. The color development is dependent on temperature, time of standing in aqueous phase, the period of extraction of the complex into $CHCl_3$ and subsequent absorbance measurement, the concentration of perchloric acid

Table 2. Determination of Osmium(VIII) in Synthetic Mixture Corresponding to Osmiridium

Metals present/ppm				Os Found	Error/%
Os	Ir	Ru	Pt		
6.0	6.0	6.0	2.0	6.01	+0.16
4.0	4.0	4.0	1.0	4.02	+0.5
2.0	0.05	0.3	0.1	1.99	−0.5

Table 3. Sensitivities of Reagents for Pd, Os, and Ir

Reagent	Sensitivity μg Pd/cm²	Reagent	Sensitivity μg Os/cm²	Reagent	Sensitivity μg Ir/cm²
8-Quinolinethiol	0.024/272 nm 0.003/286 nm	1,5-Diphenyl-carbohydrazide	0.00127/560 nm	Leucocrystal violet	0.004/590 nm
N,N-Dimethyl-*p* nitrosoaniline	0.0015/510—525 nm	2-Aminophenol-4-sulfonic acid	0.1/440 nm	4,4′-Bi-*o*-anisidine	0.016/530 nm
Methylglyoxime	3.0/427 nm	Tiron	0.033/470 nm	*N,N*-Dimethyl-*p*-nitroso-aniline	0.010/530 nm
Palladiazo	0.0032/540 nm	7-Amino-1-naphthol-3,6-disulfonic acid	0.2/480 nm	Cerium(IV) sulfate sulfuric acid	0.12/510 nm
Acenaphthene-quinone monoxime	0.0084/385 nm	Acenaphthene-quinone monoxime	0.0323/430 nm	Acenaphthene-quinone monoxime	0.021/385 nm
2-Hydroxy-1-naphthaldehyde oxime	0.0097/402 nm				
2-Methyl-1,4-naphthoquinone 4-oxime (MNQM) (Present method)	0.012/460 nm	2-Methyl-1,4-naphthoquinone 4-oxime (Present method)	0.025/460 nm	2-Methyl-1,4-naphthoquinone 4-oxime (Present method)	0.014/450 nm

and even the order of addition of the reagents. In case of 7-amino-1-naphthol-3,6-disulfonic acid,[19] sensitivity is very low, though the other platinum metals do not interfere. In acenaphthenequinone monoxime[20] 90 min heating of solution is needed and sensitivity is also low. In phenanthrenequinone monosemicarbazone[21] sensitivity is low and 5 min of heating is required.

Very few satisfactory reagents are available for the spectrophotometric determination of iridium. In Leucocrystal Violet[22] method, Rh and Fe(III) interfere seriously and this method depends upon a specific composition of the dissolved iridium salt and aged iridium solutions give green solutions of lower absorbance than those which are freshly prepared. Tin bromide method[23,24] is not selective. This method is sensitive to certain variation in the procedure such as time of contact, temperature, quantity of reagent and hydrobromic acid. In 4,4′-bi-*o*-anisidine[25] method, there is interference from associated metals from oxidants and sulfuric acid solution cannot be used. The absorbance is sensitive to the amount of reagent and to the acidity of the medium. In *N*,*N*-dimethyl-*p*-nitrosoaniline method,[26] composition of the complex is not known and the method offers no specificity among platinum metals and there is interference from nonvolatile acids. The method is sensitive to changes in the conditions. In acenaphthenequinone monoxime method,[27] most of the platinum metals interefere and prior separation of iridium is necessary and sensitivity is also low.

The present method for the determination of Pd(II), Os(VIII), and Ir(III) using 2-methyl-1,4-naphthoquinone 4-oxime, involves simple technique. The method is selective and the complexes are stable for a long time. Effect of pH, buffer, heating time, amount of reagent do not have any effect on the absorbance. Most of the associated metals do not interfere. The sensitivities of the present method are promising and compare well with other known reagents in Table 3.

A Structural Model for Octacalcium Phosphate-Succinate Double Salt

Mathai MATHEW* and Walter Eric BROWN
Paffenbarger Research Center, American Dental Association Health Foundation,
National Bureau of Standards, Gaithersburg, MD 20899, U.S.A.
(Received January 20, 1986)

A new structural model for octacalcium hydrogenpentakis(phosphate) succinate pentahydrate, $Ca_8H(PO_4)_5(C_2H_4\cdot(COO)_2)\cdot 5H_2O$, a reaction product of octacalcium dihydrogenhexakis(phosphate) pentahydrate, $Ca_8H_2(PO_4)_6\cdot 5H_2O$, OCP, and succinate ions, is proposed on the basis of similarities in the unit cell dimensions and structures of OCP and calcium succinate trihydrate. This model can be used to develop information on the mode of incorporation of dicarboxylate ions into OCP and hydroxyapatite and its possible effects on biological mineralization processes.

Monma et al.[1,2] have recently made the discovery that saturated aliphatic dicarboxylic acids, $HOOC-(CH_2)_n-COOH$ with n=1 to 6, form a series of double salts with octacalcium dihydrogenhexakis(phosphate) pentahydrate, $Ca_8H_2(PO_4)_6\cdot 5H_2O$; generally referred to as octacalcium phosphate (OCP). They proposed that the double salts are formed by substitution of an HPO_4^{2-} group in OCP by a dicarboxylate ion, with the general formula, $Ca_8(HPO_4)_{2-z}(PO_4)_4\cdot(C_nH_{2n}C_2O_4)_z\cdot mH_2O$, and gave a possible structural model. We propose here a different model for the structure of one of these double salts, octacalcium hydrogenpentakis-(phosphate) succinate pentahydrate, $Ca_8H(PO_4)_5(C_2H_4\cdot(COO)_2)\cdot 5H_2O$, based on the observation that the non-primitive, B-centered cell of calcium succinate trihydrate has b and c dimensions and the angle γ which are very similar to those of OCP[3] and hydroxyapatite (OHAp), $Ca_5(PO_4)_3(OH)$ (Table 1). It was the similarities between the same dimensions of OCP and OHAp that revealed the structural relationship between these two salts which so profoundly affects their physical and chemical properties. At this time, very little is known about the properties of the double salts, but if they form as biominerals, they probably will prove to affect properties such as crystal growth and hydrolysis, morphology, Ca/P ratio and impurity content of hydrolysates.

The structural model for the OCP-dicarboxylate complexes proposed by Monma[2] is based on the structure of OCP[3] and the structures of the corresponding dicarboxylic acids. The model was conceived on the assumption that the [Ca-HPO_4-Ca] pillar in the hydrated layer of OCP (Fig. 1) is substituted by a [Ca-dicarboxylate-Ca] pillar. The [Ca-HPO_4-Ca] pillars implicated in their model are Ca(3)-P(5)'HPO_4-Ca(4)' and Ca(4)-P(5)HPO_4-Ca(3)' (Fig. 1). Based on the structure of OCP, P(5)HPO_4 would be the most likely candidate to be involved in the replacement. Since the projection of the Ca(3)-dicarboxylate-Ca(4) pillar onto the a-b plane is nearly parallel to the a axis, the increase in d_{100} of OCP-dicarboxylate would be proportional to the length of the dicarboxylate ion.

The model proposed by Monma has several drawbacks. The plane of the COO^- group is approximately parallel to the c-axis and the model requires two dicarboxylate ions to be nearly superimposed along the relatively short c-axis (6.88 Å). Furthermore, when the whole unit cell is taken into account, particularly in the a-b plane (001), it becomes obvious from their model that there would be a relatively large volume of empty space in the center of the cell. The increase of d_{100} (e.g. from 18.7 Å in OCP to 21.4 Å in OCP-succinate) would make the apparent volume of this empty space even larger. It is unlikely that this space could be occupied by water molecules or other ions because its major boundaries would be the hydrophobic part (methylene groups) of the dicarboxylate ions. This would be particularly true for the higher members of the series. However, this model may be possible in the case of dicarboxylic acids with additional functional groups (OH, NH_2, COOH) which are more compatible with ions and water molecules.

A New Model. Our model is based on the structure of calcium succinate trihydrate. The structure is reported[4] in the space group $P\bar{1}$ with a=7.937, b=9.450, c=6.688 Å, α=91.47, β=111.80, and γ=71.60°. The transformation matrix ($2\ 0\ \bar{1}/0\ \bar{1}\ 0/0\ 0\ \bar{1}$) converts this primitive cell to a B-centered cell with the dimensions listed in Table 1. The striking similarity of this cell to those of OCP and OHAp is immediately obvious. The cell dimensions b and c and all cell angles of the succinate and OCP are nearly identical.

Table 1. Comparison of Cell Dimensions in OCP, OHAp, and Calcium Succinate Trihydrate

	OCP	OHAp	Ca succinate trihydrate
a/Å	19.692	9.432	14.759
b/Å	9.523	9.432	9.450
c/Å	6.835	6.881	6.688
α/°	90.15	90.0	91.47
β/°	92.54	90.0	93.08
γ/°	108.65	120.0	109.14
Space group	$P\bar{1}$	$P6_3/m$	$B\bar{1}$

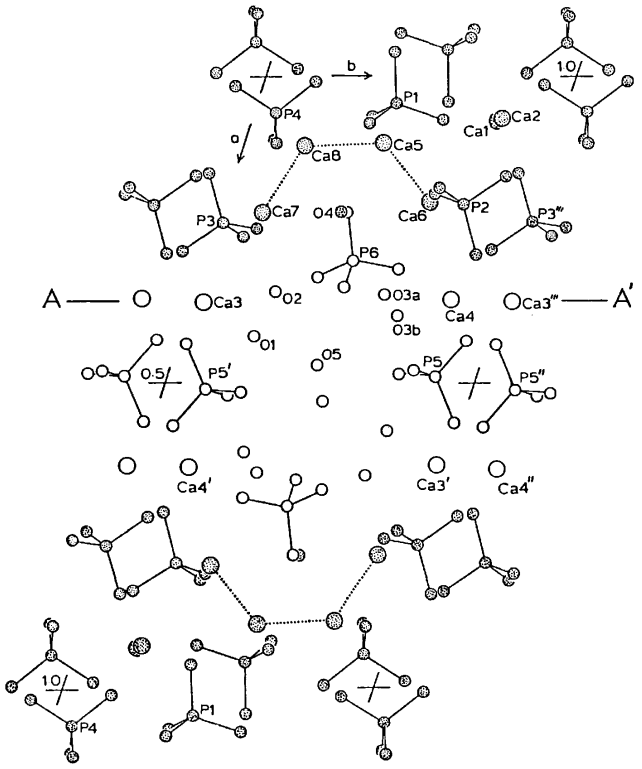

Fig. 1. Structure of OCP projected down the c* axis. The shaded portions correspond to the apatitic layer and the nonshaded atoms correspond to the hydrated layer. Atoms in the asymmetric unit are labelled. Symmetry codes for related atoms are ′ for $(1-x, 1-y, -z)$, ″ for $(1-x, 2-y, -z)$ and ‴ for $(x, 1+y, z)$.

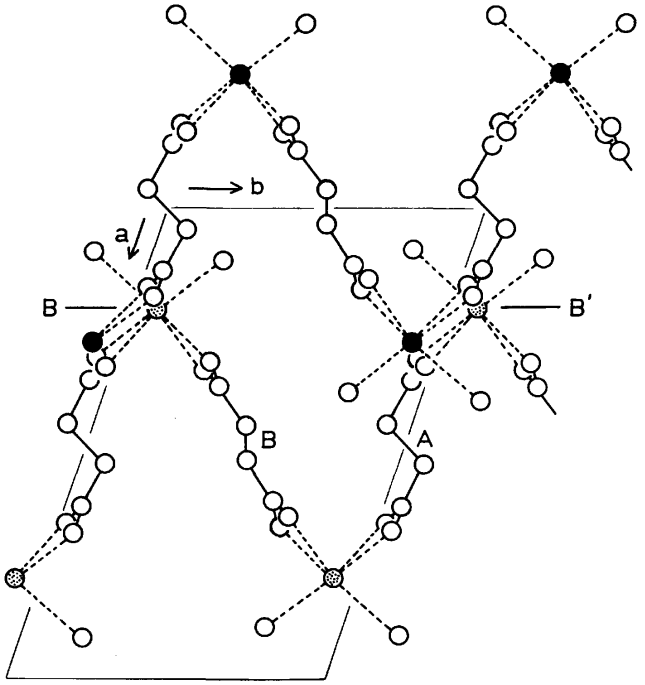

Fig. 2. Structure of calcium succinate trihydrate projected down the c* axis. The filled circles represent Ca atoms at $z=1/2$ and the shaded circles the Ca atoms at $z=0$.

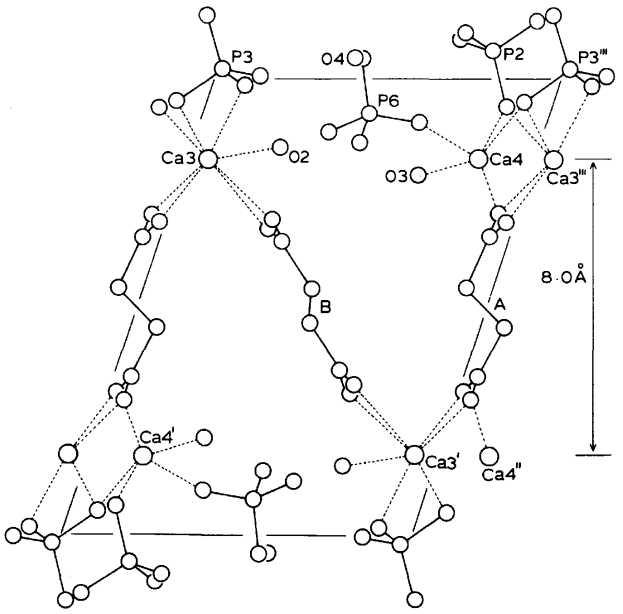

Fig. 3. The proposed model of OCP-succinate, viewed down the c* axis. Only the central portion of the OCP cell ($a=1/4$—$3/4$) showing the incorporated succinate ions is illustrated.

Comparison of the structures of OCP (Fig. 1) and calcium succinate trihydrate (Fig. 2) reveals some important structural similarities. The unit cell dimensions in the (100) planes of the two compounds are nearly the same. The relative positions of the Ca ions in a section of this plane through Ca(3)-Ca(3)‴ in OCP (A-A′ in Fig. 1) are nearly identical to those of a corresponding section, B-B′, in calcium succinate trihydrate (Fig. 2). This implies that epitaxial growth of calcium succinate on the (100) plane of OCP is possible, and that on a sub-unit cell level the OCP structure at A-A′ can be joined to the calcium succinate structure at B-B′ (Fig. 3). A feature of the structure of calcium succinate is that the succinate ions reside on crystallographic centers of symmetry and link pairs of equivalent Ca ions at the same height along c axis in a zigzag way. The succinate ions linking the Ca ions at $z=1/2$ are not on top of those linking the Ca ions at $z=0$, but related by $1/2a+1/2c$ (B-centering). This is to be expected on steric grounds.

The model we propose for the OCP-succinate complex takes into account the structural features of both OCP and calcium succinate trihydrate. Based on the structure of the calcium succinate, it is obvious that the succinate ion, which lies on a center of symmetry, can link only pairs of one type of Ca ion (either Ca(3) or Ca(4)) in the hydrated layer of OCP. On the basis of bond length calculations, Ca(3) appears to be a more probable candidate than Ca(4) for linking succinate ions in the OCP-succinate

complex. It is interesting to note that the position of Ca(3) in OCP corresponds very closely to that of a column calcium in OHAp whereas the Ca(4) position in OCP is shifted by about 1.9 Å along the b axis. Although the Ca(4)-Ca(4)″ (Fig. 1) linkage through a succinate ion is possible, an increase in d_{100} due to the incorporation of this succinate would make the Ca(4)···Ca(4)′ distance considerably longer than that which can be linked by the succinate ion unless there is a corresponding shift of Ca(4) along the b axis.

Our proposed structure contains two types of succinate ions. One succinate ion (A) links Ca(3)‴ and Ca(3)′ of OCP (Fig. 1) primarily along the a axis, thus causing a corresponding increase in d_{100}. In effect, this succinate ion replaces two HPO_4^{2-} ions of OCP. The second succinate ion (B) links Ca(3) and Ca(3)′, without affecting the d_{100} spacing. The succinate ion B is far removed from the HPO_4 ion sites of OCP and fills the void that would otherwise exist in the center of the unit cell.

The proposed model is illustrated in Fig. 3. Most of the structural features of OCP remain intact. The water molecules O(2), O(3), and O(4) in OCP would retain their respective positions in the complex; only O(1) and O(5) need to be relocated if the total amount of water content is to remain the same as in OCP as indicated by the molecular formula proposed by Monma.[2] The proposed structural model implies that at least one of these two water molecules is likely to be coordinated to Ca(4).

The [Ca-succinate-Ca] pillar length down c* in calcium succinate of 8.0 Å (Fig. 2) would make the d_{100} of the OCP-succinate complex 21.6 Å which is in reasonably good agreement with the experimental value[2] of 21.4 Å. Since the dicarboxylate ions are capable of adopting different conformations, the difference may not be significant.

In OCP, both Ca(3) and Ca(4) are coordinated to seven O atoms. In our proposed structure of OCP-succinate, four of these bonds remain intact. In the case of Ca(3), it loses three O neighbors (two from $P(5)HPO_4$ and one from water molecule O(1)), but gains four O from carboxylato groups. Thus the coordination of Ca(3) is 8. However, Ca(4) loses three O neighbors, all from $P(5)HPO_4$ groups, but appears to gain only one O from carboxylato group in succinate A. In calcium succinate, the Ca ion corresponding to Ca(4) is linked to two O atoms of the type A succinate ion, one above and one below the plane of Ca(4). The same configuration of Ca(4) may be achieved in OCP-succinate also, with minor shifts in the positions of Ca(4) and/or with succinate A.

Discussion

When it was first observed that OCP and OHAp had very similar unit-cell parameters *b*, *c*, and angle γ, it was proposed that the two compounds contain a structurally similar layer. This was subsequently established by the determination of the structure of OCP. Nearly identical unit-cell parameters, *b*, *c*, and angle γ, are present in the OCP-succinate salt and in calcium succinate trihydrate. Although this could be a coincidence, it is more likely that the OCP-succinate and the calcium succinate trihydrate contain a common layer which is compatible with the OCP structure. This hypothesis is substantiated by the presence of Ca(3) and Ca(4) in OCP which occupy positions similar to those in calcium succinate trihydrate. Furthermore, when the d_{100} of OCP, 18.7 Å, is increased to that of the OCP-succinate complex, 21.6 Å, the Ca(3)‴-Ca(3)′ and Ca(3)-Ca(3)′ distances (Fig. 1) become such that they can accept succinate bridge coordination similar to those found in calcium succinate trihydrate. We conclude, therefore, that the model proposed in Fig. 3 for OCP-succinate structure is probably a good approximation and that it can be used (i) to visualize the structure of the OCP-succinate complex and (ii) to develop mechanisms for the hydrolysis and growth of OCP-succinate crystals.

Calcium malonate has two crystalline forms, both dihydrates, whose structures are known.[5,6] However, we were not able to transform their unit cells to have *b*, *c*, and γ values compatible with OCP. Examinations of the structures did not reveal compatibilities such as those found in calcium succinate trihydrate. This does not, of course, preclude formation of an OCP-malonate complex detected by Monma,[2] but it suggests that despite the near constancy of the increase in d_{100} with increase in length of the aliphatic carbon chain, there may be substantial differences among the structures of the double salts. Another indication of this is the inability of the dicarboxylate ions with an odd number of carbon atoms to reside on a center of symmetry.

This investigation was supported in part by Grant DE 05030 to the American Dental Association Health Foundation by the National Institutes of Health-National Institute of Dental Research and is part of the Dental Research Program conducted by the National Bureau of Standards in cooperation with the American Dental Association Health Foundation.

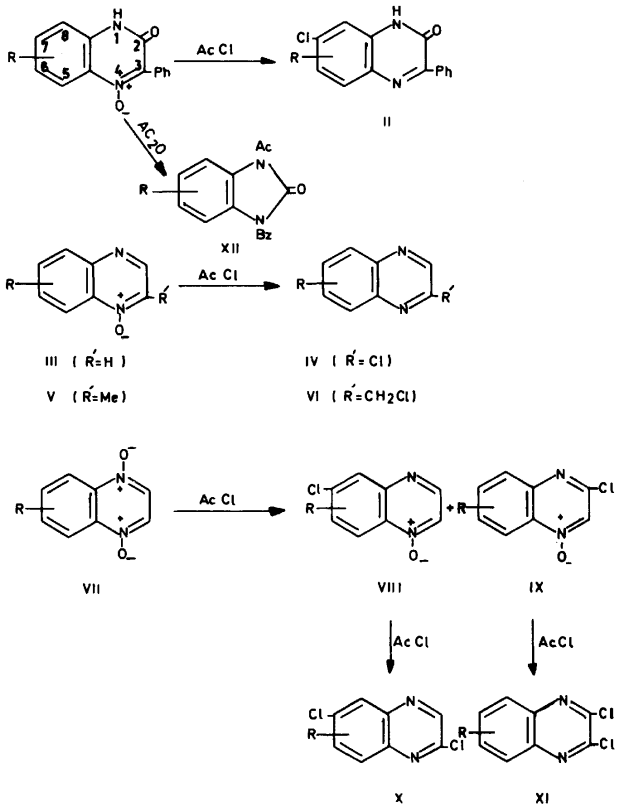
(Received December 10, 1985)

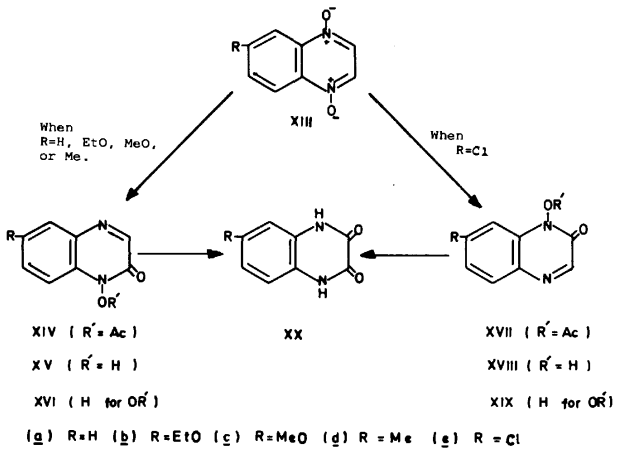
Quinoxaline 1,4-dioxide (**XIIIa**) with acetic anhydride gave 1-acetoxy-2(1*H*)-quinoxalinone (**XIVa**) which was prone to facile hydrolysis to yield 1-hydroxy-2(1*H*)-quinoxalinone (**XVa**). Both **XIVa** and **XVa** were isolated from the reaction mixture. On prolonged heating with acetic anhydride, **XIIIa**, **XIVa**, and **XVa** were converted slowly to the same end product, 2,3(1*H*,4*H*)-quinoxalinedione (**XXa**). 6-Ethoxy- (**XIIIb**), 6-methoxy- (**XIIIc**), and 6-methylquinoxaline 1,4-dioxide (**XIIId**) behaved similarly, except that the attack of the reagent took place exclusively on *N*-oxide para to the electron-donating substituents, and none of the other expected isomeric compounds **XVIIb—d** were isolated. Whereas 6-chloroquinoxaline 1,4-dioxide (**XIIIe**) bearing an electron-attracting chloro substituent on the benzene ring gave exclusively the other isomers **XVIIe**, **XVIIIe**, and **XXe**. A mechanism for this novel rearrangement is proposed and discussed.

We have reported[1] earlier that 2(1*H*)-quinoxalinone 4-oxides substituted at position 3, on heating under reflux with acetyl chloride, undergo nucleophilic chlorine substitution at C-7 position with simultaneous loss of the oxide function (**I**→**II**). In the absence of carbonyl function at C-2, the chlorine substitution primarily goes to the position adjacent to the *N*-oxide when it is unsubstituted (**III**→**IV**),[2] and in case there be a methyl group at C-3 it undergoes chlorine-substitution (**V**→**VI**);[2] both of these take place at the expense of the oxide function. In the case of 1,4-dioxides of quinoxalines (**VII**) the primary products[3] of the reactions with acetyl chloride were 6-chloroquinoxaline 1-oxides (**VIII**; 60—70%) and 3-chloroquinoxaline 1-oxide (**IX**; 30—40%). On prolonged heating these primary products gave 2,6- and 2,3-dichloroquinoxalines (**X** and **XI**), and all four products (**VIII** to **XI**) were isolated.[3] The presence of electron donating or withdrawing substituent on the benzene ring of the molecule is shown to control the direction of chlorine substitution through the attack of the reagent on one *N*-oxide in preference to the other.

It would be expected that the reaction of acetic anhydride will take place in a similar manner to that of acetyl chloride, resulting in acetoxylation instead of the chlorine nucleophilic substitution (**I**→**II**: AcO for Cl in the above reactions). In a previous paper[4] we have reported that 3-phenyl-2-(1*H*)-quinoxalinone 4-oxides (**I**) gave 1-acetyl-3-benzoyl-1*H*-benzimidazol-2(3*H*)-ones (**XII**) instead of the expected 7-acetoxy-3-phenyl-2(1*H*)-quinoxalinones (**III**; AcO for Cl).[4] However 1-methylated compound **I** gave the normal 7-acetoxy-1-methyl-3-phenyl-2(1*H*)-quinoxalinone[4] (**II**; Me for H and AcO for Cl). These observations prompted us to study the action of acetic anhydride on quinoxaline 1,4-dioxides.



First we reexamined the previous finding[5] that quinoxaline 1,4-dioxide (**XIIIa**), on heating with an excess of acetic anhydride, gave 1-acetoxy-2(1*H*)-quinoxalinone (**XIVa**) in a 30% yield. However the yield was much higher than that reported, and further we observed that **XIVa** was easily hydrolyzed to give 1-hydroxy-2(1*H*)-quinoxalinone (**XVa**) merely on leaving with water. On reduction both **XIVa** and **XVa** afforded 2(1*H*)-quinoxalinone (**XVIa**), which was identical with an authentic sample, establishing the structures of **XIVa** and **XVa**.



On prolonged heating of **XIIIa** with acetic anhydride, in addition of **XIVa** and **XVa**, a third product, 2,3(1*H*,4*H*)-quinoxalinedione (**XXa**), was also obtained. The amount of **XXa** progressively increased with prolonging the time of heating (9 h and then 16 h), while the amount of **XIVa** and **XVa** decreased, which obviously meant that **XIVa** and **XVa** were slowly converted to the same product **XXa**.

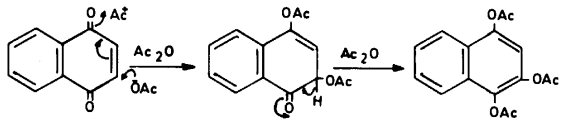
Similarly, 6-ethoxy (**XIIIb**), 6-methoxy (**XIIIc**), and 6-methylquinoxaline 1,4-dioxide (**XIIId**), on heating under reflux for 1 h with acetic anhydride, gave the corresponding 1-acetoxy (**XIVb—d**) and 1-hydroxy-6-substituted-2(1*H*)-quinoxalinone (**XVb—d**). The reduction of **XIVb—d** and **XVb—d** with sodium dithionite in aqueous ethanol gave 6-ethoxy-, 6-methoxy, and 6-methyl-2(1*H*)-quinoxalinones (**XVIb—d**), respectively, which were identical with authentic samples previously prepared and reported by us[6] or synthesized individually in this work (see Experimental). None of the other expected isomers (**XVIIb—d** and **XVIIIb—d**) were formed in these reactions.

On the other hand, the reaction of 6-chloroquinoxaline 1,4-dioxide (**XIIIe**) with acetic anhydride gave 1-acetoxy- and 1-hydroxy-7-chloro-2(1*H*)-quinoxlinone, both of which on reduction with sodium dithionite in aqueous ethanol gave 7-chloro-2(1*H*)-quinoxalinone (**XIXe**); identical with an authentic sample.[7] The other isomers **XIVe** were not formed in this case too. The results are summarized in the table in the experimental section.

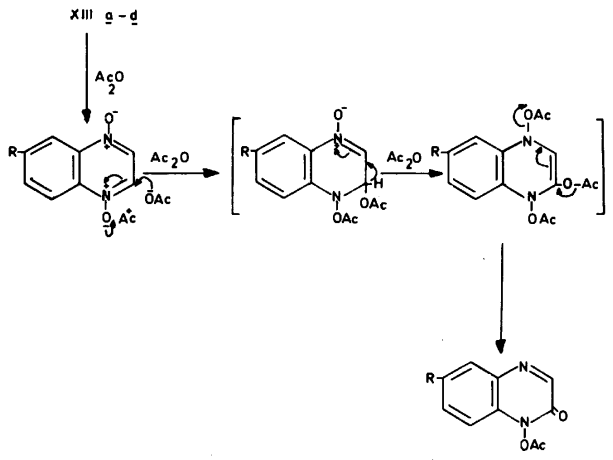
To explain the different behavior of quinoxaline 1,4-dioxides, we propose the following mechanism.

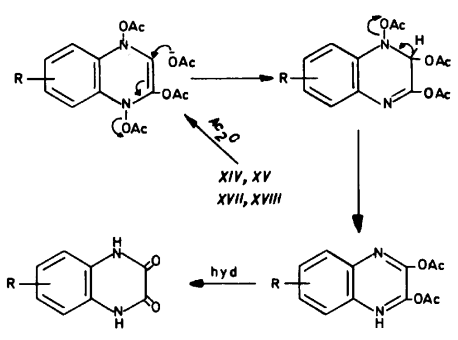
The electron-donating substituents (R) on the benzene ring increase the electron density at the oxygen atom of the *N*-oxide para to R, whereby the attack of Ac^+ takes place more favorably to this *N*-oxide than to the other *N*-oxide, resulting in the formation of 1-acetoxy-6-R-2(1*H*)-quinoxalinone as illustrated above. When R is an electron-withdrawing group (viz. chloro, as in **XIIIe**) the electron density is decreased at the oxygen atom of the *N*-oxide para to R, and the attack of Ac^+ therefore takes place to the other *N*-oxide, resulting in the formation of the other isomeric compound 1-acetoxy-7-chloro-2(1*H*)-quinoxalinone (**XVIIe**). The 1-hydroxy derivatives are formed by the facile hydrolysis of the acetoxy compounds.

The formation of the postulated triacetoxy intermediate (see above) has its analogy in the Thiel's reaction[8] of 1,4-naphthoquinone with acetic anhydride to give 1,2,4-triacetoxynaphthalene.



When the time of heating in the reaction of 1,4-dioxides (**XIIIa—e**) with acetic anhydride is prolonged from 1 to 9 h, a third product, the corresponding 2,3(1*H*,4*H*)-quinoxalinedione (**XXa—e**) is formed in addition to the acetoxy and hydroxy compounds, the quantities of which decrease accordingly. On further prolonging the time of heating, the quantities of 2,3(1*H*,4*H*)-quinoxalinediones gradually increase and those of the corresponding acetoxy and hydroxy derivatives decrease. It appears that the postulated triacetoxy intermediate further leads very slowly to the formation of the 2,3(1*H*,4*H*)-quinoxalinediones as shown below.





Experimental

Materials. Quinoxaline 1,4-dioxide (**XIIIa**), 6-ethoxyquinoxaline 1,4-dioxide (**XIIIb**), 6-methoxyquinoxaline 1,4-dioxide (**XIIIc**), 6-methylquinoxaline 1,4-dioxide (**XIIId**), and 6-chloroquinoxaline 1,4-dioxide (**XIIIe**) were prepared by the methods already reported.[9] Pet. ether means light petroleum; bp 60—80 °C. Identical structure means undepressed mixed melting point and superimposible IR spectra of the two compounds. All 1-hydroxy-2(1*H*)-quinoxalinones give blood red color on addition of aq iron(III) chloride to their ethanolic solutions (a characteristic of hydroxamic -N(OH)-CO- moiety in a molecule). The solutions were decolorized, whenever necessary, with activated charcoal.

Reaction of Quinoxaline 1,4-Dioxide (XIIIa) with Acetic Anhydride. Procedure A: A mixture of **XIIIa** (2 g) and acetic anhydride (20 ml) was heated under reflux for 1 h. The sticky brown residue, left after removal of acetic anhydride on a vacuum rotary evaporator, was exhaustively extracted with boiling pet. ether. The volume of pet. ether extract was reduced until the crystallization started, whereby small white needles of 1-acetoxy-2(1*H*)-quinoxalinone (**XIVa**); mp 110—111 °C (lit,[5] mp 110.5—111 °C) were obtained (yield 70%). To the residue which could not be extracted with pet. ether, a small amount of water was added and left overnight in a refrigerator. The solidified product, on recrystallization from ethanol gave reddish brown flakes of 1-hydroxy-2(1*H*)-quinoxalinone (**XVa**); mp 210—212 °C (lit,[5] mp 208—209 °C) in a 30% yield.

Both **XIVa** and **XVa**, on treatment with sodium dithionite in 50% aqueous ethanol, gave 2(1*H*)-quinoxalinone (**XVIa**); mp 272 °C (lit,[6] mp 270—272 °C), identical with an authentic sample.[6]

Procedure B: The time of heating was prolonged to 9 h **XIVa** and **XVa** were obtained in 60 and 25% yields, respectively. The extraction of pet. ether insoluble part with ethanol left a residue (13%). The crystallization of the residue from glacial acetic acid gave colorless needles of 2,3(1*H*,4*H*)-quinoxalinedione (**XXa**); mp >360 °C, identical with an authentic sample.[6] **XIVa** and **XVa** afforded three products **XIVa**, **XVa**, and **XXa** in each case when they were treated separately with acetic anhydride under the same conditions.

Procedure C: When the time of heating was further prolonged to 16 h, all three products **XIVa** (55%), **XVa** (20%), and **XXa** (15%) were obtained.

Similarly the results of the reactions of other quinoxaline 1,4-dioxides (**XIIIb—e**) with acetic anhydride are summarized in Table 1.

Table 1.

Starting material	Procedure	Products/%
XIIIb	A	**XIVb** (65) **XVb** (30)
	B	**XIVb** (60) **XVb** (25) **XXb** (10)
	C	**XIVb** (56) **XVb** (20) **XXb** (13)
XIIIc	A	**XIVc** (55) **XVc** (45)

	C	**XVIIe** (43) **XVIIIe** (30) **XXe** (15)

XIVb: Mp 132—133 °C (white needles from pet. ether). Found: C, 58.43; H, 5.02; N, 11.12%. Calcd for $C_{12}H_{12}N_2O_4$: C, 58.06; H, 4.83; N, 11.29%.

XVb: Mp 173—175 °C (needles from ethanol). Found: C, 58.48; H, 5.02; N, 13.58%. Calcd for $C_{10}H_{10}N_2O_3$: C, 58.25; H, 4.85; N, 13.59%.

The reactions of both **XIVb** and **XVb** with sodium dithionite in 50% aqueous ethanol gave 6-ethoxy-2(1*H*)-quinoxalinone (**XVIb**); mp 241—242 °C, identical with an authentic sample.[6]

XXb: Mp >360°, identical with an authentic sample.[6]

XIVc: Mp 115—117 °C (colorless needles from pet. ether). Found: C, 56.72; H, 4.34; N, 12.10%. Calcd for $C_{11}H_{10}N_2O_4$: C, 56.41; H, 4.27; N, 11.96%.

XVc: Mp 190—191 °C (needles from ethanol). Found: C, 56.45; H, 4.09; N, 14.62%. Calcd for $C_9H_8N_2O_2$: C, 56.25; H, 4.16; N, 14.58%.

The reactions of both **XIVc** and **XVc** with sodium dithionite in 50% aqueous ethanol gave the same compound, 6-methoxy-2(1*H*)-quinoxalinone (**XVIc**); mp 271—272 °C, identical with an authentic sample.[6]

XXc: Mp >350 °C, identical with an authentical sample.[6]

XIVd: Mp 104 °C (micro-needles from pet. ether). Found: C, 60.73; H, 4.53; N, 12.90%. Calcd for $C_{11}H_{10}N_2O_3$: C, 60.55; H, 4.59; N, 12.84%.

XVd: Mp 180—182° (ethanol). Found: C, 61.50; H, 4.51; N, 16.00%. Calcd for $C_9H_8N_2O_2$: C, 61.36; H, 4.54; N, 15.90%.

Both **XIVd** and **XVd**, on reduction with sodium dithionite in 50% aqueous ethanol, gave 6-methyl-2(1*H*)-quinoxalinone (**XVId**), mp 248 °C, identical with an authentic sample (the synthesis is described below).

XXd: Mp 345 °C, identical with sample, prepared by the condensation of 4-methyl-*o*-phenylenediamine and diethyl oxalate (yield 85%), and crystallized from ethanol as white needles, mp 345 °C. Found: C, 61.63; H, 4.61; N, 15.82%. Calcd for $C_9H_8N_2O_2$: C, 61.36; H, 4.54; N, 15.90%.

XVIIe: Mp 125—126 °C (white needles from pet. ether). Found: C, 50.42; H, 3.12; N, 11.93%. Calcd for $C_{10}H_7ClN_2O_3$: C, 50.31; H, 2.93; N, 11.74%.

XVIIIe: Mp 260 °C (ethanol). Found: C, 48.67; H, 2.50; Cl, 18.24; N, 14.01%. Calcd for $C_8H_5ClN_2O_2$: C, 48.85; H, 2.54; Cl, 18.07; N, 14.25%.

The reduction of both **XVIIe** and **XVIIIe** with sodium dithionite in 50% aqueous ethanol gave the same product, 7-chloro-2(1*H*)-quinoxalinone, (**XIXe**); mp 251—252 °C, identical with an authentic sample.[7]

XXe: Mp >360 °C, identical with an authentic sample.[6]

Preparation of Authentic 6-Methyl-2(1*H*)-quinoxalinone (XVId). α-Cyano-4-methyl-2-nitroacetanilide was prepared from 4-methyl-2-nitroaniline and ethyl cyanoacetate by the procedure described previously.[6] The anilide (yield 60%) crystallized from benzene as yellowish brown flakes; mp

146—147 °C.

Found: C, 55.20; H, 4.16; N, 19.32%. Calcd for $C_{10}H_9N_3O_3$: C, 54.80; H, 4.11; N, 19.17%.

A solution of the anilide (10 g) in pyridine (50 ml), was shaken with 1 mol dm^{-3} aq NaOH (50 ml) for 1 h. The color of the solution changed to dark red. Neutralization with dil HCl gave a precipitate, which was filtered, washed successively with dil HCl and water, and dried (yield 65%). Crystallization from ethanol gave yellowish brown needles of 3-cyano-6-methyl-2(1*H*)-quinoxalinone 4-oxide; mp 251—253 °C (decomp).

Found: C, 59.50; H, 3.56; N, 21.6%. Calcd for $C_{10}H_7N_3O_2$: C, 59.70; H, 3.48; N, 20.90%.

3-Cyano-6-methyl-2(1*H*)-quinoxalinone 4-oxide treated with sodium dithionite in 50% aqueous ethanol for elimination of the oxide, also lost the nitrile group as observed and reported by us,[6] giving an authentic sample of **XVId**; mp 248 °C.

Found: C, 67.81; H, 4.96; N, 17.63%. Calcd for $C_9H_8N_2O$: C, 67.50; H, 5.00; N, 17.50%.

We wish to thank Wellcome Research Laboratories (U. K.), and the Microanalytical Section of PCSIR Laboratories, Karachi, for the microanalyses reported in this paper.

Influence of Pressure on the Menschutkin-Type Reaction of Phenethyl Arenesulfonates with Pyridine

Soo-Dong Yoh,* Jong-Hwan Park, Kyung-A Lee, and In-Sook Han
Department of Chemistry, Teacher's College, Kyungpook National University, Daegu 635, Korea
(Received February 27, 1986)

Kinetic investigation of β-phenylethyl arenesulfonates with pyridine in acetonitrile revealed that the rates of these reactions which were lower than those of the reaction of benzyl benzenesulfonate with pyridine in acetone were increased with raising temperatures and pressures. The activation volumes were comparable to those of benzyl system, but activation entropies were negatively larger than those of benzyl system. From these phenomena it can be deduced that phenethyl system has more S_N2 character in the transition state, comparing with the reaction of benzyl system. With raising pressures the Hammett reaction parameters (ρ) were decreased, indicating that the reaction is probably closer to tight S_N2 character at higher pressures.

Menschutkin reactions—typical S_N2 reactions of alkyl halides with tertiary amine to form quaternary ammonium salts—have been widely investigated for the effects of pressure.[1-5] Recently kinetic studies of Menschutkin type reactions of benzyl benzenesulfonate with pyridine in acetone were carried out by the electric conductivity method under 1 to 2000 bars at 20 to 40 °C.[6] From the enthalpy, entropy, and volume of activation, it was found that this reaction precedes via the S_N2 reaction mechanism in which the rate of the reaction was determined by C–N bond formation in the transition state. In this connection, we studied on pressure dependence of the rate of the reaction of phenethyl arenesulfonates with pyridine which is expected to be more typical S_N2 under high pressure at 40 to 60 °C in acetonitrile to get some detailed information about the transition state.

Experimental

Instruments. Conductivity bridge and conductivity cell. The conductivity bridge is composed of B.N. 532 capacitor, B.N. 332 resistor and B.N. 1212/2 detector made by Rhode Schwarz Co., Germany. The conductivity cell shown in Fig. 1. It is composed of two parts, a glass cylinder of 5 cm^3 in which two Pt circular plate electrodes are sealed, and two-branched teflon tube of 6 cm long and 0.4 cm in diameter. The former acts as a conducting cell and the latter acts as a pressure conductor by pressing. The cell is set in the pressure vessel.

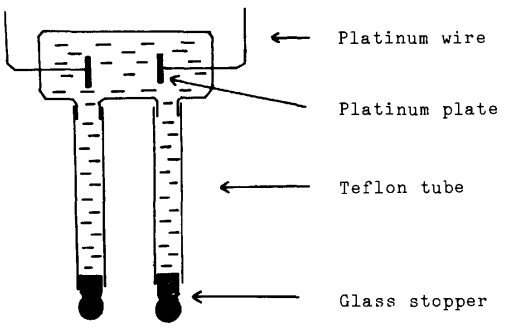

Fig. 1. Schematic drawing of the conductivity cell.

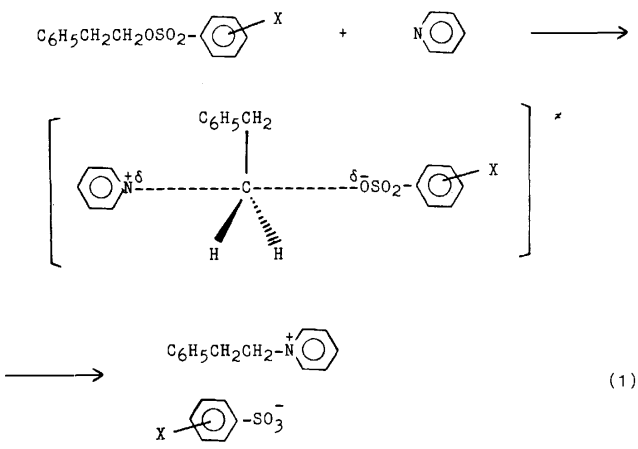
Materials. All materials used throughout were commercially available (Wako, Japan). Acetonitrile was purified by distillation after standing with anhydrous potassium carbonates for three days at room temperature. Pyridine dried over NaOH pellet was fractionated twice, bp 115—115.5 °C and stored in brown ampoule filled with nitrogen gas. IR spectra were recorded on a Hitachi EPI-2G Infrared Grating Spectrophotometer and ^1H NMR spectra were Varian 60 MHz Spectrometer.

The following arenesulfonyl chlorides were synthesized by chlorosulfonation of the corresponding substituted benzenes; *p*-Br derivative,[7] recrystd. from ligroine, (70%), mp 73 °C. Found: C, 38.05; H, 2.14%. Calcd for $C_6H_4BrClO_2S$: C, 38.33; H, 2.14%. *p*-Cl,[8] from ligroine, (58%), mp 52 °C (lit, 53 °C). *p*-MeO,[9] from pet. ether, (60%), mp 41 °C (lit, 41—42 °C). Unsubstituted benzenesulfonyl chloride[7] was obtained by purification of commercial chemicals, bp 137 °C/24 mmHg (1 mmHg=133.322 Pa) (lit, 119—121 °C/15 mmHg, mp 14.5 °C). *m*-Nitrobenzenesulfonyl chloride was prepared by chlorosulfonylation of sodium *m*-nitrobenzenesulfonate with chlorosulfuric acid. Recrystd. from ligroine, (57%), mp 61 °C (lit,[10] 61—62 °C). Found: C, 32.48; H, 1.67; N, 6.40%. Calcd for $C_6H_4ClNO_4S$: C, 32.51; H, 1.81; N, 6.32%. Phenethyl arenesulfonates were prepared from phenethyl alcohol with arenesulfonyl chloride by the Tipson's procedure[11] and purified by recrystallization from appropriate solvents.

N-Phenethylpyridinium *m*-nitrobenzenesulfonate. Pyridine (0.554 g, 0.007 mol) was added in a solution of phenethyl *m*-nitrobenzenesulfonate (2.15 g, 0.007 mol) in anhydrous acetonitrile (80 ml). The reaction mixture was heated under reflux for 4 h and then allowed to stand over night at room temperature. The product obtained was separated from solvent and washed with anhydrous ether. Recrystallization from 2-propanol gave colorless crystals, (40%), mp 122—123 °C, ^1H NMR ($CDCl_3$) δ=3.25 (2H, t, β-H), 5.15 (2H, t, α-H), 9.00 (2H, d, α-H of pyridine), 8.7 (1H, s, γ-H of pyridine); IR (Nujol) 3300, 1600, 1355, 1200, 1050, 835 cm^{-1}. Found: C, 59.52; H, 4.94; N, 7.33%. Calcd for $C_{19}H_{18}N_2O_5S$: C, 59.06; H, 4.70; N, 7.25%.

Kinetics. The reaction of phenethyl arenesulfonates with pyridine at various temperatures and pressures were followed by the conductometric method. As the reaction proceeds, the electric conductance was increased because formation of the salt increases as shown Eq. 1.[12] The conductivity cell was suspended in the high pressure vessel



(1)

with electrode leads, and the vessel was set in a thermostat kept at given temperature within ±0.1 °C. All kinetic runs were carried out under pseudo-first-order conditions, being the molar concentration of pyridine more than fifty times of that of phenethyl arenesulfonate. The Guggenheim plots[13] were used for determining the pseudo-first-order rate constant, from which the second-order rate constants were calculated. Rate constants were accurately estimated with the range of ±5% under 1 to 2000 bars and at 40, 50, and 60 °C.

Results and Discussion

Rate constants and thermodynamic parameters. The second-order rate constants for the reaction of phenethyl *p*-bromobenzenesulfonate with pyridine in acetonitrile under various pressures and at various temperatures are summarized in Table 1. As shown in Table 1, the rate constants increase with temperature and pressure and the rate constants are lower than those of the reaction of benzyl benzenesulfonate with pyridine[6] (11.46×10^{-4} dm^3 mol^{-1} s^{-1} at 40 °C, 100 bars). This is probably due to larger stability of benzyl cation.

The activation volumes obtained from the slope in Fig. 1, on the basis of Eq. 2, are shown in Table 2.

$$\left(\frac{\partial \ln k_2}{\partial P}\right)_T = \frac{-\Delta V^{\neq}}{RT} \quad (2)$$

If $\Delta V^{\neq}$ is independent of pressure, Eq. 2 can be integrated as follows

$$k_2 = k_0 \exp\left(\frac{-P\Delta V^{\neq}}{RT}\right), \quad (3)$$

where k_0 is the rate constant under 1 atm. From Table 2, we can see that the activation volumes, $\Delta V^{\neq}$, are all negative at various temperatures and the value of $|\Delta V^{\neq}|$ decrease with increasing temperature. These results are valuable to consider the physical meaning involved in each item for the reaction mechanism.

The $\Delta V^{\neq}$ is equal to $V^{\neq}-V_0$, where $V^{\neq}$ is the volume of the activated complex, and V_0 is the volume of reactants, being composed of the substrate V_m (phenethyl *p*-bromobenzenesulfonate), the nucleophile V_n (pyridine) and the solvent V_s (acetonitrile). But the apparent volume of the activated complex ($V^{\neq}$) is the sum of the volume of the complex ($V_a^{\neq}$) and the solvent $V_s^{\neq}$ (acetonitrile). In particular, $V_s^{\neq}$ is somewhat different from solvent V_s. We can assume that the sum of the volume of V_m and V_n of reactants are not so different from that of activated complex $V_a^{\neq}$ even though the complex is somewhat electronically distorted, but the volume of solvents $V_s^{\neq}$ (acetonitrile) are much different from that of initial state because the charged complex causes more electrostriction than the reactants. As we mentioned above, if the complex is more charged than reactants, it is reasonable that activation volume ($\Delta V^{\neq}$) is negative. From the Eq. 3, we could know that k_2 increase with increasing pressure because of this negative $\Delta V^{\neq}$ value. It is shown in Fig. 2 that the pressure dependence of ln k_2 has a linear relationship. This fact shows that $\Delta V^{\neq}$ is independent of pressure. The temperature dependence of $\Delta V^{\neq}$ can be also explained from the charge separation of the activated complex with the change of temperature. In other words, if temperature is elevated, it is expected that the charge separation of the activated complex is larger and the bond enlargement of the activated complex and so the $|\Delta V^{\neq}|$ value increase with temperature because of the more electrostrict effect at higher temperature.

Generally, a negative $\Delta V^{\neq}$ would be expected for S_N2 reaction where two molecules are brought together in the transition state. $\Delta V^{\neq}$ of S_N2 reaction of benzyl benzenesulfonate with pyridine in acetone at 40 °C at various high pressure was −12.97 cm^3 mol^{-1}, [6] and its negative value was about the same to that of phenethyl

Table 1. Second-Order Rate Constants, $k_2\times10^4$ (dm^3 mol^{-1} s^{-1}), of the Reaction of Phenethyl *p*-Bromobenzenesulfonate with Pyridine in Acetonitrile at Various Temperatures and Under Various Pressures

T/°C	P/bar			
	1	500	1000	1500

50	1.091	1.259	1.607	1.851
60	1.813	2.805	2.671	3.170

Table 2. Activation Volume ($\Delta V^{\neq}$) for the Reaction of Phenethyl *p*-Bromobenzenesulfonate with Pyridine in Acetonitrile at Various Temperatures

T/°C	40	50	60
$\Delta V^{\neq}$/cm^3 mol^{-1}	−12.33	−10.33	−9.56

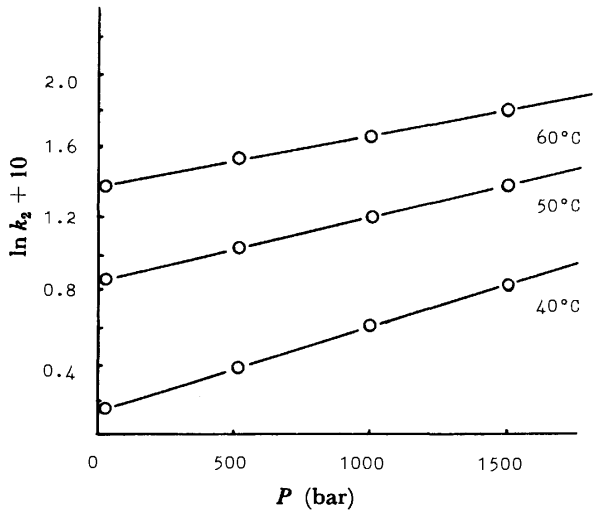

Fig. 2. The plots of ln k_2 vs. pressure at various temperatures.

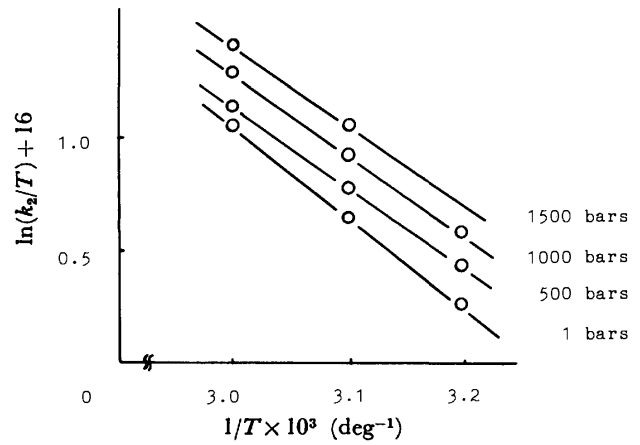

Fig. 3. The plots of ln (k_2/T) vs. $1/T$ at various temperatures.

p-bromobenzenesulfonate, but smaller than that of phenethyl *m*-nitrobenzenesulfonate.[14] This means that the S_N2 character of phenethyl *m*-nitrobenzenesulfonate is more predominant in the reaction of phenethyl *m*-nitrobenzenesulfonate than in that of benzyl benzenesulfonate.

There are other resemblance with the S_N2 Menschutkin reaction for example, of the reaction of EtI with pyridine[15] and that of hexadecyl bromide with pyridine in acetone at 40 °C, in which $\Delta V^{\neq}$ is −15—−20 ml per mole in both case. The activation parameters of the reaction of phenethyl *p*-bromobenzenesulfonate with pyridine are given in Table 4, in which the values of activation enthalpy are calculated from the slopes in Fig. 3. The plots of ln (k_2/T) against $1/T$ at various pressure for the reaction of phenethyl *p*-bromobenzenesulfonate with pyridine exhibit good linearity as shown in Fig. 3.

As shown in Table 4, $\Delta H^{\neq}$ values decrease and $\Delta S^{\neq}$ values increase negatively under higher pressure. These phenomena can be explained by that the S_N2 characters are predominant under higher pressure because the S_N2 mechanism is predominant when $\Delta H^{\neq}$ value is comparatively small and $\Delta S^{\neq}$ values negatively large.[12,16] Comparison of $\Delta S^{\neq}$ values for the reaction of benzyl system with that of phenethyl one shows that the latter is more negative[6] than the former. This result suggests that S_N2 character in the transition state of the phenethyl system is greater than that of the benzyl one, i.e., the former one should be closer to tight S_N2 than that of the latter, in the sense of concerted mechanism that the bond formation with nucleophile cooperates with the fission of leaving group in the transition state.

Table 3. Activation Parameters of the Reaction of Phenethyl *p*-Bromobenzenesulfonate with Pyridine in Acetonitrile at 50 °C

P/bar	1	500	1000	1500
$\Delta H^{\neq}$/kcal mol^{-1}	12.36	11.10	10.91	10.73
$\Delta S^{\neq}$/e.u. mol^{-1}	−38.59	−42.18	−42.30	−42.58
$\Delta G^{\neq}$/kcal mol^{-1}	24.83	24.73	24.58	24.49

Table 4. Second-Order Rate Constants, $k_2 \times 10^4$ (dm^3 mol^{-1} s^{-1}), of the Reaction of Phenethyl Arenesulfonates with Pyridine in Acetonitrile under Various Pressures at 50 °C

Substituents	*P*/bar				
	1	500	1000	1500	2000
m-NO_2	4.264	4.584	4.923	5.313	5.918
p-Cl	1.272	1.458	1.874	2.158	2.459
p-Br	1.091	1.259	1.607	1.851	
H	0.636	0.792	1.053	1.251	1.441
p-CH_3	0.403	0.533	0.728	0.885	1.027

As shown in Table 4, the rate constants increase with increasing both the pressure and the electron-withdrawing power of the substituent, which stabilize the sulfonate anion in the transition state by dispersing the charge. Hammett plots for these reactions at various pressures exhibit good linearity as shown in Fig. 4 and all the results are listed in Table 5. Hammett equation may be written in the form as linear free energy relationship.

$$\Delta\Delta G^{\neq} = -2.303\,RT\,\rho\sigma \tag{4}$$

From Eq. 4, by partial differentiation with respect to pressure *P*,

$$\frac{\partial \rho}{\partial p} = (\partial/\partial p)[-\Delta\Delta G^{\neq}/2.303\,RT\sigma)]$$
$$= (-\Delta\Delta V^{\neq})/2.303RT\sigma\,. \tag{5}$$

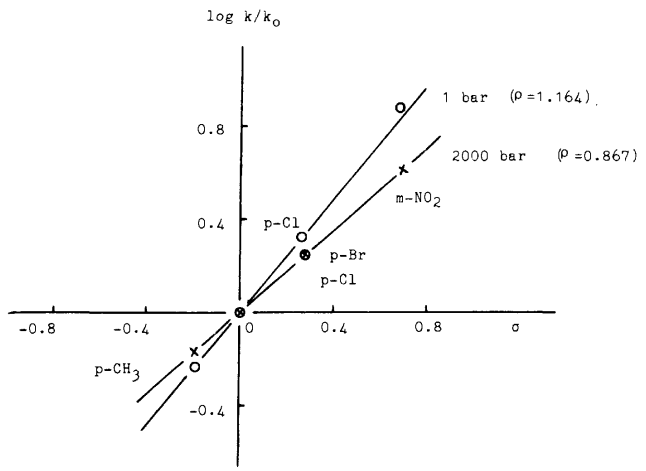

Fig. 4. Hammett plot for the reaction of phenethyl arenesulfonate with pyridine in acetonitrile at 50 °C.

Table 5. Hammett ρ Values for the Reaction of Phenethyl Arenesulfonates with Pyridine at 50 °C and Various Pressures

P/bar	1	500	1000	1500	2000
ρ	1.164	1.063	0.943	0.885	0.867
r	0.998	0.997	0.997	0.997	0.999
n	5	5	5	5	4

When neutral molecules react to produce ions like Menschutkin reaction the Hammett ρ values decrease with increase in pressure (see Table 5). This fact is probably explained by that, when P increases and the solvent becomes more compressed in the solution reaction, the contraction of the solution produced on ionization becomes smaller than the ordinary state. Due to these results, activation volume and, consequently, $|\Delta\Delta V^{*}|$ decrease and from right hand side of Eq. 5, $-\partial\rho/\partial p$ value decreases too; i.e., ρ should be decrease with increase in P. All above results and assumptions are also agreed perfectly with the idea of Fischer and his co-workers.[17]

The Present Studies were supported by the Basic Science Research Institute Program, Ministry of Education, Korea, 1984.

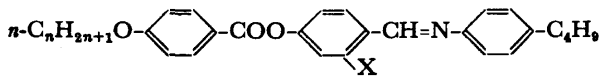
New Liquid Crystalline Homologous Series Exhibiting the Smectic C Phase

Sakumitsu SAKAGAMI*
National Industrial Research Institute of Kyushu, Tosu, Saga 841
(Received July 4, 1986)

Synopsis. A liguid crystalline homologous series of *N*-[4-(4-alkoxybenzoyloxy)benzylidene]-4-butylanilines and their hydroxyl derivatives at the 2-position were synthesized, and then the liquid-crystalline-phase transitions were determined using a differential scanning calorimeter and a polarizing microscope. All of the members exhibit a nematic phase, and a smectic C phase can be observed for the homologues with a relatively long alkoxyl chain.

It is well-established that smectic liquid crystalline phases can be further subdivided into several modifications, denoted by the letters A through I.[1,2] Among these smectic modifications, the smectic C phase has recently attracted increasing attention because the chiral compound in the smectic C phase can exhibit a spontaneous polarization and because this phase is ferroelectric.[3] The most characteristic feature of the smectic C structure is that the long axes of the molecules are tilted with respect to the planes of the layer.

Much efforts have thus far been made in order to obtain new ferroelectric smectic liquid crystals.[4,7] Unfortunately, the definite relationship between the molecular structure and the smectic C liquid crystal formation has remained unknown, although certain guidelines exist regarding the features of the molecular structure that favor the smectic C-phase formation.[2] Therefore, it is of great importance to synthesize a new liquid crystalline homologous series which exhibits the smectic C phase in connection with an attempt to find a common structural feature for the smectic C formation. In this paper we wish to report two new liquid crystalline homologous series exhibiting the smectic C phase of *N*-[4-(4-alkoxybenzoyloxy)benzylidene]-4-butylanilines and their derivatives, which have a lateral hydroxylsubstituent.



(n=1—8, X=H or OH)

Experimental

Materials. 4-Alkoxybenzoic acids obtained commercially are converted to acid chlorides by treatment with thionyl chloride in a benzene solution as the solvent. After the completion of the reaction, the excess of thionyl chloride and the solvent were removed; then the residue was distilled under reduced pressure. These acid chlorides were esterified by a reaction with 4-hydroxybenzaldehyde(2,4-dihydroxybenzaldehyde) in an ether solution including triethylamine. After they had then stood overnight, the triethylamine hydrochloride formed was removed by filtration, the ether was evaporated, and the solid residue was recrystallized from hexane. Finally, the substituted benzaldehydes thus obtained were coupled with 4-butylaniline by refluxing in an ethanol solution. The crude liquid crystals were purified by successive recrystallizations from ethanol.

Measurements. The liquid crystalline textures and the phase-transition temperatures were determined by means of a Nikon polarizing microscope equipped with a Mettler FP 52 microfurnace for sample temperature control. Checks on the transition temperatures were made using a Rigaku differential scanning calorimeter. Each sample was heated and cooled under a flow of nitrogen gas to prevent the sample from decomposing.

Results and Discussion

The transition temperatures and the liquid crystalline phases of the compounds without the lateral substituent are summarized in Table 1. All the members of this homologous series exhibit a nematic liquid crystal phase. As the length of alkoxyl chain is increased, smectic phases appear. This characteristic that the smectic phase is observed only for the homologues with a relatively long alkoxyl chain is not surprising, for the appearance of the smectic phase is not unusual; it has frequently been observed as the alkoxyl chain length increases in other homologous series of liquid crystalline materials.[8] Furthermore, it is worthwhile to state that, irrespective of the monotropic or enantiotropic transitions, the liquid crystalline phase transitions can be clearly detected by means of both the microscopic texture change and the thermal analysis.

Under polarizing microscopic observation, the smectic I phase of this homologous series exhibits broken fan-shaped or broken polygonal textures when formed on cooling from the nematic phase. These textures can be changed to a smectic schlieren texture by cover-slip displacement. All of the microscopic textures observed in the smectic I phase have been frequently found in the smectic C phase of other liquid

Table 1. Transition Temperatures of Liquid Crystals Without Lateral Hydroxyl Substituent (°C)

n	Smectic II	Smectic I(C)	Nematic	Isotropic
1			110	252
2			128	253
3			125	238
4			116	231
5	(77)	(99)	111	220
6	(76)	93	116	215
7	(77)	86	128	208
8	70	76	141	205

The figures in parentheses show the monotropic transition.

Table 2. Transition Temperatures of Liquid Crystals with Lateral Hydroxyl Substituent (°C)

n	Smectic C	Nematic	Isotropic
1		98	259
2		99	260
3		93	246
4		89	242
5		81	232
6	(77)	80	227
7	76	95	218
8	100	104	214

The figures in parentheses show the monotropic transition.

crystalline compounds and are typical textures of the smectic C phase.[2,9] In addition, it should be stressed that a homeotropic alignment, one of the textures typical of the smectic A phase, can not be observed at all in the smectic I phase. From these characteristic textures, it seems likely that the smectic I phase of this homologous series is the smectic C. On cooling from the smectic I phase to the smectic II phase, the smectic schlieren texture of the smectic C phase distinctly changes to a mosaic texture. However, the exact classification of this smectic II phase remains unclear because several different smectic modifications can exhibit a similar mosaic texture.[9]

Table 2 shows the phase transitions of another homologous series with the lateral substituent of the hydroxyl group. It is evident that, in this series, there also exist liquid crystalline phase transitions quite similar to those described above in the previous series without the lateral hydroxyl substituent. However, it should be kept in mind that the smectic II phase disappears in this homologous series; thus, no smectic polymorphism exists. Furthermore, it should be noted that a longer alkoxyl chain(C_6) is necessary for the smectic C phase to be formed compared with the previous series without the lateral substituent. It is also apparent from a comparison between the Tables 1 and 2 that the lateral hydroxyl substituent lowers the smectic C- nematic transition temperatures. These results indicate that the introduction of the hydroxyl group at the 2-position is unfavorable for the smectic formation and that it thus decreases the smectic C thermal stability. It seems that this behavior can be understood without difficulty by taking account of the change in the molecular structure. In general, it is well recognized that the lateral substituent exerts a full molecular-broadening influence, reducing the lateral intermolecular forces of attraction and thus lowering the smectic thermal stability.[10]

In addition, it is interesting to note the difference in the nematic-isotropic transition temperatures between the two series. The members with the lateral hydroxyl group exhibit higher nematic-isotropic transition temperatures than those without the lateral substituent. This result is quite likely to be associated with the strong intramolecular hydrogen bonding which has been found to occur for certain Schiff bases.[5,11] Such a hydrogen bonding will lead to a reduction in the rotational motions within the molecules and to a decrease in the twist from the noncoplanarity of a skeleton of *N*-(2-hydroxybenzylidene)aniline.[12,13] These effects are obviously favorable for the formation of the nematic structure; thus, they combine to give increased nematic thermal stability, i.e., an enhanced nematic-isotropic transition temperature.

In conclusion, we wish to point out that both the homologous series can exhibit the smectic C phase if the end alkoxyl chain is increased to a certain appropriate length.

Coordination-Site Exchange of Azaheterocyclic Ligands in Five-Coordinate Palladium(II) Complexes. Bis(4,7-dimethyl-1,10-phenanthroline)(triphenylphosphine)palladium(II) Tetrafluoroborate and the 4,7-Diphenyl Derivative

Shinsaku YAMAZAKI*
Chemistry Laboratory, Kochi Gakuen College,

(Received September 5, 1986)

Synopsis. Variable-Temperature ^{1}H NMR suggests that the fluxional motion of a potentially five-coordinate complex $[Pd(PPh_3)(4,7\text{-}R_2\text{-}phen)_2][BF_4]_2$ (R=Me, Ph) is frozen at lower temperatures, where the complex is in a rigid configuration (an unusual trigonal bipyramid). The fluxional motion is explained by two synchronous rearrangement systems, and an activation parameter, ΔG^*, for the site exchange is given.

For the ligand rearrangement systems of five-coordinate Pd(II) complexes,[1-6] most of the isolated complexes determined by means of X-ray diffraction and the discernible species in a solution detected by means of the spectra have been found to be in the form of a square pyramid, and their dynamic behavior in solution appears to proceed via the transition state of a trigonal bipyramid.

Previously, the crystal structure of the potentially five-coordinate Pd(II) complex $[PdCl(PPh_3)_2(phen)]^+$ has been described by the present author[6] as a very distorted square pyramid in which one nitrogen atom from the phen occupies the apical position, with a relatively long Pd–N distance (the two phosphines are mutually trans). Its solution structure[7] with a stereochemical non-rigidity, which has been explained by an oscillation of the apical phen, interestingly seems to be rather close to a square planar structure, with an anamalous unidentate phen. It should, however, be noticed that an analogous Pt(II) complex $[PtCl(PEt_3]_2(phen)]^+$,[3] with two phosphines mutually cis displays no dissociation processes in spite of the fact that the phen bite is loosened, in contrast to the Pd(II) complex.

This paper will deal with the dynamic motion of $[Pd(PPh_3)(phen)_2][BF_4]_2$ (R=Me, Ph) as evidenced by variable-temperature ^{1}H NMR spectroscopy.

Experimental

Preparation of Complexes-$[Pd(PPh_3)(4,7\text{-}Me_2\text{-}phen)_2][BF_4]_2$. This complex was prepared by a procedure analogous to that used for the corresponding phen complex.[8] Found: C, 56.93; H, 3.89; N, 5.40%. Calcd for $C_{46}H_{39}N_4B_2F_8PPd$: C, 57.62; H, 4.10; N, 5.84%. Conductance (acetone solution of ca. 10^{-3} M.): Λ_M, 288 Ω^{-1} cm^2 mol^{-1}. ^{1}H NMR ($CDCl_3$). vide infra.

$[Pd(PPh_3)(4,7\text{-}Ph_2\text{-}phen)_2][BF_4]_2$. This complex was prepared as above. Found: C, 64.86; H, 4.16; N, 4.36%. Calcd for $C_{69}H_{53}N_4B_2F_8OPPd$: C, 65.50; H, 4.22; N, 4.42%. IR (nujol mulls): ν(CO)(an acetone of solvation), 1710 cm^{-1}. ^{1}H NMR ($CDCl_3$): vide infra. Conductance (acetone solution of ca. 7.8×10^{-4} M.): Λ_M, 203 Ω^{-1} cm^2 mol^{-1}.

Physical Measurements. The conductivities were measured using a Denki Kagaku Keiki AO-6 instrument in dried acetone solutions. The lower-temperature ^{1}H NMR spectra were recorded, using JEOL FX-90A (89.55 MHz) in the region of 193—303 K in $CDCl_3$, at the NMG Applied Research Center of JEOL Ltd., Akishima, Tokyo.

Results and Discussion

The ^{1}H NMR spectra of $[Pd(PPh_3)(4,7\text{-}R_2\text{-}phen)_2][BF_4]_2$ (R=Me, Ph), which are dependent on the temperature, are shown in Fig. 1.

The lower-temperature ^{1}H NMR of the complex with R=H, as has been described elsewhere,[7] shows that its dynamic motion is not effectively frozen; only resonance broardening and overlapping were observed over a wide range of temperatures (173—303 K). Therefore, 4,7-Me_2 and Ph_2-phen were used as azaheterocyclic ligands, because a relatively simple spectrum with a small number of coupling patterns can then be expected.

At ambient temperatures, $[Pd(PPh_3)(4,7\text{-}R_2\text{-}phen)_2]^{2+}$ is stereochemically non-rigid, but it becomes

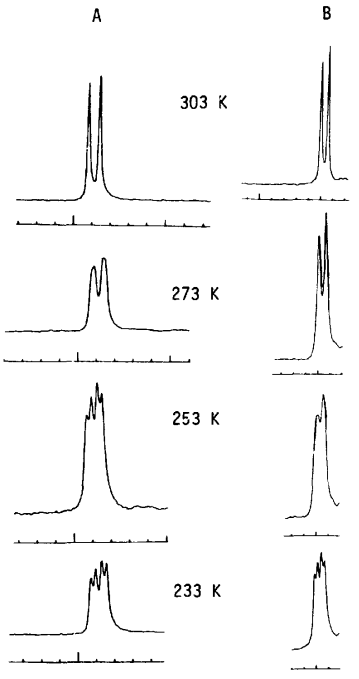

Fig. 1. Variable-temperature ^{1}H NMR (resonances due to 2,9-protons) of: A, $[Pd(PPh_3)(4,7\text{-}Ph_2\text{-}phen)_2][BF_4]_2$ B, $[Pd(PPh_3)(4,7\text{-}Me_2\text{-}phen)_2][BF_4]_2$ in $CDCl_3$.

Complex	T/°K	δ/ppm[b]	$\delta\nu$[c]	ΔG^*(kcal mol^{-1})[d]
R=Me	303	8.472		
	253(T_c)[a]	8.477		
	233	8.477 8.450	2.415	13.88
R=Ph	303	8.892		
	273(T_c)[a]	8.892		
	253	8.902 8.872	2.635	14.97

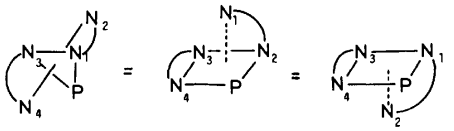
a) Coalescence temperature. b) Chemical shifts due to 2,9-protons, which are relative to Me_4Si at δ 0.00. c) Observed spacing between the two resonances due to 2 and 9-H of the azaheterocyclic ligand. d) Calculated by the use of $\Delta G^*/RT_c = 22.96 + \ln(T_c/\delta\nu)$,[10] where ΔG^* is an activation parameter for the site exchange of the azaheterocyclic ligand.

stereochemically rigid at lower temperatures. At 253 K, resonances due to 2,9-H in the 4,7-Ph_2-phen complex (Fig. 1A) were observed as two separate signals, each with coupling with the 3,8-H of the azaheterocyclic rings. The NMR spectrum at this temperature is consistent with the formation of an unsymmetrical structure (stereochemically rigid) in which two 4,7-Ph_2-phen are equivalent, while each azaheterocyclic ligand is unsymmetrically bound to the metal. Only a trigonal bipyramidal structure, with its axial positions occupied with nitrogen atoms, fits this requirement. Above 253 K, the resonance lines due to 2,9-H of the 4,7-Ph_2-phen complex become broadened, and at 273 K they coalesce into one resonance. The lines sharpen with an increase in the temperature. The ^{1}H NMR of the corresponding 4,7-Me_2-phen complex, which is dependent on the temperature, shows a pattern analogous to that observed for the 4,7-Ph_2-phen complex.

Even at lower temperatures, resonance patterns due to the CH_3 group (4,7-Me_2-phen complex) and 5,6-H (both complexes) were observed as a single resonance. These observations may not be unusual, for the 4,7-CH_3 and 5,6-H of the phen derivative may be too distant from the metal to be magnetically influenced.[9]

These NMR data are consistent with a site exchange between two nitrogen atoms of the azaheterocyclic ligand, and the fluxional motion may well be explained by means of two synchronous rearrangement systems: One a twist motion from a trigonal bipyramid to a tetragonal pyramid, and the other a concurrent oscillation of the apical 4,7-R_2-phen, which may average the magnetical environment around its two halves,[11] as is indicated in Scheme 1.

The activation parameters (ΔG^*) for the site exchange were estimated to be 13.9 kcal mol^{-1} for the 4,7-Me_2-phen complex and 15.0 kcal mol^{-1} for the 4,7-Ph_2-phen complex. The other activation parameters could not be obtained because of the relatively large $J/\delta\nu(\approx 2)$ ratio.



Scheme 1.

Although the conductivity data indicate that the association of the BF_4^- anion does not occur, it is still uncertain whether or not the fluxional motion of the complexes proceeds via dissociation processes. It should, however, be noticed that the fluxional behaviour of an analogous Pt(II) complex $[Pt(PPh_3)(phen)_2][BF_4]_2$ does not proceeds via a dissociation processes; to its ^{13}C NMR spectrum shows ^{195}Pt-C coupling at the 2,9-positions of the azaheterocyclic ligand.[12]

For the fluxional motion of $[Pd(PPh_3)(4,7\text{-}R_2\text{-}phen)_2]^{2+}$, the trigonal bipyramid is unusually the ground state, while the square pyramid is an intermediate. These findings rather resemble the dissociation processes proposed for $[Ni(CN)_2(PMe_3)_3]$,[13] the intermediate of which has been supposed to be square pyramid. In most of the five-coordinate Pt(II) and Pd(II) complexes {i.e. $[PdCl_2(PMe_3)_3]$[4] and $[Pt(CN)(phen)_2][NO_3]$[2]}, the fluxional motion has, on the other hand, been supposed to proceed via the transition state or the intermediate of the trigonal bipyramid.

The author is grateful to Mr. Hiroaki Utsumi (JEOL, LTD.) for obtaining the lower-temperature ^{1}H NMR spectra. This work was partially supported by a Grant-in-Aid for Scientific Research (No. 540402) from the Ministry of Education, Science and Culture.

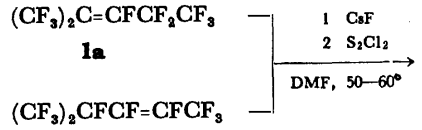
(Received August 27, 1986)

Synopsis. Perfluoro(1,1-dimethylbutanide) anion generated from hexafluoropropene dimers and cesium fluoride in *N,N*-dimethylformamide, reacts with disulfur dichloride to give the title trisulfide as the predominant product.

Compounds derived from perfluorinated hydrocarbons are characterized by chemical inertness and thermal stability, which justify their wide applications as hydraulic liquids, heat-transfer mediums, lubricants, sealants, protective coatings, etc. As part of our programme to seek perfluoroalkyl compounds of potential uses as dielectric fluids, we attempted to prepare bis[perfluoro(1,1-dimethylbutyl)] disulfide (**2**) by reacting disulfur dichloride with the anion generated from perfluorinated 2-methyl-2-pentene (**1a**) and cesium fluoride in *N,N*-dimethylformamide (*DMF*). Rather surprisingly, the main product was not the expected disulfide but bis[perfluoro(1,1-dimethylbutyl)] trisulfide (**3**) accompanied by small amounts of disulfide **2** and tetrasulfide **4**.



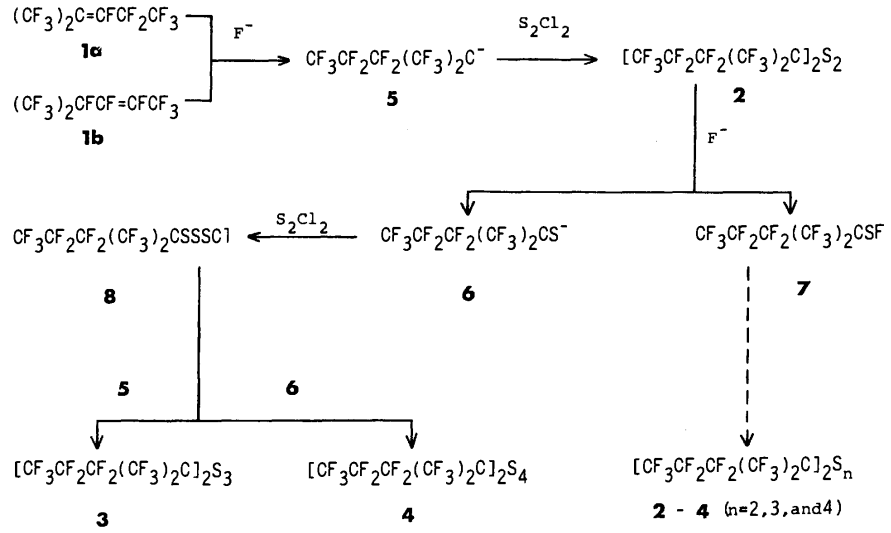
$[CF_3CF_2CF_2(CF_3)_2C]_2S_n$

2: $n=2$; **3**: $n=3$; **4**: $n=4$

Trisulfide **3** was identified by elemental analysis, ^{19}F NMR and high resolution mass spectra. It is a colorless liquid of low viscosity, which can be distilled without decomposition under reduced pressure and lacks unpleasant odor characteristic of organic sulfides. Compound **3** resists oxidation by hydrogen peroxide, potassium permanganate, and sodium periodate, but readily decomposes by the action of hydride reagents to form a complex product mixture. In spite of the difference in structure, perfluoro(4-methyl-2-pentene) (**1b**) afforded the same product, although perfluoro-olefin **1a** reacted more easily to produce **3** in a better yield. Hexafluoropropene dimer **1b** is known to isomerize into the thermodynamically more stable isomer **1a** in the presence of fluoride ion.[1] The reaction should be conducted in the presence of an excess of perfluoro(1,1-dimethylbutanide) anion **5**; otherwise an extensive liberation of sulfur occurs on addition of disulfur dichloride, leading to a poor yield of perfluoroalkyl polysulfides. Sulfur dichloride was not effective as a sulfurizing agent and led to a low yield of trisulfide as the main sulfur-containing product (≈10%). Mass spectral inspection revealed a slight incorporation of chlorine into the product.

Although the reason for preferential formation of trisulfide is not clear at present, a possible reaction passway is shown in Scheme 1.

Cleavage of a disulfide bond of **2** with fluoride ion followed by capture of the anion **6** with disulfur



Scheme 1.

dichloride affords **8**, which undergoes nucleophilic attack of anions **5** or **6** on the sulfur atom to yield oligosulfides **3** and **4**. Further fission of a sulfur-sulfur bond of **3** or **4** and subsequent trap of the resulting anionic species with sulfenyl fluoride **7** would lead to the polysulfides **2**—**4**.

Only a few descriptions of the formation of perfluoroalkyl tri- and tetrasulfides have been reported so far. They may be obtained as a by-product when perfluoroalkyl iodides of short chain length are heated with sulfur at 220—310 °C in a sealed tube or when carbon disulfide is treated with iodine pentafluoride at 195 °C in an autoclave.[2,3] Reaction of perfluoro-2-butene with potassium fluoride and elementary sulfur in sulfolane at 180 °C gives a low yield of trisulfide among other products.[4] Decomposition of azoperfluoroalkane or hexafluoroethane in the presence of sulfur vapor also forms trisulfides.[5,6] Reactions of perfluoro-olefins **1a** and **1b** with thiols or thiolate ions are known to lead to a mixture of several vinylic sulfides[7] which, of course, lack chemical inertness necessary for our purposes. Thus, our results present the first example of the preparation of perfluoroalkyl trisulfide from fluoro-olefins under mild liquid phase conditions.

Experimental

Perfluoro(2-methyl-2-pentene) (**1a**) and perfluoro(4-methyl-2-pentene) (**1b**) are commercial products available from NEOS Co. Ltd (Kano-cho, Chuo-ku, Kobe, Japan). Disulfur dichloride was purified by fractional distillation prior to use. Cesium fluoride was used as received.

Reaction of Perfluoro(2-methyl-2-pentene) with Disulfur Dichloride. A mixture of cesium fluoride (3.03 g, 20 mmol), perfluoro(2-methyl-2-pentene) (**1a**; 7.80 g, 26 mmol), and dry *DMF* (4 ml) was stirred at 50—60 °C for 1 h under nitrogen. Color gradually turned deep red. Then disulfur dichloride (1.35 g, 10 mmol; redistilled prior to use) in the same solvent (2 ml) was added dropwise during the course of 0.5 h. After addition, the mixture was kept with stirring at this temperature for 12 h and then diluted with water (15 ml). The resulting cloudy solution was filtered through a thin layer of Celite to remove free sulfur. Insoluble substance was washed with ether and the filtrate was extracted with the same solvent. The extract and washings were combined, dried with sodium sulfate, and evaporated. The residue was distilled in vacuo by Kugelrohr to give crude **3** containing about ten percent of disulfide (*m/z* 702 (M^+), 383 ($M^+-C_6F_{13}$)) and tetrasulfide (*m/z* 766 (M^+), 447 ($M^+-C_6F_{13}$)). Although these impurities tenaciously clung to **3**, they could be mostly removed by repeated chromatography on silica gel (Wako Gel C-200) using hexane as eluent. Further purification of **3** was made on a preparative liquid chromatograph (LC-08 Model, Japan Analytical Industry Co., Ltd). Isolated yield, 3.66 g (50% based on CsF). Bp 42—43 °C/0.08 mmHg (Kugelrohr) (1 mmHg=133.322 Pa). MS (20 eV) *m/z* (rel intensity) 734 (M^+; 40), 415 (100), and 181 (24); ^{19}F NMR ($CFCl_3$) δ=60.1 (12F, quint, CF_3), 80.3 (6F, t, CF_3), 103.7 (4F, m, CF_2), and 121.4 (4F, m, CF_2); IR (neat) 1335, 1200—1260 (vs), 1115, 965, 820, 735, and 710 cm^{-1}. Found: C, 19.66; F, 67.00%. Calcd for $C_{12}F_{26}S_3$: C, 19.63; F, 67.27%.

Synthesis of Bromoacetyl Derivatives by Use of Tetrabutylammonium Tribromide

Shoji KAJIGAESHI,* Takaaki KAKINAMI,† Tsuyoshi OKAMOTO,† and Shizuo FUJISAKI
Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755
†Department of Industrial Chemistry, Ube Technical College, Tokiwadai, Ube 755
(Received October 1, 1986)

Synopsis. Orange crystalline tetrabutylammonium tribromide was prepared using a simple method. The reaction of acetyl derivatives with an equimolar amount of the tribromide in dichloromethane–methanol at room temperature gave bromoacetyl derivatives in fairly good yields.

In general, bromoacetyl derivatives **1** have been synthesized by a reaction of acetyl derivatives **2** with bromine in an appropriate solvent such as water, chloroform, carbon tetrachloride, acetic acid or *N,N*-dimethylformamide.[1] The reagents, copper(II) bromide,[2] 1,4-dioxane bromooxonium bromide,[3] tribromoacetophenone,[4] and *N*-bromosaccharin,[5] have been used as brominating agents instead of bromine for **2** having unsaturated bond or functional groups (hydroxyl group, enol ester, acetal etc.) which should react promptly with bromine or hydrobromic acid. It must be a merit that these reagents can be handled more easily than liquid bromine, because of their solid character.

Furthermore, the solid reagents, organic ammonium tribromides, such as pyridinium tribromide,[6] phenyltrimethylammonium tribromide,[7,8] and tetramethylammonium tribromide,[9] have also been used as selective brominating agents. Recently, Berthelot et al.[10] have shown that tetrabutylammonium tribromide (TBA Br_3) can be used as a brominating agent for the addition of bromine to the double bonds of alkenes and for the selective bromination of acetals. In this paper, we wish to report a facile synthetic procedure of **1** from **2** by the use of TBA Br_3.

Results and Discussion

TBA Br_3 have usually been prepared from tetrabutylammonium bromide and bromine in carbon tetrachloride.[11] We readily prepared TBA Br_3 by the addition of hydrobromic acid to an aqueous solution of tetrabutylammonium bromide and sodium bromate at room temperature in quantitative yield.

The reaction of **2** with an equimolecular amount of TBA Br_3 in a dichloromethane–methanol solution for 1—5 h at room temperature readily gave **1** containing a small amount of dibromoacetyl derivatives which could easily be removed by recrystallization. The results are summarized in the Table 1.

$$\underset{\mathbf{2}}{R\text{-}COCH_3} \xrightarrow[\text{in } CH_2Cl_2\text{-}CH_3OH \text{ rt}]{(C_4H_9)_4N^+Br_3^-} \underset{\mathbf{1}}{RCOCH_2Br}$$

These reactions should proceed via an ionic species rather than radical ones. In fact, the bromination of acetophenone with TBA Br_3 in dichloromethane, dichloromethane-containing peroxides, and dichloromethane-containing a free radical inhibitor (*m*-dinitrobenzene) all proceeded at the same rate. As shown by Marquet et al.[12] for the bromination of acetophenone with phenyltrimethylammonium tribromide, the mechanism of bromination of **2** with TBA Br_3, (it is suggested) is also considered to be a slow-stage enolization of the ketone and a fast-stage bromination.

We emphasize that the synthetic procedure for bromoacetyl derivatives will be a highly useful method because of its ease, simplicity, and mildness of conditions.

Experimental

Tetrabutylammonium Tribromide (TBA Br_3). To a solution of tetrabutylammonium bromide (9.7 g, 30 mmol) and sodium bromate (1.50 g, 10 mmol) in water (60 ml) was added dropwise hydrobromic acid (47%, 7 ml) under stirring at room temperature. After the mixture was stirred for a few minutes, the immediate orange precipitate was filtered and recrystallized from ether–dichloromethane (1:1) to give TBA Br_3 as orange crystals; yield 13.7 g (95%); mp 74—75 °C (lit,[11] mp 70—72 °C). Found: Br, 50.08%. Calcd for $C_{16}H_{36}NBr_3$: Br, 49.71%.

Phenacyl Bromide (1a). As a general procedure, the preparation of **1a** was as follows: To a solution of acetophenone (0.5 g, 4.16 mmol) in dichloromethane (50 ml)–methanol (20 ml) was added TBA Br_3 (2.2 g, 4.58 mmol) at room temperature. The mixture was stirred for 1 h until a decoloration of the orange solution took place. The solvent was then distilled and the obtained precipitate was extracted with ether (30 ml×4). The ether layer was dried with magnesium sulfate and evaporated in vacuo to give a residue which was recrystallized from ethanol–water (1:2) affording as colorless needles; yield 0.65 g (78%); mp 49—50 °C (lit,[13] mp 50 °C).

Bromomethyl 2-Furyl Ketone (1j). Compound **1j** was prepared similarly: Yield 85%; colorless crystals; mp 34.5—36 °C; IR (KBr) 1675 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.30 (2H, s, CH_2Br), 6.53 (1H, dd, J=1.8 and 3.6 Hz, O-CH=C<u>H</u>-CH=), 7.26 (1H, d, J=3.6 Hz, O-CH=CH-C<u>H</u>=), and 7.56 (1H, d, J=1.8 Hz, O-C<u>H</u>=CH-CH=); MS *m/z* 189 and 191 (M^+). Found: Br, 41.88%. Calcd for $C_6H_5O_2Br$: Br, 42.27%.

Bromomethyl Thienyl Ketone (1k). Compound **1k** was prepared similarly: Yield 80%; colorless crystals; mp 33—35 °C; IR (KBr) 1665 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.40 (2H, s, CH_2Br), 7.13 (1H, dd, J=4.9 and 4.0 Hz, S-CH=C<u>H</u>-CH=), 7.70 (1H, d, J=4.9 Hz, S-C<u>H</u>=CH-CH=), and 7.80 (1H, d, J=4.0 Hz, S-CH=CH-C<u>H</u>=); MS *m/z* 205 and 207 (M^+).

Bromomethyl *t*-Butyl Ketone (1n). Compound **1n** was prepared similarly: Yield 90%; colorless liquid; bp 129—130 °C/760 mmHg (1 mmHg=133.322 Pa); IR (KBr) 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.23 (9H, s, $C(CH_3)_3$), and 4.17 (2H, s, CH_2Br); MS *m/z* 179 and 181 (M^+). Found: Br, 44.79%. Calcd for $C_6H_{11}OBr$: Br, 44.59%.

A Convenient Synthesis of Hypotensive (±)-Oudenone

Takashi SAKAI, Kohji IWATA, Masanori UTAKA, and Akira TAKEDA*
Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700
(Received September 22, 1986)

Synopsis. (±)-Oudenone, 2-(tetrahydro-5-propyl-2-furylidene)-1,3-cyclopentanedione, was conveniently synthesized by BF_3-catalyzed acylation of 1,3-cyclopentanedione with 4-chloroheptanoic anhydride and subsequent cyclization with triethylamine in a 36% overall yield.

Oudenone (**1a**) was isolated from a culture filtrate of *Oudemansiella radicata* by the group of Ohno and Umezawa[1] and found to exhibit significant hypotensive effect against spontaneously hypertensive rats due to inhibition of tyrosine hydroxylase.[2] Since it was synthesized initially in relation with the structural

1b R=Et

elucidation,[3] several synthetic methods[4-6] have been reported. Recently, Bates et al.[7] have reported a new route to (±)-**1a** which involves the acid-catalyzed C-alkylation of 1,3-cyclopentanedione (**5**) with 5-propyltetrahydro-2-furanol to give dihydrooudenone

Entry	Anhydride (R)	Method[a]	Conditions °C/h	Product (Yield/%)
1	**2c** (H)	A	110/12	**4c** (24)
2	**2c** (H)	B	90/12	**4c** (34)
3	**2c** (H)	C	95/12	**4c** (46)
4	**2b** (Et)	B	110/12	**4b** (17)
5	**2b** (Et)	C	95/12	**4b** (36)

a) A: BF_3·OEt_2, B: BF_3 in CH_2Cl_2–AcOEt, C: BF_3.

and subsequent introduction of C–C double bond via phenylselenenylation.

We report here a convenient two-step synthesis of (±)-**1a** which is characterized by boron trifluoride (BF_3)-catalyzed acylation of **5** with 4-chloroheptanoic anhydride (**2a**) to give 2-(4-chloroheptanoyl)-1,3-cyclopentanedione (**6a**). Subsequent cyclization of **6a** by triethylamine gave (±)-**1a** in a 36% overall yield (Scheme 2). While the acylation of **5** would be effective not only for the straightforward synthesis of (±)-**1a** but also for the synthesis of other biologically active compounds,[8] the reaction has not been well established.[9]

Manvik et al.[10] reported that BF_3 was effective for the acylation of carbon atom α to carbonyl group with acid anhydride. Leucht[11] used the procedure for the C-acylation of 3-alkyl-1,2,4-cyclopentanetrione. We applied the method to the present synthesis. In the first place, we examined the reaction conditions for the BF_3-catalyzed acylation of readily available 1,3-cyclohexanedione (**3**) with 4-chloroalkanoic anhydrides **2b, c** as shown in Scheme 1. Anhydrides **2a—c** were easily prepared by heating the corresponding acid chloride[12] in acetic anhydride. As shown in Table 1, the acylation of **3** with **2c** was examined as a typical example by using three conditions: a) use of BF_3·OEt_2 (Entry 1); b) addition of a mixture of **3** and **2c** to CH_2Cl_2–AcOEt after saturation with BF_3[11] (Entry 2), and c) introduction of BF_3 to a mixture of **3** and **2c**,[11] which gave the best result (Entry 3). The use of **2b** slightly decreased the yield of **4b** (Entries 4 and 5).

The BF_3-catalyzed acylation of **5** with **2a** was carried out by using the conditions C of Table 1 to give **6a** in a 74% yield (Scheme 2). Fortunately, the yield was approximately doubled as compared with that of **4b**. Compound **6a** was readily cyclized to (±)-**1a** by the treatment with triethylamine at 0 °C in a 49% yield after recrystallization. In a similar way, oudenone homolog (±)-**1b**[5b] was synthesized via **6b** in a 31% overall yield.

Experimental

Melting points were determined by a Yamato Model MP-21 apparatus and uncorrected. Infrared spectra were taken on a JASCO A-102 spectrometer. ^1H NMR spectra (60 MHz) were measured with a Hitachi R-24 spectrometer. ^{13}C NMR (25 MHz) spectra were taken on a JEOL FX-100 spectrometer. Column chromatography was performed through silica gel (Wakogel C-200). Preparative TLC was done on silica gel (Kieselgel 60 PF_{254}).

Typical Reaction for the Preparation of Anhydrides 2a—c. 4-Chloroheptanoic Anhydride (2a). A mixture of 4-chloroheptanoyl chloride[12] (4.89 g, 26.7 mmol) and acetic anhydride (9 ml, 95.2 mmol) was placed in a reaction vessel

connected with a distillation apparatus and heated at 95 °C for 3 h, removing the resulting acetyl chloride continuously. The reaction mixture was then distilled to give **2a** (2.69 g, 65% yield): bp 120—156 °C (1.0 mmHg) (1 mmHg=133.322 Pa); IR (neat) 1820, 1753, 1045 cm^{-1}; ^1H NMR (CCl_4) δ=0.97 (6H, t, J=8 Hz), 1.20—2.50 (12H, m), 2.65 (4H, t, J=8 Hz), 3.88 (2H, m). Anal. ($C_{14}H_{24}O_3Cl_2$) C, H.

4-Chlorohexanoic Anhydride (2b): Yield 71%; bp 135—143 °C (2 mmHg); IR (neat) 1815, 1745, 1045 cm^{-1}; ^1H NMR (CCl_4) δ=1.07 (6H, t, J=8 Hz), 1.35—2.45 (8H, m), 2.65 (4H, t, J=8 Hz), 3.83 (m, 2H). Anal. ($C_{12}H_{20}O_3Cl_2$) C, H.

4-Chlorobutanoic Anhydride (2c): Yield 88%; bp 120—124 °C (1.5 mmHg); IR (neat) 1815, 1750, 1045 cm^{-1}; ^1H NMR (CCl_4) δ=2.16 (4H, m), 2.64 (4H, t, J=7 Hz), 3.60 (4H, t, J=7 Hz). Anal. ($C_8H_{12}O_3Cl_2$) C, H.

Typical Reactions for Acylation. 2-(4-Chlorobutanoyl)-1,3-cyclohexanedione (4c). a. With BF_3·OEt_2. To a mixture of **3** (275 mg, 2.45 mmol) and BF_3·OEt_2 (2.55 g, 17.7 mmol) was added 4-chlorobutanoic anhydride (**2c**) (640 mg, 2.82 mmol) at room temperature. The mixture was stirred for 12 h at 110 °C. After cooling the mixture, it was poured into water and extracted with ethyl acetate. The extract was washed with water, dried over $MgSO_4$, and concentrated under vacuum. Purification of the residue by preparative TLC (hexane-ethyl acetate, 1:1, R_f=0.68) gave **4c** (112 mg, 23% yield): IR (neat) 3400 (enol OH), 1660, 1550 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.70—2.90 (8H, m), 3.16 (2H, t, J=7 Hz), 3.58 (2H, t, J=7 Hz), 17.9 (1H, s, enol OH). ^{13}C NMR ($CDCl_3$) δ=19.0 (t), 27.2 (t), 32.8 (t), 38.1 (t), 38.6 (t), 44.3 (t), 112.9 (s), 194.9 (s), 197.5 (s), 204.5 (s). These spectral data implies that **4c** is present in enol form. Anal. ($C_{10}H_{13}O_3Cl$) C, H.

b. With BF_3 in Ethyl Acetate-Dichloromethane. BF_3 generated by using sodium tetrafluoroborate ($NaBF_4$) (60 g, 546 mmol), anhydrous diboron trioxide (B_2O_3) (10 g, 144 mmol), and concd sulfuric acid (60 ml)[13] was introduced into a mixed solvent of ethyl acetate (5 ml) and dichloromethane (8 ml). After cooling the solution in an ice bath, a mixture of **3** (2.2 g, 20 mmol) and **2c** (9.05 g, 40 mmol) was added dropwise. It was stirred for 30 min at 0 °C and for additional 12 h at 90 °C. The mixture was treated in a similar manner to give **4c** (1.46 g, 34% yield) after purification by column chromatography (hexane-ethyl acetate, 5:1).

c. With BF_3. To a cooled (0 °C) mixture of **3** (2.62 g, 23.4 mmol) and **2c** (11.2 g, 49.5 mmol), was introduced BF_3 generated from $NaBF_4$ (60 g, 546 mmol), anhydrous B_2O_3 (10 g, 144 mmol), and concd sulfuric acid (60 ml).[13] The introduction was completed within 15 min. The darkened mixture was stirred for 30 min at 0 °C, for 30 min at room temperature, and for additional 12 h at 95 °C. The reaction mixture was treated in a manner similar to the foregoing experiment to give **4c** (2.31 g, 46% yield).

2-(4-Chlorohexanoyl)-1,3-cyclohexanedione (4b): IR (neat) 3400 (enol OH), 1730, 1662, 1560 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.04 (3H, t, J=8 Hz), 1.60—2.84 (10H, m), 3.22 (2H, t, J=8 Hz), 3.90 (1H, m), 17.91 (1H, br s, enol OH); ^{13}C NMR ($CDCl_3$) δ=11.0 (q), 19.2 (t), 31.6 (t), 32.5 (t), 32.9 (t), 38.1 (t), 38.8 (t), 64.9 (d), 113.1 (s), 195.3 (s), 197.9 (s), 205.3 (s). Anal. ($C_{12}H_{17}O_3Cl$) C, H.

2-(4-Chloroheptanoyl)-1,3-cyclopentanedione (6a): Yield 74% after purification by column chromatography (hexane-acetone, 8:1); IR (neat) 3420 (enol OH), 1710, 1630, 1585 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.95 (3H, t, J=7 Hz), 1.20—2.35 (6H, m), 2.35—2.90 (4H, m), 3.15 (2H, t, J=9 Hz), 4.05 (1H, m), 10.90 (1H, br s, enol OH). Anal. ($C_{12}H_{17}O_3Cl$) C, H.

2-(4-Chlorohexanoyl)-1,3-cyclopentanedione (6b): Yield 69% after purification by column chromatography (hexane-acetone, 8:1); IR (neat) 3450 (enol OH), 1710, 1625, 1580 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.92 (3H, t, J=8 Hz), 1.30—2.20 (4H, m), 2.20—2.80 (4H, m), 3.05 (2H, t, J=9 Hz), 3.86 (1H, m), 11.40 (1H, s, enol OH). Anal. ($C_{11}H_{15}O_3Cl$) C, H.

2-(5-Propyltetrahydro-2-furylidene)-1,3-cyclopentanedione (Oudenone) ((±)-1a). Triethylamine (2 ml) was added to **6a** (90 mg, 0.37 mmol) at 0 °C. After being stirred for 4.5 h at 0 °C, triethylamine unreacted was removed under reduced pressure. The residual oil was extracted with acetone, and purified by column chromatography (hexane-acetone, 1:1) followed by recrystallization from hexane to give (±)-**1a** (37 mg, 49% yield): Mp 81—82 °C (lit.[3a] 77—78 °C); IR (KBr) 3440, 1712, 1660, 1560 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.92 (3H, t, J=7 Hz), 1.08—1.96 (4H, m), 2.54 (4H, br s), 2.84—3.76 (4H, m), 4.90 (1H, m); ^{13}C NMR ($CDCl_3$) δ=13.9 (q), 18.7 (t), 26.9 (t), 33.8 (t), 34.6 (t), 35.0 (t), 36.8 (t), 90.5 (d), 109.3 (s), 184.6 (s), 200.8 (s), 204.8 (s). These spectral data were consistent with those reported.[3a,7]

2-(5-Ethyltetrahydro-2-furylidene)-1,3-cyclopentanedione ((±)-1b)[5b]: Yield 42%; mp 106—107 °C (hexane-benzene, 2:1); IR (KBr) 3375, 1712, 1660, 1560 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.97 (3H, t, J=7 Hz), 1.6—2.0 (2H, m), 2.56 (4H, s), 2.92—3.72 (4H, m), 4.84 (1H, m). Anal. ($C_{11}H_{14}O_3$) C, H.

Ester Aminolysis in the Presence of Alkylammonium Carboxylate Reversed Micelles. A Mechanistic Study

Omar A. EL SEOUD,*[1a] Rita C. VIEIRA,[1b] and Luzia P. NOVAKI[1b]
Physikalische Chemie I, University Bayreuth, Postfach 3008, D-8580 Bayreuth, West Germany
(Received November 27, 1985)

Synopsis. A study of ester aminolysis in the presence of dodecylammonium carboxylate reversed micelles showed that the catalytic role of the surfactant head-anion (general base) was concentration independent. The presence of co-solubilized water in the micelle did not lead to detectable ester hydrolysis.

Several types of reactions were found to be catalyzed by reversed micelles (RM's).[2,3] Ester aminolysis in the presence of alkylammonium carboxylate RM's has received a fair amount of attention.[4-7] Evidence has been given to show that the carboxylate ion of the surfactant is acting as a general base,[7b] not as a nucleophile.[6] In these reactions the ratio [detergent]/[ester] is usually large (typically ≥ 50). It has been argued, however, that the nucleophilic catalysis pathway can still occur if a much lower [surfactant]/[ester] ratio were used.[8] This implies that a change in the reaction mechanism (from general base to nucleophilic catalysis) can be induced by changing the concentration ratio of the reactants.[9] We checked, therefore, the concentration dependence of the catalytic role of the carboxylate ion of these surfactants and the conditions under which it can act as a nucleophile.

As recently argued,[8] co-solubilization of water in the core of the RM can lead to the occurence of hydrolysis as a competing reaction. This is not in agreement with our study of ester aminolysis in the presence of dodecylammonium diethylarsinate RM's.[7a] Since the carboxylate ion is a much weaker base than the diethylarsinate ion[11] we sought direct evidence for, or against, the occurence of hydrolysis in the case of the present RM's.

Results and Discussion

Consider the aminolysis of *p*-nitrophenyl *p*-nitrobenzoate by dodecylammonium *p*-anisate (DAPA) RM's or by a mixture of DAPA and dodecylamine (DA). The nucleophilic catalysis mechanism should proceed via attack of the *p*-anisoyloxy group on the ester to give the intermediate anhydride $O_2NC_6H_4CO\cdot O\cdot OCC_6H_4OCH_3$ whose aminolysis should yield a mixture of the amides $O_2NC_6H_4CONHC_{12}H_{25}$ and $CH_3OC_6H_4CONHC_{12}H_{25}$.[8] According to the general base catalysis mechanism only one amide, that derived from the ester, i.e., $O_2NC_6H_4CONHC_{12}H_{25}$, should be produced[7b] so that analysis of the products should settle the question. Entries 1—3 of Table 1 show the results for the aminolysis by DAPA and by DAPA+DA using small [detergent]/[ester] ratios. Only *N*-dodecyl-*p*-nitrobenzamide was obtained which clearly shows that the catalytic role of the *p*-anisoyloxy group of DAPA is concentration independent.

The question now arises: Under which conditions will the *p*-anisoyloxy group act as a nucleophile in the micellar core? Recently it has been shown that the acetate ion of $(CH_3)_4N^+{-}O_2CCH_3$ reacts with esters in aprotic solvents producing mixed anhydrides.[13] We decided, therefore, to investigate whether the same result will be obtained in the presence of the surfactant. Entries 4—7 of Table 1 show the results of the reaction of the benzoate ester with DAPA and with DAPA+DA in the presence of tetramethylammonium *p*-anisate (TMA) in CH_3CN and in CH_2Cl_2. The *p*-anisoyloxy group acted as a nucleophile (as shown by the production of amides A,B) only under the condition [TMA]$\geq$[DAPA]. While the formation of RM's in CH_3CN may be dubious[3] the reaction in CH_2Cl_2 is certainly taking place within the micellar domain since TMA is only soluble in the presence of the surfactant.

The preceding results can be rationalized as follows: In the micellar core the *p*-anisoyloxy group can act as a nucleophile only if it is "naked" or desolvated.[10,13] ^1H NMR data demonstrated that the carboxylate ion is strongly hydrogen-bonded to the alkylammonium ion[3] so that it is present in a protic microenvironment. Note that this hydrogen-bonding is an intrinsic property, i.e., it is neither dependent on the presence of the ester nor on the [detergent]/[ester] ratio. Solubilization of TMA in the RM introduces "excess" *p*-anisate ions which are not hydrogen-bonded to their cations (the $(CH_3)_4N^+$ ions) and is thus expected to favor the nucleophilic catalysis mechanism. That the latter took place only at higher [TMA] is understandable in terms of the ability of the alkylammonium

Table 1. Aminolysis of *p*-Nitrophenyl *p*-Nitrobenzoate in the Presence of Dodecylammonium *p*-Anisate Reversed Micelles in Organic Solvents[a]

a) At room temperature, ester=0.8 mmol, in 20 ml CH_2Cl_2 (Reactions 1—7) or acetonitrile (Reactions 4—7). b) For abbreviations see text. c) Determined by ^1H NMR. Amide: A=$O_2NC_6H_4CONHC_{12}H_{25}$; B=$CH_3OC_6H_4CONHC_{12}H_{25}$.

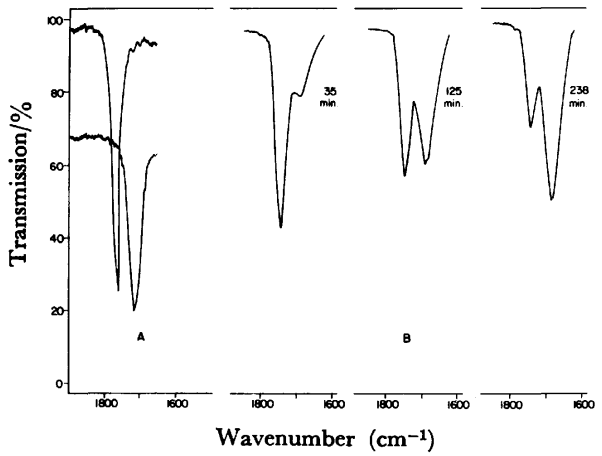

Fig. 1. Part A shows the peaks of the CO groups of methyl *p*-nitrophenyl carbonate and methyl dodecylcarbamate (both 0.05 M) in chloroform. The progress of the reaction of 0.05 M carbonate ester, 0.1 M DAP in the presence of 0.6 M water is shown in part B.

ions to complex more than one carboxylate ion.[14] The relevant point here is that due to the protic nature of the core of alkylammonium carboxylate RM's the possibility that the RCO_2^- group of the surfactant can act as a nucleophile is now essentially excluded.

The aminolysis of methyl *p*-nitrophenyl carbonate in the presence of dodecylammonium propionate (DAP)-solubilized water was studied in chloroform and in toluene. Our choice of this ester was dictated by the favorably large separation between the peaks of the CO groups of the ester (1760 cm^{-1}) and methyl dodecylcarbamate (the product of aminolysis, at 1710 cm^{-1}) as shown in part A of Fig. 1. The reaction progress is shown in part B in which the ester peak gradually disappeared and that due to the aminolysis appeared. Quantitative analysis in both solvents indicated that all the carbonate ester that reacted appeared as amide, i.e., practically no hydrolysis occurred. This is similar to the reaction of alkyl *p*-nitrophenyl carbonates with amines in aqueous solutions where only aminolysis occurs, probably because of the higher reactivity of amines relative to water.[15] Since the head-ions of DAP are strongly hydrogen-bonded it is easy to understand why the carboxylate ion (acting as a general base) accepted a proton from the dodecylammonium ion (leading to aminolysis) rather than from a water molecule (causing hydrolysis).

Experimental

All solvents (Aldrich) were purified and kept on activated 4A molecular sieves. DAP, DAPA, the benzoate, and the carbonate esters, methyl dodecylcarbamate, *N*-dodecyl-*p*-anisamide were obtained as given elsewhere.[5,7] *N*-Dodecyl-*p*-nitrobenzamide was prepared by refluxing DA and benzoyl chloride (molar ratio 2:1) in chloroform and was recrystallized from hexane–chloroform. Mp 96—97 °C. ^1H NMR (Varian T-60 spectrometer, in $CDCl_3$) δ=8.01 (d, 2H), 7.81 (d, 2H), 5.95 (m, 1H), 3.88 (m, 2H), 1.27 (apparent s, 20H), and 0.84 (t, 3H). Found: C, 68.14; H, 8.96; N, 8.29%. Calcd for $C_{19}H_{30}N_2O_3$: C, 68.26; H, 8.98; N, 8.38%. TMA was prepared by carefully neutralizing tetramethylammonium hydroxide with *p*-anisic acid in aqueous methanol. Prolonged drying in vacuo, over P_2O_5 at 70 °C gave the anhydrous salt. ^1H NMR (CD_3CN) δ=7.71 (d, 2H), 6.85 (d, 2H), 3.81 (s, 3H), and 3.21 (s, 12H). This hygroscopic salt was handled in Atomsbag (Aldrich) and was dried to a constant weight before being used. A typical aminolysis reaction in CH_2Cl_2 was as follows: The reactants were stirred overnight under N_2, the organic solution was washed with NaOH (pH=11) until the latter was colorless, with water, dried, and the solvent removed. The solid residue was washed with hexane, dried, then submitted to analysis by ^1H NMR.

IR spectra were obtained with a Perkin-Elmer 238 spectrometer using 0.2 mm CaF_2 cells. Quantitative analysis were carried out using the absorption mode. The concentrations of the reacting ester and of the produced carbamate were determined from the corresponding Beer's law plots (using peak areas and/or weights), and were accurate to ±2%.

Anisotropic Rotation of Perylene Studied by Fluorescence Depolarization Method

Takashi SASAKI, Kanji HIROTA, Masahide YAMAMOTO,* and Yasunori NISHIJIMA
Department of Polymer Chemistry, Kyoto University, Kyoto 606
(Received October 20, 1986)

Synopsis. Rotational diffusion coefficients of perylene in solution were determined by a fluorescence depolarization technique. An asymmetric rotor approximation is more appropriate than an oblate approximation for perylene. The ratio of the diffusion coefficients suggests that a partially slipping boundary condition should be taken into account for this system.

The fluorescence depolarization technique has been utilized to study the rotational Brownian motions of various fluorescent molecules.[1-3] We have investigated the anisotropic rotational diffusion of perylene and its derivatives in solution by a time-resolved technique.[4] In the present work, we reinvestigated the rotational motion of perylene with the asymmetric rotor model as well as with the spheroid model, and precisely analyzed the diffusion coefficients.

Theoretical

A theoretical treatment of the rotational relaxation of fluorescence emission anisotropy was performed in the most general manner by Chuang and Eisenthal.[5] Assuming that the transition vector of absorption is parallel to that of the emission, and coincides with one of the principal axes (z-axis in Fig. 1), we can write a reduced expression for the anisotropy ratio, $r(t)$:

$$r(t) = 0.3(\alpha+\beta)\exp[-(6D+2\Delta)t] + 0.3(\beta-\alpha)\exp[-(6D-2\Delta)t], \quad (1)$$

with

$$\alpha = (D_x+D_y-2D_z)/3\Delta, \qquad \beta = 2/3,$$
$$\Delta = (D_x^2+D_y^2+D_z^2-D_xD_y-D_yD_z-D_zD_x)^{1/2},$$

and

$$D = (D_x+D_y+D_z)/3,$$

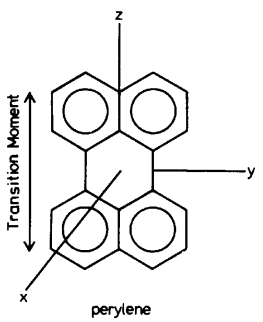

Fig. 1. Molecular fixed coordinate system for perylene.

where D_x, D_y, and D_z are the rotational diffusion coefficients about the corresponding axes. These diffusion coefficients can be related to the molecular shape according to a hydrodynamic assumption. In general, with a sticking boundary condition the rotational diffusion coefficient D_r of a rigid body in a fluid medium obeys the expression

$$1/(6D_r) = \eta\zeta V/kT, \quad (2)$$

where η is the viscosity of the medium, ζ the rotational friction coefficient, V the volume of the body, k the Boltzmann constant, and T the absolute temperature. In the case of a slipping boundary condition, it can be written as

$$1/(6D_r) = \eta\zeta V/kT + \rho_0, \quad (3)$$

where ρ_0 is related to the inertia of the body (order of picoseconds). The rotational friction coefficient for a sphere (radius R) in a fluid medium with the sticking and the slipping boundary conditions are $8\pi\eta R^3$ and zero, respectively; those for a symmetric rotor could be calculated exactly with the sticking boundary condition,[6] and numerically with the slipping boundary condition.[7] If we approximate perylene by a symmetric rotor (an oblate spheroid) with an axial ratio, $r_x:r_y(=r_z)=3:11$, the ratio of the diffusion coefficients predicted by the above theory with the sticking boundary condition is $D_{/\!/}/D_\perp=0.816$, where $D_{/\!/}=D_x$, and $D_\perp=D_y=D_z$. In the case of the slipping boundary condition, the friction coefficient about the symmetric axis (x-axis) is zero; thus $D_{/\!/} \gg D_\perp$ is obtained. On the other hand, the friction coefficients for an asymmetric rotor with the slipping boundary condition have been obtained numerically by Youngren and Acrivos.[8] According to their results, the ratio of the friction coefficients is $\zeta_x:\zeta_y:\zeta_z=1:31:22$, for the ellipsoid with the axial ratio $r_x:r_y:r_z=1:3.2:3.8$, which is estimated by the van der Waals radii of perylene molecule. This is considered to be a more appropriate approximation than the oblate approximation for a perylene molecule. To our knowledge, the friction coefficients for an asymmetric rotor with the sticking boundary condition have not been calculated so far.

Experimental

Perylene was dissolved in propylene glycol. The concentration of this solution was 10^{-5} mol dm^{-3}. The solution was degassed for measurement. A time-resolved fluorescence anisotropy measurement was performed using the nanosecond single-photon counting system in our

laboratory.[9] The data counts were accumulated to 1.3×10^5 counts at the peak of the fluorescence intensity of the parallel component; this was sufficient for ascertaining good precision regarding the data. The data analysis was executed to fit a biexponential function,

$$r(t) = r_0[a_1 \exp(-t/\rho_1) + a_2 \exp(-t/\rho_2)], \quad (4)$$

to experimental points by the method of nonlinear least-squares fitting which involved a deconvolution procedure.[10] Then, we calculated the diffusion coefficient about each axis by Eq. 1 from the obtained values. Further, to test the oblate spheroid model, the ratio a_1/a_2 was fixed at 1/3 (postulated in this case). The same analysis procedure was executed to find $D_{/\!/}$ and $D_\perp$. All these data-analysis procedures were performed on a digital computer FACOM M-382.

Results and Discussion

The results are shown in Tables 1 and 2. As a criteria of the accuracy of the fitting, the reduced sums of the squares of the residuals χ^2 are also shown in Table 1. It can be seen that the ratio $D_{/\!/}/D_\perp$ for perylene agrees neither with the theoretical value for the sticking boundary condition ($D_{/\!/}/D_\perp=0.816$) nor with that for the slipping boundary condition ($D_{/\!/} \gg D_\perp$). Thus, it is considered that the real behavior of perylene is under an intermediate boundary condition between those two ideal boundary conditions. Judging from the values of χ^2, we can say that an approximation with an asymmetric rotor is more appropriate for perylene than that with an oblate spheroid, as might have been expected. This can be clearly seen in Figs. 2 and 3, as the residual plot of the former shows an apparent systematic deviation from the theory. However, as for the values of the diffusion coefficients, it is noticed that a significant discrepancy still exists between theory and experiment, even in the case of an asymmetric rotor approximation. The experimental result is D_x: D_y: D_z=728:1:179 (from Table 2), while the theoretical value (calculated from the ratio of friction coefficients with the slipping boundary condition given in the theoretical section) is 31:1:1.4, provided that the inertia limit ρ_0 is neglected. Thus, the ideal slipping boundary condition seems to be unsatisfactory for perylene; in other words, the 'partially slipping (or sticking)' boundary condition is preferable. In the time region of our experiment, the solvent may not be regarded as a mere continuous medium; also, the discrete chemical structure of the molecules becomes significant: such small-scale molecular motions should be interpreted by jump kinetics[1] rather than by the diffusion model.

The Use of End-Loading Technique for the Sample Preparation of Organic Powders in X-Ray Powder Diffractometry

Kazuaki NAKATA* and Yoshito TAKAKI
Department of Physics, Osaka Kyoiku University, Tennoji-ku, Osaka 543
(Received August 14, 1986)

Synopsis. The end-loading technique in preparing samples for X-ray powder diffractometry is found to be an effective method for reducing preferred orientation effects of organic powder samples.

In X-ray powder diffractometry, many attempts have been made to reduce the preferred orientation of mineral powders.[1-5] The end-loading technique has been found to be a simple and effective method for preparing the powder samples.[1] In this paper we report that the end-loading technique is very useful for reducing preferred orientations of organic powders. The powder samples examined in this study are those of benzamide,[6] benzoic acid,[7] α-form of pyrazinecarboxamide (PCA),[8] A-form of DL-2-aminobutyric acid (DL-ABA)[9] and DL-norleucine (DL-NL),[10] in which the latter two samples show marked tendency to orient on the 001 preferred orientation plane. In these samples, a quantitative examination of the preferred orientations in benzamide and PCA powders prepared by the normal (back-loading) technique have been made by Nakata et al.[11] Therefore, it is very interesting to compare the preferred orientations occurring in powders prepared by the normal and the end-loading techniques.

Experimental

The samples used in this study were ground by hand in an agate mortar. The specimen holder was constructed from a usual aluminum-holder by cutting away the end piece, by cementing a ground glass-slide onto the back and by covering the top surface with a glass-slide (see Fig. 2 of Niskanen[1]). The powder sample was then poured and packed in the holder by tapping it at the bottom.

All diffraction patterns taken by the normal and the end-loading techniques were obtained using a Rigaku Geigerflex (CN2013). The experimental conditions were: Cu $K\alpha$ radiation, a nickel filter, 0.5° divergence and 0.15 mm receiving slits, a scintillation detector and a scan speed of $1/2°(2\theta\ \mathrm{min}^{-1})$. Intensity measurements of the diffraction peaks were made by cutting out background-subtracted peak areas from each of the traces and weighing.

Results and Discussion

The degree of randomness of oriented powder particles is given by[11]

$$R_0 = \frac{\Sigma|I_{obs}-I_{ran}|}{\Sigma|I_{ran}|} \quad (1)$$

where I_{obs}'s are the observed intensities and I_{ran}'s, which are calculated from F_o's obtained by single-crystal work, are the intensities from a sample with completely random orientation.

In order to assess the effect of the end-loading technique on the reduction of preferred orientation, we took two diffraction patterns from the same grounded powder using the normal and the end-loading techniques. Table 1 lists the R_0 values for the

Table 1. R_0 Values and Preferred Orientation Parameters in the Powder Samples Prepared by the Normal and the End-Loading Techniques

a) α-form of pyrazinecarboxamide. b) A-form of DL-2-aminobutyric acid. c) DL-norleucine. d) Linear absorption coefficients for Cu$K\alpha$ radiation.

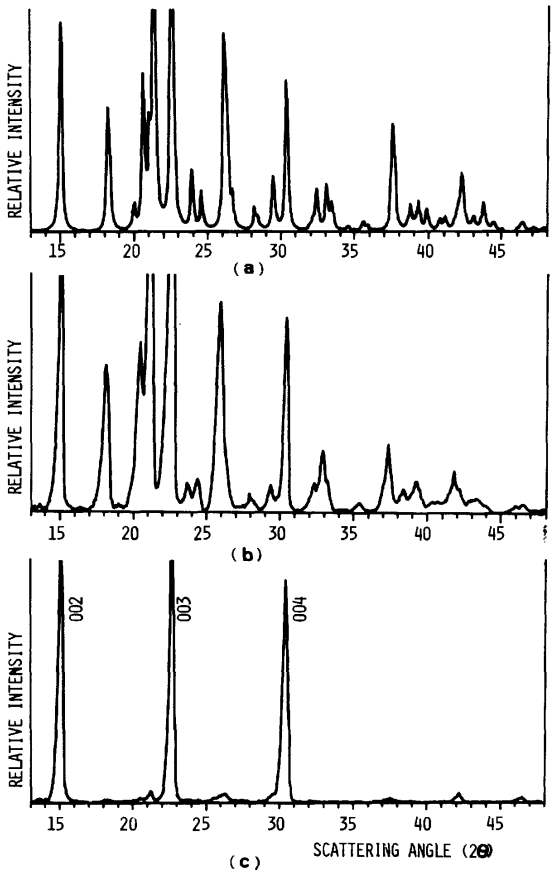

Fig. 1. The observed and calculated diffraction patterns of DL-ABA. a) An "ideal" pattern calculated from I_{ran}.[9] b) The observed pattern taken by the end-loading technique. c) The observed pattern taken by the normal technique.

powder samples of benzamide,[6] benzoic acid[7] and PCA[8] obtained by the two different techniques. Comparing R_0 values in Table 1, it is seen that the end-loading technique effectively reduces the R_0 values to under one-half of the values of the normal technique.

Further, we examined the usefulness of the end-loading technique using the samples of DL-ABA[9] and DL-NL.[10] These powder particles have a habit of thin plate with well developed (001) faces. It therefore show a marked tendency to orient on the 001 preferred orientation plane. Figure 1 shows the observed diffraction patterns of DL-ABA taken by the normal and the end-loading techniques. For comparison, an "ideal" pattern calculated from I_{ran}[9] of DL-ABA[12] is also shown in Fig. 1(a).

As can be seen in Fig. 1, the observed pattern taken by the normal technique yields only the $00l$ diffraction peaks, whereas the pattern taken by the end-loading technique is in good agreement with the "ideal" pattern. The R_0 values obtained by the normal and the end-loading techniques are 1.14 and 0.19, respectively (Table 1). Similarly, a marked decrease of the R_0 value can also be seen in the case of DL-NL; the R_0 values for the powder samples prepared by the normal and the end-loading techniques are 0.74 and 0.28, respectively.

Here, we examine quantitatively the above reduction of preferred orientations using the method of Nakata et al.[11] Table 1 lists the preferred orientation parameters, C_i and P_i, for the powders prepared by the normal and the end-loading techniques. The relative volumes of the domains, V_i, in the powder are also listed in Table 1, where a domain is defined as a collection of particles having the same preferred orientation plane or axis.[11] Comparing V_i values, one can see that the V_0 values of the end-loading technique are much larger than those of the normal technique, indicating that the randomly oriented domains are effectively increased in volume by the use of the end-loading technique. Further it is interesting that most of the preferred orientation planes or axes observed in the powders prepared by the normal technique disappear, and the different planes or axes with small relative volumes appear in the powders prepared by the end-loading technique.

The drastic reduction of preferred orientation effects described above may be explained as follows: Since the end-loading technique applies no pressure normal to the surface of the specimen, the powder particles except for those very near to the surface are not effected by the glass-slide. Furthermore, since organic substances generally have small absorption coefficients for X-rays (Table 1), the organic powder in a holder may allow considerable penetration of the X-ray beam. From the above results, the degree of preferred orientation of powder particles is estimated to be much lower than that of the normal technique.

In order to clarify the effect of absorption, we applied the normal and the end-loading techniques to inorganic powder samples gypsum[13] and olivine[14]; these samples have large absorption coefficients (see Table 1). The preferred orientation parameters, C_i and P_i, and the relative volumes of the domains, V_i, in these powders are listed in Table 1. As expected, no marked decrease in R_0 (and increase in V_0) can be seen in the powders prepared by the end-loading technique. In addition, the same preferred orientation plane or axis is found in both the powders prepared by the two techniques, and that the differences in V_i are rather small.

Consequently, we may say that the end-loading technique effectively minimizes the preferred orientations of organic powder samples, especially for those with low absorption coefficients.

Effects of Alkyl Chain Length on Molecular Interactions. II.[1] Complex Isomerism in the Alkyl *p*-Aminobenzoate–Picric Acid Systems

Atsushi TOGASHI and Yoshio MATSUNAGA*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received September 22, 1986)

Synopsis. While a combination of *p*-aminobenzoic acid and picric acid gives a yellow-colored salt by proton transfer, the esterification of the former component compound with methyl to octadecyl groups results in the formation of not only stable salts but also metastable charge-transfer complexes.

We earlier studied the charge-transfer complex formation in pyrene-*N*-alkyl-2,4,6-trinitroaniline systems.[1] The thermal stability of the orange-colored 1:1 complex between the hydrocarbon and unsubstituted 2,4,6-trinitroaniline is drastically decreased by *N*-alkylation. The *N*-octyl derivative and most of the higher homologs produce a single peritectic or a eutectic in the phase diagrams with pyrene, whereas red solids formed on rapid cooling of the melts are progressively stabilized with an increase of the alkyl chain length. Even a stable existence of the red-colored 1:1 complex can be achieved with the *N*-pentadecyl and *N*-heptadecyl derivatives. In the present paper, we compare the effects of alkyl chain length on charge-transfer and proton-transfer interactions operating in solid addition compounds between alkyl *p*-aminobenzoate and picric acid.

Experimental

Materials. Alkyl *p*-aminobenzoates were prepared by reactions between *p*-nitrobenzoyl chloride and appropriate alcohols and then by reduction with iron powder and dilute hydrochloric acid as described by Adams et al.[2] The alkyl groups employed and the melting points of the esters were as follows: methyl, 110.5 °C; ethyl, 89.5 °C; propyl, 76.5 °C; butyl, 59 °C; pentyl, 54.5 °C; hexyl, 62.5 °C; heptyl, 80.5 °C; octyl, 71.5 °C; nonyl, 73 °C; decyl, 79 °C; undecyl, 81 °C; dodecyl, 84.5 °C; tridecyl, 87.5 °C; tetradecyl, 89 °C; pentadecyl, 91 °C; hexadecyl, 89.5 °C; heptadecyl, 95 °C; octadecyl, 96 °C.

Measurements. The phase diagrams were determined using calorimetric curves recorded on a Rigaku Thermoflex differential scanning calorimeter during the process of heating and also by visual examination.[1]

Results and Discussion

The yellow-colored addition compound between *p*-aminobenzoic acid and picric acid has been characterized to be a salt on the basis of its vibrational spectrum according to Issa and El-Essawey.[3] The methyl ester forms only a 1:1 salt when it is combined with picric acid. As is shown in Fig. 1a, the phase diagram is dominated by the freezing point curve of the salt. The melting point is as high as 159 °C. The color changes from yellow to red upon fusion, indicating isomerization into a charge-transfer complex.[4] By rapid cooling solidification occurs without a color change. The melting point of this metastable phase is measurable (see a shaded circle in Fig. 1a). However, it is not clear whether the fusion is congruent or incongruent because the endothermic peak due to the fusion of this charge-transfer complex is followed by an exothermic peak due to the solidification to the stable salt. This temperature is close to the melting point of the corresponding 1,3,5-trinitrobenzene complex, 114—114.5 °C, reported by Sudborough and Beard.[5]

Figure 1b presents the phase diagram of the ethyl ester–picric acid system. This ester forms a congruently melting 1:1 salt and an incongruently melting 2:1 salt. The melting point is located at 128 °C and the peritectic point at 120 °C. The metastable red complex is obtainable by quenching of the melt at 50 mol%. The melting point of this complex is found at 104.5 °C and is significantly higher than that of the corresponding trinitrobenzene complex, 88 °C.[5] The vibrational spectrum of the 2:1 salt shows clearly the presence of both NH_2 and NH_3^+ groups. The color of specimens having the composition of about 2:1 mole ratio is deeper than

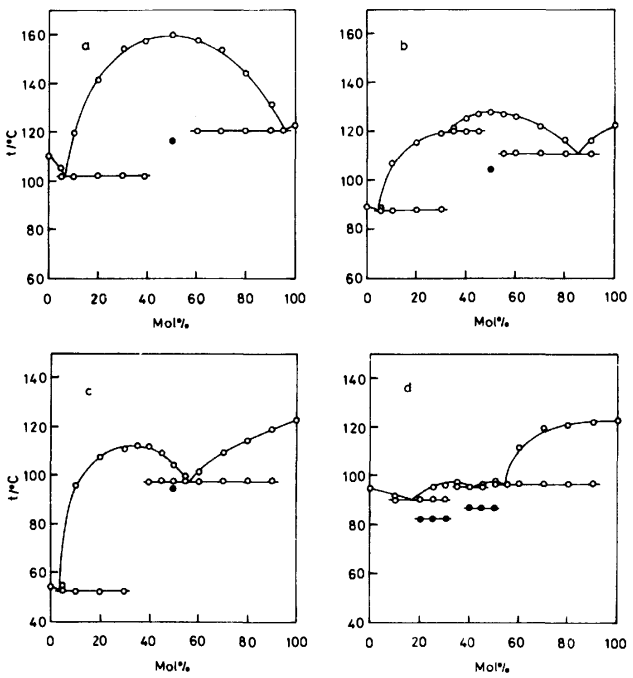

Fig. 1. Phase diagrams of the systems of picric acid with (a) methyl *p*-aminobenzoate, (b) the ethyl ester, (c) the pentyl ester, and (d) the heptadecyl ester. The shaded circles are the melting points of the metastable phase.

that of the 1:1 salt, suggesting a charge-transfer interaction between the donor molecule and the picrate anion.[6] The phase diagram of the propyl ester–picric acid system is of a type similar to that described above. The 1:1 salt melts at 114 °C and the 2:1 salt decomposes at 105.5 °C. The latter temperature is lower by 2 °C than the eutectic on the picric acid-rich side. Molten mixtures in the composition range from 50 to 80 mol% can form red solids on rapid cooling. The metastable phase melts at 89 °C regardless of the composition. The flatness over such a range may be the indication of incongruent melting of the charge-transfer complex. When the butyl ester is employed as a base, the thermal stabilities of the 1:1 and 2:1 salts are reversed. The former salt melts incongruently at 109.5 °C and the latter melts congruently at 112 °C. The charge-transfer complex melting at 97 °C is observed at 45 and 50 mol%.

The phase diagrams obtained empolying the pentyl and hexyl esters show only 2:1 salts. The red complex of the pentyl ester is found only at 50 mol% and melts at 94.5 °C (see Fig. 1c). In the case of the hexyl ester, the 2:1 salt melts at 101.5 °C and the red complex observed in the range from 40 to 50 mol% melts at 90.5 °C. These charge-transfer complexes are possibly of the 1:1 mole ratio.

Simple salts appear again in the systems with the heptyl ester and with the higher homologous members. The octyl, undecyl, and pentadecyl esters are exceptions. The diagrams given by the heptyl, nonyl, decyl, dodecyl, tridecyl, and tetradecyl esters are of the same type as that shown in Fig. 1b. However, the eutectic on the picric acid-rich side is located near 55 mol% because of the low thermal stability of the 1:1 salt. The heptyl ester is unique in the sense that two metastable complexes with distinctly different melting points are formed with picric acid. The one appearing in the range from 10 to 20 mol% melts at 71 °C and the other in the range from 40 to 50 mol% melts at 91 °C. The metastable picric acid complex of the tetradecyl ester is found in an exceptionally wide composition range, namely, from 40 to 80 mol%. The 1:1 salt melts congruently at 99 °C and the charge-transfer complex melts at 90.5 °C. In this combination, the difference in the melting point is the smallest among the similar examined combinations.

The octyl, undecyl, and pentadecyl esters produce phase diagrams which bear a certain similarity to that given in Fig. 1c. The thermal stability of the congruently melting 2:1 salts is lower than that of the salt derived from the pentyl ester. It must be noted that the stability is enhanced by an increase in the alkyl chain length; that is, 92 °C with the octyl ester salt, 95 °C with the undecyl ester salt, and 97.5 °C with the pentadecyl ester salt. The metastable charge-transfer complex is also stabilized in the same order; namely, 67.5 °C in the octyl ester complex, 82.5 °C in the undecyl ester complex, and 88 °C in the pentadecyl ester complex.

The phase diagrams given by the hexadecyl, heptadecyl, and octadecyl esters are exemplified by

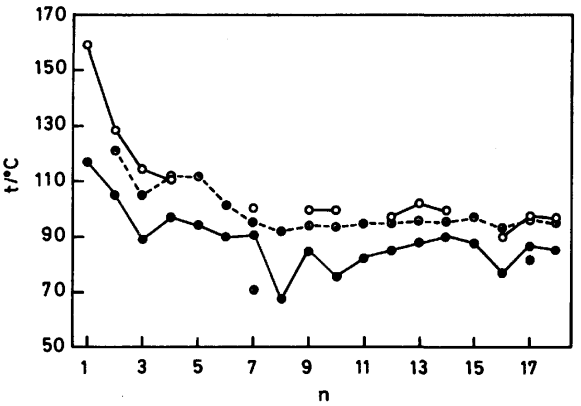

Fig. 2. Congruent or incongruent melting points of the 1 : 1 salt (○), of the 2 : 1 salt (⊙), of the 1 : 1 charge-transfer complex (●), and of the 2 : 1 complex (◑) plotted against the ester alkyl chain length (n).

that of the second member shown in Fig. 1d. Both the 1:1 and 2:1 salts melt congruently. The relative thermal stability of the 1:1 salt is increased by an increase in the alkyl chain length. While the 1:1 salt of the hexadecyl ester melts at 90.5 and the 2:1 salt at 93 °C, the former salt of the octadecyl ester melts at 97 °C and the latter at 95 °C. Note that the two salts in Fig. 1d have approximately the same melting points. Although two metastable charge-transfer complexes melting at 82.5 and 87 °C, respectively, are formed with the heptadecyl ester, the other two esters give only one kind. The hexadecyl ester complex melts at 77.5 °C and the octadecyl ester complex at 85.5 °C. They appear in the composition range covering 50 mol%.

The congruent or incongruent melting points of the 1:1 and 2:1 picrates and also of the 1:1 charge-transfer complex are plotted against the ester alkyl chain length in Fig. 2. The thermal stability of the 1:1 salt represented by open circle diminishes drastically in the first four members. The salt appears intermittently among the higher members. The charge-transfer complex shown by shaded circle is formed with all the esters examined. Contrary to the case of pyrene-*N*-alkyl-2,4,6-trinitroaniline reported earlier,[1] the complexes are similarly colored. Therefore, it is difficult to determine whether the complexes of the lower homologous members are different in the nature from those of the higher members or not. When the 1:1 salt and the 1:1 complex are obtainable with a given ester, the two products may be called isomorphs. The charge-transfer complexes found in the present series are metastable without exception. Nevertheless, one can see that the longer the alkyl group, the thermal stability of the complex comes closer to that of the salt.

The ethyl to octadecyl esters produce 2:1 salts with picric acid. The melting point is least dependent upon the ester alkyl group and is almost constant from the octyl ester to the octadecyl ester. It may be emphasized that complex isomerism is observed even in the 2:1 composition range when the heptyl and heptadecyl esters are the donor compounds.

Kinetics of the Solubilization of Pinacyanol Chloride into a Complex between Bovine Serum Albumin and Sodium Dodecyl Sulfate

Kunio TAKEDA,* Tohru OHTAWA, Kazuaki HACHIYA, and Koichiro AOKI†
Department of Applied Chemistry, Faculty of Technology, Okayama University of Science, 1-1 Ridai-cho, Okayama 700
(Received July 19, 1986)

Synopsis. The stopped-flow method was applied to the solubilization of pinacyanol chloride into a complex formed by bovine serum albumin and sodium dodecyl sulfate. The rate constant of the solubilization became larger with the step-by-step formation of the complex and finally attained values compatible with those for the pure surfactant micelle.

Various studies have been made of the interaction of bovine serum albumin (BSA) with sodium dodecyl sulfate (SDS).[1-3] However, most attention has been focused on both the binding nature of the surfactant and the conformational change in the protein. Few attempts have been made to find the nature of the bound surfactant ions themselves. The solubilization phenomenon is believed to be convenient for investigating the bound state of the surfactants on the protein. Equilibrium studies have been done on the solubilization of several dyes into the protein-surfactant complex,[4,5] but kinetic studies have not yet been done on this phenomenon.

Pinacyanol chloride is well-known as a useful dye for determining spectrophotometrically the critical micelle concentration (cmc) of anionic surfactants such as SDS.[6,7] In the present study, the solubilization of the pinacyanol chloride into the BSA–SDS complex was studied by the stopped-flow method. This paper shows a kinetic similarity of the complex to the SDS micelle in the solubilization of the dye.

Experimental

The sources of crystalline BSA and SDS have been described elsewhere.[8] The cmc of SDS by the electrical conductance method was 8.3×10^{-3} M at 25 °C (1 M=1 mol dm^{-3}).[8] The BSA concentration was determined spectrophotometrically using $E^{1\%}_{1cm}=6.8$ at 280 nm.[9] The protein concentration was kept at 1.0×10^{-5} M. The pinacyanol chloride was purchased from the Eastman Kodak Co. The absorption coefficient of the dye was assumed to be 88,000 at 600 nm at concentrations around 1.0×10^{-5} M.[7] The dye concentration was kept at 1.0×10^{-5} M. We previously experienced that the presence of an electrolyte accelerated the fading of the dye somewhat.[10-12] Thus, all the measurements were carried out in a non-buffered system, using water prepared by passing redistilled water through a mixed-bed ion-exchange column.[13]

The absorbance measurements were carried out with a Hitachi double-beam spectrophotometer, Model 220. Measurements of stopped-flow and rapid-scanning were made with a stopped-flow apparatus, RA-401, of the Union Giken Co. equipped with a kinetic data processor, RA-415. All the measurements were made at 25 °C.

Results and Discussion

The color change of pinacyanol chloride from red to blue occurs in a concentration range not very far from the cmc of the anionic surfactant.[6,7] The blue color above the cmc is characterized by two absorption bands, α- and β-bands at 607 and 562 nm, and the red color below the cmc, by the γ-band around 480 nm. The γ-band is due to the aggregate formed by the dye and the dodecylsulfate ion, while the α- and β-bands are attributable to the solubilization of the dye into the micelle.[6] (In the absence of the surfactant, the α- and β-bands appear at 600 and 550 nm respectively, probably because of the monomer-dimer equilibrium of the dye,[6] while the γ-band does not appear). Figure 1 shows the SDS concentration dependences of the absorbance at these three bands in the absence (dotted curve) and in the presence of BSA. In a SDS solution without the protein, the absorbance at the γ-band disappeared at SDS concentrations higher than 7 mM, which is slightly below the cmc. Simultaneously, the absorbances at α- and β-bands began to increase at this concentration. However, the absorbances at the α- and β-bands began to increase at much lower SDS concentrations in the presence of BSA than in the absence of BSA. This is probably due to the solubilization of the dye into the complex formed by BSA and SDS.[4,5] In the presence of BSA, the

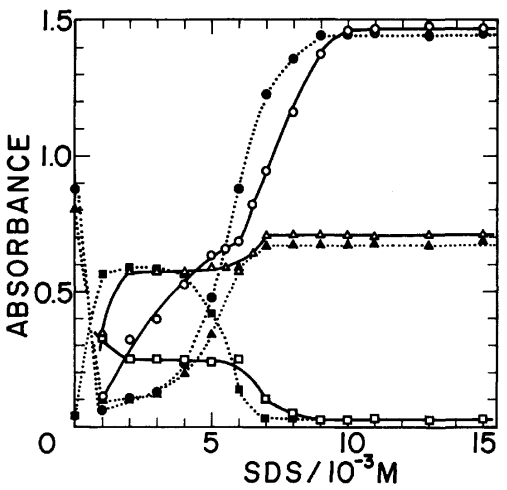

Fig. 1. The SDS concentration dependences of absorbance of pinacyanol chloride at α-(○, ●), β-(△, ▲), and γ-bands (□, ■) in the absence (dotted curve) and the presence (solid curve) of 1.0×10^{-5} M BSA.

absorption at α-band increased step-by-step until 10 mM SDS, making a clear break around 6 mM SDS, as is shown in Fig. 1. The helical structure of BSA is unfolded step-by-step by SDS both in water[13] and in a dilute phosphate buffer.[8] The major structural change is completed at 6 mM SDS in water,[13] where the break of absorbance appears at the α-band in Fig. 1.

Rapid-scanning experiments were made in the wavelength region between 450 and 620 nm, using the stopped-flow mixer to mix the dye solution with the BSA–SDS complex solution. When the pinacyanol was solubilized into the BSA–SDS complex, the absorption increased with time around the α-band in the rapid-scanning measurements, as seen in the inserted figure in Fig. 2. Since the dye has been considered to be solubilized in a state of the dye-surfactant aggregate, the mechanism of the solubilization may be expressed as follows:[12]

$$\mathrm{DS} + \mathrm{M} \longrightarrow \mathrm{MDS}, \quad (1)$$

where DS is an aggregate formed by the dye and SDS and M is one of the solubilizing sites of the micelle or of the surfactant-protein complex. The formation of the DS aggregate has been considered to be very fast compared with the time range of this work.[12] The stopped-flow measurements were made at the α-band in order to follow the solubilization of the DS aggregate. The solubilization of the dye into the SDS micelle has been observed as a pseudo-unimolecular reaction.[12] The first-order plot gave a good linear relationship also in the present kinetic study of the solubilization of the dye into the surfactant-protein complex.[14] These findings suggest that fairly many DS aggregates are solubilized into one micelle or into one surfactant-protein complex. It is generally accepted in the application of the stopped-flow method that only forward reactions can be observed in most of the time range in which the absorbance changes appreciably with the progress of the reaction.[15] Therefore, Reaction (1) can be rewritten as the following pseudo-unimolecular reaction;

$$\mathrm{DS} \xrightarrow{k} \mathrm{MDS} \quad \text{(in excess of M)} \quad (2)$$

where k is the forward rate constant.

The SDS concentration dependence of the rate constant, k_{complex}, of the solubilization of pinacyanol into the complex is shown in Fig. 2, together with the SDS concentration dependence of the rate constant, k_{micelle}, of the solubilization of the dye into the SDS micelle. The rate constant, k_{complex}, increased step-by-step with the increase in the SDS concentration, while k_{micelle} did so gradually and monotonously. On the other hand, since the BSA–SDS complexes are formed in a concentration range of SDS where the concentration of unbound surfactants is lower than the cmc, ordinary micelles do not exist in the total SDS concentrations below about 10.3 mM (=8.3 mM (cmc) of unbound SDS + about 2 mM SDS bound to 1.0×10^{-5} M BSA).[8,13] Therefore, the step-by-step change in k_{complex} below 10 mM SDS must reflect the nature of the BSA–SDS complex. In other words, k_{complex} depends on the binding number of SDS to the protein. After the sudden increase in the k_{complex}, it gave a plateau in spite of the increase in the binding number, as may be seen in Fig. 2. It appears that k_{complex} begins to increase again when a binding of about 120 SDS is attained; this can be said in view of the binding isotherm of the BSA–SDS system in a dilute phosphate buffer of an ionic strength of 0.014[8] and the dependence of the residue ellipticity, $[\theta]_{222}$, on the SDS concentration in the phosphate buffer[8] and in water.[13] Finally, it increased sharply and approached the values of k_{micelle}. However, it is not certain whether the increase in k_{complex} in the narrow concentration range of 8—11 mM SDS means the solubilization of the dye into the complex with a larger number of SDS or into the SDS micelle itself. The present results indicate that the more the surfactants bind to the protein, the faster the solubilization occurs.

Recently, a single relaxation has been found in the same BSA–SDS system by means of the pressure-jump method with conductivity detection.[13] The relaxation time of the BSA–SDS system approaches those in the SDS micelle system, just as the k_{complex} value becomes compatible with the k_{micelle} value with an increase in the SDS concentrations. This relaxation has been considered to be due to the partial breakdown and reformation of the complex.[13] The surfactant monomers participate in the partial breakdown and reformation of the complex, while pinacyanol participates in the present solubilization process.

It is worth noting that a similarity of the protein-surfactant complex to the surfactant micelle also appears in these kinetic phenomena. Both the kinetic phenomena reflect the fact that the bound states of dodecyl sulfate ions on the BSA molecule are very close to those of the SDS micelle.

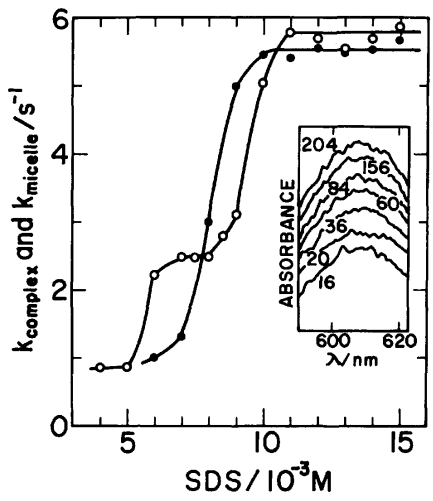

Fig. 2. The SDS concentration dependences of k_{complex} (○) and k_{micelle}(●). The rapid scanning spectra around α-band are inserted in this figure. The numerical values designate time in millisecond unit (including dead time) after mixing dye and complex solutions.

Derivation of the Quantity of Catenanes in Equilibrium Polymeric Mixtures

Kazumi SUEMATSU and Haruo OGURA
Pharmaceutical Science, Kitasato University, Shirogane, 5-9, Minato-ku, Tokyo 108
(Received July 12, 1986)

Synopsis. A theoretical consideration is introduced regarding catenation in an equilibrium mixture. The quantity of catenane from rings i and j is expressed as $[\phi(i, j)]\simeq\Phi PE\ [Ri][Rj]$. The symbols Φ, P, and E denote the catenation probability, the overlapping probability and the penetration probability. At θ points or above a critical monomer concentration C^*, $E\simeq1$. Then, the above equation leads to the analogous form reported previously.[1]

Some theoretical considerations have been reported concerning catenation from two cyclic substances.[1,5] However, there has not been any report that theoretically preestimated the catenane distribution in an equilibrium system; this should be practically important for a characterization of such extensively established industrial materials as polyester, Nylon and polyoxymethylene, or should be one of the guiding principles for challenging a non-bonding polymer gel, one of the most attractive materials that have never been realized. This paper is presented with the aim of preestimating the yields of catenanes in equilibrium, the fundamental idea of which is based on cyclization[2] and entanglement theorems.[3]

Theory

Consider a polymer solution with the Flory distribution D in a volume V and mark half of the randomly chosen molecules red. Then, each will have the equal distribution D and the following equilibria will be established.

A: red.

$$C_{i+x} \rightleftarrows C_i + C_x$$
$$C_i \rightleftarrows R_i$$

B: white.

$$C_{j+y} \rightleftarrows C_j + C_y$$
$$C_j \rightleftarrows R_j$$

Here, C denotes a linear chain, subscripts i, j, x, and y the arbitrary numbers of repeating units and R a cyclic molecule. Then, some ratio of R_i and R_j will encounter and entangle to form a catenane $\phi(i, j)$. Thus, the above equilibria can be rewritten as the following equilibria:

$$C_{i+x} \overset{K_1}{\rightleftarrows} C_i + C_x, \tag{1}$$
$$C_{j+y} \overset{K_2}{\rightleftarrows} C_j + C_y, \tag{2}$$
$$C_i \overset{K_3}{\rightleftarrows} R_i, \tag{3}$$
$$C_j + R_i \overset{K_4}{\rightleftarrows} (C_jR_i), \tag{4}$$
$$(C_jR_i) \overset{K_5}{\rightleftarrows} \phi(i, j), \tag{5}$$

Eqs. 1—5 reduce to

$$C_{i+x} + C_{j+y} \overset{K}{\rightleftarrows} C_x + C_y + \phi(i, j), \tag{6}$$

Equation 1 represents the process in which fragment C_x is released from a permitted angle $\delta\omega$ in a small volume v_s constrained around the terminal atom of fragment C_i to the whole volume V of the system. Assuming that the probabilities of lying in v_s and $\delta\omega$ are independent,† the entropy change of K_1 can be written[2]

$$e^{\Delta S/R} = \left(\frac{1}{\sigma_C}\right)(4\pi V/\delta\omega v_s N_A), \tag{7}$$

where σ_C is the number of the reaction sites of the chain if those have an equal chemical reactivity.

Let ΔH_1 be the enthalpy change of K_1. Then, the equilibrium constant of Eq. 1 is written

$$K_1 = \left(\frac{1}{\sigma_C}\right)(4\pi V/\delta\omega v_s N_A)e^{-\Delta H_1/RT}. \tag{8}$$

Similarly, we have

$$K_2 = \left(\frac{1}{\sigma_C}\right)(4\pi V/\delta\omega v_s N_A)e^{-\Delta H_2/RT}. \tag{9}$$

Equation 3 represents the process that one end of C_i is confined within the angle $\delta\omega$ in volume v_s around another terminal atom to form a new chemical bond. Let σ_{Ri} be the number of the reaction sites of the ring and $W(0)$ the probability that the end-to-end distance is zero. Then, as already pointed out, the equilibrium constant is expressed as

$$K_3 = \left(\frac{\sigma_C}{\sigma_{R_i}}\right)(\delta\omega/4\pi)W_i(0)v_s e^{-\Delta H_3/RT}. \tag{10}$$

Equation 4 represents the process in which C_j and R_i overlap one another under the condition of the phantom molecules. Let this probability be $P(i, j)$. $P(i, j)$ is given

$$P(i, j) = \frac{4\pi S^3 N_A}{3V}, \tag{11}$$

where S is the radius of the overlapping volume.

Now, let $E(i, j)$ be the probability for one molecule

† This is a reasonable assumption since the chain must be sufficiently long (30 bonds or more) for the catenation to occur.[1]

to move into the sphere of another molecule. Then, E should be equal to the ratio of the probability lying inside the sphere to that lying outside the same. If we define ψ as the volume fraction of segments per unit volume, the probaility that all of a given sequence of x lattice sites are available for occupancy by another chain molecule is $(1-\psi)^x$. Then, E is

$$E(i,j) = \left(\frac{1-\psi_i}{1-\psi_o}\right)^x, \tag{12}$$

where subscripts i and o denote the inside of the molecule and the outside, respectively. Note that ψ is not the real volume, but the excluded volume of the segment.[4] Hence, we may let

$$K_4 = P(i,j)\cdot E(i,j) = (4\pi S^3 N_A/3V\cdot[(1-\psi_i)/(1-\psi_o)]^x. \tag{13}$$

Equation 5 represents the process in which the one end of C_j meets the another end, accompanying the interlocking with R_i. If the probability for the interlocking, Φ, is independent of the cyclization probability, applying the expression in K_3 we have

$$K_5 = \Phi\cdot(\sigma_C/\sigma_{R_j})\cdot(\delta\omega/4\pi)\cdot W_j\cdot(0)\cdot v_s\cdot e^{-\Delta H_5/RT} \tag{14}$$

The product of K_1—K_5 gives the equilibrium constant of Eq. 6:

$$K = \prod_k K_k = \Phi\cdot[V^2\cdot P\cdot E/\sigma_{R_i}\cdot\sigma_{R_j}\cdot N_A^2]\cdot W_i(0)\cdot W_j(0)\cdot e^{-\Delta H/RT}, \tag{15}$$

where $\Delta H = \sum_k \Delta H_k$.

Also, the following relationship is established in the solution:

$$K = \frac{[C_x]\cdot[C_y]\cdot[\phi(i,j)]}{[C_{i+x}]\cdot[C_{j+y}]} \tag{16}$$

$$= p^{-(i+j)}[\phi(i,j)]. \tag{17}$$

For a high-molecular-weight mixture, p(the extent of reaction of linear species)$\approx$*1 and* $\Delta H\approx 0$ are approximated. Substituting Eq. 15 to Eq. 17, then we obtain

$$[\phi(i,j)] \approx \Phi\cdot P\cdot E\cdot\{V^2/\sigma_{R_i}\cdot\sigma_{R_j}\cdot N_A^2\}\cdot W_i(0)\cdot W_j(0). \tag{18}$$

Rearranging Eq. 18, we have an expression for the quantity of $\phi(i,j)$:

$$[\phi(i,j)] \approx \Phi\cdot P\cdot E\cdot\{V\cdot W_i(0)/\sigma_{R_i}\cdot N_A\}\times\{V\cdot W_j(0)/\sigma_{R_j}\cdot N_V\} \tag{19}$$

$$\equiv \Phi\cdot P\cdot E\cdot[R_i][R_j] \quad \text{(mole/V)}. \tag{19'}$$

The physical meaning that Eq. 19 suggests is easy to

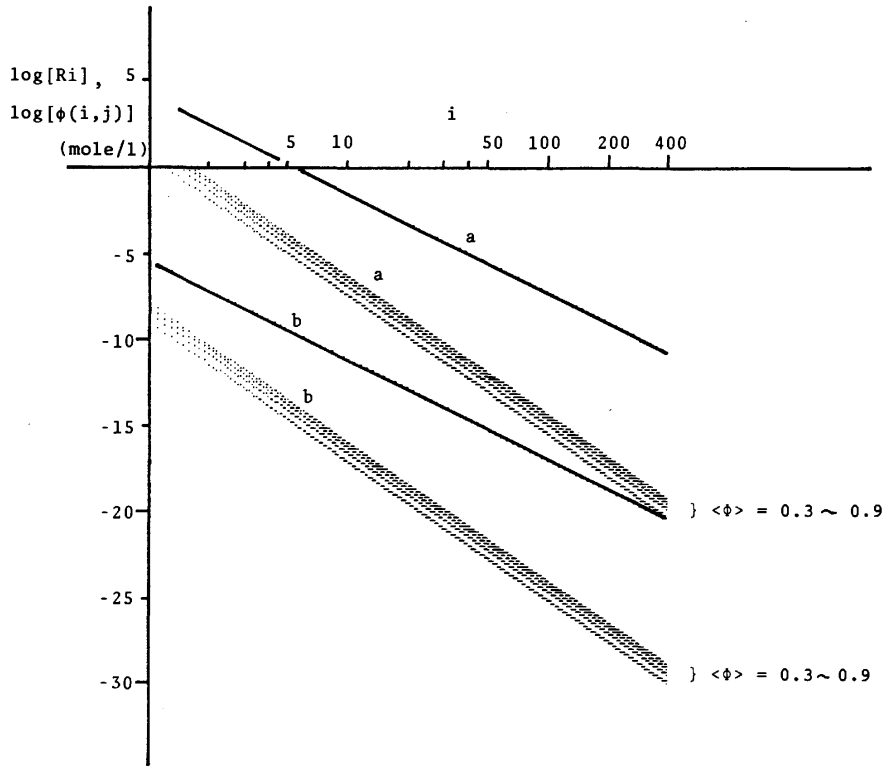

Fig. 1. Catenane distribution (broken lines) from $i=j$ rings compared to ring distribution (solid lines) for Kuhn segment number.
a: Kuhn segment length, $l=2$. b: $l=50$. Each four curves from $\langle\Phi\rangle=0.3$ to 0.9 (step 0.2) are drawn.

Table 1. The Equilibrium Constant of the Catenation between 186 DNA and $\lambda_c I_{857}$DNA

Experimental	Wang & Schwartz	Suematsu & Ogura
$K=2.2\times10^{-13}$ cm^3	7.8×10^{-13}	3.5×10^{-13}

comprehend: i.e., the quantity of the catenane $\phi(i, j)$ is proportional to the product of the concentrations of cyclic i and j-mer, and the probability for the entanglement of both.

In terms of the weight fraction $X_{\phi(i,j)}$, Eq. 19 leads to

$$X_{\phi(i,j)} \simeq \Phi PE\frac{(i+j)}{i\cdot j}C_0X_{Ri}X_{Rj}, \tag{20}$$

where C_0 is the initial monomer concentration.

Discussion

As is clear from Eq. 20, the probability that catenation occurs is proportional to the product of the cyclization probabilities of rings i and j, suggesting that catenanes will be formed only with a very low probability, especially for larger i and j.

Letting n be the segment number, since P varies roughly as $n^{3/2}$ and X_{Rn} as $n^{-3/2}$, $X_{\phi(i,j)}$ must decrease in proportion to $n^{-5/2}$. Thus, the catenane from macrocyclics may be neglected (Fig. 1).

E may be unity in θ points or above the critical concentration C^* defined by $\psi_{in}=\psi_{out}$. Finally, Eq. 19 is reduced to a conclusion analogous to previous reports[1,5]:

$$[\phi(i,j)] \simeq \Phi\left(\frac{4}{3}\pi S^3\frac{N_A}{V}\right)[R_i][R_j]. \tag{21}$$

One credible example has been reported for catenation; i.e., dimeric catenanes between 186 DNA and $\lambda_c I_{857}$DNA are formed to yield $K=2.2\times10^{-13}$ cm^3.[5]

Adopting as a value of s the sum of the radiuses of gyration of the rings and $\langle\Phi\rangle\simeq0.4-0.6$, a better agreement between theory and experiment is found (Table 1) (see Appendix I).

Appendix I

For an extreme rigid(thin) chain, the catenation probability is given by[3]

$$\Phi \cong A\exp(-\alpha s^3).$$

A and α are the constants for the given Kuhn segment number. Then, the average value of Φ may be written

$$\langle\Phi\rangle = \int_0^s 4\pi s^2\Phi ds \Big/ \int_0^s 4\pi s^2 ds.$$

A numerical calculation yields $\langle\Phi\rangle\cong0.33$ for $n=20$, 0.37 for $n=40$, 0.41 for $n=60$ and 0.43 for $n=80$ (increasing slowly with chain length). It seems to be in a rough linear relationship to the logarithm of the segment number in this range, i.e.,

$$\langle\Phi\rangle \sim \mathrm{Log}\, n.$$

Thus, $\langle\Phi\rangle\cong0.4$—0.6 is a good approximation for $n\cong200$ in DNA.

Synopsis. The crystal structure of bis[μ-(1,5-diamino-3-pentanethiolato)-*N*,*N'*, μ-S]-dinickel(II) bromide was determined by the single-crystal X-ray diffraction method. The complex has a thiolate-bridged binuclear structure, with a dihedral angle 145.2° between the two coodination planes.

Recently, 1,5-diamino-3-pentanol (Hdpl) was synthesized by our group,[1] and shown to form essentially planar binuclear complexes with copper(II) and nickel(II), whose skeletal structure illustrated in Fig. 1 was evidenced by X-ray crystal structure analysis for $Cu_2(dpl)_2Cl_2\cdot 3H_2O$[2] and by diamagnetism for the nickel complex.[1] On the analogy of the above examples, 1,5-diamino-3-pentanethiol (Hdpet) is expected to be a planar binucleating ligand. In fact, the nickel complexes formulated as $Ni_2(dpet)_2X_2$ (X=Br, ClO_4, NO_3, BPh_4) were all diamagnetic implying the planar binuclear structure similar to that shown in Fig. 1.[3] However, in thiolate-bridged binuclear nickel(II) complexes so far known, the two coordination planes are all bent at the S–S bond with dihedral angle of 82.3—110.2° and in our knowledge no planar ring has ever been reported.[4-7] Thus, we have determined the crystal structure of $Ni_2(dpet)_2Br_2$ by X-ray analysis to see whether the two coordination planes assume a coplanar or bent structure.

Experimental

Reddish brown crystals of $[Ni_2(dpet)_2]Br_2$ were prepared by the method previously reported.[3] A crystal with dimensions of 0.08×0.38×0.54 mm was used for the X-ray analysis. The unit-cell parameters and intensities were measured on a Rigaku AFC-5 automated four-circle diffractometer with graphite-monochromated Mo $K\alpha$ radiation (λ=0.71073 Å).

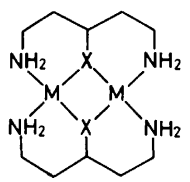

Fig. 1. The binuclear complex cation of dpl or dpet (M=Cu(II) or Ni(II); X=O or S).

Crystal Data: $Ni_2(C_5H_{13}N_2S)_2Br_2$, F.W.=543.65, monoclinic; $P2_1/m$; a=10.072(7), b=18.188(12), and c=5.162(5) Å; β=103.20(7)°; V=920.6(13) Å^3; D_m=1.92, D_c=1.96 g cm^{-3}, Z=2, μ(Mo $K\alpha$)=65.7 cm^{-1}.

The intensity data were collected by the 2θ—ω scan technique with a scan rate of 3° min^{-1}. Three standard reflections were monitored every 50 reflections, and their intensities showed a good stability. A total of 3372 reflections with $2\theta<60°$ were collected. The intensity data were corrected for the Lorentz-polarization effects and for absorption. Independent 1739 reflections with $|F_o|\geq 3\sigma(|F_o|)$ were considered as "observed" and were used for the structure analysis.

The structure was solved by the direct method. Refinement was carried out by the block-diagonal least-squares method. The weighting scheme $w=[\sigma^2_{count}+(0.015|F_o|)^2]^{-1}$ was employed. Hydrogen atoms were inserted in their calculated positions and fixed at the positions. The final discrepancy factors were $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|=0.053$ and $R'=[\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2}=0.052$. Final difference Fourier map was featureless. All the calculations were carried out on the HITAC M-680H computer at the Computer Center of the Institute for Molecular Science by the use of the UNICS-III, *MULTAN* 78, and ORTEP programs.[8] The final positional and thermal parameters with their estimated standard deviations are given in Table 1. The coordinates and isotropic temperature factors of the hydrogen atoms, the anisotropic thermal parameters of the non-hydrogen atoms, and the F_o—F_c tables have been deposited as a Document No. 0000 at the Office of the Editor.

