Reaction of Ethyl 2-Nitroalkanoates with Dipolarophiles; General Procedure: A mixture of ethyl 2-nitrobutanoate (**3**) (1.61 g, 10 mmol), 1-dodecene (1.68 g, 10 mmol), and tridecane (3.0 g) is heated to reflux over free flame for 6 h under nitrogen. After distillation of the unreacted substrates and the solvent from the reaction mixture by water aspirator, the residue was further distilled *in vacuo* to give analytically pure 5-decyl-3-ethyl-2-isoxazoline (**4a**) in 48% yield.

Synopsis. Reductive dimerization of allyl and benzyl halides has been performed by treatment with Pb/*n*-Bu_4NBr and catalytic $PbBr_2$/Al in *N*,*N*-dimethylformamide.

Reductive coupling of organic halides is of importance for making carbon–carbon linkage in organic synthesis. Various metals, e.g., Cu,[1] Te,[2] Mo,[3] Fe,[4,5] Zn,[6] V,[7] Sm,[8] Co,[9] and Ni,[10,11] have been utilized for the reductive dimerization of allyl and benzyl halides. The combination of metal halides, e.g., $TiCl_3$,[12] VCl_3,[13] $CrCl_3$,[14] and WCl_6,[15] with $LiAlH_4$ has also proved to be useful. However, many of these reagents require scrupulous attention and/or hazardous conditions to use. Meanwhile, lead is still untouched for this purpose, presumably due to the lack of suitable reaction media for the generation of organolead reagents.[16] Recently, we have reported an effective lead-promoted "Barbier-type" reaction, wherein the combination of lead with tetrabutylammonium bromide (*n*-Bu_4NBr) in *N*,*N*-dimethylformamide (DMF) is quite effective for the generation of the intermediary active lead species for the allylation of carbonyl compounds.[17] Furthermore, we have found a new lead(0)-recycling system for the allylation of carbonyl compounds, which has been successfully performed with a combination of catalytic $PbBr_2$ and Al.[18]

In the lead-promoted allylation of carbonyl compounds, especially less reactive carbonyl compounds, an excess amount of allyl bromide was required to complete the reaction.[17] Notably, when allyl bromide was treated with lead in DMF prior to treatment with carbonyl compounds, any appreciable amount of the allylation products was not obtained. These facts suggest that the reductive dimerization of allyl bromide takes place competitively and, in turn, enable us to investigate allyl–allyl coupling in the Pb/*n*-Bu_4NBr–DMF and $PbBr_2$/Al–DMF systems. Herewith, we describe that both the unique combinations of Pb/*n*-Bu_4NBr and $PbBr_2$/Al are effective for the reductive dimerization of a variety of allyl and benzyl halides at ambient temperature.

Reductive Dimerization in a Pb/*n*-Bu_4NBr System (Method A). The reductive dimerization of a variety of allyl and benzyl halides in a Pb/Bu_4NBr system took place to give the corresponding coupling products (Table 1). Thus, into a stirred mixture of cinnamyl bromide (**1a**, X=Br), *n*-Bu_4NBr, and trimethylsilyl chloride (Me_3SiCl) in DMF was immersed a Pb plate. The reaction was continued at ambient temperature until most of **1a** was consumed (Entry 1). After taking out the Pb plate (loosing ca. 0.5 equiv. Pb), usual workup of the mixture afforded the corresponding dimers **2a** (73%). The addition of Me_3SiCl was indispensable for initiation of the reaction. However, when the Pb plate was treated with aqueous 5% HCl and air-dried immediately before use, the reaction took place similarly without addition of Me_3SiCl (yield; 72%), suggesting that the addition of Me_3SiCl and/or HCl liberated in situ would effect the activation of Pb plate surface. The effect of *n*-Bu_4NBr was remarkable; in the absence of *n*-Bu_4NBr, the reductive dimerization of allyl halides scarcely occurred except for **1a** (X=Br) (Entries 1 and 4 in Table 1). When *n*-Bu_4NBr was replaced with other salts, the yield of coupling products of cinnamyl chloride (**1a**, X=Cl) decreased in the order: *n*-Bu_4NBr(63%)>NaBr(50%)>$C_6H_5CH_2N(CH_3)_3Br$(none). Although the role of *n*-Bu_4NBr in the reductive dimerization is still unclear, it is likely that *n*-Bu_4NBr effects the generation of an active organolead reagent, e.g., *n*-Bu_4NPb·[19] and (*n*-Bu_4N)($PbBr_2$($CH_2CH{=}CH_2$)).[20] The effect of solvent is also remarkable since the yield of coupling products of **1a** (X=Br) varies significantly

14	3	B_1	24	4	37
15	Ph_2CHBr 5	B_1	30	$Ph_2CHCHPh_2$ 6	67

a) Carried out at ambient temperature. b) A: With Pb/*n*-Bu_4NBr/Me_3SiCl in DMF; B_1: With $PbBr_2$/Al in DMF; B_2: with $PbBr_2$/Al in THF; B_3: with $PbBr_2$/Al in THF-H_2O (1:1). c) Unless otherwise noted, the reaction was continued until most of halides (1 mmol) were consumed. d) Isolated yields; numbers in parentheses showing the yields of coupling products obtained in the absence of *n*-Bu_4NBr. e) **2aαα/2aαγ/2aγγ** ratio of ca. 2:2:1 (^1H NMR and/or GLPC). f) Carried out at 60—65 °C. g) **2bαα/2bαγ/2bγγ** ratio of 77:20:3 (^1H NMR and/or GLPC). h) meso/dl ratio of 1:1 (GLPC).

depending on the choice of the solvent: DMF(73%)> MeCN(27%)>CH_2Cl_2(trace)>THF(none), MeOH(none).

The coupling products **2a** and **2b** were mixtures of three regio-isomers (**2aαα/2aαγ/2aγγ** ratio: ca. 2/2/1 (Entries 1—7); **2bαα/2bαγ/2bγγ** ratio: ca. 77/20/3 (Entry 8)).[21)] The product **2c** was a mixture of the corresponding meso and dl isomers in a ratio of 1:1 (Entry 9). The yield of the reductive dimerization of benzyl bromide (**3**) was not satisfactory (yield, 9%), but was improved to some extent (up to 50% yield) when the reaction was carried out at higher temperature (60—65 °C, Entry 13).

Reductive Dimerization in a $PbBr_2$/Al System (Method B). Furthermore, we found that the reductive dimerization of allyl and benzyl halides was successfully performed with the combination of $PbBr_2$ (7 mol%) and Al foils (1 equiv.) in DMF. The representative results are summarized in Table 1 (Method B_{1-3}). The reductive dimerization of **1a** (X=Br, Cl) in the $PbBr_2$/Al-DMF system took place smoothly (Entries 2 and 5). The satisfactory results were also obtained when the reaction was operated in THF (Entries 3 and 6) and THF-H_2O (1:1) (Entry 7). In a similar manner, the reaction of α-(bromomethyl)-acrylic esters **1d** (R=Me, Et), **3**, and bromodiphenylmethane (**5**) afforded the corresponding coupling products (Entries 11, 12, 14, and 15) respectively.

Although the details on the mechanism of the

$PbBr_2$/Al-promoted reductive dimerization have not been clarified yet, this system seems to involve the regeneration of Pb(0) by the reduction of $PbBr_2$ with Al (Scheme 2). The Pb(0) generated in this way would effect the reductive dimerization of the halides, since in the absence of $PbBr_2$ no appreciable coupling products were obtained. Further applications of the $PbBr_2$/Al system are in progress and will be reported in due course.

Experimental

IR spectra were taken on a JASCO IRA-1 grating spectrometer. ^1H NMR spectra were obtained on a Hitachi R-24 (60 MHz) and/or JEOL FX-100 (100 MHz), and ^{13}C NMR spectra on a JEOL FX-100 (25.05 MHz) spectrometer. Chemical shifts are expressed in parts per million downfield from Me_4Si used as internal standard. Analytical gas chromatography was carried out on a Yanaco GCG-550T using a column packed with Silicone SE-30 (10%) on Chamelite CK.

Materials. Cinnamyl halides (**1a**) (X=Br, Cl), 1-chloro-3-methyl-2-butene (**1b**), 3-bromocyclohexene (**1c**), benzyl bromide (**3**), and bromodiphenylmethane (**5**) were purchased from Tokyo Kasei Kogyo Co., LTD. and used as received. Methyl and ethyl α-(bromomethyl)acrylates (**1d**) (R=Me, Et) were prepared according to the method described in the literature.[22]

General Procedure of the Reductive Dimerization. A typical reaction procedure is as follows.

Method A: Into a stirred mixture of cinnamyl bromide (**1a**, X=Br) (1 mmol), *n*-Bu_4NBr (1 mmol), and Me_3SiCl (0.2 ml) in DMF (6 ml) was immersed a Pb plate (>99.9%; 1.5×2.0 cm^2, 0.5 mm thick) and the stirring was continued at ambient temperature until most of **1a** was consumed (14 h). After taking out the Pb plate (loosing ca. 0.5 mmol of Pb), the mixture was quenched with aqueous 5% HCl and extracted with AcOEt (6 ml×5). The extracts were washed with aqueous $NaHCO_3$ (6 ml) and brine (6 ml×4), dried (Na_2SO_4), and concentrated. The residue was chromatographed (SiO_2, hexane–AcOEt (3:1)) to give a mixture of the corresponding dimers **2a** (73%), whose GLPC analysis showed the presence of three regio-isomers **2a**$\alpha\alpha$, **2a**$\alpha\gamma$, and **2a**$\gamma\gamma$ in a ratio of 39:43:18. Identification of the products was performed by comparison of its IR, ^1H NMR, and/or ^{13}C NMR spectra with reported ones.[2]

Method B: Into a mixture of $PbBr_2$ powders (0.07 mmol) and finely cut Al foils (1 mmol) in DMF (5 ml) was added cinnamyl bromide (**1a**, X=Br) (1 mmol) and the mixture was stirred at ambient temperature until most of **1a** was consumed (24 h). The unreacted Al foils were separated and the reaction mixture was worked up in a similar manner to that described above. The corresponding dimers **2a** were obtained in 90% yield. GLPC analysis of the products showed the presence of three regio-isomers **2a**$\alpha\alpha$, **2a**$\alpha\gamma$, and **2a**$\gamma\gamma$ in a ratio of 40:41:19 (Method B_1). In a similar manner, the reductive dimerization of cinnamyl chloride (**1a**, X=Cl) (1 mmol) with $PbBr_2$ (0.07 mmol)/Al (1 mmol) in THF (Method B_2) and THF–H_2O (1:1) (Method B_3) afforded the dimers **2a** in 72 and 74% yields, respectively. GLPC analysis of these products showed the presence of three regio-isomers (the ratio of 41:40:19 and 35:43:22).

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 61225018 from the Ministry of Education, Science and Culture.

Useful Synthetic Routes to Pure *exo*-5-Vinyl-2-norbornene and *endo*-5-Vinyl-2-norbornene

Yoshiharu INOUE
Research Institute for Production Development,
15, Shimogamo Morimoto-cho, Sakyo-ku, Kyoto 606
(Received November 20, 1986)

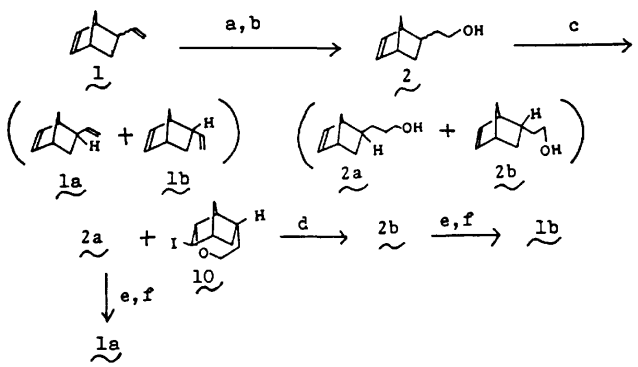
Synopsis. Hydroboration of 5-vinyl-2-norbornene (**1**) with 9-BBN mainly affords 5-(2-hydroxyethyl)-2-norbornene (**2**). The iodo ether cyclization of **2** can convert only *endo*-5-(2-hydroxyethyl)-2-norbornene (**2b**) to iodo ether **10**, followed by reductive elimination and subsequent dehydration to furnish *endo*-5-vinyl-2-norbornene (**1b**) which has not been isolated in pure form. Meanwhile, unreacted *exo*-5-(2-hydroxyethyl)-2-norbornene (**2a**) produces *exo*-5-vinyl-2-norbornene (**1a**) via dehydration.

5-Vinyl-2-norbornene (**1**), the principal product from the Diels–Alder reaction between cyclopentadiene and butadiene consists of *exo*-5-vinyl-2-norbornene (**1a**) and *endo*-5-vinyl-2-norbornene (**1b**).[1] Although a successful separation of these two isomers was accomplished by preparative gas chromatography,[1] the procedure encounters the difficulty in obtaining the isomers in pure form and in large quantities. As an alternative approach to the isolation of **1a**, of considerable utility is the thermal isomerization[2] in which **1b** was transformed into 4,7,3a,7a-tetrahydro-1*H*-indene whereas **1a** remained unchanged, allowing it to be isolated. It is difficult, however, to prevent the **1a** thus obtained from being contaminated by unreacted **1b**. Except these processes above mentioned, to the best of our knowledge no one appears to have reported on the stereoselective synthesis or isolation of **1a** and **1b**.

We now wish to report herein a convenient method for the isolation of **1a** and **1b** as well as the investigation of their chemical behavior.

Results and Discussion

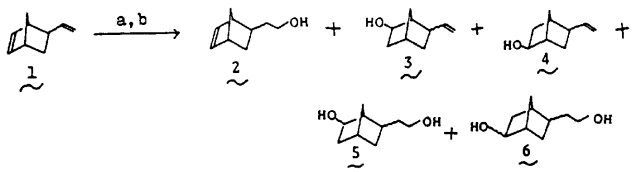
One of the most facile methods to separate **1a** and **1b** from **1**, the mixture of **1a** and **1b**, is outlined in Scheme 1.



Scheme 1.

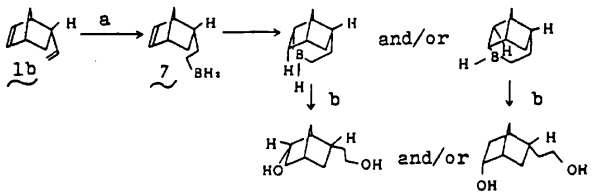
Reagents: a, 9-BBN, THF; b, H_2O_2, NaOH; c, I_2, KI, $NaHCO_3$, dioxane, H_2O; d, Zn, CH_3CO_2H; e TsCl, pyridine; f, pyridine, 100 °C.

Hydroboration of **1** with 9-borabicyclo[3.3.1]nonane (9-BBN), followed by oxidation with alkaline hydrogen peroxide, resulted in the formation of **2** in 70.7% yield, together with a 5.8% yield of a mixture of 6-vinyl-2-norbornanol (**3**) and 5-vinyl-2-norbornanol (**4**) and a 4.3% yield of a mixture of 6-(2-hydroxyethyl)-2-norbornanol (**5**) and 5-(2-hydroxyethyl)-2-norbornanol (**6**).



Reagents: a, 9-BBN, THF; b, H_2O_2, NaOH

Although this reaction could be achieved using B_2H_6 in THF, the selectivity of the hydroboration toward the vinyl group was decreased, resulting in the product ratio of **2**, the mixture of **3** and **4**, and the mixture of **5** and **6** being ca. 29:6:11. In this case, it was expected that the endo-isomer **7** of the initially formed [2-(5-norbornen-2-yl)ethyl]borane might undergo an intramolecular hydroboration[3] to give no *endo*-2-hydroxyethyl isomer **2b** as illustrated below, but in fact, evidence that this is not the case was presented by the experimental results on the formation of the iodo ether **10** from **2**, which will be described later.

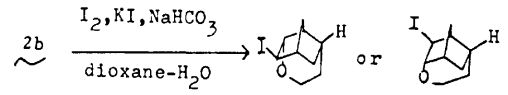


Reagents: a, B_2H_6, THF; b, H_2O_2, NaOH.

Further purification of **2** can be accomplished by utilizing the readily isolable intermediates, 2-(5-norbornen-2-yl)ethyl 3,5-dinitrobenzoate (**8**) and 2-(5-norbornen-2-yl)ethyl tetrahydro-2-pyranyl ether (**9**), which are, in turn, converted to **2**.

Turning here to Scheme 1, treatment of a solution of **2** in dioxane with iodine and KI in 0.5 M $NaHCO_3$ solution (1 M=1 mol dm^{-3}) led to the iodo ether cyclization of **2b** to form the iodo ether **10** in 42.1% yield, while **2a** remained unreacted. Separation of both products was readily achieved by a fractional distillation or recrystallization.

In considering possible modes of the iodo ether cyclization, examination of molecular models suggested that the seven-membered ring cyclization should be prohibited on steric grounds.[4]



favored

An attempt to follow the Kropp's procedure[5] where **2** was treated with I_2 and $N(C_2H_5)_3$ in methanol at a reflux temperature for 2 d failed to complete the iodo ether cyclization, providing 18% yield (based on **2b**) of **10** along with the unreacted starting material **2a** containing **2b**.

It was now ready to convert the iodo ether **10** to **2b** via a reductive elimination. Treatment of **10** with zinc in acetic acid furnished **2b** in 75.7% yield. Although the procedure for this reaction is similar to that applied to the reductive elimination of the iodo lactone[6] and the β-halo ether,[7] the observation that the β-halo ether compound in this system could be successfully effected by this treatment is noteworthy.

With these two stereoisomers **2a** and **2b** available, the dehydration step was now examined utilizing the conventional manners.[8] Both alcohols were converted individually to **1a** and **1b** in 26.8 and 28.3% yield, respectively, by treatment with tosyl chloride in pyridine, followed by elimination with pyridine at 100 °C. These two stereoisomers **1a** and **1b** thus obtained have a refractive index of n_D^{20} 1.4791 (lit,[2a] n_D^{20} 1.4794) and n_D^{20} 1.4806, respectively.

Experimental

Melting and boiling points are uncorrected. GC analysis was carried out on a Hitachi Model 163 gas chromatograph fitted with a FID detector, using a 5 mm×2 m stainless-steel column packed with 10% Silicone-30 on Chromosorb W. ^{1}H NMR spectra were recorded with a Hitachi Model R-24B, using $Si(CH_3)_4$ as an internal reference. IR spectra were obtained with a Hitachi Model 160-10 infrared spectrophotometer. Elemental analysis was performed by the Laboratory for Organic Elemental Microanalysis, Faculty of Pharmaceutical Science, Kyoto University.

Materials. 5-Vinyl-2-norbornene, obtained from Nippon Petrochemical Corp., was vacuum distilled before use. The 5-vinyl-2-norbornene employed, on the basis of ^{1}H NMR spectroscopy, consisted of *exo*- and *endo*-5-vinyl-2-norbornene in a ratio 2:3.[1]

5-(2-Hydroxyethyl)-2-norbornene (2). Method A. To a stirred solution of 5-vinyl-2-norbornene (**1**, 24.0 g, 0.200 mol) in dry THF (20 mL) at ambient temperature under a nitrogen stream was added dropwise 9-BBN (0.50 M THF solution, 400 mL) over about 1 h. The mixture was stirred at 25 °C for 2 h, and to this mixture was added dropwise water (5 mL), aq NaOH (3 M, 67 mL), then 30% aq H_2O_2 (67 mL). After being stirred at 40 °C for 2 h, the mixture was extracted three times with ether (150 mL). The ether layer was dried over $MgSO_4$ and concentrated in vacuo. The residue was distilled under reduced pressure to give a mixture of **3** and **4** (1.6 g, 5.8%) as the first fraction [64 °C/0.5 mmHg (1 mmHg=133.322 Pa) (lit,[9] 60—61 °C/0.35 mmHg)], **2** (19.5 g, 70.7%) as the second fraction (70 °C/0.5 mmHg), and then a mixture of **5** and **6** (1.3 g, 4.2%) as the third fraction (130—135 °C/1.5 mmHg). The spectroscopic data of the second and third fractions were as follows:

Alcohol **2**: IR (neat film) cm^{-1} 3350, 3080, 2930, 2870, 1640; ^{1}H NMR ($CDCl_3$) δ=6.20—5.80 (m, 2H), 3.60 (t, 2H), 2.80 (m, 2H), 2.40 (s, 1H), 2.60—1.10 (m, 7H). Found: C, 78.31; H, 10.19; O, 11.50%. Calcd for $C_9H_{14}O$: C, 78.26; H, 10.14; O, 11.60%.

A Mixture of **5** and **6**: IR (neat film) cm^{-1} 3345, 2935, 2870, 1100; ^{1}H NMR ($CDCl_3$) δ=4.75—4.50 (s, 1H), 4.35—3.75 (m, 1H), 3.60—3.20 (m, 1H), 2.45—0.80 (m, 13H). Found: C, 69.18; H, 10.35; O, 20.47%. Calcd for $C_9H_{16}O_2$: C, 69.23; H, 10.26; O, 20.51%.

Method B. To an ice-cooled, stirred solution of **1** (48.0 g, 0.400 mol) in dry THF (250 mL) was added $NaBH_4$ (4.2 g, 0.110 mol) and then added dropwise $BF_3 \cdot O(C_2H_5)_2$ (18.1 mL, 20.8 g, 0.147 mol). After being stirred at room temperature for 3 h, the reaction was quenched by adding water (32.5 mL), and then to the mixture was added aq NaOH (3 M, 44.0 mL) and 30% aq H_2O_2 (44.0 mL). After being allowed to stir at 40 °C for an additional 3 h, the reaction mixture was cooled to room temperature and then extracted three times with ether (200 mL). The organic extracts were washed with water and dried over $MgSO_4$. After removal of the solvent, the residue was distilled under reduced pressure to give a mixture of **3** and **4** (3.2 g, 5.8%), **2** (15.9 g, 28.8%), and a mixture of **5** and **6** (6.8 g, 10.9%).

Purification of 2. Via 3,5-Dinitrobenzoate 8. To an ice-cooled solution of **2** (5.0 g, 0.036 mol) in pyridine (20 mL) was added 3,5-dinitrobenzoyl chloride (7.5 g, 0.033 mol) with stirring. The reaction mixture was heated over a steam bath for 5 min and poured, with vigorous stirring, into water (50 mL). The precipitate was collected, washed with 5% aq Na_2CO_3 (25 mL), and recrystallized from a mixture of ethanol and water to give **8** (8.6 g, 78.5%): mp 68—69 °C; IR (nujol) cm^{-1} 3090, 2930, 2875, 1720, 1665, 1200; ^{1}H NMR ($CDCl_3$) δ=9.20 (s, 3H), 6.35—5.90 (m, 2H), 4.70—4.35 (t, 2H), 2.85 (broad s, 2H), 2.45—1.25 (m, 7H). Found: C, 57.92; H, 4.82; N, 8.32; O, 28.94%. Calcd for $C_{16}H_{16}O_6N_2$: C, 57.83; H, 4.85; N, 8.43; O, 28.89%.

The ester **8** (5.0 g, 0.015 mol) was added to a mixture of methanol (10 mL) and 20% aq NaOH (3.5 mL), and the mixture was refluxed for 1 h. After removal of methanol, the residue was extracted with ether–benzene (100 mL). The extract was washed with water, dried over $MgSO_4$, and concentrated in vacuo, and subsequent distillation afforded **2** (1.8 g, 87.0%) whose purity was determined to be more than 99.9% by GC analysis.

Via Tetrahydro-2-pyranyl Ether 9. A solution of **2** (10.0 g, 0.072 mol), 3,4-dihydro-2*H*-pyran (4.8 g, 0.057 mol), and *p*-toluenesulfonic acid (0.5 g) in ether (100 mL) was stirred at room temperature for 3 h and treated with 10% aq Na_2CO_3 (10 mL). The ethereal layer was washed with water, dried over $MgSO_4$, and concentrated in vacuo. The residue was distilled (102—104 °C/2.0 mmHg) to yield **9** (8.5 g, 67.2%): IR (neat film) cm^{-1} 3050, 2930, 2870, 1660; ^{1}H NMR (CCl_4) δ=6.25—5.80 (m, 2H), 3.95—3.85 (t, 1H), 3.60—3.45 (m, 4H), 2.60—1.10 (m, 15H). Found: C, 75.48; H, 9.88; O, 14.64%. Calcd for $C_{14}H_{22}O_2$: C, 75.63; H, 9.97; O, 14.40%.

A solution of the ether **9** (6.0 g, 0.027 mol), methanol (10 mL), and 2% aq HCl (3 mL) was refluxed for 3 h, and then this solution was treated with 5% aq $NaHCO_3$ (10 mL). After removal of methanol, the residual oil was extracted three times with ether–benzene (50 mL). The extracts were washed with water, dried over $MgSO_4$, and concentrated in vacuo. Distillation yielded **2** of more than 99.5% purity (2.8 g, 75.1%).

***exo*-7-Iodooctahydro-4,6-methanocyclopenta[*b*]pyran (10).** To a solution of **2** (16.2 g, 0.117 mol) in dioxane (30 mL), with stirring at room temperature, was added aq $NaHCO_3$ (0.5 M, 720 mL) and an aqueous solution (360 mL) of iodine (70.0 g, 0.276 mol) and potassium iodide (120.0 g, 0.723 mol). After being stirred at room temperature for 1 h, the mixture was extracted three times with ether–benzene (200 mL). The extracts were washed with sat. aq Na_2SO_3, water, and dried over $MgSO_4$. After removal of the solvent, the residue was distilled under reduced pressure to yield **2a** (4.4 g, 27.3%) as the first fraction (66 °C/0.2 mmHg) and then **10** (13.0 g, 42.1%) as the second fraction (100—103 °C/1.0 mmHg). The ester formed on treatment of **2a** with 3,5-dinitrobenzoyl chloride in pyridine had the mp of 72—74 °C.

The physical properties of **10** were as follows: IR (neat film) cm^{-1} 2925, 2870, 1470; ^1H NMR (CCl_4) δ=4.75—4.60 (broad s, 1H), 4.15—4.05 (t, 1H), 3.70—3.40 (m, 2H), 2.60—1.20 (m, 9H). Found: C, 41.06; H, 4.98%. Calcd for $C_9H_{13}OI$: C, 40.91; H, 4.92%.

Reaction of 2 with Iodine and Triethylamine in Methanol. A solution of **2** (10.0 g, 0.072 mol), iodine (17.9 g, 0.070 mol), and triethylamine (9.9 g, 0.098 mol) in methanol (55 mL) was refluxed for 2 d. After removal of the solvent, the reaction mixture was treated with water (35 mL), extracted twice with ether (50 mL). The extracts were washed with sat. aq Na_2SO_3, water, dried over $MgSO_4$, and concentrated in vacuo. Distillation gave **10** (2.3 g, 12.1%) and recovered **2** (6.0 g).

***endo*-5-(2-Hydroxyethyl)-2-norbornene (2b).** To an ice-cooled solution of **10** (12.0 g, 0.045 mol) in acetic acid (60 mL) was added slowly, with stirring, zinc dust (11.8 g, 0.183 mol), keeping the reaction temperature below 30 °C. Following the addition, the mixture was stirred at room temperature for 5 h, and then filtered. The resulting precipitate was washed with a 1:2 mixture of acetic acid and water (50 mL). The combined filtrates were concentrated in vacuo to remove the acetic acid. The residue was extracted with ether–benzene (200 mL), and then the extract was washed with water, dried over $MgSO_4$, and concentrated in vacuo. The residual oil was distilled (62 °C/0.6 mmHg) to furnish **2b** (4.7 g, 75.7%). The ester formed on treatment of **2b** with 3,5-dinitrobenzoyl chloride in pyridine had the mp of 77 °C.

***exo*-5-Vinyl-2-norbornene (1a) and *endo*-5-Vinyl-2-norbornene (1b).** To an ice-cooled, stirred solution of **2a** (15.0 g, 0.109 mol) in pyridine (80 mL) was added in several portions of *p*-toluenesulfonyl chloride (22.8 g, 0.120 mol). After being stirred at room temperature overnight, the mixture was treated with water (5 mL), and the pyridine was evaporated in vacuo. The residue was treated with water (50 mL) and extracted with ether–benzene (200 mL). The organic extract was washed with water, dried over $MgSO_4$, and concentrated under reduced pressure to give 2-(5-norbornen-*exo*-2-yl)ethyl *p*-toluenesulfonate (15.5 g, 48.7%) as an oil which was used in the next step without further purification: IR (neat film) cm^{-1} 3090, 2925, 2875, 1660, 1640, 1180; ^1H NMR ($CDCl_3$) δ=7.80—7.50 (m, 4H), 6.30—5.95 (m, 2H), 4.10—3.90 (t, 2H), 2.80 (broad s, 2H), 2.60 (s, 3H), 2.35—1.35 (m, 7H).

A solution of the above oil (15.5 g, 0.053 mol) in pyridine (50 mL) was refluxed for 12 h. Upon cooling to room temperature the mixture was poured into ice-water (50 mL) and extracted three times with pentane (100 mL), and the combined organic extracts were washed with water, dried over $MgSO_4$, and concentrated in vacuo. The residue was distilled [55—62 °C/25 mmHg (lit,[2a] 66.5 °C/66 mmHg)] to furnish **1a** (3.5 g, 55.0%): ^1H NMR (CCl_4) δ=6.05—6.00 (m, 2H), 5.95—5.70 (m, 1H), 5.30—4.85 (m, 2H), 2.85 (broad s, 1H), 2.70 (broad s, 1H), 2.25—1.95 (m, 2H), 1.45—1.35 (m, 3H); n_D^{20} 1.4791.

In place of **2a**, **2b** was treated in the identical manner described above to produce 2-(5-norbornen-*endo*-2-yl)ethyl *p*-toluenesulfonate (17.5 g, 55.0%) and **1b** (3.7 g, 51.4%), respectively. The physical properties of **1b** were as follows: bp 51—55 °C/20 mmHg; ^1H NMR (CCl_4) δ=6.05—5.95 (m, 2H), 5.80—5.40 (m, 1H), 5.10—4.70 (m, 2H), 2.95—2.65 (m, 3H), 2.10—1.80 (m, 1H), 1.50—1.30 (m, 2H), 1.00—0.80 (m, 1H); n_D^{20} 1.4806.

The author expresses his sincere thanks to Professor Teijiro Yonezawa of Kyoto University for helpful discussions. Special appreciation is due Nippon Petrochemical Corp. for parts of the synthetic work.

(Received September 27, 1986)

Synopsis. In syngas ($CO+H_2$) conversion to ethylene glycol (EG), rhodium catalyst modified by tributylphosphine (P^nBu_3) was found to be ca. 20 times more active under 1000 atm at 210 °C than under 500 atm. This unusual pressure effect was discussed on the basis of IR spectral data.

A pressure effect has been observed in syngas conversion to ethylene glycol (EG), where *N*-methylpyrrolidone (NMP) solution of rhodium compound was used as catalyst system.[1] Also, rhodium systems modified by phosphine have been found to be more effective than Rh alone under the syngas pressure below 500 atm.[2] We have reported the effectiveness of the addition of some phosphines for the glycol synthesis using Co–Ru mixed system in toluene or dioxane solvent under 1000 atm.[3] These findings led us to examine briefly the behavior of Rh–phosphine–NMP catalyst system under 1000 atm, in comparison with that under 500 atm.

Results and Discussion

NMP was employed as solvent, since it is one of the solvents suitable for Rh-catalyzed syngas conversion.[1] The reaction was carried out at 210 °C. The equimolar addition of some phosphines raised the catalytic activity. The effectiveness of phosphines when employed under the conditions of 1000 atm was in the order. $PCy_3(15.5)>P^iPr_3(14.6)>Cy_2PCH_2CH_2PCy_2(8.8)$[4]$>P^nBu_3(8.2)>$none$(5.8)>OPPh_3(4.4)>Me_2OPCH_2CH_2POMe_2(3.9)>P^nBu_3(2.7)>P^tBu_3(2.1)>P^sBu_3(1.8)>PPh_3(0)=P(OPh)_3(0)=P(O^nBu)_3(0)=P(O^iPr)_3(0)=PPh_2Me(0)=Ph_2PCH_2CH_2PPh_2(0)$. (Numerical values refer to turnover frequencies of ethylene glycol (N_{EG} (mol (Rh mol)$^{-1}$ h^{-1}). Here Cy denotes cyclohexyl, Pr propyl, Bu butyl, Ph phenyl, and Me methyl; the superscripts *i*, *n*, and *t* are for iso-, normal, tertiary, respectively.)

The effect of P/Rh ratio on the activity is illustrated

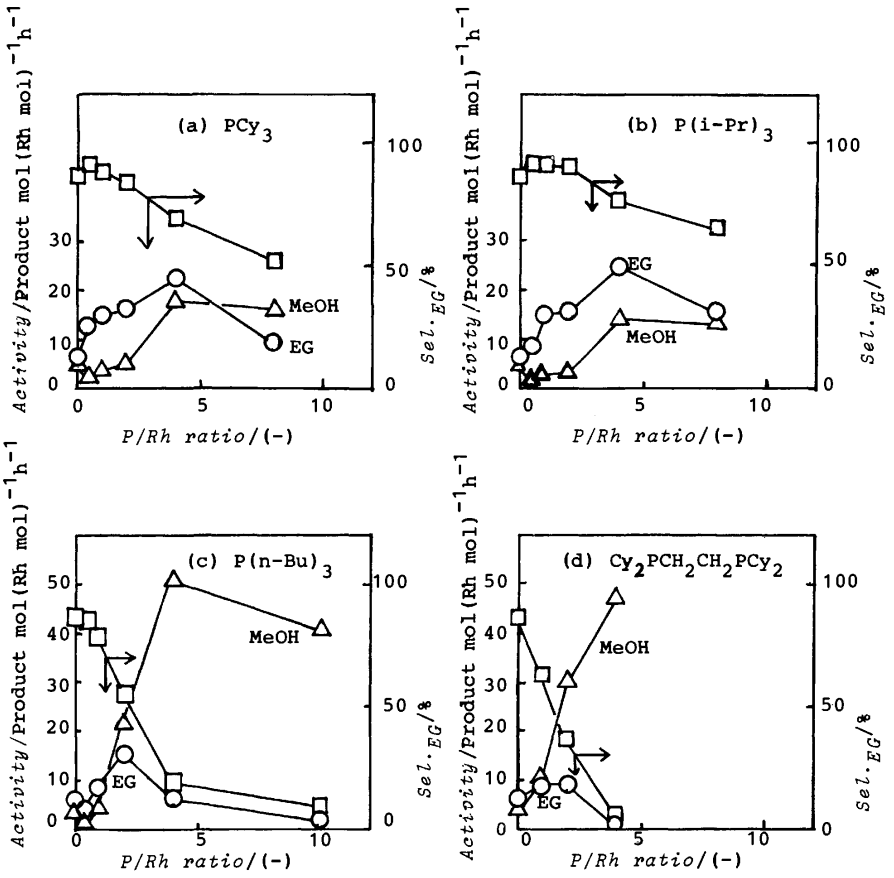

Fig. 1. Effect of P/Rh atomic ratio on catalytic activity and selectivity($Sel._{EG}$). Conditions: $Rh_4(CO)_{12}$ 0.05 mmol, NMP 20 ml, 210 °C, 3 h, 1000 atm(CO/H_2=1).

in Fig. 1. In the cases of PCy_3 and P^iPr_3, the maximum activity was achieved at P/Rh ratio of 4,[2b] whereas, in the cases of P^nBu_3[2b] and $Cy_2PCH_2CH_2PCy_2$, the optimum ratio was found to be 2. However, the methanol formation was remarkably accelerated by these catalyst systems including P^nBu_3 or $Cy_2PCH_2CH_2PCy_2$ at the P/Rh ratio above 2 and, consequently, the selectivity to the glycol decreased (Fig. 1c, d).

The activity depends on the total pressure (Fig. 2). The rate of glycol formation for the catalyst systems containing PCy_3 or P^iPr_3 under 1000 atm was 3—4 times higher than that under 500 atm. These trends were similar to that of Rh alone (▽). However, the rate for Rh-P^nBu_3 system under 1000 atm was ca. 20 times higher than that under 500 atm (Fig. 2, ○).

In order to explain this unusual improvement of the activity in Rh-P^nBu_3 system, IR spectra of catalyst solution were measured at ambient temperature under 20 atm (CO/H_2=1). The catalyst solution pretreated at 210 °C under 1000 atm exhibited IR absorption at 1952 cm^{-1}, characteristic of a dimeric rhodium such as $[Rh(CO)_3(P^nBu_3)]_2$, **A**,[2b,5] and at 1895 cm^{-1}, assigned to $[Rh(CO)_4]^-$, **B**,[2b,6] with weak shoulder bands near 2000 cm^{-1}. These spectral patterns were analogous to those[7] of Rh-PCy_3 system after the reaction under 500 atm as well as under 1000 atm. On the other hand, the solution of Rh-P^nBu_3, pretreated under 500 atm, showed weak IR absorptions of both **A** and **B** and additional broad bands at 2050—1940 cm^{-1} with 1849 cm^{-1} band, characteristic of rhodium clusters.[8] Thus, in the case of Rh-P^nBu_3 under 1000 atm conditions, two rhodium species, **A** and **B**, which seem to be responsible for the catalysis,[1b,2b] are predominantly formed at a P/Rh ratio of 2,[9] whereas cluster species, the activity of which are low,[8a] predominates under 500 atm (Scheme 1).[2,8] In conclusion, the unusual pressure effect is considered to be due to the increase in the concentration of more active Rh species than clusters: This result supports the possibility of non-cluster Rh complex as active species, as suggested previously.[1b,2]

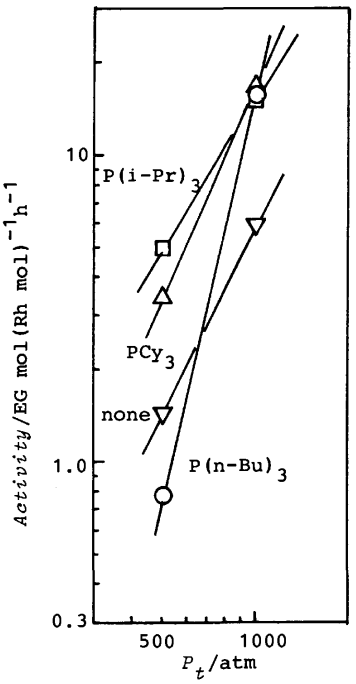

Fig. 2. Effect of total pressue. Conditions: $Rh_4(CO)_{12}$ 0.05 mmol, NMP 20 ml, phosphine 0.4 mmol, 210° C, 3 h.

Experimental

Materials. NMP and phosphines were obtained commercially and used with no further purification. $Rh_4(CO)_{12}$ was purchased from Nippon Engelhard Co.

Reaction Procedure. A catalyst solution containing $Rh_4(CO)_{12}$ (0.05 mmol) and phosphine in NMP solvent (20 ml) was placed in a Hastelloy C-autoclave (100 ml), which was subsequently charged with syngas (CO/H_2=1, 650 atm at room temp). After the reaction at 210 °C for 3 h under 1000 atm, the reaction vessel was cooled to room temperature and the solution was analyzed by GLC. The high pressure IR spectra were recorded on a JEOL A302-type spectrometer.

Product selectivity is defined by

$$\text{Sel.}_{EG} = \frac{2EG \times 100}{MeOH + MF + 2(EG + EtOH)}$$

This work is a part of "C_1 Chemistry Project," a National Research and Development Program of Agency of Industrial Science and Technology, Ministry of International Trade and Industry (M.I.T.I.), Japan.

Studies on the Lattice Dynamics in Ferrocene Derivatives by Means of Recoil-Free Fraction and Thermal Shift in Mössbauer Spectra

Kumiko IWAI,* Motomi KATADA, Izumi MOTOYAMA,† and Hirotoshi SANO
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo 158
(Received October 4, 1986)

Lattice dynamics in ferrocene derivatives, mono- and disubstituted acetyl-, carboxy-, and ethylferrocenes, tetrachloro(1,1′-diacetylferrocenato-*O*,*O*′)tin(IV) and tetrachlorobis(acetylferrocenato-*O*)tin(IV) have been studied by determining the temperature dependence of the recoil-free fraction and the thermal shift in the Mössbauer spectra. It was found that the lattice vibrations in acetyl- and carboxyferrocenes and adducts could be satisfactorily explained by assuming a harmonic oscillation model, while those of ethyl-substituted ferrocenes could not be interpreted by assuming harmonic vibrations.

Ferrocene derivatives are of great interest to the authors, since they exhibit various kinds of mesophase transitions associated with intermolecular interactions.[1-4] In order to investigate the effect of substituent groups on the lattice dynamics, such ferrocene derivatives as mono- and disubstituted acetyl-, carboxy-, and ethyl-ferrocene have been synthesized and the lattice dynamical nature of these compounds investigated in the solid state by comparing their Mössbauer spectra with the crystal structures and thermal data.

Lattice dynamics in more complicated systems, tetrachloro(1,1′-diacetylferrocenato-*O*,*O*′)tin(IV) and tetrachlorobis(acetylferrocenato-*O*)tin(IV), were also studied by Mössbauer spectroscopy. The temperature dependence of the recoil-free fraction and the thermal shift were determined for each of two the Mössbauer nuclides, ^{57}Fe and ^{119}Sn, included in the adducts, in order to investigate the total vibration of molecules.

Experimental

Preparation of Mono- and Disubstituted Ferrocenes. Mono- and disubstituted ferrocenes were prepared by following the method described in Ref. 5. The purification was carried out by repeated sublimations and recrystallizations. The purities were confirmed by checking the melting point and by elemental analyses. No impurity was detected in infrared(IR), NMR, and Mössbauer spectra.

Preparation of Adducts. Tetrachloro(1,1′-diacetylferrocenato-*O*,*O*′)tin(IV) and tetrachlorobis(acetylferrocenato-*O*)tin(IV) were prepared by modifying the method described in Ref. 6. Since the adducts are very sensitive to air, the samples for IR and Mössbauer measurements were mounted under nitrogen in a glove box. The IR spectra agreed with those of the literature.[6] However, the data of elemental analyses are not in good agreement with the calculated values, since the partial decomposition of adducts seems to occur upon exposure to air.

Mössbauer Spectra. Mössbauer spectra were measured using an Austin Science Associate Mössbauer spectrometer. A velocity calibration was carried out based on the spectra of metallic iron at room temperature. By fitting the resonance line-shape to a Lorentzian function, the Mössbauer parameters could be extracted. Low-temperature measurements were carried out by using a CA thermocouple embedded in a copper sample holder in a cryostat. The precision of this measurement was approximately ±1°.

Structure Determination and Refinement for Ferrocenecarboxylic Acid. A yellow-needle single crystal suitable for an X-ray study was obtained by slowly evaporating a methanol solution. The crystal size employed for data collection was approximately 0.05 m×0.15 mm×0.35 mm. Intensity data were collected on a four-circle diffractometer using an ω-2θ scan technique. A total of 2356 reflections were measured with Mo$K\alpha$ radiation ($2\theta<55°$); of these, 1252 were considered to have a significant intensity ($|F_o|>3\sigma|F_o|$). The intensities of the four standard reflections remained almost constant during data collection.

Crystal data for ferrocenecarboxylic acid are tabulated in Table 1. The positions of carbon and iron atoms were deduced from sharpened Patterson maps and all of the hydrogen atoms were deduced from difference syntheses. The block-least-squares program HBLS-4[7] was employed using anisotropic thermal parameters for non-hydrogen atoms and isotropic thermal parameters for hydrogen atoms. The atomic scattering factors were taken from the International Tables for X-ray Crystallograpy (1974).[8] Unit weights were adopted for all reflections. The R value reduced to 0.040 and final atomic parameters are given in Table 2. The complete F_o-F_c data have been deposited as Document No. 8736 at the

Results and Discussion

First, suitable model compounds having similar molecular weights and volumes but different intermolecular interactions caused by the substituent groups (mono- and disubstituted acetyl-, carboxy-, and ethylferrocenes) were synthesized and the temperature dependence of Mössbauer spectra was measured in order to elucidate the relationship between the recoil-free fraction or the thermal shift and the lattice vibration in these ferrocene derivatives.

The recoil-free fraction, f, can be estimated from the areal intensity of Mössbauer spectrum and is expressed by the mean-square amplitude of a Mössbauer atom, $<U^2>$:

$$f = \exp[-4\pi^2<U^2>/\lambda_\gamma^2] \quad (1)$$

where λ_γ is the wavelength of a Mössbauer γ-ray. It is difficult to obtain an absolute recoil-free fraction by using the areal intensity method, because of the absence of a suitable standard sample. Therefore, the mean-square amplitude was estimated by a high-temperature-approximation method.[2] At a temperature sufficiently high to assume $T \gg \Theta_D/2$ (where Θ_D is the Debye characteristic temperature), it is known that the mean-square amplitude is proportional to the absolute temperature. The values of the mean-square amplitude are estimated from the slope of the linear relationship.

Figure 1 shows the temperature dependence of the mean-square amplitude estimated from the areal intensities of the Mössbauer spectra for iron atoms in acetyl- and carboxyferrocenes. The mean-square amplitude is considered to be proportional to the absolute temperature nearly up to room temperature, indicating that the molecules are in harmonic vibration. The values of the mean-square amplitude at room temperature determined by applying the high-temperature approximation from 78 K to room temperature are 2.6×10^{-2}, 2.8×10^{-2}, 3.0×10^{-2}, and 4.5×10^{-2} Å^2 for ferrocenecarboxylic acid, 1,1′-diacetylferrocene, acetylferrocene, and 1,1′-ferrocenedicarboxylic acid, respectively, while those determined based on the isotropic thermal factors in X-ray diffraction study are 3.1×10^{-2}, 2.8×10^{-2},[10] 3.2×10^{-2},[3] and 4.0×10^{-2} Å^2,[11] respectively. Both values for the same compound are in fairly good agreement with each other. The value of the mean-square amplitude of ferrocenecarboxylic acid is slightly less than those of acetylferrocenes, while the value of 1,1′-ferrocenedicarboxylic acid was estimated to be about 1.5-times larger than those of other compounds.

Figure 2 shows the crystal structure of ferrocenecarboxylic acid determined by X-ray diffraction. The C-C distances in the cyclopentadienyl rings are 1.289—1.426 Å; the Fe-C distances are 2.019—2.045 Å. These results are in good agreement with acetylferrocene[3] and 1,1′-diacetylferrocene,[10] as well as molecules that exhibit an eclipsed conformation. The C(11), O(1), and O(2) atoms lie approximately on the plane of the aromatic rings, because of a existence of a

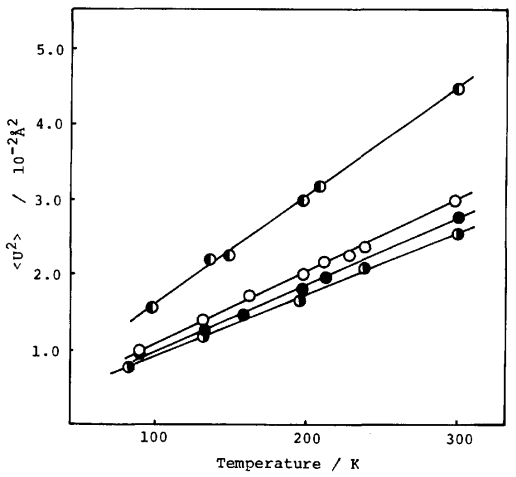

Fig. 1. The temperature dependence of mean-square amplitude for acetylferrocene (○), 1,1′-diacetylferrocene (●), ferrocenecarboxylic acid (◑), and 1,1′-ferrocenedicarboxylic acid (◐).

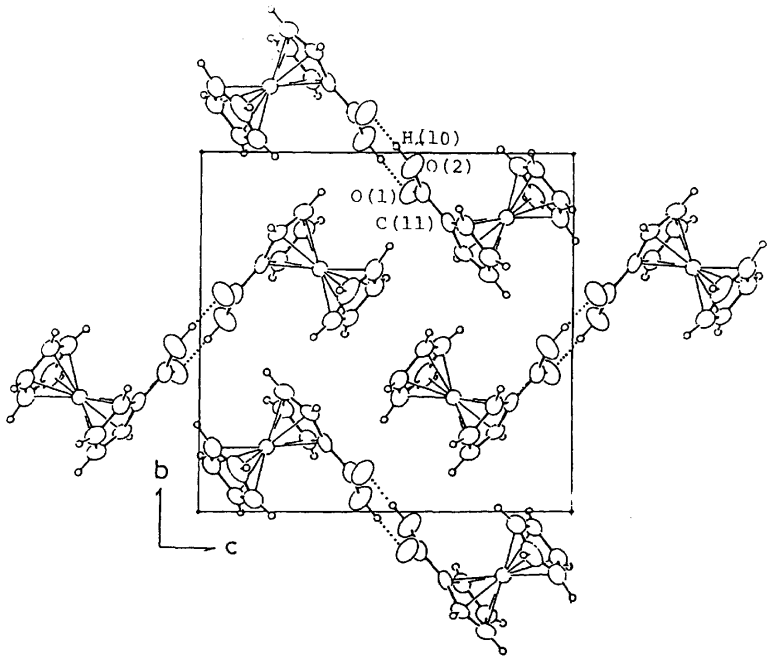

Fig. 2. Projection of the crystal structure of ferrocenecarboxylic acid along the a axis at room temperature. The hydrogen bonding O(1)···H(10) is indicated by broken lines.

complete conjugation between the carboxyl group and cyclopentadienyl rings. Two molecules of ferrocenecarboxylic acid have an intermolecular hydrogen bonding as shown in Fig. 2. The hydrogen-bonding distance between O(1) and H(10) is 1.69 Å and that between O(1) and O(2) is 2.65 Å. The H(10) is covalently bonded to the O(2) on one side of the carboxyl group. Molecules of ferrocenecarboxylic acid seem to be rigid in the crystal state owing to a significant interaction of hydrogen bonding between carboxyl groups.

On the other hand, the values of the mean-square amplitude of iron atom in 1,1′-ferrocenedicarboxylic acid are about 1.5-times larger than those found in other ferrocene derivatives. It was found by means of X-ray diffraction measurements that two 1,1′-ferrocenedicarboxylic acid molecules form a dimer through two intermolecular hydrogen bonds.[11] The present sample was determined to be a monoclinic form by Weissenberg photographs. The intermolecular hydrogen bonds seem to be so strong that the dimer molecules of 1,1′-ferrocenedicarboxylic acid behave like one molecular unit in regard to the molecular motion.

An attempt to interpret the molecular motion for 1,1′-ferrocenedicarboxylic acid was made by applying a rigid-body model. The center of gravity for this compound associated with the molecular motion is assumed to be located at the center of a dimer. Since iron atoms are far apart from the center of gravity in a dimer and its moment of inertia for librational vibration seems to be large, the large values of the mean-square amplitude for iron atoms could be explained by assuming both translational and librational motion. For the other compounds, it is roughly assumed that all the iron atoms sit at the center of mass of the molecules and, thus, the mean-square amplitudes of iron atoms have been estimated to be much smaller than that of 1,1′-ferrocenedicarboxylic acid.

As can be seen in Fig. 3, the temperature dependence of the mean-square amplitude for mono- and 1,1′-diethylferrocene derivates from a single straight line, which shows anomaly at about 150 K. There seems to

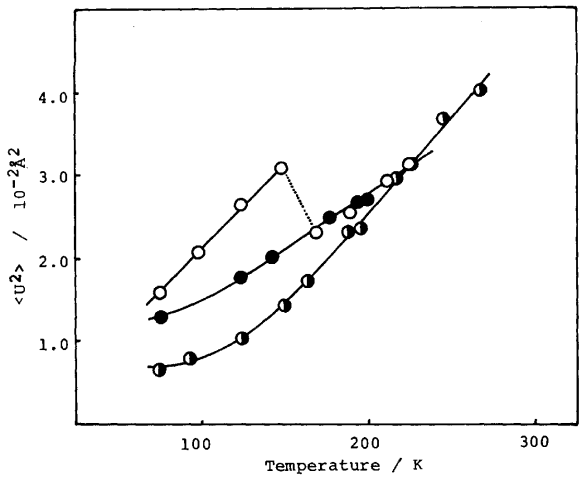

Fig. 3. The temperature dependence of mean-square amplitude in ethylferrocene (◑) and in 1,1′-diethylferrocene (○) and (●), in which open circles were obtained by heating the samples where were first cooled down to liquid nitrogen temperature; closed circles were obtained on cooling 1,1′-diethylferrocene heated up to 224 K in the heating experiment.

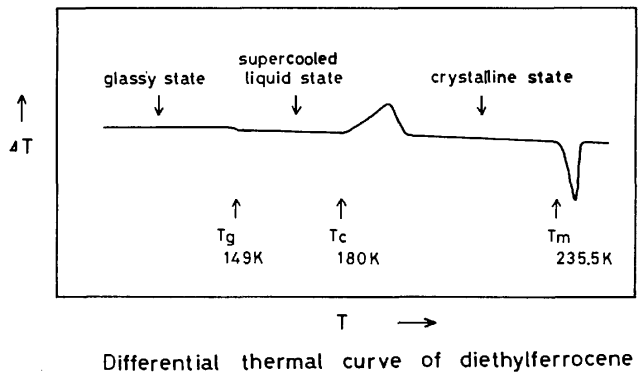

Fig. 4. Differential thermal curve of 1,1′-diethylferrocene at scanning rate of 2.2 deg min^{-1}, Tg: Transition temperature from glass to supercooled liquid state (glass transition temperature); Tc: Transition temperature from supercooled liquid to crystal state (crystallizing temperature); Tm: Melting point.

exist an anharmonicity of the intermolecular vibration in the low-temperature region owing to a loosely packed crystal structure caused by the flexibility of the ethyl groups. This observation suggests that the thermal vibration in acetyl- and carboxy-substituted ferrocenes differs considerably from that in the ethyl-substituted ones.

1,1′-Diethylferrocene was found to have a glassy state through a thermal analysis (Fig. 4).[2] The Differential Thermal Analysis (DTA) data of 1,1′-diethylferrocene reveal that this compound in a glassy state turns into a supercooled liquid state at 149 K, the glass transition temperature, T_g. After heating beyond T_g, crystallization takes place at 180 K, the crystallizing temperature, T_C, followed by melting at 235.5 K. Although the apparent T_g and T_c depend upon the scanning rate of the temperature, nearly constant values of T_g and T_c are obtained with good reproducibility at various slow scanning rates (<2 deg min^{-1}).

In Fig. 3, the open circles indicate the data obtained while heating a sample which was first cooled down to liquid-nitrogen temperature. The closed circles indicate the data obtained while cooling 1,1′-diethylferrocene (heated to 224 K during the heating experiment). The drastic anomaly observed in the recoil-free fraction at 150—170 K during the heating process could be attributed to a transition from the glass to the crystal state via a supercooled liquid state (based on the DTA data shown in Fig. 4). The apparent crystallizing temperature is a little lower than 180 K for a lower scanning speed than 2.2 deg min^{-1}. Since a measurement of the Mössbauer spectra requires about 24 h at a constant temperature, values of the mean-square amplitude between 80 and 149 K are attributed to the thermal motion of molecules in a glass state. The values above 169 K (corresponding to the T_c (180 K) in DTA) may reflect the thermal motion in a crystal state. The larger value of the mean-square amplitude found near 149 K indicates that the molecules in a glass state are much more mobile compared to the molecules near 200 K in a crystal state. Since it is impossible to change from a crystal state to a glass state during cooling, the data of the mean-square amplitude obtained in the recooled process from 224 to 80 K are ascribed to the values for the crystal state. It has been clearly observed that the mean-square amplitude of 1,1′-diethylferrocene in the crystal state differs from that in the glassy state at the same temperature. The value of the mean-square amplitude obtained for 1,1′-diethylferrocene in the crystal state near the melting point is similar in magnitude to that found at the glass transition point.

Lattice dynamics in tetrachlorobis(acetylferrocenato-*O*)tin(IV) and tetrachloro(1,1′-diacetylferrocenato-*O*,*O*′)tin(IV) have been observed by Mössbauer spectroscopy in order to investigate the total vibration of molecules.

These adducts were synthesized by Pavlik et al. in 1968 and were suggested to have a molecular structure in which oxygen atoms of acetyl groups are coordinated to tin atoms. The isomer shift and quadrupole splitting values of iron atoms in the Mössbauer spectra at nitrogen temperature for the sample mounted under nitrogen are 0.51 and 2.17 mm s^{-1} for tetrachlorobis(acetylferrocenato-*O*)tin(IV) and 0.49 and 1.98 mm s^{-1} for tetrachloro(1,1′-diacetylferrocenato-*O*,*O*′)tin(IV), respectively. The values of quadrupole splitting are smaller than other ferrocene derivatives because of the electron-attracting effect of the acetyl group coordinating to the tin atom. The isomer shift values of tin atoms in the Mössbauer spectra at nitrogen temperature are 0.46 mm s^{-1} for tetrachlorobis(acetylferrocenato-*O*′)tin(IV) and 0.39 mm s^{-1} for tetrachloro(1,1′-diacetylferrocenato-*O*,*O*′)tin(IV), respectively, which are smaller than those, 1,45—1.55 mm s^{-1}, of starting materials, $SnCl_4$. These adducts are found to have an octahedral structure which consists of an sp^3d^2 orbital since the s-electron density around tin atoms in these adducts is lower than that of $SnCl_4$. Mössbauer spectroscopic data support the results offered by Pavlik et al.

Figure 5 shows the temperature dependence of the mean-square amplitude obtained for these adducts. The values of the mean-square amplitude of iron atoms were found to be larger than those of tin atoms. The reason may be that iron atoms require not only a translational motion of the center of gravity but also a librational motion around the center of gravity, since iron atoms are located far from the center of gravity and possess a large moment of inertia for librational motion around the center of gravity. Although the crystal structures of these adducts cannot be determined because of instability in air and the difficulty of preparing a single crystal, the results obtained from the temperature dependence of the mean-square amplitude indicate that the mean-square amplitude of iron and tin atoms are apparently proportional to the

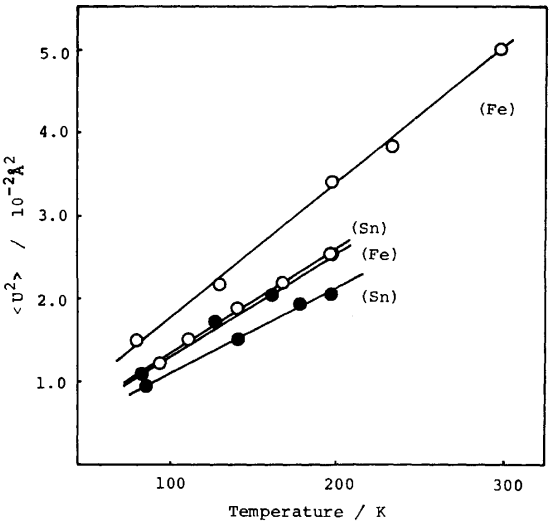

Fig. 5. The temperature dependence of mean-square amplitude determined for each of two Mössbauer nuclei, iron and tin atoms, included in the respective adducts, in which open circles were obtained for tetrachlorobis(acetylferrocenato-*O*)tin(IV); closed circles were obtained for tetrachloro(1,1′-diacetylferrocenato-*O*,*O*′)tin(IV).

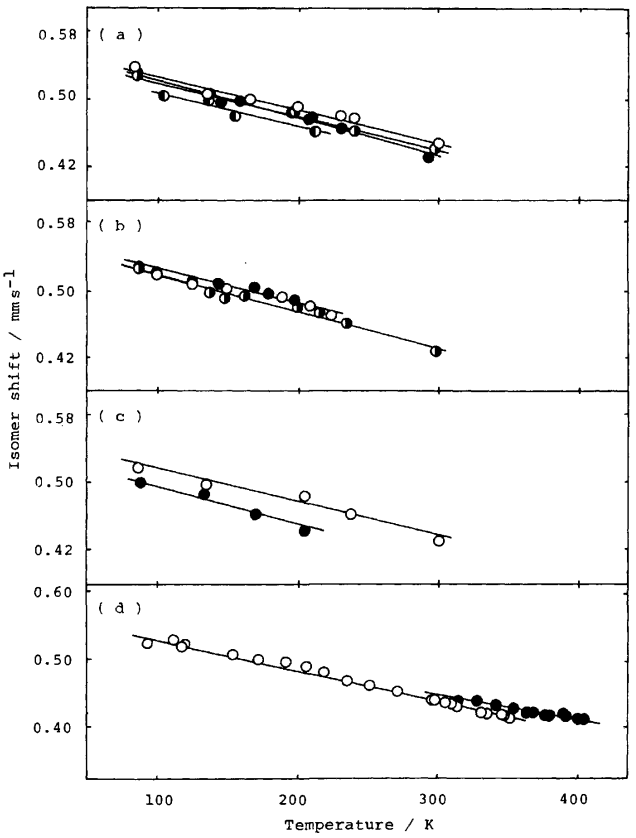

Fig. 6. The temperature dependence of thermal shift for (a) acetylferrocene (○), 1,1′-diacetylferrocene (●), ferrocenecarboxylic acid (◑), and 1,1′-ferrocenedicarboxylic acid (◐), (b) ethylferrocene (◑) and 1,1′-diethylferrocene (○) and (●), in which open circles were obtained in the crystal state; closed circles were obtained in the glassy state, (c) tetrachlorobis(acetylferrocenato-*O*)tin(IV) (○) and tetrachloro(1,1′-diacetylferrocenato-*O*,*O*′)tin(IV) (●), (d) formylferrocene (○) and 1,1′,2,2′-tetrachloroferrocene (●).

absolute temperature in the temperature range studied and that the molecular vibration for these adducts can be explained by assuming the harmonic vibration and the rigid-body model.

The thermal shift, so-called 2nd-order Dopplar Shift, extracted from the Mössbauer spectra also gives significant information about the lattice dynamics in the solid state. The thermal shift originates from the mass defects of the Mössbauer nuclei associated with a γ-ray transition. When the high-temperature approximation of the Debye model is applied, the thermal shift, ΔE, can be expressed as,

$$\Delta E = 3kTE_\gamma/2c^2M, \quad (2)$$

where E_γ is the energy of the Mössbauer γ-ray and M is the effective vibrational mass. It was known that the Mössbauer spectra shift position by both thermal and isomer shifts. Since the former depends on the temperature, the temperature dependence of center shifts in Mössbauer spectra can provide information concerning the magnitude of the thermal shift.

Figure 6 shows the temperature dependence of the center shifts. It was found that all the values are proportional to the absolute temperature and that their slopes are constant in spite of the different molecular structure. When the thermal shifts was interpreted by applying the Debye model (as shown in Eq. 2) the effective vibrational mass was estimated to be ca. 100 for all the studied samples. This fact indicates that the thermal shift dose not depend on the intermolecular interaction and that the iron atom and some atoms in its neighbourhood are involved as a unit in the molecular vibration.

It is interesting to note that the values of the thermal shifts obtained in the crystal phase and the glassy phase for 1,1′-diethylferrocene are approximately equal (Fig. 6(b)) in spite of the drastic difference in the mean-square amplitude between the crystal and glassy phases. The results were also observed in other ferrocene derivatives having a mesophase. The authors have reported that the mean-square amplitudes of formylferrocene and 1,1′,2,2′-tetrachloroferrocene drastically change at the plastic crystal phase transition points, 296.5 and 391 K, respectively.[4] In the case of the formylferrocene, the value of the mean-square amplitude in the plastic phase is about 4-times larger than those in the crystal phase. However, as shown in Fig. 6(d), the thermal shift of formylferrocene shows no significant change in the range from 78 to 343 K. For formyl- and 1,1′,2,2′-tetrachloroferrocene, the effective masses were estimated to be ca. 100, similar to the values obtained in the present work.

It is concluded that acetyl- and carboxyferrocene and

adducts exhibit harmonic thermal vibrations in the range of whole temperature but that ethyl-substituted ferrocenes do not exhibit harmonic thermal vibration at low temperatures. The values of the mean-square amplitude of iron atoms significantly depend upon the position of the iron atom in the compound associated with the moment of inertia in molecular motion. The magnitude of the mean-square amplitude is affected by the molecular arrangement in the solid state, such as the crystal and the glassy states. On the other hand, the thermal shift dose not depend on the intermolecular interaction for ferrocene derivatives studied and the values of vibrational mass estimated from Debye model remain in a constant value. It was found that the thermal shift depends on the bonding state between the Mössbauer atoms and the atoms around the Mössbauer atom.

The authors are indebted to Prof. Michiko Konno at Ochanomizu University for her kind help regarding the use of the X-ray diffractometer at the Institute for Solid State Physics, The University of Tokyo and for discussions concerning the results.

Fluorescence Behavior and Energy Transfer of Cyanine Dyes Bound to Bilayer Membranes of Double-Chain Ammonium Amphiphiles[1)]

Naotoshi NAKASHIMA, Reiko ANDO, and Toyoki KUNITAKE*
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812
(Received November 1, 1986)

Negatively-charged cyanine dyes are bound specifically to aqueous bilayer membranes of double-chain ammonium amphiphiles, as reflected in their absorption spectra. The quantum yield of the fluorescence emission of a trimethine-thiacyanine dye is remarkably enhanced (up to 0.64) when the dye is bound to crystalline bilayer membranes of certain double-chain ammonium amphiphiles. The fluorescence intensity diminished drastically with the liquid crystalline bilayers. Efficient energy transfer is noted from an oxacyanine to the thiacyanine dye in the crystalline membrane matrix. The efficiency decreases by the membrane phase transition to the liquid crystalline state. These results are discussed in terms of specific dye binding and concentration of dyes at the membrane surface.

It has been shown by us and others that a large variety of synthetic amphiphiles produce bilayer aggregates spontaneously.[2-4)] Double-chain ammonium amphiphiles belong to a representative class of the bilayer-forming compounds. These synthetic bilayers possess the two-dimensional organization which is unique as sites for controlling aggregation and orientation of chromophores.

Chromophores can be introduced into bilayers as part of component molecules and as noncovalently adsorbed guest molecules. In the former case, unique spectral and related characteristics such as extraordinary enhancement of circular dichroism, large shifts in absorption spectra, and efficient energy transfer are observed for bilayers containing benzene,[5)] biphenyl,[6)] naphthalene,[7)] anthracene,[8)] azobenzene,[5,9-11)] carbazole,[12,13)] and viologen units[14,15)] as chromophores. The latter cases include membrane-bound dyes (Methyl Orange,[16)] cyanines and merocyanines,[17,18)] and phenylenediamine[19)]) of which spectra reflect specific modes of aggregation and orientation.

As an extention of these studies, we discuss in this paper the fluorescence behavior and the energy transfer of cyanine dyes bound to ammonium bilayer membranes. Cyanine dyes have attracted wide attention because of their characteristic photochemical and photophysical properties: as sensitizers in the photographic process,[20)] as spectroscopic probes for the physical state of the biological membrane,[21)] liposomes,[22,23)] and monolayers.[24,25)] The photophysical aspects of these dyes in highly organized bilayer assemblies pose an exciting topic, since it is known that specific aggregation and orientation of chlorophyll and carotenoid molecules play crucial roles in the efficient energy transfer in the biological photosynthetic machine.

The molecular structures of amphiphiles and dyes employed in this study are given in Scheme 1. We have reported preliminary results on the fluorescence characteristics of cyanine dye **5** bound to bilayer membranes of $2C_{12}$-L-Glu-ph$C_n N^+$, (**1**, n=2 and 4) and $2C_{16}N^+2C_1$ (**4**).[18)] Amphiphiles **2** and **3** possess molecular structures closely related to **1**. The difference is in the connector portion which connects the double chain portion and the phenyl group. The glutamic acid unit is used as connector in **1**, while **2** and **3** contain aspartic acid and diethanolamine, respectively, as connector. These small structural differences lead to different binding modes of thiacyanine dye **5**. Oxacyanine dye **6** was employed to study the efficiency of energy transfer to **5** at the membrane surface.

Experimental

Materials. Preparation of amphiphile **1** (n=4) was described before,[5)] and **1** (n=2 and 10), **2**, and **3** were obtained by similar procedures. The synthesis of the whole series will be discussed separately. The preparation of $2C_{16}N^+2C_1$ was given.[26)] Cyanine dyes **5** (NK 2012) and **6** (NK 1952) were purchased from Nippon Kanko Shikiso and used without further purification.

Measurement. Amphiphiles **1**—**4** suspended in distilled water were sonicated for 3 min (Branson Cell Disruptor 185, sonic power 40 W). The transparent dispersions obtained were incubated in ice water for 30 min. The dispersions were brought to given temperatures, aqueous dyes were added, and the mixtures were kept for 20 min. The 20-min aging at temperatures of the spectral measurement was required in order to secure reproducible spectra. This aging time may correspond to equilibration of dye molecules at the membrane surface. Absorption and emission spectra were measured with Hitachi 220 spectrophotometer and Hitachi 650-10S or 650-60 spectrofluorimeter, respectively. The 650-60 instrument possesses the correction function. The emission measurement was conducted under the aerated conditions, since no spectral difference was observed between the air saturated and N_2 saturated conditions. The excitation wavelength was set at the isosbestic point when the absorption spectrum showed temperature dependence. The quantum yield of emission of Rhodamin B (Wako Pure Chemical, recrystallized twice from ethanol, absorption maximum 542 nm, emission maximum 570 nm (corrected)) was assumed to be 0.5[27)] and used as the reference.

Results and Discussion

Absorption and Fluorescence Spectra. Figure 1 displays temperature dependences of absorption and emission spectra of cyanine dye **5** bound to the bilayer matrix of $2C_{12}$-L-Glu-phC_4N^+ (**1**, n=4, X=Cl) at a molar ratio of 1/4000 (dye/bilayer). Both spectra show remarkable variations at a narrow temperature range of 27 to 29 °C. The spectral changes are small at lower temperatures (below 27 °C) and at higher temperatures (above 30 °C). The crystal-to-liquid crystal phase-transition temperature (T_c) of this bilayer is located at 31 °C (peak top temperature),[5] and the spectral variation is undoubtedly associated with the phase transition.

Similar results are found for other bilayers. The relative emission intensity (I_F) in different bilayers is plotted against temperature in Fig. 2. The dye concentration is very small (1/4000) relative to those of bilayers, and I_F is not affected by the dye concentration at this molar ratio (see below). Drastic I_F decreases are seen for the $2C_{12}$-L-Glu-phC_nN^+ (**1**) bilayers with different spacer lengths (n=2, 4, and 10) near the respective phase-transition temperatures: T_c=27 °C for n=2

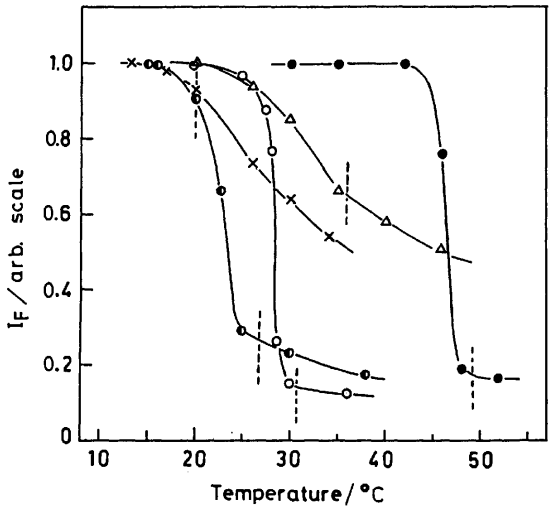

Fig. 2. Plots of I_F (arb. scale) of cyanine dye **5** against temperatures. [bilayer]=2.0×10^{-3} M, [**5**]=5.0×10^{-7} M. —◐—: $2C_{12}$-L-Glu-phC_2N^+ (**1**, n=2), —○—: $2C_{12}$-L-Glu-phC_4N^+ (**1**, n=4), —●—: $2C_{12}$-L-Glu-ph$C_{10}N^+$ (**1**, n=10), —△—: $2C_{12}$-L-Asp-phC_4N^+ (**2**), —×—: $2C_{12}$-Dea-phC_4N^+ (**3**). The emission intensity at 15 °C is taken as unity for the respective bilayer system. The dotted lines indicate the respective phase transition temperatures (peak top).

and 49 °C for n=10. The dependence on T_c is less drastic for bilayers **2** (T_c=36 °C) and **3** (T_c=20 °C). The temperature effect was also not remarkable for the bilayer of $2C_{16}N^+2C_1$ (**4**) (data not shown). These different sensitivities clearly indicate that the mode of dye binding is strongly affected by the chemical structure of the bilayer component. In particular, the structures of $2C_{12}$-L-Glu-phC_4N^+ (**1**, n=4) and $2C_{12}$-L-Asp-phC_4N^+ (**2**) are different only by one CH_2 unit in the connector portion (glutamate vs. aspartate).

Klausner and Wolf[28] incorporated a series of long-chain (C_{10} to C_{22}) cyanine dyes into lecithin vesicles and examined their fluorescence characteristics. However, the variation of I_F with the phase transition was very small.

Table 1. Quantum Yield for Cyanine Dye **5** in Various Media

Media	Φ_F		P	
	20 °C	35 °C	20 °C	35 °C
1 (n=2) (X=Br)	0.40	—	0.47	0.45
1 (n=4) (X=Cl)[a]	0.64	0.08	0.47	0.45
1 (n=6) (X=Br)	0.60	—	0.47	—
1 (n=10)(X=Br)	0.64	—	0.46	—
2	0.25	—	0.45	—

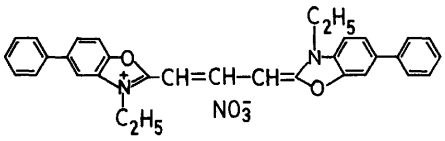
a) Φ_F is almost the same when Cl is replaced by Br.



7

Scheme 2.

Onuki et al.[29] recognized that the fluorescence intensity of double-chain cyanine dyes was modified by the phase transition of matrix liposomes, though a single-chain cyanine dye did not show such an effect.

The fluorescence quantum yields (Φ_F) of thiacyanine dye **5** in various media are summarized in Table 1. Φ_F is small in water and in methanol (ca. 0.0025), and is enhanced by a factor of 15 in the hexadecyltrimethylammonium chloride (CTAC) micelle. A similar Φ_F enhancement was reported by Grätzel and coworkers.[30] They found that the fluorescence intensity of cyanine dye **7** is enhanced 5 times in the sodium dodecyl sulfate micelle and 8 times in the cadmium lauryl sulfate micelle relative to that in methanol.

Greater Φ_F enhancements are observed in the bilayer system at $T<T_c$. Φ_F values in bilayers of $2C_{12}$-L-Glu-phC_nN^+ are ca. 20 times greater than that in the CTAC micelle and ca. 250 times greater than those in water and alcohol. Large changes in Φ_F among bilayers are noteworthy. In spite of the structural similarity, $2C_{12}$-L-Glu-phC_4N^+ and $2C_{12}$-L-Asp-phC_4N^+ give a 10 fold difference. These data are again indicative of the specific nature of the binding mode. In fact, Φ_F is drastically diminished by the gel-to-liquid crystal phase transition of the matrix bilayer. The binding specificity appears lost in the liquid crystalline bilayer.

The Φ_F enhancement may be explained in terms of suppression of the nonradiative decay due to "rigidization" of the dye specifically bound to the membrane surface. The specific binding would constrain the conformation of the dye in such ways that large absorption shifts and fluorescence enhancements result.

The influence of the dye concentration on the spectral characteristics was subsequently examined. Cyanine dye **5** bound to the rigid $2C_{12}$-L-Glu-phC_4N^+ bilayer gives an absorption maximum at 565 nm and an emission maximum at 580 nm at a molar ratio of 1/4000 (see Fig. 1). When the molar ratio is raised to 1/20, these maxima undergo red shifts by ca. 10 nm each: λ_{max} 574 nm (absorption) and 590 nm (emission). Figure 3 demonstrates the effect of the relative dye concentration on the fluorescence intensity at 20 °C (below the phase transition) and at 35 °C (above the phase transition). The absolute emission intensity is much smaller at 35 °C as shown in Fig. 2. The dye concentration is fixed at 5.0×10^{-6} M (1 M=1 mol dm^{-3}), while the bilayer concentration is varied. The relative emission intensity is constant at molar ratios of 1/1000 and below. The intensity is lessened at higher ratios, prob-

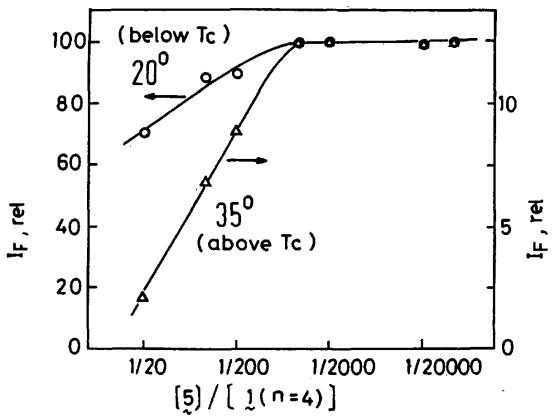


Fig. 3. Influence of the dye/bilayer molar ratio on the fluorescence intensity. [5]=5.0×10⁻⁶ M (constant). Bilayer, $2C_{12}$-L-Glu-phC_4N^+.

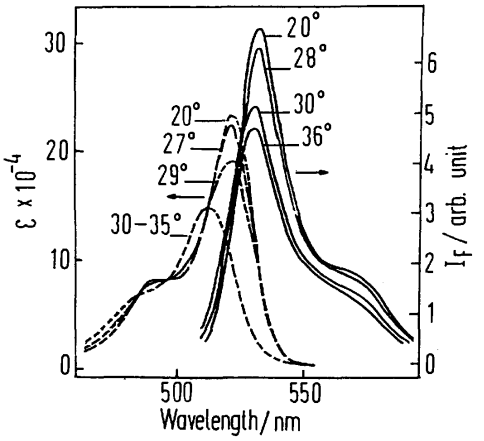

Fig. 4. Absorption (dotted line) and fluorescence (solid line, excitation at 500 nm) spectra of cyanine dye **6** bound to the aqueous bilayer of $2C_{12}$-L-Glu-phC_4N^+. [bilayer]=4.0×10⁻³ M, [dye]=1.0×10⁻⁶ M.

ably due to concentration quenching. The decrease is much larger in the crystalline bilayer, the intensity becoming ca. one third at the ratio of 1/20. This appears to be related to the enhanced energy transfer in the crystalline bilayer to be discussed later.

The emission intensity decreases drastically at T_c at the whole molar ratio range. The position of the descending line moves to higher temperatures with increasing dye concentrations. This is ascribed to the T_c rise of the dye-bound bilayer, as confirmed by the DSC measurement.[30] Similar trends were observed for absorption spectra and induced circular dichroism of this system.

The sharp emission with a small Stokes shift and the red shift in the absorption spectrum strongly suggest the formation of the J-like aggregates[20] for cyanine dye **5** concentrated in the bilayer matrix of $2C_{12}$-L-Glu-phC_nN^+. We have shown separately that many other cyanine and merocyanine dyes form the J-like aggregates in this bilayer matrix.[31] The latter dye aggregates similarly give rise to enhanced fluorescence emission.

On the other hand, a blue shift is observed in the absorption spectrum (λ_{max} 498 nm), when dye **5** is bound to the bilayer of $2C_{12}$-L-Asp-phC_4N^+. The fluorescence emission is barely recognized in this system. These spectral data are indicative of the formation of the H-aggregates.[20] It is interesting that the mode of the dye binding — orientation and aggregation — is quite different between bilayers with a minor structural variation (glutamate vs. aspartate). The bilayer physical state also plays a crucial role. The J-aggregates act as better photosensitizers. Therefore, it is expected that the migration and transfer of the excitation energy among bilayer-bound dyes are similarly affected by the variation of the binding mode.

Fluorescence Quenching and Energy Transfer. The energy transfer from an oxacyanine dye to a thiacyanine dye in the multilayer system was pioneered by Kuhn and Möbius.[24] We similarly employed an oxacyanine dye (**6**, NK 1952) as an energy donor in this study. Figure 4 snows absorption and emission spectra of **6** in the bilayer matrix of $2C_{12}$-L-Glu-phC_4N^+. The absorption maximum is located at 531 nm at 20 °C. As the temperature is raised, the maximum shifts to shorter wavelengths (511 nm at 30 °C) and the intensity decreases. The change is most drastic at 27 to 30 °C and is negligible at 30 to 35 °C. The phase transition of the bilayer is responsible for the spectral change, as also observed for bilayer-bound **5** (see Fig. 1). The emission maximum is located at 530 nm, and the intensity decreases with temperature. A comparison of Figs. 1 and 4 indicates that the emission spectrum of **6** overlap with the absorption range of **5**. Therefore, the Förster-type energy transfer from the oxacyanine to the thiacyanine is anticipated.

Figure 5 compares emission spectra of membrane-bound oxacyanine **6** alone and in the presence of equimolar (1.0×10⁻⁶ M) thiacyanine **5**. The emission of oxacyanine **6** (excitation at 500 nm) decreases in the presence of thiacyanine **5** and the emission from the latter is enhanced. This clearly indicates the energy transfer from **6** to **5**. The transfer efficiency is largest at 20—25 °C, and decreases with increasing temperatures, as can be estimated by the relative emission intensity at 530 nm and at 584 nm.

The decrease in the oxacyanine emission becomes pronounced with increasing concentrations of the thiacyanine acceptor. The quenching process can be represented by the Stern-Volmer relation

$$I_F^\circ/I_F - 1 = K_{sv}[A] \quad (1)$$

where I_F° and I_F are emission intensities of a donor dye in the absence and presence of acceptor dye A, respectively. K_{sv} is the Stern-Volmer quenching constant.

Figure 6 gives Stern-Volmer plots in the bilayer and micelle systems. The quenching process obeys Eq. 1.

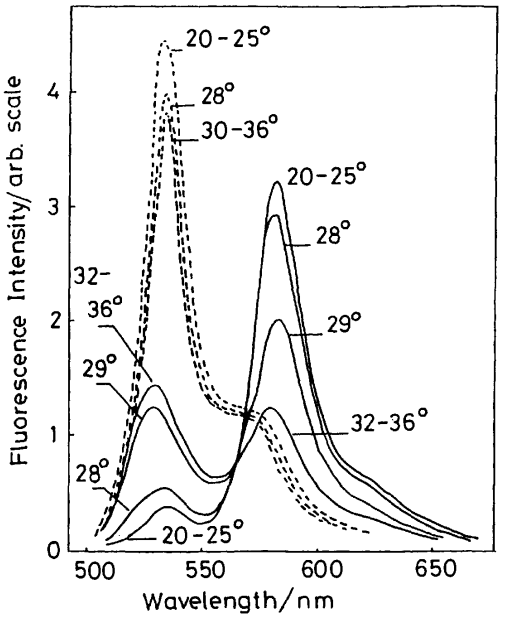

Fig. 5. Temperature dependence of fluorescence spectra of cyanine dyes (**5** or **6**) bound to the aqueous bilayer of $2C_{12}$-L-Glu-phC_4N^+. [bilayer]=1.0×10^{-3} M. Excitation at 500 nm. ----: Fluorescence spectra of **6** (1.0×10^{-6} M) alone. ——: Fluorescence spectra of **6** (1.0×10^{-6} M) plus **5** (1.0×10^{-6} M).

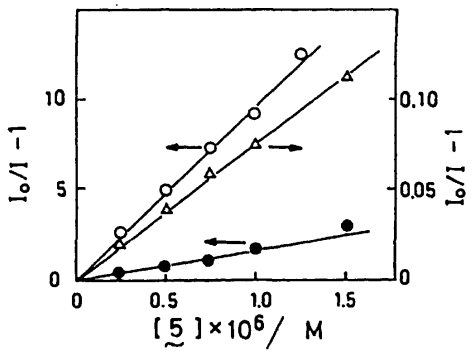

Fig. 6. Stern-Volmer plots for the emission quenching of cyanine dye **6** in the presence of dye **5**. [**6**]=1.0×10^{-6} M (constant). —○—: **1** (n=4), 1.0×10^{-3} M. —●—: **1** (n=4), 4.0×10^{-3} M. —△—: CTAB, 4.0×10^{-3} M.

The slopes in Fig. 6 give $K_{sv}=1.6\times10^6$ M^{-1} for the bilayer ($2C_{12}$-L-Glu-phC_4N^+) concentration of 4.0×10^{-3} M. The K_{sv} value is enhanced to 9.5×10^6 when the bilayer concentration is lowered to 1.0×10^{-3} M. In the CTAB micelle (4.0×10^{-3} M), $K_{sv}=7.5\times10^4$ M^{-1}, a value only 1/20 of the corresponding bilayer system. Thus the bilayer membrane provides a vehicle for energy transfer superior to the globular micelle. Concentration and specific binding of donor and acceptor dyes at the rigid bilayer surface must be responsible for the enhanced energy transfer.

Factors Affecting Fluorescence Quenching. It is apparent from Fig. 5 that the fluorescence quenching is strongly temperature-dependent. Figure 7 shows the

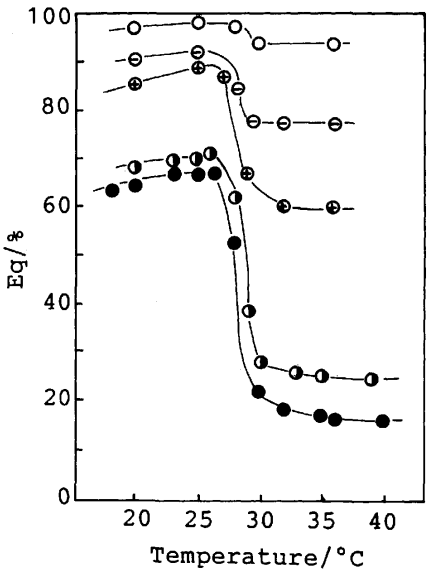

Fig. 7. Quenching efficiency (E_q) vs. temperature in the presence of the $2C_{12}$-L-Glu-phC_4N^+ bilayer. [**5**]=[**6**]=1.0×10^{-6} M. The bilayer concentration is as follows; —○—, 1.0×10^{-4} M; —⊖—, 5.0×10^{-4} M; —⊕—, 1.0×10^{-3} M; —◑—, 2.0×10^{-3} M; —●—, 4.0×10^{-3} M.

temperature dependence of the quenching efficiency

$$E_q = (1-I_F/I_F^\circ)\times 100\ (\%) \qquad (2)$$

at different concentrations of the $2C_{12}$-L-Glu-phC_4N^+ bilayer. E_q is reduced slightly at ca. 30 °C in the presence of 1×10^{-4} M of the bilayer, but remains almost unchanged at higher and lower temperature ranges. The reduction at 25—30 °C becomes drastic with increasing bilayer concentrations. In accordance with the spectral change in Fig. 5, the quenching is more efficient in the rigid bilayer matrix. The fluorescence quenching is well above 90% at all temperatures at the bilayer concentration of 1×10^{-4} M. A sonicated sample of $2C_{12}$-L-Glu-phC_4N^+ in water contains lamellar dispersions of which molecular weight cannot be less than ten millions.[31] We cannot at the moment distinguish the inter- and intra-aggregate processes. A crude estimate indicates that an average distance of the donor and acceptor dyes that are randomly distributed at the bilayer surface is 30—40 Å (the cross section of the bilayer component is 50—60 Å^2). The energy transfer via the Förster mechanism would proceed efficiently at this distance.

Reduction of the quenching efficiency with increasing bilayer concentrations is pronounced in the liquid crystalline region. For the crystalline bilayer, however, E_q is only reduced from 97 to 63% by the concentration change from 1×10^{-4} to 4×10^{-3} M. This reduction is too small to be accounted for by the concentration effect alone. It appears that E_q in the crystalline bilayer matrix remain high either due to the nonrandom distribution of dye molecules or due to the enhanced transfer rate. Absorption spectra of the dyes

bound to these bilayers display characteristic variations, implying that the modes (orientaion and aggregation) of dye binding are specific. This binding specificity may be responsible for these small concentration effects. The larger E_q reduction in the liquid crystalline bilayer matrix can be accounted for solely by the dilution effect.

The other bilayer matrices were similarly used for the quenching experiment, and the results are summarized in Fig. 8. The abrupt reduction in E_q is observed commonly for the bilayers of $2C_{12}$-L-Glu-phC_nN$^+$ (n=2, 4, and 10) at temperatures slightly below T_c (peak top temperature). However, the extent of the reduction is quite different. The difference is produced by an especially small quenching efficiency observed in the crystalline $2C_{12}$-L-Glu-phC_2N$^+$ bilayer. The binding mode in this bilayer appears not different from those in other bilayers of longer spacers, as the absorption spectrum of the bound cyanine is not sensitive to the spacer length. There could be changes in the mode of dye distribution that are not reflected in the absorption spectrum.

There are common trends in the T_c effect between the specificity of absorption spectra and the reduction of E_q. The $2C_{16}N^+2C_1$ bilayer which cannot bind dye molecules in specific manners,[31] gives almost constant E_q's at temperatures above and below T_c (28 °C). The fluid micelle of CTAB similarly gives temperature-independent E_q values. The smaller E_q value for CTAB (ca. 11%) relative to that of $2C_{16}N^+2C_1$ (ca. 21%) may reflect the smaller size of the CTAB micelle. E_q values in the fluid micelle and in the liquid crystalline bilayers are in the range of 10—20%. These data, together with the data shown in Fig. 7, unmistakably endorse the thesis that the specific nature of the dye binding enhance the efficiency of energy transfer.

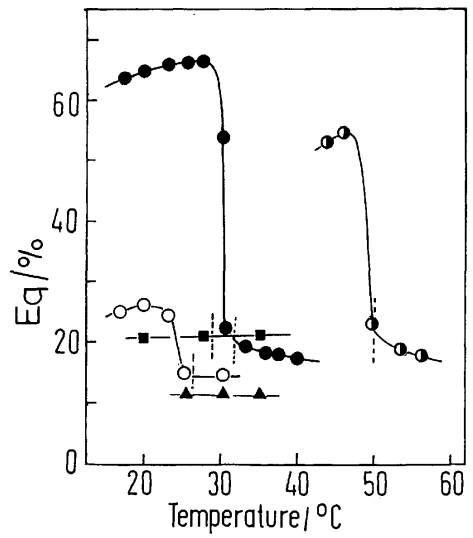

Fig. 8. Quenching efficiency (E_q) vs. temperatures in bilayers and micelles. The dotted lines indicate the phase transition temperature (peak top) of the respective bilayer.

Conclusion

The present study leads to the following conclusions.

(1) The emission characteristics of anionic cyanine dyes bound to cationic bilayer membranes are strongly affected by the chemical structure and the physical state of the matrix membrane. The fluorescence emission is remarkably enhanced in crystalline bilayers of double-chain glutamate derivatives, and is characteristic of the J-like aggregate when the dye concentration is high. These unique spectral properties are related to binding of dyes to the specific space created at the membrane surface.

(2) Dye molecules concentrated at bilayer surfaces give rise to efficient energy transfer. The efficiency is affected by the nature of the matrix bilayer. The observed data imply that the energy flow in the bilayer can be regulated by appropriate disposition of dye molecules.

It is demonstrated that bilayer membranes provide superior media for organizing chromophores in specific manners.

Kinetic Study of Liquid-Phase Esterification with Sulfonic Acid Cation-Exchange Resin of the Macroreticular Type. II.[1] Solvent Effects on Resin Catalysis

Shoichi SHIMIZU* and Choichiro HIRAI
Department of Industrial Chemistry, College of Industrial Technology, Nihon University, Izumi-cho, Narashino, Chiba 275
(Received November 28, 1986)

The rates of the esterification of octanoic acid with 1-butanol catalyzed by macroreticular sulfonated ion-exchange resin in the presence of various organic solvents and water were measured by the use of a batch reactor. The solvent effects on the rate were investigated by applying the heterogeneous-pseudohomogeneous reaction mechanism. From these results, it was found that the effects can be quantitatively estimated by means of the magnitude of the equilibrium constants, $K_{sol}^{(S)}$, for the solvent-separated ion-pair formations, which are due to the interaction of the sulfo groups in the resin with the solvents. The correlations of the $K_{sol}^{(S)}$ value with the physical properties, μ and ε; the solvatochromic parameters, π^*,α, and β, and Gutmann's parameters, AN_E and DN_B, have been examined by using linear regression analysis methods. The results of the correlations in which the protic solvents have been excluded suggest that the positions of the equilibria of solvent-separated ion-pair formations depend mainly on the electron-donor property of the solvents; that is to say, the solvents with a strong donor property diminish the number of un-ionized sulfo groups which act as catalytic species for the heterogeneous reaction.

The advantages cited most frequently for the use of ion-exchange resins as catalysts are the elimination of the necessity for product isolation by distillation or extraction procedures and their possible re-utilization. Therefore, experimental studies of the use of resin have been carried out on almost all the reactions homogeneously catalyzed by acids or bases.[2] Little, however, is known concerning the solvent effects on resin catalysis.

Tartarelli et al.[3] studied the kinetics of the esterification of benzoic acid with 1-butanol catalyzed by sulfonic acid resin of the standard type and sulfuric acid in the presence of heptane, benzene, and toluene as solvents; they reported that, taking into account the distribution of the components between the external solution and the micropore liquid in the resin, the solvent effects on the reaction rate can be explained on the basis of a mechanism involving the reaction between a positive ion and a dipolar molecule. The kinetics of ethyl acetate reesterification with methanol and 1-propanol catalyzed by a sulfonated ion-exchanger MS-25 in 1,4-dioxane and cyclohexane were likewise investigated by Setinek and Rodriguez,[4] who noted that cyclohexane behaved as an inert solvent, while 1,4-dioxane interacted with the catalyst. Recently, Regen et al.[5] pointed out that, from a qualitative point of view, the nature of the organic solvent used for polymer-based triphase catalysts may influence the observed activity of the catalysts in the following ways: (1) it can be important in determining the absorption equilibria for the reactants on the polymer; (2) when a gelular resin is used, it can control the extent of swelling, which in turn will determine the number of active sites available for catalysis, and (3) it may be important in establishing the nature of the microenvironment at the active site.

On the other hand, Gates and his coworkers have published a series of fundamentally important papers.[6-8] These papers have shown that an excess of water or alcohol can shift the catalytic species from the more active undissociated sulfonic acid to the less active solvated proton; this finding was also substantiated by our preceding work.[1] The shift of catalytically active species reveals an important relationship between the solvent system and the nature of the catalytic species.[9]

In this work, in order to clarify the solvent effects on the resin catalysis from such a point of view, we have measured the kinetics of the esterification of octanoic acid with 1-butanol catalyzed by macroreticular sulfonic acid resin (Amberlyst 15) in the presence of various organic solvents and water.

Experimental

Catalyst Preparation and Reagents. The catalyst was a macroporous sulfonated copolymer of styrene and divinylbenzene, Amberlyst 15 (Rohm and Haas Company). The hydrogen-form resin, 0.59—0.84 mm particles, was pretreated as usual[1] and then stored in a desiccator in sealed vials over silica gel. The ion-exchange capacity was 5.05 meq g^{-1} of dry resin, and the water content was 6.87 wt%.

The octanoic acid (reagent-grade for the automatic analysis of amino acids from Wako Pure Chemical Industries, Ltd.) was used without further purification. The 1-butanol was purified by drying over potassium carbonate and distillation.

Solvents. All the chemicals were of a guaranteed reagent grade. The octane and toluene were distilled and then dried over magnesium sulfate. The anisole was washed with a 0.5 mol dm^{-3} aqueous solution of sodium hydroxide and twice with distilled water, dried over calcium chloride, and then distilled. The dibutyl ether was purified by distillation and passing it through a column of activated alumina. The 2-butanol was purified in the same manner as 1-butanol. The 1,4-dioxane was refluxed over sodium and then dis-

tilled. The dimethyl sulfoxide was dried over calcium chloride and distilled under reduced pressure.

Reaction-Rate Measurement. The apparatus was the same as that described in Part I.[1] The esterification was measured at 80±0.05 °C, and the reaction medium was agitated at 250 rpm. In all experiments, the total volume of the reaction mixture, consisting of octanoic acid, 1-butanol (or with water in the runs so denoted in Fig. 2), and a solvent, was kept constant at 30 ml. The initial concentration of octanoic acid and the amount of resin were also held constant at 0.150 mol dm^{-3} and 1.25 g respectively. The initial ratio of the volume of 1-butanol to that of solvent was changed in every run for the kinetic analysis. After the start of a reaction, 40.0-μl samples were removed by using a microsyringe at appropriate time intervals and then transferred to individual capped microtubes containing a mixture of hexadecane as an internal standard and the solvent used in each run. For gas-chromatographic (GC) analysis, samples of about 1—2 μl were taken from these microtubes. The reaction rates were determined from the analyses of butyl octanoate. The instrument used to carry out the GC analyses and the operating conditions were described in detail in an earlier paper.[10]

The ester-concentration increments from 0.0200 to 0.0400 mol dm^{-3}, divided by the time required for the reaction progress, were set equal to the reaction rates for each solution composition at a conversion of 20 % and were adopted as the kinetic data, since a short induction period rarely appeared and since an initial reaction rate could not be employed.

Results and Discussion

Effects of Various Organic Solvents and Water on the Rate. The influences of various organic solvents upon the reaction rate are shown in Fig. 1. When 2-butanol was used as a solvent, *s*-butyl octanoate was formed as a by-product. However, the rate of the by-product reaction was negligibly small compared to that of the reaction of octanoic acid with 1-butanol under the present reaction conditions. In other cases, no side reaction occurred. As can be seen from Fig. 1, dimethyl sulfoxide most strongly interacted with the catalyst and inhibited the reaction, while octane did so most weakly or not at all; octane is, therefore, regarded as an inert solvent.[11] Water also inhibited the reaction, as is shown in Fig. 2.

Evaluation of Solvent Effects in the Dielectric Approach. The swelling of an unsulfonated styrene-divinylbenzene copolymer of the macroreticular type was scarcely even observed in either polar or nonpolar organic solvents, whereas the sulfonated ion-exchange resin, Amberlyst 15, was slightly swollen only in polar solvents.[12] This swelling was considered to be due to the interaction between solvents and sulfo groups in the resin.[12] In practice, even when a polar reactant or a solvent such as 2-methyl-2-propanol[13] or 1,4-dioxane[4] was used, no sulfo groups located within the gelular microspheres in about 20% crosslinked resins took part in the catalytic reaction. Therefore, it is considered that only the sulfo groups residing on the surface of the microspheres are available for a catalytic reaction, that the number of the available sulfo groups varies hardly at all with the polarity of the reaction medium, and that it is not necessary to take into account the distribution of the reactants between an external solution and micropore liquid in the microspheres, which conforms to Helfferich's standpoint.[14]

On the assumption that a reaction between a neutral dipolar molecule and a positive ion is the rate-controlling step, Tartarelli et al.[3] interpreted the solvent effects on the rate of esterification with sulfonic acid resin in the dielectric approach. According to this treatment, the kinetic data presented in Figs. 1 and 2

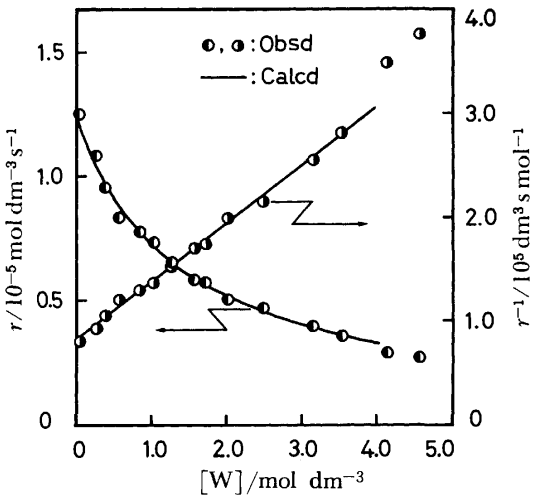

Fig. 2. Effect of water on reaction rate (r). [F]=0.120 mol dm^{-3}, [A]=9.7 mol dm^{-3}, [E]=0.030 mol dm^{-3}, solvent; octane.

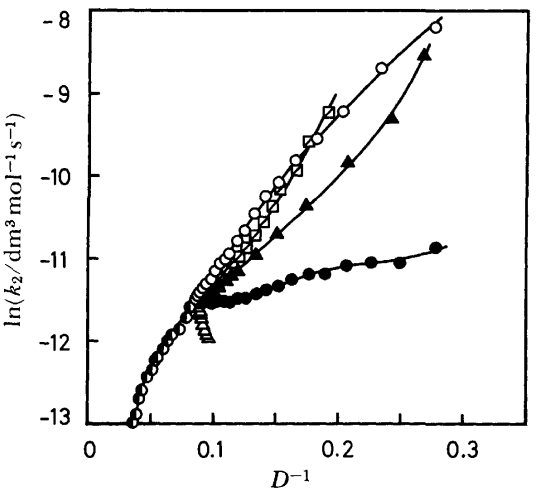

Fig. 3. Dependence of dielectric constant of reaction medium (D) on reaction rate constant ($k_2=r[F]^{-1}[A]^{-1}$). ○; Octane, ▲; toluene, △; 2-butanol, ☒; anisole, ●; 1,4-dioxane, ◐; water.

should give a straight line in the plot of ln k_2 vs. $1/D$ with a positive slope. As is shown in Fig. 3, however, curves and a line with a negative slope were obtained. These results indicate that the dielectric approach is inadequate to interpret the solvent effects on the resin catalysis.

Application of Heterogeneous-Pseudohomogeneous Reaction Mechanism[1] and Estimation of Solvent Effects by Means of Kinetic Analysis. In the preceding paper,[1] it was reported that water and 1-butanol solvate the matrix-bound sulfo groups, and that the esterification system consists of a heterogeneous reaction catalyzed by matrix-bound sulfo groups which are not ionized and a pseudo-homogeneous reaction by protons solvated with alcohol. Rate Equation 1, values calculated from which were in fair agreement with the observed ones, was presented.

$$r=\frac{\{k_{het}[F]+k_{phom}^{(A)}K_{phom}^{(A)}K_{sol}^{(A)}[F][A]^{\alpha+1}\}[Cat]M}{1+K_{sol}^{(A)}[A]^{\alpha}+K_{sol}^{(W)}[W]^{\beta}} \quad (1)$$

In the present case, it is necessary to take into account the interaction of an additional solvent with the catalyst, that is, with sulfo groups in the resin. Assuming that appropriate polar solvents also behave as solvating agents (Eq. 2), and then that the protons solvated with the solvents become catalytic agents (Eqs. 3 and 4), the reaction rate is expressed by Eq. 5.

$$\gamma X+Ⓟ\text{—}SO_3H \overset{K_{sol}^{(X)}}{\rightleftarrows} Ⓟ\text{—}SO_3^-/\gamma X/H^+ \quad (2)$$

$$F+Ⓟ\text{—}SO_3^-/\gamma X/H^+ \overset{K_{phom}^{(X)}}{\rightleftarrows} Ⓟ\text{—}SO_3^-/\gamma X+HF^+ \quad (3)$$

$$A+HF^++Ⓟ\text{—}SO_3^-/\gamma X \xrightarrow{k_{phom}^{(X)}} E+W+Ⓟ\text{—}SO_3^-/\gamma X/H^+ \quad (4)$$

$$r=\frac{\{k_{het}[F]+k_{phom}^{(A)}K_{phom}^{(A)}K_{sol}^{(A)}[F][A]^{\alpha+1}+k_{phom}^{(X)}K_{phom}^{(X)}K_{sol}^{(X)}[F][A][X]^{\gamma}\}[Cat]M}{1+K_{sol}^{(A)}[A]^{\alpha}+K_{sol}^{(W)}[W]^{\beta}+K_{sol}^{(X)}[X]^{\gamma}} \quad (5)$$

The application of Eq. 5 based on the heterogeneous-pseudohomogeneous reaction mechanism makes it possible to estimate the solvent effects on the resin catalysis in a quantitative way, provided that Eq. 5 gives good representations of the observed data plotted in Figs. 1 and 2. Hence, octane was chosen as the reference solvent, for it does not interact with the sulfo groups, that is to say, $K_{sol}^{(O)}=0$ dm^3 mol^{-1}, and the optimum values of α, β, k_{het} [Cat], $k_{phom}^{(A)}K_{phom}^{(A)}$ [Cat], $K_{sol}^{(A)}$, and $K_{sol}^{(W)}$ were determined from the results observed with octane according to the procedure previously described.[1] Next, in order to determine the values of $k_{phom}^{(X)}K_{phom}^{(X)}$ [Cat] and $K_{sol}^{(X)}$ for each solvent for integral values of the γ exponent ranging from one to three, the sum of the squares of the deviations of the predicted rates from the observed rates has been calculated with a computer. By substituting the values of these parameters, which are listed in Table 1, into Eq. 5, the most precise representation of the data for each solvent is given. When the calculated values are compared to the data in Figs. 1 and 2, the agreement between the observed and calculated values is satisfactory. These results give support to this approach for the quantitative estimation of the solvent effects on the resin catalysis.

Correlations with Physical Properties and Empirical Parameters of Solvents. The least-squares analyses were carried out for the equilibrium constants for solvent-separated ion-pair formation, $K_{sol}^{(S)}$, vs. the molecular dipole moment, μ, and the dielectric constant, ε. Equation 6 is the least-squares fit for $K_{sol}^{(S)}$ vs. μ with seven solvents, and Eq. 7, for $K_{sol}^{(S)}$ vs. ε with nine solvents.

$$K_{sol}^{(S)}=2.66\mu-1.19, \qquad R=0.838 \quad (6)$$

$$K_{sol}^{(S)}=0.103\varepsilon+0.461, \qquad R=0.814 \quad (7)$$

a) Values taken from Ref. 22. b) AN_E values are calculated from the E_T values using $AN_E=-40.52+1.29E_T$. c) DN_B values are calculated from the B^* or B values using $DN_B=-6.36+0.19B^*$. d) Values taken from Ref. 19. e) Highly-structured protic solvents. f) Values of hexane and heptane. g) Data are relatively less certain. h) dm^6 mol^{-2}.

These correlation coefficients for Eqs. 6 and 7 are not statistically acceptable. This result is consistent with the information[15] that the extent of ionization is governed by the ability of a solvent to heterolyze covalent bonds and not by its dipolar characteristics, such as the dipole moment or the dielectric constant.

Recently, an empirical solvent scale based on the solvatochromic comparison method[16] and an equation based on the linear solvation energy relationship,[17-19] which expresses the role of the contributions of individual types of solvent-solute interactions, have been proposed by Kamlet, Taft, and their coworkers.[20] In general form, this solvatochromic equation is given by

$$XYZ = XYZ_0 + s\pi^* + a\alpha + b\beta, \quad (8)$$

where XYZ is the measured quantity (a free energy or heat of transfer between solvents, the logarithm of a reaction rate or an equilibrium constant, etc.) in the given solvent, and where XYZ_0 is the same quantity obtained for a reference solvent. The π^* scale is an index of solvent dipolarity/polarizability (SPP). The α scale of hydrogen-bond donor (HBD) acidities describes the ability of the solvent to donate a proton. Similarly, the β scale of hydrogen-bond acceptor (HBA) basicities expresses the solvent's ability to accept a proton (donate an electron pair). The s, a, and b terms in Eq. 8 are measures of the responses of XYZ to changing SPP, HBD acidity and HBA basicity; they are called the solvatochromic coefficients.

For the seven solvents whose solvatochromic parameters are known, the multiple-parameter least-squares correlation of ln $K_{sol}^{(S)}$ with the π^*, α, and β values leads to

$$\ln K_{sol}^{(S)} = -3.72 + 3.88\pi^* + 0.26\alpha + 2.57\beta, \quad R=0.827. \quad (9)$$

If the data for 1-butanol and water, which are highly-structured protic solvents, are excluded, a correlation equation with an acceptable correlation coefficient,

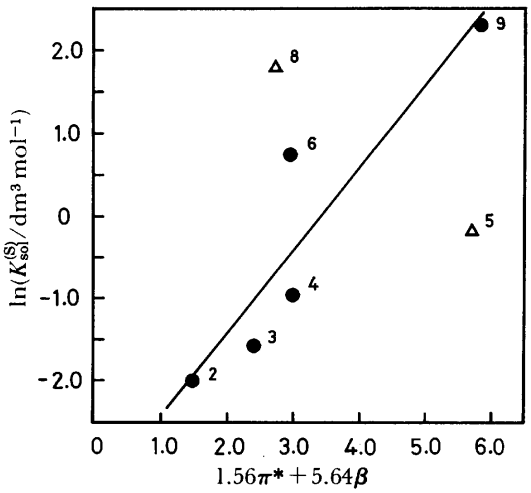

Fig. 4. Relationship between equilibrium constants ($K_{sol}^{(S)}$) and solvatochromic parameters (π^* and β). △; Highly-structured protic solvents.

represented by the regression line in Fig. 4, is given by

$$\ln K_{sol}^{(S)} = -3.43 + 1.56\pi^* + 5.64\beta, \quad R=0.917. \quad (10)$$

It is considered that, since the data points representing 1-butanol and water, which can also act as stronger hydrogen-bond donors, are not displaced from the regression line in the same direction in Fig. 4, there is no contribution of solvent HBD acidities to the $K_{sol}^{(S)}$. Furthermore, because the π^*, α, and β parameters are roughly normalized to cover the range from near 0.0 to near 1.0,[19] the b/s (5.64/1.56) ratio obtained from Eq. 10 may indicate that the positions of the equilibria of solvent-separated ion-pair formations depend largely on the solvent HBA basicities.

In contrast to the solvatochromic parameter scales of Kamlet and Taft, Gutmann and his coworkers[15,21] have proposed a "donor-acceptor" approach to describe the total solvent effects in terms of the electron-donor and electron-acceptor properties of the solvent.

As quantitative measures of these solvent properties, two empirical parameter scales, termed "donor number" (*DN*) and "acceptor number" (*AN*), have been introduced. The *DN* was defined as the negative ΔH° value for the interaction between the reference acid, $SbCl_5$, and a basic solvent in a highly dilute 1,2-dichloroethane solution. The *AN* was derived from the infinite-dilution ^{31}P NMR solvent shifts (relative to hexane) of triethylphosphine oxide in the bulk solvents.

The plot of $\ln K_{sol}^{(S)}$ vs. DN_B[22] values is shown in Fig. 5. If the points for the highly-structured protic solvents are excluded, the correlation with DN_B leads to

$$\ln K_{sol}^{(S)} = -2.857 + 0.163DN_B, \quad R = 0.934. \tag{11}$$

With the allowance of a partial dependence on AN_E also, the multiple linear regression equation becomes

$$\ln K_{sol}^{(S)} = -2.918 + 0.082AN_E + 0.129DN_B, \quad R = 0.953. \tag{12}$$

The $\ln K_{sol}^{(S)}$ values are plotted against the values of $0.082AN_E+0.129DN_B$ in Fig. 6. By a consideration of the small difference in the magnitude of the correlation coefficient between the two linear regression analyses, it is found that $K_{sol}^{(S)}$ is sensitive mainly to the donor ability of solvents. A comparison of Eqs. 11 and 12 with Eq. 10 shows that the correlations with Gutmann's parameters are somewhat better than those with the solvatochromic parameters. However, since no normalization of the AN_E and DN_B parameters has been carried out, the relative contributions of the individual solvent properties can not be discussed by a direct comparison of the coefficient value of AN_E with that of DN_B.

Taft et al.[18] have examined the relationships between Gutmann's *AN* and *DN* and the solvatochromic parameters, π^*, α, and β; they have reported that *AN* correlates well with a linear combination of π^* and α, and that *DN* is linear with β when the result for pyridine is excluded. Therefore, it seems that the signification of the correlation (Eq. 12) with Gutmann's parameters is essentially the same as that (Eq. 10) with the solvatochromic parameters. These significations are in harmony with Gutmann's description[23] that the formation of solvent-separated ion pairs is primarily influenced by the coordinating properties of the solvent.

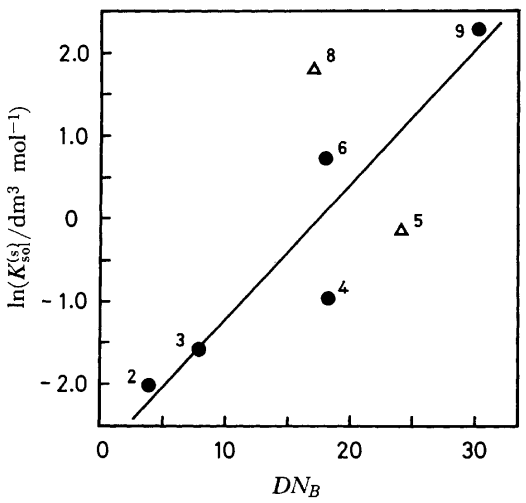

Fig. 5. Relationship between equilibrium constants ($K_{sol}^{(S)}$) and solvent donor numbers (DN_B). △; Highly-structured protic solvents.

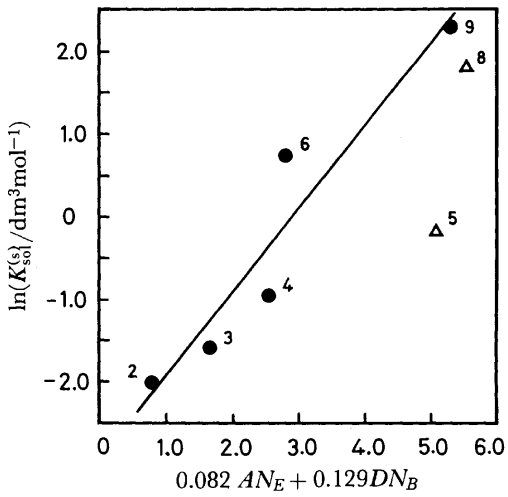

Fig. 6. Relationship between equilibrium constants ($K_{sol}^{(S)}$) and solvent acceptor and donor numbers (AN_E and DN_B). △; Highly-structured protic solvents.

As is shown in Table 1, the protons produced by the interaction of the sulfo groups with anisole and toluene, whose $K_{sol}^{(S)}$ values are relatively small, have no catalytic activity as those with water and dimethyl sulfoxide: $k_{phom}^{(S)} K_{phom}^{(S)}[Cat]=0\ dm^3\ mol^{-1}\ s^{-1}\ g^{-1}$. This result may indicate that, when the resins are immersed in anisole and toluene, some of the sulfo groups residing on the surface of the microspheres exist as contact ion pairs (or intimate ion pairs),[24] in which cations and anions are considered to be in immediate contact with each other, rather than as solvent-separated ion pairs.

In conclusion, if the solvents with a strong electron-donor property are employed as diluents in the esterification with the macroreticular sulfonic acid resin, this donor property diminishes the number of unionized sulfo groups which act as catalytic species for the heterogeneous reaction and, consequently, a decrease in the total catalytic activity is observed. Hence, it can be presumed that the extent of the selectivity of the resin catalyst related to the alkyl chain length of normal fatty acids, which was reported in an earlier paper,[10] also decreases.

The authors are grateful to Mr. Shigeru Itoh and Miss Sawako Onoda for their experimental assistance. The present work was partially supported by a Grant-in-Aid from Nihon University.

1,4-Dihydropyrrolo[3,2-*b*]pyrrole: The Electronic Structure Elucidated by Photoelectron Spectroscopy

Shoji TANAKA, Tsutomu KUMAGAI, Toshio MUKAI,* and Tsunetoshi KOBAYASHI*,†
Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Sendai 980
†The Institute of Physical and Chemical Research, Wako, Saitama 351-01
(Received December 2, 1986)

The electronic structures of 1,4-dihydropyrrolo[3,2-*b*]pyrrole and some of its alkyl derivatives were studied by means of He(I) photoelectron spectroscopy combined with the MNDO calculation and a first-order perturbation theoretical method. The first five bands of the parent pyrrolopyrrole are assigned, from the top, to the $\pi_5(a_u)$, $\pi_4(a_u)$, $\pi_3(b_g)$, $\pi_2(b_g)$, and $\sigma(a_g)$ bands respectively. The MO model, which explains well the spectral data, indicates that the nitrogen lone-pair electrons are mainly delocalized in the π_4, π_2, and π_1 orbitals. The ionization potentials of the HOMO levels of these compounds, which are characterized by the large p_z contributions from the α-carbons, are the lowest among the hitherto known π-electron-excessive heteroaromatic compounds. 1,4-Dihydropyrrolo[3,2-*b*]pyrrole is concluded to be the system with the most efficient π-electron-donating ability among 10π-electron systems.

The purpose of this work is to elucidate the electronic character of 1,4-dihydropyrrolo[3,2-*b*]pyrrole in comparison with pyrrole and indole. Dihydropyrrolopyrroles are fundamentally important heteroaromatic compounds. These heterocycles are expected to be new candidates for conducting polymers and are also of interest from the standpoint of pharmacology.[1] Their electronic structures, however, have not been explored in detail. Although the photoelectron spectrum of the parent [2,3-*b*] isomer has been measured and analyzed by Gleiter et al.,[2] recent MNDO and ab initio MO calculations suggest that the proposed assignments of the first and the second bands are questionable.[1] Here, the He(I) photoelectron (PE) spectra of 1,4-dihydropyrrolo[3,2-*b*]pyrroles **1a—d** are reported and compared with the results of semiempirical MO calculations. In addition, the shifts of the bands induced by the alkyl substitutions are analyzed by a first-order perturbation method. This approach gives information on the assignments of ionizations and on the validity of the MO models used.

Experimental

Materials. The pyrrolopyrroles **1a** and **1c** were synthesized as has been reported formerly.[3] Their 1,4-dimethyl derivatives **1b** and **1d** were obtained by the reduction of the corresponding 1,4-bis(methoxycarbonyl) derivatives[3] with lithium aluminium hydride-aluminium chloride (3 : 1) in ether.

Measurements. The vapor phase He(I) photoelectron spectra of **1a—d** were measured with the PE spectrometer described in Ref. 4. Xe gas was used as the internal standard for the calibration of the energy scale.

Results and Discussion

The He(I) photoelectron spectra of the pyrrolopyrroles **1a—d** are shown in Fig. 1. The vertical ionization potentials and the results of MO calculations for the parent compound **1a** using the HMO[5] and MNDO[6] methods are listed in Table 1.

According to the empirically parameterized method

Table 1. Comparison of the Observed Vertical Ionization Potentials of **1a** with the Orbital Energies Calculated by the HMO and MNDO Methods

Band	I_v/eV	$-\varepsilon^{HMO}$/eV	$-\varepsilon^{MNDO}$/eV

Table 2. Comparison of the Observed Vertical Ionization Potentials (I_v) of **1b—d** with Those Calculated by the Perturbation Methods

Compound		I_v/eV				
	Band	[1]	[2]	[3]	[4]	[5]
	Obsd	6.95	7.48	9.00	10.67	11.68
1b	Calcd[a]	6.94	7.43	9.16	10.57	—
		$\pi_5(a_u)$	$\pi_4(a_u)$	$\pi_3(b_g)$	$\pi_2(b_g)$	
	Obsd	6.92	7.49	8.68	—	—
1c	Calcd[a]	6.66	7.43	8.53	—	—
		$\pi_5(a_u)$	$\pi_4(a_u)$	$\pi_3(b_g)$		
	Obsd	6.76	6.98	8.42	—	—
1d	Calcd[b]	6.59	6.92	8.42	—	—
		$\pi_5(a_u)$	$\pi_4(a_u)$	$\pi_3(b_g)$		

a) Calculated by the perturbation method. The reference standard compound is **1a**; $I_v^{calcd}=I_v^{obsd}$ (**1a**)$+\Delta I_v^{calcd}$.
b) Calculated by the perturbation method. The reference standard compound is **1c**; $I_v^{calcd}=I_v^{obsd}$ (**1c**)$+\Delta I_v^{calcd}$.

based on the first order perturbation theory, the vertical ionization potential changes (ΔI_v) of π bands induced by alkyl substitutions can be estimated by using the following formula:[7]

$$-\Delta I_{v,j}=a(\sum_{\alpha} C_{\alpha j}^2+m\sum_{\beta} C_{\beta j}^2)+b$$

where j denotes the j-th MO corresponding to the certain PE spectral band in question, $C_{\alpha j}$ is the AO coefficient of the atom α in the j-th MO at which a certain substitution is introduced, and $C_{\beta j}$ is the AO coefficient of the atom β just adjacent to the atom α. The a, b, and m are the empirical parameters for a certain substitution. The parameter m is a kind of damping factor and is put equal to 1/3, as in Ref. 7. The parameters a and b are reevaluated by the least-squares method using the ionization energy data of hydrocarbons and the AO coefficients obtained by the MNDO method.[8] The ionization potentials estimated by this method and the corresponding experimental values are summarized in Table 2.

For the first three bands of the parent compound **1a**, the orbital energies calculated by the HMO and the MNDO methods correlate reasonably well with the observed ionization potentials. Therefore, these bands are assigned, from the top, to the ionization from the π orbitals, $\pi_5(a_u)$, $\pi_4(a_u)$, and $\pi_3(b_g)$ respectively. In the cases of **1a** and **1b**, the 4th and the 5th bands are rather well resolved. The HMO calculation predicts that the ionization potentials for the $\pi_2(b_g)$ and the $\pi_1(a_u)$ orbitals of **1a** are 11.59 and 13.58 eV respectively. The former is close to the observed value of the 4th band, while the latter is much higher than that of the 5th band. From these results, the 4th and the 5th bands may be ascribed to the ionizations from the $\pi_2(b_g)$ orbital and the σ orbital respectively. On the other hand, our MNDO calculation and the ab initio calculation reported by Verbist et al.[1] predict that the 4th and the 5th bands should correspond to the ionizations from the $\sigma(a_g)$ and $\pi_2(b_g)$ orbitals respectively. It is difficult to assign these bands only on the basis of the MO calculations, but additional information can be obtained from a consideration of the substituent effects on the ionization potentials.

As is shown in Table 2, the perturbation method reproduces reasonably well the observed changes for the first three bands of the alkyl-substituted derivative **1b**. This finding supports both the above assignments of the first three bands of **1a** and the applicability of this method in the assignments of the spectra of the pyrrolopyrroles. In the PE spectrum of **1b**, shifts of 0.75 and 0.42 eV were observed for the 4th and 5th bands relative to those of **1a** respectively. The shift of the $\pi_2(b_g)$ band of the parent compound **1a** by *N,N'*-dimethylation is estimated to be 0.85 eV. (This value is very close to the energy difference between the 4th band of **1a** and that of the 1,4-dimethyl derivative **1b**, 0.75 eV.) Therefore, the 4th bands of these compounds are ascribed to the ionizations from their $\pi_2(b_g)$ orbitals. As a result, the 4th and the 5th bands of the pyrrolopyrroles (**1a** and **1b**) are assigned to the $\pi_2(b_g)$ and the $\sigma(a_g)$ orbitals, and their first three bands, to the $\pi_5(a_u)$, $\pi_4(a_u)$, and $\pi_3(b_g)$ orbitals from the top, respectively. In the case of compounds **1c** and **1d** also, the first three bands are unambiguously ascribed from the top to the ionizations from the $\pi_5(a_u)$, $\pi_4(a_u)$, and $\pi_3(b_g)$ orbitals respectively, based on the perturbation theoretical calculations. Furthermore, the reasonable correspondence between the observed band shifts and those calculated by the perturbation method supports the validity of the delocalized MO pictures for these compounds given by the MO calculations. Figure 2 shows the AO coefficients of the occupied π orbitals in **1a** with the HOMO levels of pyrrole [$\pi_3(a_2)$] and indole [$\pi_5(a'')$].

The above MO model indicates that the nitrogen lone-pair electrons of **1a** are mainly delocalized in the π_4, π_2, and π_1 orbitals. The HOMO level of the pyrrolopyrrole is characterized by large p_z contributions from the α-carbon atoms. This is similar with the nature of the pyrrole HOMO level and is in contrast with that of the indole HOMO level, which has large p_z contributions from the β-carbon atom. Consistent with these results, we have found that some electrophilic substitution reactions, which are known to occur at the β-position of indoles, take place selectively at the α-position of the pyrrolopyrroles.[9] The ionization potential of the HOMO level of the parent pyrrolopyrrole **1a** (7.27 eV) is lower than those of pyrrole (8.21 eV)[10] and indole (7.91 eV).[11] In the case of indole, the oxidation potential and basicity are almost the same as those of pyrrole, although the ionization potential is appreciably lower. In contrast with this, the oxidation potential of **1a** (0.51 V vs. SCE) is much lower than those of pyrrole (1.2 V) and indole (1.2 V).[3]

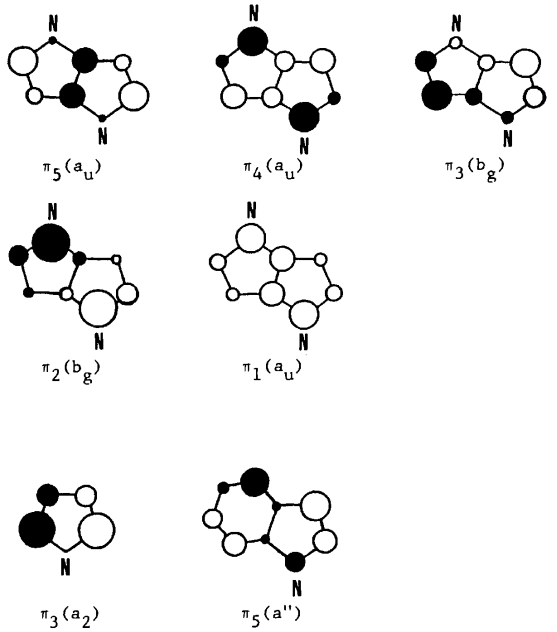

Fig. 2. Schematic representation of the occupied π molecular orbitals of 1,4-dihydropyrrolo[3,2-*b*]pyrrole, pyrrole, and indole given by the MNDO calculations.

The basicity (the pK_a value of the conjugate acid) of the pyrrolopyrrole **1c**, a stable derivative in acidic media, is +3.6; this value is much higher than those of pyrrole (−3.8)[12] and indole (−3.6).[13] In addition, it should be noted that the first ionization potential of **1a** is lower than those of the previously reported π-electron-excessive heterocycles; furan[5] (8.90 eV), thiophene[14] (8.90 eV), 1,6-dihydropyrrolo[2,3-*b*]pyrrole[2] (7.46 eV), thieno[2,3-*b*]pyrrole[2] (7.97 eV), thieno[3,2-*b*]pyrrole[2] (7.70 eV), thieno[2,3-*b*]thiophene[14] (8.32 eV), and thieno[3,2-*b*]thiophene[14] (8.10 eV). In conclusion, all the experimental results are consistent with the description of 1,4-dihydropyrrolo[3,2-*b*]pyrrole as a 10π-heteroaromatic compound possessing a more efficient π-electron-donating ability compared to the previously known π-electron-excessive heteroaromatic compounds.

8) The parameters *a* and *b* for methyl substitution were evaluated on the basis of the ionization energy data of the ethylene, butadiene, benzene, and naphthalene derivatives as reported in Ref. 7. The values are as follows: a=1.019±0.024 eV, b=0.043±0.016 eV. The standard deviation of $\Delta I_{v,j}$ is 0.036 eV. We applied these parameters for the assignments of the π bands of pyrrolopyrroles in this paper. These parameters are able to reproduce the shifts of the bands of pyrroles and indoles induced by *N*-methylations with a standard deviation of 0.044 eV. The parameters (a=1.316± 0.076 eV and b=0.042±0.069 eV) for *t*-butyl substitution were also estimated based on the data for ethylene, propene, and benzene derivatives. The standard deviation of $\Delta I_{v,j}$ is 0.087 eV. We did not estimate the band shift of the σ orbital by the perturbation method because of the complicated treatment. The photoelectron spectral datum of the parent [2,3-*b*] isomer has been published in 1977; at that time, the first and the second bands were assigned to the a_2 and the b_1 orbitals respectively.[2] Recent ab initio calculations, however, have called the proposed assignments into question.[1] Additional research using a perturbation method will be needed for the exact assignment.

Atropisomerism of Zinc Tetrakis(*o*-cyanophenyl)porphyrins. The Crystal Structure of the $\alpha\beta\alpha\beta$-Isomer and the Atropisomerization Rates

Keiichiro HATANO,* Kyoko KAWASAKI, Sonono MUNAKATA, and Yoichi IITAKA†
Department of Pharmaceutical Sciences, Nagoya City University, Mizuho-ku, Nagoya 467
†Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received December 3, 1986)

The structure of one of the four atropisomers of tetrakis(*o*-cyanophenyl)porphyrin has been determined as the zinc complex by X-ray crystallographic methods. The five-coordinate zinc porphyrin with pyridine as the axial ligand also has a pyridine solvate in the crystal lattice. The conformation of the *o*-cyanophenyl rings is $\alpha\beta\alpha\beta$ as predicted previously. The two nitrogen atoms of the CN groups on the same side of the coordinated pyridine have close *intramolecular* contacts to pyridine at the van der Waals distance. However, the structural parameters, bond distances and angles of this molecule do not indicate distinct steric effects of the CN groups. Thermal atropisomerization among the four zinc porphyrin atropisomers occurs in solution. The quantitative composition of the atropisomers at equilibrium and the rates of the isomerization reaction have been determined with aliquots separated by TLC. A nonstatistical equilibrium distribution of the atropisomers suggests some mutual interactions among the CN groups. The slower isomerization rates of the zinc complexes compared to those of the free base have been discussed in connection with the molecular structure.

The synthetic model study has been one of the most powerful approaches in probing the relationship between function and structure of the prosthetic heme group in multifunctional hemoproteins. The fundamental functions of hemes such as ligand binding and electronic state changes of the central iron are controlled by various factors including the electronic and steric effects of substituents of the porphyrin periphery. In recent years, the subtle control of the electronic properties of hemes has been investigated by means of a wide and systematic variation of the porphyrin peripheral substitution.[1-3] Steric control of the functions of hemes and metalloporphyrins is an interesting subject in the model studies considering the role of proteins. A typical steric control of oxygen binding to heme models has been accomplished notably as the "picket fence" porphyrin in which the role of the bulky pivaloylamino substituents on the one side of the porphyrin plane is attributed to the appropriate pocket for dioxygen binding and the hindrance for dimer formation.[4] However, there have been few studies to evaluate the steric effects quantitatively using a systematic variation of substituents and so on.[4d,5-7] We have been interested in the four atropisomers of *o*-substituted tetraarylporphyrin since there is a possibility in designing three dimensional models using the steric effect of the substituents under the isoelectronic conditions to control the functions of metalloporphyrin molecules. On this line, we have reported some properties of the tetrakis (*o*-substitutedphenyl)porphyrin atropisomers, i.e., electronic spectra, redox potential and metal incorporation rates, rotational rate of phenyl rings, and axial coordination reactions of bases.[7,8] The molecular structure determination of porphyrin atropisomers is expected to offer essential information as to the steric effects and the stereochemical environment around the porphyrin.

On the other hand, there is some ambiguity in the assignment of the conformation of $\alpha\beta\alpha\beta$- and $\alpha\alpha\beta\beta$-isomers of 5,10,15,20-tetrakis(*o*-cyanophenyl)porphyrin(ToCNPP[9]) free bases because of small difference in TLC separation and nonstatistical equilibrium population of these isomers.[8a] The present X-ray crystal structure determination originally aimed to establish the conformation of the $\alpha\beta\alpha\beta$-form and, subsequently, all conformations of the four atropisomers of ToCNPP. However, the ToCNPP free bases are thermally unstable and isomerize under the ambient recrystallization conditions. The coordination of metal ions to the porphyrin has been predicted to retard the rotational isomerization rate of the substituted phenyl rings.[10] Thus, the metallation of the porphyrin is expected to make it possible to isolate a pure isomer. At the same time, we are interested in the effect of the coordination of metal ions on the isomerization rate, its relationship to the structure of porphyrin, and the effect of axial ligands of the metal ion on the atropisomerization. Herein we report the X-ray structural analysis of the $\alpha\beta\alpha\beta$-isomer of ZnToCNPP and the atropisomerization rates among the isomers.

Experimental

Synthesis and Isolation of Atropisomers of ZnToCNPP. All reagents and solvents were reagent grade and used without further purification. ToCNPP was prepared as described.[8a] Metallation of ToCNPP was performed by refluxing zinc acetate and a mixture of the four atropisomers in DMF. The completion of the reaction was checked by UV-visible spectra recorded on a Shimadzu 200-S spectrophotometer. The products were precipitated by pouring an excess of water into the reaction mixture and were collected by filtration. The metallated porphyrins, ZnToCNPP, were separated by TLC (Merck; eluting solvent, 5:95 ether-

$CHCl_3$). The resolution of the four atropisomers is shown in Fig. 1 along with those of the corresponding ToCNPP and $ToNH_2PP$. The isolation of the respective atropisomers was accomplished by column chromatography on silica gel eluted with 98:2 chloroform-ether. The fractions of each isomer were evaporated to dryness immediately after elution from the column to avoid atropisomerization. The purity of each isomer was found to be more than 85%, satisfactory for the following kinetic experiments. Only the $\alpha\beta\alpha\beta$-isomer was purified further by recrystallization from chloroform-methanol, yielding purple crystals. Anal. Calcd for Zn(ToCNPP) $CHCl_3$, $C_{49}H_{25}N_8Cl_3Zn$: C, 65.57; H, 2.81; N, 12.48%. Found: C, 65.58; H, 2.51; N, 12.52%.

Crystal Structure Determination. Single crystals suitable for X-ray diffraction were obtained by vapor diffusion of pentane into a pyridine solution of the $\alpha\beta\alpha\beta$-isomer of ZnToCNPP. Crystals of $\alpha\beta\alpha\beta$-ZnToCNPP(Py)·Py were examined on a Philips PW-1100 automated diffractometer. This established a four-molecule monoclinic unit cell with *Cc* or *C2/c* as the possible space group. Least-squares refinement of the setting angles of 25 reflections gave the cell constants reported in Table 1. Table 1 also reports other details of crystal data and intensity collection. Intensity data were reduced to the structure factors without absorption corrections.

The choice of *C2/c* as the space group requires that the molecule possess a two-fold axis passing through Zn in porphyrin plane or an inversion center on Zn. However, the probable zinc locations calculated from the Patterson map lead to featureless difference Fourier maps and the Patterson map itself was incompatible with a crystallographic two-fold axis passing through the center of the tetragonal porphyrin molecule.[11] Thus, the *Cc* space group was chosen and all subsequent developments of the structure analysis of the complex were consistent with this choice.

A series of difference Fourier syntheses, phased initially by the zinc atom, revealed all non-hydrogen atoms of the porphyrin framework and a coordinated pyridine. After several cycles of refinement using these atoms, a difference Fourier map revealed six atomic positions of a solvate pyridine and several hydrogen positions of the porphyrin skeleton. The solvated pyridine was refined by assuming it as benzene i.e., six carbon atoms. All hydrogen atoms of the porphyrin and coordinated pyridine were idealized with C-H=0.95 Å and assigned isotropic temperature factors one unit higher than the associated atom. Refinement was then carried to convergence with anisotropic temperature factors for all non-hydrogen atoms using the block-diagonal least-squares and two-block 'full matrix' least-squares method.[11] At covergence, the final R and R_w values were 0.053 and 0.051, respectively. Calculations for the opposite enantiomorph gave R=0.059 and R_w=0.061. The coordinates of the first choice are reported. A final difference Fourier synthesis was featureless (<0.48 e/Å^3). A listing of observed and calculated structure factors is available as supplementary material (Table S1[12]). Tables 2 and S2[12] list final atomic coordinates with isotropic equivalent temperature factors and the associated anisotropic temperature factors, respectively.

Table 1. Summary of Crystal Data and Intensity-Collection Parameters for ZnToCNPP(Py)·Py

Formula	$ZnC_{58}H_{34}N_{10}$

R_w	0.051
Data/Parameters	6.3

Atropisomerization. A toluene or 1,1,2-trichloroethane solution of each isolated isomer (ca. 5 mg/20 ml) in a flask was placed in a heated oil bath. Aliquots sampled by a glass capillary were spotted at intervals on TLC and developed with 95:5 $CHCl_3$-ether. The separated isomers were extracted two times with $CHCl_3$ and diluted to a constant volume in a cuvette. The quantity of the four isomers was analyzed by the spectrometric absorption area in the 390—450 nm region and was normalized to a molecular ratio of four atropisomers. The rates of isomerization were determined by a combination of the Runge-Kutta simulation and least-squares curve-fitting techniques.[8]

Results and Discussion

Molecular Structure of $\alpha\beta\alpha\beta$-Zn(ToCNPP)(Py). The structure of the ZnToCNPP(Py) molecule is shown in two different orientations in Figs. 2 and 3,

Table 3. Average Values of Bond Distances and Angles of the Porphyrin Skeleton in ZnToCNPP(Py)·Py

		Bond Distance/Å			
$Zn-N_{por}$	2.076(12)	$N_{por}-Ca$	1.369(11)	Ca-Cb	1.444(13)
Cb-Cb	1.347(14)	Ca-Cm	1.398(8)		
		Bond Angle/deg.			
$Zn-N_{por}-Ca$		126.2(5)	$N_{por}-Ca-Cb$		109.5(4)
$Ca-N_{por}-Ca$		106.8(4)	$N_{por}-Ca-Cm$		125.4(4)
Ca-Cm-Ca		125.9(4)	Ca-Cb-Cb		107.1(9)

Ca, Cb, and Cm denote atoms of pyrrole-α, pyrrole-β, and methine(5,10,15,20-) positions of porphyrin skeleton, respectively.

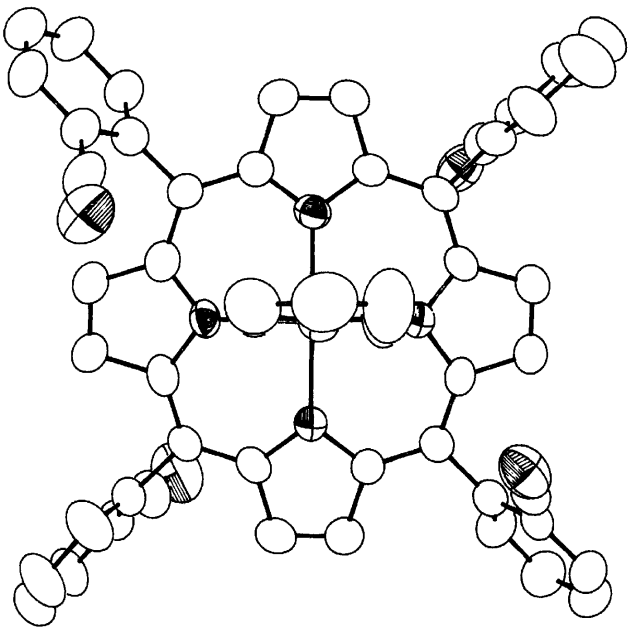

Fig. 3. Perspective view of the ZnToCNPP(Py) molecule looking down the nomal of the porphyrin plane, showing the relative orientation of coordinating pyridine and geometry of the CN groups.

which demonstrate the most significant feature of the molecule: The arrangement of the CN groups and nonbonded intramolecular contacts between the CN group and the coordinated pyridine. Figure 2 also gives the labels assigned to each non-hydrogen atom. The structure is in agreement with the conformation ($\alpha\beta\alpha\beta$) of the atropisomer identified previously by chemical properties and chromatographic separation, i.e., the atropisomer eluting most rapidly on silica gel and consequently being least polar.

Average values for the chemically equivalent bond lengths and angles of the porphinato core are given in Table 3. The numbers in parentheses are the standard deviations calculated from the differences between the average of the equivalent bonds and the individual values (Table S3[12]).[13]

The coordination state of the present zinc porphyrin is five-coordinate with a pyridine molecule in the fifth axial position. The coordination sphere around Zn is apparently normal. The average $Zn-N_{por}$ bond length of 2.076 (12) Å and the displacement (0.37 Å) of the zinc ion out of the mean plane of the four porphinato N atoms are in general accord with those observed in the five-coordinate zinc porphyrins as shown in Table 4. The $Zn-N_{py}$ bond length of 2.151 (4) Å does not display any elongation due to a steric effect between the pyridine and the two CN substituents projecting toward pyridine. Indeed the bond length is significantly shorter (by 0.049 Å) than the 2.200 (3) Å value reported for Zn(OEP)(Py)[14] which has no hindering substituents on the porphyrin periphery. This indicates that the CN substituents on the ortho position in the $\alpha\beta\alpha\beta$ phenyl conformation have little steric effect on the coordinated pyridine molecule, or, even if there is any, the effect is not necessarily hindering or repulsive.

The dihedral angle between the axial pyridine plane and the plane containing three nitrogen atoms, those of pyridine and two opposite pyrroles of the porphyrin core, is small at 8.8°. The actual ligand orientation

Table 4. Comparison of the Stereochemical Parameters of the Coordination Group for Five-Coordinate Zinc Porphyrins

Zn Porphyrin	Distance/Å			ϕ/°	Ref.
	$Zn-N_{por}$	$Zn-N_{Py}$	Zn-Ct		
$ZnTPP(H_2O)$	2.05	2.20*	0.19	—	(15)

ZnToCNPP	2.076(12)	2.151(4)	0.37	8.9	This work

* $Zn-O_{water}$ distance.

would appear to have ϕ[18] closer to a completely eclipsed conformation (i.e. ϕ=0°); the apparent value of 8.8° results in part from the pyridine plane not being precisely perpendicular to the 24-atom porphinato plane, the angle is 77.0°. As reported in Table 4, the ligand orientation of five-coordinate zinc porphyrins have, in general, small values. This means that sterically unfavoring contacts between α-hydrogen of pyridine and porphinato pyrrole nitrogen result if no other constraint controls the orientation. Although the constraint of the side arm has been explained to lead to an exceptionally small ϕ value of Zn(TPP side arm Py),[17] the present structure indicates no distinct evidence that the orientation of the ligand is controlled by the CN substituents. The closest contact of N_{CN} to non-hydrogen atoms of the coordinated pyridine is 3.49 Å (NC2-CP2), which is a normal van der Waals contact. Even if there would be a closer contact, it can be circumvented by the small rotation about the aryl-porphine bond. There is a considerable room for the rotation since the dihedral angles between cyanophenyl rings and the mean porphyrin plane are 73.3° and 64.7° on the pyridine side and 77.9° and 87.8° on the other side.

Recently, Scheidt et al. suggest that the electronic spin-state is one of the important factors correlating with ligand orientation in some iron(III) porphyrin cases.[19] The zinc ion has a d^{10} electronic configuration and all five 3d orbitals are occupied by spin-paired electrons, hence, the drastic changes in the electronic states or spin states depending implicitly on the change of axial ligands, bond lengths, or ligand orientation are *not* expected for zinc porphyrins. Consequently, the small orientation angle observed in all of the pyridine-ligated zinc porphyrins reported so far should be explained by an intrinsic electronic nature of zinc(II) ion. A possible explanation comes from consideration of the overlap of the occupied d_{zx} or d_{yz} orbital over pπ* at the N_{Py} atom, namely dπ-pπ* backdonation, because the d_{zx} or d_{yz} has a common nodal plane with pπ* at ϕ=0°.

The structural similarity of six- and five-coordinate porphyrin complexes of zinc(II) and high-spin iron(II) has been pointed out by Schauer et al.[20] The similarity includes the bond distances between the metal ion and porphinato nitrogen atoms and the axial N_{base}-metal bond length. The structural similarity can also extend to five-coordinate high-spin iron(III) complexes since a novel structure of five-coordinate [Fe(OEP)(2Mim)]ClO_4 molecule has been determined recently.[21] The structural parameters, 2.038(6) Å for average Fe-N_{por}, 2.068(4) Å for Fe-N_{2Mim}, and 0.35 Å for displacement of Fe(III) out of plane, are comparable to those of five-coordinate zinc porphyrins in Table 4. Here, a small orientational angle (ϕ=3.0—7.3°) of the 2-methylimidazole ligand can be particularly emphasized as part of the similarity. This suggests that the occupation of electrons in all of the five 3d orbitals has an essential and common effect on the coordination structure in porphyrin complexes of these two metal ions.

The structure of four peripheral cyanophenyl groups shows no abnormal feature in the bond distances and angles irrespective of whether the CN substituents are on the same side as the coordinated pyridine or not. The CN group is coplanar to each phenyl ring within 0.07 Å from the mean plane. Figure 4 shows the average bond parameters for the four chemically equivalent types with the standard deviations in parentheses. The average C-C_{CN} bond length is 1.411(13) Å, similar to the C-C bonds of the phenyl ring. Thus, the bond has a conjugated double bond character. The C≡N distance ranges from 1.128(8) Å to 1.184(9) Å and the average is 1.151(24) Å. These bond values agree well with those of benzonitrile or cyanomethanide ion disregarding whether the molecule or ion is free or coordinated to a metal.[22,23]

The nonbonded intramolecular N_{CN}-N_{CN} atomic distances are measured to be 9.15 Å at a level 3.2 Å above the porphyrin plane on the pyridine side and 8.56 Å at a level 3.4 Å below the plane on the other side. These distances correspond to a diameter of the cavity defined by the CN substituents. The diameter is comparable with the interior size of some inclusion compounds, e.g., ca. 8.5 Å for cyclohexaamyloses or ca. 8.6 Å for cyclophanes.[24,25] We have noted previously that the free base atropisomers (ToCNPP) populate in a nonstatistical equilibrium ratio (cf. Fig. 1) because of the mutual nonbonded interaction of the CN substituents on the same side of the porphyrin plane. A similar nonstatistical distribution is also observed in ZnToCNPP. The rather large diameter of the cavity requires the idea of the nonbonded tran-

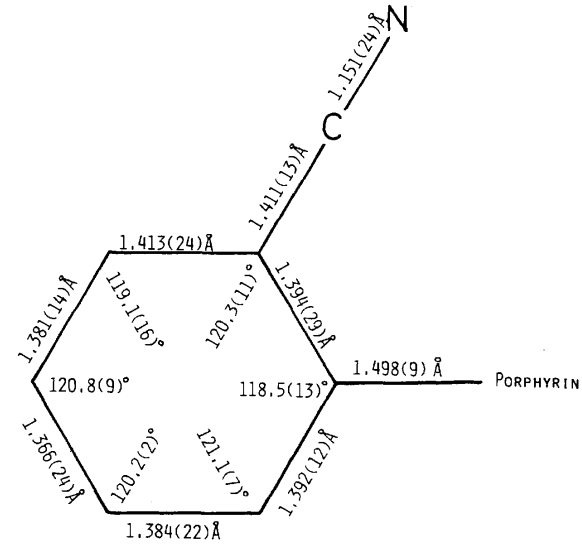

Fig. 4. A formal diagram of the average structure of four cyanophenyl rings of the molecule. Average values of bond distances and angles are displayed with the standard deviations[13] of the least significant digits in parentheses.

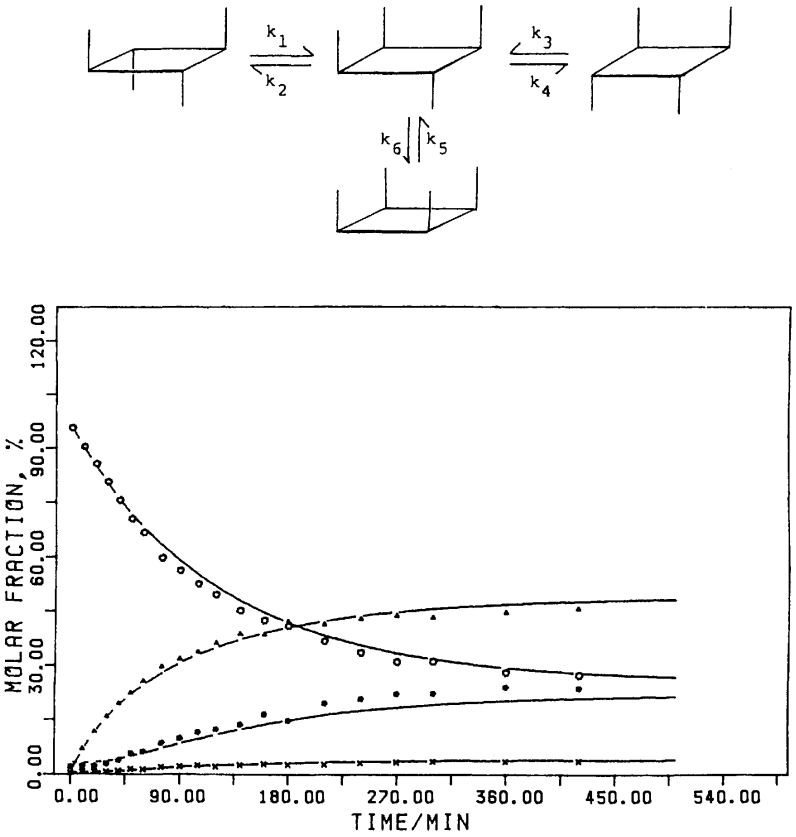

Fig. 5. The reaction scheme of the atropisomerization and a time course diagram of the reactions initiating from $\alpha\beta\alpha\beta$-isomer of ZnToCNPP at 96 °C, (○) $\alpha\beta\alpha\beta$; (●) $\alpha\alpha\beta\beta$; (▲) $\alpha\alpha\alpha\beta$; (×) $\alpha\alpha\alpha\alpha$. The solid lines in the diagram were computed by the Runge-Kutta method from the rate constants in Table 5.

sannular interaction to be not necessarily direct but maybe indirect through axial ligands or solvents in the vicinity of the cavity.

The maximum displacement from the 24-atom mean porphyrin plane is as small as 0.16 Å of the CB2 atom, namely, the porphyrin skeleton is fairly planar for ZnToCNPP. Although there seems to be no clear-cut general interpretation as to whether the porphyrin takes planar or "ruffled" skeleton depending on the metal ions and so on, the zinc coordination has a trend in favor of the planar structure. The planar structure of the porphyrin core may correlate with the inflexibility of the core for the deformation required in the transition state of the atropisomerization reaction as discussed below.

Atropisomerization of ZnToCNPP. Figure 5 depicts schematic isomerization reactions among the atropisomers along with the definition of rate constants and a typical result of kinetic experiments. The relative ratio of the amount of four atropisomers equilibrating at 96 °C for 2 d was as follows: $\alpha\alpha\alpha\alpha$,5 (2); $\alpha\alpha\beta\beta$, 48 (4); $\alpha\alpha\beta\beta$, 22 (4); $\alpha\beta\alpha\beta$, 25 (3). The ratio was found to be independent of temperatures in the range of 75° to 105 °C within the experimental deviations in parentheses. The individual reaction rates were investigated in several independent runs at 65, 75, 85, 96, and 105 °C. The observed average rate constants are listed in Table 5. Considering the constant population of the isomers in the equilibrium at any temperature in our experiments, we analyzed the rates by obtaining first the average Arrhenius activation energy (E_a) and then individual preexponential terms for six rate constants using the least-squares method. This treatment demands a constant ratio in the six rate constants at any temperature. The ratio is $1:0.51:2.9:1.3:5.3:0.46$ for $k_1:k_2:k_3:k_4:k_5:k_6$. The thermodynamic parameters could be obtained by the use of relation-

Table 5. Observed Rate Constants for Atropisomerization Reactions of Tetrakis(*o*-cyanophenyl)-porphinatozinc(II)

Temperature	Observed Rate Constant ($\times 10^5$)/s^{-1}

ships, $\Delta H^*=E_a-RT$ and $\Delta G^*=\Delta H^*-T\Delta S^*$, and the Eyring equation, $k=(k_BT/h)\exp(-\Delta G^*/k_BT)$. The values for the one representative reaction (k_1) are shown in Table 6. The kinetic data processed as above were consistent with all of the observed rate constants within the experimental errors. The activation parameters calculated similarly for the same reaction (k_1) of ToCNPP[8a)] and ToNH_2PP[8b)] are also shown in Table 6 for comparison.

The slower rates of ZnToCNPP relative to those of ToCNPP are remarkable. The ΔG^* value of 118.9 kJ mol^{-1} at 85 °C is high and comparable to the 113.1 kJ mol^{-1} value at 81 °C reported for the bulky hexadecyl derivative of ToNH_2PP.[26)] The phenyl ring rotation in *o*-substituted tetraarylporphyrins is thought to require the severe deformation of the porphyrin skeleton. The slow rates of the Zn complex suggest that the zinc ion coordination (perhaps metal ion coordination in general) brings a reinforcement of the skeletal tension against the required deformation. The higher free energy of activation of ZnToCNPP, consequently the slower rate, compared to that of ToCNPP at 60 or 65 °C also reflect the reinforcement as the part of the stabilization energy of the porphyrin acquired by the incorporation of the zinc ion. The reinforcement effect seems to correlate with the enthalpy term of the free energy of activation because of the identical entropy values obtained from the reactions of ZnToCNPP and ToCNPP (Table 6). This is contrasting with the entropy control of activation observed in a series of the free base porphyrins with bulky *o*-substituents.[8b)]

The retardation factor of the isomerization reaction induced by the coordination of zinc reaches about 20 at 60 °C and the factor is appreciably larger than the apparent value of 12.5 calculated from the data for the ToOHPP-Cu system.[10)] The difference in the retardation factor may come from the difference in the porphyrin core expansion by the two metal ions. In this connection, the bond length between the metal and the porphyrin nitrogen can be cited as 1.981 Å for CuTPP[27)] and 2.036 Å for ZnTPP:[28)] both metalloporphyrins are four-coordinate; CuTPP is ruffled whereas ZnTPP is planar.[29)] Thus, the coordination of zinc ion is thought to bring forth not simply the reinforcement against deformation but also to some extent as expansion effect on the porphyrin skeleton. The expansion of porphyrin core should weaken the transannular interaction among *o*-substituents on the same side of the porphyrin plane. This may be a possible explanation for why the equilibrium distribution of atropisomers of ZnToCNPP becomes closer to the statistical ratio than that of metal-free ToCNPP. We have speculated that the nonbonded distance between two adjacent nitrogen atoms of CN group is responsible for the nonstatistical isomer distribution.[8a)] However, the transannular interaction occur not always through the directly measured *intramolecular* distance since short *intermolecular* contacts such as van der Waals distance are frequently observed in the solid state. In solution, the intramolecular transannular interaction must be affected by the solvent molecule therein, especially the coordinating impurities in the case of metalloporphyrin. The present five-coordinate ZnToCNPP structure demonstrate a possibility of some interaction through the coordinated pyridine by the shortest contact of 3.49 Å with the CN substituent as mentioned above. The addition of pyridine as an effector into the reaction solution did not give distinct changes in the equilibrium distribution of isomers. A drastic change was observed in the presence of some other particular molecules such as 2Mim[9)] in the reaction mixture. The observed distribution in the presence of 2Mim is as follows: $\alpha\alpha\alpha\alpha$, 15(3); $\alpha\alpha\alpha\beta$, 52(5); $\alpha\alpha\beta\beta$, 19(4); $\alpha\beta\alpha\beta$, 14(3). This is almost the statistical ratio. Although the details of the mechanism and effect of 2Mim or other ligands on the atropisomerization is forthcoming, the effect must be due to the interaction through 2Mim coordinated to ZnToCNPP. This is a novel control of the rotational isomerization by the steric effect of the axial ligand. By this axial ligand effect, the distribution ratio is controlled in the favor of the $\alpha\alpha\alpha\alpha$-form.

We thank the Ministry of Education, Science, and Culture of Japan for support of the part of this work under a Grant-in-Aid for Scientific Research (#60571024). We acknowledge the discussions on the crystal structure of ZnToCNPP(Py)·Py with Professor W. R. Scheidt.

The Molecular Structure of Tricarbonyl(triple-layered [2.2]-paracyclophane)chromium at −95°C(Monoclinic Form) and −160°C (Triclinic Form)†

Hitoshi OIKE,†† Yasushi KAI,* Kunio MIKI, Nobuo TANAKA,††† and Nobutami KASAI*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received December 5, 1986)

The tricarbonylchromium complex of triple-layered [2.2]paracyclophane shows a reversible phase transition in the solid state from the monoclinic to the triclinic form at a temperature between −100 and −110 °C. The monoclinic form crystallizes in the space group $P2_1/c$, with a=15.095(6), b=9.950(3), c=15.641(5) Å, β=103.46(3)° (−95 °C), and Z=4: The triclinic form belongs to the space group $P\bar{1}$, with a=15.037(5) Å, b=9.913(2), c=15.662(5) Å, α=89.41(3), β=104.51(3), γ=89.39(4)° (−160 °C), and Z=4. In the triclinic crystal, two molecules are crystallographically independent. The crystal structures were solved by the direct method and then refined by the block-diagonal least-squares procedure to the R indices of 0.067 for 3530 (monoclinic form) and 0.079 for 6776 (triclinic form) observed reflections. No essential difference is found between the structures of the monoclinic-form molecule and the two triclinic-form molecules. The interlayer distance between the upper-layer benzene ring coordinated to the $Cr(CO)_3$ group and the middle-layer benzene ring is unusually shorter than the corresponding distance between the middle- and lower-layer benzene rings. No bond alternation is found in the upper-layer benzene ring, unlike as in the tricarbonyl(benzene)chromium complex and the (tricarbonyl)chromium complex of double-layered [2.2]paracyclophane. The phase transition of the crystal can be explained by a slight change in the molecular packing.

In a series of structural studies of layered cyclophanes, the X-ray structure determination of the (tricarbonyl)chromium complex of double-layered [2.2]-paracyclophane (TCPC).[1] has been carried out. The molecular structure of TCPC showed an unusual shortening of the distance between two benzene rings compared with the corresponding distances in other double-layered [2.2]paracyclophanes, [2.2]paracyclophane (PC),[2] 4,7,13,16-tetramethyl[2.2]paracyclophane (TMPC),[3] and 4,7-dimethyl[2.2]paracyclophane (DMPC).[3] Stimulated by this interesting feature of the [2.2]paracyclophane structure, we then determined the molecular structure of the (tricarbonyl)chromium complex of triple-layered [2.2]paracyclophane (TC3PC) by means of X-ray diffraction. A low-temperature experiment on the TC3PC revealed a reversible phase transition between the monoclinic and triclinic forms. The molecular structures determined are compared with that of 12-bromo(triple-layered [2.2]paracyclophane) (BR3PC),[4] which is the only example of a triple-layered [2.2]paracyclophane whose structure has been determined by the X-ray diffraction method.

Experimental

All the X-ray measurements were undertaken on a Rigaku automated, four-circle diffractometer with graphite-monochromatized Mo$K\alpha$ radiation. A Rigaku low-temperature apparatus was attached to the diffractometer, and the low temperature was attained by the gas-flow method of liquid nitrogen. During the process of cooling the crystal down to −160 °C from room temperature, an interesting phase transition has been found. At a temperature between −100 and −110 °C, the split and complexity of the diffraction profile of the monitor reflections were observed. At temperature below −110 °C, the profile of the same diffraction became sharp and simple again. These changes were observed reversibly. The process of the phase transition was confirmed by the oscillation photographs which were taken on the four-circle diffractometer by the use of a special film-cassette and ω-oscillation mechanism. It was revealed that the crystal belongs to the monoclinic system at −80 °C and to the triclinic system at −130 °C. The X-ray diffraction data have been collected at −95 °C for the monoclinic form and at −160 °C for the triclinic form with the same crystal. The crystal data are listed in Table 1. The triclinic form has two crystallographically independent molecules per unit cell.

The integrated intensities were measured by the θ-2θ scan technique at a 2θ scan rate of 4° min^{-1} in the range of $\Delta 2\theta=(2.0+0.7\tan\theta)°$. The backgrounds were counted for 5 s before and after the scan of each peak. Totals of 3530 and 6776 observed reflections [$|F_o|>3\sigma(F_o)$] were collected up to 2θ=54 and 50° for the monoclinic and triclinic forms respectively. The intensity data were corrected for the usual Lorentz and polarization effects, but not for the absorption [μ(Mo$K\alpha$)=5.5 and 5.6 cm^{-1} for monoclinic and triclinic crystals].

Structure Solution and Refinement

The crystal structures of the monoclinic and triclinic forms of TC3PC were solved by the direct method (*MULTAN* 78)[5] and were refined by the block-diagonal least-squares procedure (*HBLS* V),[6] with anisotropic temperature factors for nonhydrogen atoms and isotropic temperature factors for hydrogen atoms. The final R indices are 0.067 and 0.079 (R_W=0.083 and 0.135) for 3530 and 6776 observed reflections of the monoclinic and triclinic forms respectively. The weighting scheme used was $w=\{\sigma^2(F_o)+a|F_o|+b|F_o|^2\}^{-1}$. The weighting parameters

used at the final stage of the refinement were: a=0.0767 and b=0.0005 for the monoclinic form and a=0.2271 and b=0.0032 for the triclinic form. The final atomic parameters of both forms are listed in Table 2.††††

The atomic scattering factors for the Cr, O, and C atoms were taken from the International Tables for X-Ray Crystallography, Vol. IV,[8] and those for H atom, from Stewart, Davidson, and Simpson.[9] Calculations were done on an ACOS 900 computer (Computation Center) and, at the final stage, on an ACOS 850 computer, (Crystallographic Research Center, Institute for Protein Research), Osaka University.

††††Tables of the anisotropic temperature factors, the coordinates of the hydrogen atoms, and the observed and calculated structure factors are kept at the Chemical Society of Japan, Document No. 8735.

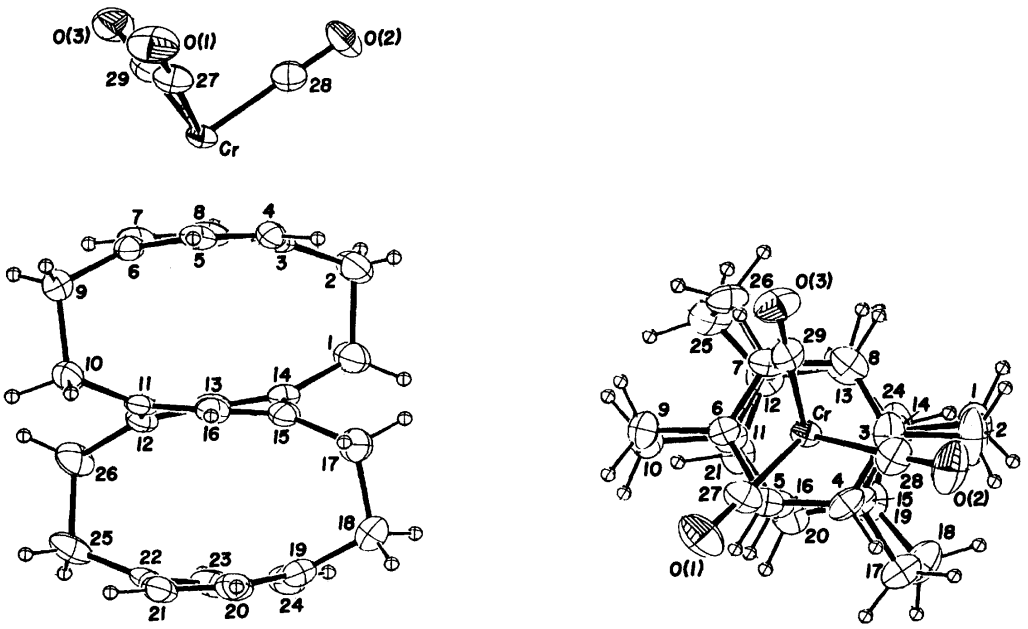

Fig. 1. A perspective view[10] of the molecule, together with the numbering scheme of the nonhydrogen atoms. Nonhydrogen atoms are drawn as thermal ellipsoids with 30% probability level, and the hydrogen atoms as spheres with B=1.0Å^2. a) Projected down from the C(16) to C(13) atoms in the middle layer benzene ring, b) projected onto the base plane of the upper layer benzene.

Results and Discussion

Molecular Structure. A perspective view (*ORTEP* drawing[10]) of the TC3PC molecule of the monoclinic form is shown in Fig. 1, along with the numbering scheme of the atoms. The interatomic bond distances and angles in the monoclinic-form and triclinic-form molecules are given in Table 3. Other important structural parameters of the cyclophane skeleton in the three TC3PC molecules are compared in Table 4 with those of BR3PC and TCPC. No essential difference is found between the structures of the one monoclinic-form molecule and the two triclinic-form molecules. Therefore, the discussion hereafter will be done on the molecular structure of the monoclinic form unless otherwise stated.

Some remarkable features of the triple-layered [2.2]paracyclophane moiety are observed. Both the upper- and lower-layer benzene rings take the boat form. This fact is commonly observed for the outermost benzene rings of multiple-layered [2.2]paracyclophanes. The upper-layer benzene ring in the present complex is less deformed from the plane than that of the lower layer benzene ($p+q<p'+q'$ in Table 4). On the other hand, the second layer benzene ring is twisted along the line passing through the C(13) and C(16) atoms, which are not linked by $-CH_2-CH_2-$ bridges; the twist angle is 13.4°, which is equal to that [13.4°] in tetramethyl quadruple-layered [2.2]paracyclophane.[11]

Table 4. Mean Molecular Structures of TC3PC and Related Compounds

	TC3PC			BR3PC[4]	TCPC[1]
	Monoclinic form (−95°C)	Triclinic form (−160°C)			
		Molecule 1	Molecule 2		
Upper-layer benzene ring

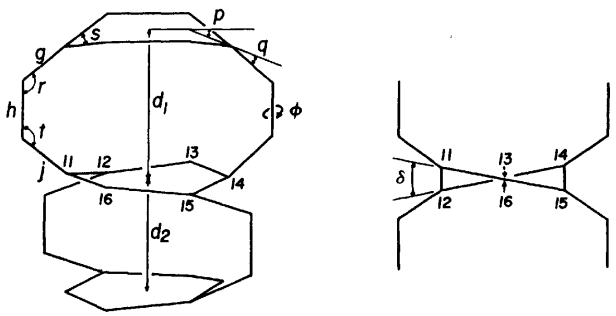
q'/°	12.5	12.8	9.5		11.2
s'/°	116.6	117.2	118.0		116.9
Interring distances between upper and middle (d_1) and between middle and lower benzenes (d_2)					
d_1/Å	2.979	3.004	2.989	3.046	
d_2/Å	3.057	3.053	3.049	3.046	



The C-C distances of the -CH_2-CH_2- bridges are 1.591(7) and 1.586(8) Å (from the upper layer to the middle) and 1.579(8) and 1.580(8) Å (from the middle layer to the lower), values which are comparable to those of TCPC [1.591(7) and 1.599(8) Å] and much longer than the usual C-C single bond. The torsional angles around the -CH_2-CH_2- bond between the upper and middle layers [13.2 and 9.7°] are much smaller than those between the middle and lower layers [20.1 and 23.6°]. As may be seen in Fig. 1(b), the three benzene rings are not in the eclipsed position; they are mutually rotated slightly in a helical way, similar to those in BR3PC and inner triple-layered paracyclophanequinone.[12]

The $Cr(CO)_3$ group in tricarbonyl(benzene)chromium (TCB)[13] takes the staggered configuration to the benzene ring because of the crystallographic mirror symmetry of the molecule, each of the three Cr-C≡O branches projected is perpendicular to the C-C bond of the benzene ring. The C-C bond distances in the benzene ring show a bond alternation. The $Cr(CO)_3$ in TCPC shows a slight deviation from the staggered position. The mean angular deviation (θ_{av}) of a Cr-C≡O branch from the staggered configuration is 3.6° in TCPC, while the remainder of the bond alternation can be seen in the upper-layer benzene ring. In the present complex, the relative positions of the $Cr(CO)_3$ group projected onto the upper-layer benzene

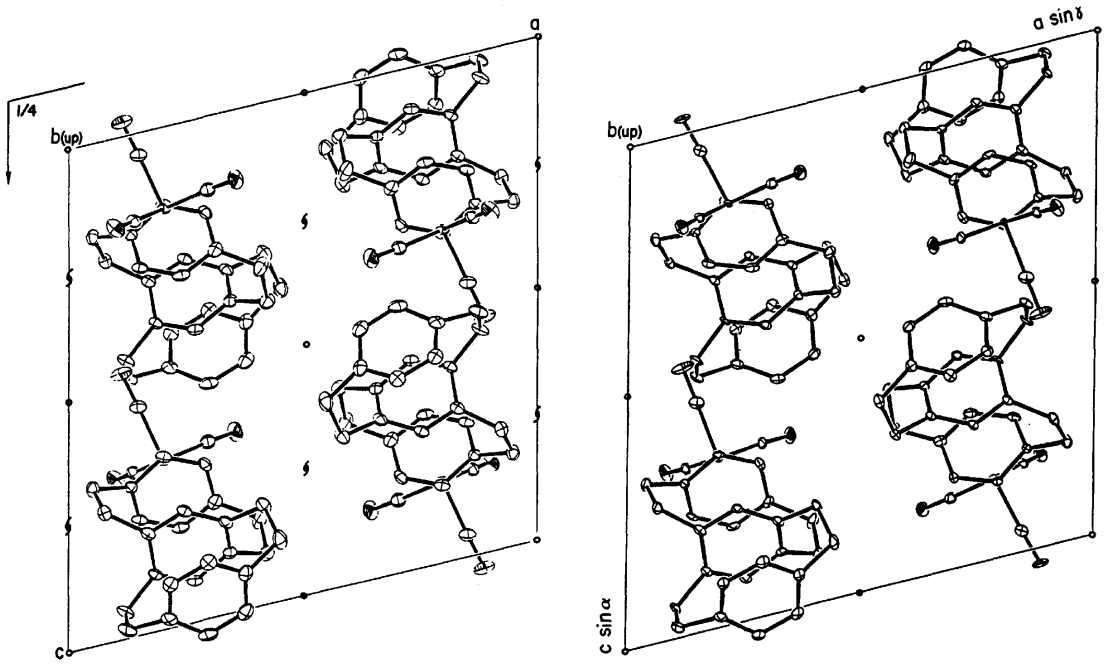


Fig. 2. Crystal structure projected along the b axis.[10] a) Monoclinic form, b) Triclinic form.

ring in the monoclinic- (θ_{av}: 15.6°) and triclinic-form (θ_{av}: 18.9 and 18.4°) molecules are in between the staggered and eclipsed configurations. No bond alternation is observed in the upper-layer benzene rings in these complexes.

The interlayer distances from the base planes of the boat-shaped upper- and lower-layer benzene rings to the least-squares plane of middle-layer twisted benzene are compared with those in BR3PC in Table 4. In TC3PC, the d_1 distance between the upper- and middle-layer benzene rings is significantly shorter than the d_2 distance between the middle- and lower-layer benzenes. The d_2 distances are essentially equal to that in BR3PC. The shortening of the d_1 compared with d_2 results from the strong electron-withdrawing effect of the $Cr(CO)_3$ group coordinated to the upper-layer benzene. However, the electronic effect of the $Cr(CO)_3$ group may not account for the shortening of d_2. The shortening of the interlayer distance by the coordination of the $Cr(CO)_3$ group to the benzene has also been found in the crystal structure of TCPC.

Crystal Structure. The packing of the molecules in the monoclinic- and triclinic-form crystals are shown in Fig. 2. The corresponding space group of the crystal changed from $P2_1/c$ to $P\bar{1}$ upon cooling. A slight difference is observed between the crystals of the two forms in their unit-cell dimensions (0.38% in a, 0.37% in b, and 0.13% in c; Table 1). Intermolecular contacts shorter than 3.5 Å were found between an oxygen atom of the $Cr(CO)_3$ moiety and a carbon atom of the upper-layer benzene ring or that of a $-CH_2-CH_2-$ bridge; in a monoclinic crystal: C(7)(x, y, z)···O(1)(x, 0.5−y, −0.5+z)=3.416(6) Å, in a triclinic crystal: C(1^{ii})(x, y, z)···O(2^{ii})(x, 1+y, z)=3.404(8) Å, C(4^{i})(x, y, z)···O(1^{ii})-($1-x$, $1-y$, $1-z$)=3.420(9) Å, and C(2^{i})(x, y, z)···O(2^{ii})($1+x$, y, z)=3.383(8) Å, where the superscripts i and ii show the two independent molecules.

The authors wish to express their deep thanks to Professor Soichi Misumi and his coworkers of the Institute of Scientific and Industrial Research, Osaka University, for supplying the crystals and for their helpful discussions.

Stabilization of Platinum-Loaded CdS Photocatalyst by Addition of EDTA

Michio MATSUMURA,* Hideyuki OHNISHI, Koji HANAFUSA, and Hiroshi TSUBOMURA
Laboratory for Chemical Conversion of Solar Energy and Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received December 6, 1986)

The photocatalytic activity of platinum-loaded CdS powder in sulfite solutions declined by illumination over 200 h, and became half the initial activity at 600 h. By addition of small amount (2 mM) of ethylenediaminetetraacetic acid (EDTA) to the solution, however, the photocatalyst was guarded from deterioration. The effect of EDTA is to prevent the platinum part of photocatalyst from the impurity metal deposition by forming stable metal-EDTA complexes in the solution. The reactivities of sulfite ions, EDTA, and metal-EDTA complexes on illuminated CdS are examined electrochemically by use of CdS-sinter electrodes.

A variety of photocatalytic reactions are induced by semiconductor particles. Hydrogen and many organic compounds are produced from aqueous solutions of organic materials, such as alcohols, aromatic hydrocarbons, etc., over the illuminated semiconductor particles loaded with noble metals.[1,2] Hydrogen production occurs also from aqueous solutions of inorganic materials, such as sulfide ions.[3,4] Efficient hydrogen production from aqueous solutions of sulfite was reported by use of noblel metal loaded CdS powder,[5-8] the sulfite ions being oxidized to sulfate and dithionate ions. This photocatalytic reaction is interesting from the viewpoint of industrial waste disposal.

The platinum-loaded CdS photocatalyst used for the hydrogen production from sulfite solutions was stable for 65 h in our previous experiment.[5] Ciba-Geigy group reported that the photocatalyst was deactivated after 6 d.[7] In this paper, the durability of the photocatalyst and its stabilization by addition of EDTA to the solution is reported.

Experimental

Photocatalytic Reaction. CdS powder of 99.999% purity purchased from Furuuchi Chemical Co., Inc. was used after heat treatment at 700 °C for 2 h under a nitrogen stream. The particle size after the heat treatment was ca. 2 μm. For the platinum loading, the CdS powder was shaken with platinum powder (Japan-Engelhard) in a glass vessel for 1 h. Aqueous solutions were prepared by use of deionized water having resistivities higher than 3.3 MΩ cm. The pH was adjusted at 8.4 by addition of boric acid (0.3 M, 1 M=1 mol dm^{-3}) and sodium hydroxide. All chemicals used were of reagent grade.

In a 100-ml glass flask, 0.5 g photocatalyst was suspended in a 50 ml sodium sulfite solution. The suspension was illuminated with a 500-W high-pressure mercury lamp, after it was deaerated by bubbling with high purity nitrogen gas for 15 min. The evolved hydrogen gas was introduced into a measuring cylinder.

Electrochemical Measurements. The CdS sintered disks for use as electrodes were prepared from CdS powder by use of a hot press under pressure of 1×10^7 Pa at 750 °C for 6 h in a nitrogen atmosphere. Electrochemical measurements were performed in a three-electrode cell with a sintered CdS electrode, a platinum counterelectrode, and an Ag/AgCl reference electrode under potentiostatic and galvanostatic conditions. A tungsten-halogen lamp was used as the light source for the photoelectrochemical measurements.

Results

The photocatalytic hydrogen evolution from sulfite solutions proceeded in our experimental conditions at the initial rate of ca. 2.7×10^{-3} mol h^{-1}. It declined to nearly zero after 50 h as shown in Fig. 1, as the sulfite ions were consumed, and the pH shifted to ca. 13. The decline of the hydrogen evolution rate was also due to the shift of pH, because the hydrogen evolution is inefficient in alkaline solutions.[5] The rate of hydrogen evolution recovered to the initial value by renewing the solution as shown by an arrow in Fig. 1.

The long-term stability of the photocatalyst was tested, renewing the solution at every 45 h. The rate of hydrogen evolution measured at 4 h after each of the renewal of the solution is shown by a solid line in Fig. 2. The rate of hydrogen evolution began to decline at ca. 200 h, and dropped to half the initial value at 600 h. However, the activity of the photocatalyst after illumination for 650 h recovered to 95% of the initial value by washing it in 0.4 M HCl for 30 min.

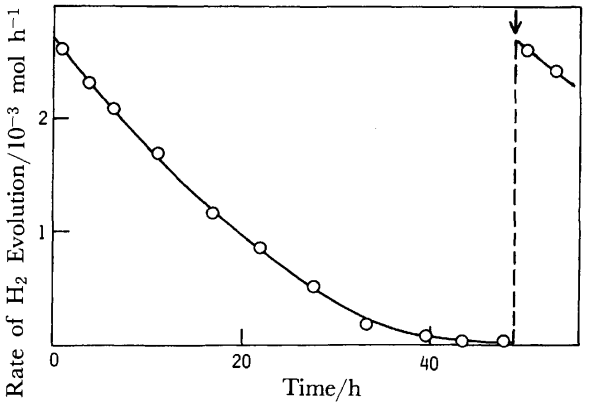

Fig. 1. Time-course of the rate of hydrogen evolution for the solution of 1 M sodium sulfite buffered at pH 8.4; the solution was renewed at the arrow.

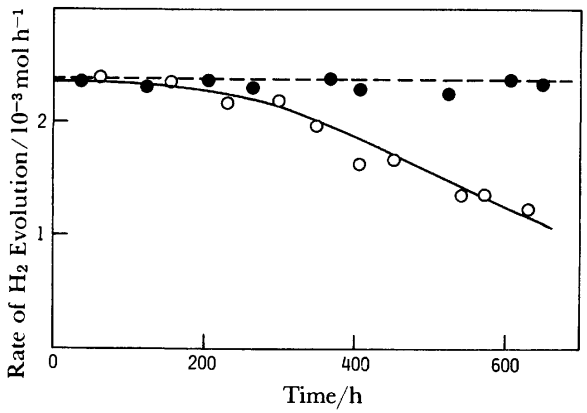

Fig. 2. Time-course of the rate of hydrogen evolution for the solutions of 1 M sodium sulfite buffered at pH 8.4 without EDTA, solid line, and with 5 mM EDTA, broken line.

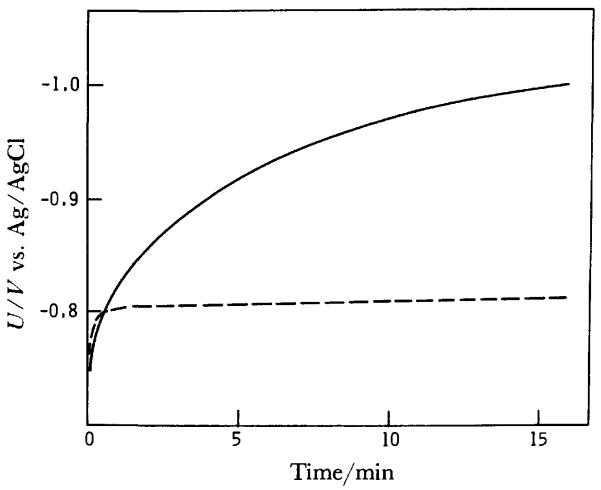

Fig. 3. Time-course of the potential of a platinum electrode observed under galvanostatic conditions at the current density of $-0.5\,mA\,cm^{-2}$ in the solutions of 0.5 M sodium sulfite buffered at pH 8.4 without EDTA, solid line, and with 5 mM EDTA, broken line.

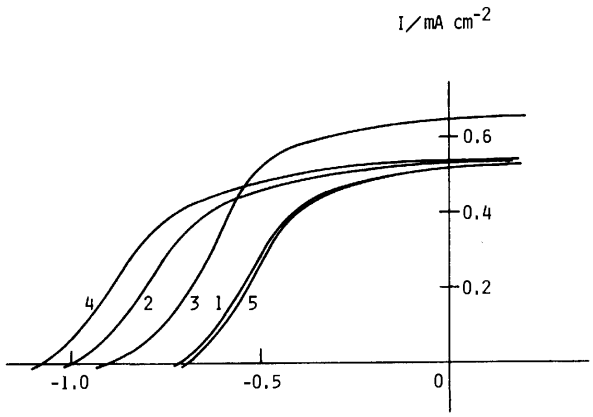

Fig. 4. *I-U* curve of a CdS sinter electrode measured under illumination with a tungsten-halogen lamp in 0.5 M sodium sulfate (curve 1), and those obtained by the addition of 0.1 sodium sulfite (curve 2), 0.1 M EDTA (curve 3), 0.1 M sodium sulfite and 0.1 M EDTA (curve 4), and 0.1 M cadmium chloride and 0.1 M EDTA (curve 5); the pH of the solutions is adjusted to 8.4.

When a small amount of ethylenediaminetetraacetic acid (EDTA, 5 mM) was added to the sulfite solution, the photocatalyst showed no decay of the activity even after illumination over 650 h, as shown by a broken line in Fig. 2. The amounts of hydrogen evolved during 650 h illumination from the solutions with and without EDTA were 13.6 and 10.7 l, respectively. Platinum-loaded CdS powder has been reported to photocatalyze hydrogen evolution from the aqueous solution of EDTA.[9] However, the rate of hydrogen evolution was negligibly small from the solution of 5 mM EDTA without sulfite. Therefore, the oxidation of EDTA at the illuminated CdS surface is excluded from the reasons of the stabilization of the photocatalyst and the increase of the amount of evolved hydrogen. By addition of 2 mM EDTA to the sulfite solution, practically the same stability of the photocatalyst was obtained as the case of 5 mM EDTA. The lower limit of the concentration of EDTA needed to stabilize the photocatalyst has not been determined.

In order to clarify the reason for the enhancement of the durability of the photocatalyst by the addition of EDTA and the deactivation of the photocatalyst in the absence of EDTA, we measured the potential of a hydrogen-evolving platinum electrode under galvanostatic conditions in 1 M sodium sulfite with and without EDTA. In the solution without EDTA, the potential of the platinum electrode shifted to negative rapidly as shown by a solid line in Fig. 3. This suggests that the catalytic activity of the platinum electrode for the hydrogen evolution decays with time. The shift of the potential of the platinum electrode was retarded drastically by addition of EDTA as shown by a broken line.

In Fig. 4 are shown the *I-U* curves of the illuminated CdS electrode in various solutions. The photocurrent in a sodium sulfate solution (curve 1) is caused by the dissolution of the CdS electrode. By addition of sulfite ions (curve 2) or EDTA (curve 3), the photocurrents now start at -1.0 and -0.91 V, respectively, which are caused by the oxidation of these species by the photogenerated positive holes in CdS. The higher reactivity of sulfite ions than that of EDTA is suggested by comparing curves 2 and 3. The increase of the saturated photocurrent density by the addition of EDTA (curve 3) is attributed to the "current doubling effect"[10] arising from the oxidation of EDTA. The disappearance of the "current doubling effect" in the presence of both EDTA and sulfite ions (curve 4) suggests that the sulfite ions are solely oxidized on the illuminated CdS electrode due to their higher reactivity than that of EDTA. The negative shift of the onset

potential of the photocurrent by the addition of EDTA to the sulfite solution (compare curves 2 and 4) is probably due to the shift of the flat band potential of the CdS electrode caused by the chemisorption of EDTA on the surface of CdS.[11] In the solution containing both EDTA and heavy metal ions, such as cadmium ions, at the same concentrations (0.1 M), the *I-U* curve nearly coincided with that measured in sodium sulfate solution (curves 1 and 5). This suggests that the heavy metal ions present in the solution are complexed with EDTA and that the complexes have very low reactivities with the positive holes photogenerated in CdS.

Discussion

The properties of the platinum-loaded CdS photocatalyst are well explained by assuming that each photocatalyst particle works as a photoelectrochemical cell having a CdS electrode and a platinum electrode.[12] Then, the deposition of metals on the platinum from impurity metal ions existing in the solution is likely to occur electrochemically in competition with the hydrogen evolution. Therefore, the deactivation of the photocatalyst by illumination in the absence of EDTA is attributable to the deposition of impurity metals on a platinum part of the photocatalyst. The recovery of the photocatalytic activity by the washing treatment of the deactivated photocatalyst in hydrochloric acid suggests the removal of metals deposited on platinum.

The metal ions which deteriorate the activity of the photocatalyst are supposed to come from water, sodium sulfite, or the photocatalyst itself. The shift of the potential of the hydrogen-evolving platinum electrode under galvanostatic conditions was accelerated by addition of CdS powder to the solution. This suggests that not only the impurities in the solution but also impurities, probably cadmium ion, from the surface of CdS powder also deactivate the photocatalyst.

It is plausible to conclude that EDTA forms stable complexes with metal ions, prevents them from depositing on the platinum, and raises the durability of the photocatalyst. The electrochemical activity of EDTA itself with positive holes photogenerated in CdS is lowered by the formation of metal complexes as shown by curve 5 in Fig. 4. This gives a good reason why the effect of EDTA is sustained for the solutions containing EDTA at low concentrations. The low reactivity of the metal-EDTA complexes is presumably due to the stabilization of the lone-electron pair of nitrogen atoms in EDTA by formation of coordination bonds with the metal ions.

On the basis of these properties of EDTA and metal-EDTA complexes, it is expected that the stability of many photocatalysts other than platinized CdS, e.g., TiO_2, ZnO, etc., and also the hydrogen-evolving electrodes of photoelectrochemical cells can be improved by addition of small amounts of EDTA or other chelating agents to the solutions. The present results for the effect of EDTA on the platinum-loaded CdS photocatalyst are, aside from aforementioned practical significances, interesting from the viewpoint of the elucidation of the working mechanism of the photocatalysts.

Characteristic Polynomial Expression and Integral Expression for Imaginary Bond-Bond Polarizability. Rules for London Susceptibility and for Ring Current

Noriyuki MIZOGUCHI
Department of Physics, Meiji College of Pharmacy, Nozawa, Setagaya-ku, Tokyo 154
(Received December 12, 1986)

The McWeeny theory for calculating magnetic properties of conjugated hydrocarbons is studied from a graph-theoretical point of view. Imaginary bond-bond polarizability is expressed in terms of characteristic polynomial. The expression clarifies the dependence of imaginary bond-bond polarizability on the structure. It is shown that the expression enables one easily to derive the equations for the quantity proved in two previous papers. The characteristic polynomial expression for imaginary bond-bond polarizability is rewritten in Coulson's integral form. The rules for London susceptibility and for ring current are proved from the integral expression.

The application of the graph theory[1] in the Hückel molecular orbital (HMO) theory enabled one mathematically to prove statements valid for a large class of unsaturated conjugated systems which clarify that there are close relationships between the chemical properties of a conjugated hydrocarbon and the topologies.[2] One of the most significant achievements is the proof of the Hückel rule, which states that cyclic conjugation of the π-electron system causes drastically different effects on the thermodynamic stability, depending on the size of the circuit.[3]

The HMO method with London's approximations[4] for calculating magnetic properties of conjugated hydrocarbons was established in differents forms by Pople[5] and by McWeeny.[6] Pople calculated ring currents from a knowledge of the field-dependent secular determinant (characteristic polynomial) while McWeeny used the usual perturbation method and expressed the magnetic susceptibility due to π-electrons (London susceptibility) in terms of imaginary bond-bond polarizability.

Although Pople did not give an explicit expression for London susceptibility (and ring current), some time ago Aihara[7] was able to express London susceptibility in terms of a characteristic polynomial and showed that the London susceptibility of a polycyclic conjugated molecule can be given as a sum of the circuit susceptibilities over all the circuits found in the system. By using Coulson's integral method[8] the present author proved a rule for London susceptibility valid for any alternant polycyclic conjugated system which states that the sign of the circuit susceptibility for a circuit in the system is determined by the number of carbon atoms in the circuit.[9] This rule has very similar aspects to Hückel rule for thermodynamical stability.[10]

The McWeeny method has been widely applied to conjugated systems by a large number of authors.[11] However the properties of imaginary bond-bond polarizability had not been studied. Recently the present author clarified the dependence of imaginary bond-bond polarizability on the mode of branching[12] and the role of "acyclic" bond in the magnetic properties of conjugated molecules.[13] Although the McWeeny theory has also been pointed out to have some topological aspects associated with a spanning tree,[6,14] the close relationship between London susceptibility and the circuit found in the Pople-Aihara theory is not known in the McWeeny theory.

The purpose of this paper is to clarify the dependence of magnetic properties on the circuit in the McWeeny method.[15] In the first part of the present paper 1) imaginary bond-bond polarizability will be expressed in terms of a characteristic polynomial and 2) it will be shown that the characterist polynomial expression for imaginary bond-bond polarizability enables one to derive easily the equations proved in two previous papers. In the second part 3) imaginary bond-bond polarizability will be represented in Coulson's integral form and the rules for London susceptibility and for ring current will be proved.

Characteristic Polynomial Expression for Imaginary Bond-Bond Polarizability

In McWeeny's perturbation approach, the partial London susceptibility for the J-th MO, χ_J, of a polycyclic conjugated system is given by[6]

$$\chi_J = 2\beta(e/\hbar c)^2\Big(\sum_{(rs)} P_{J,rs}S_{rs}^2 + \sum_{(rs)}\sum_{(tu)} \beta\pi_{J,(rs)(tu)}S_{rs}S_{tu}\Big), \quad (1)$$

where β is the field-free resonance integral, which is assumed to be equal for all the bonds in the molecule; e, $\hbar$, and c are the usual fundamental constants with these symbols; S_{rs} is the signed area of the triangle formed by an arbitrary origin and bond r-s; the sum $\sum_{(rs)}$ runs over all the bonds in the molecule; $P_{J,rs}$ is the partial Coulson bond order for the J-th MO;[8] $\bar{\pi}_{J,(rs)(tu)}$ is the partial imaginary bond-bond polarizability given by[6]

$$\bar{\pi}_{J,(rs)(tu)} = \sum_{K(\neq J)} \frac{(C_{rJ}C_{sK} - C_{sJ}C_{rK})(C_{tK}C_{uJ} - C_{uK}C_{tJ})}{(X_J - X_K)\beta}, \quad (2)$$

where X_J and C_{rJ} are the J-th eigenvalue (in units of β) and the eigenvector of the field-free Hückel Hamiltonian matrix, respectively.

In the later discussions attention should be paid to the order of the suffices in $\bar{\pi}_{J,(rs)(tu)}$ since

$$\bar{\pi}_{J,(rs)(tu)} = -\bar{\pi}_{J,(rs)(tu)} = -\bar{\pi}_{J,(rs)(tu)}. \tag{3}$$

The sign of χ_J is not dependent on the order of the suffices in the right-hand side of Eq. 1 because of Eq. 3 and $S_{sr}=-S_{rs}$.

Following Aihara,[7] in Pople's approach,[5] the London susceptibility of a polycyclic conjugated system is expressed in terms of a characteristic polynomial as follows:

$$\chi_J = \sum_j 2\beta(e/\hbar c)^2(P(G\ominus C_j; X_J)/P'(G; X_J))S(C_j)^2$$
$$= \sum_j \chi_J(C_j). \tag{4}$$

In Eq. 4 G is the graph representing the system; the sum runs over all the circuits found in G; $G\ominus C_j$ is a subgraph of G obtained by deleting circuit C_j and all the bonds incident to C_j from G; $P(G;X)$ and $P(G\ominus C_j;X)$ are the field-free characteristic polynomials of G and of $G\ominus C_j$, respectively; $P'(G;X)$ is the first derivative of $P(G;X)$ with respect to X; $S(C_j)$ is the area of C_j; $\chi_J(C_j)$ denotes the contribution of a circuit C_j to the London susceptibility of the system (circuit susceptibility).

For example, the London susceptibility of naphthalene is given by a sum of the circuit susceptibilities over three circuits C_1, C_2, and C_3 shown in Fig. 1. The circuit C_3 is produced by the fusion of two rings (fundamental circuits) R_1 and R_2 (see Fig. 1).

Equation 4 shows that the factor determining the magnetic properties of a polycylcic conjugated system is not the rings but the circuits. In other words, it shows that every circuit in the system acts as a driving force for the induction of ring current. The number of the modes of cyclic conjugation of the π-electrons is the number of the circuits found in the system. This aspect resembles Randić's "conjugated circuit" based on classical valence bond method.[16]

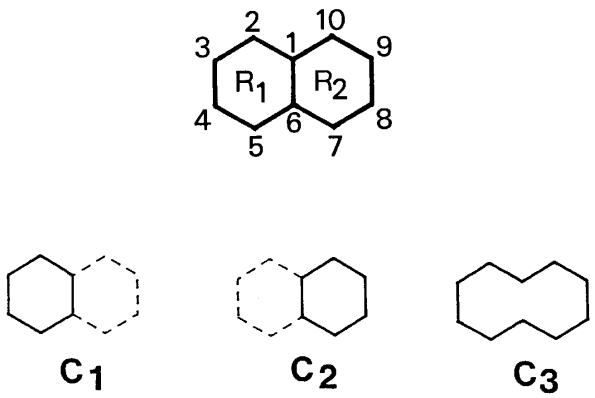

Fig. 1. Two rings and three circuits in naphthalene.

The expression for London susceptibility in McWeeny's theory, namely Eq. 1, is based on the concept "bond" while that in the Pople-Aihara theory, namely Eq. 4, is based on the concept "circuit." Since the two equations are obtained with the same approximations (London's approximations), they are equivalent mathematically.[17] Therefore comparison of the two equations will enable us to express imaginary bond-bond polarizability in terms of a characteristic polynomial. Before doing so, however it is necessary to express the London susceptibility in terms of the ring area $S(R_j)$ because the two equations are expressed in terms of the different area terms, that is, Eq. 1 is expressed in terms of triangle area S_{rs} while Eq. 4 is expressed in terms of the circuit area $S(C_j)$. Fortunately we have a unitary transformation devised by McWeeny,[6,14] which enables one to rewrite Eq. 1 in a form suitable for our purpose.

Due to McWeeny's unitary transformation we can obtain the transformed Hamiltonian matrix in which the elements for "circuit-completing" bonds for a chosen spanning tree[18] depend on an applied magnetic field but the other elements are independent of the field. From the transformed Hamiltonian matrix for a chosen spanning tree T we obtain in stead of Eq. 1 the following equation:

$$\chi_J = 2\beta(e/\hbar c)^2\Big(\sum_j (P_{J,(b_j)} + \beta\bar{\pi}_{J,(b_j)(b_j)})S(C_j)^2$$
$$+ 2\sum_j \sum_{k(>j)} (-1)^{\zeta}\beta\bar{\pi}_{J,(b_j)(b_j)}S(C_j)S(C_k)\Big). \tag{5}$$

In Eq. 5 C_j denotes a circuit completed by inserting a "circuit-completing" bond b_j for T; the sum is over all the "circuit-completing" bonds for T; ζ is a topological quantity defined as

$\zeta=0$ if the direction of the bond b_j in the circuit C_j is identical with that of the bond b_k in the circuit C_k,
$\zeta=1$ otherwise. (6)

It should be noted that the circuits appearing in Eq. 5 are only the circuits completed by inserting the "circuit-completing" bonds for a chosen spanning tree although all the circuits of the original graph appears in Eq. 4. The number of the "circuit-completing" bonds for a spanning tree for a polycyclic conjugated system equals the number of the rings (fundamental circuits) of the system. After representing the circuit area $S(C_j)$ in Eqs. 4 and 5 in terms of the ring area $S(R_j)$ and by equating the coefficients of $S(R_j)^2$ or $S(R_j)S(R_k)$ in the two equations, we can obtain the following equations:

$$P_{J,rs} + \beta\bar{\pi}_{J,(rs)(rs)} = \sum_j^{rs\,\epsilon\,C_j} (P(G\ominus C_j; X_J)/P'(G; X_J)), \tag{7}$$

and

$$\beta\bar{\pi}_{J,(rs)(tu)} = \sum_j^{rs,\,tu\,\epsilon\,Cj} (-1)^{\eta}(P(G\ominus C_j; X_J)/P'(G; X_J)), \tag{8}$$

In Eq. 7 the sum $\sum_{j}^{rs\epsilon C_j}$ runs over all the circuits which pass through the bond r-s. In Eq. 8 the sum $\sum_{j}^{rs,tu\epsilon C_j}$ runs over all the circuits which pass through the two bonds r-s and t-u and

$\eta=0$ if the directions of $r\rightarrow s$ and $t\rightarrow u$ are same in the circuit C_j

$\eta=1$ if they are different.

Further, by substituting the following equation[19]

$$P_{J,rs}=(P(G\ominus e_{rs};X_J)+\sum_{j}^{rs\,\epsilon\,C_j}P(G\ominus C_j;X_J))/P'(G;X_J), \quad (9)$$

into Eq. 7 we find that

$$\beta\bar{\pi}_{J,(rs)(rs)}=-P(G\ominus e_{rs};X_J)/P'(G;X_J), \quad (10)$$

where $G\ominus e_{rs}$ is a subgraph of G obtained by deleting bond (edge) r-s and all the bonds incident to e_{rs} from G. Figure 2 shows a subgraph $G\ominus e_{23}$ for bond 2-3 of naphthalene.

Let us take naphthalene as an example in order to illustrate the above procedure. Figure 3 shows a spanning tree for naphthalene, $T1$. The "circuit-completing" bonds for $T1$ are bonds 2-3 and 6-1. Insertion of bond 6-1 into $T1$ completes circuit C_2 (ring R_2) and that of bond 2-3 completes circuit C_3 which contains two rings R_1 and R_2 (see Fig. 1). If the spanning tree $T1$ is chosen, then in McWeey's method χ_J of naphthalene is given by (see Eq. 5):

$$\begin{aligned}\chi_J=2\beta(e/\hbar c)^2\{&(P_{J,23}+\beta\bar{\pi}_{J,(23)(23)})(S(R_1)+S(R_2))^2\\&-2\beta\bar{\pi}_{J,(23)(61)}(S(R_1)+S(R_2))S(R_2)\\&+(P_{J,61}+\beta\bar{\pi}_{J,(61)(61)})S(R_2)^2\},\end{aligned} \quad (11)$$

where the negative sign before the second term is due to the fact that the direction of $2\rightarrow 3$ is anticlockwise in circuit C_3 but the direction of $6\rightarrow 1$ is clockwise in circuit C_2 (see Figs. 1 and 3).

In Pople's method χ_J of naphthalene is expressed as a sum of the partial circuit susceptibilities for three circuits, C_1, C_2, and C_3:

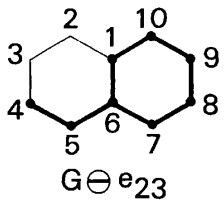

Fig. 2. Subgraph $G\ominus e_{23}$ of naphthalene.

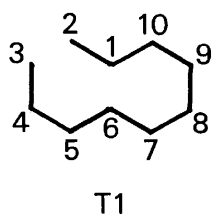

Fig. 3. Spanning tree, $T1$, for naphthalene.

$$\chi_J=\chi_J(C_1)+\chi_J(C_2)+\chi_J(C_3). \quad (12)$$

The explicit expressions for $\chi_J(C_1)$, $\chi_J(C_2)$, and $\chi_J(C_3)$ will be obvious. For example, from Eq. 4 $\chi_J(C_3)$ is

$$\chi_J(C_3)=2\beta(e/\hbar c)^2(P(G\ominus C_3;X_J)/P'(G;X_J))\,(S(R_1)+S(R_2))^2. \quad (13)$$

By equating the coefficients of $S(R_j)S(R_k)$ in Eqs. 11 and 12 we obtain the following equations:

$$P_{J,23}+\beta\bar{\pi}_{J,(23)(23)}=(P(G\ominus C_1;X_J)+P(G\ominus C_3;X_J))/P'(G;X_J), \quad (14)$$

$$\beta\bar{\pi}_{J,(23)(61)}=P(G\ominus C_1;X_J)/P'(G;X_J), \quad (15)$$

$$P_{J,61}+\beta\bar{\pi}_{J,(61)(61)}=(P(G\ominus C_1;X_J)+P(G\ominus C_2;X_J))/P'(G;X_J). \quad (16)$$

It can be ascertained that the equations obtained for $T1$, namely Eqs. 14—16, are the examples of Eqs. 7 and 8. Even if the other spanning tree is chosen, we can ascertain the validity of Eqs. 7, 8, and 10.

The Eqs. 7, 8, and 10 are the desired equations. Equation 7 shows that the quantity $P_{J,rs}+\beta\bar{\pi}_{J,(rs)(rs)}$ for bond r-s is expressed as a sum of the characteristic polynomials of the subgraphs $G\ominus C_j$ over all the circuits passing through bond r-s. Equation 8 shows that the partial imaginary mutual bond-bond polarizability for two bonds r-s and t-u, $\beta\bar{\pi}_{J,(rs)(tu)}$, is expressed as a sum of the characteristic polynomials of the subgraphs $G\ominus C_j$ over all the circuits passing through the two bonds r-s and t-u. Equation 10 shows that the partial imaginary self bond-bond polarizability for bond r-s is expressed in terms of the characteristic polynomial of the subgraph $G\ominus e_{rs}$.

Although the imaginary bond-bond polarizability represents the imaginary part of the change of Coulson's bond order due to an applied magnetic field, we can find from Eqs. 7 and 8 a similarity between the two quantities $P_{J,rs}+\beta\bar{\pi}_{J,(rs)(rs)}$ and $\beta\bar{\pi}_{J,(rs)(tu)}$ that the two quantities are expressed in terms of the same type of characteristic polynomial such as $P(G\ominus C;X)$.[13] Further it is seen from Eqs. 8 and 10 that the imaginary mutual bond-bond polarizability and the imaginary self bond-bond polarizability are different quantities because the former is associated with the subgraph $G\ominus C_j$ but the latter is associated with the subgraph $G\ominus e_{rs}$.

From Eqs. 7, 8, and 10 we can clarify the dependence of imaginary bond-bond polarizability on the topologies (circuit and connectivity). Let us first consider the properties related to the circuit. Equation 7 shows that the quantity $P_{J,rs}+\beta\bar{\pi}_{J,(rs)(rs)}$ for the bond r-s consists of the contributions of all the circuits passing through the bond r-s, and Eq. 8 shows that the partial imaginary mutual bond-bond polarizability $\beta\bar{\pi}_{J,(rs)(tu)}$ for bonds r-s and t-u consists of the contributions of all the circuits passing through the two bonds r-s and t-u. Although, as seen from Eq. 1, two quantities $P_{J,rs}+\beta\bar{\pi}_{J,(rs)(rs)}$ and $\beta\bar{\pi}_{J,(rs)(tu)}$ represent the contribution of a

bond to London susceptibility, it is interesting that the two quantities themselves show the circuit dependence mentioned above.

In a previous paper[13] we classified bonds into "acyclic" and "cyclic" and pointed out the importance of this classification in the study of magnetic properties of conjugated molecules. We proved that for an "acyclic" bond r-s,

$$P_{J,rs}+\beta\bar{\pi}_{J,(rs)(rs)}=0, \tag{17}$$

and

$$\bar{\pi}_{J,(rs)(vw)}=0, \tag{18}$$

where v-w is an arbitrary bond but not equal to r-s. The set of Eqs. 17 and 18 shows that an "acyclic" bond makes no contribution to London susceptibility and to ring current. Since an "acyclic" bond, by definition, has no circuits passing through it,[13] from Eqs. 7 and 8 we can easily obtain Eqs. 17 and 18.

The branching in a graph is one of the important factors determining the physical and chemical properties of unsaturated hydrocarbons.[2] Figure 4 shows two modes of branching in the graph representing a conjugated molecule. Since the difference in the modes of branching appears in the difference of the circuits passing through the bonds, Eqs. 7 and 8 give the imformation on the dependence of imaginary bond-bond polarizability on branching.

Let C be a circuit which passes through bond r-s in G1 shown in Fig. 4. Then the circuit C necessarily passes through bond s-t in G1 also and the directions of $r\rightarrow s$ and of $s\rightarrow t$ are the same in the circuit C. Therefore we obtain from Eqs. 7 and 8

$$\beta\bar{\pi}_{J,(vw)(rs)}=\beta\bar{\pi}_{J,(vw)(st)}, \tag{19}$$

$$P_{J,rs}+\beta\bar{\pi}_{J,(rs)(rs)}=P_{J,rs}+\beta\bar{\pi}_{J,(st)(st)}, \tag{20}$$

$$P_{J,rs}+\beta\bar{\pi}_{J,(rs)(rs)}=\beta\bar{\pi}_{J,(rs)(st)}, \tag{21}$$

where v-w is an arbitrary bond except the bonds in G1. In a similar way, it follows from Eqs. 7 and 8 that for vertices r', s', t', and u' in subgraph G2 shown in Fig. 4

$$\beta\bar{\pi}_{J,(vw)(r's')}=\beta\bar{\pi}_{J,(vw)(s't')}+\beta\bar{\pi}_{J,(vw)(s'u')}, \tag{22}$$

$$P_{J,r's'}+\beta\bar{\pi}_{J,(r's')(r's')}=\beta\bar{\pi}_{J,(r's')(s't')}+\beta\bar{\pi}_{J,(r's')(s'u')}, \tag{23}$$

where v-w is an arbitrary bond except the bonds in G2. The above five equations show the dependence of imaginary bond-bond polarizability on the mode of branching. Although Eqs. 19—23 were proved in a previous paper,[12] as seen above, Eqs. 7 and 8 provide an easier way to derive Eqs. 19—23 than that used in Ref. 12.

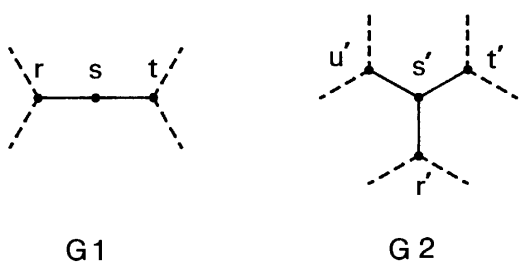

Fig. 4. Subgraphs G1 and G2.

Integral Expressions for Imaginary Bond-Bond Polarizability. Rules for London Susceptibility and for Ring Current

Coulson's integral representation technique[8] has been shown to be very powerful in the study of the dependence of the HMO π-electron indices on the structure of the conjugated molecule.[2] The characteristic polynomial expression for imaginary bond-bond polarizability obtained above is the first step for obtaining the integral expression for the quantity.

It follows from Eqs. 7, 8, and 10 that

$$P_{rs}+\beta\bar{\pi}_{(rs)(rs)}=\sum_J g_J \sum_j^{rs\in C_j}(P(G\ominus C_j;X_J)/P'(G;X_J)), \tag{24}$$

$$\beta\bar{\pi}_{(rs)(tu)}=\sum_J g_J \sum_j^{rs,tu\in C_j}(-1)^{\eta}(P(G\ominus C_j;X_J)/P'(G;X_J)), \tag{25}$$

and

$$\beta\bar{\pi}_{(rs)(rs)}=-\sum_J g_J P(G\ominus e_{rs};X_J)/P'(G;X_J), \tag{26}$$

where g_J is the occupation number of the J-th MO. According to the same procedure as in Ref. 9, for closed shell molecules Eqs. 24—26 can be written in the integral form as follows:

$$P_{rs}+\beta\bar{\pi}_{(rs)(rs)}=(-1/\pi)\sum_j^{rs\in C_j}\int_{-\infty}^{\infty}(P(G\ominus C_j;iy)/P(G;iy))dy, \tag{27}$$

$$\beta\bar{\pi}_{(rs)(tu)}=(-1/\pi)\sum_j^{rs,tu\in C_j}(-1)^{\eta}\int_{-\infty}^{\infty}(P(G\ominus C_j;iy)/P(G;iy))dy, \tag{28}$$

and

$$\beta\bar{\pi}_{(rs)(rs)}=(1/\pi)\int_{-\infty}^{\infty}(P(G\ominus e_{rs};iy)/P(G;iy))dy. \tag{29}$$

With the quantity $F(C)$ defined as[9]

$$F(G,C)=\int_{-\infty}^{\infty}(P(G\ominus C;iy)/P(G;iy))dy, \tag{30}$$

Eqs. 27 and 28 are written as follows:

$$P_{rs}+\beta\bar{\pi}_{(rs)(rs)}=(-1/\pi)\sum_j^{rs\in C_j}F(G,C_j), \tag{31}$$

and

$$\beta\bar{\pi}_{(rs)(tu)}=(-1/\pi)\sum_j^{rs,tu\in C_j}(-1)^{\eta}F(G,C_j). \tag{32}$$

It was shown that if the system G is alternant, the sign of $F(G,C)$ is determined only by the size of the circuit, $N(C)$:[9]

$$F(G,C)\begin{cases}<0 & \text{if } N(C)=4n+2\\ >0 & \text{if } N(C)=4n.\end{cases} \tag{33}$$

This equation means that the contribution of a $(4n+2)$-membered circuit is diamagnetic and that of a

$(4n)$-membered circuit is paramagnetic.

In a similar fashion it can be shown from Eq. 29 that the sign of the imaginary self bond-bond polarizability is always positive

$$\bar{\pi}_{(rs)(rs)} > 0, \tag{34}$$

where we used the fact that β is negative. This result was already obtained in another manner.[12]

If we remember that bond current for bond r-s (ring current) is expressed in terms of imaginary bond-bond polarizability as follows:[20]

$$Q(rs) = (P_{rs} + \beta\bar{\pi}_{(rs)(rs)})\, S_{rs} + \sum_{(tu)} \beta\bar{\pi}_{(rs)(tu)}\, S_{tu}, \tag{35}$$

it is seen from Eqs. 31 and 32 that the driving forces for the bond current for bond r-s are the presence of the circuits which contain the bond r-s. In other words, cyclic conjugation is the basis for the induction of bond current.

From Eqs. 31—33 we can obtain the rule for imaginary bond-bond polarizability which states that

(1) $P_{rs}+\beta\bar{\pi}_{(rs)(rs)}$ is expressed as a sum of the contributions over all the circuits passing through bond r-s and the sign of the contribution of a circuit is determined only by the size of the circuit as shown in Eq. 33.

(2) $\beta\bar{\pi}_{(rs)(tu)}$ is expressed as a sum of the contributions over all the circuits passing through two bonds r-s and t-u, and the sign of the contribution of a circuit is determined only by the size of the circuit as shown in Eq. 33.

From this rule we can predict the sign of the imaginary bond-bond polarizability by counting the size of the circuit only. For example, it is seen for naphthalene that

$$P_{23} + \beta\bar{\pi}_{(23)(23)} > 0,$$

$$\beta\bar{\pi}_{(23)(61)} > 0,$$

because the circuits passing through 2-3 are C_1 and C_3, the circuit passing through 2-3 and 6-1 is C_1, $N(C_1)=6$ and $N(C_3)=10$. Similarly we can predict that the signs of $P_{rs}+\beta\bar{\pi}_{(rs)(rs)}$ and $\beta\bar{\pi}_{(rs)(tu)}$ for any bond in a catacondensed benzenoid hydrocarbon are positive (diamagnetic) because all the circuits found in a catacondensed benzenoid hydrocarbon are $(4n+2)$-membered circuits.

Since London susceptibility and bond current are expressed in terms of $P_{rs}+\beta\bar{\pi}_{(rs)(rs)}$ and $\beta\bar{\pi}_{(rs)(tu)}$ (see Eqs. 1 and 35), we can obtain the rules for London susceptibility and for bond current. For example, we can predict for a catacondensed benzenoid hydrocarbon that the London susceptibility and the bond current for any bond are diamagnetic because all the contributions of the circuits in the system to $P_{rs}+\beta\bar{\pi}_{(rs)(rs)}$ and $\beta\bar{\pi}_{(rs)(tu)}$ are diamagnetic. This is in agreement with experimental results.[21]

Concluding Remarks

By using the equality of the expressions for London susceptibility in two different methods (McWeeny and Pople-Aihara), imaginary bond-bond polarizability was expressed in terms of characteristic polynomial (see Eqs. 7, 8, and 10). It was shown that the characteristic polynomial expressions for imaginary bond-bond polarizability reveal the dependence of the quantity on the structures such as circuit and branching and that the equations proved in previous papers[12,13] can easily be derived from these expressions. The integral expressions for imaginary bond-bond polarizability (see Eqs. 27—29) were obtained from Eqs. 7, 8, and 10. It was shown that Eqs. 27—29 give a rule for imaginary bond-bond polarizability (and for London susceptibility and for ring current) of any alternant conjugated systems.

Equations 7, 8, and 10 hold only for nondegenerate molecular orbitals because Eqs. 4 and 5 do not hold for degenerate molecular orbitals. However, Eqs. 27—29 are valid for neutral alternant conjugated systems even with degenerate orbitals provided that they have filled bonding and empty antibonding molecular orbitals.[9]

In the present paper we neglect the effect of bond alternation. Since [$4n$]-annulene without bond alternation has nonbonding molecular orbitals, the rule proved in this paper cannot be applied to the system. However it has been reported that [$4n$]-annulene with bond alternation which has no nonbonding orbitals bears a paramagnetic ring current.[22] Further we can find the numerical results by Aihara for biphenylene, cycloocta[*def*]biphenylene and dicycloocta[1,2,3,4-*def*:1′,2′,3′,4′-*jkl*]biphenylene with bond alternation, which show that circuit susceptibilities for the $(4n+2)$-membered circuits in these systems are diamagnetic and those for the $(4n)$-membered circuits are paramagnetic.[23] Accordingly it seems that the introduction of bond alternation changes the magnitude of a circuit susceptibility but does not change its sign.

The Effect of the Chain Length and the End-Groups on the Epitaxial Growth of Long-Chain Molecules

Yasukiyo UEDA
Department of Industrial Chemistry, Faculty of Engineering, Kobe University, Rokko, Nada, Kobe 657
(Received December 17, 1986)

Five paraffins (C_{30}—C_{44}) and three linear compounds with polar end-groups,such as hydroxyl, methyl-ester, and carboxyl groups, were deposited on the cleavage surface of an alkali halide crystal in vacuo. Paraffin films deposited on the substrate took the same crystal structure and molecular orientation, independent of the number of carbon atoms in the chain. In the case of derivatives, the morphology and orientation of the crystals, however, differed with the end-groups. The (110) planes of paraffins, alcohol,and methyl-ester crystals were oriented parallel to the substrate (001) plane, and their *c*-axes were parallel to the [110] direction of the substrate crystal. On the other hand, the (001) plane of the acid crystal lay parallel to the substrate surface, so that the *c*-axis of the crystal was oblique to the substrate surface. The epitaxial growth of linear molecules with different end-groups was explained by the difference in the interaction between the end-groups and the substrate.

In recent years, attempts have been made to prepare many organic compounds in the form of an ultrathin film and study the relation between the physical properties and molecular arrangements in the films. The main methods of preparing oriented thin films are the Langmiur-Blodgett method and the physical vapor deposition (PVD) method. The former has been widely applied to amphiphilic linear molecules. The orientation of their films, however, is a single-molecular arrangement normal to the substrate and it was reported, on the basis of microscopic observation, that the uniformity of the molecular packing was incomplete even in the first monolayer.[1] On the other hand, the PVD method has been applied to planar and linear molecules and could give an alternative molecular orientation, depending on the evaporation conditions.[2-10] In the case of linear molecules such as paraffin,[11] they took two orientations on the cleavage surface of alkali halide. The films deposited on the substrate kept at room temperature were found to be composed of raft-like crystallites. The (110) plane of these crystals was oriented parallel to the substrate (001) plane, while their fiber axes were parallel to the [110] direction of the substrate crystal. On the other hand, the films deposited on the substrate kept at temperatures near or above their melting points were composed of discrete, disk-like crystals, and their fiber axes were perpendicular to the substrate.

The linear polar molecules such as methyl triacontanoate also took two similar orientations.[12] The crystal morphology, however, was different from that of paraffin, although methyl triacontanoate molecules were oriented parallel to the substrate surface. It seems that the epitaxial growth of linear molecules from the vapor phase depends on the kind of end-group as well as on their crystal structures. It is well-known that paraffins have many polymorphic forms. Their polymorphs depend on even and odd number of carbon atoms,[13,14] as well as the crystallization conditions. It seemed that it would be interesting to investigate the effects of end-groups and the number of carbon atoms on the morphology and orientation of linear molecular crystals.

In this paper, paraffins containing an even or odd number of carbon atoms and their derivatives with different polar end-groups, such as hydroxyl, methyl-ester, and carboxyl groups, were evaporated on alkali halide crystals. The epitaxial growth and growth mechanisms of these linear molecules were then studied by using an electron micrograph and by electron-diffraction.

Experimental

The materials used were five paraffins ($C_{30}H_{62}$, $C_{35}H_{72}$, $C_{36}H_{74}$, $C_{40}H_{82}$, and $C_{44}H_{90}$) and three linear polar compounds containing 30 carbons($C_{30}H_{61}OH$, $C_{29}H_{59}COOCH_3$, and $C_{29}H_{59}COOH$). These materials, obtained from the Tokyo Chemical Industry Co., Ltd., were of a purity higher than 99%. These samples were sublimated from a quartz crucible heated with a tungusten coil onto the clean surface of an alkali halide in a vacuum of 1.33×10^{-3} Pa. Single crystals of alkali halide, NaCl and KCl, were cleaved in air and mounted on a metal block equipped with an electric heater as well as a thermocouple for the temperature measurement of the substrate crystal. After being heated to a higher temperature, the substrate was kept at a temperature between 20 and 100 °C. About 5 mg of each material was deposited vertically onto the substrate surface, which faced downwards on a horizontal plane separated from the crucible by about 10 cm. The rate of sublimation was about 1.5 nm min^{-1}. The temperature of the evaporation source was kept in the range from 180 to 200 °C. The thickness of the deposited films was estimated to be in the range from 80 to 100 nm by using a quartz crystal microbalance. The specimens used for electron microscopy were prepared by the dissolution of the substrate in water after they had been reinforced with evaporated carbon film. The orientation of the deposited crystal relative to the substrate crystal was determined by chromium shadowcasting along the [100] direction of the substrate crystal. Thallium(I) chloride, prepared by evaporation, was used as the standard calibration material for spacing measurements.

Results and Discussion

Crystal morphology and molecular orientation have a close relation to the surface treatment, mainly

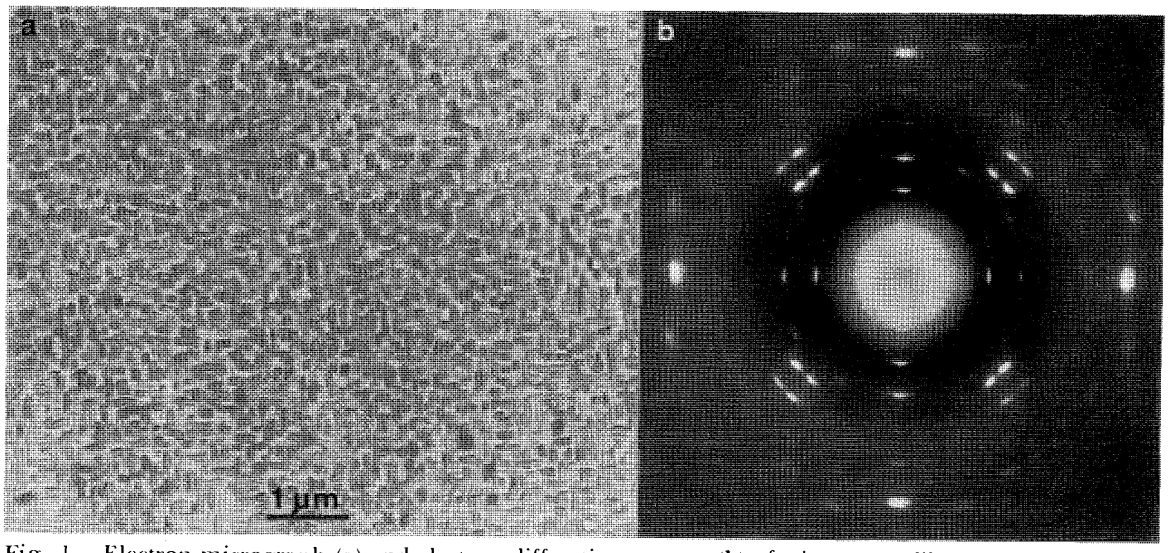

Fig. 1. Electron micrograph (a) and electron-diffraction pattern (b) of triacontane film vacuum-deposited on the (001) plane of KCl kept at 20 °C after being preheated at 150 °C.

depending on the bake-out procedure. When these compounds were evaporated onto a cleavage surface of alkali halide without any heat-treatment, the films were composed of granules with various orientations. The triacontane film vacuum-condensed on the substrate which had been heated at 150 °C for 1 h in advance and then kept at 20 °C was composed of small rod-like crystals crossing each other orthogonally, as is shown in Fig. 1(a). The needle axis of the deposited crystals was parallel to the substrate [110] direction. Corresponding to such a configuration of the film, the diffraction pattern shown in Fig. 1(b) also had an orthogonal appearance. This pattern is a superposition of two identical fiber diagrams rotated at 90° to each other. The crystals vacuum-condensed on the KCl and NaCl surfaces had the same morphology and showed identical diffraction patterns.

Crystals of such linear molecules as paraffin and its derivatives generally have a lamellar structure. They are composed of stacked layers which consist of chain molecules lying with their axes parallel to each other. In order to generalize the similarity detected among the crystal structures of chain molecules, Vand has introduced the concept of a subcell which is determined by the position of the methylene groups.[15] The most widely encountered type of subcell is an orthorhombic one occupied by two C_2H_4 groups. The diffraction pattern shown in Fig. 1(b) is composed of reflections situated at the reciprocal lattice points hkl_s of the sublattice and a series of $00l$ reflections in the small-angle region; the suffix s indicates the subcell lattice. A triacontane crystal has an orthorhombic subcell with dimensions of a_s=0.733, b_s=0.492, and c_s=0.2546 nm.[16] On the basis of the dimensions, the reflection spots in Fig. 1(b) were indexed as is shown in Fig. 2, in which the open circles represent the basic single-crystal pattern. The total pattern is overlapped by rotating the pattern at 90°. This pattern

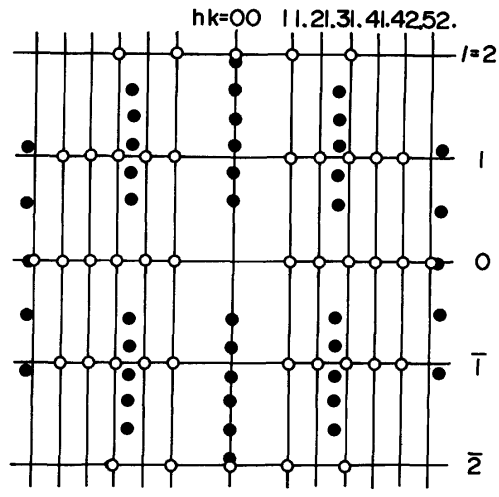

Fig. 2. The interpretation of the diffraction pattern shown in Fig. 1(b). The open circles represent the basic single crystal pattern.

is similar to the pattern obtained from hexatriacontane film grown epitaxially. From the same consideration as that applied to the orientation of the hexatriacontane crystal, the (110) plane of the triacontane crystal is found also to be oriented parallel to the substrate (001) plane, while its c-axis lies parallel to the [110] direction of the substrate crystal. The crystals of the other paraffins vacuum-condensed on alkali halide surfaces had the same morphology and showed the diffraction pattern of the identical subcell independent of the carbon atoms. This suggests that all the paraffin crystals used are composed of the same subcell and take the same orientation when they grow epitaxially on alkali halide. In addition to the reflection spots of the identical subcell, a series of reflections was found on the equator in the small-angle region. Figure 3 shows the series of $00l$ reflections corresponding to the long-spacings from each paraffin crystal. In the case of molecules with an odd number of carbon atoms, the

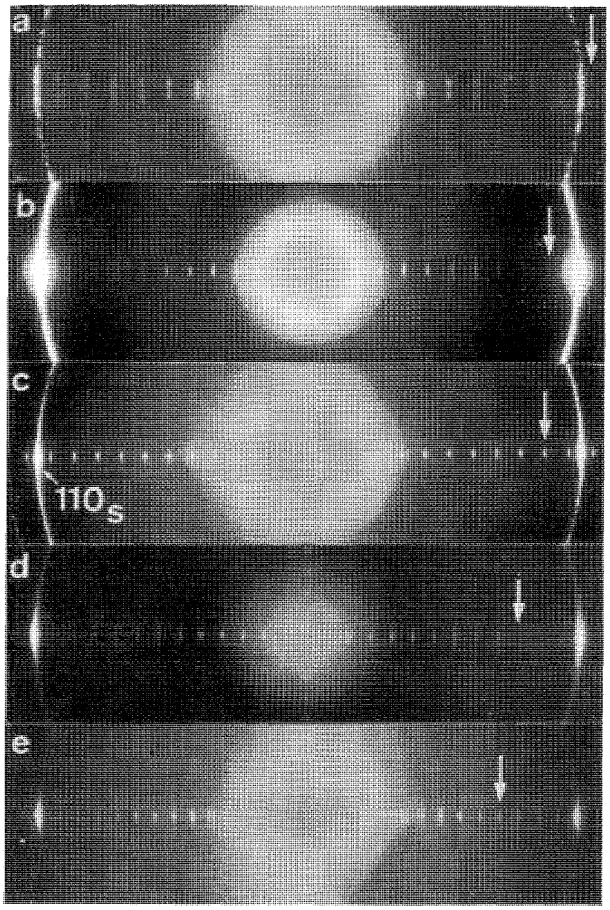

Fig. 3. Electron-diffraction patterns of the long-spacings of (a) $C_{30}H_{62}$, (b) $C_{35}H_{72}$, (c) $C_{36}H_{74}$, (d) $C_{40}H_{82}$, and (e) $C_{44}H_{90}$. Arrow indicates the tenth reflection spot.

long-spacings indicate the thickness of two molecules because of the crystal symmetry. Considering the extinction law for the crystal symmetry, l is integer for the molecules with an even number of carbon atoms, while it is even for the molecules with an odd number of carbon atoms. It is noted that the reflections can be clearly observed over the tenth order. Consequently, it seems that the crystallinities of the evaporated paraffin films are very high. These $00l$ reflections demonstrate the lamellar structure of paraffin crystals directly. The individual long-spacings obtained from the $00l$ reflections are given in Table 1. In the crystal of the orthorhombic form, the chain is perpendicular to the basal plane and the length of one zig-zag of a chain is estimated to be 0.2546 nm. The long-spacings may be expressed by an equation of this type;

$$d\,(\mathrm{nm}) = 0.1273 \times m + 0.183$$

m is the number of carbon atoms.[14] The long-spacings calculated from the equation are given in Table 1. The observed values from C_{30} to C_{44} coincide with the calculated values within the error of measurement. Figure 4 shows the high-resolution electron micrograph of hexatriacontane film. A periodicity of 4.77 nm corresponding to the molecular length is

Table 1. Long-Spacings of Paraffins

Sample	Observed Value/nm	Calculated Value/nm
$C_{30}H_{62}$	3.993	4.002
$C_{35}H_{72}$	4.634	4.639
$C_{36}H_{74}$	4.769	4.766
$C_{40}H_{82}$	5.305	5.275
$C_{44}H_{90}$	5.829	5.784

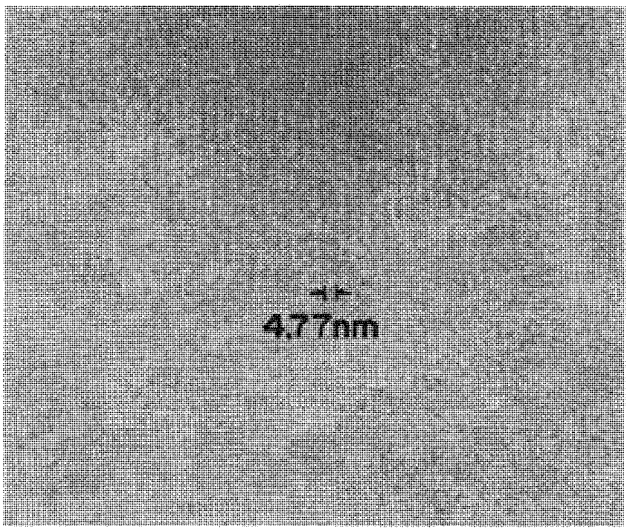

Fig. 4. The 001 lattice image of $C_{36}H_{74}$ crystal.

observed, although the paraffin crystal is very sensitive to the radiation damage by an electron beam. This finding indicates directly that hexatriacontane molecules lie parallel to the substrate surface.

The 1-triacontanol film vacuum-deposited on the substrate kept at 20 °C was composed of rod-like crystals crossing each other orthogonally, as is shown in Fig. 5(a). The electron-diffraction pattern from the film shows a pattern similar to that of triacontane film. It is well-known that linear alcohols, like other linear molecules, exhibit polymorphism.[17,18] The alcohols have a hexagonal high-temperature form (α) which is stable just below the melting point. The alcohols with an even number of carbon atoms possess two low-temperature forms; the one form is orthorhombic (β), with its chains normal to the (001) plane, while the other is monoclinic (γ), with chains inclined to the plane. In all forms, the long-spacings indicate the thickness of two molecules. The experimental formulae for the long-spacings of the three forms were classified as follows,

$$l_\alpha = 0.252n + 0.45$$
$$l_\beta = 0.252n + 0.55$$
$$l_\gamma = 0.215n + 0.32$$

n is the number of carbon atoms.[17]

The long-spacing obtained from the $00l$ reflections shown in Fig. 5(c) was 8.10 nm. This value coincided with the spacing calculated by the formula for the β form. The subcell dimensions of the β form are a_s=0.733, b_s=0.504, and c_s=0.252 nm.[17] Con-

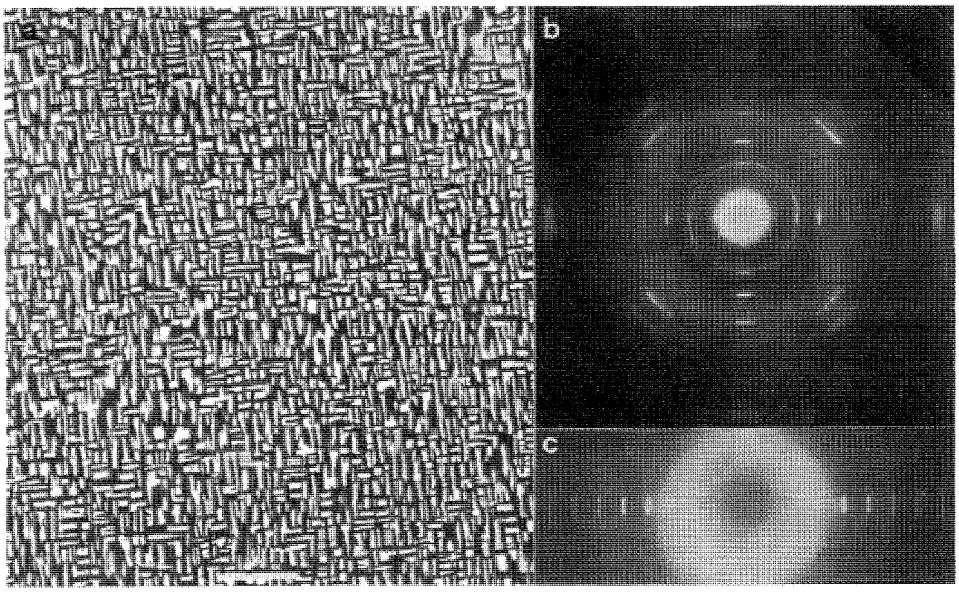

Fig. 5. Electron micrograph (a), electron-diffraction pattern (b), and the long-spacings (c) of 1-triacontanol film.

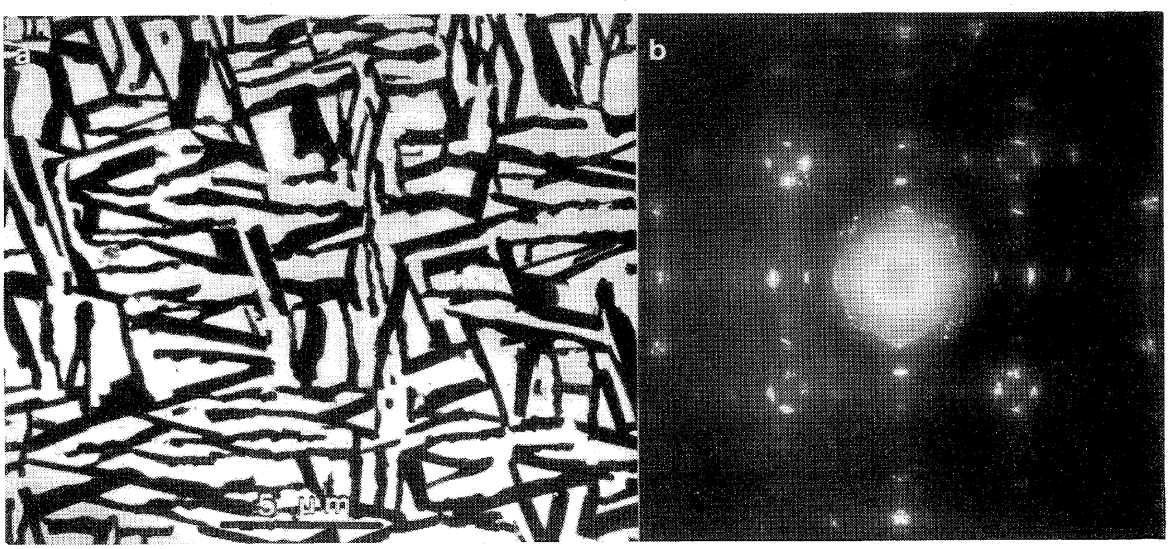

Fig. 6. Electron micrograph (a) and electron-diffraction pattern (b) of methyl triacontanoate film.

sequently, the crystal form of 1-triacontanol deposited on the substrate was assumed to be of the orthorhombic form, with dimensions of $a_s(=a)=0.733$, $b_s(=b)=0.504$, $c_s=0.252$, and $c=8.10$ nm. On the basis of these subcell dimensions, the reflection spots in Fig. 5(b) were indexed so as to be similar to the diffraction pattern of the triacontane film shown in the previous section. Therefore, it seems that the epitaxial overgrowth of 1-triacontanol molecules vacuumcondensed on the substrate is similar to that of triacontane molecules.

Figure 6(a) shows the electron micrograph of the methyl triacontanoate film deposited on the substrate kept at 30 °C. The film was composed of V-shaped crystals growing along two directions crossing at 32°, and the [110] direction of the substrate crystal corresponded to the bisectional direction of the V-shaped crystals. These crystals intersected at right angles to each other. Figure 6(b) shows the electron-diffraction pattern from the film. As has been described in a previous paper,[12] the (110) planes of the two crystals related by mirror symmetry, whose mirror plane corresponds to the (110) plan of KCl, are oriented parallel to the substrate surface. Their c-axes are parallel to the [110] direction of the substrate KCl.

The crystal morphologies differed with the end-groups when the linear molecules grew epitaxially on KCl. The epitaxial overgrowth of paraffins and 1-triacontanol crystals on the surface of KCl is represented schematically in Figs. 7(a) and (b). The (110) planes are oriented parallel to the substrate surface. The c-axes are parallel to the [110] direction of KCl. Figures 7(c) and (d) show the schematic representation of the relative orientation and the epitaxial over-

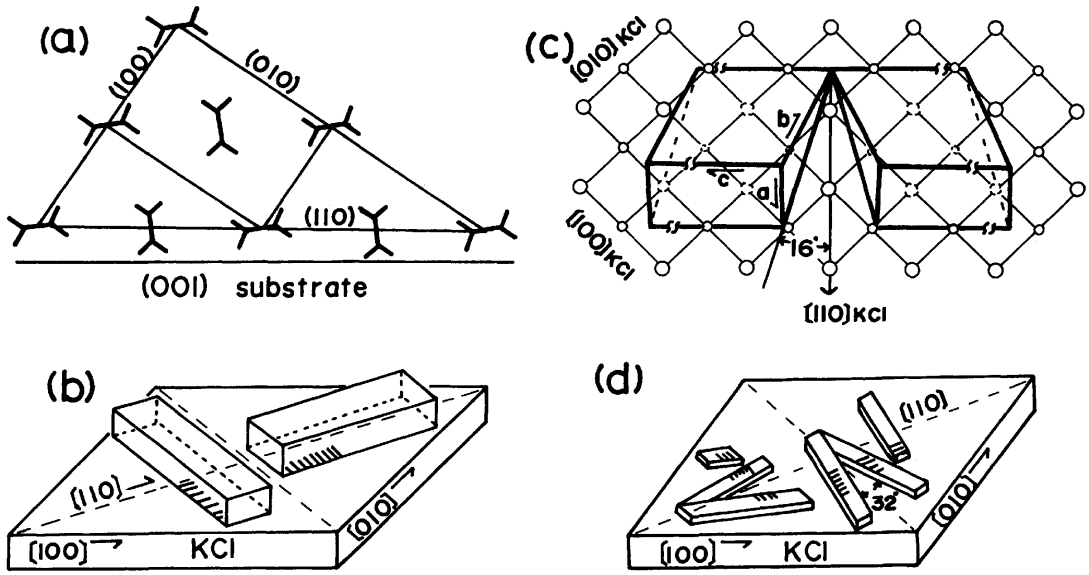

Fig. 7. (a): The relation between paraffin and alcohol molecules and the substrate surface. (b): Orientation of the deposited paraffin and alcohol crystals on the substrate surface. The chain molecules are shown in the crystals. (c): Schematic diagram of the relative orientation of methyl ester crystals and KCl (001) surface. (d): Orientation of the deposited methyl triacontanoate crystals on the substrate surface.

growth of the methyl triacontanoate crystals on the KCl (001) surface. The [110] direction of the methyl triacontanoate crystals crosses the [110] direction of the substrate crystal at 16°. The morphology of the deposited methyl triacontanoate is V-shaped, and these V-shaped crystals grow epitaxially, crossing each other orthogonally, corresponding to the C_{4v} symmetry of the substrate crystal.

The triacontanoic acid film deposited on the substrate at 20 °C was composed of randomly-oriented rod-like crystals and lamellar crystals filling in the space among the former, as is shown in Fig. 8(a). The high-resolution electron-diffraction pattern from the film showed the arc reflection spots on the ring pattern, as is shown in Fig. 8(b). This pattern was similar to the pattern obtained from hexatriacontane film, in which the crystal c-axis was oriented perpendicular to the substrate.[11] However, not all spots were indexed to the series of $hk0$ reflections. When the film was tilted about 40° around the a-axis of the crystal, the pseudo-hexagonal net-pattern appeared, as is shown in Fig. 8(c). The normal-chain carboxylic acids are known to possess several crystalline modifications. The crystals of even-numbered acids have three forms which are called the A-, B-, and C-form respectively, in order of the decrease in long-spacings.[19] The chain molecules in the B-and C-forms tilt to the basal (001) plane at angles of 62.76° and 51.54° respectively; these angles correspond to the β angle in respective monoclinic form. The B- and C-forms have the same subcell dimensions; a_s=0.740 nm and b_s=0.496 nm,[20,21] and the long-spacing of the C-form triacontanoic acid crystal is 6.52 nm.[22] The crystal parameters of the C-form triacontanoic acid crystal are a=0.936, b=0.496, c=6.52 nm, and β=128.4°. The net pattern in Fig. 8(c) was indexed with $hk0$ reflection series of the C-form. Therefore, the triacontanoic acid crystal deposited on the substrate is the C-form, and its c-axis tilts at an angle about 50° to the basal plane. Consequently, the (001) plane of the triacontanoic acid crystal is

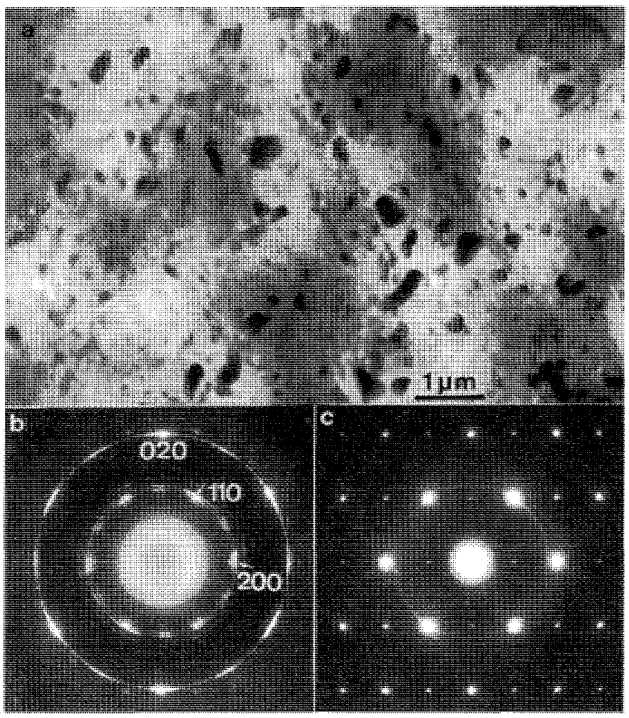

Fig. 8. Electron micrograph (a) and electron-diffraction patterns (b) (c) of triacontanoic acid film. Electron-diffraction pattern (c) was obtained from the film tilted about 40° around the a-axis of the crystal.

