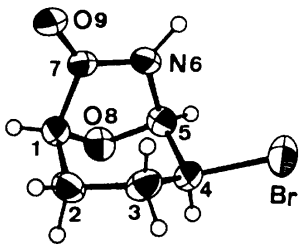
(Received July 2, 1987)

The crystal structures of the major(Major) and minor(Minor) components of the dimer obtained from the anionic reaction of the racemates of 4(*e*)-bromo-8-oxa-6-azabicyclo[3.2.1]octan-7-one (Br-BOL) have been determined by X-ray method. Crystal data are: (Major) $P2_1/c$, a=10.852(3), b=5.207(3), c=22.146(5) Å, β=92.75(2)°, Z=4, R=0.083 for 1744 reflections; (Minor) $P2_1/c$, a=16.825(5), b=7.844(3), c=11.483(3) Å, β=121.40(2)°, Z=4, R=0.038 for 2026 reflections. The structure of each dimer is constructed of an original Br-BOL skeleton at a terminus and an rearranged bicyclic skeleton at another terminus. The configuration of the chiral C atom contained in the rearranged skeleton of Major is different from that of Minor, when the chirarity of a terminal Br-BOL skeleton in Major is coincided with that in Minor.

A bicyclic epoxy lactam, 8-oxa-6-azabicyclo[3.2.1]-octan-7-one (abbreviated as BOL), is an interesting starting material for new functional polymers with water permeability and ion selectivity.[1-4] The anionic polymerization of BOL in solution leads to a high-molecular-weight polyamide (poly(BOL)) through the N^6–C^7 scission of the amide group.[1,3] The conformation of the optically active poly(BOL) was revealed to be a double-stranded 10_3 helix by the X-ray diffraction method.[5] While the oligomers are obtained in the cationic reaction of BOL, suggesting that the reaction mechanism differs from that of the anionic polymerization.[6] In order to make the reaction mechanism clear the X-ray analysis of the resulting dimer (abbreviated as $(BOL)_2$) was carried out, and supports the mechanism that the cationic oligomerization proceeds through the C^5–N^6 scission of BOL.[7] In $(BOL)_2$ the BOL skeleton is conserved at a terminus and the tetrahydropyran ring occurs by the ring-opening in the second residue.[7]



Br-BOL

Recently the 4-bromo-substituted derivative, 4(*e*)-bromo-8-oxa-6-azabicyclo[3.2.1]octan-7-one (abbreviated as Br-BOL), was synthesized in order to obtain an information upon the reactivity of the BOL skeleton.[8] The equatorial location of the Br atom with respect to the 6-membered ring was confirmed by the X-ray analysis of Br-BOL.[9] The anionic reaction of the racemates of Br-BOL forms an oligomer mixture containing mainly the dimer and the trimer.[8] By the IR and NMR studies of the oligomers the original Br-BOL skeleton was assigned at a terminus, though the remaining structure could not be confirmed. Furthermore the dimer was separated into two components, the major and minor component respectively, during the purification. The yielding ratio of the two components is about 6:1. The structural difference between the major and the minor components was conjectured to be a configurational difference of the chiral atom in each component. Therefore in order to determine the molecular structures of the dimers and to elucidate the oligomerization mechanism of Br-BOL, the crystal structure analyses of the dimers were undertaken.

Experimental

The crystals of the major component (abbr. as Major) obtained from an ethyl acetate–chloroform solution were colorless needles, and the crystals of the minor component (abbr. as Minor) grown from an ethyl acetate solution were colorless plates. The density of each component was measured by the flotation method in a 1,2-dibromoethane–CCl_4 solution. The X-ray intensity data were collected on a Rigaku four-circle diffractometer, using graphite monochromated radiation; Cu $K\alpha$(λ=1.5418 Å) for Major and Mo $K\alpha$(λ=0.71073 Å) for Minor. The intensity data were corrected for Lorentz and polarization effects, but the absorption correction was not carried out. Unit cell dimensions were obtained by the least-squares fit using 11 reflections with $55°<2\theta<70°$ for Major and 15 reflections with $20°<2\theta<32°$ for Minor. Crystal data and experimental conditions are shown in Table 1.

Both structures were solved by the heavy atom method. The refinement was carried out by the block-diagonal least-squares method (*HBLS* VI).[10] The function minimized was $\Sigma w(|F_o|-|F_c|)^2$. The weighting scheme adapted was $w=(\sigma^2(F_o)+a|F_o|^2)^{-1}$ for the observed reflections, where σ(F) is the standard deviation based on counting statistics. The isotropic temperature factors of the H atoms are fixed to the equivalent temperature factors(B_{eq})[11] of the corresponding atoms to which they are bound. At final stages of the

refinement, for Major a=0.017 and for Minor a=0.001 were applied. The final R values were 0.083 (R_w=0.111) for Major, and 0.038 (R_w=0.048) for Minor, respectively. All the scattering factors were taken from the International Tables for X-Ray Crystallography, Vol. IV.[12] The atomic parameters of the non-hydrogen atoms with B_{eq}'s are given in Table 2.[††] All the calculations were carried out on a FACOM M382 at Nagoya University Computation Center.

Results and Discussion

The bond distances and angles of Major and Minor are given in Fig. 1, together with the numbering of atoms. The corresponding bond distances and angles between the two components are in good agreements with each other, except for the N16–C22–C21 angle. The ∠N16–C22–C21 of Minor, 116.2(6)° is significantly larger than that of Major, 109.8(3)°. The fairly short contact of the Br···O28, 3.210(5) Å is observed in Minor. Therefore the widening of the ∠N16–C22–C21 of Minor may be to reduce the steric repulsion between the Br and O28 atoms. The bond distances and angles of the BOL skeleton within the two components are also quite normal when they are compared with those of BOL,[9] Br-BOL,[9] and $(BOL)_2$,[7] with the exception of the N16–C17 distance. The N16–C17 distances of 1.365(5) Å(Major) and 1.36(1) Å(Minor) are slightly longer than those of 1.329(4) Å(BOL[9]), 1.342(6) Å(Br-BOL[9]), and 1.341(5) and 1.330(5) Å($(BOL)_2$[7] in which two molecules are included in an asymmetric unit).

Stereoscopic views of Major and Minor drawn by *ORTEP* II[13] are shown in Fig. 2. At a terminus the original Br-BOL skeleton is conserved in both the

[††] The anisotropic thermal parameters of non-hydrogen atoms, the parameters of hydrogen atoms, the equations of best-planes, and the tables of the observed and the calculated structure factors were kept at the Chemical Society of Japan (as Document No. 8766).

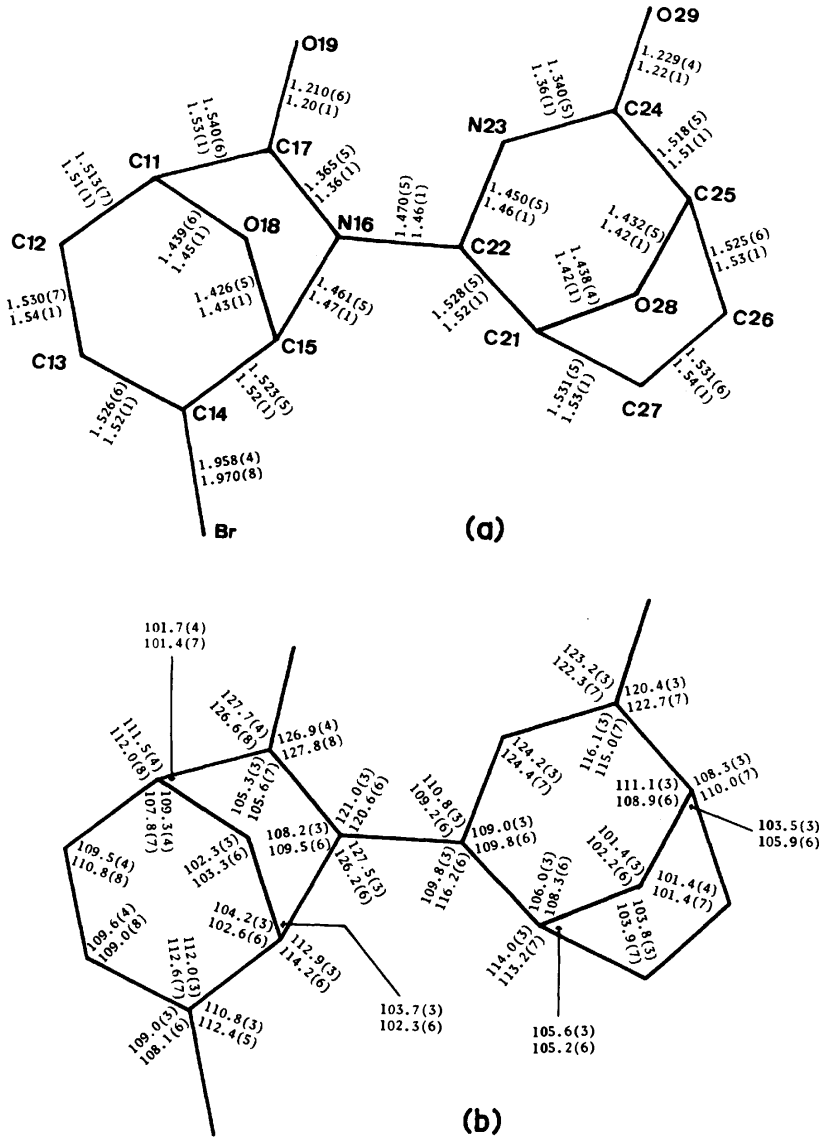

Fig. 1. (a) Bond distances(l/Å) and (b) bond angles(φ/°) for Major(upper) and Minor(lower).

components, as indicated by the spectral data.[8] A ring-opened skeleton was expected at the other terminus as similar to the structure of $(BOL)_2$.[7] The bicyclic skeleton (rearranged skeleton), however, is also kept at the other terminus in Major and Minor, though the skeletal rearrangement occurs via a transfer reaction. This may be a main reason why the structure of the oligomer could not be confirmed by the spectral data. A conformational difference around the N16–C22 bond is clearly observed between Major and Minor. For the molecules having the Br-BOL skeleton of the same configuration in Fig. 2, the torsion angles of C15–N16–C22–C21 and C15–N16–C22–N23 are 93.1(4) and −27.4(5)° for Major, and −75.5(9) and 49.4(9)° for Minor. BOL contains two asymmetric C atoms, C1 and C5, respectively. Each structure of the Br-BOL skeleton drawn in Fig. 2 is an enantiomer with C1 S and C5 R. The two components are, furthermore, essentially different in the configuration of the C25 atom contained in the rearranged skeleton, where the C25 atom corresponds to C1 in BOL. The configurations of the C11 (correspond to C1) and C25 atoms are the same in Major, and those are different in Minor. Thus it is shown that the oligomerization of Br-BOL prefers between the molecules with the same configuration of the BOL skeleton to between the molecules with the different configuration, taking the yielding ratio of the major and minor components into consideration. Therefore the configuration of the C1 and the corresponding C atoms in the trimer of Br-BOL was expected to be the same, and the expectation was confirmed by the structure analysis of the trimer.[14] A following mechanism for the oligomeric reaction is

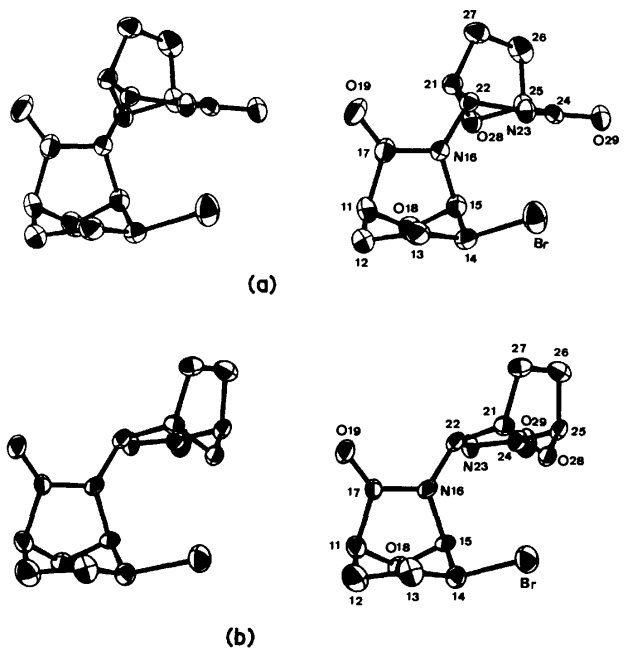

Fig. 2. Stereodrawings of (a) Major and (b) Minor. Atoms are drawn with 50% probability thermal ellipsoids. Both Br-BOL skeletons have the same configuration.

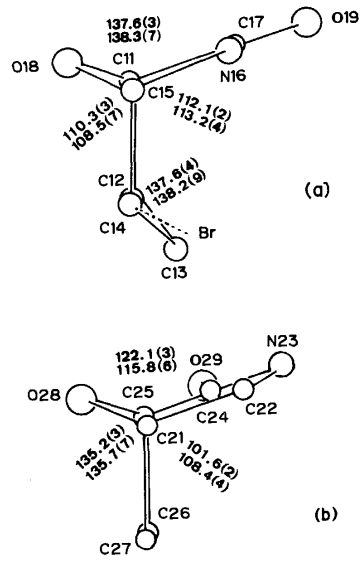

Fig. 3. Selected diheddral angles(φ/°) among the best-planes. Definitions are: (a) Br-BOL skeleton, plane I C11, C15, N16, C17, O19; plane II C11, C15 O18; plane III C11, C12, C14, C15; plane IV C12 C13, C14, (b) rearranged skeleton, plane V C22, N23, C24, C25, O29; plane VI C21, C25, O28; plane VII C21, C25, C26, C27. Major upper and Minor lower.

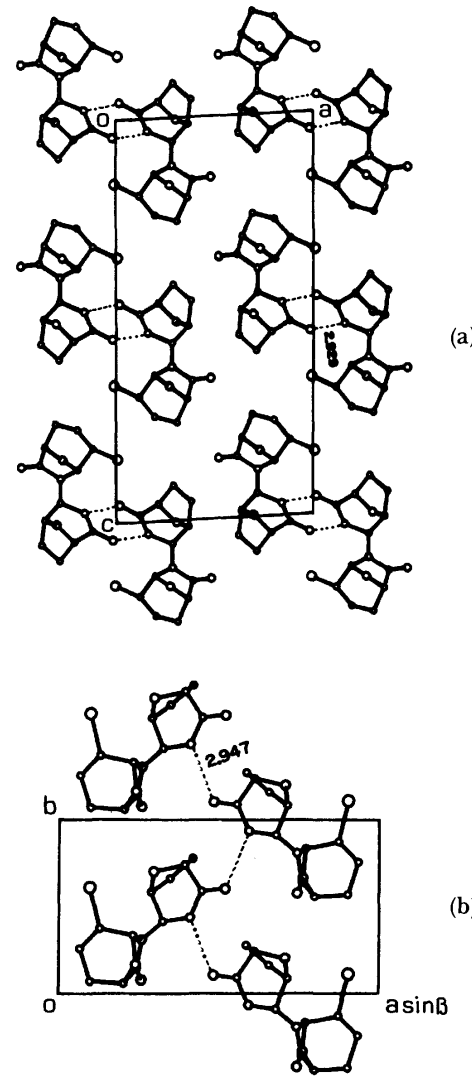

Fig. 4. Crystal Structures of (a) Major projected along the b axis, and (b) Minor projected along the c axis(Molecules on the equvalent positions (x, y, z) and ($-x$, 1/2+y, 1/2−z) only are drawn for clarity). Hydrogen bonds are shown with broken lines, and the distances are given in Å unit.

suggested; (i) The N6 atom of the amide group of a Br-BOL moiety at a terminus attacks at first the C5 atom of another Br-BOL molecule, (ii) the scission of the C5–O8 bond of the attacked part occurs, leading to the collapse of the bicyclic skeleton, (iii) the O8 atom approaches the C4 to which the Br bonds, and (iv) the formation of the C4–O8 bond generates the rearranged bicyclic skeleton, together with the elimination of the Br atom.

The dimer consists of seven planes: (a) BOL skeleton, plane I defined by C11, C15, N16, C17, and O19; plane II C11, C15, and O18; plane III C11, C12, C14, and C15; plane IV C12, C13, and C14, (b) rearranged skeleton, plane V C22, N23, C24, C25, and O29; plane VI C21, C25, and O28; plane VII C21, C25, C26, and C27. The C21 atom deviates by 0.38 Å in Major, and by 0.13 Å in Minor, from the plane V. The selected dihedral angles among the planes are given in Fig. 3. The dihedral angles in the BOL skeleton show good agreements with those found in the other

BOL skeleton.[7,9] The dihedral angles are, however, significantly different between the planes V and VI and between the planes V and VII, as compared with those in Major and Minor. This may reflect the configurational difference of the C25 atoms of Major and Minor.

The packing schemes of molecules in Major and Minor are shown in Figs. 4(a) and (b), respectively. The hydrogen bond of 2.929(4) Å occurs between N23 and O29$^{(i)}$ in Major, and that of 2.947(9) Å occurs between N23 and O29$^{(ii)}$ in Minor. [Symmetry code: (*i*) $(-x,-y,-z)$, (*ii*) $(1-x,-1/2+y,3/2-z)$] The H···O and ∠N-H···O are 2.29(5) Å and 160(6)° for Major, and 2.21(11) Å and 163(11)° for Minor. In Major a dimer structure is formed by hydrogen bonds related with an inversion center. On the other hand molecules are linked by hydrogen bonds around a two-fold screw axis, giving rise to infinite helical chains extended along the b axis in Minor.

Orientation-Dependent ^{1}H and ^{13}C Isotropic Shifts of Low-Spin Tetracyano(1,2-diamine)ferrates(III)

Yoshitaka KURODA, Masafumi GOTO,* and Tomoya SAKAI
Faculty of Pharmaceutical Sciences, Nagoya City University, Mizuho-ku, Nagoya 467
(Received February 5, 1987)

Paramagnetic ^{1}H and ^{13}C NMR signals of low-spin tetracyanodiamineferrates(III), $[Fe^{III}(CN)_4(diamine)]^-$, containing ethylenediamine, (*R*)-1,2-propanediamine, (1*R*,2*R*)-*trans*-cyclohexanediamine, and *N*,*N*′-dimethylethylenediamine, were assigned by the use of rapid electron exchange between the Fe^{III} complex and the diamagnetic Fe^{II} complex with an identical set of ligands. The C–H on the five-membered chelate ring showed isotropic shifts with different signs depending on their orientations: 14—18 ppm downfield and ca. 16—23 ppm upfield for axial and equatorial protons respectively. The isotropic shifts for the ^{13}C nuclei were attenuated, their signs alternating with each separation by one carbon–carbon bond from the metal ion. The isotropic shift is compared with that of the Ni^{II} complex qualitatively in terms of the dipolar and Fermi contact shifts.

The paramagnetic NMR spectra of Fe^{III} complexes are widely used to assign their spin states and stereochemistry for rather complex molecules, such as those with porphyrins[1] and heme proteins.[2-4] There have, however, been few studies on the paramagnetic NMR spectroscopy for the Fe^{III} complexes with simple structures. The analysis of the simple Fe^{III} complexes will provide some insights into the mechanism of the paramagnetic shift.

The Fe^{III} complexes, tetracyano(diamine)ferrates(III) $[Fe^{III}(CN)_4(diamine)]^-$,[5-8] are low spin,[7,8] and their structures are so simple that all the paramagnetic signals can be identified.

The stereochemistry of the five-membered chelate rings formed with various diamines has been investigated by means of a wide range of experimental methods.[9] The present Fe^{III} complexes offer a good opportunity to study their NMR spectra because: 1) They are kinetically inert, and so there is no need to consider complex formation equilibrium; 2) the corresponding Fe^{II} complexes, tetracyano(diamine)ferrates(II) are diamagnetic, and their NMR spectra have been analyzed by conventional methods; 3) the rapid electron exchange between low-spin Fe^{II} and Fe^{III} complexes affords the time-averaged spectra of each complex, depending on the compositions for mixtures of them, and 4) the stereochemistry of the five-membered chelate rings formed with 1,2-diamines has been extensively studied, and so the existing information about them can be utilized for reference.

Reports on the paramagnetic NMR spectra of transition metal complexes with saturated ligands such as 1,2-diamines are relatively few in number. Ni^{II} complexes with diamines have been reported by Reilley and his colleagues,[10,11] while Ni^{II} and Co^{II} complexes with monoamines have been reported by Morishima et al.[12] The former studies have revealed the usefulness of paramagnetic NMR for the analysis of the structures of metal complexes in solution and their dynamics. The latter treated the origin of the paramagnetic shift and the orientation-dependence of spin propagation by considering spin-polarization and direct-spin-delocalization mechanisms. However, the NMR signals of the Ni^{II} complexes are relatively broad, and there is a problem that the chemical species responsible for NMR is really a mixture formed by an equilibrium among several species.

We have now investigated the paramagnetic NMR of these Fe^{III} complexes in order to elucidate the mechanism of the paramagnetic shift. In this paper, the assignments of all the C–H of some 1,2-diamines coordinated to the Fe^{III} center and a qualitative conclusion about the use of the isotropic shift for the analysis of the stereochemistry of chelate rings will be described.

Experimental

Materials. Sodium tetracyano(diamine)ferrates(III), and their corresponding Fe^{II} complexes were isolated according to the methods reported previously, using ethylenediamine (en),[5,13] (*R*)-1,2-propanediamine(*R*-pn),[6,7] (1*R*,2*R*)-*trans*-cyclohexanediamine(*R*-chxn),[6,7] and *N*,*N*′-dimethylethylenediamine(s-Me_2en)[5,13] as diamines.

^{1}H and ^{13}C NMR Measurements. A weighed sample (40—50 mg) in a sample tube 5 mm in diameter was dissolved in pD 2.0 DCl–D_2O (0.3 cm^3) to prevent a disproportionation reaction with concomitant diamine dehydrogenation[14] in a neutral or basic aqueous solution, from occurring. Sodium 3-trimethylsilylpropionate-2,2,3,3-d_4 (TSP; 0.00 ppm) and 1,4-dioxane (67.44 ppm) were used as the internal stadards for the ^{1}H and ^{13}C NMR measurements respectively. The chemical shift, δ, is positive for a downfield shift from the standards. The spectra were recorded with JEOL MH-100 and FX-100 spectrometers.

The ^{1}H and ^{13}C NMR spectra of the Fe^{II} complexes were measured in a manner similar to that described above except that D_2O was used as the solvent.

Changes in Chemical Shift by the Variation in the Mixing Ratio of the Fe^{III} and the Corresponding Fe^{II} Complexes (Variation Experiment). In a 5 cm^3 flask, ca. 300 mg (10^{-3} mol) of the Fe^{II} complex was dissolved in pD 2.0 DCl–D_2O containing 0.4% sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS; 0.00 ppm) and 1,4-dioxane. Weighed amounts of the corresponding Fe^{III} complex were mixed

with this solution (0.5 cm^3) to make mixtures in various compositions. The ^1H and ^{13}C NMR spectra were measured at 300 K with JEOL MH-100 and FX-100 spectrometers.

Direct Preparation of the Sample Solution of the Fe^{III} s-Me_2en Complex. The isolated Fe^{II} s-Me_2en complex (50.2 mg) was dissolved in 0.5 cm^3 of D_2O. After standing at room temperature for more than 5 min, the solution was acidified by the addition of 45.1 mg of 37% DCl; $Na_2S_2O_8$ (104.0 mg) was then added at 0 °C. The mixture was allowed to stand at 0 °C for 2 h, and the resulting solution was used for the ^1H NMR measurement.

Results and Discussion

^1H and ^{13}C NMR Spectra of Fe^{III} Complexes and Assignments of Their Signals. Tetracyano(1,2-diamine)ferrate(III) and tetracyano(1,2-diamine)ferrate(II) complexes are both low-spin;[7,8] their electronic configurations are $(t_{2g})^5$ and $(t_{2g})^6$. The large variation in the chemical shifts and the diminution of the ^1H-^1H couplings precludes the assignments of the paramagnetic NMR signals by conventional methods. Since no previous examples of this class of Fe^{III} complex are known, we could not use any previously reported information about the chemical shift. The signals have been assigned by the use of the rapid electron exchange between the pair of low-spin Fe^{II} and Fe^{III} complexes (variation experiment). At first, the signals of the Fe^{II} complexes were assigned by conventional methods. Then the signals of the Fe^{III} complexes were correlated with those of the Fe^{II} complexes on the basis of the spectral changes induced by the variation in the ratio of the Fe^{III} complexes to the corresponding Fe^{II} complexes.

The values of the chemical shifts, δ, for the Fe^{III} and Fe^{II} complexes described below are summarized in Table 1. The numbering of the nuclei for each complex is denoted in Fig. 1 and is used throughout this paper.

(*R*)-1,2-Propanediamine Complex. The *R*-pn chelates are well known to have λ *gauche* conformations in the solid state,[15-18] in which the methyl groups are equatorial to the chelate ring. The conformations in solution have been investigated by means of ^1H NMR spectroscopy.[19-22] For example, the *R*-pn chelate ring of $[Co^{III}(CN)_4(R\text{-pn})]^-$ is predominantly in a λ *gauche* form in solution.[20,21] The ^1H NMR spectrum of $[Fe^{II}(CN)_4(R\text{-pn})]^{2-}$, has been shown to be similar to that of this Co^{III} complex.[6]

Figure 2 shows the ^1H NMR spectrum of $[Fe^{III}(CN)_4(R\text{-pn})]^-$. Three signals were observed — at 17.40, 9.31, and −20.05 ppm — with an area ratio of 2:3:1. The signal at 9.31 ppm was assigned to the methyl protons because of its area ratio. Because of an unpaired electron, the signals are distributed over the wide range of ca. 37 ppm.

Figure 3 shows the ^1H NMR spectra of the mixtures of Fe^{II} and Fe^{III} complexes obtained by varying the mole fraction of the latter, *f*, at 300 K. The spectrum

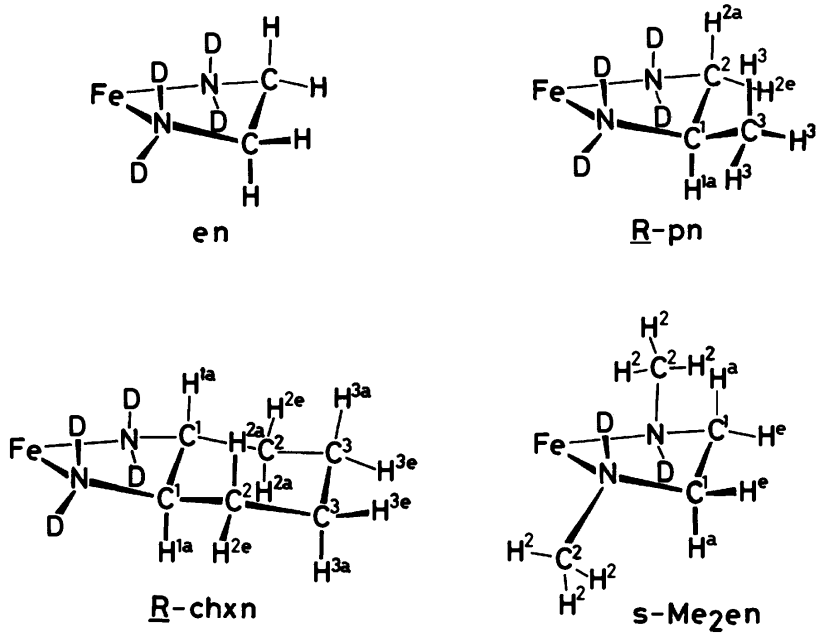

Fig. 1. Schematic structures of the chelates and the numbering of protons and carbons. Fe=Fe(CN)$_4$

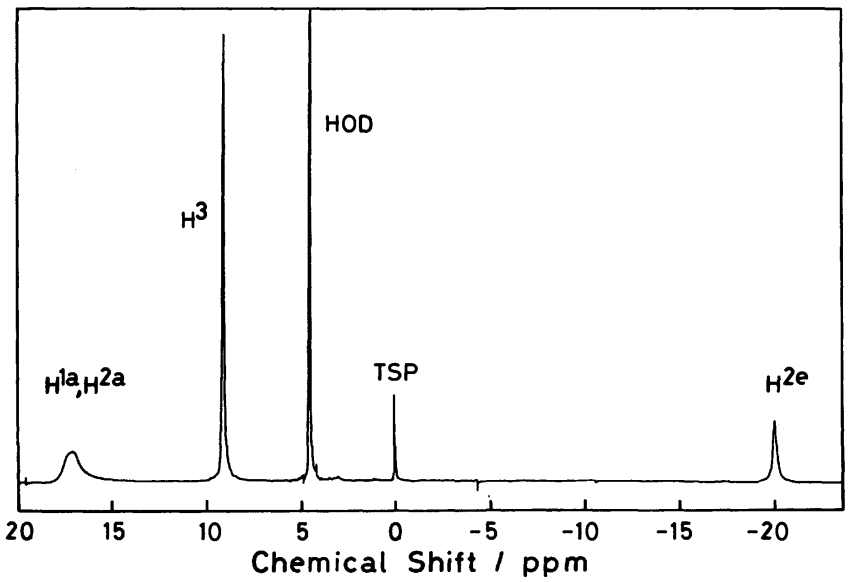

Fig. 2. ^{1}H NMR spectrum of $[Fe(CN)_4(R\text{-pn})]^-$ in 10^{-2} mol dm^{-3} DCl.

shown at the top is that of $[Fe^{II}(CN)_4(R\text{-pn})]^{2-}$; the signals at 2.74, 2.61, 2.16, and 1.22 ppm have been assigned to H^{1a}, H^{2e}, H^{2a}, and H^3 respectively.[6] When small amounts of the Fe^{III} complex were added to the Fe^{II} complex, the ^{1}H NMR spectra changed in shape depending on f: The signal of H^{2e} shifted to an upper field, but the other proton signals shifted downfield. The ^{1}H-^{1}H couplings ($^{3}J_{HCCH}$) could be observed in the region of small f values: the apparent doublet and triplet of H^{2e} and H^{2a} were observed clearly until f reached 0.055.

The δ values vary in proportion to f, as is shown in Fig. 4. This linear relationship shows that the signals for the mixtures are averaged by the rapid electron exchange between the Fe^{II} and Fe^{III} complexes.[23-25] The rate is in the region of fast-limit on the NMR time scale. By the extrapolation of f to 1.0, the Fe^{III} complex signals are assigned as listed in Table 1.

The ^{13}C NMR spectra of both $[Fe^{II}(CN)_4(R\text{-pn})]^{2-}$ and $[Fe^{III}(CN)_4(R\text{-pn})]^-$ showed three signals coupled with adjacent protons in off-resonance measurements. The signals at 241.5, 248.0, and −49.2 ppm for the Fe^{III} complex and those at 52.7, 50.9, and 19.6 ppm for the Fe^{II} complex are assigned to C^1, C^2, and C^3

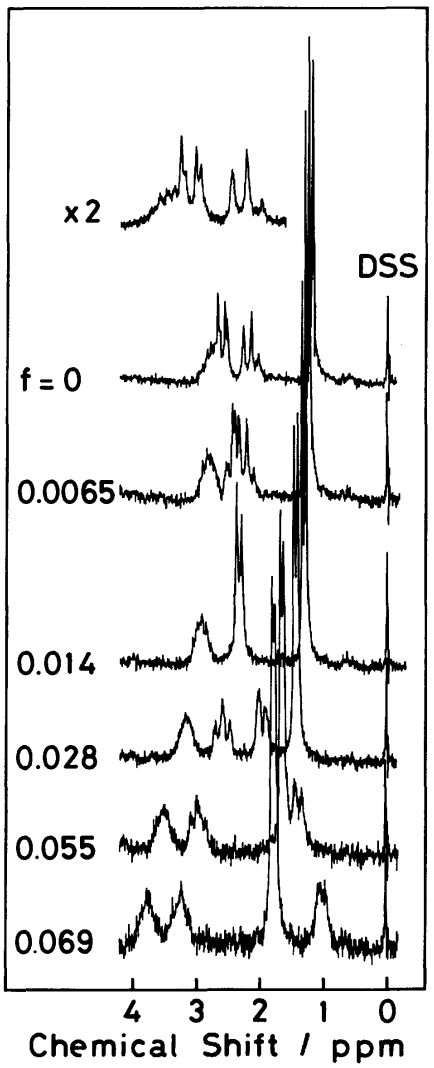

Fig. 3. ^{1}H NMR spectral changes of $[Fe(CN)_4(R\text{-pn})]^{2-}$ on addition of $[Fe(CN)_4(R\text{-pn})]^-$ in 10^{-2} mol dm^{-3} DCl. *f*: Mole fraction of the Fe^{III} chelate.

respectively.

Ethylenediamine Complex. As is shown in Table 1, only one signal is observed for each of the Fe^{III} and Fe^{II} complexes. The methylene proton signals appeared at 2.50 and −0.91 ppm for the Fe^{II} and Fe^{III} complexes respectively. Each value is in good agreement with the mean of the δ's for H^{2a} and H^{2e} of the *R*-pn chelate: 2.39 and −1.33 ppm for the Fe^{II} and Fe^{III} complexes respectively. This agreement indicates that the axial and equatorial methylene protons are averaged by the rapid interconversion of the chelate ring between δ and λ conformations.[11,19]

(1*R*,2*R*)-*trans*-Cyclohexanediamine Complex. The Fe^{II} complex, $[Fe(CN)_4(R\text{-chxn})]^{2-}$, shows three ^{13}C signals in the usual region: C^1, 60.6; C^2, 35.6; C^3, 25.3 ppm. This assignment is based on the multiplicity in the off-resonance experiment (a doublet, a triplet, and a triplet) and the electron withdrawing effect of the amino groups.

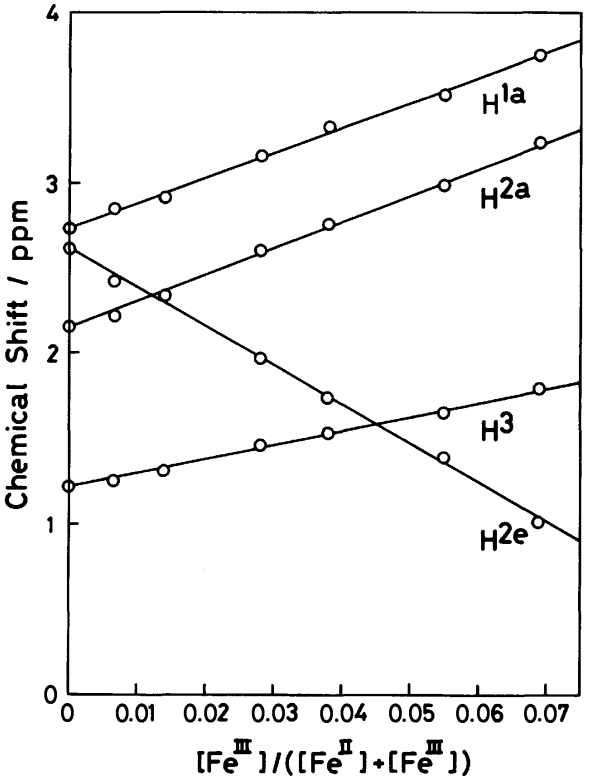

Fig. 4. Plots of chemical shifts of ^{1}H resonances of the mixture of $[Fe(CN)_4(R\text{-pn})]^{2-}$ and $[Fe(CN)_4(R\text{-pn})]^-$ vs. mole fractions of the Fe^{III} chelate.

The ^{13}C NMR spectrum of the corresponding Fe^{III} complex, shown in Fig. 5A, exhibited three signals — at 258.3, −18.9, and 30.0 ppm. These signals were correlated to those of the Fe^{II} complex as follows by means of the variation experiments: 258.3→60.6; −18.9→35.6; 30.0→25.3 ppm. They were thus assigned to C^1, C^2, and C^3 respectively.

The ^{1}H NMR spectrum of the Fe^{II} complex, shown at the top of Fig. 6, exhibited only three peaks — at 2.04, 1.65, and 1.16 ppm, with an area ratio of 2:1:2. These peaks have previously been assigned to a composite of H^{1a} and H^{2e}, H^{3e}, and a composite of H^{2a} and H^{3a} respectively.[6]

The Fe^{III} complex showed four ^{1}H NMR signals, with an area ratio of 1:2:1:1, at 15.98, 10.86, 6.61, and 1.49 ppm. These signals were correlated to those of the Fe^{II} complex by means of the variation experiments (Fig. 6). The results of the signal correlation are shown in Fig. 7.

The ^{1}H signals of the Fe^{III} complex were assigned in the following way. The signal at 1.49 ppm was correlated to the signal at 1.65 ppm attributable to H^{3e} for the Fe^{II} complex, and so it was assigned to H^{3e}. The ^{1}H selective irradiation at 6.61 or 1.49 ppm changed the Fe^{III} C^3 signal from a double-doublet (Fig. 5B) to a doublet, as is shown in Figs. 5C and D. Thus, the signal at 6.61 ppm was assigned to H^{3a}. Since the H^{1a} and H^{2a} in the Fe^{III} *R*-pn complex

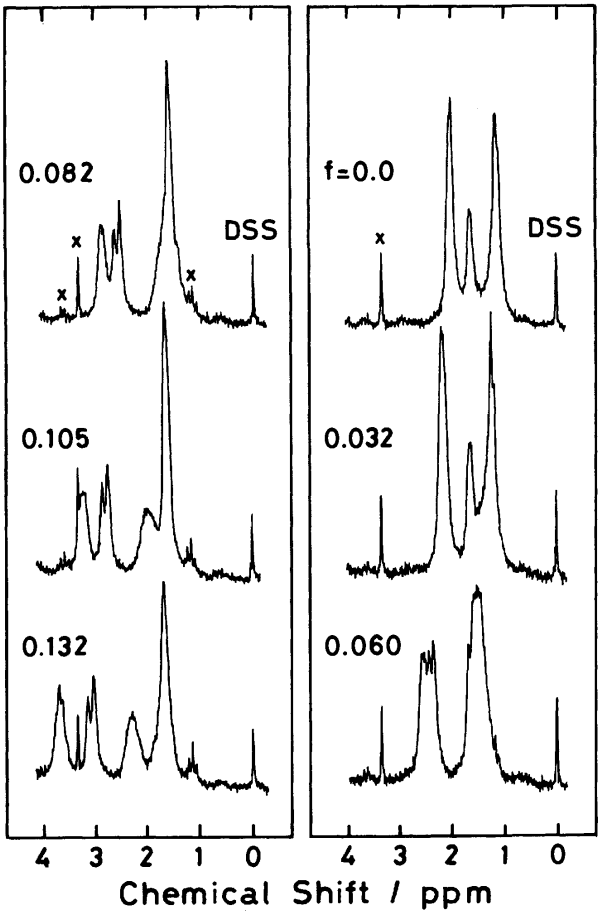

Fig. 6. ^{1}H NMR spectral changes of $[Fe(CN)_4(R\text{-chxn})]^{2-}$ on addition of $[Fe(CN)_4(R\text{-chxn})]^-$ in 10^{-2} mol dm^{-3} DCl. f: Mole fraction of the Fe^{III} chelate. X indicates signals due to methyl and ethyl alcohols.

resonated at the most downfield position, the signal at 15.98 ppm was assigned to H^{1a}. The remaining peak at 10.86 ppm corresponds to the two peaks at 1.16 and 2.04 ppm for the Fe^{II} complex and consists of H^{2a} and H^{2e} signals, with, incidentally, the same chemical shift.

***N,N'*-Dimethylethylenediamine Complex.** The s-Me_2en complex is able to adopt two kinds of geometrical isomers on coordination to a metal ion. A pair of the racemic form with two pseudoequatorial methyl groups is known to be more stable than the meso form with a pseudoaxial and a pseudoequatorial methyl group.[11,19]

The isolated $[Fe^{III}(CN)_4(s\text{-}Me_2en)]^-$ showed three ^{1}H NMR signals — at 19.84, −12.84, and −17.59 ppm with an area ratio of 1:1:3. The last signal was assigned to the methyl protons, H^2, on the basis of the area ratio. Since the Fe^{III} R-pn complex showed H^{2a} and H^{2e} signals at 17.40 and −20.05 ppm, the former two signals of the Fe^{III} s-Me_2en complex were assigned to H^a and H^e respectively. The separation of the H^a and H^e shifts by ca. 33 ppm shows that the Fe^{III} complex is the racemic form. The ^{13}C NMR spectrum

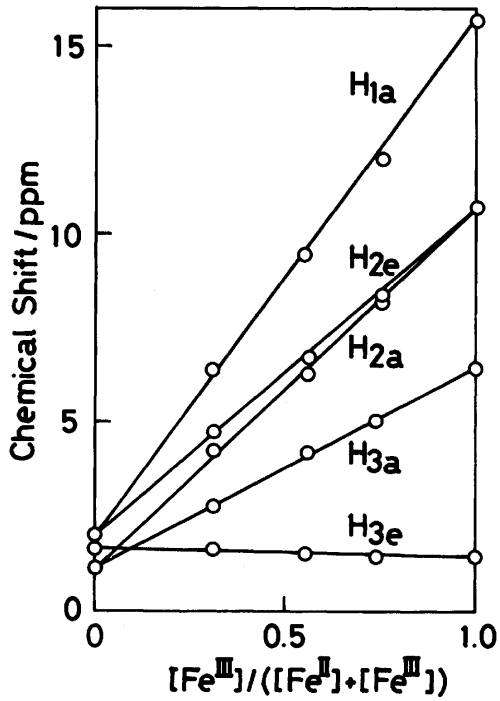

Fig. 7. Plots of chemical shifts of the mixture of $[Fe(CN)_4(R\text{-chxn})]^{2-}$ and $[Fe(CN)_4(R\text{-chxn})]^-$ vs. mole fraction of the Fe^{III} chelate.

of the Fe^{III} complex showed the methyl(C^2) and methylene(C^1) carbon signals at 156.1 and 301.1 ppm respectively.

The isolated Fe^{II} s-Me_2en complex showed the methyl signal at 2.52 ppm as a singlet and the methylene signals as an A_2B_2 multiplet, the apparent doublets of which at 2.12 and 2.78 ppm were assigned to H^a and H^e respectively, according to the results of Tiethof and Cooke.[26] However, the ^{13}C NMR spectrum of the isolated Fe^{II} complex exhibited two signals for the methylene carbon — at 54.2 and 52.8 ppm, with an intensity ratio of ca. 2:1, along with a single methyl signal at 41.8 ppm.[13] The cobalt complex isostructural to the Fe^{II} complex, $[Co^{III}(CN)_4$(s-Me_2en)]$^-$, also exhibited two methylene-carbon signals in a ratio of ca. 2:1.[27]

The results presented above suggest that the isolated Fe^{II} complex contained the racemic and meso isomers, while the isolated Fe^{III} complex consisted of only the racemic isomer. Since the meso isomer of the Fe^{III} complex was expected to have been eliminated during the procedures for isolation, the Fe^{II} complex was oxidized under acidic conditions and the resulting mixture was employed for NMR measurement without undertaking any procedure for separation. The two methylene and one methyl ^1H signals expected for the meso Fe^{III} complex were found at 6.40, 0.36, and −16.75 ppm, with an intensity ratio of 1:1:3, in addition to those for the racemic form. The chemical-shift difference of ca. 6 ppm between the two methylene singals is quite small compared with that of ca. 33 ppm for the racemic form. The s-Me_2en chelate in the meso isomer exists as an equilibrium mixture of the δ and λ forms shown in Fig. 8. Although the four methylene protons in each form are in a different magnetic environment because of the two unsymmetrical methyl groups, the conformational interconversion of the chelate ring between the two forms magnetically replace H^{1a} and H^{1e} with H^{2e} and H^{2a} respectively. Since the interconversion is very rapid in the NMR time scale at room temperature, each couple of the protons shows a mean signal. However, the difference in the chemical shift between the two mean signals can be expected to be much smaller than that for the racemic isomer, firstly because each mean signal is the average of an axial and an equatorial proton signal, and secondly because the difference in chemical shift between them arises only from the difference in position relative to the two methyl groups. Thus, the observation of the two mean signals of the methylene protons with a small separation from each other confirms the assignment of these signals to the meso isomer. The population of these isomers was obtained as racemic:meso=1.7:1 based on the signal intensities. Since the intensity ratio observed for the ^{13}C NMR spectrum of the isolated Fe^{II} complex is almost the same as this population, the signals at 54.2 and 52.8 ppm were assigned to the methylene carbon of the racemic and meso isomers respectively.

The variation experiment using the isolated Fe^{II} and Fe^{III} complexes showed the two sets of methylene and methyl signals. The intensity ratio between them was ca. 2:1. However, the changes in chemical shift observed in the variation experiment were not proportional to the mole fraction of the Fe^{III} complex, for there are electron exchange reactions among the racemic Fe^{II}, meso Fe^{II}, racemic Fe^{III}, and meso Fe^{III} complexes. The major and minor sets of signals, however, were correlated to the signals of the racemic and meso Fe^{III} complexes respectively. The analysis of this system will be described elsewhere.

The following arguments will be restricted to the racemic form.

Isotropic Shifts of the Fe^{III} Complexes and Comparison with Those of Ni^{II} Complexes. Isotropic shift for the Fe^{III} complex, δ^{iso}, is defined as the difference in chemical shift between the Fe^{III} and the corresponding Fe^{II} complexes: $\delta^{iso}=\delta_{Fe^{III}}-\delta_{Fe^{II}}$. The isotropic shifts are summarized in the third column of Table 1. The isotropic shifts of several $[Ni^{II}(H_2O)_{6-2x}$(diamine)$_x]^{2+}$,[19,28] defined as $\delta^{iso}=\delta_{Ni^{II}}-\delta_{free\ amine}$, are also incorporated in Table 1 for the sake of comparison.

The isotropic shift is the sum of two contributions: the Fermi contact shift (δ^{con}) and the dipolar shift (δ^{dip}). Since the distribution of the two unpaired spins in the $t_{2g}^6e_g^2$ configuration is spherical, δ^{dip} has been regarded as near zero for Ni^{II} complexes. Thus, the δ^{iso}'s for Ni^{II} complexes have been regarded as δ^{con}'s.[29]

A low-spin Fe^{III} complex has, on the other hand, a large magnetic anisotropy, and both terms contribute

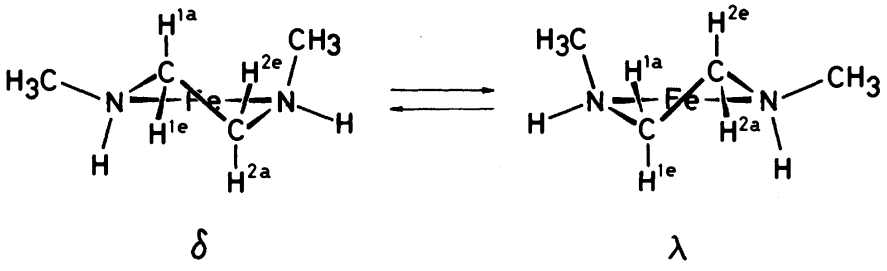

Fig. 8. Schematic structures of the meso s-Me_2en chelate. Fe=Fe(CN)$_4$

to δ^{iso}. If the δ^{iso} for the Fe^{III} complex arises from the Fermi contact interaction, the difference in spin transfer mechanism between low-spin Fe^{III} (L→vacant e_g) and Ni^{II} (L→singly occupied e_g) predicts that the sign of δ^{iso} for Fe^{III} is the opposite of that of Ni^{II}.[30] The observed sign of δ^{iso} is not, however, always opposite to that of the Ni^{II} complex, as represented by protons axial to the chelate ring. This confirms that both contributions operate in the Fe^{III} complexes. Qualitatively, however, the δ^{con} for Fe^{III} complex can reasonably be assumed to have the sign opposite to that of the Ni^{II} complex, but the magnitude is not necessarily the same.

Location Dependence of ^{13}C Isotropic Shifts. Carbon atoms bonded to the nitrogen have large positive δ^{iso}'s: 190—250 ppm for members of the chelate ring and 114 ppm for *N*-methyl carbon. The carbon atoms separated by one C–C bond from them, such as C^2 in *R*-chxn and C^3 in *R*-pn, have the smaller negative δ^{iso}'s of −54.5 and −68.8 ppm. The third carbon atom in *R*-chxn, C^3, has, in turn, the small positive δ^{iso} value of 4.7 ppm. ^{13}C δ^{iso} thus alternates in sign with each separation by one C–C bond and attenuates repidly as the number of bonds between the carbon and the Fe^{III} ion increases. This characteristic of ^{13}C δ^{iso} suggests that the Fermi contact shift, δ^{con}, predominates in ^{13}C δ^{iso} for the present Fe^{III} complexes; i.e., the unpaired electron spin is propagated through N–C and/or C–C bonds, mainly by the spin polarization effect.[31–33]

The δ^{iso} of the *N*-methyl carbon of the s-Me_2en complex is about half the δ^{iso} of the methylene carbon. However, the small difference in δ^{iso} between the methyl C^3 of *R*-pn and the methylene C^2 of *R*-chxn indicates that the spin is propagated more easily to the chelate ring than to the *N*-alkyl groups in the present Fe^{III} complexes.

The isotropic shifts of the relevant Ni^{II} complexes have been reported only for en and pn complexes.[28] The ratios of δ^{iso} for the Ni^{II} complexes to δ^{iso} for the Fe^{III} complexes are between −1.4 and −1.8 for the carbons on the chelate rings. This invariance of the ratio shows that Fermi-contact interaction makes the main contribution to the ^{13}C paramagnetic shifts of the Fe^{III} complexes as well as those of the Ni^{II} complexes.

Orientation Dependence of ^1H Isotropic Shifts. The axial protons on the five-membered chelate ring have shown positive δ^{iso}'s: 14.66 and 15.24, 13.94, and 17.72 ppm for the *R*-pn, *R*-chxn, and s-Me_2en complexes respectively. On the other hand, the equatorial protons have shown negative δ^{iso}'s: −22.66 and −15.62 ppm for the *R*-pn and s-Me_2en complexes. The results show that the axial and equatorial protons on the five-membered chelate ring show δ^{iso} values opposite in sign, whereas significant δ^{iso} values have been observed in Ni^{II} complexes only for equatorial protons.[11,19]

In the *R*-chxn complex, both protons bound to the carbon atom next to the chelate ring have positive δ^{iso}'s: H^{2a}, 9.70; H^{2e}, 8.82 ppm, but the δ^{iso}'s for protons bonded to the third carbon atom are different in sign and magnitude from each other: H^{3a}, 5.45; H^{3e}, −0.16 ppm. Thus ^1H δ^{iso} depends strongly upon the location and orientation of each nucleus within the molecule.

All axial protons have positive δ^{iso} values, which attenuate monotonously with the distance between the axial proton and the paramagnetic center, the Fe^{III} ion. However, the δ^{iso} value for the equatorial proton varies its sign with each separation by one C–C bond and attenuates more rapidly than that for the axial proton. Furthermore, the sign of δ^{iso} for each equatorial proton is opposite to that for the carbon atom to which the proton is bonded. These observations form a striking contrast to the results for the axial protons, which always show positive δ^{iso} values, and suggest the predominance of δ^{con} in δ^{iso} for the equatorial protons, i.e., the predominance of the spin-polarization effect in contributing to the spin propagation from the carbon atom to the equatorial proton. The monotonous behavior of δ^{iso} for the axial protons, on the other hand, seems to be attributable to the dominance of the dipolar shift, δ^{dip}. Thus, the δ^{iso}'s for the axial and equatorial protons are different in magnitude and sign from each other, though they are bonded to the same carbon atom in the present Fe^{III} complexes.

The present work was partially supported by a Grant-in-Aid for Scientific Research (No. 61540452) from the Ministry of Education, Science and Culture.

Potentiometric Study of Equilibria in H^+-MoO_4^{2-}-$RAsO_3H^-$ (R=OH, C_6H_5, CH_3) Systems

Atsushi YAGASAKI, Hironobu TAKAHAMA, and Yukiyoshi SASAKI*
Department of Chemistry, Faculty of Science, The University of Tokyo,
Hongo, Bunkyo-ku, Tokyo 113
(Received March 7, 1987)

The equilibria $pH^+ + qMoO_4^{2-} + rRAsO_3H^- \rightleftharpoons (H^+)_p(MoO_4^{2-})_q(RAsO_3H^-)_r$ have been studied in 1 M Na(Cl) (1 M=1 mol dm^{-3}) at 25 °C by potentiometry. Heteropoly species which have q/r ratios higher than 5 have been found in the R=CH_3 and R=C_6H_5 systems besides the well known species of q/r=3. The species, denoted by (p,q,r) according to the equation above, (10, 7, 1), (11, 7, 1), and (11, 6, 1) are proposed as those high ratio species. The formation constant of each species has been determined. The result showed an apparent correlation with pK_a's of arsenic acid and its organic derivatives. Solution structures of the heteropoly species are also discussed.

Our preliminary investigations of the molybdate-methylarsonate and molybdate-phenylarsonate equilibria[1,2] indicated the existence of heteropolyanions of high (≥4) Mo/As ratios, which were supposed to have novel structures, in addition to the As_2Mo_6 species. Some evidence of the correlation between the formation constants of heteropolyanions and the pK_a's of arsonic acids was also obtained.

We have carried out a thorough investigation of those systems. This paper reports the results of the investigation.

Method of Analysis

The equilibria for various heteropolymolybdates can be represented by the generalized equation

$$pH^+ + qMoO_4^{2-} + rC \rightleftharpoons (H^+)_p(MoO_4^{2-})_qC_r \quad (1)$$

where C stands for the heteroatom source. For brevity the complex $(H^+)_p(MoO_4^{2-})_qC_r$ will be referred as (p,q,r). The symbol β_{pqr} will be used to represent the formation constant for the (p,q,r). Hence,

$$\beta_{pqr} = \frac{[(p,q,r)]}{h^p b^q c^r} \quad (2)$$

where h=[H^+], b=[MoO_4^{2-}], and c=[C], and the units are molarity. The condition for mass balance requires

$$H = h + \Sigma p\beta_{pqr}h^p b^q c^r \quad (3)$$

$$B = b + \Sigma q\beta_{pqr}h^p b^q c^r \quad (4)$$

and

$$C = c + \Sigma r\beta_{pqr}h^p b^q c^r. \quad (5)$$

H, B, and C stand for the formal stoichiometric concentrations of the reactants H^+, MoO_4^{2-}, and C, repectively. If the constants β_{pqr}'s are given, it is possible to calculate H, b, c, and $[(p,q,r)]$ for a solution of known h, B, and C by solving Eqs. 3—5. A set of (p,q,r)'s and β_{pqr}'s, that minimizes the difference between those calculated values and the observed values, was obtained using the least-squares method.

Experimental

Chemicals. NaCl (Matsunaga, JIS primary standard) was used after heating at 150 °C for 8 h. Molybdate stock solutions were prepared by using twice recrystallized $Na_2MoO_4 \cdot 2H_2O$ (Wako, S). $Na_2HAsO_4 \cdot 7H_2O$ (Wako, S) was used without further purification. $C_6H_5AsO_3HNa$ was obtained by reacting $C_6H_5AsO_3H_2$ (Wako) with an equivalent amount of NaOH (Wako, S). The crude product was recrystallized twice from water. $CH_3AsO_3Na_2 \cdot 6H_2O$ was prepared according to Quick.[3] The product was purified by dissolving in a small amount of water and reprecipitating with ethanol.

Apparatus and emf Measurements. All the emf measurements were performed at 25.0±0.1 °C in 1 M Na (Cl) medium. The cell assembly was immersed in an oil thermostat, which was placed in a thermostatted room. During the experiments a stream of N_2 gas was bubbled through the solution for removing dissolved O_2. N_2 gas from a cylinder was bubbled through solution of 10% NaOH, 10% H_2SO_4, and pure ionic medium before it came into contact with the equilibrium solution.

Potentiometric titrations were performed with an automated titrator equipped with Dosimat E 415 burettes.[4] The hydrogen ion concentration, h, was determined by measuring the emf of the cell,
−Ag, AgCl/1M NaCl/equilibrium solution/glass electrode +.
The Ag, AgCl reference electrode was prepared according to Brown.[5] TOA Electronics HGS-2005 glass electrodes were employed. The salt bridge was of the "Kawai" type.[6] In each titration, h was varied by addition of dilute hydrochloric acid.

The reading of the emf reached a stationary value within a few minutes. For each titration point the emf was checked and found to be stable within 0.1 mV over a period of 20 min. No precipitation was observed during the series of titrations.

The mathematical analysis of the emf data was performed with the least-squares program LETAGROPVRID version ETITR.[7] The computation was performed on the HITAC M-280H/M-200H and M682H systems of the Computer Centre of the University of Tokyo. The function $U=\Sigma(H_{calc}-H)^2$ was minimized. Separate determinations of the equilibrium constants were performed for the

binary equilibria, H^+-$HAsO_4^{2-}$, H^+-$C_6H_5AsO_3^{2-}$, and H^+-MoO_4^{2-}.[1,8]

Results

H^+-MoO_4^{2-}-$C_6H_5AsO_3H^-$ System. Eight titrations were performed and 322 experimental points were obtained. The titrations covered the ranges $5.8 \geqq -\log h \geqq 2.0$, $39.0 \geqq B/\text{mM} \geqq 21.0$, $50.0 \geqq C/\text{mM} \geqq 4.7$, and $6.4 \geqq B/C \geqq 0.71$.

When only the known binary equilibria, H^+-MoO_4^{2-} and H^+-$C_6H_5AsO_3H^-$, are assumed to be present, the residuals $\Delta H = H_{calc} - H$ are very large and show systematic deviations, suggesting the existence of ternary equilibria, H^+-MoO_4^{2-}-$C_6H_5AsO_3H^-$.

Although the complexes (9,6,2) and (10,6,2) explained the data of low ($\leqq 3$) B/C ratios satisfactorily, speciation for the solutions of higher B/C ratios was less unambiguous. Three models, which are partly different in the choice of polyanions formed, explained the data equally well. The U values differ from one another only slightly, and this fact makes a simple selection based on the error-squares sum alone unrealistic. The numerical values of the formation constants are given in Table 2.

H^+-MoO_4^{2-}-$CH_3AsO_3H^-$ System. Twelve titrations were performed and 306 experimental points were obtained. The titrations covered the ranges $6.1 \geqq -\log h \geqq 2.0$, $48.0 \geqq B/\text{mM} \geqq 18.0$, $11.0 \geqq C/\text{mM} \geqq 3.6$, and $9.1 \geqq B/C \geqq 3.4$. The analysis was based on a preliminary report on the equilibria in this system.[1] The result is given in Table 3. As was the case in the H^+-MoO_4^{2-}-$C_6H_5AsO_3H^-$ system, it was not possible to choose the best model out of a number of the candidates by potentiometry alone.

H^+-MoO_4^{2-}-$H_2AsO_4^-$ System. Ten titrations were performed and 448 experimental points were obtained. The titrations covered the ranges $6.8 \geqq -\log h \geqq 2.0$, $39.0 > B/\text{mM} \geqq 18.0$, $13.0 \geqq C/\text{mM} \geqq 2.5$, and $12.0 \geqq B/C \geqq 2.0$. The best fit was obtained with the formation of (16, 9, 1), (15, 9, 1), (14, 9, 1), (13, 9, 1), (10, 6, 2), (9, 6, 2), and (8, 6, 2). The species (6, 5, 2), which was reported to exist in the 3M $Na(ClO_4)$ medium as a minor species,[9] was not needed to explain our data. Although a slightly better fit was obtained with the introduction of (p, 11, 1)'s to the system, it was not possible to explain the data without (p, 9, 1)'s. The formation constants obtained are given in Table 4.

Discussion

The existence of heteropolyanions of high ($\geqq 4$) Mo/As ratios in molybdoarsonate systems has been reconfirmed in the present research. However, our potentiometric investigation failed to determine the

composition of those species. The reason will become clear if we consider the proton consumption factor $z_{q+r}=p/(q+r)$ of those high ratio species. The proton consumption factors of (10, 7, 1), (11, 7, 1), and (10, 6, 1), the high ratio species of model a, are 1.25, 1.38, and 1.43, respectively, while (9, 6, 1), one of the species of model b, has z_{q+r} of 1.29. The high ratio species of model c, namely (12, 9, 1), (13, 9, 1), and (14, 9, 1), have z_{q+r} of 1.20, 1.30, and 1.40. As a result, each of the three models for the molybdoarsonate systems would consume about the same amounts of proton as a whole. This means that potentiometry connot make a clear distinction among the three models, since in potentiometry we measure the proton concentration from which the average proton consumption $Z_{B+C}=(H-h)/(B+C)$ is calculated.

It is true that species other than those listed in Tables 2 and 3 cannot be totally excluded. In fact the combination of (6, 4, 1) and (7, 4, 1) gives a fairly good fit so far as B/C is not larger than 5.[1] In spite of this, we have selected the three models listed in Tables 2 and 3 from numerous possible combinations

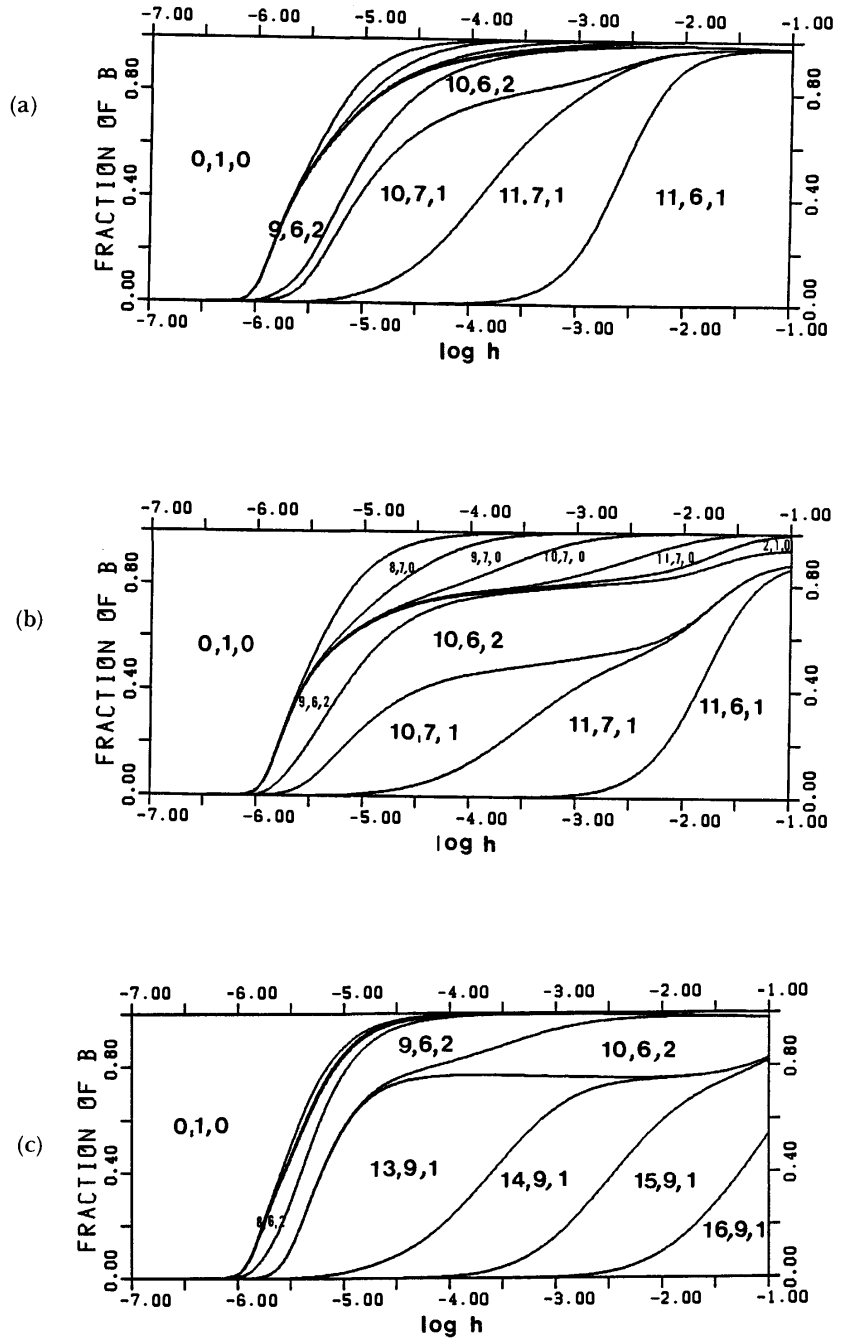

Fig. 1. Distribution of Mo among different species in H^+-MoO_4^{2-}-$RAsO_3H^-$ systems at B=30 mM and C=5 mM. (a) R=CH_3. (b) R=C_6H_5. (c) R=Oh.

as the final candidates for the molybdoarsonate systems, since the essence of least-squares analysis is to find the simplest possible model for a given system.

Among the three possible models for the molybdoarsonate system, we select model a in Tables 2 and 3, the combination of (p, 7, 1) and (11, 6, 1), as the most plausible one. Those are the species found in the molybdate-phenylphosphonate system, which have been studied by a combined emf-NMR method.[10] It is not likely that the molybdate-arsonate equilibria are totally different from the molybdate-phosphonate equilibria, since the molybdate-arsenate systems and molybdate-phosphate systems exhibit a nature similar to each other.

In the case of the H^+-MoO_4^{2-}-$H_2AsO_4^-$ system, it was possible to explain the data either with or without the $AsMo_{11}$ species. Considering the results of recent reports on the molybdate-phosphate system,[11,12] it is highly plausible that the $AsMo_6$ and $AsMo_{11}$ species co-exist in solution, in which case it is virtually impossible to determine the formation constants of them from potentiometric data alone.

The high ratio ($q/r \geqslant 6$) species of the molybdate-arsonate systems, except (11, 6, 1) of the H^+-MoO_4^{2-}-$CH_3AsO_3H^-$ system, are weak complexes. Whenever a notable amount of those species are formed, isopolymolybdates appear in a condiberable amount. This is the marked difference between the molybdate-arsonate system and molybdate-arsenate system. In the latter, isopolymolybdates hardly exist when $B/C \leqslant 9$.

The formation constants for the three systems are compared in Table 5. There exists a correlation between the formation constants of heteropolyanions and the pK_a's of arsenic and arsonic acids. The formation constants of the corresponding species increase as the pK_a increases, i.e. a certain heteropolyanion forms at a higher pH if a substance which has a greater pK_a is used to introduce heteroatoms. This tendency is clearly illustrated in Fig. 1, especially for the $AsMo_6$ species. While only 30% of the molybdenum in solution is bound in (11,6,1) at $-\log h = 2$, more than 90% is consumed to form the anion (11, 6, 1) in the molybdate-methylarsonate system at the same $-\log h$. It would be possible to obtain the As_4Mo_{12} species, which has been isolated from solution of pH<1,[13] from a less acidic solution if an arsonate which has still larger pK_a's is prepared without altering the basic tetrahedral structure very much.

Table 5. Comparison of the Formation Constants

(p, q, r)	$\log \beta_{pqr}$		
	R=CH_3	R=C_6H_5	R=OH
(9, 6, 2)	64.38	63.71	63.42
(10, 6, 2)	69.16	68.99	66.91
(11, 6, 1)	66.27	64.41	
(10, 7, 1)	67.83	67.23	
(11, 7, 1)	71.79	70.80	

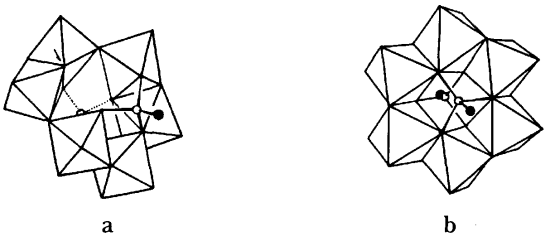

Fig. 2. Polyhedral model of (10, 6, 2). Each octahedron represents an MoO_6 unit. Open circles represent As atoms. R groups are represented by filled circles. An arrow indicates the position of the water molecule.

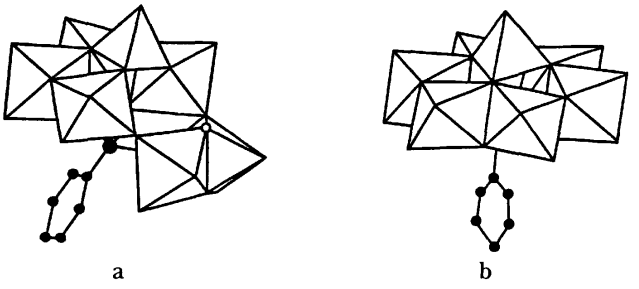

Fig. 3. Polyhedral model of (11, 7, 1). Large and small filled circles represent As and C atoms respectively. The water molecule is represented by an open circle. A tetrahedron represents an MoO_4 unit.

The species (10, 6, 2) is supposed to have the structure shown in Fig. 2a. The anion $[(C_6H_5As)_2Mo_6O_{24}(H_2O)]^{4-}$, which has the same composition as (10, 6, 2) of the H^+-MoO_4^{2-}-$C_6H_5AsO_3H^-$ system, is known to have this structure in crystals.[14] The structure shown in Fig. 2b is also possible for (10, 6, 2), and the anions $[(CH_3As)_2Mo_6O_{24}]^{4-}$ and $[H_2As_2Mo_6O_{24}]^{4-}$ have this structure in crystals.[15,16] However, IR, Raman, and ^1H NMR measurements have revealed that those anions are hydrated in aqueous solutions and have the structure shown in Fig. 2a.[16,17,18] Large-angle X-ray scattering was consistent with the structure shown in a and not with b.[19]

Both structures shown in Fig. 3 are possible for (11,7,1), and b is the one proposed for $[C_6H_5AsMo_7O_{25}]^{4-}$ by Klempere and co-workers from ^{17}O NMR measurements in anhydrous CH_3CN solutions.[20] Considering the fact mentioned above, the anions are likely to be hydrated in aqueous solution and have a structure like a. (10,7,1) can then be explained by dissociation of a proton from the water molecule. The same explanation would apply to (9,6,2) of the H^+-MoO_4^{2-}-$C_6H_5AsO_3H^-$ and H^+-MoO_4^{2-}-$CH_3AsO_3H^-$ systems.

The removal of the tetrahedral MoO_4^{2-} group from

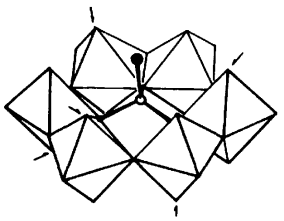

Fig. 4. Polyhedral model of (11, 6, 1). Arrows indicate the position of water molecules. Open and filled circles represent As atom and the organic group, respectively.