Table 1. Fractional Positional Parameters (×10^4) and Thermal Parameters of Non-Hydrogen Atoms with Their Estimated Standard Deviations in Parentheses

Results and Discussion

The crystal structure consists of discrete binuclear cations, $[Ni_2(dpet)_2]^{2+}$, and bromide ions. A perspective view of $[Ni_2(dpet)_2]^{2+}$ is shown in Fig. 2. The cation has a symmetry plane along the S(1)-S(2) bond. As has been anticipated, the complex ion has a thiolate-bridged binuclear structure and each nickel ion is in a square-planar N_2S_2 environment. The Ni-S and Ni-Ni distances are normal as Ni(II)-S(thiolate) and Ni(II)-N(amine) bonds.[4-7,9] Each NiS_2N_2 coordination unit is virtually planar, but the two planes are bent at the S(1)-S(2) bond with a dihedral angle of 145.2°, making a contrast with the binuclear metal complexes of dpl.[2] Structural parameters of the present complexes are listed in Table 2 together with those of other thiolate-bridged binuclear nickel(II) complexes.[4-7] As seen in Table 2, the present complex assumes the largest values in the Ni-Ni distance, Ni-S-Ni angle, and the dihedral angle of the two coordination planes, τ. This should be ascribed to the steric requirement of dpet which favors the coplanar structure as supposed from the molecular model study and the planar structure of the analogous complex, $Cu_2(dpl)_2Cl_2 \cdot 3H_2O$. It should be noted here that the dihedral angle, τ, of the present complex is between those of other thiolate-bridged complexes (82.3—110.2°) and 180°. This is understandable as a compromise of the two opposing tendencies, i.e., the steric requirements 1) of the ligand to form a planar structure (τ=180°) and 2) of the thiolate sulfur to form Ni-S bonds with a Ni-S-Ni angle smaller than 90° as observed for several complexes so far reported giving rise to a remarkable bending of the two coordination planes such as τ=82.3—110.2°.

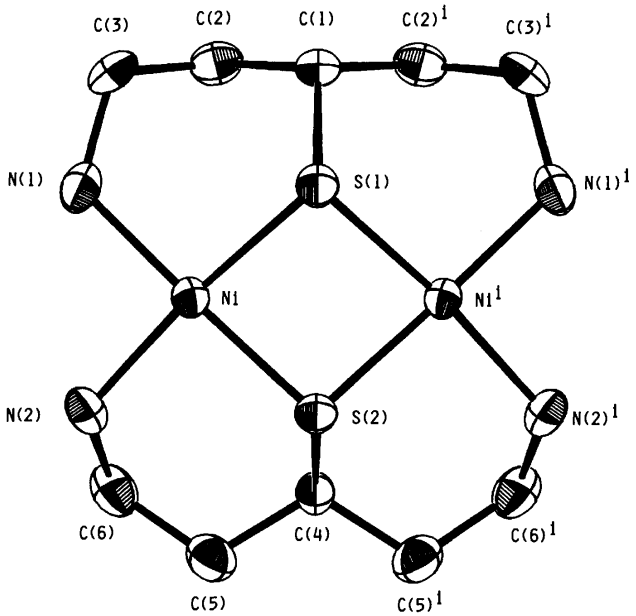

Fig. 2. A perspective view of $[Ni_2(dpet)_2]^{2+}$ ion. Selected bond lengths (l/Å) and angles (ϕ/°) are: Ni-Ni¹ 3.134(2), Ni-S(1) 2.180(2), Ni-S(2) 2.169(2), Ni-N(1) 1.950(6), Ni-N(2) 1.958(6); Ni-S(1)-Ni¹ 91.9(1), Ni-S(2)-Ni¹ 92.5(1), S(1)-Ni-S(2) 81.36(9), S(1)-Ni-N(1) 96.6(2), S(2)-Ni-N(2) 91.8(2), N(1)-Ni-N(2) 90.3(2). Superscript (i) refers to the equivalent position (x, 1/2−y, z).

The six-membered chelate ring, Ni-S(1)-C(1)-C(2)-C(3)-N(1), adopts a boat conformation where Ni and C(2) are −0.76 and −0.64 Å from the least-squares plane of the remaining four atoms, whereas the chelate ring, Ni-S(2)-C(4)-C(5)-C(6)-N(2), adopts a chair form where Ni and C(5) are −1.13 and 0.73 Å from the mean plane of the remaining four atoms.

The bromide ions are placed in the vicinity of the amino groups of dpet forming hydrogen bonds (Br···N(1)(x, y+1, z−1) 3.452(5), Br···N(1)(x, y+1, z) 3.474(6) Å).

The authors wish to express sincere thanks to Dr. Koshiro Toriumi of Institute for Molecular Science for his helpful advices and discussion.

Preparation and Characterization of the Dicobalt(III) Complexes Containing Bridging Di-μ-hydroxo Ligands

Tomoharu AMA,* Hiroshi KAWAGUCHI, and Takaji YASUI
Department of Chemistry, Faculty of Science, Kochi University,
Akebono-cho, Kochi 780
(Received September 13, 1986)

Synopsis. Three dicobalt(III) complexes, $[(L)Co(\mu\text{-}OH)_2Co(NH_3)_4]^{2+ \text{ or } +}$ (L=edda, $(gly)_2$, or nta), were newly prepared and their structures were assigned on the basis of absorption, ^1H NMR, and CD spectral data. Each of them has a structure in which the chromophores of two different types are bridged with two hydroxo ligands and with two hydrogen bonds between carboxyl and amino groups. These three complexes are stable for several days in aqueous solutions.

Although there have been many reports on the preparation and reactivity of dicobalt(III) complexes containing two bridging hydroxo ligands, only a few studies have reported on complexes in which two different cobalt(III) chromophores were bridged with the two hydroxo.[2,3] Complexes of this type are so important for investigations concerning the interaction between two cobalt atoms that a sure method to prepare a number of complexes of this type is required. In previous work,[4] we succeeded in preparing three isomers of $[(en)(gly)Co(\mu\text{-}OH)_2Co(en)(gly)]^{2+}$[1,4] in aqueous solutions. A modification of the method, which is described below, makes it possible to prepare many dicobalt complexes containing two bridging hydroxo. Two of the newly prepared complexes have chiral structures. The CD spectra of the optically resolved isomers will be reported.

Experimental

Preparation of Complexes. $[(edda)Co(\mu\text{-}OH)_2Co(NH_3)_4]Cl_2$ (1): In 20 cm³ of water, $K[Co(edda)(CO_3)]\cdot H_2O$ (1.7 g)[5] was dissolved and acidified with 60% perchloric acid (2 cm³). Separately, $[Co(NH_3)_4(CO_3)]ClO_4$ (1.5 g) were suspended in 20 cm³ of water and acidified with 60% perchloric acid (2 cm³). The two solutions were mixed with each other. The pH of the mixed solution was adjusted to 8.0 with a 2 mol dm⁻³ NaOH solution and stirred for 40 min in a water bath at 50 °C. The reacted solution was cooled to room temperature and then neutralized using a 2 mol dm⁻³ HCl solution and filtered. The filtrate was chromatographed on an SP-Sephadex column (4.7 cm×50 cm, K^+ form) and the adsorbed band was eluted with a 0.2 mol dm⁻³ KCl solution. The eluate from the dark-red band was evaporated to about 10 cm³ and the KCl deposited was filtered off. To the filtrate, methanol was added in order to eliminate any excess KCl; then, solution was filtered. A crude complex of $[(edda)Co(\mu\text{-}OH)_2Co(NH_3)_4]Cl_2$, obtained by adding ethanol to the filtrate, was optically resolved by the following procedure without further purification.

The crude complex (ca. 100 mg) was dissolved in 20 cm³ of water and the solution was poured onto an SP-Sephadex column (4.7 cm×50 cm, K^+ form). The adsorbed band was developed with a 0.1 mol dm⁻³ $K_2Sb_2(d\text{-tart})_2$ solution. The development was repeated on the same column using a micropump until the adsorbed band completely separated into two dark-red bands. The earlier and later bands denoted (−) and (+) CD signs at 574 nm, respectively. Each band was eluted out with 0.1 mol dm⁻³ $K_2Sb_2(d\text{-tart})_2$; then, each eluate was concentrated to a small volume under reduced pressure. To the concentrated solution, methanol was added to deposit $K_2Sb_2(d\text{-tart})_2$. After the deposited $K_2Sb_2(d\text{-tart})_2$ was filtered off, the filtrate was evaporated almost to dryness in order to exclude methanol. The obtained residue was dissolved in a small amount of water and reloaded on a short QAE-Sephadex column (3 cm×5 cm, Cl^- form). The solution eluted with water was concentrated to a small volume. An optically active isomer was obtained by adding methanol to the concentrated solution, which was recrystallized from water by adding methanol. Found for the $(+)^{CD}_{574}$ isomer: C, 14.84; H, 5.48; N, 17.07%. Calcd for $[(edda)Co(\mu\text{-}OH)_2Co(NH_3)_4]Cl_2\cdot H_2O = C_6H_{26}N_6O_7Cl_2Co_2$: C, 14.92; H, 5.43; N, 17.40%.

$[(gly)_2Co(\mu\text{-}OH)_2Co(NH_3)_4]S_2O_6$ (2): This complex was prepared and resolved by a method similar to that employed for **1**, except for the use of $K[Co(gly)_2(CO_3)]$[6] instead of $K[Co(edda)(CO_3)]$. The dithionate of this complex was obtained by adding a saturated solution of $Na_2S_2O_6$ to the aqueous solution (saturated) of the chloride. Found for the $(+)^{CD}_{572}$ isomer: C, 8.28; H, 4.78; N, 14.39%. Calcd for $[(gly)_2Co(\mu\text{-}OH)_2Co(NH_3)_4]S_2O_6\cdot 3H_2O = C_4H_{28}N_6O_{15}S_2Co_2$: C, 8.25; H, 4.85; N, 14.43%.

$[(nta)Co(\mu\text{-}OH)_2Co(NH_3)_4]Cl$ (3): In 12 cm³ of 15% perchloric acid, $[Co(NH_3)_4(CO_3)]ClO_4$ (1.5 g) was dissolved. Separately, $K_2[Co(nta)(CO_3)]$ (2.0 g) was dissolved in 12 cm³ of perchloric acid. The two solutions were mixed to each other. The pH of the solution was adjusted to 7.5 with a 2 mol dm⁻³ NaOH solution, and heated in a water bath (60 °C) for 30 min. After cooling to room temperature, the solution was diluted to 200 cm³ with water and poured onto an SP-Sephadex column (4.5 cm×50 cm, K^+ form). After the column was swept with 1 dm³ of water, the adsorbed band was developed with a 0.2 mol dm⁻³ KCl solution. A solution eluted from the dark-violet band (major band) was evaporated to about 10 cm³. White precipitates, which became deposited upon the addition of methanol (100 cm³) to the solution, were filtered off. To the filtrate, 100 cm³ of methanol was added once more and the methanolic solution was allowed to stand overnight in a refrigerator in order to obtain crude **3**, which was recrystallized from water by adding methanol. Found: C, 15.08; H, 4.92; N, 14.49%. Calcd for $[(nta)Co(\mu\text{-}OH)_2Co(NH_3)_4]Cl\cdot 2H_2O = C_6H_{24}N_5O_{10}ClCo_2$: C, 15.03; H, 5.04; N, 14.60%.

Results and Discussion

Structural Assignments of the Complexes. On the basis of the following five reasons, **1** was assigned to the structure given in Fig. 1 (A). (1) The column chromatogram gave a single band which was not a mixture of cationic and anionic complexes but was a cationic complex. (2) The elemental analysis data indicates that the NH_3/edda ratio is 4. (3) The absorption spectrum shows a characteristic charge-

transfer band arising from the Co(μ-OH)$_2$Co moiety at ca. 34000 cm^{-1} (Fig. 2), as [Co$_2$(μ-OH)$_2$(en)$_4$]$^{4+}$ and [Co$_2$(μ-OH)$_2$(NH$_3$)$_8$]$^{4+}$[8,9] show. (4) The first absorption band is very broad, suggesting that this complex contains chromophores of two different types. (5) In the ^{1}H NMR spectra (Fig. 3), the methylene protons of two glycinate rings (G-rings) in edda appeared as a quartet signal, suggesting that the two G-rings are equivalent in chemical environments; the edda takes an α-cis chelation form[10] (Fig. 3).

The structure illustrated in Fig. 1 (B) is proposed for the **2** on the basis of an arrangement similar to that described above. The possiblity that the Co(gly)$_2$(μ-OH)$_2$ moiety in this complex has a *trans(N)* structure can be ruled out for the following reasons. (1) The absorption spectrum of **2** is quite similar to that of **1**, having a *cis(N)* structure. (2) If the Co(gly)$_2$(μ-OH)$_2$ moiety has a *trans(N)* structure, it is expected that **2** exhibits a band (shoulder) at ca. 16000 cm^{-1}.[11,12] No such shoulder band appears, as shown in Fig. 2. Therefore, this moiety does not have a *trans(N)*-[Co(N)$_2$(O)$_4$] chromophore but has *cis(N)*. (3) Di(μ-hydroxo)dicobalt(III) complexes prefer a structure that is stabilized by two hydrogen bonds (N-H···OCO-) between the two cobalt chromophores (vide post). These hydrogen bonds can be formed in the proposed *cis(N)* structure but not in a *trans(N)* structure.

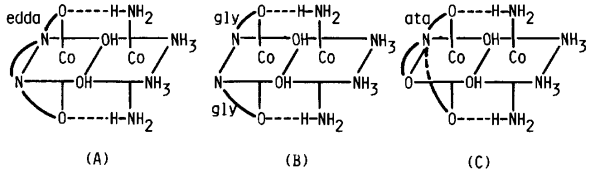

Fig. 1. Structures of the prepared complexes: (A) [(edda)Co(μ-OH)$_2$Co(NH$_3$)$_4$]$^{2+}$ (**1**), (B) [(gly)$_2$Co(μ-OH)$_2$Co(NH$_3$)$_4$]$^{2+}$ (**2**), and (C) [(nta)Co(μ-OH)$_2$Co(NH$_3$)$_4$]$^+$ (**3**).

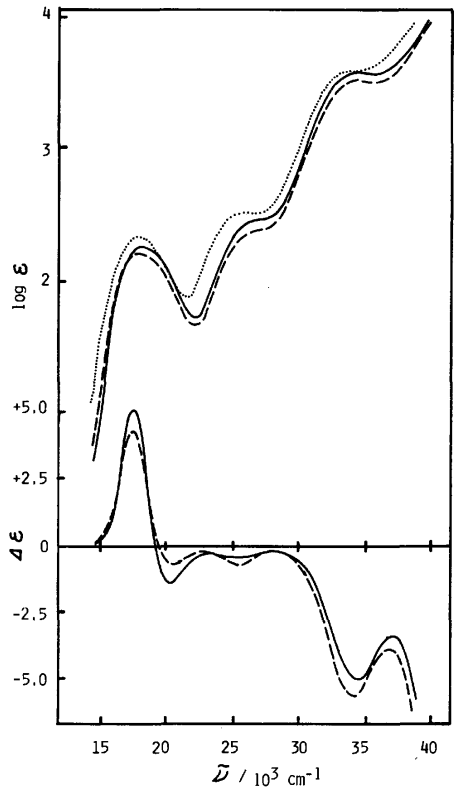

Fig. 2. Absorption and CD curves of the complexes: **1** (——), **2** (----), and **3** (·····).

The structure illustrated in Fig. 1 (C) is proposed for the **3** on the basis of the following: (1) There are three G-rings in the nta. Two of them appear as a quartet signal in the ^{1}H NMR spectra, showing that their chemical environments are equivalent, and one of them appears as a singlet signal. This result shows that there is a symmetrical plane on one of the G-rings and that the nta coordinates to Co(III) as a quadridentate. (2) The elemental analysis data indicates that the NH$_3$/nta ratio is 4. (3) The absorption spectrum of **3** shows a characteristic charge-transfer band at ca. 33900 cm^{-1} with an intensity similar to those of **1** and **2**, suggesting the di-μ-hydroxo structure. Though some geometrical isomers are possible for [(edda)Co(μ-OH)$_2$Co(NH$_3$)$_4$]$^{2+}$ and [(gly)$_2$Co(μ-OH)$_2$Co(NH$_3$)$_4$]$^{2+}$, only one geometrical isomer (achiral) is possible for this [(nta)Co(μ-OH)$_2$Co(NH$_3$)$_4$]$^+$.

CD Spectra. The CD spectra of the optically active complexes are illustrated in Fig. 2. $(+)^{CD}_{574}$ **1** and $(+)^{CD}_{572}$ **2** show quite similar CD patterns to each other. The absolute configuration around Co(gly)$_2$(μ-OH)$_2$ or Co(edda)(μ-OH)$_2$ moiety is assigned to Λ, because their main CD components in the first absorption band region are (+).[13]

A CD band ($|\Delta\varepsilon|$=4—5) was observed in the charge-transfer band region (ca. 34000 cm^{-1}) in each of the resolved complexes. However, the $|\Delta\varepsilon|$ values are about one half of that observed for the optically active isomer of the [(en)(gly)Co(μ-OH)$_2$Co(en)(gly)]$^{2+}$ complex ($|\Delta\varepsilon|$=10.0).

Stability of the Complexes. Absorption spectral changes with time were measured for aqueous solutions of some di-μ-hydroxo complexes at 20 °C. Solutions of the present complexes showed no spectal change for several days, while that of [Co$_2$(μ-OH)$_2$(NH$_3$)$_8$]Br$_4$ showed an obvious change after one day. This result means that the present complexes are more stable than [Co$_2$(μ-OH)$_2$(NH$_3$)$_8$]$^{4+}$, suggesting that some stabilizing factors exist in the present complexes. Regarding an X-ray study of [Cr$_2$(L-

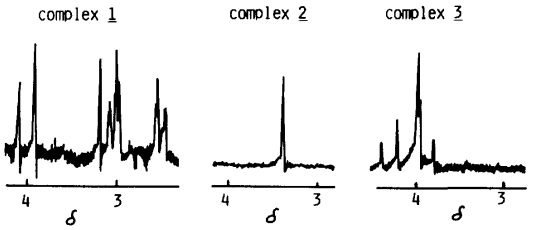

Fig. 3. ^{1}H NMR Spectra of the complexes.

pro)$_4$(μ-OH)$_2$], Oki and Yoneda[14] pointed out that the two intramolecular N–H···O hydrogen bonds (bridging two chromophores) stabilize the di-μ-hydroxo structure. Accordingly, it is reasonable to propose two hydrogen bonds as the stabilizing factor of the present complexes. It was not easy to prepare isomers having one or no hydrogen bonds, but it was easy to prepare some having two hydrogen bonds. This result agrees with that obtained for the isomers of [(en)(gly)Co$_2$(μ-OH)$_2$Co(en)(gly)]$^{2+}$,[4] suggesting that the hydrogen bond is important as one of the stabilizing factors.

(Received July 10, 1986)

Synopsis. Tetraammine(salicylamidato)cobalt(III) complexes, [Co()$(NH_3)_4$]X·$n$$H_2O$ (X: Cl, NO_3 and picrate), have been isolated and characterized by means of analytical, spectroscopic, and magnetic methods. The bond between the cobalt atom and the chelated ligand in the complex is expressed in the form of -$\bar{O}$-Co-$\bar{N}$-. The properties of the title complexes are intermediate between those of the tetraammine(salicylideneaminato)cobalt(III) complex, which has the -$\bar{O}$-Co-N- bond, and the tetraammine(salicylato)cobalt(III) complex, which has the -$\bar{O}$-Co-$\bar{O}$- bond.

The previous papers were concerned with the preparation and properties of many mixed-ligand ammine cobalt(III) complexes, such as the tetraammine(salicylideneaminato)cobalt(III) complexes, [Co()$(NH_3)_4$]X_2 (**A**),[2] the tetraammine-(8-quinolinolato)cobalt(III) complexes, [Co()-$(NH_3)_4$]X_2 (**B**),[3-5] the salicylato(triethylenetetramine)-cobalt(III) complexes, [Co()(trien)]X (**C**),[6] and the salicylaldehydato(triethylenetetramine)cobalt-(III) complexes, [Co()(trien)]X_2 (**D**).[7] The bonds between the cobalt atom and the chelated ligands in the complexes are expressed in the form of -$\bar{O}$-Co-N-, -$\bar{O}$-Co-$\bar{O}$-, and -$\bar{O}$-Co-O-. A few metal complexes for a -$\bar{O}$-Co-$\bar{N}$- bond were isolated, and the structure was confirmed by X-ray diffraction for the bis(glycylglycinato)cobaltate(III) ion, $[Co(gly\text{-}gly)_2]^-$.[8,9] However, no mixed-ligand ammine metal complex for a -$\bar{O}$-M-$\bar{N}$- bond has yet been reported, especially concerning its preparation and properties. The present paper deals with the preparation and properties of tetraammine(salicylamidato)cobalt(III) complexes, [Co()-$(NH_3)_4$]X (X: Cl, NO_3 and picrate); the properties of the complex are compared with those of two related complexes, **A** and **C**.

Experimental

Measurements. The IR spectra were recorded as potassium bromide disks with an IR-27G apparatus (Shimadzu). The visible absorption spectra were recorded with a Shimadzu UV-210 recording spectrophotometer. The electric conductivities of aqueous solutions were determined by the use of a conductometer, CM-30 (Shimadzu), at room temperature. The magnetic susceptibilities were measured by Faraday's method using a magnetic balance (Shimadzu) at room temperature. The NMR spectra were recorded with an R-40 apparatus (Hitachi) for ^1H and with an FX-60 apparatus (JEOL) for ^{13}C.

Preparation of Complexes. Tetraammine(salicylamidato)-cobalt(III) Chloride Hydrate (1): A 28% aqueous ammonia (30 cm^3) was added to an aqueous solution (20 cm^3) of $CoCl_2 \cdot 6H_2O$ (9.52 g, 40.0 mmol), and the mixture was stirred. To the solution was added slowly 6 mol dm^{-3} H_2O_2 solution (11 cm^3) in an ice bath. The color of the solution turned from brown to red. A methanol solution (60 cm^3) of salicylamide (5.48 g, 40.0 mmol) was added to the solution, and the solution was stirred at 55 °C for 22 h. Then, the solution was filtered, and the filtrate was concentrated with a rotary evaporator at 30—40 °C to ca. 50 cm^3. The precipitated salicylamide was filtered off. The filtrate was cooled to 0—5 °C. After 1 or 2 d, the precipitated russet crystals were filtered, washed with ethanol and ether, and recrystallized twice from water. Yield: 3.5 g (27.7%). Found: C, 26.57; H, 6.34; N, 22.13; Cl, 11.18%. Calcd for $CoC_7H_{19}N_5O_3Cl$ (MW 315.65): C, 26.64; H, 6.07; N, 22.19; Cl, 11.23%. Λ=113 S cm^2 mol^{-1} in water. IR spectrum: 850 cm^{-1} ($\rho_r(NH_3)_t$). ^1H NMR spectrum (cf. Fig. 1): δ 3.00 (3H, N(2)H_3), 3.15 (6H, N(1)H_3+N(4)H_3), 3.71 (4H, N(3)H_3+NH proton of salicylamidato), 6.6—7.9 (4H, ring protons of salicylamidato). ^{13}C NMR spectrum[2]: δ 120.0 (C-1), 165.8 (C-2), 117.1 (C-3), 133.2 (C-4), 123.7 (C-5), 130.7 (C-6), 171.7 (C-7). Decomp: 160 °C.

Tetraammine(salicylamidato)cobalt(III) Nitrate Hydrate (2): To an aqueous solution (9 cm^3) of **1** (1.0 g, 3.17 mmol) was added an aqueous solution (2 cm^3) of silver nitrate (0.538 g, 3.17 mmol). The mixture was stirred, and the precipitated silver chloride was filtered off. The filtrate was concentrated with a rotary evaporator at 30 °C to ca. 2 cm^3. The deposit of Complex **2** was filtered and recrystallized from water-methanol-ether (ca. 1:1:2) twice. Yield: 0.31 g (28.6%). Color: russet. Found: C, 24.78; H, 5.82; N, 24.72%. Calcd for $CoC_7H_{19}N_6O_6$ (MW 342.20): C, 24.57; H, 5.60; N, 24.56%. Λ=112 S cm^2 mol^{-1} in water. IR spectrum: 855 cm^{-1} ($\rho_r(NH_3)_t$). ^1H NMR spectrum: δ 2.97 (3H, N(2)H_3), 3.15 (6H, N(1)H_3+N(4)H_3), 3.70 (4H, N(3)H_3+NH proton), 6.6—7.9 (4H, ring protons) in 1.8 mol dm^{-3} D_2SO_4 solution. ^{13}C NMR spectrum: δ 120.0 (C-1), 165.8 (C-2), 117.0 (C-3), 133.2 (C-4), 123.6 (C-5), 130.7 (C-6), 171.7 (C-7) in D_2O. Decomp: 170 °C.

Tetraammine(salicylamidato)cobalt(III) Picrate (3): An aqueous solution of **1** (0.5 g, 1.58 mmol) was added to an

aqueous solution of picric acid (0.363 g, 1.58 mmol), and the mixture was stirred. The precipitated Complex **3** was filtered, washed with water and ethanol, and dried. Yield: 0.76 g (97.4%). Color: yellowish-brown. Found: C, 31.73; H, 4.23; N, 22.60%. Calcd for $CoC_{13}H_{19}N_8O_9$ (MW 490.28): C, 31.85; H, 3.91; N, 22.85%. IR spectrum: 840 cm^{-1} ($\rho_r(NH_3)_r$). ^1H NMR spectrum: δ 2.93 (3H, N(2)H_3), 3.10 (6H, N(1)H_3+N(4)H_3), 3.63 (4H, N(3)H_3+NH proton), 6.3—7.7 (4H, ring proton), 8.53 (2H, picrate proton) in DMSO-d_6. Absorption band in methanol: 550 nm (ε=170). Decomp: 220 °C.

Solubility. Complexes **1** and **2** are soluble in water, 35% hydrochloric acid, acetic acid, and DMSO, and are slightly soluble in methanol, but are insoluble in the common organic solvents. Complex **3** is soluble in tetrahydrofuran, DMSO and DMF, and is slightly soluble in water, alcohols, acetonitrile, and dioxane, but is insoluble in chloroform, dichloromethane, and diethyl ether.

5: $[Co(OOC\text{-}O)(NH_3)_4]Cl \cdot H_2O$

Results and Discussion

Tetraammine(salicylamidato)cobalt(III) chloride hydrate, (**1**), was isolated from a reaction mixture of $CoCl_2 \cdot 6H_2O$, 28% aqueous ammonia, 6 mol dm^{-3} H_2O_2, and salicylamide. The corresponding nitrate (**2**) and picrate (**3**) were prepared from **1** and silver nitrate or picric acid, respectively.

Complex **1** is a diamagnetic cobalt(III) complex of the low-spin type, judging from the magnetic susceptibility. The aqueous solution was neutral. The absorption spectrum in methanol showed four bands at 328, 378 (shoulder), 512 and 550 nm (Table 1). The absorption band at 378 nm is assigned to the charge-transfer band,[1-3] while the bands at 512 nm and 550 nm are assigned to the split first band.[10,11] In the ^1H NMR spectrum for **1** (Fig. 1), the multiplet signals at 6.6—7.9 ppm (4H) are assigned to the ring protons of the salicylamidato ligand, while the signals at 3.0—3.7 ppm (13H) are assigned to the ammine protons of $(NH_3)_4$ and the NH proton of the salicylamidato ligand. The assignment (cf. the Experimental section) of N(1)H_3, N(2)H_3, N(3)H_3, and N(4)H_3 for ammine protons was attempted by means of a consideration of the assignment of tetraammine(salicylideneaminato)cobalt(III) chloride hydrate, $[Co(HN{=}HC\text{-}O)(NH_3)_4]Cl_2 \cdot H_2O$ (**4**),[2] and tetraammine(salicylato)cobalt(III) chloride hydrate, $[Co(OOC\text{-}O)(NH_3)_4]Cl \cdot H_2O$ (**5**).[12]

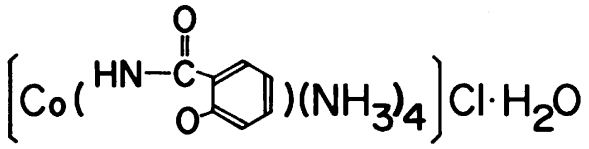
The structure of **1** is identified by means of the study of the absorption spectrum, the ^1H NMR spectrum, the IR spectrum, the property of the $-CONH_2$ group of salicylamide, the results of elemental analysis, and electric conductivity in an aqueous solution. The absorption spectrum showed two bands at 512 and 550 nm in the 450—550 nm region. The spectral feature is similar to that (two bands at 475 and 550 nm) for **4**, but is different from that (one band at 532 nm) of **5** (Table 1); i.e., the cobalt atom in **1** may be bonded to the oxygen and nitrogen of the chelated ligand. In the NMR spectrum, the chemical shifts (δ 3.00(3H), 3.15(6H), and 3.71(4H)) for ammine protons are close to those (δ 3.01(9H) and 3.83(3H)) for **4**, but different from those (δ 3.21(3H), 3.48(3H), and 3.78(6H)) for **5** (Fig. 1); i.e., the cobalt atom may also be bonded to the oxygen and nitrogen of the chelated ligand. The signal at 3.71 ppm due to the -NH proton of the

Table 1. Absorption Bands of Complexes **1**, **2**, **4**, and **5**

Complex No.	Absorption bands in methanol λ/nm (ε/cm^{-1} mol^{-1} dm^3)			
1	328 (3020)	378 sh (495)	512 (150)	550 (150)
2	327 (3160)	380 sh (510)	512 (150)	550 (150)
4[a]		378 (2750)	475 sh (185)	550 (110)
5	331 (3200)	380 sh (260)		532 (150)

a) Ref. 2.

salicylamidato ligand is very different from that at 9.91 ppm of **4**; i.e., the electronic state of the -NH proton must be different from that of the =NH proton. Further, the ring-proton signals of the chelated ligand are similar to those of **5** (Fig. 1), and the chemical shift (δ 7.73) for the H_6 proton is very close to that (δ 7.75) for **5**, but different from that (δ 7.35) for **4**; i.e., the electronic and steric effects between the oxygen and H_6 proton of the chelated ligand of **1** may be similar to those of carbonyl oxygen and the H_6 proton for **5**. The IR spectrum of **1** did not show the -C=N stretching signal in the 1620—1630 cm^{-1} region. In addition, the $-CONH_2$ group of salicylamide changes to -CONH because of the electron-attracting of the carbonyl group, such as glycylglycinecobalt(III) complexes.[8,9] Thus, Complex **1** is a tetraammine-(salicylamidato)cobalt(III) chloride hydrate, as is shown in Scheme 1. The structure is supported by the results of the elemental analysis and electric conductivity in an aqueous solution.



Scheme 1.

The properties of **1** are intermediate between those of Complexes **4** and **5**, judging from the results of ^1H NMR, their absorption spectra, and their stability is solutions. The ammine proton signals for **1** are close to those of **4**, but the ring-proton signals are close to those of **5** (Fig. 1). The spectral features in the 450—550 nm region for **1** are similar to those of **4**, but the ε at 550 nm is similar to that of **5** (Table 1). Complex **1** is more unstable than both Complexes **4** and **5** in a solution such as water and methanol, though the decomposition temperature (160 °C) of **1** is close to that of **4** (163 °C) and **5** (158 °C) in the solid state.

Ylide-Metal Complexes. XII.[1] The Preparation and Properties of Au, Be, Al, Ga, and In Complexes with Dimethylsulfoxonium Methylide

Yoshihisa YAMAMOTO
Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University,
Ishikari-Tobetsu, Hokkaido 061-02
(Received August 1, 1986)

Synopsis. The reaction of dimethylsulfoxonium methylide, $(CH_3)_2\overset{+}{S}(O)-\bar{C}H_2$ (**L**), with (triphenylphosphine)gold chloride, $(C_6H_5)_3PAuCl$, yields a new bis(dimethylsulfoxonium methylide)gold(I) chloride, $[(CH_3)_2S(O)CH_2AuCH_2S(O)(CH_3)_2]Cl$. The reaction of the ylide **L** with $BeCl_2$ yields a new compound of tetrakis(dimethylsulfoxonium methylide)beryllium dichloride, $[(CH_3)_2S(O)CH_2]_4BeCl_2$. The reactions of the ylide **L** with $AlCl_3$, $GaCl_3$, and $InCl_3$ yield new dimeric compounds of μ-chloro-bis[tris(dimethylsulfoxonium methylide)metal] pentachloride, $[\{(CH_3)_2S(O)CH_2\}_3M-Cl-M\{CH_2S(O)(CH_3)_2\}_3]Cl_5$ (M: Al, Ga, and In). All complexes are thermally stable.

In this series, we have been concerned with the preparation and properties of the metal complexes[2] with methylenetriphenylphosphorane, $(C_6H_5)_3\overset{+}{P}-\bar{C}H_2$. For the X-ray photoelectron spectroscopy measurements,[3] the phosphorane was an undesirable ylide, i.e., the separation for the carbanion in the coordinated phosphorane was difficult because the intensity ratio between carbanion and phenyl carbons was 1:18. Therefore, we surveyed sulfonium, phosphonium, and arsonium ylides, and found dimethylsulfoxonium methylide, $(CH_3)_2\overset{+}{S}(O)-\bar{C}H_2$ as a suitable one for XPS study. The intensity ratio between carbanion and methyl carbons is 1:2, and the metal complex with the sulfonium ylide has been reported only for a few compounds.[4] Thus, the present paper deals with the preparation and properties of bis(dimethylsulfoxonium methylide)-gold(I) chloride, $[(CH_3)_2S(O)CH_2AuCH_2S(O)(CH_3)_2]Cl$, tetrakis(dimethylsulfoxonium methylide)beryllium dichloride, $[(CH_3)_2S(O)CH_2]_4BeCl_2$, and μ-chloro-bis[tris(dimethylsulfoxonium methylide)metal] pentachloride, $[\{(CH_3)_2S(O)CH_2\}_3M-Cl-M\{CH_2S(O)(CH_3)_2\}_3]Cl_5$ (M: Al, Ga, In).

Experimental

Measurements. The ^1H NMR spectra were measured with R-40 (Hitachi) and XL-200 (Varian) NMR spectrometers. The electric conductivities of solutions were determined using a conductometric meter, CM-30 (Shimadzu).

Preparation of Ylide-Metal Complexes. Bis(dimethylsulfoxonium methylide)gold(I) Chloride (1): Dimethylsulfoxonium methylide[5] (**L**) was prepared by refluxing a mixture of trimethylsulfoxonium bromide (0.73 g, 4.22 mmol) and sodium hydride (0.11 g, 4.58 mmol) in dry tetrahydrofuran (20 cm³) under nitrogen until the evolution of hydrogen ceased. The product was cooled and filtered under nitrogen. To the resulting solution was added triphenylphosphine gold chloride (0.93 g, 1.88 mmol); the mixture was then stirred for 3 h at room temperature. The precipitated yellow complex was filtered, washed with dry pentane and dried under vacuum. Yield: 0.67 g (85.5%). Decomp: 165 °C. Found: C, 16.99; H, 3.70%. Calcd for $C_6H_{16}O_2S_2AuCl$ (MW 416.79) C, 17.29; H, 3.87%. Λ=100 S cm² mol⁻¹ in dry methanol at 20 °C. Λ=113 S cm² mol⁻¹ in water at 4 °C.

Tetrakis(dimethylsulfoxonium methylide)beryllium Dichloride (2): The tetrahydrofuran solution of the ylide was prepared from the mixture of trimethylsulfoxonium bromide (0.80 g, 4.62 mmol) and sodium hydride (0.12 g, 5.00 mmol) in dry tetrahydrofuran (20 cm³). To this solution was added beryllium dichloride (0.08 g, 1.00 mmol). The mixture was stirred for 5 d at room temperature. The precipitated white complex was filtered, washed with pentane and dried under vacuum. Yield: 0.45 g (88.8%). Decomp: 151 °C. Found: C, 31.85; H, 7.20%. Calcd for $C_{12}H_{32}O_4S_4BeCl_2$ (MW 448.59) C, 32.13; H, 7.19%. Λ=71 S cm² mol⁻¹ in dry methanol at −50 °C.

μ-Chloro-bis[tris(dimethylsulfoxonium methylide)aluminium] Pentachloride (3): The tetrahydrofuran solution of the ylide was prepared from the mixture of trimethylsulfoxonium bromide (0.78 g, 4.51 mmol) and sodium hydride (0.13 g, 5.42 mmol) in dry tetrahydrofuran (15 cm³) under nitrogen. Aluminium trichloride (0.15 g, 1.12 mmol) was added to the solution. The mixture was stirred for 3 d at room temperature. The precipitated white complex was filtered under nitrogen, washed with pentane and dried under vacuum. Yield: 0.68 g (61.5%). Decomp: 142 °C. Found: C, 26.11; H, 6.28%. Calcd for $C_{18}H_{48}O_6S_6Al_2Cl_6$ (MW 819.68) C, 26.38; H, 5.90%. Λ=608 S cm² mol⁻¹ in water at 5 °C. Λ=130 S cm² mol⁻¹ in dry methanol at −50 °C.

μ-Chloro-bis[tris(dimethylsulfoxonium methylide)gallium] Pentachloride (4): Gallium trichloride (0.20 g, 1.13 mmol) was added to the tetrahydrofuran solution of the ylide which was prepared from the mixture of trimethylsulfoxonium bromide of 0.78 g (4.51 mmol) and sodium hydride (0.13 g, 5.42 mmol) in dry tetrahydrofuran (15 cm³) under nitrogen. The mixture was stirred for 1 d at room temperature. The precipitated white complex was filtered, washed with pentane under nitrogen, and dried under vacuum. Yield: 0.71 g (57.4%). Decomp: 138 °C. Found: C, 23.68; H, 5.47%. Calcd for $C_{18}H_{48}O_6S_6Ga_2Cl_6$ (MW 905.16) C, 23.89; H, 5.35%. Λ=135 S cm² mol⁻¹ in dry methanol at −50 °C.

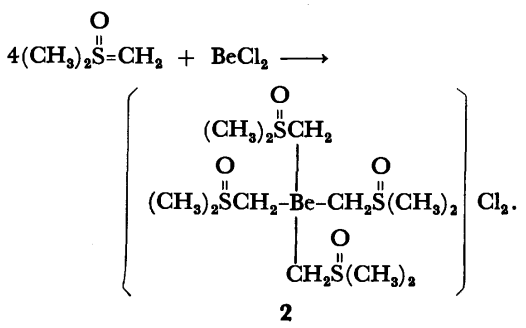
μ-Chloro-bis[tris(dimethylsulfoxonium methylide)indium] Pentachloride (5): Complex **5** was prepared from a reaction mixture of indium trichloride (0.16 g, 0.72 mmol) and a tetrahydrofuran solution of the ylide which was prepared from the mixture of trimethylsulfoxonium bromide (0.50 g, 2.89 mmol) and sodium hydride (0.08 g, 3.33 mmol) in dry tetrahydrofuran (15 cm³) under nitrogen. After 3 d at room temperature, the precipitated white complex was filtered, washed with pentane, and dried. Yield: 0.62 g (72.5%). Decomp: 160 °C. Found: C, 21.65; H, 4.86%. Calcd for $C_{18}H_{48}O_6S_6In_2Cl_6$ (MW 995.32) C, 21.72; H, 4.86%. Λ=100 S cm² mol⁻¹ in dry methanol at −50 °C.

Results and Discussion

Gold Complex. Bis(dimethylsulfoxonium methylide)gold(I) chloride (**1**) was prepared from the reaction of dimethylsulfoxonium methylide (**L**) and (triphenylphosphine)gold chloride, $(C_6H_5)_3PAuCl$. Complex **1** is slightly soluble in alcohols, DMSO, and water, but insoluble in common organic solvents such as acetone, benzene, and ether.

The ^1H NMR spectrum of **1** showed a singlet signal for the methylene group at 3.03 ppm and a singlet signal for methyl groups at 3.52 ppm in a ratio of 2:6 in CD_3OD as is shown in Table 1. The chemical shift of the methylene group is at a lower field than that of **L** (Table 1). This property is similar to those of metal complexes[2] with methylenetriphenylphosphorane, e.g. $[(C_6H_5)_3PCH_2\text{-}M\text{-}CH_2P(C_6H_5)_3]Cl_2$, M: IIB group metals.[2c] Thus, the ylide in complex is bonded to the gold atom through the carbanion donor atom.[6] Complex **1** has a free anion according to the molar conductance (cf. Experimental section). Then, the compound is a $[(CH_3)_2S(O)CH_2AuCH_2S(O)(CH_3)_2]Cl$, in which the cation has a linear configuration. The elemental analysis of **1** agreed with the proposed structure.

Beryllium Complex. Tetrakis(dimethylsulfoxonium methylide)beryllium dichloride (**2**) was prepared from a reaction mixture of dimethylsulfoxonium methylide (**L**) and $BeCl_2$. Complex **2** is soluble in methanol and slightly soluble in ethanol, but insoluble in chloroform, dichloromethane, DMSO, DMF, and water. The ylide is bonded to the beryllium atom through the carbanionic donor atom judging from the NMR spectral results (Table 1). Two coordination geometries for the compound are considered to be possible: a tetrahedral configuration of monomeric,[7] dimeric,[8] or polymeric[9] or a trigonal bipyramidal configuration of monomeric,[10] dimeric,[11] or trimeric.[12] The elemental analysis for **2** agreed with the composition of L_4MCl_2, i.e., the structure can not be a tetrahedral of dimeric or polymeric and a trigonal configuration. Complex **2** has free anions according to molar conductance. Thus, we suggest that the structure of **2** is a monomeric tetrahedron:



2

Aluminium, Gallium, and Indium Complexes. μ-Chloro-bis(dimethylsulfoxonium methylide)metal(Al (**3**), Ga (**4**), In (**5**)) pentachloride were prepared from a reaction mixture of dimethylsulfoxonium methylide (**L**) and MCl_3 (M: Al, Ga, In), respectively. Complexes **3**—**5** are slightly soluble in DMSO, DMF, methanol and water, but insoluble in chloroform, dichloromethane, and ether. Gallium complex **4** and indium complex **5** are unstable in water at 5 °C, giving the corresponding salt, $[(CH_3)_3S{=}O]Cl$ (**6**). The ylide is bonded to the metal atoms, judging from the NMR spectral results (Table 1). The elemental analysis of **3**—**5** agreed with the composition of L_3MCl_3. From the elemental analysis, four structures for the complexes are considered to be possible: a trigonal planar configuration of monomeric, $[L_3M]Cl_3$, a trigonal bipyramidal configuration of monomeric, $[L_3MCl_2]Cl$, a tetrahedral configuration of monomeric, $[L_3MCl]Cl_2$ and a tetrahedral configuration of dimeric, $[L_6M_2Cl]Cl_5$. The structure of $AlCl_3$, $GaCl_3$ and $InCl_3$ is known to be the bridge structure[13] by chlorines. In addition, the organoaluminium chlorides, bromides and iodides are generally dimeric. The most significant feature of the structure of methylaluminium dichloride, which has been determined by X-ray crystallography,[14] is that the dimer is held together through bridging atoms. Complexes **3**—**5** have free anions according to the molar conductance. Thus, we suggest that the structure of **3**—**5** comprises dimers bridged by chlorine and a metal with a tetrahedral coordination.

The Crystal and Molecular Structure of Bis(dibenzylamine)bis(thiocyanato)-cadmium(II), $Cd(SCN)_2\{(C_6H_5CH_2)_2NH\}_2$

Masahiro TANIGUCHI* and Akira OUCHI
Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received October 2, 1986)

Synopsis. The crystal and molecular structure of the title complex was determined by means of a single-crystal X-ray diffraction technique. A crystal of $CdC_{30}H_{30}N_4S_2$, F. W.=623.13, is triclinic, with a space group $P\bar{1}$, a=11.284(2), b=11.404(2), c=5.974(1) Å, α=93.31(2), β=98.37(1), γ=71.84-(1)°, U=722.6(2) Å^3, Z=1, D_m=1.42(3) D_x=1.43 Mg m^{-3}, and μ(Mo $K\alpha$)=9.17 cm^{-1}. The cadmium(II) atom is hexa-coordinated, being ligated with two thiocyanato(SCN) sulfur atoms as well as two SCN and two dibenzylamine nitrogen atoms, where the respective pairs of the same kinds of atoms are all in a *trans*-configuration. All cadmium(II) atoms are lined along the c-axis and the side-by-side metal atoms are doubly bridged by SCN ions.

It has already been found that many Lewis base(L) adducts of cadmium(II) thiocyanate, $Cd(SCN)_2L_2$ have chain structures in which respective side-by-side metal atoms are bridged by two thiocyanate (SCN) ions. Among them, in the cases of 2-imidazolinethione,[1] 1*H*-1,2,4-triazole,[2] and 3-methylpyridine adducts,[3] the planes of the side-by-side eight-membered rings by two cadmium(II) and six atoms of two SCN ions between them in the chain are parallel. On the other hand, in the cases of 2-methylpyridine,[3] 4-methyl-pyridine,[4] and tri(*p*-tolyl)phosphine adducts,[5] two kinds of planes in different directions appear alternately. Moreover, the coordination positions of the respective ligating atoms around the cadmium(II) atoms are not the same in respective complexes, although all of them, except the tri(*p*-tolyl)phosphine adduct, are in octahedral geometry. In cases of the thiocyanatocadmates(II), it was found that the chain structures bridged by SCN ions change, depending on the kinds of the counter cations. Especially in cases of salts of relatively large cations (such as rubidium and cesium) they are in complicated network structures.[6] Therefore, some special structure complexes may be found if some massive ligands are used as the additional Lewis base. From such an expectation, this time we synthesized the dibenzylamine adduct; its crystal and molecular structures were determined by the single-crystal X-ray diffraction method.

Experimental

Synthesis of Bis(dibenzylamine)bis(thiocyanato)cadmium-(II). Cadmium(II) thiocyanate (1.14 g, 5 mmol) was dissolved into 10 cm^3 of methanol; dibenzylamine (dba) (1.97 g, 10 mmol) dissolved into 10 cm^3 of ethanol was added to it. When the mixed solution was left standing for about one hour at ambient temperature, colorless needle-like crystals were deposited. Yield: 1.7 g (55%). The larger crystals deposited from a more diluted mixed solution (which was left standing several days) were used for an X-ray structure analysis. Anal. Found: Cd, 18.04; C, 57.41; H, 4.84; N, 8.96%. Calcd for ($CdC_{30}H_{30}N_4S_2$), Cd, 18.04; C, 57.82; H, 4.85; N, 8.99%.

Single-Crystal X-Ray Analysis. The crystal used for a structure determination was about 0.3×0.3×0.2 mm^3 in size and was used without shaping. The reflections in the range $3°<2\theta<60°$ (2θ) were collected on a Rigaku AFC-6A automated four-circle X-ray diffractometer using graphite-monochromated Mo $K\alpha$ radiation, by means of a ω—2θ scan technique (scan speed 4° min^{-1}; scan width 1.10+0.5 tanθ° (θ)). The intensities were corrected for Lorentz and polarization factors, but no corrections were made for absorption and extinction. Of 4596 independent reflections collected, 3565 with $|F_o|>3\sigma(|F_o|)$ were used for the structure determination.

All the calculations were carried out on a HITAC M-680H computer at the Computer Center of the University of Tokyo, using UNICS III.[7] The scattering factors were taken from Ref. 8.

The structure was solved by the heavy-atom method. The positions of the cadmium and some sulfur atoms were deduced from a three-dimensional Patterson map; other non-hydrogen atoms were located by means of successive Fourier syntheses. Their positional, isotropic and then anisotropic thermal parameters were refined by a block-diagonal least-squares method. The positions of all hydrogen atoms were obtained by a calculation which assumed C-H bond lengths to be 1.08 Å. They were added to the refinement cycles fixing their positional parameters. The final R value[9] obtained was 0.033.

Results and Discussion

The bond lengths and bond angles are shown in Table 1.[10] A perspective drawing of the complex, together with the numbering scheme of the non-

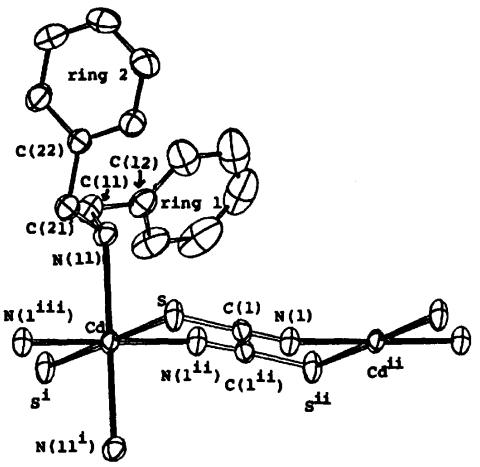

Fig. 1. A perspective drawing of the structure of the title complex with the numbering scheme of the atoms. The key to the symmetry operations; i, $-x$, $-y$, $-z$; ii, $-x$, $-y$, $1-z$; iii, x, y, $-1+z$.

hydrogen atoms, is shown in Fig. 1.[11] Projections of the unit cell along b- and c-axes are shown in Figs. 2 and 3, respectively.

The cadmium(II) atom is at the center of symmetry; it is hexa-coordinated and is in an octahedral geometry. As shown in Fig. 2, the cadmium(II) atoms are lined along the c-axis and the respective pairs of side-by-side metal atoms are bridged by two SCN ions; one of them is *S*-coordinated and the other one is *N*-coordinated to the same side metal atom, thus forming a polymeric linear chain structure.

Around one cadmium(II) atom, two SCN sulfur, two SCN nitrogen, and two dibenzylamine nitrogen atoms are coordinated, where each pair of the same kinds of the ligating atoms are all in a *trans*-configuration. The bond lengths are: Cd-N(SCN), 2.307(3) and Cd-S(SCN), 2.7576(10) Å. Bond angles are: Cd-S-C(1), 99.93(11) and Cd-N(1^{ii})-C(1^{ii}), 161.0-(2)°. These values are all not much different from those of the double SCN ion-bridging type cadmium complexes. The Cd-N(11) (Lewis base) bond length is 2.396(2) Å, longer than that of Cd-N(1^{ii}) (SCN). Moreover, this Cd-N (base) bond length is a little longer than those of the 3- and 4-methylpyridine adducts;[3,4] however, still longer Cd-N (base) bonds were found in 2-methylpyridine and bis(2-amino-methyl) amine adducts.[3,12]

An eight-membered ring, consisting of a pair of side-by-side cadmium(II) atoms and in total six atoms of a pair of SCN ions bridging them, is formed in this complex as in cases of the other cadmium(II) thiocyanate adducts.[1-3] Different from the planes of

Key to the symmetry operation: ii, $-x$, $-y$, $1-z$.

the 2-, 3-, and 4-methylpyridine adducts, which are almost in a real plane,[3,4] the ring of this complex is in a chair form; both cadmium(II) atoms are deviated up- and downwards by about 0.5 Å from the average plane of the six atoms of two SCN ions (average deviation of the six atoms from the average plane is 0.003 Å).

As shown in Figs. 2 and 3, the phenyl ring 2 of the dibenzylamine ligand is parallel to the same type ring of the next complex along the a-axis; the distance between the approaching ring planes is about 3.64 Å, and about 13% of the area overlaps each other.[13] On the other hand, as shown in Fig. 3, ring 1 of the ligand takes a position in the wide space between the side-by-side complexes along the b-axis; such an overlapping of rings was not found. This fact should be the cause of the relatively large temperature factors of ring 1 carbon atoms.

The next chains to the a- and b-axis directions are separated by 11.28 and 11.40 Å; these are the respective axis lengths. These values are far longer than those of the other Lewis base adducts of the same type: for example, in the case of 3-methylpyridine adduct, they are 8.77 and 8.33 Å (the latter value is a half of its b-axis length),[3] and the 1*H*-1,2,4-triazol adduct, 7.57 and 7.68 Å.[5] In spite of such a large separation between the polymeric chains, no fundamental discrepancies in the bridging structure were found compared with the other same type complexes, except for the above-mentioned minor differences.

Polarographic Determination of Surfactants

Hideaki KINOSHITA,* Mie KOBAYASHI, and Asao MATSUOKA
Kwassui Women's College, Higashiyamate, Nagasaki 850
(Received September 13, 1986)

Synopsis. The suppression of the polarographic oxygen maximum current and the decrease of the differential capacity at a potential of zero charge by surfactants are proportional to the concentration of the surfactants in a dilute solution. Constants representing the abilities for suppressing the maximum current and decreasing the capacity were obtained concerning some thirty surfactants.

Nowadays, surfactants are widely utilized not only as detergent powders and as liquid cleaners, but, also in the preparation of insecticides, polish and cosmetics. The development of a convenient method for the determination of surfactants seems to be very significant. After the separation of a test solution into surfactant solutions by means of a chromatographic method, a determination of surfactants is carried out mainly by the spectrophotometric method, which generally includes many complicated processes.[1] Measurements of the suppression of the polarographic maximum current and of the nonfaradaic admittance based on the adsorption of surfactants to the mercury electrode are very expedient and have been adopted for the determination of surfactants.[2,3] However, up to the present the fundamentals for the determination were not strictly explicated.

This paper tries to describe basic facts regarding the suppression of the oxygen maximum current and the decrease of the differential capacity by some thirty surfactants and to present a convenient method for a determination of surfactants.

Experimental

Chemicals. Reagent-grade chemicals purchased from Nakarai Chemical Co. and Tokyo Kasei Co. were used without further purifications. The water distilled for high-performance liquid chromatography made by Katayama Kagaku Co. was used to prepare the base solution. To prepare an oxygenated test solution this base solution was equilibrated with air by leaving it in air one day or longer.

Instruments. Dc, normal pulse (NP) and phase sensitive ac (psac) polarograms were recorded with a Yanagimoto Polarographic Analyzer P1:00, a Watanabe XY recorder WX4401 and an NF auto-lock-in amplifier LI572B. The amplitude of the superimposed alternating voltage was adjusted to 10 mV (peak to peak) and the frequency to 50 Hz. The open-circuit mercury flow rate at a dropping mercury electrode (DME) was 1.33 mg/s in distilled water at 65 cm of mercury. Usually, the dropping time of DME, t_d, was adjusted to 3 s.

Electrochemical Measurements. Measurements of the oxygen maximum current were carried out at 25 °C in a 10 mM (M=mol dm^{-3}) KCl solution and measurements of the differential capacity were at 20 °C in a 100 mM KCl solution. Potentials were referred to the saturated calomel electrode. To prepare the test solution, aliquots of a surfactant solution, usually containing 1 mg cm^{-3} of surfactant, was injected into 10 cm^3 of the base solution in an H-type cell.

Results

1. Suppression of Oxygen Maximum Current by Surfactant. In the reduction of oxygen dissolved in a KCl solution with a concentration ranging from 1 to 150 mM, a pronounced increase in the current above a limiting value was observed in the potential range between −0.2 and −0.4—−0.6 V on dc, NP, and linear potential sweep polarograms and was considered to be caused by increased transport of oxygen toward the electrode due to streaming motion of the solution.[4] The oxygen maximum current varied with the concentration of KCl and had a maximum value at the concentration of 10 mM. Dc polarograms of the reduction of oxygen in the presence of 0 to 2.5 μg cm^{-3} of sodium dodecyl sulfate (SDS) in 10 mM KCl solution are shown in Fig. 1 and NP polarograms in the presence of 0 to 6 μg cm^{-3} of SDS in Fig. 2. Heights of maximum current obtained by dc method(I) and NP method(I_p) decreased with increasing SDS concentration. These suppressions were proved to be proportional to the amount of surfactant adsorbed on

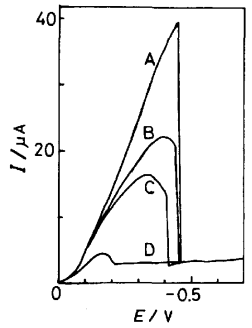

Fig. 1. Dc polarograms of reduction of oxygen in 10 mM KCl in the presence of 0 (A), 0.3 (B), 0.5 (C), and 2.5 (D) μg cm^{-3} of SDS.

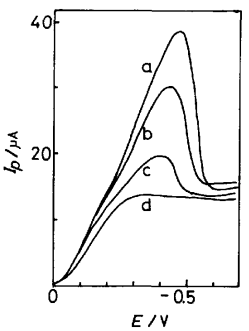

Fig. 2. NP polarograms of reduction of oxygen in 10 mM KCl in the presence of 0 (a), 0.5 (b), 2.5 (c), and 6 (d) μg cm^{-3} of SDS.; initial potential was 0 V, sampling time was 16.6 ms.

the mercury electrode, Γ, by measurements of linear potential sweep polarograms.[5] The net maximum current obtained by the dc method, I^0-I^{lim}, was larger than that obtained by the NP method, $I_p^0-I_p^{lim}$, in the absence of a surfactant. The degree of suppression of the net maximum current by the surfactant obtained by the dc method, $(I^0-I)/(I^0-I^{lim})$, was larger than that by the NP method, $(I_p^0-I_p)/(I_p^0-I_p^{lim})$, at a specific concentration of surfactant. Here I^0 and I_p^0 are the maximum currents in the absence of a surfactant and I^{lim} and I_p^{lim} are the limiting currents. In this NP method the initial potential is held at 0 V, where electrolysis scarcely occurs. Thus, streaming occurs intermittently and the supply of oxygen and surfactant to the electrode is reduced in comparison with the case of the dc method.

Figure 3 shows the dependence of the relative decrease of the oxygen maximum current measured at −0.3 V regarding the concentration of SDS(A, a) hexadecyltrimethylammonium bromide(CTAB)(B, b), and poly(oxyethylene)(20)sorbitan monolaurate-(Tween 20)(C, c) by the dc method(A, B, C) and the NP method(a, b, c). Roughly, linear relationships exist between the relative decrease of the current and the concentration of the surfactant in the range of I/I^0 and $I_p/I_p^0=2/3$ to 1 in the case of some thirty surfactants. Based on such a graph as shown in Fig. 3, the concentration of surfactant could be estimated.

2. Decrease of the Differential Double Layer Capacity by Surfactant. Figure 4 shows the differential capacity vs. potential, C-E, curves in the presence of 0 (A), 20 (B), and 50 (C) μg cm^{-3} of SDS in 0.1 M KCl measured by the psac polarographic method. With the increase in the SDS concentration the differential capacity decreased in the potential range around the potential of zero charge, PZC, which in this case was −0.5 V. For an SDS concentration lower than 20 μg cm^{-3} the relative decrease in capacity, $(C^0-C)/C^0$, was proportional to the square root of the dropping time of DME and the bulk concentration of SDS at −0.5 V, where C^0 is the capacity in the absence of a surfactant and C in the presence of a surfactant.[6]

Figure 5 shows the dependence of the relative decrease in the capacity at −0.5 V on the concentration of SDS (A), CTAB (B), and Tween 20 (C). At a lower surface coverage of the surfactant, an approximately linear relationship exists between the capacity and the bulk concentration of the surfactant. The adsorption of the surfactant at PZC is considered to be controlled by the diffusion, thus, Γ is proportional to $t_d^{1/2}$ and c. For this reason the relative decrease in the capacity might be proportional to the degree of surface coverage of the surfactant, which has a lower dielectric constant than water. The differential capacity at t_d=3 s approached the minimum value, C^m, in the presence of 30 to 40 μg cm^{-3} of water soluble surfactants and did not saturate even in the concentration of 100 μg cm^{-3} of poorly soluble surfactants. The value of the differential capacity obtained in the presence of dissolved oxygen was the same as that obtained in the absence of oxygen at a potential more negative than −0.2 V.

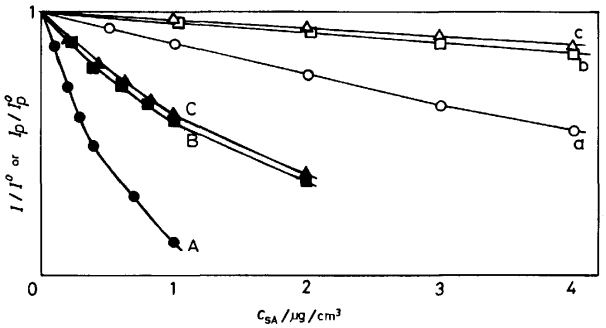

Fig. 3. Dependence of I/I^0 and/or I_p/I_p^0 at −0.3 V on the concn of SDS (A,a) ,CTAB (B,b) and Tween 20 (C,c) by dc (A,B,C) and NP (a,b,c) method.

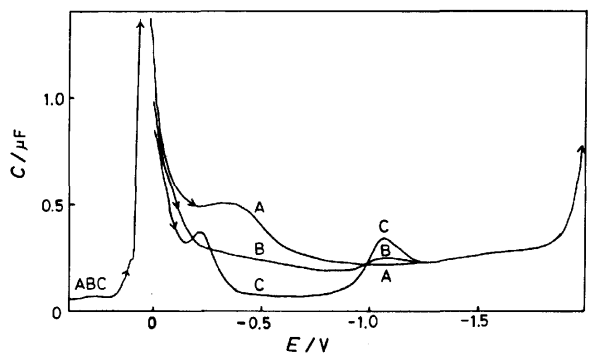

Fig. 4. C-E curves for 0 (A), 20 (B), and 50 (C) μg cm^{-3} of SDS in 100 mM KCl.

Discussion

Measurements of the oxygen maximum current and the differential capacity at a fixed potential are so simple and convenient to take that only one or two minutes are required to determine the concentration of any kind of surfactant ranging from 0.1 to 20 μg cm^{-3}. The presence of amino acids, sugars and non-surfactive fatty acids did not interfere with the measurements up to ten times the quantity of the surfactant. In the presence of any two kinds of surfactants, the total concentration of the two surfactants being lower than 20 μg cm^{-3}, their con-

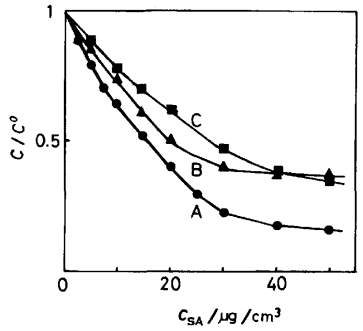

Fig. 5. Dependence of relative decrease of the differential capacity at −0.5 V on the concn of SDS (A), CTAB (B), and Tween 20 (C).

tribution in suppressing the maximum current and decreasing the capacity is independent. A rigid control of the temperature (20—30 °C) and the dropping time of DME (3—5 s), which influence the adsorption of surfactant, is desirable for a better analysis. Constants characteristic of the surfactant representing the ability to suppress the oxygen maximum current, k, and to decrease the differential capacity, K, were calculated while assuming that the following empirical equations are valid:

$$I/I^0 = 1 - kc \quad (1)$$

and

$$C/C^0 = 1 - Kc. \quad (2)$$

These concern some thirty surfactants and are summarized in Table 1. This table is useful in a polarographic determination of the surfactants.

We are grateful to Prof. Mitsugi Senda and Dr. Takashi Kakiuchi of Kyoto Univ. for their kind advice.

Ring Transformation of 1,3-Dinitroquinolizin-4-one with Enolate Anions[1)]

Masahiro ARIGA* and Eizo MATSUMURA
Department of Chemistry, Osaka Kyoiku University,
Minamikawahori-cho, 4-88, Tennoji-ku Osaka 543
(Received September 10, 1986)

Synopsis. The ring transformation of 1,3-dinitroquinolizin-4-one, which is one of the condensed ring compounds of 1-substituted 3,5-dinitro-2-pyridone series, with enolate anions, $R^1CH_2COCHCOR^2$, gave the corresponding 2-COR^2-6-R^1-4-nitrobenzene-1,3-diols. The results show that carbonyl carbon of the quinolizinone behaves as reaction site in the ring transformation.

In a previous paper,[2)] we reported the substituent effects of 4- and 6-methyl or 4-methoxyl groups on the regio-orientation of the nucleophilic ring transformation of 1-substituted 3,5-dinitro-2-pyridones with enolate anions.

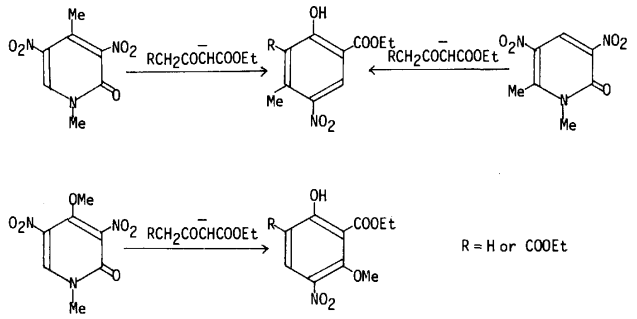

Fig. 1.

We wish to extend examinations to quinolizinone ring in order to investigate the scope and limitation of the reaction. 1,3-Dinitroquinolizin-4-one (**1**) is a 1,6-disubstituted 2-pyridone, of which 1- and 6-positions are linked with conjugated 1,3-butadiene unit, and the conjugation bonds in pyridone ring extend to pyridine unit. These structural features may cause a new type of reaction of electron-deficient 2-pyridone derivatives.

Results and Discussion

1,3-Dinitroquinolizin-4-one (**1**) was obtained by the known procedure.[3)] Treatment of **1** with 3 times equimolar ethyl sodio-3-oxobutanoate in DMF at −15—−10 °C gave colorless needles (**2a**) of mp 112.0—113.0 °C. The ^{1}H NMR spectra of **2a** indicated the presence of two aromatic *ortho*-protons and two hydroxyl protons in addition to methylene and methyl protons of ethoxycarbonyl group. From this result and IR spectra, **2a** was assigned to ethyl 2,6-dihydroxy-3-nitrobenzoate, and identified as that by comparison of spectral data with those of the sample prepared from 2,6-dihydroxy-3-nitrobenzoic acid.[4)]

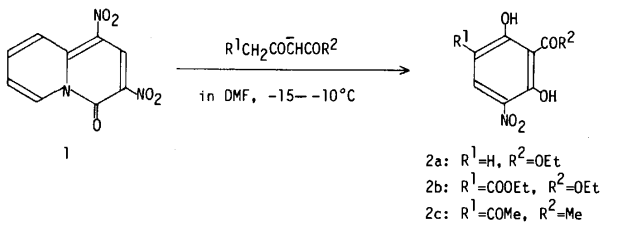

Fig. 2.

Similar reaction of **1** with 1.5 times equimolar diethyl sodio-3-oxopentanedioate gave diethyl 2,4-dihydroxy-5-nitro-1,3-benzenedicarboxylate (**2b**) in a good yield (76%).

Sodium salt of 2,4,6-heptanetrione also reacted in the similar conditions to give 3-acetyl-2,4-dihydroxy-5-nitroacetophenone (**2c**) in a moderate yield (57%).

The reaction of **1** with ethyl sodio-3-oxobutanoate was attempted to reveal appropriate reaction conditions, but no improvement of the yield of **2a** was achieved (Table 1). Diethyl 3-oxopentanedioate and 2,4,6-heptanetrione were sufficiently active to give reasonable yield of the products by using 1.5 mol of each reagent. However, the reaction of 3 molar amounts of ethyl 3-oxobutanoate did not show a good yield probably because the nucleophilic center of the reagent is methyl group which is less reactive than methylene group between two carbonyl groups.

The reaction of sodio-2,4-pentanedione in the conditions similar to those of the reaction of ethyl sodio-3-oxobutanoate gave only an unidentified resinous material.

Our previous results of the ring transformation of 3,5-dinitro-2-pyridones showed that the reaction centers were 4- and 6-positions (vinyl positions of carbonyl carbon) and not 2-position (carbonyl carbon) of 2-pyridone. In the present reaction, however, it is obvious that the product **2** consists of the reagent and C_2–C_3–C_4 part of quinolizinone ring and that carbonyl carbon (C_4 of the substrate **1**, corresponding to the 2-position of 2-pyridone) behaves as reaction site in the ring transformation. The fact is the first example

Table 1. Ring Transformation of 1,3-Dinitroquinolizin-4-one

Reagent[a)]	Reaction conditions		Products (Yields/%)
	mol. ratio	temp/°C	
a	3.0	−15—−10	**2a** (25.6)
b	1.5	−15—−10	**2b** (76.2)
c	1.5	−15—−10	**2c** (56.8)
a	3.0	25	**2a** (trace)
a	1.5	−15—−10	**2a** (trace) **1** (42.5)

a) **a**: ethyl sodio-3-oxobutanoate, **b**: diethyl sodio-3-oxopentanedioate, **c**: sodio-2,4,6-heptanetrione.

in 2-pyridone series.

Another product, 2-(nitromethyl)pyridine, which is supposedly derived from the rest of **1** in the ring transformation was not isolated. With reference to the report that 2-(nitromethyl)pyridine is an acidic and unstable compound,[5] it will give only a resinous material under the conditions of the present work.

From these results, a plausible course of the reaction is suggested as path(b) in the following scheme. The initial attack of enolate anion of β-dicarbonyl compound at the 2-position of substrate **1** (corresponding to the 4-position of 2-pyridone) was followed by the intramolecular nucleophilic attack of another nucleophilic center of introduced reagent at the 4-position of parent quinolizinone unit (carbonyl carbon) to give an intermediate **4**, of which reconstruction leads to the product **2**.

An alternative path(a) may be suggested, where the enolate anion attacks at the electrophilic centers of the quinolizinone in reverse sequence to path(b) to form the same intermediate **4** as is formed in path(b). It is well known that the nucleophilic attack generally occurs at a conjugated position and not at the carbonyl carbon in a conjugated carbonyl system, as the case of path(b). So, we prefer the path(b) as probable reaction course.

In the case of the reaction of ethyl sodio-3-oxobutanoate, a σ-complex, **3d**, may be initially formed, but direct conversion of **3d** to **4d** is unlikely, since it requires abstraction of a proton from less acidic center. Then **3d** is likely to transform to **3a** through equilibrium with **1** in view of easy cyclization to tricyclic intermediate by deprotonation from the most acidic methylene carbon in **3a**, and finally **4a** is given predominantly.[2,6,7]

The results mentioned above suggest that carbony carbon acts as electrophilic center in the intramolecular nucleophilic cyclization step of the ring transformation of 1,3-dinitroquinolizin-4-one. The fact is different from the case of 3,5-dinitro-2-pyridone, and may be explained as follows. If the reaction proceeds in the same way as 3,5-dinitro-2-pyridone,[2,8] an unfavorable crowded tricyclic intermediate, **5**, will be formed through path(c) or (d). Althogh the intermediate **5** appears to be not so unstable to be formed, its reconstruction to stable aromatic product such as **2** in path(b) is impossible. These factors will result in forming the intermediate **4** through path(b).

Experimental

All the melting points were uncorrected. ^{1}H NMR spectra were recorded by a Hitachi R-20B Spectrometer with TMS as the internal standard. IR spectra were obtained by a Hitachi 260-10 Spectrometer.

Reaction of 1 with Ethyl Sodio-3-oxobutanoate. To a solution of 500 mg (2.1 mmol) of **1** in 100 cm^3 of DMF was added dropwise ethyl sodio-3-oxobutanoate sulution, prepared from 150 mg (6.5 mmol) of sodium and 950 mg (7.3 mmol) of ethyl 3-oxobutanoate in 30 cm^3 DMF for 5 h at −15—−10 °C with stirring, and the mixture was allowed to stand at the same temperature overnight. After being quenched by addition of 3.5 cm^3 of 1 mol dm^{-3} HCl, the solvent was evaporated in vacuo, the residual oil was dissolved in 20 cm^3 water, and extracted with chloroform at pH 3.0. After the extract was dried over anhydrous magnesium sulfate chloroform was distilled off, and the residual syrup was column-chromatographed on silica gel (Wakogel C-200). From benzene elute, was obtained 126 mg

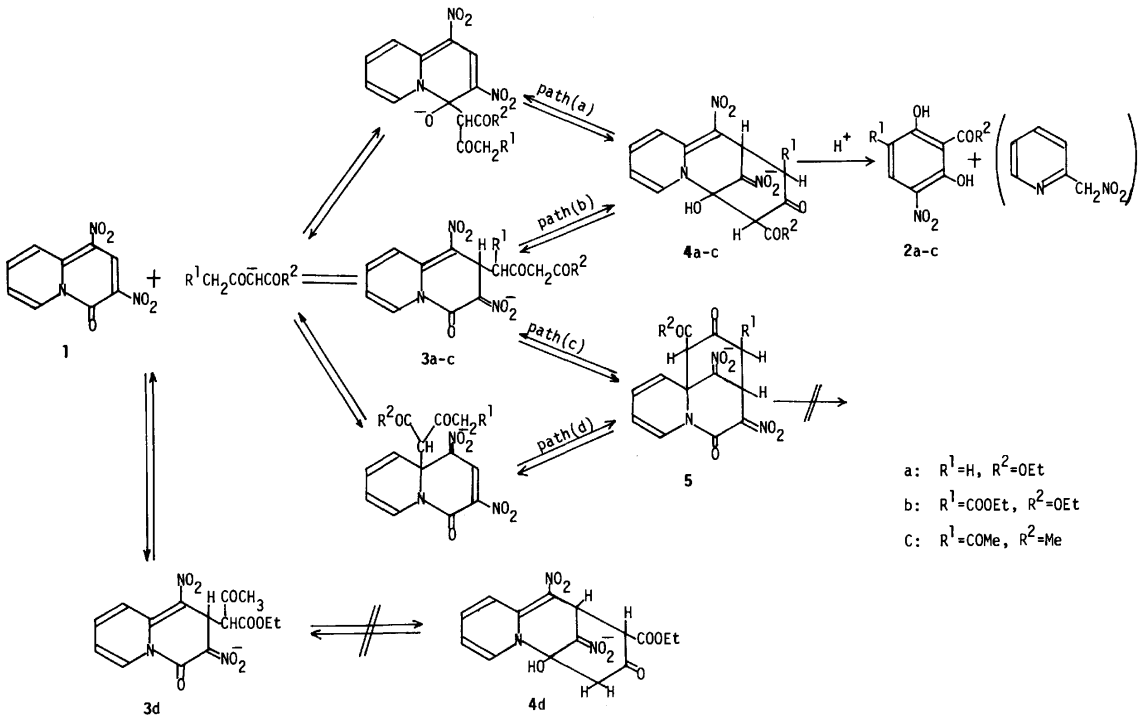

Fig. 3.

(27.7%) of ethyl 2,6-dihydroxy-3-nitrobenzoate (**2a**), which was recrystallized from petroleum benzine of bp 65—75 °C. IR(nujol) ν 3100 (OH), 1750, (C=O), 1540, 1350 (NO_2). ^1H NMR ($CDCl_3$) δ=1.44 (t, J=7.0 Hz, 3H), 4.48 (q, J=7.0 Hz, 2H), 6.52 (d, J=9.0 Hz, 1H), 8.15 (d, J=9.0 Hz, 1H), 12.43 (s, 1H), 12.61 (s, 1H). Found: C, 47.51; H, 3.81; N, 6.08%. Calcd for $C_9H_9NO_6$: C, 47.58; H, 3.99; N, 6.17%.

Reaction of 1 with Diethyl Sodio-3-oxopentanedioate. Treatment of 500 mg (2.1 mmol) of **1** with diethyl sodio-3-oxopentanedioate, prepared from 73 mg (3.2 mmol) of sodium and 720 mg (3.6 mmol) of diethyl 3-oxopentanedioate in the similar procedure as described above, gave 485 mg (76.2%) of diethyl 2,4-dihydroxy-5-nitro-1,3-benzenedicarboxylate (**2b**); colorless plates (petroleum benzine), mp 85.0—86.0 °C. IR(nujol) ν 3200 (OH), 1750 (C=O), 1540, 1350 (NO_2). ^1H NMR ($CDCl_3$) δ=1.40 (t, J=7.0 Hz, 3H), 1.43 (t, J=7.0 Hz, 3H), 4.43 (q, J=7.0 Hz, 2H), 4.44 (q, J=7.0 Hz, 2H), 8.71 (s, 1H), 11.94 (s, 1H), 12.26 (s, 1H). Found: C, 48.31; H, 4.44; N, 4.61%. Calcd for $C_{12}H_{13}NO_8$: C, 48.17; H, 4.38; N, 4.70%.

Reaction of 1 with Sodio-2,4,6-heptanetrione. According to the preliminary expriments, 500 mg (2.1 mmol) of **1** was made to react with sodio-2,4,6-heptanetrione prepared from 73 mg (3.1 mmol) sodium and 500 mg (3.6 mmol) of 2,4,6-heptanetrione to give 290 mg (56.8%) of 3-acetyl-2,4-dihydroxy-5-nitroacetophenone (**2c**); colorless columns (ethanol), mp 142.0—143.0 C. IR(nujol): ν 3100 (OH), 1620 (C=O), 1580 (C=O), 1550, 1345 (NO_2). ^1H NMR ($CDCl_3$) δ=2.69 (s, 3H), 2.82 (s, 3H), 8.73 (s, 1H), 14.94 (s, 2H). Found: C, 50.31; H, 3.89; N, 5.76%. Calcd for $C_{10}H_9NO_6$: C, 50.21; H, 3.79; N, 5.86%.

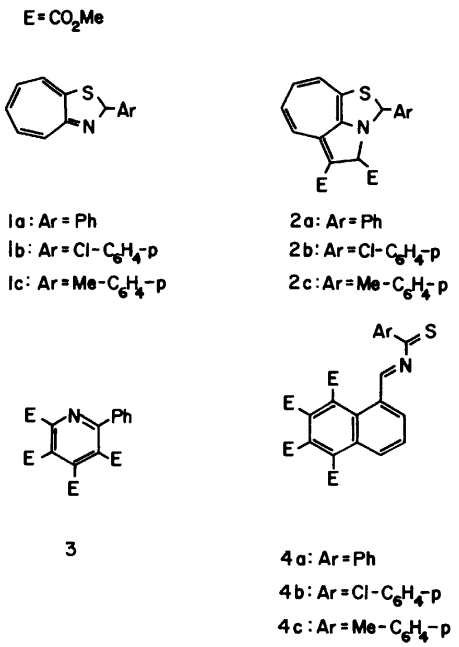
Reactions of 2-Aryl-2*H*-cycloheptathiazoles with Dimethyl Acetylenedicarboxylate

Noritaka ABE,* Satoshi KONDO, and Koichi MORITA
Department of Chemistry, Faculty of Sciences, Yamaguchi University, Yamaguchi 753
(Received September 16, 1986)

Synopsis. Reaction of 2-aryl-2*H*-cycloheptathiazoles with dimethyl acetylenedicarboxylate gave dimethyl 2-aryl-3*H*-1-thia-2a-azacyclopent[*cd*]azulene-3,4-dicarboxylate, tetramethyl 6-phenyl-2,3,4,5-pyridinetetracarboxylate, and tetramethyl 5-[(thioaroyl)iminomethyl]-1,2,3,4-naphthalenetetracarboxylate.

Concerning the cycloaddition reactions of benzothiazoles[1] and azaazulenes,[2] we have reported that the cycloaddition of 2*H*-cycloheptathiazol-2-one with acetylenic esters produced 1:1- and 1:2-cycloadducts via 1,10-dipolar intermediates.[3] Cycloadditions of 8-azaheptafulvene are also known,[4] which proceeded via similar dipolar intermediates. It is interesting to ascertain if 2-aryl-2*H*-cycloheptathiazoles, which are not fully conjugated and would be considered as substituted azaheptafulvenes, undergo a similar cycloaddition or not. We have now carried out the reaction of 2-aryl-2*H*-cycloheptathiazoles with dimethyl acetylenedicarboxylate (DMAD), and found that the reaction gave novel products in addition to the anticipated dipolar cyclization products.



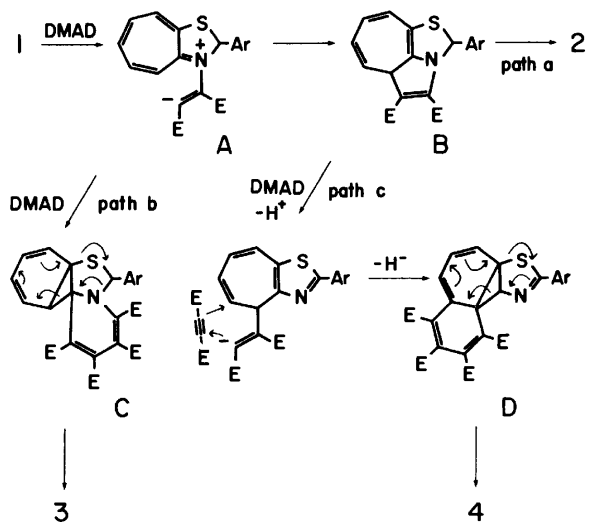
2-Aryl-2*H*-cycloheptathiazoles (**1a—c**) were prepared by the reaction of 2-aminocycloheptatrienethione (2-aminotroponethione)[5] with the corresponding aromatic aldehydes in a similar method as reported[6] for **1b**.

Treatment of **1a** with DMAD in boiling benzene gave a complex mixture, from which four products, **2a** (9%), **3** (8%), **4a** (15%), and **5a** (14%), were isolated by chromatography on silica gel. The structures of these compounds, except **5a**, were elucidated by their spectroscopic data as well as by elemental analyses.

Compound **2a** ($C_{20}H_{17}NO_4S$) was assigned to dimethyl 2-phenyl-3*H*-1-thia-2a-azacyclopent[*cd*]-azulene-3,4-dicarboxylate, which is the corresponding cycloadduct to that described before.[2,3] Its ^{1}H NMR spectrum shows two 1H-singlets at δ 5.08 and 6.10, which should be assigned to H-3 and H-2, respectively. Two ester methyl-singlets are seen at δ 2.98 and 3.72. The relatively high-field appearance of the former may be due to the shielding effect by the phenyl group at C-2. The electronic spectrum of **2a** accords with the structure as a substituted heptafulvene.

Compound **3** was identical with tetramethyl 6-phenyl-2,3,4,5-pyridinetetracarboxylate,[7,8] which was not formed in the reactions of 2*H*-cycloheptathiazol-2-one or azaazulenes.

Compound **4a** ($C_{26}H_{21}NO_8S$) was tentatively assigned to tetramethyl 5-(thiobenzoyliminomethyl)-1,2,3,4-naphthalenetetracarboxylate. In the mass spectrum, a peak at *m/z* 345 (M^+—PhCSNCH) is observed. The electronic spectrum of **1a** has several weak absorption muxima in the visible region; whereas that of **4a** does not. The ^{1}H NMR spectrum of **4a** shows a low-field resonated 1H-singlet at δ 7.67 and a 3H-multiplet at aromatic region (δ 6.85—6.95) together with four ester methyl-singlets and phenyl-multiplets. The IR spectrum of **4a** exhibits a band of medium intensity at 1630 cm^{-1} assignable to C=N in addition to the absorptions of ester carbonyls. These observations suggest that **4a** has a naphthalene nucleus and a C=N group besides four ester groups.



Scheme 1.

A yellow compound **5a** ($C_{26}H_{23}NO_2S$) was a 1:2-adduct, but the structure has not yet been elucidated.

Compounds **1b** and **1c** also reacted with DMAD to give **2b—c**, **3**, **4b—c**, and **5b—c**, respectively. From the results, no particular substituent effect was observed.

A plausible mechanism for the reaction of **1** with DMAD is shown in Scheme 1. Electrophilic attack of DMAD on the nitrogen gives the ylide intermediate **A**. A 1,10-dipolar cyclization of **A** gives **B**, and a subsequent 1,3-hydrogen shift furnishes **2** (path a). Cycloaddition of ylide **A** with DMAD gives **C**. Ring-contraction of **C** accompanied by bond cleavage affords **3** (path b). Cycloaddition of **A** with DMAD and successive rearrangement may lead to **D**, which in turn rearranges to **4** (path c).

Although the dipolar species **A** resembles to that of 2*H*-cycloheptathiazol-2-one, the reaction products differ extremely from each other. This would be associated with the difference of hybridization at C-2 carbon (sp^3 *vs.* sp^2) or the electron-attracting effect of the carbonyl group of 2*H*-cycloheptathiazol-2-one.

Experimental

Melting points are uncorrected. ^1H NMR spectra were taken with a Hitachi R-24B spectrometer (60 MHz) for solutions in $CDCl_3$ with TMS as an internal standard. Electronic spectra were measured for solutions in ethanol and IR spectra for Nujol mulls unless otherwise stated. Mass spectra were determined with a Hitachi M-80 instrument by a field desorption ionization method. Column chromatography was performed on Kieselgel 60.

Syntheses of 2-Arylcycloheptathiazoles. A mixture of 2-aminocycloheptatrienethione[5] (2.74 g, 20 mmol), benzaldehyde (2.12 g, 20 mmol), and concd hydrochloric acid (3.0 ml) in ethanol (40 ml) was refluxed for 4 h. Water (200 ml) was added, and the mixture was extracted with chloroform. The extract was washed, dried (Na_2SO_4), and evaporated. Chromatography of the residue with benzene gave **1a** (2.75 g, 61%) as yellow tar; λ_{max} 248 nm (log ε 4.19), 272 (4.04), 282 (4.03), 290 (4.01), 325 (3.78, sh), 338 (3.80), 354 (3.76), 376 (3.69), 398 (3.26, sh), 419 (3.20), 441 (3.10), 470 (2.82, sh), and 505 (2.17); ν_{max} (neat) 755 and 695 cm^{-1} (phenyl); ^1H NMR δ=6.1—6.8 (5H, m, H-4, 5, 6, 7, and 8), 7.23 (1H, s, H-2), and 7.3—7.55 (5H, m, H-phenyl); Picrate of **1a**: Yellow needles (from ethanol), mp 167—168 °C. Anal. ($C_{20}H_{14}N_4O_7S$) C, H, N.

In a similar manner, we made the following: **1b** [41%, yellow needles (from aq ethanol), mp 80—81 °C (lit,[6] 80.5—81 °C; λ_{max} 219 nm (log ε 4.17), 227 (4.15), 247 (4.15), 270 (3.85), 279 (3.85), 290 (3.84), 342 (3.59, sh), 356 (3.67), 375 (3.59), 397 (3.21), 418 (3.23), 441 (3.15), 468 (2.90), and 500 (2.34, sh); ν_{max} 835 cm^{-1} (phenyl); ^1H NMR δ=6.0—6.8 (5H, m, H-4, 5, 6, 7, and 8), 7.10 (1H, s, H-2), and 7.30 (4H, bs, H-phenyl). Anal. ($C_{14}H_{10}ClNS$) C, H, N.]; **1c** [83%, yellow tar; λ_{max} 252 nm (log ε 4.32), 271 (4.17), 292 (4.16), 342 (3.98), 356 (4.00), 375 (3.89), 395 (3.47, sh), 421 (3.47), 445 (3.38), 471 (3.14, sh), and 503 (2.37, sh); ν_{max} (neat) 820 cm^{-1} (phenyl); ^1H NMR δ=2.33 (3H, s, Me), 6.0—7.0 (5H, m, H-4, 5, 6, 7, and 8), 7.18 (1H, s, H-2), 7.18 (2H, d, J=9 Hz, H-*m*-phenyl), 7.33 (2H, d, J=9 Hz, H-*o*-phenyl). Pycrate of **1c**: Yellow needles (from ethanol), mp 144—146 °C. Anal. ($C_{21}H_{16}N_4O_7S$) C, H, N].

Reaction of 1 with DMAD. A solution of **1a** (3.23 g, 14.4 mmol) and DMAD (6.12 g, 43.1 mmol) in dry benzene (50 ml) was refluxed for 3 h, then evaporated, and the residue chromatographed. Benzene eluted **2a** (0.48 g, 9%), which was crystallized from ethanol as yellow prisms, mp 160—161 °C; λ_{max} 223 nm (log ε 4.52), 275 (3.92), 321 (3.86), and 437 (3.52); ν_{max} 1735 and 1705 cm^{-1} (C=O); 2.90, 3.72 (each 3H, s, OMe), 5.08 (1H, bs, H-4), 6.10 (1H, s, H-2), 6.5—7.1 (3H, m, H-7, 8, and 9), and 7.25—7.7 (6H, m, H-6 and phenyl). Anal. ($C_{20}H_{17}NO_4S$) C, H, N, S. Further elution gave **3** (0.45 g, 8%), which was crystallized from ethanol as colorless prisms, mp 128—129 °C (lit,[7] mp 128—129 °C), Anal. ($C_{19}H_{17}NO_8$) C, H, N. Spectral data were described in lit. 8. Elution with benzene–chloroform (1:1) gave **4a** (1.01 g, 15%), which was crystallized from ethanol as yellow prisms, mp 206—207 °C, λ_{max} 217 nm (log ε 4.66), 321 (3.91), and 390 (3.28); ν_{max} 1750, 1725, 1710, 1700 (C=O), and 1630 cm^{-1} (C=N); ^1H NMR δ=3.02, 3.70, 3.73, 3.84 (each, 3H, s, OMe), 6.85—6.95 (3H, m, H-6, 7, and 8), 7.2—7.4 (3H, m, H-*m,p*-phenyl), 7.6—7.8 (2H, m, H-*o*-phenyl), 7.67 (1H, s, HC=N); MS *m/z* (rel intensity) 507 (M^+, 100), 345 (57). Anal. ($C_{26}H_{21}NO_8S$) C, H, N, S. Further elution gave **5a** (1.06 g, 14%), which was crystallized from ethanol as yellow prisms, mp 147—148 °C; λ_{max} 217 nm (log ε 4.59), 288 (3.83, sh), 313 (3.91), and 369 (3.83); ν_{max} 1735, 1725, 1715, 1695 cm^{-1} (C=O); ^1H NMR δ=3.38, 3.62 (each 3H, s, OMe), 3.67 (6H, s, OMe), 5.00 (1H, dd, J=1.5 and 0.5 Hz), 5.77 (1H, d, J=1.5 Hz), 6.53 (1H, d, J=0.5 Hz), 6.75—6.9 (3H, m), and 7.15—7.4 (5H, m, H-phenyl). Anal. ($C_{26}H_{23}NO_8S$) C, H, N, S.

In a similar manner, **1b** gave **2b** (3%), **3** (28%), **4b** (7%), and **5b** (10%), and **1c** gave **2c** (2%), **3** (23%), **4c** (19%), and **5c** (11%).

2b: Which could not be purified but its structure was elucidated from the ^1H NMR spectrum. ^1H NMR δ=3.03, 3.75 (each 3H, s, OMe), 5.00 (1H, bs, H-4), 6.05 (1H, s, H-2), 6.4—7.0 (3H, m, H-7, 8, and 9), and 7.1—7.5 (5H, m, H-6 and phenyl).

4b: Yellow needles (from cyclohexane–dichloromethane), mp 221—222 °C; λ_{max} 219 nm (log ε 4.58), 321 (3.83), and 392 (3.17); ν_{max} 1750, 1740, 1720, 1705 (C=O), and 1625 cm^{-1} (C=N); ^1H NMR δ=3.10, 3.69, 3.72, 3.83 (each 3H, s, OMe), 6.75—7.0 (3H, m, H-6, 7, and 8), 7.27 (2H, d, J=9 Hz, H-*m*-phenyl), 7.67 (1H, s, HC=N), and 7.70 (2H, d, J=9 Hz, H-*o*-phenyl); MS *m/z* 541 (M^+). Anal. ($C_{26}H_{20}ClNO_8S$) C, H, N, S.

5b: Yellow needles (from ethanol), mp 177—179 °C; λ_{max} 221 nm (log ε 4.52), 282 (3.79), 313 (3.87), and 367 (3.79); ν_{max} 1735, 1720, 1715, and 1685 cm^{-1} (C=O); ^1H NMR δ=3.50, 3.69 (each 3H, s, OMe), 3.72 (6H, s, OMe), 5.03 (1H, dd, J=1.5 and 0.5 Hz), 5.71 (1H, d, J=1.5 Hz), 6.57 (1H, d, J=0.5 Hz), 6.8—7.1 (3H, m), and 7.30 (4H, bs, H-phenyl). Anal. ($C_{26}H_{22}ClNO_8S$) C, H, N, S.

2c: Which could not be purified but its structure was elucidated from the ^1H NMR spectrum. ^1H NMR δ=2.30 (3H, s, Me), 3.00, 3.73 (each 3H, s, OMe), 5.00 (1H, bs, H-4), 6.07 (1H, s, H-2), 6.35—7.0 (3H, m, H-7, 8, and 9), 7.2—7.6 (5H, m, H-6 and phenyl).

4c: Yellow prisms (from ethanol), mp 247—249 °C; λ_{max} 217 nm (log ε 4.70), 322 (3.92), and 395 (3.28); ν_{max} 1755, 1725, 1720, 1705 (C=O), and 1630 cm^{-1} (C=N); ^1H NMR δ=2.33 (3H, s, Me), 3.06, 3.72, 3.75, 3.85 (each 3H, s, OMe), 6.85—7.05 (3H, m, H-6, 7, and 8), 7.12 (2H, d, J=9 Hz, H-*m*-phenyl), 7.67 (2H, d, J=9 Hz, H-*o*-phenyl), and 7.72 (1H, s, HC=N); MS *m/z* (rel intensity) 521 (M^+, 16), 462 (100), 404 (68), 359 (18). Anal. ($C_{27}H_{23}NO_8S$) C, H, N, S.

5c: Yellow needles (from ethanol), mp 125.5—126 °C; λ_{max} 220 nm (log ε 4.55), 288 (3.77, sh), 314 (3.87), and 369 (3.80); ν_{max} 1735, 1725, 1715, and 1690 cm^{-1} (C=O); ^1H NMR δ=2.33 (3H, s, Me), 3.44, 3.66 (each 3H, s, OMe), 3.70 (3H, s, OMe), 5.02 (1H, dd, J=1.5 and 0.5 Hz), 5.80 (1H, d, J=1.5 Hz), 6.58 (1H, d, J=0.5 Hz), 6.8—7.05 (3H, m), and 7.15 (4H, bs, H-phenyl). Anal. ($C_{27}H_{25}NO_8S$) C, H, N.

(Received September 13, 1986)

Synopsis. The reaction of carbon dioxide with α-ethynyl tertiary alcohols has been catalyzed by cobaltocene to give α-methylene cyclic carbonates in good yields. α-Ethynyl primary or secondary alcohols give noncyclic alkyl carbonates in fair yields.

Considerable attention has been attracted in the fixation of carbon dioxide (CO_2) to organic substrates using transition metals with regard to the use of readily available primary chemicals in organic synthesis.[1] Previously we reported a few examples of cooligomerization of acetylenic compounds with CO_2 catalyzed by nickel(0) complexes to produce α-pyrone derivatives.[2]

In this paper we describe another example of the reaction of CO_2 with acetylenic alcohols catalyzed by cobaltocene ($CoCp_2$; Cp=cyclopentadienyl). α-Ethynyl tertiary alcohols **1** such as 2-methyl-3-butyn-2-ol underwent cycloaddition with CO_2 yielding α-methylene cyclic carbonates **2** in good yield in the presence of $CoCp_2$ and triethylamine.

b; $R^1=CH_3$, $R^2=C_2H_5$
c; $R^1=CH_3$, $R^2=CH_2CH(CH_3)_2$
d; $R^1=R^2=C_2H_5$

Similar types of reaction are also known to be catalyzed by CuCl[3] or $PdCl_2(MeCN)_2$.[4] Very recently $Ru_3(CO)_{12}$ was shown to catalyze the reaction of CO_2 with α-ethynyl primary or secondary alcohols to afford noncyclic 2-oxoalkyl carbonates.[5]

The cobalt-mediated reaction was performed in an autoclave under the pressure of CO_2 without employing a solvent usually. In addition to the product **2**, a small amount(<9%) of α-hydroxy ketone of the type **3** was also obtained. This may be formed from the reaction of **1** wih the water concomitant with **1**.

Table 1. Reaction of α-Ethynyl Tertiary Alcohols **1** with CO_2[a]

Alcohol 1	Solvent	Reaction temp/°C	Reaction time/h	Product 2	Yield[b] %

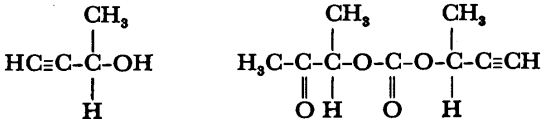
1d	—	80	5	**2d**	52
	—	100	5		83

a) **1**, 50 mmol; solvent, 20 cm^3; $CoCp_2$, 1 mmol; Et_3N, 3.6 mmol; CO_2, 50 kg cm^{-2}. b) GLC yield. c) Without NEt_3.

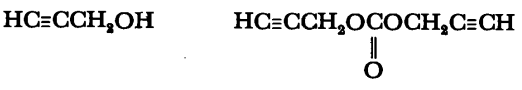
The results are shown in Table 1. At first, 2-methyl-3-butyn-2-ol (**1a**) was employed as a probe to investigate the reaction conditions. The reaction occurred at the temperature above 60 °C and proceeded smoothly at 80 °C. The reaction terminated almost in 1.5 h at this reaction temperature. Normally triethylamine was added as the co-catalyst. However the reaction took place without adding this amine although the yield of **2a** declined slightly. The employment of a solvent such as benzene, tetrahydrofuran (THF), or *N*,*N*-dimethylformamide (DMF) profoundly diminished the yield of the product **2a**.

The other α-ethynyl tertiary alcohols such as **1b—d** underwent the 1:1 cycloaddition reaction giving **2b—d**, respectively under similar reaction conditions.

3-Butyn-2-ol (**4**), an α-ethynyl secondary alcohol, did not afford the 1:1 cycloaddition product. Instead, a small amount (≈15%) of 1:2 addition product, i.e., 1-methyl-2-oxopropyl 1-methyl-2-propynyl carbonate (**5**) was obtained along with the other minor products.



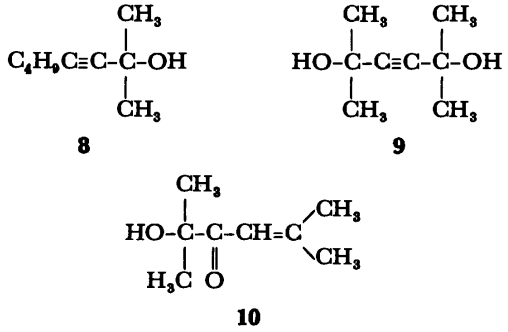
4 **5**



6 7

Propargyl alcohol (**6**), an α-ethynyl primary alcohol, afforded dipropargyl carbonate (**7**) in 6% yield together with a small amount of hydroxyacetone (≈0.2%) after the reaction at 80 °C for 5 h. Addition of an equimolar amount of PPh_3 to the catalyst increased the yield of **7** up to 24%.

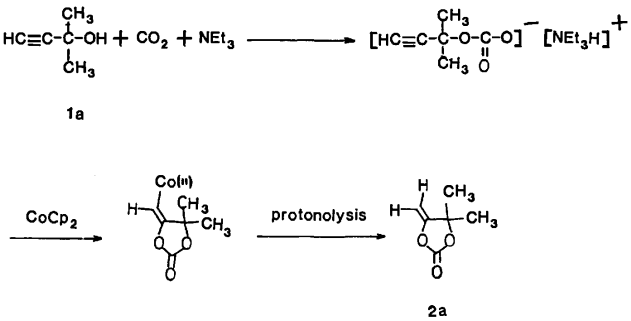
α-(1-Alkynyl) tertiary alcohols like **8** or **9** did not react with CO_2. Under forced conditions (110 °C, 5 h), **9** afforded an isomerized product **10** in a moderate yield.



8 9 10

It can be presumed that cobaltocene is oxidized to cobaltocenium ion $[CoCp_2]^+$ in the presence of water or alcohol if the air is present.[6] The possible participation of the ion to the present cyclization reaction has been studied. A solution composed of **1a**, triethylamine, and cobaltocene was stirred in the air at an ambient temperature for 0.5 h and then the mixture was submitted to the reaction with CO_2 (80 °C, 5 h) to yield **2a** in only 5%. Another experiment employing $[CoCp_2]Cl$ as catalyst afforded **2a** from **1a** in 15% yield under the standard reaction conditions. So the participation of cobaltocenium ion to this reaction is partial if any.

Although the mechanism is unknown, one possibility will be mentioned at this time. The first step of the reaction is the formation of monoalkyl carbonate ion from **1a** and CO_2. The presence of triethylamine increases the amount of the ion. Then the monoalkyl carbonate undergoes cyclization under the assist of cobaltocene. It has been reported recently that this type of cyclization occurs in a trans fashion in the palladium-catalyzed reaction.



1a 2a

To gain mechanistic information, the deuterio alcohol **1a**-d_1 was employed. This alcohol afforded the cyclic carbonate **2a**-d_1, the deuterium being located almost equally in the exo methylene protons (see the experimental part). This result indicates that exactly the same mechamism as that in the palladium case is not operative.

1a-d_1 **2a**-d_1

Experimental

Materials. Cobaltocene[7] and $[CoCp_2]Cl$[8] were prepared according to the literatures. The alcohols, **1a—d**, **4**, and **6**, were obtained commercially and distilled before use. The alcohol **9** was used as received. The alcohol **8** was synthesized according to the reported method[9] from 1-hexyne and acetone.

Reaction of α-Ethynyl Tertiary Alcohols 1 with CO_2. The reaction of 2-methyl-3-butyn-2-ol (**1a**) with CO_2 is typical. A mixture of **1a** (50 mmol), Et_3N (3.6 mmol), and $CoCp_2$ (1 mmol) was stirred at 80 °C for 5 h under the pressure of CO_2 in an autoclave. GLC analysis (FFAP, 10%, 3 m, 160 °C) showed the formation of 4,4-dimethyl-5-methylene-1,3-dioxolan-2-one (**2a**) and 3-hydroxy-3-methyl-2-butanone (**3a**) in 87 and 9% yield, respectively. The product **2a** was isolated by distillation. Liquid; bp 45 °C/3 mmHg (lit,[3] bp 82 °C/18 mmHg); (1 mmHg= 133.322 Pa). Mp 26.5—27.5 °C.

4-Ethyl-4-methyl-5-methylene-1,3-dioxolan-2-one (2b). Isolated by distillation. Liquid; bp 55 °C/3 mmHg (lit,[3] bp 95 °C/20 mmHg.).

4-Methyl-5-methylene-4-(2-methylpropyl)-1,3-dioxolan-2-one (2c). Isolated by distillation. Liquid; bp 110—125 °C/3 mmHg. Found: C, 63.36; H, 8.65%. Calcd for $C_9H_{14}O_3$: C, 63.51 H, 8.29%. IR (neat) 1820, 1680, 840 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.89 (d, 6H, J=6 Hz), 1.51 (s, 3H), 2.32—2.60 (m, 1H), 2.60—2.72 (br, 1H), 4.22 (d, 1H, J=4 Hz), 4.72 (d, 1H, J=4 Hz).

4,4-Diethyl-5-methylene-1,3-dioxolan-2-one (2d). Isolated by distilation. Liquid; bp 76 °C/66 mmHg. Found: C, 61.65; H, 7.97%. Calcd for $C_8H_{12}O_3$: C, 61.52; H, 7.74%. IR (neat) 1820, 1680, 845 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.91 (t, 6H, J=7 Hz), 1.40—2.10 (m, 4H), 4.17 (d, 1H, J=4 Hz), 4.80 (d, 1H, J=4 Hz).

Reaction of 3-Butyn-2-ol (4) with CO_2. The alcohol **4** (64 mmol) was reacted with CO_2 (50 kg cm^{-2}) in the presence of $CoCp_2$ (1 mmol) and Et_3N (3.6 mmol) at 80 °C for 5 h. GLC analysis (Silicone DC-550, 20%, 3 m, 170 °C) showed the formation of 1-methyl-2-oxopropyl 1-methyl-2-propynyl carbonate (**5**)[5] in 15% yield together with several minor products.

Reaction of Propargyl Alcohol (6) with CO_2. The alcohol **6** (86 mmol) was reacted with CO_2 (50 kg cm^{-2}) in the presence of $CoCp_2$ (1 mmol) and NEt_3 (3.6 mmol) at 80 °C for 5 h. GLC analysis (Silicone DC-550, 20%, 3 m, 170 °C) showed the formation of dipropargyl carbonate (**7**) and hydroxyacetone in 6 and 0.2% yield, respectively. Addition of PPh_3 (1 mmol) increased the yield of **7** up to 24%.

Reaction of 2,5-Dimethyl-3-hexyne-2,5-diol (9) with CO_2. The diol **9** (50 mmol) was reacted with CO_2

($50\ kg\ cm^{-2}$) in the presence of $CoCp_2$ (1 mmol) and Et_3N (3.6 mmol) at 110 °C for 5 h. GLC analysis (Silicone GE SE-52, 20%, 2 m, 85 °C) showed the formation of 2-hydroxy-2,5-dimethyl-3-hexanone (**10**) in 53% yield. The product **10** was isolated by distillatiuon. Liquid; bp 44 °C/4 mmHg. Found: C, 67.42; H, 10.25%. Calcd for $C_8H_{14}O_2$: C, 67.57; H, 9.93%. IR (neat) 3440, 1675, 1615, 1440, 1360, 1030, 960 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.30 (s, 6H), 1.91 (s, 3H), 2.16 (s, 3H), 4.12 (s, 1H), 6.20 (s, 1H).

Reaction of 2-Methyl-3-butyn-2-ol-*d* (1a-d_1) with CO_2. A 50 cm^3 flask was flushed with N_2 and was then charged with 28 cm^3 of diethyl ether, 12 cm^3 of **1a**, and 5 cm^3 of D_2O. The flask was shaken vigorously for 5 min. It was placed in a salt/ice bath, the water layer frozen, then the ethereal layer was transferred by a syringe to another flask containg D_2O. This procedure[10] was repeated for five times in all. The final ethereal solution was dried over K_2CO_3 and distilled to yield ca. 5 cm^3 of **1a**-d_1, which was 76% deuterated (by integration of the NMR). The deuterated alcohol **1a**-d_1 (37 mmol) was reacted with CO_2 ($50\ kg\ cm^{-2}$) in an autoclave in the presence of $CoCp_2$ (1 mmol) without triethylamine at 80 °C for 1 h. After that time, the resulting reaction mixture was analyzed by ^1H NMR. The yield of **2a**-d_1 was 10%. No H–D scrambling between the alcoholic deuterium and the acetylenic proton was observed during the reaction. The ratio of the exo methylene proton in the position cis to the oxidocarbonyloxy group to that in the position trans was 47:53 for the product **2a**-d_1.

Syntheses and Biological Activities of Substance P Analogs Containing L- and D-Homoglutamine and L- and D-Pyrohomoglutamic Acid at Position 5 and 6

Tadashi HASHIMOTO,* Yoshiki UCHIDA, Miwako NISHIJIMA, Naoki SAKURA, and Kyoko HIROSE
School of Pharmacy, Hokuriku University, Ho-3, Kanagawa-machi, Kanazawa 920-11
(Received October 6, 1986)

Synopsis. Six substance P (SP) analogs substituted by L- and D-homoglutamine and L- and D-pyrohomoglutamic acid (6-oxo-2-piperidinecarboxylic acid) at position 5 and 6 were synthesized by standard solid phase method. The contractile activities of the analogs were compared with that of SP on isolated guinea-pig ileum and trachea.

Substance P[1] (SP), an undecapeptide with the sequence [H-Arg-Pro-Lys-Pro-Gln-Gln-Phe-Phe-Gly-Leu-Met-NH_2[2]], is a putative neurotransmitter or a neuromodulator. Up to date, numerous SP analogs have been synthesized and their structure-activity relationships have been studied. The potencies of SP related peptides, pGlu-Gln-Phe-Phe-Gly-Leu-Met-NH_2 **1** and pGlu-Phe-Phe-Gly-Leu-Met-NH_2 **2**, have been found to be higher than the contracting activity of SP itself on guinea-pig ileum[3] (Table 1).

Our study[4,5] on the structure-activity relationships of SP and the SP related peptide **1** revealed that the elongation of the methylene group of the side chain in the Gln residue(s), that is, the substitution of L-homoglutamine (Hgn) for Gln moiety at position 5 and 6, enhanced the contractile activity on the smooth muscle of isolated guinea-pig ileum, and the replacement of the Gln residue(s) with D-Hgn moiety brought the decrease of the activity on the ileum assay. On pyrohomoglutamic acid (pHgu, 6-oxo-2-piperidinecarboxylic acid) peptide analogs[6] (Table 1) of the SP related peptides, the potency of [pHgu^6]-SP (6—11) **5** was higher than the activity of [D-pHgu^6]-SP (6—11) **6**, while [pHgu^5]-SP (5—11) **3** showed lower activity than that of [D-Hgu^5]-SP (5—11) **4**.

This paper describes syntheses and biological properties of six analogs (Fig. 1) of SP and SP related peptides: [L-Hgn^5, D-Hgn^6]- and [D-Hgn^5, L-Hgn^6]-SP and SP (4—11) and [L-pHgu^5, D-Hgn^6]- and [D-pHgu^5, L-Hgn^6]-SP (5—11). The contracting activities of the synthetic peptides were compared with that of our synthetic SP in order to examine the biological effects of the substitution and confirm the greater importance of the L-configuration of the amino acid residue at the position 6 than that of the residue at the position of 5 for the contractile activities of SP.

The SP analogs were synthesized in the same way with the preparation of L-Hgn analogs[4] by the solid phase technique on an automated peptide synthesizer by standard solid phase method[7] starting from *t*-butoxycarbonyl(Boc)-Met-benzhydrylamine-resin. α-Amino functions were protected by Boc group. The side-chain-protecting groups were benzyloxycarbonyl for Lys, tosyl for Arg and Boc for the amide nitrogen

[Hgn^5, D-Hgn^6]-SP	H-Arg-Pro-Lys-Pro—Hgn-D-Hgn-Phe-Phe-Gly-Leu-Met-NH_2	**7**
[D-Hgn^5, Hgn^6]-SP	H-Arg-Pro-Lys-Pro-D-Hgn—Hgn-Phe-Phe-Gly-Leu-Met-NH_2	**8**
[Hgn^5, D-Hgn^6]-SP (4-11)	H-Pro—Hgn-D-Hgn-Phe-Phe-Gly-Leu-Met-NH_2	**9**
[D-Hgn^5, Hgn^6]-SP (4-11)	H-Pro-D-Hgn—Hgn-Phe-Phe-Gly-Leu-Met-NH_2	**10**
[pHgu^5, D-Hgn^6]-SP (5-11)	pHgu-D-Hgn-Phe-Phe-Gly-Leu-Met-NH_2	**11**

(N^{ca}) of Hgn. The Hgn residue can be incorporated into a peptide chain by the usual solid phase technique and solution method using N^{α},N^{ca}-$(Boc)_2$-Hgn-OH[4,8], which is derived from the ester of $(Boc)_2$-Lys-OH by ruthenium tetraoxide oxidation.[9,10] The protecting group Boc on the amide of N^{α},N^{ca}-$(Boc)_2$-Hgn-OH can be removed by the same deblocking reagents as those for the protecting group on the α-amino function to produce the Hgn moiety.[8,10] Our investigation[6,11] developed a simple method for synthesis of pHgu-peptide by cyclization of Hgn residue at N-terminus in peptide chain.

The synthetic products were purified by preparative reverse-phase high-performance liquid chromatography (HPLC) using 0.1% trifluoroacetic acid in acetonitrile as eluent. Highly purified peptides (Tables 2 and 3) were obtained after gel filtration of Sephadex G-10 column. Homogeneity of the peptides was demonstrated by analytical HPLC and thin-layer chromatography (TLC). When single peak and single spot were observed for a peptide in all chromatographic systems used, the peptide was considered appropriately pure for bioassay. These chromatographic data were reinforced by the amino acid analytical data.

The agonistic effects of the synthetic peptides were compared with that of our synthetic SP on the isolated guinea-pig ileum and trachea. The results are presented in Table 4.

Table 2. Physical Properties and Yields of the Synthetic Peptides

Analog	$[\alpha]_D^{14}$ (c 0.5, 3M AcOH)/°	Retention time[a)] / min	R_f^{I}	R_f^{II}	Yield / %
7	−68.0	11.2	0.00	0.58	14.5
8	−53.8	11.3	0.00	0.58	20.6
9	−24.6	14.7	0.13	0.71	11.4
10	−39.4	14.5	0.13	0.71	20.1
11	−35.4[b)]	17.1	0.47	0.85	15.0
12	−46.2[b)]	17.2	0.46	0.85	13.3

a) Condition of analytical HPLC: column, NOVA-PAK C_{18}; flow rate, 1 ml min^{-1}; Detection, 210 nm; eluent system, linear gradient from 21% to 35% CH_3CN (15 min) in 20 mM phosphate buffer (pH 3.0). b) c 0.5, DMF.

The potency of [D-Hgn[5],Hgn[6]]-SP **8** was as high as the activity of SP itself on the guinea-pig ileum assay. The replacements of both Gln residues at the position 5 and 6 with Hgn-D-Hgn sequence brought the drastic decrease of the activities on the both assays. The C-terminal octapeptide analog **10** was found to have about 10% activity of **8** on the ileum assay. D-pHgu-peptide analog **12** possessed the highest potency among the six analogs **7**—**12** on the both assays, while pHgu-peptide analog **11** had little activities. The results indicate that the L-configuration of the amino acid residue at the position 6 may be more important than that of the residue at the position 5 for the contractile activities of SP and SP related peptides.

Experimental

Amino acid derivatives were purchased from Peptide Institute, Inc., Osaka, and benzhydrylamine (BHA) resin (available amine of the resin: 0.6 mmol g^{-1} of support) from Beckman Inc. Optical rotations were measured in a Nipponbunkoh DIP-4 Polarimeter. Amino acid analyses on samples previously hydrolyzed with 6 M HCl (1 M=1 mol dm^{-3}) (110 °C, 24 h) were performed on a Hitachi KLA-5 Amino Acid Analyzer. TLC were carried out on silica-gel plates (Merck). The following solvent systems were used: R_f^{I}, n-BuOH:AcOH:H_2O (4:1:5, upper phase); R_f^{II}, n-BuOH:pyridine:AcOH:H_2O (30:20:6:24). Analytical HPLC were effected on the following systems: column, NOVA-PAK C_{18} (3.9×150 mm); flow rate, 1 ml min^{-1}; detection, 210 nm; eluent system, linear gradient for 15 min from 21% to 35% CH_3CN in 20 mM phosphate buffer (pH 3.0).

a) Homoglutamic acid.

General Procedure for the Preparation of Analogs. The solid phase synthesis was carried out using a Beckman System 990C Peptide Synthesizer as described previously.[4] Half gram of BHA-resin hydrochloride for each analog served as the solid support. A 2.5 fold excess of amino acid derivative was used for all coupling. The coupling was effected with dicyclohexylcarbodiimide/1-hydroxybenzotriazole. The protected peptide resin was treated with anhydrous liquid HF[12] containing 10% anisole. After evaporation of HF in vacuo, the peptide was extracted with 50% AcOH. The extract of N-terminal Hgn-peptide was kept at 40 °C for 4 h to yield pHgu moiety.

Purification of the Peptides. The crude peptide was subjected to HPLC as reported previously.[4] The apparatus was composed of a model 590 pump and a U6K injector (Waters) connecting with a column (20×300 mm) of Chemcosorb ODS (Chemco). The eluates were monitored with a UV detector S-310A model-II (Soma) at 210 nm wavelength. CH_3CN–0.1% TFA solvent system was used as eluent at flow rate 10 ml min^{-1}. Each peptide was emerged at 40—60 min by isocratical elution with 20—28% CH_3CN contents of the solvent system. The desired fraction was passed through a Sephadex G-10 column (16×930 mm) eluted with 2 M AcOH. Homogeneity of the peptides was analyzed by analytical HPLC and TLC.

Bioassay. The agonistic activity of the synthetic analog was measured on ileum and trachea taken from guinea-pig, as described before.[4] The contraction was recorded by means of an isotonic transducer (Nippon Kohden, TD-111T) with load of 1 or 2 g (for trachea and ileum respectively) on a Servocorder (Watanabe Instruments, SR6204). Concentration-response curves were obtained using a cumulative dose-assay, and the time between two consecutive dose-response curves was longer than 10 min.

Kinetics of Aquation of Pentaammineglycinerhodium(III) Ion in Acidic Media

Chinmay CHATTERJEE* and Aya Singh BALI
Department of Chemistry, Indian Institute of Technology, Powai, Bombay 400 076, India
(Received February 6, 1986)

Synopsis. Acid-catalyzed aquation of pentaammineglycinerhodium(III) ion has been studied kinetically in aqueous perchloric acid media (0.05—0.45 mol dm^{-3}) over a temperature range of 60—80 °C at an ionic strength of 1.0 mol dm^{-3} adjusted with sodium perchlorate. Under these conditions the reaction occurs by two concurrent paths according to the rate law: Rate=k_o[complex]+k_{H^+}[complex][H$^+$], where k_o and k_{H^+} are the rate constants for the spontaneous and acid-catalyzed pathways, respectively. Analysis of rate data suggests cleavage of metal-oxygen bond in the rate determining step for both the processes.

Kinetics of acid-catalyzed aquation of (carboxylato)- and (aminocarboxylato)pentaamminecobalt(III) complexes have been the subject of several investigations.[1-7] The aquation rates were correlated with the electronic and steric effects of the leaving group. In comparison, limited data[2] is available for the analogous reactions of corresponding rhodium(III) substrate, thus warrants further investigations. An amino acid usually coordinates to a metal ion with its amino and carboxylato group to form a chelate ring. However, in some amino acid cobalt(III) complexes[8,9] glycine has been found to coordinate as an unidentate ligand with its carboxylato end only. Surprisingly, no data is available to date on the nucleophilic substitution reaction of rhodium(III) amino acid complex. This paper reports the results of the kinetics of acid-catalyzed hydrolysis of pentaammineglycinerhodium-(III) ion in which amino acid exists in zwitterionic form and coordinated to the metal ion with its carboxylate end. The influence of the protonated amino group on the catalytic rate constant has been discussed. Based on comparison of rate and activation parameters for the present system with other carboxylato complexes, a plausible mechanism is suggested.

Experimental

Materials and Reagents: Pentaammineaquarhodium(III) perchlorate was prepared according to standard procedures.[10] Chemical analysis confirmed the purity, as did a comparison with the published UV-visible spectral data.[11]

Pentaammineglycinerhodium(III) perchlorate was prepared by digesting an aqueous solution (50 cm^3) of pentaammineaquarhodium(III) perchlorate (5 mmol) with five fold excess of glycine at 90 °C for 3 h followed by the slow evaporation of the reaction mixture to one third of its original volume. The solution on cooling separated white crystals of glycine complex, which were collected on a filter and washed with water–ethanol (1:1) mixture. The complex was recrystallized from cold aqueous solution by the addition of 30% perchloric acid, and washed successively with water–ethanol, ethanol, and finally dried in air. Found: C, 4.35; N, 14.90; H, 3.50%. Calcd for [Rh(NH$_3$)$_5$(glyH)](ClO$_4$)$_3$: C, 4.28; N, 14.96; H, 3.56%. Since the complex has been isolated from acidic solution, the amino acid retains an acidic proton and is coordinated as an unidentate neutral ligand as is evident from the elemental analysis. The positions and intensities of the ligand field bands of the complex (λ_{max} 322 nm, ε=144.0 dm^3 mol^{-1} cm^{-1}; λ_{max} 266 nm, ε=111.0 dm^3 mol^{-1} cm^{-1}) corresponding to $^1A_{1g}\rightarrow{}^1T_{1g}$ and $^1A_{1g}\rightarrow{}^1T_{2g}$ transitions, respectively, match well with those of the pentaamminecarboxylato rhodium(III) ion,[11] in which the ligand undoubtedly coordinates to the metal with its carboxyl group. In accord with the postulate of oxygen-bonded amino acid, IR spectrum of the title complex reveals a strong band at 1630 cm^{-1} assignable to C–O stretching band of the coordinated carboxyl group and the deformation band of $-NH_3^+$ group at 1490 cm^{-1}. ^{1}H NMR spectrum of the complex in DMSO-d_6 exhibits two broad bands at δ=7.5 and 3.75 ppm against TMS as reference with an intensity ratio 1:5 attributable to the $-NH_3^+$ and NH_3 protons. Disappearance of these peaks in D_2O confirms the assignments.

Measurements. A Varian superscan-3 spectrophotometer was used for absorbance measurements. The pH measurements were made using a PHM-64 research pH meter (Radiometer-Copenhagen). ^{1}H NMR spectra were recorded on a Varian XL 100 spectrometer.

Under experimental acidity range glycine complex has been found to aquate quantitatively leading to aqua product. Final concentration of the free glycine was determined by its reaction with ninhydrin as described in the literature.[6] The course of aquation reaction was monitored by measuring the decrease in absorbance at 325 nm, where the extinction coefficients of the glycine complex and aqua product were 143 and 100 dm^3 mol^{-1} cm^{-1}, respectively. The rate studies were made by a batch sampling technique,[12] with the thermostat controlled to ±0.1 °C. All experiments were carried out in excess of perchloric acid and the pseudo-first-order rate constants, k_{obsd}, were computed from the gradients of the linear plots of $\ln(A_t-A_\infty)$ versus time by means of a least-squares program. Under identical conditions k_{obsd} evaluated by the spectrophotometric method agreed well with the value obtained by the ninhydrin method. Acid dissociation constant of [Rh(NH$_3$)$_5$(O$_2$CCH$_2$NH$_3$)]$^{3+}$ at 25 °C and ionic strength 1.0 mol dm^{-3} was determined from conventional pH titrations against carbonate free sodium hydroxide solution. The pK_a value has been estimated as 8.80±0.03. It is thus evident that in the range of acid concentration employed for the reaction, the amino acid exists in zwitterionic form.

Results and Discussion

The observed pseudo-first-order rate constants, k_{obsd}, have been determined at 60.0±0.1, 70.0±0.1, and 80.0±0.1 °C, for perchloric acid concentration 0.05—0.45 mol dm^{-3} at ionic strength 1.0 mol dm^{-3} (NaClO$_4$). The variation of k_{obsd} with [HClO$_4$] under otherwise identical conditions is shown in Fig. 1 and the results suggest the operation of two concurrent paths:

$$-\mathrm{d}\ln[\text{complex}]/\mathrm{d}t = k_{obsd} = k_o + k_{H^+}[H^+], \quad (1)$$

where k_o and k_{H^+} represent the first order rate constant for acid independent and second order rate constant describing the acid-catalyzed pathways, respectively. Their values at different temperatures, as obtained from the intercepts and slopes of the plots shown in Fig. 1 using a linear regression analysis, are summarized in Table 1 along with the activation parameters, ΔH^* and ΔS^* values evaluated using transition state equation,

$$k = (RT/Nh)\exp(-\Delta H^*/RT + \Delta S^*/R). \quad (2)$$

Sequences of changes consistent with kinetic results are depicted below:

$$[(NH_3)_5Rh\text{-}O\overset{O}{\overset{\|}{C}}CH_2NH_3]^{3+} + H_2O \xrightarrow{k_o}$$
$$[Rh(NH_3)_5(OH_2)]^{3+} + \overset{+}{N}H_3CH_2COO^- , \quad (3)$$

$$\overset{+}{N}H_3CH_2COO^- + H^+ \xrightarrow{fast} \overset{+}{N}H_3CH_2COOH , \quad (4)$$

$$[(NH_3)_5Rh\text{-}O\overset{O}{\overset{\|}{C}}CH_2NH_3]^{3+} + H^+ \overset{K}{\rightleftharpoons}$$
$$[(NH_3)_5Rh\text{-}O\overset{H^+\ O}{\overset{\|}{C}}CH_2NH_3]^{3+} , \quad (5)$$

$$[(NH_3)_5Rh\text{-}O\overset{H^+\ O}{\overset{\|}{C}}CH_2NH_3]^{3+} \xrightarrow{k_1}$$
$$[Rh(NH_3)_5(OH_2)]^{3+} + HO_2CCH_2\overset{+}{N}H_3 . \quad (6)$$

The Reaction (3) corresponds to uncatalyzed path involving the attack of solvent molecule in the rate-determining step, while the acid-catalyzed path (5 and 6) involves the fast protonation action of substrate in a pre-equilibrium step followed by the rate-determining loss of glycine from conjugate acid. The catalytic rate constant, k_{H^+} is related to K and k_1 by the relation

$$k_{H^+} = Kk_1/(1+K[H^+]) . \quad (7)$$

The absence of any deviation from linearity for the k_{obsd} vs. $[HClO_4]$ plot even at the highest acid concentration indicates, $K[H^+] \ll 1$ and hence Eq. 7 reduces to $k_{H^+}=Kk_1$. The activation parameters corresponding to k_{H^+} thus involve both rate and equilibrium constants. In conformity with the proposed scheme, the protonated species is found to be more labile than the unprotonated one. This can be ascribed to the fact that the acid catalysis involves protonation of coordinated carboxylate and thereby putting a formal positive charge on ligand oxygen atom. Strong bonding between oxygen atom and H^+ ion in the protonated form of the complex leads to electron withdrawal from Rh-O bond thus facilitating

Table 1. Rate and Activation Parameters for Aquation of Pentaammineglycinerhodium(III) ion. (I=1.0 mol dm^{-3})

Table 2. Rate Parameters for Aquation of Pentaamminecarboxylatorhodium(III) Complexes (I=0.1 mol dm^{-3})

	pK_a of the acid	Temp/°C	k_o/s^{-1}	k_{H^+}/mol dm^3 s^{-1}	Ref.
[Rh(NH$_3$)$_5$CF$_3$COO]$^{2+}$	0.3	78.9	1.5×10^{-4}	1.5×10^{-4}	2
[Rh(NH$_3$)$_5$glyH]$^{3+}$	2.35	80.0	2.0×10^{-5}	0.8×10^{-4}	Present work
[Rh(NH$_3$)$_5$Hmal]$^{2+}$	2.7	80.0	1.8×10^{-5}	3.4×10^{-4}	13
[Rh(NH$_3$)$_5$CH$_3$COO]$^{2+}$	4.75	78.7	4×10^{-6}	26.0×10^{-4}	2
[Rh(NH$_3$)$_5$CH$_3$CH$_2$COO]$^{2+}$	4.87	80.0	4×10^{-6}	30.0×10^{-4}	13
[Rh(NH$_3$)$_5$(CH$_3$)$_3$CCOO]$^{2+}$	5.05	78.6	2×10^{-6}	8.9×10^{-4}	2

the rate of release of glycine. The effect of ionic strength (I) on aquation reaction was examined at 80 °C and the values of the rate constants at I=0.1 mol dm^{-3} have been tabulated in Table 2. The uncatalyzed rate constant tend to decrease slightly whereas acid-catalyzed rate constant, k_{H^+} increases significantly with increase in ionic strength. The equilibrium constant, K, between cations such as that expressed by Eq. 5 generally increases with increasing ionic strength and hence the k_{H^+} value. The rate parameters for the analogous reaction of other pentaamminecarboxylatorhodium(III) complexes have been summarized in Table 2 for comparison. Basolo et al.[2] while studying aquation of carboxylato complexes observed that k_o values tend to decrease with increase in pK_a of the acid. This can be explained due to increase in metal-ligand bond strength with increasing basicity of the carboxylate ligand. k_o value for the title complex nicely fits into the relationship and the reactivity order follows the sequence:

$$CF_3COO^- > \overset{+}{N}H_3CH_2COO^- > CH_2C_2O_4H^- >$$
$$CH_3COO^- \simeq CH_3CH_2COO^- > (CH_3)_3CCOO^-.$$

ΔH^* value for the uncatalyzed path is comparable to that of other carboxylato complexes of rhodium(III). On the basis of comparable ΔH^* values it is reasonable to conclude that the uncatalyzed path proceed by mechanism identical to that operative in other carboxylato complexes where cleavage of metal-oxygen bond is suggested to take place in the rate-determining step.[2]

With the exception of glycine and pentaammine(pivalato)rhodium(III) ion, the acid catalyzed rate constant tend to increase with increasing pK_a of the carboxylic acids. The pK_a affects the magnitude of equilibrium constant K, as expressed by Eq. 5 and hence k_{H^+} value. Low k_{H^+} value for glycine complex can be ascribed to the retardation of protonation arising from an electrostatic effect of the $-\overset{+}{N}H_3$ group present in the neighborhood of carboxyl group, while the impediment of protonation in case of pivalato complex has been explained due to steric factor. The acid hydrolysis of metal carboxylates can proceed either by M–O or C–O bond rupture in the transition state. On the basis of kinetic studies it has been suggested that the cleavage of C–O bond in the transition state leads to a low ΔH^* value (67.0—75.0 kJ mol^{-1}) whereas cleavage of M–O falls in the range of 90—110 kJ mol^{-1} for the aquation of Rh(III) complexes.[14] The enthalpy of activation for the title complex (ΔH^*=105.8±0.8 kJ mol^{-1}) is much higher than that reported for the acid-catalyzed decarboxylation of pentaamminecarbonatorhodium(III) ion (ΔH^*=71.0±2.1 kJ mol^{-1}),[15] for which C–O bond rupture has been proposed to take place in the transition state. Hence Rh–O bond cleavage in the transition state seems to be more plausible for the present system.

Application of Pyrrole/*N*-Methylpyrrole Composite Polymer to Cathode Active Material of Lithium Secondary Battery

Katsuhiko NAOI, Takayuki HIRABAYASHI, Ichiro TSUBOTA, and Tetsuya OSAKA*
Department of Applied Chemistry, School of Science and Engineering, Waseda University,
3-4-1 Okubo, Shinjuku-ku, Tokyo 160
(Received May 23, 1986)

An electrochemically prepared polypyrrole(PPy)/poly(*N*-methylpyrrole)(PMPy) composite polymer film-(PPy-PMPy) was used as a cathode active material of a rechargeable lithium battery. The charging-discharging behavior of a Li/$LiClO_4$/(PPy-PMPy) battery was studied and compared with those of Li/$LiClO_4$/PPy and Li/$LiClO_4$/PMPy batteries. In order to rationalize the charging-discharging properties of these batteries, anion doping-undoping processes at PPy, PMPy, and PPy-PMPy electrodes were checked using the usual electrochemical techniques, such as cyclic voltammetry and potential step chronoamperometry. A PPy-PMPy film electrode gave an intermediate conductivity as well as an intermediate redox potential just between those of the PPy and PMPy electrodes. Li/$LiClO_4$/(PPy-PMPy) batteries with thin (0.3 Ccm^{-2}-charged) and thick (10 Ccm^{-2}-charged) PPy-PMPy films were found to show different charging-discharging characteristics, depending on their film thickness. The IR spectra obtained for a PPy-PMPy film showed that the composition of PPy and PMPy in the resulting PPy-PMPy film was different according to its film thickness and that the PPy content in the PPy-PMPy film became higher with an increase in its film thickness.

Electrochemical properties of electro-conductive heterocyclic polymers and their derivatives have recently been studied extensively.[1-13,18,19] Greater attention has been paid to the unique applications of these polymers by many workers.[14-19] These polymers are advantageous because of the ease of formation and strong adhesion to various substrates.[9] PPy and its derivatives are expected to be potential candidates for cathode active materials of polymer batteries.[8] Our research group has been working on the electrochemical properties of several kinds of lithium/polymer batteries, where polymers were used exclusively as cathode active materials. Lithium batteries constructed with these polymers have higher capacities per unit weight than conventional secondary batteries.[8] In our previous study,[20] an excellent PPy film suitable as a rechargeable battery material was successfully obtained by electro-oxidative polymerization in the presence of PF_6^- electrolyte anions. By polymerizing pyrrole in the presence of *N*-methylpyrrole, the resulting PPy-PMPy film showed a somewhat different morphology from a PPy film because of the incorporation of PMPy in a PPy film. Recently, copolymerization of pyrrole and *N*-methylpyrrole was attempted; the resulting composite PPy-PMPy film was applied to a Schottky barrier type diode.[18] It had already been noticed that composite PPy-PMPy films gave various conductivities ranging from 10^{-3} to 10^2 Scm^{-1} at doped states of usual anions,[1] depending on the composition ratio of pyrrole and *N*-methylpyrrole monomers in the electrolyte solution during polymerization.[7] The conductivity of a PPy-PMPy film gradually decreases with an increase in the PMPy content. This fact may indicate that the polymer layer of a PPy-PMPy film lacks planarity and that the polymer chains are more or less separated because of the bulkiness of the methyl group relative to hydrogen. Hence, the copolymerization of PPy and PMPy is expected to yield a practical means of donating a wide range of conductivities and various patterns of charging-discharging properties of Li/$LiClO_4$/(PPy-PMPy) batteries. It is also noteworthy that a PPy film can be highly stabilized in an ambient condition by copolymerizing with PMPy; the reasons for this are as follows. The degradation of a PPy film is rather substantial in the presence of oxygen or vapor. On the other hand, PMPy shows less reactivity with oxygen and water.[7] Therefore, PPy-PMPy must be more stable than a PPy film in an ambient atmosphere and must also be durable for practical use. As for its electrochemical properties, a PPy-PMPy electrode gives an intermediate redox potential in cyclic voltammograms just between those of PPy and PMPy film electrodes. The main purpose of this study was to examine the possibility of using a PPy-PMPy composite film as the positive electrode of a rechargeable lithium battery. In this connection, we examined the charging-discharging properties of a Li/$LiClO_4$/(PPy-PMPy) battery coupled with the basic electrochemical behavior of anion doping-undoping processes at PPy, PMPy, and PPy-PMPy electrodes.

Experimental

Reagent grade $LiClO_4$ and propylene carbonate (PC) were used as the electrolyte salt and the solvent, respectively in our experiment. The PC was used after purification by percolating through activated alumina. The minor water in the PC was removed by adding molecular sieves to it and then letting it stand for a few days until use.[15] All the potentials were in reference to the Ag/Ag^+ (0.01 mol dm^{-3} $AgNO_3$/PC) electrode. Polymer films were formed by electro-oxidative polymerization at a constant current density of 6.5 mA cm^{-2}. PPy and PMPy films were formed in 0.2 mol dm^{-3} $LiClO_4$/PC containing 0.2 mol dm^{-3} pyrrole or *N*-methylpyrrole monomer. A PPy-PMPy composite film was formed in 0.2 mol dm^{-3} $LiClO_4$/PC containing 0.1 mol dm^{-3} pyrrole and 0.1 mol dm^{-3} *N*-methylpyrrole monomers. A platinum plate of 0.25 cm^2 and a platinum wire were used as the deposition of polymers and counter electrodes, respectively. The depos-

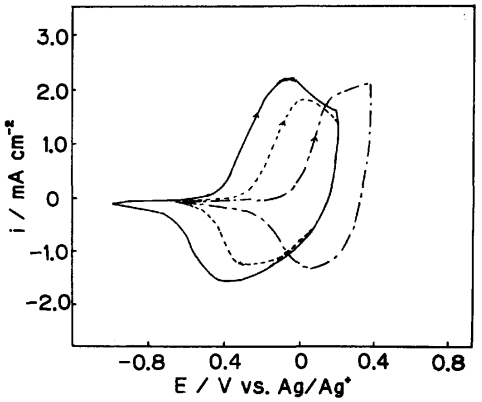

Fig. 2. Cyclic voltammograms of anion doping-undoping process for various polymer electrodes (1.8 C cm^{-2}) in 1.0 mol dm^{-3} $LiClO_4$/PC at 10 mV s^{-1}. ——: Polypyrrole, ----:pyrrole/*N*-methylpyrrole composite polymer, -·-·-: poly(*N*-methylpyrrole).

ited amount of polymers was controlled by monitoring the charge consumed during electropolymerization. Electrochemical measurements were performed in 1.0 mol dm^{-3} $LiClO_4$/PC in an Ar gas atmosphere. A Li/$LiClO_4$-PC/polymer battery was assembled with a polymer cathode and a Li anode pressed onto a Ni expanded mesh; the cell was placed in a small container purged with Ar gas and tightly sealed. Charging-discharging tests were conducted in 1.0 mol dm^{-3} $LiClO_4$/PC at a constant current density of 0.1 or 0.5 mA cm^{-2}. Apparent diffusion coefficients (D_{app}) of dopants within polymer electrodes were determined by potential step chronoamperometry, where the concentrations of dopants in the films (C_o*) were estimated from the anodization charges in cyclic voltammograms measured at 5 mV s^{-1}. Polymer films formed with different formation charges during electropolymerization, viz., 0.3 and 10 C cm^{-2} were characterized by FT-IR spectroscopy, after undoping anions by short-circuiting the cell for a sufficient time.

Results and Discussion

Figure 1 shows polymerization curves at a Pt electrode in electrolyte solutions containing three different monomers. The onset potentials for the three curves show almost the same values (ca. 0.4 V), at which each film begins to grow. As the anodic potential increases, the corresponding currents increase at the same rates, indicating that the polymerization processes for the three monomers occur at the same rate. However, the current efficiencies of the polymerization of these films may not be identical. On the basis of the above results, we formed these films at constant current densities of 6.5 mA cm^{-2}, since a moderate overpotential (ca. 0.49 V) was maintained throughout the formation of each film in order to avoid any decomposition of the films.

In order to survey the electrochemical responses of PPy, PMPy, and their composite PPy-PMPy films, cyclic voltammetry was employed; results are shown in Fig. 2. The anodic and cathodic current peaks for PPy-PMPy composite film are located just between those for PPy and PMPy films. The results suggest that a Li/$LiClO_4$/(PPy-PMPy) battery possesses intermediate charging and discharging voltages between those of a lithium battery assembled with PPy and PMPy films.

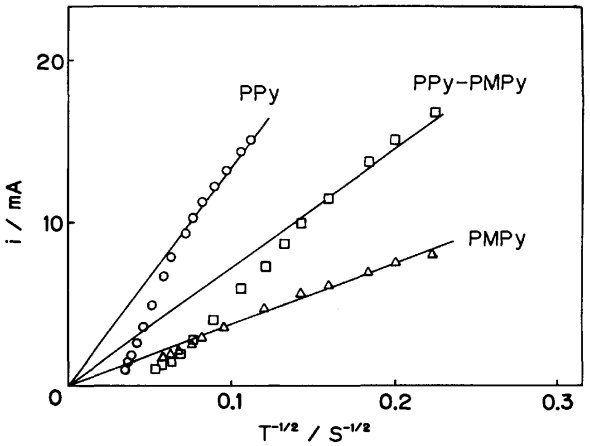

Fig. 3. Typical Cottrell plots for various polymer electrodes formed with 0.3 C cm^{-2}. Potential was stepped from −0.08 V (polypyrrole), 0.0 V (pyrrole/*N*-methylpyrrole composite) and 0.2 V (poly(*N*-methylpyrrole)) to the cathodic direction by 0.8 V.

Figure 3 shows typical Cottrell plots for 0.3 C cm^{-2}-charged films (ca. 0.6 μm) obtained by potential step chronoamperometry. A potential was initially applied at the anodic current peaks (cyclic voltammograms in Fig. 2), in order to oxidize (dope) the films so as to make the surface concentration of dopants (C_o*) in the same orders of magnitude (10^{-2} mol dm^{-3}) as indicated later. Then, the potential was stepped to the cathodic direction by 0.8 V in order to allow the films to reduce (undope). At the same time, the reduction currents of these films were monitored against time. Straight lines were obtained when plotting them against $t^{-1/2}$ (so-called Cottrell plots). Deviations of the plots from linear lines could be observed for larger t values, which

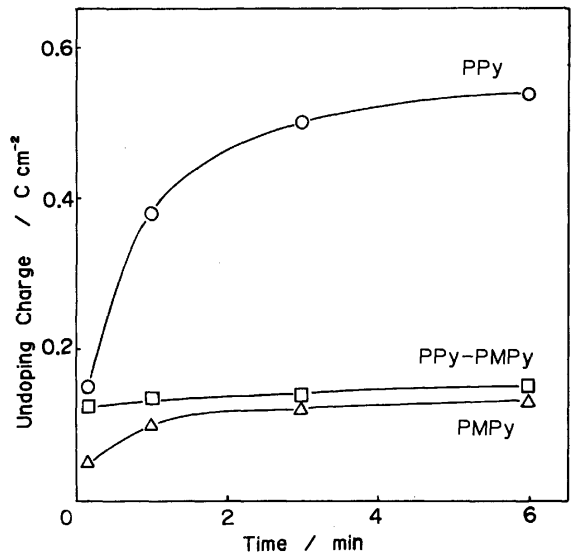

Fig. 4. Time dependence of ClO_4^- undoped charge for various polymer electrodes at −1.0 V, where these films were formed with 1.8 C cm^{-2}.

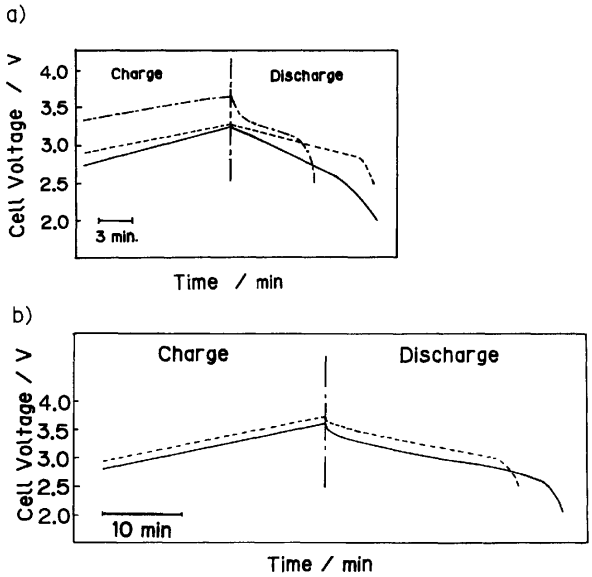

Fig. 5. Charging-discharging curves for Li/polymer batteries at a constant current of a) 0.1 mA cm^{-2} and b) 0.5 mA cm^{-2} in 1.0 mol dm^{-3} $LiClO_4$/PC. These films were polymerized with a) 1.8 C cm^{-2} and b) 10 C cm^{-2}.
——: Polypyrrole, ----: pyrrole/*N*-methylpyrrole composite polymer, -·-·-: poly(*N*-methylpyrrole).

are due to a finite diffusion layer that spread beyond the thickness of the polymer films. The apparent diffusion coefficient of dopants (D_{app}) within these films can be estimated from the slopes of the lines and C_o* by using the Cottrell equation. The D_{app} values obtained for PPy, PPy-PMPy, and PMPy films are 1.28×10^{-8}, 5.38×10^{-9}, and 3.43×10^{-9} cm^2 s^{-1}, respectively, where the C_o* values for the oxidized PPy, PPy-PMPy and PMPy films are 8.71×10^{-2}, 7.06×10^{-2}, and 4.52×10^{-2} mol dm^{-3}, respectively. The PPy-PMPy composite film has an intermediate D_{app} value just between PPy and PMPy films. This fact could be expected from the results in Fig. 2 and may have a close relation to the morphology of films having different composition ratios of PPy and PMPy polymers.

Figure 4 shows the undoping charges from polymer electrodes when the electrodes were polarized at −1.0 V. Although the cathodic current peaks in cyclic voltammograms locate more cathodic in the order of PMPy, PPy-PMPy, and PPy films, the dopants in the PPy electrode show the fastest undoping among other electrodes. The PPy-PMPy and PMPy films show a slower undoping process. The undoping behavior of these polymers can be ascribed to the film morphology and the number of effective reaction sites existing within the polymer matrix. The PPy film is considered to show the roughest morphology; also the number of reaction sites available for doping-undoping is much larger than those in PMPy and PPy-PMPy films. On the other hand, the PPy-PMPy and PMPy films show a surface-localized undoping process owing to the lesser degree of the film roughness and porosity. These facts also suggest that PMPy and PPy-PMPy films are more dense than the PPy film, and that the dopants may be confined tightly within the bulk of polymer layers and can hardly undope in spite of the negative potential step.

Figure 5 shows charging-discharging curves of Li/$LiClO_4$/polymer batteries, where the cathode films were formed with two different formation charges, viz., 1.8 C cm^{-2} for Fig. 5a) and 10 C cm^{-2} for Fig. 5b). By using thin PPy-PMPy films (Fig. 5a)), the Li/$LiClO_4$/(PPy-PMPy) battery gives intermediate curves between lithium batteries assembled with PPy or PMPy. The discharging behavior of the Li/$LiClO_4$/(PPy-PMPy) battery became flatter than those of a lithium battery constructed with PPy and PMPy, indicating better discharging characteristics. The coulombic yields for the lithium batteries constructed with PPy and PPy-PMPy films are both excellent and show almost the same values of 100%. In the case of thick films (10 C cm^{-2}), the Li/$LiClO_4$/(PPy-PMPy) battery gives 80% of coulombic yield, whereas 100% was still attained for the Li/$LiClO_4$/PPy battery. The charging-discharging curve for the Li/$LiClO_4$/PMPy battery is not given here since a 10 C cm^{-2}-charged PMPy film could not be obtained because of its high ohmic resistance. That is, under constant-current anodization, the polymerization potential of PMPy constantly increased, even beyond 5.0 V (at which PMPy film begins to decompose). The average discharge voltages for the lithium cells with the PPy and the PMPy films estimated from the figure are 3.0 and 3.2 V, respectively. The charging-discharging behavior for the lithium cells with PPy and PMPy is slightly different, depending on their film thickness. By increasing the thickness, the coulombic yield of the Li/(PPy-PMPy) battery decreases, indicating that the structure of a composite

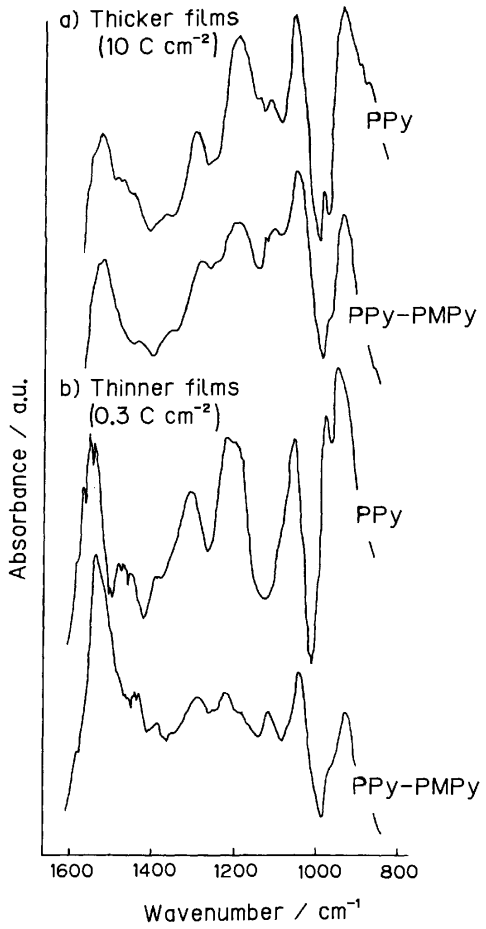

Fig. 6. Infrared spectra of a) thick and b) thin polymer films formed by passing a) 10 C cm^{-2} and b) 0.3 C cm^{-2} at the constant current density of 6.5 mA cm^{-2}.

film is dependent upon the film thickness.

Figure 6 shows the FT-IR spectra of PPy, and PPy-PMPy films of different formation charges. These charts show similar bands due to the pyrrole moiety (1300 cm^{-1}: C-N stretching; 1180, 1045 cm^{-1}: C-H deformation vibration; 965 cm^{-1}: N-H deformation vibration).[21] The IR spectrum of the PPy-PMPy (10 C cm^{-2}) film shown in Fig. 6a) is essentially the same as that of PPy film (10 C cm^{-2}). It is supposed that the PPy-PMPy film has almost the same structure as a PPy film and that the PMPy content is negligibly small in a thick PPy-PMPy film. The peaks due to ClO_4^- anions (1060~1140 cm^{-1}) shown in the two charts for thick films are slightly different. The fact indicates that the number of dopants remaining in the polymer films is different. In a thick PPy-PMPy film, greater amounts of dopants are still confined in the polymer chain than in the PPy film, although dopants have been undoped by short-circuiting the cells for the same duration of time. As for the thin films shown in the lower part of Fig. 6, the PPy-PMPy film shows less similarity to the PPy film than those shown in the thicker films. In the chart of the PPy-PMPy film, several splited peaks can be observed in the region of the C-H or N-H deformation vibration (1000~1300 cm^{-1}). The PMPy content in a PPy-PMPy film of this thickness may be larger than that in a thick PPy-PMPy film.

By comparing the IR charts shown in Figs. 6a) and 6b), the structures of the PPy-PMPy composite films show a strong dependency upon their thickness. It is also deduced from the IR results that each peak in the thick films is broadened because of the poor crystallinity of the polymer layer. Hence, a composite film contains more PMPy at the beginning of film formation. However, as the film grows thicker, the PPy content gradually becomes dominant in the composite film because of an easier growth of a PPy film on thicker polymer films (as is suggested in cyclic voltammograms shown in Fig. 2).

The composition ratio of PPy and PMPy in the PPy-PMPy film offering an optimal charging-discharging curves should await further investigation.

The authors would like to thank Prof. Noboru Oyama and Dr. Takeo Ohsaka, Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, for experimental support. Binding and Catalytic Properties of Charged β-Cyclodextrins

Yoshihisa MATSUI,* Kouichi OGAWA, Seiji MIKAMI, Misao YOSHIMOTO, and Kazuo MOCHIDA
Faculty of Agriculture, Shimane University, Nishikawatsu, Matsue 690
(Received July 24, 1986)

The effects of the signs and structures of charged groups in modified β-cyclodextrins on their binding and catalytic properties were examined in aqueous solutions by using ammonium salt of mono(6-sulfonato-6-deoxy)-β-cyclodextrin and hydrogencarbonate salts of mono(6-trimethylammonio-6-deoxy)- and mono[6-(1-pyridinio)-6-deoxy]-β-cyclodextrins as charged hosts. An ionic guest was bound more strongly to an oppositely charged host than to an identically charged host. Binding constants for charged host-guest systems were affected by a change in the ionic strength and by the addition of dimethyl sulfoxide to an aqueous solution. The catalytic effects of the charged hosts on the alkaline hydrolyses of *o*-, *m*-, and *p*-acetoxybenzoic acids were also different from those of the parent β-cyclodextrin. These results could be explained in terms of electrostatic, steric, and hydrophobic interactions between the hosts and guests.

Several intermolecular interactions have been proposed as being responsible for the formation of cyclodextrin (CD) inclusion complexes in aqueous solutions.[1-3] They are hydrophobic interactions, van der Waals interactions, hydrogen bonding, interactions due to the relief of high energy water from the CD cavity upon substrate inclusion, and interactions due to the relief of conformational strain in a CD-water complex upon substrate inclusion. These binding forces also play an important role in the binding processes of enzymes. This is one of reasons why CD has been widely studied as an enzyme model. However, an enzyme is a kind of polyelectrolyte. Electrostatic interactions between charged groups of an enzyme and an ionic substrate often contribute to the specificity of enzyme action.[4] On the other hand, CD is a neutral molecule and no electrostatic interaction can take part in its binding and catalytic processes. In order to enhance the substrate-specificity of CD, it is desirable to build up a molecular system in which a variety of intermolecular interactions, including electrostatic interactions, act simultaneously and cooperatively. Thus far, only a few studies have been reported which dealt with the binding and/or catalytic properties of charged CD's. Tabushi et al.[5] prepared a 1 : 1 complex of Zn(II) with β-CD functionalized by diethylenetriamine and showed that the positively charged host binds a negatively charged substrate, 2-oxo-1-adamantanecarboxylate, 330-times stronger than β-CD. Boger and Knowles[6] prepared positively charged triammonio-per-*O*-methyl-α-CD, which binds benzyl phosphate ca. 1000-times stronger than the corresponding monoammonium host. Matsui and Okimoto[7] examined the binding and catalytic properties of a positively charged CD, mono(6-trimethylammonio-6-deoxy)-β-CD [β-CDtma(+)]. The charged host exhibited abilities to bind an anionic dye more strongly than the parent host and to catalyze the alkaline hydrolyses of negatively charged *o*-, *m*-, and *p*-acetoxybenzoates in a manner significantly different from that of the parent β-CD.

The present investigation was undertaken to examine the effects of the sign and structure of charged groups in modified β-CD's on their binding and catalytic properties. For this purpose, we used the hydrogencarbonate salts of β-CDtma(+) and mono[6-(1-pyridinio)-6-deoxy]-β-CD [β-CDpy(+)] as positively charged CD's and the ammonium salt of mono(6-sulfonato-6-deoxy)-β-CD [β-CDsulf(−)] as a negatively charged CD. Electrostatic interactions are generally affected by such environmental factors as the ionic strength and polarity of the solution. The present study also dealt with the effects of these factors on the action of the charged hosts.

Experimental

Materials. The β-CD of a reagent grade was recrystallized from water and dried overnight in vacuo at 110 °C. Reagent-grade pyridine was dried over calcium hydride and distilled in the presence of fresh calcium hydride just before use. Mono[6-*O*-(*p*-tolylsulfonyl)]-β-CD (β-CDots) was prepared by a reaction of β-CD with *p*-toluenesulfonyl chloride in dry pyridine.[7] The β-CDtma(+) was prepared by a reaction of β-CDots with trimethylamine in *N*,*N*-dimethylformamide and then purified as described previously.[7] Reagent-grade dimethyl sulfoxide (DMSO) was distilled in the presence of calcium hydride in vacuo. Crystal Violet (CV), phenolphthalein (PP), ammonium 8-anilinonaphthalene-1-sulfonate (ANS), Methyl Orange (MO), *p*-nitrophenol (pNP), cyclohexanol (CHX), and *o*-acetoxybenzoic acid (*o*-ABA) were commercially available. The *m*- and *p*-acetoxybenzoic acids (*m*- and *p*-ABA) were prepared by reactions of the corresponding hydroxybenzoic acids with acetic anhydride in dry pyridine and were then recrystallized from chloroform.

Thin-layer chromatography (TLC) was performed on Kieselgel 60F_{254} (Merck) with a mixed solvent of acetic acid–chloroform–water [80 : 10 : 20 (v/v)]. A saturated solution of cerium(IV) sulfate in concentrated sulfuric acid was used as a spray reagent to detect the parent and modified β-CD's. The charged β-CD's were separated from the reaction mixtures by liquid chromatography with a 4.5×43 cm CM-cellulose (Serva) column, a 5×49 cm DEAE-sephadex (Pharmacia) column, and/or a 4×73 cm Sephadex G-15 (Pharmacia) column.

Apparatus. Absorption, fluorescence, and NMR spectra were recorded using a Hitachi Model 220 spectrophotometer, a Hitachi Model 650-10S fluorescence spectrophotometer, and JEOL Model JNM-MH-100 and Nicolet Model NT-300

Table 1. Binding Constants (K_a/mmol^{-1}dm^3) for 1:1 Inclusion Complexes of Parent and Charged β-CDs with Organic Guests at 25 °C

Host	CV(+)[a]	PP(−)[b]	pNP(−)[c]	ANS(−)[d]	MO(±)[e]	CHX(0)[f]	DMSO(0)[g]
β-CD	4.0	29	0.77	0.091	0.30	0.71	0.0018
β-CDsulf(−)	2.6	3.4	0.053	0.037	0.18	0.37	0.0016
β-CDtma(+)	0.43	25	1.37	0.17	0.44	0.34	0.0009
β-CDpy(+)	—	50	1.52	0.26	—	0.43	0.0009

a) Crystal Violet at pH 5.0. b) Phenolphthalein at pH 10.5. c) *p*-Nitrophenolate at pH 10.5. d) 8-Anilinonaphthalene-1-sulfonate at pH 6.8. e) Methyl Orange in 0.1 mol dm^{-3} H_2SO_4. f) Cyclohexanol at pH 10.5. g) Dimethyl sulfoxide at pH 10.5.

NMR spectrometers respectively. The optical rotation was mesured using a Union Giken Model PM-101 polarimeter.

Preparation of β-CDpy(+). A solution of β-CDots (6.00 g, 4.65 mmol) in dry pyridine (120 cm^3) was heated at 100 °C for 12 h. The reaction mixture was evaporated in vacuo at 40 °C to dryness. The residue was dissolved in water, and acetone was added to the solution to give a white precipitate. After being collected, the precipitate was dissolved in water (10 cm^3) and then chromatographed on a CM-cellulose column with 0.05 mol dm^{-3} ammonium hydrogencarbonate as an eluent. Each fraction (10 cm^3) was assayed by UV at 270 nm, polarimetry at 589 nm, and/or TLC. Fractions which gave only one spot with R_f 0.25 (fractions from No. 76 to No. 160) were combined and evaporated to dryness at 40 °C in vacuo. The residue was dissolved in water, and the solution was decolorized by activated charcoal and evaporated to dryness to afford 1.06 g (0.84 mmol; yield, 18% based on β-CDots) of the hydrogencarbonate salt of β-CDpy(+) as a white powder. The ^{1}H NMR spectrum of β-CDpy(+) in D_2O gave peaks due to pyridinium protons at δ=8.07 (t, meta-H), 8.58 (t, para-H), and 8.82 (d, ortho-H) ppm with a ratio in peak area of 2:1:2. The mono-substitution of the CD hydroxyl groups by the 1-pyridinio group was confirmed by a comparison of the peak area of the CD protons with that of the pyridinium protons.

Preparation of β-CDsulf(−). To an aqueous solution (300 cm^3) of sodium sulfite (3.11 g, 24.7 mmol) was added β-CDots (6.03 g, 4.7 mmol); the resulting mixture was heated at 100 °C for 20 h. The reaction mixture was evaporated in vacuo at 40 °C to dryness, and the residue was washed twice with hot ethanol. After being dissolved in water, the residue was chromatographed on a DEAE-sephadex column. Linear gradient elutions were applied with 1.2 dm^3 of 0.02 mol dm^{-3} NH_4HCO_3 and 1.2 dm^3 of 0.1 mol dm^{-3} NH_4HCO_3 and then with 0.3 dm^3 of 0.1 mol dm^{-3} NH_4HCO_3 and 0.3 dm^3 of 0.5 mol dm^{-3} NH_4HCO_3. Each fraction (15 cm^3) were assayed by polarimetry at 405 nm and TLC. Fractions which gave only one spot with R_f 0.10 were combined and evaporated to dryness at 40 °C. The desalting of the resulting residue was carried out with a Sephadex G-15 column to give 2.16 g (1.78 mmol; yield 38% based on β-CDots) of the ammonium salt of β-CDsulf(−). The mono-substitution of the CD hydroxyl groups by the sulfonato group was confirmed by the oxidative degradation of β-CDsulf(−) with hot nitric acid, followed by a turbidimetric determination of the resulting sulfate ion with barium chloride and gelatin.

Determination of Binding Constants for Inclusion Complexes. The charged or parent β-CD was added to an aqueous buffer solution containing 0.008 mmol dm^{-3} CV (pH 5.0, citric acid-Na_2HPO_4), 0.03 mmol dm^{-3} PP (pH 10.5, $NaHCO_3$-NaOH), 0.05 mmol dm^{-3} pNP (pH 10.5, $NaHCO_3$-NaOH), 0.01 mmol dm^{-3} ANS (pH 6.8, NaH_2PO_4-Na_2HPO_4), or 0.02 mmol dm^{-3} MO (0.1 mol dm^{-3} H_2SO_4). After thermal equilibrium at 25 °C had been reached, the UV or fluorescence spectra were recorded. Binding constants (K_a) for 1:1 inclusion complexes of the hosts with the guests were determined by a least-squares curve-fitting analysis of relationships between absorbances and host concentrations with a microcomputer. The K_a values for the DMSO and CHX systems were estimated by a least-squares curve-fitting analysis of the inhibitory effect of the guests on the complexation of the hosts with PP at pH 10.5 in a similar manner described previously.[8]

Kinetics. The rates of the alkaline hydrolyses of *o*-, *m*-, and *p*-ABAs were measured by following the appearance of the absorptions of the corresponding phenoxide anions in the same way as described previously.[7] The K_a values and catalytic rate constants (k_c) for ABA-host systems were also determined in the same way as described previously.[7]

Results and Discussion

Binding Properties of the Charged β-CD's. Table 1 shows the K_a values determined for 1:1 inclusion complexes of the parent and charged hosts with a variety of guests. A positively charged guest, CV(+), was bound more strongly to β-CDsulf(−) than to β-CDtma(+). On the contrary, negatively charged guests, PP(−), pNP(−), and ANS(−), were bound more strongly to β-CDtma(+) and β-CDpy(+) than to β-CDsulf(−). The K_a values for inclusion complexes with amphoteric [MO(±)] and neutral [CHX(0), DMSO(0)] guests were not so much affected by the charges of the hosts. These results indicate that electrostatic attractive interactions do act between an oppositely charged host and its guest, and repulsive interactions between those with charges identical in sign. However, the effect of electrostatic interactions on the binding constants was relatively small. The K_a value for an oppositely charged host-guest system was, at most, 3 times that for a corresponding β-CD system. It seems that the replacement of one of the OH groups of β-CD by a charged group results in a decrease in hydrophobic interactions between the host and a guest. In fact, the K_a value for a β-CD-CHX(0) system, where hydrophobic interactions play an important role in complexation,[8] was decreased by a factor of ca. 2 by the introduction of a charged group to the host.

Among the guests examined, ANS(−) is known to be a fluorescent probe: The wavelength (λ_{max}) of the emis-

β-CDsulf(−)	502±2	4.5±0.4	0.27
β-CDtma(+)	487±1	23.1±0.3	0.63
β-CDpy(+)	485±3	2.3±0.1	0.72

a) [Host]=10.0 mmol dm^{-3}, [ANS(−)]=0.010 mmol dm^{-3}. b) The λ_{max} and I_{rel} values for ANS(−) in the absence of a host were 519±1 nm and 1.0 respectively. c) The fraction of ANS(−) bound to each host.

sion maximum decreases and the relative intensity (I_{rel}) of the peak increases with decreasing polarity of microenvironment around the probe[9)] or with decreasing internal rotation of the probe[10,11)] accompanied by an increase in viscosity or by the association with biopolymers. Similar spectral changes have been observed for a β-CD-ANS(−) system, where the hydrophobic nature of the β-CD cavity is responsible for the spectral changes.[12)] Table 2 shows the λ_{max} and I_{rel} values for the emission maxima of ANS(−) in the presence of 10 mmol dm^{-3} neutral and charged β-CD's. The λ_{max} values decreased in the order of β-CDsulf(−)>β-CD>β-CDtma(+)>β-CDpy(+). The I_{rel} values increased in the order of β-CDpy(+)<β-CDsulf(−)<β-CD<β-CDtma(+).[13)] It is unlikey that the significant blue shifts observed for β-CDtma(+) and β-CDpy(+) systems are brought about by a decrease in microenvironmental polarity, since the cavity of the charged β-CD's may be less hydrophobic than that of neutral β-CD. It is more plausible that the internal rotaion of ANS(−) is restricted by the attractive electrostatic interactions between the charged β-CD's and the guest. Similar effects of electrostatic interactions were reported for complexes of ANS(−) with biological membranes and detergent micelles.[14)] The I_{rel} value for a β-CDpy(+) system was unusually low, compared with that for a β-CDtma(+) system. The pyridinio moiety of β-CDpy(+) may interact with the singlet excited species of ANS(−) to accelerate the quenching of the excited species. This presumption was substantiated by the fact that the addition of *N*-ethylpyridinium chloride (Etpy) in place of β-CDpy(+) to an aqueous ANS(−) solution also caused a decrease in I_{rel} (I_{rel}=0.84 at [Etpy]=18 mmol dm^{-3}).