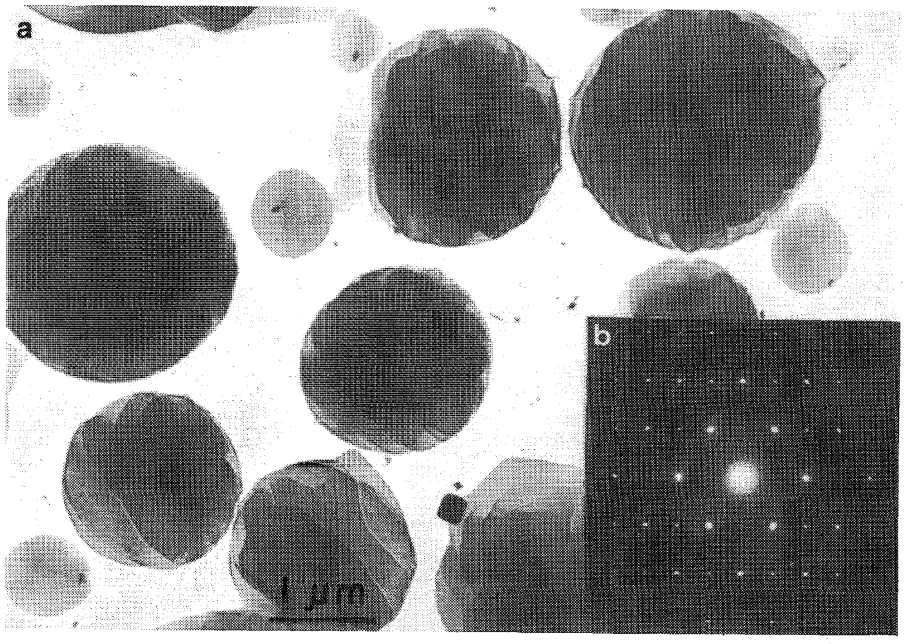

Fig. 9. Electron micrograph (a) and electron-diffraction pattern (b) of triacontane film deposited on the substrate kept at 100°C.

oriented parallel to the substrate (001) plane; as a result of such an orientation, the *c*-axis tilts at an angle of 51.54° to the substrate.

When the substrate was kept at a temperature higher than the melting point of each linear molecule, each sample vacuum-condensed on the surface formed discrete, disk-like crystals which were composed of overlapping lamellae, as is shown in Fig. 9(a). The electron-diffraction patterns from these crystals shows a single net-pattern of higher-order reflections of 100_s and 010_s, as is shown in Fig. 9(b); this indicates that the *c*-axes of the crystals are perpendicular to the substrate surface. Therefore, when linear molecules are evaporated on a substrate which is kept at a temperature above their melting points, the liquid deposit condenses in droplets due to the surface energy. On cooling, the deposited molecule probably crystallizes independently of the molecule-substrate interaction and forms the disk-like crystals composed of lamellae.

Paraffins, 1-triacontanol, and methyl triacontanoate crystals took their *c*-axes parallel to the substrate surface. On the other hand, the triacontanoic acid crystals took their *c*-axes perpendicularly to the substrate surface. It seems that the epitaxial overgrowth of long-chain molecules is dependent on the interaction between the end-groups and the substrate. Mauritz et al. pointed out that the non-polar aliphatic long-chain was oriented parallel to the alkali halide surface to minimize the total energy of molecular interaction and that the dispersion-repulsive force was most sensitive to orientation and was greater in magnitude than the electrostatic forces.[23] On the contrary, the polar end-groups probably have a tendency to come in contact with ionic species by means of dipole-dipole interaction. If the dipole-dipole interaction is strong and the interaction between the deposited molecule and the substrate is rather weak, the molecule comes into close contact with the ionic species on the substrate by the end group; the resultant orientation of the crystals is a standing *c*-axis one in order to maintain their molecular configuration. The adsorption strength of long-chain molecules with polar end-groups on metal increases in the following sequence: ester<alcohol <acid.[24] This order on metal may be applied on such ionic substrates as KCl. The more strongly the polar end-groups interact with the substrate, the more the tendency turned the standing *c*-axis orientation increases. It seems that the standing *c*-axis orientation of the triacontanoic acid crystal is caused by the strong interaction between the end-group and the substrate. If long-chain acid molecules have more carbon atoms than that of triacontanoic acid, it is probable that the influence of the polar end-group decreases and its *c*-axis becomes parallel to the substrate.

The author wishes to express his thanks to Professor Michio Ashida for his helpful discussions. Thanks are also due to Mr. Hideaki Yajima and Mr. Hisao Yanagi for their kind assistance.

The Reaction of Dibutyl Disulfide with Hydrogen Atom

Jie TANG,* Tohru KAMO, Muneyoshi YAMADA, Yozo OHSHIMA,† and Akira AMANO
Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aoba, Aramaki, Sendai 980

(Received December 25, 1986)

The title reaction was investigated at room temperature and under pressures ranging from 133 to 2660 Pa. 1-Butanethiol, butane, and 1-butene were the main products. In the reaction with deuterium atom, dibutyl disulfide and 1-butanethiol were not deuterated, while butane was monodeuterated. The following mechanism was proposed to account for the product composition and its pressure dependency as well as the deuterium labeling of the products. $C_4H_9SSC_4H_9+D\cdot \rightarrow n\text{-}C_4H_9SD + n\text{-}C_4H_9S\cdot$, $n\text{-}C_4H_9S\cdot + D\cdot \rightarrow n\text{-}C_4H_9SD^*$, $n\text{-}C_4H_9SD^*+M \rightarrow n\text{-}C_4H_9SD$, $n\text{-}C_4H_9SD^* \rightarrow \Delta'\text{-}C_4H_8+HDS$, $n\text{-}C_4H_9SD^* \rightarrow n\text{-}C_4H_9\cdot + DS\cdot$, $n\text{-}C_4H_9\cdot + D\cdot \rightarrow n\text{-}C_4H_9D$, $n\text{-}C_4H_9\cdot + D\cdot \rightarrow \Delta'\text{-}C_4H_8+HD$.

In our continuing effort to work out the mechanism of the reactions between thiols with H atom,[1-3] involvement of chemically activated thiols and metastable intermediate containing trivalent sulfur has been pointed out as its characteristic feature. The overall reaction is the hydrodesulfurization of thiols, which is initiated by

$$RSH + H\cdot \rightarrow RS\cdot + H_2 \quad (1)$$

and

$$RSH + H\cdot \rightarrow R\cdot + H_2S \quad (2)$$

taking place simultaneously. Thiyl radical, produced in reaction (1), subsequently forms chemically activated thiol, RSH*, which in turn becomes a source of the unique hydrodesulfurization. Reaction (2), a novel metathesis characteristic to the reactions of sulfur containing compounds with H atom, is considered to take place via the formation of metastable intermediate, $RSH_2\cdot$. Product composition of the overall reaction is governed by the relative importance between reactions (1) and (2).

In the present work, the study is extended to the reactions of disulfide with H and D atoms. Dibutyl disulfide is chosen as the substrate. The present experimental results can thus be compared conveniently with those of 1-butanethiol already accumulated in our laboratory.[1] As a result of the present study, mechanistic interpretation of reaction pathway turns out to be much less equivocal with this particular substrate, since it does not directly produce R· as in reaction (2).

Experimental

A conventional discharge flow apparatus was adopted. Details were described elsewhere.[1] Dibutyl disulfide and H_2 (or D_2), both diluted with excess He, were introduced into a Pyrex reactor tube of 400 mm in length and 27 mm in inside diameter. Flow rates of dibutyl disulfide, H_2 (or D_2), and He were 0.001 ml(NTP) s^{-1}, 0.01 ml(NTP) s^{-1}, and 0.72—14.4 ml(NTP) s^{-1} respectively. H atom (or D atom) was generated by passing H_2 (or D_2) through a microwave discharge cavity placed at the upstream side of the reactor. The reactor surface was coated with boric acid to prevent H atom (or D atom) from recombination.

The reaction was carried out at room temperature and under pressures ranging from 133 to 2660 Pa. Reacting gas mixture was intermittently withdrawn through a nozzle and was isolated into a side arm chilled by liquid N_2. The isolated sample was then analyzed by GC and GC-MS, using VZ-10 column (2 m, 328 K) for hydrocarbons and polyethylene glycol column (1 m, 363 K) for organosulfur compounds.

Commercially available purest grade dibutyl disulfide was purified by trap-to-trap distillation, and the fraction of better than 99% purity was used. Cylindered gases of H_2, D_2, and He were dried by passing through a train of liquid N_2 traps.

Results

1-Butanethiol, butane, and 1-butene were the main products of the reaction with H atom. Small amounts of *cis*-2-butene, *trans*-2-butene, and fragmental products such as propane, propylene, ethane, and ethylene were also formed. No sulfide was detected in the product. Based on the mass balance, methane, if any, was formed only in a limited amount.

Product composition vs. conversion relations observed with the three major products under 133, 530, and 2660 Pa are shown in Figs. 1, 2, and 3, respectively. Although 1-butanethiol was by far the most important, all the three major components were clearly the

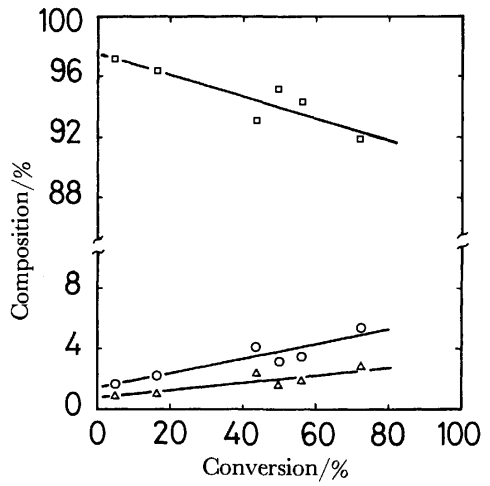

Fig. 1. Composition vs. conversion relation under 133 Pa. □: 1-Butanethiol, ○: butane, △: 1-butene.

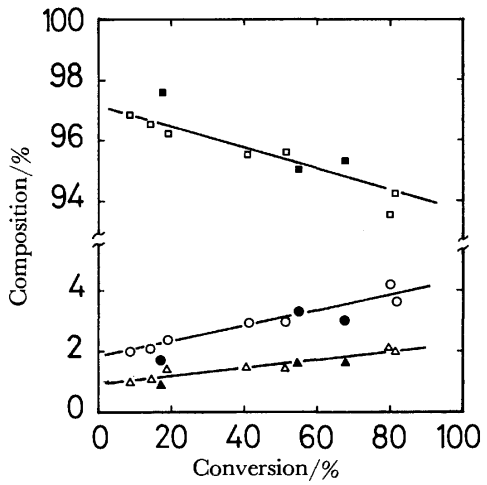

Fig. 2. Composition vs. conversion relation under 530 Pa. □: 1-Butanethiol, ○: butane, △: 1-butene. Filled symbols indicate the reaction with D atom.

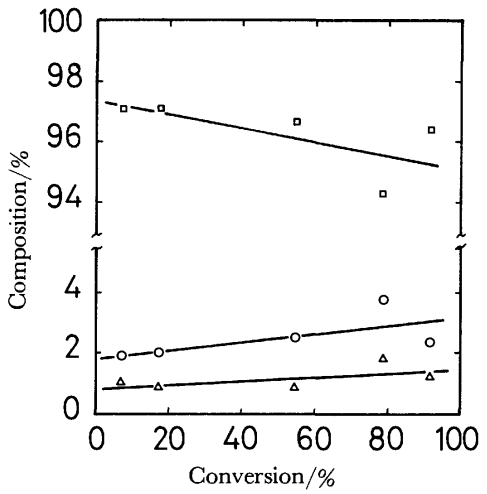

Fig. 3. Composition vs. conversion relation under 2660 Pa. □: 1-Butanethiol, ○: butane, △: 1-butene.

initial products. And, up to 90% conversion, these three together accounted practically for all the substrate consumed. As can be seen with filled symbols in Fig. 2, the product composition remained unchanged when D atom was used instead of H atom. The decreasing trend in 1-butanethiol compensated the increasing trend in butane and 1-butene. Thus, the reaction can be described by the following stoichiometry:

$$(C_4H_9S)_2 + H \rightarrow (2-a-b)\ C_4H_9SH + a\ C_4H_{10} + b\ C_4H_8$$

where a and b are stoichiometric coefficients. Irrespective of the pressure used, the ratio a/b of about 0.5 was deduced from the figures. The ratio $(a+b)/(2-a-b)$, however, decreased as the pressure increased. The latter ratios were 0.08 at 133 Pa, 0.05 at 530 Pa, and 0.03 at 2660 Pa.

Practically no isotopic mixing was observed with dibutyl disulfide left unreacted. Deuterium distributions observed with butane and 1-butene are listed in Table 1 for a few different conversions. Approximately one D atom was introduced into each butane molecule produced. Both 1-butene[D_0] and 1-butene-[D_1] were formed, and the latter became progressively important as conversion increased.

Table 1. Relative Abundance of Deuterium Labeled Products

Conversion/%	Butane			1-Butene		
	D_0	D_1	D_2	D_0	D_1	D_2
16.8	9	100	1	100	27	1
46.6	2	100		100	71	1
68.1		100		100	116	
89.1	3	100	2	100	103	2

The conventional GC-MS analysis showed no D-labeled 1-butanethiol. But, with a quadrapole mass spectrometer connected directly to the reactor tube, 1-butanethiol[D_1] was found to be an exclusive constituent. It may therefore be concluded that 1-butanethiol was monodeuterated in the course of the reaction, and that the result as observed with GC-MS was due to the retro H-D exchange between residual water in the ionization chamber and mercapto-D of 1-butanethiol[D_1].

Discussion

Heat of Formation of the Species in Relevance with the Present System. The values of the heat of formation of the species involved in the present study are estimated using a conventional additivity rule,[4] and are listed in Table 2. Error limits of the listed values are ±1.0 kcal mol^{-1} (1 kcal$_{th}$=4.184 kJ) for stable molecules, and ±2.0 kcal mol^{-1} for radicals. The reliability level of the additivity rule used here may be seen by comparing the tabulated data with literature values of $\Delta H^0_f(C_4H_9SH)$=−21.06 kcal mol^{-1},[5] and $\Delta H^0_f(C_4H_9SSC_4H_9)$=−37.63 kcal mol^{-1}.[6]

Initial Step. In analogy with the reactions of thiols and sulfides with H atom, and based on the fact that fragmentation of alkyl group was only trivial, the initial act of H atom is presumably its addition to one of the S atoms of the substrate molecule. Therefore, the following reactions are plausible.

$$C_4H_9SSC_4H_9 + D\cdot \rightarrow n\text{-}C_4H_9SD + C_4H_9S\cdot \quad (3)$$

$$C_4H_9SSC_4H_9 + D\cdot \rightarrow n\text{-}C_4H_9SSD + C_4H_9\cdot \quad (4)$$

For the sake of clarity, we hereafter write D standing for both hydrogen and deuterium atoms. Based on the

Table 2. Standard Heat of Formation of the Related Species[a)]

Species	ΔH^0_f / kcal mol^{-1}
n-C_4H_9SH	−21.1
n-C_4H_9SSH	−16.8
$C_4H_9SSC_4H_9$	−37.3
n-$C_4H_9\cdot$	15.8
n-$C_4H_9S\cdot$	17.8

a) Ref. 4.

values listed in Table 2, reactions (3) and (4) are exothermic by 18.1 and 15.8 kcal mol^{-1}, respectively. Therefore, reaction (3) is thermochemically more favorable.

We may also reject reaction (4) as a reaction of importance on the ground of the following argument. If reaction (4) takes place significantly, butyl radical should subsequently form butane and butenes through the intermolecular H transfer or else should form sulfide through the following reaction:

$$C_4H_9\cdot + C_4H_9SSC_4H_9 \rightarrow C_4H_9SC_4H_9 + C_4H_9S\cdot. \quad (5)$$

The results observed, however, turned out to be contrary to the above presumption. As will be described later, small amount of hydrocarbons observed in the product can be simply accounted for by the secondary reactions of $C_4H_9S\cdot$ produced in reaction (3). And, dibutyl sulfide, expected product of reaction (5), was not detected in the product.

The initiation quite analogous to reaction (3) was also suggested in the reactions of dimethyl and diethyl disulfides with H atom.[7] The reaction is considered to take place via the intermediary formation of the novel adduct $C_4H_9SS(H)C_4H_9$.[2] However, to date, no mention has been made on the structure and stability of such adduct. Recently, it was proposed that S-S bond in RSS(R)SR$\cdot$, formed in the reaction between RS$\cdot$ and RSSR, was weakened by at least one quarter of a normal S-S *sigma*-bond.[8]

Secondary Reactions. In their study on the reactions of dimethyl and diethyl disulfides with H atom, Strausz et al. reported the formation of a considerable amount of polymers.[7] The formation of polymers in the above instance, being due to the low concentration of H atom used in their work, made it difficult for them to elucidate the fate of thiyl radical produced by reaction (3). In the present work, H atom concentration was maintained at the level not less than the concentration of the substrate. Consequently, practically no polymer was formed, and the amount of 1-butanethiol in the product accounted for more than 90% of dibutyl disulfide consumed over the wide conversion range. This indicates that reaction (3) is followed by

$$C_4H_9S\cdot + D\cdot \rightarrow n\text{-}C_4H_9SD^* \quad (6)$$

and

$$n\text{-}C_4H_9SD^* + M \rightarrow n\text{-}C_4H_9SD, \quad (7)$$

and that dibutyl disulfide is considerably more reactive than 1-butanethiol in the reaction with H atom. The latter statement is in accord with some existing rate data listed in Table 3. Further reactions of 1-butanethiol may therefore be ignored in formulating a group of secondary reactions. It should be noted here that the asterisk denotes chemically activated species and M the bath molecule.

Conceivable reactions of the chemically activated 1-butanethiol, other than reaction (7), are

$$n\text{-}C_4H_9SD^* \rightarrow \Delta'\text{-}C_4H_8 + HDS \quad (8)$$

and

$$n\text{-}C_4H_9SD^* \rightarrow n\text{-}C_4H_9\cdot + DS\cdot. \quad (9)$$

Reactions subsequent to reaction (9) are the following:

$$n\text{-}C_4H_9\cdot + D\cdot \rightarrow n\text{-}C_4H_9D \quad (10)$$

and

$$n\text{-}C_4H_9\cdot + D\cdot \rightarrow \Delta'\text{-}C_4H_8 + HD. \quad (11)$$

According to the scheme, consisting of reactions (7)—(11), [hydrocarbon]/[1-butanethiol] ratio should decrease as pressure increases. This is quite in accord with the result mentioned earlier that the ratio $(a+b)/(2-a-b)$ decreased from 0.08 at 133 Pa to 0.03 at 2660 Pa. One D atom is introduced into butane through reaction (10), while no channel exists to produce D-labeled 1-butene. During a later stage, however, D-labeled 1-butene may be formed through the sequence comprising D-addition and H-abstraction. These are also quite in accord with the present result.

It should be noted that the sequence of elementary reactions, from reaction (6) through reaction (11), is identical with the one proposed for the reaction of 1-butanethiol with H atom, and was, therefore, thoroughly discussed already.[1,3]

1-Butene/Butane Ratio. According to the proposed mechanism, the following formula can be obtained to relate the ratio of 1-butene to butane.

$$[\text{1-butene}]/[\text{butane}] = k_8/k_9 + k_{11}/k_{10}(1 + k_8/k_9).$$

The ratio [1-butene]/[butane] was observed to be 0.5 in the present study. The ratio k_{11}/k_{10}=0.05 was estimated in the reactions of ethyl radical with H atom[10] and propyl radical with methyl radical.[11] Based on

Table 3. Rate Constant and Activation Energy of the Reaction of Sulfur Compounds with H Atom

Compound	Rate constant	Activation energy	Reference
	l mol^{-1} s^{-1}	kcal mol^{-1}	
Dimethyl disulfide	4.80×10^9	0.1	7
Diethyl disulfide	2.74×10^9	1.7	7
Dimethyl sulfide	2.10×10^8	2.6	9
Diethyl sulfide	0.80×10^8	3.8	9
Thiolane	2.92×10^8	2.0	3
Methanethiol	7.80×10^8	1.7[a], 2.6[b]	2
1-Butanethiol	1.01×10^8	2.2[a], 3.2[b]	1

a) Assigned for reaction (1). b) Assigned for reaction (2).

these values, the value of 0.43 can be deduced for the ratio k_8/k_9. On the other hand, k_8/k_9=0.18 was reported in the very low pressure pyrolysis of 1-butanethiol.[12] There is, therefore, a considerable difference between the chemically activated 1-butanethiol and the thermo-energized 1-butanethiol in their H-addition and H-abstraction rate ratios.

Microenvironmental Effects of Water-Soluble Polymers on the Chemiluminescence of Luminol and Its Analogs

Hajime KARATANI
Laboratory of Analytical Chemistry, Faculty of Textile Science, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606
(Received July 31, 1986)

The effects of water-soluble polymers(WSPs), such as bovine serum albumin(BSA) and polyethylenimine-(PEI), on chemiluminescence(CL) in an aqueous solution have been studied. The CL emission, particularly in the initial stage of the CL reaction, was strongly enhanced by increasing the concentrations of these WSPs. This was attributed to the acceleration of the chemical reactions prior to the formation of the light-emitting species. BSA was also peculiar in that it could enhance CL under neutral pH conditions. It was suggested that these WSPs offered hydrophobic and basic microenvironments well suited to the CL reaction.

The microenvironment of an aqueous solution has a substantial effect on the chemi- and the bioluminescence.[1-4] In particular, the microenvironmental effects of surfactants, such as hexadecyltrimethylammonium bromide(CTAB), polyoxyethylene sorbitan monostearate(Tween 60), polyoxyethylene(10)octylphenyl ether(Triton X-100), polyoxyethylene(23)-dodecanol(Brij-35), and sodium dodecyl sulfate(SDS), to enhance the CL emission of lucigenin(*N,N'*-dimethyl-9,9'-biacridinium dinitrate) and of luminol(5-amino-2,3-dihydro-1,4-phthalazinedione) are interesting from the standpoint of analytical chemistry.[5-8]

CL-enhancement effects can arise from several factors: (1) The rate of the reaction leading to the formation of the light-emitter, (2) the CL excitation efficiency, (3) the fluorescence quantum yield of the emitter, and (4) some combination of these factors.[6]

To date, only a few reports have dealt with the relationship between the CL-emission intensity in the presence of surfactants and the above-mentioned factors.[1,4,6] In the CL of cypridina luciferin, two factors, (1) and (3), have a substantial effects on the enhancement of its CL emission,[1] while the (2) factor is significant in the CL of MAD(9-methylene-10-dodecylacridane).[4] Two factors, (1) and (2), contribute to an increase in the CL-emission intensity of lucigenin.[6]

Such WSPs as BSA and PEI show a strong binding affinity to small aromatic anions.[9,10] These are expected to influence the CL reaction significantly. However, the effects of the WSPs on the CL emission have not yet been studied. In this paper, the effects of BSA and PEI(Mw: 70,000) on the CL emission centering around luminol were studied and were evaluated from the analytical standpoint. The other compounds used in this study were isoluminol(6-amino-2,3-dihydro-1,4-phthalazinedione) and *N*-(4-aminobutyl)-isoluminol derivatives (ABI derivatives: 6-[*N*-(4-aminobutyl)alkylamino]-2,3-dihydro-1,4-phthalazinedione) (Fig. 1).

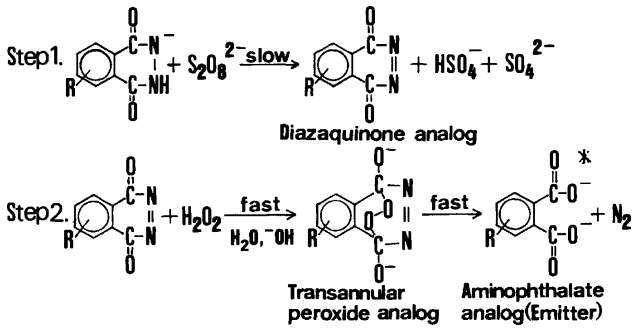
Results

The CL reaction in this study was initiated with a hydrogen peroxide(H_2O_2)-potassium peroxodisulfate($K_2S_2O_8$) co-oxidation system in 0.1 mol dm^{-3} aqueous sodium carbonate (Na_2CO_3, pH 11.4). The following scheme, Scheme 1, is proposed as the CL reaction mechanism of luminol(pK_a=6 and 13).[14,15] The CL reaction of the other compounds also seems to follow Scheme 1. The reaction is of the first order in the CL



Scheme 1.

compound and in peroxodisulfate($S_2O_8^{2-}$), but is of zero order in H_2O_2 and at hydroxide(OH^-) concentration under the conditions of this experiment.[14]

The CL quantum yield(ϕ_{CL}) based on the starting luminols is the product of several variables:[15]

$$\phi_{CL} = \phi_r \cdot \phi_{es} \cdot \phi_{fl}, \quad (1)$$

where ϕ_r is the fraction of molecules following the correct chemical reaction path, ϕ_{es} is the fraction of those product molecules that are formed in the excited emitter, i.e., the CL excitation efficiency, and ϕ_{fl} is the fluorescence quantum yield of the emitter. In this study, the ϕ_{fl} values were determined on the basis of the

total reaction mixture at the end of the CL reaction(48 h after CL initiation). The values of these variables are summarized in Table 1.

Figure 2 shows the effects of BSA on the CL of luminol. In the presence of BSA, the CL emission reached its maximum intensity at about 10 s after the initiation of the reaction and thereafter rapidly to a constant level. The CL emission intensities in both the initial stage and in the plateau region increased with the increase in the BSA concentration. The CL-spectrum maximum from 10 to 12.5 min after the initiation of the reaction was affected little by the addition of BSA, whereas the fluorescence-spectrum maximum of the total reaction mixture at the end of the reaction, 48 h after the initiation of the reaction, shifted considerably to shorter wave lengths and its intensity was lower than that obtained for the total reaction mixture in the absence of BSA. The inherent fluorescence of BSA in the total reaction mixture also

[Luminol]=8.0×10^{-5} mol dm^{-3} in 0.1 mol dm^{-3} Na_2CO_3. [H_2O_2]=0.10 mol dm^{-3}. [$K_2S_2O_8$]=2.5×10^{-4} mol dm^{-3}. [PEI]/wt%: a=0, b=0.010, c=0.050, d=0.10, e=0.25, f=0.50, g=1.0, h=2.0. Excitation: 306 nm.

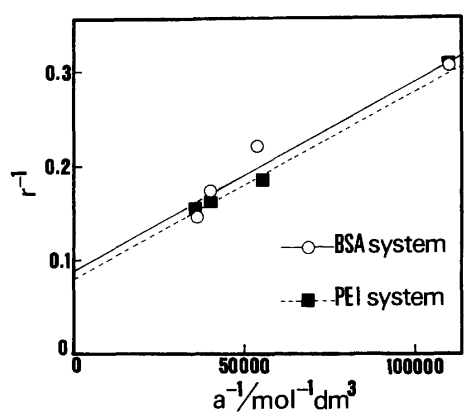

Fig. 4. Reciprocal of average mole ratio of bound luminol monoanions to WSP ($1/r$) vs. reciprocal of equilibrium concentration of luminol monoanions ($1/a$). Solvent: 0.1 mol dm^{-3} Na_2CO_3. [WSP]=0.10 wt%. [Luminol]=1.0×10^{-5}—3.0×10^{-5} mol dm^{-3}.

become weaker than in the 0.1 mol dm^{-3} Na_2CO_3 solution.

PEI also influenced the CL emission, particularly in the initial stage, as is shown in Fig. 3. In this case, much more time was required for the attainment of the CL-emission peak than in the BSA system. By analogy to the BSA, the fluorescence spectrum shifted to a shorter wavelength, and its intensity decreased, with the increase in the PEI concentration. In this case, PEI was non-fluorescent, unlike BSA.

The binding constant(K, mol^{-1} dm^3) between the luminol monoanions and the WSPs and the maximum possible number of bound luminol monoanions per WSP molecule(n) were determined using the equilibrium dialysis method following Eq. 2, as suggested by Klotz et al.:[9]

$$1/r = 1/n + 1/n \cdot K \cdot a, \quad (2)$$

where r is the moles of luminol monoanions bound to the total moles of WSP and where a is the molar concentration of free luminol monoanions at equilibrium. The measurements were made in 0.1 mol dm^{-3} aqueous Na_2CO_3. Both K and n can be calculated from a linear plot of $1/r$ vs. $1/a$. Figure 4 shows the results of the analysis of the relationship between the luminol monoanions and the WSPs. In this system containing 0.1 wt% of BSA, the K and n values were 4.41×10^4 mol^{-1} dm^3 and 11 respectively, while they were 3.72×10^4 mol^{-1} dm^3 and 12 respectively in the presence of 0.1 wt% of PEI(Mw: 70000).

Figure 5 indicates the relationship between the initial CL-emission intensity(CL intensity, I; at 10 s after the initiation of the reaction) and the concentration of WSP. The ratio of the CL intensity in the presence of WSP to that in the absence of WSP was plotted as a function of the WSP concentration.

Figure 6 indicates the effects of various surfactants on the CL emission. As is shown in Fig. 6, the surfactants did not affect the initial CL emission nearly as much as the WSPs. In addition, unlike the system containing the WSPs, the shifts of the fluorescence-spectrum maximum were not observed.

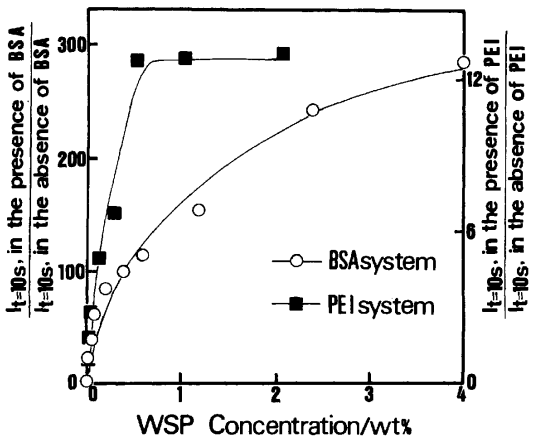

Fig. 5. Effects of BSA and PEI on the initial chemiluminescence intensity($I_{t=10s}$). [Luminol]= 8.0×10^{-5} mol dm^{-3} in 0.1 mol dm^{-3} Na_2CO_3. [H_2O_2]=0.10 mol dm^{-3}. [$K_2S_2O_8$]=2.5×10^{-4} mol dm^{-3}. [BSA]=0.10 wt%. [PEI]=0.10 wt%.

a) [Compound]=1.6×10^{-5} mol dm^{-3} in 0.1 mol dm^{-3} Na_2CO_3. b) [BSA]=0.10 wt%. c) I in the presence of BSA to I in the absence of BSA at 10 s after the initiation of the reaction.

The effects of BSA on various CL reactions were also examined. Table 2 shows the ϕ_{fl} values with and without BSA and the initial I ratio(I in the presence of BSA to I in the absence of BSA) at 10 s after the initiation of the reaction. As has been referred to earlier, the ϕ_{fl} values were determined based on the total reaction mixture at the end of the CL reaction(48 h after CL initiation). The concentration of BSA was 0.10 wt%. In such a fairly dilute system, BSA had only a small influence on the fluorescence of the total reaction mixture.

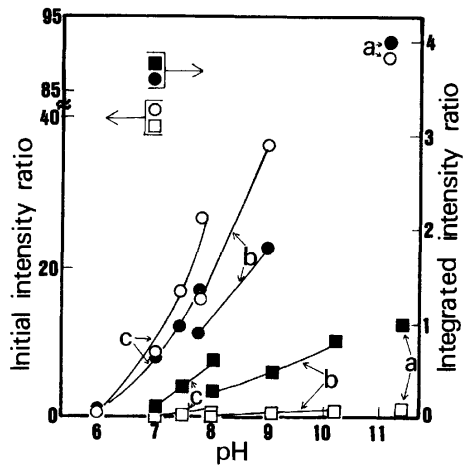

Fig. 7. Comparison of the chemiluminescence-emission intensity of luminol under various pH conditions with and without BSA. [Luminol]=8.0×10^{-5} mol dm^{-3}. [H_2O_2]=0.10 mol dm^{-3}. [$K_2S_2O_8$]=2.5×10^{-4} mol dm^{-3}. [BSA]=0.50 wt%. a: Prepared with 0.1 mol dm^{-3} Na_2CO_3, b: prepared with 0.05 mol dm^{-3} borate/NaOH buffer solution, c: prepared with 0.1 mol dm^{-3} phosphate buffer solution. ○, ●: With BSA. □, ■: Without BSA. The intensity ratios were calculated on the basis of the initial intensity (t=10 s) or the integrated intensity (during 10 min after the initiation of the reaction) measured in 0.1 mol dm^{-3} Na_2CO_3 without BSA.

Figure 7 shows the CL-emission intensities measured under various pH conditions in the presence of BSA.

Discussion

Time Course of CL Emission. The effects of BSA and PEI on the time course will be described briefly, since it is important to evaluate the features of the time course of CL emission if we are to use CL for analytical chemistry.

In the presence of BSA (Fig. 2A), the time required to reach the CL-emission peak is nearly constant and is independent of the BSA concentration, irrespective of the peak intensity. In the decay part in Fig. 2A, there are at least two decay components, one of them decays rapidly, while the other one lasts more than 10 min.

On the other hand, in the presence of PEI (Fig. 3A), the time required to reach the CL-emission peak depends on the PEI concentration and becomes shorter, approaching an almost constant value, as the PEI concentration increases. The decay feature with no prolonged emission is also different from that in the presence of BSA.

It is difficult to elucidate the time course in detail, since the interaction between these WSPs and the dissolved chemical species may well be very intricate. However, the effects of these WSPs, especially BSA, on enhancing the initial CL emission seem to have a great practical value from the analytical standpoint.

Enhancement of CL Emission. The most remarkable feature of the absorption spectra of luminol and its analogs in the 0.1 mol dm^{-3} Na_2CO_3 solution containing BSA or PEI was that the absorption peak near 230 nm becomes small and shifts to the longer wavelength side by 5—10 nm. This suggests that the monoanions of these CL compounds are bound to the hydrophobic region of BSA or PEI, like other aromatic anions.[9-13] In this connection, it was worth noting that most of the acidic groups in BSA are dissociated in the 0.1 mol dm^{-3} Na_2CO_3 solution. A similar thing is true with the ammonium protons on PEI(pK_a≈6). Therefore, BSA and PEI under the present reaction conditions are likely to afford basic binding sites(for binding acidic CL compounds) in addition to their inherent hydrophobic sites within the polymer matrix. The binding affinities of the luminol monoanions to both BSA and PEI seem similar, for there is no marked difference in the K values or n values determined in the two WSP systems.

As is shown in Figs. 2A and 3A, the microenvironments offered by BSA or PEI mentioned above caused remarkable CL-enhancing effects in the initial stage of the CL reaction. Such effects were remarkable, especially in the presence of BSA, as is shown in Fig. 5. The difference in the effects of WSPs on the initial CL emission seems to depend significantly on their basic properties rather than on their hydrophobic properties. This seems to be supported by the fact that no strong initial CL emission is observed in the presence of surfactants without basic groups in their micelles (Fig. 6A).

It should also be emphasized that the CL-enhancing effects were even observed in a very dilute WSP. Such was not the case with surfactants. They usually did not show any CL-enhancing effects below their critical micelle concentrations(cmcs).[5,6]

As is listed in Table 2, the initial I ratios in various CL reactions increased in the presence of BSA. The introduction of the electron-donating substituent to the amino group of isoluminol results in the higher ϕ_{es}.[15] This was also observed in the CL of ABI derivatives, as is summarized in Table 1. This is because the electron-donating property of the aminobutylalkyl substituents of the ABI derivatives is advantageous for the intramolecular chemically initiated electron-exchange luminescence(CIEEL) mechanism.[17,18] In the BSA molecule, various basic groups carrying lone-pair electrons seem to be able to interact with the protons of the amino and hydrazide groups of luminol, as is generally observed in the interaction between enzymes and substrates.[19] In other words, BSA in a basic solution is considered to be able to give an advantageous reaction field to the intramolecular CIEEL mechanism, particularly in the CL of luminol or isoluminol. However, in this study it is difficult to relate the microenvironmental effects to ϕ_{es} directly.

On the other hand, the effects of the WSPs on ϕ_{fl} are rather detrimental to the enhancement of the CL emission, as is shown in Figs. 2C and 3C. This was also

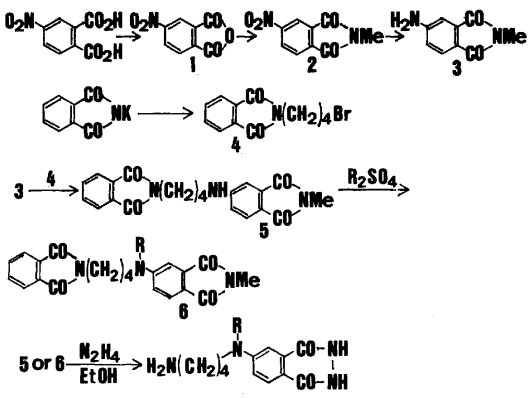
observed in the presence of a surfactant (Fig. 6C). The fluorescence intensity of 3-aminophthalate dianions (8.0×10^{-5} mol dm^{-3}) in 0.1 mol dm^{-3} Na_2CO_3 solutions containing various concentrations of BSA or PEI also decreased compared with that in the absence of BSA or PEI. However, the shifts in the fluorescence spectra shown in Figs. 2C and 3C were in conflict with the fact that there was no difference in the fluorescence-spectra maxima of 3-aminophthalate dianions in the system both with and without BSA or PEI (the shift was also not observed at 48 h after the preparation of the test solution). The shifts shown in Figs. 2C and 3C are thus at present difficult to explain.

Effects of WSP from the Analytical Standpoint. For the application of CL to clinical and biochemical analysis, it is important to obtain a strong CL emission, even under neutral pH conditions.[20] As is well known, the CL-emission intensity of luminol is much weaker under neutral conditions than under strongly alkaline conditions.[21] Thus, BSA was studied under neutral or weakly alkaline conditions in order to enhance the CL emission. As is shown in Fig. 7, the microenvironments of BSA were highly effective in producing a sufficient CL emission, even under neutral pH conditions. This indicates that BSA can be very useful enhancer of CL emission for analytical application. As is shown in Table 2, the effects of BSA on the CL emission of ABI derivatives are smaller than those of BSA in the CL emission of luminol, but BSA seems to be of practical value as a CL-enhancer with ABI derivatives also.

Experimental

Instruments. The UV and visible absorption spectra were measured by using a JASCO-610C spectrophotometer. The fluorescence and CL spectra were recorded with a Shimadzu RF-540 spectrofluorometer. In recording the CL spectra, the window of the excitation-light source was shut. In the measurements of the time course of the CL emission, the CL emission was received by a EMI 9893A/100 photomultiplier, and then the output photocurrent was amplified by a home-made preamplifier and recorded by a Matsushita VP-6431B recorder. The operational amplifier used in the I-V converter part of the preamplifier was an AD515KH apparatus. The guard ring was placed around the input terminals, and they were put on stand-off terminals made of Teflon for perfect insulation. In the measurements of the monochromatic-light-emission intensity, a Jovan-Yvon H-20 monochromator was set between the photomultiplier and a black box equipped with the CL reaction cell(inner-volume: 5 cm^3). The temperature in the black box was controlled using a thermistor. All the measurements were done at 25 °C. Mass-spectral analysis was performed by means of a Hitachi M-80B mass spectrometer.

Reagents. The BSA(F-V)(Mw: 70,000, Nakarai) was used as received. The PEI(Mw: 70,000, Wako) was dialysed against cellophane membrane for 3 days in distilled water, and then the solvent was evaporated to give a highly viscous liquid. The CTAB, SDS, Triton X-100, and Brij-35 were all purchased from Wako and used as received. The luminol (Wako), isoluminol(Tokyo Kasei), and 3-aminophthalate (Kanto Kagaku) were used after recrystallization from 0.6 mol dm^{-3} HCl. The ABI, ABMI, ABEI, ABPI, and ABBI were synthesized by a modification of the method of Schroeder et al. for ABEI.[22] The melting-point data are uncorrected values. These compounds were synthesized according to Scheme 2.



Scheme 2.

4-Amino-*N*-methylphthalimide (3). A modification of the method of Nicolet et al. was used for the syntheses of 4-nitrophthalic anhydride (**1**).[23] Compound **2** was synthesized as has been described in the literature.[22] Concentrated HCl (303 cm^3) and 48 cm^3 of water was added, drop by drop and successively, to a mixture of 50 g (0.24 mol) of **2** and 215 g (0.95 mol) of $SnCl_2\cdot2H_2O$, and then the reaction mixture was vigorously stirred for 1 h at 85 °C, resulting in a pale yellow solution. This solution was allowed to stand at room temperature over night. The product was precipitated as a white powder. Filtration and thorough washing with much water gave **3** as a yellow powder. This powder was dried at 120 °C for several hours; mp 246—248 °C.

***N*-(4-Bromobutyl)phthalimide (4).** This compound was synthesized according to the procedure in the literature.[24]

***N*-Methyl-4-*N*[4-(*N*-phthalimide)butyl]aminophthalimide (5).** This compound was likewise synthesized as has been described in the literature.[22]

The *N*-alkylation of **5** was performed by a reaction with dialkyl sulfate by reference to the literature.[22] To synthesize ABMI, a mixture of 7.5 g (0.02 mol) of **5** and 25 cm^3 (0.15 mol) of dimethylsulfate was stirred for 60 min at 140 °C under anhydrous conditions. After it had cooled to room temperature, the mixture was poured into 500 cm^3 of ice water to deposit a dark green-colored viscous fluid. This product was recrystallized from 50% H_2O-acetic acid several times to give yellow green crystals. Next, a mixture of 5 g (0.012 mol) of **6**, 14 cm^3 of anhydrous hydrazine, and 50 cm^3 of absolute ethanol was stirred for 4 h at 85 °C. Then the reaction mixture was cooled to room temperature. In the next step, after the excess hydrazine and ethanol had been removed by vaccum distillation, ABMI including the by-product was deposited as a faintly gray-colored solid. After filtration, it was mixed with 100 cm^3 of 3 mol dm^{-3} HCl to dissolve the ABMI. An insoluble by-product was removed by filtration. The filtrate was adjusted at pH 7—9 with 5 mol dm^{-3} potassium hydroxide, and soon ABMI precipitated as white crystals. They were recrystallized from 50% H_2O-*N*,*N*-dimethylformamide. Other ABI derivatives were

synthesized similarly.

Mass-Spectral Data. ABI; MS (70 eV) m/z (rel intensity) 248 (M^+; 45), 231 (15), 204 (48), 190 (100), and 177 (37); Found: m/z 248.1272. Calcd for $C_{12}H_{16}O_2N_4$: M, 248.2738. ABMI; MS (70 eV) m/z (rel intensity) 262 (M^+; 28), 218 (7), 204 (100), and 191 (11); Found: m/z 262.1415. Calcd for $C_{13}H_{18}O_2N_4$: M, 262.3007. ABEI; MS (70 eV) m/z (rel intensity) 276 (M^+; 26), 232 (5), 218 (100), 204 (8), and 190 (28); Found: m/z 276.1587. Calcd for $C_{14}H_{20}O_2N_4$: M, 276.3276. ABPI; MS (70 eV) m/z (rel intensity) 290 (M^+; 4), 248 (58), 204 (43), 190 (100), and 177 (21); Found: m/z 290.1739. Calcd for $C_{15}H_{22}O_2N_4$: M, 290.3545. ABBI; MS (70 eV) m/z (rel intensity) 304 (M^+; 34), 246 (68), 204 (34), 190 (50), and 72 (100); Found: m/z 304.1898. Calcd for $C_{16}H_{24}O_2N_4$: M, 304.3814.

The other reagents used in this study were of a reagent grade.

Determination of ϕ_{fl} and ϕ_{CL}. The fluorescence and CL spectra were corrected according to the method in the literature.[25] The correction of the intensity of the excitation light was made on the basis of the excitation spectrum of Rohdamine B (3 g dm^{-3} in ethylene glycol). The ϕ_{fl} was determined relative to the quantum yield of quinine sulfate.[25] The unknown ϕ_{fl} was given by the following equation:

$$\phi_{fl,sample}=\frac{A_{standard}\cdot N^2_{sample}\cdot I_{sample}}{A_{sample}\cdot N^2_{standard}\cdot I_{standard}}\cdot\phi_{fl,standard}, \quad (3)$$

where A, I, and N are, respectively, the absorbance, the fluorescence intensity (I=the area under the fluorescence spectrum), and the refractive index of the solution. $\phi_{fl,standard}$ is 0.55 at 25 °C. ϕ_{CL} was determined relative to the ϕ_{CL} of luminol in dimethyl sulfoxide. The unknown ϕ_{CL} was given by:[26]

$$\phi_{CL,sample}=\frac{q_{\lambda max,sample}\cdot A_{standard}\cdot f_{\lambda max,standard}}{q_{\lambda max,standard}\cdot A_{sample}\cdot f_{\lambda max,sample}}\cdot\phi_{CL,standard}, \quad (4)$$

where $q_{\lambda max}$ is the time integral of the measured phototube current at the peak wavelength of the CL spectrum, and where A is the number of the molecules reacted in the CL reaction. The fractional CL emission at λ_{max}, $f_{\lambda max}$, is calculated by integrating the area under the portion of the curve at the CL-spectrum maximum bound by the exact wavelength-band pass and by dividing it by the total area under the CL spectrum. $\phi_{CL,standard}$ is 0.0125 at 25 °C.[27]

Initiation of the CL Reaction. The CL reaction was initiated with a H_2O_2–$K_2S_2O_8$ co-oxidation system. The H_2O_2 and the $K_2S_2O_8$ were mixed just before use and then immediately injected into the CL reaction cell using a microsyringe while being stirred by the use of a magnetic stirrer for 30 s. The time required to make the solution homogeneous was within about 3 s in all CL reaction systems. In this study, a mixture of 40 μdm^3 of 35% H_2O_2 and 20 μdm^3 of 0.05 mol dm^{-3} aqueous $K_2S_2O_8$ was injected against 4 cm^3 of the solution of the CL compound in 0.1 mol dm^{-3} aqueous Na_2CO_3 (pH 11.4) (or in an appropriate pH-buffer solution). The concentrations of H_2O_2 and $K_2S_2O_8$ in the CL reaction mixtures were 0.10 and 2.5×10^{-4} mol dm^{-3} respectively.

Determination of pK_a. The pK_a values of the protonated PEI were determined by the titration of 0.46 wt% aqueous PEI (pH 10.2) with 0.05 mol dm^{-3} hydrochloric acid.

Determination of K and n. Both the K and n values were determined by reference to the literature.[9,28] The pretreatment of dialysis bags (Union Carbide, Cellophane Tubing-Seamless 30/32 inch for dialysis) was done according to the usual method.[29] The dialysis bags were filled with 20 cm^3 of the test solution, which contained 0.1 mol dm^{-3} Na_2CO_3, 0.1 wt% WSP, and various known concentrations of luminol (1.0×10^{-5}—3.0×10^{-5} mol dm^{-3}). The solution in the outside compartment (in which the dialysis bags were immersed) was the same as the test solution in volume, in Na_2CO_3 concentration, and in luminol concentration, but it contained no WSP. Three days were allowed for equilibration at 25 °C. The solution in the outside compartment was then analyzed by absorption spectrophotometry. In all systems, corrections were applied to take into account the absorption due to the WSP and due to the leachable material from the dialysis bag. The interaction between luminol and the dialysis bag was found to be negligible in the concentration range of luminol studied.

The author is grateful to Mr. Nobuaki Ohnishi, Faculty of Engineering and Design, Kyoto Institute of Technology, for the mass-spectral measurements.

The Determination of a Small Amount of a Biological Constituent by the Use of Chemiluminescence. XI. The Determination of Protein Using a 1,10-Phenanthroline-Hydrogen Peroxide-Osmium(VIII) System

Tadashi HARA* and Kazuhiko TSUKAGOSHI
Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
(Received November 12, 1986)

Osmium(VIII) was found by the authors to show extremely sensitive catalytic activity for the 1,10-phenanthroline-hydrogen peroxide chemiluminescence system. By optimizing the measurement conditions, 3.2×10^{-11}—1.3×10^{-8} mol dm^{-3} osmium(VIII) could be determined by chemiluminescence flow-injection analysis with a detection limit of 0.4 pg. The method for the determination of protein was established; it was based on the lowering of the catalytic activity of osmium(VIII) attributable to the complex formation between osmium(VIII) and protein. Similar calibration curves were obtained for bovine serum albumin, human serum albumin, and human serum γ-globulin under the optimum conditions for the determination of protein. According to the method, 5.0×10^{-6}—1.0×10^{-3} g dm^{-3} protein could be determined with a detection limit of about 250 pg and with a coefficient of variation of 2.9% (n=10) for a 1.0×10^{-4} g dm^{-3} protein solution.

Various sensitive methods for the determination of protein have been reported previously by the present authors;[1-4] in those methods, use is made of chemiluminescence(CL) flow-injection analysis for a small amount of a metal ion or a metal complex. The method is based on the lowering of the catalytic activity of a metal ion by the complex formation between a metal ion and protein. Though protein was determined by the present authors by the use of the luminol-hydrogen peroxide(H_2O_2)-osmium(VIII) oxide (Os(VIII)) CL system, neither the stability of the CL intensity nor the detection limit of protein was satisfactory.[1]

As a method for the determination of protein using the 1,10-phenanthroline(phen)-H_2O_2-ruthenium(III) system was reported in one of the previous papers,[4] the catalytic activities of iridium(III), osmium(VIII), palladium(II), platinum(IV), and rhodium(III) for the phen-H_2O_2 CL system have been investigated in the present study. Os(VIII) has been found to be very sensitive. By optimizing the measurement conditions, a micro amount of Os(VIII) could be determined by CL flow-injection analysis. The present method for the determination of Os(VIII) is 5—60 times as sensitive as the methods using a lucigenin or luminol CL system.[5-7] Here, this sensitive method for the determination of Os(VIII) was combined with the complex formation between Os(VIII) and protein to established a sensitive method for the determination of protein using CL flow-injection analysis. According to the present method, a micro amount of protein can be rapidly determined with a stable CL intensity.

The present method is 4×10^2—1×10^6 times as sensitive as the non-labeling colorimetric or fluorometric method[8] for the determination of protein and is the most sensitive method among those reported by the present authors[1-4] for the determination of protein using CL flow-injection analysis.

Experimental

All the reagents were of a commercially available special grade. Ion-exchanged water was distilled before use. A 1.2×10^{-4} mol dm^{-3} phen solution contained 5.0×10^{-3} mol dm^{-3} ethylhexadecyldimethylammonium bromide(EHDAB), 1.0×10^{-1} mol dm^{-3} sodium hydroxide(NaOH), and 1.0×10^{-9} mol dm^{-3} tetraethylenepentamine(TEPA). A 5.0 wt% H_2O_2 solution was prepared by diluting 30 wt% H_2O_2 with water. A 1.3×10^{-3} mol dm^{-3} Os(VIII) catalyst solution was prepared as a stock solution by diluting a 4% osmium(VIII) oxide aqueous solution (2 ml) (Nakarai Chemical, Ltd.) with water; it was then further diluted to the desired concentration with a buffer solution (pH 10.2) consisting of 1.0×10^{-1} mol dm^{-3} boric acid and 1.0×10^{-1} mol dm^{-3} potassium hydroxide. Bovine serum albumin(BSA) and human serum albumin (HSA) from Nakarai Chemical, Ltd., human serum γ-globulin(HγG) from the Sigma Chemical Company, and control serum(Q-PAC-Chemistry Control Serum I) from Hyland were prepared by diluting them with the above-mentioned buffer solution.

The experiment was carried out using the same apparatus as in a previous paper.[9] A phen-H_2O_2 solution and the above-mentioned buffer solution as a carrier were mixed at the point X of the apparatus. The optimum distance from the point X to a photometric flow cell and the optimum flow rates were decided by experimentation. A definite volume of Os(VIII) catalyst solution was added to a sample solution containing protein, and the resulting solution was heated for a definite period for the complexation reaction of Os(VIII) with protein. After the solution has then cooled to room temperature, an aliquot of the solution (50 mm^3) was injected into the line of a buffer solution as a carrier and the CL intensity-time profile was measured at the flow cell.

Results and Discussion

Cl Flow-Injection Analysis for a Micro Amount of Os(VIII). As the method for the determination of protein using a phen-H_2O_2-ruthenium(III) system was reported in the previous paper, the catalytic activities of iridium(III), osmium(VIII), palladium(II), pla-

tinum(IV), and rhodium(III) for the phen-H_2O_2 CL system were investigated in the present study; Os(VIII) was found to be very sensitive. Then, the effects of the flow rates, the tube length, and the reagent concentration on the CL intensity of a Os(VIII) catalyst solution were examined in the following way, and the conditions for the determination of a micro amount of Os(VIII) were established.

The CL intensity of a 6.3×10^{-9} mol dm^{-3} Os(VIII) catalyst solution was measured by the use of 10-, 100-, 200-, and 300-cm portions of tubing, which corresponded to the distance between the point X and a photometric flow cell. The maximum CL intensity was observed by the use of a 200-cm tube. Both the flow rate of a phen solution and that of a H_2O_2 solution were chosen at the same time as follows: 0.5, 0.8, 1.0, 1.3, 1.5, and 1.7 ml min^{-1}, and the CL intensity of a 6.3×10^{-9} mol dm^{-3} Os(VIII) catalyst solution (volume injected, 50 mm^3) was measured. The CL intensity increased with the increase in the flow rate, but was accompanied by an increasing noise. The flow rate of a carrier buffer solution was always set at 2.3 ml min^{-1}, the maximum capacity of the pump, so as to deal with as many samples as possible within a definite time. On the basis of the experimental results, the optimum conditions were established as follows: tube length, 200 cm; flow rates of a phen, a H_2O_2, and a buffer solution, 1.3, 1.3, and 2.3 ml min^{-1} respectively.

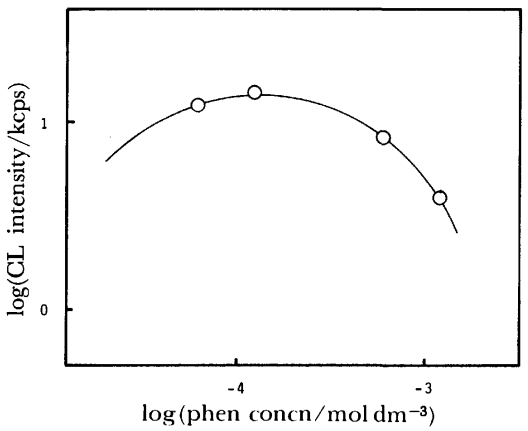

Fig. 1. Effect of phen concn on CL intensity. Conditions: 5.0×10^{-3} mol dm^{-3} EHDAB, 1.0×10^{-1} mol dm^{-3} NaOH, 1.0×10^{-9} mol dm^{-3} TEPA, 7.5 wt% H_2O_2, and 1.3×10^{-8} mol dm^{-3} Os(VIII).

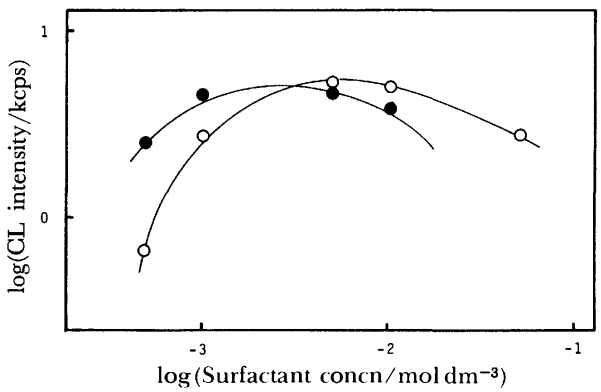

Fig. 2. Effect of surfactants on CL intensity. ○: EHDAB and ●: TOAC. Conditions: 1.2×10^{-4} mol dm^{-3} phen, 1.0×10^{-1} mol dm^{-3} NaOH, 1.0×10^{-9} mol dm^{-3} TEPA, 5.0 wt% H_2O_2, and 6.3×10^{-9} mol dm^{-3} Os(VIII).

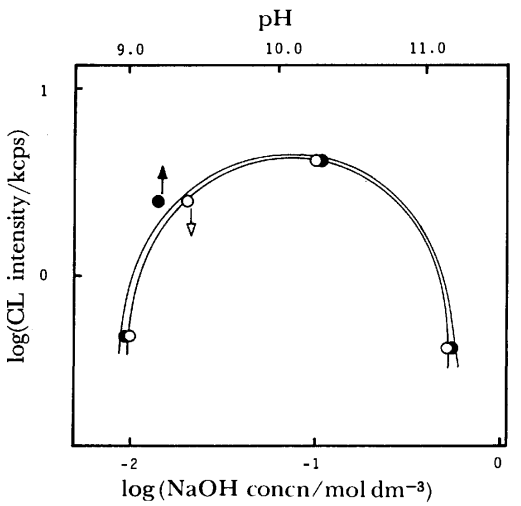

Fig. 3. Effect of NaOH concn or pH[1] on CL intensity. ○: CL intensity against NaOH concn and ●: CL intensity against pH. Conditions: 1.2×10^{-4} mol dm^{-3} phen, 5.0×10^{-3} mol dm^{-3} EHDAB, 1.0×10^{-3} mol dm^{-3} TEPA, 5.0 wt% H_2O_2, and 6.3×10^{-9} mol dm^{-3} Os(VIII). 1) The pH value refers to the value of a solution just before CL intensity is measured.

The effect of the phen, surfactant, and NaOH concentration in the phen solution on the peak CL intensity are shown in Figs. 1—3 under the optimum flow rates, as has been described above. Trimethyloctadecylammonium chloride(TOAC) and EHDAB were examined as cationic surfactants, for they had been known to show a high, enhanced action for a phen-H_2O_2-copper(II) system.[10] As can be seen from Figs. 1—3, 1.2×10^{-4} mol dm^{-3} phen, 5.0×10^{-3} mol dm^{-3} EHDAB, and 1.0×10^{-1} mol dm^{-3} NaOH were chosen as the optimum concentrations. A phen solution also contained 1.0×10^{-9} mol dm^{-3} TEPA as a masking reagent for a small amount of the metal ion. The effect of the H_2O_2 concentration on the CL intensity is shown in Fig. 4. The CL intensity increased with the increase in the concentration of H_2O_2, but was accompanied by an increasing noise. From these results, 5.0 w% H_2O_2 was chosen as the optimum concentration.

The relationship between the CL intensity and the Os(VIII) catalyst concentration was obtained under the above-mentioned conditions and is shown in Fig. 5. According to the present method, a micro amount of Os(VIII) could be determined over a range of concentration of 3.2×10^{-11}—1.3×10^{-8} mol dm^{-3}, with the detection limit of 0.4 pg at the rate of about 40 samples per hour. The coefficient of variation was 2.2% for 10 analyses of a 6.3×10^{-9} mol dm^{-3} Os(VIII) catalyst solu-

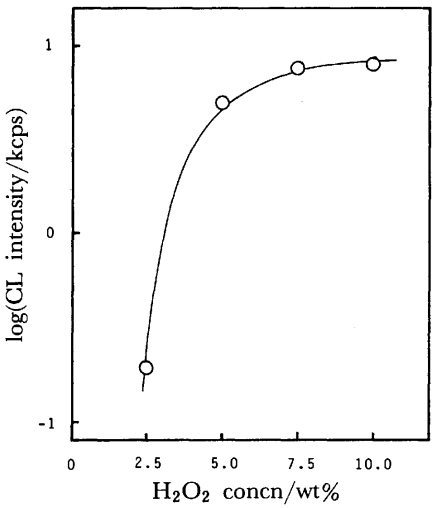

Fig. 4. Effect of H_2O_2 concn on CL intensity. Conditions: 1.2×10^{-4} mol dm^{-3} phen, 5.0×10^{-3} mol dm^{-3} EHDAB, 1.0×10^{-1} mol dm^{-3} NaOH, 1.0×10^{-9} mol dm^{-3} TEPA, and 6.3×10^{-9} mol dm^{-3} Os(VIII).

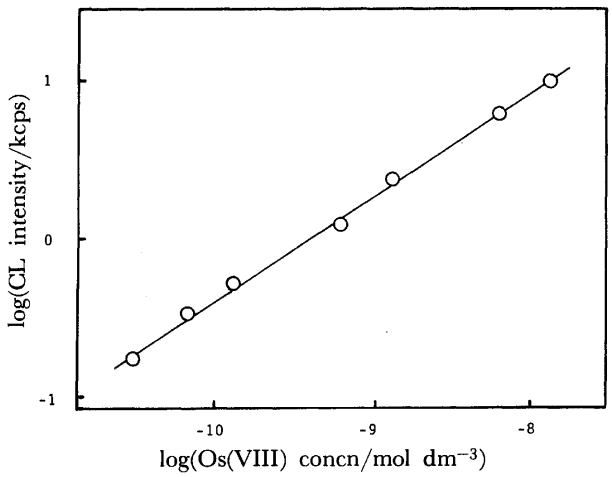

Fig. 5. Relationship between CL intensity and Os(VIII) concn. Conditions: 1.2×10^{-4} mol dm^{-3} phen, 5.0×10^{-3} mol dm^{-3} EHDAB, 1.0×10^{-1} mol dm^{-3} NaOH, 1.0×10^{-9} mol dm^{-3} TEPA, and 5.0 wt% H_2O_2.

Table 1. Detection Limit of Elements of the Platinum Group

Sample	Detection limit/mol dm^{-3}
OsO_4(VIII)	3.2×10^{-11}
$RuCl_3$(III) $3H_2O$	1.0×10^{-7}[4]
$PdCl_2$(II)	1.1×10^{-6}
$IrCl_3$(III) $1.5H_2O$	5.0×10^{-6}
$RhCl_3$(III) $3H_2O$	1.0×10^{-5}
H_2PtCl_6(IV)	1.0×10^{-4}

tion. The present method for the determination of Os(VIII) was 5—60 times as sensitive as the methods using the lucigenin or luminol CL system. By the present CL flow-injection analysis, iridium(III), palladium(II), platinum(IV), and rhodium(II) were determined with the detection limits of 5.0×10^{-6}, 1.1×10^{-6}, 1.0×10^{-4}, and 1.0×10^{-5} mol dm^{-3} respectively (Table 1).

Determination of Protein. Though protein was formerly determined by the authors by the use of the luminol-H_2O_2-Os(VIII) system, both the stability of the CL intensity and the detection limit of protein were not satisfactory. Here, a sensitive method for the determination was carried out by the use of a CL flow-injection technique using a phen-H_2O_2-Os(VIII) system.

Since protein was determined after the reaction between Os(VIII) and protein, the reaction time, the reaction temperature, and the Os(VIII) concentration required for the determination of protein were investigated in advance. Figure 6 shows the relationship between the relative CL intensity and the reaction time at 20, 60, and 95 °C. The relative CL intensity is represented as the value against the CL intensity of a BSA-free sample solution at the reaction time of 0, for

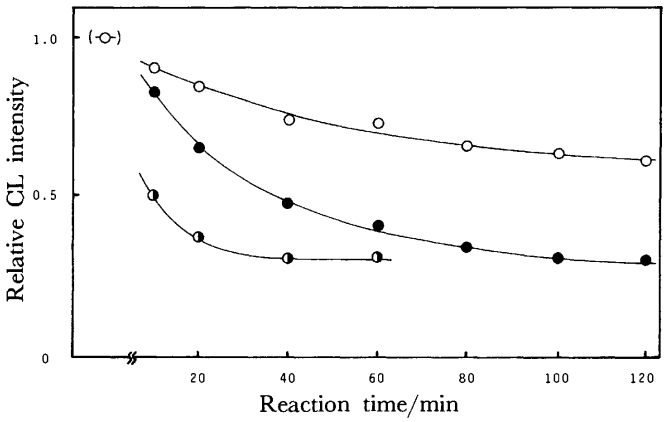

Fig. 6. Relationship between CL intensity and reaction time. ○: 20, ●: 60, ◑: 95 °C, and (—○—): BSA free. Conditions: 5.0×10^{-4} g dm^{-3} BSA and 6.3×10^{-9} mol dm^{-3} Os(VIII).

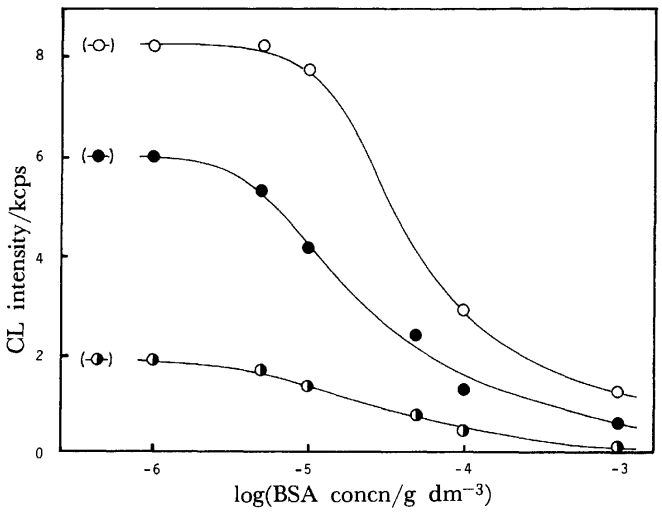

Fig. 7. Effect of Os(VIII) concn on the calibration curve of BSA. ○: 1.3×10^{-8} mol dm^{-3}-, ●: 6.3×10^{-9} mol dm^{-3}-, ◑: 3.2×10^{-9} mol dm^{-3} Os(VIII), and (—○—): BSA free.

Table 2. Lowering of CL Intensity in the Presence of 1.0×10^{-4} g dm^{-3} BSA

System	Lowering of CL intensity	Relative lowering CL intensity[a)]
phen-H_2O_2-Cu(II)	0.05	1
phen-H_2O_2-Ru(III)	0.14	2.8
phen-H_2O_2-Os(VIII)	0.75	15

a) Based on the value of the lowering of the CL intensity for the phen-H_2O_2-Cu(II) system.

the CL intensity of the BSA-free sample solution did not change upon heat treatment up to 60 min at 95 °C or up to 120 min at 20 and 60 °C. On the basis of the results pertaining to the decrease in the CL intensity and the reaction time, the CL intensity of a sample solution containing protein was examined after it had been treated for 45 min at 95 °C in the following experiments. Figure 7 shows the calibration curve of BSA obtained by the use of 3.2×10^{-9}, 6.3×10^{-9}, and 1.3×10^{-8} mol dm^{-3} portions of the Os(VIII) catalyst. The detection limit of the protein concentration and the decrease in the CL intensity for a definite amount of protein suggested that a 6.3×10^{-9} mol dm^{-3} Os(VIII) catalyst solution should be used in the present study.

The calibration curves for BSA, HSA, and HγG were obtained under the conditions specified above (Fig. 8). They could be used for the determination of protein in the concentration range of 5.0×10^{-6}—1.0×10^{-3} g dm^{-3} with a detection limit of about 250 pg. The coefficient of variation was 2.9% for 10 analyses of a 1.0×10^{-4} g dm^{-3} protein solution by the present method. The lowering of the CL activity of an Os(VIII) catalyst solution in the presence of protein seemed to be due to the formation of an Os(VIII)-polypeptide linkage, as in the previous paper.

Table 2 shows the lowering of the CL intensity by the use of copper(II), ruthenium(II), or osmium(VIII) as a catalyst for the phen-H_2O_2 CL system in the presence of 1.0×10^{-4} g dm^{-3} BSA. The values for the lowering of the CL intensity were obtained by subtracting the relative CL intensity for a sample solution in the

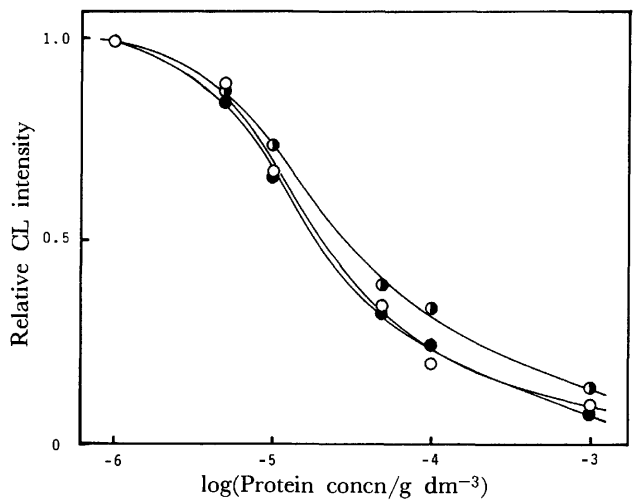

Fig. 8. Calibration curves of various proteins. ○: BSA, ●: HSA, and ◑: HγG. Conditions: 6.3×10^{-9} mol dm^{-3} Os(VIII).

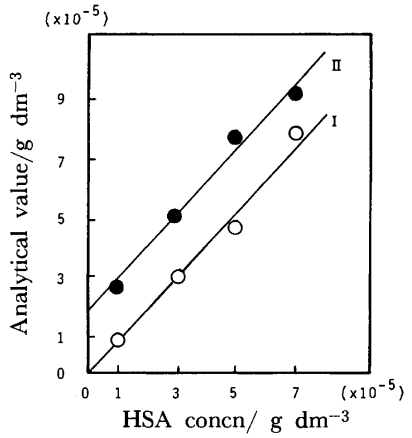

Fig. 9. Relationship between HSA concn and the observed protein concn. ○: HSA alone and ●: HSA+control serum. Conditions: 2.2×10^{-5} g dm^{-3} control serum and 6.3×10^{-9} mol dm^{-3} Os(VIII).

presence of 1.0×10^{-4} g dm^{-3} BSA from the relative CL intensity (=1.00) for a sample solution in the absence of BSA. As can be seen from these values, the present method using the Os(VIII) catalyst for a phen-H_2O_2 CL system was 5—15 times as sensitive as those using ruthenium(III) or copper(II). The present method was 4×10^2—1×10^6 times as sensitive as the non-labeling colorimetric or fluorometric method for the determination of protein and was the most sensitive method among those reported by the present authors for the determination of protein using CL flow-injection analysis.

Application to Serum Analysis. A human serum sample was measured after having been diluted because the present method was too sensitive to estimate protein in an original human serum sample and these was the possibility of interference with the coexisting constituents in human serum. Various amounts of HSA were estimated in either the presence or absence of a definite amount of control serum (diluted to a volume of 2×10^6 times with a buffer solution), and the relationship between the HSA concentration and the analytical value was obtained by the use of the calibration curve of HSA shown in Fig. 8. All the analytical values of the ordinate in Fig. 9 are represented as the amount of HSA. The difference between the straight lines, I and II, in the analytical value was approximately equal to the amount of protein in the added control serum, which was determined to be 2.2×10^{-5} g dm^{-3} by the use of the biuret method. This means that the present method was applicable to the determination of protein in a serum sample, without

any interference from coexisting constituents, when a sample solution was diluted to 2×10^6 times with a buffer solution and the resulting solution was then measured.

The authors wish to thank Mr. Masakatsu Imaki (Horiba, Ltd.) for providing the apparatus necessary for the present study.

(Received November 22, 1986)

Lanthanoid(III) picrates (Ln=La, Ce, Pr, Nd, Sm, Eu, Gd, Dy, and Yb) were prepared from picric acid and the corresponding lanthanoid carbonates in good yields. Combustion analyses, ICP emission analyses, and UV spectrophotometry have shown that the light lanthanoid picrates, i.e. Ln=La-Gd, are all undecahydrates, while the heavy ones, Dy and Yb, are octahydrates. An examination by TG-DTA has revealed that these hydrates, being fairly stable in air at ambient temperature, are quite labile to give partially or completely dehydrated samples upon drying under vacuum, in a desiccator, and/or at elevated temperatures just above 30 °C.

Picrates have long been used in industry as initiating explosives and fuel additives.[2)] They have also been used in analyses, especially in the solvent extraction technique owing to the highly lipophilic nature of the picrate ion. Recently, the cation-binding abilities of neutral ligands like crown ethers have been conveniently evaluated by the extractability of aqueous metal picrates.[3)] For this purpose, alkali (Na-Cs),[4)] alkaline earth (Mg-Ba),[3,5)] and some heavy metal (Ag, Tl) picrates[3,6)] were synthesized and isolated. On the other hand, lanthanoid picrates have only been prepared in situ in solvent extraction experiments with some crown ethers;[7)] no practical method for preparing lanthanoid picrates has been published and their characterization has not been fully described. In this paper, we wish to report on a method for preparing some lanthanoid picrates and the characterization of their crystals.

Results and Discussion

Synthesis. The reaction of picric acid with metal hydroxide is a common route to obtain metal picrates, as in the case of alkali metal picrates.[4)] Since lanthanoid hydroxides are not commercially available and some heavy metal picrates have been prepared from the metal oxides,[3,6)] we first tried lanthanoid oxide. The reaction of picric acid with La oxide was carried out in hot water, but only the starting materials were recovered from the mixture.

Lanthanoid carbonates were then tried and gave satisfactory results regarding the preparation of La, Ce, Pr, Nd, Sm, Eu, Gd, Dy, and Yb picrates. The reaction conditions were optimized in order to obtain the recommended procedure shown in the Experimental section. First examined were the effects of the molar ratio of picric acid to lanthanoid carbonate upon the product yield and purity. With Ce carbonate taken as an example, the picric acid/carbonate ratio (n) was changed from 1 to 9. Although no precipitation was obtained upon cooling when n=1, a yellow precipitate was formed at $n>3$. The yield generally increased with increasing n. However, as shown by spectrophotometric examination of dichloromethane extracts of the crystalline products, the use of excess picric acid, i.e. $n>6$, led to a significant contamination of the resulting picrate with picric acid, even after repeated recrystallizations from water. Therefore, $n<6$ should be used in order to obtain a pure sample free from picric acid in high yield.

The fresh lanthanoid picrate recrystallized from water gradually lost its weight (by ca. 10—18%) upon air-drying for 3—5 d at room temperature; after that period, practically no weight change (>1%) was observed during the next 85 d. The samples used in subsequent experiments were, therefore, air-dried for more than one week and stored in stoppered vials in the dark.

The lanthanoid picrates prepared as above were analyzed by means of an inductively coupled plasma (ICP) atomic emission analysis as well as by a combustion analysis. As shown in Table 1, the results from both analyses are in good agreement with the values calculated for the undecahydrates of light lanthanoid picrates (Ln=La-Gd) and for octahydrates of heavy ones (Dy, Yb). The UV spectra of their aqueous solutions also support this conclusion. As shown in Table 1, all picrates show almost identical molar extinction coefficients around 42000 $M^{-1}cm^{-1}$,§ indicating that they contain the same numbers of water of hydration as determined by the elemental analyses.

The fact that the light and heavy lanthanoid picrates contain different numbers of water of hydration may be related to the well-documented "*gadolinium break*" observed for thermodynamic data of the lanthanoid series in aqueous solution, where a plot of such data as a function of ionic radius often exhibits a break somewhere in the middle of the lanthanoid series. This break is considered to reflect a discontinuous variation in the hydration structures of the lanthanoid ions.[8)]

a) Determined by ICP for Ln and by combustion analysis for H, C, and N; calculated values (%) are shown in the parentheses. b) Decomposition point determined by DTA. c) Explosion point determined by DTA. d) Molar absorption coefficient at the absorption maximum (354 nm) in water.

Studies on the apparent molal volume and X-ray diffraction data of aqueous rare earth salt solutions suggest that the coordination number in the first solvation shell of a lanthanoid ion shifts from nine to eight between neodymium and terbium.[8f,g] The present change in the number of the water of hydration lies in the same line, although the coordination number in the crystalline state is not necessarily identical to that in an aqueous solution.

The Behavior of the Water of Hydration. Interestingly, the water in lanthanoid picrate hydrates was shown to be quite labile. Although the light lanthanoid picrates, La–Gd, do not change in weight (within ±1%) in open air, they gradually lose weight to reach ca. 85 % of the original weights when stored over SiO_2 in a desiccator for 3 d or more. Thus, SiO_2 removes 8—9 out of 11 water molecules, leaving a tri- or dihydrate. Vacuum-drying over P_2O_5 resulted in complete dehydration, as indicated by a 17—19% loss of the original weight which corresponds to a loss of 11 water molecules from each picrate of a light lanthanoid.

In order to further investigate the behavior of the water of hydration, samples of La picrate at different drying stages were subjected to thermal analyses. The thermogravimetry-differential thermal analysis (TG-DTA) curves obtained are shown in Fig. 1. For the air-dried sample (curves A), the first endothermic peak in the DTA curve starts just above room temperature (30 °C) and reaches a maximum at 50 °C. This causes a considerable loss of weight (cf. the TG curve A). The second weak endothermic peak appears near 90 °C with a smaller loss of weight. The weight loss at each peak roughly coincides with that observed upon drying over SiO_2 and P_2O_5 in vacuo, respectively. Further heating gives an exothermic peak at 292 °C, i.e. the

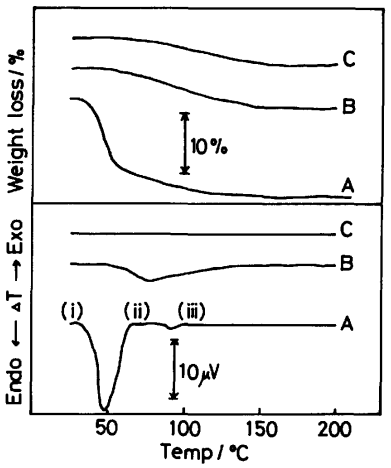

Fig. 1. TG-DTA curves for air-dried (A), SiO_2-dried (B), and P_2O_5-in vacuo dried (C) samples of La picrate; see Experimental for detailed conditions of measurement.

decomposition point of La picrate, and finally results in an explosion at 340 °C.[§§]

With the SiO_2-dried sample (curves B), only a broad peak around 75 °C appears in DTA curve B with a small decrease in the TG curve. The sample vacuum-dried over P_2O_5 did not show any evident peak in DTA curve C; TG curve C declined slightly, but this could be ascribed to the loss of a small amount of water reabsorbed before the DTA measurement since the vacuum-dried sample was highly hygroscopic.

Air-dried samples of Ce, Pr, and Nd picrate hydrates

[§§]Caution should be exercised in handling metal picrates, since they are shock- and heat-sensitive. Although most lanthanoid picrates did not explode below 300 °C, heating of sodium picrate at >250 °C resulted in an explosion which destroyed the thermocouple of the DTA apparatus.

also gave analogous TG-DTA curves with the first large endothermic peak at ca. 50 °C and a subsequent small peak at ca. 90 °C; Sm, Eu, and Gd picrates gave an additional endothermic peak around 140 °C. Dy and Yb picrate octahydrates exhibited similar TG-DTA curves with two endothermic peaks around 55 and 85 °C; however, the peak intensities were inverted. These observations support the idea that lanthanoid picrate hydrates possess at least two kinds of water; one is loosely bound and is released easily by mild drying over SiO_2 or by heating just above room temperature. The other is tightly bound and is removed by vacuum-drying over P_2O_5 or by heating up to 90—140 °C. This behavior of the water of hydration in lanthanoid picrates is in sharp contrast with that of alkali or alkaline earth picrate hydrates which do not lose water at such low temperatures as 30—50 °C. It has been reported that most mono- and divalent metal picrates show the first endothermic peak well above 100 °C,[9] which would correspond to the second peak in the lanthanoid picrate case.

The structural change of an air-dried La picrate caused by dehydration can be visualized by X-ray diffraction patterns. As can be seen in Fig. 2, the diffraction pattern of the air-dried sample (stage i in Fig. 1), indicates the presence of a well-defined crystal structure, while the sample obtained by rapid cooling just after the first endothermic peak (stage ii) yielded a more complicated diffraction pattern (which still maintained the original peaks at the same angles). This indicates that a certain phase change takes place between stages i and ii. Further heating up to 110 °C, i.e. to the end of the second endothermic peak (stage iii), leads to the disappearance of all sharp diffraction peaks (top trace in Fig. 2), indicating that the original crystal structure is totally broken by a complete loss of water. The samples dried over SiO_2 or P_2O_5 in vacuo also show no sharp X-ray diffraction patterns at all; these samples are all highly hygroscopic but do not regenerate the original undecahydrate upon standing in a moderately humid atmosphere at room temperature. Also observed was an apparent change in color of the crystalline lanthanoid picrates from yellow to deep orange or to red upon heating up to ca. 120 °C or upon drying in vacuo, which may again be accounted for in terms of the drastic structural change.

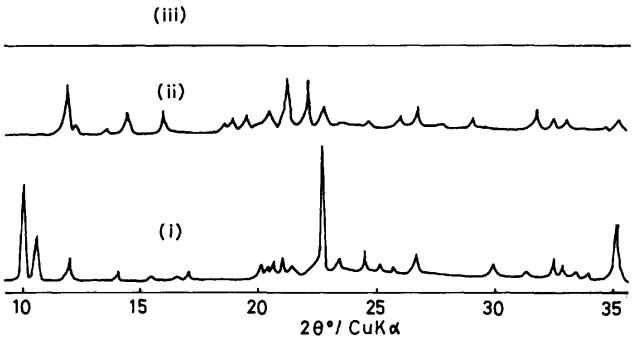

Fig. 2. X-Ray diffraction patterns of La picrate at different stages (i—iii) of the thermal analysis as shown in Fig. 1.

It may be summarized as follows: 1) the lanthanoid(III) picrates (Ln=La-Gd, Dy, Yb) are prepared in good yield by the reaction of picric acid with the corresponding carbonate in hot water, 2) the picrates prepared are undecahydrates for the light lanthanoids La-Gd and octahydrates for the heavy lanthanoids Dy and Yb, and 3) the water of hydration can be removed easily when stored over a desiccant under atmospheric or reduced pressure, to give partially or completely dehydrated samples, which suffer a phase change and turn highly hygroscopic. It is therefore recommended that the lanthanoid picrates recrystallized from water should merely be air-dried and be used as hydrates without further drying. The present method should be applicable to the synthesis of the rest of lanthanoid picrates, which are inferred to be octa- or undecahydrates.

Experimental

Materials. Commercially available picric acid and lanthanoid carbonates and oxides (G.R. or E.P. grade) were used without further purification. Deionized water was used throughout the study.

Instruments. It was first attempted to measure the melting and decomposition points in a capillary tube with a Yanaco hot-stage micro melting point apparatus. However, the obtained mps were the same (around 65 °C) for some light lanthanoid picrates, for which the release of the water of hydration must be responsible. Measurements on an open glass plate are also difficult due to an apparent carbonization of a sample above 230 °C. Decomposition and explosion points (dp and ep) were therefore determined from the extrapolated onsets of the exothermic peaks of DTA curves; these peaks accompanied a moderate and an extreme loss of weight in the TG curve, respectively.

TG-DTA curves were recorded on a Rigaku differential thermal balance model 8076 equipped with a platinel thermocouple; sample size: 5 mg picrate + 5 mg baked α-alumina; air-flow: 75 ml min^{-1} for air-dried samples and no flow for the samples dried over desiccants; scanning speed: 5 or 10 °C min^{-1}. Electronic spectra were obtained on a Shimadzu UV-365 spectrophotometer. Infrared spectra were recorded on a Jasco IR-810 instrument. X-Ray diffraction patterns were recorded on a Rigaku X-ray diffraction equipment. ICP analyses were performed on a Shimadzu GVM100P inductively coupled plasma atomic emission spectrometer. The ICP instrument was calibrated for each metal with standard solutions prepared by dissolving lanthanoid oxides which were baked at 900 °C for 2 h in hydrochloric acid or, in Ce oxide case, in a 1 : 1 mixture of sulfuric acid and concentrated hydrogen peroxide.

Synthesis. Lanthanum Picrate Undecahydrate. To picric acid (3.4 g, 15 mmol) dissolved in hot water (100 ml) was added portionwise La carbonate (trihydrate; 1.3 g, 2.5 mmol) with stirring on a water bath at 80—90 °C. The stirring was continued for an additional 10 min at that temperature. The hot mixture was filtrated and then cooled with ice. The crude La picrate, obtained as a yellow precipitate, was recrystallized three times from water and air-dried at room temper-

ature for more than one week. Yellow crystals; yield 2.8 g (56%); dp 292 °C; ep 340 °C. No further significant change of weight (>1%) was observed for at least 85 d.

Undecahydrates of the Light Lanthanoids (Ce-Gd) and Octahydrates of the Heavy Lanthanoids (Dy, Yb). These were prepared from picric acid and the corresponding carbonate as above, typically using 15 mmol of the former and 2.5 mmol of the latter. They are all yellow crystals; their yields and decomposition and explosion points are given in Table 1.

In order to check the contamination of unreacted picric acid, the crystalline lanthanoid picrates obtained above were extracted with dichloromethane. A spectral examination of the dichloromethane extracts did not show any absorbance greater than 0.01 at wavelengths >290 nm; therefore, the samples were free from picric acid. Aqueous solutions of La-Gd, Dy, and Yb picrates all showed absorption maxima at an identical wavelength of 354 nm with very close absorption coefficients (Table 1). The coefficients around 42000 $M^{-1}cm^{-1}$ are reasonable in view of those for alkali metal picrates (14400—14800 $M^{-1}cm^{-1}$) and for alkaline earth metal picrates (29100—31000 $M^{-1}cm^{-1}$).

The IR spectra of light lanthanoid picrate undecahydrates (La-Gd) are all superimposable with respect to the frequencies and relative intensities of their peaks: ν(KBr) 3400 (br), 3090, 1635, 1615, 1565, 1560, 1500, 1485, 1440, 1370, 1335, 1280, 1270, 1240, 1165, 1080, 940, 905, 795, 745, 710, 705, 545, 520 cm^{-1}. The heavy lanthanoid picrate octahydrates (Dy, Yb) also exhibit quite analogous spectra but evidently weaker absorption at 3400 cm^{-1}; ytterbium picrate possesses a broadened 3400 cm^{-1} band and two additional weak absorptions at 1425 and 1405 cm^{-1}. These spectra are essentially identical as that of sodium picrate monohydrate[4] or calcium picrate pentahydrate[3,5] except for the intensity of the O-H stretching band around 3400 cm^{-1}.

The Wetting of an Alumina Substrate by Liquid Silver

Masumi USHIO* and Yoshihiro SUMIYOSHI
Department of Applied Chemistry, Faculty of Engineering, Gunma University, Tenjin-cho, Kiryu 376
(Received December 5, 1986)

The wetting of the Al_2O_3 substrate by liquid silver was investigated by means of the sessile-drop technique in an atmosphere of argon. An empirical relation was established between the contact angle and the temperature or surface tension of the liquid drop by the use of the diameter and the height of the sessile drop. The contact angle was constant as the time increased while it decreased linearly with the increase in the temperature. The variation in the contact angle with the temperature is correlated with the surface tension of the sessile drop. The critical surface tension (γ_c) of Al_2O_3 is 361 dyn cm^{-1}, while the surface tension of liquid silver at 0 K is 790 dyn cm^{-1}.

As for all the properties of the engineering materials, the phenomenon of liquid wetting on a solid surface is an especially important problem, among the many engineering problems on the surface, in the sense that interaction between a solid and a liquid is involved. This phenomenon is also important as a fundamental factor in the related fields of electronics, printing, dyeing and metallurgy, composite materials, adhesion, etc. This wetting phenomenon may be broadly classified into three types of wetting: adhesion, diffusion, and dipping.

Metal-alumina substrates are very attractive as engineering materials. The properties of such substrates are, however, greatly influenced by the nature of the metal-alumina interface. Thus, it is essential to understand metal-alumina interactions in substrate materials.

In the present paper, the wettability of a sintered alumina subetrate, its surface polished and smooth, by liquid silver is investigated by means of the sessile-drop technique in an atmosphere of argon.

Experimental

High-purity silver (99.99%, Ishifuku Co.) was cut into a desk. The disk was 4 mm in diameter and 3 mm thick. The sintered alumina (99.5%, Kyocera Co.) used as the substrate had dimensions of 20×20×3 mm^3, and its surface had been polished to a mirrorlike finish.

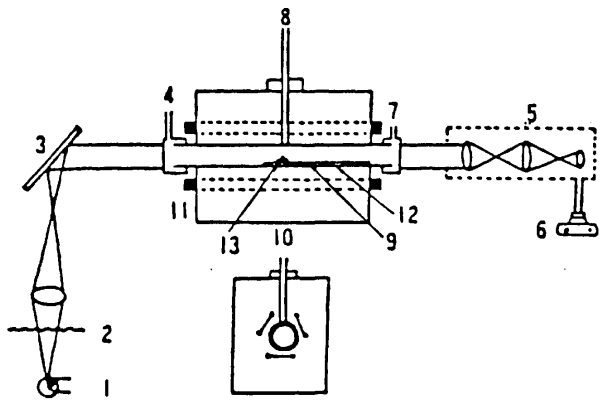

Fig. 1. Experimental apparatus for measuring the wettability. 1: Mercury lamp, 2: Green filter, 3: Reflecting mirror, 4: Argon gas inlet, 5: Microscope, 6: Camera, 7: Argon gas outlet, 8: Pt/Pt13%Rh thermocouple, 9: Porcelain plate, 10: Electric furnace, 11: SiC heater element, 12: Porcelain pipe, 13: Test sample.

An outline of the sessile-drop apparatus used to measure the contact angle is shown in Fig. 1. The temperature of a drop was measured by means of a Pt—Pt. 13% Rh thermocouple, which was located near the drop. The furnace was operated in an atmosphere of argon. The flow rate was about 0.9 L min^{-1}. The silver disk and the substrate were cleaned with acetone and then dried in a vacuum. The silver disk was placed in the furnace on an alumina substrate. The sessile drop was allowed to rest on the substrate at 980 °C for 30 min. The value of the contact angle after 30 min was assumed to be the equilibrium contact angle. The shadow of the sessile drop was then photographed from the back by using light shed by a mercury lamp. The contact angle of the drop was bilaterally measured, and its mean value was taken as the measured value.

In the case of the constant temperature, the contact angle was measured at 5-minute intervals for 60 min. On the other hand, at different temperatures from 960 to 1000 °C the contact angle of a drop was also measured at intervals of 5 °C. From these many photographs taken at 5-minute intervals for 60 min and at intervals of 5 °C, the diameters and the heights of the sessile drops were measured. These dimensions were used to calculate the surface tension of liquid silver and the critical surface tension for spreading (γ_c) for the Ag/Al_2O_3 system.

The human error was found to be about ±1 °C by measuring the contact angle from ten photographs. The temperature deviation was ±2 °C. The silver/alumina interface regions were exemined with an optical microscope and a scanning electron microscope.

Results

In the case of a constant temperature of 980 °C, the photographs used in measuring the contact angles of the drops are shown in Fig 2, while the measured values of the contact angles are shown in Table 1 and Fig. 3. These experimental results shown that a constant angle of a liquid silver sessile drop resting on an alumina substrate was about 90 °C, although there were some differences in the wettability depending on the test pieces of the alumina substances. Each straight line in Fig. 3 represents the results of two independent runs.

In the case of different temperatures from 960 to

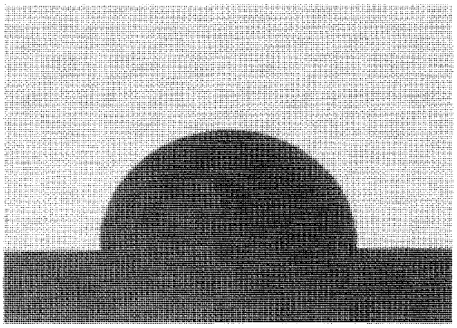

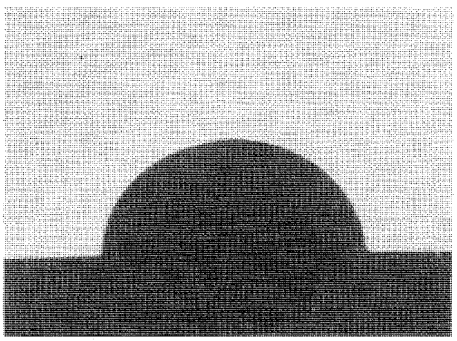

Fig. 4. Sessile drop of liquid silver on alumina for Run No. (S-3). A) At 970 °C, B) at 1000 °C.

1000 °C, with the contact angle measured at intervals of 5 °C, the photographs used in measuring the contact angle of a liquid silver sessile drop resting on an alumina substrate are shown in Fig. 4. The effect of the temperature on the contact angle is shown in Table 2 and Fig. 5. Each straight line in Fig. 5 also represents the results of two independent runs.

Table 2 shows that the degree of the variation in the θ_1 and θ_2 values for runs of (S-3) and (S-4) was different, but the contact angles of a liquid silver on the alumina substrate decrease linearly with an increase in the temperature. That is, a liquid silver is liable to wet an alumina substrate.

The condition of the surface of an alumina substrate was investigated before and after the thermal treatment. Before, it was smooth and flat, but after the thermal treatment, it was revealed that the flatness of

the surface had been destroyed. If the surface of an alumina substrate was magnified and then examined, alumina particles were observed on the surface and this surface became rough.

Discussion

As for runs of (S-1) and (S-2), the effect of the time on the contact angle of a liquid silver sessile drop resting on the alumina substrates was investigated at a constant temperature of 980 °C. Each straight line in Fig. 3 can be fitted by means of this equation:

Run (S-1)

$$\theta_1 = -0.0121x + 91.0$$

$$\theta_2 = -0.0030x + 91.4$$

Run (S-2)

$$\theta_1 = 0.0014x + 91.4$$

$$\theta_2 = 0.0045x + 88.7$$

where x is the time in minutes and where θ is the contact angle.

The slopes of these equations were within the range of the absolute value: | 0.0014—0.00121 |. These values were very small. Therefore, it can be assumed, considering the accuracy of the temperature control, the human errors of the measurements, etc., that the contact angle of a liquid silver on an alumina substrate was scarcely changed at a constant temperature of 980 °C. That is, it is not too much to say that the contact angle does not change within the present experimental range if the temperature is kept constant.

The effect of the temperature on the constant angle of a liquid silver on an alumina substrate was also investigated for the runs of (S-3) and (S-4). The values of the slopes of all the straight lines are negative, as is obvious from Fig. 5. The figure indicates that the contact angle decreases linearly with an increase in the temperature and that a liquid silver is apt to wet an alumina substrate better. The reason for this may be considered to be that the contact angle becomes small as the forces between molecules of silver decrease with an increase in the temperature and that the surface tension of silver therefore decreases.

The amount of scattering in the measured values of the contact angle (θ_1 and θ_2) is shown in Tables 1 and 2. It may be assummed, considering the human errors of measurement of ±2 °C, etc., that its scattering is due to other causes. That is, if the sintered alumina is used as a substrate, the effect of the binder agents, the difficulty of producing homogeneous finished goods, the effect of the atmosphere, etc. must be considered.

The alumina substrate was chemically inert to liquid silver in the temperature range investigated, judging from the optical-microscopy and scanning-electron-microscope studies. However, from the surface observation after the thermal treatment shown in Fig. 6, the surface of an alumina substrate became fairly rough. If the surface was worn by the thermal treatment and the atmosphere, the rough surface may be fairly much influenced by the contact angle of the liquid silver. It is necessary to increase the reproducibility in order to produce homogeneous finished goods, to clean the surface of the alumina substrate, to standarize the roughness of the work surface, to decrease the temperature fluctuation, etc.

The values of the surface tension of liquid silver have been variously reported.

The values of the surface tension were 800 dyn cm^{-1} (1 dyn=10^{-5} N) at 970 °C in air,[1] 893 dyn cm^{-1} at

Table 3. Critical Surface Tension (γ_c) and Surface Tension at 0 K (γ°_{LV}) for the Ag/Al_2O_3, AlN, and TiC Systems

Liquid metal	γ_c (dyn cm^{-1}) for ceramic		γ°_{LV} (dyn cm^{-1}) for liquid silver
Ag	Al_2O_3	361	790
	AlN	873[4]	1474[4]
	TiC	783[4]	1474[4]

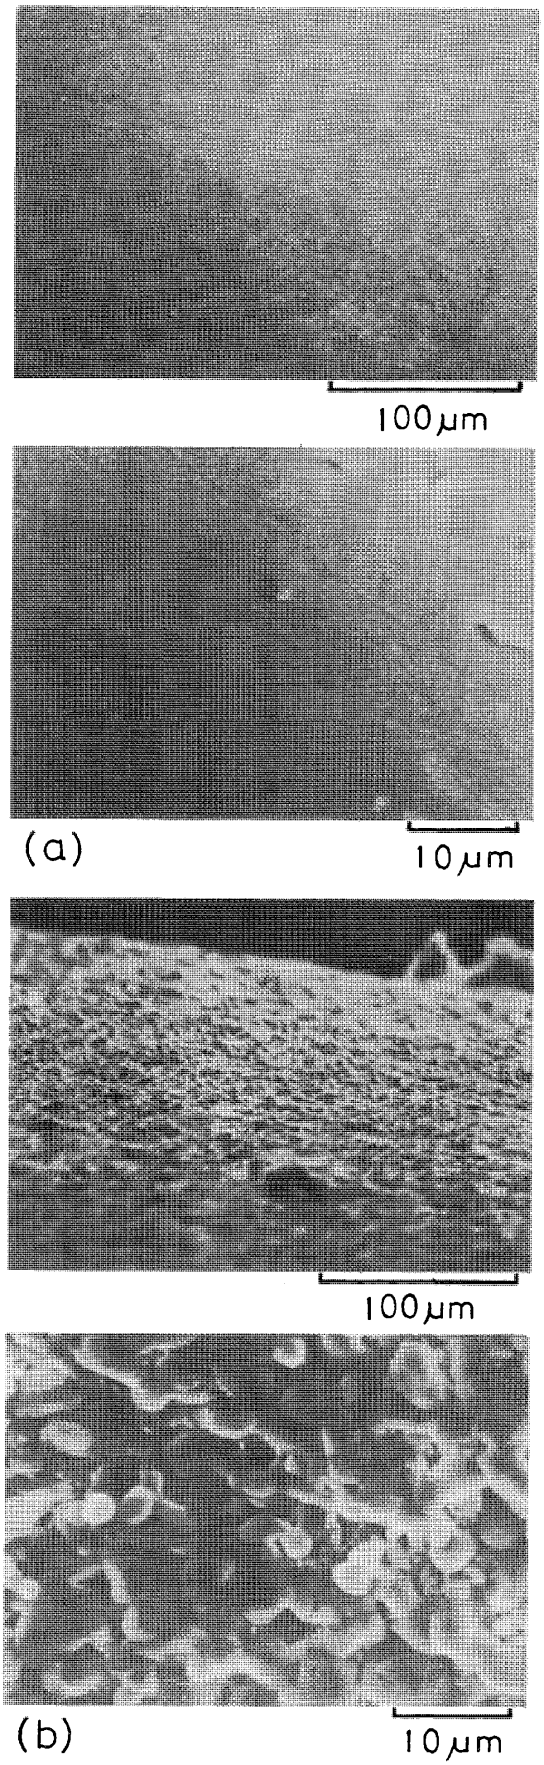

Fig. 6. Photographs of the surfaces of alumina before and after treatment for Run No. (S-3). (a) Before heat treatment, (b) after heat treatment.

1000 °C, and 849 dyn cm^{-1} at 1250 °C.[2] According to Semenchenko's publication,[3] the values of the surface tension of liquid silver are 940 dyn cm^{-1} as calculated by the Zadumkin formula, 991 dyn cm^{-1} as calculated by the Samoilovich formula, and 904 dyn cm^{-1} as calculated by the Kunin formula. On the other hand, Rhee reported that the surface tension of liquid silver followed the following equation: γ_{LV}(Ag)(dyn cm^{-1})=1092−0.14 T (°C).[4] Therefore, the surface tension at 961 °C (melting point) could be estimated to be 957 dyn cm^{-1} by the use of this equation. The values reported by Flint[5] vary from about 785 to 980 dyn cm^{-1}. Krause et al.[6] obtained the values of 930 dyn cm^{-1} at 980.8 °C and 923 dyn cm^{-1} at 1000 °C. According to Kingery,[7] the surface tension of liquid silver is 920 dyn cm^{-1} at 1000 °C in vacuo or in an atmosphere of inert gas. The surface tension of 1140 dyn cm^{-1} at 1180 K (907 °C) has also been reported.[8]

The liquid-solid interface energy, γ_{LS}, is 126 dyn cm^{-1} for silver.[9] It has also been reported that, for metal, γ_{LS}=(0.12±0.03) T_m, where T_m is the melting point (K).[10] From this equation, we can now estimate it to be from 111 to 185 dyn cm^{-1}, while Southin et al. and Zellenmoyer reported that γ_{LS}=130 dyn cm^{-1} on the average.[11]

The temperature coefficient of the surface tension of liquid silver was reported by Rhee[4] to be −0.14 dyn cm^{-1} °C, while Krause et al.[6] reported the very near value of −0.15 dyn cm^{-1} °C. On the other hand, Pawlek et al. reported a somewhat smaller value of −0.11 dyn cm^{-1} °C.[12] We should, therefore, pay special attention to controlling the temperature when high accuracy is required.

By using the present experimental results of the total height, the drop height above the maximum diameter, the maximum diameter, and the θ-value of the sessile drop that is, 0.322, 0.295, 0.499 cm and 98° (at 980 °C) respectively, and 0.311, 0.254, 0.523 cm and 89° (at 1000 °C) respectively, the surface tension of liquid silver was calculated. The calculated values of the surface tension of liquid silver were from 390 to 420 dyn cm^{-1}, as predicted by Tartar et al.'s formula,[13] 380 to 550 dyn cm^{-1} as predicted by the Porter formula,[14] and 610 dyn cm^{-1} as predicted by the Dorsey formula[15] and other formulas.[3] It was found that the values calculated by using their formulas were about 15 to 25% smaller than the values in the literature cited above.

We also attempted to calculate the critical surface tension and the surface tension at 0 K for the Ag/Al_2O_3 system and therefore adopted the values obtained by using the Dorsey formula.[15] The critical surface tension and the surface tension at 0 K were discussed by Rhee.[4]

The work of the adhesion of a liquid-solid interface can be generally defined by this equation:

$$S_{LS}=(\gamma_{LV}+\gamma_{SV})-\gamma_{LS}$$

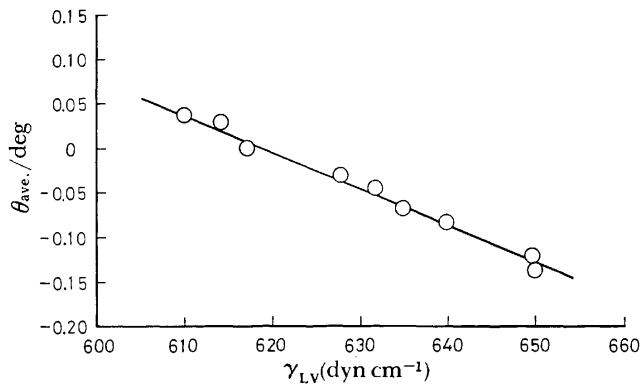

Fig. 7. Cosine of contact angle vs. surface tension of liquid silver for system Ag/Al_2O_3.

where γ_{LV}, γ_{SV}, and γ_{LS} represent the interfacial energies between the phases actually present in the Ag/Al_2O_3 system at the time of measurement. Substituting Young's equation, $\gamma_{SV}-\gamma_{LS}=\gamma_{LV}\cos\theta$, where θ is the contact angle, into the above equation gives:

$$S_{LS}=\gamma_{LV}(1+\cos\theta).$$

Since S_{LS} and $\cos\theta$ are linear functions of the temperature in the Ag/Al_2O_3 system, S_{LS} and $(\gamma_{SV}-\gamma_{LS})$ in Young's equation will vary parabolically with the temperature. If complete wetting occurs, that is, if $\cos\theta=+1$, and $\gamma_{LV}=\gamma_c$, then:

$$S_{LS}=2\gamma_{LV}=2\gamma_c=S_{LL}$$

where γ_c is the critical surface tension. The work of the adhesion of the liquid become equal to the work of cohesion. That is, the layer of vapor adsorbed on the solid surface behaves as does the liquid itself. Therefore, the critical surface tension for spreading is the surface tension of the solid with adsorbed vapor which has attained a liquidlike behavior.

As has been described above, the cosine of the contact angle increases linearly with an incresse in the temperature in the Ag/Al_2O_3 system. The variation in the cosine of the contact angle with a decrease in the surface tension of liquid silver is shown in Fig. 7 for the Ag/Al_2O_3 system. The extrapolation of the straight line to $\cos\theta=+1$ produces the critical surface tension for spreading (γ_c) for the Ag/Al_2O_3 system, with the surface tension of liquid silver at 0 K. For a liquid silver, γ_c for Al_2O_3 is always smaller than that for aluminium nitride (783 dyn cm^{-1}) and for TiC (873 dyn cm^{-1} [14]). When we obtain the values of the critical surface tension, etc., the silver vapor near the melting point may be nearly ignored and thought not to absorb on the Al_2O_3 substrate.

The writers wish to thank Mr. Hiromichi Watanuki for his assistance in the experimental work.

Prediction of Dissociation Constants of Ammonium Ion in Artificial Seawaters and in Concentrated Sodium Chloride Solutions

Masunobu MAEDA,* Masato HAYASHI, Shoichiro IKEDA, Yoshiaki KINJO,† and Kaname ITO
Department of Applied Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya 466
†Chemical Laboratory, College of Education, University of the Ryukyus, Okinawa 903-01
(Received December 11, 1986)

The dissociation constants of ammonium ion were determined at 25 °C by potentiometry with glass and ammonium-ion-selective electrodes in artificial seawaters at various salinities (25—45‰) and in concentrated sodium chloride aqueous solutions (0.72—3.2 mol kg^{-1}). The activity coefficients of ammonia in sodium chloride solutions of the same ionic strengths as those of the artificial seawaters and in the concentrated sodium chloride solutions, which were used for the theoretical estimation of the dissociation constants, were measured by a transpiration method. The dissociation constants were theoretically evaluated in terms of the ionic interaction model developed by Pitzer and co-workers, and compared with the experimental ones. The predicted dissociation constants showed a good agreement with the observed ones.

The majority of the values of thermodynamic properties such as free energy and enthalpy changes for ionic equilibria have been determined in solution containing an inert salt at a high and constant concentration.[1-3] The high electrolyte concentration is employed mainly in order to decrease the variation of the activity coefficients of the reacting species. The natural consequence is that the values of these thermodynamic properties are strongly influenced by the type and concentration of the electrolyte. Thus, the theoretical evaluation of these properties in a specified solution, or the recalculation from one ionic medium to another, is of theoretical as well as practical interest. From a theoretical point of view, the problem is reduced to estimating the effect of the ionic medium on the activity coefficients of the species participating in the ionic equilibria. The estimation of the activity coefficients of the relevant ionic species in concentrated single and mixed electrolyte solutions has been made by using various specific ion interaction theories.[4,5] Various important improvements to these theories have been made in recent years by Pitzer and coworkers.[6,7] The main point in the treatment is the consideration of short-range interactions between the species in solution through two second virial coefficient factors, $\beta^{(0)}$ and $\beta^{(1)}$, which can be a function of ionic strength. The equations derived, with various values of the β parameters along with the values of higher order electrostatic terms, give excellent fits to the experimental results up to the substantially high concentration level.

In previous works[8,9] the dissociation constant of ammonium ion, K_a,

$$NH_4^+ = H^+ + NH_3;\ K_a = [H^+][NH_3]/[NH_4^+]$$

was evaluated in $LiNO_3$, $NaNO_3$, $LiClO_4$, and $NaClO_4$ media with different concentrations (0.5—5 mol dm^{-3}) in terms of both the Brønsted-Guggenheim-Scatchard (BGS)[4,5] and the Pitzer ionic interaction models.[6,7] The predicted and observed values agreed fairly well, although in the lithium salt systems at higher concentration levels the deviations between the estimated and observed values exceeded by far the experimental uncertainties. As far as the sodium salt solutions were concerned, it was found that the values evaluated according to the Pitzer approach were in closer agreement with the observed ones than the values from the BGS approach. The Pitzer ionic interaction theory was successfully applied also to the evaluation of enthalpy changes for dissociation of ammonium ion in LiCl, NaCl, $LiNO_3$, $NaNO_3$, $LiClO_4$, and $NaClO_4$ media with different concentrations (0.5—5 mol dm^{-3}).[10]

In the present work the pK_a values for ammonium ion in artificial seawaters at salinites of 25, 30, 35, 40, and 45‰, the values at 35 and 45‰ being already reported by Khoo et al.,[11] and in the sodium chloride solutions of 0.72—3.2 mol kg^{-1} were determined at 25 °C by potentiometry with glass and ammonium-ion-selective electrodes. The activity coefficients of ammonia (γ_{NH_3}) in sodium chloride solutions at the same ionic strengths as those of the artificial seawaters and in the concentrated sodium chloride solutions were measured by a transpiration method. Since the γ_{NH_3} values in the seawaters could not be measured due to the precipitation of $Mg(OH)_2$ caused by the addition of ammonia, the experimental values for the sodium chloride solutions at the same ionic strengths must be employed. The observed pK_a values were compared with those calculated with the measured γ_{NH_3} values and the activity coefficients of H^+ and NH_4^+ evaluated in terms of the model developed by Pitzer and coworkers.

Whitfield[12,13] estimated the pK_a values for ammonium ion in artificial seawaters and sodium chloride solutions (0.5—3 mol dm^{-3}) according to a few different ionic interation approaches, and compared them with the values reported previously. It does not seem clear whether the agreement is satisfactory especially in the sodium chloride solutions, because of the divergence of the experimental values. In his calculations the γ_{NH_3} values used for the seawaters and concentrated sodium chloride solutions were just read from a straight line drawn through the reference point at

infinite dilution (ionic strength I=0, γ_{NH_3}=1) and the γ_{NH_3} values measured at 0.5, 1.0, and 1.5 mol dm^{-3} NaCl by Abegg and Riesenfeld[14] or a straight line drawn between the reference point at infinite dilution and the mean of the experimental values reported previously in electrolyte solutions at an ionic strength of 0.7 mol dm^{-3}.[14-16]

Experimental

Reagents. Sodium chloride of primary analytical standard quality was dried at 360 °C in an electric furnace and used without further purification. Reagent-grade ammonium chloride was recrystallized twice from water. A stock solution of ammonium chloride was analyzed gravimetrically for Cl^- as AgCl. Other salts and ammonia, of reagent quality, were used without further purification. Artificial seawaters were prepared according to Khoo et al.[11] The molal compositions of the artificial seawaters at five different salinities are shown in Table 1. The ionic strengths were calculated in the usual way with neglect of ion pairing.

Potentiometric Titration Procedures. The dissociation of ammonium ion was monitored by measuring the equilibrium hydrogen-ion and ammonium-ion concentrations with a glass electrode and an ammonium-ion-selective electrode, respectively. The emf's were measured for the cell of the type

$$\text{GE, } NH_4^+\text{-ISE} \mid \text{test solution} \parallel \text{ref}$$

where GE and NH_4^+-ISE denote a glass electrode and an ammonium-ion-selective electrode, respectively, and ref the reference half-cell, e.g., in the artificial seawater of 35‰ salinity.

$$\parallel \text{35‰ artificial seawater} \parallel \text{0.72 mol kg}^{-1}\text{ NaCl, satd. AgCl} \mid \text{AgCl-Ag}$$

From the emf's the equilibrium hydrogen-ion and ammonium-ion concentrations were calculated according to the equations

$$E^H = E_0^H + 59.16 \log[H^+] + E_j, \quad (1)$$

$$E^{NH_4} = E_0^{NH_4} + 59.16 \log[NH_4^+] + E_j, \quad (2)$$

where E_0's are constants, which were determined in situ in solution of known hydrogen-ion and ammonium-ion concentrations. E_j is a liquid junction potential arising between the test solution and the salt bridge. The E_j values, which were mainly caused by H^+ and OH^- ions, were negligibly small over the $-\log[H^+]$ range from 3 to 10 in all the solutions examined. The potentiometric titrations were performed by coulometric generation of OH^- ions.

A glass electrode of Beckman No.39314 and an ammonium-ion-selective liquid membrane electrode purchased from Denki Kagaku Keiki (DKK) were used in combination with a silver-silver chloride reference electrode prepared as recommended by Brown.[17] The emf's were measured (up to 0.1 mV) with pH meters(DKK, Ion-Meter model IOC-10). The titration cell was of the type designed by Tsukuda et al.[18] It was kept in a paraffin oil-thermostat maintained at 25.00±0.02 °C in a room thermostated at 25±1 °C. The hydroxide ions were generated by means of a coulometer (Metrohm, Coulostat E524) using the analogous cell assembly to that described by Biedermann and Ciavatta.[19] To avoid losses of ammonia the titration cell was kept tightly closed. Stirring was performed with a magnetic rod.

Table 1. Molal Compositions of Artificial Seawaters at Five Salinities

Component and ionic strength I	Salinity/‰

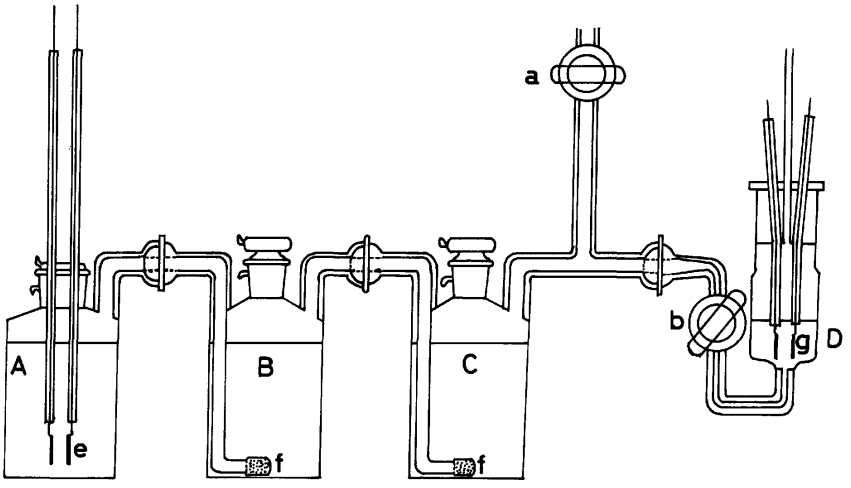

Fig. 1. Apparatus for measurement of ammonia activity. e: Platinum plates, f: sintered glass, g: platinum plates coated with platinum black.

Measurement of Activity Coefficient of Ammonia. The transpiration experiments were performed with a glass apparatus essentially similar to that used by Gaus.[20] It is schematically shown in Fig. 1. Vessel *A* was filled with a 0.5 mol dm^{-3} NaOH solution, and in vessels *B* and *C* were charged 0.4 mol dm^{-3} NH_3 solutions containing NaCl at a desired ionic strength. 10 ml of a 0.01 mol dm^{-3} HCl solution were introduced in conductivity cell *D*. The whole apparatus was immersed in a water thermostat kept at 25.00±0.01 °C. First, the detonating gas was generated in vessel *A* with stopcock *a* open and stopcock *b* closed until the empty spaces in the vessels and the tubes were saturated with the NH_3 gas. And then, in a condition of stopcock *a* being closed and stopcock *b* being open, the electrolysis of the detonating gas was carried out in small steps so that the NH_3 gas transpired by the "purging" gas was absorbed in the HCl solution in cell *D*, while the conductivity of the HCl solution being measured in each step. The electrolysis was carried out by means of a coulometer (Metrohm, Coulostat E524), and the conductivity measurement with an A. C. bridge (Delica, model DlS). The concentration of the NH_3 solution in vessel *C* before and after the experiment was measured by acid-base titrations to ascertain the invariance of the NH_3 concentration during the experiment.

Results and Discussion

Dissociation Constant of Ammonium Ion. The dissociation constants of ammonium ion were determined by the usual graphical and least-squares methods.[21] The ion products of H_2O in the artificial seawaters were taken from Culberson and Pytkowicz.[22] The pK_a values in the seawaters and in the sodium chloride solutions are tabulated in Table 2, together with those previously reported. The pK_a values obtained with a glass electrode and an ammonium-ion-selective electrode are in fairly good agreement with each other, although the uncertainties of the pK_a values determined with data from the ammonium-ion-selective electrode potentiometry are very large. The pK_a values increase with rising salinity and sodium chloride concentration. The pK_a value at 0.725 mol kg^{-1} NaCl is larger than the value in the 35‰ artificial seawater with the same formal ionic strength. The pK_a values at salinities of 35 and 45‰ are consistent with those reported by Khoo et al.[11]

Activity Coefficient of Ammonia. The experimental plots of the conductivities κ against the quantities of electricity passed (for generation of the detonating gas) Q in salt-free and 3.2 mol kg^{-1} NaCl solutions are illustrated in Fig. 2. The amount of electricity passed Q_e for the transpiration of NH_3 needed to neutralize 10 ml of a 0.01 mol dm^{-3} HCl solution was calculated from the point of the slope change. The activity coefficients of ammonia γ_{NH_3} in the sodium chloride solutions with different concentrations were determined by the use of Q_e values and ammonia concentrations C_{NH_3} (in molal units) according to Eq. 3 on the assumption that the γ_{NH_3} value in a salt-free solution be unity.

$$\gamma_{NH_3}=(Q_e^0/Q_e)\times(C_{NH_3}^0/C_{NH_3}) \quad (3)$$

where the superscript 0 is for a salt-free solution. The values of C_{NH_3} and $C_{NH_3}^0$ were adjusted practically equal to each other. The γ_{NH_3} values determined in the sodium chloride solutions of different ionic strengths are given in Table 3. It is seen that the γ_{NH_3} values increase with increasing sodium chloride concentration.

The γ_{NH_3} values in the artificial seawaters could not be determined due to the precipitation of $Mg(OH)_2$ caused by the addition of NH_3. Thus, the adequacy of the employment of the γ_{NH_3} value in the sodium chloride solution for the seawater at the same ionic strength was examined with reference to the artificial seawater at 35‰ salinity. It was suggested in the previous paper[8] that the activity coefficient of ammonia is strongly influenced by the extent of polarization of water molecules coordinated to cations. Accordingly, the Mg^{2+} ions in the artificial seawater of 35‰ salinity were replaced by the Li^+ ions which have the analogous surface charge density to that of the Mg^{2+} ions, with the ionic strength being kept at 0.725 mol kg^{-1}. The γ_{NH_3} value measured in the "artificial seawater" containing Li^+ ions was found to be 1.021, which is smaller than the value (1.057) in the 0.725 mol kg^{-1}

2.087	1.158
3.202	1.228

NaCl solution at the same ionic strength as that of the seawater at 35‰. If this is true in the real artificial seawater of 35‰ salinity, the theoretical pK_a value is lowered by 0.025 units compared with the value calculated by use of the γ_{NH_3} value (1.057) in the 0.725 mol kg^{-1} NaCl solution. However, since the concentration of the Li^+ ions in the "artificial seawater" is 2.5 times larger than that of the Mg^{2+} ions in the artificial seawater at 35‰, the adoption of 1.021 as the γ_{NH_3} value in the 35‰ artificial seawater would lead to an underestimation of the theoretical pK_a value. In conclusion, it may be said that the use of the γ_{NH_3} values obtained in the NaCl solutions at the same ionic strengths as those of the artificial seawaters is unlikely to introduce an error of more than 0.02 units into the calculation of the pK_a values in the artificial seawaters.

Prediction of p*K*a Values. The relation between the dissociation constant of ammonium ion, $K_a(I)$, and the activity coefficients of the relevant species in solution of ionic strength I is represented by Eq.4.

$$pK_a(I) = pK_a(0) + (\ln \gamma_{H^+} + \ln \gamma_{NH_3} - \ln \gamma_{NH_4^+})/2.303 \quad (4)$$

where pK_a(0) denotes the dissociation constant in a salt-free solution. The pK_a(0) value =9.245 reported by Bates and Pinching[23] was accepted in the present calculations. As is evident from Eq. 4, since the pK_a(0) value is available and the γ_{NH_3} values have been measured in the preceeding section, the present problem is reduced to the estimation of the γ values of H^+ and NH_4^+ ions in the solution at ionic strength I. For these calculations the Pitzer ionic interaction approach[6,7] was employed. The trace activity coefficients of the ionic components of unit charge, H^+ and NH_4^+, in the solution containing cations c's and anions a's of ionic strength I can be determined from Pitzer's equations which can be expressed in the ionic form.[24]

$$\ln \gamma_{M^+} = f^\gamma + \sum_c \sum_a m_c m_a B'_{ca} + \sum_{c<c'} \sum m_c m_{c'} \theta'_{cc'} + \sum_{a<a'} \sum m_a m_{a'} \theta'_{aa'} + \sum_a m_a (2B_{Ma} + ZC_{Ma}) + \sum_c m_c (2\theta_{Mc} + \sum_a m_a \psi_{Mca}) + \sum_{a<a'} \sum m_a m_{a'} \psi_{aa'M} + \sum_c \sum_a m_c m_a C_{ca} \quad (5)$$

where M^+ denotes H^+ and NH_4^+, and m the concentration (in molal units) of the ion represented by the subscript,

$$f^\gamma = -A_\phi [I^{1/2}/(1+1.2\,I^{1/2}) + (2/1.2)\ln(1+1.2\,I^{1/2})] \quad (6)$$

with A_ϕ=0.392 at 25 °C,

$$B_{Ma} = \beta_{Ma}^{(0)} + (\beta_{Ma}^{(1)}/2I)[1-\exp(-2\,I^{1/2})(1+2\,I^{1/2})] \quad (7)$$

$$B'_{ca} = (\beta_{ca}^{(1)}/2\,I^2)[-1+\exp(-2\,I^{1/2})(1+2\,I^{1/2}+2\,I)] \quad (8a)$$

Table 4. Single Electrolyte Parameters in Pitzer's Equations at 25 °C

Ca	SO_4	0.20000	2.650	−57.70	0

$$B'_{ca} = (\beta_{ca}^{(1)}/I^2)(2/1.96)[-1+\exp(-1.4I^{1/2})(1+1.4I^{1/2}+0.98I)] + (\beta_{ca}^{(2)}/I^2)(1/72)[-1+\exp(-12I^{1/2})\times(1+12I^{1/2}+72I)] \quad (8b)$$

$$Z = \sum_i m_i|z_i| \quad (9)$$

z_i being the charge of ion i,

$$C_{ca} = C_{ca}^{\phi}/2|z_c z_a|^{1/2}. \quad (10)$$

Equation 8a is for 1-1 and 1-2 electrolytes and Eq. 8b for higher valence types such as 2-2 electrolytes. The θ and θ' terms are related to like charge interactions, and the ψ term accounts for triplet ion interactions.

The values of $\beta^{(0)}$, $\beta^{(1)}$, $\beta^{(2)}$, and C^{ϕ} used in the calculations[7] are listed in Table 4. The calculations were made without the higher order terms θ, θ', and ψ, the contributions of which are usually small,[25] because their values for all the ions are not available. A comparison between the measured pK_a values and ones estimated using Pitzer's equations is shown in Table 2. It is seen that the values observed and those predicted in the present work are in good agreement each other in almost all the solutions. The pK_a values in the sodium chloride solutions measured in the present work are in closest agreement with the theoretically estimated values.

In view of the previous[8-10]and present results, it may be said that the ionic interaction model developed by Pitzer and coworkers is adequately applied to estimate free energy and enthalpy changes both in concentrated single electrolyte solutions and in mixed electrolyte solutions as complex as seawaters. However, the large discrepancies between the observed and estimated pK_a values occurred at higher ionic strengths in the lithium salts solutions.[8,9] This may be ascribed to the fact that the higher order terms θ, θ' and ψ for binary mixtures NH_4A-LiA with a common anion A(A=NO_3 or ClO_4), the contributions of which might unexpectedly be too large to be neglected, were omitted in the calculations because of their unavailableness. Thus, it may be necessary to measure the higher order terms in order to predict the values of the thermodynamic properties more accurately. With the intention to make clear this point, isopiestic measurements of NH_4A-LiA(A=NO_3 or ClO_4) are in progress.

(Received December 18, 1986)

Mixed ligand complexation of copper(II) with bromide ions and 2,2′-bipyridyl (bpy) has been calorimetrically studied in *N,N*-dimethylformamide (DMF) containing 0.16 mol dm^{-3} $(C_2H_5)_4NClO_4$ at 25 °C. Complexation of the metal ion with 2,2′-bipyridyl has been also studied in the same solution. The calorimetric titration curves obtained were satisfactorily explained in terms of formation of the mononuclear $[CuBr_p(bpy)_q]^{(2-p)+}$ (denoted as (1*pq*)) complexes such as (101), (102), (103), (111), (121), and (112), and their formation constants and enthalpies were determined. The mixed ligand (111), (112), and (121) complexes are quite stable and yielded to a large extent in the DMF solution. Electronic spectra of these complexes have been measured in DMF over the range 400—1500 nm. The thermodynamic quantities of formation and electronic spectra of the complexes thus obtained are discussed in connection with the coordination structure of the complexes in DMF. The formation of the five-coordinate $[Cu(bpy)_2(dmf)]^{2+}$ and $[CuBr(bpy)_2]^+$ complexes is suggested in the DMF solution as well as in crystal.

Complexation of bivalent transition metal ions with nitrogen-coordinating bidentate ligands such as 1,10-phenanthroline (phen) and 2,2′-bipyridyl (bpy) has so far been studied in water.[1] Mixed ligand complexes involving these ligands and a variety of amino acids (or peptides) have also been intensively studied from the biochemical point of view.[2]

As to mixed ligand complexes of copper(II) involving 2,2′-bipyridyl, Barclay et al.[3] reported the five-coordinate trigonal-bipyramidal $[CuI(bpy)_2]^+$ complex in crystal. A similar coordination structure has also been revealed for the $[CuX(bpy)_2]^+$ (X^-=Cl^-, Br^- and I^-) complex with varying counter anions.[4-8] The trigonal-bipyramidal $[Cu(bpy)_2(H_2O)]^{2+}$ complex has been observed in crystal,[9] as well as the corresponding $[Cu(phen)_2(H_2O)]^{2+}$ complex.[10-12] Besides, Faye[13] suggested from measurements of electronic spectra that both bis(1,10-phenanthroline)copper(II) and monochlorobis(1,10-phenanthroline)copper(II) complexes have the triginal-bipyramidal structure in acetone and nitromethane solutions.

Although the knowledge of the structure and electronic spectra of the five-coordinate copper(II) complexes has been so far accumulated, the thermodynamic behavior of these complexes in solution has not been well elucidated yet.

In the present work, we calorimetrically investigated the formation of ternary copper(II) complexes with bromide ions and 2,2′-bipyridyl in *N,N*-dimethylformamide containing 0.16 mol dm^{-3} $(C_2H_5)_4NClO_4$ at 25 °C. The formation of binary copper(II) complexes with 2,2′-bipyridyl has been also explored in the same ionic medium solution. The complexation of copper(II) with bromide ions has already been examined in the $(C_2H_5)_4NClO_4$ DMF solution.[14] In order to elucidate the coordination structure of the ternary copper(II) complexes in DMF, electronic spectra were measured over the range 400—1500 nm in DMF solutions in which one of the ternary complexes was predominantly formed. Electronic spectra of the 2,2′-bipyridyl complexes of copper(II) have also been measured in DMF. The thermodynamic quantities of formation and electronic spectra of the $[Cu(bpy)_n]^{2+}$ and $[CuCl_p(bpy)_q]^{(2-p)+}$ complexes thus determined will be discussed in connection with the coordination structure of the complexes in DMF.

Experimental

Reagent. All chemicals used were of reagent grade. 2,2′-*Bipyridyl* was used without further purification and dried in vacuum over P_2O_5 in a desiccator. Other chemicals were prepared or purified as described elsewhere.[14,15]

Measurements. Calorimetric measurements were carried out in a room thermostated at (25.0±0.2) °C, a Dewar vessel for calorimetric titrations being immersed in a water bath controlled at (25±0.007) °C. All test solutions contained 0.16 mol dm^{-3} $(C_2H_5)_4NClO_4$ as a constant ionic medium. 100 cm^3 of a DMF solution containing copper(II) perchlorate or copper(II) bromide with varying molar ratios of bromide to the metal ions was placed in a Dewar vessel which was filled with dry nitrogen gas and isolated from moisture with a P_2O_5 drying-tube, and then it was titrated with 0.1 mol dm^{-3} 2,2′-bipyridyl DMF solution. Heats of complexation observed at each titration point were ranged 1—5 J with certainty ±0.05 J and were corrected for heats of dilution of the titrant, although the correction was very small. Heats of dilution were determined in advance by separate experiments by titrating a 0.16 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMF solution with the 2,2′-bipyridyl solution. All of the measurements were carried out by using a fully automatic on-line system for calorimetry developed in our laboratory.[16,17]

Calorimetric data were treated with the least-squares method by taking into account the mass-balance equations for the metal and bromide ions and 2,2′-bipyridyl in solution, and the formation constants and enthalpies of assumed complexes were simultaneously optimized. The least-

§Present address: Department of Inorganic and Analytical Chemistry, A. József University, Szeged, Hungary.

squares program having been used for the binary systems in previous works[14-16] was extended for the ternary system in this work.

Electronic spectra were measured using a Cary 2300 spectrophotometer (Varian) over the range 400—1500 nm.

Results and Discussion

Calorimetric titration curves for the complexation of copper(II) ion with 2,2′-bipyridyl are depicted in Fig. 1. The corresponding curves in the ternary system are depicted in Fig. 2. In both figures, enthalpies $\Delta H^\circ = -q/(\delta v C_{L,tit})$ were plotted against C_L/C_M, where q, δv, C_L, and C_M stand for the heat evolved, the volume of an aliquot of the titrant added and the concentrations of 2,2′-bipyridyl and copper(II) ion in solution, respectively, at each titration point, and $C_{L,tit}$ denotes the concentration of 2,2′-bipyridyl in the titrant soluton.

In Fig. 1 the ΔH° values are negative and kept practically constant in the range $C_L/C_M<1$, indicating a formation of $[Cu(bpy)]^{2+}$ complex. The ΔH° values drastically change at $C_L/C_M=1$ and are slightly dependent on the concentration of the metal ion over the range $C_L/C_M=1$—4, rather weak $[Cu(bpy)_2]^{2+}$ and $[Cu(bpy)_3]^{2+}$ complexes being expected to be formed in the range. As expected, the calorimetric data were well explained in terms of the formation of $[Cu(bpy)_n]^{2+}$ (n=1—3), and their formation constants and enthalpies were optimized by the least-squares method. The overall formation constants and enthalpies of formation of the complexes thus obtained are summarized in Table 1. As seen in Fig. 1, the solid lines, the titration curves calculated by using the constants in Table 1, satisfactorily reproduce the experimental points over the whole range of C_L/C_M examined.

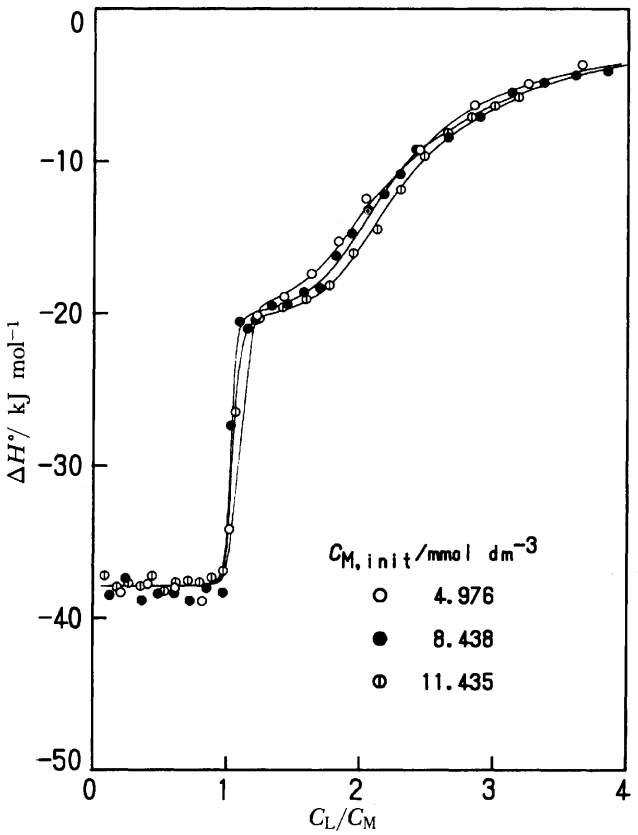

Fig. 1. Calorimetric titration curves of copper(II) 2,2′-bipyridyl DMF solutions containing 0.16 mol dm^{-3} $(C_2H_5)_4NClO_4$ at 25°C. Concentrations of copper(II) ions, $C_{M,init}$/mmol dm^{-3}, in the initial test solutions are given in the figure. The solid lines show the curves calculated by using the constants in Table 1.

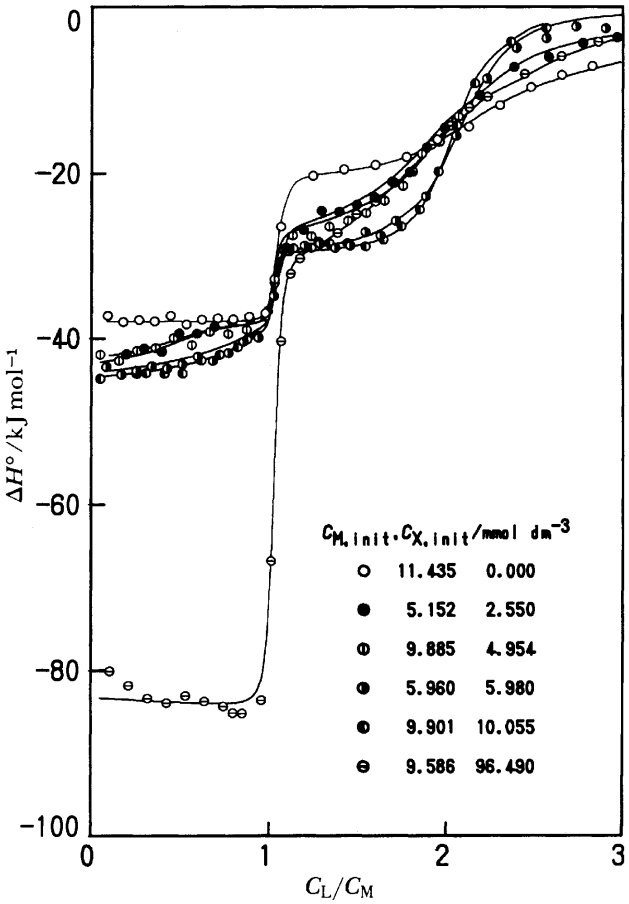

Fig. 2. Calorimetric titration curves in the ternary system obtained by titrating copper(II) bromide DMF solutions with a 2,2′-bipyridyl DMF solution, each containing 0.16 mol dm^{-3} $(C_2H_5)_4NClO_4$ at 25°C. Concentrations of copper(II) and bromide ions, $C_{M,init}$ and $C_{X,init}$/mmol dm^{-3}, in initial test solutions are given in the figure. The solid lines show the curves calculated by using the constants in Table 1.

In Fig. 2 the calorimetric titration curves are strongly dependent on the molar ratio of bromide to copper(II) ions in the solution. The curves calculated by using the only known formation constants and enthalpies of $[CuBr_n]^{(2-n)+}$ (n=1—4)[14] and those of $[Cu(bpy)_n]^{2+}$ (n=1—3) determined above hardly reproduce the experimental points, and thus the formation of ternary $[CuBr_p(bpy)_q]^{(2-p)+}$ (denoted as ($1pq$)) complexes must be considered. Ternary ($1pq$) complexes with $p+2q\leq 6$ may be plausibly formed by taking into

Values in parentheses refer to three standard deviations. The formation constants and enthalpies of formation of $[CuBr_n]^{(2-n)+}$ (n=1—4)[14] were fixed in the course of the least-squares analysis. a) Error-square sum. b) The Hamilton R-factor. c) The number of data points.

account the six-coordinate about the metal ion, together with the mono- and bidentate coordinations of bromide ion and 2,2′-bipyridyl, respectively. The possible compositions of the ternary complexes are thus (111), (121), (131), (141), (112), and (122). However, the formation of the (131), (141), and (122) complexes were eliminated in the course of the least-squares analysis. The formation constants and enthalpies of these ternary complexes were finally optimized together with those of the binary $[Cu(bpy)_n]^{2+}$ (n=1—3) complexes by using the whole set of data shown in Figs. 1 and 2, the results being also listed in Table 1. The Hamilton R-factor was 2.10% and the thermodynamic quantities of each complex was obtained with relatively small standard deviations. As seen in Fig. 2, the solid lines calculated by using the constants in Table 1 and those for the $[CuBr_n]^{(2-n)+}$ (n=1—4) previously determined,[14] satisfactorily reproduce the experimental points. The $\log\beta_{10q}$ (q=1—3) values thus obtained in the mixed ligand ternary system were in satisfactorily good agreement with those in the binary system without bromide ions.

In Fig. 3 the distribution of species is shown as the function of $-\log([bpy]/\mathrm{mol\,dm}^{-3})$ in solution with varying $R(=C_X/C_M)$ values, which is calculated by using the formation constants of the ternary copper(II) complexes with 2,2′-bipyridyl and bromide ions, together with those of relevant binary copper(II) complexes. It is indicated from the figure that the (111) and (112) complexes are predominantly formed in solution containing equimolar amounts of copper(II)

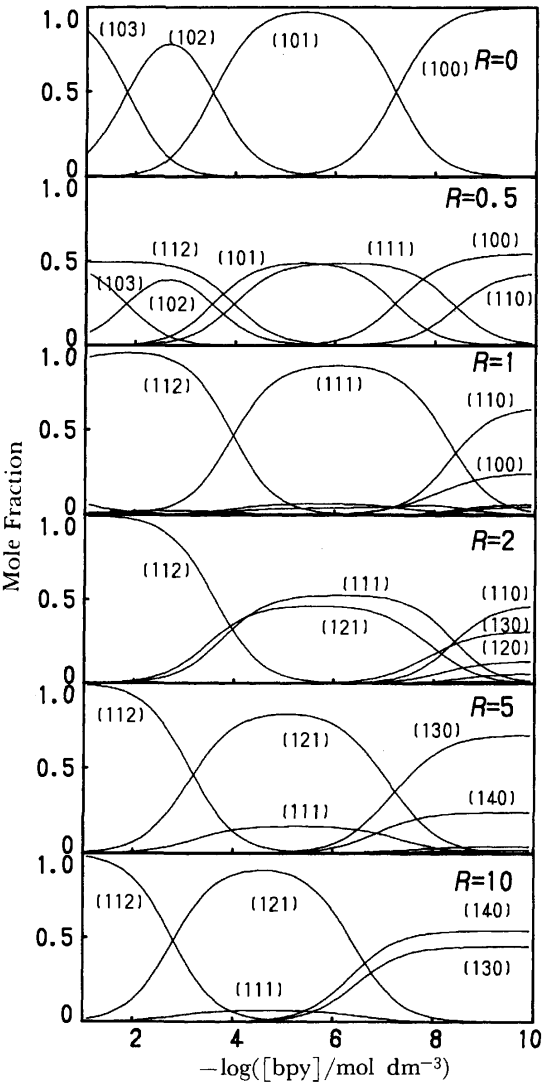

Fig. 3. Distribution of the $[CuBr_p(bpy)_q]^{(2-p)+}$ (denoted as (lpq)) complexes as the function of $-\log([bpy]/\mathrm{mol\,dm}^{-3})$ in DMF containing 0.16 mol dm^{-3} $(C_2H_5)_4NClO_4$ at 25 °C. The R value stands for the molar ratio of bromide to copper(II) ions in solution.

and bromide ions (R=1). With increasing R, the formation of the ternary copper(II) complexes is suppressed for the (111) complex but is enhanced for the (121) one. The (112) complex is formed in all the solutions. In Fig. 4 the distribution of species is represented as the function of $-\log([Br^-]/\mathrm{mol\,dm}^{-3})$ in solution with varying R' $(=C_L/C_M)$ ratios of 2,2′-bipyridyl to copper(II) ion, for comparison.

The distribution of species in Figs. 3 and 4 indicates that each of the (101), (102), (103), (111), (112), and (121) complexes is yielded as a main species in a DMF solution with a suitable composition of the ligands to copper(II) ion. Electronic spectra of DMF solutions in which each of the $[Cu(bpy)_n]^{2+}$ (n=0—3) complex is predominantly formed are depicted in Fig. 5. As well, electronic spectra of the $[CuBr(bpy)]^+$, $[CuBr(bpy)_2]^+$ and $[CuBr_2(bpy)]$ complexes are shown in Fig. 6.

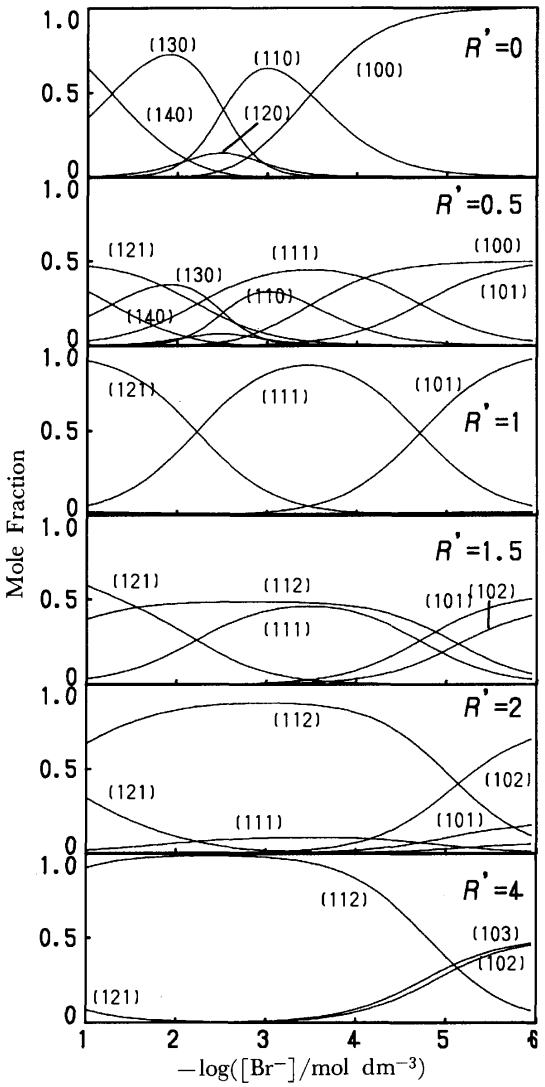

Fig. 4. Distribution of the $[CuBr_p(bpy)_q]^{(2-p)+}$ (denoted as (l*pq*)) complexes as the function of $-\log([Br^-]/\text{mol dm}^{-3})$ in DMF containing 0.16 mol dm^{-3} $(C_2H_5)_4NClO_4$ at 25°C. The *R'* value stands for the molar ratio of 2,2'-bipyridyl to copper(II) ion in solution.

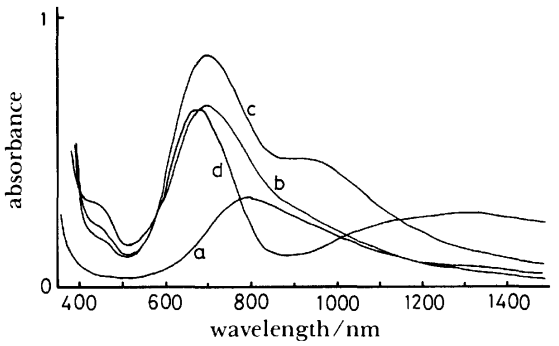

Fig. 5. Electronic spectra of various copper(II) 2,2'-bipyridyl DMF solutions. Concentrations of metal ions and ligands, C_M and C_L/mmol dm^{-3}: 9.69, 0.0 (spectrum a for $[Cu(dmf)_6]^{2+}$); 10.17, 11.60 (b for $[Cu(bpy)]^{2+}$); 9.92, 21.2 (c for $[Cu(bpy)_2]^{2+}$); 10.67, 100. (d for $[Cu(bpy)_3]^{2+}$).

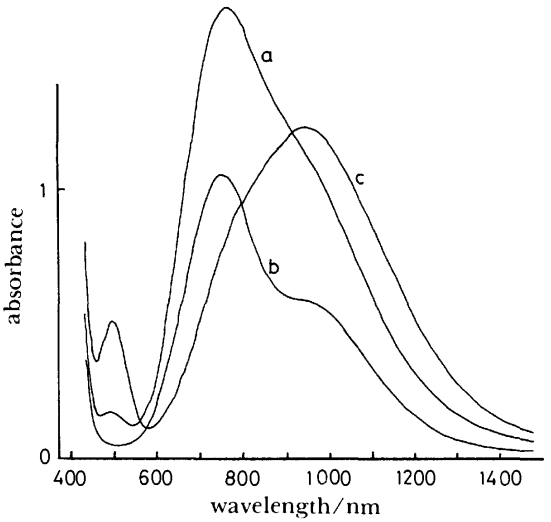

Fig. 6. Electronic spectra of the ternary copper(II) complexes with bromide ions and 2,2'-bipyridyl in DMF. Concentrations of metal and bromide ions and 2,2'-bipyridyl, C_M, C_X and C_L/mmol dm^{-3}: 10.15, 11.01, 9.97 (spectrum a for $[CuBr(bpy)]^+$); 9.87, 10.47, 20.35 (b for $[CuBr(bpy)_2]^+$); 4.00, 16.0, 4.25 (c for $[CuBr_2(bpy)]$).

These electronic spectra observed in the wavelength range 400—1500 nm may be ascribed to the d-d transition bands of copper(II) ion within the complexes.

Binary (2,2'-Bipyridyl)copper(II) Complexes. In DMF, copper(II) ion is present as $[Cu(dmf)_6]^{2+}$ with the distorted octahedral structure according to X-ray diffraction measurements.[19] The DMF molecules coordinating to copper(II) ion are stepwise replaced with 2,2'-bipyridyl molecules and the $[Cu(bpy)_3]^{2+}$ complex is finally formed in the solution. The $[Cu(bpy)_3]^{2+}$ complex may have the distorted octahedral structure in DMF because its electronic spectrum in DMF is very similar to that in crystals,[20] and the distorted octahedral $[Cu(bpy)_3]^{2+}$ complex has been revealed in the $[Cu(bpy)_3](ClO_4)_2$ crystal.[21] Similarly, the mono(2,2'-bipyridyl) complex may have the distorted octahedral structure as represented by $[Cu(bpy)(dmf)_4]^{2+}$ with two DMF molecules at the equatorial position and the others at the axial position, because its electronic spectrum shows a similar single peak to that of the $[Cu(dmf)_6]^{2+}$ complex, although the peak position of the former complex is shifted to shorter wavelength by ca. 100 nm than that of the latter.

The bis(2,2'-bipyridyl)copper(II) complex exhibits two absorption bands at ca. 690 and 950 nm in DMF as well as in water,[22] suggesting a similar coordination structure of the complex in both solutions. It is noted that the electronic spectrum of the bis(2,2'-bipyridyl) complex in solution is also very similar to that (with peaks at 708 and 930 nm) arising from the five-coordinate $[Cu(bpy)_2(H_2O)]^{2+}$ moiety in the $[Cu(bpy)_2(H_2O)]S_5O_6$ crystal.[9] Therefore, the five-coordinate $[Cu(bpy)_2(dmf)]^{2+}$ complex is plausibly formed in

DMF.

The thermodynamic quantities of stepwise formation of $[Cu(bpy)_n]^{2+}$ (n=1—3) in DMF are summarized in Table 2, together with those of $[Cu(bpy)_n]^{2+}$ (n=1—3)[1] and $[Cu(en)_n]^{2+}$ (n=1 and 2)[18] in water. The ΔH_1° value for the formation of the $[Cu(bpy)]^{2+}$ complex is large and negative and the corresponding ΔS_1° value is slightly positive in DMF. It is noted that the ΔH_2° value is significantly less negative than the ΔH_1° value in the copper(II)-2,2′-bipyridyl system both in DMF and in water. On the other hand, the ΔH_2° value is even more negative than the ΔH_1° value in the copper(II)-ethylenediamine system in water. According to X-ray diffraction measurements,[23] the bis(ethylenediamine) complex has the distorted octahedral (or practically the square planar) $[Cu(en)_2(H_2O)_{ax}(H_2O)_{ax}]^{2+}$ structure with extremely elongated two axial water molecules in water. Therefore, the significant difference observed for the ΔH_2° values in the 2,2′-bipyridyl and ethylenediamine systems may be ascribable to the difference in the coordination structure of the bis(2,2′-bipyridyl) and bis(ethylenediamine) complexes of copper(II). It is also noted that the ΔH_3° and ΔS_3° values are more negative than the corresponding ΔH_2° and ΔS_2° values in the copper(II)-2,2′-bipyridyl system. Considering the five-coordinate $[Cu(bpy)_2(dmf)]^{2+}$ complex as discussed in a preceding section, we expect that the more negative ΔH_3° and ΔS_3° values than the corresponding ΔH_2° and ΔS_2° ones may be explained in terms of the liberation of only one DMF molecule within the five-coordinate $[Cu(bpy)_2(dmf)]^{2+}$ complex followed by the formation of the six-coordinate $[Cu(bpy)_3]^{2+}$ complex.

a) Ref. 14, in 0.16 mol dm^{-3} $(C_2H_5)_4NClO_4$ DMF solution.

Ternary (2,2′-Bipyridyl)bromocopper(II) Complexes. The thermodynamic quantities of stepwise formation of ternary copper(II) complexes with bromide ions and 2,2′-bipyridyl, together with those of binary copper(II) bromo complexes, in DMF are summerized in Table 3.

As seen in Table 3, the coordination of a bromide ion to the $[Cu(bpy)_2]^{2+}$ complex is endothermic with a large and positive entropy change. Such a result can not be expected from a simple addition of bromide ion to the $[Cu(bpy)_2(dmf)]^{2+}$ complex to form a six-coordinate $[CuBr(bpy)_2(dmf)]^+$ complex. We thus expect the rupture of a Cu-dmf bond within $[Cu(bpy)_2(dmf)]^{2+}$ followed by the formation of the five-coordinate $[CuBr(bpy)_2]^+$ complex without any DMF molecule coordinating to the central metal ion, as having already been found in crystal.[7,8] The conclusion may be supported by the electronic spectra of the bis(2,2′-bipyridyl)monobromocopper(II) complex in DMF because it exhibits peaks at ca. 750 and 950 nm, and a similar spectrum with peaks at 755 and 955 nm has been observed for the five-coordinate $[CuCl(bpy)_2]^{2+}$ moiety within the $[CuCl(bpy)_2]_2S_5O_6\cdot 6H_2O$ crystal.[9] The monobromocopper(II) complex may exist as $[CuBr(dmf)_5]^+$ in DMF, as well as $[CuCl(dmf)_5]^+$.[19] DMF molecules coordinating to the $[CuBr(dmf)_5]^+$ complex are replaced with 2,2′-bipyridyl molecules and the five-coordinate $[CuBr(bpy)_2]^+$ complex may be finally formed in DNF. As seen in Table 3, in the course of the successive reactions of $[CuBr]^+$ with 2,2′-bipyridyl molecules in DMF, the formation of the $[CuBr(bpy)]^+$ complex exhibits a positive ΔS° value and the subsequent formation of $[CuBr(bpy)_2]^+$ a negative ΔS° one. Since a relatively large ΔS° value may be associated with the change from the six- to five-coordinate structure in the course of a complexation reaction, the coordination structure may be changed at the formation of the $[CuBr(bpy)]^+$ complex. As seen in Fig. 6, the electronic spectrum of the $[CuBr(bpy)]^+$ complex shows a

Table 4. Thermodynamic Quantities, $\log K$, $\Delta G°$/kJ mol^{-1}, $\Delta H°$/kJ mol^{-1}, and $\Delta S°$/J K^{-1} mol^{-1}, of Reaction, $[CuBr_p]^{(2-p)+}+[Cu(bpy)_q]^{2+}=[CuBr_p(bpy)_q]^{(2-p)+}+Cu^{2+}$ (bpy=2,2′-bipyridyl), in *N*,*N*-dimethylformamide at 25°C

Complex formed	$\log K$	$\Delta G°$	$\Delta H°$	$\Delta S°$
$[CuBr(bpy)]^+$	1.23	−7.0	−5.7	4
$[CuBr(bpy)_2]^+$	1.65	−9.4	−15.4	−20
$[CuBr_2(bpy)]$	1.38	−7.9	−18.9	−37

peak at 750 nm and a shoulder at ca. 950 nm, these bands being also observed in the spectrum of the five-coordinate $[CuBr(bpy)_2]^+$ complex. Therefore, we expect the formation of the five-coordinate $[CuBr(bpy)(dmf)_2]^+$ complex in DMF.

The electronic spectrum of the mono(2,2′-bipyridyl)-dibromocopper(II) complex exhibits a peak at 950 nm and a shoulder at ca. 750 nm, these peak positions being similar to that observed for the $[CuBr(bpy)_2]^+$ and $[CuBr(bpy)]^+$ complexes, while the relative intensity of the 950 nm band to the 750 nm one is significantly strong in the $[CuBr_2(bpy)]$ complex. It seems thus difficult to conclude whether the $[CuBr_2(bpy)]$ complex has the four- or five-coordinate structure in DMF.

The thermodynamic quantities of formation of the ternary $[CuBr(bpy)]^+$, $[CuBr(bpy)_2]^+$, and $[CuBr_2(bpy)]$ complexes according to the reaction, $[CuBr_p]^{(2-p)+}+[Cu(bpy)_q]^{2+}=[CuBr_p(bpy)_q]^{(2-p)+}+Cu^{2+}$, are summarized in Table 4. The $\Delta G°$ values are all appreciably negative, indicating the favorable formation of each ternary complex with respect to the relevant binary bromo and 2,2′-bipyridyl complexes of copper(II) ion in DMF. It should be noted that the corresponding $\Delta H°$ values are significantly large and negative.

The formation reactions of the $[CuBr(bpy)]^+$ and $[CuBr(bpy)_2]^+$ complexes may be represented as $[CuBr(dmf)_5]^+ + [Cu(bpy)(dmf)_4]^{2+} = [CuBr(bpy)(dmf)_2]^+ + [Cu(dmf)_6]^{2+} + dmf$ and $[CuBr(dmf)_5]^+ + [Cu(bpy)_2(dmf)]^{2+} = [CuBr(bpy)_2]^+ + [Cu(dmf)_6]^{2+}$, respectively, by taking into account the coordination of DMF molecules within the relevant complex species. We note that one DMF molecule may be liberated at the formation of the $[CuBr(bpy)]^+$ complex but no DMF molecule at the formation of $[CuBr(bpy)_2]^+$. In Table 4 the $\Delta H°$ and $\Delta S°$ values for the formation of $[CuBr(bpy)]^+$ are appreciably less negative than those for the formation of $[CyBr(bpy)_2]$, the result might be thus ascribed to the rupture of the metal-dmf bond at the formation of the former complex.

The present work has been financially supported by the Grant-in-Aid for Special Project Research No. 61134043 from the Ministry of Education, Science and Culture.

Association of Benzene and Alkylbenzenes with Cyclodextrins in Aqueous Medium

Isao SANEMASA* and Youko AKAMINE
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received December 23, 1986)

Formation constants of the following aromatic hydrocarbons with α-,β-, and γ-cyclodextrin(CyD) were determined in aqueous medium at 25 °C in the presence of excess CyD: benzene, toluene, ethylbenzene, propylbenzene, isopropylbenzene, (*o*-, *m*-, and *p*-)xylene, and (1,2,3-, 1,2,4-, and 1,3,5-)trimethylbenzene. The technique used to study association between host(CyD) and guest (hydrocarbon) is based on the facts that the guest molecules can be driven out to gaseous phase by introducing an inert gas at a constant flow rate into the aqueous solution and that the volatilization rate of guest decreases with increasing association with the host in the aqueous solution. The 1:1 and 2:1 (host:guest) formation constants were evaluated. As a measure of hydrophobicity of guest molecules, the free energy change of dehydration derived from Henry's law constant was used. Based on hydrophobicity and a host-guest spatial-fitting model, the formation constants have been discussed.

α-, β-, and γ-Cyclodextrins(CyD) are cyclic oligosaccharides consisting of six, seven, and eight D-glucopyranose units linked by α(1—4) bonds with a central cavity. The cavity is thought to be hydrophobic and a wide variety of inorganic and organic compounds is held if they suitably fit in the space, making CyD act as a host. Aromatic hydrocarbons, which are generally hydrophobic, have been extensively studied, but most of the hydrocarbons so far examined have hydrophilic substituent groups in order to increase solubility. There have been two reports concerning the benzene-CyD association system,[1,2] and there appears no data on alkylbenzene-CyD system. The scarcity of examination of these substances may be partially attributed to low aqueous solubility of these nonelectrolytes and partially to their high volatility; both reasons make it difficult to estimate accurately the amount of CyD-associated species formed in the aqueous medium.

In our preveous papers,[3,4] a method was presented which estimates 1:1 association constants between volatile and nonvolatile solutes in aqueous medium. The method is based on volatility of nonelectrolyte solute in aqueous solution. Volatile molecules are driven out to gaseous phase by introducing an inert gas at a constant flow rate into the aqueous solution. The volatilization rate was measured with and without addition of nonvolatile solute which associates with the volatile solute and decreased with the degree of association between the solutes. The method is simple, versatile, and applicable to such systems where (a) one of the solutes is volatile, (b) the concentration of nonvolatile solute is sufficiently high in comparison with that of volatile solute, and (c) the rate of association is rapid compared with the volatilization rate.

The method seems to be particularly suitable for studying association where solutes such as benzene and alkylbenzenes are concerned, because these solutes are highly volatile and scarecely soluble in water. The present study was undertaken to demonstrate the volatilization method and to interpret formation constants by a host-guest spatial-fitting model and hydrophobicity of guest molecule. A series of alkylbenzene have been chosen for this purpose: straight-chain series and some isomers (propylbenzenes, xylenes, and trimethylbenzenes).

Experimental

Materials and Preparation of Sample Solutions. Distilled deionized water was used throughout the experiments. Aromatic hydrocarbons used for guest are of analytical reagent grade (the purity is listed in Table 1). Cyclodextrins (α-, β-, and γ-CyD) used for host were of guaranteed grade from Nakarai Chemicals Co. Both guest and host reagents were used without further purification. An aqueous solution of each guest was prepared using a technique previously described.[5] The solute vapor in equilibrium with the liquid solute was introduced into water at 25 °C and circulated in a closed system. An aqueous solution saturated with guest liquid hydrocarbon can be prepared within 5 min by this technique. A portion of the saturated guest solution was transferred into a separatory funnel and the concentration of guest was determined by solvent extraction with chloroform, and another portion was transferred into a 2.5φ×25 cm cylindrical glass tube. A suitable amount of CyD, which had been dried over phosphorus pentaoxide under vacuum, was weighed and dissolved into the guest solution. The solution

Table 1. Experimental Conditions

Guest substance	Purity	λ[a]	N_2 flow rate
	%	nm	$cm^3 min^{-1}$

1,3,5-Trimethylbenzene	97.0	264.8	28.0

a) The wavelength for determining the concentration of guest molecules after $CHCl_3$ extraction.

was then diluted to 100 cm^3 with water. Ranges of concentration of guest and host are given in Table 3.

Amberlite XAD-2 resin (Rohm and Hass) as an adsorbent of guest vapor was ground in an agate mortar, a 150—200 mesh portion was collected and washed with ethanol by decantation until the supernatant became clear.

Apparatus and Procedures. The cylindrical glass tube containing guest and host at each desired concentration was immersed in a bath thermostated at 25.0±0.1 °C. A gas-inlet-type adaptor was mounted on the tube and N_2 was blown in the solution through Teflon tube of 1 mm i.d. at a constant flow rate controlled by a Stec Type Sec 400 mass-flow controller in the range of 15.8 to 30.0 $cm^3 min^{-1}$ (Table 1) depending on the volatility of guest and its association with host in aqueous solution. The N_2 flow rate was kept same irrespective of the presence of host. The N_2 leaving the sample solution was passed through a 0.5ϕ×12 cm glass column filled with XAD-2 resin beads of 8 cm in length. The exit and the bed top of column was plugged and covered with glass wool. After a fixed time, N_2 stream was interrupted, the XAD column was replaced by a fresh one and N_2 flow was resumed. This operation was repeated at regular time intervals. The guest hydrocarbon adsorbed on the resin was completely eluted out with $CHCl_3$ of 3 or 4 cm^3. The amount of hydrocarbon expelled from the sample solution during a fixed time, ΔQ, i.e., the amount of guest collected on a single XAD column, was determined by UV spectroscopy at the optimum wavelength for each guest hydrocarbon (Table 1) with reference to a calibration curve prepared for each guest-$CHCl_3$ solution. The XAD column can be used repeatedly by washing with $CHCl_3$ and drying in hot air.

Results

Derivation of Equation Estimating 1:1 and 2:1 (Host:Guest) Formation Constants. As for the CyD-benzene systems, the possible host : guest stoichiometric ratios are 1 : 1, 2 : 1, and 1 : 2.[2] The last one is, however, excluded under the present experimental condition that host molecules are always excess over guest molecules. Then, the reactions that should be taken into account are:

$$\mathrm{CyD}+\phi \rightleftharpoons \mathrm{CyD}\cdot\phi, (K_1) \quad (1)$$

$$\mathrm{CyD}\cdot\phi+\mathrm{CyD} \rightleftharpoons \mathrm{CyD_2}\cdot\phi, (K_2), \quad (2)$$

$$\phi\,(\mathrm{aq}) \rightarrow \phi\,(\mathrm{gas}), (k), \quad (3)$$

where ϕ refers to a hydrocarbon molecule, K_1 and K_2 are the corresponding stepwise formation constants, and k is the rate constant for transfer of guest molecules from aqueous to gaseous phase.

The guest molecules expelled into the gaseous phase are collected successively by the adsorbent, and the total amount, Q_ϕ, which is the summation of ΔQ_ϕ, is measured as a function of aeration time, t. Here, we assume that the releasing of guest molecules at a constant N_2 flow rate is of first-order with respect to the concentration of free species in the solution as follows:

$$dQ_\phi V^{-1}/dt = k[\phi], \quad (4)$$

where V is the volume of the aqueous solution. The mass-balance equations are:

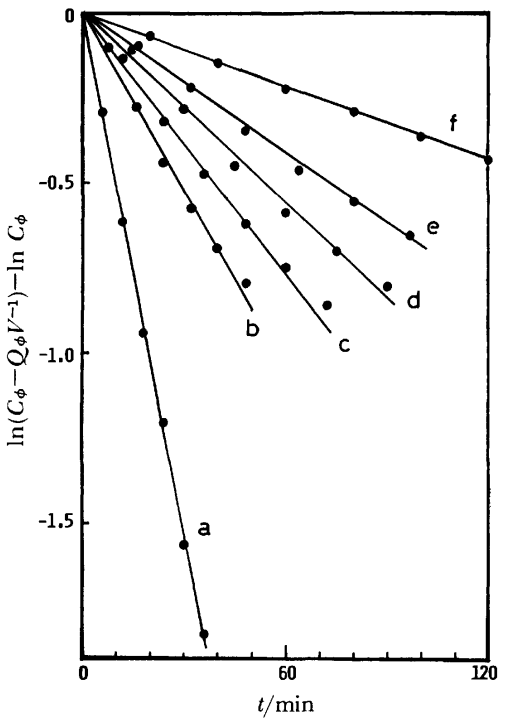

Fig. 1. Propylbenzene-α-CyD system. The plots of $\ln(C_\phi - Q_\phi V^{-1}) - \ln C_\phi$ vs. t in the absence and presence of cyclodextrin. a) $k' = k/(1+K_1C_{CyD}+K_1K_2C_{CyD}^2)$, where C_{CyD} is the total concentration of cyclodextrin. b) The initial concentration of propylbenzene.

$$C_{CyD} = [\mathrm{CyD}] + [\mathrm{CyD}\cdot\phi] + 2[\mathrm{CyD_2}\cdot\phi], \quad (5)$$

$$C_\phi = [\phi] + [\mathrm{CyD}\cdot\phi] + [\mathrm{CyD_2}\cdot\phi] + Q_\phi V^{-1}$$
$$= [\phi] + K_1[\mathrm{CyD}][\phi] + K_1K_2[\mathrm{CyD}][\phi] + Q_\phi V^{-1}, \quad (6)$$

where C_{CyD} and C_ϕ denote the total concentration of CyD and the total concentration of guest, respectively. Substituting Eq. 6 by Eq. 4 we obtain

$$dQ_\phi V^{-1}/dt = k(C_\phi - Q_\phi V^{-1})/(1+K_1[CyD]+K_1K_2[CyD]^2), \quad (7)$$

which becomes, on integration and with $Q_\phi=0$ at $t=0$,

$$\ln(C_\phi - Q_\phi V^{-1}) = -kt/(1+K_1[CyD]+K_1K_2[CyD]^2) + \ln C_\phi = -k't + \ln C_\phi, \quad (8)$$

where

$$k' = k/(1+K_1[CyD]+K_1K_2[CyD]^2). \quad (9)$$

Plots of $\{\ln (C_\phi - Q_\phi V^{-1}) - \ln C_\phi\}$ vs. t will give a straight line with a slope which corresponds to $-k'$ in the presence of CyD or to $-k$ in the absence of CyD. Under the condition that the total concentration of CyD is sufficiently higher than that of the associated complexes formed, that is, $C_{CyD} \gg [CyD\cdot\phi]+[CyD_2\cdot\phi]$, [CyD] in Eq. 9 is equal to C_{CyD}. Rearrangement of Eq. 9 gives the equation:

$$1/k' = K_1K_2C_{CyD}^2/k + K_1C_{CyD}/k + 1/k, \quad (10)$$

from which we can estimate K_1 and K_2 by plotting $1/k'$ against C_{CyD}.

Preliminary experiments show that the rate constant k is a function of gas flow rate and that the constant k' is proportional to k at a constant CyD concentration. We assume from the latter observation that the reaction (3) is the rate-determining step.

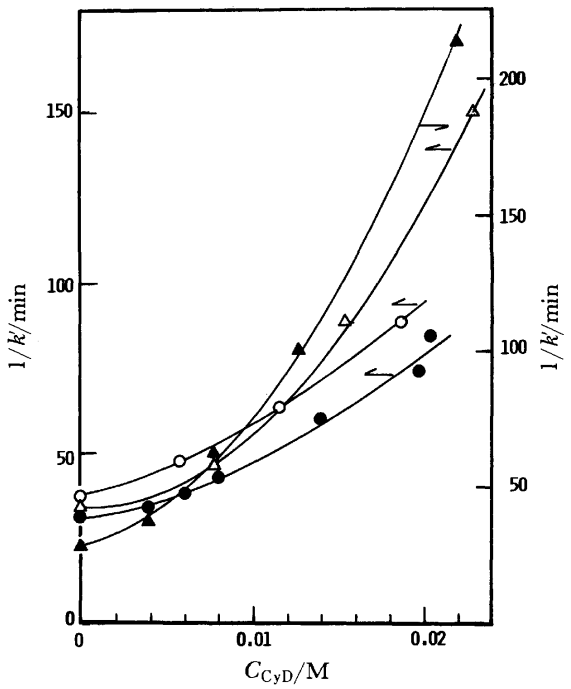

Fig. 3. The plots of $1/k'$ vs. C_{CyD}. Examples of parabolic curve. Benzene-α-CyD(●), o-xylene-γ-CyD(○), p-xylene-α-CyD(▲), 1,2,3-trimethylbenzene-α-CyD(△).

Estimation of K_1 and K_2. Plots according to Eq. 8 for propylbenzene-α-CyD system are shown in Fig. 1. The plots give straight lines up to ca. 70% release of the guest hydrocarbon from the solution. This linearity verifies the validity of the assumption that the volatilization of guest molecules follows a first-order reaction at a constant gas flow rate. The slopes of resulting straight lines, k and k', were evaluated using the least-squares method; the results for propylbenzene are shown in Table 2. Figures 2 and 3 show some typical results plotted by a curve-fitting method with the aid of Eq. 10. The $1/k'$ vs. C_{CyD} plots appear to be linear (Fig. 2) or parabolic (Fig. 3) depending on the host-guest combination. All the data were first treated by quadratic equations and when coefficients of the C_{CyD}^2 term were slightly negative, the plots were taken to be linear. The K_1 (and K_2) values thus determined are summarized in Table 3.

Discussion

Comparison of Results with Those in the Literature. In a previous paper,[4] which concerns with 1 : 1 associations of molecular iodine with α-, β-, and γ-CyD, we reported that the method making use of the difference in I_2 volatility rate with and without CyD provides formation constants in reasonable agreement with the literature values and that the method can be used to study association with a small formation constant in the order of 10. The present work is based on the same technique. In order to discuss whether we

can apply the method in the cases of aromatic hydrocarbons as guest molecules, the estimated formation constants are to be compared with those in the literature. Of the guest substances studied in this work, however, the literature data are only available for benzene. Then, we applied the method to naphthalene-β-CyD to find the formation constant K_1 to be 680 M^{-1} (M=mol dm^{-3}) at 25 °C.[6] Our estimation was in reasonable agreement with the literature value of 630 M^{-1} at 25 °C.[7]

Hoshino et al. measured fluorescence enhancement of benzene by forming inclusion complex with β-CyD, and reported K_1 for benzene-β-CyD at 28 °C to be 196 M^{-1}.[1] Tucker and Christian measured vapor pressure of benzene with and without CyD in aqueous solutions at various temperatures.[2] Their K values at 25 °C are as follows; for α-CyD K_1=31.6 M^{-1}, K_1K_2= 325 M^{-2}, for β-CyD K_1=169 M^{-1}, and for γ-CyD K_1= 9.1 M^{-1}.

The present result for benzene-β-CyD (K_1=120 M^{-1})

is smaller than each literature value. Compared with Tucker-Christian's results for benzene-α-CyD, the present K_1 (17 M^{-1}) seems considerably small. Since their K_1K_2 product (325 M^{-1}) is in reasonable agreement with our corresponding value (289 M^{-2}), our K_2 is larger than their K_2. Because of lack of data available in the literature, it is difficult at present to judge which is more reliable and to know if the agreement observed for benzene-γ-CyD is meaningful.

The vapor pressure method employed by Tucker and Christian makes use of the fact that the volatility of substrate is depressed by forming inclusion complexes with CyD and it resembles our method in this respect: the former may be called "static" and the latter "dynamic" technique. Their method seems, however, to be only applicable to a high volatile guest like benzene, because it is the total vapor pressure that can be measured. Accurate measurement of vapor pressure for low volatile solute is difficult due to the vapor pressure of water. Our present technique seems advantageous in this respect. The present method, however, accompanies large deviation of formation constants. This may arise from uncertainty in determining the amount of released guest. The overall error in Q_ϕ becomes large due to the accumulation of error in ΔQ_ϕ. Moreover, it should be noted that the present method cannot be applied for determining formation constants of guest-rich complexes. This is an unavoidable disadvantage. Tucker and Christian succeeded in determining the 1 : 2 (host : guest) formation constant for benzene-α-CyD.

Henry's Law Constant as a Measure of Hydrophobicity of Guest. Hydrogen bonding, van der Waals forces, and hydrophobic interaction are generally accepted to be the binding forces between CyD and guest molecules. The first one is excluded in the present case because the guests used have no ability to form hydrogen-bond with CyDs. It is considered that the host-guest spatial fitting plays a dominant part in van der Waals forces. On the other hand, it is generally difficult to evaluate the contribution of hydrophobic interaction. Some physico-chemical parameters such as aqueous solubility and partition coefficient of 1-octanol-water or chloroform-water systems have been used as a measure of hydrophobicity: Their logarithmic values plotted against log K gave fairly good linear relationships for some guest substances.[8,9]

Tabushi et al. have calculated the free-energy change caused by hydrophobic interaction of three model guests including benzene.[10] Their theory is reasonably based on the idea that the hydrophobic interaction arises from dehydration process, that is, a guest molecule is transferred from a hydrated state to an ideal gas state leaving behind a cavity (water cluster) which is collapsed and redistributed. A suitable parameter for describing hydrophobicity of nonelectrolyte guests like those employed in this work is Henry's law constant, K_H, a measure of free-energy

necessary to bring a nonelectrolyte from aqueous medium to vapor phase. The free-energy change associated with dehydration of a guest, ΔG_{dehyd}, can be evaluated by $\Delta G_{dehyd}=-RT \ln K_H$. The ΔG_{dehyd} values for all the guests examined were already reported in a previous paper.[5] The free-energy change in the 1 : 1 complex formation, $\Delta G_{complex}$ ($=-RT \ln K_1$) is plotted against ΔG_{dehyd} in Figs. 4 to 6; a dotted line indicates $\Delta G_{dehyd}=\Delta G_{complex}$.

Figures 4—6 show that most of the guests have considerably smaller $-\Delta G_{complex}$ than $-\Delta G_{dehyd}$ for three CyDs, especially for α- and γ-CyD. If we postulate that a guest molecule is fully embraced in the cavity of a given CyD and that the environment for the guest is just like a gaseous phase, $-\Delta G_{dehyd}$ for the nonelectrolyte will contribute in full to the $-\Delta G_{complex}$. Such circumstances are, however, hardly realized. Therefore, $-\Delta G_{dehyd}$ from K_H can be taken as an upper limit of the hydrophobic contribution.

Interpretation of Formation Constants. We try to interpret the magnitude of K_1 and K_2 determined for each host-guest combination by an inclusion (or asso-

The direction from which the host includes the guest and the extent to which the guest penetrates the host are indicated by an arrow and a dotted line, respectively. The numbers, 1 and 2, in the circle refer to the binding sites corresponding to K_1 and K_2, respectively.

ciation) model and by taking into account the hydrophobicity of guest molecule. The following data in Å unit (1 Å=0.1 nm) are used for guests; bond length: 1.04 for C-C, 1.08 for C-H in benzene ring, 1.54 for C-C, 1.08 for C-H in alkyl group, van der Waals radius:[11] 1.0 for H, 1.7 for C. Concerned with CyDs, the following data in Å reported in the literature are used; the inner diameter of cavity:[12] 4.7—5.2 for α-CyD, 6.0—6.4 for β-CyD, 7.5—8.3 for γ-CyD (the smaller value is for the primary hydroxyl group side and the larger is for the secondary hydroxyl group side), the cavity depth:[13] 6.7 for α-CyD, ≈7 for β- and γ-CyD.

Typical inclusion models are depicted for benzene, toluene, and *p*-xylene in Figs. 7—9, and their simplified models are illustrated in Fig. 10. These models were made on the following assumptions. (A) A guest enters into CyD through wider secondary hydroxyl side. (B) Alkyl group is included in CyD cavity preferentially to benzene ring if the cavity entrance radius admits. This assumption is based on the fact that aliphatic series are more hydrophobic than aromatic hydrocarbons.[14] (C) When two hosts share a single guest and K_2 is larger or nearly equal to K_1, the cross-section of secondary hydroxyl group sides of two CyDs are situated in parallel to each other in a suitable distance to form hydrogen bond,[15] and when K_2 is smaller than K_1, the distance between two CyDs is too

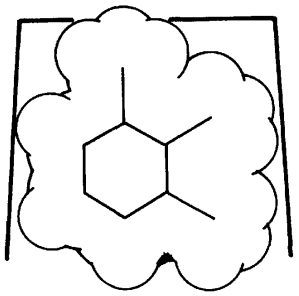

Fig. 11. 1,2,3-Trimethylbenzene-γ-CyD inclusion model.

short or too far to form hydrogen bonding or the axis along the cavity is not coincident with each CyD. (D) Guests come into contact with the wall of host as to increase contact area or to be included by host as deeply as possible. (E) The cavity size of β-CyD is a little small to include two adjacent methyl groups together. (F) The cavity size of γ-CyD is a little small to include adjacent three or alternate two methyl groups together.

For benzene and three straight-chain alkylbenzenes, $-\Delta G_{complex}$ increases almost linearly with $-\Delta G_{dehyd}$ for α-CyD (Fig. 4). The linear relationship is not so good for γ-CyD, but isopropylbenzene-γ-CyD showed a line in Fig. 6. For α-CyD, propylbenzene is far from the straight line as shown in Fig. 5, though the isomer falls on the line. These observations can be explained in terms of the host-guest spatial fitting. α-CyD accepts *n*-propyl group within the cavity, but is incapable of including bulky isopropyl group. Isopropyl group, on the other hand, can be accepted within cavities of β- and γ-CyD, which are large enough to accept the *n*-propyl group, but they are so shallow that only a part of benzene ring of propylbenzene is included; γ-CyD seems to exert less critical effect on isomeric propyl groups than does β-CyD because of its sufficiently large cavity size.

Among three trimethylbenzenes, 1,3,5-isomer exhibits an extremely low K_1 for β-CyD, while 1,2,3-isomer exhibits a large K_1 for γ-CyD. These observations can also be explained by the steric viewpoint. Two bulky methyl groups in 1,3,5-isomer hinder this guest from entering deeply into the cavity of β-CyD; *m*-xylene enters more deeply into β-CyD due to the lack of another methyl group in meta-position. For γ-CyD this steric hindrance of 1,3,5-isomer seems to operate to a less extent. The inclusion model illustrated in Fig. 11 may account for the extremely high *K* value observed for 1,2,3-isomer-γ-CyD; a large van der Waals stabilization works in this case.

The host-guest spatial fitting and the hydrophobicity of guest will be a useful guide to understand formation constants. There are, however, some host-guest combinations difficult to be interpreted. In view of hydrophobicity, *o*-xylene, 1,2,4- and 1,2,3-trimethylbenzene seem to exhibit large K_1 for three CyDs. For γ-CyD, favorable fitting may be responsible as mentioned above, but it is difficult to explain for α- and β-CyD on the same basis. β-CyD as well as α-CyD cannot include two adjacent methyl groups together, then both hosts will come into contact with these guests preferentially on the opposite site of methyl groups. Of the host-guest combinations studied in this work, two are most difficult to interpret. For α-CyD, *m*-xylene complex gave K_1 and K_2, whereas only K_1 was observed for 1,3,5-trimethylbenzene. For γ-CyD, K_1 of *p*-xylene was extraordinarily small.

Spatial fitting will contribute to van der Waals stabilization and hydrophobicity to driving force of complexation, but they don't give satisfactory explanation of the measured formation constants. Other possible energy factors, as Tabushi et al. have pointed out in their theoretical considerations,[10] and motional freedom of host, guest, and water molecules should be taken into account.

Topological Ligand Design. III. Parent Ligand Graphs, Simple Cage Graphs, and Donor-Atomic Graphs for the Octahedral Coordination

Susumu TAKAMOTO* and Chikako ENKAKU
Department of Chemistry, Faculty of Science, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171
(Received December 23, 1986)

Various computer processes to determine all parent ligand graphs, simple cage graphs, and donor-atomic graphs for the octahedral coordination are described in order to design new sexidentate ligands. A complex ligand graph is represented by a numeral comprising of 12 figures, each of which indicates the code of a unit graph of six kinds placed on 12 edges of an octahedron. Then, 1055 parent ligand graphs, excluding chiral isomers, are selected from 6^{12} permutations of the complex ligand graphs. A simple cage graph is produced by fusing a pair of adjacent lines around every point of an octahedral graph; 102 kinds of simple cage graphs, excluding chiral isomers, have been obtained. Another more practical method for ligand design has been proposed by starting from 62 donor-atomic graphs.

Recently, the enumeration and classification of various complicated compounds have been enormously developed by the use of a graph theory and computer processing. However, such applications involving ligand design remain very few.

A ligand molecule can be considered to be a set of donor atoms joined by some carbon chains capable of forming a medium-sized chelate ring. A graph-theoretical path corresponding to such a carbon chain is called a "chelate path". One of the authors has already published a designing method for ligands using a simple ligand graph, which is defined as a set of m points and n lines representing m donor-atoms and n chelate-paths, respectively. Then, all the simple ligand graphs with $m \leqq 8$ were systematically derived and clearly documented by a numeral code of eight figures.[1]

However, a simple ligand graph cannot distinguish a ligand structure which has chelate paths branched at their carbon atoms. Thus, some modifications have been applied to the ligand graphs in order to represent all the structures of general chelating ligands.[2] Also, a complex ligand graph has been preferably adopted, which is a set of main points and sub-points connected by lines (where main points, sub-points, and lines correspond to donor atoms, carbon atoms forming chelate ring, and chemical bonds among these atoms, respectively). When a metal chelate ring is limited to five or six members, including a metal ion, each chelate path consists of two or three sub-points and three or four lines. Since no more than three chelate rings can branch at a donor atom or at a carbon atom, the maximum degree of a main point and a sub-point is three (the degree of a point is the number of lines incident on it).

Complex ligand graphs can faithfully express their original ligand structures, but they are so complicated that their systematic derivation and complete enumeration are quite difficult. In order to design all the chelate ligands for a given coordination structure, a "parent ligand graph" was defined.[2] This is a complex ligand graph to which no more sub-points nor lines can be added, i.e., highest density graphs in such coordination. Several kinds of parent ligand graphs may exist for a certain coordination structure. Then, all the other complex ligand graphs can be derived by neglecting some sub-points or by removing some lines from these parent ligand graphs.

Hence, finding all of the parent ligand graphs is a step in designing complex ligand graphs. Although the parent ligand graphs for the square planar and the tetrahedral coordinations have already been published,[2] it is difficult to obtain parent graphs for octahedral coordination by similar procedures, since four edges are incident on each vertex of an octahedron, whereas the degree of a main point cannot exceed three. Thus, the degree of each main point has to be reduced by a partial fusing of some adjacent graphs. Besides, an increasing number of donor atoms causes a much accelerated increase in the number of parent ligand graphs. But whatever difficulty may arise, designing sexidentate ligands should be achieved, since the octahedral coordination is one of the most popular and important structures in complex chemistry.

Methods

(1) Parent Ligand Graphs. Unit Graphs: In order to determine all of the parent ligand graphs for octahedral coordination, "unit graphs" of six kinds are defined. These unit graphs with direction and their own codes are shown in Fig. 1. Unconnected unit graph (0), and any unit graphs containing less than five-membered ring are omitted hereafter.

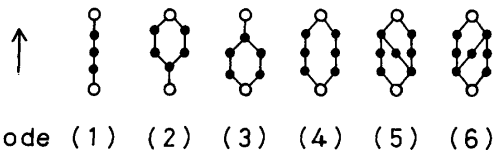

Fig. 1. Unit graphs for the parent ligand graph.

Since these unit graphs are introduced for composing the parent ligand graphs, each chelate path in these unit graphs contains three sub-points. Unit graphs (2) and (3) have directions opposite to each other. Unit graphs (5) and (6) cause an antipode relation when placed on a solid surface. The order of the unit graphs in chelate-path density is (5), (6)>(4), (3), (2)>(1).

Then, a "composite graph" is assembled by placing one of above unit graphs on every line of a donor-atomic graph with common main point each other. (A donor-atomic graph is a set of main points and lines, each of which connects a pair of main points having at least one chelate path.[2]) Next a complex ligand graph is generated when these unit graphs in a composite graph are partially fused around every vertex. As a simplified example using a terdentate ligand, a derivation of these graphs is shown in Fig. 2.

When an octahedral graph is adopted as a starting donor-atomic graph, all the complex ligand graphs derived from it have a complete cage structure, where every pair of adjacent main points is connected; they must include all the parent ligand graphs of the octahedral coordination.

In this case the fusing manner of unit graphs is uniquely definable so that the ligand molecules may have its most strainless cage structure; hence, these complex ligand graphs have one-to-one correspondence with their composite graphs. Then, the design of the complex ligand graphs may be substituted for assembling of the composite graphs.

A parent ligand graph should have the highest density as to the chelate paths; that is, it should be assembled from unit graphs of higher order as possible. Although unit graphs (5) and (6) have the highest order as to the chelate paths (both of them are parent ligand graphs of the bidentate ligand), when four such unit graphs are incident on a vertex of an octahedron, the degree of the central main point exceeds three even if they are effectively fused. Therefore, some unit graphs of the lower order are still necessary as the constituents of the parent ligand graph.

Fusing Restrictions: There are some restrictions in partially fusing the unit graphs arround a main point, subjected to the limitation of the degree of main points and sub-points, and to the steric requirements which may be confirmed by use of molecular models.

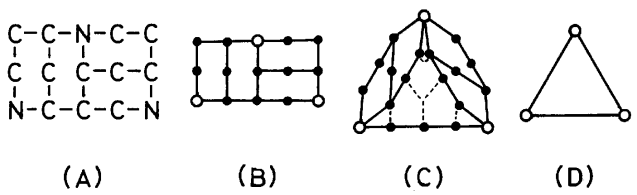

Fig. 2. Graph representations of a ligand. (A) Ligand, (B) complex ligand graph, (C) composite graph (Dotted lines indicate fusing sites.), (D) donor-atomic graph.

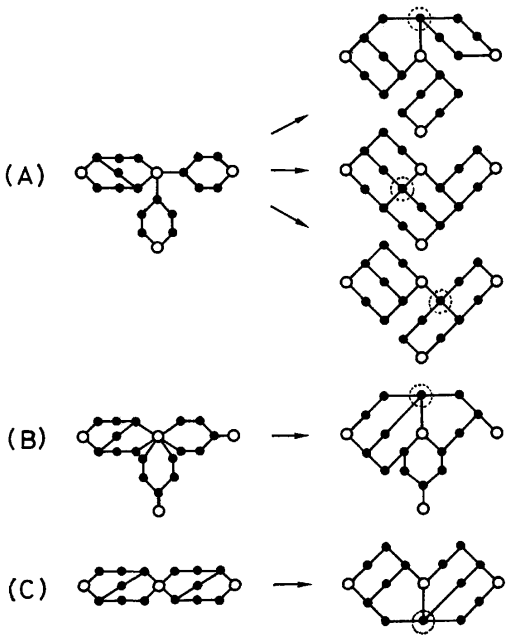

Fig. 3. Examples of impossible fusions. (A) (2)(2)(6), (B) (3)(3)(5), (C) trans (5)(5) (each dotted circle indicates over degree of a vertex.).

The following fusions of unit graphs arround a main point (a vertex on an octahedron) are impossible, and some examples are shown in Fig. 3.

(i) Two unit graphs (5) and (5), or (6) and (6) in trans position.

(ii) Two unit graphs (5) and (6), or (6) and (5) in cis position.

(iii) Following arrangements of three unit graphs in clockwise order: (6)(6)(4), (6)(6)(3), (6)(4)(4), (6)(4)(3), (6)(3)(4), (6)(3)(3), (4)(5)(5), (3)(5)(5), (4)(4)(5), (4)(3)(5), (3)(4)(5), (3)(3)(5), (6)(4)(5), (6)(3)(5), (5)(2)(6), (2)(6)(6), (2)(6)(4), (2)(6)(3), (5)(5)(2), (4)(5)(2), and (3)(5)(2).

(iv) Four unit graphs (2).

(v) Four unit graphs other than (1) or (2).

We should thus determine all the composite graphs in which any arrangement of unit graphs does not offend against above fusing restrictions.

Canonical Name: If unit graphs of six kinds are simply placed on 12 edges of an octahedron, there exist 6^{12} (=2,176,782,848) permutations, including some duplications in each structure. Hence, it is necessary to define a "canonical name" which is the unique expression of a composite ligand graph (and also of a complex ligand graph) corresponding to a structure in one to one.

Labeling of Vertices and Edges of an Octahedron: Six vertices on an octahedron are labeled along one of the Hamiltonian paths, and twelve directed edges are labeled along one of Eulerian trails (like a picture drawn with a single stroke) in the graph theory as shown in Fig. 4. Hereafter, these labels of vertices and directed edges are represented by①,②,③, ····,⑥, and

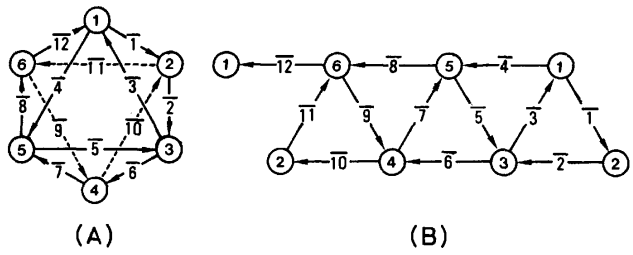

Fig. 4. Labeling of vertices and edges on an octahedron. (A) Perspective view, (B) developed diagram.

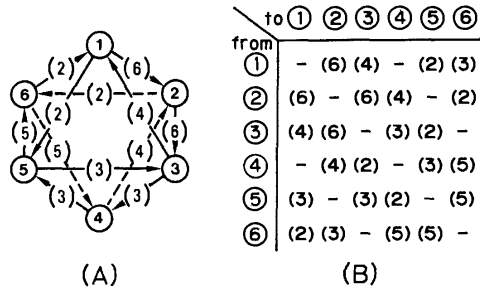

Fig. 5. An example of the composite graph. (A) Octahedral structure composing of 12 unit graphs, (B) its connection matrix.

$\overline{1}, \overline{2}, \overline{3}, \cdots, \overline{12}$ respectively, as well as (1), (2), (3), ····, (6) indicate codes of unit graphs.

Then a composite graph, as well as its complex ligand graph can be described by a numeral of 12 figures, each of which represents the code of a unit graph placed on every edge and lined up in the above-defined order. However, there exist 24 (=6×4) line-up ways of 12 edges in each octahedral structure, since such an Eulerian trail may start from any one of six vertices, and may take any one of four initial directions. The canonical name is defined as the maximum numerical in these 24 numerical names, thus the duplication of the same structure can be avoided.

For example, a composite graph for which the structure is shown in Fig. 5 can be expressed by 24 ways of numerical name given in Table 1. Then, their maximum numeral is 664 233 355 422, which becomes the canonical name of this graph.

The computer selects the possible arrangements of unit graphs from 6^{12} permutations under the abovementioned fusing restrictions, and finds their canonical names.

Parent Ligand Graph: If a complex ligand graph becomes a parent ligand graph, it must contain neither a unit graph (2), (3), nor (4) on any edge which can be replaced with another unit graph of higher order (5) or (6) subjecting to the fusing restrictions; similarly, it must contain no unit graph (1) replaceable with (2), (3), (4), (5), or (6). The computer examines all such rearrangements of unit graphs in each structure, and if every replacement causes offense against the fusing

Table 1. 24 Expressions of a Composite Graph in Fig. 5

Start	Name	Start	Name
①→②	664 233 355 422	④→⑤	333 464 622 255
①→③	423 352 534 266	④→③	264 536 353 422
①→⑤	252 625 463 334	④→②	425 352 234 663
①→⑥	336 464 222 553	④→⑥	552 223 466 334
②→③	646 222 553 334	⑤→⑥	522 346 634 253
②→①	633 455 222 346	⑤→①	342 226 453 635
②→⑥	254 633 342 526	⑤→③	333 554 226 642
②→④	425 642 335 253	⑤→④	255 333 646 422
③→④	333 425 262 546	⑥→①	225 533 346 462
③→⑤	234 663 345 522	⑥→⑤	525 342 664 233
③→①	466 342 535 223	⑥→④	542 266 423 335
③→②	642 225 533 364	⑥→②	363 534 222 645

restrictions, then the original structure can become a parent ligand graph. For example, in a structure named 664 214 553 222, if the unit graph (3) (the nineth figure) is replaced with (5), the resulting structure named 664 214 555 222 is allowed for the fusing around every vertex, then that the original structure is not a parent ligand graph. Also, the computer showed that no other unit graph in the latter structure can be replaced with any unit graph of higher order without breaking fusing restrictions; thus, the latter graph 664 214 555 222 is proved to be a parent ligand graph.

Chiral Isomers: In oreder to search the chiral-isomer couples in the parent ligand graphs, the mirror-image graphs of a given graph should be generated. Since an octahedron is reflected by a mirror (as shown in Fig. 6(A)), the correspondences of each vertex and edge between original and mirror-image graphs would be obvious.

Vertices ①, ②, ③, ④, ⑤, and ⑥, are converted into ①, ⑥, ⑤, ④, ③, and ②, respectively; also edges $\overline{1}$, $\overline{2}$, $\overline{3}$, $\overline{4}$, $\overline{5}$, $\overline{6}$, $\overline{7}$, $\overline{8}$, $\overline{9}$, $\overline{10}$, $\overline{11}$, and $\overline{12}$ are converted into $\overline{12}$, $\overline{8}$, $\overline{4}$ $\overline{3}$, $\overline{5}$, $\overline{7}$, $\overline{6}$, $\overline{2}$, $\overline{10}$, $\overline{9}$, $\overline{11}$, and $\overline{1}$, respectively, by a mirror-image transformation. As this transformation inverts also the chirality and direction of the unit graph, the unit graphs (5) and (6), as well as (2) and (3) should be converted each other.

For example, in Fig. 6(B), the graph 664 233 355 422 is transformed into its mirror-image graph 363 422 254 635; however, this representation is not its canonical name. Then the computer produces 24 kinds of numeral espressions for this structure, and finds the maximum numeral in them. Thus, 663 334 545 222 is obtained as the canonical name of the chiral isomer for the original graph.

If the canonical name of the mirror image is identical with that of the original graph, e.g. the graph named 643 541 624 522, it has no chiral isomer; in other words, its structure is achiral.

(2) Simple Cage Graph. A simple cage graph is a

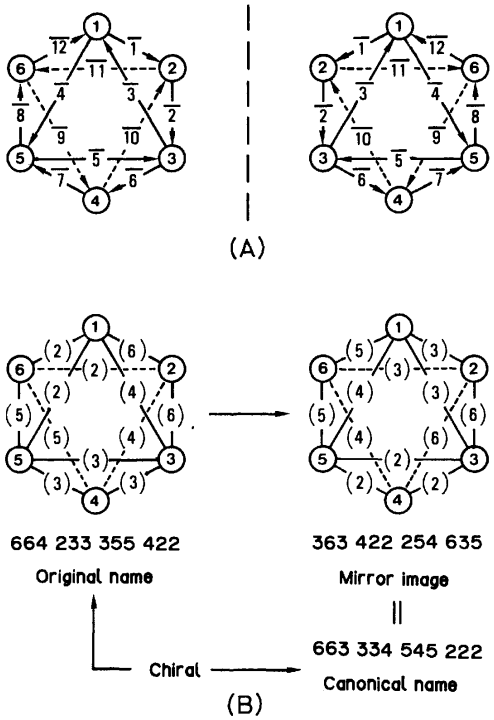

Fig. 6. An example of chiral couples. (A) Mirror reflection, (B) mirror-image transformation.

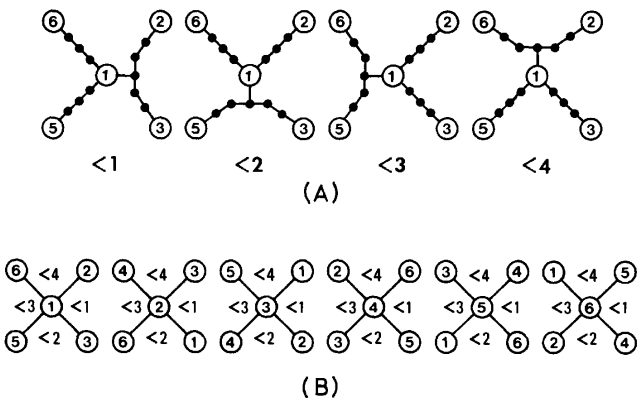

Fig. 7. Labeling of the fusing sites in the simple cage graph. (A) Four sites of fusing around the vertex 1, (B) fusing sites around each vertex.

complex ligand graph where every pair of adjacent main points is joined by only one chelate path. Accordingly, both its donor-atomic graph and its composite graph are an octahedron. Since the degree of every vertex on an octahedron is four, one adjacent pair of unit graphs (1) around every vertex must be partially fused so that the degree of each main point may become three. As there are four adjacent pairs of four edges at each of six vertices, the permutations of fusing ways come to 4^6=4096 kinds including symmetrical duplications.

Labeling of the sites, where each adjacent pair of unit graphs (1) is partially fused around every vertex, are defined as Fig. 7.

Then, a simple cage graph is expressed by a numeral consisting of six figures, each of which represents the label of fusing site around each of six vertices which are lined up in the previous order. Also, in this case 24 expressions are possible in a given structure; thus, a canonical name may be defined as the minimum numeral in these expressions. An example is shown in Fig. 8. The chiral isomers are found by the same method in the parent ligand graphs.

(3) Direct Designing of Complex Ligand Graphs. Simpler complex ligand graphs may be produced directly from some donor-atomic graphs not having complete-cage structure through neither the parent ligand graph nor the simple cage graph. When unit graphs in Fig. 9 are placed on every line of a certain donor-atomic graph in Fig. 10, a composite graph is directly generated.

Directed or chiral isomers of unit graphs are neglected in Fig. 9 for symplifying. Geometrical (or configurational) isomers of donor-atomic graphs are also omitted in Fig. 10. Then several complex ligand graphs are designed by proper fusing around main points under similar restrictions. In this case fusing is not alwalys necessary unless the degree of a main point exceeds three; thus, one-to-one correspondence is lost between a composite graph and its complex ligand graph.

These donor-atomic graphs in Fig. 10 are partial graphs of an octahedral graph, and can be systematically derived from it by removing some lines. Then each of them consists of six points and n lines ($5 \leqq n < 12$), and maximum degree of its points is four. Naturally, a pair of points in trans position of an octahedron is never connected.

The above calcurations are performed by use of a HP9831A Desktop Computer (Hewlett & Packard Co.) and a PC9801F2 Personal Computer (Nippon Electric Co.).

Results and Discussion

It was already discussed[2] that the complex ligand

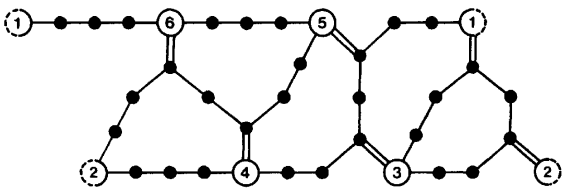

Fig. 8. An example of the simple cage graph.

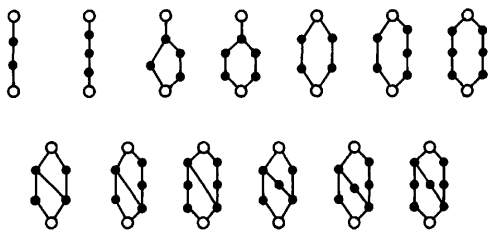

Fig. 9. General unit graphs.

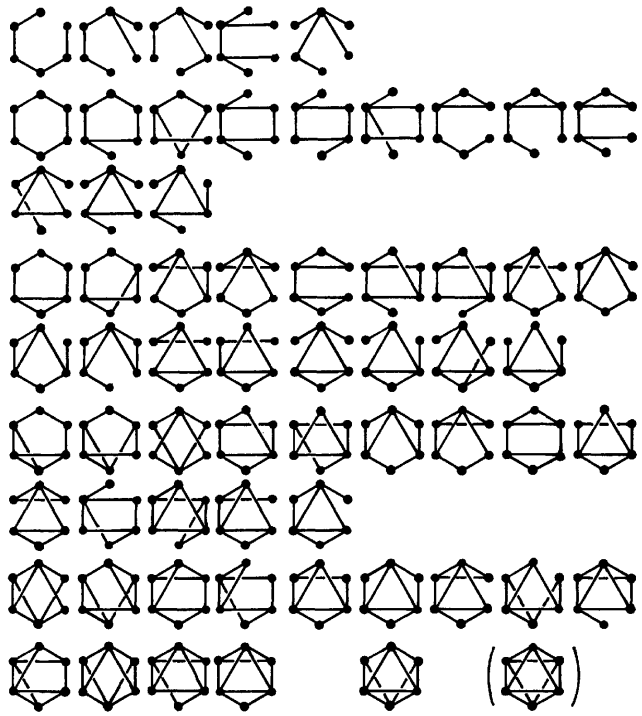

Fig. 10. Donor-atomic graphs for the octahedral coordination.

graph is the best mean for the expression of a ligand structure. The complex graph which has main points and sub-points would be very useful especially in designing of hetero-atomic compounds. The complex ligand graph can be "uniquely" decomposed into several unit graphs, and reversely assembled from them. These procedures may be also available in complicated chemical designs. In this case "uniquely" is important, because any complicated graph should have definable components as if a chemical compound consists of definite atoms. The concept of "fusing" is extensively applicable not only to the graph but also to other geometrical figures in various designings, e.g. a naphthalene frame is formed by fusing of two benzene rings.

Simple numerical expressions of molecular structures are necessary for computer processing. Since an arrangement of six kinds of unit graphs can fully express intricate ligand structures, including optical isomers, the above procedures can be extended to determine the parent ligand graphs for any other coordinations.

Computer calculations show that as many as 1055 kinds of parent ligand graphs for the octahedral coordination may exist even if chiral isomers are excluded, whereas the number of parent ligand graphs for the tetrahedral structure is only nine. They would be too many and too complicate for the application to ligand design. Although more severe restriction to the local fusing of unit graphs around a main point would be difficult, some sifting out may be possible with the totally steric hindrance as to the whole structure of a graph. Neverthless, a drastic reduction of their number would be hopeless, even upon applying such modifications. Moreover, the ligands which will be synthesized in near future will not have such complicated networks as the parent ligand graphs.

The simple cage graphs are the least complete cage-graph, where every pair of adjacent main points is connected, and they are much simpler and much fewer than the parent ligand graphs for the octahedral coordination. Computer calculations have proved that 90 chiral couples and 12 achiral graphs exist in these simple cage graphs. Therefore, they may be preferably adopted as the new starting points of the ligand design instead of parent ligand graphs, and many complex ligand graphs can be introduced by adding or omitting some sub-points and/or lines on them. Especially, this method would be well suited for designing ligands with cage or nearly cage structures.

Method (3) is most useful and most hopeful for the practical designing of ligands. When one or more donor-atomic graphs are selected from Fig. 10 for a certain purpose, some series of related structures can be systematically derived by diverse combinations of unit graphs. Since almost known ligands have topologically simple structure, various new ligands of quite different from old ones would be easily created. As the geometrical structure of a ligand largely effects on the properties and the reactions of the metal chelates, such design would extensively contribute to the development of the coordination chemistry. The applications of these ligand graphs to the designing of new ligands have already been discussed in previous papers.[1-3]

The donor-atomic graph is regarded as a back-bone of a ligand, then all ligands can be classified by their donor-atomic graphs. As this graph is one of the most simplified expression of a ligand, it is available for an easy determination of several geometrical (or configurational) isomers of a metal chelate with a complicated ligand. The donor-atomic graph resembles the simple ligand graph[1] in the graph shape. The only difference is that the degree of each point in the simple ligand graph cannot exceed three. Therefore, the donor-atomic graphs completely include the simple ligand graphs. Although the configurational isomers of donor-atomic graphs are omitted here, most of them were shown as those of the simple ligand graphs in a previous paper.[1]

Stereoselective Synthesis of Anomers of 5-Substituted 2′-Deoxyuridines

Hajime Aoyama
Research Laboratories, Toyama Chemical Co., Ltd., Shimookui, Toyama 930
(Received July 17, 1986)

The substitution reaction of 5-substituted 2,4-bis(trimethylsilyloxy)pyrimidines with 3,5-bis(*O*-*p*-chlorobenzoyl)-2-deoxy-α-D-ribofuranosyl chloride was investigated. In the presence of *p*-nitrophenol, β anomers were formed stereoselectively, whereas the addition of organic bases brought forth stereoselective formation of α anomers. Stereoselectivity of the reaction depends on the substituents at 5-position of disilylpyrimidines, additives, and the concentration of each reagent. The α and β anomers of 5-substituted 2′-deoxy-uridines were synthesized through the deacylation of α and β anomers of 5-substituted 3′,5′-di-*O*-(*p*-chlorobenzoyl)-2′-deoxyuridines.

It is well-known that 5-substituted 2′-deoxy-β-uridines (**6a—f**) have useful physiological activity for antitumor[1,2] and anti-viral[3-5] drugs. Usually, only β anomers show the physiological activity. Many investigations have been carried out to synthesize β anomers under different conditions by the Hilbert-Johnson reaction, such as reactions of sugar halide with mercury salt of uracils,[6-8] 2,4-dimethoxypyrimidines,[9-14] silylpyrimidines by fusion,[15,16] and silylpyrimidines in the presence of $SnCl_4$.[17] But up to date, no general and efficient methods have been reported for the stereoselective synthesis of 2′-deoxyuridines.

We reported recently that the reaction of 5-fluoro-2,4-bis(trimethylsilyloxy)pyrimidine (**1c**) with 3,5-bis(*O*-*p*-chlorobenzoyl)-2-deoxy-α-D-ribofuranosyl chloride (**2**) in the presence of Brönsted acids selectively gives 3′,5′-di-*O*-(*p*-chlorobenzoyl)-5-fluoro-2′-deoxy-β-uridine (**4c**).[18] Further studies on stereoselectivity of the reaction of **1c** with **2** suggested that the addition of a base such as pyridine changed the stereoselectivity of the reaction from β- to α-selectivity in proportional degrees to the concentration of the base.

This paper describes the stereoselective synthetic method of both the α and β anomers of 5-substituted 2′-deoxyuridines (**5a—f** and **6a—f**) based on the following observation. 1) In the presence of *p*-nitrophenol, **1a—f** reacts with **2** to give β anomers stereoselectively in high yields. 2) Combined use of *p*-nitrophenol and pyridine as catalyst changes β-stereoselective reaction of **1c** with **2** to an α-stereoselective reaction. 3) In the presence of other organic bases or their salts, reaction of **1c** with **2** also gives an α anomer (**3c**) stereoselectively. 4) Similarly to the reactin of **1c**, 5-substituted 2,4-bis(trimetylsilyloxy)-pyrimidines reacts with **2** in the presence of pyridine to give α anomers in high yields.

Results

Identification of Anomers of 2′-Deoxyuridine Derivatives. Rapid identification of the anomers of 2′-deoxyuridine derivatives in the reaction mixture was carried out by mean of ^{1}H NMR spectroscopy and chromatography. The properties of 5-substituted 3′,5′-di-*O*-(*p*-chlorobenzoyl)-2′-deoxyuridines are summarized in Table 1. The anomeric protons of all β anomers **4a—f** were observed as triplet at δ 6.15—6.40, whereas those of α anomers **3a—f** were multiplet.

a) N-NaOD.

Thin-layer chromatograph using a precoated silica-gel plate (Art 5715, $60F_{254}$) and a mixted solvent of hexane, benzene, and ethyl acetate (1 : 1 : 2) as well as HPLC were successfully used for separating α and β anomers (**3a—f** and **4a—f**).

The properties of 5-substituted 2′-deoxyuridines are shown in Table 2. ^{1}H NMR spectra of the anomeric protons show triplet about δ 6.03—6.28 for all β anomers, and double doublet or multiplet for α anomers. ^{1}H NMR spectra of H_6 of pyrimidine ring show doublet or singlet peaks and those of β anomers appear at higher magnetic fields in comparison with those of α anomers. The α and β anomers (**5a—f and 6a—f**) were identified by thin-layer chromatogrph using a precoated silica-gel plate (HPTLC, Art 5628, $60F_{254}$) with a mixed solvent of ethyl acetate, formic acid, and water (65 : 5 : 5).

Reaction of 1a—f with 2 in the Presence of *p*-Nitrophenol. Pyrimidine derivatives **1a—f** reacted with **2** in the presence of *p*-nitrophenol to give β anomers **4a—f** in high yields. Among Brönsted acids used, *p*-nitrophenol gave β anomer most efficiently in the reaction of **1c** with **2**.[18] The results are shown in Table 3. The β-stereoselectivity was affected by a substituent in 5-position of silylpyrimidine; electron-releasing substituents seem to give more β anomer.

Reaction of 1c with 2 in the Presence of Base and *p*-Nitrophenol. During investigation of the reaction of **1c** with **2** it was happened that β anomer **4c** is not formed, but formed α anomer **3c** when **1c** and/or **2** containing a trace of trietylamine hydrochloride[20] and/or pyridine were used. This result made the author to examine the effect of base on the stereoselectivity.

First, the effect of concentration of pyridine on the

stereoselectivity was investigated. The results are shown in Fig. 2. In the presence of a trace of pyridine, β-stereoselective reaction changed to α-stereoselective reaction in proportion to the concentration of pyridine.

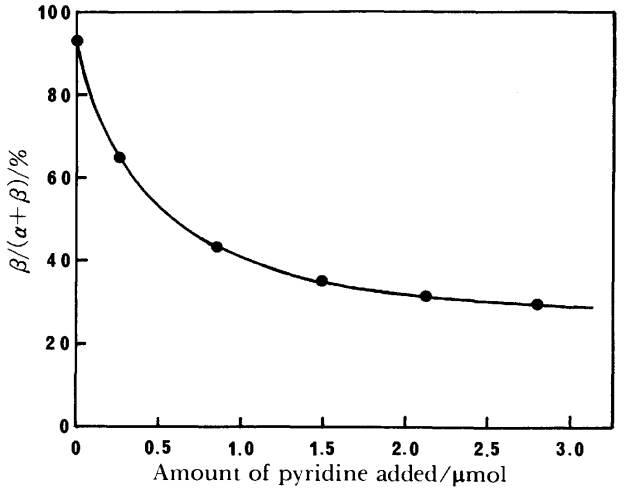

Fig. 2. The effect of the concentration of pyridine on the stereoselectivity of the reaction **1c** with **2**. Reaction conditions; **1c**: 0.197 g (0.768 mmol), **2**: 0.300 g (0.698 mmol), *p*-nitrophenol: 0.034 g (0.244 mmol), chloroform: 2.1 cm³, reaction temp: 25 °C, reaction time: 12 h.

Table 4. Effect of Additives on the Formation of **3c**[a)]

Run	Additive	Amount[b)]	Yield/%[c)]
1	Pyridine	0.1	77.8
2	α-Picoline	0.1	76.5

Table 5. α-Selective Synthesis of 5-Substituted 3′,5′-Di-*O*-(*p*-chlorobenzoyl)-2′-deoxy-α-uridines

Run	Substituent group	Yield/%[a)]	
		α Anomer	β Anomer
1	H	74.8	21.1
2	CH_3	67.4	32.5
3	F	79.3	14.6
4	Cl	77.3	10.4
5	Br	77.0	21.0
6	I	81.5	15.4

a) Yields refer to isolated products.

Second, the effect of additives such as organic bases or triethylamine hydrochloride in the reaction of **1c** with **2** on the stereoselectivity was investigated. The results are shown in Table 4. Pyridine showed higher α-stereo-selectivity than lutidine. This seems to be due to steric hindrance of methyl radicals of 2,6-lutidine to sugar halide. On the other hand, triethylamine hydrochloride showed considerable α-stereoselectivity, but *N*,*N*-dimethylformamide and acetamide showed no stereoselectivity.

α-Stereoselective Synthesis. The effect of substituents at 5-position of silylpyrimidine on α-stereoselective reactions of **1a—f** with **2** was investigated and α anomers **3a—f** were synthesized. In the presence of pyridine, **1a—f** reacted with **2** α-stereoselectively to give **3a—f** in high yields. The results are shown in Table 5.

The α-stereoselectivity was affected by the substituents at 5-position of silylpyrimidine and halogen substituents showed higher selectivity than methyl group. It is, therefore, considered that electron-attracting substituents cause higher α-stereoselectivity than electron-releasing substituents.

Deprotection by the treatment of ammonia-methanol solution to **3a—f** or **4a—f** smoothly gave **5a—f** or **6a—f**, respectively, in high yields.

Discussion

On the substitution reactions of **1a—f** with **2**, it became apparent that the stereoselectivity varies with

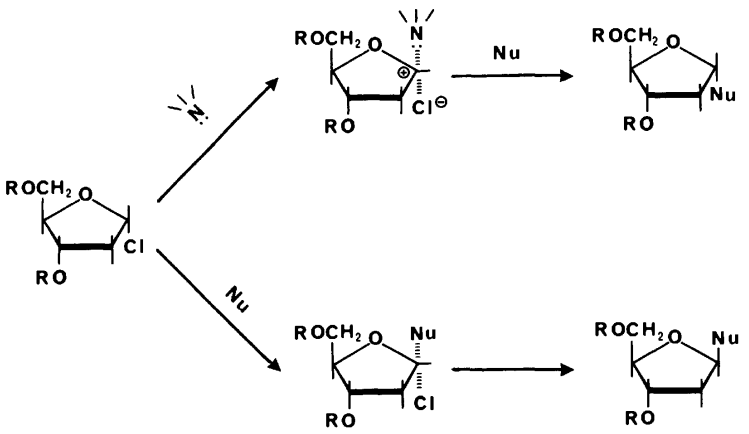

Fig. 3.

the substituent group of 5-position of silylpyrimidine, the additives, and concentration of additives.

It is improbable that both the α and β nucleosides are stereoselectively formed in the substituting reaction, by the Hilbert-Johnson reaction through nucleophilic attack of a sugar cation on aromatic pyrimidine ring.[13] In the preceding work,[18] it was proposed that β-stereoselective reaction occurs between silylpyrimidine as nucleophilic reagent and the β-face of sugar halide which is pure α anomer, in the presence of Brönsted acid.

On the other hand, the presence of organic base or its salt turned β-stereoselective substitution reaction into α-stereoselective reaction.

α-Stereoselectivity. The α-stereoselective reaction mechanism can be depicted in Fig. 3. While nucleophilic reagent attacks the β-face of sugar halide, a base attacks the nucleophilic reagent competitively. If the base has higher active in nucleophilicity than the nucleophilic reagent, the base coordinates with the β-face of sugar halide predominantly. Then the nucleophilic reagent cannot attack the β-face of sugar halide but attacks the α-face to produce an α-nucleoside. Thus, nucleophilicity of reagent seems to contribute to the stereoselectivity in substitution reaction.

Experimental

Apparatus. All the melting points measured were not corrected. IR spectra were recorded by a Hitachi 260—30 infrared spectrophotometer using KBr disk method. ^{1}H NMR spectra were obtained by a Hitachi Perkin-Elmer P-24 (60 MHz) using TMS as the internal standard. The specific rotation was measured by a JASCO DIP-181 digital polarimeter. The spectrophotometric measurement of TLC spots was done on a Shimadzu High-Speed TLC Scanner CS-920. High-performance liquid chromatography was experimented by a Shimadzu LC-3A equipped with a Shimadzu variable length spectrophotometric detector SPD-2A and a Shimadzu Chromatopac C-RIA.

Analysis by Thin-Layer Chromatography. The anomeric ratio of nucleoside was monitored during the reaction by thin-layer chromatography. Anomers were separated on the plates precoated with silica-gel $60F_{254}$ (Merck, Art 5715) with a mixed solvent of hexane, benzene, and ethyl acetate (1 : 1 : 2). R_f values of anomers **3a—f** and **4a—f**, are shown in Table 1. Measurements were run according to the preceding work[18] by using of high-speed TLC scanner.

Anomers **5a—f** and **6a—f**, were separated the plates precoated with silica-gel $60F_{254}$ (HPTLC, Merck, Art 5628) a mixed solvent of ethyl acetate, formic acid, and water (65 : 5 : 5). R_f values of the anomers are shown in Table 2.

Analysis by High-Performance Liquid Chromatography. A column (25 cm×4 mm i.d.) was packed with RP-18 chemically bonded silica-gel (LiChrosorb, 10 μm, Merck). The mobil phase was a 45 : 55 mixture of 0.03 mol dm^{-3} ammonium dihydrogenphosphate solution and acetonitrile, which was made to 1 cm^3 min^{-1} and 25 °C. The retention time values of each compound of **3a—f** and **4a—f** are shown in Table 1.

Materials. Chloroform were refluxed for 2 h over P_2O_5 and distilled. Uracil, thymine, and 5-fluorouracil purchased were used without further purification. 5-Chlorouracil, 5-bromouracil, and 5-iodouracil were prepared by the reaction of uracil with the corresponding *N*-halosuccinimide[19] in acetic acid. 3,5-Bis(*O*-*p*-chlorobenzoyl)-2-deoxy-α-D-ribofuranosyl chloride (**2**) was prepared as described in the preceding report.[18]

Table 6. Boiling Point of 5-Substituted 2,4-Bis-(trimethylsilyloxy)pyrimidines

Compound		Bp/θ_b/°C/mmHg†
No.	Substituent group	
1a	H	113—114/16
1b	CH_3	124—131/16
1c	F	110—111/15
1d	Cl	130—131/16
1e	Br	138—139/16
1f	I	124—132/4

5-Substituted 2,4-Bis(trimethylsilyloxy)pyrimidines (1a—f). These compounds were all prepared in an analogous manner.[18] A mixture of appropriate uracil (1 mol), hexamethyldisilazane (260 cm^3, 1.25 mol), and trimethylsilyl chloride (1 cm^3, 7.8 mmol) was refluxed in dry atomosphere. Ammonia gas vigorously evolved. The excess of hexamethyldisilazane was removed after 2 h of the reaction under 50 mmHg† and finally 12 mmHg at 90 °C. The residue was distilled in vacuo to give **1a—f**. The boiling point values are shown in Table 6.

Synthesis of β Anomers (4a—f). To a mixture of **1a—f** (17.9 mmol), *p*-nitrophenol (0.8 g, 5.77 mmol) in dry chloroform (49 cm^3), was added **2** (7 g, 16.3 mmol) and stirred for 12 h at 30 °C. The reaction mixture was then evaporated under a reduced pressure to give crystalline residue, which was recrystallized from acetic acid to give β anomers. From mother liquor, anomers were isolated by fractional crystallization. Results are shown in Table 3.

Effect of Pyridine on the Reaction of 1c with 2. To a mixture of **1c** (0.197 g, 0.768 mmol), *p*-nitrophenol (0.034 g, 0.244 mmol), and pyridine in chloroform (2.1 cm^3), was added **2** (0.300 g, 0.698 mmol) and stirred for 12 h at 25 °C. The ratio of each anomer was analyzed by TLC scanner. The result is shown in Fig. 2.

Effect of Additives on the Formation of 3c. To a mixture of **1c** (0.302 g, 1.1 mmol), *p*-nitrophenol (0.049 g, 0.35 mmol), and additives in chloroform (3.0 cm^3), was added **2** (0.430 g, 1.0 mmol) and stirred for 12 h at 25 °C. The ratio of each anomer was analyzed by HPLC. The results are shown in Table 4.

Synthesis of α Anomers (3a—f). To a mixture of **1a—f** (17.9 mmol), *p*-nitrophenol (0.8 g, 5.77 mmol), and pyridine (0.4 g, 5.05 mmol) in dry chloroform (49 cm^3), was added **2** (7 g, 16.3 mmol) and stirred for 12 h at 30. The reaction mixture was then evaporated under a reduced pressure to give an oily residue, which was subjected to crystallization with ethanol to give α anomers. The anomers were isolated from mother solutions by fractional crystallization. The results are shown in Table 5.

5-Substituted 2′-Deoxyuridines (5a—f, 6a—f). To a saturated ammonia-methanol solution (20 cm^3), was added 1 g of each anomer **3a—f** and **4a—f**, and stirred for 16 h at 30 °C. The reaction mixture was then treated similarly to the

† 1 mmHg=133.3 Pa.

manner as described in preceding report.[18] The 2′-deoxyuridine derivatives were isolated in 90—99% yield, of which physical properties are shown in Table 2.

Synthesis on 1,4-Diaminocyclitol Antibiotics. IV. Synthesis of 7′-Phenylfortimicin A and 7′-Phenyl-6′-epifortimicin A

Kazuaki KANAI, Seiichiro OGAWA,* and Tetsuo SUAMI†
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Yokohama 223
(Received September 18, 1986)

7′-Phenylfortimicin A and 7′-phenyl-6′-epifortimicin A have been synthesized by condensation of newly prepared 1-*O*-acetyl-2,6-bis(2,4-dinitrophenylamino)-2,3,4,6,7-pentadeoxy-7-phenyl-L-*lyxo*-heptopyranose and -D-*ribo*-heptopyranose, respectively, with 2,5-di-*O*-benzoyl-1,4-bis[*N*-(methoxycarbonyl)]fortamine B, followed by deprotection.

In the preceding paper,[1] the chemical synthesis of 7′-propylfortimicin A and its antibacterial assay were reported. In continuation of our study on modification of the diamino sugar moiety of antibiotic fortimicins,[1,2] replacement of the 6′-methyl group with benzyl group would be of interest because of anticipated enhancement both in its lipohilic nature and in the steric congestion. We now describe the synthesis and biological activities of 7′-phenylfortimicin A and 7′-phenyl-6′-epifortimicin A.

Results and Discussion

1-*O*-Acetyl-2,6-bis(2,4-dinitrophenylamino)-2,3,4,6,7-pentadeoxy-7-phenyl-L-*lyxo*-heptopyranose (**7**) and -D-*ribo*-heptopyranose (**8**) have been first prepared from methyl 2-acetamido-2,3,4,6-tetradeoxy-6-nitro-α-*erythro*-hexopyranoside (**1**).[1]

The nitro aldol reaction of **1** with benzaldehyde was effected in the presence of methanolic sodium methoxide in methanol for 2 h at 0 °C. The products were acetylated with acetic anhydride and boron trifluoride etherate, and then hydrogenated with sodium borohydride in dimethyl sulfoxide to give an inseparable mixture of methyl 2-acetamido-2,3,4,6,7-pentadeoxy-6-nitro-7-phenyl-β-L-*lyxo*- and -α-D-*ribo*-heptopyranoside (**2**) in 54% yield. The reaction using KF or CsF in acetonitrile instead of sodium methoxide resulted in a poor yield. However, when excess KF was used, **2** was obtained in 38% yield. Catalytic hydrogenation of **2** with Raney nickel in a mixture of ethanol and ethyl acetate, followed by *N*-acetylation with acetic anhydride, gave two compounds (**3**, 47% and **4**, 15%) after chromatography. The value of specific rotation +129° of **4** was more dextrorotatory than +28.2° of **3**. In addition, the ^{13}C NMR spectra of **3** and **4** revealed that C-7 signal of **4** shifted upfield by 1.83 ppm compared to that of **3** (Table 1). These results corresponded to those of the respective 7-propyl derivatives. The stereochemistry at C-6[3] of **3** and **4** has thus been confirmed as depicted in Scheme.

Compound **3** was *N*-deacetylated with sodium hydroxide in refluxing 95% aqueous 2-methoxyethanol and the free base was converted to the bis[*N*-(2,4-dinitrophenyl)] derivative **5** in 81% yield. Hydrolysis of **5** with acetic acid containing 2M†† hydrochloric acid, followed by acetylation, gave the acetate (**7**) in 61% yield.

a) In parts per million downfield from TMS.

Condensation of **7** with 2,5-di-*O*-benzoyl-1,4-bis[*N*-(methoxycarbonyl)]fortamine B (**9**)[4] in 1,2-dichloroethane in the presence of trimethylsilyl trifluoromethanesulfonate under argon gave a single condensate (**10**) in 43% yield. The ^{1}H NMR spectrum of **10** exhibited a doublet (δ 5.38, J=3 Hz) due to H-1′, supporting the conformation of the anomeric proton to be equatorial in the α-D-glycoside. Hydrolysis of **10** in refluxing aqueous 1,4-dioxane with barium hydroxide, followed by treatment with Amberlite IRA-400 (OH^-) resin, gave 7′-phenylfortimicin B (**12**) in 70% yield. Compound **12** was converted into the tris[*N*-(benzyloxycarbonyl)] derivative (**14**) in 54% yield. Treatment of **14** with *N*-[*N*-(benzyloxycarbonyl)glycyloxy]succinimide and triethylamine afforded the tetrakis-[*N*-(benzyloxycarbonyl)] derivative of 7′-phenylfortimicin A (**16**) in 77% yield. Finally, catalytic hydrogenation of **16** in the presence of 10% palladium on

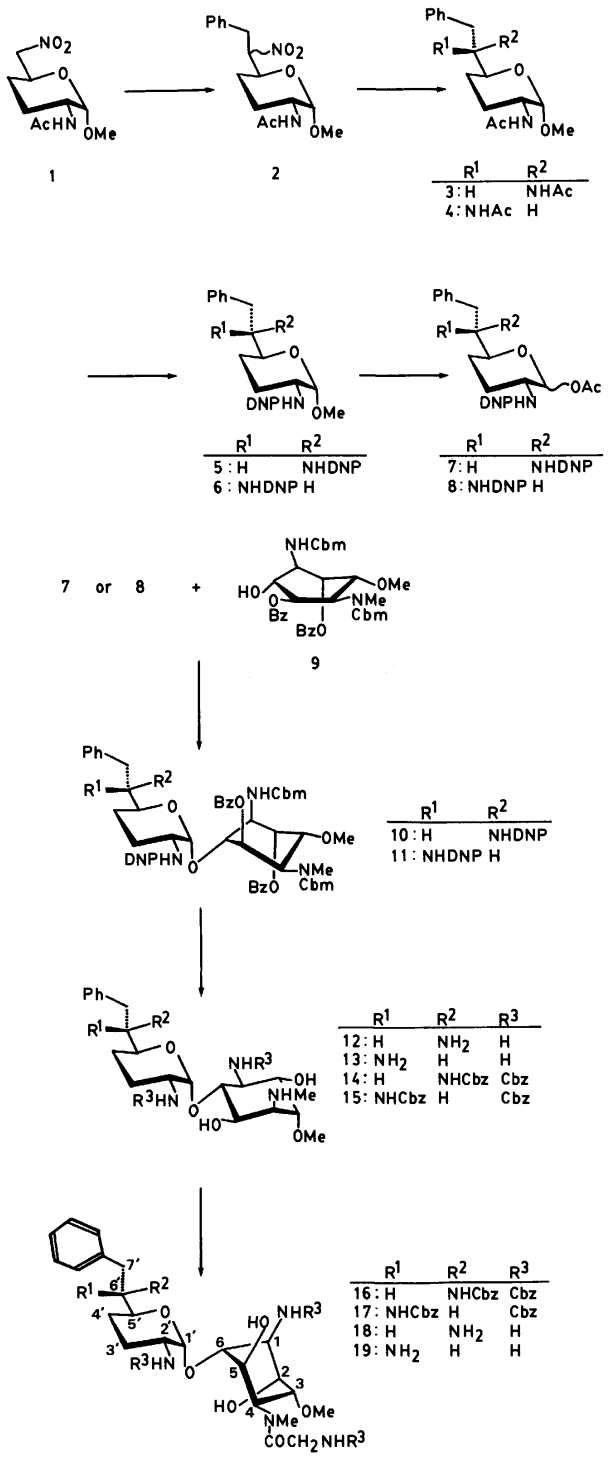
a) Minimum inhibitory concentration in μg ml^{-1}.



charcoal, followed by treatment with AG1-X2 (SO_4^{2-}) resin, gave 7′-phenylfortimicin A (**18**) as the sulfate.

7′-Phenyl-6′-epifortimicin A (**19**) has been similarly synthesized starting from **4** as described in the preparation of **18** from **3**.

The minimum inhibitory concentrations of **18** and **19** were listed together with those of fortimicin A (Table 2). 7′-Phenylfortimicin A (**18**) exhibited slightly weak activity compared to that of fortimicin A against many micro organisms. However, 7′-phenyl-6′-epifortimicin A (**19**) showed weak activity. Generally, the 6′-epi analogs[5)] of fortimicin A seem to be less active against micro organisms than those of the natural type.

Experimental[6)]

Methyl 2-Acetamido-2,3,4,6,7-pentadeoxy-6-nitro-7-phenyl-β-L-*lyxo*- and -α-D-*ribo*-heptopyranoside (2). To a solution of methyl 2-acetamido-2,3,4,6-tetradeoxy-6-nitro-α-D-*erythro*-hexopyranoside[1)] (**1**) (1.50 g) in methanol (3 ml) were added benzaldehyde (0.70 ml) and 1M sodium methoxide methanolic solution (6.7 ml) under ice cooling, and the mixture was stirred at 0 °C for 2 h. After neutralization with Amberlite IR-120 (H^+) resin, the mixture was concentrated. The residue was dissolved in acetic anhydride (10 ml) and boron trifluoride etherate (1.5 ml) was added to it under ice cooling. After stirring for 1 h, the mixture was poured into ice water (100 ml) and the mixture was extracted with dichloromethane (150 ml). The extract was successively washed with saturated aqueous $NaHCO_3$ (300 ml), brine (100 ml) and water (100 ml), and dried. After concentration, the residue was dissolved in dimethyl sulfoxide (18 ml), and a suspension of $NaBH_4$ (200 mg) in dimethyl sulfoxide (2 ml) was added to it. After stirring for 0.5 h, the mixture was acidified with Amberlite IR-120 (H^+) resin. The mixture was extracted with chloroform (100 ml) and the extract was dried. After concentration, the residue was chromatographed on silica gel with chloroform–methanol (90 : 1) to give **2** (1.13 g, 54%) and recovered **1** (0.60 g): IR (KBr) 1640 (amide), 1545, 1370 (NO_2) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.42—2.10 (4H, m, H-3,4), 1.96 (3H, s, NAc), 3.08 (2H, m, H-7), 3.33 (3H, s, OMe), 4.15 (2H, m, H-2,5), 4.58 (1H, d, *J*=3 Hz, H-1), 4.65 (1H, m, H-6), 5.73 (1H, d, *J*=8 Hz, NH), 7.04—7.42 (5H, m, phenyl).

Methyl 2,6-Diacetamido-2,3,4,6,7-pentadeoxy-7-phenyl-β-L-*lyxo*- (3) and -α-D-*ribo*-heptopyranoside (4). A solution of **2** (1.10 g) in ethanol (10 ml) and ethyl acetate (10 ml) was hydrogenated in the presence of Raney nickel in an initial hydrogen pressure of 3.4 kg cm^{-2} overnight. After removal of the catalyst, the solution was concentrated. The residue was acetylated with acetic anhydride (5 ml) in methanol (10 ml). The product was purified by chromatography on silica gel with toluene–ethanol (10 : 1) to give **3** (546 mg, 47%) and **4** (170 mg, 15%): Compound **3**; mp 241—242 °C; $[\alpha]_D^{20}$ +28.2° (*c* 0.77, MeOH); ^{1}H NMR (CD_3OD) δ=1.50—1.82 (4H, m, H-3,4), 1.87, 1.94 (each 3H, s, NAc), 2.83 (1H, dd, *J*=8.5, 14 Hz, H-7a), 2.91 (1H, dd, *J*=7, 14 Hz, H-7b), 3.42 (3H, s, OMe), 3.77 (1H, ddd, *J*=2.5, 6, 8.5 Hz, H-5), 3.90 (1H, ddd, *J*=3, 4.5, 11.5 Hz, H-2), 4.18 (1H, ddd, *J*=2.5,

7, 8.5 Hz, H-6), 4.67 (1H, d, J=3 Hz, H-1), 7.24 (5H, m, phenyl).

Found: C, 64.81; H, 7.48; N, 8.21%. Calcd for $C_{18}H_{26}N_2O_4$: C, 64.65; H, 7.84; N, 8.38%.

Compound **4**; mp 266.5—267.5 °C; $[\alpha]_D^{20}$ +129° (c 1.41, MeOH); ^{1}H NMR (CD_3OD) δ=1.60—1.90 (4H, m, H-3,4), 1.79, 1.94 (each 3H, s, NAc), 2.61 (1H, dd, J=11 Hz, 14 Hz, H-7a), 3.15 (1H, dd, J=4, 14 Hz, H-7b), 3.40 (3H, s, OMe), 3.70 (1H, ddd, J=2, 6, 11 Hz, H-5), 3.93 (1H, ddd, J=3, 6, 11 Hz, H-2), 4.07 (1H, ddd, J=4, 6, 11 Hz, H-6), 4.68 (1H, d, J=3 Hz, H-1), 7.24 (5H, m, phenyl).

Methyl 2,6-Bis(2,4-dinitrophenylamino)-2,3,4,6,7-pentadeoxy-7-phenyl-β-L-*lyxo*-heptopyranoside (5). A solution of **3** (435 mg) in 95% aqueous 2-methoxyethanol (20 ml) containing sodium hydroxide (1.6 g) was refluxed for 26 h. An additional amount of sodium hydroxide (1.6 g) was added to it and the reflux was continued for further 21 h. After cooling, the mixture was neutralized with 1M hydrochloric acid and concentrated. The residue was extracted with cold ethanol and the solution was concentrated. The residue was dissolved in methanol (20 ml), and 1-fluoro-2,4-dinitrobenzene (0.50 ml) and triethylamine (2.0 ml) were added to it. After stirring for 20 h, the mixture was extracted with chloroform (30 ml), and the extract was dried and concentrated to give a residue, which was chromatographed on silica gel with toluene-2-butanone (30:1) to give **5** (612 mg, 81%). Recrystallization from acetone-2-propanol gave an analytical sample: mp 109—114 °C; $[\alpha]_D^{20}$ −147° (c 0.95, acetone); IR (KBr) 1620, 1590 (aromatic), 1520, 1330 (NO_2) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.66—2.12 (4H, m, H-3,4), 3.10 (2H, d, J=7 Hz, H-7), 3.63 (3H, s, OMe), 5.00 (1H, d, J=3 Hz, H-1), 6.57, 6.95 (each 1H, d, J=10 Hz, H-6 of DNP), 8.03, 8.21 (each 1H, dd, J=3, 10 Hz, H-5 of DNP), 9.03, 9.09 (each 1H, d, J=3 Hz, H-3 of DNP).

Found: C, 53.36; H, 4.52; N, 14.45%. Calcd for $C_{26}H_{26}N_6O_{10}$: C, 53.61; H, 4.50; N, 14.43%.

1-*O*-Acetyl-2,6-bis(2,4-dinitrophenylamino)-2,3,4,6,7-pentadeoxy-7-phenyl-L-*lyxo*-heptopyranose (7). A solution of **5** (610 mg) in acetic acid (30 ml) containing 2M hydrochloric acid (5 ml) was stirred at 80 °C for 5 h. After cooling, the mixture was concentrated to the half volume and extracted with chloroform (60 ml). The extract was successively washed with saturated aqueous $NaHCO_3$ (20 ml) and water (20 ml), dried, and concentrated. The residue was acetylated with acetic anhydride (5 ml) in pyridine (10 ml). The mixture was concentrated to a residue, which was extracted with chloroform (100 ml) and the extract was successively washed with 1M hydrochloric acid (30 ml), saturated aqueous $NaHCO_3$ (30 ml) and water (30 ml), and dried. After concentration, the residue was chromatographed on silica gel with toluene-2-butanone (30:1) to give **7** (386 mg, 61%): mp 223 °C (decomp); $[\alpha]_D^{23}$ −172° (c 1.18, pyridine); IR (KBr) 1760 (ester), 1620, 1590 (aromatic), 1520, 1340 (NO_2) cm^{-1}; ^{1}H NMR (pyridine-d_5) δ=2.31 (3H, s, OAc), 3.20 (2H, d, J=9 Hz, H-7), 7.47 (5H, m, phenyl), 8.34 (2H, dd, J=3 Hz, 10 Hz, H-5 of DNP).

Found: C, 53.00; H, 4.33; N, 13.90%. Calcd for $C_{27}H_{26}N_6O_{11}$: C, 53.12; H, 4.29; N, 13.77%.

2,5-Di-*O*-benzoyl-2′,6′-bis[*N*-(2,4-dinitrophenyl)]-1,4-bis[*N*-(methoxycarbonyl)]-7′-phenylfortimicin B (10). To a solution of **7** (350 mg) and 2,5-di-*O*-benzoyl-1,4-bis[*N*-(methoxycarbonyl)]fortamine B (**9**)[1] (310 mg) in freshly distilled 1,2-dichloroethane in the presence of powdered molecular sieve 4A (300 mg) was added trimethylsilyl trifluoromethanesulfonate (0.12 ml), and the mixture was stirred for 5.5 h under argon. An insoluble material was filtered and washed with chloroform. The filtrate was successively washed with 5% aqueous $NaHCO_3$ (40 ml) and water (40 ml), dried, and concentrated to give a residue, which was chromatographed on silica gel with toluene-2-butanone (15:1) to give **10** (274 mg, 43%). Recrystallization from acetone-2-propanol gave an analytical sample: mp 147—153 °C; $[\alpha]_D^{27}$ −128° (c 1.08, acetone); ^{1}H NMR ($CDCl_3$) δ=2.84 (3H, s, NMe), 3.06 (2H, m, H-7′), 3.46 (3H, s, OMe), 3.56 (6H, s, Cbm×2), 4.12 (1H, dd, J=4, 9 Hz, H-3), 4.36 (1H, bs, H-6), 5.32 (1H, d, J=10 Hz, NH-1), 5.38 (1H, d, J=3 Hz, H-1′), 5.51 (1H, t, J=5 Hz, H-5), 5.78 (1H, bs, H-2), 6.32 and 6.84 (each 1H, d, J=9 Hz, H-6 of DNP), 7.15 (5H, s, phenyl), 7.40—7.66 (6H, m, benzoyl), 7.86 and 8.08 (3H and 1H, each d, J=8.5 Hz, benzoyl), 8.21 (2H, dd, J=3, 9 Hz, H-5 of DNP×2), 8.61 and 8.86 (each 1H, d, J=9 Hz, NH-2′,6′), 8.99 and 9.10 (each 1H, d, J=3 Hz, H-3 of DNP).

Found: C, 56.27; H, 4.84; N, 10.31%. Calcd for $C_{51}H_{53}N_8O_{19}$: C, 56.62; H, 4.94; N, 10.36%.

7′-Phenylfortimicin B (12). A stirred solution of **10** (206 mg) in dioxane (10 ml) and water (3 ml) in the presence of barium hydroxide octahydrate (3.5 g) was refluxed for 6 h. After cooling, the solid was filtered. Carbon dioxide was introduced to the filtrate and an insoluble material was filtered. After concentration, the residue was treated with Amberlite IRA-400 (OH^-) resin (10 ml) in a mixture of water (5 ml), methanol (10 ml) and acetone (10 ml). After stirring for 18 h, the resin was filtered, and the filtrate was concentrated. The residue was chromatographed on a column of Amberlite CG-50 (NH_4^+) resin (35 ml) with 0—0.15 M aq ammonia with gradient increase in concentration to give **12** (56 mg, 70%): $[\alpha]_D^{23}$ −23.8° (c 1.05, water); ^{1}H NMR (CD_3OD) δ=1.72 (4H, m, H-3′,4′), 2.39 (3H, s, NMe), 3.45 (3H, s, OMe), 7.27 (5H, s, phenyl).

Found: C, 55.79; H, 8.12; N, 12.40%. Calcd for $C_{21}H_{36}N_4O_5 \cdot 2/3H_2CO_3$: C, 55.86; H, 8.08; N, 12.03%.