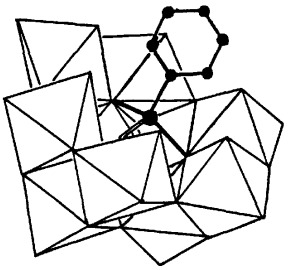

Fig. 5. Possible structure for (p, 9, 1) of the molybdate-arsonate system. Large and small filled circles represent As and C atoms respectively.

the structure shown in Fig. 3a and a slight rearrangement of the atoms yield the structure for the $RAsMo_6$ species, which is shown in Fig. 4. The anion $[CH_3AsMo_6O_{21}(H_2O)_6]^{2-}$, which has the same composition as (11,6,1) found in the H^+-MoO_4^{2-}-$CH_3AsO_3H^-$ system, has been reported to have this structure[21].

If it is (p,9,1) and not (p,7,1) that is formed in the molybdate-arsonate systems, the structure would be something like the one shown in Fig. 5.

All the structures shown in Figs. 3—5 are also possible in the inorganic molybdate-arsenate system. Those species might exist in the H^+-MoO_4^{2-}-$H_2AsO_4^-$ system as minor species.

The Formation of β-$LiFe_5O_8$ from Aqueous Suspensions and Its Properties

Masao KIYAMA,* Tokihiro KURATA,† and Toshio TAKADA††
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received March 18, 1987)

Alkaline suspensions containing iron(III) hydroxide and excess LiOH were subjected to aging at temperatures between 40 and 90 °C or to autoclaving at 120 °C or above. The resulting products, identified by X-ray analysis as a spinel phase, were further subjected to magnetic examination at 300 K, BET surface-area measurements, and electron-microscopic observation. The ferromagnetic precipitates of β-$LiFe_5O_8$ were formed at lower temperatures and less excess LiOH concentrations than those at which the nonferromagnetic precipitates of α-$LiFeO_2$ were formed. Their saturation magnetization increased near 60 emu g^{-1} (1 emu $g^{-1}=4\pi\rho10^{-4}$ T, where ρ=specific gravity) with the increase in their mean particle size, D, their coercive force depending on the D. With a rise in the temperature of the suspension, superparamagnetic particles with vacancies of the Li ion, intermingled with the ferromagnetic cubic particles, slowly grew to ferromagnetic particles and the composition approached $LiFe_5O_8$.

The ferromagnetic compounds of $LiFe_5O_8$, which has a cubic inverse spinel structure at room temperature, are obtained below 1000 °C in air by the use of a ceramic method. This compound is known to have two modifications, the ordered and disordered phases. The Li and Fe(III) ions in the octahedral(B) sites are distributed in an ordered ratio of 1:3 below 735 °C, while they are randomly disordered above 755 °C.[1] The Curie temperature and saturation magnetization are not affected by the ordering.[2]

The synthesis of $LiFe_5O_8$ from an aqueous suspension was achieved for the first time in 1980,[3] in this laboratory. In the present study, it has been found that iron(III) hydroxide can react with the Li ion in an alkaline suspension to form $LiFe_5O_8$ if we choose appropriate concentrations of the iron(III) and Li ions and a suitable reaction temperature: a nonferromagnetic precipitate of α-$LiFeO_2$ with a cubic, disordered structure[4] is also obtained.

This paper will deal with the conditions needed for the formation of $LiFe_5O_8$ and its properties.

Experimental

The starting suspensions of a gelatinous precipitate of iron(III) hydroxide were prepared by adding an excess LiOH solution to an acidic solution of iron(III) nitrate (each of an analytical grade). A number of alkaline suspensions, varying in their excess LiOH concentrations, were also prepared. Each suspension was diluted with conductivity water to 1 dm^3 in a 1.3-dm^3 flask equipped with five inlet necks. The construction of the flask was similar to what has previously been described,[5] except that an electrode for a self-recording pH meter was not inserted. The individual 1-dm^3 suspensions, containing 0.2 M (1 M=1 mol dm^{-3}) Fe(III) and different excess LiOH concentrations in the 0.03—3.0 M range, were heated and kept at desired temperatures ranging from 40 to 90 °C, and nitrogen gas was bubbled into for 5 h at a constant rate of 250 dm^3 h^{-1} for effervescent aging.

A number of alkaline suspensions (0.2 dm^3), each containing 0.2 M Fe(III), were also prepared in a 0.3-dm^3 stainless steel autoclave by varying the excess LiOH concentration in the 0.03—3.0 M range. They were then heated at the rate of 4 °C min^{-1} to the desired temperature. They were kept at temperatures ranging from 120 to 280 °C with mechanical stirring at 100 rpm for 5 h and then allowed to cool to room temperature.

The resulting products were separated by filtration, washed several times with water, treated with acetone, and then dried at 30 °C in air. The products, which were found, by means of an X-ray diffraction examination using Co $K\alpha$ radiation, to consist of the spinel phase, were then subjected to BET surface-area measurements using nitrogen and to an electron-microscopic examination. Each weighing 100 mg, they were then packed in a brass cylinder 0.6 cm in diameter and 0.2 cm in height, and magnetic measurements were carried out at room temperature in a magnetic field up to 10 kOe (1 kOe=$10^6/4\pi$ A m^{-1}), using a vibrating-sample magnetometer.

The mean particle size, D, of the $LiFe_5O_8$ samples was estimated from the BET surface area, S (m^2 g^{-1}), by assuming that the sample consisted of cubic particles with a specific gravity of 5.0. The average particle size, d, for the samples with $D<50$ nm was further estimated from the line broadening of the X-ray diffraction peak for the (311) plane of the $LiFe_5O_8$ crystal structure.

Results and Discussion

The formation at 0.2 M Fe(III) of the products by aging or by autoclaving is shown in Fig. 1 in terms of the concentration of the excess LiOH and the reaction temperature. Dark brown, ferromagnetic precipitates with the spinel structure are formed in the presence of an excess of LiOH of at least 0.3 M by selecting an appropriate concentration and temperature. Apparently, the range of the excess LiOH concentration needed for the formation of the ferromagnetic precipitate becomes narrower with an increase in the

† Present address; Toda Kogyo Corp., 4, 1-2 Funairiminami, Hiroshima 733

†† Present address; Okayama University of Science, Ridai-cho, Okayama 700

temperature beyond 120 °C. Nonferromagnetic precipitates, each consisting of spherical α-$LiFeO_2$ particles, are formed in the ranges of excess LiOH concentrations and of autoclaving temperatures higher than those at which the ferromagnetic precipitates are formed.

The properties of five typical samples with the spinel structure, A through E, are given in Table 1. Electron-microscopic examination indicates that the growth of some of the extremely fine particles with the spinel structure begins at 120 °C and is promoted by a rise in the temperature (Fig. 2). The elevation of the temperature causes a significant increase in *d*, but only a slight increase in the *D* because of the extremely fine particles remaining in each sample. An increase in the difference between the *D* and *d* values for the sample shows that the particle-size distribution becomes wider. The magnetization, *M*, at 10 kOe and the coercive force, *Hc*, depend on the *d* and *D*.

The Mössbauer spectra of several $LiFe_5O_8$ samples with different *D* values, all taken at room temperature, are shown in Fig. 3. The sample with 4.7 nm in *D* consists only of superparamagnetic particles (Fig. 3(a)), and as the *D* value increases, the superparamagnetic particles coexist with the ferromagnetic

particles, until the former decrease (b and c). It is possible to prepare the samples with $D>15$ nm at 200 °C, as will be described later, by increasing the concentration of the Fe(III) in the starting suspension or by prolonging the reaction time. Such samples contained no superparamagnetic particles (Fig. 3(d)), and their hyperfine fields (49.4 T) were almost the same as that of $LiFe_5O_8$ prepared by a ceramic method.[6]

An increase in the Fe(III) concentration in the starting suspension under the conditions where the ferromagnetic precipitate was formed was found to cause an increase in D, as will be described below. The suspensions containing a 0.6 M excess of LiOH and either 0.1, 0.5, or 1.0 M Fe(III) were also prepared and subjected to autoclaving at 200 °C. The ferromagnetic precipitates thus obtained consisted of extremely fine particles, the cubic ones being 80—140 nm in size. As the Fe(III) concentration was increased, their D values increased from 14 to 23 nm without any appreciable change in the d (50—53 nm).

In order to examine the effect of the reaction time on the particle growth, suspensions, each containing 0.2 M Fe(III) and a 0.6 M excess of LiOH, were subjected to aging at 70 °C or autoclaving at 150 and 200 °C for different times (t). The t-dependence of the d and D values at 200 °C becomes significant after 10 h (Fig. 4). The extremely fine particles were found, by the use of an electron microscope, to coexist with cubic particles 100 nm in size, even in the sample prepared by autoclaving at 200 °C for 50 h.

Similar experiments were also conducted using Fe(III) chloride or sulfate in place of the nitrate. No particular difference could be found in the conditions for the formation of the ferromagnetic precipitate and for the particle growth. The temperature for the formation of the ferromagnetic precipitate in the presence of sulfates may be raised slightly, as is evidenced by Sample F in the Table.

The M values of the ferromagnetic samples prepared under various conditions are plotted against their D values in Fig. 5. The M value increases with the D, reaching near 60 emu g^{-1}. When the M values were plotted against the d, they irregularly and

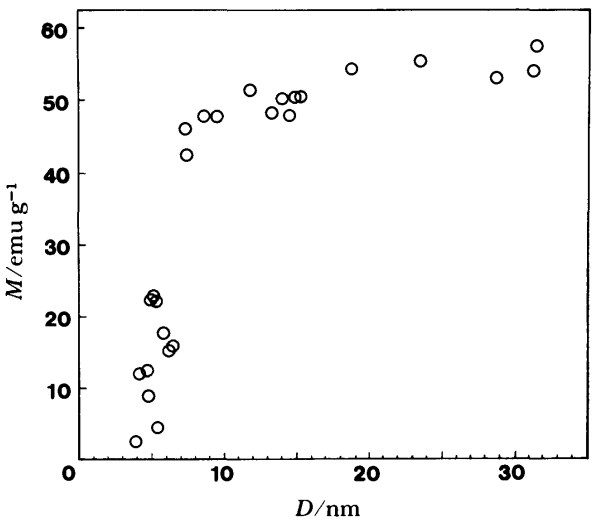

Fig. 5. Magnetization, M, at 10 kOe of $LiFe_5O_8$ samples plotted against their D values.

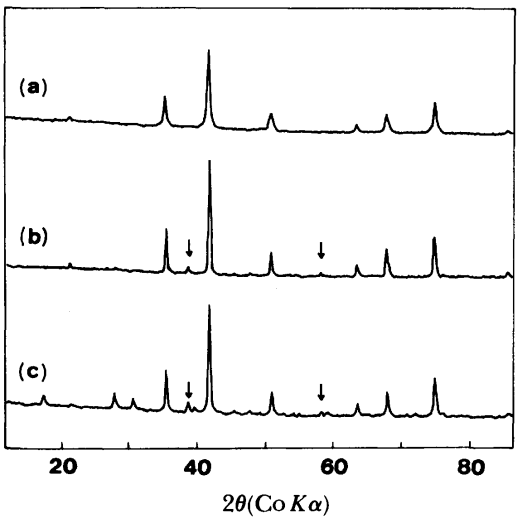

Fig. 6. X-Ray diffraction patterns of the β-$LiFe_5O_8$ sample E(a), and heat-treated samples by rapid cooling from 900 °C (b) and by slow cooling from 750 °C (c). Arrows in (b) and (c) indicate the peaks caused by the presence of α-Fe_2O_3.

remarkably increased to 40 emu g^{-1} with the increase in the d to 10 nm, while a further increase in d to 90 nm resulted in only a slight increase in M to near 60 emu g^{-1}. Presumably, an increase in the specific surface area causes an increase in the nonferromagnetic portion, which is reported to be the subsurface of the ferromagnetic particle, such as a γ-Fe_2O_3, $NiFe_2O_4$, CrO_2,[7] or $BaFe_{12}O_{19}$ particle.[8] Increasing the d values to 15 nm or the D values to 7 nm caused an increase in Hc to about 0.1 kOe as a result of the decrease in the number of superparamagnetic particles. A further increase in D or d resulted in a slight decrease in the Hc, probably because of the decrease in the number of single-domain ferromagnetic particles.

An X-ray diffraction examination showed that the ferromagnetic samples consisted of crystalline particles with a disordered spinel structure(β-$LiFe_5O_8$).[9] This indicates that the formation of β-$LiFe_5O_8$ proceeded at the temperatures where the β phase was unstable. The transformation between the α and β phases of the samples as a result of heat treatment in air was confirmed from the experimental results, where their structure remained unchanged upon rapid cooling from 900 °C, whereas it was transformed into an ordered spinel structure (α-$LiFe_5O_8$) by slow cooling from 750 °C (Fig. 6). Such heat-treated samples consisted of the spinel phase with or without the α-Fe_2O_3 phase; the content of α-Fe_2O_3 varied with the sample. Decreasing the D of the original samples from 15 to 8 nm caused a slight increase (to several %) in the content of α-Fe_2O_3, while a further decrease in the D to 4.7 nm resulted in an increase to 50% in its content. The formation of α-Fe_2O_3 by heat treatment indicates that the Li-ion content in the original sample was less than that in $LiFe_5O_8$. According to the chemical analysis by the use of inductively coupled plasma/atomic emission spectroscopy, the β-$LiFe_5O_8$ samples with $D>15$ nm contained Li and Fe ions in the atomic ratio (Li/Fe) of 0.2. This ratio decreased to 0.10 with the decrease in the D to 4.7 nm (Sample A).

In conclusion, the extremely fine particles, intermingled with ferromagnetic cubic particles, consisted of superparamagnetic and ferromagnetic particles. The superparamagnetic particles with vacancies of the Li ion slowly grew to ferromagnetic particles, and the composition approached $LiFe_5O_8$ when the D increased.

The Vapor Saturation Method for Preparing Aqueous Solutions of Solid Aromatic Hydrocarbons

Mayumi Akiyoshi, Toshio Deguchi, and Isao Sanemasa*
Department of Chemistry, Faculty of Science, Kumamoto University,
Kurokami 2-39-1, Kumamoto 860
(Received March 26, 1987)

A new method to prepare aqueous solutions saturated with solid aromatic hydrocarbons by making use of solute vapor is presented. Air is bubbled through an organic solvent in which an excess quantity of a solid hydrocarbon to be studied has been added, and the resulting vapor is introduced into water and circulated in a closed system. An aqueous solution saturated with a solid solute can thus be prepared in a short time without any need to remove solute microcrystals. Of benzene, cyclohexane, and 1-octanol used as organic solvents, 1-octanol is most promising for this purpose. Solubilities in water at 25.0 °C of nine aromatic hydrocarbons have been measured: Naphthalene, biphenyl, anthracene, phenanthrene, fluoranthene, (*o*-, *m*-, *p*-)terphenyl, and triphenylene. This method can be used for these solutes except phenanthrene.

The aqueous solubility of aromatic hydrocarbons is a fundamental physicochemical property important in both applied and theoretical chemistry. In recent years, partition studies on hydrophobic substances between 1-octanol and water have become of interest, which require convenient techniques to provide accurate solubility data.

For the preparation of aqueous solutions saturated with liquid or solid solutes, the most widely used technique is the "shake-flask" method.[1-14] This technique usually consists of two steps: (1) A mixture of water and an excess quantity of a solute is mechanically shaken for at least 24 h; (2) to ensure the removal of the excess solute phase, the mixture is allowed to stand for at least 24 h, centrifuged, or filtered. The second step is important in solubility measurements since hydrocarbons can exist in colloidal, micellar, or microparticulate form in appreciable quantities.

In order to speed up these time-consuming steps, the "generator column" method has recently been proposed.[15-19] This method adopts continuous pumping of water through a column filled with an inert support material, such as glass or quartz beads, coated with the solute of interest. When this method is combined with a second column packed with a hydrophobic support, the dissolved solute can be easily concentrated, and, moreover, in conjunction with the chromatographic technique, impurities in the solute material, when present, can be separated.

The aqueous solubility of various volatile nonelectrolytes has been observed to obey Henry's law.[20-24] This means that liquid or solid solute itself is not necessarily in contact with water to prepare aqueous solutions saturated with the solute, instead, the saturated vapor of solute at a constant temperature can be used. Based on this idea, we have proposed a method which involves a circulation of solute vapor in a closed system through water.[25] This technique has proved useful for saturating water with benzene or alkylbenzenes.[26-28] This technique, however, cannot be applied to such solutes as are present in solid state, probably due to the lack of effective vaporization of solid solute.

This study is concerned with the development of a new method to prepare aqueous solutions saturated with solid aromatic compounds. To a suitable organic solvent a solid solute to be studied is added in excess so that a part of the solute is always present in solid state in the solvent. Then, air is bubbled through the organic solvent, and the resulting vapor is introduced into water and circulated in a closed system. Our objects are (1) to compare solubility results with those reported in literatures, (2) to see the effect of organic solvents used to dissolve solid solutes on the solute aqueous solubility, and (3) to search such a possibility that the present method might offer some information about binary systems consisting of an aromatic hydrocarbon and an organic solvent.

Experimental

Materials. Distilled deionized water was used throughout this work. Naphthalene, biphenyl (98%), fluoranthene (98%), (*o*-, *m*-, *p*-)terphenyls, and triphenylene (97%), each of analytical reagent grade, and anthracene and phenanthrene, each of authentic (guaranteed) sample, were used as solutes without further purification; the minimum purities specified by the manufacturers (Wako Pure Chemical and Nakarai Chemicals Co.) are given in the parentheses. Benzene (99.5%), cyclohexane (99.5%), and 1-octanol (95%) were used as organic solvents to dissolve solid solutes. Amberlite XAD-2 resin (Rohm and Hass) of 80—100 mesh was used, when necessary, to concentrate solutes dissolved in water.

Apparatus and Procedures. The apparatus used for preparing aqueous solution saturated with solute vapor is essentially the same as that previously used,[25] except some minor modifications. The apparatus was composed of two main glass parts: a pear-shaped vessel of 30 cm^3 capacity in which a solid solute was placed together with an organic solvent (we call this vessel the "solute reservoir") and a pear-shaped vessel of 80 cm^3 capacity with a narrow orifice in the bottom in which up to 50 cm^3 water was placed (we

call this vessel the "solubility flask"). A Viton diaphragm airpump (Iwaki Type AP-32 Z) was incorporated into the assembly. The apparatus was fixed on a board and immersed, except the airpump part, in a water bath thermostated at 25.0±0.1 °C; the temperature of the airpump part was kept a few degrees higher than 25 °C.

An excess quantity of a solid aromatic hydrocarbon was added to an Erlenmeyer's flask and dispersed in an organic solvent by applying ultrasonic vibrations (Kaijo Denki "Sono Cleaner Mini") for ca. 1 h, and a 5—10 cm^3 portion with some solute crystals was pipetted out of the flask and transferred into the solute reservoir. By means of the pump, air was bubbled at a flow rate of ca. 0.5 or 1 $dm^3\ min^{-1}$ through the solute reservoir via a sintered glass ball, and the resulting vapor of the organic solvent and solid aromatic hydrocarbon was introduced through a trap into water in the solubility flask to disperse via a sintered glass ball, and circulated in a closed system.

After solubility equilibrium was attained, the apparatus was withdrawn out of the bath. A glass plug attached to the bottom of the solubility flask through a Teflon tube was removed, and a suitable portion of the aqueous phase was transferred to a 50 cm^3 cylindrical separatory funnel, in which 5 cm^3 of $CHCl_3$ had previously been placed; the funnel had been calibrated so that the volume of a water sample taken in can be read out to 0.1 cm^3. The extract, after dehydrated with anhydrous sodium sulfate, was analyzed with a Hitachi 100-50 spectrophotometer. In handling three solutes, anthracene, *p*-terphenyl, and triphenylene, 100 cm^3 of water sample (2×50 cm^3) was passed through an XAD-column and the solute adsorbed on the resin was eluted out with 5 cm^3 of $CHCl_3$.

Measurements were repeated on at least four water samples separately prepared, and the avarage was taken as the solubility.

Results

Factors Affecting Aqueous Solubility. The time required for saturating water with solute vapor will depend highly on the vapor circulation rate. In order to speed up the process, high circulation rates are desired. In practice, however, the rate was set at ca. 0.5 $dm^3\ min^{-1}$ for 1-octanol and at ca. 1 $dm^3\ min^{-1}$ for benzene and cyclohexane. With higher rates, the dead volume of the solute reservoir was so small that the organic solvent was caused to splash to a considerable degree into the adjacent trap. When 1-octanol, more viscous than the other two, was used, the circulation rate needed to be suppressed, otherwise part of the solvent was carried away into the trap.

At the prescribed circulation rate, the aqueous phase was found to become saturated with a solute in 30 min when benzene or cyclohexane was used as organic solvent and in 90 min in the case of 1-octanol. The results observed for naphthalene are shown in Fig. 1. The concentration of solute in the "saturated" aqueous solution was found to depend upon the organic solvent used to dissolve solid aromatic hydrocarbons. For three different solutes

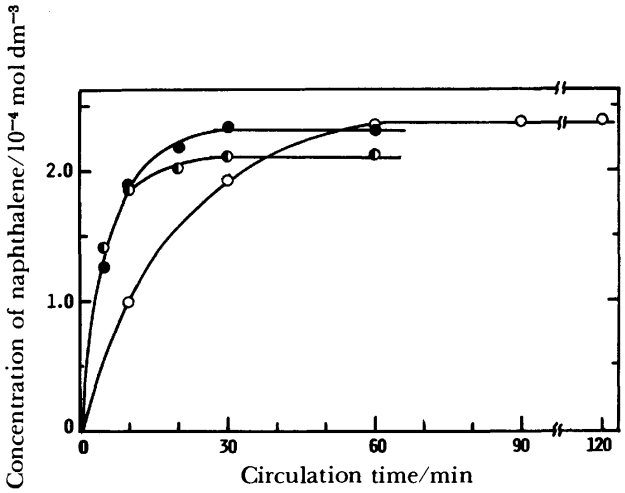

Fig. 1. Concentration of naphthalene in water at 25 °C vs. vapor circulation time. Vaporized from benzene(◐), cyclohexane(●), and 1-octanol(○) solutions.

Table 1. Dependence of Aqueous "Solubilities" of Naphthalene, Biphenyl, and *p*-Terphenyl on Organic Solvents Used to Dissolve the Solutes

Solute	Organic solvent used to dissolve the solute	Aqueous solubility measured/mol dm^{-3}
Naphthalene	Benzene	2.10×10^{-4}
	Cyclohexane	2.30×10^{-4}
	1-Octanol	2.35×10^{-4}
Biphenyl	Cyclohexane	3.92×10^{-5}
	1-Octanol	4.57×10^{-5}
p-Terphenyl	Benzene	3.8×10^{-8}
	1-Octanol	7.8×10^{-8}

the effect of organic solvents on their aqueous solubilities were studied (Table 1). The highest "solubility" was observed when the solid solute was dissolved in 1-octanol, while the lowest was observed with benzene.

Solubility of Solid Aromatic Hydrocarbons in Water. With 1-octanol as organic solvent, aqueous solutions saturated with solid aromatic hydrocarbons with two or three benzene rings were prepared, and each solubility at 25.0 °C was determined. The results are given in Table 2 together with literature values. There have been published a large number of data for naphthalene, biphenyl, anthracene, and phenanthrene and a less number for fluoranthene and triphenylene, but no data, to our knowledge, on terphenyls.

The present vapor saturation method was found inapplicable to phenanthrene; no reproducible results were obtained for this solute, and, moreover, the estimated "solubility" was far lower than the lowest literature value. Cyclohexane was used instead of 1-

Table 2. Solubilities of Solid Aromatic Hydrocarbons in Water at 25 °C

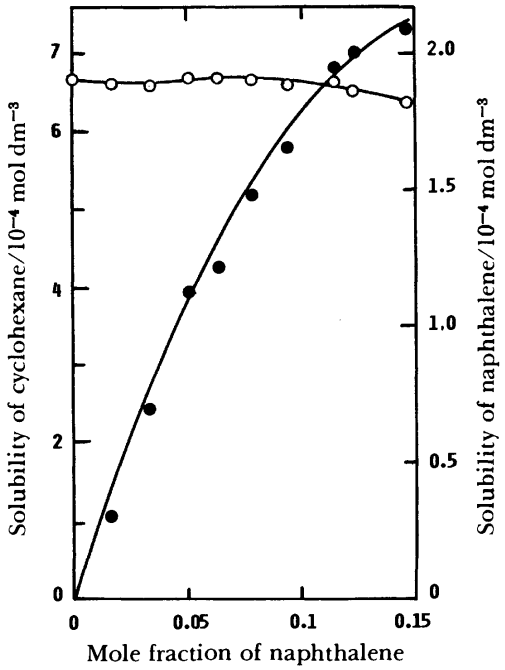

Fig. 3. Naphthalene-cyclohexane binary system. Aqueous solubility of naphthalene(●) and cyclohexane(○) at 25 °C.

octanol only to produce almost the same unsatisfactory results.

Naphthalene-Benzene and Naphthalene-Cyclohexane Binary Systems. A known quantity of naphthalene was added to a known amount of benzene or cyclohexane up to near saturation, and the vapor phase was circulated to saturate water. The concentration of each component in the water was measured after solubility equilibrium was attained.[29] The results are shown in Figs. 2 and 3 as a function of the mole fraction of naphthalene.

Discussion

Evaluation of the Present Method and Interpretation of Solubility Results. Although there are no available data on terphenyls, their solubility values estimated in this work seem to be reliable judging from their good reproducibility; the extremely low solubility observed for *p*-isomer may be ascribed to its relatively high melting point compared to the other two isomers. The generator column method gives an extremely low solubility for triphenylene,[16] but our value is in good agreement with the results obtained by the shake-flask method.

For anthracene, the solubility values reported to data are grouped into two well-defined values: 2.5 and 4.2×10^{-7} mol dm^{-3}. May et al.,[15] whose value belongs to the lower, attributed the higher value to the structural isomer, phenanthrene, present as an impurity. It is, however, still difficult to explain why one group is almost constantly 1.7 times as high as the other. When we consider that, as they insist, anthracene is contaminated with phenanthrene in at least 2% in most commercial products (the quantity sufficiently large for saturating water), that phenanthrene is ca. 20 times as water-soluble as anthracene, and that the molar absorptivity of phenanthrene is ca. 0.4 times that of anthracene at the same measuring wavelength in the same extractant, the "apparent" solubility of anthracene in water amounts to ca. 9 times the "true" solubility. Is there such a possibility that phenanthrene molecules once dissolved in water would come out to be held on the solid anthracene surface and that adsorption equilibrium would be realized between phenanthrene molecules in water and those in the solid surface to yield constantly the 1.7 times overestimated solubility of anthracene? Is there not such a possibility that anthracene molecules would dimerize in water in contact with solid anthracene? In any event, the present vapor saturation approach supports the lower value for this solute solubility.

The present method failed to saturate water with phenanthrene. At present we cannot provide satisfactory explanations to this failure. It is probable that the solid phenanthrene phase is to include 1-octanol molecules to form a complexed phase, presumably, with a changeable composition depending upon certain variables such as the ratio of solvent to solute and the size and surface state of solid particles. Since literature values themselves are scattered over a relatively wide range compared to the other solutes, we further speculate that water molecules also are more or less liable to be incorporated in the solid phenanthrene phase. There is, however, no evidence to support this.

Applicability of the Present Method. There are two potential applications of the method proposed here. One is to study the solubilizing effect of coexisting solutes such as surfactant on the aqueous solubility of solid aromatic hydrocarbons. Such studied should be conducted in the absence of solute phase of interest in excess, otherwise coexisting solute molecules will be adsorbed on the solid solute surface to change solution properties. The present method meets this requirement.

The other application of this method is to study the aqueous solubility of solid hydrocarbon as a function of its composition in an organic solvent used to dissolve the solid solute. Here, we have studied systems naphthalene-benzene and naphthalene-cyclohexane as examples. As can be seen from Figs. 2 and 3, the solubility of naphthalene increases almost linearly with its mole fraction in benzene, but this is not the case with cyclohexane. This seems to reflect the situation that the former system is nearly an ideal solution, whereas the latter system is far from being ideal.[30,31]

A question should naturally arise that the organic solvent phase is to get saturated with water vapor so as never to be made up by any "pure" binary system. We nevertheless approximate it a "binary" system, because the solubility of water in organic solvents such as benzene and cyclohexane is sufficiently low (in the case of 1-octanol this approximation is not valid because of high water solubility in this solvent).

The aqueous phase is to be saturated not only with the solid solute of interest but also with the organic solvent used to dissolve the solid solute, so that another question should arise as to whether any interaction between both the solutes takes place in the aqueous phase. Chiou et al.[32] have suggested a solubilization effect of 1-octanol; the solubility of a solute in water which has been saturated with 1-octanol is larger than that in 1-octanol-free water. This effect probably present itself only when there is an appreciable 1-octanol-solute interaction in the aqueous phase. Miller et al.,[19] on the other hand, have demonstrated, by using polynuclear aromatic hydrocarbons, biphenyl, and polychlorinated biphenyls as solutes, that 1-octanol saturated in water has little effect on the solubility of the substances in water. If any interaction does occur between solutes in water, benzene would have a stronger effect than 1-octanol and cyclohexane, because the concentration of benzene saturated in water is larger than those of 1-octanol and cyclohexane by one and two orders of magnitude, respectively.

It seems reasonable to interpret the dependence of the aqueous solubility of the solid hydrocarbon solutes on the organic solvents used to dissolve them (Table 1) in terms of the solute vapor pressure. We cannot discuss this point since no solute vapor pressures in the solute-organic solvent systems were measured in this study.

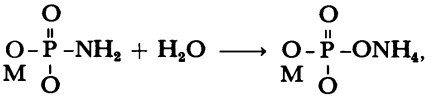
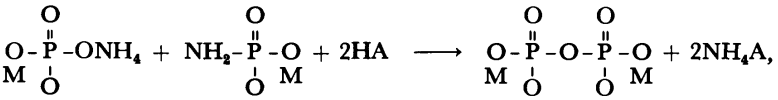
The Condensation and Decomposition of Alkaline Earth and Phenyl Phosphoramidates with Acids

Shoji SATO, Takao TAKAYANAGI, and Makoto WATANABE*
Department of Industrial Chemistry, Chubu University, Matsumoto-cho, Kasugai, Aichi 487
(Received April 21, 1987)

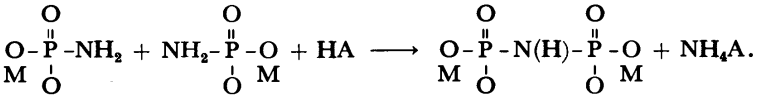
Alkaline earth and phenyl phosphoramidates were reacted with dried hydrogen chloride, acetic acid, and oxalic acid. The alkaline earth phosphoramidates other than the magnesium salt reacted with the acids to produce ortho- and polyphosphates, but did not react with them to make polyphosphates containing imino groups. The hydrolysis of the phosphoramidates to orthophosphate has been considered to be the initiation of the production of polyphosphates:



where M stands for an alkaline earth metal ion. The formation of polyphosphates can be explained, for example, by this equation:



where HA stands for acid. Magnesium phosphoramidate reacted with acetic acid and oxalic acid to produce orthophosphate, polyphosphates, and imidodiphosphate. The production of the imidodiphosphate can be indicated by the following equation:



There are many types of phosphorus-nitrogen compounds. Phosphazenes are the best-known and the most intensively investigated compounds because they can be used as inorganic rubber and have been thought to have widely varying applications in industry. Other phosphorus-nitrogen compounds have not yet been well-studied, however. Phosphoramidates can be used as a new type of chemical fertilizer, for they have a P-N covalent bond, and as flame-proof materials. They can also be used as starting materials for the preparation of many organic and inorganic phosphorus compounds. The present authors have previously reported the syntheses and thermal behavior of some phosphoramidates.[1-6] The phosphoramidates produced ortho- and polyphosphates and did not make polyphosphates containing imino groups when they were heated in air at a moderately high temperature (100—1000 °C). An amino group on phosphoramidates was, accordingly, thermally unstable in air, and it was impossible to make imidodiphosphate from phosphoramidates by thermal condensation. Therefore, in this work, the chemical reactions of alkaline earth and phenyl phosphoramidates with hydrogen chloride, acetic acid, and oxalic acid have been done in order to study the condensation and decomposition of the amino groups in the phosphoramidates.

Experimental

Preparation of Phosphoramidates. The phenyl phosphoramidate and potassium hydrogenphosphoramidate were prepared by the method described in Ref. 7. The alkaline earth phosphoramidates other than strontium phosphoramidate were prepared by wet processes.[3,4,6] The strontium phosphoramidate dihydrate, $SrPO_3NH_2 \cdot 2H_2O$, was prepared by this method: Strontium dichloride hexahydrate (5.4 g) was dissolved in 120 cm^3 of water, and the pH of the solution was adjusted to 10.5 with aqueous ammonia. Potassium hydrogenphosphoramidate (5.4 g) was dissolved in 400 cm^3 of water. The solutions were mixed by stirring at 5 °C, and a precipitate was filtered off. Acetone was added to the filtrate, and a white precipitate was filtered off, washed with 50 vol% aqueous ethanol and acetone, and then dried in air at room temperature (15—25 °C).

Reaction of Phosphoramidates with Hydrogen Chloride. About 3—5 g of a phosphoramidate sample was put in a reaction glass tube. Dried hydrogen chloride, which had been prepared by adding concentrated hydrochloric acid to concentrated sulfuric acid and by then passing the resulting gas through concentrated sulfuric acid, was introduced into the reaction tube. The reaction product was washed quickly with ethanol to remove the HCl gas adsorbed on the product.

Reaction of Phosphoramidates with Acetic Acid. About 2 g of a phosphoramidate sample was placed in a mixed

solution of 5 cm^3 of acetic acid and 20 cm^3 of chloroform. The resulting mixture was heated at 25 and 60 °C while being stirred. The solid product was filtered off and washed with ethanol. The phenyl phosphoramidate dissolved in a solution of acetic acid. After the reaction, water was added to the reaction mixture; a white precipitate was filtered off and subjected to further analysis.

Reaction of Phosphoramidates with Oxalic Acid. Oxalic acid (3 g) was dissolved in 100 cm^3 of ethanol, after which about 2 g of phosphoramidate was added to the solution. The mixture was heated at 25 and 60 °C while being stirred. The product was treated in the same way as in the reaction with acetic acid.

Quantitative Analysis of Nitrogen. The amount of total nitrogen and that of ammonium ions in a sample were measured by the Kjeldahl technique.

Paper Chromatography and Colorimetry of Phosphates. A sample (0.1 g) was dissolved in a 6% EDTA (disodium dihydrogen ethylenediaminetetraacetate dihydrate) solution by adjusting the pH of the solution to 9—10. The paper-chromatographic separation and the colorimetric determination of the phosphate species in the solution were performed by the method described in our previous paper.[1]

HPLC Technique. The HPLC system which was developed by Yoza was employed to achieve the separation and determination of phosphate species in a sample.[8] A separation column (2.6 mm×500 mm) with TSK-GEL (SAX-F0011), a Shimadzu spectrophotometer (UV-110-02), and the KCl eluents of 0.20 and 0.40 mol dm^{-3} were used to separate and determine the phosphate species in the sample solution. About 10 mg of the reaction product was dissolved in water or a 6% EDTA solution, and 200 mm^3 of the solution was injected into the column.

X-Ray Diffractometry. An X-ray diffraction diagram of a sample was taken with nickel-filtered Cu $K\alpha$ radiation using a Rigaku X-ray diffractometer, RAD-1B.

IR Spectrophotometry. An IR spectrum of a sample was recorded on a JASCO IR spectrophotometer, A-3, using the KBr disc method.

^{31}P NMR Measurement. The reaction products of alkaline earth phosphoramidates and that of phenyl phosphoramidate were dissolved in a 6% EDTA solution and ethanol respectively. The ^{31}P NMR spectra of the sample solutions were taken by means of a JNM-GX270 spectrograph. The chemical shifts are reported relative to external 85%-orthophosphoric acid, with the positive shifts being downfield.

Results and Discussion

Reaction with Hydrogen Chloride. The contents of nitrogen and phosphate species in the reaction products are presented in Table 1, along with the X-ray-diffraction data. The paper-chromatographic separation between phosphoramidate and orthophosphate could not be achieved with the developing solvents employed in this experiment. According to the results shown in Table 1, alkaline earth phosphoramidate reacted with HCl gas to produce ortho- and polyphosphates. The amino groups of the phosphoramidates were converted to ammonia at the same time. The IR spectra of the products in Fig. 1 indicate the absorption of NH_4^+ at 1400 cm^{-1} and those of the P-O-P and/or P-N(H)-P linkages at about 900 and 700 cm^{-1} respectively. The IR data agree well with those in Table 1. The polyphosphates formed by the reaction of strontium phosphoramidate with HCl gas degraded to phosphates with shorter chain lengths with the passage of the reaction time. The data in Table 1 and Fig. 1 do not provide any information about the formation of a P-N(H)-P linkage in the products. The ^{31}P NMR spectra of the products of alkaline earth phosphoramidates gave peaks due to phosphoramidate, orthophosphate, and polyphosphates; they are shown

Table 1. Compositions of the Reaction Products of Phosphoramidates with HCl Gas

Phosphoramidate	Reaction time/min	Total N/%	N/% as NH_4^+	X-Ray dif.	Phosphate (P%)			
					Amido and Ortho	Di	Tri	Higher

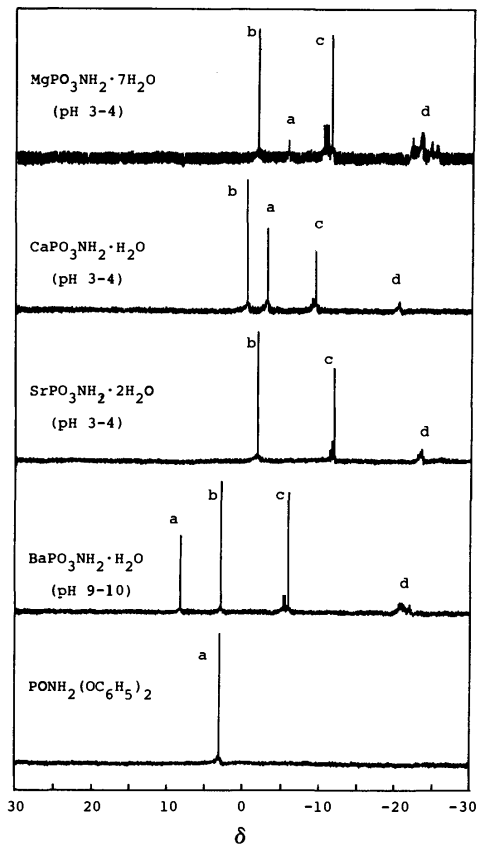

Fig. 2. ^{31}P NMR spectra of the reaction products of phosphoramidates with HCl.
a: Phosphoramidate, b: orthophosphate, c: end-PO_4 group, d: middle-PO_4 group.

data did not give any peak of a compound with a P-N(H)-P linkage. The reaction of alkaline earth phosphoramidates with HCl did not exhibit the following process:

$$-\overset{|}{\underset{|}{P}}-NH_2 + NH_2-\overset{|}{\underset{|}{P}}- + HCl \longrightarrow -\overset{|}{\underset{|}{P}}-N(H)-\overset{|}{\underset{|}{P}}- + NH_4Cl \quad (1)$$

Instead, the processes can be written thus for these reaction systems:

$$\begin{matrix} & & O & & & & O & \\ & & \| & & & & \| & \\ O & - & P & - & NH_2 & + H_2O \longrightarrow & O & - & P & - & ONH_4 \\ M & & | & & & & M & & | & & \\ & & O & & & & O & & & & \end{matrix} \quad (2)$$

$$\begin{matrix} O & & & & O & & \\ \| & & & & \| & & \\ O & - & P & - & ONH_4 + NH_2 & - & P \\ | & & & & & & | \\ M & & O & & & & O \end{matrix} \begin{matrix} - & O & \\ & \| & \\ & P & \\ & | & \\ & O & M \end{matrix} + 2HCl \longrightarrow$$

$$\begin{matrix} & & O & & O & & \\ & & \| & & \| & & \\ O & - & P & - & O & - & P \\ | & & & & & & | \\ M & & O & & O & & M \end{matrix} \begin{matrix} - & O & \\ & \| & \\ & P & \\ & | & \\ & O & M \end{matrix} + 2NH_4Cl \quad (3)$$

$$\begin{matrix} O & & O & & & & O & \\ \| & & \| & & & & \| & \\ O & - & P & - & O & + NH_2 - & P & - & O \\ | & & & & & & | & & \\ M & & O & & M & & O & & M \end{matrix} + 2HCl \longrightarrow$$

$$\begin{matrix} & & O & & O & & O & \\ & & \| & & \| & & \| & \\ O & - & P & - & O & - & P & - & O \\ | & & & & & & & & \\ M & & O & & O & & O & & M \\ & & & & M_{1/2} & & & & \end{matrix} + M_{1/2}Cl + NH_4Cl \quad (4)$$

The phosphoramidate with an OH group was considered to form a zwitterion:[9]

$$\begin{matrix} & & O & & & & \\ & & \| & & & & \\ O & - & P & - & NH_2 & + H_2O(HCl) \longrightarrow \\ M & & | & & & & \\ & & O & & & & \end{matrix}$$

$$\begin{matrix} & & O & & & & \\ & & \| & & & & \\ HO & - & P & - & NH_2 & + M_{1/2}OH(M_{1/2}Cl) \\ & & | & & & & \\ & & O & & & & \\ & & M_{1/2} & & & & \end{matrix} \quad (5)$$

$$\begin{matrix} & & O & & & & O & & \\ & & \| & & & & \| & & \\ HO & - & P & - & NH_2 & \longrightarrow & ^-O & - & P & - & NH_3^+ \\ & & | & & & & | & & & & \\ & & O & & & & O & & & & \\ & & M_{1/2} & & & & M_{1/2} & & & & \end{matrix} \quad (6)$$

This zwitterion is active and can react with water and phosphates to form ortho- and polyphosphates respectively:

$$\begin{matrix} & & O & & & & O & \\ & & \| & & & & \| & \\ ^-O & - & P & - & NH_3^+ + H_2O \longrightarrow & HO & - & P & - & ONH_4 \\ & & | & & & & | & & & \\ & & O & & & & O & & & \\ & & M_{1/2} & & & & M_{1/2} & & & \end{matrix} \quad (7)$$

$$\begin{matrix} & & O & & & & O & \\ & & \| & & & & \| & \\ ^-O & - & P & - & NH_3^+ + HO & - & P & - & ONH_4 + HCl \longrightarrow \\ & & | & & & & | & & \\ & & O & & & & O & & \\ & & M_{1/2} & & & & M_{1/2} & & \end{matrix}$$

$$\begin{matrix} & & O & & O & & \\ & & \| & & \| & & \\ HO & - & P & - & O & - & P & - & ONH_4 + NH_4Cl \\ & & | & & & & | & & \\ & & O & & & & O & & \\ & & & & M & & & & \end{matrix} \quad (8)$$

It is difficult to get information about the presence of the zwitterion, so it is impossible to determine which process is most reasonable for the reaction system. The water in the reaction is, however, thought to come from the crystal water and/or the adsorbed water of the phosphoramidates and from the slight amount of water in the gas in the reaction systems. It was difficult to remove the adsorbed water and the water in the gas completely. In the reactions of magnesium and strontium phosphoramidates, a degradation of polyphosphates to phosphates with shorter chain lengths was observed. Usually this reaction does not occur in a solid state at room temperature. The water contained in the products may be strongly acidic as a result of the dissolution of the HCl gas. The degradation can be caused by the acidic water. Phenyl phosphoramidate did not react with HCl gas at all.

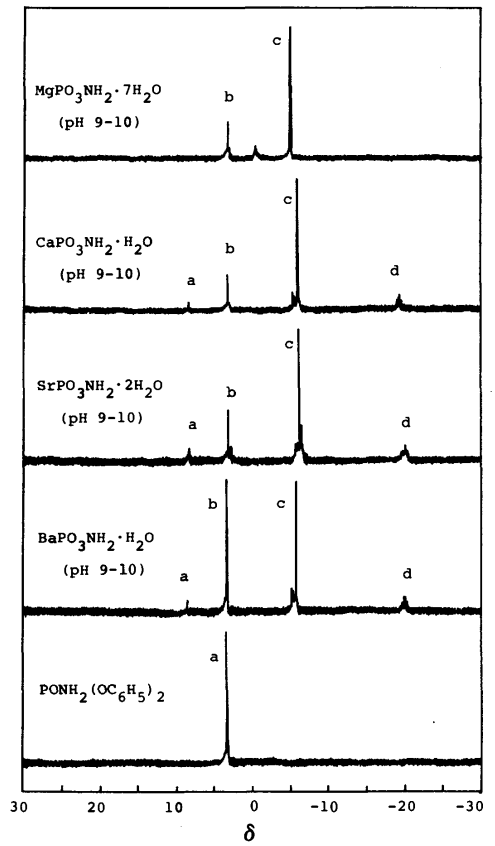

Fig. 3. ^{31}P NMR spectra of the reaction products of phosphoramidates with acetic acid.
a: Phosphoramidate, b: orthophosphate, c: end-PO_4 group, d: middle-PO_4 group.

Reaction with Acetic Acid. The chemical compositions and X-ray diffraction data of the products at 60 °C are shown in Table 2. (The data of the reaction products at 25 °C are not listed because the processes at 25 °C are almost the same as those at 60 °C except for the reaction rates.) Alkaline earth phosphoramidates reacted with acetic acid to produce ortho- and polyphosphates. The amino groups in the phosphoramidates seemed to be converted to ammonia at the same time. The total content of nitrogen in the products was small. Phenyl phosphoramidate did not react with acetic acid at all. The ^{31}P NMR spectral data in Fig. 3 indicate that the products of the alkaline earth phosphoramidates give peaks due to phosphoramidate, orthophosphate, and polyphosphates. Accordingly, the following several reaction processes can be written for the reaction systems:

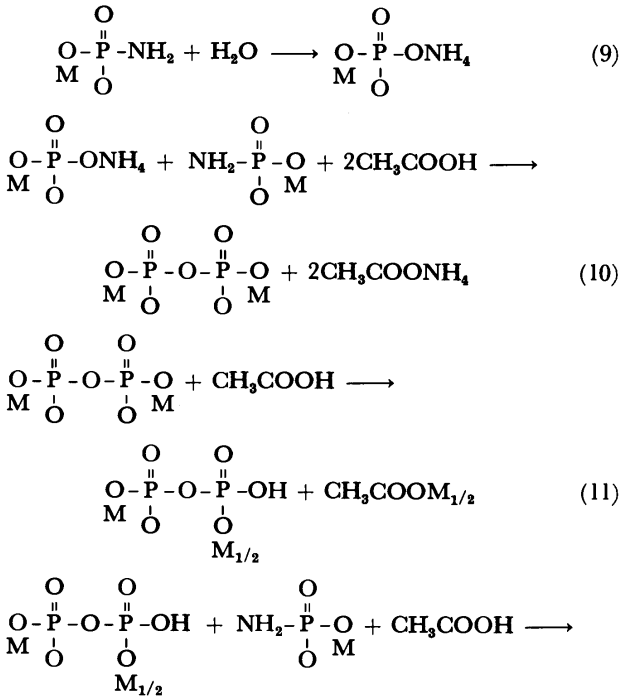

Table 2. Compositions of the Reaction Products of Phosphoramidates with Acetic Acid at 60 °C for 25 h

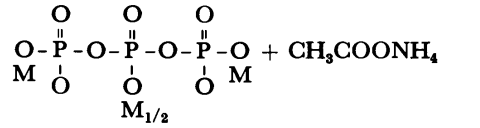
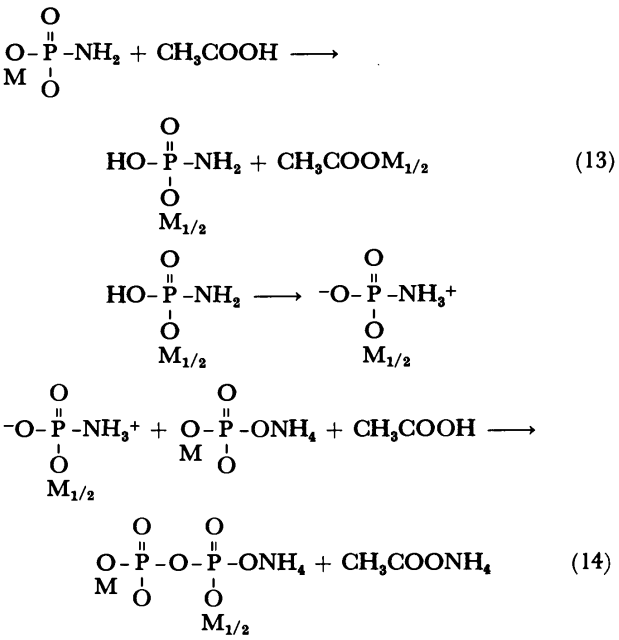
Phosphoramidate	Total N/%	N/% as NH_4^+	X-Ray dif.	Phosphate (P%)			
				Amido and Ortho	Di	Tri	Higher
$MgPO_3NH_2 \cdot 7H_2O$	2.9	2.5	AM	10.2	81.8	5.5	2.5
$CaPO_3NH_2 \cdot H_2O$	2.2	2.1	AM	18.0	64.6	17.4	
$SrPO_3NH_2 \cdot 2H_2O$	1.6	1.4	AM	23.0	60.3	15.9	0.8
$BaPO_3NH_2 \cdot H_2O$	1.9	0.5	UK	34.6	44.5	13.3	7.6
$PONH_2(OC_6H_5)_2$	5.6	—	SM	100	—	—	—

AM stands for an amorphous substance.



(12)

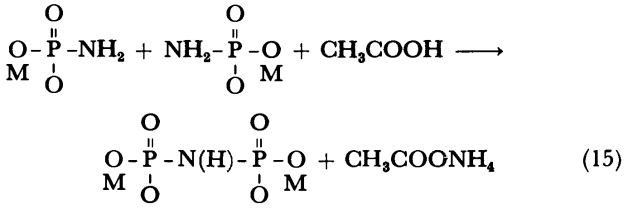
or



(13)

(14)

The water in the above equation can come from the crystal water and the adsorbed water of the phosphoramidates. The reaction product of magnesium phosphoramidate showed a small unknown ^{31}P NMR peak at about −0.3 ppm. An HPLC analysis of the product was performed in order to get information about the unknown substance. As Fig. 4 shows, the peak at 10.1 min was identified as that of imidodiphosphate. It was, therefore, concluded that magnesium phosphoramidate reacted with HCl to form orthophosphate, polyphosphates, and also imidodiphosphate according to this reaction:



(15)

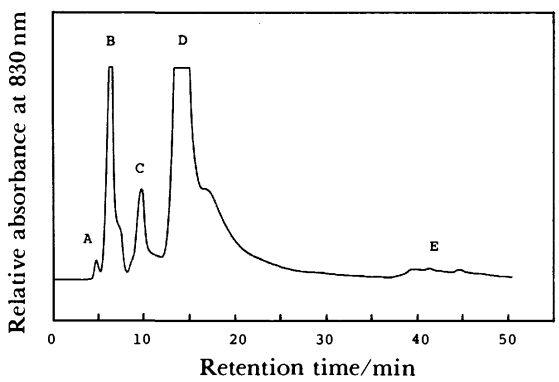


Fig. 4. HPLC profile of the reaction product of magnesium phosphoramidate with acetic acid at 60 °C for 25 h.
A: Phosphoramidate, B: orthophosphate, C: imidodiphosphate, D: diphosphate, E: higher polyphosphates.

Reaction with Oxalic Acid. The chemical compositions and X-ray diffraction data of the products are shown in Table 3, while the ^{31}P NMR spectra of the products are presented in Fig. 5. All the products except for that of the reaction of magnesium phosphoramidate were ortho- and polyphosphates. The ^{31}P NMR spectrum of the reaction product of magnesium phosphoramidate showed unknown peaks at about −0.3 and 2—4 ppm. The HPLC profile in Fig. 6 indicates that the product contains imidodiphosphate (10.3 min). Therefore, the unknown NMR peak at −0.3 ppm was concluded to be due to imidodiphosphate. The other NMR peaks at 2—4 ppm were thought to be caused by the polyphosphates containing a P-N(H)-P linkage, for the phosphates having a structure associated with a PO_4 group exhibit ^{31}P NMR peaks in a magnetic field higher than that of orthophosphate. Accordingly, one can write the following equation, for example, for the reaction of the phosphoramidates with oxalic acid:

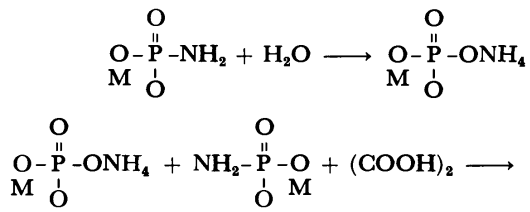

Table 3. Compositions of the Reaction Products of Phosphoramidates with Oxalic Acid at 60 °C for 25 h

Phosphoramidate	Total N/%	N/% as NH_4^+	X-Ray dif.	Phosphate (P%)			
				Amido and Ortho	Di	Tri	Higher
$MgPO_3NH_2 \cdot 7H_2O$	4.1	2.5	UK	42.8	36.8	11.8	8.6
$CaPO_3NH_2 \cdot H_2O$	4.4	3.3	SM, UK	45.2	30.3	24.5	
$SrPO_3NH_2 \cdot 2H_2O$	3.0	2.7	UK	28.2	30.8	41.0	
$BaPO_3NH_2 \cdot H_2O$	4.9	0.3	SM	85.7	10.4	3.9	
$PONH_2(OC_6H_5)_2$	5.6	—	SM	100	—	—	—

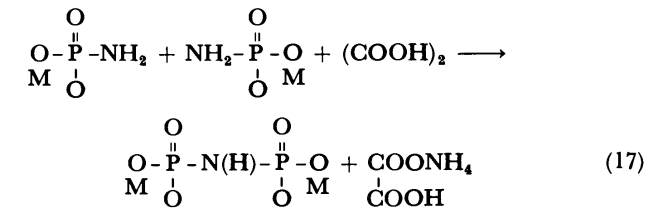
a: Phosphoramidate, b: orthophosphate, c: end-PO_4 group, d: middle-PO_4 group.

(16)

This condensation can also be written for magnesium phosphoramidate as:



(17)

The reaction rate of the phosphoramidates with oxalic acid seemed to be slower than that with acetic acid, because the amounts of unreacted phosphoramidates in the reaction products with oxalic acid were larger than those with acetic acid.

Conclusion

Alkaline earth phosphoramidates other than magnesium salt reacted with hydrogen chloride, acetic acid, and oxalic acid to produce ortho- and polyphosphates. Magnesium phosphoramidate also produced ortho- and polyphosphates when it was reacted with hydrogen chloride, while the magnesium phosphoramidate reacted with acetic acid and oxalic acid to make orthophosphate, polyphosphates, and imidodiphosphate. The amount of the imidophosphate was small. Therefore, an amino group on alkaline earth phosphoramidates was unstable in these reaction systems and was decomposed to an ammonium ion. It seemed to be difficult to make imidodiphosphate by the chemical condensation of the phosphoramidates with the acids. Phenyl phosphoramidate was very stable and did not react with these acids at all.

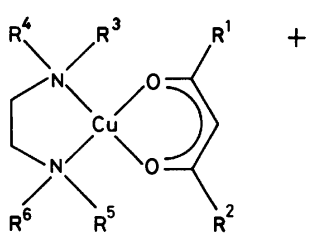
Studies on Mixed Chelates. XV. An ESR Investigation of Solvatochromic Copper(II) Complexes with Various *N*-Alkylated Ethylenediamines and β-Diketonates

Naomi HOSHINO,† Naoko KODAMA, Yutaka FUKUDA, and Kozo SONE*
Department of Chemistry, Faculty of Science, Ochanomizu University,
Otsuka, Bunkyo-ku, Tokyo 112
(Received May 5, 1987)

ESR spectra were obtained for frozen solutions of copper(II) mixed chelate complexes, [Cu(diam)(dike)]-ClO_4, having various *N*-alkylated ethylenediamines (diam) and β-diketonate ligands (dike). The ESR *g*-factor ($g_{//}$) determined from apparently axial signals may be correlated by a decreasing function to pK_a of dikeH or diam ligand for the series of [Cu(tmen)(dike)]$^+$ or [Cu(diam)(acac)]$^+$, respectively. On the other hand, the $g_{//}$ values gradually increased when the former series of complexes were dissolved in more strongly coordinating solvents, and a relationship was found between $g_{//}$ and Donor Number of the solvent. These trends are regarded as ligand substituent effect and solvent effect on the $g_{//}$ factor, and are analyzed using a crystal field model of a C_{2v} symmetry.

Previous studies from this laboratory showed that a series of mixed chelate complexes of copper(II), [Cu(diam)(dike)]$^+$, in which diam and dike designate *N*-alkylated ethylenediamines and β-diketonates, respectively (Structure I), possesses an interesting coloring behavior in organic solutions.[1] Namely, in the case of [Cu(tmen)(acac)]ClO_4 (R^1—R^6=CH_3), for instance, the color of the solutions ranges from reddish violet (in nitrobenzene) through azure (in formamide) to green (in piperidine) and it follows the donor ability of the solvent. This has been quantitatively revealed by the linear relationship between the wavenumber of the visible absorption maximum and Donor Number (DN) of the solvent.[2-4]

Demonstration of such a remarkable solvatochromism has exemplified an application of this complex as a teaching tool or a color indicator for solvent parameters.[4] On the other hand, interpretation of this solvent effect on the electronic spectra of [Cu(diam)(dike)]$^+$ in solution has been limited to rather qualitative terms. Information on the structure of the complexes and the nature of solvent interaction is essential for full understanding of the chemistry of these mixed chelate complexes. We therefore conducted a new study on the electronic structure of [Cu(diam)(dike)]$^+$ complexes in solution by means of the ESR spectroscopy and attempted to find a correlation between the previously obtained absorption spectral data and the ESR parameters for the mixed chelate complexes. The ESR *g*-factors are under electronic effects of both diam and dike substituents and also of ligated solvent molecules. Both effects were interpreted using a simple crystal field model of C_{2v} symmetry, which is described in this paper.



Structure I

† Present address: Department of Molecular Assemblies, Institute for Molecular Science, Myodaiji, Okazaki 444.

Experimental

Materials. Preparation of the complexes, [Cu(diam)-(dike)]ClO_4, used in this study has been reported elsewhere.[2] Our choice of the perchlorate salts is based on the fact that perchlorate ion does not coordinate to the mixed chelate cation in the solvents used in this study.[5] Table 1 provides a list of two series of complexes prepared, [Cu(tmen)(dike)]- and [Cu(diam)(acac)]ClO_4, and organic solvents used.

Measurements. Solvents used for ESR measurements were dried and purified by conventional methods. All of the solvents were added with tetrabutylammonium tetrafluoroborate (TBAB, 0.1 mol dm^{-3}) for the purpose of improving ESR resolution. ESR spectra were obtained for frozen solutions containing 5×10^{-3} mol dm^{-3} of complexes at 123 K in the X-band region using a JEOL JES-FE2XG spectrometer equipped with a 100 kHz magnetic field modulation. The ESR parameters were determined directly from the spectra, with the magnetic field calibrated using a standard Mn^{2+} sample (supplied by JEOL together with a computer program, GVALUE, for calculating *g*-values). Reported values involve errors within ±0.003 for $g_{//}$ values and $\pm3\times10^{-4}$ cm^{-1} for $A_{//}$ values. The $g_{//}$ was positioned at the center of four hyperfine peaks due to the Cu nucleus, three of which from lower magnetic field were well resolved.

Results and Discussion

ESR Data for [Cu(diam)(dike)]$^+$. The X-band ESR spectra obtained for the series of [Cu(diam)-(dike)]$^+$ complexes are typically of nearly axial type. An example is shown in Fig. 1. The apparent $g_{//}$

Table 1. List of Complexes and Solvents Used in This Study

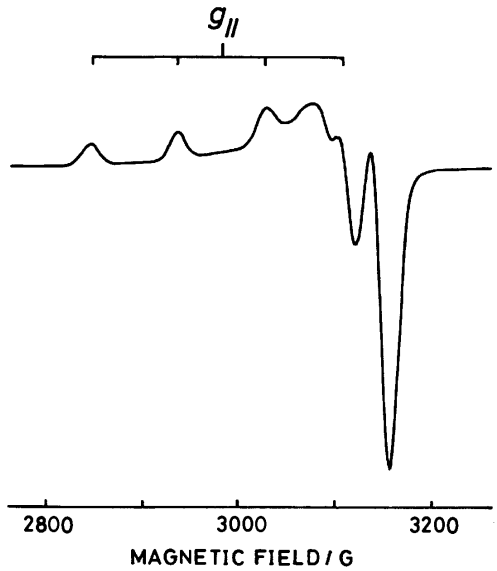

Fig. 1. ESR spectrum of $[Cu(tmen)(acac)]^+$ in acetonitrile containing 0.1 mol dm^{-3} of TBAB (ESR recorded at 123 K).

values can be determined from the spectra and fall in the range between 2.21 and 2.27, while the apparent $g_\perp$ values are found around g=2.0. As discussed below, theory predicts a slightly rhombic spectrum rather than an axial spectrum and simulation might yield two g-values resolved for the $g_\perp$ region. However, we focus our attention to the $g_{//}$ values alone in this paper. Table 2 lists the observed $g_{//}$ and $A_{//}$ values for all of the complexes studied in seven different solvents.

In analyzing the trend in g-values, two correlations are noted: (1) $g_{//}$ vs. ligand basicity (in the same solvent) and (2) $g_{//}$ vs. solvent basicity (for the same ligand pair). With regard to the first relationship, Fig. 2 compiles plots of $g_{//}$ values against pK_a of β-diketones and *N*-alkylated ethylenediamines. The pK_a of β-diketone varies widely upon substitution of R^1 and R^2 groups and is known to represent ligand basicity of β-diketonate.[6] The general trend noted in Fig. 2 is that, for each of the solvents, $g_{//}$ value of the complex decreases as the β-diketonate ligand becomes more basic or more strongly coordinating. In addition, it appears that curvature of the fitted lines increases across DCE→DMSO in the order of increasing donor ability of the solvent. Substitution on the diam ligands has little effect on the $g_{//}$ factor. Perhaps substitution of R^3—R^6 groups, which are not as remote as R^1 and R^2 groups, involves more than just electronic effect.

Table 2. ESR Parameters Determined for Various Solutions of Cu(II) Mixed Chelate Complexes

Complex	$g_{//}$ ($\lvert A_{//}\rvert/10^{-4}$ cm^{-1})

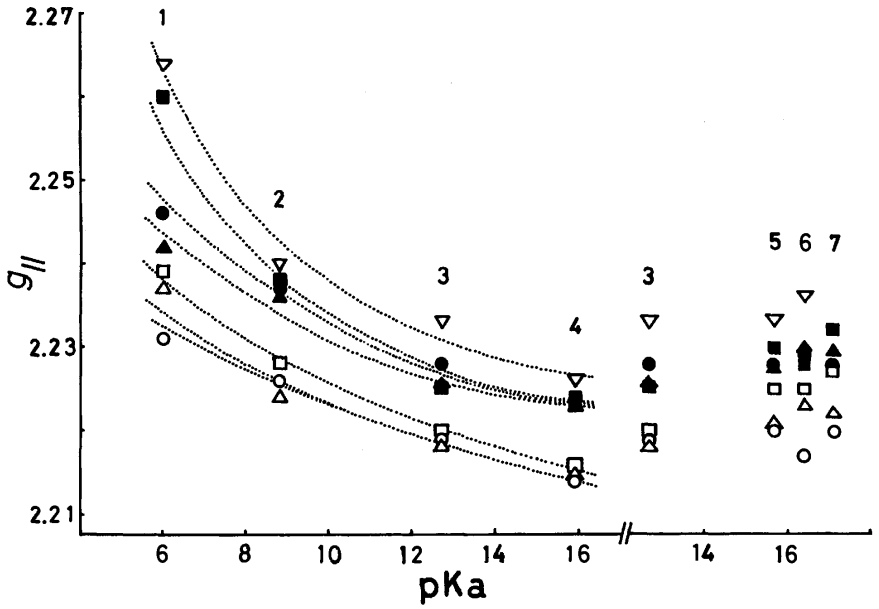

Fig. 2. Plots of $g_{//}$ values against pK_a of dikeH or diam for the series of [Cu(tmen)-(dike)]$^+$ (left) or [Cu(diam)(acac)]$^+$ (right) dissolved in different solvents.

On the other hand, Fig. 3 plots $g_{//}$ values for the series of four complexes, [Cu(tmen)(dike)]$^+$, against solvent Donor Number (DN). A general trend can be seen; for the same complex, the $g_{//}$ value increases as the solvent property changes from noncoordinating to strongly coordinating (increase in DN). Again the curvature of the fitted lines becomes greater across dipm→hfac, here in the order of decreasing in-plane ligand basicity.

Symmetry of [Cu(diam)(dike)]$^+$ and Copper d-Orbital Sequence. The molecular structure of [Cu-(diam)(dike)]$^+$ is shown schematically in Fig. 4, together with the coordinate system. It is safely assumed that the complex belongs to the point group C_{2v}. It should be noted that with this choice of coordinate system z axis remains as the unique symmetry axis so that a standard character table can be used, although the geometrical chelate plane is now in xz plane rather than more conventional xy plane. Thus each of the d-orbital wave functions is labelled as shown in Fig. 4.

Other workers have discussed the structure of Schiff base complexes of copper(II) as belonging to $C_{2v}(x)$ point group,[7,8] in which the coordinate system

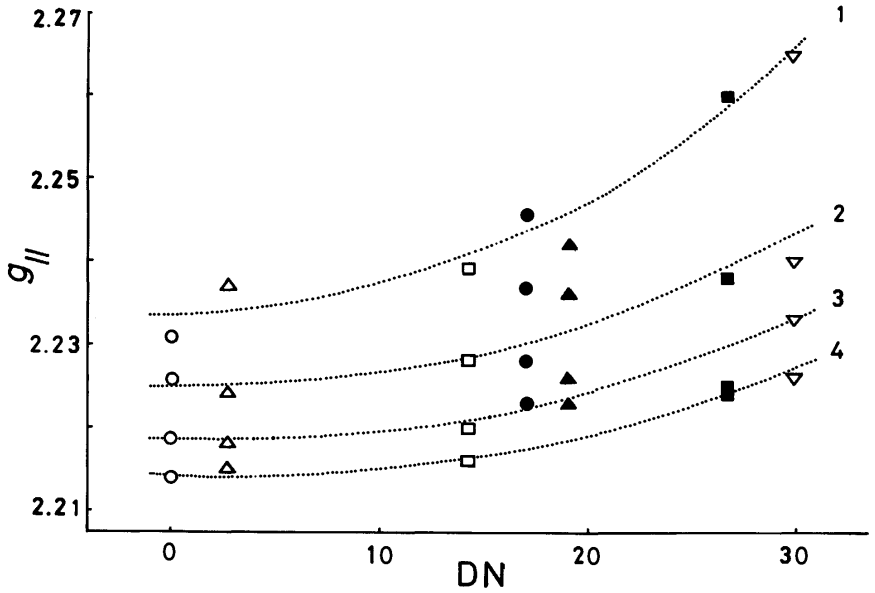

Fig. 3. Plots of $g_{//}$ values against solvent Donor Number (DN) for the series of [Cu(tmen)(dike)]$^+$ complexes.

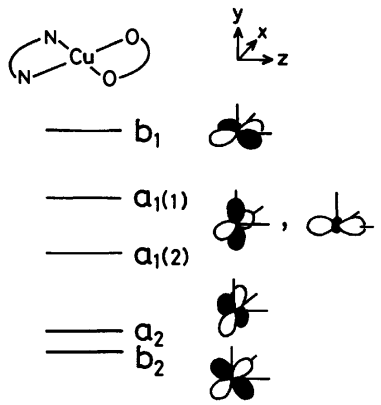

Fig. 4. Structure, coordinate system, and expected d-orbital pattern for [Cu(diam)(dike)]$^+$.

appears more familiar, with z axis perpendicular to the geometrical chelate plane but no longer being the twofold axis. The mixed chelate complex [Cu(diam)-(dike)]$^+$ used to be approximated, for convenience, to have D_{4h} symmetry indistinguishing N–N and O–O donor sets.[1] In the present paper, we use the strict C_{2v} representations particularly for the purpose of explaining the solvent effect observed in this study.

Work is in progress towards acquiring single crystal electronic spectral data on [Cu(diam)(dike)]$^+$ that we can use for sequencing the d-orbitals split under the C_{2v} crystal field. As yet, we have to make the most reasonable estimates for the orbital energies. The ground state is undoubtedly B_1 with d_{xz} orbital singly occupied. The d_{xy} (a_2) and d_{yz} (b_2) orbitals would have similar energies; they correspond to the e_g orbitals in the D_{4h} approximation. The remaining d_{z^2} and $d_{x^2-y^2}$ (a_1) should mix with each other under the crystal field;

$$a_1(1) = a \cdot d_{z^2} + b \cdot d_{x^2-y^2} \quad (1)$$

$$a_1(2) = b \cdot d_{z^2} - a \cdot d_{x^2-y^2} \quad (2)$$

in which a and b are the mixing coefficients. Then the g-values are related to the excited state energies via the orbital reduction parameters k_x, k_y, and k_z by the equations;

$$g_y = 2.0023 - 2\lambda k_y^2 \left[\frac{(\sqrt{3}a-b)^2}{E(a_1(1))} + \frac{(a+\sqrt{3}b)^2}{E(a_1(2))} \right] \quad (3)$$

$$g_x = 2.0023 - \frac{2\lambda k_x^2}{E(d_{xy})}. \quad (4)$$

$$g_z = 2.0023 - \frac{2\lambda k_z^2}{E(d_{yz})} \quad (5)$$

where λ is the spin-orbit coupling constant (-828 cm^{-1}). For the present purpose, however, it suffices to note that the spin-orbit coupling between the ground B_1 term and excited A_1 terms should include contributions from both d_{z^2} and $d_{x^2-y^2}$ orbitals. This is the major consequence of lowering the symmetry from approximate D_{4h} to the more precise C_{2v} (z axis in chelate plane). Under a condition that $\sqrt{3}a=b$ or $a=-\sqrt{3}b$, the expression for g_y is reduced to the one involving the energy of "$d_{z^2-x^2}$" orbital, which is equivalent to the results of $C_{2v}(x)$ treatment.[7,8] Since the precise symmetry of the crystal field in [Cu-(diam)(dike)]$^+$ is unknown, we leave the mixing coefficients a and b as undetermined parameters.