Effects of Ionic Strength and an Organic Solvent on Binding Constants. Thermodynamic stabilities (log K_a) for inclusion complexes of β-CD, β-CDsulf(−), and β-CDtma(+) with CV(+) and PP(−) increased in proportion to the square root of ionic strength (I_c) in a manner similar to that described preveously.[7)] Ionic strength was adjusted by use of potassium sulfate, which does not interact with the cavity of β-CD.[15)] Regression analysis of the relationships between them gave intercepts (A) and slopes (B) (Table 3). It is notable that the B values for identically charged host-guest

systems [β-CDtma(+)-CV(+) and β-CDsulf(−)-PP(−)] are larger than those for oppositely charged host-guest systems. The B values for neutral β-CD systems were intermediate between those for the charged β-CD systems. Hydrophobic interactions are generally strengthened by an increase in I_c (salting-out effect). This may be one reason why the B values for the neutral β-CD systems are positive. Electrostatic interactions are lowered by an increase in I_c (Debye-Hückel theory). In identically charged host-guest systems where electrostatic repulsive interactions as well as hydrophobic interactions are acting between host and guest, an increase in I_c weakens the repulsive interactions and strengthens the hydrophobic interactions. Thus, the B values for these systems become larger than those for the β-CD systems. In oppositely charged host-guest systems, electrostatic attractive interactions are weakened by an increase in I_c, although hydrophobic interactions are strengthened. Then, the B values for these systems become smaller than those for the β-CD systems.

The addition of an organic solvent, DMSO, to the media also changed the log K_a values for β-CD and β-CDtma(+) complexes with PP(−) and pNP(−) (Fig. 1). DMSO is bound to the hosts (Table 1), so that it competitively inhibits the complexation of the hosts with the anionic dyes. In order to shed light on the

solvent effect of DMSO, the net K_a values ($K_{a,net}$) for these systems were calculated from the apparent K_a values by use of Eq. 1, where K_i is the binding constants for the host-DMSO systems:

$$K_{a,net} = K_a(1 + K_i[\text{DMSO}]). \quad (1)$$

This equation can easily be derived on the basis of the law of mass action under conditions that the concentration of DMSO is much larger than that of a host. In neutral β-CD systems where hydrophobic interactions play an important role in complexation, the log $K_{a,net}$ values decreased greatly with increasing [DMSO]. On the other hand, the log $K_{a,net}$ values for the β-CDtma(+) systems were not so much lowered. An addition of DMSO to an aqueous solution results in a decrease in dielectric constant of the solution, which contributes to strengthening electrostatic attractive interactions between the oppositely charged host and guests. However, the attractive interactions were not so large as to overcome an accompanied decrease in hydrophobic interactions.

Effect of the Charged Hosts on the Alkaline Hydrolyses of ABAs. Kinetic parameters determined for the alkaline hydrolyses of ABAs in the presence of the hosts are shown in Table 4, where k_{un} and k_c are the first-order rate constants for free and complexed substrates, respectively. The substrates bear carboxylate anions in alkaline solutions. For *m*-ABA systems where the most remarkable effects of the charged hosts were observed among the substrates examined, kinetic parameters were also determined in the presence of DMSO.

The results were too complicated to be explained simply in terms of electrostatic interactions between hosts and guests in such a manner as described previously.[7] However, a few remarkable features are found among them. The positively charged β-CDtma(+) and the neutral β-CD accelerated, more or less, the hydrolyses of all the substrates examined. The degree of acceleration (k_c/k_{un}) was larger for β-CDtma(+)-*m*- and *p*-ABS systems than for the corresponding β-CD systems, and the reverse was true for *o*-ABA systems. Another cationic host, β-CDpy(+), decelerated the hydrolyses of *o*- and *p*-ABAs, though it accelerated the hydrolysis of *m*-ABA to a lesser extent than β-CDtma(+) or β-CD. The negatively charged β-CDsulf(−) decelerated the hydrolyses of *m*- and *p*-ABAs and accelerated that of *o*-ABA to a lesser extent than β-CD.

It is known that the degree of acceleration is closely related to the distance between the catalytic and reaction sites of the host-guest complex (proximity effect).[1,16] The catalytic site of each host is an alkoxide ion derived by the acid dissociation of a secondary OH group of the host.[1] The reaction site is an ester carbonyl carbon. Thus, the fact that the k_c/k_{un} value for a β-CDtma(+)-*m*- or *p*-ABA system is larger than that for the corresponding β-CD system implies that the reaction site is located more closely to the catalytic site in the former than in the latter. Electrostatic attractive interactions between the host and guest may be responsible, at least in part, for such a change in the geometry of an inclusion complex. Steric interactions between the charged groups of the host and guest may

also contribute to a change in the geometry. It has been reported[17] that the replacement of the primary OH group(s) of β-CD by some bulky group(s) results in significant changes in the rates of the alkaline hydrolyses of phenyl acetates. The trimethylammonio group of β-CDtma(+) is so bulky that it may be advantageous for the acceleration of the hydrolyses.

When the reaction site of a guest is deeply included within the cavity of a host, the site is protected from the nucleophilic attack of either the alkoxide ion of the host or the hydroxide ion in a bulk solution. Then, the hydrolysis of the guest is retarded by complexation. Such non-productive binding is probably brought about in β-CDsulf(−)-*m*- or *p*-ABA and β-CDpy(+)-*o*- or *p*-ABA systems. We could speculate for the case of a β-CDsulf(−) system that *m*- or *p*-ABA is inserted into the cavity of β-CDsulf(−) from the side of the acetyl group to minimize the electrostatic repulsive interactions between the sulfonate anion of the host and the carboxylate anion of the guest. However, it is difficult to reasonably explain at the present stage of investigation why β-CDpy(+) retards the hydrolyses of *o*- and *p*-ABA on one hand and β-CDtma(+) accelerates the reactions on the other hand. Further information on the geometries of the inclusion complexes is necessary in order to solve these problems.

The addition of DMSO to an aqueous solution also caused significant changes in the values of k_c/k_{un} and K_a. Generally, the k_c/k_{un} value increased and the K_a value decreased with increasing DMSO concentration. Similar DMSO effects have been reported by Trainor and Breslow.[18] The addition of DMSO may enhance the dehydration of the alkoxide ion of the hosts to facilitate its nucleophilic attack to the guests. On the other hand, DMSO is competitively bound to the hosts, as was previously described (Table 1), to weaken the binding of hosts to guests. A decrease in the polarity of a solvent with the addition of DMSO also contributes to the weakening of the hydrophobic interactions between the hosts and guests. Thus, the value of a net catalytic parameter, $K_a k_c/k_{un}$, did not always increase with increasing DMSO concentration.

Solution Properties of Dialkyl Phosphate Salts. Apparent Molar Volumes, Viscosity *B* Coefficients, Heats of Solution, and Osmotic Coefficients

Kunio TAMAKI,* Keita SUGA, and Eiko TANIHARA
Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama 236
(Received August 15, 1986)

The apparent molar volumes, viscosity *B* coefficients, and heats of solution of sodium salts of dialkyl phosphates (methyl, ethyl, and butyl) in water were measured. The limiting apparent molar volumes at 25 °C increased with the number of carbon atoms in the alkyl chains. The viscosity *B* coefficients of the salts decreased as the temperature was raised from 25 to 35 °C. The changes in heat capacity for dissolution in water, as calculated from the heats of solution at 15, 25, and 35 °C, were positive for the salts. The osmotic coefficients for lithium, sodium, and potassium salts of dimethyl phosphate were also measured. For a given concentration, the osmotic coefficients decreased in the order: $Li^+ < Na^+ < K^+$. From the results obtained, the $-(-O)_2PO_2^-$ ionic part may be classified as a structure-maker.

The physicochemical properties of organic monovalent anions, such as carboxylates and sulfonates in water, have been studied by many investigators.[1-9] Alkali metal salts of dialkyl phosphates ($(RO)_2PO_2M$) are other organic monovalent electrolytes. It seems that it would be interesting to study the properties of aqueous solutions of dialkyl phosphate anions; and the data would help to elucidate the role of the phosphate group in such a biological substance as nucleic acid. In this paper the experimental results will be reported on the apparent molar volumes, viscosity *B* coefficients, and heats of solution of sodium salts of dimethy, diethyl, and dibutyl phosphates in water. In addition, the osmotic coefficients of lithium, sodium, and potassium salts of dimethyl phosphate have also been measured in order to get information on the ion-solvent interaction of the phosphate anion.

Experimental

$(MeO)_2PO_2M$ (M=Li, Na, and K) was prepared by the reaction of trimethyl phosphate with the corresponding alkali metal iodides in acetone.[10] $(EtO)_2PO_2Na$ and $(n\text{-}BuO)_2PO_2Na$ were prepared by the neutralization of the corresponding dialkyl phosphates with a solution of sodium hydroxide, after which the water was evaporated to dryness; the salts were then extracted with ethanol. Commercial diethyl and dibutyl phosphates were purified before hand by the distribution between water and 1-pentanol according to the method of Stewart and Crandall.[11] The salts were purified by recrystallization from suitable solvents: ethanol-water solutions for $(MeO)_2PO_2Li$ and $(MeO)_2PO_2Na$, and ethanol-ethyl acetate solutions for $(MeO)_2PO_2K$, $(EtO)_2PO_2Na$, and $(n\text{-}BuO)_2PO_2Na$. All the salts were hygroscopic; they were dried in vacuo at 60 °C for several days, and the molecular weights were checked by means of volumetric analysis. A known amount of the sample was dissolved in water and passed through an ion-exchange resin in the hydrogen form; the eluent was titrated with a standard NaOH solution. It was found that the obtained samples were anhydrous. Water was triply distilled. The solutions were made by weight.

The densities were measured using a vibrating-tube densimeter, twin-type SS-D-200, of the Shibayama Scientific Co., Ltd. The viscosities were measured at 25 and 35 °C using an automatic viscometer of the Shibayama Scientific Co., Ltd. The details of the procedure were described in a previous paper.[9] The electric conductivities were measured with an LCR meter, AG-4301B, of the Ando Electric Co., Ltd., using a frequency of 1000 Hz.

The heats of solution were measured at 15, 25, and 35 °C using a twin isoperibol calorimeter, TIC-2C, of the Tokyo Riko Co., Ltd., by a method similar to that described in a previous paper.[9]

The osmotic coefficients were measured at 35 °C using a vapor pressure osmometer of Knauer & Co., Ltd. The resistance difference, ΔR, between matched thermistors, one with a drop of the solution, and the other with a drop of the solvent, was measured on a chart recorder 5 min after the application of the solution. At least 5 readings were made on each solution, and the results were averaged. The osmotic coefficents, ϕ, were calculated from the ΔR values using the relation:[12]

$$\phi = \Delta R/K\nu m, \tag{1}$$

where K is the apparatus constant; ν, the total number of ions produced by the complete dissociation of a molecule; and m, the molal concentration. The apparatus was calibrated with NaCl solutions of known molality and osmotic coefficient.[13]

Results and Discussion

Apparent Molar Volumes. The apparent molar volumes, ϕ_v, in $cm^3\,mol^{-1}$ were calculated from the densities using the following equation:

$$\phi_v = \frac{1000(\rho_0 - \rho)}{m\rho\rho_0} + \frac{M}{\rho}, \tag{2}$$

where M is the molar mass in $g\,mol^{-1}$ and ρ_0 and ρ are the densities in $g\,cm^{-3}$ of water and of a solution respectively. The apparent molar volume of the electrolytes is given by the equation:[14]

$$\phi_v = \phi_v^\circ + A_v c^{1/2} + B_v c, \tag{3}$$

where ϕ_v° is the limitimg value, which is identical with the partial molar volume at infinite dilution; A_v and B_v are the constants. The value of the constant A_v is 1.868 $cm^3\,dm^{3/2}\,mol^{-3/2}$ for water at 25 °C;[14] the rela-

tion $\phi_v - 1.868\,c^{1/2}$ versus c for a series of sodium dialkyl phosphates is shown in Fig. 1. The values of ϕ_v° and B_v are given in Table 1. It is found that the ϕ_v° values increase as the alkyl-chain length increases and that the increments in the ϕ_v° values per methylene group are 14.7 $cm^3\,mol^{-1}$ from dimethyl salt to diethyl salt and 16.1 $cm^3\,mol^{-1}$ from diethyl salt to dibutyl salt. Those results are in accord with Sakurai's opinion[15] that the increments in the ϕ_v° values per methylene group for homologous organic salts approach about 16 $cm^3\,mol^{-1}$ at 25 °C as the chain length increases. The B_v values are found to decrease with an increase in the number of carbon atoms in the alkyl chains, as is shown in Table 1; this fact is in accord with the results for other homologous compounds.[15,16]

The Viscosity *B* Coefficients. The viscosity of an aqueous solution of an electrolyte, η, for concentrations below 0.1 mol dm^{-3} can be represented by the Jones-Dole equation:[17]

$$\eta/\eta_0 = 1 + A_\eta c^{1/2} + B_\eta c, \quad (4)$$

where η_0 is the viscosity of water, and A_η and B_η, the characteristic constants of the solutes. The A_η coefficient was interpreted theoretically by Falkenhagen and Vernon;[18] it can be calculated using the data of the limiting equivalent conductivities of the salt, the cation, and the anion. The B_η coefficient is related to the ion-solvent interaction and to the size and shape of the ion, and it is highly specific for the electrolyte and the temperature. Equation 4 may be converted to:

$$\eta/\eta_0 - 1 - A_\eta c^{1/2} = B_\eta c. \quad (5)$$

When the left-hand side of Eq. 5, using the calculated values of A_η, is plotted against c, the viscosity B coefficient is obtained as the slope of a straight line. Figure 2 shows the results of plotting Eq. 5. The values of A_η and B_η are listed in Table 2.

The B_η values of homologous sodium dialkyl phosphates are found to increase with the chain length. Figure 3 shows the relationship between the B_η values and the number of carbon atoms in the alkyl chains, n, at 25 °C. The B_η values of sodium alkanoates[4,8] as well as sodium alkanesulfonates[8,9] in the literature are also included in Fig. 3. It is found that the B_η values for the three homologous organic electrolytes with the same number of carbon atoms will be in the order: $(RO)_2PO_2Na > RCOONa > RSO_3Na$. In connection with the viscosities of dialkyl and monoalkyl salts in water, it must be pointed out that the B_η values of dialkylam-

monium ions are approximately equal to those of monoalkylammonium ions with the same number of carbon atoms.[19]

The temperature dependence of the B_η values may be regarded as an index of the solute-solvent interaction; the B_η values increase with the temperature for a solvent-structure-breaking salt, while they decrease with temperature for a solvent-structure-making solute.[20] For all three compounds used, as may be seen in Table 2, that the B_η values decrease as the temperature is raised from 25 to 35 °C; these salts may therefore be considered to behave as structure-making salts in the water phase. The changes in the viscosity B coefficients which occur as the temperature is raised from 25 to 35 °C, ΔB, are also listed in Table 2. The ΔB values decrease with the number of carbon atoms in the alkyl chains of the series; this means that the hydrophobic hydration increases with the length of the alkyl chains. The B_η values are naturally made up of the sum of the contributions from both sodium and organic ions. Fortunately, the B_η values of the sodium ion are insensitive to the temperature.[21] Therefore, the temperature dependence of the viscosity B coefficients of sodium dialkyl phosphates discussed above conveniently reflects the nature of the dialkyl phosphate ions.

The solvent structural effect may also be evaluated by using the method of Desnoyers and Perron.[22] The B_η value of the ion is interpreted as consisting of two terms; the first is the effect of the ionic size, B_{size}, and the second is the contribution arising from the ion-solvent interaction, B_{solv}. If we assume that the Einstein equation derived for the case of spherical colloid may be applied approximately to the aqueous electrolyte solutions, B_{size} may be obtained by the use of the equation:

$$B_{size} = 0.0025\,\bar{V}°_{ion}, \tag{6}$$

where $\bar{V}°_{ion}$ is the partial molar volume expressed in cm^3 mol^{-1}. Thus, B_{solv} can be derived by the use of the equation:

$$B_{solv} = B_\eta - 0.0025\,\bar{V}°_{ion}. \tag{7}$$

The B_{solv} value can be used as a criterion for determining the structural effect of an ion. A positive value of B_{solv} will correspond to a structure-maker, while a negative value will indicate a structure-breaker. The B_{solv} values at 25 °C for dimethyl, diethyl, and dibutyl phosphate ions, as calculated from the data in Tables 1 and 2, are 0.187, 0.302, and 0.504 dm^3 mol^{-1} respectively, indicating that the dialkyl phosphate anions studied are all structure-making ions. In this calculation, we adopted the B_η value of sodium ion[21] as 0.084 dm^3 mol^{-1} and the $\bar{V}°_{ion}$ value of sodium ion[23] as −6.6 cm^3 mol^{-1}.

Heats of Solution. Heat-of-solution measurements were carried out in the concentration range of $(0.5-1)\times10^{-3}$ mol dm^{-3}. In this concentration range, any dependence of the heat of solution on the concentration is within the limit of experimental error, so the average of three or more measurements has been taken as the heat of solution at infinite dilution, $\Delta H_s°$. The $\Delta H_s°$ values of sodium dialkyl phosphates in water are listed in Table 3. The $\Delta H_s°$ values were all exothermic, and the results from the $\Delta H_s°$ values were used to calculate the change in the heat capacity for dissolution at infinite dilution, $\Delta C_p°$:

$$\Delta C_p° = d\Delta H_s°/dT, \tag{8}$$

where T is the temperature. The $\Delta C_p°$ values obtained at 25 °C are also listed in Table 3.

The sign and magnitude of $\Delta C_p°$ can be taken as a relative measure of the structural effect upon the solvent water.[24,25] The $\Delta C_p°$ values of simple salts indicate negative values, whereas the $\Delta C_p°$ values of hydrophobic solutes indicate positive values. As may be seen in Table 3, the sign of $\Delta C_p°$ of dimethyl phosphate salt is slightly positive, indicating that dimethyl phosphate salt behaves as a weak structure-maker. The magnitude of $\Delta C_p°$ increase with the number of carbon

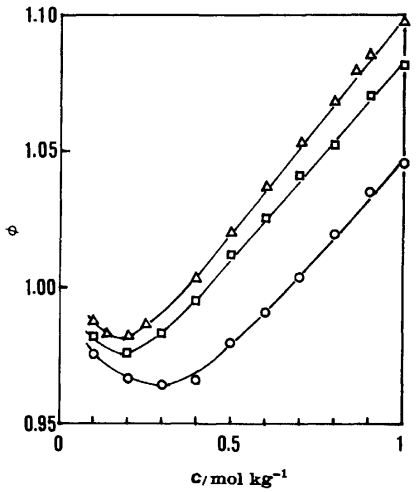

Fig. 4. Plots of osmotic coefficients against molal concentration for $(MeO)_2PO_2M$.
○: Lithium salt, □: sodium salt, △: potassium salt.

atoms in the alkyl chains, and diethyl and dibutyl phosphate salts are excellent structure-makers.

Osmotic Coefficients. Figure 4 indicates the osmotic coefficient versus concentration curves for lithium, sodium, and potassium salts of dimethyl phosphate. It may be seen that for a given concentration the ϕ values decrease in the order: $Li^+ < Na^+ < K^+$. The variation in the order of ion-ion interaction has been discussed by Gurney[26] and by Frank.[27] The rule of Gurney and Frank implied that an anion and a cation with similar structural influences—both being either structure-makers or structure-breakers—will attract each other, whereas if an anion and a cation have different structural tendencies, they will repel each other. Among the cations, Li^+ is a strong, and Na^+, a weak structure-maker, while K^+ is slightly structure-breaking.

As is shown in Fig. 4, the curve for potassium dimethyl phosphate lies at the top, while that for lithium dimethyl phosphate lies at the bottom. Therefore, potassium dimethyl phosphate may be classified as a "breaker-maker" salt, which will give a high-lying osmotic coefficient versus the concentration curve because of the greater escaping tendency between cation and anion. At the opposite extreme, lithium dimethyl phosphate may be classified as a "maker-maker"salt, which will give a lower-lying curve because of the tendency toward more attraction between cation and anion. In this manner, the $-(-O)_2PO_2^-$ ionic part may be classified as a structure-maker.

It must be noted that the acivity coefficients for the alkali metal salts of formic and acetic acids for a given concentration decrease in the order: $Li^+ < N^+ < K^+$.[28] By the application of the rule of Gurney and Frank to this results, formate and acetate ions may be classified as structure-makers. Recently, Miyajima, Sawada, and Nakagaki[4] reported that formate ion is neither a structure-maker nor a structure-breaker, because the viscosity B coefficients of formate ion were practically constant between 15 and 35 °C. However, in view of the sequence of activity coefficients for alkali metal salts of formic acid, formate ion may be considered still to behave as a weak structre-making ion, and it seems that the solvent structural effect of formate ion need to be investigated further.

In addition, the activity coefficients for the salts of *p*-toluenesulfonic acid[29] as well as those for the salts of methane- and ethanesulfonic acid[5] in dilute solutions increase in the order: $Li^+ > Na^+ > K^+$. The application of the rule of Gurney and Frank to these results indicate that these sulfonate ions may be classified as structure-breaking ions. The structure-breaking properties of sulfonate anions have been discussed by Uedaira and Uedaira[6] on the basis of their electric conductivities, and by Katayama et al.[7] on the basis of their partial molar volumes.

Thanks are due to Mr. Takashi Shibui and Mr. Takayoshi Kaneko for the preliminary experiments.

Effect of the Electron Correlational Screening upon the Calculated Transition Energies of Aromatic Hydrocarbons

Koichi HIRANO*
Department of Chemistry, Miyagi University of Education, Aramaki-aoba, Sendai 980
(Received September 11, 1986)

A new formalism for two-center repulsion $\Gamma_{\mu\nu}$, including a correlational screening factor, is presented. As a criterion of the screening strength, a parameter ρ (defined by Eq. 13) was introduced. Using $\Gamma_{\mu\nu}$ and ρ, transition energy calculations were performed for aromatic hydrocarbons based on the P.P.P scheme. Calculated transition energies decreases as ρ increases. Adjusting ρ, we can obtain correct values of the transition energies. That optimal ρ values extend over the region 0.3—0.5 indicates the extent of that electron correlation is intermediate. The screening caused by the Ohono-Klopman and Nishimoto-Mataga formulae is very close to that by $\Gamma_{\mu\nu}$'s whose ρ values are 0.2 and 0.6. A linear relationship was found between ρ and n, the number-density of π electrons. Making use of it, a trial calculation of the anthracece transition energies was made and obtained results were quite acceptable.

Electron correlation is very important in many electron systems, such as atoms and molecules.[1] In this regard, Gutefreund and Little have evaluated the effect of electron correlation upon low-lying π-π^* transitions by means of a random-phase approximation (RPA), in the framework of the P.P.P method.[2,3]

Kitaura and Nishimoto[4] also studied this problem using a different RPA formalism, derived by Dunning and Mckoy.[5] Their studies surely improved the calculation of the transition energies for π-conjugated systems.

Here, however, it must be noted that the validity of RPA is restricted to region where the electron density is high, where the inter-electronic spacing is smaller than the Bohr radius. The π electrons in conjugated systems are not so dense in the above sence. Therefore, RPA is rather inappropriate[6-8] for accurately describing the π-electron correlation. Thus, it is worthwhile studying this problem using another model which satisfies the requirement of the short-range behavior of Coulomb repulsion since at lower densities electron correlation due to short-range repulsion becomes very significant.[9] For this purpose we employed a Monte-Carlo screening potential model.[10,11] The reason for this is that this model satisfies the requirement of a radial distribution function of a two-dimensional classical electron fluid whose density is considerably low.[12] In the present paper we derived a new formula for a two-center repulsion based upon a Monte-Carlo screening potential model (MCP) while making use of it in transition energy calculations that were performed for aromatic hydrocarbons. In the following, we briefly describe the most important part of the results:

(1) The new formula for the two-center repulsion.

(2) The correlational effects upon the MO quantities.

(3) The number-density dependence of the correlational parameters.

Model and Method

New Formula for Two-Center Repulsion. According to the physics of strong-coupled classical plasmas,[13,14] let $H(r)$ be the linear screening potential due to the many-particle correlations (defined by DeWitt et al.);[15] then the effective potential between two particles, $V(r)$, in the liquid phase can be expressed in the form

$$V(r) = \frac{(Ze)^2}{r} - H(r), \tag{1}$$

where Ze is the electric charge of a particle and r is the separation between two particles. This potential satisfies the radial distribution function $g(r)$ of the particles:

$$g(r) = \exp[-V(r)/kT]. \tag{2}$$

By analyzing the results of Monte Carlo studies by Brush et al.,[10] Itho and Ichimaru[16] found that apart from the vicinty of $r=0$, $H(r)$ takes a linear form in the interval $1.0 \lesssim r/a \lesssim 2.0$:

$$H(r) = \frac{(Ze)^2}{a}\left(c_0 - \frac{c_1 r}{a}\right), \tag{3}$$

where $a=(3/4\,\pi n)^{1/3}$ is the ion-sphere radius and n the number-density of the particles; c_0 and c_1 satisfy

$$c_1 = \left(\frac{c_0}{2}\right)^2. \tag{4}$$

Here, we notice that by replacing the second term in $H(r)$ by $(c_2 r/a)^2$, we obtain a Salpeter-Horn type screening potential.[14]

Substituting $H(r)$ into Eq. 1 and putting $Z=1$, we obtain the effective potential $V(r)$ for two electrons in the liquid phase:

$$V(r) = \frac{e^2}{r} - \frac{e^2}{a}\left(c_0 - \frac{c_1 r}{a}\right), \tag{5}$$

where a is the Wigner-Seitz sphere radius via $a=(3/4\,\pi n)^{1/3}$ which corresponds to the ion-sphere radius mentioned above. This potential solely holds for two dimensional classical electron liquid.[17]

In obtaining Eq. 5, we assumed that electrons obey classical statics. In the π-electron case, however, special quantum effects must be taken into account, since

the number-densities of π electrons, (Table 1), are higher than those for a classical electron liquid.[18] In spite of this, we assume here that π electrons obey classical statics and that Eq. 5 holds for them. This is very crude; however, we accept it as the zeroth-order approximation. The reason for this is as following: Monte Carlo simulations of fermion systems[18] and analytic calculations on the correlational properties of the degenarate electron fluid have been hitherto made;[19] however, a formalism which can be applied to the π-electron systems has yet not been established. As a consequence, we derived a π-electron two-center repulsion $\Gamma_{\mu\nu}$ from Eq. 5, using a point-charge approximation:[20]

$$\Gamma_{\mu\nu} = \frac{e^2}{R_{\mu\nu}} - \frac{e^2}{d}\left(C_0 - \frac{C_1 R_{\mu\nu}}{d}\right), \quad R_{\mu\nu} < \frac{C_0}{C_1} d$$

and (6)

$$= \frac{e^2}{R_{\mu\nu}}, \qquad R_{\mu\nu} > \frac{C_0}{C_1} d,$$

where $R_{\mu\nu}$ is the internuclear separations, d is the length parameter and C_0 and C_1 are dimensionless constants. Hereafter, we call $\Gamma_{\mu\nu}$ the MCP two-center repulsion; it corresponds to $\gamma_{\mu\nu}$ of the P.P.P scheme.

Next, we consider the physical significance of the new formula $\Gamma_{\mu\nu}$. A qualititatively good description is that $\Gamma_{\mu\nu}$ implies electrostatic interactions due to a potential felt at the center of the Wigner-Seitz sphere of the electrons at the μ core from an electron on the ν-th core as well as its surrounding polarization field. It arises from a charge depletion in the vicinty of the electron by correlation. This interpretation is based on the ion-sphere model provided for the explanation of short-range screening in a strongly coupled classical plasma.[13,14]

Characteristics of $\Gamma_{\mu\nu}$. In this section, we describe a suitable parameter choice and the $R_{\mu\nu}$-dependence of $\Gamma_{\mu\nu}$. As an example, we show the pyrene case. The length parameter was evaluated as d=1.57 Å, based upon two distinct roots: Wigner-Seitz sphere radius a=1.57 Å and radius of Coulomb hole,[21,22] r_{Ch}=1.1 Å. The dimensionless parameters by which correlational screening is chrachterized were determined as C_0=0.95 and C_1=0.50, respectively, by means of a trial- and -error method.

A set of parameters, thus determined , yield

$$\Gamma_{\mu\nu} = \frac{14.398}{R_{\mu\nu}} + 4.607 R_{\mu\nu} - 10.942 \text{ eV} \quad \text{for } R_{\mu\nu} < 2.37 \text{ Å},$$

and (7)

$$= \frac{14.398}{R_{\mu\nu}} \text{ eV} \qquad \text{for } R_{\mu\nu} \geqq 2.37 \text{ Å}.$$

Making use of Eq. 7, we can calculate pyrene transition energies which are in fairly good agreement with the experimental spectra.

Then, we describe the characteristic feature of $\Gamma_{\mu\nu}$. In Fig. 1 , we display the $R_{\mu\nu}$ -dependence of in comparison with those of Ohono-Klopman,[23,24] γ^{OK}, (OK) and Nishimoto-Mataga,[25] $\gamma^{NM}_{\mu\nu}$ (NM) expressions and of the bare Coulomb repulsion:

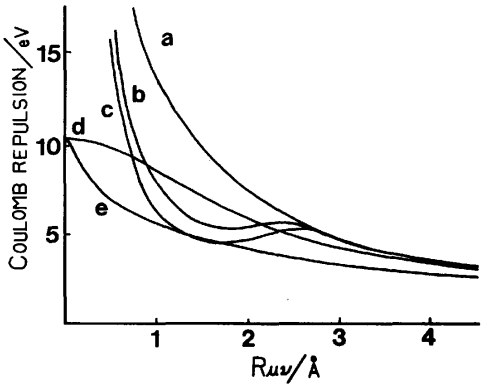

Fig. 1. Comparison of the different forms of effective Coulomb-repulsion:
a): Bare Coulomb potential, b): MCP potential, C_1=0.50, c): MCP potential, C_1=0.45, d): Ohono-Klopmamn potential, e): Nishimoto-Mataga potential.

$$\gamma^{OK}_{\mu\nu} = \frac{e^2}{\sqrt{a^2_{\mu\nu} + R^2_{\mu\nu}}}, \tag{8}$$

and

$$\gamma^{NM}_{\mu\nu} = \frac{e^2}{a_{\mu\nu} + R_{\mu\nu}}, \tag{9}$$

with

$$\frac{1}{a_{\mu\nu}} = \frac{1}{2}\left(\frac{\gamma_{\mu\mu}}{14.398} + \frac{\gamma_{\nu\nu}}{14.398}\right), \tag{10}$$

where $\gamma_{\mu\mu}$ and $\gamma_{\nu\nu}$ denote a one-center repulsion at cores μ and ν. For C-C bonds, we take $a_{\mu\nu}$=1.358 Å.

As Fig. 1 shows, the most striking features of our model potential are: (1) $\Gamma_{\mu\nu}$ has a local minimum at a small distance, $R_{\mu\nu}\approx$1.5 Å; hence, $\Gamma_{12}<\Gamma_{13}$. This result, however, is not so surprising. Since a quite similar result can be seen for the Salpeter-Horn potential[14] for the strong-screening regime. Moreover, a similar structure can also be found in the Jastrow pseudopotential curves of a Lenard-Jones Bose fluid.[26] (2) The rapid decrement of $\Gamma_{\mu\nu}$ at small distances implies a reduction of the bare Coulomb repulsion due to correlational screening; the strength of the screening is strongly parameter sensitive. Therefore, one of the reasons that $\Gamma_{12}<\Gamma_{13}$ may be ascribable to the choice of parameter. (3) By a suitable parameter choice, $\Gamma_{\mu\nu}$ can be determined so as to give the correct values of the MO quantities.

Based on the above, we can perform MO calculations that take the electron-correlation effect into account by using $\Gamma_{\mu\nu}$. This is because, in the study, we employed $\Gamma_{\mu\nu}$ as a two-center repulsion. Hence, the following equality still holds:

$$\gamma_{\mu\nu} = \Gamma_{\mu\nu}. \tag{11}$$

Table 1. Parameters for Aromatic Hydrocarbons

	Benzene	Naphthalene	Anthracene	Pyrene	Coronene
n cm^{-3}[a]	4.0×10^{22}	5.4×10^{22}	5.9×10^{22}	6.1×10^{22}	6.6×10^{22}
a Å[b]	1.69	1.64	1.59	1.58	1.53
d Å[c]	1.25	1.25	1.25	1.25	1.25
C_0	0.95	0.95	0.95	0.95	0.95
C_1	0.61	0.53	0.50[d]	0.50	0.47
ρ	0.30	0.40	0.43[e]	0.43	0.48

a) Number-density of π electrons. b) Radius of Wigner-Seitz sphere. c) Length parameter. d) Estimated from Eq. 14. e) Estimated from Eq. 18.

MO Calculation. P.P.P.-Type SCF-MO calculations were made. In the actual calculations, singly excited configurations higher than 8—10 eV were taken into account. All of the C-C bond lengths and the bond angles were set to 1.39 Å and 120°, respectively. The one-center core integral and the one-center repulsion were evaluated from the valence state ionization potentials and the electron affinities viz. $W_{\mu\mu}$=11.22 and $\gamma_{\mu\mu}$=10.60 eV.[27] A two-center core integral was evaluated by the Wolfsberg-Helmholtz's formula with K=0.96:[28]

$$\beta_{\mu\nu} = \frac{K}{2} S_{\mu\nu}(W_{\mu\mu} + W_{\nu\nu}), \tag{12}$$

where $S_{\mu\nu}$ is the overlap integral between cores μ and ν.

For simplicity, we consider that C_1 alone is variant and that the other parameters are invariant. Then, in the present calculations, we varied $\Gamma_{\mu\nu}$ by changing C_1. In Table 1 the parameters used are listed with other related quantities.

Results and Discussion

Degrees of Screening. As a criterion of electron correlation, we introduced here a new parameter ρ, degrees of screening:

$$\rho = 1 - \frac{\Gamma_0}{U_0}, \tag{13}$$

where Γ_0 and U_0 are, respectivery, the two-center and the bare Coulomb repulsion at the nearest-neighbor distance. It is obvious from the equation that when $\Gamma_0=U_0$, ρ=0, (without screening) and if Γ_0=0, ρ=1, (full screening). For intermediate screening, ρ satisfies $0<\rho<1$.

As a consequence, we can express the relative strength of the electron correlation in terms of ρ. Then, we study the effect of the electron correlation on the transition energies using ρ. For this purpose we derived a parametric formula (14) utilizing Eq. 13 and 6 (where we take a nearest-neighbor distance R_0=1.39 Å):

$$C_1 = 0.854 - 0.809\rho. \tag{14}$$

Making use of this relationship, we can determine a suitable $\Gamma_{\mu\nu}$ for setting the ρ values. This makes it possible to calculate the MO quantities as a function of ρ. Analysing the ρ-dependence of the calculated quantities, we can evaluate the electron correlation effect upon the quantities.

ρ-Dependence of Transition Energies. Here we describe the naphthalene and pylene cases. Figures 2, 3 show the ρ-dependence of the orbital energies as well as the Coulomb and exchange repulsion.

Figure 4 shows the ρ-dependence of the calculated transition energies. As was seen in Fig. 2, the HOMO-levels, E_H's, increase with increasing ρ and the LUMO-levels, E_L's, are lowerd as ρ increases. As a result, the orbital spacing becomes narrow with increasing ρ. This can be explained according to the following interpretation by Hush and Pople.[29] Let ΔE_{LH} be the orbital spacing between LUMO and HOMO; then

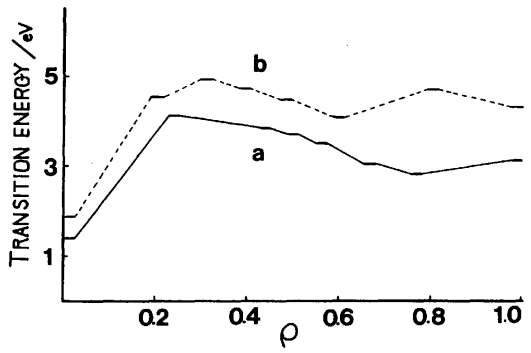

Fig. 4. ρ-Dependence of the transition energies.
a): Pyrene lowest B_{2u}, b): Naphthalene lowest B_{2u}.

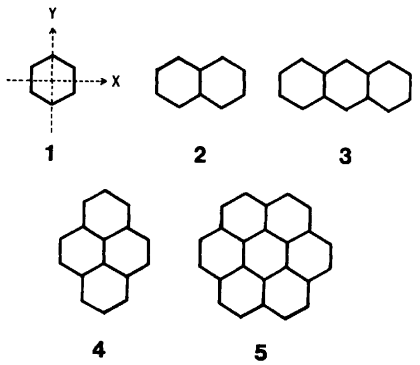

Fig. 5. Coordinate systems and carbon skeltons of the molecules. 1) Benzene, 2) Naphthalene, 3) Anthracene, 4) Pyrene, 5) Coronene.

$$\Delta E_{LH} = E_L - E_H = 2\sum_{\mu<\nu}^{\text{bond}} \beta_{\mu\nu}(C_{L\mu}C_{L\nu} - C_{H\mu}C_{H\nu}) - \sum_{\mu<\nu} P_{\mu\nu}(C_{L\mu}C_{L\nu} - C_{H\mu}C_{H\nu})\Gamma_{\mu\nu}. \quad (15)$$

Here, E_L and E_H are the orbital energies of LUMO and HOMO; $C_{L\mu}$, $C_{H\nu}$, and $P_{\mu\nu}$ are the AO coefficients and the π-bond order between cores μ and ν. To derive the above equation, we used the following approximation:

$$F_{\mu\nu} = \beta_{\mu\nu} - \frac{1}{2}P_{\mu\nu}\Gamma_{\mu\nu}, \quad (16)$$

where $F_{\mu\nu}$ is the off-diagonal elements of the $\boldsymbol{F}$-matrix[30] and $\beta_{\mu\nu}$=0 for non-neighbor μ and ν.

The above equation shows that ΔE_{LH} is reduced when $\Gamma_{\mu\nu}$ decrease; namely, ρ increases since $\Gamma_{\mu\nu}$ is inversely related to ρ and the second summation takes a positive value. This is because, the orbital spacing becomes narrow as ρ increases (Fig. 2). Next, we describe the ρ-dependence of the transition energies. As Fig. 4 shows, for intermediate ρ values (i.e., $0.2<\rho<0.6$) the transition energies decrease as ρ increases. Judging from the ρ-dependence of the ΔE_{LH}'s, this is fairly acceptable. Out of the regions, however, the ΔE's exhibit somewhat irregular changes. This abnormality is probably due to the characteristic ρ-dependence of the Coulomb and exchange repulsion, J_{LH} and K_{LH}, because these quantities are correlated with ΔE through the following formalism:[31]

$$\Delta E = \Delta E_{LH} - J_{LH} + 2K_{LH}. \quad (17)$$

To explain the ΔE vs. ρ curves more exactly, however, the ρ-dependence of the CI matrix elements must be taken into account, since changes in the CI matrix elements strongly alter the transition energies, even if the changes are not so remarkable. This problem will be reported elsewhere.

Here, we direct our attention to a comparison of the new formula $\Gamma_{\mu\nu}$ to that of OK and NM. For this purpose, the calculated results by $\gamma_{\mu\nu}^{OK}$ and $\gamma_{\mu\nu}^{NM}$ are also plotted in Figs. 2, 3. As can be seen from the figures, the values calculated by using OK and NM are in fairly good agreement with those by using $\Gamma_{\mu\nu}$'s (whose values are about 0.2 and 0.6, respectively).

This indicates that the relative values of correlational screening estimated from OK and NM are in the ratio of 1/3. With regard to this, a very similar result has been reported by Fukutome and Sasai[32] while studing the electron correlation in linear polyens. Their proposal can be summarized as follows: The value of $(\gamma_{\mu\mu}-\gamma_0)/|\beta|$ that determines the extent of electron correlation, is about 1 for OK and about 3 for NM. Here, $\gamma_{\mu\mu}$ is the one-center repulsion and γ_0 the nearest-neighbor two-center repulsion. β is the nearest-neighbor two-center core integral. These facts imply that OK is acceptable when the electron correlation is weak, whereas NM is good when the correlation is rather strong.

Transition Energies. Here, we described the transition energies calculated using $\Gamma_{\mu\nu}$. The coordinate systems[33] and carbon skeletons of the molecules are illustrated in Fig. 5. In Tables 2—5 the transition energies, oscillator strength and order of states are given in comparison with other calculated and experimental data. From the tables we can see that MCP gives fairly good results (as compared with the other calculations). In the case of MCP, the optimal ρ values are shown in parenthes, where the ρ values extend over the region 0.3—0.5. This indicates that the degrees of correlation in these molecules is intermediate.

Moreover, a striking feature found in the above tables is that the energy-level spacings and order of states calculated by the MCP are rather close to those by the β-variable method.[39,40] This is probably due to a procedural similarity between the two methods, since for both MCP and β-variable, the off-diagonal elements of $\boldsymbol{F}$-matrix are corrected so as to reproduce the experimental spectra by changing the adjustable parameters of C_1 and β_0.

Next, we describe the number-density dependence of ρ. As can be clearly seen in Table 1, when the molecular size becomes large, ρ increases in parallel with n. This feature suggests that some definite relationship

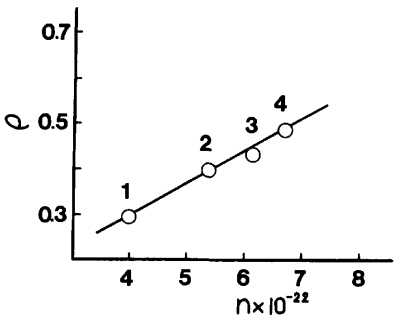

Fig. 6. Relation between ρ and n: ρ is the degrees of screening and n the number-density of π electrons.

exists between them. In fact, plots of ρ against n show the following relationship (displayed in Fig. 6):

$$\rho = 7.00n \times 10^{-24} + 0.02, \tag{18}$$

with

$$n = \frac{\nu DN}{M}. \tag{19}$$

Here, ν is the number of π electrons, D the density of the materials, N Avogadro's number and M the molecular weight. Equation 18 is an empirical formula; therefore, we can not undertake a further analysis. In spite of this, it does a very useful way to perform practical calculations since, by making use of the equation, we can evaluate ρ for an aromatic hydrocarbon when n is given.

For checking the validity of the above relationship, a trial calculation was made for anthracene. In the calculation, we took ρ=0.34 (same as putting n= 5.9×10^{22}). As Table 6 shows, the obtained results are in acceptable agreement with those reported by other authors, except for the appearance of a weak band located above the lowest B_{2u} band. Generally speaking, this band is closely related to the strength of a two-center repulsion $\gamma_{\mu\nu}$. This band appears when $\gamma_{\mu\nu}$ has a simple Coulomb-like form, as a Slater AO-type repulsion.[41] Contrariwise, the band disappeared when $\gamma_{\mu\nu}$ assumed such long-range screened forms as OK,[36] NM[42] and a cusp-like shape interaction.[43] In $\Gamma_{\mu\nu}$ case, screening is restricted within the interval $R_{\mu\nu}< C_0d/C_1$; when $R_{\mu\nu}$ increases beyond this boundary, it

results in a Coulomb-like repulsion (Eq. 6). This indicates that the long-range behavior of $\Gamma_{\mu\nu}$ is very similar to that of a Slater AO-type repulsion when $R_{\mu\nu}$ becomes large. This is because MCP calculates the weak second lowerst B_{2u} band.

From the above results, we then concluded that MCP provides a semiempirical method that is favorable for studying the electron-correlation effect upon a calculation of the transition energies, (and for which Eq. 17 is available). In order to apply this method more extensively, however, the physical concept of the linear screening potential $H(r)$ must be clarified based upon a theoretical consideration.

We wish to express our thanks to Prof. Setsuo Ichimaru of University of Tokyo and Dr. Hiroshi Yasuhara of Tohoku University for sending reprints of their work. We thank Dr. Takeshi Ikeyama of Miyagi University of Education for his helpful discussions. We also thank the Computer Center, Tohoku University, for the use of the ACOS 1000 computer.

Effects of Alkali Metals Added to Silica-Supported Ruthenium Catalysts on Hydrogenation of Carbon Monoxide

Toshiyuki ENOMOTO, Keiichiro KATA,† Toshio OKUHARA,* and Makoto MISONO*
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received September 12, 1986)

The hydrogenation of carbon monoxide to produce hydrocarbons (Fischer-Tropsch synthesis) has been studied over Ru/SiO_2 catalysts to which alkali metals (Li, Na, K, and Cs) were added. The effects of alkalis were compared by varying the amounts added and by varying the support to Al_2O_3. By the alkali addition, the CO conversion and the selectivity to methane decreased but the propagation probability as well as the olefin/paraffin ratio increased. Among the alkali metals, Li least depressed the catalytic activity of Ru/SiO_2, but was most effective for the suppression of methane formation. In contrast to a K-added catalyst, the infrared band of adsorbed carbon monoxide shifted only slightly upon Li addition, showing its small electronic effect. The results in electron microscopy and X-ray diffraction suggested that the Ru particle size remained almost unchanged upon Li addition, although the amounts of adsorbed carbon monoxide and hydrogen significantly decreased. This indicates that Ru particles were partially covered by a compound of Li. On the basis of these results, it was concluded that the suppression of methane formation by Li was due to a geometric or ensemble effect.

Chemical modification of metal catalysts by adding certain metal ions/oxides often brings about a significant increase in the catalytic activity and selectivity, e.g., for the synthesis of methanol or ethanol from CO and H_2.[1-4] Alkali metals have been reported to be effective additives to Fe,[5-7] Ni,[8,9] and Ru[10-12] catalysts for the formation of olefinic hydrocarbons from CO and H_2.

The effects of alkali metals have been attributed to an electronic effect caused by the electron-donating nature of alkali for supported metal catalysts.[8,9,12,13] However, McClory and Gonzalez suggested that the decrease of catalytic activity upon alkali addition was associated with an ensemble effect rather than an electronic effect in the case of silica-supported Ru catalysts,[14] although the changes in the selectivities were rather small.

We previously reported the effects of the dispersion of metal[15] as well as the effects of such additives as K, P, and B,[12] and transition metals[16] on the adsorption and the hydrogenation of CO over alumina-supported Ru catalysts. As an extension of these studies, we have investigated in the present work CO hydrogenation using silica-supported Ru catalysts in which the contents of Li, Na, K, and Cs were widely changed. The catalysts were characterized by infrared spectroscopy of CO chemisorption, electron microscopy, X-ray diffraction, and adsorption stoichiometries of H_2 and CO. The relationship between the catalytic property and the state of Ru particles is discussed while placing emphasis on the peculiar effect of the Li addition.

Experimental

Catalysts. Silica (Aerosil 200) was used as supports after calcination in air at 500 °C for 20 h. Silica-supported Ru catalysts were prepared by incipient-wetness impregnation with an aqueous solution of $RuCl_3$. In the case of alkali-added catalysts, the silica was first impregnated by an incipient-wetness method with an aqueous solution of alkali carbonate. Then, it was dried and calcined at 500 °C prior to impregnation with a $RuCl_3$ solution. All catalysts contained 2.5% Ru by weight. Hereafter, these catalysts will be designated as, e.g., Ru/SiO_2 or $Ru\text{-}Li(1:0.25)/SiO_2$, where the ratios in parentheses are the atomic ratios of Ru to alkali metal. A catalyst ($Li/Ru/SiO_2$) was additionally prepared by impregnating a reduced Ru/SiO_2 catalyst with a Li_2CO_3 solution (Li/Ru=0.25).

Alumina-supported Ru catalysts were also prepared in the same way as Ru/SiO_2 or $Ru\text{-}Li/SiO_2$. γ-Al_2O_3 (Reference Catalyst of Catalysis Society of Japan, ALO-4) was used after calcination in air at 400 °C for 10 h.

Procedure. The hydrogenation of CO was carried out by using conventional flow reactors. After catalysts of 0.2—1.5 g were reduced at 450 °C for 2 h in flowing H_2, a 1 : 2 mixture of CO and H_2 was fed at 260 °C under 1 or 10 atm. The products were analyzed by gas chromatographs, by using a Molecular Sieve 5A, a Porapak Q, a VZ-10 and a Silicone SE-30 column. The formation of methanol, ethanol, and acetaldehyde was checked by a Porapak R column.

Other Measurements. The surface areas of SiO_2 and Li/SiO_2 were measured by N_2 adsorption. The adsorption of CO and H_2 was volumetrically measured at room temperature after the catalysts were reduced by H_2 at 450 °C for 2 h. Infrared spectra (IR) of CO adsorbed were recorded in the same way as described previously.[15] Transmission electron micrographs (EM) were obtained with a JEOL JEM 1250 electron microscope (1000 keV, final magnification: ×150000). The particle-size distributions were calculated by counting 300—400 particles of Ru on several micrographs for each catalyst. Powder X-ray diffraction (XRD) was obtained on an X-ray diffractometer (Rotaflex, Rigaku denki). Mean diameters of Ru particles were estimated from the half width of the main peak of Ru metal (2θ=44.0°).

Results

Hydrogenation of CO. The reaction rates and the

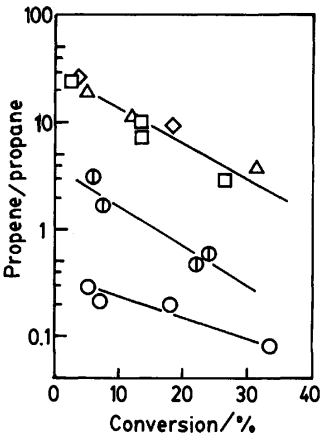

Fig. 2. Propene/propane ratio vs. conversion for the CO hydrogenation on Ru/SiO_2 and Ru-Li/SiO_2 catalysts under 1 atm at 260°C. ○: Ru/SiO_2, ⊕: Ru-Li (1:0.1)/SiO_2, □: Ru-Li (1:0.25)/SiO_2, △: Ru-Li (1:1.5)/SiO_2, ◇: Ru-Li (1:4.5)/SiO_2.

product distributions of CO hydrogenation performed under 1 atm on Ru/SiO_2 and alkali-added Ru/SiO_2 are summarized in Fig. 1. The formation of methanol, ethanol and acetaldehyde was negligible, and the yield of CO_2 was only about 0.1%. In the case of Ru/SiO_2, methane was the main product, and the contents of olefins in C_2–C_4 hydrocarbons were low. When alkali metals were added, the reaction rates decreased by more than a factor of ten. At the same time, the selectivity to methane considerably decreased, and the selectivities to higher hydrocarbons and olefins increased.

As for the relative extents of the effects, the following trends are noted. The reaction rate decreased in the order of none > Li > Na > K≈Cs, while the selectivity to methane was in the order of none > Cs≈K > Na > Li. The turnover frequency (TOF) calculated from H_2 chemisorption varied in the same order as the rate (none > Li > Na > K≈Cs), since the difference in the H/Ru ratio between alkalis was much smaller than the activity change. It is remarkable that Li showed the least suppression of activity, but was most effective for the suppression of methane. The rates of methane formation were 865 and 9.3 mmol g-Ru^{-1} h^{-1} for Ru/SiO_2 and Ru-Li(1 : 0.25)/SiO_2, respectively, exhibiting a decrease of 1/90 by Li addition. On the other hand, the rate of C_{2+} formation decreased only to 70%; 75 and 53 mmol g-Ru^{-1} h^{-1} for Ru/SiO_2 and Ru-Li (1 : 0.25)/SiO_2, respectively. The Li/Ru/SiO_2 catalyst, which was prepared in the reversed order of impregnations, showed the same activity and selectivity as Ru-Li/SiO_2 (reaction rate: 63 vs. 62 mmol g-Ru^{-1} h^{-1}, selectivity to methane: 16 vs. 15%).

The selectivity to methane was almost independent of the extent of conversion. For example, the selectivity was 93±1% for Ru/SiO_2 and 15±2% for Ru-Li (1 : 1.5)/SiO_2, in the conversion range from 3 to 35%. Distributions of the carbon number of hydrocarbons were also independent of the conversion. This fact

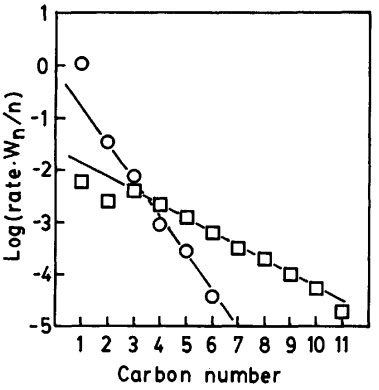

Fig. 3. Schultz-Flory plots (logarithm of (Rate W_n/n), where W_n is weight percentage, and n is carbon number). ○: Ru/SiO_2, □: Ru-Li(1:0.25)/SiO_2.

shows that the distributions of the carbon number are of the primary products. In Fig. 2, the propene/propane ratios in the products are plotted against the % conversion. Most Ru-Li/SiO_2 catalysts showed high propene/propane ratios, but the ratios tended to decrease with an increase in the conversion for both Ru/SiO_2 and Ru-Li/SiO_2. This fact indicates that the hydrogenation of olefins proceeded significantly under the reaction conditions. Li also enhanced the ethylene/ethane and butenes/butane ratios, which similarly decreased with increasing conversion.

The distributions of product hydrocarbons for Ru/SiO_2 and Ru-Li(1 : 0.25)/SiO_2 are shown according to Schultz-Flory plots in Fig. 3. The distributions obeyed the Schultz-Flory distribution for C_{3+} products. The production of C_1 produced on Ru/SiO_2 deviated upward from that predicted by the Schultz-Flory plot, but downward on Ru-Li(1 : 0.25)/SiO_2. This implies that Li addition induced a selective suppression of methane formation.

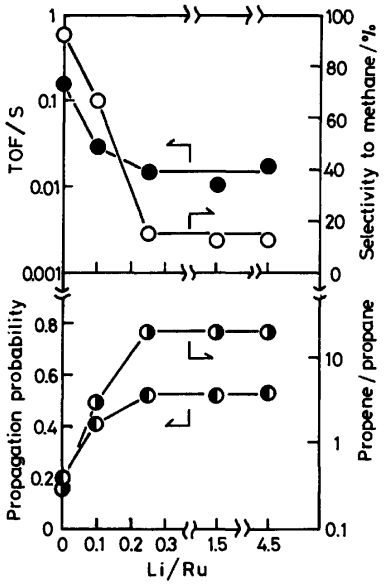

Fig. 4. Effects of the content of Li in $Ru-Li/SiO_2$ on TOF, selectivity to methane, propagation probability, and propene/propane ratio (at 5% conversion) in the CO hydrogenation under 1 atm at 260°C. ●: TOF, ○: selectivity to methane, ◐: propagation probability, ◑: propene/propane ratio.

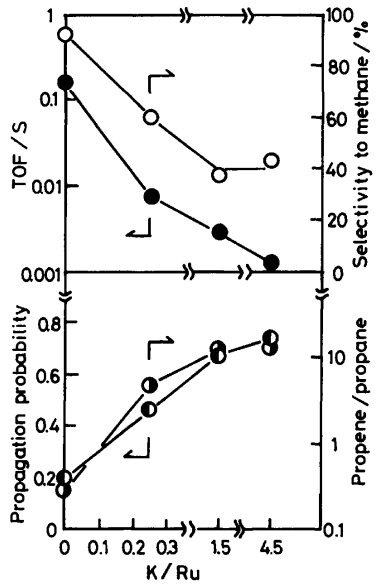

Fig. 5. Effects of the content of K in $Ru-K/SiO_2$ on TOF, selectivity to methane, propagation probability, and propene/propane ratio (at 5% conversion) in the CO hydrogenation under 1 atm at 260°C. ●: TOF, ○: selectivity to methane, ◐: propagation probability, ◑: propene/propane ratio.

In Fig. 4, TOF, selectivity to methane, propagation probability (calculated from Fig. 3), and propene/propane ratio at 5% conversion are plotted against the Li/Ru atomic ratio. In the range of Li/Ru less than 0.25, TOF and the methane formation greatly decreased, while the latter two values increased with an

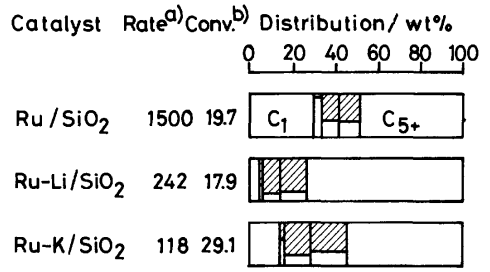

Fig. 6. Effects of alkali addition to Ru/SiO_2 on catalytic activity and product distribution in the CO hydrogenation (260°C, 10 atm, alkali/Ru= 0.25). Shaded parts indicate olefins in C_2–C_4 products. a) Reaction rate/10^{-3} mol g-Ru^{-1} h^{-1}. b) Conversion/%.

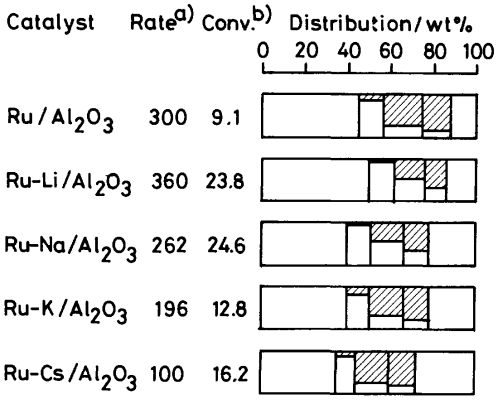

Fig. 7. Effects of alkali addition to Ru/Al_2O_3 on catalytic activity and product distribution in the CO hydrogenation (260°C, 1 atm, alkali/Ru= 3). Shaded parts indicate olefins in C_2–C_4 products. a) Reaction rate/10^{-3} mol g-Ru^{-1} h^{-1}. b) Conversion/%.

increase in Li/Ru. For Li/Ru greater than 0.25, these values were almost independent of Li/Ru.

Figure 5 shows the effect of K. In the case of K, the selectivity to methane decreased only to about 40%, even when the K/Ru atomic ratio was increased to 4.5. The decrease of TOF was greater and TOF continued to decrease with the amounts of K. The propagation probability and the propene/propane ratio increased monotonously with the amount of K.

Figure 6 shows the results of reactions performed under 10 atm. The reaction rates increased and the formation of higher hydrocarbons was promoted for all catalysts, as compared with the results obtained under 1 atm (Fig. 1). Even under 10 atm, the suppression of methane formation by Li was remarkable; the selectivity to methane decreased from 30 to 5% for $Ru-Li(1:0.25)/SiO_2$. The Schultz-Flory plots for Ru/SiO_2 and $Ru-Li/SiO_2$ showed essentially the same trend as in Fig. 3, although the slopes were less steep.

The effects of alkali-addition to Ru/Al_2O_3 are compared in Fig. 7. As already reported, Ru/Al_2O_3 formed less methane than Ru/SiO_2.[12] The extents of methane suppression by alkalis were significantly less than those observed for Ru/SiO_2, although the amounts of

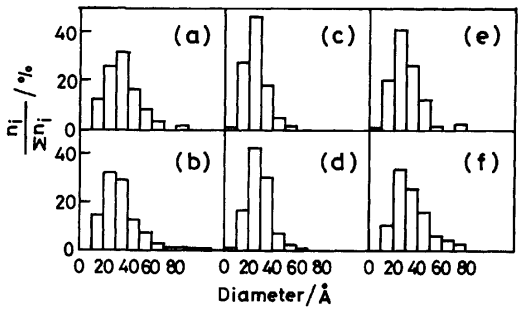

Fig. 8. Distribution of diameters of Ru particles on (a) Ru/SiO_2 after H_2 reduction at 450 °C, (b) Ru/SiO_2 after CO hydrogenation at 260 °C, (c) Ru-Li (1:1.5)/SiO_2 after H_2 reduction at 450 °C, (d) Ru-Li (1:1.5)/SiO_2 after CO hydrogenation at 260 °C, (e) Ru-Li (1:4.5)/SiO_2 after H_2 reduction at 450 °C, and (f) Ru-Li (1:4.5)/SiO_2 after CO hydrogenation at 260 °C.

alkali metals were twelve times greater than that for Ru/SiO_2.

Characterization of Catalysts. Surface areas of SiO_2 and Li-SiO_2 before Ru impregnation are shown in Table 1. The supports containing 0.018, 0.045, 0.26, and 0.77 wt% of Li correspond to atomic ratios of Li to Ru 0.1, 0.25, 1.5, and 4.5, respectively, when 2.5 wt% of Ru is loaded. The decrease in the surface area was not significant when Li was not more than 0.26 wt%. The data of H_2 and CO adsorption are also given in Table 1. The amounts decreased with the Li content. The decrease was a little greater for CO as reported for K-added Ni/SiO_2,[13] but the reason is not clear at present.

Figure 8 shows the size distributions of Ru particles on Ru/SiO_2 and Ru-Li/SiO_2 catalysts measured by EM before and after use for CO hydrogenation. For all catalysts, the distributions little changed by the use for CO hydrogenation. The distributions were centered at ca. 30 Å, and a few Ru particles were present above 60 Å. The distributions for Ru/SiO_2 were slightly wider than those on Ru-Li/SiO_2, but there was no essential difference.

Table 2 summarizes the mean diameters of Ru particles, which were determined by H_2 adsorption, EM, and XRD. The diameters determined by EM decreased upon the addition of Li, but the change was small. Those determined by XRD, which were slightly greater than those by EM, showed no significant change either. On the other hand, the apparent diameter determined by H_2 adsorption definitely increased upon the addition of Li.

Table 2. Mean Diameters of Ru Particles of Ru-Li/SiO_2 Catalysts

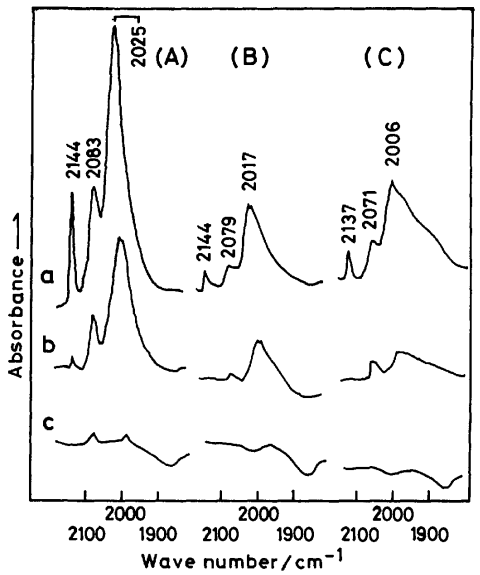

Fig. 9. IR spectra of CO adsorbed on (A) Ru/SiO_2, (B) Ru-Li (1:0.25)/SiO_2, and (C) Ru-K (1:0.25)/SiO_2. The spectra of CO were taken after evacuation at (a) 25 °C, (b) 100 °C, and (c) 200 °C.

Figure 9 shows IR spectra of CO adsorbed on Ru/SiO_2, Ru-Li(1 : 0.25)/SiO_2, and Ru-K(1 : 0.25)/SiO_2. Three peaks at 2025, 2083, and 2144 cm^{-1} were observed for CO on Ru/SiO_2 after evacuation at room temperature. The intensity decreased with an increase in the evacuation temperature, and almost disappeared after evacuation at 200 °C. In the case of Ru-Li/SiO_2, a band was observed at 2017 cm^{-1}, together with two small peaks at 2079 and 2144 cm^{-1}. The relative integrated intensity agreed with the amount of adsorbed CO shown in Table 1. The shift of the main peak was less than about 8 cm^{-1}. On the other hand, the main peak at 2006 cm^{-1} for Ru-K/SiO_2 showed a shift of

about 20 cm^{-1} and the peak envelope extended to the lower wavenumber side. The two peaks at 2083 and 2144 cm^{-1}, which were assigned to CO adsorbed on $Ru^{\delta+}$,[17,18] also shifted but to a lesser extent for $Ru-K/SiO_2$.

Discussion

The principal effects of alkali addition were: (i) a decrease in the catalytic activity, (ii) a suppression of methane formation, (iii) an increased selectivity to higher hydrocarbons, and (iv) an increase in the olefin/paraffin ratio. These effects agreed with those mentioned in the literature.[5-12] As for the kind of alkali metals and the order of catalytic activity: none > Li > Na > K≈Cs, is consistent with those reported for CO hydrogenation on Rh/TiO_2[19] and for methanol formation on Pd/SiO_2.[1] However, it is remarkable that the extent of methane suppression was Li > Na > K≈Cs > none, Li exhibiting the greatest effect. If the suppression of both activity and methane formation was controlled by one common factor like an electronic effect, these effects should show the same orders. In fact, the two orders for Ru/Al_2O_3 were the same. Thus, an additional effect must be considered in the case of $Ru-Li/SiO_2$.

Effects of Alkalis on the Adsorption of H_2 and CO. The possible effects caused by the addition of alkalis are (i) a change of particle size, (ii) an electronic effect on Ru, and (iii) a geometric or ensemble effect.

As shown in Table 2, the particle size calculated from the amounts of adsorbed H_2 (given in Table 1) definitely increased upon Li addition (more than two times), but the particles sizes determined by EM and XRD changed little or slightly decreased. Therefore, the decreases in the amounts of adsorbed CO and H_2 upon Li addition were not ascribable to the increase in the size of Ru particles. One possible explanation may be an electronic effect. Due to a change in the electronic state of Ru caused by Li, a Ru surface might lose the ability to adsorb H_2 and CO. However, the electronic effect was not significant for $Ru-Li/SiO_2$ as inferred from IR of adsorbed CO. The IR band for $Ru-Li/SiO_2$ shifted only by 8 cm^{-1} (Fig. 9), as compared to 20 cm^{-1} for $Ru-K/SiO_2$ and 40 cm^{-1} for $Ru-K/Al_2O_3$.[12]

If one considers the small electronic effect of Li as well as the small change in the particle size, it is more likely that the decreases in the amounts of adsorbed CO and H_2 were due to partial coverage of the Ru surface by Li. This is similar to a "decoration model" proposed for the SMSI effect.[20-22] It is possible that during the preparation and/or activation process of the catalyst, a portion of Li is transported in a form close to Li_2O to the surface of the Ru particles without changing the particle size. The small change observed when the impregnation order was reversed may be consistent with this explanation.

A possible reason for the smaller effects of alkali for Ru/Al_2O_3 (Fig. 7) than for Ru/SiO_2 (Fig. 1) may be that the migration of Li onto the Ru surface was suppressed by the higher affinity of Li to Al_2O_3 support.

Effects of Alkalis on the Catalytic Property in CO Hydrogenation. It has been known for Ru/Al_2O_3 that TOF of CO hydrogenation changes inversely with the particle size of Ru.[15,23,24] In contrast, when Li was added to Ru/SiO_2, although the particle size decreased slightly (Table 2), TOF considerably decreased (Fig. 4). Therefore, the decrease in TOF was not due to the change in the particle size.

We previously reported that the effects of the addition of K, P, and B to Ru/Al_2O_3 were due to an electronic effect. However, the electronic effect of Li seems much smaller than that of K (as discussed above) in spite of the fact that Li was much more effective than K for the suppression of methane. Therefore, the electronic effect is not likely to be the primary function of Li.

We also studied the effect of V addition to Ru/Al_2O_3 and explained the results in terms of a geometric effect that is similar to an ensemble effect.[16] The effects of Li observed in the present study are rather similar to those of V with regard to activity and methane formation. Therefore, a similar geometric effect may be considered to be the primary function of Li in $Ru-Li/SiO_2$. The model proposed in the preceding section, that a Li compound partially covered the Ru surface, is consistent with the presence of a geometric effect.

McClory and Gonzalez reported that the addition of alkali to Ru/SiO_2 decreased the activity, enhanced the selectivities to olefins, and slightly suppressed methane formation.[14] In their study, however, changes in selectivities were much smaller and little difference was observed among the alkali metals. The differences between their and our results are attributable to the amounts of alkalis added. The amounts were 0.1 in atomic ratio to Ru in their study as compared with 0.1—4.5 in the present study. As shown in Fig. 4, the effects became significant when Li/Ru ratio was 0.25.

McClory and Gonzalez explained the above effect of alkali by an ensemble effect which lowered the ability for hydrogenation.[14] The suppression of methane formation and the enhancement of the olefin/paraffin ratio is consistent with the lower ability for hydrogenation. Therefore, the same explanation may be applicable to the effect of alkali observed in the present study. The selective suppression of methane formation, as observed in the present study, indicates that the geometric or ensemble effect was greater for methane formation; methane formation may need larger ensembles or more adjacent sites to supply more hydrogen atoms for the hydrogenation of the CH_x intermediate to methane. Another possibility is that sites which selectively produced methane were present on the Ru surface and Li preferentially poisoned these sites. The fact that methane formation was suppressed by a factor of 90 while the C_{2+} formation decreased only

to 70% favors this explanation. However, there is no direct evidence in the present study to show the presence of those sites.

An increase in the olefin/paraffin ratio was also found in the case of K addition to Ru/Al_2O_3 in our previous study.[12] In the case of Ru/Al_2O_3, the principal effect of K was the suppression of the secondary hydrogenation of olefin due to the increased CO coverage. But, in the case of $Ru\text{-}Li/SiO_2$, secondary hydrogenation was little suppressed. This fact also indicates that the effect is different for K and Li.

We gratefully acknowledge Mr. Hideo Tsunakawa of the Engineering Research Institute of the University of Tokyo for measuring electron micrographs. The present study was supported in part by a Grant-in-Aid for Scientific Research No. 61040012 from the Ministry of Education, Science and Culture.

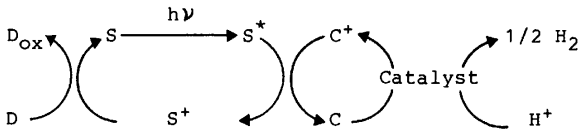
Viologen linked water-soluble porphyrins ($ZnP(C_nV)_4$) with different methylene chain lengths (n=2—5) between porphyrin and viologen were synthesized. These compounds were applied to photoinduced hydrogen evolution in a system containing NADPH-$ZnP(C_nV)_4$-hydrogenase under steady state irradiation.

Photoinduced hydrogen evolution systems containing an electron donor (D), a photosensitizer (S), an electron carrier (C), and a catalyst have been studied extensively.[1-3]



As photosensitizers metallo-porphyrins have been widely used and methyl viologen has been a popular electron carrier. In this work, viologen linked water-soluble zinc porphyrins were synthesized which may act as both a photosensitizer and an electron carrier in the same molecule; these compounds were applied to photoinduced hydrogen evolution.

Experimental

All materials were of analytical grade or the highest grade available.

The structures of viologen linked water-soluble zinc porphyrins are shown in Fig. 1. These compounds were synthesized as follows. The starting material, zinc 5,10,15,20-tetra(4-pyridyl)porphyrin (Zn-TMPyP), was synthesized

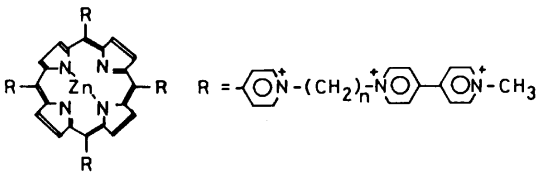


Fig. 1. Structure of viologen linked porphyrins, $ZnP(C_nV)_4$.

according to methods described in the literature.[4,5] Zn-TMPyP was then quaternized with an excess amount of α,ω-dibromoalkane at 130 °C. The quaternized porphyrin and 100—200 fold molar excess amount of 1-methyl-4,4′-bipyridin-1-ium iodide was refluxed in methanol, and the formed precipitate was filtered off and washed with methanol.

Hydrogenase was obtained from Desulfovibrio vulgaris (Miyazaki type, IAM 12604) and purified by Yagi's method.[6] Its concentration is not known, but 1.48×10^{-6} mol of hydrogen was generated by the following reaction system: hydrogenase (0.5 cm^3)-methyl viologen (4.1×10^{-5} mol dm^{-3})-$Na_2S_2O_4$ (5.7×10^{-3} mol dm^{-3}) in 5.0 cm^3 of 0.02 mol dm^{-3} Tris-HCl buffer (pH 7.0) at 30 °C for 10 min.

Electronic and fluorescence spectra were recorded on Shimadzu MPS-5000 and Hitachi model 850 instruments, respectively.

Conventional laser flash photolysis was carried out by using a Nd-YAG laser, model DCR-2A-10 from Quanta-Ray Inc. This generated second-harmonic (532 nm) pulses of 10-ns duration with an energy of 200 mJ per pulse; a repetition rate of 10 Hz was used for the excitation of sample solutions throughout this study. The light beam, after passing through a sample cell, was collimated into the entrance slit of a monochromator (model BM 50/50 from B & M Spectronik Co.). The output signal from a photomultiplier (Hamamatsu Photonics 446) attached to the slit of the monochromator was displayed on a Hitachi oscilloscope, model V-1050F.

For steady state irradiation, a 200 W tungsten lamp was used as the light source. Light of wavelengths less than 390 nm was removed by a Toshiba L-39 filter.

Photoinduced hydrogen evolution was carried out with $ZnP(C_nV)_4$ with n=2—5 under steady state irradiation at 30 °C. A sample solution containing nicotinamide-adenine dinucleotide phosphate (reduced form, NADPH), ZnP-

(C_nV)$_4$, and hydrogenase was deaerated by repeated freeze-pump-thaw cycles.

Results and Discussion

Electronic Spectra of ZnP(C_n)$_4$ and ZnP(C_nV)$_4$. The electronic spectra of the compounds are shown in Fig. 2 (a)—(e) and Table 1. Though ZnP(C_n)$_4$ contain metal ions, the Q band spectra of ZnP(C_n)$_4$ (n=2—5) (shown by dotted lines in Figs. 2 (b)—(e)) are similar to the absorption spectrum of metal-free H_2TMPyP (shown in Fig. 2 (a)). The electrons in the porphyrin ring may be significantly influenced by an interaction between the central metal ion and halogen ions connected at the end of the methylene chain.

Fig. 3. Fluorescence spectra of various porphyrins. (a): $ZnP(C_n)_4$, (b): $ZnP(C_nV)_4$.

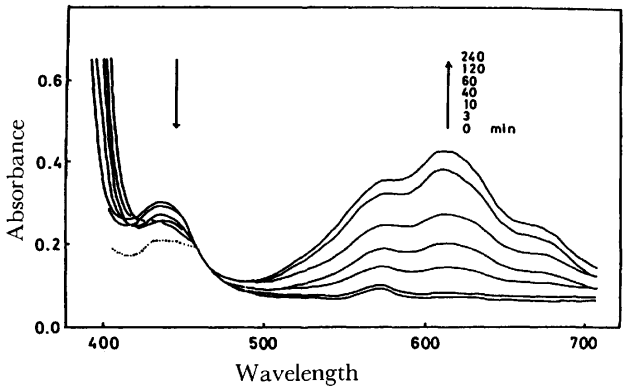

Fig. 4. Absorption spectrum of $ZnP(C_5V)_4$-NADPH system. Sample solution containing $ZnP(C_5V)_4$ (2.0×10^{-6} mol dm^{-3}) and NADPH (1.0×10^{-3} mol dm^{-3}) was irradiated at 30 °C.

The electronic spectra of $ZnP(C_nV)_4$ (shown by solid lines in Figs. 2 (b)—(e)) are similar to the spectrum of ZnTMPyP (Fig. 2 (a)) rather than that of $ZnP(C_n)_4$, showing a smaller interaction between the central metal ion and the viologen connected at the end of the methylene chain. However, there are some interactions between the porphyrin ring and viologen as the absorption spectra of $ZnP(C_nV)_4$ in the Soret region shifts to longer wavelengths.

Fluorescence Spectra $ZnP(C_n)_4$ and $ZnP(C_nV)_4$. The fluorescence spectra of $ZnP(C_n)_4$ and $ZnP(C_nV)_4$ are shown in Figs. 3 (a) and (b). The fluorescence spectra of $ZnP(C_2)_4$ and $ZnP(C_2V)_4$ are broad and the peak wavelengths are at longer wavelengths compared with the other porphyrins shown in Fig. 3. The relative fluorescence intensity obtained by integrating the spectra are shown in Table 2. The relative fluorescence intensity of $ZnP(C_nV)_4$ (n=2—4) are low compared with $ZnP(C_n)_4$. The excited singlet state of the porphyrin with viologen may be quenched by viologen linked with a porphyrin ring.

Photoreduction of Viologen. When a sample solution containing viologen linked porphyrin and NADPH was irradiated, the growth of the reduced form of viologen was observed. Figure 4 shows an example when $ZnP(C_5V)_4$ was used. Since the absorption coefficient of $ZnP(C_5V)_4$ was not known, its concentration was determined by using the absorption coefficient of ZnTMPyP. The concentration of the reduced form of viologen increased with the irradiation time and tended to reach a constant value.

Regarding the exposure of the sample solution to air, an absorption spectrum with λ_{max}=600 nm disappeared, confirming the formation of reduced viologen. The absorption spectrum intensity with λ_{max}=460 nm due to the Soret band of the porphyrin decreased upon irradiation. Owing to the exposure to air, the spectrum returned to the original shape to some extent, but did not completely return to the original shape. This fact indicates that the reduced form of the porphyrin was formed by the irradiation and that an irreversible species was formed at the same time due to the irradiation. The reduced form of the porphyrin may be formed by the reductive quenching of the photoexcited porphyrin by NADPH.

Photoinduced Hydrogen Evolution. Upon irradia-

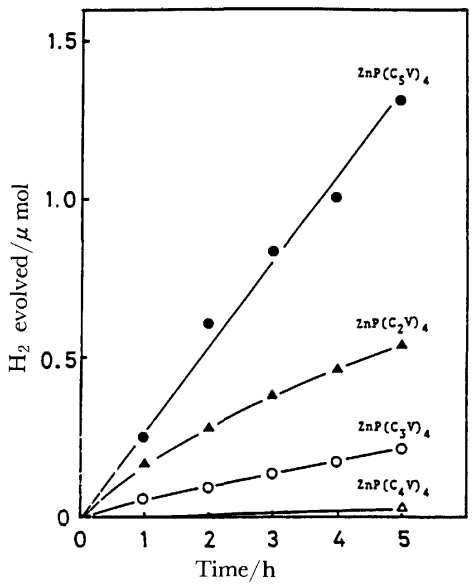

Fig. 5. Time dependence of amount of hydrogen evolved. Sample solution containing $ZnP(C_nV)_4$ (2.0×10^{-6} mol dm^{-3}), NADPH (1.0×10^{-3} mol dm^{-3}) and hydrogenase (0.5 cm^3) was irradiated at 30°C.

tion of the sample solution, hydrogen was generated; the time dependence of the amount of hydrogen evolved is shown in Fig. 5. The concentrations of $ZnP(C_nV)_4$ (n=2—5) were determined by using the absorption coefficient of ZnTMPyP. Thus, it is apparent that every compound, $ZnP(C_nV)_4$ (n=2—5), participates as both a photosensitizer and as an electron carrier in the same molecule. Since the hydrogen evolved almost linearly with irradiation time, an irreversible deactivation of the porphyrin is depressed in these systems. When an intramolecular electron transfer from porphyrin to viologen takes place, the electron can move from the reduced viologen to the catalyst hydrogenase. As shown in Fig. 5, the hydrogen evolution rate strongly depends on the methylene chain length (n) of $ZnP(C_nV)_4$. Within a certain range (n=2—4), the hydrogen evolution rate decreases with increasing chain length. In the case of $ZnP(C_5V)_4$, however, a higher hydrogen evolution rate was observed. The turnover number of hydrogen evolved against $ZnP(C_5V)_4$ was 86 per hour. The activity was at most two-times more active than that of an individual component system containing ZnTMPyP, methyl viologen, NADPH, and hydrogenase. As the chain length is sufficiently long in this case, the porphyrin ring may possibly come close enough to viologen by a conformational change of the molecule, so that the electron can transfer directly from the porphyrin ring to viologen.

Laser Flash Photolysis. Figure 6 shows oscilloscope traces of photoexcited $ZnP(C_nV)_4$ monitored at 500 nm after a laser flash. From these figures the lifetimes of the triplet state of these compounds were obtained (Table 3). There were no remarkable difference between $ZnP(C_n)_4$ and $ZnP(C_nV)_4$, indicating that

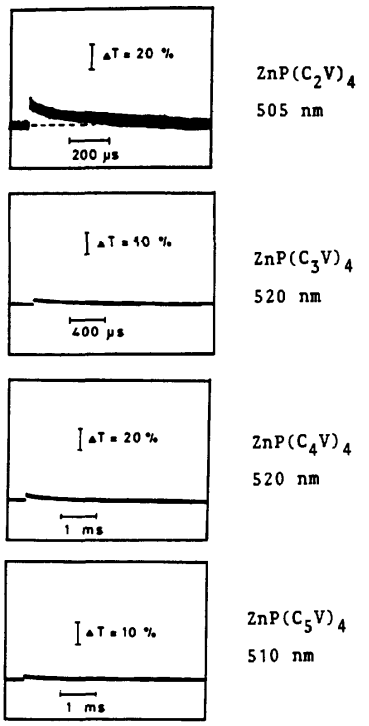

Fig. 6. Typical oscillograms for T–T absorption of $ZnP(C_nV)_4$.

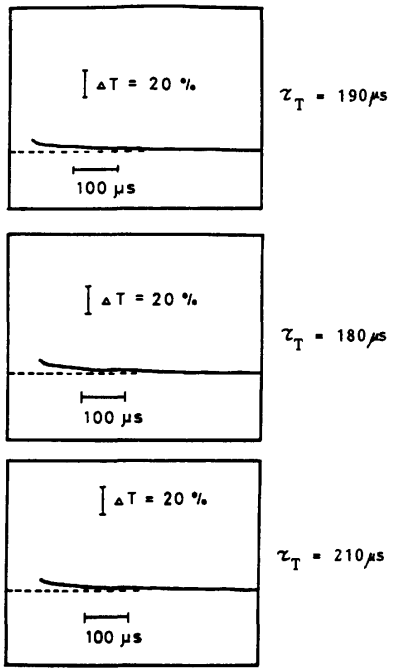

Fig. 7. Typical oscillograms for T–T absorption of $ZnP(C_2V)_4$. laser power (a): 80 mJ pulse^{-1}, (b): 60 mJ pulse^{-1}, (c): 50 mJ pulse^{-1}.

Table 3. Lifetimes of Excited Triplet State of $ZnP(C_n)_4$ and $ZnP(C_nV)_4$

	τ_T/μs		τ_T/μs
$ZnP(C_2)_4$	140	$ZnP(C_2V)_4$	190
$ZnP(C_3)_4$	530	$ZnP(C_3V)_4$	510
$ZnP(C_4)_4$	230	$ZnP(C_4V)_4$	640
$ZnP(C_5)_4$	330	$ZnP(C_5V)_4$	470

the triplet states of these compounds are not quenched by the linked viologen.

Figure 7 shows typical oscillograms for T-T absorption of $ZnP(C_2V)_4$ with different laser powers. Though the intensity of the T-T absorption depends on the laser power, the lifetimes of the triplet state were independent of the laser power, indicating that the triplet state is not quenched by another molecule in the ground state; that is, intermolecular quenching is negligible under these reaction conditions.

From the above results the following reaction mechanism is proposed:

$$^3P^*\text{-}V + D \longrightarrow P^-\text{-}V + D^+,$$

and

$$P^-\text{-}V \longrightarrow P\text{-}V^-.$$

During the first stage of the reaction, the photoexcited triplet state ($^3P^*$-V) is reductively quenched by NADPH and a reduced form of porphyrin (P^--V) is formed; then, the electron transfers from the porphyrin to viologen. This reaction mechanism is based on the fact that both intramolecular and intermolecular quenching of the photoexcited triplet state of the porphyrin did not occur, and that the reductive quenching by NADPH is predominant.

ESR and Mass-Spectrometric Studies of Methanol Combustion. I. The Correlation between Labile and Stable Chemical Entities in Free-Burning Methanol-Air Flames under Atmospheric Pressure

Masayuki TANIGUCHI and Hiroshi YOSHIDA*
Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060
(Received October 3, 1986)

The concentration profiles of labile (H, O, and OH) and stable chemical entities (CH_3OH, O_2, CH_2O, H_2, H_2O, and CO_2) in premixed methanol-air flames under atmospheric pressure have been studied by the probe-sampling-ESR method combined with mass-spectrometric detection. The concentrations of the labile intermediates have been determined by correcting their destruction in the sampling probe caused by gas-phase reactions, wall reactions, and reactions at the pinhole of the probe. The observed profiles are in good agreement with the numerical model developed previously by Westbrook and Dryer, except that the concentration changes in all the entities are quicker than expected. The dependence of the maximum concentrations of the labile intermediates on the composition of the premixed gas is essentially the same as that observed for the methanol-air flames at low pressure.

The combustion of common fuels consists of chain reactions, with atomic H and O, and the OH radical as principal chain carriers. As these labile intermediates are paramagnetic, the electron spin resonance (ESR) is possibly a useful method for combustion-chemical studies. Actually, since the pioneering work by Westenberg and Fristrom,[1] a combination of the ESR method and the probe-sampling technique has been used for examining the concentration profiles of H and O atoms in combustion flames.[2-4] In 1980, Noda et al.[5] succeeded, as a result of the continual progress in ESR technique, to detect simultaneously all the labile intermediates, H, O, and OH, in a methane-air flame; they thus showed the wide applicability of the ESR method to this research field. Since then, there have appeared extensive studies of the concentration profiles of the unstable intermediates in combustion flames by means of the ESR method.[6-8]

The present investigation concerns the chemical reactions in methanol-air flames under atmospheric pressure. This is an extension of our previous ESR investigation,[7] where only the profiles of the labile intermediates were determined. The purpose of the present investigation was to determine comprehensively both the labile intermediates and the stable entities, including reactants and final products, by combining the mass spectrometric method with the probe-sampling-ESR method.

The combustion chemistry of methanol is attracting interest, because methanol is expected to be one of the future alternatives to petroleum resources. It is one of the simplest model fuels other than hydrocarbons for combustion-chemical studies, and so it has been extensively studied both theoretically and experimentally. Westbrook and Dryer have developed a numerical model for laminar flames of methanol-air mixtures.[9] This model has been substantiated by the agreement between the concentration profiles of the stable entities calculated based on the model and those observed experimentally from low-pressure methanol-air flames by Akrich et al. using the gas-chromatographic method.[10] More recently, Pauwels et al. have determined the concentration profiles of labile intermediates in the low-pressure methanol-air flames by using the ESR method, and have claimed that the observed dependence of the maximum concentration of H, O, and OH on the composition of the premixed gas agrees well with that predicted on the basis of the model.[6] Very recently, Andersson et al.[11] have studied the concentration profiles of both labile intermediates and stable entities in the flame by means of the mass-spectrometric method. They[11,12] have also examined the numerical model on the basis of their experimental data and the rate constants recently proposed for some elementary reactions,[13] and have argued that the diffusion constants of the chemical entities used in the previous model[9] were too large, while the rate constant for the CHO decomposition were too low. In order fully to elucidate the chemical reactions in the methanol combustion, experimental data are still needed on the concentration profiles of both labile intermediates and stable entities simultaneously observed in the methanol-air flame under various conditions. The present investigation was aimed at supplementing the previous experiments on the low-pressure methanol-air flames.[6,10,11]

Experimental

The burner used was made of brass and had a mouth (8 mm in diameter) shaped in such a way that the distribution of the gas-flow velocity in the cross-section area of the mouth was approximately uniform.[7] The secondary air was not allowed to flow through in order to keep the mixing of the surrounding air into the flame as low as possible.[14] A fine stainless steel grid made of 0.3 mm meshes was put on the burner mouth to prevent flash-back. The flow rate of air from a cylinder was controlled with a precision needle valve. Liquid methanol was continuously injected into the air stream, which had been preheated to 403 K.

The reacting gas was continuously sampled from the flame through a pinhole (about 0.1 mm in diameter) of a

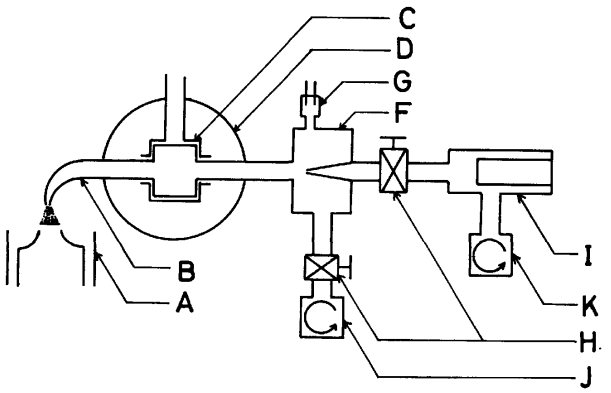

Fig. 1. Schematic view of the experimental set-up. A; burner, B; sampling probe, C; ESR cavity, D; magnet, F; condenser, G; vacuum gauge, H; vacuum valve, I; quadrupole mass spectrometer, J; primary pumping system (mechanical booster and rotary pumps), K; secondary pumping system (diffusion and rotary pumps).

quartz sampling probe, led to an ESR cavity, and subjected to ESR measurements with an X-band spectrometer (Varian, Model E-109) equipped with a large access cavity (TE_{011} mode, Model E-235) at a low pressure (24—80 Pa) in order to examine the concentrations of H, O, OH, and O_2. The calibration of the ESR signal intensities to determine the absolute concentrations within the cavity was made with reference to the intensity of O_2 (for H and O) or NO (for OH) of known concentrations.[15,16] A part of the sampled gas was further led to a quadrupole mass spectrometer (Nihon Shinku, Model MSQ-150A), and the concentrations of stable entity in it were measured at a total pressure of 10^{-3} Pa in the ionization chamber. The whole experimental set-up is shown schematically in Fig. 1. Washing the sampling probe with HF, with NaOH, and then with HNO_3 was found to be the best treatment to prevent the destruction of labile intermediates on the wall during sampling, as has been reported previously.[6]

The gas was sampled at several positions on the center axis of the flame by moving the flame with respect to the sampling probe. The flame temperature was measured with a SiO_2-coated Pt/Pt-Rh thermocouple (0.1 mm in diameter) at the same positions. No correction was made for radiation loss.

Results and Discussion

Flame and Observed Spectra. The flame obtained consisted of a flat, bright, bluish region and a faint, outer, conical region. The former lay 1—2 mm above the burner mouth and was essentially of the premixed-flame nature. The latter had the diffusion-flame nature, and the visible boundary of its top lay 10—18 mm above the burner mouth, depending on the composition of the premixed gas. The flame was found to be axially symmetric both in appearance and in the concentrations of the chemical species. No visual change was observed on inserting the sampling probe. The flow rate of the gas with a different composition was kept constant at 1.0 l min^{-1}. The sampled gas was

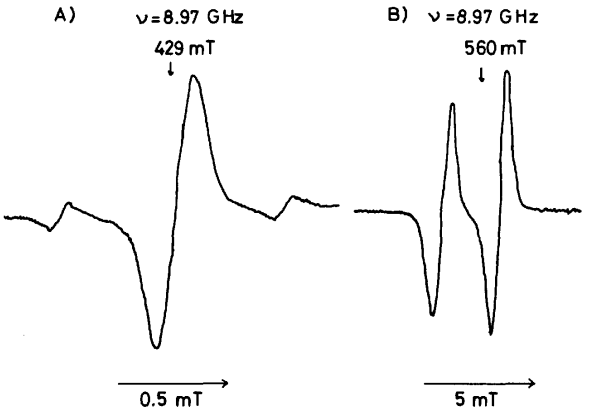

Fig. 2. Typical examples of ESR spectra due to (A) O atoms and (B) OH radicals recorded at 24 Pa.

cooled by adiabatic expansion and showed nearly the ambient temperature.

The ESR spectra due to $H(^2S)$, $O(^3P_2, ^3P_1)$, $OH(^2\Pi_{3/2}, ^2\Pi_{5/2})$, and $O_2(^3\Sigma_g^-)$ were observed from the sampled gas, as in the previous studies of methane-air[5] and methanol-air flames.[6,7] A part of the observed ESR spectra, where the spectral intensity was monitored, attributable to O and OH is shown in Fig. 2. The concentrations of these labile intermediates in the sampled gas within the ESR cavity were determined from the double integration of the observed differential spectral curves after the calibration mentioned in the Experimental section.

Intense mass spectra were detected at m/z=2, 14, 16, 17, 18, 28, 31, 32, and 44 from the sampled gas. The concentration of H_2, H_2O, CH_3OH, and CO_2 were determined directly from the spectral intensities at the mass number of 2, 18, 31, and 44 respectively. Because the peak at m/z=32 due to parent CH_3OH ions overlapped with the peak of the O_2 ions, the CH_3OH concentration was determined from the fragment peak at m/z=31. The concentration of CH_2O was determined by subtracting the contribution of CH_3OH from the spectral intensity at m/z=30. Each spectral intensity was calibrated with reference to the intensity of the corresponding gas of a known concentration. The uncertainty of the concentrations thus determined was less than 10%. The concentration of CO could not be determined because of the overlapping of the N_2 spectrum.

Reactions in the Sampling Probe and Their Correction. A serious problem involved in the probe-sampling procedure is the destruction of labile intermediates in the probe before they can be measured. There are two possible types of processes responsible for the destruction; one is bimolecular gas-phase reactions in the probe such as

$$O + OH \longrightarrow O_2 + H, \quad (1)$$

$$OH + OH \longrightarrow H_2O + O, \quad (2)$$

with a low activation energy, while the other is first-order reactions on the wall.

It was found that the logarithm of the mole fractions of the labile intermediates decreased linearly with the increase in the sampling pressure in the pressure range of 40—80 Pa, and that the gradient of the linear decrease was almost unchanged when the sampling probe was about doubled in length. If the above linear dependence on the sampling pressure is due to the first-order destruction on the wall, the gradient could be expected to be proportional to the length of the probe (residence time in the probe).[6] Therefore, the actual destruction of the labile intermediates in the probe cannot be described simply by the first order wall reaction.

Figure 3 shows the observed concentrations of the labile intermediates in the ESR cavity as a function of their residence time in the probe before reaching the ESR cavity. The residence time was changed by using extension tubes of different lengths. The pressure in the probe was kept constant at 40 Pa. All the H and O atoms and OH radicals appear to follow the first-order decay with different rate constants. However, the extrapolation of the observed straight lines to $t=0$ will not give the actual concentration of the labile intermediates in the flame, for the bimolecular gas-phase reactions become important in the early period.

Using the rate constants, $k_1=1.0\times10^7$ and $k_2=1.5\times10^3T^{1.14}$ $m^3 mol^{-1} s^{-1}$, reported by Warnatz,[17] and also the observed concentrations of all the chemical species involved in Reactions 1 and 2, and assuming a constant temperature, 300 K, of the sampled gas in the probe, the rate constants for the wall reactions were determined by computer simulations to be 1.71×10^2, 1.53×10^2, and 1.07×10^3 s^{-1} for H, O, and OH respectively for the present sampling conditions. The solid curves in Fig. 3 are the best-fitting simulation curves. The destruction caused by the bimolecular gas-phase reactions is significant for O atoms when the OH concentration is high.

Pauwels et al.[6] first reported that the wall reactions are primarily important in the destruction of the labile intermediates at low sampling pressures (5.3—13.3 Pa) and at low temperatures, but they have very recently suggested that the gas-phase reactions should not be ignored.[8] The correction for the destruction of the labile intermediates in the sampling probe made in their recent study is essentially the same as that developed independently in the present study.

Another difficult problem inherent in the probe-sampling is the destruction of labile intermediates caused by reactions at the pinhole and/or at the very end of the probe tip. The temperature and pressure of the sampled gas are necessarily much higher there than in the main body of the sampling probe, where the sampling gas has already been cooled by adiabatic expansion. Biordi et al.[18] have studied the concentration of chemical species in low-pressure CH_4-O_2-Ar flames by using molecular-beam mass spectrometry, and examined the change in the concentration profiles with sampling probes of different cone angles. Their results indicate that the destruction of OH is much more remarkable with small angled cones (smaller than 40°) than with large angled cones. We confirmed the same effect of the cone angle by using two probes, 40°-angled and 15°-angled cones: the observed OH concentrations were higher for the former probe. It should be noted, however, that the observed concentrations of H and O showed almost no difference between these two probes.

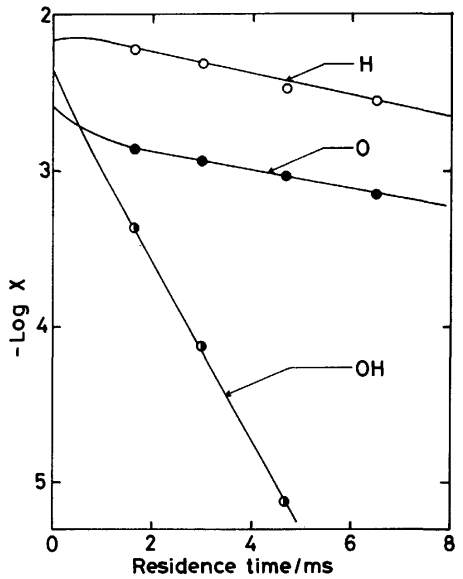

Fig. 3. The dependence of the observed concentrations (X, in mole fraction unit) of the labile intermediates in sampled gas on the residence time of the gas in the sampling probe before reaching at the ESR cavity for the methanol-air flame of stoichiometric composition under the atmospheric pressure. The curves are determined by simulating the destruction of the labile entities due to the gas phase reactions and the wall reactions in the probe (see text for detail).

The effect of the surface treatment of the probe is also significant for the destruction at the pinhole. The observed OH concentrations were found to be three times higher for the 40° cone angle and ten times higher for the 15° cone angle after the HF treatment than before, though the normal wall destruction was not affected by the HF treatment. There is no way at the moment to determine the correction factor for the OH destruction at the pinhole, and so we assumed there to be no destruction at the pinhole for the HF-treated 40°-angled probe. As a whole, the ambiguity in the ESR determination of concentrations is the largest for OH, but it is thought to be within the factor of 2.

Concentration Profiles. The chemical reactions in the outer flame region are strongly dependent on the physical conditions, such as the diffusion of the surrounding air into the flame. The concentration pro-

files of only the labile intermediates, mostly in the down-stream region, have been observed and discussed in previous studies of methane-air[5] and methanol-air[7] flames. In the present study, therefore, we focussed our attention on the concentration profiles in the inner flame region, where the behavior of the profiles shows more inherently the chemical nature of the combustion process. The concentration profiles of both labile intermediates and stable entities in the flame were determined for three different equivalence ratios, defined as $\phi=([\text{fuel}]/[O_2])_{\text{actual}}/([\text{fuel}]/[O_2])_{\text{stoichiometric}}$, of the premixed gas. The results are shown in Figs. 4—6, where all the concentration are expressed in mole fraction units. The concentrations of the labile intermediates are presented after correction for the partial destruction during sampling attributable to the gas-phase and wall reactions. The equivalence ratios examined were in the range of 0.82—1.53, because it was difficult to stabilize the flame in the low-ϕ (fuel-lean) region.

The results obtained from the stoichiometric flame (Fig. 4) show that methanol is totally consumed within the region 1 mm from the burner mouth. Correspondingly, the O_2 concentration also decreases in this region, sharply at first and then slowly. The generation of the final combustion products, CO_2 and H_2O, start at or close to the burner mouth, and their concentrations reach the plateau value when the methanol is completely consumed. The H_2O generation is observed to occur in an earlier region than the CO_2 generation. This observation is consistent with their formation routes: for H_2O, the reaction

$$CH_3OH + OH \longrightarrow CH_2OH + H_2O, \quad (3)$$

occurring in early stage of the combustion is one of the main routes, while CO_2 comes mainly from this reaction;

$$CO + OH \longrightarrow CO_2 + H, \quad (4)$$

which occurs at a later stage of the combustion.

Among the stable intermediate entities, CH_2O appears only in a narrow region and shows a concentration maximum. In contrast, H_2 is distributed over a wide region and shows two concentration maxima. The first H_2 maximum coincides in location in the flame with the CH_2O maximum. The high local concentration of CH_2O is in accord with Bowman's proposal,[19] based on a shock-wave study, that the main oxidation path of methanol at high temperatures is: $CH_3OH \rightarrow CH_2OH \rightarrow CH_2O \rightarrow CHO \rightarrow CO \rightarrow CO_2$.

The concentrations of all the labile intermediates increase sharply, simultaneously with the rapid consumption of CH_3OH and O_2. According to the model of Westbrook and Dryer,[9] the most important reactions for the methanol consumption are:

$$CH_3OH + OH \longrightarrow CH_2OH + H_2O, \quad (3)$$

$$CH_3OH + H \longrightarrow CH_2OH + H_2, \quad (5)$$

$$CH_3OH + H \longrightarrow CH_3 + H_2O, \quad (6)$$

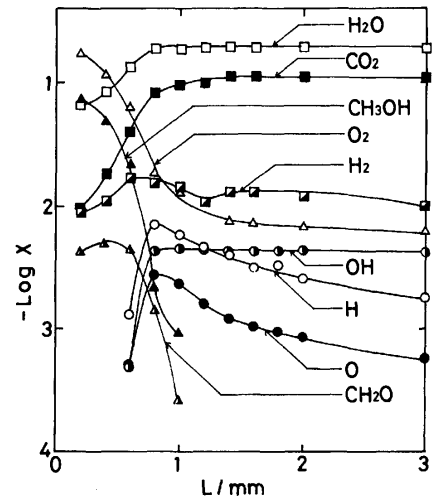

Fig. 4. Concentration profiles of both labile intermediates and stable entities in the methanol-air flame of stoichiometric composition (ϕ=1.0). The concentrations are presented in mole fraction unit (X) in the logarithmic scale. The distance (L) is between the burner mouth and the sampling point on the center axis of the flame.

$$CH_3OH + O \longrightarrow CH_2OH + OH, \quad (7)$$

and the H thus generated reacts with O_2 thus:

$$H + O_2 \longrightarrow O + OH. \quad (8)$$

The observed results agree qualitatively with the model of methanol-air combustion. The concentrations of H and O decrease slowly after passing their maxima, while that of OH remains constant. A closer examination of Fig. 4 may reveal that the sharp increase in the labile intermediates appears to be somewhat later than the rapid drop in the concentrations of CH_3OH and O_2 and the rapid increase in the concentrations of H_2O and CO_2. This apparent delay can be attributed to the effect of the diffusion of the chemical species in the flame; it will be discussed in detail in the following paper of this series.[20]

The peak of the CH_2O concentration appears to be well in advance of the accumulation of the labile intermediates. This may be attributed to its formation by the efficient reaction:

$$CH_2OH + O_2 \longrightarrow CH_2O + HO_2, \quad (9)$$

suggested by Westbrook and Dryer.[9]

Figures 5 and 6 show the effect of the increase in the equivalence ratio. Although the general features of the concentration profiles are the same for all the equivalence ratios examined, the maximum concentrations of the labile and stable intermediates depend on the ϕ value. It may be noted that the OH concentration shows slow decrease after passing through its maximum under fuel-rich conditions.

As the effect of the equivalence ratio was found to be the most noticeable for the maximum concentration of the labile intermediates, it was studied in detail over a

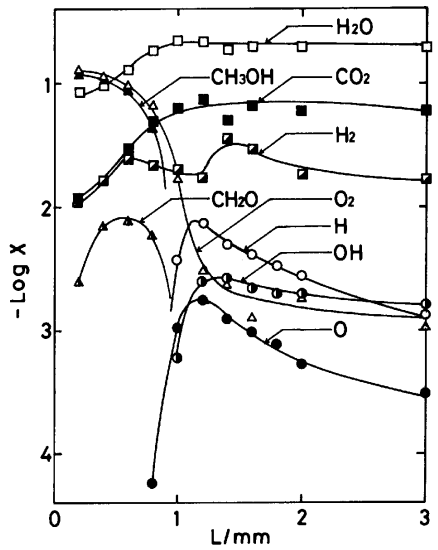

Fig. 5. Concentration profiles for the methanol-air flame of equivalence ratio ϕ=1.2.

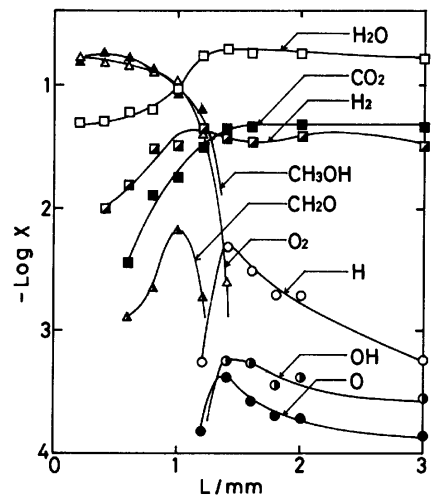

Fig. 6. Concentration profiles for the methanol-air flame of equivalence ratio ϕ=1.5.

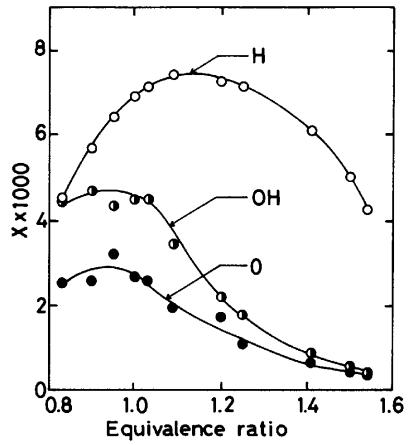

Fig. 7. Dependence of the maximum concentrations of the labile intermediates in the methanol-air flame on the equivalence ratio.

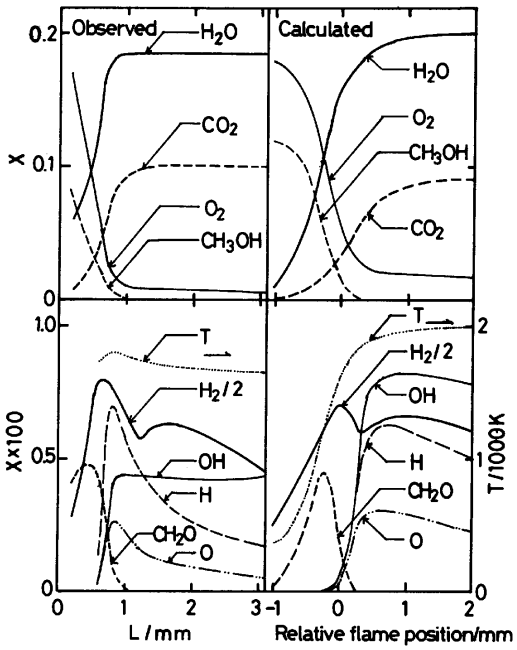

Fig. 8. Comparison of the labile intermediates and stable entities observed by the ESR and mass spectrometric methods and those calculated by Westbrook and Dryer based on the numerical model for the methanol-air flame under atmospheric pressure.

wider range of ϕ, 0.82—1.53, as shown in Fig. 7. H shows a broad maximum around ϕ=1.1. The maxima for O and OH lay at smaller ϕ values. These results, essentially the same as those reported by Pauwels et al.[6] for the low-pressure methanol-air flames, indicate that the dependence of the maximum concentration on the equivalence ratio is little dependent on the pressure.

Comparison with the Numerical Model. Westbrook and Dryer[9] have constructed a comprehensive numerical model of methanol combustion, which includes 26 chemical species and 84 elementary reactions. Based on this model, they have then calculated the concentration profiles by computer-simulation for one-dimensional methanol-air premixed flames under different pressures. Model calculations for methanol combustions have recently been made also by other research group,[11-13] but they have not shown the concentration profiles under atmospheric pressure.

The observed concentration profiles are compared with the calculated ones in Fig. 8 for the flame of ϕ=1.0. One can see suite a good coincidence between the observed and calculated profiles for both stable entities and labile intermediates, though the calculations have made for an ideal adiabatic flame isolated from its surroundings. The observed maximum concentrations of O and H are in good agreement with the calculated values. The decrease in the observed H and O concentrations after the maximum is faster than that

expected from the calculations. This may be attributed to the heat loss to the surroundings, which has not been taken into account in the model calculations. Among the labile intermediates, the concentration of OH shows the poorest agreement in absolute value, but the difference between the observed and the calculated values is within a factor of 2. This difference may be due partly to the actual temperature being lower than the calculated one and partly to the destruction of OH at the pinhole of the probe during sampling.

The calculations[9] have predicted a double-peaked concentration profile for H_2; the first peak is predominantly attributable to Reaction 5, and the second peak, to Reaction 10:

$$CH_3OH + H \longrightarrow CH_2OH + H_2, \quad (5)$$

$$H_2O + H \longrightarrow H_2 + OH. \quad (10)$$

This prediction was satisfactorily proven by the present observation of the two peaks. The observed concentration change in CH_3OH, H, H_2O, and OH is consistent with the predominance of Reactions 5 and 10, leading to the H-generation around the peak positions.

Perhaps the most significant difference between the observation and the calculation is that the transient change in all the observed concentration profiles is quicker than that of the calculated profiles. We examined the perturbation of the flame attributable to the sampling probe in a separate experiment for the methane-air flame and found that the insertion of the sampling probe into the flame caused no serious change in the concentration profiles. The effect of the spatial resolution of the sampling procedure is, if any, to flatten the transient change in the concentration profiles. It can, therefore, be suggested that the calculated concentration change is somewhat too slow. The same difference between calculation and observation has been found for low-pressure methanol-air flames; it has been suggested that it is attributable to too big diffusion coefficients and too small a rate constant for the CHO decomposition used in the calculations.[11,12]

Conclusions

In order to elucidate the chemical reactions involved in the complex combustion process, it is indispensable to determine experimentally the distribution of as many chemical species as possible, both stable and labile, in the combustion system. In the present investigation, the concentration profiles in the methanol-air flame under atmospheric pressure were comprehensively determined by means of ESR measurements combined with mass-spectrometric measurements. The results obtained are totally consistent with the reaction scheme widely accepted, and are in fairly good agreement with the prediction based on the numerical model.[9]

There is no essential difference between the present observations at atmospheric pressure and the previous observations for the stable entities[10,11] and for the labile entities,[6,11] all at low pressures. The experimental conditions of combustion-chemical studies are generally difficult to control; therefore, the results obtained here are not precise enough to check the numerical model in detail. However, it can safely be concluded that the present results give, from the experimental point of view, general support for the previous numerical model and prove that the model can predict the pressure effect properly.

The Crystal and Molecular Structures of 2,4,4,6-Tetraphenyl-1,4-dihydropyridine and 4-Benzyl-1-methyl-2,4,6-triphenyl-1,4-dihydropyridine

Fujiko IWASAKI,* Toshiya WATANABE, and Koko MAEDA†

Department of Materials Science, The University of Electro-Communications, Chofu, Tokyo 182
†Department of Chemistry, Faculty of Science, Ochanomizu University, Bunkyo-ku, Tokyo 112

(Received October 15, 1986)

The crystal structures of 2,4,4,6-Tetraphenyl-1,4-dihydropyridine (**1**) and 4-benzyl-1-methyl-2,4,6-triphenyl-1,4-dihydropyridine (**2**) have been determined by the X-ray method. The crystals of **1** are monoclinic, $P2_1/a$, $a=12.883(1)$, $b=12.953(1)$, $c=12.575(1)$ Å, $\beta=94.95(1)°$, $V=2090.7(2)$ Å^3, $Z=4$, $D_x=1.225$ Mg m^{-3}. **2** is triclinic $P\bar{1}$, $a=7.786(1)$, $b=14.324(1)$, $c=10.759(1)$ Å, $\alpha=90.51(1)$, $\beta=106.89(1)$, $\gamma=92.02(1)°$, $V=1147.2(2)$ Å^3, $Z=2$, $D_x=1.196$ Mg m^{-3}. The final R values are 0.037 and 0.044 for **1** and **2**, respectively. The 1,4-dihydropyridine ring of **1** is a flat twisted boat, while that of **2** has a boat conformation with the apexes at N(1) and C(4). For **1** the dihedral angles of the phenyl rings and the plane of four C atoms, C(2), C(3), C(5), and C(6), of the pyridine ring are 46.6, 106.4, 62.3, and 30.5° for 2-, 4-, 4-, and 6-phenyl rings, respectively. The corresponding angles of **2** are 30.4, 50.2, and 39.1° for 2-, 4-, and 6-phenyl rings. The phenyl ring of benzyl group covers to the pyridine ring making the dihedral angle between these planes of 133.7°. The bond between C(4) and the methylene carbon is 1.576 Å, which is longer than the normal Csp^2–Csp^3 length.

2,4,4,6-Tetraphenyl-1,4-dihydropyridine (**1**) crystallized as colorless needles from an oxygen free benzene solution. The crystals and deaerated solutions of **1** exhibit a violet color on irradiation with UV light. The color of crystals was retained in deaerated media for a long time at room temperature, whereas in deaerated solutions the color was stable at only 77 K but at higher temperatures it gradually faded even under irradiation.[1] In solutions with oxygen the coloration does not occur and oxygenated products, *N*-(2-hydroperoxy-4-oxo-1,3,3-triphenylbutylidene)benzamide and 2,4,4,6-tetraphenyl-3,4-dihydro-3-pyridinol, were produced in benzene whereas 2,4,4,6-tetraphenyl-3-(4*H*)-pyridinone was given in acetone.[2] 4-Benzyl-1-methyl-2,4,6-triphenyl-1,4-dihydropyridine (**2**) also showed change of color from colorless to pale greenish

diffractometer with graphite-monochromated Cu $K\alpha_1$ (λ= 1.54051 Å) radiation, using the ω-2θ scan technique with a scanning rate of 4° min^{-1} in 2θ. At both ends of the scan range 10 s background counts were taken for each reflection. Three reflections were monitored for every 50 reflections. Variations of intensities of the monitored reflections were within 3% for both **1** and **2**. Reflections of $|F_o| \geq 3\sigma(F_o)$ were used for structure determination. No absorption correction was applied.

Although the colorless crystals of **1** changed to be blue during an irradiation with X-rays, the intensities of the monitored reflections have not changed. After the intensity measurement a check on the unit cell dimensions and the space group was carried out, but no change was observed. For **2** color change could not be observed.

The structures were solved by the direct method with the program MULTAN 78.[3] All non-hydrogen atoms were refined by the block-diagonal least-squares with anisotropic temperature factors. A difference map showed the all hydrogen atoms. Further refinement with anisotropic temperature factors for non-hydrogen atoms and isotropic ones for H gave the final R values of 0.037 and 0.044 for **1** and **2**, respectively. The quantity minimized was $\sum w(|F_o|-k^{-1}|F_c|)^2$. For **1**, $w=1/(0.8208-0.0710|F_o|+0.002|F_o|^2)$ and for **2**, $w=1/(0.0617+0.0147|F_o|+0.0002|F_o|^2)$. Atomic scattering factors were taken from "International Tables for X-ray Crystallography."[4] All computations were performed on a HITAC M180 Computer of the Data Processing Center of the University of Electro-Communications with the programs UNICS III,[5] MULTAN 78, and ORTEP II.[6] The final atomic parameters are given in Table 2.[7]

Discussion

The molecular structures with the atom-numbering are shown in Fig. 1. Bond distances and angles are listed in Table 3. The torsion angles are listed in

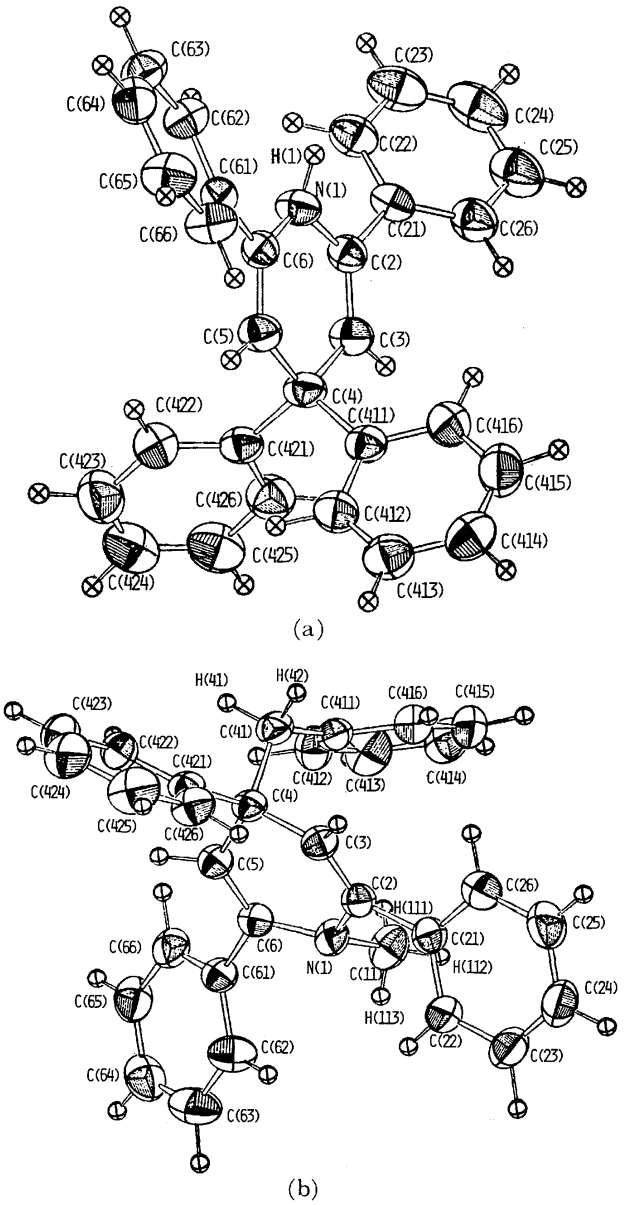

Fig. 1. Atomic numbering of the molecules. (a) **1** and (b) **2**. The thermal ellipsoids for non-H atoms are drawn at 50% probability.

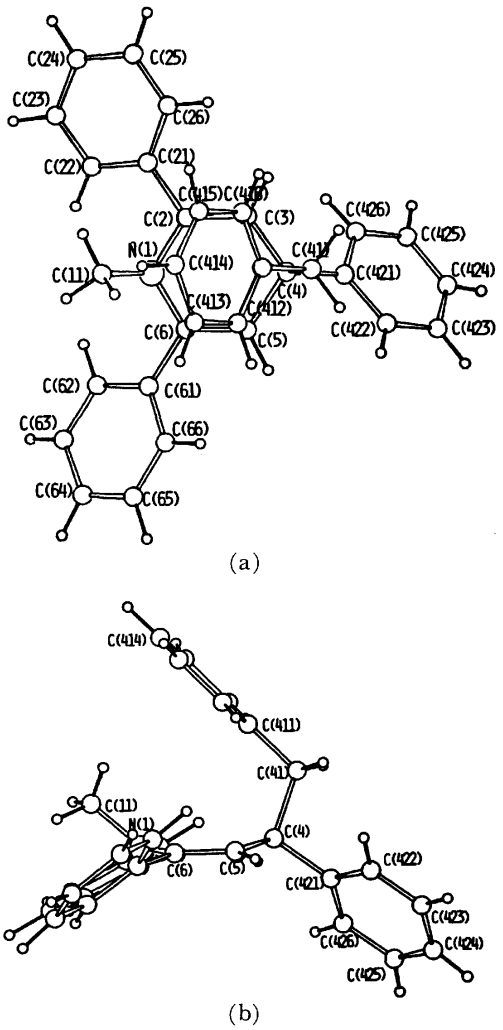

Fig. 2. (a) Projection of the molecule **2** on the dihydropyridine ring. (b) Side view of the molecule **2**.

Table 4. **2** shows a boat conformation with the apexes of C(4) and N(1). The torsion angles about C(4) ring bonds are larger than those about the N(1) bonds. The dihedral angles (boat angles) between the plane **A** defined by four atoms, C(2), C(3), C(5), and C(6), and the planes C(2)-N(1)-C(6) and C(3)-C(4)-C(5) are 10.1 and 17.5°, respectively. The dihedral angle (fold angle) between two N-C=C-C planes is 18.5°. The degree of the ring distorsions at N(1) and C(4) is the same order with those of 4-aryl-3,5-bis(methoxycarbonyl)-2,6-dimethyl-1,4-dihydropyridine.[8] For **1** the torsion angles about the N(1) and C(4) ring bonds are smaller than the corresponding angles of **2** and the other 1,4-dihydropyridines and C(4) is less distorted than N(1).

The lengths of C(2)-C(3) and C(5)-C(6) show the double bond character and are shorter than the corresponding values (1.345—1.369 Å) of the other 1,4-dihydropyridines.[8] The difference of these bond lengths may be attributed to the two methoxycarbonyl groups at 3 and 5 positions. The lengths of N(1)-C(2) and N(1)-C(6) for **2** are slightly longer than those of **1** and the others because of the 1-methyl substituent. The endocyclic angles of **1** and **2** are different from those of the others. The angles C(2)-N(1)-C(6) and C(3)-C(4)-C(5) of **1** and **2** are smaller and the other angles of **1** and **2** are larger than the corresponding angles of 3,5-bis(methoxycarbonyl) derivatives. The lengths of C(2)-C(21) and C(6)-C(61) show typical Csp^2-Csp^2 length while C(4)-C(411) and C(4)-C(421) are longer than the typical Csp^2-Csp^3 length, especially C(4)-C(411) of **2**.

For **1** the dihedral angles between the plane **A** and the four phenyl planes are 46.6, 106.4, 62.3 and 30.5° for 2-, 4-, 4-, and 6-positions, respectively. The corresponding angles of **2** are 30.4, 50.2, and 39.1° for 2-, 4-, and 6-positions, respectively.

The phenyl ring of benzyl group of **2** is trans to the

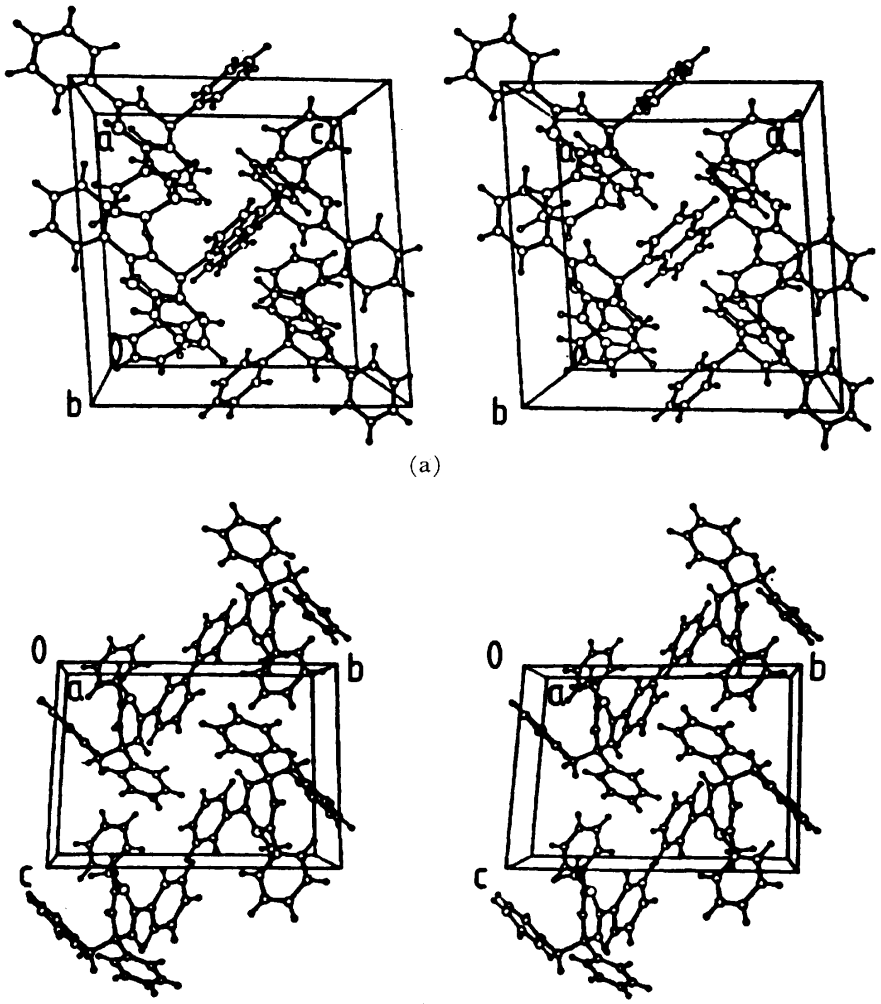

Fig. 3. Stereoscopic view of the crystal structure. (a) **1** and (b) **2**.

4-phenyl ring about the C(4)-C(41) bond and gauche to C(3) and C(5). This conformation of the benzyl group is quite interesting. Figure 2 shows the projection of **2** on the plane of the pyridine ring. The benzyl group covers the pyridine ring far from the phenyl group. The dihedral angles between the phenyl plane (C(411)—C(416)) and the plane **A** is 133.7°. Some intramolecular contacts between the phenyl ring of benzyl group and the pyridine ring, N(1)···C(411), C(2)···C(411), C(6)···C(411), C(3)···C(416), and C(5)···C(412), are 3.569(2), 3.434(3), 3.491(3), 3.344(3), and 3.332(3) Å, respectively.

Figure 3 is the stereoscopic view of the crystal packing. There are no significant contacts shorter than the sum of the van der Waals' radii.

In spite of a color changing of the crystal of **1** during an irradiation with X-rays for intensitiy measurement, the intensities, the dimensions of the unit cell and so the crystal structure have been retained. This result suggests the coloration may be attributed to an electronic effect. A slight difference of photochemical behavior between **1** and **2** may relate to the planality of the 1,4-dihydropyridine and the steric retention of the benzyl group of **2**.

We thank Miss Junko Shibuya for preparing the compounds.

Molecular-Weight Dependence of the Polymer Adsorption at Solid-Liquid Interfaces as Studied by ESR Spectroscopy

Harutoshi SAKAI† and Yoshio IMAMURA*
Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received October 15, 1986)

The conformation of poly(methyl methacrylate) adsorbed from dilute solution on nonporous silica was investigated by ESR method using three-component spectrum analysis. The fraction of the polymer segments in train, short loop, and long loop or tail, as well as the rotational correlation time for the segments were examined with regard to molecular weight (M=10^3—3×10^6), the degree of adsorption, and the particle size of silica. In CCl_4, the saturation adsorption, A_s, increased from 6 to 16×10^{-8} g cm^{-2}, the fraction of polymer segments in train, p, decreased from 0.9 to 0.4, and the segment mobility reduced with the increase in molecular weight, respectively. Remarkable changes in A_s and p were found in a range of molecular weight of 5×10^4. In benzene, the values of A_s and p were less dependent on molecular weight than the cases of adsorption in CCl_4. Marked effects of intrachain interactions on the conformation were revealed for the adsorption of coiled polymers with high molecular weight from CCl_4 solution at low degrees of adsorption, where the loop formation was observed for polymers of $M>10^4$. The intrachain force was attributed to overlapping among the segments. The difference in the adsorption behavior between the cases in CCl_4 and benzene was interpreted by the difference in the degree of deformation of polymer molecules upon adsorption.

The adsorption of linear macromolecules from solution on solid surfaces is a complicated phenomenon with many problems to be clarified. The cause is mainly due to the constitution of macromolecules with a large number of repeating monomeric units. Among molecular models proposed for characterizing adsorbed and deformed polymer molecules at the interface, the "train-loop" model would be most general and successful.

Many investigations have been published on the adsorption of polymers by the IR method; Fontana and Thomas developed the spectroscopic technique for the quantitative estimation of the segment fraction attached to the surface sites through H-bonding.[1-3] Recently, the ESR method using nitroxide spin labels, developed originally for the study of biopolymers, has been applied to the adsorption of synthetic polymers.[4-7] The ESR measurement supplies unique and important information concerning the molecular dynamics as well as the conformation at solid-liquid interface.

The chain mobility of the adsorbed polymer is different between the anchoring train on solid surface and the detached loop extending into the solution. The correlation time τ_c has the most sensitive range ($10^{-7}<\tau_c<10^{-10}$ s) where the ESR line changes drastically with the time-averaging of anisotropy in hyperfine interaction and g-factor. The ESR spectrum of nitroxide spin labels attached to the polymer chain, therefore, reflects sensitively the difference in the relaxation process between the segments in loop and in train. If any contacts of nitroxide pendant groups with the surface sites can be ignored, the resolution of the ESR spectrum observed for the adsorbed polymer will allow to estimate the average conformation. Thus, the spin-label method seems to be suitable for the polymer adsorption system in which polymer chain has polar functional groups, such as ester, amide, ether, etc.

In our previous studies on the adsorption of spin-labeled PMMA, the ESR spectrum of the adsorbed polymer was resolved into three components: train, short loop, and long loop or tail.[6,7] The three-component analysis of the adsorbed polymer showed a possibility to discuss the conformation and the molecular motion in more detail than the resolution into two components reported by other authors.[4,5] Since the time required for the ESR spectrum analysis has been much saved recently by improving the simulation program using a small computer, it has become possible to treat a lot of spectral data within a short time.

The purpose of this study is to discuss the dependence of adsorption of PMMA on molecular weight over a wide range from 10^3 to 3×10^6, with reference to molecular conformation and molecular motion.

Experimental

Sample Preparation and Measurements. The experimental techniques were basically same as those described in our previous papers.[6,7] The spin-labeled PMMA was prepared by an anionic copolymerization of methyl methacrylate and 4-methacryloyloxy-2,2,6,6-tetramethyl-1-piperidiyloxyl (200—400/1 mol ratios) in toluene at 0 °C using phenylmagnesium bromide catalyst. The polymer was repeatedly fractionated in acetone-water mixture to give narrow molecular weight distributions. The characterization of the polymer samples is listed in Table 1. Each PMMA sample had a highly isotactic microstructure which gave the IR J-value of ca. 26.[8] The spin concentration in the used polymers was in the range of one label per 150 to 450 monomeric residues. The molecular weight was determined by means of viscometry, membrane osmometry, and vapor phase osmometry, and the ratio $\bar{M}_w/\bar{M}_n$ was determined by GPC calibrated with a standard polystyrene.

Two nonporous silica samples, Cabosil M5 (Cabot) and Aerosil OX-50 (Degussa), were used as the adsorbents.

a) VPO: vapor phase osmometry of $CHCl_3$ at 37 °C. b) MO: membrane osmometry in toluene at 38 °C. c) Viscosity: the intrinsic viscosity in benzene was determined at 30 °C, and $\bar{M}_v$ was calculated by $[\eta]=5.2\times10^{-5}\bar{M}_v^{0.76}$.[14] d) The ratio $\bar{M}_w/\bar{M}_n$ was determined by GPC in THF.

Cabosil M5 had a surface area of 220 m^2g^{-1} by N_2 adsorption, and the average particle size of 14 nm. Aerosil OX-50 had the values of 50 m^2g^{-1} and 40 nm, respectively ($g=10^{-3}$ kg). Reagent grade CCl_4 and benzene were used as the solvents after fractional distillation over a desiccant.

The amount of adsorption, A, was determined by the ESR to measure the decrease of polymer concentration after the adsorption, because the peak-to-peak signal amplitude for the polymer solution was proportional to the concentration. The amplitude was calibrated by simultaneous measurement on an equal volume (0.1 cm^3) of the original solution. The typical adsorption isotherms are shown in Fig. 1. Each adsorption curve shows an initial steep rise followed by the plateau at low equilibrium concentration ($C_e=10^{-4}$ g cm^{-3}). Hence, the saturation adsorption, A_s, was determined by taking the plateau values at $C_e=1\times10^{-3}$—3×10^{-3} g cm^{-3}. The ESR spectrum of the adsorbed polymer was measured in a quartz sample tube which contained ca. 1 cm^3 of silica suspension and sealed under N_2. ESR measurements were made on a JEOL JES FE-3X spectrometer, with a X-band microwave, 100 kHz field modulation, and temperature control of ±1 °C. The g-factor and the sweep width of magnetic field were calibrated by a Mn^{2+} standard.

Analysis of ESR Spectra. The procedures for analyzing ESR spectra are principally same as those described previously with some modifications.[6,7] As shown in Fig. 2, the ESR line shape observed from the adsorption system (spectrum D) was simulated by summation of three model spectra; the triplet line with narrowed width showing high mobility (spectrum A), the intermediately broadened line showing a restricted segment motion (spectrum B), and the powder pattern showing rigid immobilization (spectrum C). The spectrum was normalized by signal intensity obtained from the second integration of first-derivative spectrum. The amplitude of each model spectrum was determined by the least squares method on the multiple regression to fit the summation of the three spectra (spectrum E) with the observed spectrum. The model spectra were selected to make the correlation coefficient close to unity between the observed spectrum and the summation of three model spec-

tra. In the three-component analysis, close curve fitting was found in every case. The intermediate components, however, were not negligible; the content was 10—25% in most cases, and good curve fitting could not be obtained without contribution of the intermediates.

The ESR model spectra of motional-narrowing components were observed at various temperatures, and in some cases calculated by Lorentzian and Gaussian approximation with reference to the temperature changes of the peak-to-peak amplitude ratios and the widths of the triplet lines observed for the polymer solution. The model spectra for the intermediate components were obtained from the amorphous polymers in the rubbery state at 120—160 °C. As for the most restricted segments (train), the model spectra were obtained from the adsorbed oligomer PMMA at a low surface concentration at different temperatures. The line shape was almost similar to that of the powder pattern and remained identical even when the temperature was lowered below 25 °C.

The rotational correlation time was calculated by the equations derived by Kivelson[9] and Goldman et al.,[10] who assumed the isotropic rotational diffusion.

Results and Discussion

1. Amount of Adsorption and the Fraction of Bound Components. The correlation between the saturation adsorption, A_s, and molecular weight of PMMA adsorbed from CCl_4 on Cabosil M5 is illustrated in Fig. 3. The fraction of the bound segments, p-value, is also plotted. The values of A_s increased from 6 to 15×10^{-8} g cm^{-2}, and the p-values decreased from 0.9 to 0.4 with the increase in molecular weight of a lower range from 10^3 to 10^5. Both values approached to constant values, $A_s=16\times10^{-8}$ g cm^{-2} and $p=0.4$, at higher molecular weight range, $M>10^5$. There is a close correlation between the changes in A_s and p; i.e., the loop content increases with the increase in A_s value. The changes in both values with molecular weight, however, were not monotonous but apparent in the molecular weight region of 5×10^4. The feature of the molecular weight dependency was reproducible in the repeated experiments using the polymer samples of different sources.

Similar phenomenon was reported by Kalnin'sh et al.[3] They studied the adsorption of atactic PMMA from several solvents on an Aerosil silica by the IR spectroscopy, and found a rapid drop of p-values with increasing molecular weight near 10^4. They reported a reflection point of p-value at the lower molecular weight region than that in this study. They attributed the rapid drop of p-values to the formation of transitional loops by adsorption of a polymer molecule on several adjacent silica particles, because the size of the polymer coil in solution became commensurate with the adsorbent particle size in the molecular weight region of 10^5.

In order to examine whether or not such a macroscopic interaction effect exists, the adsorption measurements were carried out on Aerosil OX 50 which has larger particle size (average diameter, 400 Å) than that of Cabosil M5 (140 Å) but has similar surface qualities. Figure 4 shows the correlation between the values A_s on Aerosil OX 50 and on Cabosil M5 at various molecular weights in CCl_4 solution. The amounts of polymer adsorbed per unit surface area were almost identical at the same molecular weight for both the adsorbents, yielding the same reflection point as that shown in Fig. 3. The changes of p-values with molecular weight were similar. From these results, a relatively strong molecular weight dependence appeared in the molecular weight region of 5×10^4 can not be explained by the sizes of adsorbent and polymer coil in solution. The effect of simultaneous adsorption seems to be negligible.

2. Dynamic Aspects of Adsorbed Molecule. Figure 5 shows the molecular weight dependence of the rotational correlation time, τ_c, estimated for the seg-

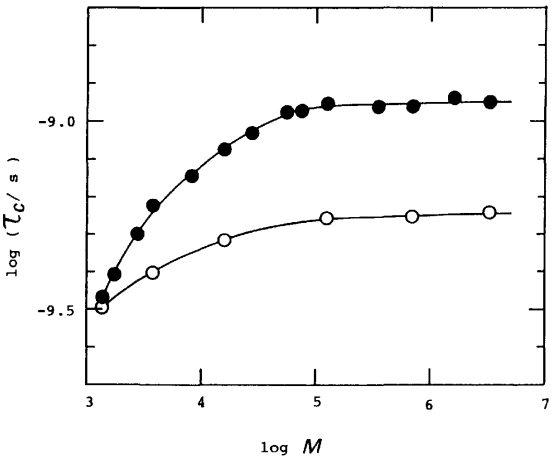

Fig. 5. Double logarithmic plots of rotational correlation time (τ_c) for loop or tail segments vs. molecular weight; ●: in adsorbed polymer, ○: in solution.

ments in long loops or tails, in comparison with that for free segments in CCl_4 solution (C=5×10^{-3} g cm^{-3}) as the reference system. The values of τ_c increase with the molecular weight when $M<10^5$, indicating a decrease of motional freedom in the loop. For $M>10^5$, the values of τ_c approach almost constant values about twice as large as for the free segments in solution. As for extremely short chain molecules, the detached segments appear to have motional freedom which is comparable to that of free segments in solution. This would be due to a contribution of the chain ends in tails.

The reduced degree of the motional freedom for higher molecular weight polymers will be interpreted from the increased segment density in the loop layer, because the A_s values increase and the p-values decrease with molecular weight as illustrated in Fig. 3. The segment motion is restricted by the intra- and interchain interactions in a dense surface layer. Above results will also predict the "compressed conformation" for higher molecular weight polymers at the interface as will be described later.

The values of τ_c of the intermediate components in ESR spectra (short loop) were in the range from 4 to 6×10^{-9} s, and were larger than the values for long loop or tail segment. Those values were less dependent on the molecular weight.

Figure 6 shows the ESR spectra of oligomer molecule (M=1370) adsorbed at a low surface coverage (θ=0.3) on Cabosil M5 in CCl_4 at various temperatures. The line shape of the spectrum at 25 °C is close to the powder pattern which reflects a complete train conformation of the adsorbed molecules. When the temperature was raised, the extreme separation width (W) of the spectrum reduced, indicating a recovery of the segment motion. However, even after keeping the adsorption system at 72 °C for 2 h, the ESR line shape indicated that the adsorbed oligomer molecules

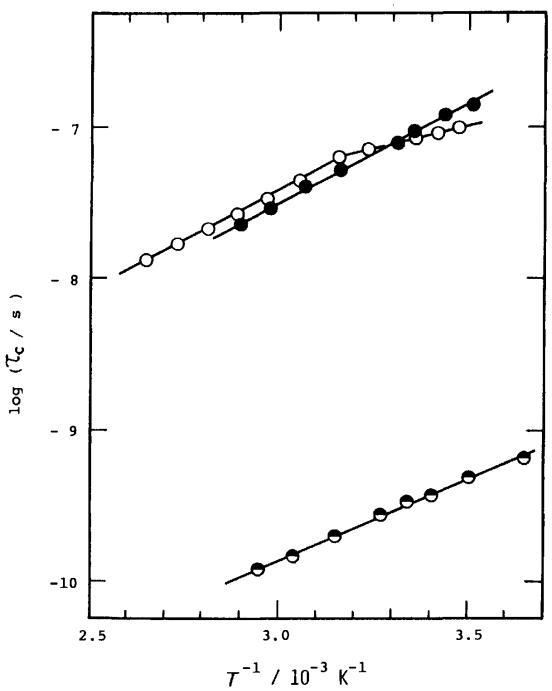

Fig. 7. Arrhenius plots of τ_c for oligomer PMMA (M=1370). ●: For train segments adsorbed on Cabosil M5 in CCl_4, ○: for amorphous solid state polymer, ◒: for free segments in CCl_4 solution (C=5×10^{-3} g cm^{-3}).

remain the deposited conformation. This would be an evidence of persistent adsorption which is characteristic of polymeric chains and different from the case of monomeric molecules.

In Fig. 7, the values of τ_c for the train segments estimated from the changes in W are plotted against the reciprocal of temperature, together with τ_c for solid polymer and free polymer in solution. The τ_c value for the train was estimated to be ca. 1×10^{-7} s at 25 °C. The relaxation time was longer than that estimated for an amorphous polymer in glassy state at 25 °C. The activation energy of rotational diffusion was estimated to

be ca. 26 kJ mol^{-1}. This value is eqivalent to that for the rubbery state polymer, but higher than that for free polymer in solution.

In the cases of the molecules with higher molecular weight than 10^5, the values of W were equal to the rigid limit value, and no longer changed over the temperature range of −120 to 70 °C. The values of τ_c for the train segments in polymers with higher molecular weight will exceed 10^{-7} s, because W did not reduce even at ca. 70 °C. In the previous study using an adiabatic rapid passage technique, we revealed that τ_c for the train segment is over 10^{-6} s in a similar adsorption system.[6] These results demonstrate that the train segments in a coiled molecule were immobilized more rigidly than segments of short chain molecule. The stronger restriction of segment motion in higher molecular weight polymers would be caused by a "compression" onto the first layer (train) from the loop layer.

3. Influence of Surface Concentration on the Conformation. The fraction of the segments in train (p), in short loop (f_{sl}), and in long loop or tail (f_{ll}) was examined at various polymer concentrations in the surface layer, in order to elucidate the contribution of intra- and interchain interactions to the conformation. The segment distribution in adsorbed two polymers with different molecular weight is shown in Fig. 8 as a function of θ. The value of θ was determined from the following experimental results: The amount of polymer segments attached directly to the surface ($p \times A_s$) increased slightly (ca. 10%) with increasing molecular weight, and became almost constant at high molecular weight range ($M > 10^5$). The results gave a saturation value $(pA_s)_{max}$ of 6.7×10^{-8} g cm^{-2}. From this value, the surface area occupied per monomer unit in the train was calculated to be 25 Å^2, which is agree with the literature value determined for the case of PVAc adsorbed at a liquid-air interface.[11] The value of θ was obtained by the ratio, $\theta = pA/(pA_s)_{max}$, on an assumption that the surface sites saturate with the polymer segments at the saturation adsorption of high molecular weight polymers.

For the polymer with molecular weight of 1370, the p-values were close to unity (f_{sl}=0 and f_{ll}=0) at unsaturated adsorption stages ($\theta < 0.6$). This means a completely deposited conformation of short chain molecules. When the adsorption approaches the saturation, the p-value reduced to ca. 0.9 with slight increases in f_{sl} and f_{ll}. On the other hand, the higher molecular weight polymers ($M > 10^5$) contain higher amount of looped conformation even at low θ; the content of loop segments is ca. 20—30%. The p-values decreased gradually with increasing θ, and then dropped to ca. 0.4 at the saturation adsorption with relatively rapid increase in f_{ll}.

The dependence of p-value on θ for the high molecular weight polymers was stronger than the published results of other polymers such as poly(alkyl methacrylate), atactic PMMA, etc.[1] The statistical mechanical treatment of polymer adsorption, however, gave evident difference between p-values of saturation adsorption (θ=1) and of an isolated molecule ($\theta \to 0$).[12] The relatively strong dependence of p-value on θ found in this study is in accord qualitatively with the theoretical prediction.

Under the adsorption conditions at low θ, intrachain interaction and interaction between polymer segments and surface sites affect the conformation, whereas interchain forces are weak. The molecular weight dependence of the conformation was examined at low θ of ca. 0.1, in order to elucidate intrachain forces.

Figure 9 illustrates the fractions of the polymer seg-

ments in short loops (f_{s1}) and in long loops or tails (f_{l1}) as a function of molecular weight. The powder pattern of the ESR spectrum was observed for the adsorbed PMMA of lower molecular weight than 10^4. (Consequently, $f_{s1}=0$, $f_{l1}=0$, and $p=1$ for $M<10^4$.) The short chain molecules were completely flattened on the surface at low θ. In the range of higher molecular weight than 10^4, the adsorbed molecules take the looped conformation. The value of f_{s1} and f_{l1} increased with the increase of molecular weight from 10^4 to 10^5, and became constant at $M>10^5$.

These phenomena suggest that there is a difference in the interaction with the surface between the lower ($M<10^4$) and the higher molecular weight polymers. The difference determines whether the molecules behave as coiled chains to the surface or not. The reason why the higher molecular weight polymers are not adsorbed with a flat conformation as the lower molecular weight polymers even at low θ is probably due to intrachain overlapping among the segments. The overlapping in chain polymer reduces the p-value and affects on excluding a volume at the surface. Effects of intrachain interaction on the conformation have been studied by statistical mechanics on the adsorption of macromolecular chain. Several authors reported recently from the computer enumeration a marked reduction in p-value owing to the excluded volume effect.[13]

4. Deformation of Polymer Coil upon Adsorption. Koral et al., studied the adsorption of PVAc, and treated experimental results of the amount of adsorption, A_s, by an adsorption model that adsorbent surface is completely covered by spherical polymer coils.[11] They discussed the deformation of the polymer coil lateral to surface plane, by comparing the experimental values of A_s with the theoretical value expected from the radius of gyration, R, of the polymer in solution. A_s can be related to the surface area (S_s) occupied per polymer coil by

$$A_s = M/S_sN_0 \text{ (g per unit area)},$$

where N_0 is Avogadro's number. If the cross section ($S_b=\pi R^2$) of the polymer coil in solution is estimated, a factor which describes the degree of deformation of polymer coil, β, lateral to the surface when the polymer collapses on the surface can be defined as

$$\beta^2 = S_s/S_b.$$

In the series of adsorption of polymers with different molecular weights, the molecular weight dependence would be more explicitly described by the lateral deformation factor. If one considers important the relative changes of β with molecular weight, the factor β would be a meaningful parameter to describe the behavior of adsorbed polymers at the interfaces.

The dimension of PMMA in a poor solvent, CCl_4, was taken from the published data on the unperturbed chains of isotactic PMMA in a theta solvent.[14] Taking

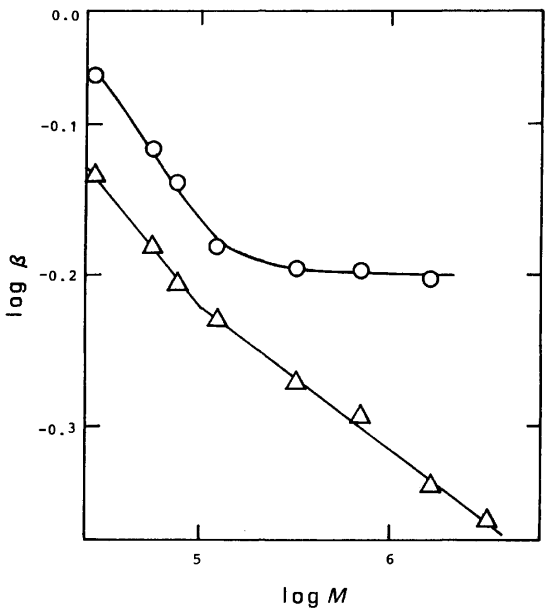

Fig. 10. Double logarithmic plots of β vs. molecular weight for PMMA with high molecular weight adsorbed on Aerosil OX 50 in CCl_4 (O) and in benzene (Δ) at 25°C.

the relationship between the root-mean-square end-to-end distance and molecular weight, $<\bar{r}_0^2>=7\times10^{-9}M^{0.50}$ (cm), the radius of gyration (R) was obtained from the relation, $R_0^2=<\bar{r}_0^2>/6$. In this case, the difference between R and R_0 was ignored in considering relative changes of β with molecular weight. For the cases in benzene, R was estimated from the intrinsic viscosity-molecular weight relationship, assuming $\alpha^{2.43}=[\eta]/[\eta]_\theta$, where α is the expansion factor defined as $\alpha=R/R_0$, and $[\eta]$ and $[\eta]_\theta$ is the intrinsic viscosity in benzene and in a theta solvent, respectively.[14]

Figure 10 illustrates the relation between β for coiled molecules and molecular weight. The logarithm β is a negative function of molecular weight. Namely, the larger the polymer coil in solution is, the smaller the lateral deformation factor upon the adsorption is. The polymer coils seem to be laterally compressed to the surface, occupying narrower space than the cross section of the polymer coil in solution. In CCl_4, the factor β tends to be constant for $M>10^5$. On the other hand, the adsorption data obtained in benzene are expressed by $\beta\propto M^{-0.1}$.

The degree of lateral deformation of the polymer coil is considered to be more significantly influenced by molecular weight in a better solvent than in a poor solvent. It is probably related to higher expansion of the polymer coil in the better solvent. In a poor solvent, the polymer molecule will be in a more compact conformation than in a good solvent, and consequently resistant to the lateral compression when the polymer collapses on the solid surface.

The total number of segments adsorbed per surface site (θ/p) was estimated from the ratio $A_s/(pA_s)_{max}$. This value is a measure of the thickness of adsorbed

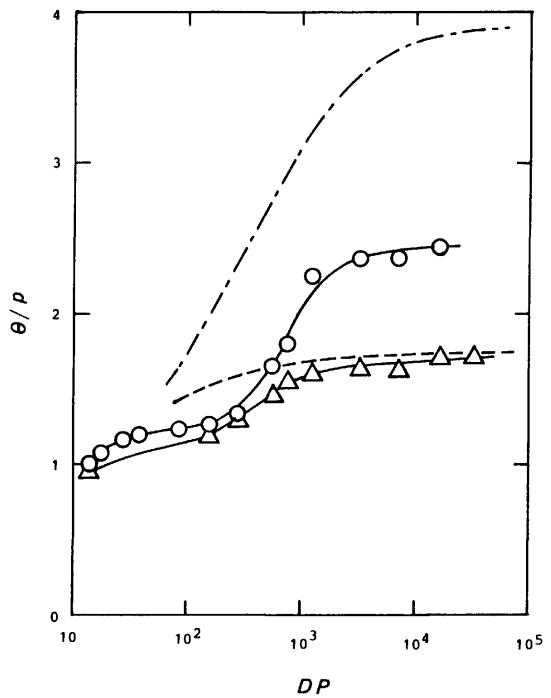

Fig. 11. Plots of θ/p vs. degree of polymerization, DP, O:In CCl_4, Δ:in benzene. Dependence predicted by Silberberg's theory is shown with -·-·- for the case of adsorption from a theta solvent and with ---- for that from an athermal solvent.

polymer layer, and would reflect the feature of the deformation in the axis normal to the surface, as well as the fractions of polymer segments (p, f_{sl}, and f_{ll}) in the surface layer. In Fig. 11, the values of θ/p are plotted against the degree of polymerization (DP). The values predicted by Silberberg's theory are also plotted for the case of adsorption from a theta solvent and an athermal solvent. Here, the values are derived from the given original parameters; $\Phi^*=10^{-4}$, $\gamma_b\gamma_s=0.1$, and $\chi_s=\infty$(namely $\theta=1$).[12]

In the case of short chain molecules ($M<2\times10^4$), the values of θ/p were nearly unity both in CCl_4 and benzene. This means monomolecular layer adsorption. The molecular weight dependence of θ/p in the better solvent (benzene) was weaker than that in the poor solvent (CCl_4), and the larger molecules still remained the flat conformation, within $\theta/p<2$. These data are consistent with the theoretical values predicted for the case of athermal solvent. In CCl_4, the values of θ/p were ca. 2.4 for $M>10^5$, and considerably lower than the predicted values for the adsorption from a theta solvent.

In the case of adsorption from the better solvent, benzene, the degree of deformation of the polymer coils seems to be much higher than the case of adsorption from CCl_4, because the polymer coil is not only flattened but laterally compressed on the surface.

Construction of an Adiabatic High-Pressure Calorimeter Using Helium Gas for Pressurization†

Osamu YAMAMURO, Masaharu OGUNI, Takasuke MATSUO, and Hiroshi SUGA*
Department of Chemistry and Chemical Thermodynamics Laboratory, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received October 20, 1986)

A novel adiabatic high-pressure calorimeter was constructed with using helium gas as a pressure transmitting medium. It works under a constant pressure up to 250 MPa in the temperature range from 12 to 370 K. Sample cell is made of Be-Cu alloy and has internal volume of 26 cm^3. The pressure transmitting tube is connected to an external pressure-control system, which enables to keep automatically the inner pressure constant within ±1 kPa over the whole pressure and temperature ranges. Thus the thermodynamic path that any specimen follows during the heat capacity measurement can be described unambiguously. Heat capacities of the sample cells loaded without and with 158.9 MPa He gas were measured in the temperature range from 25 to 370 K. The imprecision of heat capacity data of the compressed He gas was within 0.3%. Thus the present calorimeter enables us to extend the low-temperature thermodynamic study on various kinds of materials to high pressures without a significant loss of the claimed precision.

Stability of states and thermodynamic properties of a substance can be determined from its Gibbs energy as functions of some parameters, temperature and pressure being two of the most important external parameters. The surface of the energy is experimentally obtained by the accurate measurements of heat capacity vs. temperature and volume vs. pressure. Hence calorimetry over wide temperature and pressure ranges is quite important in such studies.

The most accurate calorimetry has been done under adiabatic condition at the normal pressure. There the adiabatic condition is established as closely as possible between a calorimeter cell and its surroundings, and a path of the measurement is unambiguously specified on the p-T surface so that the obtained heat capacity data can be converted correctly to a thermodynamic quantity at constant pressure. However, the extension of this method to the calorimetry under high pressure is not straightforward, owing to many experimental difficulties. Either direct or indirect contact of a pressure transmitting medium with the sample is required for the application of pressure. Since the volume of the pressure transmitting medium as well as that of the sample changes with temperature and pressure, the unambiguous specification of the path of measurement can only be achieved by taking the following two procedures. One is to follow always the pressure change of the calorimeter cell during a series of measurements and then correct the effect of pressure change by using appropriate thermodynamic data as precisely as possible. Such calorimeters, often described as the clamp-bomb type, have been reported by a number of research groups,[1-4] on account of the convenience that an ordinary adiabatic calorimeter can be used without any drastic modification of the apparatus.

The other is to keep the pressure constant by connecting the cell to a pressure control system external to the cryostat through a pressure transmitting tube and permitting the pressure transmitting medium to flow into or out of the cell. The tube must be temperature-regulated to maintain adiabaticity of the calorimeter. Only two groups[5,6] have constructed this type of apparatus with using a liquid as the pressure transmitting medium. The above two methods are both usable only under relatively low pressures, below 1 GPa. This is because, higher the pressure, the cell must be more massive to withstand the pressure, resulting in the decrease in the ratio of the sample heat capacity to the total.

The adiabatic high-pressure calorimeter on which we reported before used liquid 3-methylpentane as the pressure transmitting medium.[5] While being quite effective in that the hydrostatic pressure is easily generated and transmitted to the system, it restricts the substances to be studied to inorganic compounds which are insoluble in the medium and the measurements in the temperature range above 100 K because of the solidification of the pressure transmitting medium itself below 100 K. The former restriction precludes molecular crystals and liquid crystals from the measurements and the latter limits the consideration based on the third law entropy.

The purpose of the present work is to construct a new high-pressure calorimeter which removes these restrictions. The apparatus uses, as a pressure transmitting medium, helium gas which is chemically inert and exists in the gaseous state down to very low temperatures. The use of this apparatus enables calorimetry with high precision up to 250 MPa. The precision of the calorimetry was estimated by measuring the heat capacities of helium gas at 158.9 MPa.

Construction of Apparatus

Principle. The present apparatus employs helium gas as a pressure transmitting medium to pressurize the sample in the cell. The pressure is maintained at a fixed value by permitting the helium gas to flow into

†Contribution No. 114 from Chemical Thermodynamics Laboratory.

or out of the cell through the pressure transmitting tube connected to the high-pressure control system. Heat capacity measurement is performed by the conventional adiabatic method, i.e., by following the temperature increment due to a known quantity of supplied energy under adiabatic condition. Heat flow through helium gas is negligible because the pressure transmitting tube above the cell together with the helium gas contained was maintained the same temperature as the cell. The heat capacity of the sample is obtained by subtracting from the total the contribution of the helium gas in the cell at the average temperature, as described in detail previously.[5] The contribution can be estimated only if the volume of the space occupied by the helium gas and its heat capacity at the confining pressure per unit volume are known.

The total heat capacity C_t obtained experimentally is expressed as

$$C_t(p,T) = nC_s(p,T) + C_e(p,T) + \{V_e(p,T) - nV_s(p,T)\}C_H(p,T). \quad (1)$$

Here, C_s, C_e, and C_H denote the heat capacities at constant pressure of a mole of the sample, empty cell, and helium gas per unit volume, respectively. V_s and V_e are the molar volume of the sample and the volume of the empty cell, respectively, and n the amount of sample. The symbols in the parentheses represent variables; p is the pressure inside the cell and T is the average temperature. Pressure dependence of heat capacity of the empty cell is given by $(\partial C_e/\partial p)_T/C_e \simeq 10^{-5}$ MPa^{-1}. This indicates that the dependence is negligible within the error of measurement in the present pressure range $\approx 10^2$ MPa; i.e.,

$$C_e(p,T) \simeq C_e(T). \quad (2)$$

$C_H(p,T)$ is rewritten as

$$C_H(p,T) = C_H^*(p,T)/V_e(p,T), \quad (3)$$

where $C_H^*(p,T)$ is the heat capacity of the helium gas that occupies the whole space of the cell, and can be determined experimentally. Substituting these two relations into Eq. 1 and rearranging, the molar heat capacity of the sample $C_s(p,T)$ is expressed by

$$C_s(p,T) = [C_t(p,T) - C_e(T) - \{1 - nV_s(p,T)/V_e(p,T)\}C_H^*(p,T)]/n. \quad (4)$$

Here $V_e(p,T)$ is obtained by measuring the total heat capacity $C_t'(p,T)$ containing a standard substance whose heat capacity $C_{st}(p,T)$ and volume $V_{st}(p,T)$ at high pressure are known; *i.e.*,

$$V_e(p,T) = \frac{V_{st}(p,T)\{C_H^*(p,T) - C_e(T)\}}{C_H^*(p,T) + C_{st}(p,T) - C_t'(p,T)} \quad (5)$$

Consequently, the determination of $C_s(p,T)$ requires only the data of $C_t(p,T)$ and $V_s(p,T)$ in Eq. 4. $V_s(p,T)$ must be obtained from other measurements (X-ray diffraction etc.) or by using some reliable equations of state, since it cannot be measured directly with the present calorimeter. When the interest is getting only the anomalous part of the heat capacity, it is not always necessary to know $V_s(p,T)$.

Cryostat and Adiabatic Control. Figure 1 shows a schematic drawing of the cryostat. The pressure transmitting tube, shown in sections by A1, A2, A3, and A4, enters the cell R from the high pressure system through the center of the cryostat. They are made of stainless steel tubes of 0.6 mm I.D. and 3.1 mm O.D. They are connected in series with the couplings H1, H2, and H3. The cell R is dismountable at H1.

Temperatures as low as 12 K can be obtained by the standard cryogenic technique. Normally the cell is cooled from room temperature with the help of He gas of about 10 kPa introduced into the vacuum jackets J and L. However if the sample is volatile, it is possible to cool the cell by introducing liquid nitrogen directly into the cooling ring Q through E1, N, and P without any heat-conduction gas in the jackets. This process of cooling keeps the tubes A1-A4 at higher temperatures than the cell, preventing any volatile sample from condensing on the inner walls of the tubes.

Adiabatic condition between the cell and its envi-

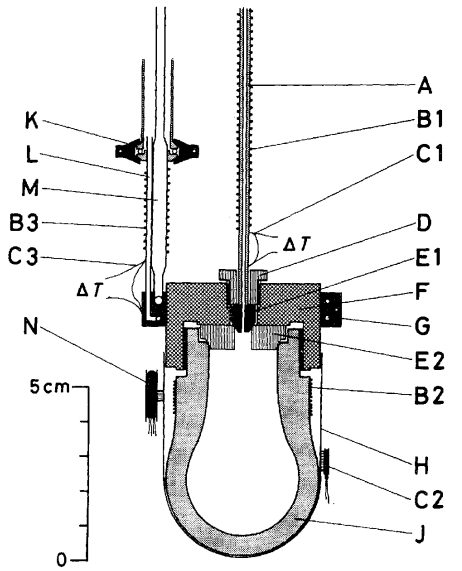

Fig. 2. Sectional drawing of the calorimeter cell. (A): High pressure transmitting tube, (B): heater wire, (C): thermocouples, (D): gland nut, (E): plugs, (F): gland lid, (G): cooling ring, (H): cell cover, (J): body, (K): joint, (L): liquid nitrogen inlet, (M): nitrogen gas outlet.

ronment is achieved during heat capacity measurements by evacuation of the space inside the jacket J and L to 10^{-4} Pa and by temperature-control of the following ten parts surrounding the cell. The inner adiabatic shields S, T, and U, the transmitting tube A1 just above the cell, and the liquid nitrogen transfer tube P are controlled at the same temperature as the cell. The outer shield M and the liquid nitrogen tank N (whose inside space is evacuated) are held a few Kelvins lower than the cell in order to control the inner shields. Furthermore, the tubes A2, A3, and A4 are kept a few Kelvins higher than the cell to prevent the condensation of sample on their inner walls. The temperature control system utilizes the temperature difference signals from the Chromel-P-constantan thermocouples (which are attached to appropriate locations of those parts to be controlled and the respective reference points) and regulates the current passing through the corresponding heaters. The upper temperature limit of the measurement is about 400 K because a low-temperature solder was used in several parts.

Calorimeter Cell. Figure 2 shows the calorimeter cell whose inside volume is 26.271 cm^3 at 30 °C and mass is 622.30 g. The main parts of the cell (J, F, D, E1, and E2) were made of copper-beryllium alloy which has high thermal conductivity and sufficient mechanical strength to withstand the applied pressure. The surface of the cell was gold-plated for reduction of radiative heat transfer and for protection against corrosion. A nearly spherical shape of the body J was devised for the purpose of minimization of the mass of the empty cell and maximization of the inside space. This increased the ratio of the sample heat capacity to the total and contributed to the improvement in the precision of the measurement.