1,2′,6′-Tris[*N*-(benzyloxycarbonyl)]-7′-phenylfortimicin B (14). To a solution of **12** (51 mg) in methanol (4 ml) was added *N*-(benzyloxycarbonyloxy)succinimide (92 mg) under ice cooling and the mixture was stirred for 1 h at 0 °C, and stirring was continued for 20 h at room temperature. The mixture was extracted with chloroform (60 ml) and the extract was dried. After concentration, the residue was chromatographed on silica gel with chloroform–methanol (50:1) to give **14** as a solid (53 mg, 54%): $[\alpha]_D^{24}$ +3.8° (c 1.98, $CHCl_3$); ^{1}H NMR ($CDCl_3$) δ=1.53 (4H, m, H-3′,4′), 2.30 (3H, bs, NMe), 3.43 (3H, s, OMe), 7.18, 7.28 and 7.31 (20H in total, each s, phenyl×4).

Found: C, 65.46; H, 6.70; N, 6.65%. Calcd for $C_{45}H_{54}N_4O_{11}$: C, 65.37; H, 6.58; N, 6.78%.

1,2′,6′-Tris[*N*-(benzyloxycarbonyl)]-4-[*N*-[*N*-(benzyloxycarbonyl)glycyl]]-7′-phenylfortimicin B (16). To a solution of **14** (44 mg) in dioxane (5 ml) were added *N*-[*N*-(benzyloxycarbonyl)glycyloxy]succinimide (20 mg) and triethylamine (0.01 ml), and the mixture was stirred for 14 h at 50 °C. After addition of 5% aqueous $NaHCO_3$ (10 ml), the mixture was extracted with chloroform (30 ml) and the extract was dried. After concentration, the residue was chromatographed on silica gel with chloroform–methanol

(50:1) to give **16** as a solid (41 mg, 77%): $[\alpha]_D^{24}$ +24.8° (*c* 1.04, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=1.64 (4H, m, H-3′,4′), 2.80 (5H, bs, NMe and H-7′), 3.29 (3H, s, OMe), 7.22, 7.27, 7.30, and 7.34 (25H in total, each s, phenyl×5).

Found: C, 64.71; H, 6.29; N, 6.76%. Calcd for $C_{55}H_{63}N_5O_{14}$: C, 64.89; H, 6.24; N, 6.88%.

7′-Phenylfortimicin A (18). A solution of **16** (28 mg) in methanol (2 ml) was hydrogenated in the presence of 10% palladium on charcoal (30 mg) under hydrogen atmosphere for 3 h. After removal of the catalyst, the filtrate was concentrated. The residue was dissolved in water, and then the solution was passed through a column of AG1-X2 (SO_4^{2-}) resin (2 ml). The eluent was concentrated to give a solid of 7′-phenylfortimicin A (**18**, 14 mg) as the sulfate: $[\alpha]_D^{24}$ +52.5° (*c* 0.48, water); ^1H NMR (D_2O) δ=1.76, 2.10 (4H in total, each m, H-3′,4′), 3.18 (3H, s, NMe), 3.54 (3H, s, OMe), 5.37 (1H, d, *J*=3 Hz, H-1′), 7.48 (5H, m, phenyl).

MS (SIMS) Found: *m/z*, 482. Calcd for $C_{23}H_{40}N_5O_6$: M+1, 482.

Methyl 2,6-Bis(2,4-dinitrophenylamino)-2,3,4,6,7-pentadeoxy-7-phenyl-α-D-*ribo*-heptopyranoside (6). A solution of **4** (392 mg) in 95% aqueous 2-methoxyethanol (18 ml) containing sodium hydroxide (1.93 g) was refluxed for 29 h. After neutralization with 1M hydrochloric acid, the mixture was concentrated and the residue was extracted with cold ethanol. The solution was concentrated to a residue, which was treated with 1-fluoro-2,4-dinitrobenzene (0.73 ml) and triethylamine (2.0 ml) in methanol (10 ml) for 13 h. The product was purified as described for the preparation of **5** to give **6** (410 mg, 60%): mp 102—108 °C; $[\alpha]_D^{20}$ +132° (*c* 1.29, acetone); IR (KBr) 1620, 1590 (aromatic), 1515, 1335 (NO_2) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.95 (4H, m, H-3,4), 2.72—3.35 (2H, m, H-7), 3.53 (3H, s, OMe), 4.91 (1H, d, *J*=3 Hz, H-1), 6.06, 6.93 (each 1H, d, *J*=10 Hz, H-6 of DNP), 7.20 (5H, s, phenyl), 7.92, 8.20 (each 1H, dd, *J*=3 Hz, 10 Hz, H-5 of DNP), 8.27, 8.89 (each 1H, d, *J*=9 Hz, NH-2,6), 8.97, 9.07 (each 1H, d, *J*=3 Hz, H-3 of DNP).

Found: C, 53.70; H, 4.50; N, 14.39%. Calcd for $C_{26}H_{26}N_6O_{10}$: C, 53.61; H, 4.50; N, 14.43%.

1-*O*-Acetyl-2,6-bis(2,4-dinitrophenylamino)-2,3,4,6,7-pentadeoxy-7-phenyl-D-*ribo*-heptopyranose (8). A solution of **6** (390 mg) in acetic acid (20 ml) containing 2M hydrochloric acid (3.5 ml) was stirred at 80 °C for 6 h. The crude product was acetylated with acetic anhydride (5 ml) in pyridine (10 ml), and the product was purified as described for the preparation of **7** to give **8** (337 mg, 83%): mp 104—108 °C; $[\alpha]_D^{25}$ +52.0° (*c* 1.2, acetone); IR (KBr) 1755 (ester), 1615, 1590 (aromatic), 1515, 1330 (NO_2) cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.19 (3H, s, OAc), 3.05 (2H, m, H-7), 4.12 (3H, m, H-2,5,6), 5.70 (1/5H, d, *J*=9 Hz, H-1), 6.34 (4/5H, d, *J*=3 Hz, H-1), 6.87, 7.08 (each 1H, d, *J*=10 Hz, H-6 of DNP), 7.21 (5H, s, phenyl), 8.06, 8.26 (each 1H, dd, *J*=3 Hz, 10 Hz, H-5 of DNP), 8.54, 8.71 (each 1H, d, *J*=9 Hz, NH-2,6), 8.98, 9.05 (each 1H, d, *J*=3 Hz, H-3 of DNP).

Correlation of Oxidation and Reduction Potentials of Reactants with Product Distribution in the Reactions of Various Organomagnesium Reagents with Aromatic Carbonyl and Nitro Compounds

Masao Ōkubo,* Toshiki Tsutsumi, and Kōji Matsuo
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840
(Received October 2, 1986)

In the electron transfer initiated fifteen reactions of five organomagnesium reagents, a semiquantitative relationship between the product distribution and the electron-donating and -accepting abilities (EDA and EAA) of reactants was obtained. The EDA was estimated by cyclic voltammetry of oxidation peak potentials of reagents and/or by the product distribution in their reactions, the decreasing order of EDA being: ArMgBr > ArSMgBr > ArNHMgBr > ArN(MgBr)$_2$ > ArOMgBr. The EAA of six quinones, eight nitroarenes, eleven aromatic ketones and an imine, and five azoxyarenes were similarly estimated by their reduction potentials (redox) in THF. The values of differences between the oxidation peak and reduction potentials were taken as an estimate of the relative efficiency of electron transfer, and were correlated to the distribution of normal (addition, condensation, replacement, and azoxy-deoxygenation) and abnormal (radical) products. Some exceptional cases were explained by modifying EDA and/or EAA based on the effect of coordination of substrate's oxygen to reagent's Mg atom.

Carbon-carbon bond formation with the use of Grignard addition to carbonyl compounds has been thoroughly investigated. In our laboratory, the methods for the formation of nitrogen-carbon and nitrogen-nitrogen double bonds based on the condensation of aryliminodimagnesium reagents (ArN(MgBr)$_2$, aryl-IDMg) with aromatic carbonyl[1] and nitro[2] compounds have been developed. A qualitative classification of reactions of the two magnesium reagents on the basis of the distribution of normal and abnormal products in terms of the combination of electron-donating and -accepting abilities(EDA and EAA) of reactants was previously proposed.[3] The lower EDA of IDMg than that of ArMgBr suggested from the product distribution[3] was established by comparing their polarographic oxidation peak potentials;[4] the reactions of these reagents with benzophenones were mechanistically distinguished.[5] The product distribution in C-C, C-S, and C-N bond formations with the use of the replacement of bromo and methoxyl groups on the β-position of α,β-enone and α,β-eneimine by ArMgBr(***C***), ArSMgBr(***S***), ArNHMgBr(***NH***), ArN(MgBr)$_2$(***N***), and ArOMgBr(***O***) was correlated to the relative EDA: ***C>S>NH>N>O***.[6] The product distribution in the deoxygenation of azoxyarenes by IDMg was also explained on the basis of relative EAA's estimated by reduction potentials.[7]

These results suggest the general applicability of the EDA-EAA concept independently of reaction manners; a quantitative basis is needed. In this study, the EAA's of aromatic nitro and carbonyl compounds were estimated from their reduction potentials(redox) measured by cyclic voltammetry in THF used as reaction solvent. The values of differences between the oxidation peak and reduction potentials were correlated to the previously given classification,[3] and the EDA-EAA concept was established semiquantitatively. The results will be described in the following.

Results and Discussion

Reduction and Oxidation Potentials of Substrates and Reagents in Tetrahydrofuran. Cyclic voltammetry by polarography was carried out in THF using n-Bu$_4$NClO$_4$ as the supporting electrolyte. The positive and negative limits of the potential window of this system are +1.5 and −2.1V, respectively. The observed reduction potentials (redox) of substrates were normalized by use of bisbiphenylchromiun(I) tetraphenylborate (BCTB) as internal reference,[8] and are summarized in the following. The negative large values indicate weak EAA.

I	Quinones	
1)	2,6-Cl$_2$-1,4-benzoquinone	−0.443V

IV Azoxyarenes(Ar^1-N(O)=N-Ar^2)

	Ar^1	Ar^2	
1)	4-MeC_6H_4	4-$MeOC_6H_4$	−1.786V
	C_6H_5	C_6H_5	−1.596V
	C_6H_5	4-ClC_6H_4	−1.423V
2)	4-ClC_4H_4	2-(4-Me)pyridyl	−1.312V
3)	Ferrocenyl	4-ClC_4H_4	−1.640V

In each group of substrates, the electron-repelling substituents give larger negative potentials[9] indicative of a weaker EAA. Taking the effect of a π-electron rich ferrocenyl group into account, the larger negative potentials (weaker EAA's) of nitro- and benzoylferrocenes than those of nitrobenzene and benzophenone, respectively, are reasonable. The potentials of the latter were unobservable since they are located out of the potential window. Also, the potential of xanthone is located out of the window due to the effect of electron-repelling resonance effect of ethereal oxygen atom.

The oxidation peak potentials, including those reported previously,[4] observed in the same solvent system were normalized by the use of ferrocene as an internal reference, and are summarized in the following. The electrode process was irreversible, and no reduction peak was observed. The positive large values are indicative of weak EDA.

C	ArMgBr[4]

O	ArOMgBr	Unobservable	

The lower oxidation peak potential of ***C*** than that of ***N*** was reported previously.[4] In both cases, the electron-repelling substituents gave smaller positive potentials[9] indicating stronger EDA. The large positive potential of 2-pyridyl-IDMg is responsible for its low reactivity observed in condensation with diaryl ketones.[1] The unsuccessful observation of the oxidation peak potential of aryloxyl reagent(***O***) derived from phenol is due to its much larger potential located out of the potential window. The reason for the unsuccessful observation of the oxidation peak potential of ***S*** is equivocal. Probably, the long and weak S-Mg bond will be responsible for the electron transfer followed by an extraordinarily quick dimerization. This is shown not only by the previous result involving a replacement reaction[6] but also by many examples concerning the one-electron oxidation of sulfide anions.[10] The oxidation peak potential of ***S*** is suggested to be located between those of ***C*** and ***NH***,[6] and to have an approximate value of 0.86V. The oxidation peak potential of the IDMg-type reagent ***NN***, which was derived from 1-methyl-1-phenylhydrazine,[1] shifts from ca. 1.0 to 1.9V during the course of repeated measurements: The reason is equivocal.

Correlation of Relative Value of Difference between Oxidation Peak and Reduction Potentials with Product Distribution in Addition, Condensation, Replacement, and Azoxy-Deoxygenation. The relative efficiency of electron transfer in individual reactions depends on the combination of EDA and EAA of reactants. It is thus reasonable that the relative values of differences (ΔE) between oxidation peak and reduction potentials are correlated to the distribution of normal and abnormal (radical) products. Previously, five reactions of ***C*** and ***N*** with some carbonyl and nitro compounds were classified into Classes A, B, and C on the basis of the product distribution.[3] As shown in Fig. 1, the three classes proved to be correlated to the relative ΔE values.

In Table 1, fifteen reactions of ***C***, ***S***, ***NH***, and ***N***, including not only addition and condensation but also replacement and azoxy-deoxygenation, are summarized. The three classes given above are designated. The ΔE values listed in the Table are approximate and were calculated using the oxidation peak potentials of *p*-Me-substituted reagents and mean values of reduction potentials of nitrobenzenes (A-1 and B-2), naphthoquinones (A-2), azoxybenzenes (B-6), and nitrobenzothiazoles (B-9) cited above. The applied reaction conditions are usual and are similar to each other, as reported previously.[1-7,11,13-15]

In Class A reactions, the ΔE values smaller than 2.2 as well as the formation of large amounts of abnormal (radical) products at the expense of normal ones are in accord with the previous characterization, i.e., "hardly controllable reactions due to a vigorous electron transfer."[3] The reduction potential of 1,3-diaryl-3-MeO-2-propen-1-one(β-MeO-α,β-enone) used in A-3 (and also in B-5) reactions[6] could not be determined. The potential was estimated with use of the ΔE values to be −1.3—−1.5 V, comparable to those of nitro-

Table 1. Correlation of Classes of Reactions, Potential Differences, and Distribution of Normal and Abnormal Products

Class of reacn	Reagent	Substrate[a]	Manner of reacn[b]	Approx. ΔE/V[c]	Product Yield/% Normal	Abnormal	Ref.
A-1	***C***	$ArNO_2$	A	2.2	ca. 50	ca. 60	2
A-2	***N***	NQ	C	1.9	10—20	ca. 80	3
A-3	***S***	MeOChl	R	—	5	95	6
A-4	***N***	Azx-Py	D	2.0—2.1	<30	>70	7

benzenes. The yields of normal products could be improved using lower temperatures (−20—−40 °C), which suppress the electron transfer (as confirmed by the present authors in A-3 reaction[6] and also by Bartoli in A-1 reaction[12]).

In Class B reactions, the medium ΔE values (2.2—2.8) are responsible for the yields of normal products higher than 65% and those of abnormal ones lower than 28%. The previously given "electron transfer controlled" character of Class B reactions is based on the fact that in B-1 and B-2 reactions the electron-attracting substituents of substrates and electron-repelling ones of reagents accelerate electron transfer leading to the higher concentration of intermediate radicals[3,5] and, consequently to a better yields of normal products. In kinetic terms, the B-1 reaction proceeds via a rapid but incomplete coordination and rate-determining electron transfer.[5] The B-2 reaction proceeds step by step via condensation and subsequent deoxygenation.[2,11] The comparable reduction potentials of nitro- and azoxybenzenes cited above may be responsible for the dependence of the final distribution of products simply on the relative EAA of substrate. The 65—90% yields of replacement products are obtained in B-3, B-4, and B-5 reactions.[6] The ΔE value in the B-5 reaction is estimated to be 2.3—2.5 (vide supra). The effect of EAA on the deoxygenation of azoxybenzenes (B-6) and an azoxypyridine (A-4) was recently reported.[7,11] In condensation reactions B-7 and B-8,[13] good yields of normal products were obtained in spite of the small ΔE values comparable to those of Class A reactions. The precise results concerning product distribution in a B-8 reaction will be reported elsewhere, but the reduction of EDA of *p*-MeC_6H_4-IDMg due to the coordination of thiazolyl group to Mg atom of reagent was confirmed.[13] In the B-9 reaction of ***NN*** with xanthone, the corresponding hydrazone was obtained in good yield.[1] The high yield and the observed manner of fluctuation of oxidation peak potential (vide supra) suggest that the actual potential of ***NN*** is lower than 0.8V (which is responsible for an efficient electron transfer to xanthone having weak EAA).

Even in the C-1 reaction having a ΔE value larger than 2.9 (which seems to be unfavorable for electron transfer), the condensation product was obtained in good yield.[5] In this reaction, the substituent effect of substrate appears in the manner reverse to that of the B-1 reaction (vide supra). The electron-repelling substituents favor the σ-complex formation by the rate-determining coordination of carbonyl oxygen to Mg atom of reagent, the reaction being thus characterized as "coordination controlled" one.[3] The weak EDA and EAA of reactants of C-1 reflect their low HOMO and high LUMO levels, respectively, but the σ-complex formation assists the substrate in lowering its HOMO and LUMO levels and in accepting electrons from the mild reagent.[3] The good yield of the normal product in C-1 is, thus, reasonable. The mechanisms of initial steps of C-1 distinct from those of B-1 were proposed for elucidating the formation of dimeric and monomeric types of abnormal products, respectively.[5]

Table 2. Relative Efficiency of Electron Transfer from ArOMgBr to Quinones Depending on EDA and EAA

ArOMgBr / Quinone	*p*-RC_6H_4OMgBr (R): MeO	Me	Cl
	strong ← (EDA) → weak		
	○○○○[a] 0 °C immediate	○○○ 0 °C immediate	○○ 55 °C 10 min
	○○○ 0 °C 5 min	○○ 55 °C 20 min	○ 55 °C 40 min
	△[b] complex formation	×	×
	×	×	×

(EAA) ↑ strong, ↓ weak

a) Relative efficiency of electron transfer is indicated by number of circles, and no color change by X.
b) In this case, the mixture turned yellow-brown but no radical species was detected by ESR. The coloration is ascribed to σ-complex formation.[3,5]

Irrespective of the small ΔE value comparable to that of B-2, the reaction of *p*-substituted benzils with IDMg reagent is characterized as C-type because the reaction is accelerated by the *p*-MeO-substituent of substrate.[3] The anomaly in C-2 reaction, however, is understood by a measurement of reduction potential of benzil in the presence of an equimolar amount of anhydrous $MgBr_2$. The potential becomes large at least in ca. 0.2V. The reduction of EAA is ascribable to chelate formation by the coordination of α-dicarbonyl oxygen atoms to Mg atom of the reagent. The actual ΔE value in the C-2 reaction may be larger than 2.5. The precise results of the study of substituent effect will be reported elsewhere.[14]

Undoubtedly, the Grignard addition to carbonyl compounds owes its great success about eighty years ago to the lucky selection of Class B combination of reactants.

Electron Transfer from Aryloxymagnesium Reagents to Quinones. Among the reagents examined, aryloxymagnesium (***O***) is suggested to be the weakest electron donor because it is unable to react with monofunctional carbonyl compounds.[6] Its oxidation peak potential was undetermined in the present measurements (vide supra), but it donates electrons to benzoquinones having strong EAA. When *p*-$MeOC_6H_4O$-MgBr was allowed to react with a sixth molar amount of 2-Br-5-*t*-Bu-1,4-benzoquinone, ca. 80% of the quinone was recovered unchanged but a small amount of quinhydrone was obtained. No replacement product was detected. Also, in the reaction with 2-MeO-5-*t*-Bu-1,4-benzoquinone, the results were similar. The precise results on product distribution will be reported elsewhere.

As shown in Table 2, the relative efficiency of electron transfer in cases of benzoquinones and no electron transfer in cases of naphtho- and anthraquinones are in line with the expectation based on the EDA-EAA concept. By mixing the THF solutions of reactants in 1 : 1 molar ratio, the mixture turned deep blue-green due to the formation of semiquinone and aryloxyl radicals. The time given in the Table indicates the period of time needed for obtaining the highest concentration of radicals under the given temperatures. Taking into account the correlation of potential difference shown in Table 1, the results of Table 2 suggest that *p*-RC_6H_4OMgBr has oxidation peak potential higher than 1.6V.

General Discussion. The characteristics of the three typical classes of reactions under usual conditions are summarized in the following.

Class A: High yields of radical products are formed as the result of a vigorous electron transfer. The small ΔE values indicate the strong EDA and/or EAA.

Class B: Good yields of normal products are formed as the result of efficient electron transfer arising from medium ΔE values. The favorable electronic effect of substituents of reactants appears in the manner raising the oxidation potential and lowering the reduction potential, i.e., strengthening both EDA and EAA.

Class C: As far as the initial formation of the σ-complex is not sterically retarded, good yields of products are formed in spite of the large ΔE values. The σ-complex formation is favored by the electron-repelling substituent of the substrates, and assists them in strengthening their EAA, resulting in a mild electron transfer.

The correlation of product distribution with the ΔE value as the first approximation must originate from the remarkable feature of reactions of magnesium reagents. As established in B-1 and C-1 reactions,[3,5] the rate-determining step is located in one of the common initial processes, i.e., the σ-complex formation and the subsequent electron transfer. Due to the strong affinity of magnesium with oxygen, the modification of EDA and/or EAA based on the second important effect of coordination is reasonable.

The EDA-EAA concept is extended further to additional cases, in which no chemical change takes place and no radical species is detected even though the mixture turns yellow-brown indicating the formation of σ-complex: The combination of *N*-(1-Br-9-fluorenylidene)aniline with ***S***,[6] and those of β-MeO-α,β-enone[6] and anthraquinone with ***O*** (Table 2). The much larger ΔE value is responsible for no transfer of electrons, even after the α-complex formation. Similarly, no color change after mixing the components, indicating no interaction, is ascribed to the very large ΔE value as exemplified by the combination of anthraquinone with ***O*** (Table 2) and/or to the steric inhibition of σ-complex formation.[5]

So far, the reactants were confined to aromatic types; the rather simple types of products obtained assisted us in revealing the governing factor. The combination of magnesium reagents with α-benzylideneacetophenones,[16] β-nitrostyrenes,[17] nitro- and benzoylferrocenes,[18] were also studied. These substrates have carbonyl and nitro groups that are not bound directly to the benzene ring; the types of products as well as the effect of substituents are explainable partly on the basis of the EDA-EAA concept. However, some additional factors have to be taken into account.[16,18] The reactions are, thus, excluded from the present classification and will be reported elsewhere.

Electron transfers in organic reactions, including that of a Grignard reagent, have been studied on the general basis of the Marcus theory.[19] Further quantitative studies are needed. However, the present classification will contribute to studies on the mechanisms and molecular orbital picture of electron transfers (vide supra) in the field of organomagnesium chemistry.[20,21] The simple relationship will also be helpful for the selection of reaction conditions and for the expectation of product yields in the synthetic applica-

tions of magnesium reagents.

Experimental

Materials, Reaction Procedures, and Measurements. Almost all the quinones, nitrobenzenes, and benzophenone were commercially available. Nitrobenzothiazoles, nitroferrocene, 1-bromo-9-fluorenone, α-benzylideneacetophenones, *p,p'*-dimethylbenzil, and azoxyarenes were prepared according to the manner given in the references. Some references will be given in the forthcomig papers. The preparation of magnesium reagents in THF was reported previously.

The reaction of *p*-$MeOC_4H_4OMgBr$ with 2-bromo-4-*t*-butylbenzoquinone was carried out by heating the mixture at 55 °C for 3 h. The products were separated by column chromatography on silica gel.

Cyclic voltammetry of oxidation peak potentials[4] and reduction potentials[7] were reported previously.

The gift of samples of BCTB by Professor Gerhard Gritzner, University of Linz, and Professor Kohsuke Izutsu, Shinshu University, is gratefully acknowledged. The authors also wish to thank Dr. Akio Ichimura and Professor Toyokichi Kitagawa, Osaka City University, for helpful advice on cyclic voltammetry. The authors are grateful also to Ministry of Education, Science, and Culture for a financial support by a Grant-in-Aid for Scientific Research (No. 60470026).

This paper is dedicated to the late Professor Ryozo Goto, Kyoto University.

Total Synthesis of 6-Hydroxy-*epi*-PS 5 and 6-Methoxy-*epi*-PS 5

Azuma WATANABE,* Yasuo FUKAGAWA, Tomoyuki ISHIKURA, and Takeo YOSHIOKA
SANRAKU INC., Central Research Laboratories, 9-1 Johnan 4 Chome, Fujisawa, 251
(Received November 13, 1986)

The stabilizing effect of the 6-methoxyl or 6-hydroxyl substituent on dehydropeptidase I sensitivity of PS 5 was examined by a new total synthesis of 6-methoxy-*epi*-PS 5 and 6-hydroxy-*epi*-PS 5 from dimethyl benzyloxycarbonylaminomalonate. The Wittig reaction of α-(*t*-butoxycarbonyl)propylidenetriphenylphosphorane with a pyrrolidine derivative predominantly afforded a *trans*-α,β unsaturated ester, which was epoxidated, *N*-deprotected and cyclized to give a bicyclic carbapenam with a C-6 hydroxyl group. After the 6-hydroxyl group was methylated, the 2-(acetamido)ethylthio side chain was introduced at C-3 of the carbapenam by benzeneselenenylation of the geminal diester, followed by eliminatlon of the seleninyl group. The resulting carbapenam was converted to 6-methoxy-*epi*-PS 5. Furthermore, 6-hydroxy-*epi*-PS 5 was synthesized by the use of tetrahydropyranyl and trimethylsilyl ethers for protection of the 6-hydroxyl group in a process similar to that for synthesis of 6-methoxy-*epi*-PS 5.

Although the carbapenem antibiotic PS 5[1] and related compounds[2] have very broad spectra of potent antimicrobial activity and high resistance to β-lactamase, they are unexpectedly sensitive to renal dehydropeptidase I (DHP-I), resulting in poor therapeutic effects in vivo. In a continued effort to improve the DHP-I stability of PS 5 to a clinically acceptable level, a variety of C-3 side chains have been introduced into PS 5,[3] but no PS 5 derivative with satisfactory DHP-I stability has yet been prepared.

Considered from the observations that the stability of cephalosporins to β-lactamase is improved by introduction of the 7α-methoxyl group[4] and that the stereochemistry of C-6 of carbapenems is not critically important for antimicrobial activity,[5] it is interesting to examine whether the introduction of the 6α-methoxyl or 6α-hydroxyl substituent serves to stabilize carbapenem against DHP-I or not. For this purpose, a new route of total synthesis of carbapenem has been developed using dimethyl benzyloxycarbonylaminomalonate as starting material. This paper describes the stereoselective total synthesis of 6-methoxy-*epi*-PS 5 (**1**) and 6-hydroxy-*epi*-PS 5 (**2**) together with their enzymological and antimicrobial evaluation.

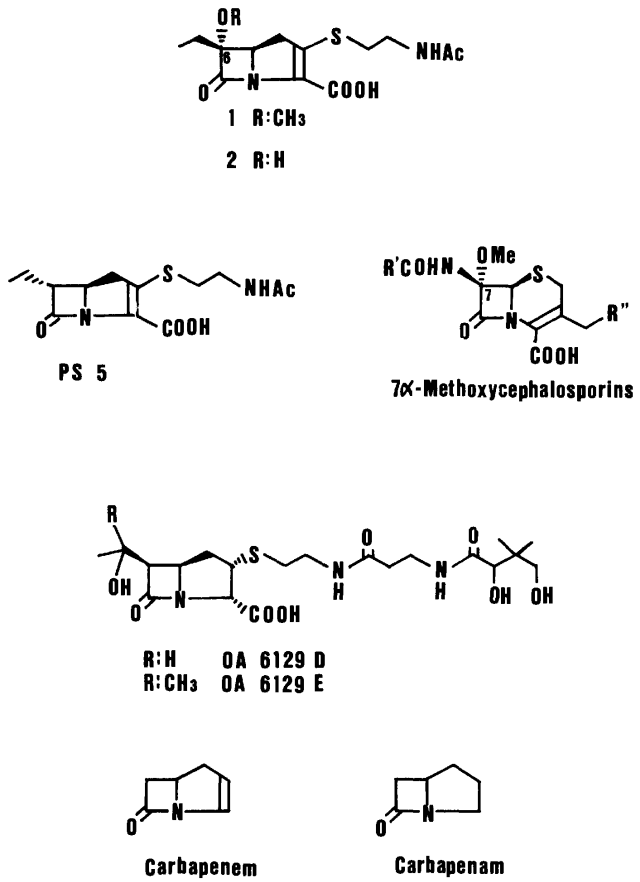

Fig. 1.

Results and Discussion

Carbapenam compounds such as OA 6129D and E[6] are physicochemically very stable and easily convertible to carbapenems. In hitherto known routes of synthesis of carbapenems, the β-lactam ring is formed before the 5-membered pyrrolidine ring is closed, whereas the reverse route has least been reported.[7] Thus it is interesting to develop a new route to synthesize 6-methoxy-*epi*-PS 5 (**1**). This comprises the initial closure of the pyrrolidine ring, the susequent formation of the β-lactam ring and the final conversion of carbapenam to carbapenem, starting from dimethyl (*N*-protected amino)malonate **H** according to the retrosynthetic strategy as shown below (Fig. 2).

The key points to the successful synthesis seem to be in the introduction of a leaving group X at C-2 (derivative **B**), followed by conversion to carbapenem **A**, and in the stereoselective preparation of a *trans*-α,β-unsaturated ester by the Wittig reaction of a pyrrolidine derivative **G** with a stable ylid **F**. If this route of synthesis is operative as described above, an optically active compound **B** will be obtained from D- or L-glutamic acid.[8]

A key intermediate carbapenam **9** for 6-methoxy-*epi*-PS 5 (**1**) was prepared as shown above. The Michael addition of dimethyl benzyloxycarbonylaminomalonate (**3**) (readily preparable from dimethyl malonate)

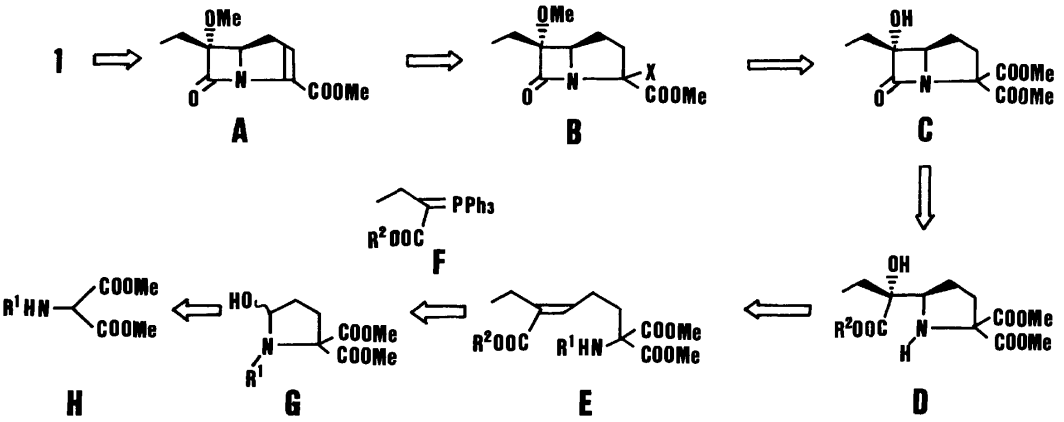

Fig. 2.

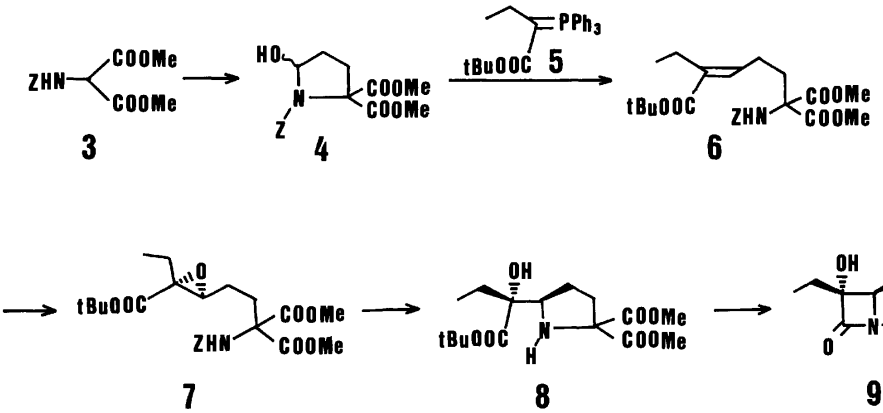

Fig. 3.

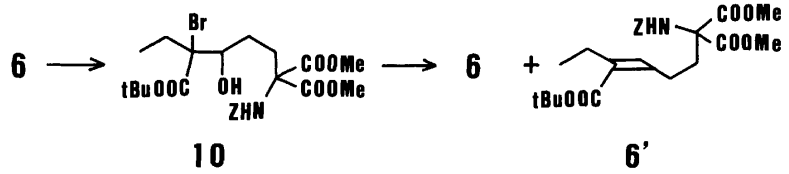

Fig. 4.

with acrylaldehyde in the presence of sodium methoxide catalyst afforded 5-hydroxypyrrolidine **4** in 85% yield. The Wittig reaction of **4** with α-(*t*-butoxycarbonyl)propylidenetriphenylphosphorane (**5**) predominantly provided a *trans*-α,β-unsaturated ester **6** in good yield under reflux in benzene for 16 h. The geometrical isomerism of **6** was examined by transformation to the cis isomer **6'** according to the following scheme (Fig. 4):

The treatment of the unsaturated ester **6** with *N*-bromoacetamide in aqueous acetone gave bromohydrins **10**, which were subjected to reduction with tributyltin hydride, methylsulfonylation with methanesulfonyl chloride and triethylamine, and β-elimination with 1,6-diazabicyclo[5.4.0]undec-7-ene, affording geometrical isomers **6** and **6'**. The cis isomer **6'** was separated by preparative silica-gel thin-layer chromatography (TLC). The NMR spectrometric comparison of these isomers by the chemical shift of the vinyl proton clearly showed that the isomerism of the predominant compound **6** was trans (δ=6.44; δ=5.64 for **6'**).[9] The oxidation of **6** with *m*-chloroperbenzoic acid in dichloromethane at 40 °C for 4 h afforded an epoxide **7** (90% yield). The cleavage of the *N*-benzyloxycarbonyl group from **7** by hydrogenation gave a pyrrolidine derivative **8** in 89% yield. After the *t*-butyl ester group was hydrolyzed in 4 mol dm^{-3} HCl in dioxane, the resulting β-amino acid was cyclized at 60 °C for 4 h with dicyclohexylcarbodiimide in acetonitrile to provide the bicyclic β-lactam **9** in 70% yield.

The methylation of the hydroxyl group of **9** with methyl iodide in the presence of silver oxide in *N*,*N*-dimethylformamide resulted in a methoxycarbapenam **11** (90% yield). The carbapenam **11** was transformed to a carbapenem **14** by selenoxide elimination which was operative under milder conditions than sulfoxide elimination. Benzeneselenenyl derivatives **13a** and **13b** are preparable from the diester **11** by two routes.

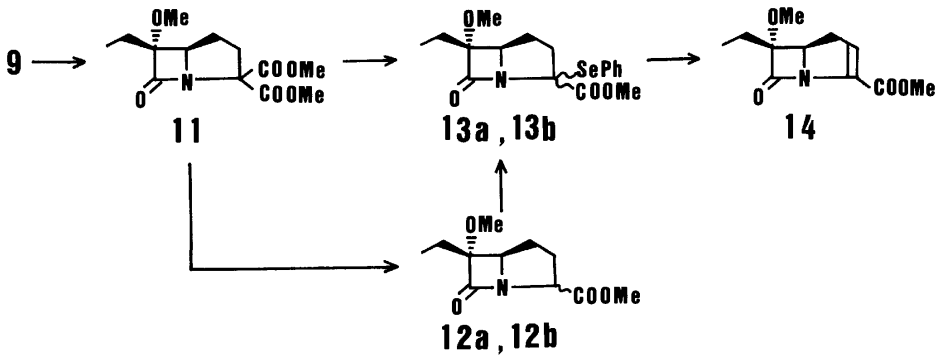

Fig. 5.

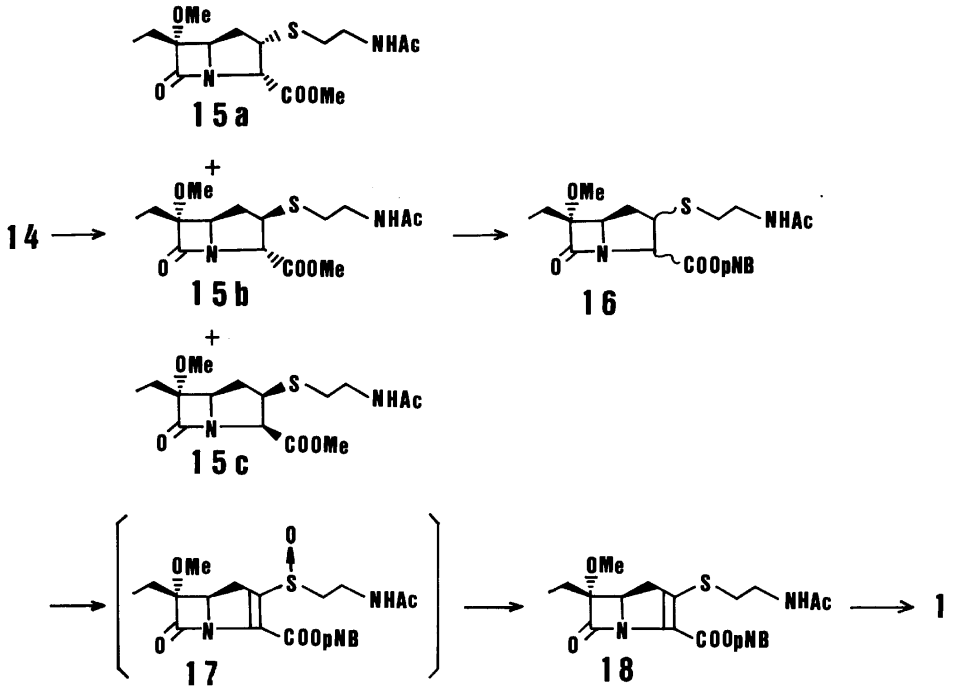

Fig. 6

First, the diester **11** was converted to the benzeneselenenyl compounds **13a** and **13b** via mono(methoxycarbonyl) derivatives **12a** and **12b**. More particularly, the diester **11** was hydrolyzed in 1 mol dm^{-3} NaOH and then heated at 100 °C in pyridine to give a diastereoisomeric mixture of the mono(methoxycarbonyl) derivatives **12a** and **12b** in 52% yield. After treatment with lithium diisopropylamide in tetrahydrofuran, the mixture was allowed to react with benzeneselenenyl chloride, leading to the benzeneselenenyl compounds **13a** and **13b** (a mixture of the two diastereoisomers) in a total yield of 61% from **12a** and **12b**.

Then the direct route of benzeneselenenylation was investigated by replacing sulfur by selenium in the procedure of Asaoka et al.[10] which was used to sulfenylate a geminal diester by demethoxycarbonylation. The reaction of 1 mol of the diester **11** with 1 mol of diphenyl diselenide in the presence of 2 mol of NaI in hexamethylphosphoric triamide at 80 °C for 2 h gave a mixture of **13a** and **13b** in 50% yield together with 31% of the unreacted diester **11**. The treatment of the isomeric mixture of the selenides **13a** and **13b** with *m*-chloroperbenzoic acid at −30 °C, followed by triethylamine addition, produced the carbapenem **14** in 78% yield via selenoxide.

The introduction of a 2-(acetamido)ethylthio side chain at C-3 of the carbapenem **14** in the presence of triethylamine in *N*,*N*-dimethylformamide give a diastereoisomeric mixture of **15a**, **15b**, and **15c** in a good yield of 95%. They were separated from each other by silica-gel column chromatography. ^{1}H NMR analysis indicated that the molar ratio of **15a** (δ=4.72, $J_{2,3}$=8.0 Hz), **15b** (δ=4.33, $J_{2,3}$=6.0 Hz), and **15c** (δ=4.19, $J_{2,3}$=8.0 Hz) was 2 : 5 : 3.[11]

The mixture **15a**, **15b**, and **15c** was hydrolyzed in 0.1 mol dm^{-3} NaOH and subjected to ester exchange with *p*-nitrobenzyl bromide to give a carbapenam *p*-nitrobenzyl ester **16** in 72% yield. The ester **16** was converted to a carbapenem **18** via a sulfoxide **17** in 54% yield by the method of Bateson et al.[12] 6-Methoxy-*epi*-PS 5 (**1**)

(sodium salt) was obtained from the *p*-nitrobenzyl ester (**18**) in 70% yield by hydrogenolytic removal of the *p*-nitrobenzyl group, followed by column chromatographic purification on QAE-Sephadex A-25 and Diaion CHP-20P.

Generally speaking, penicillins and cephalosporins are sensitive to β-lactamase and insensitive to DHP-I, whereas carbapenems are sensitive to DHP-I and insensitive to β-lactamase. The introduction of the 7α-methoxyl or 7α-hydroxyl group to cephalosporins improves the resistance to β-lactamase, but accompanies a reduction in antimicrobial activity. Thus it is interesting to compare the 6-methoxyl and 6-hydroxyl substituents of carbapenems to give useful information on the structure-activity relationship of carbapenems in antimicrobial activity, β-lactamase sensitivity, and DHP-I resistance. For this purpose, 6-hydroxy-*epi*-PS 5 (**2**) was prepared using a similar procedure.

Without protecting the 6-hydroxyl group, the alcohol **9** was converted directly to a benzeneselenenyl derivative **19** in a poor yield, which was then converted to a 6-hydroxycarbapenem **20**, also in a poor yield by oxydation, followed by elimination of the benzeneseleninyl group. For improvement of the reaction yields, the 6-hydroxyl group of **9** was protected with a tetrahydropyranyl (THP) group which survived the subsequent treatment.

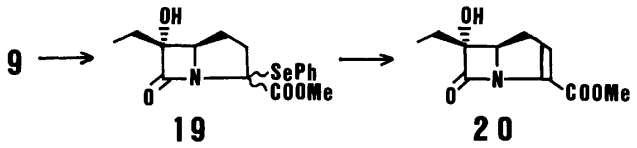

Fig. 7.

The alcohol **9** was treated with 3,4-dihydro-2*H*-pyran in the presence of *p*-toluenesulfonic acid to yield an anomeric *O*-THP derivative mixture **21**, which was led to a carbapenam **25** in four steps in the same manner as described for 6-methoxy-*epi*-PS 5. The carbapenam **25** was convertible to the corresponding carbapenem, but the deprotection of the *O*-THP group without breakdown of the β-lactam ring was unsuccessful. Therefore the *O*-THP group of the carbapenam **25** was removed by treatment with pyridinium *p*-toluenesulfonate (PPTS)[13] in ethanol to provide an alcohol **26**. As no direct conversion to the corresponding carbapenem was successful, the alcohol **26** was reprotected with the trimethylsilyl (TMS) group which was readily deprotectable under mild conditions to give an *O*-TMS carbapenam **27**. The carbapenam **27** was transformed to a carbapenem **28** and the hydrolytic cleavage of the TMS ether **28** in 0.001 mol dm^{-3} HCl-ethanol (1 : 1) at 0 °C for 30 min gave a 6-hydroxycarbapenem **29** in 87% yield. The *p*-nitrobenzyl ester **29** was hydrogenated to yield 6-hydroxy-*epi*-PS 5 (**2**), as described above for 6-methoxy-*epi*-PS 5 (**1**). It is worth noting that the TMS group is useful for protection of hydroxyl groups on the carbapenem system.

Table 1 shows the comparative antimicrobial activities of 6-methoxy-*epi*-PS 5 (**1**), 6-hydroxy-*epi*-PS 5 (**2**), PS 5 and cefazolin. It seems highly probable that the introduction of the methoxyl or hydroxyl group at C-6 of PS 5 results in a significant reduction of the antimicrobial potency, as is reported for 7α-methoxy- and 7α-hydroxycephalosporins.[14] It is interesting to note that the 6-hydroxyl group is more influential than the 6-methoxyl in reduction of the antimicrobial activity.

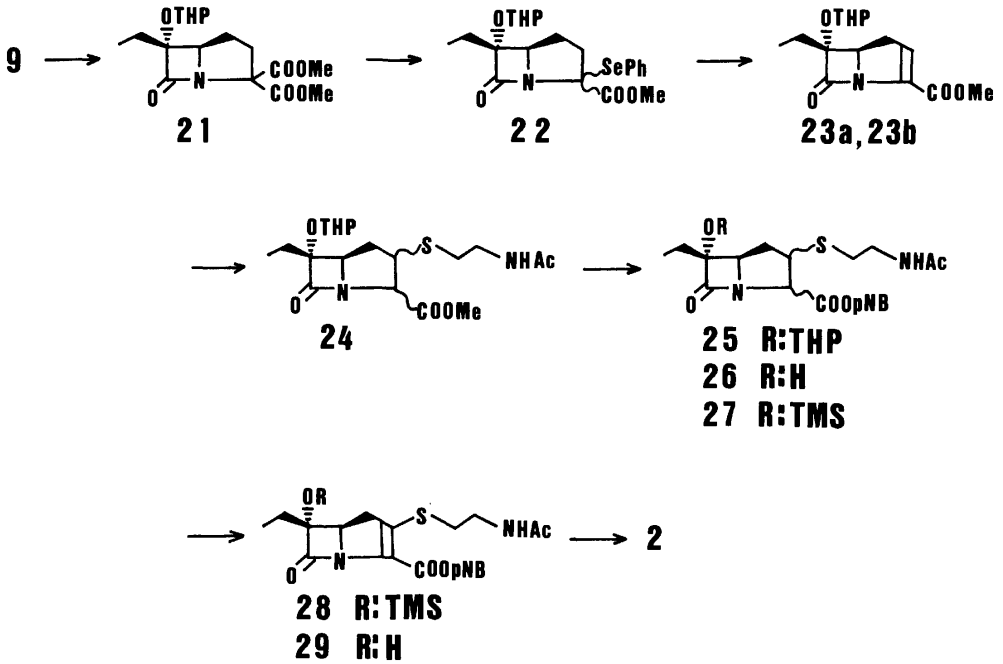

Fig. 8.

Table 1. Comparative Antimicrobial Activities of 6-Methoxy-*epi*-PS 5 (**1**), 6-Hydroxy-*epi*-PS 5 (**2**), PS 5 and Cefazolin (MIC in $\mu g\,ml^{-1}$)

Microorganism	1	2	PS 5	Cefazolin
Bacillus subtilis ATCC 6633	6.25	50	0.10	0.10
Staphylococcus aureus FDA209P	0.78	50	0.024	0.05
Staphylococcus aureus Smith	3.13	25	0.20	0.20
Citrobacter freundii GN346	>50	>50	1.56	>100
Comamonas terrigena IFO12685	0.78	—	0.012	0.10

Shigella sonnei EW33	50	>50	3.13	3.13

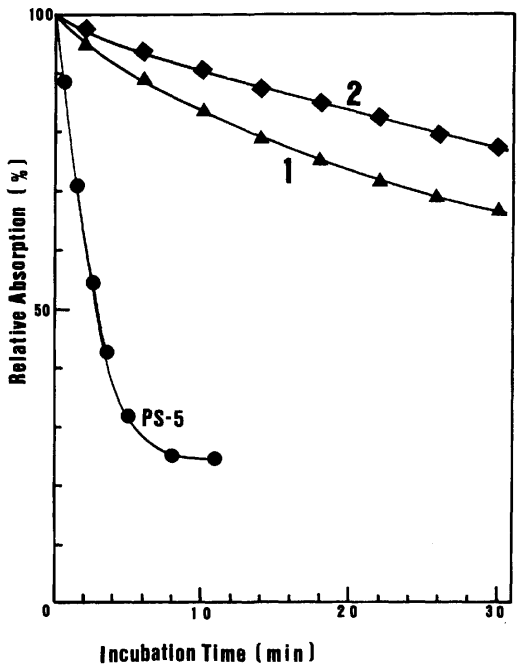

Fig. 9. Comparative DHP-I stabilities.

The comparative DHP-I stabilities of the three carbapenem derivatives are compared in Fig. 9, using the time course curves of hydrolysis by DHP-I on the relative UV absorptions at 300 nm. The DHP-I enzyme used in these assays was a partially purified preparation from hog kidney. The 6-hydroxyl substituent seems more effective than the 6-methoxyl in stabilization of carbapenem against DHP-I.

In conclusion, the introduction of the 6α-methoxyl or 6α-hydroxyl group in carbapenem significantly improves the DHP-I stability as expected, but with drastic reduction in antimicrobial activity.

Experimental

General. All mp's were measured with a YANACO apparatus and are uncorrected. Silica-gel thin-layer chromatography (TLC) and column chromatography were carried out on precoated TLC plates silica gel 60 F-254 (E. Merck) and silica gel 60 (70—230 mesh, E. Merck), respectively. Infrared (IR), ultraviolet (UV), ^{1}H NMR and ^{13}C NMR spectra were recorded with a Hitachi 260-30 infrared spectrophotometer, a Hitachi 200-20 spectrophotometer, a Varian EM-390 (90 MHz) spectrometer and a JEOL FX-100 spectrometer, respectively. Chemical shifts are given in ppm from internal TMS in $CDCl_3$ or TSP [sodium 3-(trimethylsilyl)propionate] in D_2O. Mass spectrometric data were collected on a Hitachi EM-80 spectrometer. Antimicrobial activity and DHP-I stability were measured as previously described.[15]

1-Benzyloxycarbonyl-2,2-bis(methyoxycarbonyl)-5-hydroxypyrrolidine (4). To a solution of 28.1 g (0.10 mol) of dimethyl benzyloxycarbonylaminomalonate **3** in 250 ml of benzene, 0.5 g of sodium methoxide, and 10 ml (0.20 mol) of acrylaldehyde were added and stirred for 1 h at room temperature. The reaction mixture was poured into 100 ml of cold 0.1 mol dm^{-3} HCl and the aqueous layer was separated and extracted twice with 100 ml each of benzene. The organic layer and the benzene washes were combined and rinsed with brine, dried (Na_2SO_4) and concentrated in vacuo to give a liquid. The liquid was chromatographed on a silica-gel column (250 g) using benzene-acetone (7:1) as eluent to provide 28.9 g of **4** as an oil in 85% yield: IR ($CHCl_3$) 1750, 1740, and 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.75—2.25 (2H, m), 2.25—2.85 (2H, m), 3.53 (3H, s), 3.75 (3H, s), 4.02 (1H, s), 5.10 (1H, s), 5.17 (1H, s), 5.67 (1H. br) and 7.30 (5H, s); MS (EI) m/z 319 (M^+-H_2O).

***trans*-2-Benzyloxycarbonylamino-6-(*t*-butoxycarbonyl)-2-methoxycarbonyl-5-octenoic Acid Methyl Ester (6).** A mixture of 1.1 g (3.3 mmol) of 1-benzyloxycarbonyl-2,2-bis-(methoxycarbonyl)-5-hydroxypyrrolidine (**4**) and 1.73 g (4.3 mmol) of α-(*t*-butoxycarbonyl)propylidenetriphenylphosphorane (**5**) in 50 ml of benzene was refluxed for 16 h and concentrated to dryness in vacuo. Purification by silica-gel column (50 g) chromatography with benzene-acetone (10:1) resulted in isolation of 1.20 g of **6** as needles (80% yield) (recrystallized from benzene-hexane): mp 93—94 °C; IR ($CHCl_3$) 1740, 1720, and 1700 cm^{-1}; ^{1}H NMR ($CHCl_3$) δ=0.94 (3H, t, J=7.0 Hz), 1.47 (9H, s). 1.85—2.55 (6H, m), 3.73 (6H, s), 5.08 (2H, s), 6.15 (1H, s), 6.44 (1H, t, J=7.5 Hz), and 7.30 (5H, s).

Found: C, 62.45; H, 7.28; N, 3.01%; M^++1, 464. Calcd for $C_{24}H_{33}NO_8$: C, 62.19; H, 7.18; N, 3.02%; M+1, 464.

6' (isomer of **6**): IR ($CHCl_3$) 1740 and 1715 cm^{-1}; ^1H NMR δ=0.99 (3H, t, J=7.5 Hz), 1.47 (9H, s), 2.18 (2H, q, J=7.5 Hz), 2.2—2.5 (4H, m), 3.77 (6H, s), 5.09 (2H, s), 5.64 (1H, t, J=7.5 Hz), 6.27 (1H, br), and 7.35 (5H, s).

Found: m/z 464.2270. Calcd for $C_{24}H_{34}NO_8$: M+1, 464.2281.

2-Benzyloxycarbonylamino-6-(*t*-butoxycarbonyl)-5,6-epoxy-2-(methoxycarbonyl)octanoic Acid Methyl Ester (7). *m*-Chloroperbenzoic acid (2.80 g, 16.2 mmol) was added to a solution of 3.83 g (8.3 mmol) of *trans*-2-benzyloxycarbonylamino-6-(*t*-butoxycarbonyl)-2-(methoxycarbonyl)-5-octenoic acid methyl ester **6** in 50 ml of dichloromethane, and stirred for 4 h at 40 °C. After quenching with 1.15 ml (8.0 mmol) of triethylamine, the reaction mixture was washed with aqueous saturated $NaHCO_3$ and brine, dried (Na_2SO_4), and concentrated to dryness. The residue was purified by silica-gel column (140 g) chromatography using benzene-ethyl acetate (10 : 1), providing 3.56 g of **7** as needles (recrystallized from benzene-hexane) (90% yield): mp 61—62 °C; IR ($CHCl_3$) 1740 and 1725 cm^{-1}; ^1H NHR $CDCl_3$) δ=1.01 (3H, t, J=7.5 Hz), 1.47 (9H, s), 1.2—2.05 (4H, m), 2.35—2.6 (2H, m), 3.04 (1H, t, J=6.0 Hz), 3.73 (6H, s), 5.08 (2H, s), 6.14 (1H, s) and 7.34 (5H, s).

Found: C, 60.07; H, 6.94; N, 2.94; M^+, 479. Calcd for $C_{24}H_{33}NO_9$: C, 60.11; H, 6.94; N, 2.92; M, 479.

2,2-Bis(methoxycarbonyl)-5-[1-(*t*-butoxycarbonyl)-1-hydroxypropyl]pyrrolidine (8). A suspension of the epoxide **7** (9.24 g, 19.3 mmol) and 10% Pd-charcoal (2.0 g) in 200 ml of dioxane was agitated at room temperature for 5 h at 1 atm under hydrogen, and then filtered. After the dioxane was evaporated off, the residue was chromatographed on silica gel with benzene-ethyl acetate (5 : 1) as eluent. From the eluate 5.90 g of **8** (89% yield) was provided as needles (recrystallized from benzene-hexane): mp 105—105.5 °C; IR ($CHCl_3$) 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.87 (3H, t, J=7.0 Hz), 1.46 (9H, s), 1.6—2.65 (6H, m), 3.08 (1H, d, J=5.0 Hz), 3.41 (1H, s), 3.53 (1H, m), 3.73 (3H, s), and 3.78 (3H, s); ^{13}C NMR ($CDCl_3$) δ=7.7 (q), 26.1 (t), 27.9 (q), 30.0 (t), 32.9 (t), 52.7 (q), 52.9 (q), 65.2 (d), 71.9 (s), 78.9 (s), 82.3 (s), 170.1 (s), 172.7 (s), and 173.5 (s).

Found: C, 55.73; H, 7.92; N, 4.00; M^++1, 346.1865. Calcd for $C_{16}H_{27}NO_7$: C, 55.64; H, 7.88; N, 4.06; M+1, 346.1864.

2,2-Bis(methoxycarbonyl)-6-ethyl-6-hydroxy-1-azabicyclo-[3.2.0]heptane (9). The *t*-butyl ester **8** (439 mg, 1.3 mmol) in 10 ml of 4 mol dm^{-3} HCl-dioxane was kept for 4 h at room temperature and the solution was concentrated to dryness in vacuo. The residue was subjected to Sephadex LH-20 column chromatography using methanol to give 336 mg of a β-amino acid as an amorphous solid (81% yield): IR (KBr) 1750 cm^{-1}; ^1H NMR (D_2O) δ=0.92 (3H, t, J=7.5 Hz), 1.6—3.0 (6H, m), 3.90 (6H, s), and 4.25 (1H, dd, J=8.0 and 9.5 Hz).

Dicyclohexylcarbodiimide (42 mg, 0.20 mmol) was added to a solution of 59 mg (0.18 mmol) of the β-amino acid in 5 ml of acetonitrile and stirred for 10 min. After 37 μl (0.27 mmol) of triethylamine was dropped into the solution, stirring was continued at 60 °C for 4 h. Concentration under reduced pressure gave a solid, which was taken into 4 ml of ethyl acetate and filtered. The ethyl acetate was removed by evaporation. The residue was applied on a silica-gel column (4 g) and developed with benzene-ethyl acetate (2 : 1), providing 43 mg of a bicyclic β-lactam **9** (88% yield): IR ($CHCl_3$) 1770 and 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.02 (3H, t, J=7.5 Hz), 1.65—2.2 (6H, m), 2.62 (2H, dd, J=4.5 and 9.0 Hz), 3.64 (1H, s), 3.80 (6H, s), and 3.83 (1H, m); MS (FD) m/z 271 (M^+).

2,2-Bis(methoxycarbonyl)-6-ethyl-6-methyoxy-1-azabicyclo-[3.2.0]heptan-7-one (11). A suspension of 50 mg (0.19 mmol) of the alcohol **9**, 215 mg (0.93 mmol) of silver dioxide and 0.23 ml (3.8 mmol) of methyl iodide in 5 ml of *N,N*-dimethylformamide was heated at 40 °C for 4.5 h and diluted with 20 ml of ethyl acetate. After filtration, the filtrate was evaporated to give an oil, which was purified by silica-gel column chromatography with benzene-ethyl acetate (5 : 1). A colorless oil of a methyl ether **11** (48 mg, 90% yield) was obtained from the eluate: IR ($CHCl_3$) 1765 and 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.95 (3H, t, J=7.5 Hz), 1.5—2.15 (4H, m), 2.60 (2H, dd, J=7.0 and 9.0 Hz), 3.47 (3H, s), 3.80 (6H, s), and 3.91 (1H, dd, J=7.5 and 8.5 Hz); ^{13}C NMR ($CDCl_3$) δ=6.8 (q), 23.8 (t), 25.5 (t), 39.7 (t), 53.3 (q), 53.4 (q), 68.5 (d), 70.8 (s), 84.6 (s), 167.4 (s), 168.9 (s), and 173.8 (s).

Found: C, 52.88; H, 6.28; N, 5.10; M^+, 285. Calcd for $C_{12}H_{17}NO_6$: C, 53.13; H, 6.32; N, 5.16; M, 285.

6-Ethyl-6-methoxy-2-methoxycarbonyl-1-azabicyclo[3.2.0]-heptan-7-ones (12a and 12b). A solution of 130 mg (0.46 mmol) of the diester **11** in 10 ml of acetone was mixed at 0 °C with 4.6 ml of 0.1 mol dm^{-3} NaOH, and stirred for 1 h. After the acetone was removed by evaporation, the concentrate was diluted with 26 ml of ethyl acetate and then carefully acidified to pH 2 with 0.1 mol dm^{-3} HCl (about 4.7 ml). The organic layer was separated, washed with brine, dried (Na_2SO_4), and concentrated to dryness in vacuo to afford 123 mg of a monocarboxylic acid. The crude monocarboxylic acid was dissolved in 10 ml of pyridine and heated at 100 °C for 7 h. Evaporation of the solvent gave a residue, which was dissolved in 1 ml of dichloromethane and chromatographed on 8 g of silica gel with benzene-ethyl acetate (5 : 1) to provide 45 mg (43% yield) of **12a** and 9 mg (9% yield) of **12b**. From the silica-gel column, 40 mg (31%) of the monocarboxylic acid was recovered with methanol. **12a**: IR ($CHCl_3$) 1750 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.98 (3H, t, J=7.0 Hz), 1.4—2.35 (6H, m), 3.49 (3H, s), 3.73 (3H, s), 3.97 (1H, t, J=6.5 Hz), and 4.44 (1H, t, J=6.0 Hz); MS (FD) m/z 227 (M^+).

12b: IR ($CHCl_3$) 1755 and 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.98 (3H, t, J= 7.0 Hz), 1.6—2.0 (4H, m), 2.15—2.5 (2H. m), 3.46 (3H, s), 3.74 (3H, s) and 3.7—4.0 (2H, m); MS (FD) m/z 227 (M^+), 212 (M^+-CH_3).

6-Ethyl-6-methoxy-2-phenylseleno-7-oxo-1-azabicyclo-[3.2.0]heptane-2-carboxylic Acid Methyl Esters (13a and 13b). A solution of 6.6 mmol of butyllithium in 2.83 ml of hexane was added at −30 °C under nitrogen to a solution of 0.94 ml (6.6 mmol) of diisopropylamine in 30 ml of THF and cooled to −70 °C. A solution of 285 mg (1.3 mmol) of an isomeric mixture of **12a** and **12b** was added dropwise to the reaction mixture within 5 min. After the temperature of the solution was raised to −30 °C, 1.27 g (1.3 mmol) of benzeneselenenyl chloride in 3 ml of THF was added to the mixture and stirred for 30 min below −30 °C. Ammonium chloride (0.5 g) was added to the reaction mixture and then poured in 300 ml of ethyl acetate. The ethyl acetate was separated, rinsed with water, dried (Na_2SO_4) and concentrated to dryness in vacuo. The residue was subjected to silica-gel column chromatography with benzene-ethyl acetate (10 : 1) to afford a mixture of **13a** and **13b** (300 mg, 61% total yield), and a portion of the mixture was subjected to preparative silica-gel TLC (benzene-ethyl acetate 5 : 1) to give **13a** and **13b**, respectively.

13a: IR ($CHCl_3$) 1760 and 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.92 (3H, t. J=7.5 Hz), 1.65—2.0 (4H, m), 2.25—2.75 (2H, m), 3.33 (3H, s), 3.42 (1H, t, J=7.5 Hz), 3.82 (3H, s), 7.3—7.5 (3H, m), and 7.6—7.8 (2H, m); MS (EI) m/z 384, 383, and 382.

13b: IR ($CHCl_3$) 1755 and 1730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00 (3H, t, J=7.5 Hz), 1.65—2.1 (2H, m), 2.4—2.85 (2H, m), 3.49 (3H, s), 3.57 (3H, s), 3.90 (1H, dd, J=6.5 and 10.0 Hz), 7.3—7.45 (3H, m), and 7.6—7.8 (2H, m): MS (EI) m/z 384, 383, 382, and 381.

Direct Derivation of 13a and 13b from 11. A mixture of 242 mg (0.85 mmol) of the methyl ester **11**, 253 mg (1.70 mmol) of sodium iodide and 265 mg (0.85 mmol) of diphenyl diselenide in 2 ml of hexamethylphosphoric triamide was heated at 80 °C for 2 h, poured into 5 ml of ice-water, and extracted 3 times with 10 ml each of benzene. The combined benzene extracts were washed with brine, dried (Na_2SO_4), and concentrated in vacuo, giving an oil. The oil was chromatographed on silica gel using benzene-acetone (10 : 1) to provide 95 mg of **13a** and 55 mg of **13b** (50% total yield) together with 75 mg of the methyl ester **11** (31% yield).

6-Ethyl-6-methoxy-7-oxo-1-azabicyclo[3,2,0]hept-2-ene-2-carboxylic Acid Methyl Ester (14). Into a solution of the isomeric mixture of the selenides **13a** and **13b** (45 mg, 0.12 mmol) in 8 ml of dichloromethane was dropped a solution at −30 °C of 20.3 mg (0.12 mmol) of *m*-chloroperbenzoic acid in 1 ml of dichloromethane and stirred at −30 °C for 15 min. The reaction mixture was quenched with 17 μl (0.16 mmol) of triethylamine and diluted with 50 ml of dichloromethane. The organic layer was separated, washed twice with 25 ml each of aqueous saturated $NaHCO_3$ and once with 25 ml of brine, dried (Na_2SO_4), and concentrated to dryness under reduced pressure. The residue was purified by preparative TLC (benzene-acetone 5 : 1), affording 20 mg of a carbapenem **14** as a colorless oil (76% yield): UV (CH_2Cl_2) 282 nm (ε 5000); IR ($CHCl_3$) 1775 and 1728 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.02 (3H. *t*, J=7.0 Hz), 1.65—2.05 (2H, m), 2.81 (2H, dd, J=3.0 and 9.8 Hz), 3.53 (3H, s), 3.83 (3H, s), 4.45 (1H, t, J=9.8 Hz), and 6.37 (1H, t, J=3.0 Hz).

3-[2-(Acetamido)ethylthio]-6-ethyl-6-methoxy-7-oxo-1-azabicyclo[3.2.0]heptane-2-carboxylic Acid Methyl Esters (15a—c). Triethylamine (127 μl, 0.92 mmol), and then a solution of 94 mg (0.79 mmol) of *N*-acetylcysteamine in 1 ml of *N*,*N*-dimethylformamide were added at −30 °C to 130 mg (0.61 mmol) of the carbapenem **14** in 12 ml of *N*,*N*-dimethylformamide, warmed to 25 °C, and stirred for 1 h at the same temperature. After the solvent was removed by evaporation under reduced pressure, the residue was purified by Bio-Beads S-X3 (200—400 mesh) column (100 ml) chromatography using benzene and by silica-gel column chromatography with benzene-acetone (2 : 1), giving an isomeric mixture (193 mg, 95% total yield) which was further subjected to silica-gel column chromatography for separation of each isomer (**15a**, **15b**, or **15c**) under delicately controlled development conditions:

15a: IR ($CHCl_3$) 1760 and 1670 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.06 (3H, t, J=7.0 Hz), 1.3—2.6 (4H. m), 2.00 (3H, s), 2.77 (2H, m), 3.1—3.6 (3H, m), 3.50 (3H, s), 3.79 (3H, s), 4.18 (1H, dd, J=3.0 and 8.0 Hz), 4.72 (1H, d, J=8.0 Hz), and 6.0—6.4 (1H, br); MS (EI) m/z 344 (M^+) and 316.

15b: IR ($CHCl_3$) 1760 and 1670 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.98 (3H, t, J=7.0 Hz), 1.4—3.2 (6H, m), 2.01 (3H, s), 3.2—3.6 (2H, m), 3.50 (3H, s), 3.6—4.1 (2H, m), 3.81 (3H, s), 4.33 (1H, d, J=6.0 Hz), and 6.0—6.5 (1H, br); MS (EI) m/z 344 (M^+) and 316.

15c: IR ($CHCl_3$) 1760, 1740, and 1670 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.97 (3H, t, J=7.0 Hz), 1.5—2.4 (4H, m), 2.00 (3H, s), 2.5—3.0 (2H, m), 3.2—3.5 (2H, m), 3.47 (3H, s), 3.6—4.0 (2H, m), 3.80 (3H, s), 4.19 (1H, d, J=8.0 Hz), and 5.9—6.4 (1H, br); MS (EI) m/z 344 (M^+) and 316.

3-[2-(Acetamido)ethylthio]-6-ethyl-6-methoxy-7-oxo-1-azabicyclo[3.2.0]heptane-2-carboxylic Acid *p*-Nitrobenzyl Ester (16). A tenth mol dm^{-3} NaOH (476 μl) was dropped at 0 °C into a solution of 15.8 ml (48 μmol) of the methyl ester isomers **15a—c** in 3 ml of acetone and agitated for 1.5 h. The reaction mixture was mixed at 0 °C with 240 μl of 0.1 mol dm^{-3} HCl and concentrated to dryness by repeated azeotropic evaporation with benzene. The residue was dissolved in 1.5 ml of *N*,*N*-dimethylformamide. *p*-Nitrobenzyl bromide (15.4 mg, 71 μmol) and triethylamine (17 μl, 120 μmol) were added at 0 °C to the solution, and stirred for 12 h at room temperature. The reaction mixture was diluted with 20 ml of ethyl acetate and washed twice with 7 ml each of brine. Drying (Na_2SO_4) and evaporation in vacuo give an oil, which was purified by preparative silica-gel TLC with benzene-acetone (1 : 1) to afford a mixture of *p*-nitrobenzyl esters **16** (15.3 mg, 72% yield): IR ($CHCl_3$) 1760 and 1670 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.96 (3H, t, J=7.5 Hz), 1.4—3.1 (6H, m), 2.0 (3H, s), 3.2—3.6 (2H, m), 3.50 (3H, s), 3.6—4.1 (2H, m), 4.38 (1H, d, J=6.0 Hz), 5.3 (2H, s), 5.8—6.2 (1H, br), 7.55 (2H, d, J=9.0 Hz), and 8.27 (2H, d, J=9.0 Hz).

Found: m/z 466.1629. Calcd for $C_{21}H_{28}N_3SO_7$: M^++1, 466.1644.

3-[2-(Acetamido)ethylthio]-6-ethyl-6-methoxy-7-oxo-1-azabicyclo[3.2.0]hept-2-ene-2-carboxylic Acid *p*-Nitrobenzyl Ester (18). To a solution of 15 mg (32 μmol) of the carbapenam **16** in 2 ml of dichloromethane was added dropwise at 0 °C first 13 μl (160 μmol) of pyridine containing 0.57 μl (32 μmol) of water, and then 23 mg (81 μmol) of (dichloroiodo)benzene in 0.5 ml of dichloromethane. After stirring for 30 min, 12 μl (81 μmol) of triethylamine was added to the mixture and was stirred for 15 min. further 30 min. The reaction mixture was mixed with 8 μl (33 μmol) of tributyl phosphine at 0 °C and stirred for 15 min. Silica-gel column chromatography using benzene-acetone mixtures of (10 : 1), (5 : 1), (2 : 1), and (1 : 1) gave 8.0 mg (54% yield) of a carbapenem **18**: UV ($CHCl_3$) 271 (ε 10200) and 324 nm (11400); IR ($CHCl_3$) 1772, 1700, and 1675 cm^{-1}; ^1H NMR ($CDCl_3$) δ= 1.03 (3H, t, J=7.5 Hz), 1.7—2.05 (2H, m), 1.98 (3H, s), 2.8—3.55 (6H, m), 3.50 (3H, s), 4.40 (1H, t, J=10.0 Hz), 5.22 (1H, d, J=14.0 Hz), 5.51 (1H, d, J=14.0 Hz), 6.17 (1H, br), 7.67 (2H, d, J=9.0 Hz), and 8.20 (2H, d, J=9.0 Hz).

Found: m/z 463.1401. Calcd for $C_{21}H_{25}N_3SO_7$: M, 463.1410.

3-[2-(Acetamido)ethylthio]-6-ethyl-6-methoxy-7-oxo-1-azabicyclo[3.2.0]hept-2-ene-2-carboxylic Acid Sodium Salt (6-Methoxy-epi-PS 5 Na Salt: 1). A solution of 95 mg (0.20 mmol) of the *p*-nitrobenzyl ester **18** was dissolved in 12 ml of a 2 : 1 mixture of tetrahydrofuran and 0.1 mol dm^{-3} phosphate buffer (pH 7.6) and hydrogenated at room temperature for 3 h at a hydrogen pressure of 4 kg cm^{-2} in the presence of platinum dioxide (100 mg). The filtrate was subjected to column chromatographic purification on QAE-Sephadex A-25 (Pharmacia Fine Chemicals AB, Sweden) and on Diaion CHP-20P (Mitsubishi Chemical Industries Ltd., Japan). Eluate fractions which indicated a UV absorption maximum

at 305.5 nm were combined and lyophilized to provide a white powder of the sodium salt of **1** in 70% yield (50 mg): UV (H_2O) 305.5 nm (ε 8000); IR (KBr) 1752, 1665, and 1608 cm^{-1}; ^1H NMR (D_2O) δ=0.96 (3H, t, J=7.5 Hz), 1.87 (2H, q, J=7.5 Hz), 1.97 (3H, s), 2.7—3.5 (6H, m), 3.50 (3H, s), and 4.43 (1H, t, J=10.0 Hz); ^{13}C NMR (D_2O, Dioxane) δ=7.1 (q), 22.8 (q), 23.9 (t), 31.7 (t), 35.8 (t), 40.4 (t), 54.2 (d), 60.4 (q), 92.6 (s), 128.3 (s), 130.8 (s), 168.5 (s), 175.2 (s), and 177.1 (s).

2,2-Bis(methoxycarbonyl)-6-ethyl-6-tetrahydropyranyloxy-1-azabicyclo[3.2.0]heptan-7-one (21). 3,4-Dihydro-2*H*-pyran (3.87 ml, 43 mmol) and anhydrous *p*-toluenesulfonic acid (0.15 g, 0.85 mmol) were added at 0 °C to a solution of 2.30 g (8.5 mmol) of **9** in 60 ml of ethyl acetate and stirred for 2 h at room temperature. After quenching with 0.18 ml (1.3 mmol) of triethylamine, the reaction solution was diluted with 100 ml of ethyl acetate, washed with aqueous saturated $NaHCO_3$ and brine, and dried (Na_2SO_4). The solvent was eliminated by evaporation and the residue was purified by silica-gel column chromatography with benzene-ethyl acetate mixtures of (20 : 1), (10 : 1), (5 : 1), and (3 : 1) as eluents to afford 2.91 g (97% yield) of an anomeric mixture of **21**: ^1H NMR ($CDCl_3$) δ=0.85—1.2 (3H, m), 1.25—2.25 (10H, m), 2.25—2.75 (2H, m), 3.3—4.4 (3H, m), 3.70 (6H, s), and 4.8—5.25 (1H, m), MS (FD) m/z 356 (M^++1).

6-Ethyl-7-oxo-2-phenylseleno-6-tetrahydropyranyloxy-1-azabicyclo[3.2.0]heptane-2-carboxylic Acid Methyl Ester (22). A solution containing 2.85 g (8.0 mmol) of **21**, 2.53 g (8.0 mmol) of diphenyl diselenide, and 2.41 g (16 mmol) sodium iodide in 15 ml of hexamethylphosphoric triamide was heated at 80 °C for 4 h. As described for **13a** and **13b**, a mixture of the four isomers of **22** (2.22 g, 61% yield) was obtained together with unreacted **21** (0.64 g): IR ($CHCl_3$) 1755 and 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.80—1.25 (3H, m), 1.3—2.25 (10H, m), 2.25—2.8 (2H, m), 3.3—4.45 (6H, m), 4.8—5.25 (1H, m), 7.2—7.5 (2H, m), and 7.6—7.9 (2H, m).

6-Ethyl-7-oxo-6-tetrahydropyranyloxy-1-azabicyclo[3.2.0]-hept-2-ene-2-carboxylic Acid Methyl Esters (23a and 23b). The treatment described for **14** was repeated with the isomeric mixture **22**, giving a 1 : 1 mixture of two anomers **23a** and **23b** in 80% yield. **23a**: IR ($CHCl_3$) 1780, 1737, and 1618 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.07 (3H, t, J=7.5 Hz), 1.35—2.05 (8H, m), 2.65—2.95 (2H, m), 3.3—4.2 (2H, m), 3.80 (3H, s), 4.72 (1H, t, J=10.0 Hz), 5.00 (1H, br), and 6.32 (1H, t, J=3.0 Hz); MS (FD) m/z 295 (M^+).

23b: IR ($CHCl_3$) 1780, 1737, and 1618 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.10 (3H, t, J=7.5 Hz), 1.35—2.1 (8H, m), 2.65—2.9 (2H, m), 3.4—4.2 (2H, m), 3.84 (3H, s), 4.52 (1H, t, J=10.0 Hz), 5.18 (1H, br), and 6.33 (1H, t, J=3.0 Hz); MS (FD) m/z 295 (M^+).

3-[2-(Acetamido)ethylthio]-6-ethyl-7-oxo-6-tetrahydropyranyloxy-1-azabicyclo[3.2.0]heptane-2-carboxylic Acid Methyl Ester (24). Under reaction conditions similar to those described for **15a**, **15b**, and **15c**, 4.4 g (84% yield) of an isomeric mixture of **24** was obtained from 3.7 g of the mixture of **23a** and **23b**: IR ($CHCl_3$) 1758 and 1665 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.8—1.2 (3H, m), 1.3—2.15 (9H, m), 2.00 (3H, s), 2.15—3.0 (3H, m), 3.0—4.8 (7H, m), 3.77 (3H, m), 4.8—5.25 (1H, m), and 6.20 (1H, br); MS (FD) m/z 415 (M^++1).

3-[2-(Acetamido)ethylthio]-6-ethyl-7-oxo-6-tetrahydropyranyloxy-1-azabicyclo[3.2.0]heptane-2-carboxylic Acid *p*-Nitrobenzyl Ester (25). Treatment of 134 mg (0.32 mmol) of **24** with 0.1 mol dm^{-3} NaOH and *p*-nitrobenzyl bromide gave 131 mg (76% yield) of **25**: IR ($CHCl_3$) 1750 and 1665 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.85—1.2 (3H, m), 1.3—2.15 (9H, m), 2.15—3.0 (3H, m), 3.2—3.65 (3H, m), 3.65—4.05 (2H, m), 4.15 (1H, t, J=7.0 Hz), 4.33 (1H, d, J=6.0 Hz), 4.8—5.2 (1H, m), 5.35 (2H, s), 6.00 (1H, br), 7.50 (2H, d, J=9.0 Hz), and 8.13 (2H, d, J=9.0 Hz); MS (FD) m/z 536 (M^++1).

3-[2-(Acetamido)ethylthio]-6-ethyl-6-hydroxy-7-oxo-1-azabicyclo[3.2.0]heptane-2-carboxylic Acid *p*-Nitrobenzyl Ester (26). Pyridinium *p*-toluenesulfonic acid (0.71 g, 2.8 mmol) was added to a solution of 6.0 g (11 mmol) of the tetrahydropyranyl ether **25** in 120 ml of ethanol and stirred at 50 °C for 5 h. After dilution with 600 ml of ethyl acetate, the reaction mixture was washed successively with saturated aqueous $NaHCO_3$ and with brine, dried (Na_2SO_4), and evaporated to dryness. The residue was chromatographed on a silica-gel column with benzene-acetone (2 : 1), providing 4.1 g (81% yield) of an alcohol **26**: IR ($CHCl_3$) 1745 and 1665 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.85—1.2 (3H, m), 1.45—2.0 (3H, m), 1.94 (3H, s), 2.2—2.75 (3H, m), 3.2—3.6 (3H, m), 3.6—4.0 (2H, m), 4.0—4.8 (2H, m), 5.25 (2H, s), 6.22 (1H, br), 7.45 (2H, d, J=9.0 Hz), and 8.12 (2H, d, J=9.0 Hz); MS (FD) m/z 451 (M^+).

3-[2-(Acetamido)ethylthio]-6-ethyl-7-oxo-6-trimethylsilyloxy-1-azabicyclo[3.2.0]heptane-2-carboxylic Acid *p*-Nitrobenzyl Ester (27). The alcohol **26** (2.61 g, 5.8 mmol), triethylamine (16.0 ml, 120 mmol), and trimethylchlorosilane (13.9 ml, 110 mmol) were dissolved in 100 ml of tetrahydrofuran and stirred for 12 h at room temperature. The reaction mixture was diluted with 300 ml of ethyl acetate, washed with brine, dried (Na_2SO_4), and concentrated to give a residue. The residue was purified by silica-gel column chromatography with benzene-acetone (3 : 1) to give 2.22 g of **27** (73% yield): IR ($CHCl_3$) 1755 and 1668 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.20 (9H, s), 0.8—1.15 (2H, m), 1.3—2.0 (3H, m), 1.96 (3H, s), 2.25—2.9 (3H, m), 3.2—3.55 (2H, m), 3.55—4.0 (2H, m), 4.3—4.75 (1H, m), 5.27 (2H, s), 6.51 (1H, br), 7.48 (2H, d, J=9.0 Hz), and 8.13 (2H, d, J=9.0 Hz); MS (FD) m/z 523 (M^+).

3-[2-(Acetamido)ethylthio]-6-ethyl-7-oxo-6-trimethylsilyloxy-1-azabicyclo[3.2.0]hept-2-ene-2-carboxylic Acid *p*-Nitrobenzyl Ester (28). The treatment of the carbapenam **27** as described for **18** gave a carbapenem **28**: IR ($CHCl_3$) 1770, 1700, and 1678 cm^{-1}; UV ($CHCl_3$) 271 (ε 10700) and 325 nm (12000); ^1H NMR ($CDCl_3$) δ=0.27 (9H, s), 1.07 (3H, t, J=7.5 Hz), 1.78 (2H, q, J=7.5 Hz), 1.99 (3H, s), 2.8—3.7 (6H, m), 4.20 (1H, t, J=10.0 Hz), 5.22 (1H, d, J=14.0 Hz), 5.47 (1H, d, J=14.0 Hz), 6.15 (1H, br), 7.63 (2H, d, J=9.0 Hz), and 8.16 (2H, d, J=9.0 Hz), MS (FD) m/z 521 (M^+).

3-[2-(Acetamido)ethylthio]-6-ethyl-6-hydroxy-7-oxo-1-azabicyclo[3.2.0]hept-2-ene-2-carboxylic Acid *p*-Nitrobenzyl Ester (29). Twenty milliliter of 0.001 mol dm^{-3} HCl was added dropwise at 0 °C to a solution of 46 mg (88 μmol) of the trimethylsilyl ether **28** in 20 ml of ethanol and agitated for 30 min. The solution was mixed with 200 ml of ethyl acetate, washed with cold 5% $NaHCO_3$ and brine, dried (Na_2SO_4), and concentrated to dryness. The residue was chromatographed on silica gel with benzene and acetone (1 : 1) to give 34.5 mg (87% yield) of **29** as plates (recrystallized from benzene): mp 74—75 °C: IR (KBr) 1760 and 1690 cm^{-1}; UV (CH_2Cl_2) 271 (ε 11000) and 325.5 nm (11600); ^1H NMR ($CDCl_3$) δ=1.08 (3H, t, J=7.5 Hz), 1.62 (1H, br), 1.82 (2H, q, J=7.5 Hz), 1.96 (3H, s), 2.7—3.85 (6H, m), 4.23 (1H, t, J=10 Hz), 5.18 (1H, d, J=14.0 Hz), 5.45 (1H, d, J=14.0 Hz), 5.90 (1H, br), 7.60 (2H, d, J=9.0 Hz), and 8.12 (2H, d, J=9.0 Hz).

3-[2-(Acetamido)ethylthio]-6-ethyl-6-hydroxy-7-oxo-1-azabicyclo[3.2.0]hept-2-ene-2-carboxylic Acid Sodium Salt (6-Hydroxy-*epi*-PS 5 Na Salt: 2). Under the same conditions as for **1**, the *p*-nitrobenzyl ester **29** was hydrogenated to give a white powder of **2**: IR (KBr) 1750 and 1600 cm^{-1}; UV (H_2O) 304.5 nm (ε 8900); ^1H NMR (D_2O) δ=1.00 (3H, t, *J*=7.3 Hz), 1.82 (2H, q, *J*=7.3 Hz), 2.00 (3H, s), 2.7—3.5 (6H, m), and 4.22 (1H, t, *J*=9.6 Hz).

The authors are grateful to Professor Yasuji Yamada, Tokyo College of Pharmacy, for his valuable advice throughout this study, and to Mrs. Michiko Sakamoto and Miss Fumito Satoh for the antimicrobial and enzymological evaluations.

†Department of Chemistry, College of Science, Rikkyo University, Nishi-ikebukuro, Tokyo 171
(Received November 29, 1986)

In order to investigate the structure-activity relationship of the "gratisin"-related peptide, *cyclo*(-Val-Orn-Leu-D-Phe-Pro-D-Tyr-)$_2$ (GR-I), its two analogs, *cyclo*(-Val-Orn-Leu-D-Ala-Pro-D-Tyr-)$_2$ (**6a**) and *cyclo*(-Val-Orn-Leu-D-Phe-Pro-D-Ala-)$_2$ (**6b**), were synthesized. The CD spectra of these synthetic peptides in an aqueous solution were similar to that of GR-I, indicating that these peptides have similar conformations in an aqueous solution. The activity of **6b** was half that of GR-I, whereas **6a** did not show any antibiotic activity. These results indicated that the phenyl group of the D-Phe residue preceding the Pro residue is essential for exhibiting the activity, while the *p*-hydroxyphenyl group of the D-Tyr residue following the Pro residue is not essential.

A peptide antibiotic, gratisin, which shows activity against *Bacillus subtilis* 720, was isolated from *Bacillus brevis* Y-33 by Silaev et al.[1,2] In order to determine the primary structure of natural gratisin, we have ourselves synthesized several peptides on the basis of the primary structure proposed by Silaev et al. In these synthetic studies,[3] we found that *cyclo*(-Val-Orn-Leu-D-Phe-Pro-D-Tyr-)$_2$ (GR-I)[4] possesses the strongest activity against the gram-positive microorganisms tested and that it shows the same activity as that of gramicidin S-1 (GS)[5] toward *Bacillus subtilis;* we proposed that the amino-acid sequence of GR-I is most probable as that of natural peptide. We also reported that *cyclo*(-Val-Orn-Leu-D-Phe-Pro-D-Phe-)$_2$, in which D-Tyr residues at positions 6 and 6′ of GR-I are replaced with D-Phe residues, shows almost the same activity as does GR-I, indicating that the hydroxyl groups of the D-Tyr residues at positions 6 and 6′ are not necessary for exhibiting antibiotic activity.[3]

In order to investigate further the structure-activity relationship of GR-I, we synthesized two analogs, *cyclo*(-Val-Orn-Leu-D-Ala-Pro-D-Tyr-)$_2$ (**6a**) and *cyclo*(-Val-Orn-Leu-D-Phe-Pro-D-Ala-)$_2$ (**6b**) (Fig. 1), in which D-Phe-Pro-D-Tyr sequences in GR-I are replaced with D-Ala-Pro-D-Tyr and D-Phe-Pro-D-Ala sequences respectively. The roles of the side chains of the D-Phe residues at positions 4 and 4′ and of the D-Tyr residues at positions 6 and 6′ in GR-I for exhibiting the antibiotic activity were elucidated.

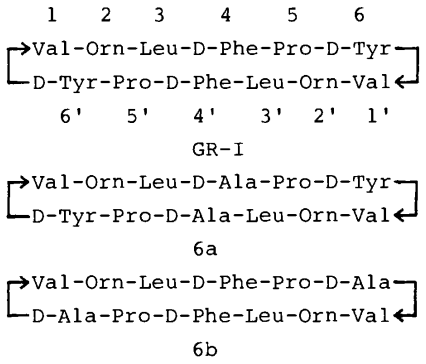

Fig. 1. Primary structures of GR-I and its analogs (**6a** and **6b**).

The routes of the syntheses of these peptides are shown in Fig. 2. In the synthesis of peptide **6a**, the Boc-hexapeptide benzyl ester (**1a**) was synthesized from the Pro benzyl ester by step-by-step elongation using dicyclohexylcarbodiimide (DCC) and 1-hydroxybenzotriazole (HOBt). Then, a part of the **1a** was converted into the corresponding hydrazide (**2a**). The coupling of **2a** with the hexapeptide benzyl ester derived from **1a** was carried out using the azide method; this afforded the Boc-dodecapeptide benzyl ester (**3a**). This ester **3a** was treated with hydrazine hydrate to give the corresponding hydrazide (**4a**), and then the Boc-group of **4a** was removed by the action of trifluoroacetic acid. The dodecapeptide hydrazide trifluoroacetate (**4a′**) thus obtained was changed to the azide by using isopentyl nitrite at −20 °C for 15 min. The azide could be cyclized under a high dilution in pyridine at 0 °C for 3 d. The resulting product was purified by means of silica-gel column chromatography, followed by recrystallization. The cyclododecapeptide (**5a**) was obtained in a 53% yield. The removal of all the masking group of **5a** by hydrogenolysis yielded **6a**. Peptide **6b** was synthesized in a similar manner. In the synthesis of **1b**, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (WSCD·HCl) was used as the coupling reagent instead of DCC. The yield of cyclization by the azide method was 67%. The homogeneities of the products were confirmed by means of thin-layer chromatography (TLC), amino-acid analysis, high-performance liquid chromatography (HPLC), and fast-atom-bombardment (FAB) mass spectrum.

The CD spectra of GR-I and its two analogs were measured in aqueous solutions (Fig. 3). Peptide **6a** showed almost the same CD curve as GR-I, although this analog does not contain aromatic side chains at positions 4 and 4′. In the CD spectrum of peptide **6b** we observed a curve similar to that of GR-I, but its trough was shallower than the troughs of GR-I. These results indicated that, in aqueous solutions, these synthetic peptides possess a conformation similar to that of GR-I; they also show that the aromatic side chains of the D-Phe residues at positions 4 and 4′ make only a

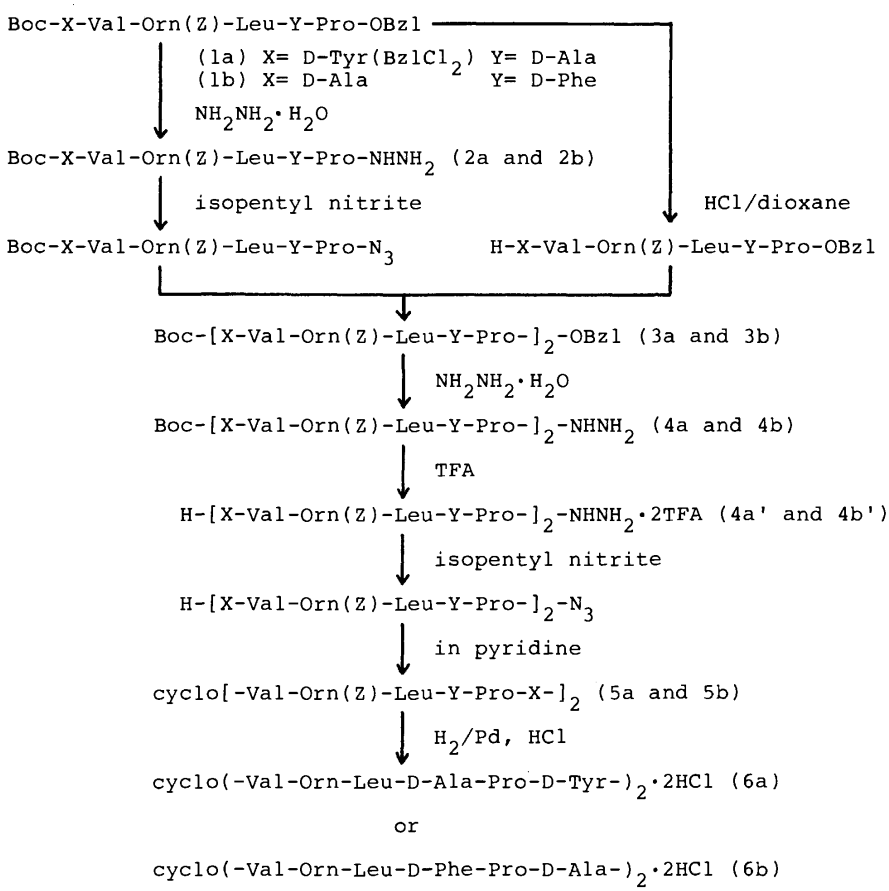

Fig. 2. Synthesis of peptides **6a** and **6b**.

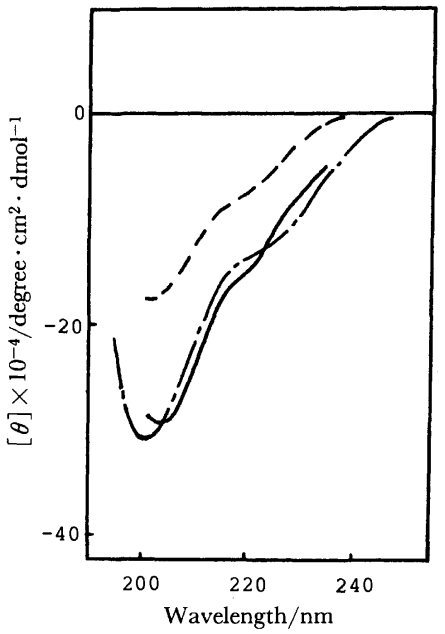

Fig. 3. CD spectra of **6a** ——, **6b**----, GR-I -·-·- in water.

small contribution to the conformation in an aqueous solution.

The antibiotic activity of these synthetic peptides is summarized in Table 1. Peptide **6a**, which has a D-Ala-Pro-D-Tyr sequence, showed no activity against the microorganisms tested, although this peptide possesses almost the same CD curve as GR-I in an aqueous solution. Lee et al.[6] reported that [D-Ala$^{4,4'}$]GS containing D-Ala residues in place of D-Phe residues preceding Pro residues possesses about 1/8 of the activity of the natural GS against *Bacillus subtillis* and *Staphylococcus aureus*, and that its ORD spectrum is similar to that of GS. The difference in activity between **6a** and [D-Ala$^{4,4'}$]GS may result from the difference in their ring sizes, in other words, the difference in the rigidity of their ring conformations. The activity of **6b**, which has a D-Phe-Pro-D-Ala sequence, was half that of GR-I. These results indicated that, in GR-analog peptides, the phenyl group of the D-Phe residue preceding the Pro residue is essential for the activity, while the *p*-hydroxyphenyl group of the D-Tyr residue following the Pro residue is not essential. Further, no relationship between the CD spectra in aqueous solution and the antibiotic activities could be found.

As for the mode of action of gratisin and GS, it is considered that the most significant role for their antibiotic action is played by each ring conformation induced during the binding of their antibiotics to the bacterial cell.[7-9] In the present studies, it is suggested that peptides **6a** and **6b** in aqueous solutions have conformations similar to that of GR-I, but that, when these peptides interact with the bacterial cell, peptide

Table 1. Antibiotic Activity of GR-I and Its Analogs[a)]

Test organism	GR-I	6a	6b
Staph. aureus ATCC 6538 P	6.3	>50	12.5

Proteus vulgaris OX 19	>50	>50	>100

a) The minimum inhibitory concentration ($\mu g\,ml^{-1}$) was determined by means of an agar-dilution method with 10^6 organisms per milliliter.

6b can take an active conformation similar to that of GR-I, while peptide **6a** can not take the active conformation. This great contrast between the two peptides is caused by the removal of the aromatic ring of the residues at positions 4 and 4'.

Experimental[4)]

All the melting points are uncorrected. The CD spectra were obtained by use of a JASCO spectropolarimeter, model J-500, using a 1-mm quartz cell at room temperature. The CD spectroscopy of GR-I and its two analogs was carried out with an aqueous solution of their dihydrochlorides at the concentration of $1.1—1.5\times10^{-4}$ M (1 M=1 mol dm^{-3}). The molecular weights of these synthetic peptides were determined by FAB mass spectrometry using a JEOL D-300 mass spectrometer. Amino-acid analyses were carried out by means of a Hitachi 835 amino-acid analyzer after the hydrolysis of the peptides in 6 M HCl at 110 °C for 24 h. HPLC was performed by means of an ODS column (ϕ 4.6×250 mm), using MeOH-5% $NaClO_4$ aq (5:1) as the elution solvent. TLC was performed on Merck silica-gel F_{254} plates with the following solvent systems (v/v): R_f^1, $CHCl_3$-MeOH (9:1); R_f^2, $CHCl_3$-MeOH-AcOH (95:5:3); R_f^3, *n*-BuOH-AcOH-H_2O (4:1:1); R_f^4, *n*-BuOH-pyridine-AcOH-H_2O (4:1:1:2).

Boc-D-Tyr(BzlCl$_2$)-Val-Orn(Z)-Leu-D-Ala-Pro-OBzl (1a). DCC (2.06 g, 10 mmol) was added to a solution of Boc-D-Ala (1.90 g, 10 mmol), HOBt (1.49 g, 11 mmol), Pro-OBzl·HCl (2.42 g, 10 mmol), and NMM (1.1 ml, 10 mmol) in $CHCl_3$ (50 ml) at 0 °C. This solution was stirred for 2 h at 0 °C and then overnight at room temperature. After the reaction mixture has then been concentrated in vacuo, AcOEt (20 ml) was added to the residue and insoluble substances were removed by filtration. The filtrate was then diluted with AcOEt (200 ml). The solution was washed successively with 5% citric acid, water, 5% Na_2CO_3 and water, and dried over sodium sulfate. After the removal of the drying reagent, the solvent was evaporated in vacuo. The residue was dissolved in 4 M HCl/dioxane (20 ml) containing anisole (0.2 ml) at 0 °C. After stirring for 30 min at room temperature, the solution was concentrated in vacuo. The residue was dissolved in $CHCl_3$ (50 ml). The solution was washed with 10% Na_2CO_3 and water under cooling with an ice bath. To this solution we then added Boc-Leu (2.40 g, 10 mmol), HOBt (1.49 g, 11 mmol), and DCC (2.06 g, 10 mmol) at 0 °C. The same procedure as has been described above was repeated for this reaction mixture. Further, Boc-Orn(Z), Boc-Val, and Boc-D-Tyr(BzlCl$_2$) were successively coupled by the same method. All the reactions were followed by TLC on a silica-gel plate. The crude, protected hexapeptide obtained from the final reaction mixture was purified by chromatography on a silica-gel column (ϕ 2×50 cm), using a solvent system of $CHCl_3$-MeOH (50:1). The fractions containing the desired product were combined and concentrated. The product was reprecipitated from AcOEt-ether; overall yield, 3.28 g (28% from Pro-OBzl); mp 161—163 °C; $[\alpha]_D^{29}$ −13.2° (*c* 1, DMF); R_f^1 0.63, R_f^2 0.55.

Found: C, 62.20; H, 6.81; N, 8.82%. Calcd for $C_{60}H_{77}O_{12}N_7Cl_2$: C, 62.17; H, 6.69; N, 8.46%.

Boc-D-Ala-Val-Orn(Z)-Leu-D-Phe-Pro-OBzl (1b). This compound was prepared from Pro-OBzl·HCl (1.45 g, 6 mmol) in a manner similar to that described for the preparation of **1a**. In the synthesis of this compound, WSCD·HCl was used instead of DCC as the coupling reagent, and the reaction mixture was washed successively in a $CHCl_3$ solution with 5% citric acid and 5% Na_2CO_3; yield, 3.84 g (64%); mp 188—193 °C; $[\alpha]_D^{29}$ −33.5° (*c* 1, DMF); R_f^1 0.76, R_f^2 0.53.

Found: C, 64.54; H, 7.47; N, 10.05%. Calcd for $C_{53}H_{73}O_{11}N_7$: C, 64.68; H, 7.48; N, 9.96%.

Boc-D-Tyr(BzlCl$_2$)-Val-Orn(Z)-Leu-D-Ala-Pro-NHNH$_2$ (2a). A solution of **1a** (1.17 g, 1 mmol) and hydrazine hydrate (1.5 ml) in DMF (10 ml) was allowed to stand for 2 d at room temperature. The solution was concentrated in vacuo, and then water was added to the residue. The resulting solid product was collected by filtration; yield, 0.96 g (88 %); mp 167—170 °C; $[\alpha]_D^{29}$ −17.6° (*c* 1, DMF); R_f^1 0.49, R_f^2 0.33.

Found: C, 58.44; H, 6.92; N, 11.69%. Calcd for $C_{53}H_{73}O_{11}N_9Cl_2$: C, 58.77; H, 6.79; N, 11.64%.

Boc-D-Ala-Val-Orn(Z)-Leu-D-Phe-Pro-NHNH$_2$ (2b). Compound **1b** (1.81 g, 1.84 mmol) was treated with hydrazine hydrate in the manner described for the preparation of **2a**; yield, 1.20 g (72%); mp 171—173 °C; $[\alpha]_D^{29}$ −34.2° (*c* 1, DMF); R_f^1 0.54, R_f^2 0.49.

Found: C, 60.64; H, 7.74; N, 13.56 %. Calcd for $C_{46}H_{69}O_{10}N_9$: C, 60.84; H, 7.66; N, 13.88%.

Boc-[D-Tyr(BzlCl$_2$)-Val-Orn(Z)-Leu-D-Ala-Pro-]$_2$-OBzl (3a). Compound **1a** (0.95 g, 0.82 mmol) was dissolved in 4 M HCl/dioxane (15 ml) containing anisole (0.5 ml) at 0 °C. After stirring at room temperature for 30 min, the solution was concentrated in vacuo. Ether was added to the residue, and the resulting solid, H-D-Tyr(BzlCl$_2$)-Val-Orn(Z)-Leu-D-Ala-Pro-OBzl·HCl, was collected by filtration. To a solution of **2a** (0.86 g, 0.8 mmol) in DMF (20 ml) we added 4 M HCl/dioxane (0.6 ml, 2.4 mmol) and isopentyl nitrite (0.12 ml, 0.9 mmol) at −40 °C. After stirring at −20 °C for 15 min, the solution was cooled again to −40 °C and neutralized with TEA (0.34 ml, 2.4 mmol). This solution was combined with the chilled solution of H-D-Tyr(BzlCl$_2$)-Val-Orn(Z)-Leu-D-Ala-Pro-OBzl·HCl mentioned above and TEA (0.12 ml, 0.82 mmol) in DMF (12 ml). The mixture was stirred at 0 °C

for 3 d and then concentrated. The residue was dissolved in AcOEt (200 ml), and the solution was washed with 5% citric acid, water, 5% Na_2CO_3, and water, and dried over sodium sulfate. After the solution has been concentrated, the residue was purified by chromatography on a silica-gel column (ϕ 1.8×30 cm), using a solvent system of $CHCl_3$-MeOH (20 : 1), and the fractions containing the desired product were combined and concentrated. Further purification was performed by reprecipitation from $CHCl_3$-ether; yield, 0.90 g (53%); mp 202—205 °C; $[\alpha]_D^{29}$ −9.36° (*c* 1, DMF); R_f^1 0.55, R_f^2 0.77.

Found: C, 61.19; H, 6.81; N, 9.43%. Calcd for $C_{108}H_{138}O_{21}N_{14}Cl_4$: C, 61.47; H, 6.59; N, 9.29%.

Boc-[D-Ala-Val-Orn(Z)-Leu-D-Phe-Pro-]$_2$-OBzl (3b). This compound was prepared from **1b** (1.08 g, 1.1 mmol) and **2b** (1.00 g, 1.1 mmol) in a manner similar to that described for the preparation of **3a**. Purification was performed by silica-gel column chromatography, followed by recrystallization from AcOEt-ether; yield, 1.16 g (60%); mp 213—216 °C; $[\alpha]_D^{29}$ −35.8° (*c* 1, DMF); R_f^1 0.53, R_f^2 0.68.

Found: C, 64.02; H, 7.67; N, 11.13%. Calcd for $C_{94}H_{130}O_{19}N_{14}$: C, 64.14; H, 7.44; N, 11.14%.

Boc-[D-Tyr(BzlCl$_2$)-Val-Orn(Z)-Leu-D-Ala-Pro-]$_2$-NHNH$_2$ (4a). Compound **3a** (0.76 g, 0.36 mmol) was treated with hydrazine hydrate as has been described for the preparation of **2a**; yield, 0.61 g (83%); mp 206—210 °C; $[\alpha]_D^{29}$ −15.8° (*c* 1, DMF); R_f^1 0.51, R_f^2 0.26.

Found: C, 59.34; H, 6.83; N, 10.98%. Calcd for $C_{101}H_{134}O_{20}N_{16}Cl_4$: C, 59.64; H, 6.64; N, 11.02%.

Boc-[D-Ala-Val-Orn(Z)-Leu-D-Phe-Pro-]$_2$-NHNH$_2$ (4b). Compound **3b** (1.00 g, 0.57 mmol) was treated with hydrazine hydrate as has been described for the preparation of **2a**; yield, 0.90 g, (92%); mp 214—218 °C; $[\alpha]_D^{29}$ −36.0° (*c* 1, DMF); R_f^1 0.59, R_f^2 0.49.

Found: C, 61.43; H, 7.61; N, 13.13%. Calcd for $C_{87}H_{126}O_{18}N_{16}\cdot H_2O$: C, 61.39; H, 7.58; N, 13.16%.

***Cyclo*[-Val-Orn(Z)-Leu-D-Ala-Pro-D-Tyr(BzlCl$_2$)-]$_2$ (5a).** Compound **4a** (0.55 g, 0.27 mmol) was dissolved in TFA (10 ml) containing anisole (0.2 ml). The mixture was stirred for 40 min at room temperature and then concentrated in vacuo. The residue was triturated with ether and collected by filtration. To a solution of the trifluoroacetate of the dodecapeptide hydrazide in DMF (5 ml), we then added 4 M HCl/dioxane (0.2 ml) and isopentyl nitrite (0.041 ml, 0.30 mmol) at −40 °C. After stirring at −20 °C for 15 min, the mixture was poured, drop by drop, into pyridine (300 ml) at 0 °C. After stirring for 3 d at 0 °C, the solution was concentrated. The addition of water to the residue afforded a precipitate, which was then filtered and washed with water. Purification was performed by recrystallization from MeOH-ether; yield, 272 mg (53%); mp 270—275 °C (decomp); $[\alpha]_D^{29}$ −9.1° (*c* 0.8, DMF); R_f^1 0.72, R_f^2 0.55.

Found: C, 59.91; H, 6.75; N, 9.59 %. Calcd for $C_{96}H_{122}O_{18}N_{14}Cl_4\cdot 2H_2O$: C, 59.50; H, 6.55; N, 10.12%.

***Cyclo*[-Val-Orn(Z)-Leu-D-Phe-Pro-D-Ala-]$_2$ (5b).** This compound was prepared from **4b** (0.70 g, 0.42 mmol) as has been described for the preparation of **5a**. The purification of this compound was performed by chromatography on a silica-gel column (ϕ 1.8×20 cm), using a solvent system of $CHCl_3$-MeOH (50 : 1), followed by recrystallization from MeOH-ether; yield, 438 mg (67%); mp 271—276 °C (decomp); $[\alpha]_D^{29}$ −86.0° (*c* 0.8, DMF); R_f^1 0.72, R_f^2 0.53.

The Reactions of Tropone Tosylhydrazone Sodium Salt with Acetylene Derivatives Possessing Electron-Withdrawing Groups: A Novel Method of Synthesis of 1*H*-1,2-Benzodiazepine Derivatives

Katsuhiro SAITO
Department of Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received December 4, 1986)

Reactions of tropone tosylhydrazone sodium salt with dimethyl and diethyl acetylenedicarboxylate gave dimethyl and diethyl 1*H*-1,2-benzodiazepin-3,4-dicarboxylate, respectively. The same reactions, but using ethyl acetylenecarboxylate and 3-butyn-2-one, afforded ethyl 1*H*-1,2-benzodiazepin-4-carboxylate and 4-acetyl-1*H*-1,2-benzodiazepine, respectively, accompanied by 8-azaheptafulvene derivatives derived from the sodium salt and the acetylene derivatives, and *p*-toluenesulfinic esters formed from *p*-toluenesulfinic acid and the acetylene derivatives. Reactions of the sodium salt with ethyl 2-butynoate gave the corresponding sulfinic ester but afforded no diazepine derivative.

It is known that upon heating or irradiation, tropone tosylhydrazone sodium salt (**1**) generates nitrogen gas, sodium *p*-toluenesulfinate (**2**), and cycloheptatrienylidene (**3**), which is considered to be a singlet nucleophilic carbene[1] and to isomerize to an allene, cycloheptatetraene (**4**).[2] When heated in the presence of silver chromate, **1** affords 2-tosyl-2*H*-indazole (**6**) via a hydrazyl radical intermediate (**5**).[3]

The reactions of **1** with olefins have been well-studied and the following results are known. In reactions with ethylene derivatives **1** gives spiro[2.6]nonatriene derivatives (**7**) via the carbene (**3**),[1] on the other hand, in reactions with suitable dienes, such as anthracene, cyclopentadienone, or isobenzofuran derivatives, **1** affords the Diels-Alder-type addition products **8** via the allene (**4**).[2] However, papers concerning the reaction of **1** with acetylene derivatives are limited to reports concerning the reaction of **1** with phenylacetylene, where [2+2]-type adduct (**9**) and 2-phenylindene (**10**) are formed. The former is afforded via the allene-form (**4**) and the latter via an isomerization of **9**.[2]

As one part of the study on the reactivity of **1**, reactions of **1** with acetylene derivatives possessing electron-withdrawing groups were investigated to form benzo-1,2-diazepine derivatives, heptafulvene derivatives, and esters of *p*-toluenesufinic acid. Here, these results will be discussed.

Results

Tropone tosylhydrazone sodium salt (**1**) was allowed to react with two molar equivalents of dimethyl acetylenedicarboxylate (**11**) at 120 °C for 15 min in anhydrous diglyme. The ether extraction of the reaction mixture followed by silica-gel column chromatographic purification gave benzo-1,2-diazepine derivative (**12**) in a 34.0% yield. The same reaction, but using diethyl acetylenedicarboxylate (**13**), afforded the corresponding benzo-1,2-diazepine derivative (**14**)[4] in a 32.3% yield.

Reactions of **1** with ethyl acetylenecarboxylate (**15**) under analogous conditions as above afforded three products, benzo-1,2-diazepine derivative (**16**), 8-azaheptafulvene derivative (**17**), and ester of *p*-toluenesufinic acid (**18**) in the yields of 51.9, 1.5, and 24.8%, respectively. The same type of reaction of **1** with 3-butyn-2-one (**19**) gave benzo-1,2-diazepine derivative (**20**) and heptafulvene derivative (**21**) in the yields of 5.7 and 6.3%, respectively. The reaction of **1** with ethyl 2-butynoate (**22**) yielded sulfinic ester (**23**) in a 9.1% yield but gave no benzo-1,2-diazepine derivative. Reactions of **1** with diphenylacetylene (**24**) and 1-butyne (**25**) afforded no reaction product except **2** and polymeric resinous material.

The structure of **14** was determined on the basis of

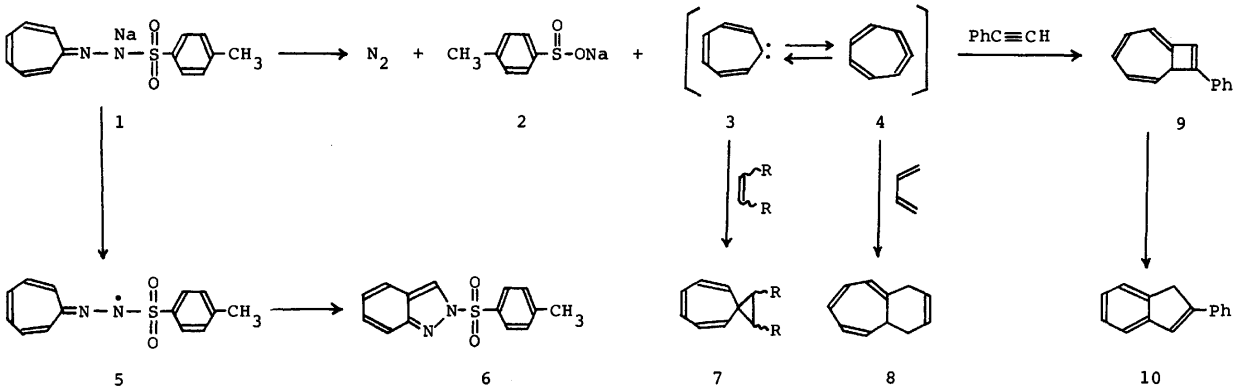

Fig. 1.

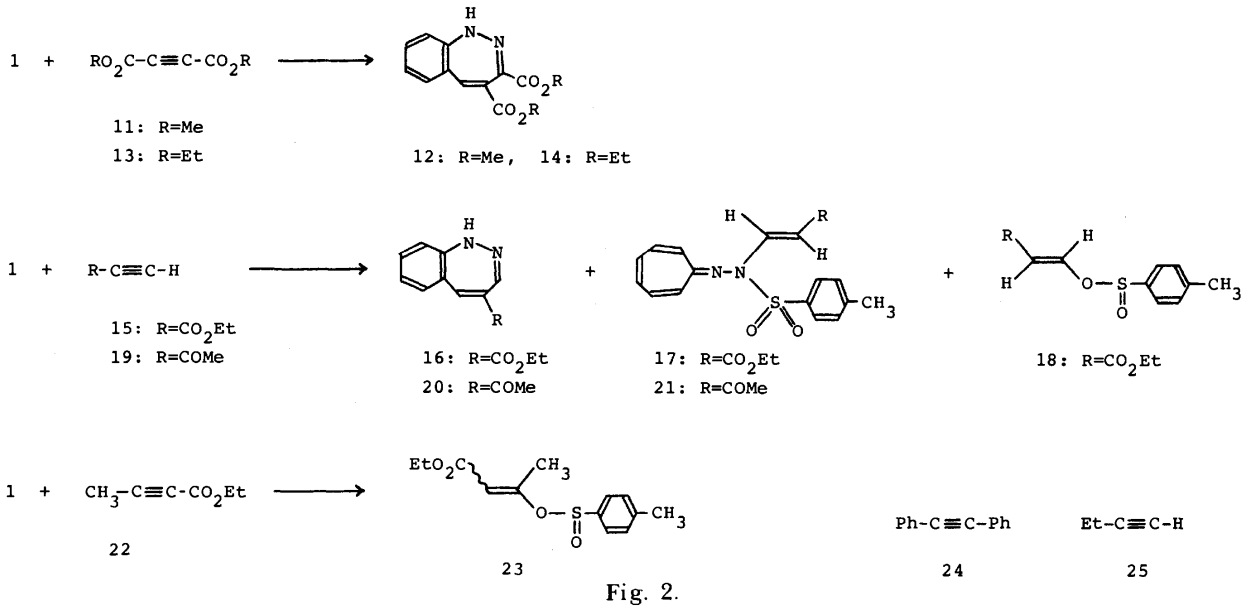

Fig. 2.

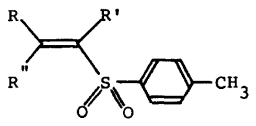

26

Fig. 3.

its spectral properties and was confirmed by a comparison of its melting point and spectral properties with those of the authentic sample.[4] The structures of the another benzo-1,2-diazepines were determined by the resemblance of their spectral properties to those of the analogous benzo-1,2-diazepines containing **14**.[4] The structures of **17** and **21** were determined as follows. The molecular ion peaks in their mass spectra and the elemental analyses show that **17** and **21** are the addition products of tropone tosylhydrazone and the corresponding acetylene derivatives (**15** and **19**), respectively. The multiplet signals corresponding to six protons at around δ 6.5—7.1 in the NMR spectra[5] and the absorption maximum at long wavelength in the UV spectra[6] suggest the existence of the 8-azaheptafulvene moiety in these products. The coupling constants (14 Hz) between the olefinic protons show that the configuration of these two protons is trans-configuration.[7]

The structures of **18** and **23** were determined on the basis of their spectral properties as follows. The coupling constant (15 Hz) between the olefinic protons shows that these two protons in **18** are in trans-configuration each other.[7] The absorption at 1150 cm^{-1} in the IR spectra demonstrates that the SO_2 groups of these products are sulfinyl groups and not sulfonyl groups such as **26**.[8]

Discussion

The formation of benzo-1,2-diazepine derivatives can be explained to be as follows. The thermal decomposition of the sodium salt (**1**) generates diazotropilidene (**27**).[9] The Michael-type addition of the anionic nitrogen atom of **27** to the acetylene derivatives[10] forms an ionic intermediate (**28**),[9e,11] which gives the bicyclic intermediate (**29**) by intramolecular cyclization. The valence tautomerization in the tropylidene moiety of **29** affords the norcaradiene-type intermediate (**30**),[12] which then forms the final products, benzo-1,2-diazepine derivatives via the cleavage of the three-membered ring.

The formation of the 8-azaheptafulvene dereivatives (**17**, **21**) and the sulfinic esters (**18**, **23**) are considered to proceed through Michael-type additions of the anions of tropone tosylhydrazone and *p*-toluenesulfinic acid to the corresponding acetylene derivatives, respectively.

There is an evident difference between reactions of **1** with acetylenes and reactions of **1** with olefins. It was clarified that reactions of **1** with acetylenes possessing electron-withdrawing groups proceed via diazotropilidene but that reactions with olefins proceed via carbene (**3**) or the allene (**4**). For example, the reaction of **1** with dimethyl acetylenedicarboxylate gives the benzo-1,2-diazepine derivative via diazotropilidene (**27**); on the other hand, reactions of **1** with dimethyl fumarate or maleate afford the spiro compounds **7** via the carbene (**3**).[1] No such product as **31** has ever been formed.

These differences in the reactivity can be explained as follows. The primary product of the decomposition of **1** is diazotropylidene (**27**).[9,13] In the case of the existence of acetylenes possessing electron-withdrawing groups, **27** reacts with the acetylenes to form **29** [Path A]. It is known that the nucleophilic reactions of reagents such as amines or imines with acetylene derivatives proceed easily more than do reactions with ethylene derivatives.[10] If there are no suitable acetylenes, **27** further decomposes to the carbene (**3**) or the allene (**4**) [Path B]. Probably, this decomposition of **27** proceeds more quickly than the reaction of **27** with olefins

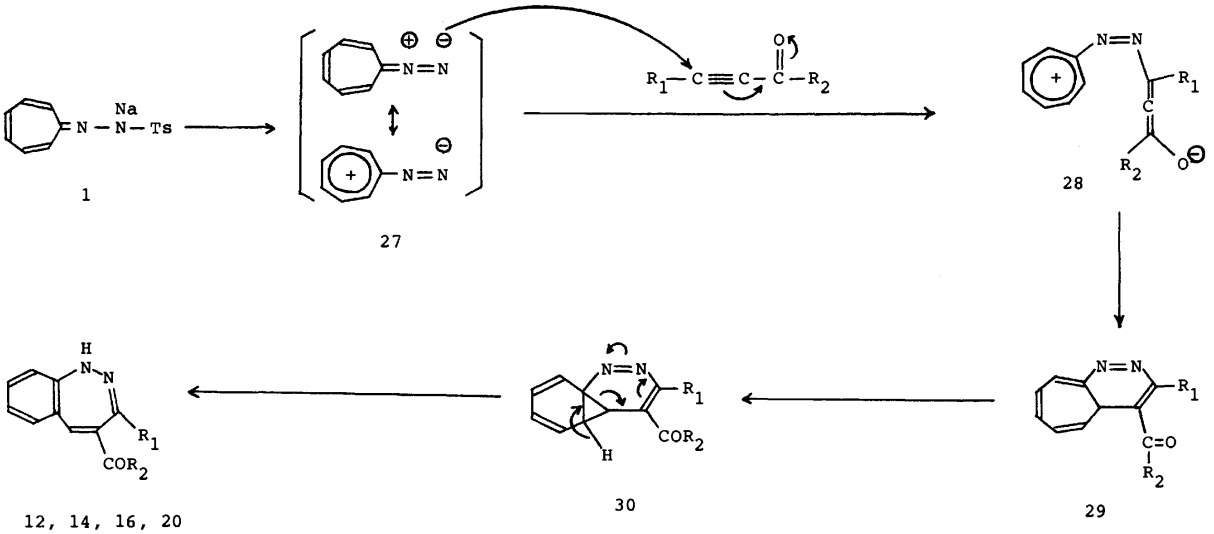

Fig. 4.

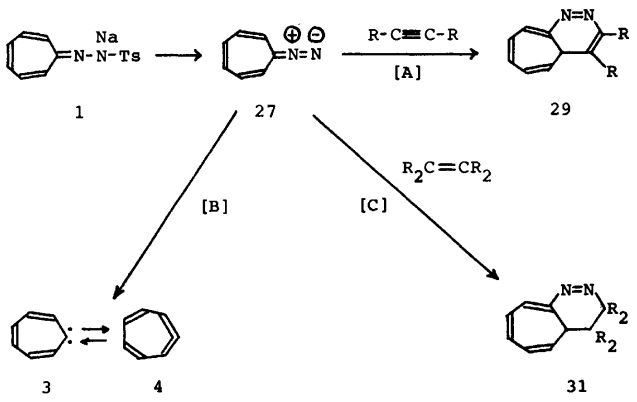

Fig. 5.

to give **31** [Path C].

The fact that reactions of **1** with the acetylene derivatives **22** and **25**, which have electron-donating groups do not afford the benzo-1,2-diazepine derivatives seems to partially support the above considerations. The inactivity of **27** toward diphenylacetylene (**24**) can be attributed to the fact that **24** have no strong electron-withdrawing groups.

Experimental

All melting points were uncorrected. NMR spectra were measured with Varian XL 200 or Hitachi R-20B spectrometers with tetramethylsilane as an internal standard. UV and IR spectra were measured with Hitachi 220A and DS-701G spectrometers, respectively. Mass spectra were measured with Hitachi M-52 or JMS-DX300 spectrometers. Wako gel C 200 and Wako gel B5F were used for column and thin-layer chromatography, respectively. Diglyme was dried over Molecular Sieves 3A 1/16.

Reaction of Tropone Tosylhydrazone Sodium Salt (1) with Dimethyl Acetylenedicarboxylate (11). A mixture of **1** (14.80 g, 50 mmol) and **11** (14.60 g, 100 mmol) in anhydrous diglyme (70 ml) was heated at 120 °C for 15 min. The reaction mixture was poured into water, extracted with ether, washed with water and brine, and dried over anhydrous sodium sulfate. After filtration the solvent was removed on a rotary evaporator to give a mixture of crystals of **12** and an oil. The crystals of **12** (4.010 g) were removed by filtration and the filtrate was column-chromatographed on silica gel to give the crystals of **12** (405 mg) by the use of benzene-ether 8:2. The total yield of **12** was 4.415 g, 34.0%. The crystals were recrystallized from cyclohexane to give pure crystals **12**.

12: Mp 153—154 °C. Found: C, 60.10; H, 4.95; N, 10.85%. Calcd for $C_{13}H_{12}N_2O_4$: C, 59.99; H, 4.95; N, 10.77%. UV (EtOH) 204 nm (log ε, 4.21), 257 (4.16), 285 (sh, 4.02). ^1H NMR (CD_3COCD_3) δ=3.70 (3H, s), 3.71 (3H, s), 6.8—7.4 (4H, m), 7.86 (1H, s), 8.10 (1H, broad s).

Reaction of Tropone Tosylhydrazone Sodium Salt (1) with Diethyl Acetylenedicarboxylate (13). A mixture of **1** (5.92 g, 20 mmol) and **13** (17.00 g, 100 mol) in anhydrous diglyme (50 ml) was heated at 120 °C for 15 min. The reaction mixture was treated as usual and chromatographed on silica gel to give crystals of **14** (1.86 g, 32.3%, mp 113—114 °C, lit,[4] 114° C) by the use of benzene-ether 8:2.

14: ^1H NMR (CD_3COCD_3) δ=1.28 (6H, two triplets), 4.15 (4H, two quartets), 6.75 (4H, m), 7.45 (1H, s), 7.80 (1H, broad s).

Reaction of Tropone Tosylhydrazone Sodium Salt (1) with Ethyl Acetylenecarboxylate (15). A mixture of **1** (5.92 g, 20 mmol) and **15** (9.80 g, 100 mmol) in anhydrous diglyme (50 ml) was heated at 120 °C for 15 min and the reaction mixture was treated as usual. The resulted oily material was column-chromatographed on silica gel to give crystals of **18** (1.26 g, 24.8%) by the use of benzene, crystals of **17** (110 mg, 1.5%) by the use of benzene-ether 50:1, and crystals of **16** (3.02 g, 51.9%) by the use of benzene-ether 50:1. The crystals of **16**, **17**, and **18** were recrystallized from cyclohexane to give pure compounds, respectively.

16: Mp 93—94 °C. Found: C, 66.59; H, 5.49; N, 13.09%. Calcd for $C_{12}H_{12}N_2O_2$: C, 66.65; H, 5.59; N, 12.96%. MS *m/z* (rel intensity): 216 (M^+, 63), 171 (14), 144 (18), 143 (100). IR (KBr) 3320, 3020, 2950, 1710, 1630. 1595 cm^{-1}. UV (EtOH): 211 nm (log ε, 4.13), 258 (4.22), 303 (sh, 3.45). ^1H NMR (CD_3COCD_3) δ=1.30 (3H, t), 4.24 (2H, q), 6.7—7.2 (4H, m), 7.32 (1H, d, J=1.5 Hz), 7.68 (1H, broad s), 7.78 (1H, d, J=1.5 Hz).

17: Mp 125—126 °C. Found: C, 61.33; H, 5.32; N, 7.41%.

Calcd for $C_{19}H_{20}N_2O_4S$: C, 61.27; H, 5.41; N, 7.52%. MS *m/z* (rel intensity): 372 (M^+, 2), 327 (3), 217 (100), 190 (3), 189 (5). IR (KBr) 3060, 2970, 1712, 1615, 1360, 1160 cm^{-1}. UV (EtOH): 235 nm (log ε, 4.39), 277 (4.18), 315 (4.05), 346 (sh, 3.95). ^1H NMR ($CDCl_3$) δ=1.25 (3H, t), 2.40 (3H, t), 4.11 (2H, q), 4.93 (1H, d, *J*=14 Hz), 6.5—7.2 (6H, m), 7.24 (2H, d, *J*=8 Hz), 7.74 (2H, d, *J*=8 Hz), 8.08 (1H, d, *J*=14 Hz).

18: Mp 89—90 °C: Found: C, 56.89, H, 5.52%. Calcd for $C_{12}H_{14}O_4S$: C, 56.69; H, 5.55%. MS *m/z* (rel intensity): 254 (M^+, 13), 145 (10), 139 (100), 97 (19). Crystal Structure of TTF·BTDA-TCNQ Complex. A New Type of CT Complex with an Inclusion Behavior and a Multi-Dimensional Structure

Takanori SUZUKI, Chizuko KABUTO,† Yoshiro YAMASHITA, and Toshio MUKAI*
Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Sendai 980
†Instrumental Analysis for Chemistry, Faculty of Science, Tohoku University, Aramaki, Sendai 980
(Received December 5, 1986)

The crystal structure of TTF·BTDA-TCNQ complex was determined by an X-ray diffraction method. The crystals are monoclinic, space group $P2_1/n$ with a=9.660(1), b=7.231(1), c=14.628(2) Å, β=91.31(1)°, and Z=2. The structure was solved by the direct method and refined by the block-diagonal least-squares method to give an R value of 0.040 for non-zero 2620 reflections. The complex is nonionic and the molecules form equally spaced mixed stacks along the b axis. These stacks are connected by strong transverse interactions resulting in a three-dimensional structure. BTDA-TCNQ molecules make cavities by S-N≡C interactions in which TTF molecules are included. This complex is not a simple CT complex with mixed stacks but rather the one with some inclusion behavior.

Recently, we have reported the preparation[1] and crystal structure[2] of bis(1,2,5-thiadiazolo)tetracyanoquinodimethan (BTDA-TCNQ),[3] which forms a two-dimensional "sheet-like network" by strong S-N≡C interactions in crystalline state. Thus, the charge-transfer complex or ion-radical salt of BTDA-TCNQ is proposed to exhibit a high-dimensional structure which could stabilize the metallic state[4] and induce the electrical conductivity along the side-by-side directions. In the course of our examination for the CT complexes of BTDA-TCNQ, the donors with the larger size such as tetrathianaphthacene (TTN) and dimethyldihydrophenazine (DMPH) have been proved to give highly conductive complexes with BTDA-TCNQ.[5,6] On the other hand, the CT complexes with tetrathiafulvalene (TTF) and its analogues exhibit very low electrical conductivities[5,6] though TTF·TCNQ complex is a representative organic metal.[7] We have succeeded in obtaining single crystals of TTF·BTDA-TCNQ.[8] This report describes the structural analysis of the title complex from which the causes of the low conductivity are discussed.

Experimental

TTF·BTDA-TCNQ complex (decomp 247—248 °C) was prepared by a diffusion method in dichloromethane using an H-shaped tube. The molar ratio was determined to be 1 : 1 on the basis of the elemental analysis. Found: C, 41.26; H, 0.58; N, 20.69; S, 36.72%. Calcd for $C_{18}H_4N_8S_6$: C, 41.20; H, 0.77; N, 21.35; S, 36.68%. A platelike crystal with dimensions of 0.15×0.20×0.25 mm was used for the data collection on a Rigaku automated four-circle diffractometer (AFC-5), equipped with a rotating anode (50 kV, 200 mA), using graphite-monochromated MoK_α radiation (λ=0.71069 Å). Crystal data are as follows; a=9.660(1), b=7.231(1), c=14.628(2) Å, β=91.31(1)°, V=1021.5(4) Å^3, $P2_1/n$, Z=2, D_{calcd}=1.71 g cm^{-3}. The ω—2θ scan mode with a scan rate of 4° min^{-1} was employed with the ω scan range (1.0+0.5 tanθ)°. A total of 2915 reflections within 2θ=55° was collected. No absorption correction was applied.

The structure was solved by the direct method using RANTAN81[9] with some modification. The parameters of all the non-hydrogen atoms were refined by the block-diagonal least-squares method with the anisotropic temperature factors. Although the positions of hydrogen atoms were located by a difference Fourier map, the geometrically calculated ones were included in the refinement. The final R value ($R=\sum||F_o|-|F_c||/\sum|F_o|$) is 0.040 for 2620 non-zero reflections. The atomic coordinates are given in Table 1.

The atomic scattering factors from the International Tables for X-ray Crystallography[10] were used. All the computation were carried out by an ACOS 1000 computer at Tohoku University using the applied library program of UNICSIII system.[11]

Results and Discussion

Molecular Structure. Figures 1 and 2 show the thermal ellipsoids of the BTDA-TCNQ and TTF molecule, respectively. Since Z=2 in the space group $P2_1/n$, BTDA-TCNQ and TTF molecules are both restrictly related by a center of symmetry in the unit cell. Each molecule takes an almost planar conformation and the slight deviations of atoms from the

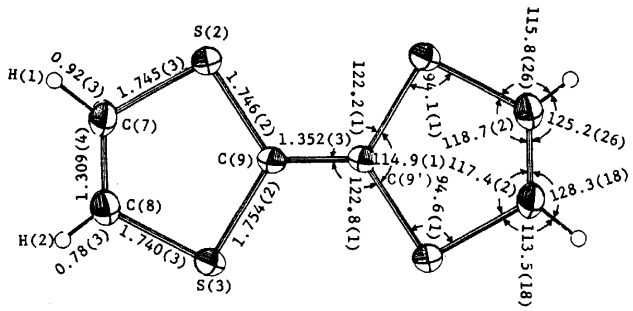

Fig. 2. ORTEP drawing of TTF molecule with the bond lengths (l/Å) and bond angles (ϕ/°).

molecular plane in BTDA-TCNQ indicate the twisting around the *exo*-methylene double bond (5.1°). Tables 2 and 3 show the comparisons of bond lengths of BTDA-TCNQ and TTF in the present complex with those in the neutral molecules or the ion-radical species. It is apparent that the present complex is nonionic as indicated by the degree of charge transfer (Z=0.06) estimated from the bond lengths of C(3)=C(4) (bond e) of BTDA-TCNQ and C(9)=C(9′) (bond a) of TTF.[14]

Crystal Structure and Molecular Packing. Three views of the crystal structure are shown in Figs. 3—5. TTF and BTDA-TCNQ form a mixed stack with the equal space of 3.40 Å. This type of a mixed stacking is often observed in the CT complexes of TCNQ which exhibit low electrical conductivities.[15] The low conductivity of the present complex can be attributed to this mixed stack formation as well as the small degree of the charge transfer from TTF to BTDA-TCNQ. The mixed stack formation is favored when the symmetry of HOMO of the donor is similar to that of LUMO of the acceptor.[15] Thus, molecules tend to overlap in a "ring-double bond type"[16] with a highly symmetrical superimposition so as to maximize the

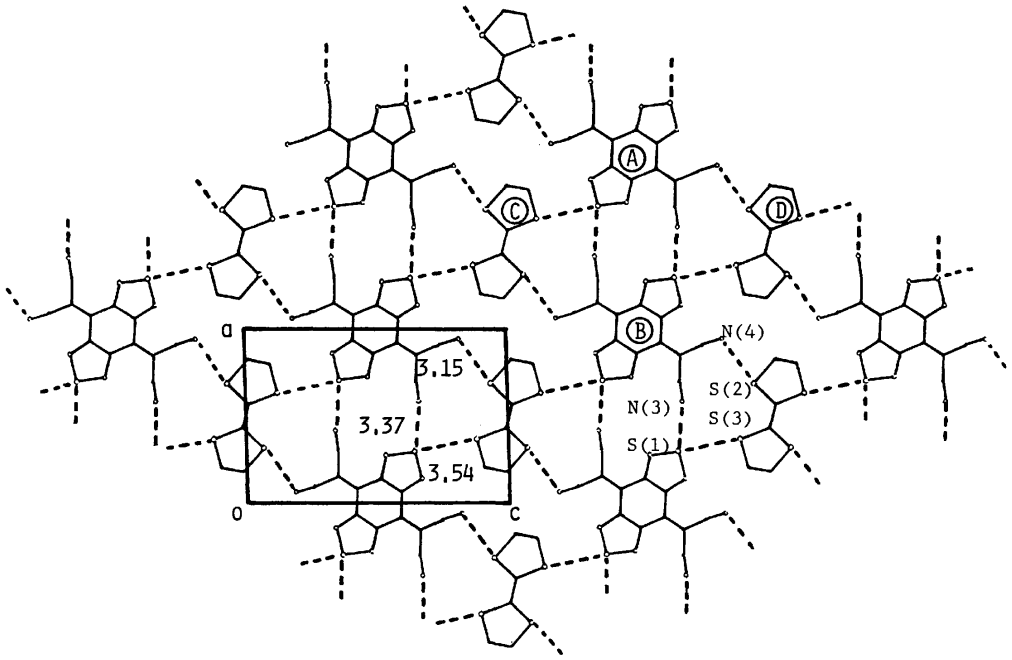

Fig. 3. "Sheet-like network" in the ac plane. S(1)-N(3)≡C(5) (3.37 Å), S(2)-N(4) (3.15 Å) and S(1)-S(3) (3.54 Å) interactions are indicated by broken line. Molecules A-D are related by the following symmetry operations: A (x,y,z and $2-x,-y,1-z$); B ($-1+x,y,z$ and $1-x,-y,1-z$); C ($x,y,-1+z$ and $1-x,-y,1-z$); D (x,y,z and $1-x,-y,2-z$).

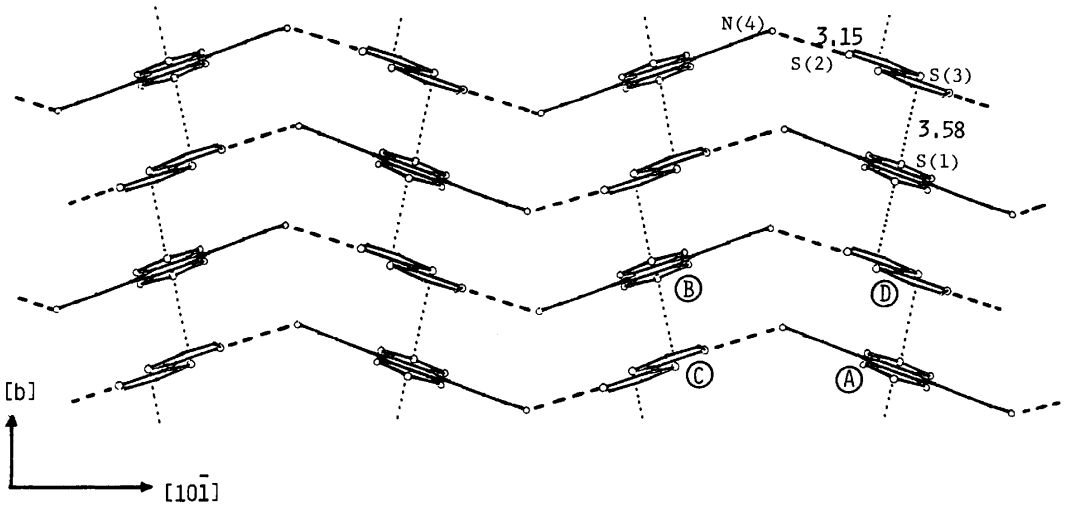

Fig. 4. Corrugation of the "sheet". The drawing of (10$\bar{1}$) plane. S(2)-N(4) (3.15 Å) interactions are indicated by broken line. S(1)-S(3) (3.58 Å) interactions along the b axis are indicated by dotted line. Molecules A—D are related by the following symmetry operations: A (x,y,z and $2-x,-y,1-z$); B ($-0.5+x,0.5-y,0.5+z$ and $1.5-x,0.5+y,1.5-z$); C (x,y,z and $1-x,-y,2-z$); D ($0.5+x,0.5-y,-0.5+z$ and $1.5-x,0.5+y,1.5-z$).

CT interaction in the mixed stacks. As shown in Fig. 6, the molecular overlapping of this complex is not such a type, but BTDA-TCNQ and TTF molecules are tightly connected by S(1)-S(3) (3.58 Å) and N(1)-S(3) (3.47 Å) interactions. These facts indicate that the mixed stacks in the present complex are formed by the direct interactions between heteroatoms rather than the charge-transfer interaction through the π-electron overlapping. Similar mode of overlapping is found in TTF·bis(1,2,5-thiadiazolo)benzoquinone[3] (1 : 1) complex and TTF·(1,2,5-thiadiazolo)naphthoquinone[3] (1 : 2) complex.[17]

The more interesting feature in the crystal is that the mixed stacks are connected by several transverse interactions resulting in the formation of a complicated three-dimensional network as a whole. In the ac plane perpendicular to the stacking b axis, the TTF and BTDA-TCNQ molecules form lines along the a axis and arranged alternately along the c axis. In this ac plane BTDA-TCNQ molecules are connected by weak S(1)-N(3)≡C(5) linkages (3.37 Å; molecules A and B in Fig. 3) and also connected by strong S(1)-S(3) (3.54 Å;

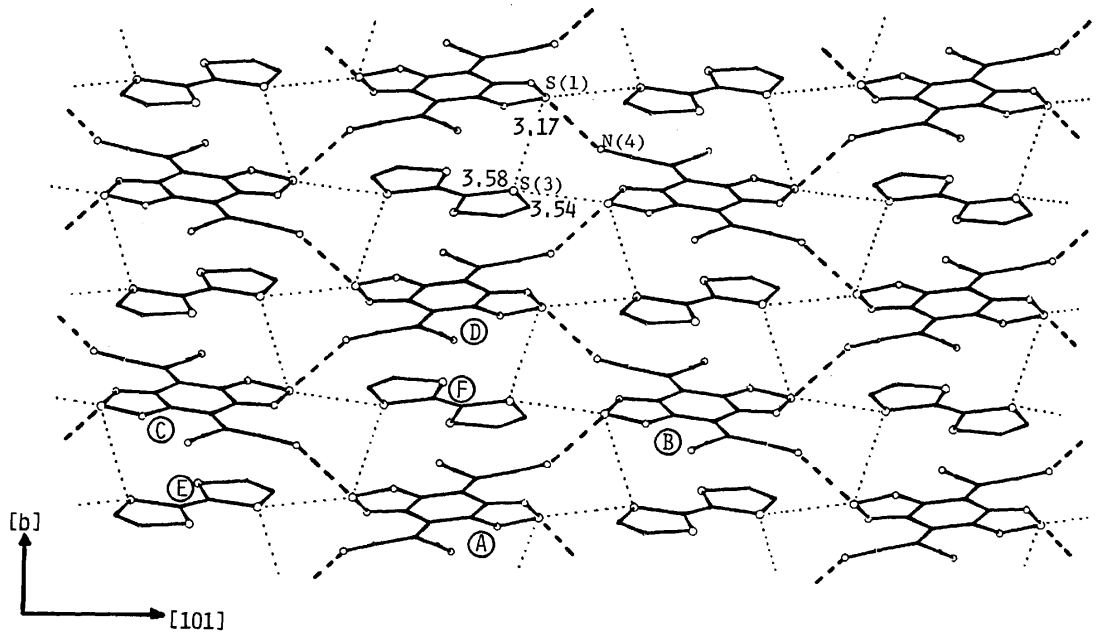

Fig. 5. Cavity formation of BTDA-TCNQ. The drawing of (101) plane. S(1)-N(4)≡C(6) (3.17 Å) interactions are indicated by broken line. S(1)-S(3) interactions along the b axis (3.58 Å) and along [101] direction (3.54 Å) are indicated by dotted line. Molecules A—F are related by the following symmetry operations: A (x,y,z and $2-x,-y,1-z$); B ($0.5+x,0.5-y,0.5+z$ and $2.5-x,0.5+y,1.5-z$); C ($-0.5+x,0.5-y,-0.5+z$ and $1.5-x,0.5+y,0.5-z$); D ($x,1+y,z$ and $2-x,1-y,1-z$); E ($x,y,z-1$ and $1-x,-y,1-z$); F ($0.5+x,0.5-y,-0.5+z$ and $1.5-x,0.5+y,1.5-z$).

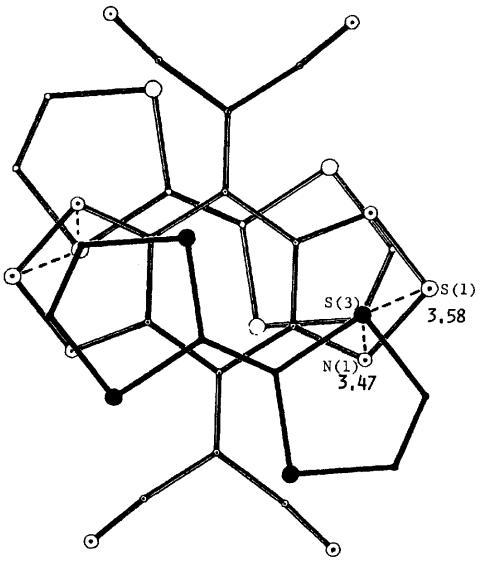

Fig. 6. Molecular overlapping of TTF and BTDA-TCNQ viewed perpendiculer to the molecular plane of BTDA-TCNQ. S(1)-S(3) (3.58 Å) and S(3)-N(1) (3.47 Å) interactions are indicated by broken line.

molecules A and C in Fig. 3) and S(2)-N(4)≡C(6) (3.15 Å; molecules A and D in Fig. 3) interactions along [101] and [10$\bar{1}$] directions with TTF, thus forming a sheet-like network on this plane. Since the molecules incline ca. 20° from the ac plane,[18] this network is not coplanar but somewhat corrugated (Fig. 4). The more important finding is that there exist strong S(1)-N(4)≡C(6) interactions (3.17 Å; molecules A, B, C, and D in Fig. 5) along [111] and [1$\bar{1}$1] directions. As a result, four BTDA-TCNQ molecules are connected to each other which surround a TTF molecule from top, bottom, and two sides. In other words, cavities which include TTF molecules are formed by BTDA-TCNQ molecules. This fact indicates that the present CT complex is more stabilized by the contribution of inclusion behavior. This inclusion behavior is also observed in the BTDA-TCNQ complexes with some aromatic hydrocarbons such as benzene.[19] It is suggested here that the present complex is not a simple CT complex with mixed stacks but rather the one with some inclusion behavior resulted from the multi-dimensional structure.

Conclusion

The crystal structure of TTF·BTDA-TCNQ complex does not exhibit a segregated columnar stack as found in TTF·TCNQ but a mixed stack resulting in the low electrical conductivity. However, the more important finding is the effects of the network formed by the strong interheteroatom interactions. It has been manifested in the anion-radical salts that the two-dimensional network of BTDA-TCNQ can enhance the electrical conductivity.[20] However, it is also true that these interactions can create the cavities leading to a mixed stack formation with the inclusion behavior for some CT complexes. In conclusion, it is suggested that a donor with a larger size and a relatively low oxidation potential which excludes the inclusion behavior observed in the present complex is needed in

order to form a highly conductive CT complex with BTDA-TCNQ.

Tables of anisotropic thermal parameters, coordinates of hydrogen atoms, and observed and calculated structure factors are kept at the Chemical Society of Japan (Document No. 8740).

Basic Autoxidation of Friedelin[1)]

Tadaaki NISHIHAMA* and Takeyoshi TAKAHASHI†

(Received December 9, 1986)

Base-catalyzed autoxidation of a triterpene ketone, friedelin, in the presence of potassium *t*-butoxide gave four products, and their structures and formation mechanism were investigated. The common intermediate to these compounds was suggested to be 4-hydroperoxyfriedelan-3-one, not friedelane-2,3-dione. 3-Oxafriedel-1-ene-2-carboxylic acid was a dehydration product of the main product, 2-hydroxy-3-oxafriedelane-2-carboxylic acid.

Autoxidation of ketones with gaseous oxygen in the presence of strong bases is known as a convenient oxidation method for the syntheses of α-diketones from the corresponding α-methylene ketones and many investigations on synthesis of steroidal α-diketones were reported, but the yields were generally not good.[2)] The autoxidation of a triterpene with a 4,4-dimethyl-3-keto structure was examined by Hanna et al. and they reported a formation of the corresponding α-diketone in 68% yield together with a lactol which was derived by the further oxidation of the α-diketone.[3)] Thus it is generally difficult to control the oxidation reaction which often proceeds exceedingly, or aldol condensation may take place concomitantly. The reaction products, therefore, consist of a complex mixture of many compounds, and frequently the isolation of desired product is difficult. Consequently, applicability of this oxidation to organic synthesis is considerably restricted.

In connection with a study on effective degradation of triterpene ketones, friedelin (**1**)** was autoxidized in the presence of potassium *t*-butoxide and a dihydropyrancarboxylic acid (**2a**) was isolated as a ring-cleavage product in ca. 30% yield.[1)] Although this oxidation reaction was found to be not useful for a practical method to degradate the triterpene ketone effectively, examination on the complicated reaction mixture gave a different result from those obtained in steroids and triterpenes with the 4,4-dimethyl-3-keto structure and offered many interesting problems from the structural and mechanistic viewpoints. This paper describes the structures and formation mechanism of autoxidation products of friedelin (**1**) and some α-oxygenated derivatives.

The oxidation reaction of friedelin (**1**) was carried out in *t*-butyl alcohol and benzene using ten-molar excess of potassium *t*-butoxide with bubbling dry oxygen at room temperature. Although the absorption of oxygen usually stopped within 2 h, the reaction was continued for 24 h to be completed. The reaction mixture was acidified with hydrochloric acid and extracted with ether. The extract (A) was concentrated to afford a residue, which, on trituration with petroleum benzine–chloroform, was separated into a soluble fraction (B) and an insoluble materials (C).

The insoluble material (C) was a crude carboxylic acid (**3a**) containing a trace amount of hydrochloric acid, and crystallized from chloroform–petroleum benzine to yield a less polar carboxylic acid (**2a**) in 20% yield, which was shown to be apparently different from **3a** by TLC examination. The insoluble material (C) was esterified with diazomethane. The crude ester (**3b**) was crystallized from the same solvents as above under acid-free conditions to yield a methyl ester (**3b**) in 35% yield, while on crystallization from the acid-containing solvents gave a less polar ester (**2b**) in 30% yield, which was identical with a methyl ester of **2a**. These observations, therefore, suggest that the less polar acid (**2a**) is a secondary reaction product derived from the polar acid (**3a**) by heating with a catalytic amount of acid.

Since the soluble fraction (B) was revealed to be a mixture of carboxylic acids, the whole extract (A) was methylated with diazomethane, separated by chromatography and recrystallized to afford four methyl esters, **3b**, **4b**, **5b**, and **6b** in 50—35, 20—3, 5—6, and 20—10% yields, respectively.

The methyl esters (**2b** and **3b**) gave the molecular formulas, $C_{31}H_{50}O_3$ and $C_{31}H_{52}O_4$, respectively, from elemental analysis and the mass spectra, and the latter showed the presence of a hydroxyl group by the IR spectrum. Therefore, **2b** was a dehydration product of **3b**. The ester (**2b**) showed the presence of α,β-unsaturated ester (IR: 1720 and 1640 cm^{-1}) with an oxygenfunction at α-position (UV: 253 nm). The ^1H NMR spectrum suggested the presence of a methoxycarbonyl (δ 3.8), -C-(C$\underline{H_3}$)-O- (δ 3.92, 1H, q, J=7 Hz), and -C=CH-CH- (δ 2.08 and 6.01, each 1H, d, J=2 Hz). These spectral data lead to the structure, methyl 3-oxafriedel-1-ene-2-carboxylate for **2b**. The structure proposed for **2b** was further confirmed including the configurations at C-4 and C-10 as follows. The oxidation of **2b** with ozone and hydrogen peroxide gave a ring-cleavage product (not isolated), which was subjected to partial reduction with lithium aluminium hydride (LAH), followed by a treatment with hydrochloric acid to afford a γ-lactone (**7**), $C_{28}H_{46}O_2$, IR 1765

**Friedelin (=friedelan-3-one); friedelane is used as a conventional skeletal name instead of D:A-friedooleanane throughout this paper.

cm^{-1}. The same γ-lactone (**7**) was also obtained by the following route from friedelin (**1**). 3a-Oxa-3a-homofriedelan-3-one (**8**)[4] derived from **1** was treated with phenylmagnesium bromide and then with acetic anhydride in acetic acid to give a diphenylethylene derivative (**9**). On oxidation with chromium trioxide, **9** afforded a δ-lactone, 3-oxafriedelan-2-one (**10**)[5], $C_{29}H_{48}O_2$. Then the δ-lactone (**10**) was submitted to a Grignard reaction using phenylmagnesiun bromide to yield 2-phenyl-3-oxafriedel-1-ene (**11**), $C_{35}H_{52}O$. Ozonolysis of **11** followed by a treatment with LAH yielded a γ-lactone (**7**) and a hemiacetal (**12**), $C_{28}H_{48}O_2$, and the latter (**12**) gave the γ-lactone (**7**) on oxidation with chromium trioxide. The dihydropyran derivative (**11**) was submitted to ozonization followed by a treatment with peracetic acid, and the reaction mixture was saponified with alkali. Acid treatment gave a mixture of two γ-lactones (**7** and **13**). One (**7**) of them was identical with that obtained by either route described above in every respect, and the configuration at C-10 was shown to be the same as that of friedelin (**1**). The other (**13**) is a C-10 epimer derived from a partial isomerization at C-10 under alkaline conditions and therefore possesses $C_{(10\beta)}$-H configuration. Since Baeyer-Villiger reaction is known to proceed with retention of the configuration of the chiral center α to the carbonyl group, the configuration at C-4 of the γ-lactone (**7**) is concluded to be the same 4R-configuration as that of friedelin (**1**). Thus the structure of 2a

19

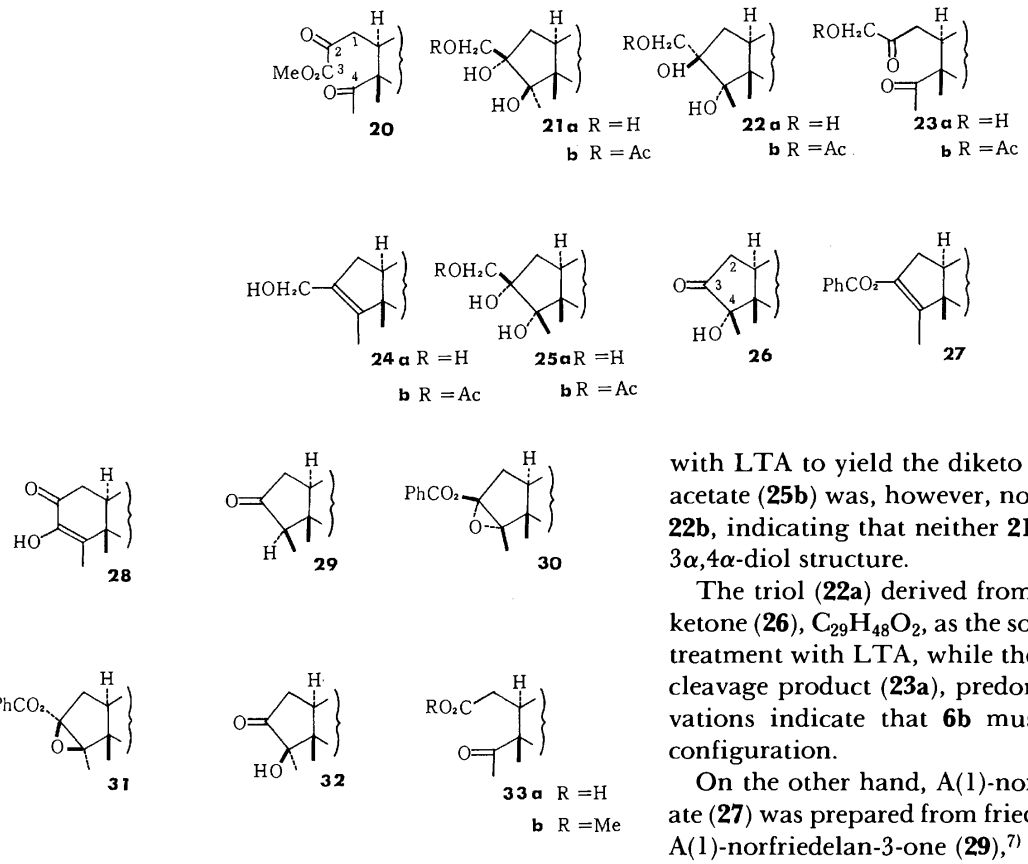
was deteremined to be 3-oxa-friedel-1-ene-2-carboxylic acid.

The structure of **3b** was deduced to be methyl 2-hydroxy-3-oxafriedelane-2-carboxylate from the spectral data and a chemical relation with **2b**. The fact that **3b** was easily converted into **2b** with $C_{(4\beta)}$-Me and $C_{(10\alpha)}$-H, implies that these configurations of **3b** are the same as those of **2b**. However, ^{1}H NMR signal due to $C_{(4\alpha)}$-H of **3b** was changed from a quartet into a multiplet on standing the solution, which indicates that **3b** in solution would exist in an equilibrium mixture of a pair of $C_{(2)}$-epimers.

Reduction of **3b** with LAH in THF under reflux gave 3,4-secofriedelane-2,3,4-triol (**14**), $C_{30}H_{54}O_3$, while in ether at room temperature afforded an unstable hemiacetal, 2-hydroxymethyl-3-oxafriedelan-2-ol (**15**) as an amorphous solid. When the hemiacetal (**15**) was warmed in benzene for recrystallization, dimerization occurred to give a dimeric ether, $C_{60}H_{100}O_4$, as a white powder, the structure of which was not further investigated. A treatment of the hemiacetal (**15**) with lead tetraacetate (LTA) gave a hemiacetal (**16**), $C_{29}H_{50}O_2$, which, on oxidation with chromium trioxide, yielded the δ-lactone (**10**). These derivations described above can be explained based on the structure **3b**.

The methyl ester (**4b**) gave the molecular formula, $C_{31}H_{52}O_3$ and showed the presence of a hydroxyl group by IR and -CH-CO- grouping (δ 2.5) by ^{1}H NMR spectrum. The ester (**4b**) did not react with lead tetraacetate nor with acetic anhydride in pyridine. The structure of **4b** was, therefore, inferred to be methyl 4-hydroxy-A(1)-norfriedelane-3-carboxylate and the structure was confirmed synthetically. Methyl 4-oxo-3,4-secofriedelan-3-oate (**17b**)[4] prepared from **1**, was refluxed with potassium *t*-butoxide in toluene and the aldol condensation mixture was esterified with diazomethane. Chromatographic separation of the product afforded a pair of hydroxy esters (**4b** and **18**) and methyl A(1)-norfriedel-3-ene-3-carboxylate (**19**).[4] One of the hydroxy ester, obtained as the major product, was identical with **4b**. The stereochemistry at C-3 and C-4 remains undetermined.

The methyl esters (**5b** and **6b**) gave the same molecular formulas, $C_{31}H_{52}O_4$, and the presence of two



hydroxyl groups was shown from IR and chemical degradation (vide infra). No signal due to any hydrogen atom on a carbon bearing the hydroxyl group was observed in the ^{1}H NMR spectra and both esters resisted acetylation under normal conditions, indicating that two hydroxyl groups were tertiary. On treatment with LTA, **5b** and **6b** gave the same diketo ester, methyl 2,4-dioxo-3,4-secofriedelan-3-oate (**20**), structure of which was supported by the ^{1}H NMR spectrum (δ 2.07, 3H, CH_3CO-; 2.2—3.0, 2H, -CH_2CO-; and 3.80, 3H, -$COOCH_3$). From these observations, methyl 3,4-dihydroxy-A(1)-norfriedelane-3-carboxylate was proposed as a planar structure for **5b** and **6b**. Stereostructures for **5b** and **6b** were determined by following examination.

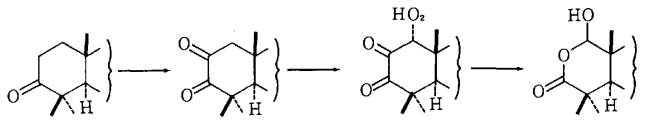
The methyl esters (**5b** and **6b**) were reduced with LAH to afford triols, **21a** and **22a**, which on acetylation gave monoacetates **21b** and **22b**, respectively. The monoacetates **21b** and **22b** were treated with LTA to afford the same diketo acetate (**23b**), $C_{32}H_{52}O_4$. The structure of **23b** was shown to be 2,4-dioxo-3,4-secofriedelan-3-yl acetate by the ^{1}H NMR spectrum, and was identical with a specimen prepared by the following route. The unsaturated ester (**19**) was subjected to reduction with LAH to afford an unsaturated alcohol (**24a**), which, after acetylation, was treated with osmium tetraoxide. The oxidizing reagent would attack the double bond from the less hindered α-side of the norfriedelene skeleton, giving rise to a *cis*-glycol acetate, 3β-acetoxymethyl-A(1)-norfriedelane-3α,4α-diol (**25b**). The glycol acetate (**25b**) was then treated with LTA to yield the diketo acetate (**23b**). The diol acetate (**25b**) was, however, not identical with **21b** nor **22b**, indicating that neither **21b** nor **22b** possesses the 3α,4α-diol structure.

The triol (**22a**) derived from **6b**, gave a norhydroxy ketone (**26**), $C_{29}H_{48}O_2$, as the sole reaction product on a treatment with LTA, while the triol (**25a**) gave a ring-cleavage product (**23a**), predominantly. These observations indicate that **6b** must possess a trans diol configuration.

On the other hand, A(1)-norfriedel-3-en-3-yl benzoate (**27**) was prepared from friedelane-2,3-dione (**28**) via A(1)-norfriedelan-3-one (**29**),[7] and subjected to epoxidation with peracetic acid. Since the double bond would be attacked by the reagent from the less hindered α-side, it was expected that the α-epoxide (**30**) would be formed as the major product. Therefore, the epoxide mixture (**30** and **31**) was hydrolyzed with potassium hydroxide to afford 4α-hydroxy-A(1)-norfriedelan-3-one (**26**) as the major product and 4β-hydroxy isomer (**32**) as the minor product. Both hydroxy norketones (**26** and **32**) gave the same keto norester (**33**)[4] on a treatment with LTA followed by methylation. The major hydroxy ketone (**26**) was identical with a specimen obtained from triol (**22a**) (vide supra). A support for the assignment of configuration at C-4 was observed on IR measurement. The pseudoequatorial[8] 4β-hydroxyl of **32** was considered to form stronger intramolecular hydrogen bond with carbonyl group than pseudoaxial 4α-hydroxyl of **26**.[9] Actually, absorption bands due to hydroxyl groups of **26** and **32** in dilute carbon tetrachloride solution appeared at 3606 and 3563 cm^{-1} respectively.

Since the hydroxyl group at C-4 of **26** was shown to be located in α-configuration and the relative configuration of $C_{(3)}$-OH and $C_{(4)}$-OH of **22b** is trans, the hydroxyl group at C-3 of **22b** and therefore that of **6b** is concluded to be in β-configuration.

The oxidation of **21a** with LTA was found to give a complicated reaction mixture, from which the hydroxy norketone (**32**) was isolated along with a small amount of the ring-cleavage diketo alcohol (**23a**). Since this observation implies that **21a** possesses a trans 3,4-diol with 4β-hydroxy configuration, the



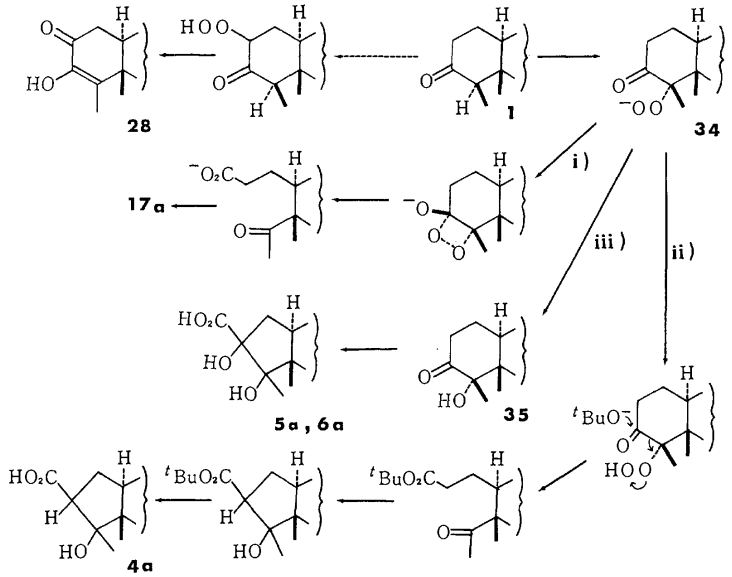
Scheme 1.

hydroxyl group at C-3 should be in α-configuration.

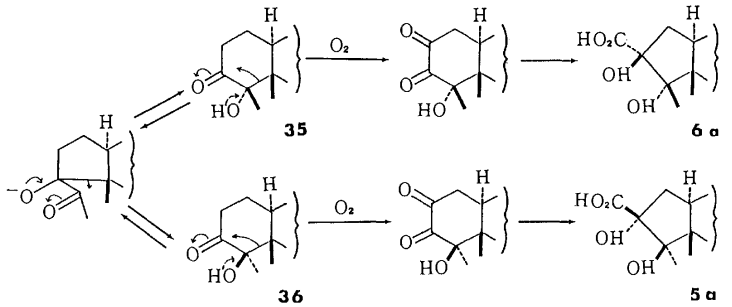
From these observations described above, it is concluded that **5a** and **6a** are formulated as 3α,4β-dihydroxy-A(1)-norfriedelane-3β-carboxylic acid and 3β,4α-dihydroxy-A(1)-norfriedelane-3α-carboxylic acid, respectively.

The basic autoxidation of ketones is known to proceed by an initial formation of α-keto carbanion (enolate anion) and followed by an attack of oxygen to yield α-hydroperoxy ketone. If the α-hydroperoxide is primary or secondary, it usually converts rapidly into the corresponding α-diketone, and then the α-diketone would be submitted to further oxidation. Many examples are reported in steroids and triterpenes with the 4,4-dimethyl-3-keto structure.[2] In the latter case, the primary oxidation product is a 2,3-dione, which is converted into a lactol via 1-hydroperoxy-2,3-dione with elimination of carbon monoxide[3] (Scheme 1). The basic autoxidation of friedelin (**1**) is not the case. The Δ^3-enolate anion being more stable than the Δ^2-enolate anion, attack of oxygen must occur at C-4 to afford a tertiary hydroperoxide (**34**) preferentially. Attack to C-2 yielding friedelane-2,3-dione (**28**) would be the minor process. In fact friedelane-2,3-dione (**28**) and several oxidation products derived from **28** were detected in the autoxidation product of **1** but in very minute quantities, and therefore, it is concluded that the process through 2,3-dione (**28**) would be of no importance.

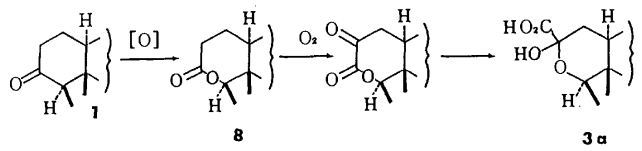
From product analysis of the autoxidation of friedelin (**1**), it is inferred that the hydroperoxy ketone (**34**) would be submitted to the following reactions;[10] i) an attack of the hydroperoxide anion of **34** to the carbonyl carbon followed by the $C_{(3)}$-$C_{(4)}$ bond fission, ii) the participation with a *t*-butoxide anion followed by the $C_{(3)}$-$C_{(4)}$ bond fission, iii) a reaction with friedelin (**1**) or some unknown process yielding 4α-hydroxyfriedelin (**35**) (Scheme 2). Process i) would produce 4-oxo-3,4-secofriedelan-3-oic acid (**17a**), but the keto acid (**17a**) was not detected in the reaction mixture. Since a separate experiment revealed that the keto acid (**17a**) was fairly stable in the autoxidation conditions and survived for long time, no detection of **17a** would deny the occurrence of process i). Process ii) would at least, partially, be responsible for the formation of 4-hydroxy-A(1)-norfriedelane-3-carboxylic acid (**4a**).



Scheme 2.



Scheme 3.



Scheme 4.

Process iii) was revealed to be the main route leading to dihydroxy carboxylic acids (**5a** and **6a**). 4α-Hydroxyfriedelan-3-one (**35**), the important intermediate in the process iii), and its 4β-hydroxy isomer (**36**) were prepared from friedelin (**1**) through an epoxidation of 3-friedelen-3-yl benzoate. The epoxidation gave a mixture of α- and β-epoxides, and the former was the main product from the reasons described for **27**. The 4α-hydroxyfriedelan-3-one (**35**) was subjected to the autoxidation under the same conditions as in the case of **1**. The reaction products, after methylation, were shown to be **5b** and **6b**. The autoxidation of 4β-hydroxy isomer (**36**) gave also **5b** and **6b** after methylation. Therefore, a rapid interconversion between **35** and **36** was suggested prior to the autoxidation and the autoxidation of **35** and **36** is considered to proceed as depicted in Scheme 3.

Since 2-hydroxy-3-oxafriedelane-2-carboxylic acid (**3a**) was not detected in the autoxidation product of **35** nor **36**, these two compounds were not intermediates leading to **3a**. A speculative formation process leading to **3a** was given in Scheme 4, and the investigation on the formation process is now under way.

Experimental

General Procedures. All melting points were uncorrected. Infrared spectra (IR) were taken on Perkin Elmer "Infracord," or Hitachi EPI-G2 spectrometer in Nujol mull. Ultra violet spectra (UV) were measured on a Hitachi EPS-3 spectrometer. ^{1}H NMR spectra were taken using Hitachi R-24 (60 MHz), Varian A-60 (60 MHz), or Varian EM-390 (90 MHz) and mass spectra (MS) were run on a Hitachi RMU-6L or JEOL DX-300 mass spectrometer at 70 eV unless otherwise noted and the relative intensities were indicated in parentheses. High performance liquid chromatography (HPLC) was run on Waters Associates 6000A with μ-PORASIL (silica gel) column and RI detector. Reduction with lithium aluminium hydride (LAH), acetylation with acetic anhydride-pyridine, methylation with diazomethane, and oxidation of glycols with lead tetraacetate (LTA) in acetic acid were done in usual manner unless specially noted.

Materials and Solvents. Friedelin (**1**) was extracted from "cork smoker wash solid"[6] (not available now) or cork powder and purified by column chromatography (alumina, benzene) and by crystallization from ethyl acetate, mp 261 °C. Friedelane-2,3-dione (**28**) was extracted from "cork smoker wash solid" and the crude material was subjected to column chromatography on alumina eluted with benzene-ethyl acetate followed by crystallization from the same solvent, mp 222 °C. Benzene was distilled before use. Dry *t*-butyl alcohol was prepared by distillation from a solution of *t*-butyl alcohol (100 parts) containing sodium *t*-butoxide (1 part). Potassium *t*-butoxide solution was prepared by dissolving potassium (1 g) in dry *t*-butyl alcohol (100 ml).

Autoxidation of Friedelin (1) with Potassium *t*-Butoxide. A solution of friedelin (**1**; 1 g) in dry benzene (100 ml) was placed in a two-necked Erlenmeyer flask equipped with a gas buret. The air inside was transferred by oxygen, and the potassium *t*-butoxide solution (100 ml) was added through a rubber septum cap. The solution, kept at 25 °C, was stirred for 24 h. A rapid absorption of oxygen was observed within first 30 min and the absorption stopped when about 85 ml of oxygen was consumed. Ether and 1 M hydrochloric acid (1 M=1 mol dm^{-3}) were added and the organic layer (A) was washed once with water and concentrated under reduced pressure to afford a residue. The residue was trituated with petroleum benzine and a soluble fraction (B) and an insoluble material (C) were obtained. A part of the insoluble material (C) crystallized from benzine-chloroform to afford 3-oxafriedel-1-ene-2-carboxylic acid (**2a**) in ca. 20% yield, mp 241—245 °C (needles from ether); IR 2360, 2340, 1705, 1640, 1460, 1390, 1285, 1140, 1120, and 1080 cm^{-1}; ^{1}H NMR (90 MHz, $CDCl_3$) δ=2.1 (1H, d, J=2 Hz; $C_{(10)}H$), 3.9 (1H, q, J=5 Hz, -O-C<u>H</u>-CH_3), 6.1 (1H, d, J=2 Hz; $C_{(1)}H$), and 7.5 (1H, br s; COOH); MS m/z (%) 456 (M^+; 11), 441 (7), 426 (37), 411 (11), 382 (27), 341 (53), 205 (100), 135 (55), 123 (62), and 109 (84). The remaining part of C was esterified with diazomethane. Recrystallization from the same solvents gave a methyl ester (**2b**) of **2a** in 30% yield, while recrystallization, after the solvents were free from acid, gave methyl 2-hydroxy-3-oxafriedelane-2-carboxylate (**3b**) in 35% yield. **2b**; Mp 214.5—215 °C; IR 1720 and 1640 cm^{-1}; UV (EtOH) 253 nm (ε 8900); ^{1}H NMR (60 MHz, $CDCl_3$) δ=2.08 (1H, d, J=2 Hz; C=CH-C<u>H</u>), 3.79 (3H, s; $COOCH_3$), 3.92 (1H, q, J=7 Hz; -O-C<u>H</u>-CH_3), and 6.01 (1H, d, J=2 Hz; C=C<u>H</u>-CH); MS m/z 470 (M^+); Found: C, 78.70; H, 10.79%. Calcd for $C_{31}H_{50}O_3$: C, 79.10; H, 10.71%. **3b**; Mp 204.5—205 °C (from petroleum benzine); IR 3670, 1740, and 1640 cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=3.7 (1H, m; -$OC_{(4)}H$) and 3.8 (3H, s; -$COOCH_3$); MS (20 eV) m/z (%) 488 (M^+; 13), 470 (47), 429 (50), 341 (38), 218 (33), and 205 (100); Found: C, 76.04; H, 10.73%. Calcd for $C_{31}H_{52}O_4$: C, 76.18; H, 10.72%.

The extract (A) was treated with diazomethane until a yellow color persisted for 5 min. Removal of the solvent in vacuo and the residue was chromatographed on silica gel. Elution with benzene gave methyl 2-hydroxy-3-oxafriedelane-2-carboxylate (**3b**), methyl 4-hydroxy-A(1)-norfriedelane-3-carboxylate (**4b**), methyl 3α,4β-dihydroxy-A(1)-norfriedelane-3β-carboxylate (**5b**), and methyl 3β,4α-dihydroxy-A(1)-norfriedelane-3α-carboxylate (**6b**) in turn. **4b**; Needles from methanol, mp 224—225 °C; IR 3630 and 1725 cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=2.5 (1H, m; -CH-CO) and 3.9 (3H, s; $COOCH_3$); MS m/z (%) 472 (M^+; 33), 454 (19), 356 (16), 274 (44), 205 (73), and 109 (100); Found: C, 78.88; H, 11.09%. Calcd for $C_{31}H_{52}O_3$: C, 78.76; H, 11.09%. **5b**; Needles from petroleum benzine, mp 205—205.5 °C; IR 3700, 3500, and 1720 cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=3.8 (3H, s; -$COOCH_3$); MS m/z (%) 488 (M^+; 70), 428 (49), 341 (36), 205 (83), and 109 (100); Found: C, 75.59; H, 10.59%. Calcd for $C_{31}H_{52}O_4$: C, 76.18; H, 10.72%. **6b**; Needles from petroleum benzine, mp 240—241 °C; IR 3500 and 1725 cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=3.75 (3H, s; -$COOCH_3$); MS m/z (%) 488 (M^+; 100), 428 (46), 205 (64), 149 (46), 123 (68), and 109 (92); Found: C, 75.94; H, 10.65%. Calcd for $C_{31}H_{52}O_4$: C, 76.18; H, 10.72%.

Oxidation of 2b with Ozone and Hydrogen Peroxide. Ozone was introduced to a solution of **2b** (100 mg) in dichlo-

romethane (50 ml), kept at −78 °C, until the solution developed blue color. A mixture of hydrogen peroxide (30%, 20 ml), acetic acid (20 ml), and sulfuric acid (1 ml) was added and the solution was heated at 100 °C. After 30 min, the solution was cooled to room temperature, neutralized with an aqueous solution of sodium carbonate, and extracted with ether. The ether layer was concentrated and chromatographed (silica gel-benzene). 3-Oxa-A(1)-norfriedelan-2-one (**7**; 53 mg) was obtained, mp 263—264 °C (from ethyl acetate); IR 1780, 1170, 1060, 1015, and 920 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=2.1 (1H, s; $C_{(10)}H$) and 4.05 (1H, q, J=7 Hz; $-OC_{(4)}H$); MS m/z (%) 414 (M^+; 23), 399 (14), 290 (70), 262 (84), 247 (26), 221 (20), and 205 (44); Found: C, 81.24; H, 11.32%. Calcd for $C_{28}H_{46}O_2$: C, 81.10; H, 11.18%.

3a-Oxa-3a-homofriedelan-3-one (8). To a solution of friedelin (**1**; 5 g) in chloroform (300 ml) was added 39% peracetic acid (40 ml) and the mixture was stirred overnight at 60 °C. Water was added and the organic layer was washed with water several times, concentrated, and crystallized from ethyl acetate to yield **8** (3.2 g), mp 292—293 °C; IR 1730, 1290, and 1230 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=2.5—2.7 (2H, m; $C_{(2)}H_2$-CO-) and 4.23 (1H, q, J=6 Hz; $-OC_{(4)}H$-); MS m/z (%) 442 (M^+; 16), 398 (25), 274 (19), 245 (23), 218 (42), 205 (61), 123 (79), and 109 (100); Found: C, 81.39; H, 11.38%. Calcd for $C_{30}H_{50}O_2$: C, 81.40; H, 11.60%.

Diphenylethylene Acetate (9). 3a-Oxa-3a-homofriedelan-3-one (**8**; 2 g) was treated with 10 molar excess of phenylmagnesium bromide in usual manner and the reaction product was dissolved in benzene, dried over sodium sulfate, and then concentrated. The residue was dissolved in a mixture (1 : 1, 200 ml) of acetic anhydride and acetic acid containing sodium acetate (2 g), and the solution was refluxed overnight. The usual work-up and chromatography (silica gel-petroleum benzine) afforded diphenylethylene acetate (**9**) as an amorphous solid, IR 1725, 1595, 1235, 1040, and 760 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=1.95 (3H, s; AcO-), 2.0—2.3 (2H, m; $C_{(1)}H_2$-C=C), 4.77 (1H, q, J=7 Hz; $-OC_{(4)}H$), 5.99 (1H, t, J=7 Hz; -C=$C_{(2)}H$), and 7.3—7.5 (5H, br s; C_6H_5-).

3-Oxafriedelan-2-one (10). Chromium trioxide (1 g) was added to a solution of **9** (1 g) in acetic acid (200 ml) with stirring at room temperature and the solution was stirred for 10 h. After removal of the solvent in vacuo, the residue was shaken with ether and 1% sulfuric acid. The organic layer was concentrated, dissolved in a mixture of dioxane (100 ml) and concd sulfuric acid (1 g). The solution was refluxed for 1 h and then poured into water to yield precipitates, which recrystallized from methanol. 3-Oxafriedelan-2-one (**10**; 300 mg) was obtained, mp 263—264 °C; IR 1735, 1245, 1080, and 1050 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=2.0—2.6 (2H, m; CH_2CO-) and 4.05 (1H, q, J=7 Hz); MS m/z (%) 428 (M^+; 9), 304 (28), 276 (23), 205 (74), 203 (20), 123 (74), 107 (69), and 109 (100); Found: C, 81.29; H, 11.35%. Calcd for $C_{29}H_{48}O_2$: C, 81.25; H, 11.29%.

2-Phenyl-3-oxafriedel-1-ene (11). One gram of **10** was added to 3 molar excess of phenylmagnesium bromide solution in ether, and the solution was refluxed for 1 h. After dil hydrochloric acid was added, the ether layer was concentrated to give a residue. The residue was chromatographed (silica gel-petroleum benzine) and crystallized from ethyl acetate to afford 2-phenyl-3-oxa-1-friedelene (**11**; 650 mg) as lustrous platelets, mp 223—225 °C; MS m/z (%) 488 (M^+; 23), 300 (9), 205 (17), and 185 (23).

Ozonolysis of 11 by Reductive Treatment. A solution of 2-phenyl-3-oxa-1-friedelene (**11**; 500 mg) in dichloromethane (200 ml) was cooled in Dry Ice-methanol bath and ozone was bubbled into the solution until the color of the solution changed to blue. A solution of LAH (200 mg) in ether (50 ml) was added and the mixture was allowed to warm up to room temperature. After addition of a small amount of acetone, the mixture was shaken with dil hydrochloric acid. The organic layer was concentrated and chromatographed (silica gel-benzene) to afford 3-oxa-A(1)-norfriedelan-2-one (**7**; 155 mg) and 3-oxa-A(1)-norfriedelan-2-ol (**12**; 75 mg), mp 236—238 °C (from benzene); IR 3200, 1100, 1060, 1010, and 730 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=3.55 (1H, q, J=6.5 Hz; $-OC_{(4)}H$) and 3.6—3.7 (2H, m; $C_{(1)}\underline{H}OH$); MS m/z (%) 398 ([M−18]$^+$; 15), 356 (17), 341 (6), 205 (56), 123 (100), and 109 (97); Found: C, 80.70; H, 11.82%. Calcd for $C_{28}H_{48}O_2$: C, 80.71; H, 11.61%. 3-Oxa-A(1)-norfriedelan-2-ol (**12**; 35 mg) in acetic acid (20 ml) was oxidized with chromium trioxide (50 mg) at reflux temperature for 1 h to afford **7** (25 mg).

Ozonolysis of 11 by Alkaline Treatment. Ozonation of **11**(500 mg) in dichloromethane was carried out in the same manner as above and the reaction product was treated with 39% peracetic acid (20 ml). The mixture was heated up to 100 °C in a hood until no peroxide was detected with a potassium iodide-acetic acid solution. After the solvent was removed in vacuo, an excess ethanolic potassium hydroxide solution was added and the alkaline mixture was refluxed for 1 h. The solution was then acidified to pH ca. 1 by addition of dil hydrochloric acid and left for 1 h at 80 °C. The reaction product was extracted with ether and subjected to separation by chromatography (silica gel-benzene) to yield 3-oxa-A(1)-norfriedelan-2-one (**7**; 75 mg) and 10-epi-3-oxa-A(1)-norfriedelan-2-one (**13**; 53 mg), mp 181—181.5 °C (from ethyl acetate); IR 1760, 1140, 1120, and 1055 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=3.90 (1H, q, J=7 Hz; $-OC_{(4)}H$), 2.0 (1H, s; $C_{(10)}HCO$-), and 3.0—3.6 (1H, m; $C_{(11)}H$); MS m/z (%) 414 (M^+; 17), 399 (20), 290 (57), 261 (100), 235 (38), and 205 (45); Found: C, 81.03; H, 11.33%. Calcd for $C_{28}H_{46}O_2$: C, 81.10; H, 11.18%.

Reduction of Methyl 2-Hydroxy-3-oxafriedelane-2-carboxylate (3b) with LAH. A solution of **3b** (500 mg) in tetrahydrofuran (THF) (100 ml) was refluxed with excess LAH for 6 h and the usual work-up gave 3,4-secofriedelane-2,3,4-triol (**14**; 280 mg) as needles, mp 203—203.5 °C (from benzene); IR 3400, 3250, 3150, 1095, 1080, and 680 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) 3.5—3.8 (4H, m; -OCH-); MS m/z (%) 462 (M^+; trace), 413 (11), 273 (7), 219 (11), 205 (40), and 109 (100); Found: C, 78.06; H, 11.71%. Calcd for $C_{30}H_{54}O_3$: C, 77.86; H, 11.76%.

A solution of **3b** (200 mg) in ether (100 ml) was reduced with LAH (50 mg) at room temperature. After 24 h, the reaction mixture was cooled with an ice bath, and treated with a small amount of acetone and then dil hydrochloric acid. The ether layer was washed with water several times and then concentrated in vacuo to give 2-hydroxymethyl-3-oxafriedelan-2-ol (**15**; ca. 150 mg) as an amorphous solid. The hemiacetal (**15**; 100 mg) was dissolved in benzene (200 ml) and the solvent was evaporated slowly on a water bath. The residue was chromatographed (silica gel-benzene) to give the dimeric ether (73 mg) as white powder, which crystallized from benzene, mp 298—299 °C; IR 1280, 1110, 1090, 1050, 980, 970, and 795 cm^{-1}. ^1H NMR (60 MHz, $CDCl_3$) δ=3.2—4.0 (6H, m; -OCH); MS m/z (%) 888 (M^+; trace), 440 (0.9), 438 (1), 424 (20), 409 (21), 341 (17), 229 (20), 205 (55), 191

(24), 138 (100), 137 (54), 123 (35), and 109 (40); Found: C, 81.20; H, 11.16%. Calcd for $C_{60}H_{100}O_4$: C, 81.39; H, 11.38%.

3-Oxafriedelan-2-ol (16). An ethereal solution of **15** (120 mg) obtained by the reduction of **3b** was added to a solution of LTA (300 mg) in acetic acid (100 ml) and the mixture was stirred for 1 h at room temperature. Ethylene glycol was added and the reaction mixture was worked up as usual to afford 3-oxafriedelan-2-ol (**16**; 83 mg), mp 228—232 °C (from benzene); IR 3400, 1270, 1245, 1105, 1050, 990, 950, and 725 cm^{-1}; MS *m/z* (%) 430 (M^+; trace), 412 (16), 218 (22), 205 (46), 135 (43), 123 (61), 121 (46), and 109 (100); Found: C, 80.67; H, 11.72%. Calcd for $C_{29}H_{50}O_2$: C, 80.87; H, 11.70%. Poor ^1H NMR spectrum was obtained due to the low solubility.

Modified Preparation of 4-Oxa-3,4-secofriedelan-3-oic Acid (17a). A solution of friedel-3-en-3-yl benzoate[6] (3 g) in dichloromethane (300 ml) was cooled in an ice-salt bath and ozone was passed though the solution until the blue color did not fade. A solution of chromium trioxide (3 g) in 90% acetic acid (300 ml) was added, and the mixture was heated at 60 °C for 1 h. Water and ether were added and the ether layer was worked up as usual. The residue crystallized from acetone-water to afford 4-oxo-3,4-secofriedelan-3-oic acid (**17a**; 2.1 g), mp 205—207 °C (needles from ether); IR 3100 (br), 1735, 1670, 1365, 1290, 1240, and 1190 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=2.1 (3H, s; Ac), 2.2—2.5 (2H, m; $-CH_2-CO-$), and 7.0—7.6 (1H, br s; -COOH); MS (20 eV) *m/z* (%) 458 (M^+; 18), 415 (14), 219 (41), and 205 (100). Preparation of **17a** by this method is more convenient than by chromic acid-oxidation of **1**.[4] On methylation, **17a** afforded methyl 4-oxo-3,4-secofriedelan-3-oate (**17b**), mp 157—158 °C (silky needles from methanol); IR 1735, 1695, and 1165 cm^{-1}. ^1H NMR (60 MHz $CDCl_3$) δ=2.1 (2H, t, *J*=3 Hz; $-CH_2CO-$), 2.15 (3H, s; CH_3CO-), and 3.65 (3H, s; $-COOCH_3$); MS *m/z* (%) 472 (M^+; 9), 429 (42), 205 (95), 123 (66), 121 (42), 109 (100), and 107 (45).

Aldol Condensation of 17b. To a solution of methyl 4-oxo-3,4-secofriedelan-3-oate (**17b**; 1 g) in toluene (200 ml) was added 200 ml of the potassium *t*-butoxide solution (the same solution as that used for the basic autoxidation) under nitrogen atmosphere and the mixture was refluxed for 24 h. After 2% hydrochloric acid (500 ml) was added, the organic layer was treated with diazomethane. The usual work-up afforded a residue, which was separated by chromatography on silica gel. Elution with benzene yielded methyl 4-hydroxy-A(1)-norfriedelane-3-carboxylate (**4b**; 143 mg), the stereoisomer (**18**; 118 mg) of **4b**, and methyl A(1)-norfriedel-2-ene-3-carboxylate (**19**; 85 mg) successively. **18**; Mp 226—228 °C (from benzene-cyclohexane); IR 3400, 1710, 1230, 1210, 1180, 1150, 1110, 1040, and 900 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=2.8—3.1 (1H, m; $-C_{(3)}HCO-$) and 3.7 (3H, s; $COOCH_3$); MS *m/z* (%) 472 (M^+; 16), 356 (11), 273 (26), 218 (39), 205 (76), 137 (59), 123 (84), and 109 (100); Found; C, 78.75; H, 10.96%. Calcd for $C_{31}H_{52}O_3$: C, 78.76; H, 11.09%. **19**; Mp 230—231.5 °C (platelet from methanol); IR 1710, 1630, 1310, 1215, and 1065 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=1.95 (3H, br s; $CH_3-C=C-$), 2.1—2.5 (2H, m; $C_{(1)}H_2-C=C$), and 3.70 (3H, s; $-COOCH_3$); MS *m/z* (%) 454 (M^+; 30), 235 (38), 234 (37), 233 (43), 205 (60), 191 (36), 165 (53), 123 (70), and 109 (100).

Oxidation of 5b and 6b with Lead Tetraacetate. An ethereal solution of **5b** (72 mg) was added dropwise to a solution of LTA (200 mg) in acetic acid. The usual work-up and crystallization from methanol aforded methyl 2,4-dioxo-3,4-secofriedelan-3-oate (**20**; 53 mg), mp 134—135 °C; IR 1730, 1695, 1365, 1275, 1265, and 1085 cm^{-1}. ^1H NMR (90 MHz, $CDCl_3$) δ=2.07 (3H, s; Ac), 2.2—3.0 (2H, m; $-C_{(1)}H_2CO-$), and 3.80 (3H, s; $-COOCH_3$); MS *m/z* (%) 486 (M^+; 15), 443 (39), 427 (29), 205 (83), 149 (56), 123 (78), and 109 (100); Found: C, 76.78; H, 10.42%. Calcd for $C_{31}H_{50}O_4$: C, 76.50; H, 10.36%. The same diketo ester (**20**; 32 mg) was obtained from **6b** (55 mg) by the same treatment.

3β-Hydroxymethyl-A(1)-norfriedelane-3α,4β-diol (21a) and Its Monoacetate (21b). Reduction of **5b** with LAH afforded **21a**, mp 260 °C (with decomp) (from petroleum benzine); IR 3430, 1365, and 1275 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=3.3—3.9 (2H, m; $-CH_2OH$); MS *m/z* (%) 442 ($[M-18]^+$; 4), 424 (20), 409 (21), 406 (27), 231 (26), 218 (68), 205 (94), 191 (45), 163 (42), 123 (64), and 109 (100); Found: C, 78.06; H, 11.16%. Calcd for $C_{30}H_{52}O_3$: C, 78.20; H, 11.38%. On acetylation, **21a** gave 3β-acetoxymethyl-A(1)-norfriedelane-3α,4β-diol (**21b**), mp 198.5—199 °C (from ether-cyclohexane); IR 3500, 1730, 1285, and 1055 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=2.10 (3H, s; AcO-) and 4.20 (2H, s; -OH); MS *m/z* (%) 502 (M^+; 1), 442 (1), 399 (7), 273 (11), 205 (57), and 109 (100); Found: C, 76.36; H, 10.78%. Calcd for $C_{32}H_{54}O_4$: C, 76.44; H, 10.83%.

3α-Hydroxymethyl-A(1)-norfriedelane-3β,4α-diol (22a) and Its Monoacetate (22b). By the same treatment as above, methyl 3β,4α-dihydroxy-A(1)-norfriedelane-3α-carboxylate (**6b**) afforded **22a** and 3α-acetoxymethyl-A(1)-norfriedelane-3β,4α-diol (**22b**). **22a**; Mp 255 °C (with decomp) (from ethyl acetate); IR 3400, 1135, 1070, 1060, 940, 920, and 890 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=3.55 and 3.93 (each 1H, d, *J*=12 Hz); MS *m/z* (%) 442 ($[M-18]^+$; 4), 427 (4), 399 (10), 273 (8), 219 (12), 205 (55), 142 (100), 113 (63), and 109 (88); Found: C, 78.15; H, 11.08%. Calcd for $C_{30}H_{52}O_3$: C, 78.20; H, 11.38%. **22b**; Mp 156—157 °C (from ether-cyclohexane); IR 3700, 3460, 1760, 1735, 1270, 1220, and 1045 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=2.10 (3H, s; AcO-), 4.13 and 4.36 (each 1H, d, *J*=10 Hz); MS *m/z* (%) 502 (M^+; trace), 442 (2), 427 (3), 409 (3), 399 (7), 381 (2), 371 (3), 341 (5), 273 (8), 205 (54), 123 (68), 121 (61), and 109 (100); Found: C, 76.25; H, 10.84%. Calcd for $C_{32}H_{54}O_4$: C, 76.44; H, 10.83%.

Treatment of 21b and 22b with Lead Tetraacetate. 3β-Acetoxymethyl-A(1)-norfriedelane-3α,4β-diol (**21b**) was treated with LTA to afford 2,4-dioxo-3,4-secofriedelan-3-yl acetate (**23b**), mp 196—197 °C (from petroleum benzine); IR 1760, 1745, 1695, 1230, 1060, and 1040 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=2.10 and 2.13 (each 3H, s; AcO- and Ac), 2.2—2.5 (2H, m; $C_{(1)}H_2CO-$), 4.50 and 4.73 (each 1H, d, *J*=18 Hz, $AcOC\underline{H}_2-CO-$); MS *m/z* (%) 500 (M^+; 1), 457 (38), 341 (20), 205 (100), 137 (52), 135 (45), 123 (66), 121 (56), 109 (80), and 107 (47); Found: C, 76.95; H, 10.68%. Calcd for $C_{32}H_{52}O_4$: C, 76.75; H, 10.47%. The same treatment of **22b** with LTA gave the same diketo acetate (**23b**).

3-Acetoxymethyl-A(1)-norfriedel-3-ene (24b). A solution of methyl A(1)-norfriedel-3-ene-3-carboxylate (**19b**) in ether was treated with LAH to give 3-hydroxymethyl-A(1)-norfriedel-3-ene (**24a**), mp 234—236 °C (from benzene); IR 3400 (br), 1640, 995, 720, and 410 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=4.10 (2H, s; $=C-CH_2OH$); MS *m/z* (%) 426 (M^+; 5), 411 (84), 205 (95), 137 (100), 123 (98), 121 (89), 119 (87), 109 (67), 107 (93), and 105 (62); Found: C, 84.61; H, 11.84%. Calcd for $C_{30}H_{50}O$; C, 84.44; H, 11.81%. Acetylation of **24a** yielded 3-acetoxymethyl-A(1)-norfriedel-3-ene (**24b**), mp 179—183.5 °C (from methanol); IR 1735, 1665, 1260, and 1030 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=2.10 (3H, s; Ac); MS

m/z (%) 468 (M^+; 2), 453 (18), 408 (14), 393 (33), 273 (11), 259 (14), 205 (42), 123 (72), 121 (78), 119 (67), 109 (100), 107 (83), and 105 (53); Found: C, 81.77; H, 11.11%. Calcd for $C_{32}H_{54}O_3$: C, 81.99; H, 11.18%.

3β-Hydroxymethyl-A(1)-norfriedelane-3α,4,α-diol (25a). To a solution of 3-acetoxymethyl-A(1)-norfriedel-3-ene (**24b**; 300 mg) in ether (20 ml) was added osmium tetraoxide (0.3 g) and the solution was allowed to stand for 1 week. After addition of ether and excess LAH, the mixture was refluxed for 30 min and then a small amount of acetone was added. The usual work-up followed by chromatographic separation (silica gel-benzene and ether) gave 3β-hydroxymethyl-A(1)-norfriedelane-3α,4α-diol (**25a**; 185 mg), mp 263—267 °C (with decomp) (from ethyl acetate); IR 3850, 1120, 1060, 1045, 1005, and 940 cm^{-1}. ^1H NMR (90 MHz, $CDCl_3$) δ=3.60 (2H, s; $-CH_2O-$); MS *m/z* (%) 460 (M^+; trace), 442 (10), 417 (68), 343 (21), 273 (23), 219 (30), 205 (100), 191 (34), 142 (55), and 109 (80); Found: C, 78.06; H, 11.21%. Calcd for $C_{30}H_{52}O_3$: C, 78.20; H, 11.38%.

3β-Acetoxymethyl-A(1)-norfriedelane-3α,4α-diol (25b). On acetylation of **25a** afforded the acetate (**25b**), mp 212—214 °C (needles from ether-cyclohexane); IR 3500, 3300, 1750, 1730, 1260, and 1065 cm^{-1}. ^1H NMR (60 MHz, $CDCl_3$) δ=2.10 (3H, s; CH_3COO-) and 4.10 (2H, s; $-CH_2OOC-$); MS *m/z* (%) 460 (M^+; trace), 442 (10), 417 (68), 273 (23), 219 (30), 205 (100), 191 (34), 142 (55), and 109 (80); Found: C, 76.17; H, 10.67%. Calcd for $C_{32}H_{54}O_4$: C, 76.44; H, 10.83%.

4α-Hydroxy-A(1)-norfriedelan-3-one (26) and 4β-Hydroxy-A(1)-norfriedelan-3-one (32). Friedelane-2,3-dione (**28**; 5 g) and potassium hydroxide (5 g) were dissolved in diethylene glycol (400 ml) and the mixture was heated at 200 °C for 10 h under a nitrogen atmosphere. The solution was then poured into 2% hydrochloric acid (1 l) with formation of white precipitates, which were collected on a filter paper and dried. Although the benzilic acid rearrangement product consisted of a mixture of stereoisomers, further purification was not done.

The crude product obtained above, was suspended in acetic acid (300 ml) and LTA was added until no starting material was detected on TLC. Then the reaction mixture was poured into water and extracted with ether. The ether layer was worked up as usual and chromatographed (silica gel-benzene) to give a mixture of A(1)-norfriedelan-3-one (**29**) and its 4-epimer.

The mixture (1 g) of **29** and its 4-epimer was refluxed with benzoyl chloride (30 ml) for 1 h. After cooling, pyridine (10 ml) and then water (10 ml) were added dropwise, and the mixture was allowed to stand until the exothermic reaction ceased. Ether was added and the ethereal solution was washed with dil hydrochloric acid. The organic layer was worked up in usual manner and subjected to chromatography on silica gel. Elution with benzene-petroleum benzine afforded A(1)-norfriedel-3-en-3-yl benzoate (**27**; 0.93 g), mp 206—209 °C (from dichloromethane-cyclohexane); IR 1740, 1685, 1250, 1100, and 710 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=7.3—8.3 (5H, m; C_6H_5-); MS *m/z* (%) 516 (M^+; 0.4), 501 (4), 155 (5), 135 (7), 121 (11), 109 (14), 107 (14), and 105 (100); Found: C, 83.41; H, 10.14%. Calcd for $C_{36}H_{52}O_2$: C, 83.66; H, 10.14%.

To a solution of the benzoate (**27**; 1 g) in dichloromethane (300 ml) was added 39% peracetic acid solution (20 ml, a trace amount of sulfuric acid in the solution was neutralized by addition of potassium acetate before use). The reaction mixture was kept in a dark place for a week, and then the remaining peroxide was decomposed with an aqueous solution of potassium iodide and sodium sulfite. The organic layer was washed with sodium carbonate solution and concentrated to yield a residue, which was hydrolyzed with ethanolic potassium hydroxide solution at room temperature for 2 d. After most of ethanol was removed in vacuo, the residue was extracted with benzene and chromatographed on silica gel. Elution was performed with benzene to afford 4α-hydroxy-A(1)-norfriedelan-3-one (**26**; 530 mg) and the 4β-epimer (**32**; 3 mg) in turn. **26**; mp 286 °C (with decomp) (from benzene); IR 3450, 1740, 1090, and 915 cm^{-1}; ν^{OH} (0.001 M carbon tetrachloride solution) 3606 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=2.18 (1H, s; -OH); MS *m/z* (%) 428 (M^+; 36), 341 (63), 205 (69), 137 (56), 135 (46), 123 (72), 121 (53), and 109 (100); Found: C, 80.95; H, 11.02%. Calcd for $C_{29}H_{48}O_2$: C, 81.25; H, 11.29%. **32**; Mp 214—216.5 °C (from cyclohexane); IR 3450, 3400, 1755, and 1745 cm^{-1}; ν^{OH} (0.001 M carbon tetrachloride solution) 3563 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=2.0 (1H, s; -OH); MS *m/z* 428 (M^+; 38), 341 (50), 205 (78), 137 (46), 123 (75), 121 (54), 109 (100), and 107 (54); Found: *m/z* 428.3624. Calcd for $C_{29}H_{48}O_2$: M, 428.3654.

Methyl 4-Oxo-3,4-seco-A(1)-norfriedelan-3-oate (33b). 4-Oxo-3,4-seco-A(1)-norfriedelan-3-oic acid (**33a**) was prepared from friedelane-2,3-dione (**28**) by the same procedure as that for the preparation of 4-oxo-3,4-secofriedelan-3-oic acid (**17a**) from friedel-3-en-3-yl benzoate (vide supra). **33a**; Mp 215—217 °C (from ethanol); IR 3450, 1740, 1200, 1180, 1150, 1070, 1050, 1010, 990, and 900 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=2.20 (3H,s; Ac) and 1.9—2.5 (2H, m; $-C\underline{H}_2-COOH$); MS *m/z* (%) 444 (M^+; 2), 401 (40), 219 (19), 205 (100), 137 (28), 135 (26), 123 (48), 121 (37), and 109 (88). On methylation with diazomethane, **33a** afforded methyl 4-oxo-3,4-seco-A(1)-norfriedelan-3-oate (**33b**), mp 166—167 °C (from ethanol); IR 1740, 1695, 1295, 1170, and 995 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=2.20 (3H, s; Ac) and 3.63 (3H, s; $-COOCH_3$); MS *m/z* (%) 458 (M^+; 6), 415 (35), 219 (12), 205 (45), 163 (20), 135 (50), 121 (78), and 109 (100).

4α-Hydroxyfriedelan-3-one (35) and 4β-Hydroxyfriedelan-3-one (36). The preparation procedure of **35** and **36** was almost the same as that of 4α- and 4β-hydroxy-A(1)-norfriedelan-3-ones (**26** and **32**) from friedelane-2,3-dione (**28**). **35**; Mp 269—271 °C (from ethyl acetate); IR 3440, 1710, 1110, and 1070 cm^{-1}; ν^{OH} (0.001 M carbon tetrachloride solution) 3620 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) no signals below δ 2.5 were observed. MS *m/z* (%) 442 (M^+; 40), 205 (74), 123 (81), 121 (52), 109 (100), and 107 (56); Found: C, 81.16; H, 11.11%. Calcd for $C_{30}H_{50}O_2$: C, 81.39; H, 11.38%. **36**; Mp 234.5—236 °C (from ethyl acetate); IR 3470, 1720, 1160, and 1125 cm^{-1}; ν^{OH} (0.001M carbon tetrachloride solution) 3520 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=2.55 (2H, m; $C_{(2)}H_2CO-$) and 3.9 (1H, s; -OH); MS *m/z* (%) 442 (M^+; 19), 399 (5), 205 (39), 189 (17), 135 (39), 121 (64), and 109 (100).

A New Synthesis of 3-Amino-2-alkenoates. Novel Synthetic Route to Amino Sugars *N*-Benzoyl-L-daunosamine and -L-acosamine

Tamejiro HIYAMA,* Kazuhiro KOBAYASHI, and Kiyoharu NISHIDE
Sagami Chemical Research Center, 4-4-1 Nishiohnuma, Sagamihara, Kanagawa 229
(Received December 9, 1986)

Alkanoate esters are found to couple with various nitriles to give (*Z*)-3-amino-2-alkenoates in good yields with the aid of a magnesium amide prepared by the reaction of ethylmagnesium bromide and diisopropylamine. The C-C bond forming reaction was applied to (2*S*,3*S*)-2,3-(cyclohexylidenedioxy)butanenitrile and the resulting adduct was successfully converted into *N*-benzoyl-L-daunosamine in 41% overall yield through a sequence of functional group manipulation; acetylation, hydrogenation, hydrolysis and benzoylation, lactonization and finally reduction. By the similar process, (2*R*,3*S*)-2,3-(cyclohexylidenedioxy)butanenitrile was transformed to *N*-benzoyl-L-acosamine in 25% overall yield.

Carbonyl addition of the enolates of carboxylic acids and their esters is well-documented and widely used for the construction of carbon framework of various target molecules.[1] For this carbonyl addition, a variety of metal enolates are employed which exhibit characteristic reactivity with respect to stereo-selection.[2] Addition of the metal enolates with nitrogen analogs of aldehydes is especially useful for β-lactam synthesis.[3] However, nitriles as the substrates remained unexplored until recently, possibly due to low reactivity of conventional enolates.[4] In fact, when we examined the reaction of *t*-butyl lithioacetate with benzonitrile, we observed that no trace of the expected adduct was produced. The failure of the nitrile addition was ascribed to the incapability of the lithium ion to take a nitrile in its ligand sphere as well as to the instability of the primary adduct. Thus, we searched for higher valent metal counter ions appropriate to the C-C bond formation. Zinc enolates grew promising upon literature survey.[5] We could not, however, achieve the nitrile addition of the Reformatsky reagent in good yields, although Hannick and Kishi later established an improved procedure for the Blaise reaction.[6] After several screening experiments, we found the magnesium enolates of alkanoate esters undergo the desired reaction to afford 3-amino-2-alkenoates efficiently[7] and applied the reaction successfully to the synthesis of amino sugars *N*-benzoyl-L-daunosamine[8] and *N*-benzoyl-L-acosamine.[9] Details of the new transformation are reported herein.

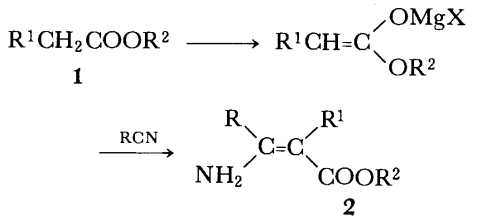
Results and Discussion

Nitrile Addition of Alkanoate Magnesium Enolates. The reaction of *t*-butyl acetate with benzonitrile was first studied. Magnesium amide was prepared by mixing equimolar amounts of ethylmagnesium bromide and a secondary amine[10] such as diisopropylamine, isopropylcyclohexylamine and hexamethyldisilazane. *t*-Butyl acetate was treated with each base at −10 to 0 °C in diethyl ether for 1 h and then with benzonitrile to give, after quenching with aqueous ammonium chloride solution and extractive workup followed by distillation, *t*-butyl 3-amino-3-phenylpropenoate (**2i**) in 53, 49, and 62% yield respectively. The yields were improved when the magnesium amide was prepared by 2 : 1 molar ratio of secondary amine and ethylmagnesium bromide. Diethyl ether was proved to be a superior solvent to tetrahydrofuran (THF). Although the structure of the magnesium amide reagent is unclear at present, a report by Wannagat and Kuckertz is informative.[11] They treated hexamethyldisilazane with a Grignard reagent in diethyl ether and obtained a complex $[(Me_3Si)_2N]_2Mg : MgX_2 : OEt_2$ which upon treatment with more basic solvent dioxane gave $[(Me_3Si)_2N]_2Mg$: (dioxane)$_3$ and MgI_2 : (dioxane)$_2$. Thus, we assumed the reagent generated from a 1 : 1 mixture of EtMgBr and HN(*i*-Pr)$_2$ would be a mixture of $[(i\text{-Pr})_2N]_2Mg$ and $MgBr_2$ solvated by diethyl ether. By use of excess diisopropylamine, the Lewis acid $MgBr_2$ would be preferentially neutralized, and, as the results, the reactivity of the magnesium amide base is enhanced.

$$2\,EtMgBr + 4\,HN(i\text{-}Pr)_2 \longrightarrow Mg[N(i\text{-}Pr)_2]_2 + MgBr_2 \cdot [HN(i\text{-}Pr)_2]_2$$

We employed diisopropylamine for all cases, as it is relatively cheap and volatile enough to be removed readily. At the early stage of our research,[7a] we employed 4 : 2 : 2 molar ratio of diisopropylamine, ethylmagnesium bromide and ester, but later found a 4 : 2 : 1 ratio is better for the reaction, since an excess ester sometimes underwent self-condensation.

The nitrile addition of magnesium ester enolate is applicable to various nitriles (Scheme 1). The mol ratio of the ester enolate to a nitrile was changed from 1 : 1 to large excess depending on the reactivity of the nitrile as summarized in Table 1. Nitriles having rela-



Scheme 1.

Table 1. Nitrile Addition of the Magnesium Enolates of Alkanoate Esters

Run	Nitrile	Alkanoate Ester 1	Reaction Condition	Product (Yield)
1	MeCN (62 mg, 1.5 mmol)	AcOt-Bu (0.35 g, 3 mmol)[a]	0 °C, 3 h	 **2a** (0.156 g, 66%)
2	 (0.104 g, 1.5 mmol)	AcOt-Bu (0.35 g, 3 mmol)[a]	0 °C, 4 h	 **2b** (0.158 g, 57%)
3	 (0.104 g, 1.5 mmol)	AcOt-Bu (0.174 g, 1.5 mmol)[a]	0 °C, 1.5 h	 **2c** (0.21 g, 74%)

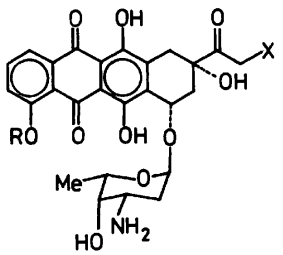
a) A mol ratio of diisopropylamine:ethylmagnesium bromide:ester was 4:2:2. b) A mol ratio of diisopropylamine:ethylmagnesium bromide:ester was 4:2:1. c) THP is tetrahydropyran-2-yl; EE is 1-ethoxyethyl group.

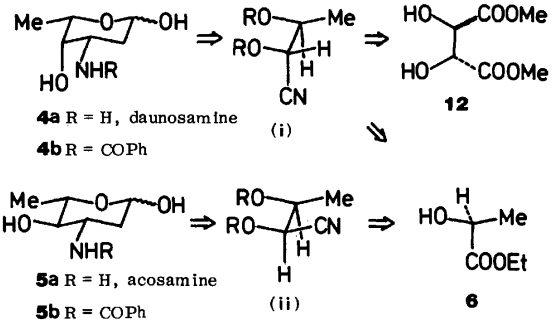
tively acidic α-hydrogen(s) gave slightly lower yields of adducts (Runs 5 and 6). The yields were not improved even by use of 6 fold mol of the ester enolate. 3-Butenenitrile did not give the desired adduct at all. The nitrile addition was applied particularly effectively to α-alkoxy nitriles or protected cyanohydrins (Runs 14 to 17). Ethyl acetate and *t*-butyl propionate can be employed in place of *t*-butyl acetate, but these required milder conditions: Both generation of magnesium enolate and the reaction with benzonitrile were preferably carried out at −78 °C, and the reaction mixture was allowed to warm up gradually (Runs 10, 11, and 17) to avoid self-condensation of the esters.

The configuration of the products **2** is all assigned as (Z) on the basis of ^{1}H NMR spectra. For example, **2a** and **2c** showed olefinic singlet absorptions at δ 4.42 and 4.47 respectively consistent with the literature values δ 4.49 and 4.56 for the ethyl ester of Z-configuration corresponding to **2a** and **2c** respectively.[12] The Z-preference is ascribed to intramolecular hydrogen bonding between amino and alkoxycarbonyl groups.[12] The geometrical preference was retained after the 3-amino-2-alkenoates were acetylated, though small amounts of (E)-isomers were produced. The resultant 3-acetamido-2-alkenoates are stable to moisture and was readily purified by preparative TLC or column chromatography in contrast to the parent compounds **2**.

As 3-amino-2-alkenoates are versatile synthetic intermediates for heterocycles such as pyridines,[13] pyrimidines, indoles,[14] and isothiazoles,[15] and, in addition, some *N*-aroyl derivatives of 3-amino-2-alkenoic acids exhibit anti-inflammatory activity,[16] various synthetic approaches have appeared.[6,17] The magnesium enolate-nitrile addition reported herein



3a R=Me, X=OH adriamycin
3b R=Me, X=H daunomycin
3c R=H, X=H carminomycin



Scheme 2.

can be characterized by simple experimental version coupled with wide applicability. We applied the new synthetic method to the total synthesis of physiologically active amino sugars.

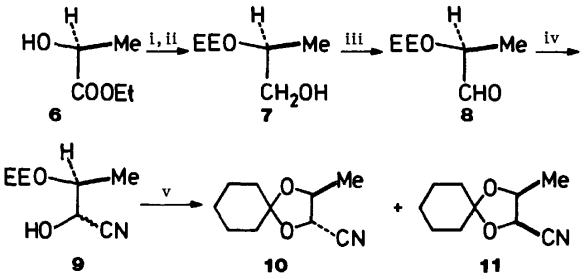
Synthesis of *N*-Benzoyl-L-daunosamine and -L-acosamine. The nitrile-ester enolate coupling reaction is applied to the synthesis of amino sugars such as L-daunosamine (**4a**) and L-acosamine (**5a**). These are sugar moieties of highly potent antitumor antibiotics adriamycin, daunomycin, and carminomycin.[18] Particularly, the cardiotoxicity is lowered remarkably by

changing the sugar part of adriamycin from daunosamine to acosamine.[19] The structural features of these amino sugars led us to retrosynthetic analysis as shown in Scheme 2. Addition of acetic acid ester enolate to the nitrile (i) or (ii) followed by stereoselective reduction of the resulting configurationally fixed C=C bond and appropriate functional group manipulation should afford daunosamine or acosamine derivatives respectively. The requisite nitriles (i) and (ii) may be derived from ethyl (*S*)-(−)-lactate (**6**). Methyl L-tartrate (**12**) can be the precursor of the nitrile (i), as the tartrate possesses the needed C_4 framework, oxygen functional groups and stereochemical arrangements all in a single molecule. Synthetic operations were carried out according to the Schemes 3 and 4.

Ethyl (*S*)-(−)-lactate (**6**) was protected with ethyl vinyl ether, and reduced with lithium aluminium hydride to give (*S*)-2-ethoxyethyl ether of 1,2-propanediol (**7**). Oxidation of **7** with dimethyl sulfoxide (DMSO)[20] gave the aldehyde **8** which was isolated by distillation. Cyanohydrin formation was effected with acetone cyanohydrin and triethylamine catalyst. The resulting cyanohydrin **9** was converted into a cyclohexylidene acetal by acetal exchange reaction with cyclohexanone dimethyl acetal and bis(trimethylsily) sulfate catalyst.[21] The diastereomeric ratio of **10** and **11** was estimated before isolation to be 45 : 55. When the cyanohydrin formation was carried out with Me_3SiCN and Et_2AlCN catalyst, the diastereomeric ratio changed to 73 : 27. These nitriles were readily separated by column chromatography. ^1H NMR study with $Eu(tfc)_3$ showed >95% optical purity of **10** and **11**. Thus, no trace of racemization occurred during the oxidation of **7**, cyanohydrin formation or acetalization leading to **10** and **11**. All attempts to epimerize the C(2) stereocenter with base failed. Either recovery of the starting nitriles (NaOEt) or total decomposition ($LiN(i\text{-}Pr)_2$) was observed in sharp contrast to the facile epimerization of the corresponding aldehydes.[22]

The (2S,3S)-isomer **10** was alternatively prepared according to the Scheme 4. Dimethyl L-tartrate (**12**) was acetalized to **13**[23] which was reduced with lithium aluminium hydride to a diol. Selective monotosylation followed by sodium borohydride reduction of the resulting tosylate gave an alcohol **14**. Oxidation by the Swern's method[20] afforded **15**.[24] Derivatization of **15** to its oxime followed by dehydration gave **10**.

With the required nitriles now at hand, we studied subsequent C_2 homologation. The (2*S*,3*S*)-nitrile **10**



i) CH_2=CHOEt, PyH·OTs, CH_2Cl_2, 0 °C to r.t.

v) *i*-Bu_2AlH, THF, −60 to −50 °C

Scheme 6.

was revealed to be reactive enough to afford **16** in 99% yield (Scheme 5). Although the C=C bond of 3-amino-2-alkenoates is recorded to be reduced under several conditions,[25] the known conditions were not applicable to **16** possibly due to unrecognized electronic and/or steric reasons. To reduce the electron density of the C=C bond of **16**, we acetylated **16** to **17**. A part of the product isomerized to the (E)-isomer.[26] The acetamide **17** was proved to be acid-stable and was readily purified by chromatography. Catalytic hydrogenation was studied under various conditions. Results are summarized in Table 2. Platinum catalyst produced predominantly the desired product **18**, whereas rhodium and palladium catalysts preferred the formation of the epimer of **18**. Under the conditions of Run 5, **18** was isolated in 82% yield in a pure form. Its epimer was isolated in 16% yield. Treatment of **18** with hydrochloric acid induced hydrolysis of the acetal, ester and amide moieties all in a single operation. Subsequent benzoylation under the Schotten-Baumann conditions followed by lactonization gave a δ-lactone **19**. The lactonization was found to proceed stepwise: Initially a γ-lactone **20** was formed which gradually isomerized to **19**. Reduction of **19** with diisobutylaluminium hydride gave *N*-benzoyl-L-daunosamine.[27,28,31]

For the synthesis of *N*-benzoyl-L-acosamine (**5b**), (2*R*,3*S*)-2,3-(cyclohexylidenedioxy)butanenitrile (**11**) is a requisite starting material. Addition of the magnesium enolate of *t*-butyl acetate to **11** was found relatively sluggish and took place at 0 °C to give **21** in 54% yield after isolation by distillation. Acetylation under the standard conditions gave **22**. Again (E)-isomer of **22** accompanied. Hydrogenation of **22** with rhodium or platinum catalyst was satisfactory in respect to stereochemical outcome. Of these, rhodium on carbon was employed in an autoclave under a hydrogen pressure of 70 kg cm^{-2}. Hereby a single isomer **23** was isolated in 84% yield. It is worthy of note that the stereochemical course of the hydrogenation of C(2)=C(3) is oriented by the configuration of C(5) rather than that of C(4) (compare the reduction of **17** with that of **22**), even though C(4) is situated closer to the reaction site.[32] Hydrolysis of **23** followed by *N*-benzoylation and lactonization afforded **24** which exhibited spectral data fully identical with the reported values.[28a] Diisobutylaluminium hydride reduction gave finally *N*-benzoyl-L-acosamine.[28,29]

Experimental

Distillation of a sample of less than 1 g was carried out by bulb-to-bulb distillation technique with Kugelrohr (Büchi) or Glass Tube Oven GTO 250R (Shibata). Larger amount of sample was distilled by a micro distillation apparatus. Reactions were carried out under an argon atmosphere unless otherwise specified. All mps and bps were uncorrected values. ^{1}H NMR spectra were obtained on a Varian EM 390 or Varian XL-100A spectrometer, chemical shifts being given in ppm units from the tetramethylsilane standard. ^{13}C NMR spectra were recorded on a Bruker AM-400 spectrometer with tetramethylsilane as the internal standard. IR spectra were taken on a JASCO A 202 spectrometer. Specific rotation was measured with a Horiba SEPA-200 or Union PM-201 machine. Low resolution mass spectra were recorded with a Hitachi RMU-6MG machine (70 eV); millimass with a Hitachi M-80A spectrometer. GLC analyses were performed with a Shimadzu GC-7A chromatograph with a FID detector. TLC analyses were performed on com-

mercial glass plates coated with Merck Silica Gel 60 F_{254} in 0.25 mm thick layer. Preparative TLC plates were prepared using Merck Kieselgel 60 PF_{254}. Column chromatography was carried out using silica gel such as Wacogel C-100 (Wako) or Kieselgel 60 (Merck). THF and diethyl ether were distilled before use from sodium-benzophenone. Diisopropylamine, *t*-butyl acetate, and DMSO were distilled over calcium hydride.

***t*-Butyl 3-Amino-2-butenoate (2a). A Typical Procedure for Generation and Nitrile Addition of the Magnesium Enolate of *t*-Butyl Acetate.** Diisopropylamine (0.61 g, 6.0 mmol) was added to an ethereal solution (0.70 M, 4.3 ml) of ethylmagnesium bromide (3.0 mmol) at 0 °C, and the reaction mixture was stirred for 1 h. To the resulting turbid solution was added *t*-butyl acetate (0.35 g, 3.0 mmol) at 0 °C. After 0.5 h acetonitrile (62 mg, 1.5 mmol) was injected with the aid of a microsyringe to the reaction mixture and allowed to react for 3 h at 0 °C. Quenching with aqueous ammonium chloride solution, extraction with diethyl ether, and purification by distillation gave *t*-butyl 3-amino-2-butenoate (**2a**) (0.156 g, 66% yield). Bp 73 °C/0.3 Torr† (lit,[16] 66 °C/0.4 Torr). IR (neat) 3460, 3345, 1650, 1615, 1558 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.46 (s, 9H), 1.84 (s, 3H), 4.42 (s, 1H), 5.0—6.7 (br, 2H).

The *t*-butyl esters of **2** (Table 1) were prepared by the similar procedure described above, and the physical properties of these are listed below.

***t*-Butyl 3-Amino-2-hexenoate (2b):** Bp 78 °C/0.25 Torr; IR (neat) 3460, 3345, 1655, 1615, 1560 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.93 (t, 3H), 1.45 (s, 9H), 1.5—1.8 (m, 2H), 2.05 (t, 2H), 4.43 (s, 1H), 5.3—6.6 (br, 2 H). Ethyl 3-Amino-3-phenyl-2-propenoate (2j). The magnesium amide was prepared by the addition of diisopropylamine (0.61 g, 6.0 mmol) to an ethereal solution (4.3 ml) of ethylmagnesium bromide (3 mmol) at 0 °C and by stirring the solution of 1 h. To the base solution cooled at −78 °C, ethyl acetate (0.132 g, 1.5 mmol) was added drop by drop and the resulting enolate solution was stirred at −78 °C for 30 min. Benzonitrile (0.155 g, 1.5 mmol) was then added, and the reaction mixture was allowed to warm to 0 °C and stirred for 1.5 h. Workup as before followed by distillation gave **2j** (0.163 g, 57% yield). Bp 112 °C/0.3 Torr (lit,[30] bp 110—112 °C/0.2 Torr).

Acetylation of 2n. A mixture of *t*-butyl 3-amino-4-trimethylsilyloxy-2-pentenoate (**2n**) (1.00 g, 3.9 mmol), acetic anhydride (10 ml) and pyridine (0.53 g, 6.6 mmol) was heated at 80 °C for 9 h. Excess acetic anhydride and pyridine was evaporated under reduced pressure, and the residue was purified by column chromatography (silica gel, hexane-ethyl acetate 3:1) to give *t*-butyl (*Z*)-3-acetamido-4-acetoxy-2-pentenoate (R_f=0.56, 0.68 g, 65% yield). IR (neat) 3230, 1745, 1720, 1660, 1630 cm^{-1}; ^1H NMR (CCl_4) δ=1.42 and 1.46 (d and s, totally 12 H), 2.03 (s, 3H), 2.11 (s, 3H), 4.99 (s, 1H), 6.31 (q, 1H), 12.2 (br, 1H). Found: C, 57.24; H, 7.66; N, 4.84%. Calcd for $C_{13}H_{21}NO_5$: C, 57.55; H, 7.80; N, 5.16%.

The (E) isomer (R_f=0.13, 0.198 g) also was obtained in 19% yield. Mp 104—105.5 °C; IR (KBr) 3350, 1745, 1710 (sh), 1695, 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.43 and 1.46 (d and s, totally 12H), 2.09 (s, 3H), 2.14 (s, 3H), 6.68 and 6.80 (q and s, 2H), 7.2 (br, 1H).

(*S*)-2-(1-Ethoxyethoxy)-1-propanol (7). A dichloromethane (26 ml) solution of pyridinium *p*-toluenesulfonate (1.53 g, 0.01 mol) was added drop by drop to a mixture of ethyl (*S*)-lactate (11.8 g, 0.10 mol), ethyl vinyl ether (10.8 g, 0.15 mol) and dichloromethane (100 ml), and the mixture was stirred at 0 °C for 50 min and at room temperature for 1 h. The reaction mixture was diluted with diethyl ether (300 ml) and washed twice with brine (50 ml) and then twice with water (50 ml). The organic layer was dried over anhydrous sodium sulfate and concentrated under reduced pressure. Distillation at 77—78 °C/26 Torr gave ethyl (*S*)-*O*-ethoxyethyl lactate (18.4 g, 97% yield). ^1H NMR ($CDCl_3$) δ=1.06—1.50 (m, 12H), 3.33—3.90 (m, 2H), 4.20 (q, *J*=7.5 Hz, 2H), 4.30 (q, *J*=6.0 Hz, 1H), 4.76 (q, *J*=6.0 Hz). IR (neat) 3000, 2950, 1750, 1445, 1390, 1370, 1270, 1200, 1175, 1150, 1090, 1055, 1025, 965 cm^{-1}. MS *m/z* (rel intensity) 189 (M^+ −1, 1), 175 (15), 145 (99), 117 (53), 102 (73), 101 (44), 74 (49), 73 (100), 72 (15), 55 (13), 45 (100). $[\alpha]_D^{24}$ −54.1° (*c* 3.87, $CHCl_3$); $[\alpha]_D^{28}$ −71.7° (*c* 4.18, MeOH). Found: C, 57.05; H, 9.77%. Calcd for $C_9H_{18}O_4$: C, 56.82; H, 9.54%.

The above lactate (14.9 g, 78.3 mmol) dissolved in diethyl ether (100 ml) was added to an ethereal solution (100 ml) of lithium aluminium hydride (4.05 g, 0.100 mol) over 25 min. After the addition was completed, the reaction mixture was heated to reflux for 7 h. Quenching the excess hydride was effected by dropwise addition of aqueous saturated solution of sodium sulfate and successively by the addition of magnesium sulfate. Filtration through a Hyflosupercell pad, concentration, followed by distillation, gave **7** (10.9 g, 94% yield). Bp 77—79 °C/17 Torr; ^1H NMR ($CDCl_3$) δ=1.06—1.38 (m, 9H), 2.62 and 3.20 (dd, *J*=(6.8, 5.3 Hz) and (8.3, 4.1 Hz) respectively, totally 1H, OH), 3.37—3.96 (m, 5H), 4.70 and 4.78 (2q, *J*=5.3 Hz each, totally 1H); IR (neat) 3450, 3000, 2950, 1450, 1380, 1340, 1130, 1105, 1060, 970 cm^{-1}; MS *m/z* (rel intensity) 147 (M^+−1, 1), 133 (2), 117 (5), 103 (15), 73 (92), 59 (43), 45 (100), 43 (12). $[\alpha]_D^{29}$ +42.2° (*c* 5.87, $CHCl_3$). Found: C, 56.91; H, 11.03%. Calcd for $C_7H_{16}O_3$: C, 56.73; H, 10.88%.

(*S*)-2-(1-Ethoxyethoxy)propanal (8). A dichloromethane (40 ml) solution of DMSO (7.9 g, 7.2 ml, 0.101 mol) was added drop by drop over 15 min to a dichloromethane (100 ml) solution of oxalyl dichloride (6.4 g, 4.4 ml, 0.050 mol) at −70 °C. After stirring for 10 min a dichloromethane (50 ml) solution of **7** (5.0 g, 0.034 mol) was added over 15 min, and the resulting mixture was stirred for 30 min at −70 °C before addition (over 15 min) of triethylamine (17.1 g, 23.5 ml, 0.168 mol). The mixture was stirred at −70 °C for 25 min, allowed to warm to 10 °C in 20 min, and then treated with brine (100 ml). The organic layer was separated, washed with brine (50 ml×2), dried over magnesium sulfate and concentrated. Distillation at 53—54 °C/17 Torr gave **8** (3.8 g, 78% yield) as a colorless oil. ^1H NMR ($CDCl_3$) δ=1.06—1.38 (m, 9 H), 3.20 (q, *J*=7.5 Hz, 2H), 3.70—4.27 (m, 1H), 4.71 and 4.81 (2q, *J*=5.3 Hz, totally 1H), 9.59 and 9.64 (2d, *J*=3.0 and 1.5 Hz respectively, totally 1H); IR (neat) 1735 cm^{-1}. $[\alpha]_D^{23}$ −56.9° (*c* 6.31, $CHCl_3$). The aldehyde was immediately used for the next transformation.

(3*S*)-3-(1-Ethoxyethoxy)-2-hydroxybutanenitrile (9). A mixture of **8** (2.2 g, 15 mmol), acetone cyanohydrin (bp 53—55 °C/8 Torr, 1.53 g, 1.64 ml, 18 mmol) and triethylamine (21 μl, 15 mg) was stirred in an ice bath for 1 h. TLC assay revealed the starting material **8** was all consumed. Evaporation of excess acetone cyanohydrin and triethylamine followed by brief column chromatography (Wacogel C-100, hexane-ethyl acetate 3:1 to 1:1) gave **9** (2.6 g, quantitative yield) as a viscous oil. ^1H NMR ($CDCl_3$) δ=1.10—1.40 (m, 9H), 3.36—4.14 (m, 3H), 4.25 and 4.28 (2d, *J*=1.5 and 4.5 Hz, respectively, totally 1H), 4.60—6.00 (m, 1H); IR (neat) 3425, 3000, 2950, 2250, 1450, 1395, 1340, 1130, 1070, 970, 940, 855, 810 cm^{-1}. The cyanohydrin was directly used for the next reaction.

(2*S*,3*S*)-2,3-(Cyclohexylidenedioxy)butanenitrile (10) and (2*R*,3*S*)-2,3-(Cyclohexylidenedioxy)butanenitrile (11). In a 100-ml flask were placed successively activated Molecular Sieve 4A (ca. 5 g), a dichloromethane (20 ml) solution of **9** (2.55 g, 14.7 mmol), a dichloromethane (20 ml) solution of 1,1-dimethoxycyclohexane (2.39 g, 16.5 mmol). The mixture was cooled to 0 °C and a 1 M dichloromethane solution of bis(trimethylsilyl) sulfate (0.45 ml, 0.45 mmol) was added and the resulting mixture was stirred at 0 °C for 10 min and at room temperature for 30 min. The reaction mixture was neutralized with pyridine (0.1 ml), and the insoluble mate-

rial was filtered off. Concentration and purification by column chromatography (Kieselgel 60, hexane-ethyl acetate 10 : 1 to 6 : 1) afforded **10** (0.69 g, R_f=0.67, hexane-ethyl acetate 3 : 1, 28% yield) and **11** (1.05 g, R_f=0.55 (vide supra), 40% yield).

Physical properties of **10** are as follows. Bp 60—61 °C/0.25 Torr; ^{1}H NMR (CCl_4) δ=1.38 (d, J=6.0 Hz, 3H), 1.50—1.80 (m, 10H), 4.02 (d, J=7.5 Hz, 1H), 4.36 (quintet, J=6.0 Hz, 1H); IR (neat) 2950, 2870, 2250, 1450, 1370, 1285, 1160, 1120, 1065, 930, 910 cm^{-1}; MS m/z (rel intensity) 181 (M^+, 9), 152 (11), 138 (100), 55 (29), 41 (15); $[\alpha]_D^{24}$ +15.5° (c 8.84, $CHCl_3$). Found: C, 66.38; H, 8.39; N, 7.57%. Calcd for $C_{10}H_{15}NO_2$: C, 66.27; H, 8.34; N, 7.73%.

Physical properties of **11** are following. Bp 73—75 °C/0.25 Torr; ^{1}H NMR (CCl_4) δ=1.45, (d, J=6.0 Hz, 3H), 1.30—1.80 (m, 10H), 4.21 (quintet, J=6.0 Hz, 1H), 4.58 (d, J=5.3 Hz, 1H); IR (neat) 2950, 2875, 2250, 1450, 1370, 1285, 1240, 1170, 1120, 1080, 920 cm^{-1}. MS m/z (rel intensity) 181 (M^+, 9), 152 (12), 138 (100), 84 (10), 55 (31), 42 (10), 41 (15); $[\alpha]_D^{26}$ +26.4° (c 5.57, $CHCl_3$). Found: C, 66.40; H, 8.44; N, 8.09%. Calcd for $C_{10}H_{15}NO_2$: C, 66.27; H, 8.34; N, 7.73%. The optical purity of **11** was checked by ^{1}H NMR with a chiral shift reagent Eu(tfc)$_3$ (1.2 mol eq) in dry CCl_4 solution. Under these conditions the doublet methine proton of (±)-**11** splitted into base-line resolved two doublets. The sample of **11** prepared as above gave only one doublet at higher field and the other doublet was not detected even after 5 times enlargement. The sample of **10** also was subjected to the chirality check, and similar results were obtained. Thus, the optical purity of **11** as well as **10** was estimated to be more than 95%.

(2*S*,3*S*)-2,3-(Cyclohexylidenedioxy)-1-butanol (14). An ethereal (20 ml) solution of dimethyl (2*R*,3*R*)-2,3-(cyclohexylidenedioxy)butanedioate[23] (5.16 g, 20 mmol) was added to an ethereal (20 ml) solution of lithium aluminium hydride (2.0 g) at 0 °C. After the addition was completed, the reaction mixture was heated to reflux for 1 h, and the excess hydride was quenched by addition of saturated aqueous solution of sodium sulfate under cooling. The reaction mixture was further dried by addition of anhydrous magnesium sulfate under vigorous stirring. Filtration through a pad of Hyflo-supercell followed by concentration gave a crude oil of (2*S*,3*S*)-2,3-(cyclohexylidenedioxy)-1,4-butanediol (2.78 g, 69% yield). Mp 52—54 °C; ^{1}H NMR ($CDCl_3$) δ=1.4—1.8 (m, 10H), 2.90 (t, J=6 Hz, 2H), 3.68—4.03 (m, 6H); IR (KBr) 3400, 2940, 1450, 1160, 1120, 1040 cm^{-1}.

The diol (13.7 mmol) was dissolved in dichloromethane (10 ml) and triethylamine (3 ml, 21.4 mmol). To the solution was added at 0 °C *p*-toluenesulfonyl chloride (2.86 g, 15 mmol) dissolved in dichloromethane (15 ml) drop by drop over a period of 3 h with the aid of a syringe drive. Stirring was continued at 0 °C for 1 h and at room temperature for 1 h. Concentration under reduced pressure, trituration of the resulting solid with diethyl ether, filtration, concentration of the ethereal filtrate, followed by purification by column chromatography (Wacogel C-100, hexane-ethyl acetate 2 : 1), afforded a ditosylate (2.13 g, 30% yield). Further elution with hexane-ethyl acetate (1 : 1) gave a monotosylate (2.13 g, 44% yield, 70% yield based on the consumed diol). Elution with ethyl acetate and methanol afforded a recovered diol (0.96 g). The monotosylate exhibited ^{1}H NMR ($CDCl_3$) δ=1.2—1.7 (m, 10H), 2.10 (s, 1H), 2.43 (s, 3H), 3.5—3.8 (m, 2H), 3.8—4.2 (m, 4H), 7.33 (d, J=8 Hz, 2H), 7.88 (d, J=8 Hz, 2H); IR (neat) 3500, 2940, 1740, 1600, 1360, 1180, 810 cm^{-1}.

The monotosylate (2.05 g, 5.7 mmol) was dissolved in DMSO (5 ml). To this solution was added sodium borohydride (0.68 g, 18 mmol) and the reaction mixture was heated at 80 °C for 2 h. At the initial stage, foaming of the reaction mixture was observed which ceased at the end of the reaction time. The reaction mixture was diluted with dichloromethane and the excess hydride was carefully quenched with brine. Dichloromethane extraction followed by usual work-up and purification by column chromatography (Wacogel C-100, hexane-ethyl acetate 3 : 1, R_f=0.27) gave **14** (0.94 g, 88% yield). ^{1}H NMR (CCl_4) δ=1.23 (d, J=6 Hz, 3H), 1.3—2.0 (m, 10H), 2.25 (br s, 1H), 3.3—3.7 (m, 3H), 3.88 (dq, J=8 and 6 Hz, 1H); IR (neat) 3450, 2940, 1440, 1360, 1160, 1100, 940 cm^{-1}.

(2*R*,3*S*)-2,3-(Cyclohexylidenedioxy)butanal (15). A dichloromethane (1 ml) solution of DMSO (0.34 ml, 4.8 mmol) was added to a dichloromethane (4 ml) solution of oxalyl dichloride (0.195 ml, 2.2 mmol) at −78 °C over a period of ca. 5 min, and the resulting solution was stirred at −78 °C for 10 min before the addition of a dichloromethane (2 ml) solution of **14** (0.375 g, 2.0 mmol) at −78 °C. After 15 min, triethylamine (1.4 ml) was added at −78 °C, and stirring was continued for 10 min. The reaction mixture was then warmed to room temperature, treated with water (ca. 6 ml), and vigorously stirred for 10 min. Separation of the organic layer, extraction of the aqueous layer with dichloromethane, drying the combined dichloromethane extract with anhydrous sodium sulfate, followed by concentration and purification by column chromatography (Wacogel C-100, CH_2Cl_2), afforded **15** (0.32 g, 87% yield). ^{1}H NMR (CCl_4) δ=1.33 (d, J=6.0 Hz, 3H), 1.4—2.0 (m, 10 H), 3.67 (dd, J=7.8 and 2.7 Hz, 1H), 4.00 (dq, J=7.8 and 6.0 Hz, 1H), 9.62 (d, J=2.7 Hz, 1H); IR (neat) 3450, 2940, 1740, 1370, 1100 cm^{-1}.

(2*S*,3*S*)-2,3-(Cyclohexylidenedioxy)butanenitrile (10). A mixture of **15** (0.29 g, 1.58 mmol), hydroxylamine hydrochloride (0.30 g, 4.3 mmol), ethanol (2 ml) and pyridine (2 ml) was heated at 80 °C for 2 h. Concentration followed by short column chromatography (Wacogel C-100, CH_2Cl_2) gave the oxime (0.32 g, quantitative yield) which exhibited ^{1}H NMR ($CDCl_3$) absorptions at δ=1.30 (d) and 1.43 (d) along with absorptions ascribed to aldoxime methine hydrogen at δ=6.80, 7.36, 7.68, and 8.60. Thus, syn-anti isomers as well as their conformational ones seem to coexist.

The oxime (40 mg, 0.20 mmol) dissolved in dichloroethane (1 ml) was heated in the presence of triphenylphosphine (80 mg, 0.30 mmol), triethylamine (42 μl, 0.3 mmol) and carbon tetrachloride (29 μl, 0.3 mmol) at 80 °C for 2 h. The reaction mixture was passed through an 8 cm column of Wacogel C-100 (CH_2Cl_2 elution) to give **10** (30 mg, 83% yield). Bp 150 °C/10 Torr.

***t*-Butyl (4*S*,5*S*,2*Z*)-3-Amino-4,5-(cyclohexylidenedioxy)-2-hexenoate (16).** The magnesium enolate of *t*-butyl acetate (0.42 ml, 3.3 mmol) was prepared as before using ethylmagnesium bromide (2.0 M ethereal solution, 3.3 ml, 6.6 mmol), diethyl ether (9.6 ml), diisopropylamine (1.96 ml, 14 mmol) at 0 °C. To this enolate solution was added an ethereal solution (3.0 ml) of **10** (0.30 g, 1.66 mmol) at 0 °C over a period of 5 min, and the mixture was stirred at 0 °C for 4 h. Workup gave a colorless solid **16** (0.49 g, 99% yield) which was homogeneous by silica gel TLC assay (R_f=0.70 (hexane-ethyl acetate 3 : 1)). Mp 102—103 °C (hexane). ^{1}H NMR ($CDCl_3$) δ=1.35 (d, J=5.3 Hz, 3H), 1.48 (s, 9H), 1.50—1.77 (m, 10H), 3.77—4.10 (m, 2H), 4.43 (s, 1H), 6.40 (br, 2H); IR (KBr) 3510,

Found: C, 64.57; H, 9.04; N, 4.63%. Calcd for $C_{16}H_{27}NO_4$: C, 64.62; H, 9.15; N, 4.71%.

***t*-Butyl (4*S*,5*S*,2*Z*)-3-Acetamido-4,5-(cyclohexylidenedioxy)-2-hexenoate (17).** A mixture of **16** (0.45 g), pyridine (4 ml) and acetic anhydride (4.0 ml) was heated at 50 °C for 6.5 d. Concentration in vacuo followed by preparative TLC (hexane-ethyl acetate 3:1) gave **17** (R_f=0.62, 0.31 g, 59% yield) along with its (E)-isomer (R_f=0.53, 97 mg, 19% yield) both as viscous oil. The compound **17** exhibited ^1H NMR ($CDCl_3$) δ=1.42 (d, *J*=6.0 Hz, 3H), 1.50 (s, 9H), 1.60—1.85 (m, 10H), 2.13 (s, 3H), 3.99 (quintet, *J*=6.0 Hz, 1H), 5.62 (s, 1H), 5.65 (d, *J*=6.0 Hz, 1H), 11.12 (br s, 1H, NH); IR (neat) 3450, 3250, 3000, 2950, 2880, 1720, 1635, 1490, 1450, 1370, 1250, 1150 cm^{-1}. The (E) isomer gave ^1H NMR ($CDCl_3$) δ= 1.37 (d, *J*=6.0 Hz, 3H), 1.47 (s, 9H), 1.60—1.80 (m, 10H), 2.08 (s, 3H), 3.80 (dq, *J*=8.3 and 6.0 Hz, 1H), 5.65 (d, *J*=8.3 Hz, 1H), 6.93 (br s, 1H), 7.87 (br s, 1H, NH).

***t*-Butyl (3*S*,4*S*,5*S*)-3-Acetamido-4,5-(cyclohexylidenedioxy)-hexanoate (18).** In an autoclave were placed **17** (34 mg, 0.1 mmol), ethyl acetate (2 ml) and platinum oxide (34 mg), and the atmosphere was replaced by hydrogen of 55 kg cm^{-2}. The autoclave was agitated at 70 °C for 24 h. Filtration of the catalyst through a Celite pad, concentration, followed by preparative TLC (hexane-ethyl acetate 1:1) afforded **18** (R_f=0.33, 28 mg, 82% yield) as a viscous oil. ^1H NMR ($CDCl_3$) δ=1.27 (d, *J*=6.0 Hz, 3H), 1.47 (s, 9H), 1.50—1.70 (m, 10H), 1.97 (s, 3H), 2.57 (dd, *J*=4.5 and 3.0 Hz, 2H), 3.55 (t, *J*=7.5 Hz, 1H), 3.75—4.10 (m, 1H), 4.15—4.50 (m, 1H), 6.40 (br d, *J*=7.5 Hz, 1H, NH); IR (neat) 3400 (br), 3100 (br), 2950, 1735, 1660, 1550, 1450, 1370, 1160, 1110, 950, 850 cm^{-1}; MS *m/z* (rel intensity) 341 (M^+, 16), 285 (18), 243 (18), 242 (100), 170 (61), 155 (37), 144 (31), 128 (35), 111 (27), 88 (23), 81 (20), 57 (35), 55 (24), 43 (40); $[\alpha]_D^{20}$ −4.8° (*c* 1.47, $CHCl_3$). Found: *m/z* 341.2186. Calcd for $C_{18}H_{31}NO_5$: M^+ 341.2200.