According to the above model, the most likely energy sequence of the d-orbitals in [Cu(diam)-(dike)]$^+$ is $d_{xz} > a_1(1)$, $a_1(2) \geqslant d_{yz} \approx d_{xy}$ and the three g-values are expected to follow the order; $g_y > g_x \approx g_z$. Comparison with actual ESR signals, which are

nearly of axial type, indicates that $g_y=g_{//}$. The dependences of $g_{//}$ values on ligand basicity and on solvent can now be explained in terms of changes in $E(a_1(1))$ and/or $E(a_1(2))$ in the expression for g_y.

Interpretation of Substituent and Solvent Effects on the $g_{//}$ Values. Figure 5(A) illustrates how the d-orbital energies of [Cu(tmen)(dike)]$^+$ complexes are affected by increasing the basicity of dike ligand. Most notable change is a rise in b_1 orbital (d_{xz}) energy since the orbital lobes are directed towards the ligand. This should bring about an increase in both $E(a_1(1))$ and $E(a_1(2))$ and consequently a decrease in the $g_{//}$ value, following Eq. 3. If pK_a of the β-diketones are linearly related to the energy terms as in the case of [Cu(dike)$_2$] complexes,[6] the $g_{//}$ values would be inversely proportional to the pK_a as long as crystal field model is appropriate. The relationships demonstrated in Fig. 2 can be reasonably taken as the inverse proportionality and lend support to the above model.

Figure 5(B) illustrates how the d-orbital energies of [Cu(diam)(dike)]$^+$ are affected upon coordination of solvent molecules (S) along the y axis, bringing about the solvent effect on the $g_{//}$ values. To simplify the discussion, the mixing coefficients a and b in Eqs. 1 and 2 are assumed to be 1 and 0, respectively (mixing is negligibly small). Then the expression for g_y is reduced to the following.

$$g_y = 2.0023 - 2\lambda k_y^2\left[\frac{3}{E(d_{z^2})} + \frac{1}{E(d_{x^2-y^2})}\right] \quad (6)$$

The d_{z^2} orbital is placed above $d_{x^2-y^2}$ in the Figure since it has some "in-plane" lobal character, though not directed to the donor atoms. At any rate, it should be noted that the primary effect of coordination of the solvent is to increase the energy of $d_{x^2-y^2}$ orbital. The d_{z^2} orbital would also rise and, as an overall effect, the decreased $E(a_1)$ terms should yield larger $g_{//}$ values. Degree of the changes in energy is dependent on coordinating ability of the solvent, for which DN can be a reasonable measure. Thus the plots of $g_{//}$ values vs. DN of solvents, shown in Fig. 3, follow the relationship in Eq. 3.

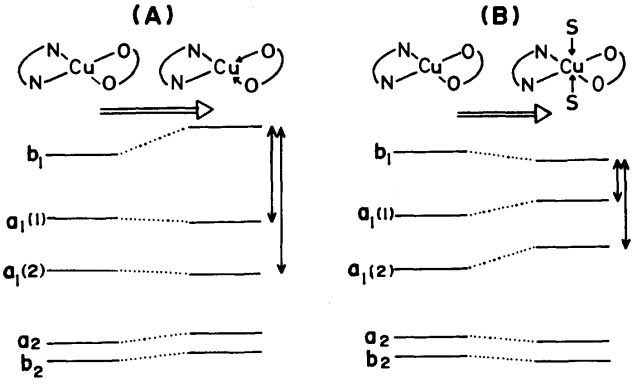

Fig. 5. The efffects of varying the substituents of dike ligand (A) and of changing the solvent (B) on the relative energies of d-orbritals in [Cu(diam)-(dike)]$^+$. Horizontal arrow shows increase in the ligand basicity (O→ in A) or the degree of solvation (S→ in B), i.e., the coordination power of dike ligand or the solvent molecules increases from left to right. Vertical arrows indicate the energy terms which appear in the $g_{//}$ expression.

ESR parameters of [Cu(dike)$_2$] have been extensively investigated by other workers.[6,9,10] In most of these studies, an MO scheme has been favorably employed. Solvent-dependency of the ESR parameters of these complexes was particularly difficult to explain, since under D_{4h} symmetry the spin-orbit coupling relates $g_{//}$ to the energy difference between $d_{x^2-y^2}$ and d_{xy}, both of which have only the in-plane lobal component. Effect of axial coordination was interpreted as an indirect effect on the energy of the highest $d_{x^2-y^2}$ orbital and/or on bonding characters in the complexes.

In contrast, the present model explains the solvent effect as a direct consequence of coordination. There may seem to be little inadequacy in D_{4h} approximation for the present CuN_2O_2 chelate complexes at first, but recognizing the fact that the lowering symmetry results in mixing of in-plane and axial d-orbitals along x, y, and z axes is important in the explanation of the remarkable solvent effect, both on the ESR parameters and on electronic spectra.

Comparison with Absorption Spectral Data. Finally, the information from the ESR spectroscopy is to be compared to the electronic spectral data obtained previously. The energies for solution absorption

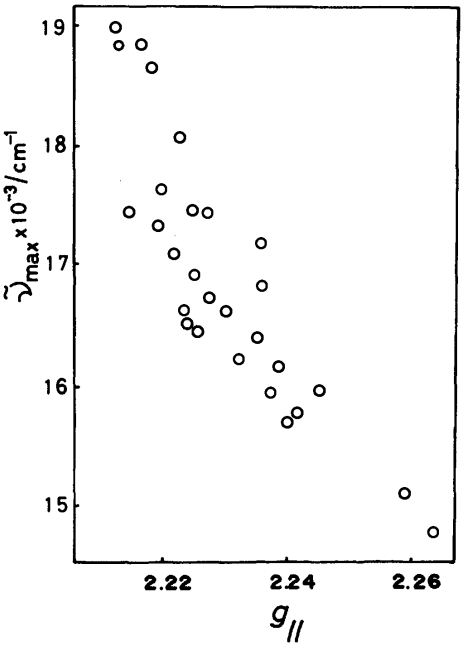

Fig. 6. Correlation between the energies of absorption spectral maxima ($\tilde{\nu}_{max}$) and ESR $g_{//}$ values for the series of [Cu(tmen)(dike)]$^+$ complexes in solution.

spectral maxima are plotted against $g_{//}$ values in Fig. 6. The 28 data points (the series of four complexes [Cu(tmen)(dike)]$^+$ in seven solvents) fall in a region on the plot that suggests the overall linear relationship between $\tilde{\nu}_{max}$ and $g_{//}$. It is clear at least that the d–d band observed in the visible region for solutions consists of $B_1 \rightarrow A_1$ transition(s). Due to the remarkable solvatochromism, the visible band at around 550 nm used to be arbitrarily assigned to $B_{1g} \rightarrow E_g$ transition under D_{4h} symmetry, which appeared to be most affected by changing degrees in solvation, despite the fact that the energy of this transition may well extend into the ultraviolet region.[11] Precise band assignment is not possible until absorption spectrum of a single crystal has been analyzed but in the meantime the C_{2v} crystal field model seems to adequately explain both absorption spectral and ESR spectral properties of [Cu(diam)-(dike)]$^+$ series.

This work was partially supported by a Grant-in-Aid for Scientific Research No. 59430009 from the Ministry of Education, Science and Culture. The authors would like to thank Dr. Makoto Chikira of Chuo University for helpful discussion.

11) The electronic absorption spectra of [Cu(diam)-(dike)]ClO_4 in organic solvents typically contain one visible band and a noticeable shoulder (390—400 nm) at the foot of intense ultraviolet absorption. If an estimated value for g_x of 2.03 and one for k_x^2 of 0.5[7] are used to calculate the energy of d_{xy} orbital, it follows that the corresponding transition should appear around 340 nm.

The Base-Catalyzed Isomerization of the Bis(ethylenediamine-*N*-acetato)cobalt(III) Complex

Hiroshi KAWAGUCHI,* Ryuichi NIIYAMA, Tomoharu AMA, and Takaji YASUI

(Received May 22, 1987)

The isomerization reaction among six geometrical isomers of $[Co(edma)_2]^+$, which were all resolved into optically active isomers except for the achiral C_i-trans(O) isomer, has been studied in a basic aqueous solution. It has been found that the reaction is stereoselective and that the main reaction schemes may be described as follows: (1) $\Lambda\Delta\Lambda$(S,S)-C_2-trans(O) $\rightleftharpoons$ $\Delta\Lambda\Delta$(R*,S)-C_1-cis(O) $\rightleftharpoons$ $\Delta\Lambda$(R,R)-cis(O)trans(NH) $\rightleftharpoons$ meso(R,S)-C_i-trans(O)$\rightarrow\Lambda\Delta\Lambda$(R,R)[or $\Delta\Lambda\Delta$(S,S)]-cis(O)trans(NH_2) and (2) meso(R,S)-C_i-trans(O)$\leftarrow(+)^{CD}_{504}$-mer$\rightarrow\Lambda\Delta\Lambda$(S,S)-$C_2$-trans(O). In each of the isomerization steps of (1), the inversion occurs at one of two secondary-N centers of the coordinated edma ligands. The rate of deuteration at the secondary-NH was also measured for all geometrical isomers; a linear relationship between the rates of the deuteration and isomerization was found. It was suggested that the isomerization of the $[Co(edma)_2]^+$ system proceeded through the deprotonated five-coordinated intermediates formed by Co–O bond-rupture in the conjugate-base forms.

Numerous data of intramolecular rearrangement (isomerization and inversion) reactions have been reported, and two major pathways of twist and bond-rupture mechanisms have been proposed.[1,2] Complexes with multidentate ligands[3,4] can be used for mechanistic studies of rearrangement reactions, because (1) the coupled chelate rings restrict the number of different possible interconversions and (2) such molecules possess more distinguishable points of reference by which the paths of specific rearrangements can be traced. Recently it has been found that an interesting rearrangement (inversion-isomerization) occurs in the chiral complexes containing multidentate ligands.[5–7] Also, in the substitution reactions of the chiral complexes containing tetradentate ligands, some examples of inversion-isomerization have been reported.[8–10] Examples concerning structure-reactivity patterns in octahedral complexes have been reviewed by House[11] and by Radanovic.[12]

The bis(ethylenediamine-*N*-acetato)cobalt(III) ion, $[Co(edma)_2]^+$, provides six geometrical isomers, as is shown in Fig. 1. When the edma ligand coordinates to a cobalt(III) ion, the secondary nitrogen (-C-NH-C-) becomes asymmetric (R or S). Although each isomer of $[Co(edma)_2]^+$ may be expected to provide several diastereomers, some of them (except for the mer isomer, E-3) do not exist because of structural restrictions. The possible configurations[13] for the geometrical isomers containing facially coordinated edma are listed in Table 1. In previous papers,[14,15] we reported the preparation and characterization of the six geometrical isomers and also the determination of the absolute configurations of the chiral isomers, except for the mer isomer (E-3).

Recently we have found that the isomers of $[Co(edma)_2]^+$ isomerized to other one with inversion at one of the secondary nitrogen (sec-N) centers of the coordinated edma ligands.[16] In this paper the details of these isomerization reactions will be reported. The deuteration reactions at the sec-N centers will also be described.

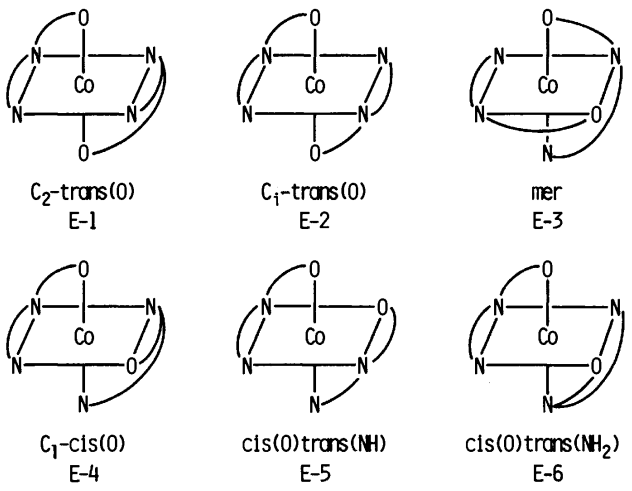

Fig. 1. The six geometrical isomers of the $[Co(edma)_2]^+$ ion.

Experimental

Complexes. The complexes examined here were prepared and resolved according to the methods described in our previous papers.[14,15] They are $(+)^{CD}_{543}$-C_2-*trans*(O)-

Table 1. Possible Configurations and CD Signs of the $[Co(edma)_2]^+$ Ion

Isomer	Possible configuration and CD sign	
E-1	$(-)^{CD}_{548}$-$\Delta\Lambda\Delta$(R,R)	$(+)^{CD}_{548}$-$\Lambda\Delta\Lambda$(S,S)
E-2	(R,S)	(achiral isomer)
E-4	$(+)^{CD}_{534}$-$\Lambda\Delta\Lambda$(S*,R)	$(-)^{CD}_{534}$-$\Delta\Lambda\Delta$(R*,S)
E-5	$(-)^{CD}_{521}$-Δ(GG)Λ(EE)(R,R)	$(+)^{CD}_{521}$-Λ(GG)Δ(EE)(S,S)
E-6	$(-)^{CD}_{509}$-$\Delta\Lambda\Delta$(R*,R*)	$(+)^{CD}_{509}$-$\Delta\Lambda\Delta$(S*,S*)

R or S: Chirality around the asymmetric nitrogen. R* or S*: Chirality around the asymmetric nitrogen being present at the position trans to ligating oxygen atom. G and E represent the glycinate-ring and ethylenediamine-ring of the edma ligand respectively.

$[Co(edma)_2]Cl\cdot 2H_2O$ (E-1), C_i-*trans*(O)-$[Co(edma)_2]Cl\cdot 2H_2O$ (E-2), $(+)^{CD}_{504}$-*mer*-$[Co(edma)_2]Br$ (E-3), $(-)^{CD}_{534}$-C_1-*cis*(O)-$[Co(edma)_2]Cl\cdot 2H_2O$ (E-4), $(-)^{CD}_{521}$-*cis*(O)*trans*(NH)-$[Co(edma)_2]Br$ (E-5), $(-)^{CD}_{509}$-*cis*(O)*trans*(NH_2)-$[Co(edma)_2]Cl\cdot 1.5H_2O$ (E-6).

Spectral Change in the Isomerization Reaction Solution. The time-course changes in the absorption and CD spectra of each isomer in a basic aqueous solution were followed by the use of a Hitachi 557 spectrophotometer and a JASCO J-22 spectropolarimeter. All the chemicals used were of a reagent grade, and the deionized water was degassed before use. The reaction was started by stirring a buffer solution into the complex solution in a reaction vessel kept in a thermostat. About 3 cm^3 of the reaction solution was then quickly transferred into the cell with a stopper in order to record the absorption and CD spectra. The following conditions were set: Complex concentration, 2.68 or 4.66×10^{-3} M (M=mol dm^{-3}); pH, 10.24—10.37 (Na_2CO_3–$NaHCO_3$ buffer); temperature, 40.1 or 30.1 °C.

Isomerization. $(-)^{CD}_{534}$-E-4 Isomer: This isomer (0.150 g) was dissolved in 200 cm^3 of water in a reaction vessel kept in a thermostated bath at 40.0 °C. The reaction was started by stirring 300 cm^3 of a buffer solution [Na_2CO_3(0.1165 M)–$NaHCO_3$(0.03887 M)] previously kept at 40.0 °C into the reaction vessel. The temperature and the pH of the reaction solution were checked with a thermister thermometer (Takara D221) and a pH meter (Toa TSC-10A) respectively. During the experiment (160 h), the reaction solution was kept at 40.0±0.1 °C, with the pH 10.35±0.02.

At prescribed time intervals, a constant volume (40.0 or 30.0 cm^3) of the reaction solution was taken out and acidified to pH 6 in order to stop the reaction. The acidified solution was poured onto an SP-Sephadex C-25 column (3.0 cm×60 cm, Na^+ form). The adsorbed band was developed with a 0.2 M NaCl aqueous solution and separated into two bands, el-1 and el-2 in order of elution. The el-1 eluate contained $(+)^{CD}_{543}$-E-1 (major) and E-2 (minor), while the el-2 eluate contained $(-)^{CD}_{534}$-E-4 and $(-)^{CD}_{521}$-E-5. Each of the el-1 and el-2 eluates was concentrated to a constant volume (10.0 or 5.0 cm^3) and used for the measurements of the absorption and CD spectra. From the binary-curve analysis of the absorption spectrum of the concentrated el-1 eluate (on the basis of the known absorption data of authentic E-1 and E-2), the amounts of E-1 and E-2 formed were calculated. The optical purity of $(+)^{CD}_{543}$-E-1 in the el-1 eluate was obtained from the CD intensity of the el-1 eluate and the concentration of E-1 estimated from the absorption data. The amounts and optical purities of $(-)^{CD}_{534}$-E-4 and $(-)^{CD}_{521}$-E-5 were also estimated from the binary-curve analyses of the absorption and CD spectra of the el-2 eluate. In these curve-analyses, the spectral data at 20—25 points in the visible region were used; the analyses were carried out on an NEC PC-9801F computer using the least-squares method.

The isomerization reactions of the other isomers were carried out by a procedure similar to that used for $(+)^{CD}_{534}$-E-4. The reaction conditions were the same as those in the case of $(+)^{CD}_{534}$-E-4.

Deuteration. The deuteration reactions were carried out for the six geometrical isomers of the $[Co(edma)_2]^+$ complex in a DCl(0.096 M)-D_2O solution and followed with a ^1H NMR spectrometer (JEOL MH-100). The solutions were 0.15—0.25 M in complex concentration. The reactions were started by dissolving the complex in DCl-D_2O solution in a thermostat at 80 °C. About 0.5 cm^3 aliquots of the reaction solutions were rapidly quenched in an ice bath, and then the ^1H NMR spectra were measured.

Results and Discussion

The Absorption and CD Spectral Changes in a Basic Aqueous Solution. $(-)^{CD}_{534}$-E-4 Isomer: Figure 2 shows the changes in the absorption and CD spectra of $(-)^{CD}_{534}$-E-4 in a basic solution (pH 10.37) at 40.1 °C. The absorption maximum in the 1st d-d band region shifts gradually to a longer wavelength (from 502 to 525 nm), and the final spectral pattern is similar to that of E-1 (λ_{max} 530 nm). The initial isosbestic points at 527 and 450 nm, which are lost at longer times, are close to the cross points (522 and 449 nm) between the absorption curve of the E-1 and that of E-4. On the other hand, the CD spectrum of $(-)^{CD}_{534}$-E-4 in a basic aqueous solution changes drastically, as is shown in Fig. 2; that is, the CD patterns in the 1st band region are almost inverted with the passage of time. In the initial stage of the reaction, isoextinct points are observed at 497 and 400 nm, which are near in position to the cross points (494 and 399 nm) between the CD curve of $(+)^{CD}_{543}$-E-1 and that of $(-)^{CD}_{534}$-E-4. Further, the final CD curve in Fig. 2 resembles that of

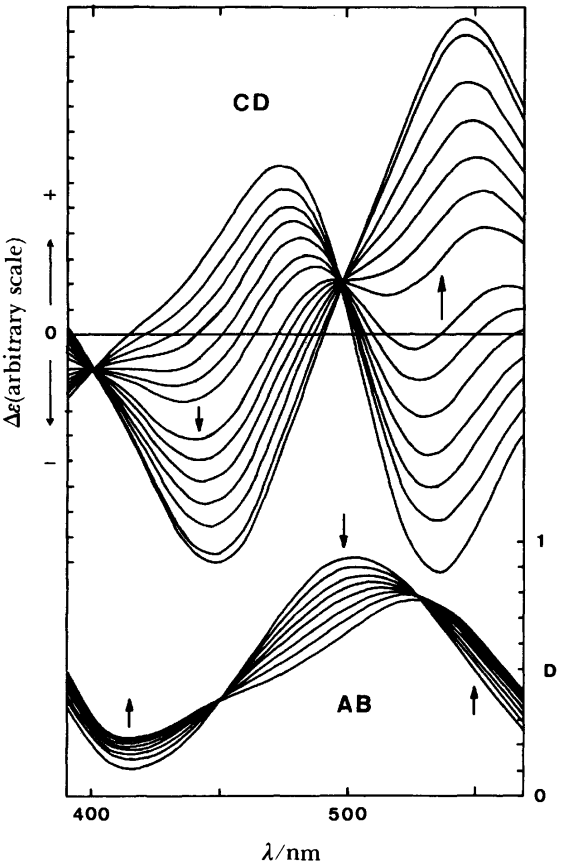

Fig. 2. The absorption (AB) and CD spectral changes of $(-)^{CD}_{534}$-E-4 in a basic aqueous solution (pH 10.37) at 40.1 °C. The final AB and CD curves were recorded after 95 h.

$(+)^{CD}_{543}$-E-1. These results indicate that optically active $(+)^{CD}_{543}$-E-1 was formed in a considerable amount from $(-)^{CD}_{534}$-E-4. No minor products in this reaction were identified by the present experimental procedure.

$(+)^{CD}_{521}$-E-5 and Other Isomers: Figure 3 shows the absorption and CD spectral changes (till 61 days) of $(+)^{CD}_{521}$-E-5, which were measured under the same conditions as those used for $(-)^{CD}_{534}$-E-4. The change in the absorption curve, in which the absorption maximum shifts to the lower energy side (from 478 to 516 nm), suggests that the trans(O) type isomers are formed in considerable concentrations at the final equilibrium stage of the reaction. It is apparent from the CD spectral change that optically active products are formed. However, the products could not be identified on the basis of those CD data.

The same measurements were performed for other isomers of $[Co(edma)_2]^+$. These absorption and CD spectral changes were complicated, indicating that some kinds of isomers were formed in the reactions. The spectral changes in the basic aqueous solutions were relatively faster in E-4, E-3, and E-6 than in the others.

The Identification and Quantification of the Isomerization Reaction Products. The band adsorbed on an SP-Sephadex C-25 column, which contains six geometrical isomers of $[Co(edma)_2]^+$ (E-1—E-6), separated into 3 bands—el-1 (E-1 and E-2), el-2 (E-3, E-4, and E-5), and el-3 (E-6) in order of elution, when developed with 0.2 M NaCl as the eluent. In order to estimate the amounts of the starting material and products in the isomerization reaction solution at an arbitrary time, this chromatographic separation technique was used. Constant volumes of the reaction solution were taken out from the reaction vessel at prescribed time intervals. The solution was acidified to pH 6 to stop the reaction and then poured onto an SP-Sephadex column. The adsorbed band was separated into 3 bands (el-1, el-2, and el-3) by development with 0.2 M NaCl. The eluate from each band was concentrated to a constant volume, and the absorption spectra of the concentrated solution were measured. The amount of the E-6 isomer was estimated from the absorption data of the el-3 eluate. This el-3 band was detected only in a case of the isomerization reaction used E-6 as the starting material. The amounts of E-1 and E-2 were estimated from the binary-curve analysis of the absorption spectrum of the concentrated el-1 solution. If the three isomers of E-3, E-4, and E-5 are present in the reaction solution, all these isomers should be included in the el-2 solution. In the preliminary isomerization reaction of each isomer (except for the E-3 isomer), the ^1H NMR spectrum of the residue obtained from the el-2 eluate was measured to check the formation of E-3 on the basis of the difference in the glycinate-ring $-CH_2-$ signal pattern of E-3 from those of the others.[14,15] In the cases of the isomers except E-3, the formation of E-3 was not detected throughout the isomerization reaction. Therefore, the absorption curve of the el-2 solution was analyzed as the curve of a mixture of E-4 and E-5. While in the isomerization reaction using E-3 as a starting material, the absorption spectrum of the el-2 eluate was identical to that of pure E-3, indicating no formation of either E-4 or E-5. (However, at longer reaction times, the absorption and CD curves of the el-2 eluate was better fitted by those of a mixture of E-3 and a very small amount of E-4.)

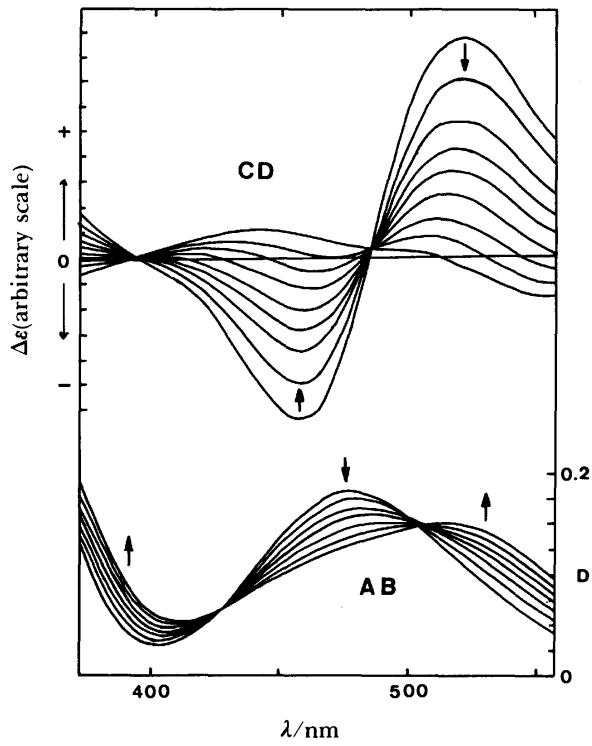

Fig. 3. The absorption (AB) and CD spectral changes of $(+)^{CD}_{521}$-E-5 in a basic aqueous solution (pH 10.25) at 40.1 °C. The final AB and CD curves were recorded after 61 days.

When the optically active isomers were used as starting materials (except for achiral E-2), the CD spectra of the el-1—el-3 eluates were also measured. The CD spectra of the el-1 and el-3 solutions are due to the optical activities of E-1 and E-6 respectively. From the binary-curve analyses of the CD and absorption spectra of the el-2 solution, the optical purities of E-4 and E-5 were estimated.

In a weak acidic or neutral solution at room temperature, the isomerization of each isomer was not observed, at least not for several days. Therefore, the progress of the isomerization reaction during such procedures as chromatographic separation and concentration under reduced pressure should be negligible. In this experiment, the solutions (el-1—el-3) used for the measurements of the absorption and CD

spectra contained a considerable amount of NaCl. As the absorption and CD spectra, especially the CD spectrum, of the $[Co(edma)_2]^+$ complex are affected by the amount of coexisting NaCl, the absorption and CD data of the isomers of $[Co(edma)_2]^+$, which were obtained in an NaCl aqueous solution, were used for the absorption and CD curve analyses of the el-1—el-3 eluates.

Base-Catalyzed Isomerization Reaction. $(-)^{CD}_{534}$-E-4 Isomer: The isomerization reaction of $(-)^{CD}_{534}$-E-4 was carried out in a carbonate buffer solution (pH 10.35) at 40.0 °C. Figure 4 shows the concentration changes in $(-)^{CD}_{534}$-E-4 and the reaction products. A part of the numerical data (five data points) are listed in Table 2, together with the enantiomer excess percentage of each product. In the isomerization reaction of E-4 over a period of 150 h, three products — E-1 (major), E-5, and E-2 — were formed. The formation of E-2 was not detected during the first ca. 50 h; after that time, its amount increased very slowly. The E-2 isomer is likely to be produced from the E-5 or E-1 isomer. Therefore, the reaction paths in this isomerization may be expected to be as follows:

$$\text{E-4} \longrightarrow \text{E-5} \xrightarrow{?} \text{E-2}$$
$$\text{E-4} \longrightarrow \text{E-1} \xrightarrow{?} \text{E-2}$$

Throughout the reaction (150 h), no racemization of the starting material occurred: The recovered $(-)^{CD}_{534}$-E-4 retained 100% optical purity. As is shown in Table 2, $(+)^{CD}_{543}$-E-1 and $(-)^{CD}_{521}$-E-5, which were formed from $(-)^{CD}_{534}$-E-4 in a basic aqueous solution, showed optical purities of ca. 100% and ca. 60% respectively: These two isomerization paths are thus stereoselective.

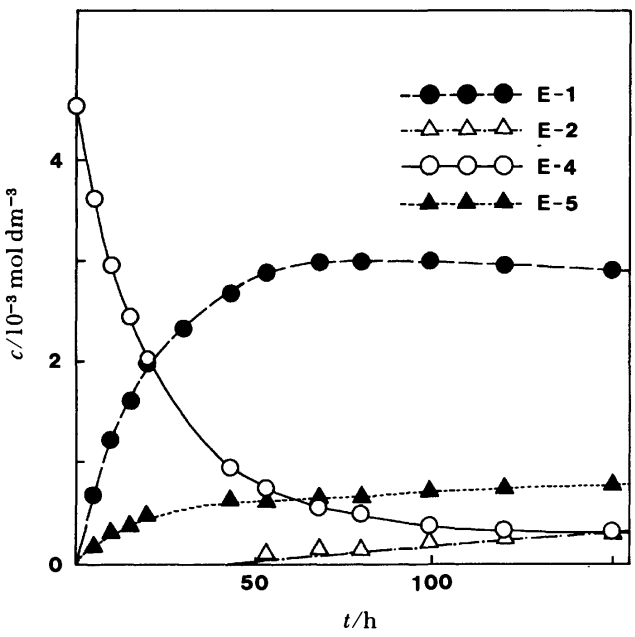

Fig. 4. The isomerization reaction of $(-)^{CD}_{534}$-E-4 in a basic aqueous solution (pH 10.35) at 40.0 °C.

$(+)^{CD}_{543}$-E-1 Isomer: In the isomerization reaction using $(+)^{CD}_{543}$-E-1 as the starting material, E-4 was formed first (Fig. 5 and Table 2). The amount of E-4

increased until ca. 50 h, but after that it was almost constant throughout the reaction examined here (150 h). The formation of E-5 was first observed ca. 20 h after the start of the reaction. The amount of E-5 increased with the passage of time and exceeded the amount of E-4 after ca. 140 h. The formation of E-2, in a very small amount, was observed later than that of E-5. From the results of the isomerization reactions of both E-1 and E-4, the following reaction path may be presumed:

$$\text{E-1} \longrightarrow \text{E-4} \longrightarrow \text{E-5} \longrightarrow \text{E-2}$$

As is shown in Table 2, $(-)^{CD}_{534}$-E-4, which was obtained by the isomerization reaction of $(+)^{CD}_{543}$-E-1, retained an optical purity of 80—90%, showing a high stereoselectivity in the E-1→E-4 change. On the other hand, the $(-)^{CD}_{521}$-E-5 produced in the same reaction retained an optical purity of only ca. 20%. This value is a little lower than the value to be expected from the presumed reaction path of $(+)^{CD}_{543}$-E-1→$(-)^{CD}_{534}$-E-4→$(-)^{CD}_{521}$-E-5, because pure $(+)^{CD}_{543}$-E-1 produced $(-)^{CD}_{534}$-E-4 with an optical purity of 80—90% and pure $(-)^{CD}_{534}$-E-4 produced $(-)^{CD}_{521}$-E-5 with an optical purity of ca. 60%. However, the successive reactions of $(+)^{CD}_{543}$-E-1→$(-)^{CD}_{534}$-E-4→$(-)^{CD}_{521}$-E-5 can also be supported by the following consideration. The absolute configurations of $(+)^{CD}_{543}$-E-1 and $(-)^{CD}_{521}$-E-5 are ΛΔΛ(S,S) and Δ(GG)Λ(EE)(R,R) respectively, as is shown in Table 1. If E-5 is formed directly from E-1, the inversions at the two asymmetric N centers must occur simultaneously. However, such inversions are very difficult judging from the consideration using molecular models. (If a direct $(+)^{CD}_{543}$-E-1→$(+)^{CD}_{521}$-E-5 change with a retention of the sec-N configuration by twist mechanism is slightly involved, the optical purity of $(-)^{CD}_{521}$-E-5 may be lowered.) The isomerization of E-1 was slower than that of E-4.

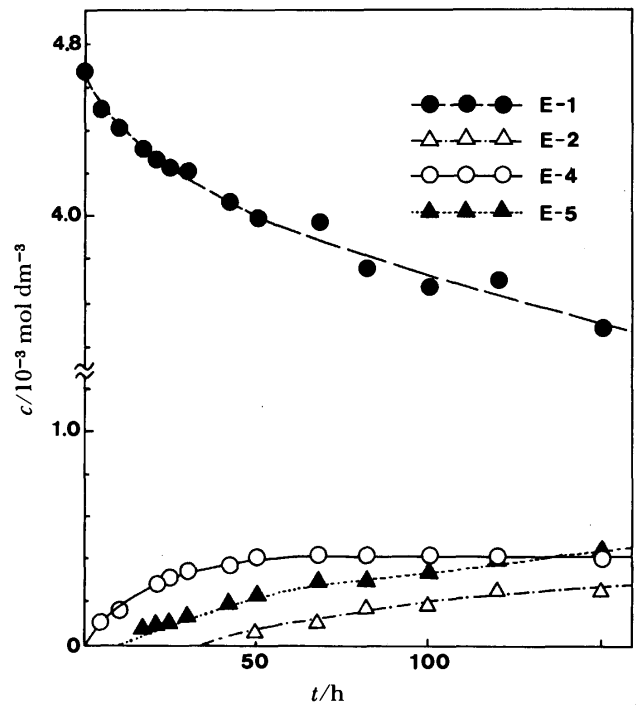

Fig. 5. The isomerization reaction of $(+)^{CD}_{543}$-E-1 in a basic aqueous solution (pH 10.35) at 40.0 °C.

$(-)^{CD}_{521}$-E-5 Isomer: The isomerization of $(-)^{CD}_{521}$-E-5 was also slow under the conditions of pH 10.35 and 40.0 °C. In this reaction, the formations of E-4 and E-2 first occurred, and then E-1 was formed. Early in the reaction (10—20 h) the amounts of the products were in the order of E-4>E-2>E-1. After ca. 30 h, the concentration of E-4 reached its maximum and thereafter did not increase, while the concentrations of E-1 and E-2 increased with the passage of time (Table 2), E-1 (after ca. 40 h) and E-2 (after ca. 70 h) exceeding E-4 in the amount formed. Thus, the following reaction paths may be presumed by considering the reaction paths of E-4:

$$\text{E-5} \longrightarrow \text{E-4} \longrightarrow \text{E-1}$$
$$\text{E-5} \longrightarrow \text{E-2}$$

We could not calculate the optical purity of the E-4 produced in the isomerization reaction of $(-)^{CD}_{521}$-E-5, because too little of it was formed for us to estimate the optical purity from the curve analyses of the absorption and CD spectra of the el-2 eluate [a mixture of E-5 (major) and E-4 (minor)]. The E-1 isomer obtained by the isomerization of $(-)^{CD}_{521}$-E-5 was of the $(+)^{CD}_{543}$ form, with an optical purity of ca. 80% (Table 2). Judging from the results of the isomerization of $(-)^{CD}_{534}$-E-4, the isomerization reaction of $(-)^{CD}_{521}$-E-5 can be expected to produce $(-)^{CD}_{534}$-E-4 selectively. This reaction path is the reverse of the isomerization path of $(+)^{CD}_{543}$-E-1 (E-1→E-4→E-5).

E-2 and $(-)^{CD}_{509}$-E-6 Isomers: The isomerization reaction of achiral E-2 is slow, and the major product is E-5, as is shown in Table 2. At longer times (>ca. 100 h), a small amount of E-1 was formed. (After 215 h, the E-1 constitutes ca. 30% of the reaction products.) It is thought that the E-1 is formed by the path of E-2→E-5→E-4→E-1. However, the formation of E-4 could not be observed. This is probably because the E-4→E-1 change is faster than the E-5→E-4 change.

The isomerization of $(-)^{CD}_{509}$-E-6 is the fastest among the reactions of this series (Table 2). The half-lives (with regard to the decrease in E-6) is ca. 4—5 h under the conditions of pH 10.35 and 40.0 °C. The isomerization reaction of $(-)^{CD}_{509}$-E-6 produced E-2 (major), E-5, and by-products. The E-5 formed in this reaction was racemate; this fact is favorable to the reaction path of E-6→E-2(achiral)→E-5. However, the observed formation rate of E-5 is a little faster than that to be expected from the path of E-6→E-2→E-5, where the E-2→E-5 change is very slow. Another reaction path passing through an achiral intermediate

(or transition state) may, therefore, be thought to exist.

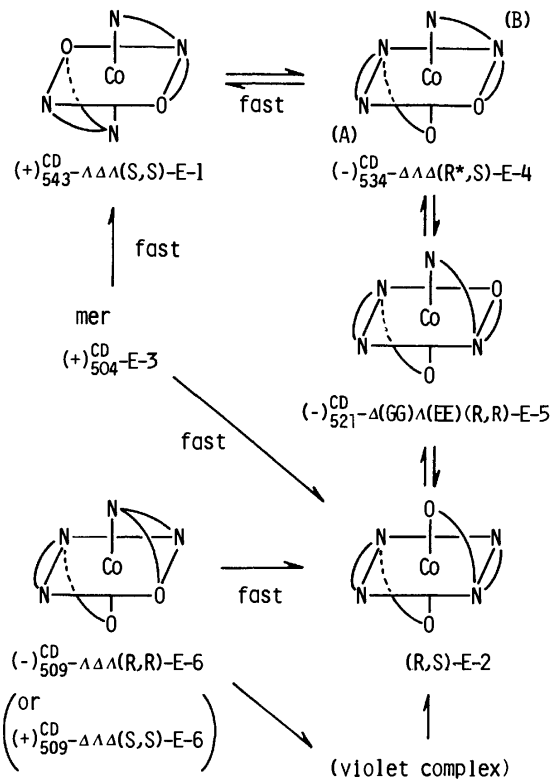
In the initial stage of the isomerization reaction of $(-)^{CD}_{509}$-E-6, a violet by-product was formed in a small amount. The amount of the violet by-product, which was a noncharged and optically active complex, was maximal ca. 3 h after the reaction start, and thereafter it gradually decreased. The violet complex could not be isolated, because it was unstable and was formed in only a small amount. During the concentration of the solution containing the violet complex under reduced pressure at 40 °C, the complex changed to E-2. In the isomerization reaction of E-6, the decomposition product, which was a species with a charge of more than +2, was observed after ca. 7 h; its amount increased slowly with the passage of time. The isomerization studies of E-6 and E-3 (to be discussed in the next section) were not sufficient, for the preparation of these isomers was very difficult.

$(+)^{CD}_{504}$-E-3 Isomer: The isomerization reaction of $(+)^{CD}_{504}$-E-3 was followed over a period of 53 h under the conditions of pH 10.35 and 40.0 °C. E-3 is thought to be thermodynamically less stable because of its meridional chelate form; however, the isomerization rate was slower than that of E-4 or E-6 (Table 2). The products were $(+)^{CD}_{543}$-E-1, with an optical purity of ca. 100%, and E-2; the formation ratio of these two isomers was ca. 1:1. The racemization of $(+)^{CD}_{504}$-E-3 was almost negligible throughout the reaction. The other products were in the limit of the accuracy of the experimental method. (However, it was presumed that a small amount of $(-)^{CD}_{534}$-E-4 was formed through the path of E-3→E-1→E-4 at longer times.) The E-3 ion provides six possible diastereomers, arising from three chiral centers (cobalt and two sec-N of coordinated two edma ligands): $\Lambda(C_2)$(R,R), $\Lambda(C_2)$-(R,S), and $\Lambda(C_2)$(S,S) and the $\Delta(C_2)$ series.[17] Judging from the racemization rate of *mer*-[Co(edma)(dien)],[18] it is presumed that the inversion of the sec-N configuration in E-3 occurs rapidly under the present reaction conditions; that is, the equilibration of the RR⇄RS⇄SS is rapidly attained. Therefore, the configuration at the cobalt center in E-3 is the main factor in determining the configuration of the E-1 formed, even though the shift of the RR⇄RS⇄SS equilibrium must also be taken into consideration. As the absolute configuration of the isolated $(+)^{CD}_{504}$- or $(-)^{CD}_{504}$-E-3 has not yet been determined, the reaction scheme of E-3 can not be discussed in detail. However, the formation of E-2 excludes the possibility of a twist mechanism for the isomerization of E-3.

The Main Isomerization Paths of the $[Co(edma)_2]^+$ Series. From the isomerization data examined here, the main paths of the isomerization of the $[Co(edma)_2]^+$ series are represented in Scheme 1.

(The "fast" in the scheme indicates qualitatively the relative rate of each path.) This isomerization scheme is different from that of the $[Co(ida)_2]^-$ system,[4] in which the isomerization proceeds through the mer isomer. In the present scheme, it is noteworthy that the inversion at one of two sec-N centers in $[Co(edma)_2]^+$ occurs in each isomerization step, except for the E-3→E-1 and E-3→E-2 changes. These experimental results can not be explained by the twist mechanism. The reasons are as follows: In all the isomers containing facially coordinated edma ligands (1) the twisting about the pseudo-C_3 axis passing through the triangle faces of the chelated edma ligands does not result in the inversion at the asymmetric sec-N of the edma ligand and (2) the possible twistings about other pseudo-C_3 axes provide E-3 (mer). (In the *fac*-$[Co(edma)_2]^+$ isomers, some of the twisting about the pseudo-C_3 axes is not possible because of the limits of the ligating manner of the linear terdentate edma ligand.) Thus, the isomerization reaction of the $[Co(edma)_2]^+$ series should be explained by the Co-O bond-rupture mechanism. (Recently, Baraniak et al. have revealed that the Co-O bond fission occurs in the $[Co(\beta\text{-ala})(en)_2]^+$ ion under alkaline conditions.[19])

When the coordination sites of the O and sec-N atoms of one edma ligand in the *fac*-$[Co(edma)_2]^+$ ion are exchanged for one another, the isomerization of the complex and the inversion at the sec-N center occur simultaneously. Such an exchange in *ΔΔΛ*(*S,S*)-E-1 leads to *ΔΔΔ*(*R*,S*)-E-4, corresponding to the $(+)^{CD}_{543}$-E-1→$(-)^{CD}_{534}$-E-4 change in Scheme 1. As E-4 is



Scheme 1.

the C_1 symmetry, the two edma ligands [(A) and (B) in Scheme 1] of E-4 are not equivalent: The sec-N of the (A) edma is in the trans position to the O atom of another edma ligand, while the sec-N of the (B) edma is in the trans position to the terminal N atom of the (A) edma ligand. The exchange of the coordination sites of the ligating sec-N and O atoms in the (A) edma ligand leads to the $(-)^{CD}_{534}$-E-4→$(+)^{CD}_{543}$-E-1 change, while the similar exchange in the (B) edma ligand leads to the $(-)^{CD}_{534}$-E-4→$(-)^{CD}_{521}$-E-5 change. Similarly, the exchange between the coordination sites of the sec-N and O atoms in one edma ligand of the $[Co(edma)_2]^+$ ion is found in the isomerization steps of $(-)^{CD}_{509}$[or $(+)^{CD}_{509}$]-E-6→E-2 and $(-)^{CD}_{521}$-E-5→$(-)^{CD}_{534}$-E-4 (Scheme 1). In the slow isomerization step of E-2⇄$(-)^{CD}_{521}$[or $(+)^{CD}_{521}$]-E-5, an exchange between the coordination sites of the terminal-N and O atoms in one edma ligand can be found. This exchange also results in the inversion at the asymmetric sec-N center.

Deuteration of the sec-NH Proton. The H–D exchange reaction of the two sec-NH protons in $[Co(edma)_2]^+$ was carried out in DCl–D_2O at 80 °C. In the ^1H NMR spectra for all isomers of $[Co(edma)_2]^+$, the two protons of the glycinate-ring (G-ring) $-CH_2-$ of the edma ligand are not equivalent, and the resulting AB system is further coupled to the proton on the adjacent sec-N atom to give an eight-line ABX spectrum. The kinetic data for the *fac*-$[Co(edma)_2]^+$ isomers were obtained by following the collapse of the ABX signal to an AB signal as the sec-NH protons exchange with D^+. The E-4 isomer has two kinds of sec-NH protons depending on the geometrical situation: Sec-NH of (A) and (B) edma in Scheme 1. The signals due to the G-ring $-CH_2-$ of (A) and (B) edma have been assigned in our previous paper.[15] However, this method was not suitable for the H–D exchange reaction of E-3, because the ABX spectrum was observed in a narrow chemical shift region. The rate data of the H–D exchange for E-3 was calculated from the decrease in the sec-NH peak area relative to the total G-ring $-CH_2-$ peak area. The H–D exchange results are collected in Table 3. The rate of the H–D exchange is fast in E-6 and in one of the edma ligands [(A) edma in Scheme 1] of E-4. These sec-NH lie in the position trans to the ligating oxygen atom (trans(O)-sec-NH). In E-3, the H–D exchange rate of sec-NH, which lies in the position trans to the ligating nitrogen atom (trans(N)-sec-NH), is comparable to those of the trans(N)-sec-NH in the fac isomers (Table 3). These results indicate that the H–D exchange rate of sec-NH is affected by the nature of the atom ligating in the trans coordination site rather than by the chelation form of the edma ligand (mer or fac).

Table 3. The H-D Exchange Rates of the Sec-NH Protons of the $[Co(edma)_2]^+$ Ion at 80 °C

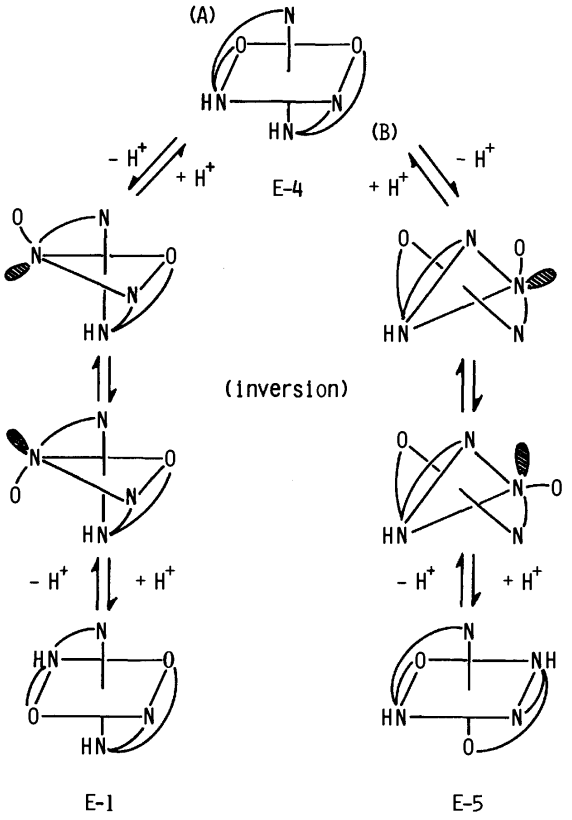
Isomer	k' / 10^{-3} s^{-1}	Isomer	k' / 10^{-3} s^{-1}	Isomer	k' / 10^{-3} s^{-1}
E-1	0.048	E-2	0.050	E-3	0.17
E-4 (A)	1.2	E-5	0.075	E-6	1.4
(B)	0.18				

(A): The position trans to the ligating O atom.
(B): The position trans to the ligating N atom.
Solvent: DCl(0.096 M)–D_2O.

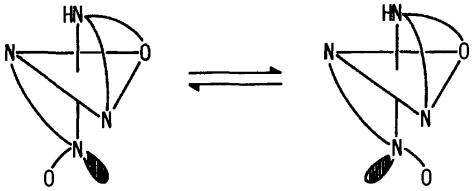
In Scheme 1, each isomerization step (except for E-3→E-1 and E-3→E-2) is shown to be accompanying the inversion at one of two asymmetric sec-N centers. In the slow isomerization paths, such as the E-4⇄E-5 change, the inversion occurs at the trans(N)-sec-N center, accompanied by a slow H–D exchange of the trans(N)-sec-NH proton. On the other hand, in the fast isomerization paths, such as E-4→E-1 and E-6→E-2, the inversion occurs at the trans(O)-sec-N center, accompanied by the fast H-D exchange of the trans(O)-sec-NH proton; a linear relationship can been seen between the rates of the isomerization and the H–D exchange. The isomerization reaction of the $[Co(edma)_2]^+$ complex is base-catalyzed and probably involves a conjugate base intermediate. Even though the $[Co(edma)_2]^+$ complex has more than one potentially acidic amine protons, the reactive conjugate base intermediate should be produced by the deprotonation at the secondary amine, for that deprotonation is essential for the inversion of the configuration about the sec-N center. (In this case, the isomerization rate constant (k_{obsd}) is represented, by using the pre-equilibrium constant (K_{CB}) and the isomerization rate constant of the conjugate base (k_0), as $k_{obsd}=K_{CB}k_0$.) If the H–D exchange rate is taken as a criterion for the degree of the deprotonation of the sec-NH proton (acidity),[20] it is probable that the acidity of the sec-NH is reflected in the difference in the isomerization rate for this series of complexes.

All the experimental data for the reactions of the $[Co(edma)_2]^+$ series are most satisfactorily accommodated by the proposal of transient five-coordinated intermediates formed by Co–O bond rupture. In the Co–O bond-ruptured state, the inversion at the sec-N of "bidentate edma" can be expected to occur easily under the present experimental conditions (40 °C, pH 10.35), judging from the inversion data of the cobalt(III) complexes containing *N*-methylethylenediamine or sarcosine as a ligand.[21–24] For the isomerization of E-4, the mechanism shown in Scheme 2 may be proposed. A similar reaction scheme may be presumed for the other isomerization process in Scheme 1. However, the postulated intermediate in the E-2⇄E-5 path may be pictured as Scheme 3, because, in this isomerization, an exchange between the coordination sites of the terminal-N and O atoms in one edma ligand occurs.

For E-3, which contains meridionaly coordinated edma, the rate of the H–D exchange at the sec-N



Scheme 2.



Scheme 3.

position is relatively slow, but the rate of the isomerization is relatively fast compared with those of the fac isomers (Tables 2 and 3); the result found for E-3 is different from those obtained in the fac isomers, in which "linear relationships" between the rates of the H-D exchange and isomerization reactions are observed. This may be attributed to the fact that the mer structure of an coordinated edma is thermodynamically less stable as a result of the strain on its mer chelate ring form. This unstability may be one of the reasons for the relatively rapid isomerization of E-3.

Kinetic Study of the Polymerization of Styrene in the Presence of Various Organic Hydroperoxides

Takeshi KOMAI* and Kazuo MATSUYAMA
Chemicals & Explosives Research Laboratory, Nippon Oil & Fats Co., Ltd.,
Taketoyo-Cho, Chita-Gun, Aichi 470-23
(Received January 5, 1987)

The polymerizations of styrene initiated by 2,2′-azobisisobutyronitrile have been carried out in the presence of various organic hydroperoxides, scuh as 1,1-dimethylethyl ($\mathbf{I}_a$), 1,1-dimethylbutyl ($\mathbf{I}_b$), and 1-methyl-1-phenylethyl hydroperoxides ($\mathbf{I}_c$) at 60 °C. The polymerization rate increased with the concentration of $\mathbf{I}_c$, but became rather retarded with that of $\mathbf{I}_a$ and $\mathbf{I}_b$. This phenomenon can be explained by the difference in the radical induced decomposition for the hydroperoxides. The hydroperoxide ($\mathbf{I}_c$) decomposes with a radical displacement on the peroxide bond; however, $\mathbf{I}_a$, and $\mathbf{I}_b$, in addition to this reaction, decompose with the radical hydrogen abstraction of the hydroperoxyl group. The peroxyl radical formed (ROO·) subsequently gave rise to a primary radical termination.

So far, many investigators have been interested in the decomposition of hydroperoxides (ROOH) which are significant substances as initiators for radical polymerization and intermediates in autoxidation processes[1] and biological systems.[2] However, the decomposition of hydroperoxides has not yet been made sufficiently clear. The decomposition mechanism of hydroperoxides is much more complicated than those of the other types of peroxides, i.e., dialkyl peroxide, diacyl peroxide and peroxyester.[3] For instance, the apparent rate constants for the decomposition reaction are considerably influenced by the structure and concentration of hydroperoxides, and on solvents.[4] This phenomenon has been attributed to the possibility that different types of decompositions occur simultaneously in the reaction. In addition to two types of homolytic radical decompositions, i.e., uni- (Eq. 1) and bimolecular decompositions (Eq. 2),

$$\mathrm{ROOH} \longrightarrow \mathrm{RO}\cdot + \cdot\mathrm{OH} \quad (1)$$

$$2\mathrm{ROOH} \longrightarrow \mathrm{RO}\cdot + \mathrm{H_2O} + \cdot\mathrm{OOR} \quad (2)$$

hydroperoxide decomposes with the following molecularly assisted homolysis (Eq. 3) and epoxidation (Eq. 4) in the presence of styrene (M). Furthermore,

$$\mathrm{ROOH} + \mathrm{M} \longrightarrow (\mathrm{MOH})\cdot + \mathrm{RO}\cdot \quad (3)$$

$$\mathrm{ROOH} + \mathrm{M} \longrightarrow \mathrm{C_6H_5CH(O)CH_2} + \mathrm{ROH} \quad (4)$$

two types of radical-induced decompositions (direct attack on the peroxide bond (Eq. 5) and hydrogen abstraction of the hydroperoxyl hydrogen atom (Eq. 6)), have also been postulated regarding the polymerization of styrene (N is polystyryl radical.).[3,5,6]

$$\mathrm{N} + \mathrm{ROOH} \longrightarrow \mathrm{NON\ (polymer)} + \mathrm{RO}\cdot \quad (5)$$

$$\mathrm{N} + \mathrm{ROOH} \longrightarrow \mathrm{NH\ (polymer)} + \mathrm{ROO}\cdot \quad (6)$$

For these reasons, the behavior of hydroperoxides in the polymerization process has not been fully understood.

Quantitative information concerning the decomposition of hydroperoxides was obtained by several kinetic studies on the polymerization. Johnson and Tobolsky[7] reported apparent chain-transfer constants of 1,1-dimethylethyl ($\mathbf{I}_a$) and 1-methyl-1-phenylethyl hydroperoxides ($\mathbf{I}_c$), 0.035 and 0.063, respectively. They did not recognize any difference of polymerization activity with the structure of hydroperoxide. A retardation of the polymerization rate has been observed for a high concentration of $\mathbf{I}_a$. Walling and Heaton explained this phenomenon kinetically by assuming a chain transfer of polystyryl radical with an $\mathbf{I}_a$ dimer to yield an unreactive species.[5] In this work, we studied kinetically polymerization in the presence of hydroperoxide using 2,2′-azobisisobutyronitrile (AIBN) as an initiator at 60 °C. The homolytic and ionic decompositions of Eqs. 1—4 are minimized under this experimental condition; the hydroperoxide may be mainly consumed with radical induced decompositions of Eqs. 5 and 6, i.e., chain-transfer reactions.

Results and Discussion

Kinetic Scheme. The bulk polymerization of styrene initiated by AIBN at 60 °C has been achieved in the presence of three hydroperoxides (**I**); the kinetic data are shown in Table 1. The overall scheme for the polymerization can be given as follows.

$$\mathrm{ROOH} = \mathrm{R_aR_bR_cCOOH} \quad (\mathbf{I})$$

$\mathbf{I}_a$: 1,1-dimethylethyl hydroperoxide ($\mathrm{R_a}=\mathrm{R_b}=\mathrm{R_c}=\mathrm{CH_3}$)

$\mathbf{I}_b$: 1,1-dimethylbutyl hydroperoxide ($\mathrm{R_a}=\mathrm{R_b}=\mathrm{CH_3}$, $\mathrm{R_c}=n\text{-}\mathrm{C_3H_7}$)

$\mathbf{I}_c$: 1-methyl-1-phenylethyl hydroperoxide ($\mathrm{R_a}=\mathrm{R_b}=\mathrm{CH_3}$, $\mathrm{R_c}=\mathrm{C_6H_5}$)

Decomposition of the initiators:

$$\mathrm{AIBN} \longrightarrow 2\mathrm{R}_1 + \mathrm{nitrogen} \quad 2f_1k_{d1}[\mathrm{AIBN}], \quad (7)$$

where R_1 is $(\mathrm{CH_3})_2\dot{\mathrm{C}}\text{-}\mathrm{CN}$, f_1, fraction of primary radical (R_1) escaping from solvent cage, k_{d1}, decomposition constant of AIBN. Chain initiation by the hydroperoxide is based on the reaction of Eqs. 1—3; however, only the bimolecular reaction between the

hydroperoxide and styrene (Eq. 3) becomes important in bulk polymerization at lower temperatures. Tobolsky and Matlack found that the rate of chain initiation (R_i) from hydroperoxide could be interpreted as bimolecular reactions of several types as shown in Eq. 8:[8]

$$R_i = k_{d2}[\mathrm{ROOH}][\mathrm{M}] + k'_{d2}[\mathrm{ROOH}][\mathrm{X}] \quad (8)$$

Here, X is a specific solvent, and k_{d2} and k'_{d2} are rate constants of bimolecular reactions, respectively. In bulk polymerization of styrene, the second term of the right-hand side in Eq. 8 can be neglected.

Chain initiation:

$$R_1 + M \longrightarrow N_1 \qquad k_{pr1}[R_1][M] \quad (9)$$

$$R_2 + M \longrightarrow N_2 \qquad k_{pr2}[R_2][M] \quad (10)$$

$$R_3 + M \longrightarrow R_5 \qquad k_{pr3}[R_3][M] \quad (11)$$

$$R_4 + M \longrightarrow N_2 \qquad k_{pr4}[R_4][M] \quad (12)$$

$$R_5 + M \longrightarrow N_2 \qquad k_{pr5}[R_5][M] \quad (13)$$

where k_{prj} is rate constant for the addition of primary radical, R_j (R_2=RO·, R_3=ROO·, R_4=(MOH)·, and R_5=ROOCH$_2$ĊHC$_6$H$_5$) to styrene and N_j is the polystyryl radical of j monomeric units. Walling and Heaton suggested that 60% of the 1-phenyl-2-*t*-alkylperoxyl ethyl radical (R_5) arising from Eq. 11 should yield styrene oxide in pure styrene at 70 °C.[5] The γ-scission of R_5 in Eq. 15 competes with the addition to styrene (Eq. 13):

$$R_5 \longrightarrow RO\cdot + \underset{\diagdown\,O\,\diagup}{CH_2\text{-}CHC_6H_5} \qquad k_\gamma[R_5] \quad (15)$$

Here, k_γ is rate constant of the γ-scission. The 2-cyano-2-propyl[9] and alkoxyl radicals[10] of R_1 and R_2 are very reactive against styrene, and R_4 and R_5 have the similar reactivity as polystyryl radical. The peroxyl radical of R_3 is most stable compared with the other radicals.

Propagation:

$$N_n + M \longrightarrow N_{n+1} \qquad k_p[N][M], \quad (16)$$

where k_p is propagation rate constant.

Chain transfer:

$$N_n + M \longrightarrow N_1 + \text{polymer} \qquad k_{trM}[N][M], \quad (17)$$

where k_{trM} is rate constant of transfer to styrene. Equations 5 and 6 are chain transfer to the hydroperoxide and the rates may be written respectively as:

$$\text{Rate of attack on the peroxide bond} = k_{trP}[N][\mathrm{ROOH}] \quad (18)$$

$$\text{Rate of hydrogen abstraction} = k_{trH}[N][\mathrm{ROOH}], \quad (19)$$

where k_{trP} and k_{trH} are the rate constants, respectively.

Termination:

$$N_n + N_s \longrightarrow \text{polymer} \qquad \bar{k}_t[N] \quad (20)$$

$$N_n + R_3 \longrightarrow \text{polymer} \qquad \bar{k}_{tpr3}[N][R_3] \quad (21)$$

where $\bar{k}_t$ is the rate constant of termination between polymer radicals, and k_{tpr3} is the rate constant of a primary radical termination between polymer and peroxyl redicals. Here, only the most stable peroxyl radical is considered to participates in a primary radical termination under these polymerization conditions.[11]

The polymerization rate is written:

$$R_p = k_p[N][M] + k_{pr1}[R_1][M] + k_{pr2}[R_2][M] + k_{pr3}[R_3][M] + k_{pr4}[R_4][M] + k_{pr5}[R_5][M] \simeq k_p[N][M] \quad (22)$$

The average chain length, $\bar{n}$, is written:

$$\bar{n} = \frac{k_p[N][M]}{\bar{k}_t[N]^2 + k_{trH}[N][M] + k_{trP}[N][M] + k_{tpr3}[N][R_3] + k_{trM}[N][M]} \quad (23)$$

Material balances under steady state condition give:

$$\frac{d[R_1]}{dt} = 2f_1k_{d1}[AIBN] - k_{pr1}[R_1][M] = 0 \quad (24)$$

$$\frac{d[R_2]}{dt} = k_{d2}[ROOH][M] + k_r[R_5] + k_{trP}[N][ROOH] - k_{pr2}[R_2][M] = 0 \quad (25)$$

$$\frac{d[R_3]}{dt} = k_{trH}[N][ROOH] - k_{tpr3}[R_3][N] - k_{pr3}[R_3][M] = 0 \quad (26)$$

$$\frac{d[R_4]}{dt} = k_{d2}[ROOH][M] - k_{pr4}[R_4][M] = 0 \quad (27)$$

$$\frac{d[R_5]}{dt} = k_{pr3}[R_3][M] - k_r[R_5] - k_{pr5}[R_5][M] = 0 \quad (28)$$

$$\frac{d[N]}{dt} = k_{pr1}[R_1][M] + k_{pr2}[R_2][M] + k_{pr4}[R_4][M] + k_{pr5}[R_5][M] - k_{trH}[N][ROOH] - k_{trP}[N][ROOH] - k_{tpr3}[N][R_3] - \bar{k}_t[N]^2 \quad (29)$$

Polymerization Initiated by AIBN. Data on a polymerization initiated by AIBN in the absence of hydroperoxide are analyzed by the conventional relationship between $\bar{n}$ and R_p.[7]

$$\frac{1}{\bar{n}} = \frac{k_{trM}}{k_p} + \frac{\bar{k}_tR_p}{k_p^2[M]^2} \quad (30)$$

Now, we obtained $k_{trM}/k_p = 6\times10^{-5}$ and $\bar{k}_t/k_p^2 = 1130$ mol s l^{-1}; the former is the same value as that of Johnson and Tobolsky, the later is between 840 and 1350 mol s l^{-1} in Ref. 12. The value of f_1k_{d1} for AIBN was found to be 3.1×10^{-6} s^{-1} from the usual polymerization rate equation.[7]

Polymerization Initiated by Hydroperoxide. The relationship among R_p, [M], and [ROOH] involving primary radical termination in the polymerization initiatedy a hydroperoxide is given by the following equation:

$$\frac{\bar{k}_tR_p^2}{k_p^2[M]^3[ROOH]} = 2k_{d2} - \frac{2(k_{tpr3}k_{trH}/k_p^2k_{pr3})(R_p/[M]^2)^2}{1+(k_{tpr3}/k_pk_{pr3})(R_p/[M]^2)} \quad (31)$$

The second term of the right-hand side in Eq. 31 shows the retardation of the rate based on a primary radical termination of the peroxyl radical. The value of the left-hand side in the equation approaches $2k_{d2}$ when $(R_p/[M]^2)^2$ is sufficiently close to zero. Figure 1 shows plots of ln $(\bar{k}_tR_p^2/k_p^2[M]^3[ROOH])$ vs. $(R_p/[M]^2)^2$ using the data from this work, the references[5,13] and the k_{d2} values obtained from the intercept of the plot (Table 2). The values of k_{d2} for $\mathbf{I}_a$ were found to be 6.1×10^{-9} s^{-1} at 60 °C and 8.4×10^{-9} s^{-1} at 70 °C, respectively.

The apparent chain transfer constant, k_{trC}/k_p, can be obtained from the conventional relationship between $\bar{n}$, R_p, [M], and [ROOH]:[5]

$$\frac{k_{trC}}{k_p} = \frac{[M]}{[ROOH]}\left(\frac{1}{\bar{n}} - \frac{k_{trM}}{k_p} - \frac{\bar{k}_tR_p}{k_p^2[M]^2}\right) \quad (32)$$

The values of k_{trC}/k_p were found to be 0.048 for $\mathbf{I}_a$, 0.065 for $\mathbf{I}_b$ and 0.117 for $\mathbf{I}_c$, respectively, from the data in Table 1. The value for $\mathbf{I}_a$ is between 0.035 at 60 °C[7] and 0.064 at 70 °C.[5]

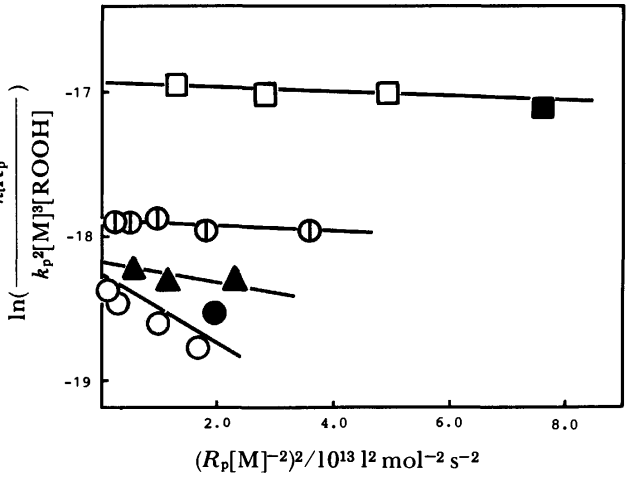

Fig. 1. Determination for chain initiation rate constants of some hydroperoxides: ○, $\mathbf{I}_a$ at 60 °C; ⊙, $\mathbf{I}_a$ at 70 °C; △, $\mathbf{I}_b$ at 60 °C; □, $\mathbf{I}_c$ at 60 °C; Closed circles, this work; Open circles, the data of references.[5,12]

Table 2. Various Rate Constants in the Polymerization of Styrene Initiated by AIBN in the Presence of Some Hydroperoxides at 60 °C

ROOH	$10^6f_1k_{d1}$ / s^{-1}	10^9k_{d2} / s^{-1}	k_{trH}/k_p	$(k_{trP}\cdot 2k_{trH})/k_p$	k_{trP}/k_p	$10^8\,k_{pr3}k_{trH}/k_{tpr3}$ / l s mol^{-1}	
						From Eq. 34.	From Eq. 36.
$\mathbf{I}_a$	2.3	6.1	0.025	0.09	0.040	1.2	1.7
$\mathbf{I}_b$	2.3	6.4	0.028	0.11	0.054	1.4	1.8
$\mathbf{I}_c$	2.3	22	0	0.117	0.117	—	—

Polymerization Initiated by AIBN in the Presence of Hydroperoxide. The relationship among R_p, [M], [AIBN], and [ROOH] in the polymerization initiated by AIBN in the presence of ROOH is

$$\frac{\bar{k}_t R_p^2}{k_p^2[M]^2[AIBN]} = 2f_1k_{d1} + 2\left(k_{d2}[M] - \frac{k_{trH}[N]}{1+k_{pr3}[M]/k_{tpr3}[N]}\right) \times \frac{[ROOH]}{[AIBN]} \quad (33)$$

When the value of $k_{tpr3}[N][R_3]$ is larger than that of $k_{pr3}[R_3][M]$, because $1/(1+k_{pr3}[M]/k_{tpr3}[N]) \simeq (1-k_{pr3}[M]/k_{tpr3}[N])$, Eq. 33 becomes:

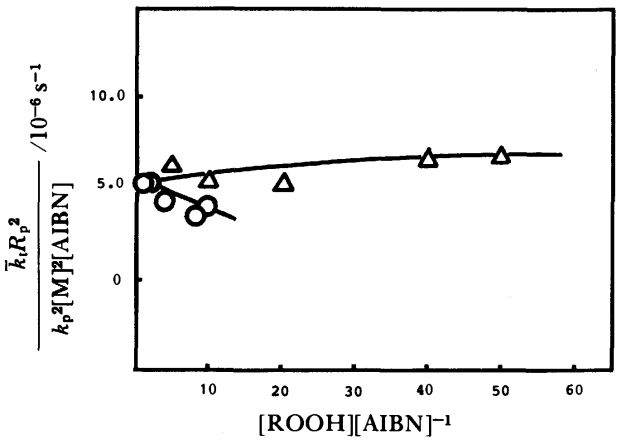

Fig. 2. Application of Eq. 34 to the data in the polymerization of styrene initiated by AIBN in the presence of I_a at 60 °C: Δ, [AIBN]=0.0048; O, [AIBN]=0.0239 mol l^{-1}; ——, Curves calculated by Lagrange's interpolation method, using the values of Table 2.

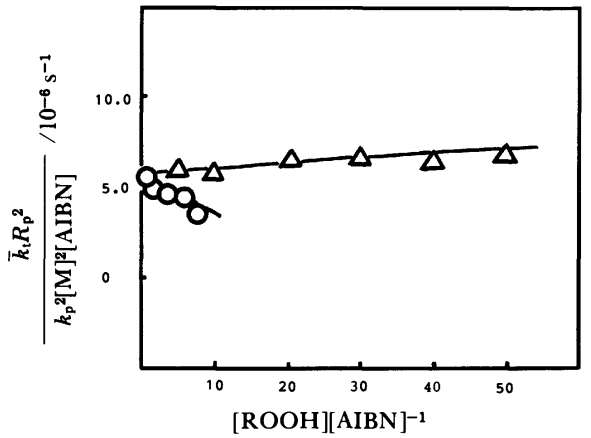

Fig. 3. Application of Eq. 34 to the data in the polymerization of styrene initiated by AIBN in the presence of I_b at 60 °C: Δ, [AIBN]=0.0048; O, [AIBN]=0.0239 mol l^{-1}; ——, Curves calculated by Lagrange's interpolation method, using the values of Table 2.

$$\frac{\bar{k}_t R_p^2}{k_p^2[M]^2[AIBN]} = 2f_1k_{d1} + 2\left(k_{d2}[M] - \frac{k_{trH}R_p}{k_p[M]} + \frac{k_{pr3}k_{trH}[M]}{k_{tpr3}}\right) \times \frac{[ROOH]}{[AIBN]} \quad (34)$$

The second term of the right-hand side in Eq. 34 shows chain initiation by hydroperoxide which depends on the polymerization rate (R_p). Figures 2—4 show plots of the values of the left-hand side in Eq. 34 against [ROOH]/[AIBN] at two concentrations of AIBN. The plots give a linear line for I_c, but two linear-like curves for I_a and I_b, respectively. The former increases linearly with [ROOH]/[AIBN]. However, the later remarkably decreases with [ROOH]/[AIBN] at a higher concentration of AIBN (higher polymerization rate) and distinctly shows a retardation owing to the hydroperoxide. The value of f_1k_{d1} was obtained from the intercept of the curves (shown in Table 2). Furthermore, the values of k_{trH}/k_p and $k_{pr3}k_{trH}/k_{tpr3}$ for I_a and I_b were estimated from Eq. 34 by a least-squares method using values of f_1k_{d1} and k_{d2} (also shown in Table 2). Using these values, the solid curves in Figs. 2 and 3 could be simulated using Lagrange's interpolation method. The value of k_{d2} for I_c obtained from the slope of the staight line in Fig. 4 was found to be 1.6×10^{-8} s^{-1}.