The pressure inside the cell is sealed by two-stage metallic cone connection instead of the traditional Bridgman method. The first plug E2 is pressed down against the tapered top of the inner wall of the body J by driving the screw of the gland lid F and the second plug E1 is pressed against the top of the inside wall of E2 by the gland nut D. The diameter of the contact circle is about 20 mm for the first plug and 5 mm for the second plug, respectively. The sample is introduced through the apertures of E2 and F, after removing plug E1. This sealing method does not require any packing (e.g., tetrafluoroethylene or indium). The packing used in the previous experiments made the pressure and temperature dependence of the cell volume complicated and ambiguous. At present, the maximum pressure that can be applied to the cell without any leak is about 250 MPa.

The cooling ring G, made of copper, serves to cool the cell while the high-pressure tubes are being kept at higher temperatures. Liquid nitrogen is introduced through the inlet L and allowed to vaporize outward through the outlet M. The L and M are controlled during the heat capacity measurement at the same temperature as the cell with the Chromel-P-constantan thermocouple C3 and manganin heater B3. The ring can be removed at the joint K for measurement with nonvolatile samples.

B2 is the manganin heater for supplying electric energy to the cell. The thin cell-cover H made of copper was installed to minimize heat leak by radiation from the heater B2 as well as to fix the thermocouple C2 for the temperature regulation of the inner shields and the copper sheath as a holder for the platinum thermometer N (470 Ω at 273 K, Minco Products, USA).

Calorimetric Measurement. Calorimetric measurement consists of the usual three steps as generally performed: initial temperature measurement, supply of electric energy, and final temperature measurement. The temperature is determined by measuring the resistance of the platinum thermometer with the automatic a.c. resistance bridge (ASL F17, U.K.). The bridge gives a ratio of the thermometer to the standard resistance as a digital output with seven digits and an additional analog output of any umbalance signal. The analog signal is digitalized by the multimeter (Keithley 195, USA), and the resultant resistance readout with eight degits in total is converted to temperature, whose resolution corresponds roughly to 10 μK at temperatures above 50 K. The supplied energy is determined using the digital multimeter (Keithley 195, USA) and the digital clock in the computer.

All operations of the measurement, data processing, and their storage are carried out with the microcomputer (Sharp MZ 2200). The use of the computer contrib-

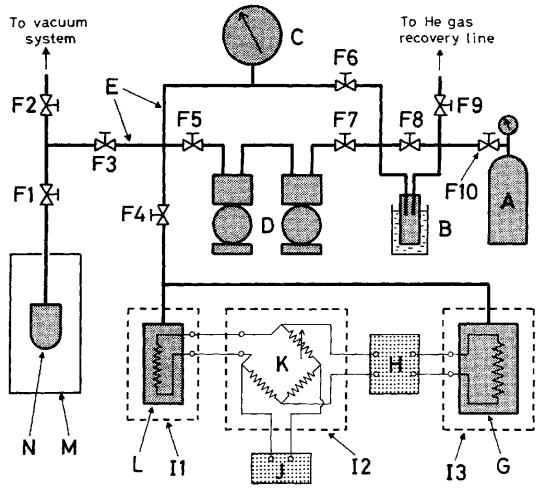

Fig. 3. Block diagram of the high pressure system. utes not only to saving labor but also to improving precision of the thermometry. Usually temperature is read out once in 60 s as the average of 12 readings taken at an interval of 5 s. This procedure of averaging reduces a scattering of data to a large extent, and consequently the precision of the thermometry is estimated to be within 50 μK at temperatures above 50 K. Detailed descriptions of the determination of temperature and input energy were given in the previous articles.[7] The thermometer was calibrated in advance on the IPTS-68.

High-Pressure System. Figure 3 shows the block diagram of the high-pressure system. The system can be divided into three parts; the cryostat in the left portion of the figure, the pressure generation system in the upper right, and the pressure control system in the lower right. Blocks shaded heavily and lightly represent high-pressure parts (A, B, C, D, G, L, and N) and electrical parts (H and J), respectively. Thick and thin solid lines represent high-pressure transmitting tubes and electric wires, respectively. All high-pressure vessels were connected by the transmitting tubes E. Broken lines represent thermostats.

Pressure is generated in the following way. The inner space of the pressure system is first evacuated after opening all valves, except F9 and F10. After closing F2, F6, and F8 and opening F10, helium gas is introduced from tank A into the system to a pressure of about 5 MPa (the specified value for the low pressure side of the compressor). The pressure of the system on the left side of F6 and F7 is increased up to desired value with the double-head model of diaphragm-type compressor D (NOVA SWISS 554.3330-2). While pressurizing, the compressor is supplied with helium gas continuously through the trap B immersed in liquid nitrogen to remove impurities (water etc.). It takes approximately 20 min to pressurize to 200 MPa. After pressurization, pressure generation system is isolated from other parts of the system by closing valve F5. The pressure is read from the Heise gauge C, whose accuracy is within ±0.1 MPa.

The pressure in the cell N is controlled by adjusting the temperature of the helium gas reservoir G, which has about 8 times larger volume than the cell. Pressure change in the cell is detected as the change in resistance of a manganin wire placed in the stainless steel vessel L. This resistance constitutes one arm of the Wheatstone bridge K, and its deviation from the value (corresponding to desired pressure preset with the variable resistance of K) is detected as an electric signal. The signal is amplified with the PID circuit H and utilized to regulate the temperature of the vessel G. Temperatures of the vessel L and of the bridge K are kept constant with air baths thermostatted at 32 °C for I1 and at 35 °C for I2, respectively. This method of pressure control is basically the same as that of the high pressure calorimeter with liquid pressure transmitting medium reported before.[5] The precision of the pressure and the temperature controls of the helium gas reservoir were, however, improved for use of helium gas which has much larger thermal expansivity than the liquid. The detailed description will be given below in separate sections.

Helium Gas Reservoir. Heat capacity measurement is performed at successively increasing temperatures. Consider the process in which the temperature of the cell loaded only with helium gas is increased by ΔT_c from T_c. Correspondingly, the temperature of the reservoir must be decreased from T_r to $T_r-\Delta T_r$ in order to keep the pressure of the system constant. Assuming that the helium behaves as an ideal gas,

$$\Delta T_r = \frac{T_r^2 \Delta T_c}{(V_r/V_c)(T_c+\Delta T_c)T_c + T_r \Delta T_c} \simeq \left(\frac{V_c}{V_r}\right)\left(\frac{T_r}{T_c}\right)^2 \Delta T_c, \quad (6)$$

where V_c and V_r are the volumes of the cell and of the reservoir, respectively. (V_c/V_r) is practically about 1/8. T_r is around room temperature (≈300 K) so that ΔT_r is estimated to be 1/8 K for ΔT_c of ≈1 K, when T_c=300 K; and 4.5 K when T_c=50 K. Since the temperature dependence of thermal expansivity of real high-pressure gas is smaller than that of the ideal gas, the latter value of ΔT_r would have been overestimated. Whatever the real ΔT_r may be, the temperature of the reservoir must be reduced by the same order of magnitude as a rise in temperature of the cell.

The helium gas reservoir and its temperature control system is shown in Fig. 4. The reservoir is made of stainless steel and has the volume of about 200 cm^3. Pressure seal of the upper part was achieved in two stages; at first the plug D2 was Ar-welded to the body J at F and supported by the nut A2, and secondly the

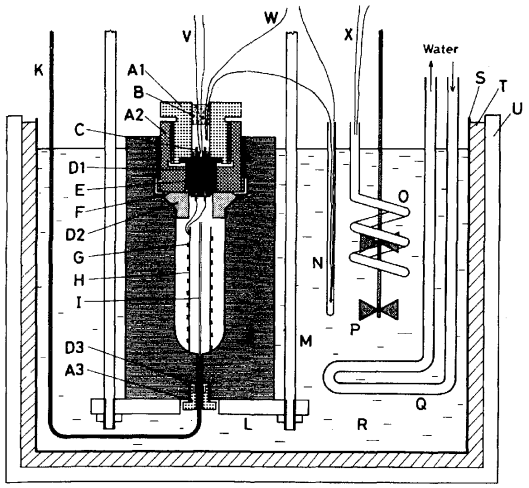

Fig. 4. Schematic drawing of the helium gas reservoir and its temperature control system.
(A): Gland nuts, (B): electric insulator, (C): electrodes, (D): plugs, (E): nylon packing, (F): Ar-welded circle, (G): manganin heater wire, (H): core copper tube, (I): copper capillary, (J): body, (K): high pressure transmitting tube, (L): holder, (M): hanging rods, (N): glass tube, (O): copper tube for heater wire, (P): stirrer, (Q): copper tube for flowing water, (R): silicone oil, (S): stainless steel box, (T): thermal insulator, (U): wooden box, (V): lead wire from PID regulator, (W): Chromel-P-constantan thermocouple, (X): lead wire for heater of oil bath from regulator.

plug D1 was pressed down against the top portion of the inside wall of plug D2 with the nut A1. Pressure seal of the lower part was achieved by the usual metallic cone connection between the plug D3 and the body J. The high pressure transmitting tube K was fixed to plug D3 with silver solder. The helium gas enters or leaves the reservoir through the copper tube I which was also soldered to plug D3. The heater wire G, used to closely control the temperature of the gas in the reservoir, was wound around the copper tube H and connected to the PID circuit through electrodes J and lead wire V. Electric insulation between C and D1 was attained with Nylon packing E.

The reservoir is placed in a variable-temperature thermostatted bath. A Chromel-P-constantan thermocouple W detects the difference in temperature between the space within A1, which reflects the temperature of helium gas in J, and the silicone oil R surrounding the body. Through this signal, the temperature difference is always kept constant by regulating the current passing through the heater installed in the copper tube O. Q is another copper tube in which cold water flows. The temperature of the oil is usually adjusted to be a few Kelvins lower than that of the inside of A1, and should decrease as the temperature of helium gas in the reservoir decreases. The usable temperature of the silicone oil bath is in the range of about 100 to 10 °C. This is broad enough to cover the entire temperature range of the measurement (30—370 K) at 200

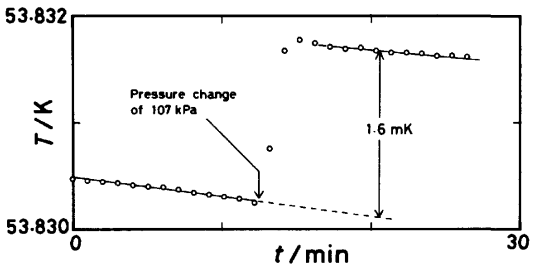

Fig. 5. Temperature response of the calorimeter cell loaded ice specimen to the helium gas pressure change of 107 kPa at 158.9 MPa and 53.83 K.

MPa, even in the case where the cell is completely filled with helium gas.

Precision of Pressure Control. Accurate pressure control is quite important, not only for obtaining the heat capacity of a definite amount of helium gas in the cell at any specified temperature and pressure, but also for attaining adiabataic condition of the cell because the heat of compression of helium gas is considerable. Let us start by deriving the relation according to which the temperature of the cell filled with helium gas is influenced by the change in the pressure within the cell under adiabatic condition. The relation may be regarded as the resultant of two processes through which the temperature of helium gas T_H changes, first by adiabatic compression and next when the gas reaches thermal equilibrium with the cell. Then the following equation is obtained;

$$\left(\frac{\partial T}{\partial p}\right)_S = \left(\frac{C_H}{C_H + C_e}\right)\left(\frac{\partial T_H}{\partial p}\right)_S, \tag{7}$$

where C_e and C_H are the heat capacities at constant pressure of the cell and the helium gas within the cell, respectively. $(\partial T_H/\partial p)_S$, which describes the first process, is given by

$$\left(\frac{\partial T_H}{\partial p}\right)_S = \frac{T_H \alpha_H V_H}{C_H}, \tag{8}$$

so that

$$\left(\frac{\partial T}{\partial p}\right)_S = \frac{T_H \alpha_H V_H}{C_H + C_e}, \tag{9}$$

where α_H and V_H are the thermal expansivity and the volume of the helium gas. If the pressure transmitting medium is liquid (*e.g.*, 3-methylpentane), α_H is of the order of 10^{-4} K^{-1} and changes little with temperature.[5] For helium gas, however, α_H is of the order of 10^{-3} K^{-1} and increases with decreasing temperature.[8] (By way of an example, the assumption of ideal gas results in α_H being proportional to $1/T$. Therefore, $(\partial T_H/\partial p)_S$ becomes large, especially at low temperatures, because both α_H and $1/(C_H+C_e)$ increase more rapidly compared with the decrease in T_H).

Figure 5 shows the observed response of the cell to pressure change of 107 kPa at 53.8 K and 158.9 MPa. The cell contained 18.2 cm^3 of ice sample so that the

volume remaining for the helium gas was about 8.1 cm^3. The temperature of the cell rose by 1.6 mK just after the compression. Substituting T_H=54 K, V_H=8.1 cm^3, C_H+C_c=81 J K^{-1} (experimental value), and α_H= 3.0×10^{-5} K^{-1} (value extrapolated from the data below 100 MPa[8]) into Eq. 9, the temperature change due to the change in pressure of 107 kPa is calculated to be 1.7 mK, which almost agrees with the observed value.

Figure 6 shows the electric signal which corresponds to the fluctuation of pressure from the preset value of 158.9 MPa at 60 K. Half an hour is normally required for one cycle of heat capacity measurement. Stability of the voltage during the measurement cycle is within 20 nV, which corresponds to about 1 kPa on the basis of the calibration in which a pressure change of 4.2 kPa gave rise to the signal of 100 nV. The fluctuation of 1 kPa corresponds roughly to a fluctuation of 15 μK in temperature from the relation shown in Fig. 5. This is small enough since the actual precision of temperature measurements is 50 μK.

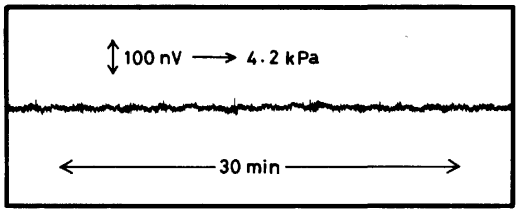

Fig. 6. Electric signal response to the fluctuations of the pressure control system at 158.9 MPa.

Heat Capacity of Helium Gas at 158.9 MPa, and Precision of the Calorimeter

The precision of the present calorimeter was examined by measuring the heat capacity of helium gas at 158.9 MPa in the temperature range between 25 and 370 K. The experimental data are given in Table 1. The starting temperature 25 K is the one below which condensation of the gas is supposed to occur. Plotted in Fig. 7 are the experimental values of the empty cell (○) and the cell fully loaded with helium gas at the constant pressure of 158.9 MPa (●), where the former was measured above 12 K. Reduction of the data to the molar heat capacities of He gas at the high pressure requires the information of equation of state of the gas and volume of the cell as functions of temperature and pressure.

Figure 8 shows the deviations of the experimental

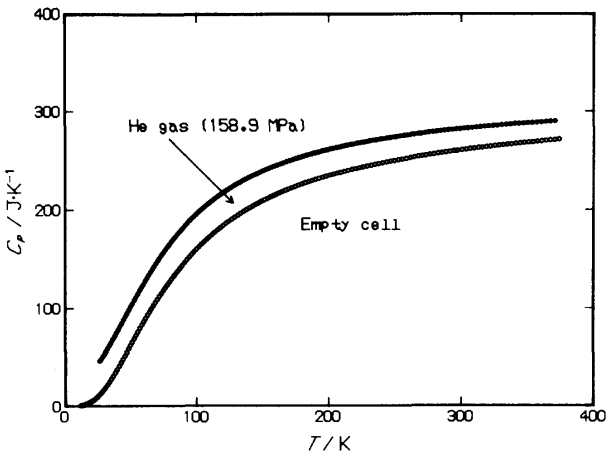

Fig. 7. Heat capacities of the empty cell (○) and of the cell with helium gas at 158.9 MPa (●). The difference between the two curves is equivalent to the heat capacity of the helium gas at 158.9 MPa.

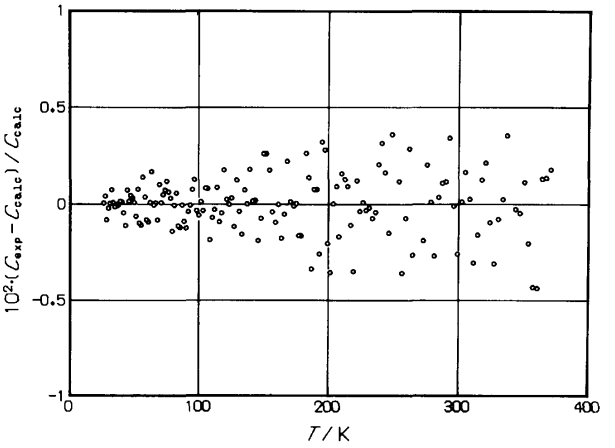

Fig. 8. Deviation plot of the observed heat capacities of helium gas at 158.9 MPa.

values from their smoothed curve. The deviation is within 0.3% over the measured temperature range; remarkably small deviation in the low temperature region is due to the special circumstances that the heat capacity of helium gas is still as large as at higher temperatures while that of the cell decreases rapidly with decreasing temperature. Heat capacities of condensed substances would generally amount only to 50—80% of that of helium gas fully loaded in the cell. The precision of the present calorimeter is therefore estimated to be within 0.5% over the experimental temperature range.

The obtained precision in this instrument is considerably poorer than that of ordinary type of calorimeters, 0.1—0.2%,[7] in the above temperature range at atmospheric pressure. This is attributed to the following two disadvantageous aspects of the present calorimeter. The heat capacity of the empty cell, reaching 270 JK^{-1} at room temperature, is almost ten times larger than that of the ordinary calorimeter. Such a large heat capacity additionally requires a longer period of energy supply for increasing the temperature, yielding the increased ambiguity of the correction for heat leakage. These aspects might have given rise to over ten times larger imprecision than that of the ordinary one unless the thermometry had been improved as described in the previous section. The decreased precision, however, is acceptable as the price for the increased information. Experimental results on some hydrogen bonded crystals will be published in due time.

This work was supported partly by a Grant-in-Aid for Scientific Research No. 57430002 from the Ministry of Education, Science and Culture. Thanks are extended to Mr. Masaharu Morimoto, Mr. Masahiro Shiomi, and Mr. Katsuji Iwamoto of the Workshop Center, Osaka University, for their help in designing and constructing the high pressure calorimeter.

The Enantioface-Differentiating Hydrogenation of the C=O Double Bond with Asymmetrically Modified Raney Nickel. XXXIX. Repeated Uses of the Catalyst in the Hydrogenation of 2-Alkanones

Tsutomu OSAWA† and Tadao HARADA*
Institute for Protein Research, Osaka University, Yamadaoka, Suita, Osaka 565
(Received October 23, 1986)

The durability of tartaric acid-sodium bromide-modified Raney nickel in the hydrogenation of 2-octanone was investigated. A remarkable lowering of the optical yield was observed in the repeated use of the catalyst. A lack of sodium ions in the reaction system was found to be the origin of this phenomenon. The addition of sodium ions to the reaction mixture was useful for attaining high optical yields in the repeated uses of the catalyst.

The tartaric acid-sodium bromide-modified Raney nickel catalyst(TA-NaBr-MRNi) has been known as an excellent catalyst for the enantioface-differentiating hydrogenation of 2-alkanones[1] as well as β-keto esters,[2] β-diketones,[3] β-keto alcohols,[4] and β-keto sulfones.[5] We have reported regarding the hydrogenation of 2-alkanones over TA-NaBr-MRNi that the addition of a large amount of carboxylic acid to the reaction system is recommended for attaining high optical yields. The addition of pivalic acid was found to be most effective for an improvement in the optical yield. For example, 2-octanone was hydrogenated to 2-octanol in an optical yield of 80% in the presence of pivalic acid, while a negligible optical yield was attained in the absence of pivalic acid.[6]

A weakness of TA-NaBr-MRNi is a lack of durability of its enantioface-differentiating ability under repeated use.[7] On the hydrogenation of methyl acetoacetate (MAA), an optical yield of around 80% in the first use of TA-NaBr-MRNi decreased to around 50% in the fourth use of the catalyst. Since the reaction mixture for the hydrogenation of 2-alkanones contains a large amount of carboxylic acid, the surface components of the catalyst might be removed more readily than during the hydrogenation of MAA. Thus, it can be assumed that a repeated use of the catalyst in the hydrogenation of 2-alkanones would result in remarkable decreases in the optical yields.

This paper describes the results of the repeated use of TA-NaBr-MRNi in the hydrogenation of 2-octanone and our efforts to develop a simple procedure for attaining high optical yields under repeated use.

Experimental

The atomic absorption spectra were recorded on a Shimadzu AA610S atomic absorption spectrophotometer. The optical rotations were measured with a Perkin Elmer 241 polarimeter.

TA-NaBr-MRNi. The Raney nickel catalyst prepared from 3.8 g of the alloy (Ni/Al=42/58) was modified at 100 °C for 1 h, using 200 ml of an aqueous solution of tartaric acid (TA, 2 g) and NaBr (the amount stated in the footnotes of Tables), adjusted to pH 3.2 with 1 mol dm^{-3} NaOH. The modified catalyst, thus obtained, was successively washed with a 20-ml portion of water, two 100-ml portions of methanol, and two 30-ml portions of THF.

Pyridine/MRNi. TA-NaBr-MRNi (prepared as described above) was shaken with pyridine (0.4 ml) in THF (30 ml) for 5 min at room temperature. After removing the supernatant by decantation, the catalyst was washed with two 30-ml portions of THF.

MRNi-T. This was prepared by a similar procedure to that for Pyridine/MRNi. TA-NaBr-MRNi prepared from 3.8 g of the alloy was shaken with a mixture of 2-alkanone (10 ml), pivalic acid (18 ml), and THF (20 ml) for 1 h in a glass flask at room temperature. After the supernatant was removed by decantation, the catalyst was washed with two 30-ml portions of THF.

Hydrogenation of 2-Alkanones. The freshly prepared mixture of 2-alkanone (10 ml), pivalic acid (18 ml), and THF (20 ml) was used as the reaction mixture, unless otherwise stated in the text. Hydrogenation was carried out at 100 or 60 °C under 90 kg cm^{-2} of an initial hydrogen pressure in a 100-ml autoclave.

Repeated Use of TA-NaBr-MRNi. After the reaction was completed, the supernatant was separated from the catalyst by decantation. The catalyst remaining in the autoclave was washed with two 30-ml portions of THF to use the successive hydrogenation. Hydrogenation was carried out under the same conditions as above.

Determination of Optical Yield. After removing the catalyst by decantation and the evaporation of THF, the hydrogenation product was dissolved in 100 ml of ether and washed with a saturated aqueous solution of K_2CO_3. The ether solution was then dried over Na_2SO_4 and concentrated in vacuo. Simple distillation gave the hydrogenation product in a quantitative chemical yield. The optical yields were estimated from the specific rotations of the pure enantiomers: (*S*)-2-octanol, $[\alpha]_D^{20}$+9.76° (neat);[8] (*S*)-3-methyl-2-butanol, $[\alpha]_D^{20}$+4.85° (neat);[9] (*S*)-2-decanol, $[\alpha]_D^{20}$+8.68° (neat).[8]

Determination of Br$^-$ Adsorbed on the Catalyst. The amount of Br$^-$ adsorbed on the catalyst was determined by Volhard's titrimetric method.[10] A 1 g portion of TA-NaBr-MRNi or MRNi-T was decomposed with 15 ml of 60% HNO_3 in the presence of a known amount of $AgNO_3$. The resulting solution was back-titrated with NH_4SCN.

Determination of Na$^+$, Co, and Fe in the Catalyst. A 250 mg portion of TA-NaBr-MRNi or MRNi-T was dissolved in 5 ml of 2 mol dm^{-3} HNO_3. The solution was diluted to

Results and Discussion

We have developed the amine-treatment procedure for TA-NaBr-MRNi in order to improve the poor durabilities of the optical yields in the repeated use of the catalyst.[7c] The catalyst (Amine/MRNi) prepared by this procedure gave durable optical yields in the hydrogenation of MAA. Optical yields of around 80% were attained even after ten times of its repeated use. However, neither TA-NaBr-MRNi nor Amine/MRNi gave any durable optical yields in the hydrogenation of 2-alkanones. Typical results of the repeated use of the catalysts for the hydrogenation of 2-octanone are listed in Table 1. The optical yields decreased remarkably after the first use of both types of catalysts. In their third use, both gave a 0% optical yield.

In order to determine the origin of the remarkable decrease of the optical yields under repeated use of the catalysts, TA-NaBr-MRNi was treated with a mixture of 2-octanone, pivalic acid, and THF before the catalyst was used for the hydrogenation of 2-octanone. After the treatment, the catalyst (MRNi-T) was separated from the supernatant by decantation. Hydrogenations over MRNi-T were carried out using two kinds of reaction mixtures. One was a freshly prepared mixture of 2-octanone, pivalic acid, and THF. The other was the supernatant recovered from the treatment of TA-NaBr-MRNi. As shown in Table 2, the optical yields are dependent on the kinds of reaction mixtures. The combination of MRNi-T and the freshly prepared mixture gave a poor optical yield. This finding shows that one or more of the constituents (**X**) of the catalyst are extracted from the catalyst surface by contact with the reaction mixture. A lack of **X** in MRNi-T might be the origin of the poor optical yield. On the other hand, when the recovered reaction mixture was employed instead of the freshly prepared one, a high opltical yield was attained on the hydrogenation over MRNi-T. From this fact it is apparent that **X** dissolved in the reaction mixture plays an important role in the improvement of the optical yield. It is noteworthy that the optical yield attained by the use of MRNi-T and the recovered mixture is similar to that attained by the combination of TA-NaBr-MRNi and the freshly prepared reaction mixture (Tables 1 and 2). This similarity of the optical yields is explicable based on the following idea. The surface state of TA-NaBr-MRNi becomes similar to that of MRNi-T by contact of TA-NaBr-MRNi with the freshly prepared reaction mixture prior to the hydrogenation of 2-octanone. The freshly prepared mixture is contaminated with **X** extracted from TA-NaBr-MRNi. If this idea is the case, the poor optical yields in the second and third uses of TA-NaBr-MRNi are expected to be improved by the addition of **X** to the reaction mixture. Thus, the identification of **X** was strongly required in order to demonstrate this idea.

Table 3. Amounts of Inorganic Substances Contained in TA-NaBr-MRNi and MRNi-T

Catalyst[a]	Inorganic Substance/10^{-5} mol·g cat^{-1}			
	Na^+	Co	Fe	Br^-
TA-NaBr-MRNi	2.8	2.0	5.1	3.7
MRNi-T[b]	0.7	2.0	4.8	3.1

a) Amount of NaBr in the modifying solution: 12g. b) 2-Octanone was used as the 2-alkanone in the mixture for the treatment of TA-NaBr-MRNi.

In the course of our survey of extracted substances, several inorganic substances contained in TA-NaBr-MRNi and MRNi-T were determined by the atomic absorption spectra (results are shown in Table 3). It is clear that the treatment of TA-NaBr-MRNi with a freshly prepared reaction mixture resulted in a remarkable decrease in the amount of sodium ions contained in the catalyst. More than 70% of the sodium ions in TA-NaBr-MRNi were extracted by the treatment. The contents of Co, Fe, and Br^- were not decreased by the treatment. These findings show the possibility that the sodium ions are **X** being effective for increasing the optical yields of the hydrogenation of 2-alkanones.

In order to confirm the above possibility, we examined the effects of the sodium ions in a freshly prepared mixture on the optical yields of the hydrogenation of several kinds of 2-alkanones over MRNi-T. The

a) Runs 1 to 4:
Catalyst: RNi modified with an aqueous solution of TA(2g) and NaBr (12g) at pH 3.2, 100°C.
Hydrogenation temperature: 100°C.
Runs 5 and 6:
Catalyst: RNi modified with an aqueous solution of TA(2g) and NaBr (30g) at pH 3.2, 100°C.
Hydrogenation temperature: 60°C.
a) The optical yields attained by the hydrogenation of 2-octanone.

resulting optical yields are listed in Table 4. The addition of a small amount of sodium pivalate to the reaction mixture remarkably improved the optical yields in the hydrogenation of 2-octanone, 3-methyl-2-butanone, and 2-decanone. The addition of 3 mg of sodium pivalate to the freshly prepared reaction mixture was enough to attain the optical yield around 60% in the hydrogenation of 2-octanone.

We then carried out repeated use of TA-NaBr-MRNi in the hydrogenation of 2-octanone, using freshly prepared reaction mixtures containing various amounts of sodium ions. The optical yields, thus attained, are shown in Table 5. It is evident that the optical yield in the first use of TA-NaBr-MRNi is somewhat decreased with an increase of the amount of the added sodium pivalate, and the durability of the optical yield in the repeated use is remarkably increased with an increase of the amount of sodium pivalate. This tendency was remarkably observed in hydrogenation at 60°C. Upon the addition of 10 mg of sodium pivalate, a high optical yield (80%) was attained and the optical yield in the first use of the catalyst was almost lost in the third use. On the other hand, when 100 mg of sodium pivalate was added, a rather low optical yield (74%) was attained in the first use and an optical yield of around 60% was attained even during the sixth use of the catalyst.

The present investigation clarified the fact that the addition of sodium ions to the reaction mixture improved the durability of the optical yield in the repeated use of TA-NaBr-MRNi for the enantioface-differentiating hydrogenation of 2-alkanones. In order to clarify the origin of the effects of sodium ions, further studies are now in progress.

The authors would like to thank Professor Yoshiharu Izumi of Osakagakuin University, Professor Akira Tai of Himeji Institute of Technology, and Dr. Hiroshi Ozaki of Osaka University for their many helpful discussions and suggestions in the course of this work. The authors also wish to express their thanks to Mr. Hitoshi Yamada of Osaka University for the help in the measurements of the atomic absorption spectra.

Self Aggregation of Cationic Porphyrin in Water

Koji KANO,* Takeshi NAKAJIMA, Masao TAKEI, and Shizunobu HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto 602
(Received October 28, 1986)

Self aggregation of 4,4′,4″,4‴-(21*H*,23*H*-porphine-5,10,15,20-tetrayl)tetrakis[1-methylpyridinium] cation ($TMPyP^{4+}$) in water has been verified by means of fluorescence and ^1H NMR spectroscopy. The novel fluorescence behavior of TMPyP such as extraordinarily red-shifted Q(0-0) fluorescence band, blue shift of this band upon dilution, effects of added sodium chloride and sodium dodecyl sulfate micelles, and short fluorescence lifetime strongly suggests the formation of a stacking-type dimer of $TMPyP^{4+}$ at the TMPyP concentrations above 1×10^{-6} mol dm^{-3}. The ^1H NMR signal due to the porphyrin ring protons was observed as a broad singlet even though the concentration of TMPyP in D_2O was 1×10^{-5} mol dm^{-3} while the signal in DMSO-d_6 was a sharp singlet, suggesting the spontaneous association of $TMPyP^{4+}$ to form the face-to-face dimer having a considerably loose structure. The π-π interaction has been assumed to be enhanced upon photoexcitation.

It has been known that various anionic porphyrins such as proto-, deutero-, and hematoporphines, and 4,4′,4″-(20-phenyl-21*H*,23*H*-porphine-5,10,15-triyl)-tris[benzenesulfonic acid](TPPS$_3$), and 4,4′,4″,4‴-(21*H*,23*H*-porphine-5,10,15,20-tetrayl)tetrakis[benzenesulfonic acid] (TPPS$_4$) tend to stack spontanously in aqueous solutions to form dimers and/or higher aggregates, the binding constants (K) for dimerization being reported to be 10^4—10^7 mol^{-1} dm^3.[1-12] Well-extended π electron systems of the porphyrins seem to promote the self aggregation which is an opposite process of electron repulsion. In agreement with this assumption, an extremely large equilibrium constant for dimerization has been reported for phthalocyanine-tetrasulfonate ($K=1.48\times10^8$ mol^{-1} dm^3 at 14 °C).[13] On the contrary, Pasternack et al. have demonstrated that a cationic porphyrin, 4,4′,4″,4‴-(21*H*,23*H*-porphine-5,10,15,20-tetrayl)tetrakis[1-methylpyridinium] cation ($TMPyP^{4+}$), and its metal complexes do not aggregate in aqueous solutions.[3,4,14,15] No evidence for self aggregation has been presented from absorption and NMR spectroscopy and temperature-jump relaxation method. In a previous communication, we reported the novel fluorescence behavior of $TMPyP^{4+}$ in water as described below.[16] (1) Although the Q(0-0) and Q(0-1) fluorescence bands of most of porphyrins are well-resolved from each other, the Q(0-0) band of the $TMPyP^{4+}$ fluorescence shifts to longer wavelength to partially overlap with the Q(0-1) band. (2) The fluorescence lifetime of $TMPyP^{4+}$ (4.1 ns) is significantly shorter than those of many other porphyrin free bases (9—14 ns). (3) Addition of methanol or sodium dodecyl sulfate (SDS) micelles causes the blue shift of the Q(0-0) band and the increase in the fluorescence quantum yield and lifetime of $TMPyP^{4+}$. (4) Coalesced Q(0-0) and Q(0-1) bands at low temperature separate each other with increasing temperature. We interpreted these fluorescence results in terms of the monomer-aggregate equilibrium of $TMPyP^{4+}$ in water.[16] Recently, Pasternack et al. criticized our previous assumption on the basis of the results on the absorption and NMR spectroscopy and the complexation of $TMPyP^{4+}$ with nucleosides and nucleotides.[15] Indeed, our previous communication lacks in the discussion about the electronic effects of the peripheral substituents on the $TMPyP^{4+}$ fluorescence. The lower pK_a of $TMPyP^{4+}$[3,17,18] compared with anionic porphyrins suggests the delocalization of positive charge on the peripheral pyridinium cations on the porphyrin ring.

In this work, we reinvestigated the $TMPyP^{4+}$ fluorescence and found that the novel fluorescence behavior cannot be explained only by the electronic effects. All of the fluorescence data could be interpreted in terms of the self association of $TMPyP^{4+}$. ^1H NMR measurements also support the stacking-type interaction of $TMPyP^{4+}$.

Experimental

The tetrakis(*p*-toluenesulfonate) salt of $TMPyP^{4+}$ (TMPyP) was prepared according to the procedures described in a literature[3] and recrystallized from methanol. The tetrachloride salt (TMPyP(Cl)) was also prepared by passing TMPyP through an ion-exchange column. Since the results were essentially the same for these two porphyrins, the former porphyrin was used in this work unless otherwise noted. Sodium dodecyl sulfate (SDS, >99%, Nakarai) was used without further purification.

The absorption spectra were taken on a Shimadzu UV-200S or a Shimadzu MPS-5000 spectrophotometer. The fluorescence spectra were measured by a Shimadzu RF-500 (excitation and emission bandwidths=10 nm) or a Hitachi 650-60 spectrofluorometer (bandwidths=5 nm). In the fluorescence measurements of very diluted sample, a Raman band due to water appeared as a background which was cancelled by using a microcomputer attached to a Hitachi 650-60 spectrofluorometer. The measurements were carried out at 25 °C under aerobic conditions unless otherwise noted. The spectroscopic measurements were done 20 min after each sample was prepared. The fluorescence lifetimes were determined using an Ortec-PRA single-photon counting apparatus. The 400-Mz ^1H NMR spectra in D_2O were obtained on a JEOL GX-400 spectrometer at 23±0.5 °C. Sodium 3-trimethylsilyl-1-propanesulfonate (Merck) was used as an external standard for measurements in D_2O. TMS (Nakarai) was used as an internal standard in DMSO-d_6.

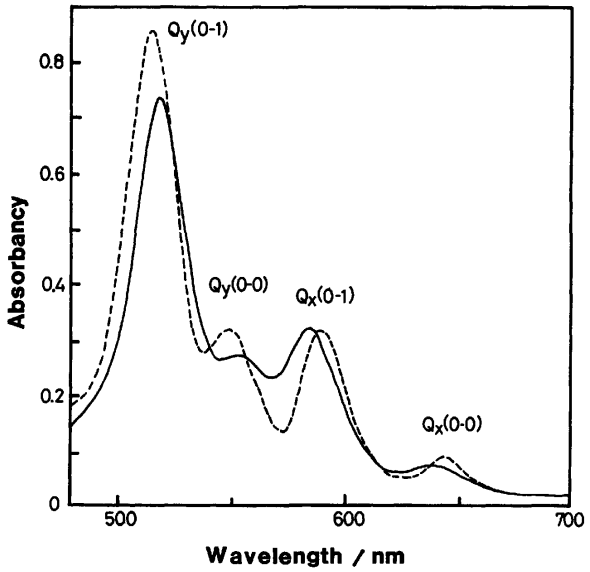

Fig. 1. Absorption spectra of TMPyP (5×10^{-5} M as monomer) in water (——) and methanol (----) at room temperature.

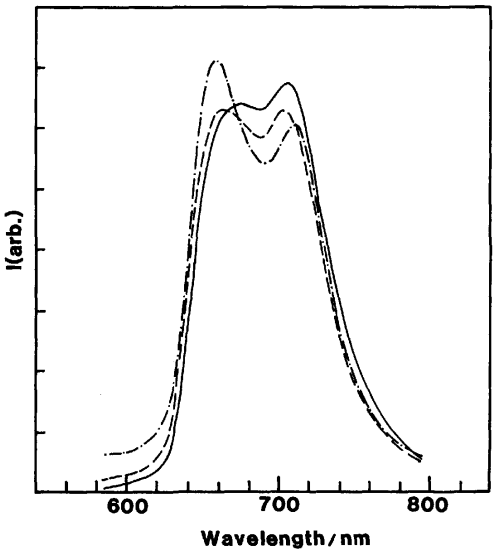

Fig. 2. Fluorescence spectra of 1×10^{-6} (——), 1×10^{-7} (----), and 1×10^{-8} M (-·-·-) TMPyP in water at 25 °C. TMPyP was excited at its Soret band. The concentrations of TMPyP are calculated as the monomer.

Results and Discussion

Electronic Spectra of TMPyP. TMPyP shows novel absorption and fluorescence spectra in aqueous solutions. Most of *meso*-substituted porphyrins show etio-type absorption spectra; i.e., the absorbancies of the Q bands decrease in the order of $Q_y(0\text{-}1)$, $Q_y(0\text{-}0)$, $Q_x(0\text{-}1)$, and $Q_x(0\text{-}0)$ bands. As shown in Fig. 1, however, the absorbancy of $Q_y(0\text{-}0)$ band of TMPyP in water is considerably smaller than that of $Q_x(0\text{-}1)$ band. In methanol, the Q_y bands shift to shorter wavelengths and the Q_x bands move to longer wavelengths compared with those in water and the absorbancy of the $Q_y(0\text{-}0)$ band is restored. The fluorescence emission spectrum of TMPyP in water also differs from those of other porphyrins. In water, the Q(0-0) and Q(0-1) fluorescence bands of 1×10^{-7} M (1 M=1 mol dm^{-3}) TMPyP appeared at 664 and 706 nm (Fig. 2), respectively. The Q(0-0) band shifts to longer wavelength compared with those of other porphyrins and two Q bands partially overlap each other. Upon dilution to 1×10^{-8} M, the Q(0-0) band shifted to shorter wavelength (654 nm) while the shift of the Q(0-1) band was relatively small (708 nm). It was confirmed that the fluorescence spectral change upon high dilution is not due to complexation with trace amounts of metal ions coexisting in the system by using water distilled three times and deionized with an ion-exchange column. The fluorescence excitation spectral maxima were observed at 422 and 430 nm for 1×10^{-7} and 1×10^{-8} M solutions, respectively. These peaks correspond to the Soret bands of the TMPyP absorption spectra.

If the positive charges on the peripheral pyridinium cations perturb the electronic states of TMPyP, the absorption and fluorescence spectra of TMPyP may be affected greatly by the solvent polarity. Table 1 shows the absorption and fluorescence maxima of the Q bands of TMPyP (5×10^{-5} M) in various solvents. We could not recognize any correlation between solvent polarity parameters and the absorption maxima of the $Q_y(0\text{-}1)$ and $Q_y(0\text{-}0)$ bands. Fairly good linear relationships were observed between dielectric constant or Kamlet-Taft's π^* value of solvent and the absorption maxima of the $Q_x(0\text{-}1)$ and $Q_x(0\text{-}0)$ bands.

In analogy with the Q_x absorption bands, both Q(0-0) and Q(0-1) fluorescence maxima shifted to shorter wavelengths with increasing solvent polarity except for the Q(0-0) band in water (Fig. 3). An extremely large red shift of the Q(0-0) fluorescence band in water indicates the stabilization of the lowest excited singlet state of TMPyP by some reason. The dissociation of TMPyP into ions may account for the novel fluorescence behavior in water. It is commonly known that aprotic dipolar solvents such as *N,N*-dimethylformamide (DMF), dimethyl sulfoxide (DMSO), and *N,N*-dimethylacetamide (DMA) can dissolve ions and stabilize cationic species due to strong solvation.[19] As is shown in Fig. 3, however, no deviations were observed for these solvents in the relation between the fluorescence maximum of the Q(0-0) band and the dielectric constant. This supports the contention that the abnormally red-shifted Q(0-0) fluorescence band in water is not due to the dissociation of the *meso*-substituents into ions. The similar red shift of the fluorescence band has been reported for a porphyrin dimer formed by pairing cationic and anionic porphyrins.[20]

The effects of NaCl on organic ions in water may be

a) DMSO: dimethyl sulfoxide, DMA: *N,N*-dimethylacetamide, DMF: *N,N*-dimethylformamide. b) Dielectric constant. c) The fluorescence spectra were measured by exciting TMPyP at $Q_x(0-1)$ absorption band.

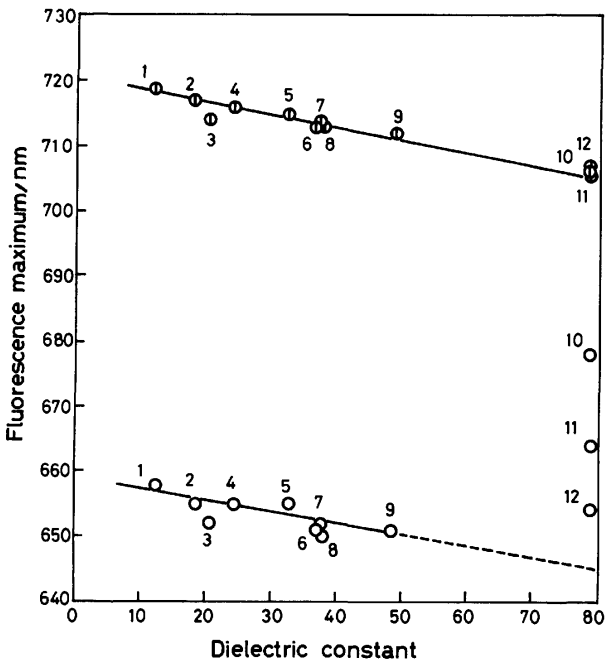

Fig. 3. Fluorescence maxima of the Q(0—0) (○) and Q(0—1) bands (⊕) of TMPyP (5×10^{-5} M as monomer) in various solvents at 25 °C: 1: pyridine, 2: 2-propanol, 3: acetone, 4: ethanol, 5: methanol, 6: *N,N*-dimethylformamide, 7: acetonitrile, 8: *N,N*-dimethylacetamide, 9: dimethyl sulfoxide, 10: water, 11: water ([TMPyP]=1×10^{-7} M as monomer), 12: water ([TMPyP]=1×10^{-8} M as monomer). TMPyP was excited at 583 nm.

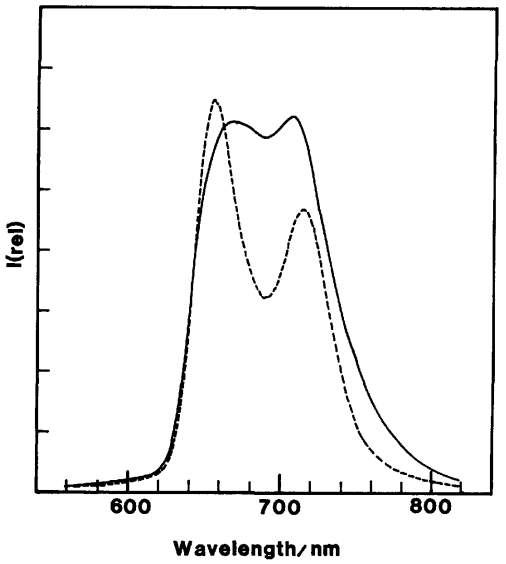

Fig. 4. Fluorescence spectra of TMPyP (1×10^{-7} M as monomer) in water (——) and in water containing 1×10^{-2} M nitrobenzene (----) at 25 °C. TMPyP was excited at 428 nm (bandwidths of spectrofluorometer=5 nm).

somewhat complex. The electrostatic repulsion between the organic ions should be reduced by added NaCl to enhance aggregation of the solute ions. Meanwhile, the dielectric constant of water is lowered upon addition of NaCl. The 1×10^{-6} M aqueous solution of TMPyP showed the fluorescence maxima at 678 and 706 nm (Fig 2). The Q(0-0) fluorescence band shifts to longer wavelength compared with those for the 1×10^{-7} and 1×10^{-8} M solutions. The Q(0-0) band further shifted to longer wavelength upon addition of 1.0 M NaCl and this fluorescence band became a shoulder of the Q(0-1) band, Q(0-0) and Q(0-1) bands being observed at around 680 (sh) and 706 nm, respectively. The shape of the fluorescence spectrum in 4.0 M aqueous NaCl was essentially the same as that in 1.0 M aqueous NaCl, but the fluorescence intensity slightly decreased. If the extraordinary red shift of the Q(0-0) band is due to the effects of the positive charges on the peripheral pyridinio substituents, the neutralization of the charges and the reduction of the dielectric constant caused by added NaCl should provide the blue shift of the Q(0-0) band.

A dramatic fluorescence spectral change was observed when nitrobenzene (1×10^{-2} M) was added to the aqueous TMPyP (1×10^{-7} M) solution without salt, as is shown in Fig. 4. Previously, we have found that nitrobenzene forms a ground-state complex with $TPPS_3$.[21] The result shown in Fig. 4 can be inter-

preted as that nitrobenzene pulls out a TMPyP molecule from the TMPyP dimer or the higher aggregates to form a 1 : 1 complex which shows a fluorescence spectrum similar to those of other porphyrin monomers. We reported the same effects of SDS micelles as that of nitrobenzene.[16] In the case of the SDS micelles, however, the charges of the pyridinium cations of TMPyP are neutralized to some extent by pairing these oppositely charged micelles. The effects of nitrobenzene, a nonionic species, on the TMPyP fluorescence strongly suggest that TMPyP in water is not in monomer form.

All fluorescence data can be explained by the TMPyP dimer (or higher aggregates) formation in water, but not by the electronic effects of the peripheral pyridinio substituents.

Fluorescence Lifetime of TMPyP. The fluorescence lifetime of TMPyP in aqueous solution is about 2-fold smaller than those of other *meso*-substituted porphyrins and of TMPyP in the glycerol and SDS micellar solutions (Table 2). TMPyP is more acidic (pK_a=1—2)[3,17,18,22] than $TPPS_3$ (pK_a=4.8),[3] $TPPS_4$ (pK_a=4.8),[23] and 4,4′,4″,4‴-(21*H*,23*H*-porphine-5,10,15,20-tetrayl)tetrakis[trimethylphenylammonium] salt (TAPP, pK_a=3.6—4.1).[24] Kalyanasundaram measured the pK_a values and the fluorescence of TMPyP and its three isomers.[22] The pK_a value of 2,2′,2″,2‴-(21*H*,23*H*-porphine-5,10,15,20-tetrayl)tetrakis[1-methylpyridinium] tetra-*p*-toluenesulfonate (TMPyP-2) is much smaller (−0.9) than the 3-substituted isomer

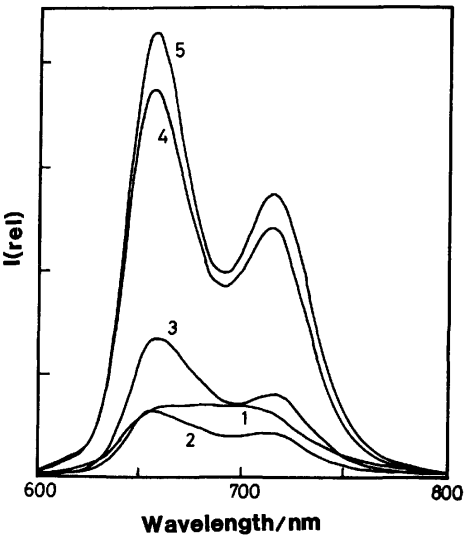

Fig. 5. Fluorescence spectra of TMPyP (1×10^{-6} M as monomer) in water in the presence of SDS at 25°C: 1: [SDS]=0, 2: 1×10^{-4}, 3: 1×10^{-3}, 4: 5×10^{-3}, 5: 1×10^{-2}M. TMPyP was excited at 420 nm.

(TMPyP-3) (1.8) and TMPyP (1.4). Since the free rotation of the peripheral pyridinio substituents of TMPyP-2 is strictly restricted by a steric factor, the positive charges of the pyridinium groups should not delocalize on the π-electron system of the porphyrin ring. In spite of this expectation, pK_a of TMPyP-2 is much smaller than those of TMPyP-3 and TMPyP. Kalyanasundaram explained the difference in the pK_a values by σ charge density in the porphyrin ring.[22] On the other hand, the Q(0-0) fluorescence band and the fluorescence lifetime are sensitive to the pyridinio substituents.[22] Namely, the Q(0-0) fluorescence maxima of TMPyP, TMPyP-3, and TMPyP-2 are 675, 653, and 641 nm, respectively, and the fluorescence lifetimes in water increase in the order of TMPyP (6.0 ns), TMPyP-3 (7.9 ns), and TMPyP-2 (13.8 ns). Such continuous substituent effects on the fluorescence of these cationic porphyrins suggest that the novel fluorescence behavior of TMPyP is ascribed to the delocalization of the positive charges of the peripheral substituents on the porphyrin ring through the π-conjugation system. As is described above, however, the TMPyP-concentration effect as well as the effects of added NaCl and nitrobenzene on the TMPyP fluorescence spectrum cannot be interpreted in terms of the electronic effects of the pyridinio substituents. It is reasonable to assume that, in the case of TMPyP, delocalized positive charges increase the polarizability of TMPyP molecule leading to enhancement of van der Waals interaction between the TMPyP molecules, which may be used as a predominant binding force for forming the TMPyP dimer. The nonradiative transition of the TMPyP dimer may be faster than that of the TMPyP monomer.

Effects of SDS Micelles. Pasternack et al.[15] reexamined our previous experiments of the effects of the SDS

micelles on the TMPyP fluorescence and found that addition of 4×10^{-4} M SDS provides the same effects as does 0.1 M SDS. However, we could not reproduce their result as shown in Fig. 5. The fluorescence yield of TMPyP decreases upon addition of small amounts of SDS (1×10^{-4} M), which may be due to the self quenching occurring in the small aggregates of the association complex of TMPyP and SDS. At near a critical micelle concentration (cmc=9.8×10^{-3} M at 25 °C),[25] the fluorescence yield markedly increased. Above the cmc, the TMPyP dimer seems to dissociate to the monomer which is included within the micelle. The shape of the TMPyP fluorescence spectrum in water containing 1×10^{-3} M SDS was very similar to those in $>5\times10^{-3}$ M SDS solutions, while the fluorescence yield was still small. This may be ascribed to the formation of premicelles which are known to yield in the detergent solutions containing various dyes.[26] The TMPyP molecules are concentrated within the premicelles and both self quenching and energy migration may lead the decrease in the fluorescence yield. The effects of the SDS micelles are also explained by the dimer model.

^{1}H NMR Spectra. The 400-Mz ^{1}H NMR spectra of TMPyP in D_2O and DMSO-d_6 are shown in Fig. 6. For the 1×10^{-2} M D_2O solution of TMPyP, the ring protons of the peripheral pyridinium cations and of the *p*-toluenesulfonate anions, the counter anions of $TMPyP^{4+}$, were observed at 9.20, 8.70, 6.86 and 5.97 ppm, respectively. Interestingly, the porphyrin ring protons appeared at ca. 8.95 ppm as a broad singlet. These signals, especially those of *p*-toluenesulfonate, were shifted to lower magnetic fileds upon dilution. The signal due to the porphyrin ring protons was not sharpened upon dilution up to 1×10^{-4} M, while that in DMSO-d_6 was observed at 9.16 ppm as a sharp singlet. Foster reported that the concentration-dependent chemical shifts of TMPyP are ascribed to a stacking-type interaction between $TMPyP^{4+}$ and its counter anion.[27] Then we measured the ^{1}H NMR spectra of TMPyP(Cl) at various concentrations (5×10^{-2}—1×10^{-5} M) (Fig. 7). At the concentrations below 1×10^{-2} M, the protons of the pyridinium ring were measured at the constant magnetic fields (9.33 and 9.00 ppm). These protons, however, resonanced at higher mag-

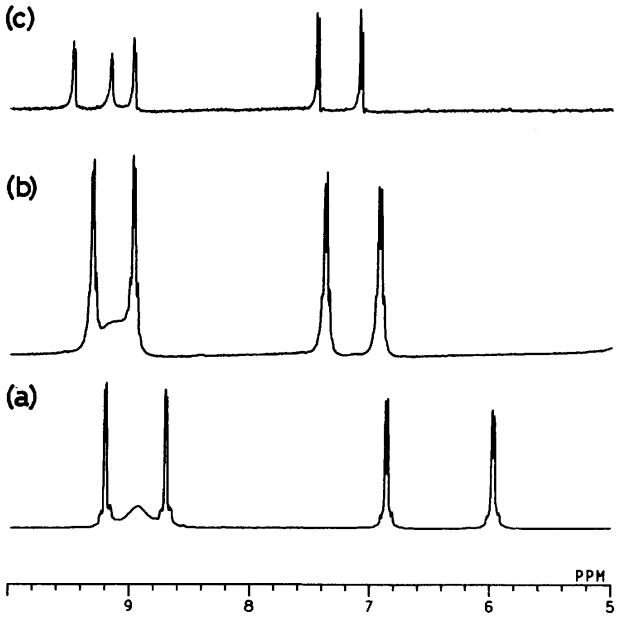

Fig. 6. 400-MHz ^{1}H NMR spectra of (a) 1×10^{-2} and (b) 1×10^{-3} M TMPyP in D_2O and (c) 1×10^{-4} M TMPyP in DMSO-d_6.

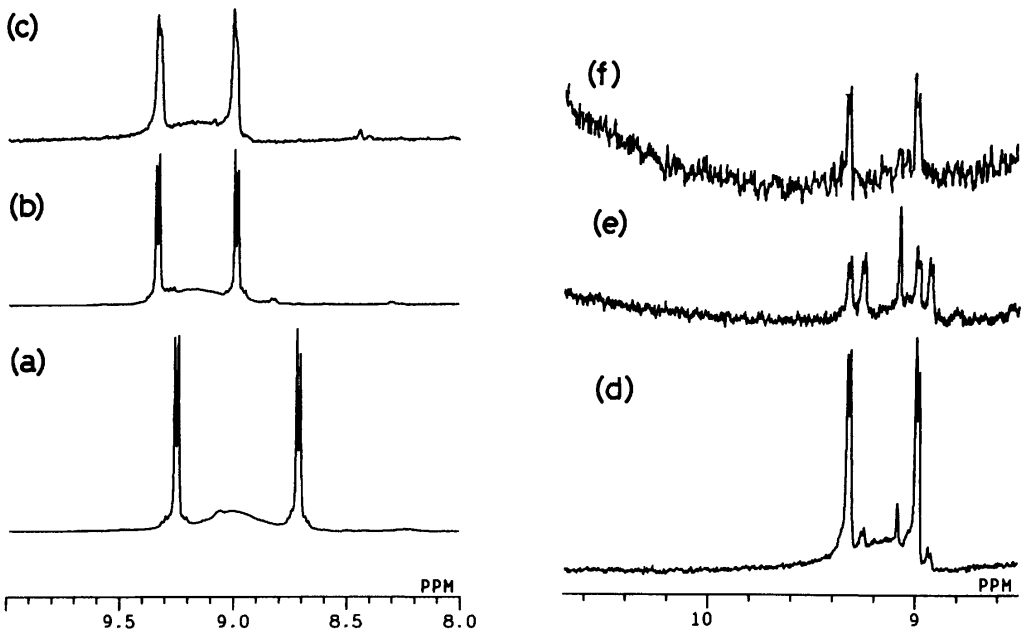

Fig. 7. 400-MHz ^{1}H NMR spectra of (a) 5×10^{-2}, (b) 1×10^{-3}, (c) 1×10^{-4}, and (f) 1×10^{-5} M TMPyP(Cl) in D_2O and of (d) 5×10^{-5} M TMPyP(Cl) in the presence of 1.25×10^{-4} M TMSPS and (e) 1×10^{-5} M TMPyP(Cl) in the presence of 2.5×10^{-5} M TMSPS in D_2O. TMSPS was used as an external standard.

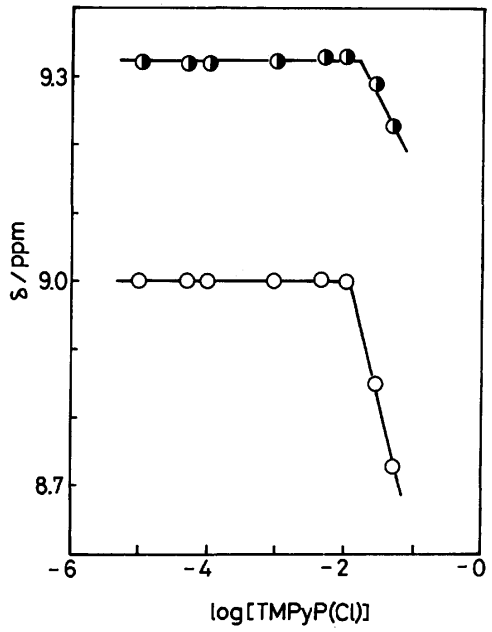

Fig. 8. Plots of the chemical shifts of the protons at the 2 and 6 (◑) and of the 3 and 5 positions (○) of the pyridinium ring of TMPyP(Cl) vs. TMPyP-(Cl) concentration in D_2O.

netic fileds at the TMPyP(Cl) concentrations above 1×10^{-2} M (Fig. 8). Pasternack et al. also studied the concentration effects ($1-50\times10^{-3}$ M) on ^{1}H NMR of TMPyP(Cl) in D_2O at μ=0.3 M and found that the chemical shift of the protons at the 2 and 6 positions of the pyridinium ring moves continuously to higher magnetic field with increasing the TMPyP (Cl) concentration in the presence of inorganic salt.[15] In the absence of inorganic salt, however, the upfield shift was observed only at the concentrations above 1×10^{-2} M. Pasternack et al. did not discuss about the porphyrin ring protons. As Fig. 7 shows, the porphyrin ring protons of TMPyP(Cl) show a very broad signal as in the case of TMPyP. The broadening of the pyrrole protons of TMPyP in ^{1}H NMR, therefore, is not ascribed to the interaction between *p*-toluenesulfonate and the porphyrin ring. It can be concluded that there is an exchange process between the two states of TMPyP in aqueous solution. The monomer-dimer equilibrium is the most plausible process for explaining the broadening of the NMR signal due to the pyrrole protons. In all cases described above, each chemical shift was determined by using 3-trimethylsilyl-1-propanesulfonate (TMSPS) as an external standard. Figure 7 also shows the effect of added TMSPS on the ^{1}H NMR of TMPyP(Cl). Two pairs of the NMR signals due to the pyridinium protons and a sharp singlet due to the porphyrin ring protons were measured clearly for the 1×10^{-5} M D_2O solution of TMPyP(Cl) containing 2.5×10^{-5} M TMSPS. Under the same conditions, we measured the fluorescence spectra, which showed that the fluorescence maximum of the Q(0-0) band at 678 nm in H_2O shifts to 670 nm in the presence

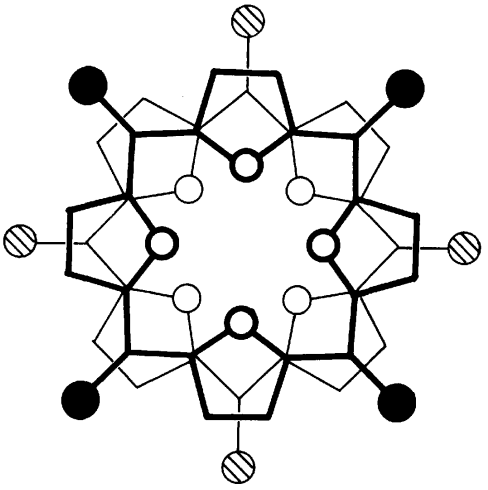

Fig. 9. Plausible structure of the TMPyP dimer in water. ● and ⊘ represent the peripheral pyridinio substituents.

of 2.5×10^{-5} M TMSPS. In the presence of large amounts of TMSPS (1×10^{-2} M) the well-resolved Q(0-0) and Q(0-1) bands of TMPyP(Cl) were observed at 654 and 712 nm, respectively. Both ^{1}H NMR and fluorescence data can be interpreted as that TMSPS binds electrostatically with TMPyP(Cl) leading to the dissociation of the TMPyP(Cl) dimer.

The ^{1}H NMR also suggests the structure of the TMPyP dimer. All of the NMR data can be interpreted in terms of the face-to-face dimer structure, where the peripheral pyridinio substituents of the two TMPyP molecules may be oriented each other to minimize the steric hindrance and the coulombic repulsion (Fig. 9). If the TMPyP dimer is a very tight π complex and the monomer scarecely exists in the system, one should observe a sharp singlet NMR signal due to the porphyrin ring. On the contrary, if the monomer-dimer equilibrium consists of very fast formation and dissociation processes, a sharp singlet signal is also expected. The broadening of the porphyrin ring protons indicates the formation of the TMPyP dimer having an intermediately loose structure. The relatively weak ring current of the pyridinium group, the relative orientation of the adjacent pyridinium groups of the TMPyP dimer (see Fig. 9), the loose structure of the dimer, and the free rotation of the peripheral substituents may account for the sharp AA'XX' multiplet due to the pyridinium ring protons.

On the basis of these results, we concluded that $TMPyP^{4+}$ dimerizes in H_2O in the concentration range, at least, from 1×10^{-2} to 1×10^{-5} M and forms higher aggregates at the concentrations above 1×10^{-2} M. The TMPyP(Cl)-TMSPS complex may include a $TMPyP^{4+}$ ion which shows a NMR spectrum of monomeric $TMPyP^{4+}$.

Dimer Model of TMPyP. As Pasternack et al.[3] indicated, no absorption spectral change was observed for TMPyP in the concentration range from 1×10^{-5} to 1×10^{-3} M.[16] TMPyP obeys Beer's law in this concen-

tration range. The fluorescence behavior is also unchanged at the concentrations above 1×10^{-6} M. These aspects suggest only one species (we assume the dimer) in the aqueous solutions of $>10^{-6}$ M TMPyP. Pasternack et al.[15] also stated that the Soret band of TMPyP does not shift markedly in the SDS solution while that of another cationic porphyrin ($PPIX(en)_4$) aggregates shifts to longer wavelength upon dissociation to the monomer in the SDS micellar solution. A TMPyP molecule has a D_{2h} symmetry. If this symmetry is ruptured by complexation, the Soret band is expected to shift. Indeed, information for the TMPyP-dimer formation could scarecely be obtained from the absorption spectral measurements through the present experiments while all fluorescence behavior can be interpreted in terms of the dimer formation. As the ^1H NMR spectral data suggest, TMPyP may form a considerably loose dimer. The electronic state of the loose dimer may be essentially the same as that of the TMPyP monomer. The intermolecular interaction may be enhanced in the photoexcited singlet state because of the formation of the face-to-face excited dimer (excimer). Pyrene is a typical π-conjugated hydrocarbon which shows excimer fluorescence at high concentration range ($>10^{-3}$ M).[28] No interaction exists between the pyrene molecules in the ground states while pyrene in the excited singlet state associates with another pyrene in the ground state to form the excited dimer (excimer). In the case of TMPyP, however, the excited dimer can be detected by means of the fluorescence spectroscopy even if the TMPyP concentration is 1×10^{-6} M. This should be ascribed to the formation of the loose ground-state dimer of TMPyP as is suggested by ^1H NMR spectroscopy. The exciton-type and charge-exchange interactions may cause stabilization of the lowest singlet state of the TMPyP dimer leading to the red shift of the Q(0-0) band. The similar red shift of porphyrin dimer has been observed for the TAPP-$TPPS_4$ association complex.[19]

Conclusion

In this work, we confirmed that TMPyP in water exists as the dimer having somewhat loose structure at the concentrations above 10^{-6} M and the intermolecular interaction is enhanced upon photoexcitation to the lowest singlet state. The extraordinarily red-shifted Q(0-0) fluorescence band of TMPyP can be explained by the formation of the excimer-like state. The formation of the higher aggregates of TMPyP may be prevented by the electrostatic repulsion between the TMPyP dimer and monomer at the concentrations below 1×10^{-2} M:[29]

$$2TMPyP^{4+} \rightleftharpoons (TMPyP)_2^{8+}, \quad (1)$$

$$(TMPyP)_2^{8+} + TMPyP^{4+} \rightleftharpoons (TMPyP)_3^{12+}, \quad (2)$$

Extraction and Transport of Ions in a Liquid Membrane Containing Crown Ether

Maria SAKIM,† Takashi HAYASHITA, Takeo YAMABE, and Manabu IGAWA*
Department of Applied Chemistry, Faculty of Engineering, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221
†Department of Chemistry, Medical College of Shin Jiang, Urumchi, Shin Jiang, China
(Received October 30, 1986)

The ion-transport mechanism through a liquid membrane containing dibenzo-18-crown-6 as a carrier was investigated by measuring the salt flux, the distribution coefficient to the membrane phase, and the membrane potential. The salt flux increased to a great extent with the activity of the source phase solution, but the effect of the activity on the distribution coefficient varied with the membrane solvent. The mobility ratio of cations to anions increased with an increase in the hydrophobicity of the membrane solvent. Although the selectivity of the cation transport is controlled mainly by the size of the crown ring, the hydrophobicity of the cation also influenced the salt flux and the flux of a slightly hydrated large cation, such as cesium ion, was high. The hydration degree of anions influenced the salt flux considerably since the stability constants of the crown ether complexes accompanied by a hydrophobic anions were very high. The salt flux correlated well with the lyotropic number of anions.

Crown ethers complex selectively with cations which have a similar diameter as the size of a crown ring[1] and have been applied for the separation and determination of various cations.[2] Especially in a separation with liquid membranes containing crown ethers as carriers, many reports have been presented up to now. Recently, some interesting applications have been attempted, such as ion transport driven by light energy,[3] by a redox potential,[4] or by a pH gradient.[5]

The basic theory of ion transport through a liquid membrane mediated by a crown ether has been constructed by Reusch and Cussler[6] and Lamb et al.[7] and salt transport equations have been reported. However, the extraction process of the most important process of salt transport has been investigated as solvent extraction separately against the investigation of the salt transport. There have been many reports regarding salt extraction with DB18C6;[8,9] however, extraction coefficients have not been measured in salt transport studies (with some exception).[10]

A membrane potential is also generated specifically during salt transport across the crown ether membrane; its principle is important for a specific determination of ions in ion electrodes.[11-13] However, the relationship between the salt transport and the membrane potential revealed in a liquid membrane containing a crown ether as a carrier has not yet been clarified and investigated.

In this paper, we will simultaneously analyze the extraction, the salt transport, and the membrane potential in a salt transport phenomenon of a liquid membrane containing a typical crown ether (dibenzo-18-crown-6) as the carrier with a flow cell.[14] We will attempt a preliminary clarification of the mutual relationship.

Experimental

Preparation of Membrane Phase and Source Phase Solutions. In this study, dibenzo-18-crown-6 (DB18C6) was used as the carrier of a liquid membrane. DB18C6 was obtained from Nippon Soda Co., as a commercial reagent and was used after recrystalization from benzene. Unless otherwise stated, the liquid membrane was a 0.1 mol dm^{-3} DB18C6 solution of tetrachloroethane and the source phase solution was a 0.1 mol dm^{-3} aqueous solution of KNO_3 (analytical grade reagent). For an investigation of the effect of a membrane solvent on ion transport, some solvents were examined; the solvents used in this study and their dielectric constants[15] were as follows: chloroform, 4.7; Chlorobenzene, 5.6; 1,1,1-Trichloroethane, 7.1; 1,1,2-Trichloroethane, 7.1; 1,1,2,2-tetrachloroethane, 8.0; Dichloromethane, 9.1 and 1,2-Dichloroethane, 10.5.

Measurements of Salt Flux and Distribution Coefficient. The salt flux was measured in a previously reported dialysis cell.[14] The cell comprised 3 compartments separated from each other by a Visking dialysis membrane (the membrane area was 6.6 cm^2, the thickness of each compartment was 3 mm; the source phase solution, membrane phase solution, and pure water of the receiving phase solution were circulated from respective reservoirs by using tubing pumps at a rate of about 15 cm^3 min^{-1}). The receiving phase solution was collected at regular time intervals and its concentration was measured by an atomic absorption spectrophotometer (Shimadzu AA-630-02). The salt flux was calculated from the concentration change with time in the receiving phase and was given in units of mol cm^{-2} min^{-1}. The distribution coefficient was measured with a cell (the same as that of a dialysis cell, except that the cell has only two compartments: a source phase compartment and a membrane phase compartment). A membrane phase solution of 0.10 cm^3 was collected at regular time intervals; each solution was diluted with both 0.9 cm^3 acetonitrile and 0.1 cm^3 pure water, and the metal concentration in it was measured using an atomic absorption spectrophotometer. Standard solutions for this determination were also prepared with the same type acetonitrile-water solution. The distribution coefficient was calculated from the salt activities in the membrane phase and in the salt solution during equilibrium.

Measurement of Membrane Potential. The membrane potential was measured with a cell (the same as that of the dialysis cell, except that both sides of the cell were bored and a salt bridge was set at the vicinity of the each outside surface

of the liquid membrane). Circulating the salt solution, the membrane phase solution, and the receiving phase solution with tubing pumps, the membrane potential was measured using a potentiometer (Toa IM-20E) connected to a recorder (Yanagimoto YR-101). The potential changed with time; after an appropriate time it approached a constant value, from which the ion mobility ratio, u_+/u_- or u_-/u_+, was calculated with

$$E = (u_+ - u_-)/(u_+ + u_-) \times RT/F \times \ln a_s/a_r. \quad (1)$$

Here, u_+ and u_- are the mobilities of the cation and anions; R, T, and F are the gas constant, absolute temperature, and the Faraday constant; and a_s and a_r are the salt activities of the source phase solution and the receiving phase solution, respectively.

Results and Discussion

Effects of Salt Activities and Membrane Solvent on Salt Transport. The salt flux depends on the salt activity of the source phase solution. Figures 1 and 2 show the relationship between the permeation characteristics and the salt activity in the cases of liquid membranes of DB18C6 in 1,1,2,2-tetrachloroethane and DB18C6 in chloroform. In the figures, the salt flux, the distribution coefficient, and the salt flux across the liquid membrane containing no carrier are shown together. These permeation characteristics depending on the salt activity can be expressed by the following equations. The distribution coefficient of the salt between the membrane phase and the source or receiving phase, k, is

$$k = a_m/a, \quad (2)$$

where a_m and a are the salt activity in the liquid membrane and that in the source or receiving phase, respectively. The salt flux, J_s, can be expressed by

$$J_s = D_s/l \times (a_{m,s} - a_{m,r}), \quad (3)$$

where D_s is the diffusion coefficient, l is the membrane thickness, and $a_{m,s}$ and $a_{m,r}$ are the activity at the liquid membrane interface adjacent to the source phase solution and that adjacent to the receiving phase solution. If the salt activity of the receiving phase is much lower than that of the feed solution, $a_{m,r}$ becomes much smaller than $a_{m,s}$ and can be ignored. Using Eq. 2, the salt flux in Eq. 3 therefore becomes

$$J_s = D_s/l \times a_{m,s} = D_s ak/l. \quad (4)$$

The crown ether compex is considered to be formed in the liquid membrane phase from the crown ether and the ion pair to be formed in the aqueous phase and distributed to the membrane phase. The formation constant of the ion pair, K_i, is

$$K_i = a_i/a^2, \quad (5)$$

and the distribution coefficient of the ion pair, D_i is

$$D_i = a_{i,m}/a_i. \quad (6)$$

Here, a_i and $a_{i,m}$ are the activity of the ion pair in the aqueous phase and that in the membrane phase, respectively. The salt flux and the distribution coefficient can be correlated with the salt activity in the source phase solution with these equations. For a derivation of the salt flux and the distribution coefficient, the total carrier activity, L_T and the formation constant of the crown ether complex in the liquid membrane phase, K_c can be defined as follows:

$$L_T = L + a_L, \quad (7)$$

and

$$K_c = a_L/(a_{i,m} \times L). \quad (8)$$

Here, L and a_L are the activities of the free crown ether and that of the complex in the liquid membrane phase. Then, a_m is correlated with $a_{i,m}$ and a_L as

$$a_m = a_{i,m} + a_L. \quad (9)$$

If $a_{i,m}$ can be ignored compared to a_L, the distribution coefficient, k, becomes

$$k = a_m/a = a_L/a. \quad (10)$$

From these equations, k can be derived as a function of the salt activity of the source phase solution as

$$k = K_{ex}L_T a/(1 + K_{ex}a^2), \quad (11)$$

where K_{ex} is an extraction coefficient defined by

$$K_{ex} = a_L/(a^2L) = K_c K_i D_i. \quad (12)$$

From Eqs. 4 and 12, the salt flux, J_s, can be derived as

$$J_s = D_s K_{ex} L_T/1 \times a^2/(1 + K_{ex}a^2). \quad (13)$$

This is the same equation reported by Reusch and Cussler.[6] In Fig. 1, both the distribution coefficient and the salt flux increased enormously with the salt activity when the salt activity was lower than 0.1 mol dm^{-3} (while the distribution coefficient was initiated to decrease and the salt flux became constant when the activity was higher than 0.1 mol dm^{-3}). These permeation phenomena can be expected from Eqs. 11 and 13. When the value of $K_{ex}\ a^2$ becomes much lower than 1 (that is, the salt activity becomes very low), Eqs. 11 and 13 can be transformed into

$$k = K_{ex}L_T a, \quad (14)$$

and

$$J_s = D_s K_{ex} L_T a^2/1, \quad (15)$$

where k and J_s are proportional to the first power and the second power of the salt activity, respectively. When the value of $K_{ex}\ a^2$ becomes much higher than 1 (that is, the salt activity becomes very high), Eqs. 11 and 13 can be transformed into

$$k = L_T/a, \quad (16)$$

and

$$J_s = D_s L_T/1, \quad (17)$$

where k is proportional to the reciprocal of the salt activity and J_s is constant.

In the figure, the salt flux through a liquid membrane containing no carrier is also shown. By using Eqs. 2—6, the flux can be expressed as

$$J_s = D_s D_i K_i a^2/1. \quad (18)$$

The salt flux, J_s, is derived to be proportional to the second power of the salt activity in this equation; however, in Fig. 1 this is true only in a high activity range and the J_s becomes a constant with a decrease in the salt activity. The transport of salt in a low-activity range may be mainly caused by leakage through the membrane; This is probably due to the microquantity of the microvolume droplets of water dispersed in the membrane. By comparing Eq. 15 and Eq. 18, the J_s ratio of Eq. 15 to Eq. 18 is found to be $K_c L_T$ when the diffusion coefficient of the crown complex can be assumed to be almost the same to that of the ion pair. As L_T is 0.1 mol dm^{-3}, K_c can be estimated to be about three orders of magnitude from Fig. 1.

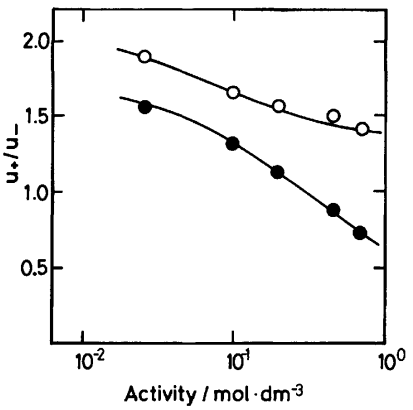

Fig. 3. Effect of salt activity on mobility ratio. Liquid membrane:0.1 mol dm^{-3} DB18C6 in 1,1,2,2-tetrachloroethane (●), chloroform (○). Ratio of salt (KNO_3) concentration: 10 to 1. The abscissa show the activity of the solution of the higher concentration side.

The salt transport characteristics depend not only on the salt activities, but also on many other conditions, such as cation species, anion species, and membrane solvents.[16,17] Figure 2 shows the effect of the salt activity on the salt flux and the distribution coefficient in a different membrane solvent, chloroform membrane containing DB18C6. In this case, the salt fluxes were smaller than those given in Fig. 1 and the dependency of the distribution coefficient on the salt activity was very small; However, the difference between the magnitude of the carrier-mediated transport in this case and that in Fig. 1 was especially small in the range of high salt activity. The independence of the distribution coefficient on the activity can not be explained on the basis of the theory described above. It is reported that in the case of chloroform the solubility of DB18C6 is high but decreases enormously by complexing[1] since the complex is more hydrophilic than DB18C6 alone and chloroform is a hydrophobic solvent. This may be the reason for the low and constant distribution coefficient. Although the distribution coefficient is constant, the ratio of the flux of the complex to that of the ion pair was larger than that in the case of Fig. 1 and must have been caused by a high formation constant of the DB18C6 complex in the hydrophobic solvent, chloroform.

In order to clarify the reason for the effect of the activity on the salt flux and the difference of the effect between the case of 1,1,2,2-tetrachloroethane and the case of chloroform, the mobility ratio of the cation to anion in the liquid membrane phase was measured; values were shown in Fig. 3. When the cation is more

stable than the anion and the permeability of the cation is larger than that of the anion in the membrane phase, the value of u_+/u_- becomes larger than 1. The cations complexed with crown ether, whose hydrophobic group was arranged outside of it, were more stable than naked anions, and the mobility ratio became greater than 1 (with some exceptions). In the case of the 1,1,2,2-tetrachloroethane solution, the values of u_+/u_- decreased with an increase in the salt activity and became smaller than 1 for a high salt activity. In the case of the chloroform solution, the values of u_+/u_- were constant, except within a low salt activity range and were higher than those of a 1,1,2,2-tetrachloroethane solution. These differences between two membrane solvents are considered to be caused by differences in the hydrophobicity of the solvent. The ratio was higher for chloroform than for 1,1,2,2-tetrachloroethane since chloroform is more hydrophobic than 1,1,2,2-tetrachloroethane. In 1,1,2,2-tetrachloroethane, the naked anions were more stable than in chloroform and their stability increased with the ionic strength of the aqueous solution on either side of the membrane.

The relationship between u_+/u_- and the dielectric constant is shown in Fig. 4 in order to investigate the effect of the hydrophobicity of the membrane solvent using chlorinated hydrocarbons for the membrane solvents. As predicted in the prior paragraph, the mobility ratio of the complexed cation to that of the naked anion increased with an increase in the hydrophobicity of the membrane solvent; also, the mobility ratio decreased, on the whole, with an increase in the dielectric constant (an indication of the hydrophilicity of the solvent).

Selective Transport of Salts. The relationship between the salt flux or the distribution coefficient and the ion radius for alkaline cations is shown in Fig. 5 in order to investigate the mechanism of the selective transport. The distribution coefficient is maximum for potassium ions since the stability constant of a DB18C6 complex is maximum for potassium ions in alkaline metal ions.[1] The value of lithium was not plotted in this figure because its concentration in the membrane phase was very low and could not be detected. The salt flux changes with a change in the distribution coefficient and the flux was also maximum for potassium salt. The salt flux through the liquid membrane with no carrier was also measured. This transport was caused by a concentration difference of ion pairs in the membrane without a carrier. Since the hydrophobicity of the ions increases with an increase in the cation radius and hydrophobic ions are easy to be transported in a hydrophobic membrane,[18,19] the flux of ion pairs increased with an increase in the ion radius. The relationship between the salt flux or the distribution coefficient and the lyotropic number[20] of anions is also shown in Fig. 6. The

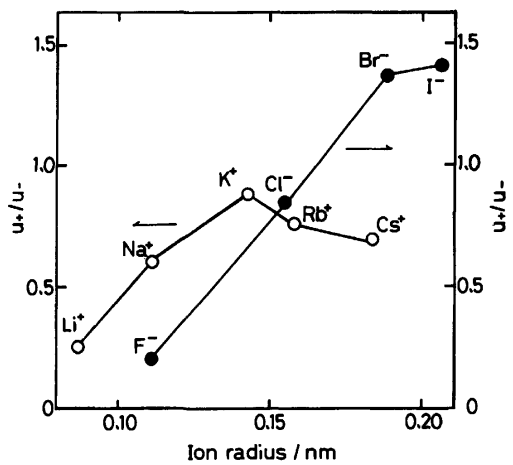

Fig. 7. Mobility ratio vs. ion radius.
Liquid membrane: 0.1 mol dm^{-3} DB18C6 organic soln. Salt concentration: 0.1—0.01 mol dm^{-3}. Counter anion is NO_3^-. Counter cation is K^+.

salt flux through a membrane containing DB18C6 as a carrier can be related well to the lyotropic number (as in the case of anion chromatography on silica gel coated with crown ether polymer;[21] Lamb et al. related the salt transport phenomena to the dehydration energies of anions).[22] The salt flux through a membrane containing no carrier also increased with increasing lyotropic number, but the degree was much smaller for the latter than for the former. The distribution coefficient increased with the salt activity in the same manner as the salt flux. Figure 7 shows the relationship between u_+/u_- and cation radius for the salt of alkaline metal ions and that between u_-/u_+ and anion radius for halogenide ions. The ratio of the mobility of a cation to that of NO_3^- was maximum for potassium ions (all the values were lower than 1). In anions, the mobility ratios increased with an increase in the anion radius and the mobilities of Br^- and I^- were much higher than that of a complexed potassium ion. It is clear that the selectivity for anions was caused by the hydrophobicity of the ions and that for cations was mainly caused by the selective complexation of DB18C6.

Nonstoichiometry and Electrical Resistivity in Two Mixed Metal Oxides, La_2NiO_{4-x} and $LaSrNiO_{4-x}$

Kenji Ishikawa,* Shin-ichi Kondo, Hirofumi Okano, Shigenori Suzuki, and Yasuo Suzuki
Department of Industrial Chemistry, Faculty of Engineering, Meiji University, Higashi-mita, Tama-ku, Kawasaki 214
(Received November 7, 1986)

Two mixed oxides, La_2NiO_{4-x} and $LaSrNiO_{4-x}$, had the K_2NiF_4 structure in the oxygen-pressure range from 58000 down to 130 Pa at 1173 K. The oxygen-vacancy concentration, x, in both La_2NiO_{4-x} and in $LaSrNiO_{4-x}$ at 1173 K was determined by thermogravimetric analysis in the oxygen-pressure range from 58000 to 1.3 Pa. The vacancy concentration of $LaSrNiO_{4-x}$ was greater than that of La_2NiO_{4-x} at the same oxygen pressure at 1173 K. The electrical resistivities of La_2NiO_{4-x} and $LaSrNiO_{4-x}$ were measured at 473—1173 K under an oxygen atmosphere at 98—58000 Pa. The density of the state and the drift mobility of oxygen stoichiometric La_2NiO_4 and $LaSrNiO_4$ were estimated from the resistivity data and from the results on the thermogravimetric analysis.

The mixed oxide La_2NiO_4, which was first prepared by Kniga and Zaretskaya,[1] has the very attractive property of a "gradual" semiconductor-metal transition.[2-4] Goodenough et al.[5-7] have previously proposed an invaluable band model which gives the origin of the semiconductor-metal transition of La_2NiO_4. The model, however, does not clearly explain why the transition proceeds "gradually."[8] It seemed that it would be worthwhile from the electrochemical point of view to elucidate the driving force of the "gradual" semiconductor-metal transition of La_2NiO_4.

Recently, Rao et al.[9] have reported on the resistivity and the magnetic susceptibility of a single crystal of La_2NiO_4. They have found a very large positive coefficient of temperature, an irreversible transition, in the resistivity curve of La_2NiO_4 at 550 K. It was presumed that the irreversible transition was attributable to the effect of strain, crystal distortion, charge density waves, or nonstoichiometry. Their finding of the irreversible transition raised the question that the "gradual" semiconductor-metal transition of La_2NiO_4 might be related to the nonstoichiometry, particularly to that of the lattice oxygen.

By the way, the analogous compound, $La_{2-x}Sr_xNiO_4$, has also been reported to exhibit the "gradual" semiconductor-metal transition.[3,10] The temperature dependence of the electrical resistivity and the transport property of $La_{2-x}Sr_xNiO_4$ have previously been measured by the present authors under an inert atmosphere,[8] though the effect of oxygen deficiency on the electrical resistivity was not considered.

In this study, the effect of the oxygen vacancy on the electrical resistivity of $La_{2-x}Sr_xNiO_{4-y}$, especially on the resistivity of La_2NiO_{4-y} (x=0) and on that of $LaSrNiO_{4-y}$(x=1), was investigated at various temperatures and oxygen pressures.

Experimental

Preparation. The two oxides, La_2NiO_{4-x} and $LaSrNiO_{4-x}$, were prepared by heating stoichiometric mixtures of La_2O_3 (Shin-etsu Chem. Ind. Co., Ltd.; 99.9%), $SrCO_3$ (prepared from reagent-grade $Sr(NO_3)_2$), and NiO (Kojundo Kagaku Co., Ltd.; 99.99%) in air at 1433 K for 25 h.

Electrical Resistivity Measurement. A sintered sample, 5 mm^2 in cross section and 5 mm long, was heated in 58000 Pa of oxygen at 1173 K for 2 h in a measurement cell before the resistivity measurements. The electrical resistivity of the sample was immediately measured in the same cell with the four-prove method in 98—58000 Pa of oxygen at 473—1173 K after preheating.

Thermogravimetric Analyses. The oxygen-vacancy concentrations, x, in La_2NiO_{4-x} and in $LaSrNiO_{4-x}$ were determined by thermogravimetric analyses. A powdered sample (about 5 g) was preheated in 58000 Pa of oxygen at 1173 K for 5 h; it was then weighed at room temperature to an accuracy of 0.01 mg. The sample was heated again at the prescribed oxygen pressure at 1173 K for 5 h and then weighed at room temperature. The oxygen vacancy concentration of a sample was evaluated from the weight and the weight loss of the sample. The vacancy content, x, was calculated from this equation:

$$x = \frac{\Delta W \times M(La_2NiO_4 \text{ or } LaSrNiO_4)}{W \times M(O)}, \quad (1)$$

where W was the weight of the sample after preheating, ΔW was the weight loss of the sample during the heating process, $M(La_2NiO_4$ or $LaSrNiO_4)$ was the formula weight of La_2NiO_4 or $LaSrNiO_4$, and $M(O)$ was the atomic weight of oxygen. It was conveniently assumed for the calculation of x that La_2NiO_{4-x} an $LaSrNiO_{4-x}$ have very few oxygen vacancies, x=0, after preheating.

Results and Discussion

The crystal structure and the oxygen vacancy concentration of La_2NiO_{4-x} and $LaSrNiO_{4-x}$ are summarized in Table 1. The La_2NiO_{4-x} oxide was stable in oxygen down to 140 Pa at 1173 K, but was decomposed to some complex materials in vacuo (7 Pa) at the same temperature, while the $LaSrNiO_{4-x}$ oxide was stable to 1 Pa of oxygen at 1173 K.

The electrical resistivities of La_2NiO_{4-x} and $LaSrNiO_{4-x}$ were measured in the oxygen pressure range from 58000 to 100 Pa (Figs. 1 and 2). The resistivities of La_2NiO_{4-x} and $LaSrNiO_{4-x}$ are not oxygen-pressure-dependent below 581 K, but they decrease with an increase in the oxygen pressure over 673 K. The irreversible transition at 550 K found by Rao et al.[9] was not observed in the resistivity curves of La_2NiO_{4-x} in Fig. 1. The resistivity data in Fig. 1 also show that the electrical resistivity of La_2NiO_{4-x} is not

a) Oxygen pressure. b) Decrease in weight of the sample during the heating process in oxygen at 1173 K. c) x in La_2NiO_{4-x} or x in $LaSrNiO_{4-x}$ (see. Eq. 1).

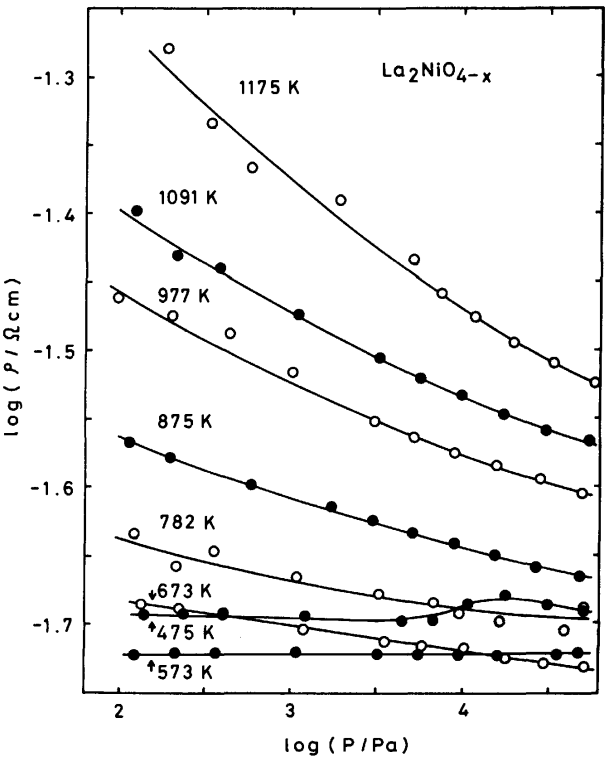

Fig. 1. Oxygen pressure dependence of electrical resistivity for La_2NiO_{4-x}.

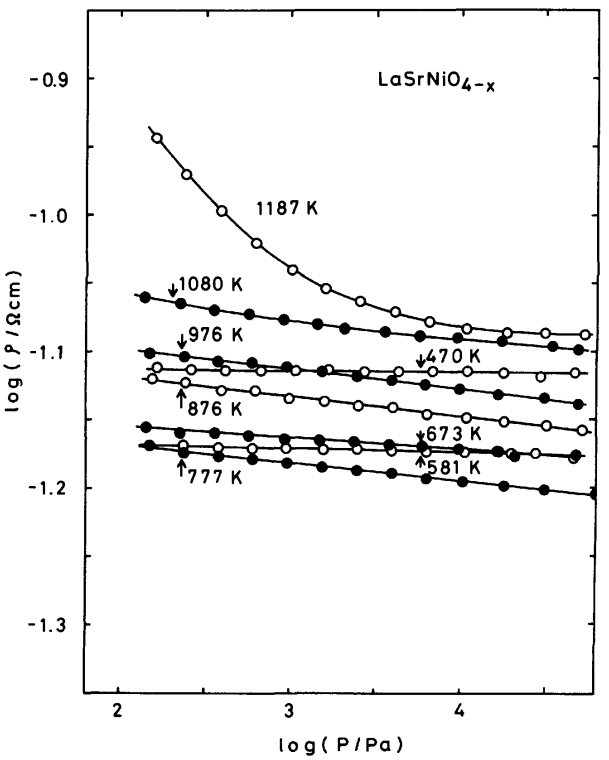

Fig. 2. Oxygen pressure dependence of electrical resistivity for $LaSrNiO_{4-x}$.

oxygen-pressure dependent at 550 K. The irreversible transition by Rao et al. would not be related to the stoichiometry of oxygen of the sample if the resistivity measurements had been performed under an atmosphere containing 100 Pa or more of oxygen.

Figures 1 and 2 show that the slopes in the resistivity curves of La_2NiO_{4-x} and $LaSrNiO_{4-}$ are negative over 673 K. Both La_2NiO_{4-x} and $LaSrNiO_{4-x}$ are p-type conductors in this temperature range. The slope of La_2NiO_{4-x} (Fig. 1) is much larger than that of $LaSrNiO_{4-x}$ (Fig. 2) at the same temperature.

Figure 3 shows the temperature dependence of the electrical resistivities for La_2NiO_{4-x} and $LaSrNiO_{4-x}$ at 316, 3160, and 31600 Pa of oxygen, where the resistivity plots are based on readings of Figs. 1 and 2. A "gradual" semiconductor-metal transition is observed in the resistivity curves of La_2NiO_{4-x} and $LaSrNiO_{4-x}$ at any oxygen pressure. The resistivity curves in Fig. 3 seem to imply that the release of the lattice oxygen is not responsible for the origin of the appearance of the

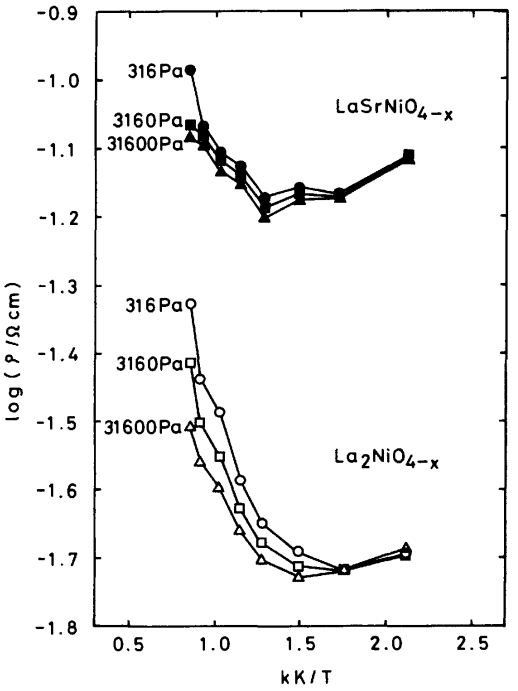

Fig. 3. Temperature dependence of electrical resistivity for La_2NiO_{4-x} and for $LaSrNiO_{4-x}$.

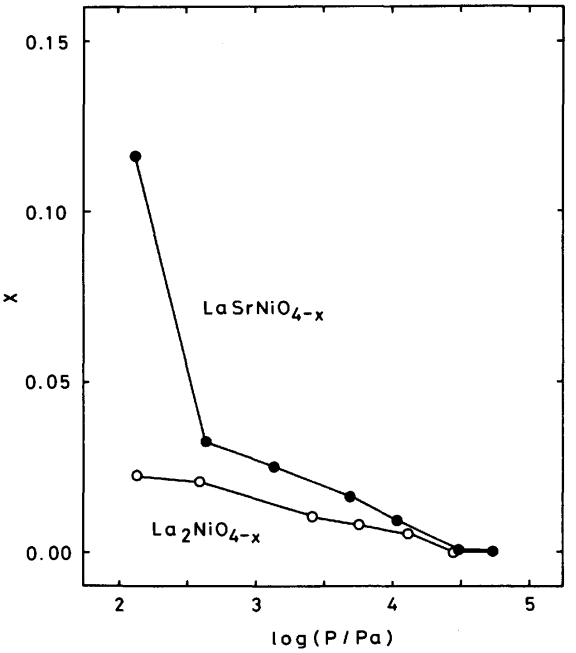

Fig. 4. Oxygen pressure dependence of oxygen content x for La_2NiO_{4-x} and for $LaSrNiO_{4-x}$.

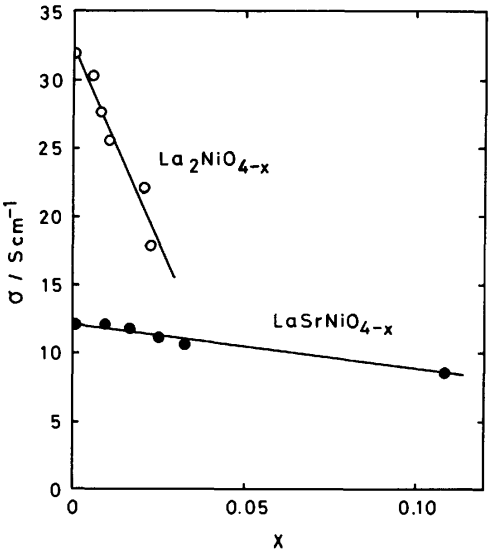

Fig. 5. Oxygen content dependence of electrical conductivity for La_2NiO_{4-x} and for $LaSrNiO_{4-x}$.

"gradual" semiconductor-metal transition. The transition temperature is, however, apparently affected by the atmospheric oxygen pressure, for the transition point is shifted to a higher temperature with the increase in the oxygen pressure.

The oxygen-pressure dependence of the oxygen-vacancy concentration of La_2NiO_{4-x} and $LaSrNiO_{4-x}$ is given in Fig. 4. The x values, the oxygen-vacancy concentration, of La_2NiO_{4-x} and $LaSrNiO_{4-x}$ are almost equal to 0.00 at $\log(P/\mathrm{Pa})=4.5$ and 4.8. The x value of La_2NiO_{4-x} is greater than that of $LaSrNiO_{4-x}$ at the same oxygen pressure at 1173 K. The lattice oxygen of $LaSrNiO_{4-x}$ is much easily released from the bulk than that of La_2NiO_{4-x}.

Figure 5 shows the electrical conductivity vs. the oxygen vacancy concentration plots of La_2NiO_{4-x} and $LaSrNiO_{4-x}$ at 1173 K. The density of the charge carriers of $LaSrNiO_4$ should be larger than that of La_2NiO_4 at 1173 K, as the slope of the conductivity curve of La_2NiO_{4-x} is larger than that of $LaSrNiO_{4-x}$.

For obtaining the density of the charge carriers of oxygenical-stoichiometric La_2NiO_4 and $LaSrNiO_4$, the data were treated as follows. In general, the electrical conductivity, σ, of a compound can be written as:

$$\sigma = ne\mu, \tag{2}$$

where n is the density of the charge carriers and where μ is the drift mobility. If (the density of the charge carriers) n is divided into two densities, that is, the electronic density at the stoichiometric oxygen composition, n_0, and the density produced from the oxygen vacancy, n_v, the electrical conductivity of the compound will be altered thus:

$$\begin{aligned}\sigma &= (n_0 + n_V)e\mu \\ &= (n_0 e\mu) + (e\mu)n_V.\end{aligned} \tag{3}$$

In the case of La_2NiO_{4-x} and $LaSrNiO_{4-x}$, the electronic density, n_v, is written as:

$$\begin{aligned}n_V &= \frac{Ax}{V(La_2NiO_{4-x} \text{ and } LaSrNiO_{4-x})} \\ &= \frac{AZx}{a_0^2 c_0},\end{aligned} \tag{4}$$

where A is a constant of 1 or 2, x is the x in La_2NiO_{4-x} or $LaSrNiO_{4-x}$, $V(La_2NiO_{4-x}$ or $LaSrNiO_{4-x})$ is the lattice volume[10,11], Z is the crystallographic Z value

(which is 2 in the case of La_2NiO_4 and $LaSrNiO_4$), and a_0 and c_0 are the lattice constant at room temperature (a_0=0.38617 nm, c_0=1.2683 nm for La_2NiO_{4-x}[11] and a_0=0.3821 nm, c_0=1.2550 nm for $LaSrNiO_{4-x}$[10]).

In the case of the electron conduction, the A constant is unity when a neutral oxygen vacancy, which is formed by the transfer of an oxygen on a normal site to the gaseous state, donates only one electron to the conduction band:

$$V_O^X \rightleftharpoons V_O^{\cdot} + e'. \quad (5)$$

The A constant is 2 when the vacancy gives two electrons to the band[12]:

$$V_O^X \rightleftharpoons V_O^{\cdot\cdot} + 2e', \quad (6)$$

but A is −1 (Eq. 5) or −2 (Eq. 6) in the case of hole conduction.

The electrical conductivity of La_2NiO_{4-x} or $LaSrNiO_{4-x}$, therefore, can be expressed as:

$$\sigma = (n_0 e\mu) + \frac{AZxe\mu}{a_0^2 c_0}. \quad (7)$$

The electrical conductivity vs. x plot in Fig. 5 show that the conductivities of La_2NiO_{4-x} and $LaSrNiO_{4-x}$ decrease linearly with the increase in x, as is to be expected from Eq. 7. This result supports the validity of the assumption at the induction of Eq. 7 that is, Eqs. 3 and 4. The negative slopes in the conductivity curves imply that the holes are charge carriers of La_2NiO_{4-x} and of $LaSrNiO_{4-x}$ ($A<0$).

The drift mobility, μ, and the density of the holes, n_0, of oxygen stoichiometric La_2NiO_4 or $LaSrNiO_4$ are given from the slope and the intercept of the conductivity line in Fig. 5 by applying Eq. 7. The results are tabulated in Table 2. Unfortunately, the calculated values of n_0 and μ have some equivocality, as it is difficult to determine from the conductivity data where A is −1 or where it is −2. Thus, n_0 and μ were calculated in two ways, namely, in the cases of A=−1 and −2.

The drift mobility of La_2NiO_4 is significantly larger than that of $LaSrNiO_4$. However, the density of the charge carriers of $LaSrNiO_4$ is much greater than that of La_2NiO_4. Table 2 shows that the 0.056—0.112 electron for La_2NiO_4 and the 0.38—0.76 electron for $LaSrNiO_4$ are in a formula.

Goodenough's model for La_2NiO_4[5-7] suggests that the electronic density of a state is not so high at the top of the conduction band of La_2NiO_4 in the metallic state. The observed value of the density, n_0, was 5.9—11.9×10^{20} cm^{-3}, as is shown in Table 2.

The $LaSrNiO_4$ oxide has the same crystal structure as La_2NiO_4. If the band structure of $LaSrNiO_4$ is the same as that of Goodenough's model for La_2NiO_4 and if $LaSrNiO_4$ has fewer conduction electrons than $LaSrNiO_4$ by one electron a formula, one hole must exist in $LaSrNiO_4$. Table 2 indicates that the number of holes in $LaSrNiO_4$ is somewhat smaller than the expected value of one. This result may imply that a few holes are not free in the conduction band of $LaSrNiO_4$.

Table 2. Drift Mobilities and Densities of State for La_2NiO_4 and $LaSrNiO_4$ at 1173 K

Formula	A[a]	μ(drift)[b]	n_0[c]	Electrons
		$cm^2 V^{-1} s^{-1}$	10^{20} cm^{-3}	Formula
La_2NiO_4	−1	0.34	5.9	0.056
	−2	0.17	11.9	0.112
$LaSrNiO_4$	−1	0.018	41.3	0.38
	−2	0.0091	82.6	0.76

a) "A" is a constant in Eq. 7

$$O \rightleftarrows V_O^X + 1/2O_2$$

$$A=\pm 1: V_O^X \rightleftarrows V_O^{\cdot} + e'$$

$$A=\pm 2: V_O^X \rightleftarrows V_O^{\cdot\cdot} + 2e'$$

b) Drift mobility. c) Density of state.

Paramagnetic Cobalt(III) Complexes with Organic Ligands. X.[1] The Preparation and Properties of Radical Diamminebis-(5-nitrosalicylideneaminato)cobalt(III) Complex and Biradical Diamminebis(5-nitrosalicyl-ideneaminato)cobalt(II) Complex

Yoshihisa YAMAMOTO* and Hidetaka KONNO†
Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University, Ishikari-Tobetsu, Hokkaido 061-02
†Faculty of Engineering, Hokkaido University, Sapporo 060
(Received July 11, 1986)

From the reaction mixture of diamminebis(salicylideneaminato)cobalt(III) complex, [Co()$_2$(NH$_3$)$_2$]Cl·H$_2$O (**1**) and 60% nitric acid, radical diamminebis(5-nitrosalicylideneaminato)-cobalt(III) complex, [Co()$_2$(NH$_3$)$_2$]Cl·NO$_3$·2H$_2$O (**2**), and biradical diamminebis(5-nitrosalicylideneaminato)cobalt(II) complex, [Co()$_2$(NH$_3$)$_2$]Cl·NO$_3$·2H$_2$O (**3**), have been isolated and characterized by analytical, magnetic, spectroscopic, and XPS methods. The effective magnetic moments of **2** and **3** were 1.7 and 5.5 BM, respectively. In the IR spectrum of **2**, a band due to the rocking deformation vibration of NH$_3$ was observed at ca. 840 cm^{-1}. The absorption spectra of **2** and **3** showed a strong absorption peak at ca. 690 nm. In the XPS, Co 2p spectra for **3** showed strong satellites, indicating the oxidation number of the cobalt to be +2, whereas no satellites were observed for the other complexes. In comparison with diamagnetic cobalt(III) complex, [Co()$_2$(NH$_3$)$_2$]NO$_3$·H$_2$O (**4**), C 1s spectra for **2** and **3** showed much larger shoulders on the higher binding energy side due to the electron-poor carbons. It suggests the presence of an unpaired spin on ligands in accordance with paramagnetism of the complexes.

Previous paper of this series was concerned with the preparation, properties and electronic state of radical tetraammine(5-nitrosalicylideneaminato)cobalt(III) complex,[2] [Co()(NH$_3$)$_4$]X$_3$ (X$_3$: Cl$_2$·NO$_3$, (NO$_3$)$_3$). The effective magnetic moment is 1.7 BM, suggesting an unpaired spin. An unpaired spin on the complex is not located on the cobalt atom, but is located over the π-orbitals of the chelated ligand of the complex judging from the physicochemical results.

In the same series of experiments, we have already isolated new paramagnetic cobalt complexes from the reaction mixture of 60% nitric acid and diamminebis(salicylideneaminato)cobalt(III) complex, [Co()$_2$(NH$_3$)$_2$]Cl·H$_2$O. However, the explanation of the electronic states of the new complexes was deferred, because the magnetic properties and XPS data were not parallel to those of the radical tetraammine(5-nitrosalicylideneaminato)cobalt(III) complex. In the present paper, we present the electronic state and structure of the new paramagnetic complexes as radical diamminebis(5-nitrosalicylideneaminato)cobalt(III) complex, [Co()$_2$(NH$_3$)$_2$]Cl·NO$_3$·2H$_2$O, and biradical diamminebis(5-nitrosalicylideneaminato)-cobalt(II) complex, [Co()$_2$-(NH$_3$)$_2$]Cl·NO$_3$·2H$_2$O, and report the preparation and properties of them.

Experimental

Measurements. The ^{1}H NMR spectra were recorded with an R-40 apparatus (Hitachi). The IR spectra were recorded in potassium bromide disks with an 270-30 apparatus (Hitachi). The visible absorption spectra were recorded with a Shimadzu UV-210 recording spectrophotometer. The magnetic susceptibilities were measured by the Faraday method using a magnetic balance (Shimadzu) from liq. N$_2$ to room temperature. The electric conductivities of aqueous solutions were determined by the use of a conductometer, CM-30 (Shimadzu) at room temperature. The XPS measurements were carried out in the same manner as described in the previous paper.[2]

Preparation of Complexes. Radical Diamminebis(5-nitrosalicylideneaminato)cobalt(III) Chloride Nitrate Dihydrate (2): Twelve cm^3 of 60% nitric acid were added, drop by drop, to 3 g (7.76 mmol) of trans,trans,trans-diamminebis(salicylideneaminato)cobalt(III) chloride hydrate[5] (**1**). The reaction proceeds with violence. A green crystalline precipitate (complex **2**) was collected by filtration. From the green filtrate, complex **3** (described below) was isolated. The complex **2** on a filter funnel was washed with 60% nitric acid (about 3 cm^3), with acetone and ether, and dried. Yield: 1.42 g (32.9%). Found: C, 30.42; H, 3.43; N, 18.05; Cl, 5.81%. Calcd for CoC$_{14}$H$_{20}$N$_7$O$_{11}$Cl (MW 556.75) C, 30.20; H, 3.62; N, 17.61; Cl, 6.37%. Color: green. D_p=185 °C. Λ=250 S cm^2 mol^{-1} in water. IR spectrum: 1620 cm^{-1} (C=N), 840 cm^{-1}

($\rho_r(NH_3)_r$).

Biradical Diamminebis(5-nitrosalicylideneaminato)cobalt-(II) Chloride Nitrate Dihydrate (3): The green filtrate (described above) was added to acetone-ether (1 : 1) solution and stirred. The green complex **3** thus precipitated was filtered, washed with acetone-ether (1 : 1) solution and with ether, then dried. From the brown filtrate, complex **4** (described below) was isolated. Yield: 1.48 g (34.3%). Found: C, 29.92; H, 3.68; N, 17.23; Cl, 5.08%. Calcd for $CoC_{14}H_{20}N_7O_{11}Cl$ (MW 556.75) C, 30.20; H, 3.62; N, 17.61; Cl, 6.37%. Color: green. D_p=183 °C. Λ=250 S cm^2 mol^{-1} in water. IR spectrum: 1625 cm^{-1} (C=N).

Diamagnetic Diamminebis(5-nitrosalicylideneaminato)-cobalt(III) Nitrate Hydrate (4): The brown colored filtrate (described above) was concentrated and the precipitated brown complex was recrystallized from water. Yield: 0.22 g (5.6%). Found: C, 33.29; H, 3.42; N, 19.65%. Calcd for $CoC_{14}H_{18}N_7O_{10}$ (MW 503.28) C, 33.41; H, 3.61; N, 19.48%. Color: brown. D_p=238 °C. Λ=95 S cm^2 mol^{-1} in water at 50 °C. IR spectrum: 1625 cm^{-1} (C=N), 835 cm^{-1} ($\rho_r(NH_3)_r$). ^{1}H NMR spectrum: The H_5[5] ring proton signal disappeared due to nitration. The H_3, H_4, H_6 ring proton, CH=N and C=NH proton signals were observed at δ 6.79 (d, 2H), 7.96 (dd, 2H), 8.41 (d, 2H), 8.51 (d, 2H), and 11.10 (d, 2H), respectively in DMSO-d_6 solution.

Solubility. Complex **2** is soluble in DMSO, DMF, and slightly soluble in water and 60% nitric acid, but insoluble in the common organic solvents such as alcohols, acetone, and ether. Complex **3** is soluble in DMSO, DMF, water, and 60% nitric acid, and slightly soluble in acetone and methanol, but insoluble in the common organic solvents such as ethanol and ether.

Results and Discussion

Previously, we reported on the preparation, properties, and structure of diamagnetic trans,trans,trans-diamminebis(salicylideneaminato)cobalt(III) chloride hydrate,[5] $[Co(\text{HN=HC-C}_6\text{H}_4\text{-O})_2(NH_3)_2]Cl \cdot H_2O$ (**1**). trans,trans,trans-configuration (abbreviation: t,t,t-) denotes the positions for the two ammine ligands, two phenoxyl groups and two CH=NH groups of the coordinated chelate ligands, respectively.

Radical diamminebis(5-nitrosalicylideneaminato)-cobalt(III) chloride nitrate dihydrate (**2**) and biradical diamminebis(5-nitrosalicylideneaminato)cobalt(II) chloride nitrate dihydrate (**3**) were isolated from a reaction mixture of complex (**1**) and 60% nitric acid.

Radical Diamminebis(5-nitrosalicylideneaminato)-cobalt(III) Chloride Nitrate Dihydrate, $[Co(\text{HN=HC-C}_6\text{H}_3(\text{NO}_2)\text{-O})_2(NH_3)_2]Cl \cdot NO_3 \cdot 2H_2O$ (2): The electric conductivity in an aqueous solution was 250 S cm^2 mol^{-1}. The magnetic susceptibility obeyed the Curie-Weiss law, with effective magnetic moment of 1.7 BM, suggesting the presence of an unpaired spin. A band due to the rocking deformation vibration of the ammine ligand was observed at 840 cm^{-1} in the IR spectrum. This is in the range for Co(III) ammine complexes.[6-10] The ^{1}H NMR spectrum of **2** could not be measured in 1.8 mol dm^{-3} D_2SO_4 solution because of the insolubility.

In the XPS, two N 1s spectra were observed at ca. 400 eV and ca. 406 eV. The lower binding energy peak was separated to two peaks which were assigned to -NH= and NH_3 nitrogens. The higher binding energy peak was also separated into two peaks which were assigned to NO_2 and NO_3 nitrogens[2-4] as shown in Table 1.

Table 1. XPS, Magnetic Moments, and Absorption Spectra of Complexes

Complex No.	Binding energies of electrons, E_B/eV						Magnetic moments μ_{eff}/BM	Curie-Weiss constants θ/K	Absorption bands in 60% nitric acid nm (ε)

a) Relative intensities in % after peak separation. The peak less than 1% was neglected. b) Ref. 2.

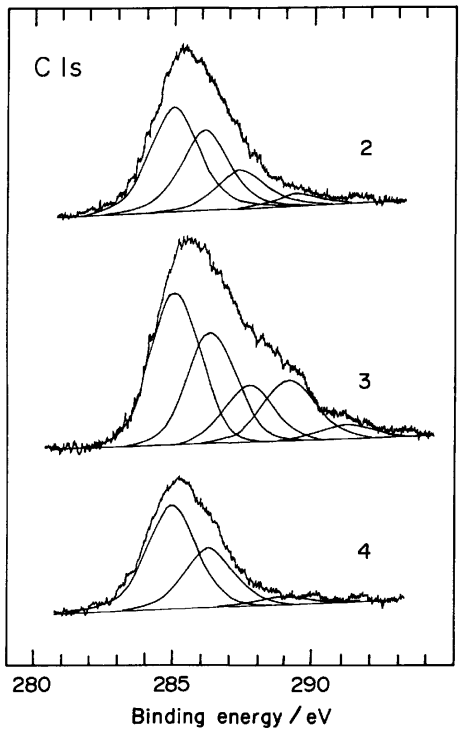

Fig. 1. The XPS in the C 1s region of **2**—**4** complexes.

2: $[Co(\text{HN=HC-C}_6\text{H}_3(\text{NO}_2)\text{-O})_2(NH_3)_2]Cl\cdot NO_3\cdot 2H_2O$,

3: $[Co(\text{HN=HC-C}_6\text{H}_3(\text{NO}_2)\text{-O})_2(NH_3)_2]Cl\cdot NO_3\cdot 2H_2O$,

4: $[Co(\text{HN=HC-C}_6\text{H}_3(\text{NO}_2)\text{-O})_2(NH_3)_2]NO_3\cdot H_2O$.

The C 1s peak was separated into four peaks having a full width at half maximum [FWHM] of 2.1 eV. The peaks that appeared in the higher binding energy region are assigned to electron-poor carbons relative to normal ring carbons at 285.0 eV. As is shown in Fig. 1 and Table 1, the proportion of the electron-poor carbons in the higher binding energy region relative to normal carbons is larger than that of the corresponding diamagnetic cobalt(III) nitrate hydrate, $[Co(\text{HN=HC-C}_6\text{H}_3(\text{NO}_2)\text{-O})_2(NH_3)_2]NO_3\cdot H_2O$ (**4**). The Co $2p_{3/2}$ peak at 782.1 eV in the XPS does not have satellites. The absorption spectrum showed a strong peak at 700 nm. The above results and the magnetic moment are closely similar to those of the green paramagnetic tetraammine(5-nitrosalicylideneaminato)cobalt(III) chloride nitrate, $[Co(\text{HN=HC-C}_6\text{H}_3(\text{NO}_2)\text{-O})(NH_3)_4]Cl_2\cdot NO_3$ (**5**), previously reported.[2] Thus, an unpaired spin on **2** is not located on the cobalt atom but is located over the chelated ligands. Therefore, complex **2** is a radical cobalt(III) complex such as Scheme 1.

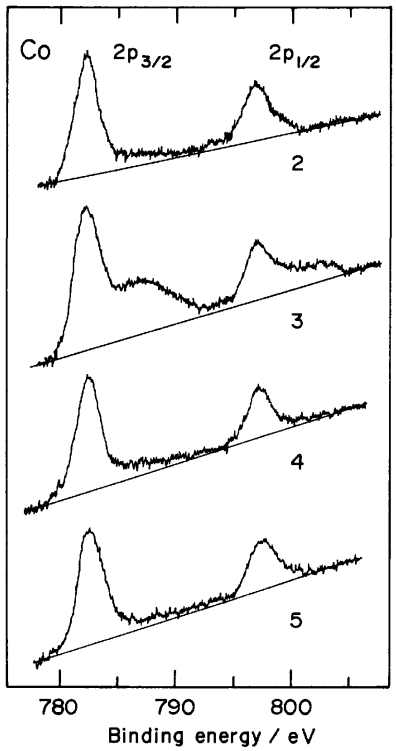

Fig. 2. The XPS in the Co 2p region of **2**—**5** complexes.

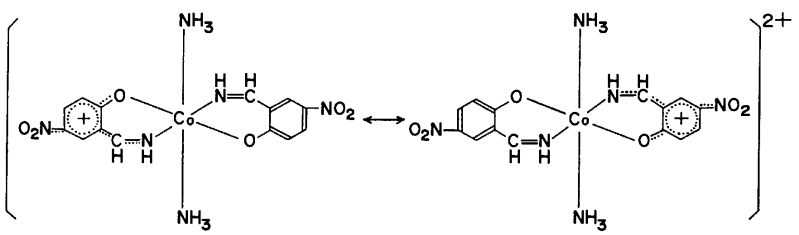
2: $[Co(\text{HN=HC-C}_6\text{H}_3(\text{NO}_2)\text{-O})_2(NH_3)_2]Cl\cdot NO_3\cdot 2H_2O$,

3: $[Co(\text{HN=HC-C}_6\text{H}_3(\text{NO}_2)\text{-O})_2(NH_3)_2]Cl\cdot NO_3\cdot 2H_2O$,

4: $[Co(\text{HN=HC-C}_6\text{H}_3(\text{NO}_2)\text{-O})_2(NH_3)_2]NO_3\cdot H_2O$,

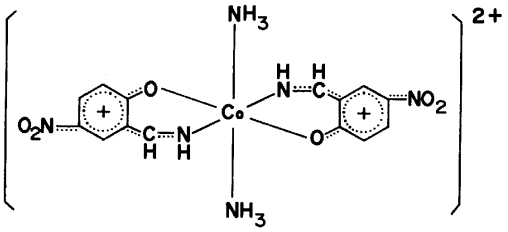
5: $[Co(\text{HN=HC-C}_6\text{H}_3(\text{NO}_2)\text{-O})(NH_3)_4]Cl_2\cdot NO_3$.

Biradical Diamminebis(5-nitrosalicylideneaminato)cobalt(II) Chloride Nitrate Dihydrate, $[Co(\text{HN=HC-C}_6\text{H}_3(\text{NO}_2)\text{-O})_2(NH_3)_2]Cl\cdot NO_3\cdot 2H_2O$ (3): The electric conductivity in an aqueous solution and



Scheme 1.

the analytical results were both similar to those for **2**. However, the results of the magnetic susceptibility, XPS, and absorption spectra were very different from those of **2**. The ^{1}H NMR spectrum of **3** in 1.8 mol dm^{-3} D_2SO_4 solution did not show the signal because of the paramagnetism. The magnetic susceptibility obeyed the Curie-Weiss low, with effective magnetic moment of 5.5 BM, suggesting the presence of five unpaired spins. The Co 2p peaks in the XPS showed strong satellites. This spectrum is very different from those of **2**, **4**, and **5** as shown in Fig. 2. The strong satellites are due to either Co(II) ions or high spin Co(III) ions. A number of Co(II) compounds are reported to show strong satellites in Co 2p spectra.[11-17] As a high spin Co(III) ion, only CoF_3 is reported to show strong satellites.[11,12] A distinction between Co(II) and high spin Co(III) ions is difficult to evaluate from the Co 2p spectrum alone, however, together with the following experimental results, the cobalt in complex **3** is considered to be Co(II). In the C 1s peak, the proportion of the electron-poor carbons in the higher binding energy region relative to a normal carbon is larger than that of complex **2** as shown in Fig. 1. In addition, the absorption peak (ε=12700) at 696 nm due to the unpaired spin[2] on the complex is much stronger than that (ε=6600) of complex **2**. All these results suggest that two unpaired spins are located over the chelated ligand, and three unpaired spins are located on the cobalt atom. Accordingly, complex **3** is considered to be a biradical diamminebis(5-nitrosalicylideneaminato)cobalt(II) complex such as Scheme 2.



Scheme 2.

The results for complex **4** are collected in Table 1 and in the Experimental section.

In the XPS data, the relative peak intensity of C 1s to N 1s did not show larger scattering than ±10% by complexes and for each measurement, indicating that the level of carbonaceous contamination was almost constant (Note that the atomic ratio between carbon and nitrogen is the same for complex **2**—**4**). Quantitative conclusions, however, were not drawn from the XPS data, as, with our data and a calculation system, E_B assignment for each carbon atom could not be performed. The probability that the higher E_B fraction in C 1s spectra is due to shake up phenomena is very low, since the known shake up satellites are observed at least 6 eV higher than the main peak and the intensity is less than 8% that of the main peak.[18] The higher E_B fraction in C 1s spectra increases in the order of complex **4**<**2**<**3**, as is clearly seen in Fig. 1, and no significant differences were observed for the N 1s spectra. Therefore taken together with the magnetic susceptibility and absorption spectra data, it is definite that one electron is missing per one ligand in complex **3**. Probably, it is on the carbon skeleton, but the location or detailed electronic configulations cannot be specified at present.

The Condensation and Decomposition of Phosphoramidates with Acids

Shoji SATO, Takao TAKAYANAGI, and Makoto WATANABE*
Department of Industrial Chemistry, Chubu University, Matsumoto-cho, Kasugai, Aichi 487
(Received July 21, 1986)

Several phosphoramidates were reacted with dried hydrogen chloride, acetic acid, and oxalic acid. The phosphoramidates reacted with the acids to produce ortho- and polyphosphates, but did not react with them to make polyphosphates containing imino groups, with the elimination of ammonia. The decomposition of the phosphoramidates to orthophosphate by the action of water was considered to be the first step in the production of polyphosphates:

$$MO\text{-}\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}\text{-}NH_2 + H_2O \longrightarrow MO\text{-}\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}\text{-}ONH_4,$$

The formation of polyphosphates can be explained, for example, by this equation:

$$MO\text{-}\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}\text{-}ONH_4 + NH_2\text{-}\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}\text{-}OM + 2HA \longrightarrow MO\text{-}\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}\text{-}O\text{-}\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}\text{-}OM + 2NH_4A,$$

where HA stands for acid.

Among phosphorus-nitrogen compounds, the most outstanding may be phosphazene polymers. Many studies have been made of these compounds, while other phosphorus-nitrogen compounds are not very well-known. We have reported on the syntheses and thermal properties of several phosphoramidates during the last few years.[1-6] The phosphoramidates are thought to be useful as new types of chemical fertilizers containing P-N covalent bonds and as flame-proof materials. These phosphoramidates produce ortho- and polyphosphates, but do not produce polyphosphates containing imino groups, when they are heated in air at a moderately high temperature (100—1000 °C). The chemical reactions of the phosphoramidates with inorganic and organic acids were performed in order to study the condensation and decomposition of the amino groups in the phosphoramidates. To prevent the hydrolysis of the phosphoramidates and the reaction products, hydrogen chloride, acetic acid, and oxalic acid were used.

Experimental

Preparation of Phosphoramidates. The phosphoramidic acid monohydrate, ammonium hydrogenphosphoramidate, sodium hydrogenphosphoramidate, potassium hydrogenphosphoramidate, and disodium phosphoramidate hexahydrate were made by the methods described in Reference 7.

Reaction of Phosphoramidates with Hydrogen Chloride. Hydrogen chloride was prepared by adding concentrated hydrochloric acid to concentrated sulfuric acid, and the HCl gas was dried with concentrated sulfuric acid. The dried HCl gas was introduced to a reaction glass-tube containing about 5 g of a phosphoramidate sample. The product was washed quickly with ethanol to remove the HCl gas adsorbed on the product.

Reaction of Phosphoramidates with Acetic Acid. A phosphoramidate sample (about 2 g) was placed in a mixture of 5 cm^3 of acetic acid and 20 cm^3 of chloroform, and the resulting mixture was reacted at 25 and 60 °C while being stirred. The solid product was filtered off and washed with ethanol. In the case of the reaction of disodium phosphoramidate hexahydrate, the reaction mixture was centrifuged and the solid product was washed with ethanol.

Reaction of Phosphoramidates with Oxalic Acid. Oxalic acid (3 g) was dissolved in 100 cm^3 of ethanol, and then a phosphoramidate sample (about 2 g) was added to the solution. The mixture was heated at 25 and 60 °C while being stirred. The solid product was filtered off and washed with ethanol.

Quantitative Analysis of Nitrogen. The amount of total nitrogen and that of ammonium ions in a sample were measured by the Kjeldahl technique.

Paper Chromatography and Colorimetry of Phosphates. A sample was dissolved in water, and the pH of the solution was adjusted to about 7 with an aqueous sodium hydroxide solution if needed. The one-dimensional paper-chromatographic separation and the colorimetric determination of the phosphate species in the solution were done by the method described in our previous paper.[1]

X-Ray Diffractometry. An X-ray diffraction diagram of a sample was taken with nickel-filtered Cu $K\alpha$ radiation using a Rigaku X-ray diffractometer, RAD-1B.

IR Spectrophotometry. An IR spectrum of a sample was recorded on a JASCO IR spectrophotometer, A-3, using the KBr disc method.

^{31}P NMR Measurement. A sample was dissolved in water and the ^{31}P NMR spectrum of the solution was taken by means of a JNM-GX270 spectrograph. The NMR chemical shifts are reported relative to external 85%-orthophosphoric acid, with the positive shifts being downfield.

Results and Discussion

Reaction with Hydrogen Chloride. The data of the chemical compositions of the products are shown in Table 1, along with the X-ray diffraction data. The chromatographic separation between phosphoramidate and orthophosphate could not be performed with the developing solvents used in this experiment. According to the results listed in Table 1, the phos-

SM and UK stand for the starting materials and an unknown substabce respectively.

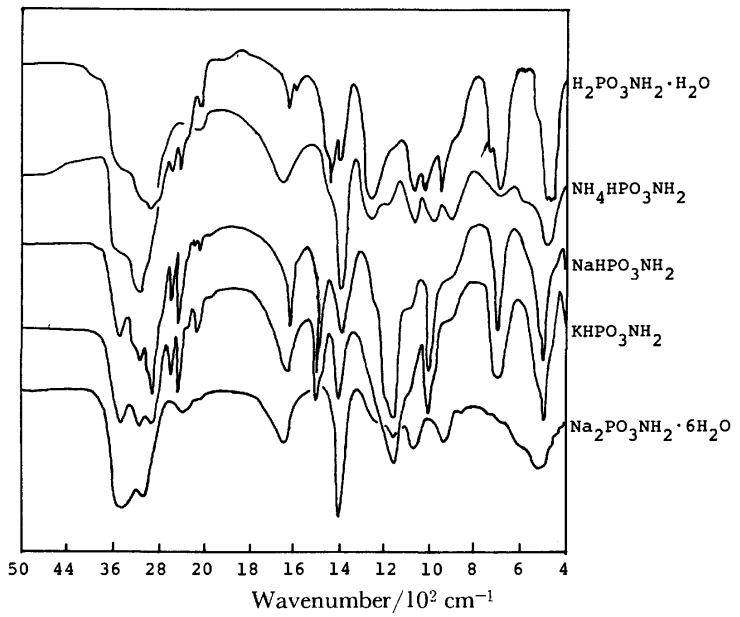

Fig. 1. IR spectra of the reaction products of phosphoramidates with HCl gas for 5 h.

phoramidic acid and phosphoramidates seemed to react with HCl gas to produce ortho- and polyphosphates. The amino group of the phosphoramidates decomposed to ammonia at the same time. The contents of NH_4^+ and polyphosphates increased with the passage of the reaction time in the reactions of $H_2PO_3NH_2 \cdot H_2O$, $NH_4HPO_3NH_2$, and $KHPO_3NH_2$. The IR spectra of the products in Fig. 1 agree well with the results in Table 1. The absorption at 1400 cm^{-1} is due to NH_4^+, while those at about 900 and 700 cm^{-1} are assigned to a P-O-P or a P-N(H)-P linkage respectively. The reaction rate of $KHPO_3NH_2$ was very low; this means that the phosphoramidate is very stable. In the reactions of $NaHPO_3NH_2$ and $Na_2PO_3NH_2 \cdot 6H_2O$, the degradation of polyphosphates to phosphates with shorter chain lengths was observed in addition to the formation of ortho- and polyphosphates. The results in Table 1 and Fig. 1 do

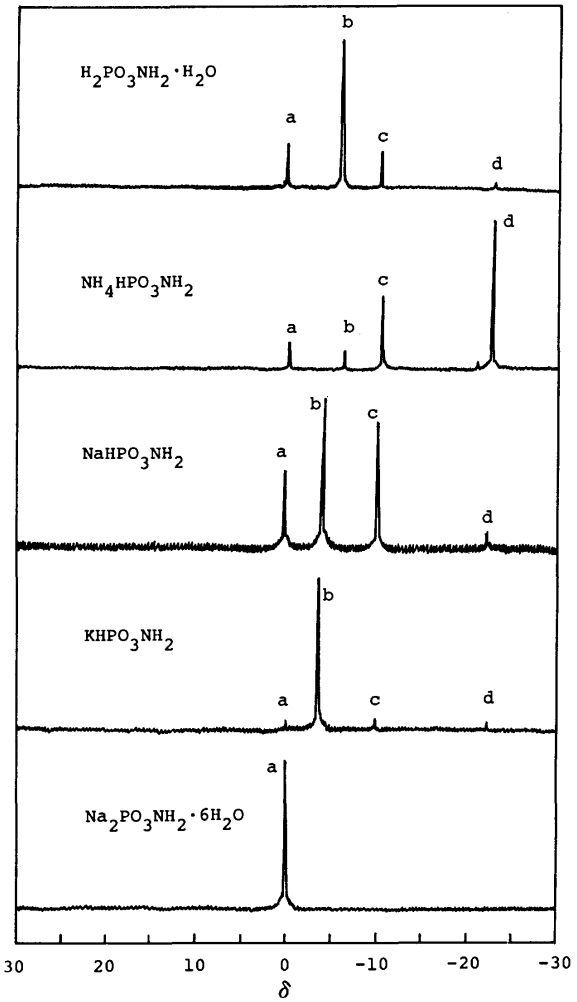

Fig. 2. ^{31}P NMR spectra of the reaction products of phosphoramidates with HCl gas at room temperature for 5 h.
a: Orthophosphate, b: phosphoramidate, c: end-PO_4 group, d: middle-PO_4 group.

not, however, give any information about the formation of a P-N(H)-P linkage. The ^{31}P NMR peaks of the products in Fig. 2 were assigned to phosphoramidate, orthophosphate, and polyphosphates. The NMR data did not give any peak of a compound with a P-N(H)-P linkage. Accordingly, the formation of a P-N(H)-P linkage, with the elimination of ammonia, by the following reaction did not occur in these reaction systems:

$$-\overset{|}{\underset{|}{P}}-NH_2 + NH_2-\overset{|}{\underset{|}{P}}- + HCl \longrightarrow -\overset{|}{\underset{|}{P}}-N(H)-\overset{|}{\underset{|}{P}}- + NH_4Cl. \quad (1)$$

Instead, the reaction processes can be written thus for these reaction systems:

$$MO-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-NH_2 + H_2O \longrightarrow MO-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-ONH_4, \quad (2)$$

$$MO-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-ONH_4 + NH_2-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-OM + 2HCl \longrightarrow$$

$$MO-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-OM + 2NH_4Cl, \quad (3)$$

$$MO-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-OM + NH_2-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-OM + 2HCl \longrightarrow$$

$$MO-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-OM + MCl + NH_4Cl. \quad (4)$$

The phosphoramidate with an OH group is considered to form a zwitterion:[8]

$$MO-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-NH_2 + H_2O(HCl) \longrightarrow$$

$$HO-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-NH_2 + MOH(MCl), \quad (5)$$

$$HO-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-NH_2 \longrightarrow {}^{-}O-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-NH_3^+. \quad (6)$$

The zwitterion is very active and can react with water and phosphates to form ortho- and polyphosphates respectively:

$$^{-}O-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-NH_3^+ + H_2O \longrightarrow HO-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-ONH_4, \quad (7)$$

$$^{-}O-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-NH_3^+ + HO-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-ONH_4 + HCl \longrightarrow$$

$$HO-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-O-\overset{\overset{O}{\|}}{\underset{\underset{M}{O}}{P}}-ONH_4 + NH_4Cl. \quad (8)$$

It is difficult at present to obtain information about the formation of the zwitterion, so it cannot be determined which process is more reasonable for the reaction system. The water in the reactions can come from the crystal water and/or the adsorbed water of the phosphoramidates and a slight amount of water in the gas in the reaction systems. It was difficult to remove the adsorbed water and the water in the gas completely. In the reactions of $NaHPO_3NH_2$ and $Na_2PO_3NH_2 \cdot 6H_2O$, a degradation of polyphosphates to phosphates with shorter chain lengths was observed. Usually this degradation can not take place in a solid state at room temperature. The water contained in the products may be strongly acidic as a result of the dissolution of HCl gas. The hydrolysis

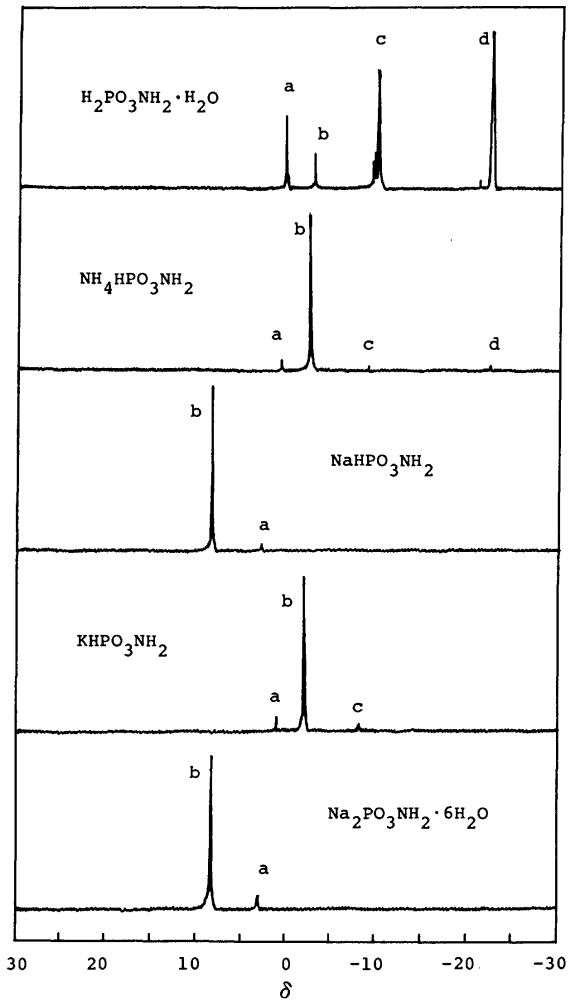

Fig. 3. ^{31}P NMR spectra of the reaction products of phosphoramidates with acetic acid at 60 °C for 25 h. a: Orthophosphate, b: phosphoramidate, c: end-PO_4 group, d: middle-PO_4 group.

of polyphosphates is very much accelerated by an H^+ ion.[9]

Reaction with Acetic Acid. The chemical compositions and X-ray diffraction data of the reaction products at 60 °C are shown in Table 2. The data at 25 °C are not listed because the reaction processes of the phosphoramidates with acetic acid at 25 °C were almost the same as those at 60 °C except for the reaction rates. As Table 2 shows, the reaction rate of the phosphoramidic acid was much faster than those of other phosphoramidates. The ^{31}P NMR spectral data in Fig. 3 support the results in Table 2. The NMR spectra of $NaHPO_3NH_2$ and $Na_2PO_3NH_2 \cdot 6H_2O$ gave a large peak of the amidate and a very small peak of orthophosphate. The NMR spectra of $NH_4HPO_3NH_2$ and $KHPO_3NH_2$ included small peaks of orthophosphate, an end-PO_4 group, and/or a middle-PO_4 group other than the large peak of the phosphoramidate. The NMR spectra of the products of $NaHPO_3NH_2$ and $Na_2PO_3NH_2 \cdot 6H_2O$ were taken by dissolving them in a basic solution (pH 9—10). The peak of phosphoramidate at about −3 — −5 in an acidic solution shifted to about +8.5 in a basic solution. The spectrum of $H_2PO_3NH_2 \cdot H_2O$ exhibited large peaks of orthophosphate, an end-PO_4 group, and a middle-PO_4 group, and a small peak of the phosphoramidic acid. No proof of the presence of imidopolyphosphates was obtained by either the chromatography or the NMR. Therefore, the formation of a P-N(H)-P linkage according to the following reaction did not occur in these systems:

$$\text{-P-NH}_2 + \text{NH}_2\text{-P-} + \text{CH}_3\text{COOH} \longrightarrow \text{-P-N(H)-P-} + \text{CH}_3\text{COONH}_4. \quad (9)$$

Considering the above results, several reaction processes can be written for these systems:

$$\text{MO-P(=O)(O M)-NH}_2 + \text{H}_2\text{O} \longrightarrow \text{MO-P(=O)(O M)-ONH}_4, \quad (10)$$

$$\text{MO-P(=O)(O M)-ONH}_4 + \text{NH}_2\text{-P(=O)(O M)-OM} + 2\text{CH}_3\text{COOH} \longrightarrow \text{MO-P(=O)(O M)-O-P(=O)(O M)-OM} + 2\text{CH}_3\text{COONH}_4, \quad (11)$$

$$\text{MO-P(=O)(O M)-O-P(=O)(O M)-OM} + \text{CH}_3\text{COOH} \longrightarrow \text{MO-P(=O)(O M)-O-P(=O)(O M)-OH} + \text{CH}_3\text{COOM}, \quad (12)$$

Table 3. Compositions of the Reaction Products of Phosphoramidates with Oxalic Acid at 60 °C for 25 h

Phosphoramidates	Total N/%	N/% as NH_4^+	X-Ray dif.	Phosphates/P%			
				Amido and Ortho	Di	Tri	Higher
$H_2PO_3NH_2 \cdot H_2O$	12.3	7.6	SM, UK	22.3	39.0	4.2	34.5

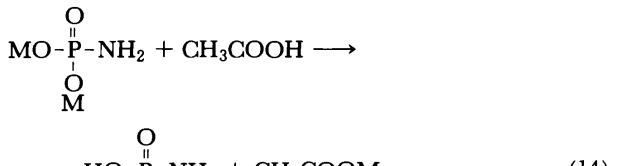
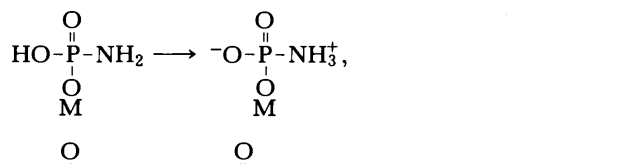
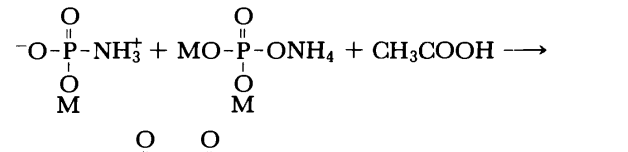
(13)

or



(14)

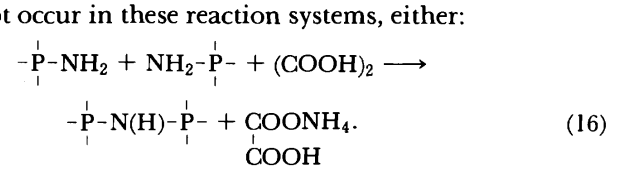




(15)

The water in Eq. 10 can come from crystal water and the adsorbed water of the phosphoramidates. As has been mentioned above, because of the lack of suitable data it is difficult to chose the most reasonable processes for the reaction systems.

Reaction with Oxalic Acid. The data on the chemical composition and the results of the X-ray diffractometry of the products are shown in Table 3, while ^{31}P NMR spectra of the products are presented in Fig. 4. Since the products were ortho- and polyphosphates, while imidopolyphosphates were not produced, the condensation with the elimination of ammonia did not occur in these reaction systems, either:



(16)

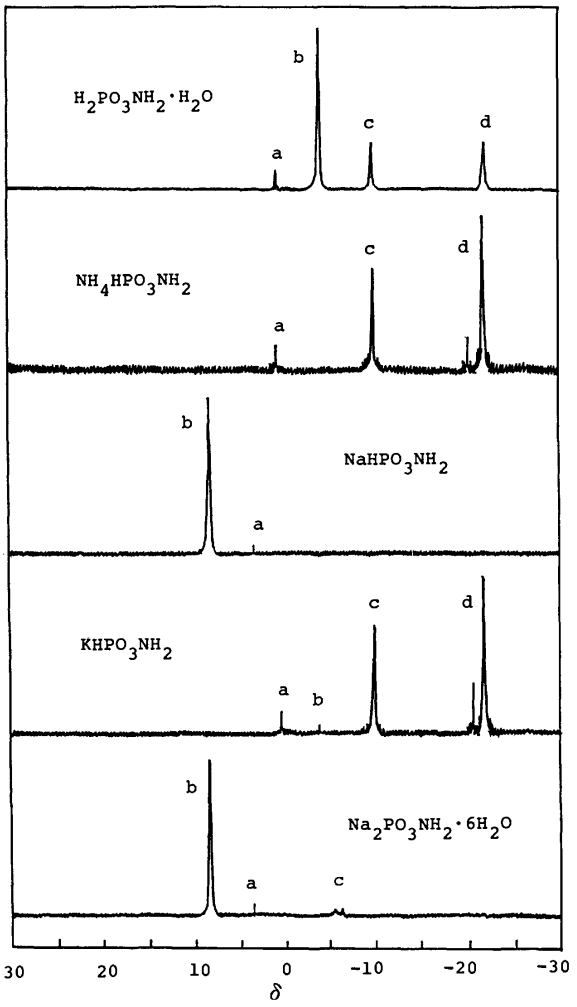


Fig. 4. ^{31}P NMR spectra of the reaction products of phosphoramidates with oxalic acid at 60 °C for 25 h. a: Orthophosphate, b: phosphoramidate, c: end-PO_4 group, d: middle-PO_4 group.

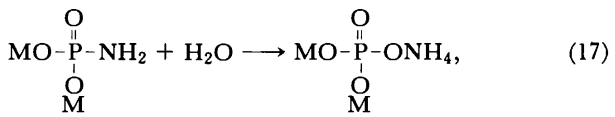
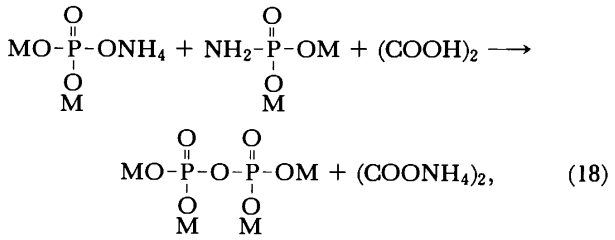
In the reaction with oxalic acid, phosphoramidic acid monohydrate, ammonium hydrogenphosphoramidate, and potassium hydrogenphosphoramidate showed a high reactivity. The reactions of sodium hydrogenphosphoramidate and disodium phosphoramidate hexahydrate were very slow. Accordingly, the reactivity of oxalic acid with the phosphoramidates seemed to be higher than that of acetic acid. As has been described above, since all the products are ortho- and polyphosphates, reaction processes similar to those of acetic

acid must take place in the reaction with oxalic acid, for example, as follows:



(17)



(18)

The water in Eq. 17 can come from the crystal water and/or the adsorbed water of the phosphoramidates. Oxalic acid has a higher reactivity to the phosphoramidates than does acetic acid. This may be explained by, for example, the faster reaction rate of Eq. 18 than that of Eq. 11.

Extraction Equilibria of Hydrochloric Acid by Trioctylamine in Low-Polar Organic Solvents

Takashi KOJIMA* and Hiroshi FUKUTOMI
Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152
(Received August 20, 1986)

Two-phase emf titrations have been performed for the extraction of hydrochloric acid from aqueous solution containing 1 M NaCl (M=mol dm^{-3}) by trioctylamine (TOA) dissolved in cyclohexane, toluene, benzene, chlorobenzene, nitrobenzene, cyclohexane-benzene mixtures, and benzene-nitrobenzene mixtures. It has been found that the extraction is accompanied with the formation of monomeric trioctylammonium chloride and its successive aggregation from dimer to micell (n-mer) in organic phase: $\overline{\text{TOA}}+\text{H}^+ + \text{Cl}^- = \overline{\text{TOAHCl}}$, K_d; $(\overline{\text{TOAHCl}})_{i-1} + \overline{\text{TOAHCl}} = (\overline{\text{TOAHCl}})_i$, $\overline{K}_i (i=2,3,\cdots,n)$, where the concentration quotients of successive aggregation, $\overline{K}_i$, satisfy the relation $2\overline{K}_2 = 3\overline{K}_3/2 = \cdots = n\overline{K}_n/(n-1)$. The quotients K_d and $\overline{K}_2$ vary with the total volume fraction of TOA in organic phase, $\bar{\psi}_R^\circ$, according to equations, $\ln K_d = \ln K_d^\circ + g\,\bar{\psi}_R^\circ$ and $\ln \overline{K}_2 = \ln \overline{K}_2^\circ + h\,\bar{\psi}_R^\circ$. Diluent effect on the equilibrium constants K_d° and $\overline{K}_2^\circ$ are discussed in detail based on the theory of regular solution.

Long-chain tertiary amines have been well-known as useful extractants of metal ions in acidic aqueous solutions, but detailed extraction mechanisms are not completely elucidated. It has been frequently assumed that the extraction of acid by the amines in water-insoluble organic solvents is accompanied with the formation of salts which exist as an ion pair in organic phase

$$\overline{\text{R}_3\text{N}} + \text{H}^+ + \text{X}^- = \overline{\text{R}_3\text{NH}^+\text{X}^-}, \quad (1)$$

and that the extraction of metal ions is substantially the anion exchange in the salts as follows:

$$\text{M}^{n+} + m\text{X}^- = \text{MX}_m^{(m-n)-}, \quad (2)$$

$$(m-n)\overline{\text{R}_3\text{NH}^+\text{X}^-} + \text{MX}^{(m-n)-} = \overline{(\text{R}_3\text{NH}^+)_{m-n}\text{MX}^{(m-n)-}} + (m-n)\text{X}^-, \quad (3)$$

where a superscript bar on symbols denotes the organic phase. However, several investigations on the extraction equilibrium of acids,[3-12] light scattering,[13] freezing point lowering[14] and vapor pressure lowering[15-19] of organic solutions of long-chain alkylammonium salts have shown that the salts have a strong tendency for electrostatic molecular aggregation into dimer, trimer and higher aggregates in nonpolar organic solvents. Therefore, in order to elucidate the extraction mechanism of metal ions, it is necessary to obtain detailed information on the aggregation equilibrium of the salts in organic solvents.

The most reliable information was given by Högfeldt et al.[3-8] who determined precisely the quantitative relationship between the total concentration of acids extracted by tridodecylamine in organic phase and the hydrogen ion concentration in aqueous phase with a constant ionic strength by using the two-phase emf titration method. They analyzed the extraction data by considering all the possible reactions represented by

$$p\overline{\text{R}_3\text{N}} + q\text{H}^+ + q\text{X}^- = \overline{(\text{R}_3\text{N})_p(\text{HX})_q}, \quad (4)$$
$$(p, q = 1, 2, \cdots)$$

and by assuming the ideal behavior of each species in organic phase, and concluded the presence of aggregates $(\text{R}_3\text{NHX})_p$. The data were best described by assuming the formation of such low aggregates as dimer and trimer, and a high aggregate containing as many as 10—90 monomers, where the aggregation number depends on the nature of amine salts and diluents. For example, tridodecylammonium nitrate forms dimer, trimer and decamer in o-xylene,[3] while tridodecylammonium perchlorate forms dimer, octamer and 90-mer in o-xylene.[8]

Kertes and Markovits[17] studied the aggregation of tridodecylammonium chloride, bromide, nitrate, perchlorate and hydrogensulfate in benzene, carbon tetrachloride and cyclohexane by vapor-pressure lowering, and showed that the salts formed dimer and two higher aggregates, which depend on the kinds of salts and organic solvents, and that the aggregation constants of the dimer in benzene increased in the order, chloride<bromide<nitrate<perchlorate<hydrogensulfate. The values of dimerization constant of the bromide and nitrate in benzene were found to be in fairly good agreement with those in o-xylene, which were obtained by the two-phase emf titration method. This agreement implies that coextracted water does not play a decisive part in determining the extent of aggregation.

Diamond and co-workers[10-12] obtained the following conclusion from the investigation of extraction equilibrium of perchloric acid and hydrohalogenic acids with tridodecylamine. Both the dielectric constant and chemical property of diluents greatly affect the extent of extraction of acids and the degree of aggregation of the resulting salts. In general, the higher the dielectric constant and the stronger the chemical interaction of diluents with one or both of the ions of the salt, the better the extraction and the smaller the degree of aggregation. By examining Diamond's data[12] for the equilibrium constants (K_1) in the extraction of HReO_4 by tridodecylamine in various diluents, Freiser[20] found that there was little correla-

tion between log K_1 and the dielectric constant of organic solvents, but a good linear relation existed between log K_1 and the solubility parameter of organic solvents. He pointed out that the postulation of specific chemical interaction between diluents and the salts might be superfluous and that the diluent effect on the equilibrium constants might be better explained on the theory of regular solution.

Kertes[21] showed that the values of solubility parameter of long-chain primary, secondary and tertiary alkylamines calculated from their solubilities in nonpolar organic solvents, based on the regular solution theory, agreed fairly well with those determined from their heats of vaporization. This agreement was taken as reasonable evidence of the validity of the theory for such binary solutions. Further, he[22] evaluated the values of solubility parameter of primary, secondary and tertiary amine hydrochlorides from their solubilities in low-polar organic solvents, and showed that the solubility parameters decreased markedly from the primary to the tertiary amine salts, and that the values of activity coefficient of these salts in the organic solvents, which were calculated by using the values of solubility parameters, increased sharply in the order of the tertiary to the primary amine salts at a given concentration. The difference in the concentration dependence of the activity coefficients was explained in terms of electrostatic molecular association of these salts. However, this explanation can not be accepted, because it was implicitly assumed in the evaluation of the solubility parameters that these salts are still monomeric in saturated solutions. Nevertheless, the calculated results shown in this investigation seem to indicate that the regular solution theory is also valid for these salt solutions, but the evaluated solubility parameters are the apparent solubility parameters, which are given by a function of the solubility parameters and concentrations of the monomeric salt and its aggregates in saturated solution.

In the present investigation, the extraction equilibria of hydrochloric acid from an aqueous solution containing 1 M NaCl by TOA in cyclohexane, toluene, benzene, chlorobenzene, and nitrobenzene were measured by using the two-phase emf titration method. The experimental results are analyzed by considering the aggregation equilibria from dimer to micelle in organic phase. The analyzed results are discussed in detail based on the regular solution theory.

Experimental

Reagents. Trioctylamine (Tokyo Chemical Industry Co., Ltd.) was distilled three times under reduced pressure, and the fraction in the range of 190—192 °C at 4×10^2 Pa was used. The other chemicals were of analytical grade and used without further purification. Laboratory distilled water was used.

Solutions. Stock solutions containing 8% (v/v) TOA were prepared by weighing appropriate amounts of TOA and diluting with cyclohexane, toluene, benzene, chlorobenzene, and nitrobenzene in measuring flasks at 25±1 °C. Less concentrated TOA solutions were prepared by dilution of the stock solutions. An aqueous solution containing 0.1 M HCl and 1.00 M NaCl was used as a titrant.

Procedure and Analysis. The extraction equilibria of HCl by TOA solutions were measured by the two-phase emf titration method[3] with a Corning digital 112 pH meter and a glass electrode GS-135 (Toa Electronics Co., Ltd.). An appropriate amount of 1.00 M NaCl aqueous solution (usually 50 cm^3) was pippetted into a titration vessel kept in a thermostat at 25±0.1 °C, and carbon dioxide dissolved in the solution was removed by stirring with a magnetic stirrer under an atmosphere of nitrogen introduced through 1.0 M NaCl solution. After the reading of the pH meter settled, a suitable amount of TOA solutions (10—40 cm^3) was pippetted and then appropriate amounts of 0.1 M HCl titrant were added through a buret. The extraction equilibria were reached by rapid stirring (500 rpm) of the organic and aqueous solutions. The equilibration time was 1—2 h for the first point and a few minutes for the last point. The hydrogen ion concentrations in the aqueous phase, $[H^+]$, were evaluated from the electrode potential E measured by the pH meter according to the equation

$$E = E_0 + j[H^+] + 59.16\log[H^+], \tag{5}$$

where E_0 and j are constants. The values of E_0 and j were determined from the titration in the absence of organic solution. The total concentration of HCl extracted into organic phase, $[\overline{HCl}]_T$, was calculated by

$$[\overline{HCl}]_T = C(V/\overline{V}) - h(v + V)/\overline{V}, \tag{6}$$

where C and h are the concentrations of HCl and H^+ in the titrant and aqueous phase, respectively, and v, V, and $\overline{V}$ denote the volumes of the titrant, 1.00 M NaCl aqueous solution, and TOA organic solutions, respectively. The concentrations of TOA in organic solutions were determined by measuring the concentrations of HCl in organic solutions at the extraction equilibrium with 1.0 M HCl aqueous solution. The measurement was carried out by back-titration with a standard base.

Results

Since it has been found that the ionic dissociation of trialkylammonium salts is practically negligible in low dielectric organic solvents,[3,11] the extraction mechanism of HCl by TOA in low-polar organic solvents can be written by

$$\overline{TOA} + H^+ + Cl^- = \overline{TOAHCl}, \tag{7}$$

$$i\,\overline{TOAHCl} = \overline{(TOAHCl)_i}, \quad (i = 2, 3, \cdots) \tag{8}$$

where TOAHCl represents $TOAH^+Cl^-$. The equilibrium constants of Eqs. 7 and 8 are given by

$$^{\circ}K_d = \frac{[\overline{RHCl}]}{[\overline{R}][H^+][Cl^-]} \cdot \frac{\bar{y}_1}{\bar{y}_R y_{H^+} y_{Cl}}, \tag{7'}$$

$$\bar{\beta}_i^{\circ} = \frac{[\overline{(RHCl)_i}]}{[\overline{RHCl}]^i} \cdot \frac{\bar{y}_i}{\bar{y}_1^i}, \tag{8'}$$

where R denotes TOA, a bracket the molarity, and y the molar activity coefficient. $\bar{y}_1$ and $\bar{y}_i$ represent the molar activity coefficients of RHCl and $(RHCl)_i$ in organic phase, respectively. Since the ionic strength in aqueous phase is kept constant (1.00 M NaCl) in this study, it is convenient to introduce another equilibrium constant defined by

$$K_d^\circ = {}^\circ K_d(y_{H^+}y_{Cl^-}) = \frac{[\overline{RHCl}]}{[\overline{R}][H^+][Cl^-]} \cdot \frac{\bar{y}_1}{\bar{y}_R}. \quad (7'')$$

On the other hand, $[\overline{R}]_T$ and $[\overline{HCl}]_T$, the total concentrations of TOA and HCl in organic phase, respectively are given by

$$[\overline{R}]_T = [\overline{R}] + \sum_{i=1} i[\overline{(RHCl)_i}], \quad (9)$$

$$[\overline{HCl}]_T = \sum_{i=1} i[\overline{(RHCl)_i}], \quad (10)$$

where the values of free TOA concentration in organic phase, $[\overline{R}]$, can be easily evaluated from those of $[\overline{R}]_T$ and $[\overline{HCl}]_T$. From Eqs. 9, 10, 7'', and 8', the average number of HCl combined with TOA, Z, is given by

$$Z = \frac{[\overline{HCl}]_T}{[R]_T} = \frac{K_d[H^+][Cl^-] + \sum_{i=2} i\bar{\beta}_i K_d^i [\overline{R}]^{i-1}[H^+]^i[Cl^-]^i}{1 + K_d[H^+][Cl^-] + \sum_{i=1}\sum_{i=2} i\bar{\beta}_i K_d^i [\overline{R}]^{i-1}[H^+]^i[Cl^-]^i}, \quad (11)$$

where K_d and $\bar{\beta}i$ are the equilibrium concentration quotients defined by

$$K_d = K_d^\circ(\bar{y}_R/\bar{y}_1) = [\overline{RHCl}]/[\overline{R}][H^+][Cl^-], \quad (12)$$

$$\bar{\beta}_i = \bar{\beta}_i^\circ(\bar{y}_1^i/\bar{y}_i) = [\overline{(RHCl)_i}]/[\overline{RHCl}]^i. \quad (13)$$

Figure 1 shows the plots of Z vs. $\log[H^+][Cl^-]$ in the extraction with toluene as a diluent. The plots give sigmoidal curves depending on $[\overline{R}]_T$. Plots similar to the plots in Fig. 1 were obtained with respect to cyclohexane, benzene, and chlorobenzene, while the plots with nitrobenzene gave a curve which is nearly independent of $[\overline{R}]_T$. These facts suggest that trioctylammonium chloride is practically monomeric in nitrobenzene, but aggregates in the other solvents. In order to obtain further detailed information on the aggregation equilibria, it is convenient to analyze the experimental data by using Eq. 14 derived from Eqs. 10, 12, and 13.

$$\frac{[\overline{HCl}]_T}{[\overline{R}][H^+][Cl^-]} = K_d + \sum_{i=2} i\bar{\beta}_i K_d^i \{[\overline{R}][H^+][Cl^-]\}^{i-1}. \quad (14)$$

As is seen in Fig. 2, the plots of $[\overline{HCl}]_T/[\overline{R}][H^+][Cl^-]$ vs. $[\overline{R}][H^+][Cl^-]$ give the curves whose intercepts and curvatures depend on $[\overline{R}]_T$. This indicates that the values of K_d and $\bar{\beta}_i$ (i=2,3,$\cdots$,n) change with $[\overline{R}]_T$, i.e. the ratios of actitvity coefficient, $\bar{y}_R/\bar{y}_1$ and $\bar{y}_1^i/\bar{y}_i$, depend on $[\overline{R}]_T$. We tried to determine the values of K_d and $\bar{\beta}_i$ at constant $[\overline{R}]_T$ by the least-squares method,

a) $[\overline{R}]_T=0.0230\,M$ $(\bar{\psi}_R^\circ=0.01)$.

varying n from 2 to 5 in Eq. 14. The calculation yielded fairly good results at $n=3$ for the extraction equilibria with the following solutions: 1, 2, 4, and 8% (v/v) TOA-nitrobenzene, 1, 2, 4, and 8% (v/v) TOA-chlorobenzene, 1 and 2% (v/v) TOA-benzene, 1 and 2% (v/v) TOA-toluene, and 1% (v/v) TOA-benzene-nitrobenzene. On the other hand, the calculation for the extraction equilibria with 4 and 8% (v/v) TOA-benzene, 4 and 8% (v/v) TOA-toluene, 1, 2, and 4% (v/v) TOA-cyclohexane and 1% (v/v) TOA-cyclohexane-benzene showed that the calculated values of $[\overline{HCl}]_T/[\overline{R}][H^+][Cl^-]$ at $n=5$ had still a systematic error for the experimental values. These results suggest that the existence of high aggregates of aggregation number>5 can not be neglected in these extraction equilibria or the values of $\bar{y}_R/\bar{y}_1$ and $\bar{y}_i/\bar{y}_i$ change with varying $[\overline{HCl}]_T$.

As is seen in Fig. 3, the plots of $[\overline{HCl}]_T/[\overline{R}][H^+][Cl^-]$ vs. $[\overline{HCl}]_T$ give good straight lines in all the extraction equilibria studied. This indicates that a quantitative relationship in the extraction equilibria can be represented by

$$\frac{[\overline{HCl}]_T}{[\overline{R}][H^+][Cl^-]} = A + B[\overline{HCl}]_T, \tag{15}$$

where A and B are constants which are independent of $[\overline{HCl}]_T$ at constant $[\overline{R}]_T$. The values of A and B calculated by the least-squares method are given in Tables 1 and 2.

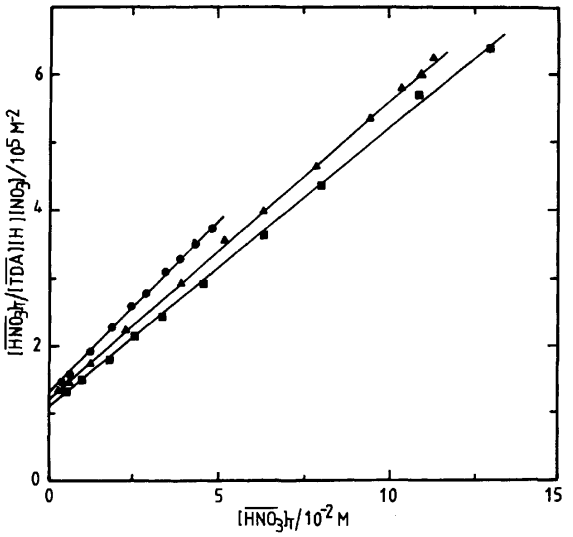

Fig. 4. Plots of $[\overline{HNO_3}]_T/[\overline{TDA}][H^+][NO_3^-]$ vs. $[\overline{HNO_3}]_T$ in the extraction of HNO_3 by TDA in toluene from HNO_3+2.75 M $LiNO_3$ solution (data from Ref. 7). ●: 0.0502 M TDA, ▲: 0.1210 M TDA, ■: 0.2460 M TDA.