(3*R*)-Isomer (5 mg, 15% yield, R_f=0.60) also was isolated and showed ^1H NMR ($CDCl_3$) δ=1.30 (d, *J*=6.0 Hz, 3H), 1.45 (s, 9H), 1.50—1.70 (m, 10H), 1.97 (s, 3H), 2.50 (d, *J*=6.8 Hz, 2H), 3.40—3.85 (m, 1H), 6.0 (br d, *J*=10.5 Hz, 1H, NH).

(3*S*,4*S*,5*S*)-3-Benzamido-4-hydroxy-5-hexanolide (19). A mixture of the *t*-butyl ester **18** (73 mg, 0.22 mmol) and 2 M hydrochloric acid (3 ml) was heated to reflux for 5 h. Excess acid and volatile material were evaporated, and the residue was dissolved in saturated aqueous sodium hydrogencarbonate solution (7.5 ml) and acetone (2.6 ml). To the resulting solution was added benzoyl chloride (0.2 ml) at 0 °C. The mixture was stirred at room temperature for 2.5 h, then acidified with 2 M hydrochloric acid to pH 1, stirred for 20 min at room temperature and extracted with ethyl acetate. Workup and preparative TLC purification gave the desired lactone **19** (50 mg, 93% yield). Mp 138—140 °C (lit,[28b] 125—127 °C); R_f=0.06 (hexane-ethyl acetate 1:1); IR (Nujol) 3500, 3350, 1745, 1740, 1640, 1530, 1460, 1380, 1035 cm^{-1}; ^1H NMR (DMSO-d_6) δ=1.14 (d, *J*=6.2 Hz, 3 H), 2.54 (AB dd, *J*=18.0 and 4.0 Hz, 1H), 2.94 (AB dd, *J*=18.0 and 9.0 Hz, 1H), 3.91 (m, 1H), 4.30 (t, *J*=3.0 Hz, 1H), 4.63 (m, 1H), 5.10 (d, *J*=5.1 Hz, 1H, OH), 7.40—7.65 (m, 3H), 7.82—8.02 (m, 2H), 8.92 (br d, *J*=7.0 Hz, 1H, NH); ^{13}C NMR (DMSO-d_6) δ=19.3 (C-6), 34.5 (C-2), 48.3 (C-3), 66.5 (C-5), 88.9 (C-4), 127.2, 128.2, 131.3, 133.7 (aromatic), 166.1 (NHCO), 175.7 (lactone C=O); $[\alpha]_D^{20}$ −20.5° (*c* 0.39, ethanol); lit,[28b] $[\alpha]_D^{20}$ −15.8° (*c* 1, ethanol). Found: *m/z* 249.1024. Calcd for $C_{13}H_{15}NO_4$: M^+ 249.1000.

At the early stage of the lactonization, 1,4-lactone (**20**) was produced and isolated. The physical properties of **20** is as follows. R_f=0.13 (hexane-ethyl acetate 1:1); ^1H NMR ($CDCl_3$) δ=1.34 (d, *J*=6.2 Hz, 3H), 2.32 (br, 1H, OH), 2.60 (AB dd, *J*=18.0 and 4.0 Hz, 1H), 3.17 (AB dd, *J*=18.0 and 9.0 Hz, 1H), 4.16 (m, 1H), 4.41 (t, *J*=3.0 Hz, 1H), 4.85 (m, 1H), 6.89 (br d, *J*=7.0 Hz, 1H, NH), 7.45—7.62 (m, 3H), 7.76—7.92 (m, 2H). IR ($CHCl_3$) 3460, 3350, 2950, 1780, 1660, 1515, 1290, 1200, 1180, 1160, 990 cm^{-1}; $[\alpha]_D^{20}$ −10.6° (*c* 0.64, EtOH).

***N*-Benzoyl-L-daunosamine (4b).** A 1 M hexane solution of diisobutylaluminium hydride (0.07 ml, 5 mol equiv) was added to a THF (1.0 ml) solution of **19** (3.4 mg, 0.014 mmol) at −60 °C, and the resulting solution was stirred at −60 to −50 °C for 1.5 h before the addition of a 1:1 mixture (2 ml) of methanol and acetone. Warming up to room temperature, filtration through a Celite pad, concentration and purification by column chromatography (ethyl acetate) gave *N*-benzoyl-L-daunosamine (3.2 mg, 94% yield). Mp 153—155 °C (ether) (lit,[31] 152 °C); $[\alpha]_D^{20}$ −109° (*c* 0.08, EtOH) (lit,[31] −108° (*c* 0.5, EtOH)); ^1H NMR (DMSO-d_6) δ=1.10 and 1.15 (each d, *J*=6 Hz, 3H, Me of α,β-isomers), 1.35—2.16 (m, 2H, C(2)-H_2 of α,β-isomers), 3.14—4.90 (C(3-5)-H of α,β-isomers and C(1)-H of β-isomer, totally 7H), 5.18 (br m, 1H, C(1)-*H* of α-isomer), 6.18 (br d, *J*=3.8 Hz, 1H, OH of α-isomer), 6.50 (br d, *J*=6.3 Hz, 1H, OH of α-isomer), 7.38—7.66 (m, 3H, aromatic), 7.80—8.10 (m, aromatic and NH, 3H); ^{13}C NMR (DMSO-d_6) δ=17.1 (C-6), 30.2 (C-2 of α-isomer), 32.9 (C-2 of β-isomer), 45.6 (C-3 of α-isomer), 49.5 (C-3 of β-isomer), 65.4 C-5 of α-isomer), 66.8 (C-4 of β-isomer), 68.1 (C-4 of α-isomer), 70.8 (C-5 of β-isomer), 90.2 (C-1 of α-isomer), 94.1 (C-1 of β-isomer), 127.2, 128.0, 130.9, 134.6 (aromatic) and 165.5 (CONH), all consistent with the literature values.[28a]

***t*-Butyl (4*R*,5*S*,2*Z*)-3-Amino-4,5-(cyclohexylidenedioxy)-2-hexenoate (21).** The nitrile **11** (1.40 g, 7.7 mmol) in diethyl ether (20 ml) was allowed to react at 0 °C for 3.5 h with the magnesium enolate of *t*-butyl acetate, which was prepared from ethylmagnesium bromide (31 mmol), diisopropylamine (8.7 ml, 62 mmol) and diethyl ether (40 ml) at 0 °C. Workup followed by distillation afforded **21** (1.23 g, 54% yield). Bp 112—113 °C/0.3 Torr; ^1H NMR ($CDCl_3$) δ=1.21 (d, *J*=6.0 Hz, 3H), 1.30—1.90 (m, 10H), 1.48 (s, 9H), 4.30—4.60 (m, 3H), 6.50 (br, 2H, NH_2); IR (neat) 3525, 3350, 1670, 1620, 1050 cm^{-1}; MS *m/z* (rel intensity) 297 (M^+, 8), 241 (28), 199 (14), 198 (93), 197 (28), 180 (30), 154 (26), 144 (20), 143 (72), 127 (14), 126 (100), 125 (29), 99 (24), 98 (15), 81 (19), 69 (14), 57 (44), 55 (33), 41 (41); $[\alpha]_D^{26}$ −7.40° (*c* 3.59, $CHCl_3$). (Received December 9, 1986)

Two new routes to 4-amino-2(5*H*)-furanones are disclosed. The one is based on the reaction of a magnesium enolate of *t*-butyl acetate or propionate with *O*-protected cyanohydrins followed by acid-treatment which effects hydrolysis of the ester group, deprotection, olefin isomerization and lactonization all in a single operation. The other is base-induced ringclosure of α-acyloxy nitriles. The two methods are applied to construction of the carbon framework of an antitumor antibiotic basidalin.

Nitrile addition of an ester enolate is proved to be a promising alternative to 3-amino-2-alkenoates[1] which are versatile synthetic intermediates.[2] The addition is particularly facilitated to nitriles having α-alkoxy groups.[3] Though the (Z)-configuration of the produced 3-amino-2-alkenoates predominates due to intramolecular hydrogen bonding, Z to E isomerization takes place readily under various conditions.[2] Thus, protected cyanohydrins, after coupling with an ester enolate, isomerization of C=C bond of the adduct followed by appropriate functional group manipulations, are expected to give rise to 4-amino-2(5*H*)-furanones[4] which are precursors of defoliant, plant growth retardants,[5] and anti-hypertensive agents.[6]

An alternative approach to 4-amino-2(5*H*)-furanones emerges which employes intramolecular nitrile addition of an ester enolate, i.e., cyclization of α-alkanoyloxy nitriles.[7] Reported herein are details of the two synthetic approaches based on the inter- and intramolecular nitrile addition of ester enolates as well as their application to the construction of the carbon framework of an antibiotic basidalin.[8]

Results and Discussion

Synthesis of 4-Amino-2(5*H*)-furanones through Intermolecular Nitrile-Ester Enolate Addition. Cyanohydrins protected by 1-ethoxyethyl (=EE) ether **1** were allowed to react with the magnesium enolate of *t*-butyl acetate or propionate (Scheme 1). The resulting adduct, *t*-butyl 4-(1-ethoxyethoxy)-3-amino-2-alkenoates **2**, were treated with various acids in order to effect hydrolysis of the ester group, deprotection, (Z)→(E) isomerization, and lactonization all in a single operation without the enamine moiety affected.

Scheme 1.

Organic acids like *p*-toluenesulfonic acid and trifluoroacetic acid gave intractable material. The best conditions we found were those which involve treatment of **2** with hydrogen halide gas in anhydrous nonpolar solvents like benzene and toluene, and the desired 4-amino-2(5*H*)-furanones (**3**) precipitated from the reaction medium. Purification by preparative TLC or column chromatography allowed us to isolate pure material. Typical results are summarized in Table 1. As the *N*-acyl derivatives of **2** are stable to acid and some of these derivatives are shown to exhibit biological activity, we prepared *N*-aroyl derivatives **4**, which underwent cyclization to give rise to 4-aroylamino-5-methyl-2(5*H*)-furanones **5**.[4] These results also are summarized in Table 1.

We also intended to prepare the *N*-ureido derivatives (vide infra) of **3** by the acid-catalyzed cyclization of the *N*-ureido derivatives of **2**. Actually, **2a** was converted into the corresponding urea derivative by the reaction

a) The reaction was carried out in the presence of 0.2 mol equiv of $Ni(acac)_2$. b) A mixture of 2-hydroxy-2-methylpropanenitrile (1.18 mmol), diketene (1.26 mmol), triethylamine (1.28 mmol) in THF (5 ml) was stirred at room temperature for 6 h.

with *t*-butyl isocyanate (KO*t*-Bu catalyst) in 58% yield. However, the acid-catalyzed transformation of the urea derivative to **6a** turned out futile.

Synthesis of 4-Amino-2(5*H*)-furanones through Intramolecular Nitrile-Ester Enolate Addition. Intramolecular nitrile addition of an ester enolate under ringclosure[9] is an alternative way to **3**. The requisite precursor is an α-acyloxy nitrile **7** which are derived from a cyanohydrin by acylation. In case that the cyanohydrin was commercially unavailable or thermodynamically unfavorable, the parent ketone was transformed to a cyanohydrin trimethylsilyl ether[10] which was subsequently acylated with an acid anhydride and iron(III) chloride catalyst.[11] Intramolecular nitrile addition of ester enolates were studied with **7d** as the model substrate. Ring closure was effected with KO*t*-Bu (0 °C), $Mg[N(i\text{-}Pr)_2]_2$ (−78 to −74 °C), $LiN(i\text{-}Pr)_2$ (−78 °C) or $LiN(SiMe_3)_2$ (−78 °C) all in tetrahydrofuran (THF) to afford **3d** in 4, 24, 60, or 82% yield respectively. In contrast to the intermolecular nitrile addition,[2] lithium amide was more effective than the magnesium amide. Since the use of 2.4 mol equiv of lithium hexamethyldisilazanide gave best yields, these conditions were applied to various kinds of α-acyloxy nitriles **7**, and the results are summarized in Table 2. Ringclosure of nitriles **7n—q** which have more acidic α-CH was preferably carried out with sodium hydride as the base. Desulfurization of **3p** with Raney Nickel is a byway to **3d**. It is apparent that the base-promoted cyclization proceeds highly efficiently, although **7a** and **7b** underwent competitive proton abstraction from C-H α to CN, and the expected product **3a** and **3b** were obtained in low yields. For **3b**, in particular, addition of $Ni(acac)_2$[12] improved the

yields. Anyhow, to these substrates, the intermolecular method is applicable as disclosed before. With various kinds of 4-amino-2(5*H*)-furanones in hand, we derivatized these to the urea **6** or **6'** by the reaction to *t*-butyl isocyanate or phenyl isocyanate with potassium *t*-butoxide catalyst. In addition to the parent 4-amino-2(5*H*)-furanones (**3**), these as well as the *N*-aroyl analogs **5** were subjected to biological screening test. Although any of **5** did not show remarkable pharmacological activity, **6d**, **6'd**, and **3j** exhibited herbicidal activity against broad leaf weeds such as *Amaranthus retroflexus* at the level of 200 g/10 a by foliage application.

Synthetic Approach to Basidalin. With the two methods in hand, we undertook synthesis of basidalin. Basidalin is an antibiotic[8] which has an antibacterial activity and antitumor activity against L1210 mouse leukemia and possesses a 4-amino-2(5*H*)-furanone structure as well as formylmethylene substituent at C(5). We planned two synthetic routes to basidalin: Key intermediates we considered were 4-amino-2(5*H*)-furanones **12** and **17**, which were synthesized according to Schemes 3 and 4.

Cyanation of commercially available 1,1,3,3-tetramethoxypropane with trimethylsilyl cyanide and boron trifluoride etherate catalyst[13] induced substitution of one MeO group with CN to give **8** in 99% yield. The required introduction of acetoxyl group was achieved as follows. Bromination of **8** under radical conditions selectively took place at CN-substituted carbon to afford a labile bromide **9** which was immediately subjected to substitution reaction with silver acetate to give the key compound **10** needed for the intramolecular nitrile addition strategy in 74% overall yield. The success of regioselective radical bromination is ascribed to the stabilization of the intermediary radical species by "capto-dative" substituents CN and MeO.[14] The α-acetoxy nitrile **10** was treated with various bases such as lithium diisopropylamide, magnesium bis(diisopropylamide) and diethylaluminium diisopropylamide in 1.0 to 4.0 mol equiv to afford 4-amino-2(5*H*)-furanone **11** in 2 to 7% yields only. The yield of **11** was improved to 76% by use of 10 mol equiv of $Et_2AlN(i\text{-}Pr)_2$ at -78 to -60 °C for 1.7 h. Hydrolysis of the acetal moiety with a standard reagent trimethylsilyl iodide or boron tribromide turned out to induce total decomposition solely. However, combination of the Lewis acid with an amine base effectively converted **11** into **12**. Best combination was BBr_3 (3 mol) and $HN(SiMe_3)_2$ (3 mol) and thus **12** was obtained in 56% yield.

Scheme 4.

The final step, elimination of methanol from **12**, grew to be extremely tough. Under various possible basic, acidic, or even neutral conditions, only decomposition resulted possibly via competitive ring opening of the lactone moiety of **12** by elimination and/or loss of the amino group.

We switched to the intermolecular strategy which required a nitrile whose α-carbon is a protected form of ketone carbonyl. For the candidate, we chose **13** which was derived from 3,3,3-triethoxypropyne[15] by a tin(II) chloride-catalyzed cyanation[13] in good yields. Reaction of **13** with *t*-butyl acetate through the magnesium enolate afforded **14** in 85% yield. Direct cyclization of **14** with various kinds of acids[4] failed to give the expected product **17**. However, protection of the C≡C bond of **14** with $Co_2(CO)_8$ followed by treatment with trifluoroacetic acid induced the desired ringformation to afford **16** in 77% yield. Complexation of the acetylene moiety with cobalt rendered us following advantages:[16] (a) Protection of the acetylenic triple bond and (2) stabilization of the cationic species involved in this transformation. Oxidative deprotection under the standard conditions gave **17**. Final transformation to basidalin unfortunately turned out fruitless in spite of numerous experiments including hydrometallation/oxidation.

Although total synthesis was unsuccessful, we could construct the basic carbon framework of basidalin and thus subjected the synthetic intermediates to in vitro test for cell growth inhibition of L1210 and P388. Of these, **15** exhibited IC_{50} (μmol ml^{-1}) 8.5×10^{-3} for L1210 and 3.1×10^{-3} for P388 comparable to the cytotoxicity of prostaglandin A_2 (2.6×10^{-3} and 2.8×10^{-3} for L1210 and P388 respectively).[17]

In conclusion, inter- and intramolecular nitrile-addition of ester enolates is found to be a facile and promising route to a biologically important 4-amino-2(5*H*)-furanone structure. As the structural feature is closely related to tetronic acids,[18] the new synthetic methods will provide us with an additional way to physiologically important tetronic acids and their derivatives.

Experimental

Experimental apparatus and instrumental facilities are the same as those of the preceding paper.[2] Additionally, FT ^{1}H NMR spectra were recorded on a Hitachi R-90H spectrometer. Trimethylsilyl cyanide and hexamethyldisilazane were purchased from Petrach Systems Inc. and distilled before use. *t*-Butyl 3-amino-4-(1-ethoxyethoxy)-2-alkenoates **2a—e** were prepared according to the procedure described in the preceding paper.[2] The yields and spectral properties are as follows. The compounds **2b** and **2d** were oily substance and labile to thin layer, column or gas chromatographic purification. Thus, these were characterized only spectrometrically.

***t*-Butyl 3-Amino-4-(1-ethoxyethoxy)-2-hexenoate (2b):** 65% yield. Bp 100—120 °C (bath temperature)/0.1 Torr.† ^{1}H NMR ($CDCl_3$) δ=0.92 and 0.95 (2t, J=6.5 Hz, 3H), 1.17 and 1.19 (2t, J=6.5 Hz, 3H), 1.30 (d, J=6.0 Hz, 3H), 1.47 (s, 9H), 1.63 (q, J=6.5 Hz, 2H), 3.30—3.78 (m, 2H), 3.84 (q, J=6.0 Hz, 1H), 4.43 and 4.47 (2s, totally 1H), 4.63 and 4.70 (2q, J=6.0 Hz, 1H), 5.5—6.7 (br, 2H). Synthesis of 4-Amino-5-methyl-2(5*H*)-furanone (3a). A Typical Procedure for Hydrogen Halide Induced Formation

†1 Torr=133.322 Pa.

of 4-Amino-2(5*H*)-furanones. Dry hydrogen chloride gas was bubbled into a benzene (100 ml) solution of *t*-butyl 3-amino-4-(1-ethoxyethoxy)-2-pentenoate (**2a**)[2] (100 mg, 0.39 mmol) over a period of 2 h. Colorless material precipitated after 30 min's bubbling. The precipitates were collected and washed twice with benzene. Purification by preparative TLC (silica gel, dichloromethane-methanol 10 : 1, R_f=0.19—0.29) gave colorless solid **3a**[5a,6] (29 mg, 65% yield), mp 151—152 °C (lit,[5a] 150—152 °C). ^{1}H NMR ($CDCl_3$-DMSO-d_6) δ=1.47 (d, J=6 Hz, 3H), 4.56 (s, 1H), 4.76 (q, J=6 Hz, 1H), 6.40—6.70 (br, 2H). IR (KBr) 3450, 3395, 3230, 3000, 1710, 1660, 1580, 1335, 1190, 1050, 950, 905, 785 cm^{-1}. MS *m/z* (rel intensity) 114 (M^++1, 7), 113 (M^+, 66), 98 (64), 70 (100), 43 (22), 42 (33), 41 (56).

Spectral properties of 4-amino-2(5*H*)-furanones prepared by the similar procedures are listed below.

4-Amino-5-ethyl-2(5*H*)-furanone (3b).[5a,b] Mp 143—143.5 °C (lit,[5a] 143—145.5 °C). ^{1}H NMR ($CDCl_3$-DMSO-d_6) δ=0.95 (t, J=6.5 Hz, 3H), 1.4—2.2 (m, 2H), 4.45—4.90 (m+s (δ=4.60), 2H), 6.0—6.6 (br, 2H). IR (neat) 3450, 3240, 2980, 2950, 2900, 1710, 1650, 1580, 1540, 1345, 1190, 1080, 980 910, 780, 720 cm^{-1}.

4-Amino-3,5-dimethyl-2(5*H*)-furanone (3c).[6] Mp 96—98 °C. ^{1}H NMR ($CDCl_3$-DMSO-d_6) δ=1.48 (d, J=6 Hz, 3H), 1.66 (s, 3H), 4.73 (q, J=6 Hz, 1H), 4.83 (br s, 2H). IR (KBr) 3480, 3370, 3250, 3025, 2950, 2900, 1720, 1670, 1620, 1430, 1340, 1122, 1105, 1060, 990, 770, 740 cm^{-1}. Found: C, 56.42; H, 7.20; N, 10.90%. Calcd for $C_6H_9NO_2$: C, 56.68; H, 7.13; N, 11.02%.

4-Amino-5,5-dimethyl-2(5*H*)-furanone (3d). Mp 205—207 °C. ^{1}H NMR ($CDCl_3$-DMSO-d_6) δ=1.48 (s, 6H), 4.48 (s, 1H), 6.4—6.7 (br, 2H). IR (KBr) 3400, 3350 (sh), 3220, 3000, 1720, 1680, 1660, 1615, 1600, 1390, 1375, 1300, 1255, 1200, 1130, 985, 945, 900, 800 cm^{-1}. MS *m/z* (rel intensity) 128 (M^++1, 6), 127 (M^+, 53), 112 (100), 70 (42), 66 (11), 59 (12), 43 (77). Found: C, 56.55; H, 7.14; N, 10.90%. Calcd for $C_6H_9NO_2$: C, 56.68; H, 7.13; N, 11.02%.

3'-Aminospiro[cyclohexane-1,2'(5'*H*)-furan]-5'-one (3e). Mp 194.5—195.5 °C. ^{1}H NMR ($CDCl_3$-DMSO-d_6 1 : 1) δ=1.2—2.0 (m, 10H), 4.48 (s, 1H), 6.4—6.7 (br, 2H). IR (KBr) 3400, 3200, 2950, 2870, 1710, 1660, 1600, 1295, 1210, 1140, 1065, 975, 940, 860, 795 cm^{-1}. MS *m/z* (rel intensity) 168 (M^++1, 5), 167 (M^+, 38), 124 (27), 112 (16), 111 (100), 99 (32), 84 (65), 83 (10), 81 (27), 69 (20), 66 (77), 55 (16). Found: C, 64.56; H, 7.60; N, 8.38%. Calcd for $C_9H_{13}NO_2$: C, 64.65; H, 7.84; N, 8.38%.

Aroylation of 3a. Benzoyl chloride (1.37 g, 9.7 mmol) and 4-dimethylaminopyridine (0.20 g, 1.64 mmol) were added to a pyridine (20 ml) solution of **3a** (1.68 g, 6.5 mmol) at 0 °C, and the reaction mixture was stirred at 0 °C for 30 min and at 50 °C overnight. The pyridine was evaporated in vacuo and the residue was purified by column chromatography (Kieselgel 60) to give an E/Z mixture of *t*-butyl 3-(benzoylamino)-4-(1-ethoxyethoxy)-2-pentenoate (**4r**) (1.03 g, 44% yield) and a compound assigned as *t*-butyl 3-benzoylamino-4-benzoyloxy-2-pentenoate (0.20 g, 10% yield). **4r** (viscous oil, R_f=0.50 (hexane-ethyl acetate 5 : 1)) showed ^{1}H NMR ($CDCl_3$) δ=1.00—1.70 (2t+d+s (δ=1.43), 18H), 3.25—3.70 (m, 2H), 3.90—4.30 (m, 1H), 4.30 (s, 1H), 4.30—4.90 (m, 1H), 7.20—7.70 (m, 3H), 7.90—8.20 (m, 2H), 12.00—12.30 (br, 1H). IR (neat) 3500, 3230, 3080, 2950, 1700, 1660, 1635, 1490, 1370, 1300, 1265, 1250, 1150, 1070, 960, 920, 740, 710 cm^{-1}. Found: C, 66.19; H, 8.22; N, 3.71%. Calcd for $C_{20}H_{29}NO_5$: C, 66.09; H, 8.04; N, 3.85%.

The *N,O*-dibenzoate (R_f 0.40) showed mp 152—153 °C; ^{1}H NMR ($CDCl_3$) δ=1.71 (d, J=7 Hz, 3H), 1.20 (s, 9H), 5.38 (s, 1H), 6.93 (q, J=7 Hz, 1H), 7.33—7.73 (m, 6H), 7.93—8.23 (m, 4H), 11.13—11.43 (br, 1H). Found: C, 70.01; H, 6.38; N, 3.45%. Calcd for $C_{23}H_{25}NO_5$: C, 69.85; H, 6.37; N, 3.54%.

In similar manners and by using the corresponding aroyl chloride, **4s**—w were prepared.

***t*-Butyl 3-(4-Bromobenzoylamino)-4-(1-ethoxyethoxy)-2-pentenoate (4s).** Pale yellow viscous oil, R_f=0.69 (hexane-ethyl acetate 5 : 1). ^{1}H NMR ($CDCl_3$) δ=1.0—1.65 (m+s (δ=1.53), 18H), 3.35—3.90 (m, 2H), 4.73 and 4.79 (2q, 1H), 5.50—5.85 (m+2s (δ=5.32 and 5.42), 2H), 7.55—7.90 (AB q, 4H), 12.4—12.7 (br, 1H). IR (neat) 3230, 3000, 2950, 1700, 1660, 1630, 1595, 1485, 1370, 1305, 1270, 1250, 1155, 1075, 1015, 920, 825, 750, 740 cm^{-1}. Found: C, 54.11; H, 6.35; N, 3.09%. Calcd for $C_{20}H_{28}BrNO_5$: C, 54.30; H, 6.38; N, 3.17%.

***t*-Butyl 3-(4-Cyanobenzoylamino)-4-(1-ethoxyethoxy)-2-pentenoate (4t).** Colorless viscous oil, R_f=0.48 (hexane-ethyl acetate 5 : 1). ^{1}H NMR ($CDCl_3$) δ=1.00—1.60 (m+s (δ=1.53), 18H), 3.35—3.80 (m, 2H), 4.60—4.90 (2q, 1H), 5.55—5.80 (2s(δ=5.57 and 5.70)+q (δ=5.70), 2H), 7.75—8.20 (AB q, 4H), 12.3—12.6 (br 1H). IR (neat) 3500, 3350, 3200, 3100, 3000, 2950, 2230, 1700, 1660, 1630, 1490, 1370, 1300, 1270, 1240, 1150, 1080, 960, 920, 860, 760 cm^{-1}. Found: C, 64.67; H, 7.41; N, 6.93%. Calcd for $C_{21}H_{28}N_2O_5$: C, 64.93; H, 7.27; N, 7.21%.

***t*-Butyl 4-(1-Ethoxyethoxy)-3-(4-fluorobenzoylamino)-2-pentenoate (4u).** Colorless viscous oil, R_f=0.54 (hexane-ethyl acetate 5 : 1). ^{1}H NMR ($CDCl_3$) δ=1.10—1.90 (m+s (δ=1.55), 18H), 3.35—3.90 (m, 2H), 4.65—4.95 (2q, 1H), 5.50—5.90 (2s (δ=5.53 and 5.67)+q (δ=5.75, J=6 Hz), totally 2H), 7.17 (t, J=9.0 Hz, 2H), 8.03 (dd, J=9.0 and 5.0 Hz, 2H), 12.0—12.5 (br, 1H). IR (neat) 3220, 3000, 2950, 1700, 1660, 1635, 1605, 1495, 1250, 1155, 1080, 760, 740 cm^{-1}. Found: C, 63.00; H, 7.33; N, 3.58%. Calcd for $C_{20}H_{28}FNO_5$: C, 62.98; H, 7.40; N, 3.67%.

***t*-Butyl 4-(1-Ethoxyethoxy)-3-(4-nitrobenzoylamino)-2-pentenoate (4v).** Pale yellow viscous oil, R_f=0.57 (hexane-ethyl acetate 5 : 1). ^{1}H NMR ($CDCl_3$) δ=1.05—1.65 (m+s (δ=1.54), 18 H), 3.40—3.80 (m, 2H), 4.60—4.90 (2q, 1H), 5.55—5.80 (2s (δ=5.59 and 5.71) +m, totally 2H), 8.10—8.45 (AB q, 4H), 12.30—12.60 (br, 1H). IR (neat) 3210, 3140, 3000, 2950, 1700, 1660, 1640, 1605, 1535, 1485, 1350, 1300, 1265, 1250, 1155, 1080, 955, 920, 870, 850, 735, 715 cm^{-1}. Found: C, 58.70; H, 6.97; N, 6.73%. Calcd for $C_{20}H_{28}N_2O_7$: C, 58.81; H, 6.91; N, 6.86%.

***t*-Butyl 4-(1-Ethoxyethoxy)-3-(4-methylbenzoylamino)-2-pentenoate (4w).** Colorless viscous oil, R_f=0.48 (hexane-ethyl acetate 5 : 1). ^{1}H NMR ($CDCl_3$) δ=1.00—1.80 (m+s (δ=1.57), 18H), 2.43 (s, 3H), 3.30—3.80 (m, 2H), 4.55—4.90 (2q, 1H), 5.45—5.85 (2s (δ=5.48 and 5.60)+m, totally 2H), 7.10—7.95 (AB q, 4H), 12.1—12.4 (br, 1H). allowed to stand for a couple of days. The precipitated crystals were collected and recrystallized from the solvent shown in Table 4. The yields listed in Table 1 are those after recrystallization. Physical properties are summarized in Table 4.

Derivatization of 2a by the reaction with *t*-butyl isocyanate was effected by the procedure described in the derivatization of **3a**, and the resulting urea derivative showed following spectra.

***t*-Butyl 4-(1-Ethoxyethoxy)-3-(*N'*-*t*-butylureido)-2-pentenoate.** Colorless prisms, mp 114—117 °C, R_f=0.56 (hexane–ethyl acetate 5:1). ^{1}H NMR ($CDCl_3$) δ=1.07—1.43 (m, 9H), 1.33 (s, 9H), 1.48 (s, 9H), 3.37—3.67 (m, 2H), 4.50—4.80 (m, 2H), 5.20 and 5.32 (2s, 1H), 5.43—5.65 (2q, 1H), 10.1—10.5 (br, 1H). Found: C, 60.30; H, 9.78; N, 7.54%. Calcd for $C_{18}H_{34}N_2O_5$: C, 60.30; H, 9.56; N, 7.82%.

Acylation of Cyanohydrin. A typical procedure is shown for the synthesis of 2-acetoxy-2-methylpropanenitrile (**7d**). To a dichloromethane (20 ml) solution of commercially available 2-hydroxy-2-methylpropanenitrile (1.70 g, 20 mmol) were added acetic anhydride (4.0 ml) and pyridine (3.2 ml) under cooling with ice, and the reaction mixture was stirred at room temperature for 2 d. The reaction mixture was then washed 3 times with 3% hydrochloric acid and once with brine, dried over magnesium sulfate, and then concentrated. Distillation at 70—75 °C/9 Torr gave **7d** (1.28 g, 50% yield). ^{1}H NMR ($CDCl_3$) δ=1.76 (s, 6H), 2.09 (s, 3H), IR (neat) 2260 (vw), 1760, 1470, 1420, 1390, 1370, 1355, 1275, 1230, 1190, 1140 cm^{-1}.

Similarly, **7e** (36%), **7m** (81%), and **7l** (46%) were prepared. Nitriles **7a** and **7b** were finally purified by preparative GLC.

2-Acetoxypropanenitrile (7a): Bp 70—75 °C/9 Torr. ^{1}H NMR ($CDCl_3$) δ=1.63 (d, J=7.2 Hz, 3H), 2.13 (s, 3H), 5.36 (q, J=7.2 Hz, 1H).

2-Acetoxybutanenitrile (7b): Bp 75—80 °C/22 Torr. ^{1}H NMR ($CDCl_3$) δ=1.10 (t, J=6.6 Hz, 3H), 1.89 (quintet, J=6.6 Hz, 2H), 2.13 (s, 3H), 5.25 (t, J=6.6 Hz, 1H). IR (neat) 3000, 2950, 2900, 2250 (vw), 1750, 1460, 1370, 1220 cm^{-1}.

1-Cyanocyclohexyl Acetate (7e): Bp 120 °C/13 Torr, mp 48.5—49 °C, colorless prisms. ^{1}H NMR ($CDCl_3$) δ=1.15—1.95 (m, 8H), 2.10 (s, 3H), 2.18—2.42 (m, 2H). IR (KBr) 3500,

2950, 2875, 2250, 1750, 1450, 1365, 1260, 1230, 1165, 1060 cm^{-1}.

2-Chloroacetoxy-2-methylpropanenitrile (7m): Bp 70—71 °C/0.5 Torr. ^1H NMR ($CDCl_3$) δ=1.80 (s, 6H), 4.04 (s, 2H). IR (neat) 3025, 2975, 2250 (w), 1770, 1750 (sh), 1470, 1410, 1390, 1370, 1320, 1290, 1230, 1185, 1135 cm^{-1}.

2-Methyl-2-propanoylpropanenitrile (7l): Bp 50 °C/0.5 Torr. ^1H NMR ($CDCl_3$) δ=1.15 (t, J=7.5 Hz, 3H), 1.74 (s, 6H), 2.34 (q, J=7.5 Hz, 2H). IR (neat) 3000, 2950, 2250, 1775, 1470, 1420, 1390, 1370, 1355, 1225, 1190, 1140 cm^{-1}.

Synthesis of α-Acyloxy Nitriles by Silylcyanation of Ketones and Acylation with Iron(III) Chloride Catalyst. Zinc iodide (20 mg, 0.06 mmol) was added to acetophenone (1.21 g, 10 mmol) and trimethylsilyl cyanide (1.5 ml, 11 mmol) dissolved in benzene (10 ml) at 0 °C and the reaction mixture was stirred at room temperature overnight. The reaction mixture was diluted with benzene (30 ml) and washed with brine (50 ml), dried over magnesium sulfate, and concentrated in vacuo to give crude 2-phenyl-2-trimethylsilyloxypropanenitrile which was dissolved in acetic anhydride (5.0 ml), to which solution was added iron(III) chloride (0.10 g) at 0 °C. Stirring was continued for 1 h at 0 °C to room temperature. The color of the reaction mixture turned to green before dilution with dichloromethane (30 ml) and quenching with water (30 ml). The organic layer was separated, washed with brine, dried over magnesium sulfate, and concentrated under reduced pressure. Distillation gave **7h** (1.70 g, 90% yield). Bp 56—58 °C/0.15 Torr. ^1H NMR ($CDCl_3$) δ=2.00 (s, 3H), 2.12 (s, 3H), 7.2—7.9 (m, 5H). IR (neat) 3080, 3050, 3010, 2950, 2250, 1760, 1600, 1495, 1370, 1220, 1140, 1090, 1070, 1010, 950, 760, 695 cm^{-1}.

By this procedure following 2-acyloxy nitriles were prepared. Overall yield from the corresponding ketone or aldehyde is given.

2-Acetoxy-2,3-dimethylbutanenitrile (7f): 65%, bp 70—73 °C/16 Torr. ^1H NMR ($CDCl_3$) δ=1.08 and 1.13 (2d, J=4.5 Hz, 6H), 1.68 (s, 3H), 2.08 (s, 3H), 2.08—2.16 (m, 1H). IR (neat) 3000, 2250 (w), 1755, 1470, 1370, 1235 cm^{-1}.

2-Acetoxy-2-methylundecanenitrile (7g): 82% yield, bp 88—90 °C/0.15 Torr. ^1H NMR ($CDCl_3$) δ=0.82—0.95 (t, 3H), 1.28 (m, 14H), 1.72 (s, 3H), 1.76—2.03 (m, 2H), 2.07 (s, 3H). IR (neat) 2925, 2855, 2230 (vw), 1750, 1710, 1460, 1370, 1230 cm^{-1}.

2-Acetoxy-2-ethylpentanenitrile (7k): 66% yield, bp 95—96 °C/20 Torr. ^1H NMR ($CDCl_3$) δ=1.05 (t, J=6.9 Hz, 6H), 2.04 (q, J=6.9 Hz, 4H), 2.09 (s, 3H). IR (neat) 3000, 2950, 2245 (vw), 1750, 1460, 1370, 1230 cm^{-1}.

2-Acetoxy-2-methyl-3-phenylpropanenitrile (7i): 63% yield, bp 140—150 °C/1 Torr. ^1H NMR ($CDCl_3$) δ=1.40 (s, 3H), 2.13 (s, 3H), 3.23 (AB q, 2H), 7.36 (br s, 5H). IR (neat) 3100, 3060, 2970, 2250 (vw), 1760, 1500, 1455, 1375, 1265, 1230, 1170, 1070, 1020, 760, 700 cm^{-1}.

2-Methyl-2-[(phenylthio)acetoxy]propanenitrile (7p). To a dichloromethane (30 ml) solution of phenylthioacetyl chloride (2.40 g, 12.8 mmol) were added 2-hydroxy-2-methylpropanenitrile (1.00 g, 11.7 mmol) and then triethylamine (1.79 ml, 0.128 mmol) at 0 °C. The reaction mixture was stirred and gradually warmed to room temperature over 3 h, then washed twice with 3% hydrochloric acid (30 ml), then with brine (30 ml) and finally with aq sat. sodium hydrogencarbonate solution (30 ml), dried over magnesium sulfate, and concentrated under reduced pressure. Distillation afforded **7p** (1.20 g, 43% yield). Bp 150—160 °C (bath temperature)/0.7 Torr. ^1H NMR ($CDCl_3$) δ=1.65 (s, 6H), 3.58 (s, 2H), 7.17—7.47 (m, 5H). IR (neat) 3075, 3020, 2950, 2340, 1740, 1585, 1470, 1435, 1390, 1370, 1265, 1225, 1200, 1115, 1025, 975 cm^{-1}. MS m/z (rel intensity) 237 (M^++2, 2), 236 (M^++1, 5), 235 (M^+, 32), 168 (10), 123 (100), 109 (13), 77 (12), 65 (10), 51 (12), 45 (41), 41 (10).

Similarly, **7o** (0.64 g, 32% yield) was prepared from 2-hydroxy-2-methylpropanenitrile (0.85 g, 10 mmol), phenylacetyl chloride (1.80 g, 11.7 mmol) and triethylamine (1.60 ml, 11.5 mmol). Bp 145—150 °C/0.8 Torr. ^1H NMR ($CDCl_3$) δ=1.40 (s, 6H), 3.62 (s, 2H), 7.28 (br s, 5H). IR (neat) 3075, 3050, 3010, 2950, 2250, 1750, 1605, 1500, 1470, 1455, 1390, 1370, 1350, 1255, 1225, 1125, 970, 730, 700 cm^{-1}. MS m/z (rel intensity) 204 (M^++1, 2), 203 (M^+, 14), 119 (4), 92 (9), 91 (100), 68 (5), 65 (10), 41 (9), 39 (7).

2-Methyl-2-[(phenylsulfinyl)acetoxy]propanenitrile (7q). *m*-Chloroperoxybenzoic acid (80—85% purity, 0.19 g) was added to a dichloromethane (5 ml) solution of **7p** (0.20 g, 0.85 mmol), and the reaction mixture was stirred at room temperature overnight before dilution with dichloromethane (20 ml) and treatment with 10% sodium thiosulfate aq solution (20 ml). Extractive workup followed by preparative TLC (hexane-ethyl acetate 1 : 1, R_f=0.25) gave **7q** (0.165 g, 77% yield) as a viscous oil. ^1H NMR ($CDCl_3$) δ=1.65 (s, 3H), 1.71 (s, 3H), 3.81 and 3.71 (AB q, J=13.5 Hz, 2H), 7.45—7.80 (m, 5H). IR (neat) 3500, 3075, 3010, 2950, 2250, 1745, 1475, 1445, 1390, 1370, 1270, 1230, 1200, 1150, 1115, 1090, 1050, 975 cm^{-1}. MS m/z (rel intensity) 253 (M^++2, 1), 252 (M^++1, 3), 251 (M^+, 20), 184 (2), 167 (3), 126 (13), 125 (100), 97 (22), 77 (27), 51 (20), 41 (11).

2-Methyl-2-(3-oxobutanoyloxy)propanenitrile (7n). Diketene (1.0 g, 12 mmol) and pyridine (0.94 g, 12 mmol) were successively added to a dichloromethane (20 ml) solution of 2-hydroxy-2-methylpropanenitrile (0.85 g, 10 mmol) at 0 °C, and the reaction mixture was stirred at room temperature overnight, then poured into 5% hydrochloric acid (30 ml), extracted with dichloromethane. The organic layer was washed with brine, dried over magnesium sulfate and concentrated. Distillation gave **7n** (1.52 g, 90% yield). Bp 155—160 °C/21 Torr. ^1H NMR ($CDCl_3$) δ=1.78 (s, 6H), 2.26 (s, 3H), 3.48 (s, 2H). IR (neat) 3015, 2950, 2250, 1760, 1725, 1630, 1560, 1470, 1410, 1370, 1365, 1320, 1260, 1230, 1135, 1025, 995, 970 cm^{-1}. MS m/z (rel intensity) 168 (M^+−1, 3), 126 (2), 100 (2), 85 (12), 84 (14), 70 (75), 69 (15), 68 (10), 58 (6), 44 (12), 43 (100), 42 (18), 41 (16).

Synthesis of 4-Amino-5,5-dimethyl-2(5*H*)-furanone (3d). A Typical Procedure for the Preparation of 5,5-Disubstituted 4-Amino-2(5*H*)-furanones with $LiN(SiMe_3)_2$. A THF solution of **7d** (0.127 g, 1.0 mmol) was added to $LiN(SiMe_3)_2$ (2.5 mmol in 3 ml of THF) drop by drop at −78 °C under an argon atmosphere. After 2 h, sat. ammonium chloride aq solution (5 ml) was added to the reaction mixture to quench the reaction. The resulting mixture was warmed to room temperature and concentrated under reduced pressure. The residue was extracted with methanol. The methanolic extract was concentrated and the residual oil was purified by preparative TLC (silica gel, dichloromethane-methanol 10 : 1) to give **3d** (0.104 g, 82% yield).

In a similar manner, following amino furanones were prepared. Physical properties of these are listed below.

4-Amino-5-isopropyl-5-methyl-2(5*H*)-furanone (3f). Mp 171—172 °C. ^1H NMR ($CDCl_3$-DMSO-d_6 10 : 1) δ=0.86 and

1.05 (2d, J=6.6 Hz, 6H), 1.42 (s, 3H), 1.93 (heptet, J=6.6 Hz, 1H), 4.54 (s, 1H), 6.23 (br s, 2H). IR (KBr) 3380, 3205, 3000, 1730 (sh), 1700, 1665, 1610, 1590, 1580, 1415, 1290, 1230 cm^{-1}. MS m/z (rel intensity) 156 (M^++1, 2), 155 (M^+, 8), 113 (11), 112 (100), 70 (23), 43 (35), 41 (12). Found: C, 61.90; H, 8.56; N, 8.97%. Calcd for $C_8H_{13}NO_2$: C, 61.91; H, 8.44; N, 9.03%.

4-Amino-5-methyl-5-nonyl-2(5*H*)-furanone (3g). Mp 104—107 °C. ^1H NMR ($CDCl_3$-DMSO-d_6 20:1) δ=0.87 (t, J=6.0 Hz, 3H), 1.0—1.4 (br s, 14H), 1.44 (s, 3H), 1.55—1.90 (m, 2H), 4.65 (s, 1H), 5.58 (br s, 2H). IR (KBr) 3440, 3350, 3225, 2925, 2870, 1735, 1710, 1660, 1585 cm^{-1}. MS m/z (rel intensity) 240 (M^++1, 3), 239 (M^+, 5), 211 (6), 154 (11), 140 (12), 127 (21), 113 (59), 112 (100), 85 (24), 70 (29), 43 (44). Found: m/z 239.1868. Calcd for $C_{14}H_{25}NO_2$: M^+ 239.1883.

4-Amino-5-methyl-5-phenyl-2(5*H*)-furanone (3h). Mp 69—71 °C. ^1H NMR ($CDCl_3$-DMSO-d_6 10:1) δ=1.90 (s, 3H), 4.68 (s, 1H), 6.31 (br s, 2H), 7.3—7.6 (m, 5H). IR (KBr) 3400, 3205, 1700, 1665 (sh), 1585, 1445, 1405, 1290, 1285, 1230, 1075, 965 cm^{-1}. MS m/z (rel intensity) 191 (M^++2, 1), 190 (M^++1, 11), 189 (M^+, 83), 175 (13), 174 (100), 146 (22), 121 (33), 112 (30), 105 (67), 103 (20), 77 (38), 70 (14), 69 (17), 68 (14), 51 (20), 43 (72), 41 (42). Found: C, 66.54; H, 6.24; N, 6.99%. Calcd for $C_{11}H_{11}NO_2 \cdot 0.5\ H_2O$: C,66.65; H, 6.10; N, 7.07%. Found: m/z 189.0776. Calcd for $C_{11}H_{11}NO_2$: M^+ 189.0788.

4-Amino-5-benzyl-5-methyl-2(5*H*)-furanone (3i). Mp 158—161 °C. ^1H NMR ($CDCl_3$-DMSO-d_6 10:1) δ=1.50 (s, 3H), 3.37 (s, 2H), 4.43 (s, 1H), 6.15 (br s, 2H), 7.20 (br s, 5H). IR (KBr) 3420, 3225, 1715, 1700, 1665, 1605, 1590, 1450, 1415, 1300, 1255, 1170, 970 cm^{-1}. MS m/z (rel intensity) 203 (M^+, 6), 112 (100), 91 (7), 84 (33), 70 (15), 66 (40), 43 (19). Found: C, 70.75; H, 6.36; N, 6.76%. Calcd for $C_{12}H_{13}NO_2$: C, 70.92; H, 6.45; N, 6.89%.

4-Amino-5-(6-methoxy-2-naphthyl)-5-methyl-2(5*H*)-furanone (3j). Mp 206—208 °C. ^1H NMR ($CDCl_3$-DMSO-d_6 4:1) δ=1.97 (s, 3H), 3.90 (s, 3H), 4.73 (s, 1H), 6.25 (br s, 2H), 7.0—7.9 (m, 6H). IR (KBr) 3450, 3350, 3240, 1730 (sh), 1725, 1645, 1595, 1440, 1390, 1370, 1270, 1220, 1200, 1165, 1140, 1020, 950 cm^{-1}. MS m/z (rel intensity) 271 (M^++2, 2), 270 (M^++1, 15), 269 (M^+, 79), 255 (18), 254 (100), 226 (10), 201 (10), 185 (40), 157 (18). Found: C, 71.23; H, 5.49; N, 5.13%. Calcd for $C_{16}H_{25}NO_3$: C, 71.36; H, 5.61; N, 5.20%.

4-Amino-5,5-diethyl-2(5*H*)-furanone (3k). Mp 162—164 °C. ^1H NMR ($CDCl_3$-DMSO-d_6 3:1) δ=0.83 (t, J=7 Hz, 6H), 1.54—1.89 (m, 4H), 4.67 (s, 1H), 5.94 (br s, 2H). IR (KBr) 3425, 3375, 3200, 3000, 1715, 1665, 1650, 1605, 1590 cm^{-1}. MS m/z (rel intensity) 156 (M^++1, 1), 155 (M^+, 9), 127 (18), 126 (100), 84 (10), 70 (14), 57 (53), 41 (12). Found: C, 61.81; H, 8.40; N, 8.95%. Calcd for $C_8H_{13}NO_2$: C, 61.91; H, 8.44; N, 9.03%.

4-Amino-3,5,5-trimethyl-2(5*H*)-furanone (3l). Mp 205—208 °C. ^1H NMR ($CDCl_3$-DMSO-d_6 3:1) δ=1.43 (s, 6H), 1.61 (s, 3H), 5.69 (br s, 2H). IR (KBr) 3400, 3230, 3000, 2950, 1710, 1665, 1600, 1475, 1430, 1345, 1215, 1195, 1100, 1000 cm^{-1}. MS m/z (rel intensity) 142 (M^++1, 16), 141 (M^+, 71), 126 (100), 98 (23), 70 (16), 56 (19), 55 (32), 54 (15), 43 (38). Found; m/z 141.0770. Calcd for $C_7H_{11}NO_2$: M^+ 141.0790.

4-Amino-3-chloro-5,5-dimethyl-2(5*H*)-furanone (3m). Mp 170—172 °C. ^1H NMR ($CDCl_3$-DMSO-d_6 1:1) δ=1.48 (s, 6H), 6.88 (br s, 2H). IR (KBr) 3450 (sh), 3375, 3220, 3000, 1720, 1670, 1650, 1600, 1300, 1225, 1140, 1040 cm^{-1}. MS m/z (rel intensity) 164 (M^++3, 3), 163 (M^++2, 18), 162 (M^+1, 8), 161 (M^+, 54), 148 (33), 146 (100), 118 (36), 104 (39), 82 (11), 76 (13), 75 (17), 70 (24), 68 (21), 43 (60). Found: m/z 161.0209. Calcd for $C_6H_8ClNO_2$: M^+ 161.0242.

4-Amino-5,5-dimethyl-3-phenylsulfinyl-2(5*H*)-furanone (3q). A Typical Procedure for the Synthesis of 3 Having Electron-Withdrawing Substituent at C(3). A THF (3 ml) solution of **7q** (50 mg, 0.20 mmol) was added drop by drop to sodium hydride (50% in oil, 20 mg, 0.40 mmol) suspended in THF (30 ml) under reflux, and the reaction mixture was heated to reflux for 2 h until all the starting material was consumed. Excess hydride was carefully quenched with sat. ammonium chloride aq solution and worked up. Isolation by column chromatography (dichloromethane-methanol 10:1) gave **3q** (43 mg, 86% yield). Mp 137—138 °C. ^1H NMR ($CDCl_3$-DMSO-d_6 10:1) δ=1.41 (s, 3H), 1.53 (s, 3H), 6.9—7.3 (br, 2H), 7.33—7.57 (m, 3H), 7.57—7.90 (m, 2H). IR (KBr) 3350, 3200, 3000, 1715, 1665, 1590, 1580 (sh), 1480, 1460, 1410, 1370, 1280, 1225, 1220, 1160, 1080, 1045 (sh), 1025 cm^{-1}. Found: m/z 235.0646. Calcd for $C_{12}H_{13}NO_2S$: M^+ 235.0665.

Desulfurization of 3p. A mixture of **3p** (15 mg, 0.064 mmol), Raney Nickel (W-2) (0.06 g) and ethanol (3 ml) was heated to reflux for 3 h. Filtration, concentration and purification by preparative TLC (dichloromethane-methanol 10:1) gave **3d** (10 mg, quantitative yield) which showed identical chromatographic and spectrometric data to those of the sample prepared before.

Derivatization of 3d to 6d. A Typical Procedure for the Synthesis of Urea 6 and 6′. To a THF (50 ml) solution of **3d** (1.27 g, 10 mmol) was added *t*-butyl isocyanate (1.50 g, 15 mmol) at room temperature and the mixture was cooled with ice bath. Potassium *t*-butoxide (1.68 g, 15 mmol) was then added, and the whole was warmed to room temperature

and stirred for 2 d. Neutralization with sat. ammonium chloride aq solution, dilution with brine (30 ml), extraction with ethyl acetate (30 ml), drying the organic extract over magnesium sulfate followed by careful evaporation of the organic solvents to ca. 5 ml afforded 4-(*N'*-*t*-butylureido)-5,5-dimethyl-2(5*H*)-furanone (**6d**) as colorless crystals (1.53 g) which were filtered. From the filtrate, another portion (0.5 g) of **6d** was obtained. Total yield was 89%. Mp 247.5—248 °C. ^{1}H NMR ($CDCl_3$–DMSO-d_6 3:1) δ=1.37 (s, 9H), 1.48 (s, 6H), 5.85 (s, 1H), 6.25 (br s, 1H), 8.56 (br s, 1H). 2,4,4-Trimethoxybutanenitrile (8). Boron trifluoride etherate (0.15 ml, 1.2 mmol) was added to a mixture of 1,1,3,3-tetramethoxypropane (1.65 g, 10 mmol) and trimethylsilyl cyanide (1.35 ml, 10 mmol) at 0 °C and the mixture was stirred at 0 °C for 3 h. GLC assay (PEG 20 M, 10%, 3 m, 180 °C) showed a single new peak. Dilution with dichloromethane, treatment with sat. sodium hydrogencarbonate aq solution, extraction with dichloromethane (4 times), drying over magnesium sulfate, followed by concentration gave **8** (1.63 g, 99% yield) as a colorless oil. Bp 70—73 °C/15 Torr. ^{1}H NMR ($CDCl_3$) δ=2.10 (t, *J*=6 Hz, 2H), 3.34 (s, 6H), 3.47 (s, 3H), 4.15 (t, *J*=6 Hz, 1 H), 4.54 (t, *J*=6 Hz, 1H). IR (neat) 3400, 2950, 2850, 2250, 1460, 1390, 1370, 1335, 1190, 1120, 1065, 1020, 980, 920, 900, 800, 605 cm^{-1}. MS *m/z* (rel intensity) 158 (M^+−1, 1), 128 (M^+−OMe, 37), 98 (11), 96 (27), 75 (100), 71 (5), 70 (89), 47 (17), 45 (17). Found: C, 52.52; H, 8.12; N, 8.85%. Calcd for $C_7H_{13}NO_3$: C, 52.81; H, 8.23; N, 8.80%.

2-Acetoxy-2,4,4-trimethoxybutanenitrile (10). A mixture of **8** (0.62 g, 3.9 mmol), *N*-bromosuccinimide (NBS) (0.76 g, 4.3 mmol), azobis(isobutyronitrile) (7 mg, 0.043 mmol) and benzene (15 ml) was heated gradually over 10 min to 90 °C and stirred for 30 min at 90 °C. The reaction mixture was diluted with hexane, and the insoluble material was filtered off through a Celite pad. Concentration gave **9** (0.87 g, 93% yield) as a pale yellow oil which exhibited ^{1}H NMR ($CDCl_3$) δ=2.76 (d, *J*=5.6 Hz, 2H), 3.40 (s, 3H), 3.41 (s, 3H), 3.70 (s, 3H), 4.73 (t, *J*=5.6 Hz, 1H), and IR (neat) 2250 cm^{-1}.

Without purification, this was employed for the next reaction. Silver acetate (0.60 g, 3.6 mmol) was added to an acetonitrile (13 ml) solution of **9** (0.87 g, 3.6 mmol) at 0 °C, and the mixture was stirred at 0 °C for 40 min. Filtration through a Celite pad followed by concentration and distillation gave **10** (0.62 g, 79% yield) as a colorless oil. Bp 110—114 °C/0.65 Torr. ^{1}H NMR ($CDCl_3$) δ=2.12 (s, 3H), 2.53 (d, *J*=6 Hz, 2H), 3.33 (s, 3H), 3.35 (s, 3H), 3.62 (s, 3H), 4.68 (t, *J*=6 Hz, 1H). IR (neat) 3025, 2975, 2860, 2260, 1760, 1735 (sh), 1450, 1375, 1235, 1200, 1120, 1075, 1015, 950, 840 cm^{-1}. MS *m/z* (rel intensity) 186 (M^+−OMe, 2), 142 (3), 126 (38), 117 (4), 112 (7), 103 (4), 100 (6), 85 (5), 75 (99), 70 (9), 58 (5), 47 (12), 43 (100). Found: C, 49.09; H, 6.87; N, 6.28%. Calcd for

$C_9H_{15}NO_5$: C, 49.09; H, 6.96; N, 6.34%.

4-Amino-5-(2,2-dimethoxyethyl)-5-methoxy-2(5*H*)-furanone (11). Lithium diisopropylamide (4.6 mmol in THF (2 ml) and hexane (2.8 ml)) was added to a mixture of diethylaluminium chloride (2.2 M hexane solution, 2.2 ml, 4.7 mmol) and THF (1 ml) at 0 °C, and the resulting solution was stirred for 1 h then cooled to −78 °C. To this base solution was added **10** (0.100 g, 0.46 mmol) dissolved in THF (1.5 ml) over 5 min. After 1.2 h, the starting material was all consumed. Quenching was effected by addition of sat. ammonium chloride aq solution (0.2 ml) at −78 °C. The mixture was warmed to room temperature, dried over magnesium sulfate, charged on the top of a short silica-gel column (Wakogel C-100, 1 cm) and eluted with methanol-dichloromethane (1 : 10). Concentration followed by prepartive TLC (dichloromethane-methanol 10 : 1) gave **12** (68 mg, 68% yield). R_f= 0.48 (CH_2Cl_2-MeOH 10 : 1). Mp 109—111 °C (colorless plates). ^{1}H NMR ($CDCl_3$) δ=2.28 (d, J=5.7 Hz, 2H), 3.23 (s, 3H), 3.32 (s, 3H), 3.37 (s, 3H), 4.63 (t, J=5.5 Hz, 1H), 4.88 (s, 1H), 5.27 (br, 2H). IR (neat) 3370, 3220, 2950, 2850, 1735, 1660, 1610, 1440, 1410, 1390, 1370, 1290, 1210, 1190, 1165, 1115, 1070, 1000, 915, 795, 730 cm^{-1}. MS m/z (rel intensity) 217 (M^+, 2), 185 (28), 155 (22), 154 (23), 128 (63), 100 (49), 75 (100). Found: m/z 217.0968. Calcd for $C_9H_{15}NO_5$: M^+ 217.0950.

4-Amino-5-methoxy-5-(2-oxoethyl)-2(5*H*)-furanone (12). Hexamethyldisilazane (0.29 ml, 1.39 mmol) and then boron tribromide (1.0 M dichloromethane solution, 1.38 ml, 1.38 mmol) were added successively to a dichloromethane (12 ml) solution of **11** (0.100 g, 0.46 mmol) at −23 °C (CCl_4-Dry Ice bath). The mixture was stirred at −23 °C for 2 h and neutralized with sat. sodium hydrogencarbonate aq solution (1 ml) at −23 °C. Concentration under reduced pressure gave a solid material which was charged on TLC plate with the aid of a solvent mixture of dichloromethane-methanol (10 : 1). Development with the same solvent mixture afforded **12** (45 mg, 56% yield). R_f=0.27 (CH_2Cl_2-MeOH 10 : 1). ^{1}H NMR ($CDCl_3$) δ=2.92 (dd, J=1.97 and 5.27 Hz, 2H), 3.21 (s, 3H), 4.87 (s, 1H), 5.28 (br, 2H), 9.67 (t, J=2.0 Hz, 1H). MS m/z (rel intensity) 171 (M^+, 8), 143 (9), 140 (M^+—OMe, 12), 129 (19), 128 (35), 115 (30), 112 (27), 111 (20), 101 (37), 100 (47), 83 (7), 71 (10), 70 (16), 69 (31), 68 (57), 59 (6), 58 (4), 57 (9), 55 (5), 44 (6), 43 (42). Found: m/z 171.0552. Calcd for $C_7H_9NO_4$: M^+ 171.0530.

2,2-Diethoxy-3-butynenitrile (13). Tin(II) chloride (0.162 g, 0.85 mmol) was added to a mixture of 3,3,3-triethoxypropyne (1.72 g, 10 mmol) and trimethylsilyl cyanide (1.50 ml, 11.2 mmol) at 0 °C under a nitrogen atmosphere, and the whole was stirred at room temperature for 30 min before dilution with ether (20 ml). The mixture was washed with brine, dried over magnesium sulfate and concentrated. Distillation gave **13** (1.08 g, 71% yield). Bp 75—80 °C (bath temperature)/5 Torr. ^{1}H NMR ($CDCl_3$) δ=1.30 (t, J=7.5 Hz, 6H), 2.80 (s, 1H), 3.80 (q, J=7.5 Hz, 4H). IR (neat) 3300, 3000, 2960, 2920, 2250, 2140, 1485, 1445, 1400, 1180, 1120, 1105, 1085, 1050, 885, 680 cm^{-1}. MS m/z (rel intensity) 108 (M^+—OEt, 72), 80 (100), 53 (65), 45 (15). Found: C, 62.41; H, 7.29; N, 9.06%. Calcd for $C_8H_{11}NO_2$: C, 62.72; H, 7.24; N, 9.14%.

***t*-Butyl 3-Amino-4,4-diethoxy-2-hexen-5-ynoate (14).** Magnesium amide base was prepared by addition of ethylmagnesium bromide (2.0 M ethereal solution, 10 ml, 20 mmol) to diisopropylamine (5.6 ml, 40 mmol) in ether (15 ml) and aged at 0 °C for 1.5 h. To this base solution *t*-butyl acetate (1.30 ml, 20 mmol) was added drop by drop over 5 min, and the mixture was stirred at 0 °C for 30 min. An ethereal solution (15 ml) of **13** (0.77 g, 5.0 mmol) was added over a period of 5 min, and the reaction mixture was stirred for 30 min. Quenching with sat. ammonium chloride aq solution (20 ml), extraction with ether (30 ml×3), washing the ethereal extract with brine, drying over magnesium sulfate, concentration, followed by distillation, gave **14** (1.14 g, 85% yield) as a pale yellow oil. Bp 115—120 °C (bath temperature)/0.15 Torr. ^{1}H NMR ($CDCl_3$) δ=1.23 (t, J=7.5 Hz, 6H), 1.48 (s, 9H), 2.60 (s, 1H), 3.63 (q, J=7.5 Hz, 4H), 5.05 (s, 1H), 6.45 (br, 2H, NH_2). IR (neat) 3525, 3360, 3300, 3000, 2950, 2910, 2130, 1675, 1625, 1555, 1455, 1395, 1370, 1290, 1255, 1155, 1130, 1100, 1080, 1050, 980, 805, 670 cm^{-1}. MS m/z (rel intensity) 269 (M^+, 3), 225 (19), 224 (23), 196 (15), 170 (11), 169 (100), 168 (27), 140 (43), 127 (34), 53 (26), 51 (16), 44 (19), 43 (17), 41 (37). Found: m/z 269.1616. Calcd for $C_{14}H_{23}NO_4$: M^+ 269.1625.

Hexacarbonyl(*t*-butyl 3-amino-4,4-diethoxy-2-hexen-5-ynoate)dicobalt (15). A pentane (50 ml) solution of **14** (0.84 g, 3.1 mmol) was added to a pentane (20 ml) solution of octacarbonyldicobalt(0) (1.06 g, 3.1 mmol) at 0 °C. The reaction mixture was warmed to room temperature over a period of 1 h, and the solvent was evaporated at ambient temperature by passing nitrogen gas. The residue was purified by column chromatography on silica gel to give **15** (1.33 g, 81% yield) as a red viscous oil. R_f=0.47 (hexane-ethyl acetate 5 : 1). ^{1}H NMR ($CDCl_3$) δ=1.21 (t, J=7.5 Hz, 6H), 1.45 (s, 9H), 3.63 (q, J=7.5 Hz, 4H), 4.88 (s, 1H), 6.13 (s, 1H). IR (neat) 3525, 3350, 3100, 3000, 2950, 2900, 2110, 2070, 2040, 1670, 1620, 1545, 1500, 1455, 1390, 1365, 1285, 1255, 1155, 1120, 1090, 1050, 980, 920, 805, 635, 580, 520, 500, 450 cm^{-1}. MS m/z (rel intensity) 527 (M^+—CO, 2), 499 (3), 471 (4), 443 (3), 415 (6), 387 (6), 359 (2), 343 (3), 331 (4), 225 (4), 224 (3), 169 (29), 149 (26), 140 (28) 122 (40), 59 (100). Found: C, 42.98; H, 4.29; N, 2.47%. Calcd for $C_{20}H_{23}NO_{10}Co_2$: C, 43.28; H, 4.40; N, 2.66%.

Hexacarbonyl(4-amino-5-ethoxy-5-ethynyl-2(5*H*)-furanone)-dicobalt (16). Trifluoroacetic acid (3.0 ml) was added to **15** (0.187 g, 0.34 mmol) at 0 °C and stirred for 30 min at 0 °C before evaporation of the trifluoroacetic acid in vacuo. Preparative TLC of the residue (hexane-ethyl acetate 1 : 1) gave **16** as red viscous oil (0.110 g, 77% yield). R_f=0.44 (hexane-ethyl acetate 1 : 1). ^{1}H NMR ($CDCl_3$) δ=1.20 (t, J=7.5 Hz, 3H), 3.40—3.80 (m, 2H), 4.90 (s, 1H), 5.00 (br, 2H), 6.08 (s, 1H). IR (neat) 3500, 3425 (sh), 3360, 3300 (sh), 3250 (sh), 3220, 3000, 2960, 2920, 2120, 2075, 2040, 1740, 1650, 1610, 1530, 1395, 1280, 1210, 1130, 1035, 985, 925, 800, 750, 630, 610, 520, 500, 450 cm^{-1}. MS m/z (rel intensity) 425 (M^+—CO, 2), 397 (4), 369 (3), 341 (7), 313 (5), 286 (6), 167 (8), 149 (7), 125 (6), 103 (5), 96 (5), 75 (4), 73 (5), 70 (5), 69 (6), 61 (6), 46 (21), 45 (51), 44 (11), 43 (23), 31 (58), 28 (100). Found: C, 37.18; H, 2.03; N, 2.89%. Calcd for $C_{14}H_9O_9Co_2N$: C, 37.10; H, 2.00; N, 3.09%.

4-Amino-5-ethoxy-5-ethynyl-2(5*H*)-furanone (17). Cerium-(IV) ammonium nitrate (0.68 g) was added portionwise to an acetone (5.0 ml) solution of **16** (47 mg, 0.11 mmol) at −78 °C under an argon atmosphere, and the reaction mixture was stirred at −78 °C for 2 h. The solvent was evaporated in vacuo, and the residue was treated with ethyl acetate (30 ml) and water (30 ml). Separation of the organic extract, drying the organic layer over sodium sulfate, concentration, followed by preparative TLC (hexane-ethyl acetate 1 : 1) gave

17 (15 mg, 83% yield). Mp 113—114 °C. R_f=0.30 (hexane-ethyl acetate 1 : 1) gave **17** (15 mg, 83% yield). Mp 113—114 °C, R_f=0.30 (hexane-ethyl acetate 1 : 1). ^{1}H NMR ($CDCl_3$) δ=1.27 (t, J=7.5 Hz, 3 H), 2.73 (s, 1H), 3.65—4.05 (m, 2H), 4.85 (s, 1H), 4.95 (br, 2H, NH_2). An Enantiospecific Synthesis of the C-21–C-37 Segment of the Aglycon of Amphotericin B†

Mitsuhiro KINOSHITA,* Hitoshi TAKAMI, Masato TANIGUCHI, and Tetsuro TAMAI
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
(Received December 17, 1986)

3-Deoxy-1,2-*O*-isopropylidene-3-*C*-methyl-α-D-allofuranose was stereoselectively converted into 3,5-dideoxy-4-*O*-(methoxymethyl)-3,5-di-*C*-methyl-6-*O*-pivaloyl-L-talose ethylene dithioacetal (**31**) via 3,5-dideoxy-4-*O*-(methoxymethyl)-3,5-di-*C*-methyl-L-talopyranuro-6,2-lactone ethylene dithioacetal (**24**) in 10 steps (23.6% overall yield). Desulfurization [Raney Ni W-4, 92% yield] of **31** followed by three-step transformation (91% yield) afforded 2,4,6-trideoxy-5-*O*-(diethylisopropylsilyl)-3-*O*-(methoxymethyl)-2,4-di-*C*-methyl-L-altrose, which was olefinated by using methyl (2*E*,4*E*)-6-(dimethoxyphosphinyl)-2,4-hexadienoate twice to give the target compound, all-*trans*-hexaenal **4** (12 steps, 38.6% overall yield from **31**).

Amphotericin B (**1**),[1] produced by *Streptomyces nodosus*, is the only member of the polyene antibiotic group which is widely used for treatment of the "deep seated" systemic fungal infections and the only polyene macrolide whose absolute structure is firmly established by X-ray crystallographic analysis.[2] Though the extremely difficult problem to isolate the free type of aglycon **2** from natural amphotericin B still remains unsolved, many synthetic approaches toward construction of such aglycon molecule have so far been reported.[3] The preparation in a protected

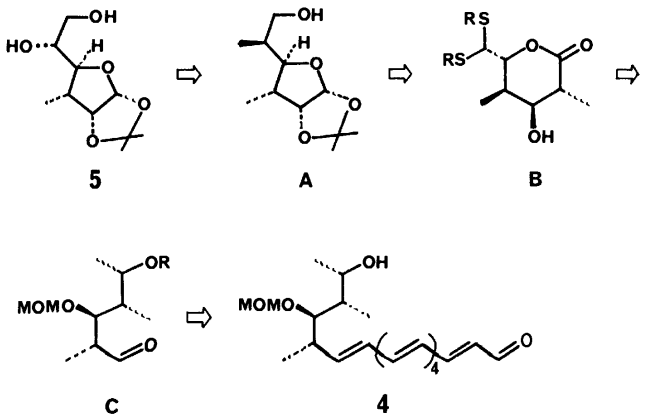
form of **2** (or its C-13 epimer) from naturally derived C-1–C-20 and C-21–C-37 segments has recently been announced by Nicolaou et al.[4] As can be seen in some of these synthetic approaches, the C-21–C-37 segments **3a**,[3l] **3b**,[3m] and **3c**[4] have already been enantiospecifically synthesized from chiral carbon sources other than carbohydrates. In our studies directed toward the total synthesis of amphotericin B (**1**), general plan for synthesis of the free aglycon **2** which was considered to be a synthetic precursor of **1**, required **4** as the C-21–C-37 synthetic segment of **2** (Scheme 1). This strategic segment was expected to be synthesized enantiospecifically from carbohydrate. In this paper, we wish to describe a synthesis of **4** from D-glucose.

The synthetic plan as broadly outlined in Scheme 1 was devised by considering that the key intermediate **B** (whose absolute stereochemistry at C-2, C-3, and C-4 correlates to that at C-17, C-16, and C-15, respectively, of **4**) is obtainable from the known sugar derivative **5**,[5] and the formation of a new chiral center (corresponding to C-14, the last asymmetric carbon atom in **4**) on C-5 of **B** should be possible by asymmetric conversion[6] of **5** into **A** which is a precursor of **B**. The synthetic route to **C** via the lactone **B** from **A** should be indispensable for the regioselective *O*-methoxymethylation toward the C-3 hydroxyl group of C. The successful pursuit of the basic elements of this synthetic plan forms the topic of this report.

The starting diol **5**,[5] which was obtainable in large scale from 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose in 41% yield, was acetylated with acetic anhydride and triethylamine in dichloromethane to afford an 85% yield of a ca. 10:1 mixture of the monoacetates **6a** and **6b**, and a 6.4% yield of the diacetate **6c** after chromatographic isolation through a

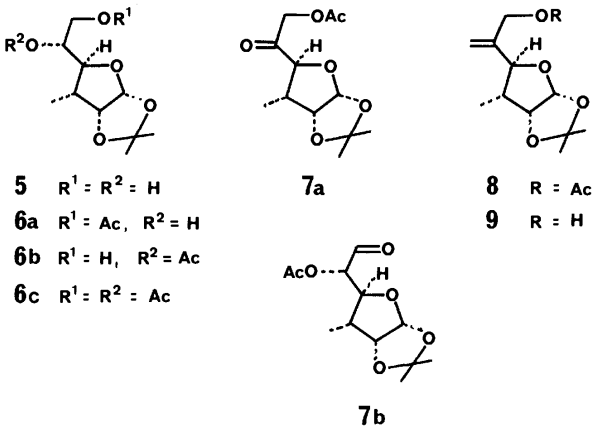


5 **A** **B**

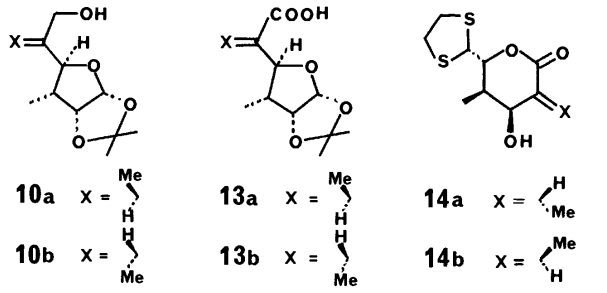
C **4**

Scheme 1.

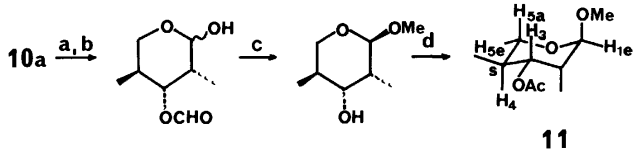
† A part of this paper was read at the 52nd National Meeting of the Chemical Society of Japan, Kyoto, April 1986, Abstr., No. 4N06.



short silica-gel column. Since the preparative separation of the desired acetate **6a** from the minor regioisomer **6b** by column chromatography was impracticable, the mixture was directly oxidized with pyridinium chlorochromate (PCC) and molecular sieves 3A powder[7] to give the chromatographically separable ketone **7a** and the aldehyde **7b** in 87.9 and 8.9% yields, respectively. Wittig methylenation[8] of **7a** with methylenetriphenylphosphorane in ether afforded a 71.5% yield of **8** and 5.4% yield of **9**. Treatment of **8** with methanolic sodium hydroxide provided **9** in 97% yield; the total yield of **9** from **5** amounted to 55.8%. Homogeneous hydrogenation of **9** with 0.2 molar equivalents of tris(triphenylphosphine)chlororhodium (I) in benzene gave a 2.3 : 1 mixture of **10a** and **10b** in 95% yield. Because the preparative separation of **10a**



from its epimer **10b** was not practicable in this stage, the separation had to be carried over to the later synthetic step. The isomeric ratio was assumed based on the intensities of the double-doublet signals due to the H-4 protons at δ 3.91 (**10a**) and δ 3.72 (**10b**) in the 250 MHz ^{1}H NMR spectrum of the mixture. The configuration at C-5 of the isolated major isomer **10a** was assigned as (*S*) by the following fashions: (a) The product **10a** was converted into **11** in four steps (Scheme 2). The ^{1}H NMR spectrum of **11** showed



Scheme 2.[a]

a) (a) 1 M HCl, rt, 5 h, 91%; (b) $NaIO_4$, 1 : 1 Me_2CO–H_2O, rt, 1 h, ca. 100%; (c) 0.15 M HCl–MeOH, rt, 1 h, α-anomer (68%); (d) Ac_2O, DMAP, py, rt, 1 h, 97%.

signals in line with the depicted structure with 4(*S*) configuration (see Experimental section). (b) The compound **11** proved to be identical spectroscopically and chromatographically with an authentic sample of **11** which was derived from the known sugar derivative **12**[9] by the sequence of reactions shown in Scheme 3.

The low stereoselectivity (**10a** : **10b**=2.3 : 1) in the hydrogenation of **9** may suggest that the difference in free energy between the possible transition states **I** and **II** (Scheme 4) corresponding to **10a** and **10b** should be very small. This result prompted us to examine the homogeneous hydrogenation of the 1,6-anhydro-derivative **15** whose rigid conformation in the ground state may be similar to that in the transition state **I**. The compound **15** could be obtained by exposure of **9** to 50% aqueous trifluoroacetic acid[6b] in 13% yield. Though direct hydrogenation of **15** could not be accomplished, its silyl ether **16** was smoothly hydrogenated with rhodium catalyst to afford **17** as a sole reduction product, which was identical with a sample of **17** derived from **10a** via **18**. This highly stereoselective hydrogenation process, however, could not be utilized in the asymmetric conversion of **9** into **B**(**14a**), because of the low yield of **15** and of undesired elongation of the synthetic route by this process.

Chromium trioxide oxidation[10] of the mixture of **10a** and **10b** provided in 98.5% yield a mixture of the carboxylic acids **13a** and **13b**, which were quite difficult to separate each other. Dithioacetalization of the mixture with 1,2-ethanedithiol and boron trifluoride etherate afforded the chromatographically separable epimeric lactones **14a** and **14b** in 46.9 and 23.4% yields, respectively. The major lactone **14a** proved to correspond to **10a** by transformation of the isolated **10a** into **14a**.

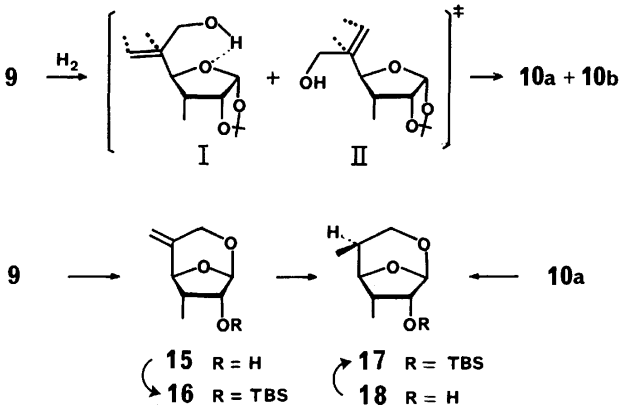
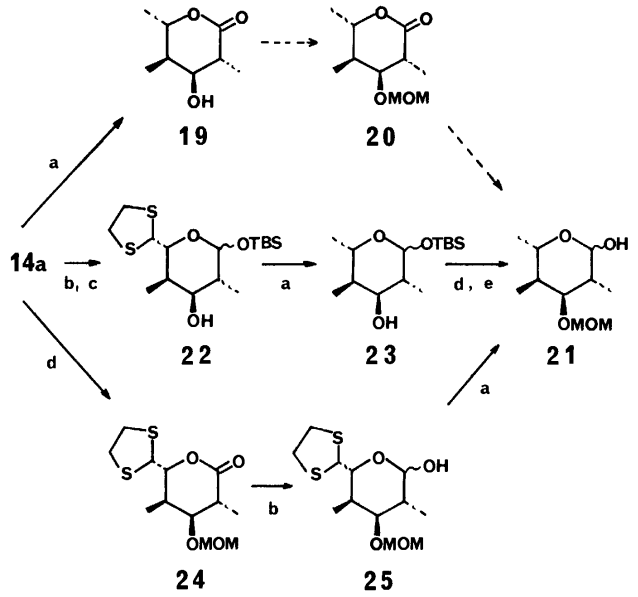


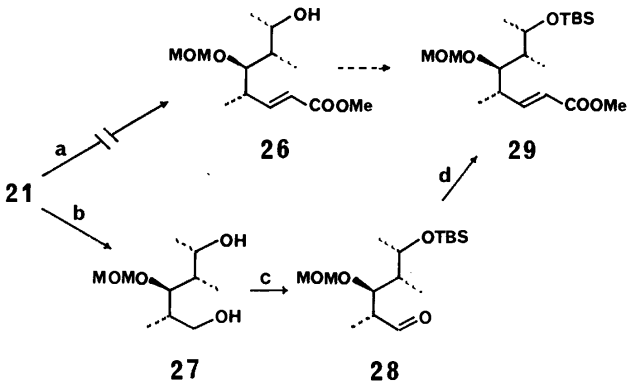
Scheme 4.

Direct desulfurization of the thioacetal group of **14a** with Raney Ni W-4 in methanol yielded only a 20% yield of **19**. Therefore, the first route to **21** via **20** from **14a** was not practicable (Scheme 5). The second route to **21** from **14a** was successful as follows. Reduction of **14a** with diisobutylaluminium hydride (DIBAL) followed by selective *t*-butyldimethylsilylation gave α-**22** (α-anomer) and β-**22** (β-anomer) in 34.8 and 43.5% yields, respectively. Desulfurization of α-**22** and β-**22** with Raney Ni W-4 in methanol afforded smoothly the corresponding α-**23** and β-**23** in 89.8 and 85.1% yields. Methoxymethylation of α-**23** and β-**23** followed by desilylation gave **21** in 96 and 99% yields, respectively. In the third route to **21**, methoxymethylation of **14a** afforded in 98% yield **24** which was treated with DIBAL to give **25** in good yield. However, desulfurization of **25** provided **21** in unsatisfactory yield (44%). The desulfurization reactions of **14a**, **22**, and **25** were carried out with irradiation in the water bath of an ultrasound laboratory cleaner. The TLC inspection of the reaction mixtures showed that, in all cases, no starting material could be detected in the supernatant layer after ultrasonic irradiation for 0.5—1 h, while at that time, only the spot of desulfurized product was observed. The precipitated nickel residue was thoroughly extracted with methanol in twenty times to provide an additional amount of product in almost pure state. The reason the desulfurizations of **14a** and **25** resulted in low yields is now indefinable.



Scheme 5.[a]

a) (a) Raney Ni W-4, MeOH; (b) DIBAL, PhMe, −78°C; (c) TBSCl, imidazole, DMF; (d) MOMCL, *i*-Pr$_2$NEt, DMF; (e) *n*-Bu$_4$NF, THF.

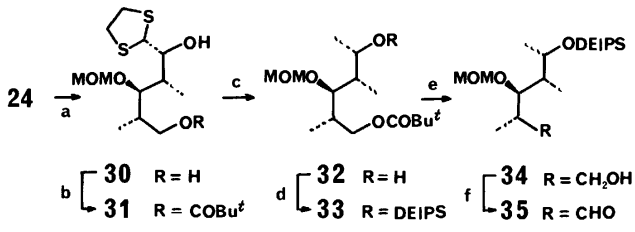


Scheme 6.[a]

a) (a) Ph_3P=CHCOOMe, PhMe, 90°C, 24 h, (b) $NaBH_4$, 2:1 MeOH–H_2O, rt, 0.5 h, ca. 100%; (c) (1) *t*-BuCOCl, py, rt, 20 h, 69%; (2) TBSCl, imidazole, DMF, 35°C, 1 h, 99%; (3) MeLi, ether, rt, 0.5 h, 92%; (4) $(COCl)_2$, CH_2Cl_2, DMSO (−60°C), Et_3N (−25°C), 98%; (d) Ph_3P=CHCOOMe, PhMe, 90°C, 1 h, 90%.

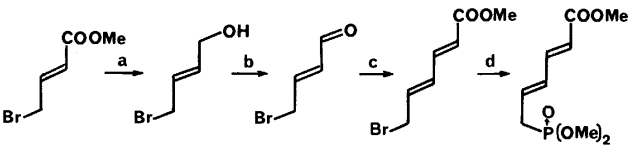
Having thus prepared the hemiacetal **21** which contains entire chiral sequence of **4** in the proper absolute configuration, we turned our attention to the facile transformation of **21** into **4**. The first attempt to convert **21** through direct Wittig olefination into a model intermediate **29** failed, because the condensation of **21** and (methoxycarbonylmethylene)triphenylphosphorane (or trimethyl phosphonoacetate) afforded no desired product **26**. The compound **29**, therefore, had to be prepared from **21** via the diol **27** and the free aldehyde **28** (Scheme 6). The overall yield of **28** from **14a** was 40.9%.

In keeping with these experimental results, the last and more facile synthetic route to **35** (equivalent to **28**) from **24** was pursued (Scheme 7). Lithium aluminium hydride reduction of **24** afforded the alcohol **30** in almost quantitative yield, which was selectively 6-*O*-pivaloylated to give **31** in 96.5% yield. Desulfurization of **31** with Raney Ni W-4 in methanol yielded **32** in 91.6% yield. *O*-Silylation of **32** with diethylisopropylsilyl chloride[11] in the presence of imidazole followed by depivaloylation of the resulting **33** with methyllithium in ether, afforded **34** in almost quantitative yield, which was subjected to Swern oxidation[12] to give the aldehyde **35** in 92% yield. The overall yield of **35** from



Scheme 7.[a]

a) (a) $LiAlH_4$, THF, rt, 1 h; (b) *t*-BuCOCl, Py, rt, 3 h; (c) Raney Ni W-4, MeOH, 0.5 h; (d) DEIPSCl, imidazole, DMF, rt, 0.5 h; (e) MeLi, ether, rt, 0.5 h; (f) $(COCl)_2$, CH_2Cl_2, DMSO, Et_3N.



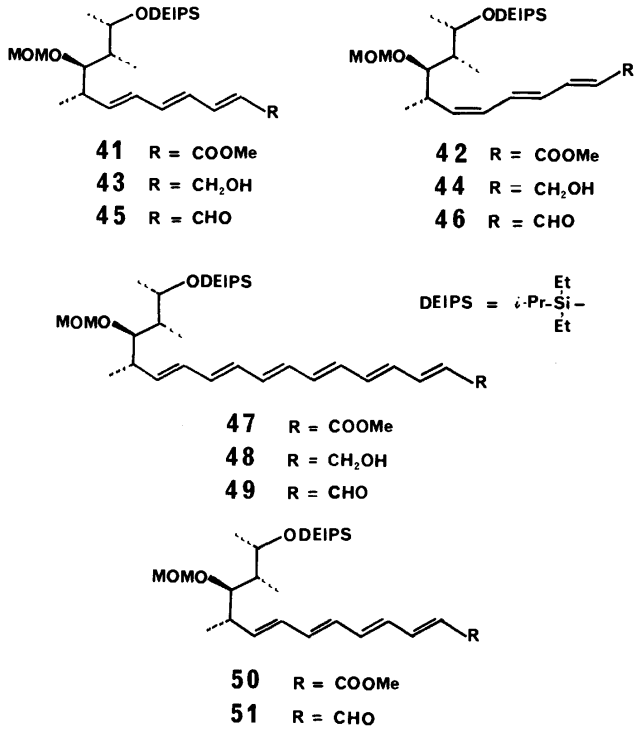
Scheme 8.[a]

a) (a) DIBAL, PhMe, −78°C, 0.5 h, ca. 100%; (b) MnO_2, CH_2Cl_2, rt, 1 h, 88%; (c) Ph_3P=CHCOOMe, PhMe, 90°C, 2 h, 70.5%; (d) $(MeO)_3P$, 120—130°C, 3 h, 88%.

14a was 79.2%.

Having effectively arrived at the key intermediate **35**, the task remained to complete a synthesis of **4** was effective elaboration of **35** to all-*trans*-hexaenal **49**. After many unsuccessful attempts, the effective construction of **49** from **35** was achieved by the repeated Wittig-type olefination procedure using methyl (2*E*,4*E*)-6-(dimethoxyphosphinyl)-2,4-hexadienoate (**40**). The preparation of **3c** by the similar olefination procedure using ethyl (2*E*,4*E*)-6-(diethoxyphosphinyl)-2,4-hexadienoate instead of **40**, have recently been reported by Nicolaou et al.[4] after our work had been completed.

A facile preparation of the reagent **40** starting from methyl 4-bromocrotonate (**36**) was first accomplished as detailed in Scheme 8. Condensation of **35** with the lithio derivative of **40** which was prepared by treatment of **40** with lithium diisopropylamide(LDA) in THF afforded a 1:2 mixture of the (2*E*,4*E*,6*E*)-trienoic ester **41** and its (6*Z*)-isomer **42** in 99.7% yield. The mixture was then isomerized[13] with 0.01 molar equivalent of iodine in dichloromethane to give a ca. 8:1 mixture of **41** and **42** in almost quantitative yield. Reduction of this mixture with DIBAL followed by oxidation of the resulting mixture of the allylic alcohol **43** and its (6*Z*)-isomer **44** with manganese dioxide, afforded after chromatographic isomeric separation, the (2*E*,4*E*,6*E*)-trienal **45** and its (6*Z*)-isomer **46** in 70 and 13% overall yields from **35**, respectively. The olefinic structures of **41**, **42**, **45**, and **46** were confirmed by ^{1}H NMR spectroscopy. It is noteworthy that the iodine-catalyzed isomerization of **46** to **45** is not practicable, because the reaction proceeds with considerable decomposition of both **45** and **46**.



The isolated **45** was again coupled with lithium derivative of **40** to give the pure all-*trans*-hexaenoic ester **47** in 96.2% yield as the only detectable product. DIBAL reduction of **47** followed by manganese dioxide oxidation of the resulting allylic alcohol **48** afforded the all-*trans*-hexaenal **49** in 73.5% overall yield. Finally, exposure of **49** to a 1M[††] solution of tetrabutylammonium fluoride in THF led to **4** in 96.8% yield. The *O*-diethylisopropylsilyl protecting group in **49** could be removed more smoothly than the *O*-*t*-butyldimethylsilyl group. The structures of **49** and **4** were confirmed[14] by their 250 MHz ^{1}H NMR spectra.

Experimental

Melting points were determined on a micro hot-stage Yanaco MP-S3 and were uncorrected. IR spectra were recorded on a Hitachi Perkin-Elmer 225 spectrometer, UV spectra on a JAS·CO UVIDEC-1 spectrometer, and ^{1}H NMR spectra in $CDCl_3$ using TMS as the internal standard on either a Varian EM-390 or a Bruker WM 250 spectrometer. Optical rotations were measured on a JAS·CO DIP-360 photoelectric polarimeter in chloroform. TLC was carried out on Merck TLC plates (60F-254, 0.25 mm). Column chromatography was performed on silica gel, Wakogel C-200 and Merck Kieselgel 60 (230—400 mesh) for "Flash Chromatography." In general, organic solvents were purified and dried by the appropriate procedure, and evaporation and concentration were carried out under reduced pressure below 30 °C, unless otherwise noted.

Acetylation of Diol 5. A mixture of **5**[5] (10.1 g, 46.4 mmol), acetic anhydride (5.30 ml, 55.6 mmol), and triethylamine (7.80 ml, 55.6 mmol) in dichloromethane (101 ml) was stirred at room temperature for 4 h, after which period ethanol (3.30 ml) was added and stirring was continued for 0.5 h. The reaction mixture was then evaporated and the residue was coevaporated with ether to a yellow syrup (18.3 g), which was chromatographed on silica gel (600 g) with 2:1 toluene-ethyl acetate to afford a mixture of **6a** and **6b** (10.2 g, 85%) and **6c** (0.90 g, 6.4%) as syrups. The mixture of **6a** and **6b** was used for the next step without further purification. Pure samples of **6a** (0.27 g) and **6b** (0.02 g) were obtained from a sample of the mixture (0.42 g) by flash chromatography on silica gel (42 g) with 2:3 toluene-ethyl acetate.

6a: R_f=0.36 (1:1 toluene-ethyl acetate); $[\alpha]_D^{27}$ +32° (*c* 1.00); IR($CHCl_3$) 1740 and 1230 cm^{-1}; ^{1}H NMR (90 MHz) δ=1.17 (3H, d, 3-Me, *J*=6.6 Hz), 1.36 and 1.53 (each 3H, each s, CMe_2), 1.7—2.0 (1H, m, H-3), 2.12 (3H, s, OAc), 2.53 (1H, d, OH, *J*=3.9 Hz), 3.8—4.3 (4H, m, H-4,5, 2×H-6), 4.57 (1H, t, H-2, *J*=3.9 Hz), and 5.78 (1H, d, H-1, *J*=3.9 Hz).

Found: C, 55.23; H, 7.71%. Calcd for $C_{12}H_{20}O_6$: C, 55.37; H, 7.74%.

6b: R_f=0.33 (1:1 toluene-ethyl acetate); ^{1}H NMR(90 MHz) δ=1.13 (3H, d, 3-Me, *J*=6.6 Hz), 1.33 and 1.51 (each 3H, each s, CMe_2), 2.12 (3H, s, OAc), 1.8—2.4 (2H, m, H-3, OH), 3.8—4.1 (3H, m, H-4 and 2×H-6), 4.55 (1H, t, H-2, *J*=4.5 Hz), 4.8—5.1 (1H, m, H-5), and 5.79 (1H, d, H-1, *J*=4.5 Hz).

6c: R_f=0.67 (1:1 toluene-ethyl acetate); $[\alpha]_D^{17}$ +53° (*c* 0.99); IR ($CHCl_3$) 1740 and 1230 cm^{-1}; ^{1}H NMR (90 MHz) δ=1.12 (3H, d, 3-Me, *J*=6.0 Hz), 1.31 and 1.50 (each 3H, each s, CMe_2), 1.7—2.0 (1H, m, H-3), 2.03 and 2.08 (each 3H, each s, 2×OAc), 3.91 (1H, dd, H-4, *J*=5.1 and 9.6 Hz), 4.20 (1H,

[††] 1 M=1 mol dm^{-3}.

dd, H-6, J=7.2, 12.0 Hz), 4.43 (1H, dd, H-6′, J=4.2, 12.0 Hz), 4.53 (1H, t, H-2, J=4.2 Hz), 5.1—5.3 (1H, m, H-5), and 5.75 (1H, d, H-1, J=4.2 Hz).

Found: C, 55.36; H, 7.30%. Calcd for $C_{14}H_{22}O_7$: C, 55.62; H, 7.33%.

6-*O*-Acetyl-3-deoxy-1,2-*O*-isopropylidene-3-*C*-methyl-α-D-*ribo*-5-hexulofuranose (7a) and 5-*O*-Acetyl-3-deoxy-1,2-*O*-isopropylidene-3-*C*-methyl-α-D-allodialdo-1,4-furanose (7b). To a stirred mixture of PCC (22.3 g, 0.10 mol), molecular sieves 3A powder (34.5 g), and dichloromethane (86 ml) was added a solution of the mixture of **6a** and **6b** (8.98 g, 34.5 mmol) in dichloromethane (50 ml) at room temperature over a period of 15 min. After being stirred at room temperature for 1 h, the reaction mixture was diluted with ether (140 ml) and filtered through a column filled with silica gel (230 g). Evaporation of the eluates left a syrupy residue (8.90 g) which was chromatographed on silica gel (600 g) with 2:1 toluene-ethyl acetate to afford **7a** (7.83 g, 87.9%) and **7b** (0.75 g, 8.4%).

7a: Colorless plates, mp 72—74 °C (ethyl acetate-hexane); R_f=0.66 (3:2 toluene-ethyl acetate); $[\alpha]_D^{27}$ −40° (c 1.01); IR (KBr) 1760, 1730, and 1240 cm^{-1}; ^{1}H NMR (90 MHz) δ=1.19 (3H, d, 3-Me, J=6.6 Hz), 1.35 and 1.51 (each 3H, each s, CMe_2), 2.16 (3H, s, OAc), 2.0—2.4 (1H, m, H-3), 4.20 (1H, d, H-4, J=10.8 Hz), 4.58 (1H, t, H-2, J=3.3 Hz), 4.77 and 5.07 (2H, ABq, 2×H-6, J=18.0 Hz), and 5.90 (1H, d, H-1, J=3.3 Hz).

Found: C, 55.52; H, 6.91%. Calcd for $C_{12}H_{18}O_6$: C, 55.81; H, 7.02%.

7b: Pale yellow syrup, R_f=0.46 (3:2 toluene-ethyl acetate); ^{1}H NMR (90 MHz) δ=1.11 (3H, d, 3-Me, J=6.9 Hz), 1.33 and 1.54 (each 3H, each s, CMe_2), 2.21 (3H, s, OAc), 1.9—2.5 (1H, m, H-3), 4.14 (1H, dd, H-4, J=3.6, 11.1 Hz), 4.53 (1H, t, H-2, J=4.5 Hz), 5.05 (1H, d-like, H-5), 5.72 (1H, d, H-1, J=4.5 Hz), and 9.53 (0.4H, s-like, CHO).

6-*O*-Acetyl-3,5-dideoxy-1,2-*O*-isopropylidene-3-*C*-methyl-5-*C*-methylene-α-D-*ribo*-hexofuranose (8) and 3,5-Dideoxy-1,2-*O*-isopropylidene-3-*C*-methyl-5-*C*-methylene-α-D-*ribo*-hexofuranose (9). A 4 M solution of methylsulfinylmethanide anion in DMSO (9.87 ml, 39.5 mmol) prepared from sodium hydride and DMSO,[8] was added dropwise to a stirred suspension of methyltriphenylphosphonium bromide (14.1 g, 39.5 mmol) in dry ether (188 ml) under argon at room temperature. The mixture was stirred at room temperature for 10 min and then to the resulting yellow suspension of ylide was added dropwise a solution of **7a** (4.08 g, 15.8 mmol) in dry ether (94 ml). After the mixture had been stirred at room temperature for 0.5 h, the reaction mixture was poured into an ice-water mixture, which was extracted with ether (3×250 ml). The organic layer was washed with saturated aqueous NaCl, dried, and evaporated. The residue (8.71 g) was chromatographed on silica gel (600 g) with 3:1 hexane-ethyl acetate to afford **8** (2.89 g, 71.5%) and **9** (0.22 g, 5.4%).

8: R_f=0.57 (3:2 hexane-ethyl acetate); IR ($CHCl_3$) 3010, 1740, 1210, and 1020 cm^{-1}; $[\alpha]_D^{25}$ +17° (c 0.99); ^{1}H NMR (90 MHz) δ=1.05 (3H, d, 3-Me, J=7.2 Hz), 1.34 and 1.52 (each 3H, each s, CMe_2), 2.07 (3H, s, OAc), 1.8—2.1 (1H, m, H-3), 4.20 (1H, d, H-4, J=10.8 Hz), 4.53 (1H, t, H-2, J=4.2 Hz), 4.60 (2H, s, 2×H-6), 5.2—5.3 (2H, m, =CH_2), and 5.77 (1H, d, H-1, J=4.2 Hz).

Found: C, 60.65; H, 7.63%. Calcd for $C_{13}H_{20}O_5$: C, 60.92; H, 7.87%.

Preparation of 9 from 8. To a solution of **8** (2.71 g, 10.6 mmol) in methanol (32 ml) was added a solution of NaOH (0.64 g) in methanol (16 ml), and stirred at room temperature for 1 h. After being neutralized (pH 7) with CO_2 gas, the reaction mixture was diluted with water (30 ml), and extracted with chloroform (3×30 ml). The organic layers were washed with a saturated aqueous NaCl solution, dried, and evaporated. The residue (2.62 g) was chromatographed on silica gel (150 g) with 3:2 hexane-ethyl acetate to afford **9** (2.20 g, 97%) as a syrup.

9: R_f=0.28 (3:2 hexane-ethyl acetate); $[\alpha]_D^{27}$ +7.5° (c 0.99); IR ($CHCl_3$) 3510, 3010, and 1020 cm^{-1}; ^{1}H NMR (90 MHz) δ=1.04 (3H, d, 3-Me, J=6.6 Hz), 1.35 and 1.54 (each 3H, each s, CMe_2), 1.8—2.3 (2H, m, H-3, OH), 4.1—4.4 (3H, m, H-4, 2×H-6), 4.60 (1H, t, H-2, J=4.2 Hz), 5.16 and 5.27 (each 1H, each s, =CH_2), and 5.84 (1H, d, H-1, J=4.2 Hz).

Found: C, 61.80; H, 8.24%. Calcd for $C_{11}H_{18}O_4$: C, 61.66; H, 8.47%.

3,5-Dideoxy-1,2-*O*-isopropylidene-3,5-di-*C*-methyl-α-L-talofuranose (10a) and D-allo Epimer (10b). A solution of **9** (2.30 g, 10.7 mmol) and tris(triphenylphosphine)chlororhodium(I) (1.99 g, 2.15 mmol) in benzene (115 ml) was stirred under an atmospheric pressure of hydrogen at room temperature for 4 h. The reaction mixture was then evaporated and the residue was passed through Florisil (100—200 mesh, 160 g) with ether to afford a pale yellow syrup after evaporation of the solvent, a mixture of **10a** and **10b** (2.20 g, 95%). This sample was utilized without further purification in the subsequent transformation. Part of this syrup was flash chromatographed on silica gel with 1:1 hexane-ethyl acetate to give pure **10a** and **10b**.

10a: R_f=0.49 (1:1 hexane-ethyl acetate); $[\alpha]_D^{26}$ +45° (c 0.54); ^{1}H NMR (90 MHz) δ=0.90 and 1.04 (each 3H, each d, 3 and 5-Me, J=6.9 and 7.2 Hz), 1.32 and 1.49 (each 3H, each s, CMe_2), 1.7—2.0 (2H, m, H-3, 5), 2.52 (1H, br-s, OH), 3.64 (2H, d, after addition of D_2O, 2×H-6, J=6.0 Hz), 3.91 (1H, dd, H-4, $J_{4,5}$=2.4, $J_{4,3}$=9.9 Hz), 4.51 (1H, t, H-2, $J_{2,1}$=$J_{2,3}$=3.6 Hz), and 5.72 (1H, d, H-1).

Found: C, 60.90; H, 9.17%. Calcd for $C_{11}H_{20}O_4$: C, 61.09; C, 9.32%.

10b: R_f=0.47 (1:1 hexane-ethyl acetate); $[\alpha]_D^{27}$ +12° (c 1.00); ^{1}H NMR (90 MHz) δ=1.06 and 1.10 (each 3H, each d, 3 and 5-Me, J=7.2, 6.9 Hz), 1.33 and 1.51 (each 3H, each s, CMe_2), 1.7—2.1 (2H, m, H-3,5), 2.5—2.7 (1H, m, OH), 3.63 (2H, d, 2×H-6, J=4.8 Hz), 3.72 (1H, dd, H-4, $J_{4,5}$=5.1, $J_{4,3}$=9.9 Hz), 4.54 (1H, t, H-2, $J_{2,1}$=$J_{2,3}$=3.9 Hz), and 5.76 (1H, d, H-1).

Found: C, 61.17; H, 9.15%. Calcd for $C_{11}H_{20}O_4$: C, 61.09; H, 9.32%.

Methyl 3-*O*-Acetyl-2,4-dideoxy-2,4-di-*C*-methyl-α-L-lyxopyranoside (11). (A) From **12**: A solution of **12**[9] (70.8 mg) in methanol (1.4 ml) was stirred with Pd-black under bubbling with H_2 gas at 25 °C for 2.5 h, and the suspension was filtered. The filtrate was evaporated to a colorless syrup (52 mg) of debenzylation product, which was treated with $NaBH_4$ (10 mg) in water (0.52 ml) at room temperature for 1 h. The reaction mixture was neutralized with CO_2 gas and evaporated. The residue was chromatographed on silica gel (5 g) with 3:1 chloroform-methanol to afford the crystalline tetrol (30.5 mg). To a solution of the tetrol (30.5 mg) in acetone (0.61 ml) was added a solution of $NaIO_4$ (32.4 mg) in water (0.72 ml) and the mixture allowed to stand at room temperature for 0.5 h. The mixture was extracted with

chloroform three times and then with ethyl acetate seven times. The combined extracts were dried and evaporated to give crude crystals of 2,4-dideoxy-2,4-di-*C*-methyl-L-lyxose (31 mg). A solution of the crystals (24.7 mg) in a 0.15M methanolic hydrogen chloride (0.49 ml) was allowed to stand at room temperature for 15 min. The reaction mixture was neutralized with saturated aqueous $NaHCO_3$, concentrated, and extracted with ethyl acetate. The dried extracts were evaporated to a syrup which was chromatographed on silica gel (2.7 g) with 8:1 benzene-acetone to afford the major anomer of methyl 2,4-dideoxy-2,4-di-*C*-methyl-L-lyxopyranoside [R_f=0.28 (8:1 benzene-acetone), 10.1 mg] and the minor anomer [R_f=0.37 (8:1 benzene-acetone), 0.9 mg]. The major anomer (9 mg) was acetylated with Ac_2O in dry pyridine and worked up by the usual way to give a crude syrup of **11**, which was chromatographed on silica gel (1 g) with 3:1 hexane-ethyl acetate to afford a pure sample of **11**: Colorless syrup, R_f=0.81 (1:1 hexane-ethyl acetate); $[\alpha]_D^{26}$ −35° (*c* 0.65); ^{1}H NMR (250 MHz) δ=0.85 and 0.97 (each 3H, each d, 2- and 4-Me, J=6.6 and 6.9 Hz), 1.9—2.3 (2H, m, H-2,4), 2.06 (3H, s, OAc), 3.36 (3H, s, OMe), 3.46 (1H, dd, H-5a, $J_{5a,4}$=10.0, $J_{5a,5e}$=11.5 Hz), 3.61 (1H, dd, H-5e, $J_{5e,4}$=5.0 Hz), 4.45 (1H, d, H-1, $J_{1,2}$=2.7 Hz), and 4.95 (1H, dd, H-3, $J_{2,3}$=4.8, $J_{3,4}$=9.0 Hz). (B) From **10a**: A solution of **10a** (166 mg) in 1M hydrochloric acid (1.7 ml) was allowed to stand at room temperature for 5 h. The reaction mixture was neutralized with saturated aqueous $NaHCO_3$, diluted with acetone, and evaporated. The residue was chromatographed on silica gel (17 g) with 5:1 chloroform-methanol to afford 3,5-dideoxy-3,5-di-*C*-methyl-L-idofuranose (123 mg, 91.2%). To a solution of the free sugar (19.2 mg) in acetone (0.38 ml) was added a solution of $NaIO_4$ (35 mg) in water (0.35 ml) and the mixture was stirred at room temperature for 1 h. The reaction mixture was extracted with ethyl acetate (3×2 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated to a syrup (21.3 mg). The syrup (19.0 mg) was dissolved in 0.15M methanolic HCl (0.38 ml) and the solution was allowed to stand at room temperature for 1 h. The reaction mixture was neutralized (pH 8) with saturated aqueous $NaHCO_3$ and evaporated. The residue was taken with ethyl acetate (2.0 ml), which was washed with saturated aqueous NaCl, dried, and evaporated to a pale yellow syrup (30 mg). This syrup was chromatographed on silica gel (2.0 g) with 8:1 benzene-acetone to afford two syrupy anomers of methyl 2,4-dideoxy-2,4-di-*C*-methyl-L-lyxopyranoside: Major anomer [R_f=0.28 (8:1 benzene-acetone)], 11.9 mg; minor anomer [R_f=0.37 (8:1 benzene-acetone)], 5.3 mg. The major anomer (8.6 mg) was acetylated with Ac_2O (6.1 µl), DMAP (0.66 mg) in dry pyridine (86 µl) at room temperature for 1 h, and worked-up to afford a syrup which was chromatographed on silica gel (1 g) with 3:1 hexane-ethyl acetate to give a colorless syrup of **11** (10.5 mg); R_f=0.81 (1:1 hexane-ethyl acetate). This sample was identical in all respects with the sample of **11** described in (A).

1,6-Anhydro-3,5-dideoxy-3-*C*-methyl-5-*C*-methylene-β-D-*ribo*-hexofuranose (15). A solution of **9** (24.1 mg) in 50% aqueous trifluoroacetic acid (TFA)(0.24 ml) was kept at room temperature for 50 h and then neutralized with Amberlite IRA-45 resin. The resin was filtered and washed with methanol (3×5.0 ml). The combined filtrates were evaporated and the residue was chromatographed on silica gel (1.8 g) with 1:1 benzene-ethyl acetate to afford **15** (2.2 mg, 13%): mp 219—224 °C; R_f=0.40 (1:1 benzene-ethyl acetate); $[\alpha]_D^{25}$ −84° (*c* 0.39); ^{1}H NMR (90 MHz) δ=1.00 (3H, d, 3-Me, J=6.6 Hz), 1.58 (1H, br-s, OH), 2.5—2.8 (1H, m, H-3), 3.70 (1H, d, H-6, $J_{6,6'}$=9.0 Hz), 4.02 (1H, d, H-4, $J_{4,3}$=4.2 Hz), 4.35 (1H, d, H-6′), 4.90 (1H, d, H-2, $J_{2,3}$=9.3 Hz), 4.91 (1H, s, H-1), and 5.07 and 5.25 (each 1H, each s, $=CH_2$).

2-*O*-*t*-Butyldimethylsilyl Derivative (16). To a stirred solution of **15** (5.0 mg) in DMF (50 µl) was added imidazole (8.7 mg) and TBSCl (14.5 mg) at 0 °C. After being stirred at room temperature for 2 h, the reaction mixture was poured into cold water, which was extracted with ethyl acetate (3×1.0 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated to a syrup (24.1 mg), which was chromatographed on silica gel (0.9 g) with 2:1 hexane-ethyl acetate to give colorless needles of **16** (8.3 mg, 95.8%): mp 139—144 °C; R_f=0.56 (20:1 benzene-ethyl acetate); $[\alpha]_D^{26}$ −29° (*c* 0.40); ^{1}H NMR (90 MHz) δ=0.8—1.0 (12H, m, *t*-Bu, 3-Me), 2.4—2.7 (1H, m, H-3), 3.63 (1H, d, H-6, $J_{6,6'}$=9.3 Hz), 3.93 (1H, d, H-4, $J_{4,3}$=3.9 Hz), 4.31 (1H, d, H-6′), 4.73 (1H, s, H-1), 4.84 (1H, d, H-2, $J_{2,3}$=9.6 Hz), and 5.03 and 5.20 (each 1H, each s, $=CH_2$).

1,6-Anhydro-3,5-dideoxy-3,5-di-*C*-methyl-α-L-talofuranose (18) and Its 2-*O*-*t*-Butyldimethylsilyl Derivative (17). A solution of **10a** (33.2 mg) in 75% aqueous TFA (0.33 ml) was kept at room temperature for 1 h. The reaction mixture was poured into saturated aqueous $NaHCO_3$ containing solid $NaHCO_3$. The mixture (pH=8) was saturated with NaCl and extracted with ethyl acetate. The extracts were dried and evaporated to a syrup which was chromatographed on silica gel (1.2 g) with 1:1 benzene-ethyl acetate to afford **18** (18.5 mg, 76.2%) as a colorless syrup; ^{1}H NMR (90 MHz) δ=0.70 (3H, d, 5-Me, J=6.9 Hz), 1.11 (3H, d, 3-Me, J=7.2 Hz), 1.62 (1H, br-s, OH), 2.2—2.5 (2H, m, H-3, 5), 3.25 (1H, dd, H-6, $J_{5,6}$=$J_{6,6'}$=10.8 Hz), 3.81 (1H, dd, H-6′, $J_{5,6'}$=6.3 Hz), 3.8—4.0 (1H, m, H-4), 4.37 (1H, d, H-2, $J_{2,3}$=7.5 Hz), and 5.15 (1H, s, H-1).

By the procedure described for the silylation of **15**, **18** (8.0 mg) obtained above was silylated to give **17** (11.6 mg, 84.4%) as a colorless syrup; R_f=0.47 (20:1 benzene-ethyl acetate); $[\alpha]_D^{27}$ −9.5° (*c* 0.37); ^{1}H NMR (90 MHz) δ=0.68 (3H, d, 5-Me, J=6.6 Hz), 0.91 (9H, s, *t*-Bu), 1.04 (3H, d, 3-Me, J=7.8 Hz), 2.1—2.5 (2H, m, H-3, 5), 3.24 (1H, dd, H-6, $J_{5,6}$=$J_{6,6'}$=11.7 Hz), 3.79 (1H, dd, H-6′, $J_{5,6'}$=6.3 Hz), 3.8—4.0 (1H, m, H-4), 4.35 (1H, d, H-2, $J_{2,3}$=7.2 Hz), and 5.03 (1H, s, H-1).

Homogeneous Hydrogenation of 16. By the procedure described for hydrogenation of **9**, **16** (4.5 mg) was hydrogenated with $(Ph_3P)_3RhCl$ (3.1 mg), to afford **17** (3.2 mg, 70.6%) after silica-gel column chromatography, by which no isomeric product was detected in the reduction product. The product **17** was identical with the sample of **17** derived from **10a** via **18** by TLC and ^{1}H NMR.

3,5-Dideoxy-1,2-*O*-isopropylidene-3,5-di-*C*-methyl-L-talofuranuronic Acid (13a) and D-allo Epimer (13b). Chromium trioxide (5.0 g, 49.9 mmol) was dissolved in a 30:1 mixture of acetic acid and pyridine (155 ml). This chromium oxidation reagent (142 ml, 45.8 mmol) was added to the aforesaid mixture of **10a** and **10b** (1.65 g, 7.63 mmol). After being stirred at room temperature for 15 h, the reaction mixture was poured into cold water (300 ml) which was extracted with chloroform (3×200 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated. The residue was co-evaporated with ether repeatedly to a

syrup (2.60 g), which was chromatographed on silica gel (200 g) with 150:5:1 chloroform-methanol-acetic acid to afford a mixture of **13a** and **13b** (1.73 g, 98.5%). Analytical samples of **13a** and **13b** were obtained from pure samples of **10a** and **10b** by the procedure described above.

13a: Colorless syrup, R_f=0.53 (100:10:1 chloroform-methanol-acetic acid) $[\alpha]_D^{31}$ +18° (*c* 0.58); IR ($CHCl_3$) 3080 and 1710 cm^{-1}; ^1H NMR (90 MHz) δ=1.09 and 1.22 (each 3H, each d, 3 and 5-Me, *J*=7.2 and 7.8 Hz), 1.34 and 1.53 (each 3H, each s, CMe_2), 1.7—2.1 (1H, m, H-3), 2.5—2.7 (1H, m, H-5), 4.10 (1H, dd, H-4, *J*=5.4, 10.5 Hz), 4.54 (1H, t, H-2, *J*=3.6 Hz), 5.76 (1H, d, H-1, *J*=3.6 Hz), and 9.67 (1H, br-s, COOH).

Found: C, 57.12; H, 7.77%. Calcd for $C_{11}H_{18}O_5$: C, 57.38; H, 7.88%.

13b: Colorless needles, R_f=0.53 (100:10:1 chloroform-methanol-acetic acid); mp 110—114 °C (ethyl acetate-hexane); $[\alpha]_D^{30}$ +43° (*c* 0.84); IR(KBr) 3200 and 1730 cm^{-1}; ^1H NMR (90 MHz) δ=1.11 and 1.29 (each 3H, each d, 3-and 5-Me, *J*=7.2 and 7.8 Hz), 1.34 and 1.53 (each 3H, each s, CMe_2), 1.9—2.3 (1H, m, H-3), 2.6—2.9 (1H, m, H-5), 4.00 (1H, dd, H-4, *J*=4.5, 9.6 Hz), 4.57 (1H, t, H-2, *J*=3.6 Hz), 5.80 (1H, d, H-1, *J*=3.6 Hz), and 10.2 (1H, br-s, COOH).

Found: C, 57.28; H, 7.69%. Calcd for $C_{11}H_{18}O_5$: C, 57.38; H, 7.88%.

3,5-Dideoxy-3,5-di-*C*-methyl-L-talopyranurono-6,2-lactone Ethylene Dithioacetal (14a) and D-allo Epimer (14b). To an ice-cooled solution of a mixture of **13a** and **13b** (1.96 g, 8.51 mmol) in 1,2-ethaneditiol (19.6 ml) was added boron trifluoride etherate (0.59 ml) and the mixture was stirred at room temperature for 1 h. The reaction mixture was neutralized (pH 7) with 10% aqueous K_2CO_3, and extracted with ethyl acetate (3×50 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated. The residue was chromatographed on silica gel (100 g) with 1:1 benzene-ethyl acetate to afford the mixture of **14a** and **14b** (1.52 g, 71.9%). The mixture was separated by flash chromatography on silica gel (200 g) with 3:2 benzene-ethyl acetate to give **14a** (0.87 g, 46.9%) and **14b** (0.49 g, 23.4%).

14a: Colorless plates, mp 113—114 °C (ethyl acetate-hexane); R_f=0.43 (1:1 hexane-ethyl acetate); $[\alpha]_D^{30}$ −42° (*c* 0.51); IR (KBr) 3400, 1700, and 1210 cm^{-1}; ^1H NMR (90 MHz) δ=1.13 and 1.36 (each 3H, each d, 3-and 5-Me, each *J*=6.9 Hz), 1.9—2.3 (1H, m, H-3), 2.72 (1H, dq, H-5, *J*=3.3 and 6.9 Hz), 2.73 (1H, br-s, OH), 3.1—3.7 (4H, m, SCH_2CH_2S), 3.76 (1H, t after addition of D_2O, H-4, *J*=3.0 Hz), 4.51 (1H, dd, H-2, $J_{2,1}$=1.8, $J_{2,3}$=9.0 Hz), and 4.73 (1H, d, H-1).

Found: C, 48.34; H, 6.50%. Calcd for $C_{10}H_{16}O_3S_2$: C, 48.36; H, 6.49%.

14b: Colorless needles, mp 115—119 °C (ethyl acetate-hexane); R_f=0.49 (1:1 hexane-ethyl acetate) $[\alpha]_D^{25}$ −36° (*c* 1.01); IR (KBr) 3460, 1710, and 1200 cm^{-1}; ^1H NMR (90 MHz) δ=1.17 and 1.33 (each 3H, each d, 3- and 5-Me, each *J*=6.9 Hz), 1.8—2.2 (1H, m, H-3), 2.23 (1H, br-s, OH), 2.63 (1H, dq, H-5, *J*=2.4 and 7.2 Hz), 3.0—3.6 (4H, m, SCH_2CH_2S), 3.83 (1H, br-s, H-4), 4.52 (1H, dd, H-2, $J_{2,1}$=1.8, $J_{2,3}$=10.2 Hz), and 4.74 (1H, d, H-1).

Found: C, 48.06; H, 6.40%. Calcd for $C_{10}H_{16}O_3S_2$: C, 48.36; H, 6.49%.

2,4,6-Trideoxy-3-*O*-(methoxymethyl)-2,4-di-*C*-methyl-L-altropyranose (21). To a cooled (−78 °C) solution of **14a** (171 mg, 0.689 mmol) in dry toluene (1.7 ml) was added a 1M solution of DIBAL in toluene (1.38 ml, 1.38 mmol) and stirred at −78 °C for 0.5 h. A 50% aqueous acetic acid solution (0.28 ml) was added to the reaction mixture which was stirred at −78 °C for 5 min and then warmed to room temperature. The mixture was filtered through a Celite and washed with acetone (3×5.0 ml). The organic layer was evaporated to afford a colorless syrup (175 mg). A mixture of this syrup (57.6 mg), TBSCl (52.0 mg), imidazole (31.3 mg), and dry DMF (0.58 ml) was stirred at room temperature for 3 h, and the mixture was poured into cold water, which was extracted with ethyl acetate (3×3.0 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated to a syrup, which was chromatographed on silica gel (8.5 g) with 7:1 hexane-ethyl acetate to **α-22** (α-anomer, 29.2 mg), **β-22** (β-anomer, 36.5 mg), and di-*O*-TBS derivative (18.6 mg). A suspension of Raney Ni W-4 (0.3 g) in a solution of **α-22** (44.8 mg) in methanol (1.1 ml) was irradiated in the water bath of an ultrasound laboratory cleaner (65W, 48KHz) for 1 h. The supernatant layer was separated and the precipitate was extracted with methanol (20×0.5 ml). The combined extracts were evaporated to a colorless syrup (48 mg), which was chromatographed on silica gel (2.4 g) with 7:1 hexane-ethyl acetate to afford **α-23** (30.3 mg, 89.8%) as a colorless syrup. By the same way, **β-23** (31.6 mg, 81.1%) was obtained from **β-22** (49.3 mg). A mixture of **α-23** (31.8 mg), methoxymethyl chloride (70.4 μl), *N*,*N*-diisopropylethylamine (242 μl), and DMF (0.32 ml) was stirred at 50 °C for 6 h. The reaction mixture was poured into cold water, which was extracted with ethyl acetate (3×2.0 ml). The extracts were worked up to give a brown syrup, which was chromatographed on silica gel (2.6 g) with 6:1 hexane-ethyl acetate to afford the 3-*O*-methoxymethyl derivative of **α-23** (35.4 mg, 95.8%). By the same way, the corresponding β-anomer (30.1 mg, 98.6%) was obtained from **β-23** (26.3 mg). The combined α- and β-anomeric 3-*O*-methoxymethyl derivatives (65.1 mg) were treated with 2 equivalents of n-Bu_4NF in THF, and worked up to a syrup, which was chromatographed on silica gel (3.3 g) with 1:1 benzene-ethyl acetate to afford **21** (39 mg): Colorless syrup, ^1H NMR (90 MHz) δ=0.8—1.3 (9H, m, 3×Me), 1.5—1.9 (1H, m, H-4), 2.0—2.3 (1H, m, H-2), 3.40 (0.8H, s, β-OMe), 3.44 (2.2H, s, α-OMe), 3.5—3.7 (1H, m, H-3), 3.8—4.0 (0.3H, m, β-OH), 3.8—4.1 (1H, m, H-5), 4.59 and 4.74 (0.7H, ABq, OCH_2O (β), *J*=6.9 Hz), 4.63 and 4.77 (1.3H, ABq, OCH_2O (α), *J*=6.3 Hz), 4.84 (0.7H, d, H-1(α), *J*=9.9 Hz), 5.06 (0.7H, d, α-OH, *J*=9.9 Hz), and 5.1—5.3 (0.3H, m, H-1(β)).

3,5-Dideoxy-4-*O*-(methoxymethyl)-3,5-di-*C*-methyl-L-talopyranurono-6,2-lactone Ethylene Dithioacetal (24). To a solution of **14a** (248 mg, 0.99 mmol) in DMF (2.50 ml) was added *N*,*N*-diisopropylethylamine (0.87 ml, 4.99 mmol) and methoxymethyl chloride (0.30 ml, 3.99 mmol) at 0 °C. After being stirred at 60 °C for 10 h, the reaction mixture was poured into an ice-water mixture, which was extracted with ethyl acetate (3×5 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated to a syrup (520 mg), which was chromatographed on silica gel (11 g) with 2:1 benzene-ethyl acetate to afford **24** (271 mg, 98.3%) as a colorless syrup: R_f=0.72 (1:1 benzene-ethyl aceta); $[\alpha]_D^{27}$ −25.9° (*c* 0.99); IR ($CHCl_3$) 1725 and 1030 cm^{-1}; ^1H NMR (90 MHz) δ=1.11 (3H, d, 3-Me, *J*=6.9 Hz), 1.34 (3H, d, 5-Me, *J*=7.5 Hz), 1.9—2.3 (1H, m, H-3), 2.84 (1H, dq, H-5, *J*=3.3, 7.5 Hz), 3.1—3.6 (4H, m, SCH_2CH_2S), 3.35 (3H, s, OMe), 3.59 (1H, t, H-4, *J*=3.3 Hz), 4.43 (1H, dd, H-2, *J*=2.1, 9.3 Hz), and 4.6—4.8 (3H, m, H-1, OCH_2O).

Found: C, 49.03; H, 6.87%. Calcd for $C_{12}H_{20}O_4S_2$: C, 49.29, H, 6.89%.

3,5-Dideoxy-4-*O*-(methoxymethyl)-3,5-di-*C*-methyl-L-talose Ethylene Dithioacetal (30). To a solution of **24** (288 mg, 1.04 mmol) in dry THF (4.30 ml) was added lithium aluminium hydride (790 mg, 2.08 mmol) at 0 °C. After being stirred at room temperature for 1 h, saturated aqueous NaCl was added to the reaction mixture until bubbling was stopped. Then, the mixture was filtered through a Celite and the filter cake was washed with acetone (5×7 ml). The filtrate and washings were evaporated and the residue was chromatographed on silica gel (20 g) with 1 : 1 benzene-ethyl acetate to afford **30** (297 mg, ca. 100%) as a colorless syrup: R_f=0.18 (1 : 1 benzene-ethyl acetate); $[\alpha]_D^{28}$ +34° (*c* 0.93); IR($CHCl_3$) 3460 and 1020 cm^{-1}; ^1H NMR (90 MHz) δ=0.89 and 1.00 (each 3H, each d, 3- and 5-Me, *J*=6.6 and 6.9 Hz), 1.8—2.4 (3H, m, H-3, H-5, OH), 2.8—3.1 (1H, m, OH), 3.2—3.4 (4H, m, SCH_2CH_2S), 3.43 (3H, s, OMe), 3.4—3.7 (3H, m, H-2, 2×H-6), 3.91 (1H, dd, H-4, *J*=3.3, 7.5 Hz), 4.65 and 4.79 (2H, ABq, OCH_2O, *J*=6.6 Hz), and 4.90 (1H, d, H-1, *J*=5.7 Hz).

Found: C, 48.67; H, 8.13%. Calcd for $C_{12}H_{24}O_4S_2$: C, 48.62; H, 8.16%.

6-*O*-Pivalate (31) of 30. To a solution of **30** (184 mg, 0.655 mmol) in dry pyridine (5.50 ml) was added pivaloyl chloride (121 µl, 0.982 mmol) at room temperature. After being stirred at room temperature for 3 h, the reaction mixture was diluted with ethyl acetate (6.0 ml) and washed with saturated aqueous K_2SO_4 (2×5.0 ml), $NaHCO_3$ (2×5.0 ml), and NaCl, dried, and evaporated. The residual syrup (350 mg) was chromatographed on silica gel (8.0 g) with 3 : 1 benzene-ethyl acetate to afford **31** (230 mg, 96.5%) as a colorless syrup: R_f=0.75 (1 : 1 benzene-ethyl acetate); $[\alpha]_D^{28}$ +6.5°, $[\alpha]_{365}$=+17° (*c* 0.99); IR ($CHCl_3$) 3500, 1720, 1280, 1150, and 1020 cm^{-1}; ^1H NMR (90 MHz) δ=0.95 and 0.98 (each 3H, each d, 3- and 5-Me, *J*=6.6 and 7.2 Hz); 1.21 (9H, s, O-Bu^t), 2.0—2.4 (2H, m, H-3, H-5), 3.1—3.4 (4H, m, SCH_2CH_2S), 3.37 (3H, s, OMe), 3.4—3.7 (1H, m, H-2), 3.74 (1H, dd, H-4, *J*=3.0, 6.9 Hz), 3.91 and 3.99 (each 1H, each s, 2×H-6), 4.59 and 4.67 (2H, ABq, OCH_2O, *J*=6.3 Hz), and 4.86 (1H, d, H-1, *J*=6.3 Hz).

Found: C, 53.67; H, 8.48%. Calcd for $C_{17}H_{32}O_5S_2$: C, 53.65; H, 8.48%.

2,4,6-Trideoxy-3-*O*-(methoxymethyl)-2,4-di-*C*-methyl-1-*O*-pivaloyl-L-altritol (32). A flask containing a solution of **31** (480 mg, 1.3 mmol) in methanol (4.80 ml) in the presence of Raney Ni W-4 (3.0 g) was ultrasonificated for 40 min. The organic layer was separated from insoluble matter which was washed with methanol (10×5.0 ml). The combined organic layers were concentrated to a crude syrup of **32** (525 mg) contaminated with a small amount of impurity. The crude syrup was chromatographed on silica gel (30 g) with 2 : 1 benzene-ethyl acetate to afford **32** (350 mg, 91.6%) as a colorless syrup: R_f=0.36 (2 : 1 benzene-ethyl acetate); $[\alpha]_D^{29}$ +11° (*c* 1.01); ^1H NMR (90 MHz) δ=0.83 and 0.96 (each 3H, each d, 2 and 4-Me, *J*=6.9 and 7.2 Hz), 1.17 (3H, d, 3×H-6, *J*=4.8 Hz), 1.23 (9H, s, Bu^t), 1.5—2.2 (2H, m, H-2, H-4), 2.83 (1H, s, OH), 3.43 (3H, s, OMe), 3.4—3.6 (1H, m, H-5), 3.7—4.1 (3H, m, 2×H-1 and H-3), and 4.68 (2H, s, OCH_2O).

2,4,6-Trideoxy-5-*O*-(diethylisopropylsilyl)-3-*O*-(methoxymethyl)-2,4-di-*C*-methyl-L-altritol (34). To a solution of **33** (213 mg, 0.506 mmol) in ether (2.13 ml) was added at 0 °C 0.5M methyllithium in ether (2.02 ml, 1.01 mmol). After being stirred at room temperature for 10 min, to the reaction mixture was added saturated aqueous NH_4Cl (3.0 ml). The mixture was extracted with ether (3×3.0 ml), and the extracts were washed with saturated aqueous NaCl, dried, and evaporated. The crude syrup (254 mg) was chromatographed on silica gel (8.5 g) with 2 : 1 hexane-ethyl acetate to afford **34** (171 mg, almost quantitative yield) as a colorless syrup: R_f=0.38 (5 : 1 hexane-ethyl acetate); $[\alpha]_D^{30}$ +50° (*c* 1.02); ^1H NMR (90 MHz) δ=0.4—1.2 (26H, m, 2-, 4-, and 5-Me, $SiEt_2Pr^i$), 1.7—2.1 (2H, m, H-2, H-4), 2.7—3.0 (1H, m, OH), 3.44 (3H, s, OMe), 3.4—3.6 (3H, m, 2×H-1 and H-3), 4.11 (1H, dq, H-5, *J*=3.0, 6.3 Hz), and 4.65 (2H, s, OCH_2O).

Found: C, 61.11; H, 11.10%. Calcd for $C_{17}H_{38}O_4Si$: C, 61.03; H, 11.45%.

2,4,6-Trideoxy-5-*O*-(diethylisopropylsilyl)-3-*O*-(methoxymethyl)-2,4-di-*C*-methyl-L-altrose (35). To a solution of oxalyl dichloride (70.1 µl, 0.803 mmol) in dry dichloromethane (374 µl) was added a mixture of dry DMSO (114 µl, 1.61 mmol) and dry dichloromethane (449 µl) at −60 °C. After being stirred at −60 °C for 0.5 h, a solution of **34** (150 mg, 0.446 mmol) in dichloromethane (446 µl) was added, and the mixture was stirred at −60 °C for 1 h. Triethylamine (311 µl, 2.23 mmol) was added to the reaction mixture, which was stirred at −40 °C for 1 h. The mixture was diluted with ether (1.50 ml) and poured into an ice-water mixture, which was extracted with ether (3×2.0 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated to give a syrup (143 mg), which was chromatographed on silica gel (7.5 g) with 3 : 1 hexane-ethyl acetate to afford **35** (137 mg, 91.9%) as a colorless syrup: R_f=0.66 (3 : 1 hexane-ethyl acetate); $[\alpha]_D^{26}$ −43° (*c* 0.95); IR ($CHCl_3$) 2966, 1720, and 1030 cm^{-1}: ^1H NMR (90 MHz) δ=0.5—1.3 (26H, m, 2,4, and 5-Me, $SiEt_2Pr^i$), 1.7—2.1 (1H, m, H-4), 2.49 (1H, dq, H-2, *J*=2.1, 6.9 Hz), 3.28 (1H, s, OMe), 3.95 (1H, dd, H-3, *J*=2.1, 9.6 Hz), 4.15 (1H, dq, H-5, *J*=3.6, 6.0 Hz), 4.50 and 4.57 (2H, ABq, OCH_2O, *J*=6.3 Hz), and 9.77 (1H, s, CHO).

Methyl (2*E*,4*E*)-6-(Dimethoxyphosphinyl)-2,4-hexadienoate (40). To a solution of methyl 4-bromocrotonate (**36**) (1.00 g, 5.59 mmol) in toluene (20.0 ml) was added dropwise a 1M solution of DIBAL in hexane (14.0 ml, 14.0 mmol) at

−78 °C. After being stirred at −78 °C for 0.5 h, 50% aqueous acetic acid (1.60 ml, 14.0 mmol) was added and the mixture was warmed to room temperature. The resulting insoluble material was removed by filtration through a Celite, and the filter cake was washed with acetone (5×10 ml). The filtrate and washings were evaporated to give a yellow syrup of allylic alcohol **37** (0.97 g). A mixture of **37** (0.73 g, 4.82 mmol), MnO_2 (12.6 g, 145 mmol), and dichloromethane (36.0 ml) was stirred at room temperature for 1 h. The insoluble material was filtered through a column filled with silica gel (2.0 g) with ethyl acetate. The filtrate was evaporated to give a syrup of crude aldehyde **38** (0.63 g, 88%). To a solution of the crude **38** (72.3 mg) in toluene (1.0 ml) was added (methoxycarbonylmethylene)triphenylphosphorane (206 mg, 0.615 mmol). The mixture was stirred at 90 °C for 2 h, and then evaporated. The residue was chromatographed on silica gel (20 g) with 5 : 1 hexane-ethyl acetate to afford **39** (70 mg, 70.5%) as a pale yellow liquid. A sample of **39** (116 mg, 0.567 mmol) was added dropwise to trimethyl phosphite (62.8 μl, 0 536 mmol) at 120—130 °C. After being stirred at 120—130 °C for 3 h, the reaction mixture was chromatographed on silica gel (7.5 g) with 10 : 1 chloroform-methanol to afford **40** (111 mg, 88%) as a pale yellow syrup: R_f=0.61 (10:1 chloroform-methanol); IR ($CHCl_3$) 3000, 2950, 2850, 1710, 1250, and 1030 cm^{-1}; UV(EtOH) 257 nm (log ε=4.45); ^1H NMR (90 MHz) δ=2.59 and 2.84 (each 1H, each d, 2×H-6, J=6.9 Hz), 3.69 , 3.74, and 3.83 (each 3H, each s, 3×OMe), 5.84 (1H, d, H-2, $J_{2,3}$=15.6 Hz), 6.08 (1H, dd, H-5, $J_{4,5}$=14.4, $J_{5,6}$=6.9 Hz), 6.29 (1H, dd, H-4, $J_{3,4}$=9.9 Hz), and 7.25 (1H, dd, H-3).

Found: C, 46.18; H, 6.38%. Calcd for $C_9H_{15}O_5P$: C, 46.16; H, 6.46%.

Methyl (8*S*,9*R*,10*R*,11*S*)-(2*E*,4*E*,6*E*)-11-[(Diethylisopropylsilyl)oxy]-9-(methoxymethoxy)-8,10-dimethyl-2,4,6-dodecatrienoate (41) and (6*Z*)-Isomer (42). To a stirred solution of *N*,*N*-diisopropylamine (32.1 μl, 0.229 mmol) in dry THF (153 μl) was added a 1.37 M solution of butyllithium in hexane (167 μl, 0.229 mmol) at −60 °C. After being kept at −60 °C for 1 h, to this solution was added a solution of **40** (50.0 mg, 0.191 mmol) in dry THF (0.50 ml). The reaction mixture was stirred at −60 °C for 0.5 h. A solution of **35** (31.7 mg, 0.0953 mmol) in dry THF (0.32 ml) was added at −60 °C and stirring was continued at −60—−40 °C for 1 h. Saturated aqueous NH_4Cl (1.5 ml) was added to the reaction mixture, which was warmed to room temperature and extracted with ethyl acetate (3×1.5 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated. The residue (93.7 mg) was chromatographed on silica gel (1.3 g) with 4 : 1 hexane-ethyl acetate to afford a 1 : 2 mixture of **41** and **42** (41.9 mg, 99.7%) as a pale yellow syrup. The R_f-values (200 : 20 : 1 hexane-ethyl acetate-methanol) of **41** and **42** were 0.42 and 0.46, respectively. The mixture (40.0 mg, 0.0908 mmol) was dissolved in a solution of iodine (0.23 mg, 9.08×10^{-4} mmol) in dry dichloromethane (1.20 ml) and the resulting mixture was stirred at room temperature for 8 h without shading the light. Then saturated aqueous $Na_2S_2O_3$ (1.5 ml) was added to the reaction mixture, which was extracted with ethyl acetate (3×2.0 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated to give a 8 : 1 mixture of **41** and **42** (40.0 mg, almost quantitative) as a pale yellow syrup. This syrup was used for the next reaction without further purification. A pure sample of **41** was obtained by flash chromatography of the isomerized product: $[\alpha]_D^{26}$ −4.6°, $[\alpha]_{577}$ −5.1°, $[\alpha]_{546}$ −5.2°, $[\alpha]_{435}$ −2.7° (*c* 0.78); IR ($CHCl_3$) 2950, 1700, and 1615 cm^{-2}; UV (EtOH) 304 nm (log ε=4.54); ^1H NMR (250 MHz) δ=0.60 (4H, q, 2×SiC<u>H</u>$_2$CH$_3$, J=8.5 Hz), 0.87 (3H, d, 10-Me, J=7.0 Hz), 1.9—1.1 (13H, m, 2×SiCH$_2$C<u>H</u>$_3$, *i*-Pr), 1.06 (3H, d, 8-Me, J=7.0 Hz), 1.07 (3H, d, 11-Me, J=6.3 Hz), 1.8—2.0 (1H, m, H-10), 2.54 (1H, ddq, H-8, J=3.8, 7.0 Hz), 3.31 (1H, dd, H-9, J=3.8, 8.3 Hz), 3.35 (3H, s, OCH$_2$O<u>Me</u>), 3.74 (3H, s, COOMe), 4.13 (1H, dq, H-11, J=4.0, 6.3 Hz), 4.54 and 4.57 (2H, ABq, OCH$_2$O, J=7.0 Hz), 5.85 (1H, d, H-2, $J_{2,3}$=15.0 Hz), 5.99 (1H, dd, H-7, $J_{7,8}$=7.0, $J_{7,6}$=15.0 Hz), 6.16 (1H, dd, H-6, $J_{6,5}$=10.5 Hz), 6.25 (1H, dd, H-4, $J_{4,3}$=11.5, $J_{4,5}$=15.0 Hz), 6.54 (1H, dd, H-5), and 7.30 (1H, dd, H-3).

Found: C, 65.57; H, 9.89%. Calcd for $C_{24}H_{44}O_5Si$: C, 65.41; H, 10.06%.

(8*S*,9*R*,10*R*,11*S*)-(2*E*,4*E*,6*E*)-11-[(Diethylisopropylsilyl)oxy]-9-(methoxymethoxy)-8,10-dimethyl-2,4,6-dodecatrienal (45) and (6*Z*)-Isomer (46). To a stirred solution of the 8 : 1 mixture of **41** and **42** (40.4 mg) in dry toluene (1.20 ml) was added dropwise a 1 M solution of DIBAL in hexane (229 μl) at −78 °C. After being stirred at −78 °C for 10 min, 50% aqueous acetic acid (262 μl) was added to the mixture, which was warmed to room temperature. The resulting insoluble matter was removed by filtration through a Celite, and the filter cake was washed with acetone (5×3.0 ml). The filtrate and washings were evaporated to give a yellow syrup (40.2 mg), which was chromatographed on silica gel (3.8 g) with 1 : 1 hexane-ethyl acetate to afford a mixture of the allylic alcohol **43** and its isomer **44** (35.4 mg, 93.6%) as a yellow syrup [R_f=0.17 (4 : 1 hexane-ethyl acetate)]. To this syrup (35.4 mg, 0.0858 mmol) was added dichloromethane (1.42 ml) and MnO_2 (423 mg, 4.87 mmol), and the mixture was stirred at room temperature for 0.5 h. The insoluble material was removed by filtration through a column filled with silica gel (0.35 g). The filtrate was evaporated to give an orange syrup (35.1 mg), which was flash-chromatographed on silica gel (7.0 g) with 140 : 20 : 1 hexane-ethyl acetate-methanol to afford **45** (27.5 mg) and **46** (5.1 mg) in 71 and 13% overall yields from **35**, respectively. **45**: Pale yellow syrup, R_f=0.41 (4 : 1 hexane-ethyl acetate); $[\alpha]_D^{25}$ −14.3° (*c* 0.48); IR ($CHCl_3$) 2960, 1725, 1670, and 1610 cm^{-1}; UV (EtOH) 319 nm (log ε=4.75); ^1H NMR (250 MHz) δ=0.61 (4H, q, 2×SiC<u>H</u>$_2$Me, J=7.8 Hz), 0.87 (3H, d, 10-Me, J=7.3 Hz), 0.9—1.1 (13H, m, 2×SiCH$_2$C<u>H</u>$_3$, *i*-Pr), 1.07 (6H, d, 8-and 11-Me, J=7.0 Hz), 1.88 (1H, m, H-10), 2.57 (1H, ddq, H-8, J=3.3, 7.0 Hz), 3.33 (1H, dd, H-9, J=3.3, 8.3 Hz), 3.36 (3H, s, OMe), 4.13 (1H, dq, H-11, J=4.5, 7.0 Hz), 4.54 and 4.58 (2H, ABq, OCH$_2$O, J=7.0 Hz), 6.10 (1H, dd, H-7, $J_{7,8}$=7.0, $J_{7,6}$=15.0 Hz), 6.14 (1H, dd, H-2, $J_{2,1}$=8.3, $J_{2,3}$=15.3 Hz), 6.21 (1H, dd, H-6, $J_{6,5}$=9.8 Hz), 6.37 (1H, dd, H-4, $J_{4,3}$=11.3, $J_{4,5}$=15.0 Hz), 6.66 (1H, dd, H-5), 7.12 (1H, dd, H-3, $J_{3,2}$=15.3 Hz), and 9.56 (1H, d, CHO, J=8.3 Hz).

Found: C, 67.45; H, 10.11%. Calcd for $C_{23}H_{42}O_4Si$: C, 67.27; H, 10.31%.

46: R_f=0.47 (4 : 1 hexane-ethyl acetate), ^1H NMR (250 MHz) δ=2.9—3.1 (1H, m, H-8), 5.77 (1H, dd, H-7, $J_{7,6}$=$J_{7,8}$=10.8 Hz), 6.10 (1H, dd, H-6, $J_{6,5}$=$J_{6,7}$=10.8 Hz), 6.17 (1H, dd, H-2, $J_{2,1}$=7.3, $J_{2,3}$=15.0 Hz), 6.44 (1H, dd, H-4, $J_{4,3}$=10.8, $J_{4,5}$=14.5 Hz), 6.65 (1H, dd, H-5), 7.17 (1H, dd, H-3), and 9.58 (1H, d, CHO).

Methyl (14*S*,15*R*,16*R*,17*S*)-(2*E*,4*E*,6*E*,8*E*,10*E*,12*E*)-17-[(Diethylisopropyl)oxy]-15-(methoxymethoxy)-14,16-dimethyl-2,4,6,8,10,12-octadecahexaenoate (47). To a stirred solution

of LDA in THF prepared from *N,N*-diisopropylamine (15.0 μl, 0.107 mmol) by the procedure described in the preparation of **41** was added a solution of **40** (23.4 mg, 0.0892 mmol) in dry THF (234 μl) at −60 °C and the mixture was stirred at −60 °C for 0.5 h. A solution of **45** (18.3 mg, 0.0446 mmol) in dry THF (183 μl) was added and stirred at −30 °C for 2 h. The reaction mixture was quenched with saturated aqueous NH_4Cl (1.0 ml), and extracted with ethyl acetate (3×1.0 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated. The residue (53.3 mg) was chromatographed on silica gel (2.0 g) with 40:1 chloroform–ethyl acetate to afford **47** (21.4 mg, 92.6%) as a yellow plates: R_f=0.45 (5:1 hexane-ethyl acetate); mp 154—157 °C; $[\alpha]_D^{25}$ +2.5°, $[\alpha]_{577}$ +4.1°, $[\alpha]_{546}$ +7.1° (*c* 0.42); IR (KBr) 1710, 1615, 1010 cm^{-1}; UV (EtOH), nm (log ε) 224 (4.07), 282 (4.10), 381 (4.90); ^1H NMR (250 MHz) δ=0.61 (4H, q, 2×SiC$\underline{H_2}$Me, *J*=7.3 Hz), 0.85 (3H, d, 16-Me, *J*=6.8 Hz), 0.9—1.1 (19H, m, 14- and 17-Me, 2×SiCH$_2$$\underline{Me}$, *i*-Pr), 1.8—1.9 (1H, m, H-16), 2.4—2.6 (1H, m, H-14), 3.29 (1H, dd, H-15, *J*=4.0, 8.8 Hz), 3.36 (3H, s, CH$_2$O$\underline{Me}$), 3.74 (3H, s, COOMe), 4.34 (1H, dq, H-17, *J*=4.3, 6.5 Hz), 4.54 and 4.58 (2H, ABq, OCH_2O, *J*=7.5 Hz), 5.83 (1H, dd, H-13, $J_{13,14}$=7.3, $J_{13,12}$=15.0 Hz), 5.88 (1H, d, H-2, $J_{2,3}$=15.3 Hz), 6.0—6.7 (9H, m, H-4,5,6,7,8,9,10,11,12), and 7.32 (1H, dd, H-3, $J_{3,4}$=11.3 Hz).

Found: C, 69.41; H, 9.52%. Calcd for $C_{30}H_{50}O_5Si$: C, 69.45; H, 9.71%.

(14*S*,15*R*,16*R*,17*S*)-(2*E*,4*E*,6*E*,8*E*,10*E*,12*E*)-17-[(Diethylisopropylsilyl)oxy]-15-(methoxymethoxy)-14,16-dimethyl-2,4,6,8,10,12-octadecahexaenal (49). By the procedure described in the preparation of **45** from **41**, above obtained **47** (49.3 mg) was transformed via the allylic alcohol **48** into **49** (33.2 mg, 73.5%).

49: Orange crystals; R_f=0.39 (5:1 hexane-ethyl acetate); mp 146—149 °C; $[\alpha]_D^{28}$ +3.5°, $[\alpha]_{577}$ +4.1°, $[\alpha]_{546}$ +9.4° (*c* 0.34); IR (KBr) 1665, 1600, 1550, 1005 cm^{-1}; UV (EtOH) nm (log ε) 228 (4.18), 288 (4.20), 408 (4.99); ^1H NMR (250 MHz) δ=0.61 (4H, q, 2×SiC$\underline{H_2}$Me, *J*=8.3 Hz), 0.87 (3H, d, I6-Me, *J*=7.0 Hz), 0.9—1.1 (13H, m, 2×SiCH$_2$$\underline{Me}$, *i*-Pr), 1.05 and 1.06 (each 3H, each d, 14- and 17-Me, *J*=6.5 Hz), 1.87 (1H, m, H-16), 2.52 (1H, ddq, H-14, *J*=3.3, 6.8 Hz), 3.30 (1H, dd, H-15, *J*=3.3, 7.8 Hz), 3.36 (3H, s, OMe), 4.15 (1H, dq, H-17, *J*=4.3, 7.0 Hz), 4.54 and 4.58 (2H, ABq, OCH_2O, *J*=7.0 Hz), 5.85 (1H, dd, H-13, $J_{13,14}$=6.8, $J_{13,12}$=15.0 Hz), 6.15 (1H, dd, H-2, $J_{2,1}$=3.4, $J_{2,3}$=15.3 Hz), 6.0—6.8 (9H, m, H-4,5,6,7,8,9,10,11,12), 7.15 (1H, dd, H-3, $J_{3,4}$=11.3 Hz), and 9.57 (1H, d, CHO).

Found: C, 71.24; H, 9.73%. Calcd for $C_{29}H_{48}O_4Si$: C, 71.26; H, 9.90%.

(14*S*,15*R*,16*R*,17*S*)-(2*E*,4*E*,6*E*,8*E*,10*E*,12*E*)-17-Hydroxy-15-(methoxymethoxy)-14,16-dimethyl-2,4,6,8,10,12-octadecahexaenal (4). To a solution of **49** (19.6 mg, 0.04 mmol) in dry THF (0.39 ml) was added a 1 M solution of *n*-Bu_4NF in THF (80.2 μl, 0.08 mmol) at 0 °C. After being stirred at 0 °C for 15 h, the reaction mixture was poured into an ice-water mixture which was extracted with ethyl acetate (3×1.0 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated. The residue (23.4 mg) was chromatographed on silica gel (2.2 g) with 2:3 hexane-ethyl acetate to afford **4** (14.0 mg, 96.8%) as orange crystals: R_f=0.15 (7:3 hexane-ethyl acetate); mp 105—114 °C; IR (KBr) 3340, 1670, 1550, and 1010 cm^{-1}; UV (EtOH) nm (log ε) 288 (4.01), 406 (4.73); ^1H NMR (250 MHz) δ=0.88 (3H, d, 16-Me, *J*=7.0 Hz), 1.08 (3H, d, 17-Me, *J*=6.8 Hz), 1.17 (3H, d, 14-Me, *J*=6.3 Hz), 1.76 (1H, q-like, H-16, *J*=7.0 Hz), 2.5—2.7 (1H, m, H-14), 3.3—3.5 (2H, m, H-15, OH), 3.40 (3H, s, OMe), 3.83 (1H, dq, H-17, *J*=6.8 Hz), 4.65 and 4.67 (2H, ABq, OCH_2O, *J*=7.5 Hz), 5.82 (1H, dd, H-13, $J_{13,14}$=7.5, $J_{13,12}$=14.5 Hz), 6.16 (1H, dd, H-2, $J_{2,1}$=8.0, $J_{2,3}$=15.0 Hz), 6.1—6.8 (9H, m, H-4,5,6,7,8,9,10,11,12), 7.14 (1H, dd, H-3, $J_{3,4}$=11.5 Hz), and 9.56 (1H, d, CHO).

Found: C, 73.02; H, 8.65%. Calcd for $C_{22}H_{32}O_4$: C, 73.30; H, 8.95%.

We are grateful to Prof. Sumio Umezawa, Institute of Bioorganic Chemistry, and Prof. Hamao Umezawa, Institute of Microbial Chemistry for their generous support of our program. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 60470091 from the Ministry of Education, Science and Culture. We would like to thank Miss Yoshiko Koyama of the Institute for 250 MHz ^1H NMR spectral analyses, and Mr. Akio Takahashi of Keio University, for elemental analyses.

14) Direct ^{1}H NMR spectroscopic confirmation of the (6E)-configuration of **47** and **49** was impossible, because, in their spectra, the signals of the H-6 and 7 protons were found in a complex multiplet due to nine olefinic protons. Therefore, their (6E)-configuration was indirectly confirmed. The reaction of **45** with (methoxycarbonylmethylene)triphenylphosphorane afforded the all-*trans*-tetraenoic ester **50** in 89% yield: ^{1}H NMR (90 MHz) δ=5.88 (1H, d, H-2, $J_{2,3}$=15.6 Hz), 6.0—6.7 (6H, m, H-4,5,6,7,8,9), and 7.37 (1H, d, H-3, $J_{3,4}$=10.8 Hz). The ester **50** was converted , by the procedure described in the preparation of **45**, into the all-*trans*-tetraenal **51** in 43.3% yield: ^{1}H NMR (90 MHz) δ=6.17 (1H, dd, H-2, $J_{2,1}$=8.1, $J_{2,3}$=15.3 Hz), 6.0—6.8 (6H, m, H-4,5,6,7,8,9), 7.16 (1H, dd, H-3, $J_{3,4}$=9.9 Hz), and 9.62 (1H, d, CHO). The reaction of **51** with methyl (2*E*)-4-(dimethoxyphosphinyl)-2-butenoate (THF, LDA, −60 °C, 0.5h) provided in almost quantitative yield the hexaenoic ester **47**, which proved to be identical in all respects with a sample of **47** obtained by the reaction of **45** and **40**.

Kinetic Studies of Antioxidant Activity of New Tocopherol Model Compounds in Solution

Kazuo MUKAI,* Satoshi YOKOYAMA, Kazuyuki FUKUDA, and Yuichi UEMOTO
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790
(Received December 26, 1986)

The second-order rate constants k_s for the reaction of 10 kinds of tocopherol (vitamin E) model compounds with stable phenoxyl radical in ethanol have been measured at 25.0 °C, using a stopped-flow spectrophotometer, as a model reaction of tocopherols with unstable free radicals (ROO·, RO·, and HO·) in biological systems. The absolute k_s values of α-, β-, γ-, and δ-tocopherol models are similar to or slightly smaller than those of the corresponding tocopherols having a long-phytyl-chain. The relative k_s values (α : β : γ : δ=100 : 53 : 50 : 24), that is, relative antioxidant activities, of α-, β-, γ-, and δ-tocopherol models are in good agreement with those (100 : 44 : 47 : 20) of α-, β-, γ-, and δ-tocopherols. The antioxidant activities of tocopherol models having two alkyl substituents, such as methyl, ethyl, isopropyl, and *t*-butyl groups, at ortho positions of OH group are similar to each other, suggesting that the effect of steric hindrance on the reaction rate is small. 5,7-Dimethyltocol model has quite similar rate constants with those of β- and γ-tocopherol models, whereas δ-tocopherol model is only ca. 24% as reactive as α-tocopherol model and tocol model is only ca. 10% as reactive as α-tocopherol model. The result indicates that the rate constants increase as the total electron donating capacity of the alkyl substituents at aromatic ring increases. For the tocopherol models log k_s was found to correlate with $\Sigma\sigma^+$ substituent constants with a ρ^+ value of −1.0.

Vitamin E (α-, β-, γ-, and δ-tocopherols) is known to scavenge peroxyl, alkoxyl, and hydroxyl radicals.[1,2] The above free radical scavenging actions by vitamin E have been ascribed to the initial reaction of the phenolic hydroxyl group with the production of a tocopheroxyl† radical.[3-7] Recently, Burton et al. have reported absolute second-order rate constants, k_1, for the reaction of α-, β-, γ-, and δ-tocopherols with poly(styrylperoxyl) radicals, using the inhibited autoxidation of styrene method (reaction 1).[8-10]

$$\mathrm{ROO\cdot + Toc \xrightarrow{k_1} ROOH + Toc\cdot} \quad (1)$$

They suggested that the relative magnitude of the second-order rate constant, k_1, of α-, β-, γ-, and δ-tocopherols is in agreement with in vivo and in vitro tests of their relative biological activities which yield: α>β>γ>δ-tocopherol.[9]

In a previous work, we have determined spectrophotometrically the rates of reaction of α-, β-, γ-, and δ-tocopherols with stable phenoxyl radical (2,6-di-*t*-butyl-4-(4-methoxyphenyl)phenoxyl (PhO·) (see Fig. 1)) in ethanol solution using stopped-flow technique, as a model reaction of tocopherols with unstable free radicals (ROO·, RO·, and HO·) in biological systems (reaction 2).[11]

$$\mathrm{PhO\cdot + Toc \xrightarrow{k_s} PhOH + Toc\cdot} \quad (2)$$

The second-order rate constants, k_s, obtained are $(5.12\pm0.36)\times10^3$ (α-Toc), $(2.24\pm0.04)\times10^3$ (β-Toc), $(2.42\pm0.16)\times10^3$ (γ-Toc), and $(1.02\pm0.10)\times10^3$ (δ-Toc) $M^{-1}s^{-1}$ in ethanol at 25.0 °C. The relative k_s values (α : β : γ : δ=100 : 44 : 47 : 20) obtained by the stopped-flow technique are in good agreement with the values (100 : 41 : 44 : 14)[10] obtained by the inhibited autoxidation of styrene method, although the absolute k_s values are about 600 times smaller than those for the reaction of tocopherols with poly(styrylperoxyl) radical in chlorobenzene. The results suggest that the relative reactivities, that is, relative antioxidant activities of tocopherols in homogeneous solution do not change depending on the kinds of radicals (phenoxyl and poly(styrylperoxyl) radicals) used, while the absolute

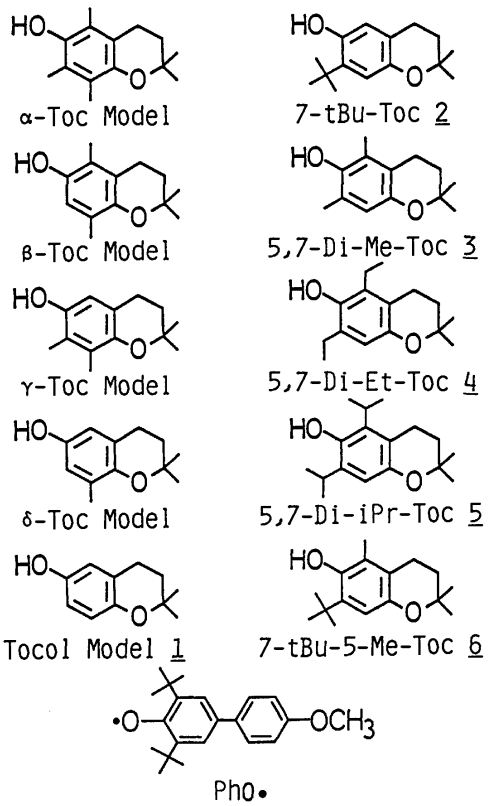

Fig. 1. Molecular structures of tocopherol model compounds and phenoxyl radical (PhO·).

†The phenoxyl radicals generated from tocopherols are named in this paper as widely used tocopheroxyl radicals for convenience rather than tocopheryloxyl radicals that conform to rules of nomenclature.

rates are considerably different from each other. Further, the above results indicate that α-tocopherol having two methyl groups at ortho positions of OH group is about two times as reactive as β- and γ-tocopherols having one methyl group at ortho positions, and, then, δ-tocopherol which has no methyl substituents at ortho positions is only ca. 20% as reactive as α-tocopherol. Antioxidant activities of tocopherols seem to increase in the order of the number of methyl substituents at ortho positions of OH group. These findings suggest that the presence of two methyl groups at ortho positions in tocopherols is of great importance to their antioxidant action.

Therefore, in the present work, in order to get the tocopherol compounds having higher antioxidant activity than α-tocopherol and in order to clear the structure-activity relationship in antioxidant action of tocopherols, we have prepared several tocopherol model compounds which have especially two alkyl substituents, such as methyl, ethyl, isopropyl, and *t*-butyl groups, at ortho positions of OH group (see Fig. 1), and measured the rates of reaction of tocopherol models with phenoxyl radical in ethanol solution, using stopped-flow spectrophotometer.[11]

Experimental

Materials. α-, β-, γ-, δ-Tocopherol models, tocol model (**1**), and 5,7-dimethyl-tocol model (**3**) were prepared according to the method of Nilsson et al.[12] Preparation of 7-*t*-butyl-tocol model (**2**), 5,7-diisopropyl-tocol model (**5**), and 7-*t*-butyl-5-methyl-tocol model (**6**) was reported in a previous paper.[13] 2,6-Diethylhydroquinone (mp 105.0—106.0 °C) were prepared from 2,6-diethylphenol by the standard procedure, as reported for the syntheses of the 2,3-, 2,5-, and 2,6-dimethylhydroquinone.[14]

The 2,6-di-*t*-butyl-4-(4-methoxyphenyl)phenoxyl (PhO·) was prepared according to the method of Müller et al.[15] Radical concentration of phenoxyl radical was obtained from the results of the paramagnetic susceptibility measurements at 20 °C. The value was 100% for phenoxyl, assuming the Curie law.

5,7-Diethyl-Tocol Model (4). 2,6-Diethylhydroquinone (3.7 g, 22 mmol) was dissolved in formic acid (99%) (50 ml) and THF (tetrahydrofuran) (5 ml), and the solution was heated to reflux. A THF (2 ml) solution of 2-methyl-3-buten-2-ol (1.9 g, 22 mmol) was added dropwise slowly during 1 h, and the refluxing was continued for an additional 3 h with stirring. The reaction mixture was poured onto crushed ice (150 g), and extracted with diethyl ether (5×25 ml). Petroleum ether (bp 40—50 °C) (25 ml) was added to the combined diethyl ether extracts and the mixture was washed with water (5×25 ml). After removal of the solvent, the residue was dissolved in methanol (75 ml), 1 ml of concn HCl was added, and the solution refluxed for 20 min to hydrolyze formate of **4** produced. The methanol was then evaporated, and the residue was taken up in diethyl ether (100 ml), washed with $NaHCO_3$ solution and with water, and the solution was dried over anhydrous sodium sulfate. The solvent was evaporated, and the residual oil was extracted three times with hot petroleum ether (bp 50—60 °C) (3×100 ml). After removal of the solvent, a viscous oil remained. The oily residue obtained was chromatographed on 50 g of silica gel with ether-petroleum ether (1 : 5) as the eluting agent. After removal of the solvent, the oily solids remained were recrystallized from petroleum ether (bp 60—70 °C), giving white crystals. Mp 80.0—80.4 °C. (Found: C, 76.63; H, 9.50%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%). UV spectrum (λ_{max}=294 nm, log ε=3.55 in ethanol). NMR spectrum (δ=1.13 (3H, t, 5- or 7-CH_2CH_3, J=7.3 Hz), 1.21 (3H, t, 5- or 7-CH_2CH_3, J=7.3 Hz), 1.28 (6H, s, 2-CH_3), 1.78 (2H, t, 3-CH_2, J=6.6 Hz), 2.56 (2H, q, 5- or 7-CH_2CH_3, J=7.3 Hz), 2.63 (2H, q, 5- or 7-CH_2CH_3, J=7.3 Hz), 2.67 (2H, t, 4-CH_2, J=6.6 Hz), 4.17 (1H, s, 6-OH), 6.46 (1H, s, 8-H); δ in $CDCl_3$ with TMS as an internal standard).

Measurement of k_s Values by the Stopped-Flow Spectrophotometer. The stopped-flow data were obtained on a UNISOKU stopped-flow spectrophotometer Model RS-450 by mixing equal volumes of ethanol solutions of phenoxyl and tocopherol model. The oxidation reactions were studied under pseudo-first-order conditions, and the observed rate constants, k_{obsd}, were calculated in the usual way using a standard least-squares analysis. All measurements were performed at 25.0±0.5 °C.

Results

The phenoxyl radical (PhO·) is stable in the absence of tocopherol models, and shows absorption peaks at λ_{max}=376 nm (ε=17600 $M^{-1}cm^{-1}$(1 M=1 mol dm^{-3})) and 580 nm (ε=4280 $M^{-1}cm^{-1}$) in ethanol. By adding an ethanol solution of α-tocopherol model (1.00 mM) to an ethanol solution of phenoxyl (0.10 mM) (1 : 1 in volume) at 25.0 °C, the absorption spectrum of the phenoxyl immediately changed to that of α-tocopheroxyl model. The absorption spectrum of α-tocopheroxyl model shows weak absorption peaks at 427 and 405 nm.[16] However, the α-tocopheroxyl model is unstable, and the absorption peaks rapidly disappeared. Similarly, the phenoxyl radical has been reacted with excess tocopherol models, showing rapid decrease of the absorption spectrum, respectively. Therefore, the oxidation rates of tocopherol model compounds by phenoxyl were studied spectrophotometrically using

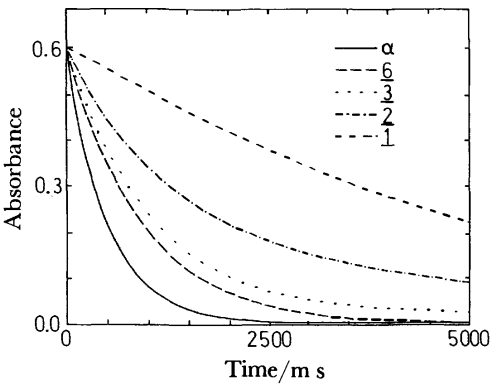

Fig. 2. The decay of phenoxyl radicals for the reaction of phenoxyls with tocopherol model compounds in ethanol at 25.0 °C. $[PhO\cdot]_{t=0}$ 0.05 mM and $[Toc]_{t=0}$ 0.50 mM. At 376 nm.

stopped-flow technique in the presence of excess tocopherol model in ethanol. The details of experiments are reported in a previous paper.[11] The rate was measured by following the decrease in absorbance at 376 and 580 nm of phenoxyl radical. The time dependence of the decrease in absorbance at 376 nm observed when 0.10 mM ethanol solution of phenoxyl is mixed with 1.00 mM ethanol solution of tocopherol models (1 : 1 in volume; final concentration of phenoxyl is 0.05 mM) is shown in Fig. 2. The stopped-flow reactions were performed at 25.0±0.5 °C.

The pseudo-first-order rate constants, k_{obsd}, observed at 376 nm and at 580 nm were linearly dependent on the concentration of tocopherol model, and, thus, the rate law is expressed as

$$-d[PhO\cdot]/dt = k_{obsd}[PhO\cdot] = k_s[Toc][PhO\cdot] \quad (3)$$

where k_s is the second-order rate constant for oxidation of tocopherol model by phenoxyl radical. The values of k_s calculated from k_{obsd} are listed in Table 1. For each tocopherol model, k_s was measured in at least 4 independent experiments. The experimental errors in k_s values was $<\pm 10\%$ in every case.

Discussion

The effect of phytyl side chain of vitamin E on its antioxidant activity has been studied by Fukuzawa et al.[17] and Niki et al.[18] They examined the inhibition effect of the oxidation of unsaturated lipids in homogeneous solution and in liposomes by α-tocopherol and α-tocopherol model. It was concluded that the antioxidative properties of α-tocopherol and α-tocopherol model without the phytyl side chain are quite similar within liposomes as well as in homogeneous solution but that the phytyl side chain enhances the retainment of α-tocopherol in liposomes and suppresses the transfer of α-tocopherol between liposomal membranes. Burton et al. have measured the rate constants k_1 for the reaction of α-tocopherol and α-tocopherol model with poly(styrylperoxyl) radical in homogeneous solution.[9,10,19] In an early report, they suggested that α-tocopherol and α-tocopherol model have similar in vitro antioxidant activity in solution.[9] However, both the absolute rate constants k_1 of α-tocopherol and α-tocopherol model and the relative rate constants ($k_1/k_1(\alpha\text{-Toc})\times 100$) reported by Burton et al. varied from early work to recent work. The values are as follows: i) α-tocopherol: $k_1 = (2.35\pm0.50)\times10^6$ M^{-1} s^{-1} (100) and α-tocopherol model: $(2.14\pm0.81)\times10^6$ (91) (1981);[9] ii) α-tocopherol: $(3.24\pm0.15)\times10^6$ (100) and α-tocopherol model: $(3.77\pm0.19)\times10^6$ (116) (1983);[19] iii) α-tocopherol: $(3.20\pm0.32)\times10^6$ (100) and α-tocopherol model: $(3.80\pm0.38)\times10^6$ (119) (1985).[10]

In the present work, we have measured the rate constants k_s for the reaction of α-, β-, γ-, and δ-tocopherol models with the stable phenoxyl radical in ethanol, using a stopped-flow spectrophotometer. The results listed in Table 1 indicate that α-, β-, γ-, and δ-tocopherol models have reactivities similar to or slightly less than those of corresponding α-, β-, γ-, and δ-tocopherols (see Table 2) in homogeneous solution. Further, the relative k_s values (α : β : γ : δ = 100 : 53 : 50 : 24), that is, relative antioxidant activities, obtained for α-, β-, γ-, and δ-tocopherol models are in good agreement with those (100 : 44 : 47 : 20) for α-, β-, γ-,

Table 1. Second-Order Rate Constants (k_s) and Relative Rate Constants for Oxidation of Tocopherol Models by Phenoxyl Radical in Ethanol at 25.0 °C, and $\Sigma\sigma^+$ Values

Tocopherol Model	$10^{-3}\,k_s$ ($M^{-1}\,s^{-1}$)	$\frac{k_s\text{ (Toc Model)}\times 100}{k_s\text{ (α-Toc Model)}}$	$\Sigma\sigma^+$
α-Toc Model	4.20±0.04	100	−0.688
β-Toc Model	2.24±0.07	53	−0.377
γ-Toc Model	2.10±0.17	50	−0.377
δ-Toc Model	1.00±0.01	24	−0.066

and δ-tocopherols having a long-phytyl-chain, respectively.

As described in a previous section, α-tocopherol which has two methyl substituents at ortho positions of OH group showed the highest antioxidant activity among α-, β-, γ-, and δ-tocopherols. Therefore, we have prepared several tocopherol model compounds especially having two alkyl substituents, such as methyl, ethyl, isopropyl, and *t*-butyl groups, and measured the antioxidant activity of tocopherol models in ethanol solution. By comparing the second-order rate constants observed for 5,7-dimethyl-tocol model (**3**) having two methyl groups at ortho position with that of α-tocopherol model, the former is only ca. 48% as reactive as the latter, against to our expectation. On the other hand, as is clear from the results listed in Table 1, the antioxidant activities of tocopherol models (**3**), (**4**), (**5**), and (**6**) having two alkyl substituents at ortho position of OH group are similar to each other, although the 5,7-diisopropyl-tocol model (**5**) shows 12—15% higher antioxidant activity than the other tocopherol models. The result suggests that the effect of steric hindrance on the reaction rate is not remarkable, but small. Further, to our surprise, 5,7-dimethyl-tocol model (**3**) has quite similar rate constants with those of β- and γ-tocopherol models, whereas δ-tocopherol model is only ca. 24% as reactive as α-tocopherol model and tocol model (**1**) is only ca. 10% as reactive as α-tocopherol model. Therefore, the relative rate constants are plotted against to the number of alkyl substituents at aromatic ring in tocopherol models. The results shown in Fig. 3 clearly suggest that the antioxidant activity of tocopherol models depends on the number of alkyl substituents at aromatic ring rather than the position of substitution. This implies that the values of the rate constants for this reaction increase as the total electron donating capacity of the alkyl substituents increases.

Howard and Ingold have measured the rate constants k_4 for the reaction of ortho-alkyl phenols with poly(styrylperoxyl) radicals.[20] They found that the logarithms of rate constants correlate with the sum of the Brown's σ^+ constants[21] for all the substituents on the phenol ($\Sigma\sigma^+$). They also reported that the steric effects due to ortho alkyl substituents are important. However, for the tocopherol models, it was observed that the steric effect on the reaction rate is not remarkable. Therefore, the values of log k_s for tocopherol models have been plotted against $\Sigma\sigma^+$. As shown in Fig. 4, the logarithms of rate constants (k_s) were found to roughly correlate with $\Sigma\sigma^+$ substituent constants. The slope of the best straight line, i.e., the ρ factor, was −1.0.

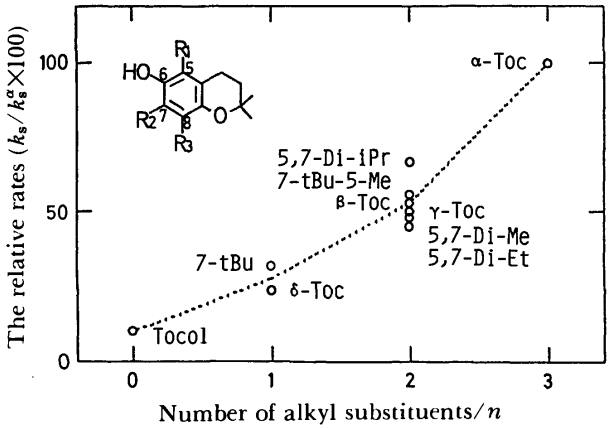

Fig. 3. Plot of the relative rate constant (k_s(Toc Model)/k_s(α-Toc Model)×100) vs. the number of alkyl substituents (n) at aromatic ring in tocopherol model compounds.

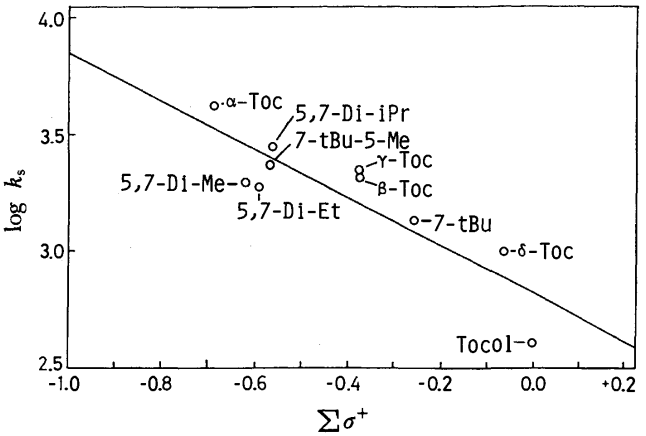

Fig. 4. Plot of log k_s for tocopherol models vs. $\Sigma\sigma^+$. The σ^+ values are from Ref. 21.

Recently, Burton et al. have reported absolute rate constants k_1 for the reaction of α-tocopherol and some related phenols (for example, 4-methoxy-2,3,5,6-tetramethylphenol) with peroxyl radicals (ROO·) (reaction 1).[9,10,19,22] By comparing the k_1 value for α-tocopherol with those found for structurally related phenols that lacked the 6-membered heterocyclic ring, they suggested that the structure of this ring was largely responsible for the high reactivity of α-tocopherol. The relative magnitudes of k_1 values for α-tocopherols and phenols can be correlated with the degree of stabilization of the radical produced by oxidation. Here, stabilization of radical depends on two factors: (i) the extent of orbital overlap between the 2p type lone pair on the para oxygen atom and the aromatic π electron system and (ii) the electron-donating or withdrawing character of the group bonded to the para oxygen atom. Therefore, Burton et al. have prepared new tocopherol model compounds having 5-membered heterocyclic ring, which is generally more planar than 6-membered ring. They found that two tocopherol models having 5-membered ring are 1.7—1.8 times as reactive as α-tocopherol. However, to our regret, all the tocopherol model compounds we have studied in the present work showed smaller reactivity than that of α-tocopherol.

We are very grateful to Professor Kazuhiko Ishizu for his valuable discussions. We also wish to thank Professor Youichi Kitamura for use of stopped-flow spectrophotometer and his helpful discussions.

Synthesis of 1,2-Di-*O*-alkyl-*sn*-glycero-3-phosphatidylcholine Using 2-Methoxyethoxymethyl and 2-(Trimethylsilyl)ethoxymethyl Protective Groups[1)]

Kiyoshi YAMAUCHI,* Mitsuyoshi HIHARA, and Masayoshi KINOSHITA
Department of Applied Chemistry, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received January 12, 1987)

2-Methoxyethoxymethyl (MEM) and 2-(trimethylsilyl)ethoxymethyl (SEM) groups were used to protect the *sn*-3-OH of optically active glycerols in the synthesis of 1,2-di-*O*-octadecyl-*sn*-glycero-3-phosphatidylcholine. Both MEM and SEM protective groups had advantages of a classical benzyl group by virtue of (i) the facile preparation of 1,2-*O*-isopropylidene-3-*O*-(2-methoxyethoxymethyl)-*sn*-glycerol and its *sn*-3-*O*-SEM analog as starting materials and (ii) the rapid demasking of the MEM and SEM moieties in lipid precursors, especially by means of titanium tetrachloride.

With increasing physicochemical and biological interests in biomembranes, various glycerophospholipids are in great demand now.[2,3)] Of representative glycerophospholipids, 1,2-di-*O*-acyl-*sn*-glycero-3-phosphatidylcholine is prepared conveniently by direct acylation of *sn*-glycero-3-phosphatidylcholine (GPC)[4)] which is derived from egg lecithin.[5)] Another representative glycerophospholipid, 1,2-di-*O*-alkyl-*sn*-glycero-3-phosphatidylcholine, can not be produced from GPC but has been obtained via the multistep synthesis which begins generally with long-chain alkylation of the *sn*-1- and *sn*-2-OH groups of 3-*O*-benzyl-*sn*-glycerol (**1**) followed by demasking of the benzyl group of the resulting 1,2-di-*O*-alkyl-3-*O*-benzyl-*sn*-glycerol by means of catalytic hydrogenolysis and the subsequent attachment of phosphorylcholine unit or the analog to the naked *sn*-3-OH group.[6-8)]

However, one would often encounter difficulty in the hydrogenolysis because of extreme sensitivity of palladium catalyst to poisoning by a trace of contaminants in the substrate or on the appratus used; thus, a large scale preparation being often rendered unpractical. Furthermore, to our experience, the hydrogenolysis tends to become inefficient with increasing alkyl-chain length in the lipid precursors.

In view of these inconveniences of the benzyl group in the glycerolipid synthesis, we attempted to protect the *sn*-3-OH groups of optically active glycerols with 2-methoxyethoxymethyl (MEM) and 2-(trimethylsilyl)-ethoxymethyl (SEM) groups, choosing natural 1,2-di-*O*-octadecyl-*sn*-glycero-3-phosphatidylcholine (**10**) as a synthetic target. The MEM and SEM groups are acid-labile protective groups and have been utilized in the preparation of carbohydrates and nucleic acid-related compounds.[9)]

Results and Discussion

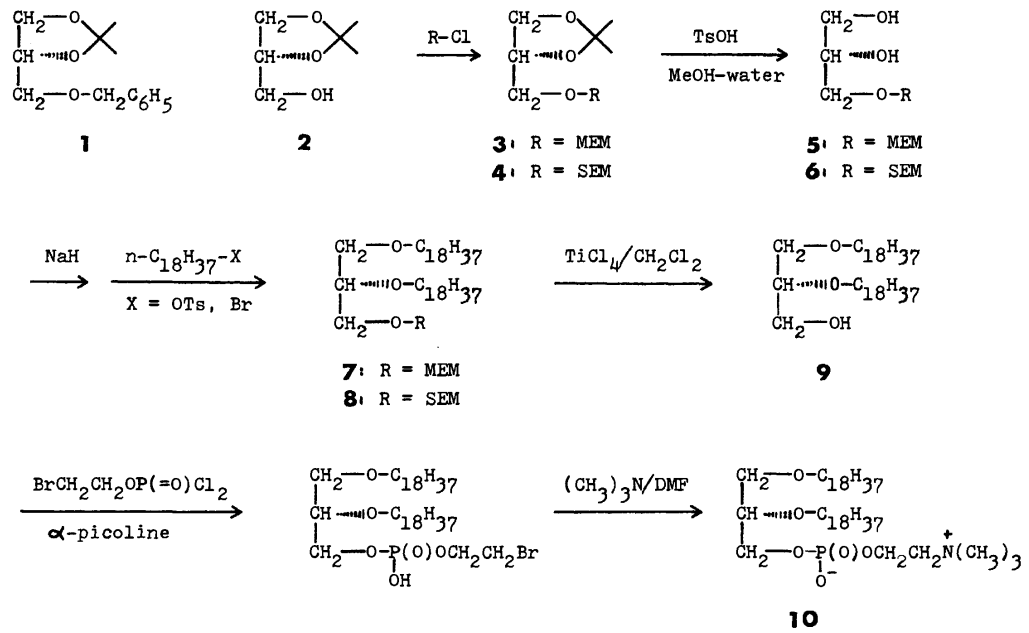
D-Mannitol was transformed into 1,2-*O*-isopropylidene-*sn*-glycerol (**2**) in a routine yield of 65—82% upon modifing a literature procedure.[10,11)] The compound **2** in THF was treated with sodium hydride, and the resulting sodium alkoxide was allowed to react with 2-methoxyethoxymethyl chloride or 2-(trimethylsilyl)ethoxymethyl chloride at ca. 0 °C for 2h. Distillation of the reaction mixtures furnished the corresponding 3-*O*-MEM and 3-*O*-SEM glycerols (**3** and **4**, respectively) in the yields of >80%.

Now, although the *O*-isopropylidene moiety and the *O*-MEM or *O*-SEM moiety of **3** and **4** are acid-labile, a treatment with 0.4 equiv of *p*-toluenesulfonic acid in 90% aqueous methanol at 25 °C for 2—3h cleaved the acetal moiety only to give 3-*O*-[(2-methoxyethoxymethyl)]- and 3-*O*-[2-(trimethylsilyl)-ethoxymethyl]-*sn*-glycerols (**4** and **5**, respectively) in the yields of 90—95% (NMR). Thus, in comparison with an analogous preparation of 3-*O*-benzyl-*sn*-glycerol (**1**) from **2**,[6)] **5**, and **6** were synthesized much readily with the yields comparable with or better than that of **1**.

Next, the sodium salts of **5** and **6** were allowed to react with octadecyl *p*-toluenesulfonate at ca. 190 °C for 0.5 h in the absence of any solvent. The modified procedure for the Williamson ether synthesis took place rapidly to give the corresponding 1,2-di-*O*-octadecylglycerols (**7** and **8**) in the yields of ca. 60%, which were higher than the values (45—47%) obtained in an ordinary procedure-reactions of the sodium alkoxide with octadecyl bromide with reflux in THF for 30h. No cleavage of the MEM and SEM protective groups was observed during the reactions.

Deprotection of the MEM and SEM-ether linkages could be performed by means of diphosphorus tetraiodide, triphenylmethyl tetrafluoroborate and zinc bromide.[9)] But, titanium tetrachloride ($TiCl_4$) was the most effective reagent of converting **7** and **8** into 1,2-di-*O*-octadecyl-*sn*-glycerol (**9**); i.e., an action of 0.6—1 equiv of $TiCl_4$ to a dichloromethane solution of **7** or **8** at ca. 0 °C for 0.5—1 h resulted in a quantitative demasking of the *sn*-3-*O*-ether moiety. No racemization occurred during the demasking reaction as judged from an optical activity of the resulting **9**.

Transformation of **9** into the phospholipid **10** was achieved as usual;[7,12)] i.e., a reaction of **9** with 2-bromoethyl phosphorodichloridate and the subsequent treatment of the reaction mixture with trimethy-



lamine afforded **10** in the yield of 35—51%.

In conclusion, the MEM and SEM groups were very useful to protect the *sn*-3-OH groups of the optically active glycerols (**2**—**8**). The protective groups were superior to the classical benzyl group with regard to (i) the facile preparation of **3** and **4** and (ii) the rapid demasking of the *sn*-3-*O*-MEM and -SEM moieties from **7** and **8**, especially by means of $TiCl_4$. Both MEM and SEM groups were similar in reactivity in the masking and demasking reactions.

Experimental

1,2-*O*-Isopropylidene-*sn*-glycerol (**2**) was derived from D-mannitol as described previously.[11] 2-Methoxyethoxymethyl chloride, 2-(trimethylsilyl)ethoxymethyl chloride, and deprotecting reagents including $TiCl_4$ were used without further purification. Column chromatography was carried out using silica gel (Merck 7734, 70—230 mesh). Mobility (R_f) in thin-layer chromatography was measured on precoated silica-gel sheet (Merck 17345, $60F_{254}$) using the following solvent systems: A, hexane-ethyl acetate (10 : 1 v/v); B, hexane-ethanol (7 : 1 v/v); C, chloroform-methanol-concentrated ammonia (65 : 35 : 5 v/v/v). Compound spots in TLC were visualized under ultraviolet light spraying with 0.0012% aqueous Rhodamine 6G (for compounds having long-chain alkyl groups) and the Dittmer-Lester reagent[13] (for phosphoric acid esters). Mp's were measured using a Yanagimoto hot stage appratus and uncorrected. Optical rotations were recorded by means of a JASCO DIY-360 polarimeter. ^{1}H NMR spectra were measured on a JEOL PS-100 using dilute solution in $CDCl_3$ or $CDCl_3$-methanol-d_4 (2 : 1 v/v) with $SiMe_4$ as an internal standard.

1,2-*O*-Isopropylidene-3-*O*-(2-methoxyethoxymethyl)-*sn*-glycerol (3). Sodium hydride (60% in oil, 1.4 g, 35 mmol) was added to a stirred THF solution (200 ml) of **2** (3.5 g, 26.5 mmol) at room temperature. After 30 min, (2-methoxyethoxy)-methyl chloride (3.6 ml, 31.5 mmol) was added dropwise to the sodium alkoxide solution cooled in an ice-water bath, and the mixture was swirled at ca. 0 °C for 2 h. The solution was then concentrated and the residue was extracted with chloroform (300 ml). The organic layer was filtered and concentrated to afford the liquid, which was distilled under reduced pressure to give **3** as a colorless substance, 4.8 g (82%); bp 92—94 °C/2 mmHg (1 mmHg=133.322 Pa); $[\alpha]_D^{25}$ +11.3° (neat); ^{1}H NMR ($CDCl_3$) δ=1.34 and 1.40 (3H, s, CH_3), 3.38 (3H, s, OCH_3), 3.47—4.16 (8H, complex m, CH_2CHCH_2 and OCH_2CH_2O), 4.28 (1H, m, CH), and 4.76 (2H, s, OCH_2O). Anal. ($C_{10}H_{20}O_5$) C, H.

1,2-*O*-Isopropylidene-3-*O*-[2-(trimethylsilyl)ethoxymethyl]-*sn*-glycerol (4). Using sodium hydride (60% in oil, 1.5 g, 37.5 mmol), **2** (4.1 g, 31 mmol) was converted into the sodium alkoxide, which was then allowed to react with 2-(trimethylsilyl)ethoxymethyl chloride (5.6 ml, 32 mmol) in a manner similar to that mentioned in the preparation of **3**, 6.5 g (80%); bp 118—120 °C/8 mmHg; $[\alpha]_D^{18}$ +10.0° (neat); ^{1}H NMR ($CDCl_3$) δ=0.0 [9H, s, $Si(CH_3)_3$], 0.93 (2H, t, J=16.4 Hz, CH_2Si), 1.30 and 1.37 (3H, s, $C(CH_3)_2$), 3.3—4.3 (7H, complex m, CH_2CHCH_2 and OCH_2CH_2Si), and 4.56 (2H, s, OCH_2O). Anal. ($C_{12}H_{26}O_4Si$) C, H.

3-*O*-(2-Methoxyethoxymethyl)-*sn*-glycerol (5). *p*-Toluenesulfonic acid monohydrate (1.5 g, 7.9 mmol) was added to a methanol-water (10 : 1 v/v) solution (55 ml) of **3** (4.7 g, 21 mmol) at 25 °C. After stirring the mixture at the same temperature for 2 h, the solution was neutralized with powdery sodium hydrogencarbonate. The supernatant was concentrated to give the residue which was extracted with chloroform. Evaporation of the solvent from a dried organic extract on anhydrous sodium sulfate furnished **5** as a colorless liquid, 3.4 g (89%); the ^{1}H NMR and IR spectra were almost identical with those of an authentic sample obtained by distillation, 1.2 g (31%); bp 120—125 °C/1 mmHg; $[\alpha]_D^{26}$ −1.58° (*c* 9.2, methanol); ^{1}H NMR ($CDCl_3$) δ=3.33 (3H, s, OCH_3), 3.1—4.5 (9H, complex m, CH_2CHCH_2 and OCH_2CH_2O), and 4.68 (2H, s, OCH_2O). Anal. ($C_7H_{16}O_5$) C, H.

3-*O*-[2-(Trimethylsilyl)ethoxymethyl]-*sn*-glycerol (6). Compound (**4**, 5.1 g, 19.4 mmol) was processed with *p*-toluenesulfonic acid monohydrate (1.5 g, 7.9 mmol) in 90% aqueous methanol (55 ml) in a manner similar to that men-

tioned in the preparation of **5**. The reaction mixture was neutralized with sodium hydrogencarbonate, concentrated and extracted with chloroform. Evaporation of the solvent from the dried organic extract on anhydrous sodium sulfate gave crude **6** (3.9 g, 91%), which that the IR and ^{1}H NMR spectra almost identical with those of the distilled material, 1.9 g (43%); bp 129—131 °C/3 mmHg; $[\alpha]_D^{24}$ +4.1° (neat); ^{1}H NMR ($CDCl_3$) δ=0.0 [9H, s, $Si(CH_3)_3$], 0.93 (2H, t, J=16.4 Hz, CH_2Si), 3.46—4.21 (7H, complex m, CH_2CHCH_2 and OCH_2CH_2Si), and 4.54 (2H, s, OCH_2O). Anal. ($C_9H_{22}O_4Si$) C, H.

1,2-Di-*O*-octadecyl-3-*O*-(2-methoxyethoxymethyl)-*sn*-glycerol (7). Compound **5**, (1.5 g, 8.3 mmol) in THF (100 ml) was stirred with sodium hydride (60% in oil, 0.7 g, 18 mmol) at room temperature for 30 min. Octadecyl *p*-toluenesulfonate (8.5 g, 20.0 mmol) was added to the alkoxide solution, and the mixture was heated to remove the solvent. The resulting semisolid residue was further heated in an oil bath at 190—200 °C for 30 min. A chloroform solution of the cooled reaction mixture was washed with water and concentrated to provide a residue which was dissolved in ethanol (150 ml) and allowed to stand in a refrigerator of ca. 10 °C overnight. The resulting solid was collected by suction-filtration, then applied to a silica-gel column. Elution with hexane-ethyl acetate (10 : 1 v/v) gave **7**, which was purified by recrystallization from acetone, 3.1 g, (54%). The mother liquior provided another crop of **7** through a similar purification process, 0.8 g (14%); mp 32—33 °C; $[\alpha]_D^{22}$ −2.2° (*c* 2.68, chloroform); R_f=0.54 (solvent B); ^{1}H NMR ($CDCl_3$) δ=0.89 (6H, two t separated by ca. δ 0.002, $2CH_3$), 1.25 [64H, coherent peak, $2(CH_2)_{16}$], ca. 1.53 (4H, m, $2OCH_2$), 3.38 (3H, s, OCH_3), 3.38—3.77 (9H, complex m, CH_2CHCH_2 and OCH_2CH_2O), and 4.73 (2H, s, OCH_2O). Anal. ($C_{43}H_{88}O_5$) C, H.

1,2-Di-*O*-octadecyl-3-*O*-[2-(trimethylsilyl)ethoxymethyl]-*sn*-glycerol (8). In a manner similar to that mentioned above, **8** was prepared from **6** in a yield of 65%. It was also obtained by the next Williamson synthesis. Compound (**6**, 2.4 g, 10.8 mmol) in THF (100 ml) was stirred with sodium hydride (60% in oil, 1.0 g, 25 mmol) at room temperature for 30 min. Octadecyl bromide (9.0 ml, 26.4 mmol) was added to the alkoxide solution, and the mixture was heated with reflux for 30 h. The cooled reaction mixture was concentrated to afford the residue which was then extracted with chloroform. The organic solution was washed with water, dried over anhydrous sodium sulfate, concentrated and applied to a silica-gel column. Elution with hexane-ethyl acetate (10 : 1 v/v) gave crude **8**, which was purified by recrystallization from acetone, 3.6 g (46%); mp 29—30 °C; $[\alpha]_D^{18}$ −1.5° (*c* 5.6, chloroform); R_f=0.54 (solvent A); ^{1}H NMR ($CDCl_3$) δ=0.0 [9H, s, $Si(CH_3)_3$], 0.80—1.07 (8H, complex m, $2CH_3$ and CH_2Si), 3.25—3.79 (9H, complex m, CH_2CHCH_2 and two $OCH_2C_{17}H_{35}$), and 3.64 (2H, t, J=16.4 Hz, CH_2CH_2Si); *m/z* (rel intensity, %) (a JEOL JMS-06 spectrometer at 75 eV at 70 °C ion source temperature) 727 (M^+, 18), and 578 (M^+ −HO-SEM, 7). Found: C, 73.92; H, 13.50%. Calcd for $C_{45}H_{94}O_4Si$: C, 74.31; H, 13.03%.

1,2-Di-*O*-octadecyl-*sn*-glycerol (9). Titanium tetrachloride (0.4 ml, 3.64 mmol) was added to a cooled dichloromethane solution of **7** (0.74 g, 1.1 mmol) in an ice-water bath. After swirling 1 h, the reaction mixture was stirred vigorously with 1 M (1 M=1 mol dm^{-3}) sodium hydrogencarbonate, then extracted with chloroform. The organic solution was washed with water, dried over anhydrous sodium sulfate and concentrated to give **9**, 0.64 g (≈100%) which was purified by a silica-gel column chromatography using a mixture of hexane and ethyl acetate (8 : 1 v/v), 0.39 g (61%); mp 57—58 °C (lit,[6] 53.5—54.5 °C); $[\alpha]_D^{25}$ −7.47° (*c* 1.6, chloroform) (lit,[6] −6.85°); R_f=0.43 (solvent B); the IR and ^{1}H NMR spectra as well as the R_f of the product were identical with those of an authentic sample, which was prepared by hydrogenolysis of 1,2-di-*O*-octadecyl-3-*O*-benzyl-*sn*-glycerol.[11]

Similarly, **8** was demasked into **9** in a yield of 72% after column chromatographic purification. The mp and the ^{1}H NMR spectrum were identical with those of **9** obtained from **7**.

1,2-Di-*O*-octadecyl-*sn*-glycero-3-phosphatidylcholine (10). The literature procedure[6] was slightly modified. A mixture of **9** (0.5 g, 0.83 mmol), 2-bromoethyl phosphorodichloridate (0.31 g, 1.3 mmol) and α-picoline (2 ml) in chloroform (30 ml) was stirred at ca. 40 °C overnight. The reaction mixture was then processed in a manner similar to that reported to give rise crude 2-bromoethyl 1,2-di-*O*-octadecyl-*sn*-glyceryl hydrogenphosphate, which was subsequently heated with 6.25 M DMF solution of trimethylamine (25 ml) at 55 °C overnight. The resulting solution was concentrated to give the residue which in 90% aqueous methanol (30 ml) was stirred vigorously with silver acetate (1.1 g, 6.6 mmol) for 1 h. The resulting precipitate was removed by filtration and the filtrate was concentrated and applied to a silica-gel column. Elution with a mixture of chloroform, methanol and water (65 : 35 : 5 v/v/v) furnished **10** as amorphous solid which was recrystallized from ethyl acetate, 0.26 g (42%); mp 205 (softening)—210 °C (melting) (lit,[8] 201—202 °C); $[\alpha]_D^{25}$ +2.1° [*c* 0.5, chloroform-methanol (2 : 1 v/v)] (lit,[8] +1.3°); R_f=0.30 (solvent C). The IR and ^{1}H NMR spectra as well as the R_f were identical with those of an authentic sample.

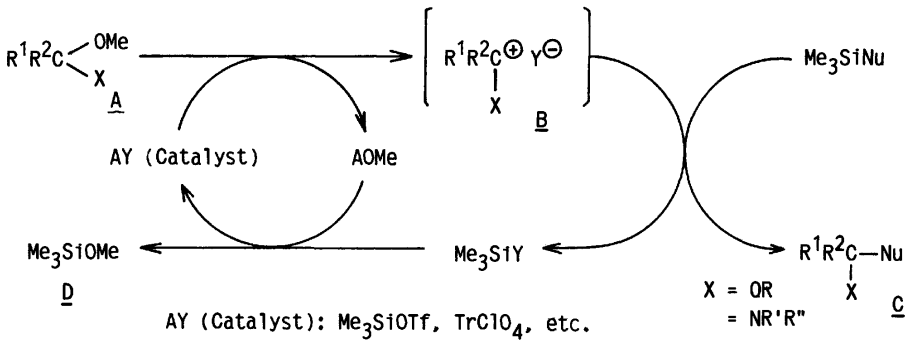
Exquisite use of electrogenerated acid (EG acid) in the silicon-mediated acid-catalyzed reactions; e.g., aldol reactions, allylations, cyanations, and hydride additions is described. The aldol reaction of acetals **1** with enol trimethylsilyl ethers **3** and 1,2-bis(trimethylsiloxy)alkenes **4** gives the corresponding adducts **5** and **6**, respectively. The reaction proceeds smoothly with EG acid derived from perchlorate salts such as $LiClO_4$, n-Bu_4NClO_4, and $Mg(ClO_4)_2$ in dichloromethane using platinum electrodes. The amount of electricity required to complete the reaction implies a cationic process which is mediated by the trimethylsilyl moiety. This aldol reaction is further developed with unprotected carbonyl compounds **2** with **3**, giving the trimethylsilyl ethers of the adducts **7**. Further utility of this EG acid as a catalyst for a chain reaction is exemplified by the successful application in the following conversions: (1) The allylation of acetals **1** with allyltrimethylsilane (**8**) to give **9**, (2) the cyanation of acetals **1** and unmasked **2** with trimethylsilyl cyanide (**10**) to give **11**, **12**, and **13**, and (3) the hydride addition of acetals **1** with triethylsilane (**14**) to give **15**.

The reaction of organosilicon compounds[1] bearing a nucleophilic site with an electron-deficient center has demonstrated one of the most efficiently designed examples of acid-catalyzed reactions, in which the silyl moiety serves as a chain carrier.[2] This reaction can be understood as illustrated in Scheme 1.

Thus, acetals and aldehydes **A** are activated by an acid-catalyst to give cationic intermediates **B**. These carbocations $[R^1R^2C\text{-}X]^+$ (X=OR, NR'R", etc.) may be stabilized by buffering with counter ion such as perchlorate ion or triflate ion present in the media. When nucleophilic silicon compounds are added to this media, cation **B** undergoes nucleophilic attack to produce the substituted product C together with a stable methoxysilane **D**. The formation of methoxysilane **D**, therefore, favors the equilibration of this acid-catalyzed reaction to proceed to completion. These silicon-mediated cationic reactions including aldol reaction,[2,3] acetalization,[2,12] allylation,[2] hydride additions,[2] cyanation,[2,4] and others[2,5] have been effected by very oxophilic reagents such as trimethylsilyl triflate (TMSOTf),[2] triphenylmethyl perchlorate ($TrClO_4$),[3,5,6] and other Lewis acids.[4] Unfortunately, these moisture sensitive reagents are cumbersome to use and it is still of considerable interest to develop new effective reagents which can be easily prepared and handled. In the previous paper from our laboratory, we have explored the potential utility of an electrogenerated acid (EG acid)[7] as a catalyst for selective epoxy ring openings,[8] tetrahydropyranylation of alcohols,[9] conversion of nerolidol to bisaborol,[10] biogenetic-type cyclization,[11] and acetalization of carbonyl compounds.[12] These results indicates an oxophilic ability of EG acid to oxygen containing compounds and prompted us to investigate the possibility of EG acid as an alternative to hitherto known catalysts in the above silicon-mediated catalytic reactions. In this paper, we describe an EG acid-assisted activation of acetals as well as unprotected aldehydes and ketones in the presence of organosilicon compounds bearing a nucleophilic site, leading to (1) aldol reactions, (2) allylations, (3) cyanations, and (4) hydride additions.

Results and Discussion

Aldol Reaction of Acetals, Aldehydes, and Ketones with Enol Trimethylsilyl Ethers. The aldol condensation has long been recognized to be one of the most versatile synthetic tools for a carbon-cabon bond formation.[13] The reaction of acetals **1** with enol silyl



Scheme 1.

ethers **3** is an important method of obtaining the corresponding adducts **5**, selectively.[3,14-16] The electrochemical version of this condensation was attempted using benzaldehyde dimethyl acetal (**1a**) and cyclohexanone enol trimethylsilyl ether (**3a**) as a typical substrate. Thus, the electrolysis was carried out by using platinum foil electrodes in dichloromethane (CH_2Cl_2) containing lithium perchlorate ($LiClO_4$) and/or tetrabutylammonium perchlorate (n-Bu_4NClO_4) for both an electrolyte and a source of the electrogenerated acid (EG acid). During the electrolysis a constant current of 2.67 mA cm^{-2} (applied voltage: 8—10 V) was charged until the starting materials **1a** or **3a** disappeared completely on TLC. After the electrolysis (0.07 F mol^{-1} of electricity based on the starting **3a** as one electron process has been passed), the reaction was quenched with a few drops of triethylamine and the concentrated products, without aqueous working up, were purified by column chromatography on silica gel to give *threo*-**5a** and *erythro*-**5a** in 93% yield as an isolable 14:86 mixture. No polycondensation product, self-condensation product, or α,β-unsaturated enone was formed by this reaction. The stereochemistry of the diastereoisomers **5a** was determined based on the ^{1}H NMR signals due to the methine proton on the methoxylated carbon (spectral data are given in the Experimental).[14b] On the other hand, no aldol reaction was observed for the acetal **1a** with cyclohexanone enol acetate, cyclohexanone enol methyl ether, and cyclohexanone morpholine enamine by treatment with the EG acid.

In order to know the applicability of the present procedure to the large-scale operation, we attempted to perform this reaction in the circulating flow-cell system as illustrated in Fig. 1, in which the electrolyte was circulated at a linear rate of about 15 cm min^{-1}. By using this flow-cell system, we were capable of preparing the aldol **5a** in 82—86% yields by the electrolysis of an appreciably concentrated solution of **1a** and **3a** (0.8—1.3 M in $ClCH_2CH_2Cl$) with SUS-27 electrodes.

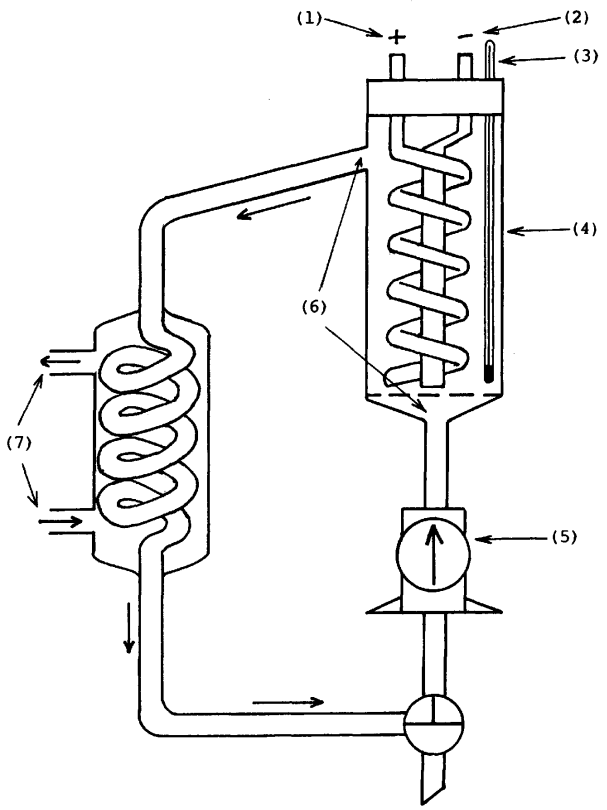


Fig. 1. Schematic drawing of a circulating flow cell for EG acid catalyzed reaction; (1): anode (SUS-27), (2): cathode (SUS-27), (3): thermometer, (4): glass electrolysis cell. (ca. 30 mm diameter and 150 mm height), (5): circulating pump, (6): electrolyte outlet and inlet, (7): heat exchanger by cold ethanol.

The effect of a supporting electrolyte is remarkable in this aldol reaction. The current efficiencies summarized in Table 1 were determined at the time when the necessary amount of electricity for the complete conversion has been passed based on the starting material **3a**. As shown in Entries 5—7, good to excellent conversion yields were obtained with perchlorate salts

Table 1. Effect of Electrolytes and Temperature in the Aldol Reaction of **1a** and **3a** to **5a**[a]

Entry	Electrolyte[b]	Solvent[c]	Temp °C	F mol^{-1}[d]	Yield of **5a**[e]/% (CE)[f]	(erythro/threo)[g]
1	$LiClO_4$-n-Bu_4NClO_4 (1:1)	CH_2Cl_2	20	0.01	75 (7500)	(79/21)
2	$LiClO_4$-n-Bu_4NClO_4 (1:1)	CH_2Cl_2	0	0.02	78 (3900)	(85/15)
3	$LiClO_4$-n-Bu_4NClO_4 (1:1)	CH_2Cl_2	−30—−40	0.04	86 (2150)	(83/17)

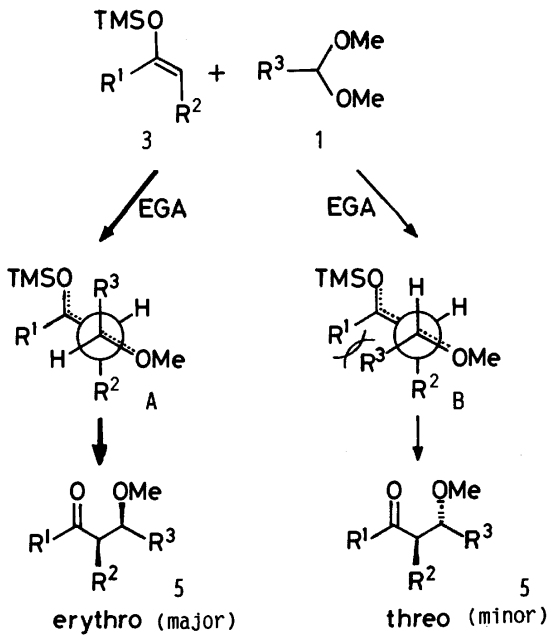
9	Et_4NOTs	CH_2Cl_2	−78	0.30	—	
10	Et_4NBr	CH_2Cl_2	−78	0.30	—	

a) Carried out by using **1a** (1.2 mmol) and **3a** (1.0 mmol) with Pt electrodes (1.5 cm^2) at a constant current density of 2.67 mA cm^{-2} in an undivided cell. b) 0.1 Mol equivalent of the electrolyte to the substrate **3a** was used. c) 3 Ml was used. d) Electricity consumed (based on **3a** as an one-electron process). e) Based on isolated products. f) Current efficiency on the basis of one electron reaction. g) Determined based on isolated materials.

such as $LiClO_4$, n-Bu_4NClO_4, and $Mg(ClO_4)_2$. A combination of $LiClO_4$ and n-Bu_4NClO_4 (1/1 mixture), employed to get enough electric conductivity through the electrolysis media, gave the best conversion yield of **5a** (Entry 4). Other supporting electrolytes such as lithium tetrafluoroborate, tetraethylammonium tosylate, and tetraethylammonium bromide are less useful for this purpose (Entries 8—10). Halogenated solvents such as dichloromethane and 1,2-dichloroethane are highly effective for the formation of the aldol **5a**, while AcOEt, hexane, and THF are less effective. In order to increase the solubility of $LiClO_4$, $Mg(ClO_4)_2$, and $LiBF_4$ in CH_2Cl_2, THF was added to the solution in approximately 10 vol% (Entries 6—8). As shown in Table 1, Entries 1—4, the yield and erythro/threo selectivity of **5a** increase with lowering the temperature from 20 to −78 °C, although the current efficiency decreases. Meanwhile, feasibility of the present reaction at wide temperature range enables to raise the reactivity of rather less reactive acetals and unmasked carbonyl compounds (Entries 4 and 26 in Table 2). The yield and erythro/threo (e/t) selectivity of **5a** obtained by an EG acid-catalyzed reaction are comparable to the literature data obtained by other reagents such as TMSOTf (−75 °C/10 h, 89% yield, e/t=93 : 7),[2] $TrClO_4$ (−75 °C/0.25 h, 96% yield, e/t=88 : 12),[3a] and $TiCl_4$ (1 equiv) (−75 °C/2 h, 95% yield, e/t=50 : 50).[15a] The erythro selectivity of this reaction can be rationalized in terms of an acyclic extended transition state of Type **A** (Scheme 2), in good accordance with the results obtained with TMSOTf[2] or $TrClO_4$[3a] as a catalyst. This EG acid-catalyzed procedure could be applied to aldol reaction of a variety of acetals **1** and enol silyl ethers **3**, and the results are shown in Table 2, Entries 1—12. Acetals of aromatic aldehydes generally gave reasonable results, whereas acetals of saturated aliphatic aldehydes and ketones provided the corresponding adducts slightly lower yields or lower current efficiencies.



Scheme 2.

Aldols derived from 1,2-bis(trimethylsiloxy)cycloalkenes **4** and acetals **1** are synthetically valuable as precursors of 1,3-cycloalkanediones by rearrangement.[16a] Keto esters can also be prepared from these aldol products by oxidative or reductive ring cleavage.[16] These aldol reactions of **4** with acetals **1** have been carried out by using a stoichiometric amount of Lewis acid such as $TiCl_4$ and $BF_3 \cdot OEt_2$. However, aldol products derived from 1,2-bis(trimethylsiloxy)-cyclobutene **4c** are susceptible to undergo further rearrangement with acid-catalyst such as TMSOTf, TFA, and p-TsOH to give 1,3-cyclopentanediones. We have succeeded in the EG acid-catalyzed aldol reaction of **4** with acetals **1**, giving the corresponding adducts **6**, selectively (Table 2, Entries 13—20). Any by-products due to acid-catalyzed rearrangement have not been observed in the reaction products, except for the free alcohols which is due to partial hydrolysis of the trimethylsiloxy group of **6** (4—6%).

On the other hand, it is noted that the aldol reaction of enol silyl ethers **3** with unmasked ketones and aldehydes **2** is unsuccessful with a catalytic amount of TMSOTf[14a] as an acid-catalyst, while $TrClO_4$ effects this condensation, smoothly.[3] Stimulated by these findings, we attempted the EG acid-catalyzed aldol reaction of aldehydes **2** with enol silyl ethers **3** to compare the stereochemical outcome of the product with that obtained from **1** and **3**. The electrolysis of benzaldehyde **2a** and **3a** in CH_2Cl_2 containing an 1 : 1 mixture of $LiClO_4$ and n-Bu_4NClO_4 produced the desired aldol product **7a** in 85% yield. However, erythro/threo ratio of the product **7a** decreased to 69 : 31 in comparison with the ratio 86 : 14 obtained from the acetal **1a** and **3a**. In this reaction, aldols **7** are isolated as a silyl ether. The aldol reaction with ketones required a higher temperature than that for the reaction with aldehydes. Typical results of electrochemical aldol reaction of unmasked **2** with enol silyl ethers **3** are summarized in Table 2, Entries 21—26.

In order to gain an insight into the behavior of the EG acid in this aldol reaction, an electrolysis procedure different from that above mentioned was examined. Thus, electrolysis of the solution in the absence of **1a** and **3a** by passing about 0.05 F mol^{-1} of electricity was followed by the addition of the substrates **1a** and **3a** at −78 °C (stirring was continued for 10 min) to give the following results. The desired aldol adducts **5a** were obtained in almost identical yields with those obtained in the concurrent electrolysis. However, the electrolysis in the presence of a small amount of bases such as pyridine and triethylamine prevents the condensation, completely. These results along with erythro-selectivity of the adducts suggest the formation of EG acid of Brønsted acid character like as $HClO_4$[7]

a) Unless otherwise noted electrolyses were carried out under a constant current of 2.67 mA cm^{-2} with two platinum electrodes (1.5 cm^2) in an undivided cell under argon at −78 to −60 °C (for unmasked aldehyde as well as acetals derived from aldehydes) or at 0 °C (for unmasked ketone as well as acetal derived from ketone). b) Faradays/mole during preparative run. c) Products from **1** and **4** (Entries 13—20) are contaminated with 4—6% of the free alcohol due to the partial hydrolysis of silyl protecting group. d) Based on isolated products in complete conversion of 1.0—1.2 mmol of the substrates. e) Determined either by direct separation of isomers by SiO_2 column chromatography or by ^{1}H NMR spectra.

during the electrolysis in a CH_2Cl_2-$LiClO_4$-*n*-Bu_4NClO_4-(Pt) system. The EG acid could be concentrated at the vicinity of the anode during the electrolysis so that the aldol condensation proceeds even with EG acid generated with a catalytic amount of electricity.

Allylation with Allyltrimethylsilane. Addition of an allyl group to carbonyl compounds using allyltrimethylsilane (**8**) is of value due to the versatility of adducts in organic transformation.[17] The activation of the carbonyl function for this transformation has been effected by a stoichiometric amount of Lewis acid[18] such as $TiCl_4$, $BF_3 \cdot OEt_2$, and $AlCl_3$ and a catalytic amount of TMSOTf.[19] We attempted to use the EG acid as a catalyst for this allylation. Thus, allyltrimethylsilane was reacted with acetals **1** at 0 °C in CH_2Cl_2 with the aid of the EG acid to give the corresponding homoallylic alcohol methyl ethers **9** in high yields. However, the reaction of aldehyde **2** with allyltrimethylsilane was unsuccessful. The reaction of 4-*t*-butylcyclohexanone dimethyl acetal **1k** at 0 °C furnished a mixture of equatorial:axial adducts **9k** in 90:10 ratio (80% yield).[2] Some additional results are given in Table 3.

Cyanation of Acetals with Trimethylsilyl Cyanide. α-Alkoxyalkanenitriles **11**, a protected form of cyanohydrins, are synthetically useful compounds as precursors of 3-amino-2-alkenenitriles,[20] α-alkoxy ketone[21] and are accepted as synthons of acyl carbanion equivalents.[22] Although the preparation of α-alkoxy nitriles by cyanation of acetals with trimethylsilyl cyanide (**10**) using Lewis acid has been reported,[4,24] a highly convenient procedure is still in demand. We have succeeded in a facile cyanation of dimethyl acetals **1** with trimethylsilyl cyanide (**10**) by using EG acid, giving **11**.

The reaction procedure is similar to that of the aldol reaction. Thus, a mixture of heptanal dimethyl acetal (**1c**) and trimethylsilyl cyanide (**10**) in CH_2Cl_2 containing $LiClO_4$ and Et_4NClO_4 (1 : 1) was electrolyzed with plat-

Table 4. Preparation of Cyanohydrin Methyl Ether **11** from Acetal **1** and Trimethylsilyl Cyanide (**10**)[a]

a) Unless otherwise noted electrolyses were carried out at an applied voltage of 15 V (current: 12 mA) with two platinum electrodes (1.5 cm^2) in an undivided cell under argon at room temperature. b) Faradays/mole during preparative run. c) Based on isolated products in complete conversion of 1.0—1.2 mmol of the substrates.

inum electrodes at an applied voltage of 15 V (current: 12—13 mA). After electrolysis for 32 min (electricity: 0.077 F mol^{-1} based on acetal **1c** as one electron process) and an additional stirring for 5 min, the reaction was quenched with pyridine (2 drops). Concentration in vacuo followed by either column chromatography (SiO_2, hexane-AcOEt, 50:1) or bulb to bulb distillation gave the cyanide **11c** in 89% yield. Electrolysis with either $LiBF_4$ or Et_4NOTs as a supporting electrolyte resulted only in the recovery of the starting acetal **1c**.

As shown in Table 4, most of the acetals **1** could be smoothly converted into the corresponding cyanohydrin methyl ethers **11** with a catalytic amount of electricity. Cyclic α-methoxy amine **1o** underwent smooth cyanation through the replacement of the methoxyl group to give 2-cyanopiperidine **11o**.

Alternatively, the EG acid-catalyzed cyanation of unprotected aldehydes and ketones with trimethylsilyl cyanide (**10**) was examined. Cyanohydrin derived from ketones were obtained as a form of trimethylsilyl ethers **12**, while adducts of aldehydes were isolated as a cyanohydrins **13** due to the instability of the corresponding silyl ether to moisture. The reaction of α,β-enone **2i** with trimethylsilyl cyanide gave 1,2-adducts **12i**, predominantly (Table 5).

Hydride Addition to Acetals. Trialkylsilanes have attracted a considerable interest because of their utility as a mild hydrogen doner in modern synthetic reaction.[23] Acetals have been reduced to ethers with this reagent by the aid of TMSOTf.[24] We have also succeeded in this transformation using EG acid as a catalyst. Thus, the electrolysis of acetals **1** in the presence of a slightly excess of triethylsilane (**14**), performed in a similar manner as described for the aldol reaction, resulted in the replacement of methoxyl group with hydrogen to give the corresponding ethers **15** in good yields. Some examples of this reaction are listed in Table 6.

In this paper the EG acid has been shown to be a viable alternative as a catalyst for silicon-mediated cationic reaction in terms of its easy and clean operation, short reaction time, and high current efficiency. By analogy with the reactions catalyzed by TMSOTf[2] and $TrClO_4$,[3,5,6] the present EG acid catalyzed reactions of acetals **a** and Me_3SiNu are rationalized as depicted in Scheme 3. Thus, the EG acid generated from perchlorate salts is strong enough to activate **a** to allow the carbenium ion **b** buffered by perchlorate ion. The cation **b** undergoes smoothly nucleophilic attack of Me_3SiNu to produce the desired **c**. In this step, the intermediacy of trimethylsilyl perchlorate (Me_3SiClO_4) is considered, but the Me_3SiClO_4 is quickly hydrolyzed by methoxide ion to stable methoxytrimethylsilane **d**, allowing to regenerate the EG acid. Although the nature of EG acid was not unveiled completely, its electrophilic character to the oxygen function was demonstrated, resembling with that of conventional catalyst such as TMSOTf and $TrClO_4$ especially in the aldol reactions. As noted above briefly, if EG acid, generated in a CH_2Cl_2-$LiClO_4$-n-Bu_4NClO_4-(Pt) system, has a character of Brønsted acid like $HClO_4$, the results accomplished in this paper are the first example, to our knowledge, that is achieved by the acid not having Lewis acid character. Further study aimed at the extended application of the EG acid for organic transformation is currently under investigation.

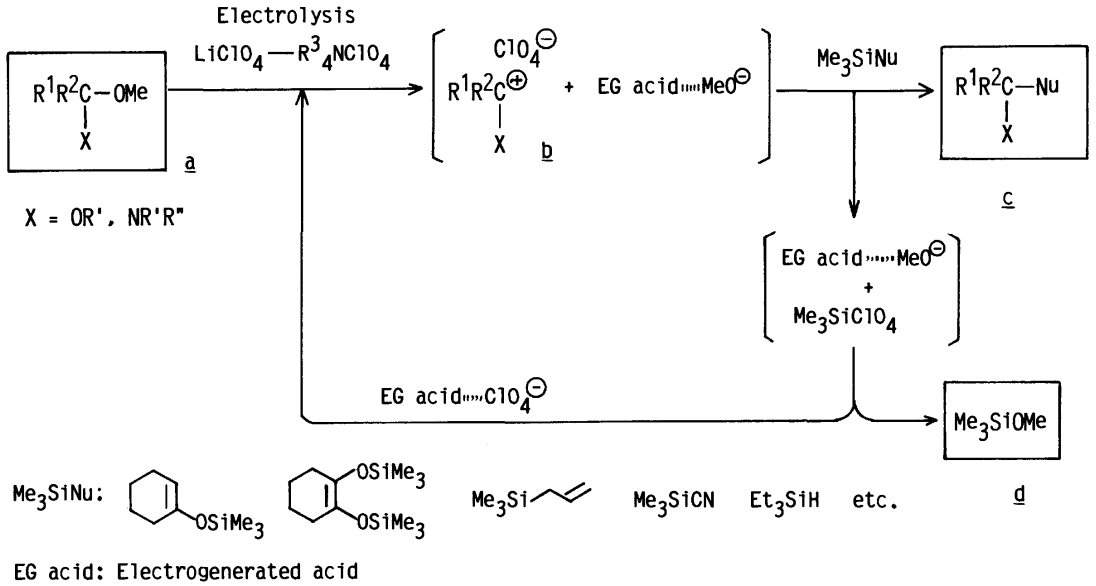
Experimental

General. Melting points are uncorrected and boiling points are indicated by an air-bath temperature without correction. IR spectra were recorded with a JASCO IRA-1 grating spectrometer. Unless otherwise noted, ^1H NHR spectra were determined at 60 MHz with either a Hitachi R-24 or a JEOL JNM-PMX 60 and ^{13}CNMR spectra were recorded with a JEOL FX-100 (25.05 MHz) spectrometer. Samples were dissolved in $CDCl_3$ and the chemical shifts are expressed in δ values (ppm) relative to Me_4Si as an internal standard. Satisfactory elemental analyses were obtained for the new compounds: C ±0.29, H ±0.29.

Materials. Enol silyl ethers **3**[25] and 1,2-bis(trimethylsiloxy)-cycloalkenes **4**[26] were prepared by the reported methods. Commercially available allyltrimethylsilane (**8**), trimethlsilyl cyanide (**10**), triethylsilane (**14**) were used as received. $LiClO_4$, n-Bu_4NClO_4, and Et_4NClO_4 purchased from Tokyo Kasei Kogyo (Japan) were used without further purification. Dichloromethane and 1,2-dichloroethane were distilled once over P_2O_5 before use.

Electrolysis Apparatus. A simple cylindrical glass tube (1.5 cm diameter×10.5 cm height) was equipped with a gas inlet tube, stirring bar, and two platinum foil electrodes (1.5 cm^2) placed parallel to each other 3 mm apart. The vessel was immersed in a cooling bath as indicated in the Experimental. The reactions were usually carried out under argon.

Typical Procedure for the Aldol Condensation of Acetal 1 with Enol Trimethylsilyl Ether 3. Into the electrolysis vessel were added $LiClO_4$ (10.6 mg, 0.1 mmol) and n-Bu_4NClO_4 (34.2 mg, 0.1 mmol) and the resulting mixture was dried at about 100 °C under vacuum for 1 h and then purged with argon. To this mixture was added a solution of cyclohexanone enol trimethylsilyl ether (**3a**, 170.3 mg, 1.0 mmol), benzaldehyde dimethyl acetal (**1a**, 182.6 mg, 1.2 mmol) in



Scheme 3.

CH_2Cl_2 (3 ml). The entire mixture was electrolyzed under a constant current of 2.67 mA cm^{-2} (applied voltage: 8—10 V) at −78 °C. Soon after electric current was communicated, the surface of the cathode was covered with a black deposite (presumably with lithium metal). The progress of reaction was monitored by TLC and the reaction was quenched with Et_3N (3 drops) when the starting **3a** was completely consumed (about 30 min and after 0.07 F mol^{-1} of electricity has been passed). The volatiles were removed on a rotary evaporator and the residue was subjected to purification by column chromatography (SiO_2, hexane-AcOEt 5 : 1) to give 174 mg (80 %) of *erythro*-**5a** (R_f 0.5, Merck Silica Gel 60 F-254, hexane-AcOEt 5 : 1) and 29 mg (13 %) of *threo*-**5a** (R_f 0.3). *erythro*-**5a**:[3a] bp 56—58 °C/0.009 Torr (1 Torr=133.322 Pa); IR (neat) 3040, 3010, 2920, 2840, 2800, 1710 (C=O), 1610 (C=C), 1500, 1450, 1140, 1125 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.2—2.1 (m, 6, CH_2), 2.27—2.93 (m, 3, CH_2CO, CHCO), 3.27 (s, 3, OCH_3), 4.78 (d, J=5 Hz, 1, CH-O), 7.3 (s, 5, PhH); ^{13}C NMR ($CDCl_3$) δ=24.6 (t), 26.4 (t), 27.0 (t), 42.2 (t), 57.2 (q), 57.4 (d), 80.1 (d), 126.9 (d, 2c), 127.2 (d), 128.2 (d, 2c), 140.9 (s), 210.4 (s). *threo*-**5a**: bp 56—58 °C/0.009 Torr; IR (neat) 3040, 3010, 2920, 2840, 2800, 1710 (C=O), 1610 (C=C), 1500, 1450, 1140, 1125 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.05—2.20 (m, 6, CH_2), 2.27—2.93 (m, 3, CH_2CO, CHCO), 3.18 (s, 3, OCH_3), 4.55 (d, J=9 Hz, 1, CH-O), 7.25 (s, 5, PhH).

The electrolysis of **1a** and **3a** in 1,2-dichloroethane was carried out in the same manner as that in dichloromethane, giving the adducts in 90% yield.

The procedure for the aldol reaction by using a circulating flow cell system: Into a flow cell as dipicted in Fig. 1 were added consecutively a solution of benzaldehyde dimethyl acetal (**1a**, 4.87 g, 35 mmol), trimethylsiloxycyclohexene (**3a**, 5.1 g, 30 mmol), $LiClO_4$ (0.32 g, 3 mmol), and n-Bu_4NClO_4 (0.34 g, 1 mmol) in THF (2 ml) and 1,2-dichloroethane (60 ml). These stuffs were mixed by circulating at a linear rate of ca. 15 cm min^{-1} by flowing pump. The mixture was then electrolyzed at a current of 15 mA with stainless steels (SUS-27, anode area: 0.5×32 cm^2) as electrodes. During the electrolysis, temperature of the solution was maintained at −20 °C by cooling externally from heat-exchanger. The electrolysis was continued until 0.02 F mol^{-1} of electricity (based on **3a**) has been passed. The mixture was then treated with triethylamine (0.5 ml) and then concentrated. The crude product thus obtained was purified by column chromatography (SiO_2, hexane-AcOEt 10 : 1) to give 5.5 g (84%, erythro/threo 71 : 29) of **5a** (based on **3a**).

Preparation of **6g** from 1,2-Bis(trimethylsiloxy)cyclobutene (**4c**). A similar electrolysis of **1a** (152.2 mg, 1.0 mmol) and **4c** (277 mg, 1.2 mmol) in CH_2Cl_2 (3 ml) in the presence of $LiClO_4$ (10.6 mg, 0.1 mmol) and n-Bu_4NClO_4 (34.2 mg, 0.1 mmol) at −78 °C for 30 min (0.087 F mol^{-1} of electricity being passed) provided **6g** in 81% yield.

Spectral data for the adducts **5—7** listed in the Table 2 are as follows.

Preparation of Homoallyl Alcohol Methyl Ether 9 from Acetal 1 and Allyltrimethylsilane (8); General Procedure. A mixture of $LiClO_4$ (11 mg, 0.10 mmol) and n-Bu_4NClO_4 (35 mg, 0.10 mmol) in the same electrolysis vessel as described above was dried under reduced pressure over P_2O_5 for 1 h and then purged with argon. To this mixture were added acetal **1a** (154 mg, 1.0 mmol), allyltrimethylsilane (117 mg, 1.0 mmol), and CH_2Cl_2 (3 ml). The mixture was electrolyzed using platinum foil electrodes (1.5 cm^2) at a constant current of 4 mA (applied voltage: 9—11 V) with external cooling at 0 °C. After passing 0.07 F mol^{-1} of electricity (for about 27 min), the reaction was quenched with Et_3N (2 drops), and the resulting mixture was concentrated in vacuo. The residue was purified by column chromatography (SiO_2, hexane-AcOEt 5:1) to give 135 mg (82%) of **9a**[2] as an oil: bp 75.0 °C/2.5 Torr; IR (neat) 3060, 2830, 2810, 1638 (C=C), 1475, 1460, 1362, 1080, 993, 913, 850, 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.45 (m, 2, CH_2), 3.19 (s, 3, OCH_3), 4.12 (t, J=6.5 Hz, 1, CH-O), 4.72—6.10 (m, 3, CH_2=CH), 7.22 (s, 5, PhH).

4·(4·*t*·Butylphenyl)·4·methoxy·1·butene (9f): Bp 110.5 °C/4 Torr; IR (neat) 3060, 2855, 2802, 1640 (C=C), 1616 (C=C), 1507, 1460, 1362, 1262, 1190, 1100, 920, 834 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.32 (s, 9, CH_3), 2.49 (m, 2, CH_2), 3.20 (s, 3, OCH_3), 4.12 (t, J=6.5 Hz, 1, CH-O), 4.80—6.25 (m, 3, CH_2=CH), 7.05—7.40 (m, 4, PhH). Found: C, 81.51; H, 10.19%. Calcd for $C_{15}H_{22}O$: C, 82.52: H, 10.16%.

4·Methoxy·4·(4·methoxyphenyl)·1·butene (9g): Bp 105.5 °C/4.5 Torr; IR (neat) 3050, 2820, 2800, 1639 (C=C), 1610 (C=C), 1580, 1504, 1460, 1440, 1350, 1300, 1242, 1163, 1030, 990, 917, 826, 803 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.20—2.65 (m, 2, CH_2), 3.15 (s, 3, OCH_3), 3.75 (s, 3, OCH_3), 4.15 (t, J=6.5 Hz, 1, CH-O), 4.70—6.10 (m, 3, CH_2=CH), 6.77, 7.13 (d, J=9 Hz, 4, PhH).

4·Methoxy·4·(3,4,5·trimethoxyphenyl)·1·butene (9h): Bp 142.0 °C/3 Torr; IR (neat) 3075, 2815, 1644 (C=C), 1600 (C=C), 1505, 1463, 1420, 1358, 1330, 1240, 1191, 1130, 1110, 1024, 934, 843 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.42 (m, 2, CH_2), 3.20 (s, 3, OCH_3), 3.81, 3.82 (s, 9, OCH_3), 4.15 (t, J=6.5 Hz, 1, CH-O), 4.72—6.00 (m, 3, CH_2=CH), 6.45 (s, 2, PhH); ^{13}C NMR ($CDCl_3$) δ=42.6 (t), 56.1 (q, 2c), 56.7 (q), 60.7 (q), 83.9 (d), 103.5 (d, 2c), 116.8 (t), 134.9 (d), 137.3 (s), 137.6 (s), 153.3 (s, 2c). Found: C, 66.80; H, 7.95%. Calcd for $C_{14}H_{20}O_4$: C, 66.65; H, 7.99%.

4·(4·Cyanophenyl)·4·methoxy·1·butene (9i): Bp 118.0 °C/4 Torr; IR (neat) 3080, 2810, 2242 (C≡N), 1640 (C=C), 1615 (C=C), 1502, 1415, 1360, 1310, 1282, 1240, 1200, 1110, 1100, 920, 840 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.44 (m, 2, CH_2), 3.21 (s, 3, OCH_3), 4.19 (t, J=6 Hz, 1, CH-O), 4.70—6.10 (m, 3, CH_2=CH), 7.32, 7.60 (d, J=7 Hz, 4, PhH); ^{13}C NMR ($CDCl_3$) δ=42.1 (t), 57.0 (q), 83.0 (d), 117.7 (t), 118.7 (s), 127.4 (d, 2C), 132.2 (d, 2C), 133.6 (s), 133.6 (d), 147.4 (s).

3·Methoxy·1·phenyl·1,5·hexadiene (9j):[19] Bp 100.5 °C/2.5 Torr; IR (neat) 3072, 3014, 2805, 1640 (C=C), 1600 (C=C), 1579, 1492, 1448, 1360, 1190, 1100, 965, 916, 747, 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.39 (m, 2, CH_2), 3.30 (s, 3, OCH_3), 3.75 (m, 1, CH-O), 4.81—5.22 (m, 2, CH_2=C), 5.52—6.68 (m, 3, CH=C, CH=CH), 7.00—7.50 (m, 5, PhH).

3·(1·Methoxy·4·*t*·butylcyclohexyl)·1·propene (9k):[19] IR (neat) 3060, 2820, 2810, 1638 (C=C), 1390, 1360, 1080, 993, 910, 850, 810, 738 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.83 (s, 9, CH_3), 0.95—2.00 (m, 8, CH_2), 2.15 (d, J=6 Hz, 2, CH_2), 3.13 (s, 3, OCH_3), 4.75—6.10 (m, 3, CH=C).

Cyanation of Acetals 1 with Trimethylsilyl Cyanide (10) to α·Alkoxyalkanenitriles 11; General Procedure. A mixture of heptanal dimethyl acetal (**1c**, 541 mg, 3.38 mmol), trimethylsilyl cyanide (**10**, 0.7 ml, 5.26 mmol), $LiClO_4$ (23 mg, 0.22 mmol), and Et_4NClO_4 (52 mg, 0.18 mmol) in CH_2Cl_2 (5 ml) was electrolyzed with platinum electrodes (1.5 cm^2) in an

undivided cell at an applied voltage of 15 V (current: 12—13 mA). After electrolysis for 32 min (passed electricity: 0.077 F mol^{-1} based on the acetal **1c**) and an additional stirring for 5 min at room temperature, the reaction was quenched with pyridine (2 drops). Concentration of the mixture under vacuum followed by either column chromatography (SiO_2, hexane-AcOEt, 50 : 1) or bulb to bulb distillation gave 430 mg (89%) of **11c** as an oil.

2-Methoxy-2-phenylethanenitrile (11a):[4] Bp 105 °C/9 Torr; IR (neat) 3060, 3040, 3005, 2835, 2260 (C≡N), 1601 (C=C), 1590, 1500, 1458, 1320, 1284, 1207, 1100, 1037, 1008, 975, 918, 843, 760, 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.50 (s, 3, OCH_3), 5.17 (s, 1, CH-O), 7.40 (br, 5, PhH).

2-(2-Furyl)-2-methoxyethanenitrile (11b): Bp 105 °C/9 Torr; IR (neat) 3153, 3120, 3000, 2830, 1500, 1460, 1390, 1320, 1303, 1243, 1235, 1195, 1180, 1150, 1140, 1080, 1018, 962, 958, 910, 890, 880, 822, 797, 750 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.47 (s, 3, OCH_3), 5.30 (s, 1, CH-O), 6.41 (m, 1, CH=C), 6.62 (d, J=4 Hz, 1, CH=C), 7.47 (d, J=2 Hz, 1, CH=C).

2-Methoxyoctanenitrile (11c):[4] Bp 85 °C/9 Torr; IR (neat) 2970, 2900, 2810, 2800, 1465, 1370, 1330, 1130, 1100 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.97 (m, 3, CH_3), 1.31 (br, 10, CH_2), 3.46 (s, 3, OCH_3), 3.95 (t, J=6 Hz, 1, CH-O).

2-Methoxy-4-phenyl-3-butenenitrile (11j): Bp 90 °C/3 Torr; IR (neat) 3040, 3020, 3002, 2800, 2240 (C≡N), 1598, 1570, 1485, 1440, 1330, 1190, 1120, 1090, 960, 900, 740, 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.50 (s, 3, OCH_3), 4.81 (dd, J=6, 1 Hz, 1, CH-O), 6.13 (dd, J=16, 6 Hz, 1, CH=C), 6.92 (dd, J=16, 1 Hz, CH=C), 7.33 (br, 5, PhH).

2-Methoxy-3-phenylpropanenitrile (11l):[4] Bp 110 °C/9 Torr; IR (neat) 3075, 3040, 3005, 2840, 1600 (C=C), 1500, 1460, 1340, 1120, 1080, 750, 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.06 (d, J=7 Hz, 2, CH_2), 3.44 (s, 3, OCH_3), 4.18 (t, J=7Hz, 1, CH-O), 5.25 (s, 5, PhH).

2-(2-Methoxycarbonylethyl)-1-methoxycyclohexanecarbonitrile (11m): Bp 91 °C/3 Torr; IR (neat) 2840, 2803, 2240 (C≡N), 1730 (C=O), 1442, 1430, 1130, 1250, 1195, 1170, 1100, 1070, 1050, 1010, 980, 945, 922, 910, 884, 840, 725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00—2.08 (m, 10, CH_2), 2.08—2.60 (m, 3, CH_2CO, CH), 3.40 (s, 3, OCH_3), 3.65 (s, 3, CO_2CH_3).

3-Methoxycarbonyl-2-methoxypropanenitrile (11n): Bp 75 °C/5 Torr; IR (neat) 2815, 1740 (C=O), 1435, 1367, 1280, 1202, 1165, 1115, 1010, 982 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.87 (d, J=6 Hz, 2, CH_2), 3.51 (s, 3, OCH_3), 3.74 (s, 3, CO_2CH_3), 4.48 (t, J=6 Hz, 1, CH-O).

***N*-Ethoxycarbonyl-2-cyanopiperidine (11o):** Bp 83 °C/3 Torr; IR (neat) 2945, 2860, 1710 (C=O), 1420, 1260, 1180, 1040 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.25 (t, J=7 Hz, 3, CH_3), 1.30—2.20 (m, 7, CH_2, N-CH_2), 2.95 (m, 1, N-CH_2), 4.12 (q, J=7 Hz, 2, CO_2CH_2), 5.22 (m, 1, N-CH).

1-(Trimethylsiloxy)cyclododecanecarbonitrile (12e):[27] IR (neat) 2245 (C≡N), 1473, 1450, 1255, 1100, 1045, 1008, 863, 850 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.25 (s, 9, $OSiMe_3$), 1.36 (m, 18, CH_2), 1.61—2.11 (m, 4, CH_2).

2-Ethyl-2-(trimethylsiloxy)butanenitrile (12f):[26] IR (neat) 2240 (C≡N), 1460, 1250, 1160, 1130, 1077, 1018, 880, 845, 757 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.22 (s, 9, $OSiMe_3$), 1.11 (t, δ=7 Hz, 6, CH_3), 1.75 (q, J=7 Hz, 4, CH_2).

2-Methyl-2-(trimethylsiloxy)heptanenitrile (12g):[28] IR (neat) 2245 (C≡N), 1466, 1380, 1257, 1195, 1142, 1105, 1080, 1033, 850, 760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.23 (s, 9, $OSiMe_3$), 0.90 (m, 3, CH_3), 1.30—1.85 (m, 8, CH_2), 1.55 (s, 3, CH_3).

Ethyl 2-Cyano-2-(trimethylsiloxy)propionate (12h): Bp 58—60 °C/2 Torr; IR (neat) 2280(C≡N), 1774 (C=O), 1458, 1383, 1262, 1200, 1156, 1008, 926, 860, 742 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.25 (s, 9, $OSiMe_3$), 1.32 (t, J=8 Hz, 3, CH_3), 1.75 (s, 3, CH_3), 4.26 (q, J=8 Hz, CH_2). Found: C, 49.96; H, 8.20; N, 6.34%. Calcd for $C_9H_{17}NO_3Si$: C, 50.20; H, 7.96; N, 6.51%.

2-Trimethylsiloxy-2-phenylpropanenitrile (12d):[28] IR (neat) 3043, 3010, 2240 (C≡N), 1600, 1490, 1445, 1370, 1250, 1223, 1150, 1120, 1000, 910, 843, 760, 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.17 (s, 9, $OSiMe_3$), 1.83 (s, 3, CH_3), 7.20—7.65 (m, 5, PhH).

5-Isopropenyl-2-methyl-1-trimethylsiloxy-2-cyclohexene-1-carbonitrile (12i): Bp 79—81 °C/2 Torr; IR (neat) 3070, 3020, 2960, 2240 (C≡N), 1645, 1450, 1260, 1135, 1055, 960, 910, 850, 760 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.20 (s, 9, $OSiMe_3$), 1.73 (s, 3, CH_3), 1.77 (s, 3, CH_3), 1.10—2.60 (m, 5, CH_2, CH), 4.72 (m, 2, CH_2=C), 5.60 (m, 1, CH=C). Found: C, 67.41; H, 7.96; N, 6.34%. Calcd for $C_{14}H_{23}NOSi$: C, 67.41; H, 9.29; N, 5.61%.

2-Hydroxyoctanenitrile (13j): IR (neat) 2920, 2840, 2240 (C≡N), 1460, 910, 730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (m, 3, CH_3), 1.10—2.10 (m, 10, CH_2), 2.60—3.40 (brs. 1, OH), 4.48 (t, J=6 Hz, 1, CH-O).

2-Hydroxy-2-phenylethanenitrile (13a): IR (neat) 3390 (OH), 3050, 2255 (C≡N), 1500, 1455, 1200, 1040, 1025, 940, 760, 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.72 (brs , 1, OH), 5.43 (s, 1, CH-O), 7.41 (s, 5, PhH).

2-Hydroxy-2-(4-methoxyphenyl)ethanenitrile (13c): IR (neat) 3400 (OH), 2840, 2235 (C≡N), 1620, 1595, 1520, 1260, 1180, 1035, 840 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.74 (s, 3, OMe), 3.50—4.00 (brs, 1, OH), 6.82 (d, J=10 Hz, 2, PhH), 7.32 (d, J=10Hz, 2, PhH).

2-Hydroxy-2-(4-cyanophenyl)ethanenitrile (13k): Mp 71—73 °C; IR ($CHCl_3$) 3400 (OH), 2245 (C≡N), 1420, 1200, 920, 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.5—4.5 (brs, 1, OH), 5.60 (s, 1, CH-O), 7.62 (s, 4, PhH). Found: C, 68.18; H, 3.80; N, 17.57%. Calcd for $C_9H_6N_2O$: C, 68.35, H, 3.82; N, 17.71%.

2-Hydroxy-4-phenyl-3-butenenitrile (13l): IR (neat) 3400 (OH), 3040, 3020, 2250 (C≡N), 1495, 1450, 970, 750, 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.70—4.30 (brs, 1, OH), 5.07 (d, J=6 Hz, 1, CH-O), 6.15 (dd, J=15, 6 Hz, 1, C=CH), 6.82 (d, J=15 Hz, 1, C=CH), 7.29 (s, 5, PhH).

Reaction of Acetals 1 with Triethylsilane (14); General Procedure. A mixture of acetal (**1a** 922 mg, 5.06 mmol) and Et_3SiH (**14**, 605.6 mg, 5.21 mmol) in CH_2Cl_2 (5 ml) containing $LiClO_4$ (42 mg, 0.39 mmol) and n-Bu_4NClO_4 (135.7 mg, 0.40 mmol) was electrolyzed at a constant current of 4 mA (applied voltage: 7—8 V) with platinum electrodes (1.5 cm^2) at 0 °C under argon. After passing 0.07 F mol^{-1} of electricity (it took about 25 min), the reaction was quenched with Et_3N (3 drops). Concentration followed by column chromatography (SiO_2, hexane-AcOEt, 5 : 1) gave 543 mg (88%) of **15a**[2] as an oil: IR (neat) 3080, 3060, 3020, 1605, 1450, 1380, 1100, 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.36 (s, 3, OCH_3), 4.43 (s, 2, CH_2-O), 7.29 (s, 5, PhH).

1-*t*-Butyl-4-(methoxymethyl)benzene (15f): Bp 88.5 °C/2 Torr; IR (neat) 2960, 2860, 2810, 1630, 1515, 1478, 1460, 1412, 1380, 1365, 1270, 1215, 1195, 1185, 1112, 1100, 1020, 970, 920, 855, 838, 818, 670, 660 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.30 (s, 9, CH_3), 3.35 (s, 3, OCH_3), 4.38 (s, 2, CH_2-O), 7.20—7.40 (m, 4, PhH).

1-Methoxy-4-(methoxymethyl)benzene (15g): Bp 91.5 °C/4 Torr; IR (neat) 2950, 2900, 2870, 2830, 1618, 1590, 1515, 1465, 1440, 1412, 1380, 1365, 1300, 1270, 1250, 1170, 1100, 1038, 1018, 1005, 960, 910, 850, 820, 740, 660 cm^{-1}; ^1H NMR

($CDCl_3$) δ=3.29 (s, 3, OCH_3), 3.72 (s, 3, OCH_3), 4.31 (s, 2, CH_2-O), 6.77, 7.16 (d, J=8.5 Hz, 4, PhH).