The relationship among $\bar{n}$, R_p, [M], and [ROOH] is

$$\frac{1}{\bar{n}} = \frac{k_{trM}}{k_p} + \left[\frac{k_{trP}}{k_p} + \left(\frac{2k_{tpr3}[N]+k_{pr3}[M]}{k_{tpr3}[N]+k_{pr3}[M]}\right)\frac{k_{trH}}{k_p}\right]\frac{[ROOH]}{[M]} + \frac{\bar{k}_t R_p}{k_p^2[M]^2} \quad (35)$$

The second term of the right-hand side in Eq. 35 exhibits a dependence on the chain length for chain transfers to hydroperoxide and the primary radical termination of the peroxyl radical. This term changes

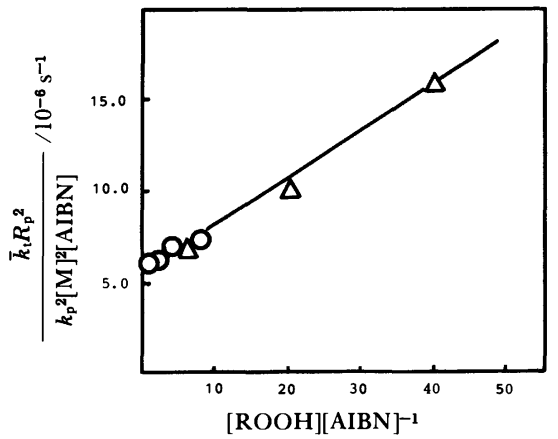

Fig. 4 A plot of $\bar{k}_tR_p^2/k_p^2[M]^2[AIBN]$ vs. [ROOH]/[AIBN] for the polymerization of styrene initiated by AIBN in the presence of I_c at 60 °C: Δ, [AIBN]=0.0048: O, [AIBN]=0.0239 mol l^{-1}.

largely with the relationship between $k_{tpr3}[N][R_3]$ and $k_{pr3}[M][R_3]$. When the value of $k_{tpr3}[N][R_3]$ is larger than that of $k_{pr3}[M][R_3]$, because $(2k_{tpr3}[N]+k_{pr3}[M]/(k_{tpr3}[N]+k_{pr3}[M])\simeq(2-k_{pr3}[M]/k_{tpr3}[N])$, Eq. 35 becomes:

$$\frac{1}{\bar{n}} = \frac{k_{trM}}{k_p} + \left(\frac{k_{trP}+2k_{trH}}{k_p} - \frac{k_{pr3}k_{trH}[M]^2}{k_{tpr3}R_p}\right)\frac{[ROOH]}{[M]} + \frac{\bar{k}_tR_p}{k_p^2[M]^2} \quad (36)$$

When $k_{tpr3}[N][R_3] \ll k_{pr3}[R_3][M]$, the value of $(2k_{tpr3}[N]+k_{pr3}[M])/(k_{tpr3}[N]+k_{pr3}[M])$ changes slightly with the value of $k_{pr3}[M]/k_{tpr3}[N]$: For example, it is 1.5 when $k_{pr3}[M]=k_{tpr3}[N]$, and 1.0 when $k_{pr3}[M] \gg k_{tpr3}[N]$. The values of $(1/\bar{n}-k_{trM}/k_p-\bar{k}_tR_p/k_p^2[M]^2)[M]/[ROOH]$ rearranged from Eq. 36 are plotted against $1/R_p$ for $\mathbf{I}_a$ and $\mathbf{I}_b$ in Figs. 5. and 6, respectively. The figures show that the value of $(1/\bar{n}-k_{trM}/k_p-\bar{k}_tR_p/k_p^2[M]^2)[M]/[ROOH]$ decreases with increasing $1/R_p$ and aproaches to a nearly constant value near the value of 3.0×10^4 l s mol^{-1} where $k_{tpr3}[N]\simeq k_{pr3}[M]$. The values of $(k_{trP}+2k_{trH})/k_p$ and $k_{pr3}k_{trH}/k_{tpr3}$ are estimated from the intercept and slop of Figs. 5 and 6 (Table 2). The value of $(1/\bar{n}-k_{trH}/k_p-\bar{k}_tR_p/k_p^2[M]^2)[M]/[ROOH]$ for $\mathbf{I}_c$ is constant against $1/R_p$ and the value of $(k_{trP}+2k_{trH})/k_p$ was found to be 0.117. The values of k_{trP}/k_p were calculated using the data in Table 2.

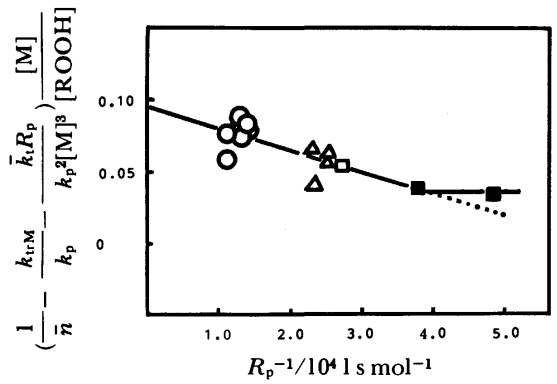

Fig. 5. Application of Eq. 36 to the data in the polymerization of styrene initiated by AIBN in the presence of $\mathbf{I}_a$ at 60 °C: □, [AIBN]=0; ■, [AIBN]=0 (the data of Baysal and Tobolsky[13]); △, [AIBN]=0.0048; ○, [AIBN]=0.0239 mol l^{-1}.

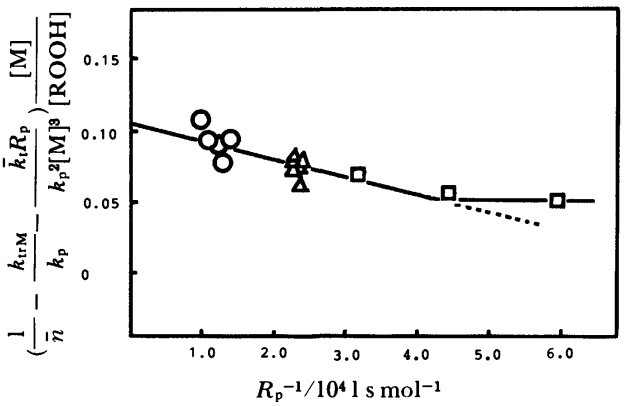

Fig. 6. Application of Eq. 36 to the data in the polymerization of styrene initiated by AIBN in the presence of $\mathbf{I}_b$ at 60 °C: □, [AIBN]=0; △, [AIBN]=0.0048; ○, [AIBN]=0.0239 mol l^{-1}.

Table 2 summarizes the rate constants in the polymerization of styrene initiated by AIBN in the presence of hydroperoxide at 60 °C. The same values of f_1k_{d1} for three hydroperoxides agree with those for a polymerization initiated only by AIBN. The values of k_{d2} and k_{trP}/k_p for $\mathbf{I}_c$ are larger than those of $\mathbf{I}_a$ and $\mathbf{I}_b$. The value of k_{trP}/k_p for $\mathbf{I}_a$ agrees reasonably well with 0.39 of k_{trC}/k_p for 1,1-dimethylethyl deuterioperoxide,[5] which hardly seemed to undergo a deuterium abstraction reaction of the deuterioperoxyl group. The value of k_{trH}/k_p for $\mathbf{I}_a$ is almost similar to that of $\mathbf{I}_b$, but is very different with that of $\mathbf{I}_c$. The values of $k_{pr3}k_{trH}/k_{tpr3}$ for $\mathbf{I}_a$ are almost similar to those of $\mathbf{I}_b$ in the cases in Eqs. 34 and 36; the values obtained from Eq. 34 are approximately equal to those from of Eq. 36. The values of $k_{pr3}k_p/k_{tpr3}$ calculated from the data in Table 2 were found to be in the range 5 to 7×10^{-7} l s mol^{-1}. These values are hardly influenced by the structure of the hydroperoxides and are much smaller than those of benzoyl peroxide and AIBN at 60 °C.[14] The bimolecular reaction between radicals is diffusion controlled; this result indicates that the rate constant (k_{pr3}) for the addition of the *t*-alkylperoxyl radical to styrene is one to six-hundredth as large as those of the primary radicals from benzoyl peroxide and AIBN. In fact, a rate constant of 1.3 l mol^{-1} s^{-1} for the addition of the 1,1-dimethylethylperoxyl radical to styrene at 30 °C was reported[15] to be much smaller than 55 mol^{-1} s^{-1} of the polystyryl radical. The ratio of the addition to styrene against the primary radical termination for *t*-alkylperoxyl radical was found to be in the range 0.3 to 1.2 in this work. Thus, the unexpected behavior of $\mathbf{I}_a$ and $\mathbf{I}_b$ may be sufficiently explained by the usual primary radical termination between polymer and peroxyl radicals[14] without assuming a chain transfer with the hydroperoxide dimer to yield unreactive species.[5] The phenomenon of inhibition and retardation in polymerization by traces of molecular oxygen may also be explained by the termination between the polymer radical and the peroxyl radical formed.[16]

In conclusion, the rates of the styrene-assisted homolysis and the radical displacement reaction on the peroxide bond of the hydroperoxides are considerably influenced by the structure of hydroperoxides, and the oders in the both reactions: $\mathbf{I}_c \gg \mathbf{I}_b > \mathbf{I}_a$.[17] A radical hydrogen abstraction reaction by polystyryl radical was observed for *t*-alkyl hydroperoxides ($\mathbf{I}_a$ and $\mathbf{I}_b$), but not for α-aryl-substituted *s*-alkyl hydroperoxides ($\mathbf{I}_c$).

Experimental

Materials. The commercial products of I_a and I_b from Nippon Oil & Fats Co., Ltd. were distilled under reduced pressure. The commercial product of I_c from Nippon Oil & Fats Co., Ltd. was purified by isolation of the sodium salt, regeneration of the hydroperoxide by carbon dioxide and vacuum distillation. The distilled materials were shown to be 97—99% pure by iodometric titration. The commercial product of AIBN was purified by recrystallization. Styrene was fractionated under reduced pressure, stored at −20 °C and used within 24 h.

Procedure. Styrene and initiators were put in a glass ampoule and degassed under reduced pressure by the freeze-thaw technique. The polymerization of styrene was carried out at 60.0±0.2 °C. The conversions were estimated by gel permeation chromatography (GPC). Ultimate conversions were less than 10%. The average molecular weight of polymer was estimated by GPC.

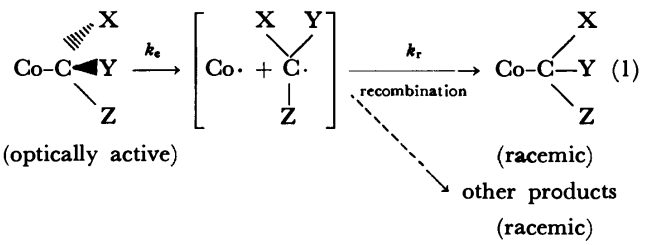
Preparation and Reaction of Optically Active Organotransition Metal Complexes. II.[1] Preparation and Photoracemization of Optically Active (1-Cyanoethyl)cobaloxime Complexes Coordinated with Various Axial Ligands

Shoe BABA,† Yoshiaki OHGO,* and Seiji TAKEUCHI
Niigata College of Pharmacy, 5-13-2 Kamishin'ei-cho, Niigata 950-21
†Niigata Academy of Medical Technology, 5-13-3 Kamishin'ei-cho, Niigata 950-21
(Received March 16, 1987)

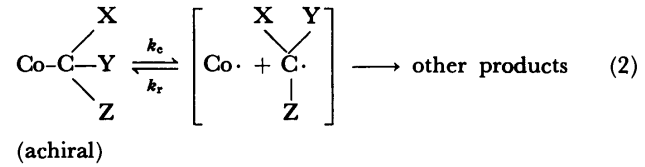
Optically active (1-cyanoethyl)cobaloxime complexes coordinated with various pyridines, phosphines and amines etc. as axial ligands were prepared and their photoracemization rates were measured in a solution state. It was found that the steric factor, rather than the electronic, of the axial ligand controlled, predominantly, the rate of Co–C bond homolysis in these alkylcobaloximes.

Syntheses and reactions of chiral alkyl transition metal complexes can provide a clearer description of the elementary process of catalytic reactions involving alkyl transition metal intermediates. We have shown various useful properties of optically active alkyl cobalt complexes for an elucidation of solution-state and solid-state reactions of the Co–C bond formation and cleavage.[1-4,7]

In relation to coenzyme B_{12} chemistry, extensive investigations on the reactions of alkyl cobalt complexes, including thermal and photochemical decompositions, have been made by UV-VIS and NMR spectroscopies using achiral complexes. However, spectroscopic methods involving achiral complexes include, in general, possibilities for underestimating or overestimating the rate of Co–C bond cleavage unless an elaborated kinetic treatment is made.[4] A chiroptical measurement using optically active alkyl metal complexes provides a more simple, precise evaluation of the forward rate, since alkyl radicals formed by bond homolysis are "planar or rapidly inverting pyramid".[5] Thus, recombinations of these species with Co(II) and all other subsequent reactions such as radical coupling, beta-elimination etc., will give substantially racemic or achiral products (Eqs. 1 and 2).[4]



(1)



(2)

Consequently, Eqs. 3 and 4 were established for the Co–C bond homolysis of the optically active alkyl complexes:

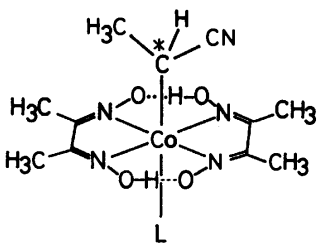
$$-\mathrm{d[R]}/\mathrm{d}t = k_c[\mathrm{R}] \quad (3)$$

and

$$-\mathrm{d}\alpha/\mathrm{d}t = k_c\alpha. \quad (4)$$

Here, k_c is the rate constant for the Co–C bond cleavage, k_r the rate constant for the recombination, [R] the concentration of the reactant and α the optical rotation.

We wish to describe here the preparation of optically active (1-cyanoethyl)bis(dimethylglyoximato)-cobalt(III) complexes which have chirality at the carbon bound directly to the cobalt atom (Fig. 1) as well as the influence of the axial ligand on the rate of the photochemical Co–C bond homolysis.



L: pyridines
phosphines
amines
etc.

Fig. 1. Chiral (1-cyanoethyl)cobaloximes coordinated with various axial ligands.

Results and Discussion

Preparation of Optically Active (1-Cyanoethyl)-cobaloximes. Optically active (1-cyanoethyl)cobaloximes which are coordinated with various axial ligands were prepared according to the method described in a previous paper.[1] The newly prepared

complexes were characterized by elemental analyses as well as IR and NMR spectra. The ^{1}H NMR spectra and main bands of the IR spectra are shown in Tables 1 and 2. Their configurations and specific rotations are given in Table 3.

Photoracemization Reaction for (4-Substituted Pyridine)-Coordinated Cobaloximes. The optical rotations of a methanol solution of the optically active (1-cyanoethyl)cobaloxime complexes coordinated with various 4-substituted pyridines gradually decreased owing to Co–C bond cleavage upon visible-light irradiation. ln α vs. time were approximately linear. The k_c values obtained from the slopes of these first-order rate plots decreased only slightly with increasing pK_a value of the axial ligand (Table 4). This trend coincides with that in a thermal reaction,[4] and shows that the electron-donation ability of 4-substituted pyridine ligand influences, to some degree, the rate of the Co–C bond photolysis. However, the effect is very small in this series.

Photoracemization Reaction of Phosphine-Coordinated Cobaloximes. A photoracemization reaction of the optically active (1-cyanoethyl)cobaloxime complexes coordinated with various phosphines was carried out under the same conditions as that of (4-substituted pyridine)-coordinated complexes, except for the use of chloroform as the solvent.

The ^{1}H NMR spectrum of the PPh_3-coordinated complex solution suggested that the equilibrium accompanying an axial ligand dissociation existed in this system (Eq. 5).

In order to obtain the rate for the "ligand-on" form, free phosphine was added to the cobaloxime solution and photoracemization experiments were carried out. The value of k_c increased with increasing added free PPh_3 and reached a maximum in the case of the PPh_3 complex **10** (Fig. 2). This phenomenon shows that the rate of racemization is faster in "ligand-on" form than in "ligand-off" form, because addition of PPh_3 will promote the formation of "ligand-on" complex. A similar phenomenon was also observed in the P(*p*-$ClC_6H_4)_3$-coordinated complex **11** (Fig. 2). On the contrary, the addition of free phosphine did not substantially affect the photoracemization rate in the case of complexes coordinated with PEt_3, P(*n*-Bu)$_3$, $PMePh_2$, and $PEtPh_2$ (**5**, **6**, **8**, and **9**) (Fig. 3). These

results show that the degree of ligand dissociation is negligibly small in the latter complexes, even without the addition of free phosphine since these phosphines have both stronger basicities and smaller steric

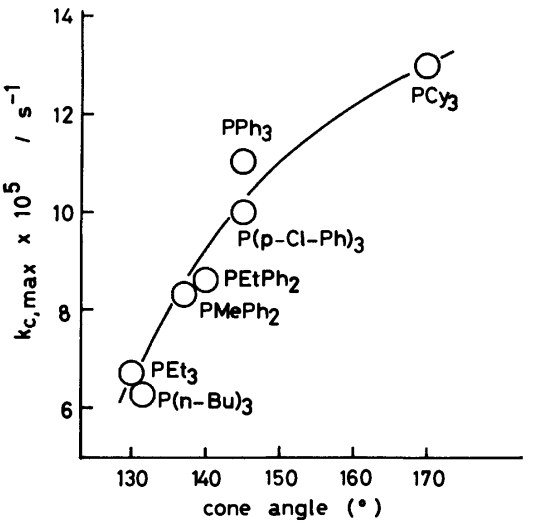

Fig. 5. Relationship between $k_{c,max}$ and the cone angle for phosphine-coordinated cobaloximes.

hindrances than PPh_3 and $P(p\text{-}ClC_6H_4)_3$. This can be seen from Table 5, which shows the large pK_a values of the conjugated acids and the small Tolman's cone angles[6] on these phosphines. On the other hand, the Co–P bonds in the former complexes (**10** and **11**) are weakened owing to the weak basicity and steric bulkiness of the triarylphosphines; therefore, ligand dissociation will be promoted.

Steric Influence of the Axial Phosphine on the Co–C Bond Photocleavage. Table 5 gives $k_{c,max}$, the maximum value of photoracemization rate constant obtained for the "ligand-on" form whose formation was promoted by the addition of free phosphine. The value of $k_{c,max}$ increased in the following order: $PEt_3 \lesssim P(n\text{-}Bu)_3 < PMePh_2 \lesssim PEtPh_2 < P(p\text{-}ClC_6H_4)_3 < PPh_3$. Either the electronic or steric factor of the phosphine ligand is responsible for this order. As can be seen from Table 5, the value of $k_{c,max}$ increased with an increase in the cone angle as well as a decrease in the pK_a value. Therefore, it cannot be determined whether the electronic or the steric effect acts as a dominant factor in influencing the value of $k_{c,max}$.

Tricyclohexylphosphine (PCy_3) has maximum values with respect to both the cone angle (170° [6]) and pK_a (9.70[9]), compared with preceding phosphines. Therefore, if the electronic factor is dominant in the case of the PCy_3-coordinated complex, the photoracemization rate will be minimum. On the contrary, if the steric factor is dominant, the maximum photoracemization rate will be obtained. Unfortunately, a PCy_3-coordinated complex could not be isolated, perhaps owing to its instability. However, the PCy_3-coordinated complex was formed in situ by the addition of PCy_3 to a chloroform solution of the aqua-coordinated complex **15**. This was confirmed by the ^1H NMR spectrum. The photoracemization experiment on this solution revealed that $k_{c,max}$ is $13 \times 10^{-5}\ s^{-1}$ (Fig. 4); this is the largest value obtained for all the cobaloxime complexes coordinated with pyridines and phosphines.

Consequently, as revealed by Fig. 5, these experimental data clearly demonstrate that the cone angle of a phosphine ligand is a dominant factor influencing the value of $k_{c,max}$ (the rate of Co–C bond photocleavage).††

In Table 6, the structural parameters around the Co atom based on the X-ray crystallographic analyses[7] are summarized for the complexes coordinated with $P(n\text{-}Bu)_3$, $PEtPh_2$, and PPh_3 (**6**, **9**, and **10**). The values of θ (the acute dihedral angle between the planes of the two glyoximato groups), d (the displacement of the Co

†† Recently Halpern et al. have reported a similar result in thermal reaction for the alkylcobaloximes.[8]

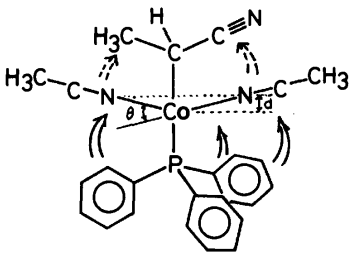

Fig. 6. Repulsive interaction in the PPh_3-coordinated cobaloxime.

atom toward the P atom from the mean plane composed of four nitrogen atoms in the equatorial ligand), and the Co-P distances increased with an increase in the cone angle of the phosphine ligand, probably in order to avoid the shortest contacts between the substituents of the phosphine ligand and the cobaloxime moiety. On the other hand, the Co-C bond length varied little. Therefore, with increasing steric bulkiness of the phosphine ligand, the 1-cyanoethyl group and the cobaloxime moiety come so close together that their mutual repulsion increases and the Co-C bond becomes strongly strained. This situation is depicted in Fig. 6 using, as an example, the PPh_3-coordinated cobaloxime.

In a solution state, the steric effect of the phosphine ligand on the Co-C bond may operate in a similar manner as that of the above description regarding a crystalline state. Thus, it is concluded that the acceleration of the photocleavage of the Co-C bond is responsible for the increase of the strain on this bond, arising from an increase in the steric bulkiness of the phosphine ligand. The electronic effect of the axial ligand on the Co-C bond photocleavage is found to be much smaller than the steric effect and, therefore, to be masked by the steric factor within this series.

Experimental

Apparatus. The IR spectra were recorded on a JASCO A-3 spectrometer using KBr disks. The ^1H NMR spectra were obtained on a JEOL FX-200 spectrophotometer, using TMS as the internal standard.

The optical rotations were measured on a Perkin-Elmer 241 polarimeter.

Photoracemization. The sample for photoracemization was dissolved under dim light at ca. 2×10^{-3} mol dm^{-3} in chloroform which was freed from dissolved oxygen by bubbling with a stream of argon for about 30 min. The sample solution was placed in a glass (Pyrex) cell for a measurement of the optical rotation; photoreactions were carried out under the conditions of visible-light irradiation using four 40-W fluorecent lamps "white" (Matsushita Elec. Ind. Co.) at 25±2 °C. The cell was placed at the distance of ca. 3.0 m from the light source; at that distance the radiation intensity was 0.008 mW cm^{-2}. The optical rotations (α), which gradually decreased upon irradiation, were measured at regular time intervals. In the dark conditions, the optical rotation didn't vary while standing overnight.

Materials. All chemicals were reagent grade commercial materials and used without further purification.

All chiral (1-cyanoethyl)cobaloximes coordinated with various pyridines, phosphines, amines etc. were prepared by a ligand exchange reaction for [(*R*) or (*S*)-1-cyanoethyl]bis-(dimethylglyoximato)[(*S*)-1-phenylethylamine]cobalt(III) (**1**(*R*) or **1**(*S*)) prepared according to a preceding paper.[1] All the preparative operations were performed in the dark.

[(*R*)-1-Cyanoethyl](4-cyanopyridine)bis(dimethylglyoximato)cobalt(III) (2): To a methanol solution (10 cm^3) of 0.50 g of **1**(*R*) were added 0.8 cm^3 of 2 mol dm^{-3} hydrochloric acid and 0.17 g of 4-cyanopyridine. After standing for 4 h at 30 °C, water (10 cm^3) was added to the reaction mixture; the solution was then cooled overnight. Deposited dark brown crystals were collected by filtration; 0.44 g (91%). The crude product was recrystallized several times from acetone-water to give plates. Found: C, 45.34; H, 5.10; N, 22.14%. Calcd for $C_{17}H_{22}N_7O_4Co$: C, 45.64; H, 4.96; N, 21.92%.

(4-Chloropyridine)[(*R*)-1-cyanoethyl]bis(dimethylglyoximato)cobalt(III) (3) and [(*R*)-1-Cyanoethyl]bis(dimethylglyoximato)(4-methylpyridine)cobalt(III) (4): These were similarly prepared for **2** by using 4-chloropyridine and 4-methylpyridine, respectively, in place of 4-cyanopyridine. For **3**: Crude yield, 71%. Brown needles (acetone-water). Found: C, 42.14; H, 5.08, N, 18.71%. Calcd for $C_{16}H_{22}N_6O_4ClCo$: C, 42.07; H, 4.85; N, 18.40%. For **4**: Crude yield, 74%. Brown needles (acetone-water). Found: C, 46.37; H, 5.82; N, 19.34%. Calcd for $C_{17}H_{25}N_6O_4Co$: C, 46.79; H, 5.77; N, 19.26%.

[(*S*)-1-Cyanoethyl]bis(dimethylglyoximato)(triethylphosphine)cobalt(III) (5): To a acetone (30 cm^3) solution of a 1.5 g of **1**(*S*) were added 1.62 cm^3 of 2 mol dm^{-3} hydrochloric acid and 0.72 cm^3 of PEt_3. After having been stirred for 20 h under a nitrogen atmosphere at room temperature, a 10 cm^3 of water was added to the solution. The resulting solution was concentrated under reduced pressure. Deposited orange crystals were collected by filtration; 1.25 g (84%). The crude product was recrystallized from methanol-water to give columns. Found: C, 44.09; H, 7.53; N, 15.07%. Calcd for $C_{17}H_{33}N_5O_4CoP$: C, 44.25; H, 7.21; N, 15.18%.

[(*R*)-1-Cyanoethyl]bis(dimethylglyoximato)(triphenylphosphine)cobalt(III) (10): A 0.50 g of **1**(*R*) was dissolved in methanol (20 cm^3) and then 0.42 g of PPh_3 and 0.54 cm^3 of

2 mol dm^{-3} hydrochloric acid were added. The reaction mixture was stirred overnight under an argon atmosphere at room temperature. Then, 10 cm^3 of water was added and the resulting solution was cooled. Deposited dark brown crystals were collected by filtration; 0.57 g (87%). The crude product was recrystallized several times from methanol–water to give flakes. Found: C, 56.66; H, 5.79; N, 11.26%. Calcd for $C_{29}H_{33}N_4O_5CoP$: C, 57.52; H, 5.49; N, 11.57%.

[(*R*)-1-Cyanoethyl]bis(dimethylglyoximato)(tributylphosphine)cobalt(III) (6) and [(*R*)-1-Cyanoethyl]bis(dimethylglyoximato)(diphenylmethylphosphine)cobalt(III) (8): These complexes were similarly prepared for **10** by using P(*n*-Bu)$_3$ and PMePh$_2$ respectively in place of PPh$_3$. For **6**: Crude yield, 56%. Orange columns (methanol–water). Found: C, 50.85; H, 8.85; N, 12.85%. Calcd for $C_{23}H_{45}N_5O_4CoP$: C, 50.64; H, 8.31; N, 12.84%. For **8**: Crude yield, 68%. Brown plates (acetone–water). Found: C, 52.97; H, 5.82; N, 12.97%. Calcd for $C_{24}H_{31}N_5O_4CoP$: C, 53.04; H, 5.75; N, 12.89%.

[(*R*)-1-Cyanoethyl][diethyl(phenyl)phosphine]bis(dimethylglyoximato)cobalt(III) (7): 1.0 g of **1**(*R*) was dissolved in methanol (30 cm^3) and then 0.6 cm^3 of PEt$_2$Ph and 1.08 cm^3 of 2 mol dm^{-3} hydrochloric acid were added. The solution was stirred for 46 h under a nitrogen atmosphere at room temperature and then concentrated under reduced pressure. 10 cm^3 of acetone was added to the residual syrup. After the deposited white needles were removed by filtration, water was added to the filtrate and the resulting solution was cooled. Deposited brown crystals were collected by filtration; 0.70 g (64%). The crude product was recrystallized several times from acetone–water. Found: C, 49.34; H, 6.72; N, 13.67%. Calcd for $C_{21}H_{33}N_5O_4CoP$: C, 49.51; H, 6.53; N, 13.75%.

[(*R*)-1-Cyanoethyl]bis(dimethylglyoximato)(diphenylethylphosphine)cobalt(III) (9): 1.0 g of **1**(*R*) was dissolved in acetone (20 cm^3) and then 0.77 cm^3 of PEtPh$_2$ and 1.08 cm^3 of 2 mol dm^{-3} hydrochloric acid were added. The solution was stirred for 23 h under a nitrogen atmosphere at room temperature and then dried under reduced pressure. To the acetone solution of the residue was added water. Deposited brown crystals were collected by filtration; 0.76 g (63%). The crude product was recrystallized twice from acetone–water to give plates. Found: C, 53.74; H, 6.09; N, 12.55%. Calcd for $C_{25}H_{33}N_5O_4CoP$: C, 53.86; H, 5.97; N, 12.56%.

Aqua[(*R*)-1-cyanoethyl]bis(dimethylglyoximato)cobalt(III) (15): To a methanol (20 cm^3) solution of 4.0 g of **1**(*R*) was added 8.6 cm^3 of 2 mol dm^{-3} hydrochloric acid and the solution was stirred for 16 h under a nitrogen atmosphere at room temperature. A 17 cm^3 of 6 mol dm^{-3} hydrochloric acid was added. The resulting aqua complex was extracted with three 60 cm^3 portions of dichloromethane. The extract was neutralized by adding solid potassium carbonate. After standing overnight, the dichloromethane was dried under reduced pressure to give a crystalline mass of **15**; 2.2 g (87%). This complex was satisfactorily used for further syntheses of **11**, **13**, and **14**. The structure of **15** was confirmed by the ^{1}H NMR spectrum.

[(*R*)-1-Cyanoethyl]bis(dimethylglyoximato)[tris(*p*-chlorophenyl)phosphine]cobalt(III) (11): A 0.65 g of **15** was dissolved in dichloromethane and 0.70 g of P(*p*-ClC$_6$H$_4$)$_3$ was added. The solution was stirred for 7 h under a nitrogen atmosphere at room temperature and then the solvent was removed under reduced pressure. To the resulting syrup acetone (20 cm^3) and a small amount of water were added. After the white precipitate had been removed by filtration, the filtrate was cooled. The deposited brown crystals were collected by filtration. The crude product was recrystallized from acetone–water. The structure of **11** was confirmed by the ^{1}H NMR spectrum. The pattern of spectrum was analogous to that of **10**.

[(*R*)-1-Cyanoethyl]bis(dimethylglyoximato)(piperidine)cobalt(III) (13): A 0.80 g of **15** was dissolved in methanol (5 cm^3) and 0.38 cm^3 of piperidine was added. The solution was allowed to stand overnight at room temperature. A 5 cm^3 of water was added and the resulting solution was cooled overnight to give dark brown flakes; 0.55 g (58%). The crude product was recrystallized several times from methanol–water. The structure of **13** was confirmed by the ^{1}H NMR spectrum.

[(*R*)-1-Cyanoethyl]bis(dimethylglyoximato)(pyrrolidine)cobalt(III) (14): This complex was similarly prepared for **13** by using pyrrolidine in place of piperidine. Crude yield, 0.25 g (45%). Dark brown plates (methanol–water). The structure of **14** was confirmed by the ^{1}H NMR spectrum.

[(*R*)-1-Cyanoethyl]bis(dimethylglyoximato)(triethylphosphite)cobalt(III) (12): A 0.35 g of **2** was dissolved in dichloromethane (3 cm^3) and 0.15 cm^3 of P(OEt)$_3$ was added. After having been stood for 1 h at room temperature, the solution was dried under reduced pressure. To the residual syrup were added 0.5 cm^3 of methanol and successively 2 cm^3 of water and then the solution was cooled overnight to give yellow leaflets; 0.12 g (30%). The crude product was recrystallized from methanol–water. The structure of **12** was confirmed by the ^{1}H NMR spectrum.

The Effect of Intramolecular Hydrogen Bonding on the Rotational Barriers about the C-N Bonds of *o*-Hydroxyarenecarboxamides

Hiroko SUEZAWA,* Kin-ya TSUCHIYA, Eiji TAHARA, and Minoru HIROTA
Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Hodogaya-ku, Yokohama 240
(Received April 2, 1987)

Rotational barriers about the C-N bonds of several *o*-hydroxyarenecarboxamides were determined in four solvents (namely, chloroform, pyridine, methanol, and dimethyl sulfoxide) by DNMR spectroscopy and compared with those of arenecarboxamides void of ortho-hydroxyl group. The height of the rotational barrier is correlated with the strength of the intramolecular O-H···O=C hydrogen bond. The unusual solvent effect on the rotational barriers of these hydroxy-amides are ascribed to the cleavage of the intramolecularly hydrogen bonded chelate ring which occurs in both hydrogen-donating and -accepting solvents.

Rather extensive studies have been reported on the dynamic NMR spectroscopic behaviors of amides,[1-7] and rotational barriers about the C-N bonds of unsaturated and aromatic amides have been shown to be strongly affected by the conjugative properties of their hydrocarbon moiety with the carbonyl group, as revealed by the rotational barriers of *N,N*-dimethylacrylamide[1] and *N,N*-dimethylbenzamide[2] (69.8 and 64.9 kJ mol^{-1}, respectively) which are considerably lower than that of *N,N*-dimethylformamide (87.4 kJ mol^{-1}).[3] Several *o*-substituted benzamides have higher rotational barriers than those of the unsubstituted and the high barrier has been ascribed to the steric inhibition, at least partly, of the conjugation between the aryl and the carboxamide groups.[2,7] Several years ago, we reported on the effect of intramolecular hydrogen bonding on the rotational barrier of *N,N*-dimethylsalicylamide.[8] The report showed that the rotational barrier of the *o*-hydroxy amide is significantly lower than those of usual *N,N*-dimethylbenzamides. Similar lowering in the rotational barrier due to the effect of hydrogen bonding was also illustrated with *o*-aminobenzamide by Jackman in his book.[9]

In this research, the rotational barriers of several other *N,N*-dimethyl-*o*-hydroxyarenecarboxamides were determined in order to further clarify the effect of intramolecular hydrogen bonding. Solvent effect on the rotational barriers of several benzamides were also studied systematically and the peculiar solvent effect on the rotational barriers of *o*-hydroxyarenecarboxamides was disclosed and interpreted.

Experimental

N,N-Dimethyl- and *N,N*-dibenzylarenecarboxamides were prepared as usual by the reaction of the corresponding aroyl chlorides with dimethyl- and dibenzylamines, respectively.

^{1}H and ^{13}C NMR spectra were recorded on a JEOL FX-90Q spectrometer using 10-mm probe. The samples for the measurements were prepared by dissolving ca. 100 mg of the amide in ca. 1.5 ml of the solvent, the concentrations of the solutions being adjusted to be ca. 0.5 mol dm^{-3}. Chloroform-*d*, methanol-d_4, pyridine-d_5, and dimethyl-d_6 sulfoxide (DMSO-d_6) were used as solvents throughout this work. The ^{1}H and ^{13}C spectra were obtained at 89.56 and 22.50 MHz, respectively. Temperature-dependent NMR in order to obtain ΔG^* were measured with an aid of JES-VT-3 variable temperature apparatus. The ΔG^* values were determined at the coalescence temperatures. In order to evaluate the ΔG^* values very accurately, the rates of exchange between the two sites were computed by the simulation of line shapes near the coalescence temperature and used supplementally.

Results and Discussion

Variable temperature measurements on the methyl ^{1}H signals of various *N,N*-dimethyl- and *N,N*-dibenzyl-*o*-hydroxyarenecarboxamides were carried out in four perdeuterated solvents, namely, chloroform, methanol, pyridine, and dimethyl sulfoxide (DMSO) and the free energies for of activation of the internal rotation about the C-N partial double bonds (hereafter named "rotational barrier(s)" and noted as ΔG^*) were determined.[10] The rotational barriers of the amides hereby measured in these solvents are given in Table 1a together with some from the similar measurements on methyl ^{13}C signals. The rotational barriers from the both nuclei agree with each other excellently, showing the reliability of the ΔG^* values.

The rotational barriers about the C-N partial double bonds of amides were shown to become higher as the solvents become more polar. This trend was ascribed to the effect of polar solvents which favor the polar mesomeric structure **II** and stabilize the ground state rather than the transition state of the internal rotation.[7] In this investigation, the solvent effect was reexamined with the aim of elucidating the effect of hydrogen-donating and hydrogen-accepting abilities of solvents on the rotational barriers of the amides.

a) The asterisks in the table denote the rotational barriers (and T_c) from ^{13}C DNMR. b) $\Delta\Delta G^*_{solv} = \Delta G^*$(solvent) $- \Delta G^*(CDCl_3)$.

Strong intramolecular C=O···H-O hydrogen bond in *o*-hydroxyarenecarboxamides is expected to be kept intact in chloroform which is known as a less polar solvent. The persistence of the intramolecular hydrogen bond was proved by the appearance of the chelated O-H absorption in their infrared spectra (Table 3).[11] Methanol is a protic solvent and may interact with the amides as a hydrogen donor. Thus, its hydroxyl group can form a hydrogen bond very probably with the carbonyl oxygen atom of the amide.

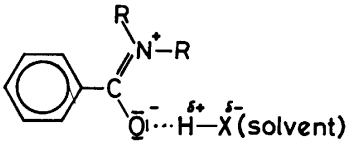
Since the oxygen atom can behave as a biligated ligand, the intermolecular hydrogen bond itself may not induce directly the destruction of the intramolecular hydrogen bond but should, at least, weaken the bond considerably. Both pyridine and DMSO are known as strong hydrogen acceptors and expected to cleave the intramolecular hydrogen bond. Of these two, the hydrogen accepting power of DMSO is particularly strong and the intramolecular hydrogen bond in the *o*-hydroxy amides should be destroyed almost completely in this solvent.

Though it is not the main purpose of this paper, it may be useful to survey briefly the general tendency of the perturbation caused by the solvent on the rotational barriers of the amides void of *o*-hydroxyl group. As easily deduced from the $\Delta\Delta G^{\ddagger}$ solv values defined as the difference in $\Delta G^{\ddagger}$ between the respective solvent and chloroform ($\Delta\Delta G^{\ddagger}_{solv}=\Delta G^{\ddagger}(solvent)-\Delta G^{\ddagger}(CDCl_3)$) and given in Table 1, the rotational barrier icreases in the following order of the solvent: pyridine chloroform DMSO methanol. This sequence does not agree with the increasing order of dielectric constants[10] but coincides with the order of increasing acidity of C-H or O-H group in the solvent molecule, suggesting the participation of the hydrogen-bond-like interaction **III** of the solvent X-H group with the carbonyl oxygen of the amide, which stabilizes the mesomeric structure II. However, the effect is not very significant and perturbs the rotational barrier at most by 3 or 4 kJ mol^{-1}.



(III)

In contrasts, the rotational barriers of *o*-hydroxy amides **9**—**13**, **19**, and **24**—**26** suffer a very large solvent effect. The increases in the rotational barriers by about 10 kJ mol^{-1} were observed both in hydrogen-donating and in hydrogen-accepting solvents. In order to rationalize the large increase in $\Delta G^{\ddagger}$ by the influence of the solvent, the effect of *o*-hydroxyl group on the rotational barrier was reinvestigated. Ortho-substituent effect can be evaluated separately by the increment $\Delta\Delta G^{\ddagger}_{ortho}$ which is defined as the difference in $\Delta G^{\ddagger}$ between the ortho-substituted and the unsubstituted (para-substituted) amides.

The $\Delta\Delta G^{\ddagger}_{ortho}$ values for several ortho-substituted arene-carboxamides are given in Table 2. Considerably large positive $\Delta\Delta G^{\ddagger}_{ortho}$ values (more than 10 kJ mol^{-1} in many cases) for *o*-substituted *N,N*-dimethylarenecarboxamides **6**—**8**, **14**, **27**—**29** can be attributed to the steric inhibition of resonance pointed out by Jackman et al.[2] In *N,N*-dibenzyl amides **20** and **21**, the ortho effect is apparently diminished, probably due to the destabilization of planar (or nearly planar) ground state caused by the bulkier benzyl group.

On the contrary, *o*-hydroxyarenecarboxamides **9**—**13**, **19**, and **24**—**26** have negative $\Delta\Delta G^{\ddagger}_{ortho}$ values. The decrease in the rotational barrier comes to as large as ca. 17 kJ mol^{-1} in chloroform in which the dissolved amide is supposed to maintain the chelation by intramolecular hydrogen bonding. When the solvent is capable of forming hydrogen bond with the *o*-hydroxy amide either as a hydrogen acceptor or a hydrogen donor, the difference ($\Delta\Delta G^{\ddagger}_{ortho}$) tends to be less negative. The $\Delta\Delta G^{\ddagger}_{ortho}$ becomes even positive in DMSO which is known to act as a very strong hydrogen acceptor in forming hydrogen bond. Negative $\Delta\Delta G^{\ddagger}_{ortho}$ value corresponds to the fact that the rotational barrier is lower than that of the unsubstituted or para-substituted amide used as the reference. On the basis of MO calculations, the lowering of the rotational barrier is attributed to the

decreased C–N bond order in chelated *o*-hydroxyarenecarboxamide in our previous report.[8]

If the chelation is responsible for the low rotational barrier, the barrier is expected to gain the normal height when the intramolecular hydrogen bond is cleaved. As observed with **19** and **26**, this was realized by dissolving the *o*-hydroxy amides in DMSO. Small positive $\Delta\Delta G^{\ddagger}_{ortho}$ might arise from the normal ortho effect due to steric hindrance caused by the solvated hydroxyl group at the ortho-position. In sharp contrast to the *o*-hydroxy amides, the corresponding *o*-methoxyarenecarboxamides **7**, **14**, **21**, and **27—29** showed normal ortho effect due to steric hindrance to the aryl-carbonyl conjugation. Therefore, the lowering of the rotational barrier observed with the *o*-hydroxyamides is ascribable to the effect of intramolecular hydrogen bonding.

The strength of the intramolecular hydrogen bond in the six-membered chelate ring of this type has been correlated with the bond order (or bond length) of the bond joining the ring carbon atoms holding the hydroxyl and carbonyl substituents.[12,13] The chelate rings of *o*-hydroxyarenecarbaldehydes and *o*-hydroxyaryl ketones have been shown to be more stable when the double bond character of the respective C–C bond is higher and, hence, its bond length is shorter. From this point of view, the rotational barriers of three *o*-hydroxyamides **9**, **25**, and **26** were compared

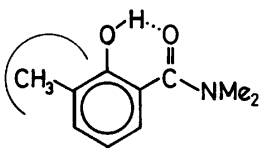
$\nu_{C=O}$/cm^{-1} [b]	1634	1638	1648
ν_{O-H}/cm^{-1} [b]	3158(shoulder)[c]	3228	3245

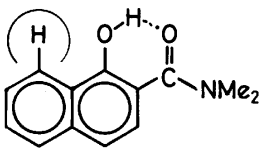
a) Chemical shifts at infinite dilution in chloroform-*d*. b) Infrared absorption spectra both in the hydroxyl and carbonyl stretching regions were measured with the dilute carbon tetrachloride solutions using a 1 cm cell. c) Overlapped with C–H absorption bands.

(Table 3). As discussed previously, the partial double bond character of the amide C-N bond is expected to be reduced as the endocyclic C-C bond order increases and, hence, the chelation becomes favorable. Thus the higher bond order of the C-C bond holding the hydroxyl and carboxamide groups should result in the lower rotational barrier. Strengths of the intramolecular hydrogen bond of this type can be evaluated by the chemical shift of hydroxyl proton at infinite dilution, since the chemical shift in a very dilute solution of an inert solvent is affected predominantly by the intramolecular circumstances and tends to shift towards lower field as the hydrogen bond becomes stronger.[12,13] The infrared carbonyl spectra also help us to estimate the strength of the chelation by the low frequency shift which reflects the lowering of the carbonyl bond order. As shown in Table 3, the lowest OH chemical shift and the lowest carbonyl frequency of **25** provide experimental supports to the theoretical consequence that its chelation should be the strongest of the three hydroxyamides in Table 3. As a whole, the evidence from the spectra supports the conclusion from the bond order, and the chelation becomes gradually strong in the order of **26**, **9**, and **25**. In accord with this conclusion and the above deduction, the rotational barrier in chloroform is the lowest with **25** and the highest with **26**.

The rotational barrier of *N,N*-dimethylsalicylamide **9** seems insensitive to the electronic effect by the substituent para to the hydroxyl group. The ΔG^* values for a series of 5-substituted salicylamides **9**—**13** are identical with each other within the limit of experimental error (Table 1). *N,N*,3-Trimethylsalicylamide **13** is less susceptible to the solvent effect than other salicylamides **9**—**12** investigated. 3-Methyl group might prevent the hydroxyl group from taking the conformation anti to the carbonyl group in one hand and hinder the access of the solvent molecule to the hydroxyl group on the other hand. In this way, the intramolecular hydrogen bond of salicyl moiety is protected towards the attack of the solvent by the neighboring methyl group. Peri-hydrogen atom in 1-hydroxy-2-naphthamide **25** may also play a similar role in protecting its intramolecular hydrogen bond. Therefore, these amides are less sensitive to the effect of solvents capable of forming hydrogen bonds.



(IV)



(V)

Chemical shifts of the CH_3 signals of *N,N*-dimethyl amides and the CH_2 signals of *N,N*-dibenzyl amides at temperatures higher than their coalescence temperatures (T_c) are given in Table 1b. Methyl and benzyl CH_2 signals should move towards down-field in the increasing order of ΔG^* due to increasing positive charge by the mesomeric contribution of **II**. As the solvent induced shift of the ^1H chemical shift is quite small, it seemed rather difficult to derive a definite conclusion from the solvent shift of the signal of individual amide. However, a general survey on the data in Table 1 allowed the conclusion that the expected trend is partly observed with the CH_3 signals of substituted benzamides **1**—**8** and naphthamides **23**, **24**, **27**—**29** void of an *o*-hydroxyl group, which showed up-field shifts of CH_3 signals and the lowering of ΔG^* in pyridine compared to those in chloroform. Apparently inverse solvent shift was observed with *o*-hydroxy amides **9**—**14**, **24**—**26**. This might be caused by the magnetic anisotropy effect by the hydrogen-bonded chelate ring. However, further study on the solvent effect is needed before we conclude the nature of the effect undoubtedly.

In conclusion, significantly low rotational barriers about the C-N partial double bonds of *N,N*-dialkylsalicylamides were shown very confidently to be originated from the chelation by intramolecular hydrogen bonding by examining the effects of solvents and structural changes on the barrier.

The authors wish to express their hearty thanks to Professor Masatsune Kainosho, Tokyo Metropolitan University, for his very valuable advice throughout this work. We are also very grateful to Professor L. M. Jackman, Pennsylvania State University, for his valuable discussion and encouragement which we received from him when he visited our university. This research is partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture,

(Received June 5, 1987)

Triiron tetraoxide pretreated by polyhalomethane was shown to catalyze the halgen-exchange reactions of polyhalomethanes $CH_lBr_mCl_n$(l=1 or 2). The exchange proceeds consecutively giving, for example, $CHBrCl_2$, $CHBr_2Cl$, and $CHBr_3$ as the main products from $CHCl_3$. The mechanism of the reaction is discussed briefly.

In recent decades, the contamination of environment with polyhalogenated compounds have induced serious problems in several countries.[1] Thus, thermal and photochemical behaviors of polyhalogenated hydrocarbons have been investigated rather extensively aiming the potential applications for their detoxication.[2–5] We have also studied the acid-catalyzed and the photochemical dehalogenation and rearrangement of polyhalobenzenes in this point of view.[6–8] One of our studies concerned with the dechlorination of polychlorobenzenes over Fe_3O_4.[9] This modification of iron oxide was shown to catalyze the cleavage of carbon–halogen bonds of polyhalobenzenes effectively and gave the dehalogenated products in the presence of hydrogen donor such as hexane and decahydronaphthalene.

In this paper, we wish to report on the halogen-exchange reactions of polyhalomethanes over Fe_3O_4 in order to clarify further the behaviors of Fe_3O_4 towards halogenated hydrocarbons.

Experimental

Materials. The polyhalomethanes were commercially available. Their purities were certified by gas chromatography. Triiron tetraoxide (magnetite, Fe_3O_4) was prepared according to the method described by Kiyama.[10] Firstly, 6 M†† aqueous solution of sodium hydroxide was added gradually to an aqueous solution containing iron(II) and iron(III) chlorides in a 1:2 molar ratio so as to regulate the final pH of the solution to be ca. 11. The suspension of colloidal iron hydroxides was then filtered, washed with several portions of water, and calcinated at 623 K. Active Fe_3O_4 thus obtained is very fine and its specific surface area was determined to be 92.6 $m^2 g^{-1}$ by the BET adsorption measurement. Thus prepared Fe_3O_4 was employed as the catalyst for the halogen-exchange reactions. In each run of the halogen-exchange reaction, a 300 mg portion of the Fe_3O_4 catalyst was pretreated at 623 K with 50 microliter of chloroform or bromoform in the stream of helium. In order to maintain the catalytic activity uniform throughout a series of the experiments, the catalyst was heated further at the same temperature for about 2 h until the evolution of hydrogen halide ceased completely.

Procedures for the Pulse Thermolysis and the Analyses of the Products. The reaction was carried out at temperatures ranging from 393 to 593 K using a pulse micro-reactor connected directly to a gas chromatograph. The sample was introduced in portions of 1 microliter to the thermostatic inlet connected to the reaction chamber containing 300 mg of Fe_3O_4 and carried to the reactor by a stream of helium. The products of the reaction were analyzed by a Shimadzu GC-4C PTF gas chromatograph using a 2 m stainless steel column containing DNP (20 wt%). Peaks on the chromatogram were identified by comparing them with those of authentic samples and by GC/MS measurements. GC/MS were recorded on a Shimadzu GC/MS QP 1000 mass spectrometer. Details of the apparatus for the reaction were described in one of our previous papers.[11]

Results and Discussion

Role of the Pretreatment with Polyhalomethane and the Mechanism of Halogen Exchange. When polyhalomethanes were treated with freshly prepared Fe_3O_4 at 623 K without prior treatment with trihalomethanes, the oxidative decomposition took place giving carbon dioxide and water. Thus the reaction is potentially applicable to the detoxication of polyhaloalkanes. Hydrogen halide (HCl or HBr) was not detected as a gaseous product in the process of these reactions when the catalyst is new. The oxidative decomposition reaction seemed to proceed irreversibly, and repeated feeds of polyhalomethane gradually reduce the catalytic activity of Fe_3O_4 for the oxidative decomposition. Deactivation of the catalyst is undesirable from the view point of applying the reaction to the detoxication. Thus the reactions over polyhalomethane-poisoned Fe_3O_4 were further studied. The peak for the unreacted starting material becomes observable in the chromatogram after several repetition of the pulse reaction with polyhalomethanes (dichloromethane (**1**), trichloromethane (**3**), dibromomethane (**6**), and tribromomethane (**7**)). At the same time, evolution of hydrogen halide became observable after repeated dose of polyhalomethane. When a mixed halomethane $CH_lCl_mBr_n$ was fed under similar conditions or when polybromomethane was introduced over polychloromethane-pretreated Fe_3O_4 (or vice versa), there appeared several other peaks ascribable to the products of halogen-exchange reactions in the gas chromatogram. An example

†† 1 M=1 mol dm^{-3}.

which shows the formation of $CHCl_3$, $CHBrCl_2$, and $CHBr_2Cl$ from $CHBr_3$ is illustrated in Fig. 1. This reveals the fact that the pretreated catalyst promotes the halogen exchange of polyhalomethanes. The activity of the Fe_3O_4 catalyst for the oxidative decomposition tends to be a constant stationary value when the total dose of **1** or **3** exceeds ca. 0.2 mmol (ca. 20 microliter) (Fig. 2).[12] At this stage, the formation of iron(II) chloride on the surface of the catalyst was evidenced by detecting iron(II) ion from the aqueous extract obtained by washing the pretreated catalyst with water. Chloride ion, and/or bromide ion in cases when bromo-substituted methane was subjected to the reaction, was also present, but iron(III) ion was detected in neither cases. Thus the oxidative decomposition should proceed via the reductive chlorination of Fe(III) oxide. As a result, the surface of Fe_3O_4 is expected to become covered partly by iron(II) chloride in the process of pretreatment by polychloromethanes, and similarly covered by iron(II) bromide when treated with polybromomethanes. The pretreated catalysts were used for the halogen-exchange reactions throughout this series of experiments. The catalyst regains its reactivity for oxidative

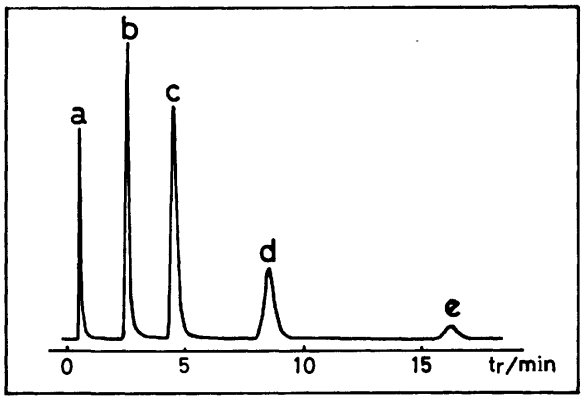

Fig. 1. Gas chromatogram of the reaction products obtained by introducing $CHBr_3$ over Fe_3O_4 (pretreated by $CHCl_3$) at 433 K. Peaks **a**—**e** are assigned to CO_2, $CHCl_3$, $CHBrCl_2$, $CHBr_2Cl$, and unreacted $CHBr_3$, respectively.

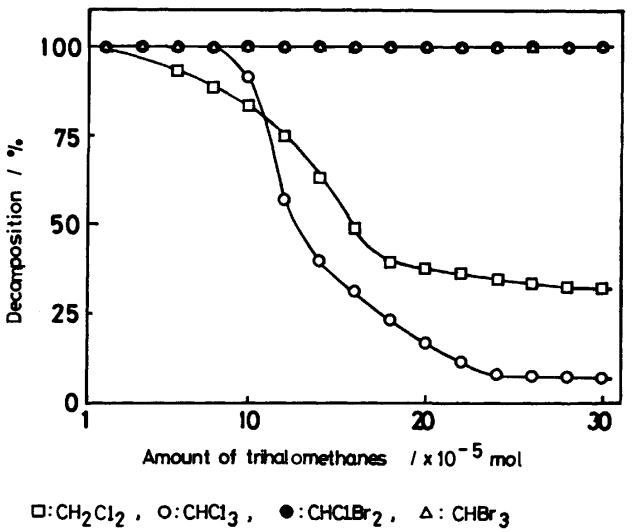

Fig. 2. Effect of the repeated doses of polyhalomethanes on the activity of Fe_3O_4 for the oxidative decomposition producing CO_2 at 623 K.

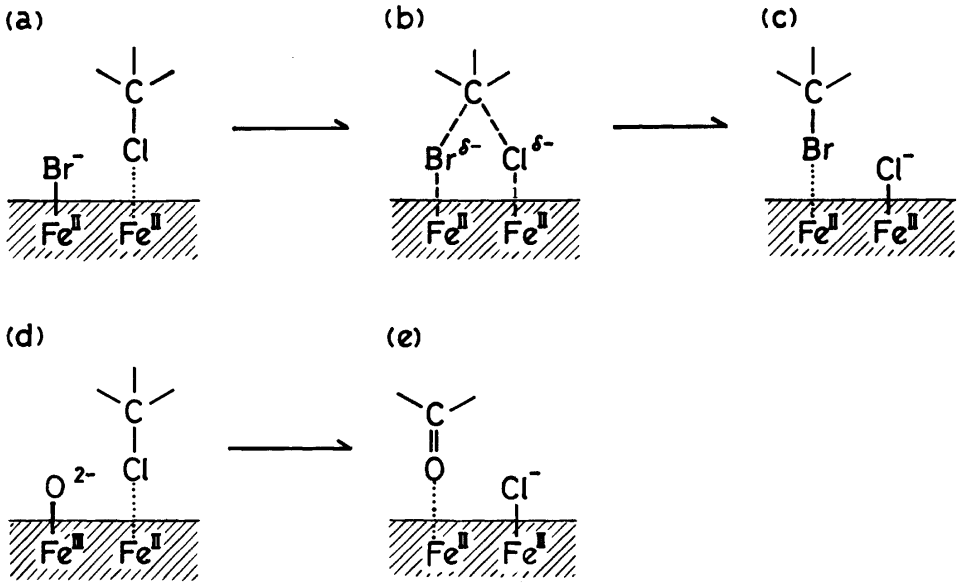

Fig. 3. Schematic description of the proposed mechanism of the halogen-exchange reactions over Fe_3O_4 pretreated by polyhalomethane.[14] Schema **a** to **c** shows the process of replacement of chlorine to bromine on the surface of $CHBr_3$-pretreated Fe_3O_4 catalyst. During the process of pretreatment, oxide ion (O^{2-}) bound to Fe(III) is assumed to be replaced reductively by halide ion as illustrated by schema **d** and **e**.

decomposition after being washed with water.

In a run in which a well-blended and annealed mixture of newly prepared Fe_3O_4 and a small amount of iron(II) chloride was used as catalyst, the oxidative decomposition took place as usual but the halogen exchange did not proceed to a measurable extent. This fact suggests that nonhalogenated iron sites (probably Fe(II)) on the suface of the catalyst should play a critical role in the pathway of the halogen-exchange reaction. The mere contact of polyhalomethane with chloride ion does not seem to induce the exchange of halogen measurably, since the chlorine atoms of chlorinated methanes were shown to exchange very slowly with chloride ion even in a homogeneous liquid phase.[13] On the other hand, neither oxidative decomposition nor halogen exchange proceeds to give considerable amounts of the products when Fe_2O_3 (hematite) was employed instead of Fe_3O_4 as the catalyst. These facts imply that Fe(II) species should play a crucial role in the reaction. By all accounts, Fe(II) species linked to halogen is assumed to behave as a halogen donor and Fe(II) species adjacent to the Fe(II)-halogen linkage to act as a halogen acceptor in the reaction.

A mechanism which involves a bridged transition state (shown in Fig. 3b) might be one of the most probable pathways which explains the exchange reaction. The reaction is supposed to proceed through the following three steps in this mechanism. The mechanism is illustrated by the example of dechlorination-bromination in Fig. 3. (i) In the first step, the chlorine atom of a chlorinated methane molecule (ClCXYZ) forms a coordinative bond to the free iron(II) site located adjacent to the brominated iron(II) species. (ii) A bridged structure like illustrated in Fig. 3b is formed on the surface of the catalyst. Bromide transfer from an Fe(II) site to carbon and chloride transfer from carbon to an adjacent free Fe(II) site proceeds simultaneously through this bridge. (iii) Newly formed brominated methane (BrCXYZ) leaves from the surface. Halogen ligated Fe(II) group on the surface is expected to be

a) Bold figures in the Tables 1 and 2 represent the percentages of the remaining reactant.

formed by the reductive chlorination–deoxygenation of Fe(III)–O group by a polyhalomethane during the process of pretreatment (as illustrated by the process from (d) to (e) of Fig. 3). The scheme includes a bridged structure which has not been supported by direct experimental evidence and, therefore, is rather speculative. However this explains the overall process of the halogen-exchange reaction if we assume that C–Cl bonds are considerably more difficult to cleave than C–Br bonds. Especially, the fact that the well-blended mixture of Fe_3O_4 and $FeCl_2$ does not activate the exchange reaction supports the participation of the neighboring Fe(II)–Cl and nonligated Fe(II) sites of the surface.

Quantitative Survey on the Halogen-Exchange Reactions. Dichloromethane (**1**), bromochloromethane (**2**), trichloromethane (**3**), bromodichloromethane (**4**), and dibromochloromethane (**5**) were vaporized in the stream of helium at various temperatures and introduced to the reactor filled with fine particles of the Fe_3O_4 catalyst pretreated with bromoform. The products of the pulse reactions are given as a function of temperature in Table 1. The results of the similar reactions of dibromomethane (**6**), **2**, tribromomethane (**7**), and **4** over the Fe_3O_4 catalyst pretreated with chloroform are also shown in Table 2.

Both dechlorination–bromination and debromination–chlorination reactions proceed predominantly in the runs carried out at lower temperatures. Multiple exchange also occurs giving, for example, bromodichloro-, dibromochloro-, and tribromomethanes starting from chloroform. Since the singly exchanged product is the most predominant and the triply exchanged one the least predominant, only one halogen atom must be exchanged by a single contact of the substrate (polyhalomethane) on the surface of the pretreated Fe_3O_4. The halogen atoms are exchanged consecutively, giveing a multiply exchanged product after multiple contacts to the active site of the catalyst. The oxidative decomposition producing carbon dioxide becomes significant in the runs at elevated temperatures. Trihalomethanes are more susceptible to the decomposition, producing carbon dioxide and water as the most predominant product at higher temperatures. In contrasts, dihalomethanes (**1**, **2**, and **6**) produce carbon dioxide only subsidiarily in the range of temperature investigated.

The dechlorination–bromination reactions in Table 1 behave remarkably different from the debromination–chlorination reactions in Table 2 in some respects. The dechlorination–bromination seems to be a kinetically controlled reaction of which rate-determining step is the cleavage of C–Cl bond. The

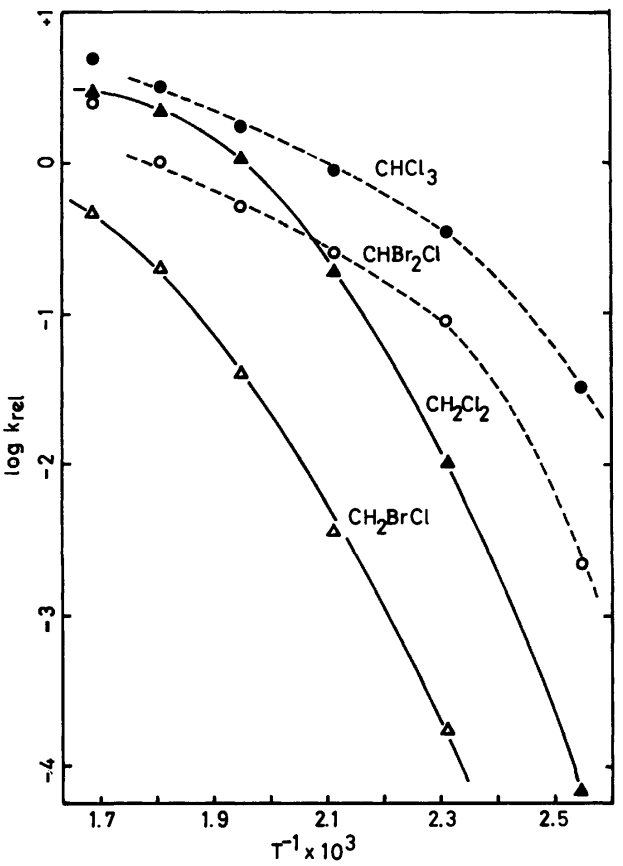

Fig. 4. The Arrhenius plots for the consumption of chlorinated methanes over Fe_3O_4 pretreated by $CHBr_3$.

plots of logarithm of the relative rate[15] (k_{rel}) versus the inverse of reaction temperature ($1/T$), illustrated in Fig. 4, gave the activation energies for the decay of (poly)chloromethanes. The apparent activation energies (E_a) at 427 K for **1**, **2**, **3**, and **5** are 47.2, 54.0, 16.1, and 18.3 kJ mol^{-1}, respectively. The E_a values for trihalomethanes **3** and **5** are considerably lower than those for dihalomethanes **1** and **2**. The lower E_a for trihalomethanes can partly be accounted for the contribution of the steric and electrostatic repulsion among three halogen atoms of trihalomethanes, which facilitates the release of halogen atom.

On the contrary, debromination-chlorination reactions were more complicated. It produced a mixture of a significant amounts of multiply exchanged, further-chlorinated, and oxidized products in addition to the singly exchanged product. The decrease of the starting material was irregularly dependent on the reaction temperature, suggesting that the initial cleavage of C-Br bond is not rate-determining at least at elevated temperatures and that multiple exchange and retro-exchange(dechlorination-bromination) proceed rather extensively. Some bond-forming steps in these secondary processes must determine the rate of the reaction. Since the C-Br bond energy is considerably lower than that of C-Cl bond and, therefore, chlorinated methanes are more stable than the corresponding brominated methanes, the above interpretation is reasonable.

The authors are grateful to Professor S. Fukushi, Chiba Institute of Technology, for his valuable advice and encouragement throughout this work. They also thank heartily to Dr. Tetsuo Ishii, Yokohama Research Institute for Environmental Protection, for his discussion from the view of environmental science and for the measurement of GC/MS spectra.

Racemic Structure and Optical Resolution by Preferential Crystallization of DL-Cysteine Salts of Substituted Benzenesulfonic Acids

Tadashi SHIRAIWA,* Hirohide TAZOH, Michio SUNAMI, Yujin SADO, and Hidemoto KUROKAWA
Faculty of Engineering, Kansai University, Yamate-cho, Suita, Osaka 564
(Received April 9, 1987)

Infrared absorption spectrum, solubility, and thermodynamic analysis indicated that DL-cysteine salts of benzenesulfonic acid (DL-BA salt) and 4-ethylbenzenesulfonic acid (DL-4-EB salt) are conglomerates at room temperature, but DL-BA salt forms a racemic compound at the melting point. These DL-salts were optically resolved by the preferential crystallization. As for DL-4-EB salt, suitable conditions were estimated by the free energy of critical nucleation in supersaturated solutions. The successive preferential crystallization in ethanol at 20 °C was found to give D- and L-4-EB salts with optical purity of 97—100% in the resolution yield of 83—90%. Purification and following treatment with triethylamine gave optically pure D- and L-Cys's.

L-Cysteine (abbreviated as L-Cys) is a useful material for medicines, food additives, and cosmetics, and D-Cys is also noted to be useful for medicines.[1] Since L-Cys has been obtained from hair, optical resolution by preferential crystallization of DL-Cys has been reported only for DL-cysteine hydrochloride monohydrate[1] and DL-4-thiazolidinecarboxylic acid.[2,3] This paper describes a possibility of optical resolution by the preferential crystallization of DL-cysteine salts of substituted benzenesulfonic acids. These DL-salts include benzenesulfonate (DL-BA salt), 4-methylbenzenesulfonate (DL-4-MB salt), 4-ethylbenzenesulfonate (DL-4-EB salt), 3-aminobenzenesulfonate, 4-amino-3-methylbenzenesulfonate, and 2-hydroxy-5-sulfobenzoate.

Since only DL-BA salt has the melting point, its racemic structure was examined by the thermodynamic analysis.[4,5] As for other DL-salts that decompose on heating, the racemic structures were estimated by comparing infrared absorption spectra or solubility values of the DL-salts with those of the corresponding L-salts. The DL-BA and -4-EB salts seemed to be conglomerate at room temperature, but DL-BA salt appeared to form a racemic compound at the melting point. These DL-salts were subjected to optical resolution by preferential crystallization. As for DL-4-EB salt, suitable conditions were examined by the free energy of critical nucleation in supersaturated solutions,[3,6-8] and the successive preferential crystallization was tried in ethanol at 20 °C.

Experimental

Materials. DL- and L-Cysteines were purchased from Sigma Chemicals Co. and Wako Pure Chemicals Ind., respectively, and substituted benzenesulfonic acids and triethylamine from Wako Pure Chemicals Ind. and Kanto Chemical Co. Ltd., respectively.

Preparation of Salts. A mixture of 0.005 mol of DL- or L-Cys and equimolar substituted benzenesulfonic acid in 15 cm^3 of methanol was stirred for 30 min at 40 °C. After addition of 30 cm^3 of diethyl ether, the solution was stirred for 30 min in an ice bath. The salt formed was filtered and recrystallized from ethanol. In the cases of DL- and L-BA salts, the initial mixture was allowed to stand for 1 d at 5 °C, and the salts formed were recrystallized from 1-propanol.

DL-BA salt: Mp 179 °C; Found: C, 38.62; H, 4.66; N, 5.04% (Calcd for $C_9H_{13}O_5NS_2$: C, 38.70; H, 4.69; N, 5.01%). L-BA salt: Mp 205 °C; Found: C, 38.63; H, 4.69; N, 5.03%; $[\alpha]_{436}^{20}$ +9.23° (*c* 1.00, 5 mol dm^{-3} HCl).

DL-4-MB salt: Mp 212—215 °C (decomp); Found: C, 40.76; H, 5.10; N, 4.66% (Calcd for $C_{10}H_{15}O_5NS_2$: C, 40.94; H, 5.15; N, 4.77%). L-4-MB salt: Mp 225—227 °C (decomp); Found: C, 40.91; H, 5.11; N, 4.74%; $[\alpha]_{436}^{20}$ +8.08° (*c* 1.00, 5 mol dm^{-3} HCl).

DL-4-EB salt: Mp 176—179 °C (decomp); Found: C, 42.83; H, 5.58; N, 4.59% (Calcd for $C_{11}H_{17}O_5NS_2$: C, 42.98; H, 5.58; N, 4.59%). L-4-EB salt: Mp 199—200 °C (decomp); Found: C, 42.87; H, 5.56; N, 4.55%; $[\alpha]_{436}^{20}$ +7.15° (*c* 1.00, 5 mol dm^{-3} HCl).

D-4-EB salt with 89% optical purity was obtained from the mother liquor in the optical resolution of the corresponding DL-salt. After refluxing a mixture of 1.76 g of the D-salt and 5 cm^3 of ethanol for 20 min, the mixture was stirred for 30 min at 20 °C. The precipitated salt was collected by filtration to give optically pure D-salt in 1.43 g yield; mp 199—201 °C (decomp); $[\alpha]_{436}^{20}$ −7.15° (*c* 1.00, 5 mol dm^{-3} HCl).

Table 1. Preparation of Supersaturated Solutions

DL-Salt	Solvent[a]	Degree of supersaturation[b]	Mass of DL-salt
		%	g
BA[c]	Ethanol	118	8.485
	1-Propanol	149	2.887
	1-Butanol	215	1.534
4-EB[d]	Ethanol	143	3.084
		153	3.299
		160	3.450
		165	3.558
		170	3.666
		188	4.054

a) Solvent: 50 cm^3. b) Temperature: 20 °C. c) BA: Benzenesulfonate. d) 4-EB: 4-Ethylbenzenesulfonate.