Discussion

Equation 15 or a similar equation has not been presented in the literature so far and Eq. 15 can not be derived unconditionally from Eq. 14. Accordingly, we examined whether Eq. 15 is compatible with the experimental results on the extraction of acids by tridodecylamine (TDA) reported by Högfeldt and coworkers.[7,8] Figure 4 shows that Eq. 15 is also applicable to these experimental results. Hence, we sought the conditions to derive Eq. 15 from Eq. 14. Equation 14 can be rewritten as follows:

$$\frac{[\overline{HCl}]_T}{[\overline{R}][H^+][Cl^-]} = K_d + \sum_{i=2} i\left(\prod_{j=2}^{i} \overline{K}_j\right) K_d^i \{[\overline{R}][H^+][Cl^-]\}^{i-1}, \quad (16)$$

$$\overline{K}_j = \overline{\beta}_i/\overline{\beta}_{i-1} = \overline{K}_j^\circ(\bar{\gamma}_{j-1}\bar{\gamma}_1/\bar{\gamma}_j), \quad (17)$$

where $\overline{K}_j$ and $\overline{K}_j^\circ$ are the equilibrium concentration quotient and equilibrium constant, respectively, in the successive aggregation expressed by

$$\overline{(TOAHCl)}_{j-1} + \overline{TOAHCl} = \overline{(TOAHCl)}_j. \quad (18)$$

In the case where the following condition is satisfied,

$$2\overline{K}_2 = \frac{3}{2}\overline{K}_3 = \cdots\cdots = \frac{n}{n-1}\overline{K}_n, \quad (19)$$

Eq. 16 can be transformed to

$$\frac{[\overline{HCl}]_T}{[\overline{R}][H^+][Cl^-]} = K_d\{1 + \sum_{i=2}^{n}(2\overline{K}_2 K_d[\overline{R}][H^+][Cl^-])^{i-1}\}. \quad (20)$$

When n is a large number, i.e. there is a series of aggregates from dimer to micell (n-mer), the following condition

$$2\overline{K}_2 K_d[\overline{R}][H^+][Cl^-] < 1, \quad (21)$$

leads to Eq. 22.

$$\frac{[\overline{HCl}]_T}{[\overline{R}][H^+][Cl^-]} = K_d + 2\overline{K}_2 K_d[\overline{HCl}]_T, \quad (22)$$

A comparison of Eqs. 15 and 22 yields K_d=A and $2\overline{K}_2K_d$=B. Although there is still a question about the validity of an assumption of Eq. 19, we will advance a detailed discussion on K_d and $\overline{K}_2$ determined by Eq. 22, and the physical meaning of Eq. 19 will be mentioned later.

As is seen in Table 1, the values of K_d (=A) and $\overline{K}_2$ (=B/2A) are well correlated with those of total volume fraction of TOA ($\overline{\psi}_R^\circ$) and solubility parameter of diluents (δ_S). This result suggests that the change of K_d and $\overline{K}_2$ with varying $\overline{\psi}_R^\circ$ and diluents may be explained on the basis of the regular solution theory. According to the theory, the activity of components j, a_j, in which a pure liquid is chosen as the reference state, in the solution constituted of m components is given by[23]

$$\ln a_j = \frac{v_j}{RT}\{\sum_{i=1}^{m}(\delta_j - \delta_i)\psi_i\}^2 + \ln\psi_j + \sum_{i=1}^{m}(1 - \frac{v_j}{v_i})\psi_i, \quad (23)$$

where δ_i, v_i, and ψ_i are the solubility parameter, molar volume and volume fraction of component i, respectively. When a total solute concentration is not so high, a molar activity coefficient of solute j, $\dot{y}_j$ ($=\dot{a}_j/c_j$: c_j, molar concentration), may be evaluated approximately by the following equation,

$$\ln\dot{y}_j = \frac{v_j}{RT}(\delta_j - \delta_S)^2(1 - 2\psi_{sol}^\circ) + \ln\frac{v_j}{1000} + (1 - \frac{v_j}{v_S})(1 - \psi_{sol}^\circ), \quad (24)$$

where ψ_{sol}° is the total solute volume fraction, and δ_S and v_S are the solubility parameter and molar volume of solvents S, respectively. Since the molar activity coefficient of solute j, y_j, in which the infinitely dilute solution is chosen as the reference state, is given by

$$y_j = \dot{y}_j/\dot{y}_j(\psi_{sol}^\circ \to 0, \psi_S \to 1), \quad (25)$$

the following equation can be obtained by subtitution of Eq. 24 into Eq. 25.

$$\ln y_j = -\{2v_j(\delta_j - \delta_S)^2/RT + (1 - v_j/v_S)\}\psi_{sol}^\circ, \quad (26)$$

Application of Eq. 26 to $\bar{y}_R$ and $\bar{y}_1$ in Eq. 12 leads to

$$\ln K_d = \ln K_d^\circ + g\overline{\psi}_R^\circ, \quad (27)$$

$$g = (2/RT)\{v_1(\delta_1 - \delta_S)^2 - v_R(\delta_R - \delta_S)^2\} + (v_R - v_1)/v_S, \quad (28)$$

where $\overline{\psi}_R^\circ$ is the total volume fraction of TOA in organic phase, and δ_1 and v_1 denote the solubility parameter and molar volume of TOAHCl, respectively. As is seen from Fig. 5, the plots of $\ln K_d$ vs. $\overline{\psi}_R^\circ$, where the values of A (=K_d) in Table 1 were used, give good straight lines as expected from Eq. 27. The values of $\ln K_d^\circ$ and g calculated by the least-squares method are shown in Table 3. The values of g decrease with increasing the solubility parameter of diluents, and satisfy the relation $\partial g/\partial\delta_S < 0$ which is derived from Eq. 28 by considering that δ_R=7.6 $cal_m^{1/2}$ $cm^{-3/2}$,[21]

Table 3. Values of $\ln K_d^\circ$, g, $\ln \bar{K}_2^\circ$, and h

Diluent (S)	S / $cal^{1/2}cm^{-3/2}$	$\ln K_d^\circ$	g	$\ln \bar{K}_2^\circ$	h
Cyclohexane	8.20	2.90	11.4	5.11	−6.4

Benzene	9.16	8.84	−1.2	2.91	−3.8
Chlorobenzene	9.68	10.79	−3.6	1.58	0.2
Nitrobenzene	10.78	14.78	−5.0	0.19	4.8

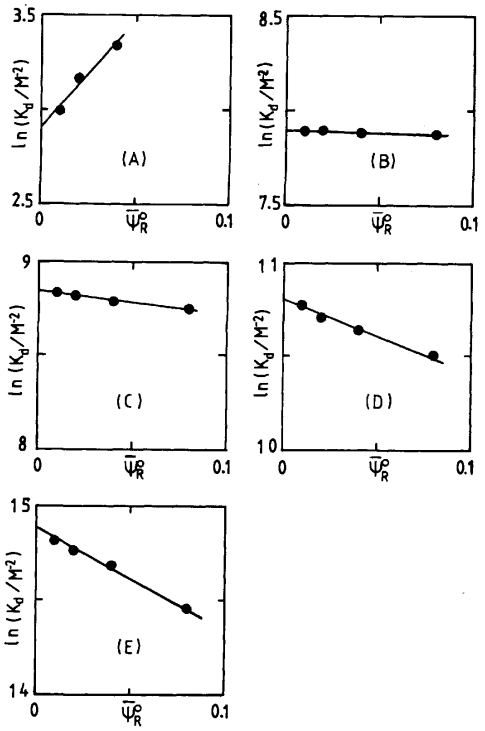

Fig. 5. Plots of $\ln K_d$ vs. $\bar{\psi}_R^\circ$ in the extraction of HCl by TOA in various organic solvents. (A): cyclohexane, (B): toluene, (C): benzene, (D): chlorobenzene, (E): nitrobenzene.

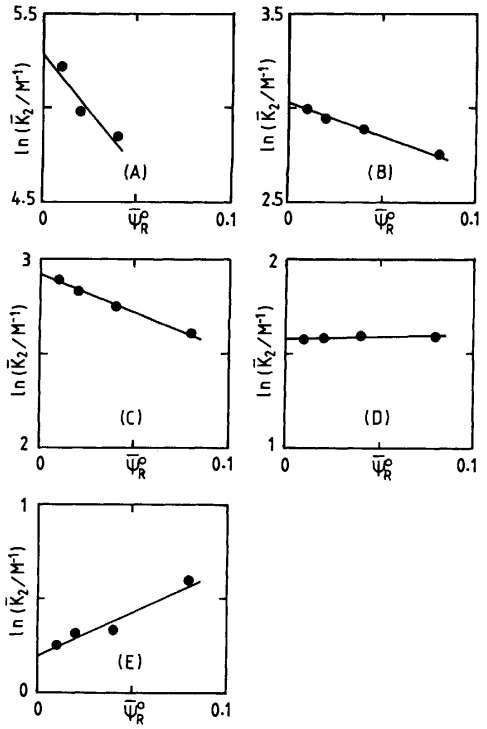

Fig. 6. Plots of $\ln \bar{K}_2$ vs. $\bar{\psi}_R^\circ$ for the aggregation of TOAHCl in various organic solvents. (A): cyclohexane, (B): toluene, (C): benzene, (D): chlorobenzene, (E): nitrobenzene.

δ_1=10.6 $cal_{th}^{1/2}$ $cm^{-3/2}$ [22] and $(v_1-v_R)/v_R \ll 1$.

From Eqs. 17 and 26, the following equation can be obtained by neglecting the volume change in aggregation of TOAHCl,

$$\ln \bar{K}_2 = \ln \bar{K}_2^\circ + h\bar{\psi}_R^\circ, \tag{29}$$

$$h = (4v_1/RT)(\delta_2 - \delta_1)(\delta_1 + \delta_2 - 2\delta_S), \tag{30}$$

where δ_2 denotes the solubility parameter of $(TOAHCl)_2$. Figure 6 shows the plots of $\ln \bar{K}_2$ vs. $\bar{\psi}_R^\circ$, where the values of B/2A (=$\bar{K}_2$) in Table 1 were used. The plots also give fairly good straight lines as expected from Eq. 29. The calculated values of $\ln \bar{K}_2^\circ$ and h are shown in Table 3. The values of h increase with the solubility parameter of diluents, and also satisfy the relation $\partial h/\partial \delta_S > 0$ which is derived from Eq. 30 by assuming that $\delta_1 > \delta_2$.

In order to evaluate the diluent effect on K_d°, it is convenient to introduce another equilibrium constant $K_d^\circ(1)$, where the liquid of TOA and the hypothetical liquid of TOAHCl are chosen as the reference states. The relation between K_d° and $K_d^\circ(1)$ is given by

$$K_d^\circ = K_d^\circ(1)\frac{\bar{\gamma}_R(\bar{\psi}_R \to 0, \bar{\psi}_S \to 1)}{\bar{\gamma}_1(\bar{\psi}_R \to 0, \bar{\psi}_S \to 1)}. \tag{31}$$

Application of Eq. 24 to $\bar{\gamma}_R$ and $\bar{\gamma}_1$ in Eq. 31 leads to

$$\ln K_d^\circ = A_0 + A_1\delta_S + A_2\delta_S^2, \tag{32}$$

$$A_0 = \ln K_d^\circ(1) + (v_R\delta_R^2 - v_1\delta_1^2)/RT + (v_R - v_1)/v_S, \tag{33}$$

$$A_1 = 2(v_1\delta_1 - v_R\delta_R)/RT, \tag{34}$$

$$A_2 = (v_R - v_1)/RT, \tag{35}$$

As is seen in Fig. 7, the plot of $\ln K_d^\circ$ vs. δ_S gives a parabolic curve with upward curvature which satisfies the relations $A_1 > 0$ and $A_2 < 0$ derived from Eqs. 34 and 35 by considering $\delta_1 > \delta_R$ and $v_1 > v_R$. The values of A_0, A_1, and A_2 were determined by the least-squares method as 110.9±2.1, 21.0±0.3 $cal_{th}^{1/2}$ $cm^{3/2}$ and −0.87 ±0.03 cal_{th}^{-1} cm^3, respectively. Equation 35 gives 515

± 18 cm^3 mol^{-1} for $(v_1 - v_R)$ at RT=592 cal$_{th}$ mol^{-1}, but this value is too large for the difference in molar volume of TOA and TOAHCl. Therefore, this result shows that the regular solution theory can not give an exact explanation for the diluent effect of K_d°, but the above equations describe a semiquantitative relationship between ln K_d° and δ_S.

With respect to the diluent effect on the dimerization constant of TOAHCl, the following equations can be obtained in a similar manner to the derivation of Eq. 32 by neglecting the volume change in dimerization,

$$\ln \bar{K}_2^\circ = B_0 + B_1\delta_S, \tag{36}$$

$$B_0 = \ln K_2^\circ(1) + 2v_1(\delta_1^2 - \delta_2^2), \tag{37}$$

$$B_1 = 4v_1(\delta_2 - \delta_1), \tag{38}$$

where $\bar{K}_2^\circ(1)$ is the dimerization constant, and the hypothetical liquids of TOAHCl and $(TOAHCl)_2$ are chosen as the reference states. The plot of ln $\bar{K}_2^\circ$ vs. δ_S gives no straight line, but a parabolic curve with downward curvature as shown in Fig. 8. This fact indicates that ln $\bar{K}_2^\circ$ is expressed by

$$\ln \bar{K}_2^\circ = B_0 + B_1\delta_S + B_2\delta_S^2. \tag{39}$$

The values of B_0, B_1, and B_2 are 55.3±1.2, −9.35±0.18 cal$_{th}^{-1/2}$ cm$^{3/2}$, and 0.393±0.012 cal$_{th}^{-1}$cm^3, respectively. The negative value of B_1 suggests that $\delta_1 > \delta_2$, and is consistent with the presumption that higher aggregates will have lower solubility parameters.

Next we deal with extraction equilibria in mixed solvents. According to Eq. 23, the molar activity coefficient of solute i, $\dot{y}_i$, in the mixed solvents (S1 and S2) containing amall amounts of solutes is given by

$$\ln \dot{y}_j = (v_j/RT)(\delta_j - \delta_{S1})^2 + (\delta_j - \delta_{S2})(\delta_{S1} - \delta_{S2})\bar{\psi}_{S2} + (\delta_{S1} - \delta_{S2})^2\bar{\psi}_{S2}^2 + \ln(v_j/1000) + (1 - v_j/v_{S1}) + v_j(1/v_{S1} - 1/v_{S2})\bar{\psi}_{S2}. \tag{40}$$

The extraction equilibrium constant of HCl by TOA in the mixed organic solvents, K_d°, is correlated to that in S1, K_d°(S1), by

$$K_d^\circ = K_d^\circ(S1)\frac{\bar{y}_R(\bar{\psi}_R \to 0, \bar{\psi}_{S2})\bar{y}_1(\bar{\psi}_R \to 0, \bar{\psi}_{S2} = 0)}{\bar{y}_R(\bar{\psi}_R \to 0, \bar{\psi}_{S2} = 0)\bar{y}_1(\bar{\psi}_R \to 0, \bar{\psi}_{S2})}$$

From Eqs. 40 and 41, the following equations can be derived by neglecting the sixth term in Eq. 40.

$$\ln K_d^\circ = C_0 + C_1\bar{\psi}_{S2} + C_2\bar{\psi}_{S2}^2, \tag{42}$$

$$C_0 = \ln K_d^\circ(S1), \tag{43}$$

$$C_1 = 2\{v_1(\delta_1 - \delta_{S1}) - v_R(\delta_R - \delta_{S1})\}(\delta_{S2} - \delta_{S1})/RT, \tag{44}$$

$$C_2 = (v_R - v_1)(\delta_{S2} - \delta_{S1})^2/RT, \tag{45}$$

When $\delta_{S1} < \delta_{S2}$, it may be expected that $C_1 > 0$ and $C_2 < 0$. Figure 9 shows that the plots of ln K_d° vs. $\bar{\psi}_{S2}$ in the extraction with cyclohexane(S_1)-benzene(S_2) and benzene(S_1)-nitrobenzene(S_2) mixtures give the curves with upward curvatures which are in agreement with the expectation. The calculated values of C_0, C_1, and

Table 4. Values of C_0, C_1, and C_2

Cyclohexane	Benzene	5.22	5.19±0.10 (5.10±0.12)[a]	−3.33±0.12 (−2.99±0.12)[a]	1.06±0.08 (0.79±0.08)[a]
Benzene	Nitrobenzene	2.89	2.58±0.53 (1.98±0.27)[a]	−6.2±0.5 (−3.7±0.5)[a]	4.0±1.4 (2.1±0.5)[a]

a) The values in parentheses were obtained from the calculation except for the value of $\ln \bar{K}_2^\circ$ at $\bar{\psi}_{S2}=0$.

C_2 are shown in Table 4. In the extraction with cyclohexane-benzene mixtures, the C_0 value is very close to that of $\ln K_d^\circ$ (cyclohexane), but the agreement between C_0 and $\ln K_d^\circ$ (benzene) is not so good in benzene-nitrobenzene mixtures. Since this difference appears to indicate that there is a specific interaction between TOAHCl and nitrobezene molecules, we carried out the calculation except for the data at $\bar{\psi}_{S2}=0$ in order to make more clear the difference, and the values are given in parentheses in Table 4. Recalculated values in cyclohexane-benzene do not change so much, but those in benzene-nitrobenzene change significantly. These facts strongly suggest that nitrobenzene molecules preferentially solvate to TOAHCl.

In a similar manner to derivation of Eq. 42, the following equations can be obtained for the dependence of $\bar{K}_2^\circ$ on the composition of mixed diluents by neglecting the volume change in the dimerization of TOAHCl,

$$\ln \bar{K}_2^\circ = D_0 + D_1 \bar{\psi}_{S2}, \tag{46}$$

$$D_0 = \ln \bar{K}_2^\circ(\mathrm{S1}), \tag{47}$$

$$D_1 = 4v_1(\delta_1 - \delta_2)(\delta_{S1} - \delta_{S2})/RT, \tag{48}$$

where $\bar{K}_2^\circ$ (S1) denotes the dimerization constant in solvent S1. In the preceding discussion, since it was found that $\delta_1 > \delta_2$, it may be expected that $D_1 < 0$ when $\delta_{S1} < \delta_{S2}$, i.e. the plot of $\ln \bar{K}_2^\circ$ vs. $\bar{\psi}_{S2}$ gives a straight line with a negative slope. However, the plots for mixed diluents do not yield straight lines as shown in Fig. 10. This indicates that the dependence of $\ln \bar{K}_2^\circ$ on the composition of the mixed diluents may be represented as follows:

$$\ln \bar{K}_2^\circ = D_0 + D_1 \bar{\psi}_{S2} + D_2 \bar{\psi}_{S2}^2, \tag{49}$$

where D_1 and D_2 are constants. The calculated values of D_0, D_1, and D_2 are listed in Table 5. The values of

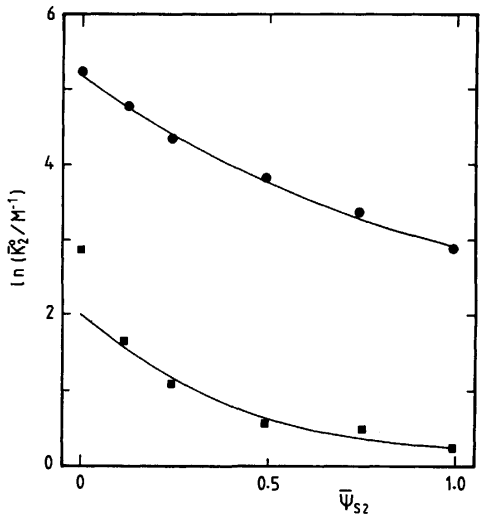

Fig. 10. Plots of $\ln \bar{K}_2^\circ$ vs. $\bar{\psi}_{S2}$ for the aggregation of TOAHCl in mixed solvents. ●: Cyclohexane(S1)-benzene(S2), ■: benzene(S1)-nitrobenzene(S2).

D_0 in cyclohexane-benzene is very close to that of $\bar{K}_2^\circ$ (cyclohexane), but the difference between D_0 in benzene-nitrobenzene and $\bar{K}_2^\circ$ (benzene) is not little. The recalculated values except for the data at $\bar{\psi}_{S2}=0$ are given in parentheses in Table 5. The relationship between the values obtained from the two calculations are similar to that obtained for the values of C_0, C_1, and C_2 as shown in Table 4. The results in Table 5 also suggest that nitrobenzene molecules solvate to TOAHCl and contribute to weaken the aggregation.

From the above discussion, it was found that the experimental results in the present work can be explained fairly well on the assumption of Eqs. 19 and 23.

Estimation of the monomer concentration and mean aggregation number of trioctylammonium chloride in organic phase is carried out by using the total concen-

tration and the dimerization quotient. Since Eq. 22 is rewritten as

$$[\overline{HCl}]_T = [\overline{RHCl}]\{1 + 2\bar{K}_2[\overline{HCl}]_T\},$$

the monomer concentration, $[\overline{RHCl}]$, is given by

$$[\overline{RHCl}] = \frac{[\overline{HCl}]_T}{1 + 2\bar{K}_2[\overline{HCl}]_T}. \quad (50)$$

On the other hand, in order to estimate the mean aggregation number $<i>$ defined by

$$<i> = \frac{\sum_{i=1} i[(\overline{RHCl})_i]}{\sum_{i=1}[(\overline{RHCl})_i]} = \frac{[\overline{HCl}]_T}{[\overline{RHCl}] + \sum_{i=2}\bar{\beta}_i[\overline{RHCl}]^i}, \quad (51)$$

it is necessary to estimate the value of the denominator of Eq. 51. From Eqs. 17 and 19

$$\bar{\beta}_i = \frac{1}{i}(2\bar{K}_2)^{i-1}, \quad (52)$$

and

$$[\overline{RHCl}] + \sum_{i=2}\bar{\beta}_i[\overline{HCl}]^i = -\frac{1}{2\bar{K}_2}\ln(1 - 2\bar{K}_2[\overline{RHCl}]). \quad (53)$$

Substitution of Eqs. 53 and 50 into Eq. 51 yields

$$<i> = \frac{2\bar{K}_2[\overline{HCl}]_T}{\ln(1+2\bar{K}_2[\overline{HCl}]_T)}. \quad (54)$$

Consequently, the values of $<i>$ can be easily calculated by using $[\overline{HCl}]_T$ and $\bar{K}_2$. The calculated values of $<i>$ in several solutions are given in Fig. 11 as a function of $[\overline{HCl}]_T$. Figure. 13 shows that the values of $<i>$ depend markedly on diluents and increase in the order nitrobenzene < chlorobenzene < benzene < toluene < cyclohexane, where $<i>$ values are determined to be 1.04, 1.17, 1.61, 1.70, and 7.82 at $[\overline{HCl}]_T$=0.1 M in 8% (v/v) TOA solutions, respectively.

Finally, we should consider the physical meaning of Eq. 19. The fact that the extraction equilibria are well explained on Eqs. 19 and 23 seems to indicate that the volume fraction is a more reasonable concentration scale than the molarity to describe the extraction equilibria. We introduce a new equilibrium concentration quotient for the successive aggregation, which is defined by

$$\bar{K}_i(\bar{\psi}) = \frac{\bar{\psi}}{\bar{\psi}_{i-1}\bar{\psi}_1}. \quad (55)$$

This quotient can be related to $\bar{K}_i$ by

$$\bar{K}_i(\bar{\psi}) = \frac{1000\,v_i}{v_{i-1}v_1}\bar{K}_i. \quad (56)$$

When the volume change in aggregation is negligible, i.e. $v_i = i\,v_1$, Eq. 56 shows that Eq. 19 is equivalent to

$$\bar{K}_2(\bar{\psi}) = \bar{K}_3(\bar{\psi}) = \cdots\cdots = \bar{K}_n(\bar{\psi}). \quad (57)$$

Equation 57 implies that the binding energy of the aggregate $(TOAHCl)_i$ increases in proportion to the aggregation number, i, and the molar entropy change

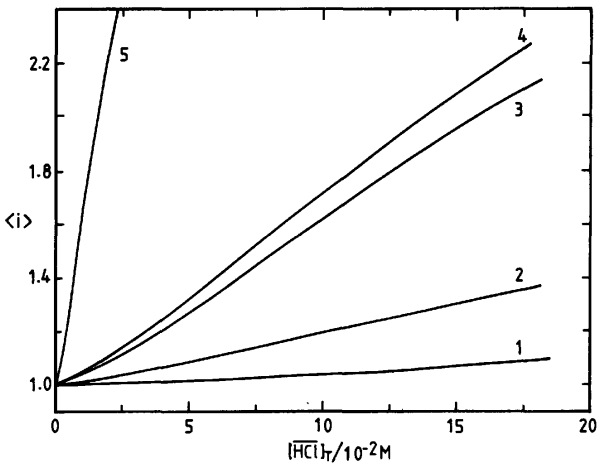

Fig. 11. Mean aggregation numbers of TOAHCl <i> in various organic solvents at 25°C as a function of $[\overline{HCl}]_T$ at 8% (v/v) TOA. 1: Nitrobenzene, 2: chlorobenzene, 3: benzene, 4: toluene, 5: cyclohexane (4% (v/v) TOA).

of each aggregate is proportional to the logarithm of volume fraction of the aggregate. However, we can not answer a question that why the aggregates have such property with respect to the binding energy. In order to make clear the validity of Eq. 19 or Eq. 57, it is instructive to analyze the experimental data so far reported on the aggregation equilibria of trialkylammonium salts by using Eqs. 19 or 57.

As mentioned in the introduction, the most reliable information on the aggregation equilibria was given by the two investigations which were carried out by the two-phase emf titration[3-8] and osmotic measurement.[15-19] The data analysis for the former investigation was carried out based on the following equations assuming the ideal behavior of organic phase,

$$Z = U/W, \quad (58)$$

$$U = \sum_{i=1} i k_i u^i, \quad (59)$$

$$W = w + \sum_{i=1} i k_i u^i, \quad (60)$$

where $u = w\,[H^+][X^-]$, U and W denote the total molar concentrations of acid (HX) and amine, respectively, w is the molar concentration of free amine, and k_i is an equilibrium constant corresponding to $(K_d)^i\bar{\beta}_i$ in the present work. The data of the two-phase emf titration were best described with the formation of monomer, two low aggregates and one high aggregate of the salts in organic phase, i.e. Eqs. 59 and 60 were expressed by

$$U = k_1 u + p k_p u^p + q k_q u^q + r k_r u^r, \quad (59')$$

$$W = w + k_1 u + p k_p u^p + q k_q u^q + r k_r u^r, \quad (60')$$
$$(1 < p < q < r).$$

Values of the aggregation equilibrium constants β_p, β_q, and β_r, where $\beta_i = k_i/k_1^i$, were determined by calcu-

lating the values of k_1, k_p, k_q, and k_r, which give the minimum value of the error-square sum $\sum(Z_{exp}-Z_{cal})^2$. The values of β_p, β_q, and β_r of tridodecylammonium bromide perchlorate in *o*-xylene, and tridodecylammonium nitrate in toluene are given in Table 6 together with those of the dimerization concentration quotient $\overline{K}_2$, which were evaluated by assuming the validity of Eq. 19. Values of the aggregation equilibrium concentration quotients $\overline{\beta}_p$, $\overline{\beta}_q$, and $\overline{\beta}_r$, which were evaluated by using the equation $\overline{\beta}_i=(1/i)(2\overline{K}_2)^{i-1}$, corresponding to those of β_p, β_q, and β_r, respectively, are given in Table 6.

In the osmotic measurements, the concentration dependence of osmotic coefficient Φ of the solution containing trialkylammonium salt was analyzed by

$$\Phi = Y/W, \tag{61}$$

$$W = w_1 + \sum_{i=2} i\beta w_1{}^i, \tag{62}$$

$$Y = w_1 + \sum_{i=2} \beta w_1{}^i, \tag{63}$$

where W and w_1 denote the total molar concentration of the salts and the molar concentration of monomer. Kertes and Markovits[17] assumed the formation of three aggregates, which follows the equations

$$W = w_1 + p\beta_p w_1{}^p + q\beta_q w_1{}^q + r\beta_r w_1{}^r, \tag{62'}$$

$$Y = w_1 + \beta_p w_1{}^p + \beta_q w_1{}^q + \beta_r w_1{}^r, \tag{63'}$$

and evaluated the values of β_p, β_q, and β_r, which give the lowest value of the error-square sum $\sum(W_{exp}-W_{cal})^2+\sum(Y_{exp}-Y_{cal})^2$. The values of β_q, β_q, and β_r of tridodecylammonium bromide, nitrate and perchlorate in benzene are also shown in Table 6. In the above report, it was implicitly assumed that the change in activity of solvents resulted from only the change in effective concentration of the solute on the formation of aggregates, but it is found from the present work that this assumption is only applicable to very dilute solutions. Therefore, it is necessary to take into account the change in activity of solvents with varying the total salt concentration and the distribution of aggregates for evaluation of accurate values of aggregation equilibrium concentration quotient from the values of osmotic coefficient. According to Eq. 23, the activity of solvent, a_S, in the solution containing monomer to n-mer of trialkylammonium salt is given by

$$\ln a_S = \frac{v_S}{RT}\left\{\sum_{i=1}^{n}(\delta_S-\delta_i)\psi_i\right\}^2 + \ln \psi_S + \sum_{i=1}^{n}(1-\frac{v_S}{v_i})\psi_i. \tag{64}$$

Equation 64 can be rewritten as

$$-\ln a_S = \sum_{i=1}^{n}\frac{v_S}{v_i}\psi_i + (\frac{1}{2}-\sigma)\psi_T^2 + \frac{1}{3}\psi_T^3 + \cdots, \tag{64'}$$

$$\psi_T = \sum_{i=1}^{n}\psi_i, \tag{65}$$

$$\sigma = (v_S/RT)(<\delta> - \delta_S)^2, \tag{66}$$

$$<\delta> = \sum_{i=1}^{n}\delta_i\psi_i/\sum_{i=1}^{n}\psi_i. \tag{67}$$

Under the condition $\psi_T \ll 1$, Eq. 64′ reduces to

$$-\ln a_S = \frac{v_S}{RT}\sum_{i=1}^{n}w_i + (\frac{1}{2}-\sigma)(\frac{v_S}{1000})^2W^2, \tag{68}$$

where W and w_i are the total molar concentration of the salt and the molar concentration of its i-mer, respectively. Application of Eq. 19 to the successive

a) The values of $\overline{K}_2$ and ρ were determined by using the data in Ref. 17.

aggregation concentration quotient $\overline{K}_i$, which is defined by $\overline{K}_i=w_i/w_1w_{i-1}$, leads to Eq. 69 under the condition $2\overline{K}_2w_1<1$.

$$-\ln \dot{a}_S = \frac{v_S}{1000}\frac{1}{2\overline{K}_2}\ln(1+2\overline{K}_2W) + (\frac{1}{2}-\sigma)(\frac{v_1}{1000})^2W^2, \quad (69)$$

Substitution of the relation $-\ln \dot{a}_S=(v_S/1000)\,W$[17] into Eq. 69 yields

$$W\Phi = (1/2\overline{K}_2)\ln(1+2\overline{K}_2W) + \rho W^2, \quad (70)$$

$$\rho = (1/2-\rho)(v_1^2/1000v_S). \quad (71)$$

Accordingly, the values of $\overline{K}_2$ and ρ can be determined from Φ and W by the least-squares method. The values of $\overline{K}_2$ and ρ for tridodecylammonium chloride, bromide, nitrate, perchlorate and hydrogensulfate in benzene, carbon tetrachloride and cyclohexane are given in Table 7, where the data of Kertes and Markovits[17] were used. Regardless of the salts, Table 7 shows that the temperature dependences of $\overline{K}_2$ and ρ are as follows: 1) The values of $\overline{K}_2$ in benzene are approximately independent of temperature ($(\partial\overline{K}_2/\partial T)\simeq 0$). 2) The values of $\overline{K}_2$ in cyclohexane decrease with the increase of temperature ($(\partial\overline{K}_2/\partial T)<0$). 3) The values of ρ in benzene increase with temperature ($(\partial\rho/\partial T)>0$). 4) The values of ρ in cyclohexane are nearly independent of temperature ($(\partial\rho/\partial T)\simeq 0$).

The reason why such temperature dependences are obtained is explained mathematically as follows. Equation 67 is rewritten as

$$<\delta> = \frac{1}{2\overline{K}_2W}\sum_{i=1}^{n}\delta_i\{\frac{2\overline{K}_2W}{1+2\overline{K}_2W}\}^i. \quad (72)$$

When $\delta_1<\delta_2<\cdots<\delta_n$, i.e. higher aggregates have lower solubility parameters, Eq. 72 leads to $(\partial<\delta>/\partial\overline{K}_2)<0$. Therefore, it is obvious from the relation $(\partial<\delta>/\partial T)=(\partial<\delta>/\partial\overline{K}_2)(\partial\overline{K}_2/\partial T)$ that $(\partial<\delta>/\partial T)\simeq 0$ at $(\partial\overline{K}_2/\partial T)\simeq 0$ and $(\partial<\delta>/\partial T)>0$ at $(\partial\overline{K}_2/\partial T)<0$. On the other hand, Eq. 73 is derived from Eqs. 71 and 66,

$$\frac{\partial\rho}{\partial T} = \frac{v_1^2(<\delta>-\delta_S)}{1000RT^2}\{(<\delta>-\delta_S) - 2T(\partial<\delta>/\partial T)\}, \quad (73)$$

and this leads to the following relations: $(\partial\rho/\partial T)>0$ at $(\partial<\delta>/\partial T)\simeq 0$ or $(\partial\overline{K}_2/\partial T)\simeq 0$ and $(\partial\rho/\partial T)\simeq 0$ at $(\partial<\delta>/\partial T)\simeq(<\delta>-\delta_S)/2T>0$. The former relation is consistent with the temperature dependences of $\overline{K}_2$ and ρ in benzene, and the latter corresponds to those of $\overline{K}_2$ and ρ in cyclohexane. Accordingly, it is obvious that the values of $\overline{K}_2$ and ρ evaluated based on Eq. 19 have no self-contradiction. This presents suggestive evidence that Eq. 19 is valid, or at least not an unreasonable relationship for the aggregation equilibria of long-chain trialkylammonium salts in low-polar organic solvents.

In order to compare the values of aggregation equilibrium constants (concentration quotients) of tridodecylammonium salts (TDAHX), some values of $\overline{K}_2$ obtained by our analysis are shown in Table 6. As is seen in Table 6, the values of $\overline{\beta}_2$, $\overline{\beta}_3$, and $\overline{\beta}_r$ for TDAHBr and $TDAHNO_3$ having relatively small values of $\overline{K}_2$ are in fairly good agreement with those of β_2, β_3, and β_r, respectively, except for the value of β_2 for $TDAHNO_3$ in benzene obtained by extrapolation from the osmometric data.[15] The values of $\overline{\beta}_2$, $\overline{\beta}_8$, and $\overline{\beta}_r$ for $TDAHClO_4$ with relatively large values of $\overline{K}_2$ are considerably small compared with those of β_2, β_8, and β_r, respectively. The reason for these results can be explained as follows. Since the bromide and nitrate in *o*-xylene, toluene, and benzene have relatively small values of $\overline{\beta}_i$ ($i=2,3,\cdots$), the concentrations of intermediate and high aggregates may be negligibly small

compared with those of such low aggregates as dimer and trimer in the wide range of total concentration of the salts. On the other hand, in *o*-xylene and benzene solutions of the perchlorate with relatively large values of $\overline{\beta}_i$ (i=2,3,$\cdots$), the concentrations of intermediate aggregates may not be neglected compared with those of low aggregates even at the low total concentration of the salt. Accordingly, it seems that the values of β_2, β_8, and β_r for $TDAHClO_4$, which were determined based on Eqs. 59′ and 60′ or Eqs. 62′ and 63′, are not the true values, but the mean values of formation constants of low, intermediate and high aggregates, respectively, i.e. the calculated values of β_2, β_8, and β_r correspond to those of β'_2, β'_8, and β'_r, respectively, which are represented by

$$\beta'_2 = \sum_{i=2}^{s} \beta_i w_1^i / w_1^2, \tag{74}$$

$$\beta'_8 = \sum_{i=s+1}^{t} \beta_i w_1^i / w_1^8, \tag{75}$$

$$\beta'_r = \sum_{i=t+1} \beta_i w_1^i / w_1^r, \tag{76}$$

$$(2 < s < 8 < t < r).$$

From Eqs. 74, 75, and 76, it is estimated that when the values of β_i equal to those of $\overline{\beta}_i$, the values of β'_i become larger than those of $\overline{\beta}_i$ and the ratios of $\beta'_i/\overline{\beta}_i$ increase with the increase of $\overline{\beta}_i$. These relations agreed with those between the calculated values of β_i and $\overline{\beta}_i$ shown in Table 6. This agreement may be taken as additional evidence that Eq. 19 or Eq. 57 is valid not only for the aggregation equilibrium of trioctylammonium chloride, but also for the aggregation equilibria of other long-chain trialkylammonium salts, and the assumption of the formation of at most three aggregates, which was introduced by Högfeldt et al.[3-8] and by Kertes and Markovits,[17] seems to be too simplified, particularly for tridodecylammonium perchlorate in *o*-xylene and benzene.

From the above-mentioned discussion, the following conclusion can be drawn. The extraction of hydrochloric acid by trioctylamine in low-polar organic solvents is accompanied with the formation of trioctylammonium chloride which exists as an ion-pair and of electrostatic molecular aggregates from dimer to micelle. The concentration quotients for the successive aggregation equilibria satisfy Eqs. 19 or 57. Equation 19 is valid also for the aggregation equilibria of other long-chain trialkylammonium salts in the organic solvents. The total solute concentration dependence on the quotients for the extraction equilibrium of hydrochloric acid by trioctylamine and for the successive aggregation of trioctylammonium chloride can be explained reasonably by the theory of regular solution. The diluent effect on the extraction equilibrium constant and on the successive aggregation constant can be also explained reasonably by the theory.

The Crystal and Molecular Structures of Bis(2-methylpyridine)-, and Bis(3-methylpyridine)bis(thiocyanato)cadmium(II) in Polymeric Forms, $[Cd(SCN)_2(CH_3C_5H_4N)_2]_n$

Masahiro TANIGUCHI, Yoshihiko SUGITA, and Akira OUCHI*
Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received August 26, 1986)

The crystal and molecular structures of the title complexes were determined by the single-crystal X-ray diffraction method. Both of them are triclinic, with the space group $P\bar{1}$. The crystallographic data: 2-methylpyridine (α-pic) adduct, $a=11.076(3)$, $b=18.478(8)$, $c=9.299(3)$ Å, $\alpha=104.60(3)$, $\beta=114.84(2)$, $\gamma=81.12(3)°$, $Z=4$, final R value is 0.037; 3-methylpyridine (β-pic) adduct, $a=8.7667(16)$, $b=16.655(4)$, $c=5.8447(10)$ Å, $\alpha=91.406(18)$, $\beta=100.571(14)$, $\gamma=92.525(18)°$, $Z=2$, final R value is 0.041. In both complexes, all cadmium atoms are in 4*N*2*S*-hexa-coordination, being in an octahedral geometry; they are oriented as any pair of side-by-side metal atoms being bridged by two thiocyanate ions. In the α-pic adduct, the chain is oriented approximately along the [111] axis. In the chain, the metal atoms in two kinds of orientations appear alternately: Around one kind of the metal atoms three kinds of ligating atoms are all in *trans*-configurations, and around the other kind of the metal atoms the respective pairs of N(base) and S(SCN) atoms are in *cis* and the pair of the N(SCN) atoms in a *trans*-configuration. In the β-pic adduct, the chain is along the [001] axis and pairs of three kinds of ligating atoms are all in *trans*-configurations.

The structures of cadmium(II) thiocyanate and several kinds of its Lewis base adducts have already been elucidated.[1-8] Many of them are in a linear polymeric form having double thiocyanate (SCN) ion bridgings between any pair of adjacent metal atoms.[5-8] Previously, we determined the structure of bis(4-methylpyridine)bis(thiocyanato)cadmium(II), $Cd(SCN)_2(\gamma\text{-pic})_2$ (where γ-pic=γ-picoline=4-methylpyridine).[8] In this complex, there are three kinds of crystallographically independent cadmium atoms. They are oriented approximately along the [111] axis; side-by-side metal atoms are bridged by two SCN ions. This type of the chain structure had not yet been found in the other Lewis base adducts of cadmium(II) thiocyanate. Therefore, it is interesting to make a comparative study of a variety of chain structures caused by differences in the additional Lewis base, especially when the structure of the base molecules are not much different from each other. For this purpose, we determined the structures of the title complexes, $Cd(SCN)_2(\alpha\text{-pic})_2$ (α-pic=α-picoline=2-methylpyridine), and $Cd(SCN)_2(\beta\text{-pic})_2$ (β-pic=β-picoline=3-methylpyridine), by a single-crystal X-ray diffraction method.

Experimental

Synthesis of Bis(2-methylpyridine)bis(thiocyanato)cadmium(II) and Bis(3-methylpyridine)bis(thiocyanato)cadmium(II). These complexes were obtained in almost the same way as that of Ahuja.[9] The crystal used for the X-ray analysis was obtained as follows: crystals of the α-pic adduct were deposited from a mixture of $Cd(SCN)_2$ (0.57 g, 2.5 mmol) in 15 cm^3 of ethanol-water (1 : 1=v/v) and 2-methylpyridine (0.47 g, 5.0 mmol) in 10 cm^3 of ethanol after being left standing at ambient temperature for several hours. The crystals of the β-pic adduct were obtained from a mixed solution of $Cd(SCN)_2$ (0.57 g, 2.5 mmol) and 3-methylpyridine (0.47 g, 5.0 mmol) in 20 and 10 cm^3 methanol, respectively, after being left standing for several hours at ambient temperature. Anal. (for both complexes), ($CdC_{14}H_{14}N_4S_2$), Cd, C, H, N. The wavenumbers of their infrared spectral bands almost coincide with the respective values of the references.[9]

X-Ray Structure Analysis. The crystallographic data, the size of the used crystal, and some experimental conditions to determine intensity data are listed in Table 1. Reflections were collected on a Rigaku AFC-6A automated four-circle X-ray diffractometer with graphite-monochromated Mo$K\alpha$ radiation, the ω—2θ scan technique being employed (scan speed 4° min^{-1} (θ)). The intensities were corrected for Lorentz and polarization factors, but no correction was made for absorption and extinction.

Structure Determination. Their structures were solved by the heavy-atom method. The positions of the cadmium and some sulfur atoms were deduced from a three-dimensional Patterson map; other non-hydrogen atoms were located by successive Fourier syntheses. Their positional, isotropic and then anisotropic thermal parameters were refined by a block-diagonal least-squares method. All the hydrogen atoms of the pyridine rings were at respective calculated positions, assuming their B_{iso}'s to be 8.0 Å^2, and C-H bond lengths to be 1.08 Å. All the calculations were carried out on a HITAC M-680H computer at the computer center of the University of Tokyo using a local version of the UNICS program.[10] The atomic scattering factors were taken from Ref. 11.

Results and Discussion

The final atomic parameters of the non-hydrogen atoms of the complexes are listed in Tables 2 and 3; their selected bond lengths and bond angles are tabulated in Tables 4 and 5.[12] A perspective drawing of the skeleton of the polymeric chain of the α-pic adduct, as well as that around a metal atom of the β-pic complex, together with their numbering scheme of the atoms, are shown in Figs. 1 and 2. Their crystal packing diagrams are given in Figs. 3 and 4.

In the α-pic complex, the arrangement of the cadmium atoms, the coordination geometries of the respective metal atoms, and the bridging modes of the SCN ions resemble those of the γ-pic complex.[8]

There are crystallographically three kinds of cad-

Table 1. Crystallographic Data and Some Experimental Conditions to Obtain the Reflection Intensities of the Complexes; $Cd(SCN)_2(\alpha\text{-pic})_2$ and $Cd(SCN)_2(\beta\text{-pic})_2$

d) See below Table 2.

mium atoms; two of them, Cd(1) and Cd(2), are at the centers of symmetry, 0, 0, 0 and 0.5, 0.5, 0.5, while the Cd(3) atom is situated between them. Any pair of adjacent cadmium atoms are bridged by two SCN ions, where one SCN ion is *S*-coordinated, and the other SCN ion is *N*-coordinated to the same side metal atom. The polymeric chain lines approximately along the [111] axis, in the order ···Cd(1)···Cd(3)···Cd(2)···Cd(3^{ii})··· (Key to the symmetry operation: see Fig. 1, caption). All cadmium atoms are 4*N*2*S*-hexa-coordinated, being in an octahedral geometry. Around the Cd(1) and Cd(2) atoms all N(SCN), S(SCN), and N(α-pic) atoms are in *trans*-configurations, while around the Cd(3) atom, N(SCN) atoms are in *trans*; however, the other two kinds of atoms are in *cis*-configurations. Between Cd(1) and Cd(3), as well as Cd(3) and Cd(2) atoms, there are eight-membered rings consisting of the two metal and two SCN ion atoms bridging them. The average positional deviation of the atoms from the average planes of the rings are 0.047 and 0.051 Å, respectively.

On the other hand, there are some differences between the structures of the α-pic and γ-pic adducts, as follows.

The interatomic distances, Cd(1)···Cd(3) and Cd(3)···Cd(2), in the α-pic adduct are 5.834(3) and 5.836(2)

Table 4. Interatomic Distances and Bond Angles of $Cd(SCN)_2(\alpha\text{-pic})_2$ with the Standard Deviations in Parentheses

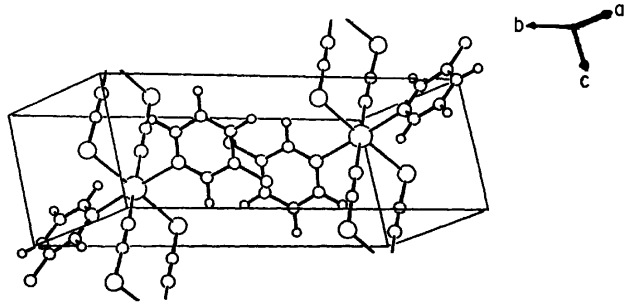

Fig. 4. Crystal packing diagram of $Cd(SCN)_2(\beta\text{-pic})_2$.

Å, respectively, while the corresponding bond lengths in the γ-pic adduct are on the average 5.778 Å. Moreover, the Cd-N(base) bond length of the former, especially those around the Cd(1) and Cd(2) atoms, are longer than the corresponding lengths of the latter complex. These differences are likely caused by a steric effect of the substituted methyl groups on the pyridine rings of the ligands. In the α-pic adduct the methyl groups approach the Cd···Cd chain and prevent the next cadmium, as well as the ligating α-pic nitrogen atoms, from approaching the central metal atom.

The directions of the coordinating ligands in the α- and γ-pic complexes are not the same. As shown in Fig. 3, in the α-pic adduct, the 4-carbon atoms of the pyridine rings of the ligands are directed rather in the c-axis direction, while in the γ-pic adduct, they are directed approximately in the a-axis direction.[8] As a result, the a-axis length of the α-pic adduct (11.076(3) Å) is shorter than that of the γ-pic adduct (11.323(4) Å). This is because in the latter adduct the methyl group of the ligand is directed along the a-axis direction. On the other hand, the b- and c-axis lengths of the α-pic adduct are longer than the respective lengths of the γ-pic adduct; in total, the cell volume of the α-pic adduct (1668.6(10) Å^3) is a little smaller than that of the γ-pic one (1691.7(15) Å^3): the α-pic adduct is a little more closely packed in the crystal.

The crystal structure of the β-pic adduct is drastically different from those of the α- and γ-pic adducts, though the difference between their molecules is only the substituted positions of a methyl group on the Lewis base ligand. In the β-pic adduct, crystallographically, there is only one kind of cadmium atom: 4*N*2*S*-hexa-coordinated with an octahedral geometry, where the respective pairs of N(SCN), S(SCN), and N(β-pic) atoms are ligated in *trans*-configurations. Any pair of adjucent metal atoms is bridged by two SCN ions as in cases of the α- and γ-pic complexes and line along [001] axis. As the intermetallic distance along the line, which is the same as the c-axis length, is 5.8447(10) Å, it is longer than that of the γ-pic adduct; however, it is not much different from that of the α-pic one. The volume per one metal atom is also not much different from those of the α- and γ-pic adducts.

The planarity of the eight-membered ring, comprising two bridging SCN ion atoms and two metal atoms, is not so good as those of the α- and γ-pic adducts; the average deviation of the atoms from the average plane is about twice (0.120 Å) as much. However, the puckering of the ring is not as large as the other complex ones where all eight-membered rings in the chain are parallel.[5,6]

It is interesting to consider the reason why the β-pic adduct takes a different structure. Although an exact quantitative explanation is difficult at this stage (because of the scarcity of available reference data), some considerations will be presentaed from a comparison between the structures of the adducts $Cd(SCN)_2L_2$ (L=Lewis base) where the metal atoms are doubly bridged by SCN ions. In addition to the β-pic adduct, complexes of 1*H*-1,2,4-triazol (trz),[6] dibenzylamine,[14] and imidazolinethione (etu)[5] possess the same type of structure: all have eight-membered rings comprizing the bridging of two SCN ions and two metal atoms. They are parallel in the chain and, crystallographically, only one kind of cadmium atom is in the chain. The anion of the $[(CH_3)_4N]_2[Cd(SCN)_4]$[15] also has the same type of bridge. Therefore, the twisted chains of the α- and γ-pic adducts are rather thought to be exceptional, although the pyridine (py) adduct, $Cd(SCN)_2py_2$, is expected to have a different type of long-period chain.[16]

The volume of the Lewis base is probably not the only factor to determine the type of structure since the massive dibenzylamine as well as the smaller trz adduct have the same type crystal structure as the β-pic adduct.

One probable explanation is that when some interaction between the ligand molecules is dominant, they are regularly laid on a line or accumulated with their planar molecules in parallel. This is because their respective eight-membered rings of the double SCN bridges are in parallel as is found in the β-pic adduct type chain. However, here the interaction means a long-distance type which may be weak in strength.

In trz and etu adducts, the existence of such an interaction between ligands was reported[5,6] and in the dibenzylamine adduct, half of the ligand benzene rings were reported to partially overlap.[14] Also, the unidentate SCN ions in the anion of the $[(CH_3)_4N]_2[Cd(SCN)_4]$ salt have been shown to be electrostatically connected via the cations.[15]

In the case of the α-pic adduct, as the directions of the respective methyl groups of the ligands are quite limited and prevent them from excessively approaching the SCN chain, it is difficult to place the pyridine planes of the ligand in parallel in order to have them overlap in the crystal. In the case of the γ-pic adduct, as the ligand pyridine ring has a methyl group at the 4-position, the next ligand pyridine ring cannot approach or sufficiently overlap, even though they are oriented almost parallel in the crystal.[8] On the other hand, in the case of the β-pic adduct, such obstacles do not exist.

There is another possible explanation regarding the stronger interaction between the pyridine rings of the β-pic adduct. Although the density of the delocalized electrons of the non-substituted pyridine ring is poor, when some electron donating group, such as a methyl group, is introduced as in the case of the β-pic ligand, the electron density of the ring is much increased. It can, thus, form a stronger interaction with the parallel ring of the next ligand than that of the non-substituted pyridine complex. In cases of the α- and γ-pic ligands, although the electrons are similarly supplied from the methyl group, they are absorbed by the ring nitrogen

and/or the ligating metal atom since the methyl group takes the 2- and 4-position of the ring; the increase of the ring electron density is not much. Thus, the interaction of the β-pic ligand is stronger than those of the α- and γ-pic as well as of the py ones.

When such an inter-ligand force is minor, some other type of the chain can be adopted to achieve a closest packing in the crystal. The α- and γ-pic adducts have such twisted chain structures, and they are slightly different from each other and can pack the respective molecules in the most effective way.

As the structure of some methylpyridine adducts of the polymeric metal thiocyanates (Ag(SCN)L (L=α- and β-pic),[17] and Cu(SCN)L_2 (L=α-, β-, and γ-pic))[18] were already elucidated, we can refer to their results and compare them with the results concerning cadmium complexes.

In the case of the Ag(SCN)L type complex,[17] both of the α- and β-pic adducts are in the two-dimensional polymeric structure, where each metal atom is 2S2*N*-tetra-coordinated, and the side-by-side metal atoms are bridged by one SCN ion. Although their space group, as well as their *Z* numbers, are different from each other, the main structural difference between them is some deformation of the Ag(SCN) network. Their best packings are attained mainly by a change in the polymeric network of the complex. As the ligands around the metal atom are not very closely packed, the steric effect of the 2-methyl group of the ligand is not very strong, although the 2,6-dimethylpyridine adduct has a very different skeleton due to the stronger steric effect of the methyl groups.

In cases of the Cu(SCN)L_2 type complex,[18] all of the α-, β-, and γ-pic adducts have one-dimensional polymeric structures, where each metal atom is tetra-coordinated and each pair of the metal atoms are bridged by one SCN ion. Their space groups and the *Z* numbers are different from each other. The polymeric chain of the α-pic adduct is in a zig-zag form, while the chains of the β- and γ-pic adducts have a quasi-mirror plane parallel to the chain line; the structures of the latter two resemble each other. As was discussed by the authors,[18] the steric hindrance of the 2-methyl group is important and, consequently, only the α-pic adduct has a very different type of structure. As the single SCN chain of the type of adduct is easily deformed, the most closely packed, as well as energetically the most stable arrangement, is attained mainly by the deformation of the chain.

On the other hand, in cadmium thiocyanate adducts, the double SCN ion chain is very rigid and is always oriented approximately along one direction. To attain the closest packed and the most stable arrangement, only a deviation of the ligand molecule direction and/or a twisting of the chain are allowed. Therefore, the effect of the interaction between the ligands is rather likely to be dominant, as mentioned in the former part of this paper. The steric effect of the 2-methyl group is not the strongest one, though there is some; this is because the stable double SCN chain is not able to be deformed by the approach of a methyl group.

Simultaneous Determinations of Inorganic and Organic Acids by Ion Chromatography

Hisaaki ITOH* and Yoshio SHINBORI
Faculty of Pharmaceutical Sciences, Josai University, Sakado, Saitama 350-02
(Received September 13, 1986)

The elution behavior of seven common inorganic anions (F^-, Cl^-, NO_2^-, Br^-, NO_3^-, SO_4^{2-}, and phosphate) and a large number of organic acids in an AS-5 separator column using a weak carbonate eluent was examined and the possibility of simultaneous determinations of the inorganic and organic acids in a single injection was investigated. For pharmaceutical samples, such as a Ringer's solution which contains some inorganic anions and a single organic anion as anion contents, each anion could be simultaneously analyzed with a relative standard deviation of below 0.6%. Furthermore, it was found that even in a sample such as the liquor of canned goods having a complex matrix, both inorganic and dicarboxylic acid contents could be simultaneously analyzed without any tedious pretreatment, except for a simple dilution with distilled and deionized water. For the liquor samples, the relative standard deviation for five measurments was less than 5.0%.

Ion chromatography, first described in 1975,[1] has become a widely used analytical technique for the determination of ionic species in aqueous samples.[2-14] Today, based on the developments of column technology and a detection system, many separator columns with different selectivities and detection systems have been made available commercially. It should also be noted that with the spread of the application area and an increased need to analyze samples having complex matrices, the key point of success of an analysis primarily depends upon the best selection of a combination of the separator column and the detection mode.

An AS-5 separator column, which was packed with poly(styrene-divinylbenzene) copolymer base pellicular ion exchange resins (particle size: 15 μm), is one type of anion separator column that is commercially available from Dionex (California, USA). It makes it possible to rapidly and sensitively analyze such anions as I^-, SCN^-, and CrO_4^{2-},[15] which have relatively high affinities on the resins, using a mixed solution of *p*-hydroxybenzonitrile, sodium carbonate, and sodium hydrogencarbonate (0.8, 4.4, and 5.4 in mmol dm^{-3}, respectively) as the eluent and conductivity detection. Furthermore, it should be noted that this separator can also be used for the separation of common inorganic anions (except for nitrate and bromide ions) by using a weak eluent such as 2.5 mmol dm^{-3} sodium carbonate/0.25 mmol dm^{-3} sodium hydrogencarbonate.

In previous papers we described both the elution behavior of seven common inorganic anions in AS-1[16] and AS-4[17] separator columns by using carbonate-hydrogencarbonate as the eluent as well as the separation characteristics of many organic acids in an ICE separator column[18,19] using carbonic acid as the eluent and its application to the determination of valproic acid in drugs and patient plasma.[20] The present paper describes the elution behavior of seven common inorganic anions and a large number of organic acids in an AS-5 separator column using a weak carbonate-hydrogencarbonate eluent and its application to simultaneous determinations of inorganic and organic acids in various pharmaceuticals and canned goods.

Experimental

Materials. All reagents used were of reagent grade. All inorganic anion standard solutions were prepared by dissolving the corresponding sodium salts in distilled and deionized water. Organic acid standard solutions were also prepared by dissolving the acid or the corresponding alkali salts in distilled and deionized water, and/or dissolving the acid in aliquots of 1 mol dm^{-3} NaOH solution and then diluting with distilled and deionized water. The active carbon for the chromatograph was from commercial sources and was used after a pretreatment: wash with 1-propanol by means of a Soxhlet extractor for 3 h, filter using suction rinsing with distilled and deionized water, then dry in an electric drier oven at 150 °C for 24 h.

Chromatographic System. A Dionex Model 2000i ion chromatograph equipped with an AG-5 guard column, an AS-5 anion separator column, an AFS-1 anion fiber suppressor, and a conductivity detector was used. In applications to canned-good samples, a UVIDEC-100-VI variable UV-VIS detector (Japan Spectroscopic Co., Ltd.) was also used in series between the separator column and the suppressor. A sample loop with a volume of 50 mm^3 was used. For conductivity suppression, a 0.0125 mol dm^{-3} H_2SO_4 solution was used with a flow rate of c.a. 3 $cm^3 min^{-1}$ for all the eluent solutions used. The column temperature was not regulated but the eluent solution temperature was regulated by immersing the eluent reservoir into a water bath controlled at 25 °C. Chromatograms were recorded by the use of a Pantos U-228 dual-pen recorder.

Results and Discussion

Elution Behavior of Inorganic Anions. Figure 1 exemplifies a chromatogram of seven common anions obtained by using a 2.5 mmol dm^{-3} Na_2CO_3/0.25 mmol dm^{-3} $NaHCO_3$ solution as the eluent. Figure 2 shows the variation in the retention time of seven common anions with a change of the pH of the eluent solution; this was obtained by changing the composition of sodium carbonate/sodium hydrogencarbonate. However, the total concentration of the eluent was held constant at 2.75 mmol dm^{-3}. It can be seen that

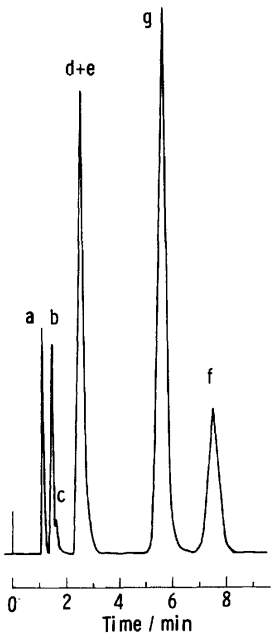

Fig. 1. A typical chromatogram of common seven anions. Column: AS-5 separator column with AG-5 guard column; eluent: 2.5 mmol dm^{-3} Na_2CO_3/0.25 mmol dm^{-3} $NaHCO_3$; flow rate: 2.0 cm^3 min^{-1}; anion fiber suppressor regenerant: 12.5 mmol dm^{-3} H_2SO_4 solution at c.a. 3 cm^3 min^{-1}; detection: conductivity at 30 μS FS; Peak notation: a=fluoride, b=chloride, c=nitrite, d=bromide, e=nitrate, f=phosphate, g=sulfate.

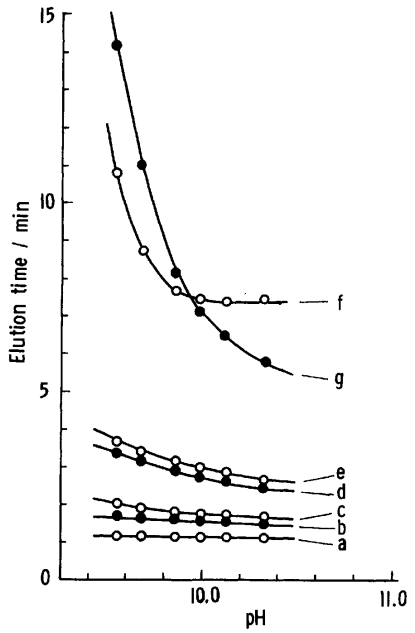

Fig. 2. Variations in the retention time of common seven anions with pH of the eluent solution. All chromatographic conditions except for eluent composition are the same as shown in Fig. 1. The total concentration of the eluent was held constant at 2.75 mmol dm^{-3}.

the effect of the pH of the eluent solution on the retention time of polyvalent ions (SO_4^{2-} and phosphate) is much greater than that of monovalent ions (Cl^-, Br^-, and NO_3^-) and that the difference of the retention time between monovalent and polyvalent ions. Thus, the separation of these ions was very good. It should also be noted that the elution behavior of these ions in an AS-5 separator column is fairly different from that in another previously reported separator columns.[16,17]

Elution Behavior of Organic Acids. Having noticed the observations described above and directing simultaneous determinations of inorganic and organic acids, the elution characteristics of a large number of organic acids in an AS-5 separator column were investigated.

Table 1 lists the various kinds of carboxylic acids examined. Figure 3 shows the variation in the retention time of carboxylic acids with a change of the pH of the eluent solution. The change of the pH of the eluent solution hardly affected the elution time of the monovalent anions. All of the monocarboxylic acids, regardless of the aliphatic and unsaturated acids (including keto acids), were first eluted for approximately the same elution time as fluoride anion. These results show that since any of the acids examined are fully dissociated in the pH of the eluent solution used, the retention of these ions are based on the eluting power of carbonate ions. Furthermore, these results also imply the possibility of a simultaneous determination of inorganic and carboxylic acids in a single injection.

Applications to the Analysis of Pharmaceuticals. For analytical chemists and analysts who work, especially, in laboratories of pharmaceutical companies and/or in hospitals, measurements of both organic acids and inorganic anions in a single sample solution are among the most frequently encountered determinations from the standpoint quality control. In such case, if possible, it would be the most desirable way for analysts to simultaneously determine both ions in a single measurement without any tedious treatment. The ion chromatography system described in this article offers a simple, rapid, and precise means for such an analysis. The sample preparation required is only a simple dilution with distilled and deionized water.

Figure 4 shows a typical chromatogram of a Rin-

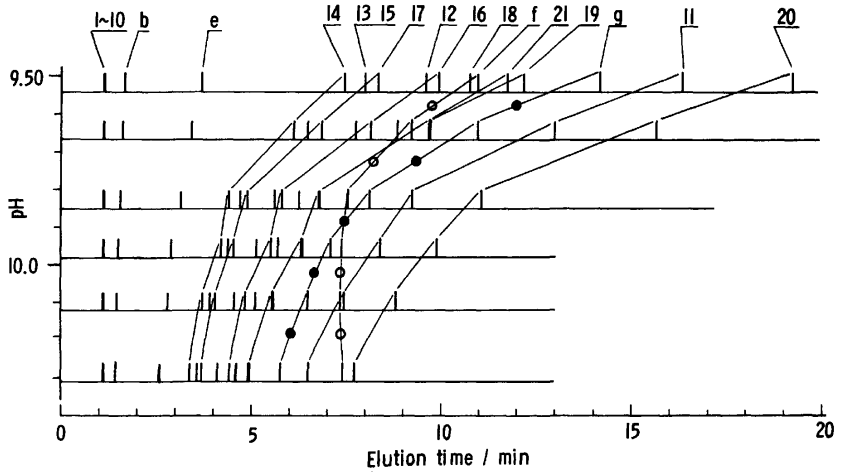

Fig. 3. Variations in the retention time of carboxylic acids with pH of the eluent solution. All chromatographic conditions are the same as shown in Fig. 2. Notations for inorganic and organic anions are the same as shown in Fig. 1 and Table 1, respectively.

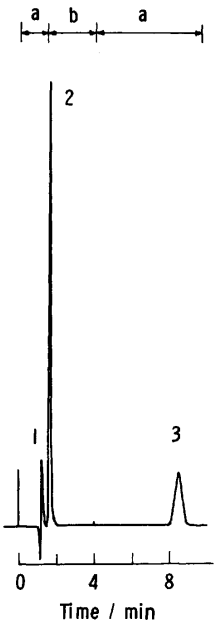

Fig. 4. A chromatogram of a Ringer's solution. All chromatographic conditions except for the eluent composition and the detector range are the same as shown in Fig. 1. Eluent: 1.25 mmol dm^{-3} Na_2CO_3/ 1.50 mmol dm^{-3} $NaHCO_3$ (pH=9.72); detector range: a=10 μS, b=30 μS; peak notation: 1=acetate, 2=chloride, 3=phosphate.

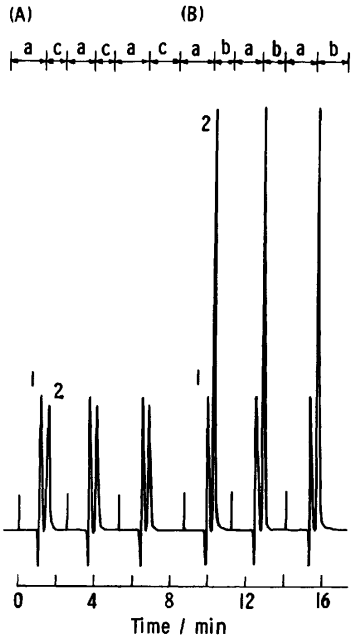

Fig. 5. Chromatograms of a Ringer's solution obtained by the repeated injections. All chromatographic conditions except for the detecor range are the same as shown in Fig. 4. Detector range: a=10 μS; b=30 μS; c=100 μS; Peak notation: 1=lactate, 2=chloride.

ger's solution which contains acetate, chloride, and phosphate as anion components. The detector range was switched from 10 to 30 μS immediately after the elution of an acetate peak and then again to 10 μS at 4 min after injection. Figure 5 also shows chromatograms obtained by repeated injections of a Ringer's solution, which contains lactate and chloride as anion components. In this case, the detector range was also switched from 10 to 100 μS (A) and to 30 μS (B) immediately after the elution of an lactate peak. The analytical results are summarized in Table 2. The determination of each ion was performed by comparing its peak height with that of a standard. The relative standard deviation of all ions in five measurements was less than 0.6%. These results probably indicate that the present system is effectively applicable for a simultaneous determination of organic and inorganic anions in such a routine analysis of pharmaceutical samples as a Ringer's solution.

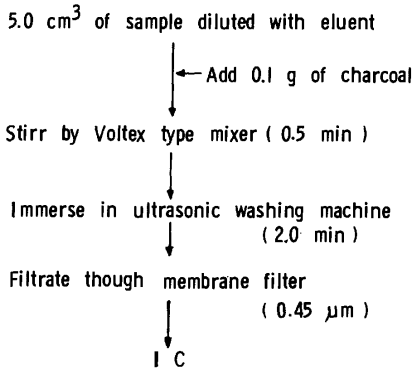

Fig. 7. A sample pretreatment procedure.

ned Goods. A Ringer's solution is a typical example having a clean matrix. However, it is more general for one to have to analyze ionic species in a sample having a complex matrix. In order to estimate the applicability of the present system to an analysis of a sample having a complex matrix, the analysis of anions in the liquor of canned goods was attempted.

Figures 6(A) and 9(A) show typical chromatograms of the liquor of canned watermelons and peachs, respectively, that were diluted with distilled and deionized water and then injected into the sample loop of the chromatograph through a membrane filter (Millipore, HA type, 0.45 μm). In these figures, chromatograms (a) and (b) were obtained by monitoring with a UV detector at 235 nm and a conductivity detector at 10 μS, respectively. In both chromatograms (b) of Figs. 6(A) and 9(A), an identification of each peak is possible by comparing their retention times with those of standard anions (as shown in each figure). However, since both chromatograms (a) in Figs. 6(A) and 9(A) show relatively complex profiles (notably, in the former, the nitrate peak is eluted as an adjacent one to a relatively large unknown one which does not show any clear peak at the corresponding retention time in the chromatogram (b)), a sample pretreatment was attempted in order to confirm the response of each ion in the conductivity detector and the assignment of each peak in chromatogram (b).

After considerable exploratory experiments using Amberlite XAD-2 and XAD-4 resins (Rohm & Haas Co.), Dowex 50W-X8 resin (200—400 mesh, Dow Chemical Co.), SEP-PAK® C_{18} cartridges (Waters Associates), Darco G-60 (active carbon, Darco Dept., Atlas Powder Co.), and active carbon for a chromatograph (Wako Pure Chemical Industries Ltd.), the sample pretreatment procedure using active carbon for a chroma-

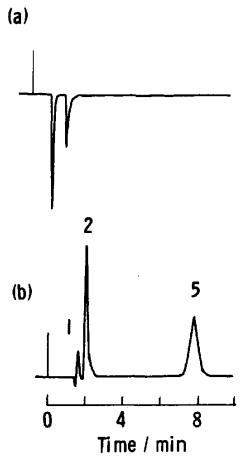

Fig. 8. A typical chromatogram of a blank solution prepared by following the pretreatment procedure using the eluent solution only. All chromatographic conditions and peak notations are the same as shown in Fig. 6.

tograph was determined (Fig. 7).

Although the active carbon was pretreated (described in the experimental section), a blank solution prepared by following a pretreatment procedure using only an eluent solution showed three peaks; this corresponds to the retention time of monocarboxylate, chloride, and sulfate ions (Fig. 8). However, in this experiment, no further pretreatment of the active carbon was performed since the reproducibility of the peak heights of these peaks were extremely good and no other peaks were observed. Furthermore, in this procedure, a liquor of canned goods was diluted with an eluent solution in the place of distilled and deionized water since a decrease of about 30—50% in the peak height of each peak obtained by the conductivity detector before and after the pretreatment procedure was observed when a liquor of canned goods was diluted with distilled and deionized water. However, diluting with an eluent solution resulted in no decrease in the peak height of each peak (as shown below).

Figure 6(B) shows typical chromatograms of liquor of a canned watermelon prepared by following the pretreatment procedure. Chromatogram (a) clearly shows three peaks which can be assigned to monocarboxylate (unidentified), nitrate, and malate ions, respectively. On the other hand, chromatogram (b) shows no changes in the elution profile of nitrate, malate, and phosphate peaks; however, by excluding the first eluted peak, only an increase of the peak heights of the chloride and sulfate peaks (which correspond to the peak height of each ion observed in Fig. 8) can be observed. This means that by the presence of the eluent, any loss of malate and inorganic anions in the sample solution could not be observed before and after the pretreatment procedure. Moreover, it was confirmed that peak 3 of chromatogram (b) in Fig. 6(B) as well as in Fig. 6(A) was based only on a nitrate ion, by

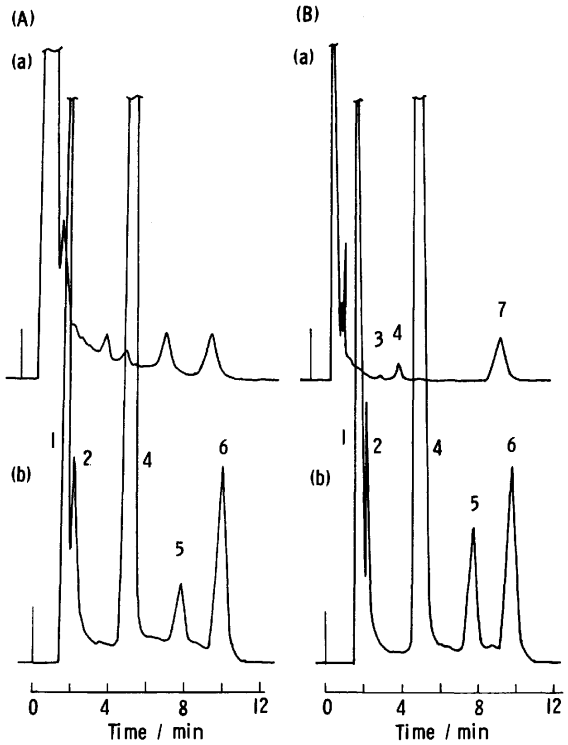

Fig. 9. Chromatograms of the liquor of a canned peach. All chromatographic conditions and peak notations except for fumarate ion are the same as shown in Fig. 6. Peak notation: 7=fumarate.

comparing the response of the sample with that of a standard nitrate ion obtained from both UV and conductivity monitors. Finally, these results indicate that by using a conductivity detector chloride, nitrate, malate, sulfate, and phosphate ions in the liquor of a canned watermelon can be simultaneously analyzed without any tedious pretreatment, except for simple dilution with distilled and deionized water and/or an eluent solution.

Figure 9(B) shows chromatograms of a liquor of canned peachs, prepared by following the pretreatment procedure. In chromatogram (a) obtained from a UV monitor, three peaks can be assigned to nitrate, malate, and fumarate ions, respectively. On the other hand, chromatogram (b), obtained from the conductivity monitor, did not show any changes of the elution profile, except for an increase in the peak heights of chloride and sulfate peaks. In addition, although fumarate and phosphate ions are eluted at the extremely near position, it can be concluded that peak 6 of chromatogram (b) in Fig. 9(B) as well as in Fig. 9(A) is based on only phosphate ions since fumarate ion shows no response for the conductivity detector at 10 μS in the concentration level observed.

The analytical results are summarized in Table 3. The concentration of the fumarate ion in the liquor of canned peach was determined by comparing its peak height with that of standard fumarate ion obtained from the UV monitor. The relative standard deviation

of all ions in five measurements was less than 5.0%.

These results indicate that the present system, using a conductivity detector and/or, if necessary, combined with a UV detector, an AS-5 separator column, and a dilute sodium carbonate sodium hydrogencarbonate solution as eluent, is also applicable to a simultaneous determination of dicarboxylic acids and inorganic anions in such samples having complex matrices as the liquor of canned goods. Furthermore, it should be noted that the pretreatment procedure developed in this study is a useful technique for further application studies.

The authors wish to express their thanks to Professor Shigero Ikeda of Osaka University for his helpful discussion.

Medium Effects on the Redox Properties of 12-Molybdophosphate and 12-Molybdosilicate

Eiki ITABASHI
Miyagi University of Education, Aoba, Aramaki, Sendai 980
(Received September 20, 1986)

The formal redox potentials of 12-molybdophosphate and 12-molybdosilicate up to the twelve-electron reduction per heteropolymolybdate ion were determined by cyclic voltammetry at a glassy carbon electrode in 50% (v/v) water-organic media containing some inorganic acids. These heteropolymolybdates in the presence of 1,4-dioxane (DO) or tetrahydrofuran (THF) display five two-electron reversible cathodic waves, followed by an irreversible two-electron wave, whereas the same heteropolymolybdates in the presence of 1,2-dimethoxyethane, *N*,*N*-dimethylformamide, acetonitrile, ethanol, or acetone yield five successive redox couples of 2, 2, 2, 4, and $2e^-$ (electrons) each. The eight-electron reduction species of 12-heteropolymolybdates are stabilized by cyclic ethers such as DO or THF. The stabilization of the eight-electron reduction species by the addition of a cyclic ether has been explained by taking into account the adduct formation between the molecules of the cyclic ether and 12-heteropolymolybdate.

Many electrochemical studies of 12-molybdophophoric acid (12-MPA) and related 12-heteropolymolybdates have been carried out in order to make clear the redox properties of a series of mixed valence Mo(V, VI) complexes known as a Kiggin structure. The previous voltammetric and polarographic investigations have shown that 12-MPA as well as 12-molybdosilicic acid (12-MSA) in acidic solutions containing some organic solvents undergoes a series of consecutive two-electron reduction to yield various mixed valence Mo(V, VI) complexes.[1] It seems likely that the first three two-electron redox couples of 12-heteropolymolybdates in acidic solutions containing dioxane (DO) or ethanol (EtOH) are remarkably fast and reversible.[2-6] On further reduction above six electrons, however, different results have been reported concerning the fourth and subsequent redox reactions of 12-heteropolymolybdates in acidic solutions containing DO or EtOH.[2,3]

Tsigdinos and Hallada[2] have shown that 12-MSA in 50% (v/v) water-dioxane solutions containing hydrochloric acid exhibited five two-electron reduction waves. Recently, an identical result was reported on the reduction processes of both 12-MPA and 12-MSA in aqueous dioxane media containing sulfuric acid.[5] On the other hand, Souchay and his colleagues[3] have reported that the reduction processes of both 12-MPA and 12-MSA in 50% (v/v) water-ethanol media containing hydrochloric acid displayed three two-electron waves, and 12-heteropoly acids were not further reduced above six electrons in acidic media containing ethanol.

These results suggest that the redox processes of 12-heteropolymolybdates in acidic solutions are influenced by the nature of organic solvent.

This paper presents some unusual solvent effects on the gradual reduction processes of 12-heteropolymolybdates in acidic solutions containing some organic solvents at a glassy carbon electrode.

Experimental

All electrochemical measurements were carried out with a potentiostat (Fuso Co., Model 311) equipped with a function generator (Fuso Co., Model 321) and a recorder (Riken Denshi Co., Model F-43P). A Tokai glassy carbon disc electrode (GCE) with a geometric surface area of 0.071 cm^2 was employed as a working electrode. The counter electrode was a platinum spiral. The potential of the working electrode was measured against a saturated calomel electrode (SCE).

12-Molybdophosphoric acid was purchased from Alfa Chemical Products Co., and was used as received. 12-molybdosilicic acid was obtained from High Purity Chemical Institute (Saitama). Data reported here for both 12-MPA and 12-MSA refer to the stable α-form.[1] All other chemicals were of analytical reagent grade and were used without further purification. All solutions were made up with twice-distilled water and were deaerated with water-pumped nitrogen. All measurements were performed at 25 °C.

Results and Discussion

12-Molybdophosphoric Acid. Figure 1 shows typical cyclic voltammograms of 12-MPA in 50% (v/v) water-dioxane medium containing 0.5 mol dm^{-3} H_2SO_4. The cathodic sweep up to −0.8 V displays six peaks and one flat wave. The first four cathodic waves are reversible. Each step of these waves shows the following characteristics. The cathodic and anodic peak potentials (E_{pc} and E_{pa}) are invariant with scan rate (v) for v between 10 and 200 mV s^{-1}, and the potential difference $\Delta E_p(=E_{pc}-E_{pa})$ is −(29±2) mV. This corresponds closely to the theoretical value of −29 mV for a Nernstian two-electron wave at 25 °C. The fifth cathodic peak is also invariant with scan rate, however, ΔE_p is −(40±2) mV, and the peak height is approximately half of the first cathodic peak. The potential separation between the fifth cathodic peak and the rising potential of the irreversible wave near −0.45 V is about 50 mV. This result suggests that the potential separation on the successive reductions is so small that the fifth peak is distorted by the following wave. It has been pointed out by Polcyn and Shain[7] that the indi-

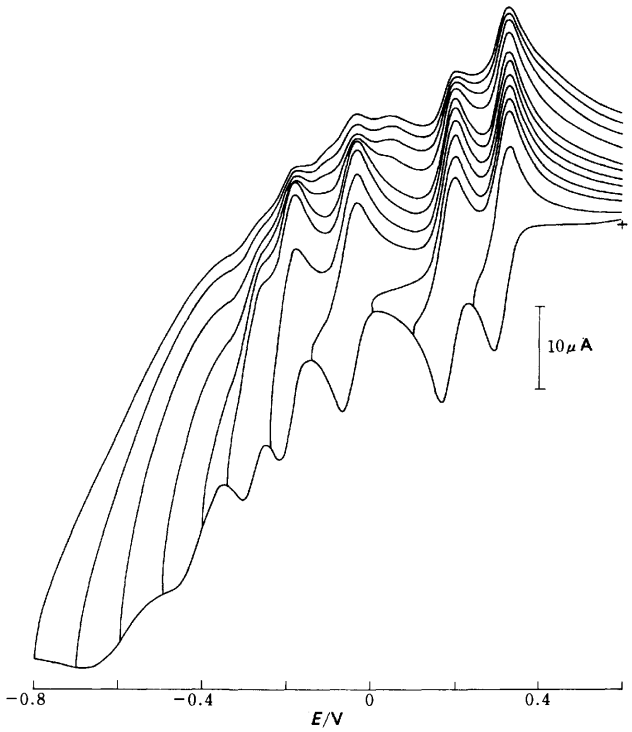

Fig. 1. Cyclic voltammograms of 1×10^{-3} mol dm^{-3} 12-molybdophosphoric acid in 50%(v/v) water-dioxane solution containing 0.5 mol dm^{-3} H_2SO_4 at sweep rate 0.05 V s^{-1}.

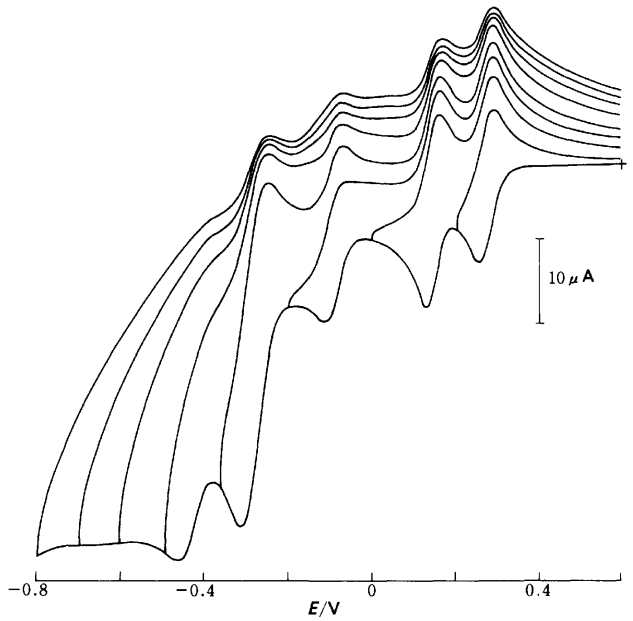

Fig. 2. Cyclic voltammograms of 1×10^{-3} mol dm^{-3} 12-molybdophosphoric acid in 50%(v/v) water-DMF solution containing 0.5 mol dm^{-3} H_2SO_4 at sweep rate 0.05 V s^{-1}.

vidual waves of the stepwise reductions merge into one broad distorted wave whose peak height and shape is no longer characteristic of a reversible wave, as the potential separation between the successive reductions becomes less than about 100 mV n^{-1}, where n is the number of electrons involved in the electrode process. In order that the cyclic voltammograms on the successive reductions behave as independent reversible waves, a certain minimum potential separation of about 118 mV n^{-1} is required.

The first five cathodic waves have been previously assigned to the addition of two electrons for each step.[2,5]

The flat wave near −0.45 V is irreversible. The flat wave increased in height with increase in scan rate, however, it shifted toward more negative potentials, and merged into the broad wave near −0.65 V at scan rates above 200 mV s^{-1}. The height of the flat wave is nearly equal to the first cathodic peak. It is reasonable to infer that the flat wave corresponds to a two-electron process. The broad wave near −0.65 V is also irreversible, and exhibits a plateau current rather than a peak at scan rates above 100 mV s^{-1}. The plot of the current function $i_{pc}v^{-1/2}$ vs. v decreased with increasing scan rate, where i_{pc} was measured from the base current observed in acidic dioxane solution in the absence of 12-MPA. The variation of the current function (i_{pc} $v^{-1/2}$) with scan rate would indicate that the total current function of the broad wave is made up of charge transfer coupled to homogeneous chemical reactions.[8]

A similar cyclic voltammogram with six cathodic peaks and one flat wave was also observed in acidic solutions containing tetrahydrofuran (THF).

On the other hand, 12-MPA in acidic solution containing *N,N*-dimethylformamide (DMF) gives five well-defined cathodic peaks, as shown in Fig. 2. The first three cathodic waves correspond to a two-electron process for each step.[2,5] The fourth step is also reversible, but its peak height is approximately 2.65 times the height of the first cathodic peak. The peak current on the stationary electrode voltammetry is proportional to $n^{3/2}$, where n is the number of electrons involved in the electrode process.[8] If the fourth step corresponds to a four-electron process, the height of the fourth step is $2^{3/2}$ times the height of the first two-electron reversible wave. Accordingly, the fourth step is attributable to a four-electron process. Although the fifth cathodic wave is less reversible than the first cathodic one, the first and fifth cathodic steps have nearly equal height. It is reasonable to assign that the fifth cathodic step slso corresponds to a two-electron process. Similar cyclic voltammograms with five cathodic steps up to −0.80 V were observed in acidified mixed solvents containing 1,2-dimethoxyethane (DME), acetonitrile (MeCN), EtOH, or acetone. A four-electron transfer process on the one-step has been considered to be a phenomenon that appears only rarely, however, the four-electron transfer has been found for the reduction processes of $[X_2Mo_{18}O_{62}]^{6-}$ in acidic solutions, where X is P or As.[1]

The formal redox potential $E_f^{\circ\prime}$ was determined by using the equation $E_f^{\circ\prime}=(E_{pc}+E_{pa})/2$. These data are summarized in Table 1.

a) The concentration of 12-MSA was 1×10^{-3} mol dm^{-3}. The abbreviation of the organic solvent is the same as that of Table 1.

12-Molybdosilicic Acid. The same set of experiments was performed for 12-MSA. 12-MSA in acidic solutions containing DO or THF is reduced in six steps. Each step appears to correspond to the addition of $2e^-$ (electrons). Whereas, the same heteropoly acids with DME, DMF, MeCN, EtOH, or acetone present give five cathodic peaks of 2, 2, 2, 4, and $2e^-$ each.

12-MSA is moderately stable for the hydrolytic degradation in acidic solutions even though organic solvent is not present in the solution. Some experiments were carried out in acidic solutions in the absence of organic solvent. 12-MSA in aqueous solutions containing H_2SO_4, HNO_3, or HCl is reduced in five steps of 2, 2, 2, 4, and $2e^-$ each, up to −0.80 V. The formal redox potentials of 12-MSA in acidic solutions with and without organic solvent present are listed in Table 2.

Solvent Effect. In acidic solution alone, 12-MPA undergoes hydrolytic degradation, however, it is stabilized by addition of comparatively large amounts of organic solvent. On the other hand, 12-MSA is stable in acidic media with and without organic solvent present. The most striking aspect of the present work is that the eight-electron reduction species of both 12-MPA and 12-MSA are stabilized by cyclic ethers such as DO or THF, however, they are unstable in the presence of DME, DMF, MeCN, EtOH, or acetone. It seems likely that the dielectric constant of the organic solvent plays an important role in the stabilization of the eight-electron reduction species of heteropolymolybdates. A decrease in dielectric constant of the solvent should be accompanied by a decrease in the dissociation of ionic aggregates such as 12-heteropolymolybdates.

Pure DMF, MeCN, EtOH, and acetone have high dielectric constants, ranging from 20 to 50.[9] For ethers such as DO, THF, and DME, the range of the dielectric constants is about 2—8. Consequently, extensive ionic aggregation and a suppression of reorganization are expected for 12-heteropolymolybdates in acidic mixed solvents containing ethers. In spite of the fact that DME and DO have nearly the same dielectric constants, DO rather than DME in acidic mixed solvents is better suited for stabilizing the eight-reduction species

of 12-heteropolymolybdates. This finding raises the question whether the dielectric constant of the solvent serves to any significant extent for stabilizing heteropoly molybdenum blues in acidic solvents. Ethers employed in the present work have low dipole moments, ranging from 0.5 to 1.7.[9] However, the eight-electron reduction species of 12-heteropolymolybdates is not stabilized in acidic solutions containing DME. The possibility can be ruled out that the dipole moment of the organic solvents plays an important role in the stabilization of the eight-electron reduction species of heteropolymolybdates.

12-MSA in sulfuric acid solutions containing DO or THF is reduced at more positive potentials than that in the same electrolyte solution without organic additive present, as is shown in Table 2. The opposite effect was observed in the presence of DME, DMF, MeCN, EtOH, or acetone. The voltammetric behavior of 12-MSA in sulfuric acid solution containing DME is almost identical to that in the same electrolyte solution containing DMF, MeCN, EtOH, or acetone.

The fact that 12-MSA in acidic solutions containing cyclic ethers is reduced at potentials more positive than the hydrated 12-MSA in acidic solutions in the absence of organic solvents suggests that the cyclic ether stimulates the electroreduction of 12-MSA, and that a specific interaction is involved between 12-MSA and the cyclic ether. Such an interaction should be regarded as the coordination of the cyclic ether to the Mo atoms, or the formation of Lewis acid-base adducts between 12-MSA and cyclic ether. It has been shown that the formal redox potentials of the first three redox couples of 12-MPA in sulfuric acid solutions containing DO shift toward more positive potentials with increase in concentration of DO over the concentration range from 10 to 50% in volume.[4] A solid 12-MSA containing 1,4-dioxane molecules instead of water as a crystallization solvent molecule has been prepared.[2] These results further indicate that a strong solvation force is involved between 12-heteropoly acids and 1,4-dioxane. It seems reasonable to suppose that the cyclic ether acts as a Lewis base even in acidic solutions, since large amounts of ether are present in the electrolyte solutions.

The redox behavior of 12-heteropolymolybdates in acidic media is little influenced by the kind of inorganic acid. It has been shown from the conductivity measurements that hydrochloric acid in water-dioxane mixtures behaves as a strong electrolyte, even up to 70% dioxane.[10] Accordingly, it seems likely that various inorganic acids remain unassociated at the concentration employed in the present work.

(Received September 25, 1986)

The process of the thermal decomposition of lead *cyclo*-tetraphosphate dihydrate (P_{4m}), $Pb_2P_4O_{12}\cdot 2H_2O$, was investigated using X-ray analysis, DTA-TG, HPLC, Isotachophoresis (IP), and IR spectrometry. P_{4m} lost water of crystallization at about 100 °C. In the region of 150—170 °C, P_{4m} decomposed to form oligo phosphates, and at about 190 °C, oligo phosphates changed to a crystalline material which contained ortho- and triphosphate. At about 300 °C, the crystalline material changed to *cyclo*-octaphosphate (P_{8m}) through a new type of *cyclo*-tetraphosphate (P_{4m}*). However, in the presence of a higher water-vapor pressure than the atmospheric one, the crystalline material changed mainly to the new type of P_{4m}* with a little P_{8m}, while at a low water-vapor pressure, the reverse tendency was observed: mainly P_{8m} and a little P_{4m}*.

It is well-known that upon heating condensed phosphates hydrolyse or condense to form various kinds of phosphates.[1-10] The products obtained are pure phosphates or a mixture of linear and/or cyclic phosphates with different numbers of phosphorus atoms. These reactions are affected by the kind of metal, the degree of dryness in the crystal, the atmosphere, the temperature, and the time and rate of heating, thus resulting in the formation of different phosphates. However, these conditions have not yet been comprehensively examined.

In this work, therefore, the effect of water vapor on the thermal decomposition of lead *cyclo*-tetraphosphate (P_{4m}) was investigated in detail. The higher-membered cyclic phosphates, such as six-membered *cyclo*-tri and eight-membered *cyclo*-tetraphosphate, are very important electrolytes because of their high negative charge on a relatively compact structure.[10] Schülke[11] reported in 1968 that P_{4m} decomposed at about 300 °C to form lead *cyclo*-octaphosphate (P_{8m}). Using metals other than lead, such as alkaline earth metals (Mg, Ca, Sr, and Ba), the present authors have investigated the thermal decompositions of *cyclo*-tetraphosphates. P_{8m} could not be obtained. Further, little is known about the detailed formation conditions; i.e., in the synthesis of P_{8m} by the method of Schülke, the product varies with the degree of the dryness of the sample used and with the method of heating. This may be attributable to the effect of water vapor in the reaction process. In this work, therefore, for the purpose of establishing the optimum conditions for the preparation of P_{8m}, the process of the thermal decomposition of P_{4m} was investigated by means of X-ray analysis, thermal analysis (DTA-TG), high-performance liquid chromatography-flow injection analysis (HPLC-FIA), Isotachophoresis (IP), and IR spectrometry.

Experimental

Chemicals. The lead *cyclo*-tetraphosphate (P_{4m}), $Pb_2P_4O_{12}\cdot 2H_2O$, was prepared by the method given in the literature.[11] Unless otherwise stated, guaranteed reagents were used without further purification.

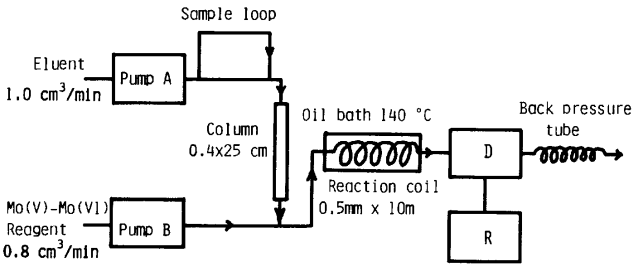

Fig. 1. Flow diagram of chromatograph and detection system. D: detector, R: recorder.

The X-ray diffraction analysis was carried out with a Rigaku Denki Geigerflex diffractometer using nickel-filtered Cu $K\alpha$ radiation. The thermal analysis (DTA-TG) was carried out by means of a Rigaku 8002 SD thermal analyzer. The isotachopherograms were recorded on a Shimadzu IP-2A apparatus equipped with a potential gradient detector (PGD). The operational system and procedure of the isotachophoretic analysis used were as have been described previously.[12-15] The IR spectra were taken by means of a KBr tablet and recorded on a JASCO DS-701G Diffraction Grating Infrared Spectrophotometer.

A diagram of an HPLC-flow injection analysis (FIA) system is shown in Fig. 1. A JASCO TRIROTER V Liquid Chromatograph was used. The sample solution (100 µl) was introduced via a loop-valve sampler onto a separation column and chromatographed at a flow-rate of 1.0 cm^3 min^{-1}. The separations were performed on a column (250×4.0 mm I.D.) packed with a polystyrene-based anion-exchanger (TSK gel SAX, d_p=10 µm, Toyo Soda). The eluents for the chromatographic separation of polyphosphates were comprised of appropriate concentrations of potassium chloride and 0.1% (w/v) Na_4EDTA (pH 10). The Mo(V)-Mo(VI) reagent for the analysis of phosphates was prepared by the method of Lucena-Conde and Prat,[16] and was diluted 10-fold with distilled water. The diluted reagent was merged, at a flow-rate of 0.8 cm^3 min^{-1}, into the stream of the column effluent. The mixed solution was then heated at 140 °C in an oil bath by passing it through 10 m of 2.0×0.5 mm I.D. PTFE tubing. The heteropoly blue complex thus formed was detected at 830 nm in the flow cell. A back-pressure PTFE coil (1.5 m×2.0 mm O.D.×0.25 mm I.D.) was connected to the end coil of the flow-cell outlet to pre-

vent the formation of air bubbles on heating.[17-22]

The sample solutions for HPLC-FIA was prepared as follows. Fifteen-mg portions of samples of phosphates were dissolved in 2 cm^3 of a 1.0 wt% sodium sulfide solution, and the lead sulfide thus precipitated was filtered out. A 1 cm^3 of the filtrate was diluted to 100 cm^3 with distilled water. A 100-μl portions of this solution was used for HPLC-FIA. The insoluble polyphosphate ($P_{high\ poly}$) was determined in the manner described above after decomposition by heating with 3 cm^3 of 1.0 mol dm^{-3} of hydrochloric acid.

The furnace used in the calcination experiments is shown in Fig. 2. The humidity in the furnace was controlled with an Ace Constant-humidity Generator Model AHC-1 (Ace Scientific Laboratory Co., Ltd.) and/or a Heatless Air Drier HF 200-9-30 (Nippon Pure Gas Co., Ltd.). The humidity of the entering air is controlled by passing the air through two water-bubbling towers maintained at the appropriate temperature to give the desired water-vapor pressure. In anhydrous experiments, the air was dried by passage through a molecular-sieve tower. The amounts of water in the dried air detected with a gas detector (GASTEC) were less than 0.1 mg dm^{-3}.

The sample (0.1—0.2 g) was spread on the porcelain boat in a layer less than 1 mm thick to reach, almost instantly, the desired atmosphere.

Results and Discussion

The Thermal Decomposition by DTA-TG at Three Different Atmospheres.

For the purpose of investigating the effect of water vapor upon the thermal-reaction process of P_{4m}, the heating products under atmospheric pressure, reduced pressure, and with a semi-closed cell were compared. Figure 3 shows the DTA-TG curves of P_{4m} at atmospheric pressure. Four endothermic peaks at about 100, 130, 160, and 280 °C, with a weight loss, and two exothermic peaks at about 150 and 190 °C are observed. To clarify these thermal changes at each temperature, the chromatography (HPLC) of the products at 130, 190, 260, and 335 °C, where the thermal changes were completed, was carried out. Figure 4 shows the chromatograms of the products obtained at each temperature. At 130 °C, P_{4m} lost two molecules of water of crystallization. The chromatogram at 190 °C shows that oligo phosphates such as ortho-(P_1), pyro-(P_2), tri-(P_3), and tetraphosphate(P_4) were formed; ring-opening reactions occurred at this temperature, followed by the condensation of these species to form long-chain phosphates. At 260 °C, oligo phosphates were rearranged to P_1 and P_3. Perhaps, they were formed as a double salt. Schülke[11] named the double salt a "crystal compound." The large peak on the chromatogram at about 53 min for the product at 335 °C indicates the formation of P_{8m}. At the same time, the amounts (peak heights) of P_1 and P_3 decreased with the increase in the amount of P_{8m}. The product heated at 600 °C was not dissolved in the sodium sulfide solution, indicating that insoluble polyphosphates ($P_{high\ poly}$) were formed. As is shown in Fig. 5, the rate of the dehydration condensation reaction after ring opening under reduced pressure (about 5 Torr (1 Torr=133.322 Pa)) was faster than that under atmospheric pressure (Fig. 4), with the result that more condensed species, such as penta-(P_5), hexa-(P_6), and heptaphosphate (P_7), was formed in an appreciable abundance. In the 260—335 °C region, P_{4m} formed again; its X-ray pattern was different from that of $Pb_2P_4O_{12}$ prepared by dehydrating $Pb_2P_4O_{12}$.

$2H_2O$.

Schülke[11] reported previously that P_{4m} formed again in this temperature range. However, the P_{4m} species formed in the present work had another crystal structure. Further, from the IP[12-15] and IR spectra[23] it was confirmed that the P_{4m} species formed in the present work was cyclic phosphate. This *cyclo*-tetraphosphate is named "high-temperature-type *cyclo*-

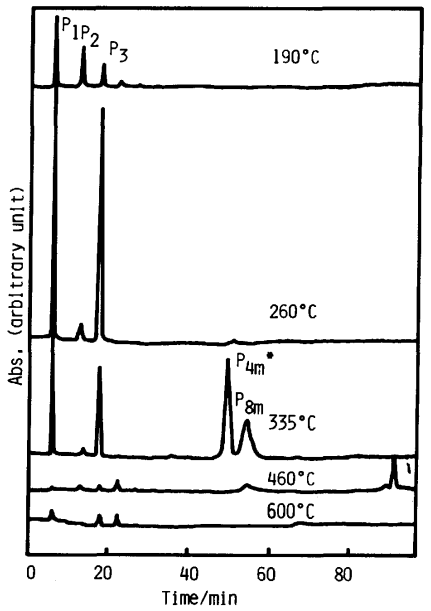

Fig. 6. Chromatograms of the products heated with semi-closed cell.

tetraphosphate (P_{4m}*)." In the case of heating with a semi-closed cell, as is shown in Fig. 6, the hydrolysis proceeded rather faster than the atmospheric pressure. Even at 190 °C, P_{4m} was somewhat changed to P_1, P_2, and P_3. P_{4m} almost entirely turned to P_1 and P_3 at 260 °C. At 335 °C, P_{4m}* was formed, plus a small amount of P_{8m}. Large amounts of the polyphosphates were formed at 460 °C.

Isothermal Change. On the basis of the above results, the effect of water vapor upon the thermal decomposition of P_{4m} was found to be significant; therefore, the influence of water vapor upon thermal decomposition was investigated by means of isothermal heating in an electric furnace at the temperatures of the respective DTA peaks. Figure 7 shows the changes in composition attributable to the calcination time of P_{4m} at 190 °C and at the relative humidities of 0 and 50%. In the case of the relative humidities of 15, 50, and 90%, approximately the same results were obtained. In the 180—200 °C region, a crystalline material containing components of P_1 and P_3 (molar ratio=ca. 1 : 1) was formed under a 15—90% relative humidity (at 25 °C). In a dry-air atmosphere (r.h.=0%), this crystalline material was changed to P_{4m}* (about 45% after 30 min). At 260 °C, as is shown in Fig. 8, the crystalline material changed partially to P_{4m}* (about 45%) at a 50% relative humidity; the same results were obtained in the 15—90% range of relative humidity. However, under the dry-air conditions, both P_{8m} and polyphosphates were produced. Moreover, insoluble polymers were formed in a considerable amount (about 70% at the maximum). This fact indicates that, under dry-air conditions, these condensation reactions proceeded more rapidly than under atmospheric conditions. When $Pb_2P_4O_{12}$ anhydride was used as the

starting material, similar results were obtained. Therefore, the crystalline material was formed at 260 °C,

Table 1. Changes in the Amounts of Phosphorus Compounds in the Samples Heated at 250 °C at Various Relative Humidities (r.h.) for 40 min (with a crystalline material containing components of P_1 and P_3 as the starting material)

Compound	P_1	P_2	P_3	P_{4m}*	P_{8m}	P_{oligo}
(r.h., %)	%	%	%	%	%	%
0	20.0	4.0	29.4	35.7	10.3	0.6
15	16.0	3.3	37.5	42.8	0	0.4
50	17.3	3.2	37.9	40.6	0	1.0
90	11.9	5.0	52.5	29.0	0	1.6

Table 2. Changes in the Amounts of Phosphorus Compounds in the Samples Heated at 280 °C at Various Relative Humidities (r.h.) for 40 min (with a crystalline material containing components of P_1 and P_3 as the starting material)

Compound	P_1	P_2	P_3	P_{4m}*	P_{8m}	P_{oligo}
(r.h., %)	%	%	%	%	%	%
0	0	0	2.8	5.7	89.3	2.2
15	8.0	1.4	24.2	28.5	37.9	0

90	14.0	3.9	34.0	43.0	4.1	1.0

regardless of the starting material. In the dry-air atmosphere, even at 200 °C, P_{4m}* was already formed in an amount of 46%. As has been mentioned above, a crystalline material containing components of P_1 and P_3 was formed at about 200 °C by means of an exothermic reaction. Whatever the starting material ($Pb_2P_4O_{12}\cdot 2H_2O$ or $Pb_2P_4O_{12}$), the crystalline material was formed. To clarify the effect of the water content in the heating atmosphere at the second endothermic peak, the process of the formation of P_{8m} was investigated using the crystalline material which had been prepared by heating $Pb_2P_4O_{12}\cdot 2H_2O$ at 200 °C for 40 min in an electric furnace. Table 1 shows the changes in the amounts of phosphorus compounds in the samples heated at 250 °C. At 250 °C, a temperature before the endothermic peak (Fig. 3), we expected a remarkable effect of the water vapor upon the formation of P_{8m}. In the dry-air atmosphere (0%), the amounts of P_1 and P_3 decreased, P_{4m}* was formed, and P_{8m} was obtained in about a 10% yield. However, in a 15—90% relative-humidity atmosphere (at 25 °C), P_{4m}* increased with the decrease in P_1 and P_3, while P_{8m} was not formed at all. Further, at 280 °C and at a 0% relative humidity atmosphere, as is shown in Table 2, the amount of P_{8m} reached about 90%, and at a 15—50% relative humidity (at 25 °C), that of P_{8m}, 35—38%. In the dry-air atmosphere, P_1 and P_3 decreased, while, in turn, P_{4m}* was formed, followed by the formation of P_{8m} in fairly large quantities. However, in a 90% relative humidity, P_1 and P_3 remained in fairly large quantities, resulting

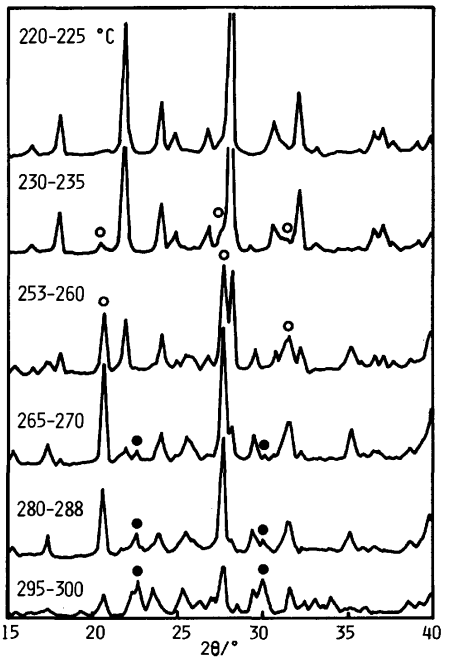

Fig. 9. X-Ray diffraction patterns of products on heating. O: P_{4m}*, ●: P_{8m}.

in the formation of P_{4m}* in a large quantity, and a little P_{8m} was formed.

The process of the thermal decomposition of lead *cyclo*-tetraphosphate under several humid atmospheres may be summarized schematically as follows:

1) $Pb_2P_4O_{12}\cdot 2H_2O$ as the starting material.

$$Pb_2P_4O_{12}\cdot 2H_2O \underset{\text{dry and r.h.}=15-90\%}{\overset{100℃}{\rightleftharpoons}} Pb_2P_4O_{12} \xrightarrow{150-170℃} P_{oligo}$$

$$\xrightarrow[\text{r.h.}=15-90\%]{180-200℃} P_1 + P_3 \xrightarrow{260℃} P_1 + P_3, P_{4m}^*$$

$$\xrightarrow[\text{dry}]{180-200℃} P_1 + P_3 \ll P_{4m}^* \xrightarrow{260℃} P_{8m}, P_{\text{high poly}}$$

2) P_1+P_3 as the starting material.

$$P_1 + P_3 \xrightarrow[\text{r.h.}=90\%]{250℃} P_1 + P_3 > P_{4m}^* \xrightarrow{280℃} P_1 + P_3, P_{4m}^*$$

$$P_1 + P_3 \xrightarrow[\text{r.h.}=15-50\%]{250℃} P_1 + P_3, P_{4m}^* \xrightarrow{280℃} P_1 + P_3, P_{4m}^*, P_{8m}$$

$$P_1 + P_3 \xrightarrow[\text{dry}]{250℃} P_1 + P_3, P_{4m}^* > P_{8m} \xrightarrow{280℃} P_{8m} \gg P_{4m}^*$$

P_1+P_3: crystalline material. The symbols>and≫show the quantitative relations between the products.

X-Ray Analysis on Heating P_{4m}. In order to clarify the facts presented above, X-ray measurements were performed. Figure 9 shows the X-ray diffraction patterns of $Pb_2P_4O_{12}\cdot 2H_2O$ at several stages of heating in an electric furnace attached to the X-ray diffractometer. In the 200—225 °C region, P_1 and P_3 remained unchanged. At 230—235 °C, the characteristic diffraction lines of P_{4m}* at 2θ=20.6 and 27.7° began to appear; they gradually increased with the heating temperature. The X-ray diffraction pattern at 265—270 °C showed P_{4m}*, the diffraction lines of P_1 and P_3 became very small, and small peaks of P_{8m} began to appear. At 280—288 °C, the peaks of P_1 and P_3 disappeared and P_{4m}* began to form (or the peaks of P_{4m}* began to be recognized). At the same time, the peaks of P_{8m} also increased. At 295—300 °C, the peaks of the diffraction pattern are those of P_{4m}* and P_{8m}. The peaks of P_{8m} appeared distinctly with the temperature. These results confirmed that the crystalline material changes to P_{8m} through P_{4m}*. The optimum conditions for preparing P_{8m} are as follows. It is desirable to have a low water-vapor pressure when P_1 and P_3 condense to P_{8m} through a new type, P_{4m}*, at about 300 °C.

The authors wish to thank Mr. Nobuyuki Tada for his helpful work.

Crystal and Molecular Structures of Two Isomers for Chlorobis-(2-methyl-8-quinolinolato)nitrosylruthenium(III)

Yukiko KAMATA, Takashi KIMURA,† Reiko HIROTA, Eiichi MIKI, Kunihiko MIZUMACHI, and Tatsujiro ISHIMORI*

Department of Chemistry, College of Science, Rikkyo University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171
†The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received October 1, 1986)

Two isomers of [RuCl(2mqn)$_2$(NO)] (2mqn=2-methyl-8-quinolinolate ion) were isolated and their crystal structures were determined by X-ray diffraction. In both the isomers, the Cl atom lies cis to the NO group and the O atom of one of the quinolinolato ligands lies trans to the NO group. One of the two isomers, (**1**), is in cis(O,O) and trans(N,N) configuration for the two quinolinolato ligands, another, (**2**), being in cis(O,O) and cis(N,N). Crystal data: **1**, space group $P2_1/c$ (monoclinic), a=7.412(1), b=27.241(6), c=9.752(1) Å, β=105.49(1)°; **2**, space group $P2_1/c$ (monoclinic), a=7.157(2), b=20.205(4), c=13.359(3) Å, β=107.70(2)°. The final R values for **1** and **2** are 0.044 for non-hydrogen atoms and 0.037 for all the atoms, respectively. The coordination geometries of **1** and **2** are distorted octahedron. The interatomic distances are qualitatively discussed on the basis of π- and σ-bonding abilities of the NO group, the Cl, and the coordinating atoms, N and O, of the quinolinolato ligands.

There has been a report for the solvent extraction of nitrosylruthenium(III) with 8-quinolinol.[1] However, there has been no report on the isolation of nitrosylruthenium(III) complexes with 8-quinolinol or its derivatives. In the reactions of nitrosylruthenium(III) species with 2-methyl-8-quinolinol in ethanol, we isolated two geometrical isomers of [RuCl(2mqn)$_2$(NO)] (2mqn=2-methyl-8-quinolinolate ion). The crystal structures of the isomers were determined by X-ray diffraction. Further, the isomers were characterized by NMR and IR.

Experimental

Materials. Hydrated trichloronitrosylruthenium(III) (Ru=30.8%) was prepared by nitrosylation of commercial $RuCl_3 \cdot 3H_2O$ in a hydrochloric acid solution and evaporation of the solution.[2] The other reagents used were of special grade.

Preparation and Separation of the Isomers of Chlorobis(2-methyl-8-quinolinolato)nitrosylruthenium(III). An ethanol solution of 2-methyl-8-quinolinol (5.4 mmol in 80 cm^3) was added to an ethanol solution of the hydrated trichloronitrosylruthenium(III) (0.90 mmol in 10 cm^3). After the mixture solution had been refluxed for 5 h, it was allowed to stand overnight at room temperature, and evaporated with a rotary evaporator. The dried residue was dissolved in 50 cm^3 of dichloromethane. The dark red solution was added on the silica-gel column (Wakogel C-200, ϕ 3 cm×15 cm). Two red adsorption bands were eluted with dichloromethane. The species in the front and back bands were named **1** and **2**, respectively. The eluates containing **1** and **2** were separately concentrated with a rotary evaporator to a small volume and dried in the open air to obtain reddish brown **1** and dark reddish brown **2**. Yield: 42% for **1** (based on the ruthenium compound); and 9% for **2**. Found: Ru, 21.3; Cl, 7.6; C, 49.6; H, 3.3; N, 8.8% for **1**; Ru, 20.9; Cl, 7.7; C, 49.8; H, 3.2; N, 8.7% for **2**. Calcd for [RuCl($C_{10}H_8NO$)$_2$(NO)]: Ru, 20.9; Cl, 7.3; C, 49.7; H, 3.4; N, 8.7%. The ruthenium was determined by the ruthenate method.[3] The C, H, N, and Cl were analyzed by the Organic Analysis Center of the Institute of Physical and Chemical Research.

X-Ray Crystallographic Analysis. The crystalline samples were prepared by concentrating a dilute CH_2Cl_2-$CH_3COOC_2H_5$ solution of **1**, and a dilute CH_2Cl_2-CH_3CN solution of **2** in the open air. The crystals of **1** with dimensions 0.1×0.15×0.25 mm and **2** with 0.1×0.2×0.55 mm were used for intensity measurements. X-Ray diffraction data were collected on a Rigaku AFC-4 automated four-circle diffractometer at the X-Ray Analysis Center of the Institute of Physical and Chemical Research with graphite-monochromatized Mo $K\alpha$ radiation (λ=0.71073 Å). The space groups were determined with the observed systematic absences, and the lattice parameters were determined by the least-squares refinement using ten high-angle reflections for **1**, and twenty for **2**. The crystal data are shown in Table 1. Intensities were measured by ω—2θ scanning techniques at a ω-scanning speed of 4°/min. The diffraction intensities were monitored by three standard reflections for every 100 reflections recorded. No signs of decomposition of the crystals were observed. The ordinary Lorenz and polarization corrections were applied, but no absorption correction was applied. Independent reflections with $|F_o|>3\sigma(|F_o|)$, 2268 ($2\theta<50°$) and 4702 ($2\theta<70°$) reflections for **1** and **2**, respectively, were used for the structure determinations. Calculations were performed on a FACOM 230-75 computer for **1** and a FACOM M-200 computer for **2** using the UNICS-III Program System.[4] The structures were solved by the heavy atom method,

and refined by standard Patterson, Fourier, and block-diagonal least-squares techniques. The final R values were 0.044 for **1** with anisotropic temperature factors for non-hydrogen atoms, and 0.037 for **2** with anisotropic temperature factors for non-hydrogen atoms and isotropic for hydrogen atoms. The atomic parameters of **1** and **2** are given in Table 2.

The complete F_o—F_c data are deposited as Document No. 8727 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Other Measurements. ^{1}H and ^{13}C NMR spectra were recorded on a JEOL JNM FX-90Q spectrometer. CD_2Cl_2 was used as solvent and the chemical shifts were referred to internal TMS. IR spectra were measured by the Nujol mull method with JASCO A-202 spectrometer. Electronic spectra in dichloromethane were recorded on a HITACHI 340 spectrometer. Conductivities of the dichloromethane solutions were measured at 25.0 °C using a conventional bridge (Model 4225A of Yokogawa-Hewlett-Packard Ltd.).

The UV, IR, conductivity, and NMR data of **1** and **2** are as follows; **1**: UV (CH_2Cl_2) 31300 (log ϵ 3.49) and 25000 cm^{-1} (log ϵ 3.75); IR (Nujol) 1835 cm^{-1} (N-O stretching of the nitrosyl group); Λ_m (CH_2Cl_2, 4.86×10^{-4} mol dm^{-3}, 25 °C) 3.48×10^{-7} S m^{2}mol^{-1}; ^{1}H NMR (CD_2Cl_2) δ=3.06 (3H, s, CH_3), 3.27 (3H, s, CH_3), 6.80—7.48 (8H, m, the hydrogen atoms of the two quinoline rings except the H(3) and the H(13)),[5] 8.18 (1H, d, the H(3) or the H(13)), 8.22 (1H, d, the H(13) or the H(3)); ^{13}C NMR (CD_2Cl_2) δ=27.30 (s, CH_3), 27.63 (s, CH_3), 115—140 (m, the two quinoline rings except the quaternary carbons). **2**: UV(CH_2Cl_2) 31300 (log ϵ 3.45) and 25300 cm^{-1} (log ϵ 3.77); IR (Nujol) 1840 cm^{-1} (N-O stretching of the nitrosyl group); Λ_m (CH_2Cl_2, 5.29×10^{-4} mol dm^{-3}, 25 °C) 11.7×10^{-7} S m^2 mol^{-1}); ^{1}H NMR (CD_2Cl_2) δ=1.83 (3H, s, CH_3), 3.14 (3H, s, CH_3), 6.77—7.55 (8H, m, the

Results and Discussion

The wave numbers of the N-O stretching bands[6] and the molar conductivities (Λ_m)[7] of **1** and **2** were consistent with the molecular structures determined as will be mentioned later.

Molecular Structures. The molecular and crystal structures of the two isomers of [RuCl(2mqn)$_2$(NO)], **1** and **2**, are shown in Figs. 1 and 2, respectively. In both isomers, the Cl atom is in cis position to the NO group, the O atom of one of the quinolinolato ligands being in trans to the NO group. On the other hand, the geometry of the N and O atoms of the two quinolinolato ligands is in trans (N,N) and cis (O,O) for **1**, and in cis (N,N) and cis (O,O) for **2**. Hence, in **2**, the methyl group of the C(10) lies under the other quinoline ring.

The bond distances and the angles are shown in Table 3. In **1**, the Cl-C(10) distance is shorter than the sum of the van der Waals radii of methyl group (2.0 Å) and Cl (1.8 Å), and the Cl-Ru-N(2) angle is larger than 100° due to the repulsion between the Cl atom and the methyl group. In **2**, the N(2)-Ru-N(3) angle is about 100° due to the repulsion of the methyl group of the C(10) by the other quinoline ring. The N(1)-Ru-N(3) angle is larger than 100° in both **1** and **2** due to the repulsion between the methyl and the NO groups.

The Ru-N(1) distance in **1** is longer than that in **2**. On the other hand, the N(1)-O(1) distance in **1** is shorter than that in **2** which is about the same with those

in other six-coordinate mononitrosylruthenium complexes with the linear {RuNO}^{6} group, 1.11—1.17 Å.[6,8]

For nitrosyl complexes, the trans-influence of the NO group has been examined on the basis of the accurate X-ray crystal structure analyses[9] and the molecular orbital theory treatment.[10] Relative bond strengths between the metal ion and the donor atoms of the ligands trans to each other depend on the σ- or π-bonding ability of the donor atoms.[10,11] Since the Ru-N(1)-O(1) angles for **1** and **2** are close to 180°, the NO group is formally bound as NO^+.[6] The NO^+ is a strong π-acceptor and weak σ-donor. Chloride ion and the ligating atoms, the N and O atoms, of the quinolinolato ligands seem to be moderate σ-donor, hence are better σ-donor than the NO^+, while these are poor π-acceptor than the NO^+. When the ligand (L) trans to the NO is a good σ-donor and poor π-acceptor, the Ru-NO and Ru-L bond distances are shortened by the mutual reinforcement of the σ- and π-bonding.[10] Thus, in both **1** and **2**, both the σ- and π-electron densities of the O(3) flow into the NO^+ by way of the Ru; the Ru-O(3) bond distances are expected to be shorter than the Ru-O(2). The differences is 0.034 Å for **1** and 0.024 Å for **2** as shown in Table 3. The Ru-Cl bond distances in **1** and **2** are the same as those of the Ru-Cl (cis to NO) in $[RuCl_5(NO)]^{2-}$, av 2.374 Å, but are longer than those of the Ru-Cl (trans to NO), av 2.358 Å,[9] because the ligand trans to the Cl in **1** and **2** does not possess the trans shortening effect. No effects of the methyl group in the quinoline rings on the Ru-Cl bond distance were found.

In addition to the bond angles, the following torsion angles were calculated. Table 4 gives the clockwise torsion of the bond 3—4 with reference to the bond 1—2 when looking the atom-3 from the atom-2. In **2**, the Ru, the N(2), the C(1), and the C(10) are arranged in a plane as well as the Ru, the N(3), the C(11), and the C(20) are. On the other hand, in **1**, the methyl groups undergo considerable torsion; the C(10) and the C(20) are repulsed by the Cl and the NO group, respectively. The two quinoline rings are practically flat in both **1** and **2**.

The NMR spectral data were consistent with the determined molecular structures. The ^1H resonance peaks of the two methyl groups were observed at δ=3.06 and 3.27 for **1**, while at δ=1.83 and 3.14 for **2**. The methyl carbons resonated at δ=27.30 and 27.63 for **1**, while at δ= 24.38 and 27.70 for **2**. According to the molecular structural analysis, the methyl carbon, the C(10), in **2** lies just under the plane of the other quinoline ring. Evidently it causes high field shifts of the methyl carbon, the C(10), and the methyl protons owing to ring-current effect of the quinoline ring. Thus, the resonance peaks at δ=24.38 and 1.83 of **2** can be assigned to the C(10) and the protons attached to it, respectively.

A few six-coordinate metal complexes containing two 2-methyl-8-quinolinolato ligands have been characterized by X-ray structure analysis and NMR measurement. The geometrical arrangement of **1** for the quinolinolato ligands was the same as found for $[Co(2mqn)_2en]$,[12] that of **2** being the same as found for $[TcCl(2mqn)_2O]$.[13] Recently, Bottomley et al. have reported the similar geometrical isomers of *cis*-$[RuCl(pyca)_2(NO)]$ (pyca=2-pyridinecarboxylate ion) as found for the present isomers.[14]

Solvatochromism of [Diamine-*N,N'*-polycarboxylato]chromium(III) and -cobalt(III) Complexes

Naoko MIURA, Makoto SHIMURA, and Hiroshi OGINO*
Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Sendai 980
(Received October 24, 1986)

Visible absorption spectra of [diamine-*N,N'*-polycarboxylato]chromium(III) and -cobalt(III) complexes were measured in twelve different solvents. The diamine-*N,N'*-polycarboxylates used in this work were ethylenediamine-*N,N,N',N'*-tetraacetate ($edta^{4-}$), 1,2-cyclohexanediamine-*N,N,N',N'*-tetraacetate ($cydta^{4-}$), *N'*-(2-hydroxyethyl)ethylenediamine-*N,N,N'*-triacetate ($hedtra^{3-}$), and *N'*-methylethylenediamine-*N,N,N'*-triacetate ($medtra^{3-}$). The first d-d absorption maxima of these complexes depend considerably on the solvents. From the solvatochromic behaviors of these complexes, it was concluded that solid complexes, K[Co(edta)]·$2H_2O$, K[Co(cydta)]·$3H_2O$, [Co(hedtra)(H_2O)], [Co(medtra)(H_2O)]·$3H_2O$, Na[Cr(cydta)]·$4.5H_2O$, and probably K[Cr(edta)]·$2H_2O$, dissolve in the solvents while holding their first coordination sphere intact; in some solvents, however, [Cr(medtra)(H_2O)]·$1.5H_2O$ and [Cr(hedtra)(H_2O)]·$1.5H_2O$ undergo substitutions of the coordinated water molecule to form [Cr(medtra)(solvent)] and [Cr(hedtra)(solvent)], respectively.

It has been known that the metal to ligand or ligand to metal charge-transfer absorption bands of transition metal complexes are solvent-dependent.[1-3] The first d-d absorption bands of the octahedral cobalt(III) or chromium(III) complexes, on the other hand, are generally insensitive to the solvents, and there are only a few reports concerning solvent-dependent d-d absorptions.[4-7] Bjerrum et al. measured the electronic absorption spectra of amine complexes of chromium (III) and cobalt(III) in water, methanol, acetone, and nitromethane, and reported for the first time that the d-d absorption band maxima are practically independent of the solvents.[4] Later, Adamson investigated visible absorption spectra of $K[Cr(NCS)_4(NH_3)_2]$ in eleven different solvents and found that the first ligand field band appears between 518 and 530 nm, depending on the solvents.[5] Nishimura et al. observed rather large solvatochromism for the d-d transition bands of $[CrCl_2(CH_3)(tetrahydrofuran)_3]$.[6] Recently, Taura has reported that the peak position (λ_{max}) for the first d-d absorption band of K[Co(edta)]·$2H_2O$[7,8] changes with solvents and correlates with the acceptor numbers of the solvents which were proposed by Mayer, Gutmann, and Gerger.[9]

In the present paper, solvatochromism of the chromium(III) and cobalt(III) complexes containing diamine-*N,N'*-polycarboxylates was investigated. The ligand, L, used were classified into two types. One is tetraacetates ($edta^{4-}$ and $cydta^{4-}$) to form uninegatively charged complexes and the other is triacetates ($hedtra^{3-}$ and $medtra^{3-}$) to form neutral complexes.

As the Co(III) complexes are substitution inert,[10-12] the incorporation of a solvent molecule into the first coordination sphere does not occur. In fact, the Co(III)-L complexes did not show any spectral change with time in various solvents. Such inertness towards ligand substitution allowed us to measure the absorption spectra of [Co(edta)]$^-$, [Co(cydta)]$^-$, [Co(hedtra)(H_2O)], and [Co(medtra)(H_2O)] in various solvents without incorporating the solvent molecules into their first coordination spheres.

The Cr(III)-L complexes, on the other hand, have variable reactivities towards ligand substitution. Although chromium(III) complexes have been known to be substitution inert, substitutions at the site of the coordinated water molecule in [Cr(edta)(H_2O)]$^-$ and [Cr(hedtra)(H_2O)] proceed very rapidly:[13]

$$[CrL(H_2O)]^{n-} + X^- \rightleftharpoons [CrXL]^{(n+1)-} + H_2O \quad (1)$$

Ligand substitution reactions of [Cr(medtra)(H_2O)] are much slower than those of [Cr(edta)(H_2O)]$^-$ and [Cr(hedtra)(H_2O)], but are still considerably faster than the reactions of ordinary chromium(III) complexes.

An X-ray crystal structure analysis of K[Cr(edta)]·$2H_2O$ has shown that the complex contains sexidentate $edta^{4-}$ and does not contain a water molecule in the first coordination sphere.[14] Although we have formulated the Cr(III)-EDTA complex as [Cr(edta)(H_2O)]$^-$, there is a serious problem concerning the structure of the Cr(III)-EDTA complex in an aqueous solution: whether the $edta^{4-}$ ion acts as a quinquedentate ligand or as a sexidentate ligand.[15-17] Therefore, it is of interest to determine whether the Cr(III)-EDTA complex is present as [Cr(edta)]$^-$, [Cr(edta)(H_2O)]$^-$, or [Cr(edta)(solvent)]$^-$ in various solvents.

The differences in solution behaviors of Co(III)-L and Cr(III)-L complexes should be reflected in the solvatochromism of these complexes, which led us to make the present study.

Experimental

Materials. The chromium(III) and cobalt(III) complexes, K[Cr(edta)]·$2H_2O$,[18] Na[Cr(cydta)]·$4.5H_2O$,[19] [Cr(hedtra)(H_2O)]·$1.5H_2O$,[13] [Cr(medtra)(H_2O)]·$1.5H_2O$,[13] K[Co(edta)]·$2H_2O$,[20,21] K[Co(cydta)]·$3H_2O$,[22] [Co(hedtra)(H_2O)],[11] and [Co(medtra)(H_2O)]·$3H_2O$[23] were prepared by methods described in the literature. Methyltrioctylammonium chloride (Tokyo Kasei), Dicyclohexano-18-crown-6 (Nippon Soda Co.), and dibenzo-18-crown-6 (Aldlich) were used without further purification.

Solvents. Hexamethylphosphoric triamide (HMPA) was

purified by distillation over calcium hydride. Other solvents, acetone (AC), acetonitrile (AN), formamide (FA), *N*-methylformamide (NMF), *N,N*-dimethylformamide (DMF), *N,N*-dimethylacetamide (DMA), dimethyl sulfoxide (DMSO), nitromethane (NM), methanol (MA), ethanol (EA), and toluene were of reagent grade, and were used as received.

Spectral Measurements. The visible absorption spectra were recorded on a Hitachi 330 or a Union-Giken SM 401 recording spectrophotometer. Most of the measurements were made at room temperature. Solutions of the complexes were prepared by simply dissolving a complex in solvents. Some anionic complexes with low solubility were dissolved with dibenzo-18-crown-6 or dicyclohexano-18-crown-6. Dissolution rate of the complexes varied depending on the complex and the solvent. In order to achieve sufficient concentrations of the complexes in solution, it was necessary, in some cases, that the mixtures of the complexes and the solvents were shaken vigorously or sonicated for 3—4 h before the spectral measurements. Among the complexes investigated in this study, [Cr(medtra)(H_2O)] and [Cr(eedtra)(H_2O)] revealed spectral changes with times over 1—2 h after dissolution into various solvents. The spectral data for these complexes were those taken after spectral changes came to an end. No spectral changes with time were observed for other complexes examined in this study. Lists of the $\tilde{\nu}_{max}$ values for the complexes measured in this study are deposited at the office of the Chemical Society of Japan (Document No. 8726).

Results and Discussion

Solvatochromism of the Cobalt(III) Complexes Containing Diamine-*N,N'*-polycarboxylate. It is well-established that the edta^{4-} and cydta^{4-} ions act as sexidentate ligands in [Co(edta)]$^-$ and [Co(cydta)]$^-$, respectively.[11,24,25] When the $\tilde{\nu}_{max}$ values for [Co(cydta)]$^-$ in various solvents are plotted against those of the $\tilde{\nu}_{max}$ values for [Co(edta)]$^-$, a linear relation is obtained

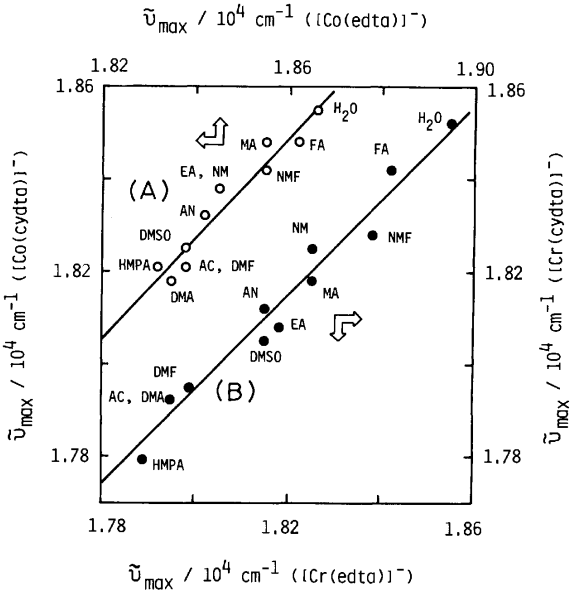

Fig. 1. Linear relationships between $\tilde{\upsilon}_{max}$([Co(cydta)]$^-$) and $\tilde{\upsilon}_{max}$([Co(edta)]$^-$) (A), and between $\tilde{\upsilon}_{max}$([Cr(cydta)]$^-$) and $\tilde{\upsilon}_{max}$([Cr(edta)]$^-$) (B).

as shown in Fig. 1. The slopes of the plots are close to unity (Table 1). Therefore, the solvatochromism of both [Co(cydta)]$^-$ and [Co(edta)]$^-$ arises from common effect(s) which is(are) induced by the solvent molecules surrounding the first coordination sphere.

Good linear correlations between the $\tilde{\nu}_{max}$ values for [Co(edta)]$^-$ (or [Co(cydta)]$^-$) and those for the neutral complexes, [Co(hedtra)(H_2O)] and [Co(medtra)(H_2O)], could also be observed (Fig. 2 and Table 1). These show that the factor(s) governing the solvatochromism of the [Co(edta)]$^-$ and [Co(cydta)]$^-$ complexes is also effective to the solvatochromism of the neutral com-

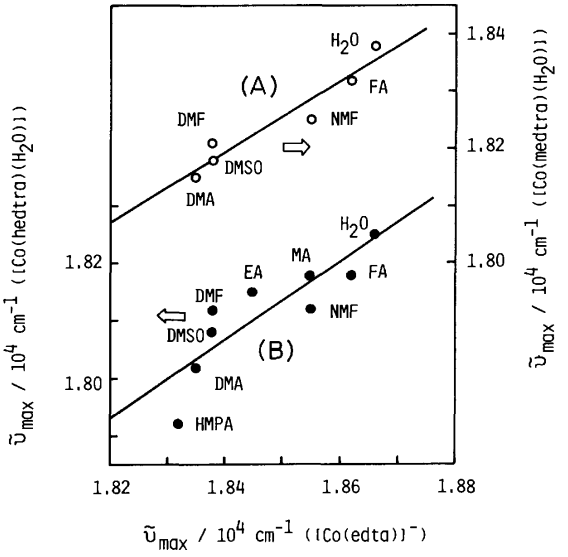

Fig. 2. Plots of $\tilde{\nu}_{max}$([Co(medtra)(H_2O)]) against $\tilde{\nu}_{max}$([Co(edta)]$^-$) (A), and the plots of $\tilde{\nu}_{max}$([Co(hedtra)(H_2O)]) against $\tilde{\nu}_{max}$([Co(edta)]$^-$) (B).

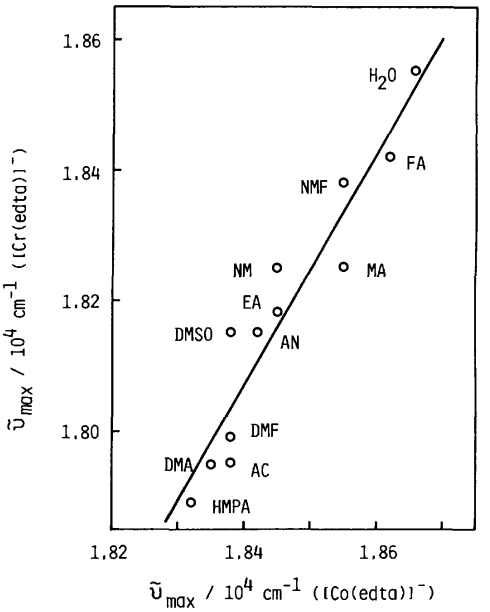

Fig. 3. Plots of $\tilde{\nu}_{max}$([Cr(edta)]$^-$) against $\tilde{\nu}_{max}$([Co(edta)]$^-$).

plexes. However, the degree of the solvent effect is smaller for the neutral complexes than for the [Co(edta)]$^-$ or [Co(cydta)]$^-$: The slopes of the plots in Fig. 2 are only about 0.6.

Solvatochromism of the Chromium(III) Complexes Containing Diamine-*N,N'*-polycarboxylate. The structure of [Cr(edta)]$^-$ in a crystal of K[Cr(edta)]·$2H_2O$ has been determined to be an octahedral coordination with the sexidentate edta^{4-}.[14] Similarly, Na[Cr(cydta)]·$4.5H_2O$ contains the sexidentate cydta^{4-}.[17] However, there have been controversial discussions concerning the structure of the Cr(III)-EDTA complex in an aqueous solution, as to whether it contains a quinquedentate edta^{4-} or a sexidentate one.[15-17] A similar problem may arise when the complex is dissolved in a solvent other than water. If

$$[Cr(edta)]^- + \text{solvent} \rightleftharpoons [Cr(edta)(\text{solvent})]^- \quad (2)$$

takes place in various solvents, the correlation between $\tilde{\nu}_{max}$ values of [Cr(edta)]$^-$ and [Co(edta)]$^-$ is expected to be poor, since the [Co(edta)]$^-$ maintains its strucure in solution. However, plots of the $\tilde{\nu}_{max}$ values of [Cr(edta)]$^-$ against those of [Co(edta)]$^-$ show a good linear relation (Fig. 3 and Table 1). This indicates that [Cr(edta)]$^-$ in K[Cr(edta)]·$2H_2O$ retains its original strucure in most solvents, i.e. octahedral coordination with sexidentate edta^{4-}.[26]

In connection with this, interesting phenomena were found: The Cr(III)-EDTA complex can be extracted from an aqueous solution of K[Cr(edta)]·$2H_2O$ to toluene in the presence of a phase-transfer catalyst, methyltrioctylammonium chloride. The extracted species is reddish violet in a toluene layer and shows visible absorption maximum at 544 nm (only 5 nm longer than the absorption maximum of the aqueous solution (λ_{max}=539 nm)). When solid K[Cr(edta)]·$2H_2O$ is dissolved directly into toluene with methyltrioctylammonium chloride, a bluish violet solution (λ_{max} =554 nm) is obtained, which may indicate that [CrCl(edta)]$^{2-}$ is formed. In the toluene extract from the aqueous solution of K[Cr(edta)]·$2H_2O$, the complex may be present as [Cr(edta)]$^-$ or [Cr(edta)(H_2O)]$^-$. A similar phenomenon was also observed for [Cr(hedtra)(H_2O)].

There is a tendency that the metal complexes containing sexidentate cydta^{4-} are much more stable than corresponding complexes containing both quinquedentate cydta^{4-} and a unidentate ligand: There is no spectral change when an acetate buffer solution is added (up to 1 mol dm^{-3}) to an aqueous solution of Na[Cr(cydta)]·$4.5H_2O$, suggesting that the acetate ions do not coordinate to Cr(III)-CyDTA complex.[27] Although there have been moderately stable cobalt(III) complexes, [CoX(edta)]$^{2-}$ (X=Cl$^-$, Br$^-$, NO_2^-, OH$^-$, NCS$^-$, SCN$^-$)[28-30] and [Co(edta)(H_2O)]$^-$,[31] no cydta^{4-} analogue of this type has been known except [CoCl(cydta)]$^{2-}$.[22] Moreover, [CoCl(cydta)]$^{2-}$ is quite unstable and quickly changes to [Co(cydta)]$^-$ in an aqueous solution. These findings and some other facts[11,19,32] suggest that a Cr(III)-CyDTA complex contains a sexidentate cydta^{4-} ligand in aqueous solution.

The $\tilde{\nu}_{max}$ values of [Cr(cydta)]$^-$ in various solvents correlate linearly well with those of [Cr(edta)]$^-$ and [Co(cydta)]$^-$ as shown in Fig. 1 and Table 1. These facts may indicate that K[Cr(edta)]·$2H_2O$ and Na[Cr(cydta)]·$4.5H_2O$ dissolve in various solvents to form [CrL]$^-$ ions which contain sexidentate L^{4-} without the coordinated solvent molecule. The solvatochromic shifts of [Cr(cydta)]$^-$ and [Cr(edta)]$^-$ observed in this study are larger than those of [Co(edta)]$^-$.

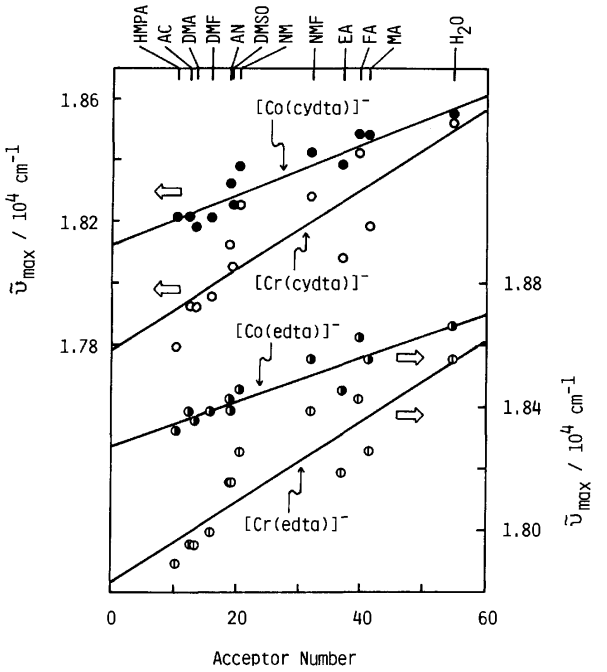

Fig. 4. Relationships between the $\tilde{\nu}_{max}$ values of $[ML]^-$ (M=Cr, Co; L=edta^{4-}, cydta^{4-}) and the acceptor numbers of the solvents. ●: $[Co(cydta)]^-$, ○: $[Cr(cydta)]^-$, ◑: $[Co(edta)]^-$, ⊕: $[Cr(edta)]^-$.

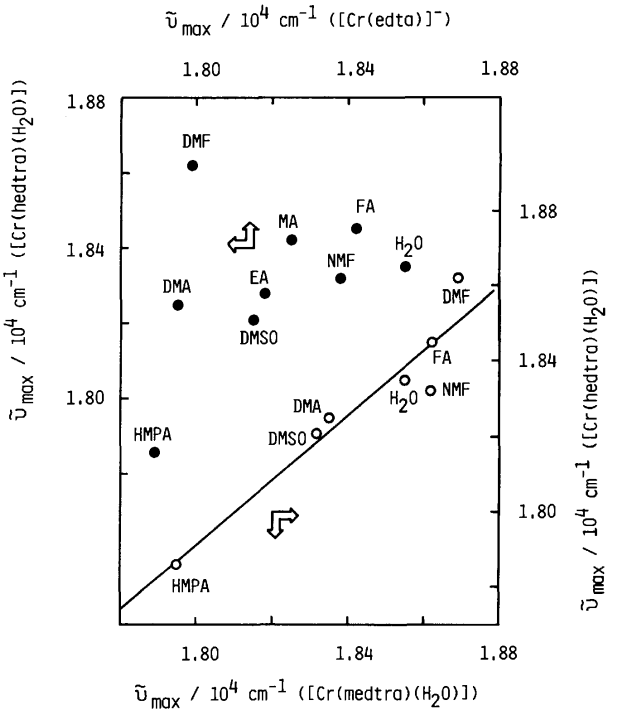

Fig. 5. Plots of $\tilde{\nu}_{max}([Cr(hedtra)(H_2O)])$ against $\tilde{\nu}_{max}([Cr(edta)]^-)$ (●), and linear relationship between $\tilde{\nu}_{max}([Cr(hedtra)(H_2O)])$ and $\tilde{\nu}_{max}([Cr(medtra)(H_2O)])$ (○).

Taura reported that a linear relation could be obtained between the plots of the λ_{max} values of $[Co(edta)]^-$ and the acceptor numbers of the solvents.[7] On the basis of the more extensive measurements in this study, Taura's observation was confirmed, as shown in Fig. 4.[33] It is also shown in Fig. 4 that a linear relation exists between the $\tilde{\nu}_{max}$ values of $[Co(cydta)]^-$, $[Cr(edta)]^-$, or $[Cr(cydta)]^-$ and the accepter numbers. This is quite natural since linear relations exist mutually among the $\tilde{\nu}_{max}$ values of $[Co(edta)]^-$, $[Co(cydta)]^-$, $[Cr(edta)]^-$, and $[Cr(cydta)]^-$ as shown in Figs. 1 and 3 and Table 1.

There is no correlation between $\tilde{\nu}_{max}$ values of $[Cr(hedtra)(H_2O)]$ or $[Cr(medtra)(H_2O)]$ and those of $[Cr(edta)]^-$ or $[Cr(cydta)]^-$ as exemplified in Fig. 5. This is contrasted to the cases of the corresponding cobalt(III) complexes (Fig. 2). A poor correlation (Fig. 5) may be best explained by the occurence of reaction 3, at least in some solvents:

$$[CrL(H_2O)] + \text{solvent} \rightleftharpoons [CrL(\text{solvent})] + H_2O \quad (3)$$
$$(L = \text{hedtra}^{3-}, \text{medtra}^{3-})$$

where the coordinated water molecule is replaced by a solvent molecule.

If the occurrence of reaction 3 is the case, a spectral change with time should be observed in the time scale corresponding to the ligand substitution rates of those chromium(III) complexes. When an aqueous solution of $[Cr(medtra)(H_2O)]$ was mixed with DMF or DMSO, a slow spectral change was observed. The initial λ_{max} value (539 nm) in an aqueous solution shifts to a shorter wavelength in a reaction with DMF, and to a longer wavelength in a reaction with DMSO; the rate of the spectral change is reasonable in view of the kinetic data of the ligand substitution reactions of $[Cr(medtra)(H_2O)]$.[34] When an aqueous solution of $[Cr(eedtra)(H_2O)]$ was mixed with DMF or DMSO, a spectral change similar to the case of $[Cr(medtra)(H_2O)]$ system was observed. These findings are consistent with the occurence of reaction 3. Therefore, the solvatochromism of those complexes such as $[Cr(medtra)(H_2O)]$ contains two factors: The change in chromophore introduced by the formation of [CrL(solvent)], and the solvation at the outer coordination sphere.

The scattered plots in Fig. 5 suggest that $[Cr(hedtra)(H_2O)]$ also undergoes reaction 3. The substitution reaction of the water molecule in $[Cr(hedtra)(H_2O)]$ with a solvent molecule is expected to occur in the stopped-flow time scale.[13,34] However, the stopped-flow experiments were hampered by heat evolving upon mixing, incomplete mixing, and/or cavitation. These unfavorable phenomena are often encountered upon the mixing of different solvents. Therefore, it is impossible to determine whether reaction 3 is completed within the time of mixing or does not take place: in other words, whether the complex exists in the solvents as [Cr(hedtra)(solvent)] or $[Cr(hedtra)(H_2O)]$. However, the $\tilde{\nu}_{max}$ values of $[Cr(hedtra)(H_2O)]$ correlates linearly with those of $[Cr(medtra)(H_2O)]$, as shown in Fig. 5 and Table 1. This may indicate that

[Cr(hedtra)(H_2O)] also undergoes reaction 3.

The formation of [Cr(hedtra)(solvent)] in some solvents raises a question why [Cr(edta)]$^-$ does not accomodate a solvent molecule into the first coordination sphere in most of the solvents, but [Cr(hedtra)(H_2O)] does. The formation of [Cr(edta)(solvent)]$^-$ would be less favorable than that of [Cr(hedtra)(solvent)], since the formation constants of the mixed ligand complexes, [CrX(edta)]$^{2-}$ (X=OAc^-, N_3^-, NCS^-), in aqueous solutions have been known to be 17—28 times smaller than those of the corresponding [CrX(hedtra)]$^-$.[13,34]

33) In Taura's original paper,[7] the λ_{max} values are plotted against acceptor numbers. However, the λ_{max} values are replaced by the $\tilde{\nu}_{max}$ values ($\tilde{\nu}_{max}=10^2/\lambda_{max}$) in Fig. 4. This change does not influence the linear correlation practically, since the $\tilde{\nu}_{max}$ values lie in a rather narrow range: 1.79×10^4—1.86×10^4 cm^{-1}.

Preparation and Crystal Structures of Binuclear Copper(II) Complexes of *N,N',N'',N'''*-Tetrakis(2-aminoethyl)-1,4,8,11-tetraazacyclotetradecane Containing Azide, Cyanate, or Thiocyanate Ion

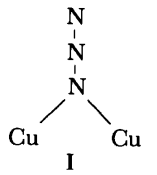
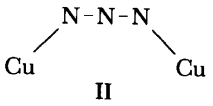
(Received October 24, 1986)

Three binuclear copper(II) complexes of *N,N',N'',N'''*-tetrakis(2-aminoethyl)-1,4,8,11-tetraazacyclotetradecane (taec), $[Cu_2(taec)N_3](ClO_4)_3$ (**1**), $[Cu_2(taec)(NCO)](ClO_4)_3$ (**2**), and $[Cu_2(taec)(NCS)_2](ClO_4)_2 \cdot H_2O$ (**3**), were prepared and characterized. The crystal structures of these complexes were determined by single-crystal X-ray analysis. In all the complexes taec coordinates to each copper through two ring- and two pendant-nitrogen atoms. Complexes **1** and **2** adopt similar structures, where N_3^- and NCO^- are incorporated into the cavity of taec as a bridging group (end-on fashion). The structure of **3** is substantially different from those of **1** and **2** in that each copper is independently coordinated by NCS^--nitrogen. The spectral and magnetic properties were discussed in relation to the molecular structures.

μ-Azidodicopper(II) complexes have been extensively studied in the last half decade, because of the interest in the fields of molecular magnetism and bioinorganic chemistry.[1-4] It is well-known that azide ion can bridge two copper(II) ions either in end-on fashion I or in end-to-end fashion II.[1] It has been established



I



II

that the end-on bridge of azide ion favors the triplet ground state whereas the end-to-end bridge brings about a strong antiferromagnetic interaction.[2] The latter type of μ-azido complexes is of interest as models for azide derivatives of the active site of methemocyanine and met-tyrosinase in which a pair of copper(II) ions are strongly coupled antiferromagnetically.[3]

Recently we have prepared a new octadentate ligand, *N,N',N'',N'''*-tetrakis(2-aminoethyl)-1,4,8,11-tetraazacyclotetradecane (abbreviated as taec) and its metal complexes.[5-7] Interestingly, all the complexes obtained are 2 : 1 (metal : taec) binuclear complexes. So far, two types of coordination modes are known for the taec ligand: one is the trans III form[8] concerning the cyclam ring (chair form, Fig. 1 (A)) as found for $[Cu_2(taec)](ClO_4)_4$[5] and the other is the trans I form[8] (boat form, Fig. 1 (B)) as found for $[Cu_2(taec)Br](ClO_4)_3$.[6] In the latter case, single bromide ion is incorporated into the cavity of the ligand and coordinated to both copper ions. Using this unique property, we have prepared μ-azidocopper(II) complex of taec, $[Cu_2(taec)N_3](ClO_4)_3$, and determined the X-ray crystal structure in order to examine the bridging mode of the azide ion in the cavity of taec. We have also prepared copper(II) complexes with the isoelectronic cyanate and thiocyanate ions, $[Cu_2(taec)(NCO)](ClO_4)_3$ and $[Cu_2(taec)(NCS)_2](ClO_4)_2 \cdot H_2O$. Here, we report the preparation, the crystal structures, and the magnetic and spectral properties of these binuclear copper(II) complexes.

Fig. 1. Coordination mode of taec.

Experimental

Preparation. The preparative method for taec was already reported in the preceding papers.[5,6]

$[Cu_2(taec)N_3](ClO_4)_3$: To an aqueous solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (185 mg) and taec (93 mg) was added NaN_3 (16 mg), and the mixture was heated at 80 °C for 20 min. The resulting blue solution was filtered. When the filtrate was allowed to stand overnight, blue needles were separated. The crystals were collected and desiccated over P_2O_5. Found: C, 25.64; H, 5.31; N, 18.19%. Calcd for $C_{18}H_{44}Cl_3Cu_2N_{11}O_{12}$: C, 25.74; H, 5.28; N, 18.34%.

$[Cu_2(taec)(NCO)](ClO_4)_3$: The complex was obtained as blue needles in the same way as that of $[Cu_2(taec)N_3](ClO_4)_3$

except for using potassium cyanate instead of sodium azide. Found: C, 26.72; H, 5.32; N, 14.83%. Calcd for $C_{19}H_{44}Cl_3Cu_2N_9O_{13}$: C, 27.17; H, 5.28; N, 15.01%.

$[Cu_2(taec)(NCS)_2](ClO_4)_2\cdot H_2O$: The complex was obtained as blue needles in the same way as that of $[Cu_2(taec)N_3](ClO_4)_3$ except for using potassium thiocyanate instead of sodium azide. Found:, C, 29.43; H, 5.75; N, 17.37%. Calcd for $C_{20}H_{46}Cl_2Cu_2N_{10}O_9S_2$: C, 28.85; H, 5.57; N, 16.82%.

Measurements. Carbon, hydrogen, and nitrogen analyses were carried out at the Service Center of Elemental Analysis, Kyushu University. Electronic spectra were measured with a Shimadzu Multipurpose Spectrophotometer Model MSP-5000 at room temperature. Magnetic susceptibility was measured by the Faraday method over the temperature range 80—300 K. The apparatus was calibrated by the use of $[Ni(H_2NCH_2CH_2NH_2)_3]S_2O_3$. The susceptibilities were corrected for the diamagnetism of the constituent atoms by the use of Pascal's constants.[9)] Effective magnetic moments were calculated from the equation, $\mu_{eff}=2.828\sqrt{(\chi_A-N\alpha)T}$, where χ_A is the atomic magnetic susceptibility and $N\alpha$ is the temperature-independent paramagnetism.

X-Ray Crystal Structure Analysis. A Rigaku AFC-5 automated four-circle diffractometer was used for all measurements at 18 °C. Crystal data and details of the data collection are given in Table 1. Lattice constants were determined by least-squares refinement based on 40 reflections with $20<2\theta<30°$. The intensity data were corrected for Lorentz-polarization effects, but not for absorption. The structures were solved by the direct methods. Refinements were carried out by the block-diagonal least-squares methods. In the course of refinement it became apparent that the carbon atom, C(3), is subjected to disorder in $[Cu_2(taec)X](ClO_4)_3$ (X=N_3 and NCO). The carbon atom was divided into two positions with an occupancy factor 0.5 on the basis of a difference Fourier map. Hydrogen atoms were inserted in their calculated positions and included in the refinement. The final discrepancy factors were $R=\sum||F_o|-|F_c||/\sum|F_o|=0.054$, $R'=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}=0.082$ for $[Cu_2(taec)N_3](ClO_4)_3$, $R=0.062$, $R'=0.089$ for $[Cu_2(taec)(NCO)](ClO_4)_3$, and $R=0.066$, $R'=0.096$ for $[Cu_2(taec)(NCS)_2](ClO_4)_2\cdot H_2O$. The weighting schemes were $w=(6.1+|F_o|+0.010|F_o|^2)^{-1}$ for $[Cu_2(taec)N_3](ClO_4)_3$, $(7.6+|F_o|+0.010|F_o|^2)^{-1}$ for $[Cu_2(taec)(NCO)](ClO_4)_3$, and $(8.0+|F_o|+0.008|F_o|^2)^{-1}$ for $[Cu_2(taec)(NCS)_2](ClO_4)_2\cdot H_2O$.

The atomic scattering factors for Cu, Cl, S, O, N, C, and H and the anomalous dispersion corrections, $\Delta f'$ and $\Delta f''$, for Cu, Cl, S, O, N, and C were taken from Ref. 10. All the calculations were carried out on the FACOM M-200 computer at the Computer Center of Kyushu University using a local version of the MULTAN 78,[11)] UNICS-III,[12)] and ORTEP[13)] programs. The final positional and thermal parameters with their estimated standard deviations are given in Table 2. The coordinates and isotropic temperature factors of hydrogen atoms, the anisotropic thermal parameters of the non-hydrogen atoms, the remaining bond distances and angles, and the F_o—F_c tables have been deposited as a Document No. 8731 at the Office of the Editor.

Results and Discussion

Crystal Structures. $[Cu_2(taec)N_3](ClO_4)_3$: A perspective drawing of the complex cation of $[Cu_2(taec)N_3](ClO_4)_3$ and the numbering system are illustrated in Fig. 2. The complex cation has a mirror plane containing Cu(1), Cu(2), N(5), N(6), and N(7). The cyclam ring assumes the trans I form[8)] and the coordination mode of taec is similar to that of $[Cu_2(taec)Br](ClO_4)_3$.[6)] The taec ligand forms two 5-5-5 fused che-

a) Anisotropically refined atoms are given in the form of the isotropic equivalent thermal parameter defined as $4/3[a^2B(1,1)+b^2B(2,2)+c^2B(3,3)+ab(\cos\gamma)B(1,2)+ac(\cos\beta)B(1,3)+bc(\cos\alpha)B(2,3)]$.

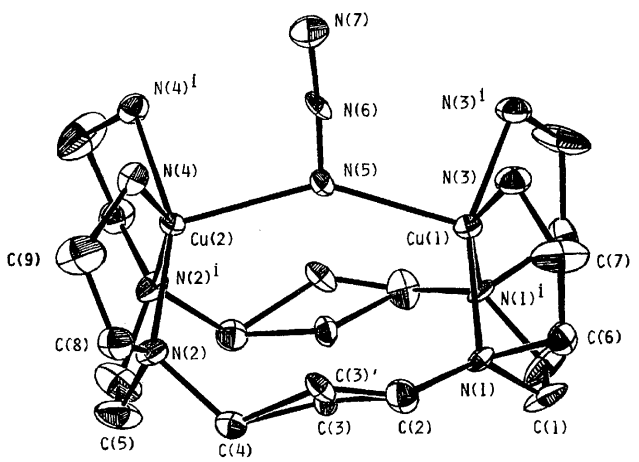

Fig. 2. ORTEP diagram of $[Cu_2(taec)N_3]^{3+}$. Superscript i refers to the equivalent position $(-x, y, z)$.

late rings with two copper ions. The coordination geometry of each copper ion is an elongated square pyramid. The basal plane is formed by two nitrogens of the cyclam ring and two nitrogens of the pendant amino groups. The basal plane is perfectly planar as required from the symmetry (the mirror plane) of the molecule and the copper ion is displaced by 0.45 Å from the plane toward the azide ion. The azide ion lies on the mirror plane and bridges the two copper ions at the apical positions with Cu-N distances of 2.240(12) and 2.263(12) Å. This is the first example of an end-on bridging of azide ion at axial sites of copper(II) ions. The Cu(1)-Cu(2) distance and Cu(1)-N(5)-Cu(2) angle are 4.312(1) Å and 146.5(3)°, respectively.

Of the three perchlorate ions, two are hydrogen bonded to the pendant amino groups (O(1)···N(4) 3.253(9), O(2)···N(4) 3.283(11), O(4)···N(3) 3.238(13),

a) Superscript i refers to the equivalent position ($-x$, y, z). b) Superscript i refers to the equivalent position ($-x$, y, z). c) Superscript i and ii refer to the equivalent positions (x, y, $-z$) and ($-x$, $1-y$, z), respectively.

O(5)···N(3) 3.271(11) Å), and one (designated as Cl(3), O(7), O(8), O(9), and O(9)($-x$, y, z)) is not bound to any special atoms.

$[Cu_2(taec)(NCO)](ClO_4)_3$: The crystal of $[Cu_2(taec)(NCO)](ClO_4)_3$ is isomorphous to that of $[Cu_2(taec)N_3](ClO_4)_3$. The complex cation, $[Cu_2(taec)(NCO)]^{3+}$, has a mirror plane containing Cu(1), Cu(2), N(5), C(10), and O(10) (Fig. 3). The nitrogen atom of NCO^- bridges the two copper ions. The Cu(1)-Cu(2) distance and Cu(1)-N(5)-Cu(2) angle are 4.340(2) Å and 145.3(4)°, respectively. This bridging mode of NCO^- was found in $[Cu_2(C_{17}H_{27}N_4O)(CH_3COO)(NCO)][PF_6]$ recently.[4]

$[Cu_2(taec)(NCS)_2](ClO_4)_2\cdot H_2O$: A perspective drawing of the complex cation, $[Cu_2(taec)(NCS)_2]^{2+}$, is shown in Fig. 4. The cation has the center of symmetry and a mirror plane formed by C(3), Cu, N(3), C(6), S, C(3)^{ii}, Cu^{ii}, N(3)^{ii}, C(6)^{ii}, and S^{ii}. Contrary to $[Cu_2(taec)X](ClO_4)_3$ (X=N_3 and NCO), the cyclam ring assumes the trans III form and the coordination mode of taec is the same as that of $[Cu_2(taec)](ClO_4)_4$[5] in which axial coordination sites do not face to each other but face rather opposite directions and are independently coordinated with NCS^-. The coordination geometry of each copper is a square pyramid with a thiocyanate nitrogen at the top (Cu-N(3) 2.191(7) Å).

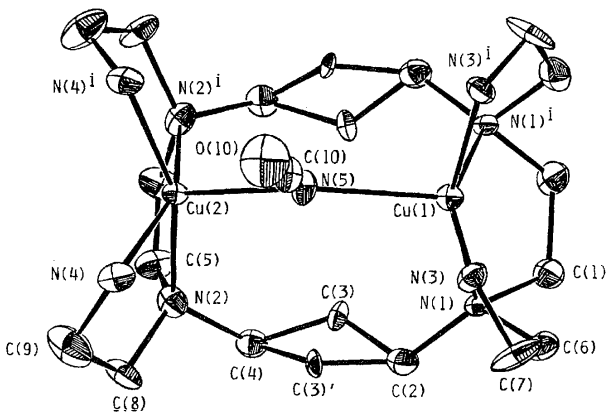

Fig. 3. ORTEP diagram of $[Cu_2(taec)(NCO)]^{3+}$. Superscript i refers to the equivalent position ($-x$, y, z).

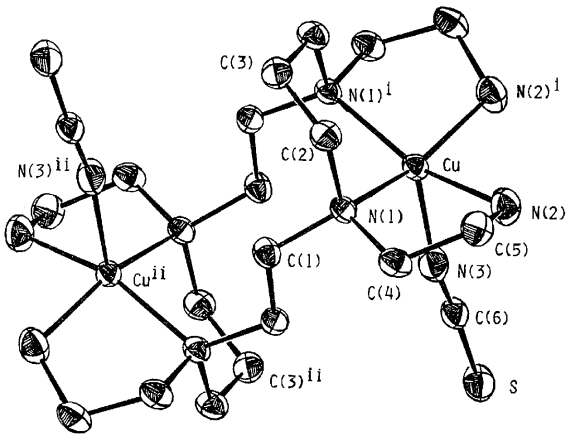

Fig. 4. ORTEP diagram of $[Cu_2(taec)(NCS)_2]^{2+}$. Superscripts i and ii refer to the equivalent positions (x, y, $-z$) and ($-x$, $1-y$, z), respectively.

The basal plane formed by two nitrogens of the cyclam ring and two terminal nitrogens is perfectly planar as required from the symmetry (C_{2h}) of the molecule, and the copper atom deviates by 0.37 Å from the basal plane toward thiocyanate ion.

Each water molecule is located in a vicinity of the pendant amino group of taec forming hydrogen bonds with the amino nitrogen and a perchlorate ion (N(2)$\cdots$OW($1/2+x$, $1/2-y$, $1/2-z$) 2.993(7) Å, O(3)$\cdots$OW(x, $1+y$, z) 2.929(23) Å).

Spectral and Magnetic Properties and Crystal Structures. Nujol mull spectra of $[Cu_2(taec)N_3](ClO_4)_3$, $[Cu_2(taec)(NCO)](ClO_4)_3$, and $[Cu_2(taec)(NCS)_2](ClO_4)_2\cdot H_2O$ each show a d-d band at 15.7, 15.6, and 17.1×10^3 cm^{-1}, respectively. The difference of the wavenumber in these complexes must be mainly due to the degree of the deviation of copper ion from the basal plane, i.e., 0.45, 0.46, and 0.37 Å, respectively. The bands of the azido and cyanato complexes are blue-shifted in aqueous solution relative to those in nujol mull, i.e., 15.7→16.1 (ε=217) and 15.6→15.8×10^3 cm^{-1} (ε=203), indicating the hydrolysis of coordinated anions in aqueous solution in more or less degree (the thiocyanato complex is sparingly soluble in water).[14]

The magnetic moments per copper ion of $[Cu_2(taec)N_3](ClO_4)_3$, $[Cu_2(taec)(NCO)](ClO_4)_3$, and $[Cu_2(taec)(NCS)_2](ClO_4)_2\cdot H_2O$ are 1.82, 1.77, and 1.75 B.M., respectively, at room temperature. All the complexes obey the Curie-Weiss law in the temperature range 80—300 K with the Weiss constants, −1, 0, and −5 K for the azido, cyanato, and thiocyanato complexes, respectively. The very small values indicate that there is no significant magnetic interaction between the copper ions. The result is quite understandable in view of that in these complexes an unpaired electron of a copper(II) ion is localized in the $d_{x^2-y^2}$ orbital of the basal plane of the CuN_5 square-based pyramid so that no overlapping of the magnetic orbitals is feasible.

The Identification of Insoluble Adducts of Lewis Acids with Bases by Extension of the Continuous Variation Method to Solid-Liquid Reactions

Goro HIHARA,* Kazuhiro MITANI, Hiroshi MIYAMAE, and Miharu NAGATA
Department of Chemistry, Faculty of Science, Josai University, Keyakidai, Sakado, Saitama 350-02
(Received October 25, 1986)

A method has been developed for identifying occurrence and composition of all the insoluble adducts formed in solid-liquid reactions by extension of the continuous variation method to the heterogeneous systems that were produced by the reactions of PbX_2 (X=Cl, Br, and I) with ethylenediamine(=en) in ethanol solution. Four new adducts, $PbX_2 \cdot i$(en) (i=1/2 and 1; X=Cl and Br), were found. The developed method was effective in identifying formation of the adducts such as $PbCl_2 \cdot 1/2$(en) and $PbBr_2 \cdot 1/2$(en) whose formation is liable to be overlooked in extending the mole ratio method to solid-liquid reactions.