1,2,3-Trimethoxy-5-(methoxymethyl)benzene (15h): Bp 127.0 °C/4.5 Torr; IR (neat) 2930, 2830, 1600, 1510, 1470, 1430, 1390, 1370, 1340, 1240, 1190, 1130, 1110, 1050, 1020, 995, 925, 845, 795, 740, 705, 675 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.39 (s, 3, OCH_3), 3.82 (s, 9, OCH_3), 4.35 (s, 2, CH_2-O), 6.50 (s, 2, PhH).

4-(Methoxymethyl)benzonitrile (15i): Bp 104.0 °C/3.5 Torr; IR (neat) 2980, 2930, 2880, 2820, 2250 (C≡N), 1615, 1505, 1470, 1452, 1415, 1385, 1245, 1210, 1200, 1108, 1058, 1022, 990, 975, 925, 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.40 (s, 3, OCH_3), 4.47 (s, 2, CH_2-O), 7.35, 7.60 (d, J=8 Hz, 4, PhH).

Syntheses of Optically Active Pentaacetates of Pseudo-β-L-allopyranose and Pseudo-α-D-mannopyranose

Kin-ichi TADANO,* Chiyoko FUKABORI, Masayuki MIYAZAKI, Hiroshi KIMURA, and Tetsuo SUAMI*
Department of Applied Chemistry, Faculty of Science and Technology, Keio University,
Hiyoshi, Kohoku-ku, Yokohama 223
(Received November 13, 1986)

Diisobutylaluminium hydride reduction of D-glucose-derived chiral synthon, (1*R*,6*R*,8*R*,9*R*)-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]non-4-en-3-one (**1**), gave a 7:1 mixture of (1*R*,3*S*,6*R*,8*R*,9*R*)- and (1*R*,3*R*,6*R*,8*R*,9*R*)-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]non-4-en-3-ol, (**2**) and (**2'**). Introduction of cis-diol to the double bond of 3-*O*-acetyl derivatives of **2** and **2'** by osmium tetraoxide oxidation provided the diastereomeric mixture of (1*R*,3*S*,4*R*,5*S*,6*S*,8*R*,9*R*)-3-acetoxy-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]-nonane-4,5-diol (**5**) and (1*R*,3*R*,4*S*,5*R*,6*S*,8*R*,9*R*) diastereomer. Compound **5** was transformed to optically active pseudo-β-L-allopyranose effectively via (1*R*)-1-[(1*S*,2*S*,3*S*,4*R*,5*S*)-3,4,5-tris(benzyloxy)-2-hydroxycyclohexyl]-1,2-ethanediol (**9**). Cyclohexanecarbaldehyde formed by glycol cleavage of **9** was treated with methanesulfonyl chloride and reduced with lithium aluminium hydride to give (3*S*,4*R*,5*S*)-3,4,5-tris(benzyloxy)-1-cyclohexene-1-methanol (**13**). Compound **13** was efficiently converted to pseudo-α-D-mannopyranose pentaacetate by stereoselective hydroboration as a key reaction. The Wharton reaction of (1*R*,4*S*,5*S*,6*S*,8*R*,9*R*)-4,5-epoxy-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]nonan-3-one derived from **1** gave (1*R*,5*R*,6*S*,8*R*,9*R*)-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]non-3-en-5-ol, into which (3*S*,4*S*)-diol was stereoselectively introduced by oxidation with osmium tetraoxide.

The pseudo-sugars, 1-hydroxymethyl-2,3,4,5-cyclohexanetetrols, are found in components of antibiotics and enzyme inhibitors.[1] Optically active pseudo-sugars have currently been investigated by several subtle approaches to these carbocyclic analogues of carbohydrates.[2] This situation made us use chiral synthon as a starting compound for the pseudo-sugar synthesis. In the previous papers,[3] we demonstrated a practicable access to the chiral synthon **1**, from which some optically active pseudo-sugars and pseudo-2-amino sugars were synthesized by stereoselective introduction of triol or azido diol on the cyclohexenone moiety of **1**. In our further study of synthesizing the optically active carbocyclic natural products and pseudo-sugars,[4] we described another approach to pseudo-sugars starting from synthon **1**. The approach features a stereoselective cis-diol introduction to the double bond of two allyl acetates **4** and **19**, both of which are easily prepared from **1**, to give (3*S*,4*R*,5*S*)- and (3*S*,4*S*,5*S*)- protected triols **5** and **20**. Compound **5** was transformed to pentaacetyl derivatives of pseudo-α-L-allopyranose and pseudo-α-D-mannopyranose, **11** and **15**, efficiently.

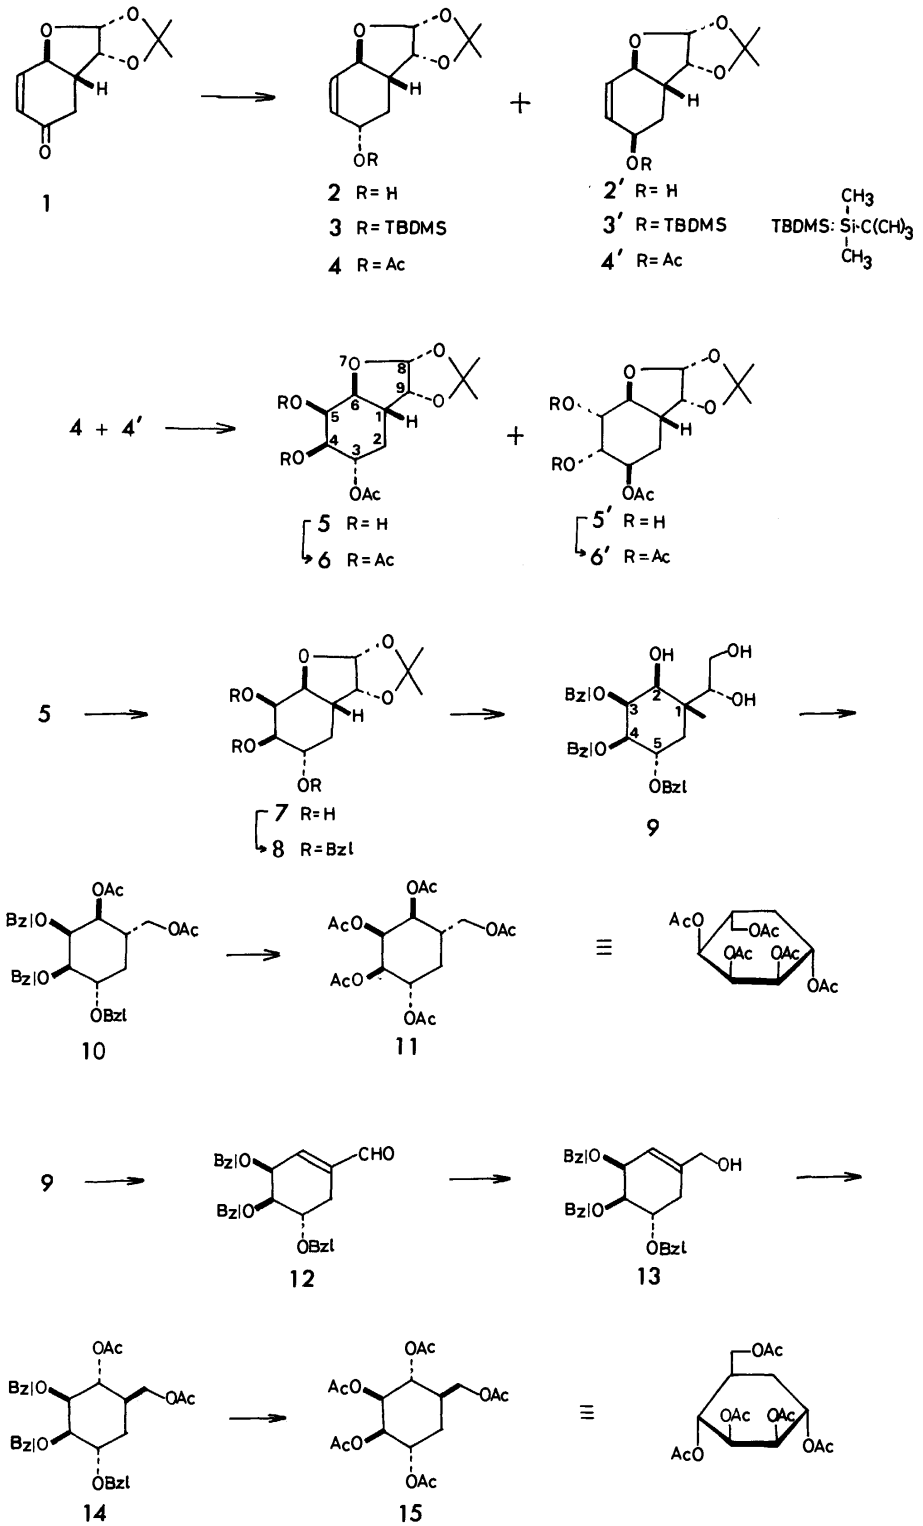
Results and Discussion

Synthesis of Pentaacetates of Pseudo-β-L-allopyranose and Pseudo-α-D-mannopyranose, (11) and (15) (Scheme 1). Diisobutylaluminium hydride (DIBAL-H) reduced chiral synthon **1**, which was prepared from 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose by seven-steps reaction in an overall yield of 37%,[3] at −78 °C to give an inseparable mixture of allyl alcohols **2** and **2'** in 69% yield. The ratio of **2** to **2'** was 7:1 by conversion of the mixture to *t*-butyldimethylsilyl ethers **3** and **3'**, which were separated by silica-gel chromatography.[5] Although we were unable to confirm stereochemically C-3 (H-C-OH) of **2** and **2'** unambigously by ^{1}H NMR analysis of **3** and **3'**, the configuration of C-3 of the main product **2** was tentatively assigned to be (*S*), as was confirmed later. Osmium tetraoxide oxidation of an inseparable mixture of allyl acetates **4** and **4'**, which was prepared by acetylation of a mixture of **2** and **2'**, with aqueous hydrogen peroxide in *t*-butyl alcohol at room temperature gave (1*R*,3*S*,4*R*,5*S*,6*S*,8*R*,9*R*)- and (1*R*,3*R*,4*S*,5*R*,6*S*,8*R*,9*R*)-3-acetoxy-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]nonane-4,5-diol, (**5**) and (**5'**), in 53 and 6% yield, respectively. The structure of main product **5** was verified by ^{1}H NMR spectrum of tri-*O*-acetyl derivative **6**, which was prepared in 96% yield. In the ^{1}H NMR spectrum of **6**, H-6 signal appeared at δ 3.85 as a double doublet with $J_{1,6}$=10.5 Hz and $J_{5,6}$=3 Hz, indicating that 5-acetoxyl group is axial. Three acetoxyl methyl signals of **6** appeared at δ 2.00, 2.03, and 2.12 indicate that acetoxyl groups on C-3, 4, and 5 are equatorial, equatorial, and axial, respectively.[6] The configurations at C-3 to C-5 are, therefore, (3*S*,4*R*,5*S*) as depicted. The structure of **5'**, (3*R*,4*S*,5*R*), was also confirmed by ^{1}H NMR spectrum of acetyl derivative **6'** obtained in 97% yield. In the ^{1}H NMR spectrum, H-6 of **6'** appeared at δ 4.02 as a triplet with $J_{1,6}$=$J_{5,6}$=9.5 Hz, indicating that 5-acetoxyl group is equatorial. Three acetoxyl methyl signals of **6'** appeared at δ 2.00 (3H) and 2.10 (6H), indicating that acetoxyl groups on C-3, 4, and 5 are axial, axial, and equatorial.[6] Stereoselective cis-diol introduction was thus achieved for both allyl acetates **4** and **4'**, and osmate formation in both cases occurred from the opposite side of acetoxyl group, providing **5** from **4** and **5'** from **4'**.[7]

Pseudo-sugar **11** was synthesized from **5** as follows. *O*-Deacetylation of **5** and successive benzylation with excess benzyl bromide in the presence of sodium

hydride gave tri-*O*-benzyl derivative **8** in 88% yield. Hydrolysis of **8** with 80% aqueous acetic acid to remove *O*-isopropylidene group, followed by reduction with sodium borohydride, gave pseudo-heptopyranose **9** in 56% yield. The glycol cleavage of **9** with sodium periodate, reduction of the resulting aldehyde group with sodium borohydride, and acetylation gave a fully protected pseudo-β-L-allopyranose **10** in 85% yield. Finally, hydrogenolysis of **10** in the presence of palladium-black to remove *O*-benzyl groups and successive acetylation gave compound **11** as crystals in 79% yield. The ^{1}H NMR spectrum of **11** was identical with that of authentic DL-**11**.[8]

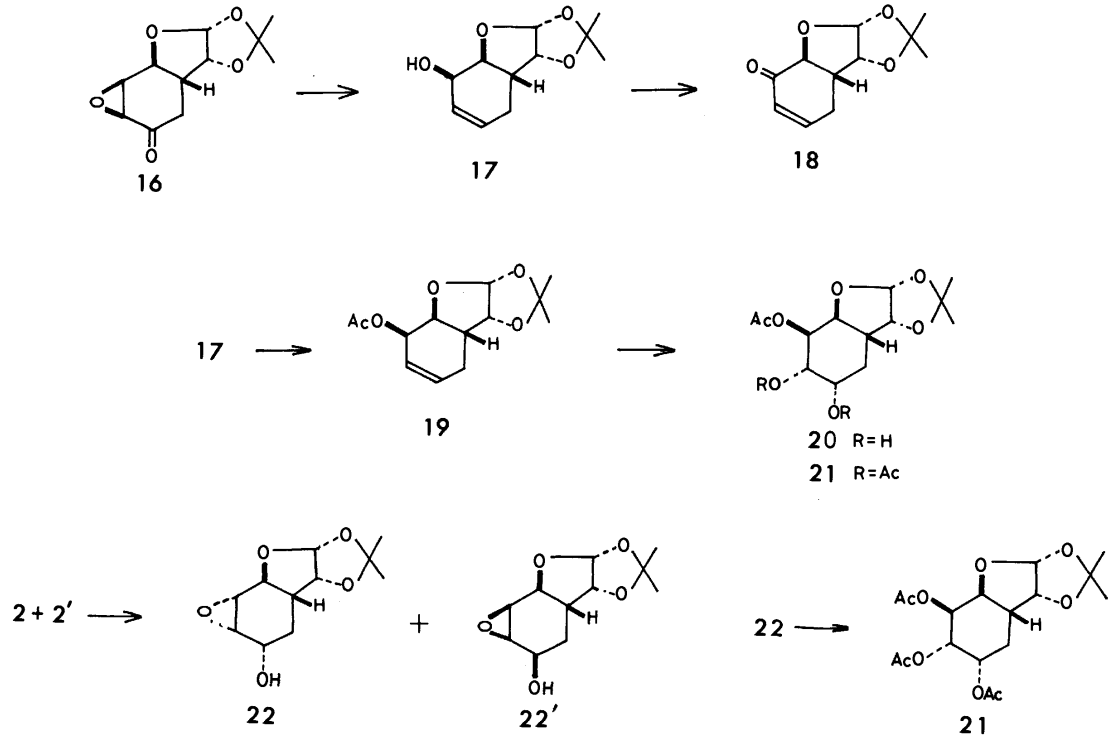
The synthesis of pseudo-α-D-mannopyranose pen-



Scheme 1.

taacetate (**15**) from compound **9** was achieved as follows. The glycol cleavage of **9** as described above and successive treatment of the resulting cyclohexanecarbaldehyde with excess methanesulfonyl chloride at room temperature gave α,β-unsaturated 1-cyclohexene-1-carbaldehyde, which was reduced with lithium aluminium hydride to give 1-cyclohexene-1-methanol **13** in 37% yield from **9**. Hydroboration of **13** with borane-THF complex, treatment with alkaline hydrogen peroxide, and acetylation gave a fully protected pseudo-α-D-mannopyranose **14** in 47% yield. Since pseudo-β-L-allopyranose **10** was not detected in the reaction mixture, hydroboration of **13** seems to proceed stereoselectively from less-hindered side opposite to the benzyloxy groups on C-3 and C-4.[9] Hydrogenolysis of **14** in the presence of palladium-black followed by acetylation gave compound **15** as crystals in 56% yield. The ^{1}H NMR spectrum of **15** was identical with that of authentic DL-**15**.[10]

Synthesis of (1*R*,5*R*,6*S*,8*R*,9*R*)-8,9-Isopropylidenedioxy-7-oxabicyclo[4.3.0]non-3-en-5-ol (17) and Stereoselective Introduction of Two Hydroxyl Groups to the Double Bond in Acetate (19) of 17 (Scheme 2). Our next interest was to investigate stereoselectivity of introduction of two hydroxyl groups to the double bond located at C-3 and C-4 in the appropriate model **17**. Compound **17** was synthesized by the Wharton reaction[11] of known epoxy ketone **16**, which was obtained by stereoselective epoxidation of **1**.[3] Treatment of **16** in ethanol with each 5 molar equivalent of hydrazine hydrate and acetic acid at room temperature for 2.5 min gave compound **17** in 74% yield. Longer reaction time decreased the yield. In the ^{1}H NMR spectrum of **17**, H-6 signal appeared at δ 3.72 as a double doublet with $J_{1,6}$=10.5 Hz and $J_{5,6}$=4.5 Hz. Meanwhile, oxidation of **17** with pyridinium chlorochromate (PCC) gave (1*S*,6*S*,8*R*,9*R*)-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]non-3-en-5-one (**18**) in 87% yield. In the ^{1}H NMR spectrum of **18**, H-6 signal appeared at δ 4.45 as a doublet with $J_{1,6}$=12 Hz. From these spectral data, it was concluded that hydroxyl group in the Wharton reaction product is at C-5 with (R)-configuration (a pseudo-axial orientation). Treatment of allyl acetate **19**, which was prepared by acetylation of **17** in 98% yield, with osmium tetraoxide in *t*-butyl alcohol in the presence of hydrogen peroxide gave cis diol **20** as a sole product in 35% yield. No stereoisomer was detected. The structure of **20** was estimated from the ^{1}H NMR spectrum of tri-*O*-acetyl derivative **21**, where H-6 signal appeared at δ 4.05 as a double doublet with $J_{1,6}$=10.5 Hz and $J_{5,6}$=3 Hz, indicating that 5-acetoxyl group is axial. Three acetoxyl methyl signals of **21** appeared at δ 1.99 (3H) and 2.10 (6H) and those signals were assigned to one equatorial and two axial acetoxyl groups.[6] Based on the results of oxidation of compound **4** and **4'** catalysed with osmium tetraoxide, cis diol introduction to compound **19** proceeded presumably from less-hindered side opposite to the 5-acetoxyl group to give solely (1*R*,3*S*,4*S*,5*S*,6*S*,8*R*,-9*R*)-5-acetoxy-8,9-isopropylidenedioxy-7-oxabicyclo-[4.3.0]nonane-3,4-diol (**20**). The possibility of formation of other stereoisomer possessing (1*R*,3*R*,4*R*,5*S*,6*S*,-8*R*,9*R*)-configuration, however, could not be excluded. To confirm the structure of **21**, we examined the sol-



Scheme 2.

volysis of (1*R*,3*S*,4*S*,5*R*,6*S*,8*R*,9*R*)-4,5-epoxy-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]nonan-3-ol (**22**). The solvolysis of **22** in aqueous solvent in the presence of sodium acetate was expected to give compound **21** via diaxial opening of epoxy ring by hydroxide ion and acetylation of the solvolytic product. The synthesis of **22** was carried out as follows. Epoxidation of an inseparable mixture of **2** and **2'** with *m*-chloroperbenzoic acid (MCPBA) in refluxing dichloromethane gave two products **22** and **22'** in 50 and 16% yield, respectively. The ^{1}H NMR spectrum of **22'**, which was derived from a minor allyl alcohol **2'**, was identical with that of authentic sample.[3] The ^{1}H NMR spectrum of **22** was apparently different from that of another possible epoxy alcohol possessing (3*S*,4*R*,5*S*)-configuration, which was prepared from **1** by (1) epoxidation and (2) sodium borohydride reduction.[3] The structure of **22** was confirmed. In epoxidation of **2** and **2'**, hydroxyl groups governed the direction of attack of the peroxy acid.[12] As expected, the solvolysis of **22** and successive acetylation gave compound **21**, which was identical with the compound derived from **19**, in 79% yield, and the structure of **21** was thus confirmed. The compound **20** seems to be a promising precursor for synthesizing pseudo-β-L-altropyranose and pseudo-α-D-glucopyranose.[13]

Experimental

General. Reactions were performed at room temperature unless otherwise stated. Evaporation was done under a reduced pressure at below 40 °C with a bath. Melting points were determined with a Mitamura Riken micro mp apparatus. Specific rotation was measured by a Jasco DIP-4 polarimeter with a 10 mm cell. Column chromatography was performed with Kieselgel 60 (Merck), and thin-layer chromatography (TLC) by a glass plate coated with Kieselgel 60 GF_{254} (Merck), followed by UV light detection and charring with sulfuric acid. IR spectra were recorded with a Hitachi 225 spectrometer by the KBr method or with a Jasco A-202 spectrometer by the $CHCl_3$ method. ^{1}H NMR spectra were recorded with a Varian EM-390 (90 MHz) for solutions in $CDCl_3$ with an internal standard of Me_4Si. High-resolution mass spectra were obtained by a Hitachi M-80 spectrometer.

Dichloromethane and *N*,*N*-dimethylformamide (DMF) were dried over CaH_2 and distilled. Pyridine was distilled over NaOH. Tetrahydrofuran (THF) was distilled over $LiAlH_4$ and then over benzophenone.

Mixture of (1*R*,3*S*,6*R*,8*R*,9*R*)- and (1*R*,3*R*,6*R*,8*R*,9*R*)-8,9-Isopropylidenedioxy-7-oxabicyclo[4.3.0]non-4-en-3-ol, (2) and (2'). To a solution of (1*R*,6*R*,8*R*,9*R*)-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]non-4-en-3-one (**1**)[3] (1.20 g, 5.70 mmol) in dichloromethane (20 ml) was added with stirring DIBAL-H (1.5 mol dm^{-3} in toluene, 6.08 ml, 9.12 mmol) at −78 °C under an argon atmosphere. The mixture was stirred at the same temperature for 1 h, diluted with water (50 ml), and warmed to room temperature. The resulting insoluble materials were filtered with Celite pad, and the filtrate was condensed by evaporation. The residue was partitioned between dichloromethane (60 ml) and water (50 ml), and the aqueous layer was extracted with dichloromethane (60 ml×2). The organic layer was dried on Na_2SO_4 and condensed. The residue was chromatographed with silica gel (100 g, ethyl acetate-hexane=1 : 4), and the fraction corresponding to R_f 0.17 (ethyl acetate-hexane=1 : 2) was evaporated to give inseparable mixed crystals of **2** and **2'** (830 mg, 69% yield), mp 99—101.5 °C. IR ν_{max}^{KBr} 3500, 3000, 2950, 2900, 2845, 1450, 1400, 1385, 1375, 1315, 1265, 1240, 1210 cm^{-1}; ^{1}H NMR δ=1.33, 1.50 (3H×2, each s, $C(CH_3)_2$), 1.60—2.13 (3H, m, H-2,2', OH), 2.27—2.60 (1H, m, H-1), 4.07—4.50 (2H, m, H-3,6), 4.58 (1H, t, *J*=4.5 Hz, H-9), 5.87—5.97 (1H, m, H-4 or 5), 5.83 (1H, d, *J*=4.5 Hz, H-8), 6.00—6.33 (1H, m, H-4 or 5). Found: C, 62.51; H, 7.51%. Calcd for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%.

(1*R*,3*S*,6*R*,8*R*,9*R*)- and (1*R*,3*R*,6*R*,8*R*,9*R*)-3-(*t*-Butyldimethylsilyloxy)-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]non-4-ene, (3) and (3'). To a solution of inseparable mixture of **2** and **2'** (24.8 mg, 0.12 mmol) in DMF (1 ml) were added *t*-butylchlorodimethylsilane (158.7 mg, 1.09 mmol) and imidazole (68.1 mg, 1.03 mmol) with stirring. The mixture was stirred at 70 °C for 72 h, and diluted with ethyl acetate (15 ml). The solution was washed with water (15 ml×3), and the organic layer was dried on Na_2SO_4 and condensed by evaporation. The residue was chromatographed with silica gel (4 g, ethyl acetate-hexane=1 : 50). The fraction corresponding to R_f 0.71 (ethyl acetate-hexane=1 : 4) was evaporated to give **3'** (3.4 mg, 9%) as a colorless syrup, and the fraction corresponding to R_f 0.60 was evaporated to give **3** (23.5 mg, 62% yield) as a colorless syrup. **3**: $[\alpha]_D^{25}$ −14.6° (*c* 1.14, $CHCl_3$); IR ν_{max}^{KBr} 2990, 2960, 2940, 2880, 1460, 1380, 1375, 1260, 1215 cm^{-1}; ^{1}H NMR δ=0.08 (6H, s, $OSiC(CH_3)_3(C\underline{H}_3)_2$), 0.90 (9H, s, $OSiC(C\underline{H}_3)_3(CH_3)_2$), 1.31, 1.49 (3H×2, each s, $C(CH_3)_2$), 1.60—1.78 (2H, m, H-2,2'), 2.18—2.37 (1H, m, H-1), 4.35—4.47 (2H, m, H-3,6), 4.54 (1H, t, *J*=3.5 Hz, H-9), 5.45—5.58 (1H, m, H-4 or 5), 5.81 (1H, d, *J*=3.5 Hz, H-8), 5.94—6.17 (1H, m, H-5 or 4). **3'**: ^{1}H NMR δ=0.08 (6H, s, $OSiC(CH_3)_3(C\underline{H}_3)_2$), 0.88 (9H, s, $OSiC(C\underline{H}_3)_3(CH_3)_2$), 1.31, 1.48 (3H×2, each s, $C(CH_3)_2$), 1.87—1.97 (3H, m, H-1, 2,2'), 4.03—4.39 (2H, m, H-3,6), 4.60 (1H, t, *J*=3.5 Hz, H-9), 5.47—5.65 (1H, m, H-4 or 5), 5.72 (1H, d, *J*=3.5 Hz, H-8), 6.03—6.22 (1H, m, H-5 or 4).

Mixture of (1*R*,3*S*,6*R*,8*R*,9*R*)- and (1*R*,3*R*,6*R*,8*R*,9*R*)-3-Acetoxy-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]non-4-ene, (4) and (4'). An inseparable mixture of **2** and **2'** (596 mg, 2.81 mmol) was acetylated with acetic anhydride (6 ml) in pyridine (6 ml) for 4 h and the mixture was evaporated. The residue was chromatographed with silica gel (20 g, ethyl acetate-hexane=1 : 8), and the fraction corresponding to R_f 0.50 (ethyl acetate-hexane=1 : 2) was evaporated to give an inseparable mixed crystals of **4** and **4'** (683 mg, 96% yield), mp 63—66 °C°; IR ν_{max}^{KBr} 3000, 2980, 2965, 2940, 2840, 1735, 1370, 1325, 1300, 1265, 1240, 1210 cm^{-1}; ^{1}H NMR δ=1.35, 1.50 (3H×2, each s, $C(CH_3)_2$), 1.60—2.00 (2H, m, H-2, 2'), 2.05 (3H, s, $OCOCH_3$), 2.33—2.60 (1H, m, H-1), 4.10—4.50 (1H, m, H-6), 4.58 (1H, t, *J*=4.5 Hz, H-9), 5.30—5.70 (2H, m, H-3, H-4 or 5), 5.87 (1H, d, *J*=4.5 Hz, H-8), 6.13—6.43 (1H, m, H-5 or 4). Found: C, 61.55; H, 7.07%. Calcd for $C_{13}H_{18}O_5$: C, 61.40; H, 7.13%.

(1*R*,3*S*,4*R*,5*S*,6*S*,8*R*,9*R*)- and (1*R*,3*R*,4*S*,5*R*,6*S*,8*R*,9*R*)-3-Acetoxy-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]nonane-4,5-diol, (5) and (5'). To a solution of the inseparable mixture of **4** and **4'** (675.8 mg, 2.66 mmol) in *t*-butyl alcohol (15 ml) were added osmium tetraoxide in *t*-butyl alcohol (0.02

mol dm^{-3} solution, 2.66 ml, 0.053 mmol) and aqueous hydrogen peroxide (35wt%, 1.5 ml) with stirring. The solution was stirred in dark for 38 h and evaporated. The residue was chromatographed with silica gel (50 g, ethyl acetate-hexane=2 : 3). The fraction corresponding to R_f 0.10 (ethyl acetate-hexane=1 : 1) was evaporated to give crystals of **5′** (49.5 mg, 6% yield). The fraction corresponding to R_f 0.06 was evaporated to give crystals of **5** (406.3 mg, 53% yield). **5**: Mp 154—155 °C; $[\alpha]_D^{21}$ +71.5° (*c* 1.57, $CHCl_3$); IR ν_{max}^{KBr} 3450, 2990, 2980, 2940, 2880, 1710, 1445, 1390, 1375, 1365, 1265, 1250, 1210 cm^{-1}; ^{1}H NMR δ=1.32, 1.50 (3H×2, each s, $C(CH_3)_2$), 1.95—2.40 (3H, m, H-1,2, 2′), 2.06 (3H, s, $OCOCH_3$), 3.20—3.78 (4H, m, H-4 or 5, 6, 2×OH), 4.32—4.50 (1H, m, H-5 or 4), 4.59 (1H, t, *J*=3 Hz, H-9), 4.99 (1H, dt, *J*=11 and 5 Hz, H-3), 5.88 (1H, d, *J*=3 Hz, H-8). **5′**: Mp 191—193 °C; $[\alpha]_D^{22}$ −7.9° (*c* 1.29, $CHCl_3$); IR ν_{max}^{KBr} 3450, 3300, 2980, 2930, 2890, 1730, 1450, 1370, 1350, 1330, 1305, 1250, 1220 cm^{-1}; ^{1}H NMR δ=1.32, 1.52 (3H×2, each s, $C(CH_3)_2$), 1.67—2.00 (3H, m, H-1, 2, 2′), 2.05 (3H, s, $OCOCH_3$), 2.70—3.20 (1H, br s, OH), 3.75—4.15 (4H, m, H-4, 5, 6, OH), 4.58 (1H, t, *J*=3.5 Hz, H-9), 5.22 (1H, q, *J*=3 Hz, H-3), 5.85 (1H, d, *J*=3.5 Hz, H-8).

Tri-*O*-acetyl Derivatives 6 and 6′ of 5 and 5′. Compounds **5** and **5′** were acetylated with acetic anhydride in pyridine. **6**: (96% yield): TLC R_f 0.61 (ethyl acetate-hexane=1 : 1); mp 66—67 °C; $[\alpha]_D^{23}$ +41.8° (*c* 0.97, $CHCl_3$); IR ν_{max}^{KBr} 2980, 2940, 1740, 1375, 1230, 1165, 1130, 1105 cm^{-1}; ^{1}H NMR δ=1.32, 1.50 (3H×2, each s, $C(CH_3)_2$), 2.00, 2.03, 2.12 (3H×3, each s, 3×$OCOCH_3$), 2.10—2.40 (3H, m, H-1, 2, 2′), 3.85 (1H, dd, $J_{1,6}$=10.5 Hz and $J_{5,6}$=3 Hz, H-6), 4.57 (1H, t, $J_{1,9}$=$J_{8,9}$=3 Hz, H-9), 4.90—5.20 (2H, m, H-3,5), 5.73—5.90 (2H, m, H-4, 8). (1*R*,3*S*,4*R*,5*S*,6*S*,8*R*,9*R*)-3,4,5-Tris(benzyloxy)-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]nonane (8). To a solution of **5** (302.5 mg, 1.05 mmol) in methanol (5 ml) was added sodium methoxide in methanol (1 mol dm^{-3} solution, 1.57 ml, 1.57 mmol) at 0 °C with stirring. The mixture was stirred at 0 °C for 30 min and neutralized by addition of Amberlite IR 120B (H^+). After removal of the resin by filtration, the filtrate was evaporated to give crude (1*R*,3*S*,4*R*,5*S*,6*S*,8*R*,9*R*)-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]-nonane-3,4,5-triol (**7**) which was *O*-benzylated without purification. Sodium hydride (60% emulsion in mineral oil, 630 mg, 15.8 mmol) was washed with hexane (1 ml×2), dried, and suspended in DMF (5 ml). To the suspension was added a DMF (10 ml) solution of crude **7** and the mixture was stirred for 10 min. Benzyl bromide (1.87 ml, 15.8 mmol) was added. After the mixture was stirred for 12 h, ethanol (1 ml) was added and evaporated. The residue was dissolved in water (80 ml) and extracted with dichloromethane (80 ml×3). The extract was dried on Na_2SO_4 and evaporated. The residue was chromatographed with silica gel (90 g, ethyl acetate-hexane=1 : 15). The fraction corresponding to R_f 0.46 (ethyl acetate-hexane=1 : 3) was evaporated to give **8** (473.8 mg, 88% yield) as a colorless syrup, $[\alpha]_D^{21}$ +36.7° (*c* 1.15, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3060, 3000, 2930, 2880, 1490, 1455, 1385, 1375, 1360, 1305, 1260, 1200 cm^{-1}; ^{1}H NMR δ=1.28, 1.45 (3H×2, each s, $C(CH_3)_2$), 1.67—2.33 (3H, m, H-1, 2, 2′), 3.88 (1H, dd, *J*=9.5 and 3 Hz, H-6), 3.53—4.00 (2H, m, H-3, 4), 4.23 (1H, t, *J*=3 Hz, H-5), 4.52 (1H, t, *J*=4.5 Hz, H-9), 4.58—4.83 (6H, m, 3×$OCH_2C_6H_5$), 5.83 (1H, d, *J*=4.5 Hz, H-8), 7.13—7.52 (15H, m, 3×$OCH_2C_6H_5$). Found: *m/z* 516.2522. Calcd for $C_{32}H_{36}O_6$: M, 516.2510.

(1*R*)-1-[(1*S*,2*S*,3*S*,4*R*,5*S*)-3,4,5-Tris(benzyloxy)-2-hydroxycyclohexyl]-1,2-ethanediol (9). A solution of **8** (161 mg, 0.31 mmol) in a mixture of 80% aqueous acetic acid (32 ml) and dioxane (1.5 ml) was refluxed for 30 min and evaporated. The residue was dissolved in ethanol (4 ml) and sodium borohydride (24 mg, 0.64 mmol) was added. After stirring for 19 h, 35% aqueous hydrogen peroxide (1 ml) was added and stirred for further 15 min. The solution was neutralized with 1 mol dm^{-3} HCl and saturated aqueous sodium sulfite (1 ml) was added. The solution was diluted with water (20 ml) and extracted with dichloromethane (20 ml×3). The extract was dried on Na_2SO_4 and evaporated. The residue was chromatographed with silica gel (12 g, ethanol-toluene=1 : 25), and the fraction corresponding to R_f 0.26 (ethanol-toluene=1 : 7) was evaporated to give **9** (84 mg, 56% yield) as a colorless syrup, $[\alpha]_D^{22}$ +4.4° (*c* 1.09, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3300, 3050, 2900, 2850, 1600, 1580, 1490, 1400, 1360, 1300, 1200 cm^{-1}; ^{1}H NMR δ=1.67—2.17 (3H, m, H-1, 6, 6′), 2.83—3.25 (1H, m, 2×OH), 3.35 (1H, dd, *J*=10 and 3 Hz, H-2), 3.45—4.23 (7H, m, H-3, 4, 5, $CH(OH)CH_2OH$, OH), 4.57—5.15 (6H, m, 3×$OCH_2C_6H_5$), 7.28—7.47 (15H, m, 3×$OCH_2C_6H_5$). Found: *m/z* 479.2407. Calcd for $C_{29}H_{35}O_6$: M+H, 479.2430.

(1*S*,2*S*,3*S*,4*R*,5*S*)-2-Acetoxy-1-acetoxymethyl-3,4,5-tris(benzyloxy)cyclohexane (10). To a solution of **9** (77 mg, 0.16 mmol) in methanol (2 ml) was added an aqueous solution (0.5 ml) of sodium periodate (38 mg, 0.18 mmol) at 0 °C with stirring. The mixture was stirred at 0 °C for 2 h and evaporated. The residue was dissolved in water (10 ml) and extracted with dichloromethane (25 ml×5). The extract was dried on Na_2SO_4 and evaporated to give crude (1*R*,2*S*,3*S*,4*R*,-5*S*)-3,4,5-tris(benzyloxy)-2-hydroxycyclohexanecarbaldehyde, which was subjected to next step without purification. The residue was dissolved in ethanol (2 ml) and sodium borohydride (12 mg, 0.32 mmol) was added. The mixture was stirred for 1 h and 35% aqueous hydrogen peroxide (0.5 ml) was added, and stirred for 15 min. The solution was neutralized with 1 mol dm^{-3} HCl and saturated sodium sulfite (0.5 ml) was added. The solution was diluted with water (60 ml) and extracted with dichloromethane (60 ml×3). The extract was dried on Na_2SO_4 and evaporated. The residue (TLC R_f 0.37, ethanol-toluene=1 : 7) was acetylated with acetic anhydride (1 ml) in pyridine (1 ml) for 14 h. The mixture was evaporated and the residue was chromatographed with silica gel (5 g, ethyl acetate-hexane=1 : 5). The fraction corresponding to R_f 0.72 (ethanol-toluene=1 : 10) was evaporated to give **10** (73 mg, 85% yield) as a colorless syrup, $[\alpha]_D^{18}$ −40.2° (*c* 1.00, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3000, 2950, 2900, 2870, 1730, 1495, 1450, 1370, 1245, 1205 cm^{-1}; ^{1}H NMR δ=1.23—1.58 (2H, m, H-6, 6′), 1.97, 2.00 (3H×2, each s, 2×$OCOCH_3$), 2.08—2.45 (1H, m, H-1), 3.43 (1H, dd, $J_{3,4}$=3 Hz and $J_{4,5}$=9 Hz, H-4), 3.83—4.24 (4H, m, H-3,5, CH_2OAc), 4.57—4.92 (7H, m, H-2, 3×$OCH_2C_6H_5$), 7.29—7.47 (15H, m, 3×$OCH_2C_6H_5$). Found: *m/z* 533.2538. Calcd for $C_{32}H_{37}O_7$: M+H, 533.2537.

(1*S*,2*S*,3*S*,4*R*,5*S*)-2,3,4,5-Tetraacetoxy-1-(acetoxymethyl)-

cyclohexane, Pentaacetate of Pseudo-β-L-allopyranose (11). A solution of **10** (53.5 mg, 0.10 mmol) in methanol (2 ml) was hydrogenolyzed in the presence of palladium-black in the Parr apparatus for 14 h. The catalyst was removed by filtration and washed with methanol. The mixture of filtrate and washing methanol was evaporated to give crude *O*-debenzylated product, which was acetylated with acetic anhydride (1 ml) in pyridine (1 ml) for 46 h. The mixture was evaporated and the residue was chromatographed with silica gel (1 g, ethyl acetate-hexane=1 : 4). The fraction corresponding to R_f 0.29 (ethyl acetate-hexane=1 : 2) was evaporated to give crystals of **11** (30.5 mg, 79% yield). **11**: Mp 135—136 °C; $[\alpha]_D^{18}$ +3.7° (*c* 1.41, $CHCl_3$); IR ν_{max}^{KBr} 1750, 1740, 1425, 1375, 1225, 1095, 1075 cm^{-1}; ^1H NMR δ=1.10—2.60 (3H, m, H-1, 6, 6′), 2.00, 2.03, 2.05, 2.14 (6H, 3H, 3H, and 3H, each s, 5×$OCOCH_3$), 4.03—4.08 (2H, m, CH_2OAc), 4.91 (1H, dd, *J*=10 and 3 Hz, H-2 or 4), 5.03—5.43 (2H, m, H-4 or 2, 5), 5.59 (1H, t, *J*=3 Hz, H-3). The ^1H NMR spectrum of **11** was identical with that of authentic DL-**11**.[8] Found: C, 52.63; H, 6.15%. Calcd for $C_{17}H_{24}O_{10}$: C, 52.57; H, 6.23%.

(3*S*,4*R*,5*S*)-3,4,5-Tris(benzyloxy)-1-cyclohexene-1-methanol (13). Compound **9** (245 mg, 0.51 mmol) was converted to a glycol-cleaved compound as described in the preparation of **10**. The crude residue extracted with dichloromethane was dissolved in pyridine (10 ml) and methanesulfonyl chloride (0.32 ml, 4.1 mmol) was added. The mixture was stirred for 14 h and evaporated. The residue was partitioned between dichloromethane (60 ml) and water (30 ml). The aqueous layer was extracted with dichloromethane (60 ml×2). The organic layer was dried on Na_2SO_4 and evaporated to give crude (3*S*,4*R*,5*S*)-3,4,5-tris(benzyloxy)-1-cyclohexenecarbaldehyde (**12**) (256 mg). To a solution of crude **12** in THF (4 ml) was added a suspension of lithium aluminium hydride (39 mg, 1.0 mmol) in THF (4 ml) at 0 °C with stirring. The mixture was stirred at 0 °C for 4 h and ethyl acetate (1 ml) was added. The resulting solids were removed with Celite pad. The filtrate was evaporated and the residue was chromatographed with silica gel (10 g, ethyl acetate-hexane=1 : 4). The fraction corresponding to R_f 0.18 (ethyl acetate-hexane=1 : 2) was evaporated to give **13** (81 mg, 37% yield) as a colorless syrup, $[\alpha]_D^{21}$ +61.7° (*c* 0.85, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3580, 3000, 2910, 2860, 1490, 1450, 1360, 1140 cm^{-1}; ^1H NMR δ=1.20—1.63 (1H, OH), 1.90—2.65 (2H, m, H-6, 6′), 3.63—4.27 (5H, m, H-3, 4, 5, CH_2OH), 4.63—4.72 (6H, m, 3×$OCH_2C_6H_5$), 5.67—5.83 (1H, m, H-2), 7.35 (15H, s, 3×$OCH_2C_6H_5$). Found: *m/z* 430.2135. Calcd for $C_{28}H_{30}O_4$: M, 430.2141.

(1*R*,2*R*,3*S*,4*R*,5*S*)-2-Acetoxy-1-acetoxymethyl-3,4,5-tris(benzyloxy)cyclohexane (14). To a solution of **13** (81 mg, 0.19 mmol) in THF (2 ml) was added borane-THF complex (1 mol dm^{-3} in THF, 0.66 ml, 0.66 mmol) at 0 °C under an argon atmosphere with stirring. The mixture was stirred at 0 °C for 20 min, and at room temperature for 2 h. To the mixture were added water (1.8 ml), 3 mol dm^{-3} aqueous NaOH (0.6 ml), and hydrogen peroxide (35 wt% in water, 0.96 ml), successively. The mixture was stirred for 2 h and 1 mol dm^{-3} HCl was added for neutralization. The solution was evaporated, and the residue was dissolved in water (30 ml), extracted with dichloromethane (30 ml×3). The extract was dried on Na_2SO_4 and evaporated. The residue was acetylated with acetic anhydride (2 ml) in pyridine (2 ml) for 12 h. The mixture was evaporated and the residue was chromatographed with silica gel (7 g, ethyl acetate-hexane=1 : 10). The fraction corresponding to R_f 0.73 (ethyl acetate-hexane=1 : 2) was evaporated to give **14** (46 mg, 47% yield) as a colorless syrup, $[\alpha]_D^{19}$ +7.0° (*c* 0.97, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3000, 2920, 2860, 1730, 1490, 1450, 1365, 1240 cm^{-1}; ^1H NMR δ=1.75—2.10 (3H, m, H-1, 6, 6′), 2.00, 2.02 (3H×2, each s, 2×$OCOCH_3$), 3.60—4.07 (5H, m, H-3, 4, 5, CH_2OAc), 4.37—4.73 (6H, m, 3×$OCH_2C_6H_5$), 5.36 (1H, t, $J_{1,2}=J_{2,3}$=10 Hz, H-2), 7.17—7.47 (15H, m, 3×$OCH_2C_6H_5$). Found: *m/z* 532.2448. Calcd for $C_{32}H_{36}O_7$: M, 532.2458.

(1*R*,2*R*,3*S*,4*R*,5*S*)-2,3,4,5-Tetraacetoxy-1-(acetoxymethyl)cyclohexane, Pentaacetate of Pseudo-α-D-mannopyranose (15). A solution of **14** (44.5 mg, 0.08 mmol) in methanol (2 ml) was hydrogenolyzed in the presence of palladium black in the Parr apparatus for 45 h. After the catalyst was removed, the filtrate was evaporated. The residue was chromatographed with silica gel (2 g, chloroform-methanol=15 : 1), and the fraction corresponding to R_f 0.42 (chloroform-methanol=8 : 1) was evaporated. The colorless syrup was acetylated with acetic anhydride (0.5 ml) in pyridine (0.5 ml) for 2 h. The mixture was evaporated, and the residue was chromatographed with silica gel (1 g, ethyl acetate-hexane=1 : 4). The fraction corresponding to R_f 0.30 (ethyl acetate-hexane=1 : 2) was evaporated to give crystals of **15** (18 mg, 56% yield). **15**: Mp 80—81 °C; $[\alpha]_D^{19}$ +27.8° (*c* 0.84, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2950, 1740, 1430, 1370, 1220 cm^{-1}; ^1H NMR δ=1.50—2.70 (3H, m, H-1, 6, 6′), 1.97, 2.03, 2.05, 2.13 (3H, 3H, 3H, and 6H, each s, 5×$OCOCH_3$), 3.87—4.27 (2H, m, CH_2OAc), 5.03—5.40 (4H, m, H-2, 3, 4, 5). The ^1H NMR spectrum of **15** was identical with that of authentic DL-**15**.[10] Found: C, 52.79; H, 6.14%. Calcd for $C_{17}H_{24}O_{10}$: C, 52.57; H, 6.23%.

(1*R*,5*R*,6*S*,8*R*,9*R*)-8,9-Isopropylidenedioxy-7-oxabicyclo[4.3.0]non-3-en-5-ol (17). To a solution of (1*R*,4*S*,5*S*,6*S*,-8*R*,9*R*)-4,5-epoxy-8,9-isopropylidenedioxy-7-oxabicyclo-[4.3.0]nonan-3-one (**16**)[3] (373 mg, 1.65 mmol) in ethanol (54 ml) were added hydrazine hydrate (0.40 ml, 8.26 mmol) and acetic acid (0.47 ml, 8.26 mmol) with stirring. The mixture was stirred for 2.5 min, and added to a saturated aqueous $NaHCO_3$ solution (170 ml). The aqueous solution was extracted with chloroform (170 ml×5). The combined extract was dried on Na_2SO_4 and evaporated. The residue was chromatographed with silica gel (13 g, ethyl acetate-hexane=1 : 3), and the fraction corresponding to R_f 0.44 (ethyl acetate-hexane=1 : 1) was evaporated to give **17** (258 mg, 74% yield), mp 95—98 °C; $[\alpha]_D^{22.5}$ −136.4° (*c* 1.00, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3490, 3000, 2900, 1635, 1460, 1440, 1420, 1380, 1320, 1305, 1250 cm^{-1}; ^1H NMR δ=1.33, 1.50 (3H×2, each s, $C(CH_3)_2$), 1.80—2.50 (4H, m, H-1, 2,2′, OH), 3.72 (1H, dd, δ=10.5 and 4.5 Hz, H-6), 4.43 (1H, t, *J*=4.5 Hz, H-5 or 9), 4.61 (1H, t, *J*=4.5 Hz, H-9 or 5), 5.70—6.10 (3H, m, H-3, 4, 8). Found: C, 62.07; H, 7.54%. Cacld for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%.

(1*S*,6*S*,8*R*,9*R*)-8,9-Isopropylidenedioxy-7-oxabicyclo[4.3.0]non-3-en-5-one (18). To a solution of **17** (128.5 mg, 0.61 mmol) in dichloromethane (12 ml) were added PCC (521 mg, 2.42 mmol) and molecular sieves (4A powder, 150 mg) with stirring. The mixture was stirred for 1.5 h and evaporated. The residue charged on a silica-gel column (10 g) was eluted with ether to give crystals of **18** (110.4 mg, 87% yield; TLC R_f 0.57, ethyl acetate-hexane=3 : 2), mp 96—98 °C; $[\alpha]_D^{24}$ −141.0° (*c* 0.70, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2975, 2925, 2825, 1700, 1595, 1445, 1425, 1370, 1320, 1300, 1240, 1210 cm^{-1}; ^1H NMR δ=1.35, 1.52 (3H×2, each s, $C(CH_3)_2$), 2.00—2.50 (1H, m,

H-1), 2.55—2.80 (2H, m, H-2, 2′), 4.45 (1H, d, J=12 Hz, H-6), 4.69 (1H, t, J=4.5 Hz, H-9), 5.88 (1H, d, J=4.5 Hz, H-8), 5.98 (1H, d, J=12 Hz, H-4), 6.91 (1H, dt, J=12 and 4.5 Hz, H-3). Found: C, 62.96; H, 6.72%. Calcd for $C_{11}H_{14}O_4$: C, 62.85; H, 6.71%.

(1*R*,5*R*,6*S*,8*R*,9*R*)-5-Acetoxy-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]non-3-ene (19). Acetylation of **17** (162 mg, 0.76 mmol) with acetic anhydride (5 ml) in pyridine (5 ml) for 14 h, and chromatographic purification with silica gel (4 g, ethyl acetate-hexane=1 : 3) gave **19** (191 mg, 98% yield), TLC R_f 0.47 (ethyl acetate-hexane=1 : 2); mp 121—122 °C; $[\alpha]_D^{24}$ −262.1° (c 0.62, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3040, 2975, 2925, 2875, 1730, 1630, 1450, 1370, 1330, 1290, 1250 cm^{-1}; ^{1}H NMR δ=1.33, 1.46 (3H×2, each s, $C(CH_3)_2$), 2.03 (3H, s, $OCOCH_3$), 2.10—2.50 (3H, m, H-1, 2, 2′), 3.86 (1H, dd, J=12 and 4.5 Hz, H-6), 4.60 (1H, t, J=4.5 Hz, H-9), 5.50 (1H, t, J=4.5 Hz, H-5), 5.70—6.20 (3H, m, H-3, 4, 8). Found: C, 61.16; H, 7.11%. Calcd for $C_{13}H_{18}O_5$: C, 61.40; H, 7.13%.

(1*R*,3*S*,4*S*,5*S*,6*S*,8*R*,9*R*)-5-Acetoxy-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]nonane-3,4-diol (20). To a solution of **19** (190 mg, 0.74 mmol) in t-butyl alcohol (4 ml) were added osmium tetraoxide in t-butyl alcohol (0.02 mol dm^{-3} solution, 0.37 ml, 0.007 mmol) and hydrogen peroxide (35% in water, 0.26 ml) with stirring. The mixture was stirred for 88 h in dark. The mixture was evaporated and the residue was chromatographed with silica gel (15 g, ethyl acetate-hexane=1 : 2). The fraction corresponding to R_f 0.37 (ethanol-toluene=1 : 6) was evaporated to give crystals of **20** (75 mg, 35% yield), mp 174—175 °C; $[\alpha]_D^{22}$ −0.19 ° (c 0.90, MeOH); IR ν_{max}^{KBr} 3500, 3450, 2990, 1725, 1375, 1255 cm^{-1}; ^{1}H NMR δ=1.31, 1.52 (3H×2, each s, $C(CH_3)_2$), 1.70—2.10 (5H, m, H-1, 2, 2′,2×OH), 2.07 (3H, s, $OCOCH_3$), 3.66—4.35 (3H, m, H-3, 4, 6), 4.56 (1H, t, J=4.5 Hz, H-9), 5.43 (1H, t, J=3 Hz, H-5), 5.81 (1H, d, J=4.5 Hz, H-8). Found: C, 54.31; H, 6.83%. Calcd for $C_{13}H_{20}O_7$: C, 54.15; H, 6.99%.

(1*R*,3*S*,4*S*,5*S*,6*S*,8*R*,9*R*)-3,4,5-Triacetoxy-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]nonane (21). Acetylation of **20** (23 mg, 0.08 mmol) with acetic anhydride (1 ml) in pyridine (1 ml), and chromatographic purification with silica gel (2 g, ethyl acetate-hexane=1 : 3) gave crystals of **21** (27 mg, 90% yield, TLC R_f 0.71 (ethanol-toluene=1 : 6); mp 135—137 °C; $[\alpha]_D^{22}$ +28.5° (c 0.94, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2990, 2930, 1745, 1370, 1250 cm^{-1}; ^{1}H NMR δ=1.30, 1.52 (3H×2, each s, $C(CH_3)_2$), 1.80—2.40 (3H, m, H-1, 2, 2′), 1.99, 2.10 (3H and 6H, each s, 3×$OCOCH_3$), 4.05 (1H, dd, J=10.5 and 3 Hz, H-6), 4.58 (1H, t, J=4.5 Hz, H-9), 4.90—5.56 (3H, m, H-3,4,5), 5.83 (1H, d, J=4.5 Hz, H-8). Found: C, 55.12; H, 6.50%. Calcd for $C_{17}H_{24}O_9$: C, 54.83; H, 6.50%.

(1*R*,3*S*,4*S*,5*R*,6*S*,8*R*,9*R*)- and (1*R*,3*R*,4*R*,5*S*,6*S*,8*R*,9*R*)-4,5-Epoxy-8,9-isopropylidenedioxy-7-oxabicyclo[4.3.0]nonan-3-ol, (22) and (22′). A solution of inseparable mixture of **2** and **2′** (106 mg, 0.50 mmol) in dichloromethane (4 ml) containing MCPBA (429 mg, 2.5 mmol) was refluxed for 41 h. The solution diluted with water (20 ml) was extracted with dichloromethane (20 ml×6). The combined extract was washed with saturated aqueous sodium sulfite (30 ml), dried on Na_2SO_4, and evaporated. The residue was chromatographed with silica gel (13 g, ethyl acetate-hexane=1 : 7). The fraction corresponding to R_f 0.29 (ethyl acetate-hexane=2 : 1) was evaporated to give **22′**[3] (18 mg, 16% yield), which was identical with authentic sample in TLC, mp, and ^{1}H NMR. The fraction corresponding to R_f 0.23 was evaporated to give crystals of **22** (57 mg, 50% yield), mp 159—161 °C; $[\alpha]_D^{21}$ −21.0° (c 1.00, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3560, 3000, 2850, 1460, 1380, 1300, 1265, 1255, 1215 cm^{-1}; ^{1}H NMR δ=1.30, 1.50 (3H×2, each s, $C(CH_3)_2$), 1.12—2.24 (3H, m, H-1, 2, 2′), 2.49—2.75 (1H, br, OH), 3.32 (1H, t, J=3 Hz, H-5), 3.58—3.83 (2H, m, H-4,6), 4.04—4.32 (1H, m, H-3), 4.51 (1H, t, J=4 Hz, H-9), 5.85 (1H, d, J=4 Hz, H-8). Found: C, 57.52; H, 6.90%. Calcd for $C_{11}H_{16}O_5$: C, 57.88; H, 7.07%.

Solvolysis of 22 and Successive Acetylation. Compound **21** from **22**. A solution of **22** (36 mg, 0.16 mmol) in a mixture of water and 2-methoxyethanol (3 : 10 v/v, 5 ml) in the presence of sodium acetate (39 mg, 0.48 mmol) was refluxed for 47 h and evaporated. The residue was acetylated with acetic anhydride (1.3 ml) in pyridine (1.3 ml) for 2 h. After the mixture was condensed by evaporation, the residue was partitioned between dichloromethane (10 ml) and water (10 ml). The aqueous layer was extracted with dichloromethane (10 ml×2). The organic layer was dried on Na_2SO_4 and evaporated. The residue was chromatographed with silica gel (5 g, ethyl acetate-hexane=1 : 4 to 1 : 3), and the fraction corresponding to R_f 0.59 (ethanol-toluene=1 : 6) was evaporated to give **21** (46 mg, 79%), which was identical with the compound prepared from **19** in TLC, mp, $[\alpha]_D$, and ^{1}H NMR.

The authors express their sincere thanks to Professor Seiichiro Ogawa of Keio University for his valuable discussion on the structural identification of the synthesized pseudo-sugars, and to Mr. Akio Takahashi for elemental analyses.

Chemical Synthesis of a Biosynthetic Precursor of Lipid A with a Phosphorylated Tetraacyl Disaccharide Structure

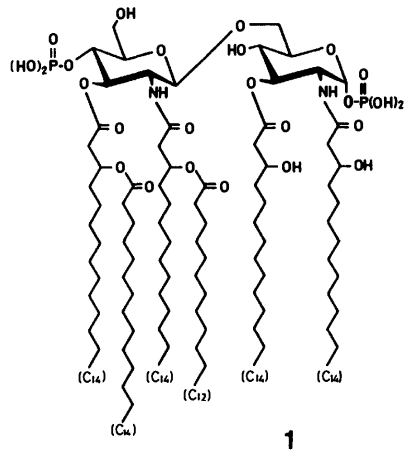
Masahiro IMOTO, Hiroyuki YOSHIMURA, Michiharu YAMAMOTO, Tetsuo SHIMAMOTO, Shoichi KUSUMOTO, and Tetsuo SHIBA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

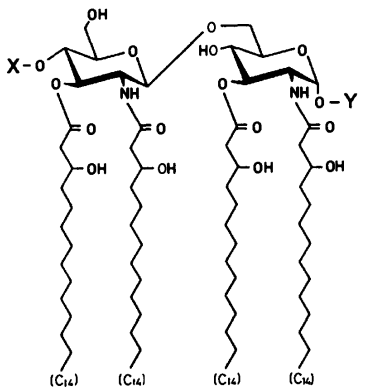
(Received December 15, 1986)

2,2′-*N*:3,3′-*O*-Tetrakis[(*R*)-3-hydroxytetradecanoyl]-β(1-6)-D-glucosamine disaccharide 1,4′-bis(phosphate) and its dephospho derivatives were synthesized. The bisphosphate prepared was shown to be identical with a natural biosynthetic precursor of lipid A which corresponds to the lipophilic part of lipopolysaccharide (LPS) in bacterial cell wall. The synthetic bis- and monophosphates exhibited many of typical endotoxic activities of LPS. Consequently, this work established the chemical structure of the biosynthetic precursor of lipid A and elucidated the fundamental structure required for the expression of these activities.

Gram-negative bacteria contain in their cell surface a toxic principle which causes fever and lethal shock in higher animals. This toxin is called endotoxin since it is firmly bound to the cells in living bacteria and released only after the cells are destroyed. Endotoxin exhibits not only undesired toxic activities mentioned above but also beneficial ones such as stimulation of immune responses and induction of a tumor-necrotizing factor.[1] These toxic and beneficial biological activities have been shown to be attributed to the lipopolysaccharide (LPS) moiety which is a complex amphipathic molecule characteristic of the outer membrane of Gram-negative bacterial cells.[1] In 1954, Westphal and Lüderitz[2] isolated the lipophilic part of LPS by mild acidic hydrolysis and termed it "lipid A". They described that lipid A manifested most of the endotoxic activities of LPS. Although there had been some confusions due to the heterogeneous character of natural lipid A preparations,[3] this concept was unequivocally confirmed by our recent total synthesis of *Escherichia coli* lipid A (**1**).[4] In this paper we described in detail a total synthesis of a biosynthetic precursor (**2**) of lipid A and its dephospho derivatives. As reported previously in a preliminary form,[5] this synthetic work was the first successful chemical construction of a compound possessing definite endotoxic activities.[6]



1



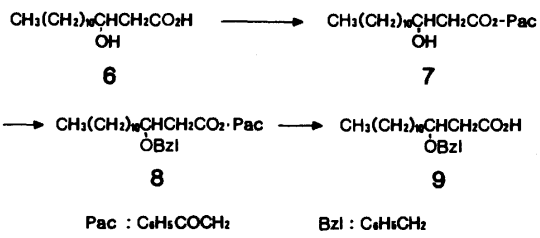
2 X = Y = PO(OH)$_2$
3 X = PO(OH)$_2$, Y = H
4 X = H, Y = PO(OH)$_2$
5 X = Y = H

The chemical structure of lipid A had been studied by the group of Westphal.[1] They demonstrated that lipid A's from many bacterial species share a common basic structure composed of polyacylated D-glucosamine β(1→6) disaccharide 1,4′-bis(phosphate). However, because of the heterogeneity of natural lipid A preparations studied before our synthetic work, the exact number and location of acyl groups could not be determined, the positions of acylation being rather tentatively assigned to the 2,2′-amino and 3,4,6′-hydroxyl groups. Since this assignment then proved incorrect by our synthesis of corresponding compounds,[7] we started a structural study on a purified main component of *E. coli* lipid A and elucidated that the bisphosphorylated disaccharide backbone is acylated at 2,2′-amino and 3,3′-hydroxyl groups with four moles of (*R*)-3-hydroxytetradecanoic acid[8] which is a typical constituent acid of LPS.

With this information, we took the structure **2** as the first target of our synthesis in order to confirm the newly proposed acylation pattern. We already knew that a biosynthetic precursor of lipid A which contained only four moles of 3-hydroxytetradecanoic acid possessed most of endotoxic activities.[9,10] The precursor designated "acidic precursor" and now renamed "precursor Ia"[11] was first isolated from a temperature-sensitive mutant of *Salmonella typhimurium*.[12] The location of the fatty acids in precursor Ia had not been determined but the structure **2** could be most reasonably assigned to it by taking our results on *E. coli* lipid A into consideration.[13]

The strategy for the synthesis was decided on the basis of our knowledges accumulated during the previous works[7] on the compounds with the incorrect old-type acylation pattern. Thus the target compound **2** was constructed via the following steps: 1) preparation of a $\beta(1\rightarrow6)$ disaccharide without long-chain acyl groups, 2) introduction of 3-benzyloxytetradecanoic acids to the two amino and two hydroxyl groups of the disaccharide, 3) phosphorylation of 4′-position, 4) phosphorylation of the glycosidic position, 5) hydrogenolytic deprotection. Phosphorylation of the glycosidic position had to be carried out at the last stage of the synthesis, since glycosyl phosphates are unstable. Thus, the 1-hydroxyl function was protected with allyl group which could be removed without affecting other functional and protecting groups. For persistent protection of other hydroxyl and 4′-phosphate groups were used benzyl and phenyl groups respectively.

In order to investigate the role of phosphate moieties for the biological activities, the corresponding monophosphates (**3** and **4**) and the dephospho derivative **5** were also prepared by slight modification of the synthetic route.



(*R*)-3-Benzyloxytetradecanoic acid (**9**) was prepared from optically pure (*R*)-3-hydroxytetradecanoic acid (**6**)[14] via the corresponding phenacyl ester **7**. For the next *O*-benzylation of **7**, strongly basic conditions should not be used since the 3-benzyloxy derivative formed was susceptible to base-induced β-elimination. Acid catalyzed *O*-benzylation by means of benzyl trichloroacetimidate-trifluoromethanesulfonic acid[15] proved to be preferable to the benzyl bromide-silver(I) oxide method employed in our previous work.[7] With the former method, a comparable yield of the benzylated product **8** could be obtained in a much shorter reaction time. The phenacyl group of **8** was removed with zinc dust in acetic acid to give the 3-benzyloxy acid **9**.

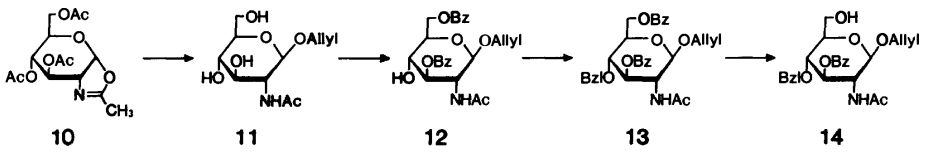
As the glycosyl acceptor was designed the compound **14**, whose 4-hydroxyl function was protected with persistent benzyl group and glycosidic position with allyl group for the reasons mentioned above. The starting material, β-allyl glycoside of *N*-acetyl-D-glucosamine (**11**), was prepared from D-glucosamine hydrochloride via peracetylated oxazoline **10** obtained by the new method, which is suitable for a large-scale preparation of the oxazoline **10**. Compound **11** thus obtained was selectively benzoylated with benzoyl chloride-pyridine at low temperature (−65 °C) to afford the 3,6-dibenzoate **12**.[16] Acid-catalyzed benzylation[15] of **12** gave 4-*O*-benzylated derivative **13**. Under these conditions, the *N*-acetyl group was partially converted into benzyl imidate, which could be reconverted to *N*-acetyl group via mild acidic hydrolysis and reacetylation. Compound **13** was purified by column chromatography on DIAION HP-20 (high-porous polystyrene gel). The recovered starting material **12** and trichloroacetamide formed from the reagent were readily removed by this chromatography. The benzoyl group on the primary hydroxyl function of **13** was selectively split off by transesterification to afford the glycosyl acceptor **14**.

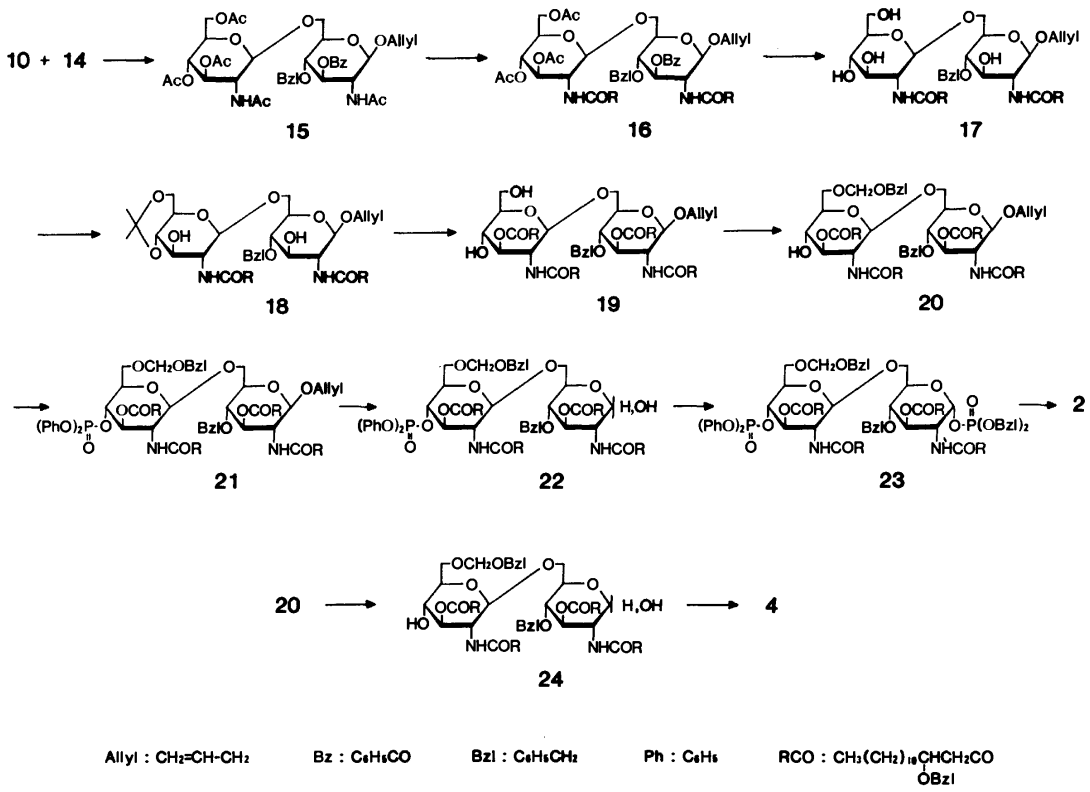
Coupling of **14** with the oxazoline **10** yielded a disaccharide **15**. The β-configuration of the newly formed glycosidic linkage was confirmed by the coupling constant value (8 Hz) of the signal due to the anomeric proton in the ^{1}H NMR spectrum of **15**.

The next step in the synthesis was introduction of 3-benzyloxytetradecanoic acid (**9**) into the disaccharide backbone. Both *N*-acetyl groups of the disaccharide **15** were cleaved by an action of Meerwein's reagent, triethyloxonium tetrafluoroborate, followed by acid hydrolysis of the resultant imidates. The free amino functions were acylated with 3-benzyloxy acid **9** and dicyclohexylcarbodiimide (DCC) to give *N,N*′-diacylated disaccharide **16**. Thereafter all the ester-type protecting groups of **16** were removed and the 4′- and 6′-hydroxyl groups were protected by isopropylidenation. The remaining two hydroxyl functions on 3- and 3′-position of **18** were acylated with 3-benzyloxy acid **9**, DCC, and 4-dimethylaminopyridine (DMAP). Hydrolysis of the isopropylidene group afforded the product **19**, which possessed four acyl groups at the desired positions.

After protection of the primary hydroxyl function of **19** by benzyloxymethylation, the hydroxyl function on 4′-position of the product **20** was phosphorylated with diphenyl phosphorochloridate-pyridine-DMAP according to the procedure by Szabo et al.[17] to give **21**.

The final two steps of the synthesis were the introduction of the 1-α-phosphate moiety and deprotection.





Thus, the glycosidic allyl group of **21** was removed by two-step conversion. It was first isomerized into 1-propenyl group with 1,5-cyclooctadienebis(methyldiphenylphosphine)iridium hexafluorophosphate[18] and then cleaved off by an action of iodine in aqueous THF[19] to afford the compound **22** with a free glycosidic position. 1-α-Phosphorylation of **22** was accomplished by using butyllithium-dibenzyl phosphorochloridate.[20] The protected 1-α,4′-bis(phosphate) **23** thus obtained was immediately hydrogenolyzed in order to prevent a decomposition of the labile dibenzyl ester of the glycosyl phosphate. After removal of all the benzyl-type groups with palladium catalyst, the phenyl groups on the 4′-phosphate were hydrogenolyzed with platinum.

The final product **2** was isolated by silica-gel column chromatography. Although **2** showed a behavior identical with that of natural precursor Ia in TLC analysis, the solubility of the former in water was lower than that of the natural compound. This seemed to be due to the formation of salts at the phosphate residues with inorganic cations from silica gel. It is known that the solubility as well as the biological activities of lipid A's are much influenced by counter cations of phosphate moieties.[21] Therefore the synthetic product was once converted into the free acid form and then to the triethylammonium salt, which is the most soluble form in water, by the following procedures. An aqueous suspension of synthetic **2**, the pH of which was adjusted to 9 with triethylamine, was electrodialyzed[21] under the conditions described in the experimental part. By this procedure, the solubility of the material increased considerably, but it was found that the phosphate groups still formed a monobasic salt as judged from TLC analysis after treatment with diazomethane. Removal of cations was completed by acidic precipitation method.[22] By addition of cold diluted hydrochloric acid to an aqueous solution of the electrodialyzed material under ice-cooling, pure **2** of free acid form was precipitated. The material thus obtained gave a satisfactory result in elemental analysis. The sample was supplied for biological tests as bis(triethylammonium) salt, which was prepared by lyophilization from aqueous solution of **2** after addition of a calculated amount of triethylamine.

The 4′-phosphate **3** was prepared by direct deprotection of the above intermediate **22**. Thus, the benzyl and phenyl groups of **22** were cleaved by hydrogenolysis with palladium and platinum respectively. In order to remove inorganic impurities resulted from catalyst, the product was subjected to the acidic precipitation method to afford the pure 4′-monophosphate **3**. This compound gave the same R_f value on silica-gel TLC with the corresponding 4′-monophosphate which was derived from natural precursor Ia by mild acidic hydrolysis of the unstable glycosyl phosphate. For more strict identification, synthetic and natural 4′-monophosphates were converted into the dimethyl esters by treatment with ethereal diazomethane. Both dimethyl esters of 4′-phosphate were indistinguishable on TLC as well as 360 MHz ^{1}H NMR spectrometry.

1-Monophosphate **4** was derived from the intermediate **20** by removal of the glycosidic allyl group followed by 1-*O*-phosphorylation. Since the reactivity of the hindered 4′-hydroxyl group is much lower than that of the glycosidic hydroxyl group, selective phos-

phorylation of the latter position of **24** was accomplished with a limited amount of butyllithium and dibenzyl phosphorochloridate.[7] Hydrogenolytic deprotection followed by column chromatography on silica gel afforded the desired 1-monophosphate **4**, which was purified by means of electrodialysis and acidic precipitation as described for **2**. Dephospho derivative **5** was prepared from the nonphosphorylated intermediate **19** by direct deprotection.

As had already been reported elsewhere,[6] the synthetic bisphosphate **2** showed fully identical biological activities with those of natural biosynthetic precursor obtained from *Salmonella*. The activities include lethal toxicity, B-cell mitogenicity, induction of interferon and so on.[23] These results together with the NMR spectroscopic and TLC identification of the synthetic and natural compounds described above led us to the following unequivocal conclusions. First, biosynthetic precursor Ia of lipid A has the structure formulated as **2**. Secondly, our new proposal of the location of the acyl groups on the disaccharide backbone[8] was correct. Finally, at least the most of the typical biological activities[23] of bacterial endotoxin can be attributed to this type of phosphorylated acyl disaccharide, which is now synthetically accessible.

Furthermore, this work demonstrated for the first time that a precise study became possible on the relationship between the chemical structures and biological activities of lipid A analogs by synthetic approaches. For example, the importance of the phosphate moieties was elucidated by a comparative study on the biological activities of the above synthetic derivatives: The two monophosphates **3** and **4** exhibited somewhat weaker than **2** but definite endotoxic activities whereas the dephospho derivative **5** was completely inactive.[6] Further synthetic studies in this line is described in the accompanying paper.

Experimental

All melting points are uncorrected. ^{1}H NMR spectra were measured on a Varian XL-100-15 spectrometer (100 MHz) or a JEOL PMX-60 spectrometer (60 MHz) for chloroform-*d* solutions unless noted otherwise. The chemical shifts are given in δ values with TMS as the internal standard. Optical rotations were measured with a Perkin-Elmer 141 polarimeter. High resolution EI-MS was obtained on a JEOL O1-SG mass spectrometer. Conventional and medium-pressure (2—4 kg cm^{-2}) column chromatography were carried out with Kieselgel 60 (E. Merck), 0.063—0.2 mm and 0.040—0.063 mm, respectively. Precoated Kieselgel F_{254} plates (0.5 mm thickness; E. Merck) were used for preparative TLC. For electrodialysis and acidic precipitation procedures was used a pyrogen-free water (Otsuka). Organic solutions were dried over magnesium sulfate and evaporated in vacuo.

Phenacyl (*R*)-3-Hydroxytetradecanoate (7). To a suspension of (*R*)-3-hydroxytetradecanoic acid (**6**) (21.8 g, 89.2 mmol) in ethyl acetate (400 ml) were added phenacyl bromide (19.1 g, 96.0 mmol) and triethylamine (10.6 g, 105 mmol) at 0 °C. The mixture was stirred at 0 °C for 10 min then at room temperature overnight. The precipitate was filtered off and the filtrate was washed with water, dried, and evaporated. The residue was recrystallized from hexane; yield 30.0 g (94%); mp 76—77 °C; $[\alpha]_D^{11}$ −5.1° (*c* 2.17, chloroform). Found: C, 72.88; H, 9.42%. Calcd for $C_{22}H_{34}O_4$: C, 72.89; H, 9.45%. ^{1}H NMR (60 MHz) δ=0.9 (3H, br t, CH_3), 1.1—1.7 (20H, br s, CH_2), 2.6 (2H, m, -$COCH_2$-), 3.1 (1H, s, -OH), 4.1 (1H, m, -C<u>H</u>(OH)-), 5.4 (2H, s, -$C\underline{H}_2COC_6H_5$), and 7.3—8.0 (5H, m, aromatic H).

Phenacyl (*R*)-3-Benzyloxytetradecanoate (8). To a solution of **7** (36.2 g, 100 mmol) and benzyl trichloroacetimidate (30.0 g, 119 mmol) in anhydrous dichloromethane (500 ml) was added dropwise trifluoromethanesulfonic acid (1.8 ml, 20 mmol) at 0 °C under argon atmosphere. After stirring at 0 °C for 2 h, the mixture was washed with a saturated aqueous solution of sodium hydrogencarbonate and water, dried, and concentrated. The residue was subjected to silica-gel column chromatography (1 kg). Elution with benzene gave a syrup; yield 33.3 g (74%). ^{1}H NMR (60 MHz) δ=0.9 (3H, br t, CH_3), 1.0—1.8 (20H, br s, CH_2), 2.8 (2H, AB-type, -$COCH_2$-), 3.9 (1H, m, -C<u>H</u>($OCH_2C_6H_5$)-), 4.5 (2H, s, -$C\underline{H}_2C_6H_5$), 5.3 (2H, s, -$COOCH_2$-), 7.1—7.9 (5H, m, -COC_6H_5), and 7.3 (5H, s, -$CH_2C_6\underline{H}_5$).

Further elution with benzene-ethyl acetate (9 : 1) gave the starting material **7**, which was recrystallized from hexane; 8.5 g (19 %).

(*R*)-3-Benzyloxytetradecanoic Acid (9). Zinc dust (30 g) was added to a solution of **8** (33.3 g, 73.6 mmol) in acetic acid (650 ml) and the mixture was stirred at 50 °C. After 2 h zinc dust (15 g) was added and the mixture was stirred for additional 1 h. Insoluble materials were filtered and washed with ethyl acetate. After evaporation of the solvent, the residue was dissolved in ethyl acetate, washed with water, dried, and concentrated. The residue was subjected to silica-gel column chromatography (500 g). The product eluted with chloroform–methanol (3 : 1) was dissolved in ethyl acetate, washed with 1 M† hydrochloric acid and water, and dried. Evaporation of the solvent gave a colorless syrup, which was used for the following reactions without further purification; yield 19.8 g (80%); $[\alpha]_D^{17}$ −6.6° (*c* 3.65, chloroform). EI-MS: *m/z* 334 (M^+). Found: C, 75.64; H, 10.10%. Calcd for $C_{21}H_{34}O_3$: C, 75.40; H, 10.34%. ^{1}H NMR (60 MHz) δ=0.9 (3H, br t, CH_3), 1.0—1.7 (20H, br s, CH_2), 2.6 (2H, d, J=7 Hz, -$COCH_2$-), 3.9 (1H, m, -C<u>H</u>($OCH_2C_6H_5$)-), 4.6 (2H, s, -$C\underline{H}_2C_6H_5$), and 7.3 (5H, s, aromatic H).

3,4,6-Tri-*O*-acetyl-2-amino-2-deoxy-1-α-*O*:2-*N*,*N*-ethylidyne-D-glucopyranose (10). 2-Acetamido-1,3,4,6-tetra-*O*-acetyl-2-deoxy-D-glucopyranose (100 g, 0.257 mol) was dissolved in anhydrous chloroform (1 l). The solution was saturated with dry hydrogen bromide at 0 °C and left overnight at room temperature in a stoppered flask. Pyridine (100 ml) was added dropwise to the mixture over 10 min at 0 °C with stirring. After stirring for additional 20 min at room temperature, the mixture was washed with water, dried, and evaporated. The residual pyridine was removed by coevaporation with toluene three times. The pale yellow syrup thus obtained was used for the following step without further purification; yield 79.4 g (94%). High resolution EI-MS Found: *m/z* 329.1092. Calcd for $C_{14}H_{19}NO_8$: M, 329.1111. ^{1}H NMR (60 MHz) δ=2.1 (12H, s, CH_3), 3.6 (1H, dt, $J_{5,4}$=8 Hz, $J_{5,6}$=4 Hz, H-5), 4.1 (1H, m, H-2), 4.2 (2H, d, $J_{6,5}$=4 Hz,

† 1 M=1 mol dm^{-3}.

H-6), 4.9 (1H, dd, $J_{4,3}$=2 Hz, $J_{4,5}$=4 Hz, H-4), 5.2 (1H, t, $J_{3,2}$=$J_{3,4}$=2 Hz, H-3), and 5.9 (1H, d, $J_{1,2}$=8 Hz, H-1).

Allyl 2-Acetamido-3,6-di-*O*-benzoyl-2-deoxy-β-D-glucopyranoside (12). Allyl 2-acetamido-2-deoxy-β-D-glucopyranoside (**11**) was prepared by heating a solution of oxazoline **10** in chloroform with allyl alcohol and *p*-toluenesulfonic acid followed by removal of *O*-acetyl groups with 0.01 M sodium methoxide; mp 173—175 °C.

To a solution of **11** (10.0 g, 76.0 mmol) in pyridine (200 ml) and THF (90 ml) was added benzoyl chloride (30.6 ml, 264 mmol) dropwise at −65 °C. The mixture was stirred at −60 °C for 1 h. After addition of water (150 ml), the mixture was concentrated. The residue was dissolved in ethyl acetate and worked up as usual, and the product was recrystallized from ethyl acetate; yield 24.7 g (69%); mp 194—195 °C; $[\alpha]_D^{19}$ +2.1° (*c* 1.02, chloroform). Found: C, 62.77; H, 5.80; N, 2.99%. Calcd for $C_{25}H_{27}NO_8 \cdot 0.5H_2O$: C, 62.75; H, 5.90; N, 2.93%. ^{1}H NMR (100 MHz) δ=1.82 (3H, s, NAc), 4.74 (1H, d, *J*=9 Hz, H-1), 5.04—5.35 (2H, m, $-OCH_2CH=C\underline{H}_2$), 5.66—6.04 (1H, m, $-OCH_2C\underline{H}=CH_2$), 6.12 (1H, d, *J*=9 Hz, NH), and 7.2—8.1 (10H, m, aromatic H).

Allyl 2-Acetamido-3,6-di-*O*-benzoyl-4-*O*-benzyl-2-deoxy-β-D-glucopyranoside (13). To a solution of **12** (30.0 g, 63.9 mmol) and benzyl trichloroacetimidate (56.5 g, 244 mmol) in anhydrous dichloromethane (1.5 l) was added trifluoromethanesulfonic acid (8.5 ml, 96 mmol) at −45 °C under argon atmosphere. The mixture was stirred overnight at 4 °C. After addition of saturated aqueous sodium hydrogencarbonate, the organic layer was washed with water, dried, and evaporated. The oily residue was dissolved in THF (300 ml) and treated with 1 M hydrochloric acid (130 ml) at room temperature for 1 h. To the solution were added triethylamine (30 ml) and acetic anhydride (13.5 ml). The mixture was stirred overnight at room temperature. After removal of the insoluble materials, the filtrate was concentrated. The residue was subjected to column chromatography on DIAION HP-20 (2 l). Elution by 70% aqueous methanol afforded first trichloroacetamide and then the starting material **12** which was recrystallized from ethyl acetate: 4.6 g (15%). The product was eluted by methanol and recrystallized from ethyl acetate; yield 17.2 g (48%); mp 160—162 °C; $[\alpha]_D^{15}$ +2.5° (*c* 1.21, chloroform). Found: C, 68.39; H, 5.96; N, 2.51%. Calcd for $C_{32}H_{33}NO_8$: C, 68.68; H, 5.94; N, 2.50%. ^{1}H NMR (100 MHz) δ=1.82 (3H, s, NAc), 5.02—5.34 (2H, m, $-OCH_2CH=C\underline{H}_2$), 5.58 (1H, dd, *J*=8 and 10 Hz, H-3), 5.68—6.07 (1H, m, $-OCH_2C\underline{H}=CH_2$), 7.06 (5H, s, $-CH_2C_6\underline{H}_5$), and 7.2—8.2 (10H, m, $-COC_6H_5$).

Allyl 2-Acetamido-3-*O*-benzoyl-4-*O*-benzyl-2-deoxy-β-D-glucopyranoside (14). Compound **13** (16.7 g, 30.0 mmol) was treated with 0.02 M sodium methoxide (600 ml) at 0 °C for 6 h. After neutralization with Dowex 50 (H^+ form) and silica-gel column chromatography (300 g, chloroform–methanol 9:1) the product was recrystallized from ethyl acetate–hexane; yield 10.8 g (79%); mp 165—167 °C (with sintering at 137 °C); $[\alpha]_D^{19}$ −54.1° (*c* 2.06, chloroform). Found: C, 66.01; H, 6.44; N, 3.06%. Calcd for $C_{25}H_{29}NO_7$: C, 65.92; H, 6.42; N, 3.07%. ^{1}H NMR δ=1.83 (3H, s, NAc), 4.60 (1H, d, *J*=8 Hz, H-1), 4.61 (2H, s, $-C\underline{H}_2C_6H_5$), 5.02—5.36 (2H, m, $-OCH_2-CH=C\underline{H}_2$), 5.51 (1H, dd, *J*=9 and 10 Hz, H-3), 5.68—6.08 (1H, m, $-OCH_2-C\underline{H}=CH_2$), 6.20 (1H, d, *J*=9 Hz, NH), 7.14 (5H, s, $-CH_2C_6\underline{H}_5$), and 7.3—8.1 (5H, m, $-COC_6H_5$).

Allyl 2-Acetamido-6-*O*-(2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosyl)-3-*O*-benzoyl-4-*O*-benzyl-2-deoxy-β-D-glucopyranoside (15). A solution of **10** (13.0 g, 39.6 mmol), **14** (9.0 g, 19.8 mmol), and *p*-toluenesulfonic acid (1.5 g, 7.0 mmol) in anhydrous chloroform (450 ml) was heated under reflux for 7 h. After cooling, the mixture was washed with aqueous sodium hydrogencarbonate and water, dried, and concentrated. The residue was subjected to column chromatography on silica gel (500 g, chloroform–acetone 3:1) and recrystallized from methanol; yield 10.0 g (64% based on **10**); mp 222—224 °C (decomp); $[\alpha]_D^{17}$ −38.1° (*c* 0.43, chloroform). Found: C, 59.38; H, 6.16; N, 3.57%. Calcd for $C_{39}H_{48}N_2O_{15}$: C, 59.68; H, 6.16; N, 3.57%. ^{1}H NMR (100 MHz, $CDCl_3$–CD_3OD) δ=1.82 and 1.87 (each 3H, s, NAc), 2.02 (9H, s, OAc), 4.52 (1H, d, *J*=8 Hz, anomeric H), 4.52 (2H, s, $-C\underline{H}_2C_6H_5$), 4.82 (1H, d, *J*=8 Hz, anomeric H), 5.67—6.08 (1H, m, $-OCH_2C\underline{H}=CH_2$), 7.14 (5H, s, $-CH_2C_6\underline{H}_5$), and 7.3—8.1 (5H, m, $-COC_6H_5$).

Allyl 6-*O*-[3,4,6-Tri-*O*-acetyl-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-β-D-glucopyranosyl]-3-*O*-benzoyl-4-*O*-benzyl-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-β-D-glucopyranoside (16). To a solution of **15** (8.2 g, 10.4 mmol) in anhydrous dichloromethane (300 ml) were added anhydrous potassium carbonate and triethyloxonium tetrafluoroborate (6.0 g, 31.2 mmol). After stirring at room temperature for 13 h, insoluble materials were filtered off, the filtrate washed with aqueous sodium hydrogencarbonate and water, dried, and evaporated. To a solution of the residue in THF (180 ml) was added 1 M hydrochloric acid (20.8 ml). After stirring for 3 h at room temperature, the mixture was concentrated and coevaporated with anhydrous benzene three times. To a solution of the residue in anhydrous THF (250 ml), 3-benzyloxytetradecanoic acid (**9**) (10.5 g, 31.3 mmol) and DCC (6.47 g, 31.2 mmol) were added at 0 °C. The mixture was stirred for 19 h at room temperature, and then a small amount of acetic acid was added. After removal of the precipitate by filtration, ethereal diazomethane was added to the filtrate. The product was purified by silica-gel chromatography (300 g, chloroform–acetone 9:1) and recrystallized from ethyl acetate–hexane; yield 5.8 g (41%); mp 165—169 °C; $[\alpha]_D^{18}$ −13.2° (*c* 1.11, chloroform). Found: C, 68.99; H, 8.15; N, 2.01%. Calcd for $C_{77}H_{108}N_2O_{17} \cdot 0.5H_2O$: C, 68.88; H, 8.18; N, 2.09%. ^{1}H NMR (100 MHz) δ=0.90 (6H, t, *J*=6 Hz, CH_3), 1.1—1.5 (40H, br s, CH_2), 1.98 (3H, s, OAc), 2.01 (6H, s, OAc), 2.24—2.42 (4H, m, α-CH_2 of fatty acids), 6.31 (1H, d, *J*=9 Hz, NH), 6.41 (1H, d, *J*=9 Hz, NH), and 7.0—8.1 (20H, m, aromatic H).

Allyl 4-*O*-Benzyl-2-[(*R*)-3-benzyloxytetradecanoylamino]-6-*O*-[2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-β-D-glucopyranosyl]-2-deoxy-β-D-glucopyranoside (17). To a solution of **16** (15.0 g, 11.2 mmol) in methanol (225 ml) and THF (225 ml) was added 1 M sodium methoxide (22.4 ml). After stirring at room temperature for 5 h, the mixture was neutralized with Dowex 50 (H^+ form). The solvent was evaporated and the residue recrystallized from methanol; yield 10.4 g (84%); mp 193—197 °C (decomp); $[\alpha]_D^{18}$ −18.3° (*c* 1.04, chloroform–methanol 3:1). Found: C, 68.04; H, 8.87; N, 2.42%. Calcd for $C_{64}H_{98}N_2O_{13} \cdot 1.5H_2O$: C, 68.00; H, 9.01; N, 2.48%. ^{1}H NMR (100 MHz, $CDCl_3$–CD_3OD) δ=0.90 (6H, br t, CH_3), 1.2—1.4 (40H, br s, CH_2), 2.34—2.56 (4H, m, α-CH_2 of fatty acids), 5.6—6.0 (1H, m, $-OCH_2C\underline{H}=CH_2$), and 7.25—7.4 (15H, br s, aromatic H).

Allyl 4-*O*-Benzyl-2-[(*R*)-3-benzyloxytetradecanoylamino]-6-*O*-[2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-4,6-*O*-isopropylidene-β-D-glucopyranosyl]-2-deoxy-β-D-glucopyr-

anoside (18). A mixture of **17** (10.0 g, 9.06 mmol), 2,2-dimethoxypropane (1.66 ml, 13.5 mmol), and *p*-toluenesulfonic acid (345 mg, 1.81 mmol) in chloroform (150 ml) and THF (150 ml) was stirred at room temperature for 4 h. After neutralization with triethylamine and evaporation of the solvent, the residue was dissolved in chloroform, washed with water, and dried. The product was recrystallized from chloroform-methanol; yield 8.75 g (84%); mp 105—108 °C (with sintering at 95 °C); $[\alpha]_D^{19}$ −28.3° (*c* 1.12, chloroform). Found: C, 68.92; H, 8.98; N, 2.34%. Calcd for $C_{67}H_{102}N_2O_{13} \cdot 1.5H_2O$: C, 68.75; H, 9.04; N, 2.39%. ^{1}H NMR (100 MHz) δ=0.89 (6H, br t, CH_3), 1.2—1.4 (40H, br s, CH_2), 1.44 and 1.52 (each 3H, s, isopropylidene), 2.31—2.53 (4H, m, α-CH_2 of fatty acids), and 7.2—7.35 (15H, aromatic H).

Allyl 4-*O*-Benzyl-3-*O*-[(*R*)-3-benzyloxytetradecanoyl]-6-*O*-[3-*O*-[(*R*)-3-benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-β-D-glucopyranosyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-β-D-glucopyranoside (19). To a solution of **18** (2.0 g, 1.8 mmol) in anhydrous dichloromethane (80 ml) were added **9** (1.8 g, 5.3 mmol), DCC (1.1 g, 5.3 mmol), and DMAP (107 mg, 0.88 mmol). The mixture was stirred at room temperature for 4 h. After addition of acetic acid (1 ml) and removal of the precipitate, the filtrate was washed with 1 M hydrochloric acid and water, dried, and evaporated to give a pale yellow solid. It was heated in 90% acetic acid (80 ml) at 90 °C for 2 h. After the evaporation of the solvent, the residue was recrystallized from methanol; yield 2.5 g (82 %); mp 117—119 °C; $[\alpha]_D^{17}$ −14.5° (*c* 0.40, chloroform). Found: C, 72.31; H, 9.32; N, 1.59%. Calcd for $C_{106}H_{162}N_2O_{17} \cdot H_2O$: C, 72.57; H, 9.42; N, 1.60%.

Allyl 4-*O*-Benzyl-6-*O*-[6-*O*-benzyloxymethyl-3-*O*-[(*R*)-3-benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-β-D-glucopyranoside (20). To a solution of **19** (7.78 g, 4.48 mmol) in anhydrous dichloromethane (150 ml) were added benzyloxymethyl chloride (1.40 g, 8.94 mmol) and *N,N*-diisopropylethylamine (1.56 ml, 8.95 mmol). The mixture was stirred for 23 h at room temperature with addition of benzyloxymethyl chloride (0.70 and 0.35 g) and *N,N*-diisopropylethylamine (0.78 and 0.39 ml) after 1 and 8 h, respectively. The mixture was worked up as usual and the product was recrystallized from methanol; yield 7.97 g (96%); mp 137—139 °C; $[\alpha]_D^{19}$ −12.3° (*c* 1.12, chloroform). Found: C, 73.12; H, 9.19; N, 1.48%. Calcd for $C_{114}H_{170}N_2O_{18} \cdot H_2O$: C, 73.04; H, 9.25; N, 1.49%.

Allyl 4-*O*-Benzyl-6-*O*-[6-*O*-benzyloxymethyl-3-*O*-[(*R*)-3-benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-β-D-glucopyranoside 4′-(Diphenyl Phosphate) (21). To a solution of **20** (1.70 g, 0.92 mmol) in anhydrous dichloromethane (70 ml) were added pyridine (0.24 ml, 3.0 mmol), DMAP (0.33 g, 2.7 mmol) and diphenyl phosphorochloridate (0.57 ml, 2.7 mmol). After stirring at room temperature for 7 h, the mixture was worked up as usual and the product was recrystallized from chloroform-methanol; yield 1.45 g (76%); mp 71—72 °C; $[\alpha]_D^{18}$ −7.3° (*c* 0.51, chloroform). Found: C, 72.50; H, 8.73; N, 1.40%. Calcd for $C_{126}H_{179}N_2O_{21}P$: C, 72.45; H, 8.64; N, 1.34%.

4-*O*-Benzyl-6-*O*-[6-*O*-benzyloxymethyl-3-*O*-[(*R*)-3-benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-D-glucose 4′-(Diphenyl Phosphate) (22). Compound **21** (1.39 g, 0.75 mmol) and 1,5-cyclooctadienebis(methyldiphenylphosphine)-iridium hexafluorophosphate (65 mg) were dissolved in degassed THF (50 ml). After activation of the iridium catalyst with hydrogen,[18] the mixture was stirred at 50 °C under nitrogen atmosphere for 80 min and then cooled to room temperature. Water (15 ml) and iodine (0.38 g. 1.50 mmol) were added and the mixture was stirred for 5 min. To the mixture were added 5% aqueous solution of sodium sulfite and chloroform. The organic layer was washed with water, dried and evaporated. The product was isolated by medium-pressure column chromatography on silica gel (83 g, chloroform-acetone 9:1) and recrystallized from chloroform-methanol; yield 750 mg (55%); mp 78—83 °C; $[\alpha]_D^{15}$ +10.6° (*c* 1.09, chloroform-methanol 3:1). Found: C, 71.88; H, 8.69; N, 1.39%. Calcd for $C_{123}H_{175}N_2O_{21}P$: C, 72.11; H, 8.61; N, 1.37%. ^{1}H NMR (100 MHz) δ=0.88 (12H, t, J=6 Hz, CH_3), 2.1—2.6 (80H, br s, CH_2), 2.06—2.60 (8H, m, α-CH_2 of fatty acids), and 7.0—7.3 (40H, m, aromatic H).

2-Deoxy-6-*O*-[2-deoxy-3-*O*-[(*R*)-3-hydroxytetradecanoyl]-2-[(*R*)-3-hydroxytetradecanoylamino]-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-hydroxytetradecanoyl]-2-[(*R*)-3-hydroxytetracedanoylamino]-α-D-glucopyranose 1,4′-Bis(phosphate) (2). Compound **22** (500 mg, 0.24 mmol) was dissolved in anhydrous THF (15 ml) and cooled to −70 °C under argon atmosphere. The solution was treated with 1.6 M butyllithium in hexane (0.18 ml, 0.28 mmol) and then dibenzyl phosphorochloridate (70 μl, 0.28 mmol). The mixture was stirred at −70 °C for 5 min and then palladium black was added to it. The mixture was stirred under 6 kg cm^{-2} of hydrogen at room temperature for 17 h. After removal of palladium catalyst, platinum oxide was added and the mixture was stirred under 7 kg cm^{-2} of hydrogen at room temperature for 2 h. The catalyst was filtered off and the filtrate was neutralized with triethylamine. The product was isolated by medium-pressure column chromatography on silica gel (80 g, chloroform-methanol-water-triethylamine 50:50:10:1) as colorless solid (200 mg).

Electrodialysis and Acidic Precipitation of 2. Electrodialysis was carried out according to the method of Galanos and Lüderitz.[21] The apparatus for electrodialysis consisted of three compartments separated by two sheets of dialysis membrane (prepared by cutting Cellophane Tubings-Seamless, Union Carbide Co.). The two outer chamber were equipped with platinum electrodes and filled with distilled water (each 7 ml).

The crude product **2** (176 mg) obtained by the above silica-gel chromatography was suspended in pyrogen-free water (9 ml). The pH of the suspension was adjusted to 9 with triethylamine, sonicated and put in the middle chamber. Direct electric current was applied to the apparatus, voltage being increased gradually to 150 V, while current was maintained less than 30 mA. After 1 h, the pH value of the middle chamber dropped to 3 and some precipitate appeared, which was dissolved again by adjusting the pH of the solution to 9 with triethylamine. The temperature of the solution was kept below 20 °C by cooling water throughout the operations. A series of these operations was repeated three times. Thereafter the suspension in the middle chamber was lyophilized to afford a white powder (145 mg).

A suspension of the product in pyrogen-free water (40 ml)

was adjusted to pH 9 with triethylamine, sonicated and centrifugated at 17500 rpm for 10 min at 0 °C in order to remove insoluble materials. To the supernatant was added 1 M hydrochloric acid (4.4 ml) at 0 °C and then the resultant precipitate was collected by centrifugation under the same conditions as above. After centrifugal washing with 0.1 M hydrochloric acid and water, the substance was lyophilized to give a white powder; yield 69 mg (20% from **22**); $[\alpha]_D^{19}$ +2.1° (*c* 1.05, chloroform-methanol 3:1). Found: C, 56.33; H, 9.37; N, 2.01%. Calcd for $C_{68}H_{130}N_2O_{23}P_2 \cdot 2.5H_2O$: C, 56.30; H, 9.38; N, 1.93%.

2-Deoxy-6-*O*-[2-deoxy-3-*O*-[(*R*)-3-hydroxytetradecanoyl]-2-[(*R*)-3-hydroxytetradecanoylamino]-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-hydroxytetradecanoyl]-2-[(*R*)-3-hydroxytetradecanoylamino]-D-glucose 4′-Phosphate (3). A solution of **22** (750 mg, 0.37 mmol) in THF (20 ml) and acetic acid (1.5 ml) was hydrogenolyzed for 38 h in the presence of palladium black under 6.5 kg cm^{-2} of hydrogen. After removal of the catalyst and addition of platinum oxide, the mixture was stirred for 15 h under 6.5 kg cm^{-2} of hydrogen. The catalyst was filtered and the filtrate was neutralized with triethylamine and then evaporated. Lyophilization from dioxane gave the crude product as a white powder (360 mg). A part of this material (149 mg) was purified further by means of acidic precipitation as described for compound **2**; yield 104 mg; $[\alpha]_D^{15}$ −13.6° (*c* 0.84, chloroform-methanol 3:1). Found: C, 59.47; H, 9.66; N, 2.17%. Calcd for $C_{68}H_{129}N_2O_{20} \cdot 2.5H_2O$: C, 59.59; H, 9.85; N, 2.04%.

Identification of Synthetic and Natural Dimethyl Ester of 3. Synthetic compound **3** (42.5 mg, 3.2×10^{-5} mol) in chloroform-methanol (9:1, 8 ml) was treated with ethereal diazomethane. The product was purified by preparative silica-gel TLC (chloroform-methanol 6:1) and lyophilized from dioxane; yield 27.3 mg (64%). This material is identical with the dimethyl ester of 4′-monophosphate prepared from natural precursor Ia as described below.

A suspension of crude natural precursor Ia (25 mg) in 2% aqueous acetic acid (10 ml) was heated at 95 °C for 1 h. The mixture was cooled and lyophilized to give a white powder, which was dissolved in chloroform-methanol (9:1, 15 ml). The solution was acidified with 1 M hydrochloric acid (1 ml), sonicated, and concentrated in vacuo. The residue was dissolved again in chloroform-methanol (9:1, 10 ml) and treated with ethereal diazomethane. Purification by preparative TLC and lyophilization from dioxane afforded a white powder; yield 3.0 mg.

4-*O*-Benzyl-6-*O*-[6-*O*-benzyloxymethyl-3-*O*-[(*R*)-3-benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-D-glucose (24). Compound **20** (990 mg, 0.53 mmol) was treated with the iridium complex (50 mg) then with iodine (270 mg, 1.06 mmol) as described for compound **22**. The product was isolated by medium-pressure column chromatography on silica gel (75 g, chloroform-acetone 5:1) and recrystallized from methanol; yield 660 mg (68%); mp 117—121 °C; $[\alpha]_D^{15}$ +3.1° (*c* 1.11, chloroform-methanol 3:1). Found: C, 72.64; H, 9.24; N, 1.47%. Calcd for $C_{111}H_{166}N_2O_{18}$: C, 72.67; H, 9.23; N, 1.53%.

2-Deoxy-6-*O*-[2-deoxy-3-*O*-[(*R*)-3-hydroxytetradecanoyl]-2-[(*R*)-3-hydroxytetradecanoylamino]-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-hydroxytetradecanoyl]-2-[(*R*)-3-hydroxytetradecanoylamino]-α-D-glucopyranose 1-Phosphate (4). A solution of compound **24** (770 mg, 0.424 mmol) in THF (25 ml) was cooled to −70 °C under argon atmosphere and treated with 1.6 M butyllithium in hexane (0.30 ml, 0.47 mmol) and then with dibenzyl phosphorochloridate (0.12 ml, 0.48 mmol). After 20 min, palladium-black (500 mg) was added and the mixture was hydrogenolyzed under 6 kg cm^{-2} of hydrogen atmosphere at room temperature for 17 h. Isolation by medium-pressure column chromatography on silica gel (80 g, chloroform-methanol-water-triethylamine 250:100:15:1) gave a crude product as white solid (260 mg).

This material was purified by a combination of electrodialysis and acidic precipitation method as described for **2**; yield 183 mg (33%); $[\alpha]_D^{21}$ −5.1° (*c* 1.03, chloroform-methanol 9:1); Found: C, 60.21; H, 9.83; N, 2.14%. Calcd for $C_{68}H_{129}N_2O_{20}P \cdot 1.5H_2O$: C, 60.38; H, 9.83; N, 2.07%.

2-Deoxy-6-*O*-[2-deoxy-3-*O*-[(*R*)-3-hydroxytetradecanoyl]-2-[(*R*)-3-hydroxytetradecanoylamino]-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-hydroxytetradecanoyl]-2-[(*R*)-3-hydroxytetradecanoylamino]-D-glucose (5). Compound **19** (700 mg, 0.40 mmol) was treated with the iridium complex (35 mg) and then with iodine (137 mg, 0.54 mmol) as described above for **22**. Isolation by medium-pressure column chromatography on silica gel (25 g, chloroform-acetone 2:1) gave a solid, which was dissolved in THF (20 ml) and acetic acid (1 ml). The solution was hydrogenolyzed with palladium-black under 7 kg cm^{-2} hydrogen. The product was recrystallized from methanol; yield 141 mg (28%); mp 210—212 °C (decomp). $[\alpha]_D^{18}$ −19.2° (*c* 1.02, chloroform-methanol 9:1). Found: C, 64.42; H, 10.40; N, 2.20%. Calcd for $C_{68}H_{128}N_2O_{17} \cdot H_2O$: C, 64.63; H, 10.37; N, 2.22%.

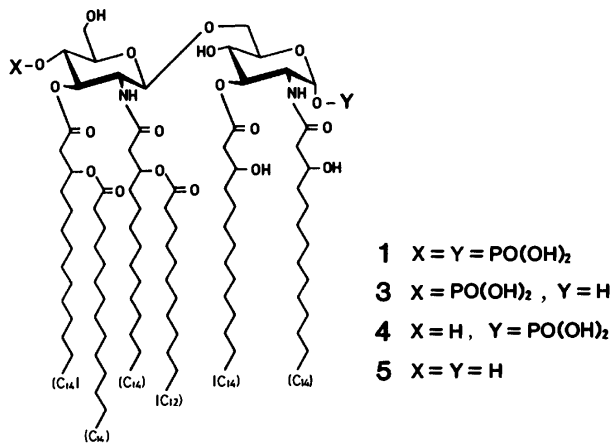
(Received December 15, 1986)

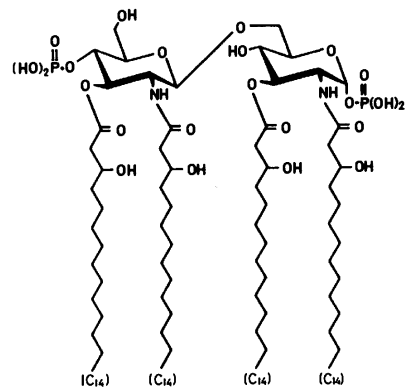
Chemical syntheses are described of polyacylated $\beta(1\rightarrow6)$ glucosamine disaccharide 1,4′-bis(phosphate), which corresponds to the proposed structure of *E. coli* lipid A, and of its dephospho derivatives. The synthetic bisphosphate proved to be identical with the corresponding natural specimen. The chemical structure of lipid A was thus established.

As described in the preceding paper,[1] lipopolysaccharide (LPS) which is located on the cell surface of gram-negative bacteria is called endotoxin and causes a diversity of toxic and beneficial biological responses in animals.[2] Its lipophilic part which could be liberated by mild acid hydrolysis of LPS was designated "lipid A" and has been believed to be responsible for most of the endotoxic activities.[2]

We recently elucidated the complete chemical structure **1** of lipid A isolated from *Escherichia coli* cells.[3] The structure contains a backbone of $1\alpha,4'$-bisphosphorylated $\beta(1\rightarrow6)$ disaccharide of D-glucosamine. The backbone is acylated at 2,2′- and 3,3′-positions with four moles of (*R*)-3-hydroxytetradecanoic acid. The 3-hydroxyl groups of amide- and ester-bound 3-hydroxytetradecanoic acid on the distal glucosamine residue are acylated with docosanoic and tetracosanoic acid respectively.



1 X = Y = $PO(OH)_2$
3 X = $PO(OH)_2$, Y = H
4 X = H, Y = $PO(OH)_2$
5 X = Y = H



2

In the meantime we synthesized a biosynthetic precursor ("Precursor Ia") (**2**) of lipid A.[1,4] This compound contains four moles of 3-hydroxytetradecanoic acid but lacks the non-hydroxylated acids found in **1**. The results of biological tests showed that the precursor Ia (**2**) exhibits not all but many of definite endotoxic activities such as lethal toxicity.[5] This fact clearly demonstrates that an acyl disaccharide phosphate like **2** is certainly responsible for the activities of LPS. Simultaneously, it could be assumed that the 3-acyloxyacyl structure which is typical of *E. coli* and other natural mature lipid A's but absent in the biosynthetic precursor **2** is important for manifestation of pyrogenicity and Shwartzman reactivity[6] which are typical endotoxic activities not observed in both synthetic and natural precursor Ia (**2**).[5] In order to confirm this assumption as well as to construct chemically a compound with full endotoxic activity and finally to confirm the proposed structure of *E. coli* lipid A, we aimed at a total synthesis of **1**. As described in our preliminary communications,[7,8] the structure **1** was first confirmed by this synthesis and synthetic **1** proved to have identical biological activities with those of lipid A isolated from *E. coli* cells.[9] It could now be concluded that **1** is indeed the active structural principle of endotoxin thirty years after the report of Westphal and Lüderitz by whom lipid A was first described.[10] In this paper we describe the details of the synthesis of **1** and its dephospho derivatives (**3**, **4**, **5**).

Most of the problems in the synthetic approach to *E. coli*-type lipid A had been already solved in our previous works.[1,11] These include, for example, preparation of optically pure (*R*)-3-hydroxytetradecanoic acid, its protection and introduction of an α-glycosyl phosphate. The distinct feature of the present synthesis lies in the following point. As seen in the structural formula, the two glucosamine residues of *E. coli* lipid A (**1**) contain different acyl groups each other. For its synthesis, therefore, two appropriately acylated glucosamine units were first prepared and then coupled together to form an acylated disaccharide. This approach, which is different from that used in our previous synthesis of **2**, seemed to be advantageous to

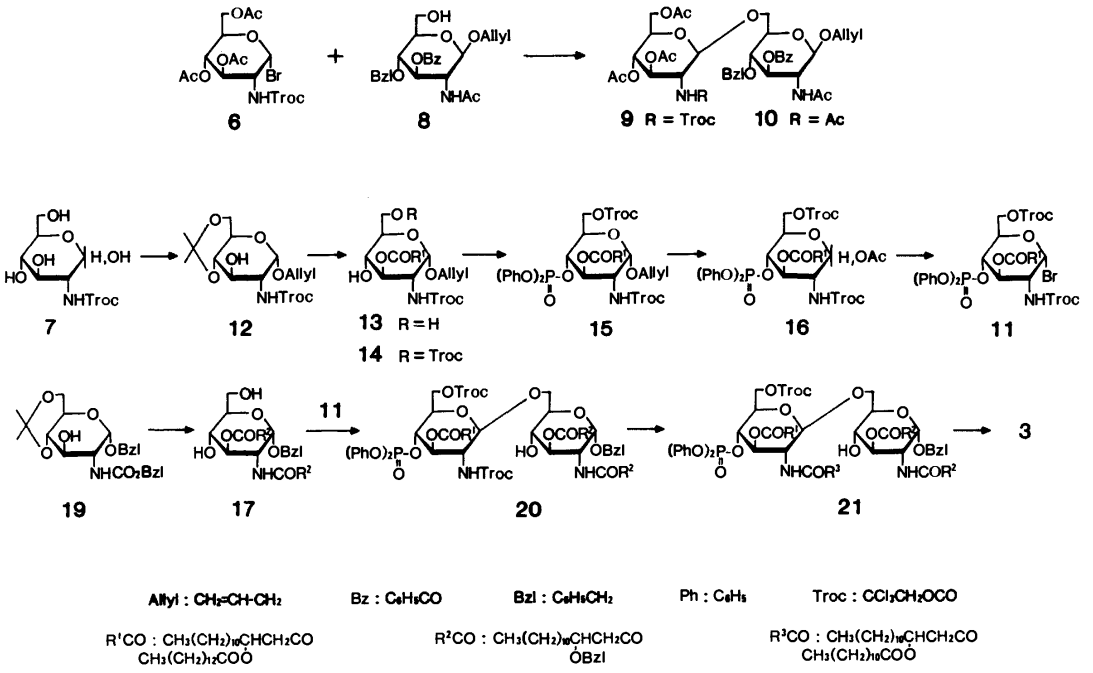
minimize the use of temporary protecting groups for the attempted synthesis of **1**.[12] The phosphate moiety on 4′-position was also introduced at the monosaccharide stage for the same reason.

Among the four acyl groups bound to the disaccharide, however, 3-dodecanoyloxytetradecanoyl group on the 2′-amino function had to be introduced after the formation of the disaccharide. Preliminary model experiments revealed that *N*-bound 3-acyloxyacyl group on a glucosamine molecule underwent a β-elimination to form Δ^2-acyl group when the glycosidic position was activated for glycoside bond formation.[13]

Use of 2,2,2-trichloroethoxycarbonyl (Troc) group[14] was examined for the temporary protection of the particular amino group during the glycosidation reaction with a glycosyl halogenide. The carbonyl group of 2-Troc-amino function was expected to participate the neighboring glycosyl cation in a similar manner to a usual acyl group and thus to assist the formation of a desired 1,2-trans β-glycosidic bound. Furthermore, Troc was expected to be advantageous since this urethane type group does not form an oxazoline which is one of the main side products in the glycosidation reaction with 2-acylamino glycosyl halogenides. 2-*N*-Troc-glucosamine **6** as a model donor compound was prepared from *N*-Troc-glucosamine (**7**). Thus, peracetyl derivative of **7** was converted almost quantitatively to the bromide **6** on reaction with dry hydrogen bromide in dichloromethane as monitored by TLC. Coupling of **6** with a model acceptor **8** proceeded satisfactorily in the presence of mercury(II) cyanide in boiling chloroform to give a disaccharide **9**. The glycosyl bromide of *N*-Troc-glucosamine was less reactive and hence more stable than a corresponding *N*-acetyl-type derivative. Undesirable side reactions were not obvious in the coupling reaction of the former. The $\beta(1\rightarrow6)$ structure of **9** was ascertained at the corresponding acetyl derivative which was prepared by displacing the Troc of **9** with acetyl group. The resultant bis(*N*-acetyl) disaccharide **10** was identical with a sample obtained in our previous work.[1] As expected, Troc group proved to be suitable for the amino protection: It assures formation of the desired β-glycoside and is removable selectively after formation of the disaccharide.

In order to examine the synthetic strategy according to the above considerations, we first attempted to prepare the 4′-monophosphate derivative **3** of *E. coli* lipid A. This synthesis seemed to be urgently important for the purpose of confirming the structure of lipid A because the dimethyl ester of **3** was the sole chemical entity so far derived in a pure state from a natural source.[3a,15] Direct identification of the natural and synthetic dimethyl ester of **3** was expected to provide a decisive evidence for the structure **1**.

The glycosyl donor **11** for this synthesis was prepared from *N*-Troc-D-glucosamine (**7**). Reaction of **7** with allyl alcohol in the presence of hydrogen chloride gave predominantly the α-glycoside. The α/β ratio was approximately 5/1. Isopropylidenation of the glycoside mixture followed by a simple recrystallization afforded almost pure α-allyl glycoside **12** in an acceptable yield.[16] After 3-*O*-acylation of **12** with (*R*)-3-tetradecanoyloxytetradecanoic acid which was prepared via phenacyl (*R*)-3-hydroxytetradecanoate,[1] the isopropylidene group was removed to give **13**. Selective 6-*O*-mono(trichloroethoxycarbonylation) followed by phosphorylation with diphenyl phosphorochloridate and pyridine-4-dimethylaminopyridine (DMAP).[17,18] Gave a glucosamine derivative **15** which contained all required substituents for the glycosyl donor. The allyl group in **15** was then cleaved off via



isomerization with an iridium complex to 1-propenyl group[19] followed by a reaction with iodine.[20] The product was converted via 1-*O*-acetate **16** to the glycosyl bromide **11** which was used for the coupling reaction without purification.

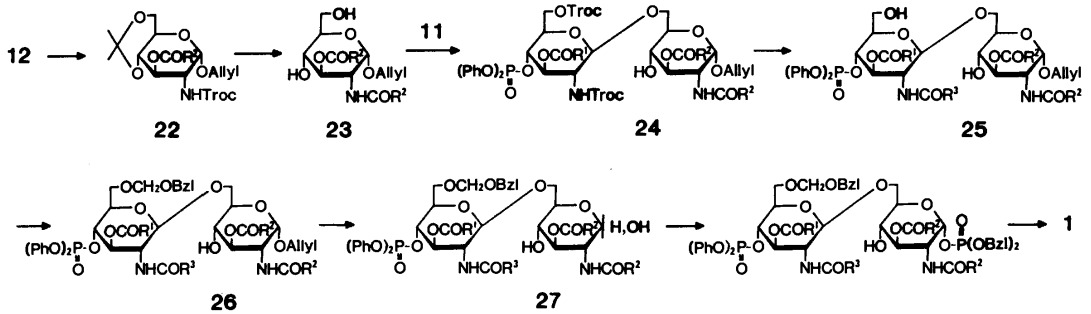
The glycosyl acceptor **17** was prepared from benzyl *N*-benzyloxycarbonyl-α-D-glucosaminide (**18**)[21] by 4,6-*O*-isopropylidenation, selective hydrogenolysis of *N*-benzyloxycarbonyl group[21] and simultaneous 3-*O*- and 2-*N*-acylation with (*R*)-3-benzyloxytetradecanoic acid[1] followed by deisopropylidenation. Because a primary 6-hydroxyl group has generally much higher reactivity than a 4-hydroxyl group in a glucopyranoside structure, preferential formation of the (1→6)-glycoside linkage was reasonably expected in the reaction of **17** without protecting the 4-position.[11] Furthermore, the 4-hydroxyl group becomes more hindered after formation of the β(1→6)disaccharide as observed in our previous work.[11] Therefore, a protection of this particular group seemed to be not necessary even during the further transformation of more reactive positions like 1- and 6′-hydroxyl groups of the disaccharide.

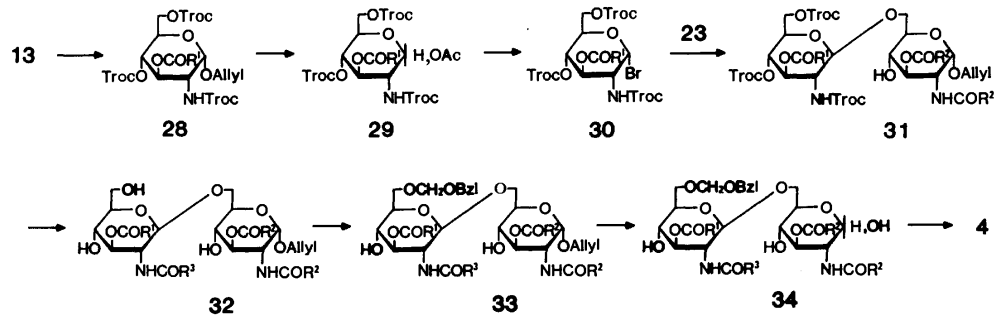
Coupling of the bromide **11** and the acceptor **17** was effected as the above model reaction with mercury(II) cyanide to give a sole disaccharide **20**, whose structure was confirmed by examination of its ^{1}H NMR spectrum. After cleavage of Troc groups of the disaccharide **20**, the last acyl group, i.e., (*R*)-3-dodecanoyloxytetradecanoyl group, was finally introduced to the 2′-amino function by use of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride. When dicyclohexylcarbodiimide was used for this step in place of the above water-soluble carbodiimide, the acylation reaction itself proceeded as well, but *N*-acyl-*N*,*N*′-dicyclohexylurea formed as a by-product made the chromatographic purification of the desired product difficult.

The acylation product **21** which contained all required functional groups on the respective positions was then subjected to two-step hydrogenolytic deprotection first with palladium and then with platinum. The deprotected compound **3** was identified by TLC with the corresponding 4′-monophosphate derived from *E. coli* lipid A.

For more strict identification by ^{1}H NMR, the product **3** was attempted to be converted to the dimethyl ester. However, the synthetic monophosphate was found to contain inorganic impurities and metal cations resulted from the hydrogenolysis catalysts. Some of cations formed salts with the phosphate group of **3**. Because the phosphate group must be converted to a free form prior to the reaction with diazomethane, removal of the inorganic contaminants was next tried. Removal of metal ions was also indispensable for preparation of triethylammonium salt which is a necessary form for biological tests.[22] Whereas the synthetic bisphosphate **2** and both its monophosphate analogs of the precursor-type could be freed from the contaminating cations by a combination of electrodialysis and acidic precipitation,[1] this method could not be applied to the present monophosphate **3** which has more lipophilic acyl groups and less solubility in water than the precursor-type derivatives. However, washing of a chloroform–methanol solution of **3** with cold hydrochloric acid under controlled conditions to avoid decomposition of the target compound was found to be effective to obtain salt-free **3**. It was then treated with diazomethane to give a compound which was identical on TLC with the corresponding dimethyl ester obtained from a natural source.[3] The synthetic and natural specimens were unequivocally identified by comparison of the 360 MHz ^{1}H NMR spectra of these dimethyl esters and their peracetates. Although the spectrum of the natural dimethyl ester still exhibited signals due to small amount of impurities, its peracetate purified and the corresponding synthetic one gave superimposable spectra.

Conclusively, the structure of *E. coli* lipid A proposed by us was confirmed by the present synthesis of 4′-monophosphate (**3**). The next step in our study was a chemical construction of the complete *E. coli* lipid A structure **1** containing both phosphate moieties. This could be performed in the same way as the above synthesis except that the glycosidic position of the disaccharide was protected with allyl group. This protecting group could be removed for the introduction of the unstable glycosyl phosphate just before the final hydrogenolysis. The corresponding glycosyl acceptor monosaccharide **23** was prepared from the same intermediate, 4,6-*O*-isopropylidenated allyl glycoside of *N*-Troc-D-glucosamine (**12**) described above. Condensation of **23** with the same glycosyl bromide (**11**) gave the disaccharide **24**. After removal of the two Troc group





and introduction of (*R*)-3-dodecanoyloxytetradecanoyl group to the 2′-amino function, the 6′-hydroxyl group was protected by benzyloxymethylation for the subsequent glycosidic phosphorylation to give **26**.[23] Cleavage of the allyl group of **26**, glycosyl phosphorylation[11] and hydrogenolysis were successively performed in the same manner as described previously.[1]

The product (**1**) was purified by silica-gel column chromatography. Owing to the improved solubility in water compared to the 4′-monophosphate (**3**) above, the product (**1**) could be freed from inorganic contaminants by electrodialysis and precipitation with cold hydrochloric acid. This synthetic compound was identified on TLC with the main component of lipid A from *E. coli* Re cells. Further identification on TLC with the natural specimen was performed after cleavage of the glycosyl phosphate and methyl esterification.

As in the case of the biosynthetic precursor described in the preceding paper,[1] both 1-monophosphate (**4**) and dephospho derivative (**5**) of *E. coli*-type lipid A were also prepared. Comparison of the biological activities of a set of pure synthetic materials which have the same acyl disaccharide skeleton, but are only different in presence of phosphate groups, could give important informations particularly concerning the effect of the phosphates on the activities.

For the preparation of **4** and **5**, a glycosyl bromide **30** devoid of 4-phosphate moiety was prepared from **13** as a glycosyl donor. The 4-hydroxyl group of **30** was also protected with Troc group during the glycosidation. After coupling of the bromide **30** with the acceptor **23** to form a disaccharide **31**, the all Troc groups were removed and the 2′-amino group was acylated. Protection of 6′-position followed by glycosyl phosphorylation as above and deprotection afforded the 1-monophosphate (**4**). Chromatographic purification and washing with hydrochloric acid as described for 4′-monophosphate (**3**) gave pure **4**. The dephospho derivative **5** was obtained by direct deprotection of a intermediate **34** without phosphorylation.

Comparative studies were carried out on the biological activities of the synthetic products (**1**, **3**—**5**) and the corresponding natural lipid A. As already described,[9] the synthetic bisphosphate (**1**) manifested complete and identical activities including pyrogenicity and Shwartzman reactivity with the natural specimen. In conclusion, this work established first a synthetic route for lipid A and consequently provided the evidence that this structure should be certainly responsible to the active principle of endotoxin. Owing to these results, it becomes now possible to prepare any desired structural analogs of lipid A in a chemically pure forms by appropriate modification of the above synthesis. In addition, precise studies will be possible on the relationships between the biological activities and chemical structures of this type of unique glycolipid.

Experimental

All melting points are uncorrected. ^{1}H NMR spectra were measured for chloroform-*d* solutions on a Varian XL-100-15 spectrometer (100 MHz) unless noted otherwise. The chemical shifts are given in δ values with TMS as the internal standard. Optical rotations were measured with a Perkin-Elmer 141 polarimeter. Conventional and medium-pressure (2—4 kg cm^{-2}) column chromatography were carried out with Kieselgel 60 (E. Merck), 0.063—0.2 and 0.040—0.063 mm, respectively. Organic solutions were dried over magnesium sulfate.

2-Deoxy-2-(2,2,2-trichloroethoxycarbonylamino)-D-glucose (7). 2,2,2-Trichloroethoxycarbonyl chloride (50.0 g, 236 mmol) was added portionwise to an ice-cooled solution of 2-amino-2-deoxy-D-glucose hydrochloride (34.0 g, 158 mmol) and sodium hydrogencarbonate (34.0 g, 405 mmol) in water (500 ml). The mixture was stirred in an ice bath for 2 h and then at room temperature overnight. The colorless precipitate was collected by filtration, washed with water and ether, and then recrystallized from ethanol; yield 48.9 g (87%); mp 183—184 °C (decomp); $[\alpha]_D^{19}$ +50.4° (*c* 0.84, methanol). Found: C, 29.98; H, 4.19; N, 3.88; Cl, 29.20%. Calcd for $C_9H_{14}NO_7Cl_3 \cdot 0.5H_2O$: C, 29.73; H, 4.16; N, 3.85; Cl, 29.25%.

1,3,4,6-Tetra-*O*-acetyl-2-deoxy-2-(2,2,2-trichloroethoxycarbonylamino)-D-glucopyranosyl Bromide (6). A solution of the syrupy tetraacetate (500 mg, 0.96 mmol) obtained from **7** by the usual manner was dissolved in anhydrous dichloromethane (100 ml). The solution was saturated with dry hydrogen bromide at 0 °C and left at room temperature in a sealed flask for 18 h. After evaporation of the solvent in vacuo, the residual syrup was dried in vacuo over diphosphorus pentaoxide and sodium hydroxide; yield 520 mg. It was used for the following reaction without further purification.

Allyl 2-Acetamido-6-*O*-[3,4,6-tri-*O*-acetyl-2-deoxy-2-(2,2,2-trichloroethoxycarbonylamino)-β-D-glucopyranosyl]-3-*O*-benzoyl-4-*O*-benzyl-2-deoxy-β-D-glucopyranoside (9). A solution of the bromide **6** (520 mg, 0.96 mmol), allyl 2-acetamido-3-*O*-benzoyl-4-*O*-benzyl-2-deoxy-β-D-glucopyr-

anoside[1] (432 mg, 0.96 mmol) and mercury(II) cyanide (480 mg, 1.90 mmol) in anhydrous chloroform (10 ml) was heated under reflux for 40 min. After removal of the insoluble materials by filtration, the filtrate was washed successively with a saturated aqueous solution of sodium hydrogencarbonate and water, dried, and evaporated in vacuo. Purification by medium-pressure silica-gel column chromatography (90 g, chloroform–acetone 3:1) afforded a colorless solid; yield 390 mg (45%). ^{1}H NMR δ=1.81 (3H, s, NAc), 2.01 (6H, s, OAc), 2.04 (3H, s, OAc), and 7.1—8.2 (11H, m, aromatic H and NH).

Allyl 2-Acetamido-6-*O*-(2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosyl)-3-*O*-benzoyl-4-*O*-benzyl-2-deoxy-β-D-glucopyranoside (10). Zinc powder (780 mg) was added to a solution of **9** (390 mg, 0.43 mmol) in acetic acid (10 ml). The mixture was heated at 50 °C with stirring for 30 min and then cooled to room temperature. After removal of the insoluble materials by filtration, the solvent was evaporated in vacuo. The residue was dissolved in chloroform, washed with water, and dried. The syrupy residue obtained after evaporation of the solvent in vacuo was again dissolved in chloroform and treated with triethylamine (67 μl, 0.48 mmol) and acetic anhydride (60 μl, 0.48 mmol). After usual work-up, the product was recrystallized from methanol–ether; yield 200 mg (59%); mp 220—223 °C (decomp). This product was identified with an authentic sample of **10** obtained in our previous work[1] by comparison of mps, TLC and ^{1}H NMR.

Allyl 2-Deoxy-4,6-*O*-isopropylidene-2-(2,2,2-trichloroethoxycarbonylamino)-α-D-glucopyranoside (12). Compound **7** (35.0 g, 98.7 mmol) was heated with stirring at 100 °C in allyl alcohol (230 ml) containing 2(w/v)% of dry hydrogen chloride for 20 min. The mixture was cooled and the solvent evaporated in vacuo. The residue dried by coevaporation with toluene three times was again dissolved in anhydrous acetone (400 ml). The solution was stirred with anhydrous calcium sulfate before 2,2-dimethoxypropane (37.8 ml, 296 mmol) and *p*-toluenesulfonic acid monohydrate (4.0 g, 19.7 mmol) were added to the solution. The mixture was stirred at room temperature for 3.5 h, neutralized by addition of aqueous sodium hydrogencarbonate and worked up as usual. The product was recrystallized from ethanol–ethyl acetate; yield 17.5 g (41%); mp 185—187 °C; $[\alpha]_D^{19}$ +59.8° (*c* 1.04, chloroform). Found: C, 41.57; H,4.93; N,3.20; Cl, 24.07%. Calcd for $C_{15}H_{22}NO_7Cl_3$: C, 41.45; H, 5.10; N, 3.22; Cl, 24.47%.

(*R*)-3-Tetradecanoyloxytetradecanoic Acid. Tetradecanoyl chloride (16.7 g, 67.6 mmol) was added dropwise to a solution of phenacyl (*R*)-3-hydroxytetradecanoate[1] (16.4 g, 45.3 mmol) in pyridine (100 ml) at room temperature. The mixture was stirred at room temperature for 1 h. Methanol (50 ml) was added and the mixture was stirred for additional 30 min. After evaporation of the solvent in vacuo, the residue was dissolved in benzene, and the solution was washed successively with 1 M† hydrochloric acid, saturated aqueous solution of sodium hydrogencarbonate, and water. The organic layer was treated with diazomethane and then dried. The syrupy residue obtained by evaporation of the solvent in vacuo was dissolved in acetic acid (300 ml). Zinc powder (45 g) was added and the mixture was stirred at 50 °C for 3 h. The mixture was filtered and the filtrate evaporated in vacuo. After coevaporation with toluene several times, the residue was subjected to column chromatography on silica gel (280 g, benzene) to give a colorless syrup; yield 17.6 g (86%); $[\alpha]_D^{17}$ −1.5° (*c* 4.99, chloroform). EI-MS: *m/z* 454 (M^+). Found: C, 73.99; H, 11.91%. Calcd for $C_{28}H_{54}O_4$: C, 73.99; H, 11.91%.

Allyl 2-Deoxy-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-2-(2,2,2-trichloroethoxycarbonylamino)-α-D-glucopyranoside (13). To a solution of **12** (10.0 g, 23.0 mmol) and (*R*)-3-tetradecanoyloxytetradecanoic acid (11.5 g, 25.3 mmol) in anhydrous dichloromethane (350 ml) were added 4-dimethylaminopyridine (DMAP) (1.41 g, 11.5 mmol) and dicyclohexylcarbodiimide (DCC) (5.22 g, 25.3 mmol). The mixture was stirred at room temperature for 2 h. The insoluble materials were removed by filtration and the filtrate was worked up as usual. After purification by silica-gel column chromatography (500 g, chloroform–acetone 30:1), the acylation product was heated in 90% acetic acid (200 ml) at 95 °C for 10 min. The solvent was evaporated in vacuo and the product recrystallized from hexane; yield 12.7 g (66%); mp 68—70 °C; $[\alpha]_D^{19}$ +43.7° (*c* 0.92, chloroform). Found: C, 57.90; H, 8.51; N, 1.75; Cl, 12.71%. Calcd for $C_{40}H_{70}NO_{10}Cl_3$: C, 57.79; H, 8.49; N, 1.68; Cl, 12.79%. ^{1}H NMR δ=0.87 (6H, t, *J*=6 Hz, CH_3), 1.1—1.45 (42H, br s, CH_2), 2.31 (2H, t, *J*=7 Hz, -COC$\underline{H}_2$CH$_2$-), 2.46—2.54 (2H, m, -COC$\underline{H}_2$CH-(OCOR)-), 4.73 (2H, s, CH_2 of Troc), and 4.94 (1H, d, *J*=4 Hz, H-1).

Allyl 2-Deoxy-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-6-*O*-(2,2,2-trichloroethoxycarbonyl)-2-(2,2,2-trichloroethoxycarbonylamino)-α-D-glucopyranoside (14). 2,2,2-Trichloroethoxycarbonyl chloride (0.89 ml, 6.5 mmol) was added to an ice-cooled solution of **13** (2.70 g, 3.25 mmol) in pyridine (60 ml). The mixture was stirred in an ice bath for 20 min. Then water was added and the mixture was stirred at room temperature. Usual work up and chromatographic purification on a silica-gel column (100 g, chloroform–acetone 30:1) gave a syrup; yield 2.00 g (61%). ^{1}H NMR δ=0.87 (3H, t, *J*=6 Hz, CH_3), 1.1—1.45 (42H, br s, CH_2), 2.27 (2H, t, *J*=7 Hz, -COC$\underline{H}_2$CH$_2$-), 2.52 (2H, d, *J*=6 Hz, -COC$\underline{H}_2$CH-(OCOR)-), 4.80 (2H, AB-type, CH_2 of Troc), and 4.88 (2H, s, CH_2 of Troc).

Allyl 2-Deoxy-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-6-*O*-(2,2,2-trichloroethoxycarbonyl)-2-(2,2,2-trichloroethoxycarbonylamino)-α-D-glucopyranoside 4-(Diphenyl Phosphate) (15). To a solution of **14** (2.00 g, 1.99 mmol) in anhydrous dichloromethane (60 ml) were added pyridine (0.24 ml, 3.0 mmol), DMAP (0.36 g, 3.0 mmol) and diphenyl phosphorochloridate (0.62 ml, 3.0 mmol). The mixture was stirred at room temperature for 2 h. The mixture was washed successively with 1 M hydrochloric acid, water, saturated aqueous sodium hydrogencarbonate, and water, and dried. After removal of the solvent, the residue was purified by medium-pressure chromatography on silica gel (90 g, chloroform–acetone 90:1) to give a syrup; yield 2.2 g (89%). ^{1}H NMR δ=0.87 (6H, t, *J*=6 Hz, CH_3), 1.1—1.6 (42H, br s, CH_2), 2.16 (2H, t, *J*=7 Hz, -COC$\underline{H}_2$CH$_2$-), 2.44 (2H, d, *J*=7 Hz, -COC$\underline{H}_2$-CH(OCOR)-), 4.66 and 4.70 (each 2H, s, CH_2 of Troc), 4.98 (1H, d, *J*=4 Hz, H-1), and 7.1—7.5 (10H, m, aromatic H).

1-*O*-Acetyl-2-deoxy-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-6-*O*-(2,2,2-trichloroethoxycarbonyl)-2-(2,2,2-trichloroethoxycarbonylamino)-α-D-glucopyranose 4-(Diphenyl Phosphate) (16). Compound **15** (17.9 g, 14.4 mmol) was dissolved in tetrahydrofuran (THF) (150 ml) and treated

† 1 M=1 mol dm^{-3}.

with 1,5-cyclooctadienebis(methyldiphenylphosphine)-iridium hexafuluorophosphate (200 mg) under nitrogen atmosphere at 50 °C for 40 min after activation of the iridium catalyst with hydrogen.[19] After cooling, water (8 ml) and iodine (7.3 g, 28 mmol) were added and the mixture was stirred for 10 min at room temperature. Purification by medium-pressure column chromatography on silica gel (500 g, chloroform-acetone 20 : 1) afforded a syrup. It was dissolved in anhydrous chloroform (120 ml) and treated with pyridine (3.3 ml, 42 mmol) and acetic anhydride (3.9 ml, 42 mmol). After usual work-up, the product was recrystallized from hexane; yield 8.00 g (45%); mp 77—80 °C $[\alpha]_D^{29}$ +35.6° (*c* 0.55, chloroform). Found: C, 52.32; H, 6.31; N, 1.13; Cl, 17.34%. Calcd for $C_{54}H_{78}NO_{16}Cl_6$: C, 52.27; H, 6.34; N, 1.13; Cl, 17.14%. ^{1}H NMR δ=0.88 (6H, t, *J*=6 Hz, CH_3), 1.1—1.5 (42H, br s, CH_2), 2.20 (3H, s, OAc), 2.20 (2H, t, *J*=7 Hz, $-COCH_2CH_2-$), 2.46 (2H, d, *J*=7 Hz, $-COCH_2CH(OCOR)-$), 4.45 (2H, AB-type, CH_2 of Troc), 4.72 (2H, s, CH_2 of Troc), 6.33 (1H, d, *J*=3.5 Hz, H-1), and 7.0—7.5 (10H, m, aromatic H).

Benzyl 2-Benzyloxycarbonylamino-2-deoxy-4,6-*O*-isopropylidene-α-D-glucopyranoside (19). Benzyl 2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside (**18**)[21] (20.0 g, 49.6 mmol) was dissolved in anhydrous acetone (700 ml) and treated with 2,2-dimethoxypropane (12.1 ml, 99.2 mmol) and *p*-toluenesulfonic acid monohydrate (1.89 g, 9.94 mmol) at room temperature for 4 h. Usual work-up followed by chromatographic purification on silica gel (500 g, chloroform-acetone 5 : 1) afforded a solid; yield 16.5 g (75%).

Benzyl 3-*O*-[(*R*)-3-Benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-α-D-glucopyranoside (17). Compound **19** (7.3 g, 16.5 mmol) was dissolved in methanol (80 ml) and hydrogenolyzed in the presence of palladium-black catalyst at room temperature under atmospheric pressure for 6 h. After usual work-up, the product was dissolved in dichloromethane (200 ml). To this solution were added (*R*)-3-benzyloxytetradecanoic acid (15.1 g, 45.1 mmol), DMAP (1.0 g, 8.3 mmol) and DCC (9.3 g, 45 mmol). The mixture was stirred at room temperature for 30 min. Usual work-up gave a syrup which was heated in 90% acetic acid at 90 °C for 20 min. After evaporation of the solvent in vacuo, the residue was recrystallized from methanol-ether-hexane; yield 7.00 g (47%); mp 88—89 °C; $[\alpha]_D^{27}$ +48.9° (*c* 0.50, chloroform). Found: C, 73.03; H, 9.13; N, 1.52%. Calcd for $C_{55}H_{83}NO_9$: C, 73.22; H, 9.27; N, 1.55%. ^{1}H NMR δ=0.89 (6H, t, *J*=6 Hz, CH_3), 1.1—1.5 (40H, br s, CH_2), 2.25—2.65 (4H, m, α-CH_2 of fatty acids), 4.88 (1H, d, *J*=4 Hz, H-1), 7.3 (15H, br s, aromatic H).

Benzyl 3-*O*-[(*R*)-3-Benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-6-*O*-[2-deoxy-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-6-*O*-(2,2,2-trichloroethoxycarbonyl)-2-(2,2,2-trichloroethoxycarbonylamino)-β-D-glucopyranosyl]-α-D-glucopyranoside 4′-(Diphenyl Phosphate) (20). Bromide **11** was prepared from **16** (4.00 g, 3.22 mmol) in anhydrous dichloromethane (800 ml) as described for the preparation of **6**.

To a solution of the bromide **11** in anhydrous chloroform (60 ml) were added anhydrous calcium sulfate (4.0 g), **17** (1.45 g, 1.61 mmol) and mercury(II) cyanide (1.63 g, 6.4 mmol). The mixture was heated under reflux for 22 h. After removal of the insoluble materials by filtration, the filtrate was washed successively with aqueous solution of potassium iodide and water, dried, and the solvent evaporated in vacuo. The residue was subjected to medium-pressure column chromatography on silica gel (90 g, chloroform-acetone 15 : 1) to give a syrup; yield 2.70 g (80% from **17**). Found: C, 60.81; H, 7.66; N, 1.28; Cl, 10.39%. Calcd for $C_{107}H_{157}N_2O_{23}PCl_6 \cdot 1.5H_2O$: C, 60.91; H, 7.64; N, 1.33; Cl, 10.08%. ^{1}H NMR δ=0.88 (12H, t, *J*=6 Hz, CH_3), 1.1—1.7 (82H, broad, CH_2), 2.1—2.7 (8H, m, α-CH_2 of fatty acids), 6.11 (1H, d, *J*=9 Hz, NH-2), and 7.0—7.4 (25H, m, aromatic H).

(*R*)-3-Dodecanoyloxytetradecanoic Acid. This compound was obtained as a syrup from phenacyl (*R*)-3-hydroxytetradecanoate and dodecanoyl chloride as described for the corresponding 3-tetradecanoyloxy derivative above; yield 6.1 g (95%); $[\alpha]_D^{11}$ −1.2° (*c* 5.54, chloroform). EI-MS: *m/z* 426 (M^+). Found: C, 73.23; H, 11.77%. Calcd for $C_{26}H_{50}O_4$: C, 73.19; H, 11.81%.

Benzyl 3-*O*-[(*R*)-3-Benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-6-*O*-[2-deoxy-2-[(*R*)-3-dodecanoyloxytetradecanoylamino]-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-β-D-glucopyranosyl]-α-D-glucopyranoside 4′-(Diphenyl Phosphate) (21). Zinc powder (5,4 g, 83 mmol) was added to a solution of **20** (2.70 g, 1.30 mmol) in acetic acid (75 ml). The mixture was stirred at room temperature for 30 min. After usual work-up, the crude product was dissolved in chloroform, and washed with 1 M hydrochloric acid and water, and dried. The solid obtained by evaporation of the solvent in vacuo was dissolved in dioxane. The solution was adjusted to pH 3 by addition of 1 M hydrochloric acid and then lyophilized to give colorless solid of hydrochloride of the 2′-amino derivative (2.18 g, 95%).

To a solution of a part of the solid (1.98 g, 1.12 mmol) in anhydrous dichloromethane (30 ml) was added triethylamine (0.16 ml, 1.15 mmol) and the solvent was evaporated. The residue was dissolved in anhydrous dichloromethane (30 ml) and dodecanoyloxytetradecanoic acid (716 mg, 1.68 mmol) and 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (322 mg, 1.68 mmol) were added under ice-cooling. The mixture was stirred at room temperature for 22 h and worked up as usual. The crude product was dissolved in chloroform and treated with diazomethane and then subjected to medium-pressure chromatography on silica gel (90 g, chloroform-acetone 9 : 1) to give a syrup; yield 1.29 g (49%); $[\alpha]_D^{18}$ +19.5° (*c* 0.81, chloroform). Found: C, 70.96; H, 9.59; N, 1.36%. Calcd for $C_{127}H_{203}N_2O_{22}P$: C, 71.25; H, 9.56; N, 1.31%. ^{1}H NMR δ=0.88 (18H, t, *J*=6 Hz, CH_3), 1.1—1.8 (120H, broad, CH_2), 2.1—2.6 (12H, m, α-CH_2 of fatty acids), 6.12 (1H, d, *J*=9 Hz, NH), 6.25 (1H, d, *J*=8 Hz, NH), 7.0—7.4 (25H, m, aromatic H).

2-Deoxy-6-*O*-[2-deoxy-2-[(*R*)-3-dodecanoyloxytetradecanoylamino]-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-hydroxytetradecanoyl]-2-[(*R*)-3-hydroxytetradecanoylamino]-D-glucose 4′-Phosphate (3). Compound **21** (860 mg, 0.402 mmol) was dissolved in a mixture of THF (22 ml) and acetic acid (1.4 ml) and hydrogenolyzed first in the presence of palladium black at room temperature under atmosphere of hydrogen (6.5 kg cm^{-2}) for 4 d. After removal of palladium and addition of platinum oxide, hydrogenolysis was continued under the same conditions for 6 h. Evaporation of the solvent followed by lyophilization from dioxane afforded colorless solid; yield 651 mg (94%).

The crude product obtained above (42.5 mg) was dissolved in chloroform-methanol (9 : 1, 6 ml). Cold 1 M hydrochloric acid (660 μl) was added and the homogeneous solution was

sonicated under ice-cooling for 5 min. The solvent was evaporated with stream of nitrogen, the residue dissolved in chloroform-methanol (9:1, 6 ml) and evaporated. The residue was again dissolved in the same solvent mixture and washed twice with water. Lyophilization from dioxane afforded a pure product; yield 39.2 mg; $[\alpha]_D^{18}$ −2.1° (*c* 0.58, chloroform). Found: C, 64.45; H, 10.31; N, 1.64%. Calcd for $C_{94}H_{177}N_2O_{22}P \cdot 2H_2O$: C, 64.35; H, 10.40; N, 1.60%.

Dimethyl Ester of 3 and Its Pentaacetate. Crude **3** (229 mg) was treated with 1 M hydrochloric acid as above and dissolved in chloroform-methanol (9:1, 9 ml). To the solution was added an ethereal solution of diazomethane. The product was purified by medium-pressure chromatography on silica gel (25 g, chloroform-methanol 15:1) and lyophilized from dioxane to give colorless solid; yield 68.2 mg (29%); $[\alpha]_D^{18}$ −2.5° (*c* 0.40, chloroform-methanol 9:1). Found: C, 65.15; H, 10.31; N, 1.55%. Calcd for $C_{96}H_{181}N_2O_{22}P \cdot 1.5H_2O$: C, 65.02; H, 10.46; N, 1.58%.

The dimethyl ester (30.0 mg, 0.017 mmol) was acetylated with acetic anhydride and pyridine in dichloromethane and purified by preparative TLC on silica gel (chloroform-acetone 5:1). The product was lyophilized from dioxane to give a colorless powder; yield 19.1 m (57%); $[\alpha]_D^{30}$ +17.9° (*c* 0.39, chloroform). Found: C, 65.17; H, 9.86; N, 1.46%. Calcd for $C_{106}H_{191}N_2O_{27}P$: C, 65.07; H, 9.84; N, 1.43%. The corresponding natural specimen: $[\alpha]_D^{30}$ +19.0.[3]

Allyl 3-*O*-[(*R*)-3-Benzyloxytetradecanoyl]-2-deoxy-4,6-*O*-isopropylidene-2-(2,2,2-trichloroethoxycarbonylamino)-α-D-glucopyranoside (22). To a solution of **12** (13.0 g, 29.9 mmol) in anhydrous chloroform (250 ml) were added (*R*)-3-benzyloxytetradecanoic acid[1] (10.0 g. 29.9 mmol), DCC (6.17 g, 29.9 mmol), and DMAP (731 mg, 5.98 mmol). The mixture was stirred at room temperature for 1 h and worked up as usual. Purification by silica-gel column chromatography (500 g, chloroform-acetone 30:1) afforded a colorless syrup; yield 14.5 g (64%). ^{1}H NMR δ=1.42 and 1.50 (each 3H, s, CH_3), 2.67 (1H, d, *J*=2 Hz, -OH), 4.70 (2H, AB-type, CH_2 of Troc), 4.86 (1H, d, *J*=3 Hz, H-1), 5.06—5.40 (3H, m, $-OCH_2-CH=C\underline{H}_2$ and NH), and 5.67—6.07 (1H, m, $-OCH_2-C\underline{H}=CH_2$).

Allyl 3-*O*-[(*R*)-3-Benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-α-D-glucopyranoside (23). Compound **22** (14.5 g, 19.3 mmol) was treated with zinc powder (29 g) in acetic acid (290 ml) as described for the preparation of **21**. After washing with hydrochloric acid and water, triethylamine (2.69 ml, 19.3 mmol) was added to a solution of the product in chloroform. The solvent was once evaporated in vacuo and the residue was again dissolved in anhydrous chloroform (250 ml). (*R*)-3-Benzyloxytetradecanoic acid (7.75 g, 23.2 mmol) and DCC (4.78 g, 23.2 mmol) were added to the solution. The mixture was stirred at room temperature for 30 min. After usual work-up, the crude product was heated in 90% acetic acid (250 ml) in a boiling water bath for 30 min. The product was purified by a silica-gel column (500 g, chloroform-acetone 5:1) and recrystallized from hexane; yield 9.53 g (58%); mp 80—82 °C; $[\alpha]_D^{19}$ +37.2° (*c* 1.02, chloroform). Found: C, 71.85; H, 9.67; N, 1.62%. Calcd for $C_{51}H_{81}NO_9$: C, 71.88; H, 9.58; N, 1.64%. ^{1}H NMR δ=0.88 (6H, t, *J*=6 Hz, CH_3), 1.1—1.5 (40H, br s, CH_2), 2.25—2.63 (4H, m, α-CH_2 of fatty acids), 4.47 (4H, s, $-C\underline{H}_2C_6H_5$), 4.75 (1H, d, *J*=3 Hz, H-1), 4.98—5.26 (2H, m, $-OCH_2-CH=C\underline{H}_2$), 5.50—5.92 (1H, m, $-OCH_2-C\underline{H}=CH_2$), 6.23 (1H, d, *J*=9 Hz, NH), and 7.22 (10H, s, aromatic H).

Allyl 3-*O*-[(*R*)-3-Benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-6-*O*-[2-deoxy-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-6-*O*-(2,2,2-trichloroethoxycarbonyl)-2-(2,2,2-trichloroethoxycarbonylamino)-β-D-glucopyranosyl]-α-D-glucopyranoside 4′-(Diphenyl Phosphate) (24). The glycosyl bromide (**11**) prepared from the acetate **16** (3.94 g, 3.18 mmol) as described above was dissolved in anhydrous chloroform (120 ml). Compound **23** (1.35 g, 1.58 mmol), mercury(II) cyanide (1.62 g, 6.33 mmol), and anhydrous calcium sulfate (4.0 g) were added to the solution and the mixture was heated under reflux. After 20 h, **23** (1.35 g, 1.58 mmol) was added and the mixture was heated for additional 13 h. Usual work-up followed by chromatography on a silica-gel column (110 g, chloroform-acetone 15:1) afforded a solid; yield 4.54 g (70%); $[\alpha]_D^{19}$ +18.4° (*c* 1.04, chloroform). Found: C, 60.74; H, 7.69; N, 1.29; Cl, 10.70%. Calcd for $C_{103}H_{155}N_2O_{23}Cl_6P$: C, 60.85; H, 7,68; N, 1.38; Cl, 10.46%. ^{1}H NMR δ=0.87 (12H, t, *J*=6 Hz, CH_3), 1.1—1.7 (82H, br s, CH_2), 2.12—2.84 (8H, m, α-CH_2 of fatty acids), 4.47 (4H, s, $-C\underline{H}_2C_6H_5$), 6.14 (1H, d, *J*=9 Hz, NH), and 7.0—7.4 (20H, m, aromatic H).

Allyl 3-*O*-[(*R*)-3-Benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-6-*O*-[2-deoxy-2-[(*R*)-3-dodecanoyloxytetradecanoylamino]-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-β-D-glucopyranosyl]-α-D-glucopyranoside 4′-(Diphenyl Phosphate) (25). Compound **24** (4.48 g, 2.20 mmol) was treated with zinc powder (9.0 g) in acetic acid (140 ml) and then with triethylamine (0.31 ml, 2.2 mmol) as described above for the preparation of **23**. To a solution of the product in anhydrous chloroform (80 ml) were added (*R*)-3-dodecanoyloxytetradecanoic acid (1.13g, 2.65 mmol) and DCC (546 mg, 2.65 mmol). The mixture was stirred at room temperature for 17 h. Usual work-up and chromatography on a silica-gel column (90 g, chloroform-acetone 9:1) afforded a colorless syrup; yield 3.25 g (71%). A part of the syrup was lyophilized from dioxane to give a colorless powder which was used for elemental analysis. Found: C, 69.97; H, 9.62; N, 1.43%. Calcd for $C_{123}H_{201}N_2O_{22}P \cdot H_2O$: C, 70.05; H, 9.70; N, 1.47%. ^{1}H NMR δ=0.87 (18H, t, *J*=6 Hz, CH_3), 1.0—1.7 (120H, br s, CH_2), 2.08—2.66 (12H, m, α-CH_2 of fatty acids) 4.47 (4H, s, $-C\underline{H}_2C_6H_5$), 6.18 (1H, d, *J*=9 Hz, NH), 6.36 (1H, d, *J*=8 Hz, NH), and 7.0—7.4 (20H, m, aromatic H).

Allyl 6-*O*-[6-*O*-Benzyloxymethyl-2-deoxy-2-[(*R*)-3-dodecanoyloxytetradecanoylamino]-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-α-D-glucopyranoside 4′-(Diphenyl Phosphate) (26). To a solution of **25** (3.14 g, 1.50 mmol) in anhydrous dichloromethane (100 ml) were added benzyloxymethyl chloride (352 mg, 2.25 mmol) and *N,N*-diisopropylethylamine (0.39 ml, 2.2 mmol). The mixture was stirred at room temperature for 48 h with portionwise addition of total 2.5 equivalent of each reagent. After usual work-up, the product was purified by silica-gel column chromatography (180 g, chloroform-acetone 15:1) to give a syrup; yield 2.17 g (65%). A part of the syrup was lyophilized from dioxane to give a colorless powder which was used for elemental analysis. Found: C, 70.80; H, 9.56; N, 1.30%. Calcd for $C_{131}H_{209}N_2O_{23}P \cdot 0.5H_2O$: C, 70.87; H, 9.53; N, 1.26%. $[\alpha]_D^{19}$ +18.3° (*c* 1.01, chloroform). ^{1}H NMR δ=0.88 (18H, t, *J*=6 Hz, CH_3), 1.1—1.7 (120H, br s, CH_2), 2.12—2.64 (12H, α-CH_2 of fatty acids), 6.11 (1H, d, *J*=9 Hz, NH), 6.24 (1H, d, *J*=8 Hz, NH), and 7.0—7.4 (25H, m,

aromatic H).

6-*O*-[6-*O*-Benzyloxymethyl-2-deoxy-2-[(*R*)-3-dodecanoyloxytetradecanoylamino]-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-D-glucose 4'-(Diphenyl Phosphate) (27). Compound **26** (2.11 g, 0.954 mmol) was treated with the iridium complex[19] (105 mg) in THF and then with water and iodine (500 mg) as described above for the preparation of **16**. Purification by medium-pressure column chromatography on silica gel (80 g, chloroform–acetone 10 : 1) followed by lyophilization from dioxane afforded a pale yellow powder; 1.31 g (63%). Found: C, 70.40; H, 9.44; N, 1.33%. Calcd for $C_{128}H_{205}N_2O_{23}P \cdot 0.5H_2O$: C, 70.52; H, 9,52; N, 1.29%. ^{1}H NMR δ=0.87 (18H, t, *J*=6 Hz, CH_3), 1.1—1.8 (120H, br s, CH_2), 2.10—2.62 (12H, m, α-CH_2 of fatty acids), 7.0—7.4 (25H, m, aromatic H).

2-Deoxy-6-*O*-[2-deoxy-2-[(*R*)-3-dodecanoyloxytetradecanoylamino]-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-hydroxytetradecanoyl]-2-[(*R*)-3-hydroxytetradecanoylamino]-α-D-glucopyranose 1,4'-Bis(phosphate) (1). A solution of **27** (600 mg, 0.276 mmol) in anhydrous THF (12 ml) was cooled to −70 °C under argon atmosphere. To this solution were added 10(w/v)% hexane solution of butyllithium (210 μl, 0.33 mmol) and dibenzyl phosphorochloridate (85 μl) as described in our preceding paper.[1] After 20 min, palladium black was added to the cold mixture and the mixture was subjected to hydrogenolysis under 8 kg cm^{-2} of hydrogen at room temperature for 2 h. The catalyst was substituted with platinum oxide and then hydrogenolysis was continued under the same conditions. After purification by medium-pressure chromatography on silica gel (80 g, chloroform–methanol–water–triethylamine 200 : 100 : 20 : 1), the product was subjected to electrodialysis and acid precipitation as described previously[1] to afford colorless powder; yield 137 mg (27%). Found: C, 61.04; H, 10.05; N, 1.46%. Calcd for $C_{94}H_{178}N_2O_{25}P_2 \cdot 3H_2O$: C, 60.95; H, 10.01; N, 1.51%. $[\alpha]_D^{15}$ +11.3° (*c* 0.56, chloroform–methanol 9 : 1).

Allyl 2-Deoxy-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-4,6-bis[*O*-(2,2,2-trichloroethoxycarbonyl)]-2-(2,2,2-trichloroethoxycarbonylamino)-α-D-glucopyranoside (28). A solution of 2,2,2-trichloroethoxycarbonyl chloride (3.7 ml, 27 mmol) in THF (20 ml) was added to a solution of **13** (9.00 g, 10.8 mmol) in anhydrous pyridine (150 ml) cooled in an ice bath. The mixture was then stirred at room temperature for 50 min and worked up as usual. Chromatographic purification on a silica-gel column (500g, chloroform) afforded a colorless syrup; yield 12.8 g (quantitative). ^{1}H NMR δ=0.87 (6H, t, *J*=6 Hz, CH_3), 1.1—1.6 (42H, broad, CH_2), 2.24 (2H, t, *J*=7 Hz, -COC$\underline{H_2}$CH$_2$-), 2.50 (2H, d, *J*=6 Hz, -COC$\underline{H_2}$-CH(OCOR)-), 4.70 (2H, br s, CH_2 of Troc), and 4.72 and 4.73 (each 2H, s, CH_2 of Troc).

1-*O*-Acetyl-2-deoxy-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-4,6-bis[*O*-(2,2,2-trichloroethoxycarbonyl)]-2-(2,2,2-trichloroethoxycarbonylamino)-α-D-glucopyranose (29). Compound **28** obtained above (12.8 g) was treated with the iridium complex[19] (200 mg) in THF and then with iodine (5.5 g) and water as described for the preparation of **16**. Purification by column chromatography on silica gel (500 g, chloroform–acetone 50 : 1) afforded a pale yellow syrup (13.1 g), which was dissolved in anhydrous dichloromethane (200 ml) and treated with pyridine (3.7 ml) and acetic anhydride (2.2 ml, 23 mmol). Usual work-up and chromatographic purification on a silica-gel column (500 g, chloroform–acetone 100 : 1) gave colorless syrup; 12.6 g (93%). Found: C, 45.95; H, 6.06; N, 1.20; Cl, 27.16%. Calcd for $C_{45}H_{70}NO_{15}Cl_9$: C, 45.65; H, 5.96; N, 1.18; Cl, 26.95%. ^{1}H NMR δ=0.87 (6H, t, *J*=6 Hz, CH_3), 1.1—1.7 (42H, broad, CH_2), 2.15 (3H, s, OAc), 2.26 (2H, t, *J*=7 Hz, -COC$\underline{H_2}$CH$_2$-), 2.50 (2H, d, *J*=6 Hz, -COC$\underline{H_2}$CH(OCOR)-), 4.66 (2H, AB-type, CH_2 of Troc), 4.71 and 4.74 (each 2H, s, CH_2 of Troc), and 6.25 (1H, d, *J*=3 Hz, H-1).

Allyl 3-*O*-[(*R*)-3-Benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-6-*O*-[2-deoxy-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-4,6-bis[*O*-(2,2,2-trichloroethoxycarbonyl)]-2-(2,2,2-trichloroethoxycarbonylamino)-β-D-glucopyranosyl]-α-D-glucopyranoside (31). Syrupy **29** (12.6 g, 10.6 mmol) was converted to glycosyl bromide **30** and treated with **23** (5.50 g, 6.45 mmol) in the presence of mercury(II) cyanide (5.38 g) and anhydrous calcium sulfate in anhydrous chloroform (200 ml) under the same conditions as for the synthesis of **20**. Chromatography on a silica-gel column (500 g, chloroform–acetone 15 : 1) afforded a colorless syrup; yield 6.97 g (54% from **23**). A portion of the syrup was lyophilized to give colorless powder; $[\alpha]_D^{33}$ +19.3° (*c* 0.83, chloroform). Found: C, 56.82; H, 7.48; N, 1.44; Cl, 16.30%. Calcd for $C_{94}H_{147}N_2O_{22}Cl_9$: C, 57.13; H, 7.50; N, 1.42; Cl, 16.15%. ^{1}H NMR δ=0.88 (12H, t, *J*=6 Hz, CH_3), 1.1—1.7 (82H, broad, CH_2), 2.18—2.6 (8H, m, α-CH_2 of fatty acids), 4.47 (4H, s, $C_6H_5C\underline{H_2}$), 6.16 (1H, d, *J*=9 Hz, NH-2), and 7.22 (10H, br s, aromatic H).

Allyl 3-*O*-[(*R*)-3-Benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-6-*O*-[2-deoxy-2-[(*R*)-3-dodecanoyloxytetradecanoylamino]-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-β-D-glucopyranosyl]-α-D-glucopyranoside (32). This compound was prepared from **31** (6.97 g, 3.53 mmol) as described for the preparation of **21**, i.e., removal of Troc group with zinc (14 g) followed by acylation with (*R*)-3-dodecanoyloxytetradecanoic acid (2.26 g, 5.30 mmol) and DCC (1.09 g, 5.28 mmol) in dichloromethane. Purification by medium-pressure chromatography on silica gel (190 g, chloroform–acetone 6 : 1) followed by precipitation from methanol gave colorless solid; yield 3.00 g (46%); mp 99—102 °C (with sintering at 85 °C; $[\alpha]_D^{27}$ +15.1° (*c* 1.04, chloroform). Found: C, 71.27; H, 10.35; N, 1.51%. Calcd for $C_{111}H_{192}N_2O_{19} \cdot 0.5H_2O$: C, 71.38; H, 10.36; N, 1.50%. ^{1}H NMR δ=0.88 (18H, t, *J*=6 Hz, CH_3), 1.1—1.8 (122H, broad, CH_2), 2.2—2.65 (12H, m, α-CH_2 of fatty acids), 4.48 (4H, s, $C_6H_5C\underline{H_2}$), 5.96 (1H, d, *J*=9 Hz, NH), 6.14 (1H, d, *J*=8 Hz, NH), and 7.22 (10H, br s, aromatic H).

Allyl 6-*O*-[6-*O*-Benzyloxymethyl-2-deoxy-2-[(*R*)-3-dodecanoyloxytetradecanoylamino]-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-α-D-glucopyranoside (33). To a solution of **32** (3.00 g, 1.61 mmol) in anhydrous dichloromethane (100 ml) were added *N,N*-diisopropylethylamine (1,26 ml, 7.2 mmol) and benzyloxymethyl chloride (1.13 ml, 7.2 mmol). After 30 h at room temperature, the mixture was worked up as usual. The product was purified by medium-pressure chromatography on silica gel (90 g, chloroform–acetone 10 : 1) and recrystallized from methanol; yield 2.37 g (74%); mp 92—95 °C; $[\alpha]_D^{27}$ +14.5° (*c* 1.07, chloroform). Found: C, 71.51; H, 10.04; N, 1.42%. Calcd for $C_{119}H_{200}N_2O_{20}$: C, 71.58; H, 10.09; N, 1.40%. ^{1}H NMR δ=0.88 (18H, t, *J*=6 Hz, CH_3), 1.1—1.8 (122H, broad, CH_2), 2.2—2.5 (12H, m, α-CH_2 of fatty acids), 4.48

(4H, s, $C_6H_5C\underline{H}_2$), 4.58 (2H, s, $C_6H_5C\underline{H}_2OCH_2O$-), 4.76 (2H, s, $C_6H_5CH_2OC\underline{H}_2O$-), 7.1—7.4 (15H, aromatic H).

6-*O*-[6-*O*-Benzyloxymethyl-2-deoxy-2-[(*R*)-3-dodecanoyloxytetradecanoylamino]-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-benzyloxytetradecanoyl]-2-[(*R*)-3-benzyloxytetradecanoylamino]-2-deoxy-D-glucose (34). This compound was prepared from **33** (3.30 g, 1.67 mmol) as described for **16** and purified by silica-gel column chromatography (90 g, chloroform–acetone 6 : 1) followed by recrystallization from methanol; yield 1.77 g (55%); mp 115—117 °C (with sintering at 81 °C); $[\alpha]_D^{19}$ +2.6° (*c* 0.66, chloroform). Found: C, 71.48; H, 10.19; N, 1.42%. Calcd for $C_{116}H_{196}N_2O_{20}\cdot 0.5H_2O$: C, 71.53; H, 10.14; N, 1.44%. ^{1}H NMR δ=0.88 (18H, t, *J*=6 Hz, CH_3), 1.1—1.8 (122H, broad, CH_2), 2.1—2.6 (12H, m, α-CH_2 of fatty acids), 4.45 and 4.47 (each 2H, s, $C_6H_5C\underline{H}_2$), 4.57 (2H, s, $C_6H_5C\underline{H}_2$-OCH_2O-), 4.76 (2H, s, $C_6H_5CH_2OC\underline{H}_2O$-), 7.1—7.4 (15H, aromatic H).

2-Deoxy-6-*O*-[2-deoxy-2[(*R*)-3-dodecanoyloxytetradecanoylamino]-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-hydroxytetradecanoyl]-2-[(*R*)-3-hydroxytetradecanoylamino]-α-D-glucose 1-Phosphate (4). A solution of **34** (200 mg, 0.103 mmol) in anhydrous THF (10 ml) was treated under the same conditions as described for **1** with a solution of butyllithium in hexane (66 μl, 0.10 mmol) and dibenzyl phosphorochloridate (26 μl, 0.10 mmol). Hydrogenolysis with palladium black at room temperature at 6 kg cm^{-2} followed by medium-pressure chromatography on silica gel (15 g, chloroform–methanol–water–triethylamine 500 : 100 : 10 : 1) gave a crude product as colorless solid; 63.7 mg. A portion (58 mg) of the crude product was dissolved in chloroform–methanol (9 : 1, 5.8 ml) and treated with cold 1 M hydrochloric acid as described for the purification of **3** and lyophilized from dioxane; yield 43 mg. $[\alpha]_D^{18}$ +6.0° (*c* 0.42, chloroform–methanol 9 : 1). Found: C, 63.58; H, 10.27; N, 1.50%. Calcd for $C_{94}H_{177}N_2O_{22}P\cdot 3H_2O$: C, 63.70; H, 10.41; N, 1.58%.

2-Deoxy-6-*O*-[2-deoxy-2[(*R*)-3-dodecanoyloxytetradecanoylamino]-3-*O*-[(*R*)-3-tetradecanoyloxytetradecanoyl]-β-D-glucopyranosyl]-3-*O*-[(*R*)-3-hydroxytetradecanoyl]-2-[(*R*)-3-hydroxytetradecanoylamino]-D-glucose (5). Hydrogenolysis of **34** (217 mg) in THF (5 ml) and acetic acid (0.2 ml) under conditions described for **4** followed by recrystallization from methanol afforded the product; yield 155 mg (85%); mp 169—173 °C (decomp), $[\alpha]_D^{19}$ −5.5° (*c* 0.56, chloroform). Found: C, 68.29; H, 10.76; N, 1.70%. Calcd for $C_{94}H_{176}N_2O_{19}\cdot H_2O$: C, 68.16; H, 10.71; N, 1.69%.

Effect of Cationic Charge in Electrolyte-Amphoteric Ion-Exchange Membrane System

Yutaka HIRATA, Masashi DATE, Yukiko YAMAMOTO, Akira YAMAUCHI,* and Hideo KIMIZUKA
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812
(Received October 4, 1986)

In order to clarify the membrane phenomena in an amphoteric membrane, four different experiments were carried out in a simple electrolyte-amphoteric membrane system. The ion transport numbers obtained from the membrane potential and electrodialysis were approximately in agreement with each other. It was indicated that the transport numbers strongly depended on the ionic valence in electrolyte solution. The membrane permeability coefficient representing the dynamic behavior of ion within membrane was evaluated in terms of membrane potential, transport number, and membrane conductance. In addition, the ionic concentrations within membrane equilibrated with outer electrolyte solution were measured to obtain the mobilities within membrane. The membrane phenomena were discussed on basis of the present experimental results.

The studies on an amphoteric membrane with cation- and anion-exchange sites have not been reported so many in comparison with those as to an ion-exchange membrane with homogeneous exchange sites. One of the reasons from physicochemical standpoint would be the complexity of ionic behavior within the membrane. However, the attractive possibilities concerning the amphoteric character have been predicted in various fields.[1-5] We also have recognized the valuable properties and investigated the fundamental membrane phenomena generated in simple electrolyte solution-amphoteric membrane system in which the amphoteric membranes developed by Central Research Laboratory of Kanegafuchi Chemical Industry Co., Ltd. were used.[6-8] The membrane phenomena have been examined through only the measurements of membrane potentials and membrane conductances in one of the works.[6] However, the membrane phenomena in the amphoteric membrane containing two kinds of exchange sites are too complicated to obtain the better understanding. More informations such as the experiments due to different amphoteric membrane or the determination of the concentration within membrane should be therefore accumlated.

Thus, the studies on the membrane having the different base membrane but the similar ion exchange sites as that of previous paper have been started in this series. In the previous reports of this series,[9,10] the membrane potential controlled by the ionic charge in the electrolyte solution was observed and was explained qualitatively by the apparent transport number, which can be obtained from the relation between the membrane potential and the activity in outer electrolyte solution. In order to confirm the results further, the alternative transport number which is evaluated from the measurement of ions transfered under the supplied currents, i.e., the electrodialysis experiment should be examined. Thus, the electrodialysis experiments were carried out, and the transport numbers were obtained about three species of electrolytes involving the cations of different valences. In addition, the ionic mobilities were estimated owing to know the ionic concentration within membrane. The details about the behavior of ion within membrane will be discussed in this work.

Experimental

Materials. The amphoteric ion exchange membrane used in the present study is coded as a "Neosepta CSV" and was supplied by Tokuyama Soda Co., Ltd., which was characterized with sulfonic acid group for cation-exchange site and *N*-methylpyridinium group for anion-exchange site. The characteristics of membrane were shown elsewhere.[9,10]

Before measurements, the membranes were conditioned by immersing successively in 0.1 M† aqueous ammonia, 0.5 M HCl, and 1.0 M NaCl aqueous solution, and the process was repeated a few times. The membranes thus obtained were washed with twice distilled water until the washing solutions did not contain any ions. The electrolytes(NaCl, $CaCl_2$, $LaCl_3$) were extra pure reagents and used without further purification. The aqueous electrolyte solutions indicated almost the same pH as that of distilled water equilibrated with carbon dioxides. For example, pH value of 10^{-2} mol dm^{-3} $LaCl_3$ solution was 5.46±0.05.

Apparatus. The cells for membrane potential, membrane conductance, and electrodialysis were made of glass, and consisted of two 20 cm^3 compartments. Two 1.57 cm^2 platinum black electrodes were equipped in the glass cells for membrane conductance. The membrane was placed between two compartments, and the available areas of membrane were 0.78 cm^2 for membrane potential and 3.14 cm^2 for membrane conductance and electrodialysis, respectively.

Measurements.

Membrane Potential: The membrane potential was measured according to the conventional method.[9,10] The results were obtained with the system in which the concentration of the electrolyte solution was kept constant in compartment(I) at 5.0×10^{-3} mol dm^{-3}, and was changed in compartment(II) from 1.0×10^{-3} to 1.0×10^{-1} mol dm^{-3}.

Electrodialysis: For the electrodialysis experiments, 10^{-2} mol dm^{-3} solutions of NaCl, $CaCl_2$, and $LaCl_3$ were used. In the electrodialysis experiment, a pair of silver-silver chloride electrodes with 2 cm^2 in area was inserted into aqueous electrolyte solutions at both sides of membrane. The currents of 0.1, 0.2, and 0.4 mA were supplied from phase(II) to phase(I) through Current Supply Equipment (Yokogawa

† 1 M=1 mol dm^{-3}.

Electric Works DC Voltage Current Standard Type 2853). After a passage of time, a constant volume (1 ml) was pipetted from both compartments and the concentration changes of ion from the initial electrolyte solutions were determined by the atomic absorption spectroscopy (Hitachi Co., Ltd., Model 180-50). In the case of La ion, the colorimeric method with arsenazo III reagent was employed because the sensitivity of atomic absorption was not effective.

Membrane Conductance: The membrane resistance was measured with Universal Bridge (Yokogawa-Hewlett-Packard Co., Model 4265B) through two platinum black electrodes in the sample solutions. After 10^{-2} mol dm^{-3} solutions of the respective electrolytes were poured into both compartments, the electrical resistances of the system with and without membrane were measured. The membrane resistance, R_m was obtained by subtracting the solution resistance without membrane from the total resistance. The membrane conductance, G_m was calculated by dividing $1/R_m$ with the available membrane area, 3.14 cm^2.

Ionic Concentration within Membrane: After the membrane (5×5 cm^2) was equilibrated with 10^{-2} mol dm^{-3} electrolyte solution for 72 h, the membrane was dipped into the distilled water for 72 h in order to remove the electrolyte due to donnan adsorption. Then, the ionic concentrations within membrane due to ion exchange with sites were eluted by 1.0 M HNO_3. The concentrations were determined by the same method as in electrodialysis experiment. The concentration of Cl ion was determined by Mohr's method. The total concentration of the electrolytes was taken as the concentration within membrane.

Throughout this study, the twice experiments for a single system were at least performed and the average value was taken as a reliable value. The solution phases were sufficiently stirred by the magnetic stirrers and the temperature of phases were kept at 25 °C.

Results and Discussion

Figure 1 shows the relations between the potentials and the mean activities of ions in the outer solutions for NaCl, $CaCl_2$, and $LaCl_3$. The mean activities were taken from the values in literature.[11] From dependence of the membrane potentials on activities in 1—1 valent electrolyte, NaCl, it was suggested that the membrane functions as a cation-exchange membrane regardless of having the anion-exchange site. On the other hand, in the case of 2—1 valent electrolyte, $CaCl_2$, the relation between the membrane potential and logarithmic mean activity of $CaCl_2$ deviated slightly from the linearity and the slope of potential per decade concentration decreased with suggesting the strong interaction of divalent cation with the cation-exchange site. Furthermore, in the system of $LaCl_3$ having tervalent cation, the inversion of the slope took place as seen in Fig. 1. In order to discuss the results quantitatively, it is convenient to use transport numbers which can be calculated from the membrane potential vs. mean activity relationships in Fig. 1.

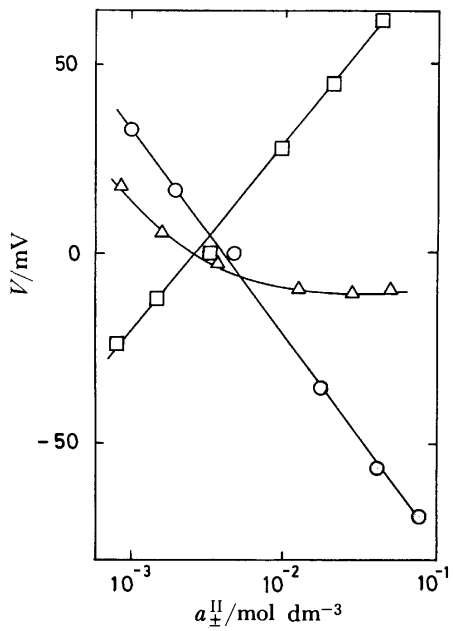

Fig. 1. Membrane potentials as a function of mean activities of electrolytes uni- to tervalent cations in phase (II). ○: NaCl, △: $CaCl_2$, □: $LaCl_3$.

Generally, the relationship between the membrane potential, V, and the mean activity of electrolyte, $a_\pm$, for amphoteric membrane was given as follows,

$$V = \left(\frac{t_M}{Z_M} + \frac{t_{Cl}}{Z_{Cl}}\right)\frac{RT}{F}\ln\frac{a_\pm(I)}{a_\pm(II)}, \quad (1)$$

where t_M and t_{Cl} indicate the transport numbers of cation and anion; Z_M and Z_{Cl}, the valences of M and Cl ions; respectively. Transport numbers were calculated from the slope in Fig. 1 by means of Eq. 1 and were summarized in Table 1. In the case of $CaCl_2$, the transport number was calculated from the tangent slope at 10^{-2} mol dm^{-3} $CaCl_2$ concentration.

As shown in Table 1, it is obvious that the transport numbers, t_M or t_{Cl}, correspond to the slopes in membrane potential vs. the activity of electrolyte solution relationships. In the case of $LaCl_3$, t_{La} was remarkably reduced to 0.13. The value means that Cl ion can be relatively transported more than La ion, and it may be supposed that La ion is trapped around the cation-exchange sites owing to the strong electrostatic attraction.

In order to confirm the results obtained above further, the transport number by electrodialysis method was estimated. A typical example for NaCl system (10^{-2} mol dm^{-3}, 0.2 mA) was shown in Fig. 2. Sodium ion in phase(I) increased and that in phase(II) decreased with a passage of time under the supplied

Table 1. Transport Numbers, t_M and t_{Cl} Evaluated from Membrane Potential and Electrodialysis

Salt	Membrane potential		Electrodialysis	
	t_M	t_{Cl}	t_M	t_{Cl}
NaCl	0.95	0.05	0.94	0.06
$CaCl_2$	0.82	0.18	0.83	0.17
$LaCl_3$	0.13	0.87	0.12	0.88

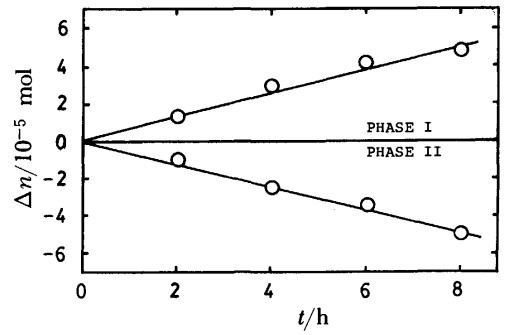

Fig. 2. The increase and decrease of Na ions in phase (I) and phase (II) against the passage of time for NaCl system (1.0×10^{-2} mol dm^{-3}, 0.2 mA).

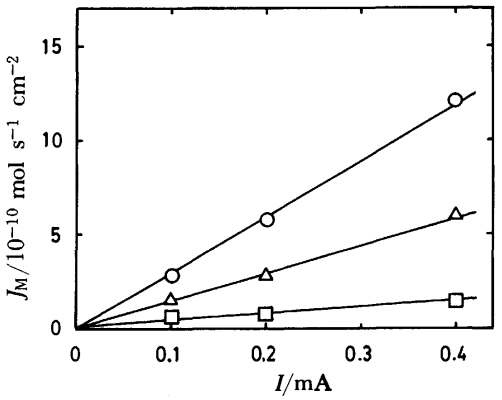

Fig. 3. The relationship between flux and current for each cation. ○: Na, △: Ca, □: La.

current of 0.2 mA. The concentration change from the initial Na ion concentration, Δn_{Na}, showed the straight line against time in both phases and the absolute values of the slope were approximately the same. The similar results were also obtained at the other systems. The absolute values of the concentration change in both phases were averaged, and the ion fluxes were evaluated with Eq. 2 from the slopes of the linear portion,

$$J_M = \frac{\Delta n}{sA}, \tag{2}$$

where Δn, s, and A denote moles of transfered ion, time in sec during the supplied currents and membrane area in cm^2, respectively. The relation between flux and current for each cation was shown in Fig. 3. The cationic current due to cation transfered, i_M, can be evaluated by the Eq. 3 taking account of the quantity of electricity on the flux,

$$i_M = Z_M F J_M A. \tag{3}$$

The transport number, t_M, can be obtained from the relationship between i_M and I according to the following relation,

$$t_M = \frac{i_M}{I}, \tag{4}$$

where I is the total supplied current. The transport numbers, t_M, due to the electrodialysis were shown together with t_{Cl} which were calculated by a relation, $t_M+t_{Cl}=1$, in Table 1. As seen in Table 1, the values of t_M decrease with increase of the cationic valences in accordance with t_M obtained by the membrane potential measurement.

In order to discuss the dynamic behavior of ions within the membrane in more detail, it would be effective to introduce the membrane permeability coefficients presented in previous papers.[6,12] The permeability coefficient reflects the dynamic behavior of ion within membrane and is a function of the membrane potential, V, membrane conductance, G_m, and transport number, t, and is expressed as follows,

$$P_M = \frac{t_M G_m RT}{Z_M^2 F^2 (a_M^I \cdot a_M^{II})^{1/2}} \cdot \frac{Z_M F(V-V_M)/2RT}{\sinh(Z_M F(V-V_M)/2RT)}, \tag{5}$$

$$P_{Cl} = \frac{t_{Cl} G_m RT}{Z_{Cl}^2 F^2 (a_{Cl}^I \cdot a_{Cl}^{II})^{1/2}} \cdot \frac{Z_{Cl} F(V-V_{Cl})/2RT}{\sinh(Z_{Cl} F(V-V_{Cl})/2RT)}, \tag{6}$$

where V_M and V_{Cl} denote the equilibrium potentials of ions, M and Cl, respectively, and $(a^I \cdot a^{II})^{1/2}$, geometrical mean activity in phase(I) and phase(II). On the

$LaCl_3$	1050	3.03×10^{-4}

a) Concentration of salt solution: 1.0×10^{-2} mol dm^{-3}.

Table 3. Membrane Permeabilities, P_M and P_{Cl} Evaluated from Membrane Potential and Electrodialysis

Salt	Membrane potential			Electrodialysis		
	P_M	P_{Cl}	P_M/P_{Cl}	P_M	P_{Cl}	P_M/P_{Cl}
	cm s^{-1}	cm s^{-1}		cm s^{-1}	cm s^{-1}	
NaCl	4.14×10^{-4}	2.18×10^{-5}	18.99	2.97×10^{-4}	1.56×10^{-5}	19.04
$CaCl_2$	4.75×10^{-5}	4.17×10^{-5}	1.14	7.06×10^{-5}	2.90×10^{-5}	2.43
$LaCl_3$	2.27×10^{-7}	1.64×10^{-5}	0.017	5.77×10^{-7}	1.27×10^{-5}	0.045

other hand, G_m was measured in the same system as that of electrodialysis experiment. In calculation of P_M and P_{Cl}, the membrane potentials generated between 5×10^{-3} mol dm^{-3} in phase(I) and 1×10^{-2} mol dm^{-3} in phase(II), the respective mean activities, the transport numbers from membrane potentials and the membrane conductances in Table 2 were inserted into Eqs. 5 and 6. The results were shown in Table 3. The values of P_M were largely changed by the cationic valences while P_{Cl} showed almost constant values in three systems. For example, in the case of NaCl system, the membrane permeability coefficient of cation, P_{Na}, was approximately 20-fold larger than P_{Cl}. The large difference indicated that Na ion can be easily transported. In the case of $CaCl_2$, P_{Ca} decreased slightly. Contrary to former two cases, P_{La} in $LaCl_3$ was remarkably reduced, and as a result, Cl ion can be transported. The ratios, P_M/P_{Cl}, which were also given in Table 3, reflect the permselectivity of ions through membrane. The facts confirm again that membrane potential in the present system is determined by the difference of the membrane permeability coefficients for cation and anion. In other words, the membrane potentials strongly depend upon the cationic valences.

Here, it is interesting that the present result is compared with that of the previous paper at 10^{-2} mol dm^{-3} electrolyte solution.[6] The evaluated membrane permeabilities except for La ion in this study were almost the same order of magnitude as in previous one, but the membrane permeability ratios of cations to anions indicated large discrepancies between two kinds of the membranes. The values of present ratios were strongly dependent on the valency of electrolyte, and particularly, in the case of NaCl, the membrane indicated a high permselectivity to Na ion over Cl ion, while the permeability ratio of La ion to Cl ion was less than unity in the case of $LaCl_3$. On the other hand, the magnitude of cationic permeabilities exceeded that of anionic one as shown in Fig. 5 of previous paper though there is no result about $LaCl_3$. The reason is not clear at present, but it may be partly attributed to the difference of the membrane skeleton.

In the present electrodialysis and conductance experiments, the electrolyte solutions having the same concentration were placed at phase(I) and phase(II). Therefore, V, V_M, are V_{Cl} in Eqs. 5 and 6 are almost reduced to zero, and the potential terms can be dropped out. Furthermore, under the experimental conditions described above, $(a^{I}_{M}\cdot a^{II}_{M})^{1/2}$ and $(a^{I}_{Cl}\cdot a^{II}_{Cl})^{1/2}$ can be replaced by $a_{\pm M}$ and $a_{\pm Cl}$. Finally, taking account of $t_M G_m \delta = Z_M F^2 \bar{U}_M \bar{C}_M$, we can obtain Eqs. 7 and 8 as the alternative expression for P,

$$P_M = \frac{RT\bar{U}_M}{\delta}\cdot\frac{\bar{C}_M}{(a^{I}_{M}\cdot a^{II}_{M})^{1/2}}, \tag{7}$$

$$P_{Cl} = \frac{RT\bar{U}_{Cl}}{\delta}\cdot\frac{\bar{C}_{Cl}}{(a^{I}_{Cl}\cdot a^{II}_{Cl})^{1/2}}, \tag{8}$$

where δ denotes membrane thickness; $\bar{C}$, concentration of ion within membrane; $\bar{U}$, absolute mobility of ion within membrane. Equations of 7 and 8 are sufficiently applicable to the present systems in which the concentrations of electrolyte in both phases, I and II, were identical. The evaluated values of P were also shown in Table 3. The results were in good agreement with those obtained by means of Eqs. 5 and 6. Equations of 7 and 8 have the instructive expression for understanding of physicochemical meaning as to the membrane permeability coefficient, P. It is clear that P largely depends on a product of the mobility and the concentration within membrane under the present experimental conditions.

At present stage, it is possible to know the mobility of ion within membrane provided the ionic concentration within membrane, $\bar{C}$, is given. The ionic concentration, $\bar{C}$, was determined according to the method described in experimental section and given in Table 4. The ionic mobilities for three electrolyte systems examined were calculated in terms of Eqs. 7 and 8, and the results were summarized in Table 5 together with using mean activities. The mobilities indicated a similar tendency with membrane permeability coefficients. In the case of NaCl system, $\bar{U}_{Na}$ was larger than $\bar{U}_{Cl}$. In the system of $LaCl_3$ having tervalent cation, $\bar{U}_{La}$ was remarkably small. In this system, P_M and P_{Cl} could be mainly determined by the dynamic factor($\bar{U}$)

Table 4. Ionic Concentrations within Membrane

Salt	$\bar{C}_M$	$\bar{C}_{Cl}$
	mol dm^{-3}	mol dm^{-3}
NaCl	2.21	1.24
$CaCl_2$	5.76×10^{-1}	6.33×10^{-1}
$LaCl_3$	3.81×10^{-1}	5.81×10^{-1}

Table 5. Ionic Mobilities within Membrane, $\bar{U}_M$ and $\bar{U}_{Cl}$ Evaluated from Electrodialysis

Salt	$a_\pm$	$\bar{U}_M$	$\bar{U}_{Cl}$	$\bar{U}_M/\bar{U}_{Cl}$
	mol dm^{-3}	cm s^{-1} dyn^{-1}	cm s^{-1} dyn^{-1}	
NaCl	9.02×10^{-3}	5.81×10^{-12}	6.61×10^{-13}	8.79
$CaCl_2$	7.31×10^{-3}	4.34×10^{-12}	1.62×10^{-12}	2.69
$LaCl_3$	5.60×10^{-3}	4.08×10^{-14}	5.92×10^{-13}	0.07

rather than static factor($\bar{C}$). It is considered that La ion having large charge was trapped around the cation-exchange sites owing to the strong electrostatic attraction. It may be said that ionic permeability through membrane is controlled by the valence of cation.

The present work was partially supported by Grant-in-Aid for Scientific Research No. 58470007 from the Ministry of Education, Science and Culture.

ESR spectra of duroquinone anion radical (DQ^-), methyl viologen cation radical (MV^+), and 5,10-dimethyl-5,10-dihydrophenazine cation radical ($DMPZ^+$) were measured in various aqueous surfactant solutions. The line width of each peak of the ESR spectra for DQ^- in cationic and anionic surfactant solutions showed a quadratic dependence on the total nuclear quantum number, $M=\Sigma m_i$ (i=1 to 12), of methyl protons of DQ^-. The rotational correlation times, τ_c, of DQ^- determined from these dependences, were 10^{-9}—10^{-8} s in cationic surfactant (dodecyl-, tetradecyl-, and hexadecyltrimethylammonium bromide) solutions, and 10^{-10}—10^{-9} s in nonionic surfactant (Triton X-100) solution. ESR spectra of MV^+ and $DMPZ^+$ in anionic surfactant (sodium dodecyl sulfate; SDS) solution showed anomalous patterns as not exhibiting the hyperfine splittings due to the nitrogen nucleus. These anomalies were explained by the more significant broadening of the outer peaks due to nitrogen splitting compared with the broadening of the central peaks corresponding to the nuclear quantum number of nitrogen, $M_N=m_{N1}+m_{N2}=0$. From these results, the rotational correlation time for $DMPZ^+$ in SDS solution was estimated as about 10^{-10} s.

Many nitroxide radicals have been used as spin probes in order to study the dynamic properties of micelles and bilayers.[1-12] ESR spectra of nitroxide radicals solubilized into micelles have unsymmetric hyperfine structure mainly consisting of three peaks due to the nitrogen atom in the nitroxide radical. These unsymmetric properties of spectra are explained by the incomplete averaging of the anisotropic g tensor and the hyperfine coupling tensor. By the analysis of the unsymmetry of these spectra, dynamic properties of micelle and micelle solubilized substances have been determined.[1-12] We are studying the electron-transfer reactions of ion radicals captured by the micelle. In order to study the correlation between the reactivities and the dynamic properties of ion radicals, it is necessary to know the dynamic properties of these ion radicals. However, the ESR spectra of paramagnetic substances solubilized into a micelle other than nitroxide radicals have received little attention. In this paper, we report the characteristics of the ESR spectra of duroquinone anion radical (DQ^-), the 5,10-dimethyl-5,10-dihydrophenazine cation radical ($DMPZ^+$) and the methyl viologen cation radical (MV^+) in several surfactants solutions. Furthermore, we report the dynamic properties, as a rotational correlation time, of ion radicals captured by the micelle obtained from these ESR spectra.

Experimental

Duroquinone (DQ) and methyl viologen dibromide ($MV^{2+}Br_2^{2-}$) used were reagent grade and were used without further purification. 5,10-Dimethyl-5,10-dihydrophenazine (DMPZ) was provide by Dr. Y. Ohsawa in this laboratory. Sodium dodecyl sulfate (SDS), dodecyltrimethylammonium bromide (C_{12}TMAB), tetradecyltrimethylammonium bromide (C_{14}TMAB), hexadecyltrimethylammonium bromide (C_{16}TMAB) and Triton X-100 (TX-100) were reagent grade and used without further purification.

†Present address: Seiko Instruments Inc., Takatsuka, Matsudo, Chiba 271.

Sample solutions of DQ^- and MV^+ were prepared by the reduction of aqueous solutions of DQ and MV^{2+} with sodium dithionite ($Na_2S_2O_4$) in the presence or absence of a surfactant. Sample solutions of $DMPZ^+$ were prepared by the oxidation of aqueous micellar or acetonitrile solution of DMPZ with ceric sulfate ($Ce(SO_4)_2$).

Sample cells for ESR measurements were Pyrex glass capillary cells with about 1 mm inner diameter. ESR spectra were measured by a JEOL-FE3XI ESR spectrometer equipped with a variable temperature adapter. Computer simulation of ESR spectra were carried out with the Hitachi M-280H computer system at the Computer Center of Tokyo Institute of Technology.

Results and Discussion

ESR Spectra for DQ^- in Various Surfactant Solutions. Figure 1 shows the ESR spectra for DQ^- in various solutions. The ESR spectrum for an aqueous solution of DQ^- without surfactant was symmetric and the relative intensity of each peak agreed reasonably with those calculated theoretically. The observed hyperfine coupling constant for twelve equivalent methyl protons of DQ^- in this spectrum was 1.90 G (1G=10^{-4} T) and agreed well with the value for DQ^- in C_2H_5OH[13] and in CH_3OH-H_2O mixture.[14] The ESR spectrum for the DQ^- in 0.5 M (1 M=1 mol dm^{-3}) SDS solution was similar to that mentioned above. On the other hand, the ESR spectra for DQ^- in the nonionic and cationic surfactant solutions were unsymmetrical and the degree of dissymmetry was larger for those in the cationic surfactant solutions than that in the nonionic surfactant solution. Furthermore, for the cationic surfactant solutions, the longer the carbon chain of the surfactant molecule, the larger the degree of dissymmetry.

ESR Spectra of $DMPZ^+$ and MV^+ in SDS Solution. Figure 2 (a) shows the ESR spectrum of $DMPZ^+$ in 0.1 M SDS solution at 40 °C. This spectrum was analyzed as the hyperfine structure with A_1(6H)=6.15 G, A_2(4H)=1.68 G, and A_3(4H)=0.66 G. In fact, as shown

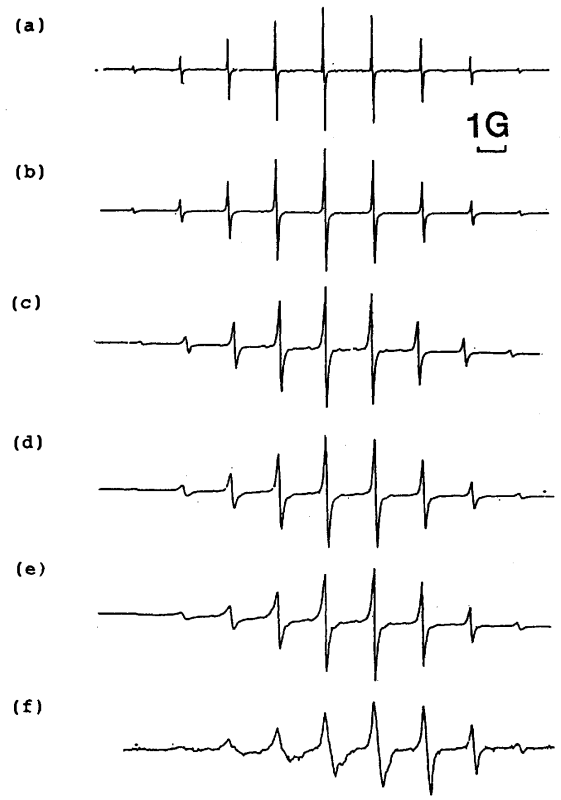

Fig. 1. The ESR spectra of DQ^- in aqueous solutions in the presence or absence of various surfactants at 20°C. (a) Without surfactant; (b) 0.5 M SDS; (c) 0.3 M TX-100; (d) 0.5 M C_{12}TMAB; (e) 0.5 M C_{14}TMAB; (f) 0.5 M C_{16}TMAB.

in Fig. 2 (b), the computer simulated spectrum with these parameters well-reproduced the experimental spectrum. Evidently, this spectrum appeared to have no hyperfine splitting due to the nitrogen nucleus in a $DMPZ^+$ ion. On the other hand, the ESR spectra of $DMPZ^+$ in AN and in aqueous solution without surfactant showed the hyperfine splittings due to the nitrogen nucleus.

Figure 3 (a) shows the ESR spectrum of MV^+ in 0.1 M SDS solution at 30°C. This spectrum also appears to have no hyperfine splittings due to the nitrogen nucleus, as shown by the comparison with the computer simulated spectrum with $A_1(6H)=3.99$ G, $A_2(4H)=1.57$ G, and $A_3(4H)=1.33$ G in Fig 3 (b). On the other hand, the ESR spectrum of MV^+ in aqueous solution agreed well with the computer simulated spectrum with $A(2N)=4.23$ G, $A_1(6H)=3.99$ G, $A_2(4H)=1.57$ G, and $A_3(4H)=1.33$ G.

Theoretical Basis for Line-Width Analysis. In order to simplify the analysis of the line width of the ESR spectrum, we assume that the g tensor and the hyperfine coupling tensor have cylindrical symmetry. Under this assumption, from the theory of Kivelson,[15] the line width of each hyperfine lines for an ESR spectrum of a free radical in a doublet state ($S=1/2$) is given by the following equation:

$$T_2^{-1} = \tau_c[(4/45)(\Delta\gamma H)^2+\sum(3/8)\sigma_{ii}^2[<J_i(J_i+1)>_{M_i}-M_i] + \sum\sigma_{ij}M_iM_j-(4/15)(\Delta\gamma H)b_iM_i] \quad (1)$$

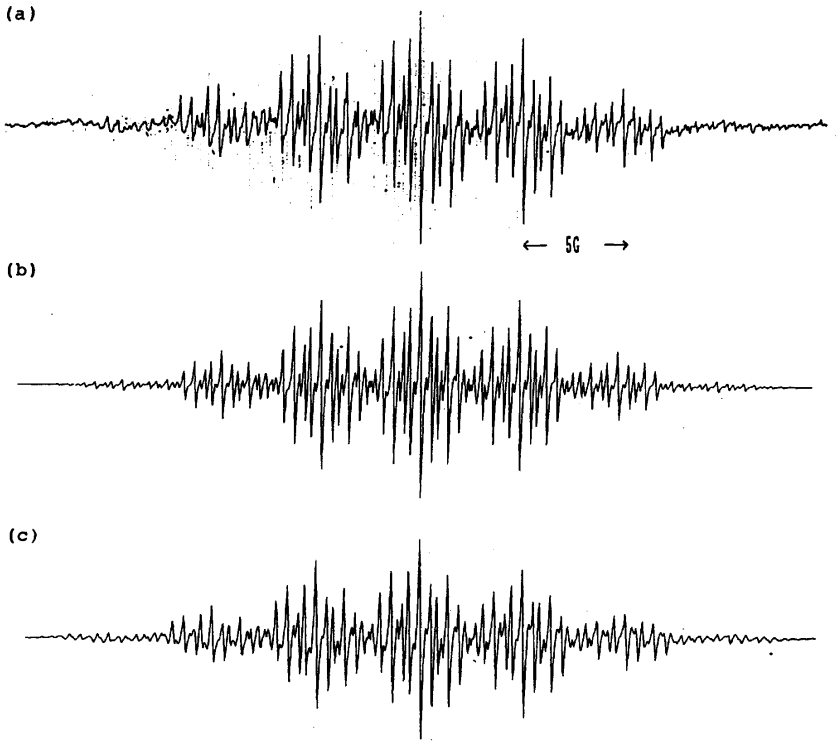

Fig. 2. The ESR spectra of $DMPZ^+$ (a) observed in 0.1 M SDS solution at 40°C; (b) simulated with $A_1(6H)=6.15$ G, $A_2(4H)=1.68$ G, $A_3(4H)=0.66$ G, and ΔH_{pp}(all peaks)=0.120 G; (c) simulated with $A(2N)=6.63$ G, $A_1(6H)=6.15$ G; $A_2(4H)=1.68$ G, $A_3(4H)=0.66$ G, $\Delta H_{pp}(M_N=\pm2)=0.570$ G, $\Delta H_{pp}(M_N=\pm1)=0.256$ G, and $\Delta H_{pp}(M_N=0)=0.120$ G.

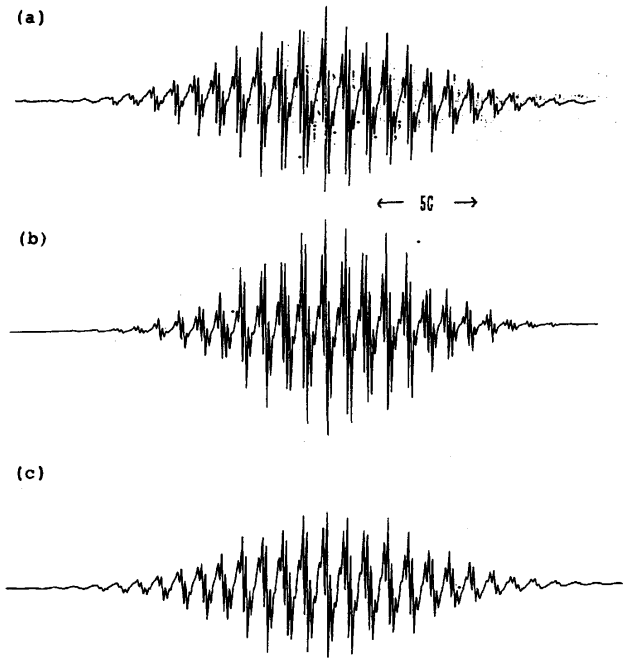

Fig. 3. The ESR spectra of MV^+ (a) observed in 0.1 M SDS solution at 30°C; (b) simulated with A_1(6H)=3.99 G, A_2(4H)=1.57 G, A_3(4H)=1.33 G, and ΔH_{pp}(all peaks)=0.120 G; (c) simulated with A(2N)=4.23 G, A_1(6H)=3.99 G; A_2(4H)=1.57 G, A_3(4H)=1.33 G, $\Delta H_{pp}(M_N=\pm 2)$=0.570 G, $\Delta H_{pp}(M_N=\pm 1)$=0.256 G, and $\Delta H_{pp}(M_N=0)$=0.120 G.

In this equation

$$\Delta\gamma=\gamma_{//}-\gamma_{\perp},$$
$$\sigma_{ij}=(1/5)b_ib_j,$$
$$b_i=(4\pi/3)\{(A_i)_{//}-(A_i)_{\perp}\}$$

and τ_c, H, M_i, and $\langle J_i(J_i+1)\rangle$ are the rotational correlation time, the value of the stationary magnetic field, the quantum number corresponding to the component of the stationary magnetic field of the ith group of equivalent nuclei, and the average value of $J_i(J_i+1)$ for a given value of M_i, respectively. And, $\gamma_{//}$, $\gamma_{\perp}$, $(A_i)_{//}$, and $(A_i)_{\perp}$ are the parallel and the perpendicular components of the principal values of gyromagnetic ratio tensor and hyperfine coupling tensors of the ith nuclear groups.

For one group of equivalent nuclei with I=1/2,

$$\langle J_i(J_i+1)\rangle=(1/2)n_i+M_i^2$$

where n_i is the number of nuclei in the group. When n_i=2 and I=1, $\langle J_i(J_i+1)\rangle$ is 6, 4, and 8/3 for M_i value of 2, 1, and 0, respectively.

Rotational Correlation Times for DQ^- in Micelle. The dissymmetry of the ESR spectra of DQ^- in nonionic and cationic micellar solutions may be explained by the incomplete averaging of the anisotropic g tensor and hyperfine coupling tensor for these radicals due to the restriction of the rotational Brownian motion by the solubilization to a micelle, as explained for nitroxide radicals solubilized into a micelle used as spin probe.

From the Eq. 1, the line width of each of the hyperfine lines for the ESR spectrum of DQ^- with equivalent twelve protons is expressed as follows,

$$(T_2)^{-1} = \tau_c\{[(9/20)b^2+(4/45)(\Delta\gamma H)^2] - (4/15)b\Delta\gamma HM + (b^2/5)M^2\}. \quad (2)$$

If the line width due to other relaxation mechanisms is given by ΔH_o, from Eq. 2 the total peak to peak line width, ΔH_{pp}, in the magnetic field unit is expressed as follows,

$$\Delta H_{pp} = a_1 + a_2M + a_3M^2 + \Delta H_o \quad (3)$$

where $a_1=(2\hbar\sqrt{3}g\beta)[9/20)b^2+(4/45)(\Delta\gamma H)^2]\tau_c$, $a_2=(2\hbar/\sqrt{3}g\beta)(4/15)b(\Delta\gamma H)\tau_c$, and $a_3=(2\hbar/\sqrt{3}g\beta)(b^2/5)\tau_c$.

Figure 4 shows the dependence of the observed line width for each peak of the ESR spectra of DQ^- in 0.5 M C_{12}TMAB solution at 10 and 20°C upon the value of M. These line width values agreed well with the quadratic fitted curves according to Eq. 3, and from these curves the parameters a_1, a_2, a_3, and ΔH_o were determined.

In order to determine the value of τ_c, however, the value of b and $\Delta\gamma$ must be known. Fortunately, as shown in Fig. 5, the ESR spectrum of DQ^- in C_{16}TMAB solution has marked unsymmetrical profile, and is similar to those in a solid matrix, especially at low temperature. The DQ^- molecule does not have exact cylindrical symmetry, but the spectrum in Fig. 5 shows that the principal values of the gyromagnetic ratio tensor and hyperfine coupling tensor of this

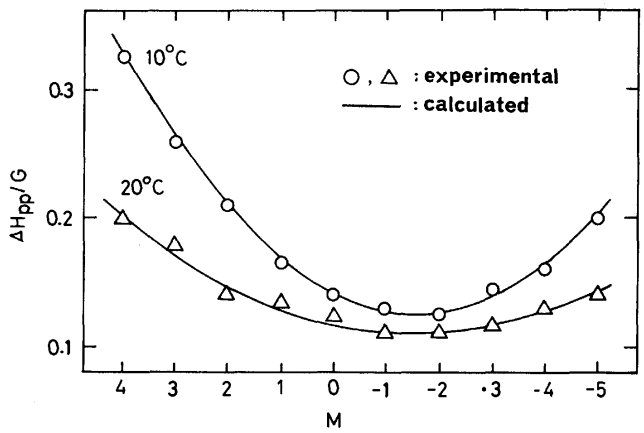

Fig. 4. The dependence of the line width, ΔH_{pp}, of the ESR spectrum of DQ^- in 0.5 M C_{12}TMAB solution on the total nuclear quantum number, M, of twelve hydrogens at 10 and 20°C.

Table 1. Rotational Correlation Times of the Duroquinone Anion in Various Surfactant Micelles

Surfactant Solution	$\tau_c \times 10^9$/s			
	10°C	20°C	30°C	40°C
0.5 M C_{12}TMAB	3.4	1.5	—	—
0.5 M C_{14}TMAB	—	3.2	2.2	—
0.5 M C_{16}TMAB	>3	>3	>3	2.9
0.3 M TX-100	0.85	0.53	0.37	—

molecule are nearly cylindrically symmetric. From this spectrum, we have estimated the value of $|A_{//}-A_{\perp}|$ and $|g_{//}-g_{\perp}|$ as 0.225 G and 1.49×10^{-3}, respectively. The values of τ_c were determined from the values of a_1, a_2, and a_3 independently, and they agreed well with each other. Table 1 shows the values of τ_c for DQ^- in various micellar solutions. These values of τ_c decrease with the increase of temperature, and increase with the length of the alkyl chain of the surfactants. The τ_c of DQ^- in C_{16}TMAB solution at low temperature can not be determined because of the complexity of the ESR spectrum due to the large anisotropy as shown in Fig. 5. However, these values of τ_c may be nearly 10^{-8} s at 10 or 20 °C, because this large anisotropic character of the spectrum indicates the larger correlation time of DQ^- in this solution. In previous works, almost only the values of τ_c for nitroxide radicals in micellar solutions have been reported. Furthermore, the majority of these values were measured in anionic micellar solutions such as SDS. These values of τ_c for nitroxide radicals in anionic micellar solutions were about 10^{-10} s,[1,3,4,7,12] and those in nonionic micellar solutions were about 10^{-9} s.[6,8,11]

The values of τ_c for DQ^- in the nonionic surfactant solution was smaller than those of nitroxide radicals in nonionic surfactant solutions. This result may be due to the fact that DQ^- is not only in a micellar phase but also in an aqueous phase in the nonionic surfactant solution, because the diffusion coefficient of DQ^- in the nonionic surfactant solution determined by cyclic voltammogram was larger than those of micelle itself. On the other hand, it was shown by cyclic voltammetry that DQ^- in the cationic surfactant solutions was almost completely captured by the micelle. The values of τ_c for DQ^- in the cationic surfactant solutions measured in this experiment are larger by one or more orders than those for nitroxide radicals in anionic surfactant solutions cited in the literatures.[1,3,4,7,12] This result shows that the rotational diffusion of DQ^- in the cationic micelle was more strongly restricted by the micelle than the nitroxide radical in the anionic micelles.

Rotational Correlation Times for $DMPZ^+$ and MV^+ in the SDS Micelle. From the results for the ESR spectra of $DMPZ^+$ and MV^+ in SDS solution, it is suggested that the peaks of the ESR spectra of $DMPZ^+$ and MV^+ split by the hyperfine interaction with the nitrogen nucleus are extremely broadened except for the central peaks corresponding to the zero value of the total nuclear quantum number of nitrogen, $M_N=0$.

If the contribution to the line width of each hyperfine lines due to the anisotropy of the gyromagnetic ratio tensor and the hyperfine coupling tensors other than nitrogen nucleus are neglected, the line width of each peak is determined only by the value of M_N. In such a situation, from Eq. 1, the line width of the hyperfine lines corresponding to the value of M_N, which equals to 0, ±1, and ±2, are $(8/40)b_N^2\tau_c$, $(17/40)b_N^2\tau_c$, and $(38/40)b_N^2\tau_c$, respectively.

Figures 2 (c) and 3 (c) show the computer simulated spectra considering the hyperfine splitting by nitrogen nucleus: $A(2N)=6.63$ G ($DMPZ^+$),[16] $A(2N)=4.43$ G (MV^+),[17] and the contribution to the line width due to the anisotropy of the hyperfine coupling tensor of the nitrogen nucleus described above: $\Delta H_{pp}(M_N=\pm2)=0.570$ G, $\Delta H_{pp}(M_N=\pm1)=0.256$ G, and $\Delta H_{pp}(M_N=0)=0.120$ G. These spectra reproduced the observed spectra (Fig. 2 (a), 3 (a)) more exactly than the simulated spectra obtained by neglecting the hyperfine splitting due to the nitrogen nucleus.

These results show that the ESR spectra of $DMPZ^+$ and MV^+ in 0.1 M SDS solutions appear to have no nitrogen hyperfine splittings because of the larger anisotropy of the nitrogen hyperfine coupling tensor compared with those of the other coupling tensors and the g tensor.

In order to determine the rotational correlation times for $DMPZ^+$ and MV^+ captured by the SDS micelle, it is necessary to know the anisotropy parameter of the nitrogen hyperfine coupling tensors of these cation radical, b_N. Unfortunately, these values have not yet been determined experimentally. Therefore, we must estimate these values from those of nitrogen-containing paramagnetic compounds. Typical principal values of hyperfine coupling tensors for the nitrogen nucleus of nitroxide radicals are about 32, 6, and 6 G.[18] From these values, an anisotropy parameter, and an isotropic coupling constant are obtained: $b_N=26$ G, $A_N=15$ G. The relative anisotropy parameter defined here, $b_N/A_N=1.73$, of nitroxide radical is the largest among those of the nitrogen-containing paramagnetic compounds.[19] If we adopt this value as the relative anisotropy parameter for $DMPZ^+$ and MV^+, the calculated rotational correlation times of these cation radicals may be the lowest limit of these values. Assuming that the values of b_N's for $DMPZ^+$ and MV^+ are $6.63\times1.73=11.5$ G and $4.23\times1.73=7.3$ G, respectively, the rotational correlation times for these cation radicals can be evaluated from the following equation,

$$\Delta H_{pp}(M_N=0)=(2/\sqrt{3})(\hbar/g\beta)(38/40)b_N^2\tau_c. \quad (4)$$

Using the observed line width at 40 °C, i.e. 0.12 G for $DMPZ^+$ and MV^+, the calculated rotational correlation times are 1.4×10^{-11} and 3.4×10^{-11} s. These values are small compared with those for DQ^- in cati-

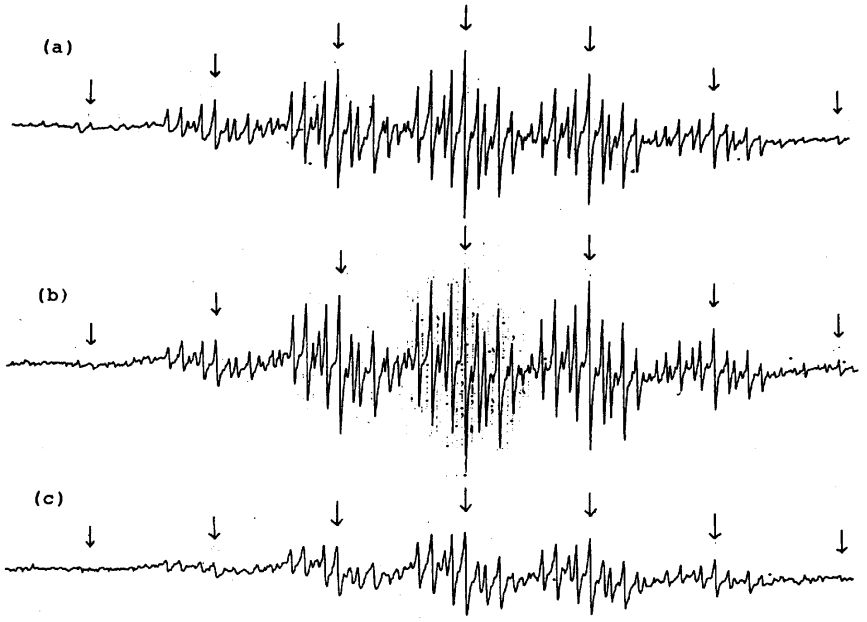

Fig. 6. The ESR spectra of $DMPZ^+$ in 0.1 M SDS solution at (a) 40 °C; (b) 20 °C; (c) 0 °C. Arrows shows the main peaks splitted by the hyperfine interaction of an electron spin with six methyl hydrogens.

onic micelles. However, these values are their lower limit, as described above. Therefore, it is desirable to determine their upper limit by the other method.

In the above discussion, we have neglected the effect of the anisotropy of the hyperfine coupling tensors of the hydrogen atoms. In fact, their anisotropy did slightly affect the ESR spectrum of $DMPZ^+$ at 40 °C, but appreciably more at lower temperatures. Figure 6 shows the temperature dependence of the ESR spectrum of $DMPZ^+$. Peaks indicated by arrows are the main peaks split by the hyperfine interactions of an electron spin with methyl hydrogens. Their intensities became more unsymmetrical with decreasing temperature. The degree of dissymmetry is smaller compared with that of DQ^- in cationic micelle at 20 °C (ref. Fig. 1). The twelve hydrogens of DQ^- is a β hydrogen with respect to an odd electron on the ring carbon atoms. Similarly, the methyl hydrogen of $DMPZ^+$ is also a β hydrogen with respect to an odd electron on the ring nitrogen atoms. The degree of anisotropy of the hyperfine coupling tensor for a β hydrogen is generally smaller compared to an α hydrogen. For DQ^-, the relative anisotropy parameter b_H/A_H is about 0.1. It is reasonable to assume that the relative anisotropy parameter for methyl hydrogens of $DMPZ^+$ is about 0.1. The isotropic hyperfine coupling constant of methyl hydrogens is 6.2 G, and about three times larger than that for the hydrogens of DQ^-. The contribution of an anisotropy parameter to the line width of an ESR spectrum is proportional to its square. Therefore, it is shown that the rotational correlation time (τ_c) of $DMPZ^+$ is at least smaller than a tenth of those for DQ^- in cationic micelles, i.e. about 10^{-9} s. The upper limit of the rotational correlation time of MV^+ in the SDS micelle can not be determined because of the complexity of the ESR spectrum of MV^+.

From the results shown above, it is concluded that the rotational coorrelation times (τ_c) of $DMPZ^+$ in the SDS micelle have a value between 10^{-9} and 10^{-11} s, and probably about 10^{-10} s. The large difference between the rotational correlation times for $DMPZ^+$ in the SDS micelle and DQ^- in a cationic micelle is a remarkable fact. The reason for this is not yet known, but it may be noteworthy that the cationic surfactant has three methyl groups at the positively charged hydrophilic part, $(CH_3)_3N^+$-, while the anionic surfactant (SDS) has only the $-SO_3^-$ group at the hydrophilic part.

We wish to thank Profs. Hiroshi Fukutomi and Hiroshi Tomiyasu for giving us facilities in ESR measurement at The Research Laboratory for Nuclear Reactor in Tokyo Institute of Technology.

(Received September 18, 1986)

The catalase-like activity of anion-exchange resins (Amberlite IRA 900) modified with various metalloporphyrins in the acceleration of reaction (1) was evaluated by efficiency in color reaction (2) based on dye formation:

$$H_2O_2 + CH_3OH \xrightarrow{\text{catalase}} 2H_2O + HCHO \quad (1)$$

$$HCHO + \text{4-amino-3-hydrazino-5-mercapto-1,2,4-triazole} + KIO_4 \xrightarrow{OH^-} \text{Dye } (\lambda_{max} = 550\ \text{nm}). \quad (2)$$

Amberlite IRA 900 modified with Mn^{3+}-tetrakis(sulfophenyl)porphine ($MnTPPS_r$) was found to exhibit the highest catalase-like activity among the resins tested and was applied as a mimesis of catalase to the determination of hydrogen peroxide by the use of reactions (1) and (2). The molar absorption coefficient for hydrogen peroxide was found to be $2.37\times10^4\ mol^{-1}\,dm^3\,cm^{-1}$, which is larger than twice that in the control catalase method ($0.97\times10^4\ mol^{-1}\,dm^3cm^{-1}$). Interferences by common foreign substances tested were found to be small. $MnTPPS_r$ gave a better result than catalase in the determination of hydrogen peroxide.

In clinical analyses, catalase has been used commonly for the determination of hydrogen peroxide released from some substances which are the target of the general clinical analyses. However, this enzyme is not stable and low reproducibility of its activity is a problem which we encounter sometimes. Attempts to develop stable and useful mimesis of catalase in the study of its model complex in solution did not give any success, for all investigations.[1-4] Previously, we have reported that some ion-exchange resins modified with metalloporphyrins (M-P resins) exhibit the catalase-like activity to accelerate the decomposition of hydrogen peroxide.[5,6] In order to apply the catalase-like activity of the M-P resins to the practical uses, we carried out the evaluation of their catalase-like activity in reaction (1) shown in Fig. 1, through the efficiency in the dye formation by reaction (2). In addition, we attempted to develop a new method for the determination of hydrogen peroxide by reactions (1) and (2) using an anion-exchange resin (Amberlite IRA 900) modified with Mn^{3+}-tetrakis(sulfophenyl)porphine ($MnTPPS_r$), which gave the highest activity.

Experimental

Material. Tetrakis(sulfophenyl)porphine (H_2TPPS), tetrakis(*p*-carboxyphenyl)porphine (H_2TCPP) and protoporphyrin (H_2PP) were purchased from Tokyo Kasei Co., Ltd., and used without further purification for the preparation of metalloporphyrins. Metalloporphyrins except for commercially available Fe^{3+}- and Cu^{2+}-chlorophyllins (M-CP) were prepared as aqueous solutions by the methods reported in the literatures.[7-10] Catalase (Type I, from beef liver) was purchased from Boeringer Co., Ltd. Other reagents were of analytical or reagent grade.

Modification of Amberlite IRA 900 with Metalloporphyrins. The resins modified with metalloporphyrins (M-P resins or $M\text{-}P_r$, subscript "r" indicates the resin modified with metalloporphyrin) were prepared by shaking 4 g of dry Amberlite IRA 900 (nitrate form) with the solutions of metalloporphyrin (100 μmol in 200 ml) in a 1 : 1 mixture of acetone and water as reported previously.[5,6] In all cases, metalloporphyrins were adsorbed on IRA 900 completely and not detected in the solution after adsorption.

The M-P resins were stable for at least one year at room temperature in the dark and the decrease of their activities was not observed.

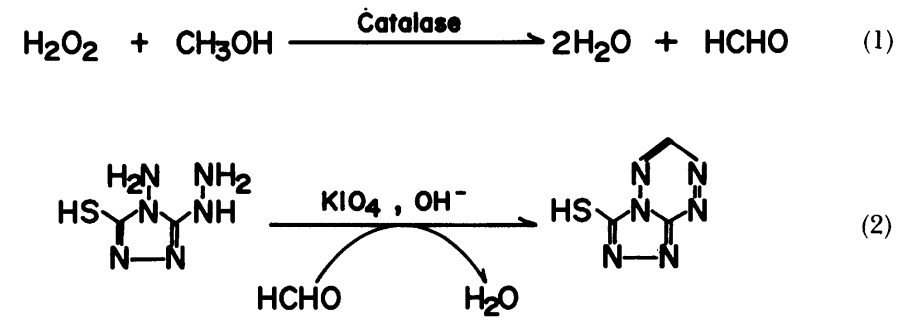

Fig. 1. Reactions.

Apparatus. The absorption spectra and the absorbances were measured on a Shimadzu UV-180 double beam spectrophotometer and a Shimadzu UV-100 spectrophotometer, respectively, with 10 mm quartz cells.

Procedure for the Examination of Catalase-Like Activity. The M-P resin was added into a mixture of hydrogen peroxide solution (0.5 ml), pH 11.0 carbonate buffer (4.0 ml, 0.2 M, 1 M=1 mol dm^{-3}) and distilled methyl alcohol (2.0 ml), and the mixture was incubated at 37 °C for 10 min. The supernatant taken (0.5 ml) was added to a mixture of 4-amino-3-hydrazino-5-mercapto-1,2,4-triazole (AHMT) solution (2.0 ml, 10 mg ml^{-1} in 0.5 M HCl) and 3 M KOH (2.0 ml), and the mixture was allowed to stand for 10 min. A solution of potassium periodate (2 ml, 0.02 M in 0.2 M KOH) was added to the mixture and the absorbance at 550 nm of the colored solution was measured against the reagent blank. The final solution corresponds to 0.888 μg ml^{-1} of hydrogen peroxide solution.

Procedure for the Determination of Hydrogen Peroxide. MnTPPS$_r$ was applied as a M-P resin to the solution of hydrogen peroxide (0.5 ml, 50—300 μg ml^{-1}, 0.296—1.776 μg ml^{-1} in the final solution) and the sample solutions were treated as described above.

Procedure for the Control Catalase Method.[11,12] A solution of hydrogen peroxide (0.1 ml, 5—60 μg ml^{-1}) was added to a mixture of 30% methyl alcohol (0.5 ml) and a solution of catalase (1.0 ml, 0.1 mg ml^{-1}) in 1/15 M phosphate buffer (pH 7.0). The mixture was incubated for 60 min at 37 °C, and 0.5 ml of the reaction mixture was taken and treated as described above.

Results and Discussion

Selection of Chromogen. In the clinical analyses, Hantzch[13] and AHMT[11] methods have been used for the determination of formaldehyde produced from methyl alcohol by reaction (1). In the present study, we selected the AHMT method, because of its higher sensitivity than that of the Hantzch method, although the reproducibility of the AHMT method was found to be a little lower in our preliminary examination by the use of standard formaldehyde solution.

Selection of Optimal Conditions. In MnTPPS$_r$, the absorbance of the dye formed from formaldehyde was the highest in the incubation for 10 min at pH 11.0 as shown in Fig. 2. The examination of the activity was carried out at pH 11.0, which seems to be the optimal pH for the catalase-like activity of these M-P resins.

Carbonate buffer gave the largest absorbance among the buffers tested, as shown in Table 1. Low activity caused by the use of glycinate buffer may be attributed to the coordinating property of glycinate ion to the central metal ion. We selected 0.2 M carbonate buffer (pH 11.0) for this study.

The activity did not vary so much at incubation temperatures from 20 to 45 °C except for MnTPPS$_r$ and CoPP$_r$. The activities of all the M-P resins were examined at 37 °C, which is also the optimal temperature for catalase, because MnTPPS$_r$ gave its highest activity at this temperature as shown in Fig. 3.

As seen in Fig. 4, reaction (1) proceeded fairly rapidly and attained its equilibrium in 10 min. It is of interest in the cases of Co- and Fe-TPPS$_r$, which

Table 1. Effect of Buffer (pH 11.0) on Absorbance[a,b]

	MnTPPS$_r$	MnTCPP$_r$	CoTPPS$_r$
Carbonate buffer	0.562 (100)	0.515 (100)	0.201 (100)
Borate buffer	0.555 (99)	0.497 (97)	0.126 (63)
Phosphate buffer	0.566 (101)	0.507 (98)	0.137 (68)
Ammonium buffer	0.525 (93)	0.442 (86)	0.150 (75)
Glycinate buffer	0.334 (60)	0.272 (53)	0.070 (35)

a) The values in parentheses indicate the ratios (%) to the values obtained by carbonate buffer. b) 150 μg ml^{-1} of H_2O_2 in the initial sample solution=0.888 μg ml^{-1} of H_2O_2 in the final solution; incubated at 37 °C for 10 min.

exhibit a medium activity, that the amount of resulting formaldehyde did not increase in the incubation for more than 10 min, suggesting that reaction (1) comes to an end in spite of insufficient formation of the dye. We examined the activity of the M-P resins in the incubation for 10 min.

The absorbance increased in accord with the increase of the concentration of methyl alcohol as seen in Fig. 5. Pure methyl alcohol was then added in the present study, whereas 30% methyl alcohol was added in the catalase method.[11,12] Addition of methyl alcohol with high concentration caused the elution of metalloporphyrin in some cases.

CoPP$_r$	0.398*	H_2TCPP$_r$	0.005

* A little elution of metalloporphyrin was observed.
a) 150 μg ml^{-1} of H_2O_2 in the sample solution = 0.888 μg ml^{-1} of H_2O_2 in the final solution; incubated in carbonate buffer (pH 11) at 37°C for 10 min.

Catalase-Like Activity of the M-P Resins. Table 2 represents the absorbance of the dye resulting from formaldehyde formed by the catalytic effect of the M-P resins. The resins containing Mn, Fe, and Co showed relatively high catalase-like activity, indicating that the activity seems to depend upon the presence of these metals. It is of interest that MnTPPS$_r$ exhibits the highest catalase-like activity in reaction (1) which is a kind of oxidation, similar to the case in the decomposition of hydrogen peroxide.[5] This result indicates the significance of Mn as a central atom in these reactions. Previously, we have found in the simple decomposition of hydrogen peroxide that the catalase-like activity of the resins modified with Co-porphyrins was approximately four times that of the resins modified with Fe-porphyrins.[5] In reaction (1), the activity of CoTPPS$_r$ is slightly smaller than that of FeTPPS$_r$, similar to the case of peroxidase-like activity of the M-P resins.[14] MnTPPS$_r$ is the best and is expected to be used as a mimesis of catalase in reaction (1). On the other hand, MnTPPS$_r$ exhibited the peroxidase-like

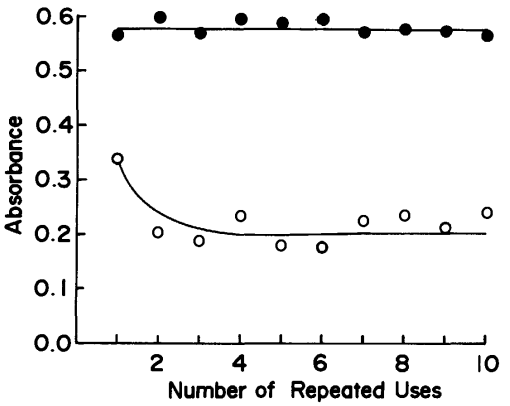

Fig. 6. Effect of repeated uses. ●: MnTPPS$_r$, ○: CoPP$_r$. Incubation for 10 min at 37°C (pH 11.0).

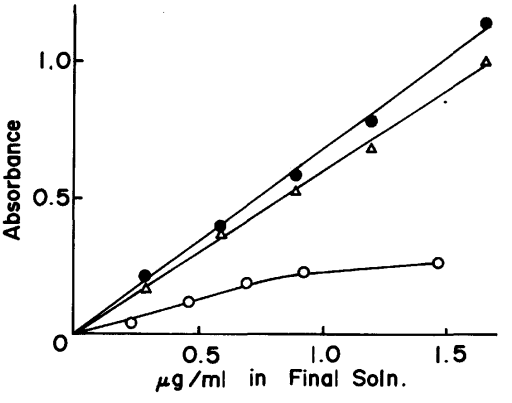

Fig. 7. Calibration curves. ●: MnTPPS$_r$, △: MnTCPP$_r$, ○: Catalase. 150 μg ml^{-1} of H_2O_2 in sample solution = 0.888 μg ml^{-1} of H_2O_2 in the final solution.

activity and the activity was the highest at around pH 7,[14] instead of pH 11 in the catalase-like activity as mentioned above. The difference of the optimal pH in these activities suggests that either catalase-like or peroxidase-like activity of the M-P resins can be utilized depending upon pH, and the mechanisms of these activities are different from each other.

Effect of Repeated Uses. In order to realize that $MnTPPS_r$ acts as a catalyst, the effect of repeated uses of $MnTPPS_r$ on the formation of formaldehyde was examined. As shown in Fig. 6, the decrease of the absorbance based on formaldehyde formed was slight in ten-times use. This result indicates that $MnTPPS_r$ acts as a catalyst like catalase in the oxidation of methyl alcohol.

Determination of Hydrogen Peroxide by the use of $MnTPPS_r$ as a Mimesis of Catalase. The calibration curve obtained by the use of $MnTPPS_r$ in place of catalase in reaction (1) is shown in Fig. 7, together with that obtained by the use of catalase as a control. Beer's law was applicable to the amount of hydrogen peroxide ranging from 0.296—1.776 $\mu g\,ml^{-1}$ in the final solution, whereas the catalase method was not applicable to the amount more than 0.80 $\mu g\,ml^{-1}$ of hydrogen peroxide, and in addition, the longer incubation time was required than $MnTPPS_r$ method. The molar absorption coefficient was $2.37\times10^4\,mol^{-1}\,dm^3\,cm^{-1}$, which is larger than twice the maximum value ($0.97\times10^4\,mol^{-1}\,dm^3\,cm^{-1}$) obtained by the control catalase method. The value of coefficient of variation (4.3%, $n=10$) was rather large in the AHMT method as pointed out above section.

Table 3. Effect of Foreign Substances[a]

Substance	μg	Error/%[b]
Heparin	500	3.5
EDTA	500	3.2
PO_4^{3-}	500	−4.9
Cl^-	500	−0.6
Ascorbic acid	500	−0.3
Na^+	500	−4.9
K^+	500	7.8
	50	−4.0
Ca^{2+}	500	0.3
Mg^{2+}	500	−17.0
	50	−3.0

a) 150 μg of H_2O_2 as the sample solution = 0.888 $\mu g\,ml^{-1}$ in the final solution; incubated in borate buffer (pH 11) at 37°C for 10 min. b) Error(%) = 100{H_2O_2(added) − H_2O_2 (found)}/H_2O_2(added).

The effect of foreign substances were summarized in Table 3. The presence of 500 μg of K^+ caused a slight increase of the absorbance and the presence of 500 μg of Mg^{2+} caused a decrease of the absorbance, but their interferences were negligible when their amounts were less than 50 μg. Any interference was not observed by other substances tested. It is noteworthy that the presence of 500 μg of ascorbic acid, which gives serious interference in the catalase method,[12] did not interfere at all in this method.

In conclusion, $MnTPPS_r$ is regarded as a good artificial mimesis of catalase, and exhibits higher sensitivity than the enzyme and hence is expected to be used practically in place of catalase or immobilized catalase for various purposes.

Comparison of Stability Constants of Alkaline Earth Chlorides between Conductometric and Potentiometric Studies

Hidekazu Doe,* Kenichi Wakamiya, and Toyokichi Kitagawa
Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received October 3, 1986)

The stability constants of alkaline-earth metal chlorides, MCl^+ (M^{2+}=Ca, Sr, Ba), were determined by conductometric and potentiometric measurements in methanol. The conductometric study was made at 5, 15, 25, 35, and 45 °C; the potentiometric study was at 25 °C. The formation of MCl_2 was neglected in the conductometric study, while in the potentiometric study it was taken into account, though it was too slight to determine a reliable value of the stability constant of MCl_2. The stability constants of MCl^+, K_1, determined by conductometric measurements were compared with the previous conductometric results of the same metal(II) perchlorates, K_{1A}. The magnitudes of K_1 and K_{1A} increase in the orders Ca≃Sr<Ba and Ca<Sr<Ba, respectively. K_1 is larger than K_{1A} for calcium and strontium, though the K_1 and K_{1A} values for barium are similar to each other; that is, the degree of such an increase in K_{1A} is larger than that in K_1. Both enthalpy and entropy changes determined by conductometric measurements were positive for all the chlorides and perchlorates. However, the enthalpy changes of the chlorides were 1.2—1.4 times as large as those of the perchlorates. On the other hand, the K_1 from potentiometry was smaller for every chloride and also increased more steeply (in the order Ca< Sr<Ba) than that from conductometry. Therefore, the difference of K_1 between conductometry and potentiometry decreases in going from Ca to Ba.

We previously studied the stability constants of Ca(II), Sr(II), and Ba(II) chlorides in methanol with a potentiometric method.[1] Then, the K_1 of Sr(II) was about 4-times larger than those of Ca(II) and Ba(II). Regarding this abnormal results, we gave no explanation in the previous work, though we had a little doubt about the influence of impurities in the metal salts used on the stability constants. On the other hand, we were a little anxious about the accuracy of our potentiometric determination in the case of small stability constants, such as the alkaline-earth chlorides. Thus, with the main purpose of checking the abnormal result of Sr(II) chloride, we have made conductometric measurements. At the same time, the potentiometric experiment was repeated. However, the experimental method has been partly improved in order to determine the small stability constant more accurately. We also made a careful purification of the metal(II) salts, especially strontium perchlorate.

It is frequently thought that an ion pair, which is generally less stable than a highly covalent metal complex, does not exist as only one type of contact structure (contact ion pair) but also has various types of solvent-separated structures in which the cation and/or anion remain solvated (solvent-separated ion pair).[2] Therefore, in varying degrees of solvent-separation, if species detected as an ion pair vary according to experimental methods, it is natural that a different experiment yields a different stability constant of the ion pair. Being interested in the relation between ion pairing and solvation, we have carefully examined the results obtained by two quite different methods of conductometry and potentiometry in this study; the former showed an increase in the solution resistance but the latter showed a decrease in the concentration of the free anions caused by ion pairing.

Experimental

Materials. Conductometry: Calcium(II) and Strontium(II) chlorides hexahydrates were prepared by neutralizing the corresponding carbonates with hydrochloric acid and purifying by triple recrystallizations from distilled deionized-water. The calcium chloride was dried on a vacuum line over diphosphorus pentaoxide during heating under an infrared lamp for 1 day; the strontium chloride was vacuum dried in an oven over silica gel at 120 °C for 10 hours. After drying, these chlorides became nearly anhydrous salts. Barium(II) chloride anhydrous of a commercially available material (Rare Metallic, 99.99%-grade) was vacuum dried in an oven over silica gel at 120 °C for 10 h.

Potentiometry: By dissolving in perchloric acid, calcium(II) perchlorate trihydrate was prepared from calcium nitrate purified by double recrystallizations from distilled deionized-water and strontium(II) perchlorate dihydrate from strontium carbonate. The calcium perchlorate was recrystallized from distilled deionized-water and dried on a vacuum line over diphosphorus pentaoxide for 3 d and monohydrate was obtained. The strontium perchlorate was recrystallized from distilled deionized-water, and furthermore from purified methanol, and then vacuum dried in an oven over silica gel at 120 °C for 1 day and anhydrous perchlorate was obtained. Barium(II) perchlorate anhydrous (Wako, special grade) which was vacuum dried in an oven over silica gel at 120 °C for 1 day was used without any purification.

The purification of methanol has been described previously.[1,3] Stock solution of these metal(II) salts (except barium chloride) were standardized by titration with EDTA; the barium chloride stock solution was standardized by a gravimetric method.

Measurements. The detailed procedure of conductometric measurements has been described previously.[3] However, in this experiment temperatures were controlled within an accuracy of ±0.01 °C by a Neslab RTE-5 refrigerated circulating bath which was monitored by a Guildline digital platinum resistance thermometer (model 9535).

Outline of potentiometric measurements could be found in previous manuscripts.[4-6] All potentiometric measure-

ments were made at 25.0±0.1 °C, and ionic strength, I, was kept nearly constant at 0.05 M (M=mol dm^{-3}). In order to attain an accurate determination of a small K_1, measurements of the standard electromotive force, emf, were improved as follows. In the previous method, standardization was achieved by measuring the emf of a standard solution free from metal(II) ions (which were prepared aside) after every potentiometric titration was performed in the usual way. In this manner, a titrated sample solution must be replaced with a standard solution in a measuring cell when the standardization is carried out. It is possible that this displacement becomes a cause of experimental errors. In order to remove such a cause of errors, we rechecked the standard emf by measuring the emf of a solution which was prepared by the addition of an appropriate amount of metal(II) ions to the usual metal(II)-free standard solution already measured.

If K_2 is negligible relative to K_1, K_1 can be determined merely by the above standardization procedure. Using this procedure, the K_1 of Ca(II) and Ba(II) have been determined at several metal-ion concentrations, because it is assured by the previous study[1] and the present results of Sr(II) that K_2 of Ca(II), Sr(II), and Ba(II) chlorides are negligibly small.

Data Treatment

In a sample solution,

$$M^{2+} + Cl^- \rightleftarrows MCl^+ \quad (K_1) \tag{1}$$

$$MCl^+ + Cl^- \rightleftarrows MCl_2 \quad (K_2) \tag{2}$$

$$M^{2+} + ClO_4^- \rightleftarrows MClO_4^+ \quad (K_{1A}) \tag{3}$$

are major equilibria: However, the last case (Eq. 3) does not take place in the solution of conductometric measurements since no salts other than MCl_2 are contained in that solution.

Conductometry. Conductometric data were treated by a modified Fuoss and Edelson method[3] in which the equilibrium (Eq. 2) was not completely taken into account. The modified Fuoss and Edelson equation is

$$\Lambda F = \Lambda_0 - XK_1/\Lambda_0, \tag{4}$$

where

$$X = cy_{2+}\Lambda F(\Lambda F - \Lambda_0/2)$$

and

$$F = [\{1-\delta_c^{1/2}/(1+Ba I^{1/2})\}^{-1} + (\Lambda_0-\lambda_0)/2\Lambda]/\{1+(\Lambda_0-\lambda_0)/2\Lambda_0\}.$$

Here, Λ and Λ_0 are the molar and the limiting molar conductances of $1/2MCl_2$, respectively. λ_0 and c are the limiting molar conductance of Cl^- and the total concentration of Cl^-, respectively. Onsager's slope divided by Λ_0 is δ. The ion activity coefficient of M^{2+}, y_{2+}, was calculated by the Debye-Hückel second approximation:

$$\log y = -Az_i^2 I^{1/2}/(1+Ba I^{1/2}), \tag{5}$$

where a is an ion-size parameter which has been 5 Å (for Sr^{2+} and Ba^{2+}) or 6 Å (for Ca^{2+}). The ionic strength, I, is 1.5 times as large as the total concentration of Cl^-, c.

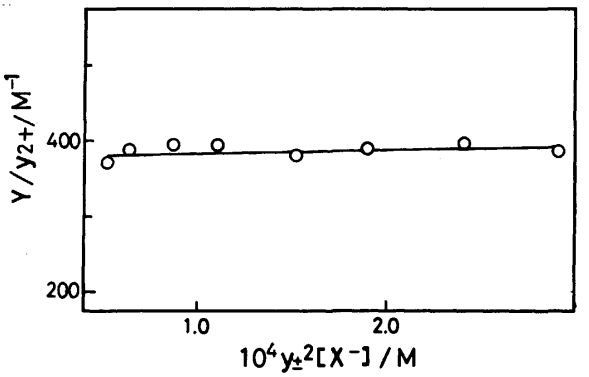

Fig. 1. The plot according to Eq. 6 for strontium chloride. $C°_M$=8.072×10^{-3} M, $C°_I$=0.035 M.

Potentiometry. Our latest treatment of potentiometric data was previously described in detail.[4] According to the treatment,

$$Y/y_{2+} = K_1 + 2K_1K_2(y_\pm^2[X^-]), \tag{6}$$

where

$$Y = (C°_X - [X^-])/([M^{2+}][X^-]),$$

is a key equation. Here, $C°_X$ is the total concentration of NaCl and $y_\pm$ is the ion activity coefficient of a monovalent ion which has been calculated by Eq. 5 at a=4 Å. In the present study, X^- is Cl^-. In order to plot Y/y_{2+} against $y_\pm^2[Cl^-]$, it is necessary to calculate the $[M^{2+}]$, $[Cl^-]$, and y's. The detailed procedure of the calculation could he found in a previous manuscript.[4]

If K_2 is negligible relative to K_1, we can determine the K_1 value from the data of a change in $[Cl^-]$ caused by the addition of M^{2+}, $C°_X$-$[Cl^-]$, and $[M^{2+}]$ after the M^{2+}-addition, which are obtained by the preceding standardization of emf.