Optical Resolution. Preferential Crystallization: DL-BA or -4-EB salt was dissolved in 50 cm^3 of ethanol, 1-propanol, or 1-butanol at 40 °C to give racemic solutions with the degree of supersaturation of 118—215% at 20 °C; results of preparation of these supersaturated solutions were summarized in Table 1. The solution was slowly cooled to 20 °C and seeded with 0.050 g of the L-salt. After the solution was stirred at 120 rpm by a 1.5 cm×4.0 cm stirrer at 20 °C, the precipitated salt was collected by filtration, washed with diethyl ether, and dried. The optical purity, yield of optically pure modification (YOPM), and degree of resolution of the L-salt were determined by the equations described in a previous paper.[9]

Successive Preferential Crystallization: The DL-4-EB salt (3.450 g) was dissolved in 50 cm^3 of ethanol at 40 °C. After cooling to 20 °C, the solution was seeded with 0.050 g of the L-salt and stirred for 62 min at 120 rpm and 20 °C. The precipitated salt was collected by filtration, and 0.465 g of the DL-4-EB salt was dissolved in the filtrate at 40 °C. After being seeded with 0.050 g of D-salt at 20 °C, the procedure was followed in a similar way. The optical resolution was performed for the initial solution containing 3.450 g of the DL-4-EB salt and 0.100 g of the L-salt in the same manner as in the single-step resolution. The degree of resolution of the D- and L-4-EB salts was calculated by

Degree of resolution/%=[YOPM×100/g]/[(Operation amount of D- or L-salt/g)−1.078].

Preparation of Optically Active Cysteine. Optically pure D- or L-4-EB salt (1.363 g) was dissolved in 25 cm^3 of methanol. After the solution was adjusted at pH 5—6 with triethylamine and stirred for 30 min in an ice bath, the precipitated Cys was collected by filtration to give about 0.51 g each of optically pure D- and L-Cys's. D-Cys: $[\alpha]_D^{20}$ +16.5° (*c* 1.00, water). L-Cys: $[\alpha]_D^{20}$ −16.5° (*c* 1.00, water) (lit,[10] $[\alpha]_D^{20}$ −16.5° (water)).

Measurements. The specific rotation was measured by a Union Giken PM-101 digital polarimeter with a quartz cell of 1.0 dm path length. Infrared spectra were obtained in the range 4000—400 cm^{-1} by a JASCO A-102 infrared spectrophotometer by the KBr disk method. The enthalpy of fusion was determined by a Rigaku Denki differential scanning calorimeter DSC-8230.

The mixture of the DL- or L-salt (BA, 4-MB, and 4-EB salts) and solvent (ethanol, 1-propanol, and 1-butanol for the BA salt; ethanol for the 4-MB and 4-EB salts) was stirred at 20 °C, in the presence of the solid salt. A constant volume of the solution was withdrawn from the mixture, avoiding contamination of the solid salt, diluted in an appropriate concentration, and the absorbance was measured at 263 nm by a Shimadzu double-beam spectrophotometer UV-150-02 with a quartz cell of 0.1 dm path length. After stirring the mixture until the absorbance showed a constant value, the solubility was determined on the basis of the absorbance calibration curves prepared previously.

Results and Discussion

Racemic Structure. In the salts that decompose on heating, infrared spectra of the DL-salts were compared with those of the corresponding L-salt. DL-4-MB and -4-EB salts showed infrared spectra identical with those of L-salts. The solubility of DL-4-EB salt was 2.21 times as large as that of the L-salt. However, the solubility of DL- and L-4-MB salts was approximately equal to each other, as listed in Table 2; the value of α is 1.19 (α=solubility of DL-salt/solubility of L-salt). DL-4-EB salt was optically resolved by preferential crystallization, as will be described in a later section, whereas DL-4-MB salt was unable to resolve by this procedure.

The above results suggest that the DL-4-EB salt is a conglomerate at room temperature, and that the DL-4-MB salt forms a racemic solid solution.[11-14]

Other DL-salts form racemic compounds because their infrared spectra are different from those of the corresponding L-salts.[11]

Racemic Structure of DL-Benzenesulfonate. Only the DL- and L-BA salts show melting points. The mole fraction of the L-salt at the eutectic point was calculated to be 0.61 from the melting point and the

Table 2. Solubility of Cysteine Salt of Substituted Benzenesulfonic Acids[a]

Salt	Solvent	Solubility/g/(100 cm^3 solvent)		
		DL-Salt	L-Salt	α[b]
BA[c]	Ethanol	14.381	9.305	1.55
	1-Propanol	3.875	2.725	1.42
	1-Butanol	1.427	0.980	1.46
4-MB[d]	Ethanol	2.296	1.932	1.19
4-EB[c]	Ethanol	4.313	1.952	2.21

a) Temperature: 20 °C. b) α=solubility of DL-salt/solubility of L-salt. c) See notes in Table 1. d) 4-MB: 4-Methylbenzenesulfonate.

Table 3. Thermodynamic Data of Cysteine Salt of Benzenesulfonic Acid

Salt	Mp θ_m/K	ΔH^f[a] / kJ mol^{-1}	ΔG_T^f[b]/kJ mol^{-1}		Eutectic point		
			ΔG_{453}^f	ΔG_{293}^f	Mole fraction[c]	Temperature/K Found	Calcd[c]
DL-BA[d]	452	31.8	−0.91	+0.12	0.61	451	451
L-BA[d]	478	33.9	—	—			

a) ΔH^f: Enthalpy of fusion. b) ΔG_T^f: Gibbs energy of formation of racemate at *T* K. The ΔG_T^f's at the melting point (ΔG_{453}^f) and at 293 K (ΔG_{293}^f) were calculated from the equations in Refs. 4 and 5. c) These values were calculated from the Schröder-Van Laar and Prigogine-Defay equations. d) See note in Table 1.

enthalpy of fusion (ΔH^f),[4] and the observed melting point of mixture with the composition agreed with the calculated eutectic temperature (451 K);[4] these values are listed in Table 3 and the binary melting point diagram is shown in Fig. 1. These results indicated that DL-BA salt forms a racemic compound at the melting point.[4]

The Gibbs energy of formation of the racemate from its antipode at melting point (ΔG^F_{452}/kJ mol^{-1}) and 293 K (ΔG^F_{293}) was calculated from the melting temperature and ΔH^f,[4,5] and listed in Table 3. The negative ΔG^F_{452} value supports the above result. However, the positive ΔG^F_{293} suggests that DL-BA salt does not form a racemic compound at 293 K, although the absolute value is small (+0.12 kJ mol^{-1}). The DL-BA salt shows infrared spectrum identical with that of the L-salt and is more soluble than the L-salt, as listed in Table 2; the values of α are 1.42—1.55 in ethanol, 1-propanol, and 1-butanol.[11-14]

The above results indicate that DL-BA salt is a conglomerate at room temperature though the DL-salt forms a racemic compound at the melting point.

Preferential Crystallization. Optical resolution of the DL-BA and -4-EB salts was attempted by preferential crystallization at 20 °C with the L-salt as seed crystals, and the results are given in Tables 4 and 5, respectively.

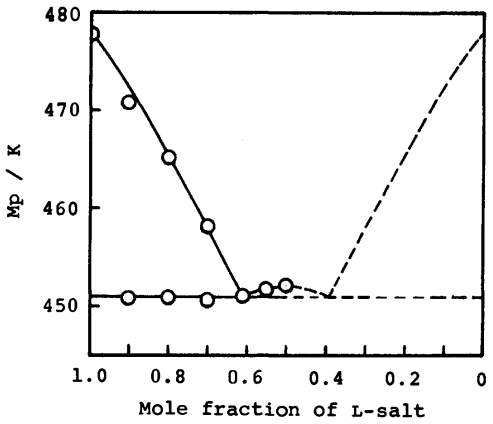

Fig. 1. Binary melting point diagram of cysteine salt of benzenesulfonic acid.

Since it was possible to resolve these DL-salts by preferential crystallization, it was confirmed that the DL-BA and -4-EB salts are conglomerates at room temperature. Although the L-BA salt with approximately 90% optical purity is obtained from 1-propanol and 1-butanol solutions, the yield of optically pure modification (about 0.05 g) and degree of resolution (about 12%) are extremely low. The small absolute value of ΔG^F_{293} of DL-BA salt may be the reason why the optical resolution by preferential crystallization is poor.

On the other hand, the optical resolution of the DL-4-EB salt gave better result than that of the DL-BA salt. This result indicates that the use of the DL-4-EB salt is more favorable for obtaining optically pure Cys in a high yield.

Estimation of Suitable Conditions for Optical Resolution. Relationship between Factors for Crystallization and Free Energy of Critical Nucleation: Suitable conditions for optical resolution of the DL-4-EB salt were estimated by free energy of critical nucleation (Δg_{max}/J nucleus^{-1}) and factors of crystallization of the D- and L-salts for different degrees of supersaturation of 143, 153, and 188%;[3,8] the values of Δg_{max} were calculated by the equations described in the previous papers.[8,15] The amounts of crystallization of the D- and L-salts were calculated from the data in Table 5.[16] The relationship between the amount of crystallization and resolution time is shown in Fig. 2. The speed of crystallization of the L-salt (R_L/g min^{-1}) was calculated from linear plots of Fig. 2; the straight lines had the correlation coefficient of 0.97—0.99. The retardation time for crystallization of the D-salt (θ_D/min) was defined as the time that elapsed before the D-4-EB salt begins to crystallize rapidly and was estimated from Fig. 2. The values of Δg_{max}, R_L, and θ_D are listed in Table 6.

Table 4. Preferential Crystallization of DL-Cysteine Salt of Benzenesulfonic Acid[a]

Solvent	Degree of supersaturation / %	Resolution time / min	Yield / g	Optical purity / %	YOPM[b] / g	Degree of resolution / %

160	62	0.515	98.2	0.456	70.5
	70	0.601	82.7	0.447	69.1
165	50	0.524	92.5	0.435	62.1
	60	0.656	77.0	0.455	64.9
170	40	0.485	96.1	0.416	55.1
	50	0.684	71.2	0.437	57.9
188	5	0.111	100	0.061	6.4
	15	0.245	92.2	0.176	18.5
	18	0.325	94.2	0.256	27.0
	20	0.412	91.7	0.328	34.6
	25	0.653	79.2	0.467	49.2
	35	1.241	12.5	0.105	11.1

a) Solvent: 50 cm³ of ethanol. Seed crystals: 0.050 g of L-salt. Temperature: 20 °C. b) YOPM: See note in Table 4.

The relationship between R_L and Δg_{max} for the degree of supersaturation of 143, 153, and 188% and that between θ_D and Δg_{max} are then obtained as

$$\ln R_L = -1.660 \ln \Delta g_{max} - 70.92, \quad (1)$$

$$\ln \theta_D = 1.526 \ln \Delta g_{max} + 64.76, \quad (2)$$

where the correlation coefficients are higher than 0.999.

Suitable Conditions for Optical Resolution: The optical resolution at θ_D-5 min seems to be a better criterion for evaluating the results of optical resolution than that at θ_D min, because the unseeded D-salt begins to crystallize rapidly after θ_D min. The amount of crystallization of L-salt at θ_D-5 min ($W^c_{(-5)}/g=R_L(\theta_D-5)$) is derived from Eqs. 1 and 2 and expressed by

$$W^c_{(-5)} = 2.120 \times 10^{-3} \Delta g_{max}^{-0.1344} - 7.950 \times 10^{-31} \Delta g_{max}^{-1.660}. \quad (3)$$

Since the values of R_L for the degree of supersaturation of 143, 153, and 188% are calculated by the least-squares method from linear plots in Fig. 2,

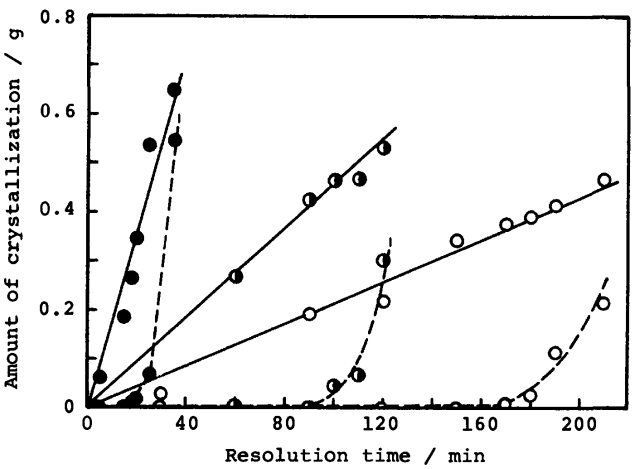

Fig. 2. Relationship between amounts of crystallization of D- and L-cysteine salts of 4-ethylbenzenesulfonic acid and resolution time.
Conditions: Solvent 50 cm³ of ethanol; seed crystals 0.050 g of L-salt; temperature 20 °C. Degree of supersaturation: ○ 143%; ◑ 153%; ● 188%. ——: L-Salt. ——: D-Salt.

a) Conditions of crystallization: Solvent 50 cm^3 of ethanol; seed crystals 0.050 g of L-salt; temperature 20 °C. b) Δg_{max}: Free energy of critical nucleation at 20 °C in ethanol. c) R_L: Speed of crystallization of L-salt. d) θ_D: Retardation time for crystallization of D-salt. e) $W_{(-5)}$: Amount of crystallization of L-salt at θ_D-5 min. f) These values of $W_{(-5)}$ were calculated from Eq. 3. g) These values of $W_{(-5)}$ were calculated from Eq. 5. h) These values of R_L were calculated from Eq. 1.

the straight lines obtained do not always pass through the origin. Therefore, the calculated values of $W^c_{(-5)}$ from Eq. 3 show relatively large deviation from experimental values at θ_D-5 min ($W_{(-5)}$/g); the values of $W^c_{(-5)}$ are listed under "Calcd I" in Table 6 and those of $W_{(-5)}$ are also listed under "Found" in Table 6. On the other hand, the linear relationship between $W^c_{(-5)}$ and $W_{(-5)}$ for the degree of supersaturation of 143, 153, and 188% is expressed by

$$W_{(-5)} = 6.249W^c_{(-5)} - 2.084, \quad (4)$$

where the correlation coefficient is 0.998. Eliminating $W^c_{(-5)}$ in Eqs. 3 and 4, we have

$$W_{(-5)} = 1.325 \times 10^{-2}\Delta g_{max}{}^{-0.1344} - 4.969 \times 10^{-30}\Delta g_{max}{}^{-1.660} - 2.084. \quad (5)$$

In order to test Eq. 5, the values of $W_{(-5)}$ for the degree of supersaturation of 160, 165, and 170% calculated from Eq. 5 are listed in Table 6 as Calcd II. The optical resolution for these degrees of supersaturation was carried out at the resolution time approximately equal to the calculated value of θ_D-5 from Eq. 2. The resulting data are listed in Table 5. The amounts of crystallization of the L-salt obtained from the data agree well with the calculated values of $W_{(-5)}$ from Eq. 5, as shown in Table 6. The values of $W_{(-5)}$ for other degree of supersaturation were also calculated from Eq. 5, and the relationship between $W_{(-5)}$ and degree of supersaturation is shown in Fig. 3.

Figure 3 suggests that the maximum amount of the L-4-EB salt with high optical purity can be obtained with degree of supersaturation of 160—165%. When $W_{(-5)}$ in Eq. 5 or $W^c_{(-5)}$ in Eq. 4 is differentiated with respect to Δg_{max} and the differential coefficient is put equal to zero, the value of Δg_{max} that gives the maximum $W_{(-5)}$ or $W^c_{(-5)}$ was calculated to be 5.55×10^{-18} J nucleus^{-1}. This value is approximately equal to the value for an ethanol solution with 160% degree of supersaturation (5.87×10^{-18} J nucleus^{-1}); the

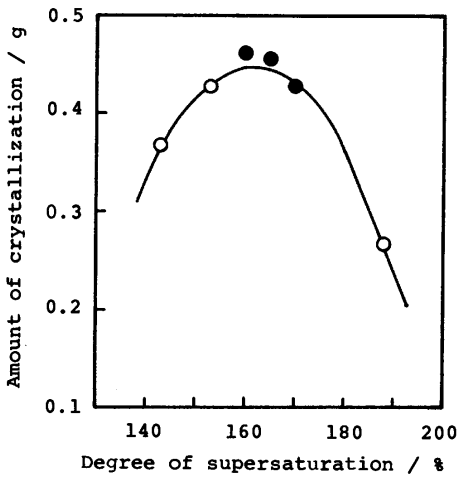

Fig. 3. Crystallization of L-cysteine salt of 4-ethylbenzenesulfonic acid at θ_D-5 min.
Conditions: Solvent 50 cm^3 of ethanol; seed crystals 0.050 g of L-salt; temperature 20 °C. ——: Calculated amount of crystallization of L-salt at θ_D-5 min from the data for degree of supersaturation of 143, 153, and 188% (○). ●: Experimental amount for degree of supersaturation of 160, 165, and 170%.

value of Δg_{max} for 165% degree of supersaturation is 5.06×10^{-18} J nucleus^{-1}.

The above result suggests that the optical resolution with 160% degree of supersaturaiton at resolution time of 62 min is the most favorable for obtaining the L-4-EB salt with high optical purity in high yield; θ_D calculated from Eq. 2 is 67 min. The results in Table 5 indicate that the optical resolution under these conditions gives the L-4-EB salt with 98.2% optical purity in 70.5% degree of resolution and the yield of optically pure modification (0.456 g) is maximum at θ_D-5 min. This result supports the above suggestion.

Successive Preferential Crystallization of DL-4-Ethylbenzenesulfonate. In order to obtain the D- and L-4-EB salts with high optical purity, the successive

Table 7. Successive Preferential Crystallization of DL-Cysteine Salt of 4-Ethylbenzenesulfonic Acid[a)]

Run	Added amount of DL-salt	Operation amount[b)]/g		Resolution time	Salt obtained				
					Yield	Optical purity	YOPM[c)]	Degree of resolution

2	0.465	1.953	1.497	52	D 0.578	93.0	0.486	55.7	
1[e)]	3.450	1.725	1.825	30	L 0.736	98.5	0.675	90.3	
2	0.686	2.062	1.488	30	D 0.912	97.3	0.837	85.0	
3	0.862	1.643	1.905	40	L 0.782	100	0.732	88.4	
4	0.732	2.009	1.539	40	D 0.828	100	0.778	83.4	

a) Solvent: 50 cm^3 of ethanol. Seed crystals: 0.050 g of D- or L-salt. Temperature: 20 °C. b) The operation amounts of D- and L-salts in solution were calculated on the basis of analyses of the salt obtained in Run 1 or 1—3. c) YOPM: See note in Table 4. d) Degree of supersaturation of the initial solution: 160%. e) DL-Salt (3.450 g) and 0.100 g of L-salt were dissolved in the initial solution.

preferential crystallization was attempted with an initial solution with 160% degree of supersaturation; the result is listed in Table 7. Although it was also possible to obtain the D-4-EB salt with 93.0% optical purity, the degree of resolution (55.7%) was not so high as expected.

The L-4-EB salt (0.100 g) was dissolved in the initial solution to induce more rapid crystallization of the L-salt with high optical purity. This optical resolution was found to give the D- and L-4-EB salts with optical purity of 97—100% in degree of resolution of 83—90%, as shown in Table 7. The yields of optically pure modification of the D- and L-salts obtained also increased to 19—24% of the amounts of the DL- and L-salts contained in the initial solution. The purified D- and L-4-EB salts were treated with triethylamine to give optically pure D- and L-Cys's in 93—94% yield, respectively.

The above results show that suitable conditions are predictable by Δg_{max} and that the optical resolution by preferential crystallization of DL-4-EB salt efficiently gives the optically active Cys.

Mathematical Analysis of Noncatalytic Coal Dissolution Using Tetralin and the Prediction of Coal Conversion, SRC Yield and Aromaticity of SRC

Hideyuki TAGAYA,* Masayuki SUGAI, Kazuo ITO, Hisako ANDO, and Koji CHIBA*

Department of Chemical Engineering, Faculty of Engineering, Yamagata University, Johnan, Yonezawa 992

(Received April 10, 1987)

Mathematical analyses of noncatalytic coal dissolution using tetralin at 350—460 °C were carried out. Coal conversion, SRC yield and aromaticity of SRC could be predicted fairly well by regression equations using liquefaction conditions as explanation variables. The equation derived from coal conversions in 67 experiments using the C% and volatile matter of 6 coals and liquefaction conditions could predict coal conversions fairly well (R=0.972). The conversions predicted by the proposed equation were also compared with those reported by previous investigators. Although it was suggested that long heating-up period was detrimental to coal conversion, the equation was a good indication of the conversion in solvent extract liquefaction.

There are three alternative processes for direct coal liquefaction (solvent extraction, catalytic hydrogenation and carbonization). In the solvent extraction process coal may be extracted and dissolved at temperatures of 350—450 °C by the action of hydrogen donor solvents with and without catalyst or molecular hydrogen being present.[1] Several solvent extraction process using different modes have been developed. The Pott-Broche process was developed in Germany in 1920s and the process was a prototype of the SCF process in 1950s, the SRC process in the early 1960s and the EDS process in 1960s. It has been well-understood that in noncatalytic coal dissolution, hydrogen from the donor solvents reacts directly with coal molecules to produce hydrocarbon liquids.[2] Therefore, many researchers have attempted to evaluate the hydrogen-donor ability of coal-liquefaction solvents[3] and hydroaromatic compounds such as tetralin are known as donors.[4] In the Pott-Broche and the SCF processes tetralin was used as a solvent. Recently, many laboratory-scale liquefaction processes using tetralin have been intensively investigated.[5-20] Coal conversion has proved to be largely dependant not only on the rank of coal but also on the liquefaction conditions. However, most of the previous studies using tetralin were investigations concerning specific liquefaction conditions[5,7-18] and those using specific coal.[6,19,20] A quantitative evaluation of coal conversion by suitable variables is required for the effective dissolution by establishment of optimal conditions. The object of the present study is to obtain the relationship between explanation variables (coal properties, liquefaction conditions) and observed variables (coal conversion, SRC yield and aromaticity of SRC) and to compare the coal conversions predicted by the proposed relation with the actual conversions obtained in this study and in the previous investigators.[5-16]

Experimental

Coal Sample and Solvent. Seven coals were used in this study. Analyses of these coals are given in Table 1. They were ground to a size that could pass through a 100-mesh (149 μm) screen and were dried at 107 °C in a nitrogen atmosphere. Six types of coal, except Wandoan coal, were used in the study in order to obtain regression equations. Reagent-grade tetralin was used after distillation under reduced pressure.

Coal Liquefaction Procedure. Coal (6—18 g) and tetralin (6—18 g) were placed in a magnetically stirred autoclave and pressurized to ≈5.1 MPa with hydrogen or nitrogen. The autoclave was heated to the reaction temperature and maintained for the nominal reaction time. At the completion of a run, the autoclave was cooled by an electric fan to room temperature. Materials remaining in the autoclave after the liquefaction were extracted with benzene. Conversion to a benzene-soluble material was calculated according to the following equation:

Conversion (wt%, daf coal basis)=
100(coal charged−benzene insoluble material)/daf coal.

Tetralin was recovered from the benzene extract by vacuum distillation at 240 °C and 933 Pa and was analyzed by GC to calculate the transferred hydrogen from tetralin to

Table 1. Analyses of Coals (wt%)

Coal	Ultimate analysis (daf)				Proximate analysis (coal)			
	C	H	N	Odiff	Mois	FC	VM	Ash
Yallourn	69.8	4.0	0.8	25.4	13.3	51.9	32.8	2.0
Wandoan	77.6	6.2	0.8	15.4	9.2	38.6	44.9	7.3
Taiheiyo	77.9	5.8	0.7	15.6	4.8	35.8	47.5	11.9
Horonai	79.4	6.0	1.1	13.4	3.1	44.6	45.4	6.9

Minamiohyubari	83.5	6.1	1.3	9.3	1.3	40.8	52.2	5.7
Miike-2	85.9	6.1	1.3	6.7	2.3	46.9	43.9	6.9

coal. The distillation residue was weighed as a solvent refined coal (SRC).

Calculation of Aromaticity of SRC. The aromaticity of SRC was calculated using the Brown-Ladner method.[21] The ^{1}H NMR data required for the calculation were obtained using a Hitachi R 22 apparatus (90 MHz). The distribution of hydrogen was estimated from the intensities of the three different ^{1}H NMR bands (hydrogen on aromatic carbon atoms; δ=6—9, hydrogen on α carbon atoms; δ=2—4.5, hydrogen on other nonaromatic carbons; δ=0.3—2).

Statistical Method. To obtain the relationship between explanation variables (coal properties, liquefaction conditions) and observed variables (coal conversion, SRC yield and aromaticity of SRC), a factorial experimental design was used.[20,22] Thus, the variables of interest were identified and a set of 10 experiments (at least) was performed in which the reaction conditions were changed in a systematic way.[23] The conversion, SRC yield, and aromaticity of SRC were measured under various conditions.

Results and Discussion

Yallourn (a set of 11 experiments), Taiheiyo (15), Horonai (10), Miike-1 (10), Minamiohyubari (11), and Miike-2 (10) coals were liquefied in a hydrogen atmosphere (0—5.1 MPa) using tetralin at 350—460 °C. Under these liquefaction conditions, coal conversion increased linearly with the amounts of transferred hydrogen from tetralin to coal. This indicated that the undesirable regression reaction was minor in these conditions. The observed Yallourn coal conversion, SRC yield and aromaticity of SRC are shown in Table 2. The reproducibility of the data is indicated by the values for duplicate runs at 440 °C under 5.1 MPa for 20 min and at 410 °C under 2.5 MPa for 40 min. This reproducibility shows that application of the data to a regression analysis is possible.[23] Least-squares regression analyses were performed using these data and the resulting equations allowed for a calculation of the conversion, SRC yield and aromaticity of SRC (f_a). The equations derived from the data in Table 2 are given in Eqs. 1—3, where T is the temperature (°C), P the pressure (MPa), and t the time (min):

$$\text{Conversion} = -164.18 + 0.513T - 0.0369P + 0.136t, \quad (1)$$

$$\text{SRC yield} = -59.82 + 0.191T + 0.0221P + 0.0691t, \quad (2)$$

and

$$f_a \times 1000 = -138 + 1.77T - 1.53P + 0.500t. \quad (3)$$

Coefficients of correlation for Eqs. 1—3 were as large as 0.996, 0.936, and 0.934, respectively. Predicted values using the Eqs. 1—3 are also shown in Table 2 (in parentheses). It is clear that the predicted values are close to the observed values.

For other coals, satisfactory results, as well as for Yallourn coal, were obtained. The resulting coefficients for 6 coals for the factors (temperature, pressure, solvent/coal ratio, and time) and correlation coefficients are listed in Table 3. Needless to say, the temperature was main factor for predicting coal conversion and SRC yield. In liquefaction using a catalyst, it was reported that the reaction-rate constant for the liquefaction increased linearly with the reaction pressure.[24] Even in a non-donor solvent like decalin without a catalyst, participation of hydrogen molecules in the liquefaction was suggested.[25] However, it was understood that a donor solvent like tetralin fulfilled the main role of hydrogen donation in the solvent-extraction process.[26] For the equations of conversion, the coefficients in pressure for Yallourn and Taiheiyo coals were negative. However, their absolute values were small. The effect of hydrogen pressure on coal conversion was small under these conditions. Positive values of coefficients in pressure

Table 2. Observed (Obs.) and Predicted (Pred.) Yallourn Coal Conversion, SRC Yield and Aromaticity of SRC Using Tetralin in a Hydrogen Atmosphere

Temp °C	Press MPa[a]	Time min	Conversion		SRC yield		Aromaticity

410	2.5	40	52.2	(51.7)	21.1	(21.3)	0.604	(0.606)

a) Total pressure was 5.1 MPa (2.5 MPa and 0 MPa mean 2.5 MPa of hydrogen+2.5 MPa of nitrogen and 5.1 MPa of nitrogen, respectively).

were obtained for the equations of SRC yields, except for Taiheiyo coal. This indicated that increasing pressure suppressed the formation of gaseous products.[19]

The aromaticity of SRC tended to increase with the reaction temperature, except for Miike coal-2 in which negative coefficient (−0.167) was obtained although its absolute value was small. From the increasing aromaticity of SRC, two reaction mechanisms were considered: In one mechanism, the value of aromaticity increased owing to a further reaction of the liquefaction products. In the other mechanism, compounds having higher values of aromaticity were liquefied proceeding liquefaction. The aromaticity of SRC scarcely changed upon a thermal treatment.[27] This indicated that the latter mechanism in which, as the liquefaction proceeded, compounds having more condensed-ring were cleaved and liquefied, was reasonable.

If the coefficients were well correlated with the coal properties, the meaning of the coefficients might be clear; however, we could find no good correlations between the coefficients for the factors and the coal properties. Figure 1 is a plot of the conversion predicted from the regression equation against the actual conversion for the 6 coals. The predicted conversions are in fair agreement with the observed conversions over the wide conversion range (5—90%). Figure 1 also shows the conversions under a nitrogen atmosphere (12 experiments) as a closed key. They were also in good agreement with the predicted values. It is evident that the role of molecular hydrogen to increase coal conversion is minor under these mild liquefaction conditions with no catalyst.[19]

Similar satisfactory relationships between predicted and observed SRC yield were also attained. However, a smaller coefficient of correlation than that for conversion was observed in the case of the relationship between predicted and observed aromaticity of SRC. As shown in Table 2, the difference of aromaticity in repeated runs at 440 and at 410 °C were 0.19 and 0.19 (not small). The smaller coefficient of correlation is partly due to an experimental error in determining the aromaticity of SRC.

A useful way for attaining an effective solvent extraction of coals is to obtain an equation which can describe the change in coal conversion by using the properties of the coals. Regression analyses using coal properties (C%, H%, N%, H/C, volatile matter, fixed carbon, and ash) and liquefaction conditions as explanation variables were carried out in various combinations. We choose C%, volatile matter and liquefaction conditions since the coefficient of correlation was largest when they were used. The equations derived from the 67 experiments using 5 explanation variables (2 coal properties and 3 liquefaction conditions) are given in Eqs. 4—6, where C is the C% of coal (wt%), VM the volatile matter based on dry coal (wt%), T the temperature (°C), P the pressure (MPa), and t the time (min):

Table 3. Results of Multiple Regression Analyses

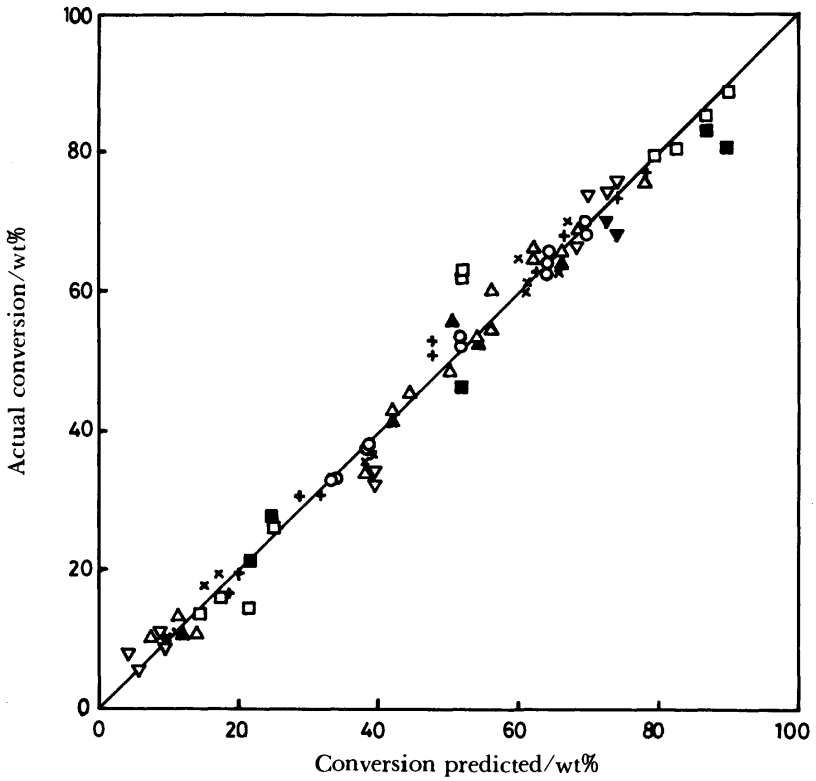

Fig. 1. Comparision of conversions predicted by the six regression equations for each coal and actual conversions obtained: ○, Yallourn (H_2); △, Taiheiyo (H_2); ▲, Taiheiyo (N_2); +, Horonai (H_2); □, Miike-1 (H_2); ■, Miike-1 (N_2); ×, Minamiohyubari (H_2); ▽, Miike-2 (H_2); ▼, Miike-2 (N_2).

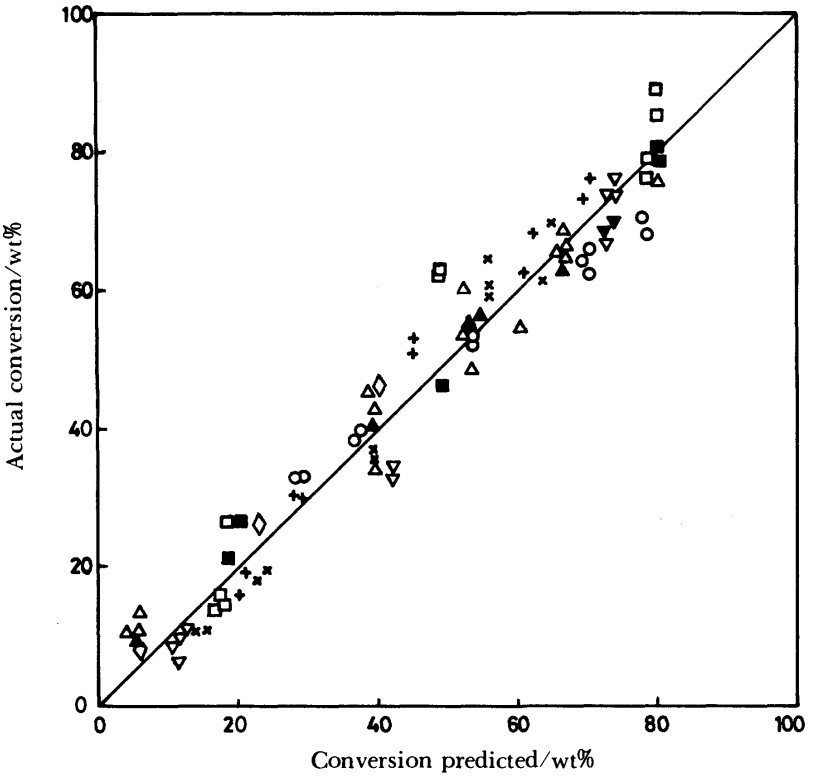

Fig. 2. Comparision of conversions predicted by the regression equation and actual conversions obtained: The key is as in Fig. 1; ◇, Wandoan (N_2).

$$\text{Conversion} = -208.01 + 0.188C - 1.08VM + 0.684T + 0.210P + 0.212t, \quad (4)$$

$$\text{SRC yield} = -203.93 + 0.868C - 0.367VM + 0.417T + 0.571P + 0.242t, \quad (5)$$

and

$$f_a \times 100 = -9.523 + 0.708C - 0.685VM + 0.108T - 0.220P + 0.0332t. \quad (6)$$

Coefficients of correlation for Eqs. 4—6 were 0.972, 0.900, and 0.795, respectively. A smaller coefficient of correlation (0.948) was obtained when the regression equation was derived using C, T, P, t as explanation variables (except for VM). Volatile matter is known to decrease with an increase in the coal rank;[28] however, volatile matters of higher-rank coals in this study (Miike coal-1 and -2) are smaller than those of lower-rank coals (Taiheiyo and Horonai coals). The present study, in which volatile matter and coal rank are two important variables, indicates the possibility that they are significant independant properties of coal. The possibility that volatile matter concerned well with the amounts of linkages which were easily cleaved and the resulted radical consumed hydrogen was not excluded. Comparision of predicted values and actual values using the Eqs. 4—6 are shown in Fig. 2—4. Figure 2 shows that the conversions obtained with wide-range conditions and coal ranks can be well predicted only from one Eq. 4. We also added to Fig. 2 the conversions obtained in the liquefaction of Wandoan coal (a set of 3 experiments). The difference between observed and predicted conversions of Wandoan coal were only 3—6%. Although there are small scatter in Figs. 3 and 4, especially in Fig. 4, the equations are sufficient for predicting SRC yield and aromaticity of SRC.

We compared the conversion predicted by the proposed Eq. 4 with the results obtained by previous investigators,[5-16] as shown in Fig. 5. There is considerable scatter. Actual conversions by investigators 4, 8, and 10 were fairly larger than predicted; however, those by investigators 2, 3, and 5 were smaller than predicted. Here, we must note the difference of liquefaction apparatus among investigators as shown in Table 4. Investigators 4, 8, and 10 used tubing bomb as the reactor which did not require so long heating up period (0.5—1.5 min). Investigator 5 used 4l autoclave and required 120 minutes to reach reaction temperature (400 °C). In addition, investigators 2, 3, and 6 used 300 ml and investigator 12 used 500 ml autoclave. We used 100 ml magnetically stirred autoclave and required 60 minutes to 400 °C. These facts indicate that in a prediction using Eq. 4, the conversion is overestimated for a larger reactor which requires a long heating-up period and is underestimated for a smaller reactor like tubing bomb. It is well-known that coal liquefaction is proceeded even in the course of heating-up period.[29] However, our results suggest that extending the heating-up period

does not contribute to an increase in coal conversion. The influence of the heating-up period on brown coal carbonization was reported by Mochida et al.[30] They found that the occurrence of some fusion of the coal was evident at rapid heating rates (600 °C/3 min and 2 s) whereas that did not occur at low heating rates (600 °C/1 h). They also concluded that the rapid heating rates and high liquefaction temperatures might allow the rapid transfer of reactive, and relatively inert, hydrogen in the solvent to the thermal decomposition fragments of the coal to stabilize them. A detrimental effect, involving pretreatment at low temperatures, on the conversion was confirmed during the liquefaction of Miike coal-2. Conversion of pretreatment coal (pretreatment at 200 °C for 60 min in tetralin) at 400 °C for 60 min (35.9%) was almost similar to 35.4% of no pretreatment coal. However, the conversion of pretreatment coal at 250 °C for 60 min in tetralin was 29.0%, about 6% lower than that of no pretreatment coal. This is directly related to the bad influence of the long heating-up period on coal conversion. In the conversion prediction using Eq. 4, the influence of the heating-up period was not considered. Including the influence of the heating-up period into the prediction is difficult, however, qualitative discussion as long heating up period is detrimental is possible. It is clear that the Eq. 4 is a good indication of the conversion in solvent extract liquefaction.

Conclusion

Conversion, SRC yield and aromaticity of SRC of six kinds of coals (Yallourn, Taiheiyo, Horonai, Miike-1, Minamiohyubari and Miike-2) at 350—460 °C under hydrogen atmosphere were fairly predicted by 18 regression equations (coefficients of correlation were 0.747—0.996) using liquefaction conditions as explanation variables. Conversions under nitrogen atmosphere were also in good agreement with the predicted. Following equation was derived from coal conversions in 67 experiments using 2 coal properties (C% and Volatile matter) and 3 liquefaction conditions having a high coefficient of correlation (0.972):

$$\text{Conversion} = -208.01 + 0.188C\% - 1.08\ \text{Volatile matter} + 0.684\ \text{Temperature} + 0.210\ \text{Pressure} + 0.212\ \text{Time}$$

Coal conversions of previous investigators using small reactor as tubing bomb were underestimated by the above equation and those using large reactor were overestimated. It was suggested that a long heating up period was detrimental. Above equation is a good indication of the conversion in solvent extract liquefaction. Sufficient prediction of SRC yield and aromaticity of SRC were attained by regression equations using same 2 coal properties and 3 liquefaction conditions as explanation variables.

Optical Resolution of Alcohols as Carbamates by HPLC on Cellulose Tris(phenylcarbamate) Derivatives[1)]

Yoshio Okamoto,* Zun-Kui Cao,† Ryo Aburatani, and Koichi Hatada
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received April 17, 1987)

The optical resolutions of various alcohols as phenylcarbamates were examined by HPLC on chiral stationary phases derived from sixteen cellulose tris(phenylcarbamate) derivatives. The optical resolving power of chiral stationary phases was greatly influenced by substituents on the phenyl groups of the cellulose derivatives. Also, cellulose tris(3,5-dimethylphenylcarbamate) could very efficiently resolve many racemic phenylcarbamates, including the carbamates of 2-butanol, 3-buten-2-ol, and 1-phenylethanol. Racemic phenylcarbamates having electron-donating substituents on the phenyl group were better resolved than those having electron-withdrawing substituents. The benzoates of most alcohlos were not resolved as efficiently as the carbamates.

Optical resolution by chiral high-performance liquid chromatogaphy (HPLC) has been attracting much attention as a procedure for obtaining optical isomers and determining their purity; many chiral stationary phases (CSP) have been reported over the past several years.[2)] We recently reported that phenylcarbamate derivatives of polysaccharides,[3)] particularly cellulose,[4-10)] show characteristic optical resolving abilities to a variety of enantiomers. The optical resolving power of nineteen cellulose tris(phenylcarbamate) (CTPC) derivatives depended greatly on the inductive effect of substituents on the phenyl group and either 3,5-dimethyl or 3,5-dichloro derivatives (CTPC-3,5-Me_2 or -3,5-Cl_2) showed the best resolution to many of the racemic compounds examined.[4)] CTPC-3,5-Me_2, which has the most electron-donating substituent, seemed to effectively resolve polar compounds that could interact with the carbonyl group of the urethane bond of the carbamate. However, CTPC-3,5-Cl_2 seemed to possess a higher resolving power for compounds that can be adsorbed on the NH group of the urethane bond.

The optical resolution of alcohols is laborious and usually they are resolved as diastereomeric salts of acid phthalates. A direct resolution of alcohols by chiral HPLC has been attained only for several aromatic alcohols.[4,11,12)] However, many alcohols, including aliphatic alcohols, have been successfully resolved by chiral HPLC as proper derivatives, such as esters[12,13)] or urethanes.[14,15)] Racemic 3,5-dinitrophenylcarbamates of racemic alcohols have been utilized for effective chiral discrimination through a π–π interaction.[14,15)] In this work, in order to attain an efficient resolution of alcohols by HPLC, the urethanes of various racemic alcohols were prepared by reactions with twelve substituted phenyl isocyanates; they were subjected to optical resolution on 16 CTPC derivatives **1**—**16**.

Experimental

Materials. Details on the preparation of CSPs were described previously.[4)] CTPC derivatives (25wt% of silica gel) were adsorbed on macroporous silica gel (diameter 10 μm, pour size 400 nm), and used as CSPs. Racemic alcohols were allowed to react with substituted phenyl isocyanates in the presence of a small amount of pyridine to give racemic carbamates. The carbamates were purified by either distillation or recrystallization.

Chromatographic Analyses. CSPs were packed in a stainless-steel tube (25 cm×0.46(id) cm) by a slurry method. Chromatographic analyses were carried out on a JASCO TRIROTAR-II chromatograph equipped with UV (JASCO UVIDEC-100-III) and polarimetric (JASCO DIP-181C) detectors. The optical resolution was monitored in a flow cell (50 mm×2(id) mm) at full lamp (mercury) intensity without a filter. Optical resolution was performed with a hexane-2-propanol mixture at a flow rate of 0.5 or 1.0 ml min^{-1} at 25 °C. Dead time (t_0) of the chromatograph system was estimated with 1,3,5-tri-*t*-butylbenzene as a non-retained compounds.[16)]

Results and Discussion

2-Butanol was completely resolved into enantiomers as phenylcarbamate on cellulose tris(4-ethylphenylcarbamate) (**2**) as shown in Fig. 1. Capacity

factors (k_1' and k_2') for the first- and second-eluting isomers, which were estimated as $(t_1-t_0)/t_0$ and $(t_2-t_0)/t_0$, were obtained as 0.88 and 1.61, respectively, and separation factor ($\alpha=k_2'/k_1'$), which represents the chiral recognition ability of CSP, was determined to be 1.83. The resolution factor (R_s), which stands for the efficiency of a column, can be estimated by $2(t_2-t_1)/(W_1+W_2)$, where W_1 and W_2 are bandwidths of the peaks. Here, R_s was 3.84. Such an effective optical resolution of simple aliphatic alcohol derivatives by HPLC does not seem to have been reported before.[4,11-15]

Phenylcarbamates of 2-butanol and 1-phenylethanol were subjected to resolution on CTPC derivative columns (Table 1). Chiral recognition abilities of CSPs depended greatly on the substituents of CTPCs. Among nine para-substituted CTPCs **1**—**9**, methyl and ethyl derivatives exhibited better resolving powers for both racemic carbamates, suggesting that an electron-donating group would be preferable to an electron-withdrawing group. However, a more electron-donating substituent, methoxyl, was not better than alkyl. This may be attributed to the adsorption of the solute on the methoxyl group.[4] Since the methoxyl group is far from a chiral glucose

unit, such an adsorption must lower the optical resolving power of CSP. To attain an effective chiral recognition, solutes must be adsorbed on the urethane bond of CSP.

Dimethyl-substituted derivatives **11** and **12**, particularly the former, possessed a better resolving power over monosubstituted derivatives. However, 2,6-dimethyl-substituted derivative **13** showed no chiral recognition, as observed in the previous work.[4] 2,6-Dichloro derivative **16** also exhibited no resolving power. In almost all cases, (±)-1-phenylethyl phenylcarbamate was better resolved than (±)-*s*-butyl phenylcarbamate and both (*S*) isomers were eluted first. Reversed elution order of enantiomers was observed only in the resolution of (±)-1-phenylethyl phenylcarbamate on **8**. The reason for this is not clear.

s-Butyl phenylcarbamates (*s*-$C_4H_9OCONHC_6H_4X$) having various substituents were resolved on **4** and **11** (Table 2). The latter column always showed better resolving power than the former, and good resolution was attained on racemic unsubstituted phenylcarbamate (X=H) and methyl-substituted phenylcarbamates except for 2,6-dimethyl and 3-methyl derivatives. In all runs, (+)-isomers were eluted first. These results suggest that simple unsubstituted phenylcabamates of racemic alcohols may be one of the most suitable carbamates for resolution. Electron-withdrawing substituents were not suitable.

The resolution of phenylcarbamates of various aliphatic alcohols, including an allyl alcohol, were examined on columns packed with **4** and **11** (Fig. 2 and Table 3). All alcohols having a hydroxy group on the asymmetric carbon were sufficiently resolved as carbamates particularly on **11**, probably eluting (*S*)-(+)-isomers first. However, the carbamates of alcohols carrying a methylene group between hydroxy group and asymmetric carbon were not resolved as efficiently as the above alcohols. It can be expected that chiral discrimination will become more difficult as the distance between the urethane group and asymmetric center of racemic carbamates increases, since the urethane group must be adsorbed on CTPCs.

Table 4 shows the comparison data of the resolution of phenylcarbamates and benzoates of racemic alcohols on an **11** column. Most alcohols were better

a) Eluent: A, hexane–2-propanol(98:2) B: hexane–2-propanol (90:10) C: hexane–2-propanol(80:20). b) 1.0 ml min^{-1}. c) 0.5 ml min^{-1}. d) As 3,5-dichlorophenylcarbamate. e) As 3,5-dichlorobenzoate.

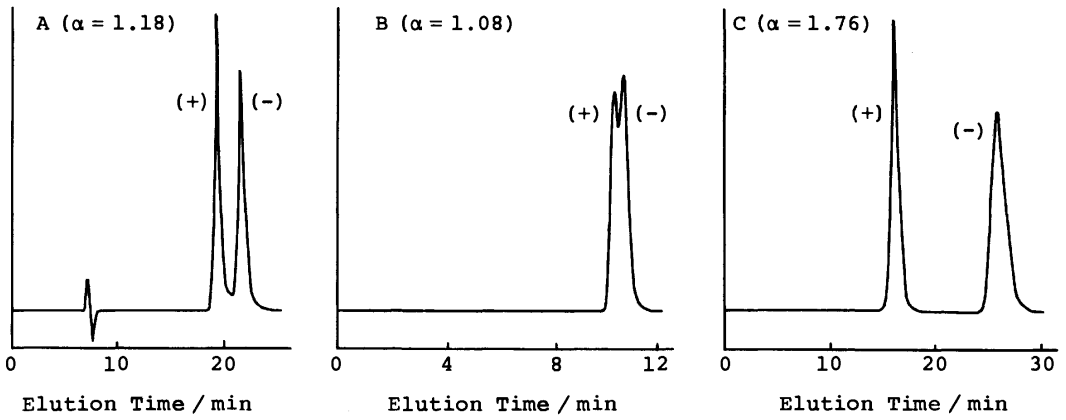

Fig. 3. Resolution of benzoates of glycidol (A) and 1,2,3,4-tetrahydro-1-naphthol (B), and carbamate of tetrahydrofurfuryl alcohol (C) on cellulose tris(3,5-dimethylphenylcarbamate) (A, B: hexane–2-propanol(98:2), 0.5 ml min^{-1}, 25 °C, C: hexane–2-propanol(80:20), 1.0 ml min^{-1}, 25 °C).

resolved as phenylcarbamates than benzoates. The benzoates of glycidol and 1,2,3,4-tetrahydro-1-naphthol were exceptionally better resolved than the carbamates (Fig. 3). The carbamate of tetrahydrofurfuryl alcohol was much better resolved than the benzoate (Fig. 3). Although glycidol and tetrahydrofurfuryl alcohol possess a methylene group between asymmetric center and hydroxyl group, these were resolved as phenylcarbamates. Adsorption on ether groups may contribute effective chiral discrimination.

Several 1,2- and 1,3-diols were also separated into enantiomers as phenylcarbamates (Table 5). The separation of diastereomers and the resolution of enantiomers were attained on 2,4-pentanediol.

One of possible space-filling structure (CPK) of CTPC is shown in Fig. 4. The carbamate and phenyl groups are aligned without any difficulty so that hydrogen bonds are formed between 2-3 carbamate groups and 2-6 carbamate groups.[17] These hydrogen bonds must contribute to the fixation of the adjacent glucose units which may lead to the formation of a liquid crystal phase.[18] The regularly arranged -NHCOO- groups of CTPC must be the most attractive adsorbing sites. Since the racemic esters were not well resolved, the hydrogen bonding and dipole interactions between the urethane bond of CTPC and the ester group of the solutes do not seem to strong enough to attain effective chiral discrimina-

Table 5. Resolution of Diols as Phenylcarbamates on Cellulose Tris(3,5-dimethylphenylcarbamate)[a]

Racemate	k_1'	α	R_s
$CH_3CHOCONHC_6H_5$ $CH_2OCONHC_6H_5$	4.24(−)	1.90	3.42

$CH_3CH_2CH_2CHOCONHC_6H_5$ $CH_3CH_2CHOCONHC_6H_5$	2.01(+)[c]	1.25	0.89
	0.71(−)	1.31	0.97

a) Eluent: hexane–2-propanol (80:20), 0.5 ml min^{-1}, 25 °C. b) Capacity factor of meso-isomer was 1.92. c) Only one enantiomeric pair was found.

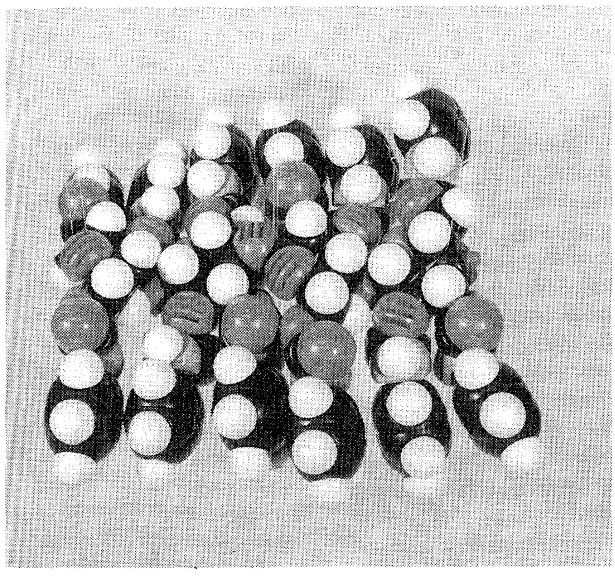

Fig. 4. CPK model of cellulose tris(phenylcarbamate).

tion. A stronger interaction between the two urethane groups of CTPC and solutes may be responsible for the effective chiral discrimination of the racemic carbamates.

The authors wish to thank Mr. Mitsunobu Kawashima for his support in the experiment. This work was partially supported by a Grant-in-Aid for Scientific Research No. 61470108 from the Ministry of Education, Science and Culture and the Mitsubishi Foundation.

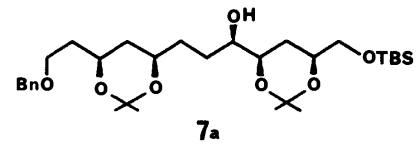
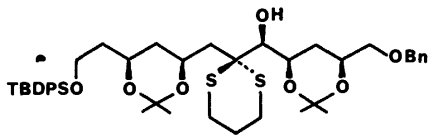
Synthetic Studies of Amphotericin B. II.[1] A Facile Synthesis of the C-1—C-12 Segments of the Amphotericin B Aglycon†

Mitsuhiro KINOSHITA,* Masahiko MORIOKA, Masato TANIGUCHI, and Jun SHIMIZU
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
(Received April 23, 1987)

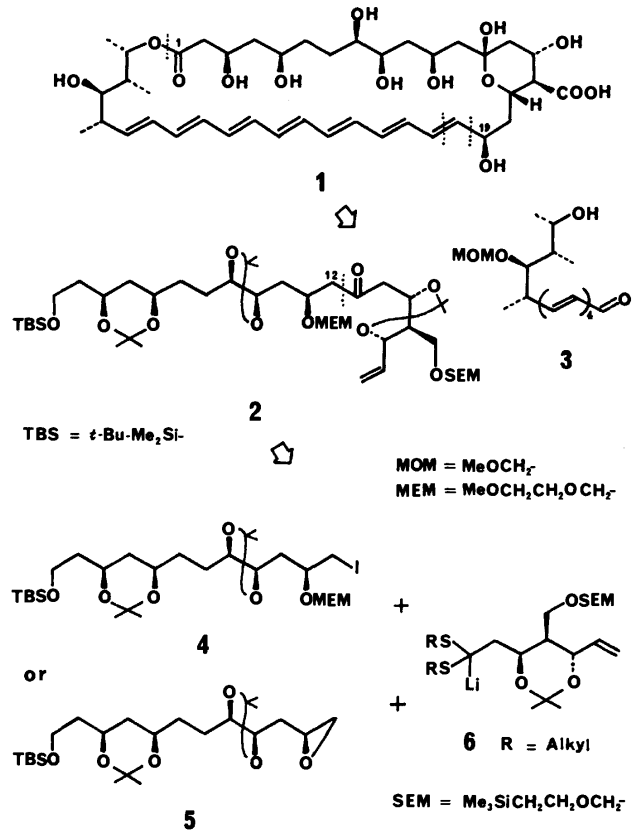
3-Deoxy-1,2-*O*-isopropylidene-α-D-*glycero*-D-*erythro*-pentofuranose (**11**) was stereoselectively converted into the Witting salt **8** corresponding to the C-1—C-6 portion of amphotericin B aglycon (**1**) in 57% overall yield in 8 steps. The aldehydic segment **9** or **10** corresponding to the C-7—C-12 portion of **1** was also derived in 6 steps from **11** in 53 or 38% overall yield, respectively. Wittig condensation of **8** with **9** or **10** followed by four-step conversion afforded the C-1—C-12 segment, (3*S*,5*R*,8*R*,9*R*,11*S*)-1-*O*-*t*-butyldimethylsilyl-12-iodo-3,5:8,9-di-*O*-isopropylidene-11-*O*-[(2-methoxyethoxy)methyl]-1,3,5,8,9,11-dodecanehexol (**4**) or (2*S*,4*R*,5*R*,8*R*,10*S*)-1,2-anhydro-12-*O*-*t*-butyldimethylsilyl-4,5:8,10-di-*O*-isopropylidene-1,2,4,5,8,10,12-dodecaneheptol (**5**) in 26 or 15% overall yield from **11**, respectively.

In our studies directed toward the total synthesis of amphotericin B,[2] a clinically valuable important member of the polyene macrolide antibiotics, our general synthetic plan[1] of its free aglycon **1** required two major segments, **2** and **3** corresponding to the C-1—C-19 and C-21—C-37 portions of **1**, respectively. The enantiospecific synthesis of the latter **3** from carbohydrate has already been accomplished in our laboratories.[1] The retrosynthetic examination of **2** revealed that a disconnection of the C-12—C-13 bond devided **2** into the C-1—C-12 segment **4** or **5** and the C-13—C-19 segment **6** (Scheme 1). The asymmetric synthesis of other kinds of C-1—C-12 segments, **7a**[3] and **7b**[4] have been reported. Recent synthetic efforts

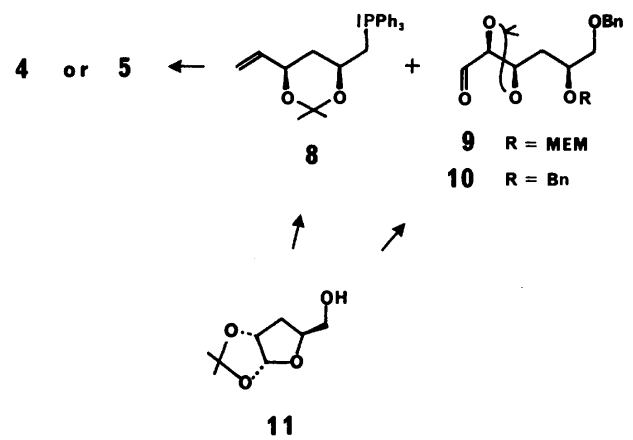




of **1** and its chiral building blocks have been announced.[5] In this paper, we wish to describe a facile syntheses of **4** and **5** from D-glucose. As shown in the synthetic plan of **4** and **5** (Scheme 2), both the C-1—C-6 segment **8** and the C-7—C-12 segment **9** or



Scheme 1.

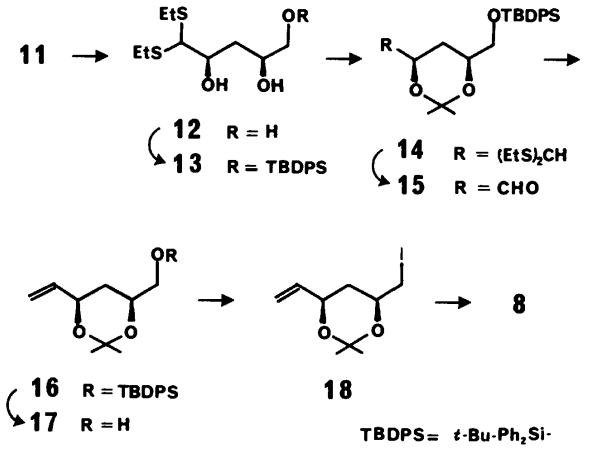


Scheme 2.

† A part of this paper was read at the 52nd National Meeting of the Chemical Society of Japan, Kyoto, April 1986, Abstr., No. 4N05.

10 would be derived from the common 3-deoxy-1,2-*O*-isopropylidene-α-D-*glycero*-D-*erythro*-pentofuranose (**11**)[6] which is obtainable from D-glucose. Wittig coupling of **8** with **9** or **10** followed by a sequence of reactions involving hydroboration and catalytic hydrogenation would give **4** or **5**.

Preparation of 8. Dithioacetalization of **11** with ethanthiol and boron trifluoride etherate afforded **12** which was regioselectively *t*-butyldiphenylsilylated[7] to give **13** in 92% overall yield from **11**. 2,4-*O*-Isopropylidenation of **13** with 2,2-dimethoxypropane (DMP) and a catalytic amount of H_2SO_4 in acetone afforded **14**, which was treated with 1:1 $HgCl_2$–HgO (red) in 80% aqueous acetone to give the aldehyde **15** in 94% overall yield from **13**. Wittig methylenation[8] of **15** with methylenetriphenylphosphorane in ether afforded **16** in 90% yield. Desilylation of **16** with tetrabutylammonium fluoride (TBAF) in THF gave **17** in 99% yield. Treatment[9] of **17** with triphenyl-

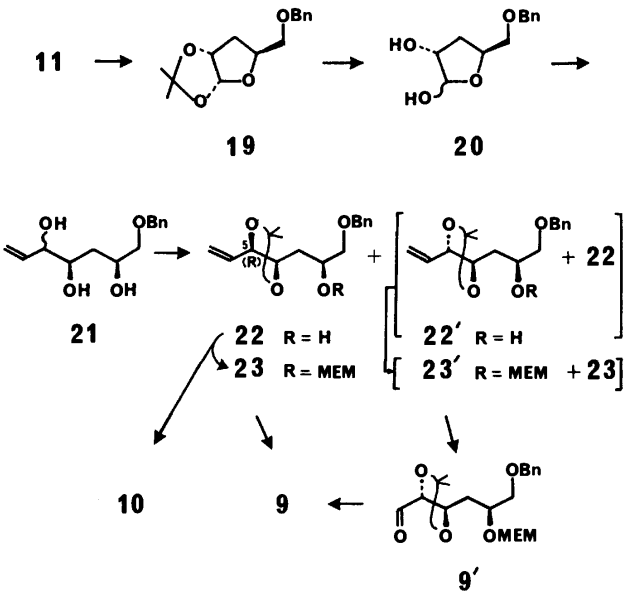


Scheme 3.

phosphine, imidazole, and iodine in benzene afforded the iodide **18** in 88% yield, which was allowed to react with triphenylphosphine in refluxed benzene to provide **8** in 88% yield. The overall yield of **8** from **11** was 57% in 8 steps.

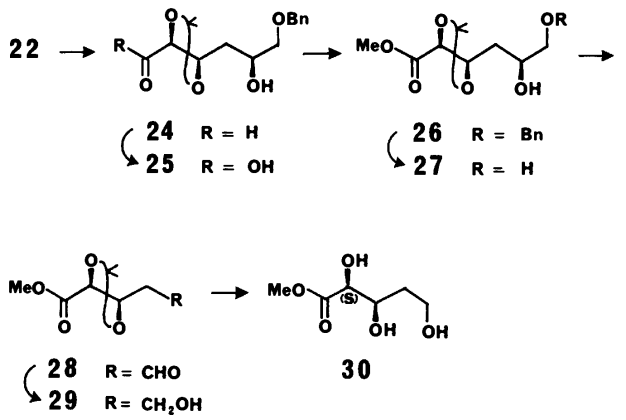
Preparation of 9 and 10. 5-*O*-Benzylation of **11** with sodium hydride and benzyl bromide in DMF afforded **19** in 97% yield. Hydrolysis of **19** with a 1:1 mixture of 3.2 M†† hydrochloric acid and dioxane gave **20** in 92% yield. Grignard reaction of **20** with large excess of vinylmagnesium bromide in THF afforded a ca. 3.5:1[10] syn/anti diastereomeric mixture **21** in 95% yield. Regioselective 4,5-*O*-isopropylidenation[11] of **21** with a catalytic amount of iodine in acetone gave a 54% yield of the major product **22** and a 24% yield of a mixture of **22** and its 3-epimer **22′** after chromatography. The chromatography also afforded a third fraction which consisted of **22**, **22′**, and a small amount of inseparable mixture of two epimeric 2,4-*O*-isopropylidene derivatives of **21**. Methoxyethoxy-

†† 1 M=1 mol dm^{-3}.



Scheme 4.

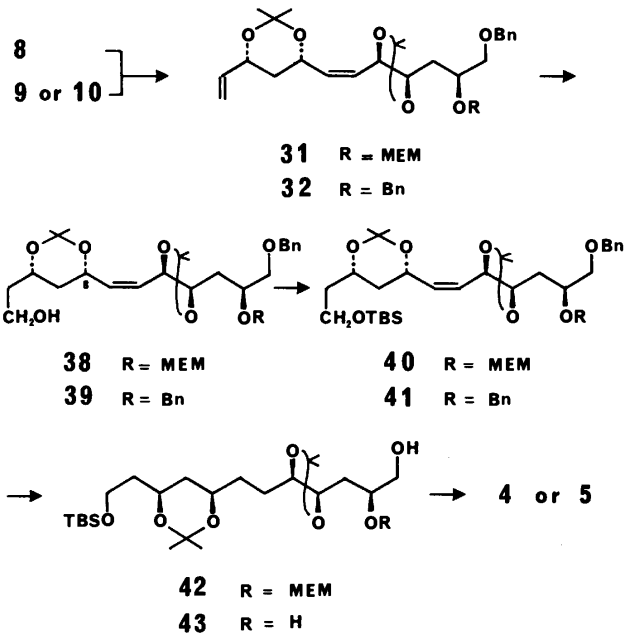
methylation of **22** with (2-methoxyethoxy)methyl chloride (MEM-Cl) and *N*,*N*-diisopropylethylamine gave **23** in 98% yield, which was oxidized with OsO_4–$NaIO_4$[12] to afford **9** in 92% yield. The mixture of **22** and **22′** was methoxyethoxymethylated to give in 94% yield a mixture of **23** and **23′**, which was oxidized with OsO_4–$NaIO_4$ to afford **9** and its epimer **9′** in 38 and 26% yields, respectively after chromatography. An isomerically pure sample of **22′** obtained by chromatographic separation of the aforesaid epimeric mixture was methoxyethoxymethylated and then oxidized to yield a mixture of **9** (20%) and **9′** (50%). Exposure of **9′** to methanolic K_2CO_3 at 23 °C for 4.5 h gave **9** in 68% yield. No starting **9′** was detected by ^{13}C NMR of the unpurified product. The total yield of the major product **9** from **11** amounted to 53%. The complete epimerization of **9** to **9′** indicated that the aldehyde **9** had presumably the desired 2,3-syn structure which would be thermodynamically more stable than the anti structure (in the basic conditions of epimerization). The structures of **22** and **22′** were thus presumed as depicted in Scheme 4. The (5R)-configuration of **22** was confirmed by the transformation of **22** into the (2*S*)-2-hydroxy ester **30** as shown in Scheme 5. Oxidation of **22** with OsO_4–$NaIO_4$ afforded the free aldehyde **24**. No hemiacetal structure was detected by ^1H NMR of the reaction product. This observation also supported the 2,3-syn structure of **24**. Oxidation of **24** with the periodite reagent (K_2CO_3, I_2, KI)[13] followed by treatment of the resulting carboxylic acid **25** with diazomethane gave **26** which was hydrogenolyzed over Pd-black to yield **27**. Periodate-oxidation of **27** followed by $NaBH_4$(0.5 molar) reduction of the resulting **28** afforded **29**. Finally, **29** was de-*O*-isopropylidenated to give **30**. Since the CD spectrum of **30** showed the (+)-CD Cotton effect which reflected



Scheme 5.

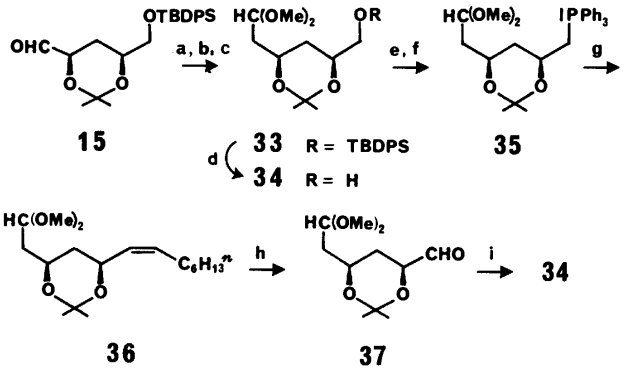
the (S)-configuration at the C-2 carbon atom,[14] the (5R)-configuration of **22** as depicted was confirmed. On the other hand, benzylation of **22** followed by OsO_4–$NaIO_4$ oxidation provided another C-7—C-12 segment **10** in 82% yield.

Preparation of 4 and 5. Wittig coupling between **8** and **9** or **10** was best achieved under the modified Secruist and Wu's conditions.[15] Treatment of 1 equivalent of **8** with 1 equivalent of butyllithium in 2:1 THF–HMPA at −70 °C under argon generated an orange-colored ylide which condensed with 0.9 equivalents of **9** or **10** at −50 °C to afford a single product **31** or **32** in 70 or 52% yield, respectively. The ^1H NMR examination showed both **31** and **32** to be the



Scheme 6.

isomerically pure (6Z)-olefines. The configurational integrity[15] of left half of the condensation product **31** or **32** was confirmed by the following experimental results (Scheme 7). The aforesaid aldehyde **15** was converted in 3 steps into its homologous aldehyde dimethyl acetal **33** according to the procedure developed in our laboratories.[16] The acetal **33** was transformed via the intermediate **34** into the Wittig salt **35**. Wittig reaction of **35** with heptanal was carried out by the same procedure as described for the reaction of **8** with **9** to afford only the condensation product **36** of (Z)-configuration. OsO_4–$NaIO_4$ oxidation of **36** followed by $NaBH_4$ reduction of the product **37** gave **34** which proved to be identical in all respects with a sample of the intermediate **34** derived from **15**, cleanly indicating that the (2S)-configuration of **35** was retained during the Wittig reaction.



(a) $MeOCH_2PPh_3Cl$, $NaCH_2SOMe$, ether; (b) NBS, MeOH; (c) *n*-Bu_3SnH, AIBN, PhMe; (d) TBAF, THF; (e) Ph_3P, DEAD, MeI; (f) Ph_3P, PhH, 84 °C, 4 d; (g) *n*-BuLi, 2:1 THF–HMPA; *n*-$C_6H_{13}CHO$; (h) OsO_4, $NaIO_4$, 3:1 dioxane–H_2O; (i) $NaBH_4$, MeOH.

Scheme 7.

The regioselective hydroboration of **31** or **32** with 1.8 equivalents of dicyclohexylborane in THF at 25 °C followed by treatment with alkaline hydrogen peroxide at 50 °C afforded **38** or **39** in 90 or 85% yield, respectively. The *t*-butyldimethylsilylation (TBS-Cl, Py, 23 °C) of **38** or **39** gave the silyl ether **40** or **41** in 95 or 90% yield, respectively. Simultaneous catalytic reduction of the double bond and benzyloxy group in **40** proceeded effectively with Raney Ni W-4 in ethanol to give **42** in 84% yield. Whereas the reduction of **40** with Pd-black in *t*-butyl alcohol provided a complex mixture involving the partially desilylated and de-*O*-isopropylidenated products. On the contrary, the catalytic reduction of **41** with Pd-black in *t*-butyl alcohol proceeded cleanly to afford the diol **43** in 98% yield. Iodination[17] of **42** with triphenylphosphine, diethyl azodicarboxylate (DEAD), and methyl iodide in benzene provided the segment **4** in 92% yield. One stage epoxidation[18] of **43** with triphenylphosphine, DEAD, and 3A molecular sieves in benzene afforded another segment **5** in 70% yield.