In previous papers,[1-3] we have developed the methods to identify the insoluble adducts formed in solid-liquid reactions by extending either the mole ratio method[4] or the continuous variation method[5] to the heterogeneous reactions. However, the mole ratio method extended to the reactions has a drawback that formation of insoluble adducts is liable to be overlooked when the region of occurrence is narrow as in the cases of $PbI_2 \cdot 2/3$(en)[1] and $PbI_2 \cdot 1/2$(diethylenetriamine)(=dien).[2] The purpose of this psper is to develop theoretically a method for identifying occurrence and composition of insoluble adducts by extending the continuous variation method discussed in the preceding paper[3] to solid-liquid reactions in order to overcome the drawback of the mole ratio method.

Theoretical

Let us assume that an insoluble Lewis acid, A, reacts with a soluble Lewis base, B, in a solution according to Eqs. 1 and 2 to yield two insoluble adducts:

$$\mathrm{A(solid)} + m\mathrm{B(soln.)} = \mathrm{A} \cdot m\mathrm{B(solid)}, \quad (1)$$

$$\mathrm{A} \cdot m\mathrm{B(solid)} + n\mathrm{B(soln.)} = \mathrm{A} \cdot (m+n)\mathrm{B(solid)}. \quad (2)$$

Suppose that A and B react in varying proportions at fixed temperature and pressure in a fixed volume of the reaction solution so that the sum of A and B is kept constant at D mol. Provided that the concentration of B remaining unreacted in solution ([B] mol dm^{-3}) is determined after an equilibrium has been reached, the relation between [B] and B at the beginning of the reaction is depicted by a curve in Fig. 1, which is termed "concentration curve".

As discussed on the basis of the phase rule in a previous paper,[2] the region where [B] increases and the region where [B] becomes constant appear alternately on the concentration curve. Two regions 2 and 4, where the concentration curve is flat, represent two invariant states. Accordingly, A and A·mB coexist in region 2 and A·mB and A·$(m+n)$B, in region 4 in each solid phase. On the other hand, three regions 1, 3, and 5 where the curve has a certain slope represent three monovariant states and correspond to the presence of A, A·mB, and A·$(m+n)$B in the solid phase, respectively.

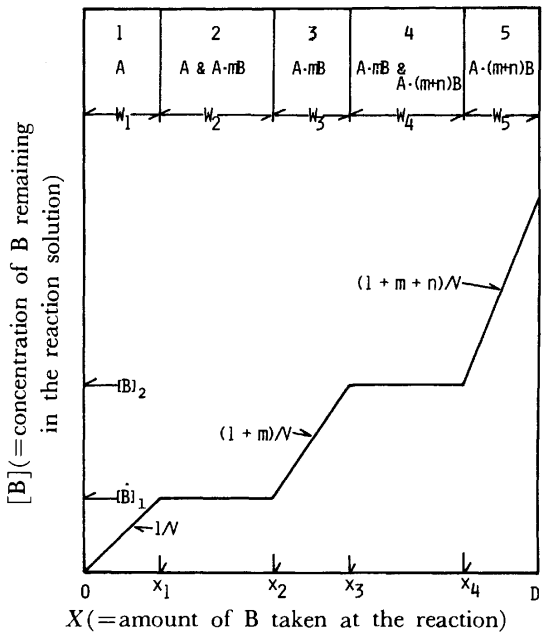

Fig. 1. A typical phase diagram for a ternary system consisting of A, B, and solvent where two insoluble adducts, A·mB and A·$(m+n)$B, form.

Let us consider how the slope on the concentration curve changes in each monovariant region. If the volume of reaction solution (V dm^3) remains unchanged during the reaction and species involving A dissolve sparingly into the solution, [B] is given by:

$$[\mathrm{B}] = (x - yz)/V, \quad (3)$$

where x and z are the amounts of B and A in mol at the beginning of the reaction, respectively, and y is the mole ratio of B/A in the sediment. Since the reaction is carried out under the condition that D is constant,

$$D = x + z = \text{constant}. \quad (4)$$

Equation 5 is obtained from Eqs. 3 and 4 by eliminating z:

$$[\mathrm{B}] = \frac{x - y(D-x)}{V} = \frac{(1+y)}{V}x - \frac{yD}{V}. \quad (5)$$

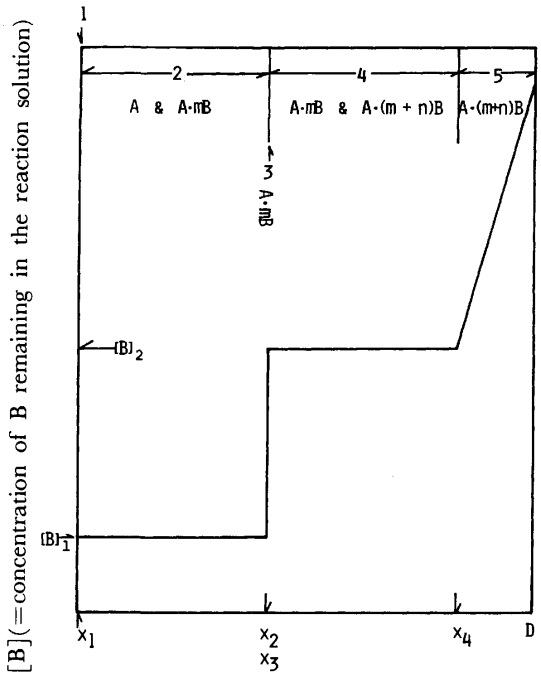

Fig. 2. A typical phase diagram for a ternary system where both $[B]_1$ and $[B]_2$ are very low.

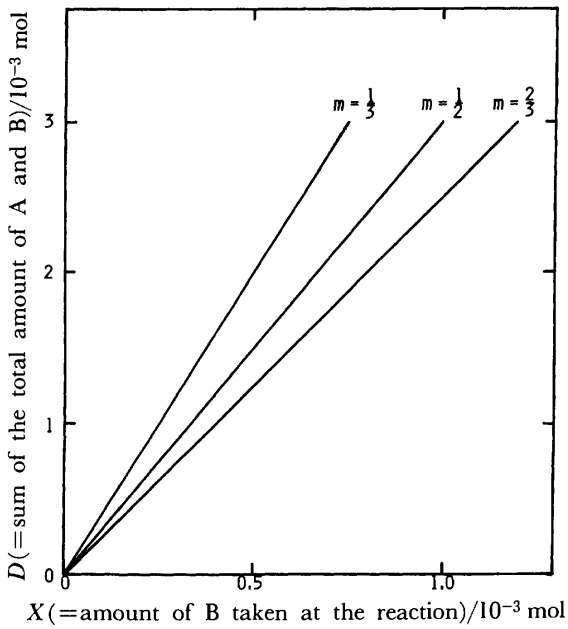

Fig. 3. Relation between the point of phase boundary and D when $[B]_1$ and $[B]_2$ are low.

The value of the slope equals $1/V$ in region 1 where only A is present in the solid phase, because $y=0$. Similarly, the values of the slope are $(1+m)/V$ and $(1+m+n)/V$ in regions 3 and 5, respectively, because $y=m$ and $y=m+n$. Therefore, once the concentration curve is obtained experimentally, the composition of the formed adducts can be determined by the slope of the concentration curve in each monovariant region.

If the equilibrated concentrations of B are $[B]_1$ and $[B]_2$ in the respective invariant regions 2 and 4, the amount of B in the boundary between monovariant and invariant region is given by substituting either $[B]_1$ or $[B]_2$ for [B] in Eq. 5 and solving for x:

$$x_1 = [B]_1V, \tag{6}$$

$$x_2 = (mD + [B]_1V)/(1 + m), \tag{7}$$

$$x_3 = (mD + [B]_2V)/(1 + m), \tag{8}$$

$$x_4 = ((m + n)D + [B]_2V)/(1 + m + n). \tag{9}$$

The width of each region, $W_1, \cdots, W_5$, is given by calculating successively the difference in each x with Eqs. 6—9:

$$W_1 = x_1 - 0 = [B]_1V, \tag{10}$$

$$W_2 = x_2 - x_1 = m(D - [B]_1V)/(1 + m), \tag{11}$$

$$W_3 = x_3 - x_2 = ([B]_2 - [B]_1)V/(1 + m), \tag{12}$$

$$W_4 = x_4 - x_3 = n(D - [B]_2V)/(1 + m + n)(1 + m), \tag{13}$$

$$W_5 = D - x_4 = (D - [B]_2V)/(1 + m + n). \tag{14}$$

Let us consider how each width depends on $[B]_1$ and $[B]_2$ when they are less than 10^{-3} M (1 M=1 mol dm^{-3}). Solid-liquid reactions are usually carried out under the condition that D is 1—2 mmol and V is 10 cm^3. The value of $[B]_1V$ or $[B]_2V$ ($10^{-3}M \times 10^{-2}$ dm^3=10^{-5} mol) is much smaller than mD ($m \times 10^{-3}$ mol). Therefore, both W_1 and W_3 are nearly equal to zero, as is shown in Fig. 2. Hence, Eq. 15 is derived from Eqs. 7 snd 8, because $[B]_1 \approx [B]_2 \approx 0$:

$$x_2 = x_3 = mD/(1 + m). \tag{15}$$

Equation 15 shows that the B value in the boundary between invariant regions 2 and 3, and between 3 and 4, depends on D and composition m. This relation is illustrated in Fig. 3, which shows how the value changes with D. Accordingly, if equilibrated concentration of B is low in invariant regions, the composition of adducts can be determined by Eq. 15.

Experimental

Apparatus. A Toa Denpa HM-18E pH meter was used to determine potentiometrically the concentration of en in equilibrated reaction solutions. Low concentration of en was determined by a Shimazu MPS-2000 double beam spectrophotometer to measure the absorbance at 430 nm. The reactions were carried out in a Taiyo WB-3 incubator with mechanical shaking.

Reagents. The preparation of PbI_2 was described previously.[2] $PbBr_2$ was prepared by mixing a solution of $Pb(NO_3)_2$ with that of KBr in the stoichiometric ratio, the sediment was separated from the solution, dried at 110 °C for about 12 h, and stored in the dark. $PbCl_2$ was purified by recrystallization from distilled water. Ethylenediamine (99.0% pure) purchased from Wako Pure Chemical Co. was used without further purification. Ethanol was dehydrated with molecular sieves (3A1/16) and then distilled.

The Solid-Liquid Reactions of PbX_2 (X=Cl, Br, and I) with en. (1) Extension of the Mole Ratio Method. 0.500 g

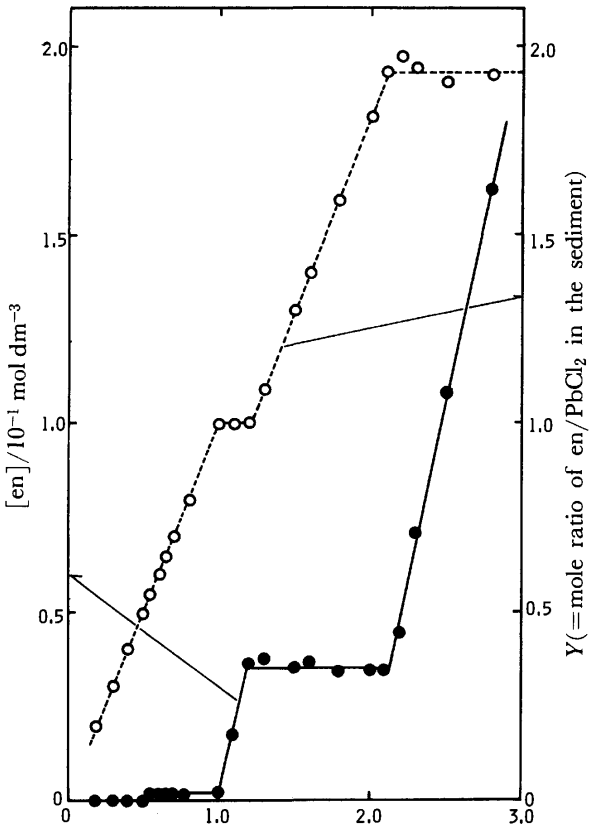

Fig. 4. Relation between the concentration of ethylenediamine remaining in the solution and mole ratio of en/$PbCl_2$ taken at the reaction when the mole ratio method was extended to the reaction of $PbCl_2$ with en: —●—●—, concentration curve; --O--O--, composition curve (definition, see text).

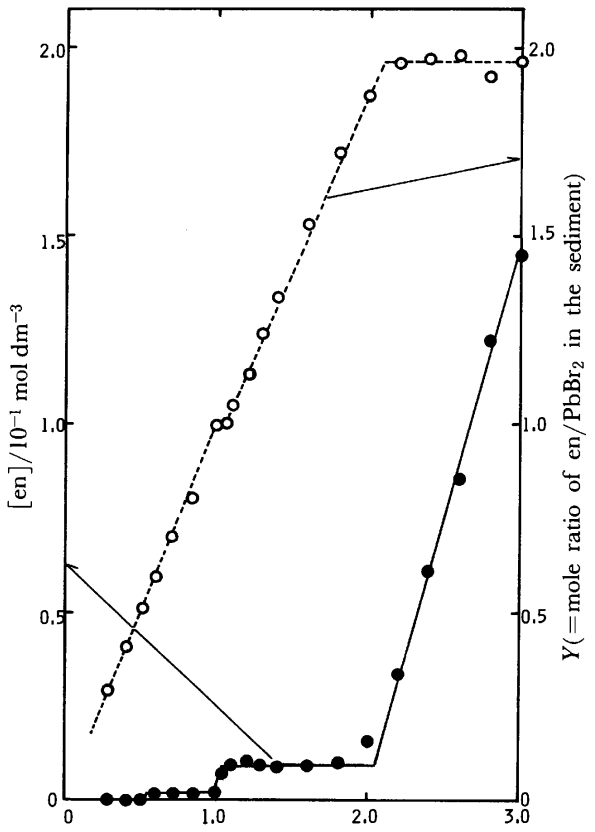

Fig. 5. Relation between the concentration of ethylenediamine remaining in the solution and mole ratio of en/$PbBr_2$ taken at the reaction when the mole ratio method was extended to the reaction of $PbBr_2$ with en: —●—●—, concentration curve; --O--O--, composition curve.

of finely powdered PbX_2 (X=Cl and Br) suspended in 10.0 cm^3 ethanol solution containing various amounts of en was put into ampoule. After several glass beads (about 0.2 cm in diameter) were added, the ampoule was sealed and shaked at 25.0±0.2 °C for about one month in the incubator. The mole ratio of en/PbX_2 at the beginning of reaction varied in the range of 0.3—3.0. Each ampoule was covered with an aluminium film in the case of the reaction of $PbBr_2$ with en to prevent the $PbBr_2$ from turning black owing to exposure to light. Reaction solution was separated from sediment after the reaction reached the equilibrium and then was subjected to chemical analysis.

(2) Extension of the Continuous Variation Method. Various amounts of finely powdered PbX_2 (X=Cl, Br, and I) and 10 cm^3 of ethanol solution containing various amounts of en were mixed in ampoule in varying proportions that the sum of PbX_2 and en is constant. The suspension was then treated as described above. The adopted D was 2.0 mmol for $PbCl_2$, $PbBr_2$, and PbI_2 and 1.5 mmol for $PbCl_2$.

Chemical Analysis of the Equilibrated Reaction Solutions. The concentration of en in the equilibrated reaction solutions was determined either potentiometrically when the concentration is high and spectrophotometrically[6] when low. [Pb^{2+}] was determined complexometrically[7] for some solutions.

Results and Discussion

Preliminary experiments confirmed that PbX_2 (X=Cl, Br, and I) does not react with ethanol and is sparingly soluble in it even in the presence of en.

Wharf et al. prepared $PbX_2 \cdot 2(en)$ (X=Cl, Br, and I).[8] We ascertained, however, the formation of $PbI_2 \cdot 2/3(en)$ and $PbI_2 \cdot en$ in addition to $PbI_2 \cdot 2(en)$.[1] Therefore, solid-liquid reactions of PbX_2 (X=Cl and Br) with en were carried out by extension of the mole ratio method in order to confirm if any other adducts than $PbX_2 \cdot 2(en)$ are formed. Figures 4 and 5 show the results of the reactions of $PbCl_2$ and $PbBr_2$ with en, respectively. The concentration curve of Fig. 4 ascends slightly near 0.5 of x/z and then becomes flat when x/z approaches 1.0. It ascends again at 1.0 of x/z and becomes flat between 1.2 and 2.1 of x/z. Namely, three plateaus appear on the concentration curve in the ranges of x/z of 0.3—0.5, 0.55—1.0, and 1.2—2.1. The concentration curve of Fig. 5 behaves in the same manner as that of Fig. 4 except that the concentration of en in the range of 1.1—2.1 of x/z is lower than that in Fig. 4. According to the phase rule, these facts mean

that three insoluble adducts form in each solid-liquid reaction.

As discussed in Refs. 1 and 2 on extension of the mole ratio method, the slope of monovariant regions on the concentration curve is equal to a certain fixed value depending on the adopted experimental conditions and independent of the composition of the formed adducts. Their compositions can be calculated by Eq. 16, which is converted from Eq. 3:

$$y = (x - [\mathrm{B}]V)/z = (x - [\mathrm{en}]V)/z, \qquad (16)$$

where [en] is the concentration of en in the equilibrated reaction solution. The compositions calculated from Eq. 16 are also shown in open circles in Figs. 4 and 5, where the broken line is termed "composition curve." Two plateaus appear clearly on each composition curve in monovariant regions where each concentration curve has specific slope; nearly equal to 1 and 2 of y in the right ordinate. Two insoluble adducts, $PbX_2 \cdot en$ and $PbX_2 \cdot 2(en)$, seem to correspond to each reaction. On the other hand, each composition curve shows no plateau corresponding to the rise in the concentration curve which occurs near 0.5 of x/z. The occurrence of these adducts is liable to be overlooked because of disappearance of the plateau in the composition curve and slight increase in the concentration curve. This is a drawback in extension of the mole ratio method to solid-liquid reactions. A similar situation was noticed when $PbI_2 \cdot 2/3(en)$[1] and $PbX_2 \cdot 1/2(dien)$[3] are formed. In the case of $PbI_2 \cdot 1/2(dien)$, its formation can be confirmed of not only by a slight concentration rise but also by the powder X-ray diffraction of the solid sediments.

In order to show that extension of the continuous variation method overcomes the drawback of the mole ratio method, the former was applied to the reactions of PbX_2 (X=Cl, Br, and I) with en in ethanol. Figure 6 shows the results of the reactions. When D is 2 mmol, each concentration curve has two plateaus and ascends sharply at 0.7 and 1.0 mmol of x for the reactions of $PbCl_2$ and $PbBr_2$. The reaction of PbI_2 with en also shows two plateaus and ascends at 0.8 mmol of x. When D is 1.5 mmol, the concentration curve ascends at 0.5 mmol of x in the reaction of $PbCl_2$. According to Eq. 15, the value of x where [B] increases sharply is 0.67 mmol for $m=1/2$, 0.8 mmol for $m=2/3$, and 1.0 mmol for $m=1$ when D is 2 mmol, while it is 0.5 mmol for $m=1/2$ when D is 1.5 mmol. Since each value of x found in Fig. 6 is equal to x calculated by Eq. 15, three insoluble adducts, $PbCl_2 \cdot 1/2(en)$, $PbBr_2 \cdot 1/2(en)$, and $PbI_2 \cdot 2/3(en)$, seem to be identified. Similarly, each sharp concentration rise at 1.0 mmol of x in Fig. 6 corresponds to formation of $PbCl_2 \cdot en$ and $PbBr_2 \cdot en$.

In order to prepare adducts with a mole ratio of en/PbX_2 higher than two, suspended PbX_2 powders were made to react with en without solvent. However, resulting adducts were found to be $PbX_2 \cdot 2(en)$ by chemical analysis and powder X-ray diffractometry.

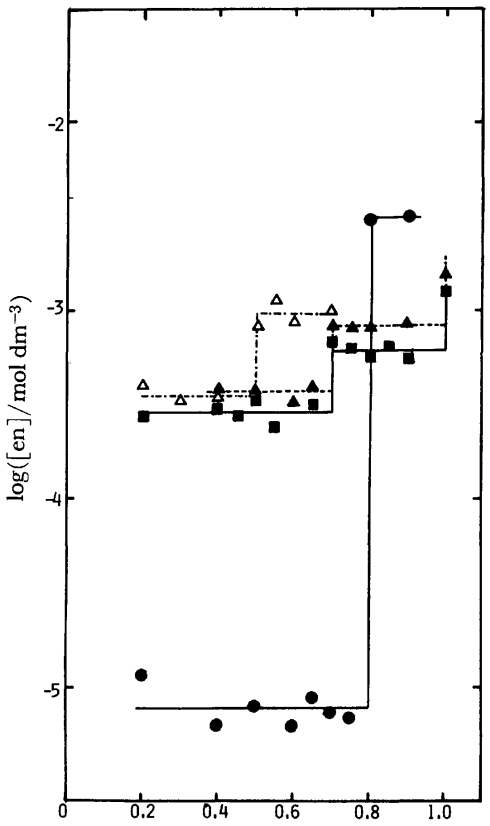

Fig. 6. Relation between the concentration of ethylenediamine remaining in the solution and the amount of en taken at the reaction when the continuous variation method was extended to the reaction of PbX_2 with en: —●—●—, PbI_2, D=2 mmol; —■—■—, $PbBr_2$, D=2 mmol; --▲--▲--, $PbCl_2$, D=2 mmol; -·-Δ-·-Δ-·-, $PbCl_2$, D=1.5 mmol.

When the equilibrated concentration of Lewis bases is high at invariant regions, the composition of formed adducts can be determined by extension of the continuous variation method to the reaction of PbI_2 with pyridine[3] on the basis of the slope at monovariant regions on the concentration curve. In the present work, the extension has been examined in the reactions of PbX_2 (X=Cl, Br, and I) with en where the equilibrated concentration of en is very low at the invariant regions. In this case, their compositions are determined on the basis of the values of sharp rises in the concentration curve. The values are proportional to D, the sum of Lewis acid and base, as shown in Fig. 3. This fact was also demonstrated by the reaction of $PbCl_2$ with en where formation of the same adduct, $PbCl_2 \cdot 1/2(en)$, was confirmed at two different D's, 1.5 and 2.0 mmol. If low concentration of Lewis bases can be accurately determined, the continuous variation method is effective in identifying formation of the adducts such as $PbCl_2 \cdot 1/2(en)$ and $PbBr_2 \cdot 1/2(en)$ whose formation is liable to be overlooked in the mole ratio method, because the composition curve tends to

lose the plateaus corresponding to the rises in the concentration curve.

Formation of $PbX_2 \cdot 2(en)$ (X=Cl, Br, and I) has been reported by Wharf et al.[8] By extension of the mole ratio method, three adducts, $PbI_2 \cdot i(en)$ (i=2/3, 1, and 2), were identified.[1] In the present paper, $PbX_2 \cdot i(en)$ (X=Cl and Br; i=1/2, 1, and 2) were confirmed. The mole ratio method as well as the continuous variation method are necessary to confirm all the adducts formed in solid-liquid reactions. Many adducts have been reported on PbX_2 with monodentate Lewis bases.[8-10] Most of them have the compositions of 1 : 1 and/or 1 : 2 PbX_2: base ratio. $PbCl_2 \cdot 1/2(en)$ and $PbBr_2 \cdot 1/2(en)$ correspond to adducts with PbX_2/base ratio of 1 : 1 and $PbX_2 \cdot en$ with the ratio of 1 : 2, because ethylenediamine is considered to be a bidentate ligand. Therefore, $PbX_2 \cdot 2(en)$ and $PbI_2 \cdot 2/3(en)$ have unusual compositions.

Preparation and Some Properties of Cobalt(III) Complex with D- and/or L-Selenomethioninates

Hideki UMEHARA,* Takumi KONNO, Ken-ichi OKAMOTO, and Jinsai HIDAKA
Department of Chemistry, University of Tsukuba, Sakura, Ibaraki 305
(Received October 25, 1986)

A novel cobalt(III) complex with D- and/or L-selenomethioninates (D- and/or L-semet) functioning as terdentate-*N,O,Se* ligand was prepared and separated into the five geometrical isomers, trans(N), trans(O), trans(Se), cis,cis,cis, and trans,trans,trans. Of these isomers *trans(N)*- and *trans(O)*-[Co(D- or L-semet)$_2$]$^+$ and *cis,cis,cis*-[Co(D-semet)(L-semet)]$^+$, which were obtained as the crystalline state, were optically resolved by the column chromatographic method. All the isomers were characterized by the electronic absorption, ^{1}H NMR, and CD spectra. The trans(N), trans(O), and cis,cis,cis isomers in the crystalline state take the selective configurations with respect to the absolute configuration, R(Se) or S(Se), of the two coordinated selenium atoms. While, these isomers in an aqueous solution are a mixture of some configurations in the equilibrium state. For the inversion on the asymmetric selenium donor atom of the trans(N) and cis,cis,cis isomers, the rate constants and the ΔG^* values are investigated on the basis of the absorption and ^{1}H NMR spectral changes. The trans(N) and cis,cis,cis isomers showed the characteristic CD spectral behavior in the d-d absorption band region depending on the inversion on the asymmetric selenium donor atoms.

Biochemical roles of selenium-containing amino carboxylates have been remarked in association with transition metals.[1] One of them selenomethioninate (semet) has three donor sites and is potentially terdentate-*N,O,Se* ligand, which has a framework similar to methioninate (met). Accordingly, the stereochemistry of the cobalt(III) complex with semet can be compared effectively with those of the methioninato cobalt(III) complex[2] and its analogues.[3-5] Hence, in order to examine the spectrochemical and stereochemical properties of the coordinated selenium atom, we have undertaken the preparation of the cobalt(III) complex with D- and/or L-selenomethioninates.

In this work, the cobalt(III) complex with D- and/or L-selenomethioninates were prepared and chromatographically separated into the five geometrical isomers: *trans(N)*-, *trans(O)*-, and *trans(Se)*-[Co(D- or L-semet)$_2$]$^+$,[6] and *cis,cis,cis*- and *trans,trans,trans*-[Co(D-semet)(L-semet)]$^+$ (Fig. 1). All isomers were characterized by their electronic absorption spectra in comparison with those of the isomers of the cobalt(III) complex with D- and/or L-methioninates.[2] For the trans(N) and cis,cis,cis isomers which exhibited the electronic absorption, CD, and ^{1}H NMR spectral changes with time in an aqueous solution, an inversion on the asymmetric selenium donor atom is investigated by the spectrophotometric method. The CD spectral behaviors are also discussed in relation to the absolute configuration of the asymmetric selenium donor atom.

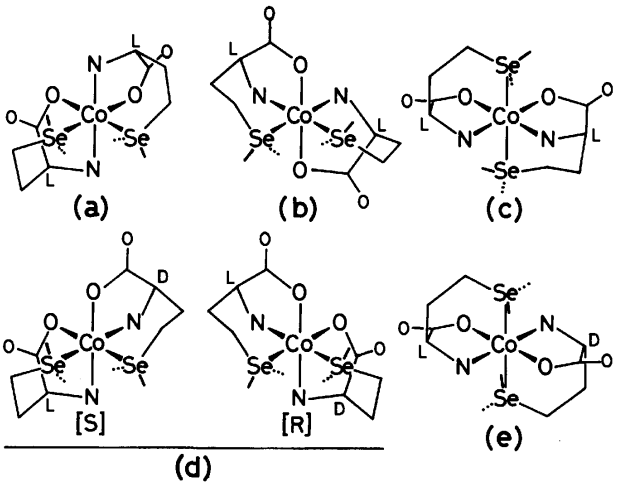

Fig. 1. Possible geometrical isomers of [Co(L-semet)$_2$]$^+$ and [Co(D-semet)(L-semet)]$^+$: (a) trans(N), (b) trans(O), (c) trans(Se), (d) cis,cis,cis, and (e) trans,-trans,trans.

Experimental

Preparation of Complex. A solution containing 1.8 g of $CoCl_2 \cdot 6H_2O$ in 10 cm^3 of water was added to a suspension containing 3.0 g of the racemic Hsemet[7] in 50 cm^3 of water. After the mixture was stirred at 60 °C for 5 min, to this were added 0.5 g of activated charcoal and 8.0 g of PbO_2. The mixture was further stirred at 60 °C for 20 min and then filtered to remove insoluble materials. The dark brown filtrate was poured onto an SP-Sephadex C-25 column (Na^+ form, 4×100 cm). After sweeping the column with water, the adsorbed band was eluted with a 0.015 mol dm^{-3} aqueous solution of Na_2SO_4. A circulating-chromatographic technique was employed for the separation of the isomers. After circulating the eluates in the same column several times, the eluates were separated into the five colored ones, dark violet (A-1), yellow (A-2), violet (A-3), red-violet (A-4), and yellow (A-5) in this order. It was found from the absorption spectral measurements that the eluates A-1, A-4, and A-5 contained *trans(O)*-, *trans(N)*-, and *trans(Se)*-[Co(D- or L-semet)$_2$]$^+$, respectivily, and the eluate A-3 contained *cis,cis,cis*-[Co(D-semet)(L-semet)]$^+$. The formation ratio of the isomers, trans(O): cis,cis,cis: trans(N): trans(Se), was about 1 : 7 : 9 : 1. Each eluate except the eluate A-2 was concentrated with a rotary evaporator below 25 °C and Na_2SO_4 deposited was filtered off. The filtrate was then passed through a QAE-Sephadex A-25 column (ClO_4^- form, 2.5×20 cm) by eluting with water. The eluate was concentrated with a rotary evaporator again and the crystals were collected by filtration. The A-5 isomer could not be obtained as a solid because of

the small amount of the eluate A-5, and then the concentration of the A-5 isomer was evaluated on the basis of the plasma emission spectral analysis. The A-2 isomer, whose formation was very poor, could not be separated as a pure form because of the isomerization during the procedure of the chromatographic separation. Found for A-1: C, 21.18; H, 3.96; N. 4.92%. Calcd for $[Co(semet)_2]ClO_4 \cdot H_2O$=$CoC_{10}H_{20}N_2O_8ClSe_2 \cdot H_2O$: C, 21.20; H, 3.91; N. 4.94%. Found for A-3: C, 22.02; H, 3.66; N, 5.08%. Found for A-4: C, 21.99; H. 3.71; N, 5.09%. Calcd for $[Co(semet)_2]ClO_4$: C, 21.89; H, 3.67; N, 5.11%.

Resolution of Isomers. $(-)^{CD}_{500}$-*trans*(*N*)-[Co(D-semet)$_2$]ClO$_4$ and $(+)^{CD}_{500}$-*trans*(*N*)-[Co(L-semet)$_2$]ClO$_4$. About 0.1 g of *trans*(*N*)-[Co(D- or L-semet)$_2$]ClO$_4$ (A-4) was dissolved in a small amount of water and poured onto an SP-Sephadex C-25 column (Na^+ form, 3.5×100 cm). After sweeping the column with water, the adsorbed band was eluted with a 0.015 mol dm^{-3} aqueous solution of $K_2[Sb_2(d\text{-tart})_2] \cdot H_2O$. After circulating the eluates in the same column twice, the eluates were separated into the two bands and then fractionated. It was found from the CD spectral measurements that the earlier moving band contained $(-)^{CD}_{500}$-*trans*(*N*)-[Co(D-semet)$_2$]$^+$ and the later one contained $(+)^{CD}_{500}$-*trans*(*N*)-[Co(L-semet)$_2$]$^+$. Each of the fractions was concentrated to a small volume with a rotary evaporator below 25 °C and deposited $K_2[Sb_2(d\text{-tart})_2]$ was filtered off. The filtrate was converted into the perchlorate salt using a QAE-Sephadex A-25 column (ClO_4^- form) by eluting with water. The eluate was concentrated to a small volume again and kept in a refrigerator for several days. The resulting crystals were collected by filtration.

$(-)^{CD}_{550}$-[*R*]- and $(+)^{CD}_{550}$-[*S*]-*cis,cis,cis*-[Co(D-semet)(L-semet)]ClO$_4$. *cis,cis,cis*-[Co(D-semet)(L-semet)]ClO$_4$ (A-3) was resolved by a procedure similar to that used for the trans(N) isomer, using the racemic cis,cis,cis isomer (0.1 g) instead of the trans(N) one. The earlier moving adsorbed band contained $(-)^{CD}_{550}$-[*R*]-*cis,cis,cis*-[Co(D-semet)(L-semet)]$^+$ and the later one contained the $(+)^{CD}_{550}$-[*S*] one.

$(-)^{CD}_{600}$-*trans*(*O*)-[Co(D-semet)$_2$]ClO$_4$ and $(+)^{CD}_{600}$-*trans*(*O*)-[Co(L-semet)$_2$]ClO$_4$. *trans*(*O*)-[Co(D- or L-semet)$_2$]ClO$_4 \cdot H_2O$ (A-1) was also resolved by a procedure similar to that used for the trans(N) isomer, except for using about 0.02 g of the trans(O) isomer and an SP-Sephadex C-25 column (Na^+ form, 3.0×40 cm). The earlier moving adsorbed band contained $(+)^{CD}_{600}$-*trans*(*O*)-[Co(L-semet)$_2$]$^+$ and the later one contained $(-)^{CD}_{600}$-*trans*(*O*)-[Co(D-semet)$_2$]$^+$.

The $\Delta\varepsilon$ values of the trans(N), cis,cis,cis, and trans(O) isomers were evaluated from their absorption spectral data.

Kinetic Measurements. The inversion on the asymmetric selenium donor atom of *trans*(*N*)-[Co(D- or L-semet)$_2$]$^+$ and *cis,cis,cis*-[Co(D-semet)(L-semet)]$^+$ in the aqueous solution was monitored spectrophotometrically with a JASCO UVIDEC-1 spectrophotometer equipped with a thermostated cell compartment. The concentrations of the isomers were ca. 1.5×10^{-3} mol dm^{-3}. The temperature of the solutions, T, was in the range of 16.9—25.9 °C and kept constant within ±0.1 °C by use of a temperature-controlled circulating bath, Yamato-Komatsu CTR-220. The absorbance changes with time were followed at 511 nm for the trans(N) isomer and at 556 nm for the cis,cis,cis one, respectively. The first-order rate constant, k, for the trans(N) or cis,cis,cis isomer was determined from the plot of $\ln\{(A_0-A_\infty)/(A_t-A_\infty)\}$ against time, where A_0, A_∞, and A_t stand for absorbances at the initial state, at equilibrium, and at time t, respectively.

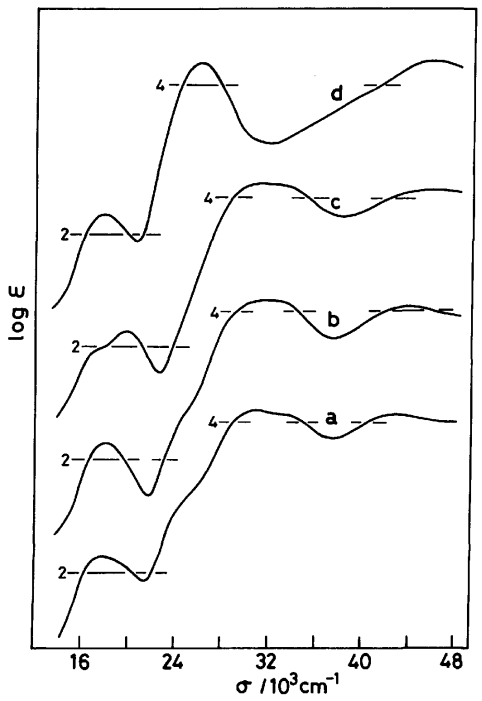

Fig. 2. Absorption spectra of [Co(D- or L-semet)$_2$]$^+$ and [Co(D-semet)(L-semet)]$^+$: (a) trans(O), (b) cis,cis,cis, (c) trans(N), and (d) trans(Se).

The activation parameters were yielded from the Eyring treatment of log (k/T) vs. T^{-1}.

Measurements. The electronic absorption spectra were recorded with JASCO UVIDEC-1 and UVIDEC-610 spectrophotometers and the CD spectra with a JASCO J-20 spectropolarimeter. All measurements were carried out in aqueous solution. The concentration of *trans*(*Se*)-[Co(D- or L-semet)$_2$]$^+$ (A-5 isomer) was determined with a Jarrel-Ash Model 96-975 Plasma Atom Co. The ^{1}H NMR spectra were recorded in deuterium oxide with a JEOL JNM-FX-100 NMR spectrometer at the prove temperature. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) was used as an internal reference.

Results and Discussion

Characterization. Five geometrical isomers are possible for the cobalt(III) complex with D- and/or L-selenomethioninates: trans(N), trans(O), and trans(Se) for [Co(D- or L-semet)$_2$]$^+$, and cis,cis,cis and trans,trans,-trans for [Co(D-semet)(L-semet)]$^+$, as in the case of the cobalt(III) complex with D- and/or L-methioninates[2] and its analogues (Fig. 1).[3-5] As shown in Fig. 2 and Table 1, each absorption spectrum of the present five isomers is quite similar to that of the corresponding isomers of [Co(D- or L-met)$_2$]$^+$ and [Co(D-met)(L-met)]$^+$, though the first absorption bands of the selenomethioninato isomers and, especially, the charge-transfer bands due to the selenium to metal (ca. 30—33×10^3 cm^{-1} for A-1, A-3, and A-4, and ca. 26×10^3 cm^{-1} for A-5) shift significantly to lower energy than those of the methioninato isomers.[2] These results are consistent with the absorption behavior observed for the

Table 1. Absorption Spectral Data of Equilibrium State for [Co(D- or L-semet)$_2$]$^+$ and [Co(D-semet)(L-semet)]$^+$

Complex	d–d band	Charge transfer band
trans(*N*)-[Co(D- or L-semet)$_2$]$^+$	17.44 (1.99 sh) 19.49 (2.21)	31.06 (4.18) 32.68 (4.16 sh) 45.66 (4.12)
trans(*O*)-[Co(D- or L-semet)$_2$]$^+$	17.61 (2.21) 19.27 (2.14 sh) 24.88 (3.01 sh)	30.67 (4.16) 32.95 (4.11 sh) 42.74 (4.10)
trans(*Se*)-[Co(D- or L-semet)$_2$]$^+$	17.67 (2.27)	25.97 (4.28) 45.66 (4.30)
cis,cis,cis-[Co(D-semet)(L-semet)]$^+$	17.94 (2.26) 25.07 (2.74 sh)	31.55 (4.20) 43.67 (4.13)

Wavenumbers and log ε values (in parentheses) are given in 10^3cm^{-1} and mol^{-1}dm^{3}cm^{-1}, respectively. sh denotes a shoulder.

[Co(bidentate-*N*,*Se* or -*N*,*S*)(en or tn)$_2$] type complexes.[8,9] Accordingly, the A-1, A-3, A-4, and A-5 isomers are assignable to trans(O), cis,cis,cis, trans(N), and trans(Se), respectively. Hence, it is noted that the selenium to metal charge-transfer bands for the three cis(Se) type selenomethioninato isomers split distinctly in comparison with the sulfur to metal charge-transfer band for the three cis(S) type methioninato isomers (Fig. 2).[2] The absorption spectrum of the A-2 isomer could not be measured because of the its partial isomerization to the cis(Se) type isomer during the chromatographic separation. However, it is probable that the eluate A-2 mainly contains the trans,trans,-trans isomer, because the eluate A-2 exhibits the selenium to metal charge-transfer band in a similar position (ca. 26×10^3 cm^{-1}) to *trans*(*Se*)-[Co(D- or L-semet)$_2$]$^+$, whose band locates at lower energy than those of the cis(Se) type isomers.

Inversion on the Asymmetric Selenium Donor Atom. When the crystals of *trans*(*N*)-[Co(D- or L-semet)$_2$]ClO$_4$ were dissolved in water, the absorption spectral change was observed with time at room temperature and the absorption spectrum exhibited two distinct isosbestic points at 552 and 652 nm (Fig. 3). This spectrum attained equilibrium after 4.5 h, and the absorption spectrum at equilibrium coincided with that of the eluate A-4 obtained by the chromatographic separation. Further, the solution at equilibrium exhibited only the same adsorbed band as that of the eluate A-4 in the rechromatographic separation. Similar trend was also observed for *cis,cis,cis*-[Co(D-semet)(L-semet)]$^+$, namely, the absorption spectrum exhibited the isosbestic points at 463 and 645 nm and attained equilibrium after 6 h. These absorption spectral changes for the trans(N) and cis,cis,cis isomers were simultaneously accompanied by the CD and ^{1}H NMR spectral changes (vide infra). Accordingly, it seems to indicate that the spectral changes for the trans(N) and cis,cis,cis isomers are caused by the inversion on the asymmetric selenium donor atom of the ligand. These are confirmed by the following ^{1}H NMR spectral behaviors.

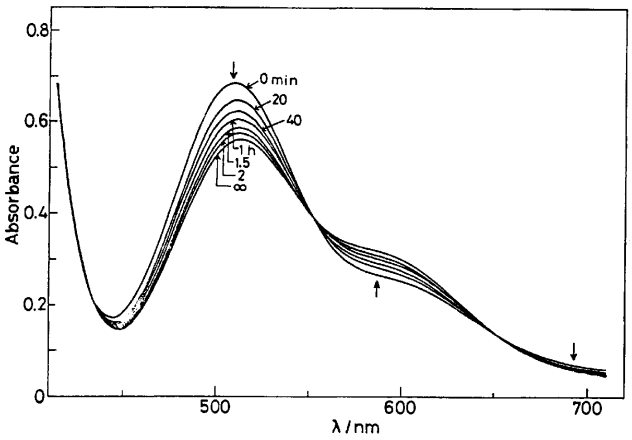

Fig. 3. Change in absorption spectrum with time for *trans*(*N*)-[Co(D- or L-semet)$_2$]$^+$ in water at 25.9°C. The measured times are indicated on the spectral curves. Trends of the spectral change with time are shown by arrows.

Just after *trans*(*N*)-[Co(D- or L-semet)$_2$]ClO$_4$ was dissolved in water, the ^{1}H NMR spectrum exhibited only one resonance line at 2.04 ppm in the *Se*-methyl proton region as shown in Fig. 4-a. Taking the configuration, R(Se) or S(Se), of the asymmetric selenium donor atom into consideration, the ^{1}H NMR spectrum of the R(Se),R(Se) or S(Se),S(Se) isomer having C_2 axis can be expected to exhibit only one resonance line in the corresponding region, while the R(se),S(Se) isomer to exhibit two resonance lines. The present result suggests that the trans(N) isomer in the crystalline state is either R(Se),R(Se) or S(Se),S(Se). The model constructions reveal that the two asymmetric selenium donor atoms take the R(Se)$_D$,R(Se)$_D$ or S(Se)$_L$,S(Se)$_L$ configuration for *trans*(*N*)-[Co(D- or L-semet)$_2$]$^+$, because the S(Se)$_D$,S(Se)$_D$ or R(Se)$_L$,-R(Se)$_L$ configuration has the intramolecular steric interaction between the two *Se*-methyl groups, where

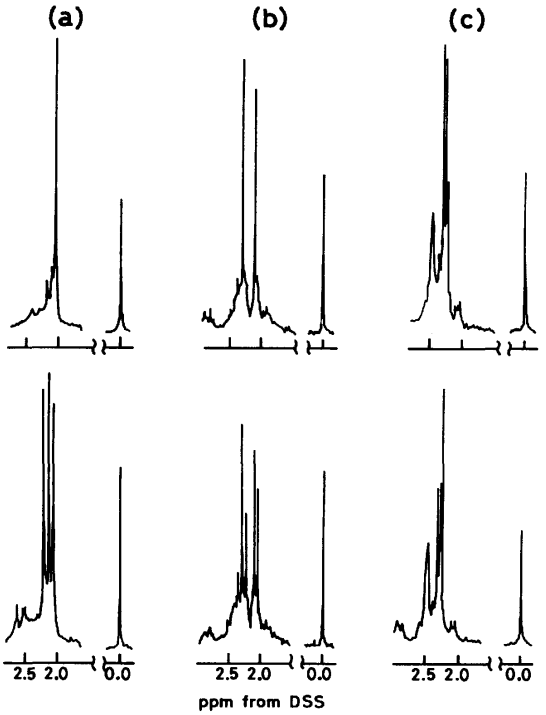

Fig. 4. ^{1}H NMR spectra of [Co(D- or L-semet)$_2$]$^+$ and [Co(D-semet)(L-semet)]$^+$: (a) trans(N), (b) cis,cis,cis, and (c) trans(O); initial state (upper) and equilibrium state (lower).

the subscripts, D and L, correspond to the absolute configurations, R(C) and S(C), for the asymmetric carbon atom of the selenomethioninate. In the aqueous solution, two resonance lines at 2.10 and 2.19 ppm gradually appeared and their intensities increased with time, and finally three resonance lines with the equal intensities were observed at equilibrium (Fig. 4-a). The two resonance lines which newly appeared seems to be due to the R(Se),S(Se) configuration. Accordingly, the ^{1}H NMR spectral behavior suggests that *trans(N)*-[Co(D- or L-semet)$_2$]$^+$ in the aqueous solution at equilibrium is a mixture of the R(Se)$_D$,R(Se)$_D$ and S(Se)$_L$,-S(Se)$_L$ configurations and the R(Se)$_D$,S(Se)$_D$ and R(Se)$_L$,S(Se)$_L$ ones (1 : 2). Namely, the absorption and ^{1}H NMR spectral behaviors of *trans(N)*-[Co(D- or L-semet)$_2$]$^+$ indicate that the inversion on the asymmetric selenium donor atom takes place as follows:

$$R(Se)_D,R(Se)_D \longrightarrow R(Se)_D,S(Se)_D \quad (1a)$$

$$S(Se)_L,S(Se)_L \longrightarrow R(Se)_L,S(Se)_L \quad (1b)$$

Similar trend was also observed for the cis,cis,cis iomer. *cis,cis,cis*-[Co(D-semet)(L-semet)]$^+$ has [R] and [S] configurations based on the chiral arrangement of the coordinated atoms, N, O, and Se.[10] Moreover, four geometrical isomers for each of the [R] and [S] configurations, R(Se)$_D$,R(Se)$_L$, R(Se)$_D$,S(Se)$_L$, S(Se)$_D$,R(Se)$_L$, and S(Se)$_D$,S(Se)$_L$, are possible. Just after the perchlorate salt of the cis,cis,cis isomer was dissolved in water, the ^{1}H NMR spectrum exhibited two resonance lines at 2.11 and 2.30 ppm (Fig. 4-b). This spectrum indicates that the cis,cis,cis isomer in the crystalline state takes only one configuration of the four geometrical isomers. While, in the aqueous solution of this isomers two resonance line at 2.06 and 2.24 ppm gradually appeared and their intensities increased with time, though they were accompanied by the minor two resonance lines at 2.14 and 2.37 ppm (Fig. 4-b). At equilibrium, the intensity ratio of the resonance lines at 2.06, 2.11, 2.24, and 2.30 ppm was about 2 : 3 : 2 : 3 (Fig. 4-b). The model constructions for the cis,cis,cis isomer reveal that the [R]-S(Se)$_D$,R(Se)$_L$ or [S]-R(Se)$_D$,-S(Se)$_L$ isomer has the intramolecular steric interaction between the *Se*-methyl group and the amine protons in the other D- or L-semet ligand. Further, the [R]-S(Se)$_D$,-S(Se)$_L$ or [S]-R(Se)$_D$,R(Se)$_L$ isomer has the interaction between the two *Se*-methyl groups. While, the [R]-R(Se)$_D$,R(Se)$_L$ or [S]-S(Se)$_D$,S(Se)$_L$ isomer and the [R]-R(Se)$_D$,S(Se)$_L$ or [S]-S(Se)$_D$,R(Se)$_L$ one have only a little intramolecular steric interaction. The steric interaction in the cis,cis,cis isomer seems to increase in the order [R]-R(Se)$_D$,R(Se)$_L$ or [S]-S(Se)$_D$,S(Se)$_L$<[R]-R(Se)$_D$,S(Se)$_L$ or [S]-S(Se)$_D$,R(Se)$_L$<[R]-S(Se)$_D$,R(Se)$_L$ or [S]-R(Se)$_D$,S(Se)$_L$<[R]-S(Se)$_D$,S(Se)$_L$ or [S]-R(Se)$_D$,-R(Se)$_L$. Therefore, the ^{1}H NMR spectral behavior suggests that *cis,cis,cis*-[Co(D-semet)(L-semet)]$^+$ in the aqueous solution at equilibrium takes mainly a mixture of the [R]-R(Se)$_D$,R(Se)$_L$ and [S]-S(Se)$_D$,S(Se)$_L$ configurations and the [R]-R(Se)$_D$,S(Se)$_L$ and [S]-S(Se)$_D$,R(Se)$_L$ ones containing the minor [R]-S(Se)$_D$,-R(Se)$_L$ and [S]-R(Se)$_D$,S(Se)$_L$ ones. From these consideration, the cis,cis,cis, isomer in the crystalline state seems to take the [R]-R(Se)$_D$,R(Se)$_L$ and [S]-S(Se)$_D$,-S(Se)$_L$ configurations. The absorption and ^{1}H NMR spectral behaviors for *cis,cis,cis*-[Co(D-semet)(L-semet)]$^+$ indicate the following inversion on the asymmetric selenium donor atom:

$$[R]\text{-}R(Se)_D,R(Se)_L \longrightarrow [R]\text{-}R(Se)_D,S(Se)_L \quad (2a)$$

$$[S]\text{-}S(Se)_D,S(Se)_L \longrightarrow [S]\text{-}S(Se)_D,R(Se)_L \quad (2b)$$

For *trans(O)*-[Co(D- or L-semet)$_2$]$^+$, three isomers, R(Se),R(Se), R(Se),S(Se), and S(Se),S(Se), are possible as well as the trans(N) isomer. In contrast with the trans(N) and cis,cis,cis isomers, the ^{1}H NMR spectral change of the trans(O) isomer could be measured, although the absorption spectral change occurred too fast to be followed. Just after the perchlorate salt of the trans(O) isomer was dissolved in water, the ^{1}H NMR spectrum showed two intense resonance lines at 2.26 and 2.29 ppm and one minor resonance line at 2.23 ppm (Fig. 4-c). This fact suggests that the trans(O) isomer in the crystalline state takes mainly the R(Se),-S(Se) configuration having C_1 symmetry. After 20 min, the inversion reaction attained the equilibrium and the intensities of the two resonance lines at 2.26 and 2.29 ppm are weaker than that at 2.23 ppm (Fig. 4-c). The model constructions reveal that the steric

Table 2. Rate Constants for Inversion on Selenium Atom

trans(*N*)-[Co(D- or L-semet)$_2$]$^+$	16.9	(7.62±0.15)×10^{-5}
	21.7	(1.74±0.08)×10^{-4}
	25.9	(3.34±0.12)×10^{-4}
cis,cis,cis-[Co(D-semet)(L-semet)]$^+$	16.9	(7.50±0.11)×10^{-5}
	21.7	(1.39±0.05)×10^{-4}
	25.9	(2.29±0.09)×10^{-4}

Table 3. Thermodynamic Parameters for Inversion on Selenium Atom

Complex	ΔH^*	ΔS^*	$\Delta G^*_{25°C}$
	kJ mol^{-1}	J mol^{-1} K^{-1}	kJ mol^{-1}
trans(*N*)-[Co(D- or L-semet)$_2$]$^+$	116.1±1.4	76.7±5.0	93.2±0.1
cis,cis,cis-[Co(D-semet)(L-semet)]$^+$	87.2±2.0	−23.1±7.0	94.1±0.1

interaction in the trans(O) isomer increases in the order S(Se)$_D$,S(Se)$_D$ or R(Se)$_L$,R(Se)$_L$<R(Se)$_D$,S(Se)$_D$ or R(Se)$_L$,S(Se)$_L$<R(Se)$_D$,R(Se)$_D$ or S(Se)$_L$,(Se)$_L$. Therefore, in the aqueous solution at equilibrium, the trans(O) isomer seems to take a mixture of the S(Se)$_D$,-S(Se)$_D$ and R(Se)$_L$,R(Se)$_L$ configurations (C_2 symmetry) and the R(Se)$_D$,S(Se)$_D$ and R(Se)$_L$,S(Se)$_L$ ones (C_1 symmetry) (ca. 1 : 1). Accordingly, the ^{1}H NMR spectral behavior seems to indicate the following inversion:

$$R(Se)_D,S(Se)_D \longrightarrow S(Se)_D,S(Se)_D \quad (3a)$$

$$R(Se)_L,S(Se)_L \longrightarrow R(Se)_L,R(Se)_L \quad (3b)$$

Rate constants of the inversion on the asymmetric selenium donor atom for the equations (1) and (2) were determined by monitoring the change in absorbance with time. The absorbance at 511 nm of *trans*(*N*)-[Co(D- or L-semet)$_2$]$^+$ in the aqueous solution at a constant temperature decreased monotonically with time (Fig. 3). The plot of $\ln\{(A_0-A_\infty)/(A_t-A_\infty)\}$ against time gave a straight line, from which the first-order rate constants of the inversion were obtained (Fig. 5-a and Table 2). Similarly, the absorption spectral data for the cis,cis,cis isomer were treated in the same way (Fig. 5-b and Table 2). The rate constant of the trans(N) isomer agreed well with that of the cis,cis,cis one. These rate constants for the inversion are in agreement with those of *t*-[Co(RSeCH$_2$CH$_2$NH$_2$)-(tren)]$^{3+}$ (R=CH$_3$, CH$_3$CH$_2$, and C$_6$H$_5$CH$_2$, and tren=N(CH$_2$CH$_2$NH$_2$)$_3$) and *t*-[Co(CH$_3$SeCH$_2$COO)-(tren)]$^{2+}$.[11] These suggest that the inversion for the present isomers arises from a mechanism similar to that for the tren cobalt(III) complexes with RSeCH$_2$-CH$_2$NH$_2$ (R=CH$_3$, CH$_3$CH$_2$, and C$_6$H$_5$CH$_2$).[11]

Eyring treatments of $\log(k/T)$ vs. T^{-1} yielded activation parameters for the trans(N) and cis,cis,cis isomers (Table 3). Their ΔG^* values at 25 °C resemble each other and agree well with those of the tren cobalt-(III) complexes with RSeCH$_2$CH$_2$NH$_2$ (R=CH$_3$, CH$_3$CH$_2$, and C$_6$H$_5$CH$_2$).[11] Taking account of the stereochemical differences between the trans(O) isomer and the trans(N) or cis,cis,cis one, whose inversion

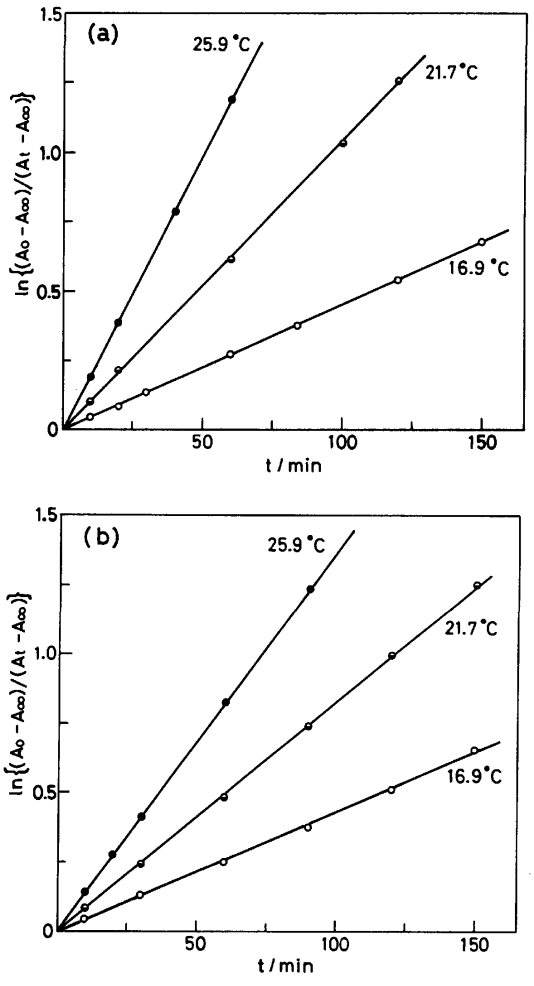

Fig. 5. Plot of $\ln\{(A_0-A_\infty)/(A_t-A_\infty)\}$ against time for (a) *trans*(*N*)-[Co(D- or L-semet)$_2$]$^+$ and (b) *cis,cis,cis*-[Co(D-semet)(L-semet)]$^+$ in water at 16.9, 21.7 and 25.9 °C.

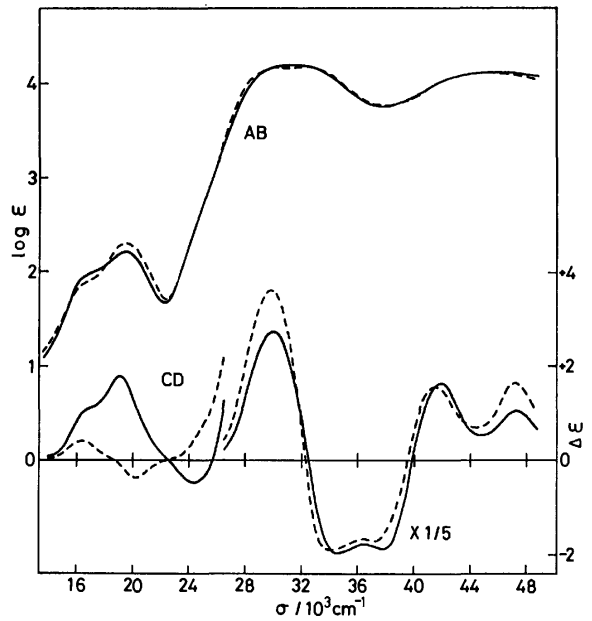

Fig. 6. Absorption and CD spectra of the $(+)^{CD}_{500}$-*trans*(*N*)-[Co(L-semet)$_2$]$^+$: initial state (----) and equilibrium state (——).

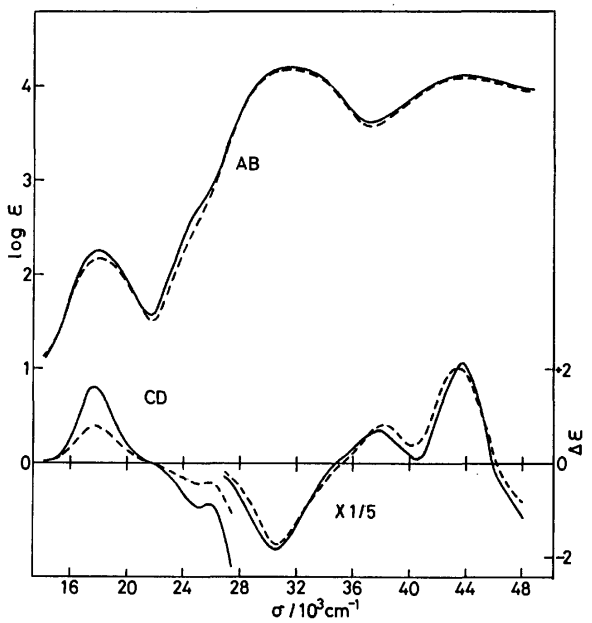

Fig. 7. Absorption and CD spectra of the $(+)^{CD}_{550}$-[*S*]-*cis,cis,cis*-[Co(D-semet)(L-semet)]$^+$: initial state (----) and equilibrium state (——).

mechanism may resemble each other, a somewhat overvalued differences in ΔH^* and ΔS^* between the trans(N) and cis,cis,cis isomers seems to reflect the difference in the stereochemistry around the selenium donor atoms during the kinetic processes, as mentioned about the ^{1}H NMR spectral behavior. Namely, the difference in ΔH^* and ΔS^* seems to associate with the steric effect and rotational freedom for the methyl group on the selenium donor atom on going from the initial to the transitional state.

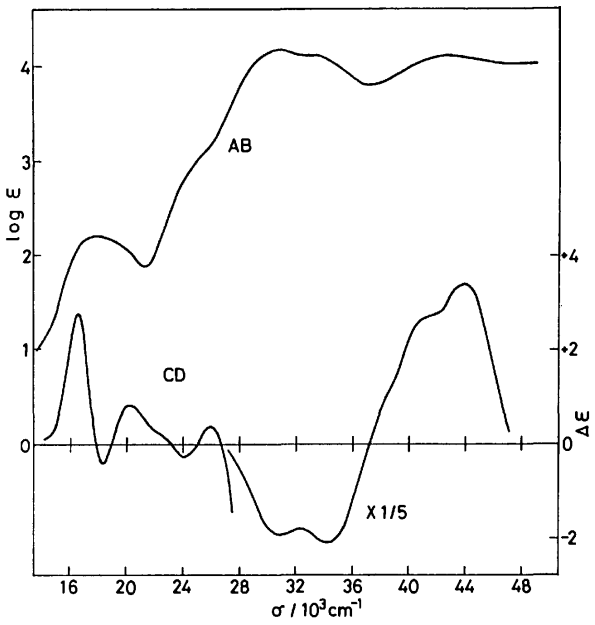

Fig. 8. Absorption and CD spectra of the $(+)^{CD}_{600}$-*trans*(*O*)-[Co(L-semet)$_2$]$^+$.

CD Spectra. The CD spectra at equilibrium of $(+)^{CD}_{600}$-*trans*(*O*)- and $(+)^{CD}_{500}$-*trans*(*N*)-[Co(D- or L-semet)$_2$]$^+$, and $(+)^{CD}_{550}$-*cis,cis,cis*-[Co(D-semet)(L-semet)]$^+$ are shown in Figs. 6—8, together with those of the trans(N) and cis,cis,cis isomers just after dissolved in water, and their spectral data are summarized in Table 4. In the equilibrium state, the $(+)^{CD}_{500}$-trans(N) isomer exhibits a quite similar CD spectral pattern in the whole region to *trans*(*N*)-[Co(L-met)$_2$]$^+$ (Fig. 6),[2] the $(+)^{CD}_{550}$-cis,cis,cis isomer to [*S*]-*cis,cis,cis*-[Co(D-met)(L-met)]$^+$ [12] and -[Co(D-smp)(L-smp)]$^+$ (Fig. 7),[5] and the $(+)^{CD}_{600}$-trans(O) isomer to *trans*(*O*)-[Co(L-met)]$^+$ (Fig. 8).[2] The CD bands of the semet isomers shift to the lower energy in the d-d transition and ligand to metal charge-transfer band regions than those of the corresponding met isomers as in the case of their absorption spectral behavior. These are in line with the fact that the CD spectra of the selenolato, selenenato, and selenoether cobalt(III) complexes shift to a lower energy than those of the corresponding thiolato, sulfenato, and thioether complexes.[8,9] These facts support that the present isomers are assigned to $(+)^{CD}_{500}$-*trans*(*N*)-[Co(L-semet)$_2$]$^+$, $(+)^{CD}_{550}$-[*S*]-*cis,cis,cis*-[Co(D-semet)-(L-semet)]$^+$, and $(+)^{CD}_{600}$-*trans*(*O*)-[Co(L-semet)$_2$]$^+$, respectively.

For $(+)^{CD}_{500}$-*trans*(*N*)-[Co(L-semet)$_2$]$^+$ and $(+)^{CD}_{550}$-[*S*]-*cis,cis,cis*-[Co(D-semet)(L-semet)]$^+$, the CD spectral changes, which are accompanied by their absorption and ^{1}H NMR spectral changes, were observed at room temperature (Figs. 6 and 7). These CD spectral changes seem to correspond with the equations (1b) and (2b). It is noteworthy that the CD pattern of the trans(N) isomer changes drastically with time and the

Table 4. CD Spectral Data of Equilibrium State for $[Co(L\text{-semet})_2]^+$ and $[Co(D\text{-semet})(L\text{-semet})]^+$

Complex	d-d band region	Charge transfer band region
$(+)^{CD}_{500}$-*trans*(*N*)-$[Co(L\text{-semet})_2]^+$	17.15(+1.12 sh) 19.15(+1.80) 24.51(−0.48)	30.12(+13.58) 34.60(−9.92) 38.02(−9.56) 42.02(+8.24) 47.17(+5.29)
$(+)^{CD}_{600}$-*trans*(*O*)-$[Co(L\text{-semet})_2]^+$	16.50(+2.78) 18.32(−0.44) 20.20(+0.84) 24.04(−0.28) 25.91(+0.38)	30.86(−9.72) 34.01 (−10.47) 41.15 (+13.46 sh) 43.86 (+17.05)
$(+)^{CD}_{550}$-[*S*]-*cis,cis,cis*-$[Co(D\text{-semet})(L\text{-semet})]^+$	17.70(+1.60) 25.13(−0.95)	30.49(−9.16) 37.74(+3.45) 43.67 (+10.63)

Wavenumbers and $\Delta\varepsilon$ values (in parentheses) are given in $10^3\,cm^{-1}$ and $mol^{-1}\,dm^3\,cm^{-1}$, respectively. sh denotes a shoulder.

CD spectrum exhibited the isodichroic point at 441.5 nm, without the change in the region of $27—46\times10^3$ cm^{-1} (Fig. 6). A similar CD spectral change was also observed for the cis,cis,cis isomer in the d-d transition band region (the isodichroic point at 458 nm) (Fig. 7). Judging from the investigations of the ^1H NMR and absorption spectral changes mentioned above, the CD spectra of initial state and equilibrium one for *trans*(*N*)-$[Co(L\text{-semet})_2]^+$ suggest the change from the $S(Se)_L,S(Se)_L$ configuration to the mixture of the $R(Se)_L,S(Se)_L$ and $S(Se)_L,S(Se)_L$ configurations, and [*S*]-*cis,cis,cis*-$[Co(D\text{-semet})(L\text{-semet})]^+$ from the $S(Se)_D,S(Se)_L$ configuration to the mixture of $S(Se)_D,R(Se)_L$ and $S(Se)_D,S(Se)_L$ configurations. The results in this work indicate that the change of the configuration of the asymmetric selenium atoms contributes remarkably to the absorption and CD spectra in the d-d transition band region and differs significantly from the stereochemical behavior of the asymmetric sulfur atom in the methioninato complex.[2,13]

The authors wish to express thanks to Mr. Tsutomu Watanabe and Mrs. Yoko Koizumi for their aid in the experiment.

Effect of Sodium Dodecyl Sulfate on Spectral Properties of Five- and Six-Coordinate Nitrosyl(protoporphyrin IX dimethyl esterato)iron(II) Complexes

Tetsuhiko YOSHIMURA
The Environmental Science Institute of Hyogo Prefecture, Yukihira-cho, Suma-ku, Kobe 654
(Received October 28, 1986)

EPR and electronic spectra of five- and six-coordinate nitrosyl(protoporphyrin IX dimethyl esterato)iron(II) (Fe(ppixdme)(NO)) complexes as model systems for nitrosylhemoproteins have been investigated in the absence and the presence of sodium dodecyl sulfate (SDS). Dimethyl sulfoxide, an O-donor ligand, is weakly coordinated to iron in an axial vacant position trans to a nitrosyl group in Fe(ppixdme)(NO). Upon addition of SDS to Fe(ppixdme)(NO) in dimethyl sulfoxide, EPR and electronic spectra were changed into five-coordinate type spectra. On the other hand, the addition of SDS to Fe(ppixdme)(NO)(NMeIm) in dimethyl sulfoxide resulted in EPR and electronic spectra arising from a mixture of five- and six-coordinate complexes. Accordingly, sodium dodecyl sulfate was found to hinder the interaction of dimethyl sulfoxide with the sixth axial vacant position of Fe(ppixdme)(NO), and to cleave only partly the iron to imidazole bond in Fe(ppixdme)(NO)(NMeIm) complex.

Sodium dodecyl sulfate (SDS), an anionic detergent, has been known to solubilize insoluble porphyrins and metalloporphyrins in aqueous solution in monomer form.[1,2] Effect of SDS on spectral properties of iron(II) and iron(III) porphyrin complexes with various axial ligands has been investigated.[2] Furthermore, it has been demonstrated that the hydrophobic part of SDS penetrates into the hydrophobic core of the protein to cause a considerable structural change of hemoglobin, myoglobin,[3] and cytochrome c′,[4] and that both the EPR and electronic spectra of NO-hemoglobin[5] and NO-cytochrome c′ modified by SDS[6] resemble those of five-coordinate model nitrosylheme in nonpolar organic solvents in spectral line shape.[7,8]

The clarification of the interaction of SDS and hydrophobic environments around heme in NO-hemoproteins seems to bear a significant implication in understanding the structure of the heme environments of the hemoproteins. In this paper, it is reported that EPR and electronic spectra of five- and six-coordinate nitrosyl(protoporphyrin IX dimethyl esterato)iron(II) (Fe(ppixdme)(NO)) complexes as model systems for NO-hemoproteins are changed upon addition of SDS.

Experimental

Materials and Methods. Fe(ppixdme)Cl and Fe(ppixdme)(NO) were prepared as described before.[7,9] Nitrogen monoxide (99.5% minimum) purchased from Seitetsu Kagaku Co. Ltd. was passed through a KOH column to remove higher nitrogen oxides. ^{15}NO gas was generated by the reaction of $Na^{15}NO_2$ (99.2% enrichment, Prochem) with an aqueous solution of ascorbic acid. 1-Methylimidazole (NMeIm) and dimethyl sulfoxide were distilled by flowing N_2 under reduced pressure and were deoxygenated by bubbling with pure N_2 prior to use. Sodium dodecyl sulfate (Wako chemicals) was purchased and used without further purification. All other chemicals used were obtained as the best available grade and were used without further purification.

EPR and electronic spectral measurements were carried out as described previously.[10]

Sample Preparation. EPR and electronic spectral samples were prepared by following two method. (a) Under N_2 atmosphere, Fe(ppixdme)(NO) was dissolved into dimethyl sulfoxide or NMeIm-dimethyl sulfoxide solution, in the absence or the presence of SDS. (b) The reaction of NO with Fe(ppixdme)Cl in dimethyl sulfoxide or NMeIm-dimethyl sulfoxide solution, in the absence or the presence of SDS was carried out in a Thunberg-type tube with an optical cuvette or with an EPR tube. The solutions were carefully degassed in the Thunberg tube by repeated freezing and thawing in vacuo and then were equilibrated with NO gas at about 1 atm.

Then, the solutions obtained by method (a) or (b) were transferred into an optical cuvette or an EPR tube (or flat cell). Both methods resulted in identical spectral results.

The concentrations of Fe(ppixdme)(NO), NMeIm, and SDS in EPR samples were 0.1—0.6 mM†, 80 mM, and more than 80 mM, respectively; those in electronic spectral samples were 0.016 mM, 0.51—2.03, and 0.10—1.16 M, respectively.

Results and Discussion

It was shown that the N-donor ligands can be coordinated,[8,10-12] both at room temperature and at low temperature, to iron in the axial position trans to a nitrosyl group in Fe(ppixdme)(NO), while the weak ligands such as O- and S-donor ones can be, in general, coordinated only at low temperature.[13] However, the axial coordination of dimethyl sulfoxide, an O-donor ligand, to Fe(ppixdme)(NO) not only at low temperature but also at room temperature has been confirmed by the following findings: EPR g values (g_{iso}), the NO stretching frequencies, and the Soret band maxima of Fe(ppixdme)(NO) in various non-donor solvents at room temperature almost linearly decrease with an increase of a solvent polarity parameter (E_T), and on the other hand, those in dimethyl sulfoxide distinctly deviate from such linear relationships.[8,12]

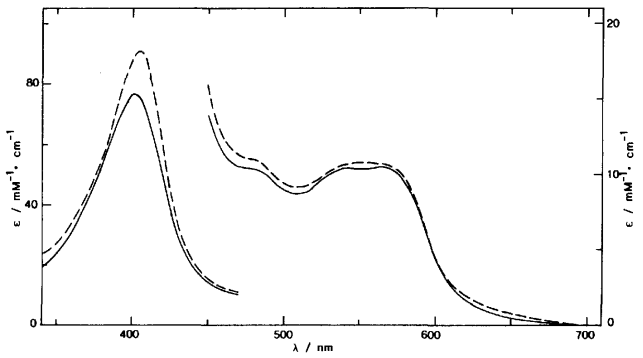

Fig. 1. Electronic spectra of Fe(ppixdme)(NO) (0.016 mM) in dimethyl sulfoxide in the presence (0.1 M) (——) and the absence (----) of sodium dodecyl sulfate at room temperature.

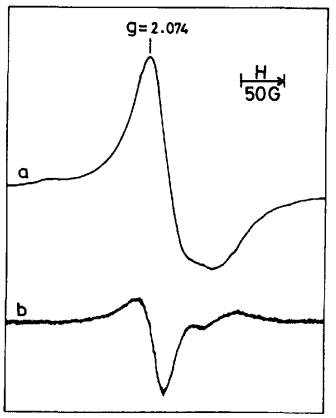

Fig. 2. EPR spectra of Fe(ppixdme)(NO) (0.4 mM) in dimethyl sulfoxide at 77 K; (a) first derivative, (b) second derivative. Instrument settings are given in caption of Fig. 3.

trum of Fe(ppixdme)(NO) in dimethyl sulfoxide (Table 1 and Fig. 1), the Soret band was revealed at 405 nm, which is located at longer wavelength than that (about 396 nm) predicted by λ_{max}(Soret)-E_T relationship,[8] and α- and β-bands were not resolved, suggesting the coordination of a dimethyl sulfoxide to the sixth axial position. On the other hand, the addition of SDS to the dimethyl sulfoxide solution resulted in a spectral change. With an increase in SDS concentration, the Soret band was shifted to shorter wavelength side and the α- and β-bands were resolved. The apparent spectral pattern thus obtained (Fig. 1) resembles those of Fe(ppixdme)(NO) in non-donor solvents such as toluene and benzene[8] and of NO-cytochrome c′ (*Alcaligenes* sp. NCIB 11015) with SDS.[6]

At room temperature, the EPR spectra of Fe(ppixdme)(NO) in organic solvents exhibit a well-resolved triplet.[7] The g_{iso} values at central signal of a triplet in non-donor solvents were in the range of 2.053 to 2.050,[12] while that in dimethyl sulfoxide was 2.048 (Table 2). At 77 K, Fe(ppixdme)(NO) in non-donor

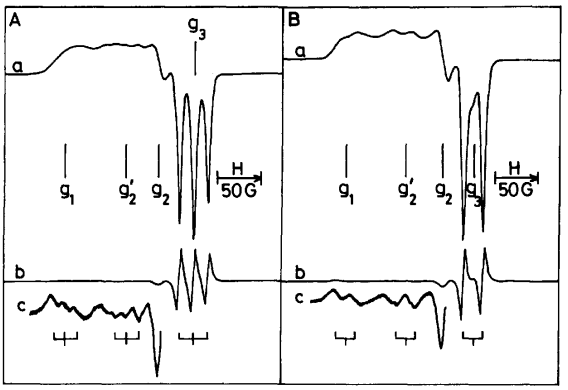

Fig. 3. EPR spectra of (A) Fe(ppixmde)(^{14}NO) and (B) Fe(ppixdme)(^{15}NO) (0.6 mM) in dimethyl sulfoxide in the presence of sodium dodecyl sulfate (0.8 M) at 77 K; (a) first derivative, (b) second derivative, and (c) expansion of the ordinate of (b). Instrument settings: modulation frequency and amplitude, 100 kHz and 2 G; microwave frequency and power, 9.166—9.171 GHz and 10 mW.

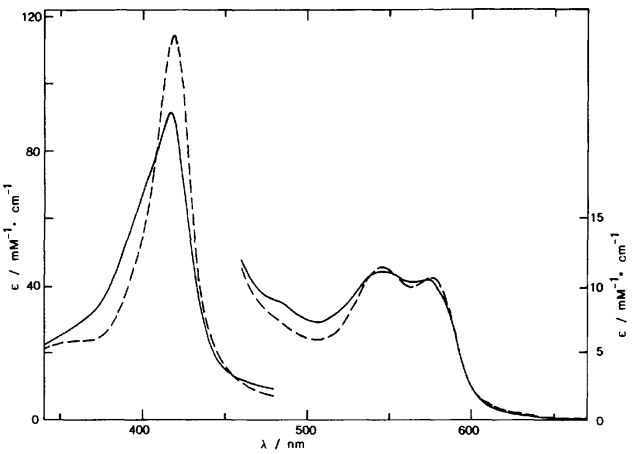

Fig. 4. Electronic spectra of Fe(ppixdme)(NO)(0.016 mM)-NMeIm(0.51 M) in dimethyl sulfoxide in the presence (1.16 M) (——) and the absence (----) of sodium dodecyl sulfate at room temperature.

solvents exhibits characteristic EPR spectra with an intense triplet in g_3 (or g_z) absorption,[7,14] while the spectral line shape in dimethyl sulfoxide was markedly different from such usual ones as shown in Fig. 2. Thus, the EPR spectral results of Fe(ppixdme)-(NO) in dimethyl sulfoxide both at room temperature and at 77 K also suggest the pronounced interaction of a dimethyl sulfoxide with the vacant axial position of Fe(ppixdme)(NO).

The EPR spectrum of Fe(ppixdme)(NO) in dimethyl sulfoxide was markedly changed upon addition of SDS. Both the line shape and the parameters of the spectra thus obtained were quite similar to those of five-coordinate model nitrosylheme,[9,14] of NO-hemoglobin modified by SDS,[5] and of NO-cytochrome c′ (*Alcaligenes* sp. NCIB 11015) with SDS[6] (Table 2 and Fig. 3). Although nitrosylporphyrinatoiron(II) in nonpolar solvents occasionally exhibits complicated EPR spectra arising from a mixture of monomer and dimer below frozen temperature,[12,15,16] the satellite absorptions which are attributable to a dimer were not observed at all in the EPR spectrum of Fe(ppixdme)-(NO) with SDS in dimethyl sulfoxide (Fig. 3).

These results indicate that sodium dodecyl sulfate hinders the interaction of dimethyl sulfoxide, O-donor ligand, with the axial vacant position in Fe(ppixdme)-(NO) and the dimerization of Fe(ppixdme)(NO) molecule.

Both the Soret band maximum and g_{iso} value of Fe(ppixdme)(NO) with SDS in dimethyl sulfoxide were quite similar to those in toluene, a nonpolar solvent (Tables 1 and 2). This suggests that Fe(ppixdme)-(NO) molecule is surrounded by hydrophobic part of SDS and consequently the polarity of molecular environment is decreased locally.

Thus, the nitrosylheme in both NO-hemoproteins modified by SDS and model system with SDS is surrounded by the hydrophobic part of SDS or the environment with a very small polarity.

It has been recently demonstrated from the EPR study on the single crystal of Fe(tpp)(NO) doped in Zn(tpp) (tpp, *m*-tetraphenylporphyrinato) that g_2 (or g_y) value is 2.028.[17] Thus, the 'g_2 absorption' of Fig. 3 and Table 2 can be identified as a lowest field line of triplet or doublet in such a g_2 absorption, which is derived from an ^{14}N nucleus of ^{14}NO or an ^{15}N nucleus of ^{15}NO, respectively. Accordingly, the g_2' absorption of Fig. 3 and Table 2 remains unidentified.

Addition of Sodium Dodecyl Sulfate to Fe(ppixdme)-(NO)(NMeIm) in Dimethyl Sulfoxide. The Soret band in the electronic spectrum of six-coordinate Fe(ppixdme)(NO)(NMeIm) in dimethyl sulfoxide (Fig. 4) was narrower and more intense and was located at longer wavelength side than that of five-coordinate Fe(ppixdme)(NO) in non-donor solvents.[8] Upon addition of SDS to the solution, the Soret band was weakened, the shoulder absorptions was revealed at around 400 and 485 nm, and α- and β-bands were broadened (Fig. 4), which are compatible with the appearance of five-coordinate complex and concomitant decrease in concentration of six-coordinate complex. From the Soret band intensity in the solution with SDS (Fig. 4), the contents of the six- and five-coordinate complexes are estimated to be 60 and 40%, respectively. On freezing the solution with SDS at 77 K, the positions of the band maxima were slightly varied to 400sh, 419.5, 485sh, 542, and 575 nm and the absorptions derived from five-coordinate complex were decreased in intensity. However, the spectrum could not be completely changed to that of five-coordinate complex even in much higher concentration of SDS.

The EPR spectrum of Fe(ppixdme)(NO)(NMeIm) in dimethyl sulfoxide at 77 K exhibited the line shape characteristic of six-coordinate nitrosylheme with

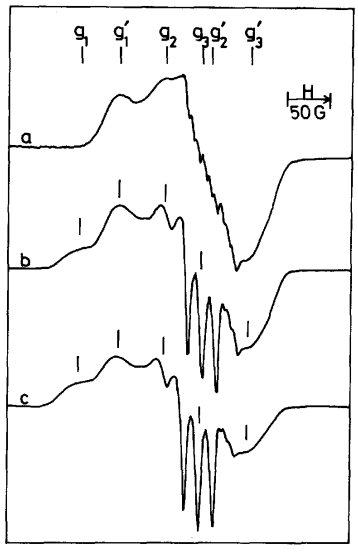

Fig. 5. EPR spectra of Fe(ppixdme)(NO)(0.4 mM)-NMeIm(80 mM) in dimethyl sulfoxide (a) in the absence and (b,c) in the presence of sodium dodecyl sulfate (b, 0.32 M; c, 4 M-almost saturated) at 77 K (g_1=2.10, g_2=2.035, g_3=2.010; g_1'=2.070, g_2'=2.004, g_3'=1.97). Instrument settings are given in caption of Fig. 3.

three g values (g_1', g_2', and g_3' in Fig. 5). Upon addition of SDS, the absorptions (g_1, g_2, and g_3) being attributable to five-coordinate complex were appeared and intensified (Figs. 5-b,c). Even trace amounts of five-coordinate complex were found to be detectable in the EPR spectrum of the sample containing nitrosylheme because the triplet in g_3 absorption of the five-coordinate complex is extremely intense.

Accordingly, the clevage of iron to 1-methylimidazole bond probably results from the interaction of the hydrophobic part of SDS with 6th coordination position or, possibly, from the intercalation of the five-coordinate complex into the micelles of SDS in dimethyl sulfoxide. However, since unhindered N-donor ligands such as imidazoles and pyridines are strongly coordinated to iron in the axial position trans to a nitrosyl group in nitrosylporphyrinatoiron(II),[12] all the iron to nitrogen bond can not be cleaved even in almost saturated solution of SDS.

Mixed Ligand Complexes of Trivalent Metal Ions with an Amine-*N*-polycarboxylate and Fluoride

Akio YUCHI,* Hitoshi HOTTA, Hiroko WADA, and Genkichi NAKAGAWA
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received October 28, 1986)

The formation constants of the mixed ligand complexes MLF(M: Al^{3+}, Ga^{3+}, In^{3+}, Fe^{3+}, Sc^{3+}, Y^{3+}, La^{3+}; L: nta^{3-}, $hedta^{3-}$, $edta^{4-}$, $cdta^{4-}$) were determined. Reactivity of a trivalent metal ion with fluoride generally decreases by the coordination of an amine-*N*-polycarboxylate. From the decrease the structures of the parent and mixed ligand complexes are discussed.

Fluoride ion is a unique ligand in that it shows almost pure electrostatic interactions with metal ions in solution. Since the fluoride ion-selective electrode was developed in 1966,[1] the formation constants of nearly every metal fluoro complexes have been determined.[2]

Recently we have found the general presence of the mixed ligand complexes containing fluoride in the equilibrium study on the reaction of aluminum fluoro complexes with masking reagents.[3] Such complexes have never been reported so far as we know. In this paper, the formation constants of a series of the mixed ligand complexes MLF (M: Al^{3+}, Ga^{3+}, In^{3+}, Fe^{3+}, Sc^{3+}, Y^{3+}, La^{3+}; L: nta^{3-}, $hedta^{3-}$, $edta^{4-}$, $cdta^{4-}$; charges of complexes are omitted)[4] are determined.

Experimental

Reagents and Equipments. Aluminum, gallium, lanthanum and iron solutions were prepared by dissolving their nitrates in dilute nitric acid. Indium, scandium, and yttrium solutions were obtained by reacting metallic indium, scandium oxide and yttrium oxide with nitric acid, respectively. All these solutions were standardized against EDTA. Potassium fluoride was dried for 24 h at 110 °C. Fluoride solutions were stored in polyethylene containers. Potassium nitrate was recrystallized twice. Carbonate-free potassium hydroxide solution was prepared as described in the literature.[5] All other chemicals used were of reagent grade.

Throughout this work the ionic strength was adjusted to 0.1 mol dm^{-3} with potassium nitrate. A measuring cell made of polypropylene was placed in a water bath thermostated at 25±0.1 °C. A fluoride ion-selective electrode (Denki Kagaku Keiki Co.; DKK type 7200), a HF-resistant glass electrode (Ohkura electric Co.; GP 1200) and two reference electrodes with a junction made of porous Teflon (DKK type 4400) were soaked in the sample solution, and potentials were measured to 0.1 mV with two potentiometers (DKK IOC-10). The fluoride ion-selective electrode was calibrated with several potassium fluoride solutions between 10^{-2}—10^{-6} mol dm^{-3} made by serial dilution, whereas the glass electrode was calibrated with several nitric acid solutions. Both electrodes gave Nernstian responses. Before and after a series of measurements standard potentials of these electrodes were determined with a 1.00×10^{-2} mol dm^{-3} potassium fluoride solution and a 1.00×10^{-2} mol dm^{-3} nitric acid solution, respectively. The presence of complexing reagents did not affect the standard potential of the fluoride ion-selective electrode.

Procedure. Stability constants of simple metal fluoro complexes and protonation constants of metal amine-*N*-polycarboxylate complexes were determined by the conventional methods.[2] When ternary systems were studied, 10% excess of a ligand against a metal ion was added to suppress the dissociation of an amine-*N*-polycarboxylate complex but not to form a bis complex, ML_2. With a dilute nitric acid or a potassium hydroxide solution, $-\log[H^+]$ was adjusted. This solution being titrated with potassium fluoride solution, $-\log[H^+]$ and $-\log[F^-]$ were measured after each addition. Constant potentials were obtained within 10 min. In the systems containing aluminum, potentials were read after 24 h using a batch method.

Results

Trivalent Metal Fluoro Complexes. The equilibria of reactions between proton and fluoride were first studied at 25 °C and at 0.1 mol dm^{-3} KNO_3. The results were analyzed as described previously,[6] and the following constants were obtained.

$$H^+ + F^- \rightleftharpoons HF: \quad \log K_{HF} = 2.99 \pm 0.03$$

$$HF + F^- \rightleftharpoons HF_2^-: \quad \log K_{HF_2} = 0.38 \pm 0.08$$

The complexation equilibria of trivalent metal ions with fluoride were studied for the comparison described below. The formation functions of metal fluoro complexes

$$\bar{n} = (C_F - [F^-] - [HF] - 2[HF_2^-])/C_M, \qquad (1)$$

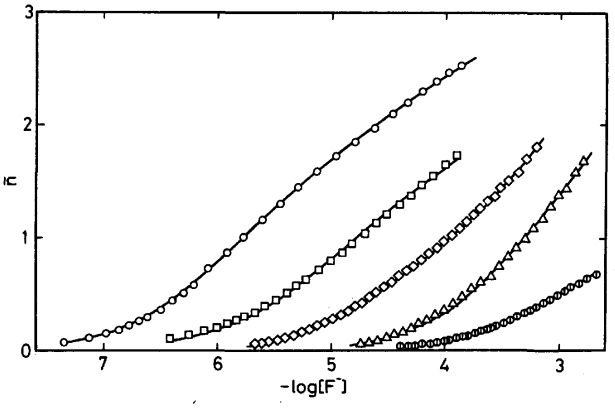

Fig. 1. Plots of $\bar{n}$ vs. $-\log[F^-]$ for trivalent metal fluoro complexes (25 °C, 0.1 mol dm^{-3} KNO_3). Trivalent metal: ○, scandium; □, iron; ◇, gallium; △, indium; ○, proton. Data for aluminum and yttrium complexes are omitted for clarity. The solid curves were calculated with the constants in Table 1.

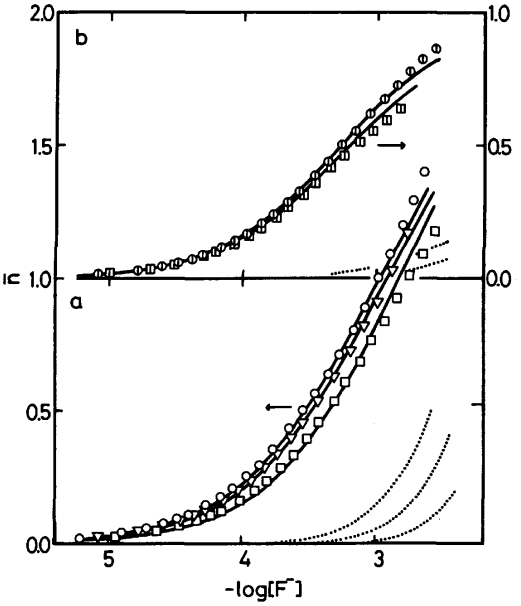

Fig. 2. Plots of $\bar{n}$ vs. $-\log[F^-]$ for Fe-NTA-F and Fe-HEDTA-F systems (25 °C, 0.1 mol dm^{-3} KNO_3). System: a, Fe-NTA-F; b, Fe-HEDTA-F. $-\log[H^+]$: ○, 2.9; ▽, 3.3; □, 3.85;○, 2.9; □, 3.2. The solid curves were calculated with the constants in Table 2. The dotted curves were expected by assuming no mixed ligand complex formation.

are plotted against $-\log[F^-]$ in Fig. 1. The change in the total concentration of a metal ion (from 5×10^{-4} to 2×10^{-3} mol dm^{-3}) or hydrogen ion did not displace the formation functions. Thus neither polymerized fluoro complexes nor hydrolyzed species were formed. The stepwise formation constants of metal fluoro complexes

$$MF_{m-1} + F^- \rightleftharpoons MF_m : K_m,$$

were refined to give a minimum error square sum about $\bar{n}$ (Table 1). Constants smaller than $10^{3.0}$ are less reliable because of low precision of the numerator in Eq. 1. Formation of lanthanum fluoro complexes could not be studied by the same method due to the precipitation of lanthanum trifluoride.

Mixed Ligand Complexes in Fe-NTA-F and Fe-HEDTA-F Systems. Figure 2 shows the formation functions at various $-\log[H^+]$ in Fe-NTA-F and Fe-HEDTA-F systems.

Table 2. Average Deviation of $\bar{n}$ for Various Combinations of Species in Fe-NTA-F and Fe-HEDTA-F Systems[a]

System	No.	Species considered			$\Delta\bar{n}$
		MLF	MLF_2	ML(OH)F	
Fe-NTA-F	1	×	×	×	0.627
	2	○	×	×	0.181
	3	○	○	×	0.042
	4	○	○	○	0.040
Fe-HEDTA-F	1	×	×	×	0.442
	2	○	×	×	0.041
	3	○	○	×	0.040
	4	○	○	○	0.040

a) Numbers of data used for the calculation were 73 for Fe-NTA-F and 67 for Fe-HEDTA-F, respectively.

The parent complex ML hydrolyzes at higher $-\log[H^+]$.

$$ML(OH) + H^+ \rightleftharpoons ML : K^H_{ML}$$

These constants were potentiometrically determined to be $10^{3.96}$ for Fe-NTA and $10^{3.86}$ for Fe-HEDTA. On the other hand, the complex is protonated at lower $-\log[H^+]$.

$$ML + H^+ \rightleftharpoons MHL : K^H_{MHL}$$

Among these species, ML and MHL react with fluoride to form mixed ligand complexes.[3] It was difficult, however, to study the reactivity of MHL, because MHL forms only in strongly acidic solution where on the addition of fluoride the substitution reaction prevails over the formation of the mixed ligand complex. Thus we adopted the data in the $-\log[H^+]$ range where only ML and ML(OH) existed.

Formation of the mixed ligand complex MLF_n is expressed by

$$MLF_{n-1} + F^- \rightleftharpoons MLF_n : K^F_{MLF_n}.$$

For each experimental point, two simultaneous equations in [M] and [L] were solved,

$$C_M = [M] + [ML] + [ML(OH)] + \Sigma[MF_m] + \Sigma[MLF_n], \quad (2)$$

$$C_L = [L]\alpha_{L(H)} + [ML] + [ML(OH)] + \Sigma[MLF_n], \quad (3)$$

a) Numbers in parentheses are estimated errors. b) At ionic strength 0.5 mol dm^{-3} $NaClO_4$. A. Aziz and S. J. Lyle, *J. Inorg. Nucl. Chem.*, **32**, 1925 (1970).

where $\alpha_{L(H)}$ is the side reaction coefficient taking account of the protonation of L. Using [M], [L], $[H^+]$, and $[F^-]$, $\bar{n}$ was calculated.

$$\bar{n}_{cald} = \frac{\sum m[MF_m] + \sum n[MLF_n]}{C_M} \quad (4)$$

Various combinations of the mixed ligand complexes were assumed and $K^F_{MLF_n}$ values in each set were refined to give a minimum error square sum, $\Delta\bar{n}=(\sum(\bar{n}_{obsd}-\bar{n}_{cald})^2/N)^{1/2}$ (Table 2).

When no mixed ligand complex was assumed there were large systematic deviations (dotted curves in Fig. 2 or No.1 in Table 2). By considering the formation of MLF satisfactory agreement between experimental and calculated values was obtained in Fe-HEDTA-F system but not in Fe-NTA-F system (No. 2), where presence of MLF_2 must also be taken into account (No. 3). Further improvement was not obtained by assuming the formation of ML(OH)F (No. 4).

Other Systems. As the K^H_{ML} values of the other complexes are larger than those of Fe(nta) and Fe(hedta),[7] $-\log[H^+]$ can be adjusted so that only ML exists in the solution containing a metal ion and an excess ligand: the concentration of ML(OH) as well as those of MHL and free M is low. When small amounts of fluoride are added to such solutions, formation of MF_m and MLF_n ($n>1$) is negligible. Then Eq. 2 is simplified as

$$C_M = [ML] + [MLF], \quad (2')$$

and [MLF] is obtained by

$$[MLF] = C_F - ([F^-] + [HF] + 2[HF_2^-]). \quad (5)$$

The K^F_{MLF} values can be calculated only with these equations.

Table 3 gives some of the data in Ga-NTA-F system. At lower total concentrations of fluoride (until No. 11) K^F_{MLF} values are constant. On the other hand, $\bar{n}$ and thus K^F_{MLF} abruptly increases at higher C_F because of the dissociation of the ligand from the complex

accompanied by the formation of GaF_m. The K^F_{MLF} values thus obtained are given in Table 4.

Discussion

Metal Fluoro Complexes. Correlation between $\log K_1$ and $Z_+/(r_+ + r_-)$, where Z_+ is the charge of a metal ion and r_+ and r_- are the radii of the metal and fluoride ions, respectively, has been suggested from a simple electrostatic consideration,[8] but it is not satisfactory. For example, Al^{3+} and Sc^{3+} have almost the same formation constants in spite of very different ionic radii. The role of the solvent is completely neglected in this consideration.

As shown in Table 1, the ratio K_2/K_3 is larger than K_1/K_2, and this indicates the irregular change in the solvation during the stepwise complexation,[9] which cannot be quantitatively evaluated at this stage.

M-NTA-F and M-HEDTA-F. Reactivity of a trivalent metal ion with fluoride generally decreases by the coordination of an amine-*N*-polycarboxylate. As NTA and HEDTA complexes hold more than one coordinated water molecules, formation of their mixed ligand complexes corresponds to substitution of water molecules with fluoride ions as in the formation of simple fluoro complexes. The decrease in the reactivity is thus ascribed to the decrease in the statistical factor, the neutralization of the positive charge on the metal ion by the ligand and the decrease in the degree of solvation.

The first effect is not expected to contribute so much but certainly operates so that small decreases in K^F_{MLF} are observed from NTA complexes with tetradentate chelation to HEDTA complexes with pentadentate chelation. The second effect is more decisive but would be relieved for larger ions because positive charges on these ions can only locally be neutralized. This is the case for scandium group and the difference between K^F_{MF} and K^F_{MLF} decreases in the order of $Sc^{3+} > Y^{3+} > La^{3+}$. But the reverse order is found for aluminum group, where again the third effect must prevail.

M-EDTA-F and M-CDTA-F. The K^F_{MLF} values of Ga(edta), Fe(edta), and Sc(edta) are much smaller than those of their HEDTA and NTA complexes, respectively. This suggests that one carboxylato group must become free on the formation of the mixed ligand complex and also that the parent complexes involve the complete hexadentate chelation of EDTA irrespective of the coordination number of metal ions.[10] On the other hand, for aluminum, similar large decrease in K^F_{MLF} is rather found between EDTA and CDTA complexes. This means the weak coordination of one carboxylato group in Al(edta) complex, which agrees with the fact that $K^H_{MH(edta)}$ of aluminum complex ($10^{2.8-3.4}$) is definitely higher than those of other trivalent metal complexes (less than 10^2 except for large metal ion complexes).[7]

If a CDTA complex of a metal also forms the mixed ligand complex with the pentadentate chelation, $K^F_{M(edta)F}$ is expected to be smaller than $K^F_{MH(edta)F}$, because CDTA has a more rigid skeleton and must have more difficulty in detaching one carboxylato group. This is the case for aluminum, gallium, and iron, but the reverse order is found for indium, scandium, yttrium and lanthanum. As these ions have larger ionic radii, fluoride can coordinate to a metal ion with keeping the hexadentate chelation of the ligand as in the reaction of Co(II)(cdta) with cyanide.[16]

10) Fe(edta) is seven coordinate both in the solid[11] and in the solution[12] with a coordinated water. But it is ascribed to the unbalanced affinities to amino nitrogen and carboxylate oxygen rather than the size of ionic radius.[13] Once the ligand becomes pentadentate, the metal becomes six coordinate with relaxation of ring constrain as seen in [Fe(hedta)]$_2$O and Fe(Hedta)H_2O.[14,15] This agrees with our observation that the highest species were Fe(nta)F_2 and Fe(hedta)F.

Synthesis of a 24-Epimeric Mixture of 4α,14α,24-Trimethyl-9(11)-cholesten-3-one

Masahiko YAMASHITA, Misuzu NAORA (nee NAMIKAWA), Tatsushi MURAE, Takahiko TSUYUKI,* and Takeyoshi TAKAHASHI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

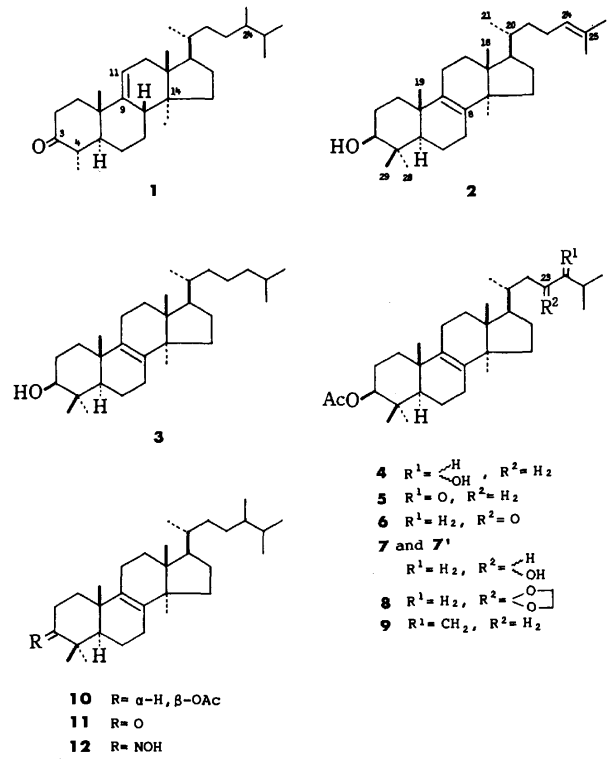
(Received July 25, 1986)

A 24-epimeric mixture of 4α,14α,24-trimethyl-9(11)-cholesten-3-one was synthesized from lanosterol through 4α,14α,24-trimethyl-8-cholesten-3β-ol and 4α,14α,24-trimethyl-7,11-dioxocholestan-3β-yl acetate as key intermediates.

A triterpene mixture (ca. 4 mg) was obtained from the plant fossil (ca. 50 g) collected at the Ningyo-toge area on the border between Tottori and Okayama Prefectures.[1] Preparative gas chromatographic separation of the mixture afforded three components, **a** ($C_{29}H_{48}O$), **b** ($C_{29}H_{50}O$), and **c** ($C_{30}H_{50}O$), which weighed about hundreds μg, respectively. Spectral examination suggested that the component **c** is a mixture of two unsaturated tetracyclic triterpene ketone and one of them might be 4α,14α,24ξ-trimethyl-9(11)-cholesten-3-one. However, a paucity of the material prevented us from the further confirmation of the proposed structure. This paper describes a preparation of a 24-epimeric mixture of 4α,14α,24-trimethyl-9(11)-cholesten-3-one (**1**)[2] from lanosterol (**2**) as an authentic sample, whose ^{1}H NMR and mass spectra are compared with those of the natural specimen.

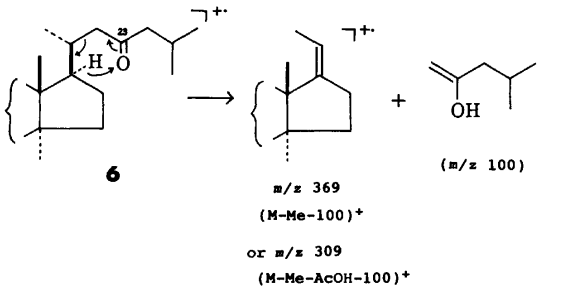
A commercial lanosterol containing ca. 45% dihydrolanosterol (=8-lanosten-3β-ol) (**3**) was acetylated and subjected to hydroboration using diborane in tetrahydrofuran (THF) to afford a mixture of 24-hydroxy-8-lanosten-3β-yl acetate (**4**) and dihydrolanosteryl acetate, the former of which, after separation, was oxidized with Jones reagent to yield 24-oxo-8-lanosten-3β-yl acetate (**5**).

When the hydroboration was effected in situ with diborane generated by sodium borohydride and boron trifluoride etherate in THF, and oxidation with sodium dichromate was followed without isolation of 24-hydroxy-8-lanosten-3β-yl acetate (**4**), the hydroboration-oxidation reaction[3] was found to give a mixture of two ketones, one of which was shown to be identical with **5** by GLC examination and ^{1}H NMR spectrum. The mixture was treated with sodium borohydride to afford a mixture of three hydroxy acetates, one of which was identical with 24-hydroxy-8-lanosten-3β-yl acetate (**4**). The other two showed similar IR, ^{1}H NMR, and MS spectra to those of **4**, and were inferred to be epimeric secondary alcohols (**7** and **7'**), because they gave almost the same ^{1}H NMR spectra each other and the same peak area at δ 3.8 due to *H*-C-OH as that at δ 4.5 due to *H*-C-OAc, respectively. Therefore, the epimeric alcohols (**7** and **7'**) were oxidized with Jones reagent, respectively, to give the same acetoxy ketone (**6**), which showed fragment peaks at *m/z* 369 ([M−Me−100]$^+$) and *m/z* 309 ([M−Me−AcOH−100]$^+$). Since the appearance of these peaks indicates a loss of $C_6H_{12}O$ (*m/z* 100) derived from McLafferty rearrangement,[4] the location of the carbonyl group was deduced to be at C-23 (Scheme 1). This conclusion was confirmed by characteristic fragment peaks at *m/z* 471 and *m/z* 129 observed in the mass specrtum of ethylene acetal (**8**) of the ketone (**6**) (Scheme 2). From these findings, the ketone (**6**) could be formulated as 23-oxo-8-lanosten-3β-yl acetate. Since the absence of 23-ene in the starting material was certified by the ^{1}H NMR examination, the formation of **6** is inexplicable. Further investigation on the formation mechanism is under way.

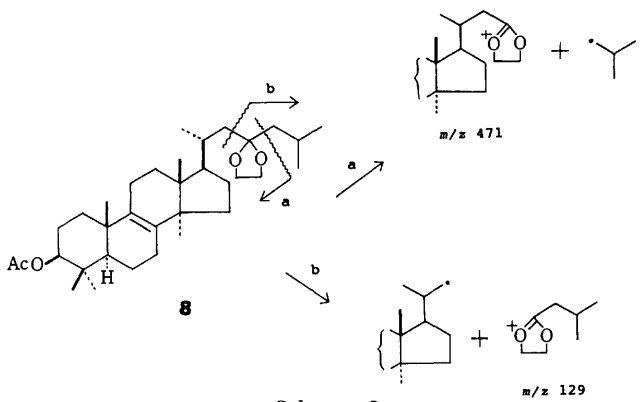


24-Oxo-8-lanosten-3β-yl acetate (**5**) was converted into 24-methylene derivative (**9**) by Wittig reaction, which was subjected to hydrogenation to yield a 24-epimeric mixture of 24-methyl-8-lanosten-3β-yl acetate (**10**)†. 4β-Demethylation of **10** was carried out by

†All 24-methyl derivatives obtained by the preparation described below in this paper are 24-epimeric mixtures, respectively.



Scheme 1.

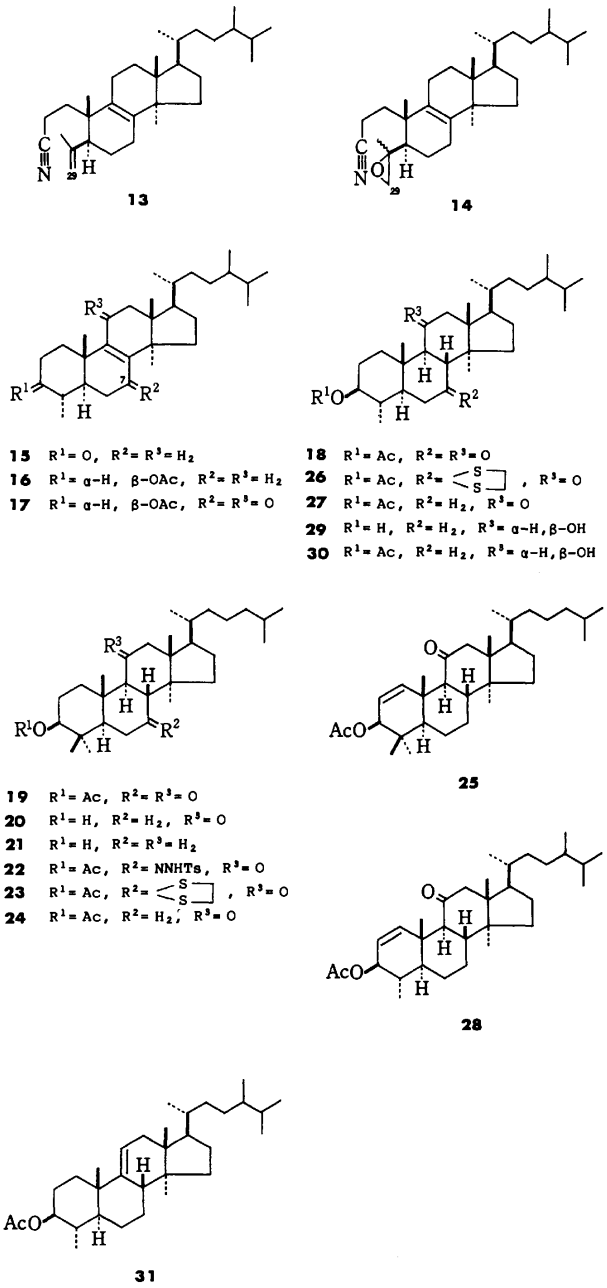


Scheme 2.

the same procedure as described in the previous paper;[1] hydrolysis of 24-methyl-8-lanosten-3β-yl acetate (**10**) followed by Jones oxidation gave a ketone (**11**), which was converted into the corresponding oxime (**12**), a seconitrile (**13**), and then a nitrile epoxide (**14**). On a treatment with boron trifluoride etherate, **14** afforded the demethylation product, 4α,14α,24-trimethyl-8-cholesten-3-one (=24-methyl-29-nor-8-lanosten-3-one) (**15**) in about 6.1% yield from **10**.

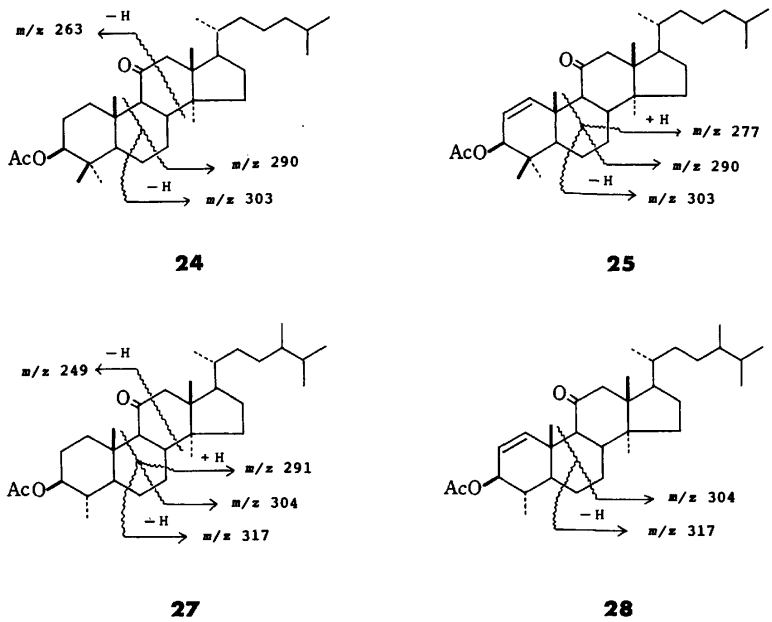
4α,14α,24-Trimethyl-8-cholesten-3β-yl acetate (**16**), $C_{32}H_{54}O_2$ [*m/z* 470.4159 determined by high resolution mass spectrometry (HR-MS)] derived from **15** was subjected to an allylic oxidation with chromium trioxide[5] in acetic acid-hexane to afford 4α,14α,24-trimethyl-7,11-dioxo-8-cholesten-3β-yl acetate (**17**), $C_{32}H_{50}O_4$ (*m/z* 498.3709) in 55% yield. An absorption band due to the unsaturated carbonyl group was observed at 1680 cm^{-1} in the IR spectrum. On heating with zinc dust in acetic acid,[5] **17** afforded a saturated dione acetate (**18**), $C_{32}H_{52}O_4$ (*m/z* 500.3896), in 66% yield.

Selective decarbonylation at C-7 was examined using 7,11-dioxolanostan-3β-yl acetate (**19**)[6] as a model compound. Wolff-Kishner reduction of **19** under standard conditions afforded a 7-deoxo derivative (**20**) in 41% yield accompanied with a 7,11-dideoxo derivative, lanostan-3β-ol (**21**), in 18% yield. The formation of **21** was reduced by removing the excess hydrazine at reduced pressure after hydrazone formation.[7] However, this modification could not improve the yield of **20**. Next, the reduction of a tosylhydrazone (**22**) of **19** with sodium (cyano-*C*)trihydroborate[8] was investigated, but the tosylhydrazone (**22**) could not be prepared in a good yield in ethanol nor in acetic acid.[9]



Then the 7,11-dione (**19**) was converted into 7,7-ethylenedithio-11-oxolanostan-3β-yl acetate (**23**), which was treated with Raney nickel W2[10] in dioxane to afford the desired 7-deoxo derivative (**24**) in 86% yield from **19**.[11] Thioacetalization and desulfurization in a large scale, however, afforded a mixture of **24** and an olefin (**25**), latter of which was inferred to be 11-oxo-1-lanosten-3β-yl acetate by ^1H NMR spectrum and GC-MS examination (Scheme 3).[12,13] This was supported by hydrogenation of the mixture (**24** and **25**) giving rise to the single product, **24**.

According to the procedures described above, 4α,14α,24-trimethyl-7,11-dioxocholestan-3β-yl acetate (**18**) was converted into a 7,7-ethylenedithio derivative (**26**), which was treated with Raney nickel W2.[10] The reaction product was also found to consist of two com-



Scheme 3.

pounds by GLC examination. The ^{1}H NMR spectrum of the mixture showed two singlet signals due to acetoxyl groups at δ 2.03 and 2.04 and a couple of doublet signals due to vicinal olefinic protons at δ 5.47 and 5.72, respectively. These findings and the mass spectrum revealed that the mixture consisted of the desired 11-oxo derivative (**27**) together with an olefinic by-product (**28**), whose double bond was confirmed to be 1-ene from the fragment ions at *m/z* 304 and *m/z* 317 (Scheme 3).[12,13] The mixture was hydrogenated to afford the single product, which was identical with **27**. The formation mechanism of **25** and **28** was not made clear yet.

The introduction of a double bond between C-9 and C-11 was achieved by usual manner; 4α,14α,24-trimethyl-11-oxocholestan-3β-yl acetate (**27**) was reduced with lithium aluminium hydride (LAH) to afford a 3β,11β-diol (**29**), which, after a partial acetylation, was treated with phosphoryl chloride, 4α,14α,24-trimethyl-9(11)-cholesten-3β-yl acetate (**31**), mp 119—120 °C (lit,[2] mp 123—125 °C; lit,[14] mp 117.5—118.5 °C), being obtained. Hydrolysis of **31** followed by Jones oxidation gave 4α,14α,24-trimethyl-9(11)-cholesten-3-one (**1**). In the ^{1}H NMR spectrum of **1**, an olefinic proton at C-11 was observed at δ 5.35 and two singlet signals due to C-18 and C-19 methyl groups appeared at δ 0.69 and 1.23, respectively. The ^{1}H NMR spectral data of acetate (**31**) and ketone (**1**) are compatible with 9(11)-ene structure.[1,2,15]

The synthetic 24-epimeric mixture of 4α,14α,24-trimethyl-9(11)-cholesten-3-one (**1**) exhibited the same ^{1}H NMR spectrum at 270 MHz and the same fragment pattern in the mass spectrum as those of the natural specimen obtained from the plant fossil. However, the absolute configuration at C-24 of the natural specimen could not be determined unequivocally from only this finding.

Experimental[16]

24-Oxo-8-lanosten-3β-yl Acetate (5). A mixture (1.0 g) of lanosteryl acetate and dihydrolanosteryl acetate in a ratio of 5:4 was prepared from a commercial lanosterol (**2**) (E. Merck) and dissolved in THF (20 ml). To the solution kept at 1—2 °C, diborane in THF (1.1 mmol ml^{-1}; 1.2 ml) was added with stirring. The stirring was continued for 5.5 h at room temperature, and further for 1.5 h after addition of water (0.13 ml). The solution was cooled to 2—4 °C and 3 M (1 M=1 mol dm^{-3}) sodium hydroxide solution (0.33 ml) and 30% hydrogen peroxide (0.2 ml) were added with stirring. After stirring was continued at room temperature and then at 40—60 °C for 3.5 h, the usual work-up and chromatographic separation on silica gel (12 g) eluted with 10—40% ether in hexane gave dihydrolanosteryl acetate (283 mg) and 24-hydroxy-8-lanosten-3β-yl acetate (**4**; 256 mg).

A cold solution of 24-hydroxy-8-lanosten-3β-yl acetate (**4**; 204 mg) in acetone (15 ml) was treated with Jones reagent (0.25 ml) and the solution was stirred for 5 min. 2-Propanol (0.5 ml) was added and the usual work-up gave a residue, which was crystallized from ether-methanol to afford 24-oxo-8-lanosten-3β-yl acetate (**5**; 118 mg), mp 128—129.5 °C.

23-Oxo-8-lanosten-3β-yl Acetate (6). Sodium borohydride (30 mg) was added to a solution of the mixture (1 g) of lanosteryl acetate and dihydrolanosteryl acetate in THF (5 ml) under a nitrogen atmosphere and the solution was kept at 25—30 °C. Boron trifluoride etherate (0.03 ml) in THF (0.12 ml) was added and the solution was stirred for 6 h. After addition of water (0.15 ml), a solution of sodium dichromate in sulfuric acid [prepared by dissolving $Na_2Cr_2O_7 \cdot 2H_2O$ (0.33 g) in concd sulfuric acid (0.25 ml) and water (ca. 1.2 ml)] was added dropwise. The usual work-up afforded a residue, which was chromatographed on silica gel (55 g). Elution with 10—25% ether in hexane afforded a mixture (224 mg) of 24-one (**5**) and 23-one (**6**), the ratio of which was found to be 2:3 by GLC examination.

The mixture (120 mg) of **5** and **6** in ethanol was reduced with sodium borohydride (22 mg) for 32 h and the usual work-up afforded a residue, which was subjected to separation by preparative TLC developed with 40% ether in hexane twice to afford (23*S* or *R*)-23-hydroxy-8-lanosten-3β-yl acetate (**7**; 28 mg), 24-hydroxy derivative (**4**; 35 mg), and (23*R* or *S*)-23-hydroxy derivative (**7'**; 14 mg). The 24-hydroxy derivative, mp 142—143 °C, was completely identical with the authentic sample (**4**) derived by hydroboration of lanosteryl acetate. **7**: Mp 171—172 °C (colorless needles from ether-methanol); IR (Nujol) 3570, 1730, and 1270 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.72 (3H, s; 18-Me), 0.88—1.00 (Me's), 2.03 (3H, s; AcO), 3.78 (1H, m; 23-H), and 4.50 (1H, m; 3α-H); MS *m/z* (%) 486 (M^+; 34), 471 (54), 453 (40), 411 (100), 393 (62), 369 (25), 311 (19), and 309 (23). **7'**: Mp 152—153 °C (colorless needles from ether-methanol); IR (Nujol) 3300, 1740, and 1240 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.70 (3H, s; 18-Me), 0.88—1.00 (Me's), 2.03 (3H, s; AcO), 3.78 (1H, m; 23-H), and 4.49 (1H, m; 3α-H); MS *m/z* (%) 486 (M^+; 19), 471 (33), 453 (32), 411 (100), 393 (60), 369 (18), 311 (25), and 309 (26).

A solution of an epimeric alcohol (**7**; 44 mg) in acetone (3 ml) was treated with Jones reagent (0.05 ml) at 0 °C with stirring for 5 min and 2-propanol (0.3 ml) was added to the reaction mixture. The usual work-up gave a residue, which was separated by silica-gel chromatography (C-200, 2 g). 23-Oxo-8-lanosten-3β-yl acetate (**6**; 31 mg) was eluted with 10—30% ether in hexane, mp 135—136 °C (colorless needles from methanol); IR (Nujol) 1720, 1710, 1265, 1035, and 980 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=0.72 (3H, s; 18-Me), 0.84—1.00 (Me's), 2.03 (3H, s; AcO), and 4.50 (1H, m; 3α-H); MS *m/z* (%) 484 (M^+; 31), 469 (76), 424 (8), 409 (100), 369 (48), and 309 (79). The other epimer (**7'**; 17 mg), on oxidation, afforded the same ketone (**6**; 13 mg).

23,23-Ethylenedioxy-8-lanosten-3β-yl Acetate (8). To a solution of a ketone (**6**; 23 mg) in benzene (8 ml), ethylene glycol (0.75 ml) and a small amount of *p*-toluenesulfonic acid were added, and the solution was heated under reflux using a Dean-Stark separator containing Molecular Sieves 4A 1/16 for 10 h. After addition of 10% sodium hydroxide solution, an organic layer was separated and worked up as usual. A residue was purified by silica-gel chromatography (C-200, 3 g, elution with 10—30% ether in hexane) to afford 23,23-ethylenedioxy-8-lanosten-3β-yl acetate (**8**), MS *m/z* 528 (M^+), 513, 471, and 129 (base peak).

24-Methylene-8-lanosten-3β-yl Acetate (9). To the Wittig reagent prepared from methyltriphenylphosphonium bromide (1.41 g) in THF (30 ml) and butyllithium in hexane (10 w/v %, 2.5 ml), a solution of 24-oxo-8-lanosten-3β-yl acetate (**5**; 1.81 g) in THF (7 ml) was added under nitrogen. After reflux for 17 h, solvents were removed and the residue was dissolved in a mixture of ether-water (1 : 1; 60 ml). The ethereal layer was separated and the aqueous layer was extracted with ether three times (each 20 ml). The organic layer and extracts were combined and worked up as usual to afford a residue. Chromatographic separation on silica gel (elution with 2—40% ether in hexane) yielded 24-methylene-8-lanosten-3β-yl acetate (**9**; 1.02 g) together with the starting material (**5**; 197 mg). **9**: Colorless plates (from ether-methanol) sublimes on heating; IR (Nujol) 1720, 1640, 1250, and 890 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.70 (3H, s), 0.89—1.06 (Me's), 2.04 (3H, s; AcO), ca. 4.4 (1H, m; *H*-C-OAc), 4.67 and 4.72 (each 1H, br s; H_2C=C); MS *m/z* (%) 482 (M^+; 33), 467 (85), 407 (59), and 155 (100).

24-Methyl-8-lanosten-3β-yl Acetate (10). 24-Methylene derivative (**9**; 772 mg) in ether (60 ml) was hydrogenated in the presence of platinum oxide (81 mg) under atmospheric pressure for 48 h to afford 24-methyl-8-lanosten-3β-yl acetate (**10**; 780 mg), mp 127—128.5 °C; IR (Nujol) 1720 and 1245 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.69 (3H, s), 1.00 (3H, s), 2.03 (3H, s; AcO) and 4.51 (1H, m; *H*-C-OAc); MS *m/z* (%) 484 (M^+; 22), 469 (98), and 409 (100).

24-Methyl-8-lanoten-3-one (11). 24-Methyl-8-lanosten-3β-yl acetate (**10**; 91 mg) was hydrolyzed with potassium hydroxide (0.2 g) in boiling ethanol to afford 24-methyl-8-lanosten-3β-ol (83 mg), mp 156—158 °C (colorless needles from ether-methanol); IR (Nujol) 3300 and 3200 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=ca. 3.2 (1H, m; *H*-C-OH); MS *m/z* (%) 442 (M^+; 23), 427 (100), and 409 (48).

24-Methyl-8-lanosten-3β-ol (620 mg) in acetone (70 ml) was oxidized with Jones reagent (2 ml) at 0 °C. The usual work-up and chromatographic separation on silica gel (elution with 5—10% ether in hexane) gave 24-methyl-8-lanosten-3-one (**11**; 350 mg), mp 109—111 °C; IR 1720 cm^{-1}; MS *m/z* (%) 440 (M^+; 18) and 425 (100).

Demethylation of 24-Methyl-8-lanosten-3-one (11). A mixture of ketone (**11**; 1.12 g), potassium acetate (4.9 g), and hydroxylamine hydrochloride (97%, 2.6 g) in methanol (490 ml) was refluxed for 3 h. The reaction product was crystallized from ether-methanol to give the corresponding oxime (**12**; 1.07 g), mp 200—203 °C (colorlsee needles); IR (Nujol) 3270, 950, and 930 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=3.03 and 3.20 (total 1H); MS *m/z* (%) 455 (M^+; 13), 440 (90), 424 (23), and 69 (100); Found: *m/z* 455.4116. Calcd for $C_{31}H_{53}NO$: M, 455.4126.

A mixture of oxime (**12**; 1.05 g) and *p*-toluenesulfonyl chloride (recrystallized from hexane; 1.66 g) in pyridine (17 ml) was refluxed for 3 h under nitrogen. Ether (85 ml) was added and the mixture was washed with 2 M hydrochloric acid three times (each 85 ml). The organic layer was washed with a saturated sodium hydrogencarbonate solution and then brine. Chromatographic separation on silica gel (elution with 1—3% ether in hexane) yielded a crude 24-methyl-3,4-seco-4(29),8-lanostadiene-3-nitrile[17] (**13**; 826 mg) as a pale yellow oil, IR (neat) 2250 and 1640 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=1.77 (Me), 4.67 (1H), and 4.90 (1H); MS *m/z* (%) 437 (M^+; 82), 422 (83), 394 (22), and 383 (100); Found: *m/z* 437.4003. Calcd for $C_{31}H_{51}N$: M, 437.4020.

m-Chloroperbenzoic acid (80%, 609 mg) was added to a solution of the crude seconitrile (**13**; 732 mg) in dichloromethane (150 ml) kept at 0 °C and the mixture was allowed to stand for 72 h at this temperature. The usual work-up gave a residue, which was subjected to column chromatography on silica gel. Elution with 10—30% ether in hexane yielded 4,29-epoxy-24-methyl-3,4-seco-8-lanostene-3-nitrile[17] (**14**; 359 mg) as a colorless oil, IR (neat) 2250 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=2.67 (2H, s; H_2C C); MS *m/z* (%) 453 (M^+; 5), 438 (27), 420 (8), 410 (7), 399 (16), 381 (10), 370 (5), 86 (100); Found: *m/z* 453.3953. Calcd for $C_{31}H_{51}NO$: M, 453.3969.

The epoxy nitrile (**14**; 404 mg) in toluene (47 ml) was heated with boron trifluoride etherate (0.8 ml) for 3 h under nitrogen and the heating was continued for 1 h after addition of 4 M hydrochloric acid (27 ml). The organic layer was separated and worked up as usual. Purification by column

chromatography on silica gel (elution with 5% ether in hexane) followed by crystallization from ether–methanol afforded 4α,14α,24-trimethyl-8-cholesten-3-one (**15**; 113 mg), mp 109—113 °C; IR (Nujol) 1710 cm^{-1}; MS *m/z* (%) 426 (M^+; 17) and 411 (100); Found: *m/z* 426.3783. Calcd for $C_{30}H_{50}O$: M, 426.3860.

4α,14α,24-Trimethyl-8-cholesten-3β-yl Acetate (16). 4α,14α,24-Trimethyl-8-cholesten-3-one (**15**; 113 mg) was treated with LAH (66 mg) in ether to afford a 3β-alcohol, mp 156—158 °C; IR (Nujol) 3350 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=ca. 3.1 (1H, m; *H*-C-OH); MS *m/z* (%) 428 (M^+; 17), 413 (100), and 395 (26). This alcohol (70 mg) was acetylated with acetic anhydride (1.4 ml) and pyridine (2.8 ml) to yield 4α,14α,24-trimethyl-8-cholesten-3β-yl acetate (**16**) quantitatively, mp 119—121 °C (colorless needles from methanol); IR (Nujol) 1740 and 1245 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.70 (3H, s; 18-Me), 0.74—0.98 (Me's), 2.05 (3H, s; AcO), and 4.38 (1H, dt, *J*=5 and 10 Hz; 3α-H); MS *m/z* (%) 470 (M^+; 39), 455 (100), 410 (5), and 395 (51); Found: *m/z* 470.4159. Calcd for $C_{32}H_{54}O_2$: M, 470.4124.

4α,14α,24-Trimethyl-7,11-dioxo-8-cholesten-3β-yl Acetate (17). 4α,14α,24-Trimethyl-8-cholesten-3β-yl acetate (**16**; 80 mg) was dissolved in a mixture of acetic acid (6.5 ml) and hexane (1.3 ml) and chromium trioxide (70 mg) in acetic acid (90%, 1 ml) was added to the solution and then the reaction mixture was refluxed for 3 h. After addition of water, the reaction product was extracted with ether and the ethereal extract was worked up as usual to afford a residue, which was chromatographed on silica gel (C-200, 5 g). Elution with 10% ether in hexane gave 4α,14α,24-trimethyl-7,11-dioxo-8-cholesten-3β-yl acetate (**17**; 47 mg), mp 153—155 °C; IR (Nujol) 1740, 1680, and 1240 cm^{-1}; UV (EtOH) 270 nm (ε 7800); ^1H NMR (90 MHz, $CDCl_3$) δ=0.75—0.91 (18H; Me×6), 1.19 (3H, s; Me), 1.31 (3H, s; Me), 2.05 (3H, s; AcO), and 4.40 (1H, dt, *J*=5 and 10 Hz; 3α-H); MS *m/z* (%) 498 (M^+; 100) and 438 (20); Found: *m/z* 498.3709. Calcd for $C_{32}H_{50}O_4$: M, 498.3709.

4α,14α,24-Trimethyl-7,11-dioxocholestan-3β-yl Acetate (18). Zinc dust (420 mg) was added to a boiling solution of 4α,14α,24-trimethyl-7,11-dioxo-8-cholesten-3β-yl acetate (**17**; 81 mg) in acetic acid (4 ml) portionwise and the reaction mixture was refluxed for 5—6 h. After filtration, the filtrate and the washings were evaporated to afford a residue. Water was added to the residue and the reaction product was extracted with ether. The ethereal extract was worked up as usual and a residue was subjected to separation by chromatography on silica gel (C-200, 7.6 g). Elution with 5—20% ether in hexane gave 4α,14α,24-trimethyl-7,11-dioxocholestan-3β-yl acetate (**18**; 54 mg), mp 203 °C (colorless needles from methanol); IR (Nujol) 1730, 1700, and 1260 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.72—0.89 (Me's), 1.23 (3H, s; Me), 1.27 (3H, s; Me), 2.05 (3H, s, AcO), and 4.37 (1H, dt, *J*=5 and 10.5 Hz; 3α-H); MS *m/z* (%) 500 (M^+; 100) and 440 (18); Found: *m/z* 500.3896. Calcd for $C_{32}H_{52}O_4$: M, 500.3866.

Wolff-Kishner Reduction of 7,11-Dioxolanostan-3β-yl Acetate (19) under Standard Conditions. A mixture of dioxo acetate (**19**; 77 mg), diethylene glycol (1.5 ml), and hydrazine hydrate (80%, 1 ml) was refluxed for 1.5 h at 135 °C with stirring. After cooling, potassium hydroxide (0.3 g) was added and the mixture was heated. The excess hydrazine was distilled off until the vapor temperature reached to 200 °C, and then the mixture was refluxed for 2 h. The usual work-up and chromatographic separation on silica gel (C-200, 5 g, elution with 10—40% ether in hexane) afforded lanostan-3β-ol (**21**; 12 mg) and 3β-hydroxylanostan-11-one (**20**; 28 mg), mp 164—164.5 °C.

Wolff-Kishner Reduction of 19 under Modified Conditions. A mixture of **19** (50 mg), diethylene glycol (2.5 ml), and hydrazine hydrate (0.5 ml) was refluxed for 1.5 h at 130 °C with stirring, and then the excess hydrazine was removed off at 65 °C under reduced pressure. Potassium hydroxide (0.1 g) was added and the mixture was refluxed for 3 h. The same work-up afforded **20** (26 mg) and **21** (trace).

A Tosylhydrazone (22) of 7,11-Dioxolanostan-3β-yl Acetate (19). A mixture of diketo acetate (**19**; 20 mg) and *p*-tolylsulfonylhydrazine (52 mg) in ethanol (0.7 ml) was refluxed for 2 h. The solvent was removed to give a residue, which was separated by preparative TLC developed with ethyl acetate–hexane. A small amount of mono-*p*-tosylhydrazone (**22**) was obtained together with the starting material (**19**). **22**; IR (Nujol) 1730, 1700, 1330, 1250, 1170, 1150, and 810 cm^{-1}; UV (EtOH) 225 nm (ε 10960); ^1H NMR (90 MHz, $CDCl_3$) δ=0.65 (3H, s; 18-Me), 0.84—0.91 (Me's), 1.11 (3H, s; Me), 2.05 (3H, s; AcO), 2.44 (3H, s; *p*-CH_3-C_6H_4-), 4.40 (1H, m; 3α-H), 7.26, 7.36, 7.79, and 7.89 (each 1H; aromatic proton). The same reaction was examined in acetic acid as a solvent, but the yield of **22** could not be improved.

7,7-Ethylenedithio-11-oxolanostan-3β-yl Acetate (23). 1,2-Ethanedithiol (1.2 ml) was added to 7,11-dioxolanostan-3β-yl acetate (**19**; 44 mg) in chloroform (3 ml), and the solution was stirred with introducing hydrogen chloride at 0 °C for 4 h. The solvent was removed under reduced pressure and a residue was subjected to separation by column chromatography on silica gel (C-200, 5 g). Elution with 10—25% ether in hexane afforded the ethylenedithio derivative (**23**; 46 mg), mp 174.5—175 °C (colorless needles from ether–methanol); IR (Nujol) 1730, 1700, and 1260 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.83—0.90 (Me's), 1.13 and 1.33 (each 3H, s; Me), 2.04 (3H, s; AcO), 3.26 (4H, s; S-CH_2-CH_2-S), and 4.56 (1H, m; 3α-H); MS *m/z* (%) 576 (M^+; 23), 548 (44), 516 (51), 270 (46), 238 (52), 210 (75), and 185 (100).

11-Oxolanostan-3β-yl Acetate (24). A crude 7,7-ethylenedithio derivative (**23**) prepared from **19** (25 mg) was dissolved in dioxane (10 ml) and the solution was added to Raney nickel W2[10] (ca. 0.4 g) in a flask. The mixture was refluxed for 6 h and filtered. The filtrate and washings were combined and evaporated to afford a residue. Column chromatography on silica gel (C-200, 2.5 g, elution with 10—25% ether in hexane) afforded 11-oxolanostan-3β-yl acetate (**24**; 21 mg), mp 144—145 °C (colorless needles from ether–methanol). When the desulfurization was carried out in a large scale using **23** prepared from **19** (3.5 g), an inseparable mixture (2.94 g) of 11-oxolanostan-3β-yl acetate (**24**) and 11-oxo-1-lanosten-3β-yl acetate (**25**). Gas chromatography (2% Dexsil 300GC) and ^1H NMR examination revealed that the mixture consisted of **24** and **25** in a ratio of 4:1. A mixture of **24** and **25**; ^1H NMR (90 MHz, $CDCl_3$) δ=0.72—0.91 (Me's), 1.08, 1.10 (Me's), 2.03, 2.04 (total 3H, each s; AcO), 4.49 (1H, m), 5.53, and 5.69 (each 0.2H, d, *J*=10.5 Hz); GC-MS **24**; *m/z* (%) 486 (M^+; 13), 426 (31), 411 (14), 383 (46), 303 (100), 290 (38), and 263 (79). **25**; *m/z* (%) 484 (M^+; 13), 424 (60), 409 (35), 303 (100), 290 (32), and 277 (42).

Hydrogenation of the Mixture of 24 and 25. The mixture (39 mg) of **24** and **25** in a ratio of 4:1 was dissolved in ethanol (8 ml) and hydrogenated in the presence of 10% palladium on carbon (25 mg) at room temperature under

atmospheric pressure for 48 h. The usual work-up and chromatography on silica gel (C-200, 3.8 g, elution with 10—15% ether in hexane) afforded the single product, 11-oxolanostan-3β-yl acetate (**24**; 35 mg), mp 144—145 °C (from ether-methanol); IR (Nujol) 1740, 1700, 1245, and 1030 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.72 (3H, s; Me), 0.83—0.90, 1.07—1.10 (Me's), 2.03 (3H, s; AcO), 2.32, and 2.50 (each 1H, d, J=13.5 Hz; 12-H). ^{13}C NMR (22.5 MHz, $CDCl_3$) δ=14.6, 15.9, 16.8, 17.1, 18.4, 21.1, 21.2, 22.5, 22.8, 24.0, 28.0, 28.2, 28.3, 29.2, 33.0, 36.0, 36.4, 36.6, 37.4, 38.2, 39.5, 40.5, 47.9, 48.7, 49.9, 53.0, 55.1, 61.3, 80.7, 170.8, and 211.5; MS m/z (%) 486 (M^+; 31), 426 (36), 411 (8), 383 (20), 303 (100), 290 (24), and 263 (72); Found: m/z 486.4101. Calcd for $C_{32}H_{54}O_3$: M, 486.4073. HR-MS m/z 303.2676 ($C_{21}H_{35}O$), m/z 290.2615 ($C_{20}H_{34}O$), and m/z 263.1683 ($C_{16}H_{23}O_3$).

4α,14α,24-Trimethyl-7,7-ethylenedithio-11-oxocholestan-3β-yl Acetate (26). 1,2-Ethanedithiol (1.5 ml) was added to a solution of 4α,14α,24-trimethyl-7,11-dioxocholestan-3β-yl acetate (**18**; 54 mg) in chloroform (2 ml). The solution was cooled in an ice bath, and hydrogen chloride was introduced with stirring for 3 h. The same work-up as before afforded a residue, which was purified by column chromatography on silica gel (C-200, 4.8 g). Elution with 10—30% ether in hexane gave 4α,14α,24-trimethyl-7,7-ethylenedithio-11-oxocholestan-3β-yl acetate (**26**; 56 mg), mp 195—196 °C (colorless needles from ether-methanol); IR (Nujol) 1730, 1700, and 1255 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.75—0.89 (Me's), 1.07 and 1.38 (each 3H, s; Me), 2.04 (3H, s; AcO), 3.26 (4H, s; S-CH_2-CH_2-S), and 4.42 (1H, dt, J=5 and 10 Hz; 3α-H); MS m/z (%) 576 (M^+; 39), 548 (10), 516 (45), and 284 (100); Found: m/z 576.3700. Calcd for $C_{34}H_{56}O_3S_2$: M, 576.3670.

Desulfurization of 4α,14α,24-Trimethyl-7,7-ethylenedithio-11-oxocholestan-3β-yl Acetate (26). A solution of **26** (56 mg) in dioxane (5 ml) was added to Raney nickel W2[10] (ca. 2 g) and the mixture was refluxed for 5—6 h. The same work-up as before and chromatography on silica gel (C-200, 4 g, elution with 2—15% ether in hexane) yielded an inseparable mixture (42 mg) of 4α,14α,24-trimethyl-11-oxocholestan-3β-yl acetate (**27**) and the corresponding 1-ene derivative (**28**), whose ratio was determined to be ca. 1 : 1 by gas chromatography. The mixture of **27** and **28**; ^1H NMR (90 MHz, $CDCl_3$) δ=0.72—0.89 (Me's), 1.02—1.08 (Me's), 2.03 and 2.04 (total 3H, each s; AcO), 4.36 (1H, m; 3α-H), 5.47, and 5.72 (total 1H, d, J=10.5 Hz; CH=CH); GC-MS **27**; m/z (%) 486 (M^+; 19), 426 (34), 411 (7), 317 (66), 304 (35), 291 (8), and 249 (100). **28**; m/z (%) 484 (M^+; 37), 469 (10), 456 (11), 424 (100), 409 (26), 317 (60), 304 (41), and 290 (52).

Hydrogenation of the Mixture of 27 and 28. The mixture (**27** and **28**; 11 mg) in ethanol was hydrogenated in the presence of 10% palladium on carbon (16 mg) for 64 h under the same conditions as before. Crystallization from ether-methanol yielded 4α,14α,24-trimethyl-11-oxocholestan-3β-yl acetate (**27**; 11 mg), mp 141.5—142.5 °C; IR (Nujol) 1730, 1695, 1250, 1020, and 970 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.72—0.89 (Me's), 1.05 and 1.09 (each 3H, s; Me), 2.04 (3H, s; AcO), 2.32 and 2.52 (each 1H, d, J=13.5 Hz; 12-H), 2.74 (1H, dt, J=3 and 13.5 Hz; 1β-H), and 4.36 (1H, dt, J=6 and 10.5 Hz; 3α-H); MS m/z (%) 486 (M^+; 20), 426 (40), 411 (9), 317 (76), 304 (39), 291 (9), and 249 (100); Found: m/z 486.4080. Calcd for $C_{32}H_{54}O_3$: M, 486.4072.

4α,14α,24-Trimethylcholestane-3β,11β-diol (29). 4α,14α,24-Trimethyl-11-oxocholestan-3β-yl acetate (**27**; 41 mg) in ether (8 ml) was refluxed with LAH (28 mg) for 1.5 h under nitrogen. Ethyl acetate (ca. 2 ml) and 2 M hydrochloric acid (13 ml) were added and the reaction product was extracted with ether. By column chromatography on silica gel (C-200, 4.6 g) eluted with 10—20% ethyl acetate in hexane, 4α,14α,24-trimethylcholestane-3β,11β-diol (**29**; 35 mg) was obtained, mp 206—207 °C (colorless needles from ether-methanol); ^1H NMR (90 MHz, $CDCl_3$) δ=0.75—0.93 (Me's), 1.01 and 1.11 (each 3H, s; Me), 3.07 (1H, dt, J=4.5 and 10 Hz; 3α-H), and 4.22 (1H, m; 11α-H); MS m/z (%) 446 (M^+; 2), 428 (53), 413 (100), 410 (19), and 395 (43).

4α,14α,24-Trimethyl-11β-hydroxycholestan-3β-yl Acetate (30). A solution of diol (**29**; 41 mg) in acetic anhydride (0.5 ml) and pyridine (1 ml) was allowed to stand for 19 h at room temperature and the reaction mixture was worked up as usual. The residue was purified by column chromatography on silica gel eluted with 10—30% ether in hexane to give 4α,14α,24-trimethyl-11β-hydroxycholestan-3β-yl acetate (**30**; 39 mg) as colorless needles after crystallization from ether-methanol; ^1H NMR (90 MHz, $CDCl_3$) δ=0.74—0.88 (Me's), 1.00, and 1.12 (each 3H; Me), 2.03 (3H, s; AcO), 4.22 (1H, m), and 4.37 (1H, dt, J=4.5 and 10.5 Hz; 3α-H); MS m/z (%) 488 (M^+; 3), 470 (60), 455 (100), 410 (27), and 395 (83); HR-MS m/z 470.4187. Calcd for $C_{32}H_{56}O_3$ ($M-H_2O$): m/z 470.4122.

4α,14α,24-Trimethyl-9(11)-cholesten-3β-yl Acetate (31). To a solution of the acetate (**30**; 39 mg) in pyridine (2 ml) was added phosphoryl chloride (0.01 ml) and the mixture was stirred at 90 °C for 3 h. Water was added and the reaction mixture was extracted with ether. The usual work-up gave a residue, which was subjected to column chromatography on silica gel (C-200, 5 g). Elution with 10—20% ether in hexane yielded 4α,14α,24-trimethyl-9(11)-cholesten-3β-yl acetate (**31**; 38 mg) as colorless crystals (from ether-methanol), mp 119—120 °C; ^1H NMR (90 MHz, $CDCl_3$) δ=0.66 (3H, s; Me), 0.76—0.90 (Me's), 1.00 (3H, s; Me), 2.04 (3H, s; AcO), 4.37 (1H, m; 3α-H), and 5.30 (1H, m; 11-H); MS m/z (%) 470 (M^+; 70), 455 (100), 410 (5), and 395 (41); Found: m/z 470.4161. Calcd for $C_{32}H_{54}O_2$: M, 470.4124.

4α,14α,24-Trimethyl-9(11)-cholesten-3-one (1). A solution of the acetate (**31**; 38 mg) in ethanol (5 ml) containing potassium hydroxide (0.1 g) was refluxed for 1.5 h. After the solvent was removed in vacuo, aqueous ammonium chloride solution was added. Extraction with ether and the usual work-up afforded a residue (33 mg), which was purified by crystallization from ether-methanol to give 4α,14α,24-trimethyl-9(11)-cholesten-3β-ol as colorless needles; ^1H NMR (90 MHz, $CDCl_3$) δ=0.66 (3H s; Me), 0.75—1.10 (Me's), 3.07 (1H, m; 3α-H), and 5.28 (1H, m; 11-H); MS m/z (%) 428 (M^+; 3), 413 (14), 410 (41), and 495 (100).

The alcohol (33 mg) above obtained was dissolved in acetone (15 ml) and treated with Jones reagent (3 drops) with stirring at 0 °C. After stirring was continued for 10 min at the same temperature, 2-propanol (10 drops) was added and the reaction mixture was stirred for 10 min. The solvent was evaporated, water (10 ml) was added, and the reaction product was extracted with ether. The extract was washed with a saturated sodium hydrogencarbonate solution and followed by the usual work-up to give a residue, which was chromatographed on silica gel (C-200, 5 g). Elution with 10% ether in hexane afforded 4α,14α,24-trimethyl-9(11)-cholesten-3-one (**1**; 27 mg), mp 143—144 °C (from ether-methanol); $[\alpha]_D^{23}$ 76° (c 0.54, EtOH); IR (Nujol) 1705 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=0.69 (3H, s; 18-Me), 0.74 (3H,

s; Me), 0.77—0.90 (Me's), 1.02 (3H, d, J=7.3 Hz; Me), 1.23 (3H, s; 19-Me), and 5.35 (1H, m; 11-H); MS m/z (%) 426 (M^+; 45), 411 (100), 299 (11), 257 (10), 243 (18), and 251 (21); Found: m/z 426.3899. Calcd for $C_{30}H_{50}O$: M, 426.3861.

Syntheses and Properties of [1,1′-Bis(α-Aminoisobutyric Acid)]Gramicidin S and [1-α-Aminoisobutyric Acid]Semigramicidin S

Michio KONDO,* Mikio KIMURA, Ken-ichi SATO, and Hideaki HORIMOTO
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840
(Received July 28, 1986)

Analogs of gramicidin S, [1,1′-bis(α-aminoisobutyric acid)]gramicidin S (**18**) and [1-α-aminoisobutyric acid] semigramicidin S (**11**), have been synthesized by a conventional solution method. The cyclization reactions of a linear pentapeptide active ester and a linear decapeptide active ester yielded exclusively a protected cyclic pentapeptide and a protected cyclic decapeptide, respectively. After deprotection of these peptides, we obtained the final products (**11** and **18**). The mobility of **18** in paper electrophoresis was the same as that of gramicidin S, however, the CD spectrum of **18** in a methanol solution showed a markedly different pattern from that of gramicidin S. Both analogs (**11** and **18**) are inactive against the Gram-positive microorganisms tested. The results suggest that the positions of the valine residues in gramicidin S require a hydrophobic amino acid having L-configuration to show activity.

Gramicidin S (GS) is a cyclic peptide antibiotic which exhibits a strong activity against Gram-positive bacteria. Its secondary structure is well-known to be an antiparallel β-pleated sheet including four intramolecular hydrogen bonds with C_2 symmetry as shown in Fig. 1.

Regarding the contribution of the side chains of the Val residues in GS to the antibacterial activity, several GS analogs have been synthesized by one of the authors (M.K) and it has been reported that [Ala$^{1,1'}$]GS and [Leu$^{1,1'}$]GS were as active as natural GS toward several microorganisms, whereas [Gly$^{1,1'}$]GS exhibited no antibacterial activity.[1,2] Thus, it is suggested that side chains as bulky or hydrophobic as methyls might be required at positions 1 and 1′ for the interaction between GS and sensitive bacteria.[3] On the other hand, in the syntheses of the above analogs using a dimeric cyclization reaction of the corresponding pentapeptide active esters, the ratio of a cyclic dimer to a cyclic monomer decreases in the order of steric hindrance of an N-terminal amino acid in each pentapeptide active ester substituted with Val,[4] Leu,[2] and Ala.[1] Finally Gly substitution[1] results in only a cyclic monomer as shown in Table 1. From these previous investigations it appears that the steric nature of the side chain of the N-terminal amino acid in a pentapeptide active ester greatly influences the cyclization reaction and consequently induces ring closure to a dimer by dimerization.[5]

In this connection, an analog of GS containing α-aminoisobutyric acid (Aib) in place of Val is of interest in demonstrating the specific contribution of Aib to the activity. This Aib is found in several antibiotics, alamethicin,[6] suzukacillin,[7] antiamebins,[6] emerimicins,[6] trichotoxin A-40,[8] and hypelcins.[9] They are peptide ionophores functioning as transmembrane channels for ion transport.[10] The Aib includes two methyl groups as side chains which have similar bulkiness or hydrophobicity to that of Ala, and is optically inactive as Gly. In addition, the steric hindrance caused by the two methyl groups of Aib sometimes prevents introducing a protecting group, converting to the corresponding active ester, and coupling with other amino acids or peptide.[11-13] Accordingly a moderate yield of a dimer was expected from the cyclization reaction of the pentapeptide active ester containing Aib at the N-terminus. Furthermore, such a synthetic [Aib$^{1,1'}$]GS analog should exhibit biological activity because the side chains of Aib, two methyl

Table 1. Ratio of Protected Monomer and Dimer after Cyclization of Linear Pentapeptide *p*-Nitrophenyl Ester[a]

p-Nitrophenyl ester of pentapeptide					Ratio of compounds in product[b]		Ref.
					Z-cyclic monomer	Z_2-cyclic dimer	
1	2	3	4	5			
Val	Orn(Z)	Leu	D-Phe	Pro	32	68	4
Leu					78	22	2
Ala					91	9	1
Gly					100	0	1

a) The concentration was approximately 3×10^{-3} mol dm^{-3}. b) The ratios shown are weight by weight.

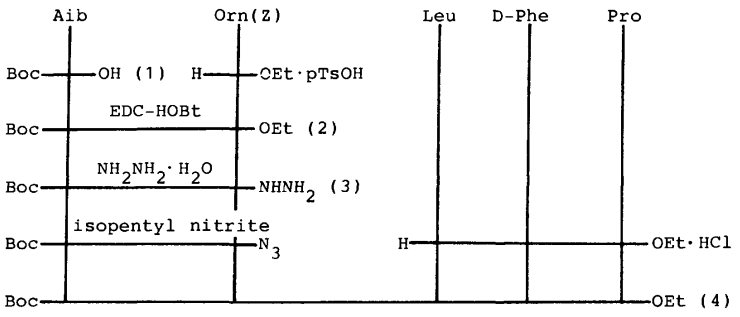

Fig. 2. Synthesis of Boc-pentapeptide.[14]

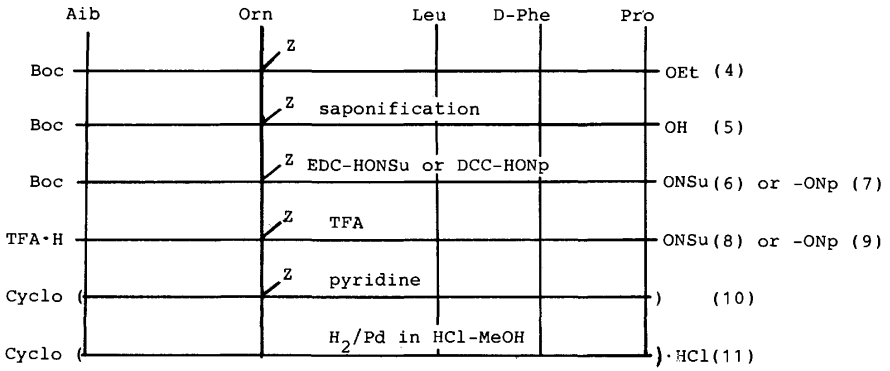

Fig. 3. Cyclization of linear pentepeptide active esters.

groups, in the analog have the same hydrophobicity as that of Ala in [Ala$^{1,1'}$]GS of which the biological activity is as strong as natural GS.[1]

The present paper will describe the syntheses, antibacterial properties, and CD measurements of [Aib$^{1,1'}$]-GS and [Aib^{1}]semiGS.

The route for the synthesis of a protected pentapeptide is indicated in Fig. 2. The dipeptide derivative (**2**) was effectively synthesized by the EDC-HOBt method involving stirring for a long time and extracting with ether, followed by conversion to the hydrazide (**3**). The condensation of the azide derived from **3** with a tripeptide ester gave an acylpentapeptide ester (**4**). The synthetic route for cyclization reactions of two pentapeptide active esters is shown in Fig. 3. The Boc-pentapeptide ester (**4**) was converted to the corresponding Boc-pentapeptide (**5**) by saponification. To investigate the best method for the cyclization reaction, two active esters using *N*-hydroxysuccinimide ester (**6**) and *p*-nitrophenyl ester (**7**) were prepared, and their Boc-groups were removed by the action of TFA at 0 °C. The cyclization of **8** or **9** at a concentration of 3×10^{-3} mol dm^{-3} in pyridine and subsequent purification of the crude cyclopeptide with Dowex 1 and 50 yielded exclusively the Z-substituted cyclic monomer (**10**), instead of the expected bis(Z-substituted) cyclic dimer. Its molecular weight was confirmed by mass spectrometry. The strong tendency of **8** or **9** to ring closure by monomerization indicates that the structural restriction imposed by Aib results in a favorable conformation of the cyclic pentapeptide and in this case of a cyclization of the pentapeptide active ester, L-configuration of the N-terminal amino acid plays basically a more important role than the steric nature in regard to its dimerization reaction. The Z-[Aib^{1}]semiGS (**10**) thus obtained was hydrogenated to afford [Aib^{1}]-semiGS·HCl (**11**) as crystals.

In order to obtain the cyclodecapeptide, a cyclization reaction of a decapeptide active ester was employed for the preparation of Z_2-[Aib$^{1,1'}$]GS. The route outlined in Fig. 4 was employed for synthesis of Z_2-[Aib$^{1,1'}$]GS. The Boc-decapeptide ester (**13**) was synthesized by the EDC-HOBt method from **5** and a pentapeptide ester trifluoroacetate, and **13** was saponified to give the Boc-decapeptide (**14**). The compound **14** was converted to the Boc-decapeptide succinimide ester (**15**). The bis(Z-substituted) cyclodecapeptide (**17**) was obtained through the cyclization reaction at a high dilution in pyridine after treatment of **15** with TFA, and the crude product was then purified with Dowex 1 and 50, gel chromatography on Sephadex LH-20 and silica-gel columns. Its molecular weight determination with a vapor pressure osmometer demonstrated that the molecular size of **17** corresponds to that of the bis(Z-substituted) cyclic decapeptide. The compound **17** was subjected to hydrogenolysis, and the final product **18** was obtained as crystals. Its homogeneity was confirmed by paper and thin-layer chromatographies and paper electrophoresis.

Biological assay of [Aib$^{1,1'}$]GS and [Aib^{1}]semiGS shows no antibiotic activity against all the Gram-positive microorganisms listed in Table 2. The bio-

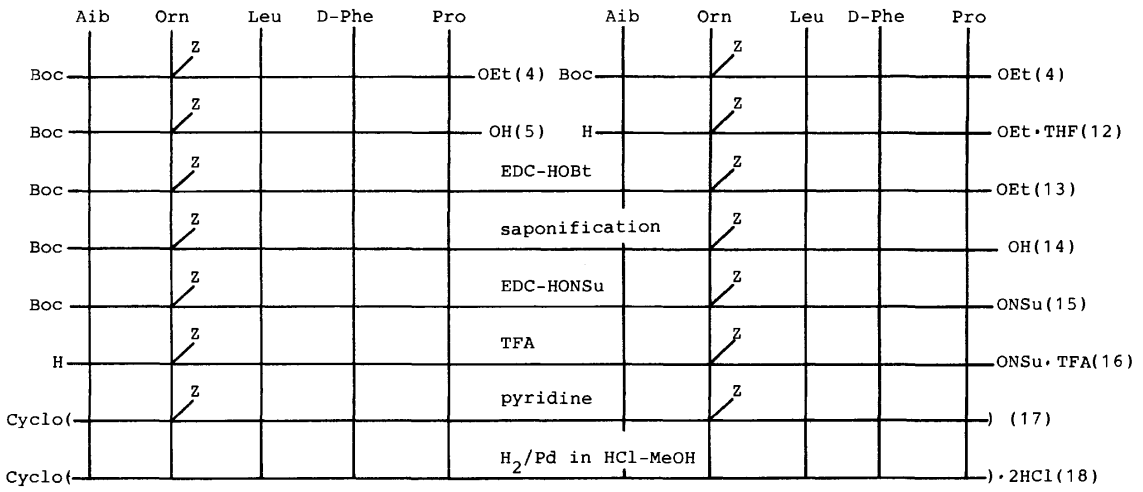

Fig. 4. Synthesis of [Aib$^{1,1'}$] GS·2HCl (**18**).

Table 2. Inhibitory Activity of [Aib^1] semiGS (**11**), [Aib$^{1,1'}$] GS (**18**) and GS on Microorganisms

Test organisms	GS	**11**	**18**
S. Aureus	3	>100	>100
B. subtilis	3	>100	100
E. coli	>100	>100	>100
S. flexneri	6	>100	>100
P. vulgaris	>100	>100	>100
P. aeruginosa	>100	>100	>100

Minimum inhibitory concentration, μg ml^{-1}.

logical data demonstrate that the Val residues in GS can not be substituted by the Aib residues without affecting the biological activity. Further, it has been reported that synthetic GS analogs such as [Aib$^{4,4'}$]GS and [Aib$^{5,5'}$]GS exhibited no antibiotic activity against all the microorganisms tested.[12,13] These results and our study of CPK model indicate that the rigid β-sheet structure of the GS molecule might be destabilized by the steric hindrance of the Aib residue in the GS analog. Hence the loss of sidedness structure affects the biological activity of the analog.[15]

The CD spectra of Boc-pentapeptide-ONSu and the protected cyclopentapeptide were measured to obtain information on a conformational change of the active ester just before ring closure, as shown in Fig. 5. A negative maximum and a shoulder of the protected cyclic pentapeptide (**10**) are about twice as great as those of the protected linear peptide active ester (**6**). Their characteristic shapes resemble each other. This seems to support the view that the conformation of the peptide backbone before ring closure is similar to that after ring formation and the cyclization reaction of the pentapeptide-ONSu afforded a cyclic monomer in good yield (73%) and no cyclic dimer. As shown in Fig. 6, the ellipticities of the negative troughs near 200 nm of three analogs, [Gly^1], [Ala^1], and [Aib^1]semiGS, are considerably smaller than that of GS, and the negative maximum bands of the analogs show blue shifts from that of GS. The shoulder at 218 nm is observed in

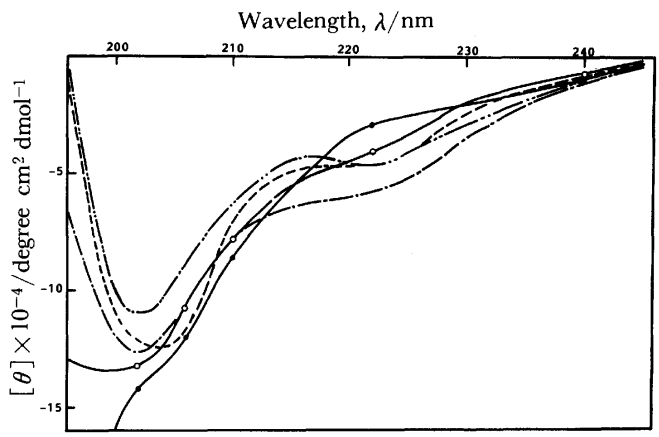

Fig. 7. CD spectra of protected linear **13**, **14**, **15**, **16**, and cyclic decapeptide (**17**) in MeOH. ----: **13**, -·-·-: **14**, -··-··-: **15**, —○—○—: **16**, —●—●—: **17**.

[Gly[1]]semiGS and [Ala[1]]semiGS, but it is not detectable in [Aib[1]]semiGS (**11**). The small and simple Cotton effect of **11** might be due to the influence of the large steric hindrance of Aib residue on the peptide backbone. The CD spectra of the linear decapeptide derivatives before ring closure and the protected cyclic decapeptide in MeOH are shown in Fig. 7. Each of the linear peptides shows a negative trough at 203 nm and a shoulder near 223 nm. However, the spectrum of the cyclic peptide shows only a shoulder instead of a trough at 203 nm, and the trough gives a blue shift from that of the linear decapeptide derivatives. It is obvious that the backbone conformations of the linear peptides and that of the cyclic peptide are different. The CD curves of [Aib[1]]semiGS (**11**) and [Aib[1,1']]GS (**18**) in MeOH as well as that of GS are shown in Fig. 8. The spectral shapes of these compounds indicate that these molecular conformations of **11** and **18** become significantly different from that of GS. The CD pattern of **18** exhibits no characteristic negative Cotton effect shown in GS at 206 and 217 nm, but its CD spectrum is similar to that of [D-Val[1,1']]GS recently synthesized by Tamaki et al.[16] It is also worthy to note that the [D-Val[1,1']]GS has practically no activity. On the basis of these results and observations, several reasonable explanations for the structure-activity relationship of **18** are considered as follows. (a) The Aib residues in **18** behave like D-amino acid residues at positions 1 and 1'. (b) The presence of geminal methyl groups at an α-carbon of Aib greatly restricts the range of accessible conformation for a β-turn of the cyclic peptide containing Aib. (c) This restrictive effect results in a distortion of the molecular conformation of a sidedness feature which is required for exhibiting the activity of antibiotic GS.

Conformational study of the β-turn part in GS analogs containing Gly, Ala, or Aib in place of Val is in progress to elucidate the effect of the amino acid residues at positions 1 and 1' in the peptide backbone on the antibacterial activity.

Experimental

All the melting points are uncorrected. All the $[\alpha]_{589}$ measurements were obtained using a JASCO spectropolarimeter model J-20. The molecular weight of Z-[Aib[1]]semiGS was determined by mass spectrometry using a JMS-D300 mass spectrometer. Amino acid analyses were performed with a Hitachi amino acid analyzer KLA-5. The ratio in parentheses after a solvent system was indicated by volume. Thin-layer chromatography was performed on silica gel (Merck 60 GF_{254}) with the following solvent systems: R_f^1, $CHCl_3$-MeOH (5:1); R_f^2, $CHCl_3$-MeOH (9:1); R_f^3, $CHCl_3$-MeOH-AcOH (8:1:1); R_f^4, $CHCl_3$-MeOH-98% NH_3 (8:4:1); R_f^5, *n*-BuOH-AcOH-H_2O (4:1:2); R_f^6 *n*-BuOH-AcOH-pyridine-H_2O (4:1:1:2).

Boc-Aib-OH (1): To a solution of Aib (3.35 g, 32.5 mmol) in 2 mol dm^{-3} NaOH (15.9 ml, 32.5 mmol) were added Et_3N (4.55 ml, 32.5 mmol) and $(Boc)_2O$ (5.46 g, 25.0 mmol) in dioxane (35 ml). After stirring for 40 h at room temperature, the solution was evaporated in vacuo to remove dioxane and diluted with water (200 ml). After extraction twice with ether (200 ml), the aqueous layer was cooled to 0 °C and adjusted to pH 2.5 with citric acid solution containing NaCl. The reaction product was then extracted twice with EtOAc (200 ml). The combined organic layers were washed twice with water (100 ml), dried over sodium sulfate, and triturated by the addition of petroleum ether. The resulting solid was recrystallized from ether; yield, 4.98 g (98% calculated from $(Boc)_2O$); mp 114—116 °C (lit, 119—120 °C); R_f^1 0.58, R_f^4 0.32.

Found: C, 52.98; H, 8,30; N, 6.93%. Calcd for $C_9H_{17}O_4N$: C, 53.19; H, 8.43; N, 6.89%.