Results and Discussion

Conductometry. From plots according to Eq. 3, Λ_0 and K_1 were determined (Tables 1 and 2). In the tables, K_{1A} of perchlorate salts is included; however, these values were determined by the recalculation of previous data[7] in the modified Fuoss and Edelson method. The difference between the modified and original Fuoss and Edelson methods was discussed in a previous manuscript.[3] Lee and Wheaton studied Ca, Sr, and Ba chlorides in methanol by using their original conductance equation; according to their results at 25 °C, K_1 were 410±2.6, 425±4.3, and 430±7.7 M^{-1} for Ca, Sr, and Ba, respectively (Λ_0 were 110.0, 112.2, and 112.9 S cm^{2}mol^{-1}, respectively).[8] Pethybridge recalculated these values using the data and calculation of Lee-Wheaton; K_1 were 450, 393, and 480 M^{-1} for Ca, Sr, and Ba, respectively.[9] In spite of our quite different data treatment, our K_1 are in relatively good agreement

with theirs. The λ_o of Cl^- is 52.35 $S cm^2 mol^{-1}$ at 25 °C.[10] The other λ_o, which have been evaluated proportionally to the λ_o of ClO_4^- in methanol.[3,7] are 39.5, 45.7, 59.8, and 67.9 $S cm^2 mol^{-1}$ at 5, 15, 35, and 45 °C, respectively.

According to the familiar Gibbs-Helmholtz equation, thermodynamic functions have been determined at 25 °C (Table 3). The results of perchlorates are also listed there for reference. The shapes of $\ln K_1$ vs. T^{-1} plots for the chloride systems were strikingly identical to those for the perchlorate systems, which were slightly concave downward (Fig. 2 in Ref. 7).

On the basis of previous discussions,[3,7] we wil give some explanations for the next two problems: 1) Why K_1 is larger than K_{1A} at Ca and Sr whereas those are similar to each other at Ba and 2) why both $\Delta H_1^\ominus$ and $\Delta S_1^\ominus$ of chlorides are larger than those of perchlorates. Relating to the problems, there are the following properties of M^{2+}, Cl^-, and ClO_4^- in methanol: a) The solvation of M^{2+} becomes strong in the order of Ba< Sr<Ca.[7] b) The solvation of Cl^- seems to be stronger than that of ClO_4^-, because of $\lambda_o(Cl^-)<\lambda_o(ClO_4^-)$: the hydration free energies, $\Delta G_h^\ominus$, of Cl^- and ClO_4^- are −317 and −190 $kJ mol^{-1}$, respectively.[11] c) The degree of covalency in MCl_2 bonding is in the order of Ca> Sr>Ba and the binding energy of MCl_2 is also in the same order in gas phase.[12] d) Cl^- has a greater preference for covalent bonding than ClO_4^-, because almost all metal perchlorates seem to be very unstable in solutions even if these metals are typical soft acids.[13]

As an important remark, here we propose from the previous discussion concerning the solvent-separated ion pair[7] that ion pairs separated with over one methanol molecule of solvent contribute little to their stabilities; that is, in this system we just consider the coexistence of ion pairs from a directly contacted one to a solvent-separated one with one methanol molecule though the two extremes may be major species on a time-average. Consequently, it means that anion (Cl^- or ClO_4^-) solvation is forced to reduce considerably by ion pairing since anion solvation is very weak relative to divalent cation solvation. This must be a direct cause of problem 2), because of property b).

Using property a), we previously explained why the stability of the perchlorate, K_{1A}, is of the order Ca< Sr<Ba.[7] That explanation can be simply summarized as: In the case that a cation is solvated more weakly than a certain limit, the cation forms a more stable ion

pair as the cation solvation becomes weaker. Examining problem 1) under the consideration of property d), we infer that the above rule regarding the stability of an ion pair depending on its cation solvation is more pronounced for an ion pair having a higher ionic bonding. Strictly speaking, since the bonding nature of Ba (Ba is the most ionic metal of them; Property c)) is so ionic, that Property d) has little effect on the stability constsnts. Hence, K_1 and K_{1A} are similar to each other for Ba. However, because, as shown in the binding energies of chlorides in gas phase, K_1 probably gains some larger contribution from covalency in $CaCl^+$ and $SrCl^+$ bonding than from that in $BaCl^+$ bonding (Property c)), the difference of K_1 and K_{1A} increases for Ca and Sr. Thus, problem 1) can be well explained by Properties a), c), and d).

Potentiometry. Since the slopes of plots according to Eq. 6 were very gentle (Fig. 1), K_2 of Sr was so small relative to K_1 that it was impossible to make an accurate determination of K_2. The K_1 values are summarized in Table 4; here the conductometric results at 25 °C are also listed. Only the reference a-value of Ca is 6 Å;[6,14] however, the stability constants calculated at a=5 Å are also indicated in the table in order to check the contribution of a to the results. According to the results, the values at a=5 Å are lower by 3% for conductometry and higher by 3.5% for potentiometry than those at a=6 Å. These differences will probably have little importance in our present discussion and, thus, even in comparison with their standard deviations.

Before the potentiometric and conductometric results are compared, we must explain the discrepancies between the previous[1] and present potentiometry results. In our potentiometry, stability constants are determined by measuring the concentration of free anions ($[Cl^-]$ in this study) which remain after combining with M^{2+}. Therefore, some metal compounds as impurities which form very stable chloride compounds have a considerably large influence on potentiometric data, even if the amount is so small that there is no problem in conductometric experiments. In fact, a measurement using a metal perchlorate of insufficient purification yielded a large stability constant; furthermore, the obtained stability constants varied with the total metal concentration, $C°_M$. Thus, the previous abnormally large K_1 of $SrCl^+$ was probably caused by some metal impurities. It is sure that the present K_1 of $CaCl^+$ and BaCl have also gained a higher reliability than the previous ones due to the experimental improvement.

Table 4. Comparison of Stability Constants between Potentiometry and Conductometry at 298.15 K

	a/Å	K_1/M^{-1} Poten.	K_1/M^{-1} Conduc.	K_{1A}/M^{-1} Conduc.
Ca	6	288± 8	408± 7	254±12
	5[a]	298± 8	398± 8	245±12
Sr	5	343±27	403±12	345±12
Ba	5	399±27	464±11	451±17

a) Calculated to know the effect of a.

As shown in Table 4, K_1 from potentiometry is smaller than that from conductometry for all the metals. This is a cause for neglecting K_2 in conductometry, though it may have only a negligibly small effect. That is to say, if the formation of MCl_2 is not taken into account in the data treatment, K_1 is evaluated to a higher value by a decrease in conductance caused by the MCl_2 formation than would be expected.

Regarding K_1(potentiometry)<K_1(conductometry), there is another general explanation which was slightly mentioned in the introduction: Simply expressed, a different measurement yields a different result. With this simple explanation our discussion may come to the end; however, it would be interesting to discuss the result that the difference in K_1 between conductometry and potentiometry increases in going from Ba to Ca. At least, here, we will be able to infer that the Ag-AgCl electrode responds to the Cl^- which weakly binds to M^{2+}, where the weak ion pair works to reduce the net conductance a little. That is, there is a weak ion pair which is potentiometrically detected as being dissociated, but conductometrically as being associated. Therefore, K_1(potentiometry)<K_1(conductometry). According to the previous discussion,[7] on the other hand, $CaCl^+$ is probably separated by solvent molecules more strongly than $BaCl^+$ because of the strong solvation and small K_1 of Ca^{2+} compared to Ba^{2+}. That is, Cl^- enters into the solvation shell of Ba^{2+} more deeply than into that of Ca^{2+}. Therefore, it is inferred that the fraction of weak ion pairs which may be detected as dissociated by other experimental methods is larger for Ca than for Ba. Consequently, if the solvent-separated species take a larger part of properties relating to ion pairing (that is, if the ion solvation is stronger and the stability of an ion pair is smaller) such an investigated system will have a higher possibility of yielding different results from other measurements.

This study has been partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Hydrogenation of Carbon Monoxide over Solid Catalysts Dispersed in the Liquid Medium. I. Slurry-Phase Fischer-Tropsch Synthesis with Supported Ruthenium Catalysts

Kaoru FUJIMOTO* and Masahiko KAJIOKA
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received October 31, 1986)

Fischer-Tropsch synthesis on supported ruthenium catalysts were operated successfully in the slurry phase, using ethyl cyclohexane solvent, in spite of the high selectivity of waxy products. Titania, fumed silica, and Nb_2O_5 were found to be excellent carriers for ruthenium. A Ru/SiO_2 catalyst yielded a hydrocarbon product with the rate as high as 600 mg(g-cat)$^{-1}$h^{-1} at 240 °C and 40 bar. The optimum metal loading was 2% by weight. Calcination of the catalyst precursor at 300 °C or above caused a marked decrease in the metal dispersion, which was essential for the high catalytic activity and chain-growth ability. The maximum chain-growth probability obtained on a calcined Ru/Al_2O_3 catalyst was 0.94.

Fischer-Tropsch synthesis (F-T synthesis), which produces hydrocarbon mixtures from synthesis gas, is one of the most promising coal liquefaction processes. Usually, the reaction is an exothermic reaction, which generates the heat from 54 to 39 kcal (1 cal_{th}=4.184 J) per mole of CO depending on the product. Therefore, it is quite important, in order to conduct the reaction on a large scale, to remove the heat of reaction effectively from the catalyst bed and to maintain its temperature at the suitable level. Typical reactor systems of the F-T synthesis are a multi-tube fixed bed reactor, a fluidized bed reactor, an ebulating bed reactor, and a slurry bed reactor. The multi-tube fixed bed reactor and the fluidized bed reactor are now in commercial operations.

The slurry bed reactor system was postulated and developed by Koelbel et al. since 1935.[1,2] The process utilizes fine powdery catalysts dispersed in a mineral oil medium, whereinto synthesis gas is fed in the bubble form to carry out the reaction. The characteristic features of the slurry bed reactor are: (1) The reactor structure is quite simple; (2) the removal of reaction heat can be effectively carried out to attain quite a flat temperature profile in the reactor;[2] and (3) it has no wax trouble because the high-boiling product on the catalyst surface is quickly removed by being dissolved into the liquid medium. Thus, the slurry-phase system is thought to be the most economical F-T synthesis reactor system.[3]

Almost all of the works on the slurry-phase F-T synthesis have been carried out by using precipitated iron catalyst or fused iron catalyst. In the present work the activities and selectivities of supported ruthenium catalysts were studied in the slurry-phase in comparing with the gas-phase reaction.

Experimental

Catalyst Preparation and Characterization. Several kinds of alumina were used as carrier materials in this study. γ-Al_2O_3-A (220 m^2g^{-1}) was prepared by hydrolyzing aluminium isopropoxide and calcining in air at 600 °C for 3 h. γ-Al_2O_3-B was a commercially available one (Tokai Konetsu, TKS-99651, 300 m^2mg^{-1}, and γ-Al_2O_3-C (Aerosil Al_2O_3-C, 100 m^2g^{-1}) was obtained from Japan Aerosil Co. γ-Al_2O_3-D was also a commercially available one (Sunbead AN, 340 m^2g^{-1}), γ-Al_2O_3-E (JRC-ALO-3, 123 m^2g^{-1}) and γ-Al_2O_3-F (JRC-ALO-4, 177 m^2g^{-1}) were obtained from Japan Catalyst Society. α-Al_2O_3 was a commercially available one (Tokai Konetsu, TAS-90337, <1 m^2g^{-1}). Other carrier materials than alumina were Aerosil SiO_2, Davison ID SiO_2, TiO_2, Nb_2O_5, ZrO_2, and Th_2O_5. These materials were commercially available ones and were already used by the present authors as carrier materials of ruthenium for the vapor-phase F-T synthesis.[5] Supported ruthenium catalysts were prepared by impregnating carrier materials with $RuCl_3 \cdot 3H_2O$ from its aqueous solution, drying up at 100 °C and then drying overnight at 120 °C in an air oven. The catalyst precursors thus obtained were ground to fine powders (under 150 mesh), calcined if needed, and then activated by reducing in flowing hydrogen at 150 °C for 1 h and 400 or 450 °C for 2 h in series. After the activation, the catalyst was directly introduced in the solvent which had been deoxygenated by bubbling CO_2 for 30 min, and then introduced into the F-T synthesis reactor as a slurry.

The dispersion of ruthenium metal was determined by means of CO chemisorption. Chemisorption was measured at room temperature by using a flow-through cell connected to a glass vacuum system. Catalyst samples were first activated in flowing hydrogen in situ, at 150 °C for 1 h and at 450 °C for 2 h, and then evacuated at 450 °C for 2 h. Chemisorption of CO was determined as the difference between the first isotherm and the second isotherm which was measured following the evacuation for 30 min at room temperature after the measurement of the first isotherm. The metal dispersion was calculated assuming one CO molecule was chemisorbed by one surface ruthenium atom.

Apparatuses and Procedures of Synthesis Gas Reaction and Analysis. The flow sheet of the reaction system is shown in Fig. 1. Synthesis gas reactions were conducted in a stainless steel autoclave reactor (volume 100 cm^3). Only gaseous substances were treated in a flow system, and the gas flow from the reactor was kept at 50 cm^3min^{-1} under the standard temperature and pressure. The effluent from the reactor was withdrawn in the gaseous state through a heated pressure regulator and analyzed by gas chromatographs. Most of the solvent and produced hydrocarbons were refluxed while small parts of product hydrocarbon and solvent came out of the reactor with the unreacted synthesis gas.

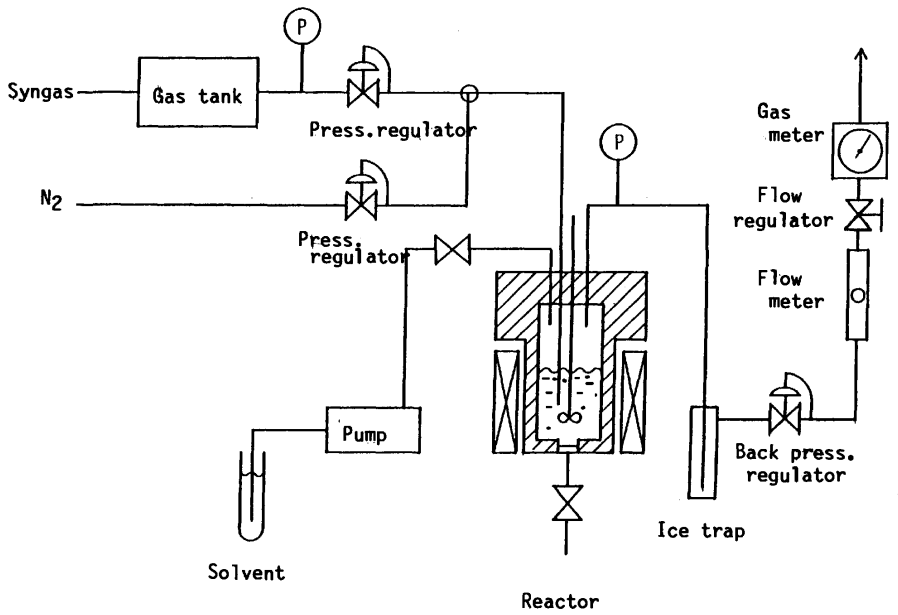

Fig. 1. Reaction apparatus for slurry-phase Fischer-Tropsch synthesis.

The volume of solvent (ethylcyclohexane) was 30 cm^3 and from 2 to 3 gram of catalyst was used for the reaction depending on its catalytic activity. The reaction pressure indicates the total pressure at the reaction temperature, including the vapor pressure of the solvent (about 10 bar). Synthesis gas was introduced from a cylinder through an activated carbon column. Activities and selectivities of the supported ruthenium catalysts were measured mainly under the following conditions: 240 °C, 40 bar, $H_2/CO=2$, and 4 h of reaction, and then the average formation rate of hydrocarbons and the hydrocarbon distribution were calculated.

Gaseous compounds were analyzed on line by gas chromatographs. CO, CH_4, and CO_2 were analyzed by an activated charcoal column using a TCD detector. Light hydrocarbons (C_1—C_6) were analyzed by a Porapak Q column using a FID detector. Liquid products dissolved in the solvent were analyzed after the reaction was over. Hydrocarbons with 2 to 21 carbon atoms were analyzed with a Silicone SE-30 column and hydrocarbons with 11 to 45 carbon atoms were analyzed with a Dexsil 300 GC column, respectively. Eicosane (n-$C_{20}H_{42}$) was used as an internal stan-dard material and a FID detector was used in each analysis

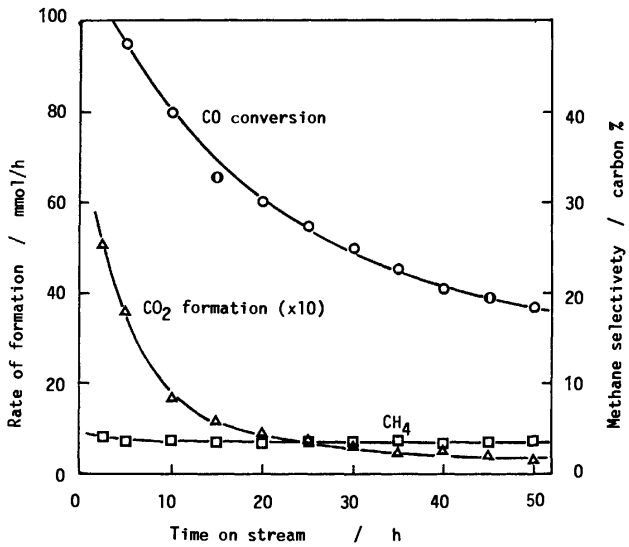

Fig. 2. Changes in the catalytic performance of a Ru/Al_2O_3 catalyst. 2 wt% Ru/γ-Al_2O_3-E, 400 °C calcined, temperature: 240 °C, pressure: 40 bar, H_2/CO: 2/1(mole ratio).

Results and Discussion

Catalyst Durability. In Fig. 2 are shown the changes in the rate of CO conversion, methane selectivity, and the rate of CO_2 formation for the synthesis gas reaction on a 2 wt% Ru/TiO_2 catalyst. It is clear that the catalytic activity (the rate of CO conversion) decreased constantly over 50 h of reaction. However, the methane selectivity was almost constant, irrespective of the catalytic activity. Although the reason of the decrease in the activity is not clear yet, it might be attributed to the coverage of ruthenium surface by carbon, as suggested by the marked decrease in the CO_2 formation, which should be attributed partly to the disproportionation of CO ($2CO \rightarrow C+CO_2$).

Effect of Carrier Materials. Tables 1 and 2 show the activities (formation rates of hydrocarbons and CO_2) and the selectivities (hydrocarbon distribution) of the slurry-phase F-T reaction using supported ruthenium catalysts which loaded 2 wt% ruthenium as metal. Most of the hydrocarbons were normal paraffins, and small amounts of isoparaffins and olefins were also produced. Formations of aldehydes and alcohols were quite small (less than 0.1% selectivity). The hydrocarbon distribution was well-simulated by the Anderson-Schulz-Flory (A-S-F) equation as demonstrated in Figs. 3 and 4. The plot is obviously divided into two straight lines. This fact has been observed also in the vapor-phase reaction, which has

Table 1. Activity and Selectivity of Supported Ruthenium Catalysts[a)]

been most likely attributed to the wide distribution of ruthenium particles.[7)]

As shown in Table 1 and Figs. 3 and 4, the activities and/or selectivities of the catalysts are markedly different from one another depending on the kind of the carrier materials even if they load the same amount of ruthenium. Especially, the ruthenium supported on TiO_2, Aerosil SiO_2 and Nb_2O_5 showed the high activities and the high chain-growth abilities when they

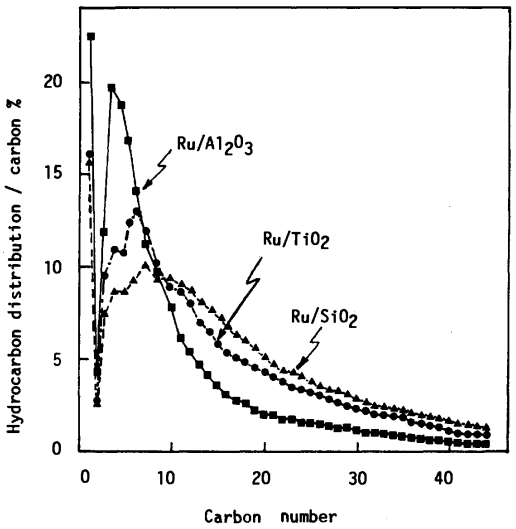

Fig. 3. Hydrocarbon distribution of the products on supported ruthenium catalyst. 2 wt% Ru on carriers, temperature: 240°C, pressure: 40 bar, H_2/CO: 2/1 (mole ratio).

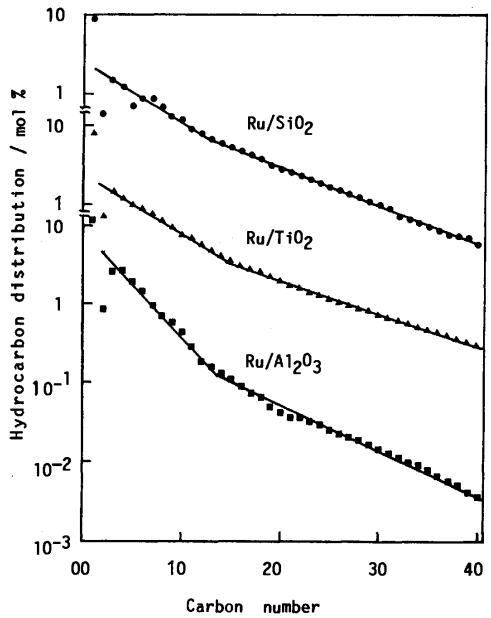

Fig. 4. Anderson-Schulz-Flory plot of the products. The same experiment as in Fig. 3.

were reduced without any pretreatment. This is the same trend which has been observed in the vapor-phase reaction over the same catalyst.[3)] It should be also noted that the Ru/TiO_2 catalyst made more CO_2 than other catalysts. The formation of CO_2 could be attributed mostly to the CO shift reaction of the product water. The high CO shift activity of the Ru/TiO_2 catalyst has been already reported by Kikuchi et al.[8)]

The high abilities of C-C chain growth of the Nb_2O_5-, ZrO_2-, and Ta_2O_5-supported catalysts have been observed also in the vapor-phase reaction.[7] As has been reported by us, the ruthenium particles with low dispersion are suitable for the production of high-molecular-weight hydrocarbons. The ruthenium dispersions on the carrier materials mentioned above are all lower than 20% (Table 1). Thus, their high chain-growth ability should be cased by the low dispersion of ruthenium particles.

The data in Table 2 shows that both the activity and selectivity vary with the kinds of the alumina carriers. Especially, the Ru/γ-Al_2O_3-B catalyst showed an extraordinary low activity and a low chain-growth ability. It could be attributed to sulfur-poisoning effect, because the carrier material which was prepared from aluminum sulfate contained SO_4^{2-} (about 2 wt%) and the sulfate ion is converted to hydrogen sulfide during the hydrogen treatment to poison the ruthenium. Although the reason why the chain-growth probability on the γ-Al_2O_3-B is lower than other alumina-supported ruthenium catalyst is not clear yet, the phenomenon itself is similar to that of a sulfur-poisoned cobalt catalyst,[9] Other γ-Al_2O_3-supported catalysts exhibited the similar activity and selectivity except the γ-Al_2O_3-based catalyst. Its reason will be discussed in the later chapter.

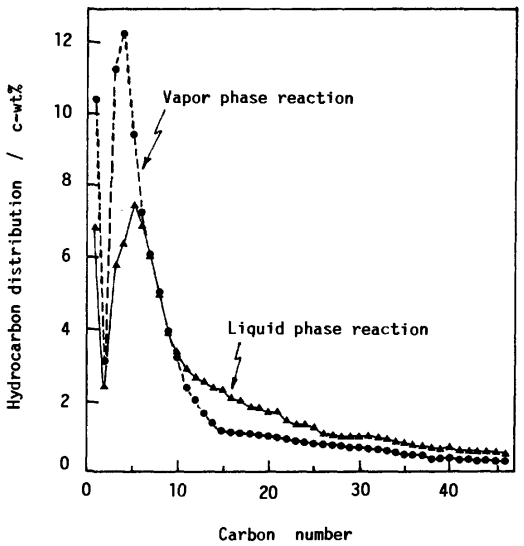

Fig. 5. Hydrocarbon distribution of the products from the vapor-phase reaction and the slurry-phase reaction. 2wt% Ru/TiO_2; noncalcined, temperature: 230°C (vapor phase); 240°C (slurry phase), pressure: 20 bar (vapor phase); 40 bar (slurry phase), H_2/CO: 2/1 (mole ratio).

In Fig. 5 are compared the difference in the hydrocarbon distribution between the products from the vapor-phase reaction and those from the liquid-phase reaction using the same catalyst. Obviously, the product from the vapor-phase reaction is rich in lower hydrocarbons. However, the degrees of chain-growth probability of both systems are very close, for example α_{15-} and α_{16+} are 0.72 and 0.88 for the vapor-phase reaction and 0.80 and 0.92 for the liquid-phase reaction. The higher selectivity of the high-molecular weight fraction in the liquid-phase reaction should be attributed to the fact that the higher fraction stays in the reactor and might grow further, whereas the lower fraction comes out of the reactor quickly.

Preparative Factors Which Control Catalytic Features. a. Metal Lording: As shown in Table 3, the rate of hydrocarbon formation increases with the increase in the metal loading on the catalyst weight base, while the dispersion of ruthenium decreases monotonously with increasing metal loading. It should be noted that the specific activity of ruthenium (the rate of hydrocarbon formation per unit weight of ruthenium) increases with increasing metal loading up to 2 wt%. It could be attributed to the decrease in the ruthenium dispersion. As previously reported by the present authors,[7] the catalytic activity of a low-dispersion-catalyst increases almost proportionally to the operating pressure up to 20 bar or higher in the vapor-phase reaction, while that of a high-dispersion catalyst levels off at 6 bar or lower. Thus, under the present reaction conditions where the operating pressure is 40 bar, the specific activity of the low-dispersion catalyst is higher than that of the high-dispersion catalyst.

Another charateristic feature wnich should be noted is that the chain-growth probility increased with the increase in the metal loading up to 2 wt% as shown in Table 3 and Fig. 6. This phenomenon is also attributable to their metal dispersions. It has been demon-

Table 3. Catalytic Features of Titania-Supported Ruthenium Catalysts[a]

a) Reaction temperature 240°C; total pressure 40 bar; H_2/CO=2/1 (mole ratio). b) mg-hydrocarbon $g^{-1}h^{-1}$. c) mmol-CO_2 $g^{-1}h^{-1}$. d) Turnover frequency. e) g-hydrocarbon (g-Ru)$^{-1}h^{-1}$.

strated by several research groups that the chain growth probability on supported ruthenium catalysts increases with the decrease in the ruthenium dispersion.[7,10,11] However, the change of metal loading is less effective in changing its activity and selectivity than the air calcination treatment, which has been pointed out in the vapor-phase reaction[7] and also will be discussed in the later chapter of this report. It could be explained in terms of two reasons. One is that the change in the dispersion level with the change in the loading is not so remarkable as that of air calcination. For example, the dispersion of a 4 wt% Ru/TiO_2, which has the lowest dispersion (46%), is about half of the dispersion of a 0.2 wt% Ru/TiO_2 (88%), which has the highest dispersion, whereas the dispersion level of a 2 wt% Ru/γ-alumina decreases from 72 to 12% with the rise in the calcination temperature from 120 to 400 °C. The present authors have pointed out that the turnover frequency (TOF) and the chain-growing ability of a supported ruthenium catalyst are markedly promoted when the average dispersion of ruthenium particles (measured by CO chemisorption) is less than about 20%.[7] Another is a more important reason that the particles of ruthenium metal formed by the conventional impregnation method have a wide distribution in size.[2] Thus, the unlcined catalyst should have much small particles as well as large particles as demonstrated by an A-S-F plot of the product with a winding point (Fig. 6). As the result, the characters of large particles should be diluted by those of small particles.

b. Air Calcination: It is possible to change the activity and selectivity of the supported catalysts by means of air calcination before hydrogen reduction.[3,4] In Table 4 and Fig. 7 are shown the dispersion, the catalytic activity, the TOF, and the product selectivity of the 2 wt% Ru/γ-Al_2O_3 catalysts which have been

a) 2 wt% loading of Ru; reaction temperature 240 °C; total pressure 40 bar; $H_2/CO=2/1$ (mole ratio). b) mg-hydrocarbon $g^{-1}h^{-1}$. c) mmol-CO_2 $g^{-1}h^{-1}$. d) Turnover frequency.

calcined in air at temperatures from 120 to 400 °C before reduction. The rate of hydrocarbon formation was promoted twice by calcining the virgin catalyst at 200 °C. Also the TOF was increased from 25×10^{-3} to 40×10^{-3} s^{-1} by calcining at 200 °C. Above 200 °C, the rate of hydrocarbon formation per unit weight of ruthenium is almost constant irrespective of the calcination temperature up to 400 °C. However, the TOF increased from 40×10^{-3} to 246×10^{-3} s^{-1} as the calcination temperature was increased from 200 to 400 °C. Concerning the product selectivity, the rate of CO_2 formation decreased and the chain growth-probability of the product was increased as the calcination temperature was increased. It should be attributed to the fact that the ruthenium dispersion decreased from 79 to 12% as the calcination temperature was increased from 200 to 400 °C. Also, it means that the surface character was changed as the ruthenium dispersion decreased.

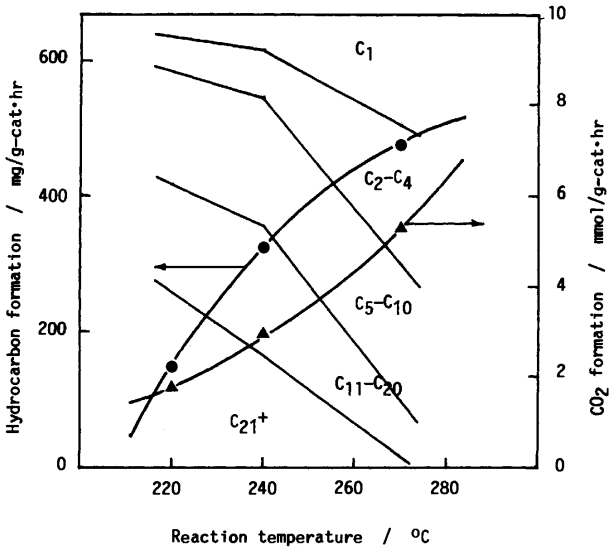

Fig. 8. Temperature effects on the slurry-phase Fischer-Tropsch synthesis on a 2wt% Ru/TiO_2 (non-calcined) catalyst. Pressure: 40 bar, H_2/CO: 2/1 (mole ratio).

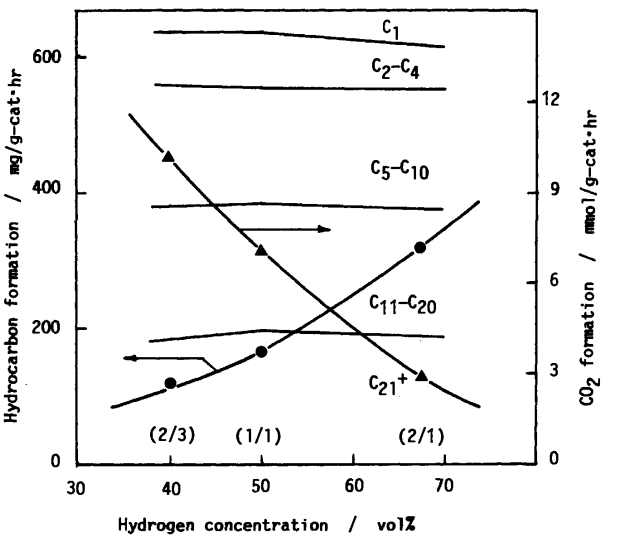

Fig. 9. Effects of feed gas composition on the slurry-phase Fischer-Tropsch synthesis on a 2wt% Ru/TiO_2 (noncalcined) catalyst. Temperature: 240 °C, pressure: 40 bar. Figures in parenthesis express the H_2/CO mole ratio in the feed gas.

Effect of Operating Factors on the Activity and Selectivity. Reaction Temperature: As is shown in Fig. 8, the rate of hydrocarbon formation on the Ru/TiO_2 catalyst was increased with increasing reaction temperature from 220 to 270 °C. The observed apparent activation energy for the hydrocarbon formation was about 12 kcal mol^{-1}. The rate of carbon dioxide formation was also increased with the rise of the reaction temperature, most likely due to the increase in the rate of water-gas shift reaction. In regard to the hydrocarbon distribution, the fraction of low-boiling hydrocarbons (C_1—C_4, especially methane) was increased drastically, which resulted in the change of the chain-growth probability (α) from 0.81 (220 °C) to 0.66 (270 °C).

H_2/CO Ratio of Feed Gas: Figure 9 also shows the effect of the H_2/CO ratio of the feed gas under the standard total pressure (40 bar). With the decrease in the H_2/CO ratio (2/1 to 2/3), the rates of hydrocarbon formation was decreased. These results are quite reasonable because the reaction rate on the ruthenium catalyst is usually first-order with respect to the partial pressure of hydrogen and zero or negative order with respect to the partial pressure of carbon monoxide[13] and because the solubility of either hydrogen or carbon monoxide in the solvent follows the Henry's law. As shown in Fig. 9, the hydrocarbon distribution obtained on a TiO_2-supported ruthenium catalyst was scarcely affected by the H_2/CO ratio. This result is in contrast to the characters on iron catalyst,[14] cobalt,[15] and ruthenium catalysts[16] in the vapor-phase reaction, which are markedly affected by the H_2/CO ratio. The fact that the hydrocarbon distribution is hardly affected by the H_2/CO ratio in the feed gas is one of the special features of the liquid-phase F-T synthesis with supported ruthenium catalysts, which should be studied further.

Conclusion

Highly active and selective ruthenium catalysts for Fischer-Tropsch synthesis were prepared by impregnating $RuCl_3$ on TiO_2, Nb_2O_5, or SiO_2 and then reducing in flowing hydrogen or by impregnating $RuCl_3$ on sulfur free γ-Al_2O_3, calcining at 300 °C or above, and then reducing. They were favorably used in the slurry-phase reaction.

The slurry-phase Fischer-Tropsch synthesis showed characters which was substantially similar to those of the vapor-phase reaction, but produced higher hydrocarbons with higher selectivity. However, no wax trouble was encountered under any conditions. The most effective condition could be chosen for the liquid

hydrocarbon synthesis. For instance, the highest selectivity of kerosene and gas oil (C_{11}—C_{20} hydrocarbons) calculated from the Anderson-Schulz-Flory distribution is 32.5% (α=0.87), while their highest selectivity value, 31.6%, was obtained in this study when the 2 wt% Ru/γ-Al_2O_3-A catalyst calcined in air at 400 °C was used with no troubles in spite of the high wax (C_{21}^+) selectivity, 43.5%.

Financial support by the Grant-in-Aid for Energy Research from the Ministry of Education, Science and Culture is greatly acknowledged.

Direct Determination of Absolute Light Intensity in UV-Transmitting and UV-Dispersive Fluoro Polymer Tubes

Hitoshi FUNAYAMA* and Takuo SUGAWARA†

Department of Industrial Chemistry, Akita National College of Technology, 1-1 Bunkyo-cho, Iijima, Akita 011
†Department of Chemical Engineering for Resources, Mining College, Akita University, 1-1 Gakuen-cho, Tegata, Akita 010

(Received November 25, 1986)

To determine the absolute light intensity (including the reflective, scattered, and incident light intensity) in a UV-transmitting and UV-dispersive fluoro polymer tube, a new chemical actinometer, DPOF system, was introduced which was composed of dilute potassium tris(oxalato)ferrate(III), 0.03 mol m^{-3}; 1,10-phenanthroline, 0.135 mol m^{-3}; and potassium oxalate, 1.5 mol m^{-3}. The overall light intensity was determined with a simple procedure based on a precise analysis of the photochemical kinetics of a DPOF system. The absolute intensities at 366 nm in the UV-transmitting and UV-dispersive Teflon FEP and Folaflon PVdF tubes were detected to be higher than that in a fused-silica tube of similar size while the incident light intensities in the former tubes were always lower than that in the latter. In addition, the dispersive effect of a Teflon FEP tube was rather independent of the wall thickness and the tube diameter under the experimental conditions studied, owing to its high dispersibility of light. The dispersive effect was much more remarkable for the Folaflon PVdF tube. The property of light transmission with dispersion, with the characteristic of antifouling, would make the fluoro polymer tubes useful for novel photoreactors in various areas.

Photoreactions offer promising new processes for synthesis, conservation, and energy conversion. Sterilization by means of irradiation with ultraviolet rays(UV-sterilization process), for example, has recently attracted the attention not only of the pharmaceutical, biological and medical fields, but also the hygienic and electronic engineering fields concerning the antibacterial pretreatment.[1] The UV-sterilization may well be expected to play an important role in the future. However, UV-sterilizers and conventional photochemical reactors have an intrinsic problem in that they generally need restricted reactor-wall materials which are light-transmitting and resistant to fouling. In addition, a precise estimatiom of the light intensity is required for a design and performance evaluation for high quality-control standards. Even though it is permissible to estimate the incident intensity with the use of a conventional potassium tris(oxalato)ferrate (III) chemical actinometer[2] for a photoreactor with negligible reflection and dispersion, it is generally inconvenient to apply the system to other types of photoreactors which have considerable light reflection and dispersion at the reactor wall.[3] The estimation of light intensity is the characteristic and principal parameter required for the design of photoreactors (as stated above); thus, information concerning both hardware and software has long been desired. These include information concerning of new materials, other than fused-silica glass for the reactor wall, which are light-transmitting and resistive to fouling, and of new chemical actinometer system which readily determines the number of reflective and dispersive as well as the incident photons.

In the 1970's it was discovered that some fluoro polymers transmitted ultraviolet light and were stable under long-term irradiation.[4] In 1984, Funayama and coworkers developed a new chemical actinometer[5] (DPOF sysyem, named after the initial letters of dilute, potassium, oxalato, and ferrate) which detects the reflective and dispersive light as well as the incident absolute intensity in any type of photoreactor. The DPOF system has also the characteristic that the analytical procedure is very simple: the extent of conversion can be spectrophotometrically determined without any additional treatment for the reaction product. In the present paper, we determined the absolute light intensity at 366 nm in two kinds of UV-transmitting and UV-dispersive fluoro polymer tubes, compared with that in a fused-silica tube, with the use of the newly developed DPOF chemical actinometer to get fundamental information of novel wall-materials for photoreactors.

Experimental

Materials. All chemicals used were of special reagent grade distributed by Nakarai Chem. Co. Solutions were prepared with distilled and deionized water. Fluoro polymer tubes and sheets made of copolymer of tetrafluoroethylene with hexafluoropentene (denoted as Teflon FEP afterwards) and poly(vinylidene fluoride) (denoted as Folaflon PVdF afterwards) were supplied by Chiyoda Kohan Co. and Showa Denko Co., respectively.

DPOF Chemical Actinometer. The composition of DPOF chemical actinometer is listed in Table 1, as introduced in a previous paper.[5] The stoichiometry of this actinometer, Eq.1, holds in the photolysis of dilute potassium tris(oxalato)ferrate(III) (species A) aqueous solution with 1,10-phenanthroline (species B, denoted as phen afterwards), and potassium oxalate (species S), based on a preliminary

Table 1. Composition of DPOF Chemical Actinometer

Component	C_{j0} / mol m^{-3}
A : $K_3Fe(C_2O_4)_3$	0.03
B : 1,10-Phenanthroline(phen)	0.135
R : $Fe(phen)_3C_2O_4$	0.0
S : $K_2C_2O_4$	1.5

study[6] of the interaction of potassium tris(oxalato)ferrate(III) with phen and potassium oxalate:

$$A + 3B \longrightarrow R + (3/2)S + I_g. \quad (1)$$

Here, species R and I_g represent iron(II)oxalate-phen complex and carbon dioxide, respectively. Kinetics were examined at the wavelength 366 nm with the use of the apparatus combined with the batch-photochemical reactor and the spectrophotometric system which was a part of the stopped flow unit (as discussed in a previous paper).[5] The observed overall rate for reactant species A is

$$(-r_A) = 2\phi_1 I_a C_A/(C_A + k), \quad (2)$$

where ϕ_1, I_a, and k represent the primary quantum yield of DPOF chemical actinometer, the absorbed light, and the ratio of the rate constants of elementary two steps, respectively. Equation 2 holds for any light field irradiated from an arbitrary direction. When we use the DPOF system with a negligible optical thickness (within a few centimeters for the case of irradiation at 366 nm), we can obtain the overall light intensity I_1 in a general form,[5] as

$$I_1 = \{K(1/Z_A - 1) - \ln Z_A\}/(K_1'\theta), \quad (3)$$

where Z_A and θ represent the unconverted fraction of species A and the irradiation time, respectively. Values of K_1' and K, or ϕ_1 ($=K_1'/(2\alpha_A)$) and $k(=KC_{A0})$, experimentaly determined by changing the temperature from 20 to 40 °C are summarized in Fig. 1, (α_A and C_{A0} mean molar absorption coefficient and initial concentration of species A, respectively).

Experimental Apparatus and Procedures. To determine the absolute light intensity in fluoro polymer tubes, the monochromatic and parallel light of a 100 mm circular beam at 366 nm was irradiated on a sample tube by means of a parallel light irradiation unit L_1 (Ushio Electric Co., UI-501C) and a monochromator M_0 (JASCO, CT-25N) as shown in Fig. 2. The light source used was a 500 W superhigh-pressure mercury lamp(Ushio, USH-500D). The absolute light intensity (including the reflective and dispersive as well as incident light) was determined with the use of the DPOF chemical actinometer. On the other hand, the incident light intensity was determined with the use of the Parker's chemical actinometer.[2] The concentration of reaction product, iron(II)oxalate-phen complex, for the both chemical actinometers was quantitatively determined at the wavelength of 510 nm with the use of spectrophotometer (JASCO, UVIDEC-510). A neutral filter was used to change the radiant intensity. All of the procedures were carried out in a dark and constant-temperature room at 25 °C.

Results and Discussion

Light-Dispersibility of Fluoro Polymer Tubes. Figure 3 shows a spectral distribution of light transmitted through fluoro polymer films, where the transmitted intensity measured with a spectrophotometer (JASCO, UVIDEC-510) was restricted to a narrow beam in order to exclude most of the scattered light. We may well conclude from the figure that fluoro polymer is not as good a material as quartz for transmitting ultraviolet light, especially at shorter wavelengths. However, these fluoro polymer tubes are highly light-dispersive compared with a fused-silica tube as shown for the sample of a Teflon FEP tube in Fig. 4. The light-scattering patterns in a fused-silica tube and a fluoro polymer tube are schematically illustrated in Fig. 5. Figure 5(b) shows a more remarkable dispersion of light inside a fluoro polymer tube than a fused-silica tube in Fig. 5(a). We could not determine

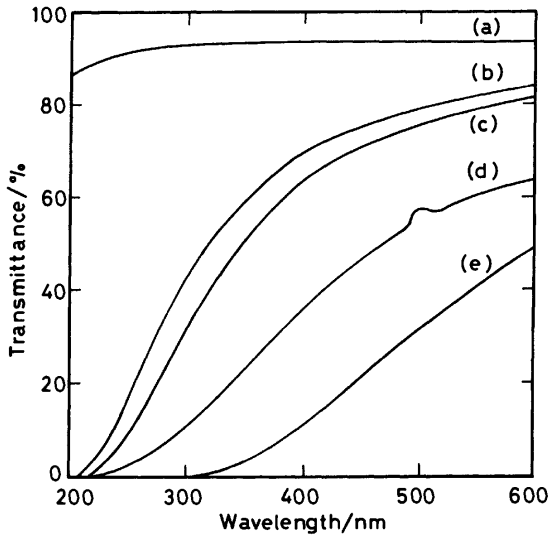

Fig. 3. Spectral distribution of light transmitted through a fluoro polymer film. (a) Fused-silica(thickness 1.0 mm), (b) Teflon FEP 1000 A(0.25), (c) Teflon FEP 1400 A(0.35), (d) Folaflon PVdF(1.0), (e) Teflon FEP 6000 L(1.75).

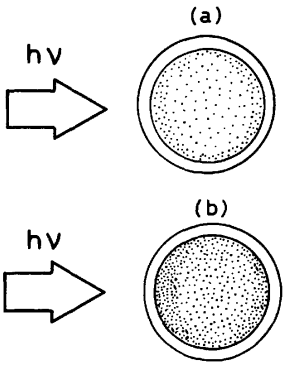

Fig. 5. Illustration of light-scattering pattern in a fused-silica (a) and a fluoro polymer tube (b).

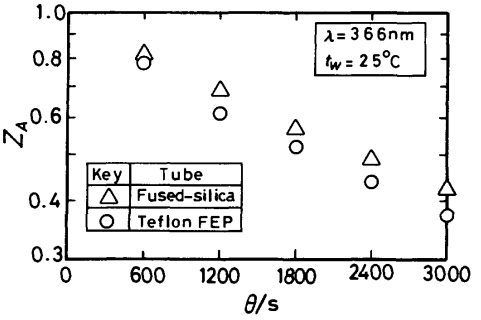

Fig. 6. Actinometry with the use of DPOF chemical actinometer in a fused-silica tube and a Teflon FEP tube having the same inside and outside diameters (10 mm×12 mm).

the absolute overall light intensity in this type of highly light-dispersive tube without the use of such a chemical actinometer as the DPOF system which detects reflective and dispersive as well as incident photons.

Determination of the Absolute UV-Intensity Involving the Effect of Dispersion. The overall light intensity, I_1, is obtained by substituting the relation of the fraction of A unconverted Z_A and irradiation time θ, and the values of K_1' and K into Eq. 3. An example of the experimental results of actinometry with the use of DPOF chemical actinometer is shown in Fig. 6. The figure indicates that the absolute light intensity I_1 is higher in a Teflon FEP tube than in a fused-silica tube having the same inside and outside diameters.

Determination of Incident UV-Intensity. The incident UV-intensity was determined with the use of conventional Parker's actinometer system. A batch analysis with the monochromatic irradiation (Fig. 7) gives

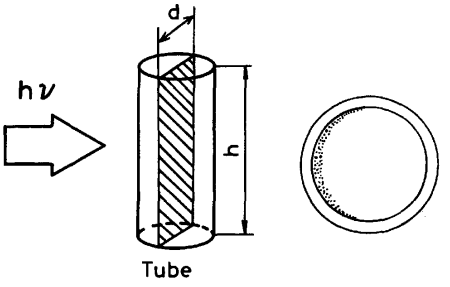

Fig. 7. Determination of incident intensity I_0 and illustration of light absorbed pattern.

Eq. 4 for the performance of the reaction

$$\phi_0 I_a = (S/V)\phi_0 I_0\{1-\exp(-\mu_l l)\} \fallingdotseq (S/V)\phi_0 I_0 \quad (\mu_l l \gg 1), \tag{4}$$

where $S(=h\cdot d)$, $V(=h\cdot \pi d^2/4)$, and ϕ_0 denote the irradiation area, the reaction volume, and the quantum yield of Parker's actinometer, respectively. The term,

$\mu_l l$, represents the optical thickness. The incident photons are perfectly absorbed near the incident wall under the condition of the conventional actinometry: $\mu_l l \gg 1$ as illustrated in Fig. 7. The incident light intensity I_0 was evaluated using

$$I_0 = \frac{(h \cdot \pi d^2/4)}{(h \cdot d)} \cdot \frac{1}{\phi_0} \cdot \frac{dC_R}{d\theta} = \frac{\pi d}{4} \cdot \frac{1}{\phi_0} \cdot \frac{C_R}{\theta}. \quad (5)$$

An example of the experimental results for the actinometry with the use of Parker's actinometer is shown in Fig. 8 for the same sample tubes as shown in Fig. 6. The figure indicates that the incident intensity I_0 is higher in a fused-silica tube than in a Teflon FEP tube having the same inside and outside diameters.

Absolute Light Intensity in Fluoro Polymer Tubes. A comparison of the overall intensity I_1 obtained from Fig. 6 through Eq. 3 and the incident intensity I_0 from Fig. 8 through Eq. 5 tells us that Teflon FEP is a UV-transmitting and highly UV-dispersive material: the characteristics of light scattering can be evaluated well by means of the DPOF actinometry by comparing it with the conventional Parker's actinometry (as discussed above). Table 2 shows an example of the data for the overall light intensity I_1 and the incident light intensity I_0 in both the Teflon FEP and the Folaflon PVdF tubes compared with those in a fused-silica tube as a reference. Three levels of incident intensity were achieved by means of the neutral filter (as mentioned in the experimental section).

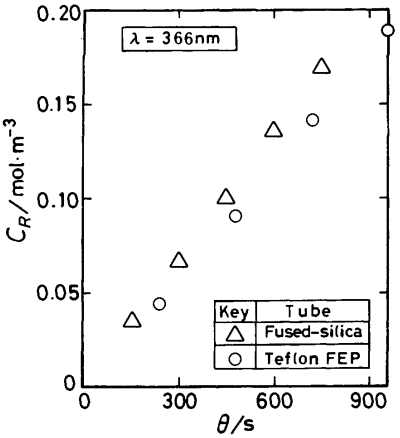

Fig. 8. Actinometry with the use of Parker's chemical actinometer in a fused-silica tube and a Teflon FEP tube having the same inside and outside diameters.

As for the case in the Teflon FEP tube, the overall light intensity I_1, is higher than in a fused-silica tube although Fig. 3 indicates the transmitted light apparently decreases to a considerable degree at 366 nm. In addition, it is noticeable that I_1 seems to be independent of the wall thickness and the tube diameter for the Teflon FEP tube. As for the Folaflon PVdF tube, the overall light intensity I_1 can also be inferred to be higher than that in a fused-silica tube of similar size, whereas it becomes lower as the wall gets thicker. The incident intensity I_0 in both the Teflon FEP and the Folaflon PVdF tubes is always lower than that in a fused-silica tube.

The characteristics of light transmission and dispersion of crystalline fluoro polymer are, in general, closely related to the crystallinity of polymer itself; the transmittance decreases with increasing crystallinity while dispersibility increases with it. First of all, from a comparison of the incident intensity I_0 in a Teflon FEP tube with that in a fused-silica tube having the same inside and outside diameters (Table 2), it is suggested that the crystallinity of fluoro polymer caused the decrease in transmittance in the former tube. Second, the fact that the overall intensity I_1 in a Teflon FEP tube is higher than that in a fused-silica tube whould indicate that the effect of dispersibility exceeds the effect of the decrease in the transmittance in the Teflon FEP tube. As for the Folaflon PVdF tubes, the effect of the decrease in transmittance owing to the crystallinity becomes more remarkable as the wall becomes thicker. Although the absolute values of data shown in Table 2 may slightly change with the sample tube selected, they would reflect the optical characteristics of fluoro polymer in general.

Figure 9 shows a comparison of the relative light intensities for the Teflon FEP and Folaflon PVdF tubes. The relative intensity in the fluoro polymer tubes studied is always higher than that in a fused-silica tube referred. It is remarkable that these effects seem to be practically independent of the wall thick-

Table 2. Overall Light Intensity I_1 and Incident Intensity I_0 in Fluoro Polymer Tubes at 366 nm Compared with Those in a Fused-Silica Tube

Tubes	Inside diameter	Wall thickness	I_1	I_0
	mm	mm	10^{-6} mol m^{-2} s^{-1}	
Teflon FEP	10	1.0	2.65	1.30
	10	0.5	2.51	1.35
	6	1.0	2.59	1.20

(a) Inside diameter (mm)×outside diameter (mm).

ness and the tube diameter for a Teflon FEP tube under the experimental conditions studied. As for the Folaflon PVdF tube, the dispersive effect is much more considerable. Considering the observed results above, we conclude that UV-scattering effect is remarkable in these kinds of fluoro polymer tubes. The property of light transmission with dispersion, with the characteristic of antifouling, would make the fluoro polymer tubes useful for novel photoreactors in various areas.

Conclusion

To determine the reflective and scattered as well as the incident light intensity in UV-transmitting and UV-dispersive fluoro polymer tubes, a new chemical actinometer, the DPOF system, was introduced which was composed of dilute potassium tris(oxalato)ferrate, 0.03 mol m^{-3}; 1,10-phenanthroline, 0.135 mol m^{-3}; and potassium oxalate, 1.5 mol m^{-3}. The overall light intensity at 366 nm was determined with a simple procedure at 25 °C, based on the precise photochemical kinetics of the DPOF system.

The overall light intensities in UV-transmitting and UV-dispersive fluoro polymer tubes, Teflon FEP and Folaflon PVdF, were always higher than that in a fused-silica tube of similar size, although the transmitted light through the film apparently decreased to a considerable degree when observed with a restricted narrow beam. The incident intensity in the fluoro polymer tubes was always lower than that in a fused-silica tube. As for the Teflon FEP tube, the overall light intensity was practically independent of wall thickness and the tube diameter under the condition studied. The dispersive effect is much more remarkable for the Folaflon PVdF tube.

The authors wish to express their thanks to Associate Professor Nobumichi Ohno of Akita National College of Technology for his helpful discussion on the crystallinity of fluoro polymer. The present work was partially supported by a Grant-in-Aid for Scientific Research (59750752) from the Ministry of Education, Science and Culture. They would like to thank Chiyoda Cohan Co. for its financial assistance and offer of Teflon FEP tubes and sheets. Appreciation is also for Showa Denko Co. for the supply of Folaflon PVdF tubes and sheets. The assistance of student colleagues in Akita National College of Technology (Messrs. Hitoshi Kato, Yasumi Kaneya, Masayuki Watanabe, Shunji Tashiro, Katsuhiko Kikuchi, Akira Hashimoto, and Yoshikazu Yachi) is also appreciated.

Spectroelectrochemical Determination of Redox Potential of Cytochrome *c'* in *Rhodospirillum rubrum* Chromatophores

Tatsuo ERABI,* Yoshiharu YAMASHITA, Kumiko NISHIMURA, and Masanori WADA
Department of Industrial Chemistry, Faculty of Engineering, Tottori University, Koyama, Tottori 680
(Received December 22, 1986)

Synopsis. A spectroelectrochemical technique has been used for redox study of cytochrome *c'* in chromatophores in the presence of Toluidine Blue O as a mediator. The midpoint potential of cytochrome *c'* thus determined was 0 mV (n=1) at pH 7.0, which agreed well with the value determined by redox titration.

Studies of the redox properties of the components in photosynthetic and other several biological electron-transport chains become more important for understanding of their reaction mechanism, combined with the development of new disintegrating methods of biomembrane. Although the thin-layer spectroelectrochemistry[1] offers several advantages for the study of the redox chemistry of biological electron-transport components, many difficulties to be solved lies under our eyes. One of the difficulties is of measuring small absorbance change between oxidized and reduced forms of electroactive species due to the very short light path length in a thin-layer cell and extremely dilute suspension of the disintegrated membrane. So, few spectroelectrochemical studies on redox components in biomembrane have been reported so far except for study on fluorescence yield of chloroplast fragments,[2] whereas many studies on electron-transport components in soluble state[3-6] can be found. But this problem can be overcome to some extent by integrating the spectrum data with use of a microcomputer. This paper describes an attempt of such spectroelectrochemical measurement of indirect reduction of cytochrome *c'* in chromatophore membrane from *Rhodospirillum rubrum* (G-9).

Experimental

Chromatophores were prepared from the light grown cells of *Rs. rubrum* (G-9) according to the method described previously.[7] Chromatophores were suspended in 0.6 M (M=mol dm^{-3}) GTA buffer, consisting of a mixture of 0.2 M 3,3-dimethylglutaric acid, 0.2 M tris(hydroxymethyl)aminomethane and 0.2 M 2-amino-2-methyl-1,3-propanediol, which was adjusted to various pH by adding HCl or NaOH, and the concentration of chromatophores was expressed in terms of absorbance of bound bacteriochlorophyll at 873 nm (A_{873}). The sample solution was deoxygenated prior to use by vacuum-nitrogen cycling on a vacuum-purified nitrogen double manifold and loaded into a thin-layer cell by using rubber septum caps and syringe techniques,[6] because of the autooxidizability of cytochrome *c'*. The spectroelectrochemical thin-layer cell was used in a Hitachi Model 557 spectrophotometer equipped with Hitachi MB-6890 microcomputer at 25 °C. Our present spectroelectrochemical thin-layer cell design was reported previously.[8] The midpoint potential (E_m) was determined by sequentially applying a series of potentials (E_{appl}) against a micro Ag/AgCl electrode using a Hokuto Model HA-501 potentiostat. Each potential was maintained until electrolysis ceased so that the equilibrium of the ratio of the concentration of oxidized to reduced from ([Ox]/[Red]) was established as defined by the Nernst equation (for about 10—60 min), and each corresponding value of [Ox]/[Red] to the series of E_{appl}'s was estimated from the absorbance change at 430 nm. The absorbance spectra were recorded as the average of five times scanning for improvement the ratio of signal to noise.

Results and Discussion

It was suggested by a conventional electrochemical method that cytochrome *c'* in chromatophores could not directly exchange electrons at an electrode, presumably due to the insulation of redox site from the electrode by surrounding proteins. However, spectroelectrochemical measurement can be made on cytochrome *c'* in chromatophores by adding another redox species (a mediator-titrant[9]), which transports electrons between the electrode and cytochrome *c'*, to the suspension. The ideal properties for the mediator were discussed in detail.[9] Among the redox reagents tested, Toluidine Blue O (E_m=+34 mV at pH 7.0[10]) was finally chosen as the mediator, fulfilling some properties for mediator, and the properties were examined in some detail by means of conventional electrochemical and spectrophotometric techniques as described.[11] So, all the measurements described hereafter were carried out in the presence of 50 μM Toluidine Blue O and the concentration of cytochrome *c'* in chromatophores was adjusted to 4.2 μM (estimated from A_{873}=100[12]).

The computer-calculated reduced-minus-oxidized difference absorption spectra at several steps of electrolytic reduction are shown in Fig. 1.

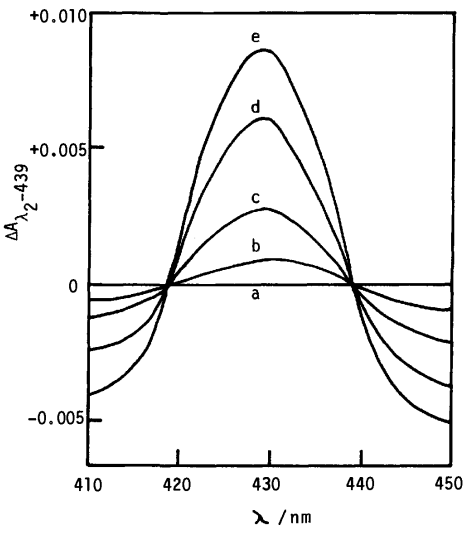

Fig. 1. Difference absorption spectra of cytochrome *c'* in chromatophores at thin-layer cell for series of applied potentials at pH 7.0.
E_{appl}; (a): +75, (b): +25, (c): 0, (d): −25, (e): −75 mV.

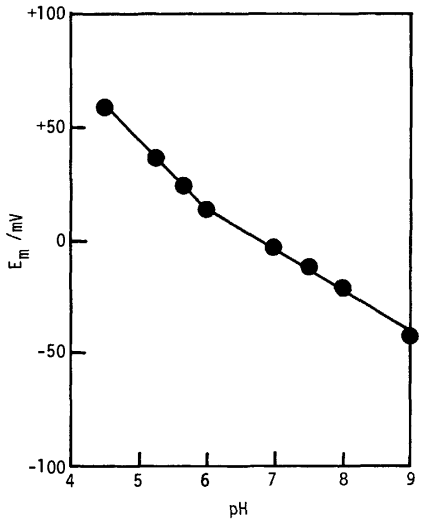

Fig. 2. Effect of pH on E_m values of cytochrome c' in chromatophores.

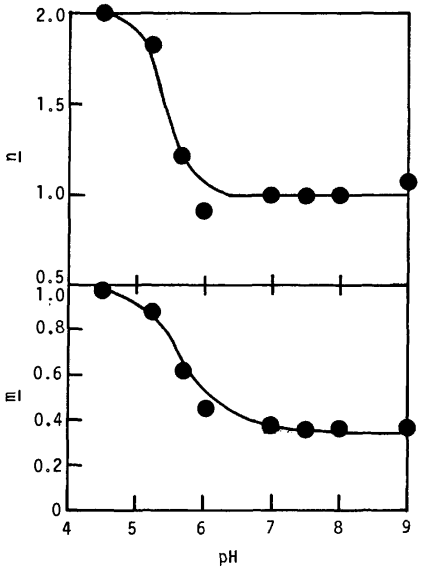

Fig. 3. Values of n and m at various pH's for cytochrome c' reduction.

The Nernst plots at various pH's showed good linear relationships. The E_m at pH 7.0 was 0 mV, which agreed well with the value determined by redox titration.[13] The pH-dependence of E_m was divided in two straight lines; one with a slope of −29 mV/pH in the acidic region below pH 6.0, and the other with −21 mV/pH in the more basic region. This result indicates the presence of a heme-linked ionization probably in the reduced form as described by Clark.[14] The ionization constant (K_{red}) became to be 1×10^{-6} M (pK_{red}=6.0). This result is supported by a spectrophotometric result on pH-dependence of absorbance at 430 nm for electro-reduced cytochrome c', where pK_{red} was estimated to be 5.95 according to the method by Moore et al.[15]

The number of electrons (n) involved in the reduction process was 2 in more acidic region than pH 5.0 and 1 in more basic region than pH 6.0 (Fig. 3). Values for the number of protons transferred (m) accompanying with cytochrome c' reduction are also shown in Fig. 3 as a function of pH. The value of m was about 1 near pH 5.0, and 0.4 in the more basic region. The small value of m may indicate the conformational change of cytochrome molecule or chromatophore membrane with pH change and/or the considerably slower rate of proton transfer than that of electron transfer probably due to hydrophobicity of the surrounding proteins.

In conclusion, it became clear that this spectroelectrochemical technique was very useful to determine the redox potential of the extremely small amounts of redox components in a biomembrane or the fragments such as photosynthetic reaction center, bc_1 and b_6f complexes.

The most parts of measurements were carried out at the Division of Enzymology, Institute for Protein Research, Osaka University. We wish to express our thanks to Professor Takekazu Horio and Dr. Tomisaburo Kakuno for their cordial guidance and helpful discussion.

(Received January 8, 1987)

Synopsis. 1′,1‴-Dimethyl-, 1′,1‴-dipentyl-, 1′,1‴-dihexyl-, and 1′,1‴-didecylbiferrocene were synthesized and Mössbauer spectroscopic measurements of their monocation salts were carried out at various temperatures in order to know the mixed-valence states. Effects of alkyl substituent on the valence states of iron atoms in the monocation salts of 1′,1‴-dialkylbiferrocenes are discussed.

Biferrocene derivatives are easily monooxidized to give the corresponding monocation salts, in which iron atoms are in a mixed-valence state. The electronic interaction and the electron-transfer process between the two metal sites in different oxidation states have been extensively investigated by means of Mössbauer spectroscopy. These compounds can be classified into two types of valence states of the iron atoms, a trapped-valence type and an averaged-valence type, by means of Mössbauer spectroscopy.[1] The former type has different states of iron atoms corresponding to ferrocene-like bivalent and ferricenium-like tervalent iron atoms, while the latter has an equivalent state of iron atom averaged over ferrocene-like bivalent and ferricenium-like tervalent iron atoms.

Iijima et al. first observed an interesting temperature-dependence of the mixed-valence state in 1′,1‴-diethyl- and 1′,1‴-dipropylbiferrocenium triiodide, which are of an averaged-valence type above ca. 200 K but of a trapped-valence type below ca. 200 K.[2] Similar temperature-dependences were also observed later in one crystal form of 1′,1‴-dibutylbiferrocenium triiodide[3] and in biferrocenium triiodide.[3,4]

In the present paper, the triiodide salts of other 1′,1‴-dialkylbiferrocene monocations shown in Fig. 1, such as 1′,1‴-dimethyl- (**1**), 1′,1‴-dipentyl- (**2**), 1′,1‴-dihexyl- (**3**), and 1′,1‴-didecylbiferrocene monocation (**4**), were synthesized and investigated by means of Mössbauer spectroscopy in order to clarify the effect of 1′,1‴-dialkyl substitution on the valence states of iron atoms.

Mössbauer Spectroscopic Measurements. A ^{57}Co(Pt) source moving in a constant-acceleration mode was used for Mössbauer spectroscopic measurements. The Mössbauer spectra were obtained by using an ELSCINT Mössbauer spectrometer with a proportional counter. The isomer shifts were referred to metallic iron foil. The Mössbauer parameters (isomer shift, *I. S.*, and quadrupole splitting, *Q. S.*) were obtained by least-squares fitting to Lorentzian peaks.

Results and Discussion

The Mössbauer parameters are summarized in Table 1, while typical spectra are shown in Fig. 2. The spectra of 1′,1‴-dimethylbiferrocenium triiodide (**1**) at 78 and 298 K consist of an inner- and an outer-doublet with nearly 1:1 ratio in areal intensity, which are

Table 1. Mössbauer Parameters

a) Isomer-shift data are reported with respect to metallic iron foil.

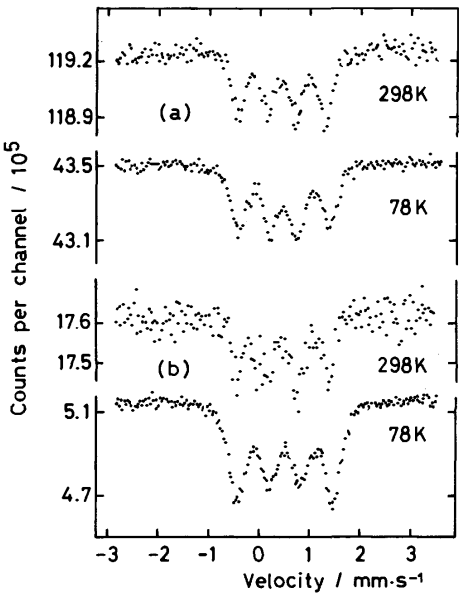

Fig. 2. Typical Mössbauer spectra of (a) 1′,1‴-dimethyl- and (b) 1′,1‴-dihexylbiferrocenium triiodide at 78 and 298 K.

ascribable to ferricenium-like tervalent and ferrocene-like bivalent states, respectively. Compound **1** is of trapped-valence type and temperature-independent. Table 1 shows that 1′,1‴-dipentyl- (**2**), 1′,1‴-dihexyl- (**3**), and 1′,1‴-didecylbiferrocenium triiodide (**4**) are classified into a trapped-valence type and are temperature-independent as well as **1**. The measurements of Mössbauer spectra of compound **4** were unsuccesful at room temperature because of its decreased recoil-free fraction.

The values of *Q. S.* of ferrocene-like bivalent iron atoms in these compounds are smaller than those of biferrocenium picrate (2.141 mm s^{-1} at 78 K and 2.053 mm s^{-1} at 298 K)[5] and biferrocenium triiodide (2.119 mm s^{-1} at 4.2 K and 2.013 mm s^{-1} at 300 K).[6] On the other hand, the values of *Q. S.* of ferricenium-like tervalent for these compounds are larger than those of biferrocenium picrate (0.288 mm s^{-1} at 78 K and 0.302 mm s^{-1} at 298 K)[5] and biferrocenium triiodide (0.381 mm s^{-1} at 4.2 K and 0.400 mm s^{-1} at 300 K).[6] Similar trends have been observed in 1′,1‴-diethyl-, 1′,1‴-dipropyl-, and 1′,1‴-dibutylbiferrocenium triiodide at low temperatures, although this effect seems to decrease in the case of 1′,1‴-didecylbiferrocenium triiodide.

As mentioned in the introduction, the Mössbauer spectra of 1′,1‴-diethyl- and 1′,1‴-dipropylbiferrocenium triiodide, and one crystal form of 1′,1‴-dibutylbiferrocenium triiodide show a remarkable temperature-dependence; i. e., iron atoms are in a trapped-valence state at low temperatures and in an averaged-valence state near room temperature. On the other hand, all the spectra obtained in the present study show the trapped-valence type from 78 K to room temperature. Although the Mössbauer parameters observed for the monocation salts in the present study at 78 K resemble those of 1′,1‴-diethyl-, 1′,1‴-dipropyl-, and 1′,1‴-dibutylbiferrocenium triiodide at 78 K, the temperature-dependences are not observed.

It was suggested that the environment surrounding each cation in a number of mixed-valence compounds in the solid state determines whether or not an intramolecular electron transfer occurs.[3,7] One of the most important factors controlling intramolecular electron transfer can be a symmetric structure of each binuclear mixed-valence cation experiencing weak or moderate electronic coupling between the two metal ions, associated with the positions of each anion. In the case of longer chain alkyl substituents, the possibility to have a center of symmetry for the dialkylbiferrocenium cation will also be reduced because of the increased possibility of having various kinds of conformational arrangements in the substituent.

The results suggest that the length of the chain of the alkyl substituent has an important effect on the mixed-valence states of 1′,1‴-dialkylbiferrocenium triiodides, probably because the alkyl substituents are too long or too short. The terminal atoms of the I_3^- anion will then be situated closer to one of the iron atoms of a given cation, even near room temperature. Detailed crystallographical studies of some of dialkylbiferrocenium triiodides are now being studied.

The authors wish to express their thanks to Dr. Sei'ichiro Iijima of the Research Institute for Polymer and Textiles for his helpful discussion.

Activation of C-H Bonds of Heterocyclic and Alicyclic Compounds Using Calcium Atoms[1)]

Kunio MOCHIDA,* Kenji KOJIMA, and Yasuhiro YOSHIDA
Department of Chemistry, Faculty of Sciences, Gakushuin University, 1-5-1 Mejiro, Tokyo 171
(Received December 19, 1986)

Synopsis. Calcium atoms have been inserted into C-H bonds of heterocyclic (furans and thiophene) and alicyclic compounds (cyclohexanes and cyclopentane) to give the corresponding organocalcium hydrides. The organocalcium hydrides thus produced reacted with trimethylchlorosilane to give trimethylsilyl-substituted heterocyclic and alicyclic compounds, and a reduced product (trimethylsilane).

The study of metal-vapor reactions is of considerable interest in organometallic chemistry and organic synthesis because by these methods, it is possible to synthesize organometallic compounds which would be difficult, if not impossible, to prepare by other methods, and to study their reactive intermediates.[2)]

Activation of the C-H bond by metal atoms, clusters, and metal complexes is an area of intense research activity. In spite of this activation of the C-H bond by main group-metal atoms is still a rare phenomenon. Recently, we reported on the activation of the C-H bonds of substituted benzenes by calcium atoms.[3)] We have carried out the activation of the C-H bonds of heterocyclic and alicyclic compounds by calcium atoms.

In this paper, we describe the activation of the C-H bonds of heterocyclic and alicyclic compounds by calcium atoms.

Results and Discussion

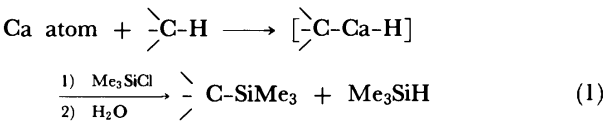
Calcium atoms were generated by evaporation from a tungsten filament using essentially the same apparatus and conditions as have been described in the literature (ca. 900 °C and 5×10^{-3} Torr, 1 Torr=133.322 Pa).[3-7)] Calcium metal was evaporated at a rate of ca. 20 mg min^{-1} while excess of the heterocyclic or alicyclic compound was co-condensed on the walls of the reaction flask containing the crucible and a perforated inlet tube through which the heterocyclic or alicyclic compound was admitted. The reaction flask was immersed in liquid nitrogen during the calcium evaporation. After the calcium evaporation and admission of the organic substrate was completed, the reaction flask was warmed to room temperature and the excess of trimethylchlorosilane was admitted as vapor and the reaction flask left to stand for 1.5 h. After removal of the reaction flask from a vacuum line, the reaction mixture was slowly hydrolyzed with water. The organic layer was extracted with ether.

Table 1. Reactions of Calcium Atoms/Heterocyclic and Alicyclic Compound Vapors with Trimethylchlorosilane[a)]

Substrate	Products	(Yield/%[b)])	
		(3.0)	Me_3SiH (1.0)
		(4.0)	Me_3SiH (4.0)
		(1.0)	Me_3SiH (1.0)
		(1.0)	Me_3SiH (1.0)
		(1.0)	Me_3SiH (1.0)
		(1.0)	Me_3SiH (1.0)

a) Reactions were performed at room temperature for 1.5 h. b) Yields of products were based on the calcium metal consumed.

Hydrolysis of the products gave trimethylsilyl-substituted products, and a reduced product (trimethylsilane) (Eq. 1). All products were identified by comparing their GC-MASS and retention times on GLC with those of authentic samples. The results are summarized in Table 1.



$$\text{Ca atom} + \text{-C-H} \longrightarrow [\text{-C-Ca-H}] \xrightarrow[2)\ H_2O]{1)\ Me_3SiCl} \text{-C-SiMe}_3 + Me_3SiH \quad (1)$$

As shown in Table 1, the reaction products of calcium atoms/furan, 2-trimethylsilylfuran, and thiophene vapors when treated with trimethylchlorosilane gave 2-trimethylsilylfuran, 2,5-bis(trimethylsilyl)furan, and 2-trimethylsilylthiophene, respectively, and trimethylsilane in very low yields. No 3-trimethylsilylfuran, 2,3-, 2,4-bis(trimethylsilyl)furan, and 3-trimethylsilylthiophene were produced. A theoretical calculation for anion radicals of five-membered ring compounds has been made.[8)] It appears that the position of calcium atom attack may be influenced by the unpaired spin density. Accordingly we suggest that the reaction sequence may be (1) electron transfer to form a Ca^+ five-membered ring compound$^-$, and (2) attack of the Ca^+ at the most electron-rich site. Thus selective insertion of calcium atoms into C-H bonds may depend upon the spin densities of the heterocyclic compound anion radicals.

The reaction products of calcium atoms/cyclohexane, methylcyclohexane, and cyclopentane vapors when treated with trimethylchlorosilane gave cyclohexyltrimethylsilane, 4-methylcyclohexyltrimethylsilane, and cyclopentyltrimethylsilane, respectively, and trimethylsilane in very low yields as shown in Table 1. The insertion mechanism of C-H bonds of alicyclic compounds with calcium atoms is not clear. It is not possible to predict whether electron transfer occurs between calcium atoms and the alicyclic compound in the vapor state.

Although the yields of products are very low as shown in Table 1, this is a first example of sp^3C-H bond activation with calcium metal.

Calcium hydride is known to be incapable of reducing trimethylchlorosilane. However, the organic calcium hydride thus prepared can reduce trimethylchlorosilane to give trimethylsilane.

The yields of trimethylsilyl-substituted products and reduced product (trimethylsilane) as shown in Table 1 are very low. The yields of these products were determined on the basis of the amount of calcium metal consumed on the assumption that all of the vaporized calcium metal reacted completely with the heterocyclic and alicyclic compound vapors. Therefore, taking into consideration that the calcium insertion products include a large amount of unreacted calcium metal, the yields of the products as shown in Table 1 may be considerably underestimated.

The co-condensation product which was formed by deposition of calcium atoms onto the frozen layer of heterocyclic and alicyclic compound or by condensation of the organic substrate vapor onto the layer of calcium atoms did not react with trimethylchlorosilane under these reaction conditions.

Experimental

GLC analyses were performed on a Shimazu GC-6A and 8A gas chromatograph with 2m 20% SE-30 and 2m 30% Apiezon L columns. GC-MASS spectra were obtained with JEOL JMS-DX 303 mass spectrometer. NMR spectra were obtained with a Varian FT-80A spectrometer using $CDCl_3$ as the solvent and TMS as the internal standard.

Materials. Calcium metal (granule, 99% pure, Wako chemicals) was commercially available. Furan, thiophene, cyclohexane, methylcyclohexane, and cyclopentane were dried and distilled prior to use. 2-Trimethylsilylfuran,[9] 2,5-bis(trimethylsilyl)furan,[10] 2-trimethylsilylthiophene,[9] cyclohexyltrimethylsilane,[11] 4-methylcyclohexyltrimethylsilane,[12] and cyclopentyltrimethylsilane[13] were prepared as described in the references cited.

Reactions of Calcium Atoms/Heterocyclic and Alicyclic Compound Vapors with Trimethylchlorosilane. As a typical example, the reaction of calcium atoms/furan vapor with trimethylchlorosilane is described. Calcium metal (200 mg, 5.0 mmol) was vaporized at a temperature of ca. 900 °C using a filament of tungsten in vacuo (ca. 5×10^{-3} Torr) at a rate of ca. 20 mg min^{-1}. During the vaporization of calcium metal, furan (20 cm^3, 276 mmol) was introduced into the reaction vessel as vapor. Calcium atoms/furan vapor condensed on the wall of the reaction vessel which was cooled to 77 K with liquid nitrogen. The initial product at 77 K was a muddy yellow. The reaction vessel was warmed to room temperature and trimethylchlorosilane (15 cm^3, 118 mmol) was then admitted as vapor. The reaction vessel was left to stand for 1.5 h. After removal of the reaction vessel from a vacuum line, the reaction mixture was slowly hydrolyzed with water. The organic layer was extracted with ether. The products were identified by comparing their GC-MASS and retention times on GLC with those of authentic samples. The yields of the products were determined by an internal-standard method.

A Convenient Method for the Synthesis of Alkylsilyl Cyanides Using Potassium or Sodium Cyanide Impregnated on Amberlite XAD Resin

Kazuaki SUKATA
Nihon Tokushu Kagaku Kogyo Co., Ltd., 1 Takijiri-aza-hashimoto, Izumi-cho, Iwaki, Fukushima 970-04
(Received December 18, 1987)

Synopsis. Potassium and sodium cyanide impregnated on Amberlite XAD resin were found to be effective for converting alkylsilyl chloride to the corresponding alkylsilyl cyanide under mild conditions.

Alkylsilyl cyanides are versatile and important reagents for organic synthesis. Among these, trimethylsilyl cyanide (Me_3SiCN) has been most widely used for preparing useful nitriles and isonitriles: Carbonyl compounds[1] and imines[2] react with Me_3SiCN to give silylated cyanohydrins and aminonitriles, respectively. The reaction of acetals and orthoesters with Me_3SiCN gives alkoxynitriles.[3] The reaction of oxiranes with Me_3SiCN produces trimethylsilyloxynitriles in the presence of aluminium chloride[4] or diethylaluminium chloride,[5] whereas in the presence of zinc iodide it gives the corresponding isonitriles.[6] On the other hand, other alkylsilyl cyanides, *t*-butyldimethylsilyl cyanide (*t*-$BuMe_2SiCN$)[7] and dimethylsilyl dicyanide ($Me_2Si(CN)_2$),[8] also have recently been employed as cyanation agents.

A number of methods for the synthesis of Me_3SiCN have been reported.[1d,9] In many reported methods, however, there seem to be few methods that can be utilized for preparing other alkylsilyl cyanides in satisfactory yields. Although only the method reported by Mai and Patil[10] affords good yields of alkylsilyl cyanides, it requires the use of lithium cyanide which is prepared by the reaction of butyllithium and Me_3SiCN[10] or by the reaction of lithium hydride with hydrogen cyanide[1d] or acetone cyanohydrin.[9e]

In previous papers, it has been shown that potassium and sodium cyanide impregnated on macroporous polymer resins such as Amberlite XAD resins (KCN/XAD, NaCN/XAD) are effective reagents for some reactions.[11] This paper shows that the reaction of alkylsilyl chlorides with KCN/XAD or NaCN/XAD gives alkylsilyl cyanides in good yields under mild conditions.

$$R_{4-n}SiCl_n \xrightarrow{\text{KCN or NaCN/XAD}} R_{4-n}Si(CN)_n$$

In a preliminary experiment, the reaction of trimethylsilyl chloride (Me_3SiCl) with KCN/XAD-4 was carried out in various solvents. Table 1 shows the results. In *N*-methylpyrrolidone (NMP), the reaction was so fast that the complete conversion of Me_3SiCl occured within 0.5 h at room temperature giving Me_3SiCN in 92—94% yields (GLC). In acetonitrile, the reaction afforded 94—95% yield of Me_3SiCN at 60 °C after 1.5 h. Contrary to expectations, the yields in 1,2-dimethoxyethane (DME) and in tetrahydrofuran (THF) were very similar to that without any solvent. In a nonpolar solvent such as benzene or hexane, the

$Ph_2Si(CN)_2$[d]	NaCN	40	4.0	70	121—122/0.35 (44—47)	110—115/0.1[10] (45—47)[10]	2185

a) Unless otherwise noted, reactions were carried out with alkylsilyl chloride (15 mmol), alkali metal cyanide (30 mmol)/XAD-4 (7.5 g), and acetonitrile (40 ml). b) Isolated yields. The values in parentheses are the yields determined by GLC. c) Me_3SiCl (24 mmol) and NMP (20 ml) were used. d) R_2SiCl_2 (10 mmol) was used.

reaction was very slow. The reaction of Me_3SiCl with KCN impregnated on alumina or silica gel was also performed. No Me_3SiCN was obtained, though the coversion of Me_3SiCl was very fast. Although NMP is an appropriate solvent for Me_3SiCN because of the ease in separating the product from the solvent, its use is limited in the preparation of other alkylsilyl cyanides having high boiling points. Table 1 shows that acetonitrile, which has a low boiling point, can be used for this purpose though the reaction is slower than that in NMP.

Table 2 shows the results of the preparation of alkylsilyl cyanides using KCN/XAD-4 or NaCN/XAD-4 in acetonitrile. These results are comparable to that using LiCN[10] and indicates that KCN/XAD-4 and NaCN/XAD-4 are very effective reagents for the synthesis of alkylsilyl cyanides. On the other hand, a small amount of siloxanes was produced because of the incomplete drying of the system. In particular, since the boiling points of Me_3SiCN and the by-product, hexamethyldisiloxane, are very similar, the isolated yield of Me_3SiCN was considerably lower than those of the other alkylsilyl cyanides.

For certain cyanosilylation, the use of isolated silyl cyanides will not be necessary. In fact, the one-pot cyanosilylation of aldehydes and ketones was found to proceed smoothly under mild conditions using KCN/XAD or NaCN/XAD producing silylated cyanohydrins in good yields.[12]

Experimental

Materials. Solvents were dried with molecular sieves 3A or 4A. Dimethylsilyl dichloride and Me_3SiCl (Toray Silicone Co.), *t*-$BuMe_2SiCl$, phenyldimethylsilyl chloride, diethylsilyl dichloride (Shin-Etsu Chemical Industries) and diphenylsilyl dichloride (Wako Pure Chemical Industries) were used without further purification. KCN/XAD and NaCN/XAD were prepared according to the method previously reported,[11] dried at 90 °C and 0.1 mmHg (1 mmHg=133.322Pa) for 5 h.

Typical Procedure for the Reaction of Alkylsilyl Chloride with KCN or NaCN/XAD-4. In all reactions, alkylsilyl chloride was added directly to the flask in which the KCN or NaCN/XAD-4 had been made and dried. All the products were known compounds.

The Reaction of Me_3SiCl with KCN/XAD-4 in Various Solvents. A mixture of KCN/XAD-4 made from KCN (15 mmol) and XAD-4 (3.75 g), Me_3SiCl (7.5 mmol), and a solvent (20 ml) was stirred under the conditions presented in Table 1. The yield of Me_3SiCN was determined by GLC using toluene as the internal standard.

Me_3SiCN: A mixture of NaCN (1.47 g, 30 mmol)/XAD-4 (7.5 g), Me_3SiCl (2.60 g, 24 mmol), and NMP (20 ml) was stirred for 0.5 h at 25 °C. The solid material was filtered and meticulously washed with dichloromethane. The filtrate and washings were combined. After the dichloromethane had been carefully removed, the residual solution was carefully distilled under reduced pressure (≈120 mmHg) giving the crude product. The total crude product obtained from triplicates was carefully redistilled with a 15 cm Vigreaux column, giving 4.33 g (61%) of Me_3SiCN, bp 114—118 °C (lit,[1d] bp 117—118 °C); IR (CCl_4) 2190 cm^{-1}.

***t*-$BuMe_2SiCN$:** A mixture of NaCN (1.47 g, 30 mmol)/XAD-4 (7.5 g), *t*-$BuMe_2SiCl$ (2.26 g, 15 mmol), and acetonitrile (40 ml) was stirred at 60 °C for 4 h. The solid material was filtered and meticulously washed with 100 ml of benzene-dichloromethane (2 : 1). The filtrate and the washings were combined. After removal of the solvent, the residual solid was distilled under reduced pressure, giving 1.80 g (85%) of *t*-$BuMe_2SiCN$, bp 77—79 °C/45 mmHg, mp 79—81 °C (lit,[10] bp 163—167 °C, mp 82—83 °C); IR (CCl_4) 2185 cm^{-1}.

Diethylsilyl Dicyanide ($Et_2Si(CN)_2$): A mixture of KCN (1.95 g, 30 mmol)/XAD-4 (7.5 g), diethylsilyl dichloride (2.36 g, 15 mmol) and acetonitrile (40 ml) was stirred at 60 °C for 4 h. The resulting mixture was treated according to the same method as *t*-$BuMe_2SiCN$. After removal of the solvent, the residual solid was distilled under reduced pressure giving 1.56 g (75%) of $Et_2Si(CN)_2$, bp 89—92 °C/9.5 mmHg, mp 35—37 °C (lit,[10] bp 210—215 °C); IR (CCl_4) 2195 cm^{-1}.

12) For example, the one-pot cyanosilylation of benzaldehyde with KCN/XAD and Me_3SiCl in acetonitrile gave the corresponding trimethylsilylated cyanohydrin in 98% yield (GLC) under mild conditions. The study of this reaction is now in progress.

Synthesis of Sterically Hindered Bicyclo[2.2.2]octanes by Lewis Acid Catalyzed Reaction of 2-(Trimethylsiloxy)-1,3-cyclohexadienes with 4-Methyl-3-penten-2-one

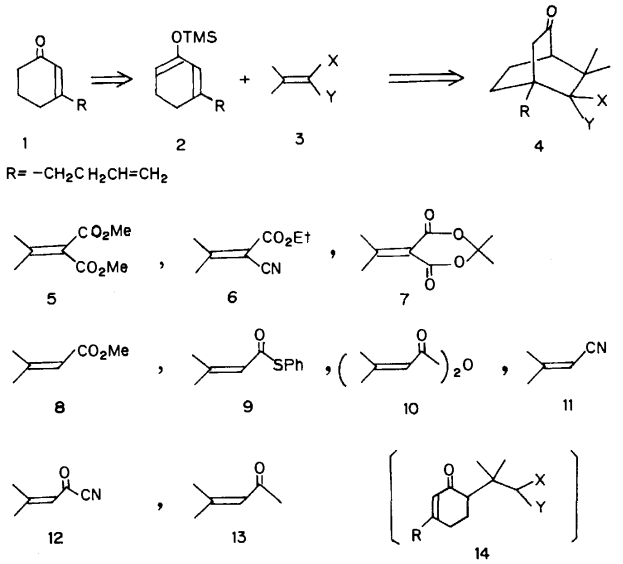
Morio ASAOKA,* Keiji ISHIBASHI, Wataru TAKAHASHI, and Hisashi TAKEI
Department of Life Chemistry, Tokyo Institute of Technology, Nagatsutacho, Midori-ku, Yokohama 227
(Received December 25, 1986)

Synopsis. Dienol silyl ethers of various 2-cyclohexenones reacted with 4-methyl-3-penten-2-one(mesityl oxide) or methyl acrylate in the presence of Lewis acid to give bicyclo[2.2.2]octanes in moderate yields.

In the course of the total synthesis of (±)-eremolactone,[1] we needed to develop a new method for the construction of crowded bicyclo[2.2.2]octane skeleton.

Some reports on the synthesis of bicyclo[2.2.2]octane skeleton starting from 2-cyclohexenones using sequential Michael reaction or thermal Diels-Alder reaction via enol silyl ethers are known,[2] however, none of these methods are applicable to the construction of crowded tricyclo[5.2.2.$0^{1,5}$]undecane derivative suitable for the synthesis of (±)-eremolactone.

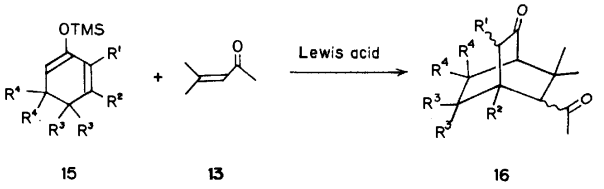
Thus, we investigated the Lewis acid catalyzed reaction of the dienol silyl ether **2** prepared from 2-cyclohexenone **1** with various 3-methyl-2-butenoic acid derivatives.



Scheme 1.

First, the reaction of dienol ether **2** with electron deficient tri- or tetra-substituted olefins (**5**—**13**) was examined in the presence of Lewis acid such as $SnCl_4$ or $TiCl_4$. In the case of the reaction of **5** or **6**, no bicyclo[2.2.2]octane but Michael adduct **14** was obtained as a major product and the attempts for the conversion of **14** to **4** under various (basic or acidic) conditions resulted in a failure. In the case of the reaction of other 3-methyl-2-butenoic acid derivatives **7**—**12**, none of desired products **4** nor **14** was obtained. When mesityl oxide (**13**) was used in the presence of $TiCl_4$, however **4** was successfully obtained in 44% yield. Then the reaction of mesityl oxide with some dienol silyl ethers derived from 2-cyclohexenones in the presence of $TiCl_4$ was carried out and the results are summarized in Table 1. The desired compounds were obtained except in the case of **15g**, in which case the reaction gave a complex mixture presumably due to the steric hindrance. As for the stereochemistry of the products, at least 2 isomers (endo- and exo-isomer) are possible, but only one isomer was isolated in the cases of **15a**, **15b**, **15e**, and **15f**, though the geometry of acetyl group is presently unknown. The dienol ether **15c** gave a mixture of two isomers and **15d** gave four isomers.[4] One of the tricyclic products synthesized from **15d** was used successfully for the synthesis of (±)-eremolactone.[1]

The mechanism of the reaction seems to involve a sequential Michael addition, because **14** was isolated when the reaction was quenched in the course of the process. For example, when the reaction of **15a** with



Scheme 2.

15 17 18

Scheme 3.

13 was carried out at −78 °C for 2 h, almost all the starting materials were consumed and 38% yield of **14** (X=Ac, Y=H) was obtained along with **16a** (29%). To make clear the scope and limitation, the reactions of dienol silyl ethers **15** with α,β-unsaturated esters were also examined. Although methyl crotonate gave no cyclo-adduct, methyl acrylate afforded the corresponding [2.2.2]bicyclo-products in moderate yields as shown in Table 2. We assigned all of the major products as endo-isomers by the comparison with authentic samples prepared by the methods[2] which are reported to give endo-isomers predominantly.

In conclusion, Lewis acid catalyzed reaction of dienol silyl ethers derived from 2-cyclohexenones with α,β-unsaturated carbonyl compounds is effective for the synthesis of crowded bicyclo[2.2.2]- or tricyclo-[5.2.2.$0^{1,5}$]-derivatives. In addition, this method is of importance especially when base labile compounds are subjected to such type of the reactions,[3] since this reaction proceeds under acidic conditions.

Experimental

Nuclear magnetic resonance spectra were taken on a JEOL PS-100 (100 MHz) or Hitachi R-24B (60 MHz). Infrared spectra were recorded on a Hitachi 260-50 spectrophotometer.

Typical Procedure: To a mixture of 1-methyl-3-trimethylsiloxy-1,3-cyclohexadiene **15b** (184 mg, 1 mmol), mesityl oxide (196 mg, 2 mmol) in dichloromethane (5 ml) was added $TiCl_4$ (2 mmol) in dichloromethane (5 ml) at −40 °C under an argon atmosphere. The solution was stirred at the temperature for 3 h, mixed with aqueous K_2CO_3 solution, and then extracted with dichloromethane. The extracts were dried over $MgSO_4$ and evaporated under reduced pressure. The residue was purified by silica-gel column chromatography to give **16b** (114 mg, 55%); mp 94—96 °C. IR (KBr) 1700 and 1720 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=0.84 (3H, s), 0.94 (3H, s), 1.34 (3H, s), 2.21 (3H, s), 2.58 (1H, d, J=2 Hz), 3.14 (1H, dd, J=2 and 18 Hz), 1.14—2.30 (6H, m). 3) Lewis acid catalyzed simple 1,4-addition of enol silyl ether to enones is reported; K. Narasaka, K. Soai, Y. Akikawa, and T. Mukaiyama, *Bull. Chem. Soc. Jpn.*, **49**, 7799 (1976). Recently, they also reported sequential Michael reaction of dienol silyl ethers; T. Mukaiyama, Y. Sagawa, and S. Kobayashi, *Chem. Lett.*, **1986**, 1821.

4) The X-ray analysis and the chemical transformation of **16d** proved that exo-products are formed predominantly in this case. The stereoselectivity is opposite to the results shown in Table 2, presumable due to the steric hindrance.

New Flavonoids Isolated from Infected Sugarbeet Roots

Hajime TAKAHASHI,* Teruji SASAKI, and Masaaki ITO
Chemistry Laboratory, Department of General Education, Higashi Nippon Gakuen University, Tobetsu, Hokkaido 061-02
(Received January 8, 1987)

Synopsis. New flavonoid compounds, 3,5-dihydroxy-6,7-methylenedioxyflavanone, 2′,5-dihydroxy-6,7-methylenedioxyisoflavone, and 5-hydroxy-6,7-methylenedioxyflavone were isolated from sugarbeet roots infected with *Rhizoctonia solani*.

Results

Phytoalexin, betagarin (**1**), and betavulgarin (**2**) have been recently isolated from the infected leaves of sugarbeet with *Corcospora beticola*.[1] We now report the isolation of some flavonoids from the sugarbeet roots infected with *R. Solani*. We also report that the compounds **3** and **4** have the weak inhibition effect of hypha growth, on the other hand, the compound **5**, being only the demethylated substance of betavulgarin (**2**), haven't that effect in the least.

The sliced and infected sugarbeet roots were extracted by a dipping in methanol at room temperature. The separation of the extracts by the column and preparative plates chromatographies on silica gel allowed an isolation of the pure six flavonoids. By the IR, UV, and ^{1}H NMR spectra datas, the compounds (**1**, 6.5×10^{-4}% yield), (**2**, 2.3×10^{-2}%), and (**3**, 7×10^{-4}%) were identified with the known betagarin, betavulgarin, and dihydrooroxylin A,[2] respectively.

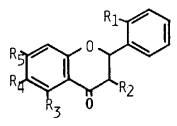
It was indicated that each of the flavonoids (**4**, 4.5×10^{-5}% yield), (**5**, 7.5×10^{-4}%), and (**6**, 1.7×10^{-2}%) had one methylenedioxy group and one or some hydroxyl groups by IR, MS, and ^{1}H NMR spectra. In the each mass spectrum of **4**, **5**, and **6**, each peak (*m/z*, 180 or 181) due to a fragment ion $C_8H_4O_5$ via retro Diels Alder pathway[3] was observed and suggested that one hydroxyl group and one methylenedioxy group attached to each A-ring of these compounds. In the ^{1}H NMR spectra of **4**, **5**, and **6**, one proton signal (singlet) respectively appeared at δ 10.92, 12.15, and 12.83, and assigned as the chelated hydroxyl group. In the UV spectra of **4**, **5**, and **6**, the respective maximum of absorption was bathochromically shifted by addition of aluminium chloride, and then, the shifted maxima were not again moved by the addition of hydrochloric acid. These results indicated that the all hydroxyl groups attached to the A-rings of **4**, **5**, and **6** oriented to the 5-positions. The Gibbes tests (all positive) of **4**, **5**, and **6** suggested that all 8-positions were free, and so all methylenedioxy groups oriented to 6- and 7-positions.

In the ^{1}H NMR of **4**, signals of two protons appeared as an AB-quartet at δ 5.09 and 4.55 (J=12 Hz) were assigned as a C-2-H and a C-3-H (trans configuration), and indicated that **4** had a flavanonol structure. Two singlets and one multiplet were also observed at δ 6.14 (1H, C-8-H), 6.04 (2H, -OCH_2O-), and 7.50 (5H, W_H=8 Hz, B-ring's protons), separately, in the ^{1}H NMR. By these results, it was confirmed that **4** is 3,5-dihydroxy-6,7-methylenedioxyflavanone.

Two maxima (245 and 272 nm) in the UV of **5** and the appearance of C-2-H (δ 8.06, s) in the ^{1}H NMR indicated that **5** had an isoflavone structure. The position of B-ring's hydroxyl group of **5** was easily determined by the NMR. The splitting patterns of the aromatic four protons on the B-ring was characteristic of *ortho*-disubstituted benzene.[4] Two singlets also appeared at δ 6.61 (1H, C-8-H) and 6.15 (2H, -OCH_2O-) in the ^{1}H NMR. The compound **5** was ultimately derived by a demethylation of the known **2**. Thus, It was confirmed that **5** was 2′,5-dihydroxy-6,7-methylenedioxyisoflavone.

It was also estimated that the compound **6** was 5-hydroxy-6,7-methylenedioxyflavone by the followed data. In the UV spectrum of **6**, the maxima (275 and 316 nm) of the absorptions suggested that **6** had a flavone structure. In the ^{1}H NMR of **6**, the signals of the C-3-H (δ 6.61, s) and the five protons (δ 7.80, m, 2′6′-protons and δ 7.50, m, 3′4′5′-protons) also supported its structure.

The investigation of the inhibition effect of the isolated flavonoids allowed that the compounds **3** and **4** had more weak activities than **1** and **2**, and that **5** (the demethylated compound of the active **2**) and **6** haven't the activities in the least.



1: R_1=R_3=OCH_3, R_2=H, R_4,R_5=OCH_2O

Experimental

All melting points are uncorrected. IR, UV, and ^{1}H NMR were determined with a Shimazu IR-400 spectrometer, with a Shimazu MPS-5000 spectrometer (solvent, ethanol), and with a JEOL-JNM-FX-90 spectrometer (solvent, chloroform-*d*; internal reference tetramethylsilane). MS spectra were taken with a Shimazu KLB-5000 spectrometer. High resolution MS spectra were taken by the staff of the Faculty of Agriculture, Hokkaido University, with a JEOL-D-500 spectrometer. TLC and column chromatographies were carried out on Merck kiesel gel and Cica silica gel.

Aphanomyces euteiches and *Rhizoctonia solani* were applied for screening test of growth inhibition properties. It was surely confirmed that methanol extract of the sliced and non-

infected sugarbeet roots had never the inhibition activity.

Isolation of the Flavoniods (1)—(6). Sliced sugarbeet roots (20 kg) were infected with *R. solani*, and stayed for 3 days at 25 °C, and dried at room temperature, and dipped in methanol (10 liters). After filtration of the extracts, the methanol solution was evaporated. Ethyl acetate solution of the obtained residue was washed with saturated water by sodium chloride, and dried (sodium sulfate). The produced residue by removal of solvent was washed with hexane (this hexane solution haven't the inhibition activity). The residue (20 g) was separated on column chromatography (solvent system; benzene, chloroform, and ethyl acetate). Further, the purification of the fractions was carried out by preparative TLC plates.

The known (**1**, 13 mg), (**2**, 450 mg), and (**3**, 14 mg) were identified with the standard compound **3** and the other data.

3,5-Dihydroxy-6,7-methlenedioxyflavanone (4): Yellow crystals (9 mg), mp 179—180 °C; Gibbes test (+); MS *m/z* 300 (M^+, 48%), 180 (M−120, 100); UV, λ_{max} (EtOH) 246 nm (ε 14150), 294 (ε 16500), λ_{max} (EtOH, $AlCl_3$ or $AlCl_3$, HCl) 245 nm (ε 6430), 322 (ε 20800); IR, 3450 cm^{-1} (OH), 1670 and 1620 (C=O); ^1H NMR δ=10.92 (1H, s, C-5-OH), 7.50 (5H, m, W_H=8 Hz, B-ring protons), 6.14 (1H, s, C-8-H), 6.04 (2H, s, $-OCH_2O-$),5.09 and 4.55 (2H, AB-q, J=12 Hz, C-2-H and C-3-H); High MS. Found: 300.0635. Calcd for $C_{16}H_{12}O_6$: 300.0634.

2',5-Dihydroxy-6,7-methylenedioxyisoflavone (5): Pale yellow crystals (15 mg), mp 230—233 °C; Gibbes Test (+); MS *m/z* 298 (M^+, 32%), 180 (M−118, 100); UV, λ_{max} (EtOH) 272 nm (ε 22600), 290 (shoulder), λ_{max} (EtOH, $AlCl_3$ or $AlCl_3$, HCl) 282 nm (ε 28000), 320 (ε 14000); IR, 3250 cm^{-1} (OH), 1670 and 1620 (C=O); ^1H NMR, δ 12.15 (1H, s, C-5-OH), 8.06 (1H, s, C-2-H), 7.30 (1H, m, C-6'-H), 7.10 (3H, m, C-3',4',5'-H), 6.61 (1H, s, C-8-H), 6.15 (2H, s, $-OCH_2O-$); High MS. Found: 298.0475. Calcd for $C_{16}H_{10}O_6$: 298.0477.

5 from 2: The mixture of **2** (100 mg), dry $AlCl_3$ (300 mg), and K_2CO_3 in ether (20 ml) was refluxed for 3 h. After an addition of acetic acid (10 ml) in the reaction mixture, removal of the solvent gave the residue. Chloroform solution of the residue was washed and dried (Na_2SO_4). Removal of solvent gave crystals **5**.

5-Hydroxy-6,7-methylenedioxyflavone (6): Yellow crystals (340 mg), mp 205 °C (decomp); Gibbes test (+); MS *m/z* 282 (M^+, 100%), 180 (M−102, 31), UV, λ_{max} (EtOH) 275 nm (ε 19700), 316 (ε 15200), λ_{max} (EtOH, $AlCl_3$ or $AlCl_3$, HCl) 284 nm (ε 20600), 292 (shoulder), 346 (ε 17800); IR, 3400 cm^{-1} (OH), 1670 and 1620 (C=O); ^1H NMR, δ=12.83 (1H, s, C-5-OH), 7.80 (2H, m, C-2',6'-H), 7.50 (3H, m, C-3',4',5'-H), 6.68 (1H, s, C-8-H), 6.61 (1H, s, C-3-H), 6.11 (2H, s, $-OCH_2O-$); High MS, Found: 282.0539. Calcd for $C_{16}H_{10}O_5$: 282.0529.

The authors wish to express their gratitude to Dr. Ryouzoh Yokosawa, Higashi Nippon Gakuen University, for infection and screening test by him, to Mr. Juichi Sugawara, Hokkaido Togyo co. LTD., for his supply of sugarbeet, to Dr. Akiyo Sakushima, Faculty of Pharmaceutical Sciences of Higashi Nippon Gakuen University for his valuable suggestions, and to Professor Shuzo Takagi, Faculty of Pharmaceutical Sciences, Mukogawa Women's University for his kind supply of dihydrooroxylin A.

Silaethene in Pyrolysis of Spiro[silacyclobutane-1,9′-[9*H*-9]silafluorene]

Daiyo TERUNUMA,* Makoto NAKAMURA, Eiji MIYAZAWA, and Hiroyuki NOHIRA
Department of Applied Chemistry, Faculty of Engineering, Saitama University, Urawa, Saitama 338
(Received January 26, 1987)

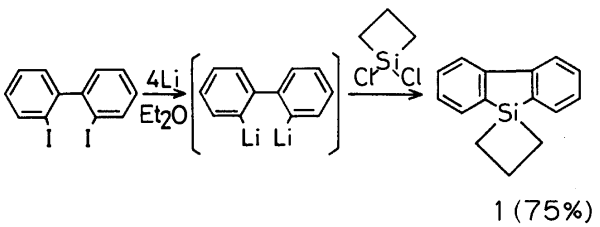
Synopsis. A new silaspiro compound, i.e., spiro[silacyclobutane-1,9′-[9H-9]silafluorene](**1**) was synthesized in 75% yield. It was found that the pyrolysis of **1** at 650 °C under a reduced pressure gave a head-to-tail silaethene dimer in 15% yield. Copyrolysis of **1** in the presence of benzophenone gave 1,1-diphenylethene and a siloxane oligomer in 50 and 30% yield, respectively.

Current attention has been concentrated to the preparation and characterization of a silicon-carbon double bond.[1] It is suggested that 1-silafulvene systems have strong π stability and high reactivity, on the contrary 2-silafluvene systems have weak π stability and low reactivity.[2] In this connection, the generation of 1-silafluvene was already investigated.[3]

In the course of our studies on the synthesis of silicon-containing cyclic compounds,[4] we have interested in spiro[silacyclobutane-1,9′-[9H-9]silafluorene] (**1**). Because the generation of 2-silafluvene type intermediate would be expected with extrusion of ethene in the pyrolysis of **1**.

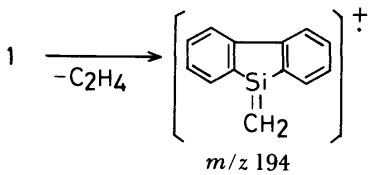
Results and Discussion

Compound **1** was obtained by treating 1,1-dichlorosilacyclobutane with biphenyl-2,2′-diyldilithium in 75% yield (Scheme 1).



Scheme 1.

The mass spectrum of **1** shows relatively simple fragmentation including the base peak (m/z 194) corresponded to the silaethene fragment (Scheme 2).

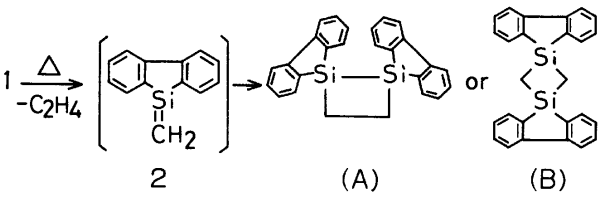


m/z 194

Scheme 2.

Then the pyrolysis of **1** was carried out at 650 °C under a reduced pressure (ca. 10^{-3} Torr†). A white crystalline product was obtained. The parent peak of the mass spectrum of the product was consistent with the molecular weight of a dimer of 2-silafluvene derivative (**2**) (m/z 388). Thus it is clear that **2** is generated under these reaction conditions and successive reaction of **2** occurs to give the dimer (Scheme 3).

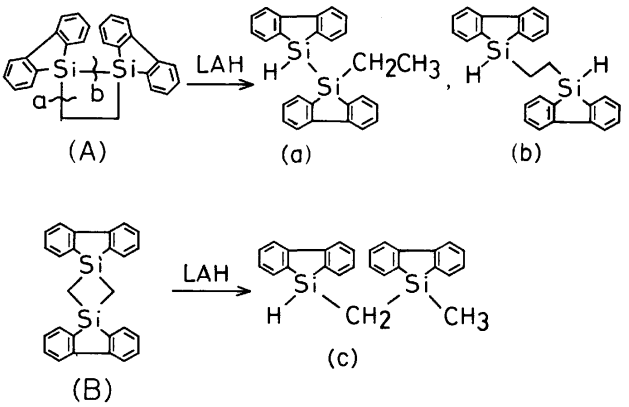
†1 Torr=133.322Pa.



Scheme 3.

On the other hand, the silaethene can be dimerized in the two manners,[5] head-to-head (A) and head-to-tail (B).

NMR spectrum (^{29}Si) of the dimer (δ +2.1 based on TMS) suggests 1,3-disilacyclobutane structure (B).[6] The disilacyclobutane derivative has been known to undergo ring-openning reaction in the presence of lithium aluminum hydride (LAH).[7] The dimer was treated with LAH. The expected product from A and B are shown in Scheme 4.

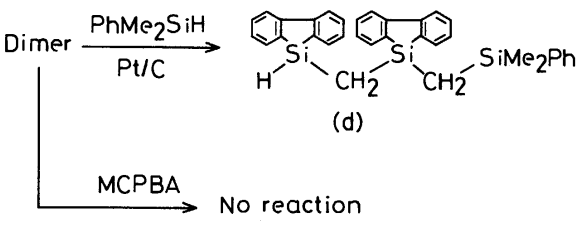


Scheme 4.

NMR spectra data of the product [^{13}C NMR ($CDCl_3$) δ −5.20 (t, CH_2), −2.27 (q, CH_3)] shows (c) in Scheme 4 which indicates the dimer structure of (B).

Furthermore, the reaction of the dimer with dimethylphenylsilane in the presence of platinum/carbon[8] afforded corresponding ring-opened product (d) (Scheme 5), but no reaction occurred with *m*-chloroperbenzoic acid (MCPBA).

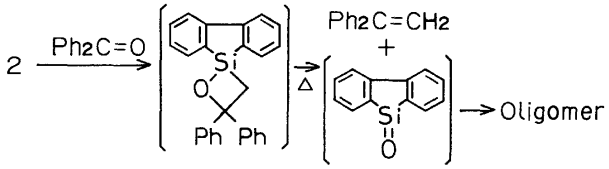
These results show that the dimer has the structure of type B.



Scheme 5.

Then copyrolysis of **1** with benzophenone was investigated. The reaction was carried out at 540 °C under a

reduced pressure (ca. 10^{-3} Torr). 1,1-Diphenylethene and a siloxane oligomer were obtained in a 50 and 30% yield, respectively. Although we could not find out the direct evidence for the existence of the intermediates, it seems to be reasonable to consider that the reaction proceeds via a manner similar to that described in the copyrolysis of the silacyclobutane derivatives with benzophenone[9] (Scheme 6).



Scheme 6.

Experimental

The melting points and boiling points are uncorrected. The IR spectra were determined with a JASCO IR-A 302 spectrometer. The NMR spectra were determined at 90 MHz with a JEOL FX90Q and at 200 MHz with a JEOL FX200 spectrometers in $CDCl_3$ using TMS as an internal standard. The mass spectra were recorded on a JEOL-01SG instrument. Biphenyl-2,2′-diyldilithum was prepared in a manner similar to that described in the literature.[10]

Spiro[silacyclobutane-1,9′-[9H-9]silafluorene] (1). In a flask lithium (2.0 g, 0.29 gram-atoms) and dry ether (30 ml) were placed. A solution of 2,2′-diiodobiphenyl (12.0 g, 29.6 mmol) in dry ether (50 ml) was added to the mixture at reflux temperature with stirring under a dry nitrogen atmosphere. The mixture was refluxed for 1 h after the addition was complete. In another flask, a solution of 1,1-dichlorosilacyclobutane (4.0 g, 28.4 mmol) in dry ether (40 ml) was placed. The etheral solution of biphenyl-2,2′-diyldilithium was added to the solution of the chlorosilane by means of a syringe at 0 °C. The reaction mixture was stirred at 0 °C for 1 h, allowed to stand at room temperature for 1 h. The reaction mixture was hydrolyzed and the organic layer was separated and dried (Na_2SO_4). Evaporation and distilation gave **1** in 4.4 g (75%) yield. Bp 131 °C/0.25 Torr. n_D^{25} 1.6511. IR (neat) 2900, 1600, 1430, 1350, 1260, 1130, 1060, 850, 740, 720, 680, 540 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.56 (t, 4, Si-CH_2), 2.38 (quintet, CH_2), 7.1—7.8 (m, 8, Ar). ^{13}C NMR ($CDCl_3$) δ=15.0 (Si-CH_2), 19.29 (CH_2), 120.55, 127.48, 130.68, 133.11, 135.61, 147.58 (Ar). ^{29}Si NMR ($CDCl_3$) δ=12.9. UV (cyclohexane) ε_{max}(nm) 237 (4.51×10^4), 244 (3.84×10^4), 281 (1.40×10^4), 293 (1.21×10^4). Found: C, 81.00; H, 6.51%. Calcd for $C_{15}H_{14}Si$: C, 81.02; H, 6.34%.

Pyrorysis of 1. Pyrolysis was carried out using a vacuum flow system. Compound **1** (527 mg, 2.4 mmol) was added into a quartz tube (l=40 cm, d=0.8 cm) maintained at 640 °C through preheated tube (ca. 300 °C) under a reduced pressure (4×10^{-3} Torr). The products were collected in a liq. N_2 trap, and washed out with benzene. Evaporation and filtration gave crystalline product. It was purified by recrystallization from benzene. Yield 70 mg (15%). Mp 323—326 °C. MS M^+ 388. IR (KBr) 3050, 1600, 1435, 1340, 1260, 1130, 1080, 940, 770, 730, 710, 630 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.17 (s, 4H, Si-CH_2), 7.2—8.0 (m, 16H, Ar). ^{13}C NMR ($CDCl_3$) δ=1.10 (Si-CH_2), 121.1, 128.0, 131.0, 132.8, 137.5, 147.5 (Ar). ^{29}Si NMR ($CDCl_3$) δ=+2.1. UV (cyclohexane) ε_{max} (nm) 238 (9.65×10^4), 245 (1.02×10^5), 283 (3.44×10^4).

Copyrorysis of **1** (500 mg, 2.25 mmol) in the presence of benzophenone (410 mg, 2.25 mmol) was carried out at 540 °C in a manner similar to that described above. 1,1-Diphenylethene and the siloxane oligomer were separated from the reaction mixture by TLC (benzene-hexane 4 : 1) in 50% (200 mg) and 30% (130 mg) yield, respectively. 1,1-Diphenylethene; ^1H NMR (CCl_4) δ=5.35 (s, 2H, =CH_2), 7.20 (s, 10H, Ph). Oligomer IR (KBr) 3000, 1590, 1420, 1260, 1120, 1060, 740, 500 cm^{-1}. ^1H NMR (CCl_4) δ=7.0—8.2 (Ar).

Reaction of the Dimer with LAH. LAH (50 mg, 1.3 mmol) was added to a solution of the dimer (200 mg, 0.5 mmol) in dry ether (30 ml). The mixture was refluxed for 1 h with stirring. Usual work-up and purification by TLC (benzene) gave ring-opened product in 120 mg (60%) yield. ^1H NMR ($CDCl_3$) δ=0.40 (s, H, Si-CH_3), 0.61 (d, 2H, Si-CH_2-Si), 4.87 (t, 1H, Si-H), 7.1—7.8 (m, 16H, Ar). ^{13}C NMR ($CDCl_3$) δ=−5.20 (t, CH_2), −2.27 (q, Si-CH_3), 120.77, 127.33, 130.20, 130.33, 132.99, 133.64, 135.46, 138.19, 147.69, 148.34 (Ar).

Reaction of the Dimer with Dimethylphenylsilane in the Presence of Pt/C Catalyst. A mixture of the dimer (39.8 mg, 0.10 mmol), dimethylphenylsilane (1.00 g, 7.4 mmol), and 5% Pt/C (10 mg) was placed in a test tube. The tube was sealed under a dry nitrogen atmosphere, and it was kept at 100 °C for 55 h. After evaporation of excess dimethylphenylsilane, the product was separated by TLC (hexane-benzene 3 : 1) and recrystallized from pentane. Yield 16.1 mg (30%). ^1H NMR ($CDCl_3$) δ=−0.06 (s, 6H, Si-CH_3), 0.44 (s, 2H, Si-CH_2-Si), 0.58 (d, 2H, Si-CH_2), 4.82 (t, 1H, Si-H), 7.1—7.8 (m, 21H, Ar).

The authors are grateful to Professor Yasuhiro Nakadaira for help and advice in the determination of the structure of the dimer, and Asocciate Professor Sumio Tokita for letting us know the improved preparation method of 2,2′-diiodobiphenyl.

The authors also wish to thank the Shin-etsu Chemical Industry Co. for the gift of silanes.

The ν_8 Infrared Band of Ethylidynephosphine $CH_3C{\equiv}P$ and Its Perdeuteride $CD_3C{\equiv}P$

Keiichi OHNO* and Hiroatsu MATSUURA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received January 14, 1987)

Synopsis. The gas-phase infrared spectra of ethylidynephosphine $CH_3C{\equiv}P$ and its perdeuteride $CD_3C{\equiv}P$ were measured in the 50—400 cm^{-1} region with a resolution of 0.12 cm^{-1}. The molecular constants for the $\nu_8^{\pm1}$ and $2\nu_8^0-\nu_8^{\pm1}$ bands were determined by the $^{P,R}Q_K$ branch analysis.

Vibrational spectra of ethylidynephosphine (1-phosphapropyne)$CH_3C{\equiv}P$ and its perdeuteride $CD_3C{\equiv}P$ have been analyzed previously by infrared spectroscopy and the wavenumbers of the fundamental transitions have been determined.[1] Of the eight fundamentals, the $\nu_8^{\pm1}$ band, which is associated with the lowest vibrational level, has been detected only in the solid state, but no information has been available on this band for the gaseous state. In the present study, we have investigated the gas-phase infrared spectra of $CH_3C{\equiv}P$ and $CD_3C{\equiv}P$ in the 50—400 cm^{-1} region with a resolution of 0.12 cm^{-1} and the molecular constants for the $\nu_8^{\pm1}$ band have been determined. These constants will be eventually important for vibration-rotation analyses of the band systems in which the overtone and/or combination of $\nu_8^{\pm1}$ is involved.

Experimental

Samples of $CH_3C{\equiv}P$ and $CD_3C{\equiv}P$ were prepared by the pyrolyses of $C_2H_5PCl_2$ and $C_2D_5PCl_2$, respectively.[2] The far-infrared spectra were recorded on a JEOL JIR-40X Fourier transform infrared spectrometer. A globar source, a 6-μm Mylar beam splitter, and a TGS detector with a polyethylene window were used. The sample pressure was about 5 kPa in a 12-cm gas cell fitted with polyethylene windows. Dry nitrogen gas was continuously passed through the instrument during the measurement to get rid of water vapor.

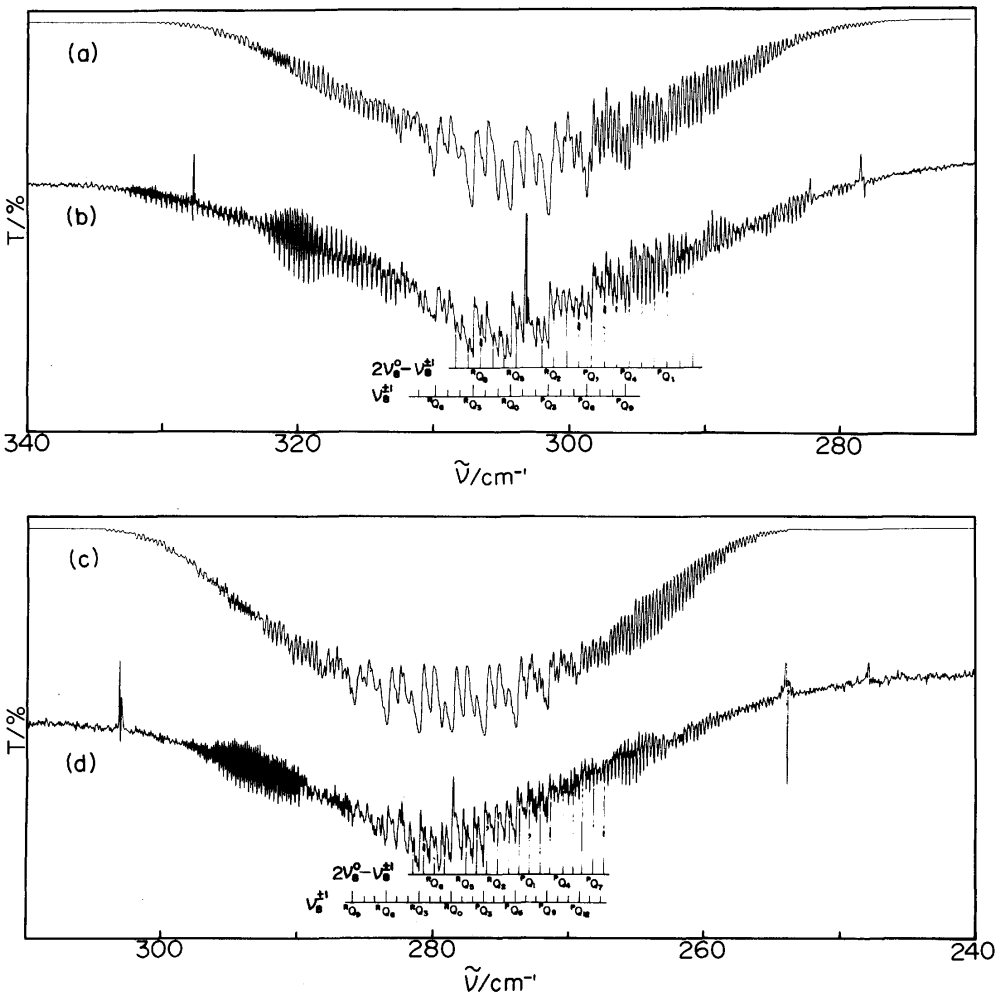

Fig. 1. Infrared spectra of the $\nu_8^{\pm1}$ and $2\nu_8^0-\nu_8^{\pm1}$ bands of $CH_3C{\equiv}P$ and $CD_3C{\equiv}P$. (a) Simulated spectrum of $CH_3C{\equiv}P$, (b) observed spectrum of $CH_3C{\equiv}P$, (c) simulated spectrum of $CD_3C{\equiv}P$, and (d) observed spectrum of $CD_3C{\equiv}P$.

Results and Discussion

Figure 1 shows the infrared spectra of the $\nu_8^{\pm 1}$ band region of $CH_3C{\equiv}P$ and $CD_3C{\equiv}P$. The $\nu_8^{\pm 1}$ band is due to the perpendicular transition of the prolate symmetric-top molecule. The wavenumbers for the $^{P,R}Q_K$ branches of $\nu_8^{\pm 1}$ are expressed by

$$ {}^{R}_{P}\nu^{Q}=\nu_0+[A'(1-2\zeta^z)-B']\pm 2[A'(1-\zeta^z)-B']K +[(A'-B')-(A''-B'')]K^2+(B'-B'')J(J+1), \quad (1) $$

where the centrifugal distortion terms are neglected. Thus, the $^{P,R}Q_K$ branches were easily assigned on the basis of a successive spacing of approximately $2[A'(1-\zeta^z)-B']=0.8$—0.9 cm^{-1} and the nuclear spin statistics, i.e., the $K=3|n|$ levels (n: integer) are stronger in intensity than the other K levels in the ground state. The assignments of the $^{P,R}Q_K$ branches are shown in Fig. 1. Definitive assignments of the $^{P,R}R_K$ and $^{P,R}P_K$ branch lines of individual subbands could not be made, because the small spacing of $2[A'(1-\zeta^z)-B']$ made the P and/or R branch lines overlap each other. The molecular constants ν_0, A', and $A'\zeta^z$ in the usual quadratic expression were determined by the least-squares method so as to fit the observed $^{P,R}Q_K$ branch wavenumbers, where other rotational and centrifugal distortion constants were constrained to the microwave values.[2] The observed line positions of the $^{P,R}Q_K$ branches are given in Table 1. The molecular constants determined are listed in Table 2.

The spectra of the $\nu_8^{\pm 1}$ band for $CH_3C{\equiv}P$ and $CD_3C{\equiv}P$ were simulated by using the molecular constants obtained. The simulation spectra have revealed the existence of additional series of lines in the experimental spectra. These lines may be ascribed to hot bands with which $\nu_8^{\pm 1}$ is associated. For the hot band $2\nu_8-\nu_8$, which is due to a transition from the most populated excited state, there are three possible cases; i.e., two perpendicular-type bands $2\nu_8^0-\nu_8^{\pm 1}$ and

Table 1. Observed $^{P,R}Q_K$ Line Positions of the $\nu_8^{\pm 1}$ and $2\nu_8^0-\nu_8^{\pm 1}$ Bands of $CH_3C{\equiv}P$ and $CD_3C{\equiv}P$[a]

a) The observed wavenumbers with asterisk are not included in the least-squares fit. J values were assumed to be $J=K+1$ for the ^RQ_K lines and $J=K$ for the ^PQ_K lines. b) $\nu_{obsd}-\nu_{calcd}$.

Table 2. Molecular Constants for the $\nu_8^{\pm 1}$ and $2\nu_8^0-\nu_8^{\pm 1}$ Bands of $CH_3C{\equiv}P$ and $CD_3C{\equiv}P$[a]

Molecular constant	$CH_3C{\equiv}P$		$CD_3C{\equiv}P$	
	$\nu_8^{\pm 1}$	$2\nu_8^0-\nu_8^{\pm 1}$	$\nu_8^{\pm 1}$	$2\nu_8^0-\nu_8^{\pm 1}$
$(\nu_0)_v$	308.338 (48)	294.217 (37)	280.330 (37)	271.207 (44)
A_v	5.1703 (14)	5.1692 (35)	2.58820 (53)	2.5878 (10)
$(A\zeta^z)_v$	4.5320 (31)	4.5320[b]	2.0470 (18)	2.0470[b]

a) In units of cm^{-1}. The three times standard deviations, given in parentheses, apply to the last significant figures. $A_0=5.17264$ cm^{-1} for $CH_3C{\equiv}P$ and $A_0=2.58826$ cm^{-1} for $CD_3C{\equiv}P$. b) Assumed.

$2\nu_8^{\pm2}-\nu_8^{\pm1}$ and one parallel-type band $2\nu_8^{\mp2}-\nu_8^{\pm1}$. Of these, only the $2\nu_8^{0}-\nu_8^{\pm1}$ band is likely to be observed in this region, since the microwave analysis of $CH_3C{\equiv}P$[2] has given the anharmonicity constant g_{88} to be 6.11±0.86 cm^{-1} which includes a Coriolis term $A_8(\zeta_8^z)^2$. The wavenumbers for the $^{P,R}Q_K$ branches of $2\nu_8^{0}-\nu_8^{\pm1}$ are given by

$$^{R}_{P}\nu^{Q}=\nu_0+A'-B'\pm2[A'-A''\zeta^z-B']K+[(A'-B')-(A''-B'')]K^2+(B'-B'')J(J+1). \quad (2)$$

The successive spacing of $2[A'-A''\zeta^z-B']$ is nearly equal to that for the $\nu_8^{\pm1}$ band. The transitions with the $|K-l|=3|n|$ levels in the lower vibrational state, i.e., ..., $^{R}Q_5$, $^{R}Q_2$, $^{P}Q_1$, $^{P}Q_4$, ... are stronger than the others. The assignments of the $^{P,R}Q_K$ branches of $2\nu_8^{0}-\nu_8^{\pm1}$ were made, as shown in Fig. 1, on the basis of the above criterion and the anharmonicity constant x_{88} for $CH_3C{\equiv}N$[3] and $x'_{88}\simeq(\omega'_8/\omega_8)x_{88}$. The observed line positions of the $^{P,R}Q_K$ branches are given in Table 1 and the molecular constants determined are given in Table 2.

The composite simulation spectrum of the $\nu_8^{\pm1}$ and $2\nu_8^{0}-\nu_8^{\pm1}$ bands is shown in Fig. 1(a) for $CH_3C{\equiv}P$ and in Fig. 1(c) for $CD_3C{\equiv}P$. It is seen that the $\nu_8^{\pm1}$ band is well simulated but the intensities of $2\nu_8^{0}-\nu_8^{\pm1}$ are not reproduced satisfactorily with the Boltzmann factor alone.

Table 3. Vibrational Parameters of the $\nu_8^{\pm1}$ Band of $CH_3C{\equiv}P$ and $CD_3C{\equiv}P$

Compound	ω_8^0/cm^{-1}	x_{88}/cm^{-1}	g_{88}/cm^{-1}
$CH_3C{\equiv}P$	303.18	−0.95	6.11[a]
$CD_3C{\equiv}P$	277.38	−0.81	3.75[b]

a) Microwave value (Ref. 2). b) The anharmonic terms in g_{88} are assumed to be the same as those for $CH_3C{\equiv}P$.

The determined band origins for $\nu_8^{\pm1}$ of $CH_3C{\equiv}P$ and $CD_3C{\equiv}P$ in the gaseous state are smaller by 8—7 cm^{-1} than those observed in the solid state: 316 cm^{-1} for the former and 287 cm^{-1} for the latter.[1] The band origins for $\nu_8^{\pm1}$ and $2\nu_8^{0}-\nu_8^{\pm1}$ and the microwave value[2] for g_{88} of $CH_3C{\equiv}P$ yield the vibrational parameters for $CH_3C{\equiv}P$ and $CD_3C{\equiv}P$ as given in Table 3. By using these parameters, the band origin for $3\nu_8^{\pm1}$ of $CD_3C{\equiv}P$ is estimated to be 828.6 cm^{-1}. An experimental value of 829.7±0.4 cm^{-1} has been obtained for this band origin from the $^{P,R}Q_K$ branch analysis of a Fermi-interacting band system $\nu_7^{\pm1}$ and $3\nu_8^{\pm1}$ with the assumption that $(\zeta_{eff}^z)_{888}=0.791$.[1] The Coriolis constant ζ_8^z was obtained to be 0.876 for $CH_3C{\equiv}P$ and 0.791 for $CD_3C{\equiv}P$, in good agreement with 0.865 and 0.772, respectively, calculated from the molecular force field.[1] The molecular parameters for $CH_3C{\equiv}P$ may also be compared with those for $CH_3C{\equiv}N$: $\omega_8^0=360.27$ cm^{-1}, $x_{88}=-0.963$ cm^{-1}, $g_{88}=5.75$ cm^{-1}, and $\zeta_8^z=0.874$.[3]

The authors wish to express their thanks to Miss Ikuko Shimooka for her assistance in the spectral analysis.

Topological Charge Stabilization Rule and Quasi-Aromaticity

Jun-ichi AIHARA
Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422
(Received January 26, 1987)

Synopsis. Stabilities of the oxocarbon dianions and some quasi-aromatic compounds can be rationalized in terms of Gimarc's topological charge stabilization rule. The term "quasi-aromatic" is recommended for describing those non-aromatic compounds which behave like aromatics owing to the operation of this rule.

Monocyclic oxocarbon dianions with the general formula $C_nO_n^{2-}$ (**1**—**4**) are fairly stable substances.[1,2] West et al.[1,3] and Herndon[4] considered them as a kind of aromatic species, stabilized by π electron delocalization around the ring. Two research groups, however, showed that extra stabilization energy scarcely arises from the cyclic conjugation in these ions.[5,6] So-called topological resonance energy (TRE) is very small except the deltate dianion (**1**).[5] Only $C_3O_3^{2-}$ seems to be aromatic with large TRE. Associating bond orders with aromaticity, Jug showed that for the oxocarbon dianions the aromaticity decreases rapidly as the ring size increases.[7]

In 1964 Lloyd and Marshall proposed that molecules should be called quasi-aromatic only if they contain an acyclic conjugated π-electron system and show chemical properties typical of aromatic compounds, especially reaction by substitution with retention of the original conjugated system.[8] They first used the term "quasi-aromatic" with this meaning to describe the behavior of the 2,3-dihydro-1,4-diazepinium salts (**5**).[8,9] The α,ω-diazapolymethinium salts (**6**)[10] and the transition-metal chelates of β-diketones (**7**)[11] can also be classified as quasi-aromatics. Although the metal chelates of acetylacetone apparently have a cyclic conjugated system, Musso et al. demonstrated that no ring currents are induced in these complexes.[12] This indicates that the π-electron conjugation is interrupted at the metal atom. All these quasi-aromatic species have no TRE since there are no cyclic paths for π electrons.

What then is the main origin of stability of the monocyclic oxocarbon dianions and the quasi-aromatic compounds? It is very true that their aromatic behavior and stability cannot be related to the cyclic conjugation of π electrons. The purpose of this note is to solve this problem using Gimarc's topological charge stabilization rule.[13-15]

In 1983 Gimarc stressed that the pattern of charge densities in a molecule is determined primarily by the connectivity or topology of the molecule.[13,14] Many examples showed that nature prefers to place atoms of greater electronegativity in those positions where the topology of the structure tends to pile up extra charge in the isoelectronic hydrocarbon.[13,15] Since such heteroatomic systems are preferentially stabilized by molecular topology, Gimarc called the effect the rule of topological charge stabilization.[13]

Oxocarbon Dianions

An oxocarbon dianion with n carbonyl groups is referred to as [n]oxocarbon dianion. Radialene with n exomethylenes is likewise referred to as [n]radialene. The [n]radialene dianion is iso-π-electronic with the [n]oxocarbon dianion. Such an iso-π-electronic hydrocarbon has been called a uniform reference frame (URF).[13] The [n]oxocarbon dianion and its URF have the same geometry with the same number of π electrons ($2n+2$). Charge densities were calculated for the URF's of **1**—**4**, (i.e., four radialene dianions) using the simple HMO model. They are shown in Fig. 1.

It is noteworthy that these radialene dianions have maximum charge densities at the exomethylene carbons. The oxocarbon dianions are formed by replacing all these carbons by more electronegative oxygens. Thus, the framework of every oxocarbon dianion is favored from the standpoint of the topological charge stabilization rule.[13] In other words, the stability of most oxocarbon dianions is largely due to the presence of oxygens at positions where, for purely geometrical reasons, the π electrons congregate.[13,14] This possibly constitutes the primary reason why the oxocarbon dianions have often been regarded as aromatics.

Many oxocarbon analogues have been synthesized by replacing one or more oxygens by other hetero atoms, such as nitrogens and sulfurs.[1,2] The topological charge stabilization rule necessarily operates in these compounds.

Oxocarbon acids of the general formula $C_nO_nH_2$ (**8**—**11**)[1,2] are acids conjugate to the oxocarbon dianions. The URF of each oxocarbon acid is identical with that of the corresponding oxocarbon dianion. A given oxocarbon acid is formed by replacing two of the exomethylene carbons in the URF by hydroxyl oxygens and the remaining ones by carbonyl oxygens. Thus, the carbons of maximum charge density in the URF are all replaced by electronegative oxygens. All oxocarbon acids are known indeed.

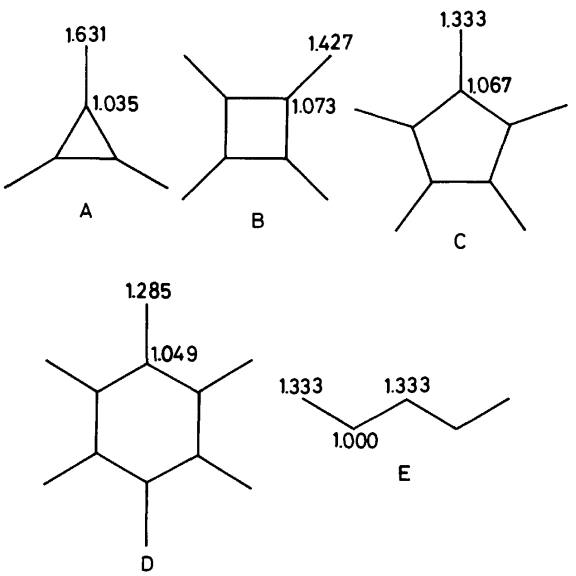

Fig. 1. Charge densities in: (A) the [3]radialene dianion (the URF of **1**); (B) the [4]radialene dianion (the URF of **2**); (C) the [5]radialene dianion (the URF of **3**); (D) the [6]radialene dianion (the URF of **4**); and (E) the pentadienide anion (the URF of **5** and **7**).

Unfortunately, the topological charge stabilization rule is not applicable to the neutral oxocarbons (C_nO_n). The URF of neutral [$2m$]oxocarbon is [$2m$]radialene. Since this is an alternant hydrocarbon, the charge distribution is uniform over the entire conjugated system. A similar situation is seen in the case of the URF of neutral [$2m+1$]oxocarbon. Although [$2m+1$]radialene is not an alternant hydrocarbon, the charge distribution is fairly uniform. These facts may not account for the instability of neutral oxocarbons, but coincide with it.

Quasi-Aromatic Compounds

Pentadienide ion ($C_5H_7^-$) is iso-π-electronic with the conjugated systems of the quasi-aromatic compounds **5** and **7**. As shown in Fig. 1, this URF has the maximum charge densities at one central and two edge carbons. If the two edge carbons are replaced by electronegative nitrogens, in such a manner that the entire conjugated system preserves the number of π electrons, we obtain the conjugated system of the 2,3-dihydro-1,4-diazepinium ion (**5**). If they are replaced by oxygens, we obtain the conjugated subsystem of the β-diketonate ion in **7**. Therefore, the stability of these quasi-aromatic systems can again be rationalized by the topological charge stabilization rule. A similar explanation applies to the quasi-aromaticity of other α,ω-polymethinium ions (**6**). We might safely say that the tendency of these compounds to retain the original conjugated system[8] arises primarily from such topological charge stabilization in the ground electronic state.

Concluding Remarks

The oxocarbon dianions and some acyclic systems have been classified as aromatics or quasi-aromatics although they have essentially zero TRE. It was shown that chemical behaviors and stability of these compounds can be rationalized well in terms of the topological charge stabilization rule. These compounds are thermodynamically favored since the constituent atoms are arranged such that their electronegativities match the pattern of charge densities of the iso-π-electronic hydrocarbon.[13,14] Considering that there have been no other widely accepted theories for the stability of these compounds, the present simple rationale seems to be the best one available.

It is suggested that to avoid confusion the term "aromatic" be restricted to compounds with relatively large TRE.[5] The term "quasi-aromatic" is instead recommended for describing those essentially non-aromatic conjugated compounds which tend to retain their own conjugated systems. The quasi-aromatic compounds defined here are those which are stabilized by the operation of the topological charge stabilization rule but not by cyclic conjugation. The oxocarbon dianions with $n>3$ should be classified as quasi-aromatic compounds, rather than as aromatic com-

pounds.

As already pointed out by Gimarc,[13] Y-aromaticity in guanidinium (**12**) and carbonate (**13**) ions[16] can also be rationalized in terms of the topological charge stabilization rule. These Y-aromatic compounds should again be classified as quasi-aromatic species.

The Preconcentration and Determination of a Trace Amount of Strontium in Fresh Water as Its 1-Phenyl-3-methyl-4-benzoyl-5-pyrazolone Chelate by Means of Solvent Extraction

Takaharu HONJO* and Takashi NAKATA
Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa 920
(Received September 6, 1986)

Synopsis. The behavior of a trace amount of alkaline earth metals (magnesium, calcium, strontium, and barium) on solvent extraction has been examined with PMBP (1-phenyl-3-methyl-4-benzoyl-5-pyrazolone) in benzyl alcohol; the results have also been applied to the preconcentration and determination of a trace amount of strontium in ppb order in fresh water as its PMBP chelate by means of solvent extraction.

The content of strontium in fresh water is generally known to be in ppb order, and it must be concentrated up to ppm order, prior to its determination by means of a usual atomic absorption method. Solvent extraction, especially chelate extraction, is a simple and highly selective convenient method for the preconcentration and determination of a trace amount of metals like heavy metals[1-6,8] and alkaline earth metals[3,6,7] in natural waters. Among the extractive chelating agents of 8-hydroxyquinoline, β-isopropyltropolone, 2-thenoyltrifluoroacetone, and PMBP (1-phenyl-3-methyl-4-benzoyl-5-pyrazolone), PMBP has been reported to be most useful for the extraction of alkaline earth metals.[3,6-8]

In this investigation, the behavior of a trace amount of alkaline earth metals (magnesium, calcium, strontium, and barium) in solvent extraction has been examined with PMBP in benzyl alcohol; the results have been applied to the preconcentration and determination of a trace amount of strontium in ppb order in fresh water as its PMBP chelate by means of solvent extraction for the subsequent atomic absorption analysis.

Experimental

Apparatus. A model 323 Hitachi Recording Spectrophotometer; a model 239 Hitachi Digital Spectrophotometer; a model 170—50 Hitachi Atomic Absorption/Flame Spectrophotometer; a Hitachi-Horiba glass electrode pH meter, model M-5; an Iwaki shaking machine, model KM; a Kubota centrifuge machine, and a Tomi-Seiko Swing Type centrifuge, model CD-50R, were used.

Materials. PMBP (1-phenyl-3-methyl-4-benzoyl-5-pyrazolone) was synthesized by the condensation of 1-phenyl-3-methyl-5-pyrazolone with benzoyl chloride in dioxane, as described previously.[8] The PMBP was purified by recrystallization from a mixture of methanol and a dilute hydrochloric acid solution; it crystallizes in yellow plates (keto type) having the same reference value, melting point of 92 °C. The organic solvents used were all reagent-grade materials and if necessary were purified by an ordinary method. Benzyl alcohol was used within one week after opening the sealed bottle, because of its gradual degradation caused by air oxidation.

Distribution of PMBP. The distribution behavior of PMBP between various organic solvents and water was examined as follows: An equal volume (5 cm^3) of 5×10^{-5}—10^{-3} M (1M=1 mol dm^{-3}) each of various organic solutions of PMBP and buffer solutions of pH 1—12 adjusted to the desired value by mixing an appropriate amount of 0.1 M of hydrochloric acid, acetic acid, sodium acetate, boric acid, sodium borate, and sodium hydroxide, was equilibrated by shaking both phases for 30 min. After centrifugation at 2000 rpm for 15 min, the concentration of PMBP in the organic phase was determined spectrophotometrically by measuring its absorbance at 290—300 nm, around the absorption maxima of PMBP. The pH of the aqueous phase was checked again after the distribution.

Extraction of Alkaline Earth Metals. A 10 cm^3 of 10^{-3} M alkaline earth metal ion solution adjusted to the desired pH with buffer solutions described above and a 10 cm^3 of 10^{-2} M PMBP in organic solvent were placed in a 30 cm^3 glass-stoppered centrifuge tube and agitated on a shaking machine for 30 min. After the separation of the two phases by centrifugation at 2000—3000 rpm for 15—30 min, a 5 cm^3 of the organic phase was shaken with 0.1 M hydrochloric acid solution; the amount of metal ion stripped in the aqueous phase was determined by atomic absorption at 285.21 nm for magnesium, at 422.67 nm for calcium, and at 460.73 nm for strontium. The concentration of barium was determined by flame photometry at 553.6 nm. The pH of the aqueous phase was measured again after the extraction.

Results and Discussion

The distribution behavior of PMBP in various organic solvents was first studied in order to find the proper solvent having a higher distribution ratio and better phase separation in the basic region, where alkaline earth metals can be extracted quantitatively.[3,6-8] The preliminary experiments revealed that the distribution of PMBP expressed by percent extraction (%E) in an organic solution increased in the order of benzene, butyl acetate, isobutyl methyl ketone (0%) <chloroform (5%)<isopentyl alcohol, hexyl alcohol, decyl

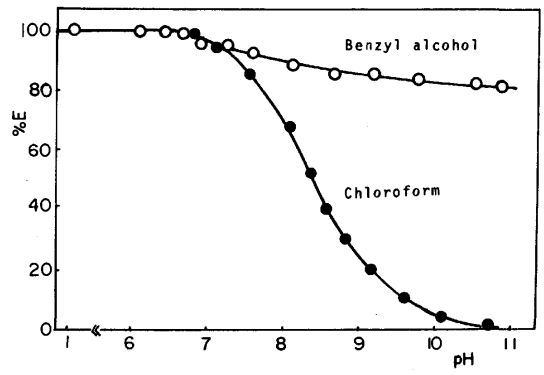

Fig. 1. Distribution of 5×10^{-5}—10^{-3} M PMBP in chloroform and benzyl alcohol as a function of pH.

alcohol, octyl alcohol (40—60%)<benzyl alcohol (83%) at pH 10 (Fig. 1). Judging from the higher distribution of PMBP in the organic phase and the better separation of the two phases by centrifugation at 2000 rpm for 15 min, it was evident that benzyl alcohol was most suitable for the extraction of alkaline earth metals with PMBP. Next, the pH dependence of the extractability of alkaline earth metals (magnesium, calcium, strontium, and barium) with 10^{-2} M PMBP in benzyl alcohol was examined in the region of pH 1.0 to 10.0. The results (Fig. 2) are shown in terms of percent extraction (%E) vs. pH plots of alkaline earth metals extracted in benzyl alcohol. The quantitative extraction of the PMBP chelate in benzyl alcohol was achieved in the pH region above 6 for magnesium, in the pH region above 7.0 for calcium, and in the pH region of 7.5—8.5 for strontium. Barium was not extracted completely in any pH region. The log D vs. pH plots gave straight lines having a slope of about 2, which gave the number of the PMBP molecule bound to alkaline earth metals. In general, the extractability of alkaline earth metals with PMBP in benzyl alcohol is better than in chloroform, benzene, and cyclohexane, without synergic extraction with the aid of TOPO (trioctylphosphine oxide).[3,6-8] On the basis of these results, it was decided that the extraction of strontium with 10^{-2} M PMBP in benzyl alcohol should be carried out at pH 8.0. Although the complete and quantitative extraction was achieved after 3 min of shaking, the two phases were shaken for 5—10 min. When the volume of the organic phase of 10^{-2} M PMBP in benzyl alcohol was kept at 10 cm^3, and when that of the aqueous phase was varied from 10 to 100 cm^3, almost the same extractability (100±1%) was obtained in each case. The effect of the presence of foreign ions, which exist in fresh water, on the extraction of strontium is given in Table

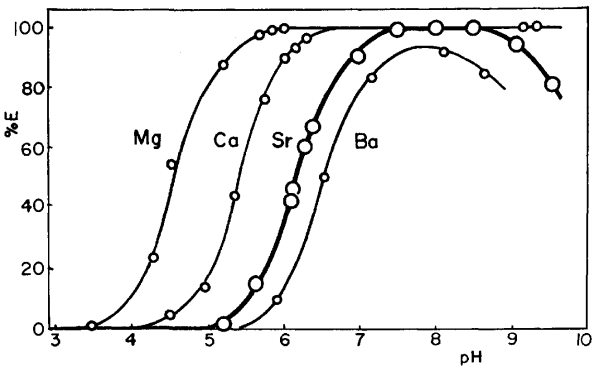

Fig. 2. Extraction of 10^{-3}M alkaline earth metals with 10^{-2}M PMBP in benzyl alcohol as a function of pH.

Table 1. Effect of Foreign Ions

Ion added		Sr^{2+} taken	Sr^{2+} found
ppm		ppm	ppm
Ca^{2+}	50	0.20	0.21
Mg^{2+}	10	0.20	0.20
Al^{3+}	1	0.20	0.21
HCO_3^-	100	0.20	0.20
SO_4^{2-}	20	0.20	0.20
PO_4^{3-}	1	0.20	0.20

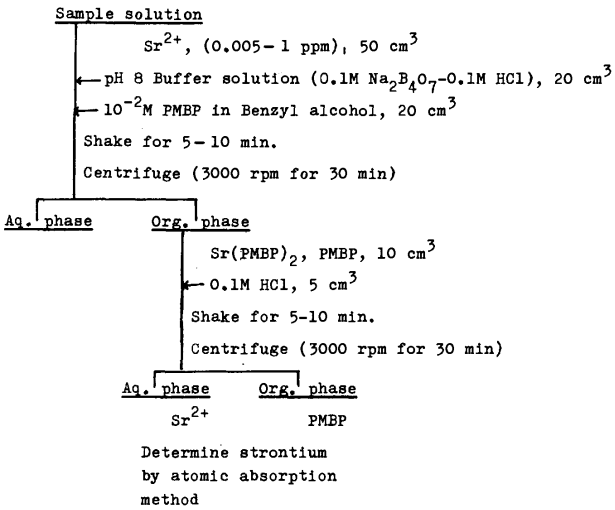

Fig. 3. Analytical scheme for the preconcentration and determination of a trace amount of strontium in fresh water.

Table 2. Content of Strontium, Calcium, and Magnesium Ions in Fresh Water near Kanazawa University

Sample	Solution volume	Sr^{2+} added	Sr^{2+} found	Sr^{2+} content[a]	Ca^{2+} content[b]	Mg^{2+} content[b]
	cm^3	μg	μg	ppb	ppm	ppm
Tap water	50	0	3.55	71±1	14.4	6.2
		0	3.65	73±1	14.4	6.2
		1.0	4.60	72±1	14.4	6.2
OHTEBORI moat water	50	0	3.65	73±1	14.1	5.5
Thawing water	50	1.0	1.35	7±1	1.6	1.2

a) Mean and relative standard deviation for at least three determinations. The experimental results obtained by adding a definite amount of strontium to fresh water revealed that the recovery of strontium was about 100±1%. In the case of thawing water, the absortance of atomic absorption of strontium gave very small value, and the result obtained by adding a definite amount of strontium to fresh water was shown in Table 2. b) The experimental results obtained by direct determinations of magnesium and calcium in fresh water with atomic absorption method without preconcentration.

1. The concentration of these ions was prepared so as to be somewhat larger than that of general fresh water as river water and underground water. None of the ions investigated interfered with the extractability of strontium with PMBP in benzyl alcohol. Finally, the systematic experimental procedures (Fig. 3) for the determination of strontium in natural waters based on the extraction and atomic absorption spectrophotometric determination of strontium with 10^{-2} M PMBP in benzyl alcohol have been applied to the preconcentration and determination of a trace amount of strontium in ppb order in fresh water in the vicinity of Kanazawa University.

The results are given in Table 2 together with the values obtained for calcium and magnesium in ppm order without preconcentration, showing that the proposed method was useful for the preconcentration and determination of strontium in ppb order (7—73±1 ppb) in fresh water.

The authors wish to thank Prof. Kikuo Terada of Kanazawa University for his valuable advice.

Synthetic Inorganic Ion-Exchange Materials. XXXXVI. Ion-Exchange Behavior of Titanium(IV) Antimonate Cation Exchanger for Alkali Metal Ions in Ammonium Nitrate Media

Ramesh CHITRAKAR and Mitsuo ABE*
Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, 2-12-1 Ookayama, Meguro-ku, Tokyo 152
(Received November 27, 1986)

Synopsis. Titanium(IV) antimonate (TiSbA) showed an extremely high selectivity for lithium ions in ammonium nitrate media, the increased selectivity order for microamounts being $Rb^+<Na^+<Cs^+<K^+\ll Li^+$. The selective separation of lithium ions from other alkali metal ions can be achieved on small columns of TiSbA by a mixed solution of nitric acid and ammonium nitrate.

The synthesis and ion-exchange properties of tin(IV) antimonate and titanium(IV) antimonate (SnSbA and TiSbA) have been studied first by Abe et al.[1-3] Both of SnSbA and TiSbA behave as cation exchangers with high selectivity for lithium ions. The following unusual selectivities for microamounts of alkali metal ions in nitric acid media were observed: $Na^+<K^+<Rb^+<Cs^+\ll Li^+$ on SnSbA,[2] and $Na^+<K^+<Rb^+<Li^+<Cs^+$ on TiSbA[3,4] as compared to increased order of the selectivity with increasing ionic crystal radii for alkali metal ions on a strong acid type polystyrene resin. The high selectivity for lithium on SnSbA and TiSbA can be applied for the recovery of lithium ions from seawater and hydrothermal water.[5,6]

The ion-exchange behavior of various ions on SnSbA and TiSbA has been studied extensively.[7-10]

Isolation of lithium ions from other alkali metal ions on H^+ form TiSbA with nitric acid solution as an eluant is very difficult because of low values of separation factor for pairs of Rb^+-Li^+ and Li^+-Cs^+. It has been known that the selectivity depends much on a variety of solutions used as eluants.

The present work describes the adsorption of alkali metal ions by TiSbA in ammonium nitrate media and the chromatographic separation of lithium from other alkali metal ions.

Experimental

Chemicals. Chemical grade of antimony(V) chloride supplied by Yotsuhata Chemical Co. Ltd., and titanium(IV) chloride supplied by Wako Chemical Co. Ltd., (99% as metal) were used without further purification. The other chemicals were of analytical grade.

Preparation of TiSbA. A 4 M† antimony(V) chloride solution (80 cm^3) was mixed with a 4 M titanium(IV) chloride solution (120 cm^3) at 60 °C and the mixed solutions were immediately hydrolyzed in 4.8 dm^3 demineralized water at the same temperature. The precipitate obtained was kept in mother liquor overnight, filtered and washed with cold demineralized water using a centrifuge operated at 10000 rpm until the pH of supernatant solution was in the range of 1.5—1.8. The product obtained was dried at 60 °C for 4d, ground and sieved to 100—200 mesh size, washed with cold demineralized water in order to remove fine adherent particles, and conditioned with 1 M nitric acid until free from Na^+ ions. The sample was re-washed with demineralized water and air dried.

Preparation of TiSbA in Ammonium Ion Form. The hydrogen form of TiSbA was converted to ammonium form as follows: A solution containing 0.3% aq NH_3 and 0.1 M NH_4NO_3 was passed through a column packed with 10 g of TiSbA in H^+ form until the pH of the effluent was the same as that of the feed solution. Finally, the exchanger was washed with demineralized water and air dried.

pH Titration Curve. The pH titration curve was determined by equilibrating 0.10 g of TiSbA in H^+ form with 10.0 cm^3 of solution containing (NH_4NO_3+HNO_3) or (NH_4NO_3 +NH_3aq) at an ionic strength of 0.1 with intermittent shaking for one week at 30 °C. After equilibrium was attained, the pH of the supernatant solution was measured with a Toa Dempa pH meter, model HM-5B. The concentration of NH_4^+ in the solution was determined as described by Tsuji and Abe.[11]

Distribution Coefficients, (K_d). The K_d values of alkali metal ions were determined by equilibrating 0.10 g of TiSbA in NH_4^+ form with 10.0 cm^3 of 10^{-4} M alkali metal ions, except Li^+ at different concentrations of ammonium nitrate with intermittent shaking at 30 °C. The K_d of Li^+ at an initial concentration of 10^{-4} M showed extremely high values even at 5M NH_4NO_3 solution and could not be determined, because of the detection limit of atomic absorption analysis. Its K_d values were determined at the initial concentration 10^{-3} M of Li^+. The concentrations of metal ions in the solid and liquid phases were deduced from the concentration relative to the initial concentration in the solution. The K_d values were calculated at equilibrium using the following equation:

$$K_d = \frac{\text{Amount of metal ions in exchanger}}{\text{Amount of metal ions in solution}} \times \frac{\text{cm}^3 \text{ of solution}}{\text{g of exchanger}}$$

The concentrations of metal ions were determined by using a Varian Techtron 1100 Atomic Absorption Spectrometer.

Column Experiment. Relatively small columns (2 cm× 0.5 cm i.d.) of TiSbA in NH_4^+ form were used during column experiment. The flow rate was regulated by using a high pressure pump (Nihon Seimitsu Kagaku, model NSP-800-5UDX) and the effluents were collected by using a dropping-counting type fraction collector (Ohtaki Works, model UM-160).

Results and Discussion

Characterization of TiSbA. The TiSbA was characterized by X-ray diffraction and thermal analysis. The results showed a good agreement with the previous result.[4] The chemical composition of TiSbA used was determined by chemical analysis and weight loss at 700 °C by assuming that the ignition product was free from water. The empirical formula of TiSbA was $3.1TiO_2 \cdot Sb_2O_5 \cdot 4.9H_2O$.

pH Titration Curve. The pH titration curve of

†1 M=1 mol dm^{-3}.

NH_4^+ showed apparent monobasic acid behavior which was similar to that reported for alkali metal ions[4] (Fig. 1, top). The dependence of apparent capacity of NH_4^+ on pH (Fig. 1, bottom) is consistent with the titration curve. The uptake of NH_4^+ ions increased with increasing pH of the solution as reported for Na^+ and Li^+ ions. The uptakes of NH_4^+ correspond well to the difference between pH titration curve and blank titration curve, indicating that the ion-exchange reaction is predominant over the whole range of pH studied. Compared with the previous result,[4] the increased order of the uptakes was found to be $Cs^+ < Na^+ < NH_4^+ < Li^+$ at pH 9.

Distribution Coefficients, (K_d). The time dependence of adsorption of alkali metal ions on NH_4^+ form TiSbA in ammonium nitrate was measured in order to determine the equilibrium distribution coefficients. The exchange reaction in ammonium nitrate media was relatively fast and the equilibrium was attained within 24 h for all alkali metal ions studied (Fig. 2), while the reaction for Li^+ and Cs^+ in nitric acid media was slow, about 3 weeks being required for attainment of equilibrium. After equilibration, the K_d values were determined and shown in Fig. 3 as log-log plots of K_d vs. $a_{NH_4NO_3}$. A linear relationship with a slope of -1 was observed for all metal ions studied, indicating an ideal ion-exchange mechanism. The TiSbA in NH_4^+ form showed an extremely high selectivity for Li^+ ion in ammonium nitrate media, the selectivity order being $Rb^+ < Na^+ < Cs^+ < K^+ \ll {}^+Li$, which is not included in the 11 selectivity series predicted by Eisenman.[12] This selectivity is quite different from $Na^+ < K^+ <$

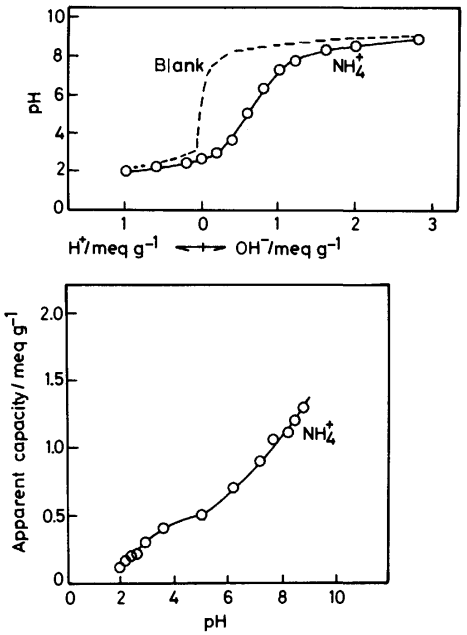

Fig. 1. pH Titration curve (top) and apparent capacity (bottom) of TiSbA.
TiSbA: 0.10 g. Soln.: 0.1 M (NH_4NO_3+HNO_3) or (NH_4NO_3+NH_3aq). Total vol: 10.0 cm^3. Temp: 30±0.5 °C.

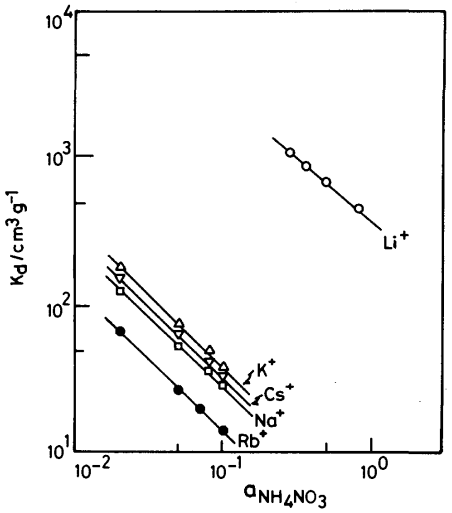

Fig. 3. Log-log plots of K_d values of alkali metal ions on NH_4^+ form TiSbA vs. activity of ammonium nitrate.
TiSbA: 0.10 g. Total vol: 10 cm^3. Other conditions are the same as in Fig. 2.

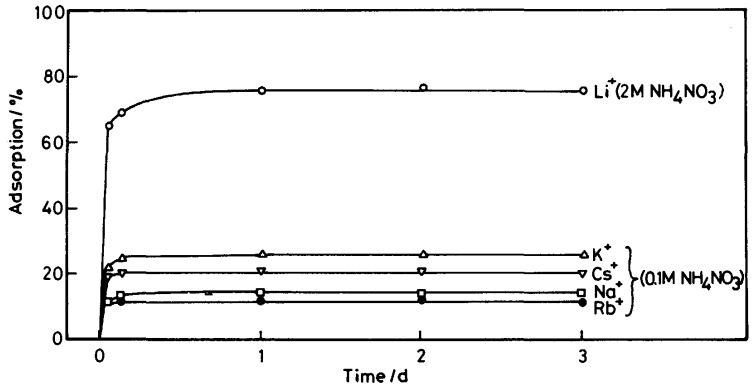

Fig. 2. Time dependence of adsorption of alkali metal ions on NH_4^+ form TiSbA.
TiSbA: 0.25 g. Initial concn of metal ions: 10^{-4} M for Na^+, K^+, Rb^+, and Cs^+, 10^{-3} M for Li^+. Total vol: 25.0 cm^3. Temp: 30±0.5 °C.

Table 1. K_d Values and Separation Factors(α) for Alkali Metal Ions on TiSbA and Bio-Rad AG 50W·X8

Ion exchanger	Media	Parameter					
			Rb^+	Na^+	Cs^+	K^+	Li^+
TiSbA (Ti/Sb=1.5)	0.1 M NH_4NO_3	K_d	14	18	31.3	35.4	$>10^5$
		α	1.3	1.7	1.1	>2800	
TiSbA[4] (Ti/Sb=1.5)	0.1 M HNO_3		Na^+	K^+	Rb^+	Li^+	Cs^+
		K_d	3.8	42	96	220	550
		α	11.1	2.3	2.3	2.5	
Bio-Rad AG 50W-X8[13]	0.1 M HNO_3		Li^+	Na^+	K^+	Rb^+	Cs^+
		K_d	33.1	54	99	118	148
		α	1.6	1.8	1.2	1.2	

$Rb^+<Li^+<Cs^+$ observed on H^+ form TiSbA in acid media.[3,4]

The K_d values and separation factors ($\alpha_A^B=K_{d_B}/K_{d_A}$), for a neighboring pair in NH_4NO_3 media, are summarized in Table 1, in which the K_d values on H^+ form of TiSbA and Bio-Rad AG 50W-X8[13] are included for comparison. The α value for neighboring pairs of alkali metals on H^+ form TiSbA are larger than those reported on Bio-Rad AG 50W-X8. But the values of α for neighboring pairs of alkali metals except Li^+ on NH_4^+ form TiSbA are comparable to Bio-Rad. However, the α value between Li^+ and other alkali metal ions are extremely high i.e. $>2.8\times10^3$.

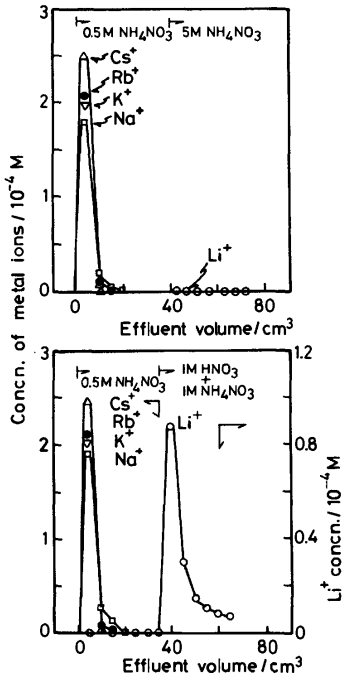

Fig. 4. Elution curves of alkali metals with NH_4^+ form TiSbA.
Column: 1.5 cm×0.5 cm i.d. (0.3 g of TiSbA), Metal ion loading: 1 μmol of each metal ion, Flow rate: 0.12 $cm^3\,min^{-1}$.

Ion-Exchange Separation. It is evident from the studies of K_d values that lithium can be separated from other alkali metals. A solution containing 1 μmol of alkali metal ions was added to the top of the small column (2 cm×0.5 cm i.d.) containing TiSbA in NH_4^+ form. The alkali metals except lithium were eluted with 100% recovery using 0.5 M NH_4NO_3 solution, while the adsorbed lithium could not be eluted even by using 5 M NH_4NO_3 solution as an eluant (Fig. 4, top). The elution of Li^+ was performed with 75% recovery upto 30 cm^3 of the eluant of 1M NH_4NO_3+1M HNO_3 solution (1+1) after elution of other alkali metal ions by a 0.5M NH_4NO_3 solution (Fig. 4, bottom). This procedure is very useful for isolation of lithium from other alkali metal ions.

(Received December 15,1986)

Synopsis. The crystal structure of μ-oxo-μ-sulfido cysteinato Mo(V) dimer, $Ca[Mo_2O_3S(SCH_2CH(NH_2)CO_2)_2]\cdot 3H_2O$ has been determined from X-ray diffraction data. The structure of the complex anion is similar to those of di-μ-oxo- and di-μ-sulfido- Mo(V) dimers. The trans influence of sulfur atoms is observed.

As model compounds of some enzymes,[1] many molybdenum(V) complexes with di-μ-oxo, μ-oxo-μ-sulfido, or di-μ-sulfido bridges have been prepared and characterized. Cysteine (or its derivatives) is one of the ligands most frequently used in these investigations; Raman and resonance Raman spectra[2] and pulse-radiolysis study[3] on the cysteinato complexes have been reported and the X-ray structures of di-μ-oxo-[4] and di-μ-sulfido-bis[(cysteinato)oxomolybdate(V)][5] complexes have also been revealed. However, the X-ray structure of μ-oxo-μ-sulfido-bis [(cysteinato)oxomolybdate(V)], has not yet been determined. In view of the importance of this complex, we have carried out the X-ray crystal structure analysis of the title compound and we report here the result obtained.

Experimental

Preparation of Calcium μ-Oxo-μ-sulfido-bis[(cysteinato) oxomolybdate(V)] Trihydrate, $Ca[Mo_2O_3S(cys)_2]\cdot 3H_2O$. Corresponding sodium salt[6] (1 g) was dissolved in 10 mL of water and filtered. Solid $CaCl_2\cdot 2H_2O$ (ca. 1 g) was added to the filtrate. Cooling of the filtrate in a refrigerator gave red crystals (ca. 0.7 g). Anal. Found: N, 4.39; C, 11.54; H, 2.76%. Calcd for $C_6H_{12}O_{10}N_2S_3CaMo_2$: N, 4.66; C, 12.00; H, 2.01%.

X-Ray Data Collection. Crystal data: F. W.=600.3, orthorhombic, space group $P2_12_12_1$, a=16.430 (2), b=10.557 (2), c=9.782(2) Å, Z=4, D_c=2.35 g cm^{-3}, μ(Mo $K\alpha$)=21.4 cm^{-1}, λ(Mo $K\alpha$)=0.7107 Å, V=1696.7 (4) Å^3. The intensities were measured on a Philips PW1100 diffractometer. Crystal size: 0.20×0.26×0.45 mm^3; scan speed, 0.033° s^{-1}; scan range, 1.2°; back ground measurement at each side of the scan range, half of the scan time; maximam 2θ value, 50°; number of reflections ($F_o^2 \geqq 2\sigma(F_o^2)$), 2150. No correction was made for absorption. The refinement of the structure was performed by the block diagonal least-squares method. The function minimized was $w(|F_d|-|F_d|)^2$, where $w=1/\sigma^2(F_o)$ was used. The final R value was 0.026, $R_w=[\Sigma w\Delta F^2/\Sigma wF_o^2]^{1/2}=$ 0.036. In the final cycles of the refinement hydrogen atoms were included but their parameters were not refined. All the hydrogen atoms except for those bound to the water oxygens were located at the calculated positions. All the parameter shifts were less than 0.3σ. The maximum peak in the final difference synthesis was 1.0 e Å^{-3}. The atomic scattering factors, with corrections for anormalous scattering of Mo and S, were taken from Ref. 7. The F_o—F_c tables, anisotropic thermal parameters, and coordinates of the hydrogen atoms are preserved by the Chemical Society of Japan (Document No. 8744). The atomic coordinates are listed in Table 1. Computations were performed on a FACOM 230-60 computer at Osaka City University and on a ACOS 900 computer at the Crystallographic Research Center, Institute for Protein Research, Osaka University. The figure was drawn by the use of ORTEP.[8] The programs in the UNICS[9] were employed.

Results and Discussion

Recrystallization of the sodium salt gives only a

powdery product. Addition of solid KCl or NH_4Cl to the aqueous solution of the sodium salt provides no precipitate, while that of $CaCl_2 \cdot 2H_2O$, $BaCl_2 \cdot 2H_2O$, or $MgCl_2 \cdot 6H_2O$ gives crystals of respective salts, of which calcium salt is best for the X-ray analysis. Perspective view of the complex anion, $[Mo_2O_3S(cys)_2]^{2-}$ (**1**), is shown in Fig. 1. The structure of the anion is similar to those of the di-μ-oxo- ($[Mo_2O_2(cys)_2]^{2-}$, (**2**)) and di-μ-sulfido ($[Mo_2O_2S_2(cys)_2]^{2-}$, (**3**)) complexes. Interatomic distances and bond angles are listed in Table 2. Comparison of dimensions is made in Table 3. The Mo-Mo distance and dihedral angle of the μ-oxo-μ-sulfido complex is closer to the respective values of the di-μ-sulfido complex than to those of the di-μ-oxo complex. The Mo-O-Mo angle of **2** is larger than the corresponding angles of **1**, while the Mo-S-Mo angle of **2** is smaller than those of **3**. The trans influence of sulfur atoms (S_{bridge} and $S_{cysteine}$) is observed in **1**, as is observed in **2** and **3**: Mo-N, Mo-O, and Mo-S bonds trans to the sulfur atom (S_{bridge} or $S_{cysteine}$) are longer than those trans to ligating N or O atom, respectively.

We are grateful to Mr. Motoji Akiyama for the help of the preparative work.

Photochemical Synthesis of η-Acetylene Complex of an Orthometalated Manganesecarbonyl Derivatives, $(PhO)_2P(OC_6H_4)Mn(CO)_3(PhC{\equiv}CPh)$, and Its Structural Study by ^{13}C and ^{31}P NMR Spectroscopies

Satoru ONAKA,* Nobuhiro FURUICHI, and Yukinobu TATEMATSU
Department of Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received January 16, 1987)

Synopsis. Photochemical reaction of an orthometalated manganesecarbonyl derivative, $(PhO)_2P(OC_6H_4)Mn(CO)_4$ with PhC≡CPh in benzene yielded $(PhO)_2P(OC_6H_4)Mn(CO)_3(PhC{\equiv}CPh)$ and its structure was studied by ^{13}C and ^{31}P NMR spectroscopy based on ^{13}C and ^{31}P NMR data for relevant orthometalated metal carbonyl derivatives including $(o\text{-}CH_3C_6H_4O)_2P[OC_6H_3(CH_3)]Mn(CO)_3P[OC_6H_4(CH_3)]_3$ which was first synthesized in this study.

Previous reports from this labolatory revealed that orthometalated triphenyl phosphite manganesecarbonyl derivatives, $(PhO)_2P(OC_6H_4)Mn(CO)_4$ (**1**) and $(PhO)_2P(OC_6H_4)Mn(CO)_3P(OPh)_3$ (**2**) dissociate the ligand CO or L (L=$P(OPh)_3$) quite easily upon photolysis in solutions.[1,2]

$$(PhO)_2P(OC_6H_4)Mn(CO)_4 \xrightarrow{h\nu} (PhO)_2P(OC_6H_4)Mn(CO)_3\ (\mathbf{3}) + CO \quad (1)$$

$$(PhO)_2P(OC_6H_4)Mn(CO)_3L \xrightarrow{h\nu} (PhO)_2P(OC_6H_4)Mn(CO)_3\ (\mathbf{3}) + L \quad (2)$$

This observation prompted us to "trap" the 16 electron intermediate, $(PhO)_2P(OC_6H_4)Mn(CO)_3$ (**3**) by reacting with other nucleophiles such as diphenylacetylene. Present paper reports isolation of $(PhO)_2P(OC_6H_4)Mn(CO)_3(PhC{\equiv}CPh)$ (**4**) and its structural study by ^{13}C and ^{31}P NMR spectroscopies based on the spectral data for relevant orthometalated triphenyl phosphite metal carbonyl derivatives. Synthesis of $(o\text{-}CH_3C_6H_4O)_2P[OC_6H_3(CH_3)]Mn(CO)_3P[O(o\text{-}CH_3C_6H_4)]_3$ is also reported.

Experimental

Photolysis was performed under an argon atmosphere with a Riko 100 W high pressure Hg lamp. Solvent was purged with argon gas sufficiently before use. The sample of **1** was prepared according to the literature method[3] and other samples of **2** and $(PhO)_2P(OC_6H_4)Mn(CO)_2L_2$ (**5**) were obtained as was described in the previous papers.[1,2] IR spectra were measured with a Jasco 701G spectrometer for Nujol mull samples and ^{13}C and ^{31}P NMR were measured for ca. 0.5 mol dm^{-3} chloroform-*d* solutions at 30 °C on a Varian XL-200 spectrometer operated at 50.309 and 80.984 MHz respectively with Fourier transform mode for naturally abundant levels. The spectra were recorded using a 10 mm o.d. sample tube. Chemical shifts were referenced to internal Me_4Si standard for ^{13}C nucleus and to external H_3PO_4 standard contained in a 1 mm capillary for ^{31}P nucleus. A positive chemical shift designates a resonance to a lower field than that of the resonance of the respective standard.

Synthesis of $(C_6H_5O)_2P(OC_6H_4)Mn(CO)_3(C_6H_5C{\equiv}CC_6H_5)$ (4). A 0.996 g (2.1 mmol) sample of **1** and 0.372g (2.1 mmol) of diphenylacetylene, **dpa**, were dissolved into 50 ml of benzene and the mixture was photolyzed for 8 h. From the resulting yellow solution, the solvent was vacuum-stripped to leave an yellow oil. This oil was dissolved into a minimum amount of benzene and was loaded on a Florisil column. Unreacted starting materials (**1** and **dpa**) were eluted with petroleum ether. Then, mixed solvent of benzene and hexane (1 : 1) eluted a white product, which was recrystallized from mixed solvent of benzene and petroleum ether (1 : 1) to yield 200 mg of $(PhO)_2P(OC_6H_4)Mn(CO)_3(PhC{\equiv}CPh)$ (**4**). (Yield 15%). Retention of the orthometalated ring was exemplified by detection of three weak peaks at 1105, 960, and 795 cm^{-1} in IR which are characteristic of the orthometalated triphenyl phosphite.[1,2] Found: C, 66.76; H, 3.57; P, 4.70%. Calcd for $(PhO)_2P(OC_6H_4)Mn(CO)_3(PhC{\equiv}CPh)$, $C_{35}H_{24}O_6MnP$: C, 67.10; H, 3.86; P, 4.95%. IR ν(CO) (Nujol mull) 2080 (vs), 1995 (vs), and 1961(s) cm^{-1}.

Synthesis of $BrMn(CO)_3L'_2$ (L'=$(o\text{-}CH_3C_6H_4O)_3P$) (6). A 1.56 g (5.7 mmol) sample of $BrMn(CO)_5$ and 10 g (28 mmol) of $(o\text{-}CH_3C_6H_4O)_3P$, L', (hereafter L' denotes $(o\text{-}CH_3C_6H_4O)_3P$ and L denotes $P(OPh)_3$) were dissolved into 80 ml of choloroform and the mixture was stirred at 55 °C for 18 h. Then the solvent was almost vacuum-stripped and 50 ml of hexane was added to precipitate yellow crystals of $BrMn(CO)_3L'_2$ (**6**): Yield 2.6 g (53%). IR ν(CO) (Nujol mull) 2065 (m), 1990 (vs), and 1932 (vs) cm^{-1}.

Synthesis of $MeMn(CO)_3L'_2$ (7). A 2.0 g (2.2 mmol) sample of **6** in 40 ml of THF was reduced to $NaMn(CO)_3L'_2$ by stirring over Na amalgam for 3 h. To the supernatant THF solution of $NaMn(CO)_3L'_2$, 0.5 g (3.5 mmol) of CH_3I in 20 ml of THF was added and the mixture was stirred at room temperature overnight. Solvent was distilled off at reduced pressure to leave cleam yellow solid. This solid was extracted three times with each 20 ml of benzene. Then the benzene was almost distilled off at reduced pressure from the combined extracts and 10 ml of petroleum ether was added. The mixture was stored in a refrigerator to give pale yellow crystals of $MeMn(CO)_3L'_2$ (**7**). Yield 1.1 g (62%). IR ν(CO) (benzene solution) 2030 (w), 1953 (vs), and 1929 (s) cm^{-1}. Found: C, 64.30; H, 5.31%. Calcd for $CH_3Mn(CO)_3L'_2$, $C_{46}H_{45}MnO_9P_2$: C, 64.34; H, 5.28%.

Synthesis of $(o\text{-}CH_3C_6H_4O)_2P[OC_6H_3(CH_3)]Mn(CO)_3L'$ (8). A 0.9g (1 mmol) sample of **7** was dissolved into 50 ml of benzene and the solution was photolyzed for 4 h. The solution was concentrated to about 5 ml at reduced pressure and it was loaded on a Florisil column. After elution of unknown products and unreacted **7** with petroleum ether, pale yellow product of **8** was eluted with benzene. After

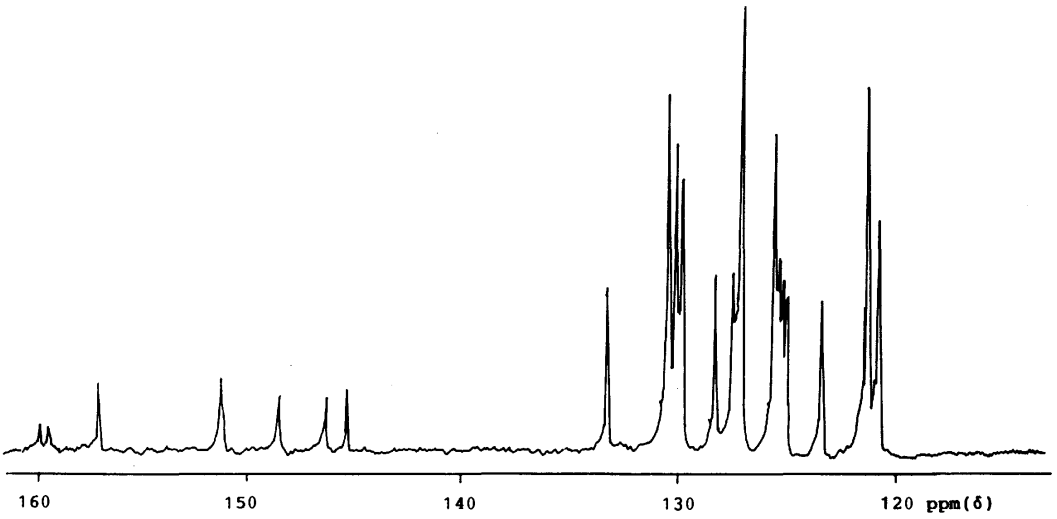

Fig. 1. ^{13}C NMR spectrum of $(PhO)_2\overline{P(OC_6H_4)}\overline{Mn(CO)_3}(PhC{\equiv}CPh)$ in $CDCl_3$.

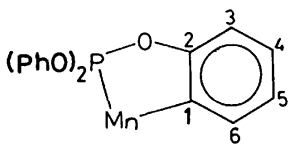
recrystallization from mixed solvent of benzene-petroleum ether (1 : 1), 100 mg of pure product **8** was obtained. (Yield 12%) Found: C, 64.00; H, 5.09%. Calcd for $(o\text{-}CH_3C_6H_4O)_2\overline{P[OC_6H_3(CH_3)]Mn(CO)_3}L'$, $C_{45}H_{41}MnO_9P_2$: C, 64.14; H, 4.90%. IR ν(CO) (benzene solution) 2040 (w), 1970 (vs), and 1940 (s) cm^{-1}.

X-Ray Data Collection. A colorless crystal of **4** with approximate dimensions 0.30×0.35×0.70 mm^3, which was grown-up from cyclohexane-petroleum ether, was mounted on a Rigaku AFC-5 automated four circle diffractometer equipped with Mo $K\alpha$ radiation (λ=0.71073 Å). The crystal belongs to triclinic system with unit cell dimensions a=22.904(8), b=22.918(8), c=12.795(5) Å, α=106.32(3), β=106.28(3), γ=85.53(3)°, and V=6187(4) $Å^3$. A total of 8639 independent reflections with $|F_o|>3\sigma(|F_o|)$ were obtained at room temperature using the $\omega-2\theta$ scan technique up to 2θ=50°. The structure has so far been solved neither by the standard heavy atom method nor direct method based on $P\bar{1}$ space group (UNICS-III program package, MULTAN 78 program and a HITAC M-200H computer).

Spectral Assignments

As is shown in Fig. 1, ^{13}C NMR spectrum of **4** is very complex. Therefore, the assignment of each peak is rather laborious without the aid of ^{13}C NMR data of relevant orthometalated triphenyl phosphite derivatives. When the ^{13}C NMR spectrum of **4** is compared with those of $(PhO)_2\overline{P(OC_6H_4)}Fe(CO)Cp$ (**9**) and $(PhO)_2\overline{P(OC_6H_4)}Fe(L)Cp$ (L=$P(OPh)_3$) (**10**),[4] we are tempted to opt following assignments of peaks observed in the lower field than 140 ppm; the doublet at 159.6 ppm is assignable to C_2 carbon and the singlet at 151.2 ppm is assigned to P-O-C carbon of unmetalated benzene rings.[4,5] The doublet at 145.7 ppm is assignable to C_1 carbon and the signlet at 148.4 ppm to C_6 carbon (Scheme 1). The alkyne carbon resonance at 89.2 ppm for free PhC≡CPh disappears in **4** and a new resonance appears at 157.0 ppm instead, which is assignable to coordinated alkyne carbons to the Mn atom.[6,7] ^{13}C NMR spectrum of **4** is devoid of the doublet at around 111 ppm due to C_3 carbon resonance which is detected at 110.9 and 110.2 ppm in the spectra of **9** and **10**;[4,8] the doublet is not strong in **9** and **10** and this doublet is presumably hidden behind strong resonances around 120 ppm in **4**. The strong resonances between 120 and 133 ppm are so complex that it seems prudent to leave the assignment unsettled except just describing that these resonances are originated from phenyl carbon atoms of **dpa**, unmetalated phenyl carbons of P-O-Ph groups and phenyl carbons of metalated P-O-C_6H_4-groups. Thus, resonances due to C_4 and C_5 are not assigned but just pointing out that these resonances may be located at around 125 ppm.[4] Table 1 collates selected ^{13}C and ^{31}P NMR data of **4** together with those of relevant orthometalated manganesecarbonyl derivatives.



Scheme 1.

Results and Discussion

It is well recognized that ^{31}P NMR spectroscopy is very convenient and useful structural probe to discriminate between metalated and unmetalated triphenyl phosphite ligands;[9,10] that is, orthometalation of the ligand causes a large downfield chemical shift (≈30 ppm) compared to unmetalated coordinated $P(OPh)_3$. This criterion holds for present series of orthometalated manganese-carbonyl derivatives, **1**, **2**, **5**, and **8** except **4**, as is seen from Table 1; the internal ^{31}P-chemical shift between metalated and unmetalated phosphite ligands ranges from 30.5 to 36.5 ppm and the resonance of metalated phosphite ligand is detected at lower field than 190 ppm. However, ^{31}P chemical shift of **4** is observed at about 20—30 ppm upfield as for metalated phosphite and is close to those of unmetalated ligand(s) in **7**, **11**, and **12**. According to the ^{31}P NMR studies by Stewart's group,[10] the chemical shift of coordinated triphenyl phosphite is very sensitive to the nature of the trans ligand. Therefore, 21.4 ppm upfield shift for **4** compared to **1** seems to reflect the different trans effect of PhC≡CPh from that of CO. These lines of evidence prompt us to postulate the trans structure for **4** as is illustrated in Scheme 2, although definitive evidence of this issue must wait for future success of single crystal X-ray structure analysis.

Table 1. Selected ^{13}C and ^{31}P NMR Data

Compound	^{13}C Resonances (δ, ppm)					^{31}P Resonances (δ, ppm)	
	-C≡C-	C_1	C_2	C_3	C_6	Orthometalated	Unmetalated
$(PhO)_2P(OC_6H_4)Mn(CO)_3(PhC{\equiv}CPh)$ (**4**)	157.0	145.7	159.6		148.4	171.7

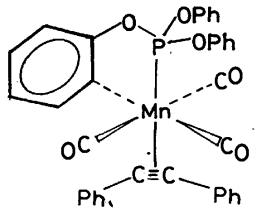
a) J_{pp}=100.7 Hz. b) J_{pp}=103 Hz. c) J_{pp}=121 Hz. L denotes $P(OPh)_3$; L′ denotes $(o\text{-}CH_3C_6H_4O)_3P$; Cp denotes η-(C_5H_5).



Scheme 2.

According to the previous report,[2] photolysis of $MeMn(CO)_3L_2$ yielded three kinds of orthometalated products, that is **1** (1 : 1), **2** (1 : 2), and **5** (1 : 3).[11] However, photolysis of $MeMn(CO)_3L'_2$ afforded only 1 : 2 type orthometalated compound **8**. Steric crowdness due to the methyl group located at another ortho position may partly be responsible for the lack of 1 : 3 type metalation product. However, the reason of the lack of 1 : 1 type metalation product is not clear at present. Presumably the yield of 1 : 1 type product is low and eluded isolation.

Carbonyl stretching pattern in IR of **8** is very close to that of **2**. This resemblance suggests that **8** has a similar cis structure to that of **2**.[1]

The present study was supported by Grant-in-Aid for Scientific Research No. 57470036 from the Ministry of Education, Science and Culture. Thanks are also due to the Institute for Molecular Science for permission to use the AFC-5 automated X-ray diffractometer (the Instrument Center) and the computer (the Computer Center).

Enantioselective Ion-Association Mode between the Tris(ethylenediamine)-cobalt(III) Cation and the Bis(μ-(−)$_{589}$-2,3-dimethyltartrato)-diantimonate(III) Anion in Solution

Hayami YONEDA,* Ushio SAKAGUCHI, and Hiroshi NAKAZAWA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received January 20, 1987)

Synopsis. By analyzing the intensity changes in the circular dichroism spectra, the association constants of the Λ- and Δ-$[Co(en)_3]^{3+}$ ions with the bis(μ-(−)$_{589}$-2,3-dimethyltartrato)diantimonate(III) ion were determined to be 58.4±1.9 and 38.6±0.4 respectively in H_2O (mol^{-1} dm^3 at 25 °C and μ=0.1 ($NaClO_4$)). Based on these data together with the chromatographic data, the enantioselective association mode was discussed.

It is well-known that the bis(μ-*d*-tartrato)diantimonate(III) ion, $[Sb_2(d\text{-tart})_2]^{2-}$, is an effective chiral selector for chromatographic optical resolution of many types of octahedral metal chelate complexes.[1] Concerning the mechanism of chiral discrimination by this anion, we proposed previously the L-J model where attention was paid to an opening formed between chelate rings of a complex to be resolved.[2] An opening between chelate rings in the Λ configuration has a shape of L and is called an L-shaped channel. In contrast, an opening between chelate rings in the Δ configuration has a shape reverse to an L-shaped channel and is called a J-shaped channel. A counter ion which makes a good fit to an L-shaped channel does not make a good fit to a J-shaped channel. Such a counter ion associates more favorably with a complex having an L-shaped channel than with a complex having a J-shaped channel, and can be utilized as a chiral selector. The $[Sb_2(d\text{-tart})_2]^{2-}$ anion is considered to have a skeleton which makes a good fit to the L-shaped channel in a complex cation. Based on this idea the efficiency of chiral discrimination by this anion was successfully explained for a series of $[Co(N)_6]^{3+}$ complex cations having different numbers of L-shaped channels.[2]

The L-J model was originally born as a conceptual idea having no specified mode of association. However, using molecular models, we found that either one of the two tartrate backbones bridging the two Sb atoms makes a good fit to an L-shaped channel, and proposed a concrete mode of ion association for chiral discrimination in which the anion accepts a complex cation coming along the y direction in Fig. 1. This mode of association does not exclude any other possibilities for the $[Sb_2(d\text{-tart})_2]^{2-}$ anion to discriminate the chirality of the complex cation. In fact, it was shown by Sakaguchi et al. that the $[Sb_2(d\text{-tart})_2]^{2-}$ anion can discriminate the chirality of the $[Co(en)_3]^{3+}$ and its related complex cations coming along the x direction in Fig. 1.[3] In addition, the third concrete mode of association was put forward by Miyoshi et al., in which the two oxygen atoms of the $[Sb_2(d\text{-tart})_2]^{2-}$ anion participate in the double hydrogen bonding to two of the three axial N-H bonds directed along the C_3 axis of the complex, and the remaining part of the anion is disposed opposite to the third N-H bond which is not involved in hydrogen bonding.[4] In this third association mode, the $[Sb_2(d\text{-tart})_2]^{2-}$ anion accepts the complex cation coming along the x direction in Fig. 1.

All these modes of association basically explain the situation of chiral discrimination of $[Co(N)_6]^{3+}$ complex cations, but differ in the mode of orientation of the complex cation around the $[Sb_2(d\text{-tart})_2]^{2-}$ anion. To specify the direction of access of the complex cation toward the $[Sb_2(d\text{-tart})_2]^{2-}$ anion, we have prepared the methyl-substituted derivative of this anion, bis(μ-(−)$_{589}$-2,3-dimethyltartrato)diantimonate(III) anion (abbreviated as $[Sb_2((-)\text{-dmt})_2]^{2-}$) in which each tartrate backbone has two methyl substituents. According to the original L-J model, a good fit to an L-shaped channel is expected to be lost by such methyl substitution. Therefore, the efficiency of chiral discrimination should be markedly decreased with methyl substitution. In contrast, according to the other models, the methyl groups do not seem to effect any significant steric repulsion in ion-association, so that the efficiency of chiral discrimination should not be influenced greatly by methyl substitution. The results of the experiments in the present study imply that when the chiral anion discriminates the chirality of complex cations, it directs the x axis towards the complex cations.

Experimental

Material. The complexes used were the perchlorate salts of Λ- and Δ-$[Co(en)_3]^{3+}$. $Na_2[Sb_2((-)\text{-dmt})_2]\cdot 4H_2O$ was prepared according to the literature,[5] and purified by recrystallization from water.

Measurements of Ion-Association Constants and Chromatographic Resolution. The ion-association constants were

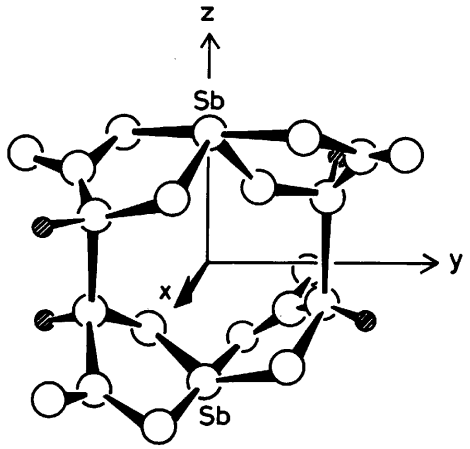

Fig. 1. Structure of $[Sb_2(d\text{-tart})_2]^{2-}$.

obtained by using CD intensity changes upon addition of chiral anions. The CD spectra were measured on a JASCO J-40CS recording spectropolarimeter. The sample cell was kept at 25±0.2 °C with a Haake circulator Model FK. For the Δ-$[Co(en)_3]^{3+}$ cation, the concentration of the cation, C_M, was fixed at 3.0×10^{-3} mol dm^{-3}, and that of the $[Sb_2((-)\text{-dmt})_2]^{2-}$ anion, C_A, was varied from 0 to 2.7×10^{-2} mol dm^{-3}. A sample cell of 1-cm length was used. In the case of the Λ-$[Co(en)_3]^{3+}$ cation, C_M was set to 6.0×10^{-4} mol dm^{-3} (C_A=0 to 1.5×10^{-2} mol dm^{-3}), because of the low solubility of the $[Sb_2((-)\text{-dmt})_2]^{2-}$ salt of this enantiomer, and the sample cell of 10-cm length was used for the CD measurement. The ionic strength was adjusted to μ=0.1 with sodium perchlorate. The CD intensity change of the chiral complex upon addition of $[Sb_2((-)\text{-dmt})_2]^{2-}$ salt was measured at 440 nm.

Chromatographic data were obtained as follows. The aqueous solution containing the racemic $[Co(en)_3]^{3+}$ complex was loaded on the IEX-510 cation-exchange resin (7.5×0.75 cm I. D.). The adsorbed complex was eluted with a 0.1 mol dm^{-3} aqueous solution of $Na_2[Sb_2((-)\text{-dmt})_2]$. Blue Dextran 2000 was used as a marker for the void volume measurememt of the column. The eluate was guided to a flow cell to detect the complex at 460 nm with a Shimadzu UV-140 spectrophotometer. The adjusted retention volumes were estimated from the elution curve thus recorded.

Results and Discussion

According to our recent X-ray analysis of Λ-$[Co(en)_3]$ $[Sb_2((-)\text{-dmt})_2]ClO_4\cdot7H_2O$, the absolute configuration of the 2 and 3 carbons of the 2,3-dimethyltartrate moiety in the $[Sb_2((-)\text{-dmt})_2]^{2-}$ was established to be R, R which corresponds to those of the 2 and 3 carbons of the *d*-tartrate moiety in $[Sb_2(d\text{-tart})_2]^{2-}$.[6]

The CD spectra of Λ-$[Co(en)_3]^{3+}$ with and without $[Sb_2((-)\text{-dmt})_2]^{2-}$ are shown in Fig. 2 together with their difference (DCD spectrum). The DCD spectrum is quite similar in shape to that obtained with the unmethylated anion used as an additive, and the both DCD spectra have the same sign.[3]

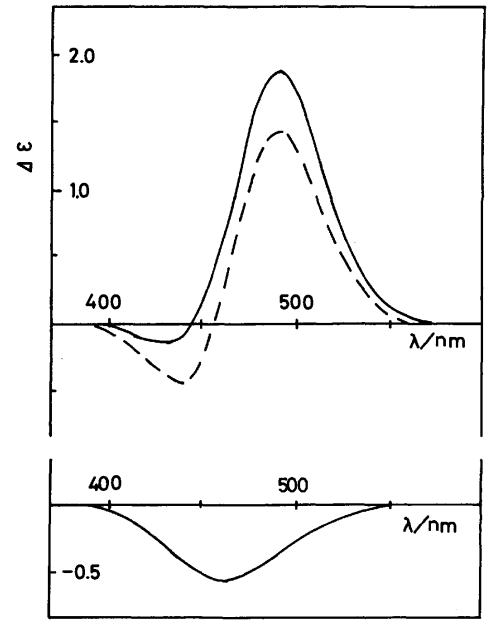

Fig. 2. Upper curves: CD spectra of Λ-$[Co(en)_3]^{3+}$ (——) and of the ion-pair with $[Sb_2((-)\text{-dmt})_2]^{2-}$ (----). Lower curve: the DCD spectrum.

Table 1. Association Constants at 25°C and μ=0.1 ($NaClO_4$)

System	K	D
Λ-$[Co(en)_3]^{3+}$ ..... $[Sb_2(d\text{-tart})_2]^{2-}$	47.3±0.6	29
Δ-$[Co(en)_3]^{3+}$ ..... $[Sb_2(d\text{-tart})_2]^{2-}$	26.0±0.3	
Λ-$[Co(en)_3]^{3+}$ ..... $[Sb_2((-)\text{-dmt})_2]^{2-}$	58.4±1.9	20
Δ-$[Co(en)_3]^{3+}$ ..... $[Sb_2((-)\text{-dmt})_2]^{2-}$	38.6±0.4	

$$D=\frac{K_\Lambda-K_\Delta}{K_\Lambda+K_\Delta}\times100$$

Table 2. Retention Volume(V) and Separation Factor(α) of $[Co(en)_3]^{3+}$

Eluent	V_1 (ml)	V_2 (ml)	α
$Na_2[Sb_2(d\text{-tart})_2]$	40.9 (Λ)	59.9 (Λ)	1.46
$Na_2[Sb_2((-)\text{-dmt})_2]$	27.9 (Λ)	38.6 (Λ)	1.38

The ion-association constants obtained by using the CD intensity changes upon addition of the chiral anion are listed in Table 1 with those for the $[Co(en)_3]^{3+}\cdots[Sb_2(d\text{-tart})_2]^{2-}$ system. Comparison of the corresponding values revealed the following two points. The first point noted is that the value of K_Λ is greater than that of K_Δ in both the methylated and unmethylated chiral anions. This suggests that the methyl substitution does not cause inversion of chiral discrimination. The second point noted is that the values of K for both Λ and Δ-$[Co(en)_3]^{3+}$ complexes are greater in $[Sb_2((-)\text{-dmt})_2]^{2-}$ than in $[Sb_2(d\text{-tart})_2]^{2-}$ (58.4 vs. 47.3 and 38.6 vs. 26.0). However, the value of D which is defined as $(K_\Lambda-K_\Delta)/(K_\Lambda+K_\Delta)\times100$ and is considered as a measure of the efficiency of chiral discrimination, shows only a slight decrease from the original chiral anion to the methyl-substituted chiral anion.

These features are reflected in the chromatographic data as shown in Table 2.[7] The values of V_1 and V_2 for $[Sb_2((-)\text{-dmt})_2]^{2-}$ are both smaller than the corresponding values for $[Sb_2(d\text{-tart})_2]^{2-}$. The value of the separation factor α for $[Sb_2((-)\text{-dmt})_2]^{2-}$ is smaller than that for $[Sb_2(d\text{-tart})_2]^{2-}$. However, the decrease in the values of α is not so great.

It can be concluded that the methyl substitution does not cause a significant influence upon the chiral discrimination on a chiral selector. Thus, we feel tempted to look with favor upon the models in which the chiral anion directs its x axis to the complex cation to recognize the chirality.

The preparation of the bis(μ-$(-)_{589}$-2,3-dimethyltartrato)diantimonate(III) salt was performed by U.S. in the laboratory of Prof. Yoshiharu Izumi, Director of Institute for Protein Research, Osaka University, under his instruction. His kind and helpful guidance is highly appreciated. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 60470047 from the Ministry of Education, Science and Culture.

Crystals of *Λ*-tris(ethylenediamine)-cobalt(III) bis(μ-$(-)_{589}$-2,3-dimethyltartrato)diantimonate(III) perchlorate heptahydrate, *Λ*-$[Co(en)_3][Sb_2((-)\text{-dmt})_2]\cdot ClO_4\cdot 7H_2O$, are bright orange, trigonal, space group $P3_121$, a=10.496(3), c=29.570(6) Å, Z=3, D_c=1.87 g cm^{-3}. The structure was solved from 1723 Mo K_α reflections ($F_o > 3\,\sigma\,F_o$). The final discrepancy factors were R=0.067 and R_w=0.072. In the $(-)_{589}$-2,3-dimethyltartrato groups, the absolute configuration of the two asymmetric carbon atoms are both having an R configuration from the comparison with that of the *Λ*-$[Co(en)_3]^{3+}$ cation.

7) The order of the ion-association constants in Table 1 and that of the retention volumes in Table 2 are not exactly the same, presumably because the entity of ion-associated species recognized by CD spectra and that by ion-exchange chromatography are not always the same.

(Acetylacetonato)(*N,N,N',N'*-tetramethylethylenediamine)copper(II) Tetraphenylborate as a Solvent Basicity Indicator

Rudolf Werner SOUKUP† and Kozo SONE*
Department of Chemistry, Faculty of Science, Ochanomizu University, Ohtsuka, Bunkyo-ku, Tokyo 112

(Received February 12, 1987)

Synopsis. The title complex, [Cu(acac)(tmen)]BPh_4, is a color indicator for solvent basicity which serves better than the corresponding perchlorate in very weak donor solvents owing to its reluctance in ion-pair formation. The complex cation $[Cu(acac)(tmen)]^+$ decomposes in very strong donor solvents, but these indicators may still be used in them with some care.

(Acetylacetonato)(*N,N,N',N'*-tetramethylethylenediamine)copper(II) perchlorate, abbreviated as [Cu(acac)(tmen)]ClO_4, is known to be strongly solvatochromic, owing to the subtle structure changes caused by the solvation processes.[1,2] The coordination center which determines the position of the visible d-d band is extremely sensitive to nucleophilic solvent attack; this fact led to the proposal to use it as a color indicator for solvent basicity, which is expressed in Gutmann's donor number (DN).[2,3]

The use of this complex to estimate the DN of solvents gives reasonably good results when the DN lies between 5 and 30. However, anomalies appear in very weak or very strong donor solvents. As can be seen from the first column of Table 1, the λ_{max} value of this complex decreases with the decrease of DN in going from pyridine to nitromethane, but when the basicity gets smaller it increases notably again. Moreover, in such very weak donor solvents, the λ_{max} values become slightly concentration dependent, decreasing by a few nanometers upon strong dilution. Concentration dependence of λ_{max} appears again, and much more strongly, in very strong donor solvents, but here the λ_{max} increases with dilution.

In order to understand these anomalies better, the tetraphenylborate of the same complex cation was prepared, and its spectral behavior was compared with that of the perchlorate.

Experimental

Preparation of [Cu(acac)(tmen)]BPh_4. 10 g (ca. 0.026 mol) of twice recrystallized [Cu(acac)(tmen)]ClO_4[1] was dissolved in 120 ml of water, and 50 ml of a warm aqueous solution containing 12 g (ca. 0.035 mol) of $NaBPh_4$ was added with stirring. The pale red violet precipitate obtained was filtered off, washed with warm water, and dried in vacuo for several hours at 30 °C. Found: C, 70.34; H, 7.27; N, 4.70%. Calcd for $C_{35}H_{43}BCuN_2O_2$: C, 70.29; H, 7.25; N, 4.68%.

Solvents. The solvents used were all purified according to the literature.

Spectral Measurements. Use was made of a Cary 17 spectrophotometer, with quartz cells of various path lengths. Measurements were made at room temperature (ca. 20 °C).

Results and Discussion

As can be seen from the second column of Table 1, the visible spectra of [Cu(acac)(tmen)]BPh_4 in various solvents of DN>5 are very similar to those of the perchlorate, but the anomalies in very weak donor solvents disappear. The λ_{max} value continues to decrease, even in these solvents, with the decrease of solvent basicity, which can be expressed in terms of Schmid's DN_B,[4] and its concentration dependence is nearly imperceptible. The difference in color between the tetraphenylborate and the perchlorate in such a solvent can be quite large; for example, they are red and blue, respectively, in chlorobenzene, and the difference in their λ_{max} amounts to ca. 100 nm.

Now the curves shown in Fig. 1 reveal that, in addition to the d-d band, there is a continuous background absorption in the blue part of the spectrum, which seems to be the tail of a strong CT band in the near

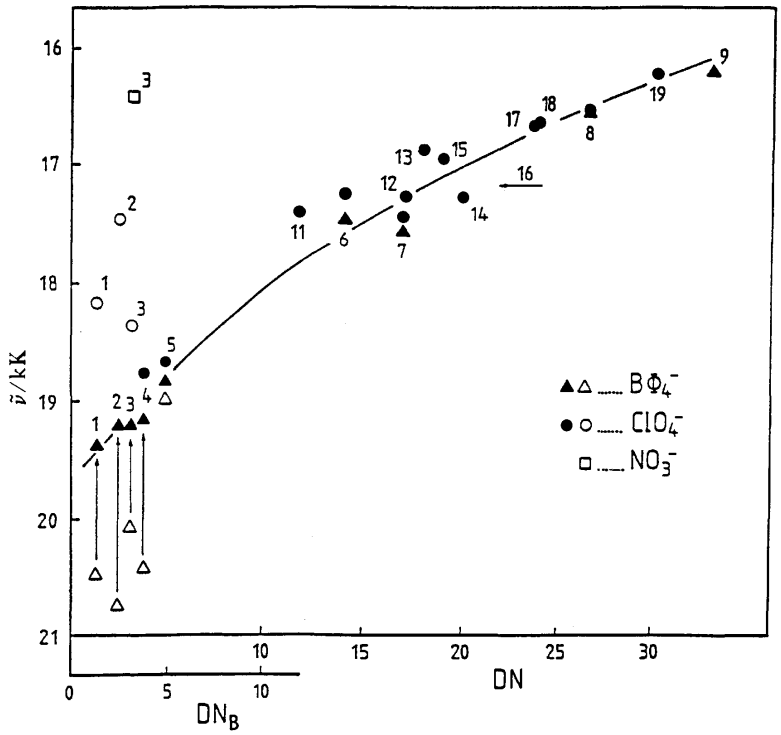

Fig. 2. A plot of the wavenumbers of the d-d band ($\tilde{\nu}_{max}$) against DN or DN_B. Notations of the solvents 1—9: see Table 1. Solvents 11 to 19 correspond, respectively, to benzonitrile, ethyl acetate, water, tetrahydrofuran, methanol, *t*-butyl alcohol, trimethyl phosphate, formamide, and DMSO. For solvents 1—5, DN_B values were used instead of DN. Full triangles 1 to 5 denote corrected values, while open triangles denote observed ones (cf. Table 1). Open circles, and a square for the nitrate, denote the cases where remarkable ion-pair formation takes place. The arrow for 16 indicates a range for its DN estimated from its DN_B.[4] (kK=10^3 cm^{-1}).

ultraviolet. With the decrease of DN or DN_B, this absorption is shifted toward the red, and overlaps remarkably with the d-d band in very weak donor solvents. So the λ_{max} values of the d-d band in such solvents should be corrected for this overlap. This correction was made by assuming that the d-d band in these solvents has the same $\tilde{\nu}$-symmetrical, pseudo-Gaussian shape as in other solvents; the obtained values are given in the third column of Table 1.

When the $\tilde{\nu}$-values corresponding to the λ_{max} values in Table 1 are plotted against DN or DN_B, it can be seen that the points for the tetraphenylborate (full triangles) and those for the perchlorate (full circles) lie along a smooth curve (Fig. 2). However, the points for the latter in three solvents 1—3 deviate strongly from the curve (open circles), confirming that the tetraphenylborate is a better solvent basicity indicator than the perchlorate.[5] The fact that this deviation tends to

a) Extrapolated by plotting λ_{max} against (1/[tmen]).

increase with the decrease of DN_B supports the view that ion-pair formation, i.e., weak coordination of ClO_4^- on the chelate plane, is responsible for it, which was formerly proposed by Fukuda et al.[6] to explain this type of spectral anomaly found in dichloroethane. In the case of the tetraphenylborate, such an ion-pair formation will not occur effectively since BPh_4^- is so large and inert; the regular spectral trend continues, therefore, in very weak donor solvents with no anomaly.

As to the anomaly in very strong donor solvents, there is no marked difference between the two complex salts. This anomaly is the result of the decomposition of the chelate cation caused by solvent attack. In the case of pyridine, it seems that the tmen ligand is driven off, since the addition of tmen to the solution apparently suppresses the decomposition, shifting λ_{max} to the blue (Table 2). With increasing tmen, the λ_{max} approaches a limit (613 nm); this may be taken as the λ_{max} value for the solvated complex cation [Cu(acac)(tmen)]$^+$ in pyridine, as the corresponding point on Fig. 2 is at a reasonable spot. The present indicators may still be used in such a strong donor solvent, therefore, by adding excess tmen to the solution.[7]

The solutions of the two complex salts in strong donor solvents are thermochromic, becoming more greenish on heating. This fact indicates that the decomposition equilibria in them, e.g.,

[Cu(acac)(tmen)]$^+$+$n$py $\rightleftarrows$ [Cu(acac)(py)$_n$]$^+$+tmen

are shifted to the right-hand side by heating.

5) Some authors are dubious about the significance of the concept of DN for protic solvents like water, formamide or alcohols (cf., e.g., L. L. Rusnak, E. S. Yang, and R. B. Jordan, *Inorg. Chem.*, **17**, 1810 (1978); M. Munakata, S. Kitagawa, and M. Miyazima, *ibid.*, **24**, 1638 (1985); M. H. Abraham, *Pure Appl. Chem.*, **57**, 1055 (1985)). In the present case, however, no remarkable deviation of such solvents from the general trend is observable. Of course, the donor ability of a highly structured solvent is always some function of the acceptor strength of the solute. Hence it seems that the acceptor ability of the cation [Cu(acac)(tmen)]$^+$ is essentially similar to that of $SbCl_5$, the reference compound for the DN scale.

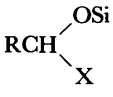
7) I. Persson (*Pure Appl. Chem.*, **58**, 1153 (1986)) has collected more data on the λ_{max} of [Cu(acac)(tmen)]ClO_4 and [Cu(acac)(tmen)]BPh_4 in strong donor solvents, obtaining information on the latter complex from one of us (R. W. S.). He stated that there is a good correspondence between λ_{max} and DN even when the latter is very high (ca. 50), seemingly without taking the decomposition of the complexes into account.

Reactions of Trimethylsilyl Isothiocyanate with Aldehydes and Acetals. Synthesis of Symmetrically and Unsymmetrically Isothiocyanato-Substituted Ethers

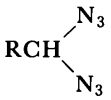
Kozaburo NISHIYAMA* and Makoto OBA
Department of Chemistry, Tokyo Metropolitan University, 2-1-1 Fukasawa, Setagaya-ku, Tokyo 158
(Received November 28, 1986)

Synopsis. The reactions of trimethylsilyl isothiocyanate (TMSTC) with aldehydes catalyzed by Lewis acid gave α,α′-diisothiocyanato ethers in good to excellent yields. Similarly, unsymmetrical α-isothiocyanato ethers were obtained from the reactions of TMSTC with acetals in appropriate yields.

Silicon compounds carrying a functional group play important roles in organic synthesis.[1] For example, silyl cyanides and silyl azides have been shown to be highly versatile reagents, which converted carbonyl compounds into α-siloxy cyanides (**1a**),[1] α-siloxy azides (**1b**),[2] and *gem*-diazides (**2**).[3,4] As a part of our continuing studies on such silicon compounds, we investigated the synthetic utility of trimethylsilyl isothiocyanate (TMSTC) because there have been a few reports[5] on its reactivity to date. In this paper, we would like to describe $ZnCl_2$-promoted reactions of TMSTC with aldehydes and acetals to give α,α′-diisothiocyanato and α-isothiocyanato ethers, respectively.



1a, X=CN; **1b**, X=N_3

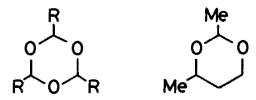


2

Results and Discussion

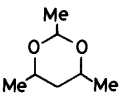
The Reaction of TMSTC with Aldehyde. Contrary to the reaction of silyl azide with aldehyde,[4] an 89% of bis(1-isothiocyanato-2-methylpropyl) ether (**4c**) was obtained by a reaction of 2-methylpropanal (**3c**) and TMSTC (2.2 equiv) in the presence of a catalytic amount of $ZnCl_2$ at room temperature for 24 h. Even when the reaction of **3c** with 1.2 equiv of TMSTC was carried out at room temperature for 4 h, the sole product was compound **4c** although the yield became poor. The reaction was also promoted by $SnCl_2$, giving the corresponding ether. By carrying out the reaction for other aldehydes under similar conditions, we obtained some symmetrically disubstituted ethers in good yields. The results and the spectral data of the products are summarized in Table 1. Trichloroethanal and benzaldehyde did not give any products under similar conditions and benzaldehyde was quantitatively recovered after the work-up. Such aldehydes reacted with silyl azide to afford adducts, **1b** and **2**.[4] By using hydrosilanes, several synthetic methods for ethers have been reported under various conditions.[6]

When the reaction of 2-methylpropanal (**3c**) with TMSTC in the presence of $ZnCl_2$ (catalytic amount) was carried out at 90 °C for 0.5 h, 2,4,6-tris(1-methylethyl)-1,3,5-trioxane (**5c**) along with ether **4c** (22%) was isolated in a 36% yield. The trioxane **5c** was also isolated in an 83% yield from the reaction of the aldehyd **3c** with $ZnCl_2$ (0.05 equiv) in the absence of TMSTC at room temperature for 1 h. In addition, a mixture of **5c**, TMSTC, and $SnCl_2$ was stirred for 1.5 h at room temperature, giving a 70% yield of **4c**, and 2,4,6-trimethyl-1,3,5-trioxne (**5f**) was also converted into bis(1-isothiocyanatoethyl) ether (**4f**) in a 73% yield. However, 1,3,5-trioxane (**5e**), 2,4-dimethyl-1,3-dioxane (**6a**), and 2,4,6-trimethyl-1,3-dioxane (**6b**) were recovered quantitatively under similar conditions.



5e, R=H; **f**, R=Me

6a



6b

On the basis of these findings, we propose that the reaction of TMSTC with aldehydes takes place as path A rather than path B of the Scheme, i.e. 1,3,5-trioxane **5** initially generated by $ZnCl_2$-catalyzed trimerization of the aldehyde is substituted by TMSTC to form ether **4** and bis(trimethylsilyl) acetal. The latter again trimerizes to trioxane **5** under these conditions. Otherwise, the yield of the product **4** should be at most 67%. As for path B, Mukaiyama et al. considered it a plausible reaction course of ether formation,[6d] i.e. 2:1-addition of aldehyde with silicon compound followed by condensation of the adduct with another silicon compound. That trichloroethanal and benzaldehyde were not converted into ether **4** shows that such aldehydes would not give trioxane **5** under the conditions employed.

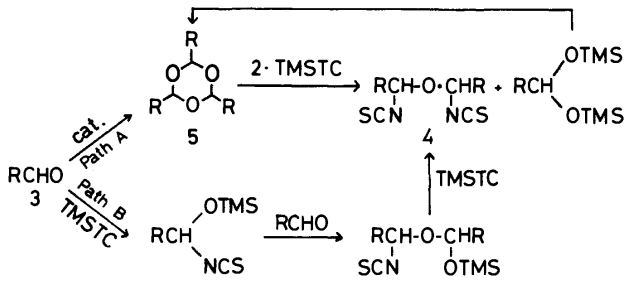
a) Aldehyde/TMSTC=1/2.2. b) The compound was obtained from 2,4,6-trimethyl-1,3,5-trioxane (**5f**) and TMSTC.



a, R=Et; b, R=n-Pr; c, R=i-Pr; d, R=t-Bu

Scheme 1.

The Reaction of TMSTC with Acetal. As described above, the substitution reaction of trioxane derivatives **5** by TMSTC occurred to give the corresponding ether **4** exclusively. This led us to examine a possibility of unsymmetrical ether formation from acetal with TMSTC.

When a mixture of propanal dimethyl acetal (**7b**), TMSTC, and $ZnCl_2$ was stirred for 4 h at room temperature, the desired ether **8b** was obtained in a 67% yield. This method could be applied to various acetals, and the results are compiled in Table 2. A conversion of acetals **7** into ethers **8** was achieved in good yields, but an isolation of the products depended upon their sensitivity to moisture. Notably, we could not isolate any of the *p*-methoxy derivative **8c** although compound **7c** was quantitatively converted into **8c**, determined by the ^1H NMR spectrum.

In conclusion, the synthesis of α-substituted and α,α′-disubstituted ethers was easily realized by using TMSTC, acetal, and aldehyde. While such ether synthesis is also considered to be achieved by a reaction of halogeno precursor with sodium thiocyanate, the applicability of the method as a general synthetic route to **4** and **8** is limited, due to the inaccessibility of the reagents.

Experimental

Materials. Trimethylsilyl isothiocyanate (TMSTC) was prepared from chlorotrimethylsilane and sodium thiocyanate according to the literature.[7] Acetals, except for commercial products, were synthesized by the reported methods.[8] Commercial products including aldehydes were purified if necessary.

The Reaction of Aldehyde 3 with TMSTC. As an example the reaction of 2-methylpropanal (**3c**) with TMSTC is shown. A mixture of **3c** (3.0 g, 42 mmol), TMSTC (12.0 g, 92 mmol), and $ZnCl_2$ (341 mg, 2.5 mmol) was stirred at room temperature for 24 h. After removal of low-boiling substances, the reaction mixture was triturated with hexane and the resulting precipitates ($ZnCl_2$) were filtered off. The filtrate was stirred with water for an additional 0.5 h. The extract with CH_2Cl_2 was dried over $MgSO_4$, the solvent were evaporated in vacuo, and the residual oil chromatographed on silica gel. Elution with hexane contained 4.6 g (89%) of bis(1-isothiocyanato-2-methylpropyl) ether (**4c**). ^{13}C NMR ($CDCl_3$) δ=17.04, 17.20, 35.10, 89.54, and 138.91. Other spectral data of **4c** and related compounds are shown in Table 1. **4a**: Found: C, 44.21; H, 5.63; N, 12.98%. Calcd for $C_8H_{12}N_2S_2O$: C, 44.41; H, 5.59; N, 12.95%. **4b**: Found: C, 49.00; H, 6.57; N, 11.51%. The Reaction of Acetal 7 with TMSTC. When the boiling points of the products (unsymmetrically substituted ethers) were close to that of TMSTC, the following was representative of the reaction of acetal **7** with TMSTC. A mixture of propanal dimethyl acetal (**7b**, 6.3 g, 60 mmol), TMSTC (3.9 g, 30 mmol), and $ZnCl_2$ (0.4 g, 3 mmol) in dichloromethane (15 cm^3) was stirred at room temperature for 4 h. With aromatic derivatives, the quantities of compound **7** and TMSTC were altered to 30 and 60 mmol, respectively, and trimethylsilyl trifluoromethanesulfonate (TMSOTf) was used as a catalyst in order to avoid a complicated isolation. Work-up was similar to that for **4c** described above. 2.7 g (67%) of 1-isothiocyanatopropyl methyl ether (**8b**) was obtained by distillation at reduced pressure, bp 72—73 °C/55 mmHg. Physical and spectral data of compound **8** are listed in Table 2.

One of us (K. N.) wishes to thank the ministry of Education, Science and Culture for Grant-in-Aid (No 60540338).

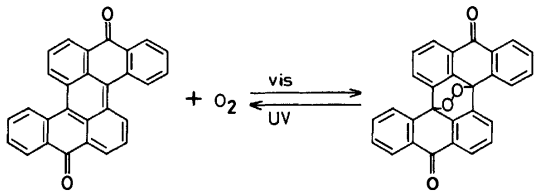
Improved Synthesis of Dibenzo[*a,j*]perylene-8,16-dione

Kiyoichi HIRAKAWA,* Eriko OGIUE, Jiro MOTOYOSHIYA, and Toshio KAKURAI
Department of Chemistry, Faculty of Textile Science and Technology, Shinshu University, Ueda, Nagano 386
(Received January 5, 1987)

Synopsis. An improved method for the synthesis of the title compound **1** has been achieved through an application of the Scholl reaction. The key to the new approach is to use the dimeric compounds of 10-methyleneanthrone as the precursors of **1**.

Photochromic systems which are based on photoreversible addition of O_2 to arene derivatives have recently received much attention in connection with their potential use as photoresponsive materials.[1-12] The photochromic conversion of dibenzo[*a,j*]perylene-8,16-dione (heterocoerdianthrone) (**1**) into 4b,12b-epidioxy-4b,12b-dihydrodibenzo[*a,j*]perylene-8,16-dione (*endo*-peroxide) (**2**) is among the most extensively investigated reactions.[1-8,11] The self-sensitizing photooxidation of reddish violet **1** by visible light irradiation in air-saturated solution leads to the formation of colorless **2**, which reproduces the parent compound **1** and O_2 in a singlet state by ultraviolet light. The photochromic system consisting of **1** and **2** is highly reversible and thermally stable.[4,6,11]



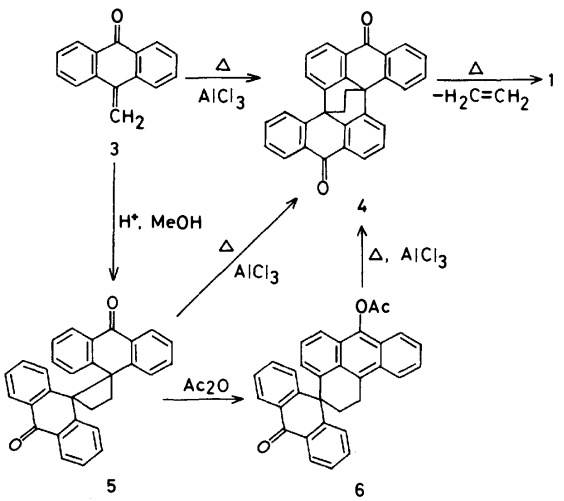
1 2

The methods reported to date for the synthesis of **1** are as follows: (a) Dehydration of 9,10-diphenyl-1,5-anthracenedicarboxylic acid which is prepared in four steps from the readily available starting material, 9,10-anthraquinone-1,5-dicarboxylic acid,[13] (b) thermolysis of 4-chloroanthrone whose preparation is difficult,[14] (c) reaction of 4-chloroanthrone with zinc chloride in pyridine,[15] and (d) the Scholl reaction of readily available 10-methyleneanthrone (**3**) with aluminium chloride.[16] The overall yield of **1** from the anthraquinonedicarboxylic acid by method (a), which is often employed, is low (ca. 23—25%). In method (d), **1** is prepared in one step from **3**. However, its detailed direction and yield have not been published. We have, therefore, examined the convenient synthesis of **1** using the Scholl reaction of **3** and its dimeric compounds.

Treatment of **3** with aluminium chloride-sodium chloride at 200 °C, in a modification of literature method,[16] gave very low yield of **1** (16%), together with anthraquinone (4%). The addition of a proper amount of the hydrogen acceptor, manganese dioxide, resulted in an increase in the yield of **1**. Similar treatment of **3** in the presence of manganese dioxide, 2—3 wt%/aluminium chloride, led to **1** in a 22% yield. However, addition of an organic base, e.g., pyridine, was without effect. The similar reaction of **3** at the reaction temperature of 150—170 °C afforded the intermediate, 4b,12b-dihydro-4b,12b-ethanodibenzo[*a,j*]perylene-8,16-dione (**4**), the structure of which followed from spectral data and thermolysis to **1**. Its IR spectrum indicates absorption for the carbonyl group at 1650 cm^{-1} and its ^1H NMR spectrum reveals an A_2B_2 multiplet due to the ethylene group at δ 1.92—2.26 and 2.40—2.74. Heating of **4** at its melting point gave **1** in a high yield, together with evolution of ethylene.

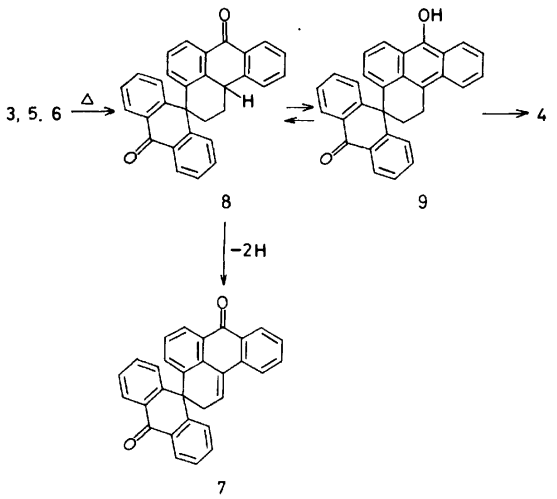
It seemed to us, based on the formation of **4**, that the dimeric compounds of **3**, dispiro[anthracene-9(10*H*), 1′-cyclobutane-2′,9″(10″*H*)-anthracene]-10,10″-dione (**5**) and 7′-acetoxy-1′,2′-dihydrospiro[anthracene-9(10*H*), 3′-[3*H*]benz[*de*]anthracene]-10-one (**6**),[17] would be favorable precursors for conversion to **1** via the Scholl reaction. The dimer **5** and its acetylated compound **6** were prepared from **3** in high yields according to the previously studied method (**5**: 97%; **6**: 89%), as shown in the scheme. The dimeric compounds **5** and **6** gave the expected dye **1** or its intermediate **4** under the Scholl reaction conditions (Table 1). The yields of **1** or **4** from **5** and **6** were much higher than those from **3**; under the optimum conditions, the reactions of **5** and **6** led to **1** in 33 and 26% yields, respectively. In addition, the Scholl reactions of **5** and **6** did not yield anthraquinone whose separation from **1** using the means of vatting process is troublesome, whereas **3** led to a significant amount of anthraquinone. Thus, the method involving the Scholl reaction of the dimer **5**, prepared from **3**, to **1** (**3**→**5**→**1**) is preferable to the other two (**3**→**1** and **3**→**5**→**6**→**1**) in terms both of convenience and yield. A similar treatment of **5** with zinc chloride as a Friedel-Crafts reagent did not give **1**, but, instead, gave spiro[anthracene-9(10*H*),3′-[3*H*]benz[*de*]anthracene]-7′,10(2′*H*)-dione (**7**).[17]

It seems likely that the formation of **1** occurs through **8** and its enol **9** and in turn **4**, since (a) all of



5 6

the reaction of **8**, **5**, and **6** with aluminium chloride at low temperature (150—170 °C) gave the intermediate **4** which yielded **1** by thermolysis, and (b) similar reactions at 135—140 °C led to **7** which probably arises from the dehydrogenation of **8** or **9**,[17] (c) the acid-catalyzed reaction of **3** in organic solvents readily gave **5**, which thermally rearranged with a synchronous ring expansion to give unstable **8** and/or **9**.[17] These peri-condensation reactions effected by aluminium chloride occured in the presence of a trace of water or hydrogen chloride.[18,19] In addition, hydrogen acceptors such as air, supplied by vigorous stirring of the reaction mixture, and manganese dioxide resulted in an increase in the yield of **1**. A conceivable mechanism for the formation of **1** from **3**, **5**, and **6** may be as follows: First, the formation of the enol **9** from **3**, **5**, and **6**, second, the protonation on the anthracene moiety of **9** by moist aluminium chloride to give σ complexes[20] which undergo the electrophilic substitution (cyclization) involving the C-11'b and C-4 atoms, third, the dehydrogenation promoted by air or manganese dioxide to lead to **4**, and finally, the retro Diels-Alder reaction of **4** to give **1** and ethylene. The low yields of these Scholl reactions might result from the deactivation at the 4-position by the inductive effect of the carbonyl group and the steric hindrance in the intramolecular electrophilic substitution of the σ complex. However, the synthetic method of **1** via the Scholl reaction of the dimer **5** can compete in terms of convenience and yield with those through 9,10-diphenyl-1,5-anthracenedicarboxylic acid.



Experimental

The following compounds were prepared according to previously known procedures: **3**,[21] **5**,[17] and **6**.[17]

Dibenzo[*a,j*]perylene-8,16-dione (1). To a finely ground mixture of aluminium chloride (50 g), sodium chloride (15 g), and manganese dioxide (1.00 g), 5 (5.00 g) was added. The mixture was vigorously stirred and heated until TLC showed the absence of the intermediate **4**. The reaction temperature was kept at 160 °C during the first 10 min and then raised to 200 °C in 5—10 min, where it was kept for ca. 2 h. The resulting mixture was poured into ice-water (500 g) followed by addition of hydrochloric acid (100 ml). After boiling, the precipitate was filtered off and washed with water. The product mixture was extracted repeatedly with a hot alkaline sodium dithionite solution (NaOH, 10 g; $Na_2S_2O_4$, 10 g; H_2O, 500 ml). The alkali-soluble leuco product (deep green) was oxidized to the crude dye by contact with air. The dye was washed with water, dried, and recrystallized from chlorobenzene or pyridine to give pure **1** (33%) as reddish violet microcrystals, identical with an authentic specimen:[13] mp 363—365 °C (lit,[4] 361 °C); IR (KBr) 1643 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=7.55—7.95 (6H, m), 8.15—8.30 (2H, m), 8.50—8.65 (2H, m), 8.83 (2H, dd), and 9.00 (2H, d), MS *m/z* 382 (M^+); Anal. ($C_{28}H_{14}O_2$) C, H.

Results of the reactions of **3**, **5**, and **6** under the different conditions are summarized in Table 1.

4b,12b-Dihydro-4b,12b-ethanodibenzo[*a,j*]perylene-8,16-dione (4). The procedure for the Scholl reaction was similar to that for **1** except that the reaction was carried out without manganese dioxide at 160 °C for 1 h until TLC showed the absence of the starting material. The product mixture from **5** was chromatographed on silica (benzene as

Table 1. Scholl Reactions of **3**, **5**, and **6**

6	10	3	0.2	210	2	26	0
6	10	3	0	160[b]	1	Trace	22

a) The reaction gave anthraquinone (ca. 4—5%) as by-product. b) At this reaction temperature, the addition of manganese dioxide resulted in an inadequate melting of aluminium chloride-sodium chloride medium. Consequently, it led to a decrease in the yield of **4**.

eluant). Recrystallization of the appropriate fraction from benzene-hexane gave **4** (24%) as nearly colorless microcrystals: TLC (Merck, silica gel 60 F_{254}, precoated plastic sheet, 0.2 mm, benzene) R_f 0.35; mp 319—321 °C; IR (KBr) 1650 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.92—2.26 (2H, m), 2.40—2.74 (2H, m), 7.15—7.40 (4H, m), 7.50—7.95 (6H, m), 8.15 (2H, dd), and 8.50—8.70 (2H, m); MS m/z 410 (M^+); Anal. ($C_{30}H_{18}O_2$) C, H.

Results for the similar reactions of **3** and **6** are shown in Table 1.

Thermolysis of 4. Compound **4** (2.05 g, 50 mmol) was heated at its melting point in a test tube for 5 min during which time gas was evolved. The violet product was recrystallized from chlorobenzene to give **1** (1.74 g, 89%). GLC analysis of the gas evolved in the thermolysis showed the presence of ethylene.

Favorskii-Type Rearrangement of α,α′-Dihalo Ketones with Sodiomalonates Leading to Conjugated Enone Derivatives

Takashi SAKAI,* Mutsumi ISHIKAWA, Eiichiro AMANO, Masanori UTAKA, and Akira TAKEDA
Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700
(Received January 14, 1987)

Synopsis. A new synthetic method of conjugated enones by the use of carbanion-induced Favorskii-type rearrangement is described. The reaction of α,α′-dihalo ketones $R^1R^2(X)CC(O)CH_2X$ with sodiomalonates $Na^+ {}^-CR^3(CO_2R^4)_2$ in THF at 0 °C—room temperature gave conjugated enones $R^1R^2C{=}CHC(O)CR^3(CO_2R^4)_2$ in 42—66% yields. The reaction can be also adaptable to the enolates of ethyl cyanoacetate or malononitrile to give the corresponding enones.

We recently reported that certain α,α′-dihalo ketones caused the Favorskii-type rearrangement by the action of enolate anions derived from β-keto esters[1] and ethyl (diethoxyphosphinyl)acetate,[2] giving dihydro-4-pyrones and α-(diethoxyphosphinyl) β-oxo γ,δ-unsaturated esters, respectively. In the previous communication,[1] we simply pointed out that the reaction of 1,3-dichloro-3-methyl-2-butanone (**1a**) with ethyl sodiomalonate (**2a**) gave diethyl (3-methyl-2-butenoyl)malonate (**3a**). Continuous interests to extend the synthetic utility stimulated us to apply the reaction to other α,α′-dihalo ketones and enolate anions.

The reaction of **1a** with two equivalents of **2a** in THF at 0 °C—room temperature gave **3a**[3] in a 52% yield exclusively (Scheme 1). The yield of **3a** was further improved up to 66% by the use of 3-bromo-1-chloro-3-methyl-2-butanone (**1b**) in place of **1a**. The mechanism for the formation of the unsaturated keto ester is explained in parallel with that described previously.[1]

Replacement of the chloro substituent at C-1 by bromine resulted in loss of the product selectivity. Thus the reaction of 1,3-dibromo-3-methyl-2-butanone (**1c**) with **2a** afforded diethyl (3-bromo-3-methyl-2-oxobutyl)malonate (**4**) (43% yield) in addition to the formation of **3a** (49% yield) (Scheme 2). These results

Table 1. Synthesis of Conjugated Enone Derivatives

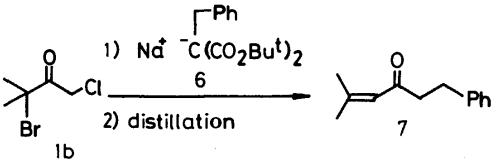
Dihalo ketone	Enolate anion[a]	Product (Yield/%)
 1a	 2b	 3b(42)
 1b	 2c	 3c(48)
 1d	 2a	 3d(53)[b]
 1e	2a	 3e(45)
1a	 2d	 3f(38)
1b	 2e	 3g(59)

a) Sodium salt (NaH, THF). b) A ca. 1:3 mixture of cis- and trans-isomers on the basis of ^1H NMR analysis (see also Ref. 4).

suggest that the Favorskii-type rearrangement and the nucleophilic substitution of **2a** at C-1 occur competitively. The latter reaction would be accelerated in the case of **1c**.

Application of the reaction to the synthesis of various enones **3b—g** is summarized in Table 1. The reaction of 1,3-dichloro-3-methyl-2-pentanone (**1d**) with **2a** gave trans-enone **3d**[4] predominantly. It is worthwhile to note here that the reaction of **1a** with sodiocyanoacetate (**2d**) also gave **3f**, although the enolate gave only the S_N2 product in the reaction with 3-bromo-3-methyl-2-butanone (**5**).[5] The difference would come from the ease of abstraction of the C-1 proton of **1a**, **b**, as compared with that of **5**, by the less basic enolate **2d**. The present reaction provides synthetically useful conjugated enone derivatives (**3a—g**) by the use of the Favorskii-type rearrangement.

Furthermore, a similar reaction of **1b** with di-*t*-butyl sodiobenzylmalonate (**6**) afforded 5-methyl-1-phenyl-4-hexen-3-one (**7**) as a result of the decarboxylative decomposition of the Favorskii product in the course of vacuum distillation (Scheme 3).



Scheme 3.

Experimental

Melting points were determined on a Yamato MP-21 apparatus and are uncorrected. The bulb-to-bulb distillation was done using a Büchi Kugelrohrofen at the pressure and the oven temperature indicated. IR spectra were taken on a JASCO A-102 spectrometer. ^{1}H NMR spectra were measured with a JEOL JNM PMX60-SI spectrometer. Both ^{1}H NMR (100 MHz) and ^{13}C NMR (25 MHz) spectra were taken on a JEOL FX-100 spectrometer using Me_4Si as an internal standard. HPLC analysis was performed by using Yanagimoto L-2000 apparatus. Elemental analyses were carried out with Yanagimoto MC-2 apparatus. Column chromatography was performed through silica gel (Wakogel C-200). TLCs were done on a silica gel (Kieselgel 60 PF_{254}).

Dihalo Ketones. Compound **1c**[6] was prepared by the bromination (Br_2, ether) of 3-methyl-2-butanone. Bromo chloro ketone **1b**[7] as well as dichloro ketones **1a**,[8] **1d**,[8] and **1e**[8] were prepared in a different way from that reported.[7,8]

1,3-Dichloro-3-methyl-2-butanone (1a).[8] Sulfuryl chloride (135 g, 1.0 mol) was added to 3-methyl-2-butanone (34.5 g, 0.41 mol) with stirring at room temperature. After being stirred for 25 h at 40—50 °C, the solution was poured into cold water carefully. The organic layer was separated and the aqueous layer was extracted with dichloromethane. The combined organic layer was washed with water, dried ($CaCl_2$), and concentrated under reduced pressure. The residual oil was distilled to give **1a** (44.7 g, 70%): bp 55—59 °C (9 mmHg, 1 mmHg=133.322 Pa).

Dichloro ketones **1d**[8] and **1e**[8] were prepared in a similar way in 53 and 40% yields, respectively.

3-Bromo-1-chloro-3-methyl-2-butanone (1b).[8] A mixture of 3-methyl-2-butanone (9.9 g, 0.115 mol), *N*-bromosuccinimide (20.4 g, 0.115 mol), benzoyl peroxide (2.1 g, 0.0087 mol), and CCl_4 (96 ml) was heated under reflux for 5 h. The mixture was filtered, washed with water and brine, dried ($CaCl_2$), and then concentrated. The residual oil was subjected to vacuum distillation to give 3-bromo-3-methyl-2-butanone,[9] (15.9 g, 84%): bp 73—77 °C (93 mmHg). The bromide was then treated with sulfuryl chloride (10.2 g, 0.076 mol) for 11 h at room temperature. Unreacted sulfuryl chloride was removed under reduced pressure. The resulting oil was treated in a manner similar to the foregoing experiment to give **1b** (13.1 g, 68%): bp 90—95 °C (24 mmHg); IR (neat) 1730 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.90 (6H, s), 4.53 (2H, s).

Reaction of 1b with Diethyl Sodiomalonate (2a). Synthesis of Diethyl (3-Methyl-2-butenoyl)malonate (3a).[3] A mixture of diethyl malonate (3.04 g, 19.0 mmol), NaH (457 mg, 19.0 mmol), and THF (25 ml) was heated under reflux for 4 h and then cooled to 0 °C in an ice bath. To the suspension was added a solution of **1b** (1.90 g, 9.52 mmol) and THF (7 ml). After being stirred for 2 h at 0 °C and then for additional 20 h at room temperature, the mixture was acidified with 10% HCl, washed with water, dried ($MgSO_4$), and then concentrated under reduced pressure. The residual oil was purified by column chromatography (hexane-acetone, 10:1) to give **3a** (1.52 g, 66%). It was subjected to vacuum distillation to afford an analytical sample of **3a**: bp 120—140 °C (1.0 mmHg); IR (film) 1760, 1738, 1697, 1644, 1623 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.25 (1.8 H, t, J=7Hz), 1.28 (1.2 H, t, J=7 Hz), 1.90 (3H, br s), 2.09 (3H, br s), 3.94—4.38 [4.4H, m, ester 2 CH_2 and $CH(CO_2Et)_2$], 6.00 (1H, m), 13.47 (0.6 H, s, enol OH).

A similar reaction of dichloro ketone **1a** with **2a** gave **3a** in a 52% yield.

Reaction of 1c with 2a. The crude product was separated by column chromatography (hexane-acetone, 15:1) to give **3a** (49%) and **4** (43%). **4**: IR (neat) 1760—1720 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.28 (6H, t, J=7 Hz), 1.88 (6H, s), 3.42 (1H, d, J=8 Hz), 3.43 (1H, d, J=6.5 Hz), 3.77 (1H, dd, J=6.5 and 8 Hz), 4.26 (4H, q, J=7 Hz). Found: C, 44.46; H, 5.87%. Calcd for $C_{12}H_{19}O_5Br$: C, 44.59; H, 5.92%.

Di-*t*-butyl (3-Methyl-2-butenoyl)malonate (3b): Bp 125—145 °C (3 mmHg); IR (neat) 1730, 1690, 1625 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.44 (18H, s), 1.91 (3H, br s), 2.13 (3H, br s), 3.98 (0.8H, s), 6.08 (1H, m), 13.16 (0.2H, s, enol OH). Found: C, 64.26; H, 8.85%. Calcd for $C_{16}H_{26}O_5$: C, 64.41; H. 8.78%.

Diethyl 5-Methyl-3-oxo-4-hexene-2,2-dicarboxylate (3c): Bp 125—145 °C (1.0 mmHg); IR (neat) 1735, 1697, 1623 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.27 (6H, t, J=7 Hz), 1.51 (3H, s), 1.94 (3H, br s), 4.18 (4H, q, J=7 Hz), 6.09 (1H, m); ^{13}C NMR ($CDCl_3$) δ=13.7 (q), 18.0 (q), 20.9 (q), 27.7 (q), 61.7 (t), 66.8 (s), 120.8 (d), 158.1 (s), 168.6 (s), 191.0 (s). Found: C, 60.86; H, 7.72%. Calcd for $C_{13}H_{20}O_5$: C, 60.92; H, 7.87%.

Diethyl (3-Methyl-2-pentenoyl)malonate (3d). The crude product was purified by TLC (hexane-ether, 5:1) to give **3d**;[4] IR (neat) 1730, 1690, 1620 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.07 (3H, t, J=7 Hz), 1.27 (4.7H, t, J=7 Hz), 1.29 (1.3H, t, J=7 Hz), 1.89 (0.65H, br s, CH_3 of *cis*-**3d**), 2.10 (2.35H, br s, CH_3 of *trans*-**3d**), 2.02—2.72 (2H, m), 3.9—4.4 (4.46H, m, ester 2 CH_2 and OH), 5.95 (1H, m), 12.65 (0.54H, br s, enol OH). Found: C, 60.87; H, 7.62%. Calcd for $C_{13}H_{20}O_5$: C, 60.92; H, 7.87%.