Experimental

Melting points were determined on a micro hot stage Yanaco MP-S3 and were uncorrected. Optical rotations

were measured on a Carl Zeiss photoelectric polarimeter and a JASCO DIP-360 photoerectric polarimeter in chloroform, and ^{1}H NMR spectra in $CDCl_3$ using TMS on either a Varian EM-390 or a Bruker WM 250 spectrometer. ^{13}C NMR spectra were measured on a JEOL FX 90A in $CDCl_3$, and IR spectra on a Hitachi Perkin-Elmer spectropotometer. High-performance liquid chromatography (HPLC) was carried out on a Waters 208 Compact Liquid Chromatograph, and TLC on Merck TLC plates (60F-254, 0.25 mm) and on Merck HPTLC plates (60F-254) for "HPTLC." Column chromatography was performed on silica gel, Wakogel C-200 and Merck Kieselgel 60 (230—400 mesh) for "Flash Chromatography." In general, organic solvents were purified and dried by the appropriate procedure, and evaporation and concentration were carried out under reduced pressure below 30 °C, unless otherwise noted.

(2*S*,4*R*)-5,5-Bis(ethylthio)-1,2,4-pentanetriol (12). To an ice-cooled solution of **11**[6] (8.05 g, 46.2 mmol) in ethanethiol (240 ml) was added boron trifluoride etherate (2.40 ml) and the mixture was stirred at room temperature for 2 h. The reaction mixture was neutralized (pH=7) with triethylamine and evaporated. The residue was chromatographed on silica gel (220 g) with 10:1 chloroform–methanol to afford **12** (10.5 g, 95%): colorless syrup, R_f=0.41 (10:1 chloroform–methanol); $[\alpha]_D^{35}$ +61.5° (*c* 1.05); IR ($CHCl_3$) 3440 cm^{-1}; ^{1}H NMR (90 MHz) δ=1.27 (6H, t, 2×MeCH$_2$S, *J*=7.0 Hz), 1.50—2.10 (2H, m, 2×H-3), 2.70 (4H, q, 2×MeCH$_2$S), and 3.40—4.10 (8H, m, 3×OH, 2×H-1, H-2, H-4, H-5).

Found: C, 45.04; H, 8.14%. Calcd for $C_9H_{20}O_3S_2$: C, 44.97; H, 8.39%.

(2*S*,4*R*)-1-*O*-(*t*-Butyldiphenylsilyl-5,5-bis(ethylthio)-1,2,4-pentanetriol (13). To an ice-cooled solution of **12** (2.02 g, 8.4 mmol) in DMF (20.2 ml) was added dropwise imidazole (744 mg, 10.9 mmol) and *t*-butyldiphenylsilyl chloride (2.62 ml, 10.8 mmol), and the mixture was stirred at 25 °C for 0.5 h. The reaction mixture was then poured into cold water (40 ml) and extracted with chloroform (3×40 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated to a syrup which was chromatographed on silica gel (200 g) with 7:1 benzene–ethyl acetate to give a pure sample of **13** (3.69 g, 92%): coloreless syrup; R_f=0.60 (3:1 toluene–ethyl acetate); $[\alpha]_D^{25}$ +14.6° (*c* 1.64); IR($CHCl_3$) 3480, 1110 cm^{-1}; ^{1}H NMR (90 MHz) δ=1.13 (9H, s, *t*-Bu), 1.27 (6H, t, 2×MeCH$_2$S, *J*=7.0 Hz), 1.41—2.00 (2H, m, 2×H-3), 2.70 (4H, dd, 2×MeCH$_2$S), 2.85—3.20 (2H, brs, 2×OH), 3.63 (2H, d, 2×H-1, *J*=6.6 Hz), 3.76—4.13 (3H, m, H-2, H-4, H-5), and 7.20—7.81 (10H, m, 2×Ph).

Found: C, 62.80; H, 7.89%. Calcd for $C_{25}H_{38}O_3S_2Si$: C, 62.72; H, 8.00%.

(2*S*,4*R*)-1-*O*-(*t*-Butyldiphenylsilyl)-5,5-bis(ethylthio)-2,4-*O*-isopropylidene-1,2,4-pentanetriol (14). To an ice-cooled solution of **13** (11.9 g, 37.4 mmol) and 2,2-dimethoxypropane (9.2 ml, 74.8 mmol) in dry acetone (360 ml) was added 1.0% H_2SO_4 in acetone (1.8 ml). After being stirred at room temperature for 20 min, the mixture was neutralized with $NaHCO_3$ (pH=7) under ice cooling, and evaporated. The residue was partitioned between ethyl acetate and water. The organic layer was separated, and washed with water and saturated aqueous NaCl, dried, and evaporated to afford an essentially pure sample of **14** (19.4 g, 100%) as a pale yellow syrup. An analytical sample was obtained after silica gel column chromatography with 10:1 hexane–ethyl acetate: R_f=0.80 (3:1 hexane–ethyl acetate); $[\alpha]_D^{32}$ −14.2° (*c* 1.00); IR ($CHCl_3$) 1110 cm^{-1}; ^{1}H NMR (90 MHz) δ=1.08 (9H, s, *t*-Bu), 1.28 (6H, t, 2×MeCH$_2$S, *J*=7.5 Hz), 1.40 (6H, s, CMe$_2$), 1.58—1.88 (2H, m, 2×H-3), 2.73 (4H, q, 2×SCH$_2$), 3.42—4.25 (5H, m, 2×H-1, H-2, H-4, H-5), and 7.21—7.90 (10H, m, 2×Ph).

(2*R*,4*S*)-6-*O*-(*t*-Butyldiphenylsilyl)-2,4-*O*-isopropylidene-2,4,5-trihydroxypentanal (15). A mixture of the aforesaid sample of **14** (19.1 g, ca. 36.8 mmol), aqueous 80% acetone, $HgCl_2$ (43.0 g, 162 mmol), and HgO(red)(35.1 g, 162 mmol) was stirred vigorously at room temperature for 20 min. The resulting mixture was filtered through a Celite and the filter cake was washed with acetone. The combined filtrate and washings were concentrated to remove acetone. The aqueous residue was extracted with chloroform (3×40 ml) and extracts were washed with aqueous 10% KI (2×30 ml) and saturated aqueous NaCl, dried, and evaporated. The residue was chromatographed on silica gel (760 g) with 3:1 hexane–ethyl acetate to afford **15** (14.3 g, 94% from **13**): colorless syrup, R_f=0.34 (3:1 hexane–ethyl acetate); $[\alpha]_D^{26}$ +16.6° (*c* 1.06); IR($CHCl_3$) 1735, 1110 cm^{-1}; ^{1}H NMR (90 MHz) δ=1.10 (9H, s, *t*-Bu), 1.45 (6H, s, CMe$_2$), 1.66—2.00 (2H, m, 2×H-3), 3.43—4.57 (4H, m, H-2, H-4, 2×H-5), 7.10—7.91 (10H, m, 2×Ph), and 9.63 (1H, d-like, CHO).

(2*S*,4*R*)-1-*O*-(*t*-Butyldiphenylsilyl)-2,4-*O*-isopropylidene-5-hexene-1,2,4-triol (16). A 4 M solution of methylsulfinylmethanide anion in DMSO (5.0 ml, 20 mmol) prepared from sodium hydride and DMSO was added dropwise to a stirred suspension of methyltriphenylphosphonium bromide (7.1 g, 19.9 mmol) in dry ether (82 ml) under argon at 25 °C. The mixture was stirred at 25 °C for 25 min, and to the resulting yellow suspension of ylide, a solution of **15** (2.05 g, 4.97 mmol) in dry ether (41 ml) was added dropwise over a 5-min period. After being stirred at 25 °C for 20 min, the reaction mixture was poured into an ice–water (100 ml) and the mixture was extracted with ether(3×50 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated. The residue was chromatographed on silica gel (100 g) with 15:1 hexane–ethyl acetate to afford **16** (1.84 g, 90%): colorless syrup, R_f=0.79 (4:1 hexane–ethyl acetate); IR($CHCl_3$) 1105 cm^{-1}; $[\alpha]_D^{25}$ +2.0°, $[\alpha]_{365}^{25}$ +10.0° (*c* 1.00); ^{1}H NMR (90 MHz) δ=1.04 (9H, s, *t*-Bu), 1.38 (6H, s, CMe$_2$), 1.50—1.90 (2H, m, H-3), 3.33—3.65 (2H, m, 2×H-1), 3.80—4.15 (1H, m, H-2), 4.20—4.50 (1H, m, H-4), 5.07 (1H, ddd, H-6*Z*, J_{gem}=$J_{6Z,4}$=ca. 1.2, $J_{6Z,5}$=9.3 Hz), 5.21 (1H, ddd, H-6*E*, $J_{6E,4}$=ca. 1.2, $J_{6E,5}$=15.9 Hz), 5.82 (1H, ddd, H-5, $J_{5,4}$=5.7 Hz), and 7.0—7.9 (10H, m, 2×Ph).

Found: C, 73.16; H, 8.25%. Calcd for $C_{25}H_{34}O_3Si$; C, 73.13; H, 8.35%.

(2*S*,4*R*)-1-Iodo-2,4-*O*-isopropylidene-5-hexene-2,4-diol (18). To a solution of **16** (10.9 g, 26.5 mmol) in THF (100 ml) was added dropwise a 1M solution of TBAF in THF (53 ml). After being stirred at 24 °C for 15 min, the mixture was poured into cold water (150 ml) and extracted with ethyl acetate (3×150 ml). The combined extracts were washed with saturated aqueous NaCl, dried, and evaporated to afford a syrup which was chromatographed on silica gel (230 g) with 1:1 hexane–ethyl acetate to give **17** (4.54 g, 99%) as a colorless syrup. A mixture of the alcohol **17** (4.33 g, 25.1 mmol), triphenylphosphine (13.2 g, 50.3 mmol), imidazole (3.46 g, 50.3 mmol), iodine (9.6 g, 37.7 mmol), and benzene (65 ml) was stirred at 60 °C for 45 min. The resulting mixture was then cooled to 0 °C and aqueous $Na_2S_2O_3$ and $NaHCO_3$ were added in sequence. After

vigorous stirring at 0 °C for 10 min, the reaction mixture was extracted with ethyl acetate (3×50 ml) and the extracts were washed with saturated aqueous NaCl, dried, and evaporated. The residue was chromatographed on silica gel (350 g) with 12:1 hexane–ether to give **18** (5.93 g, 84%) and a mixture of **18** and triphenylphosphine (2.3 g) which was separated by chromatography to afford an additional sample of **18** (0.28 g, 4%). The total yield of **18** was 6.21 g (88%): colorless syrup, R_f=0.84 (3:1 hexane–ethyl acetate); $[\alpha]_D^{33}$ +19.4° (*c* 1.04); ^{1}H NMR (90 MHz) δ=1.25 (1H, ddd, H-3, $J_{3,2}=J_{3,4}$=10.5, J_{gem}=12.0 Hz), 1.47 (6H, s, CMe_2), 1.90 (1H, ddd, H-3, $J_{3,2}=J_{3,4}$=3.3 Hz), 3.07—3.30 (2H, m, 2×H-1), 3.83—4.13 (1H, m, H-2), 4.27—4.57 (1H, m, H-4), 5.07 (1H, ddd, H-6Z, $J_{gem}=J_{6Z,4}$=ca. 1.5, $J_{6Z,5}$=9.3 Hz), 5.20 (1H, ddd, H-6E, $J_{6E,4}$=ca. 1.5, $J_{6E,5}$=15.9 Hz), and 5.86 (1H, ddd, H-5, $J_{5,4}$=5.7 Hz)

Found: C, 38.32; H, 5.24%. Calcd for $C_9H_{15}O_2I$: C, 38.32; H, 5.36%.

[[(4*S*,6*R*)-2,2-Dimethyl-6-vinyl-1,3-dioxan-4-yl]methyl]triphenylphosphonium Iodide (8). A mixture of **18** (5.57 g, 19.7 mmol), triphenylphosphine (13.0 g, 49.3 mmol), and benzene (30 ml) was stirred at 80 °C for 5 d. The resulting insoluble matter was collected by filtration and washed with hexane (100 ml) and benzene (200 ml), then dried over NaOH pellets under reduced pressure for 10 h to afford **8** (9.5 g, 88%) as a white powder. An analytical sample was obtained by column chromatography with 10:1 chloroform–methanol: mp 194—196 °C; R_f=0.52 (10:1 chloroform–methanol); $[\alpha]_D^{33}$ +32.0° (*c* 1.02); IR (KBr) 1435, 1108 cm^{-1}; ^{1}H NMR (90 MHz) δ=0.83, 1.13 (each 3H, each s, CMe_2), 1.21—2.10 (4H, m, 2×H-5, CH_2P), 3.50—4.00 (1H, m, H-4), 4.07—4.53 (1H, m, H-6), 5.08 (1H, ddd, CH=C$\underline{H}_2$ (*Z*), $J_{gem}=J_{Z,6}$=ca. 1.2, J_Z=10.2 Hz), 5.24 (1H, ddd, CH=C$\underline{H}_2$ (*E*), $J_{E,6}$=ca. 1.2, J_E=15.6 Hz), 5.79 (1H, ddd, C$\underline{H}$=CH_2, *J*=6.0 Hz), and 7.46—8.07 (15H, m, 3×Ph).

Found: C, 59.88; H, 5.63%. Calcd for $C_{27}H_{30}O_2PI$: C, 59.57; H, 5.55%.

5-*O*-Benzyl-3-deoxy-1,2-*O*-isopropylidene-α-D-*glycero*-D-*glycero*-pentofuranose (19). To a solution of **11**[6] (5.0 g, 28.7 mmol) in DMF (50 ml) was added 55% NaH (2.5 g, 57.4 mmol) at 0 °C. The mixture was stirred at 25 °C for 0.5 h, and benzyl bromide (5.12 ml, 43.0 mmol) was added dropwise at 0 °C. After being stirred at 25 °C for 0.5 h, the reaction mixture was poured into cold water (300 ml) which was extracted with ethyl acetate (3×150 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated. The residue was chromatographed on silica gel (400 g) with 4:1 hexane–ethyl acetate to afford **19** (7.42 g, 97%): pale yellow syrup, R_f=4:1 (hexane–ethyl acetate); $[\alpha]_D^{28}$ −15° (*c* 1.00); ^{1}H NMR (90 MHz) δ=1.31, 1.50 (each 3H, each s, CMe_2), 1.70—2.25 (2H, m, 2×H-3), 3.50—3.80 (2H, m, 2×H-5), 4.20—4.55 (1H, m, H-4), 4.60 (2H, s, C$\underline{H}_2$Ph), 4.71 (1H, dd, H-2, $J_{2,1}=J_{2,3}$=4.0 Hz), 5.82 (1H, d, H-1), and 7.33 (5H, s, Ph).

5-*O*-Benzyl-3-deoxy-D-*glycero*-D-*glycero*-pentofuranose (20). To an ice-cooled solution of **19** (7.39 g, 28.0 mmol) in dioxane (74 ml) was added dropwise 3.2M aqueous HCl (74 ml) over a 15-min period. After being stirred at 25 °C for 1.25 h, the reaction mixture was neutralized (pH=7) with solid $NaHCO_3$ (3.0 g). The insoluble matter was filtered and washed with dioxane. The combined filtrate and washings were evaporated. The residue was taken up in dioxane and the resulting precipitates were filtered and washed with dioxane (5×8 ml). The filtrate and washings were evaporated, and the residue was chromatographed on silica gel (63 g) with 1:4 toluene–ethyl acetate to give a pure sample of **20** (5.78 g, 92%): colorless syrup, R_f=0.21 (1:1 toluene–ethyl acetate); $[\alpha]_D^{26}$ −14° (*c* 1.03, EtOH after 2d); ^{1}H NMR (90 MHz, after addition of D_2O) δ=1.70—2.20 (2H, m, 2×H-3), 3.30—3.75 (2H, m, 2×H-5), 4.10—4.30 (1H, m, H-4), 4.30—4.70 (1H, m, H-2), 4.58 (2H, s, C$\underline{H}_2$Ph), 5.22 (ca. 0.6H, s, β-H-1), 5.32 (ca. 0.4H, α-H-1, *J*=4.0 Hz), and 7.34 (5H, s, Ph).

Found: C, 63.98; H, 7.21%. Calcd for $C_{12}H_{16}O_4$: C, 64.27; H, 7.19%.

(2*S*,4*R*,5*R*)-1-*O*-Benzyl-6-heptene-1,2,4,5-tetrol (21) and Its (5*S*)-Epimer (21′). To a solution of vinylmagnesium bromide in THF which was prepared from vinyl bromide (18.2 ml, 258 mmol) and magnesium (6.27 g, 258 mmol) in THF (125 ml), was added dropwise a solution of **20** (5.78 g, 25.8 mmol) in THF (52 ml) over a 7-min period. After being stirred at 25 °C for 3.5 h, the reaction was quenched by addition of $Na_2SO_4\cdot 10H_2O$ (solid), and the resulting mixture was filtered through a Celite. The filter cake was washed with acetone (5×50 ml) and the combined filtrate and washings were evaporated. The residue was charged together with silica gel (15 g) on a column of silica gel (325 g) by using 15:1 chloroform–methanol and then eluted with the same solvent system to afford a mixture of **21** and its epimer **21′** (6.19 g, 95%): colorless syrup, R_f=0.36 (1:4 toluene–ethyl acetate); ^{1}H NMR (90 MHz) δ=1.50—1.80 (2H, m, 2×H-3), 3.17 (3H, s, 3×OH), 3.30—3.55 (2H, m, 2×H-1), 3.60—4.25 (3H, m, H-2, 4, 5), 4.55 (2H, s, C$\underline{H}_2$Ph), 5.10—5.45 (2H, m, 2×H-7), 5.65—6.10 (1H, m, H-6), and 7.33 (5H, s, Ph).

Found: C, 66.59; H, 8.06%. Calcd for $C_{14}H_{20}O_4$: C, 66.65; H, 7.99%.

(2*S*,4*R*,5*R*)-1-*O*-Benzyl-4,5-*O*-isopropylidene-6-heptene-1,2,4,5-tetrol (22) and Its (5S)-Epimer (22′). A mixture of **21** (1.57 g, 6.24 mmol), acetone (78.7 ml), and iodine (475 mg, 1.87 mmol) was stirred at 25 °C for 2 h. To the reaction mixture was added saturated aqueous $Na_2S_2O_3$ (30 ml), and the mixture was extracted with chloroform (3×100 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated. The residue (2.18 g) was flushchromatographed on silica gel (270 g) with 7:1 chloroform–ethyl acetate to afford a pure sample of **22** (622 mg), a mixture of **22** and **22′** (799 mg), and a mixture of **22**, **22′**, and two epimeric 2,4-acetonides (288 mg). The fraction containing **22** and **22′** (799 mg) was again flushchromatographed on silica gel (80 g) with 4:1 hexane–ethyl acetate to give a pure sample of **22** (363 mg) and a mixture of **22** and **22′** (435 mg). A total yield of **22** amounted to 985 mg (54%). **22**: colorless syrup, R_f=0.59 (6:1 chloroform–ethyl acetate, HPTLC); $[\alpha]_D^{27}$ −5.13°, $[\alpha]_{365}^{27}$ −27.4° (*c* 1.44); ^{1}H NMR (90 MHz) δ=1.35 (6H, s, CMe_2), 1.78 (2H, dd, 2×H-3, $J_{3,2}=J_{3,4}$=4.5 Hz), 2.77 (1H, br-s, OH), 3.45 (2H, d, H-1, $J_{1,2}$=5.4 Hz), 3.66—4.27 (3H, m, H-2, 4, 5), 4.56 (2H, s, C$\underline{H}_2$Ph), 5.23 (1H, ddd-like, H-7Z, J_{gem}=2.4, $J_{7Z,5}$<1.0, $J_{7Z,6}$=10.0 Hz), 5.37 (1H, ddd-like, H-7E, $J_{7E,5}$<1.0, $J_{7E,6}$=15.6 Hz), 5.82 (1H, ddd, H-6, $J_{6,5}$=6.9 Hz), and 7.35 (5H, s, Ph).

Found: C, 70.10; H, 8.22%. Calcd for $C_{17}H_{24}O_4$: C, 69.84; H, 8.27%.

A pure sample of **22′** was obtained by flashchromatog-

raphy of a sample of ca. 1:1 mixture of **22** and **22′** in other experiment. **22′**: colorless syrup, R_f=0.48 (6:1 chloroform–ethyl acetate, HPTLC); $[\alpha]_D^{24}$ +4.0°, $[\alpha]_{365}^{24}$ +14.4° (*c* 0.96); ^{1}H NMR (90 MHz) δ=1.38, 1.51 (each 3H, each s, CMe_2), 1.65 (2H, dd, 2×H-3, *J*=6.0, 6.0 Hz), 3.03 (1H, br-s, OH), 3.46 (2H, d, 2×H-1, *J*=5.4 Hz), 3.80—4.20 (1H, m, H-2), 4.20—4.70 (2H, m, H-4, 5), 4.59 (2H, s, $C\underline{H}_2Ph$), 5.26 (1H, ddd-like H-7Z, J_{gem}=2.1, $J_{7Z,5}$<1.0, $J_{7Z,6}$=9.6 Hz), 5.31 (1H, ddd-like, H-7*E*, $J_{7E,5}$<1.0, $J_{7E,6}$=18.0 Hz), 5.82 (1H, ddd, H-6, $J_{6,5}$=8.1 Hz), and 7.38 (5H, s, Ph).

(2*S*,3*R*,5*S*)-6-*O*-Benzyl-2,3-*O*-isopropylidene-5-*O*-[(2-methoxyethoxy)methyl]-2,3,5,6-tetrahydroxyhexanal (9). To a stirred solution of **23** (477 mg, 1.25 mmol) in 75% aqueous dioxane (19.1 ml) was added OsO_4. (15.9 mg, 0.063 mmol) at 23 °C. After 15 min to this mixture was added sodium periodate (powder, 802 mg, 3.75 mmol). After being stirred at 23 °C for 2.5 h, the mixture was filtered through a Celite and the filter cake was washed with dioxane. The filtrate and washings were concentrated and diluted with chloroform (20 ml). The mixture was washed with saturated aqueous $Na_2S_2O_3$ and NaCl, dried, and evaporated. The residue was chromatographed on silica gel (24 g) with 6:1 chloroform–acetone to afford **9** (439 mg, 91.5%): colorless syrup, R_f=0.41 (6:1 chloroform–acetone), $[\alpha]_D^{27}$ −3.3°, $[\alpha]_{365}^{27}$ −26.9° (*c* 1.04); IR($CHCl_3$) 1730 cm^{-1}; ^{1}H NMR (90 MHz) δ=1.34, 1.77 (each 3H, each s, CMe_2), 1.98 (2H, dd, 2×H-4, *J*=6.0, 6.0 Hz), 3.34 (3H, s, OMe), 3.34—3.83 (6H, m, $-OCH_2CH_2O-$, 2×H-6), 3.83-4.30 (3H, m, H-2, 3, 5), 4.52 (2H, s, CH_2Ph), 4.77 (2H, s, $-OCH_2O-$), 7.30 (5H, s, Ph), and 9.72 (ca. 0.6H, CHO, *J*=1.8 Hz); ^{13}C NMR (22.50 MHz) δ=25.99, 26.99 (each q, $C\underline{M}e_2$), 35.44 (t, C-4), 58.74 (q, OMe), 66.97, 71.57, 73.12, 73.44 (each t, $\underline{C}H_2Ph$, $-OCH_2O-$, $-OCH_2CH_2O-$), 71.82, 73.63 (each d, C-3, 5), 84.77 (dd, C-2), 94.82 (t, C-6), 110.77 (s, $\underline{C}Me_2$), 127.48, 127.54, 128.19 (each d, Ph), 138.05 (s, Ph), and 200.35 (d, CHO).

(2*R*)-Epimer 9′ of 9. By the method described in the preparation of **23**, the aforesaid mixture of **22** and **22′** (416 mg) was methoxyethoxymethylated to afford a mixture of **23** and **23′** (508 mg, 94%). This mixture was oxidized with OsO_4–$NaIO_4$ by the same procedure as described in the preparation of **9** to give a crude mixture of **9** and **9′** which was flashchromatographed on silica gel (51 g) with 7:1 chloroform–ethyl acetate to afford **9** (193 mg, 38%) and **9′** (182 mg, 36%). **9′**: colorless syrup, R_f=0.66 (6:1 chloroform–acetone); $[\alpha]_D^{24}$ −7.6°, $[\alpha]_{365}^{24}$ −47.2° (*c* 1.02); IR($CHCl_3$) 1730 cm^{-1}; ^{1}H NMR (90 MHz) δ=1.37, 1.57 (each 3H, each s, CMe_2), 1.73—2.10 (2H, m, 2×H-4), 3.36 (3H, s, OMe), 3.40—3.80 (6H, m , $-OCH_2CH_2O-$, 2×H-6), 3.80—4.20 (1H, m, H-5), 4.20—4.80 (2H, m, H-2, 3), 4.54 (2H, s, CH_2Ph), 4.79 (2H, s, $-OCH_2O-$), 7.30 (5H, s, Ph), and 9.63 (1H, d, CHO, *J*=3.0 Hz); ^{13}C NMR (22.50 MHz) δ=25.13, 27.48 (each q, $C\underline{M}e_2$), 31.57 (t, C-4), 58.74 (q, OMe), 67.01, 71.53, 73.05, 73.56 (each t, $\underline{C}H_2Ph$, $-OCH_2O-$, $-OCH_2CH_2O-$), 71.53, 75.05 (each d, C-3, 5), 81.69 (dd, C-2), 94.80 (t, C-6), 110.26 (s, $\underline{C}Me_2$), 127.49, 128.27 (each d, Ph), 138.00 (s, Ph), and 201.87 (d, CHO).

Epimerization of 9′ to 9. To a sample of **9′** (182 mg, 0.475 mmol) was added a solution of K_2CO_3 (20 mg, 0.143 mmol) in methanol (3.63 ml). After being stirred at 23 °C for 4.5 h, the reaction mixture was evaporated. The residue was partitioned between chloroform (10 ml) and water. The chloroform layer was separated and washed with saturated aqueous NaCl, dried, and evaporated. The residue was flushchromatographed on silica gel (18.2 g) with 7:1 chloroform–ethyl acetate to afford **9** (123 mg, 68%) whose TLC, ^{1}H and ^{13}C NMR spectra were identical with those of the aforesaid sample of **9** derived from **23**.

Methyl (2*S*,3*R*,5*R*)-6-*O*-Benzyl-2,3-*O*-isopropylidene-2,3,5-trihydroxyhexanoate (26). By the procedure described in the preparation of **9**, **22** (197 mg, 0.673 mmol) was oxidized with OsO_4–$NaIO_4$ to afford crude aldehyde **24** (192 mg, 97%). To a solution of this aldehyde in 70% aqueous dioxane (6.70 ml) was added a solution of K_2CO_3 (568 mg, 4.11 mmol) and $KHCO_3$ (411 mg, 4.11 mmol) in water (7.70 ml) and then added a solution of KI (649 mg, 3.91 mmol) and I_2 (248 mg, 0.978 mmol) in water (0.96 ml) dropwise under stirring. The mixture was stirred at 23 °C for 1.75 h, after which period $Na_2S_2O_3$ (960 mg) was added to the reaction mixture at 0 °C. This mixture was washed with ether (10 ml) and the aqueous layer was acidified (pH =2—3) with 10% aqueous H_2SO_4 at 0 °C. The mixture was immediately extracted with chloroform (3×10 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated to give the crude acid **25** (161 mg, 77% from **22**) as white crystals. The crystalline **25** was dissolved in a solution of diazomethane in ether and then evaporated to afford a syrup which was flushchromatographed on silica gel (5.1 g) with 3:1 chloroform–ethyl acetate to give **26** (163 mg, 74% from **22**): colorless syrup, R_f=0.49 (1:1 toluene–ethyl acetate); IR ($CHCl_3$) 1750 cm^{-1}; $[\alpha]_D^{26}$ +9.3°, $[\alpha]_{365}^{26}$ +21.8° (*c* 1.23); ^{1}H NMR (90 MHz) δ=1.44 (6H, s, CMe_2), 1.70—2.15 (2H, m, 2×H-4), 2.3—2.90 (1H, br-s, OH), 3.47 (2H, d, 2×H-6, *J*=3.0 Hz), 3.78 (3H, s, COOMe), 3.90—4.40 (3H, m. H-2, 3, 5), 4.58 (2H, s, CH_2Ph), and 7.35 (5H, s, Ph).

Methyl (2*S*,3*R*)-2,3,5-Trihydroxypentanoate (30). A mixture of **26** (289 mg, 0.89 mmol), Pd-black, and methanol (5.8 ml) was vigorously stirred at room temperature for 10 min under bubbling with H_2 gas, and then filtered. The filtrate was evaporated to a colorless syrup of **27** (209 mg,

100%). To a solution of this syrup in acetone (2.10 ml) was added a solution of $NaIO_4$ (381 mg, 1.78 mmol) in water (3.8 ml) under ice-cooling. After being stirred for 15 min, the precipitate was filtered and washed with acetone. The combined filtrate and washings were concentrated. The aqueous residue was extracted with dichloromethane 6 times. The extracts were dried and evaporated to afford a syrup of **28** (180 mg). To an ice-cold solution of this syrup (33 mg, 0.163 mmol) in methanol (0.33 ml) was added $NaBH_4$ (31 mg, 0.082 mmol). After being stirred at 0 °C for 10 min, the mixture was neutralized with CO_2 and then evaporated. The residue was pertitioned between ethyl acetate and saturated aqueous NaCl, and the aqueous layer was extracted with ethyl acetate three times. The organic layers were dried and evaporated to give a syrup which was chromatographed on silica gel (2.3 g) with 1:1 hexane–ethyl acetate to afford **29** (23.5 mg, 70% yield from **26**) as a syrup. A solution of **29** (23.5 mg) and *p*-toluenesulfonic acid (2.2 mg, 0.015 mmol) in methanol (0.23 ml) was stirred at 33 °C for 19 h. The reaction mixture was neutralized with Amberlite IR-45 (OH type) at 0 °C, and then filtered. The resin was washed with methanol, and the combined filtrate and washings were evaporated to afford a syrup (21 mg). This syrup was chromatographed on silica gel (1.0 g) with 5:1 chloroform–methanol to give **30** (16 mg, 84% yield from **29**): colorless syrup, R_f=0.42 (5:1 chloroform–methanol); IR ($CHCl_3$) 3370, 1735 cm^{-1}; $[\alpha]_D^{30}$ +17.9° (*c* 0.47); CD $[\theta]_{210}$ +4105 (*c* 0.10, H_2O); ^1H NMR (90 MHz) δ=1.77—2.17 (2H, m, 2×H-4), 2.57—2.93 (1H, br-s, OH), 3.17—4.47 (6H, m, 2×OH, H-2, 3, 2×H-5), and 3.87 (3H, s, COOMe).

(2*S*,3*R*,5*S*)-5,6-Di-*O*-benzyl-2,3-*O*-isopropylidene-2,3,5,6-tetrahydroxyhexanal (10). To an ice-cold solution of **22** (570 mg, 1.95 mmol) in DMF (3.3 ml) was added 55% NaH (255 mg, 5.85 mmol), and the mixture was stirred at 24 °C for 0.5 h, after which period TBAF (72 mg, 0.195 mmol) was added, and after 5 min, to the stirred mixture was added benzyl bromide (464 µl, 3.90 mmol) dropwise under ice-cooling. After being stirred at 24 °C for 3 h, the reaction mixture was poured into cold water (8.0 ml) and the mixture was extracted with ethyl acetate (3×8.0 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated. The residue (1.12 g) was chromatographed on silica gel (75 g) with 8:1 hexane–acetone to afford a colorless syrup of the 2-*O*-benzyl derivative of **22** (710 mg, 95%). A sample (1.59 g, 4.17 mmol) of this benzyl derivative was oxidized with OsO_4–$NaIO_4$ by the procedure described in the preparation of **9**. The crude product was chromatographed on silica gel (80 g) with 2:1 hexane–ethyl acetate to give **10** (1.38 g, 86%): colorless syrup, R_f=0.21 (2:1 hexane–ethyl acetate); IR($CHCl_3$) 1730 cm^{-1}; $[\alpha]_D^{27}$ −3.6°, $[\alpha]_{365}^{27}$ −29.7° (*c* 0.99); ^1H NMR (90 MHz) δ=1.41, 1.45 (each 3H, each s, CMe_2), 2.00 (2H, dd, 2×H-4, $J_{4,3}$=$J_{4,5}$=5.4 Hz), 3.40—4.40 (ca. 5.5H, m, H-2, 3, 5, 2×H-6, H-1), 4.55 (2H, s, CH_2Ph), 4.52, 4.66 (2H, ABq, CH_2Ph, *J*=9.6 Hz), 7.37 (10H, s, 2×Ph), and 9.66 (ca. 0.5H, CHO, *J*=ca. 1.5 Hz).

(2*S*,4*R*,5*R*,8*S*,10*R*)-(6*Z*)-1-*O*-Benzyl-4,5:8,10-di-*O*-isopropylidene-2-*O*-[(2-methoxyethoxy)methyl]-6,11-dodecadiene-1,2,4,5,8,10-hexol (31). To a suspension of **8** (77.8 mg, 0.143 mmol) in 2:1 THF–HMPA (477 µl) was added a 1.56M butyllithium in hexane (92 µl, 0.143 mmol) at −70 °C under Ar, and the mixture was stirred at −70 °C for 22 min. To the yellow colored mixture was added a solution of **9** (48.4 mg, 0.127 mmol) in THF (149 µl), and the mixture was stirred at −70 °C for 0.5 h. The reaction mixture was allowed to warm to −50 °C and diluted with THF (1.2 ml). The reaction was quenched by addition of aqueous NH_4Cl at room temperature. This mixture was extracted with ethyl acetate (3×1.0 ml), and the extracts were washed with saturated aqueous NaCl, dried, and evaporated. The residue was chromatographed on silica gel (3.5 g) with 3:1 hexane–ethyl acetate to afford a pure sample of **31** (46.0 mg, 70%): colorless syrup, R_f=0.45 (3:1 hexane–ethyl acetate); $[\alpha]_D^{32}$ −8.5°, $[\alpha]_{365}^{32}$ −38.5° (*c* 1.20); ^1H NMR (250 MHz) δ=1.34, 1.40, 1.49, 1.53 (12H, each s, 2×CMe_2), 1.70—1.86, 1.92—2.05 (4H, each m, 2×H-3, 2×H-9), 3.36 (3H, s, OMe), 3.46—4.04 (8H, m, 2×H-1, H-2, 4, -OCH_2CH_2O-), 4.33—4.43 (1H, m, H-10), 4.38 (1H, dd, H-5, $J_{5,4}$=$J_{5,6}$=8.8 Hz), 4.47 and 4.59 (2H, ABq, CH_2Ph, *J*=11.25 Hz), 4.69—4.85 (1H, m, H-8), 4.80 (2H, s, -OCH_2O-), 5.13 (1H, ddd, H-12*Z*, J_{gem}=$J_{12Z,10}$=ca. 1.2, $J_{12Z,11}$=10.5 Hz), 5.25 (1H, ddd, H-12*E*, $J_{12E,10}$=ca. 1.2, $J_{12E,11}$=17.8 Hz), 5.45 (1H, dd, H-6, $J_{6,7}$=11.2 Hz), 5.62 (1H, dd, H-7, $J_{7,8}$=7.5 Hz), and 5.81 (1H, ddd, H-11, $J_{11,10}$=4.8 Hz).

Found: C, 66.95; H, 8.29%. Calcd for $C_{29}H_{44}O_8$: C, 66.90; H, 8.52%.

(2*S*,4*R*,5*R*,8*S*,10*R*)-(6*Z*)-1,2-Di-*O*-benzyl-4,5:8,10-di-*O*-isopropylidene-6,11-dodecadiene-1,2,4,5,8,10-hexol (32). By the procedure described in the preparation of **31**, the ylide generated from **8** (66.0 mg, 0.121 mmol) was allowed to react with **10** (42.4 mg, 0.110 mmol) to afford, after silica gel chromatography with 4:1 hexane–ethyl acetate, the coupling product **32** (30.1 mg, 52%): colorless syrup; R_f=0.75 (2:1 hexane–ethyl acetate $[\alpha]_D^{30}$ −19.4° (*c* 1.80), ^1H NMR (250 MHz) δ=1.37, 1.39, 1.44, 1.45 (each 3H, each s, 2×CMe_2), 1.50—1.60, 1.79—2.04 (each 2H, each m, 2×H-3, 2×H-9), 3.50—3.62 (2H, m, 2×H-1), 3.75—3.92 (2H, m, H-2, 4), 4.19—4.32 (1H, m, H-10), 4.53 (2H, s, CH_2Ph), 4.52 and 4.70 (2H, ABq, CH_2Ph, *J*=11.3 Hz), 4.42—4.79 (2H, m, H-5, 8), 5.12 (1H, ddd, H-12Z, J_{gem}=$J_{12Z,10}$=ca. 1.2, $J_{12Z,11}$=11.2 Hz), 5.23 (1H, ddd, H-12E, $J_{12E,11}$=17.5, $J_{12E,10}$=ca. 1.2 Hz), 5.41 (1H, dd, H-6, $J_{6,5}$=9.5, $J_{6,7}$=10.5 Hz), 5.58 (1H, dd, H-7, $J_{7,8}$=7.5 Hz), 5.78 (1H, ddd, H-11, $J_{11,10}$=5.0 Hz), and 7.20—7.45 (10H, m, 2×Ph).

(2*S*,4*R*)-2,4-*O*-Isopropylidene-6,6-dimethoxy-1,2,4-hexanetriol (34). A 4M methylsulfinylmethanide anion in DMSO[8] (1.25 ml, 4.98 mmol) was added dropwise to a stirred suspension of (methoxymethyl)triphenylphosphonium chloride (1.71 g, 4.98 mmol) in ether under Ar at room temperature. The mixture was sirred for 20 min and then, to the resulting red suspension of the ylide, a solution of **15** (1.03 g, 2.49 mmol) in ether (20 ml) was added dropwise. After being stirred at room temperature for 10 min, the resulting suspension was poured into an ice–water, and the mixture was extracted with ethyl acetate (3×80 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated. The residue was chromatographed on silica gel (100 g) with 6:1 hexane–ethyl acetate to a syrup (1.10 g, 96.5%) of methyl enol ether of the homologus aldehyde of **15**. To an ice-cold solution of the methyl enol ether (0.91 g, 2.07 mmol) in methanol (9.0 ml) were added solid $NaHCO_3$ (0.21 g, 2.48 mmol) and NBS (0.44 g, 0.248 mmol) successively. After being stirred at 0 °C for 0.5 h, the mixture was evaporated and the residue was extracted with ethyl acetate (20 ml). The extract was washed with water and saturated

aqueous NaCl, dried, and evaporated to a syrup which was chromatographed on silica gel (80 g) with 6:1 hexane–ethyl acetate to afford a syrup (1.10 g, 96.5%) of the bromo dimethyl acetal. A solution of this bromo acetal (1.10 g), tributylstannane (0.8 ml) and AIBN (66 mg) in toluene (17 ml) was stirred at 60 °C for 2 h and then evaporated. The residue was chromatographed on Kieselgel (50 g) with 10:1 toluene–ethyl acetate to give a syrup of **33** (0.78 g, 83%). A mixture of **33** (228 mg), THF (2.3 ml), and 1M TBAF in THF (0.96 ml) was stirred at 0 °C for 1.5 h and then poured into cold water (10 ml). The mixture was extracted with ethyl acetate (3×15 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated. The residue was chromatographed on silica gel (4.5 g) with 1:2 hexane–ethyl acetate to afford **34** (88 mg, 78%): colorless syrup, R_f=0.52 (3:1 hexane–ethyl acetate); $[\alpha]_D^{26}$ −11°(*c* 0.97); ^{1}H NMR (90 MHz) δ=1.38, 1.45 (each 3H, each s, CMe_2), 1.03—1.60 (2H, m, 2×H-3), 1.73 (2H, dd-like 2×H-5, $J_{5,4}=J_{5,6}$=5.4 Hz), 1.96—2.26 (1H, br-s, OH), 3.36, 3.39 (each 3H, each s, 2×OMe), 3.41—3.66 (2H, m, 2×H-1), 3.76—4.22 (2H, m, H-2, 4), and 4.53 (1H, t, H-6).

[[(4*R*,6*R*)-2,2-Dimethyl-6-(2,2-dimethoxyethyl)-1,3-dioxan-4-yl]methyl]triphenylphosphonium Iodide (35). A solution of **34** (265 mg, 1.13 mmol), triphenylphosphine (889 mg, 3.39 mmol), and DEAD (0.53 ml, 3.39 mmol) in benzene (5.0 ml) was stirred at 0 °C and then methyl iodide (0.21 ml, 3.39 mmol) was added. The mixture was stirred at room temperature for 1 h and then evaporated. The residue was taken up in ethyl acetate (10 ml) which was washed successively with saturated aqueous $NaHCO_3$ (7.5 ml), $Na_2S_2O_3$ (7.5 ml), and NaCl, dried, and evaporated. The residue was chromatographed on silica gel (12 g) with 5:1 hexane–ethyl acetate to afford a syrup of iodide (276 mg, 71%). A solution of this syrup (235 mg) and triphenylphosphine (386 mg) in benzene (0.76 ml) was stirred at 84 °C for 5 d. The reaction mixture was evaporated and the residual solid was triturated with hexane (10×7.0 ml) to give the Wittig salt **35** (348 mg, 78%): colorless crystals, mp 200—201 °C (MeOH–ether); $[\alpha]_D^{15}$+14.6° (*c* 1.03); ^{1}H NMR (90 MHz) δ=0.77,1.09 (each 3H, each s, CMe_2), 3.28, 3.31 (each 3H, each s, 2×OMe), and 4.51 (1H, *t*, C<u>H</u>$(OMe)_2$, *J*=6.0 Hz).

Found: C, 57.08; H, 6.02; I, 20.62%. Calcd for $C_{29}H_{36}O_4PI$: C, 57.43; H, 5.98; I, 20.92%.

(3*R*,5*S*)-(6*Z*)-1,1-Dimethoxy-3,4-*O*-isopropylidene-5-tridecene-3,4-diol (36). By the procedure described in the preparation of **31**, the ylide generated from **35** (109 mg, 0.179 mmol) was condensed with heptanal (36.1 μl, 0.269 mmol) to afford, after silica-gel chromatography with 8:1 hexane–ethyl acetate and with 16:1 hexane–acetone, the condensation product **36** (18.2 mg, 32%): colorless syrup, R_f=0.35 (8:1 hexane–ethyl acetate); ^{1}H NMR (250 MHz) δ=0.89 (3H, t, 3×H-13, *J*=7.0 Hz), 1.20—1.85 (12H, m, 2×H-2, 2×H-4, -C<u>H</u>$_2$C<u>H</u>$_2$C<u>H</u>$_2$C<u>H</u>$_2$Me), 1.40, 1.50 (each 3H, each s, CMe_2), 2.0—2.2 (2H, m, 2×H-8), 3.34, 3.38 (each 3H, each s, 2×OMe), 4.0—4.1 (1H, m, H-3), 4.57 (1H, dd, H-1, $J_{1,2}$=4.5, 7.0 Hz), 4.69 (1H, ddd, H-5, $J_{5,4}$=2.8, 11.8 Hz, $J_{5,6}$=8.0 Hz), 5.35 (1H, approximately dd, dd after decoupled with 2×H-8 protons, H-6, $J_{6,7}$=11.8 Hz), and 5.4—5.6 (1H, m, d after decoupled with 2×H-8 protons, H-7).

Preparation of 34 from 36 via 37. By the procedure described in the preparation of **9**, a sample of **36** (103 mg) was oxidized with OsO_4–$NaIO_4$ to afford a crude syrup of the aldehyde **37** (30.4 mg, 40%): ^{1}H NMR (90 MHz) δ=1.45 (6H, s, CMe_2), 3.34, 3.35 (each 3H, each s, 2×OMe), and 9.61 (0.5H, s, CHO). To an ice-cold solution of the syrup (30 mg) in methanol (0.3 ml) was added $NaBH_4$ (10.0 mg). After being stirred at 0 °C for 2 h, the mixture was neutralized with CO_2 and treated successively with IR-45 and CG-50 resin. The resulting methanol solution was evaporated to a syrup which was purified by silica-gel chromatography with 1:1 hexane–ethyl acetate to afford **34** (19 mg) in 24% overall yield from **36**. This sample proved to be identical with the sample of **34** obtained from **15** by TLC, $[\alpha]_D$ and ^{1}H NMR.

(2*S*,4*R*,5*R*,8*S*,10*S*)-(6*Z*)-1-*O*-Benzyl-4,5:8,10-di-*O*-isopropylidene-2-*O*-[(2-methoxyethoxy)methyl]-6-dodecene-1,2,4,5,8,10,12-heptol (38). To a solution of dicyclohexylborane (0.854 mmol) in THF (0.48 ml) was added a solution of **31** (247 mg, 0.475 mmol) in THF (0.74 ml) at 0 °C under Ar, and the mixture was stirred at 25 °C for 25 min. The reaction was quenched by addition of water (1.22 ml). To this mixture was added 3M aqueous NaOH (0.284 ml) and 30% H_2O_2 (0.256 ml) at 0 °C. After being stirred at 5 °C for 1 h, the reaction mixture was extracted with chloroform (3×2.0 ml). The extracts were washed with saturated aqueous NaCl, dried, and evaporated. The residue was chromatographed on silica gel (13 g) with 1:3 hexane–ethyl acetate to afford a pure sample of **38** (229 mg, 90%): colorless syrup, R_f=0.48 (1:3 hexane–ethyl acetate); $[\alpha]_D^{30}$ −6.7°, $[\alpha]_{365}^{30}$−24.1° (*c* 1.77); ^{1}H NMR (250 MHz) δ=1.34, 1.37, 1.39, 1.48 (each 3H, each s, 2×CMe_2), 1.20—2.07 (7H, m, 2×H-3 2×H-9, 2×H-11, OH), 3.36 (3H, s, OMe), 3.43-3.63 (4H, m, -OCH_2CH_2O-), 3.63—4.21 (7H, m, 2×H-1, H-2, 4, 10, 2×H-12), 4.36 (1H, ddd-like, H-5, $J_{5,7}$<1.0, $J_{5,4}=J_{5,6}$=8.8 Hz), 4.46 and 4.61 (2H, ABq, CH_2Ph, *J*=12.5 Hz), 4.65-4.80 (1H, m, H-8), 4.80 (2H, s, -OCH_2O-), 5.45 (1H, dd, H-6, $J_{6,7}$=10.5 Hz), 5.62 (1H, dd, H-7, $J_{7,8}$=7.5 Hz), and 7.20—7.54 (5H, m, Ph).

By the procedure described in the preparation of **40**, a sample of **39** (76.0 mg) was silylated to afford, after silica-gel chromatography with 6:1 hexane–ethyl acetate, **41** (82.6 mg, 90%): colorless syrup R_f=0.47 (5:1 hexane–ethyl acetate); $[\alpha]_D^{31}$ −18.7° (*c* 1.43); ^{1}H NMR (90 MHz) δ=0.94 (9H, s, *t*-Bu), 1.40 and 1.46 (each 6H, each s, 2×CMe$_2$), 1.40—2.20 (6H, m, 2×H-3, 2×H-9, 2×H-11), 3.40-4.20 (7H, m, 2×H-1, H-2, 4, 10, 2×H-12), 4.30—4.90 (6H, m, H-5, 8, 2×CH$_2$Ph), 5.20—5.80 (2H, m, H-6, 7), and 7.37 (10H, s, 2×Ph).

Found: C, 69.35; H, 8.75%. Calcd for $C_{38}H_{58}O_7Si$: C, 69.69; H, 8.93%.

(2*S*,4*R*,5*R*,8*R*,10*S*)-12-*O*-*t*-Butyldimethylsilyl-4,5:8,10-di-*O*-isopropylidene-2-*O*-[(2-methoxyethoxy)methyl]-1,2,4,5,8,10,12-dodecaneheptol (42). A solution of **40** (28.1 mg) in ethanol (0.56 ml) was stirred with a catalytic amount of Raney Ni W-4 for 2 h under bubbling with H_2 gas. The reaction mixture was filtered through a sintered-glass funnel and the catalyst was washed with ethanol. The combined filtrate and washings were evaporated, and the residue was chromatographed on silica gel (1.0 g) with hexane–ethyl acetate to afford **42** (20.5 mg, 84%): colorless syrup, R_f=0.34 (1:1 hexane–ethyl acetate); $[\alpha]_D^{33}$ +35.7° (*c* 0.74); ^{1}H NMR (90 MHz) δ=0.90 (9H, s, *t*-Bu), 1.38, 1.42 (each 6H, each s, 2×CMe$_2$), 1.17—2.10 (10H, m, 2×H-3, 2×H-6, 2×H-7, 2×H-9, 2×H-11), 2.90 (1H, br-s, OH), 3.40 (3H, s, OMe), 3.43—4.30 (13H, m, 2×H-1, H-2, 4, 5, 8, 10, 2×H-12, -OCH$_2$CH$_2$O-), and 4.81 (2H, s, -OCH$_2$O-).

Found: C, 59.84; H, 9.81%. Calcd for $C_{28}H_{56}O_9Si$: C, 59.54; H, 9.99%.

(2*S*,4*R*,5*R*,8*R*,10*S*)-12-*O*-*t*-Butyldimethylsilyl-4,5:8,10-di-*O*-isopropylidene-1,2,4,5,8,10,12-dodecaneheptol (43). A mixture of **41** (138 mg), Pd-black, and *t*-BuOH was vigorously stirred at 30 °C for 1 h under bubbling with H_2 gas, and then the suspension was filtered. The filtrate was evaporated to a syrup which was chromatographed on silica gel (5.0 g) with 1:2 hexane–ethyl acetate to afford **43** (99 mg, 98%): colorless syrup, R_f=0.52 (1:2 hexane–ethyl acetate); $[\alpha]_D^{28}$ +10.3° (*c* 0.66); ^{1}H NMR (90 MHz) δ=0.87 (9H, s, *t*-Bu), 1.32, 1.36, 1.38 (12H, each s, 2×CMe$_2$), 1.10—1.90 (10H, m, 2×H-3, 2×H-6, 2×H-7, 2×H-9, 2×H-11), and 2.70—4.20 (11H, m, 2×H-1, H-2, 4, 5, 8, 10, 2×H-12, 2×OH).

Found: C, 60.51; H, 9.69%. Calcd for $C_{24}H_{48}O_7Si$: C, 60.47; H, 10.15%.

(3*S*,5*R*,8*R*,9*R*,11*S*)-1-*O*-*t*-Butyldimethylsilyl-12-iodo-3,5:8,9-di-*O*-isopropylidene-11-*O*-[(2-methoxyethoxy)methyl]-1,3,5,8,9,11-dodecanehexol (4). To a cold (10 °C) solution of **42** (41.3 mg, 0.073 mmol) and triphenylphosphine (57.5 mg, 0.219 mmol) in benzene (0.83 ml) was added DEAD (0.045 ml, 0.219 mmol). After being stirred at 24 °C for 10 min, methyl iodide (0.0136 ml, 0.219 mmol) was added to the mixture at 10 °C. The mixture was stirred at 24 °C for 3 h and then water (1.5 ml) was added. The mixture was extracted with benzene (3×1.0 ml), and extracts were washed with saturated aqueous NaCl, dried, and evaporated. The residue was chromatographed on silica gel (2.4 g) with 4:1 hexane-ethyl acetate to afford **4** (45.1 mg, 92%): colorless syrup, R_f=0.43 (4:1 hexane–ethyl acetate); $[\alpha]_D^{26}$ +11.3° (*c* 1.28); ^{1}H NMR (250 MHz) δ=0.89 (9H, s, *t*-Bu), 1.36, 1.37 (each 6H each s, 2×CMe$_2$), 1.43—1.93 (10H, m, 2×H-2, 2×H-4, 2×H-6, 2×H-7, 2×H-10), 3.39 (3H, s, OMe), 3.30—4.22 (13H, m, 2×H-1, H-3, 5, 8, 9, 11, 2×H-12, -OCH$_2$CH$_2$O-), and 4.80 (2H, s, -OCH$_2$O-).

Found: C, 50.20; 8.04%. Calcd for $C_{28}H_{55}O_8SiI$: C, 49.84; H, 8.22%.

(2*S*,4*R*,5*R*,8*R*,10*S*)-1,2-Anhydro-12-*O*-*t*-butyldimethylsilyl-4,5:8,10-di-*O*-isopropylidene-1,2,4,5,8,10,12-dodecaneheptol (5). A mixture of **43** (24.2 mg, 0.051 mmol), triphenylphosphine (29.3 mg, 0.112 mmol), molecular sieves 3A powder (242 mg) and benzene (1.21 ml) was vigorously stirred at 85 °C for 10 min, and DEAD (17.6 μl, 0.112 mmol) was added dropwise to the mixture. After being stirred at 85 °C for 4 d, the cold reaction mixture was filtered through a sintered-glass funnel and filter cake was washed with benzene (5×1.0 ml). The combined filtrate and washings were evaporated. The residue was flushchromatographed on silica gel (2.3 g) with 4:1 hexane–ethyl acetate to give **5** (16.3 mg, 70%): colorless syrup, R_f=0.50 (4:1 hexane-ethyl acetate) $[\alpha]_D^{30}$ +8.4°, $[\alpha]_{365}^{30}$ +21.5° (*c* 1.05); ^{1}H NMR (90 MHz) δ=0.89 (9H, s, *t*-Bu), 1.36, 1.39 (each 6H, each s, 2×CMe$_2$), 1.20—2.00 (10H, m, 2×H-3, 2×H-6, 2×H-7, 2×H-9, 2×H-11), 2.53 (1H, dd, H-1, $J_{1,2}$=2.7 Hz, J_{gem}=5.1 Hz), 2.77 (1H, dd, H-1), 3.0—3.3 (1H, m, H-2), and 3.40—4.20 (6H, m, H-4,5,8,10).

Found: C, 62.89; H, 9.63%. Calcd for $C_{24}H_{46}O_6Si$: C, 62.84; H, 10.11%.

We are grateful to the Institute of Microbial Chemistry for the generous support of our program. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 60470091 from the Ministry of Education, Science and Culture. We would like to thank Miss Yoshiko Koyama of the Institute for 250 MHz ^{1}H NMR spectral analyses, and Dr. Morio Yashiro for ^{13}C NMR spectral analyses. We are also thank Messers Saburo Nakada and Akio Takahashi of Keio University for elemental analyses.

Preparation of Methyl 2-Arylpropanoates by the Reaction of 2-Hydroxypropiophenone Dimethyl Acetals with Sulfuryl Chloride in the Presence of an Amide or a Weak Base

Takayoshi YAMAUCHI,* Kaneaki HATTORI, Kenji NAKAO, and Kentaro TAMAKI
Sakai Research Laboratories, Sakai Plant, Kyowa Hakko Kogyo Co. Ltd.,
1-1-53, Takasu-cho, Sakai-shi, Osaka 590
(Received May 2, 1987)

Treatment of 2-hydroxypropiophenone dimethyl acetals [*p*-$RC_6H_4C(OMe)_2CH(OH)Me$] (**1**; R=H, *i*-Bu, OMe, Ph, Br) with sulfuryl chloride in the presence of an amide or a weak base affords methyl 2-arylpropanoates (**2**) in good to excellent yields via 1,2-aryl migration of **1**. The hydrolysis of **2** leads to the corresponding acids, some of which are pharmaceutically important compounds having nonsteroidal anti-inflammatory and analgesic activities. The aryl migration proceeds stereospecifically with complete inversion of configuration at the β-carbon atom.

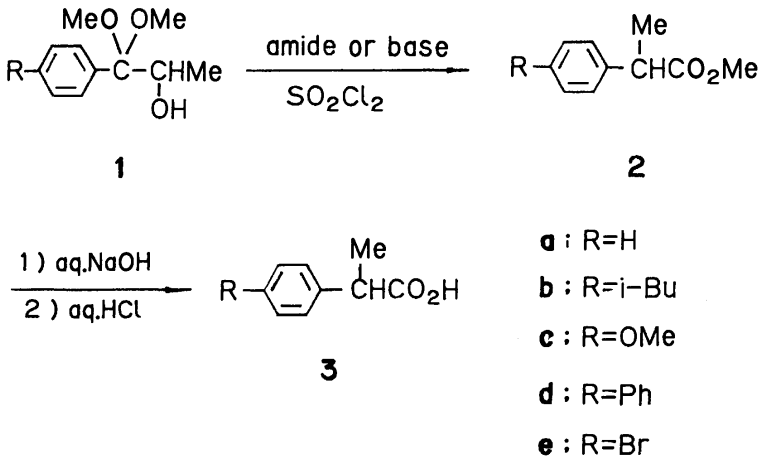
It has been known that 2-arylpropanoic acids are useful medical drugs having antipyretic action or nonsteroidal antiinflammatory activity[1,2] Some of these acids are required to be optically active. Many preparative methods for optically active or inactive 2-arylpropanoic acids have so far been developed. Among them, methods using 1,2-aryl migration in alkyl aryl ketones and their derivatives have proven to be very useful;[3] alkyl esters of 2-arylpropanoic acids were obtained by direct oxidation of alkyl aryl ketones in alcohols with thallium(III) nitrate trihydrate,[4-7] (diacetoxyiodo) benzene,[8] iodine-silver nitrate[7] and also by treatment of enamines with diphenyl phosphorazidate.[9] Further, the same compounds were produced as well from aryl 1-haloalkyl ketones or their acetals either by treating them with silver salts[10,11] or Lewis acids,[12,13] or by heating them in protic polar solvents in the absence of metal catalysts.[14] Recently, we also disclosed several new methods for the synthesis of 2-arylpropanoic acid alkyl esters from aryl 1-haloalkyl ketones and related substances.[15-18]

Tsuchihashi et al.[19-21] reported that a base-promoted rearrangement of chiral acetals of 1-aryl-2-sulfonyloxy-1-alkanones proceeds with a complete inversion of the configuration to afford optically active 2-arylalkanoic acids.

We report here a new and facile one-pot preparative method of methyl 2-arylpropanoates from 2-hydroxypropiophenone dimethyl acetals by using sulfuryl chloride in the presence of an amide or a weak base.

Results and Discussion

The reaction was generally carried out by adding sulfuryl chloride to a mixture of 1-aryl-1,1-dimethoxy-2-propanol (**1**) and weak bases or amides in dichloromethane at −50—0 °C. The resulting mixture was stirred for 1—3 h at the same temperature. The main product was methyl 2-arylpropanoate (**2**) and its alkaline hydrolysis afforded the corresponding acid **3** (Scheme 1). Typical results are summarized in Table 1. In these reactions pyridine, diisopropylamine or potassium acetate was found to be effective as a base. *N,N*-Dimethylformamide (DMF) worked as solvent as well as a base and, thus, the treatment of **1** with sulfuryl chloride in this solvent resulted in a high yield formation of **2**. The yield of the rearranged product is satisfactory at lower



Scheme 1.

reaction temperatures, and generally high when the substituent R is an electron-releasing group such as isobutyl, methoxyl, or phenyl. This tendency is similar to that observed in thallium(III) nitrate-mediated[16] and silver salt-mediated[11] synthesis of alkyl 2-arylpropanoates from aryl 1-haloethyl ketones. The treatment of **1b** in DMF with thionyl chloride instead of sulfuryl chloride at 20 °C for 3 h afforded the expected **2b** in only 17% yield, 2-chloro-4'-isobutylpropiophenone being the main product (47%). The rearrangement did not occur with thionyl bromide or seleninyl chloride ($SeOCl_2$) in pyridine. From the viewpoint of industrial applications of this preparative method, experiments involving the combinational use of sulfur dioxide and halogen gas instead of sulfuryl chloride were also carried out. The reaction proceeded using SO_2–Cl_2, which was revealed to be more economical. Typical results are shown in Table 2. When sulfur dioxide and bromine were used, the yield of **2b** was low, while the rearrangement hardly occurred with a combination of sulfur dioxide and iodine.

Next, the stereochemistry of this rearrangement was investigated using optically active (*R*)-(−)-1-(4-isobutylphenyl)-1,1-dimethoxy-2-propanol [(*R*)-(−)-**1b**] derived from (*S*)-(−)-**1**-(4-isobutylphenyl)-2-methylsulfonyloxy-1-propanone [(*S*)-(−)-**5b**] which in turn was synthesized from L-(+)-lactic acid (**4**) via 5 steps by the known methods[21] (Scheme 2, see Experimental section). Compound (*R*)-(−)-**1b** was obtained in 91% chemical yield by treating optical pure (*S*)-(−)-**5b** with sodium methoxide in methanol at room temperature for 1 h. This procedure is known to proceed with an inversion of the configuration at asymmetric carbon.[22,23] Thus, the stereochemistry of (*R*)-(−)-**1b** should be that shown in Scheme 2. The optical purity of (*R*)-(−)-**1b** was estimated to be 74% ee by NMR measurement using a chiral shift reagent, Eu(hfc)$_3$, indicating the occurrence of a slight racemization under this acetalization condition. A treatment of (*R*)-(−)-**1b**, thus obtained, with sulfuryl chloride in pyridine at −50 °C afforded (*S*)-(−)-**2b** of 74% ee. The result clearly shows that the rearrangement of (*R*)-(−)-

Table 1. Preparation of **2** from **1**[a]

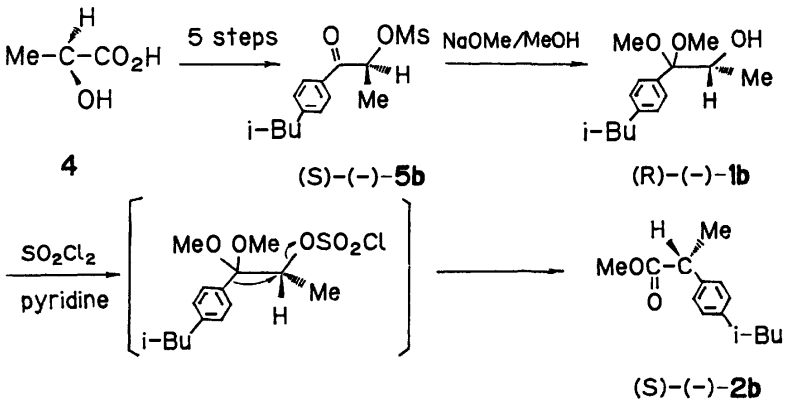
Compound	Base or amide	Reaction condition		Yield of **2**[b]
		Temp/°C	Time/h	%
1a	Pyridine	−50	3	55
1b	Pyridine	−50	3	86
1b	Pyridine	0	1	73
1b	(*i*-Pr)$_2$NH[d]	0	3	72[c]
1b	*i*-PrNH$_2$[d]	0	3	61[c]
1b	AcOK[d]	0	3	64
1b	DMF[e]	−50	3	84
1b	DMF[e]	0	3	86[c]
1c	Pyridine	−50	3	85
1d	Pyridine	−50	3	87
1e	Pyridine	−50	3	54

a) Carried out using **1** (5 mmol), SO_2Cl_2 (7.5 mmol), and a base or an amide (12.5 ml) in dichloromethane (12.5 ml). b) Isolated yield by column chromatography. c) Determined by GLC analysis. d) 10 mmol. e) DMF was used as the solvent (12.5 ml).

Table 2. Preparation of **2b** from **1b** Using Halogen, Sulfur Dioxide, and Base[a]

Base	Halogen	Yield of **2b**[b]
		%
Et_3N	Cl_2	95 (88)[d]
Et_3N	Cl_2[c]	93
Pyridine	Cl_2	94
Pyridine	Br_2	48
Pyridine	I_2	Trace
i-PrNH$_2$	Cl_2	75
Et_2NH	Cl_2	52

a) Carried out using **1b** (10 mmol), base (15 mmol), sulfur dioxide (15 mmol), halogen (15 mmol), and dichloromethane (61 ml) at −50 °C for 3 h. b) Determined by GLC analysis. c) 10 mmol. d) Isolated yield.



Scheme 2.

1b to (*S*)-(−)-**2b** proceeded with a complete inversion of the configuration at the β-carbon atom (Scheme 2). This new and economical method for the preparation of an optically active 2-arylalkanoic acid is industrially important.

Experimental

^{1}H NMR spectra were recorded with a JEOL FX-90Q (90 MHz) instrument on solutions in $CDCl_3$ with Me_4Si as an internal standard. GLC analyses were carried out with a Shimadzu 4CMPF apparatus by using DEGS (2%) on Gas Chrom Q (3 mm×1.5 m) and OV-101 (0.24 mm×30 m) columns (N_2 as carrier gas). IR spectra were recorded with a Shimadzu IR-435 spectrometer. Melting points were determined with Yanagimoto MP micro melting-point determination apparatus and were uncorrected. Optical rotations were measured on a Union PM-201 automatic polarimeter.

All organic and inorganic materials were commercial products of the purest grade. 1-Aryl-1,1-dimethoxy-2-propanols (**1**) were prepared by the literature method[19] from methanol, sodium methoxide, and 2-halopropiophenone.

Rearrangement of 1 to Methyl 2-Arylpropanoates (2). A typical example is as follows. To the solution of **1b** (1.26 g, 5 mmol) in pyridine (12.5 ml) and dichloromethane (12.5 ml) was added sulfuryl chloride (1.01 g, 7.5 mmol) at −50 °C under stirring. After the mixture was stirred for 3 h at the same temperature, saturated aqueous $NaHCO_3$ (25 ml) was added and then an aqueous layer was extracted with chloroform (3×75 ml). The extract was dried over $MgSO_4$ and the solvent was removed by evaporation under reduced pressure. The resulting oily residue was purified by column chromatography on SiO_2 [hexane–ethyl acetate (30:1) as eluent] to give **2b** (0.95 g, yield 86%) as a pale yellow oil.

An experiment using isopropylamine, diisopropylamine or potassium acetate as a base was carried out in a 1/5-fold scale and **2b** was analyzed by GLC using triphenylmethane as an internal standard [2% DEGS on Gas Chrom Q, (3 mm×1.5 m) column at 100→200 °C (5 °C min^{-1})]. The yield of **2a**, **2c**, **2d**, and **2e** was determined by GLC on OV-101 (0.24 mm×30 m) column [at 120→260 °C (4 °C min^{-1})] using an internal standard: pentamethylbenzene for **2a** and **2c**, and biphenyl for **2d** and **2e**.

Experiments using $SOCl_2$/DMF, $SOBr_2$/pyridine, and $SeOCl_2$/pyridine were similarly carried out.

Alkaline hydrolysis of **2** to **3** was carried out as previously reported.[15–17]

Rearrangement of 1b with Sulfur Dioxide and Halogen. To a solution of **1b** (10 mmol) in dichloromethane (40 ml) were added an amine (15 mmol) and a solution of sulfur dioxide (0.96 g, 15 mmol) in dichloromethane (7 ml) successively, and the resulting mixture was cooled down to −50 °C. To the mixture was added dropwise a solution of halogen (15 mmol) in dichloromethane (14 ml) and the mixture was stirred at −50 °C for 3 h. After a similar treatment as above, **2b** in the extract was analyzed by GLC and isolated by column chromatography in a pure form (as described above).

Synthesis of (*R*)-(−)-1-(4-Isobutylphenyl)-1,1-dimethoxy-2-propanol [(*R*)-(−)-1b]. **(a) (−)-Ethyl L-Lactate (6).** A solution of L-(+)-lactic acid (**4**, 89.2 g, 0.99 mol) and concentrated sulfuric acid (8.93 g, 91 mmol) in ethanol (893 ml) was refluxed for 2 h. After it had been cooled down, the mixture was neutralized to pH 5.2 with saturated aqueous $NaHCO_3$. Evaporation of the solvent left an oily residue which was distilled to give **6**; bp 78.5 °C/43 Torr (1 Torr=133.322 Pa) (67.3 g, 57 mmol, 57.5% yield); $[\alpha]_D^{19}$ −10.7° (neat) [lit,[24] $[\alpha]_D^{19}$ −11.26° (neat)]; Found: C, 76.05; H, 9.13%. Calcd for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%. ^{1}H NMR ($CDCl_3$) δ=1.30 (3H, t), 1.42 (3H, d), 3.32 (1H, s), 4.1—4.4 (3H, m).

(b) (−)-Ethyl (*S*)-2-(Methylsulfonyloxy) propanoate (7). To a solution of **6** (64.7 g, 548 mmol) in dichloromethane (110 ml) was added methylsulfonyl chloride (81.6 g, 712 mmol) at −20 °C, then pyridine (52.0 g, 657 mmol) was added dropwise at −15—−20 °C for 1 h. After the mixture was stirred at −15 °C for 3 h, it was quenched with water (137 ml), neutralized to pH 4.7 with 3 mol dm^{-3} sodium hydroxide (190 ml), and extracted with dichloromethane (356 ml). The organic layer was washed with brine (685 ml) and dried ($MgSO_4$). The solvent was evaporated under reduced pressure and an only residue was distilled in vacuo to give **7**; bp 106 °C/2.5 Torr (74.1 g, 378 mmol, 68.9% yield, lit,[21] bp 97—102 °C/2 Torr); $[\alpha]_D^{22}$ −52.3 °C (*c* 1.00, $CHCl_3$) [lit,[21] $[\alpha]_D^{19}$ −50.55 (*c* 1.00, $CHCl_3$)]; ^{1}H NMR ($CDCl_3$) δ=1.29 (3H, t), 1.58 (3H, d), 3.11 (3H, s), 4.22 (2H, q), 5.06 (1H, q).

(c) (*S*)-(−)-2-(Methylsulfonyloxy)propionic Acid (8). A solution of potassium hydroxide (25 g, 446 mmol) in water (250 ml) was slowly added to **7** (72.8 g, 371 mmol) at 5—10 °C during 1 h. The mixture was stirred at 10—15 °C for 3 h, then acidified to pH 1.0 with concentrated hydrochloric acid (35 ml), and extracted with ethyl acetate (3×450 ml). The organic layer was dried ($MgSO_4$) and evaporated under reduced pressure. The crystalline residue was suspended with hexane (180 ml) and filtered to give crude **8**; mp 69 °C (55.1 g, 328 mmol, 88.4% yield, lit,[21] mp 65—72 °C); $[\alpha]_D^{22}$ −53.9° (*c* 1.00, $CHCl_3$) [lit, [21] $[\alpha]_D^{22}$ −49.8° (*c* 1.00, $CHCl_3$)]; ^{1}H NMR ($CDCl_3$) δ=1.68 (3H, d), 3.12 (3H, s), 5.15 (1H, q), 9.10 (1H, br s).

(d) (*S*)-(−)-2-(Methylsulfonyloxy)propionyl Chloride (9). A mixture of **8** (55.1 g, 328 mmol) and thionyl chloride (78 g, 656 mmol) was refluxed for 4 h. The mixture was distilled in vacuo to give **9**; bp 91—93 °C/2 Torr (52.9 g, 283 mmol, 86.4% yield, lit,[21] bp 70—74 °C/1.5 Torr); ^{1}H NMR ($CDCl_3$) δ=1.75 (3H, d), 3.17 (3H, s), 5.28 (1H, q).