Boc-Aib-Orn(δ-Z)-OEt (2): To a solution of **1** (3.25 g, 15.0 mmol) in DMF (35.0 ml) were added NMM (1.73 g, 15.8

mmol), Orn(δ-Z)-OEt·*p*-TosOH (7.35 g, 15.8 mmol), HOBt (2.43 g, 18.0 mmol), and EDC·HCl (3.22 g, 16.8 mmol) at 0 °C. After stirring for 3 d at room temperature, the reaction mixture was evaporated in vacuo. The residue was dissolved in ether (800 ml). The solution was washed successively with water, 10% citric acid, water, 0.5 mol dm^{-3} $NaHCO_3$ and water, and then dried over sodium sulfate. After removal of the drying agent, the solution was evaporated in vacuo to a small volume. The oily residue was crystallized by letting it stand for 2 h at room temperature. The product was collected by filtration; yield, 6.35 g (88%); mp 87—89 °C; $[\alpha]_{589}$ −7.7°(*c* 2.1, MeOH); R_f^1 0.71, R_f^2 0.58, R_f^4 0.80.

Found: C, 58.87; H, 7.57; N, 8.37%. Calcd for $C_{24}H_{37}N_3O_7 \cdot 1/2H_2O$: C, 59.00; H, 7.84; N, 8.60%.

Boc-Aib-Orn(δ-Z)-NHNH$_2$ (3): A solution of **2** (1.50 g, 3.14 mmol) and hydrazine hydrate (1.57 ml, 31.4 mmol) in MeOH (6.0 ml) was allowed to stand for 16 h at 28 °C. The solution was concentrated in vacuo. The foamy residue was dissolved in CH_2Cl_2 (300 ml), washed with water (200 ml), and then dried over sodium sulfate. After removal of the drying agent, the solution was evaporated in vacuo. The precipitate which formed upon the addition of ether was collected by filtration; yield, 1.34 g (92%); mp 75—76 °C; $[\alpha]_{589}^{22}$ −15.9° (*c* 2.0, MeOH); R_f^1 0.50.

Found: C, 56.64; H, 7.52; N, 15.03%. Calcd for $C_{22}H_{35}N_5O_6$: C, 56.76; H, 7.58; N, 15.04%.

Boc-Aib-Orn(δ-Z)-Leu-D-Phe-Pro-OEt (4): To a solution of **3** (883 mg, 1.90 mmol) in DMF (8.0 ml) were added 4.14 mol dm^{-3} HCl/dioxane (0.916 ml, 3.80 mmol) and isopentyl nitrite (0.290 ml, 2.08 mmol) at −50 °C. After stirring for 10 min at −20 °C, Et_3N (0.531 ml, 3.80 mmol) was added at −50 °C. The reaction mixture was combined with a chilled solution of H-Leu-D-Phe-Pro-OEt·HCl (959 mg, 2.18 mmol)[17] and Et_3N (0.305 ml, 2.18 mmol) in DMF (6.0 ml). The solution was stirred for the 5 d at 0 °C and concentrated to a small volume. The residue was dissolved in EtOAc (300 ml) and it was washed as described for the preparation of **2**. After removal of the drying agent, the solution was evaporated in vacuo. The precipitate which was formed upon the addition of petroleum ether was collected by filtration. The product was recrystallized from EtOAc-petroleum ether; yield, 1.16 g (73%); mp 74—78 °C; $[\alpha]_{589}^{23}$ −43.8°(*c* 2.0, MeOH); R_f^1 0.70, R_f^3 0.91.

Found: C, 62.81; H, 7.79; N, 9.91%. Calcd for $C_{44}H_{64}N_6O_{10}$: C, 63.14; H, 7.71; N, 10.04%.

Boc-Aib-Orn(δ-Z)-Leu-D-Phe-Pro-OH (5): To a solution of **4** (853 mg, 1.02 mmol) in MeOH (5.0 ml) was added 0.94 mol dm^{-3} NaOH (2.17 ml, 2.04 mmol) at 0 °C. The solution was allowed to stand for 5 h at 32 °C, evaporated in vacuo to a small volume, and diluted with water (15 ml). After extraction of the unreacted compound (**4**) with EtOAc (5 ml), the aqueous layer was cooled to 0 °C and adjusted to pH 3 with citric acid, and then extracted twice with CH_2Cl_2 (25 ml). The combined CH_2Cl_2 layers were washed twice with saturated aqueous NaCl (20 ml), dried over sodium sulfate, and then evaporated in vacuo. The precipitate which formed upon the addition of petroleum ether was collected by filtration; yield, 794 mg (96%); mp 103—105 °C; $[\alpha]_{589}^{23}$ −37.6° (*c* 2.0, MeOH); R_f^1 0.47; R_f^3 0.70; R_f^4 0.68.

Found: C, 61.16; H, 7.43; N, 9.85%. Calcd for $C_{42}H_{60}N_6O_{10}\cdot H_2O$: C, 61.00; H, 7.56; N, 10.16%.

Boc-Aib-Orn(δ-Z)-Leu-D-Phe-Pro-ONSu (6): To a solution of **5** (657 mg, 0.812 mmol) in DMF (3.0 ml) were added HONSu (188 mg, 0.812 mmol) and EDC·HCl (315 mg, 1.62 mmol) at 0 °C, and the mixture was then stirred for 26 h at room temperature. The reaction mixture was evaporated in vacuo and diluted with $CHCl_3$ (100 ml). This was washed with 0.5 mol dm^{-3} $NaHCO_3$ and water, and dried over sodium salfate. After removal of the drying agent, the solution was evaporated in vacuo. The residue was solidified with petrolem ether; yield, 599 mg (82%); mp 98—100 °C; $[\alpha]_{589}^{23}$ −40.5° (*c* 1.1, MeOH); R_f^1 0.60.

Found: C, 60.00; H, 7.37; N, 10.18%. Calcd for $C_{46}H_{63}N_7O_{12}\cdot H_2O$: C, 59.79; H, 7.09; N, 10.61%.

Boc-Aib-Orn(δ-Z)-Leu-D-Phe-Pro-ONp (7): To a solution of **5** (649 mg, 0.80 mmol) in pyridine (7.0 ml) were added *p*-nitrophenol (222 mg, 1.60 mmol) and DCC (189 mg, 0.92 mmol) at 0 °C. After stirring for 25 h at room temperature, the precipitated urea was filtered off and the filtrate was concentrated. The residue was worked up as described for the synthesis of **6**; yield, 500 mg (67%); mp 67—70 °C; R_f^1 0.75.

H-Aib-Orn(δ-Z)-Leu-D-Phe-Pro-ONSu·TFA (8): Compound **6** (588 mg, 0.649 mmol) was dissolved in TFA (4.0 ml) at 0 °C. After 30 min, the solution was evaporated, and the residue was triturated with a mixture of ether and petroleum ether. The crystals which remained were collected by filtration; yield, 585 mg (98%); mp 110—112 °C; $[\alpha]_{589}^{23}$ −48.6° (*c* 1.0, MeOH); R_f^1 0.62, R_f^3 0.47, R_f^5 0.57.

Found: C, 54.30; H, 6.20; N, 10.23%. Calcd for $C_{43}H_{56}N_7O_{12}F_3\cdot 2H_2O$: C, 54.02; H, 6.32; N, 10.26%.

H-Aib-Orn(δ-Z)-Leu-D-Phe-Pro-ONp·TFA (9): This compound was prepared from **7** (476 mg, 0.512 mmol) as described for the preparation of **8**; yield, 350 mg (72%); mp 100—103 °C; R_f^1 0.57, R_f^3 0.38.

***Cyclo*[Aib-Orn(δ-Z)-Leu-D-Phe-Pro] (10):** This compound was synthesized by (1) ONSu method and (2) ONp method.

(1) A solution of **8** (374 mg, 0.406 mmol) in DMF (2.6 ml) was added dropwise into pyridine (120 ml) at room temperature. After stirring for 5 d at room temperature, the solution was evaporated in vacuo. The residue was dissolved in a mixture of MeOH and water (2 : 1) and applied to columns (1.8×12 cm) of Dowex 1 and 50. The eluate (ca. 500 ml) was evaporated to dryness. A few mg of the crude product were subjected to hydrogenolysis, and paper electrophoresis of the hydrogenated material showed one spot. The crude product was chromatographed over a silica-gel column (Wako silica gel CQ-3, 2×30 cm) using hexane-$CHCl_3$-MeOH (2 : 3 : 1) as eluent; yield, 204 mg (73%, 59% from **9**); mp 100—102 °C; $[\alpha]_{589}^{23}$−64.8° (*c* 2.0, MeOH); R_f^2 0.50, R_f^3 0.85, R_f^5 0.72, R_f^6 0.78.

Found: C, 63.13; H, 7.39; N, 11.46%; M^+, 690. Calcd for $C_{37}H_{50}N_6O_7\cdot H_2O$: C, 62.69; H, 7.39; N, 11.86%.

(2) A solution of **9** (148 mg, 0.156 mmol) in DMF (5.0 ml) was added dropwise to pyridine (70 ml) heated to 62 °C. After stirring for 6 h at 62 °C and for 10 h at room temperature, the reaction mixture was worked up as described above. The hydrogenated material from a few mg of the crude showed one spot in paper electrophoresis. The crude oily product was crystallized from ether-hexane; yield, 67.0 mg (62%, 30% from **9**); mp 101—103 °C; $[\alpha]_{589}^{23}$ −65.2° (*c* 2.0, MeOH); R_f^3 0.85, R_f^5 0.72, R_f^6 0.78.

Found: C, 62.51; H, 7.30; N, 11.67%; M^+, 690. Calcd for $C_{37}H_{50}N_6O_7\cdot H_2O$: C, 62.69; H, 7.39; N, 11.86%; M^+, 690.

***Cyclo*(Aib-Orn-Leu-D-Phe-Pro)·HCl (11):** A solution of **10** (162 mg, 0.230 mmol) in 1.67 mol dm^{-3} HCl/EtOH

(0.155 ml, 0.250 mmol) and MeOH (10 ml) was subjected to hydrogenolysis in the presence of Pd-black. After 3 h, the catalyst was filtered off and the filtrate was evaporated to dryness; yield, 132 mg (95%); mp 202—206 °C; $[\alpha]_{589}^{23}$ −67.5°(*c* 2.0, MeOH); R_f^1 0.21, R_f^3 0.40, R_f^4 0.94, R_f^5 0.41, R_f^6 0.65.

Found: C, 53.56; H, 7.84; N, 12.60%. Calcd for $C_{58}H_{90}N_{12}O_{10}Cl_2 \cdot 6H_2O$: C, 53.82; H, 7.94; N, 12.98%.

Paper Electrophoresis. This was carried out on Toyo Roshi No. 51A paper with a HCOOH-AcOH-MeOH-H_2O solvent system (2:9:18:30, pH 1.8) for 3 h at 500 V/30 cm. Each of these analogs showed a single spot. Figure 9 shows that [Aib$^{1,1'}$]GS (**18**) migrates faster toward the cathode than [Aib^1]semiGS (**11**), and that the mobility of **18** is indistinguishable from that of the natural GS.

Microbiological Assay and CD Measurements. The microorganisms employed are listed in Table 2. The minimum amount of the compound necessary for the complete inhibition of growth was determined by a dilution method using a trypticase soy agar. As is shown in Table 2, [Aib$^{1,1'}$]GS (**18**) and [Aib^1]semiGS (**11**) exhibited no antibacterial activity against any of the microorganisms tested. The CD spectra were obtained using a JASCO spectropolarimeter model J-20 in MeOH solution at room temperature.

The authors wish to express their thanks to Dr. Masahiko Fujino of Takeda Chemical Industries, Ltd. for the biological assay. Special thanks are due to Prof. Nobuo Izumiya of Laboratory of Chemistry, Kurume Institute of Technology for his suggestions and a stimulus for our work.

Action of Serine Carboxypeptidases on Endopeptidase Substrates, *N*-Acyldipeptideamides

Shigeru KUNUGI,* Kazuo TANABE, Kouji YAMASHITA, and Mitsuhiro FUKUDA†
Department of Applied Chemistry, Fukui University, Bunkyo, Fukui 910
†Department of Practical Life Studies, Hyogo University of Teacher Education, Yashiro-cho, Hyogo 673-14
(Received August 9, 1986)

Action patterns of two serine carboxypeptidases, one from yeast (Y) and the other from wheat bran (W), on *N*-[3-(2-furyl)acryloyl]-(Fua-) dipeptideamide substrates were examined by HPLC and amino acid analysis. In the reaction of the wheat enzyme the substrates were hydrolyzed to Fua-amino acid and no sufficient amount of Fua-dipeptides were detected on HPLC in the product mixtures. Very few or no free amino acids were observed by amino acid analysis. This indicates that the wheat enzyme exhibited carboxamidopeptidase activity on these substrates. On the contrary, carboxypeptidase Y gave Fua-amino acids and Fua-dipeptides as products, depending on the structure of the substrates. Accordingly, liberations of free amino acids were detected in some cases. This result shows that the yeast enzyme acts on some of the substrates in a two step manner: First by amidase and second by a carboxypeptidase activity. Based on these results the substrate binding mechanisms of these enzymes are discussed.

Serine carboxypeptidase [EC3.4.16.1] includes cathepsin A, and carboxypeptidases from yeast,[1] molds and plants.[2] They are considerably different from metallo-carboxypeptidases represented by carboxypeptidase A.[3,4] In particular, some of the serine carboxypeptidases show hydrolytic activities towards synthetic chymotrypsin-type substrates, such as Ac-Tyr-OEt and Bz-Tyr-NH-Np.[5-8] Recently, carboxamidopeptidase activities against several peptide hormones have also been reported,[9-12] further, we have found that *N*-substituted peptide amides with such a large 7-amino-4-methyl-2*H*-1-benzopyran-2-one can be hydrolyzed by, for example, an enzyme from yeast (carboxypeptidase Y).[13]

These endopeptidase-like activities of this class of enzyme, especially the esterase activity, have been utilized for peptide synthesis, by aminolysis of the ester or by transpeptidation.[14,15] However, this variety of activities, on the other hand, makes the prediction of the condensation product very complicated. Therefore, we investigate the hydrolysis pattern for the enzymes from yeast and wheat bran (carboxypeptidase W) on *N*-acyldipeptideamides in order to improve the design of the peptide formation by these enzymes. It would also be helpful to obtain an understanding of the substrate binding mechanisms of these enzymes.

Experimental

Materials. Five *N*-acyldipeptideamides (*N*-[3-(2-furyl)-acryloyl]-(Fua-) Gly-Phe-NH_2, Fua-Gly-Leu-NH_2, Fua-Phe-Gly-NH_2, Fua-Phe-Leu-NH_2, and Fua-Phe-Phe-NH_2) and corresponding Fua-dipeptides or Fua-amino acids were prepared as previously reported.[16] Carboxypeptidases Y and W were the same as those used in the previous studies.[13,17,18] The active concentration of the enzyme was determined by a steady state rate constant of the hydrolysis of Fua-Phe-Phe or Fua-Phe-OEt.[19] 2-Morpholinoethanesulfonic acid (Mes) and 2-[4-(2-hydroxyethyl)-1-piperazinyl]-ethanesulfonic acid (Hepes) were from the Dohjindo Laboratories (Kumamoto). Other reagents were of commercial grade and were used without further purifications.

Methods. The absorbance spectrum was measured on a Uvidec 650-C spectrophotometer (Nippon Bunkou Co.; Tokyo). The reaction velocity of the hydrolysis of Fua-substrates at the bond including the carbonyl group of the substituted amino acid was measured by the absorbance decrease at 320—345 nm. The hydrolyzed product was analyzed by the high-pressure liquid chromatography of a Shimadzu LC-5A system attached to a Cosmosil 5C18 reversed-phase column. The absorbance was monitored at 305 nm through a UV-detector (Shimadzu SPD-1) and integrated (Shimadzu CR3A). The release of an amino acid or an amino acid amide was checked by an amino acid analysis on a Shimadzu LC3A-FLD1 system with fluorometric detection by the phthalaldehyde method.

Results and Discussion

The reactivity of carboxypeptidase W towards five Fua-dipeptideamide substrates was measured at pH 5—7.5 and 25 °C. Table 1 shows the amounts of products observed in the reaction mixtures after overnight incubation, relative to the initial amount of the substrate. This pH range was selected since carboxypeptidase W loses its catalytic activity above pH 8.[18] Among the five substrates studied, Fua-Phe-Leu-NH_2 was most susceptible to hydrolysis; only Fua-amino acid was observed as a product in the applied pH range and the pH dependency was not obvious. Fua-Phe-Phe-NH_2 and Fua-Phe-Gly-NH_2 were also susceptible and no sufficient amount of Fua-dipeptide was detected in the reaction mixture. Fua-Gly-Phe-NH_2 and Fua-Gly-Leu-NH_2 were less reactive. The former substrate gave some *N*-Fua dipeptide in the reaction mixture at high pH.

Table 2 shows the result for carboxypeptidase Y catalysis. This enzyme gave a somewhat different pattern from that for carboxypeptidase W. It hydrolyzed Fua-Phe-Leu-NH_2 and Fua-Phe-Phe-NH_2. The degree of hydrolysis was higher at higher pH. In the case of Fua-Phe-Phe-NH_2 nearly half of the product was Fua-dipeptide while in Fua-Phe-Leu-NH_2 only Fua-amino acid was the final product. Fua-Phe-

Fua-Gly-Leu-NH_2	5.0	11.0	6.0	0
	7.5	5.2		
Fua-Gly-Phe-NH_2	5.0	1.3	5.0	0
	7.5	6.4	7.0	0

a) Amount of liberated amino acid relative to the initial amount of each substrate.

Gly-NH_2 fell in the latter category, though its reactivity was not very high and Fua-Gly-Phe-NH_2 and Fua-Gly-Leu-NH_2 showed moderate reactivities and also gave Fua-dipetides as products.

To determine whether the Fua-amino acids observed in these reaction mixtures were produced directly from the substrates by carboxamidopeptidase activity or via Fua-dipeptide, i.e., hydrolyzed first by the amidase activity and successively by carboxypeptidase activity, some of the reaction mixtures were analyzed on an amino acid analysis system. Table 3 shows the detected amount of the corresponding free amino acid, relative to the initial amount of the substrate. In the case of carboxypeptidase W very few or no free amino acid was observed and these substrates were known to be hydrolyzed by this enzyme simply by carboxamidopeptidase activity. On the contrary, a sufficient amount of free amino acid was observed in some of the carboxypeptidase Y catalyzed hydrolyses. As in Table 2, Fua-Phe-Leu-NH_2 was completely hydrolyzed to *N*-Fua amino acid by carboxypeptidase Y at higher pH during the present reaction period; however, a major part of it was produced via two-step hydrolysis. The substrate was hydrolyzed once to Fua-Phe-Leu by amidase activity and then to Fua-Phe and Leu by intrinsic carboxypeptidase activity. Though this activity decreased with increasing pH,[7,20] it was still sufficient to hydrolyze the Fua-dipeptide produced

from the substrate, even at higher pH: at pH 8.0 and 25 °C, k_{cat}/K_m for the carboxypeptidase activity was in the order of 10^5 $M^{-1}s^{-1}$ (1M=1 mol dm^{-3}) for Fua-Phe-Leu.[21]

In the case of Fua-Phe-Phe-NH_2 the reaction proceeded in a similar fashion, but the amidase activity was higher than the carboxypeptidase activity at higher pH, with a considerable amount of the product accumulated at the state of Fua-Phe-Phe. At low pH where the amidase activity decreased,[7,12] a considerable portion of the substrate was left intact after the applied reaction time; only Fua-Phe was observed as a product. Therefore, the relative magnitude of the two activities determined the product distribution. Fua-Phe-Gly-NH_2 is a rather poor substrate of carboxypeptidase Y and was mostly hydrolyzed directly to Fua-Phe by carboxamidopeptidase activity. In Fua-Gly-Phe-NH_2 and Fua-Gly-Leu-NH_2 amidase activity was not very high and the two pathways were more or less concurrent.

The complexity of the hydrolysis of Fua-Phe-Leu-NH_2 by carboxypeptidase Y was reflected in the kinetics of the reaction observed by a change in the UV absorbance. The apparent second-order rate constant of the hydrolysis was obtained from the initial rate divided by both enzyme and substrate concentrations or by a pseudo-first-order analysis at $[E]_0$=50—100 nM and $[S]_0$=10—20 μM. It changed with pH as shown in Fig. 1 (○ and ◐) with an apparent maximum at about pH 7. In the pH range of 6.5—8, however, a semi-logarithmic plot of the absorbance change as a function of time shows a convex shape (insert in Fig. 1); the rate constants given in the figure were evaluated from the later portions of the plots. In contrast to this, the hydrolysis of the same substrate by carboxypeptidase W gave normal pseudo-first-order rate curves (though not shown here); the pH profile of the second-order rate constant (Fig. 1, ●) could be explained by the following simple equation assuming $k_{A(lim)}$=7.96×10^4 $M^{-1}s^{-1}$ and pK_a=6.60 ($k_{A(lim)}$: pH-independent (maximum) value of k_{cat}/K_m):

$$k_{cat}/K_m = k_{A(lim)}/(1 + [H^+]/K_a). \quad (1)$$

For a further consideration of the mechanism of serine carboxypeptidase, we cite here the previously reported change of the reaction parameters with the variation in the side-chain structures of *N*-acyl-dipeptides substrates (*N*-furylacryloyl-substrate for carboxypeptidase W[18] and *N*-benzyloxycarbonyl-substrate for carboxypeptidase Y[7]). Carboxypeptidase W has a relatively broader specificity, compared with carboxypeptidase Y, especially for the k_{cat} parameter. We note that there are some differences in the specificity of the carboxypeptidase activity and the carboxamidopeptidase or amidase activity.

These two carboxypeptidases were shown to exhibit fairly different pK_a values for peptidase activity, sug-

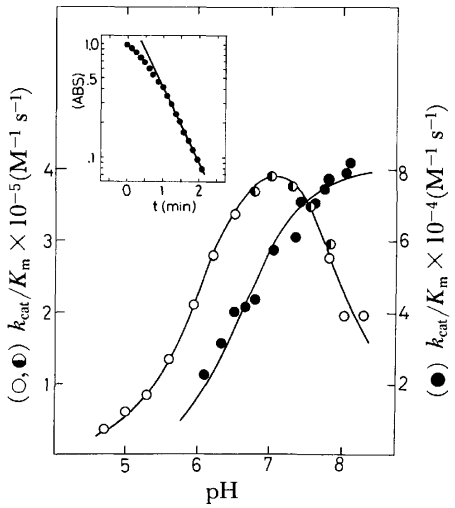

Fig. 1. pH Dependences of k_{cat}/K_m of the hydrolysis of FuaPheLeuNH_2 catalyzed by carboxypeptidase Y (○,◐) and by carboxypeptidase W (●) at 25 °C. (-His-Leu)[22]) for carboxypeptidase Y. b) In parentheses are k_{cat}/K_m values relative to the value of -Phe-Gly.

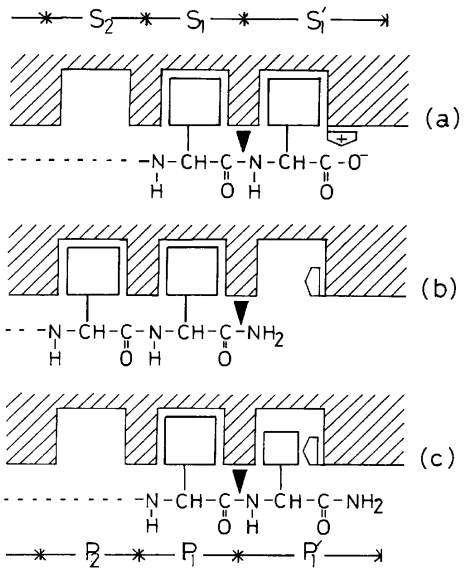

Fig. 2. Scheme of the substrate binding site of carboxypeptidase Y. S_i,S_i': The binding site for the C-terminal amino acid residue of the substrate. P_iP_i': The amino acid residues of the substrate in corresponing binding sites. Dark triangle shows the scissile point. (a) At low pH with a substrate having free carboxylate terminal and bulky amino acid residues. (b) At neutral pH with a substrate having amide end and bulky trerminal amino acid. (c) At neutral pH with a substrate having amide end and a ternial amino acid residue of a smaller size.

gesting that the anion-recognizing residue might be different. Our previous study[18] revealed that the catalytic sites for the carboxypeptidase activity and endopeptidase-like activity of carboxypeptidase W plausibly involved different functional groups. In view of the fact that the catalytic activity of carboxypeptidase Y involves a His residue,[4] and the apparent pK_a value in the substrate binding process[20] implies that this or another protonated His residue can act as an anion-recognition site of carboxypeptidase Y.

These considerations lead to a schematic picture of the substrate binding site of carboxypeptidase Y (Fig. 2): (a) The protonation of a His residue is essential for the binding of substrates having a carboxylate end. (b) At neutral and alkaline pH, the His residue loses its charge and some structural or conformational change might occur in the substrate-binding site. This process limits the size of the S_1' site and prevents the binding of a dipeptideamide substrate which has a bulky residue at P_1'. Therefore, such a substrate is not cleaved at the P_1-P_1' bond but rather at the terminal amide bond. (c) In the case of a dipeptide amide having a smaller residue at P_1', it penetrates into the corresponding position and a carboxamidopeptidase activity occurs. A neutral His residue can also be helpful for the binding of a moderate size residue at P_1'.

The authors gratefully acknowledge the encouragement of Profs. Norio Ise and Yoshiharu Nakamura throughout the work. They also acknowledge the kind advice of Prof. R. Hayashi.

(Received August 9, 1986)

Dipeptide synthesis from *N*-[3-(2-furyl)acryloyl]-acylated (Fua-) amino acid ethyl ester and amino acid amide catalyzed by wheat bran carboxypeptidase (carboxypeptidase W) was studied. The optimum pH for peptide formation was at pH 8; more than 60% of the initial *N*-Fua-L-phenylalanine ethyl ester was converted to *N*-Fua-L-phenylalanylglycinamide under optimum conditions. The dependence of peptide formation on the concentration of amino acid amide showed an apparent saturation; this could be successfully explained by a reaction scheme which involved an acylated enzyme attacked by an enzyme-bound amine. The results for a reaction in the presence of two different amine components also supported this mechanism. Gly-NH_2 had a better affinity to the acylated carboxypeptidase and the apparent dissociation constant ($K_{N(app)}$) was about 50 mM. These results were compared with those for those reactions catalyzed by carboxypeptidases from yeast and malt.

Serine carboxypeptidases [EC 3.4.16.1] from various origins[1-9] are characterized by the broad substrate specificity and by esterase and/or amidase activity in addition to intrinsic carboxypeptidase.[3,6-11] Some of the enzymes of this group have been successfully utilized for peptide synthesis from *N*-acyl amino acid esters and amino acid amides or esters.[12-14] In addition to these practical aspects, the aminolysis reaction and transpeptidation reactions[15] have been considered as indirect evidence for a reaction mechanism which includes an acylated intermediate. The existence of such an intermediate was observed by a stopped-flow technique in the case of carboxypeptidase Y.[16,17] A carboxypeptidase from wheat bran (carboxypeptidase W)[18] is considered to be a member of this group of enzymes; we have studied the kinetics of its reaction for peptide and ester hydrolyses.[19,20] In due course we found that this carboxypeptidase is useful for peptide synthesis by the aminolysis of an ester substrate. Here, we examine some fundamental points for such a utilization.

Experimental

Materials. Carboxypeptidase W was obtained from Pentel Co. Ltd. (Tokyo, Lot 68305031). Enzyme solutions were prepared by dissolving it in deionized water; it was stored as a concentrated solution (0.05 mM (1M=1 mol dm^{-3})) at 4 °C. The protein concentration was determined from the absorbance at 280 nm using $A1^{\%}_{cm}$=19.6 and Mr=118000.[18] Carboxypeptidase Y was obtained from Oriental Yeast Co. (Osaka) and used as described before.[19] *N*-[3-(2-furyl)acryloyl] amino acids were synthesized by the *N*-hydoxysuccinimide method. Their analytical data have been described previously.[22-24] Other chemicals were of reagent grade and were used without further purifications.

Methods. Reactions were carried out at 37 °C in the presence of 0.2 M NaCl and 15% *N*,*N*-dimethylformamide, unless otherwise mentioned. The pH was adjusted by adding concd HCl or NaOH solutions. After incubation for the indicated time, a portion was taken out, quenched by mixing with a 5-fold volume of acetonitrile, filtered on Millipore FHLP013, and then analyzed on a reversed-phase chromatography (Waters HPLC 6000A-440 with Cosmosil 5C18). The eluent solution contained 45% CH_3CN, 50 mM Na_2SO_4 and approximately 5 mM H_3PO_4.

Results and Discussion

Figure 1 shows the pH dependence of the peptide formation from Fua-Phe-OEt and Leu-NH_2 after incubation for 5 h under the indicated conditions. They are given in a form of conversions (=(total consumption of the ester)/(initial amount of the ester)) and yield (=(produced amount of the dipeptide amide)/(initial amount of the ester)). Since the catalytic activity of carboxypeptidase W decreased at a pH above 8,[19] the conversion efficiency decreased above 8 and the maximum yield was obtained at a pH around 8. Similar pH profiles were obtained at different enzyme concentrations. This result is in contrast to

Table 1. Product Distribution in the Aminolysis Reaction of Fua-Phe-OEt Catalyzed by Carboxypeptidases W and Y with Several Nucleophiles at [Fua-Phe-OEt]=2 mM, [Nucleophile]=0.1 M, [enzyme]=0.5 mM, [NaCl]=0.2 M, 15% *N,N*-Dimethylformamide 37 °C and pH 8.0

Nucleophile	pK_a[a]	Carboxypeptidase W					Carboxypeptidase Y

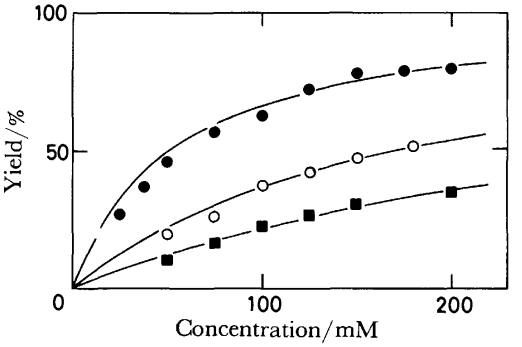

Fig. 3. Amino acid amide concentration dependence of peptide formation at 37 °C. [Fua-Phe-OEt]=2 mM, [enzyme]=0.5 μM, [NaCl]=0.2 M, 15% *N,N*-dimethylformamide and pH 8.0. ●: With Gly-NH_2, ○: with Leu-NH_2, ■: with Phe-NH_2

that for carboxypeptidase Y-catalyzed peptide formation using the same substrates, where the yield increased monotonously (up to pH 10) with an increase in pH (Shima et al. unpublished result). At optimum pH, The time course of the reaction by carboxypeptidase W was as shown in Fig. 2. Under these conditions, the ratio (□) of the hydrolyzate (Fua-Phe) and the aminolysis product (Fua-Phe-Leu-NH_2) was practically constant during the reaction period. Table 1 shows the results for product analyses for reactions with different nucleophiles, together with the results for carboxypeptidase Y under similar conditions. As we have shown in a preceding paper,[20] the amidase activity of carboxypeptidase W is low and the production of *N*-acyldipeptide with carboxylate terminal is practically negligible in the present case. This result is also in contrast to the case of carboxypeptidase Y. Gly-Gly was not an effective nucleophile, while Gly-NH_2 was the best among three amino acid amides used here.

The amide concentration dependency of the peptide yield is shown in Fig. 3 for three amino acid amides. To explain the results we postulate a competition between the hydrolysis and the aminolysis of the acyl-enzyme intermediate, while taking account of a possible inhibitory action of added nucleophile, as shown in Eqs. 1—4:

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} E\cdot S \xrightarrow{k_2} EA \quad (1)\ \text{[Acyl-enzyme formation]},$$

$$EA \xrightarrow{k_3} E + P_0 \quad (2)\ \text{[Hydrolysis of acyl-enzyme]},$$

$$EA + N \overset{K_N}{\rightleftharpoons} EA\cdot N \xrightarrow{k_n} E + P_1 \quad (3)\ \text{[Aminolysis]},$$

$$E + N \overset{K_N^i}{\rightleftharpoons} E\cdot N \quad (4)\ \text{[Competitive inhibition]}.$$

Here, the k_i's are the respective rate constants. S, P_i's, E, E·S, and EA are the substrate (ester), products (amino acid and peptide), enzyme, enzyme-substrate complex and acylated enzyme, respectively. EA·N and E·N are a complex formed from the acylated enzyme and the nucleophile and enzyme-nucleophile complex, respectively. K_N and K_N^i are the respective dissociation constants. These expressions are similar to those provided by Bender[26] and by Fastrez and Fersht[27] to explain the partitioning of the acyl-enzyme intermediate of chymotrypsin by water and an acceptor (nucleophile). However, the specific binding of the nucleophile to the enzyme active site is considered in the present case. They are also analogous to expressions given for the reaction of papain by Fink and Bender[28]; here, a reaction path which includes the ternary complex composed of EA and two molecules of N is out of the consideration. In a steady state analysis of the reaction, Eq. 1 is considered to be equivalent to

$$E + S \overset{K_m}{\rightleftharpoons} EA, \quad (5)$$

Table 2. Carboxypeptidase W-Catalyzed Aminolysis of Fua-Phe-OEt with two Amino Acid Amides (Xxx-NH_2 and Yyy-NH_2) at [Fua-Phe-OEt]=2 mM, [Xxx-NH_2]=[Yyy-NH_2]=0.1 M, 15% *N,N*-Dimethylformamide 37 °C and pH 8.0

Xxx-NH_2	Yyy-NH_2	Yield of Fua-Phe-Xxx-NH_2 (f_1) (%)	Yield of Fua-Phe-Yyy-NH_2 (f_1') (%)	f_1/f_1'[a]
Gly-NH_2	Phe-NH_2	61	7.8	7.8 (7.0)
Gly-NH_2	Leu-NH_2	57	14	4.1 (3.4)
Leu-NH_2	Phe-NH_2	29	14	2.1 (7.0)

a) Numbers in parentheses were calculated by Eq. 16.

where $K_m=\{(k_{-1}+k_2)/k_1\}\{k_3^*/(k_2+k_3^*)\}$ and $k_3^*=k_3+k_n[N]/K_N$. Then, we obtain the rates of the formation of two products (P_0 and P_1) as

$$v_0 = dP_0/dt = k_3([S]/K_m)[E]_0 / \{1 + (K_m/[S])(1 + [N]/K_N) + [N]/K_N^i\}, \quad (6)$$

and

$$v_1 = dP_1/dt = k_n([N]/K_N)([S]/K_m)[E]_0 / \{1 + (K_m/[S])(1 + [N]/K_N) + [N]/K_N^i\}. \quad (7)$$

Since [N] is in great excess to the enzyme in each case and there are no cross terms in Eqs. 6 and 7, the ratio of two reaction rates is constant during the reaction period (the case in Fig. 3). Therefore, these equations, though originally written for the initial state of the reaction, can be related to the fraction (f_1) of the aminolysis product over the total consumption of the ester substrate:

$$f_1 = v_1/(v_0 + v_1) = k_n([N]/K_N)/\{k_3 + k_n([N]/K_N)\} = 1/\{1 + (k_3/k_n)(K_N/[N])\}. \quad (8)$$

Equation 8 predicts that an apparent saturation is observed in the concentration dependence of the peptide yield and that the apparent saturation parameter ($K_{N(app)}$) ($=(k_3/k_n)K_N$) shows a total affinity of aminolysis. The observed concentration dependency was analyzed by a least-square method and $K_{N(app)}$ was evaluated (Table 1). Since the nucleophilicity of Gly-NH_2 is weakest, the smallest $K_{N(app)}$ value observed for this amide is due to the smallest K_N value, i.e., the affinity of Gly-NH_2 to the acylated enzyme is best among the three. This is in contrast to the fact that in the hydrolysis reaction K_m values of Fua-Phe-Leu and Fua-Phe-Phe are five- to seven-fold smaller than that of Fua-Phe-Gly at low pH.[19]

When two kinds of amino acid amides are present in a reaction mixture, the product distributions (fractions of two peptide products; f_1 and f_1') are listed in Table 2. For such systems we have to add two equations concerning the second amine component (N'):

$$EA + N' \overset{K_{N'}}{\rightleftharpoons} EA\cdot N' \xrightarrow{k_n'} E + P_1', \quad (9)$$

and

$$E + N' \overset{K_{N'}^i}{\rightleftharpoons} E\cdot N'. \quad (10)$$

In these equations $K_{N'}$, k_n', and $K_{N'}^i$ have similar meanings as K_N, k_n, and K_N^i, respectively.

Then, v_1, v_1', and v_0 are

$$v_0 = k_3([S]/K_m)[E]_0 / \{1 + (K_m/[S])(1 + [N]/K_N + [N']/K_{N'}) + [N]/K_N^i + [N']/K_{N'}^i\}, \quad (11)$$

$$v_1 = k_n([N]/K_N)([S]/K_m)[E]_0 / \{1 + (K_m/[S])(1 + [N]/K_N + [N']/K_{N'}) + [N]/K_N^i + [N']/K_{N'}^i\}, \quad (12)$$

and

$$v_1' = k_n'([N']/K_{N'})([S]/K_m)[E]_0 / \{1 + (K_m/[S])(1 + [N]/K_N + [N']/K_{N'}) + [N]/K_N^i + [N']/K_{N'}^i\}. \quad (13)$$

Also,

$$f_1 = k_n([N]/K_N)/\{k_3 + k_n([N]/K_N + k_n'([N']/K_{N'})\}, \quad (14)$$

and

$$f_1' = k_n'([N']/K_{N'})/\{k_3 + k_n([N]/K_N + k_n'([N']/K_{N'})\}. \quad (15)$$

This means that the ratio of the fractions for two amino acid amides is

$$f_1/f_1' = \{k_n([N]/K_N)\}/\{k_n'([N']/K_{N'})\}. \quad (16)$$

Where [N]=[N'], f_1/f_1' can be calculated from $K_{N(app)}$; the results are listed in parentheses. They are comparable to the experimental values. This supports the scheme presently considered for the reaction of carboxypeptidase W. Under similar conditions, carboxypeptidase Y gave more complex results: Fua-Phe-Phe was 37%, Fua-Phe-Gly-NH_2 18%, and Fua-Phe 45% at [Phe-NH_2]=[Gly-NH_2]=0.1 M. In this case an apparent "activation" of the amidase action on the once produced Fua-Phe-Phe-NH_2[20] was observed in the

presence of the second nucleophile (Gly-NH_2) (compare with the result listed in Table 1) and the present mechanism for carboxypeptidase W was not sufficient for explaining these results.

Thus, carboxypeptidase W was shown to have an efficient activity for a peptide synthesis from *N*-acyl amino acid ester and amino acid amide by an aminolysis of the acylated enzyme intermediate.

We gratefully acknowledge the advice and encouragement of Professor Norio Ise of Kyoto University.

Solid Phase Synthesis of Oligodeoxyribonucleotides Utilizing the Phenylthio Group as a Phosphate Protecting Group

Jun-ichi MATSUZAKI, Kyoko KOHNO, Shin-ichiro TAHARA, Mitsuo SEKINE, and Tsujiaki HATA*
Department of Life Chemistry, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227
(Received September 6, 1986)

Oligodeoxyribonucleotide synthesis utilizing the phenylthio group as a phosphate protecting group was applied to the solid phase method. The base residues of deoxyguanosine and deoxyadenosine were protected with bis(isobutyryloxy)ethylene (Bibe) and phthaloyl groups to avoid the base modification and depurination, respectively. A key synthetic intermediate of N^2-isobutyryl-N^1,N^2-bis(isobutyryloxy)ethylenedeoxyguanosine was prepared in high yield by four-step reaction from deoxyguanosine and used for preparation of the building blocks of deoxyguanosine required for the polymer support synthesis. Two kinds of polymer supports, i.e., 1% cross-linked polystyrene and controlled pore glass were chosen. The latter was employed for the synthesis of dodecadeoxyribonucleotides by using an automated DNA synthesizer.

In chemical synthesis of oligodeoxyribonucleotides, application of the phosphotriester[1] and phosphoramidite[2] methods to the solid phase synthesis has enabled us to prepare rapidly and practically DNA fragments of defined sequences.[3] Although the latter approach became accessible more successfully to molecular biologists, the former has recently been remarkably improved by introduction of new condensing agents and protecting groups.[4] Especially, we have also developed our own triester approach utilizing the phenylthio group as a phosphate protecting group.[5] In this paper, we wish to report application of our approach to the solid phase method.

Results and Discussion

Partially protected nucleosides (**1a—e**) were prepared by the literature method.[6,7] The amino goup of deoxyadenosine was protected with the benzoyl or phthaloyl group. Our recent study showed that the latter protecting group had considerable retarding effects on the depurination.[7]

Reese[8] and we[9] originally reported side reactions at the O^6-position of guanine residues when the remaining reactive site was not protected during condensations. To avoid such undesired reactions a number of new protecting groups have been proposed showing remarkable improvements.[10-15] In a previous paper,[12] we demonstrated the utility of the bis(isobutyryloxy)ethylene (Bibe) group as the so-called protected protecting group for the guanine base. This protecting group was readily removed under the same conditions as used for removal of the usual *N*-acyl protecting groups. However, the Bibe group has been introduced into the guanine residue only at the last stage of the synthesis of the deoxyguanosine monomer unit.[11] This is a drawback of the Bibe group although its introduction to the guanine base could be very easily performed by simple addition of glyoxal followed by acylation without coloration. Therefore, we searched for synthetic routes to N^2-isobutyryl-N^1,N^2-bis(isobutyryloxy)ethylenedeoxyguanosine (**1f**) which was a versatile synthetic intermediate for synthesis of

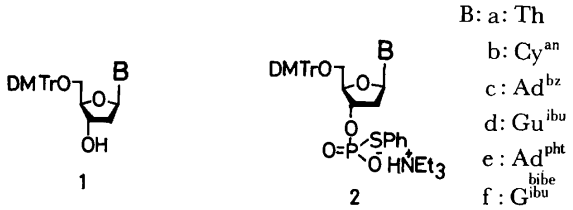

Fig. 1. Nucleoside and nucleotide units for the synthesis.

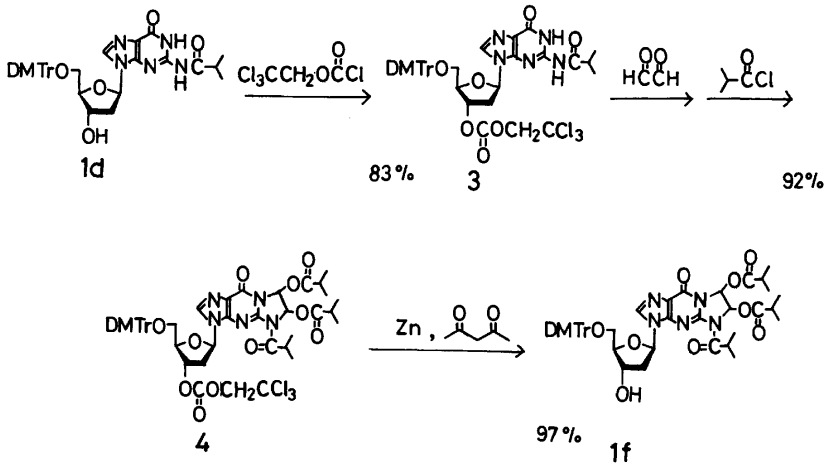

Fig. 2. Introduction of the bibe group into guanosine.

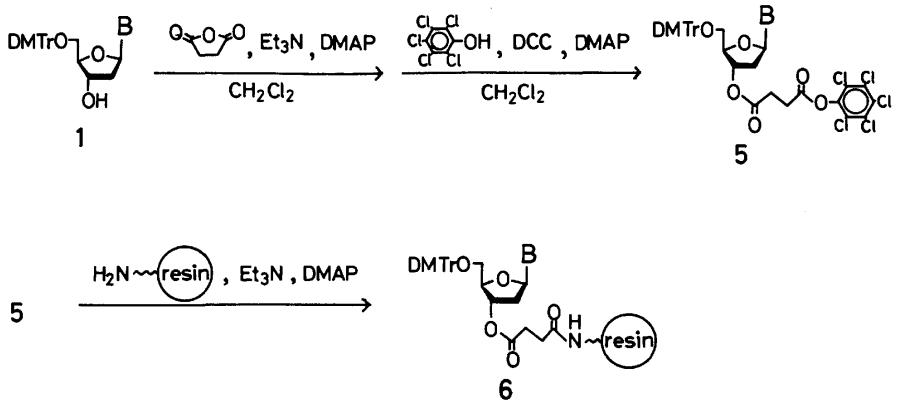

Fig. 3. Immobilization of the nucleosides onto resins.

appropriately protected deoxyguanosine derivatives (**5**, B=G^{ibu} and **2f**). For this purpose, the use of the transient protection procedure using trimethylsilyl chloride seemed to be difficult since the glyoxalation required a large excess of glyoxal which might work as a nucleophile toward the silyl group. Therefore, we chose a more stable protecting group as the 3′,5′-diol protecting group, i.e., the 2,2,2-trichloroethoxycarbonyl (TCECb)group.[7] As s hown in Fig. 2, deoxyguanosine was allowed to react with 2,2,2-trichloroethyl chloroformate and then the Bibe group was introduced to the guanine moiety. Finally, the fully protected nucleoside (**4**) was converted by treatment with zinc-acetylacetone to the desired compound (**1f**) in a 74% overall yield from **1d**.

Solid supports chosen in this study were controlled pore glass (CPG)[17] as an unswellable inorganic resin and 1% cross-linked polystyrene (P.S.)[18] as a swellable organic resin. The 3′-free nucleosides (**1**) were immobilized to the polymer supports according to the modified method of Itakura[19] (Fig. 3). Succinylation of **1** was performed by treatment with succinic anhydride in the presence of triethylamine and a catalytic amount of 4-dimethylaminopyridine (DMAP) in CH_2Cl_2 followed by esterification of the resulting carboxylic acid with pentachlorophenol by dicyclohexylcarbodiimide (DCC) and DMAP in CH_2Cl_2 after extraction. The activated nucleosides (**5**) were immobilized to the 3-aminopropyl group on the resin. The amounts of the nucleosides loaded on the supports were determined by spectroscopic estimation of DMTrOH released by the acid treatment and summarized in Table 2.

Oligomer Synthesis on Polystyrene. One % cross-linked polystyrene has been known to be one of suitable supports for the synthesis of oligonucleotides as reported by Itakura[18a] and Ohtsuka.[18b] We chose this support to prepare oligothymidylates by the use of the phenylthio group and bifunctional condensing reagents.[20] The phosphodiester (**2a**) of thymidylic acid was condensed to the thymidine resin (**6a**) by isodurenedisulfonyl chloride (DDS)[4a] and 3-nitro-1,2,4-triazole (NT)[21] for 1 h. For the detritylation, 1% trifluoroacetic acid (TFA) was used and the capping reaction was performed in the usual way. Reasonable results were obtained (Table 3) but not yet satisfactory. To realize a more smooth reaction on the swellable support, solvents capable of increasing the swellability in the reaction should be chosen. Therefore, dichloromethane was used in the condensation reaction and a few drops of pyridine was added to dissolve the catalyst, NT. A pentathymidylate was synthesized by using this solvent system under the same conditions as used in the above experiment but the reaction required 30 min. Better yields were obtained and the first coupling was optimized (Table 4). The capping reaction was performed by the use of acetic anhydride-triethylamine in dichloromethane in the presence of 0.1 M† DMAP for 5 min.

Table 1. Yields of the Activated Ester (**5**)

B	Succinylation/h	Esterification/h	Yield/%
Th	3	2	81
Cy^{an}	4	1	92
Ad^{bz}	4	1	87
Gu^{ibu}	4	2	96
Gu^{bibe}_{ibu}	4	2	88

Deprotection of the fully protected pentathymidylate was performed in two ways: A) 1) 0.1 M NaOH, pyridine-H_2O (1 : 1, v/v), 3 h 2) 80% AcOH, 15 min. B) 1) 2-pyridinecarbaldehyde oxime-tetramethylguanidine (TMG), pyridine-H_2O (9 : 1, v/v), 22 h 2) 80% AcOH, 15 min.

Isolation of the oligomer was performed by ion exchange HPLC (Partisil 10 SAX) and the yields of $T(Tp)_3T$ were 22 and 43% for methods A and B, respectively. These results would be ascribed to the swellability of the resin in the solvent used in the deprotection (step 1). Even in step 1 of method A, the resin was less swelled than in the condensation reaction where CH_2Cl_2 was used. After removal of the oligomer by filtration and washing with pyridine-H_2O (9 : 1, v/v),

Yield/%	91	91	89	92
	91	92	90	100

Condensation: Tymidine P.S. (50 mg, 5 μmole), phosphodiester (T, 50 μmole), DDS (100 μmole), NT (200 μmole), CH_2Cl_2-pyridine (50:3, v/v, 500 μl), r.t., 30 min. Capping; Acetic anhydride-triethylamine-CH_2Cl_2 (2:3:16, v/v/v, 1 ml), DMAP (0.1 mmole), r.t., 5 min.

TFA treatment of the resulting resin indicated that some amounts of oligomers remained in the cage of the resin. This phenomenon was not observed in the case of the CPG described below.

Oligomer Synthesis on the Glass Support. Controlled pore glass (CPG) has been reported as a suitable support for the synthesis of oligodeoxyribonucleotides in the phosphotriester[22] and the phosphoramidite[17] approaches. The thymidylic acid unit was condensed to deoxyribonucleosides on three kinds of CPG (Funakoshi) having the pore sizes of 170, 560, and 1500 A. The yields were essentially dependent on the pore size of resin and the reaction on 560 A CPG gave good results (Table 5). A similar result was obtained by Köster[17b] in his eary study on polymer supported synthesis. In this study, a rapid method for condensation reported by Effimov[23] was introduced to the present system by use of CPG. The sequence of dGpTpApC

Table 5. First Coupling Yields on CPGs

Pore size/A	Mesh	Coupling time/h	Yield/%
171	120—200	1	63
559	120—200	1	80
547	200—400	1	89
1489	120—200	1	11

Condensation: Cytidine CPG (100 mg, 3.2 μmole), phosphodiester (T, 32 μmole), DDS (64 μmole), NT (96 μmole), pyridine (320 μl), r.t., 1 h. Capping: The same conditions described as in Table 3.

was synthesized to search for a suitable condensation system. A phosphodiester (20 equiv), a condensing agent (20 equiv), and *N*-methylimidazole (MeIm) (30 equiv) were used in CH_3CN and the reaction was performed for 40 min. The bifunctional condensing reagent of DDS was not suitable because of its low solubilities compared with monofunctional reagents. A better result was obtained by using mesitylenesulfonyl chloride (MS) as the condensing reagent (Table 6). 2,4,6-Triisopropylbenzenesulfonyl chloride (TPS) gave relatively low yields. The yield, however, slightly increased with an increase of MeIm (100 equiv). Low viscosity of CH_3CN and rigidity of CPG were suitable for synthesis of oligomers by the use of a fully automated DNA synthesizer. To ascertain the coupling efficiency of the MS-MeIm system on CPG, we tried to prepare three kinds of fully protected sequences of dodecadeoxyribonucleotides involving $dT(pT)_{11}$ (**7**), dCpApTpTpApTpTpApApTpApC (**8**), and dGpTpApTpTpApApTpApApTpG (**9**). The latter two sequences were corresponding to a DNA analog of the 5′-terminus of brome mosaic virus (BMV) mRNA No. 4 filament[24] and its complementary sequence (Fig. 4), respectively. In the case of **8**, both the stepwise condensation and the block condensation were tried. The elongation program of DNA synthesizer (SAM 1, Biosearch) is presented in Table 7 and the yields of the condensation reactions are summarized in Fig 5. Among the fully protected dodecadeoxyribonucleotides synthesized on CPG, the protected dodecamers **8b** and **9** were deprotected according to the following conditions: 1) 0.1 M NaOH, pyridine-H_2O

Table 6. Synthesis of dGTAC on CPG

Isolation of the unprotected oligomer **8b** and **9** was performed by reversed phase HPLC (μBondapak C_{18}) in the usual manner. A typical example is shown in Fig. 6a. This standard separation procedure gave finally the pure 12 mers **8b** and **9** in 18 and 4% yields. An alternative procedure for isolation of the 12 mer **9**

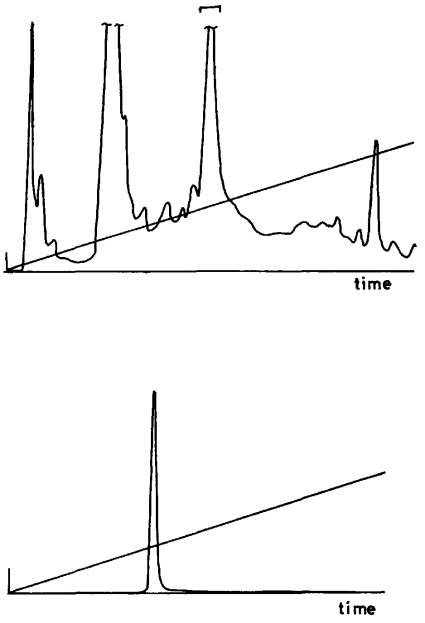

Fig. 6a. Chromatograms of dGTATTAATAATG on μBondapak C_{18}. Upper: After ammonia treatment, lower: Finally purified product.

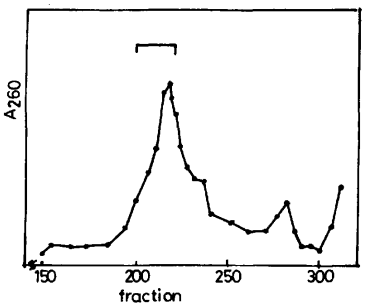

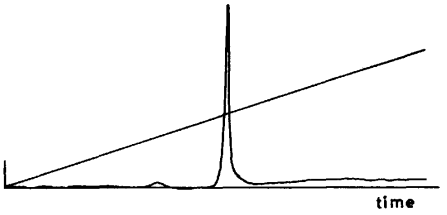

Fig. 6b. Chromatograms of dGTATTAATAATG on Sephadex G50 column (upper) and purified product on μBondapak C_{18} (lower).

was also conducted by using gel permeation column chromatography (Sephadex G 50). This gave an improved yield (12%) of the 12 mer. The separation profiles of the 12 mer are shown in Fig. 6b. The oligomers obtained were characterized by polyacrylamide gel electrophoresis (PAGE) and a modified Maxam-Gilbert sequencing method.[25]

Experimental

General Remarks. ^{1}H NMR spectra were recorded at 100 MHz on a JNM-PS-100 spectrometer using ppm according to tetramethylsilane as an internal reference. UV spectra were obtained on a Hitachi 124 spectrophotometer. Column chromatography was performed with silica gel C-200 purchased from Wako Co., Ltd. Thin-layer chromatography was performed on precoated TLC plates, silica gel 60 F-254 (Merck). Reagent grade pyridine was distilled twice from *p*-toluenesulfonyl chloride and CaH_2 and then stored over molecular sieves 4A. Dichloromethane was dried over phosphorus pentoxide overnight, decanted, distilled from potassium carbonate and then stored over molecular sieves 4A. Acetonitrile was distilled from calcium hydride and stored over molecular sieves 4A. 3-Aminopropyl polystyrene (1% cross linked) was purchased from Peptide Laboratory and aminopropyl CPGs from Electro Nucleonics Inc.. Deoxynucleosides were purchased from Yoshitomi-Seiyaku Co., and properly protected according to the literature.[4,5] The phosphodiester units were prepared according to our previous paper.[4] Ion-exchange HPLC was performed on a Partisil 10 SAX (Whatman) column using a linear gradient of 0.05 M KH_2PO_4 (pH 6.4), 20% CH_3CN to 0.5 M KH_2PO_4 (pH 6.5), 20% CH_3CN for 32 min at a flow rate of 1.5 ml ml^{-1}. Reversed phase HPLC was performed on a μBondapak C_{18} (Waters) using a liner gradient of 0.1 M NH_4OAc to 40% CH_3CN in the same buffer for 40 min at a flow rate of 2 ml at 50 °C. Elemental analysis was performed by the Microanalytical Laboratory, Tokyo Institute of Technology, at Nagatsuta.

5′-*O*-(4,4′-Dimethoxytrityl)-3′-*O*-(2,2,2-trichloroethoxycarbonyl)-N^2-isobutyryldeoxyguanosine (3). 5′-*O*-(4,4′-Dimethoxytrityl)-N^2-isobutyryldeoxyguanosine (3.2 g, 2 mmol) was rendered anhydrous by repeated coevaporation with dry pyridine and dissolved in dry pyridine (30 ml). 2,2,2-Trichloroethyl chloroformate (865 µl, 6 mmol) was added dropwise and the solution was stirred at room temperature for 2 h. Then the mixture was transferred into a separatory funnel with $CHCl_3$ and washed twice with 5% $NaHCO_3$. The aqueous layers were back-extracted with $CHCl_3$ and the combined organic layers were dried over Na_2SO_4. The solvent was removed under reduced pressure and the last traces of pyridine were coevaporated with toluene. The resulting foam was applied to a column of silica gel and eluted with CH_2Cl_2 containing methanol (0—1%, v/v) to give the title compound (3.24 g, 83%); mp 135 °C (decomp); ^{1}H NMR ($CDCl_3$) δ=0.98 (m, 12 H, $CH(CH_3)_2$), 2.69 (m, 2H, 2′H), 3.42 (m, 4H, 5′H, and $CH(CH_3)_2$), 3.80 (s, 6H, CH_3), 4.35 (m, 1H, 4′H), 4.79 (s, 2H, CH_2CCl_3), 5.58 (m, 1H, 3′H), 6.24 (m, 1H, 1′H), 6.82 (m, 4H, DMTr), 7.22—7.56 (m, 9H, ArH), 7.84 (s, 1H, 8).

Found: C, 55.62; H, 4.88; N, 8.33%. Calcd for $C_{38}H_{38}N_5O_9Cl_3$: C, 55.99; H, 4.70; N, 8.59%.

5′-*O*-(4,4′-Dimethoxytrityl)-N^2-isobutyryl-N^1,N^2-bis(isobutyryloxy)ethylenedoxyguanosine (4). Introduction of the Bibe group to **3** was performed according to our previous paper[6] in 92% yield. The fully protected guanosine derivative (2.2 g, 2 mmol) was coevaporated with dry pyridine (3×3 ml) and dissolved in dry pyridine (30 ml). To the solution, activated zinc powder (2.6 g, 40 mmol) and acetylacetone (4.1 ml, 40 mmol) was added and the suspension was stirred at room temperature. After 1 h, the solid material was filtered off and washed with pyridine. The filtrate and the washings were concentrated to one half the volume, transferred into a separatory funnel with $CHCl_3$, and washed three times with phosphate buffer (pH 6.0). The aqueous layers were back-extracted with $CHCl_3$ and the organic layer was washed with water. The organic layers were combined and dried over Na_2SO_4 and the solvent was removed under reduced pressure. Silica-gel column chromatography gave the desired compound in 97% yield (1.6 g); mp 123 °C (decomp); ^{1}H NMR ($CDCl_3$) δ=1.20 (m, 18H, $CH(CH_3)_2$), 2.60 (m, 5H, 2′H, and $CH(CH_3)_2$), 3.43 (m, 2H, 5′H), 3.82 (s, 6H, CH_3O), 4.18 (m, 1H, 4′H), 4.61 (m, 1H, 3′H), 6.32 (t, J=6 Hz, 1H, 1′H), 6.86 (m, 5H, 2,6-ArH of DMTr and one of OCH-CHO), 7.23—7.38 (m, 10H, ArH and one of OCH-CHO), 7.88 (s, 1H, 8H).

Found: C, 64.75; H, 6.54; N, 7.75%. Calcd for $C_{45}H_{51}N_5O_{11}$: C, 64.50; H, 6.14; N, 8.36%.

Pentachlorophenyl Nucleoside-3′-*O*-succinate (5). Typical procedure: 5′-*O*-DMTr-N^4-anisoyldeoxycytidine (680 mg, 1 mmol) was coevaporated with dry pyridine several times and dissolved in dry dichloromethane (10 ml). To the solution were added succinic anhydride (120 mg, 1.2 mmol), DMAP (12 mg, 0.1 mmol), and triethylamine (168 µl, 1.2 mmol). The reaction was performed at room temperature for 4 h. Then the mixture was transferred into a separatory funnel with dichloromethane (50 ml), and washed with an aqueous solution of citric acid (0.9%, 50 ml×2). The aqueous layers were back-extracted with CH_2Cl_2 (50 ml) and the organic layer was washed with water. These organic layers were combined and dried over Na_2SO_4. The solvent was removed under reduced pressure and pentachlorophenol (300 mg, 1.1 mmol) was added to the resulting foam. The mixture was rendered anhydrous by repeated coevaporation with dry pyridine and dissolved with dry CH_2Cl_2 (10 ml). DMAP (12 mg, 0.1 mmol) and DCC (310 mg, 1.5 mmol) were added to the solution and the mixture was stirred at room temperature for 1 h. Then the solid material was removed by filtration and washed with benzene. The filtrate and the washings were mixed and the solvent was removed under reduced pressure. Benzene (5 ml) was added and the resulting solid was filtered and washed with benzene (3 ml×3). The same procedure for removal of *N*,*N*′-dicyclohexylurea (evaporation, addition of benzene and filtration) was repeated one more time. The final filtrate and washings were evaporated and dissolved in CH_2Cl_2 (2 ml) and dropped into hexane–ether (7 : 1, v/v, 300 ml) with continuous stirring. The white precipitate was collected by filtration and dried in a desiccator (946 mg, 92%). This compound was characterized by comparison of its NMR spectrum with that of an authentic material.

Immobilization of Deoxyribonucleosides on Resins. General Procedure: A 3-aminopropyl resin (1 g) was rendered anhydrous by coevaporation with dry pyridine. An activated nucleoside (**5**) (0.1 mmol) and DMAP (0.01 mmol) dissolved in dry CH_2Cl_2 (10 ml) were added to the resin. Triethylamine (0.1 mmol) was added dropwise to the mix-

ture and the resulting suspension was slowly rotated for 1 h by the use of an evaporator. The resin was filtered and washed with CH_2Cl_2 and the unreacted amino group was blocked by the acetyl group by the reaction with acetic anhydride and DMAP in dry pyridine for 1 h. Finally, the nucleoside resin was obtained by filtration, washing with pyridine and CH_2Cl_2, and drying in vacuo. The loading amounts of nucleosides on the resin are listed in the text.

Synthesis of Oligomers on Resins. In the mannual preparation, the synthetic reactions were most conveniently carried out in a glass column with a sintered glass filter and a two way value which end was connected with a collection tube. During the drying step, the top of the column was joined to a vacuum pump and rotated by a rotary evaporator.

A reaction cycle consisted of the following steps: 1) A nucleoside resin in the column was treated with 1% TFA for 30 seconds repeatedly until the color of DMTr cation had disappeared, and the resin was washed with $CHCl_3$ (3 ml) three times. 2) The resin was rendered anhydrous by coevaporation with dry pyridine and mixed with a phosphodiester previously dried by coevaporation with dry pyridine. A condensing reagent was added to the mixture and the final concentration of the phosphodiester was about 0.1 M. The reaction was performed at room temperature with gentle rotation in the case of the CPG or with standing in the case of the polystyrene. 3) After the condensing reaction, all soluble reagents were washed out with pyridine several times, and the remaining 5′-hydroxyl group was blocked by the usual capping reaction, 4) The resin was washed with pyridine and then with $CHCl_3$ several times. Return to step 1, for the next cycle.

In the case of using the automated synthesizer, the resin was packed in a mini column and the reactions were carried out by continuous flow by a solvent pump. All reagents and solvents were delivered from reagent bottles being confirmed with the cycle program listed in the Table 7.

Yields of the condensing reactions were determined by estimation of released DMTr cation with a value of ε_{498}= 71700 (60% $HClO_4$: EtOH=3 : 2, v/v).

Deprotection of Oligomers by NaOH Method. The synthetic oligomer immobilized to a resin was treated with 0.1 M NaOH in pyridine-water (1 : 1, v/v) at room temperature for 1 h. The heterogeneous reaction mixture was applied to a mini column of Dowex 50 W×2 (pyridinium form, 1.5 ml of wet volume) and eluted with pyridine-water (1 : 1, v/v, 10 ml). All the eluent was collected and concentrated in vacuo and treated with concd aqueous ammonia at room temperature for 30 h and then at 50 °C for 1 h. The solution was carefully evaporated under reduced pressure, and in the case of the purification procedure by reversed phase HPLC, the resulting mixture was chromatographed on a μBondapak C_{18} (Waters) column and the desired fraction was collected and lyophilized to the solid. Then 5′ DMTr group was removed by treatment with 80% acetic acid for 15 min and concentrated by evaporation in vacuo. The oligomer was finally purified by rechromatography on a reversed phase HPLC column or by gel filtration chromatography with Shephadex G50 (2×150 cm, 0.05 M HCO_3^-). Purities of the oligomers obtained were analyzed by the HPLC or polyacrylamide gel electrophoresis (UV illumination) and the sequences were determined by the modified Maxam-Gilbert method.[15]

We thank Dr. Akiko Kume, Mr. Yasuo Ohta, Mr. Hitoshi Hotoda for their technical assistance and also thank Mrs. Chieko Sugimura for preparation of this manuscript. This work was supported by a Grant-in-Aid from the Ministry of Education, Science and Culture.

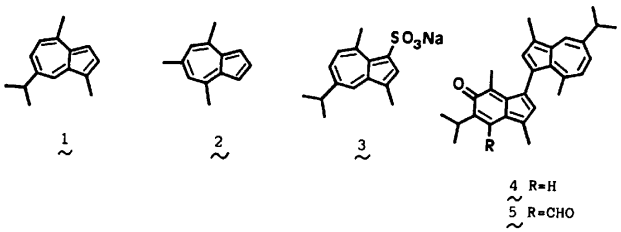
(Received September 16, 1986)

Autoxidation of guaiazulene and 4,6,8-trimethylazulene at 100—120 °C in DMF (or HMPA) respectively yielded 25 and 17 separable products, including several known compounds. Most of these new compounds were derivatives of 1,5- and 1,7-azulenequinone, 1*H*-inden-1-one, naphthoquinone, and benzenoid, or dimeric and trimeric forms; structures of these products were established on the basis of spectroscopic (NMR, UV, IR, and MS) and half-wave potential ($E_{1/2}$) data. ^{1}H NMR (200-MHz) parameters of various azulene derivatives are given for comparative study. Possible reaction pathways are suggested for the formation of such a wide variety of interesting products.

Azulene and its derivatives constitute a highly interesting class of compounds due to the fused five-seven bicyclic aromatic ring system. Thus azulenes have been regarded as one of the representative examples of nonbenzenoid aromatic hydrocarbons, which usually do not undergo Diels-Alder-type addition reactions but are easily susceptible to many electrophilic substitution reactions (most easily at the 1 and/or 3 position).[2)]

It has been long-known that some azulenes gradually suffer oxidation even on exposure to air at room temperature and this air oxidation is facilitated by light. Pailer and Lobenwein[3)] have found that, when adsorbed on the surface of silic gel and exposed to air, naturally originating guaiazulene (**1**) gave three major products: 3,3′-biguaiazulene (**1B**, see below) and two guaiazulenylindenones for which the 5*H*-inden-5-one structures (**4**, **5**) were presented. Precise studies on the facile autoxidation of azulenes (especially **1**) are exceedingly of interest in view of preparation of a number of pharmacologically important azulenes because of the fact that a clinically used anti-inflammatory sodium guaiazulene-3-sulfonate (**3**), for example, gradually decomposes on standing but is stabilized by the presence of oxygen-absorbers in the tablet package.[4)] Moreover, information on a general aspect of the reaction mechanism of oxidation of azulenes would be important in exploiting an expedient conversion of azulenes directly to many valuable compounds such as polyazulenes[5)] and azulenequinones,[6)] syntheses of which are currently drawing an increasing interest because of the potential utility of their physicochemical properties as well as biological activity. In this paper, by employing two trialkylazulenes [**1** and 4,6,8-trimethylazulene[7)] (**2**)] as model compounds, we wish to describe the first detailed study on autoxidation of azulenes, together with presumable reaction pathways for the formation of a wide variety of the products, most of which possess highly interesting structures.



Results and Discussion

Autoxidation of Guaiazulene (1). The oxidation was carried out by passing finely bubbling oxygen into a solution of the substrate **1** in DMF (or HMPA) at 100 °C. When the reaction was monitored by the use of silica-gel TLC and the reversed phase high-pressured liquid chromatography (HPLC), simultaneous formation of more than twenty kinds of products was observed over a period of 24 h (see Fig. 1). In order to examine an earlier stage of the oxidation, the reaction products were separated into each component by using chromatography, when about a half of the starting material was consumed. The products thus obtained as pure components (25 altogether besides the recovered starting material **1**) are referred to as Compounds **1A—S** according to their decreasing R_f values on silica-gel TLC (developed with 15 : 85 AcOEt–hexane); when more than two products are separated from the same fraction by using a different kind of solvent system, they are further distinguished by a subscript number (see Fig. 1).

In Chart I are summarized structures of these products which were established by UV-visible, IR, high-resolution mass (MS), and ^{1}H NMR (and ^{13}C NMR for some compounds) spectroscopy as will be explained below. The theoretical yields of these isolated products (see Experimental Section) totaled to 54%; besides these, there still remained ca. 34% (w/w) yield of unidentified resinous polar products of rather high molecular weights.

Compound $\mathbf{1A}_1$ was the unreacted starting material **1** from the spectroscopic and chromatographic data.

a) Chemical shifts (δ) are parts per million from Me_4Si measured in $CDCl_3$ (concn <ca. 0.5% v/v). Coupling constants (J, Hz) were confirmed by double resonance. b) Me. c) *i*-Pr; J=7.0 Hz. d) $J_{2,3}$=4.0 Hz. e) $J_{5,6}$=11.0 Hz. f) $J_{6,8}$=2.0 Hz. g) CH_2. h) Ac. i) CHO. j) For the purpose of comparison, the numbering of this compound corresponds to that of the starting material. k) δ 3.05 and 3.17 (both 3H, s, Me_2NCOO-3). l) COOH. m) $J_{2,8}$=0.5 Hz. n) $J_{Me(1),2}$=1.5 Hz. o) There exist a set of three singlets (3:2:1) due to (-CH_2NMeCHO) at (**a**) δ 2.82, 5.00 and 8.13, (**b**) δ 2.72, 5.11 and 8.13, **a** and **b** being a 3:2 mixture due to restricted rotation of the C-N bond in the amide group; a large number of similar patterns are observed for many amide, e.g., see A. Mannschreck, *Tetrahedron Lett.* **1965**, 1341. p) $J_{5,7}$= 0.5 Hz. q) OHCCH-1; also present is a doublet at δ 10.06 (1H, J=2.3 Hz, CHO). r) $J_{5,Me(6)}$=1.5 Hz. s) There singlets (3:2:1) due to (-CH_2NMeCHO) at δ 3.08, 5.25, and 8.23. t) A set of there singlets (3:2:1) due to (-CH_2NMeCHO) at (**a**) δ 2.88, 5.07, and 8.21, (**b**) 2.77, 5.16 and 8.21, **a** and **b** being a 3:2 mixture; see Ref. in o).

For the purpose of comparison in determining the structures of the oxidation products, the 200-MHz ^{1}H NMR parameters for **1** and other important azulene derivatives obtained in the present study are summarized in Table 1, although slightly different values have been reported for a few of these azulenes (mostly measured at 60-MHz in much concentrated CCl_4 or CH_2Cl_2 solutions).[3,8] Compound **1A$_2$**, one of the major products of this oxidation, was spectroscopically (MS and ^{1}H NMR) identical with known 3,3′-methylenebisguaiazulene.[9] While the chemical shifts of other signals of **1A$_2$** closely resembled those of **1**, an appreciable upfield shift (δ ca. 0.5) was observed for the H-2 signal (see Table 1) presumably due to an electronic as well as an anisotropic effect by a nonplanar conformation of the two azulene nuclei owing to the steric repulsion.

Compound **1A$_3$** was shown to have a composition of $C_{30}H_{34}$ by MS and the structure of 2,3′-biguaiazulene was assigned to this minor product by the careful comparison of the ^{1}H NMR spectral data (see Table 1), as well as their melting points, with those of the reported 2,2′- and 3,3′-biguaiazulenes.[10] Compound **1B** was confirmed by spectroscopy to be identical with 3,3′-biguaiazulene;[3,10] an appreciable upfield shift (δ ca. 0.65) for Me-4 signal in the ^{1}H NMR spectrum (see Table 1) by the same reason as described for **1A$_2$** should be noticed.

Compounds **1A$_5$** ($C_{15}H_{18}$) and **1A$_4$** ($C_{30}H_{34}$ by MS) were shown spectroscopically to be 4-isopropyl-1,6-dimethylnaphthalene (cadalene) and its 2,2′-dehydro dimer, respectively. The assignment of the oxidative coupling position of the new naphthalene dimer **1A$_4$** was based on the ^{1}H NMR data (see the Experimental Section). Compounds **1D** and **1R** were identified by MS, IR, UV, and NMR spectroscopy to be 8-isopropyl-2,5-dimethyl-1,4-naphthoquinone[11] and the 1,2-naphthoquinone derivative,[11b] respectively, both of which had been obtained by autoxidation of **1A$_5$** under the same conditions.[11b]

Compound **1C** ($C_{29}H_{32}O$) and **1H$_1$** ($C_{30}H_{32}O_2$ by MS) appeared to be identical (by ^{1}H NMR) with the autoxidation products which had been obtained[3] from **1** by autoxidation on the surface of silica gel and respectively assigned to be the 3-guaiazulenyl-5*H*-inden-5-one derivatives **4** and **5**. The 1*H*-inden-1-one structures **1C** and **1H$_1$**, however, were apparently more compatible with the observed spectral data, taking into account the spectral parameters for the related 1*H*-inden-1-one derivatives **1E** and **1I**, as well as consider-

ing the mode of formation of these products from **1** (see later); the corrected assignments of the 200-MHz ^{1}H NMR data of **1C** and **1H$_1$** are shown in the Experimental Section.

Compounds **1E** and **1G** (both $C_{14}H_{16}O$ by MS) turned out to be non-azulenic compounds (by UV) but contained a conjugated carbonyl group (IR). Structures of 1*H*-inden-1-one (**1E**) and the prototropic isomer 2,3-dihydro-3-methylene-1*H*-inden-1-one (**1G**) were assigned to these products by taking into consideration the reported ^{1}H NMR data of structurally related parent 1*H*-inden-1-one[12] and 2,3-dihydro-3-alkylidene-1*H*-inden-1-ones.[13] It has been noted that 1*H*-inden-1-one (**1E**) was converted to **1G** gradually on standing (or more quickly when dissolved in $CDCl_3$) at 25 °C, and then slowly gave four kinds (by TLC and GC-MS) of colorless dimers.[14] The lability of these indenones **1E** and **1G** are in analogy with the case of the parent 1*H*-inden-1-one which has been recorded to dimerize quickly at room temperature.[12] Compound **1I** ($C_{15}H_{16}O_2$ by MS) were assigned to the 6-formyl derivative of **1E** on the basis of IR and ^{1}H NMR spectra. Interestingly, this monoformyl compound has been found, on standing at 25 °C, to rearrange to the diformyl compound **1N** (see below). The assignments of the NMR data, which are in good agreement with the proposed structures **1E**, **1G**, and **1I**, are recorded in the Experimental Section.

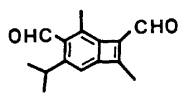
Compounds **1F$_1$** and **1F$_2$** (both $C_{14}H_{18}O$ by MS) were found spectroscopically to be both benzenoid derivatives, namely (*Z*)-4-(5-isopropyl-2-methylphenyl)-3-buten-2-one and (*Z*)-3-(5-isopropyl-2-methylphenyl)-2-butenal, respectively. Compound **1P** was the corresponding carboxylic acid of **1F$_2$** on the evidences of the MS, UV, IR, and NMR spectra (Experimental Section). The (*Z*) configuration of **1F$_1$** was derived from the magnitude of the medium $J_{3,4}$ value (11.0 Hz), while the same (*Z*) configuration of **1F$_2$** and **1P** were decided on the basis of the close similarity in the UV absorption maximums (and the δ values of H-2 and H-6′) between **1F$_1$** and **1F$_2$**/**1P**.

Compound **1H$_2$** was an extremely minor product which possessed a trimeric composition of $C_{45}H_{48}O$ (by MS) and a carbonyl group (1720 cm^{-1}) attached to C-1 of a guaiazulene nucleus (UV λ_{max} 538 nm). Although its NMR data were not available because of the limited amount of the material, the structure of **1H$_2$** shown in Chart 1 is proposed for this compound from the above spectral data and also by considering the most favorable mode of oxidative trimerization of guaiazulene.

Compound **1J** possessed an acetyl group (instead of an isopropyl) conjugated to the azulene nucleus (by UV, IR, and ^{1}H NMR). Structure of 7-acetyl-1,4-dimethylazulene was therefore assigned to this extremely minor product; see Table 1 for the NMR parameters for **1J**. Compounds **1K** and **1O** were indentified spectroscopically as 7-isopropyl-4-methyl-1-azulenecarbaldehyde and the corresponding carboxylic acid derivative, respectively.[15] Compound **1L** was found to be also the known 3-formyl derivative[15,16] of **1** on the basis of spectral data. The 200-MHz ^{1}H NMR parameters for these compounds are given in Table 1.

Compound **1M$_1$** was spectroscopically identical with bis(3,3′-guaiazulenyl) ketone;[17] although Fry et al.[18] have reported 60-MHz ^{1}H NMR data, more precise 200-MHz parameters for this compound are given in Table 1. Compound **1M$_2$** ($C_{18}H_{23}NO_2$ by MS) contained a dimethylcarbamoyloxy group attaching to guaiazulene nucleus on the evidence of the UV, IR, and ^{1}H NMR data (Table 1). The position (C-3) of the carbamoyl group on the guaiazulene nucleus was derived from the close resemblance of the visible absorption maximums (634 and 654 nm) with those of structurally similar 1-azulenyl benzoate (610 and 644 nm),[19] as well as by judging from the appearance of H-2 signal at relatively low field (7.35) in the NMR spectrum.

Compound **1N**, which is a structural isomer (by MS) of **1I** (see above), contained two formyl groups (1715 and 1700 cm^{-1}; δ 10.56 and 10.68, both singlets) and only one aromatic proton (δ 7.02, singlet), in addition to two methyl (δ 2.68 and 2.90, singlets) and an isopropyl (δ 1.28 and 3.65) groups. The UV spectra (λ_{max} 269, 317, 344, and 418 nm) suggested no azulenyl structure in the molecule. This compound was stable even in air when kept as solid at below 5 °C, but in a $CHCl_3$ solution at 25 °C **1N** gradually gave four kinds (by TLC and GC) of colorless dimers.[14],*



6

Compound **1Q** ($C_{15}H_{16}O_2$ by MS) was assigned to 5-isopropyl-3,8-dimethyl-1,7-azulenequinone on the evidences of UV, IR, NMR spectral data which were in conformity with the reported values of parent 1,7-azulenequinone;[6d] the assignments of the ^{1}H and ^{13}C NMR data are shown in Table 1 and Experimental Section, respectively. This compound is stable on standing at room temperature as in the case of the parent 1,7-azulenequinone.[6d] The quinone structure was confirmed by rather low values of the two half-wave potentials (E_1=−1.13 and E_2=−1.52 V) of **1Q** obtained by cyclic voltammetry.[20]

Compound **1S** was found to be a condensation product of **1** with a molecule of DMF; the position of the substitution at C-2 was derived by comparison of the ^{1}H NMR data (Table 1) with those of **2L** and **2M** (see later).

*For a possible structure of **1N** we tentatively suggested[1] 4-isopropyl-2,6-dimethylbenzocyclobutene-1,5-dicarbaldehyde (**6**). However, the precise structure for **1N** is currently under investigation in relation to those of the dimeric products.[14]

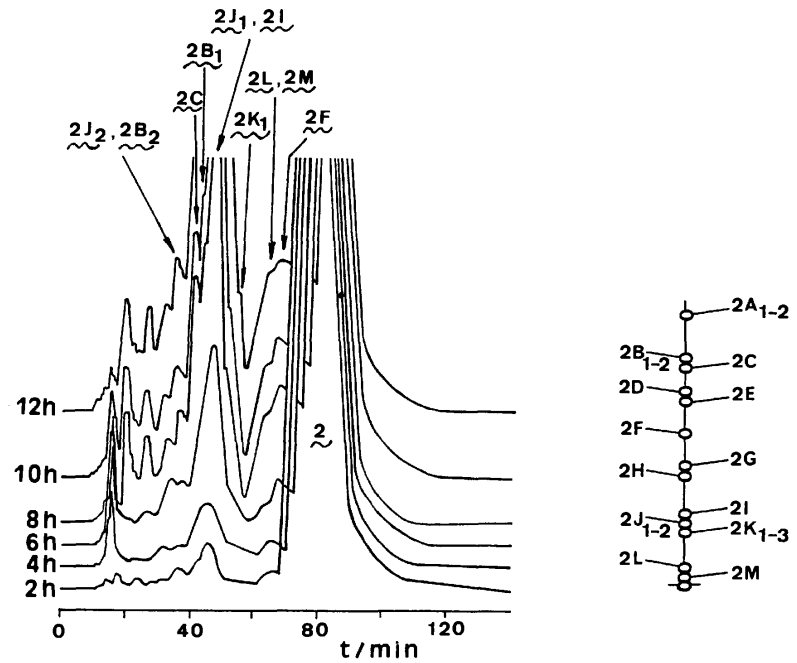


Fig. 2. Time-dependent HPLC diagram of autoxidation of **2** in DMF at 120°C and TLC diagram of the oxidation products from **2**.

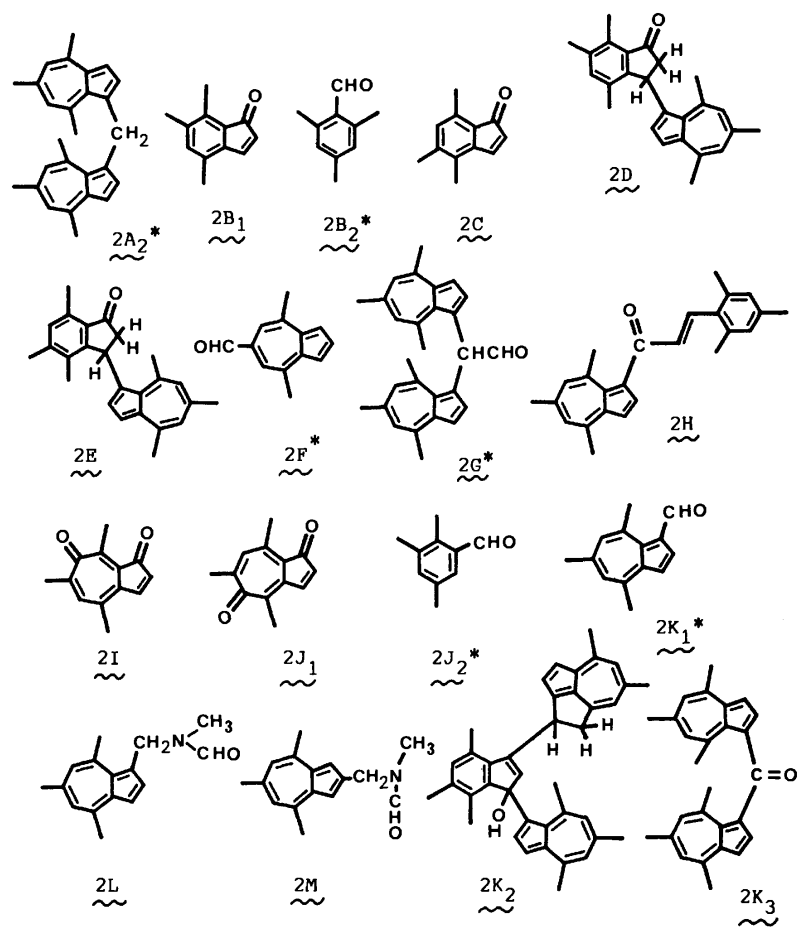

Chart 2. Structures of autoxidation products of 4,6,8-trimethylazulene (**2**); *Previously known compounds.

Autoxidation of 4,6,8-Trimethylazulene (2). The oxidation was carried out in DMF or HMPA at 120 °C for 12 h in a manner similar to that described for **1** and a complex HPLC diagram (Fig. 2) was also obtained, when the reaction was monitored by HPLC; in contrast to that of **1**, the oxidation of **2** took place very slow by at 100 °C. The resulting mixture (see TLC in Fig. 2) was carefully separated by using chromatography, and 17 products (**2A—M**) were obtained as pure components besides the recovered starting material **2** (**2A**$_1$). Structures of these products which have been established as follows are shown in Chart 2. The total theoretical yields of these isolated products were 28%, although there still remained a large amount (59% w/w) of unidentified polar products of relatively high molecular weights as well as a certain amount of inseparable **2**.

Compounds **2A**$_2$ ($C_{27}H_{28}$) and **2K**$_3$ ($C_{27}H_{26}O$ by MS) were readily found to possess structures 1,1′-methylenebis(4,6,8-trimethylazulene) and bis(4,6,8-trimethyl-1-azulenyl) ketone on the basis of their ^{1}H NMR data which closely resembled those of **1A**$_2$ and **1M**$_1$, respectively. The NMR parameters for these new compounds are summarized in Table 1.

Compounds **2B**$_1$ and **2C** (both $C_{12}H_{12}O$ by MS) were spectroscopically assignable to two isomers of 1*H*-inden-1-one having three methyl substituents on the six-membered ring: The structures were presumed to be 4,6,7-trimethyl- and 4,5,7-trimethyl-1*H*-inden-1-one, respectively, when the chemical shifts of the concomitant methyl and ring proton signals (δ 2.22 and 6.88 for **2B**$_1$ vs. δ 2.15 and 6.76 for **2C**) were compared in view of an electronic and anisotropic shift exerted by the carbonyl group on the five-membered ring. Assignments of the NMR data are given in the Experimental Section. Indenones **2B**$_1$ and **2C** both yielded three kinds of dimers[14] on standing at 20 °C.

Compounds **2B**$_2$ and **2J**$_2$ were identified as 2,4,6-[21] and 2,3,5-trimethylbenzaldehyde,[22] respectively, by spectroscopy (MS and NMR).

Compounds **2D** and **2E** (both $C_{25}H_{26}O$ by MS) consisted of a 4,6,8-trimethyl-1-azulenyl group and a 2,3-dihydro-1*H*-inden-1-one moiety having three methyl groups on the six-membered ring. The presence of ABX proton signals (at δ 2.7, 3.3, and 5.4—5.5) as well as a considerable upfield shift (δ ca. 1.0) of the Me-4 signal of the 1-azulenyl moiety indicated that the azulenyl group was linked to C-3 of the indenone moiety for both **2D** and **2E**. The chemical shifts of the singlets at δ 7.14 and 7.00 due to the aromatic six-membered ring proton of **2D** and **2E** suggested the structures of 4,6,7-trimethyl- and 4,5,7-trimethylindenone, respectively, for these products. The assignments of the NMR signals are recorded in the Experimental Section.

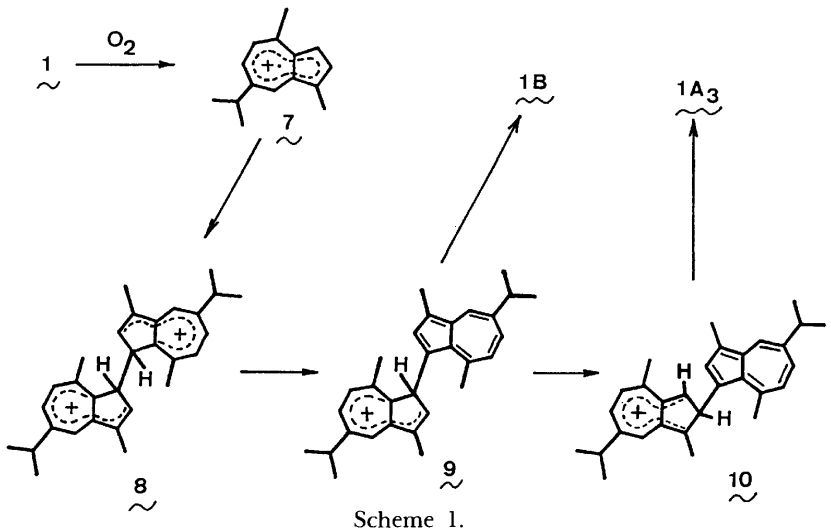
Compounds **2F**, **2G**, and **2K**$_1$ were identified by spectroscopy to be all known compounds, namely 4,8-dimethyl-6-azulenecarbaldehyde,[23] bis(4,6,8-trimethyl-1-azulenyl)acetaldehyde,[24] and 4,6,8-trimethyl-1-azulenecarbaldehyde,[16a] respectively; the 200-MHz ^{1}H NMR parameters for these products are summarized in Table 1. Compound **2H** ($C_{25}H_{26}$ by MS) contained a carbonyl group (1710 cm^{-1}) attached to C-1 of the 4,6,8-trimethylazulene moiety (from UV and ^{1}H NMR data). In addition, **2H** possessed a unique (*E*)-(2,4,6-trimethyl)styryl group linked to the carbonyl group on the ground of the NMR data; the (*E*) configuration was derived from the large *J* value (16 Hz) of the vinyl proton coupling; see Experimental Section for assignments of the NMR data.

Compounds **2I** and **2J**$_1$ (both $C_{13}H_{12}O_2$ by MS) were shown by the analysis of their spectroscopic data to be 4,6,8-trimethyl-1,7-azulenequinone and the corresponding 1,5-quinone, respectively. All data were in accord with those of the reported parent 1,7- and 1,5-azulenequinone[6d] as well as that of the trialkyl derivative **1Q**; see Table 1 and Experimental Section for the assignments of ^{1}H and ^{13}C NMR data. These trimethylazulenequinones are stable on standing at room temperature as in the case of **1Q**. The two half-wave potential values[20] (E_1/E_2) obtained for **2I** and **2J**$_1$ were −1.05/−1.5 and −1.05/−1.46 V, respectively, which are slightly higher than those of **1Q** (see above).

Compound **2K**$_2$ ($C_{39}H_{38}O$ by MS) contained a hydroxyl group (3750—3150 cm^{-1}) and a 4,6,8-trimethyl-1-azulenyl group (UV and ^{1}H NMR). Furthermore, the careful analysis of the NMR data obtained by a decoupling technique indicated the presence of 1,3-disubstituted 1*H*-inden-1-ol having three methyl groups on the six-membered ring. The rest of the molecule constituted of 1,8-disubstituted 4,6-dimethylazulene that exhibited ABX proton signals at δ 4.10, 4.39, and 5.40 (J_{AB}=4.0, J_{AX}=7.5, and J_{BX}=0.5 Hz). Combination of these spectral data led to 3-(1,2-dihydro-5,7-dimethylcyclopenta[*c*,*d*]azulen-2-yl)-4,6,7-trimethyl-1-(4,6,8-trimethyl-1-azulenyl)-1*H*-inden-1-ol as the most probable structure for **2K**$_2$.

Compounds **2L** and **2M** (both $C_{16}H_{19}NO$ by MS) were shown by UV, IR, and ^{1}H NMR data to be 4,6,8-trimethylazulene having an *N*-formyl-*N*-methylaminomethyl group at C-1 and C-2, respectively; see Table 1 for assignments of the NMR data of these compounds.

Possible Reaction Pathways for the Formation of Autoxidation Products of 1 and 2. The findings that the present autoxidation of the trialkylazulenes **1** and **2** has resulted in the simultaneous formation of many kinds of products even at an early stage are strongly indicative of the presence of a large number of highly competitive processes during the oxidation obviously initiated by attack of oxygen diradical[25] (or various other free radical species) on several sites of the azulene nucleus. Although electrophilic substitution reactions of azulenes are well-known to take place most easily at the 1 position,[2] no detailed study on radical reactions of azulenes has been made thus far, except for a few, brief descriptions on radical methylation,[26] benzyla-



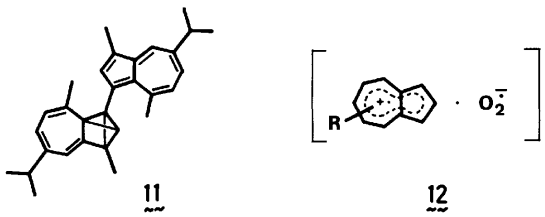
Scheme 1.

tion,[27] and bezoyloxylation,[19] all of which yield the corresponding substitution products preferentially at C-1. Nevertheless, since an unprecedented large number of products have been isolated in a high total, reproducible yield by noncatalyzed autoxidation of the two trialkylazulenes and most of their structures have been established in the present study, an attempt will now be made to suggest presumable reaction pathways for the formation of such a variety of products for the purpose of further detailed investigations of oxidation reactions of azulenes. For convenience, mechanistic considerations on the products from both **1** and **2** are concurrently made after having been divided into several groups according to the site of the oxidation on the azulene nucleus and the type of the products, as illustrated in the following Schemes 1—7.

Oxidative Dimerization. Because of the relatively high reduction potential (E_{pa} 0.71 V vs. SCE),[5] guaiazulene **1** is expected to be very easily oxidized by molecular oxygen, giving the radical cation **7** (see Scheme 1). This in turn undergoes a radical dimerization with a second molecule of **7** to give **8**. Subsequent proton loss from this dimeric cation would lead to the intermediate **9**, which then yields a major product 3,3′-biguaiazulene (**1B**) and a smaller proportion of the 2,3′-isomer (**1A**$_3$) (most likely through the isomerized intermediate **10**). It is assumed that the linkage of the coupling takes place between the sites (C-3) of the highest spin density in the cation radical **7** in the above radical dimerization. At present stage, we consider that such a pathway as described here is the most favorable for this dimerization on the grounds of (a) a preliminary theoretical calculation of the π-electron density in **1** and **7** in connection with the problem of the linkage[28a] and (b) isolation of a high yield of a 2 : 1 mixture of **1B** and **1A**$_3$ by the anodic oxidation of **1** which apparently proceeds through condensation of the radical cation **7**.[28b]

Both dimers **1B** and **1A**$_3$ have remained virtually unchanged on heating in DMF at 100 °C for 24 h in the absence of oxygen. Therefore, once these products are formed, no radical-catalyzed, thermal interconversion would exist between these two products through an equilibrium intermediate **11** analogous to the one proposed for the thermal conversion of 1-phenylazulene to the 2-phenyl isomer.[29]

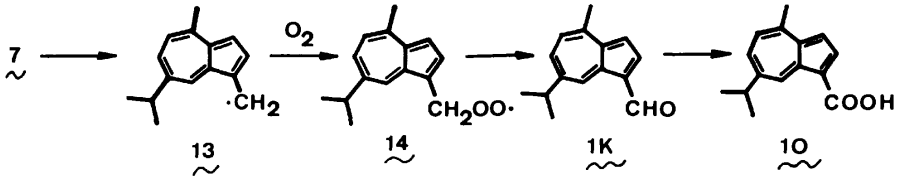
No such 1,1′- or 1,2′-dimer was isolated among the products from 4,6,8-trimethylazulene **2** under these autoxidation conditions apparently due to further polymerization at 1,3-positions, whereas an appreciable amount of a 2 : 1 mixture of such 1,1′-dimer and a trimer containing 1,2′-linkage were obtained by the anodic oxidation of **2**.[28b]



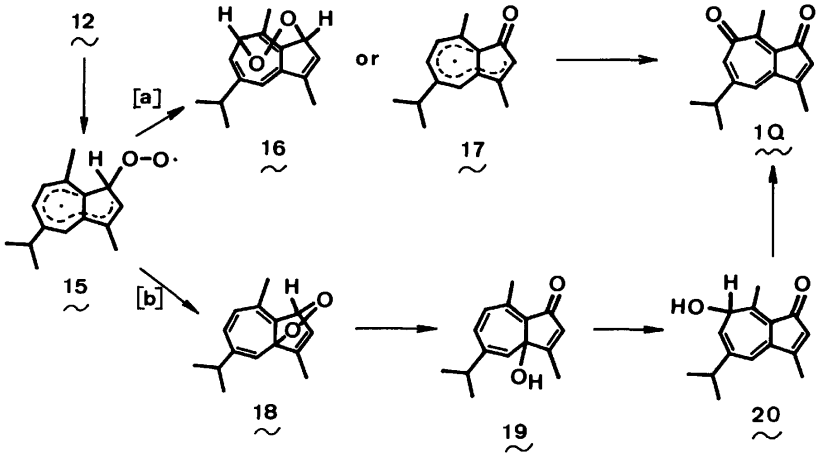
11 **12**

Although such oxidative dimerization described above takes place as one of the major pathways, other products are derived by oxidation of the starting azulenes with oxygen molecule ($^3O_2$), apparently proceeding through a complex shown as formula **12** by an electron transfer.[30] This complex is then expected to lead to a covalent linkage between the azulene nucleus and active radical species such as $^{\cdot}OO^-$, $^{\cdot}OOH$, and $^{\cdot}OH$ (or even $^1O_2$ produced during the oxidation) at various positions according to the ease of their affinity and steric requirement, thus providing several kinds of key intermediates for the formation of a wide variety of other products as outlined in Schemes 2—7.

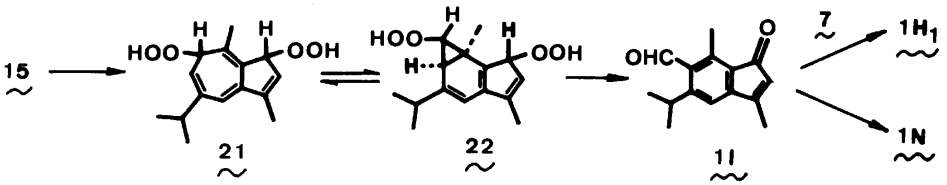
Oxidation of Side Chain. Scheme 2 illustrates the proposed reaction pathways for the products formed by oxidation of the side chains. One of the major product **1K** is considered to be derived by the attack of



Scheme 2.



Scheme 3.



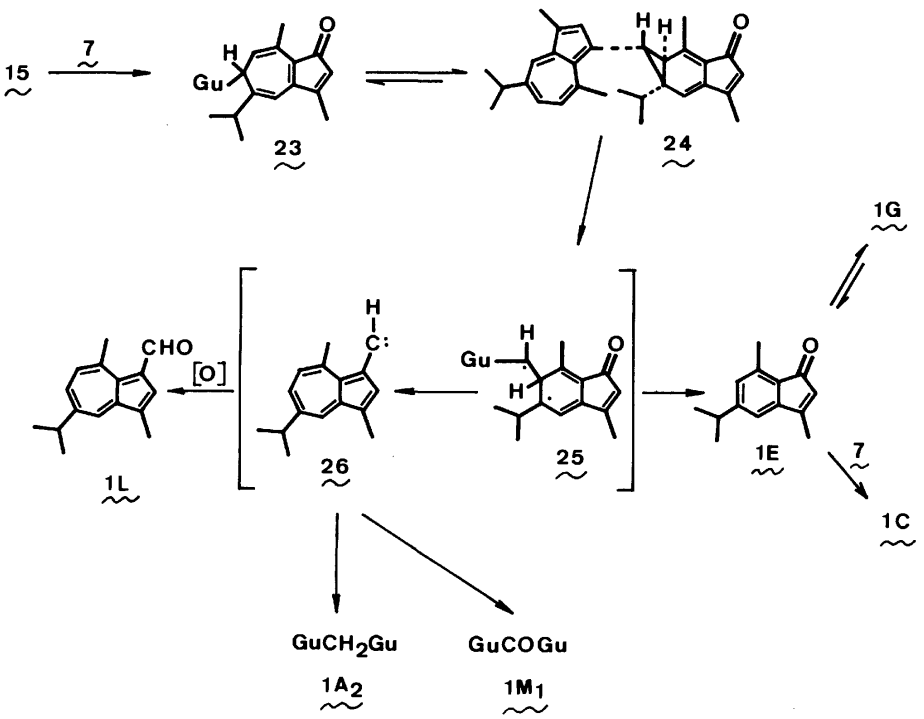
Scheme 4.

an oxygen molecule upon the alkyl side chain of the radical intermediate **13** (derived from **7**) to form the primary peroxyl radical **14** in a manner similar to the well-accepted mechanism for the autoxidation of side chains of alkylbenzenes and naphtalenes.[31] Further autoxidation of the aldehyde **1K** in the usual way gives the carboxylic acid **1O**. The oxidation of the side chain on the 1 position constitutes one of the major pathways in the autoxidation of **1** under the present conditions. The 7-acetylazulene **1J** is available only in an extremely samll amount by oxidation of the isopropyl group of **1**. These facts contrast with the efficient preparation of acetophenone derivatives from isopropylbenzenes by the same autoxidation in DMF.[32] Only an extremely small extent of the side chain oxidation is observed for **2**, affording 6-formyl derivative **2F**. Both **1J** and **2F** are obviously formed via pathways through the radical intermediates similar to those for **1K** outlined in Scheme 2.

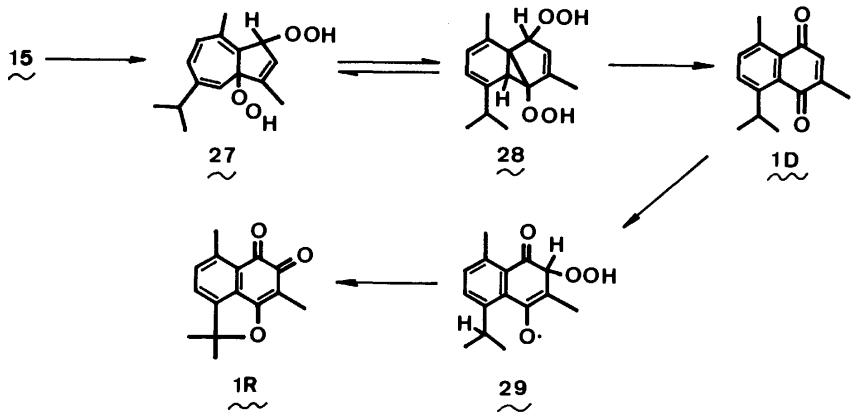
Azulenequinones. Scheme 3 illustrates a major reaction pathway when the azulene-oxygen complex **12** from **1** is transformed into the 3-guaiazulenylperoxyl diradical **15**.[33] As in the case of oxidation with singlet oxygen in protic solvent, a stepwise transformation of **15** into a precursor **20** via endo-peroxide **18** and hydroxy ketone **19** by a thermal [1,5] shift of the OH group on the seven-membered ring (path-b) may not be excluded for the formation of **1Q**. However, the fact that 1,7-guaiazulenequinone **1Q** has also been obtained on standing **1** in the dark even at 25 °C for a prolonged period (in as high as 15% yield)[34] suggests to us the transient formation of a highly strained, cross-linked endo-peroxide like **16** (or of a radical ketone **17**) (path-a), as a more likely pathway.

The same type of oxidative pathways for **2** would account for the formation of two azulenequinones $\mathbf{2J}_1$ and **2I**.

6-Formyl-1*H*-inden-1-ones and Related Compounds. Possible reaction pathways for the formation of these compounds are illustrated in Scheme 4. Addition of hydroperoxyl radical to the 5 position of **15** is considered to give an intermediate such as hydroperoxide **21** that would be converted into the 6-formylindenone **1I** most likely through the equilibrated norcaradiene form[35] (e.g. **22**). The formation of no such 6-formylindenone from **2** is obviously due to the presence of the three methyl groups at such positions as to suppress the transformation of the corresponding norcaradiene



Scheme 5.



Scheme 6.

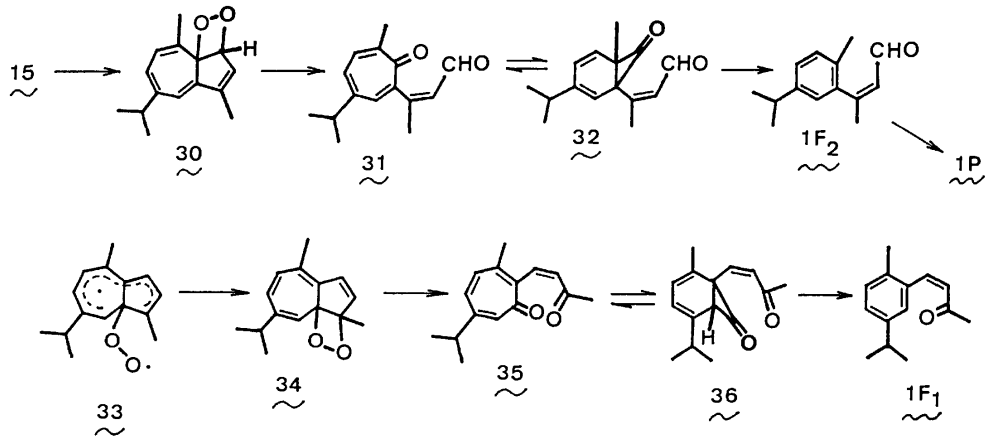
form (cf. **22**) into the formyl-substituted six-membered ring.

From indenones **1I** and **1E** (which has liberated one carbon by the rearrangement, see Scheme 5) several secondary products are derived: (i) oxidative coupling of **1I** and **1E** with the 2 position of the unreacted starting material **1** (or more probably **7**) to afford 2-(3-guaiazulenyl)indenones $\mathbf{1H_1}$ and **1C**, respectively, (ii) isomerization to **1N**, and (iii) transformation of **1E** into the thermodynamically more stable prototropic isomer **1G**.

Compounds Formed by Intermolecular One-Carbon Transfer. It should be particularly noticed in the present autoxidation of the trialkylazulenes **1** and **2** that compounds having extra-carbon(s) such as 3-formylguaiazulene (**1L**), 3,3′-methylenebisguaiazulene ($\mathbf{1A_2}$), and related compounds ($\mathbf{1M_1}$, $\mathbf{2A_2}$, $\mathbf{2G_1}$, **2K**) have always been obtained in relatively high yields.

The facts that compound **24**[36] has recently been proved to degrade to **1E** and **1L** on standing in air and the reaction of **24** with an equivalent of guaiazulene **1** under nitrogen in DMF at 100 °C has given $\mathbf{1A_2}$ as one of the major products strongly suggest that this dimeric norcaradiene **24** (formed through **23**) is the most likely key intermediate (Scheme 5). Compound **24**, which is expected to be thermodynamically more stable than **23** due to the absence of a cyclpentadienone form, would then undergo fragmentation (through diradical **25**) to give 1*H*-inden-1-one **1E** and a certain intermediate having a reactive extra-carbon side chain (such as a carbene species **26**). Then, a condensation reaction of the latter with the starting material **1** would afford $\mathbf{1A_2}$, whereas oxidation with $^3O_2$ is considered to give 3-formylguaiazulene **1L**.

Similar pathways for **2** involving intermediates illustrated for **1** would account for the formation of the



Scheme 7.

bis-trimethylazulenyl derivative **2A**$_2$ and indenones **2B**$_1$ and **2C**, as well as the 1-formyltrimethylazulene **2K**$_1$.

Naphthalenoid Compounds. Proposed pathways for these products are outlined in Scheme 6. Among these products, the formation of the naphthoquinones **1D** and **1R** constitute one of the major reaction pathways from **1**. Taking into account the results of an independent model study,[11b] this transformation may be explained in terms of the process through the intermediates **15** (Scheme 3) and then **27** formed by the addition of the second molecule of oxygen to C-8a of guaiazulene nucleus, followed by the rearrangement involving the norcaradiene intermediate **28** and loss of two hydroxyl radicals. An addition of hydroperoxyl radical at C-2 of **1D** to give an intermediate **29**, and subsequent loss of hydroxyl and H radicals would afford **1R**.

Benzenoid Compounds. The formation of a number of further degraded benzenoid derivatives (**1F**$_2$, **1P**, and **1F**$_1$) from **1** is most likely explained by the intramolecular radical cyclization of **15** at C-3a and of **33** at C-1 to give the dioxetane intermediates **30** and **34** which subsequently yield the benzenoid products through the ring-opened tropone-norcaradiene dicarbonyl compounds **31**, **32** and **35**, **36**, respectively, followed by facile decarbonylation, as illustrated in Scheme 7. The benzenoid compounds (**2B**$_2$, **2H**, and **2J**$_2$) from **2** are derived via essentially similar ring-opening schemes as those described for the benzenoid products from **1**.

The detailed mechanistic consideration for the formation of other minor compounds, however, is not made here because of the limited evidences at this stage with regard to the reaction pathways. Besides these isolated compounds described so far, considerable amounts (34 and 57%) of intractable resinous substances are accompanied by the autoxidation (of **1** and **2**, respectively). Of particular, it is noted that the latter substrate (**2**) bearing no substituents at the most reactive sites C-1 and C-3 tends to give a larger proportion of the polymerized products.

It has now become apparent that the autoxidation of the trialkylazulenes is extraordinarily complex and highly competitive involving oxidation of the nucleus (at various positions), substitutions, ring contraction, and other reactions such as the rearrangement to naphthalenes, although the exact mechanism is under further investigation in detail by employing azulene itself and various other alkylazulenes under various reaction conditions. Nevertheless, the present findings are believed to provide valuable information on exploitation of a convenient preparative route for some useful azulenoid compounds.[37] It is further of interest in relation to the recent isolation, from the polyps of a deep sea gorgonian (at −350 m), of a number of azulene derivatives, including 3,3′-methylenebisguaiazulene[38a] (**1A**$_2$) and 1,7-guaiazulenequinone[38b] (**1Q**) which coincide with the autoxidation products described in this paper.

Experimental

Melting points were determined with a Yanagimoto MP-S3 instrument and are uncorrected. Column chromatography was performed with Wako C-300 silica gel. TLC was conducted on plates precoated with silica gel 60F (0.25 mm, Merck) by using 15 : 85 AcOEt–hexane as eluant. HPLC was carried out with Hitachi gel #3011 with methanol as solvent.

UV (in MeOH) and IR (as KBr disk, unless otherwise stated) spectra were taken on Hitachi 323 and a Nihonbunko IR-A-202 Grating spectrometer, respectively. NMR spectra were recorded in $CDCl_3$ with a JEOL-FX200 cryospectrometer (200-MHz for ^1H and 50 MHz for ^{13}C) at 27 °C. Chemical shifts are reported as δ values in parts per million relative to tetramethylsilane (δ 0.0) as the internal standard. The assignments of all signals were made by employing a first-order analysis with the aid of decoupling technique and the parameters were confirmed by a computer-assisted simulation analysis; those values for simple azulene derivatives are summarized in Table 1. Mass spectra were taken on a Shimadzu LKB-9000 (with a Shimadzu PAC 90 mass data system) low resolution or a JEOL JMS-HX100 (with a JEOL JMA-DA5000 mass data system) high-resolution instrument (for chemical ionization with isobutane), and are given in terms of m/z (rel. intensity) compared with the base peak.

Oxidation of Guaiazulene (1) in DMF. A solution of **1**[39]

(1.00 g) in freshly distilled DMF (20 cm^3) was placed in a Pyrex flask (ϕ 1.8 cm, 60 cm height) and subjected to autoxidation by allowing finely bubbling oxygen to pass through the solution (from the bottom of the flask) for 24 h at 100±5 °C. After cooling, the mixture was diluted with water (200 cm^3) and extracted with AcOEt (4×50 cm^3). The combined organic layers were washed with water, dried (Na_2SO_4), and evaporated in vacuo, giving a brown oil (0.98 g); the HPLC and TLC diagrams of this crude mixture are given in Fig. 1. This residue was preliminarily separated into five fractions by means of preparative HPLC with Hitachi gel #3019 (100 g) using methanol as eluant. Then each fraction was carefully separated by silica-gel column or thin layer with AcOEt–hexane; when necessary, this chromatographic procedure was repeated. Thus, the following 25 products were obtained as pure substances, besides the recovered starting material **1** (**1A**$_1$: 0.41 g; R_f=0.95; ^{1}H NMR, see Table 1) and polar resinous substances [0.20 g, 34% (w/w); R_f=0.0]. The yield of each product is based on the consumed starting material (0.59 g).

3,3′-Methylenebisguaiazulene[9] **(1A$_2$):** Dark blue prisms; 50 mg (8.2% yield); mp 188 °C (Ref. 9a, 187—189 °C); R_f=0.95; ^{1}H NMR, see Table 1. (Found: *m/z* 408.2883).

2,3′-Biguaiazulene (1A$_3$): Dark green prisms; 5 mg (0.9%); mp 149 °C; R_f=0.95; UV ($CHCl_3$) 250, 299, 311, 353, 368,^{sh} 446, and 610 nm (log ε 4.42, 4.46, 4.47, 4.20, 4.07, 3.94, and 2.91); ^{1}H NMR, see Table 1; EI MS, *m/z* 394 (M^+; 56), 379 (100), 336 (19), 321 (20), and 198 (17).

Found: *m/z* 349.2654. Calcd for $C_{30}H_{34}$: M, 394.2660.

4,4′-Diisopropyl-1,1′,6,6′-tetramethyl-2,2′-binaphthalene (1A$_4$): Pale yellow-green oil; 2 mg (0.4%); R_f=0.95; UV 231, 291, 326, and 441 nm (log ε 4.82, 3.82, 2.45, and 2.50); ^{1}H NMR 1.38 (12H, d, *J*=7.0 Hz, 2 *i*-Pr-4), 2.55 (6H, s, 2Me-6), 2.64 (6H, s, 2Me-1), 3.72 (2H, sept, 2CH-4), 7.22 (2H, s, 2H-3), 7.34 (2H, dd, $J_{7,8}$=9.0, $J_{5,7}$=1.7 Hz, 2H-7), 7.90 (2H, d, 2H-5), and 7.91 (2H, d, 2H-8); EI MS, *m/z* 394 (M^+; 100), 379 (30), 351 (35), and 197 (30).

Found: *m/z* 394.2666. Calcd for $C_{30}H_{34}$: M, 394.2661.

4-Isopropyl-1,6-dimethylnaphthalene (Cadalene)[40] **(1A$_5$):** Colorless oil; 5 mg (0.9%); R_f=0.95; ^{1}H NMR 1.32 (6H, d, *J*=7.0 Hz, *i*-Pr-4), 2.49 (3H, s, Me-6), 2.58 (3H, s, Me-1), 3.68 (1H, sept, CH-4), 7.13 (1H, d, *J*=7.0 Hz, H-2), 7.22 (1H, d, H-3), 7.26 (1H, dd, *J*=8.0, 1.0 Hz, H-7), 7.85 (1H, d, H-8), and 7.89 (1H, d, H-5); EI MS, *m/z* 198 (M^+; 100).

3,3′-Biguaiazulene[3,10] **(1B):** Greenish blue prisms; 40 mg (6.8%); mp 144 °C (Ref. 15, 142 °C); R_f=0.93; ^{1}H NMR, see Table 1; EI MS, *m/z* 394 (M^+; 100).

2-(3-Guaiazulenyl)-5-isopropyl-3,7-dimethyl-1*H*-inden-1-one (1C): Dark red prisms; 13 mg (2.2%); R_f=0.86; UV 252, 293, 305,^{sh} 352, 370,^{sh} and 500 nm (log ε 4.59, 4.66, 4.60 4.06, 4.00, and 3.51); IR (CCl_4) 1690 (C=O) cm^{-1}; ^{1}H NMR 1.28 (6H, d, *J*=7.0 Hz, *i*-Pr-5), 1.34 (6H, d, *J*=7.0 Hz, *i*-Pr-7′), 2.08 (3H, s, Me-3), 2.52 (3H, s, Me-7), 2.62 (3H, s, Me-4′), 2.64 (3H, s, Me-1′), 2.89 (1H, sept, CH-5), 3.04 (1H, sept, CH-7′), 6.83 (2H, bs, H-4,6), 6.90 (1H, d, $J_{5',6'}$=11.0 Hz, H-5′), 7.32 (1H, dd, $J_{6',8'}$=2.0 Hz, H-6′), 7.36 (1H, s, H-2′), and 8.12 (1H, d, H-8′); CI MS, *m/z* 397 (M+1; 100).

Found; *m/z* 396.2438. Calcd for $C_{29}H_{32}O$: M, 396.2453.

8-Isopropyl-2,5-dimethyl-1,4-naphthoquinone[11] **(1D):** Yellow oil; 35 mg (5.1%); R_f=0.81; CI MS, *m/z* 229 (M+1; 100).

5-Isoproply-3,7-dimethyl-1*H*-inden-1-one (1E): Pale yellow oil; 10 mg (1.7%); R_f=0.78; UV ($CHCl_3$) 250, 331, 341,^{sh} and 370^{sh} nm (log ε 4.33, 3.73, 3.69, and 3.05); IR (neat) 1680 (C=O) cm^{-1}; ^{1}H NMR 1.23 (6H, d, *J*=7.0 Hz, *i*-Pr-5), 2.20 (3H, d, $J_{2,Me}$=1.5 Hz, Me-3), 2.44 (3H, s, Me-7), 2.88 (1H, sept, CH-5), 5.61 (1H, q, H-2), 6.79 (1H, bs, H-4*), and 6.83 (1H, bs, H-6*), *the assignments may have to be interchanged; ^{13}C NMR 198.79 (C-1), 160.24, 154.11, 146.75, 136.65, 129.64, 124.45, 115.92, 34.45, 23.59, 17.11, and 13.72; CI MS, *m/z* 201 (M+1; 100).

Found: *m/z* 200.1140. Calcd for $C_{14}H_{16}O$: M, 200.1201.

(*Z*)-4-(5-Isopropyl-2-methylphenyl)-3-buten-2-one (1F$_1$): Colorless oil; 10 mg (1.7%); R_f=0.72; UV 279 nm (log ε 4.36); IR (neat) 1680 (C=O) cm^{-1}; ^{1}H NMR 1.21 (6H, d, *J*=7.0 Hz, *i*-Pr-5′), 1.92 (3H, s, H_3-1), 2.26 (3H, s, Me-2′), 2.85 (1H, sept, CH-5′), 6.16 (1H, d, *J*=11.0 Hz, H-3), 7.03 (1H, bs, H-6′), 7.09 (1H, bd, $J_{3',4'}$=8.0 Hz, H-4′), 7.13 (1H, d, H-3′), and 7.15 (1H, d, H-4); EI MS, *m/z* 202 (M^+; 100).

Found: *m/z* 202.1264. Calcd for $C_{14}H_{18}O$: M, 202.1357.

(*Z*)-3-(5-Isopropyl-2-methylphenyl)-2-butenal (1F$_2$): Colorless oil; 10 mg (1.7%); R_f=0.72; ^{1}H NMR 1.24 (6H, d, *J*=7.0 Hz, *i*-Pr-5′), 2.22 (3H, s, Me-2′), 2.24 (3H, d, $J_{2,4}$=1.5 Hz, H_3-4), 2.88 (1H, sept, CH-5′), 6.14 (1H, dq, $J_{1,2}$=8.0 Hz, H-2), 6.92 (1H, bd, $J_{4',6'}$=1.0 Hz, H-6′), 7.10 (1H, dd, $J_{3',4'}$=8.0 Hz, H-4′), 7.16 (1H, d, H-3′), and 9.20 (1H, d, H-1); EI MS, *m/z* 202 (M^+; 100).

Found: *m/z* 202.1295. Calcd for $C_{14}H_{18}O$: M, 202.1357.

2,3-Dihydro-5-isopropyl-7-methyl-3-methylene-1*H*-inden-1-one (1G): Colorless needles; 5 mg (0.8%); mp 84 °C; R_f=0.69; UV 245, 265,^{sh} and 330 nm (log ε 4.32, 4.17, and 3.79); IR (CCl_4) 1720 (C=O) cm^{-1}; ^{1}H NMR 1.29 (6H, d, *J*=7.0 Hz, *i*-Pr-5), 2.62 (3H, s, Me-7), 2.96 (1H, sept, CH-5), 3.25 (2H, dd, 2H-2), 5.24 [1H, t, $J_{2,HC(3)}$=1.8 Hz, (*E*)-H-C-3], 5.78 [1H, t, $J_{2,HC(3)}$=2.0 Hz, (*Z*)-H-C-3), 7.02 (1H, d, $J_{4,6}$=1.0 Hz, H-6], and 7.43 (1H, d, H-6).

Found: *m/z* 200.1205. Calcd for $C_{14}H_{16}O$: M, 200.1202.

2-(3-Guaiazulenyl)-5-isopropyl-3,7-dimethyl-1-oxo-1*H*-indene-6-carbaldehyde (1H$_1$): Reddish brown prisms; 13 mg (2.1%); mp 147 °C (decomp); R_f=0.64; UV 225,^{sh} 256, 293, 307,^{sh} 353, 369, and 537 nm (log ε 4.43, 4.53, 4.60, 4.53, 4.00, 3.93, and 3.50); IR (CCl_4) 1690 and 1680 (C=O) cm^{-1}; ^{1}H NMR 1.33 (6H, d, *J*=7.0 Hz, *i*-Pr-7′), 1.37 (6H, d, *J*=7.0 Hz, *i*-Pr-5), 2.14 (3H, s, Me-3), 2.64 (6H, s, Me-1′, 4′), 2.80 (3H, s, Me-7), 3.01 (1H, sept, CH-7′), 3.79 (1H, sept, CH-5), 6.95 (1H, d, $J_{5',6'}$=11.0 Hz, H-5′), 7.08 (1H, s, H-4), 7.36 (1H, dd, $J_{6',8'}$=2.0 Hz, H-6′), 7.39 (1H, s, H-2′), 8.16 (1H, d, H-8′), and 10.60 (1H, s, OHC-6); CI MS, *m/z* 425 (M+1; 100).

Found: *m/z* 424.2444. Calcd for $C_{30}H_{32}O_2$: M, 424,2404.

3-Guaiazulenyl 3-(3-Guaiazulenyl)-7-isopropyl-4-methyl-1-azulenyl Ketone (1H$_2$): Reddish brown paste; 1 mg (0.2%); R_f=0.64; UV ($CHCl_3$) 248, 290, 394, and 538 nm (log ε 4.70, 4.70, 3.24, and 3.34); IR 1720 (C=O) cm^{-1}; EI MS, *m/z* 604 (M^+; 100), 589 (7), 561 (4), 408 (17), 393 (5), 198 (20), and 183 (19).

Found: *m/z* 604.3670. Calcd for $C_{45}H_{48}O$: M, 604.3704.

5-Isopropyl-3,7-dimethyl-1-oxo-1*H*-indene-6-carbaldehyde (1I): Yellow needles; 20 mg (2.9%); mp 87 °C; R_f=0.55; UV ($CHCl_3$) 268, 342, and 374^{sh} nm (log ε 4.27, 3.96, and 3.66); IR 1700 and 1695 (C=O) cm^{-1}; ^{1}H NMR 1.32 (6H, d, *J*=6.9 Hz, *i*-Pr-5), 2.26 (3H, d, $J_{2,Me}$=1.4 Hz, Me-3), 2.76 (3 H, s, Me-7), 3.72 (1H, sept, HC-5), 5.80 (1H, q, H-2), 7.04 (1H, s, H-4), and 10.58 (1H, s, CHO); ^{13}C NMR 197.56, 193.41, 159.19, 157.44, 149.91, 138.40, 134.26, 129.70, 127.13, 115.28, 29.02, 23.59, 13.67, and 13.37; EI MS, *m/z* 228 (M^+; 100), 213 (47), 199 (23), and 185 (32).

Found: m/z 228.1132. Calcd for $C_{15}H_{16}O_2$: M, 228.1150.

7-Acetyl-1,4-dimethylazulene (1J): Violet bule prisms; 2 mg (0.3%); mp 55 °C; R_f=0.52; UV 245, 304, 396, and 575 nm (log ε 4.47, 4.68, 3.76, and 2.72); IR 1670 (C=O) cm^{-1}; ^1H NMR, see Table 1; EI MS, m/z 198 (M^+; 100), 183 (75), and 155 (52).

Found: m/z 198.1014. Calcd for $C_{14}H_{14}O$: M, 198,1045.

7-Isopropyl-4-methyl-1-azulenecarbaldehyde[15] (1K): Red prisms; 50 mg (7.9%); mp 61 °C (Ref. 15, 61 °C); R_f=0.49; ^1H NMR, see Table 1; EI MS, m/z 212 (M^+; 100).

3-Guaiazulenecarbaldehyde[16] (1L): Brownish red needles; 10 mg (1.5%); mp 86 °C (Ref. 16, 85—86 °C); R_f=0.38; ^1H NMR, see Table 1; EI MS, m/z 226 (M^+; 100).

Bis(3,3′-guaiazulenyl) Ketone[17] ($1M_1$): Dark green prisms; 10 mg (1.6%); mp 191 °C (Ref. 17, 189—190 °C); R_f=0.35; ^1H NMR, see Table 1; EI MS, m/z 422 (M^+; 17), 407 (69), 331 (20), 198 (16), 169 (81), 109 (50), and 43 (100).

3-Guaiazulenyl Dimethylcarbamate ($1M_2$): Dark blue paste; 5 mg (0.6%); R_f=0.35; UV ($CHCl_3$) 249, 290, 352, 368, 634, and 654^{sh} nm (log ε 4.20, 4.26, 3.78, 3.75, 2.67, and 2.63); IR (CCl_4) 1705 (C=O) cm^{-1}; ^1H NMR, see Table 1; EI MS, m/z 285 (M^+; 10), 213 (58), 72 (100), and 42 (12).

Found: m/z 285.1733. Calcd for $C_{18}H_{23}NO_2$: M, 285.1728.

Compound 1N: Pale yellow crystals; 2 mg (0.3%); R_f=0.26; UV 229,^{sh} 242,^{sh} 254,^{sh} 269, 317, 344, and 418 nm; IR (CCl_4) 1715 and 1700 (C=O) cm^{-1}; ^1H NMR* 1.28 (6H, d, J=7.0 Hz, *i*-Pr-4), 2.68 (3H, s, Me-7), 2.90 (3H, s, Me-2), 3.65 (1H, sept, HC-4), 7.02 (1H, s, H-5), 10.56 (1H, s, OHC-8), and 10.68 (1H, s, OHC-3), *the assignments were made for the tentative structure **6** (see the footnote on p. 1418); CI MS, m/z 229 (M+1; 100).

7-Isopropyl-4-methyl-1-azulenecarboxylic Acid[15] (1O): Red-violet needles; 10 mg (1.5%); mp 169 °C (Ref. 15, 169 °C); R_f=0.23; ^1H NMR see Table 1; EI MS, m/z 228 (M^+; 100).

(*Z*)-3-(5-Isopropyl-2-methylphenyl)-2-butenoic Acid (1P): Colorless needles; 15 mg (2.3%); mp 128 °C; R_f=0.20; UV 269 and 278 nm (log ε 4.31 and 4.23); IR 3200—2300, 1680—1660 (COOH) cm^{-1}; ^1H NMR 1.21 (6H, d, J=7.0 Hz, *i*-Pr-5′), 2.12 (3H, d, $J_{2,4}$=1.5 Hz, H_3-4), 2.14 (3H, s, Me-2′), 2.84 (1H, sept, HC-5′), 4.16 (1H, m, COOH; D_2O exchangeable), 5.92 (1H, q, H-2), 6.78 (1H, dd, $J_{4',6'}$=2.0, $J_{3',6'}$=0.5 Hz, H-6′), 7.05 (1H, $J_{3',4'}$=8.0 Hz, H-4′), and 7.08 (1H, dd, H-3′); ^{13}C NMR 169.47 (C-1), 159.02, 146.11, 140.27, 130.58, 129.82, 125.38, 124.15, 118.02, 33.64, 27.45, 24.00, and 18.57.

Found: m/z 218.1308. Calcd for $C_{14}H_{18}O_2$: M, 218.1307.

5-Isopropyl-3,8-dimethyl-1,7-azulenequinone (1Q): Yellow needles; 10 mg (1.5%); mp 94 °C; R_f=0.18; $E_{1/2}$ −1.13 and −1.52 V (vs. SCE); UV ($CHCl_3$) 232, 252, 288,^{sh} 310,^{sh} 386, 394,^{sh} and 420^{sh} nm (log ε 4.14, 4.14, 3.95, 3.92, 3.74, 3.73, and 3.53); IR 1680 and 1590 (C=O) cm^{-1}; ^1H NMR, see Table 1; ^{13}C NMR 196.57 (C-1), 189.38 (C-7), 164.16 (C-3), 154.99 (C-5), 148.91 (C-8), 144.53 (C-3a), 133.09 (C-6), 133.04 (C-8a), 131.45 (C-4), 124.10 (C-2), 37.84 (Me-8), 29.67 (Me_2CH-5), 22.54 (Me_2CH-5), and 14.25 (Me-3); EI MS, m/z 228 (M^+; 100), 213 (80), 199 (16), 195 (12), 185 (26), and 171 (16).

Found: m/z 228.1138. Calcd for $C_{15}H_{16}O_2$: M, 228.1150

2,2,5,8-Tetramethyl-2*H*-naphtho[1,8-*bc*]furan-6,7-dione[11b] (1R): Orange needles; 5 mg (0.7%); mp 220 °C (Ref. 11b, mp 220 °C); R_f=0.05; EI MS, m/z 242 (M^+; 54) and 171 (100).

***N*-(2-Guaiazulenylmethyl)-*N*-methylformamide (1S):** Blue paste; 5 mg (0.6%); R_f=0.02; UV 245, 285, 349, and 608 nm (log ε 4.38, 4.60, 3.68, and 2.64); IR (CCl_4) 1665 (C=O) cm^{-1}, ^1H NMR, see Table 1; EI MS, m/z 269 (M^+; 27), 254 (25), 226 (26), 213 (100), and 198 (23).

Oxdation of 1 in HMPA. The same oxidation procedure was employed, and virtually the same products were obtained except for certain compounds in which fragments from the solvent are incorporated (e.g., $1M_2$ and **1S**).

Oxidation of 4,6,8-Trimethylazulene (2) in DMF. Autoxidation **2**[39] (1.00 g) in DMF (20 cm^3) was carried out for 12 h at 120±5 °C in a manner similar to that described for **1**, thus affording, after the careful chromatographic separation, 17 products as pure compounds (**2A—M**; see Fig. 2 for HPLC and TLC), besides the recovered starting material **2** ($2A_1$, 0.45 g, R_f=0.94; ^1H NMR, see Table 1) and polar resinous substances [0.324 g, 59% (w/w); R_f=0.0]. They yield of each product is based on the consumed starting material (0.55 g).

1,1′-Methylenebis(4,6,8-trimethylazulene) ($2A_2$): Dark violet prisms; 10 mg (1.8%); mp 205 °C; R_f=0.94; UV ($CHCl_3$) 249, 306, 356, and 570 nm (log ε 4.80, 4.89, 4.27, and 2.97); ^1H NMR, see Table 1; EI MS m/z 352 (M^+; 68), 182 (100), and 170 (84).

Found: m/z 352.2176. Calcd for $C_{27}H_{28}$: M, 352.2190.

4,6,7-Trimethyl-1*H*-inden-1-one ($2B_1$): Yellow needles; 30 mg (5.4%); mp 38 °C; R_f=0.79; UV 249, 313, and 400 nm (log ε 3.87, 3.50, and 3.02); IR 1700 (C=O) cm^{-1}; ^1H NMR 2.20 (3H, s, Me-4), 2.22 (3H, s, Me-6), 2.43 (3H, s, Me-7), 5.74 (1H, d, $J_{2,3}$=6.0 Hz, H-2), 6.88 (1H, s, H-5), and 7.58 (1H, d, H-3); EI MS, m/z 172 (M^+; 100) and 129 (20).

Found: m/z 172.0888. Calcd for $C_{12}H_{12}O$: M, 172.0888.

2,4,6-Trimethylbenzaldehyde[21] ($2B_2$): Colorless oil; 2 mg (0.4%); R_f=0.79; ^1H NMR 2.31 (3H, s, Me-4), 2.56 (6H, s, Me-2,6), 6.90 (2H, s, H-3,5), and 10.56 (1H, s, CHO): EI MS, m/z 148 (M^+; 100).

4,5,7-Trimethyl-1*H*-inden-1-one (2C): Yellow needles; 30 mg (5.4%); mp 64 °C; R_f=0.78; UV 247, 349, and 400^{sh} nm (log ε 3.88, 3.52, and 3.25); IR 1695 (C=O) cm^{-1}; ^1H NMR 2.15 (3H, s, Me-5), 2.20 (3H, s, Me-4), 2.42 (3H, s, Me-7), 5.78 (1H, d, $J_{2,3}$=6.0 Hz, H-2), 6.76 (1H, s, H-6), and 7.62 (1H, d, H-3); ^{13}C NMR 200.01, 146.81, 143.31, 143.13, 135.19, 132.91, 131.75, 128.59, 127.13, 19.97, 16.76, and 13.78; EI MS, m/z 172 (M^+; 100) and 129 (22).

Found: m/z 172.0880. Calcd for $C_{12}H_{12}O$: M, 172.0888.

2,3-Dihydro-4,6,7-trimethyl-3-(4,6,8-trimethyl-1-azulenyl)-1*H*-inden-1-one (2D): Violet prisms; 10 mg (1.8%); mp 145 °C; R_f=0.69; UV 266, 297, 359, 563, and 600^{sh} nm (log ε 3.66, 4.30, 3.49, 2.67, and 2.61); IR 1695 (C=O) cm^{-1}; ^1H NMR 1.82 (3H, s, Me-4), 2.32 (2H, s, Me-6), 2.58 (2H, s, Me-6′), 2.64 (3H, s, Me-4′), 2.67 (1H, dd, $J_{2,2}$=18.0, $J_{2,3}$=3.0 Hz, H-2), 2.78 (3H, s, Me-8′), 3.14 (3H, s, Me-7), 3.26 (1H, dd, $J_{2,3}$=8.0 Hz, H-2), 5.42 (1H, dd, H-3), 6.75 (1H, d, $J_{2',3'}$=4.0 Hz, H-2′), 6.94 (1H, s, H-5′), 6.96 (1H, s, H-7′), 7.12 (1H, d, H-3′), and 7.14 (1H, s, H-5); EI MS, m/z 342 (M^+; 10) and 170 (100).

Found: m/z 342.1969. Calcd for $C_{25}H_{26}O$: M, 342.1984.

2,3-Dihydro-4,5,7-trimethyl-3-(4,6,8-trimethyl-1-azulenyl)-1*H*-inden-1-one (2E): Violet prisms; 10 mg (1.8%); mp 145 °C; R_f=0.63; UV 266, 297, 359, 563, and 600^{sh} nm (log ε 3.59, 4.30 3.44, 2.62, and 2.56); IR 1695 (C=O) cm^{-1}; ^1H NMR 1.80 (3H, s, Me-4), 2.28, (3H, s, Me-5), 2.60 (3H, s, Me-6′), 2.64 (3H, s, Me-4′), 2.65 (1H, dd, $J_{2,2}$=18, $J_{2,3}$=3.0 Hz, H-2), 2.78 (3H, s, Me-8′), 3.16 (3H, s, Me-7), 3.26 (1H, dd, $J_{2,3}$=8.0 Hz, H-2), 5.49 (1H, dd, H-3), 6.71 (1H, d, $J_{2',3'}$=4.0 Hz, H-2′), 6.95 (1H, s, H-5′), 6.97 (1H, s, H-7′), 7.00 (1H, s, H-6), and 7.11 (1H, d, H-3′); EI MS, m/z 342 (M^+; 22) and 170 (100).

Found: m/z 342.1979. Calcd for $C_{25}H_{26}O$: M, 342.1984.

4,8-Dimethyl-6-azulenecarbaldehyde[23] (2F): Dark green

prisms; 3 mg (0.5%); mp 98 °C (Ref. 23, 98 °C); R_f=0.57; ^{1}H NMR, see Table 1; EI MS, m/z 184 (M^+; 100).

Bis(4,6,8-trimethyl-1-azulenyl)acetaldehyde[24] (2G): Dark violet prisms; 3 mg (0.5%); mp 167 °C (Ref. 24, mp 177 °C); R_f=0.41; UV ($CHCl_3$) 249, 298,^{sh} 308, 355, 560, and 640^{sh} nm (log ε 4.63, 4.63, 4.63, 4.45, 2.79, and 2.61): IR 2810 and 1720 (CHO) cm^{-1}; ^{1}H NMR, see Table 1; EI MS, m/z 380 (M^+; 8), 351 (100), 321 (35), 183 (25), and 170 (32).

Found: m/z 380.2108. Calcd for $C_{28}H_{28}O$: M, 380.2140.

4,6,8-Trimethyl-1-azulenyl-(*E*)-2,4,6-Trimethylstyryl Ketone (2H): Dark orange prisms; 3 mg (0.5%); mp 132 °C; R_f=0.37; UV ($CHCl_3$) 244, 298, 340, 428, and 530^{sh} nm (log ε 4.52, 4.40 4.22, 4.21, and 2.99); IR (CCl_4) 1710 (C=O) cm^{-1}; ^{1}H NMR 2.22 (6H, s, Me-2′, 6′), 2.30, (3H, s, Me-4′), 2.56 (3H, s, Me-6), 2.69 (3H, s, Me-4), 2.82 (3H, s, Me-8), 6.79 (1H, d, J=16 Hz, CH-CO), 6.84 (2H, s, H-3′,5′), 7.01 (1H, d, $J_{5',7'}$=1.0 Hz, H-5), 7.08 (1H, d, H-7), 7.29 (1H, d, $J_{2',3'}$=4.0 Hz, H-3), 7.94 (1H, d, H-2), and 8.14 (1H, d, CH=C-CO); EI MS, m/z 342 (M^+; 25), 327 (100), 196 (25), 181 (73), 165, (43), 147 (85), 119 (38), and 91 (24).

Found: m/z 342.1946. Calcd for $C_{25}H_{26}O$: M, 342.1984.

4,6,8-Trimethyl-1,7-azulenequinone (2I): Yellow needles; 15 mg (2.3%); mp 118 °C decomp; $E_{1/2}$ −1.05 and −1.5 V (vs. SCE); R_f=0.25; UV 260, 307, 370, 386, and 404^{sh} nm (log ε 4.35, 4.19, 3.95, 3.95, and 3.87); IR 1695 and 1580 (C=O) cm^{-1}; ^{1}H NMR, see Table 1; ^{13}C NMR 197.21 (C-1), 187.28 (C-7), 150.84 (C-3), 148.16 (C-6), 143.95 (C-8), 143.54 (C-3a), 140.56 (C-5), 138.17 (C-8a), 137.70 (C-4), 133.61 (C-2), 23.94 (Me-8), 21.67 (Me-4), and 16.12 (Me-6); EI MS, m/z 200 (M^+; 100), 172 (8), 149 (10), 128 (8), 80 (12), 57 (10), and 43 (10).

Found: m/z 200.0833. Calcd for $C_{13}H_{12}O_2$: M, 200.0837.

4,6,8-Trimethyl-1,5-azulenequinone ($2J_1$): Yellow needles; 15 mg (2.3%); mp 120 °C (decomp); R_f=0.23; $E_{1/2}$ −1.05 and −1.46 V (vs. SCE); UV 245, 318, 380,^{sh} and 400^{sh} nm (log ε 4.17, 3.83, 3.75, and 3.65); IR 1695 and 1575 (C=O) cm^{-1}; ^{1}H NMR, see Table 1; ^{13}C NMR 198.67 (C-1), 189.97 (C-5), 151.25 (C-3), 145.99 (C-6), 144.30 (C-4), 139.10 (C-8), 138.99 (C-7), 138.87 (C-3a), 133.67 (C-8a), 130.81 (C-2), 23.53 (Me-8), 21.55 (Me-4), and 14.72 (Me-6); EI MS, m/z 200 (M^+; 100), 172 (57), 157 (16), 144 (16), 129 (68), 115 (20), 91 (10), 77 (16), and 51 (20).

Found: m/z 200.0829. Calcd for $C_{13}H_{12}O_2$: M, 200.0837.

2,3,5-Trimethylbenzaldehyde[22] ($2J_2$): Colorless needles; 2 mg (0.4%): R_f=0.23; ^{1}H NMR 2.29 (3H, s, Me-5), 2.32 (3H, s, Me-4), 2.47 (3H, s, Me-2), 6.72 (1H, s, H-3), 7.08 (1H, s, H-6), and 9.98 (1H, s, CHO); EI MS, m/z 148 (M^+; 100).

4,6,8-Trimethyl-1-azulenecarbaldehyde[16a] ($2K_1$): Red prisms; 5 mg (0.8%); mp 107 °C (Ref. 16a, 107 °C): R_f=0.18; ^{1}H NMR, see Table 1; EI MS, m/z 198 (M^+; 100).

3-[1,2-Dihydro-5,7-dimethyl-cyclopenta[*c*,*d*]azulen-2-yl]-4,6,7-trimethyl-1-(4,6,8-trimethyl-1-azulenyl)-1*H*-inden-1-ol ($2K_2$): Dark violet prisms; 1 mg (0.2%); mp 202 °C (decomp); R_f=0.18; UV ($CHCl_3$) 247, 306, 340, 566, and 652^{sh} nm (log ε 4.46, 4.45, 4.13, 2.80, and 2.46); IR (CCl_4) 3750—3150 (OH) cm^{-1}; ^{1}H NMR 1.56 (1H, m, OH), 2.14 (3H, s, Me-7), 2.22 (3H, s, Me-6), 2.48 (3H, s, Me-6″), 2.53 (3H, s, Me-7′), 2.69 (3H, s, Me-8″), 2.73 (3 H, s, Me-4″), 2.80 (3H, s, Me-5′), 2.97 (3H, s, Me-4), 4.10 (1H, $J_{1',2'}$=7.5, $J_{1',1'}$=4.0 Hz, H-1′), 4.39 (1H, $J_{1',2'}$=0.5 Hz, H-1′), 5.40 (1H, H-2′), 6.36 (1H, s, H-2), 6.59 (1H, d, $J_{6',8'}$=0.5 Hz, H-8′), 6.64 (1H, d, $J_{5'',7''}$=0.5 Hz, H-7″), 6.82 (1H, d, H-5″), 6.86 (1H, d, H-6′), 6.86 (1H, s, H-5), 7.11 (1H, d, $J_{2'',3''}$=4.0 Hz, H-3″), 7.32 (1H, d, $J_{3',4'}$=4.0 Hz, H-4′), 7.43 (1H, d, H-2″), and 7.85 (1H, d, H-3′); EI MS, m/z 522 (M^+; 9), 364 (53), 350 (43), 335 (100), 180 (36), 170 (85), and 155 (38).

Found: m/z 522.2932. Calcd for $C_{39}H_{38}O$: M, 522.2922.

Bis(4,6,8-trimethyl-1-azulenyl) Ketone ($2K_3$): Orange prisms; 1 mg (0.2%); mp 171 °C; R_f=0.18; UV ($CHCl_3$) 249, 329, 404, and 480^{sh} nm (log ε 4.55, 4.53, 4.25 and 3.59); IR 1635 (C=O) cm^{-1}; ^{1}H NMR, see Table 1; EI MS, m/z 366 (M^+; 0.8), 351 (3), 331 (3), 197 (100), 169 (14), 153 (11), and 43 (25).

***N*-Methyl-*N*-[(4,6,8-trimethyl-1-azulenyl)methyl]formamide (2L):** Blue paste; 6 mg (0.8%); R_f=0.06; UV 247, 294, 358, 600, 625,^{sh} and 650^{sh} nm; IR (CCl_4) 1690 (C=O) cm^{-1}; ^{1}H NMR, see Table 1; EI MS, m/z 241 (M^+; 66), 226 (27), 198 (22), 183 (100), 167 (38), 153 (34), 141 (20), 128 (24), and 42 (62).

***N*-Methyl-*N*-[(4,6,8-trimethyl-2-azulenyl)methyl]formamide (2M):** Violet needles 20 mg (2.6%); mp 90 °C; R_f=0.02; UV 251, 292, 354, and 550 nm (log ε 4.60, 4.66, 4.17, and 2.78); IR 1655 (C=O) cm^{-1}: ^{1}H NMR, see Table 1; EI MS, m/z 241 (M^+; 100), 226 (41), 198 (24), 183 (83), 167 (29), and 153 (19).

Found: m/z 241.1471. Calcd for $C_{16}H_{19}NO$: M, 241,1467.

Oxidation of 2 in HMPA. The same procedures as those for **2** were employed, and virtually the same products were obtained except for certain compounds in which fragments from the solvent are incorporated (e.g., **2L** and **2M**).

We wish to thank Professors Kahei Takase (Tohoku Univ), Ichiro Murata (Osaka Univ), Teruo Matsuura (Kyoto Univ), Wataru Ando (Tsukuba Univ) and Lawrence T. Scott (Nevada Univ) for valuable discussions.

(Received October 2, 1986)

The base-catalyzed rearrangement of 2-(2-nitro-, 4-nitro-, and 4-cyanobenzyloxy)tropones smoothly yielded corresponding 2-[(aryl)hydroxymethyl]tropones, while their thermolysis gave 3-(arylmethyl)tropolones. This reaction has no precedent analogy in troponoid chemistry, and this rearrangement is widely applicable to the 2-troponyl ethers of alcohols carrying an electron-attractive substituent on the α-position, as was verified by the occurrence of 2-(1-hydroxy-2-oxo-2-phenethyl)tropone from 2-(2-oxo-2-phenethyloxy)tropone.

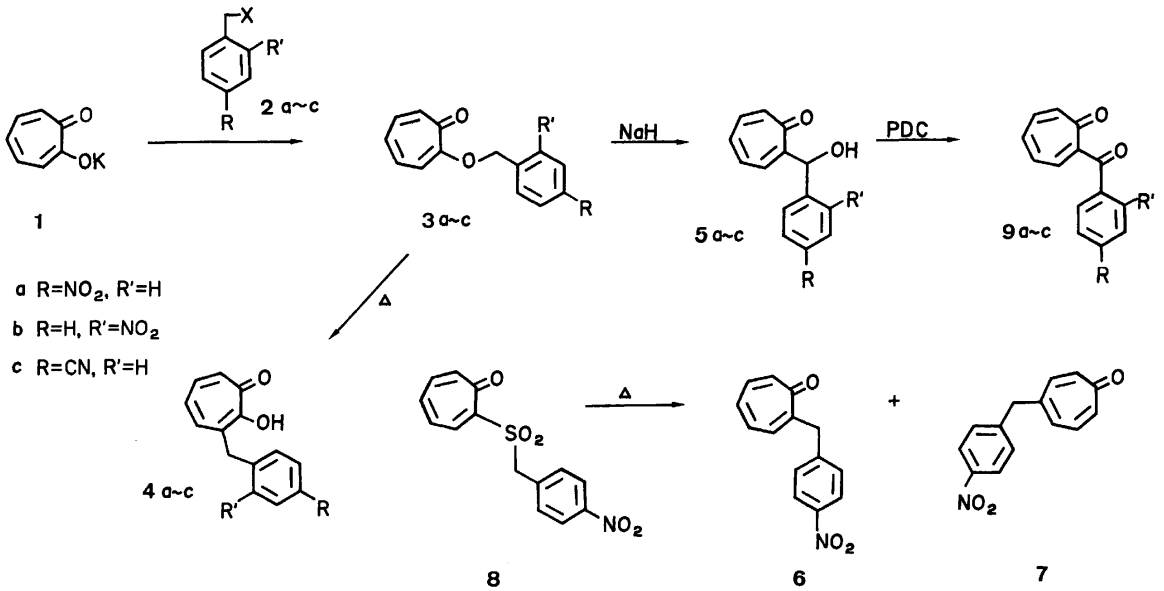
Among the chemical properties of troponoids, base-promoted ring-contraction to benzenoid derivatives from various functionalized tropone derivatives has been one of the most outstanding features.[1] However, to overcome this disadvantage has been a synthetic problem. In the course of our study on the thermal reaction of troponoids, we have found a new radical reaction of 2-troponyl benzyl ethers to the 3- and 5-(arylmethyl)tropolones.[2] The rearrangement mechanism could be clarified by a kinetic analysis and isotope-labelling experiments. Similar rearrangements also occurred when 2-(2-furyl- and 2-thienylmethoxy)tropones were heated in decalin; i.e., 2-(2-furylmethoxy)tropone gave 3- and 5-(2-furylmethyl)-tropolones and 3- and 5-(5-methyl-2-furyl)tropolones,[3] and 2-(2-thienylmethoxy)tropones gave 3- and 5-(2-thienylmethyl)tropolones.[4] During the preparation of 2-(2- and 4-nitrobenzyloxy)tropones from tropolone and nitrobenzyl halides under basic conditions, we found an unprecedented rearrangement in the troponoid chemistry to form a C-C bond. We will, herein, describe this novel base-catalyzed reaction of 2-troponyl ethers of alcohols having an electron-attractive substituent on their α-position, such as 2-(2- and 4-nitrobenzyloxy)tropones and 2-(2-oxo-2-phenethyloxy)tropone (2-phenacyloxytropone).

Results and Discussion

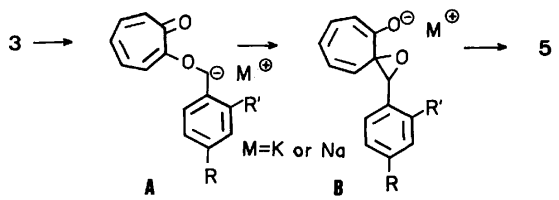
When a hexamethylphosphoric triamide (HMPA) solution of potassium tropolonate (**1**) and 4-nitrobenzyl chloride (**2a**) was stirred at 50 °C for 10 h, three products (**3a**, **4a**, and **5a**) were isolated by silica-gel column chromatography in 69, 0.3, and 8% yields, respectively. The structures of **3a** and **4a** were identified to be 2-(4-nitrobenzyloxy)tropone and 3-(4-nitrobenzyl)tropolone; i.e., the ^{1}H NMR of **3a** revealed a methylene signal at a lower field, δ=5.24, and nine aromatic protons, while the ^{1}H NMR spectrum of **4a**, showed a methylene signal at a higher field, δ=4.21, and eight aromatic protons. The ^{13}C NMR spectral comparison of **3a** and **4a** with a series of previously prepared derivatives[2] supported this conclusion.

The third product, **5a**, had a secondary hydroxyl group and the tropone ring was retained. In the ^{1}H NMR, a singlet signal ascribable to the newly-formed methine proton appeared at δ=5.86. It was further noticed that its ^{13}C NMR spectrum closely resembled, except for an sp^3-carbon, those of 2-benzyltropones.[5] Following our previous method, the model compounds, 2-(4-nitrobenzyl)tropone (**6**) and 4-(4-nitrobenzyl)tropone (**7**), could be prepared by a thermolysis of 2-(4-nitrobenzylsulfonyl)tropone (**8**).[5,6] The chemical shift differences, $\Delta\delta$(**5a**−**6**), between **5a** and **6**, thus prepared, showed a good correlation: For the seven-membered ring carbons, they were 1.4 (C-1), 0.6 (C-2), 1.3 (C-3), 1.8 (C-4), 1.0 (C-5), 1.0 (C-6), and 0.2 (C-7). In addition, the benzoyl derivative **9a**, a pyridinium dichromate(PDC)-oxidation product of **5a**, showed no singlet proton signal in the region of δ=7 to 7.5. This eliminated the alternative 3-substituted tropone structures;[7] therefore, **5a** must be the α-hydroxylated derivative of **6**, 2-[hydroxy(4-nitrophenyl)methyl]tropone.

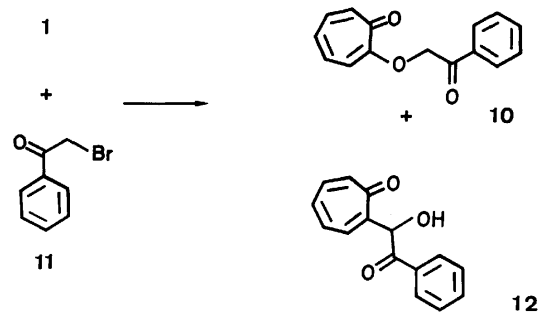
When **3a** was kept at room temperature in HMPA, no reaction occurred after 5 h; but when **3a** was refluxed in 1,2-dichlorobenzene (DCB), **4a** was formed in good yield. Furthermore, when **3a** was added to an HMPA solution of sodium hydride, the mixture instantly caused a change in color to yield **5a** in 72%, but no **4a**. Therefore, **3a** is not the precursor of **4a** already formed during preparation, and **4a** is likely to be formed by a direct C-attack. Clearly, the base was responsible for the formation of **5a**. For the rearrangement, the presence of an electron-attractive substituent, such as a nitro group, might be essential in order to generate a delocalized benzyl anion, since the unsubstituted 2-benzyloxytropone (**3d**)[2] gave no rearrangement product under comparable conditions. Such a stable anion (**A**) can be converted to the epoxide (**B**) by the assistance of a coordination with alkali metal ions to the carbonyl group. The following C-O bond cleavage should give **5** by another electrocyclic recombination.



Scheme 1.



Scheme 2.



Scheme 3.

This base-promoted reaction was also applicable to the corresponding 2-isomer, **3b**: By a reaction of **1** with 2-nitrobenzyl chloride (**2b**) in HMPA, 2-(2-nitrobenzyloxy)tropone (**3b**) was obtained in 88% yield together with 2-[hydroxy(2-nitrophenyl)methyl]tropone (**5b**). An alkali treatment of **3b** with sodium hydride in HMPA afforded **5b** in 95% yield, but the thermolysis of **3b** in DCB slowly produced **4b**; its yield was ca. 44% at 32% conversion after 13-h period. This low reactivity of thermolysis might be attributable to a steric hindrance of the bulky 2-nitro group. An attempted purification of **4b** resulted in an extensive decomposition of the material. The PDC-oxidation of **5b** yielded 2-(2-nitrobenzoyl)tropone (**9b**).

The rearrangement must be applicable to other derivatives whose ethereal carbon can generate a stable carbanion. This was verified when 2-(4-cyanobenzyloxy)tropone (**3c**), prepared from **1** and 4-cyanobenzyl bromide (**2c**), was converted to 2-[(4-cyanophenyl)-hydroxymethyl]tropone (**5c**). Furthermore, **3c** was thermolyzed to 3-(4-cyanobenzyl)tropolone (**4c**) in good yield.

Moreover, 2-(2-oxo-2-phenethyloxy)tropone (**10**), prepared similarly by condensation of **1** with phenacyl bromide (**11**, ω-bromoacetophenone), disclosed similar features. Thus, the attempted preparation of **10** resulted in a rearrangement product, 2-(1-hydroxy-2-oxo-2-phenethyl)tropone (**12**) in 59% yield; the isolated yield of **10** was only 17%.

Therefore, this base-promoted rearrangement has a considerable utility for introducing functionalized carbon side chains into the tropone system; particularly, there is no versatile method of C-C bond formation on the tropone system. Namely, a Grignard reaction has been generally employed to prepare 2-substituted tropones,[8] but its utility was severely restricted by the low yields of the desired products and a formation of ring-contracted phenyl derivatives; e.g., triphenylmethanol formation from phenylmagnesium bromide and 2-methoxytropone is inevitable.[9] It is also well known that 2-alkoxytropones are unstable under basic conditions and cause a ring-contraction to benzenoids.[1] The sole occurrence of substitution without ring-contraction under the present conditions is rather surprising. The marked difference should primarily be attributed to the different nature of the solvent used; one for protic solvents, such as alcohols which are sufficiently nucleophilic, and another for a bulky and polar-aprotic HMPA, being weakly nucleophilic. This newly-recognized property of 2-alkoxytropones[10] will make various reactions under basic conditions promising.

Experimental

The elemental analyses were performed by Miss S. Hirashima, the Research Institute of Industrial Science, Kyushu University. The mps were measured with a Yanagimoto Micro mp Apparatus and are uncorrected. The NMR spectra were measured with a JEOL FX 100 Spectrometer in $CDCl_3$ solution, and the chemical shifts expressed were in δ units. The mass spectra were measured with a JEOL 01SG-2 Spectrometer. The IR spectra were taken as KBr disks using a Jasco IR-A 102 Spectrometer. The UV spectra were taken with a Hitachi 124 Model Spectrophotometer.

Condensation Reactions of Potassium Tropolonate with Benzyl Halides under Basic Conditions. Following our previous method,[2] to anhydrous HMPA (2 cm^3) of **1** (ca. 1 mmol), an HMPA solution (2 cm^3) of **2a—c** (ca. 1 mmol) was added dropwise at room temperature and kept at 50—100 °C under an N_2 atmosphere. The mixture was then diluted with water, acidified with dil HCl, and extracted with ether. Silica-gel column chromatography of the extracts afforded **3a—c**, **4a**, and **5a**, **b**.

3a: Colorless plates, mp 164—166 °C, 69%. Found: C, 65.25; H, 4.30; N, 5.61%. Calcd for $C_{14}H_{11}O_4N$: C, 65.36; H, 4.31; N, 5.45%. ^1H NMR δ=5.24 (2H, s), 6.6—7.0 (3H, m), 7.1—7.2 (2H, m), 7.60 (2H, d, J=9 Hz), and 8.19 (2H, d, J=9 Hz). ^{13}C NMR δ=69.7, 115.5, 124.1 (2C), 127.8 (2C), 129.3, 132.5, 136.8, 138.0, 141.3, 148.0, 164.1, and 180.8. IR ν: 1620, 1600, 1570, and 1510 cm^{-1}. UV λ_{max}^{MeOH}: 265 nm (ε=11000) and 317 (9900).

4a: Yellow crystals, mp 167—169 °C, 0.3%. Found: C, 65.26; H, 4.29; N, 5.87%. ^1H NMR δ=4.21 (2H, s), 6.99 (1H, ddd, J=9.5, 6, 5 Hz), 7.2—7.6 (3H, m), 7.38 (2H, d, J=9 Hz), and 8.08 (2H, d, J=9 Hz). ^{13}C NMR δ=40.9, 120.5, 123.9 (2C), 127.7, 130.0 (2C), 136.9, 139.5, 140.1, 147.0, 147.3, 167.9, and 173.6. IR ν: 1600, 1545, and 1340 cm^{-1}. UV λ_{max}^{MeOH}: 244 nm (ε=24000), 269 (11600), 322 (7400), 356 (6200), 372 (5900), and 401 (1700).

5a: Yellow crystals, mp 170—172 °C, 8%. Found: C, 65.48; H, 4.37; N, 5.73%. ^1H NMR δ=3.40 (1H, br s, OH), 5.86 (1H, s), 6.9—7.2 (4H , m), 7.46 (1H, d, J=5.5 Hz), 7.58 (2H, d, J=9 Hz), and 8.12 (2H, d, J=9 Hz). ^{13}C NMR δ=75.2, 123.7 (2C), 127.5 (2C), 134.4, 135.4, 135.9, 137.0, 142.2, 147.5, 149.5, 153.3, and 187.5. IR ν: 3250, 1620 and 1595 cm^{-1}. UV λ_{max}^{MeOH}: 275 nm (ε=14000) and 315 (10500).

3b: Yellow needles, mp 151—153 °C, 88%. Found: C, 65.26; H, 4.29; N, 5.87%. Calcd for $C_{14}H_{11}O_4N$: C, 65.36; H, 4.31; N, 5.45%. ^1H NMR δ=5.55 (2H, s), 6.7—7.3 (5H, m), 7.4—7.8 (2H, m), and 8.0—8.2 (2H, m). ^{13}C NMR δ=67.7, 114.9, 125.2, 128.5, 128.8 (2C), 132.7, 134.8, 136.8 (2C), 137.9, 146.7, 164.2, and 180.8. IR ν: 1622, 1590, 1565, and 1515 cm^{-1}. UV λ_{max}^{MeOH}: 237 nm (ε=28600), 319 (9800), 347 (7300), and 362 (4400).

5b: Brown crystals, mp 165—167 °C, 5%. Found: C, 65.12; H, 4.46; N, 5.88%. ^1H NMR δ=6.36 (1H, s) and 6.9—8.0 (9H, m). ^{13}C NMR δ=70.4, 124.8, 128.8, 129.2, 133.5, 134.2, 134.5, 134.9, 136.7, 141.7, 148.9, 153.0 (2C), and 187.4. IR ν: 3250 and 1620 cm^{-1}. UV λ_{max}^{MeOH}: 227 nm (ε=27800) and 306 (8900).

3c: Colorless plates, mp 144—145 °C, 75%. Found: C, 75.95; H, 4.70; N, 5.98%. Calcd for $C_{15}H_{11}O_2N$: C, 75.93; H, 4.67; N, 5.90%. ^1H NMR δ=5.24 (2H, s), 6.6—7.1 (3H, m), 7.1—7.3 (2H, m), 7.53 (2H, d, J=8.5 Hz), and 7.66 (2H, d, J=8.5 Hz). ^{13}C NMR δ=69.8, 112.1, 115.4, 118.7, 127.7 (2C), 129.1, 132.5, 132.7 (2C), 136.7, 137.9, 141.1, 164.1, and 180.7. IR ν: 2225, 1615, 1595, 1565, 1490, 1465, and 1400 cm^{-1}. UV λ_{max}^{MeOH}: 237 nm (ε=40000), 320 (8900), and 345 (6900).

Base-Promoted Rearrangement of 3a. An anhydrous HMPA solution (2 cm^3) of **3a** (49 mg) was treated with NaH (4 mg) at room temperature for 5 min. Silica-gel column chromatography of the mixture gave **5a**, 35.3 mg (72%), which was identical with the sample prepared as described above.

Thermolysis of 3a. A DCB solution (17.5 cm^3) of **3a** (202 mg) was heated in a sealed tube at 180 °C for 12 h. Column chromatography of the mixture afforded **4a**, 161 mg (80%), which was identical with the sample described above.