Diethyl (Cyclohexylideneacetyl)malonate (3e). The crude product was purified by TLC (hexane-ether, 5:1) to give **3e**: IR (neat) 1730, 1640, 1560 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.28 (3.3H, t, J=7 Hz), 1.31 (2.7H, t, J=7 Hz), 1.50—2.94 (10H, m), 3.93—4.42 [4.45H, m, ester 2 CH_2 and $CH(CO_2Et)_2$], 5.94 (1H, s), 13.42 (0.55H, br s, enol OH). Found: C, 63.72; H, 8.03%. Calcd for $C_{15}H_{22}O_5$: C, 63.81; H, 7.85%.

Ethyl 2-Cyano-5-methyl-3-oxo-4-hexenoate (3f). The reaction of **1a** (1.55 g, 0.01 mol) with **2d** [ethyl cyanoacetate (1.94 g, 0.02 mol) and NaH (0.48 g, 0.02 mol) in THF (50 ml)] was done in a similar way. The crude product was purified by column chromatography (hexane-acetone, 5:1) to give **3f** (990 mg, 38%): mp 36—37 °C ($CHCl_3$); IR (KBr) 3700—3100, 2190, 1660, 1640 cm^{-1}; ^{1}H NMR (CD_3COCD_3) δ=1.13 (3H, t, J=7 Hz), 1.86 (3H, br s), 2.10 (3H, br s), 4.16 (2H, q, J=7 Hz), 3.6—4.5 (3H, br s), 6.31 (1H, m). Found: C, 61.49; H, 6.45%. Calcd for $C_{10}H_{13}O_3N$: C, 61.53; H, 6.71%.

(3-Methyl-2-butenoyl)malononitrile (3g). The reaction of **1a** (1.55 g, 0.01 mol) with **2e** [malononitrile (1.32 g, 0.02 mol) and NaH (0.48 g, 0.02 mol) in THF (40 ml)] was carried out in the usual manner. The crude product was purified by column chromatography (hexane-acetone, 5:1) to give **3g** (0.87 g, 59%): mp 162—163 °C ($CHCl_3$); IR (KBr) 2220, 2200 1624 cm^{-1}; ^{1}H NMR (CD_3COCD_3) δ=2.04 (3H, d, J=0.14 Hz), 2.08 (3H, d, J=1.5 Hz), 6.14 (1H, m), 9.28 (1H, br s, enol OH). Found: C, 64.72; H, 5.46%. Calcd for $C_8H_8ON_2$: C, 64.85; H, 5.44%.

5-Methyl-1-phenyl-4-hexen-3-one (7). The reaction of **1b** (1.99 g, 0.01 mol) with **6** [di-*t*-butyl benzylmalonate[10] (3.06 g, 0.01 mol) and NaH (0.528 g, 0.022 mol) in THF (100 ml)] was carried out in a usual manner. The crude product was subjected to vacuum distillation [bp 150—160 °C (0.3 mmHg)] and purified by column chromatography (hexane-acetone, 20:1) to give **7** (661 mg, 35%): IR (neat) 1693, 1625 cm^{-1}; ^{1}H NMR (CCl_4) δ=1.74 (3H, d, J=1.5 Hz), 2.11 (3H, d, J=1.5 Hz), 2.41—3.06 (4H, m), 5.94 (1H, m), 7.09 (5H, br s). Found: C, 82.86; H, 8.61%. Calcd for $C_{13}H_{16}O$: C, 82.94; H, 8.57%.

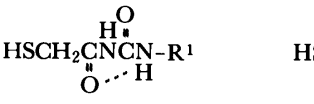
Evidence for the Similarity Recognition Hypothesis. Structure Dependence of the Selectivity in Oxidation of a Pair of Associating Thiols Each Having an Alkyl Group

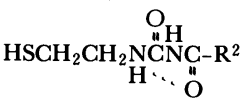
Tadashi ENDO,* Takeshi UEDA, Takashi ISAGO, Jun-ichi KATO, Takashi SUZUKI, Makoto MISAKA, and Masato M. ITO
Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157
(Received January 17, 1987)

Synopsis. In base-catalyzed oxidation of a pair of associating thiols [$HSCH_2$-CONHCONH-R^1 and $HSCH_2CH_2$-NHCONHCO-R^2] (R^1=n-C_4H_9, R^2=n-C_nH_{2n+1}) with oxygen, the selectivity (a measure of molecular recognition) at 35.0 °C reached a maximum for R^1=R^2 (=n-C_4H_9) both in aqueous acetonitrile (n=2 to 6) and in aqueous ethanol (n=3 to 5).

The elucidation of factors controlling specific biological recognition is very significant in chemistry as well as in biology. In order to solve this problem, we have studied (i) the dependence of the selectivity in oxidation of a pair of associating thiols (**1** and **2**) on



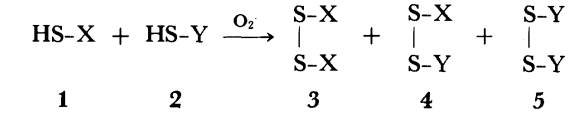
1a R^1=n-C_4H_9



2a R^2=C_2H_5
b R^2=n-C_3H_7
c R^2=n-C_4H_9
d R^2=n-C_5H_{11}
e R^2=n-C_6H_{13}

the structures of R^1 and R^2,[1,2] (ii) the dependence of the crystalline 1 : 1 complex formation between a pair of acylurea derivatives on the structures of their substituents,[2,3] and (iii) the stacking mode of the substituents in the crystalline 1 : 1 complexes by X-ray diffraction.[2,3] From these studies using a pair of associating compounds, it has been proposed that the three dimensional shape similarity between interacting groups in reacting molecules is responsible for more specific and precise molecular recognition than would otherwise be achieved.[2] In the above investigations on the selectivity, one of the substituents (R^1 and R^2) was an aryl group: (i) R^1=p-$Me_2NC_6H_4$ and R^2=Me_2CH-$(CH_2)_m$ (m=0 to 4)[1a] and (ii) R^1=p-$Me_2NC_6H_4$ and R^2=p-ZC_6H_4 (Z=$CHMe_2$, NO_2, Me, and Cl).[2] We report here the experimental evidence to support the above "similarity recognition hypothesis," using straight-chain alkyl groups as both substituents.

Triethylamine-catalyzed oxidation of a pair of thiols (**1** and **2**) with oxygen gives one unsymmetrical (**4**) and two symmetrical disulfides (**3** and **5**). The selectivity (r, a measure of the degree of the recognition between **1** and **2**) is represented by the logarithmic ratio of the yield of **4** to twice that of **3**: r=ln([**4**]/(2[**3**])). The butyl group was chosen as R^1.



1 **2** **3** **4** **5**

Table 1 lists the yields of the disulfides (**4** and **3**) and the selectivity (r) in oxidation of **1a** and **2** at 35.0 °C in aqueous acetonitrile [mole fraction of water (x_w)=0.42]. In Fig. 1, r values are plotted against the structures of R^2. The selectivity (r) has proved to pass through a maximum at the butyl group, the same group used as R^1. Moreover, the selectivity was examined in another aqueous solvent, water-ethanol (x_w=0.75). The results are illustrated in Table 2 and Fig. 1.[4] Also in this case, the r has been found to reach a maximum for R^2=n-C_4H_9 (=R^1).

Table 1. Yields of Disulfides (**4** and **3**) and Selectivity (r) in Oxidation of **1a** and **2** at 35.0 °C in Aqueous MeCN (x_w=0.42)

R^2	Yield/%		r[a]
	4	**3**	
C_2H_5	18.4	32.9	−1.27±0.03
n-C_3H_7	76.8	9.2	1.4 ±0.1
n-C_4H_9	83.9	1.6	3.3 ±0.1
n-C_5H_{11}	85.5	2.6	2.8 ±0.1
n-C_6H_{13}	25.5	34.4	−0.99±0.06

a) Errors given are the standard deviations.

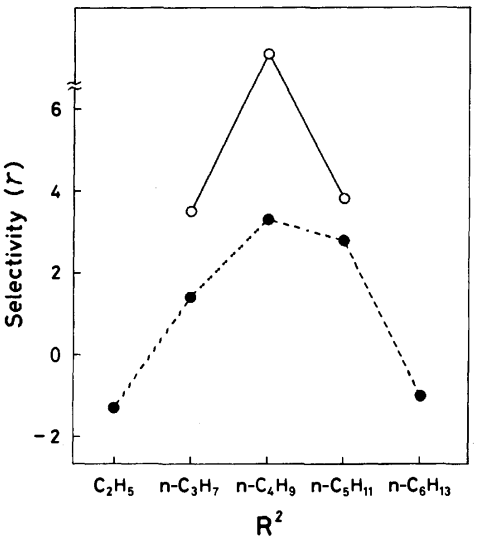


Fig. 1. Dependence of the selectivity (r) in oxidation of a pair of thiols (**1a** and **2**) on the structures of R^2 at 35.0 °C. ●, In aqueous acetonitrile [mole fraction of water (x_w)=0.42]; ○, in aqueous ethanol (x_w=0.75).

Table 2. Yields of Disulfides (**4** and **3**) and Selectivity (r) in Oxidation of **1a** and **2b—d** at 35.0 °C in Aqueous EtOH (x_w=0.75)

R^2	Yield/%		r[a]
	4	**3**	
n-C_3H_7	91.8	1.5	3.4±0.1
n-C_4H_9	88.1	<0.1	>6
n-C_5H_{11}	94.0	1.1	3.8±0.2

a) Errors given are the standard deviations.

Fig. 2. Association scheme in a typical tetramer **6**. -----, Hydrogen bonds in dimers; ·····, noncovalent weak interactions responsible for stabilization of tetramers. The symbols X' and Y' represent R^1 and R^2, respectively.

In connection with the observations that the selectivity in the oxidation is sensitive to temperature,[1] we examined the temperature dependence of r values (R^1=n-C_4H_9) in aqueous acetonitrile (x_w=0.42). Unexpectedly, the r values at 20.0 °C remain almost unchanged with the structures of R^2: 3.7±0.1 (n-C_3H_7), 3.6±0.1 (n-C_4H_9), and 3.8±0.1 (n-C_5H_{11}). Furthermore, at a higher temperature (i.e., 50.0 °C), r values increase progressively with increasing number of carbon atoms in R^2: −0.59±0.04 (n-C_3H_7), 2.2±0.1 (n-C_4H_9), and 3.0±0.1 (n-C_5H_{11}).[5]

The findings shown in Fig. 1 are not understandable in terms of the following factors influencing chemical selectivity. First, electronic effects of R^2 fail to account for the selectivity data, because the order of σ_p values[7] for R^2 [−0.15 (C_2H_5), −0.13 (n-C_3H_7), −0.16 (n-C_4H_9), and −0.15 (n-C_5H_{11})] differs sharply from that of the corresponding r values (Fig. 1). Second, steric effects cannot explain the observed selectivity, because the order of E_s values for R^2 [−0.07 (C_2H_5), −0.36 (n-C_3H_7), −0.39 (n-C_4H_9), and −0.40 (n-C_5H_{11})][8] differs essentially from that of the corresponding r values (Fig. 1).[9] Third, the hydrophobic effect is not responsible for the selectivity data, because π values[11] increase with increasing number of carbon atoms in straight-chain alkyl groups, the π being a measure of the hydrophobic effect. Fourth, the reactivity differences between thiols **1a** and **2** cannot explain the selectivity. This is because r values should be negative, regardless of the structures of R^2, if the selectivity depends upon the reactivity differences: r values are largely positive for R^2=n-C_3H_7, n-C_4H_9, and n-C_5H_{11} (Fig. 1).

It has been shown that (i) the oxidation proceeds through tetramers (reaction intermediates) such as **6** (Fig. 2), which are formed by dimerization of dimers produced from **1** and **2** through two NH ··· O intermolecular hydrogen bonds between the inner -NHCO- units in the -CONHCONH- groups[12] and (ii) the product ratio in this type of oxidation is kinetically controlled.[1]

In conclusion, the experimental results and discussions presented here demonstrate that the similarity recognition hypothesis holds true for straight-chain alkyl groups at temperatures around 35 °C.

Experimental

The melting points were uncorrected. ^{1}H NMR (270 MHz) spectra were measured on a JEOL GX-270 spectrometer using tetramethylsilane as an internal standard. The mass spectra were taken on a Hitachi RMU-6M mass spectrometer.

Materials. Acetonitrile was dried, purified by distillation from calcium hydride and phosphorus pentaoxide, and stored over molecular sieves. Water was distilled after deionization. Ethanol was dried, purified by distillation from magnesium ethoxide,[13] and stored over molecular sieves.

Thiol **1a** was prepared as described before,[14] recrystallized from ether-hexane, and had the following properties: Mp 104—105 °C; ^{1}H NMR ($CDCl_3$) δ=0.94 (3H, t, J=7 Hz), 1.31—1.60 (4H, m), 2.09 (1H, t, J=9 Hz), 3.27—3.34 (4H, m), 8.29 (1H, s), 9.57 (1H, s). Found: C, 44.09; H, 7.56; N, 14.54; S, 17.30%; M^+, 190. Calcd for $C_7H_{14}N_2O_2S$: C, 44.19; H, 7.42; N, 14.72; S, 16.85%; M, 190.

Thiols **2** were synthesized as described before,[1b] recrystallized from ether-hexane, and had the following properties.

2a: Mp 117.5—119.0 °C; ^{1}H NMR ($CDCl_3$) δ=1.19 (3H, t, J=7 Hz), 1.43 (1H, t, J=8 Hz), 2.38 (2H, q, J=7 Hz), 2.67—2.75 (2H, m), 3.47—3.54 (2H, m), 8.79 (2H, s). Found: C, 41.16; H, 6.79; N, 15.98; S, 18.17%; M^+, 176. Calcd for $C_6H_{12}N_2O_2S$: C, 40.90; H, 6.87; N, 15.90; S, 18.17%; M, 176.

2b: Mp 119—120 °C; ^{1}H NMR ($CDCl_3$) δ=0.98 (3H, t, J=7 Hz), 1.42 (1H, t, J=9 Hz), 1.63—1.74 (2H, m), 2.31 (2H, t, J=7 Hz), 2.66—2.75 (2H, m), 3.46—3.53 (2H, m), 8.76 (2H, s). Found: C, 44.12; H, 7.51; N, 14.56; S, 17.11%; M^+, 190. Calcd for $C_7H_{14}N_2O_2S$: C, 44.19; H, 7.42; N, 14.72; S, 16.85%; M, 190.

2c: Mp 105.5—106.0 °C; ^{1}H NMR ($CDCl_3$) δ=0.94 (3H, t, J=7 Hz), 1.31—1.45 (3H, m), 1.59—1.70 (2H, m), 2.33 (2H, t, J=7 Hz), 2.66—2.74 (2H, m), 3.46—3.53 (2H, m), 8.79 (2H, s). Found: C, 47.18; H, 7.74; N, 13.66; S, 15.85%; M^+, 204. Calcd for $C_8H_{16}N_2O_2S$: C, 47.05; H, 7.90; N, 13.73; S, 15.67%; M, 204.

2d: Mp 107.5—108.5 °C; ^{1}H NMR ($CDCl_3$) δ=0.91 (3H, t, J=7 Hz), 1.30—1.45 (5H, m), 1.61—1.69 (2H, m), 2.32 (2H, t, J=8 Hz), 2.66—2.86 (2H, m), 3.46—3.53 (2H, m), 8.79 (2H, s). Found: C, 49.26; H, 8.38; N, 12.76; S, 14.74%; M^+, 218. Calcd for $C_9H_{18}N_2O_2S$: C, 49.52; H, 8.31; N, 12.83; S, 14.69%; M, 218.

2e: Mp 102—103 °C; ^{1}H NMR ($CDCl_3$) δ=0.86—0.91 (3H, m), 1.30—1.45 (7H, m), 1.60—1.68 (2H, m), 2.32 (2H, t, J=7 Hz), 2.66—2.74 (2H, m), 3.46—3.53 (2H, m), 8.73 (2H, s). Found: C, 51.89; H, 8.67; N, 12.08; S, 14.01%; M^+, 232. Calcd for $C_{10}H_{20}N_2O_2S$: C, 51.70; H, 8.68; N, 12.06; S, 13.78%; M, 232.

Symmetrical disulfide **3** (R^1=n-C_4H_9) was prepared as described before,[1b] and had the following properties: Mp 195—197 °C [tetrahydrofuran (THF)]; ^{1}H NMR (dimethyl-d_6 sulfoxide) δ=1.20 (6H, t, J=7 Hz), 1.56—1.79 (8H, m), 3.4—3.5 (4H, m), 3.97 (4H, s), 8.49 (2H, s), 10.75 (2H, s). Found: m/z 378.1380. Calcd for $C_{14}H_{26}N_4O_4S_2$: M, 378.1398.

Unsymmetrical disulfides **4** (R^1=n-C_4H_9) were synthesized as described before,[15] and had the following properties.

4a (R^2=C_2H_5): Mp 161.5—162.5 °C (MeCN); ^{1}H NMR ($CDCl_3$) δ=0.93 (3H, t, J=7 Hz), 1.18 (3H, t, J=8 Hz), 1.39—1.57 (4H, m), 2.36—2.41 (2H, m), 2.87—2.92 (2H, m), 3.28—3.30 (2H, m), 3.58 (2H, s), 3.61—3.70 (2H, m), 8.37 (1H, s), 8.74 (1H, s), 9.39 (1H, s), 9.83 (1H, s). Found: m/z 364.1205. Calcd for $C_{13}H_{24}N_4O_4S_2$: M, 364.1241.

4b (R^2=*n*-C_3H_7): Mp 171.0—173.5 °C (THF); ^{1}H NMR ($CDCl_3$) δ=0.91—1.00 (6H, m), 1.33—1.42 (2H, m), 1.50—1.58 (2H, m), 1.65—1.73 (2H, m), 2.34 (2H, t, J=7 Hz), 2.91 (2H, t, J=6 Hz), 3.27—3.34 (2H, m), 3.52 (2H, s), 3.65—3.72 (2H, m), 8.36 (1H, s), 8.76 (1H, s), 9.50 (1H, s), 10.18 (1H, s). Found: m/z 378.1410. Calcd for $C_{14}H_{26}N_4O_4S_2$: M, 378.1398.

4c (R^2=*n*-C_4H_9): Mp 174—176 °C (THF); ^{1}H NMR ($CDCl_3$) δ=0.91—0.96 (6H, m), 1.33—1.64 (8H, m), 2.36 (2H, t, J=7 Hz), 2.91 (2H, t, J=6 Hz), 3.29—3.31 (2H, m), 3.52 (2H, s), 3.69—3.71 (2H, m), 8.34 (1H, s), 8.73 (1H, s), 9.34 (1H, s), 10.08 (1H, s). Found: m/z 392.1567. Calcd for $C_{15}H_{28}N_4O_4S_2$: M, 392.1554.

4d (R^2=*n*-C_5H_{11}): Mp 168.0—169.5 °C (THF); ^{1}H NMR ($CDCl_3$) δ=0.88—0.96 (6H, m), 1.32—1.66 (10H, m), 2.35 (2H, t, J=7 Hz), 2.91 (2H, t, J=6 Hz), 3.29—3.31 (2H, m), 3.51 (2H, s), 3.68—3.70 (2H, m), 8.35 (1H, s), 8.76 (1H, s), 9.54 (1H, s), 10.24 (1H, s). Found: m/z 406.1725. Calcd for $C_{16}H_{30}N_4O_4S_2$: M, 406.1711.

4e (R^2=*n*-C_6H_{13}): Mp 174—175 °C (MeCN); ^{1}H NMR ($CDCl_3$) δ=0.89—0.96 (6H, m), 1.2—1.7 (12H, m), 2.3—2.4 (2H, m), 2.8—3.0 (2H, m), 3.2—3.4 (2H, m), 3.53 (2H, s), 3.6—3.8 (2H, m), 8.35 (1H, s), 8.73 (1H, s), 9.25 (1H, s), 9.99 (1H, s). Found: m/z 420.1859. Calcd for $C_{17}H_{32}N_4O_4S_2$: M, 420.1868.

Oxidation of a Pair of Thiols. A mixture of **1a** (0.50 mmol) and **2** (0.50 mmol) in 12.5 ml of the solvent was stirred vigorously under oxygen for 15 min in a well-stirred water bath which was thermostated to ±0.1 °C. To this mixture was added Et_3N (0.05 mmol), and vigorous stirring was continued for the time required to complete the oxidation. When the oxidation was completed, the reaction mixture was evaporated to dryness. The yields of **3** and **4** in the reaction mixture were determined exactly by an integrator after separation by HPLC using LiChrosorb CN [hexane–isopropyl alcohol (94 : 6—97 : 3)]. The r values are reproducible in two or more experiments within the errors described in Tables 1 and 2.

We thank Mr. Hajime Ishijima and Mr. Kazuo Tanaka, JEOL, for measuring high resolution mass spectra. We are grateful to Mr. Koki Tajima for his valuable assistance. This work was partly supported by a Grant-in-Aid for Scientific Research No. 61226012 from the Ministry of Education, Science and Culture.

Partially Benzylated Derivatives of 6-Deoxy-D-glucose

Shinkiti KOTO,* Naohiko MORISHIMA,[1] Yoko MORI,[1] Hitoshi TANAKA, Seiichi HAYASHI, Yumi IWAI, and Shonosuke ZEN
School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108
(Received January 24, 1987)

Synopsis. Several partially benzylated derivatives of 6-deoxy-D-glucose (D-quinovose) were synthesized from appropriate di-*O*-benzyl-D-glucosides whose primary hydroxyl group is unprotected, via unimolar tosylation and subsequent reduction with $LiAlH_4$.

6-Deoxy-D-glucose (D-quinovose, **1**) consititutes various sugar-clusters occurring in saponins, antibiotics, etc.[2] An attempt to synthesize such clusters by a direct coupling reaction[3] between a protected saccharide with a hemiacetal OH and that with the OH to be glycosylated requires various benzyl derivatives of **1**. This report describes the synthetic routes for several D-quinovosyl donors and glycosyl acceptors of **1** from the known di-*O*-benzyl derivatives of appropriate D-glucosides with unprotected 6-OH.

The acceptor **13** had been synthesized from **11**[4] via unimolar tosylation and reduction by $LiAlH_4$ (LAH).[5] This routine was carried out for **2**[6] and **5**[7] to give **4** and **7**, respectively. Compound **7** was also obtained by a controlled benzylation[8] of **10**.

As for donors, **17** was first synthesized from **14**[9] via benzylation with $PhCH_2Br$ and NaH in DMF,[10] reduction and hydrolysis. It was found that an analogous benzylation of **14** in DMSO[11] mainly gave the 2,4-dibenzyl ether **23**.

The replacement of one benzyl of **17** with participating Ac or non-participating allyl (AL) as a temporary protecting group[12] was then carried out. The 2-*O*-AL derivative **21** was synthesized from **18**[6] via tosylation and reduction, followed by allylation and hydrolysis. This process was also applied for the conversion of **22**[7] and **26**[13] into **25** and **29**, respectively.

The 2-*O*-Ac derivative **32** was synthesized from **31** by a through-process including orthoester formation.[14] The starting **31** was prepared from **14**[9] via LAH-reduction,[15] acetylation and acetolysis. On the other hand, the 3- and the 4-*O*-acetates **38** and **43** were syn-

thesized from the 2-methoxyethyl (ME) glucoside **33**.[16] The acetate **35** derived from **33** was directly converted into the 2,4-dibenzyl ether **36** by a controlled benzylation[8,17] with $PhCH_2Cl$ and KOH in a 37% yield. The structure of the acetate **37** was confirmed by the measurement of ^1H NMR at 400 MHz; the most deshielded (δ=5.19) was H-3 among five ring protons.[8] Regeneration of 1-OH[17] gave **38**. The dibenzyl ether **40** was transformed into **43** via tosylation and reduction, followed by acetylation and regeneration of 1-OH.

Experimental[3,6-8]

The solvent systems for gradient elusion for column chromatography on silica gel were toluene-2-butanone (TB), hexane-EtOAc (HE), and $CHCl_3$-MeOH (CM).

Benzyl 3,4-Di-*O*-benzyl-6-*O*-tosyl-α-D-glucopyranoside (3). To a flask containing **2**[6] (443 mg) and tosyl chloride (225 mg), pyridine (4.5 ml) was added under stirring at −10 °C. The mixture was stirred for 1 h and then left for 3 h at room temp. Work-up[9] and chromatography (TB) gave **3** (378 mg, 64%).

A similar procedure was applied for **5**,[7] **8**,[18] **11**,[4] **18**,[6] **22**,[7] **26**,[13] **33**,[16] and **40** to give **6** (71%), **9** (60%, CM instead of TB), **12** (82%), **19** (75%), **23** (91%), **27** (75%), **34** (75%, CM instead of TB), and **41** (65%), respectively.

Benzyl 3,4-Di-*O*-benzyl-6-deoxy-α-D-glucopyranoside (4). Compound **3** (269 mg) was refluxed in Et_2O (6 ml) containing LAH (70 mg) for 1 h. After quenching with EtOAc, filtration, and evaporation, chromatography (TB) gave **4** (179 mg, 92%).

A similar reduction was carried out for **6**, **12**, **15**, **19**, **23**, **27**, and **41** to afford **7** (74%), **13** (100%), **16** (98%), **20** (97%), **24** (84%), **28** (84%), and **42** (84%), respectively.

Methyl 2,3,4-Tri- and 2,4-Di-*O*-benzyl-6-*O*-tosyl-α-D-glucopyranosides (15 and 23). To a mixture of **14** (305 mg), $PhCH_2Br$ (1.2 ml) and DMF (3 ml), NaH in oil suspension (300 mg; 60% of NaH by wt) was added at 0 °C. The mixture was stirred for 50 min and then for 40 min at room temp. Work-up[10] and chromatography (HE) gave **15** (413 mg, 76%).

An analogous benzylation of **14** (154 mg) using $PhCH_2Br$ (0.45 ml), NaH in oil suspension (74 mg; 60% of NaH by wt), and DMSO (1.7 ml) for 45 min at 15 °C gave **15** (≈70 mg, ≈25%) and **23** (116 mg, 50%).

Benzyl 2,4-Di-*O*-benzyl-6-deoxy-α-D-glucopyranoside (7). Compound **10** (33.3 mg) was stirred in $PhCH_2Cl$ (0.7 ml) containing crushed KOH (22 mg) for 1 h at 120 °C, followed by work-up and chromatography (TB),[8] to give **7** (30.4 mg, 53%).

2,3,4-Tri-*O*-benzyl-6-deoxy-D-glucopyranose (17). A mixture of **16** (295 mg), AcOH (4 ml), and aq H_2SO_4 (3M (M=mol dm^{-3}), 0.05 ml) was stirred for 2 h at 90 °C. Work-up and chromatography (TB)[19] gave **17** (118 mg, 42%).

2-*O*-Allyl-3,4-di-*O*-benzyl-6-deoxy-D-glucopyranose (21). A mixture of **20** (80.4 mg), NaH in oil suspension (40.4 mg; 60% of NaH by wt), and ALBr (0.58 ml) was refluxed for 40 min. Filtration and evaporation gave a residue, which was stirred in a mixture of AcOH (1.6 ml) and aq H_2SO_4 (3M, 26

μl) for 1 h at 100 °C. Work-up and chromatography (TB)[19] gave **21** (39.3 mg, 46%).

A similar procedure was applied for **24** and **28** to furnish **25** (56%) and **29** (62%), respectively.

Methyl 2,3,4-Tri-*O*-acetyl-6-deoxy-α-D-glucopyranoside (30). A mixture of **14**[9] (500 mg), LAH (145 mg), and Et_2O (15 ml) was refluxed for 4 h. After quenching with EtOAc, filtration, and evaporation,[15] the solid obtained was acetylated with Ac_2O (10 ml) in pyridine (10 ml) for 2h at 80 °C. Evaporation and chromatography (TB) gave **30** (333 mg, 77% (Found: C, 51.50; H, 6.72%)), mp 73—75 °C, $[\alpha]_D^{20}$ +156° (*c* 0.8, $CHCl_3$) (lit,[20] mp 76—77 °C, $[\alpha]_D^{20}$ +153° (*c* 1.6, $CHCl_3$)).

A similar procedure was applied for **34** to give **35** (50%). The tosylate **9** was similarly reduced, followed by chromatography (CM) without acetylation, to give **10** (63%).

1,2,3,4-Tetra-*O*-acetyl-6-deoxy-α-D-glucopyranose (31). To a soln of **30** (107 mg) in Ac_2O (2.2 ml), a soln of H_2SO_4 in Ac_2O (10%, 1.2 ml) was added at 0 °C. The mixture was stirred for 1 h at room temp and then poured onto ice. Work-up and chromatography (TB) gave **31** (75.2 mg, 64% (Found: C, 50.68; H, 6.13%)), mp 116—118 °C, $[\alpha]_D^{20}$ +113° (*c* 0.3, $CHCl_3$) (lit,[21] mp 117 °C, $[\alpha]_D^{20}$ +122° (*c* 1.3, $CHCl_3$)).

2-*O*-Acetyl-3,4-di-*O*-benzyl-6-deoxy-D-glucopyranose (32). To a soln of **31** (72.4 mg) in $CHCl_3$ (1 ml) containing AcBr (86 μl), H_2O (15 μl) was added at 0 °C. The mixture was stirred for 1 h at room temp and then evaporated. The residue was treated with 2,6-dimethylpyridine (0.14 ml) and ethanol (0.17 ml) in $MeNO_2$ (0.26 ml) overnight at room temp. The soln was diluted with $CHCl_3$ and poured into aq $NaHCO_3$ (5%, 5 ml). The organic layer was evaporated and then stirred in $PhCH_2Cl$ (1.5 ml) containing KOH (0.63 g) for 2 h at 120 °C. The mixture was diluted with toluene and washed with H_2O. The organic layer was evaporated and then stirred in aq AcOH (80%, 2 ml) for 1 h at 50 °C. Work-up and chromatography (TB)[14] gave **36** (33.0 mg, 39%).

2-Methoxyethyl 2,4-Di-*O*-benzyl-6-deoxy-β-D-glucopyranoside (36). A mixture of **35** (63.6 mg), crushed KOH (71.6 mg) and $PhCH_2Cl$ (1.5 ml) was stirred for 3.5 h at 100 °C. Work-up and chromatography (TB)[8] gave **36** (27.6 mg, 38%).

3-*O*-Acetyl-2,4-di-*O*-benzyl-6-deoxy-D-glucopyranose (38). Acetylation of **36** (27.5 mg) with Ac_2O (1 ml) and pyridine (1 ml), followed by chromatography (TB), gave **37** (28.4 mg); ^1H NMR recorded with a Varian XL-400 spectrometer in H-H COSY mode (CCl_4) δ=1.31 (3H, d, $J_{5,6}$=6.0 Hz, $C\underline{H}_3$-5), 1.98 (3H, s, $C\underline{H}_3CO$), 3.17 (1H, t, $J_{3,4}$=$J_{4,5}$=9.5 Hz, H-4), 3.33 (1H, dd, $J_{1,2}$=8.0 Hz, $J_{2,3}$=9.5 Hz, H-2), 3.38 (3H, s, $C\underline{H}_3O$), 3.46 (1H, m, H-5), 4.48 (1H, d, H-1), 5.19 (1H, t, H-3). This was then treated with $TiCl_4$ (4.3 μl) in CH_2Cl_2 (0.6 ml) for 15 min at room temp, processed, and adsorbed on silica-gel column.[17] The column was left overnight and then eluted with TB to give **38** (18.9 mg, 72% form **36**).

A similar two-step routine for **42** gave **43** (74%).

2-Methoxyethyl 4,6-*O*-Benzylidene-β-D-glucopyranoside (39). Compound **33**[16] (6.28 g) was treated with PhCHO (45 ml) containing $ZnCl_2$ (7 g) for 5.5 h at room temp. Work-up and crystallization with diisopropyl ether furnished **39** (5.72 g, 66%).

2-Methoxyethyl 2,3-Di-*O*-benzyl-β-D-glucopyranoside (40). The acetal **39** (300 mg) was stirred in $PhCH_2Cl$ (6 ml) containing KOH (0.8 g) for 5 h at 100 °C. After filtration and evaporation, the residue was stirred in aq AcOH (80%, 6 ml) for 0.3 h at 100 °C. Work-up and chromatography (TB) gave **40** (314 mg, 82%).

List of characteristic signals (δ) of ^1H NMR recorded at 90 MHz with a Varian EM-390 spectrometer (T=CCl_4, C=$CDCl_3$, W=D_2O (ext. Spin-Trapping of Alkyl Radicals by a Water-Soluble Nitroso Aromatic Spin-Trap, 3,5-Dibromo-4-nitrosobenzenesulfonate

Toshihiko OZAWA* and Akira HANAKI
National Institute of Radiological Sciences, 9-1 Anagawa-4-chome, Chiba 260
(Received January 29, 1987)

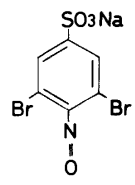
Synopsis. Some short-lived alkyl radicals generated by the oxidation with either Ti^{3+}-H_2O_2 or Fe^{2+}-H_2O_2 system were trapped by a water-soluble nitroso aromatic spin-trap, 3,5-dibromo-4-nitrosobenzenesulfonate (DBNBS, **1**), in aqueous solutions to yield the stable spin-adducts which could be easily detected and identified by electron spin resonance (ESR) spectroscopy.

The spin-trapping compounds react with the short-lived free radicals to form the more stable radical products, spin adducts, which can be detected and identified by electron spin resonance (ESR) technique.[1-6] Recently, a new water-soluble spin-trap, sodium 3,5-dibromo-4-nitrosobenzenesulfonate (DBNBS, **1**), was synthesized and was found to be an efficient radical trap in aqueous, or partially aqueous, solutions.[7] This new spin-trap does not yield observable spin adduct with hydroxyl radical (OH·) which is formed by the photolysis of hydrogen peroxide (H_2O_2), but dimethyl sulfoxide (DMSO) included in the aqueous H_2O_2 system gives the adduct with methyl radical which arises via hydroxyl radical attack on DMSO.[8]

In a previous paper,[9] we have reported that superoxide ion, O_2^-, can be easily trapped by DBNBS in aqueous solutions and that besides the intense signal due to O_2^- adduct, weak ESR signals assignable to methyl radical adduct are observed. Then, using DBNBS, we have further investigated the oxidation of some organic substrates by Fenton-type systems such as Ti^{3+}-H_2O_2 and Fe^{2+}-H_2O_2, both of which are known to be potent oxidizing agents,[10] and found that these Fenton-type systems give radical adducts similar to those obtained by the photolysis of the aqueous H_2O_2 system containing some organic substrates.

Experimental

Reagents. $TiCl_3$ (20% v/v), $FeCl_2$, and sulfuric acid (H_2SO_4) were purchased from Wako Pure Chemical Co. Ltd. and were used without further purification. H_2O_2 (30%) was obtained from Mitsubishi Gas Chemical Co. Ltd. Organic substrates were commercially available and were distilled prior to use. Deionized and triply distilled water was used throughout. Sodium 3,5-dibromo-4-nitrosobenzenesulfonate (DBNBS, **1**) was synthesized from 3,5-dibromosulfanilic acid by oxidation with H_2O_2 in glacial acetic acid.[7]



(1)

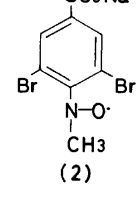
Procedure. Both 0.01 mol dm^{-3} metal ion (Ti^{3+} or Fe^{2+}) and 0.1 mol dm^{-3} H_2O_2 solutions were acidified by H_2SO_4 to pH 2.0. DBNBS (0.05 mol dm^{-3}) and organic substrates (0.1 mol dm^{-3}) were included in the aqueous H_2O_2 solutions. Reactions were started by adding the metal ion solutions to H_2O_2 solutions. The reaction solutions were immediately transferred to a JEOL quartz flat cell to measure ESR spectra. All the procedures were done in the air.

ESR Measurements. ESR spectra were obtained at room temperature on a JEOL-PE-1X (X-band) ESR spectrometer with 100 kHz field modulation. ESR parameters were calibrated by comparison with a standard Mn^{2+}/MgO marker and 2,2-diphenyl-1-picrylhydrazyl (DPPH, g=2.0036).

Results and Discussion

No ESR spectrum was observed from the following aqueous solutions: DBNBS, metal ion (Ti^{3+} or Fe^{2+}) with DBNBS, H_2O_2 with DBNBS.

When aqueous solutions of Ti^{3+} ion were mixed with aqueous solutions of H_2O_2 containing DBNBS, no ESR signal was observed. This result is consistent with the fact that DBNBS does not yield observable spin adduct with hydroxyl radical.[7,9,11] However, when DMSO was included in Ti^{3+}-H_2O_2-DBNBS system, an intensive ESR spectrum was observed as shown in Fig. 1. ESR parameters can be determined as follows: a^N (1)=13.9 G,[12] $a^H_{CH_3}$ (3)=12.8 G, a^H_{phenyl} (2)=0.7 G and g=2.0062 (1G=10^{-4} T). The ESR spectrum shown in Fig. 1 is almost identical with that of methyl radical adduct of DBNBS generated by the photolysis of aqueous solutions of H_2O_2 containing DMSO in the presence of DBNBS.[7] Therefore, the radical species observed in Fig. 1 can be assigned to the methyl radical adduct (**2**). In the Ti^{3+}-H_2O_2 system



(2)

containing DMSO, methyl radical may be formed as follows:

$$Ti^{3+} + H_2O_2 \rightarrow Ti^{4+} + \cdot OH + OH^- \quad (1)$$

$$\cdot OH + (CH_3)_2SO \rightarrow CH_3SO_2H + CH_3\cdot \quad (2)$$

$$CH_3\cdot + \text{DBNBS} \rightarrow \text{methyl radical adduct (2)} \quad (3)$$

It is known that methyl radical is formed by the OH radical attack on DMSO (Eq. 2).[8] In Fig. 1, ESR spectrum is somewhat asymmetrical. Such a spectral pattern is often observed in even relatively small nitroxide molecules in aprotic media.[13] This phenomenon may be caused by anisotropic motion in isotropic media.[13]

When methyl alcohol was included in Ti^{3+}-H_2O_2-DBNBS system, ESR spectrum [a^N (1)=13.4 G, $a^H_{CH_2}$ (2)=7.4 G, a^H_{phenyl} (2)=0.8 G, and g=2.0064] was observed. Since these ESR parameters are almost identical with those

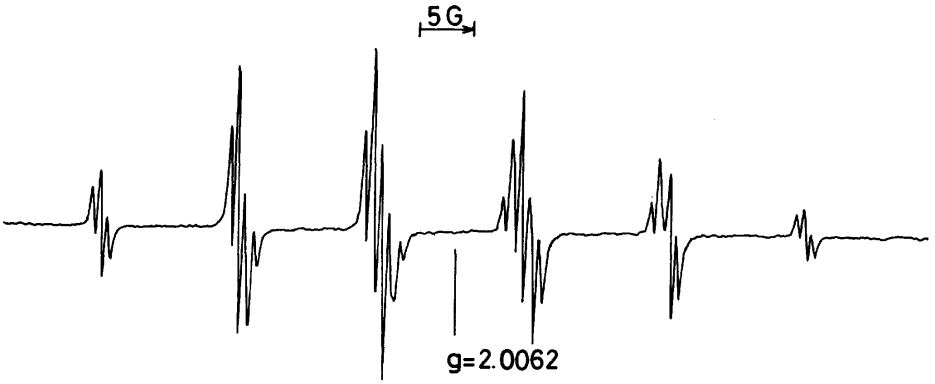


Fig. 1. ESR spectrum observed by the oxidation of DMSO with Ti^{3+}-H_2O_2 system in the presence of DBNBS in aqueous solutions.
Reaction conditions: 0.01 mol dm^{-3} Ti^{3+}, 0.1 mol dm^{-3} H_2O_2, 0.05 mol dm^{-3} DBNBS, 0.1 mol dm^{-3} DMSO. Instrument settings: microwave power, 10 mW; modulation amplitude, 0.5 G; amplitude, 10×100; time constant, 0.3 s; scan time, 8 min.

Table 1. ESR Parameters for Selected Spin Adducts of DBNBS

Substrate	Trapped radical	Method of generation of radical	Hyperfine splitting const (G)		
			a^N	a^H_{phenyl}	a^H_{other}
DMSO	CH_3·	Ti^{3+}-H_2O_2	13.9	0.7	12.8 (CH_3)
	CH_3·	Fe^{2+}-H_2O_2	14.1	0.7	13.3 (CH_3)
	CH_3·	$h\nu$-H_2O_2[a]	14.50		13.50(CH_3)
CH_3OH	$\dot{C}H_2OH$	Ti^{3+}-H_2O_2	13.4	0.8	7.4 (CH_2)
	$\dot{C}H_2OH$	Fe^{2+}-H_2O_2	13.6	—[b]	9.1 (CH_2)
	$\dot{C}H_2OH$	$h\nu$-H_2O_2[a]	13.70		9.20(CH_2)
C_2H_5OH	$\dot{C}H_2CH_2OH$	Ti^{3+}-H_2O_2	14.2	—[b]	12.2 (CH_2)
					—[b] (CH_2)
	$\dot{C}H_2CH_2OH$[c]	Fe^{2+}-H_2O_2	14.3	—[b]	13.6 (CH_2)
					9.2 (CH_2)
	$\dot{C}H_2CH_2OH$	$h\nu$-H_2O_2[a]	14.00		11.30(CH_2)
	$CH_3\dot{C}HOH$	$h\nu$-H_2O_2[a]	14.00		9.20(CH)

a) Deuteriated DBNBS was used as a spin-trap.[7] b) Not measured. c) A weak, unanalyzable signal was also observed.

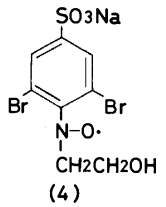
of hydroxymethyl radical (·CH_2OH) adduct of DBNBS formed by the photolysis of aqueous solutions of H_2O_2 containing methyl alcohol in the presence of DBNBS,[2] the radical species observed can be assigned to the radical (**3**). In this reaction, hydroxymethyl radical is formed as follows:

(3)

$$\cdot OH + CH_3OH \rightarrow \cdot CH_2OH + H_2O \quad (4)$$

$$\cdot CH_2OH + DBNBS \rightarrow \text{hydroxymethyl radical adduct (3)} \quad (5)$$

When ethyl alcohol was included in Ti^{3+}-H_2O_2-DBNBS system, a weak ESR spectrum [a^N (1)=14.2 G, $a^H_{CH_2}$ (2)=12.2 G, and g=2.0063] which could be assigned to hydroxyethyl radical (·CH_2-CH_2OH) adduct of DBNBS (**4**) was observed.



(4)

In this reaction system, another weak signal, which could not be analyzed, was also observed.

The same radical species were obtained from the Fe^{2+}-H_2O_2 system. These results are summarized in Table 1, along with the radical species observed by photolysis.

It is apparent from Table 1 that the same radical species were generated from both photolysis of H_2O_2 and Fenton-type reaction systems. However, the hyperfine coupling constants are somewhat different from each other, depending on the different reducing agents for H_2O_2.

The present experimental results indicate that a new water-soluble spin-trap, DBNBS, is an effective trapping agent for some alkyl radicals generated by the

oxidation with Fenton-type systems such as Ti^{3+}-H_2O_2 and Fe^{2+}-H_2O_2 in aqueous solutions. Recently, nitrone spin-traps such as 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO) and *N*-*t*-butyl-α-phenylnitrone (PBN) are often used in biological systems. DBNBS may be compared with DMPO and PBN. DBNBS has a high solubility in aqueous solutions compared with PBN and, while DMPO is susceptible to decomposition by light,[6] DBNBS in aqueous solutions is stable under light. Further, DBNBS does not yield the observable spin-adduct with OH radical. From these facts, it is indicated that DBNBS is a useful spin-trap in aqueous reaction systems in which OH radical is formed as a first intermediate.

We wish to express our thanks to Prof. Yutaka Kirino, Faculty of Pharmaceutical Sciences, Kyushu University, for valuable discussions.

Optical Resolution and Absolute Configuration of Axially Dissymmetric 2,2′-Dihydroxy-6,6′-dimethylbiphenyl

Shigeyoshi KANOH, Nobuyuki TAMURA, Masatoshi MOTOI, and Hiroshi SUDA*
Department of Chemistry and Chemical Engineering, Faculty of Technology, Kanazawa University, 2-40-20 Kodatsuno, Kanazawa 920
(Received February 10, 1987)

Synopsis. 2,2′-Dihydroxy-6,6′-dimethylbiphenyl (**1**) was successfully resolved into its optically pure forms by the recrystallization of the diastereomeric salts derived from the hydrogenphosphate of **1** and cinchonidine or quinine. The dextrorotatory **1** was determined to have R-configuration.

It is well-known that axially dissymmetric biaryl compounds possess salient ability for chiral recognition. 1,1′-Binaphthyl unit has been very common in the design and construction of chiral auxiliaries,[1] while biphenyl[2,3] and 9,9′- or 4,4′-biphenanthryl units[4] have been applied as well. When biaryl derivatives, even though the nuclei of which are different from each other, have the same functional groups, they serve in most cases as quite similar catalysts for an asymmetric reaction with respect to stereochemistry.[3,5] In some cases, however, we have observed that the stereochemical outcomes are in disagreement.[3,6] Inspection of such results might provide an important clue of the consideration on the structure of active species or the steric factors operating in the reaction. It seems, therefore, to be important to compare the chiral catalysts derived from analogous biaryl compounds.

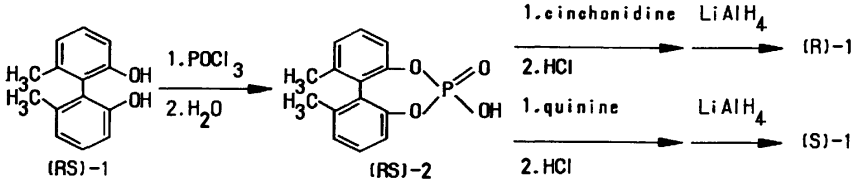
The most famous compound of a series of biaryls is 2,2′-dihydroxy-1,1′-binaphthyl, which is an important intermediate for the preparations of chiral crowns[7] and the *BINAL-H* reagent[8] as reported by Cram et al. and Noyori et al., respectively, and for the asymmetric Ullmann reaction as shown by Miyano.[9] More recently, its biphenanthryl analogs have been resolved on an optically active column in a preparative scale.[4]

Recently, we have reported briefly a synthesis of optically active 2,2′-dihydroxy-6,6′-dimethylbiphenyl (**1**) as a biphenyl analog and asymmetric reductions of alkyl phenyl ketones by using $LiAlH_4$- and borane-**1** complexes.[5,6] In this paper, we wish to describe the effective optical resolution of (*RS*)-**1** in more detail. In addition, each resolved **1** was confirmed to be optically pure, and the absolute configuration was determined.

The preparation of (*RS*)-**1** was carried out according to the method described in the literature.[10] The excellent method for the optical resolution of (*RS*)-2,2′-dihydroxy-1,1′-binaphthyl via its cyclic phosphate has been developed by Jacques et al.[11] The procedure is essentially applicable to the present case, as shown in the scheme. (*RS*)-**1** was easily converted to (*RS*)-6,6′-dimethylbiphenyl-2,2′-diyl hydrogenphosphate (**2**) by the reaction with phosphoryl chloride followed by hydrolysis in a high yield. We found that cinchonidine or quinine readily forms crystalline salt with the opposite enantiomer of **2** to each other. In the first step, the diastereomeric salts were prepared by mixing equimolar amounts of (*RS*)-**2** and cinchonidine in aqueous methanol. The crystalline salt deposited upon cooling, and the filtration afforded (*R*)-**2**·cinchonidine salt in a satisfactory yield of 45% based on (*RS*)-**2** used. The mother liquor containing the salt of (*S*)-enriched **2** was unsuitable for recrystallization. Crystallinity was greatly improved by employing quinine as a resolving reagent. Simple recrystallization of a mixture of the recovered **2** and an equimolar amount of quinine from aqueous methanol gave (*S*)-**2**·quinine salt in 40% yield. Further recrystallization of both salts of cinchonidine and quinine did not come about noticeable change in optical rotation. Decomposition of each salt with a diluted hydrochloric acid yielded (*R*)-(−)- and (*S*)-(+)-**2** in 42 and 38%, respectively. Each alkaloid used was recovered from the acidic filtrates. Reductive cleavage of (−)- and (+)-phosphates with $LiAlH_4$ yielded optically active **1** in 37 and 33%, respectively (overall yields based on the starting (*RS*)-**1**), whose specific rotations were $[\alpha]_D^{18}$ +91.5° and $[\alpha]_D^{20}$ −91.1° (*c* 1.0, ethanol), respectively.

The optical purity of each **1** thus resolved was determined from the ^1H NMR spectrum of the methyl 6,6′-dimethylbiphenyl-2,2′-diyl phosphate (**3**) derived from the intermediate **2**, in the presence of $Eu(tfc)_3$. The spectra are shown in Fig. 1. In the case of racemic **3**, the signals due to the aromatic methyl protons and the ester methyl protons split owing to the diastereomeric lanthanoide induced shift. On the other hand, each of the spectra, measured under the same conditions, of the optically active **3** shows the lack of the peaks due to opposed enantiomer. This fact reveals that each resolved **2** was optically pure.

The (R)-configuration of (+)-**1** was determined by



Scheme 1.

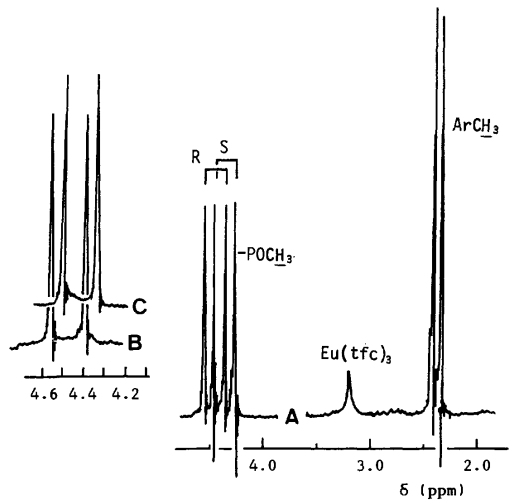


Fig. 1. ^{1}H NMR spectra of **3** (20 mg) in the presence of Eu(tfc)$_3$ (6 mg) in $CDCl_3$ (0.5 ml). A: (*RS*)-**3**, B: (*R*)-**3**, C: (*S*)-**3**.

chemical correlation with (+)-2,2′-diamino-6,6′-dimethylbiphenyl. The absolute configuration of the latter is known to be R from the X-ray crystallography of its *N,N′*-disalicylidene derivative,[12] and Sandmeyer-type reactions of biarylamines are known to proceed in a retention manner.[13] Thus, the optically pure (+)-diamine was treated with $NaNO_2$ in a diluted sulfuric acid. Thermal decomposition of the bis(diazonium) salt in an aqueous medium gave dextrorotatory **2**. The specific rotation ($[\alpha]_D^{19}$ +91.4° (*c* 1.0, ethanol)) is in good agreement with that observed for (+)-**1** resolved. This means that (+)-**1** has R-configuration.

More recently, Okamoto et al. have reported that racemic **1** of our sample can be directly resolved by a high performance liquid chromatography on optically active columns of cellulose tris(phenylcarbamate) derivatives.[14]

Experimental

Melting points are uncorrected. IR and NMR spectra were recorded on a JASCO A-202 and a JEOL JNM-PS-100 (100 MHz) spectrometer, respectively. Optical rotations were measured on a JASCO DIP-SL automatic polarimeter.

Racemic **1** was prepared through six-step reactions from *m*-cresol with slight modification of the reported method.[10] Mp 161.5—162.5 °C (lit,[10] 164 °C). IR (KBr) 3470, 3420, 1180 cm^{-1}. ^{1}H NMR (DMSO-d_6) δ=1.85 (s, 6H), 6.6—7.1 (m, 6H), 8.75 (s, 2H).

6,6′-Dimethylbiphenyl-2,2′-diyl Hydrogenphosphate (2). Fifty grams (0.23 mol) of (*RS*)-**1** and phosphoryl chloride (26 ml, 0.28 mol) were mixed in 230 ml of dichloromethane. Triethylamine (80 ml, 0.57 mol) was added dropwise to the stirred mixture under a gentle reflux. Reflux was continued for an additional 3 h. After cooling the precipitates were collected and washed thoroughly with cold water. The remaining solids were chlorophosphate of **1**. Extractive work-up of the filtrate led to an additional yield of the chloride. The combined crude chloride was hydrolyzed in a mixture of tetrahydrofuran (THF) (300 ml) and water (100 ml) with stirring at 50 °C for 3 h. The solution was freed from THF under reduced pressure, and the precipitates were collected. Recrystallization from aqueous methanol gave (*RS*)-**2** (61 g, 94% based on **1** used): mp 285—286 °C; IR (KBr) 3000—2000, 1255, 1215, 1020, 1000 cm^{-1}.

Optical Resolution of (*RS*)-2. All yields were based on (*RS*)-**2** used. Cinchonidine (68 g, 0.23 mol) and (*RS*)-**2** (61 g, 0.22 mol) were dissolved in 500 ml of boiling methanol. After the addition of 100 ml of water the solution was cooled in a refrigerator overnight. The crystals deposited were collected and washed with cold methanol to give (*R*)-**2**·cinchonidine salt (57 g, 45%): mp 185—188 °C (decomp); $[\alpha]_D^{24}$ −155° (*c* 0.5, methanol). The cinchonidine salt was decomposed in 6 mol dm^{-3} HCl (700 ml) with stirring at 50 °C for 1 h. After cooling the precipitates were collected. Recrystallization from aqueous methanol gave (*R*)-**2** (25.5 g, 42%): mp 299—305 °C (decomp); $[\alpha]_D^{19}$ −179° (*c* 0.5, methanol).

The (*S*)-enriched **2** was recovered by evaporating the mother liquor to dryness and subsequently treating the gamy residue with 6 mol dm^{-3} HCl. It was similarly reacted with an equimolar amount of quinine, and recrystallization from aqueous methanol gave (*S*)-**2**·quinine salt: mp 276—278 °C (decomp); $[\alpha]_D^{18}$ −43.0° (*c* 0.5, methanol). Decomposition of the salt followed by recrystallization in a similar way yielded (*S*)-**2** (23 g, 38%): mp 299—304 °C (decomp); $[\alpha]_D^{18}$ +177° (*c* 0.5, methanol).

Methyl 6,6′-Dimethylbiphenyl-2,2′-diyl Phosphate (3). In order to determine the optical purity of each resolved **2**, it was suspended in diethyl ether and treated with a large excess amount of diazomethane in ether. After standing overnight, removal of the solvent and drying under vacuum gave **3** in a nearly quantitative yield. The ^{1}H NMR spectrum of **3** (20 mg) was measured in a $CDCl_3$ solution (0.5 ml) containing Eu(tfc)$_3$ (6 mg) at room temperature. Crystalline **3** was obtained by recrystallizing from chloroform–ether in about 90% yield. (*RS*)-**3**: Mp 219—220 °C; IR (KBr) 2860, 1300, 1235, 1050, 1005 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.21 (s, 6H), 3.94 (d, 3H, J_{PH}=11 Hz), 7.0—7.5 (m, 6H). (*R*)-**3**: Mp 227—228 °C; $[\alpha]_D^{20}$ −119° (*c* 0.5, methanol). (*S*)-**3**: Mp 226—228 °C; $[\alpha]_D^{19}$ +117° (*c* 0.5, methanol).

(*R*)·/(*S*)-1. Powdered $LiAlH_4$ (8.4 g, 0.22 mol) was added in portions into a stirred suspension of the above phosphate (−)-**2** (25.5 g, 92 mmol) in dry THF (350 ml) at 0 °C. After the mixture was refluxed for 5 h, the reaction was quenched by successive additions of ethyl acetate, moist ether, and 6 mol dm^{-3} HCl with stirring at 0 °C. The organic layer was separated, washed with dil HCl and brine, and dried over Na_2SO_4. Evaporation of the solvents followed by recrystallization from benzene–petroleum ether gave (*R*)-**1** (18.4 g, 39% based on (*RS*)-**2** used): Mp 159—160 °C; $[\alpha]_D^{18}$ +91.5° (*c* 1.0, ethanol). Similarly, reduction of (+)-**2** led to (*S*)-**1** (16.5 g, 35%): Mp 159—160 °C; $[\alpha]_D^{20}$ −91.1° (*c* 1.0, ethanol).

Chemical Correlation between (+)-1 and (*R*)-2,2′-Diamino-6,6′-dimethylbiphenyl. A solution of the (*R*)-(+)-diamine (2.0 g, 9.3 mmol) ($[\alpha]_D^{25}$ +50.5° (*c* 1.0, ethanol))[15] in 25% aqueous sulfuric acid (25 ml) was cooled at 0 °C. To this was added an aqueous $NaNO_2$ (1.74 g, 25 mmol) with stirring at 0—5 °C. The resulting solution of the bis(diazonium) salt was occasionally dropped in small portions into a boiling solution of Na_2SO_4 (80 g) in 18 mol dm^{-3} H_2SO_4 (100 ml) over a period of 2 h. During the reaction, products were distilled away by bubbling steam into the reaction mixture. The distillate was extracted with ether. The organic layer was decolorized with charcoal and dried over Na_2SO_4. After the ether was removed, recrystallization gave (+)-**1** (0.17 g, 9%). The selected spectroscopic data were in agreement with those of the authentic sample. Mp 159—160 °C, $[\alpha]_D^{19}$ +91.4° (*c* 1.0, ethanol).

The authors are indebted to Dr. Yoshio Okamoto of Osaka University for the chromatographic separation of (*RS*)-**1** on the optically active cellulose column.

Synthesis of Liquid Hydrocarbons from Carbon Monoxide and Water with a Hybrid Catalyst

Hiro-o TOMINAGA, Michiharu MIYAUCHI, and Kaoru FUJIMOTO*
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Hongo, Tokyo 113
(Received October 16, 1986)

Synopsis. Liquid hydrocarbons were produced from carbon monoxide and water at temperatures from 220 to 280 °C and under moderately pressurized conditions (3 atm), by utilizing a hybrid catalyst composed of a Co/SiO_2 catalyst and a CO shift conversion catalyst. Most of the steam, either added or formed, was converted to hydrogen in the reaction of H_2O with CO on the CO shift catalyst.

It has been known that the synthesis gas produced by modern coal gasifiers has CO/H_2 ratios between 1 and 2.[1] On the other hand the CO/H_2 ratio of feed gas for the Fischer-Tropsch (F-T) synthesis is about 0.5. In order to regulate the difference, a part of CO should be converted to CO_2 and H_2 by the reaction with added steam, and the CO_2 is removed from the product by a conventional method.[2] In this process a CO shift converter is necessary and a large amount of steam is consumed.

Koelbel et al.[3] have demonstrated that CO and H_2O are able to be directly utilized with a precipitated iron catalyst to produce a hydrocarbon mixture. Since iron catalysts are active for the $CO-H_2$ reaction as well, a synthesis gas with high CO/H_2 ratio can be used for hydrocarbon synthesis without any added steam. Because, the water produced by the $CO-H_2$ reaction could be utilized to form hydrocarbons.

$$CO + 2H_2 \rightarrow -CH_2- + H_2O \quad (1)$$
$$2CO + H_2O \rightarrow -CH_2- + CO_2 \quad (2)$$
$$3CO + 2H_2 \rightarrow 2\text{-}CH_2- + CO_2 \quad (3)$$

The present authors examined the same reaction with a fused iron catalyst and found that the catalyst is quickly carbulized by CO and oxidized by water during the reaction to lose its catalytic activity.[4]

The authors have developed a highly active supported cobalt catalyst for the Fischer-Tropsch synthesis.[5] Although the catalyst is highly resistant to oxidation with water, it has little activity for the CO shift reaction. Thus, if the cobalt catalyst mixed with a CO shift catalyst is subjected to the synthesis gas reaction, CO and H_2 should react on the cobalt catalyst to form hydrocarbons and H_2O, then the resultant water should react in situ with CO, on the CO shift catalyst to form CO_2 and H_2.

$$CO + 2H_2 \rightarrow -CH_2- + H_2O \quad (4)$$
$$CO + H_2O \rightarrow H_2 + CO_2 \quad (5)$$
$$2CO + H_2 \rightarrow -CH_2- + CO_2 \quad (6)$$

Experimental

The hybrid catalyst was prepared by physically mixing the granules (20—40 mesh) of a 10 wt% Co/SiO_2 catalyst with a commercial available Cu-Cr oxide catalyst (Nikki N-201). The Co/SiO_2 catalyst was prepared by impregnating a commercially available silica gel (Fuji Davison ID gel) with cobalt nitrate from its aqueous solution, calcining in air at 450 °C for 3 h, and then reducing the catalyst precursor in hydrogen flow at 400 °C for 15 h. The reduced Co/SiO_2 catalyst was mixed with the Cu-Cr oxide catalyst under nitrogen atmosphere and packed in a tubular reactor. The hybrid catalyst was activated by reducing, in situ, in flowing hydrogen at 250 °C for 3 h.

The reaction was conducted using a fixed bed flow type reaction apparatus under pressurized conditions. The details of this apparatus has been described elsewhere.[3] Water was fed by a micro-feeder and was evaporated in a container connected to the upper part of the reactor. All products effused from the reactor were withdrawn in the gaseous states from the pressurized zone and were analyzed by gas chromatographs. The details of analysis has been described elsewhere.[6]

Results and Discussion

The catalytic activity of Nikki N-201 for the CO shift reaction was tested under conditions: 240 °C, 1—5 atm, CO/H_2O=3/1 (mole ratio) and was shown to keep 100% H_2O conversion for more than 24 h.

In Fig. 1 are shown the yields of hydrocarbons, CO_2, and methane over the hybrid catalyst as a function of process time. The yield of CO_2 decreased gradually from the initial value, 50% (on CO base) to 30% within about 6 h and reached a steady state. Also the yields of product hydrocarbons and methane decreased in the similar manner as that of CO_2. The decrease in CO_2 yield could be attributed most probably due to the covering of active sites on the CO shift catalyst by high-boiling hydrocarbons, because a hybrid catalyst containing a supported ruthenium catalyst, which pro-

duced higher hydrocarbons than the Co/SiO_2 catalyst, lost its activity more quickly. On the other hand, the decrease in the hydrocarbon formation should be attributed to the decrease in the partial pressure of hydrogen in the reaction mixture caused by the decrease in the conversion of CO and H_2O to hydrogen. All data described below were taken after the catalyst activity reached the steady state.

Some of the typical data of CO–H_2, CO–H_2O, and CO–H_2–H_2O reactions on the Co/SiO_2 catalyst or the hybrid catalyst are shown in Table 1 and Fig. 2. It is clear from the data in the table that while little CO_2 is formed on the Co/SiO_2 catalyst alone, almost all of water, irrespectively of that it is added or formed, reacted with CO to form CO_2 and hydrogen on the hybrid catalyst. For example, in experiments Nos. 2 and 3, the amount of CO_2 equal the sum of hydrocarbons (on carbon base) and added water. Since one molecule of water is formed for every one CO molecule reacted in the F-T synthesis reaction the sum of hydrocarbons and add water is the total amount of water supplied to the catalyst.

It should be also noted that the addition of steam to the system markedly accelerates its productivity of hydrocarbons, while the hydrocarbon productivity of the Co/SiO_2 catalyst was scarcely affected by the addition of CO shift catalyst only. It should be attributed to the increase in the practical partial pressure of hydrogen caused by CO shift reaction, because the rate of

hydrocarbon formation on the Co/SiO_2 catalyst is almost proportional to the partial pressure of hydrogen.[7]

The product pattern, shown in Fig. 2 and Table 1, is markedly affected by the CO shift catalyst and steam. The reaction of $CO-H_2O$ system gave a product rich in olefins and higher hydrocarbons (C_{15+}), whereas the $CO-H_2-H_2O$ reaction on the hybrid catalyst gave lower hydrocarbons rich in paraffins. The reaction of a synthesis gas ($2CO+1\ H_2$) on the Co/SiO_2 and the hybrid catalysts gave products with intermediate characters as compared with other two cases mentioned above. Although the carbon number distribution of the products from the Co/SiO_2 and the hybrid catalyst systems are fairly close to each other, the hybrid catalyst gave a product which is richer in methane and paraffins than that on the Co/SiO_2 catalyst.

The characteristic features mentioned above are well interpreted by the partial pressures of CO and H_2. As it has been well known high CO/H_2 ratio in the synthesis gas is favored for the production of high molecular weight hydrocarbons and high olefin content in the F-T synthesis. The CO/H_2 ratio in the reaction mixture is in the order: Run 2 > Run 3 > Run 4 > Run 1. The order is just the same as that of the average molecular weight and that of the olefin content in the product hydrocarbons.

Figures 3 and 4 illustrate the effects of reaction temperature on the product yields for the $CO-H_2-H_2O$ system and the $CO-H_2O$ system, respectively. In either system the yield of CO_2 reached the level which corresponds to 100% conversion of H_2O to H_2 and CO_2. The hydrocarbon yield increased monotonously with the increase in reaction temperature in the similar manner to that of the F-T synthesis on the same catalyst. The levels of hydrocarbon yield and space time yield were much higher for the $CO-H_2-H_2O$ system than the $CO-H_2O$ system because of the higher H_2 pressure and the lower CO pressure for the former system, as mentioned before.

This work was financially supported by the Special Grant for Energy Research from the Ministry of Education, Science and Culture, which is greatly appreciated.

Enthalpy and entropy changes for ion-pair extractions of tetraalkylammonium ions (Me_4N^+, Et_4N^+, n-Pr_4N^+, n-Bu_4N^+) with picrate anions, overall extractions of alkali metal (Na, K, Rb, Cs) picrates with 18-crown-6 (18C6), and distribution of 18C6 itself were determined between benzene and water, Me, Et, n-Pr, and n-Bu denoting methyl, ethyl, propyl, and butyl groups, respectively. All the extracted 18C6 complexes were 1:1:1 complexes (alkali metal ion:18C6:picrate anion). The values of enthalpy and entropy changes are negative for overall extractions of all the alkali metal picrates with 18C6. Plots of thermodynamic quantities for ion-pair extractions of R_4NA vs. the number of carbon atoms of R_4N^+ show a linear relationship, R_4N^+ and A^- being tetraalkylammonium ion and picrate anion, respectively. Enthalpy and entropy changes were calculated for ion-pair extractions of 18C6-alkali metal ion complexes with picrate anions. The thermodynamic parameters for ion-pair extractions of 18C6-alkali metal picrate complexes were compared with those of R_4NA, and were discussed in detail from the standpoint of molecular grounds. It was found from these data that the 18C6-K^+ complex acts as a structure breaker in water.

Numerous data have been presented on complexing power of crown compounds for metal ions. However, a few reports have been published on solvation properties of the crown compound complexes. Ion-pair extraction study of crown compound complexes provides very valuable information on solute-solvent interaction of the crown compound complexes in water.[1]

One of the principal objects of this paper is to investigate solvation behavior of the crown compound complexes in water. In the present work, enthalpy and entropy changes for ion-pair extraction of 18-crown-6 (18C6)-alkali metal ion complexes and tetraalkylammonium ions (R_4N^+) with picrate anions (A^-) have been determined between benzene and water. Thermodynamic quantities for ion-pair extraction of 18C6- and 15-crown-5 (15C5)-alkali metal picrate complexes were compared with those of R_4NA, and were discussed in detail from the standpoint of molecular grounds.

Experimental

Materials. Tetramethyl-, tetraethyl-, tetrapropyl-, and tetrabutylammonium hydroxides (Wako-Pure Chemicals Ltd.) were used as received. 18-Crown-6 (Nisso Co., Ltd.) was recrystallized from acetonitrile and, prior to use, dried at 80 °C in vacuo. Benzene, picric acid, $LiOH \cdot H_2O$, NaOH, and KOH were analytical grade reagents. Rubidium and caesium hydroxides were of reagent grade. Benzene was washed three times with distilled water.

Extraction Procedure. (1) Ion-pair extraction of tetraalkylammonium picrate. A benzene phase and an aqueous phase of R_4NOH (1.7×10^{-4}—3.2×10^{-2} M†), LiOH (0.1 M), and picric acid (4.2×10^{-5}—5.1×10^{-3} M) in stoppered glass tubes (30 ml) or Erlenmeyer flasks with stoppers (300 ml) were shaken for 2 h in a water bath thermostated at 20, 25, 30, 35, and 40±0.2 °C, and centrifuged. For Et_4NA, n-Pr_4NA, and n-Bu_4NA systems, the initial volume of each phase was 12 ml, whereas, for the Me_4NA system, those of benzene and aqueous phases were 200 and 20 ml, respectively. Extractions were conducted at pH 12.5—13.1. A portion of the benzene phase (10 ml for the former systems and 100 ml for the latter system) was transferred to a beaker and allowed to evaporate over several days. The residue was dissolved in 0.01 M NaOH aqueous solution (4 ml) and the picrate concentration was determined spectrophotometrically at 356 nm ($\varepsilon=1.45\times10^4$ cm^{-1} M^{-1}). (2) Extraction of alkali metal picrates with 18C6. Experimental procedures and concentrations of 18C6, alkali metal hydroxides, and picric acid were almost the same as those described in a previous paper.[2] Extractions were performed at pH 11.1—12.3 at 20, 30, 35, and 40±0.2 °C.

The Distribution Coefficient of 18C6. A 12 ml benzene solution of 18C6 (2.0×10^{-5}—9.3×10^{-4} M) and an equal volume of distilled water in a stoppered glass tube were shaken in a thermostated water bath for 1 h and centrifuged. A portion (11 ml) of the benzene phase and an equal volume of aqueous solution (pH 11.7—12.3) of KOH (3×10^{-2} M) and picric acid (8×10^{-3} M) were placed in a stoppered glass tube and agitated. After centrifuging, the picrate in the benzene phase was back-extracted into 8 ml of 0.01 M NaOH aqueous solution, and the picrate concentration was determined spectrophotometrically ($\lambda_{max}=356$ nm, $\varepsilon=1.45\times10^4$ cm^{-1} M^{-1}). Experiments were carried out at 20, 30, 35, and 40±0.2 °C. Each distribution coefficient value of 18C6 is the average of about seven measurements.

Results

Ion-Pair Extraction of R_4NA. In an equilibrium between benzene and an aqueous solution of R_4NA, the equilibrium constants are defined as

$$K_A(R_4NA) = [R_4NA]/[R_4N^+][A^-], \quad (1)$$

$$K_D(R_4NA) = [R_4NA]_o/[R_4NA], \quad (2)$$

† 1 M=1 mol dm^{-3}.

$$K_{ex,ip}(R_4NA) = [R_4NA]_o/[R_4N^+][A^-] = K_A(R_4NA)K_D(R_4NA), \quad (3)$$

where the subscript "o" and the lack of subscript denote the organic and aqueous phases, respectively. The distribution ratio of R_4N^+ is represented by

$$D = [R_4NA]_o/([R_4N^+] + [R_4NA]). \quad (4)$$

Combination of Eqs. 1—4 leads to

$$D^{-1} = K_D(R_4NA)^{-1} + (K_{ex,ip}(R_4NA)[A^-])^{-1}. \quad (5)$$

A plot of D^{-1} against $[A^-]^{-1}$ shows a straight line in every case. Values of $K_{ex,ip}(R_4NA)$ were calculated from the slopes of these straight lines. $K_D(R_4NA)$ and $K_A(R_4NA)$ values could be obtained only for the *n*-Bu_4NA system at 25 °C (K_D=4, K_A=1.4×10³). K_D values of *n*-Bu_4NA and K(18C6)A (3.7[3]) are almost the same, but, K_A value of *n*-Bu_4NA is one order of magnitude over that of K(18C6)A (140[3]).

$R\ln K_{ex,ip}(R_4NA)$ vs. T^{-1} plots are found to be linear in every system. Enthalpy change ($\Delta H_{ex,ip}(R_4NA)$) and entropy change ($\Delta S_{ex,ip}(R_4NA)$) for Eq. 3 were calculated from these data. The thermodynamic quantities are listed in Table 1.

Extraction of Alkali Metal Picrates with 18C6. When an equilibrium is established between an aqueous phase of alkali metal ion (M^+) and picrate ion, and a benzene phase of crown ether (L), the equilibrium constants are defined as

$$K_{ex} = [MLA]_o/[M^+][L]_o[A^-], \quad (6)$$
$$K_D(L) = [L]_o/[L], \quad (7)$$
$$K_{ML} = [ML^+]/[M^+][L], \quad (8)$$
$$K_{ex,ip}(MLA) = [MLA]_o/[ML^+][A^-]. \quad (9)$$

Thus, K_{ex} can be written as

$$K_{ex} = K_{ML} \cdot K_{ex,ip}(MLA) \cdot K_D(L)^{-1}. \quad (10)$$

The distribution ratio of the alkali metal is represented by

$$D = [MLA]_o/[M^+]. \quad (11)$$

Table 1. Thermodynamic Quantities for Ion-Pair Extraction of Tetraalkylammonium Picrates between Benzene and Water

	$\log(K_{ex,ip}$/ mol^{-1} dm^3) (at 25°C)	$\Delta H^\circ_{ex,ip}$/ kJ mol^{-1}	$T\Delta S^\circ_{ex,ip}$/ kJ mol^{-1} (at 25°C)
Me_4NA	−2.06	0	−12.1
Et_4NA	−0.60	5.3	1.8
n-Pr_4NA	1.61	10.3	19.5
n-Bu_4NA	3.67	15.1	35.8

Combination of Eqs. 6 and 11 leads to

$$D = K_{ex}[L]_o[A^-]. \quad (12)$$

Log (D/[A^-]) vs. log $[L]_o$ plots give a straight line with a slope of 1 in every case. This indicates that the K_{ex} can be described by Eq. 6. The values of $[L]_o$ and $[A^-]$ in Eq. 12 were calculated by

$$[L]_o = ([L]_t - [MLA]_o)/(1 + K_D(L)^{-1}), \quad (13)$$
$$[A^-] = [HA]_t - [MLA]_o, \quad (14)$$

where the subscript "t" refers to the total concentration.

$R\ln K_D(L)$ vs. T^{-1} and $R\ln K_{ex}$ vs. T^{-1} plots show a linear relationship in every system. Enthalpy and entropy change for Eqs. 6 and 7 were calculated from these data in the same manner as that mentioned above. The thermodynamic parameters are summarized in Table 2.

Discussion

Ion-Pair Extraction of R_4NA. It can be seen from log $K_{ex,ip}$ values in Table 1 that the larger the size of R_4N^+ is, the more extractable into benzene it is. Plots of log $K_{ex,ip}(R_4NA)$ against the number of carbon atoms of R_4N^+ give a straight line with a slope of

a) at 25°C.
b) $\Delta H^\circ_{ex} = -\Delta H^\circ_D(L) + \Delta H^\circ_{ML} + \Delta H^\circ_{ex,ip}$.
c) $\Delta S^\circ_{ex} = -\Delta S^\circ_D(L) + \Delta S^\circ_{ML} + \Delta S^\circ_{ex,ip}$, where subscripts "ex, D, ML, and ex,ip" refer to reactions represented by Eqs. 6—9, respectively.

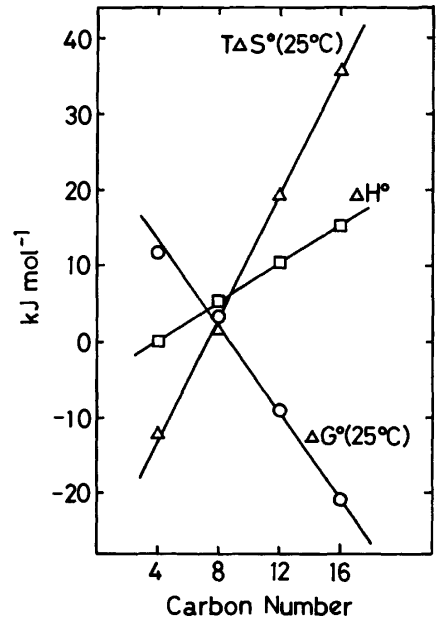

Fig. 1. Plots of thermodynamic parameters for ion-pair extraction of R_4NA vs. the number of carbon atoms of R_4N^+.

0.48_5. This indicates that the contribution of a methylene group to extraction constants of ion-pairs (Π_{CH_2}) at 25 °C between benzene and water is 0.48_5. The Π_{CH_2} value determined from the extraction of ion-pairs of alkanesulfonate ions with cationic dyes between benzene and water at 25 °C has been reported to be 0.64,[6] and is larger than that of this study. This may be due largely to the difference in the shape of tetraalkylammonium and alkanesulfonate ions.

Plots of thermodynamic parameters for ion-pair extraction of R_4NA vs. the number of carbon atoms of R_4N^+ in Fig. 1 show a linear relationship. Contributions of a methylene group to ΔH and ΔS of ion-pair extraction ($\Delta H_{ex,ip}(CH_2)$ and $\Delta S_{ex,ip}(CH_2)$) between benzene and water were found from the slopes to be 1.2_5 kJ mol^{-1} and 13.5 J K^{-1} mol^{-1}, respectively. Positive $\Delta H_{ex,ip}(CH_2)$ and $\Delta S_{ex,ip}(CH_2)$ values suggest that a methylene group may undergo hydrophobic hydration in the aqueous phase. From values of enthalpy and entropy changes of hydration of hydrocarbons (methane-butane),[7] enthalpy and entropy increments per methylene group were calculated to be -3.63 kJ mol^{-1} and -12.5 J K^{-1} mol^{-1}, respectively. Values of $\Delta H_{ex,ip}(CH_2)$ and $\Delta S_{ex,ip}(CH_2)$ determined in this work are comparable to the reported values. It follows from this finding that dehydration of CH_2 plays a very important role in the transfer equilibrium of CH_2 from water to benzene. The value of $T\Delta S_{ex,ip}(CH_2)$ at 25 °C is 3.2 times larger than that of $\Delta H_{ex,ip}(CH_2)$. This indicates that when the alkyl chain in R_4N^+ lengthens, an increase in extractability of R_4NA is largely entropy controlled.

Table 1 shows that the ion-pair extraction process of n-Pr_4NA and n-Bu_4NA is mostly entropy controlled, resulting in the positive $\log K_{ex,ip}$ values, whereas, for Me_4NA and Et_4NA, unfavorable entropy and enthalpy change cause the negative $\log K_{ex,ip}$ values, respectively.

The larger the size of R_4N^+, the greater the $\Delta S_{ex,ip}$ value and the more endothermic is the ion-pair extraction process of R_4NA ($\Delta H_{ex,ip}=0$ for Me_4NA). The negative $\Delta S_{ex,ip}$ value is observed only for Me_4NA. This tendency seems to reflect the change from structure-breaking effect of Me_4N^+ to structure-making effect of n-Bu_4N^+ in an aqueous solution.[8]

A plot of $\Delta H_{ex,ip}$ against reciprocal of the radius of R_4N^+ shows a better linear relationship compared to the case of $\Delta S_{ex,ip}$ (correlation coefficient $r=-0.992$ and -0.983 for $\Delta H_{ex,ip}$ and $\Delta S_{ex,ip}$, respectively). This indicates that $\Delta H_{ex,ip}$ is composed more largely of electrostatic interaction compared to $\Delta S_{ex,ip}$.

Distribution of Crown Ethers. Values of $\log K_D(L)$ at 25 °C of 12-crown-4 (12C4) and 15C5 between benzene and water are -0.82[9] and -0.80_6,[2] respectively. From $\log K_D(L)$ values of 12C4, 15C5, and 18C6, the contribution of an ether oxygen atom to $\log K_D(L)$ (Π_o) at 25 °C between benzene and water can be evaluated by means of Π_{CH_2} value determined in this work ($\Pi_o=(\log K_D(L)-\Pi_{CH_2}\times a)\div b$, a and b being the number of methylene groups and ether oxygen atoms, respectively). Values of Π_o are -1.17, -1.13_1, and -1.16_9 for 12C4, 15C5, and 18C6, respectively. They are almost the same. The Π_o value is -1.16 on the average. It can be seen from Π_{CH_2} and Π_o values that a methylene group is lipophilic, whereas an ether oxygen atom is hydrophilic. Values of $\log K_D(L)$ at 25 °C of crown ethers between benzene and water, which are unknown, can be estimated from these empirical parameters.

In a similar manner as above, the contribution of an ether oxygen atom to $\Delta H_D(L)$ ($\Delta H_D(o)$) and $\Delta S_D(L)$ ($\Delta S_D(o)$) between benzene and water was calculated from $\Delta H_D(L)$ and $\Delta S_D(L)$ of 15C5 (20.9 kJ mol^{-1} and 53.9 J K^{-1} mol^{-1}, respectively[10]) and 18C6 by use of $\Delta H_{ex,ip}(CH_2)$ and $\Delta S_{ex,ip}(CH_2)$ determined in this study ($\Delta H_D(o)=(\Delta H_D(L)-\Delta H_{ex,ip}(CH_2)\times a)\div b$, $\Delta S_D(o)=(\Delta S_D(L)-\Delta S_{ex,ip}(CH_2)\times a)\div b$). Values of $\Delta H_D(o)$ and $\Delta S_D(o)$ are 1.7 kJ mol^{-1} and -16 J K^{-1} mol^{-1} for 15C5, and 3.8 kJ mol^{-1} and -10 J K^{-1} mol^{-1} for 18C6, respectively. They are roughly equal. Values of $\Delta H_D(o)$ and $\Delta S_D(o)$ are 2.8 kJ mol^{-1} and -13 J K^{-1} mol^{-1} on the average, respectively. Positive $\Delta H_D(o)$ value and negative $\Delta S_D(o)$ value seem to reflect the interaction between the ether oxygen atom and water. The strong interaction of an ether oxygen atom with water has been reported.[11] By using these empirical thermodynamic parameters, $\Delta H_D(L)$ and $\Delta S_D(L)$ of crown ethers between benzene and water can be roughly estimated.

Transfer process of 18C6 from water to benzene is endothermic, and the ΔS_D(18C6) value between benzene and water is positive. Favorable $T\Delta S_D$(18C6) value at 25 °C for transfer of 18C6 from water to benzene is completely canceled by larger unfavorable ΔH_D(18C6) value, resulting in relatively large negative log K_D(18C6) value. A similar tendency is observed for partition of 15C5 itself between benzene and water.[10]

Extraction of Alkali Metal Picrates with 18C6. Table 2 shows that both ΔH_{ex} and ΔS_{ex} values of 18C6 for all the alkali metals are negative. The same trend is observed for 15C5,[10] benzo-15-crown-5,[12] and dibenzo-18-crown-6[13] between benzene and water, and for 15C5[14] and 18C6[15] between $CHCl_3$ and water. Differences in ΔH_{ex} values among K, Rb, and Cs are small, whereas ΔH_{ex} value of Na is much larger than the others. The same is true for $T\Delta S_{ex}$ values. The smallest ΔH_{ex} value of K is balanced by the second smallest $T\Delta S_{ex}$ value, leading to the largest log K_{ex}, and much the greatest ΔH_{ex} and $T\Delta S_{ex}$ values of Na compensate each other, resulting in the smallest log K_{ex}. Values of ΔH_D(18C6) and ΔS_D(18C6) play a major role in determining the magnitude of ΔH_{ex} and ΔS_{ex} values, respectively, whereas ΔH_{ML}, $\Delta H_{ex,ip}$, ΔS_{ML}, and $\Delta S_{ex,ip}$ values play a minor role.

Ion-Pair Extraction of Crown Ether-Alkali Metal Ion Complexes with Picrate Anions. Ion-pair extractability at 25 °C of M(18C6)A between benzene and water increases in the order, Na<Cs<Rb<K (Table 2). Much the largest $\Delta H_{ex,ip}$ and $\Delta S_{ex,ip}$ values of Na compensate each other, resulting in the lowest ion-pair extractability (Table 2). Ion-pair extraction of K(18C6)A and Cs(18C6)A is completely enthalpy controlled. The smallest $\Delta H_{ex,ip}$ and $\Delta S_{ex,ip}$ values of Rb balance each other, leading to the second greatest ion-pair extractability.

As can be seen from Table 2, both $\Delta H_{ex,ip}$ and $\Delta S_{ex,ip}$ values vary fairly with the alkali metal ion. This may reflect differences in interactions of 18C6-alkali metal ion complexes with picrate anions in an aqueous phase and water molecules.

Values[15] of log $K_{ex,ip}$, $\Delta H_{ex,ip}$, and $T\Delta S_{ex,ip}$ of 18C6-alkali metal picrate complexes between $CHCl_3$ and water are as follows.

	Na	K	Rb	Cs
$\log(K_{ex,ip}/\text{mol}^{-1}\,\text{dm}^3)$ (at 25°C)	3.46	4.83	4.88	4.42
$\Delta H^\circ_{ex,ip}$/kJ mol^{-1}	−18.8	−33.9	−45.6	−43.1
$T\Delta S^\circ_{ex,ip}$/kJ mol^{-1} (at 25°C)	0.6	−6.6	−17.8	−18.1

Log $K_{ex,ip}$(MLA) value of the $CHCl_3/H_2O$ system is about 2 larger than that of the benzene/H_2O system. The difference in log $K_{ex,ip}$(MLA) values between $CHCl_3$ and benzene systems (ca. 2) is smaller than that in individual extraction constants for solvents between $CHCl_3$ and benzene (3.4—4.2).[16] It is impossible to explain the large difference at the present time.

Both $\Delta H_{ex,ip}$ and $\Delta S_{ex,ip}$ of the 18C6-alkali metal picrate complex increase very much from $CHCl_3$ to benzene. This indicates that the interaction of the 18C6-alkali metal picrate complex with $CHCl_3$ is much stronger than that with benzene. It thus appears that ion-pair of the 16C6-alkali metal ion complex with picrate anion is extracted into $CHCl_3$ much more than into benzene.

Differences in $\Delta H_{ex,ip}$ and $\Delta S_{ex,ip}$ values of the 18C6-alkali metal picrate complex between benzene and $CHCl_3$ ($\Delta(\Delta H_{ex,ip})$ and $\Delta(\Delta S_{ex,ip})$) express enthalpy and entropy change of transfer of the 18C6 complex, respectively, from benzene (or $CHCl_3$) to $CHCl_3$ (or benzene). A large difference in $\Delta(\Delta H_{ex,ip})$ values of 18C6 complexes is found between a group of Na and Cs and that of K and Rb. The same is true for $\Delta(\Delta S_{ex,ip})$ values. This may reflect the difference in solute-solvent interactions caused by the difference in structures of the 18C6-alkali metal picrate complexes; namely, K^+ and Rb^+ have more suitable sizes for the 18C6 cavity than Na^+ and Cs^+.

Values[10] of log $K_{ex,ip}$, $\Delta H_{ex,ip}$, and $T\Delta S_{ex,ip}$ of 15C5-sodium picrate complex between benzene and water are 2.40 (at 25 °C), −18.1 kJ mol^{-1}, and −4.6 kJ mol^{-1} (at 25 °C), respectively. Since Na^+ and K^+ fit most nicely into 15C5 and 18C6 cavity, respectively, the metal ion trapped in the cavity is most effectively screened by the crown ether from environmental solvents. A nitrogen atom of tetraalkylammonium ion is well-shielded by four alkyl groups. Sizes of n-Pr_4N^+ and n-Bu_4N^+ ions are nearly equal to those of 15C5-Na^+ and 18C6-K^+ complexes, respectively.[17] Thus, it is interesting to compare the ion-pair-extraction process of 15C5-NaA and 18C6-KA complexes with that of n-Pr_4NA and n-Bu_4NA, respectively, from a thermodynamic point of view. A striking difference is found between the crown ether complexes and the tetraalkylammonium picrates. Values of $\Delta H_{ex,ip}$ and $\Delta S_{ex,ip}$ of 15C5-NaA and 18C6-KA complexes except for $\Delta S_{ex,ip}$ value of the 18C6-KA complex are negative, and $\Delta S_{ex,ip}$ value of the 18C6-KA complex is nearly equal to zero (Table 2). On the contrary, all the $\Delta H_{ex,ip}$ and $\Delta S_{ex,ip}$ values of n-Pr_4NA and n-Bu_4NA are positive. Values of $\Delta H_{ex,ip}$ and $\Delta S_{ex,ip}$ of the crown ether complex (18C6-KA, 15C5-NaA) are much smaller than those of the corresponding R_4NA (n-Bu_4NA, n-Pr_4NA). Ion-pair extraction of the crown ether complexes is enthalpy controlled, whereas, that of n-Pr_4NA and n-Bu_4NA is entropy controlled. Ion-pair extractability at 25 °C of the 18C6-KA complex is lower than that of n-Bu_4NA, and the contrary holds for the 15C5-NaA complex and n-Pr_4NA. From the above discussion and the fact that both n-Pr_4N^+ and n-Bu_4N^+ are structure makers in an aqueous solution,[8] it may be concluded that both

18C6-K^+ and 15C5-Na^+ complexes act as a structure breaker in water. In a series of our conductance studies,[5,18-20] it was reported that the 18C6-K^+ complex acts as a structure breaker in protic solvents. The result of this study for the 18C6-K^+ complex agrees with that of conductometry.

Hydrates of Organic Compounds. XIII. The Confirmation of the Formation of Clathrate-Like Hydrates of Tetrabutylammonium and of Tetraisopentylammonium Polyacrylates

Haruo NAKAYAMA
Department of Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240
(Received December 1, 1986)

A thermal analytic method using a differential scanning calorimeter has been applied to aqueous solutions of a series of tetraalkylammonium polyacrylates ($(R_4NOOCCHCH_2)_n$; R=CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, n-C_5H_{11}, and i-C_5H_{11}). It was found that only tetrabutylammonium polyacrylate and tetraisopentylammonium polyacrylate could form stable hydrates having a large number of moles of water per single $R_4NOOCCHCH_2$ unit of the polyacrylates (hydration numbers). The melting points and hydration numbers of these two hydrates were 11.2 °C, 30±1 for the tetrabutylammonium polyacrylate hydrate and 19.5 °C, 42±2 for the tetraisopentylammonium polyacrylate hydrate, respectively. Judging from the melting points, hydration numbers, and the concentration dependence of the dissolution temperatures, these hydrates were regarded as clathrate-like. The tetrabutylammonium polyacrylate hydrate seems to be iso-structural with $(n$-$C_4H_9)_4NF$ hydrate and the tetraisopentylammonium polyacrylate hydrate with $(i$-$C_5H_{11})_4NF$ hydrate.

A single-crystal X-ray examination by Jeffrey and his coworkers on the hydrates of tetraalkylammonium salts such as $(n$-$C_4H_9)_4NF$,[1] $(n$-$C_4H_9)_4NOOCC_6H_5$,[2] and $(i$-$C_5H_{11})_4NF$,[3] showed that these hydrates were clathrate-like hydrates similar to the so-called gas hydrates.[4] The water structure is a hydrogen-bonded framework and is essentially a regular arrangement of polyhedra like pentagonal dodecahedra, tetrakaidecahedra, and pentakaidecahedra. The latter two polyhedra enclose either a n-C_4H_9 or a i-C_5H_{11} group of the tetraalkylammonium cations, whereas pentagonal dodecahedra are empty. Fluoride ion and oxygen atoms of carboxylate anion are hydrogen-bonded to the water frameworks and form part of the polyhedral structure.

Although the tetraalkylammonium cation which can form a clathrate-like hydrate is almost exclusively limited either to tetrabutylammonium ion or to tetraisopentylammonium ion,[5-7] various types of anions are permissble. Of these anions, carboxylate anions are of interest since they can extend the diversity of the clathrate-like hydrates of tetraalkylammonium salts due to the variation of the alkyl groups of the carboxylate anions. The formation of a clathrate-like hydrate of tetrabutylammonium carboxylates has been confirmed for many carboxylates.[2,3,5,8-12] Experimental results found so far are briefly summarized as follows: (1) a series of tetrabutylammonium carboxylates, $(n$-$C_4H_9)_4NOOCR$, with R ranging from CH_3 to n-$C_{10}H_{21}$ can form clathrate-like hydrates whose hydration numbers are around 30;[10,12] and (2) a series of tetrabutylammonium dicarboxylates, $[(n$-$C_4H_9)_4N]_2(OOC(CH_2)_nCOO)$ (n=0—8), can also form clathrate-like hydrates with hydration numbers around 60 and the salt of n=3 forms the most stable hydrate whose melting point is 20.2 °C.[9]

The crystal structure of these carboxylate and dicarboxylate hydrates was assumed to be iso-structural with that of the $(n$-$C_4H_9)_4NF$ hydrate[1] from the fact that the hydration numbers (about 30 for one $(n$-$C_4H_9)_4N^+$ cation) and unit cell dimensions for some of the hydrates[12] are almost identical with those of the $(n$-$C_4H_9)_4NF$ hydrate. This speculation also means that the alkyl groups of carboxylate anions and methylene chains of dicarboxylate anions are enclosed in vacant pentagonal dodecahedra.

From such a versatile availability of vacant pentagonal dodecahedra and from the fact that, for dicarboxylate salts, the $-(CH_2)_3-$ methylene chain is the most suitable chain to form a stable clathrate-like hydrate, the formation of a clathrate-like hydrate of tetrabutylammonium polyacrylate and of tetraisopentylammonium polyacrylate may be anticipated, though such a hydrate has not been known previously.

In this paper, through a thermal analytic method using a differential scanning calorimeter for binary mixtures of a series of tetraalkylammonium polyacrylates ($(R_4NOOCCHCH_2)_n$; R=CH_3—n-C_5H_{11}, and i-C_5H_{11}) with water, an extensive study has been carried out in order to confirm the formation of clathrate-like hydrates of teraalkylammonium polyacrylates.

Experimental

Aqueous solutions of sodium polyacrylate and of tetraalkylammonium polyacrylates ($(R_4NOOCCHCH_2)_n$; R=CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, n-C_5H_{11}, and i-C_5H_{11}) were obtained by the neutralization of an aqueous solution of polyacrylic acid with aqueous solutions of sodium hydroxide and of the corresponding tetraalkylammonium hydroxide. The aqueous solutions of tetraalkylammonium hydroxides were prepared by reacting tetraalkylammonium iodides with freshly prepared silver hydroxide in water with vigorous shaking, followed by filtration of resulting silver iodide in a CO_2-free atmosphere. Tetrabutylammonium

iodide, tetrapentylammonium iodide, and tetraisopentylammonium iodide were synthesized by reacting each trialkylamine with the corresponding alkyl iodide in ethyl acetate and were purified by recrystallization from ethyl acetate–acetone mixture.[7] Other iodides were purchased from the Tokyo Kasei Kogyo Co. and were recrystallized either from ethyl acetate–ethanol mixture or from ethanol. An aqueous solution of polyacrylic acid was purchased from Wako Pure Chemical Industries, Ltd. and was used without further purification. The mean degree of polymerization of polyacrylic acid was estimated to be about 2100 from viscosity measurements of the aqueous solutions of its sodium salt in 1 mol dm^{-3} NaCl solution at 25 °C using the equation proposed by Kagawa et al.[13]

The concentrations of each sample were determined either by measuring the water content using the Karl Fischer titration method on a MK-II apparatus (Kyoto Electronics Manufacturing Co.) for sodium polyacrylate and tetramethyl-, tetraethyl-, tetrapropyl-, and tetrapentylammonium polyacrylates or by measuring the amount of tetraalkylammonium cations by titration with a sodium tetraphenylborate solution which was standardized by pure tetrabutylammonium iodide for tetrabutyl- and tetraisopentylammonium polyacrylates.

The differential scanning calorimeter used was the model DSC-10 with SSC-580 thermal controller, manufactured by Seiko Instruments and Electronics Ltd. Each sample solution (about 15 mg) was sealed in a 15 μl aluminum pan and was either cooled or heated at the rate of 0.5 °C per minute. An empty 15 μl aluminum pan was used as a reference.

Results and Discussion

(1) Thermal Behavior of Aqueous Solutions of Sodium Polyacrylate and of Tetraalkylammonium Polyacrylates. The cooling and heating curves in the differential scanning calorimetry (DSC) for aqueous solutions of sodium polyacrylate (NaPA), tetramethylammonium polyacrylate ($(CH_3)_4NPA$), tetraethylammonium polyacrylate ($(C_2H_5)_4NPA$), tetrapropylammonium polyacrylate ($(n\text{-}C_3H_7)_4NPA$), tetrabutylammonium polyacrylate ($(n\text{-}C_4H_9)_4NPA$), tetrapentylammonium polyacrylate ($(n\text{-}C_5H_{11})_4NPA$) and tetraisopentylammonium polyacrylate ($(i\text{-}C_5H_{11})_4NPA$) are shown as a function of temperature for solutions of X=0.01 in Fig. 1 and of X=0.02 in Fig. 2 (X is the mole fraction of the polyacrylates based on the monomeric unit). It is obvious that in the cooling process steep exothermic peaks in the −15—−20 °C range indicate the solidification of supercooled water, and in the heating process endothermic peaks in the −10—0 °C

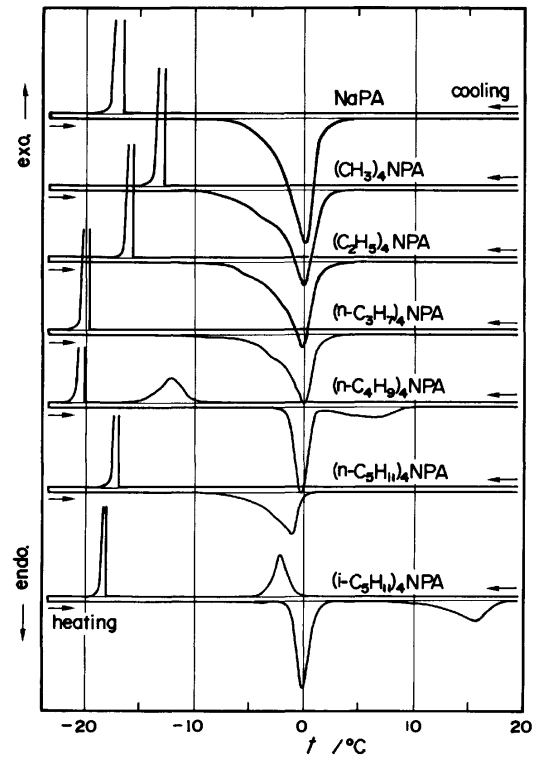

Fig. 1. Temperature dependence of the DSC signals, expressed in an arbitrary unit, for aqueous solutions of sodium polyacrylate (NaPA) and of a series of tetraalkylammonium polyacrylates (R_4NPA; R= CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, n-C_5H_{11}, and i-C_5H_{11}). The mole fraction (X), based on the monomeric unit, is equal to 0.01 for all the solutions.

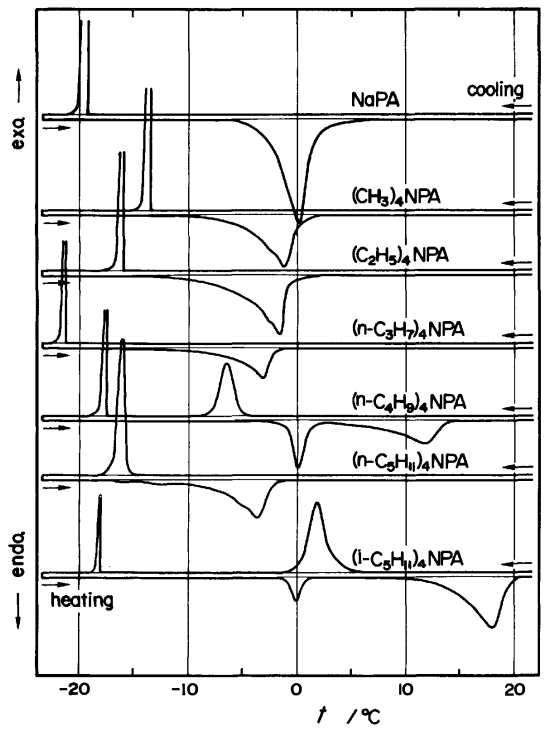

Fig. 2. Temperature dependence of the DSC signals, expressed in an arbitrary unit, for aqueous solutions of sodium polyacrylate (NaPA) and of a series of tetraalkylammonium polyacrylates (R_4NPA; R= CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, n-C_5H_{11}, and i-C_5H_{11}). The mole fraction, based on the monomeric unit, is equal to 0.02 for all the solutions.

range are attributable to the melting of the ice phase.

However, the thermal behavior of $(n\text{-}C_4H_9)_4NPA$ and $(i\text{-}C_5H_{11})_4NPA$ solutions differs markedly from that of the other five solutions. In these two solutions, besides the peaks due to an ice phase exothermic peak occurs at around $-12\,^\circ C$ for $X=0.01$ and around $-7\,^\circ C$ for $X=0.02$ in the $(n\text{-}C_4H_9)_4NPA$ solutions and at around $-2\,^\circ C$ for $X=0.01$ and at around $+2\,^\circ C$ for $X=0.02$ in the $(i\text{-}C_5H_{11})_4NPA$ solutions and the endothermic peak occurs at temperatures above $0\,^\circ C$ depending both on the concentration and on the kind of salt. This clearly indicates that another solid phase other than ice is formed in these two systems and further that this solid phase contains some water, i.e., a hydrate, since the areas of both the exothermic peaks due to the solidification of supercooled water and of the endothermic peak due to the melting of the ice phase decrease markedly with increasing concentration of the salt. Further details of these hydrates will be discussed in the following sections.

Finally, the quantities $\Delta H/(6.0095\times10^3 n_0)$ for all the solutions examined are listed in Table 1, where ΔH (J unit) is the total endothermic enthalpy change in the heating process and n_0 is the total number of moles of water contained in each solution and the value 6.0095×10^3 is the molar heat of fusion (J unit) of pure water at $0\,^\circ C$.[14] This quantity may be regarded as an approximate index of the relative thermal stability of the solid phase as compared with that of pure ice. The values obtained are very small for the $X=0.02$ solution of $(n\text{-}C_3H_7)_4NPA$ and both $X=0.01$ and $X=0.02$ solutions of $(n\text{-}C_5H_{11})_4NPA$. At the same time, Figs. 1 and 2 show that the melting processes of the solid phase in these three solutions are completed at lower temperatures than those in the other solutions. These phenomena indicate that the degree of amorphousness of the ice phase formed around the $(n\text{-}C_3H_7)_4NPA$ and $(n\text{-}C_5H_{11})_4NPA$ molecules remarkably increases.

Table 1. The Quantity $\Delta H/(6.0095\times10^3 n_0)$ for Aqueous Solutions of Sodium Polyacrylate and of Tetraalkylammonium Polyacrylates

Polyacrylate	$\Delta H/(6.0095\times10^3 n_0)$	
	$X=0.01$	$X=0.02$
NaPA	0.98	0.99
$(CH_3)_4NPA$	0.96	0.80
$(C_2H_5)_4NPA$	1.00	0.75
$(n\text{-}C_3H_7)_4NPA$	0.82	0.50
$(n\text{-}C_4H_9)_4NPA$	0.88	0.77
$(n\text{-}C_5H_{11})_4NPA$	0.62	0.60
$(i\text{-}C_5H_{11})_4NPA$	0.85	0.87

All the notations are explained in the text. These values are averages of 3—5 measurements.

(2) The Confirmation of the Formation of a Clathrate-Like Hydrate of Tetrabutylammonium Polyacrylate. In a preliminary experiment it was found that when about 10 wt% aqueous solution of $(n\text{-}C_4H_9)_4NPA$ was cooled to about $-20\,^\circ C$, a white and powderly solid phase was formed which remained undissolved at $2\,^\circ C$. This suggests the formation of a solid phase other than ice. The cooling and heating curves for the $(n\text{-}C_4H_9)_4NPA$ solutions in various concentrations are shown in Fig. 3 as a function of temperature. The most important characteristic of both the cooling and heating curves is the occurrence of two kinds of peaks except for the solutions whose X's are either very small or very large. The areas of both the exothermic peaks corresponding to the solidification of ice and the endothermic peak corresponding to the melting of ice decrease markedly with increasing concentration and both peaks become very small when $X=0.0330$. Therefore, the solid phase other than ice seems to be a hydrate whose composition is approximately equal to $X=0.0330$, i.e., the hydration number of the hydrate is close to 29.

The thermal behavior shown in Fig. 3 shows a striking resemblance to that of the aqueous solutions

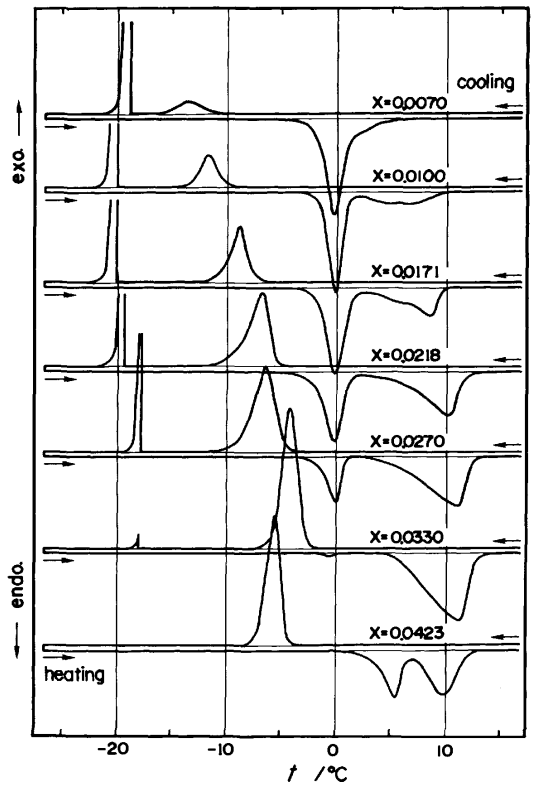

Fig. 3. Temperature dependence of the DSC signals, expressed in an arbitrary unit, for aqueous solutions of tetrabutylammonium polyacrylate ($(n\text{-}C_4H_9)_4NPA$) in various concentrations. The X is the mole fraction of the salt based on the monomeric unit.

of tetrabutylammonium chloride,[15] which is well-known to form a clathrate-like hydrate with hydration numbers around 30.[5,7,16] A thermal analytic procedure for obtaining hydration numbers and melting pont of a hydrate, and for determining the dissolution temperatures by DSC measurements has precisely been discussed in a previous paper.[15] The hydration numbers, m, of a hydrate can approximately be calculated by the following relation for solutions whose X's are equal to or smaller than the congruent composition:

$$m = \frac{1}{n_1}\left(n_0 - \frac{\Delta H_1 - \Delta H_2}{6.0095 \times 10^3}\right), \quad (1)$$

in which ΔH_1 (J unit) is the total enthalpy change during the whole heating processes for the solid phases which are solidified both by the first-step and by the second-step solidification; ΔH_2 (J unit) is the enthalpy change in the heating process for the solid phase which is solidified by the first-step solidification process only; n_0 and n_1 are the total number of moles of water and of (n-C_4H_9)$_4$NPA based on the monomeric unit, respectively. Some representative values of ΔH_1, ΔH_2, the dissolution temperatures observed, and the calculated hydration numbers m are listed in Table 2, together with some data for the solutions at concentrations higher than X=0.0330. These are briefly discussed in the last part of this section.

All the calculated values of m lie near 30 and the X=0.0330 solution has the highest dissolution temperature of 11.2 °C and almost the same values of ΔH_1 and ΔH_2, indicating that the congruent composition of the hydrate is close to X=0.0330 as observed above. In conclusion, the hydration numbers and the melting point of the (n-C_4H_9)$_4$NPA hydrate are determined to be 30±1 and 11.2 °C, respectively. The presence of the (n-C_4H_9)$_4$NPA hydrate has not been known previously. From the facts that the hydration numbers of the hydrate are 30±1, and the congruent melting pont is fairly high (11.2 °C), this hydrate seems to have a clathrate-like structure similar to such hydrates as (n-C_4H_9)$_4$NF·30H_2O and (n-C_4H_9)$_4$NCl·30H_2O.[15,16]

The solid-liquid phase diagram for the (n-C_4H_9)$_4$NPA-H_2O binary system, which is depicted by

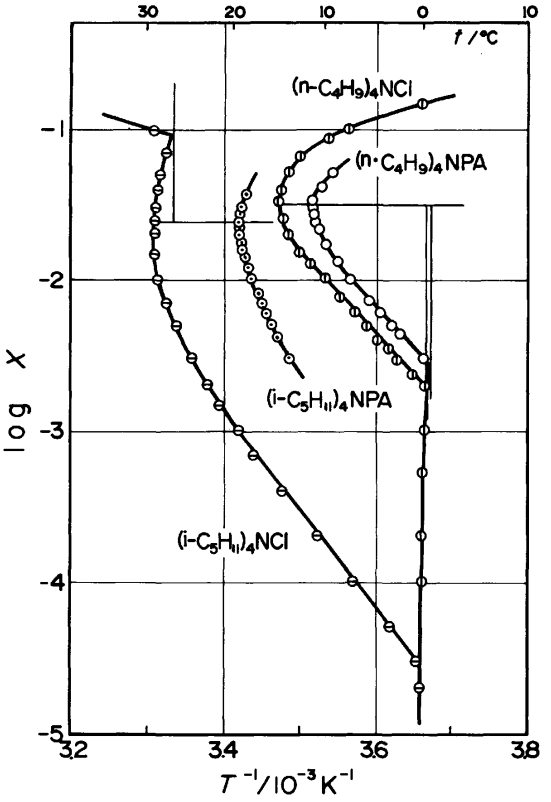

Fig. 4. The solid-liquid phase diagrams for binary systems of tetrabutylammonium polyacrylate ((n-C_4H_9)$_4$NPA)-water and of tetraisopentylammonium polyacrylate ((i-C_5H_{11})$_4$NPA)-water determined by the DSC experiments, together with those for binary systems of (n-C_4H_9)$_4$NCl-water and of (i-C_5H_{11})$_4$NCl-water determined previously by an ampoule method.[7,16]

a) These values are averages of 3—5 measurements.

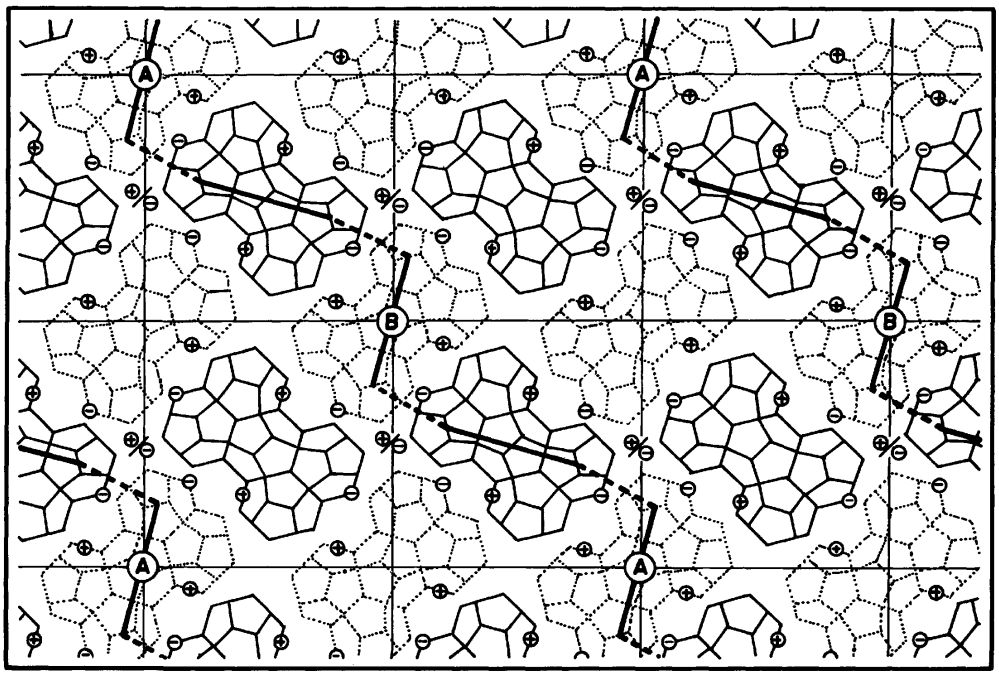

Fig. 5. One of the possible ways for polyacrylate chains (written by bold lines) to be accommodated within the structure which is iso-structural with $(n\text{-}C_4H_9)_4NF$ hydrate. Explanation is given in the text.

plotting the logarithm of the mole fraction X of each solution against their dissolution temperatures after conversion to the reciprocal of the absolute temperature, is shown in Fig. 4, together with that of the $(n\text{-}C_4H_9)_4NCl\text{-}H_2O$ system determined previously by an ampoule method.[16] A striking resemblance of both phase diagrams, especially a similar value of the slope of $-\partial \log X/\partial(1/T)$ in the concentration range between the eutectic composition and the congruent composition, provides another indication for the formation of a clathrate-like hydrate of $(n\text{-}C_4H_9)_4NPA$ similar to that of $(n\text{-}C_4H_9)NCl$. This slope has been proved to be approximately proportional to the hydration number of a hydrate.[17].

Although there is no information about the crystal structure of the $(n\text{-}C_4H_9)_4NPA$ hydrate, the most probable way of accommodating a polyacrylate chain within a water lattice is illustrated in Fig. 5 based on the assumptions that (1) the crystal structure is iso-structural with that of the $(n\text{-}C_4H_9)_4NF$ hydrate[1] and (2) the polyacrylate chain penetrates through associated, vacant pentagonal dodecahedra forming a hydrogen-bonded anionic host structure with water. In this figure only an arrangement of a block of vacant pentagonal dodecahedra in the planes perpendicular to the c-axis is shown. Each block represented by a solid line lies at the level of the $Z=0$ plane and the one represented by a dotted line lies at the level of the $Z=1/2$ plane. The marks $\oplus$ and $\ominus$ represent the positions of a nitrogen atom and of a fluorine atom, respectively, in the original $(n\text{-}C_4H_9)_4NF$ hydrate. The C-C main chain of the polyacrylate anion is illustrated by bold lines. The dotted portion of the bold line indicates the shift of the C-C chain between the $Z=0$ and $Z=1/2$ plane by breaking a single hydrogen-bond which connects two blocks of the pentagonal dodecahedra. The distance from position A to B in Fig. 5 is about 45 Å and the monomeric unit chain length of the polyacrylate chain is expected to be slightly shorter than 2.51 Å, which is the longest distance when the C-C chain is fully extended. This is because of the restriction that each carboxyl group must be incorporated within the water framework. Therefore, it will be reasonable to assume that 20 monomeric units of the polyacrylate chain are present between A and B. According to the structural analysis by Jeffrey et al.,[1] there exist 10 pentagonal dodecahedra (i.e., two blocks of pentagonal dodecahedra represented in Fig. 5) and five $(n\text{-}C_4H_9)_4NF$ molecules within a unit cell. Thus the above mentioned 20 units of negative charge are four times larger than the positive charge, leading the conclusion that only a fourth of all the pentagonal dodecahedra are used to accommodate the polyacrylate chain. This may be possible, for instance, if only the pentagonal dodecahedra existing within alternate unit cells arranged in the directions both perpendicular and parallel to the c-axis are used. Figure 5 is drawn according to this view.

In Fig. 6 two apparent quantities, $\Delta H_1/n_0$ and

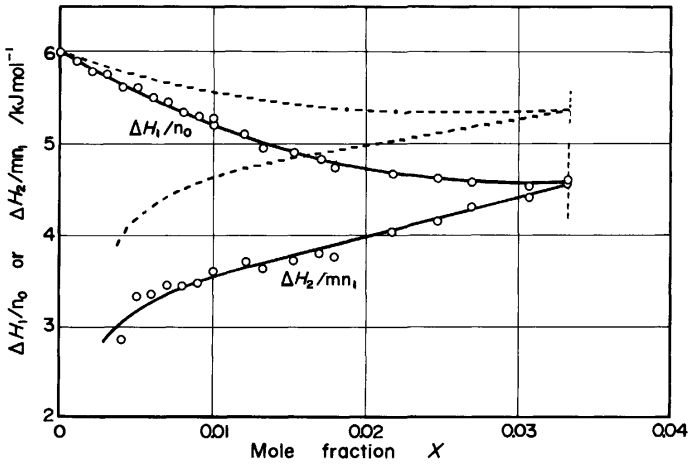

Fig. 6. The concentration dependence of the apparent total enthalpy change per mole of water, $\Delta H_1/n_0$, and of the apparent enthalpy change due to the dissolution of the hydrate solid per mole of water which forms hydrogen-bonded networks in the hydrate, $\Delta H_2/mn_1$, in the $(n\text{-}C_4H_9)_4NPA\text{-}H_2O$ binary system. Dotted lines represent similar quantities for the $(n\text{-}C_4H_9)_4NCl\text{-}H_2O$ system[15] for comparison.

$\Delta H_2/mn_1$, are plotted against the mole fraction X, together with the corresponding curves for the $(n\text{-}C_4H_9)_4NCl\text{-}H_2O$ system.[15] The quantity $\Delta H_1/n_0$ means apparent, total enthalpy change per mole of water and the quantity $\Delta H_2/mn_1$ means apparent enthalpy change due to the dissolution of the hydrate solid per mole of water which forms hydrogen-bonded networks in the hydrate solid. These two quantities become equal at the congruent composition as expected from Eq. 1. Although these curves cannot be analyzed in detail because of the lack of other thermodynamic information (especially of the data concerning the enthalpies of mixing of a hydrate melt with water), a striking resemblance of these curves between the $(n\text{-}C_4H_9)_4NPA$ hydrate and the $(n\text{-}C_4H_9)_4NCl$ hydrate suggests that the thermal behavior of water molecules in the $(n\text{-}C_4H_9)_4NPA$ hydrate is similar to that in the $(n\text{-}C_4H_9)_4NCl$ hydrate. However, the value of $\Delta H_2/mn_1$ (or $\Delta H_1/n_0$) at the congruent composition for the $(n\text{-}C_4H_9)_4NPA$ hydrate, 4.60 kJ mol^{-1}, is considerably smaller than that (5.47 kJ mol^{-1}) found for the $(n\text{-}C_4H_9)_4NCl$ hydrate.[15] This suggests that the hydrogen-bonded water frameworks in the $(n\text{-}C_4H_9)_4NPA$ hydrate are appreciably deformed as compared with those in the $(n\text{-}C_4H_9)_4NCl$ hydrate.

Finally, the thermal behavior of the solutions whose X's are larger than 0.0330 must be briefly discussed. Only two solutions with X=0.0423 and X=0.0506 have been examined and the results are included in Table 2. The thermal behavior of the X=0.0423 solution is represented in Fig. 3. The heating curve indicates the existence of two kinds of hydrates. The hydrate which melts at a higher temperature is the same as that discussed above (m=30±1) judging from the value of the dissolution temperature as well as from the concentration dependence of ΔH_2. The hydration numbers, m', of the other hydrate can approximately be estimated by the following equation using m=30:

$$m' = \left(n_0 - \frac{\Delta H_2}{4.60\times 10^3}\right) \Big/ \left(n_1 - \frac{\Delta H_2}{4.60\times 10^3 m}\right), \qquad (2)$$

where ΔH_2 is the second-step enthalpy change in the heating process, which is approximately separated from the total enthalpy change ΔH_1 (Table 2) and the value of 4.60×10^3 stands for the molar enthalpy of fusion (J unit) of the water which forms the hydrate of m=30 as determined above. The calculated values of m' are 16.8±1.9 for the X=0.0423 solution and 17.8±0.9 for the X=0.0506 solution, respectively. This hydrate seems to be a kind of clathrate-like hydrate since its melting point is high (about 6 °C) and its hydration number, m', is large (17—18) in comparison with that of ordinary hydrates of many other organic compounds.

(3) The Confirmation of the Formation of a Clathrate-Like Hydrate of Tetraisopentylammonium Polyacrylate. In a preliminary experiment it was found that when about 10 wt% aqueous solution of $(i\text{-}C_5H_{11})_4NPA$ was cooled to about −20 °C, a transparent crystalline phase was obtained as well-formed prisms which remained undissolved even at 10 °C. This phenomenon suggests the formation of a solid phase other than ice. The cooling and heating curves for $(i\text{-}C_5H_{11})_4NPA$ aqueous solutions are shown

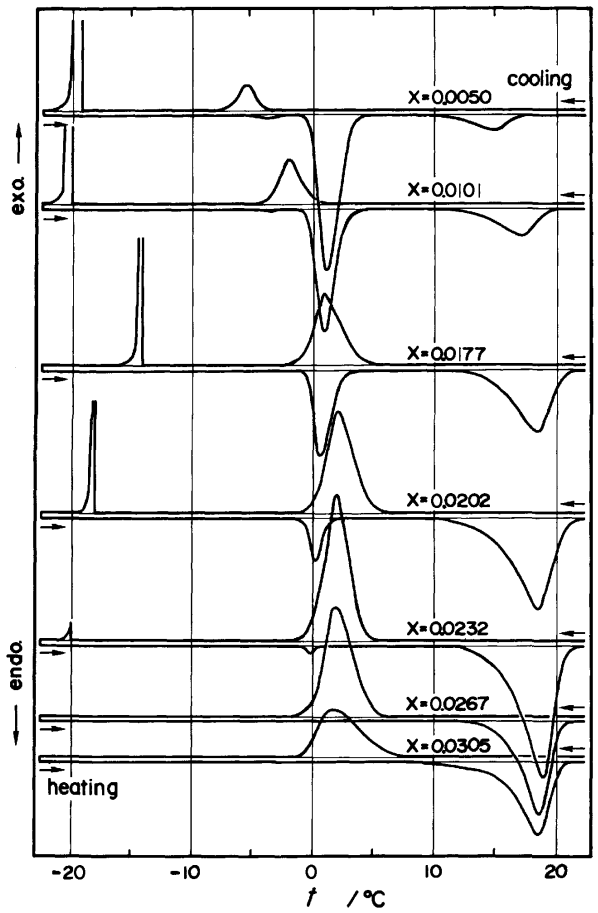

Fig. 7. Temperature dependence of the DSC signals, expressed in an arbitrary unit, for aqueous solutions of tetraisopenylammonium polyacrylate ((*i*-$C_5H_{11})_4$NPA) in various concentrations.

in Fig. 7 in a similar manner as in Fig. 3. The thermal behavior of these curves resembles that of the (*n*-$C_4H_9)_4$NPA solutions, suggesting the formation of a clathrate-like hydrate of (*i*-$C_5H_{11})_4$NPA. Thus, these curves can be analyzed in the same way as those of the (*n*-$C_4H_9)_4$NPA-H_2O system, giving each peak a similar physical meaning as before. Representative values of ΔH_1, ΔH_2, and dissolution temperatures observed, and the hydration numbers calculated by Eq. 1 are listed in Table 3.

The congruent composition, which gives the highest dissolution temperature (19.5 °C), is close to X=0.0232, indicating the hydration numbers of the (*i*-$C_5H_{11})_4$NPA hydrate are around 42. The hydration numbers calculated for the solutions in the concentration range of X=0.0121—0.0232 are also around 42, although those for the solutions with X's smaller than 0.0121 are larger than 42. It is not clear whether another kind of hydrate which has larger hydration numbers than 42 is formed in such dilute solutions. In conclusion, (*i*-$C_5H_{11})_4$NPA can form a clathrate-like hydrate with hydration numbers of 42±2 and melting point of 19.5 °C. The formation of such a hydrate has not been reported previously.

A solid-liquid phase diagram for the (*i*-$C_5H_{11})_4$NPA-H_2O system, determined in the same manner as in the case of the (*n*-$C_4H_9)_4$NPA-H_2O system, is also shown in Fig. 4, together with that of the (*i*-$C_5H_{11})_4$NCl-H_2O system which has been known to form a clathrate-like hydrate with hydration numbers around 40.[7] The striking resemblance of the phase diagrams of both systems affords an additional reason for concluding that the (*i*-$C_5H_{11})_4$NPA hydrate is a clathrate-like hydrate similar to the (*i*-$C_5H_{11})_4$NCl hydrate whose crystal structure is believed to be iso-

All the notations are the same as those in Table 2.

a) These values are averages of 3—5 measurements. b) Calculated values from $5.45\times10^3 n_0$.

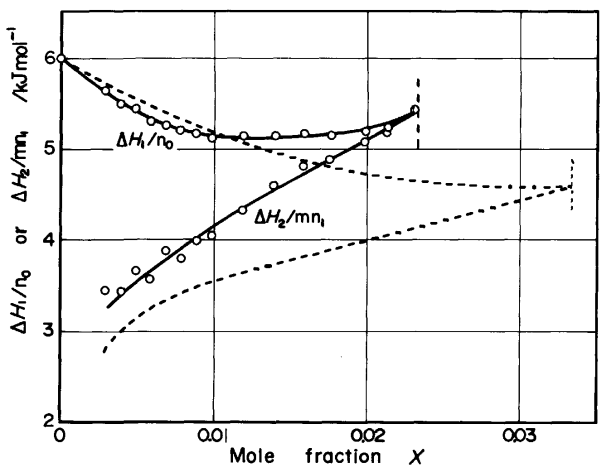

Fig. 8. The concentration dependence of $\Delta H_1/n_0$ and of $\Delta H_2/mn_1$ for the $(i\text{-}C_5H_{11})_4NPA\text{-}H_2O$ system. The physical meaning of these quantities are identical with those in Fig. 6. Dotted lines represent similar quantities for the $(n\text{-}C_4H_9)_4NPA\text{-}H_2O$ system (Fig. 6) for comparison.

structural with $(i\text{-}C_5H_{11})_4NF$ hydrate.

According to the crystal structure examination of the $(i\text{-}C_5H_{11})_4NF$ hydrate by Jeffrey et al.,[3] this hydrate consists of a regular arrangement of columns of tetrakaidecahedra extended in the c-axis direction by sharing hexagonal faces; these columns are connected by alternate layers of pentagonal dodecahedra and pentakaidecahedra which face-share congruently. A possible way to accommodate the polyacrylate chain in vacant pentagonal dodecahedra may be either to use the pentagonal dodecahedra layer extended in the direction perpendicular to the c-axis or to use pentagonal dodecahedra existing in the alternate layers in the c-axis direction by replacing fluorine atoms in the original $(i\text{-}C_5H_{11})_4NF$ hydrate by oxygen atoms of carboxyl groups of the polyacrylate chain. Precise structural analysis is awaited. A single-crystal X-ray examination will be possible since the $(i\text{-}C_5H_{11})_4NPA$ hydrate solid can be obtained as well-formed prisms.

In Fig. 8, the two apparent quantities, $\Delta H_1/n_0$ and $\Delta H_2/mn_1$, are plotted against the mole fraction X similarly to Fig. 6. The value of $\Delta H_2/mn_1$ (or of $\Delta H_1/n_0$) at the congruent composition is equal to 5.45 kJ mol^{-1}. This value is appreciably larger than that of the $(n\text{-}C_4H_9)_4NPA$ hydrate (4.60 kJ mol^{-1}), indicating that the water networks in the $(i\text{-}C_5H_{11})_4NPA$ hydrate are less deformed than those in the $(n\text{-}C_4H_9)_4NPA$ hydrate. This results coincides with a general trend that the water frameworks surrounding a $(i\text{-}C_5H_{11})_4N^+$ cation are more stable than those surrounding a $(n\text{-}C_4H_9)_4N^+$ cation if both cations have the same kind of anions.[17]

The thermal behavior of the solutions with X's higher than the congruent composition (X=0.0267 and 0.0305 in Fig. 7 and X=0.0244, 0.0267, and 0.0305 in Table 3) shows no formation of another kind of hydrate other than the one discussed above (m=42±2). In Table 3 the observed values of ΔH_1 (or of ΔH_2) are compared with the values calculated by a relation of $5.45\times10^3 n_0$. The quantity, $5.45\times10^3 n_0$, means the enthalpy of fusion of the hydrate (J unit) if we assume that all the water molecules participate in the hydrate formation and further that the enthalpy of fusion is equal to 5.45 kJ mol^{-1} as determined above. The observed value of ΔH_1 for X=0.0244 solution is almost compatible with the calculated one, whereas in more concentrated solutions (X=0.0267 and 0.0305) the observed values of ΔH_1 become small as compared with the calculated ones. At present a quantitative interpretation cannot be made because of a lack of information concerning the state of the solid-liquid mixture in such concentrated solutions.

Studies of Collectors. VIII. The Flotation of the Gallium Ion with Oxine-Type Surfactants

Yoshifumi KOIDE,* Hisashi HOKONOHARA, Kuniaki JINNAI, and Kimiho YAMADA
Department of Applied Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860
(Received December 8, 1986)

Oxine-type surfactants(5-alkanoyl-8-quinolinol, R_nOx, n=2, 8, 12, 18) and $R_{12}OOx$ were prepared and used as ion-flotation collectors. Cu^{2+}, Fe^{3+}, Zn^{2+}, and Pb^{2+} were floated with $R_{12}Ox$ around a neutral pH, and the selective removal of Cu^{2+} from the mixture of these four metal ions was observed at pH 1.0. The floatability of Ga^{3+} was also high around the neutral pH, and the selective Ga^{3+} flotation from an Al^{3+} (100 ppm)-Ga^{3+}(20 ppm) mixture was observed by using R_8Ox in the pH regions of 3—4 and 10—13.3 (0.2 M NaOH soln), while $R_{12}Ox$ did not float the Ga^{3+} so much at pH 10—13.3. By the addition of a small amount of R_nPy to the $R_{12}Ox$ or by the solvent sublation, an effective flotation of Ga^{3+} was observed in the pH range of 10—13.3. The Ga^{3+} flotation was superior to the Ga^{3+} extraction in pH 2—4. However, in a strong alkaline region the floatability was lower than the extractability.

The recovery of a metal ion from an acidic or a basic solution is usually difficult even if it is necessary to do so. The recovery by ion flotation from such a solution is considered to be more effective than that by extraction because the metal ion can be floated with the collector as a 1 : 1 complex, as has been reported in a previous paper.[1,2] In recent years, Ga^{3+} has drawn much attention in the electronics market as material of a Ga-As semiconductor. For the purpose of recovering the Ga^{3+} from a Bayer solution, 7-(3,3,5,5-tetramethyl-1-vinylhexyl)-8-quinolinol(KELEX 100) has been used as an extraction reagent.[3] The KELEX 100 has a large distribution coefficient. However, it is expensive and requires a larger amount for extraction than the collector used in ion flotation. In this connection, 8-quinolinol(Ox) is quite interesting since it is a well known as a chelating reagent, and 8-quinolinol with a long side chain can be expected to be useful as an ion-flotation collector for Ga^{3+}, just like alkylated acetylacetone.[2] In the present paper, a higher alkanoyl group was introduced to oxine, and the 5-alkanoyl-8-quinolinol(R_nOx, n denotes the carbon number of the alkanoyl group, 2, 6, 8, 12, 18) was used as an ion-flotation collector. The preparation of R_nOx is far easier than that of KELEX 100, and its hydrophile-lipophile balance(HLB) can be regulated by varying the alkyl group or by converting the carbonyl group into an oxime derivative. There are many reports concerning Ga^{3+} extraction.[4] However, no study of a Ga^{3+} flotation using an oxine-type surfactant has yet been reported as far as the present authors are aware, except for an ion flotation of Ga^{3+} in hydrochloric acid with cationic surfactants.[5]

Experimental

Materials. The Ox was obtained from Wako Pure Chemical Industries, Ltd. The R_nOx was prepared by the Fries rearrangement of the alkanoic acid Ox ester.[6,7] The preparation of $R_{12}Ox$ was as follows: Equimolar quantities (0.05 mol) of Ox and dodecanoyl chloride were dissolved in nitrobenzene below 5 °C, and then 0.1 mol of aluminium chloride was added to the nitrobenzene solution. The reaction mixture was heated at 80—85 °C for 15—16 h. After cooling to room temperature, 100 cm^3 of a 10% HCl solution was added to the reaction mixture, and then the nitrobenzene was steam-distilled. Twenty cm^3 of 35% HCl was then poured into the residue. The precipitant, crude $R_{12}Ox$, was filtered and recrystallized with methanol after neutralization. The R_2Ox, R_6Ox, R_8Ox, and $R_{18}Ox$ were obtained by the same procedure. The oxime derivative, $R_{12}OOx$, was prepared from $R_{12}Ox$ by reference to the phenylglyoxime preparation.[8] A 40-cm^3 portion of a 70% ethanol solution containing 0.02 mol of $R_{12}Ox$ and 0.1 mol of hydroxylamine was refluxed for 6 h. The solvent was evaporated, and the remainder, $R_{12}OOx$, was washed with cold water. The yields were: R_2Ox 67%, R_6Ox 12%, R_8Ox 39%, $R_{12}Ox$ 55%, $R_{18}Ox$ 50%, and $R_{12}OOx$ 90%. The structures were confirmed by means of their IR spectra (Shimadzu IR-408), ^1H NMR spectra (JEOL JMN-MH-100), and elementary analyses (Yanako CHN Corder MT-3). Mp: R_2Ox, 114.0—115.4 °C; $R_6Ox \cdot HCl$, 172.0—174.0 °C; R_8Ox, 63.5—64.2 °C; $R_{12}Ox$, 66.8—68.5 °C; $R_{18}Ox$, 83.2—85.0 °C; $R_{12}OOx$, 151.0—152.5 °C. IR(KBr): ν_{CH} 2900, 2850 cm^{-1}, $\nu_{C=O}$ 1670 cm^{-1}, $\nu_{C=C,C=N}$ 1620, 1570, 1510 cm^{-1}. ^1H NMR (CCl_4): δ=0.9 (3H, t, CH_3-C-C-), 1.3 (methylene in alkane), 3.0 (2H, t, -CH_2-CO-), 7.2, 7.8, 8.2, 9.0, 9.8 (5H, -C_9H_5NO). R_2Ox Found: C, 70.23; H, 4.77; N, 7.43%; Calcd for $C_{11}H_9O_2N$: C, 70.59; H, 4.81; N, 7.49%. $R_6Ox \cdot HCl$ Found: C, 64.29; H, 6.37; N, 4.98%; Calcd for $C_{15}H_{18}O_2NCl$: C, 64.40; H, 6.49; N, 5.01%. R_8Ox Found: C, 74.85; H, 7.67; N, 5.23%; Calcd for $C_{17}H_{21}O_2N$: C, 75.25; H, 7.80; N, 5.16%. $R_{12}Ox$ Found: C, 76.64; H, 9.00; N, 4.19%; Calcd for $C_{21}H_{29}O_2N$: C, 77.02; H, 8.93; N, 4.28%. $R_{18}Ox$ Found: C, 78.45; H, 10.27; N, 3.49%; Calcd for $C_{27}H_{41}O_2N$: C, 78.78; H, 10.04; N, 3.40%. $R_{12}OOx$ Found: C, 73.20; H, 8.73; N, 7.90%; Calcd for $C_{21}H_{30}N_2O_2$: C, 73.64, H, 8.83; N, 8.18%.

The surface tensions of a R_nOx solution and a $R_{12}OOx$ solution were measured by the use of a Du Noüy surface-tension balance. The surface tensions of aqueous solutions of R_8Ox, $R_{12}Ox$, and $R_{12}OOx$ at their critical micellar concentrations (cmc) are 47 dyn cm^{-1} (1 dyn=1×10^{-5}N) for 4×10^{-4} M (1 M=1 mol dm^{-3}) R_8Ox at pH 0.6, 39 dyn cm^{-1} for 2×10^{-4} M $R_{12}Ox$ at pH 0.6, and 41 dyn cm^{-1} for

7×10^{-4} M $R_{12}OOx$ at pH 0.6, 46 dyn cm^{-1} for 4×10^{-3} M R_8Ox at pH 13, and 44 dyn cm^{-1} for 4×10^{-3} M $R_{12}Ox$ at pH 13. $R_{18}Ox$ was scarcely soluble in water. The concentrations of these surfactants were kept below their cmc in the following ion flotation.

Apparatus and Procedures. The removals of seven metal ions (Ga^{3+}, Al^{3+}, Fe^{3+}, Cu^{2+}, Zn^{2+}, Pb^{2+}, and Ag^{+}) were measured by the methods of ion flotation, solvent sublation, and extraction. The apparatus and procedures of ion flotation and extraction were the same as those previously reported.[1] The apparatus used in the solvent sublation was the same as that used in the ion flotation; a cell made up of a glass cylinder containing 500 cm^3 of an aqueous solution (Cu^{2+})-25 cm^3 of benzene or 200 cm^3 of an aqueous solution (Ga^{3+})-50 cm^3 of benzene. The determined amount of R_nOx was added to the aqueous solution, the pH of which had been adjusted to the desired value. Nitrogen gas was introduced through a sintered-glass disk (No.4) into the aqueous solution. The rate of gas flow was kept at 36—40 $cm^3\ s^{-1}$. The concentrations of metal ions were determined with an atomic-absorption spectrophotometer (Hitachi 170-30).

The floatabilities of the metal ions in the ion flotation and in the solvent sublation or the extractabilities of the metal ions were calculated using this equation:

$$F(\%) = \frac{a_0 - a_1}{a_0} \times 100$$

where a_0 and a_1 denote the initial and final metal-ion concentrations in a solution respectively.

Results and Discussion

Flotation and Extraction from an Acidic Solution. The series of R_nOx's were used as ion-flotation collectors and extraction reagents in the acidic pH range. The effect of the removals of Cu^{2+}, Fe^{3+}, and Zn^{2+} are shown in Fig. 1. R_nOx bearing a long alkyl chain floated the metal ions. The Cu^{2+} flotation in the pH regions of 1—2 was more effective than the Fe^{3+} or Zn^{2+} flotation and than the metal extractions in that pH region. The floatabilities varied with the difference in the alkyl-chain length, resulting in the variation of their surface activities (HLB). Pb^{2+} and Ag^{+} didn't float in this acidic pH range, but these five metal ions were floated with R_nOx around a neutral pH. They are not shown in the figures except for Cu^{2+}. The Cu^{2+} floatabilities by using 4×10^{-5} M KELEX 100 were 0% at pH 1.0, 14% at pH 2.0, and 18% at pH 3.0. On the other hand, by using R_nOx the Cu^{2+} and Fe^{3+} were extracted into the benzene layer above the pH values of 3 and 5 respectively, and their extractabilities for the solution containing equimolar amounts of R_nOx and metallic ions were almost independent of the alkyl-chain length. It is likely that the extractabilities are affected by the alkyl group in the presence of an excess of R_nOx. Figure 2 shows the Cu^{2+} flotation and the Cu^{2+} extraction by using a molar amount of R_nOx double that of Cu^{2+}. The

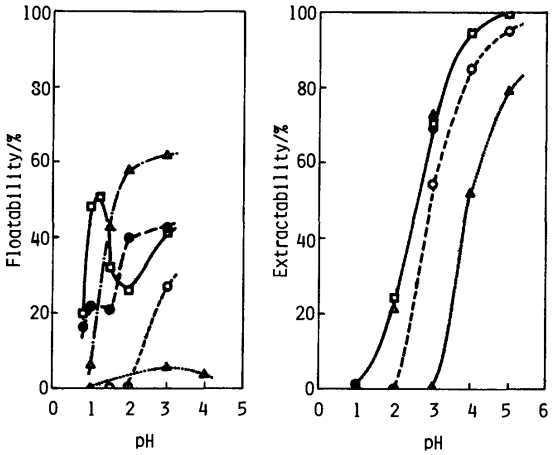

Fig. 2. Effects of alkyl-chain length on Cu^{2+} floatability and Cu^{2+} extractability. Initial concn: Cu^{2+} 1×10^{-5} M, R_nOx 2×10^{-5} M. ▲: Ox, ○: R_2Ox, △: R_8Ox, □: $R_{12}Ox$, ●: $R_{18}Ox$.

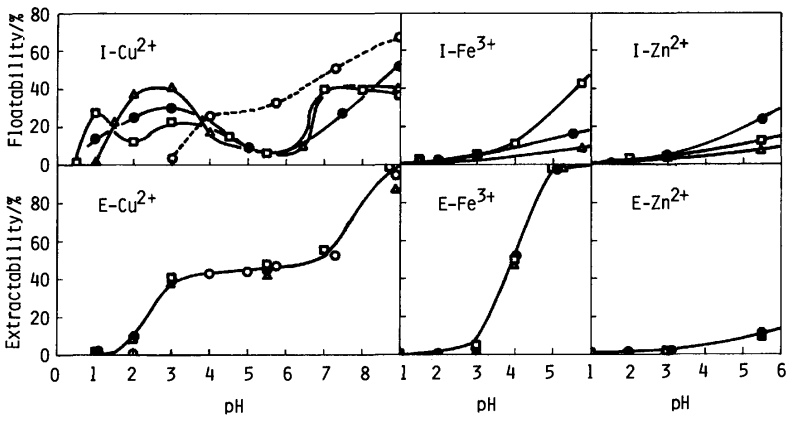

Fig. 1. Ion flotation and extraction. Initial concn: metal ion 1×10^{-5} M, R_nOx 1×10^{-5} M. I: ion flotation, E: extraction; ○: R_2Ox, △: R_8Ox, □: $R_{12}Ox$, ●: $R_{18}Ox$.

R_nOx bearing a long alkyl chain was far superior to the R_2Ox or Ox. The stability constants of Ox complexes are high (Cu^{2+} log K_{ML} 12.2, log K_{ML_2} 11.2, Fe^{3+} log K_{ML} 12.3, log K_{ML_2} 11.3).[2] The stability constants of the R_nOx complexes are presumed to be similar to the values of the Ox complexes. Therefore, the Cu^{2+} and Fe^{3+} could be complexed with equimolar R_nOx at a low concentration and a low pH. The 50% (Cu^{2+}) and 100% (Fe^{3+}) extractabilities in acidic pH indicate that the R_nOx/Cu^{2+} ratio in the extracted complex is 2:1 and the R_nOx/Fe^{3+} ratio is 1:1. These ratios were also confirmed by the method of continuous variation; e.g., for the $R_{12}Ox$-Cu complex, the concentration in benzene was measured with the absorbance at λ_{max} 415 nm. Their calculated HLB values, based on the Oda equation,[9] were $(R_{12}Ox)_2$-Cu 3.5 and $R_{12}Ox$-$Fe(OH)_2$ 6 respectively, so that they would have large distribution coefficients[10] and be extracted.

Then, the difference in the method of adding the collector in ion flotation was examined at pH 1.0, as may be seen in Fig. 3. A remarkable difference in the Cu^{2+} floatabilities was observed when 3—5×10^{-5} M $R_{12}Ox$ was added to the 1×10^{-5} M Cu^{2+}-mixed solution. The step-by-step addition was more effective than adding everything at one time, and the Cu^{2+} could be floated more selectively from a mixture of Cu^{2+}, Fe^{3+}, Zn^{2+}, and Pb^{2+} by the former method. The $R_{12}Ox/Cu^{2+}$ ratio in the scum was confirmed by the elementary analyses to be 1:1 (Found: C, 61.57; H, 7.57; N, 3.01%; Calcd for $C_{21}H_{28}O_2N \cdot Cu \cdot H_2O$: C, 61.66; H, 7.58; N, 3.44%). The complexes at pH 1.0 were surface-active $(R_nOx\text{-}M)^{m+}$, and their calculated HLB values[9] were $(R_{12}Ox\text{-}Cu)^+$ 9 and $(R_{12}Ox\text{-}Fe)^{2+}$ 15. Therefore, the hydrophobic Cu^{2+} complex would be floated selectively, and the hydrophilic Fe^{3+} complex thus produced would disperse the $(R_{12}Ox\text{-}Cu)^+$ complex into the solution. Actually, an excellent Cu^{2+}-selectivity from the mixture of all the metal ions except for Fe^{3+} was observed even when 3—5×10^{-5} M $R_{12}Ox$ was added all at one time. These results were similar to that shown in Fig. 3-(1) and so are not shown in the figures. The scum ($R_{12}Ox$-Cu complex) was dissolved in 20 cm^3 of benzene, and the benzene solution was shaken with 20 cm^3 of a 1 M or 3 M HCl solution. The recoveries of $R_{12}Ox$ from the benzene layer were 100% with 1 M HCl and 93% with 3 M HCl, while those of Cu^{2+} from the aqueous layer were 96% with 1 M HCl and 100% with 3 M HCl.

Ga^{3+} Flotation and Extraction from an Acidic Solution. The recovery of Ga^{3+} (20 ppm) was further examined. Figure 4 shows the pH effect on the floatability of Ga^{3+} from equimolar solutions (2.87×

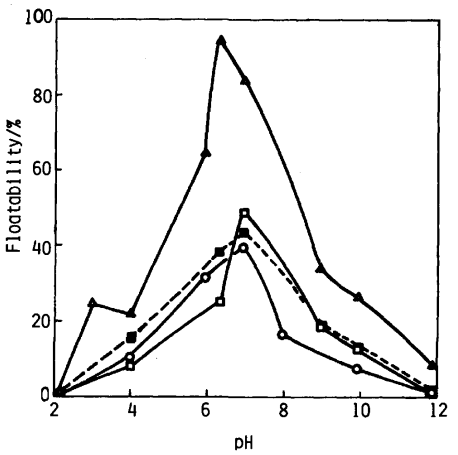

Fig. 4. Effect of pH on Ga^{3+} flotation. Initial concn: Ga^{3+} 2.87×10^{-4} M(20 ppm), R_nOx 2.87×10^{-4} M. O: R_2Ox, △: R_8Ox, □: $R_{12}Ox$, ■: $R_{12}OOx$.

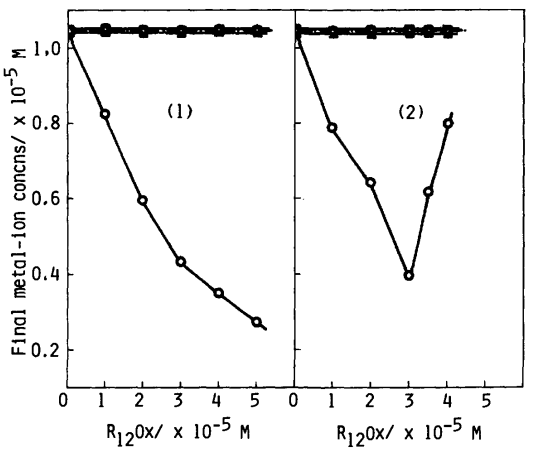

Fig. 3. Selective removal of Cu^{2+} at pH 1.0. Initial concn of metal ions mixture: Cu^{2+}, Fe^{3+}, Zn^{2+}, and Pb^{2+} 1×10^{-5} M, respectively. (1) Stepwise addition of $R_{12}Ox$. (2) Additions of $R_{12}Ox$ at a time. O: Cu^{2+}, ■: Fe^{3+}, △: Zn^{2+}, ▲: Pb^{2+}.

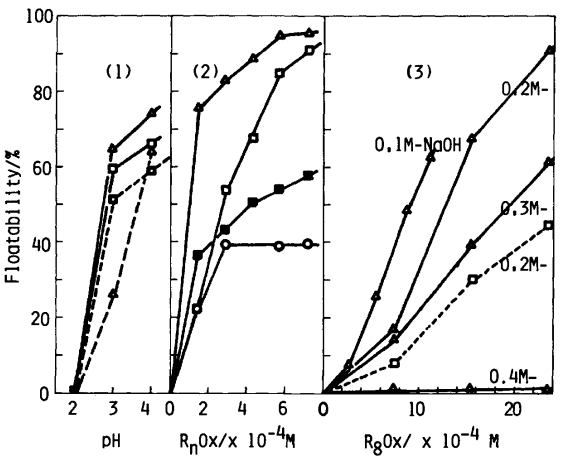

Fig. 5. Ga^{3+} flotation. Initial concn: Ga^{3+} 2.87×10^{-4} M(20 ppm). (1) R_nOx 5.74×10^{-4} M; ▲: extraction using R_8Ox, □: extraction using $R_{12}Ox$. (2) pH 7. (3) 0.1—0.4 M NaOH soln. O: R_2Ox; △: R_8Ox, □: $R_{12}Ox$, ■: $R_{12}OOx$.

10^{-4} M) of R_nOx and Ga^{3+}. A high floatability was observed around the neutral pH. R_8Ox was the most effective collector among the R_nOx homologues. The Ga^{3+} floatability increased as the concentration of R_nOx increased, as is shown in Fig. 5: The floatabilities for a 2.87×10^{-4} M Ga^{3+} solution were 65—72% in the pH regions of 3—4 with 5.74×10^{-4} M R_8Ox, and 96% at pH 7 with $5.7—7.2\times10^{-4}$ M R_8Ox. However, the Ga^{3+} floatability when R_2Ox or Ox was used was low: 40% at pH 7 with R_2Ox and 0% in the pH region of 0—14 with $0—5\times10^{-5}$ M Ox. The Ga^{3+} flotation at pH 3 was surperior in efficiency to the Ga^{3+} extraction at pH 3, but they were similar at pH 4. Furthermore, the Ga^{3+} was found to float selectively from a Ga^{3+}-Al^{3+} mixture in pH 3—4, but it was floated simultaneously with Al^{3+} at pH 7, as is shown in Fig. 6. The stability constants (log K_{ML}) of the Ox and the 8-hydroxy-5-quinolinesulfonic acid (OxS) complexes are Ox-Ga 14.51,[11] OxS-Ga 13.56,[12] and OxS-Al 9.76.[12] The values of the R_nOx complexes are presumed to be similar to those of the Ox and OxS complexes.[9] Therefore, the more stable Ga^{3+} must be floated selectively. The Ga^{2+} flotation and selectivity in the alkaline region will be discussed in the next section.

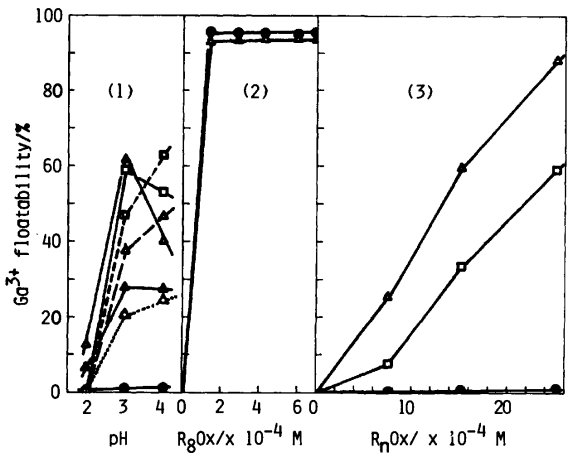

Fig. 6. Ga^{3+} selectivity from Ga^{3+}-Al^{3+} mixture. Initial concn of metal ions mixture: Ga^{3+} 2.87×10^{-4} M(20 ppm)-Al^{3+} 3.71×10^{-3} M(100 ppm). (1) R_nOx 5.74×10^{-4} M; ——△——: extraction using R_8Ox, ——□——: extraction using $R_{12}Ox$. ▲: ion flotation using 2.87×10^{-4} M R_8Ox, ---△---: extraction using 2.87×10^{-4} M R_8Ox. (2) pH 7. (3) 0.2 M NaOH soln. △: R_8Ox, □: $R_{12}Ox$, ●: floatability of Al^{3+} by using R_8Ox.

Flotation and Extraction from an Alkaline Solution. The Ga^{3+} floatabilities of 2.87×10^{-4} M Ga^{3+} at pH 10 were similar to those at pH 4, while the floatabilities at pH 11 were 63% with 5.74×10^{-4} M R_8Ox and 94% with 8.61×10^{-4} M R_8Ox. The amount of R_8Ox remaining after the Ga^{3+} flotation was below 10^{-5} M. Therefore, the R_8Ox/Ga^{3+} ratio in the scum was determined to be 2:1 from the elementary analyses{Found (pH 11): C, 65.61; H, 6.72; N, 5.05%; Found (pH 4): C, 66.76; H, 6.74; N, 4.70%; Calcd for R_8Ox-Ga: C, 60.04; H, 5.93; N, 4.12%; Calcd for $(R_8Ox)_2$-Ga: C, 66.90; H, 6.61; N, 4.59%; Calcd for $(R_8Ox)_3$-Ga: C, 69.54; H, 6.87; N, 4.77%}. Consequently, the equimolar R_8Ox is considered to float. The Ga^{3+} flotation from a strong alkaline solution is shown in Fig. 5-(3). The Ga^{3+} could be floated from the alkaline solution with a large excess of R_8Ox or $R_{12}Ox$. However, the R_nOx became insoluble in a strong NaOH solution (R_8Ox above 0.4 M, $R_{12}Ox$ above 0.3 M), while no flotation effect was observed when R_6Ox was used because of the soluble Ga^{3+} complex (yellow green). The Ga^{3+} flotation using KELEX 100 was less effective than those using R_8Ox and $R_{12}Ox$: The Ga^{3+} floatabilities from the 2.87×10^{-4} M (20 ppm) Ga^{3+} in a 0.1 M NaOH solution were 13% with 8.6×10^{-4} M KELEX 100, 31% with 17.2×10^{-4} M, 52% with 25.8×10^{-4} M, and 70% with 34.4×10^{-4} M. The R_nOx used as a collector was regenerated by the treatment of the scum with 5 M HCl, resulting in the precipitation of R_nOx and a Ga^{3+} solution. The Ga^{3+} selectivity from the Ga^{3+}-Al^{3+} mixture in a 0.2 M NaOH solution is shown in Fig. 6-(3). The Ga^{3+} was also found to float selectively. The complexes produced in the alkaline solution were presumed to be something like the hydroxo-Ga complexes, $\{(R_nOx)_2$-$Ga(OH)_2\}^-$, because the hydrolysis constants (pK_n) for the aqua-Ga complexes were pK_1 2.8—2.9, pK_2 3.5—4.4, pK_3 4.5, pK_4—, pK_5 10.3, and pK_6 11.7.[13] The flotation effect was evaluated first by the degree of the formation of a surface-active complex. The HLB

values of these complexes are in the range of 4—13, as is indicated in Table 1; the HLB value of the Ga^{3+} complex is the same as that of the Al^{3+} complex. However, the Ox, R_2Ox, and R_6Ox complexes were surface-inactive in spite of their HLB values being in the range of 5—13; the surface tension of a 2.87×10^{-4} M R_6Ox solution was 60 dyn cm^{-1} at 15 °C. Presumably they could not float the Ga^{3+} because of their structural characteristics. The reaction rate of the complex formation is considered to be another factor in the selectivity of ion flotation. Since the reaction rates of Al^{3+} with general chelating agents are known to be slow,[14] the Ga^{3+} selectivity from a Ga^{3+}-Al^{3+} mixture was examined after a sufficient time for the formation of the Al^{3+} complex. However, the Ga^{3+} was floated selectively at 60 °C or after it had stood for 24 h; therefore, the complex stability was considered to be a dominant factor in the Ga^{3+} selectivity. On the other hand, Cu^{2+} was effectively floated with the R_nOx or $R_{12}OOx$ below pH 13, but Fe^{3+} was not effectively floated above pH 10, as is shown in Fig. 7-(1). In this connection, we made coflotation experiments on the Fe^{3+}-Cu^{2+} and Ga^{3+}-Cu^{2+} systems in order to study the possibility of enhancing the floatabilities of Fe^{3+} and Ga^{3+} by the addition of Cu^{2+}. The Fe^{3+}-Cu^{2+} coflotation was done at pH 10 and 13, and the Ga^{3+}-Cu^{2+} coflotation was done at pH 10 and 12. The floatability of 5×10^{-5} M Fe^{3+} was 20% at pH 10 with 10^{-4} M $R_{12}Ox$ in the absence of Cu^{2+} and 80% in the presence of 5×10^{-5} M Cu^{2+}. The Fe^{3+}-Cu^{2+} coflotation at pH 13 was also effective, as is shown in Fig. 7-(2). However, the Ga^{3+}-Cu^{2+} coflotation was ineffective; the floatabilities of 2.87×10^{-4} M Ga^{3+} at pH 10 in the absence of Cu^{2+} and in the presence of 5×10^{-4} M Cu^{2+} were 55 and 43% respectively with 5×10^{-4} M $R_{12}Ox$, and 99 and 58% respectively with 10^{-3} M $R_{12}Ox$. The floatabilities at pH 12 when $R_{12}OOx$ was used were also high for Cu^{2+}, but low for Ga^{3+}, as is shown in Fig. 7-(3). Furthermore, the Ga^{3+} selectivity from a Ga^{3+} (2.87×10^{-4} M)-Al^{3+} (3.70×10^{-3} M)-Cu^{2+}(5×10^{-4} M) mixture was found to be less: The floatabilities of metal ions at pH 10 when 15×10^{-4} M $R_{12}OOx$ was used were Ga^{3+} 66%, Al^{3+} 49%, and Cu^{2+} 99%. The difference between the floatabilities of Fe^{3+} and Ga^{3+} may be due to the hydrophilic property caused by their hydrolysis.

Flotation with Cationic Surfactants. Ga^{3+} in an alkaline solution exists as an anionic polyhydroxo species, $Ga(OH)^{3-x}_{x(=4,5,6)}$, and the R_nOx probably forms an anionic hydroxo-gallium complex, e.g., $\{(R_nOx)_2\text{-}Ga(OH)_2\}^-$.[13] Therefore, the effects of the addition of a cationic surfactant were examined. Four *N*-alkylpyridinium bromides (R_nPy, n=8, 12, 18, 22) were prepared by the procedure of Knight et al.,[15] and their structures were identified by means of their melting points and the results of elementary analyses. The flotation of Ga^{3+} with the cationic R_nPy was examined in the absence of R_nOx. However, the R_8Py, $R_{12}Py$, $R_{18}Py$, and $R_{22}Py$ were not useful for Ga^{3+} flotation in the alkaline region. Then, both surfactants, the chelating R_nOx and the cationic R_nPy, were added to the Ga^{3+} solution. The Ga^{3+} floatabilities when R_8Ox-R_nPy was used were less than those without R_nPy; in the absence of the R_nPy, the R_8Ox was more effective than $R_{12}Ox$, as is shown by the dotted line in Fig. 8. On the other hand, the Ga^{3+} floatabilities when $R_{12}Ox$-R_nPy was used became higher than that without R_nPy, but were steeply lowered in a high concentration of $R_{12}Ox$, as is shown in Fig. 8-(2). The $R_{12}Ox$ in the presence of

2.87×10^{-4} M R_nPy enhanced the Ga^{3+} floatability more {Fig. 8-(3)}. These floatabilities varied a little with the difference in the alkyl-chain length of R_nPy. The cationic R_nPy was considered to be attracted to the anionic R_nOx-gallium complex or to the anionic R_nOx, resulting in a green suspension. Consequently, the colloidal $R_{12}Ox$-Ga complex may be floated with the surface-active R_nPy, but the Ga^{3+} floatability would be lowered in a high concentration of $R_{12}Ox$ (above 3-fold molar to Ga^{3+}) because of the complexation of R_nPy with the excess $R_{12}Ox$. On the other hand, the hydrophilic R_8Ox-Ga complex should be solubilized by the surface-active R_nPy. In addition, the more hydrophilic R_nOx, R_2Ox-R_nPy, R_6Ox-R_nPy, and $R_{12}OOx$-R_nPy did not show any flotation effect(these data are not shown in Fig. 8). The selective flotation of the Ga^{3+} at pH 13 from a Ga^{3+} (2.87×10^{-4} M, 20 ppm)-Al^{3+} (3.70×10^{-3} M, 100 ppm) mixture was also done, as is shown in Fig. 9. A highly selective flotation of Ga^{3+} at pH 13 is, of course, observed with the increase in the $R_{12}Ox$-R_nPy concentration, as is shown in Fig. 9-(2), (3); the floatabilities of metal ions when 11.5×10^{-4} M $R_{12}Ox$-5.76×10^{-4} M $R_{22}Py$ was used were Ga^{3+} 71% and Al^{3+} 0%. The Ga^{3+} selectivities when R_8Ox-R_nPy was used were almost identical with those without R_nPy, as is shown in Fig. 9-(1). Because the cationic R_nPy ions combine with the large excess of $Al(OH)^{3-x}_{x(=4,5,6)}$ ions, the Ga^{3+} floatabilities in the Ga^{3+}-Al^{3+} mixture are unaffected by the presence of R_nPy. The Al^{3+} did not float with any of the collectors used because of its lower stability.

Solvent Sublation. Solvent sublation is known as a nonfoaming, absorptive, bubble-separation process.[10] Trace amounts of metal ions were concentrated, by means of ion flotation with collectors, and then the ion-associates were dissolved in an organic solvent for their analyses, e.g., for Cr^{6+}, with diphenylcarbazide-sodium dodecyl sulfate;[16] for Fe^{3+}, with 1, 10-phenanthroline-sodium dodecyl sulfate,[17] and for Ge, with phenylfluorone-cyclohexane.[18] The collectors used in such flotation are generally a combination of complexing agents and oppositely charged surfactants or basic dyes.[19] However, a chelating surfactant has not yet been applied to a solvent-sublation collector.[20] Therefore, the R_nOx was examined as a solvent-sublation collector. Figure 10 shows the solvent sublation from an acidic (Cu^{2+}) and a basic solution (Ga^{3+}). The Cu^{2+} floatability when $R_{12}Ox$ was used at pH 1.0 varied with the aeration time and with the acid species. The Cu^{2+} could be floated initially as a 1:1 complex, and then the composition of the complex sublated, as well as that of that extracted, finally became 2:1. The formation of the Cu^{2+} complex with a small amount of $R_{12}Ox$ in a HCl solution was more difficult than that in a HNO_3 solution because of the formation of the stable Cu^{2+}-chloro complex.[2] The Ga^{3+} floatabilities by solvent sublation in the alkaline region (0.1, 0.3, 0.4 M NaOH) were superior to those by ion flotation, but inferior to the Ga^{3+} extractabilities. Thus, the R_nOx used as a solvent-sublation collector in the alkaline region showed properties intermediate between those of the ion-flotation collector and the extraction reagent. The solvent sublation using KELEX 100 was similar to that using R_8Ox, but the extraction was less: the floatabilities from the 2.87×10^{-4} M (20 ppm) Ga^{3+} in a 0.1 M NaOH solution were 45—47% with 8.6—14.3×10^{-4} M KELEX 100, while the extractabilities were 25% with

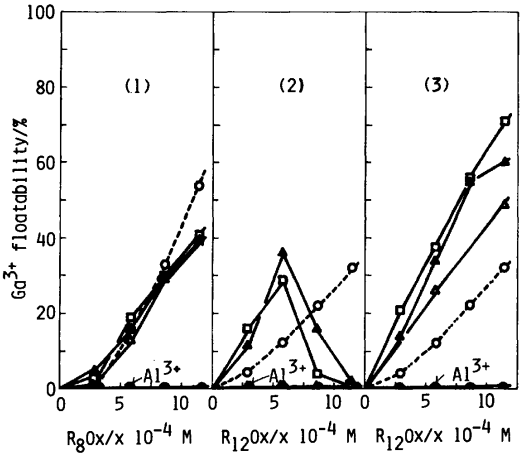

Fig. 9. Selectivity using R_nOx-R_nPy at pH 13. Initial concn of metal ions mixture: Ga^{3+} 2.87×10^{-4} M(20 ppm)-Al^{3+} 3.70×10^{-3} M(100 ppm). (1) R_nPy 1.44×10^{-4} M. (2) R_nPy 1.44×10^{-4} M. (3) R_nPy 4.31×10^{-4} M. △: $R_{12}Py$, ▲: $R_{18}Py$, □: $R_{22}Py$, ○: without R_nPy, ●: Al^{3+} floatability by using R_nOx-$R_{18}Py$.

Ga^{3+} Initial concn: Ga^{3+} 2.87×10^{-4} M(20 ppm) in 0.1—0.4 M NaOH soln and in soln of pH 4 or 11, R_8Ox 8.61×10^{-4} M; Volume: aq(200 cm^3)-benzene(50 cm^3). ▲: Solvent sublation. △: extraction.

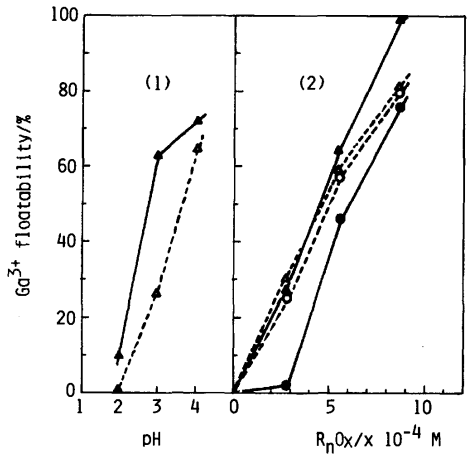

Fig. 11. Solvent sublation of Ga^{3+}. Initial concn: Ga^{3+} 2.87×10^{-4} M(20 ppm). (1) R_8Ox 5.74×10^{-4} M. ▲: Solvent sublation, △: extraction. (2) pH 11. ▲: Solvent sublation using R_8Ox, △: extraction using R_8Ox, ●: solvent sublation using $R_{12}Ox$, ○: extraction using $R_{12}Ox$.

8.6×10^{-4} M and 50% with 28.7×10^{-4} M. However, the gelation of a kerosene solution of R_nOx took place upon Ga^{3+} extraction from a Bayer solution, and KELEX 100 was still effective: 58% with 0.27 M KELEX 100 in kerosene (KELEX 100/$Ga^{3+}\approx80$). Therefore, the solvent sublation of Ga^{3+} using R_8Ox was superior to the Ga^{3+} extraction in the pH region from 3 to 11, as is shown in Fig. 11. As regards the solvent sublation for the Ga^{3+}-Al^{3+} system, the Ga^{3+} was floated selectively from the mixture at pH 3—4 and pH 11, but the Ga^{3+} and Al^{3+} were floated simultaneously in pH 5—10. Such a behavior of Ga^{3+} flotation from the mixture was similar to that for the solution of Ga^{3+} alone.

Thus, R_8Ox and $R_{12}Ox$ were confirmed to be more effective collectors than KELEX 100 for Cu^{2+} in an acidic solution and for Ga^{3+} in a basic solution and to favour the selective ion flotation of Cu^{2+} from a metal-ion mixture and that of Ga^{3+} from a Ga^{3+}-Al^{3+} mixture. These results prove that a useful collector in an acidic or a basic solution can be designed by the selection of a stronger complexing ligand and the regulation of its HLB, as well as by the preparation of a usual collector.[1)]

Reaction Mechanism for Selective Synthesis of Gasoline-Range Isoalkanes from Syngas over RuPtHY Zeolites. II.[1] Role of Metals and Acid Sites

Yong-Gong SHUL, Yukari ARAI, Takashi TATSUMI,* and Hiro-o TOMINAGA
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received December 16, 1986)

Role of metals and acid site in selective synthesis of gasoline-range isoalkanes from syngas catalyzed by zeolite Y supported Ru-Pt alloy has been studied. As a probe molecule 1-alkene was added into syngas over the various combination of catalysts. Alloying Ru with Pt enhanced 1-octene conversion as well as CO conversion. Reaction of 1-octene over metal-free DAHY (dealuminated HY) zeolite produced cracking products with high selectivity for isobutanes; C_{3+} carbon number distribution was similar to that from CO hydrogenation over DAHY2R2P (Ru and Pt 2 wt%, respectively), suggesting that the selective formation of isoalkanes in gasoline-range from CO–H_2 over DAHY2R2P could be essentially due to acid-catalyzed reactions on zeolites. Cracking of 1-octene was affected by the support and increased in the order: NaY2R2P<HY2R2P<DAHY2R2P. Products via disproportionation were predominant for NaY2R2P and HY2R2P and those via simple cracking prevailed in DAHY2R2P. This could account for shift to light side in carbon number distribution from simple CO hydrogenation over DAHY2R2P. From syngas H_2/CO ratio= 13/2, methane was the main product. However, methane production was virtually unchanged on addition of 1-octene, implying that the presence of CO suppressed the hydrogenolysis of 1-octene on RuPt bimetallic site. Effects of contact time and temperature on selectivity for products were also discussed.

Non-Schulz-Flory kinetics in Fischer-Tropsch synthesis has been studied by several authors.[2-8] Limitation on chain growth has been reported for RuNaY,[2] RuLaY,[3] FeNaY,[4] RuPtHY,[5] and Co-alumina[6] catalysts. With Co-alumina, a maximum in carbon number distribution was dependent on the pore size of the support. Over the ruthenium-encaged NaY or LaY zeolite, the product contained no hydrocarbons larger than C_{11}; the chain growth probability suddenly dropped as chain length increased. This product pattern was ascribed to particle size effect of the ruthenium metals in zeolite.[7]

In a previous paper, we reported the selective synthesis of gasoline-range products rich in isoalkanes over RuPt-HY or DAHY (dealuminated HY).[5] The deviation from the Schulz-Flory product pattern was attributed to secondary reactions rather than the effect of particle size,[7] since increasing the ruthenium particle size in HY had no effect on final products pattern.[5] The evidence for secondary reactions was obtained by adding 1-alkenes (C_n) in the range of C_3—C_{11} as probe molecules into synthesis gas.[1] Addition of light alkenes (n=3,4) resulted in a pronounced increase in the yield of C_{n+1} and heavier, which could be ascribed to the oligomerization of feed alkene followed by cracking. On the other hand, simple cracking predominated in the case of addition of heavy alkenes ($n \geq 7$).

In the present paper, we report a study of the role of acid sites and Ru-Pt bimetallic sites in the selective formation of gasoline-range isoalkanes from synthesis gas. The dependence of H_2/CO ratio, contact time and temperature on the product selectivity is also discussed from mechanistic viewpoints.

Experimental

Catalysts were prepared by simultaneous ion exchange with an aqueous solution containing $[Ru(NH_3)_6]Cl_3$ and $[Pt(NH_3)_4]Cl_2$, as described previously.[5] NaY (SiO_2/Al_2O_3= 4.8) was obtained from Nikka Seiko Co. HY was prepared by ion exchange of NaY with an aqueous solution of NH_4NO_3, followed by calcination at 400 °C. DAHY (dealuminated HY, SiO_2/Al_2O_3=7.6) was obtained from Shokubai Kasei Co. The designation of catalyst is, for example, DAHY2R2P which stands for a catalyst with 2% Ru and 2% Pt by weight supported on DAHY. Reaction was carried out with a continuous flow tubular reactor containing 1 g of catalyst. The standard reaction conditions were 240 °C, 1.5 MPa, H_2/CO=3/2, and W/F=12.5 g-cat. h mol.$^{-1}$ Liquid alkene was added by use of a high pressure microfeeder and homogeneously mixed with synthesis gas over the preheated quartz wool-packed bed before the reaction zone. Detailed analysis of hydrocarbon products was carried out on a gas chromatograph equipped with a chemically bonded OV-1 capillary column. Each product was identified with a Shimadzu QP-1000 mass spectrometer. Chemisorption of NH_3 was carried out by using a grease-free glass constant-volume adsorption system. The sample was evacuated at ambient temperature and then subjected to temperature-programmed desorption (TPD) analysis of NH_3. The heating rate was 7 °C min^{-1} and the amount of NH_3 was determined mass spectrometrically.

Results and Discussion

Effect of Metal Loadings. The catalyst activity substantially declined during the course of a catalytic run. Figure 1 shows the change of CO conversion with time on stream over DAHY2R and DAHY2R2P in the absence and presence of 1-octene. Deactivation proceeded faster in the presence of 1-octene than in its

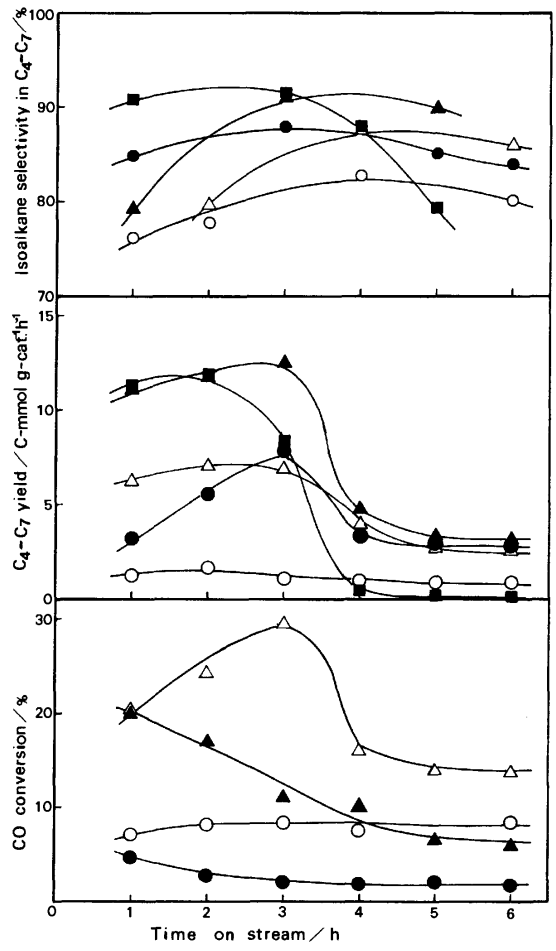

Fig. 1. Change of catalytic performance with time on stream. Reaction conditions: 240 °C, 1.5 MPa, $H_2/CO=3/2$, $W/F=12.5$ g-cat. h mol^{-1}, 1-octene feed rate=1.9 mmol g-cat.$^{-1}$ h^{-1}. Simple CO hydrogenation: △, DAHY2R2P; ○, DAHY2R. 1-Octene addition: ▲, DAHY2R2P; ●, DAHY2R; ■, DAHY (under He).

absence. In view of previous work,[8] this could be interpreted in terms of acceleration of coke deposition. Alloying of Ru with Pt enhanced CO conversion,as was observed with the HY-supported catalysts.[5] This was also the case in the presence of 1-octene.

The changes of the yield of and the isoalkane selectivity for C_4—C_7 fraction with time on stream are also shown in Fig 1. The effect of metal loadings on products is summarized in Table 1, where data obtained after 2—3 h on stream are adopted. The addition of 1-octene resulted in an increase in the yield of C_4—C_7, associated with the increase in their i/n ratios. Products in the C_4^+ range consisted mostly of branched alkanes. Alkanes with quaternary C-atoms were negligible for all the catalysts.[1,5] In most cases the fractions of monobranched alkanes in the range of C_4—C_6 were far above the equilibrium. Higher-than-equilibrium i/n ratios of C_4 and C_5 should be taken as evidence for the occurrence of carbenium ion cracking process.[1,9]

DAHY2R2P was similar to DAHY2R in the carbon number distribution of the products from CO-H_2 except for slightly increased selectivity for C_4—C_7.[5] The apparent conversion of 1-octene was considerably higher over DAHY2R2P than over DAHY2R. This higher cracking activity might be the cause of higher i/n ratios of C_4 and C_5 in simple CO hydrogenation over DAHY2R2P.[1] DAHY2P showed prolonged cracking activity of 1-octene than the other cases.

Cracking behavior of 1-octene under He flow over metal-free DAHY was also investigated. High initial selectivity for C_4 and no appreciable formation of C_1 and C_2 were observed, as would be expected for the acid-catalyzed cracking. As shown in Table 1, there were similarities between simple CO hydrogenation over DAHY2R2P and 1-octene cracking over DAHY in C_3^+ products distribution and selective formation of isoalkanes. Thus the selective formation of isoalkanes in gasoline-range from CO-H_2 over DAHY2R2P could be essentially due to acid-catalyzed reactions on zeolites. It should be noted that the metal-free DAHY support gave products exceptionally rich in branched isomers in C_4 and C_5 fractions, especially in the initial stage of the reaction. This could be caused by an increase in lifetime of carbenium ions associated with a low reactivity of hydrogen in the absence of metals,[10,11] resulting in the increased probability of isomerization before desorbing. The presence of metallic components should promote the hydrogenation of alkene to alkane and also may enhance hydrogen spillover to acid site,[12,13] leading to the formation of more normal isomers. In this regard, the proximity of metal and acid sites should be important to balancing these two functions.[5] On metal-free DAHY, decay of acid catalyzed cracking proceeded fast (Fig. 1) and the recovery of 1-octene added was ca. 60% after 2—3 h on stream, which suggested significant coke deposition.[8]

Effect of Support. Carbon number distribution of the products from CO-H_2 reaction was shifted to light side in the order: NaY2R2P[14,15]<HY2R2P<DAHY2R2P.[5] When 1-octene was added to syngas, product distribution was affected by concurrent cracking of 1-octene; apparent conversion[1] of 1-octene after 2—3 h on stream increased in the order: NaY2R2P (15%)< HY2R2P (26%)<DAHY2R2P (65%). As a result, yield of C_3—C_7 hydrocarbons increased by 1-octene addition in the same order: NaY2R2P<HY2R2P<DAHY2R2P.

TPD (temperature-programmed desorption) measurement of NH_3 revealed that the amounts of weak and strong acid, defined as the amount of ammonia desorbed below and above 350 °C, respectively, were as follows: NaY2R2P (1.51/0.20 mmol g-cat.$^{-1}$), HY2R2P (4.17/0.43 mmol g-cat.$^{-1}$), and DAHY2R2P (3.42/0.68 mmol g-cat.$^{-1}$). Therefore, the cracking tendency of 1-octene could be related to the amount of strong acid

sites on the catalysts: NaY2R2P<HY2R2P<DAHY2R2P. It is generally known that cracking requires strong acid sites.[16] Selectivity for C_4 fraction and apparent 1-octene conversion are plotted against the amount of strong acid sites of the catalysts in Fig. 2. The content of isobutane amounted to more than 80% of C_4 fraction. The increase in isobutane should come from simple cracking of 1-octene following skeletal isomerization of carbenium ion on acid sites. This type of simple cracking was remarkable for DAHY2R2P, which possesses stronger acid sites than HY2R2P or NaY2R2P.

$$C_8 \rightarrow 2C_4 \quad (1)$$

The increase in the yield of C_7 and C_6 should originate from the disproportionation of feed 1-octene, since neither C_6 nor C_7 can be directly formed by β-scission of C_8 carbenium ions.

$$2C_8 \rightarrow [C_{16}] \begin{cases} \nearrow C_7 + C_9 \\ \searrow C_6 + C_{10} \end{cases} \quad (2)$$

An attempt was made to estimate the contribution of the disproportionation and the simple cracking to the carbon number distribution. Based on the Eqs. 1 and 2, the ratio of C_7/C_4 was taken as a crude measure of the ratio of disproportionation to simple cracking and shown in Fig. 2. The C_7/C_4 ratio decreased in the order: NaY2R2P>HY2R2P>DAHY2R2P. This indicates low selectivity for disproportionation with the catalysts with a large amount of strong acid sites, as was proposed by Corma et al.[17] Molar ratios

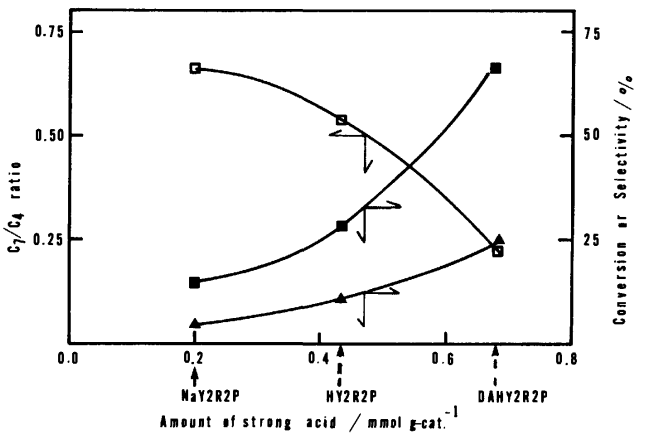

Fig. 2. 1-Octene conversion over NaY2R2P, HY2R2P, and DAHY2R2P. Reaction conditions: 240 °C, 1.5 MPa, $H_2/CO=3/2$, W/F=12.5 g-cat. h mol^{-1}, 1-octene feed rate=1.9 mmol g-cat.$^{-1}$ h^{-1}, after 2—3 h on stream. □, C_7/C_4 ratio; ■, 1-octene conversion;[1)] ▲, C_4 selectivity.

of C_7/C_9 and C_6/C_{10} are much larger than unity, suggesting subsequent cracking of heavy disproportionation products. The disproportionation/cracking ratio was also dependent on chain length of feed alkenes. With DAHY2R2P the ratio increased with decreasing the chain length as follows: $C_8<C_7<C_6$.[1]

Isomer distribution of C_8 fractions was scarcely dependent on the support, as shown in Fig. 3. The remaining C_8 feed consisted mostly of monobranched alkanes and dibranched alkanes. This suggests that relatively strong acid sites are not required for skeletal isomerization.[18] Cracking of alkanes and alkenes on large pore zeolite is considered to be preceded by conversion to readily formed branched isomers. With all this, it could be understood that the reaction path of 1-alkene should be strongly dependent on the acid properties of supports. The observed shift to the light side in carbon number distribution from simple CO hydrogenation over DAHY2R2P, compared to that over HY2R2P, was attributable to relatively large amount of strong acid sites.

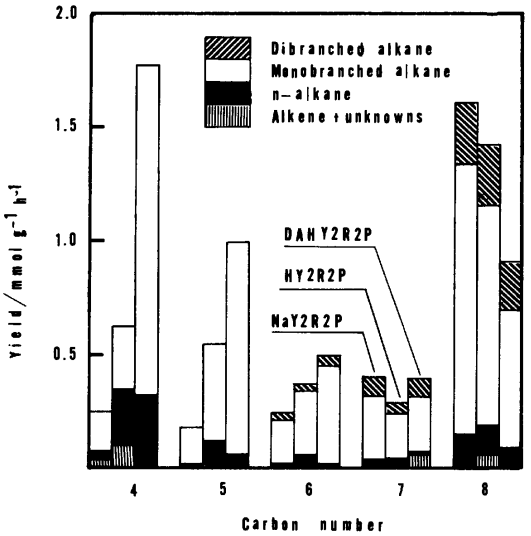

Fig. 3. Isomer distribution of product over NaY2R2P, HY2R2P, and DAHY2R2P. Reaction conditions: 240 °C, 1.5 MPa, $H_2/CO=3/2$, $W/F=12.5$ g-cat. h mol^{-1}, 1-octene feed rate=1.9 mmol g-cat.$^{-1}$ h^{-1}, after 2—3 h on stream.

Effect of H_2/CO Ratio. Effect of the partial pressure of H_2 and CO on products from DAHY2R2P was investigated by varying the H_2/CO ratio under the total pressure kept constant at 1.5 MPa. The obtained carbon number distribution is shown in Fig. 4. Isomer distribution is listed in Table 2. In the case of simple CO hydrogenation with high H_2/CO ratio large amount of methane was produced and the carbon number distribution shifted to light side. Activity decay was mitigated under these conditions, which was in agreement with the findings that the stabilized activity was obtained in case CH_4 was the main product.[8] Data obtained after 2—3 h on stream are shown in Table 2 and Fig. 4. Interestingly, only dimethyl isomers were detected for C_6 and C_7. Under these conditions the probability of skeletal isomerization could be high; the long chain alkenes and alkanes were virtually absent, resulting in the decrease in the rate of competitive adsorption and hydride transfer and hence prolonged lifetime of carbenium ion on acid site.[10,19]

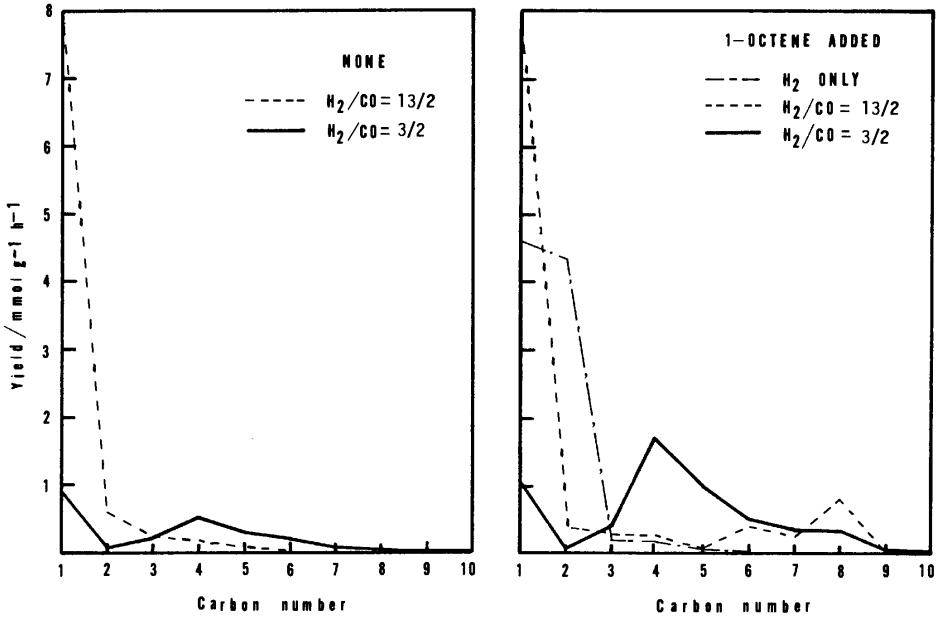

Fig. 4. Effect of H_2/CO ratio on carbon number distribution. Catalyst: DAHY2R2P; Reaction conditions: 240 °C, 1.5 MPa, $W/F=12.5$ g-cat. h mol^{-1}, 1-octene feed rate= 1.9 mmol g-cat.$^{-1}$ h^{-1}, after 2—3 h on stream.

a) Catalyst : DAHY2R2P; reaction conditions : 240°C, 1.5 MPa, W/F=12.5 g-cat. h mol^{-1}, data obtained after 2—3 h on stream, M : methyl, DM : dimethyl, TM : trimethyl, *c* : cis, *t* : trans. b) 1-Octene feed rate : 1.9 mmol g-cat.$^{-1}$h^{-1}.

Contribution of acid-catalyzed cracking to the carbon number distribution in the case of 1-octene addition seems to be less significant with H_2/CO= 13/2 than with H_2/CO=3/2. The addition of 1-octene to syngas with H_2/CO=13/2 resulted in the slight increase in the yield of C_6 and C_7, as shown in Fig. 4. In both cases, methane production was virtually unchanged on addition of 1-octene, suggesting methane formed mostly derived from CO hydrogenation directly. The higher H_2/CO ratio gave lower cracking conversion of 1-octene and larger portion of straight-chain products (Table 2). This would be caused by facile metal-promoted hydrogenation of 1-octene and other alkenes desorbed before hydrocracking since alkanes are less susceptible to hydrocracking than alkenes.[1)] One must also consider the desorption of alkanes from carbenium ions promoted by higher concentration of activated hydrogen,[12,13,19)] resulting in decrease in the chance of skeletal isomerization.

In the absence of CO, 1-octene converted to methane and ethane owing to hydrogenolysis on Ru-Pt bimetallic alloy (Fig. 4). It should be noteworthy that isobutane comprises most of the C_4 fraction. It was imagined that a large portion of 1-octene underwent carbenium ion type reactions on acid sites and the formed primary products were further hydrocracked to methane and ethane on metallic site. The relatively high yield of ethane can be accounted for by the

increasing order of activation energy of C-C bond breaking: $C_4<C_3\ll C_2$.[20] Small amount of CO (13%, $H_2/CO=13/2$) was sufficient to retard the hydrogenolysis of 1-octene. Further increase in CO fraction ($H_2/CO=3/2$) suppressed the methane formation during the courses of F-T synthesis. These findings imply negligible contribution of hydrogenolysis on metals to carbon number distribution of products in simple CO hydrogenation under standard conditions.

Effect of Contact Time. Effect of time factor on product distribution for DAHY2R2P was studied. The ratio of 2-M (2-methyl) and 3-M (3-methyl) isomers was employed as a measure of approach to equilibrium of the reaction products.[21,22] For simple CO hydrogenation, the short contact time (W/F=6.3 g-cat. h mol^{-1}) resulted in the 2-M/3-M ratios far below the equilibrium, as shown In Fig. 5. Low rate of 2-M isomers formation as primary products can be accounted for by a branching mechanism via protonated cyclopropanes.[22] With increasing contact time, the 2-M/3-M ratios increased.

The addition of 1-undecene resulted in the increase in 2-M/3-M ratios in C_6—C_8. This should come from the increased yield of 2-M isomers by cracking of 1-undecene and is in agreement with expectation based on carbenium ion-cracking mechanism.[23] These results suggest that there was only a minor contribution of cracking of heavy products to formation of C_6—C_8 fraction in the initial stage of CO-H_2 reaction. In the advanced stage, however, cracking of heavy fractions, which had been formed by oligomerization of light alkenes, seemingly occurred to a considerable extent.[1]

Effect of Temperature. Effect of temperature on the catalytic performance of DAHY2R2P is listed in Table 3. Simple CO hydrogenation at 300 °C exhibited remarkable increase in CO conversion and formation of methane and light hydrocarbons, compared to that at 240 °C. However, no significant change was observed for the *i/n* ratios of C_6—C_8 fractions. Slight decrease in the *i/n* ratios of C_4 and C_5 could result from contribution of cracking not preceded by formation of multibranched isomers. The addition of 1-undecene exhibited trends similar to simple CO hydrogenation. The yield of C_2 and C_3 was virtually unchanged on addition of 1-undecene at 300 °C, indicating little contribution of metal-promoted hydrogenolysis.

High temperature would lead to the promotion of CO hydrogenation on Ru-Pt alloy to produce light hydrocarbons. Simultaneously acid-catalyzed reaction should be also facilitated to give C_6—C_8 products rich in isoalkanes, although C_6—C_8 selectivity was significantly lowered. Thus the *i/n* ratios were kept at rather high levels while carbon number distribution

a) Catalyst : DAHY2R2P; reaction conditions : 1.5 MPa, W/F=12.5 g-cat. h mol^{-1}, $H_2/CO=3/2$, 1-undecene feed rate=1.9 mmol g-cat.$^{-1}h^{-1}$. Data obtained after 2—3 h on stream.

was largely changed. The deactivation degree of the catalysts was strongly dependent on the operating temperature. High temperature seemed to be favorable to durability of cracking activity. In this respect, suppression of light alkane formation at high temperature on metallic site should be indispensable to develop a gasoline-forming catalyst with good activity, selectivity and life for practical use.

Conclusion

Addition of 1-alkenes has been successful to elucidate the role of acid site and metallic site in CO hydrogenation over RuPtHY and RuPtDAHY zeolite catalysts. Carbon number distribution and products composition are dependent on factors such as the activity for hydrogenation of CO and alkene as primary products on the metals, the amount of acid sites, and the acid strength distribution on the support as well as operating conditions such as partial pressure of H_2 and CO, H_2/CO ratio, temperature, and time factor.

Acid sites are crucial to producing isoalkanes in gasoline range products via secondary reactions. There is a dependence of major reaction path on acid strength; while simple β-cracking of carbenium ion is favorable on strong acid sites, disproportionation of carbenium ion is feasible on relatively weak ones, effecting changes in carbon number distribution of the products from CO-H_2.

Cross Sections for the Quenching of Hg(6s6p$^1P_1$)

Hironobu UMEMOTO,* Akeo KASAKURA,† Jun KIKUMA, and Shin SATO†
Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
†Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received December 27, 1986)

Absolute cross sections for the quenching of Hg(6s6p$^1P_1$) by simple molecules were measured by employing a Stern-Volmer type intensity measurement combined with a phase-shift measurement of effective radiative lifetime. The cross sections are approximately gas kinetic, except for rare gas atoms and tetrafluoromethane. The cross sections can be correlated with the C_6 long-range force parameter to the power 0.52.

Mercury is the most fundamental and widely used photosensitizer. Study on mercury-photosensitized reactions has the longest history in the field of photochemistry and relevant reactions have been dealt with in many review articles.[1-8] However, most of the study has been concentrated on the triplet excited-state mercury, the Hg(6s6p$^3P_1$) and Hg(6s6p$^3P_0$) states, and much less study has been made on Hg(6s6p$^1P_1$)-sensitized reactions.[9-15] No absolute values of cross section for the quenching of this state have been reported yet. Since the energy of Hg($^1P_1$) is 175 kJ mol^{-1} higher than that of Hg($^3P_1$), it is expected that some chemical exit channels which are not available in reactions of Hg($^3P_1$) or Hg($^3P_0$) are open in reactions of Hg($^1P_1$). For example, CO is not produced efficiently in the Hg($^3P_1$)-sensitized reaction of CO_2, while CO is one of main products in the Hg($^1P_1$)-sensitized decomposition of CO_2.[14] Quenching processes of the $^1P_1$ excited states of Cd, Zn, Mg, and Ca have been studied more extensively than reactions of Hg($^1P_1$).[7,8,16-26] It has been revealed that the $^1P_1$ states of these metal atoms are far less selective in quenching than the lower-energy ^3P_J states, and that the quenching cross sections are very large, comparable to those for gas kinetic collisions, except for rare gas atoms and perfluoroalkanes.[7,8,16-20,24-26] In other words, the quenching processes of these excited atoms are entrance-channel controlled. The cross sections for the deactivation of these $^1P_1$ states as well as the metastable $^3P_2$ and $^3P_0$ states of rare gas atoms can be correlated with the C_6 long-range force parameter to a power between 0.2 and 1.0, for cross sections larger than 50×10^{-20} m^2.[7,8,20] As for the Hg($^1P_1$) state, a similar relationship between cross sections and C_6 parameters has also been postulated on the basis of measurements of relative quenching efficiency obtained by Granzow et al.[7-9,27] In the present work, absolute cross sections for quenching of Hg(6s6p$^1P_1$) by simple molecules are determined and compared with those of analogous $^1P_1$ states of the other groups IIA and IIB metal atoms.

Experimental

The basic principle of lifetime measurement is the same as that described previously.[28] Resonance radiation at 184.9 nm from a microwave-powered mercury lamp was amplitude modulated at a frequency of 80, 100, or 120 kHz. This resonance radiation was used to irradiate a cylindrical reaction vessel made of Suprasil quartz, 31 mm in length and 27 mm in internal diameter, which contained a drop of mercury. The resonance fluorescence from the mercury vapor in the vessel as well as the exciting light from the lamp was detected alternately, with the aid of an aluminium mirror, with the same photomultiplier tube (Hamamatsu, R106) in conjunction with a vacuum ultraviolet monochromator (JASCO, VUV-1B). The phase difference between the photomultiplier signal and the internal reference signal of a lock-in amplifier (NF Circuit Design Block, 5610) was measured. The lifetime is given by the tangent of a phase delay angle of fluorescence relative to the excitation divided by the angular frequency of the modulation. In order to check the effect of the resonance radiation at 253.7 nm, some measurements were performed with a γ-ray irradiated LiF plate, which absorbed the 253.7 nm line more than 99% while transmitting the 184.9 nm line around 50%. It was confirmed that the lifetime is independent of the 253.7 nm light intensity.

In Stern-Volmer type experiments, the output of the mercury lamp was modulated at 70 Hz. At this frequency, steady-state can be assumed. The ratio of the fluorescence intensity in the absence of quencher, I_0, to that in the presence of quencher, I, was measured as a function of quenching gas pressure. The detection system was the same as that used for the lifetime measurement. The bimolecular rate constant for the quenching of Hg($^1P_1$), k_q, was determined by using:

$$\frac{I_0}{I} = 1 + k_q\tau_{eff}[Q], \quad (1)$$

where, τ_{eff} is the effective radiative lifetime of Hg($^1P_1$) in the absence of quencher as derived from the phase-shift measurement, and [Q] is the concentration of quencher. The validity of Eq. 1 will be discussed later. In order to avoid the effect of pressure broadening, measurements were performed in the presence of 8 kPa of He, which is much larger than the quencher gas pressure, except in the case of quenching by rare gas atoms. In the case of rare gas atoms, the total pressure was kept constant at 33 kPa. Since the quenching gases used in the present work do not absorb the 184.9 nm resonance line, no correction was necessary for direct absorption. The quenching cross section, σ_q, can be obtained by dividing k_q by the mean relative velocity,

$(8RT/\pi\mu)^{1/2}$, where R is the gas constant, T is the absolute temperature, and μ the reduced mass. The pressure of gases was measured with a mercury manometer. Low pressures, below 1 kPa, were estimated by the expansion technique using a known volume ratio. Experiments were performed at 306±2 K.

Similar experiments to determine the cross sections for the quenching of $Hg(^3P_1)$ by H_2 and D_2 were also performed. In this case, a glass cut-off filter was inserted between the lamp and the reaction vessel to remove the 184.9 nm resonance radiation.

Research-grade He (Japan Helium Center), N_2 (Toyo Sanso), H_2 (Showa Denko), D_2 (Takachiho Kako), and CO (Takachiho Kako) were used after being passed through a column of heated copper chips at 590 K and a trap filled with molecular sieve 4A cooled at 77 K. Ar (Nihon Sanso) and Xe (Takachiho Kako) were used after being treated in the same procedure of purification except that the temperature of the cold trap was raised properly. The organic compounds except n-C_4H_{10} (Tokyo Kasei) were products of Takachiho Kako and used without further purification. Hg was used after repeated distillation under vacuum.

Results

Quenching of $Hg(^3P_1)$ by H_2 and D_2. In advance of quenching measurements of $Hg(^1P_1)$, the cross sections for the quenching of $Hg(^3P_1)$ by H_2 and D_2 were measured. It was found that the apparent radiative lifetime of $Hg(^3P_1)$ in the absence of quencher is dependent on the modulation frequency. The measured lifetime in the presence of 8 kPa of He increased from 1.2 to 1.5 μs when the modulation frequency was changed from 30 to 120 kHz. A similar increase in lifetime with increase in modulation frequency has also been observed in the case of $Cd(^3P_1)$, and this has been attributed to the effect of radiation imprisonment.[29] On the other hand, the Stern-Volmer plots under the steady-state conditions in the presence of H_2 and D_2 were found to be linear. If we employ the average of the measured lifetimes between 30 and 120 kHz, 1.3 μs, as the effective radiative lifetime, the absolute quenching cross sections are calculated to be 28×10^{-20} and 29×10^{-20} m^2 for H_2 and D_2, respectively, by employing Eq. 1. These values agree well with the literature values.[30-32] Although there is an uncertainty in the estimation of effective lifetime, the above agreement should be enough for check of the present apparatus. In addition to this, it was found that the reciprocal of the measured lifetime of $Hg(^3P_1)$ in the presence of H_2, $1/\tau$, increased linearly with the H_2 pressure, and the slope did not show any marked dependence on the modulation frequency. If this value can be correlated with the quenching rate constant by the following equation, which is an exact expression when the radiation trapping can be ignored:

$$\frac{1}{\tau} = \frac{1}{\tau_{eff}} + k_q[Q], \qquad (2)$$

then, the quenching cross section for H_2 is calculated to be 29×10^{-20} m^2, which agrees well with that determined by the first procedure as well as the literature values.

Imprisonment Lifetime of $Hg(^1P_1)$. Because of the presence of radiation trapping, the effective radiative lifetime of $Hg(^1P_1)$ measured in the absence of quencher was much longer than the natural radiative lifetime, 1.4 ns,[7,8] but it showed no dependence on the modulation frequency between 80 and 120 kHz in contrast to the $Hg(^3P_1)$ case. On the other hand, the lifetime depended not only on the temperature of the system but also on the He pressure. Since the addition of a buffer gas is considered to broaden the spectral line, we supposed, at first, that the imprisonment lifetime would be shortened by the addition of a buffer gas even if the quenching efficiency by the gas is negligible. However, the lifetime in the absence of any buffer gas was found to be around 100 ns, which was shorter than that in the presence of a few kPa of He. The imprisonment lifetime increased with increase in the He pressure up to 0.5 kPa, and then began to decrease. Under the present experimental conditions, i.e., in the presence of 8 kPa of He and at 306±2 K, the effective radiative lifetime was around 160 ns. The fluctuation in the lifetime during the 1 or 2 h period necessary to perform a Stern-Volmer measurement for one species was less than the random error due to the uncertainty in the phase-angle measurement of the fluorescence, ±10 ns.

Quenching Cross Sections of $Hg(^1P_1)$. Figure 1 shows Stern-Volmer plots for four representative quenchers. Linearity of similar plots for the other quenchers was also good. The cross sections for the quenching of $Hg(^1P_1)$ were determined by employing

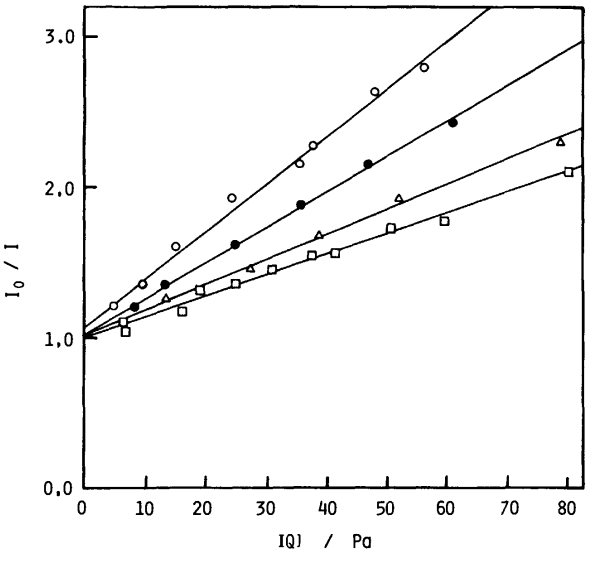

Fig. 1. Stern-Volmer plots for H_2(○), D_2(●), C_3H_8 (△), and N_2(□).

Table 1. Cross Sections for the Quenching of $Hg(^1P_1)$[a]

Quencher	Cross section $10^{-20}m^2$
Ar	<1
Xe	<1
N_2	79
H_2	44
D_2	44
CO	71
CH_4	52

C_3H_8	132
n-C_4H_{10}	135
neo-C_5H_{12}	198
CF_4	<1

a) The error limits are ±9%; see text.

Eq. 1. In general, Eq. 1 is not a correct expression when the radiation trapping cannot be ignored.[33] However, according to the numerical calculation by Phillips,[34] under the condition of large optical depth, the effective radiative lifetime measured by the phase-shift method is nearly identical with that characteristic of the Stern-Volmer measurement. In other words, Eq. 1 may be used to evaluate quenching rate constants. Boxall et al.[35] have also shown experimentally that there is no significant difference between escape factors for pulsed and steady-state excitations at high opacities. The absolute quenching cross sections determined in this way are summarized in Table 1. These values are much larger than those for $Hg(^3P_1)$ or $Hg(^3P_0)$. The random statistical error from the least-squares best-fit slopes of the Stern-Volmer plots was around ±3%. Taking into account the uncertainty in the lifetime measurement, ±6%, the total uncertainty is estimated to be ±9%.

Discussion

Imprisonment Lifetime of $Hg(^1P_1)$. The increase in the imprisonment lifetime caused when a small amount of He was added, cannot be explained in terms of the concept of line broadening or quenching. In order to explain this increase, we considered that the decay of $Hg(^1P_1)$ in an evacuated system was controlled mainly by deactivation on walls. The mean free path in such a system is controlled by the vapor pressure of mercury and is about 2 cm. On the other hand, a simple calculation shows that, if the resonance radiation at 184.9 nm from the lamp has a Doppler broadened line shape at 1000 K and the hyperfine structure splitting of the $^1P_1$ state is much smaller than the Doppler width at 306 K, then 50% of the incident light is absorbed within 0.05 mm from the cell wall. Of course, the spectral line shape of the resonance radiation from the microwave-powered lamp we used must have been severely reversed, and the excitation in the reaction vessel should have been much more uniform, but the incident radiation from the lamp should still have been absorbed mainly within a thin layer near the cell wall. The addition of a small amount of a buffer gas decreases the mean free path and diffusion rate of $Hg(^1P_1)$ atoms, and increases the apparent lifetime. Similar deactivation processes of excited metal atoms at cell walls have also been reported recently with Zn and Cd.[24,36] The decrease in the imprisonment lifetime caused when more than 0.5 kPa of He was added can easily be explained by the increase in the escaping factor due to the change in the absorption line profile. The effective radiative lifetime without a buffer gas estimated by extrapolating the values above 0.5 kPa is 350 ns. This lifetime is a factor of 3 or 4 shorter than that predicted by the Holstein theory on the assumption of infinite slab or cylinder geometry.[37] This difference may be attributed to the difference in geometry of the reaction vessels. The effective radiative lifetime calculated numerically by Phillips for a realistic geometry is also one order of magnitude shorter than that calculated by the Holstein formula for infinite geometry.[34,37]

Table 2. Comparison of the Relative Quenching Cross Sections[a]

Quencher	This work	Granzow et al.[b]	Madhavan et al.[c]
N_2	(1.00)	(1.0)	(1.0)
Ar	<0.01	1.1	
H_2	0.56	0.2	
D_2	0.56		0.55
CO	0.89	1.0	2.3
CH_4	0.65	0.3	2.3
C_2H_6	1.01		4.8
C_3H_8	1.66		2.1

a) N_2 was chosen as a standard. b) Ref. 9. c) Ref. 10.

Comparison with the Literature Values. There have been no measurements of absolute cross section for the quenching of $Hg(^1P_1)$, but relative values have been reported by Granzow et al.[9] and Madhavan et al.[10] Granzow et al.[9] employed a Stern-Volmer measurement, while Madhavan et al.[10] estimated the cross sections by measuring production rates of $Hg(^3P_1)$ from $Hg(^1P_1)$. In Table 2, the results are compared. The agreement is very poor. If we choose N_2 as a standard, the value for CO reported by Granzow et al.[9] is in reasonable agreement with the present result, but their result for H_2 is a factor of 3 smaller than the present one. Granzow et al.[9] have described nothing about total pressure. Therefore, we suspect that they did not keep the total pressure constant. If they did not, this may be a cause of error, because the effective radiative lifetime as well as the

amount of light absorbed is considered to depend on the total pressure. It is more difficult to explain their result for Ar. Since the quenching of the $^1P_1$ states of Mg, Cd, and Zn by Ar is inefficient,[7,8,16,19,24,25] we are sure that the present result for Ar is much more reasonable. The quenching efficiency by Ar observed by Granzow et al.[9] is too large to be explained by effects of impurities in Ar, such as quenching and direct absorption of the 184.9 nm resonance line. Therefore, it is hard to give any reasonable explanation for this discrepancy. The agreement between the present results and those of Madhavan et al.[10] is still worse. The change in total pressure may also be a cause for the discrepancy in this case. However, in any cases, we suspect that their method is too indirect for quantitative determination of cross sections.

Recently, Callear and Du[13] have discovered three emission bands from a mixture of Hg($^1P_1$) and Xe. They have assigned the carrier of a broad band near 215 nm to a bound complex of Hg($^1P_1$) with Xe formed in a slow termolecular process, and the other carriers to excited complexes which are correlated to Hg($^3P_2$). They have also demonstrated that the production of Hg($^3P_2$) from Hg($^1P_1$) by Xe occurs in a bimolecular process with a considerably large cross section, 4×10^{-20} m^2. The former conclusion is consistent with the present results, while the cross section they obtained for the formation of Hg($^3P_2$) is fairly large compared with the present value for the quenching of Hg($^1P_1$).

Correlation with the C_6 Parameter. In the case of the $^1P_1$ states of Cd, Zn, Mg, and Ca, the quenching cross sections can be correlated with the proportionality constant for the attractive part of the Lennard-Jones 6—12 potential, C_6, to a power between 0.2 and 0.9.[7,8,16-20] Breckenridge and Renlund[18] have also pointed out that if only the quenching by simple alkane hydrocarbons are considered, the cross section increases rather linearly with increase in the C_6 parameter in the case of Cd($^1P_1$) and Zn($^1P_1$). In the present case, the cross sections are very large except for CF_4 and rare gas atoms and a good correlation could be obtained between $\log_{10}\sigma_q$ and $\log_{10}C_6$ as illustrated in Fig. 2. Figure 2 also suggests that a still better correlation can be obtained if only the cross sections by the alkane hydrocarbons are plotted. This will be discussed later. It should be noted that the cross sections for the quenching of Mg($^1P_1$) and Cd($^1P_1$) by CF_4 are also much smaller than those expected from the C_6 correlation.[16,19] The C_6 parameters were estimated by using the Slater-Kirkwood approximation. The procedure was the same as that employed by Breckenridge and Umemoto.[19,20] In general, for entrance-channel controlled quenching, net coupling to the final states must occur at a distance greater than

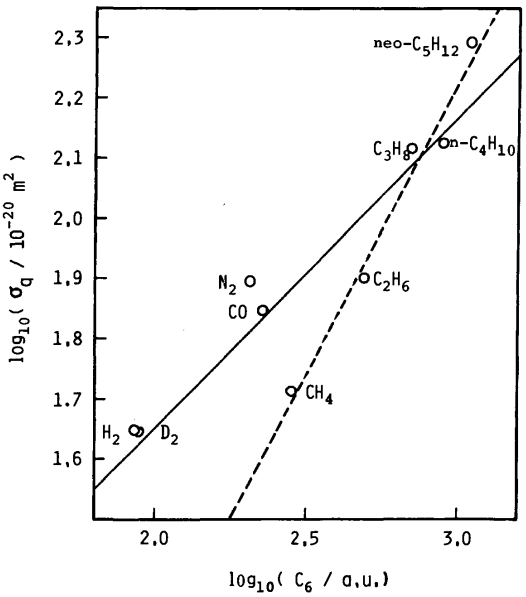

Fig. 2. A log-log plot of the cross sections for the quenching of Hg($^1P_1$) versus the long-range forces C_6 parameter. The solid line is the least-squares fit of the data, while the dashed line is the fit for only alkane hydrocarbons. The C_6 parameters are in atomic unit.

the hard-sphere collision distance. As for quenchers with positive or slightly negative electron affinities, such as N_2 and CO, the large quenching efficiencies have been explained in terms of the charge-transfer mechanism, in which it is assumed that facilitating potential surfaces with appreciable charge-transfer character are sufficiently low in energy.[7,8] On the other hand, in the case of saturated hydrocarbons, since the electron affinity is considerably negative, the above charge-transfer mechanism cannot be applied. It has been postulated that a strong chemical interaction of the $^1P_1$ states with individual C-H bonds provides necessary attractive potential surfaces.[7,8] Then, the inertness of CF_4 may be attributed to the lack of attractive chemical interaction between the $^1P_1$ states and the C-F bonds. In the reaction of Mg($^1P_1$) with alkyl C-H bonds, two processes have been postulated; insertion into C-H bonds and direct abstraction of H atoms.[22] Both of these chemical interactions should be less attractive in the case of C-F bonds because of the stronger bond strength,[38] as well as the heavier atomic weight of atom F. The least-squares slope of the log-log plot shown in Fig. 2 is 0.52 ± 0.08. Very similar results could also be obtained if the parameters for the dispersion forces were estimated from polarizabilities and ionization potentials according to the formula presented in Ref. 39. In this case, the slope is 0.54 ± 0.09. These values are smaller than those for Cd($^1P_1$) and Zn($^1P_1$) and nearly equal to the value for Mg($^1P_1$). It is interesting that

the empirical rule proposed by Breckenridge that the slope increases with increase in the electronic energy of the excited state, is not fulfilled in the present case.[7,8] On the other hand, if we restrict the discussion only to the quenching by the alkane hydrocarbons, the slope of the log-log plot shown in Fig. 2 is 0.96±0.10. Very similar results can be obtained for the other groups IIA and IIB metal atoms. The slopes are 0.85±0.16 for $Cd(^1P_1)$, 1.04±0.14 for $Zn(^1P_1)$, 0.86±0.06 for $Mg(^1P_1)$, and 0.78±0.17 for $Ca(^1P_1)$. These results are more consistent with the absorbing sphere model.[7,8]

The authors are grateful to Professor Toshihiro Ichimori of this Institute for permitting them to use the monochromator. They are indebted to Mr. Tadamasa Akutagawa of this Institute for the design of the microwave power generator. They are also grateful to Professor William H. Breckenridge of the University of Utah and one of the editors of this Bulletin for their suggestive comments.

ESR and Mass-Spectrometric Studies of Methanol Combustion. III. The Effect of CS_2 and CH_3NH_2 Additions on the Concentration Profiles of Chemical Species in a Methanol-Air Flame

Masayuki TANIGUCHI, Nobuhito HIRASAWA,† and Hiroshi YOSHIDA*
Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060
(Received December 27, 1986)

The concentration profiles of chemical species (labile and stable) in methanol-air free-burning flames with and without the addition of CS_2 and CH_3NH_2 have been examined by means of the probe-sampling-ESR method, combined with mass-spectrometric measurements. In addition to the principal labile intermediates (H, O, and OH) and stable species (CH_3OH, O_2, H_2, CH_2O, CO_2, and H_2O), SO_2 and NO have been detected from the flame when it has been doped with CS_2 or CH_3NH_2 respectively. The observed results indicate that the addition of these dopants depresses the concentration of OH and raises the concentration of H_2 in the primary reaction zone, where SO_2 and NO are efficiently generated. The observed concentration profiles have been discussed in terms of the reaction mechanism of the oxidation of sulfur and nitrogen compounds.

In the previous works of this series,[1,2] we studied the concentration profiles of labile intermediates (H, O, and OH) and stable species (CH_3OH, O_2, CH_2O, CO, H_2, H_2O, and CO_2) in methanol-air premixed flames at atmospheric and low pressures by means of the probe-sampling-ESR method, combined with mass-spectrometric measurements. The chemical reactions during methanol combustion have been examined on the basis of the experimental results. The study will be extended here to the methanol-air flame doped with CS_2 and CH_3NH_2 in order to elucidate the chemical effects of these compounds on methanol combustion. CS_2 and CH_3NH_2 are examples of sulfur and nitrogen compounds which have simple chemical structures.

The chemical reactions of combustion involving sulfur and nitrogen compounds are interesting to study because their oxidation products, such as SO_x and NO_x, are the main sources of air pollution. In addition, sulfur compounds are believed to modify chemically the combustion processes in these flames. For example, it is known that SO_2 catalyzes the recombination of labile free radical intermediates in hydrogen,[3,4] hydrocarbon,[5] and carbon monoxide flames.[6] It is also known that the formation of NO from combustion is much affected by the presence of a sulfur compound in the flames.[4,7] However, there has been little investigation thus far reported on the chemical aspects of doping the flames with sulfur and nitrogen compounds.

As has been shown in the previous studies of our group[8,9] and others,[10] the concentration profiles of the labile intermediates in combustion flames can be examined comparatively easily by the ESR method. These previous studies have indicated that both the formation and the decay of the labile intermediates are sensitively dependent on the combustion conditions. Therefore, the chemical modification of combustion processes may be expected to be proven by observing the concentration profiles of the labile intermediates. With this expectation, the present study was planned. During the course of the preparation of this paper, Pauwels et al.[11] have reported the effect of H_2S addition on the concentration profiles of the labile intermediates in low-pressure methanol-air flames studied by the ESR method. In the present study, CS_2 and CH_3NH_2 are used as dopants. These studies as a whole will shed light on the chemical effects of doping the combustion of methanol under various combustion conditions.

Experimental

The burner used was made of brass and had a mouth 8 mm in diameter, as has been described previously.[1,9] Reagent-grade methanol was used as a fuel without further purification. Methanol with and without dissolved carbon disulfide, CS_2, and methylamine, CH_3NH_2, of reagent grade was continuously injected into the air stream supplied from a cylinder, regulated with a rotermeter, and preheated to 403 K. The composition of the premixed gas may be expressed by the equivalence ratio, ϕ, defined as: $\phi=([\text{fuel}]/[O_2])_{\text{actual}}/([\text{fuel}]/[O_2])_{\text{stoichiometric}}$. The flow rate of the premixed gas was kept constant at 1.0 l min^{-1}. The flame thus obtained was found to be axially symmetric. It consisted of a flat, bluish inner flame 1—2 mm above the burner mouth and a cone-shaped, faint-bluish outer flame 10 mm in height. The flame temperature was estimated by using a fine SiO_2-coated Pt/Pt-Rh thermocouple (0.1 mm in diameter) without correction for the radiative heat loss.

The concentration profiles of such labile intermediates as H, O, OH, and NO, together with O_2, in the flames were determined by means of the probe-sampling-ESR technique with an X-band ESR spectrometer previously described in detail.[1] About one-fifth of the reacting gas was continuously sampled through a pin hole (about 0.1 mm in diameter), and subjected to ESR measurements at 24 Pa. The residence time of the sampled gas in the sampling probe before reaching the ESR cavity was about 1.5 ms. A fraction of the sampled gas was then led to a quadrupole mass spectrometer to determine the concentration profiles of

† Present address: Marubeni, Ltd., Chiyoda-ku, Tokyo 100.

stable species (CH_3OH, CO_2, H_2O, H_2, CS_2, and SO_2). The mass spectrometric measurements were made at a total pressure of 10^{-3} Pa. The concentration profiles (all in mole fraction unit) were obtained on the center axis of the flame.

Results and Discussion

Observed ESR and Mass Spectra. ESR spectra due to H, O, OH, and O_2 were detected from both the doped and undoped flames. The features of the spectra were the same as has been reported previously.[1,8,9] When the fuel methanol was doped with a small amount of CH_3NH_2, an ESR spectrum with nine hyperfine lines centered at 830 mT (at 8.97 GHz) due to NO was additionally detected. The hyperfine splitting was found to be 2.7 mT, in agreement with that of NO($^2\Pi_{3/2}$) studied previously.[12] When the methanol was doped with CS_2, no additional spectrum was detected. Pauwels et al.[11] have recently observed the ESR spectrum due to SO and SH from low-pressure methanol flames doped with H_2S. The concentrations of SO and SH in the present atmospheric pressure flame are probably too low for ESR detection.

The intensity of the ESR spectra was calibrated with reference to the spectrum of O_2 (for H and O) and NO (for OH and NO) of known concentrations in the ESR cavity. The correction for the destruction of H, O, and OH in the sampling probe was made in the way described previously.[1]

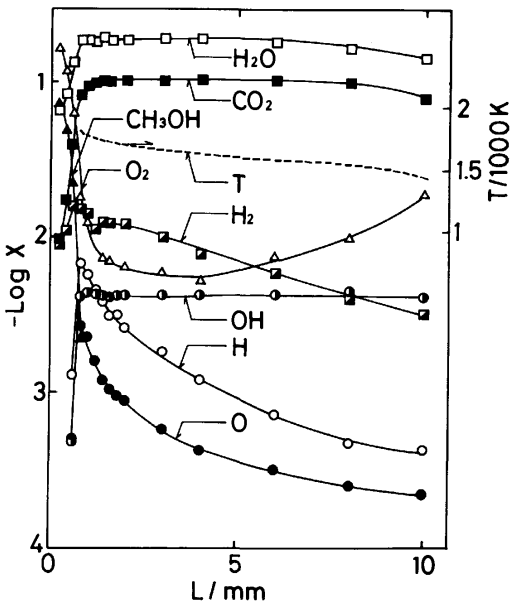

Fig. 1. The profiles of concentrations of stable and labile chemical species and temperature in a free-burning methanol-air flame of stoichiometric composition. The concentrations are presented in mole fraction units (X) on a logarithmic scale. The distance (L) is between the burner mouth and the sampling point on the center axis of the flame.

CH_3OH, H_2, CH_2O, CO_2, and H_2O were detected from both the doped and undoped flames by using the mass spectrometric method. When a small amount of CS_2 was added to the fuel methanol, additional intense spectra at m/z=64 and 76 were also detected. They are attributable to SO_2 and CS_2. The concentrations of these stable species were determined from the observed spectral intensities with reference to those of mixtures of known concentrations.

Concentration Profiles in the Undoped Flame. Figure 1 shows the concentration profiles of the labile intermediates and stable species in the flame of methanol-air premixed gas with the stoichiometric equivalence ratio: ϕ=1.0 (CH_3OH: 12.3%, O_2: 18.4%, and N_2: 69.3%). The concentration profile of CH_2O is not shown in Fig. 1 in order to avoid complexity of illustration, because the distribution of CH_2O was found to be limited to a restricted region in the inner flame. The concentration profiles in the inner flame region of the undoped methanol-air flame at atmospheric pressure were studied and reported in detail previously.[1]

The observed results in Fig. 1 show that O_2 and CH_3OH are consumed, while CO_2, H_2O, and H_2 are generated rapidly, in the inner-flame region. After the rapid generation, H_2O and CO_2 remain unchanged in concentration in the outer flame region. In contrast, H_2 decreases in concentration monotonously. The O_2 concentration shows a minimum value at about 4 mm above the burner mouth, and then it gradually increases. This increase is due to the diffusion of O_2 from the surrounding air into the flame.

The flame temperature reaches a maximum in the inner-flame region, after which it decreases monotonously downstream.

The concentrations of H, O, and OH increase rapidly and reach the maximum value in the inner flame region. The concentration of H and O then decrease continuously in the outer flame region, whereas the concentration of OH remains unchanged. Comparing the present results with those for the fuel-rich (ϕ=1.25) methane-air and fuel-lean (ϕ=0.75) methanol-air flames reported previously,[8,9] the overall features of the concentration profiles of the labile intermediates can be said to be little dependent on the equivalence ratio around ϕ=1.0, in both the inner- and outer-flame regions.

Effect of CS_2 Addition. Figure 2 shows the concentration profiles of CS_2 and SO_2 in the CS_2-doped flame. The premixed gas had a composition of CH_3OH: 11.6%, O_2: 18.5%, N_2: 69.4%, and CS_2: 0.46%. This composition gives almost a stoichiometric equivalence ratio, ϕ=1.02, if the combustion of CS_2 is expressed as $CS_2+3O_2 \rightarrow CO_2+2SO_2$. The concentration profiles of CH_3OH, H_2O, and CO_2 are also shown in Fig. 2 for the sake of comparison. CS_2 is rapidly consumed and SO_2 is concomitantly generated in the

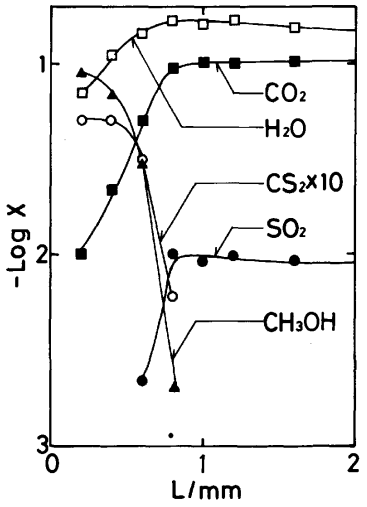

Fig. 2. Concentration profiles of CS_2, SO_2, CH_3OH, CO_2, and H_2O in a free-burning methanol-air flame doped with CS_2.

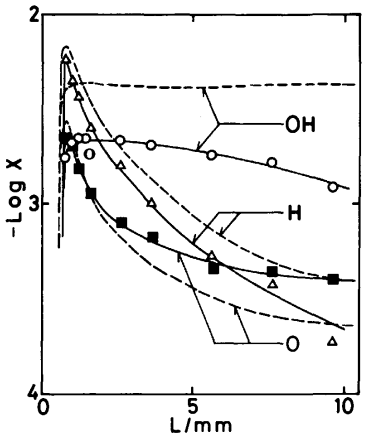

Fig. 3. Effects of CS_2 addition on the concentration profiles of labile intermediates in a free-burning methanol-air flame. The dashed lines and the solid lines denote the flame without and with addition of 0.46% CS_2.

inner-flame region, where CH_3OH is converted effectively and rapidly into H_2O and CO_2. The SO_2 thus-formed keeps a constant concentration throughout the downstream region of the flame, where almost all the S atoms exist in the form of SO_2.

The effect of the CS_2 addition on the concentration profiles of the labile intermediates is shown in Fig. 3. The maximum concentration of OH in the inner flame region is reduced by as much as 50%. In contrast, the maximum concentrations of H and O are not very much affected.

The dependence of the maximum concentration of the labile intermediates on the concentration of the added CS_2 was also studied. Qualitatively, the depression of the concentration of the labile inter-

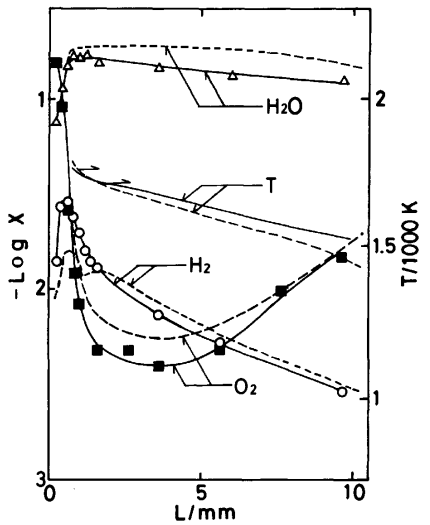

Fig. 4. Effects of CS_2 addition on the profiles of concentrations of stable species and temperature in a free-burning methanol-air flame. The dashed lines and the solid lines denote the flame without and with addition of 0.46% CS_2.

mediates becomes more remarkable with an increase in the CS_2 concentration. The effect of $(CH_3)_2SO$ as a dopant was also studied for comparison. The results were found to be qualitatively the same as those for CS_2.

The effect of CS_2 addition on the concentration profiles of the stable species is shown in Fig. 4. The concentration profiles of CH_3OH, CH_2O, and CO_2 are not affected significantly; therefore, they are not shown in Fig. 4. The flame temperature is lowered in the inner flame region and raised in the outer flame region by CS_2 addition.

One of the most remarkable effects of CS_2 addition is an increase in the H_2 concentration in the inner-flame region. According to the reaction model proposed by Westbrook and Dryer,[13] the main source of H_2 in the upstream region of the undoped methanol-air flame is the following reaction:

$$CH_3OH + H \longrightarrow H_2 + CH_2OH. \quad (1)$$

However, the rate of Reaction 1 in the inner-flame region is not promoted by the addition of CS_2, because the concentration of H is decreased, and the concentration of CH_3OH is not affected by the addition of CS_2.

Pauwels et al.[11] have recently studied the effect of the addition of H_2S to low-pressure methanol-air flames. They found an increase in the H_2 concentration as in the present case of the CS_2 addition. They have interpreted the increase as being due to the additional path of H_2 formation in the presence of H_2S:

$$H_2S + H \longrightarrow H_2 + SH. \quad (2)$$

However, the present results for CS_2 addition cannot be interpreted in the same way as those for H_2S addition; CS_2 cannot act as a primary source of H_2 because it has no H atoms. No hydrogen source, such as H_2S, originating from the added CS_2 could be observed in a concentration high enough to be responsible for the significant additional H_2 formation.

Another possible mechanism is that the increase in the H_2 concentration is attributable to the scavenging of OH by the added CS_2. The decrease in the OH concentration depresses the reaction;

$$H_2 + OH \longrightarrow H_2O + H, \quad (3)$$

which is otherwise an effective loss process of the H_2 generated by Reaction 1. Actually, the significant decrease in the OH concentration was observed in the inner-flame region on adding CS_2 to the flame.

The concentrations of H, O, and OH can be calculated by assuming a partial equilibrium in the flame based on the following rapid reactions:

$$H_2 + OH \rightleftharpoons H_2O + H \quad (3)$$
$$H_2 + O \rightleftharpoons OH + H \quad (4)$$
$$O_2 + H \rightleftharpoons O + OH \quad (5)$$

The partial equilibrium concentrations are given as:

$$X_e(OH) = [K_4K_5X(H_2)X(O_2)]^{1/2} \quad (6)$$
$$X_e(H) = K_3X(H_2)^{3/2}[K_4K_5X(O_2)]^{1/2}/X(H_2O) \quad (7)$$
$$X_e(O) = K_3K_5X(H_2)X(O_2)/X(H_2O) \quad (8)$$

By using the equilibrium constants in the literature[14]: $K_3=0.21\exp(7640/T)$, $K_4=2.27\exp(-938/T)$, and $K_5=300\cdot T^{-0.372}\exp(-8565/T)$, the observed concentrations of the corresponding stable species, and the observed flame temperatures, the equilibrium concentrations have been calculated to be $X_e(OH)=5.8\times10^{-3}$, $X_e(H)=7.0\times10^{-3}$, and $X_e(O)=2.2\times10^{-3}$ for the undoped flame and $X_e(OH)=5.5\times10^{-3}$, $X_e(H)=1.1\times10^{-2}$, and $X_e(O)=2.3\times10^{-3}$ for the CS_2-doped flame, both at a position 1.0 mm above the burner mouth. Considering the uncertainty in the observed flame temperatures caused by the radiative heat loss, the uncertainty of the calculated equilibrium concentrations is estimated to be within a factor of 1.5. The observed X values agree with the calculated X_e values in the undoped flame. In contrast, the observed X(H) and X(OH) values are significantly lower than the equilibrium concentrations for the CS_2-doped flame. These disagreements indicate that a decrease in the concentrations of labile intermediates upon the addition of CS_2 is not to be interpreted as being due to a decrease in the flame temperature. The decrease in the labile intermediates is probably caused by rapid reactions between the labile intermediates and sulfur species, such as CS_2, S, SO, and SO_2.

The comparison between calculated X_e and observed X values was originally made by Pauwels et al.[11] for undoped and H_2S-doped methanol flames: the observed X values of the labile intermediates were found to be generally lower than the calculated X_e values when the flame was doped with H_2S. This effect of H_2S addition is especially significant for H and OH. The present results are in general accordance with those reported by Pauwels et al.

As is shown in Fig. 3, the concentrations of H and OH are depressed by the addition of CS_2 in the outer flame region, where the added CS_2 has almost entirely been converted to SO_2. This effect can be interpreted in terms of the well-known function of SO_2 in catalyzing the recombination of the labile intermediates:[15]

$$X + SO_2 + M \longrightarrow XSO_2 + M \quad (9)$$
$$Y + XSO_2 \longrightarrow XY + SO_2 \quad (10)$$

where X and Y represent H, O, or OH. According to Reactions 9 and 10, the concentration of O can also be expected to be depressed by the existence of SO_2 in the outer-flame region. Actually, an enhancement of the O concentration was observed, as is shown in Fig. 3. Necessarily, an additional reaction path (or paths) of generating O can be expected in the outer-flame region when the flame is doped with CS_2, but it or they are not yet known. The diffusion of O_2 from the surrounding air into the present flame under the ambient conditions may play an important role in this.

Effect of CH_3NH_2 Addition. Figure 5 shows the effects of the addition of CH_3NH_2 on the concentration profiles of the labile intermediates. The composition of the premixed gas for this doped flame was CH_3OH: 11.6%, O_2: 18.4%, N_2: 69.4%, and CH_3NH_2: 0.58%. The equivalence ratio was 1.02, based on the presumed combustion reaction: $CH_3NH_2+(9/4)O_2\rightarrow$

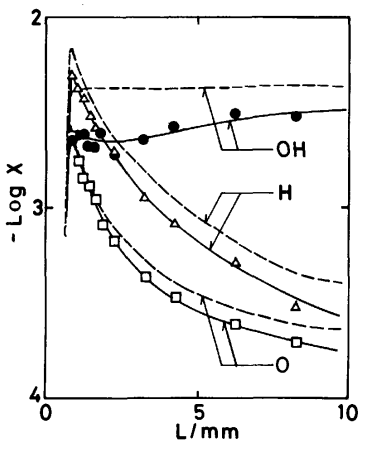

Fig. 5. Effects of CH_3NH_2 addition on the concentration profiles of labile intermediates in a free-burning methanol-air flame. The dashed lines and the solid lines denote the flame without and with addition of 0.58% CH_3NH_2.

CO_2+(5/2)H_2O+(1/2)N_2. The concentrations of the labile intermediates are qenerally lowered by the CH_3NH_2 addition. The effect is most significant for OH in the inner-flame region. It was also found that the depression of the concentrations of H and OH was more and more significant with an increase in the concentration of CH_3NH_2 added within the examined concentration range up to 1.2%, while the change in the concentration of O was rather insensitive in the higher CH_3NH_2-concentration range.

Dzotsenidze et al.[16] have studied the effect of the addition of CH_3NH_2 and NO on the H concentration in a rarefied H_2-O_2 flame at 700 K by using the ESR method: They have found a decrease in the H concentration upon the addition of CH_3NH_2 and NO. They have also found that the effect of added NO on the H concentration is significant. We examined also, in a separate experiment, the effect of adding NO to a methanol-air flame at atmospheric pressure. In this high-temperature flame, NO addition shows little effect on the concentrations of H, O, and OH. Thus, the effect of doping with CH_3NH_2 on the concentration of the labile intermediates seems to be the same for both high- and low-temperature flames, whereas the effect of doping with NO is not.

The effects of added CH_3NH_2 on the concentration profiles of stable species are shown in Fig 6. NO is rapidly formed from the added CH_3NH_2 in the inner-flame region, and it keeps a constant concentration downstream. About 50% of the N atoms of the added CH_3NH_2 exist in the form of NO in the flame after such a rapid NO formation. The concentration profiles of CH_3OH, H_2O, and CO_2 were found to be unchanged by the addition of CH_3NH_2 to the flame. The concentrations of CH_2O and CH_3NH_2 in the CH_3NH_2-doped flame could not be determined because of the overlap of their mass-spectral lines with those of NO (m/z=30) and CH_3OH (m/z=32) respectively.

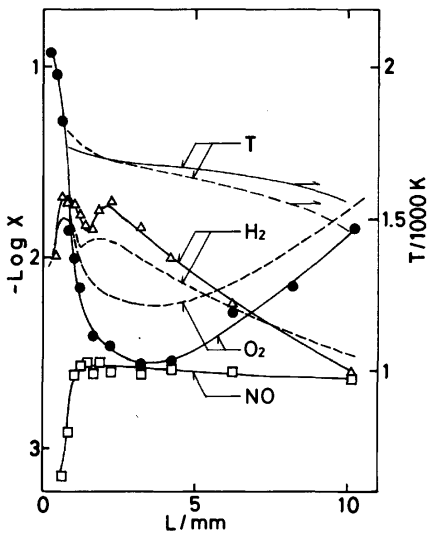

Fig. 6. Effects of CH_3NH_2 addition on the profiles of concentrations of H_2 and O_2, and temperature in a free-buring methanol-air flame. The dashed lines and the solid lines denote the flame without and with addition of 0.58% CH_3NH_2.

Two of the most significant effects of CH_3NH_2 addition are the enhancement of H_2 formation and the depression of the OH concentration occurring concomitantly in the inner-flame region. Such changes in the concentration of H_2 can be interpreted in the same way as for CS_2 addition: The decrease in OH caused by CH_3NH_2 addition depresses the oxidation of H_2 through Reaction 3.

Another possible mechanism is the formation of H_2 through the following reaction:

$$CH_3NH_2 + H \longrightarrow CH_3NH(\text{or } CH_2NH_2) + H_2. \quad (11)$$

According to the rate constant, $k_{11}=1.8\times10^7 \exp(-2670/T)$ m^3 mol^{-1} s^{-1}, reported by Blumberg and Wagner,[17] this reaction can have a rate constant of the same order of magnitude as that of the main H_2-forming reaction in the inner flame region (Reaction 1),[18] $k_1=4.0\times10^7 \exp(-3070/T)$ m^3 mol^{-1} s^{-1}, at the observed flame temperature. However, the enhancement of H_2 formation can not be attributed solely to Reaction 11, because the added concentration of CH_3NH_2 is not high enough for Reaction 11 to proceed at a significant rate.

The observed concentrations of H, O, and OH at the position 1 mm above the burner mouth were compared with the concentrations calculated by assuming a partial equilibrium based on Equations 6—8. It was found that the observed concentration is lower than the equilibrium concentration for H and OH in the CH_3NH_2-doped flame. This is the same trend as that observed in the CS_2-doped flame. The only different effect of doping between CH_3NH_2 and CS_2 is that the O concentration in the outer-flame region is lowered by CH_3NH_2 addition, whereas it is increased by the CS_2 addition. This may be due to the reaction of the NO oxidation, NO+O→NO_2, in the CH_3NH_2-doped flame.

Conclusion

The concentration profiles of the labile intermediates and the stable species in a methanol-air flame at atmospheric pressure with and without added carbon disulfide and methylamine were examined by means of a probe-sampling ESR method combined with mass-spectrometric measurements. The two dopants were found to be oxidized quickly into SO_2 and NO respectively. These products were comparatively stable, even in a high-temperature methanol-air flame. These dopants affect the chemical reactions in the inner-flame region by depressing the concentra-

tion of labile OH and by effectively enhancing the formation of H_2 from the principal fuel, CH_3OH. The effect of the H_2S-doping of the low-pressure methanol-air flame has very recently been studied by Pauwels et al.[11] The present results for the CS_2-doping are essentially the same as for H_2S-doping. These two studies by means of the ESR method show some of the general aspects of the chemical effects of sulfur compounds on the combustion reactions of methanol. They also show the usefulness of utilizing the ESR method for studies of the chemical modification of combustion. It should be stressed that the concentration profiles of labile intermediates are more sensitively dependent on the doping than are the concentration profiles of the stable intermediates.

A Localized Molecular Orbital Approach to Bond Moment Theory. II. The Transferability of Bond Moment Derivatives

Hiroyuki SHINODA
Faculty of Pharmaceutical Science, Toyama Medical and Pharmaceutical University,
2630 Sugitani, Toyama 930-01
(Received February 2, 1987)

The transferability of bond moment derivatives(BMDs) in the bond moment theory was investigated by the use of localized molecular orbitals derived from INDO canonical orbitals. Five series of molecules were treated, two for a terminal C-H stretching motion and three for an O-H one. It is concluded that the transferability of BMDs with significant values is recognized among the molecules which have the same structure within the second neighbor bonds; it is also concluded that the changes in the molecular moiety beyond the third neighbor bonds slightly affect the BMDs of all the bonds, with the exception of the stretching one. These conclusions were confirmed by theoretical considerations, such as perturbation expansion.

It is well-known that the infrared-absorption intensity of a normal vibration described by the normal coordinate Q_j relates to the total dipole moment derivative with respect to Q_j, that is $(\partial\mu_{tot}/\partial Q_j)_o$, where μ_{tot} is the total dipole moment. Several methods of analyzing $(\partial\mu_{tot}/\partial Q_j)_o$ have thus far been presented;[1-6] they differ in the point of setting the intensity parameters. The bond moment theory has been of interest as one method of analyzing infrared intensities.[1] The theory is based on the assumption that the total dipole moment of a molecule is given as the sum of all the bond moments in the molecule. In using this theory, the bond moment derivatives(BMDs) with respect to the internal coordinates are used as intensity parameters, and $(\partial\mu_{tot}/\partial Q_j)_o$ is evaluated by means of their sum. Formally, a total dipole moment derivative with respect to any vibrational coordinate is a function of all the BMDs. In practice, however, their values can not be determined because the number of experimental information is less than the number of the BMDs. In order to overcome this difficulty, a large part of the BMDs are neglected and the transferability of a particular kind of BMD, e.g., C-H BMD, from one molecule to another has to be introduced. In a previous paper,[7] which will hereafter be called Part I, the bond moments and their derivatives with respect to a C-H stretching motion in some simple molecules were calculated by means of the localized molecular orbital approach, which is useful for discussing the bond moment theory because the approach can present the same situation as the basic assumption described above. In Part I the following two interesting results were obtained: The direction of each BMD is neither along the bond itself nor along the stretching bond, but the direction of the total dipole moment derivative is nearly along the stretching bond. Secondly, the change in a trans-sited bond moment is quite large. It was concluded from the results in Part I that the first-order approximation of the bond moment theory is inadequte to interpret an infrared-absorption intensity, since, in the first-order approximation, the direction of the BMD of a stretching bond was assumed to be parallel to the bond and the trans-sited BMD was never taken into account. Figeys et al. reached a similar interpretation.[8] They calculated the bond moments and their derivatives for cyanoacetylene and chloroacetonitrile by means of the ab initio molecular orbital method and said that there was quantum chemical evidence for the failure of the classical bond moment hypothesis for stretching modes.

In the present study, the BMDs with respect to C-H or O-H stretchings have been calculated for several series of molecules; their transferability will be discussed. The methods of calculation for localized molecular orbitals and the definition of bond moments are the same as those in Part I. In the calculation, the equilibrium geometries of molecules followed the data presented by Pople and Gordon.[9] Furthermore, the transferability of BMDs will be discussed along with considerations such as perturbation expansion.

Results and Discussion

Five series of molecules were considered in the present study, two for a C-H stretching and three for an O-H stretching; they are shown in Fig. 1. The numbering of the atoms and the designation of the lone-pair orbitals are also shown. The BMDs calculated for the molecules of the five series are listed in Tables 1—5. The BMDs of the bonds in the substituents X and Y in Fig. 1 were not included in the tables, since they were very small; most of them were smaller than 0.03D Å^{-1} (1D=3.33564×10^{-30} C m). Some exceptions were, however, found in the third neighbor bonds, which were connected with the trans-sited bond in a zigzag manner from a stretching bond.