(e) (*S*)-(−)-1-(4-Isobutylphenyl)-2-methylsulfonyloxy-1-propanone [(*S*)-(−)-5b]. To a solution of isobutylbenzene (20.1 g, 150 mmol) and **9** (18.7 g, 100 mmol) in nitromethane (100 ml) was added iron(III) chloride (17.8 g, 110 mmol) at 5—10 °C. The mixture was stirred at room temperature for 4 h, then quenched with water (200 ml), and extracted with ethyl acetate (2×100 ml). The organic layer was washed with brine (200 ml) and dried ($MgSO_4$). The solvent was evaporated under reduced pressure to leave an oily residue which was purified by column chromatography on SiO_2 [hexane–ethyl acetate (30:1—4:1) as eluent] to give (*S*)-(−)-**5b**; mp 82.5 °C (15.0 g, 52.9 mmol) 52.9% yield, lit,[21] mp 81—82 °C), $[\alpha]_D^{24}$ −52.53° (*c* 1.00, $CHCl_3$) [lit,[21] $[\alpha]_D^{24}$ −52.48° (*c* 1.00, $CHCl_3$)], IR (KBr disk) 2960, 1697, 1609, 1240, 1180, 1023, and 745 cm^{-1}, ^{1}H NMR ($CDCl_3$) δ=0.90 (6H, d), 1.63 (3H, d) 1.6—2.1 (1H, m), 2.53 (2H, d), 3.10 (3H, s), 6.00 (1H, q), 7.23 (2H, d), 7.83 (2H, d).

(f) (*R*)-(−)-1b. To a solution of (*S*)-(−)-**5b** (10.0 g,

35 mmol) in methanol (70 ml) was added a solution of sodium methoxide (3.78 g, 70 mmol) in methanol (47 ml) at room temperature and the mixture was stirred for 1 h. After water (300 ml) and ethyl acetate (100 ml) were added to the mixture, two layers were separated and the aqueous layer was then extracted with ethyl acetate (100 ml). The combined organic layers were dried ($MgSO_4$). Evaporation of the solvent under reduced pressure left an oily residue which was distilled in vacuo to give (*R*)-(−)-**1b**; bp 97—100 °C/0.2 Torr (8.07 g, 32 mmol, 91.4% yield); $[\alpha]_D^{21}$ −1.64 °C (*c* 1.00, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=0.89 (6H, d), 0.97 (3H, d), 1.6—2.1 (1H, m), 2.35 (1H, br. s), 2.45 (2H, d), 3.20 (3H, s), 3.36 (3H, s), 3.95—4.20 (1H, m), 7.08 (2H, d), 7.34 (2H, d); when the signal at δ=3.36 of methoxy group was determined in the presence of 5 mol% of tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato] europium(III) [Eu(hfc)$_3$], this signal was separated into two signals at δ=3.93 and 4.03. From the integration value of these signals, the ratio of (−)-form/(+)-form was determined to be 87/13 (74±2% ee).

(−)-Methyl (*S*)-2-(4-Isobutylphenyl) propanoate [(*S*)-(−)-2b]. To a solution of (*R*)-(−)-**1b** (5.0 g. 19.8 mmol), pyridine (3.13 g, 39.6 mmol), and dichloromethane (3.96 ml) was added sulfuryl chloride (4.01 g, 29.7 mmol) at −50 °C for 10 min. The mixture was stirred at the same temperature for 3 h and then quenched with saturated aqueous $NaHCO_3$ (50 ml). The resulting mixture was added with water (100 ml) and chloroform (100 ml). The two layers were separated and the aqueous layer was extracted with chloroform (100 ml). The combined organic layers were washed with brine (100 ml) and dried ($MgSO_4$). Evaporation of the solvent left a light-yellow oil which was subjected to column chromatography on SiO_2 [hexane–ethyl acetate (10:1—5:1) as eluent] to give (*S*)-(−)-**2b**; bp 85—86 °C/0.3 Torr (3.46 g, 15.7 mmol, 79.3% yield); $[\alpha]_D^{23}$ −48.4° (*c* 1.00, $CHCl_3$) lit,[21] $[\alpha]_D^{23}$ −56.2° (*c* 1.00, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=0.09 (6H, d), 1.47 (3H, d), 1.6—2.1 (1H, m), 2.44 (2H, d), 3.63 (3H, s), 3.68 (1H, q), 7.05 (2H, d), 7.18 (2H, d); when the signal at δ=3.63 of ester methyl group was determined in the presence of 80 mol% of Eu(hfc)$_3$, this signal was separated into two signals at δ=5.68 and 5.74. From the integration value of these signals, the ratio of (−)-form/(+)-form was determined to be 87/13 (74±2% ee).

We thank Dr. Sakae Uemura of Kyoto University for useful discussions.

NAD(P)$^+$-NAD(P)H Models. 64. The Quantitative Elucidation of the Mechanistic Aspects in the Silica Gel-Catalyzed Reduction of α,β-Unsaturated Carbonyl Compounds by a Model of NAD(P)H

Shinro YASUI,* Masayuki FUJII,† and Atsuyoshi OHNO†
Tezukayama College, Gakuen-Minami, Nara 631
†Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received May 9, 1987)

Eight α,β-unsaturated carbonyl compounds, 1-(2′- or 4′-substituted phenyl)-3-phenyl-2-propen-1-ones (2′- or 4′-substituted chalcones), were subjected to the reduction by an NAD(P)H model in the presence of silica gel in benzene. All of these afforded quantitatively the corresponding saturated carbonyl compounds, whereas no 1,2-reduction took place. For 2′-methoxy, 4′-methyl, 4′-bromo, and 4′-nitro derivatives as well as the unsubstituted carbonyl compound, the apparent reactivity of the substrate increases with the increase in electron-withdrawing ability of the substituent, whereas the degree of the adsorption onto the surface of silica gel decreases. It is also apparent that the 4′-hydroxy derivative exerts lower reactivity than the 2′-hydroxy derivative in spite of much more efficient adsorption of the former. In order to uniformly interpret the apparent results, the data obtained were quantitatively analyzed in terms of kinetics as well as equilibrium constants for the adsorption of the substrates onto the surface of silica gel. It has been revealed that the silanol group on the surface of silica gel acts as a general-acid catalyst in the reduction.

Attentions have been paid recently upon the selective reductions by an NAD(P)H model with its advantage in mildness of reducing ability.[1-6] A certain catalyst sometimes plays a crucial role in such reductions, and there is no doubt that the success for highly selective reduction by an NAD(P)H model depends on a novel catalytic system. For example, we presented the rhodium complex-catalyzed reductive dehalogenation by an NAD(P)H model as a selective reaction applicable to organic halides of several types.[4] Recently, we found that silica gel acts as a catalyst in the selective hydrogenations of carbon-carbon multi-bonds in 1,2-bis(ethoxycarbonyl)alkenes and -alkynes with an NAD(P)H model although the yield of the reduction product was not satisfactory.[5] Semiquantitative analyses of the reduction have suggested that silanol groups on the surface of silica gel contribute to the reaction through general acid catalysis. The analysis was based on the comparisons of the reactivity and the equilibrium constant for the adsorption of these substrates onto the surface of silica gel. We also suggested a possibility that a hydride-equivalent transfers from the NAD(P)H model adsorbed on the surface of silica gel to the substrate in the bulk phase. Nevertheless, the role of silica gel could not be definitively clarified, because the structures of the substrates subjected to the reduction were largely different from each other and quantitative argument on the structure-reactivity relationship was little possible.[5]

More striking catalysis by silica gel was found in the 1,4-reduction of α,β-unsaturated carbonyl compound by an NAD(P)H model; the reduction brings about the corresponding saturated carbonyl compound in quantitative amount whereas no 1,2-reduction takes place.[6] Moreover, functional groups such as carbonyl and ester groups as well as isolated carbon-carbon double bond are inert under the conditions. Then, we intended to examine the reduction of a series of α,β-unsaturated carbonyl compounds by an NAD(P)H model in details to elucidate the role of silica gel.

In this article, we wish to report the results for the reduction of α,β-unsaturated carbonyl compounds, 1-(2′- or 4′-substituted phenyl)-3-phenyl-2-propen-1-ones (2′- or 4′-substituted chalcones) (**1a—h**), by an NAD(P)H model, 3,5-bis(ethoxycarbonyl)-1,4-dihydro-2,6-dimethylpyridine (Hantzsch ester: HEH), in the presence of silica gel in benzene. The reduction of **1a—h** afforded the corresponding saturated carbonyl compounds, 1-(2′- or 4′-substituted phenyl)-3-phenyl-1-propanone (**2a—h**), respectively. No 1,2-reduction was detected. Detailed discussion on the mechanism will be presented based on kinetics and thermodynamics.

Results

In order to obtain reliable results in the product analyses, the kinetics, and equilibrium constants for the adsorption onto the surface of silica gel, silica gel of relatively large mesh, silica gel 60 with 35—70 mesh (Nakarai Chem. Co.), was employed as a catalyst.[5] As an NAD(P)H model, HEH was used because of its higher tolerance against self-decomposition in the presence of silica gel during the reaction.[6] It has been confirmed that water contained in commercial silica gel affects little both the reactivity and the equilibrium,[7] and then neither dryness nor purification of the silica gel is necessary prior to use. Benzene has been found to be the best in this reaction among the solvents examined.

Reduction with HEH. The reaction of 1.0×10^{-1}

mmol of **1** with 1.5×10^{-1} mmol of HEH in the presence of 0.2 g of the silica gel in 1 ml of benzene was carried out under the nitrogen atomosphere at 70 °C in the dark with mechanical stirring. After appropriate period, the reaction mixture was analyzed on VPC according to the procedure described previously.[5] The results are summarized in Table 1. From the viewpoint of amounts of the starting material and the product, it is obvious that the 1,4-reduction is almost exclusive process. The order of apparent reactivity is **1d<1e≃1c≤1f<1a<1g<1b<1h**.

a) 1.0×10^{-1} mmol of **1** and 1.5×10^{-1} mmol of HEH were used. The reaction was carried out in 1 ml of benzene at 70 °C in the dark under N_2 atmosphere in the presence of 0.2 g of the silica gel. b) The yield determined by VPC analysis based on the amount of the substrate used. The values in parentheses indicate the isolated yield from the reaction of 5.0×10^{-1} mmol of **1** and 7.5×10^{-1} mmol of HEH in the presence of 1.0 g of the silica gel in 5 ml of benzene. c) The yield of the recovered starting material. d) The yield of the reduction product, corresponding saturated carbonyl compound. e) Not detected. f) Without the silica gel.

Reduction products isolated from the run in larger scale after enough reaction period were analyzed on NMR and IR spectrometers. Importantly, all substrates examined afforded the corresponding saturated carbonyl compounds **2a—h** in quantitative yields along with 3,5-bis(ethoxycarbonyl)-2,6-dimethylpyridine (HE_{ox}), the oxidized form of HEH, in slightly more than theoretical amount, whereas no 1,2-reduction products were recognized.[8] Small portion of HE_{ox} may be resulted from autoxidation of HEH on the surface of silica gel although the details are not clear.

Adsorption onto the Surface of Silica Gel. As described previously,[5] the degree of the adsorption of **1** onto the surface of silica gel can be evaluated by an equilibrium constant K_{Ad} ($=S_{Ad}/(S_{Bulk}\cdot Q_{free})$) (Eq. 1)

$$S_{Bulk} + Q_{free} \overset{K_{Ad}}{\rightleftarrows} S_{Ad} \quad (1a)$$

$$Q_{free} = Q_0 - S_{Ad} \quad (1b)$$

where S_{Bulk} and S_{Ad} are the amounts (mmol) of **1** in bulk phase and adsorbed one, respectively. Q_0 is the "effective" amount (mmol) of adsorbing centers for **1** on the 0.2 g of silica gel, which can be counted as the maximum amount (mmol) of **1** to be adsorbed. The equilibrium constant K_{Ad} was obtained from the slope and the intercept of the plot of $1/S_{Ad}$ vs. $1/S_{Bulk}$ with the amount of **1** being variable, based on Eq. 2 derived from Eq. 1. Excellent linear correlations (correlation coefficients; $r>0.999$) were seen in the double-reciprocal plots for all substrates.

$$\frac{1}{S_{Ad}} = \frac{1}{K_{Ad}\cdot Q_0}\cdot\frac{1}{S_{Bulk}} + \frac{1}{Q_0} \quad (2)$$

Since the experiment was performed in 1 ml of benzene, each term with the dimension of mmol is equivalent to molarity (M (M=mol dm^{-3})) and the equilibrium constant K_{Ad} thus obtained has a

HEH

2

HE_{ox}

dimension of M^{-1}. The values of K_{Ad} for **1a—h** are summarized in Table 2 together with that for HEH reported previously.[5] Table 2 also involves the values for 4-phenyl-3-buten-2-one (**3**), 4-phenyl-2-butanone (**4**), and **2f** as well as HE_{ox}. It should be emphasized that, as expected from the Eq. 2, each plot gave the identical value for the intercept within experimental error. Since the substrates have wide range of K_{Ad} values (from 3.33 M^{-1} for **1b** to 693 M^{-1} for **1a**), Q_0 of $(7.25\pm0.25)\times10^{-2}$ mmol was obtained with an excellent accuracy. The value of Q_0 elucidated here is well coincident with that previously calculated-($(7.37\pm0.28)\times10^{-2}$ mmol) based on the same method for diethyl maleate, fumarate, and acetylenedicarboxylate as well as for HEH.[5] Recently, the amount of acidic active sites on a silica gel as well as its B.E.T. surface area was reported based on a measurement by means of titration with pyridine.[9] From the values reported, the amount of acidic active sites on the 0.2 g of silica gel is calculated to be 7.0×10^{-2} mmol, which excellently agrees with Q_0 elucidated in the present study, suggesting that the "adsorbing center" defined above corresponds to the "acidic active site" in the literature.

Kinetics. The data listed in Table 1 were kinetically investigated. Since no reduction of **1** with HEH takes place in the absence of silica gel, there remains no doubt that the reaction proceeds according to any one of Eqs. 3—5:

$$\mathbf{1}_{Ad} + HEH_{Ad} \xrightarrow{k_{AA}} \text{Products} \quad (3)$$

$$\mathbf{1}_{Bulk} + HEH_{Ad} \xrightarrow{k_{BA}} \text{Products} \quad (4)$$

$$\mathbf{1}_{Ad} + HEH_{Bulk} \xrightarrow{k_{AB}} \text{Products} \quad (5)$$

The corresponding rate expressions are those shown in Eqs. 6—8, respectively.

$$\text{rate} = k_{AA}[\mathbf{1}]_{Ad}[HEH]_{Ad} \quad (6)$$

$$\text{rate} = k_{BA}[\mathbf{1}]_{Bulk}[HEH]_{Ad} \quad (7)$$

$$\text{rate} = k_{AB}[\mathbf{1}]_{Ad}[HEH]_{Bulk} \quad (8)$$

It is not straightforward to obtain second-order rate constants k_{AA}, k_{BA}, and k_{AB} because each concentration term is governed by complex functions of either equilibrium constants K_{Ad} for coexisting components, **1**, **2**, HEH, and HE_{ox}, or their stoichiometric concentrations, which change complicatedly during the reaction. Here, it may be profitable to simulate the change of $[\mathbf{1}]_{Ad}$, $[\mathbf{1}]_{Bulk}$, $[HEH]_{Ad}$, and $[HEH]_{Bulk}$ as a function of stoichiometric concentration of **1**, $[\mathbf{1}]_{Total}$ ($=[\mathbf{1}]_{Ad}+[\mathbf{1}]_{Bulk}$). The computer-assisted simulation was performed by using the K_{Ad} values for **1**, **2**, HEH, and HE_{ox}.[10] The K_{Ad} values for the reduction products **2** were not obtained experimentally except for that for **2f**. However, arbitrary change in K_{Ad} for **2** from one-fifth to twice of that for the corresponding **1** scarcely affected the simulations.[11] The simulation curves for the reactions of 1.0×10^{-1} mmol of the substrate with 1.5×10^{-1} mmol of HEH in 1 ml of the solvent (the reaction conditions in the present study) are depicted in Figs. 1 and 2.

The simulations for **1b—h** afforded the results with a similar propensity as exemplified in Fig. 1 for **1f**, where $[\mathbf{1}]_{Ad}$, $[\mathbf{1}]_{Bulk}$, $[HEH]_{Ad}$, and $[HEH]_{Bulk}$ are linearly correlated with $[\mathbf{1}]_{Total}$ approximately. Then, for **1b—h** Eqs. 6—8 can be analyzed in terms of second-order rate equations with respect to $[\mathbf{1}]_{total}$.[12] The second-order rate equations thus derived from Eqs. 6—8, respectively, are mathematically equivalent. Accordingly, the data in Table 1 afforded kineticaly indistinguishable three sets of second-order rate constants for the reactions of **1b—h**. The data after long reaction period in Table 1 were, unfortunately, not available for the kinetic analyses, because the reaction gives rise to the decomposition of HEH and/or the change in the activity of the silica gel after long period. However, that the rate constant were obtained with moderate reliability (correlation

coefficients; $r>0.99$) demonstrates the validity of the treatment at least at an early stage of the reaction. Table 3 summarizes the second-order rate constants k_{AA}, k_{BA}, and k_{AB} corresponding to Eqs. 6—8, respectively, for **1b—h**.

On the other hand, Fig. 2 shows that during the decrease in $[\mathbf{1a}]_{Total}$ from 1.0×10^{-1} M to ca. 0.4×10^{-1} M, $[HEH]_{Ad}$ was kept almost constant (1.34×10^{-2} M$\simeq$ 1.40×10^{-2} M under the assumption that K_{Ad} for **2a** is 139 M^{-1}), whereas $[HEH]_{Bulk}$ dramatically decreased. In fact, it was found that the observed rate for the reduction of **1a** obeys a first-order rate equation with respect to $\mathbf{1a}_{Ad}$ or $\mathbf{1a}_{Bulk}$ with an excellent linear correlation at least before ca. 50% of **1a** was consumed

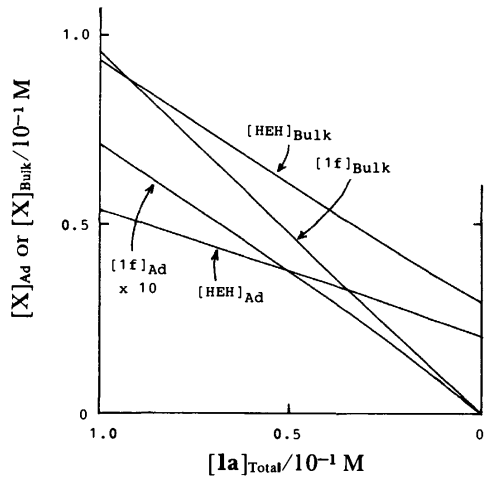

Fig. 1. The simulation curves of $[\mathbf{1f}]_{Ad}$, $[\mathbf{1f}]_{Bulk}$, $[HEH]_{Ad}$, and $[HEH]_{Bulk}$ as a function of $[\mathbf{1f}]_{Total}$.

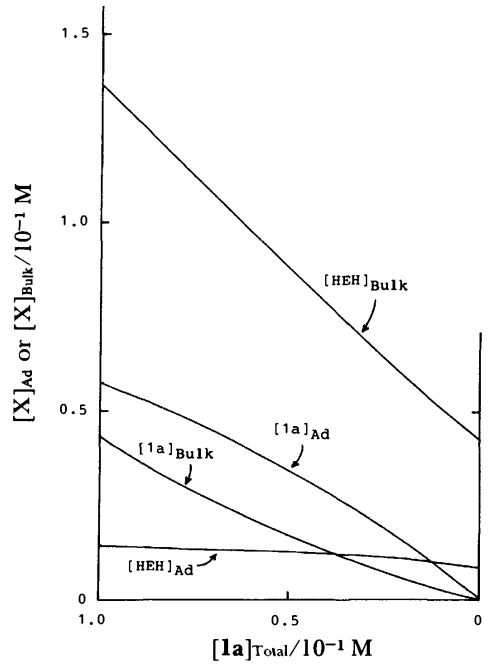

Fig. 2. The simulation curves of $[\mathbf{1a}]_{Ad}$, $[\mathbf{1a}]_{Bulk}$, $[HEH]_{Ad}$, and $[HEH]_{Bulk}$ as a function of $[\mathbf{1a}]_{Total}$.

(correlation coefficients; $r>0.999$). The finding manifests invalidity of Eq. 8 composed of two varying terms ($[\mathbf{1a}]_{Ad}$ and $[HEH]_{Bulk}$), and in turn excludes Eq. 5 as a possible reaction path. Therefore, we obtained second-order rate constants k_{AA} and k_{BA} for the reaction of **1a** by dividing the observed first-order rate constants by 1.3×10^{-2} M (=$[HEH]_{Ad}$ in Fig. 2). The results are listed in Table 3.

Deuterium Isotope Effect. In the reduction of **1f** by 3,5-bis(ethoxycarbonyl)-1,4-dihydro-2,6-dimethylpyridine-4,4-d_2 (HEH-4,4-d_2), the NMR spectrum of the product **2f** confirmed the incorporation of quantitative amount of a deuterium into the β-position. Thus, Michael-type migration of a hydride-equivalent occurs in this reaction. Interestingly, it has been confirmed that the hydrogen at the 4-position of 1-benzyl-1,4-dihydronicotinamide, an NAD(P)H model, also migrates onto the β-position of 4-(unsubstituted or *p*-bromo- and *p*-nitrocinnamoyl)-pyridines in the presence of magnesium perchlorate in acetonitrile.[13]

Reductions of **1a**, **b**, **f**, and **g** by HEH-4,4-d_2 were kinetically followed, and primary kinetic deuterium isotope effects calculated for k_{AA} are listed in Table 4. The values indicate that a hydride-equivalent transfers from HEH to **1** in the rate-determining step.

Discussion

In Fig. 3, $\log(K^X_{Ad}/K^H_{Ad})$ derived from the values in Table 2 are plotted against the substituent σ-values. The σ-values for the 4′-substituents are tentatively

1h	15.1 ±2.1	7.50 ±1.04	9.23 ±1.18

a) Derived from the data in Table 2. b) Errors contain those originated from uncertainty of K_{Ad} for **2** along with standard deviation; see text for details.

Table 4. Primary Kinetic Deuterium Isotope Effect

Substrate	k^H_{AA}/k^D_{AA}
1a	5.2±0.6
1b	5.5±0.9
1f	5.1±0.7
1g	5.4±1.0

used for the corresponding 2′-substituents, because the electronic effects of substituents at the 2′- and 4′-positions upon a side chain are reasonably assumed to be equivalent. The plot for **1a** locates far above the area, so it is omitted. For **1c—g**, a linear correlation (correlation coefficient; r=0.990) is seen with ρ=−0.50, indicating that, for these substrates, the more electron-releasing the substituent, the larger the K_{Ad} value. That **1c** and **1d** has almost identical K_{Ad} suggests that an ortho-substituent exerts no steric effect on the adsorption. The K_{Ad} value for **1b** is much smaller than expected from its σ-value. The finding supports the importance of carbonyl oxygen for the adsorption. That is, the adsorption through the carbonyl oxygen would be prevented in **1b** by its strong coordination with the 2′-hydroxyl group through a hydrogen-bonding to form a stable six-membered ring, which can be recognized by anomalously low chemical shift (δ from TMS=12.8 in $CDCl_3$) of the 2′-hydroxyl proton in the NMR spectrum of **1b**. The absence of appreciable absorption in the 3500—3600 cm^{-1} range in the IR spectrum also supports the proposal. The K_{Ad} for **1a** is unexpectedly large, which seems to be mainly attributed to the extremely low solubility of **1a** in benzene. Interestingly, the nitro group in **1h** is likely to result in an additional contribution to the adsorption. Smaller K_{Ad} values for the saturated carbonyl compounds **2f** and **4** than those for the corresponding α,β-unsaturated carbonyl compounds **1f** and **3**, respectively, may be due to thermodynamically less stable coordination of the former compounds than those of the latter compounds, respectively. That is, the induced small positive charge on the carbonyl group is not mesomerically stabilized by the phenyl ring on the β-position in saturated compounds. Alternatively, the π-bond in the carbon-carbon double bond of an α,β-unsaturated carbonyl compound may contribute to the adsorption.

All data listed in Table 2 reveals that electrostatic interaction between the carbonyl oxygen of **1** and the silanol group on the surface of silica gel is a predominant factor in the adsorption of **1**, as proposed previously for diethyl maleate, fumarate, and acetylenedicarboxylate.[5]

Figure 4 shows an excellent linear correlation between $\log(k^X_{AA}/k^H_{AA})$ derived from the data in Table 3 and the Hammett σ-value (ρ=1.22: correlation coefficient; r=0.998) except for **1b** and **1d**, where points for 2′-substituted derivatives are plotted against σ-values of the corresponding 4′-substituents (vide supra). As will be described later, there are convincing reasons against the deviations of plots for **1b** and **1d**. On the other hand, rather a U-shaped correlation between $\log(k^X_{BA}/k^H_{BA})$ and the σ-values can be seen in Fig. 5, with the plot for **1a** being largely deviated positively. There is no reason for the reaction between **1** in the solution and HEH on the surface of silica gel to exert a U-shaped Hammett relationship. The Hammett plot for k^X_{AB}/k^H_{AB} shows slightly positive deviations for **1c** and **1e** as seen in Fig. 6. Thus, the correlation in k^X_{AB}/k^H_{AB} is poorer than that in k^X_{AA}/k^H_{AA}. Note that the definition of k_{AB} is impossible for the reaction of **1a** as mentioned above. Finally, we infer that the reactions in the present study are most reasonably interpreted in terms of the kinetics represented by Eq. 6 instead of those in Eqs. 7 and 8.

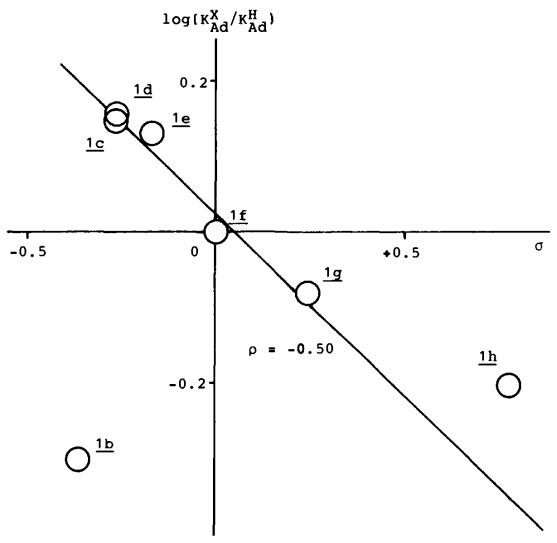

Fig. 3. The Hammett plot of $\log(K^X_{Ad}/K^H_{Ad})$ vs. σ-value.

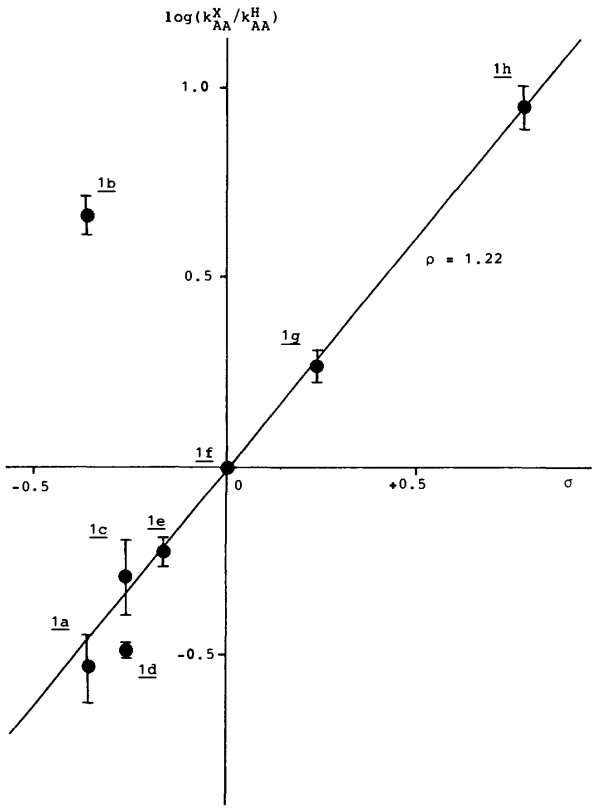

Fig. 4. The Hammett plot of $\log(k^X_{AA}/k^H_{AA})$ vs. σ-value.

Namely, since the equilibration is much faster process than the reduction,[5] the transfer of a hydride-equivalent appears to take place between HEH and **1**, both adsorbed on the surface of silica gel.

Nevertheless, our previous study on the reductions of diethyl maleate, fumarate, and acetylenedicarboxylate by HEH in the presence of silica gel has postulated that the transfer of a hydride-equivalent takes place from the HEH adsorbed on the surface of silica gel to the substrate in bulk phase.[5] First-order dependency of the reaction rate on both $[\mathbf{1}]_{Ad}$ and $[HEH]_{Ad}$ in the present reaction (Eq. 6) does not necessarily require the transfer of a hydride-equivalent between HEH and **1**, both adsorbed on the surface of silica gel, at the rate-determining step. Alternatively, we can take into account the local concentration(s) of **1** and/or HEH in the outer sphere of the silica gel. Since adsorption and desorption of the materials are in rapid equilibrium at the interface of the silica gel and the bulk phase, the local concentrations of HEH and **1** in the outer sphere would be approximately proportional to $[HEH]_{Ad}$ and $[\mathbf{1}]_{Ad}$, respectively. If this is the case, kinetic results obtained from the present study might accommodate the transfer of a hydride-equivalent from HEH to **1** in the outer sphere of the silica gel. As proposed previously, it is also possible that one of the two components, perhaps HEH counterpart, exists on the surface of silica gel during the transfer of a hydride-equivalent.[5]

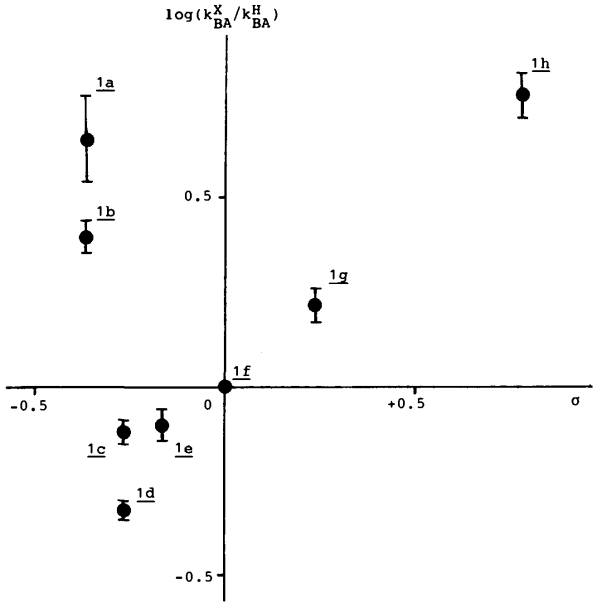

Fig. 5. The Hammett plot of $\log(k^X_{BA}/k^H_{BA})$ vs. σ-value.

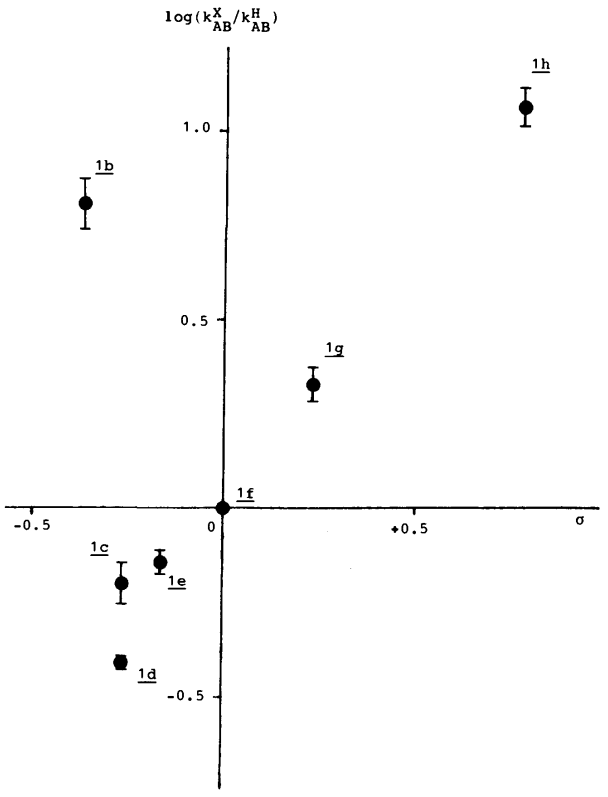

Fig. 6. The Hammett plot of $\log(k^X_{AB}/k^H_{AB})$ vs. σ-value.

The values of primary kinetic deuterium isotope effects listed in Table 4 clearly indicate that a hydrogen is migrating more or less in the rate-determining step.[14] It is also evident that these are approximately identical in magnitude irrespective of the reactivity of the substrate, which would postulate that the same mechanism persists for a hydride-equivalent transfer steps for **1a**, **f**, and **g**, as that for **1b**.[15] Unexpectedly high reactivity of **1b** is reasonably attributable to the intramolecular acid catalysis by the 2′-phenolic hydrogen in **1b**. Indeed, **1b** is reduced to **2b** by HEH in benzene without silica gel although the yield is low (Table 1). The transition state for the other substrates may stabilized as well by a hydroxylic proton of silanol group on the surface of silica gel. Considering that **1** is absorbed onto the surface of silica gel through the interaction of its carbonyl oxygen with a proton of a silanol group, a participation of the silanol group to the carbonyl oxygen of **1** in the outer sphere would be reasonably anticipated. Such a participation of the acidic silanol group may be not specific- but general-acid catalysis in view of extremely low basicity of the carbonyl oxygen of **1**[16] and moderate acidity of the silanol group,[17] although it cannot be demonstrated at present that the protonation is partially rate-determining. The positive ρ-value in this reaction shows the predominance of the hydride-equivalent transfer from HEH compared with the proton transfer from the silanol group at the transition state. Interestingly, in the reduction of *p*-methoxybenzaldehyde by NADH-dependent yeast alcohol dehydrogenase, the transfer of a proton from a water molecule onto the carbonyl oxygen does not participate in the rate-determining step, whereas the

transfer of a hydride equivalent onto the carbonyl carbon constitutes the sole rate-determining step.[18]

The present simulation has predicted that a large amount of silanol groups remain free during the reaction. It should be noted that the value of Q_0 does not represent the amount of all silanol groups on the surface, but it merely designates the "effective" amount of adsorbing centers on the surface for the materials used in the present study. A previous report has shown that only "free" silanol groups on the convex outer surface, the amount of which is calculated from the reported data to be 0.64 mmol per 0.2 g of silica gel, is ethoxylated by treating silica gel with ethanol. 2-Propoxylation and 2-methyl-2-propoxylation of silanol groups takes place, to the extents of two-third and one-third of that of ethoxylation, respectively, when silica gel is treated with 2-propanol and 2-methyl-2-propanol under the same conditions.[19] In addition, note that benzene molecule as a solvent in the present study does not perturb the silanol group because of its nonpolarity. Thus, during the present reaction, quite numerous silanol groups on the surface of silica gel possibly act as general-acid catalysts.

The mechanism is partly supported by the fact that k_{AA} for **1d** is smaller than that for **1c** even though these compounds have practically identical K_{Ad}. The ortho-substituent in **1d** may intervene an assistance by a silanol group during the process for the transfer of a hydride-equivalent.

Our previous study has revealed that active aluminas give rise to no reduction in spite of comparable adsorption of both a substrate and HEH onto their surfaces as those onto silica gel.[5] This fact indicates that silica gel not only adsorbs the materials but also plays a crucial role such as general-acid catalysis by the silanol group on the surface, as shown schematically in Fig. 7. Interestingly, an infrared spectroscopic study has revealed that when ethanol is adsorbed through hydrogen bonding, the silanol groups of silica gel act as proton donors, whereas on alumina the surface oxygen atoms play a dominant role as proton acceptors.[20]

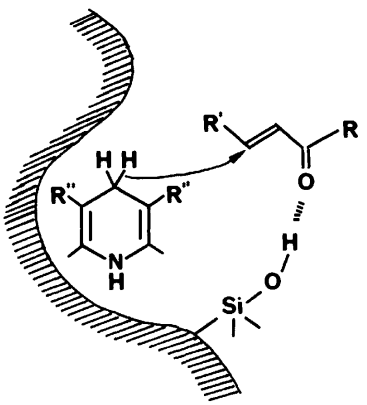

Fig. 7. Schematic representation of the reaction of **1** with HEH in the presence of silica gel.

In conclusion, we believe that the quantitative analysis in the present study has proven general-acid catalysis by silanol groups on the surface of silica gel in the reduction of α,β-unsaturated carbonyl compounds by an NAD(P)H model. Moreover, the silica gel unambiguously withdraws the materials subjected to the reduction closer to its surface. The dual roles of silica gel may be claimed as "enzyme-like." There are several examples for enzymatic hydrogenation of carbon–carbon double bond with a coenzyme NADH or NADPH, a redox potential of which is known to be equivalent to that of NAD(P)H models so far studied.[21] Thus, in a mimetic system an enzyme-like catalyst which exerts the dual ability, binding and catalysis, is required.

Finally, we wish to emphasize that the reduction system composed of HEH and silica gel is an excellent tool for chemo- and regio-selective reduction of α,β-unsaturated carbonyl compound due to its simplicity relative to other systems described in the recent reports.[22]

Experimental

Apparatus. VPC analyses and elemental analyses were performed on a Yanaco G-180 gas chromatograph and a Yanaco MT-3 elemental analyzer, respectively. ^{1}H NMR and IR spectra were recorded on a JEOL GX 400 FT NMR spectrometer and a Hitachi 260-10 infrared spectrophotometer, respectively. Computer-assisted simulations were run on an NEC PC-9801 VM2 personal computer with an N_{88} BASIC program.

Materials. 3,5-Bis(ethoxycarbonyl)-1,4-dihydro-2,6-dimethylpyridine (HEH) was prepared as reported previously.[23] HEH-4,4-d_2 was synthesized according to the same procedure as described for HEH using paraformaldehyde-d_6 in place of formaldehyde. 400 MHz ^{1}H NMR spectrum confirmed deuterium content at the 4-position to be 98%. 2′- or 4′-Substituted chalcones **1a**—**h** were obtained by condensation of benzaldehyde with the corresponding 2′- or 4′-substituted acetophenone followed by recrystalization from ethanol.[24] Spectral data as well as the results of elemental analyses of these compounds were satisfactory. Silica gel 60 (35—70 mesh) (Nakarai Chem. Co.) was commercially available.

Procedures. Measurements of adsorption onto the surface of the silica gel and product analyses were succeeded according to the procedures described previously.[5]

10) Each concentration term is simulated by resolving the following equations simultaneously without any approximation,

$$K^{1}_{Ad} = [\mathbf{1}]_{Ad}/(([\mathbf{1}]_{Total}-[\mathbf{1}]_{Ad})\cdot[Q]_{free})$$
$$K^{2}_{Ad} = [\mathbf{2}]_{Ad}/(([\mathbf{2}]_{Total}-[\mathbf{2}]_{Ad})\cdot[Q]_{free})$$
$$K^{HEH}_{Ad} = [HEH]_{Ad}/(([HEH]_{Total}-[HEH]_{Ad})\cdot[Q]_{free})$$
$$K^{HE\text{-}ox}_{Ad} = [HE_{ox}]_{Ad}/(([HE_{ox}]_{Total}-[HE_{ox}]_{Ad})\cdot[Q]_{free})$$
$$[Q]_{free} = [Q^{0,\cdot 2}_{0}]-[\mathbf{1}]_{Ad}-[\mathbf{2}]_{Ad}-[HEH]_{Ad}-[HE_{ox}]_{Ad}$$

and

$$[\mathbf{1}]_{Total}+[\mathbf{2}]_{Total} = 1.0\times10^{-1}\ M$$
$$[HEH]_{Total}+[HE_{ox}]_{Total} = 1.5\times10^{-1}\ M$$
$$[\mathbf{1}]_{Total}-[\mathbf{2}]_{Total} = [HEH]_{Total}-[HE_{ox}]_{Total}$$

where superscripts **1**, **2**, HEH, and HEox denote the values referred to **1**, **2**, HEH, and HE_{ox}, respectively.

11) The approximations may be reasonable considering that the observed K_{Ad} values for saturated carbonyl compounds **2f** and **4** are 1/3.57 and 1/1.75 of those for the corresponding α,β-unsaturated carbonyl compounds **1f** and **3**, respectively (Table 2).

12) The simulation allows the following approximations:

$$[\mathbf{1}]_{Ad} = A[\mathbf{1}]_{Total}$$
$$[\mathbf{1}]_{Bulk} = A'[\mathbf{1}]_{Total}$$
$$[HEH]_{Ad} = B[\mathbf{1}]_{Total}+C$$
$$[HEH]_{Bulk} = B'[\mathbf{1}]_{Total}+C'$$

where the parameters A, A', B, B', C, and C' are constants directly given by the correlation plotted in Fig. 1. Discrepancy between concentrations simulated and thus approximated is ca. 4×10^{-4} M (<1%) in maximum (for **1d**; when $[\mathbf{1d}]_{Total}=0.5\times10^{-1}$ M under the assumption of K_{Ad} (for **2d**)=1.93 M^{-1}.) Based on these approximations, Eqs. 6—8 afford a second-order rate equation with respect to $[\mathbf{1}]_{Total}$ as a following formula:

$$kt = c_1\cdot\ln\{(c_2\cdot(c_3[\mathbf{1}]_{Total}+c_4))/([\mathbf{1}]_{Total}\cdot(c_2\cdot c_3+c_4))\}$$

where c_1, c_2, c_3, and c_4 are constants, and in the equation derived from Eq. 6 where $k=k_{AA}$, for example, they are put as $c_1=1/(A\times C)$, $c_2=0.1$ (an initial concentration of **1**), $c_3=B$, and $c_4=C$, respectively.

13) S. Yasui and A. Ohno, unpublished result.

14) The mechanism of the transfer of a hydride-equivalent in the present study may be investigated in terms of successive transfers of an electron and a hydrogen atom (or an electron, a proton, and an electron) as proposed in NAD(P)H model-mediated reductions of several types of the substrates. Unfortunately, the present data in our hands provide no informations in this respect. Note that since **1** is supposed to be a strongly electron-deficient substrate under the silica gel catalysis, the step of an initial electron transfer would not be experimentally appreciable. See: S. Yasui and A. Ohno, *Bioorganic Chem.*, **14**, 70 (1986).

15) The theory demands, of course, identical values of kinetic primary deuterium isotope effect only when the position of the transition state along the reaction coordinate are exactly the same. There is no reason at all that the values of k^{H}_{AA}/k^{D}_{AA} obtained here must be identical. We only note that the values are roughly identical in the magnitude, which would certify the consideration in this place at least qualitatively.

New Synthetic Method of [2.2]Cyclophanes via Diselena[3.3]cyclophanes

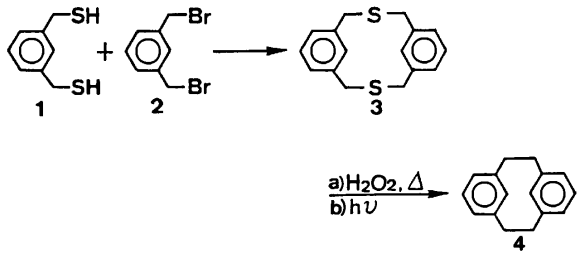
Hiroyuki HIGUCHI, Keita TANI, Tetsuo OTSUBO,† Yoshiteru SAKATA, and Soichi MISUMI*

The Institute of Scientific and Industrial Research, Osaka University, Ibaraki, Osaka 567
†Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Higashihiroshima, Hiroshima 724

(Received May 25, 1987)

Syntheses of cyclic diselenides through diselenolates and the following deselenation reactions by means of three ways were studied. The preparation of the cyclic diselenides in the presence of excess sodium borohydride gave thirty-eight diselenides containing diselena[3.3]cyclophanes and alicyclic diseleno compounds in high yields in addition to two triple-bridged selenacyclophanes. Photodeselenation of the diselenides in tris(dimethylamino)phosphine afforded series of [2.2]cyclophanes in much higher yields than those of the other two methods, i.e. benzyne-Stevens rearrangement/Raney nickel hydrogenolysis and pyrolytic deselenation at ca. 650 °C. The present study demonstrates that the photodeselenation method, combined with the synthesis of their precursor diselenides, is much superior to the conventional dechalcogenation methods.

The chemistry of cyclophanes has been drastically developed by the emergence of the synthetic methods via various types of desulfurizations of dithia cyclophanes.[1] Especially, pyrolysis of disulfones has been appreciated to be very useful for the preparation of [2.2]cyclophanes.[2] Organoseleniums are also



expected to be applicable to the synthesis of cyclophanes in place of the corresponding organosulfur compounds because C–Se bonds undergo more easily bond fission both thermally and photochemically than the corresponding C–S bonds.

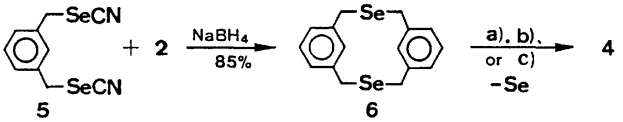
In fact, bis(arylmethyl) selenide and diselenide thermally decomposed with extrusion of elemental selenium to give 1,2-diarylethane.[3] Recently, we reported flash vacuum pyrolysis of a series of dibenzyl selenides and diselenides at 600 °C to give bibenzyl derivatives in high yields[4,5] and the formation (23% yield) of [2.2]paracyclophane by a similar pyrolytic way of 1,4-bis(phenylselenomethyl)benzene.[5,6] An attempt to synthesize cyclophanes via diselenacyclophanes was carried out first by Mitchell but it gave a low yield of [2.2]metacyclophane derivative.[7]

The bibenzyl formation by thermal selenium extrusion stimulated us to develop general synthetic methods for [2.2]cyclophanes via diselena[3.3]cyclophanes.

After various examinations on reaction conditions, we found a general synthesis of diselenacyclophanes in high yields by reductive coupling of bisselenocyanate and dihalide.[8] Here we report general synthetic methods of a variety of [2.2]cyclophanes from diselena[3.3]cyclophanes by a few deselenation ways, i.e. (a) benzyne-Stevens rearrangement/hydrogenolysis, (b) photodeselenation with tris(dimethylamino)phosphine, and (c) flash pyrolysis under reduced pressure.

Results and Discussion

Selenacyclophanes: Synthesis and Properties. Dithia[3.3]cyclophane, a good precursor of [2.2]cyclophane, is generally prepared by coupling of appropriate dithiol and dihalide with potassium hydroxide. On the other hand, diselenol or diselenolate anion is unsuitable to synthesize diselena[3.3]cyclophane **6**,



because it is highly air-sensitive under alkaline conditions to give hardly separable diselenide polymer. The first synthesis of **6** was achieved by coupling of dihalide with sodium selenide and by deselenation of tetraselena[4.4]cyclophane with $P(NEt_2)_3$ both in low yield.[7,9]

After many examinations of reaction conditions, we found an improved synthesis of **6** by coupling of bisselenocyanate **5** and dibromide **2** under reductive environment: A mixture of **2** and **5** (1:1 ratio) in EtOH–THF is dropwise added to a large excess of $NaBH_4$ in EtOH–THF using high dilution technique.

A wide range of mixing ratio of EtOH–THF is usable as the reaction solvent according to solubilities of reactant and a ratio of 5:95 (EtOH–THF) is convenient for the coupling in good yield. A suspension of excess $NaBH_4$ is also effective for high yield of coupling product, by holding the reaction system in reductive condition for suppression of oxidative polymerization.

Table 1. Yields, Melting Points, Crystal Forms, and ^{1}H NMR and Analytical Data of Selenacyclophanes

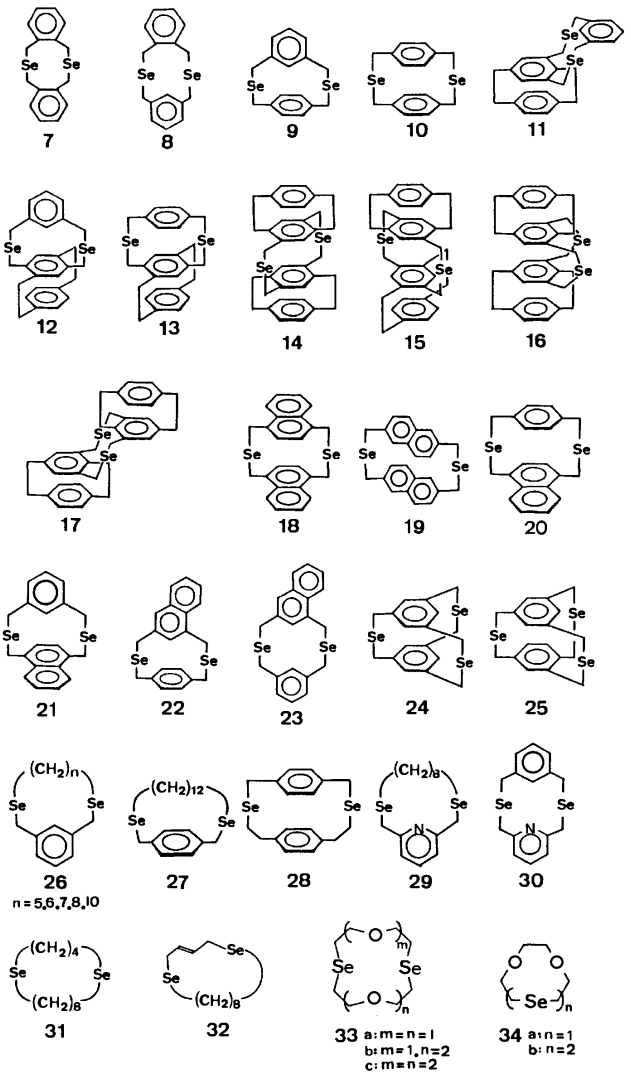
a) Hexane. b) Pairs of selenacyclophanes (**14** and **15**, **16** and **17**, syn and anti **64**, **66** and **68**) were obtained at the same time by appropriate coupling reaction. The structure of **66** and **68** was determined by ^{77}Se NMR measurement. c) Ref. 7. d) Ref. 5. e) Ref. 11.

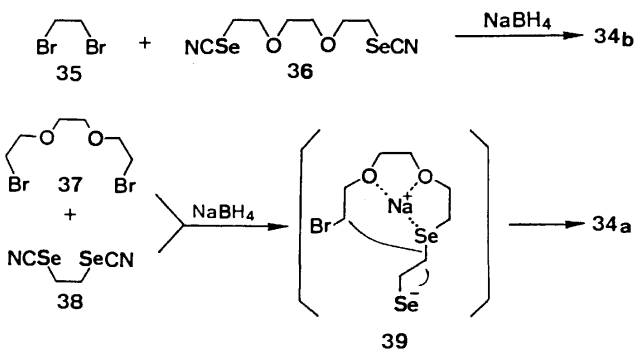
Table 1 shows yields of a variety of selena[3^n]cyclophanes including triple-bridged compounds. This method is convenient to prepare unsymmetrical diselenacyclophanes as well as symmetrical ones and easy to purify the product because tedious polymer is not formed. The yields of such selenacyclophanes are much higher than those of the corresponding thiacyclophanes,[10] just as multilayered ones and triple-bridged ones. For example, triselena[3^3](1,3,5)-cyclophane **24** is afforded in a good yield by more than 10 times that (5.3% yield) of the corresponding trithiacyclophane.[10m] Two pairs of isomeric quadru-



ple-layered selenacyclophanes (**14** and **15**; **16**[11] and **17**[11]) are obtained as a mixture of about 1:1 isomeric ratio and separated by silica-gel column chromatography.

It is not clear whether 2,11-diselena[3.3]metacyclophane **6** consists of an equilibrating mixture of syn- and anti-conformers in solution at room temperature,[12] whereas the corresponding dithiacyclophane **3** exists only in syn-conformer in both solid state and solution.[13] A conformational equilibrium is expected from molecular model examination also for triple-layered diselenacyclophane **11** and diselenanaphthalenometacyclophane **23**, both of which contain the partial structure, diselena[3.3]metacyclophane. On the basis of ^{1}H NMR data, that is, the chemical shifts of the inner aromatic protons and the coupling pattern of bridge methylene protons, cyclophane **23** is in similar equilibrium, while cyclophane **11**, on the contrary, exists as anti-conformer only.[14] A reasonable explanation for the predominance of anti-conformer is steric repulsion among vicinal three methylenes attached to the inner benzene ring. Both of symmetrical naphthalenophanes, **18** and **19**, exist only in one of two conformers, and the structure of **18** is confirmed to be antiform by comparison of its ^{1}H NMR spectrum with that of the corresponding dithia[3.3]naphthalenophane.[10g]

Diselena[*m*]cyclophanes (**26** and **27**), diselenapyridinophanes (**29** and **30**), alicyclic diselenides (**31** and **32**), and diselenocrown ethers (**33** and **34**) are similarly prepared in good yields as shown in Table 2. 2,13-Diselena[4.4]paracyclophane **28** is prepared by two ways, i.e. couplings of 1,4-bis(bromoethyl)benzene with 1,4-bis(cyanoselenatomethyl)benzene in 38% yield and of 1,4-bis(2-cyanoselenatoethyl)benzene with 1,4-bis(bromomethyl)benzene in 77% both in the presence of $NaBH_4$. The difference in the yields suggests a preferable S_N2 substitution of bromine at benzyl position by selenolate anion. On the other hand, coupling reactions of two pairs of dibromides and diselenocyanates, i.e. **35**+**36** and **37**+**38**, unexpectedly give different selenocrown compounds, **34b** and **34a**, respectively. The formation of unusual ring-contracted compound **34a** seems reasonable to assume a template effect of sodium ion in an intermediate **39**. Similar ring contractions were observed in cyclizations of polythioethers.[15]



The structures of all selenacyclophanes were determined by MS and ^{1}H NMR spectra and elemental analyses as shown in Table 1.

Syntheses of Cyclophanes by Deselenation: Desulfurization of polythia[3^n]cyclophanes to [2^n]cyclophanes has usually been carried out by i) Stevens or Wittig rearrangement and the following Raney Ni hydrogenolysis, ii) irradiation in the presence of $P(OR)_3$, and iii) oxidation to the corresponding sulfone and the following pyrolytic desulfonation. Selenium extrusion reactions are carried out by modifying the above-stated desulfurization methods. A series of [2^n]cyclophanes are obtained from polyselena[3^n]cyclophanes by three methods, (A)—(C), as follows:

(A) Benzyne-Stevens rearrangement/hydrogenolysis,

(B) Photodeselenation with tris(dimethylamino)phosphine $P(NMe_2)_3$,

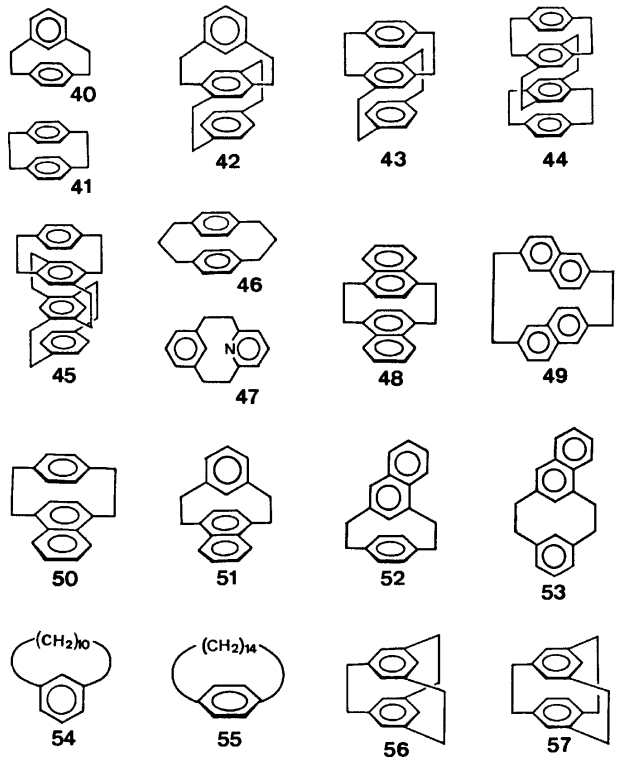
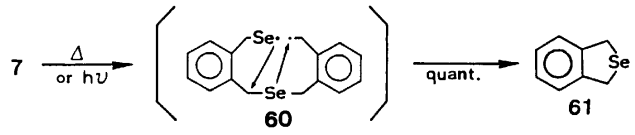
a) Hexane.

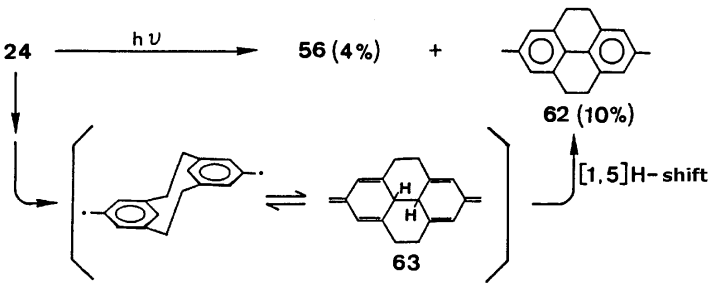


(C) Flash pyrolysis under reduced pressure.
The yields of [2.2]cyclophanes as well as multilayered, naphthaleno-, and pyridino-cyclophanes are shown in Table 3. The table reveals that the benzyne-hydrogenolysis method (A) is obviously superior to the direct extrusion by flash pyrolysis (C) and the yields are comparable to those of the transformation of the corresponding dithiacyclophanes into cyclophanes by benzyne-hydrogenolysis method. Pyrolysis of **28** gives 1,4-divinylbenzene (73% yield) as main product and [2.2]paracyclophane **41**[16] (6%) as a by-product without the desired [3.3]paracyclophane **46**. The reaction seems to proceed via a biradical intermediate **59** which was presumed to generate by pyrolysis of diselenide **58**.[5]

The second method, photodeselenation (B) generally gives higher yield of [2.2]cyclophane than those of the two methods, (A) and (C), as seen in Table 3. Tris(dimethylamino)phosphine is an effective reagent of many well-known reagents for dechalcogenation.[17] The photodeselenation by this reagent proceeds more rapidly than desulfurization with trialkyl phosphite $P(OR)_3$ from the corresponding dithiacyclophane and gives easily separable products. In the case of diselena[3.3]orthometacyclophane, the desired [2.2]-orthometacyclophane is not afforded even by the use of all methods, probably due to highly severe strain predicted in the product. Also, diselena[3.3]ortho-cyclophane **7**[5] affords quantitative yield of benzo-selenophene **61**[5] which may be formed by favorable



intramolecular cyclization of intermediary biradical species **60** into two of the five-membered ring. Both triple-bridged cyclophanes, **56** and **57**, are given in low yield because of more severe strain. Compound **57**, which polymerizes easily at room temperature,[10k,l] is obtained in fairly good yield (11%) at lower temperature in spite of severe strain. On irradiation of triselenacyclophane **24**, an unexpected 2,7-dimethyl-tetrahydropyrene **62**[10n] is afforded in higher yield (10%) than the normal product **56**[10n] (4%). The formation of **62** is explainable in terms of 1,5-hydrogen shift of transannularly bridged intermediate **63**.



Consequently, Table 3 shows the photodeselenative synthesis of [2.2]cyclophane to be the most useful method compared to the other ones, (A) and (C). This method is particularly convenient for synthesis of para-para series [2.2]cyclophanes such as **41**,[16] **43**,[18] **44**,[18] **45**,[18] **48**,[19] and **50**,[16a] compared to those of meta-para and meta-meta series. Firstly we assume from this finding that the yield of cyclophane may increase with the increase in rigidity of starting diselena[3.3]cyclophane. In order to confirm such an assumption, three isomeric diselena[3.3]metacyclophane derivatives, **64**, **66**, and **68**, were synthesized and subjected to the photodeselenation reaction. The

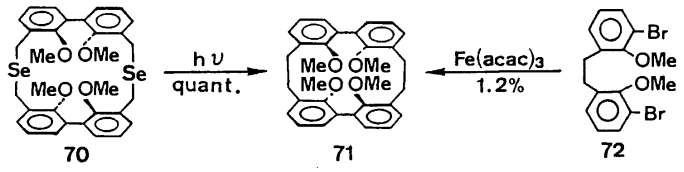
most rigid isomer **64** (syn and anti) gives similarly rigid anti-dimethoxy[2.2]metacyclophane **65** in quantitative yield, whereas isoelectronically substituted, but flexible isomers, **66** and **68**, afford the corresponding dimethoxymetacyclophanes, **67**[20] and **69**,[20] both in low yield.

Furthermore a typical example for our assumption is deselenation of diselena[3.3]biphenylophane **70** to



spherand-like macrocyclic compound **71** which is a rigidly constructed molecule and has a cavity suited to encapsulate selectively lithium ion.[21] In fact, the photodeselenation of **70** proceeds with quantitative yield of **71**, compared to low yield (1.2%) by the previous method. Unfortunately, this photodeselenation method is not suitable for cyclic selenides other than dibenzyl selenide form, e.g. diselenides **27**, **28**, and **32**. Consequently, the present synthetic method of [2.2]cyclophanes by means of the photodeselenation of diselenides demonstrates that this method is much more superior to any other conventional dechalcogenation method reported so far.

Experimental

All melting points are uncorrected. ^{1}H NMR spectra were recorded on a JEOL FX-100 (100 MHz) and Bruker WM360 (360 MHz) spectrometers using chloroform-*d* as a solvent and tetramethylsilane as an internal standard. Phenyl selenocyanate (PhSeCN)[22] was employed as the external standard for ^{77}Se measurement of **66** and **68**. Mass spectra were recorded on a Hitachi RMU-7 spectrometer (70 eV) using the direct injection technique and described here for organoselenium compounds.

General Synthetic Method of Selenides, 6—34, 64, 66, and 68. All selenium compounds were prepared by coupling of di- or tri-halides with bis- or tris-selenocyanates,[4] which were easily obtained by treatment of the corresponding halides with potassium selenocyanate, in the presence of large excess of sodium borohydride. The general procedure will be illustrated below by using the synthesis of 2,11-diselena[3.3]paracyclophane **10** as an example.[8]

A solution of 1,4-bis(selenocyanatomethyl)benzene (1.60 g, 5.1 mmol) and 1,4-bis(bromomethyl)benzene (1.32 g, 5.0 mmol) in 100 ml of ethanol and peroxide-free THF (1:1 v/v) was added to a suspension of an excess of $NaBH_4$ (commercial grade, ca. 2 g) in a mixture (1l) of ethanol and peroxide-free THF (1:19 v/v) under bubbling Ar with vigorous stirring at 40—50 °C for 13 h. After adding a small amount of ice, the reaction mixture was concentrated to ca. 100 ml. Dichloromethane and water were added to the concentrate and the organic layer was separated, washed with sat. NaCl aq, and dried over anhyd magnesium sulfate. The crude colorless residue obtained by evaporation of the solvent was recrystallized from benzene-dichloromethane to give colorless prisms of diselenaparacyclophane **10** (1.35 g, 73% yield).

In the case of oily products, **26** (n=10), **33a—b**, **34**, pale yellow oil obtained by solvent evaporation was purified by gel-permeation liquid chromatography with chloroform.

General Procedures of Deselenation. (A) Benzyne-Stevens Rearrangement/Raney Nickel Hydrogenolysis. To a solution of selenacyclophane (1 mmol) and isopentyl nitrite (2 g) in 1,2-dichloroethane (20 ml) was dropwise added a solution of anthranilic acid (4 mmol, 2 equiv.) in dichloromethane (20 ml) with vigorous stirring at reflux for more than 4 h under a nitrogen atmosphere. After removal of the solvent, the residue was chromatographed on silica gel with carbon tetrachloride or benzene to give a pale yellow solid or semisolid. A suspension of this rearranged product and Raney Ni (W-2, ca. 1 g) in ethanol (50 ml) was stirred at gentle reflux for 17—23 h under hydrogen. Worked up the mixture, a semisolid residue was chromatographed on silica gel with benzene-hexane to give cyclophane in a yield shown in Table 3.

(B) Photodeselenation with Tris(dimethylamino)phosphine. A solution of selenacyclophane (50—100 mg) and excess tris(dimethylamino)phosphine (1—1.5 g) in peroxide-free THF (30—80 ml) was irradiated with a 400 W high-pressure mercury lamp at room temperature under bubbling nitrogen until the starting material consumed completely. The residue obtained by solvent evaporation was chromatographed on silica gel with benzene-hexane or purified by gel permeation liquid chromatography to give cyclophane as shown also in Table 3. All of the cyclophanes described in Table 3 were identified by comparison of their ^{1}H NMR spectra, other physical properties and/or elemental analyses.

(C) Flash Pyrolysis under Reduced Pressure. A pyrex tube closed at one end, 45 cm long and 1 cm diameter, was used for pyrolysis. A sample (ca. 100 mg) of selenacyclophane was placed at the closed end of the tube. The other end was connected to a vacuum system (1—5 mmHg (1 mmHg=133.322 Pa)) and cooled with Dry Ice or liq. nitrogen. The middle part was placed in an electric furnace (25 cm long) preheated at 650 °C. After heating for ca. 3 min, the sample part was slidden within the furnace. Pyrolysis immediately occurred and the pyrolysate condensed at the cooled part. The organic products were

extracted with dichloromethane and purified by gel permeation liquid chromatography (Nihon Bunseki Kogyo LC-08) with chloroform or column chromatography on silica gel with benzene–hexane to give cyclophane as shown also in Table 3.

The authors wish to express their deep thanks to the Material Analytical Center, ISIR, Osaka University, for measurements of NMR and MS spectra and microanalyses. They also wish to thank the Ministry of Education of Japan for their finacial support.

Chemical Studies on Products Obtained from Verdohemochrome IXα Dimethyl Ester by Treatment with Ammonia under Air

Setsuo SAITO* and Norihiro TAMURA†

Faculty of Pharmaceutical Sciences, Josai University, Keyakidai 1-1, Sakado, Saitama 350-02

†Department of Chemistry, Josai Dental University, Keyakidai 1-1, Sakado, Saitama 350-02

(Received May 25, 1987)

Verdohemochrome IXα dimethyl ester [bis(pyridine)iron(II) 5-oxaprotoporphyrin IX dimethyl ester] gave 5-azaprotohemin IX dimethyl ester (**2**) and six tripyrrin derivatives upon treatment with ammonia under air, followed by methylation. The reaction of **2** with concd HCl in acetic acid in the presence of ferrous sulfate, followed by methylation gave demetallated product, 5-azaprotoporphyrin IX dimethyl ester (**8**), accompanied by products obtained by the hydration and reduction of both or one of the vinyl groups of **8**. 8,12-Bis[2-(methoxycarbonyl)ethyl]-3,7,13-trimethyl-1-oxo-2-vinyltripyrrin-14-carbaldehyde, obtained as a major tripyrrin product by an oxidative degradation of **1**, gave a pyrromethene derivative, 3,7-bis[2-(methoxycarbonyl)ethyl]-2,8-dimethyl-1-methoxy-5-pyrromethene-9-carbaldehyde by the reaction with $Tl(OAc)_3$ under air. The structures of all products obtained in the present study were determined by spectral measurements.

In human beings and many animals, endogenous heme (protoheme IX) is oxidized by heme oxygenase at the α-position to eliminate the α-carbon bridge, resulting in cleavage of the porphyrin ring and formation of an open chain tetrapyrrolic compound, biliverdin IXα.[1] The latter is subsequently reduced to bilirubin IXα by biliverdin reductase.[2] Verdohemochrome IXα was postulated as being an intermediate in the reaction process.[3,4] Biliverdins are the final products in coupled oxidation, a term used by Lemberg et al.[3b] to describe an analogous reaction of heme in a pyridine solution in the presence of ascorbic acid under air.[5] Jackson et al.[6] and Bonnett et al.[7] observed the formation of the verdohemochromes by

Scheme 1.

oxygenation of the corresponding oxyporphyrins; their results, thus, supported Lemberg's proposal[5a] for the formation of verdohemochromes. Lagarias[8] and Hirota and Itano[9] elucidated the structure of octaethylhemochrome, which was obtained by the coupled oxidation of octaethylheme in pyridine, as bis(pyridine)iron(II) octaethyloxaporphyrin.

We previously prepared verdohemochrome IXα by the coupled oxidation of hemoglobin and myoglobin.[4] We recently synthesized verdohemochromes by ring closure of the corresponding biliverdins.[10] Verdohemochromes are particularly susceptible to oxidative attack at the *meso*-carbons[11] at which four pyrrole rings are linked to constitute the oxaporphyrin macrocycle. Furthermore, the oxonium bridge of verdohemochromes are easily subjected to hydrolysis to open the porphyrin ring, resulting in the formation of biliverdins.[12] On successive treatment with KOH–MeOH and excess mineral acid, verdohemochrome IXα undergoes hydrolysis and demetallation to give biliverdin IXα. This reaction is accompanied by autoxidation of the chromophore to give a small amount of pink compounds. It was thought that verdohemochrome IXα gave many degradation products because of its asymmetric structure. We previously reported the oxidative degradation of octaethylverdohemochrome, a symmetric molecule, as a model compound to obtain various tripyrrins.[13]

In this paper, the detailed spectral studies of 5-azaprotohemin IX dimethyl ester (**2**) are reported. Furthermore, the isolation and structural investigations of demetallation products obtained by the reaction of **2** with concd HCl in acetic acid in the presence of iron(II) sulfate, and those of tripyrrin derivatives obtained by oxidative degradation of verdohemochrome IXα dimethyl ester (**1**) in ammonia under air are reported. The degradation of tripyrrin (**21**) with thallium(III) acetate under air is also reported.

Results and Discussion

We previously reported the formation of 5-azaprotohemin IX dimethyl ester (**2**) in good yield by treatment of verdohemochrome IXα dimethyl ester (**1**) with ammonia under argon.[10] This reaction was accompanied by the formation of a small amount of impurities that appeared as pink spots on thin layer chromotography (TLC). In an attempt to increase the yield of the pink compounds, **1** was treated with ammonia under air. The reaction mixture showed, after methylation, six pink spots (products I—VI) and a greenish brown spot (product VII) on TLC (CH_2Cl_2–MeOH, 98:2, v/v). The all products were isolated by column chromatography and preparative high performance liquid chromatography (HPLC).