Preparation of 6 and 7 from 2-(4-Nitrobenzylsulfonyl)-tropone (8) by Thermolysis.[6] A decalin solution (20 cm^3) of **8** (157 mg) [colorless crystals, mp 162—163.5 °C. Found: m/z, 305.0365. Calcd for $C_{14}H_{11}O_4NS$: M, 305.0358. ^1H NMR δ=4.94 (2H, s), 6.8—7.3 (4H, m), 7.52 (2H, m), 7.86 (1H, dd, J=8, 1 Hz), and 8.14 (2H, m). ^{13}C NMR δ=60.5, 123.6 (2C), 131.3, 131.6 (2C), 134.8, 135.8, 139.5, 140.3, 143.9, 145.9, 160.1, and 182.3], prepared from an oxidation of the corresponding sulfinyl derivative by m-chloroperbenzoic acid,[5] was heated at 205 °C for 2 h. The mixture was then chromatographed on a silica-gel column to give a colorless oil, **6**, 28 mg (23%) [Found: m/z, 241.0740. Calcd for $C_{14}H_{11}O_3N$: M, 241.0740. ^1H NMR δ=4.03 (2H, s), 6.9—7.3 (5H, m), 7.40 (2H, d, J=9 Hz), and 8.09 (2H, d, J=9 Hz). ^{13}C NMR δ=40.9, 123.6 (2C), 129.9 (2C), 133.4, 133.6, 135.7 (2C), 136.1, 141.0, 147.0, 152.7, and 186.1], and a colorless oil, **7**, 7 mg (6%) [Found: m/z, 241.0739. ^1H NMR δ=3.93 (2H, s), 6.8—7.1 (5H, m), 7.30 (2H, m), and 8.16 (2H, m)].

PDC-Oxidation of 5a. Formation of 9a. To a CH_2Cl_2 suspension (10 cm^3) of PDC (440 mg) and Celite (1.5 g), a CH_2Cl_2 solution of **5a** (100.4 mg) was added and stirred at room temperature for 5 h. The mixture was then purified by chromatography with Florisil column to give pale yellow crystals, mp 174—176 °C, 72 mg (72%), **9a** [Found: C, 65.77; H, 3.63; N, 5.64%. Calcd for $C_{14}H_9O_4N$: C, 65.88; H, 3.55; N, 5.49%. ^1H NMR δ=7.0—7.5 (5H, m), 7.91 (2H, d, J=9 Hz), and 8.23 (2H, d, J=9 Hz). ^{13}C NMR δ=124.1 (2C), 130.0 (2C), 134.2, 136.8, 137.0, 137.5, 141.0, 143.9, 150.1, 150.5, 186.2, and 195.1. IR ν: 1675, 1625, and 1603 cm^{-1}. UV λ_{max}^{MeOH}: 228 nm (ε=20000), 265 (16000), and 305 (9400)].

Thermolysis of 3b. Similarly, a DCB solution (2 cm^3) of **3b** (100 mg) was heated in a sealed tube at 180 °C for 13 h. The chromatography of the mixture afforded **4b**, 14.3 mg (44%) [Found: m/z, 257.0663. Calcd for $C_{14}H_{11}O_4N$: M, 257.0686. ^1H NMR δ=4.41 (2H, s), 7.2—7.5 (7H, m), and 7.94 (1H, dd, J=9, 2 Hz)], along with unchanged **3b** (67.6 mg; 68%).

Base-Promoted Rearrangement of 3b. An anhydrous HMPA solution (1.5 cm^3) of **3b** (150 mg) was treated with NaH (12.5 mg) at room temperature to give **5b**, 142 mg (95%).

Base-Promoted Rearrangement of 3c. An anhydrous HMPA solution (2.5 cm^3) of **3c** (121.8 mg) was treated with NaH (55%, 6 mg) at 0 °C for 5 min. The mixture was then diluted with water, and extracted with AcOEt. Silica-gel column chromatography of the extract yielded yellow brown crystals, mp 131—133 °C, **5c**, 40.4 mg (62%) [Found: C, 76.00; H, 4.74; N, 5.96%. Calcd for $C_{15}H_{11}O_2N$: C, 75.93; H, 4.67; N, 5.90%. ^1H NMR δ=5.83 (1H, s), 6.9—7.3 (4H, m), 7.45 (1H, d, J=5 Hz), and 7.51 (4H, s). ^{13}C NMR δ=74.9, 111.3, 127.2

(2C), 132.1 (2C), 134.2, 135.1, 135.7, 136.8, 142.0 (2C), 147.4, 153.3, and 187.2. IR ν: 3350, 2240, 1630, 1605, 1575, and 1400 cm^{-1}. UV λ_{max}^{MeOH}: 235 nm (ε=31000) and 314 (7800)], and the recovered **3c** (56.7 mg; 47%).

Thermolysis of 3c. A DCB solution (1.5 cm^3) of **3c** (55.7 mg) was heated at 180 °C for 9 h. Silica-gel column chromatography of the resultant mixture afforded colorless needles, mp 116—118 °C, **4c**, 21.5 mg (55%) [Found: C, 75.76; H, 4.61; N, 5.88%. Calcd for $C_{15}H_{11}O_2N$: C, 75.93; H, 4.67; N, 5.90%. ^1H NMR δ=4.18 (2H, s) and 6.8—7.6 (8H, m), ^{13}C NMR δ=41.4, 110.7, 119.1, 120.7, 127.6, 129.9 (2C), 132.5 (2C), 136.8, 139.5, 140.0, 145.1, 168.1, and 173.5. IR ν: 3200, 2240, 1605, 1550, 1485, 1415, and 1385 cm^{-1}. UV λ_{max}^{MeOH}: 236 nm (ε=30300), 324 (7400), 372 (5500), and 400 (2500)], and **3c** (16.9 mg; 30%).

PDC-Oxidation of 5b. Formation of 9b. To a CH_2Cl_2 suspension (10 cm^3) of PDC (133 mg) and Celite (500 mg), a CH_2Cl_2 solution (10 cm^3) of **5b** (30.1 mg) was added and stirred at room temperature for 5 h. The mixture was worked up in a manner similar to the case of **5a** and afforded yellow crystals, mp 131—133 °C, 15 mg (50%), **9b** [Found: C, 65.72; H, 3.67; N, 5.78%. Calcd for $C_{14}H_9O_4N$: C, 65.88; H, 3.55; N, 5.49%. ^1H NMR δ=6.9—7.3 (4H, m), 7.4—7.8 (3H, m), and 8.0—8.2 (2H, m). ^{13}C NMR δ=123.9, 124.8, 129.0, 130.3, 133.4, 134.1, 135.6, 137.8, 138.5, 140.1, 144.3, 146.5, 185.6, and 193.7. IR ν: 1670, 1620, 1570, 1515, and 1340 cm^{-1}. UV λ_{max}^{MeOH}: 237 nm (ε=28600), 319 (9800), 347 (7300), and 362 (4400, sh)].

PDC-Oxidation of 5c. Formation of 9c. To a CH_2Cl_2 suspension (5 cm^3) of PDC (122.6 mg) and Celite (500 mg), a CH_2Cl_2 solution (5 cm^3) of **5c** (25.1 mg) was added and similarly oxidized to give a light yellow crystals, mp 166—168 °C, 18.5 mg (74%), **9c** [Found: C, 76.44; H, 3.91; N, 5.97%. Calcd for $C_{15}H_9O_2N$: C, 76.58; H, 3.86; N, 5.96%. ^1H NMR δ=7.0—7.5 (5H, m), 7.67 (2H, d, J=8.5 Hz), and 7.87 (2H, d, J=8.5 Hz). ^{13}C NMR δ=116.6, 127.4, 129.5 (2C), 132.7 (2C), 134.2, 136.6, 136.9, 137.3, 139.4, 143.8, 150.2, 186.1, and 195.2. IR ν: 3050, 2220, 1670, 1620, 1560, 1460, and 1395 cm^{-1}. UV λ_{max}^{MeOH}: 233 nm (ε=24500) and 313 (7200)].

Condensation of 1 with 11. Formation of 10 and 12. An anhydrous HMPA solution (3 cm^3) of **1** (300.6 mg) and **11** (305 mg) was stirred at 50 °C for 2.5 h. The mixture was then acidified with dil HCl and extracted with AcOEt. The AcOEt extract was, after drying on $MgSO_4$, chromatographed on a silica-gel column to afford **10** [light brown crystals, mp 132—133 °C, 63.5 mg; 17%. Found: C, 74.97; H, 5.04%. Calcd for $C_{15}H_{12}O_3$: C, 74.99; H, 5.03%. ^1H NMR δ=5.52 (2H, s) and 6.7—8.1 (10H, m). ^{13}C NMR δ=71.7, 117.8, 128.4 (2C), 129.1 (3C), 129.7, 132.7, 134.3, 136.8, 138.4 (2C), 164.3, and 193.6. IR ν: 1685, 1625, 1590, 1565, 1495, 1470, 1450, 1430, 1405, 1395, 1375, and 1300 cm^{-1}. λ_{max}^{MeOH}: 241 nm (ε=31000), 321 (8800), 346 (7300, sh), and 361 (4700, sh)], **12** [colorless crystals, mp 118—120 °C, 222 mg; 59%. Found: C, 75.15; H, 5.08%. ^1H NMR δ=4.4—4.8 (1H, br), 6.19 (1H, s), 6.8—7.2 (4H, m), 7.2—7.6 (4H, m), and 7.8—8.1 (2H, m). ^{13}C NMR δ=73.9, 128.9 (2C), 129.0 (3C), 134.1 (2C), 135.4, 136.4, 137.2, 142.4, 151.4, 185.7, and 199.1. IR ν: 3300, 1670, 1620, 1590, 1535, 1515, 1465, 1445, 1405, and 1330 cm^{-1}. λ_{max}^{MeOH}: 233 nm (ε=25000) and 307 (7900)], and unreacted tropolone [36.8 mg; 16%].

Conversion of 10 to 12. An HMPA solution (1 cm^3) of NaH (trace) and **10** (25.1 mg) was stirred at room temperature for 10 min. After acidification with dil HCl, the mixture was extracted with AcOEt and chromatographed on a silica-gel column to give **12**, 11.1 mg (44%).

Attempted Base-Treatment of 2-Benzyloxytropone (3d). An anhydrous HMPA solution (1.5 cm^3) of NaH (6.8 mg) and **3d**[2] (60 mg) was kept at room temperature for 1.5 h. Thin-layer chromatograms of the mixture gave the recovered **3d** [44 mg; 74%] as the sole identifiable compound.

The authors wish to thank the Ministry of Education, Science and Culture for a financial support through a Grant-in-Aid for Scientific Research to A. M. (No. 60470025).

Synthesis of 2,2-Di-*C*-methyl-2-deoxy- and 4,4-Di-*C*-methyl-4-deoxypyranosides via Michael Addition of Conjugated Enopyranosiduloses

Nobuya KAWAUCHI, Ken-ichi SATO, Juji YOSHIMURA, and Hironobu HASHIMOTO*
Laboratory of Chemistry of Natural Products, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227
(Received October 7, 1986)

Three hexopyranosides having *gem*-di-*C*-methyl group at 2- or 4-positions were synthesized by Michael addition to 2-enopyranosid-4-ulose and 3-enopyranosid-2-ulose derivatives, respectively, followed by hydroboration. A heptopyranosid-6-ulose having *gem*-di-*C*-methyl group at C-4 was also synthesized from 4-enopyranosid-6-ulose derivative in a similar way.

In recent years, carbohydrates have been used widely as chiral sources for synthesis of natural products.[1] *gem*-Dialkylation of carbohydrates has progressed on this utilization. For example, the following *gem*-dialkyl groups have been constructed: a) *C*-cyano-*C*-nitromethyl as well as *C*-methyl-*C*-nitromethyl group from the *C*-nitromethylene group by Michael addition,[2] b) *C*-(ethoxycarbonylmethyl)-*C*-methyl group by enolate alkylation of the ulose derivative,[3] c) *C*-formylmethyl-*C*-vinyl group from *C*-[2-(vinyloxy)ethylidene] group by Claisen rearrangement.[4] On the other hand, introduction of *gem*-dimethyl group into the carbohydrate skeleton has not yet been reported except a recently published paper[5] and our preliminary one,[6] although *gem*-dimethylation has been achieved for non-carbohydrate compounds by several methods.[7-11] In this paper we should like to report on the synthesis of *gem*-di-*C*-methylpyranosides by Michael addition of methylcuprates(I) to conjugated enopyranosiduloses. This method has been proved to be useful for construction of *gem*-dimethyl function at C-2 and C-4 positions of hexopyranosides, while the method by hydrogenolytic cleavage of spirocyclopropane ring for that at C-3 position.[6]

Results and Discussion

Four kinds of conjugated enopyranosiduloses **2**—**5** were used for this study. The first two branched-chain enopyranosiduloses **2** and **3** were derived from a common starting compound, i.e., methyl 6-*O*-trityl-α-D-*glycero*-2-enopyranosid-4-ulose (**6**).[12] Conjugate 1,4-addition of a lithium (cyano)dimethylcuprate(I), $Me_2Cu(CN)Li_2$, to **6** followed by treatment with chlorotrimethylsilane, gave the corresponding enol trimethylsilyl ether **7**. Dehydrosilylation of **7** with *p*-benzoquinone in the presence of palladium(II) acetate[13] afforded **2** in 55% yield from **6**. Alternatively, the enone **2** was prepared from methyl 4,6-*O*-benzylidene-2-deoxy-2-*C*-methyl-α-D-altropyranoside (**9**) via the 3-enopyranoside **8**, which was formed selectively by treatment of the 3-mesylate **10** of **9** with potassium *t*-butoxide. Palladium-catalyzed enone formation[14] was proved to be effective for the enolate **8** to give enone **1**, which was converted into **2** by a conventional tritylation. The total yield of **2** from **9** was 11.4%. The latter route proved to be rather convenient than the previous one[15] in the steps of elimination and enone formation.

On the other hand, the enone **3** was already prepared[16] by pyridinium chlorochromate oxidation of 1,2-adduct **11** obtained by treatment of **6** with methyllithium. In the addition reaction the ratio of **11** and its 4-epimer was proved to be 4 : 3, while with methylcerium(III) reagent[17] instead of methyllithium **11** was obtained exclusively in a quantitative yield. Thus it is noteworthy that the methylcerium reagent tends to facilitate axial attack of carbanion, which was also observed in the reaction of methyl 3,4-dideoxy-6-*O*-trityl-α-D-*glycero*-3-enopyranosid-2-ulose.[18] Furthermore, oxidation of **11** with pyridinium fluoroformate[19] instead of chloroformate gave **3** in a higher yield (86%), indicating that this less acidic oxidant are convenient and effective for allylic alcohol.

The enone **4** was derived from methyl 6-*O*-benzyl-2,3-di-*O*-methyl-α-D-glucopyranoside (**12**)[20] according to a similar strategy to Hanessian et al.[21] Swern oxidation of **12** gave the corresponding 4-ulose, which was converted stereoselectively with methylmagnesium iodide into the 4-*C*-methyl derivative **13** of D-*galacto* configuration in 77% yield in two steps. Methylation of **13** followed by hydrogenolytic removal of 6-*O*-benzyl group and Swern oxidation gave a dialdose **14** in 79% yield. Then, **4** was obtained in 65% yield by treatment of **14** with calcium hydroxide. As shown in

Table 1 the reaction of **4** with various methylcuprates(I) gave in good yields the 1,2-adduct **15**, from which the enone **5** was derived quantitatively by Swern oxidation.

17 $R^1=R^2=H$

The reaction of these enones **2**, **3**, and **5** with lithium (cyano)dimethylcuprate(I), $Me_2Cu(CN)Li_2$, gave preferentially 1,4-adducts, *gem*-di-*C*-methyl-pyranosiduloses **18**, **19**, and **20**, respectively, in high yields as shown in Table 1. In the case of **3** very small amount of by-product, the *β*-anomer of **19**, was isolated. On the other hand, the reaction of the enal **4** afforded an epimeric mixture of 1,2-adduct **15** together with small amount of reduced product **17**. The distinct difference of regioselectivity in the addition reactions between **4** and **5** coincide with the fact that aldehydes react easily with lithium organocuprates, while ketones not.[22]

Table 1. Reaction of Methyl Branched Enones **2**—**5** with Lithium Methylcuprates (I)

Enone	Product	Yield/%	
		Me_2CuLi	$Me_2Cu(CN)Li_2$
2	**18**	72	77
	5-epimer of **18**	8.4	3.1
3	**19**	82	93
	β-anomer of **19**	6.9	4.1
4[a]	**15**	62	90
	17	12	trace
5	**20**	83	89

a) With $Me_5Cu_2Li_3$ the yield of **15** was 93%.

Thus, it was turned out that *gem*-dimethylation in hexopyranoside ring could be performed very easily using conjugate addition to the enopyranosiduloses. Furthermore, in the cases of **18** and **19** asymmetric carbons lost during the enone formation was also recovered by hydroboration of the silyl enolates[23] e.g., **18** → **21** → **24** or **19** → **23** → **26**. The enolates **21** and **23** were obtained by quenching the above mentioned Michael addition with chlorotrimethylsilane in good yields. Hydroborations of **21** and **23** were examined using various reagents and the products were analyzed after hydrolysis and acetylation. As summarized in Table 2, hydroboration with 3 equivalents of diborane gave the best results. In the case of **21**, only 2-deoxy-2,2-di-*C*-methyl-hexopyranoside derivative **24** was obtained as hydroboration product, where a small amount of 3-deoxy-D-*erythro*-hexopyranoside **25** and 3-enopyranoside **22** were also formed. In the case of **23**, 4-deoxy-4,4-di-*C*-methyl-D-*xylo*- **26** and D-*arabino*-hexopyranoside derivatives **28** were obtained in a ratio of 3 to 1, and 3-deoxy-D-*erythro*-hexopyranoside **27** was also formed. Hydroboration with borane formed in situ from sodium borohydride and Lewis acids such as titanium(III) chloride[24] and cobalt(II) chloride[25] gave also the desired products in moderate yields, although recovery of the uloses were increased. On the other hand, hydroboration with disiamylborane and 9-borabicyclo[3.3.1]nonane (9-BBN) gave small amount of the reduced by-products, **25** and **27**, while the uloses were recovered in high yield. Only in the case of **23** hydroboration with disiamylborane afforded **26**, albeit in 17% yield, stereoselectively. The structures of **24**, **26**, and **28** were confirmed on the basis of two acetyl signals and the coupling constants of methine protons

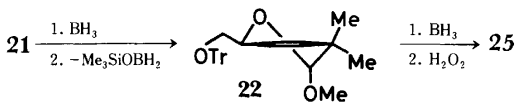
with acetoxyl groups, i.e., $J_{3,4}$=8.0 Hz, $J_{2,3}$=7.8 Hz, and $J_{2,3}$=4.0 Hz, respectively. While those of **25** and **27** by one acetyl signal and the coupling constants of methine protons with acetoxyl group, i.e., $J_{3ax,4}$=7.8 Hz and $J_{2,3ax}$=13.3 Hz, respectively.

The formation of the deoxygenated derivatives, **25** and **27**, may be rationalized by trans β-elimination[26] of trimethylsiloxyborane from the hydroboration products, giving the corresponding de(trimethylsilyloxy) derivative. Actually in the reaction of **21**, the de(trimethylsilyloxy) intermediate **22** was isolated. Further hydroboration of **22** followed by oxidation may give **25**, where the stereoselectivity was well-explained by a half-chair conformation as depicted in the following scheme.



Thus, Michael addition of lithium methylcuprate to 2-enopyranosid-4-ulose and 3-enopyranosid-2-ulose derivatives, followed by hydroboration-oxidation, opened the synthetic routes of hexopyranosides having *gem*-di-*C*-methyl group at 2- and 4-positions, respectively.

Experimental

General Methods. Melting points determined with a Yanagimoto micro melting point apparatus, were uncorrected. Optical rotations were measured in chloroform, by using a 0.5-dm tube with a Carl Zeiss LEP-Al polarimeter. Infrared spectra were recorded on a Hitachi EPI-G2 grating spectrometer. ^{1}H and ^{13}C NMR spectra were recorded at 100 MHz with a JEOL JMN PS-100 spectrometer and at 22.5 MHz with a JEOL FX-90Q spectrometer, respectively, in $CDCl_3$ with tetramethylsilane as internal standard. Column chromatography was performed on silica gel (Wakogel C-300: Wako Pure Chemical Industries, Ltd.) ^{1}H and ^{13}C NMR data of pyranosides having *gem*-di-*C*-methyl group are summarized in Table 3.

Methyl 2,3-Dideoxy-2-*C*-methyl-6-*O*-trityl-α-D-*glycero*-hex-2-enopyranosid-4-ulose (2). To a mixture of palladium(II) acetate (112 mg, 0.5 mmol) and *p*-benzoquinone (54 mg, 0.5 mmol) was added under argon a solution of **7** (460 mg, 0.95 mmol), whose preparation is described below, in acetonitrile (4 ml). The mixture was stirred at 50 °C for 6 h, and fractionated directly on a silica-gel column with benzene-acetone (15 : 1) to give **2** (241 mg, 62%). IR and NMR data of **2** coincided with the reported data.[15]

Methyl 3,4-Dideoxy-4-*C*-methyl-6-*O*-trityl-α-D-*glycero*-hex-3-enopyranosid-2-ulose (3). A solution of pyridinium fluorochromate (2.36 g, 11.9 mmol) and **11** (2.72 g, 6.6 mmol) in dichloromethane (84 ml) was stirred at room temperature for 6 h. The undissolved materials were filtered off, and the filtrate was washed with 2.5% aqueous sodium hydroxide and water, and dried with potassium carbonate. Evaporation of the filtrate gave a syrup, which was purified on a short column of silica gel with hexane-ethyl acetate (18 : 1) to afford **3** (2.33 g, 86%) as a colorless syrup. ^{1}H NMR data was identical with those reported.[16]

Methyl 4-Deoxy-2,3-di-*O*-methyl-4-*C*-methyl-β-L-*threo*-hexodialdo-4-enopyranoside-(1,5) (4). To a solution of **14** (500 mg, 2.0 mmol) in tetrahydrofuran (5 ml) and water (5 ml), was added 0.5 M (1 M=1 mol dm^{-3}) aqueous solution of barium hydroxide (4 ml). The mixture was kept at room temperature for 6 h, then saturated with ammonium chloride and extracted with chloroform. The extract was washed with aqueous sodium chloride, dried over magnesium sulfate, and evaporated to give a crude mixture of products, which was fractionated on a column of silica gel with hexane-acetone (5 : 1) to give **4** (284 mg, 65%), methyl 2,3-di-*O*-methyl-4-*C*-methylene-β-L-*threo*-hexodialdo-4-enopyranoside-(1,5) (17 mg, 3.9%), and starting material (29 mg, 5.8%).

4: Mp 148—150 °C, $[\alpha]_D^{20}$ +31.2° (*c* 0.7, $CHCl_3$). IR (KBr) 1680 (CO) and 1640 cm^{-1} (C=C), ^{1}H NMR δ=5.06 (1H, d, H-1), 3.92 (1H, dd, $J_{1,2}$=2.2 Hz, H-2), 3.60 (1H, d, $J_{2,3}$=7.8 Hz, H-3), 9.76 (1H, s, H-6), 2.12 (3H, s, C-Me), 3.44 (3H, s, OMe) and 3.52 (6H, s, OMe).

Found: C, 55.38; H, 7.48%. Calcd for $C_{10}H_{16}O_5$: C, 55.54; H, 7.46%.

The *exo*-methylene compound was a syrup, and had $[\alpha]_D^{20}$ +10.1° (*c* 0.88, $CHCl_3$). ^{1}H NMR δ=4.96 (1H, d, $J_{1,2}$=3.0 Hz, H-1), 3.6—3.7 (2H, m, H-2 and H-3), 3.98 (1H, bs, H-5), 9.54 (1H, bs, H-6), 3.52 (3H, s, OMe), and 3.56 (6H, s, OMe).

Found: C, 55.41: H, 7.60%. Calcd for $C_{10}H_{16}O_5$: C, 55.54; H, 7.46%.

Methyl 4,7-Dideoxy-4-*C*-methyl-2,3-di-*O*-methyl-β-L-*threo*-hept-4-enopyranosid-6-ulose (5). To a suspension of cerium(III) chloride (318 mg, 1.3 mmol) in tetrahydrofuran (5 ml), was added an ethereal solution of methyllithium (1.2 M solution, 1.1 ml, 1.3 mmol) at −78 °C, and then after 1 h a solution of **4** (260 mg, 1.1 mmol) in tetrahydrofuran (5 ml). The mixture was kept at −78 °C for 4 h and poured into a saturated ammonium chloride solution and extracted with dich-

loromethane. The extract was washed with aqueous sodium chloride, dried with sodium sulfate, and evaporated to give crude 1,2-adduct as a syrup. The syrup was oxidized with dimethyl sulfoxide (0.3 ml) and oxalyl dichloride (0.2 ml) in dichloromethane (4.5 ml) in the same manner as described for compound **14**. Crude **5** was purified on a column of silica gel with hexane-ether (3:1), yield, 206 mg (82%); syrup, IR (NaCl) 1700 (C=O) and 1660 cm^{-1} (C=C). ^1H NMR δ=4.96 (1H, d, $J_{1,2}$=3.6 Hz, H-1), 3.44 (1H, dd, $J_{2,3}$=6.4 Hz, H-2), 3.72 (1H, d, H-3), 1.88 and 1.96 (each 3H, each s, CMe), 3.50 (3H, s, OMe) and 3.58 (6H, s, OMe).

Found: C, 57.66; H, 8.17%. Calcd for $C_{11}H_{18}O_5$: C, 57.38; H, 7.88%.

Preparation of Enol Trimethylsilyl Ethers 7, 21, and 23 from Enones 6, 2, and 3. To a reaction mixture of an enone with lithium (cyano)dimethylcuprate(I) as described latter, was added after 4 h at −78 °C triethylamine (1.7 ml per 1.0 mmol of enone), hexamethylphosphoric triamide (0.3 ml per 1.0 mmol of enone), and chlorotrimethylsilane (1.7 ml per 1.0 mmol of enone). Being kept at 0 °C for 1 h, the mixture was processed in the same manner as described for **13**. The enol ethers were used for further reaction without purification.

Methyl 2,3-Dideoxy-2-*C*-methyl-4-*O*-trimethylsilyl-6-*O*-trityl-α-D-*threo*-hex-3-enopyranoside (7). Treatment of **6**[12] as described above gave **7** quantitatively, which was characterized only by ^1H NMR δ=4.72 (1H, d, $J_{1,2}$=4.8 Hz, H-1), 2.54 (1H, dq, $J_{2,Me}$=6.8 Hz, H-2), 4.66 (1H, bs, H-3), 4.22 (1H, dd, $J_{5,6}$=4.4 Hz, $J_{6,6'}$=8.0 Hz, H-5), 3.40 (1H, t, $J_{5,6'}$=8.0 Hz, H-6), 3.52 (1H, dd, H-6'), 0.12 (9H, s, SiMe), 1.02 (3H, d, C-Me), 3.62 (3H, s, OMe) and 7.2—7.6 (15H, m, Tr).

Methyl 2,3-Dideoxy-2,2-di-*C*-methyl-4-*O*-trimethylsilyl-α-D-*glycero*-hex-3-enopyranoside (21). Treatment of **2** as described above gave **21** quantitatively, which was characterized only by ^1H NMR δ=4.62 (1H, s, H-1), 4.68 (1H, bs, H-3), 3.0—3.4 (2H, m, H-5 and H-6'), 3.84 (1H, dd, $J_{5,6}$=4.0 Hz, $J_{6,6'}$=6.6 Hz, H-6), 0.18 (9H, s, SiMe), 0.98 and 1.00 (each 3H, each s, C-Me), 3.56 (3H, s, OMe), and 7.2—7.6 (15H, m, Tr).

Methyl 3,4-Dideoxy-4,4-di-*C*-methyl-2-*O*-trimethylsilyl-6-*O*-trityl-α-D-*glycero*-hex-2-enopyranoside (23). Treatment of **3**[16] as described above gave **23** quantitatively, which was characterized only by ^1H NMR δ=4.70 (1H, s, H-1), 4.94 (1H, s, H-3), 3.92 (1H, dd, $J_{5,6}$=3.8 Hz, $J_{5,6'}$=6.2 Hz, H-5), 3.36 (1H, dd, $J_{6,6'}$=7.0 Hz, H-6), 3.28 (1H, dd, H-6'), 0.18 (9H, s, SiMe), 0.76 and 0.84 (each 3H, each s, C-Me), 3.66 (3H, s, OMe) and 7.2—7.6 (15H, m, Tr).

Methyl 6-*O*-Benzyl-2,3-di-*O*-methyl-4-*C*-methyl-α-D-galactopyranoside (13). Swern oxidation of **12**,[20] as described for **14**, gave the corresponding 4-ulose in 84% yield. To a solution of methylmagnesium iodide (2.17 mmol) in ether (5 ml) was added the ulose (227 mg, 0.72 mmol) at 0 °C. After 12 h at the same temperature, the solution was mixed with saturated aqueous ammonium chloride and extracted with dichloromethane. The extract was washed with aqueous sodium chloride, dried over magnesium sulfate, and evaporated. The crude mixture of products was fractionated on a column of silica gel with hexane-ethanol (18:1) to give **13** (187 mg, 81%) and its 4-epimer (23 mg, 10%).

13: Syrup, $[\alpha]_D^{20}$ +62.5° (*c* 0.86, $CHCl_3$); ^1H NMR δ=4.96 (1H, d, $J_{1,2}$=3.6 Hz, H-1), 3.24 (1H, dd, H-2), 3.6—3.8 (4H, m, H-3, H-5, H-6 and H-6'), 1.06 (3H, s, C-Me), 3.44, 3.52, and 3.60 (each 3H, each s, OMe), 4.64 (2H, bs, $CH_2C_6H_5$) and 7.44 (5H, bs, C_6H_5).

Found: C, 63.08; H, 7.56%. Calcd for $C_{17}H_{24}O_6$: C, 62.95; H, 7.46%.

4-Epimer of **13**: Syrup $[\alpha]_D^{20}$ +43.1° (*c* 0.81, $CHCl_3$);

^{1}H NMR δ=5.02 (1H, d, $J_{1,2}$=3.6 Hz, H-1), 3.26 (1H, dd, $J_{2,3}$=6.6 Hz, H-2), 3.6—3.8 (4H, m, H-3, H-5, H-6, and H-6'), 1.32 (3H, s, C-Me), 3.68 (6H, s, OMe), 4.62 (2H, bs, $CH_2C_6H_5$) and 7.44 (5H, bs, C_6H_5).

Found: C, 62.66; H, 7.28%. Calcd for $C_{17}H_{24}O_6$: C, 62.95%; H, 7.46%.

When this reaction was performed at −78 °C, only **13** was obtained in 90% yield. Furthermore, treatment of the ulose with methyllithium in ether at −78 °C for 5 h and at room temperature overnight, gave **13** and its 4-epimer 42 and 36% yields, respectively.

Methyl 2,3,4-Tri-*O*-methyl-4-*C*-methyl-α-D-*galacto*-hexodialdo-pyranoside-(1,5) (14). Treatment of **13** with sodium hydride in *N*,*N*-dimethylformamide for 4 h and then with methyl iodide at 0 °C, gave the 4-*O*-methyl derivative in 94% yield, which was hydrogenolyzed under 3 atm (1 atm=1.01×10^5 Pa) in the presence of 10% palladium on carbon in methanol and water (10 : 1) at room temperature overnight to give the *O*-debenzylated derivative in 93% yield.

To a solution of oxalyl dichloride (0.92 ml, 10.8 mmol) in dichloromethane (30 ml) was added a solution of dimethyl sulfoxide (0.94 ml, 12.9 mmol) in dichloromethane (10 ml) at −78 °C and then the *O*-debenzylated derivative (2.1 g, 8.5 mmol) at −78 °C. The reaction mixture was kept at −78 °C for 30 min, quenched with triethylamine, poured into water, and extracted with chloroform. The extract was washed with water, dried over magnesium sulfate, and evaporated to give **14** (1.87 g, 90%) as colorless syrup, $[\alpha]_D^{20}$ +41.6° (*c* 1.30, $CHCl_3$); ^{1}H NMR δ=5.02 (1H, d, $J_{1,2}$=3.0 Hz, H-1), 3.28 (1H, dd, $J_{2,3}$=8.0 Hz, H-2), 3.62 (1H, d, H-3), 3.88 (1H, bs, H-5), 9.62 (1H, bs, H-6), 1.40 (3H, s, C-Me) and 3.38, 3.42, 3.48, and 3.54 (each 3H, each s, OMe).

Found: C, 53.45; H, 8.27%. Calcd for $C_{11}H_{20}O_6$: C, 53.22; H, 8.12%.

Reaction of Enones 2—5 with Lithium Dimethylcuprate-(I). To a suspension of copper(I) iodide (0.68 g, 3.6 mmol) in ether (10 ml) was added methyllithium (6 ml of 1.2 M ethereal solution, 7.2 mmol) at 0 °C under an atmosphere of argon, and then a solution of an enone (1.2 mmol) in ether (5 ml). The reaction mixture was kept at 0 °C for 4 h and processed in the same manner as described for **13** to give a mixture of products, which was fractionated on a column of silica gel with the solvent system given below in individual cases.

Reaction of Enones 2—5 with Lithium (Cyano)dimethylcuprate(I). To a suspension of copper(I) cyanide (424 mg, 4.73 mmol) in ether (13 ml), was added methyllithium (12.9 ml of 1.2 M ethereal solution, 9.5 mmol) at −78 °C. When the solution became clear, a solution of an enone (1.58 mmol) in ether (6.5 ml) was added, and the same temperature was kept for 4 h. The reaction mixture was processed in the same manner as described above and the results are summarized in Table 1.

A Mixture 15 of Methyl 4,7-Dideoxy-2,3-di-*O*-methyl-4-*C*-methyl-α-D-*xylo*-hept-4-enopyranoside and Its 6-Epimer. The reactions of **4** as described above gave a mixture of unseparable two epimers **15** and methyl 4-deoxy-2,3-di-*O*-methyl-4-*C*-methyl-β-L-*threo*-hex-4-enopyranoside (**17**), which were separated on a silica gel column with hexane-ethyl acetate (3 : 1). The epimeric mixture **15** was only characterized by ^{1}H NMR.

15: Syrup, ^{1}H NMR (major): δ=4.80 (d, $J_{1,2}$=2.0 Hz, H-1), 3.46 (H-2), 3.62 (bd, $J_{2,3}$=6.6 Hz, H-3), 4.54 (bq, $J_{6,7}$=6.4 Hz, H-6), 1.36 (d, H-7), 1.58 (bs, C-Me) and 3.46 (s, OMe), (minor): δ=4.76 (d, $J_{1,2}$=2.0 Hz, H-1), 1.34 (d, H-7) and 3.38 (s, OMe).

Furthermore, conventional acetylation of **15** with acetic anhydride and pyridine gave **16** as colorless syrup, **16**: ^{1}H NMR (major) δ=4.96 (d, H-1), 3.56 (H-2), 3.74 (d, $J_{2,3}$=8.8 Hz, H-3), 5.76 (q, H-6), 1.74 (bs, C-Me), 1.42 (d, H-7), 2.08 (s, OAc) and 3.56 (bs, OMe), (minor) δ=4.94 (d, $J_{1,2}$=2.2 Hz, H-1), 3.78 (d, H-3), 5.76 (q, $J_{6,7}$=6.2 Hz, H-6), 1.40 (d, H-7) and 3.50 (s, OMe).

17: Syrup, $[\alpha]_D^{23}$ +28.5° (*c* 0.43, $CHCl_3$), IR (NaCl) 3500 (OH) and 1610 cm^{-1} (C=C); ^{1}H NMR δ=4.76 (1H, d, $J_{1,2}$=3.6 Hz, H-1), 3.22 (1H, dd, $J_{2,3}$=5.8 Hz, H-2), 3.68 (1H, d, H-3), 3.38 (2H, bs, H-6), 1.74 (3H, bs, C-Me) and 3.42, 3.44, and 3.50 (each 3H, each s, OMe).

Found: C, 54.88; H, 8.27%. Calcd for $C_{10}H_{18}O_5$: C, 55.03; H, 8.31%.

Methyl 2,3-Dideoxy-2,2-di-*C*-methyl-6-*O*-trityl-α-D-*glycero*-hexopyranosid-4-ulose (18). The reactions of **2** with lithium methylcuprates(I) as described above gave a mixture of **18** and its 5-epimer, methyl 2,3-dideoxy-2,2-di-*C*-methyl-6-*O*-trityl-β-L-*glycero*-hexopyranosid-4-ulose, which were separated on a column of silica gel with hexane-ethyl acetate (15 : 1).

18: Syrup, $[\alpha]_D^{23}$ +104.1° (*c* 2.2, $CHCl_3$); IR (NaCl) 1740 cm^{-1} (C=O). The ^{1}H and ^{13}C NMR data are given in Table 3.

Found: C, 78.25; H, 7.09%. Calcd for $C_{28}H_{30}O_4$: C, 78.11; H, 7.02%.

5-Epimer of **18**: Syrup, $[\alpha]_D^{23}$ +38.6° (*c* 1.41, $CHCl_3$); IR (NaCl) 1740 cm^{-1} (C=O), ^{1}H NMR δ=4.36 (1H, s, H-1), 2.12, and 2.48 (each 1H, each d, J=16.0 Hz, H-3 and H-3'), 4.12 (1H, dd, $J_{5,6}$=3.6 Hz, $J_{5,6'}$=5.4 Hz, H-5), 3.4—3.6 (2H, m, H-6), 1.02 and 1.00 (each 3H, each s, C_2-Me), 3.38 (3H, s, OMe) and 7.1—7.5 (m, Tr).

Found: C, 78.05; H, 7.02%. Calcd for $C_{28}H_{30}O_4$: C, 78.11; H, 7.02%.

Methyl 3,4-Dideoxy-4,4-di-*C*-methyl-6-*O*-trityl-α-D-*glycero*-hexopyranosid-2-ulose (19). The reaction of **3** with lithium methylcuprates(I) as described above gave crude **19**, which was purified on a column of silica gel with hexane-ethyl acetate (10 : 1), syrup, $[\alpha]_D^{23}$ +27.1° (*c* 1.5, $CHCl_3$), IR (NaCl) 1740 cm^{-1} (C=O). The ^{1}H and ^{13}C NMR data are given in Table 3.

Found: C, 77.93; H, 7.24%. Calcd for $C_{28}H_{30}O_4$: C, 78.11; H, 7.02%.

Methyl 4,7-Dideoxy-2,3-di-*O*-methyl-4,4-di-*C*-methyl-α-D-*xylo*-heptopyranosid-6-ulose (20). The reactions of **5** with lithium methylcuprates(I) as described above gave crude **20**, which was purified on a column of silica gel with hexane-ethyl acetate (4 : 1), syrup, $[\alpha]_D^{23}$ +55.2° (*c* 0.44, $CHCl_3$), ^{1}H NMR δ=4.68 (1H, d, $J_{1,2}$=3.2 Hz, H-1), 3.4—3.6 (2H, m, H-2), 1.36 and 1.56 (each 3H, each s, C_4-Me), 1.82 (3H, s, C_6-Me), 3.52 (6H, s, OMe) and 3.46 (3H, s, OMe).

Found: C, 58.29; H, 9.20%. Calcd for $C_{12}H_{22}O_5$: C, 58.51; H, 9.00%.

Hydroborations of 21 and 23. (i) With Borane in Tetrahydrofuran. To a solution of a enol trimethylsilyl ether (503 mg, 1.0 mmol) in tetrahydrofuran (6.5 ml), was added calculated amount of borane (the amount given in Table 2, 1 M solution in tetrahydrofuran) at 0 °C under an atmosphere of argon. Being kept at room temperature for 6 h, the reaction mixture was poured into water (10 ml). To a separated organic layer was added, at 0 °C with vigorous stirring, 10%

aqueous sodium hydroxide (5 ml) and hydrogen peroxide (30%, 5 ml) and the stirring was continued at 45 °C for 30 min. The reaction mixture was extracted with chloroform and the extract was washed with aqueous sodium chloride, dried over magnesium sulfate, and evaporated to give a mixture of products as a colorless syrup. The mixture was acetylated conventionally with acetic anhydride (2 ml) and pyridine (3 ml). In the case of **21**, fractionation of the products on a column of silica gel with hexane-ethyl acetate (15 : 1) afforded **22**, **24**, and **25** in the yields given in Table 2, while in the case of **23** with hexane-ethyl acetate (25 : 1) **26**, **27**, and **28**.

(ii) With Sodium Borohydride and Titanium(III) Chloride. To a mixture of sodium borohydride (100 mg, 2.6 mmol) and 18-crown-6 (132 mg, 0.5 mmol) in tetrahydrofuran (10 ml) was added titanium(III) chloride (85 mg, 0.55 mmol), and the mixture was stirred at 30 °C for 1 h under argon. After the color of the solution turned to be dark violet, a solution of enol silyl ether (503 mg, 1.0 mmol) in tetrahydrofuran (5.5 ml) was added, and the mixture was stirred at the same temperature for 8 h. To the mixture was added methanolic sodium methoxide (3 ml of 3 M solution) and then 30% aqueous H_2O_2 (5 ml). Being kept at 40 °C for 1 h, the reaction mixture was processed in the same manner as described above.

(iii) With Sodium Borohydride and Cobalt(II) Chloride. To a suspension of cobalt(II) chloride (325 mg, 2.5 mmol) in tetrahydrofuran (8 ml), was added with stirring at 0 °C under argon sodium borohydride (195 mg, 5 mmol). After 1 h a solution of enol silyl ether (0.66 mmol) in tetrahydrofuran (3 ml) was added after stirring at room temperature for 1.5 h, and the mixture was stirred at room temperature for 8 h. The successive oxidation was performed as described for hydroboration with titanium(III) chloride and sodium borohydride.

(iv) With Disiamylborane. To a 0.6 M solution of disiamylborane (2 ml) in tetrahydrofuran was added a solution of enol silyl ether (503 mg, 1.0 mmol) in tetrahydrofuran (6 ml) at room temperature, and the mixture was stirred at room temperature for 8 h. The oxidation was performed in the same manner as described above.

(v) With 9-Borabicyclo[3.3.1]nonane (9-BBN). To a 0.5 M solution of 9-borabicyclo[3.3.1]nonane (2.4 ml) in tetrahydrofuran was added a solution of enol silyl ether (503 mg, 1.0 mmol) in tetrahydrofuran (5.5 ml). The mixture was heated under reflux for 6 h. The oxidation was performed in the same manner as described above.

Methyl 3,4-Di-*O*-acetyl-2-deoxy-2,2-di-*C*-methyl-6-*O*-trityl-α-D-*arabino*-hexopyranoside (24). Hydroboration of **21** with 3 equivalents of diborane in the same manner as described above gave a mixture of **24**, methyl 4-*O*-acetyl-2,3-dideoxy-2,2-di-*C*-methyl-6-*O*-trityl-α-D-*erythro*-hexopyranoside (**25**), and methyl 2,3,4-trideoxy-2,2-di-*C*-methyl-6-*O*-trityl-α-D-*glycero*-hex-3-enopyranoside (**22**).

24: Syrup, $[\alpha]_D^{23}$ +150.6° (*c* 1.2, $CHCl_3$), IR (NaCl) 1720 cm^{-1} (C=O). The ^1H and ^{13}C NMR data are given in Table 3.

Found: C, 72.11; H, 6.85%. Calcd for $C_{32}H_{36}O_7$: C, 72.16; H, 6.81%.

25: Syrup, $[\alpha]_D^{23}$ +13.7° (*c* 0.97, $CHCl_3$), IR (NaCl) 1720 cm^{-1} (C=O). The ^1H and ^{13}C NMR data are given in Table 3.

Found: C, 75.68; H, 7.50%. Calcd for $C_{30}H_{34}O_5$: C, 75.92; H, 7.22%.

22: Syrup, $[\alpha]_D^{23}$ +12.0° (*c* 1.14, $CHCl_3$), IR (NaCl) 1680 cm^{-1} (C=C), ^1H NMR δ=4.44 (1H, s, H-1), 5.62 (1H, bd, $J_{3,4}$=9.2 Hz, H-3), 5.58 (1H, bdd, $J_{4,5}$=4.6 Hz, H-4), 3.82 (1H, bdd, $J_{5,6}$=4.0 Hz, $J_{5,6'}$=6.8 Hz, H-5), 3.12 (2H, m, H-6), 1.02 and 1.10 (each 3H, each s, C_2-Me), 3.52 (3H, s, OMe) and 7.2—7.6 (15H, m, Tr).

Found: C, 80.96; H, 7.43%. Calcd for $C_{28}H_{30}O_3$: C, 81.13; H, 7.29%.

Methyl 2,3-Di-*O*-acetyl-4-deoxy-4,4-di-*C*-methyl-6-*O*-trityl-α-D-*xylo*-hexopyranoside (26) and Methyl 2,3-Di-*O*-acetyl-4-deoxy-4,4-di-*C*-methyl-6-*O*-trityl-α-D-*arabino*-hexpyranoside (28). Hydroboration of **23** in the same manner as described above gave **26**, **28**, and methyl 2-*O*-acetyl-3,4-dideoxy-4,4-di-*C*-methyl-6-*O*-trityl-α-D-*erythro*-hexopyranoside (**27**).

26: Syrup, $[\alpha]_D^{23}$ +91.5° (*c* 0.89, $CHCl_3$), IR (NaCl) 1700 and 1710 cm^{-1} (C=O). The ^1H and ^{13}C NMR data are given in Table 3.

Found: C, 72.02; H, 6.92%. Calcd for $C_{32}H_{36}O_7$: C, 72.16; H, 6.81%.

28: Syrup, $[\alpha]_D^{23}$ +113.1° (*c* 1.3, $CHCl_3$), IR (NaCl) 1720 cm^{-1} (C=O). The ^1H and ^{13}C NMR data are given in Table 3.

Found: C, 71.96; H, 6.79%. Calcd for $C_{32}H_{36}O_7$: C, 72.16; H, 6.81%.

27: Mp 128—130 °C, $[\alpha]_D^{23}$ +51.2° (*c* 1.2, $CHCl_3$), IR (NaCl) 1710 cm^{-1} (C=O), ^1H NMR δ=4.87 (1H, dd, $J_{1,2}$=3.4 Hz, $J_{1,3}$=0.6 Hz, H-1), 4.89 (1H, ddd, $J_{2,3}$=5.3 Hz, $J_{2,3'}$=13.3 Hz, H-2), 1.42 and 1.76 (each 1H, each dd, $J_{3,3'}$=11.5 Hz, H-3 and H-3'), 3.74 (1H, dd, $J_{5,6}$=3.8 Hz, $J_{5,6'}$=9.8 Hz, H-5), 3.10 (1H, dd, $J_{6,6'}$=9.8 Hz, H-6), 3.22 (1H, t, H-6'), 0.78 and 0.82 (each 3H, each s, C-Me), 2.16 (3H, s, OAc), 3.58 (3H, s, OMe) and 7.2—7.6 (m, Tr). The data for H-1, H-2, H-3, and H-3', were obtained by simulation.

Found: C, 75.63; H, 6.95%. Calcd for $C_{30}H_{34}O_5$: C, 75.92; H, 7.22%.

^1H NMR data of deacetylated **27**: δ=4.86 (1H, d, $J_{1,2}$=3.8 Hz, H-1), 3.58 (1H, dt, $J_{2,3}$=3.8 Hz, $J_{2,3'}$=6.2 Hz, H-2), 1.44 and 1.64 (each 1H, each dd, $J_{3,3'}$=12.0 Hz, H-3 and H-3'), 3.59 (1H, dd, $J_{5,6}$=4.0 Hz, $J_{5,6'}$=7.6 Hz, H-5), 3.14 (1H, dd, $J_{6,6'}$=7.6 Hz, H-6), 3.28 (1H, t, H-6'), 0.72 and 0.80 (each 3H, each s, C-Me), 3.60 (3H, s, OMe) and 7.2—7.6 (m, Tr).

Reaction of Enohexopyranoside Acetates with Lithium Dimethylcuprate(I) and Its Application to Synthesis of Prelog-Djerassi Lactone

Nobuya KAWAUCHI and Hironobu HASHIMOTO*
Department of Life Science, Faculty of Science, Tokyo Institute of Technology, Nagatsuta, Midori-ku, Yokohama 227
(Received October 7, 1986)

In the reaction of two 2-*O*-acetyl-3-enohexopyranosides and four 4-*O*-acetyl-2-enohexopyranosides including 2-*C*-methyl and 4-*C*-methyl derivatives, respectively, with lithium dimethylcuprate(I), anti S_N2' substitution was proved to be preferential, giving the corresponding *C*-methylated derivatives. On the other hand, S_N2 substitution occurred in the reaction of the 2-enopyranoside without methyl branch and D-glucal triacetate.

Allylic structure is readily introduced into hexopyranoside ring by elimination of vicinal diol among three consecutive hydroxyl groups.[1] Alkylation of allylic ester with lithium organocuprates[2] have been widely used for synthesis of such natural products as prostaglandin D_2.[3] In this paper, the reaction of unsaturated sugars having allylic acetate structure in the hexopyranoside ring with lithium dimethylcuprate(I) was studied in order to develop a new method for preparation of *C*-methylated chiral synthons, one of which was used for synthesis of Prelog-Djerassi lactone.

Results and Discussion

Because preliminary studies on reactions of such allylic alcohols as **1** and **2** with $MeCu \cdot BF_3$[4] or with methylmagnesium bromide in the presence of bis(triphenylphosphine)nickel(II) chloride[5] did not give promising results,[6] the reaction of allylic acetate with lithium dimethylcuprate(I) was examined. Nine pyranosides having allylic acetate structure (**3**, **4**, **6**, **9**, **10**, **12**, and **15**—**17**) and one glycal acetate (**20**) were subjected for this reaction. The syntheses of **3**,[9] **9**,[10] and **16**[11] were reported by Fraser-Reid et al., while that of **15** by Ferrier and Prasad.[12] 2-*C*-Methyl-branched (**4** and **6**) and 4-*C*-methyl-branched (**10** and **12**) allylic acetates were prepared by 1,2-addition reaction of the corresponding enone **21**[9] and **23**,[13] respectively, with methyllithium or methylcerium(III) dichloride,[14] followed by acetylation. It was noteworthy that the reactions with the latter reagent gave almost exclusively axially attacked products **4** and **10**, while those with the former reagent afforded the same epimers a little preferentially, as shown in Table 1. 4-*C*-Methyl allylic acetate **17** was prepared by 1,2-reduction of the 4-*C*-methyl enone **22**[15] with sodium borohydride and cerium(III) chloride,[16] also followed by acetylation. The

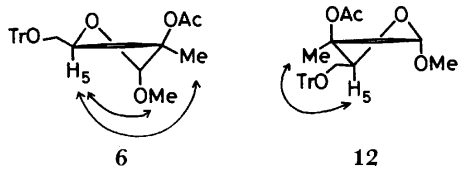
structures of these methyl-branched enopyranosides were ascertained by ^{1}H NMR data shown in Table 3, while the configurations at the branched carbon were determined by NOE. The *C*-methyl signal of **6** showed clear NOE when H-5 or *O*-methyl protons were irradiated, while that of **4** not. Further, the *C*-methyl signal of **12** was slightly enhanced when H-5 was irradiated. These configurational assignment was supported also by stereochemical course of reactions, i.e., above-mentioned selectivity of 1,2-addition reaction and the anti S_N2' substitution mechanisms which was observed in cyclohexenyl system.[17]



6 12

The reaction of the above-described nine allylic acetates with lithium dimethylcuprate(I) were performed in ether and the results were summarized in Table 2. The configurations of methyl-branching carbons in the products were determined by $J_{4,5}$ (the coupling constant between H-4 and H-5 in ^{1}H NMR) for the 2-enopyranosides such as **24** and **25** and by $J_{1,2}$ and $J_{2,3}$ (allylic geminal coupling)[7] for 3-enopyranosides such as **18**, **19**, and **26** (Table 3). Four enopyranosides having tertiary acetoxyl group at the branching carbon (**4**, **6**, **10**, and **12**) gave stereoselectively *C*-methylated derivatives (**24**, **25**, **18**, and **19**, respectively) in good yields except the last one. The anti S_N2' type reaction may be predominant as reported for cyclohexene derivatives.[18] On the other hand, unbranched 3-eno-**3** and 2-enopyranoside **9** gave the same 2-*C*-methyl derivative **8**, and another unbranched 2-enopyranoside **15** gave, after acetylation, the corresponding 2-*C*-methyl derivative **26**, in each case stereoselectively. The structure of **26** was confirmed by chemical conversion into **8** by deacetylation and tritylation. Because the possibility of 2-enopyranoside **14** could not be excluded completely from the ^{1}H NMR spectrum, compound **8** was further converted, by oxidation with osmium tetroxide and acetylation, into the corresponding 3,4-diacetoxy derivative **28**. Its ^{1}H NMR data analyzed by decoupling technique confirm the 2-*C*-methyl structure. This indicates the reaction of **3** proceeded via S_N2 type mechanism. The result may be attributed to the higher reactivity of the 2-acetoxyl group which lies between olefinic and electron-withdrawing anomeric center. However, introduction of methyl group into the acetoxyl group-bearing carbon reduces the reactivity of S_N2 reaction to prefer rather normal S_N2' reaction as shown in the case of 4. Furthermore, introduction of methyl group into the olefin moiety showed a limitation of this reaction, that is, **16** and **17** did not react at all and the expected *gem*-di-*C*-methyl derivative could not obtained. In the case

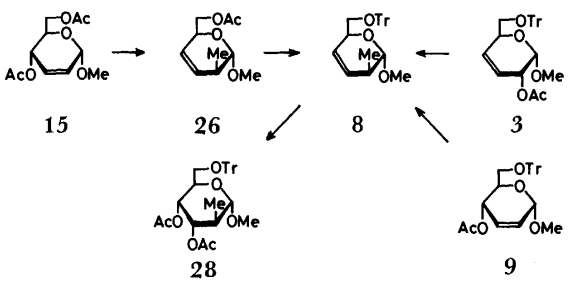
of a glycal **20** only S_N2 substitution was observed to give a 3-*C*-methyl derivative **27**. These results indicate the predominance of anti S_N2' mechanism except the cases of **3** and **20**. The result of **15** is consistent with that of the corresponding ethyl glycoside, reaction of which with several organolithium derivatives including lithium dimethylcuprate(I) was reported very recently to give 2-*C*-substituted derivatives.[18]



Prelog-Djerassi lactone (**35**) has been one of the key compounds for macrolide construction since synthesis of methymycin[20] and was also synthesized from D-glucose by a few groups.[21] As described above a convenient method for preparation of **25** was developed and then its utilization for synthesis of **35** was undertaken. Hydrogenation of **25** in the presence of palladium(II) hydroxide gave **29** preferentially in 43% yield. This yield seems to be fairly good in comparison with its preparation from the 4-*C*-methyl enone **22** via the corresponding 2-*C*-methylene derivative, where the yield for the latter step were not reported.[21a] Although the synthetic route from **29** to **35** has been already reported,[21a] the following alternative route was also developed.

Swern oxidation of **29** afforded a dialdopyranoside **30** in 75% yield. Treatment of **30** with nitromethane in the presence of sodium methoxide in methanol gave an epimeric mixture of condensation product **31**, which was converted into a nitro olefin **32** with acetic anhydride and pyridine in dichloromethane in 84% yield in two steps. For the last step a conventional treatment with methanesulfonyl chloride and triethylamine gave only poor results. Addition reaction of **32** with $MeCu \cdot BF_3$ in ether gave 6-*C*-methylated product **33** as an epimeric mixture with a ratio of 3 to 2 in 54% yield. On the other hand, the same reactions with lithium dimethylcuprate(I) or $Me_2Cu(CN)Li_2$ proved to give **33** trace and in 26% yield, respectively. Oxidation of **33** with potassium permanganate followed by treatment with acetic acid gave an uronic acid **34**, which was further oxidized with chromium trioxide afforded a mixture of **35** and its 6-epimer. Pure **35** was obtained as crystal from pentane–ether in 7% yield from **33**.

Experimental

General Methods. Melting points determined with a Yanagimoto micro melting point apparatus, were uncorrected. Optical rotations were measured in chloroform, by using a 0.5-dm tube with a Carl Zeiss LEP-Al polarimeter. Infrared spectra were recorded on a Hitachi EPI-G2 grating spectrometer. ^1H and ^{13}C NMR spectra were recorded at 100 MHz with a JEOL JMN PS-100 spectrometer and at 22.5 MHz with a JEOL FX-90Q spectrometer, respectively, in $CDCl_3$ with tetramethylsilane as internal standard. Column chromatography was performed on silica gel (Wakogel C-300: Wako Pure Chemical Industries, Ltd.).

Reaction of Allylic Alcohols 1 and 2 with MeCu · BF_3. To a suspension of copper(I) iodide (0.22 g, 1.2 mmol) in ether (35 ml) were added 1.2 M (1 M=1 mol dm^{-3}) ethereal solution of methyllithium (1 ml, 1.2 mmol) at −30 °C, and then after 30 min boron trifluoride etherate (0.14 ml, 1.2 mmol) at −78 °C. After 30 min, to this mixture was added a solution of **1** (380 mg, 0.94 mmol) in ether (2 ml) at 0 °C. Being stood at this temperature for 24 h, the reaction mixture was stirred with saturated ammonium chloride solution and extracted with dichloromethane. The extract was washed with water, dried over sodium sulfate, and evaporated to a syrupy mixture of a few components, which was fractionated on a column with hexane-ethyl acetate (50 : 1). The products, whose yields are give in references,[6] were characterized only by ^1H NMR.

(*S*)-2-[1-Hydroxy-2-(trityloxy)ethyl]furan (36): Mp 89—91 °C (decomp); ^1H NMR δ=6.32 (2H, bs, H-3 and H-5), 7.10 (1H, bs, H-4), 4.68 (1H, bdd, $J_{1',2'a}$=4.4 Hz, $J_{1',2'b}$=6.8 Hz, H-1'), 3.34 (1H, dd, $J_{2'a,2'b}$=8.0 Hz, H-2'a), 3.58 (1H, dd, H-2'b), and 7.2—7.6 (15H, m, Ph).

Reaction of Allylic Alcohol 2 with Methylcopper(I) Trifluoroborate. The reaction was performed in the same manner as described above using **2** instead of **1**. The products[6] were characterized only by ^1H NMR.

(*S*)-2-[1-Hydroxy-2-(trityloxy)ethyl]-4-methylfuran (37): ^1H NMR δ=7.66 (1H, m, H-5), 6.24 (1H, m, H-3), 4.72 (1H, bt, H-1'), 3.90 (2H, bd, CH_2OTr), 2.06 (3H, m, C-Me), and 7.2—7.6 (15H, m, Ph).

(*S*)-3,5-Dimethyl-2-trityloxymethyl-2*H*-pyran (38): ^1H NMR δ=7.78 (1H, m, H-6), 6.14 (1H, m, H-4), 3.84 (1H, bt, H-2), 3.66 (2H, bd, CH_2OTr), 2.12 (3H, bs, CMe), 1.98 (3H, m, CMe), and 7.2—7.6 (15H, m, Ph).

Reaction of Allylic Alcohol 1 with Methylmagnesium Bromide in the Presence of Bis(triphenylphosphine)nickel-(II) Chloride. To bis(triphenylphosphine)nickel(II) chloride (131 mg, 0.2 mmol) was added under argon a solution of **1** (2 mmol) in THF (8 ml), and the mixture was stirred at room temprature for 5 min. Then, to this solution was added 1 M tetrahydrofuran solution of methylmagnesium bromide (8 ml, 8 mmol). Being kept at room temperature for 24 h, the mixture was quenched with aqueous ammonium chloride, and extracted with dichloromethane. The extract was washed with water, dried over sodium sulfate, and evaporated to give a mixture of **39** and **1**, which was fractionated on a column with hexane-ethyl acetate (50 : 1). The compound **39** was characterized only by ^1H NMR data.

Methyl 2,3,4-Trideoxy-6-*O*-trityl-2,4-dienopyranoside (39): ^1H NMR δ= 4.84 (1H, d, $J_{1,2}$=1.4 Hz, H-1), 5.08 (2H, bs, H-2 and H-4), 6.22 (1H, bs, H-3), 3.82 and 3.90 (2H, ABq, J=10.4 Hz, H-6 and H-6'), 3.26 (3H, s, OMe), and 7.2—7.6 (15H, m, Ph).

Reaction of Enones 21 and 23 with Methyllithium. To a solution of the enone (582 mg, 1.45 mmol) in ether (60 ml), was added 0.8 M ethereal solution of methyllithium (7.3 ml, 5.8 mmol) at −78 °C. Being kept at the same temperature for 4 h, the reaction mixture was poured into water and extracted with ethyl acetate. The extract was washed with water, dried over magnesium sulfate, and evaporated to give a crude epimeric mixture of 1,2-addition product, whose separation was described in the following paragraph.

Methyl 2-*O*-Acetyl-3,4-dideoxy-2-*C*-methyl-6-*O*-trityl-α-D-*erythro*-hex-3-enopyranoside (4) and Methyl 2-*O*-Acetyl-3,4-

dideoxy-2-*C*-methyl-6-*O*-trityl-α-D-*threo*-hex-3-enopyranoside (6). The reaction of **21** with methyllithium as described above gave a mixture of **5** and **7**, which was separated on a column with hexane-ethyl acetate (12 : 1).

5: Syrup, $[\alpha]_D$ −13.7° (*c* 0.9, $CHCl_3$); IR (NaCl) 3400 (OH) and 1610 cm^{-1} (C=C).

Found: C, 77.52; H, 6.83%. Calcd for $C_{27}H_{28}O_4$: C, 77.86; H, 6.78%.

7: Syrup, $[\alpha]_D$ +173.5° (*c* 1.9, $CHCl_3$); IR (NaCl) 3400 (OH) and 1610 cm^{-1} (C=C).

Found: C, 77.90; H, 6.48%. Calcd for $C_{27}H_{28}O_4$: C, 77.86; H, 6.78%.

Acetylation of **5** and **7** with acetic anhydride and pyridine in the presence of 4-(dimethylamino)pyridine geve **4** and **6**, respectively, which were purified on a column with hexane-ethyl acetate (15 : 1).

4: Syrup $[\alpha]_D$ +44.7° (*c* 0.9, $CHCl_3$); IR (NaCl) 1730 (C=O) and 1600 cm^{-1} (C=C).

Found: C, 75.80; H, 6.33%. Calcd for $C_{29}H_{30}O_5$: C, 75.96; H, 6.59%.

6: Syrup, $[\alpha]_D$ +38.9° (*c* 5.1, $CHCl_3$); IR (NaCl) 1730 (C=O) and 1600 cm^{-1} (C=C).

Found: C, 75.53; H, 6.28%. Calcd for $C_{29}H_{30}O_5$: C, 75.96; H, 6.59%.

The ^1H NMR data for compounds **4**—**7** are given in Table 3.

Methyl 4-*O*-Acetyl-2,3-dideoxy-4-*C*-methyl-6-*O*-trityl-α-D-*erythro*-hex-2-enopyranoside (10) and Methyl 4-*O*-Acetyl-2,3-dideoxy-4-*C*-methyl-6-*O*-trityl-α-D-*threo*-hex-2-enopyranoside (12). The reaction of **23** with methyllithium as described above gave a mixture of **11** and **13**, which were separated on a column with hexane-ethyl acetate (14 : 1).

11: Syrup, $[\alpha]_D$ −11.8° (*c* 0.6, $CHCl_3$); IR (NaCl) 3400 (OH) and 1600 cm^{-1} (C=C).

Found: C, 77.94; H, 6.58%. Calcd for $C_{27}H_{28}O_4$: C, 77.86; H, 6.78%.

13: Syrup, $[\alpha]_D$ +17.5° (*c* 0.93, $CHCl_3$); IR (NaCl) 3400 (OH) and 1600 cm^{-1} (C=C).

Found: C, 77.95; H, 7.04%. Calcd for $C_{27}H_{28}O_4$: C, 77.86; H, 6.78%.

Acetylation of **11** and **13** with acetic anhydride and pyridine in the presence of 4-(dimethylamino)pyridine gave **10** and **12**, respectively, which were purified on a column with hexane-ethyl acetate (18 : 1).

10: Syrup, $[\alpha]_D$ +56.9° (*c* 2.3, $CHCl_3$); IR (NaCl) 1740 (C=O) and 1610 cm^{-1} (C=C).

Found: C, 76.04; H, 6.74%. Calcd for $C_{29}H_{30}O_5$: C, 75.96; H, 6.59%.

12: Syrup, $[\alpha]_D$ −25.5° (*c* 1.5, $CHCl_3$); IR (NaCl) 1740 (C=O) and 1610 cm^{-1} (C=C).

Found: C, 76.11; H, 6.41%. Calcd for $C_{29}H_{30}O_5$: C, 75.96; H, 6.59%.

The ^1H NMR data for compounds **10**—**13** are given in Table 3.

Reaction of Enones 21 and 23 with Methylcerium(III) Dichloride. To a suspension of finely powdered and dried cerium(III) chloride (740 mg, 3 mmol) in tetrahydrofuran (15 ml), was added with stirring 1.2 M ethereal solution of methyllithium (2.5 ml, 3 mmol) at 0 °C under argon. To this suspension was added a solution of enone (400 mg, 1 mmol) in tetrahydrofuran (3 ml) at −78 °C. The stirring was continued for 7 h at −78 °C, and the mixture was processed as in the same manner described for **4** and **6** or **10** and **12**. The results are summarized in Table 1.

Methyl 2-*O*-Acetyl-3,4-dideoxy-4-*C*-methyl-6-*O*-trityl-α-D-*erythro*-hex-3-enopyranoside (17). To a solution of **22**[15] (414 mg, 1 mmol) in ethanol (1 ml), was added with stirring cerium(III) chloride (490 mg, 2 mmol) and then sodium borohydride (75 mg, 2 mmol) at 0 °C. The stirring was continued for 3 h until gas evolution ceased. The reaction mixture was then poured into aqueous sodium chloride and extracted with dichloromethane. The extract was washed with aqueous sodium chloride, dried over magnesium sulfate, and evaporated to give a crude allylic alcohol as syrup, which was acetylated with acetic anhydride (3 ml) and pyridine (5 ml). The 2-acetate **17** was purified on a column with hexane-ethyl acetate (15 : 1). Yield, 348 mg (76%).

17: Syrup, $[\alpha]_D$ −24.7° (*c* 0.9, $CHCl_3$); IR (NaCl) 1730 (C=O) and 1600 cm^{-1} (C=C); ^1H NMR δ=5.16 (1H, bd, $J_{1,2}$=4.2 Hz, H-1), 5.54 (1H, m, H-2), 5.88 (1H, m, H-3), 4.32 (1H, bt, H-5), 3.36 (2H, bd, $J_{5,6}$=7.8 Hz, H-6 and H-6′), 1.98 (3H, bs, CMe), 2.00 (3H, s, OAc), 3.42 (3H, s, OMe), and 7.2—7.6 (15H, m, Ph).

Found: C, 75.92; H, 6.41%. Calcd for $C_{29}H_{30}O_5$: C, 75.96; H, 6.59%.

Reaction of Allylic Acetates with Lithium Dimethylcuprate-(I). To a suspension of CuI (3 equiv) in ether were added 1.2 M ethereal solution of methyllithium (6 equiv) at 0 °C, and then, after 5 min, a solution of an allylic acetate (1 equiv) in ether. The reaction mixture was poured into saturated aqueous ammonium chloride, and extracted with dichloromethane. The extract was evaporated to give residue, which was purified on a column with a solvent system given in each case. In the reaction of **15** the product was acetylated in usual manner. The yields, ^1H NMR and ^{13}C NMR data of the products (**8**, **18**, **19**, **24**, **25**, **26**, and **27**) are given in Table 2, 3, and 4, respectively.

Methyl 2,3,4-Trideoxy-2-*C*-methyl-6-*O*-tirtyl-α-D-*threo*-hex-3-enopyranoside (8). (a) From 3 or 9. The reaction of **3** or **9** with lithium dimethylcuprate(I) as described above gave crude **8**, which was purified on a column with hexane-ethyl acetate (15 : 1).

8: $[\alpha]_D$ −19.3° (*c* 2.1, $CHCl_3$); IR (NaCl) 1610 cm^{-1} (C=C).

Found: C, 81.27; H, 6.92%. Calcd for $C_{27}H_{28}O_3$: C, 80.97; H, 7.05%.

(b) From 26. To a solution of **26** (25.6 mg, 0.13 mmol) in methanol (1 ml) was added a drop of 1 M sodium methoxide and after 5 min the mixture was neutralized with IR-120 (H^+). The residue obtained by evaporation of the filtrate was treated with trityl chloride (55.8 mg, 0.2 mmol) in pyridine (0.5 ml) in a conventional manner. The crude product was purified on a column with hexane-ethyl acetate (25 : 1) to give **8** (49.9 mg, 88%), which was identified by ^1H NMR spectrum.

Methyl 2,3,4-Tridexoy-2,4-di-*C*-methyl-6-*O*-trityl-α-D-*threo*-hex-3-enopyranoside (18). The reaction of **10** with lithium dimethylcuprate(I) as described above gave crude **18**, which was purified on a column with hexane-ethyl acetate (20 : 1).

18: Syrup, $[\alpha]_D$ +47.5° (*c* 1.4, $CHCl_3$); IR (NaCl) 1610 cm^{-1} (C=C).

Found: C, 81.23; H, 7.51%. Calcd for $C_{28}H_{30}O_3$: C, 81.13; H, 7.29%.

Methyl 2,3,4-Trideoxy-2,4-di-*C*-methyl-6-*O*-trityl-α-D-*erythro*-hex-3-enopyranoside (19). The reaction of **12** with lithium dimethylcuprate(I) as described above gave crude **19**, which was purified on a column with hexane-ethyl acetate

(20 : 1).

19: Syrup, $[\alpha]_D$ −34.0° (*c* 1.0, $CHCl_3$); IR (NaCl) 1610 cm^{-1} (C=C).

Found: C, 81.12; H, 7.07%. Calcd for $C_{28}H_{30}O_3$: C, 81.13; H, 7.29%.

Methyl 2,3,4-Trideoxy-2,4-di-*C*-methyl-6-*O*-trityl-α-D-*threo*-hex-2-enopyranoside (24). The reaction of **4** with lithium dimethylcuprate(I) as described above gave crude **24**, which was purified on a column with hexane-ethyl acetate (15 : 1).

24: Syrup, $[\alpha]_D$ −18.3° (*c* 0.7, $CHCl_3$); IR (NaCl) 1600 cm^{-1} (C=C).

Found: C, 81.01; H, 7.01%. Calcd for $C_{28}H_{30}O_3$: C, 81.13; H, 7.29%.

Methyl 2,3,4-Trideoxy-2,4-di-*C*-methyl-6-*O*-trityl-α-D-*erythro*-hex-2-enopyranoside (25). The reaction of **6** with lithium dimethylcuprate(I) as described above gave crude **24**, which was purified on a column with hexane-ethyl acetate (20 : 1).

25: Syrup, $[\alpha]_D$ +6.5° (*c* 0.8, $CHCl_3$); IR (NaCl) 1600 cm^{-1} (C=C).

Found: C, 80.95; H, 7.38%. Calcd for $C_{28}H_{30}O_3$: C, 81.13; H, 7.29%.

Methyl 6-*O*-Acetyl-2,3,4-trideoxy-2-*C*-methyl-α-D-*threo*-hex-3-enopyranoside (26). The reaction of **15** with lithium dimethylcuprate(I) as described above, followed by a conventional acetylation with acetic anhydride in pyridine, gave crude **26**, which was purified on a column with hexane-acetone (7 : 1).

26: Syrup, $[\alpha]_D$ −19.3° (*c* 2.1, $CHCl_3$); IR (NaCl) 1730 (C=O) and 1610 cm^{-1} (C=C).

Found: C, 60.02; H, 8.14%. Calcd for $C_{10}H_{16}O_4$: C, 59.98; H, 8.05%.

4.6-Di-*O*-acetyl-1,5-anhydro-2,3-dideoxy-3-*C*-methyl-D-*ribo*-hex-1-enitol (27). The reaction of **20** with lithium dimethylcuprate(I) as described above gave crude **27**, which was purified on a column with hexane-acetone (3 : 1).

27: Syrup, $[\alpha]_D$ +3.7° (*c* 0.8, $CHCl_3$); IR (NaCl) 1740, 1720 (C=O) and 1620 cm^{-1} (C=C).

Found: C, 58.19; H, 6.21%. Calcd for $C_{11}H_{14}O_5$: C, 58.40; H, 6.24%.

Methyl 3,4-Di-*O*-acetyl-2-deoxy-2-*C*-methyl-6-*O*-trityl-α-D-altropyranoside (28). To a solution of **8** (120 mg, 0.29 mmol) in oxolane (1.5 ml)-acetone (1.5 ml)-water (1.5 ml) was added *N*-methylmorpholine *N*-oxide (50 mg, 0.43 mmol) and osmium tetroxide (3.3 mg). Being stood at room temperature for 2 d, the reaction mixture was poured into water and extracted with chloroform. A conventional processing of the extract gave a syrupy residue, which was acetylated in a conventional manner with acetic anhydride (3 ml) and pyridine (4 ml). A syrup obtained by usual processing was purified on a column with hexane-ethyl acetate (13 : 2) to give **28**, 87.2 mg (58%), mp 136—139.5 °C (white needles), $[\alpha]_D$ +51.5° (*c* 1.0, $CHCl_3$); ^1H NMR δ=4.45 (1H, d, $J_{1,2}$=3.0 Hz, H-1), 2.15 (H-2), 5.00 (1H, dd, $J_{2,3}$=5.6 Hz, $J_{3,4}$=3.6 Hz, H-3), 5.14 (1H, dd, $J_{4,5}$=8.0 Hz, H-4), 4.12 (1H, ddd, $J_{5,6}$=3.0 Hz, $J_{5,6'}$=4.5 Hz, H-5), 3.25 (2H, m, H-6 and H-6'), 1.14 (3H, d, $J_{2,Me}$=7.5 Hz, CMe), 1.81 and 2.02 (each 3H, each s, OAc), 3.40 (3H, s, OMe), and 7.1—7.5 (15H, m, Ph).

Found: C, 71.64; H, 6.55%. Calcd for $C_{31}H_{34}O_7$: C, 71.80; H, 6.61%.

Methyl 2,3,4,6,7-Pentadeoxy-2,4-di-*C*-methyl-7-nitro-α-D-*ribo*-hept-6-enopyranoside (32). Compound **25** (3.7 g, 8.9 mmol) was hydrogenolyzed (1 atm) in ethanol (200 ml) in the presence of $Pd(OH)_2$-carbon (20%, 0.3 g) at room temperature for 1 week. Undissolved materials were filtered off, and the filtrate was evaporated and then distilled (86 °C/20 mmHg (1 mmHg=133.322 Pa)) to give acolorless oil **29**, (667 mg, 43%), whose NMR data was identical with those reported.[21a] Then, **29** (500 mg, 2.9 mmol) was oxidized with DMSO (0.29 ml, 3.4 mmol) and oxalyl dichloride (0.27 ml, 3.4 mmol) in dichloromethane (50 ml) at −78 °C for 1 h. The reaction mixture was quenched with triethylamine, poured into water and extracted with dichloromethane. Evaporation of the extract gave **30** (363 mg, 75%).

To a solution of nitromethane (1.4 ml) in methanol (2.5 ml), were added 2 M sodium methoxide (0.22 ml) and then a solution of **30** (530 mg, 3.0 mmol) in methanol (2 ml) at 0 °C. Being kept at 0 °C for 3 h, the reaction mixture was acidified with 10% acetic acid and extracted with chloroform. The extract was washed with water, dried over magnesium sulfate and evaporated to give a crude **31** as a mixture of 6-epimers.

To a solution of crude **31** in pyridine (6 ml), was added acetic anhydride (3 ml) and the mixture was kept at room temperature overnight. A usual processing gave crude **32**, which was purified on a column with hexane-ethyl acetate (3 : 1). Yield, 611 mg (84%).

32: Syrup, $[\alpha]_D$ +103° (*c* 0.9, $CHCl_3$); IR (NaCl) 1360, 1530 (NO_2) and 1655 cm^{-1} (C=C). ^1H NMR δ=5.22 (1H, d, $J_{1,2}$=3.4 Hz, H-1), 4.24 (1H, bd, $J_{4,5}$=6.6 Hz, H-5), 7.28 (2H, bs, H-6 and H-7), 1.16 and 1.30 (each 3H, d, C-Me), 1.8—2.3 (4H, m, H-2, H-3,3', and H-4), 3.48 (3H, s, OMe).

Found: C, 55.83; H, 7.67: N, 6.84%. Calcd for $C_{10}H_{17}NO_4$: C, 55.80; H, 7.96; N, 6.51%.

Prelog-Djerassi Lactone (35). To a suspension of copper(I) iodide (162 mg, 0.85 mmol) in ether (10 ml), were added methyllithium (1.2 M in ether, 0.71 ml, 0.85 mmol) at −10 °C, and then after cooling to −30 °C a solution of boron trifluoride etherate (0.11 ml, 0.85 mmol) in ether (10 ml). The mixture was stirred for 20 min at −30 °C, then cooled to −78 °C, and to this mixture was added a solution of **32** (60.3 mg, 0.28 mmol) in ether 5 ml. The stirring was continued for 4 h at −30 °C and, the reaction mixture was poured into water, extracted with dichloromethane, dried over magnesium sulfate, and evaporated. Purification of the residue on a column with hexane-ethyl acetate (2 : 1) gave **33** as a mixture of 6-epimers (35 mg, 54%).

To a suspension of **33** (163 mg, 0.71 mmol) in water (5 ml) was added 0.1 M potassium hydroxide (0.76 mmol) and then, after 20 min, 2 M aqueous manganese(II) sulfate (1 ml) and potassium permanganate (266 mg, 1.5 mmol) in two portions. The reaction mixture was stirred for 6 h at room temperature, and to this mixture was added aqueous sodium thiosulfate. After removal of the precipitated manganese dioxide by filtration, the filtrate was adjusted at pH 2—3 with 10% acetic acid, stood at room temperature for 1 h and then extracted with chloroform-1-butanol. The extract was dried over magnesium sulfate, and evaporated to give crude **34**. To a solution of **34** in acetic acid (15 ml) and water (5 ml) was added chromium trioxide (90 mg, 0.9 mmol) at 0 °C. Being kept at 0 °C for 6 h, the reaction mixture was extracted with chloroform-DMF. The extract was washed with saturated aqueous sodium thiosulfate, and evaporated. Crude product was passed through a short column with chloroform -methanol-acetic acid (5 : 1 : 0.1) to give white syrup (32 mg, 22%) which was crystallized from pentane-ether to give pure **35** (10 mg, 7% from **33**). The data of **35** were identical to

the reported ones. Mp 125—126 °C; lit, mp 124—125 °C;[22] mp 126—128 °C,[23] $[\alpha]_D$ +37.2° (*c* 1.0, $CHCl_3$), lit,[23] $[\alpha]_D$ +38.0° (*c* 1.9, $CHCl_3$). ^{13}C NMR ($CDCl_3$) δ=8.5 (α-CH_3), 16.6 and 17.1 (C_3-CH_3 and C_5-CH_3), 30.6 (C_4), 36.2 and 37.0 (C_3 and C_5), 41.2 (C_α), 86.1 (C_2), 174.4 and 174.9 (HO_2C and C_6), lit,[17b] δ=8.4 (α-CH_3), 16.8 and 17.2 (C_3-CH_3 and C_5-CH_3), 30.8 (C_4), 36.2 and 37.1 (C_3 and C_5), 41.0 (C_α), 86.4 (C_2), 174.7 and 177.6 (HO_2C and C_6).

Found: C, 59.76; H, 8.24%. Calcd for $C_{10}H_{16}O_4$; C, 59.98; H, 8.05%.

Asymmetric Hydrogenation of *N,N'*-Dimethyl-5-alkylidene- and arylmethylenehydantoins Catalyzed by (Achiral Base)bis(dimethylglyoximato)cobalt(II)-Chiral Cocatalyst System[1)]

Seiji TAKEUCHI* and Yoshiaki OHGO

(Received October 16, 1986)

Asymmetric hydrogenation of *N,N'*-dimethyl-5-alkylidene- and arylmethylenehydantoins catalyzed by an achiral base coordinated bis(dimethylglyoximato)cobalt(II)-chiral 2-quinuclidinecarboxamide was examined. Attempts resulted in a maximum optical yield in this system (82.1% ee), strongly supporting a proposed asymmetric hydrogenation mechanism in which the chiral base acts as a proton donor, namely, a cocatalyst.

The authors have previously reported the asymmetric hydrogenation of activated ketones and olefins catalyzed by an achiral base coordinated bis(dimethylglyoximato)cobalt(II)-chiral base system (abbreviated as $Co(Hdmg)_2 \cdot B\text{-}B^*$; B and B* are achiral and chiral bases, respectively).[2)] For example, $Co(Hdmg)_2 \cdot B$-quinine catalyzes the hydrogenation of benzil to benzoin with 78% ee[3)] and $Co(Hdmg)_2 \cdot B$-(*S*)-*N*[(*R*)-1-phenylethyl]-2-quinuclidinecarboxamide catalyzes the hydrogenation of *N,N'*-dimethyl-5-benzylidenehydantoin with 79.1% ee.[4)] In the course of our study regarding asymmetric hydrogenation, we proposed an asymmetric hydrogenation mechanism in which $Co(Hdmg)_2 \cdot B$ acts as an electron donor to the substrate or intermediate and a protonated chiral base acts as a chirality-recognizing proton donor to the intermediate carbanion.[3)]

Here, we wish to describe our attempts to obtain a higher optical yield and to find supporting evidence for the proposed asymmetric hydrogenation mechanism.

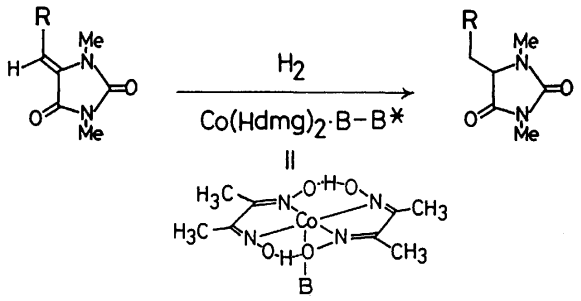
Results and Discussion

The preparation method for chiral 2-quinuclidinecarboxamides are described in the Experimental section. Structures and their abbreviations are summarized in Table 1.

An asymmetric hydrogenation of *N,N'*-dimethyl-5-alkylidene- and arylmethylenehydantoins with $Co(Hdmg)_2 \cdot B\text{-}B^*$ was examined under various conditions (Scheme 1). The enantioselectivity was affected by the structure of B*, the structure of the substrate, the molar ratio of B* to the cobalt complex, the character of the axial base, the reaction temperature and the basicity of B*.



Scheme 1. Asymmetric hydrogenation of *N,N'*-dimethyl-5-alkylidene- and arylmethylenehydantoins with $Co(Hdmg)_2 \cdot B\text{-}B^*$.

Effect of Structure of B*. Hydrogenation of *N,N'*-dimethyl-5-benzylidenehydantoin was carried out using the chiral 2-quinuclidinecarboxamides as B*. The results are shown in Table 2.

The configuration of the predominant enantiomer of the hydrogenated product in every case is determined with that of the chiral center of the 2-quinuclidinecarboxylic acid moiety (Runs 1—7) and in the case of using the chiral secondary amides, the enantioselectivity is little affected by the structure of the amine moiety (Runs 1—5) (QC-(*S*)*R* is the most effective cocatalyst). However, the lack of N-H of amide group causes a remarkable decrease in the enantioselectivity (Runs 6 and 7). Accordingly, a structure excluding the alkyl group of the amine moiety mainly determines the enantioselectivity; also, the presence of N-H of amide group is extremely important.

These indicate the importance of the hydrogen bond

Table 2. Effect of Structure of B* on the Asymmetric Hydrogenation of *N,N'*-Dimethyl-5-benzylidenehydantoin[a)]

Run	B	B*	*N,N'*-Dimethyl-5-benzylhydantoin

between N-H of the chiral cocatalysts and the carbonyl group of the substrates.[4)]

Effect of Substituent of Substrate. The results of the hydrogenation of *N,N'*-dimethyl-5-alkylidene- and arylmethylenehydantoins are shown in Table 3.

Enantiomeric excesses of the hydrogenated products (except for *N,N'*-dimethyl-5-benzylhydantoin) were determined by ^1H NMR spectra in the presence of a chiral lanthanoid shift reagent.

Enantioselectivity for 5-(arylmethylene)hydantoins was higher than that of 5-isobutylidenehydantoin. Among the 5-(arylmethylene)hydantoins there is little difference in the enantioselectivity. The difference between 5-(arylmethylene)- and 5-isobutylidenehydantoin can be explained by a conformation of their intermediate carbanion[4)] (depicted in Fig. 1).

Conformation A is preferred to B for 5-(arylmethyl)-hydantoin carbanion because of an electrostatic repulsion between a lone pair on the asymmetric carbon atom and the π-electron on the aromatic ring. However, conformation B is rather preferred to A for 5-isobutylhydantoin carbanion because of a steric repulsion between the isobutyl group and the hydantoin ring and of a decrease in the electrostatic repulsion. One of the two enantiomers in conformation A is smoothly protonated by protonated QC-(*R*)*S* (abbreviated as QC-(*R*)*S*·H^+) to give (*R*)-5-(arylmethyl)hydantoin predominantly via a transition state having a hydrogen bond between N-H of QC-(*R*)*S*·H^+ and C=O of the carbanion of 5-(arylmethyl)hydantoin (CPK model C in Fig. 1). On the other hand, such hydrogen bonding is impossible in conformation B; this should cause a decrease in the enantioselectivity.

Effect of Molar Ratio of B* to the Cobalt Complex. Hydrogenation of *N,N'*-dimethyl-5-benzylidenehydantoin was carried out in various molar ratios of QC-(*R*)*S* (or QC-(*S*)*R*) to the cobalt complex (abbreviated as QC-(*R*)*S*/Co). The results are shown in Table 4.

The optical yield increases with increasing ratio QC-(*R*)*S*/Co and reaches a maximum value (82.1% ee) when the ratio is 7 (Run 5). This can be explained as follows.

A simplified catalytic cycle of this hydrogenation is shown in Fig. 2.[5)]

The point of contact of reaction ② and cycle ④ is the enantioselectivity-determining step: protonation to the intermediate carbanion. Although the electron-

a) The molar ratio of substrate to cobalt was 10:1, while those of PPh_3, $P(Bu^n)_3$, and QC-(*R*)*S*·HCl (or QC-(*R*)*S*·HCl) to cobalt were all 1:1. Solvent was benzene. b) Values in parentheses represent the molar ratio of B* to cobalt. c) Maximum velocity: $10^{-3}s^{-1}$. d) Configuration.

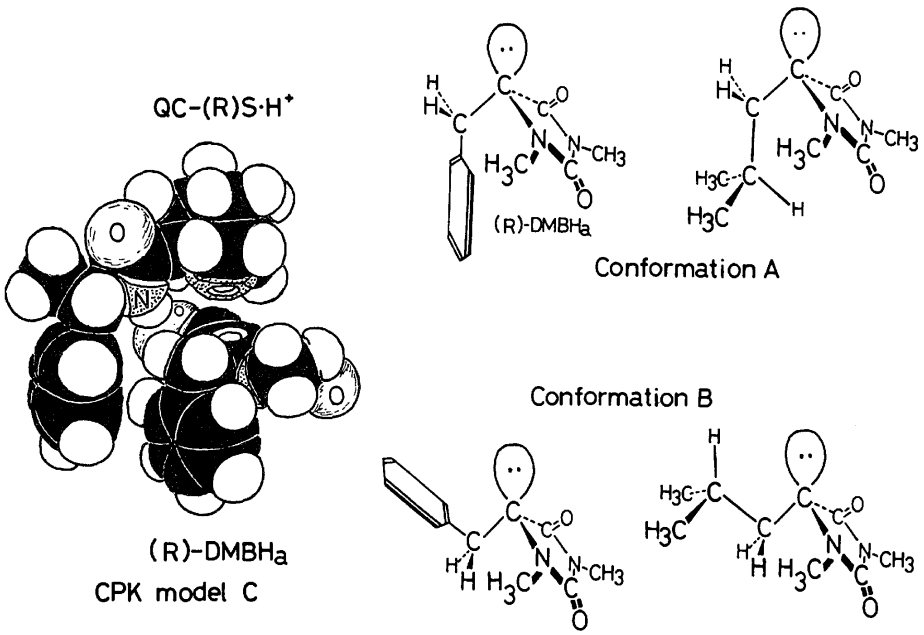

Fig. 1. Conformations of isobutyl- and benzylhydantoin (as representative of 5-(arylmethyl)hydantoin), and CPK model of the chirality-recognizing transition state (the hydrogen atom attached on the nitrogen atom of quinuclidine and the lone pair on the asymmetric carbon atom of (*R*)-*N,N'*-dimethyl-5-benzylhydantoin carbanion, (*R*)-$DMBH_a$, are not depicted).

donating cycle ③ and the proton-donating cycle ④ are independently conjugated with the reductive alkylation ① and the reduction of the alkyl complex ②, the two cycles ③ and ④ are joined by the following equilibrium. QC-(*R*)*S*·HCl in the reaction

$$H\cdot Co(Hdmg)_2\cdot B + QC\text{-}(R)S \rightleftharpoons \bar{C}o(Hdmg)_2\cdot B + QC\text{-}(R)S\cdot H^+$$

solution is included in the equilibrium as QC-(*R*)*S*·H^+. The equilibrium remains constant under a stationary state and, therefore, the optical yield is determined by the ratio of QC-(*R*)*S*·H^+ to H·Co(Hdmg)$_2$·B and other protonated achiral base (B·H^+) in the reaction system. If the ratio has reached a value near the maximum, even in QC-(*R*)*S*/Co=1, the increasing degree of the optical yield should be small and the optical yield should readily reach a maximum even though the ratio QC-(*R*)*S*/Co increases to a great extent.

Effect of σ-Donor Character of Axial Base. Hydrogenation of *N,N'*-dimethyl-5-benzylidenehydantoin was carried out using benzylamine (BA), $P(Bu^n)_3$ and PPh_3 as B. The results are shown in Table 5.

As outlined above, QC-(*R*)*S*·H^+ acts as a chirality-recognizing proton donor. On the other hand, H·Co(Hdmg)$_2$·B or B·H^+ can also act as a proton donor; hence, they competitively disturb the enantioselective proton-donation reaction by QC-(*R*)*S*·H^+ to decrease the optical yield. Since BA is a stronger base than QC-(*R*)*S*, the enantioselective protonation is strongly disturbed by BA·H^+ and decreases the optical yield (Run 1). PPh_3 and $P(Bu^n)_3$ can scarcely act as a proton acceptor since they are considerably weaker and more soft base than QC-(*R*)*S*. The lower optical yield in

a) The molar ratio of substrate to cobalt was 10:1, while those of PPh_3, $P(Bu^n)_3$, BA and QC-(*S*)*R*·HCl (or QC-(*R*)*S*·HCl) to cobalt were all 1:1 except for Run 7. Solvent was benzene. b) Values in parentheses represent the molar ratio of B* to cobalt. c) Configuration. d) Maximum velocity: $10^{-3}s^{-1}$. e) No base other than QC-(*S*)*R* was used. f) The molar ratio of PPh_3 to cobalt was 4.

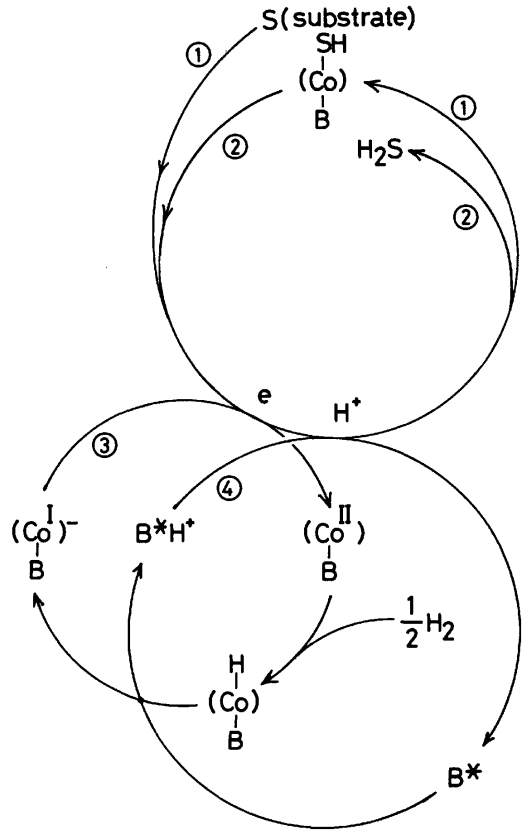

Fig. 2. Simplified catalytic cycle: S= R Me

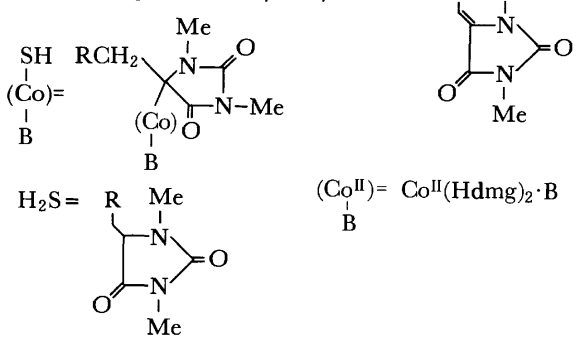

Run 2 than that in Run 3 should be due to the stronger basicity of $P(Bu^n)_3$ than PPh_3. Needless to say, QC-(*R*)*S*·H^+ can not disturb the enantioselective protonation of itself and, hence, the low optical yield in Run 5 compared with those in Runs 2 and 3 must be due to a disturbance by H·Co(Hdmg)$_2$·QC-(*R*)*S*. A comparison of the results in Runs 3 and 4 with those in 5 and 6, respectively, clarifies the role of QC-(*R*)*S*. The optical yield increases in Run 4 but decreases in Run 6 with increasing ratio QC-(*R*)*S*/Co. The axial ligand of the cobalt complex is chiefly PPh_3 in Runs 3 and 4, whereas it is QC-(*R*)*S* in Runs 5 and 6. Consequently, it is clear that coordination of QC-(*R*)*S* to the cobalt complex decreases the optical yield.

Effect of Reaction Temperature. Hydrogenation of *N,N'*-dimethyl-5-benzylidenehydantoin was carried out at room temperature and at −10 °C in benzene and in mesitylene, respectively. The results are shown in Table 6.

The optical yield increases upon using quinine as a cocatalyst (Run 2) but decreases upon using QC-(*R*)*S* as a cocatalyst (Run 4) with decreasing reaction temperature. This should be due to the solubility of QC-(*R*)*S*·HCl in mesitylene, since the optical yield increases upon using only QC-(*R*)*S* (Run 6), but decreases upon using only QC-(*R*)*S*·HCl (Run 8) with decreasing reaction temperature. Since QC-(*R*)*S*·HCl is slightly soluble in such a nonpolar solvent as benzene and mesitylene (even at room temperature), it becomes much less soluble at −10 °C. Such a decreased solubility should result in a decreasing optical yield, since both the chiral base and its hydrochloride are required to obtain a maximum optical yield in this system.[3]

If this deduction is correct, it is possible to attain a much higher optical yield in nonpolar and aprotic solvent systems which easily dissolve QC-(*R*)*S*·HCl, even at low temperatures.

Effect of Basicity of B*. Hydrogenation of *N,N'*-dimethyl-5-benzylidenehydantoin was carried out using quinine and/or QC-(*R*)*S* as cocatalyst. The results are shown in Table 7.

(*S*)-Configuration product with 51.4%ee was obtained upon using a system mixed with quinine, QC-(*R*)*S* and their hydrochlorides (Run 3) although an opposite configuration and a higher optical yield

6	$P(Bu^n)_3$	Quinine (1) QC-(*R*)*S* (1)	— —	95.0	−31.8	*S*	37.0	2.1

a) The molar ratio of substrate to cobalt was 10:1, while that of $P(Bu^n)_3$ to cobalt was 1:1. Solvent was benzene. b) Configuration. c) Maximum velocity: $10^{-3}\,s^{-1}$. d) Values in the parentheses represent the molar ratio of B* or B*·HCl to cobalt. e) B*·HCl was not used.

were obtained in Run 2 compared with those in Run 1. A similar tendency was observed in the absence of the hydrochlorides, except for a higher optical yield upon using a system mixed with quinine and QC-(*R*)*S* (Run 6) than that using only quinine (Run 4). Thus, the enantioselectivity of QC-(*R*)*S* is masked and that of quinine predominates in a mixed system. Since QC-(*R*)*S* is a weaker base (namely, a weaker proton acceptor than quinine), it should hardly act as a proton acceptor in mixed systems.

This can be demonstrated by the ^{13}C NMR spectra of a mixed system in $CDCl_3$. The ^{13}C NMR spectra of quinine·HCl(I), quinine(II), QC-(*R*)*S*·HCl(III), QC-(*R*)*S*(IV) and their mixture (V and VI) are shown in Fig. 3.

The values near the peaks represent the chemical shift (ppm) of C-9 in quinine or quinine·HCl and that of carbonyl carbon in QC-(*R*)*S* or QC-(*R*)*S*·HCl. From these data the ratio of the components in the solution was estimated. For example, quinine exists almost as hydrochloride (96.9%) in a solution of QC-(*R*)*S*·HCl (3.56×10^{-5} mol) and quinine (3.545×10^{-5} mol) (V); and QC-(*R*)*S* exists completely as free base in that of QC-(*R*)*S*·HCl (1.70×10^{-5} mol), QC-(*R*)*S* (1.66×10^{-5} mol) and quinine (3.45×10^{-5} mol) (VI).[6] These results demonstrate that quinine is a much stronger proton acceptor than QC-(*R*)*S*.

Conclusion

The main problem regarding the mechanism of this asymmetric hydrogenation is what role the chiral base performs. Since the chiral base can coordinate to the cobalt complex, one may think that the chiral cobalt complex is a chirality-recognizing species itself. However, we have proposed another unique asymmetric hydrogenation mechanism (described above). Although the possibility of an enantioselective reaction by the chiral cobalt complex[7] can not be completely excluded, the results obtained above strongly support the proposed asymmetric hydrogenation mechanism. These are summarized as follows: (1) The optical yield increases with increasing ratio QC-(*R*)*S*/Co and reaches a maximum value, (2) coordination of QC-(*R*)*S* to the cobalt complex decreases the optical yield, and (3) the enantioselectivity for a stronger proton acceptor (quinine) predominates in a system mixed with quinine and QC-(*R*)*S*.

Experimental

The melting points were determined by a Yanagimoto micro-melting point apparatus and were uncorrected. The IR spectra were recorded on a JASCO A-3 spectrometer. The ^1H and ^{13}C NMR spectra were obtained on a JEOL-FX 200 spectrometer. The optical rotations were measured with a

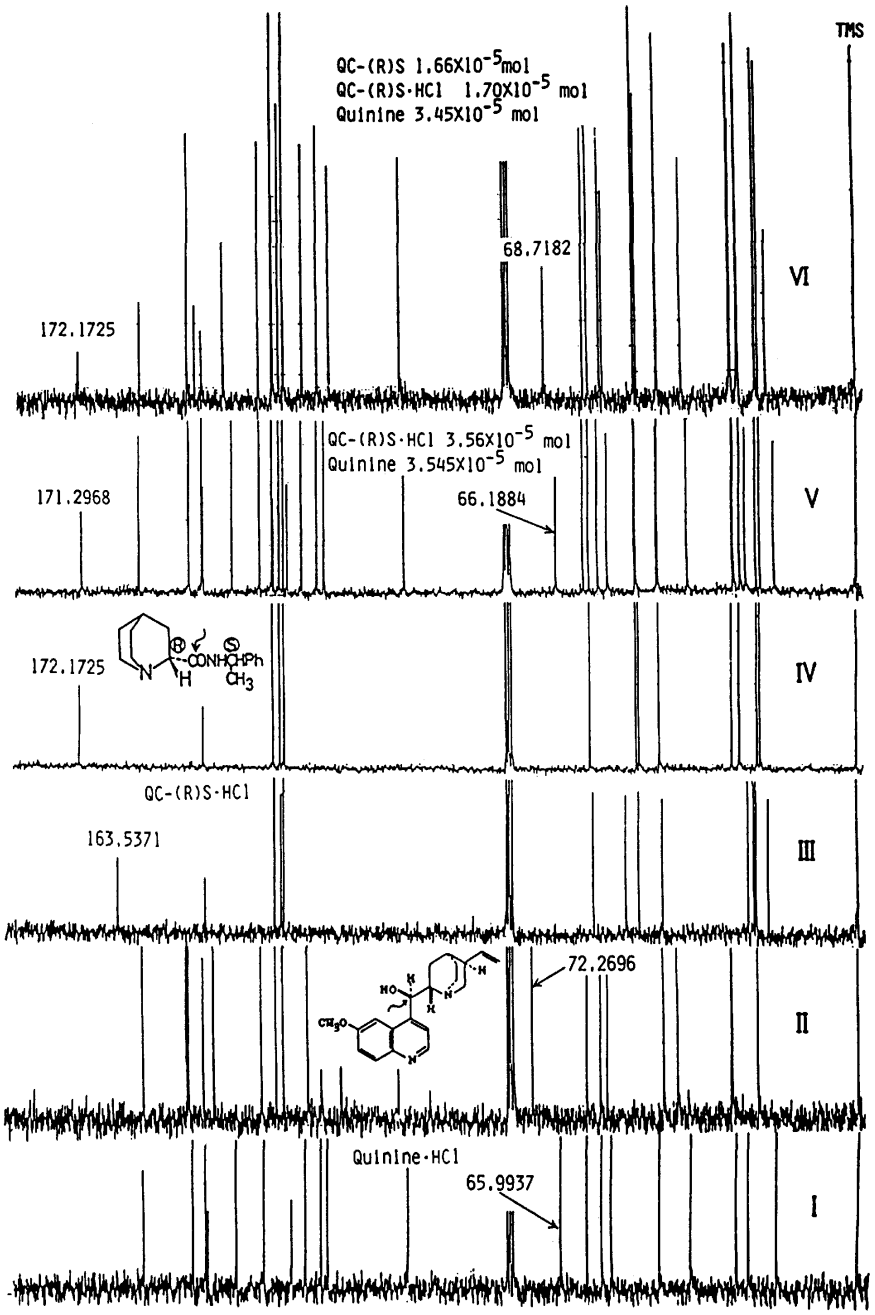

Fig. 3. ^{13}C NMR spectra in $CDCl_3$(0.6 ml).

Perkin Elmer 241 polarimeter.

Preparation of Cocatalyst. As the preparation of QC-(*R*)S and its enantiomer were described in a previous paper,[4] only those of QC-(*S*)*R*-NCH_3, QC-(*S*)*R*-Naph and QC-(*R*)-$NHCH_3$ are described below.

(*S*)-*N*-Methyl-*N*-[(*R*)-1-phenylethyl]-2-quinuclidinecarboxamide (QC-(*S*)*R*-NCH_3). Thionyl chloride (25 g) and (*S*)-2-quinuclidinecarboxylic acid hydrochloride (1.5 g, 7.8 mmol; $[\alpha]_D^{20.1}$ −96.8° (*c* 1.022, H_2O), lit,[8] $[\alpha]_D$ −96.2° (*c* 1, H_2O)) were refluxed for 20 min and the homogeneous solution was concentrated *in vacuo* to remove excess thionyl chloride. To the residue was added dry benzene and concentrated to dryness (repeated twice). To the crystalline residue dry ether was added and then (*R*)-*N*-methyl-1-phenylethylamine (3.6 g, 26.6 mmol) were added on ice cooling with stirring.[9] Stirring was continued for 3 d at room temperature and then to the solution was added a 50% aqueous potassium carbonate solution until the water layer became basic. The ether layer was decanted and the water layer was extracted twice with ether (200 ml×2) and the ether layers were combined and dried (Na_2SO_4). The ether solution was concentrated in order to also remove any excess (*R*)-*N*-methyl-1-phenylethylamine to give oil (1.73 g, 6.3 mmol). The oil and *p*-toluenesulfonic acid monohydrate (1.2 g, 6.3 mmol) were dissolved in methanol and concentrated to dryness. The residue was gradually solidified in ether. After standing overnight the ether was decanted and the residual solid was recrystallized from ethyl acetate to give prisms. The prisms were dissolved in water and the solution was made basic with a 50% aqueous potassium carbonate solution. The solution

was extracted twice with ether (200 ml×2) and then dried (Na_2SO_4). The concentration of the ether solution gave oil (0.79 g).

The oil (0.13 g, 0.48 mmol) was dissolved in methanol and to the solution was added 0.04 ml of concentrated hydrochloric acid. The solvent was removed and the residue was dried by evaporation with dry benzene to give crystals. These were recrystallized from ethanol-ether to give needles (0.1 g): mp>250 °C (sublimed from ca. 220 °C); $[\alpha]_D^{22.0}$ +45.0° (*c* 0.511, CH_3OH); IR (KBr) 2300—2500 (N^+H) and 1640 cm^{-1} (amide C=O); ^1H NMR ($CDCl_3$ and DMSO-d_6) δ=1.50 (2.3H,[10] d, *J*=7.34 Hz, $C\underline{H}_3$-CH), 1.60 (0.7H, d, *J*=6.60 Hz, $C\underline{H}_3$-CH), 1.76 (5H, m), 2.12 and 2.36 (2H, m), 2.63 (0.7H, s, N-$C\underline{H}_3$), 2.73 (2.3H, s, N-$C\underline{H}_3$), 3.28 (3H, m), 4.81 (1H, t, *J*=9.6 Hz, C-2 methine proton), 5.17 (0.23H, q, *J*=6.60 Hz, CH_3-$C\underline{H}$), 5.80 (0.77H, q, *J*=7.34 Hz, CH_3-$C\underline{H}$) and 7.24 (5H, m, Ph). Found: C, 66.11; H, 8.16; N, 9.09. Calcd for $C_{17}H_{25}ClN_2O$: C, 65.77; H, 8.26; N, 8.93.

(*S*)-*N*-[(*R*)-1-(1-naphthyl)ethyl]-2-quinuclidinecarboxamide (QC-(*S*)*R*-Naph). Thionyl chloride (25 g) and (*S*)-2-quinuclidinecarboxylic acid hydrochloride (2.0 g, 10.4 mmol; $[\alpha]_D^{18.2}$ −90.0° (*c* 1.026, H_2O)) were treated as described above. The crystalline residue were suspended in dry ether (200 ml) and to the solution (*R*)-1-(1-naphthyl)ethylamine (1.79 g, 10.5 mmol) and triethylamine (3.3 g, 32.6 mmol) were added on ice cooling with stirring. Stirring was continued for 6 d at room temperature and followed a similar procedure as that for QC-(*S*)*R*-NCH_3 to give syrup (2.84 g, 9.2 mmol). The syrup was reacted with *p*-toluenesulfonic acid monohydrate (1.87 g, 9.8 mmol) and treated similarly as QC-(*S*)*R*-NCH_3 to give crystals (0.92 g). These were recrystallized from petroleum ether to give large columns (0.7 g): mp 134.0—136.0 °C; $[\alpha]_D^{22.4}$ −43.4° (*c* 1.008, $CHCl_3$); IR (KBr) 3370 (NH) and 1662 cm^{-1} (amide C=O); ^1H NMR ($CDCl_3$) δ=1.28 (2H, m), 1.44 (2H, m), 1.64 (3H, d, *J*=6.85 Hz, $C\underline{H}_3$-CH), 1.84 (3H, m), 2.42 (2H, t), 2.83 (2H, m), 3.34 (1H, t, *J*=9.17 Hz, C-2 methine proton), 5.96 (1H, quintet, *J*=6.85 Hz, CH_3-$C\underline{H}$), 7.44 (5H, m, naphthyl and NH), 7.76 (2H, m, naphthyl) and 8.08 (1H, d, naphthyl). Anal. ($C_{20}H_{24}N_2O$)-C,H,O.

(*R*)-*N*-Methyl-2-quinuclidinecarboxamide (QC-(*R*)-$NHCH_3$). Ethyl (*R*)-2-quinuclidinecarboxylate (1.0 g; $[\alpha]_D^{24.6}$ +89.4° (*c* 1.013, ethanol), lit,[8] $[\alpha]_D^{22}$ −88.4° (*c* 1, abs ethanol)) was dissolved in an aqueous 35-41% methylamine solution (150 ml); the solution was allowed to react overnight. The solution was concentrated and the residue was extracted with ether (200 ml). The ether solution was dried (Na_2SO_4) and concentrated to give crystals (0.66 g). These were recrystallized from petroleum ether to give large needles (0.47 g): mp 85.0—87.0 °C; $[\alpha]_D^{24.5}$ +117.1° (*c* 1.008, $CHCl_3$); IR (KBr) 3350 (NH) and 1660 cm^{-1} (amide C=O); ^1H NMR ($CDCl_3$) δ=1.48 (4H, m), 1.87 (3H, d), 2.71 (2H, t), 2.82 (3H, d, *J*=4.9 Hz, $C\underline{H}_3$-NH), 2.89 (2H, m), 3.28 (1H, t, *J*=9.3 Hz, C-2 methine proton), 6.96 (1H, broad s, NH). Anal. ($C_9H_{16}N_2O$)C,H,O.

Asymmetric Hydrogenation of *N,N'*-Dimethyl-5-alkylidene- and Arylmethylenehydantoins with $Co(Hdmg)_2$·B-B*. The hydrogenation (under 1 atm of H_2) and the isolation of the hydrogenated product were carried out according to the procedure described in a previous paper,[4] except for the following case. When a cocatalyst with more than an equimolar amount of the cobalt complex was used, it was dissolved in a solution of the substrate to be injected into the reaction vessel[4] together with the substrate. When PPh_3 and $P(Bu^n)_3$ are not used as B, the purification by column chromatography was not carried out.[11]

Determinations of enantiomeric excesses of the hydrogenated products were similarly performed as that described in a previous paper using tris(3-trifluoroacetyl-*d*-camphorato)-europium(III).[4]

The authors wish to express their thanks to Professor Chung-gi Shin and Assistant Professor Yasuchika Yonezawa, Kanagawa University, for their valuable discussions and generous gift of samples; and to Miss Tatsuko Sakai, Meijho University, for her elemental analyses. We would also like to thank Mr. Masakazu Yamaguchi, Mr. Noriyuki Kameda, Mr. Koji Yamada, and Mr. Takefumi Momose for the preparation of substrates and chiral 2-quinuclidinecarboxamides.

5) As this scheme is too simplified, see reference 3) where the detailed asymmetric hydrogenation mechanism is described.

6) Since proton exchange is rapid on the NMR time scale, the observed chemical shift of C-9 or carbonyl carbon should be that in a weighted average of free base and its hydrochloride. Accordingly, the percentage of quinine·HCl in the mixed system (V) can be evaluated by the equation:

$$\frac{72.2696-66.1884}{72.2696-65.9937}\times 100 = 96.9(\%).$$

9) H. Pracejus, F. W. Wilke, and K. Hanemann, *J. Prak. Chem.*, **319**, 219 (1977).

10) The separation of signals ($C\underline{H}_3$-CH, $C\underline{H}_3$-N and CH_3-$C\underline{H}$) is due to rotational isomerization of QC-(*S*)*R*-NCH_3·HCl, which is confirmed by comparison of the ^1H NMR spectrum with that of QC-(*R,S*)*R*-NCH_3·HCl (QC-(*R,S*) represents racemate). Thus the ratio of the number of protons (2.3 : 0.7) represents that of the rotational isomers in the solution. The similar phenomenon was observed for QC-(*R*)*S*-NCH_3 and the ratio was 2.1 : 0.9 in $CDCl_3$.

11) The purification resulted in little change of optical rotation in this case. For example, 1.64 g of *N,N'*-dimethyl-5-benzylhydantoin (in Run 6 of Table 5) whose optical rotation is −55.4° was purified by the column chromatography to give 1.62 g of $[\alpha]_D$ −56.0°. This also indicates that enantiomeric enrichment does not occur in the purification procedure.

Selective 1,4-Chiral Induction in the Reaction of Enolates Generated from *t*-Butyl δ-Hydroxy Carboxylates

Koichi NARASAKA,* Yutaka UKAJI, and Kazutoshi WATANABE
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received October 20, 1986)

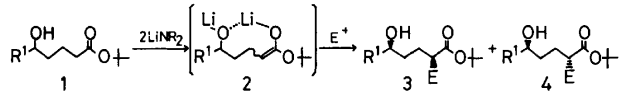
Lithium enolates generated from *t*-butyl esters of δ-hydroxy carboxylic acids with lithium dialkylamides in THF-HMPA were alkylated stereoselectively to give the corresponding *syn*-α-alkylated δ-hydroxy esters. The generation of the enolates was accelerated by the addition of lithium trifluoromethanesulfonate, and the successive aldol and hydroxylation reactions of the enolates also proceeded in a stereoselective manner.

In recent years a number of efforts have been devoted on the exploration of stereoselective reactions in acyclic precursors, and various excellent methods have been developed toward the diastereoselection between adjacent carbon atoms (1,2-relationships).[1] However, general approaches to the construction of remote chiral relationships in acyclic systems are rare, and such a control of the diastereoselectivity between remote carbons has still been a challenging problem in organic synthesis.

Concerning 1,3-chiral induction[1b,2] we have reported the stereoselective preparations of *syn*-1,3-diols and *syn*-β-amino alcohols from β-hydroxy ketones.[3] In this paper, we describe the rusults of a study on 1,4-chiral induction[2b,4] directed by a hydroxyl group in the reaction of lithium enolates derived from δ-hydroxy esters.[5]

Results and Discussion

The formation of 6-membered chelate is known to well regulate the 1,2-chiral induction in the reaction of dilithio derivatives generated from β-hydroxy esters.[6] It was considered that the lithium enolate dianion **2** prepared from δ-hydroxy esters would also form even a strained 8-membered chelate by the strong interaction between lithium and the oxygen of the alkoxide group. Hence the successive reaction of **2** with electrophiles would proceed in a stereoselective manner.



By the above hypothesis, the alkylation reaction of ester enolates generated from **1** was firstly examined. *t*-Butyl 5-hydroxyhexanoate (**1A**) was treated with 2 molar amounts of lithium diisopropylamide (LDA) in THF at −78 °C and the resulting enolate was alkylated with methyl iodide, however, a ca. 1 : 1 mixture of **5a** and **6a** was obtained. When the formation of the enolate from **1A** and the successive alkylation were carried out using hexamethylphosphoric triamide (HMPA) as a co-solvent with THF, the remarkable stereoselectivity was observed to give a *syn*[7]-α-alkylated product **5a** and an *anti*-product **6a** in a ratio of 86 : 14. It was also observed that the enolization of *t*-butyl 5-hydroxynonanoate (**1B**) with LDA in THF or in THF-HMPA at −78 °C was followed by the addition of butyl iodide to furnish **5b** and **6b** in a ratio of 52 : 48 or 88 : 12, respectively.

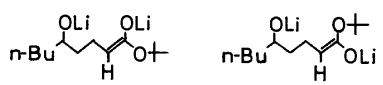
b	*n*-Bu	*n*-Bu	THF	52:48
			THF-HMPA	88:12

a) The ratios were determined by capillary gas chromatography (PEG-HT).

The geometry of the enolates generated from **1B** in THF and THF-HMPA was studied by trapping the enolates with *t*-butyldimethylsilyl chloride according to the Ireland's procedure,[8] and in each case, the silyl enol ether of the different configuration was formed predominantly. Based on the Ireland's study, lithiation in THF and THF-HMPA was considered to mainly afford the *trans*[9]-enolate *trans*-**2B** and the *cis*-enolate *cis*-**2B**, respectively. Furthermore, the observation that the vinylic proton of the silyl enol ether of the enolate generated in THF-HMPA appears at 0.03 ppm lower field than the corresponding resonance for that generated in THF supported the above stereochemical assignment.[8]



cis-2B trans-2B

We supposed that the enhanced selectivity by the addition of HMPA may be due to the formation of an 8-membered chelate of a *cis*-enolate. In the 8-membered chelate of the *cis*-enolate, the attack of an electrophile would be expected to proceed from the less hindered side in the preferable conformations such as T_1 (no-symmetry) or T_2 (twist chair)[10a] to result in the formation of the *syn*-alkylated product **5**. On the con-

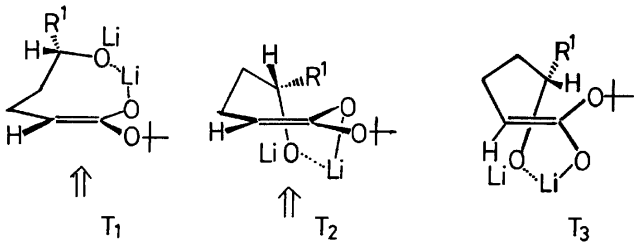
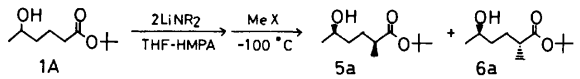
a) The alkylation reaction was performed at −78°C.

trary, the formation of a chelate T_3 should be difficult for the *trans*-enolate because of the severe steric strain,[10] therefore any stereoselection was not observed in the alkylation reaction.

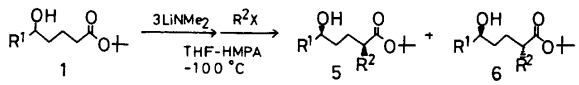


Our initial report that the *syn*-stereoselection is controlled by the addition of HMPA without regard to the configuration of the generating lithium enolate was noted to be incorrect. By the experiments of the reproducibility, it was found that the addition of HMPA after the generation of the enolate (in THF at −78°C) little changed the selectivity of the successive alkylation.

In order to improve the selectivity toward *syn*-alkylated products, the enolate formation was examined using various lithium amides. It is noteworthy that the treatment of the *t*-butyl ester **1A** with less hindered lithium amides such as lithium diethylamide, lithium dimethylamide, or lithium pyrrolidinide in THF-HMPA at lower temperature (−100°C) realized the significant stereoselectivity (Table 2).



Based on these preliminary investigations, the lithium enolates generated from δ-hydroxy esters (**1A** and **1B**) with 3 molar amounts of lithium dimethylamide in THF-HMPA at −100°C were treated with alkylating reagents. The corresponding *syn*-α-alkylated δ-hydroxy esters **5** were found to be obtained in excellent stereoselectivity (Table 3).



The stereochemistry of **5a** and **5b** was confirmed by the following results. Acid treatment of the *syn*-

Table 3. Stereoselective Alkylation Reaction of **1**

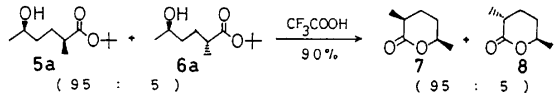
d	*n*-Bu	Me_2SO_4	94:6	92

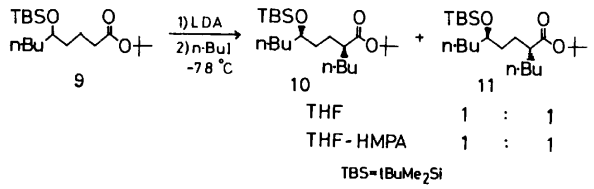
a) The ratios were determined by capillary gas chromatography (PEG-HT). b) Instead of lithium dimethylamide, lithium pyrrolidinide was used. c) Instead of lithium dimethylamide, lithium diethylamide was used. d) After the addition of *n*-BuI, the reaction mixture was stirred for 1 h at −100°C and gradually warmed to −78°C.

alkylated ester **5a** readily afforded the sex pheromone of the carpenter bee, (±)-*cis*-2-methyl-5-hexanolide (**7**).[11,12]



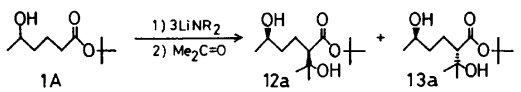
The *syn*-alkylated ester **5b** was also transformed to *cis*-2-butyl-5-nonanolide, which was identical with the authentic *cis*-lactone derived from *cis*-2,5-dibutylcyclopentanone by the Bayer-Villiger reaction.

To confirm the influence of a hydroxyl group on the stereoselection, we examined the alkylation of *t*-butyl 5-hydroxynonanoate (**1B**) after the protection of the hydroxyl group as a *t*-butyldimethylsilyl ether. Although the alkylation reaction of the silyl ether **9** proceeded smoothly, the ratio of the products **10** and **11** was almost 1:1 even when a mixture of THF-HMPA was employed as a solvent. Accordingly, the transformation of a hydroxyl group to lithium alkoxide should be indispensable for the present chiral 1,4-induction.

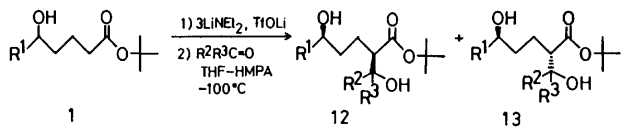


Due to the demonstrated efficiency for the stereoselection in the alkylation of δ-hydroxy carboxylic acid esters, we next investigated the 1,4-chiral induction in the aldol reaction of δ-hydroxy esters with acetone and cyclohexanone.

Hydroxy ester **1A** was lithiated under the same reaction conditions as the alkylation reaction (3 molar amounts of lithium pyrrolidinide, −100 °C), and the successive treatment with acetone was firstly examined. The aldol adducts **12a** and **13a** were obtained in a moderate (81 : 19) ratio, however, the total yield of the products was only 33%. When 3 molar amounts of lithium diethylamide was employed in the above reaction, the yield of the aldol products was not also sufficient (53%). On the other hand, as can be seen in Table 3, the alkylation reaction proceeded smoothly in over 80% yield in the same reaction conditions. By comparison of these results, it was noted that the enolization of δ-hydroxy esters **1** was not sufficient in the first lithiation stage (at −100 °C for 1 h) and that the enolization proceeds furthermore after the addition of an alkylating reagent. The presence of an alkylating reagent or a lithium salt genarated during alkylation reaction would be considered to accelerate the lithiation of δ-hydroxy esters, and the lithiation of **1** was examined in the presence of various lithium salts. Finally lithium trifluoromethanesulfonate (LiOTf) or lithium iodide was found to enhance the lithiation.[13] Thus the hydroxy ester **1A** was smoothly converted to the enolate **2A** with 3 molar amounts of lithium diethylamide in the presence of 3 molar amounts of LiOTf even at −100 °C in THF-HMPA, and the reaction with acetone gave the aldol adducts **12a** and **13a** in 92% yield (Table 4). Furthermore, the high stereoselectivity toward the *syn*-aldol product was also achieved by the addition of LiOTf (**12a** : **13a**=91 : 9). When LiOTf and then acetone were added succesively after the enolate formation at −100 °C, the yield of the aldol products was lower (74%). These observations suggested that LiOTf is not effective to promote the aldol reaction, but accelerates the enolization.



The aldol reaction of **1A** and **1B** with acetone and cyclohexanone was conducted by the combined use of LiOTf and lithium diethylamide with the results shown in Table 5. In all cases, the *syn*-aldol products **12** were obtained in high yield with high stereoselectivity.



The confirmation of the relative stereochemistry of **12a** was carried out by the transformation of **12a** to **17**,

carbons (-CH(OH)-) of the *syn*-isomers **12** appear at lower fields about 0.4—0.7 ppm and 0.5—1.0 ppm than those of the *anti*-isomers **13**, respectively.

As the significant effect for the acceleration of the enolate formation was observed by the addition of LiOTf, the alkylation reaction was reexamined in the presence of LiOTf. The enolate formation of **1A** (3 $LiNEt_2$, 3LiOTf in THF-HMPA, −100 °C, 2 h) and the successive alkylation with dimethyl sulfate was carried out at −100 °C. The alkylated products **5a** and **6a** were however obtained in low yield (20%). This result means that LiOTf accelerates the formation of the ester enolate but disturbs the reaction with alkylation reagents.

Next, we have used the lithium enolates of δ-hydroxy esters **1** in the stereoselective preparation of *syn*-1,4-diols by the direct oxidation of the enolates. And it has been found that the α-hydroxylation reaction of this system proceeded with an oxidant, oxaziridine.[14,15] The δ-hydroxy ester **1A** was transformed into the lithium enolate (3 equiv $LiNEt_2$, THF-HMPA, −100→−78 °C) and treated with an excess amount of the oxaziridine **22**. After an immediate reaction, the *syn*-α,δ-dihydroxy ester **20a** and the *anti*-isomer **21a** were obtained in high selectivity (**20a**:**21a**=92:8). It was evident that the sense of chiral induction in this hydroxylation paralleled the observation made in the alkylation and aldol reactions. However, the yield of the diols was modest. As a reaction of the enolate with the generated sulfonylimine was considered to be accompanied, we modified the hydroxylation reaction by means of an employment of more sterically hindered oxaziridines. When a newly synthesized oxaziridine **25** was utilized to the hydroxylation, the yield of diols consequently improved up to 70%. Moreover, the enolate formation at −100 °C in the presence of LiOTf and the treatment of the resulting enolates with **25** afforded the corresponding diols **20** and **21** in superior yield and stereoselectivity (Table 6).

Experimental

All the boiling points and the melting points are uncorrected. The IR spectra were determined on a Hitachi Model 260-30 spectrometer. The ^1H NMR spectra were recorded with a Hitachi R-24B, a Varian EM-390, and a JEOL GX-400 spectrometers, and ^{13}C NMR spectra were measured with a JEOL FX-90Q spectrometer with tetramethylsilane as an internal standard. Tetrahydrofuran (THF) and diethyl ether were freshly distilled from sodium benzophenone ketyl. Dichloromethane, hexamethylphosphoric triamide (HMPA) and pyridine were distilled from CaH_2 and stored over Molecular Sieves. Purification of products was performed by column chromatography on silica gel (Wakogel C-200 or C-300), preparative TLC on silica gel (Wakogel B-5F).

Preparation of *t*-Butyl 5-Hydroxyhexanoate (1A). 5-Oxohexanoic acid[17] (6.09 g, 47 mmol) was treated with an excess amount of 2-methylpropene and three drops of concd H_2SO_4 in autoclave and was stirred at room temperature overnight.[18] The reaction mixture was quenched with triethylamine and was extracted with CH_2Cl_2. The combined extracts were washed with brine, dried over Na_2SO_4,

and condensed under reduced pressure. Purification by column chromatography (hexane:ethyl acetate=2:1, v/v) gave *t*-butyl 5-oxohexanoate (8.72 g, 74%). IR (neat) 1720 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.43 (9H, s), 1.73—2.29 (4H, m), 2.13 (3H, s), 2.29—2.67 (2H, m). Next, to a solution of *t*-butyl 5-oxohexanoate (2.15 g, 11.5 mmol) in CH_2Cl_2 (50 mL) and methanol (10 mL) was added sodium borohydride (1.31 g, 34.6 mmol) at 0 °C, and stirred for 15 min at room temperature. The mixture was quenched with sat. aqueous NH_4Cl and extracted with CH_2Cl_2. The separated organic layer was dried over Na_2SO_4 and was condensed under reduced pressure. Purification by column chromatography on silica gel (hexane:ethyl acetate=3:1, v/v) gave *t*-butyl 5-hydroxyhexanoate (**1A**) (2.09 g, 96%). Bp 80 °C/0.15 mmHg (1 mmHg=133.322 Pa). IR (neat) 3430, 1720 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.13 (3H, d, J=6.0 Hz), 1.45 (9H, s), 1.23—1.90 (4H, m), 1.90—2.53 (2H, m), 3.36—3.98 (2H, m). Found: C, 63.51; H, 10.98%. Calcd for $C_{10}H_{20}O_3$: C, 63.79; H, 10.71%.

Preparation of *t*-Butyl 5-Hydroxynonanoate (1B). To a CH_2Cl_2 (20 mL) solution of 5-oxononanoic acid[19] (5.61 g, 33 mmol) was added concd H_2SO_4 (2 mL). Into the resulting mixture was bubbled 2-methylpropene for 1 h.[20] The reaction was quenched with water and extracted with CH_2Cl_2, then washed with water and brine. The organic layer was dried over Na_2SO_4 and condensed in vacuo. The residue was purified by column chromatography on silica gel (hexane: ethyl acetate=9:1, v/v) to give *t*-butyl 5-oxononanoate (5.10 g, 69%). IR (neat) 1720 cm^{-1}. ^1H NMR (CCl_4) δ=0.62—2.43 (15H, m), 1.29 (9H, s). Reduction of *t*-butyl 5-oxononanoate with $NaBH_4$ as described for **1A** gave *t*-butyl 5-hydroxynonanoate (**1B**) in 92% yield. Bp 135 °C (bath temp)/4 mmHg. IR (neat) 3440, 1735 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.55—1.83 (14H, m), 1.35 (9H, s), 1.97—2.28 (2H, m), 3.07—3.62 (1H, m). Found: C, 67.65; H, 11.61%. Calcd for $C_{13}H_{26}O_3$: C, 67.78; H, 11.38%.

Stereoselective Alkylation Reaction of 1A with Dimethyl Sulfate. To a THF (7 mL) solution of lithium dimethylamide (2.37 mmol), which was prepared from an excess amount of dimethylamine (ca. 0.5 mL) and butyllithium (2.37 mmol), was added a THF (1 mL) solution of HMPA (0.83 mL, 4.77 mmol) at −78 °C under an argon atmosphere, and cooled to −100 °C. A THF (2 mL) solution of *t*-butyl 5-hydroxyhexanoate (**1A**) (149 mg, 0.79 mmol) was added to the mixture and stirred for 1 h at that temperature. Then a THF (2 mL) solution of dimethyl sulfate (316 mg, 2.51 mmol) was added to the mixture. After being stirred for 1 h at −100 °C, the reaction was quenched with sat. aqueous NH_4Cl and extracted with ether. The combined ether extracts were washed with water and brine, dried over Na_2SO_4, and condensed under reduced pressure. Purification by column chromatography (hexane: ethyl acetate=8:1, v/v) gave *t*-butyl *syn*-5-hydroxy-2-methylhexanoate (**5a**) and the *anti*-isomer **6a** (total 140 mg, 87%) in the ratio of 94:6, respectively.

The stereoselective preparations of **5b—d** were carried out by the same procedure. All the alkylated products were obtained as a mixture of *syn*- and *anti*-isomers **5** and **6**, which were not able to be separated by column chromatography or TLC. Each pair of isomers was indistinguishable by ^1H NMR (90 MHz) spectra, and the following spectral and analytical data were for a mixture of *syn*- and *anti*-isomers (90:10—95:5), respectively.

t-Butyl *syn*-5-hydroxy-2-methylhexanoate (**5a**) and the *anti* isomer **6a**: IR (neat) 3425, 1725 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.00 (3H, d, J=5.6 Hz), 1.06 (3H, d, J=6.4 Hz), 1.20—1.80 (4H, m), 1.31 (9H, s), 1.92—2.42 (1H, m), 2.67 (1H, br s), 3.38—3.92 (1H, m). Found: C, 65.19; H, 11.25%. Calcd for $C_{11}H_{22}O_3$: C, 65.31; H, 10.96%.

t-Butyl *syn*-2-butyl-5-hydroxynonanoate (**5b**) and the *anti* isomer **6b**: IR (neat) 3450, 1725 cm^{-1}. ^1H NMR ($CDCl_3$) δ= 0.53—2.39 (24H, m), 1.32 (9H, s), 3.17—3.59 (1H, m). Found: C, 71.55; H, 12.18%. Calcd for $C_{17}H_{34}O_3$: C, 71.28; H, 11.96%.

t-Butyl *syn*-2-butyl-5-hydroxyhexanoate (**5c**) and the *anti* isomer **6c**: IR (neat) 3430, 1725 cm^{-1}. ^1H NMR (CCl_4) δ= 0.53—2.24 (14H, m), 0.98 (3H, d, J=5.8 Hz), 1.31 (9H, s), 2.90 (1H, br s), 3.23—3.79 (1H, m). Found: C, 68.60; H, 11.84%. Calcd for $C_{14}H_{28}O_3$: C, 68.81; H, 11.55%.

t-Butyl *syn*-5-hydroxy-2-methylnonanoate (**5d**) and the *anti* isomer **6d**: IR (neat) 3430, 1730 cm^{-1}. ^1H NMR (CCl_4) δ=0.63—1.87 (14H, m), 1.07 (3H, d, J=6.8 Hz), 1.42 (9H, s), 1.90—2.47 (1H, m), 3.18—3.63 (1H, m). Found: C, 68.58; H, 11.49%. Calcd for $C_{14}H_{28}O_3$: C, 68.81; H, 11.55%.

Transformation of a Mixture of 5a and 6a to the Lactones. A 95:5 mixture of **5a** and **6a** (total 140 mg, 0.69 mmol) was dissolved in trifluoroacetic acid (2mL), and stirred for 2 h. After evaporation of the excess trifluoroacetic acid in vacuo, the residue was purified by preparative TLC on silica gel (hexane:ethyl acetate=1:1, v/v) to afford *cis*-2-methyl-5-hexanolide (**7**) and the *trans*-isomer **8** (total 80 mg, 90%) in the ratio of 95:5, respectively. Isomeric ratio was determined by capillary gas chromatography (OV-101, 95 °C).

cis-2-Methyl-5-hexanolide (**7**) and the *trans* isomer **8**: IR (neat) 1720 cm^{-1}. ^1H NMR (400 MHz) ($CDCl_3$) δ=1.23 (2.85H, d, J=6.8 Hz, *cis*), 1.31 (0.15H, d, J=6.4 Hz, *trans*), 1.36 (2.85H, d, J=6.4 Hz, *cis*), 1.37 (0.15H, d, J=6.4 Hz, *trans*), 1.50—1.68 (2H, m), 1.90—2.13 (2H, m), 2.41—2.48 (0.05H, m, *trans*), 2.55—2.64 (0.95H, m, *cis*), 4.43—4.51 (1H, m).

cis-2-Butyl-5-nonanolide. A solution of *cis*-2,5-dibutylcyclopentanone[21] (126 mg, 0.64 mmol) in acetic acid (3 mL) was mixed with 30% hydrogen peroxide (1 mL) and stirred at 50 °C for 3 d.[22] The reaction mixture was poured into water, extracted with ether and washed with aqueous $NaHCO_3$ and brine, dried over Na_2SO_4, and condensed in vacuo. Purification by preparative TLC on silica gel (hexane:ethyl acetate=6:1, v/v) to give *cis*-2-butyl-5-nonanolide (41 mg, 30%). IR (neat) 1740 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.53—2.59 (23H, m), 3.83—4.42 (1H, m). Found: C, 73.55; H, 11.59%. Calcd for $C_{13}H_{24}O_2$: C, 73.53; H, 11.39%.

By capillary gas chromatography (OV-101, 135 °C), the authentic lactone was identical with the major isomer of the lactones derived from **5b** and **6b**.

Stereoselective Aldol Reaction of 1A with Acetone. To a THF (5 mL) solution of LiOTf (323 mg, 2.07 mmol) was added a THF (5 mL) solution of diethylamine (179 mg, 2.44 mmol) under an argon atmosphere, and cooled to −78 °C. Butyllithium (1.25 mL of a 1.54 M solution in hexane (1 M=1 mol dm^{-3})) was added and the solution was stirred at that temperature for 15 min followed by the addition of a THF (1 mL) solution of HMPA (0.66 mL, 3.79 mmol) and then cooled to −100 °C. A THF (4 mL) solution of **1A** (119 mg, 0.63 mmol) was added to the mixture and stirred for 2 h at that temperature, and then a THF (4 mL) solution of acetone (91 mg, 1.57 mmol) was added. After being stirred for 30 min at −100 °C, the reaction was quenched with sat. aqueous NH_4Cl and extracted with ether. The ethereal

extracts were washed with water and brine, dried over Na_2SO_4, and condensed in vacuo. Purification by preparative TLC on silica gel (hexane : ethyl acetate=1 : 2, v/v) to give *t*-butyl *syn*-5-hydroxy-2-(1-hydroxy-1-methylethyl)-hexanoate (**12a**) and the *anti*-isomer **13a** (total 142 mg, 92%) in a ratio of 91 : 9, respectively.

Stereoselective syntheses of **12b—d** were carried out by the same procedure. All the *syn*- and *anti*-isomers of the aldol products **12** and **13** were not separable by column or thin-layer chromatography. In the ^1H NMR spectra (90 MHz), each isomer was not distinguished.

t-Butyl *syn*-5-hydroxy-2-(1-hydroxy-1-methylethyl)-hexanoate (**12a**) and the *anti* isomer **13a**: IR (neat) 3400, 1725 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.18 (3H, d, J=6.0 Hz), 1.22 (6H, s), 1.33—1.97 (4H, m), 1.45 (9H, s), 2.10—2.41 (1H, m), 3.03 (2H, br s), 3.37—3.97 (1H, m). ^{13}C NMR ($CDCl_3$) δ=56.20 (Cα, *anti*), 56.66 (Cα, *syn*), 66.90 (Cδ, *anti*), 67.63 (Cδ, *syn*). Analytical data for the corresponding 5-*O*-acetate; Found: C, 62.22; H, 10.13%. Calcd for $C_{15}H_{28}O_5$: C, 62.47; H, 9.79%.

t-Butyl *syn*-5-hydroxy-2-(1-hydroxycylohexyl)hexanoate (**12b**) and the *anti* isomer **13b**: Mp 90.1—90.2 °C (hexane). IR (KBr) 3400, 1715 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.17 (3H, d, J=5.4 Hz), 1.28—1.97 (14H, m), 1.47 (9H, s), 2.10—2.57 (1H, m), 2.94 (1H, br s), 3.10 (1H, br s), 3.47—4.17 (1H, m). ^{13}C NMR ($CDCl_3$) δ=55.01 (Cα, *anti*), 55.42 (Cα, *syn*), 67.39 (Cδ, *anti*), 67.93 (Cδ, *syn*). Found: C, 67.17; H, 10.84%. Calcd for $C_{16}H_{30}O_4$: C, 67.09; H, 10.56%.

t-Butyl *syn*-5-hydroxy-2-(1-hydroxy-1-methylethyl)-nonanoate (**12c**) and the *anti* isomer **13a**: IR (neat) 3390, 1725 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.60—1.88 (13H, m), 1.08 (3H, s), 1.12 (3H, s), 1.35 (9H, s), 1.97—2.27 (1H, m), 2.53 (2H, br s), 3.20—3.63 (1H, m). ^{13}C NMR ($CDCl_3$) δ=56.34 (Cα, *anti*), 57.01 (Cα, *syn*), 70.91 (Cδ, *anti*), 71.86 (Cδ, *syn*). Analytical data for the corresponding 5-*O*-acetate; Found: C, 65.45; H, 10.56%. Calcd for $C_{18}H_{34}O_5$: C, 65.42; H, 10.37%.

t-Butyl *syn*-5-hydroxy-2-(1-hydroxycyclohexyl)nonanoate (**12d**) and the *anti* isomer **13d**: Mp 58.0—60.5 °C (2-propanol-H_2O). IR (KBr) 3480, 1695 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.68—2.70 (25H, m), 1.48 (9H, s), 2.84—3.19 (1H, m), 3.30—3.77 (1H, m). ^{13}C NMR ($CDCl_3$) δ=54.88 (Cα, *anti*), 55.47 (Cα, *syn*), 71.02 (Cδ, *anti*), 71.89 (Cδ, *syn*). Found: C, 69.19; H, 11.33%. Calcd for $C_{19}H_{36}O_4$: C, 69.47; H, 11.05%.

Transformation of 12a and 13a to 17 and 18. a) *t*-Butyl 5-*t*-butyldimethylsilyloxy-2-(1-hydroxy-1-methylethyl)-hexanoate (**14**). A 4 : 1 mixture of **12a** and **13a** (total 531 mg, 2.15 mmol), *t*-butyldimethylsilyl chloride (395 mg, 2.63 mmol), triethylamine (328 mg, 3.24 mmol), and a catalytic amount of 4-dimethylaminopyridine in DMF (6 mL) was stirred for 15 h at room temperature under an argon atmosphere.[23] Then the reaction was quenched with ice and the mixture was extracted with ether. The ether extracts were washed with water and brine and dried over Na_2SO_4. The ether solution was concentrated and the residue was purified by column chromatography on silica gel (hexane: ethyl acetate=10 : 1, v/v) to give the silylated ester **14** (698 mg, 90%). IR (neat) 3450, 1725 cm^{-1}. ^1H NMR (CCl_4) δ=0.03 (6H, s), 0.81 (9H, s), 1.01 (6H, s), 1.01 (3H, d, J=6.0 Hz), 1.25—2.25 (6H, m), 1.40 (9H, s), 2.55 (1H, br s), 3.50—4.00 (1H, m). b) 3-hydroxymethyl-2-methyl-6-*t*-butyldimethylsilyloxy-2-heptanol (**15**). To an ether (5 mL) solution of **14** (698 mg, 1.94 mmol) was added an ether (2.5 mL) solution of lithium aluminum hydride (3.88 mmol) at 0 °C under an argon atmosphere, and stirred for 16 h at that temperature. The mixture was quenched with sat. aqueous Na_2SO_4 (1.8 mL) and the resulting precipitate was filtered off. The condensed filtrate was purified by column chromatography on silica gel (hexane: ethyl acetate=4 : 1, v/v) to furnish the diol **15** (430 mg, 76%). IR (neat) 3340 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.06 (6H, s), 0.90 (9H, s), 1.11 (3H, d, J=6.0 Hz), 1.18 (3H, s), 1.29 (3H, s), 3.33—4.04 (3H, m), 3.73 (2H, d, J=5.0 Hz). c) 6-(*t*-Butyldimethylsilyloxy)-2-methyl-3-(*p*-tolylsulfonyloxymethyl)-2-heptanol (**16**). A mixture of **15** (430 mg, 1.48 mmol), *p*-toluenesulfonyl chloride (427 mg, 2.24 mmol), and a catalytic amount of 4-dimethylaminopyridine in pyridine (2 mL) was stirred for 2 h at room temperature under an argon atmosphere. After evaporation of the excess pyridine in vacuo, the residue was purified by column chromatography on silica gel (hexane : ethyl acetate=4 : 1, v/v) to afford the corresponding tosylate **16** (621 mg, 94%). IR (neat) 3550, 1365 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.06 (6H, s), 0.72 (9H, s), 0.91 (3H, d, J=6.0 Hz), 0.92—1.81 (5H, m), 1.00 (3H, s), 1.04 (3H, s), 3.20—3.80 (1H, m), 3.27 (3H, s), 3.98 (2H, d, J=5.4 Hz), 7.13—7.71 (4H, m). d) 6-*O*-(*t*-Butyldimethylsilyl)-2,3-dimethyl-2,6-heptanediol **17** and **18**. Under an argon atmosphere, an ether (1.83 mL) solution of lithium aluminum hydride (2.82 mmol) was added to an ether (20 mL) solution of **16** (621 mg, 1.41 mmol) at room temperature, and stirred for 30 min. The mixture was quenched with sat. aqueous Na_2SO_4 (0.8 mL) and the resulting precipitate was filtered off. The condensed filtrate was purifued by column chromatography on silica gel (hexane : ethyl acetate=4 : 1, v/v) to give **17** and **18** (268 mg, 69%). IR (neat) 3375 cm^{-1}. ^1H NMR (CCl_4) δ=0.02 (6H, s), 0.53—0.88 (3H, m), 0.75 (9H, s), 0.88—1.86 (5H, m), 0.95 (3H, d, J=6.0 Hz), 0.96 (6H, s), 3.28—3.80 (1H, m). ^{13}C NMR ($CDCl_3$) δ=0.81, 14.29, 17.90, 23.53 (**17**), 23.72 (**18**), 25.75 (**17**), 26.21 (**18**), 26.43 (**17**), 26.65 (**17**), 26.81 (**18**), 27.51 (**18**), 38.46, 44.33, 68.79, 73.07.

Transformation of 5a and 6a to 18 and 17. e) *t*-Butyl 5-(*t*-butyldimethylsilyloxy)-2-methylhexanoate (**19**). A 4 : 1 mixture of α-methylated ester **5a** and **6a** (total 299 mg, 1.48 mmol) and triethylamine (222 mg, 2.19 mmol), *t*-butyldimethylsilyl chloride (275 mg, 1.83 mmol), and a catalytic amount of 4-dimethylaminopyridine in DMF (6 mL) was stirred for 18 h at room temperature under an argon atmosphere. The reaction was quenched with ice, and the mixture was extracted with ether. The ether extracts were washed with water and brine and dried over Na_2SO_4. The ether solution was condensed and the residue was purified by column chromatography on silica gel (hexane : ethyl acetate=15 : 1, v/v) to give the silylated ester **19** (419 mg, 90%). IR (neat) 1725 cm^{-1}. ^1H NMR (CCl_4) δ=0.03 (6H, s), 0.87 (9H, s), 1.02 (3H, d, J=6.6 Hz), 1.05 (3H, d, J=6.0 Hz), 1.22—1.76 (4H, m), 1.40 (9H, s), 1.80—2.57 (1H, m), 3.43—4.00 (1H, m). f) 6-*O*-(*t*-Butyldimethylsilyl)-2,3-dimethyl-2,6-heptanediol **18** and **17**. To an ether (5 mL) solution of **19** (92 mg, 0.92 mmol) was added methyllithium (0.49 mL of a 1.29 M solution in ether) at 0 °C under an argon atmosphere, and stirred for 30 min at that temperature. To the mixture was added sat. aqueous NH_4Cl and the organic layer was extracted with CH_2Cl_2. The separated organic layer was dried over Na_2SO_4 and was condensed under reduced pressure. Purification by preparative TLC (hexane: ethyl acetate=5 : 1, v/v) to give **18** and **17** (total 71 mg, 89%).

7*b*-Phenyl-7*bH*-oxazirino[2,3-*b*][1,2]benzisothiazole 3,3-dioxide (**25**). A mixture of 3-phenyl-1,2-benzisothiazole 1,1-

dioxide[24] (1.00 g, 4.1 mmol) in $CHCl_3$ (16 mL) and $NaHCO_3$ (1.05 g, 13 mmol) in water (12 mL) was cooled to 0 °C and rapidly stirred and *m*-chloroperbonzoic acid (2.20 g, 13 mmol) in $CHCl_3$ (30 mL) was added dropwise.[14] After the addition was complete, the solution was stirred overnight and the $CHCl_3$ solution was washed with 10% Na_2SO_3 and 10% $NaHCO_3$. After the solution was dried over K_2CO_3 at 0 °C, the solvent was removed. The residue was dissolved in a small amount of ethyl acetate and precipitated by slow addition of pentane with stirring to give the oxaziridine **25** (0.95 g, 89%). Mp 123 °C. IR (KBr) 1325 cm^{-1}. ^1H NMR ($CDCl_3$) δ=7.42 (5H, s), 7.53—7.68 (4H, m). Found: C, 59.94; H, 3.38; N, 5.26; S, 12.14%. Calcd for $C_{13}H_9NO_3S$: C, 60.22; H, 3.50; N, 5.40; S, 12.37%.

Stereoselective Preparation of 1,4-Diols 20a. To a THF (5 mL) solution of LiOTf (303 mg, 1.94 mmol) was added a THF (4 mL) solution of diethylamine (134 mg, 1.83 mmol) under an argon atmosphere, and cooled to −78 °C. Butyllithium (1.16 mL of a 1.54 M solution in hexane) was added and the solution was stirred at that temperature for 15 min followed by the addition of a THF (1 mL) solution of HMPA (0.62 mL, 3.56 mmol) and then cooled to −100 °C. A THF (4 mL) solution of **1A** (112 mg, 0.59 mmol) was added to the mixture and stirred for 2 h at that temperature, and then a THF (5 mL) solution of the oxaziridine **25** (465 mg, 1.79 mmol) was added. After being stirred for 30 min at −100 °C, the reaction was quenched with sat. NH_4Cl and extracted with ether. The combined extracts were washed with water and brine, dried over Na_2SO_4, and condensed under reduced pressure. Purification by column chromatography on silica gel (hexane: ethyl acetate=4 : 1, v/v) to give *t*-butyl *syn*-2,5-dihydroxyhexanoate (**20a**) and the *anti*-isomer **21a** (total 101 mg, 83%) in a ratio 92 : 8, respectively. The *syn*-and *anti*-isomers **20a** and **21a** could not be separated, and in ^1H NMR (90 MHz) spectrum, two isomers were indistinguishable. IR (neat) 3380, 1725 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.18 (3H, d, J=6.0 Hz), 1.35—1.99 (4H, m), 1.47 (9H, s), 2.16—2.68 (2H, m), 3.62—4.03 (1H, m), 4.21—4.41 (1H, m). Analytical data for the corresponding diacetate; Found: C, 58.07; H, 8.36%. Calcd for $C_{14}H_{24}O_6$: C, 58.31; H, 8.39%.

Stereoselective preparation of **20b** was carried out by the same procedure. The resulting diols **20b** and **21b** were isolated as corresponding diacetates by the treatment with acetic anhydride, pyridine and a catalytic amount of 4-dimethylaminopyridine because the diols **20b** and **21b** were not separable from generated sulfonyl imine.

t-Butyl *syn*-2,5-diacetoxyhexanoate and *anti*-isomer: IR (neat) 1735 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.63—2.32 (13H, m), 1.47 (9H, s), 2.02 (3H, s), 2.09 (3H, s), 4.64—5.06 (2H, m). ^{13}C NMR ($CDCl_3$) δ=13.90, 20.53, 21.02, 22.56, 27.06, 27.52, 28.06, 29.63, 33.83, 72.51, 73.51 (*syn*), 73.70 (*anti*), 82.02, 169.02, 170.13, 170.48. Found: C, 61.65; H, 9.21%. Calcd for $C_{17}H_{30}O_6$: C, 61.79; H, 9.15%.

Conversion of 20a and 21a to 30 and 31. g) *t*-Butyl 2,5-bis(*t*-butyldimethylsilyloxy)hexanoate (**26**). A 3 : 1 mixture of dihydroxy esters **20a** and **21a** (total 291 mg, 1.42 mmol), triethylamine (446 mg, 4.41 mmol), *t*-butyldimethylsilyl chloride (572 mg, 3.80 mmol), and a catalytic amount of 4-dimethylaminopyridine in DMF (10 mL) was stirred for 2 d at room temperature under an argon atmosphere. The reaction was quenched with ice, and extracted with ether. The ethereal extracts were washed with water and brine, dried over Na_2SO_4, and condensed in vacuo. Purification by column chromatography on silica gel (hexane: ethyl acetate=15 : 1, v/v) afforded **26** (613 mg, 99%). IR (neat) 1745 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.01 (3H, s), 0.04 (6H, s), 0.07 (3H, s), 0.88 (9H, s), 0.89 (9H, s), 1.08 (3H, d, J=6.0 Hz), 1.26—1.96 (4H, m), 1.43 (9H, s), 3.48—4.14 (2H, m). h) 5-*t*-Butyldimethylsilyloxy-1,2-hexanediol (**27**). To a THF (10 mL) solution of **26** (613 mg, 1.42 mmol) was added lithium aluminum hydride (125 mg, 3.30 mmol) under an argon atmosphere, and stirred overnight. The mixture was quenched with sat. aqueous Na_2SO_4 (3 mL) and the resulting precipitate was filtered off. The condensed filtrate was purified by TLC on silica gel (ethyl acetate) to give the monosilylated **27** (274 mg, 78%). IR (neat) 3350 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.07 (6H, s), 0.88 (9H, s), 1.12 (3H, d, J=6.0 Hz), 1.27—1.60 (4H, m), 3.13—4.03 (4H, m), 3.37 (2H, br s). i,j) 5-*O*-(*t*-Butyldimethylsilyl)-2,6-hexanediol (**29**). A mixture of **27** (55 mg, 0.22 mmol) and *p*-toluenesulfonyl chloride (67 mg, 0.36 mmol) in pyridine (3 mL) was stirred at −10 °C for 6 h, then 0 °C overnight under an argon atmosphere. The reaction mixture was quenched with ice, extracted with CH_2Cl_2, dried over Na_2SO_4, and condensed under reduced pressure. Purification by preparative TLC on silica gel (hexane: ethyl acetate=3 : 1, v/v) gave **28** (51 mg). Then to a MeOH (3 mL) solution of **28** was added sodium methoxide (1.15 mL of a 0.12 M solution in MeOH) under an argon atmosphere, and was stirred at room temperature overnight. After the addition of sat. aqueous NH_4Cl the mixture was extracted with CH_2Cl_2, dried over Na_2SO_4, and condensed in vacuo to give a crude epoxide. Next, the crude epoxide was dissolved in THF (5 mL) and cooled to 0 °C. To the solution was added lithium aluminum hydride (0.25 mL of a 1.54 M solution in ether), and stirred at room temperature overnight. After the addition of sat. aqueous Na_2SO_4 (0.1 mL), the resulting precipitate was filtered off and the filtrate was condensed. Purification by preparative TLC on silica gel (hexane: ethyl acetate=4 : 1, v/v) furnished **29** (26 mg, 50% from **27**). IR (neat) 3350 cm^{-1}. ^1H NMR (CCl_4) δ=0.03 (6H, s), 0.87 (9H, s), 1.10 (3H, d, J=6.4 Hz), 1.28—1.65 (4H, m), 1.83—2.28 (1H, m), 3.35—3.98 (1H, m). k) *O*-Bis(*t*-butyldimethylsilyl)-2,5-hexanediol (**30** and **31**). **29** (25 mg, 0.11 mmol) was silylated as described above to give bis(silyl) ether **30** and **31** (35 mg, 93%). ^1H NMR ($CDCl_3$) δ=0.05 (12H, s), 0.88 (18H, s), 1.08 (6H, d, J=6.0 Hz), 1.16—1.52 (4H, m), 3.30—3.90 (2H, m). ^{13}C NMR ($CDCl_3$) δ=−4.65, −4.32, 18.23, 23.86, 25.98, 35.80 (**30**), 35.89 (**31**), 68.68 (**30**), 68.99 (**31**). The ^{13}C NMR spectrum of the major isomer **30** was agreed with that of the authentic sample derived from *dl*-2,5-hexanediol.[16]

The authors are grateful to Professor Teruaki Mukaiyama for valuable discussion during this work.

Racemic Structure and Optical Resolution by Preferential Crystallization of Organic Ammonium Salts of *N*-Formyl-DL-tyrosine

Tadashi SHIRAIWA,* Hideya MIYAZAKI, Atsushi URAMOTO, Michio SUNAMI, and Hidemoto KUROKAWA
Faculty of Engineering, Kansai University, Yamate-cho, Suita, Osaka 564
(Received October 23, 1986)

The Gibbs energy of formation of racemate, binary melting point diagram, and ternary solubility diagram indicated that dicyclohexylammonium salt of *N*-formyl-DL-tyrosine (DL-DCH salt) forms a racemic compound at melting point, but is a conglomerate at room temperature. The optical resolution of the DL-DCH salt was successfully performed by preferential crystallization. A successive preferential crystallization in methanol at 10 °C followed by purification gave D- and L-tyrosines with 100% optical purity.

L-Tyrosine (abbreviated as L-Tyr) as an important substance in vivo has been obtained by hydrolysis of proteins, because no industrially efficient synthesis has been established.[1] Optical resolution by preferential crystallization of DL-Tyr, therefore, has not been reported,[1,2] though DL-Tyr can be optically resolved by the diastereomeric procedure.[3,4] If DL-Tyr is synthesized in an industrial scale, the optical resolution is needed to obtain optically active tyrosines. It was attempted in this study to resolve organic ammonium salts of *N*-formyl-DL-tyrosine (DL-FrTyr) by preferential crystallization.

In the 16 ammonium salts, the salts showing respective melting points are pentylammonium (PTA), 1,1,3,3-tetramethylbutylammonium (TMB), dibutylammonium (DBA), dicyclohexylammonium (DCH), dibenzylammonium (DBZ), and 4-methylpiperidinium (4-MP) salts. The racemic structure of these DL-salts was determined by thermodynamic analysis.[5-7] As for other salts that decompose on heating, the racemic structure was examined by comparing infrared spectra of the DL-salt with those of the corresponding L-salt or ternary solubility diagram; these are propylammonium, isopropylammonium, butylammonium, isobutylammonium, *t*-butylammonium, cyclohexylammonium, benzylammonium, diisopropylammonium, diisobutylammonium, and *N*-methylcyclohexylammonium salts. The DL-DCH salt which seemed to be a conglomerate at room temperature was subjected to optical resolution by preferential crystallization.

Experimental

Materials. DL- and L-Tyrosine were purchased from Sigma Chemicals Co., and amines from Wako Pure Chemicals Ind. or Kanto Chemical Co., Ltd.

***N*-Formylation.** *N*-Formyl-DL- and -L-tyrosine were prepared by formylating each tyrosine similarly to the preparation of ordinary amino acids;[8] specific rotation of L-FrTyr $[\alpha]_D^{20}$ +84.4° (*c* 0.50, ethanol) (lit,[9] $[\alpha]_D$ +84.8° (ethanol)).

Preparation of Organic Ammonium Salts. A mixture of 0.01 mol of DL- or L-FrTyr and equimolar amine in 80 cm^3 of acetone was stirred for 30 min at room temperature. The formed salt was filtered and recrystallized from methanol.

L-DCH salt: Found C, 67.57; H, 8.76; N, 7.11% (calcd for $C_{22}H_{34}N_2O_4$: C, 67.66; H, 8.78; N, 7.17%); $[\alpha]_D^{20}$ +35.1° (*c* 0.50, water), $[\alpha]_D^{20}$ +43.1° (*c* 0.50, ethanol); solubility 3.660 g/(100 cm^3 methanol), 0.504 g/(100 cm^3 ethanol) at 10 °C. DL-DCH salt: Found C, 67.40; H, 8.78; N, 7.13%; solubility 7.181 g/(100 cm^3 methanol), 1.090 g/(100 cm^3 ethanol) at 10 °C.

D-DCH salt obtained from mother liquor in the optical resolution of DL-salt was recrystallized twice from ethanol to give D-salt with 100% optical purity; mp 232 °C; $[\alpha]_D^{20}$ −35.1° (*c* 0.50, water).

Optical Resolution. Preferential Crystallization: DL-DCH salt was dissolved in methanol or ethanol at 40 °C; 2.154 g in 25 cm^3 of methanol, 1.370 g in 100 cm^3 of ethanol. The solution was slowly cooled to 10 °C and seeded with L-salt; 0.050 g for methanol solution, 0.100 g for ethanol solution. After stirring the mixture at 10 °C, the precipitated salt was filtered, washed with a small amount of diethyl ether, and dried. The optical purity, yield of optically pure modification (YOPM), and degree of resolution of the salt were determined by the equations described in our previous paper.[10]

Successive Preferential Crystallization: DL-DCH salt (2.154 g) was dissolved in 25 cm^3 of methanol at 40 °C. After being cooled to 10 °C, the solution was seeded with 0.050 g of L-salt and stirred for 130 min. The precipitated salt was collected by filtration, and DL-DCH salt (0.122 g) was dissolved in the filtrate at 40 °C. After being seeded with 0.050 g of D-salt at 10 °C, the mixture was treated similarly. The degree of resolution of D- and L-DCH salts was calculated by

$$\text{Degree of resolution}/\% = [\text{YOPM}/\text{g} \times 100]/[(\text{Operation amount of D- or L-salt}/\text{g}) - 0.898].$$

Preparation of Optically Active Tyrosine. D- or L-DCH salt (4.00 g) with optical purity of about 93% was dissolved in ethanol at an elevated temperature. After concentrating the solution to 100 cm^3 under reduced pressure at 40 °C, the resulting solution was allowed to stand for 2 d at 5 °C. The precipitated salt was collected by filtration to give about 3.5 g each of optically pure D- and L-salts.

D- or L-DCH salt (3.90 g) was dissolved in a mixture of 10 cm^3 of 1 mol dm^{-3} aqueous sodium hydroxide and 100 cm^3 of water. After removing the liberated dicyclohexylamine by extracting with diethyl ether, 10 cm^3 of 1 mol dm^{-3} hydrochloric acid was added to the aqueous solution. The solution was dried under reduced pressure at 50 °C. After being added 20 cm^3 of methanol to the residue, the mixture was filtered. To the filtrate was added 10 cm^3 of 1 mol dm^{-3} hydrochloric acid. After refluxing the solution for 2 h, the pH was adjusted to 6 with concentrated aqueous ammonia. Precipitated Tyr was filtered, washed with a small amount of cold water and methanol, and dried to give about 1.70 g each of D- and L-Tyr's. D-Tyr: $[\alpha]_D^{20}$ +11.8° (*c* 4.00, 5 mol dm^{-3} HCl).

Table 1. Thermodynamic Data for Organic Ammonium Salts of *N*-Formyltyrosine

Salt	Mp/K		ΔH^{f}[a]/kJ mol^{-1}		ΔG^{F}_{mp}[b]
	DL-Salt	L-Salt	DL-Salt	L-Salt	kJ mol^{-1}
PTA[c]	405	411	35.2	29.0	−1.91
TMB[d]	429	440	36.9	38.0	−1.52
DBA[e]	412	425	34.1	32.8	−1.37
DCH[f]	501	505	39.1	51.7	−2.48
DBZ[g]	437	442	45.4	46.7	−1.99
4-MP[h]	430	443	35.2	31.2	−1.56

a) ΔH^{f}: Enthalpy of fusion. b) ΔG^{F}_{mp}: Gibbs energy of formation of racemate at melting point. c) PTA: Pentylammonium salt. d) TMB: 1,1,3,3-Tetramethylbutylammonium salt. e) DBA: Dibutylammonium salt. f) DCH: Dicyclohexylammonium salt. g) DBZ: Dibenzylammonium salt. h) 4-MP: 4-Methylpiperidinium salt.

L-Tyr: $[\alpha]_D^{20}$ −11.8° (*c* 4.00, 5 mol dm^{-3} HCl) (lit,[11] $[\alpha]_D^{20}$ −11.8° (5 mol dm^{-3} HCl)).

Measurements. The specific rotation was measured by a Union Giken PM-101 digital polarimeter with a quartz cell of 0.5 dm path length. Infrared spectra were obtained in the range 4000—400 cm^{-1} by a JASCO A-102 infrared spectrophotometer by the KBr disk method.

Saturated methanol or ethanol solutions of DL- and L-DCH salts were prepared at 10 °C and diluted in appropriate concentrations when used. The absorbance was measured at 279 nm with a Shimadzu double-beam spectrophotometer UV-150-02 with a quartz cell of 0.1 dm path length. The solubility of the salts was determined from calibration curves.

Results and Discussion

Racemic Structure. Racemic Structure at Melting Point: The Gibbs energy of formation of racemate in the solid state at *T* K (ΔG^{F}_{T}) is calculated by the following equation:[5]

$$\Delta G^{F}_{T} = -\Delta\Delta H^{f} + T\Delta\Delta S^{f} - RT\ln 2 + \Delta C_p(\Delta T^{f} - T\ln T^{f}_{R}/T^{f}_{A}) + (\Delta C^{s}/2T^{f})(T^{f} - T)^2, \quad (1)$$