Tables 1 and 2 include the BMDs with respect to a C-H stretching. In Table 1, the BMDs in any column resemble each other. The only exception is revealed in the BMDs of the stretching bond; they are roughly

divided into two groups by whether their values are larger or smaller than 0.14D Å^{-1}. The division of the BMDs seems to be attributable to the difference in the molecular fragments in the substituent X. Indeed, in the molecules which have an OH function directly connecting to the carbon atom of No. 5, the BMD of the stretching bond is less than 0.14D Å^{-1}. In the case of C^2-H^1 stretching, furthermore, the BMD of the stretching bond increases with the change in the substituent in X from -H to -C_2H_5, although the magnitude of the increase is small in comparison with that of the decrease in the presence of the OH function described above. On the other hand, in C^2-H^3 stretching the BMD of the stretching bond is only slightly affected by the substituent change from -H to -C_2H_5. Therefore, it can be said that the BMD of a stretching bond is very sensitive to the change in the substituent at a trans-sited position.

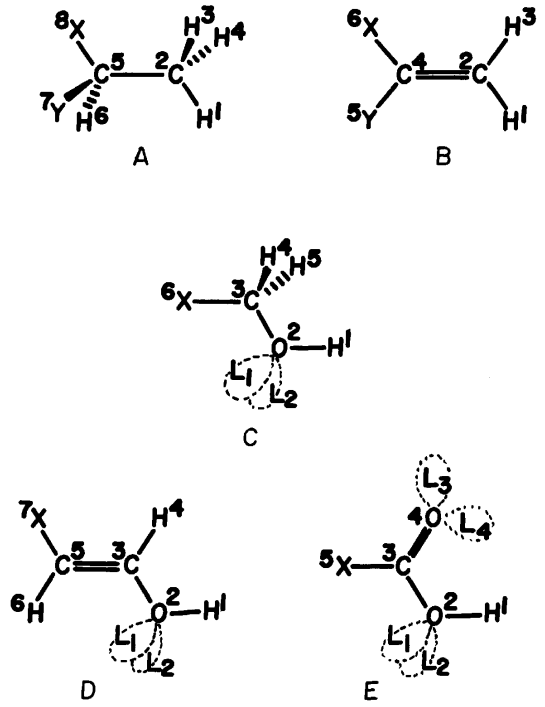

Fig. 1. The numbering of atoms and designation of lone pair orbitals for five series of molecules.

The results in Table 2 reveal the same tendency as those in Table 1, although the similarity of the BMDs in each type of bond is smaller than that shown in Table 1. The average of the BMDs for the adjacent C-H bond in Table 1 is 0.33D Å^{-1}; this is different from the corresponding value, 0.45D Å^{-1}, calculated from the results in Table 2. For the trans-sited C-H bonds, the averages from Tables 1 and 2 are also different from each other, their values being 0.21 and 0.29D Å^{-1} respectively. Such disparities are to be expected from the types of the adjacent carbon-carbon bonds, i.e., C-C or C=C, which bring different types of hybrids in the carbon atoms of the C-H bonds. On the basis of a study of the BMD of a stretching C-H bond for several hydrocarbons, Gussoni et al. pointed out that the hybridization of the carbon atom is the most important factor in deciding the BMD which increases with the increase in the s-character in the hybrid orbital.[4]

Tables 3—5 include the BMDs with respect to an O-H stretching. In Table 3 the similarity of the BMDs in each type of bond is recognized to some degree, and in the O-H stretching as well as the C-H stretchings, the spread of the BMDs for the stretching bond is wider than those of other bonds. Table 5 shows the same tendency. In Table 4 the similarity among the BMDs in each column is very well kept; it

is better than those in Tables 3 and 5, and the molecules treated in the series D have quite the same structure within the second neighbor bonds. Therefore, it can be said that the BMDs with significant values are only slightly affected by the change in the structure beyond the third neighbor bonds. The BMDs of the adjacent C–O bond in Table 5 are considerably different from those in Tables 3 and 4; also, the BMDs of L_1 and L_2 in Table 5 are different from those in Tables 3 and 4. It can be said, on the basis of these results, that the type of second-neighbor bond affects not only the BMDs of the adjacent C–O bond, but also those of the L_1 and L_2 lone-pair orbitals. It is noticeable that the BMDs of L_4 in Table 5 are not so small as to be negligible, but those of L_3 are small. These facts give us a new insight to be added to the bond moment theory. That is, even when the number of the intervening bonds between a certain bond and a stretching one is larger than or equal to two, the BMD of the bond is not always small. In other words, if the direct separation between two bonds is not large, and if the relative orientation of the bond with respect to the stretching one is proper, the change in the bond moment is significant.

In part I, the number of BMDs which were needed to interpret an infrared-absorption intensity could not be offered, though it was pointed out that the first-order approximation is inadequate. The results shown in Tables 1—5 support the following several conclusions: (1) The stretching of a terminal bond always induces changes in the bond moments of the stretching bond, the adjacent bonds, and the adjacent lone-pair orbitals. In addition to them, the bond moments of the bonds which do not connect to the stretching bond, but which are located at any suitable position, especially at a trans-sited position, change with a considerably large magnitude. (2) The transferability of the BMDs with significant values is recognized among the molecules which have the same structure within the second neighbor bonds. (3) The change in the molecular structure beyond third neighbor bonds slightly affects the BMDs of all the bonds with the one exception of the stretching one.

In order to explain the results in Tables 1—5, we will now try to develop a theoretical consideration like the perturbation technique. When a Z–H stretching motion is the perturbation, only the hydrogen atom in the Z–H bond moves along the bond. Without the loss of generality, the stretching bond can be fixed on the z-axis. Therefore, the perturbation operator can be written as $(\partial H/\partial z_H)_o$, where H is the Hamiltonian of a system and where z_H is the z-component of the Cartesian coordinate of the hydrogen atom. Within the framework of the INDO method,[10] only two expressions are necessary to evaluate the matrix elements of $(\partial H/\partial z_H)_o$: $\partial S^{HA}_{\mu\nu}/\partial z_H$ and $\partial \gamma_{HA}/\partial z_H$, where $S^{HA}_{\mu\nu}$ is the overlap integral between the χ^H_μ and χ^A_ν atomic orbitals and where γ_{HA} is the two-center electronic repulsion integral between the electrons in the H and A atoms. The master formulas of the expressons are listed in Pancir's paper.[11] The distance dependency of $\partial S^{HA}_{\mu\nu}/\partial z_H$ was examined in the cases of typical atomic orbitals for χ^A_ν. The results are shown in Fig. 2, which shows that the derivatives of the overlap integrals are almost negligible at distances longer than 4.0 Å. The orientation dependency of $\partial S^{HA}_{\mu\nu}/\partial z_H$ is not simple. It was found in Part I that localized molecular orbitals are mainly constructed as linear combinations of two hybrid orbitals or of one hybrid orbital and one hydrogen 1 s orbital. In a special case, only one hybrid orbital itself becomes a localized molecular orbital. We will, therefore, examine two examples of the orientation dependency of $\partial S^{HA}_{\mu\nu}/\partial z_H$ in the cases of a carbon sp^3 hybrid orbital and a hydrogen 1s orbital as χ^A_ν. It is supposed that the A atom and also the hybrid orbital exist on the xz-plane of the Cartesian coordinate space, at the origin of which the H atom in the Z–H bond is fixed. The directions of the A atom and of the lobe of the hybrid orbital are symbolized by θ and α respectively; they are defined as is shown in Fig. 3. The orientation dependency of the hybrid orbital is shown in Fig. 4. It is found from the figure that the value of $\partial S^{HA}_{\mu\nu}/\partial z_H$ largely depends on the values of θ and α. It is easy to

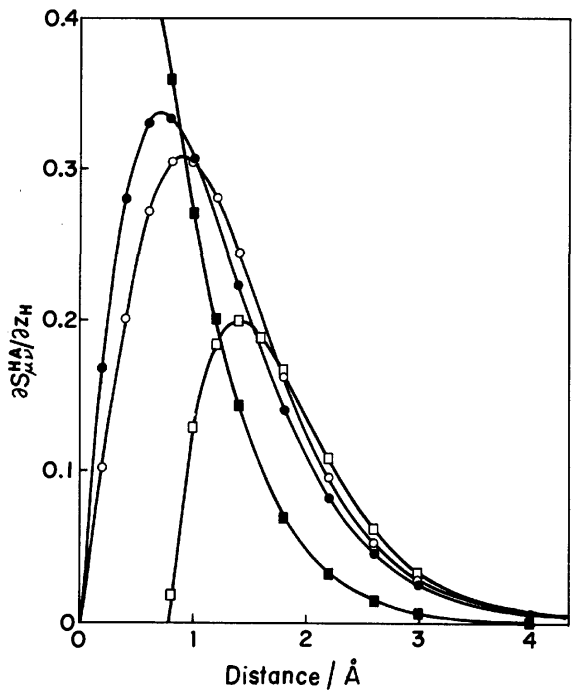

Fig. 2. The distance dependency of $\partial S^{HA}_{\mu\nu}/\partial z_H$ in a.u. (1a.u.=1.8898×10^{10} m^{-1}). The hydrogen 1s orbital, χ^H_μ, in H atom is located at the origin. (●): Hydrogen 1s orbital on z-axis for χ^A_ν, (○): carbon 2s orbital on z-axis for χ^A_ν, (■): carbon $2p_z$ orbital on x-axis for χ^A_ν, (□): carbon $2p_z$ orbital on z-axis for χ^A_ν.

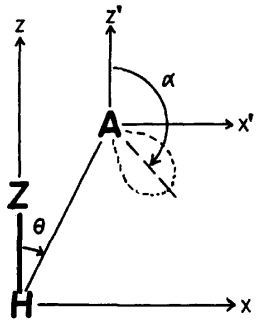

Fig. 3. The definition of θ and α. The z' and x' axes are parallel to z and x axes, respectively.

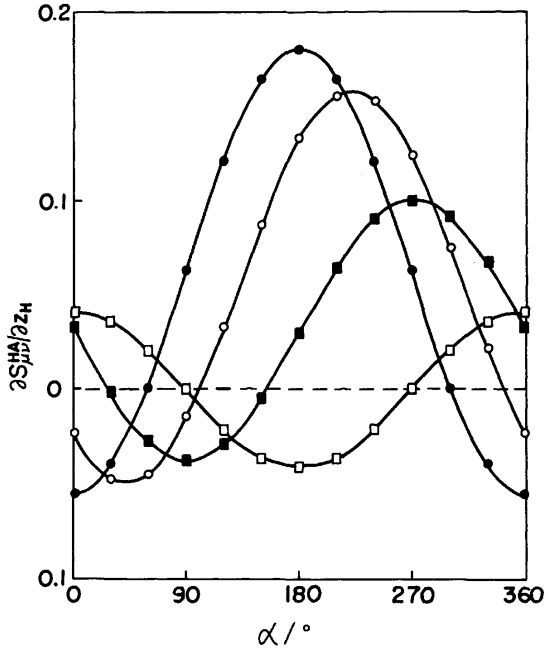

Fig. 4. The orientation dependency of $\partial S_{\mu\nu}^{HA}/\partial z_H$ in a.u. in the case of carbon sp^3 hydrid orbital for χ_ν^A. The distance between the H and A atoms is 2.0 Å. (●): θ=0°, (○): θ=30°, (■): θ=60°, (□): θ=90°.

derive that the variation of $\partial S_{\mu\nu}^{HA}/\partial z_H$ with respect to α at any constant value of θ corresponds to a *sin* curve as follows:

$$\frac{\partial}{\partial z_H}\int \chi_{1s}^H \chi_{sp^3}^A dv = \frac{1}{2}\left[\frac{\partial}{\partial z_H}\int \chi_{1s}^H \chi_{2s}^A dv + \sqrt{3}\,T\sin(\alpha+t)\right], \tag{1}$$

where:

$$T = \left[\left(\frac{\partial}{\partial z_H}\int \chi_{1s}^H \chi_{2p_z}^A dv\right)^2 + \left(\frac{\partial}{\partial z_H}\int \chi_{1s}^H \chi_{2p_x}^A dv\right)^2\right]^{1/2},$$

$$\sin(t) = \left(\frac{\partial}{\partial z_H}\int \chi_{1s}^H \chi_{2p_z}^A dv\right)/T,$$

and

$$\cos(t) = \left(\frac{\partial}{\partial z_H}\int \chi_{1s}^H \chi_{2p_x}^A dv\right)/T,$$

In these expressions, the derivatives of the overlap integrals with respect to z_H are the functions of θ. Therefore, the α_m value at which the maximum of Eq. 1 is given depends on the value of θ. In the results shown in Fig. 4, the α_m is 180° at θ=0°, and it continuously increases with the increase in θ until finally at θ=90° it becomes 360°. The maximum value of Eq. 1 also depends on the value of θ. The maximum at θ=0° is 0.18a.u.(1a.u.=1.8898×10^{10} m^{-1}), while at θ=90° it is 0.04a.u., which is small in comparison with that at θ=0°. However, we can not neglect it at θ=90° for the following two reasons. First, it can be seen from Fig. 4 that the value of Eq. 1 depends on α and becomes negligibly small in some regions of α, even at θ=0°. Second, in the localized molecular orbital which is constructed by a linear combination of two hybrid orbitals, their contributions to the derivative of the overlap integral are cancelled in some degree because the hybrid orbitals are located face-to-face. On the other hand, in the lone-pair orbital which is constructed by only one hybrid orbital, such a cancellation can never occur. The orientation dependency of $\partial S_{\mu\nu}^{HA}/\partial z_H$ in the case of a hydrogen 1 s orbital as χ_ν^A is very simple because of the spherical symmetry of the orbital. It is written as follows:

$$\partial S_{\mu\nu}^{HA}/\partial z_H = \cos(\theta)\left[\frac{\partial}{\partial z_H}\int \chi_{1s}^H \chi_{1s}^A dv\right]_{\theta=0}, \tag{2}$$

where the subscript θ=0 means that the A atom exists at θ=0° in Fig. 3. It is clear from Eq. 2 that the maximum of $\partial S_{\mu\nu}^{HA}/\partial z_H$, when χ_ν^A is the 1s orbital, is given at θ=0° and that $\partial S_{\mu\nu}^{HA}/\partial z_H$ continuously decreases until it reaches zero at θ=90°.

As is shown in Pancir's paper,[11] the orientation dependency of $\partial\gamma_{HA}/\partial z_H$ is the same as that of Eq. 2. The distance dependency of $\partial\gamma_{HA}/\partial z_H$ is shown in Fig. 5. It may be found from the figure that the derivatives are negligible at distances longer than 5.0 Å.

From the discussion of the distance and orientation dependencies of $\partial S_{\mu\nu}^{HA}/\partial z_H$ and $\partial\gamma_{HA}/\partial z_H$, it is concluded that the relative orientation of a bond with respect to the stretching one is an important facor in deciding the magnitude of the BMD of the bond. In other words, the BMDs of two bonds which are equidistant from the stretching bond are quite different if the orientaions of the bonds are different. It is also concluded that the bond moment of a bond separated from a stretching one by a distance of more than 5 Å changes slightly during the stretching motion. These conclusions do not contradict the results in Tables 1—5.

When the localized molecular orbitals of unperturbed and perturbed systems are denoted by $\{\phi_i^0\}$ and

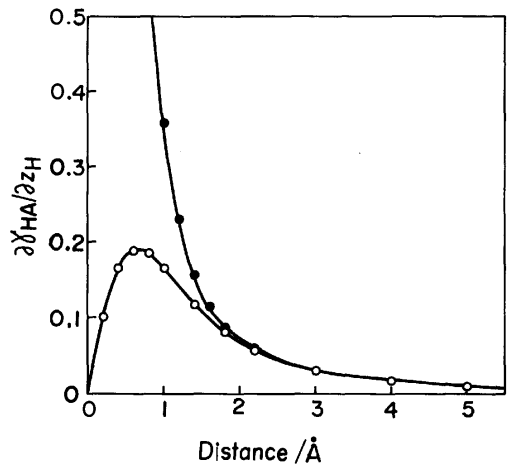

Fig. 5. The distance dependency of $\partial\gamma_{HA}/\partial z_H$ in a.u. (1a.u.=8.2390×10^{-8} J m^{-1}). The direction of A atom from H atom is parallel to z-axis. (●): The A atom is carbon, (O): the A atom is hydrogen.

$\{\phi_i\}$ respectively, ϕ_i is formally given by a linear combination of $\{\phi_i^\circ\}$ as follows:

$$\phi_i = \phi_i^\circ + \sum_{j\neq i} C_{ij} \langle \phi_j^\circ | \partial H/\partial z_H | \phi_i^\circ \rangle \phi_j^\circ, \quad (3)$$

where C_{ij} is the energy denominator in the first order perturbation expansion. The absolute value of the integral $\langle \phi_j^\circ | \partial H/\partial z_H | \phi_i^\circ \rangle$ is small unless ϕ_i° and/or ϕ_j° are localized on a stretching bond. Therefore, if ϕ_i° is localized on the stretching bond, all the terms in Eq. 3 remain more or less, but if ϕ_i° is not localized on the stretching bond, only the term with the ϕ_j° which is localized on the stretching bond remains. The above consideration fairly well explains the facts shown in Tables 1—5 that the influence of the changes of substituents beyond the second neighbor bond is found more in the BMD of a stretching bond than in those of other bonds.

Galabov and his coworkers have investigated the transferability of infrared intensity parameters by the method of bond polar parameters (BPPs), which are the derivatives of the total dipole moment with respect to the linear and angular coordinates, associated with individual bond vibrational distortions. In their study of F_2CO, Cl_2CO, F_2CS, and Cl_2CS,[12] it is shown that the transferability of BPPs does not hold among the molecules. Furthermore, from the results of their MO calculation for the series of C_1—C_5 normal paraffins and their 1-fluoro and 1-nitro derivatives, they concluded that the C-H BPPs are transferable between various hydrocarbon molecules and that the effect of polar substituents on BPPs may be quite significant because of intramolecular charge polarization; two methylene groups, however, almost entirely block their influence.[13] These conclusions from the investigations of Galabov et al. may also be well interpreted in terms of the theoretical discussion presented here.

The above theoretical consideration was performed along the INDO approximation. If the ab initio calculation is done, the number of kinds of the integrals which appear in the calculation is larger than that treated here. However, the distance dependency of the derivatives will be analogous to those in Figs. 2 and 5. Therefore, our qualitative conclusions derived from the results in Tables 1—5 will not be altered in the ab initio calculations. However, if a detailed and quantitative study of the infrared-absorption intensities is done, the selection of the basis set in the ab initio calculation becomes an important factor, since Miyazaki et al. pointed out, as a result of their investigation of carbon monoxide, that the expansion coefficients of the dipole moment with respect to the internal coordinate are highly sensitive to the selection of the basis sets.[14]

The calculation in this study was carried out at the Data Processing Center of Kyoto University.

Adsorption of Dodecyltrimethylammonium Chloride from the Micellar Solution at Water/Air Interface

Makoto Aratono,* Toru Okamoto, and Kinsi Motomura
Department of Chemistry, Faculty of Science, Kyushu University 33, Fukuoka 812
(Received March 6, 1987)

The surface tension of the aqueous solution of dodecyltrimethylammonium chloride (DTAC) was measured as a function of temperature under atmospheric pressure at concentrations below and above the critical micelle concentration. The thermodynamic quantity changes associated with the adsorption of DTAC from its monomeric and micellar states were evaluated and proved to satisfy the thermodynamic relation derived on the assumption that the micelle formation can be treated as the appearance of a macroscopic bulk phase in the solution. Further their values were compared with those of the aqueous solution of dodecylammonium chloride and the influence of the chemical structure of the head group on the adsorption and micelle formation were discussed from the thermodynamic viewpoint.

It has been observed in the previous papers[1,2] that the entropy changes associated with surface adsorption and micelle formation of surfactant at concentrations around the critical micelle concentration (cmc) in its aqueous solution have negative values for dodecylammonium chloride and positive ones for 2-(octylsulfinyl)ethanol. Further the micelle has been proved to be treated thermodynamically as a macroscopic bulk phase in the solution when the thermodynamic quantities of micelle are replaced by the excess one with reference to the dividing surface chosen so that the excess number of moles of water equals zero. This treatment has been supported by measurements of the temperature and pressure dependence of interfacial tension of the aqueous solution of surfactant against oil.[3-6]

It is now interesting to investigate what influence the chemical structure of the polar head group of surfactant has on the thermodynamic quantity changes associated with adsorption and micelle formation. In this paper we are concerned with the adsorption of dodecyltrimethylammonium chloride (DTAC) at its aqueous solution/air interface at concentrations below and above the critical micelle concentration (cmc). The surface tension is measured as a function of temperature at fixed concentrations under atmospheric pressure and the thermodynamic quantity changes are evaluated by applying thermodynamic equations. The results are compared with those of dodecylammonium chloride (DAC).

Experimental

Dodecyltrimethylammonium chloride was synthesized and purified according to the method described previously[7] and its purity was checked by observing no minimum on the surface tension vs. concentration curve. Water was triply distilled from alkaline permanganate solution. The surface tension was measured by the drop volume technique described previously[8] and reproducible within 0.05 mN m^{-1}. The temperature was kept constant within 0.05 K by immersing the measuring cell in a thermostated water bath.

Results and Discussion

The surface tension γ was measured as a function of temperature under atmospheric pressure at various molalities m_1 of dodecyltrimethylammonium chloride in the aqueous solution. The surface tension vs. temperature curves are shown in Figs. 1a and 1b. It is seen that the value of γ decreases with increasing temperature and the curves at low concentrations are concave upward. At high concentrations, however, the curves seem to be linear. Therefore, it is expected that a break point will be observed on a surface tension vs. temperature curve at an intermediate concentration. Actually the curve 2 in Fig. 1b is found to have a break point, of which the concentration can be proved to be the critical micelle concentration.

Figure 2 illustrates the γ vs. m_1 curve depicted by picking up the γ values at a given temperature in Fig. 1. The sharp break is observed on the curve and its molality is referred to as the critical micelle concentration. The cmc values are shown as a function of temperature in Fig. 3 together with those of DAC. It is seen that the values depend remarkably on temperature and the cmc vs. T curve has a minimum. Comparing this curve with that of DAC, we notice that the chemical structure of the head group of surfactant has a considerable influence on the cmc value and temperature dependence of cmc. Making reference to our previous paper,[1] we also notice that the surface tension of DTAC at the cmc is considerably different from that of DAC.

The temperature derivative of surface tension obtained from Fig. 1 is plotted against molality at constant temperature in Fig. 4. It is seen that the value of $\partial\gamma/\partial T$ depends on temperature remarkably at concentrations below the cmc, while it is independent of temperature at concentrations above the cmc. Accordingly, the $-\partial\gamma/\partial T$ vs. m_1 curve is observed to vary discontinuously at the cmc. This observation supports the view that the micelle formation of DTAC is treated thermodynamically as if a macroscopic

phase appears in the solution at the cmc.

It has been shown that the temperature dependence of surface tension of an aqueous micellar solution provides useful information upon the structures and properties of adsorbed films and micelles.[1-3] According to the thermodynamics of the adsorption of surfactant from its micellar solution,[1] the derivative of surface tension with respect to temperature under atmospheric pressure at a concentration below the cmc is related to the entropy change associated with the adsorption of surfactant from the aqueous solution $\Delta s(1)$:

$$(\partial\gamma/\partial T)_{p,m_1} = -\Delta s(1), m_1 < \text{cmc}, \quad (1)$$

while the derivative at a concentration above the cmc is related to the entropy change associated with the adsorption of surfactant from the micellar state $\Delta s(\text{M})$:

$$(\partial\gamma/\partial T)_{p,m_1} = -\Delta s(\text{M}), m_1 \geqq \text{cmc}, \quad (2)$$

on the assumption that the micelle formation may be treated thermodynamically like an appearance of a

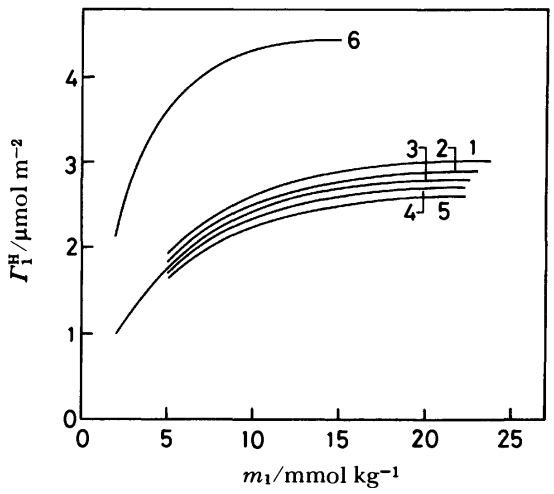

Fig. 5. Surface excess number of moles vs. concentration curves at constant temperature under atmospheric pressure: (1) 288.15 K; (2) 293.15 K; (3) 298.15 K; (4) 303.15 K; (5) 308.15 K; (6) 298.15 K (DAC).

new macroscopic phase and the behavior of micelle is determined only by temperature and pressure in a limited concentration range. Here $\Delta s(1)$ and $\Delta s(M)$ are respectively defined by

$$\Delta s(1) = \Gamma_1^H(s^H/\Gamma_1^H - s_1) \tag{3}$$

and

$$\Delta s(M) = \Gamma_1^H(s^H/\Gamma_1^H - s^M/N_1^M), \tag{4}$$

where Γ_1^H and s^H are the surface excess number of moles of surfactant and surface excess entropy with reference to the two dividing planes making the surface excess numbers of moles of air and water to be zero,[8,9] respectively, N_1^M and s^M are the number of surfactant ions in the micelle and the molar entropy of micelle defined with respect to the spherical dividing surface making the excess number of moles of water to be zero,[1] respectively, and s_1 is the partial molar entropy of monomeric surfactant in the solution.

Comparing the above equations with the results given in Fig. 4, it is found that $\Delta s(1)$ and $\Delta s(M)$ have positive values and accordingly the excess entropy of adsorbed film per mole of surfactant is larger than the partial molar entropy of monomeric surfactant and the excess entropy of micelle per mole of surfactant. This behavior is slightly different from that of DAC (curve 6). Further it is seen that the value of $\Delta s(1)$ decreases with increasing the concentration and depends on temperature remarkably, while that of $\Delta s(M)$ is almost independent of the concentration and temperature. On the other hand the discontinuous change of the $-\partial\gamma/\partial T$ vs. m_1 curve at the cmc, $\Delta s(1)-\Delta s(M)$, is correlated to the derivative of cmc

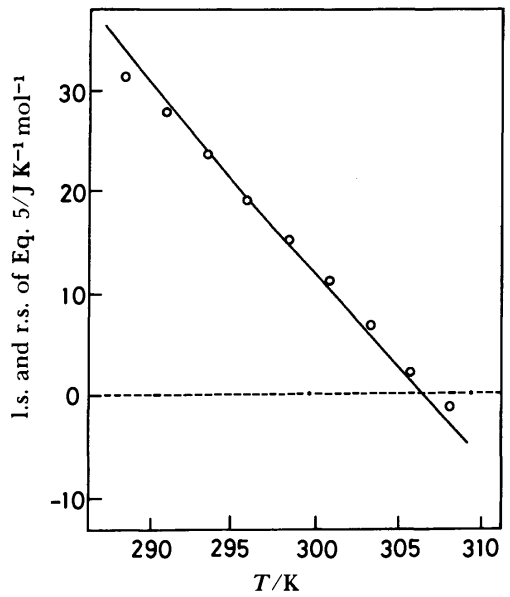

Fig. 6. Comparison between the left and the right side of Eq. 5: (O) left side; (—) right side.

with respect to T by the expression:[1]

$$[\Delta s(1) - \Delta s(M)]/\Gamma_1^H = -(2RT/\text{cmc})(\partial \text{cmc}/\partial T)_p. \tag{5}$$

The left side of Eq. 5 is numerically evaluated at the cmc by using the values of $\Delta s(1)$ and $\Delta s(M)$ given in Fig. 4 and the values of Γ_1^H which are calculated by applying the relation

$$\Gamma_1^H = -(m_1/2RT)(\partial\gamma/\partial m_1)_{T,p} \tag{6}$$

to the γ vs. m_1 curves and shown in Fig. 5 at constant temperature under atmospheric pressure. The right

side is calculated by the temperature dependence of the cmc values shown in Fig. 3. In Fig. 6, the values of the left side are plotted by circles and those of the right side are drawn by the full line. The values of both sides are in fair agreement with each other within the experimental error. Therefore, we can say that the present results concerning DTAC support the view that the micelle formation is treated like an appearance of a macroscopic phase in the solution in a limited concentration range.

It is now required to examine an effect of the head group of surfactant on the thermodynamic states of adsorbed film and micelle. This can be done by comparing the results of the DTAC system with those of the DAC system obtained in our previous paper.[1] Comparison between their temperature dependences of cmcs are made in Fig. 3. Looking at Fig. 4, the entropy change associated with the adsorption is found to be affected considerably by the difference in the head group. Since $\Delta s(1)/\Gamma_1^H$ gives the difference of the mean partial molar entropy of surfactant in the adsorbed film $\bar{s}_1^H$ from s_1 approximately at a large value of Γ_1^H,[2] the $\bar{s}_1^H$ value of DTAC may be said to be larger than that of DAC. This seems to be related to the fact that DTAC has fairly smaller Γ_1^H values than DAC as shown in Fig. 5. Further, it is noted that the $\Delta s(M)$ value of DTAC is positive, while that of DAC is negative. Taking into account that $\Delta s(M)/\Gamma_1^H$ is approximately equal in magnitude to $\bar{s}_1^H - \bar{s}_1^M$,[2] where $\bar{s}_1^M$ is the mean partial molar entropy of surfactant in the micelle, the value of $\bar{s}_1^H$ may be concluded to be larger than that of $\bar{s}_1^M$ in the case of DTAC in contrast with the case of DAC. Moreover, it is interesting that the corresponding entropy changes of 2-(octylsulfinyl)ethanol, which is a nonionic surfactant, behave similarly. These results indicate that the size and shape of the head group have a great influence on the packing of the surfactant molecules in the adsorbed film, the aggregation number of micelle,[10] and the distribution of counter ions.

Now we can obtain the thermodynamic quantities of micelle formation from the values of $\Delta s(1)$ and $\Delta s(M)$ at the cmc, because the adsorbed film, the micelle, and the monomeric surfactant in the solution are in equilibrium with each other when the adsorption takes place from the micellar solution. From Eqs. 3 and 4, we have

$$[\Delta s(1) - \Delta s(M)]/\Gamma_1^H = s^M/N_1^M - s_1. \quad (7)$$

The entropy change defined by the right side is referred to as the entropy of micelle formation $\Delta_W^M s$.[11] The values of $\Delta_W^M s$ evaluated by using the results in Figs. 4 and 5 are plotted against temperature with those of DAC in Fig. 7. It can be seen that the $\Delta_W^M s$ values of both systems decrease similarly with temperature and change their signs at high temperatures. Therefore we may say that the partial molar

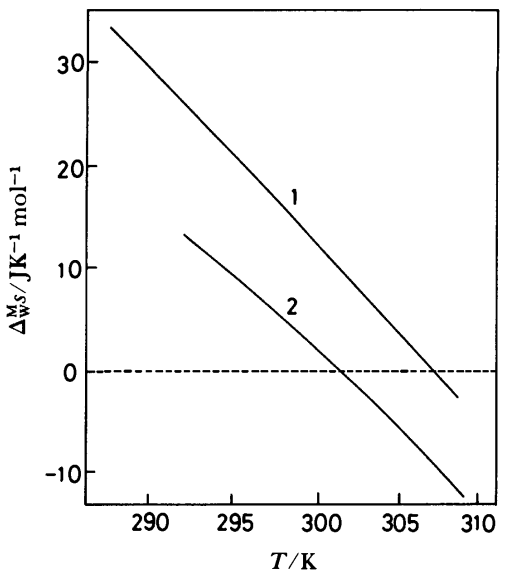

Fig. 7. Entropy change of micelle formation vs. temperature curves under atmospheric pressure: (1) DTAC; (2) DAC.

entropy of surfactant in the micelle is larger than that of monomeric surfactant at low temperature and is smaller at high temperature. Comparing the values of $\Delta_W^M s$ of DTAC with those of DAC, it is probable that the mean partial molar entropy of DTAC in the micelle is larger than that of DAC in conformity with the observation that the mean partial molar entropy of DTAC in the adsorbed film is larger than that of DAC.

Finally let us consider the micelle formation from an energetic point of view. The energy change associated with the adsorption of surfactant from the monomeric state $\Delta u(1)$ and that from the micellar state $\Delta u(M)$ are evaluated respectively by use of the relations

$$\Delta u(1) = \gamma + T\Delta s(1) - p\Delta v(1) \quad (8)$$

and

$$\Delta u(M) = \gamma + T\Delta s(M) - p\Delta v(M), \quad (9)$$

where $\Delta v(1)$ and $\Delta v(M)$ are the corresponding volume changes, respectively. The $\Delta u(1)$ and $\Delta u(M)$ values obtained by disregarding the pv terms on the right side[8] are illustrated in Fig. 8 at 298.15 K under atmospheric pressure. It is seen that $\Delta u(1)$ decreases with increasing concentration and is changed discontinuously at the cmc to $\Delta u(M)$ which is nearly constant for both surfactant systems. Comparing the $\Delta u(M)$ values of DTAC and DAC, though the $\Delta s(M)$ values of DTAC and DAC are opposite in sign as shown in Fig. 4, they are found to be positive, which suggests that the energy of the adsorbed state is larger than that of the micellar state for the two systems. It is further found that the $\Delta u(1)$ and $\Delta u(M)$ values of

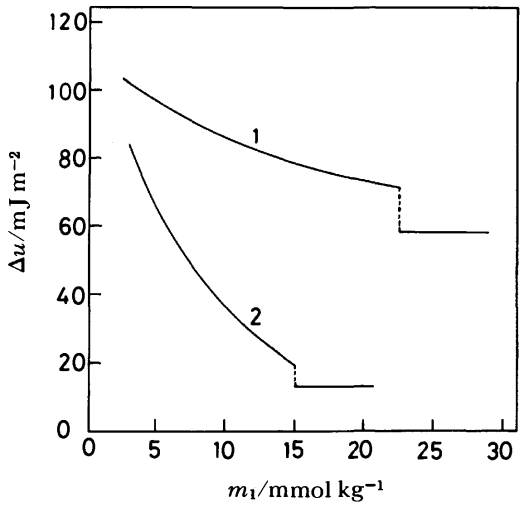

Fig. 8. Energy change associated with the adsorption vs. concentration curves at 298.15 K under atmospheric pressure: (1) DTAC; (2) DAC.

DTAC are larger than those of DAC. These results indicate that the energy states of the adsorbed film and micelle of surfactant are affected appreciably by the chemical structure of its head group. Further information regarding the effect of the head group will be obtained by investigating the systems of alkyldimethylammonium chloride and alkylmonomethylammonium chloride.

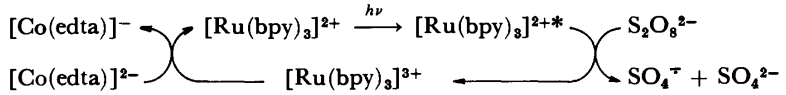
Light-induced Electron-transfer Reactions. 5. Kinetics of the Oxidation of Ethylenediaminetetraacetatocobaltate(II) Complexes by Peroxodisulfate Ion, Induced by Irradiation with Visible Light of Aqueous Solutions Containing Tris(2,2′-bipyridine)ruthenium(II) Ion

Suzuko NISHIDA and Masaru KIMURA*
Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630
(Received November 4, 1986)

The oxidation reaction of ethylenediaminetetraacetatocobaltate(II) ($[Co(edta)]^{2-}$) by peroxodisulfate ion ($S_2O_8^{2-}$) is greatly accelerated by irradiation with visible light of aqueous solutions containing tris(2,2′-bipyridine)ruthenium(II) ion ($[Ru(bpy)_3]^{2+}$). The overall reaction is $2[Co(edta)]^{2-}+S_2O_8^{2-} \rightarrow 2[Co(edta)]^{-}+2SO_4^{2-}$. The $[Ru(bpy)_3]^{2+}$ ion acts as a photosensitizer and -catalyst for this reaction, and the mechanism consists of a chain reaction being initiated by the quenching reaction of the photoexcited ruthenium(II) complex ion ($[Ru(bpy)_3]^{2+*}$) by $S_2O_8^{2-}$ ion. The mechanism of the reaction is presented to account for the results obtained.

There has been much interest in the photoinduced electron-transfer reactions containing $[Ru(bpy)_3]^{2+}$ from viewpoints of solar energy conversion.[1-3] In order to produce oxygen by the water photolysis, it is generally required to combine oxidative quenching reactions with redox catalytic steps with solid catalysts such as RuO_2, $RuO_2 \cdot xH_2O$, and IrO_2. Peroxodisulfate ion ($S_2O_8^{2-}$) is one of the most useful oxidative quenchers because $S_2O_8^{2-}$ decomposes to two sulfate ions upon photoreduction and thus, the reverse electron-transfer reaction can be completely prevented. Actually, there have been several reports using $S_2O_8^{2-}$ for the production of oxygen from water by use of $[Ru(bpy)_3]^{2+}$ as a photocatalyst.[4-13]

The photoexcited ruthenium(II) complex ($[Ru(bpy)_3]^{2+*}$), is quenched rapidly by the peroxodisulfate ion, generating $[Ru(bpy)_3]^{3+}$, $SO_4^{\cdot-}$, and SO_4^{2-}.[4] Both the species $[Ru(bpy)_3]^{3+}$ and $SO_4^{\cdot-}$ are strong oxidants and are able to oxidize various compounds. Thus, it is possible to design various kinds of light-induced oxidation reactions by using the peroxodisulfate ion containing $[Ru(bpy)_3]^{2+}$ as a photocatalyst. In previous works,[14,15] we studied the light-induced oxidation reactions of oxalate ions and formate ions by the peroxodisulfate ion. The present paper describes an experiment for the light-induced electron-transfer reaction between $[Co(edta)]^{2-}$ ($edta^{4-}$=ethylenediaminetetraacetate ion) and $S_2O_8^{2-}$ by employing $[Ru(bpy)_3]^{2+}$ as a photo-catalyst. This reaction hardly proceeded in the absence of $[Ru(bpy)_3]^{2+}$ under the conditions in the present paper and we demonstrate that the proposed scheme (v.i.) operates well in solutions over the pH range 1.9—7.0. Proposed scheme:



Hereafter, we use the abbreviation EDTA for all the forms of H_4edta, H_3edta^-, H_2edta^{2-}, $Hedta^{3-}$, and $edta^{4-}$.

Experimental

Chemicals. $[Ru(bpy)_3]Cl_2 \cdot 6H_2O$ and $K[Co(edta)] \cdot 2H_2O$ were prepared as described in the literature[16] and recrystallized twice from redistilled water. Reagent grade potassium peroxodisulfate (Wako Pure Chemicals Co.) was recrystallized twice from redistilled water and dried at room temperature in a vacuum desiccator. Sodium perchlorate used for adjusting ionic strength was recrystallized twice from redistilled water. Disodium dihydrogen ethylenediaminetetraacetate (Na_2H_2edta), cobalt sulfate($CoSO_4 \cdot 7H_2O$), and other chemicals were of guaranteed-reagent grade and used without further purification. Redistilled water was prepared from deionized water first by successive distillation from alkaline permanganate solution and then without addition of any reagents in a glass still.

Procedures. The reaction vessel was a colorless glass bottle (capacity 0.5 dm^3, diameter 80 mm, thickness 1 mm with 10 mm neck) and was placed in a thermostatted water bath made of colorless glass (2×3×3 dm^3, thickness 6 mm). Unless otherwise stated, the sample solution was irradiated with light from two 100-W tungsten lamps that were placed 3 dm to the right- and left-hand sides to the center of the reaction vessel. Irradiation was continued throughout the reaction. Oxygen was removed by bubbling pure nitrogen gas through the solution. Aliquot samples were withdrawn at appropriate times and mixed with a cation-exchange resin (Dowex 50W-X8, 200—400 mesh, hydrogen form, washed well with distilled water) in order to remove $[Ru(bpy)_3]^{2+}$ from the reaction solution and to stop the

reaction. After filtration, the concentration of $[Co(edta)]^-$ formed was determined spectrophotometrically by using the maximum molar absorption coefficient 295 $dm^3\ mol^{-1}\ cm^{-1}$ at 536 nm. The concentration of the peroxodisulfate ion remaining was determined polarographically at 0.1 V vs. SCE in a solution of 0.01 mol dm^{-3} perchloric acid, 0.1 mol dm^{-3} sodium perchlorate and 0.01% gelatine at 25 °C.

It was confirmed from the difference spectra between the reaction solution and the filtrate after removing $[Ru(bpy)_3]^{2+}$ with the cation-exchange resin (see above) that the concentration of $[Ru(bpy)_3]^{2+}$ maintained constant in the presence of $[Co(edta)]^{2-}$. The concentrations of $[Ru(bpy)_3]^{2+}$ and $[Ru(bpy)_3]^{3+}$ in the absence of $[Co(edta)]^{2-}$ were determined from the measurements of absorbance by using the values of molar absorption coefficients ($dm^3\ mol^{-1}\ cm^{-1}$) 1.1×10^4 and 3.3×10^3 at 420 nm, respectively, and 1.4×10^4 and 2.8×10^2 at 452 nm, respectively.[17] The Stern-Volmer plots were obtained from measurements of the luminescence of $[Ru(bpy)_3]^{2+*}$ by using a Hitachi 850 spectrofluorometer at an excitation energy of 452 nm after removing oxygen by bubbling pure argon gas through the solution.

Results and Discussion

As seen in Fig. 1, when the solutions containing $[Ru(bpy)_3]^{2+}$, $[Co(edta)]^{2-}$, and $S_2O_8^{2-}$ were irradiated with visible light, the concentration of $S_2O_8^{2-}$ decreased and that of $[Co(edta)]^-$ increased with the irradiation time (t). Both the kinetic curves in plots of $[S_2O_8^{2-}]$ vs. t and $[[Co(edta)]^-]$ vs. t were not influenced by the ratio of $[Co(II)]_{added}/[EDTA]_{added}$ over the range 1—3, but were seriously influenced at the ratio of 0.1.

Stoichiometry. When the light-induced reaction proceeded to large extent under the conditions $[Co(II)]_{added} \geq [EDTA]_{added}$, the concentrations of $[Co(edta)]^-$ and $S_2O_8^{2-}$ were determined. The ratio of $[[Co(edta)]^-]_{formed}/[S_2O_8^{2-}]_{decomposed}$ was 2.0±0.1 as an average of 7 runs. This indicates that the stoichiometry (and the overall reaction) is expressed by Eq. 1.

$$2[Co(edta)]^{2-} + S_2O_8^{2-} \longrightarrow 2[Co(edta)]^- + 2SO_4^{2-} \quad (1)$$

(in the case of $[Co(II)]_{added} \geq [EDTA]_{added}$)

On the other hand, when the concentration of cobalt(II) ion added was less than that of EDTA, the decomposition rate of $S_2O_8^{2-}$ became much faster, while the formation rate of $[Co(edta)]^-$ did not change so much. At the ratio $[Co(II)]_{added}/[EDTA]_{added}=0.1$, the rate of decomposition of $S_2O_8^{2-}$ became almost two times faster than that at the ratios of 1—3 (see the plots ▲ in Fig. 1). After the results and mechanisms of reaction under the conditions of $[Co(II)]_{added}=[EDTA]_{added}$ are presented, we discuss such behavior under the conditions of $[Co(II)]_{added} \ll [EDTA]_{added}$. As stated before, the concentration of $[Ru(bpy)_3]^{2+}$ remained constant during the reaction. However, after all the $[Co(edta)]^{2-}$ ion was oxidized to the $[Co(edta)]^-$ ion,

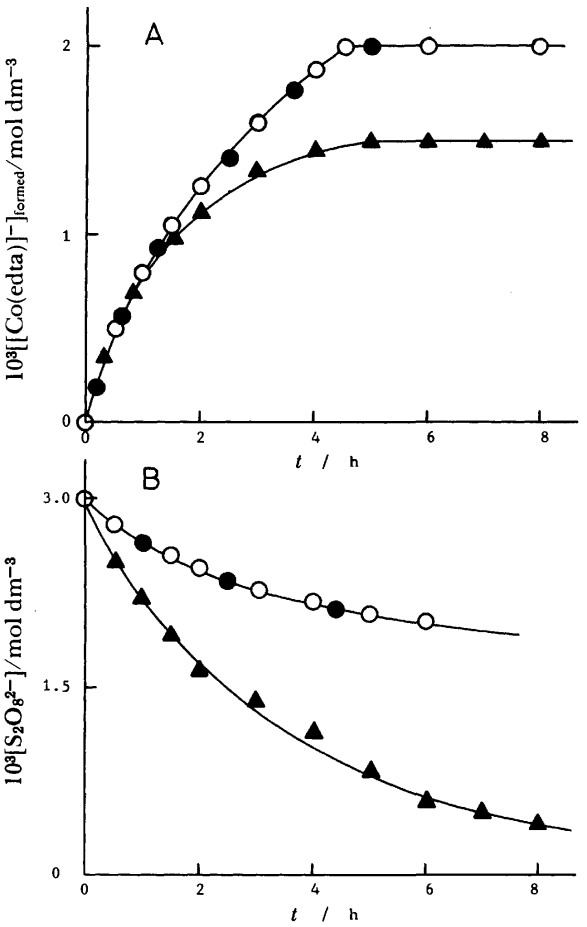


Fig. 1. Plots of $[[Co(edta)]^-]$ vs. t (A) and $[S_2O_8^{2-}]$ vs. t (B). Initial concentrations of $CoSO_4$ and EDTA are, respectively, 0.006 and 0.002 (-○-), 0.002 and 0.002 (-●-), and 0.002 and 0.020 mol dm^{-3} (-▲-), and those of $K_2S_2O_8$ and $[Ru(bpy)_3]Cl_2$ are 0.003 and 5×10^{-5} mol dm^{-3}, respectively. Reaction solution was irradiated with two 100-W tungsten lamps and saturated with nitrogen gas. pH 4.6. 30 °C. μ= 0.1 mol dm^{-3}.

the $[Ru(bpy)_3]^{2+}$ concentration began to decrease accompanying the formation of $[Ru(bpy)_3]^{3+}$. This fact is given in Fig. 2. After the complete change of $[Co(edta)]^{2-}$ to $[Co(edta)]^-$ the latter concentration remained constant, but the concentrations of $[Ru(bpy)_3]^{2+}$ as well as $[Ru(bpy)_3]^{3+}$ decreased gradually. The $[Ru(bpy)_3]^{3+}$ ion oxidizes slowly water, and some of $[Ru(bpy)_3]^{3+}$ appears to dissociate in such a solution without any reductants[9] and the dissociated bipyridine may be oxidized by the SO_4^- radical.

Effect of Hydrogen Ion Concentration. The effect of the hydrogen ion concentration on the reaction rates ($[S_2O_8^{2-}]$ vs. t and $[[Co(edta)]^-]$ vs. t) was examined over the pH range 1.1—7.0 under the conditions of the plots● in Fig. 1. The rate of the reaction was independent of the hydrogen ion concentrations over the pH range 1.9—7.0, and at pH 1.1, the rate of

the reaction became very slow, because $[Co(edta)]^{2-}$ in solution could dissociate to large extent at such a strong acidity.[18] Hereafter, all the experiments were carried out at pH 4.6.

Effect of Concentrations of Reactants, $[Co(edta)]^{2-}$ and $S_2O_8^{2-}$. Under the conditions of plots● in Fig. 1, i.e., $[Co(II)]_{added}=[EDTA]_{added}$, the rates of the reaction $-d[S_2O_8^{2-}]/dt$ and $d[[Co(edta)]^-]/dt$ were independent of the initial concentrations of $[Co(edta)]^{2-}$ over the range 0.001—0.005 mol dm^{-3}, and were, however, dependent on those of peroxodisulfate ion. The initial rate of the reaction $\Delta[[Co(edta)]^-]_i/\Delta t(=V_i)$ was determined at various concentrations of $S_2O_8^{2-}$, and the reciprocal V_i was plotted against the reciprocal of the initial concentration of $S_2O_8^{2-}$. As seen in Fig. 3, the plots of V_i^{-1} vs. $[S_2O_8^{2-}]_i^{-1}$ showed a straight line with an intercept, and the slope of the plot was dependent on the ionic strength(μ).

Thus the empirical rate law can be written as follows.

$$V_i^{-1}=\left(\frac{\Delta[[Co(edta)]^-]_i}{\Delta t}\right)^{-1}=\left(-\frac{2\Delta[S_2O_8^{2-}]_i}{\Delta t}\right)^{-1}$$
$$=\alpha+\beta[S_2O_8^{2-}]_i^{-1} \quad (2)$$

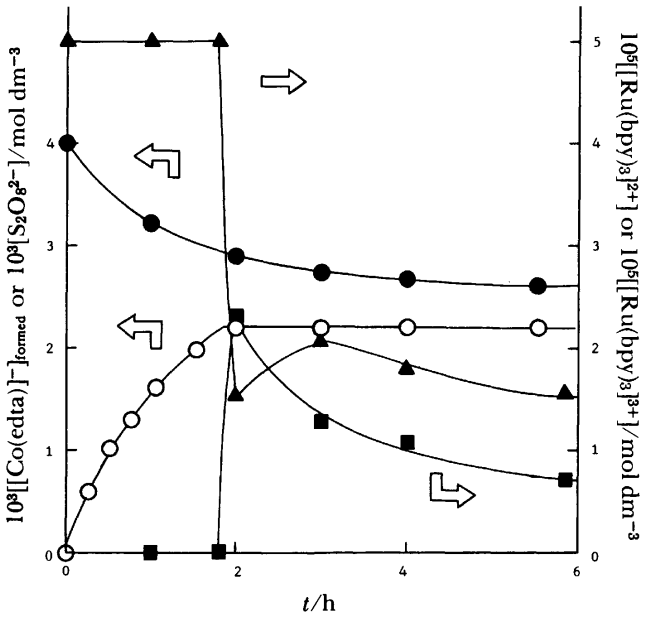

Fig. 2. Variations of the reactants' concentrations against reaction time. Plots ●, ○, ▲, and ■ indicate the variations of concentrations of $S_2O_8^{2-}$, $[Co(edta)]^-$, $[Ru(bpy)_3]^{2+}$, and $[Ru(bpy)_3]^{3+}$, respectively. Initial concentrations are 0.004 mol dm^{-3} in $K_2S_2O_8$, 2.2×10^{-3} mol dm^{-3} in $Na_2[Co(edta)]$, and 5×10^{-5} mol dm^{-3} in $[Ru(bpy)_3]Cl_2$. Reaction solution was irradiated with four 100-W tungsten lamps. μ=0.03 mol dm^{-3}. Other conditions are the same as in Fig. 1.

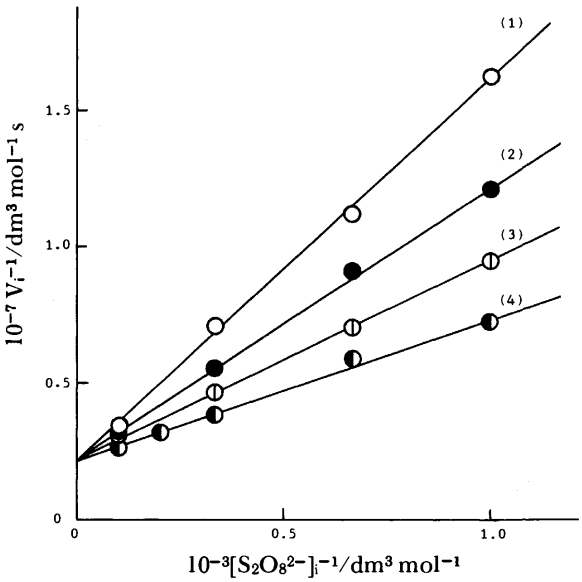

Fig. 3. Plots of Eq. 2. Conditions are the same as in Fig. 1, but $[Co(II)]_{added}=[EDTA]_{added}$=0.002 mol dm^{-3} and the ionic strengths(μ) are 0.5, 0.3, 0.2, and 0.1 mol dm^{-3} for lines(1), (2), (3), and (4), respectively.

		Av. 2.13±0.11				

a) Conditions are as in Fig. 3. The k_q and k_q' values are calculated by using $\tau_0=660$ ns and $k_0=\tau_0^{-1}=1.52\times10^6$ s^{-1}.[20] b) Values obtained from the Stern-Volmer plots of the quenching of the luminescence from $[Ru(bpy)_3]^{2+*}$ by $S_2O_8^{2-}$(see Ref. 14)). c) Values obtained from the Stern-Volmer plots of the quenching of the luminescence from $[Ru(bpy)_3]^{2+*}$ by $[Co(edta)]^-$: the Stern-Volmer constants K_{sv} were 1.94×10^3, 1.65×10^3, 1.50×10^3, and 1.44×10^3 dm^3 mol^{-1} for ionic strengths 0.1, 0.2, 0.3, and 0.5 mol dm^{-3}, respectively.

The values of α and β in Eq. 2 obtained at various temperatures and ionic strengths are given in Table 1 together with the rate constants.

Effect of Incident Light. No appreciable formation of $[Co(edta)]^-$ and no appreciable decomposition of $S_2O_8^{2-}$ were found in the dark under the conditions given. It was found that the formation rate of $[Co(edta)]^-$(or twofold decomposition rate of $S_2O_8^{2-}$) was proportional to the number of lamps used: V_i in Eq. 2 was 1.18×10^{-7}, 2.27×10^{-7}, 3.50×10^{-7}, and 4.86×10^{-7} mol dm^{-3}s^{-1} at the number of lamps of 1, 2, 3, and 4, respectively.

Effect of Concentration of Photocatalyst. The initial rate (V_i in Eq. 2) increased with concentrations of $[Ru(bpy)_3]^{2+}$ and then reached a limiting value (see Fig. 4). This behavior is thought to be due to the change of the amount of light absorbed according to the concentation change of photo-catalyst $[Ru(bpy)_3]^{2+}$ and is accounted for by Eq. 3.

$$I_a = I_0(1-\exp(-A[[Ru(bpy)_3]^{3+}])), \tag{3}$$

where I_0 is the intensity of the incident light, I_a is the amount of light absorbed by $[Ru(bpy)_3]^{2+}$, and A is an empirical constant comprising the length of the light path and the molar absorption coefficient of $[Ru(bpy)_3]^{2+}$.

The rate of reaction (V_i) is proportional to I_a (see Eq. 10), and thus, a curve shown in Fig. 4 coincides with the expression of Eq. 3.

Mechanisms of the Reaction. The following mechanism of the reaction is presented to account for the results obtained.

$$[Ru(bpy)_3]^{2+} + h\nu \xrightarrow{I_a}$$
$$[Ru(bpy)_3]^{2+*} \xrightarrow{k_0} \begin{cases} \rightarrow [Ru(bpy)_3]^{2+} + h\nu'(\text{emission}) \\ \rightarrow [Ru(bpy)_3]^{2+} + \Delta(\text{thermal energy}) \end{cases} \tag{4}$$

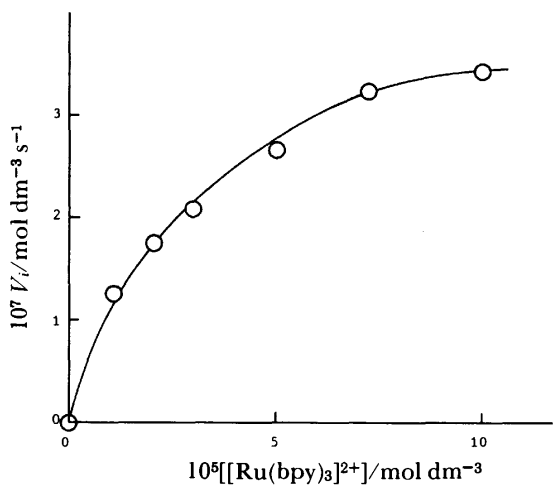

Fig. 4. Effect of the $[Ru(bpy)_3]^{2+}$ ion concentration on the reaction rate. Conditions as in Fig. 1, but $[Co(II)]_{added}=[EDTA]_{added}=0.002$ mol dm^{-3}.

$$[Ru(bpy)_3]^{2+*} + S_2O_8^{2-} \xrightarrow{k_q} [Ru(bpy)_3]^{3+} + SO_4^{\cdot-} + SO_4^{2-} \tag{5}$$
$$[Ru(bpy)_3]^{2+} + SO_4^{\cdot-} \xrightarrow{k_1} [Ru(bpy)_3]^{3+} + SO_4^{2-} \tag{6}$$
$$[Co(edta)]^{2-} + SO_4^{\cdot-} \xrightarrow{k_2} [Co(edta)]^- + SO_4^{2-} \tag{7}$$
$$[Co(edta)]^{2-} + [Ru(bpy)_3]^{3+} \xrightarrow{k_3} [Co(edta)]^- + [Ru(bpy)_3]^{2+} \tag{8}$$
$$[Ru(bpy)_3]^{2+*} + [Co(edta)]^- \xrightarrow{k_q'} [Ru(bpy)_3]^{3+} + [Co(edta)]^{2-} \tag{9}$$

Assuming the steady state concentrations of $SO_4^{\cdot-}$, $[Ru(bpy)_3]^{3+}$, and $[Ru(bpy)_3]^{2+*}$, the following rate law is obtained.

$$\frac{d[[Co(edta)]^-]}{dt} = \frac{2k_qI_a\phi[S_2O_8^{2-}]}{k_0 + k_q[S_2O_8^{2-}] + k_q'[[Co(edta)]^-]}, \tag{10}$$

where ϕ is the formation efficiency of the excited species, I_a is the amount of light absorbed by $[Ru(bpy)_3]^{2+}$ (see Eq. 3) and $I_a\phi$ corresponds to the formation rate of $[Ru(bpy)_3]^{2+*}$. Reaction 9 and the term $k_q'[[Co(edta)]^-]$ in Eq. 10 might be negligible at least for the initial period of the reaction, and thus, the following rate law can be applied under such conditions.

$$V_i^{-1} = \frac{1}{2I_a\phi} + \frac{k_0}{2I_a\phi k_q}[S_2O_8^{2-}]_i^{-1} \tag{11}$$

Equation 11 is equivalent to Eq. 2 obtained empirically, and is in agreement with all the results. The α and β values in Eq. 2 correspond to $(2I_a\phi)^{-1}$ and $k_0/(2I_a\phi k_q)$, respectively, and thus, the values of k_q/k_0 were obtained from the plots of V_i^{-1} vs. $[S_2O_8^{2-}]_i^{-1}$. It is to be noted that the reaction rate of the light-induced reaction was hardly dependent on temperature. The values of k_q/k_0 were almost independent of the temperature of solution, and thus, the activation energy of the quenching reaction(E_q) is almost equal to that of the nonradiative quenching of the photoexcited species(E_0=10.6 kJ mol^{-1} for k_0-path in Eq. 4[21]). The quenching rate constants k_q' and k_q were determined by the measurements of the luminescence of $[Ru(bpy)_3]^{2+*}$ in solutions of various concentrations of $[Co(edta)]^-$ and $S_2O_8^{2-}$. The k_q values determined by using Eq. 11 were in good agreement with those determined by the measurements of quenching luminescence. This fact supports the validity of the mechanism and the rate law proposed.

Confirmation of Rate Law (Eq. 11). The integral form of Eq. 10 is given by

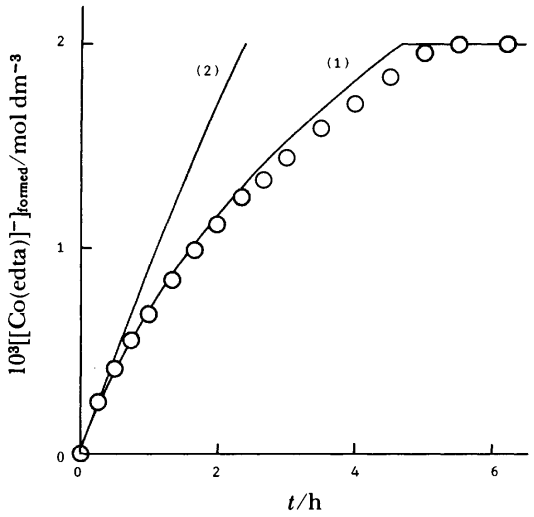

Fig. 5. Plots of Eq. 12. Conditions as in Fig. 1, but $[Co(II)]_{added}=[EDTA]_{added}=0.002$ mol dm^{-3}. The solid curve(1) indicates the calculated values using Eq. 12 and plots indicate the data obtained experimentally. Another solid curve(2) indicates the calculated values by using Eq. 12'.[22]

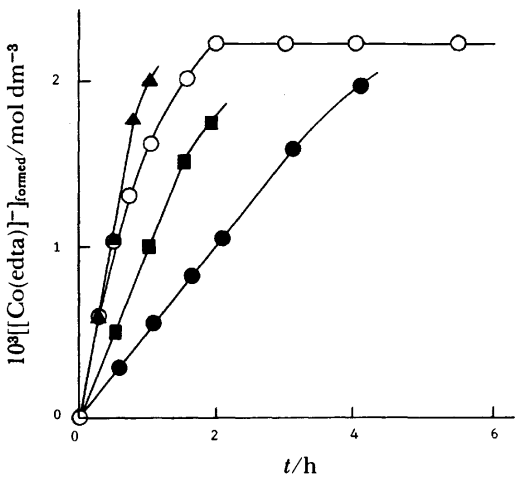

Fig. 6 Comparison with the silver(I) ion-catalyzed reaction. Plots O indicate the experimental data obtained under the same conditions as in Fig. 2. Plots ▲, ■, and ● indicate the silver(I) ion-catalyzed reaction. Conditions are 5×10^{-3} mol dm^{-3} in $AgClO_4$ and 30 °C (-▲-), 5×10^{-3} mol dm^{-3} in $AgClO_4$ and 20 °C (-■-), 1×10^{-3} mol dm^{-3} in $AgClO_4$ and 30 °C (-●-), and the other conditions are the same as in the plots O.

$$\left(\frac{1}{2}k_q - k_q'\right)[[Co(edta)]^-]_{t=t} - (k_0 + 2k_q'[S_2O_8^{2-}]_{t=0}) \times \ln\frac{[S_2O_8^{2-}]_{t=t}}{[S_2O_8^{2-}]_{t=0}} = k_q I_a \phi t \quad (12)$$

Using values of k_q, k_q', k_0, and $I_a\phi$, we can calculate a curve of the plots [[Co(edta)]$^-$] vs. t. The calculated curve was in good agreement with the data obtained experimentally (see curve(1) in Fig. 5). A slight deviation only near the completion of the reaction seems to be attributable to the inner-filter effect of [Co(edta)]$^-$ which is produced according to the progress of reaction time. It is to be noted that the calculated curve is greatly altered by neglecting the term k_q'[[Co(edta)]$^-$] in Eq. 10 (compare curve(2) to curve(1) in Fig. 5), and that the validity of Eq. 11 is limited to the reaction time less than 20 minutes.

As stated before and seen in Fig. 1, under the conditions of $[Co(II)]_{added}/[EDTA]_{added}=0.1$, the formation rate of [Co(edta)]$^-$ decreased to a small extent, while the decomposition rate of $S_2O_8^{2-}$ was accelerated greatly. These facts may indicate the occurrence of the following reactions.

$$EDTA + [Ru(bpy)_3]^{3+} \longrightarrow EDTA^{+} + [Ru(bpy)_3]^{2+} \quad (13)$$

$$S_2O_8^{2-} + EDTA^{+} \longrightarrow SO_4^{-} + SO_4^{2-} + \text{products} \quad (14)$$

$$EDTA + SO_4^{-} \longrightarrow EDTA^{+} + SO_4^{2-} \quad (15)$$

Reaction 13 is a competitive reaction with reaction 8, and thus, the formation rate of [Co(edta)]$^-$ might have been decreased. Successively, the EDTA radicals will react with peroxodisulfate and thus, the rate of decomposition of $S_2O_8^{2-}$ can be greatly accelerated (the reaction mechanisms might become more complex).

It is known that the oxidation reactions by the peroxodisulfate ion are catalyzed by the silver(I) ion.[23] We have compared the light-induced reaction using $[Ru(bpy)_3]^{2+}$ as a catalyst with the silver(I) ion-catalyzed reaction (see Fig. 6). The reaction rate of the silver(I) ion-catalyzed reaction was dependent on the pH[23] as well as the temperature of the solution. On the other hand, the reaction rate of the light-induced reaction using $[Ru(bpy)_3]^{2+}$ as a photo-catalyst was little dependent on both temperature and pH over the range of pH 1.9—7.0. It may be also simply stated that the activity of the light-induced reaction under four lamps is almost 100 times larger than that of the silver(I) ion-catalyzed reaction under the same concentration of each catalyst.

The Synthesis of CdTe by Means of Fused Salt Electrolysis and Its Characterization

Hideki MINOURA,* Masakazu KITAKATA, Takashi SUGIURA, Minoru MURAYAMA, and Yasusada UENO

Department of Synthetic Chemistry, Faculty of Engineering, Gifu University, 1-1 Yanagido, Gifu 501-11

(Received December 22, 1986)

Crystalline cadmium telluride layers of a cubic structure have been deposited potentiostatically on graphite cathodes by means of fused salt electrolysis employing $CdCl_2$ and TeO_2/Na_2TeO_3 in an LiCl-KCl eutectic melt at 450 °C. X-Ray diffraction and scanning-electron-microscope studies show that (i) these layers have a tendency to grow with a preferred orientation along the ⟨111⟩ direction and (ii) the surface morphology changes drastically with the change in the applied potential. Voltammetric analyses indicate two distinct mechanisms for cadmium telluride deposition; one is the codeposition of cadmium and tellurium occurring at potentials more negative than −0.2 V(vs. Ag/AgCl), and the other is the ionic reaction of the cathodically formed telluride ion with the cadmium ion occurring at potentials more negative than −0.7 V(vs. Ag/AgCl). As-deposited crystals are either n- or p-type, depending on the melt composition and the applied potential.

The electrodeposition from fused salts seems to be one of most promising of the new methods of obtaining semiconductor films. The important merits of this method are as follows; (i) it is easy to control the deposition conditions, as is common in the case of electrochemical deposition methods, and (ii) it enables us to obtain compound semiconductors with a high crystallinity since the deposition takes place at a relatively high temperature compared to that of aqueous solutions. In spite of its usefulness, however, no systematic studies of the preparation of semiconductor materials by means of fused salt electrolysis have been reported thus far, although a few reports dealing inadequately with this subject are available in the literature.[1-5] In the past decade our laboratory has been engaged in a major effort to produce polycrystalline cadmium chalcogenide films/layers by employing various methods aimed at their efficient use in photoelectrochemical cells.[6] As a part of this series of investigations, we have already reported the crystal growth of CdSe by means of fused salt electrolysis and its applicability in a photoelectrochemical cell.[7,8]

This paper deals with the electrodeposition of CdTe by means of fused salt electrolysis. CdTe is a promising material for solar photovoltaic devices because it possesses a direct bandgap of 1.44 eV, which is close to the maximum of the solar spectrum, and because it has a high absorption coefficient. Besides, with it both n-type and p-type forms can be conveniently prepared. Actually, polycrystalline CdTe has already been successfully used in a CdS/CdTe heterojunction solar cell for commercial use by Matsushita's group.[9] The electrodeposition of CdTe films from an aqueous solution and a nonaqueous solution has already been reported.[10-13] Electrodeposition is a low-temperature process (usually a room-temperature process) without resort to any vacuum technology and is subject to minimum losses of materials; thus, it offers a convenient and inexpensive method of film fabrication. However, as-deposited films obtained by this method generally have a poor crystallinity, a subsequent heat-treatment is required for its use in a photovoltaic device. In this particular aspect, the electrodeposition from fused salt has the advantage that no such subsequent heat-treatment is required because of the simultaneous occurrence of the electrodeposition and the crystal growth.

In this paper, the mechanism of CdTe deposition by means of fused salt electrolysis will be proposed on the basis of the previously proposed mechanism for the similarly deposited CdSe. We have also examined the possibility of getting n- and p-type samples of CdTe selectively by changing the deposition conditions, namely, the electrolytic potential and the salt composition.

Experimental

The experimental apparatus and procedures are nearly the same as those described in a previous paper.[7]

Almost all the electrodeposition procedures from the fused salts thus far reported have been carried out under galvanostatic condition in a two-electrode configuration.[1-4] In order to carry out the potentiostatic electrolysis, we adopted a three-electrode system consisting of a graphite working electrode (a substrate onto which CdTe is deposited), a graphite counter electrode, and an Ag/AgCl reference electrode. The potentiostatic electrolysis is required to examine the potential-dependent deposition, as has been emphasized earlier in the case of CdSe.[8] All the potential values in the present paper are expressed with respect to this reference electrode.

$CdCl_2$ and Na_2TeO_3/TeO_2 were added to the LiCl-KCl electrolyte of the eutectic composition as the source materials of cadmium and tellurium respectively. Electrolyses were carried out at 450 °C.

The crystal structure and the morphology of the deposits were examined by means of an X-ray diffractometer (Rigaku Denki) and a scanning electron microscope (Hitachi H-8010) respectively.

To determine the type of the majority carrier, the current-potential curves under illumination were recorded for the deposits in an aqueous sulfide solution.

Results and Discussion

According to our preliminary experiments, CdTe has been found to be deposited by electrolysis in the melts containing $CdCl_2$ and TeO_2 at the bath temperature of 450 °C. Therefore, prior to the analysis of the CdTe deposition reaction, the cathodic polarization curves of a cadmium-source material and tellurium-source materials have been examined separately in order to understand the CdTe deposition mechanism by using the same method as was reported previously for CdSe.[8] The results on the voltammetric curves of a cadmium source will be omitted in the present paper, as they have already been reported in a previous paper.[8]

Reduction of Te(+4). A voltammetric curve under cathodic polarization in Na_2TeO_3-containing melts is shown in Fig. 1. A cathodic current starts to flow at +0.2 V, reaches the saturation value at −0.3V, and rises again at −0.7 V. The deposit obtained at the first wave exhibits a metallic gray color and was identified as a metallic tellurium by means of the X-ray diffraction data. It has been noticed that, when polarized more cathodically than −0.7 V, the deposit on the substrate gradually disappears. These results indicate that the deposition of a metallic tellurium takes place at the first cathodic wave, while the further reduction of the metallic Te to Te(−2) proceeds at the second cathodic wave, analogous to the reduction of Se(+4) reported in the previous paper.[8] Bodewig and Plambeck[15] examined the electrochemical behavior of a tellurium electrode in the fused LiCl-KCl eutectic and reported the formation of a stable lithium-tellurium intermetallic compound, i.e,. Li_2Te, at −0.67 V. However, we could not detect such an intermetallic compound in our X-ray diffractograms. This particular result can perhaps be attributed to the difference in the electrodes used, i.e, a tellurium electrode in their work and a tellurium-deposited graphite electrode in our work.

In order to understand what reactions are taking place in the second-wave reduction process, cyclic voltammetric experiments were performed in the potential range between −0.6 and −0.9 V. Figure 2 shows cyclic voltammograms with different sweep rates. The peak potential is independent of the sweep rate within our experimental sweep rate range, and the oxidation-peak height is smaller than the reduction-peak height. The peak current density is proportional to the square root of the potential sweep rate and the concentration of Na_2TeO_3, as is indicated in Figs. 3 and 4. It follows that the cathodic reaction occurring in the potential region is a reversible reaction involving a soluble product. From the plot

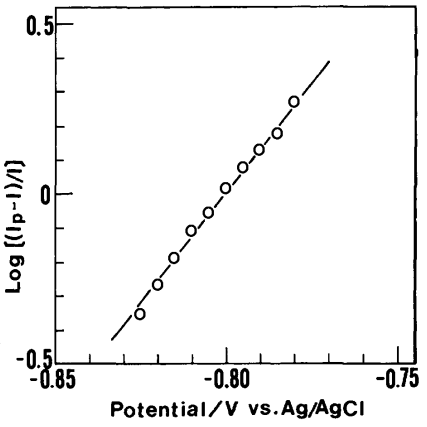

Fig. 5. Plots of log $[(i_p-i)/i]$ vs. electrode potential for the reduction of Na_2TeO_3. Na_2TeO_3 concentration: 4.85×10^{-4} mol%, Sweep rate: 16.7 mV s^{-1}.

shown in Fig. 5, and by applying Matsuda and Ayabe's equation,[16] the number of electrons involved in this cathodic process, n, was calculated by using the procedure reported in a previous paper.[8] This calculation yields the value of 1.89. In this way, it is confirmed that the reduction expressed as:

$$Te(0) + 2e \longrightarrow Te(-2)$$

proceeds at potentials more negative than −0.7 V.

Almost the same behavior was observed when a TeO_2-containing melt was used instead of an Na_2TeO_3-containing melt, with the only exception of a small increase in the cathodic current.

Deposition of CdTe. In the melt containing both $CdCl_2$ as a cadmium source and Na_2TeO_3 as a tellurium-source in an equimolar composition, the cathodic current starts to flow at around +0.2 V,

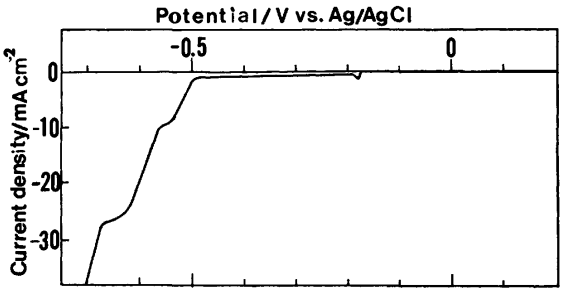

Fig. 6. Voltammograms for the deposition of CdTe in LiCl(0.236 mol)-KCl(0.172 mol)-$CdCl_2$(0.005 mol)-Na_2TeO_3(0.005 mol). Sweep rate: 0.1 mV s^{-1}.

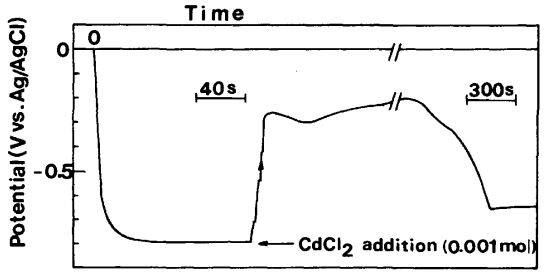

Fig. 7. Electrode potential change with time by the addition of $CdCl_2$ under galvanostatic electrolysis of −10 mA in LiCl(0.236 mol)-KCl(0.172 mol)-Na_2TeO_3(0.005 mol) melt. Electrode surface area: 3.4 cm^2.

which corresponds to the reduction of Te(+4) to Te(0). As is shown in the voltammogram of Fig. 6, a characteristic peak appears at about −0.2 V and the current remains constant with an increase in the cathodic polarization to −0.5 V. The CdTe deposit was observed at potentials more negative than −0.2 V. The appearance of the cathodic peak at around −0.2 V will be discussed later. The redox potential of Cd/Cd^{2+} was reported to be −0.589 V; our result implies that the deposition of cadmium metal starts to take place at −0.59 V. A comparison of the CdTe deposition onset potential of −0.2 V with this standard redox potential of Cd/Cd^{2+} clearly shows the occurrence of the underpotential deposition of CdTe.

The small peak at around −0.2 V in the voltammogram shown in Fig. 6 can be explained by assuming that the tellurium which had been deposited at the potentials more positive than −0.2 V was changed into CdTe at −0.2 V by the incorporation of cadmium, which starts to be deposited at this potential. In order to confirm this assumption, galvanostatic measurements were performed. Figure 7 presents the potential-time curve during the galvanostatic electrolysis. As can be seen from this curve, the electrode potential changes toward negative values and reaches the stationary value of −0.8 V when a

graphite electrode is polarized cathodically in melts containing only the tellurium source. After carrying out this electrolysis for 2 minutes and adding $CdCl_2$ to the melt, the potential suddenly changes to about −0.2 V. This potential corresponds to the small peak in Fig. 6. It is further seen that the potential gradually shifts to more negative values and then reaches the stationary value of −0.64 V. Taking into account the small peak at −0.2 V in Fig. 6, the transition time at −0.2 V in Fig. 7 can be regarded as the time for changing the deposited tellurium to CdTe by the incorporation of the deposited cadmium metal. Therefore, this transition time probably depends on the quantity of the deposited tellurium. Actually, this idea is supported by the results shown in Figs. 7 and 8, which demonstrate that halving the electrolysis time before $CdCl_2$ addition (Fig. 8) results in the reduction of the transition time at −0.2 V to about one-half of that in Fig. 7. The corresponding peak was not observed in the case of CdSe deposition, although a similar process can be expected to occur. This difference is attributable to the difference in the melting points of selenium(220.2 °C) and tellurium (449.8 °C). As the deposited selenium is in a liquified state, it is unlikely to stick to the graphite substrate.

The observation that the cathodic current rises again at −0.59 V suggests the occurrence of a usual cadmium deposition together with the above-mentioned underpotential deposition. The increase in the cathodic current at −0.7 V may be due to the reduction of Te(0) or Te(+4) to Te(−2). Thus, CdTe formation by a reaction of Te^{2-} with Cd^{2+} in the melt should take place in addition to the above-mentioned codeposition. Therefore, the deposition reactions at various potentials can be summarized in the manner shown in Fig. 9.

To get further information on the CdTe deposition process, the change in the surface morphology as the electrolysis progressed was monitored by means of a

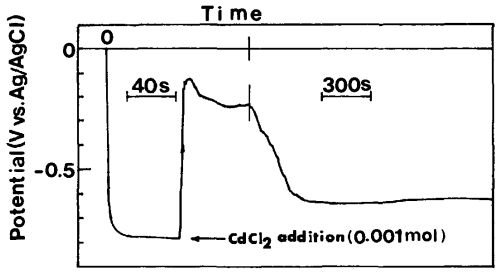

Fig. 8. Electrode potential change with time by the addition of $CdCl_2$ under galvanostatic electrolysis of −10 mA in LiCl(0.236 mol)-KCl (0.172 mol)-Na_2TeO_3(0.005 mol) melt. Electrode surface area: 1.9 cm^2. Electrolysis time before $CdCl_2$ is a half of that in Fig. 7.

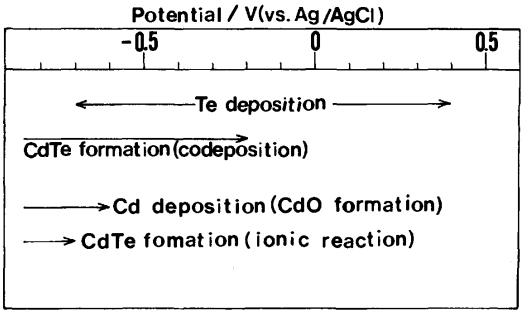

Fig. 9. Deposition reactions at different electrolytic potentials.

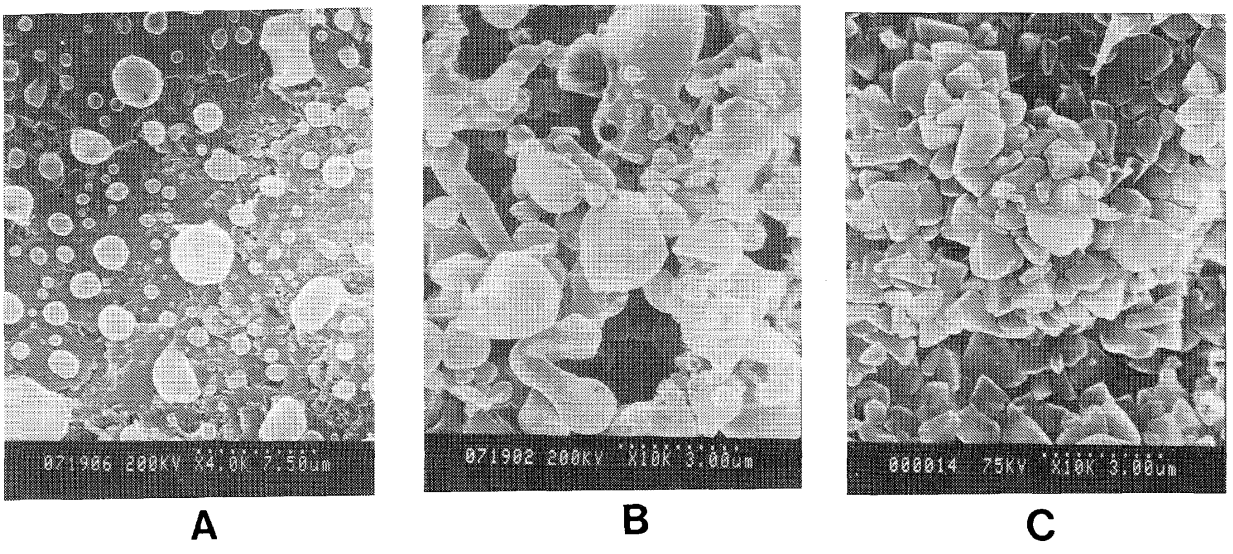

Fig. 10. SEM micrographs of the deposits obtained at −0.6 V. Quantity of electricity passed during electrodeposition; (A) 1.3 C cm^{-2}, (B) 1.3 C cm^{-2}, (C) 2.5 C cm^{-2}. (B) is a different place from (A) in the same sample.

scanning electron microscope. Figure 10 presents SEM micrographs of the deposits obtained at various stages of the electrolysis carried out at −0.6 V. Initially, spherical-shaped deposits appeared, as is shown in Fig. 10 (A). The EPMA results revealed that these deposits are metallic tellurium. This characteristic morphology becomes quite obvious if we consider the fact that the bath temperature is nearly the same as the melting point of tellurium. With the increase in the amount of electricity passed through, other deposits, but with a linear edge in contrast to the above-mentioned spherical-shaped ones, appear, as is shown in Fig. 10 (C). These deposits were identified as CdTe by means of the X-ray diffractograms and the EPMA results. The corresponding photographs show that tellurium is first deposited onto the substrate, and then cadmium is deposited and incorporated into tellurium deposits, resulting in CdTe formation. Thus, our SEM data further support the above-mentioned mechanism of CdTe codeposition.

Figure 11 shows the relationship between the weight gain and the amount of electricity passed through during fused salt electrolysis at −0.6 V. It is clear from these results that the weight of the deposits is directly proportional to the amount of electricity passed through; in other words, the current efficiency remains nearly constant during the electrolysis. Assuming that the overall reaction for CdTe deposition is expressed as:

$$Cd^{2+} + Te^{4+} + 6e \longrightarrow CdTe$$

the apparent current efficiency estimated on the basis of Faraday's law, is 43%. Such a low current efficiency may be attributable to a falling down of some deposited material while the cathode was dipped in a 1% HCl solution after electrolysis. This dipping procedure was employed to remove the solvents and solutes stuck to the deposits. Therefore, we feel that the real current efficiency must be higher than 43%.

Characterization of the Deposits. X-Ray diffractograms of the deposits obtained at the electrolytic potentials of −0.4 and −0.7 V are shown in Fig. 12. All these peaks match well with the ASTM data of cubic CdTe (zinc blende type). In the diffractograms of the deposit at −0.4—−0.6 V, there are some prominent peaks due to CdTe, the intensities of which are in good agreement with the standard powder diffraction data for CdTe. Interestingly, in the diffractogram of the deposits obtained at −0.7 V, only one strong peak corresponding to the (111) plane appears; it is indicative of the crystal growth with a preferred orientation along the ⟨111⟩ direction. This can be ascribed to a relatively high deposition rate at −0.7 V, in which the preferential growth of crystal nuclei with the most stable (111) plane may proceed.

We determined the conductivity type of our deposits by studying the current-potential curves under illumination in an aqueous solution. The deposit which exhibits an anodic photocurrent is referred to as the n-type, while that which exhibits a cathodic

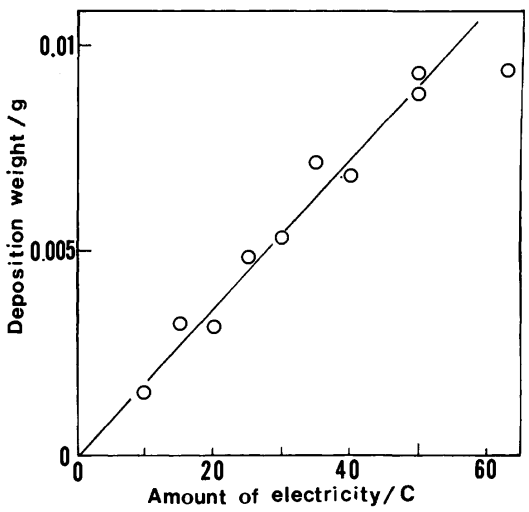

Fig. 11. Deposition weight vs. amount of electricity during electrodeposition from LiCl(0.236 mol)-KCl (0.172 mol)-$CdCl_2$(0.005 mol)-Na_2TeO_3(0.005 mol) melt at −0.7 V.

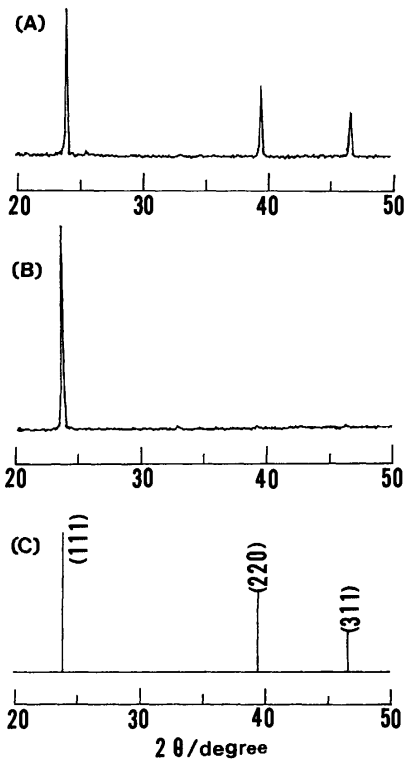

Fig. 12. X-Ray diffraction patterns of the deposits obtained from LiCl(0.236 mol)-KCl(0.172 mol)-$CdCl_2$(0.005 mol)-Na_2TeO_3(0.005 mol) melt. Deposition potential; (A) −0.4 V, (B) −0.7 V. (C) is the ASTM data for cubic CdTe.

photocurrent is referred to as the p-type, in the present paper.

Table 1 summarizes the electrical-conduction type as well as the chemical composition of the deposits obtained under various melt compositions and electrolytic potentials. The chemical compositions correspond to those estimated by means of X-ray diffractograms of the deposits.

From the melt with equimolar $CdCl_2$ and TeO_2, both n-type and p-type CdTe were obtained. At −0.1 V, no CdTe was deposited, however; only metallic tellurium was detected. At potentials more negative than −0.2 V, CdTe was deposited. It should be noted that both n-type and p-type are obtained by controlling the electrolytic potential applied. At potentials more negative than −0.6 V, only n-type CdTe was obtained. This interesting result seems quite reasonable if we consider that −0.59 V is the potential at which cadmium deposition starts to occur and that the n-type is associated principally with an excess of cadmium.

From the melt containing an excess of $CdCl_2$, an n-type sample is more likely to be deposited. Some weak peaks which can be assigned to CdO were found in the X-ray diffractograms. This indicates that a further excess of cadmium leads to the CdO formation. On the other hand, from a melt with an excess of a tellurium source, a p-type sample was found to be deposited, even at −0.7 V. In this case, the deposits were found to contain metallic tellurium, whereas no CdO was detectable. This is attributable to the slower rate of the deposition of cadmium compared to that of tellurium. Such an excess of tellurium in the deposits can be removed by subsequent heat-treatment, as has been reported in the case of CdTe films deposited from an aqueous solution.[13] These results are consistent with the above consideration of the deposition reaction.

When we add Na_2TeO_3 instead of TeO_2 as a tellurium-source material, an n-type is more likely to be deposited. This is attributable to a smaller cathodic current caused by a tellurium deposition, as was mentioned above.

Figure 13 displays SEM micrographs of the deposits obtained at various electrolytic potentials from KCl-LiCl melts containing 0.005 mol $CdCl_2$ and 0.005 mol Na_2TeO_3. As can clearly be seen from these photographs, the deposits at −0.4—−0.6 V have similar morphologies with tetrahedron-shaped crystals. However, it is interesting to note that, with the

The amount of electricity consumed during electrodeposition is 20 C cm^{-2}. a) Estimated from X-ray diffractograms: VS, very strong, S, strong, M, medium, W, weak, VW, very weak, —, undetectable. b) A deposit which shows an anodic photoresponse is termed "n", while that which shows a cathodic photoresponse is termed "p". When a deposit exhibits both anodic and cathodic photoresponses, the weaker one is shown in parentheses.

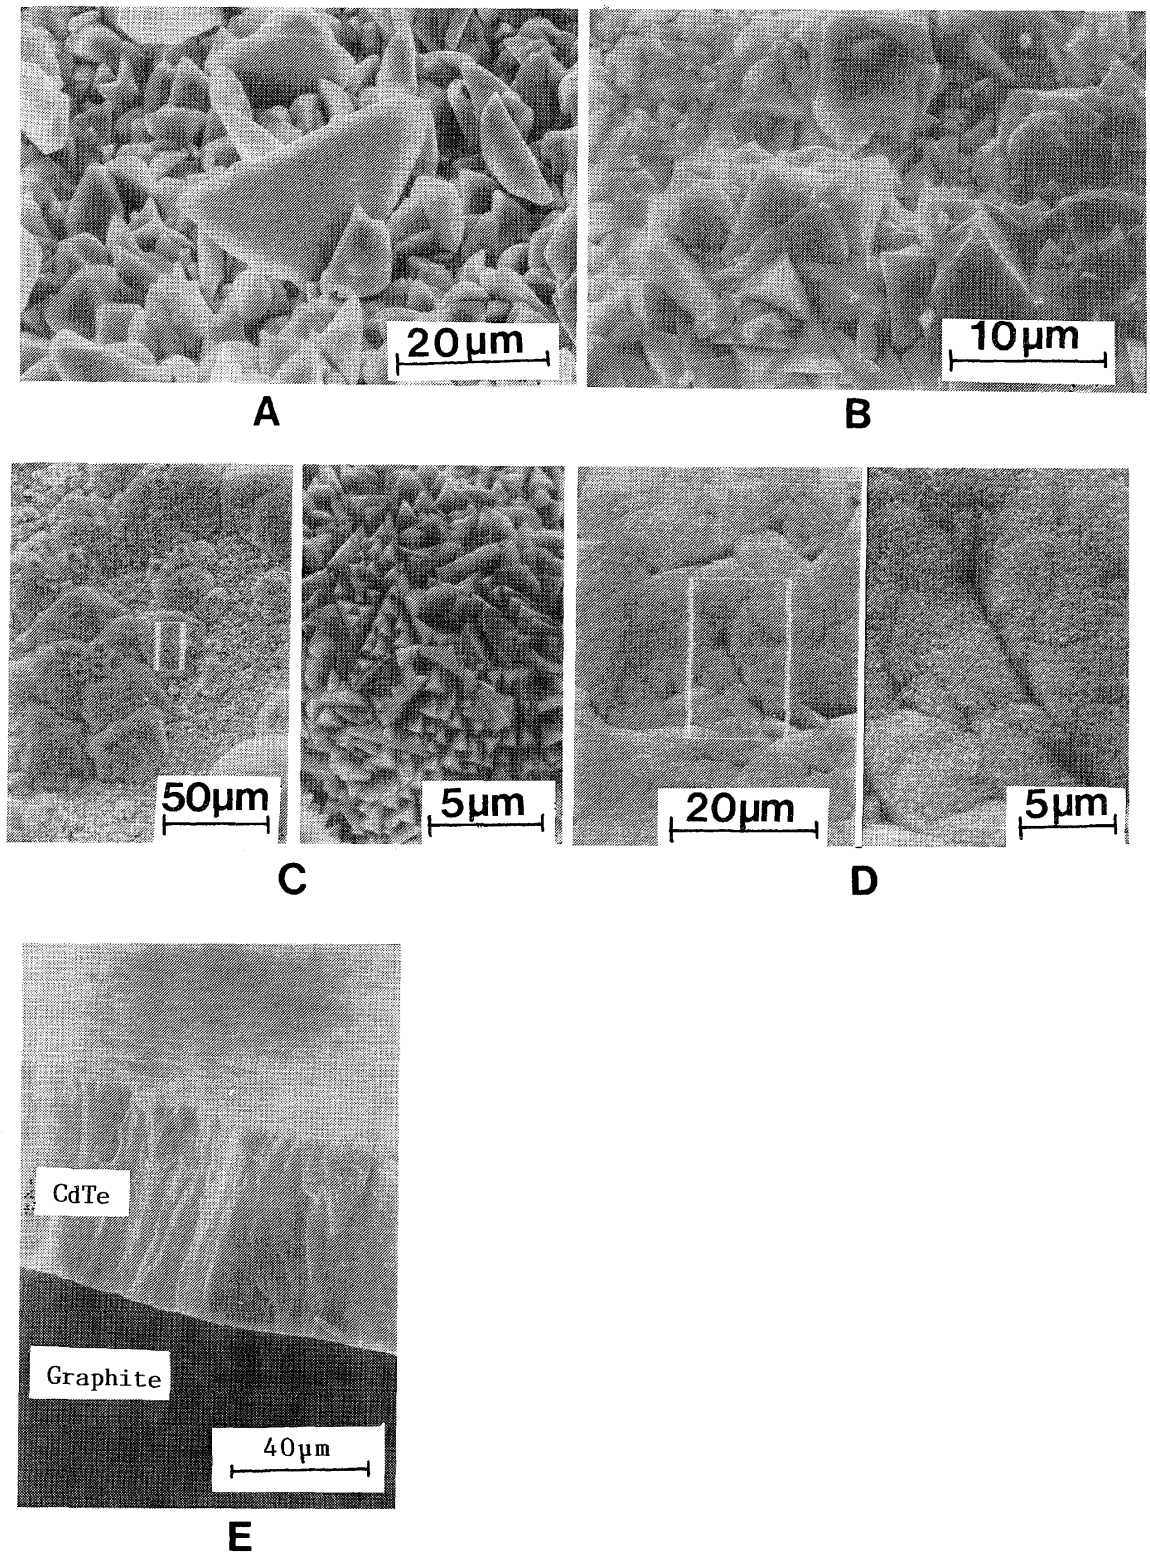

Fig. 13. SEM micrographs of the deposits obtained at different electrolytic potentials from LiCl(0.236 mol)-KCl(0.172 mol)-$CdCl_2$(0.005 mol)-Na_2TeO_3(0.005 mol) melt. Deposition potential; (A) −0.4 V, (B) −0.5 V, (C) −0.6 V, (D) −0.7 V. (E) is the cross section picture of the deposit obtained at −0.7 V.

more negative potentials, smaller crystals are deposited. The size of one crystal is 10—50 μm when deposited at −0.4 V, 5—10 μm at −0.5 V, and about 1 μm at −0.6 V. The deposits at −0.7 V have a slightly different morphology which seems to consist of very fine grains. Figure 13(E) shows a cross-section of the deposit at −0.7 V. The deposit has a columnar structure and a comparatively uniform thickness. We can conclude from this morphology that when a uniform coating of CdTe is required, −0.7 V is the optimum electrolytic potential. Deposition at less negative potentials, in contrast, may be useful for getting a single crystal of CdTe. A further study along these lines is now in progress.

Application of Mössbauer Spectroscopy to a Structural Study of Superionic Conducting AgI-Ag_2O-B_2O_3 Glasses

Tetsuaki NISHIDA,* Michiko OGATA, and Yoshimasa TAKASHIMA

A structural study of silver borate glasses containing 20 mol% AgI and 1 mol% $^{57}Fe_2O_3$ has been performed by Mössbauer spectroscopy. A Mössbauer spectrum of these glasses consists of an asymmetric quadrupole doublet with an isomer shift smaller than 0.4 mm s^{-1} with respect to metallic iron. This indicates that the individual Fe^{3+} ions are present at the substitutional sites of the tetrahedral boron atoms constituting BO_4 units as a network former. An increase in the Ag_2O content results in continuous decreases in the isomer shift and the quadrupole splitting when the Ag_2O content exceeds about 16 mol%, which corresponds to the Ag_2O/B_2O_3 ratio of 0.25 and the alkali oxide content of 20 mol% in the binary borate glasses. These results are ascribed to the formation of nonbridging oxygen atoms in the tetrahedral BO_4 and FeO_4 units. A glass transition temperature (T_g) of the glasses shows a distinct composition dependency, having a maximum around 16 mol% Ag_2O. These lead to the conclusions that planar BO_3 units are changed into the tetrahedral BO_4 units in the lower Ag_2O content region and that the nonbridging oxygen atoms are formed in the BO_4 and FeO_4 units when the Ag_2O content is higher than 16 mol%. These conclusions are well consistent with the composition dependency of the electric conductivity which shows a minimum when the Ag_2O content is 10—15 mol%.

Superionic conducting glasses have attracted much attention because of the scientific interest in the conduction mechanism as well as the high technological applicability. The electric conductivity of the superionic conducting glasses is known to reach the order of 10^{-2} S cm^{-1},[1-13] which is almost equivalent to that of the crystalline superionic conductor (solid state electrolytes) such as α-AgI and β-Al_2O_3. Comparing the magnitude of the electric conductivity of the superionic conducting glasses to that of ordinary oxide glasses such as borate and phosphate glasses, which is usually smaller than about 10^{-12} or 10^{-13} S cm^{-1},[14] it is easily understood that the former is extraordinary larger than the latter. The high electric conductivity of the superionic conducting glasses is assumed to be due to an "ion migration" of monovalent cations such as Ag^+, Li^+, and Na^+ which are present at the interstitial sites of the network structure. As for the role of the Ag^+ ions in the conduction mechanism of the superionic conducting glasses, Minami et al.[1,5,6] suggested the presence of two types of Ag^+ ions; those originated from AgX molecules (X=Cl, Br, and I) and those from Ag_2O molecules. The former is considered to be ionically bonded with the halide ions at the interstitial sites of the network structure, being primarily concerned with the electric (ionic) conduction. The latter is considered to be covalently bonded with oxygen atoms constituting a network structure and is less mobile than the former. Raman and EXAFS studies of the superionic conducting glasses revealed that the mobile Ag^+ ion is surrounded by four halide ions at the interstitial sites of network structure and is forming a microdomain or a distorted sublattice of α-AgI phase having a high electric conductivity.[9,10,12] On the other hand, Chiodelli et al.[13] ruled out the presence of the high electric conducting α-AgI phase dispersed in the glass network, for the electric conductivity of the silver borate glasses containing AgI shows a marked increase with increasing Ag_2O content when the AgI content is constant and also the conductivity of binary Ag_2O-B_2O_3 glasses is much higher than that of ordinary alkali borate glasses. The conductivity measurements of binary Ag_2O-B_2O_3 glasses performed by Matusita and Sakka[15] and Tsuchiya et al.[16] revealed that the conductivity of $30Ag_2O \cdot 70B_2O_3$ glass is about 10^{-6} S cm^{-1} at 100 °C and is higher than 10^{-8} S cm^{-1} at room temperature. These experimental results suggest that a part of the Ag^+ ions originating from Ag_2O also participate in the electric conduction. Tsuchiya et al.[16] ascribed the high conductivity of the Ag_2O-B_2O_3 glasses to an electron hopping from the colloidal Ag^0 to the Ag^+ ions. A structural study of the superionic conducting AgCl-Ag_2O-B_2O_3 glasses containing 1 mol% $^{57}Fe_2O_3$ has already been performed by means of Mössbauer spectroscopy,[17] where the present authors elucidated the relationship between the distinct composition dependency of the electric conductivity and the structural role of the Cl^- ions in those glasses. Namely the highest conductivity is observed when both the mobile and electric conducting Ag^+ ions and the Cl^- ions are present at the interstitial sites of the network structure, i.e. when the Ag_2O content is lower than about 10 mol% in the case of the silver borate glasses containing 20 mol% AgCl. Nishida et al.[17] also elucidated that the conductivity shows a distinct decrease when the Cl^- ions are incorporated into the network structure, as nonbridging chlorine atoms, of the borate glasses having the Ag_2O content higher than about 10 mol%. In these glasses, it was concluded

that the mobility of the Ag^+ ions is depressed because of the increased chemical bond strength between the Ag^+ ion and the Cl^- ion when the latter ion is present as a nonbridging chlorine atom. This conclusion is consistent with those given by Minami et al.[1,5,6] that only the Ag^+ ions originating from AgX molecules (X=Cl, Br, and I) contribute to the electric conduction and that the Ag^+ ions originating from Ag_2O molecules are almost immobile. This will be the case for the Ag^+ ions linked with the nonbridging chlorine atoms in the network structure. In contrast to the distinct composition dependency of the structural role of the Cl^- and Br^- ions in borate glasses,[18-20] all the I^- ions are known to be present at the interstitial sites of the network structure irrespective of the composition of the borate glasses.[20] The I^- ions are quite different from the Cl^- or Br^- ions in terms of the nature of the chemical bond with the Ag^+ ions; the chemical bond between the Ag^+ and the I^- ions is known to be always ionic and therefore the mobility of the Ag^+ ions is expected not to be affected by the structural role of the I^- ions.

Because of the background described above, the present Mössbauer study was performed in order to elucidate the local structure of the silver borate glasses containing 20 mol% AgI. Mössbauer spectroscopy has so far been applied to the structural study of several borate glasses.[17-19,21-25] As a result, several conclusions have been obtained such as a formation of nonbridging oxygen, chlorine, and bromine atoms and a structural change from glass to glass-ceramics. These structural studies by means of Mössbauer spectroscopy suggest that the Mössbauer spectroscopy is a very effective method for the structural study of glasses and that small amounts of iron (Fe^{3+} and Fe^{2+}), which are used as a Mössbauer probe, are easily incorporated into the glasses either as a network former or as a network modifier. DTA measurements of the silver borate glasses containing 20 mol% AgI and 1 mol% Fe_2O_3 were also performed because glass transition temperature (T_g) is known to reflect the structural changes such as a change in the coordination number of network-forming atoms (network former) and a destruction or a depolymerization of the network structure due to a formation of nonbridging oxygen atoms.[26-34]

Experimental

Silver borate glasses containing 20 mol% AgI and 1 mol% Fe_2O_3 were prepared by fusing the individual mixtures of commercially available AgI, Ag_2O, B_2O_3, and $^{57}Fe_2O_3$, of a guaranteed reagent grade, at 1020 °C for 3 h in an electric muffle furnace. After the fusion in the ambient atmosphere, each melt in a platinum crucible was immediately quenched with ice-cold water. Mössbauer measurements of pulverized samples were performed by a constant acceleration method at room temperature using a proportional counter and a 1024 channel multichannel analyzer. Cobalt-57 (10 mCi) diffused into a palladium foil was used as the Mössbauer source. As a standard material for the isomer shift, a metallic iron foil enriched with iron-57 was used. The iron foil was also used for the velocity-calibration of the spectrometer. Each Mössbauer spectrum was analyzed into a quadrupole doublet with the same linewidth. DTA measurements of these glasses were performed ranging from room temperature to 700 °C with a heating rate of 5 °C min^{-1}. An Al_2O_3 powder was used as a standard material in the DTA measurements. Electric-conductivity measurements were performed at room temperature by applying a DC voltage of 3 V. Before the measurement, each glass sample was pressed into a pellet at a net pressure of 2.6×10^6 g cm^{-2}.

Results and Discussion

All the transparent silver borate glasses prepared in the present study change their color from yellowish brown to reddish brown with increasing Ag_2O content. This is the same as the case of the silver borate glasses containing 20 or 30 mol% AgCl and 1 mol% $^{57}Fe_2O_3$.[17] The composition dependency of the color may be due to the different sizes of the colloidal Ag^0 present at the interstitial sites of the glass network.[16] A Mössbauer spectrum of the silver borate glass denoted by $20AgI\cdot25Ag_2O\cdot54B_2O_3\cdot1Fe_2O_3$ is shown in Fig. 1. It is seen from Fig. 1 that the spectrum consists of an asymmetric quadrupole doublet due to high spin Fe^{3+} species[35,36] and that the absorption intensity of the lower energy peak due to $\pm1/2\leftrightarrow\pm1/2$ transition is higher than that of the higher energy peak due to $\pm1/2\leftrightarrow\pm3/2$ transition. The asymmetric spectrum is known to be caused by the anisotropic recoil-free fraction referred to as the "Goldanskii-Karyagin effect."[37,38] In the case of the borate glasses, the asymmetric Mössbauer spectra are often observed especially in the borate glasses with lower alkali oxide contents, where the fraction of the planar BO_3 units is generally known to be large. The asymmetric Mössbauer spectra may be caused by the anisotropic chemical bond strength in the B-O or Fe-O bonds constituting the BO_4 or FeO_4 tetrahedra, brought about by the presence of the planar BO_3 units at the neighboring sites. It is seen from Fig. 1 that the doublet peaks are a little broadened around the base line. This will be due to a magnetic relaxation effect because of the relatively low Fe^{3+} concentration in the glasses, although the magnetic relaxation effect is not so strong as to exhibit a hyperfine spectrum composed of six absorption lines. All the Mössbauer parameters of the silver borate glasses studied in the present paper are summarized in Table 1, from which it is seen that the isomer shifts are located in a range of 0.32—0.25 mm s^{-1}. As for the coordination number of iron in glasses, earlier works are reviewed by Kurkjian[39] and Coey.[40] Recent Mössbauer results on the structure of glasses are reviewed by Müller-Warmuth

$20AgI \cdot 20Ag_2O \cdot 59B_2O_3 \cdot 1Fe_2O_3$	0.28	1.14	0.93
$20AgI \cdot 25Ag_2O \cdot 54B_2O_3 \cdot 1Fe_2O_3$	0.26	1.10	0.82
$20AgI \cdot 30Ag_2O \cdot 49B_2O_3 \cdot 1Fe_2O_3$	0.25	1.11	0.83

a) Isomer shift. b) Quadrupole splitting. c) Linewidth.

and Eckert.[41] According to Coey,[40] most Fe^{3+} ions are known to occupy the tetrahedral sites in borate and silicate glasses. This is well consistent with the Mössbauer results of a series of alkali borate[17-19,21-25] and alkali borosilicate[42,43] glasses containing small amounts of Fe_2O_3, obtained by the present authors. In these Mössbauer studies,[17-19,21-25,42,43] all the isomer shifts proved to lie in a range of 0.38—0.22 mm s^{-1} with respect to metallic iron. (The experimental error for the isomer shift has usually been estimated to be $\pm$0.01 mm s^{-1}.) Judging from the experimental results shown in the reviews[39-41] and the recent Mössbauer results on the structure of glasses performed by the present authors,[17-19,21-25,42,43] the isomer shift of the Fe^{3+} ions is concluded to be smaller than about 0.40 mm s^{-1} when they are tetrahedrally coordinated. On the other hand, octahedrally coordinated Fe^{3+} ions have been observed in several phosphate glasses,[44-46] where all the isomer shifts proved to be larger than 0.42 mm s^{-1}. Those experimental results lead to the conclusion that the criterion of the isomer shift, with respect to metallic iron, lies at about 0.40 mm s^{-1} for the tetrahedrally and octahedrally coordinated Fe^{3+} ions. The symmetries refer to "distorted" tetrahedral or octahedral configurations, for the bond lengths and the bond angles are more or less distributed in glasses. This is well reflected in the large linewidth values summarized in Table 1, where the linewidth is much larger than that of the ordinary crystalline compounds containing iron.[35,36] The large linewidth of the glasses studied in the present paper is partially due to the magnetic relaxation effect described above. The present Mössbauer results therefore suggest that most of the Fe^{3+} ions are present at the tetrahedral environments in the silver borate glasses. This indicates the presence of the tetrahedral FeO_4 units at the substitutional sites of the tetrahedral BO_4 units. It is considered that the Fe^{3+} ions are easily incorporated into the matrix of borate glasses. The substitution of the iron for the other metal or metalloid ions will easily occur in the high energy and nonequilibrium states when the glass samples are prepared by fusion.

The composition dependencies of the isomer shift and the quadrupole splitting of the Fe^{3+} ions are shown in Figs. 2 and 3, respectively. It is seen from Fig. 2 that the isomer shift shows a distinct decrease when the Ag_2O content exceeds about 16 mol%. A distinct decrease in the isomer shift of the Fe^{3+} ions has already been observed in alkali borate[21-25] and borosilicate[42,43] glasses when the alkali oxide (K_2O) content is higher than 20 and 8—10 mol%, respectively. In these glasses,[21-25,42,43] the decrease in the isomer shift of the Fe^{3+} ion, which is present at the substitutional site of the tetrahedral boron or silicon atoms, was ascribed to the formation of nonbridging oxygen atoms ($-O^-$) in the BO_4 or SiO_4 tetrahedral units, because the formation of the nonbridging oxygen atoms results in decreased interatomic distances in the B-O or Si-O bonds. This will be the case for the chemical bond length in the Fe-O bond. On the other hand, germanate glasses,[30,47] of which network structure is composed of GeO_4 and GeO_6 units, showed a drastic increase in the isomer shift of Sn^{4+} ions when nonbriding oxygen atoms are formed in the tetrahedral GeO_4 units. In the case of the ^{119}Sn-Mössbauer spectroscopy, an increase in the s-electron density at the tin nucleus results in an increase in the isomer shift. This is apparently opposite to the case of the ^{57}Fe-Mössbauer spectroscopy.[35,36] It should be noted that the formation of the nonbridging oxygen atoms in the GeO_4 tetrahedra was concluded through an increase in the isomer shift of the Sn^{4+} ions present at the interstitial sites of the network structure composed of the GeO_4 tetrahedra and the GeO_6 octahedra. These experimental results lead to the conclusion that the distinct decrease in the isomer shift shown in Fig. 2, observed when the Ag_2O content is equal to or higher than about 16 mol%, is due to the formation of nonbridging oxygen atoms in the tetrahedral BO_4 or FeO_4 units. This conclusion is consistent with the distinct and continuous decrease in the quadrupole splitting in the similar Ag_2O content region (Fig. 3). It is seen from Fig. 3 that the quadrupole splitting shows a distinct decrease when the Ag_2O content is equal to or higher than 15 mol%. As to the composition dependency of the quadrupole

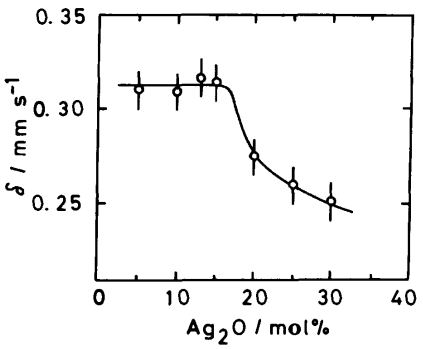

Fig. 2. Composition dependency of the isomer shift (δ) of the Fe^{3+} ions in the Ag_2O-B_2O_3 glasses containing 20 mol% AgI and 1 mol% $^{57}Fe_2O_3$.

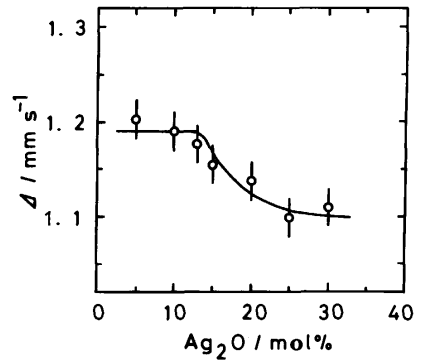

Fig. 3. Composition dependency of the quadrupole splitting (Δ) of the Fe^{3+} ions in the Ag_2O-B_2O_3 glasses containing 20 mol% AgI and 1 mol% $^{57}Fe_2O_3$.

splitting of the Fe^{3+} ions in glasses, distinct decreases have been observed when the nonbridging oxygen atoms are formed in alkali borate,[21-25] borosilicate,[42,43] and phosphate[45,46] glasses. The decrease in the quadrupole splitting of the Fe^{3+} ions is ascribed to an increased symmetry around the Fe^{3+} ions, because the Fe^{3+} ions of high spin state have a symmetric electron configuration of $3d^5$ in the outermost orbital and therefore only the electric field gradient brought about by the neighboring atoms or ions primarily affects the electric field gradient at the iron nucleus. Similar phenomenon has been observed in the case of potassium germanate glasses containing tin (Sn^{4+}), which also has a symmetric electron configuration of $4d^{10}$,[30,47] in spite that the Sn^{4+} ions are ionically present at the interstitial sites of the network structure. In the germanate glasses, the formation of nonbridging oxygen atoms was concluded to start when the alkali oxide content exceeds about 16 mol%. In the light of these reasons, the decrease in the quadrupole splitting of the Fe^{3+} ions observed in the present study is ascribed to the formation of nonbridging oxygen atoms in the tetrahedral BO_4 and FeO_4 units. (Each Fe^{3+} ion is concluded to be present at the substitutional site of the tetrahedral boron atom as described above.) These conclusions are well consistent with those obtained in the previous Mössbauer[21-25] studies of alkali borate glasses, i.e., the formation of nonbridging oxygen atoms in the BO_4 units starts when the alkali oxide content is equal to or higher than 20 mol%. The alkali oxide content of 20 mol% in the binary alkali borate glasses corresponds to about 16 mol% in the present ternary silver borate glass system containing 20 mol% AgI. (The Ag_2O/B_2O_3 ratio of 16/63 (=0.25) is consistent with the K_2O/B_2O_3 ratio of 20/80.) Effect of the Fe_2O_3 on the structure of the borate glasses can be neglected because the content is very low, i.e. 1 mol% in the present study and 0.33 mol% in the previous studies.[23,24] The same results have also been obtained in the borate glasses with the Fe_2O_3 content of 7 mol%.[21,22,25] These results suggest that the structure of the silver borate glasses is essentially the same as that of the alkali borate glasses and that the I^- ions are present at the interstitial sites of the network structure all over the compositional range studied in the present paper. This is obviously different from the case of the Cl^- and the Br^- ions which change their structural role from the interstitial anions to the nonbridging halogen atoms, depending on the composition.[17-20]

Each DTA curve of silver borate glasses containing 20 mol% AgI and 1 mol% Fe_2O_3 consists of a simple endothermic peak due to glass transition and one or two exothermic peak(s) due to crystallization. All the glass transition temperatures (T_g) obtained in the present study are shown in Fig. 4, where the T_g is plotted against the Ag_2O content of the glasses. DTA studies of several glasses have revealed that T_g shows a close relationship with a change in the coordination number of the network-forming atoms (network former) and with the formation of nonbridging oxygen or halogen atoms which means a destruction or depolymerization of the glass matrix.[17,26-34] In general. T_g shows a distinct increase when the coordination number of the network forming atoms increases. For example the change in the coordination

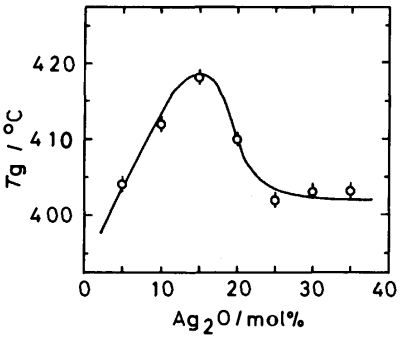

Fig. 4. Composition dependency of the glass transition temperature (T_g) of the Ag_2O-B_2O_3 glasses containing 20 mol% AgI and 1 mol% Fe_2O_3.

number of Ge from 4 to 6 in germanate glasses is observed as a continuous increase in the T_g.[27,28,30] The increase in the T_g, observed with increasing Ag_2O content of the silver borate glasses in the lower Ag_2O content region (Fig. 4), is therefore ascribed to the well-known structural change from the BO_3 triangles to the BO_4 tetrahedra in the ordinary borate glasses, i.e. an increase in the coordination number of boron from 3 to 4. Contrary to this, the formation of nonbridging oxygen atoms results in a decrease in the T_g.[27,28,30,34] These experimental results suggest that a decrease in the T_g, observed in the present silver borate glasses having the Ag_2O contents higher than 15 mol% (Fig. 4), is due to the formation of nonbridging oxygen atoms in the tetrahedral BO_4 or FeO_4 units. This is well consistent with the Mössbauer results described above.

Composition dependency of the electric conductivity is shown in Fig. 5a, from which it is seen that the conductivity of the silver borate glasses containing AgI shows a slight increase with increasing Ag_2O content when the Ag_2O content exceeds about 15 mol%. This is very contrary to the composition dependency of the silver borate glasses containing the same amount (20 mol%) of AgCl,[17] shown with a broken line (Fig. 5b). In the silver borate glasses containing 20 mol% AgCl and 1 mol% $^{57}Fe_2O_3$,[17] the drastic decrease in the conductivity was ascribed to the decreased number of the mobile Ag^+ ions present at the interstitial sites of the network structure, brought about as a result of the change in the structural role of the Cl^- ions. (Most of the Cl^- ions were concluded to change their structural role from the interstitial anions to the nonbridging chlorine atoms when the Ag_2O content exceeds about 10 mol%.[17]) Also, the decrease in the mobility of the electric conducting Ag^+ ions was concluded to be due to the increased chemical bond strength between the Ag^+ ions and the nonbridging chlorine atoms.[17] Judging from the structural information on the silver borate glasses containing 20 mol% AgI, obtained from the Mössbauer and DTA measurements in the present study, the slight increase in the conductivity observed with increasing Ag_2O content (Fig. 5a) is ascribed to the open structure of the borate glasses brought about as a result of the formation of nonbridging oxygen atoms in the tetrahedral BO_4 (or FeO_4) units. This means a destruction of the complicated network structure composed of the planar BO_3 and the tetrahedral BO_4 (and FeO_4) units linked with bridging oxygen atoms. In these glasses, the mobility of the Ag^+ ions will be enhanced because of the decreased physical and chemical interactions between the Ag^+ and the glass matrix. These results are well consistent with the general rule that the ionic conduction in solids is enhanced when the electric charge and the ionic radius of cations are small and the size of space or "tunnel," where the conducting ions actually pass through under an electric field, is large enough. This is also the case for the decrease in the electric conductivity observed in the Ag_2O content region lower than about 15 mol% (Fig. 5a), since the increase in the Ag_2O or alkali oxide contents results in a structural change from the planar BO_3 to the tetrahedral BO_4 units, as described above. This structural change will bring about a more complicated network structure of the borate glasses compared to that of the original boric (B_2O_3) glass having only the planar BO_3 units. The complicated structure will result in a decreased mobility of the electric conducting Ag^+ ions.

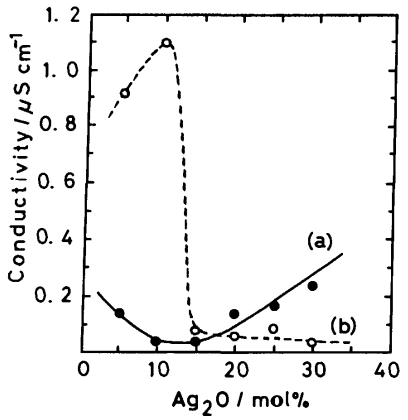

Fig. 5. Composition dependencies of the electric conductivity of the Ag_2O-B_2O_3 glasses containing (a) 20 mol% AgI and 1 mol% Fe_2O_3, and (b) 20 mol% AgCl and 1 mol% Fe_2O_3.[17]

The authors are indebted to Mr. Toshiharu Hirai of Chemical and Catalysis Industrial Corporation for his kind help in the electric conductivity measurements. Preparation and Properties of Ammonium Hexachlorozirconate(IV) and Its Reaction with Gaseous Ammonia

Masao OHASHI,* Shoji YAMANAKA, Yuhki MORIMOTO, and Makoto HATTORI
Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Higashi-Hiroshima 724
(Received January 30, 1987)

Ammonium hexachlorozirconate $(NH_4)_2ZrCl_6$ was prepared by the direct reaction of $ZrCl_4$ with NH_4Cl. The X-ray powder diffraction and the density measurements showed that it has a face-centered cubic lattice with a=10.127(2) Å and is isostructural with K_2PtCl_6. The hexachlorozirconate undergoes ammonolysis in gaseous ammonia at room temperature, forming $ZrCl_3(NH_2)\cdot xNH_3$ and NH_4Cl. The ammonolysis product reverts to the initial $(NH_4)_2ZrCl_6$ on heating to 250 °C in the ammonia atmosphere. The hexachlorozirconate vaporizes at about 450 °C. The reaction of $ZrCl_4$ with gaseous ammonia was also studied in comparison with that of the hexachlorozirconate.

Most fine powders used for production of nitride ceramics are prepared by the reactions of metal chlorides with ammonia at elevated temperatures. Therefore, it is essentially important to understand these reaction mechanisms to obtain more refined powders for the production of improved nitride ceramics. In the reaction system of $ZrCl_4$–NH_3, a layer structured compound β-ZrNCl is formed in the intermediate temperature range prior to the formation of zirconium nitride at higher temperatures.[1] In previous papers,[2,3] we showed that this layer compound forms lithium intercalates Li_xZrNCl and could be a promising candidate for electrochromic electrode material.

Usually β-ZrNCl is prepared according to the method reported by Juza and Heners:[4] the solid sample of anhydrous $ZrCl_4$ is heated stepwise to 600 °C in dry ammonia. However, this method suffers the disadvantage of low yield. Yajima et al.[1] reported that in the reaction of $ZrCl_4$ vapor with ammonia, an adduct $ZrCl_4\cdot 2NH_3$ was formed in the temperature range below 400°C. The same ammonia adduct seems to be formed during the above preparation procedure for β-ZrNCl. It is very likely that the formation of this adduct is responsible for the low yield, because the adduct vaporizes easily at above 400 °C and is transported to the cooler part without decomposing to β-ZrNCl.

In the course of the present study for a better understanding of the properties of the adduct, we have found that the true composition of the adduct is $(NH_4)_2ZrCl_6$ rather than $ZrCl_4\cdot 2NH_3$. The same compound has been prepared by the direct reaction of $ZrCl_4$ with NH_4Cl and its thermal behavior in ammonia has been investigated.

Experimental

Preparation of $(NH_4)_2ZrCl_6$. Ammonium hexachlorozirconate(IV) $(NH_4)_2ZrCl_6$ was prepared by the dry method similar to that reported by Lister and Flengas[5] for K_2ZrCl_6 in the following procedure: Zirconium tetrachloride was purified by sublimation and mixed with ammonium chloride dried at 180 °C under vacuum in the molar ratio of 1:2 in a dry box. The mixture was placed in a Pyrex boat and heated to 400 °C in a stream of dry nitrogen. After the mixture was kept at the temperature for 5 h, the resulting residue in the Pyrex boat was taken out and vacuum sealed in a Pyrex tube, which was then placed in a two-zone furnace. The temperature of the residue was regulated at 400 °C, the other end of the sealed tube being at 100 °C. After standing for 5 h, white crystals of $(NH_4)_2ZrCl_6$ were transported to the lower temperature zone. Found: Zr, 27.4; N, 8.23; Cl, 62.6%. Calcd for $(NH_4)_2ZrCl_6$: Zr, 26.8; N, 8.24; Cl, 62.6%.

Analyses. Since most of the products treated in this study are sensitive to the humidity in air, those were manipulated in a dry box unless otherwise noted. X-Ray powder diffraction (XRD) patterns were measured under a dry argon atmosphere by using a cylindrical cover having thin polyethylene windows; nickel filtered Cu $K\alpha$ radiation was used.

Elemental analyses for zirconium, chlorine and nitrogen were carried out after the sample was dissolved in 2 mol dm^{-3} sulfuric acid. The nitrogen content was determined by Kjeldahl method; zirconium and chlorine were determined gravimetrically as ZrO_2 and AgCl, respectively. The density of $(NH_4)_2ZrCl_6$ was measured pycnometrically with toluene at 25 °C.

Thermogravimetric Study in Ammonia. The amount of ammonia taken up by $(NH_4)_2ZrCl_6$ was measured gravimetrically by using a quartz spring balance as a function of pressure of ammonia at 25 °C. The sample was heated in an ammonia stream (flow rate of 50 ml min^{-1}) to 650 °C for a heating rate of 3 °C min^{-1}. For comparison similar experiment was performed on $ZrCl_4$.

Results

X-Ray Diffraction Study. The XRD data of $(NH_4)_2ZrCl_6$ is shown in Table 1. The XRD pattern is very similar to that of K_2ZrCl_6 reported by Lister and Flengas[5] and all the diffraction peaks can be indexed on the basis of a cubic lattice with a=10.127(2) Å. Moreover, the lattice type of $(NH_4)_2ZrCl_6$ is face-centered cubic because the diffraction peaks are only present when h,k,l are all even or all odd. Engel[6] showed that a series of hexachloro complexes with the

general formula A_2MCl_6 (A=K, NH_4, Rb, Cs, Tl; M=Ti, Se, Zr, Sn, Te, Pt, Pb) has the K_2PtCl_6 structure and that for the complexes with an A ion in common, the lattice constants can be related with those of the corresponding Rb- salts by a linear relation as shown in Fig. 1. Although $(NH_4)_2ZrCl_6$ is not included in his plot, the value obtained above fits well on the line for the ammonium series. This fact indicates that $(NH_4)_2ZrCl_6$ has the K_2PtCl_6 structure. The density determined for the $(NH_4)_2ZrCl_6$ prepared by the direct method in this study is 2.14 g cm^{-3}, which is in good agreement with the value of 2.17 g cm^{-3} calculated on the basis of the K_2PtCl_6 structure with a=10.127 Å.

Ammonium hexachlorozirconate can be also prepared by the wet method from hot aqueous solutions of zirconium dichloride oxide and ammonium chloride.[7,8] If the solution is saturated with hydrogen chloride and gradually cooled, the crystals of $(NH_4)_2ZrCl_6$ precipitate. It is found that the crystals thus prepared exhibit the XRD pattern identical to that of the crystals obtained by the direct method. Toptygina and Barskaya[7] prepared $(NH_4)_2ZrCl_6$ by the wet method and reported its XRD data, which however, do not coincide with ours. Since their chemical analysis data are in agreement with ours for $(NH_4)_2ZrCl_6$, they probably used the sample hydrolyzed in air for the measurement of the XRD pattern. Yajima et al.[1] investigated the reaction of gaseous $ZrCl_4$ with ammonia at elevated temperatures, and reported that in the temperature range 300—400 °C, white crystals with composition $ZrCl_4 \cdot 2NH_3$ were formed. Strangely, the XRD pattern reported by them for the crystal is identical to that of $(NH_4)_2ZrCl_6$. Although the detailed procedures are not reported, it is likely that Yajima et al. analyzed the as-deposited sample without purification: the sample was probably a mixture of $(NH_4)_2ZrCl_6$ and noncrystalline zirconium amide trichloride $ZrCl_3(NH_2) \cdot xNH_3$ and the overall ratio of Zr:N:Cl of the mixture is 1:2:4. The formation of the zirconium amide trichloride will be discussed later in more details.

Table 1. X-Ray Diffraction Data of $(NH_4)_2ZrCl_6$

Uptake of Ammonia by $(NH_4)_2ZrCl_6$. Figure 2 shows the amounts of ammonia taken up by $(NH_4)_2ZrCl_6$ at 25 °C as a function of increasing-decreasing pressure of ammonia. The amount was recorded after standing for 2 d at each pressure although the rate of uptake or release of ammonia is so slow that it takes more than 2 d to attain complete equilibrium. As seen in the figure, the amount of uptake gradually increases with the pressure and approaches 9 mol per mole of $(NH_4)_2ZrCl_6$ at the pressure of about 1 atm. On reducing the pressure to 1.4×10^3 Pa, only 2 mol of ammonia are removed. By prolonged evacuation at the pressure of 10^{-1} Pa for 4 d, additional 5 mol of ammonia are removed, but 2 mol of ammonia are tenaciously retained.

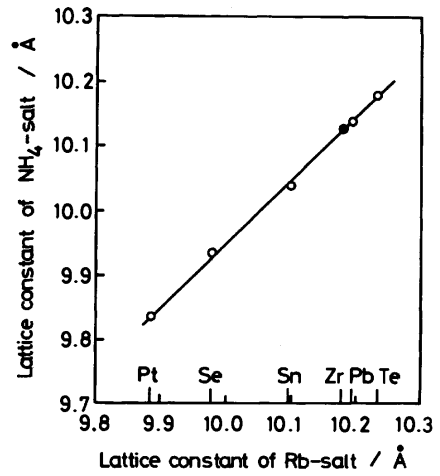

Fig. 1. Linear relationship between the lattice constants of NH_4-salts and those of Rb-salts. (●): This work, (○): results done by Engel.[6]

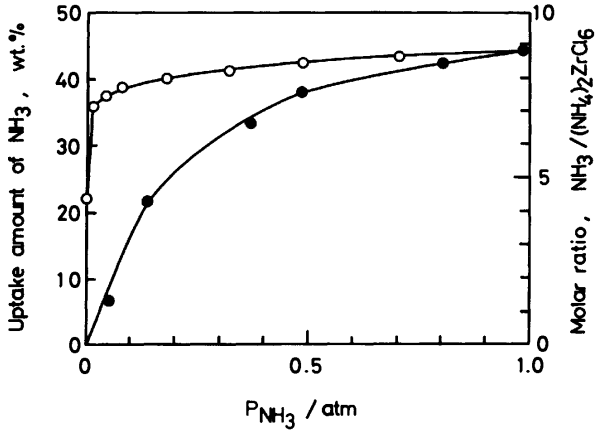

Fig. 2. Amount of ammonia taken up by $(NH_4)_2ZrCl_6$ at 25 °C as a function of the pressure of ammonia. (●), increasing pressure; (○), decreasing pressure.

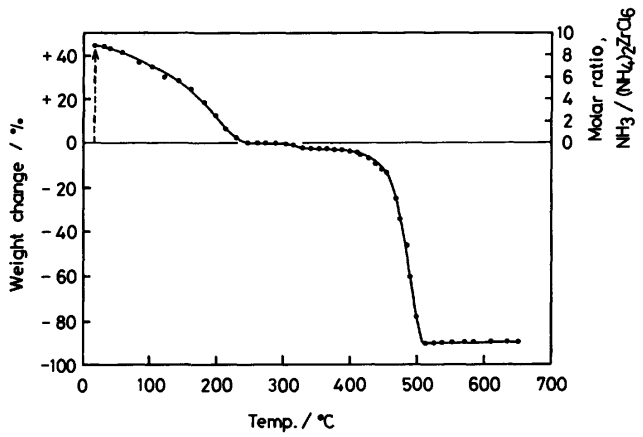

Fig. 3. Thermogravimetric curve for $(NH_4)_2ZrCl_6$ in an ammonia stream.

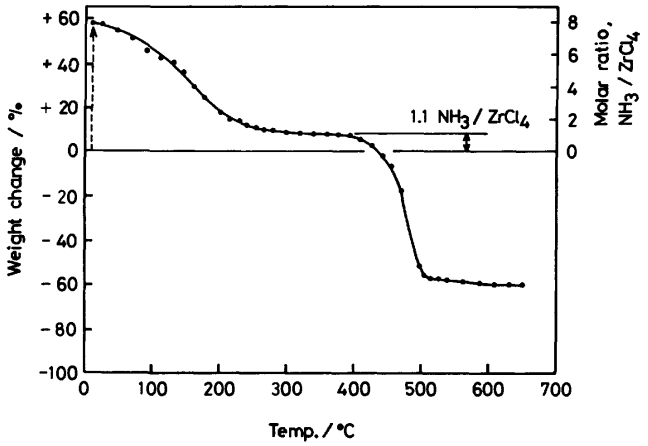

Fig. 4. Thermogravimetric curve for $ZrCl_4$ in an ammonia stream.

Separate samples of $(NH_4)_2ZrCl_6$ were also treated similarly and taken out to see the crystalline phases present at the different stages of uptake of ammonia. The XRD pattern of the sample equilibrated with 1 atm of ammonia exhibited the intense diffraction peaks due to NH_4Cl with the disappearance of the peaks due to $(NH_4)_2ZrCl_6$. The sample evacuated after the uptake of ammonia still exhibited only the peaks due to NH_4Cl.

The thermogravimetric analysis of $(NH_4)_2ZrCl_6$ was carried out in a stream of ammonia after about 9 mol of ammonia were taken up. As shown in Fig. 3, the ammonia is gradually removed with an increase in the temperature, and at 250 °C the sample reverts to the initial state in weight. The XRD pattern of the sample measured at this state indicated that the diffraction peaks of NH_4Cl extremely decreased in the intensity and, on the contrary, those of $(NH_4)_2ZrCl_6$ were almost completely recovered. The sample vaporized at about 450 °C and only 15% of the initial weight was left in the thermogravimetric analysis cell. The residue was found to be a mixture of α- and β-ZrNCl.

For comparison similar analysis was performed on $ZrCl_4$ in a stream of ammonia. During standing in ammonia of the pressure of 1 atm for 8 h, one mole of $ZrCl_4$ took up ammonia as much as 8 mol. Then, the temperature of the sample was raised in the manner similar to that of the analysis of $(NH_4)_2ZrCl_6$. Figure 4 shows the thermogravimetric curve observed. The curve is very similar to that observed for $(NH_4)_2ZrCl_6$ except that the weight does not revert to the initial state; as seen from the figure, about 1 mol of ammonia is retained up to 400 °C at which the vaporization of the sample begins. On heating to 650 °C, about 60% of the initial weight was lost and the residue was β-ZrNCl.

Discussion

Drake and Fowles[8] studied the ammonolysis of $(NH_4)_2ZrCl_6$ with liquid ammonia. They showed that $(NH_4)_2ZrCl_6$ behaves essentially like $ZrCl_4$. $ZrCl_4$ is subjected to ammonolysis to only one Zr–Cl bond in liquid ammonia, giving the zirconium amide chloride:[9]

$$ZrCl_4 \xrightarrow{NH_3} ZrCl_3(NH_2)\cdot xNH_3 + NH_4Cl. \quad (1)$$

Similarly $(NH_4)_2ZrCl_6$ undergoes ammonolysis to one Zr–Cl bond

$$(NH_4)_2ZrCl_6 \xrightarrow{NH_3} (NH_4)_2[ZrCl_5(NH_2)]\cdot xNH_3 + NH_4Cl. \quad (2)$$

On washing with liquid ammonia, the complex decomposes into ammonium chloride and zirconium amide trichloride:

$$(NH_4)_2[ZrCl_5(NH_2)]\cdot xNH_3 \longrightarrow 2NH_4Cl + ZrCl_3(NH_2)\cdot xNH_3. \quad (3)$$

The tensimetric study by Fowles and Pollard,[10] and our previous study[11] on the decomposition of the zirconium amide trichloride showed that x is about 6—7 in the above equations.

The results of thermogravimetric analyses seem to suggest that $(NH_4)_2ZrCl_6$ and $ZrCl_4$ are subjected to ammonolysis with gaseous ammonia in a similar manner:

$$(NH_4)_2ZrCl_6 + 9NH_3 \longrightarrow 3NH_4Cl + ZrCl_3(NH_2)\cdot 7NH_3, \quad (4)$$

$$ZrCl_4 + 8NH_3 \longrightarrow NH_4Cl + ZrCl_3(NH_2)\cdot 6NH_3. \quad (5)$$

In the reaction with gaseous ammonia, however the resulting NH_4Cl is not washed out, but remains in the product. The XRD pattern of the product indicates the formation of NH_4Cl with the disappearance of $(NH_4)_2ZrCl_6$. The zirconium amide trichloride $ZrCl_3(NH_2)\cdot xNH_3$ is likely a noncrystalline polymeric solid as suggested by Allbutt and Fowles.[12] The XRD results tell us that on heating, the reaction of Eq. 4 is reversed, and NH_4Cl reacts with $ZrCl_3(NH_2)$ and reforms $(NH_4)_2ZrCl_6$. A very small drop in weight is observed at 330 °C in the thermogravimetric curve of Fig. 3. This drop can be attributed to the sublimation of NH_4Cl remaining unreacted in the system.

In the case of $ZrCl_4$, one mole of ammonia remains in the system above 250 °C until the vaporization of the sample begins at 400 °C. This difference in the behavior of the ammonolysis products of $(NH_4)_2ZrCl_6$ and $ZrCl_4$ can be interpreted in terms of the insufficient NH_4Cl in the latter ammonolysis product. Since only one mole of NH_4Cl is present in the product (Eq. 5), only one third of $ZrCl_3(NH_2)$ is converted into $(NH_4)_2ZrCl_6$ according to the following reaction:

$$ZrCl_3(NH_2)\cdot 6NH_3 + NH_4Cl \longrightarrow \frac{1}{3}(NH_4)_2ZrCl_6 + \frac{2}{3}ZrCl_3(NH_2) + 6\frac{2}{3}NH_3. \quad (6)$$

It is interesting to note that the abrupt decreases in weight occur at the same temperature irrespective of the kinds of starting samples. It is apparent that the temperature of 450 °C corresponds to the vaporization of $(NH_4)_2ZrCl_6$, although the decomposition of $ZrCl_3(NH_2)$ to β-ZrNCl is also accompanied around this temperature.[11]

In summary, ammonium hexachlorozirconate $(NH_4)_2ZrCl_6$ can be prepared by the direct reaction of $ZrCl_4$ with NH_4Cl. $ZrCl_4$ and $(NH_4)_2ZrCl_6$ are subjected to ammonolysis with gaseous as well as liquidous ammonia and form the amide $ZrCl_3(NH_2)\cdot nNH_3$. The amide reverts to $(NH_4)_2ZrCl_6$ in the presence of NH_4Cl at elevated temperature. In the preparation procedure of β-ZrNCl from $ZrCl_4$ and NH_3, the formation of $(NH_4)_2ZrCl_6$ as a by-product is unavoidable, which is removed from the reaction system by vaporization above 400 °C. This should be responsible for the low yield of β-ZrNCl.

The Pyrolysis of Heptathiazocine

Yoshiyuki KUDO and Shuichi HAMADA*
Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received March 5, 1987)

Heptathiazocine was pyrolyzed into ammonia, tetrasulfur tetranitride, and tetrasulfur dinitride above 383 K in an argon atmosphere; then, the latter two intermediates finally degraded into sulfur and nitrogen. According to the stoichiometric correlation among the final pyrolytic products, an overall pyrolysis can be expressed as: $S_7NH \rightleftharpoons 7/8\ S_8+1/3\ N_2+1/3\ NH_3$. The differential scanning calorimetry of heptathiazocine gave the standard enthalpy of the formation as 89.3 ± 1.1 kJ mol^{-1} by combining the enthalpy change of the pyrolysis with its molar heat capacity and known thermodynamic data of the concerned species. The standard enthalpies of the formation of this compound were also calculated as being 93 and 91 kJ mol^{-1} on the basis of Sanderson's method, assuming that hydrogen bonds were negligible in the crystal (which were comparable to that observed in this work).

Heptathiazocine (heptasulfur imide, S_7NH) is a stable compound at room temperature with a melting point of 386.7 K.[1,2] This compound is soluble in various organic solvents, of which the solubility parameter has been estimated in a previous paper.[1] Little information on the pyrolysis of this compound is available, though heptathiazocine decomposes above its melting point.[3] Becke-Goehring and Schwarz[4] have estimated its standard enthalpy of formation on the basis of pyrolysis in vacuo.

In this work, the pyrolysis of heptathiazocine was studied within the temperature range 353—513 K under an argon atmosphere in order to verify the thermal decomposition process and the thermodynamic quantities.

Experimental

Materials. The heptathiazocine was prepared by a method described by Heal and Kane,[5] followed by purification by repeated recrystallization and column chromatography.[1] Thin-layer chromatography (TLC) showed that the heptathiazocine, thus obtained, was sufficiently pure to use in this work.

Procedures. Differential thermal analysis (DTA) and thermal gravimetry (TG) on the heptathiazocine were carried out at heating rates of 3—15 K min^{-1} in an argon atmosphere with a Rigaku Denki Thermoflex (model 8002). Pyrolytic products of the heptathiazocine were identified by TLC[6] and with a Yanagimoto Seisakusho (model 80) gas chromatograph.

The stoichiometric correlation among the pyrolytic products was estimated as follows: The sample (≈300 mg) was heated at 433 K for 2 h in an argon flow (25 cm^3 min^{-1}). The ammonia produced was introduced together with argon into 4.04×10^{-2} mol dm^{-3} perchloric acid and then titrated with a 3.06×10^{-2} mol dm^{-3} sodium hydroxide solution. The quantity of nitrogen was estimated with an azotometer after the accompanying ammonia was removed by passing it through 0.5 mol dm^{-3} perchloric acid, while carbon dioxide was used as a carrier gas. Respective amounts of the residual heptathiazocine and solid pyrolytic products were determined spectrophotometrically at different wavelengths using their carbon tetrachloride solution.

The molar heat capacity of heptathiazocine and the enthalpy change of the decomposition were estimated at heating rates of 8 and 16 K min^{-1} with a Perkin-Elmer (model DSC-1B) differential scanning calorimeter. The sample was carefully weighed and sealed by the same method described in a previous paper.[7] The DSC instrument was calibrated with indium of 99.999% purity; quartz was used as a reference for the measurement of the molar heat capacity.

Results

Pyrolytic Products and Differential Thermal Analysis. The heptathiazocine (≈2 mg) sealed under the argon atmosphere was heated at the heating rate of 7.5 K min^{-1} up to the specified temperatures. The remaining solid was dissolved in carbon tetrachloride and identified by TLC (Table 1). Tetrasulfur tetranitride (S_4N_4) and tetrasulfur dinitride (S_4N_2) were observed as intermediates above 413 K under these conditions, whereas these two nitrides completely degraded into sulfur and nitrogen above 453 K. The heptathiazocine did not degrade below its melting point (386.7 K)[2] by rapid heating faster than 5 K min^{-1}. However, this compound obviously decomposed, even at 383 K, by prolonged heating for 1.5 h in an argon atmosphere.

a) Heating rate of 7.5 K min^{-1}. b) Trace amount.

Nitrogen and ammonia were detected as gaseous products above 413 K by gas chromatography. Hydrogen sulfide was not detectable under the conditions applied in this work.

Table 2 shows the molar ratios of the final pyrolytic products to the original heptathiazocine upon heating at 433 K for 2 h. However, trace amounts of the tetrasulfur tetranitride and tetrasulfur dinitride were still detectable as $n(S_4N_4)/n(S_7NH)=5\times10^{-3}$ and $n(S_4N_2)/n(S_7NH)\approx1\times10^{-4}$, respectively, even under the conditions. As shown in Table 1, these two nitrides finally decomposed into sulfur and nitrogen.[8] Thus, the corresponding amounts of sulfur and nitrogen were taken into account to the molar ratios in Table 2. The stoichiometric correlation clearly indicated that the overall pyrolysis of heptathiazocine could be expressed as[9]

$$S_7NH = 7/8\ S_8 + 1/3\ N_2 + 1/3\ NH_3. \quad (1)$$

A differential thermal analysis of the heptathiazocine showed a sharp endothermic peak due to its fusion at 387 K and a broad exothermic peak at 430 K in an argon atmosphere at a heating rate of 10 K min^{-1} (as also shown in the DSC pattern (Fig. 1)). These peak temperatures shifted from 387 to 390 K and from 423 to 440 K, respectively, upon increasing the heating rate from 3 to 15 K min^{-1}. The TG curve obtained at a heating rate of 10 K min^{-1} showed a weight loss of about 6% between 398 and 443 K (Fig. 1). This weight loss approximately corresponded to a total mass of NH groups in the heptathiazocine molecules. As is also clearly shown in the gas-chromatographic analysis, these NH groups were partly converted to ammonia and nitrides.

Table 2. Molar Ratios of Final Pyrolytic Products of Heptathiazocine at 433 K

$n(S_7NH)$	Molar ratio of pyrolytic product		
mmol	$n(S_8)/n(S_7NH)$	$n(N_2)/n(S_7NH)$	$n(NH_3)/n(S_7NH)$
1.26	0.88_0	—	0.32_3
1.25	0.88_7	—	0.32_5
1.31	0.85_5	—	0.33_8
1.18	0.89_0	0.33_6	—
1.05	0.87_7	0.33_4	—
1.18	0.84_6	0.31_8	—
Average[a]	$0.87_3\pm0.02_2$	$0.32_9\pm0.01_7$	$0.32_9\pm0.01_4$

a) The uncertainty value was defined as $\pm3.0\,\sigma/\sqrt{n}$, where σ and n are the standard deviation and the number of data respectively.

Heat Capacity of Heptathiazocine. In order to determine the heat capacity, the sample was sealed in an aluminium container under an argon atmosphere. Measurements were carried out at a heating rate of 8 K min^{-1} between 328 and 368 K. The sample, thus heated, did not show any chemical change according to TLC, even after each run for 20 min. Figure 2 shows the molar heat capacity of heptathiazocine as a function of temperature. This procedure was confirmed to be reasonably reliable by comparing the molar heat capacities of α-sulfur[10] with those observed under the same conditions (±1.4%). The molar heat capacity of heptathiazocine at 298.15 K was deduced as 0.196±0.004 kJ mol^{-1}K^{-1} from a linear relationship in the given temperature range ($C_p=0.135+2.05\times10^{-4}T$) as shown in Fig. 2.

Enthalpy Change during Pyrolysis of Heptathiazocine in Argon Atmosphere. The enthalpy change during the overall pyrolysis of heptathiazocine was measured over a temperature range from 353 to 513 K in a closed system. Figure 1 shows the DSC pattern of the heptathiazocine obtained at a heating rate of 8 K min^{-1}, in addition to the base line (dotted line) taken in this work. Table 3 indicates the results of the enthalpy changes of the fusion, ΔH_{fus}, and of the thermal decomposition, ΔH, of the heptathiazocine, in which the average values were estimated as being 18.8±0.6 and −104.9±1.1 kJ mol^{-1}, respectively.

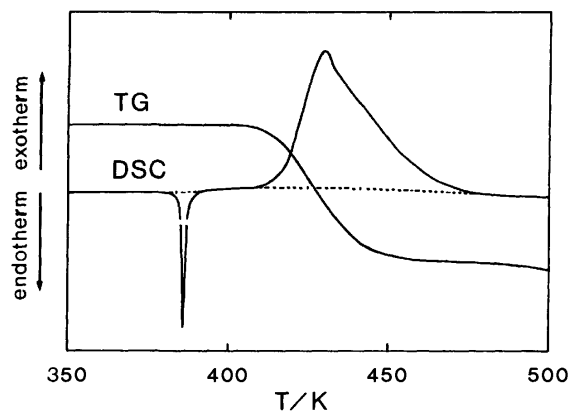

Fig. 1. DSC and TG patterns of heptathiazocine in argon atmosphere.

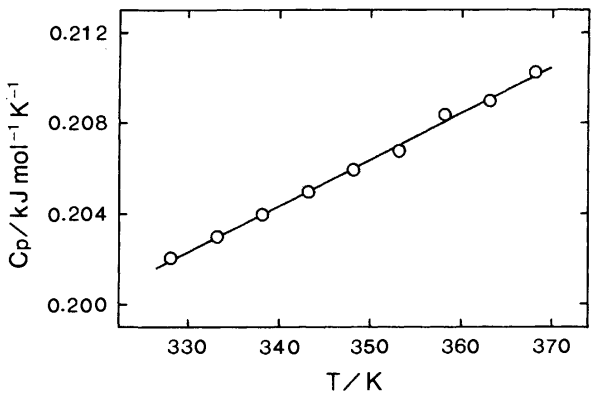

Fig. 2. Molar heat capacity of heptathiazocine observed at heating rate of 16 K min^{-1}.

Table 3. Enthalpy Changes of Fusion and Decomposition of Heptathiazocine

$n(S_7NH)$ / μmol	ΔH_{fus} / kJ mol^{-1}	$-\Delta H$ / kJ mol^{-1}
3.94	19.4	$105._0$
5.16	18.8	$104._2$
5.59	18.9	$107._2$
4.89	19.2	$105._7$
5.33	19.0	$104._7$
4.89	19.3	$104._1$
4.86	18.6	$104._7$
4.88	18.1	$103._5$
5.65	17.6	$104._8$
Average[a)]	18.8±0.6	$104._9$±$1._1$

a) The uncertainty value was shown in the same manner in Table 2.

On the basis of the stoichiometric correlation (Eq. 1), the standard enthalpy of the formation of heptathiazocine can be obtained by the following equation as:

$$\Delta H_f(S_7NH, s, 298.15\,K) = -\Delta H - \Delta H_{fus} + 2/3\,RT + 7/8(\Delta H_t(\alpha,\beta) + \Delta H_m(\beta,\lambda) + X\Delta H_p) + 1/3\,\Delta H_f(NH_3, g, 298.15\,K) - \int_{298.15}^{T} \Delta C_p dT \quad (2)$$

where $\Delta H_t(\alpha,\beta)$ and $\Delta H_m(\beta,\lambda)$ are the enthalpy changes of the transition from S_α to S_β (3.2 kJ mol^{-1})[10,11] and of the fusion of S_β (13.8 kJ mol^{-1}),[10,11] ΔH_p the enthalpy change of the polymerization from S_λ to S_μ (13.3 kJ mol^{-1}),[10,11] X the fraction of S_μ as the S_8 unit,[10,12] $\Delta H_f(NH_3, g, 298.15\,K)$ the standard enthalpy of the formation of ammonia (−45.9 kJ mol^{-1}),[11] and ΔC_p the difference in the molar heat capacities between the initial and final states, respectively. The reaction temperature, T, was taken as 429 K at the maximum of broad exothermic peak (Fig. 1). The integral term was calculated as 0.1 kJ mol^{-1} using the observed molar heat capacity of heptathiazocine. However, the peak temperature (429 K) was just below the initiation temperature (432 K)[12] of rapid polymerization of S_λ. Thus, the fraction of S_μ, X, was calculated to be 0.096 as that at 442.8 K: S_μ reaches the maximum degree of polymerization at this temperature.[12]

Accordingly, the standard enthalpy of the formation of heptathiazocine, $\Delta H_f(S_7NH,s,298.15\,K)$, was estimated to be $89._3$±$1._1$ kJ mol^{-1}, assuming that the formation of S_π was negligible.

Discussion

Pyrolytic Processes of Heptathiazocine. The heptathiazocine finally decomposed into sulfur, nitrogen, and ammonia above 383 K in the argon atmosphere through the tetrasulfur tetranitride and tetrasulfur dinitride as the intermediates. Hydrogen sulfide was undetectable as a gaseous pyrolytic product in this work, whereas Becke-Goehring[2] has reported its formation in vacuo. The thermal degradation of 1,3,5,7,2,4,6,8-tetrathiatetrazocine (tetrasulfur tetraimide, $S_4(NH)_4$), also took place step by step without the formation of hydrogen sulfide in the argon atmosphere.[6] The primary pyrolytic reaction of this compound can be expressed as[6]

$$S_4(NH)_4 = 1/6\,S_8 + 2/3\,S_4N_4 + 4/3\,NH_3. \quad (3)$$

According to these facts, the heptathiazocine may also release all the hydrogen atoms as in the form of ammonia during the first step of pyrolysis above 383 K in the argon atmosphere as

$$S_7NH = 19/24\,S_8 + 1/6\,S_4N_4 + 1/3\,NH_3. \quad (4)$$

The tetrasulfur tetraimide yielded a fairly large amount, $n(S_4N_4)/n(S_4(NH)_4)$=0.43, of the tetrasulfur tetranitride at 383 K for 1.5 h in an argon atmosphere, in addition to the tetrasulfur dinitride which was produced by a secondary degradation of tetrasulfur tetranitride in the presence of sulfur.[6] On the other hand, the heptathiazocine gave only small quantities of tetrasulfur tetranitride and tetrasulfur dinitride, $n(S_4N_4)/n(S_7NH)$=0.02 and $n(S_4N_2)/n(S_7NH)<0.01$ respectively, during pyrolysis under the same conditions.

The decomposition of tetrasulfur tetranitride can be promoted in the presence of sulfur as:[6]

$$S_4N_4 = S_4N_2 + N_2(\text{in the presence of sulfur}) \quad (5)$$

$$S_4N_2 = 1/2\,S_8 + N_2. \quad (6)$$

The decomposition degree of tetrasulfur tetranitride was examined in the presence of different amounts of sulfur using two kinds of sulfur-mixed samples. The compositions of the sample were specified as $n(S_8)/n(S_4N_4)$=0.25 and 4.0, where n refers to the initial number of moles (these molar ratios correspond approximately to those expressed in Eqs. 3 and 4 respectively). Figure 3 shows the decomposition degree, α, of the tetrasulfur tetranitride as a function of heating time at 413 K in the closed system (≈10 cm^3). The tetrasulfur tetranitride degraded slowly in the presence of a small amount of sulfur. On the other hand, the sulfur-rich sample was pyrolyzed much faster than the former sample through a pseudo first-order reaction. As clearly shown in Eq. 4, a large amount of sulfur is produced during primary pyrolysis; thus, the overall degradation of heptathiazocine would be greatly promoted. Thus, only small amounts of tetrasulfur tetranitride and tetrasulfur dinitride would be observed during the pyrolysis of heptathiazocine, in contrast to that of tetrasulfur tetraimide.

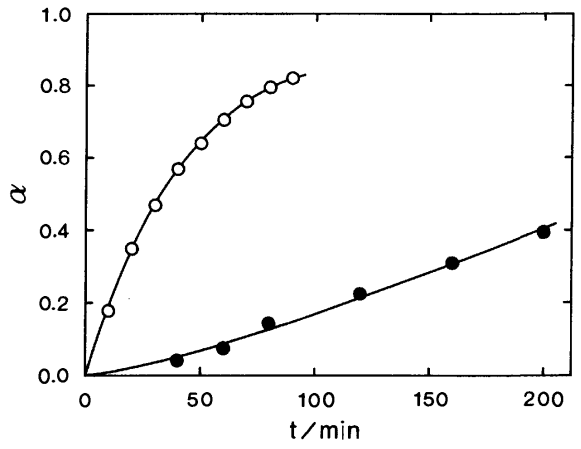

Fig. 3. Change in degradation degree of S_4N_4 in the presence of sulfur at 413 K in the closed system. Symbols: ○; $n(S_8)/n(S_4N_4)=4.0$ ●; $n(S_8)/n(S_4N_4)=0.25$.

Calculation of Standard Enthalpy of the Formation of Heptathiazocine. The heptathiazocine molecule consists of an eight-membered heterocyclic ring structure.[13] Its standard enthalpy of the formation can be deduced on the basis of the S-S, S-N, and N-H bond energies in the molecule and the standard enthalpies of the formation of atomic sulfur, nitrogen, and hydrogen, in addition to the enthalpy change of the sublimation of heptathiazocine. The standard enthalpies of the formation of these atomic species have been estimated as 277.4, 427.7, and 218.0 kJ mol^{-1},[14] respectively. The Sanderson method[15] gave the S-S, S-N, and N-H bond energies in the heptathiazocine molecule as 263, 245, and 363 kJ mol^{-1} based on their respective bond lengths.[13,16] Thus, the enthalpy of the formation of gaseous heptathiazocine, $\Delta H_f(S_7NH,g, 298.15\ K)$, was calculated to be 200 kJ mol^{-1} using the above values.

The solubility parameter, δ, and molar volume, V, of heptathiazocine have been reported to be 26.0 $J^{1/2}\,cm^{3/2}$ and 127 $cm^3\,mol^{-1}$, respectively.[1] The former term is defined as $(E_v/V)^{1/2}$, where E_v is the vaporization energy; thus, the enthalpy change of the vaporization, ΔH_v, of heptathiazocine can be estimated as 88.2 kJ mol^{-1} by

$$\Delta H_v = \delta^2 V + RT. \quad (7)$$

The enthalpy change of the fusion of this compound was obtained as 18.8±0.6 kJ mol^{-1} (Table 3). Thus, the enthalpy change of the sublimation is estimated to be 107 kJ mol^{-1}.

On the other hand, the enthalpy change of the sublimation was also deduced from the London dispersion force, calculated by means of the Slater-Kirkwood equation as described in the previous paper.[7] The interatomic distances were calculated on the basis of the coordinates of atoms in the crystal lattice[13] assuming the N-H bond length to be 108 pm.[16] The enthalpy change of the sublimation was estimated as 109.0 kJ mol^{-1} taking into account 123 interatomic distances less than 500 pm.

The standard enthalpies of the formation of heptathiazocine were estimated as 93 and 91 kJ mol^{-1} by combining the enthalpy of the formation of gaseous state (200 kJ mol^{-1}) with the enthalpy changes of the sublimation (107 and 109 kJ mol^{-1}). The value, thus calculated, were close to the experimental value determined in this work (89.3 ± 1.1 kJ mol^{-1}). Consequently, the standard enthalpy of the formation of heptathiazocine, $\Delta H_f(S_7NH,s,298.15\ K)$, obtained by the DSC measurement, is considered reasonable.

Action of Electron-Accepting Quenchers in Photoisomerization of Naphthylethylenes in Polar and Nonpolar Solvents

Takahisa Oguchi, Tatsuo Arai,* Hirochika Sakuragi, and Katsumi Tokumaru*
Department of Chemistry, University of Tsukuba, Sakura-mura, Ibaraki 305
(Received January 5, 1987)

The quantum yield of trans-cis isomerization of 3,3-dimethyl-1-(2-naphthyl)-1-butene was measured in the presence of various electron-accepting quenchers in benzene or in acetonitrile. In benzene the quantum yield was increased by addition of some of the quenchers; however, in acetonitrile it was decreased under similar conditions. This was attributed to more efficient formation of olefin triplets through an exciplex in benzene than through radical ion pairs in acetonitrile.

Recently, much attention has been paid to photoinduced electron transfer leading to characteristic reactions.[1-5] Among these reactions, isomerization of olefins by charge-transfer (CT) interaction with electron donors or acceptors were reported for stilbenes,[6-8] styrylnaphthalene,[9,10] and 1,2-dicyanoethylene.[11] Most studies on stilbenes in the presence of electron acceptors were carried out in very high concentrations of both components, and thus the reaction is usually initiated by excitation of ground state CT complexes. In these cases excitation of the CT complexes gives, by way of radical ion pairs, olefin triplets which play an important role in the isomerization. However, the reaction mechanism upon excitation of monomer olefins without exciting their ground state CT complex has scarcely been explored because of the short lifetime of the singlet excited state of most olefins. It has been reported that photochemical reactions on ground state CT excitation were often different from those on direct excitation of free molecules followed by diffusional CT quenching.[12] Since we have found that the singlet lifetime of an aromatic olefin, *trans*-3,3-dimethyl-1-(2-naphthyl)-1-butene (*trans*-DMNB), is as long as 63 ns in both polar and nonpolar solvents, we attempted to investigate the quenching effects of acceptors on behavior of the excited singlet *trans*-DMNB and also 2-styrylnaphthalene (SN) in acetonitrile and in benzene.

Experimental

Materials. *cis*- and *trans*-DMNB were obtained by the same method as described.[13] *cis*- and *trans*-SN were prepared and isolated as reported.[14] 1,2-Dicyanoethylene (FN) was purified by recrystallization in benzene followed by sublimation. Dimethyl terephthalate (TM), and *o*- (*o*-DCB), *m*- (*m*-DCB), and *p*-dicyanobenzene (*p*-DCB) were purified by recrystallization in ethanol. Benzene was distilled over calcium hydride. Acetonitrile was distilled over diphosphorus pentoxide followed by distillation over potassium carbonate.

Quantum Yield Measurements. Benzene or acetonitrile solutions of pure *trans*-DMNB (0.01 mol dm^{-3}) in the presence or absence of electron acceptors (0—0.02 mol dm^{-3}) in Pyrex tubes were degassed by bubbling argon for more than thirty minutes or by freeze-thaw cycles and were irradiated with 313-nm line of a 400 W high-pressure mercury lamp. The 313-nm mercury line was isolated by a Toshiba UV-D33S glass filter and a filter solution of potassium chromate.[15] Light intensity was determined by potassium tris(oxalato)ferrate(III) actinometry.[15] After irradiating for 1—2 h the conversion was determined by gas chromatography, a Shimadzu GC-4CM-PF gas chromatograph equipped with an FID. The experiments of *trans*-SN were carried out under similar conditions except olefin concentration (5×10^{-4} mol dm^{-3}) and an analytical procedure. The conversion was determined by both gas chromatography and by high-pressure liquid chromatography, a Shimadzu LC-6A and a spectro multichannel photodetector MCPD-350PC (Otsuka electronics).

Photostationary State Isomer Ratios. Photostationary state isomer ratios were determined in the presence of desired concentrations of a quencher and a sensitizer. The solutions were degassed using freeze-thaw cycles and irradiated with a 400W high-pressure mercury lamp. The compositions of the isomer were determined by gas chromatoraphy.

Fluorescence and Laser Photolysis Studies. Fluorescence spectra were obtained on a Hitachi MPF-2A or a Hitachi F-4000 fluorescence spectrophotometer. Fluorescence quantum yields were determined using anthracene (ϕ_f=0.27)[15] as a standard. Laser flash photolyses were performed as described elsewhere.[13] Sample solutions containing *trans*-DMNB (0.01 mol dm^{-3}) and acceptors (0.05 mol dm^{-3}) were deaerated by bubbling argon for 30 min. Fluorescence lifetimes of monomer and exciplex species were measured using a single photon counting apparatus, Applied Photophysics Model SP-3X.

Redox Potentials. Redox potentials were measured by cyclic voltammetry with a Hokuto-Denko Function Generator HB-104 and a Potentiostat/Galvanostat HA-201. Electrochemical measurements were carried out using a three-electrode cyclic voltammetric cell. The working electrode was a platinum wire. Tetraethylammonium perchlorate was used as a supporting electrolyte. The reference electrode was Ag/$AgNO_3$ (0.1 mol dm^{-3}) under an atmosphere of dried argon. The voltammograms were scanned at 100 mV s^{-1}. In some cases, the voltammograms showed no reversible peaks. In such cases, half-peak potentials were employed as half-wave redox potentials. Substrate concentrations were 5×10^{-3} mol dm^{-3}.

Results and Discussion

Fluorescence Quenching of DMNB by Various Electron Acceptors. The fluorescence quantum yield of *trans*-DMNB was determined as 0.61 in benzene and 0.60 in acetonitrile. The fluorescence lifetime of *trans*-DMNB was as long as 63 ns in both benzene and acetonitrile in contrast with those reported for other olefins, for example, 52 ps for *trans*-stilbene,[16] and the fluorescence of *trans*-DMNB was quenched efficiently by electron acceptors. In benzene, a new weak emission of exciplex appeared in longer wavelength. A typical example is shown in Fig. 1 for the case of *trans*-DMNB and *p*-dicyanobenzene. The emission maxima were in the range of 385—485 nm and the emission lifetimes were 5.2 to 27 ns as determined by single photon counting (Table 1). The exciplex lifetime in the case of a methoxycarbonyl-substituted acceptor, TM, is shorter than those in the cases of cyano-substituted acceptors, *o*-DCB, *m*-DCB, *p*-DCB, and FN.

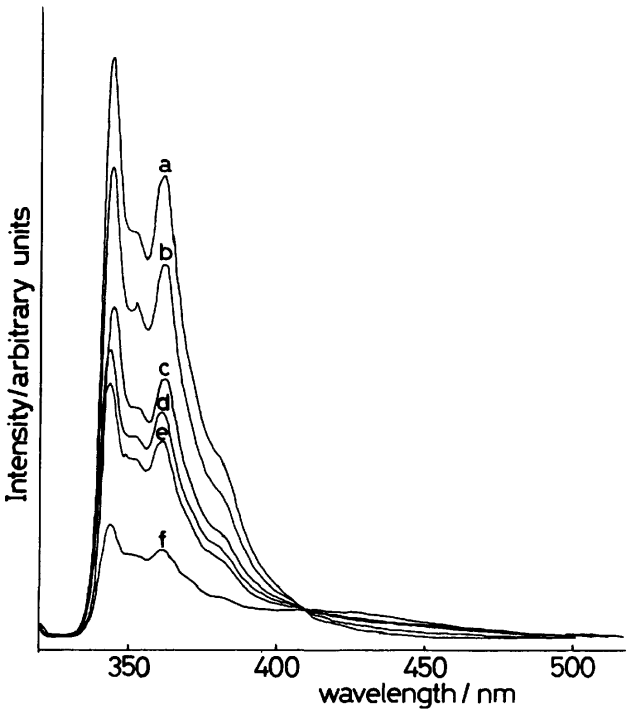

Fig. 1. Fluorescence spectra of *trans*-DMNB in the presence of different concentrations of *p*-DCB in benzene. The concentrations of *p*-DCB are a) 0, b) 4.7×10^{-3}, c) 1.4×10^{-2}, d) 1.9×10^{-2}, e) 2.4×10^{-2}, f) 8.2×10^{-2} mol dm^{-3}.

The rate constants for quenching by electron transfer in acetonitrile usually obey the well-known Weller equation (Eq. 1),[1,17] where ΔG° is the standard change of Gibbs free energy for the electron transfer from a singlet excited state to an electron acceptor calculated according to Eq. 2 and $\Delta G^{\circ *}$ denotes the Gibbs free energy of activation obtained from Eq. 3. The value $\Delta G^{\circ *}(0)$ is the Gibbs free energy of activation at $\Delta G^\circ=0$ kcal mol^{-1} (1 cal=4.184 J). The values for E_{red} and E_{ox} are the reduction potential of acceptors and the oxidation potential (1.23 V) of *trans*-DMNB, respectively, determined in acetonitrile and $E_{0,0}$ stands for the singlet excitation energy (83.6 kcal mol^{-1}) of *trans*-DMNB.

$$k_q = \frac{20\times10^9 \text{ mol}^{-1}\text{ dm}^3\text{ s}^{-1}}{1+0.25\{\exp(\Delta G^{\circ *}/RT)+\exp(\Delta G^\circ/RT)\}} \quad (1)$$

$$\Delta G^\circ = E_{ox} - E_{red} - 0.06 - E_{0,0}/\text{eV} \quad (2)$$

$$\Delta G^{\circ *} = \{(\Delta G^\circ/2)^2 + (\Delta G^{\circ *}(0))^2\}^{1/2} + \Delta G^\circ/2 \quad (3)$$

$$\Delta G^{\circ *}(0) = 2.4 \text{ kcal mol}^{-1} \quad (4)$$

Table 1 lists the observed quenching rate constants (k_q) of the fluorescence of *trans*-DMNB in both deaerated solvents, the reduction potentials (E_{red}), and ΔG° calculated by Eq. 2. Figure 2 plots the energies (E^{ex}_{max}) corresponding to the maximum wavelength of the exciplex emission (λ^{ex}_{max}) in benzene vs. ΔG°, and shows that the energies of the exciplexes over the ground state nearly linearly decrease with the decrease of ΔG°. This result shows that the larger the extent of charge transfer as revealed by the amount of ΔG°, the more stabilized the resulting exciplex.

In Fig. 3, the plot of the quenching rate constants of monomer fluorescence of *trans*-DMNB by electron acceptors in acetonitrile against ΔG° well fit the curve (curve a) calculated from Eqs. 1—4.[1,17] On the other hand, the plot of the quenching rate constants in benzene is shifted considerably from curve a, and best fit curve b, which is depicted

Table 1. Quenching Rate Constants, Exciplex Lifetimes, and Some Kinetic Values

Quencher	In acetonitrile				In benzene			
	E_{red}[a]	ΔG°[b]	$k_q\tau_0$[c]	k_q[d]/10^9	$k_q\tau_0$[c]	k_q[d]/10^9	λ^{ex}_{max}[e]	τ_{ex}[f]
m-DCB	−2.19	−6.12	535	8.49	71	1.13	385	12.6

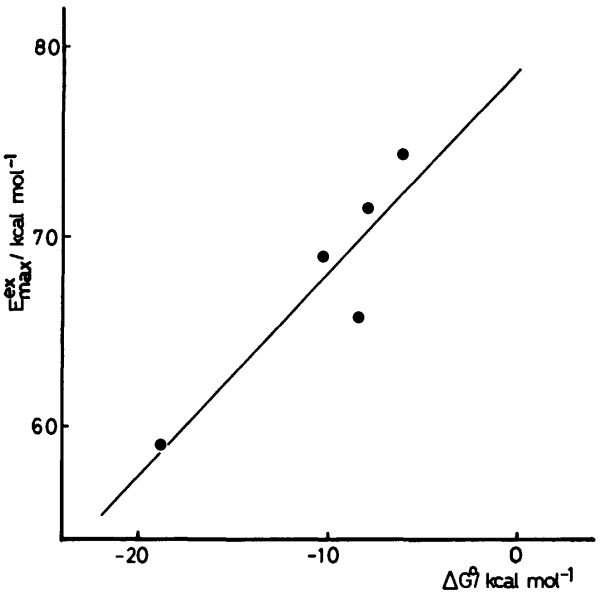

Fig. 2. The linear dependence of the exciplex emission maximum vs. the change of Gibbs free energy.

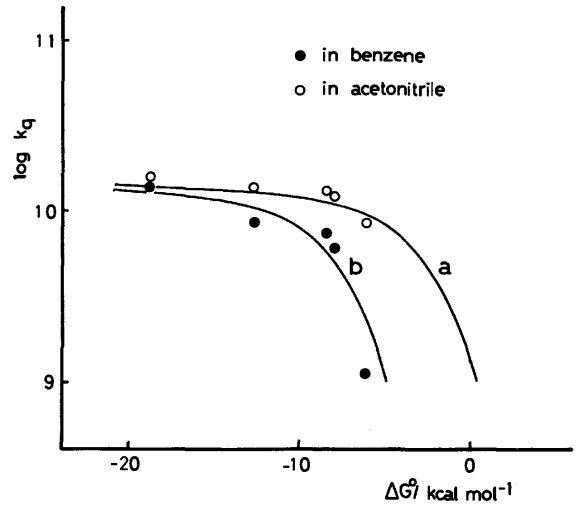

Fig. 3. The relation of the quenching rate constants vs. the change of Gibbs free energy. The curve a (in acetonitrile) is depicted according to Eqs. 1 and 2 (after Weller[17]) and the curve b (in benzene) is the best fitting one according to Eqs. 1 and 5.

by using Eq. 5 instead of Eq. 2. In Eq. 5, the value of 0.16 was chosen to give the best fitting. The energy of

$$\Delta G^\circ = E_{ox} - E_{red} + 0.16 - E_{0,0}/\text{eV} \quad (5)$$

$$E_e = E_{ox} - E_{red} + 0.15 \pm 0.10/\text{eV} \quad (6)$$

an exciplex (E_e) in nonpolar solvents can be generally expressed by Eq. 6,[1,17] which can lead to an equation similar to Eq. 5 showing the Gibbs free energy change in the electron transfer reaction in a nonpolar solvent. The above result means that the stabilization

Table 2. The Effect of Ferrocene on the Photostationary State Isomer Ratios $([t]/[c])_{pss}$ of DMNB on 2-Acetylnaphthalene Sensitization[a]

a) In the presence of 0.2 mol dm^{-3} of 2-acetylnaphthalene in benzene.

energy of the resulting radical ion pair solvated in acetonitrile is 0.22 eV larger than that in benzene. Therefore, it is safely concluded that the quenching of singlet excited state of *trans*-DMNB by electron acceptors proceeds by electron transfer.

Quantum Yields of Trans-Cis Isomerization. The quantum yields ($\phi_{t\to c}$) for the isomerization of *trans*- to *cis*-DMNB were 0.13 in benzene and 0.14 in acetonitrile, respectively, in the absence of quenchers. In benzene, $\phi_{t\to c}$ increased with increasing concentration of TM, *o*-DCB, and *p*-DCB, but slightly decreased with *m*-DCB and FN. The trans-cis isomerization was most effective through the exciplex with a quencher having moderate electron acceptability in benzene. On the other hand, in acetonitrile $\phi_{t\to c}$ was decreased on addition of any quenchers examined. These results indicate that behavior of the exciplex considerably changes with electron acceptors which control critically the efficiency of the isomerization.

Mechanism of Trans-Cis Isomerization in the Presence of Electron Acceptors. The isomerization of *trans*-DMNB on direct irradiation can occur in the singlet excited state as well as in the triplet excited state. If the isomerization proceeds on the triplet manifold, $\phi_{t\to c}$ should decrease with the increase of the concentration of an added triplet quencher such as ferrocene, because ferrocene can quench the transoid triplet state of DMNB. Actually, on benzophenone sensitization, the composition of the trans-isomer at the photostationary state of DMNB increased with the increase of ferrocene concentration (Table 2). However, $\phi_{t\to c}$ on direct excitation was not changed on addition of ferrocene. Therefore, it is clear that the isomerization of *trans*-DMNB on direct irradiation proceeds on the singlet manifold.

In view of the fact that $\phi_{t\to c}$ is much higher for triplet sensitization (0.46)[18] than $\phi_{t\to c}$ for direct irradiation, the increase of $\phi_{t\to c}$ in benzene by addition of some quenchers suggests that the triplet state of DMNB is produced in benzene possibly from the exciplex formed from the excited singlet DMNB and the acceptors. Actually, nitrogen laser excitation of *trans*-

Scheme 1.

DMNB in the presence of the quenchers, e.g. *p*-DCB, gave the transient absorption due to the DMNB triplet (λ_{max}: around 420 and 580 nm)[13] in benzene. In acetonitrile the absorption due to DMNB radical cation (λ_{max}: 430, 640, and 700 nm)[19] was observed, although that of triplet DMNB was escaped from detection by interference of the absorption due to the radical ions. However, the intermediacy of the excited triplet state of DMNB was supported by the magnetic field effect on the photoisomerization in acetonitrile.[20] Therefore, it is reasonable to propose the preceding mechanism (Scheme 1) for photoisomerization of the olefin in the presence of the electron acceptors. According to Scheme 1, the quantum yield for trans-cis isomerization is described as Eq. 7 (in benzene) or 8 (in acetonitrile).

$$\phi_{t\to c} = \frac{(1-\beta)k_d + k_q[Q]\times\dfrac{(1-\alpha)k_T^e}{k_f^e + k_T^e + k_d^e}}{k_f + k_d + k_q[Q]}$$

$$= \frac{(1-\alpha)k_T^e}{k_f^e + k_T^e + k_d^e} + \frac{(1-\beta)k_d\tau_0 - \dfrac{(1-\alpha)k_T^e}{k_f^e + k_T^e + k_d^e}}{1 + k_q\tau_0[Q]}$$

$$\left(1/\tau_0 = k_f + k_d,\ k_q = \frac{k_{en}k_{ex}}{k_{-en} + k_{ex}}\right) \quad (7)$$

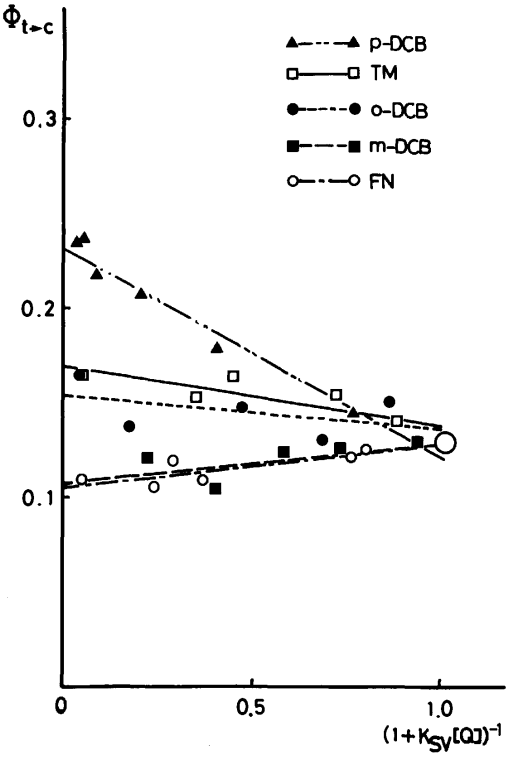

Fig. 4. Plots of the quantum yields for trans-cis isomerization vs. $(1+k_q\tau_0[Q])^{-1}$ in benzene.

Table 3. Quantum Yields for Trans-Cis Isomerization ($\phi_{t\to c}$) and Some Rate Constants

a) In $10^7\ s^{-1}$.

$$\phi_{t\to c} = \frac{(1-\beta)k_d + k_q[Q]\times\dfrac{(1-\alpha)k_T^r}{k_d^r + k_T^r}}{k_f + k_d + k_q[Q]}$$

$$= \frac{(1-\alpha)k_T^r}{k_d^r + k_T^r} + \frac{(1-\beta)k_d\tau_0 - \dfrac{(1-\alpha)k_T^r}{k_d^r + k_T^r}}{1 + k_q\tau_0[Q]}$$

$$\left(1/\tau_0 = k_f + k_d,\ k_q = \frac{k_{en}k_{rad}}{k_{-en} + k_{rad}}\right) \quad (8)$$

Dependence of Charge-Transfer Interaction and Subsequent Steps on Quencher Properties. As Figs. 4 and 5 show, the quantum yields depend linearly upon $(1+k_q\tau_0[Q])^{-1}$. By extrapolating to the infinite quencher concentration, i.e. $(1+k_q\tau_0[Q])^{-1}\to 0$, one can obtain the quantum yields of trans-cis

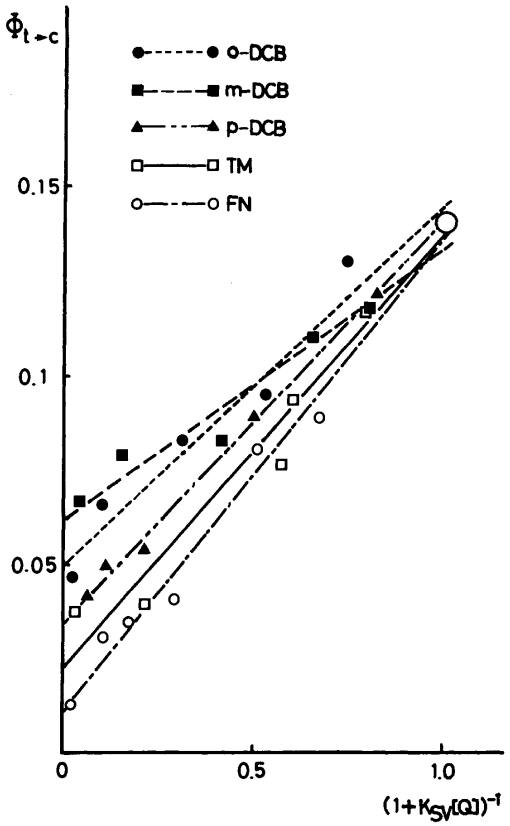

Fig. 5. Plots of the quantum yields for trans-cis isomerization vs. $(1+k_q\tau_0[Q])^{-1}$ in acetonitrile.

isomerization taking place solely through the exciplex or radical ion pairs ($\phi_{t\to c}^{\infty}$), as listed in Table 3. The $\phi_{t\to c}^{\infty}$ values are larger in benzene (0.11—0.23) than in acetonitrile (0.01—0.06). According to the Scheme 1, the quantum yield of triplet formation, ϕ_T, is expressed as $\phi_T=\phi_{t\to c}^{\infty}/(1-\alpha)$ where α, the decay fraction of the triplet DMNB producing the trans-isomer, is 0.48.[18] Accordingly, ϕ_T is obtained as 0.21—0.44 in benzene and 0.02—0.12 in acetonitrile varied with quenchers employed.

The trans-cis isomerization of 2-styrylnaphthalene (SN) was reported to be efficient in the presence of *p*-DCB in acetonitrile ($\phi_{t\to c}=0.53$) as well as in dichloromethane ($\phi_{t\to c}=0.25$).[10] The quantum yields for stilbene isomerization were also reported in the presence of FN in benzene ($\phi_{t\to c}=0.11$) and in acetonitrile ($\phi_{t\to c}=0.22$).[21] In those cases the quantum yields of the trans-cis isomerization increased with the increase of solvent polarity. This is in contrast with the present findings for DMNB. The reason for the difference in exciplex behavior is not certain. In the case of stilbene, however, because of the short lifetime of its excited singlet state, the experiments were done in very high concentrations of both stilbene and acceptors. Therefore, the excitation of a ground state CT complex cannot be ruled out at any wavelength and the isomerization mechanism must be rather complicated. For 2-styrylnaphthalene we have measured the quantum yields of the trans-cis isomerization at 313-nm irradiation and found that with the increase of *p*-DCB concentration in acetonitrile $\phi_{t\to c}$ decreased, while in benzene $\phi_{t\to c}$ increased. The $\phi_{t\to c}^{\infty}$ value was obtained from similar treatments using Eqs. 7 and 8 to be 0.18 (in benzene) and 0.04 (in acetonitrile).[22] The present results in acetonitrile are different from the previous one[10] in which irradiation was performed at 335 nm and trans-cis conversions were analyzed by a UV spectrometer. For analysis we used a gas chromatograph and a high-pressure liquid chromatograph with a multichannel photodiode detector to avoid contamination of side products. Actually, we observed in acetonitrile an unknown product which absorbs at similar wavelengths to *cis*- and *trans*-SN and this may be the reason of an overestimation of the quantum yield for its trans-cis isomerization.[10] Of course, the effect of the irradiation wavelength on the $\phi_{t\to c}^{\infty}$ value can also explain the above difference.

To examine the effects of acceptors on the decay process of exciplex, we have calculated the rate constant of the triplet DMNB production from the exciplex (k_T^e) and the sum of the rate constants for nonfluorescent and fluorescent decay $k_d^e+k_f^e$ as described below. The quantum yields of the triplet formation are expressed as $\phi_T=k_T^e\tau_{ex}$ in benzene and $\phi_T=k_T^r/(k_d^r+k_T^r)$ in acetonitrile. In the case of cyano-substituted compounds, as shown in Table 3, the k_T^e value seems constant regardless of the strength of charge-transfer interaction, $k_T^e=(1.7\pm0.3)\times10^7$ s^{-1}, while the $k_d^e+k_f^e$ value changed. To compare the efficiency of the isomerization among the isomeric cyanobenzenes for simplicity, it is to be noted that the apparent isomerization efficiency is not governed by the rate for triplet production from the exciplex (k_T^e) but by the rate for the deactivation of the exciplex ($k_d^e+k_f^e$). Among the dicyanobenzene isomers, the $k_d^e+k_f^e$ value tends to decrease as the exciplexes are more stabilized compared to the DMNB singlet excited state.

The low quantum yields in acetonitrile indicate that the ion pairs resulting from quenching of the singlet DMNB neither efficiently produce the triplet DMNB, though the radical ion pair (65—77 kcal mol^{-1}) lies sufficiently higher in energy than triplet-DMNB (52 kcal mol^{-1})[18], nor undergo isomerization in the form of the radical cation of DMNB. These results suggest that in acetonitrile the production of DMNB triplet by back electron transfer is not so efficient as in benzene. The radical ions of *cis*-β-methylstyrene and *cis*-stilbene were reported to isomerize effectively into the trans-isomer,[23,24] while the reverse process is inefficient. These facts are in accordance with our results and the assumption that $t^{+\cdot}$ should be thermodynamically more stable than $c^{+\cdot}$.

Conclusion

The quenching rate constants of the DMNB singlet state by various electron acceptors in acetonitrile and in benzene fit the curves for electron-transfer quenching mechanism. The electron-transfer process plays the key step for the trans-cis isomerization of *trans*-DMNB. However, once the exciplex is formed, the subsequent processes seem not to be linearly dependent on the reduction potentials of acceptors or the polarity of solvent. The trans-cis isomerization is more efficient in benzene than in acetonitrile, and also in benzene the exciplexes composed of the quenchers with moderate electron acceptability could efficiently produce the DMNB triplet state, the isomerization intermediate.

The Synthesis of Ar-abietatrien-12,16-oxide and Its C-15 Epimer

Takashi MATSUMOTO,* Sachihiko IMAI, Takashi YOSHINARI, and Kazuaki TSURUTA
Department of Chemistry, Faculty of Science, Hiroshima University,
Higashisenda-machi, Naka-ku, Hiroshima 730
(Received January 10, 1987)

In order to elucidate the absolute configuration of C-15 in natural ar-abietatrien-12,16-oxide, (15*R*)-12,16-epoxy-8,11,13-abietatriene (**1a**) and its (15*S*)-epimer (**1b**) have been synthesized. Treatment of (15*R*)-8,11,13-abietatriene-12,16-diol with a mixture of chloromethyl methyl ether, dicyclohexano-18-crown-6, and potassium carbonate afforded **1a** as a minor product and (15*R*)-12-methoxymethyl ether as a major product. The latter was further converted into **1a**. A similar treatment of (15*S*)-8,11,13-abietatriene-12,16-diol gave **1b**. Catalytic hydrogenations of 12,16-epoxy-8,11,13,15-abietatetraene, methyl 12,16-epoxy-8,11,13,15-abietatetraen-19-oate (**5**), and methyl 12,16-epoxy-8,11,13,15-abietatetraen-18-oate (**7**) afforded the corresponding (15*R*)-dihydrobenzofuran derivatives and their (15*S*)-epimers. Conversions of the hydrogenation products from **5** and **7** into **1a** and **1b** were also carried out. The synthetic **1a** was identical with natural ar-abietatrien-12,16-oxide.

The two new abietane-type diterpenes, ar-abietatrien-12,16-oxide and 16-hydroxyferruginol, have been isolated from the seed of *Thujopsis dolabrata* Sieb. et Zucc. var. *dolabrata* by Hasegawa and Hirose.[1] On the basis of chemical and spectroscopic studies they deduced the structures of ar-abietatrien-12,16-oxide and 16-hydroxyferruginol to be 12,16-epoxy-8,11,13-abietatriene (**1**) and 8,11,13-abietatriene-12,16-diol (**2**), respectively. However, the absolute configurations of C-15 in both natural compounds remained unsettled. On the other hand, in the course of the synthetic work of coleon C tri-*O*-methyl ether (**3**) Burnell et al.[2] carried out the conversion of 12,16-epoxy-8,11,13,15-abietatetraene (**4**)[3] into a mixture of the C-15 epimeric dihydrobenzofuran derivatives (**1a** and **1b**) by catalytic hydrogenation. Although this mixture could not be separated at this stage, they assigned the stereochemistry of C-15 in the major product to be R-configuration from an examination of molecular models; that is, the hydrogenation is selectively from the convex β-face of **4**. The same assignment[4] was also reported on the catalytic hydrogenation products of methyl 12,16-epoxy-8,11,13,15-abietatetraen-19-oate (**5**).[5] However, it seems to be necessary to confirm the stereochemistry of the catalytic hydrogenation of these benzofuran derivatives by unambiguous methods. In a previous paper,[6] we reported the total syntheses of (15*R*)-8,11,13-abietatriene-12,16-diol (**2a**) and its (15*S*)-epimer (**2b**); synthetic **2a** was shown to be identical with natural 16-hydroxyferruginol. In order to elucidate the absolute configuration of C-15 in natural ar-abietatrien-12,16-oxide we have now attempted syntheses of the C-15 epimeric 12,16-epoxy-8,11,13-abietatrienes (**1a** and **1b**). This paper describes the syntheses of **1a** and **1b** starting from methyl 12-methoxy-8,11,13-abietatrien-18-oate (**6**),[7] and the stereochemistries of the catalytic hydrogenations of three benzofuran derivatives, **4**, **5**, and methyl 12,16-epoxy-8,11,13,15-abietatetraen-18-oate (**7**).

Reduction of **6** with lithium aluminium hydride in ether, followed by tosylation of the resulting alcohol **8** with *p*-toluenesulfonyl chloride in pyridine at 80—85 °C, afforded a tosylate **9**. This was treated with sodium iodide and zinc powder in *N*,*N*-dimethylformamide at 120—125 °C to give the corresponding 4,4-dimethyl compound **10** in 84.7% yield from **6**. According to the method of Akita and Oishi[8] with slight modifications, compound **10** was converted into 13-acetyl-8,11,13-podocarpatrien-12-ol (**11**: 4.2%) and its methyl ether (**12**: 74.5%) by a treatment with acetyl chloride and anhydrous aluminium chloride in dichloromethane at room temperature for 40 min. Demethylation of **12** with anhydrous aluminium chloride in refluxing dichloromethane afforded **11** (94.6%) which gave back **12** (88.2%) by methylation with methyl iodide and potassium *t*-butoxide in refluxing *t*-butyl alcohol. The acetyl methoxy compound **12** was further converted into (15*R*)-8,11,13-abietatriene-12,16-diol (**2a**) and its (15*S*)-epimer (**2b**) as reported in our previous papers.[9,10]

The (15*R*)-diol **2a** was then refluxed with a mixture

of chloromethyl methyl ether, dicyclohexano-18-crown-6, and anhydrous potassium carbonate in tetrahydrofuran–dichloromethane (1 : 1) to give (15*R*)-12,16-epoxy-8,11,13-abietatriene (**1a**: 10.3%) and 12-methoxymethyl ether (**13a**: 61.2%) along with small amounts of 16-methoxymethyl ether (**14a**: 8.5%) and 12,16-dimethoxymethyl ether (**15a**: 4.1%). The major product **13a** was mesylated with methanesulfonyl chloride in pyridine to give a mesylate **16a** which was converted into an iodide **17a** by refluxing with sodium iodide in ethyl methyl ketone. Hydrolysis of the methoxymethyl group in **17a** was carried out by refluxing with dilute hydrochloric acid in tetrahydrofuran; the resulting phenolic compound **18a** was cyclized with anhydrous potassium carbonate in refluxing ethyl methyl ketone to give the crystalline **1a**[11] in 60.2% yield from **13a**. Synthetic **1a** was identical with natural ar-abietatrien-12,16-oxide.

Similar methoxymethylation of (15*S*)-diol **2b** afforded (15*S*)-12,16-epoxy-8,11,13-abietatriene (**1b**: 8.4%), 12-methoxymethyl ether (**13b**: 60.1%), 16-methoxymethyl ether (**14b**: 10.3%), and 12,16-dimethoxymethyl ether (**15b**: 3.6%). The major product **13b** was further converted into an oily **1b** in 56.8% yield from **13b** via a mesylate **16b**, an iodide **17b**, and a phenol **18b**.

Subsequently, methyl 12,16-epoxy-8,11,13,15-abietatetraen-18-oate (**7**) was prepared as follows. Treatment of **6** with acetyl chloride and anhydrous aluminium chloride in dichloromethane at room temperature afforded three 13-acetyl compounds; **19** (15.9%), **20** (75.9%), and **21** (4.8%). Hydrolysis of **21** with dilute hydrochloric acid in refluxing ethanol produced **19** (97.9%), which was methylated to **20** (97.8%) by refluxing with methyl iodide and potassium *t*-butoxide in *t*-butyl alcohol. Demethylation of **20** with anhydrous aluminium chloride in refluxing dichloromethane afforded **19** (95.0%). The phenolic compound **19** was refluxed with ethyl bromoacetate and anhydrous potassium carbonate in ethyl methyl ketone, and the resulting ester **22** was then hydrolyzed with aqueous sodium hydroxide in refluxing ethanol to give the corresponding acid **23**.

This was cyclized by refluxing with acetic anhydride and sodium acetate to yield **7** in 54.1% yield from **19**.

In order to ascertain the results of Burnell et al.[2,4] the catalytic hydrogenations of the three benzofuran derivatives **4**, **5**, and **7** were carried out at room temperature under an atmosphere of hydrogen. The conditions used and the results are summarized in Table 1. The ratio of the C-15 epimers was estimated by the intensities of doublet signals due to the C-15 methyls in the ^{1}H NMR spectrum[12] of the mixture. The hydrogenation mixture from **5** was separated by repeated column chromatography on silica gel and recrystallization to give the pure crystalline methyl (15*R*)-12,16-epoxy-8,11,13-abietatrien-19-oate (**24a**) and its (15*S*)-epimer (**24b**). The absolute configurations of C-15 in these epimers were determined by the following correlation. Reductions of **24a** and **24b** with lithium aluminium hydride in ether, followed by oxidation of the resulting alcohols with pyridinium chlorochromate in dichloromethane, afforded the corresponding aldehydes. These aldehydes, **25a** and **25b**, were converted, respectively, into the known **1a** and **1b** by Huang-Minlon reductions. The hydrogenation mixture from **7** was also separated to the pure methyl (15*R*)-12,16-epoxy-8,11,13-abietatrien-18-oate (**26a**) and its (15*S*)-epimer (**26b**), which were, respectively, converted into **1a** and **1b** by a series of reactions; reduction with lithium aluminium hydride in ether, tosylation with *p*-toluenesulfonyl chloride in pyridine, and treatment with sodium iodide and zinc powder in *N,N*-dimethylformamide. In the catalytic hydrogenations of **4** and **5** the major products were apparently the (15*S*)-epimers (**1b** and **24b**), but not the (15*R*)-epimers (**1a** and **24a**) as reported by Burnell et al.[2,4] The stereoselectivity can be explained as follows. Since the β-faces in these compounds are hindered by axial substituents at C-4 and C-10, hydrogen attacks predominantly the less hindered α-faces to give the (15*S*)-epimers as the major products. The less stereoselectivity of **7** is due to the presence of a bulky methoxycarbonyl group in the α-face; that is, the α-face approach of hydrogen is somewhat hindered by a methoxycarbonyl group. The hydrogenations over less active Pd-C catalyst were more stereoselective than those over more active PtO_2 catalyst.

From the present study, the stereochemistry of C-15 in natural ar-abietatrien-12,16-oxide was conclusively assigned as R-configuration.

Experimental

All melting points are uncorrected. The IR spectra and optical rotations were measured in chloroform, and the ^{1}H NMR spectra in carbon tetrachloride at 90 MHz with tetramethylsilane as an internal standard unless otherwise stated; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, t: triplet, m: multiplet. The column chromatography was performed using Merck silica gel (0.063 mm).

12-Methoxy-8,11,13-abietatriene (10). A solution of methyl 12-methoxy-8,11,13-abietatrien-18-oate (**6**)[7] (50.760 g) in dry ether (130 ml) was added dropwise to a stirred suspension of lithium aluminium hydride (3.635 g) in dry ether (180 ml) over a period of 20 min with cooling in an ice-water bath. The mixture was refluxed for 1 h. After the excess of lithium aluminium hydride had been decomposed with ethyl acetate, the mixture was poured into a mixture of ice and dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated in vacuo to give 12-methoxy-8,11,13-abietatrien-18-ol (**8**) (47.547 g) which, without purification, was used in the next reaction.

A mixture of the crude **8** (47.547 g) and *p*-toluenesulfonyl chloride (33.710 g) in pyridine (200 ml) was heated at 80—85 °C for 3.5 h. The mixture was cooled, poured into a mixture of ice and dilute hydrochloric acid, and extracted with chloroform. The chloroform extract was washed with brine, dried over sodium sulfate, and evaporated in vacuo to give 12-methoxy-18-tosyloxy-8,11,13-abietatriene (**9**) (66.066 g) as a solid which, without purification, was used in the next reaction. The crude **9** obtained from another experiment was recrystallized from acetone-petroleum benzine, mp 147—149 °C. Found: C, 71.18; H, 7.97%. Calcd for $C_{28}H_{38}O_4S$: C, 71.45; H, 8.14%.

A stirred mixture of the crude **9** (66.066 g), sodium iodide (110.441 g), and zinc powder (48.170 g) in *N,N*-dimethylformamide (400 ml) was heated at 120—125 °C for 6 h. The mixture was cooled, diluted with benzene, and then filtered. The filtrate was poured into dilute hydrochloric acid and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried over sodium sulfate, and evaporated in vacuo. The crude product was chromatographed on silica gel (350 g), using hexane-benzene (9:1) as eluent, to give **10** as an oil (37.481 g: 84.7% from **6**). ^{1}H NMR (60 MHz) δ=0.97 (6H, s, $-C(CH_3)_2$), 1.17 (6H, d, J=7 Hz, $-CH(CH_3)_2$), 1.18 (3H, s, $C_{10}-CH_3$), 3.75 (3H, s, $-OCH_3$), 6.58 (1H, s) and 6.69 (1H, s) (C_{11}-H and C_{14}-H). Found: C, 83.88; H, 10.84%. Calcd for $C_{21}H_{32}O$: C, 83.94; H, 10.73%.

13-Acetyl-8,11,13-abietatrien-12-ol (11) and 13-Acetyl-12-methoxy-8,11,13-abietatriene (12). Anhydrous aluminium chloride (10.982 g) was added to a stirred solution of **10** (12.373 g) and acetyl chloride (5.9 ml) in dichloromethane (80 ml) at 5—10 °C over a 10-min period. The mixture was further stirred at 5 °C for 10 min and at room temperature for 40 min, poured into a mixture of ice and dilute hydrochloric acid, and then extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried, and evaporated in vacuo. The crude product was chromatographed on silica gel (250 g), using hexane-benzene (6:4) and ether-benzene (3:97) as eluents, to give **11** (0.500 g: 4.2%), mp 129—131 °C (from methanol), IR 1640 cm^{-1}, ^{1}H NMR (60 MHz) δ=2.52 (3H, s, $-COCH_3$), 6.73 (1H, s, C_{11}-H), 7.27 (1H, s, C_{14}-H), and **12** (9.222 g: 74.5%), mp 79—81 °C (from hexane), IR 1670 cm^{-1}, ^{1}H NMR (60 MHz) δ=2.48 (3H, s, $-COCH_3$), 3.86 (3H, s, $-OCH_3$), 6.72 (1H, s, C_{11}-H), 7.31 (1H, s, C_{14}-H). Anal. of **11**, Found: C, 79.51; H, 9.18%. Calcd for $C_{19}H_{26}O_2$: C, 79.68; H, 9.15%. Anal. of **12**, Found: C, 79.83; H, 9.53%.

Calcd for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39%.

Demethylation of 12. A stirred mixture of **12** (2.240 g) and anhydrous aluminium chloride (1.988 g) in dichloromethane (25 ml) was refluxed for 2 h. The mixture was cooled, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed with brine, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (30 g), using benzene as eluent, to give **11** (2.019 g: 94.6%), mp 129—131 °C (from methanol).

Methylation of 11. A mixture of **11** (321 mg) and potassium *t*-butoxide (151 mg) in *t*-butyl alcohol (4.0 ml) was stirred at room temperature for 10 min. After the addition of methyl iodide (0.14 ml), the mixture was stirred at room temperature for 20 min and then refluxed for 2 h. The mixture was evaporated in vacuo, acidified with dilute hydrochloric acid, and extracted with ether. The ether extract was washed successively with water, aqueous sodium thiosulfate, and water. The dried solution was evaporated in vacuo. The residue was chromatographed on silica gel (10 g), using benzene as eluent, to give **12** (297 mg: 88.2%), mp 79—81 °C (from hexane).

Methoxymethylation of (15*R*)-8,11,13-Abietatriene-12,16-diol (2a). A mixture of **2a** (314.0 mg), dicyclohexano-18-crown-6 (54.9 mg), and anhydrous potassium carbonate (287.0 mg) in tetrahydrofuran–dichloromethane (1:1, 10 ml) was stirred at room temperature for 30 min. After the addition of chloromethyl methyl ether (0.16 ml), the mixture was refluxed for 3 h, cooled, and then diluted with ether. The ether solution was washed with brine, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (30 g), using hexane–benzene (8:2) as eluent, to give (15*R*)-12,16-epoxy-8,11,13-abietatriene (**1a**) (30.4 mg: 10.3%), mp 54—56 °C (from ether), $[\alpha]_D$ +57.3° (*c* 0.89). Elution with ether–benzene (1:99) gave 12,16-dimethoxymethyl ether **15a** as an oil (16.5 mg: 4.1%) and 16-methoxymethyl ether **14a** as an oil (30.5 mg: 8.5%), IR 3600 and 3330 cm^{-1}. ^1H NMR ($CDCl_3$) of **15a** δ=0.91 (3H, s) and 0.93 (3H, s) (-C(CH$_3$)$_2$), 1.17 (3H, s, C_{10}-CH_3), 1.27 (3H, d, J=7 Hz, C_{15}-CH_3), 3.30 (3H, s, C_{16}-OCH_2OCH_3), 3.47 (3H, s, C_{12}-OCH_2OCH_3), 4.60 (2H, s, C_{16}-OCH_2O-), 5.13 (2H, s, C_{12}-OCH_2O-), 6.84 (1H, s) and 6.94 (1H, s) (C_{11}-H and C_{14}-H). ^1H NMR ($CDCl_3$) of **14a** δ=0.91 (3H, s) and 0.93 (3H, s) (-C(CH$_3$)$_2$), 1.17 (3H, s, C_{10}-CH_3), 1.31 (3H, d, J=7 Hz, C_{15}-CH_3), 3.30 (3H, s, C_{16}-OCH_2OCH_3), 4.63 (2H, s, C_{16}-OCH_2O-), 6.75 (1H, s) and 6.78 (1H, s) (C_{11}-H and C_{14}-H), 7.11 (1H, s, C_{12}-OH). Further elution with ether–benzene (1:9) gave 12-methoxymethyl ether **13a** (220 mg: 61.2%), $[\alpha]_D$ +66.6° (*c* 5.44), ^1H NMR ($CDCl_3$) δ=0.91 (3H, s) and 0.93 (3H, s) (-C(CH$_3$)$_2$), 1.17 (3H, s, C_{10}-CH_3), 1.23 (3H, d, J=7 Hz, C_{15}-CH_3), 3.47 (3H, s, C_{12}-OCH_2OCH_3), 3.69 (2H, bd, J=7 Hz, -CH_2OH), 5.14 (2H, s, C_{12}-OCH_2O-), 6.84 (1H, s) and 6.97 (1H, s) (C_{11}-H and C_{14}-H). Found: C, 76.18; H, 10.03%. Calcd for $C_{22}H_{34}O_3$: C, 76.26; H, 9.89%.

Methoxymethylation of (15*S*)-8,11,13-Abietatriene-12,16-diol (2b). A mixture of **2b** (283.0 mg), dicyclohexano-18-crown-6 (49.5 mg), anhydrous potassium carbonate (258.6 mg), and chloromethyl methyl ether (0.14 ml) in tetrahydrofuran–dichloromethane (1:1, 10.0 ml) was treated as described above. The crude product was chromatographed on silica gel to give four oily products, (15*S*)-12,16-epoxy-8,11,13-abietatriene (**1b**) (22.4 mg: 8.4%),$[\alpha]_D$ +60.7° (*c* 1.12), 12,16-dimethoxymethyl ether **15b** (13.2 mg: 3.6%), 16-methoxymethyl ether **14b** (33.4 mg: 10.3%), IR 3600 and 3330 cm^{-1}, and 12-methoxymethyl ether **13b** (194.7 mg: 60.1%), $[\alpha]_D$ +46.5°(*c* 4.59). Found: C, 76.42; H, 10.07%. Calcd for $C_{22}H_{34}O_3$: C, 76.26; H, 9.89%. ^1H NMR ($CDCl_3$) of **15b** δ=0.91 (3H, s) and 0.93 (3H, s) (-C(CH$_3$)$_2$), 1.17 (3H, s, C_{10}-CH_3), 1.24 (3H, d, J=7 Hz, C_{15}-CH_3), 3.30 (3H, s, C_{16}-OCH_2OCH_3), 3.47 (3H, s, C_{12}-OCH_2OCH_3), 4.60 (2H, s, C_{16}-OCH_2O-), 5.13 (2H, s, C_{12}-OCH_2O-), 6.84 (1H, s) and 6.94 (1H, s) (C_{11}-H and C_{14}-H). ^1H NMR ($CDCl_3$) of **14b** δ=0.92 (6H, s, -C(CH$_3$)$_2$), 1.17 (3H, s, C_{10}-CH_3), 1.31 (3H, d, J=7 Hz, C_{15}-CH_3), 3.30 (3H, s, C_{16}-OCH_2OCH_3), 4.63 (2H, s, C_{16}-OCH_2O-), 6.77 (1H, s) and 6.79 (1H, s) (C_{11}-H and C_{14}-H), 7.09 (1H, s, C_{12}-OH). ^1H NMR ($CDCl_3$) of **13b** δ=0.92 (6H, s, -C(CH$_3$)$_2$), 1.17 (3H, s, C_{10}-CH_3), 1.22 (3H, d, J=7 Hz, C_{15}-CH_3), 3.47 (3H, s, C_{12}-OCH_2OCH_3), 3.70 (2H, bd, J=7 Hz, -CH_2OH), 5.14 (2H, s, C_{12}-OCH_2O-), 6.84 (1H, s) and 6.97 (1H, s) (C_{11}-H and C_{14}-H).

Conversion of 13a into 1a. A mixture of **13a** (196 mg) and methanesulfonyl chloride (0.09 ml) in pyridine (1.5 ml) was heated at 75—80 °C for 2.5 h. The mixture was cooled, diluted with ether, and washed successively with dilute hydrochloric acid and brine. The dried solution was evaporated in vacuo to give a crude mesylate **16a** as an oil (225 mg), IR 1350 and 1170 cm^{-1}, ^1H NMR (60 MHz, $CDCl_3$) δ=0.96 (6H, s, -C(CH$_3$)$_2$), 1.18 (3H, s, C_{10}-CH_3), 1.35 (3H, d, J=7 Hz, C_{15}-CH_3), 2.84 (3H, s, -OSO_2CH_3), 3.49 (3H, s, -OCH_2OCH_3), 5.18 (2H, s, -OCH_2O-), 6.84 (1H. s) and 6.99 (1H, s) (C_{11}-H and C_{14}-H).

A mixture of the crude **16a** (225 mg) and sodium iodide (170 mg) in ethyl methyl ketone (5.0 ml) was refluxed for 4 h. The mixture was cooled, diluted with ether, and then washed successively with water, aqueous sodium thiosulfate, and brine. The dried solution was evaporated in vacuo to give a crude iodide **17a** (240 mg). ^1H NMR (60 MHz, $CDCl_3$) δ=0.95 (6H, s, -C(CH$_3$)$_2$), 1.18 (3H, s, C_{10}-CH_3), 3.48 (3H, s, -OCH_2OCH_3), 5.13 (2H, s, -OCH_2O-) 6.84 (1H, s) and 6.99 (1H, s) (C_{11}-H and C_{14}-H).

A mixture of the crude **17a** (240 mg) and dilute hydrochloric acid (15%: 0.2 ml) in tetrahydrofuran (5.0 ml) was refluxed for 3 h. The mixture was cooled, diluted with ether, and washed with brine. The dried solution was evaporated in vacuo to give a crude phenolic compound **18a** (234 mg), IR 3595 and 3325 cm^{-1}. ^1H NMR (60 MHz, $CDCl_3$) δ=0.96 (6H, s, -C(CH$_3$)$_2$), 1.17 (3H, s, C_{10}-CH_3), 1.39 (3H, d, J=6.5 Hz, C_{15}-CH_3), 6.61 (1H, s) and 6.79 (1H, s) (C_{11}-H and C_{14}-H).

A mixture of the crude **18a** (234 mg) and anhydrous potassium carbonate (600 mg) in ethyl methyl ketone (5.0 ml) was refluxed for 2.5 h. The mixture was cooled, diluted with water, and extracted with ether. The ether extract was washed with brine, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (20 g), using hexane–benzene (3:1) as eluent, to give **1a** (97 mg: 60.2% from **13a**) which was recrystallized from ether, mp 54—56 °C, $[\alpha]_D$ +59.8° (*c* 3.33), IR (KBr) 1620, 1485, 1240, and 995 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.91 (3H, s) and 0.93 (3H, s) (-C(CH$_3$)$_2$), 1.17 (3H, s, C_{10}-CH_3), 1.27 (3H, d, J=7 Hz, C_{15}-CH_3), 3.44 (1H, m, C_{15}-H), 3.98 (1H, dd, J=7

and 8 Hz) and 4.61 (1H, t, J=8 Hz) ($-CH_2O-$), 6.70 (1H, s) and 6.80 (1H, s) (C_{11}-H and C_{14}-H). Found: C, 84.64; H, 10.21%. Calcd for $C_{20}H_{28}O$: C, 84.45; H, 9.92%. The synthetic **1a** was identical with natural ar-abietatrien-12,16-oxide (lit,[1] mp 49—52 °C).

Conversion of 13b into 1b. A mixture of **13b** (195 mg) and methanesulfonyl chloride (0.09 ml) in pyridine (1.5 ml) was heated at 75—80 °C for 2.5 h to give a crude mesylate **16b** (230 mg), IR 1350 and 1170 cm^{-1}, ^{1}H NMR (60 MHz, $CDCl_3$) δ=0.97 (6H, s, $-C(CH_3)_2$), 1.19 (3H, s, C_{10}-CH_3), 1.35 (3H, d, J=7 Hz, C_{15}-CH_3), 2.84 (3H, s, $-OSO_2CH_3$), 3.50 (3H, s, $-OCH_2OCH_3$), 5.19 (2H, s, $-OCH_2O-$) 6.86 (1H, s) and 7.00 (1H, s) (C_{11}-H and C_{14}-H).

A mixture of the crude **16b** (230 mg) and sodium iodide (169 mg) in ethyl methyl ketone (5.0 ml) was refluxed for 4 h to give a crude iodide **17b** (240 mg), ^{1}H NMR (60 MHz, $CDCl_3$) δ=0.97 (6H, s, $-C(CH_3)_2$), 1.19 (3H, s, C_{10}-CH_3), 3.50 (3H, s, $-OCH_2OCH_3$), 5.18 (2H, s, $-OCH_2O-$), 6.81 (1H, s) and 6.98 (1H, s) (C_{11}-H and C_{14}-H).

The crude **17b** (240 mg) was hydrolyzed with dilute hydrochloric acid (15%: 0.2 ml) in refluxing tetrahydrofuran (5.0 ml) for 3 h to give a crude phenolic compound **18b** (227 mg), IR 3600 and 3325 cm^{-1}, ^{1}H NMR (60 MHz, $CDCl_3$) δ=0.95 (6H, s, $-C(CH_3)_2$), 1.15 (3H, s, C_{10}-CH_3), 1.37 (3H, d, J=6.5 Hz, C_{15}-CH_3), 6.61 (1H, s) and 6.80 (1H, s) (C_{11}-H and C_{14}-H).

A mixture of the crude **18b** (227 mg) and anhydrous potassium carbonate (600 mg) in ethyl methyl ketone (5.0 ml) was refluxed for 2.5 h. The crude product was chromatographed on silica gel (30 g), using hexane–benzene (3:1) as eluent, to give an oily **1b** (91 mg: 56.8% from **13b**), $[\alpha]_D$ +61.3° (c 1.88), IR (KBr) 1620, 1485, 1240, and 995 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.92 (6H, s, $-C(CH_3)_2$), 1.17 (3H, s, C_{10}-CH_3), 1.28 (3H, d, J=7 Hz, C_{15}-CH_3), 3.45 (1H, m, C_{15}-H), 3.98 (1H, dd, J=7 and 8 Hz) and 4.61 (1H, t, J=8 Hz) ($-CH_2O-$), 6.70 (1H, s) and 6.80 (1H, s) (C_{11}-H and C_{14}-H). Found: C, 84.42; H, 10.21%. Calcd for $C_{20}H_{28}O$: C, 84.45; H, 9.92%.

Conversion of Methyl 12-Methoxy-8,11,13-abietatrien-18-oate (6) into 13-Acetyl Derivatives 19, 20, and 21. Anhydrous aluminium chloride (1.463 g) was added to a stirred solution of **6**[7] (1.260 g) and acetyl chloride (0.52 ml) in dichloromethane (10 ml) at 6—9 °C over a 7 min period. After stirring at this temperature for 13 min and at room temperature for 40 min, the mixture was poured into a mixture of ice and dilute hydrochloric acid, and then extracted with ether. The ether extract was washed with brine, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (30 g), using benzene as eluent, to give methyl 13-acetyl-12-hydroxy-8,11,13-abietatrien-18-oate (**19**) (0.192 g: 15.9%) which was recrystallized from methanol, mp 154—155 °C, $[\alpha]_D$ +74.7° (c 5.25), IR 1723 and 1640 cm^{-1}. ^{1}H NMR (60 MHz) δ=1.20 (3H, s) and 1.23 (3H, s) (C_4-CH_3 and C_{10}-CH_3), 2.52 (3H, s, $-COCH_3$), 3.63 (3H, s, $-CO_2CH_3$), 6.70 (1H, s, C_{11}-H), 7.27 (1H, s, C_{14}-H), 11.77 (1H, s, C_{12}-OH). Found: C, 72.49; H, 8.24%. Calcd for $C_{20}H_{26}O_4$: C, 72.70; H, 7.93%.

Elution with ether-benzene (1:99) afforded methyl 13-acetyl-12-methoxy-8,11,13-abietatrien-18-oate (**20**) (0.956 g: 75.9%) which was recrystallized from hexane, mp 86—87 °C, $[\alpha]_D$ +62.0° (c 4.32), IR 1721 and 1670 cm^{-1}, ^{1}H NMR (60 MHz) δ=1.19 (3H, s and 1.22 (3H, s) (C_4-CH_3 and C_{10}-CH_3), 2.44 (3H, s, $-COCH_3$), 3.61 (3H, s, $-CO_2CH_3$), 3.83 (3H, s, $-OCH_3$), 6.67 (1H, s, C_{11}-H), 7.26 (1H, s, C_{14}-H).

Further elution with ether–benzene (5:95) afforded methyl 12-acetoxy-13-acetyl-8,11,13-abietatrien-18-oate (**21**) (0.066 g: 4.8%) which was recrystallized from acetone-hexane, mp 107—108 °C, $[\alpha]_D$ +71.7° (c 3.78), IR 1757, 1716, and 1680 cm^{-1}; ^{1}H NMR (60 MHz) δ=1.21 (3H, s) and 1.24 (3H, s) (C_4-CH_3 and C_{10}-CH_3), 2.23 (3H, s, $-OCOCH_3$), 2.40 (3H, s, $-COCH_3$), 3.62 (3H, s, $-CO_2CH_3$), 6.78 (1H, s, C_{11}-H), 7.34 (1H, s, C_{14}-H). Found: C, 71.07; H, 7.64%. Calcd for $C_{22}H_{28}O_5$: C, 70.94; H, 7.58%.

Hydrolysis of 21. A solution of **21** (2.587 g) and dilute hydrochloric acid (15%: 2.5 ml) in ethanol (20 ml) was refluxed for 1.5 h. After the usual work-up, the crude product was recrystallized from methanol to give **19** (2.248 g: 97.9%), mp 154—155 °C.

Methylation of 19. A mixture of **19** (5.148 g) and potassium t-butoxide (2.098 g) in t-butyl alcohol (60 ml) was stirred for 10 min. After the addition of methyl iodide (1.92 ml), the stirred mixture was refluxed for 2 h, and then treated as described above. The crude product was chromatographed on silica gel (35 g), using ether–benzene (5:95) as eluent, to give **20** (5.248 g: 97.8%), mp 86—87 °C (from hexane).

Demethylation of 20. A stirred mixture of **20** (200 mg) and anhydrous aluminium chloride (271 mg) in dichloromethane (4.0 ml) was refluxed for 3 h. After the work-up, as described above, the crude product was chromatographed on silica gel (10 g), using benzene as eluent, to give **19** (182 mg: 95.0%), mp 154—155 °C (from methanol).

Methyl 12,16-Epoxy-8,11,13,15-abietatetraen-18-oate (7). A mixture of **19** (4.00 g), ethyl bromoacetate (2.29 ml), and anhydrous potassium carbonate (10.0 g) in ethyl methyl ketone (30 ml) was refluxed for 8 h. The mixture was cooled, diluted with ether, and washed successively with water, aqueous sodium thiosulfate, and water. The dried solution was evaporated in vacuo to give a crude ester **22** (5.82 g), IR 1725 and 1665 cm^{-1}, ^{1}H NMR (60 MHz) δ=1.18 (3H, s, C_{10}-CH_3), 1.22 (3H, s, C_4-CH_3), 1.28 (3H, t, J=7 Hz, $-CO_2CH_2CH_3$), 2.55 (3H, s, $-COCH_3$), 3.61 (3H, s, $-CO_2CH_3$), 4.18 (2H, q, J=7 Hz, $-CO_2CH_2CH_3$), 4.61 (2H, s, $-OCH_2CO_2-$), 6.64 (1H, s, C_{11}-H), 7.29 (1H, s, C_{14}-H).

The crude **22** (5.82 g) was hydrolyzed with aqueous sodium hydroxide (10%: 10 ml) in refluxing ethanol (20 ml) for 1 h. The mixture was evaporated in vacuo, acidified with dilute hydrochloric acid, and extracted with chloroform. The chloroform extract was washed with brine, dried, and evaporated in vacuo to give a crude acid **23** (5.01 g), IR 3500—2400, 1720, and 1660 cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.21 (3H, s) and 1.29 (3H, s) (C_4-CH_3 and C_{10}-CH_3), 2.65 (3H, s, $-COCH_3$), 3.68 (3H, s, $-CO_2CH_3$), 4.72 (2H, s, $-OCH_2CO_2H$), 6.78 (1H, s, C_{11}-H), 7.42 (1H, s, C_{14}-H), 10.32 (1H, bs, $-CO_2H$).

A mixture of the crude **23** (5.01 g) and sodium acetate (9.0 g) in acetic anhydride (20 ml) was refluxed for 7.5 h. The mixture was cooled, diluted with ether, and washed successively with water, aqueous sodium hydrogencarbonate, and water. The dried solution was evaporated in vacuo to give the crude benzofuran derivative (1.70 g). The alkaline washing was acidified with dilute hydrochloric acid, and extracted with chloroform. The chloroform extract was washed with brine, dried, and evaporated in

vacuo to give the recovered **23** (3.00 g). This was also submitted to cyclization to give the crude benzofuran derivative (1.04 g) and the recovered **23** (1.40 g). The combined crude benzofuran derivative was chromatographed on silica gel (30 g), using benzene as eluent, to give **7** (2.14 g: 54.1%) which was recrystallized from hexane, mp 123.5—124 °C, $[\alpha]_D$ +68.6° (*c* 9.50), IR 1721 cm^{-1}, ^1H NMR (60 MHz, $CDCl_3$) δ=1.23 (3H, s) and 1.30 (3H, s) (C_4-CH_3 and C_{10}-CH_3), 2.17 (3H, d, *J*=1 Hz, C_{15}-CH_3), 3.67 (3H, s, -CO_2CH_3), 7.12 (1H, s) and 7.29 (1H, s) (C_{11}-H and C_{14}-H), 7.24 (1H, m, overlap, C_{16}-H). Found: C, 77.21; H, 8.17%. Calcd for $C_{21}H_{26}O_3$:C, 77.27; H, 8.03%.

Catalytic Hydrogenation of 12,16-Epoxy-8,11,13,15-abietatetraene Derivatives 4, 5, and 7. a) A mixture of 12,16-epoxy-8,11,13,15-abietatetraene (**4**)[3] (303 mg) and 10% Pd-C (100 mg) in acetic acid (10 ml) containing four drops of 70% perchloric acid was hydrogenated at room temperature under an atmosphere of hydrogen for 7 h. After the usual work-up, the crude product was chromatographed on silica gel (20 g), using hexane-benzene (8:2) as eluent, to give a mixture (1:3) of (15*R*)-12,16-epoxy-8,11,13-abietatriene (**1a**) and its (15*S*)-epimer (**1b**) (291 mg: 95.4%).

b) A mixture of methyl 12,16-epoxy-8,11,13,15-abietatetraen-19-oate (**5**)[5] (100 mg: mp 130—131.5 °C) and PtO_2 (20 mg) in acetic acid (10 ml) was hydrogenated at room temperature under an atmosphere of hydrogen for 35 min. After the usual work-up, the crude product was chromatographed on silica gel (10 g), using benzene as eluent, to give a mixture (1:3) of methyl (15*R*)-12,16-epoxy-8,11,13-abietatrien-19-oate (**24a**) and its (15*S*)-epimer (**24b**) (91 mg: 90.7%). This mixture was separated by repeated column chromatography on silica gel using hexane-benzene (1:1) as eluent and recrystallization to give **24a**, mp 160—162 °C (from hexane), $[\alpha]_D$ +128.1° (*c* 0.96), and **24b**, mp 150—151.5 °C (from hexane), $[\alpha]_D$ +132.4° (*c* 3.70). Anal. of **24a**, Found: C, 76.63; H, 8.77%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%. Anal of **24b**, Found: C, 76.81; H, 8.81%. Calcd for $C_{21}H_{28}O_3$:C, 76.79; H, 8.59%. ^1H NMR ($CDCl_3$) of **24a** δ=1.01 (3H, s, C_{10}-CH_3), 1.25 (3H, s, C_4-CH_3), 1.27 (3H, d, *J*=7 Hz, C_{15}-CH_3), 3.64 (3H, s, -CO_2CH_3), 3.99 (1H, dd, *J*=7 and 8 Hz) and 4.62 (1H, t, *J*=8 Hz) (-OCH_2-), 6.67 (1H, s) and 6.79 (1H, s) (C_{11}-H and C_{14}-H). ^1H NMR ($CDCl_3$) of **24b** δ=1.01 (3H, s, C_{10}-CH_3), 1.25 (3H, s, C_4-CH_3), 1.28 (3H, d, *J*=7 Hz, C_{15}-CH_3), 3.64 (3H, s, -CO_2CH_3), 3.99 (1H, dd, *J*=7 and 8 Hz) and 4.62 (1H, t, *J*=8 Hz) (-OCH_2-), 6.67 (1H, s) and 6.79 (1H, s) (C_{11}-H and C_{14}-H).

c) A mixture of **7** (100 mg) and 10% Pd-C (30 mg) in ethyl acetate (10 ml) was hydrogenated at room temperature under an atmosphere of hydrogen for 6.5 h. After the usual work-up, the crude product was chromatographed on silica gel (10 g), using benzene as eluent, to give a mixture (1:2) of methyl (15*R*)-12,16-epoxy-8,11,13-abietatrien-18-oate (**26a**) and its (15*S*)-epimer (**26b**) (97 mg: 96.3%). This mixture was separated by repeated column chromatography on silica gel using hexane-benzene (4:6) as eluent and recrystallization to give **26a**, mp 142.5—143.5 °C (from hexane), $[\alpha]_D$ +63.7° (*c* 3.33), and **26b** as an oil, $[\alpha]_D$ +56.3° (*c* 2.90). ^1H NMR ($CDCl_3$) of **26a** δ=1.17 (3H, s) and 1.25 (3H, s) (C_4-CH_3 and C_{10}-CH_3), 1.27 (3H, d, *J*=7 Hz, C_{15}-CH_3), 3.66 (3H, s, -CO_2CH_3), 3.99 (1H, dd, *J*=7 and 8 Hz) and 4.62 (1H, t, *J*=8 Hz) (-OCH_2-), 6.67 (1H, s) and 6.78 (1H, s) (C_{11}-H and C_{14}-H). ^1H NMR ($CDCl_3$) of **26b** δ=1.17 (3H, s) and 1.25 (3H, s) (C_4-CH_3 and C_{10}-CH_3), 1.28 (3H, d, *J*=7 Hz, C_{15}-CH_3), 3.66 (3H, s, -CO_2CH_3), 3.99 (1H, dd, *J*=7 and 8 Hz) and 4.62 (1H, t, *J*=8 Hz) (-OCH_2-), 6.67 (1H, s) and 6.78 (1H, s) (C_{11}-H and C_{14}-H). Anal of **26a**, Found: C, 76.84; H, 8.80%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%. Anal. of **26b**, Found: C, 76.75; H, 8.74%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%. The other hydrogenations were summarized in Table 1.

(15*R*)-12,16-Epoxy-8,11,13-abietatrien-19-al (25a) and Its (15*S*)-Epimer (25b). a) A suspension of **24a** (128.0 mg) and lithium aluminium hydride (14.8 mg) in dry ether (5.0 ml) was stirred at room temperature for 1 h and then refluxed for 20 min. The mixture was poured into dilute hydrochloric acid and extracted with ether. The ether extract was washed with water, dried, and evaporated in vacuo to give a crude alcohol (120.0 mg).

A mixture of the crude alcohol (120.0 mg) and pyridinium chlorochromate (126.0 mg) in dichloromethane (5.0 ml) was stirred at room temperature for 1.5 h. After the addition of ether and aqueous sodium hydrogencarbonate, the mixture was extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and water, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (10 g), using benzene as eluent, to give **25a** (94.4 mg: 81.2%) which was recrystallized from ethanol, mp 150—152 °C, $[\alpha]_D$ +89.4° (*c* 1.23), IR 2730 and 1716 cm^{-1}, ^1H NMR (60 MHz, $CDCl_3$) δ=1.03 (3H, s) and 1.09 (3H, s) (C_4-CH_3 and C_{10}-CH_3), 1.27 (3H, d, *J*=7 Hz, C_{15}-CH_3), 3.2—3.7 (1H, m, C_{15}-H), 3.97 (1H, dd, *J*=7 and 8 Hz) and 4.60 (1H, t, *J*=8 Hz) (-OCH_2-), 6.68 (1H, s) and 6.81 (1H, s) (C_{11}-H and C_{14}-H), 9.81 (1H, d, *J*=1.5 Hz, -CHO). Found: C, 80.51; H, 8.73%. Calcd for $C_{20}H_{26}O_2$: C, 80.49; H, 8.78%.

b) A suspension of **24b** (498.0 mg) and lithium aluminium hydride (57.5 mg) in dry ether (7.0 ml) was stirred at room temperature for 1 h and then refluxed for 20 min. The crude alcohol (503.0 mg) was immediately oxidized with pyridinium chlorochromate (490.3 mg) in dichloromethane (5.0 ml) at room temperature for 1.5 h. After the work-up, as described in **a)**, the crude product was chromatographed on silica gel (15 g), using benzene as eluent, to give **25b** (334.0 mg: 73.8%) which was recrystallized from ethanol, mp 138—140 °C, $[\alpha]_D$ +94.4° (*c* 3.13), IR 2730 and 1712 cm^{-1}, ^1H NMR (60 MHz, $CDCl_3$) δ=1.06 (3H, s) and 1.10 (3H, s) (C_4-CH_3 and C_{10}-CH_3), 1.30 (3H, d, *J*=7 Hz, C_{15}-CH_3), 3.2—3.7 (1H, m, C_{15}-H), 3.97 (1H, dd, *J*=7 and 8 Hz) and 4.60 (1H, t, *J*=8 Hz) (-OCH_2-), 6.65 (1H, s) and 6.78 (1H, s) (C_{11}-H and C_{14}-H), 9.78 (1H, d, *J*=1.5 Hz, -CHO). Found: C, 80.28; H, 9.00%. Calcd for $C_{20}H_{26}O_2$: C, 80.49; H, 8.78%.

Conversion of 25a into 1a. A mixture of **25a** (82.6 mg) and 80% hydrazine hydrate (0.42 ml) in diethylene glycol (4.0 ml) was refluxed for 2.5 h and powdered sodium hydroxide (443 mg) was then added. The mixture was heated at 185—190 °C for 3 h, cooled, diluted with water, and extracted with ether. The ether extract was washed with water, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (10 g), using hexane-benzene (85:15) as eluent, to give **1a** (32.8 mg: 41.7%), mp 53—55 °C (from ether), $[\alpha]_D$ +58.0° (*c* 0.81).

Conversion of 25b into 1b. A mixture of **25b** (291.0 mg) and 80% hydrazine hydrate (1.8 ml) in diethylene glycol (10 ml) was refluxed for 2.5 h and powdered sodium

hydroxide (1.560 g) was then added. The mixture was heated at 185—190 °C for 3 h. The crude product was chromatographed on silica gel (10 g), using hexane–benzene (7:3) as eluent, to give **1b** as an oil (139.9 mg: 50.4%), $[\alpha]_D$ +61.6° (*c* 4.39).

Conversion of 26a into 1a. A suspension of **26a** (334 mg) and lithium aluminium hydride (39 g) in dry ether (10 ml) was stirred at room temperature for 1.5 h. The mixture was poured into dilute hydrochloric acid and extracted with ether. The ether extract was washed with water, dried, and evaporated in vacuo to give a crude alcohol (343 mg).

The crude alcohol was tosylated with *p*-toluenesulfonyl chloride (388 mg) in pyridine (3.0 ml) at 95—100 °C for 5.5 h. The mixture was cooled, poured into dilute hydrochloric acid, and extracted with chloroform. The chloroform extract was washed with aqueous sodium hydrogencarbonate and water, dried, and evaporated in vacuo to give a crude tosylate (650 mg).

A mixture of the crude tosylate, sodium iodide (762 mg), and zinc powder (333 mg) in *N,N*-dimethylformamide (5.0 ml) was heated at 120—125 °C for 7 h. The mixture was cooled, poured into dilute hydrochloric acid, and extracted with ether. The ether extract was washed successively with water, aqueous sodium thiosulfate, and brine. The dried solution was evaporated in vacuo and the residue was chromatographed on silica gel (10 g), using hexane–benzene (85:15) as eluent, to give **1a** (241 mg: 83.3%) which was recrystallized from ether, mp 52—55 °C, $[\alpha]_D$ +59.7° (*c* 0.75).

Conversion of 26b into 1b. The ester **26b** (198 mg) was reduced with lithium aluminium hydride (23 mg) in dry ether (3.0 ml) at room temperature for 1 h to give a crude alcohol (208 mg).

The above alcohol was tosylated with *p*-toluenesulfonyl chloride (345 mg) in pyridine (2.0 ml) at 95—100 °C for 5.5 h to afford a crude tosylate (400 mg).

A mixture of the crude tosylate, sodium iodide (452 mg), and zinc powder (197 mg) in *N,N*-dimethylformamide (3.0 ml) was heated at 120—125 °C for 7 h. The crude product was purified by column chromatography on silica gel (10 g), using hexane–benzene (7:3) as eluent, to give **1b** as an oil (90 mg: 52.4%), $[\alpha]_D$ +59.4° (*c* 0.96).

The authors are grateful to Professor Yoshiyuki Hirose, Science University of Tokyo, for kindly supplying the spectra of natural ar-abietatrien-12,16-oxide.

(*p*-Hydroxyphenyl)dimethylsulfonium methyl sulfate(HODMSP·$MeSO_4^-$) was found to be an excellent coupling reagent having a water-soluble property and a high reactivity; it worked as satisfactory as usual active esters in regard to the reactivity, product purity, and racemization. The marked advantage of the HODMSP·$MeSO_4^-$ active ester method was the fact that bifunctional residues such as Arg, Lys, Cys, and Tyr could be selectively acylated when the pH of the reaction mixture was controlled. The molluscan neuropeptide FMRFamide(Phe-Met-Arg-Phe-NH_2) was synthesized by this new active ester method for an evaluation of this method to further applications involving peptide syntheses.

The active ester method, which allows the formation of an amide bond under a very mild condition, is known to be useful for peptide syntheses or chemical modifications of proteins. The reaction process of this active ester method proceeds by activating a carbonyl carbon atom in the carboxyl component, as shown in Fig. 1. In spite of many studies[2-5)] about the active ester method, most reactions require organic solvents since these active esters are not soluble in water due to the hydrophobic character of their molecules.

Recently, Kawasaki et al. applied *p*-trimethylammoniophenyl ester[6)] as a water-soluble active ester to peptide synthesis. They also reported that the active ester was advantageous for the removal of any unreacted active ester and resultant hydroxy compound from the reaction mixture. As a new application of the water-soluble active ester, we have considered applying it to the peptide forming reaction in an aqueous solution. The most notable effectiveness of a reaction in an aqueous solution seems to be that the selective aminolysis reaction of amino acids which have functional groups in their side chain (such as Arg, Glu, Lys, Cys, His, or Tyr) is possible only by controlling the pH of the reaction mixture. For this application, we focused on *p*-dialkylsulfoniophenols (HODASP·X^-) as water-soluble active ester reagents. These compounds generally exhibited high acidity[7)] and high solubility in water, due to the presence of the dialkylsulfonio group in the molecule which showed both hydrophilic and electron-withdrawing characteristics.

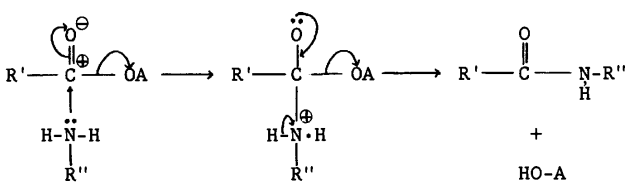

Fig. 1. Mechanism of aminolysis with active ester.

In this paper, we present such characteristic of HODASP·X^- as solubility in water or reactivity of their esters as well as fundamental information regarding applications to peptide syntheses, by making comparisons with other conventional HOSu or HONp active ester methods. Furthermore, the synthesis of FMRFamide, a molluscan neuropeptide, is also presented as an example application of the new method to a peptide synthesis in an aqueous solution.

Results and Discussion

pK_a of HODASP·X^- and Solubility of Their Esters in Water. Many kinds of HODASP·X^- were prepared in order to develop a water-soluble active ester reagent according to the procedure shown in Scheme 1. The pK_a values of HODASP·X^-, which have ClO_4^- as a counter anion (**1**—**7**), were measured in 30% aqueous ethanol and compared with that of HONp or other phenols having a sulfur group at the para position. Furthermore, the solubility in water of these compounds were examined (Table 1). The pK_a values of **1** and **2** were nearly the same level as that of HONp and their solubilities in water were more than 30%. Compounds **8**$_{a-d}$ were prepared by changing the counter anion of **1** (R_1=H, R_2=Me, and R_3=Me), and examined in the same manner described above. As shown in Table 1, these compounds (**8**$_{a-d}$) exhibited the same property as **1**. Owing to the pK_a and solubility in water, we judged **8**$_{a-d}$ and **1** to be

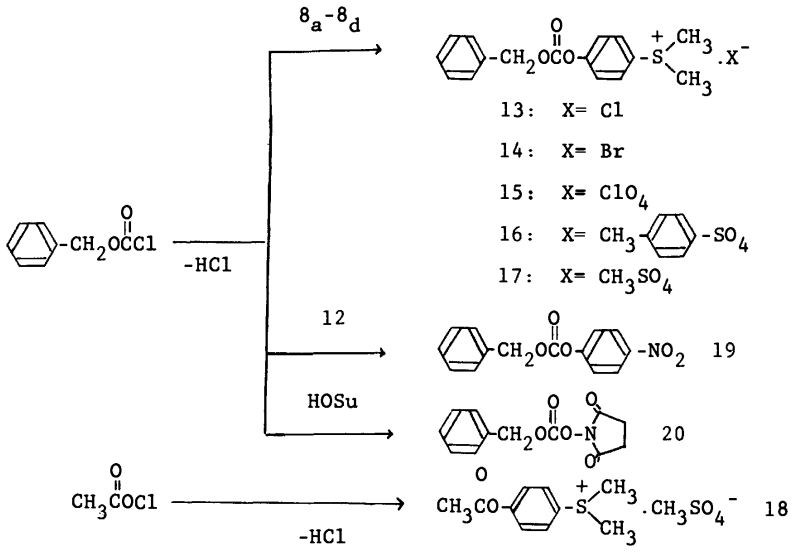

Scheme 2.

excellent reagents for the water-soluble active ester method. They were employed for the following investigation.

To examine the solubility of the esters derived from **1** and $\mathbf{8}_{a-d}$ in water, we prepared their benzyl carbonates using benzyloxycarbonyl chloride as benzyloxycarbonyl donor, according to the procedure shown in Scheme 2. The benzyl carbonates from HONp and HOSu were also prepared in the same procedure. The solubilities of these compounds in water and organic solvent are summarized in Table 2. A benzyl carbonate in which a methyl sulfate anion is present as a counter anion **17** exhibited a high solubility in water (more than 30%) in spite of the hydrophobic benzyl group in its molecule. Similarly, acetyl derivative **18** of $\mathbf{8}_d$, which was prepared from acetyl chloride and $\mathbf{8}_d$ was also very soluble in water. In addition, **17** and **18** were also very soluble in DMF, $CHCl_3$, and CH_3CN. These results indicate that the esters of $\mathbf{8}_d$ possess sufficient solubilities to be applied to a coupling reaction in an aqueous environment.

Reactivity of the Ester of HODMSP·$MeSO_4^-$($\mathbf{8}_d$) in Aminolysis. In order to compare the reaction of the benzyl carbonate (**17**) of HODMSP·$MeSO_4^-$ with that of the benzyl carbonates of HONp and HOSu, we examined their reaction rates with Gly in CH_3CN-H_2O at 25 °C (Fig. 2). As a result, it was found that **17** exhibited as a high reactivity as benzyl carbonates derived from HONp or HOSu. Furthermore, the water-soluble acylating agents derived from HODMSP·$MeSO_4^-$ were practically allowed to react with amino acids in aqueous solution (Table 3). As a result, the reaction of **17** or **18** with neutral amino acids proceeded in aqueous solution and the products were isolated in good yield. The acylation on the amino acids or peptides, which have a functional group on their side chain (such as Arg, Glu, Lys, Cys, or Gly-Tyr) was examined. The reaction with benzyl carbonate of HODMSP·$MeSO_4^-$ with Arg, Glu, His, Lys, or Gly-Tyr gave α-acylated compounds predominantly (at the controlled pH condition). Particularly, it was notable that reaction of **17** with Arg at pH 8.0 gave only an α-acylated derivative without any sub-reaction on guanidino group. However, the reaction of **17** with Cys or Lys gave an acylated product, mainly on a side functional group. This fact could explain why the reactivity of the functional group of the side chain was higher than that of the α-amino group. For the acylation of Tyr, Gly-Tyr was submitted to a test. As shown in Table 4, when the reaction proceeded at pH 6.0, the acylation was

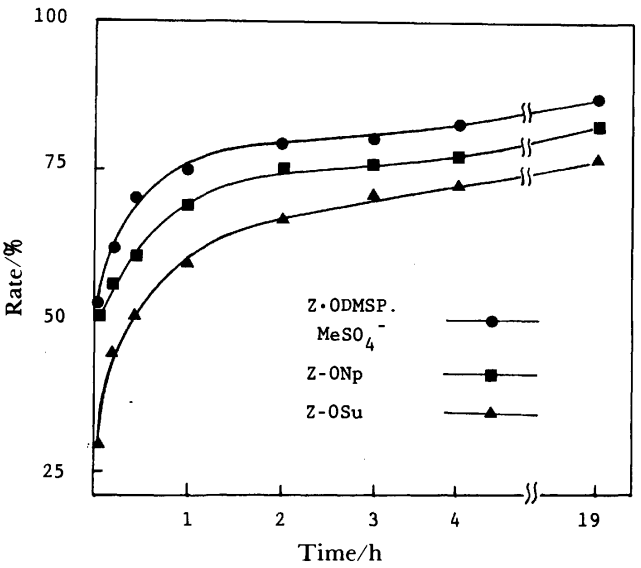

Fig. 2. Rates of aminolysis with Gly in CH_3CN-H_2O at 25 °C.

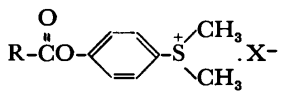
Table 2. Solubility of Esters Prepared



Run	R	X	Solubility	
			Water[a]	Organic solvent[b]
13	Benzyloxy	Cl	is	DMF, CH_3CN
14	Benzyloxy	Br	is	DMF, CH_3CN

16	Benzyloxy	TosO	s(3%)	DMF, CH_3CN, $CHCl_3$
17	Benzyloxy	$MeSO_4$	vs(>30%)	DMF, CH_3CN, $CHCl_3$
18	Methyl	$MeSO_4$	vs(>30%)	DMF, CH_3CN, $CHCl_3$
19			is	Ether, AcOEt, THF
20			is	Ether, AcOEt, THF

TosO=*p*-toluensulfonate, Me=methyl, AcOEt=ethyl acetate.

a) Solubility in water at 25°C, vs=very soluble, s=soluble, is=insoluble (<1%). b) The solvents having solubility above 10% were listed.

predominantly inclined on the α-amino group of Gly moiety; while at pH 8.0, the acylation toward the phenolic hydroxy group of the Tyr moiety was increased. Because of the results described above, the esters of HODMSP·$MeSO_4^-$ were subjected to aminolysis in an aqueous solution to easily form an amide bond. In addition to this fact, a selective acylation was carried out at the suitable pH. We considered that the esters of HODMSP·$MeSO_4^-$ are quite useful as amino-protecting reagents.

Application of HODMSP·$MeSO_4^-$ Active Ester for Peptide Synthesis. In order to know whether the