Product VII was identified as authentic 5-azaprotohemin IX dimethyl ester (**2**) by mixed TLC, HPLC, and electronic absorption spectrophotometry, and by the ^{1}H NMR spectrum of iron(II) 5-azaprotoporphyrin IX dimethyl ester obtained by reduction of **2** with $Na_2S_2O_4$.

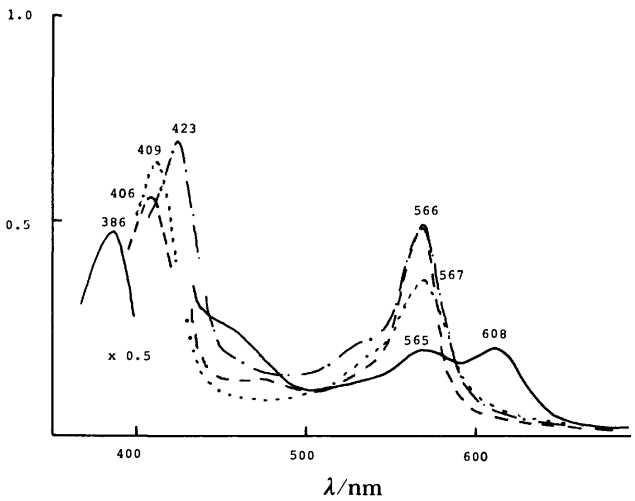

Fig. 1. Electronic absorption spectra. Spectra (1% pyridine–CH_2Cl_2, v/v) of 5-azaprotohemin IX dimethyl ester (**2**) (2.5×10^{-5} M), ——; bis(pyridine)iron(II) 5-azaprotoporphyrin IX dimethyl ester (**3**), – – –; carbon monoxide co-ordination complex (**4**), ····; bis(tosylmethyl isocyanide) complex (**5**), —·—·.

The electronic absorption spectrum of compound **2** in 1% pyridine–CH_2Cl_2 showed peaks at 386, 565, and 608 nm (Fig. 1). This spectrum was not changed by the addition of excess tosylmethyl isocyanide ($TsCH_2NC$) or by the introduction of carbon monoxide. The ^{1}H NMR spectrum of **2** in $CDCl_3$ showed broadened signals (Fig. 2a). These results indicate that the oxidation state of the central metal atom of **2** is Fe(III). This was also suggested from that the addition of sodium azide resulted in the spectrum of bis(azide)-iron(III) 5-azaprotoporphyrin IX dimethyl ester with maxima at 408 and 565 nm (the data was not shown). The addition of sodium dithionite resulted in the spectrum of iron(II) 5-azaprotoporphyrin IX dimethyl ester bis(pyridine) complex **3** with maxima at 406 and 566 nm (Fig. 1). Introduction of carbon monoxide into the solution of complex **3** produced iron(II) 5-azaprotoporphyrin IX dimethyl ester carbon monoxide complex **4**. Addition of excess $TsCH_2NC$ to the solutions of **3** and **4** resulted in the electronic spectrum of iron(II) 5-azaprotoporphyrin IX dimethyl ester bis($TsCH_2NC$) complex **5**, which was identified by FAB-mass spectrum data and elemental analysis as well as the ^{1}H NMR spectral data (Fig. 2b).

Demetallation of Compound 2. Various methods for the removal of iron from hemins are known.[13] Lemberg et al.[14] and Morell et al.[15] recommended the use of the iron(II) sulfate method as the mildest and most convenient method for the preparation of

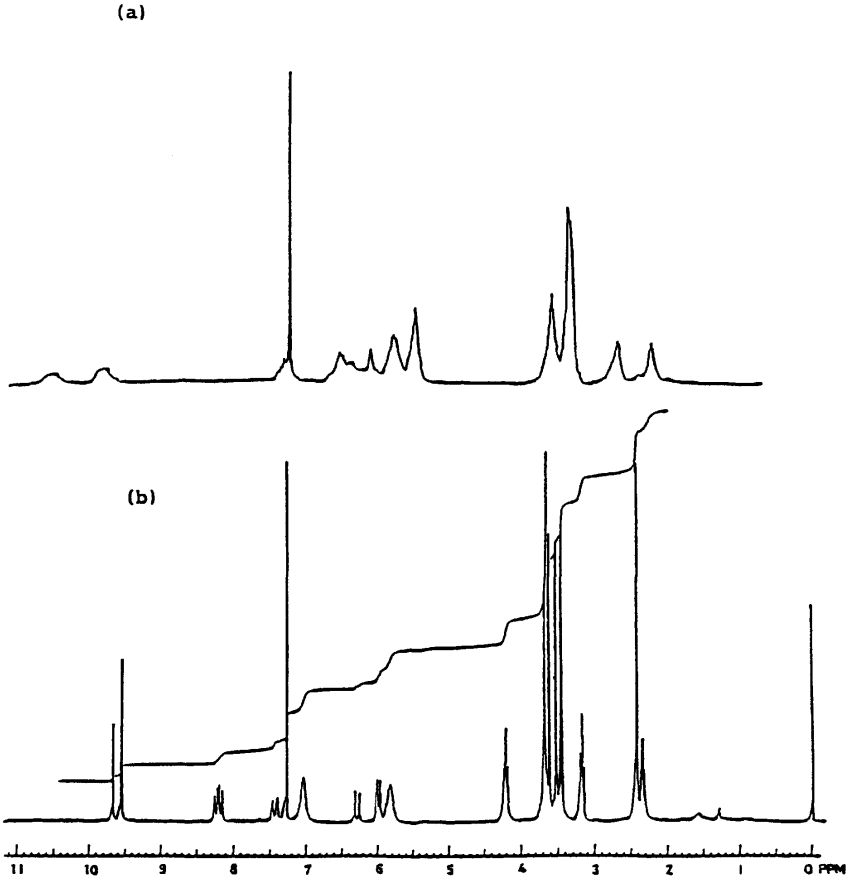

Fig. 2. 270 MHz FT ^{1}H NMR ($CDCl_3$). (a) 5-Azaprotohemin IX dimethyl ester (**2**), (b) Bis(tosylmethyl isocyanide)iron(II) 5-azaprotoporphrin IX dimethyl ester (**5**).

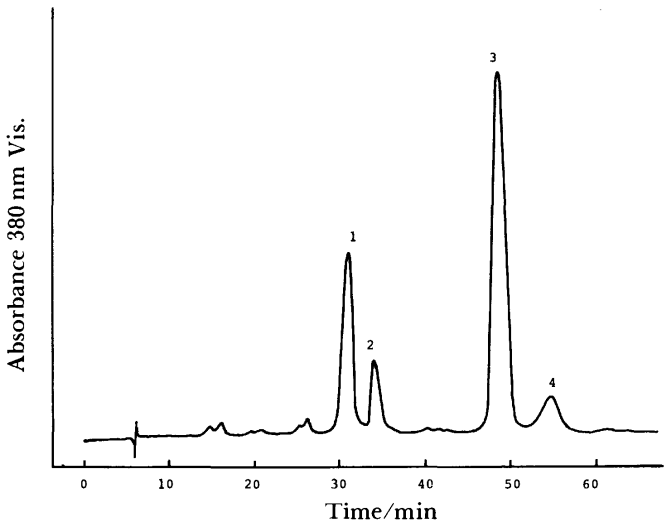

Fig. 3. High-performance liquid chromatogram of a reaction mixture obtained by the reaction of **1** with concd HCl in acetic acid in the presence of $FeSO_4$. Condition: column, SSC-ODS-H-4251, 10ϕX250 mm; mobile phase, benzene-MeOH (1:99, v/v); visible 380 nm; flow rate, 1.0 ml min^{-1}; chart speed, 0.5 cm min^{-1}.

protoporphyrin having a labile vinyl side chain. We previously reported that the removal of iron from octaethylazahemin **6** by treatment with concd HCl in acetic acid in the presence of iron(II) sulfate gave a single product, octaethylazaprophyrin (**7**), in good yield.[10] However, compound **2** gave a mixture composed for the most part of four azaporphyrin derivatives, **8**—**11**, by the same method. Figure 3 illustrates the separation of the four products by analytical HPLC with use of isocratic elution. The products were isolated by preparative HPLC.

All products **8**—**11** showed the proton signals of three *meso*-methine groups and two imino groups in their ^{1}H NMR spectra (Table 1). In addition, the major product **8** showed the proton signals of two vinyl groups. The FAB-mass spectrum of compound **8** showed a molecular ion peak at *m/z* 591. These results suggest that compound **8** is 13,17-bis[2-(methoxycarbonyl)ethyl]-3,8-divinyl-2,7,12,18-tetramethyl-5-azaporphyrin.

Product **9** showed the proton signals of two ethyl groups as well as those of three *meso*-methine groups and two imino groups, but no vinyl protons in its ^{1}H NMR spectrum. These results indicate that

compound **9** is 3,8-diethyl-13,17-di[2-(methoxycarbonyl)ethyl]-2,7,12,18-tetramethyl-5-azaporphyrin. This conclusion was supported by the FAB-mass spectrum, which showed a molecular ion peak at m/z 611.

Product **10** showed the proton signals of one vinyl group and one 1-hydroxyethyl group (-CH(OH)CH_3) as well as those of three *meso*-methine groups and two imino groups. The FAB-mass spectrum of **10** showed a molecular ion peak at m/z 609. These results indicate that one of two vinyl groups of compound **8** is hydrated to obtain compound **10a** or **10b** during demetallation. For an elucidation of the structure of compound **10**, chemical shifts of vinyl protons in

compound **10** were compared with those of porphyrin derivatives **5**, **8**, **12**, and **13** in the ^{1}H NMR spectra. In this discussion, all vinyl protons on both vinyl groups at C-3 and C-8 are lettered A—F (Table 1).

The porphyrin derivatives **5**, **8**, **12**, and **13** had two vinyl groups at C-3 and C-8. In the partial structure (Table 1), when the bridge-head atom X was nitrogen (N) or oxonium (O^+), the H_A protons (δ 7.42 in **5**, 7.45 in **8**, and 6.69 in **13**) had lower chemical shifts than the other terminal vinyl protons, H_B, H_D, and H_E (δ 6.0—6.4) (Table 1). When X was the methine group (CH), as in compound **12**, all terminal vinyl protons (H_A, H_B, H_D, and H_E) in **12** appeared at δ 6.1—6.3, close to the chemical shifts of H_B, H_D, and H_E protons of compounds **5**, **8**, and **13**. These results suggest that the H_A-proton on the vinyl group at C-3 in compounds **5**, **8**, or **13** is favorably located close to the adjacent hetero atom and appears at lower field in the ^{1}H NMR spectra. Compound **12** had no bridge-head hetero atom on the porphyrin ring, therefore all terminal vinyl protons (H_A, H_B, H_D, and H_E) of compound **12** resulted in similar shifts (δ 6.1—6.3). H_D and H_E protons of the vinyl group at C-8 of compounds **5**, **8**, and **13** were located too far from the bridge-head hetero atoms and the chemical shifts of those protons (δ 6.0—6.4) were close to those to the terminal vinyl protons (H_A, H_B, H_D, and H_E) (δ 6.1—6.3) of compound **12**. In the ^{1}H NMR spectrum of compound **10** which had one vinyl group, two terminal vinyl protons appeared at δ 6.40 and 6.18, close to the chemical shifts of the terminal vinyl protons (H_D, δ 6.35 and H_E, 6.13) on the vinyl group at C-8 of compound **8**. Therefore the terminal vinyl protons appeared at δ 6.40 and 6.18 were assignable to H_D and H_E proton, respectively, on the vinyl group at C-8 of compound **10a**. These results suggest that compound **10** is 13,17-bis[2-(methoxycarbonyl)ethyl]-3-(1-hydroxyethyl)-2,7,12,18-tetramethyl-8-vinyl-5-azaporphyrin (**10a**).

Product **11** showed the proton signals of the 1-hydroxyethyl group and the ethyl group, but not those of the vinyl group. Either structure **11a** or structure **11b** was assignable to compound **11**. Though the exact structure of compound **11** was not determined, structure **11a** seems more likely because the vinyl group at C-3 in compound **8** would be more readily hydrated than that at C-8.

Scheme 2.

Table 2. Electronic Absorption Spectra of 5-Azaporphyrins in CH_2Cl_2

Compound	λ_{max}/nm (ε_{mM})					
	Soret band	V	IV	III	II	I
8	389(138.0)	517(11.5)	548(25.7)	570(12.5)	625(26.8)	670(10.8)
9	381(151.5)	509(9.7)	540(24.4)	562(10.6)	616(25.4)	661(11.1)
10	375(145.2)	500(8.4)	534(25.7)	560(10.3)	610(25.2)	651(3.3)
11	376(142.6)	502(9.1)	535(26.4)	559(9.3)	611(25.9)	650(1.2)

in CH_2Cl_2 are listed in Table 2. All spectra showed five satellite bands, numbered I to V, as well as Soret band, respectively. The molar extinction of each band decreased with decrease in number of vinyl groups. Hypochromic shifts in the Soret bands (389→381→375 and 376 nm) corresponded to the number of vinyl groups, two in **8**, one in **10**, and none in **9** and **11**. Similar hypochromic shifts were observed in bands I—V. The extinction coefficients of band II and IV were greater than those of bands I, III, and V in all spectra. The extinction coefficients of band I of compounds **9** and **11**, which had no vinyl group, were especially small.

Preparation of Zinc Azaporphyrin (14). Iron azaprotoporphyrin complex **2** was easily obtained from the corresponding verdohemochrome **1** by treatment with ammonia. However, the reaction of zinc 5-oxaprotoporphyrin dimethyl ester **13** with ammonia, followed by methylation, gave only an open chain tetrapyrrole compounds, biliverdin IXα dimethyl ester **15**,[10,16,17] by hydrolysis but not zinc azaporphyrin complex **14**. Zinc 5-azaprotoporphyrin IX dimethyl ester **14** was prepared by the reaction of azaprotoporphyrin IX dimethyl ester **8** with $Zn(OAc)_2$ in methanol. The ^1H NMR spectra (Table 1) of the zinc complex **14** was similar to that of **8**; the H_A-proton (δ 7.40) was shifted to lower field than the other terminal vinyl protons (H_B, H_D, and H_E) (δ 6.11—6.34). The FAB-mass spectrum showed fragment ion peaks at *m/z* 653, 655, and 657, which correspond to the cations $C_{35}H_{35}N_5O_4{}^{64}Zn^+$, $C_{35}H_{35}N_5O_4{}^{66}Zn^+$, and $C_{35}H_{35}N_5O_4{}^{68}Zn^+$, respectively.

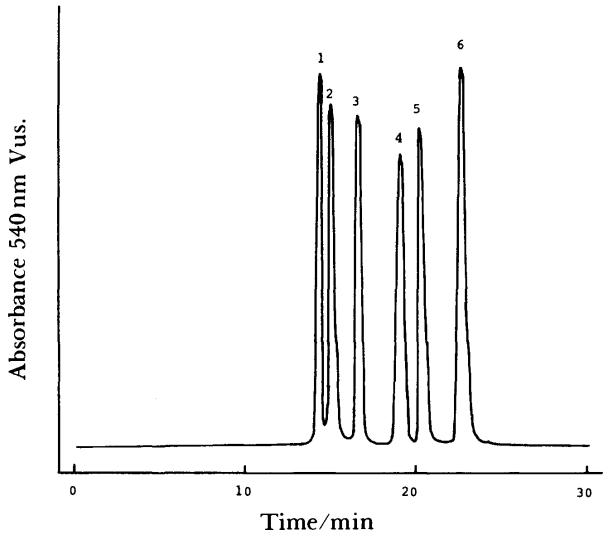

Fig. 4. High-performance liquid chromatogram of the degradation products. Condition: column, LiChrosorb SI-60, 4.6ϕ×250 nm; mobile phase, CH_2Cl_2-MeOH, 97.5:2.5 (v/v); visible, 540 m,; flow rate, 1.0 ml min^{-1}; chart speed, 0.5 cm min^{-1}. Injection was at time zero. Peak 1, **16**; 2, **17**; 3, **18**; 4, **20**; 5, **19**; 6, **21**.

Structures of Tripyrrins 16—21. Products (I—VI) were isolated by column chromatography and preparative HPLC. Figure 4 shows HPLC chromatogram for the isolated products (I—VI). The products (I—VI) showed the proton signals of two methine groups, three methyl groups, two 2-(methoxycarbonyl)ethyl groups, and one vinyl group in their ^1H NMR spectra (Table 3). These results indicate that the products (I—VI) are tripyrrin derivatives which are derived by the loss of one of the terminal pyrrole rings from the tetrapyrrole derivatives, verdohemochromes and biliverdins by oxidative degradation.[18,19] In addition to these signals, products I and II showed the singlet of the methoxycarbonyl group (δ 3.98 in I and 3.98 in II, respectively). The EI mass spectra of both I and II showed molecular ion peaks at *m/z* 535 (relative intensity: 38.4% in I and 92.7% in II, respectively). These results suggest that products I or II is either of the two tripyrrins (**16** or **17**).

Products III and V showed the proton signals of the dimethyl acetal group [δ 5.61 (-C<u>H</u>$(OCH_3)_2$) and 3.38 (-CH$(OC\underline{H}_3)_2$) in III, and 5.61 (-C<u>H</u>$(OCH_3)_2$ and 3.38 (-CH$(OC\underline{H}_3)_2$) in V, respectively] as well as those of

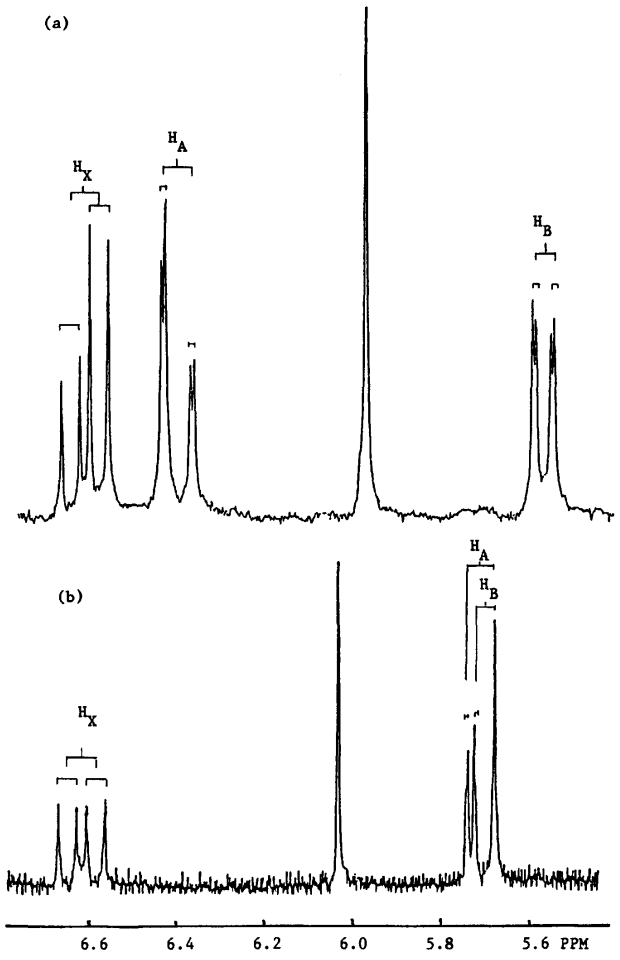

Fig. 5. Partial ^1H NMR spectra (downfield) of compounds **16** and **17**. (a), **16**; (b), **17**.

two *meso*-methine groups, two 2-(methoxycarbonyl)-ethyl groups, and one vinyl group in their ^{1}H NMR spectra. These results suggest that product III or V is either of the two tripyrrins **18** or **19**. This conclusion was also suggested by the EI mass spectra of III and V, which showed molecular ion peak at *m/z* 551.

The ^{1}H NMR spectra of products IV and VI showed the proton signals of the aldehyde group (δ 9.83 in IV and 9.82 in VI, respectively) as well as those of two *meso*-methine groups, two 2-(methoxycarbonyl)ethyl groups, and one vinyl group. The EI mass spectra of IV and VI showed molecular ion peak at *m/z* 505. These results suggest that product IV or VI is either of two tripyrrins **20** or **21**.

The exact structures of these products **16—21** were elucidated by comparing the chemical shifts of the vinyl protons of the products **16—21** with those of porphyrin derivatives **5**, **8**, and **13**, and those of biliverdin derivatives **15**, and **22—24** in the ^{1}H NMR spectra (Tables 3 and 4, and Fig. 5). As mentioned

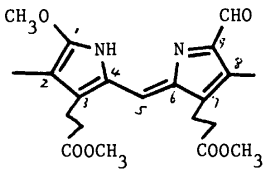
(24)



(27)

Scheme 3.

above, porphyrins **5**, **8**, and **13** have two vinyl groups at C-3 and C-8. The H_A-protons on the vinyl groups at C-3 in compounds **5**, **8**, and **13** appeared at lower field than the other terminal vinyl protons (H_B on vinyl group at C-3, and H_D and H_E on vinyl group at C-8). This conclusion will be applied to the assignment of the vinyl groups of biliverdins **15** and **22**—**24**.

Rasmussen et al.[17] reported the ^{1}H NMR spectra of four biliverdin dimethyl ester isomers **15** and **22**—**24**, of the IX series, but did not report detailed assignment of the vinyl protons. All vinyl groups of compounds **23** and **24**, and the vinyl groups at C-3 of **15** and at C-13 of **22** were located apart from the carbonyl groups of the terminally located pyrrole rings; all terminal vinyl protons (H_A and H_B in Table 4) of these vinyl groups appeared at δ 5.38—5.66. On the other hand, the protons marked with an asterisk (*) on the vinyl group at C-18 of **15** and that at C-18 of **22** were located close to the carbonyl groups (at C-19). These protons (H*) of **15** and **22**, therefore, appeared at lower fields (δ 6.12) in the ^{1}H NMR spectra of these compounds (Table 4).

Six tripyrrin derivatives **16**—**21** were divided into two groups (A and B) (Table 5) by comparison of the chemical shifts of the terminal vinyl protons (H_A and H_B) in their ^{1}H NMR spectra (Table 3). Figure 6 showed the partial ^{1}H NMR spectra (downfield) of compounds **16** and **17**. A comparison of the spectra shows the H_A-proton at a lower field (δ 6.39) than the H_B-proton (δ 5.56) in compound **16**. On the other hand, both the H_A and H_B protons of **17** showed nearly the same chemical shift at δ 5.71 and 5.70, respectively. The results indicate that the vinyl group of compound **16** is located close to the carbonyl group at C-1, and that the vinyl group of compound **17** is located at C-3 at a greater distance from the carbonyl group. Therefore, products I and II are identified as 14-methoxycarbonyl-8,12-bis[2-(methoxycarbonyl)-ethyl]-3,7,13-trimethyl-2-vinyltripyrrin-1-one (**16**) and 14-methoxycarbonyl-8,12-bis[2-(methoxycarbonyl)ethyl]-2,7,13-trimethyl-3-vinyltripyrrin-1-one (**17**), respec-

tively.

The same comparisons were done between products III and V, and also between IV and VI. The H_A-protons of products III and V appeared at lower fields (δ 6.35 in III and 6.54 in V, respectively). H_A-protons of V and VI were observed at δ 5.69 in IV and 5.70 in VI, respectively; these chemical shift values were close to those of the H_B-protons (δ 5.68 in IV and 5.69 in VI). Thus, products III—VI were identified as 8,12-bis[2-(methoxycarbonyl)ethyl]-3,7,13-trimethyl-1-oxo-2-vinyltripyrrin-14-carbaldehyde dimethyl acetal (**18**), 8,12-bis[2-(methoxycarbonyl)ethyl]-3,7,13-trimethyl-1-oxo-2-vinyltripyrrin-14-carbaldehyde (**20**), 8,12-bis[2-(methoxycarbonyl)ethyl]-2,7,13-trimethyl-1-oxo-3-vinyltripyrrin-14-carbaldehyde dimethyl acetal (**19**), and 8,12-bis[2-(methoxycarbonyl)-ethyl]-2,7,13-trimethyl-1-oxo-3-vinyltripyrrin-14-carbaldehyde (**21**), respectively. Compounds **16**, **18**, and **20** in group A (Table 5) accordingly were products of the loss of pyrrole ring B from compound **1** by oxidation degradation, and compound **17**, **19**, and **21** were products of the loss of ring A from **1**.

The electronic absorption spectra of compounds **16**—**21** are listed in Table 6. In comparisons of the spectra of compounds in group A with those of compounds in group B (Tables 5 and 6), individual bands of compound **16** had higher wavelength by 5—6 nm than the corresponding bands of compound **17**, 543, 509, 475sh, and 327 nm in **16** and 537, 504, 470sh, and 322 nm in **17**. The same results were obtained

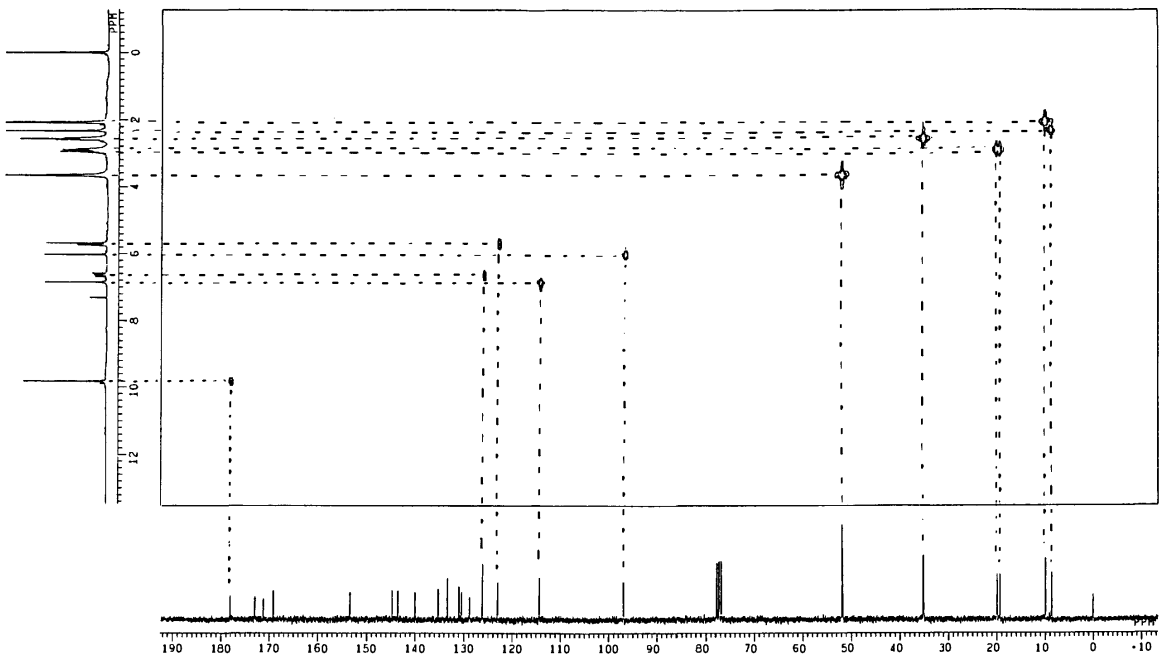

Fig. 6. Two dimensional (^1H-^{13}C) NMR spectrum of **21**.

between **18** and **19**, and between **20** and **21**.

The ^{13}C NMR spectra of compounds **20** and **21**, which were major products by oxidative degradation of **1**, are given in Table 7. The carbon signals were assigned by the single pulse hetero decoupling method (with NOE) and by the two dimentional (^1H-^{13}C) NMR spectra (the 2D NMR spectrum of **21** is shown in Fig. 6).

Degradation of Compound 1 on TLC under Air. Verdohemochrome IXα dimethyl ester **1** showed a single band at R_f 0.53 on preparative TLC (CH_2Cl_2–MeOH, 9:1, v/v). When the TLC plate was allowed to stand for a week under air, the color of the green band changed to pink. The band was scraped off and extracted. The extracts showed two major spots (R_f 0.36 and 0.32) and two minor spots (R_f 0.06 and 0.04) on TLC (CH_2Cl_2–MeOH, 98:2, v/v). The major products with R_f 0.36 and 0.32 were identified as compounds **20** and **21**, respectively, by mixed TLC, HPLC, and ^1H NMR spectra. The minor products with R_f 0.06 and 0.04 were unstable. The products showed the ^1H NMR spectra similar to those of **20** and **21**, respectively, except for absence of the signal of the methoxyl methyl proton. After methylation, the product with R_f 0.06 gave compound **20**, and that with R_f 0.04 gave compound **21**. These results suggest that the minor products with R_f 0.06 and 0.04 on TLC are compounds **25** and **26**, respectively.

Oxidative Degradation of 8 with Tl(OAc)$_3$. We previously reported the oxidative degradation of octaethylbiliverdin with thallium(III) acetate under air.[18] Further oxidation of the major tripyrrin derivative **21** was studied. The mixture obtained by the reaction of **21** with $Tl(OAc)_3$ in CH_2Cl_2–MeOH (9:1) under air showed two yellow spots (R_f 0.42 and 0.31) on TLC (benzene–acetone, 9:1, v/v). The compound with R_f 0.42 was isolated by column chromatography, but the compound with R_f 0.31 was so unstable that its isolation was unsuccessful. The ^1H NMR spectrum of the compound with R_f 0.42 on TLC showed the proton signals of an aldehydo group (δ 9.68) and a metoxyl group (δ 4.13) as well as those of two 2-(methoxycarbonyl)ethyl groups and two methyl groups but no vinyl group. The EI mass spectrum showed a molecular ion peak at m/z 402 and fragment ion peaks at m/z 387 (M^+-CH_3), 371 (M^+-OCH_3), and 343 ($M^+-COOCH_3$). These results suggest that the product is 3,7-bis[2-(methoxycarbonyl)ethyl]-2,8-dimethyl-1-methoxy-5-pyrromethene-9-carbaldehyde (**27**).

Thus, tripyrrin derivatives **16**—**21** were easily obtained from verdohemochrome IXα dimethyl ester **1** by oxidative degradation. Tripyrrin **21** was also oxidatively degraded to produce pyrromethene derivative **27**. Schaefer et al.[20] reported that cytochrome P-450 and free ferriprotoporphyrin IX were destroyed to obtain propentdyopents (dipyrrole derivatives) by NADPH-P-450 reductase in the presence of NADPH and O_2. In the present study, though the product **27** obtained by the reaction of tripyrrin **21** with $Tl(OAc)_3$ under air is different from those obtained by Shaefer et al. because of the difference of the reaction methods, the possibility of the presence of new metabolic path way for heme, heme→verdohemochrome→tripyrrins→dipyrrole derivatives, is offered.

Experimental

Materials. Verdohemochrome IXα dimethyl ester (**1**) was obtained by the method of Saito and Itano.[4] All chemicals and solvents were of reagent grade and were obtained from commercial sources.

Measurements. Electronic absorption spectra were recorded with a Hitachi Model 100-50 spectrophotometer. EI and FAB mass spectra were obtained with JEOL JMS-DX 300 mass spectrometer. High resolution mass spectra were obtained with JEOL OISG-2 mass spectrometer. ^1H NMR spectra at 270 MHz and ^{13}C NMR spectra at 67.8 MHz of samples in $CDCl_3$ solution containing Me_4Si were recorded with a JEOL JNM-GX 270 FT NMR spectrometer. The Shimadzu LC-6A liquid chromatograph, equipped with a Shimadzu system controller SCL-6A, a Shimadzu SPD-6AV UV-VIS spectrophotometric detector, and a Shimadzu C-R3A Chromatopac, were used for analytical high-performance liquid chromatography (HPLC), and were further equipped with an SSC autoinjector 6310 and an SSC fraction collector 6320 (Senshu Scientific Co. LTD.) for preparative HPLC. Analytical thin layer chromatography (TLC) and preparative TLC were performed on DC-Alufolien Kieselgel 60 HF_{254} (Merck) and Kieselgel 60 HF_{254} (Merck), respectively. Wacogel C-200 was used for column chromatography. Melting points were determined with a Yanako micro melting apparatus.

Reaction of 1 with Ammonia. Verdohemochrome IXα dimethyl ester (**1**) (460 mg, 502 μmol) was dissolved in the solution of pyridine (5 ml) and concd ammonia (50 ml) and allowed to stand under air overnight. The reaction mixture was poured into ice water (100 ml) and extracted with CH_2Cl_2 (150 ml×3). The combined organic extracts were washed with H_2O, dried over Na_2SO_4, and filtered. The filtrate was dissolved in 5% H_2SO_4–MeOH (150 ml) and allowed to stand overnight. The reaction mixture was poured into ice water (200 ml) and extracted with CH_2Cl_2 (200 ml×3). The combined organic extracts were washed with H_2O, dried over Na_2SO_4, and filtered. The filtrate was evaporated to give a residue which showed six pink spots (I, R_f 0.49; II, 0.44; III, 0.41; IV, 0.38; V, 0.34; and VI, 0.30) and a greenish brown spot (VII, 0.07) on TLC (CH_2Cl_2–MeOH, 98:2, v/v). The residue was dissolved in CH_2Cl_2 (5 ml) and subjected to column chromatography (CH_2Cl_2–MeOH, gradient up to 10%, v/v). Product VII was isolated, and products I—VI were partially purified. The partially purified products were subjected to preparative HPLC (LiChrosorb SI-60, 10φ, 250 mm, solvent system: CH_2Cl_2–MeOH, 97.5:2.5, v/v).

Product VII, yield 93.3 mg, 27.3%, was identified as 5-azaprotohemin IX dimethyl ester (**2**) by mixed TLC and electronic absorption spectrum, and the ^1H NMR spectrum of iron(II) bis(tosylmethyl isocyanide)-5-azaprotoheme IX dimethyl ester derived from **2** by the method of Saito and Itano.[10]

Product I: Yield 8 mg (3.0%), EI MS (70 eV) *m/z* (rel intensity) 535 (M^+, 38.4), 504 (M^+-OCH_3, 9.5), 503 (M^+-HOCH_3, 11.3), 462 (12.0), 448 (5.4), 444 (11.3), 430 (15.5), 416 (10.8), 388 (6.0), 239 (13.3), 237 (9.5), 234 (8.4), 235 (7.1), 183 (10.0), 178 (19.6), 85 (13.1), 83 (11.1), 71 (16.2), 69 (13.4), 57 (32.5), 44 (41.1), 43 (26.9), 32 (24.2), 28 (100). Found: *m/z* 535.2326. Calcd for $C_{29}H_{33}N_3O_7$: M, 535.2316.

Product II: Yield 15 mg (5.6%), EI MS (70 eV) *m/z* (rel intensity) 535 (M^+, 92.7), 504 (M^+-OCH_3, 22.5), 503 (M^+-HOCH_3, 9.5), 476 ($M^+-COOCH_3$, 6.6), 462 (13.9), 449 (10.0), 448 (33.8), 444 (20.0), 430 (19.9), 416 (28.0), 388 (14.8), 375 (11.0), 165 (8.9), 57 (11.4), 43 (9.6), 32 (18.5), 28 (100). Found: *m/z* 535.2303. Calcd for $C_{29}H_{33}N_3O_7$: M, 535.2316.

Product III: Yield 16 mg (5.8%), EI MS spectrum *m/z* (rel intensity) 551 (M^+, trace), 368 (5.1), 279 (5.6), 149 (22.8), 127 (6.4), 125 (7.2), 114 (6.7), 111 (12.9), 99 (11.9), 97 (22.5), 86 (62.0), 84 (79.9), 44 (100). Found: *m/z* 551.2631. Calcd for $C_{30}H_{37}N_3O_7$: M, 551.2629.

Product V: Yield 26 mg (9,4%), EI MS (70 eV) *m/z* (rel intensity) 551 (M^+, 5.5), 491 (5.0), 368 (6.0), 300 (9.0), 124 (5.1), 115 (12.3), 124 (17.4), 100 (41.9), 96 (35.9), 86 (17.3), 84 (22.3), 72 (96.4), 44 (48.1), 43 (100). Found: *m/z* 551.2625. Calcd for $C_{30}H_{37}N_3O_7$: M, 551.2629.

Product IV: Yield 32 mg (12.6%), EI MS (70 eV) *m/z* (rel intensity) 505 (M^+, 5.5), 418 (10.5), 358 (6.3), 181 (7.2), 148 (11.0), 136 (5.2), 122 (6.8), 108 (11.7), 94 (9.7), 57 (5.0), 44 (22.9), 43 (5.6), 32 (23.0), 28 (100). Found: *m/z* 505.2209. Calcd for $C_{28}H_{31}N_3O_6$: M, 505.2211.

Product VI: Yield 75 mg (29.6%), EI MS (70 eV) *m/z* (rel intensity) 505 (M^+, 60.4), 474 (10.0), 446 (5.3), 432 (22.5), 418 (26.1), 358 (10.8), 345 (6.6), 330 (8.9), 313 (5.5), 300 (5.0), 225 (6.1), 57 (13.6), 44 (14.0), 43 (8.9), 32 (20.6), 28 (100). Found: *m/z* 505.2215. Calcd for $C_{28}H_{31}N_3O_6$: M, 505.2211.

Demetallation of 2. To a solution of compound **2** (85 mg) in pyridine (1 ml) and acetic acid (30 ml), a solution of $FeSO_4$ (80 mg) in concd HCl (1 ml) was added under argon, and the reaction mixture was allowed to stand for 30 min. The reaction mixture was poured into ice water (50 ml) and extracted with CH_2Cl_2 (50 ml×3). The combined organic extracts were washed with water, dried over Na_2SO_4, and filtered. The filtrate was evaporated to give a residue which was dissolved in 5% H_2SO_4–MeOH (200 ml) and allowed to stand overnight. The mixture was poured into ice water (300 ml) and extracted with CH_2Cl_2 (150 ml×3). The combined organic extracts were washed with water, dried over Na_2SO_4, and filtered. The filtrate was evaporated to give a residue which was subjected to preparative HPLC (column: SSC-ODS-H-4251, 10ϕ, 250 mm; solvent system: 1% benzene–MeOH) to isolate compounds **8**—**11**. All products **8**—**11** had melting points over 300 °C.

Compound **8**: yield 33.5 mg (47.3%), FAB MS *m/z* 591 (100%). Found: C, 70.93; H, 6.31; N, 11.59%. Calcd for $C_{35}H_{37}N_5O_4$: C, 71.05; H, 6.30; N, 11.84%.

Compound **9**: yield 6.1 mg (8.6%), FAB MS *m/z* 595 (100%). Found: C, 70.47; H, 6.96; N, 11.69%. Calcd for $C_{35}H_{41}N_5O_4$: C, 70.56; H, 6.94; N, 11.76%.

Compound **10**: yield 3.4 mg (4.8%), FAB MS *m/z* 609 (100%). Found: C, 69.02; H, 6.41; N, 11.38%. Calcd for $C_{35}H_{39}N_5O_5$: C, 68.95; H, 6.45; N, 11.49%.

Compound **11**: yield 7.9 mg (10.7%), FAB MS *m/z* 611 (100%). Found: C, 68.85; H, 6.75; N, 11.22%. Calcd for $C_{35}H_{41}N_5O_5$: C, 68.72; H, 6.76; N, 11.45%.

Reaction of 13 with Ammonia. Compound **13** (20 mg) was dissolved in pyridine (1 ml) and concd aqueous ammonia (30 ml) under argon. The mixture was allowed to stand overnight, poured into ice water (150 ml), and extracted with CH_2Cl_2 (150 ml×3). The combined organic extracts were washed with water, dried over Na_2SO_4, and filtered. The filtrate was evaporated to give a residue which was dissolved in 5% H_2SO_4–MeOH (100 ml) and allowed to stand overnight. The reaction mixture was poured into ice water (200 ml) and extracted with water, dried over Na_2SO_4, and filtered. The filtrate was evaporated to give a residue which was subjected to column chromatography (benzene–acetone, gradient up to 5%) to obtain biliverdin IXα dimethyl ester (**15**), which was identified by TLC, mass spectrum, and ^1H NMR spectrum. No azaporphrin derivative was obtained by this reaction.

Preparation of 14. To a solution of compound **8** (12 mg) in CH_2Cl_2 (5 ml), a solution of zinc acetate (20 mg) in MeOH (10 ml) was added and warmed at 60 °C for 30 min. The solvent was evaporated, and the resulting residue was dissolved in CH_2Cl_2 (10 ml) and filtered and washed with CH_2Cl_2 (10 ml×3). The combined filtrates were evaporated to obtain a residue which was subjected to column chromatography (CH_2Cl_2–MeOH, gradient up to 5%) to isolate compound **14**. Found: C, 63.99; H, 5.41; N, 10.43%. Calcd for $C_{35}H_{35}N_5O_4Zn$: C, 64.13; H, 5.38; N, 10.68%. λ_{max} (CH_2Cl_2) nm (ε_{mM}) 588 (31.7), 547 (8.4), and 406 (87.1).

Iron(II) Bis(tosylmethyl isocyanide)-5-azaprotoporphyrin IX Dimethyl Ester (5). To a solution of **2** (17 mg) in pyridine (5 ml) and CH_2Cl_2 (20 ml), a solution of sodium dithionite (30 mg) in H_2O (1 ml) was added. The solution was vigorously shaken, and the mixture was washed with H_2O (20 ml×2), dried over Na_2SO_4, and filtered. The filtrate was added with pure $TsCH_2NC$ (25 mg) and subjected to column chromatography (CH_2Cl_2) to obtain compound **5**. Yield 17.5 mg (60.6%). Found: C, 61.05; H, 5.27; N, 9.14%. Calcd for $C_{53}H_{53}N_7O_8S_2Fe$: C, 61.44; H, 5.16; N, 9.46%.

Autoxidation of 1 on TLC. Compound **1** (150 mg) was dissolved in CH_2Cl_2 (1 ml) and chromatographed by prep. TLC (CH_2Cl_2–MeOH, 9:1, v/v). After development, the TLC plate was allowed to stand for a week under air at room temperature. The colored band was scraped off and extracted with CH_2Cl_2–MeOH (9:1, v/v). The extract was evaporated to give a residue, which was subjected to column chromatography (CH_2Cl_2–MeOH, gradient up to 10%) to obtain major product **20** (15.2 mg, 18.4%) and **21** (23.1 mg, 27.9%), and two minor products **25** (4.0 mg, 5.0%) and **26** (7.3 mg, 9.1%). The major porducts were identified with compounds **20** and **21**, respectively, by mixed TLC, HPLC, and ^1H NMR spectra. Though the minor products **25** and **26** were unstable, their ^1H NMR spectra were obtained. ^1H NMR ($CDCl_3$) of **25** δ=11.23—10.50 (2H, exchangeable with D_2O), 9.40 (1H, NH, exchangeable with D_2O), 6.84 (1H, s, *meso*-H), 6.59 (1H, dd, J=17.8 and 11.1 Hz, H_X), 6.38 (1H, dd, J=17.8 and 2.1 Hz, H_A), 5.96 (1H, s, *meso*-H), 5.55 (1H, dd, J=11.6 and 2.1 Hz, H_B), 3.67 and 3.65 (each 3H, s, $COOCH_3$), 2.96 (4H, >-CH_2-×2), 2.55 (4H, -CH_2CO-×2), 2.32, 2.18, and 2.07 (each 3H, s, CH_3). ^1H NMR ($CDCl_3$) of **26** δ=11.20—10.00 (2H, exchangeable with D_2O), 9.45 (1H, exchangeable with D_2O), 6.84 (1H, s, *meso*-H), 6.65 (1H, dd, J=17.8 and 11.0 Hz, H_X), 6.05 (1H, s, *meso*-H), 5.66 (1H, dd, J=17.8 and 1.4 Hz, H_A), 5.67 (1H, dd, J=11.0 and 1.4 Hz, H_B), 3.67 and 3.65 (each 3H, s, $COOCH_3$), 2.95 (4H,

$\gtrless$-CH_2-×2), 2.56 (4H, -CH_2CO-×2), 2.28, 2.07, and 2.04 (each 3H, s, CH_3).

Reaction 21 with Tl(OAc)$_3$. To a solution of **21** (50 mg) in CH_2Cl_2 (45 ml), a solution of thallium(III) acetate sesquihydrate (41 mg) in MeOH (5 ml) was added under air. The reaction mixture was poured into ice water (100 ml) and extracted with CH_2Cl_2 (100 ml×3). The combined organic extracts were washed with H_2O, dried over Na_2SO_4, and filtered. The filtrate was evaporated to obtain a residue which showed two yellow spots (R_f 0.42 and 0.31, benzene–acetone, 9:1, v/v). The residue was subjected to column chromatography to isolate the product **27** (22.7 mg, 57.0%) with R_f 0.42. The product with R_f 0.31 was so unstable that it could not be isolated. EI MS (70 eV) *m/z* (rel intensity) 402 (M^+, 100), 387 (14.7), 371 (17.3), 343 (16.5), 330 (8.6), 329 (38.8), 316 (10.1), 315 (47.4), 314 (25.7), 313 (61.8), 287 (8.0), 285 (8.8), 281 (7.3), 225 (11.9). λ_{max} (CH_2Cl_2) (ε_{mM}) 421 (30.1), 401 (27.8), and 380sh (16.0). ^{1}H NMR ($CDCl_3$) δ=11.75 (1H, NH, exchangeable with D_2O), 9.68 (1H, CHO), 6.45 (1H, s, *meso*-H), 4.13 (3H, s, $\gtrless$-OCH_3), 3.68 and 3.65 (each 3H, s, $COOCH_3$), 2.90 and 2.85 (each 2H, t, J=7.7 Hz, $\gtrless$-CH_2–), 2.55 and 2.52 (each 2H, t, J=7.7 Hz, -CH_2CO–), 2.31 and 1.91 (each 3H, s, CH_3). Found: *m/z* 402.1777. Calcd for $C_{21}H_{26}N_2O_6$: M, 402.1790.

Utilization of Sulfide, Sulfoxide, and Sulfone Groups as Regiochemical Control Elements in the Diels-Alder Reaction of Naphthoquinones

Masatomo Iwao* and Tsukasa Kuraishi
Department of Chemistry, Faculty of Liberal Arts, Nagasaki University,

(Received May 27, 1987)

The Diels-Alder reactions of 2-phenylthio-, 2-phenylsulfinyl-, and 2-phenylsulfonyl-1,4-naphthoquinones, which were unsymmetrically substituted by methoxyl group on the benzenoid ring, with some vinylketene acetals were studied. The regioselectivity of the reactions was cleanly controlled by each of these sulfur substituents. In addition, the reactivity of the naphthoquinones were greatly enhanced by introduction of the sulfone or sulfoxide group. As a result of this study, several anthraquinones including natural products, such as pachybasin and phomarin 6-methyl ether, and 11-deoxyanthracyclinones were efficiently synthesized.

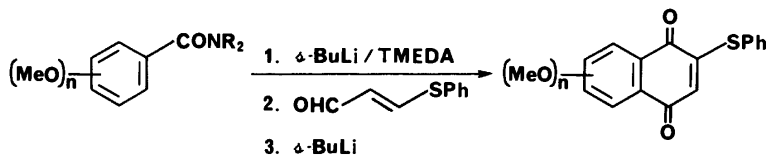
The Diels-Alder reaction of naphthoquinone derivatives with a variety of polarized dienes has been regarded as one of the most efficient methods for the synthesis of highly substituted anthraquinones[1] and tetracyclic anthracyclinone systems.[2] The regioselectivity of this reaction has been proved to be controlled by several factors in the naphthoquinone moiety, such as intramolecular hydrogen bonding between peri hydroxyl group and quinone carbonyl,[3] resonance effect of oxygen functionalities on the benzenoid ring,[3,4] and inductive effect of halo substituents (Cl, Br) on the quinonoid ring.[1,2] Of these, the directing priority of the halo substituents seems to be the highest and consequently they have been employed most widely as regiochemical control elements of the reactions. However, it is sometimes difficult[5] to synthesize pure halonaphthoquinones regiospecifically in a few steps, except by the Diels-Alder approaches developed independently by Brassard[1c,f] and Cameron[1b,g,h]. Therefore, it is desirable to devise new directing groups which may be readily and regiospecifically introduced into the quinonoid ring.

Recently, we have developed[6] a regiospecific one-pot synthesis of 2-phenylthionaphthoquinones from substituted tertiary benzamides using directed lithiation strategy (Scheme 1). We expected that the phenylthio group in these quinones could excert a powerful regiochemical controlling effect for the Diels-Alder reaction by its conversion into the corresponding electron-withdrawing sulfoxide or sulfone groups. Boeckman et al.[3,7] were the first to examine the Diels-Alder reaction of this type of quinone, namely, tolylsulfinyljuglones, with isoprene or the diene derived from 7,7-dimethoxybicyclo-[4.2.0]oct-1(6)-en-2-one, and observed modest regioselectivities. In addition, Kraus and Woo[8] reported recently on a similar reaction using several different types of dienes but did not pursue regiochemical studies. In this paper, we describe the regioselective Diels-Alder reaction of naphthoquinone sulfoxides **2a—c**, sulfones **3a—c**, and sulfides **1a—c** with the vinylketene acetals **5**, **6**, **26**, and isoprene (**33**).

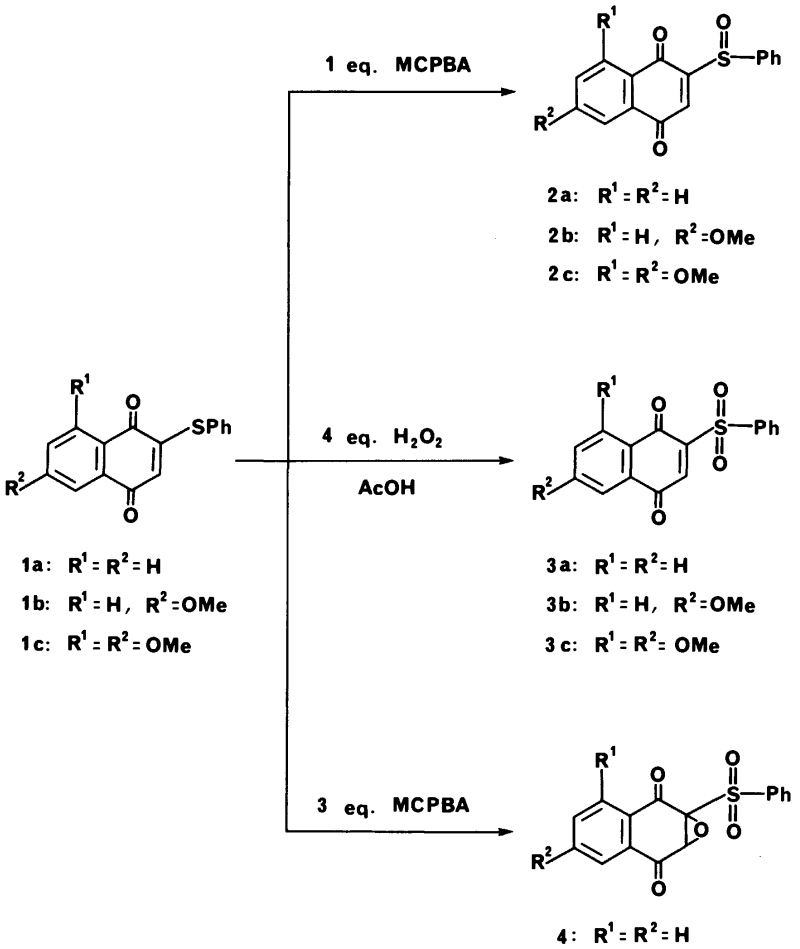
Results and Discussion

The sulfoxides **2a—c** were easily prepared in good yields from the corresponding sulfides **1a—c** by treatment with 1 equivalent of *m*-chloroperbenzoic acid (MCPBA)[3] in chloroform at 0 °C. However, the corresponding sulfone could not be obtained by MCPBA oxidation. Thus, TLC indicated that treatment of **1a** with 2 equivalents of MCPBA did not produce the sulfone **3a**, but a mixture of **1a**, **2a**, **4**, and another unidentified product. The epoxy sulfone **4** was obtained in good yield by treatment of **3a** with 3 equivalents of MCPBA. On the other hand, oxidation of **1a** with 4 equivalents of hydrogen peroxide[9] in refluxing acetic acid for 15 minutes gave the desired sulfone **3a** in 84% yield. In a similar manner, **3b** was obtained in 83% yield from **1b**. Oxidation of **1c** under similar conditions gave tarry material. However, at a lower temperature (80 °C), the sulfone **3c** was obtained in 66% yield.

We examined initially the Diels-Alder reaction of the quinones **2a**, **3a**, and **1a**, unsubstituted on the benzenoid ring, with mixed vinylketene acetal **5**[1d] readily prepared from methyl 3-methyl-2-butenoate. The sulfoxide **2a** was treated with 2 equivalents of **5** in



Scheme 1.



Scheme 2.

toluene at 0 °C. After 1 hour, TLC indicated the disappearance of starting quinone **2a**. However, the yellow color of the quinone did not disappear during this period which may indicate that the elimination of benzenesulfenic acid from the Diels-Alder adduct **7** (n=1, R^1=R^2=H, R^3=Me) is spontaneous under these conditions to regenerate the quinonoid structure. After evaporation of toluene, the residual oil was treated with aqueous methanolic HCl to effect aromatization to give 1-hydroxy-3-methylnaphthoquinone (pachybasin) (**8**) and its *O*-methyl derivative **9** in low yields and poor selectivity (**8**: 28%; **9**: 14%). On the other hand, the base-catalyzed aromatization using triethylamine which was employed at first by Rapoport[2g] in their aklavinone synthesis provided **8** almost exclusively although the yield again was low (Table 1: Entry 1). We used this mild and highly selective aromatization method as a standard procedure for other cases described below. The Diels-Alder reaction of the sulfone **3a** with **5** is very rapid. When **5** was added to a toluene solution of **3a** at 0 °C, the yellow color of **3a** disappeared almost instantaneously and TLC indicated the absence of starting quinone **3a**. On treatment with triethylamine, smooth elimination of benzenesulfinic acid and methanol from the adduct **7** (n=2, R^1=R^2=H, R^3=Me) took place and **8** was obtained in 86% yield accompanying with a trace amount of **9** (Entry 2). The sulfide **1a** is much less reactive toward **5** compared with **2a** and **3a**. It took 12 hours to complete the Diels-Alder reaction in refluxing benzene and additional 2 days for the triethylamine-catalyzed aromatization. In this reaction, the selectivity of **8** to **9** is somewhat low, but the total yield of the quinonoid products is excellent (Entry 3).

Next, we examined the Diels-Alder reaction of 6-methoxynaphthoquinones **2b**, **3b**, and **1b** with vinylketene acetal **5** to see the regiochemical controlling effect of the sulfoxide, sulfone, and sulfide groups (Entries 4—6). In every case, the reaction proceeded regiospecifically to give 1-hydroxy-6-methoxy-3-methylanthraquinone (phomarin 6-methyl ether) (**10**) as a major product in addition to a minor amount of its *O*-methyl derivative **11**.

In order to confirm the regiospecificity of these reactions, we have synthesized the regioisomer of **10**, 1-hydroxy-7-methoxy-3-methylanthraquinone (**24**), using the directed lithiation strategy developed by

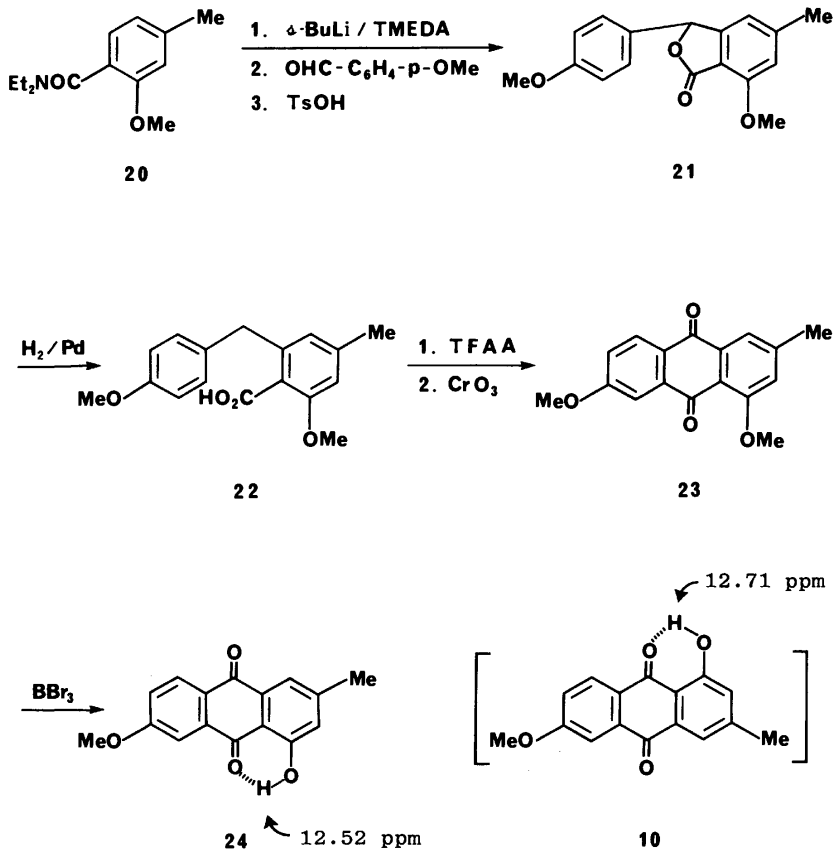
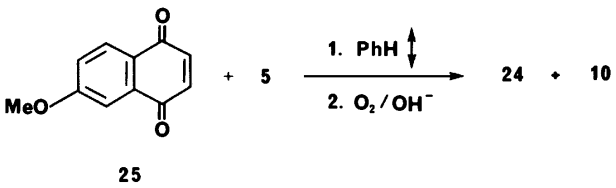
Snieckus[10] (Scheme 3). Thus *N,N*-diethyl-2-methoxy-4-methylbenzamide (**20**) was sequentially ortho-lithiated (*s*-BuLi-TMEDA-ether/−78 °C) and treated with *p*-anisaldehyde. The crude condensation product was treated with *p*-toluenesulfonic acid in refluxing benzene to give the phthalide **21** in 45% yield. Compound **21** was hydrogenated over palladium on charcoal to give the benzylbenzoic acid **22**. Without purification, crude **22** was treated with trifluoroacetic anhydride (TFAA) in dichloromethane followed by chromium trioxide to give the anthraquinone **23** in 29% overall yield from **21**. Selective demethylation of **23** with boron tribromide afforded the desired isomer **24** in 86% yield. The most characteristic difference between **10** and **24** was observed in their ^{1}H NMR spectra. Thus, the



Scheme 3.

absorptions of the strongly hydrogen-bonded peri hydroxyl protons for these compounds appeared at considerably different chemical shifts (**10**: δ 12.71, **24**: δ 12.52). This is apparently due to the difference of the resonance effect[2b,g] of the methoxyl group in the hydrogen-bonded quinone carbonyl in each isomer. This result suggests that the regioselectivity of the Diels–Alder reaction of mixed vinylketene acetals of type **5** with methoxy-substituted naphthoquinones could be generally established by ^{1}H NMR spectroscopy.

Next, we carried out the Diels–Alder reaction of 6-methoxy-1,4-naphthoquinone (**25**) with **5** to confirm the necessity of the sulfur substituents for the regiospecific Diels–Alder reactions (Scheme 4). When **25** was treated with **5** in refluxing benzene for 20 hours, and the crude Diels–Alder adduct was oxygenated under alkaline conditions, a 3.1 : 1 mixture of **24** and **10** was obtained in 78% yield. The ratio of **24** to **10** was determined by integration of the hydroxyl proton NMR absorptions of each isomer in the mixture. This result could be rationalized[4,23] as follows. The electron-donating effect of the methoxyl group at the 6 position weakens the electron-withdrawing effect of the C-1 carbonyl compared with C-4 which causes the electron-rich center of **5** to react preferentially at the C-2 position of the quinone **25** to give the anthraquinone **24** as a major product after



Scheme 4.

oxidative and hydrolytic work-up. This experiment revealed that the sulfur substituents on the quinonoid ring of **2b**, **3b**, and **1b** can overcome the electronic effect of 6-methoxyl group, and are essential for the regiospecific Diels–Alder reactions.

It is of interest to determine the effect of an additional methoxyl group in 5,7-dimethoxynaphthoquinone derivatives **2c**, **3c**, and **1c** on the regioselectivity of the Diels–Alder reaction. In these compounds, the electron-releasing effect of two methoxyl groups at 5 and 7 positions should result in considerable increase of electron density of the quinonoid ring and decrease of the electron-withdrawing effect of C-4 carbonyl rather than C-1. These effects should reduce both reactivity and regioselectivity of these compounds compared with monomethoxylated quinones described above.

The sulfoxide **2c** was actually much less reactive

toward **5** compared with unsubstituted sulfoxide **2a** or mono-methoxylated compound **2b**. However, the Diels-Alder reaction was completed within 5 hours at room temperature and, after triethylamine-catalyzed aromatization, 1-hydroxy-6,8-dimethoxy-3-methylanthraquinone (emodin 6,8-dimethyl ether) (**12**) and its *O*-methyl derivative **13** were obtained in 42% and 5% yields, respectively (Table 1: Entry 7). The regioselectivity of this reaction was proved by careful examination of the hydroxyl proton region of ^{1}H NMR spectrum of the crude product, which showed only a sharp singlet at δ 13.09 which was identical with a reported value[1e] for emodin 6,8-dimethyl ether. In addition, structure of **13** was identified by direct spectroscopic and TLC comparisons with an authentic sample.[11] The sulfone **3c** was more reactive than the sulfoxide **2c**, and the Diels-Alder reaction with **5** was completed within 1 hour at room temperature. After triethylamine-catalyzed aromatization, **12** was obtained in good yield (81%) in addition to a small amount of **13** (8%) (Entry 8). The sulfide **1c** was much less reactive toward **5**. It took 68 hours in refluxing benzene to complete the reaction. However, the reaction was again regiospecific, and emodin derivatives were obtained in modest yields after triethylamine-catalyzed aromatization (Entry 9). Therefore, it was revealed from these experiments that the directing and activating effects of the sulfur substituents attached directly on the quinonoid ring were quite strong to outweigh the electronic effect of two methoxyl groups on the benzenoid ring. It appears that the effects of the sulfur substituents are stronger than those of the halo substituents since Brassard has reported[1d] that 3-chloro-5,7-dimethoxynaphthoquinone was almost unreactive toward the vinylketene acetals of type **5**.

The vinylketene acetal **6**[1d] was also allowed to react with some sulfur-substituted naphthoquinones, and the expected anthraquinone products were obtained regiospecifically in good yields (Table 1: Entries 10—14).

The synthesis of anthracyclinone aglycone is of current interest due to the potent antitumor activity of anthracycline antibiotics.[12] Based on the studies described above, some 11-deoxyanthracyclinones were easily synthesized regiospecifically by cycloaddition of

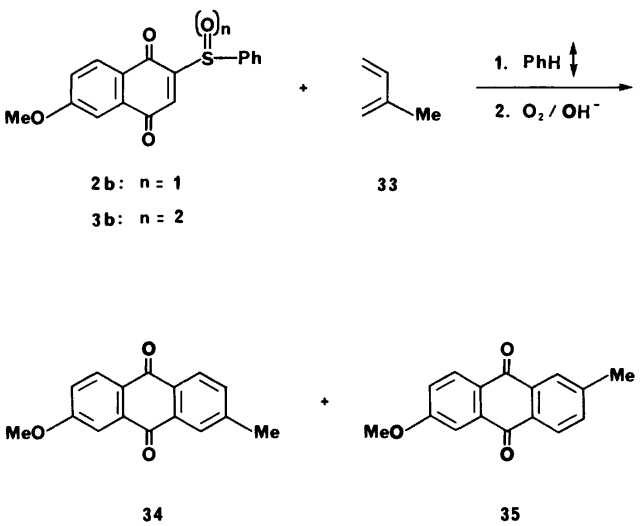
a) A: Diels-Alder(0 °C, 1 h), aromatization(0 °C→room temperature, 18 h); B: Diels-Alder(room temperature, 1 h), aromatization(0 °C→room temperature, 18 h). All reactions were carried out in toluene. b) Isolated yield after chromatography.

Gesson's vinylketene acetal **26**,[2d] prepared in two steps from commercially available Hageman's ester, with the naphthoquinone sulfoxides **2a—c** and sulfones **3a—c**. The results are summarized in Table 2. In general, the sulfoxides reacted with **26** in good yields to give, after triethylamine-catalyzed aromatization, mixtures of 5-hydroxyanthracyclinones and their *O*-ethyl derivatives. However, the selectivity of the former compounds to the latter was very poor (Entries 1,3,5). On the other hand, the total yields of anthracyclinone products from the sulfones were somewhat lower, but the hydroxy compounds were obtained in good selectivity (Entries 2,4,6).

Finally, the regiochemical outcome of the Diels–Alder reactions of the sulfoxide **2b** and the sulfone **3b** with isoprene (**33**) was briefly examined (Scheme 5). Although the sulfoxide **2b** reacted smoothly with **33** in refluxing benzene, the reaction was not regiospecific and, after oxidation, a mixture of the anthraquinone products **34** and **35** was obtained in the ratio of 7:3, as determined by gas chromatography using nematic liquid crystals[4,13] as stationary phase. From the sulfone **3b**, a mixture of **34** and **35** was obtained in a somewhat improved ratio (8:2). It therefore appears that both sulfoxide and sulfone groups are insufficiently strong directing group for the regiospecific Diels–Alder reaction with relatively unpolarized diene **33**. Therefore, use of the polarized dienes such as vinylketene acetals is essential[14] for the regiospecific Diels–Alder reaction of the sulfur-substituted naphthoquinones.

In conclusion, we have shown that the sulfone, sulfoxide and sulfide groups, especially the former two, offer effective regiochemical control and activating elements in the Diels–Alder reaction of naphthoquinones. Since the regiospecific synthesis of 2-phenylthionaphthoquinones has been established,[6] the sulfur-directed Diels–Alder reaction described herein provides easy access to a wide range of highly substituted anthraquinones and anthracyclinones under mild conditions.



Scheme 5.

Experimental

General. All melting points are uncorrected. Mass spectra (MS) were determined on JEOL JMS-DX303 spectrometer. IR spectra were obtained in Nujol mulls with JASCO A-100 spectrometer. UV spectra were recorded in 95% ethanol on Hitachi 323 spectrometer. High field ^{1}H NMR spectra (400 MHz) were obtained with JEOL JNM-GX400 spectrometer using $CDCl_3$ as a solvent and TMS as an internal standard. Routine ^{1}H NMR spectra (60 MHz) were recorded on Hitachi R-600 machine. Elemental analyses were performed at microanalytical laboratory in Nagasaki University. Gas chromatography was performed on a Shimadzu GC-8A apparatus using flame ionization detector. Thin-layer chromatography was performed on Merck 0.2 mm precoated aluminum sheets of silica gel 60 F_{254} (Art 5554). For column chromatography, Merck silica gel 60 (230—400 mesh) (Art 9385) was employed.

2-Phenylsulfinyl-1,4-naphthoquinone (2a): Under ice-cooling, 2.16 g (10 mmol) of 80% MCPBA was added portionwise to a solution of 2.66 g (10 mmol) of **1a** in 150 ml of chloroform, and stirred for 4 h. The chloroform solution was washed with sodium hydrogencarbonate solution, dried over sodium sulfate, and evaporated. The residue was recrystallized from dichloromethane–hexane to give 2.64 g (94%) of **2a** as orange needles. An analytical sample was purified by recrystallization from methanol; mp 158.5—160 °C. IR: 1655, 1580, 1055, and 1050 cm^{-1}. ^{1}H NMR (400 MHz) δ=7.49 (m, 3H, H-3′, H-4′, H-5′), 7.65 (s, 1H, H-3), 7.76 (m, 2H, H-6, H-7), 7.85 (m, 2H, H-2′, H-6′), 8.00 (near d, 1H, H-5 or H-8, J=ca. 8 Hz), and 8.10 (near d, 1H, H-8 or H-5, J=ca. 8 Hz). Found: C, 68.10; H, 3.48; S, 11.50%. Calcd for $C_{16}H_{10}O_3S$: C, 68.07; H, 3.57; S, 11.36%.

6-Methoxy-2-phenylsulfinyl-1,4-naphthoquinone (2b): This compound was obtained from **1b** in a similar manner as described above in 89% yield; yellow needles from methanol; mp 181—181.5 °C. IR: 1670, 1650, 1585, and 1045 cm^{-1}. ^{1}H NMR (400 MHz) δ=3.94 (s, 3H, OMe), 7.18 (dd, 1H, H-7, J=8.8 and 2.6 Hz), 7.49 (m, 3H, H-3′, H-4′, H-5′), 7.52 (d, 1H, H-5, J=2.9 Hz), 7.60 (s, 1H, H-3), 7.85 (m, 2H, H-2′, H-6′), and 7.94 (d, 1H, H-8, J=8.8 Hz). Found: C, 65.23; H, 3.78; S, 10.31%. Calcd for $C_{17}H_{12}O_4S$: C, 65.37; H, 3.87; S, 10.27%.

5,7-Dimethoxy-3-phenylsulfinyl-1,4-naphthoquinone (2c): This compound was prepared from **1c** in a similar manner as described for **2a** in 98% yield; yellow needles from dichloromethane–methanol; mp 231.5—233.5 °C (decomp). IR: 1650, 1635, 1595, and 1045 cm^{-1}. ^{1}H NMR (400 MHz) δ=3.93 (s, 3H, OMe), 3.94 (s, 3H, OMe), 6.69 (d, 1H, H-6, J=2.2 Hz), 7.25 (d, 1H, H-8, J=2.2 Hz), 7.46 (m, 3H, H-3′, H-4′, H-5′), 7.53 (s, 1H, H-3), and 7.87 (m, 2H, H-2′, H-6′). Found: C, 63.29; H, 4.03; S. 9.37%. Calcd for $C_{18}H_{14}O_5S$: C, 63.15; H, 4.12; S, 9.37%.

2-Phenylsulfonyl-1,4-naphthoquinone (3a): To a hot solution of 1133 mg (4.25 mmol) of **1a** in 100 ml of acetic acid was added 2.0 ml (17.6 mmol) of 30% hydrogen peroxide solution, and the mixture was refluxed for 15 min. The solution was concentrated under reduced pressure to several

ml to precipitate yellow fine crystals, which were collected by filtration and washed with methanol giving 1061 mg (84%) of practically pure sulfone **3a**. Recrystallization from methanol afforded yellow fine plates; mp 190—191.5 °C (lit,[15] mp 192 °C). IR: 1665, 1585, 1330, and 1165 cm^{-1}. ^1H NMR (400 MHz) δ=7.59 (near t, 2H, H-3′, H-5′, J=ca. 7.5 Hz), 7.68 (near t, 1H, H-4′, J=ca. 7.5 Hz), 7.78 (m, 2H, H-6, H-7), 7.85 (s, 1H, H-3), 8.03 (m, 1H, H-5 or H-8), 8.08 (m, 1H, H-8 or H-5), and 8.15 (d, 2H, H-2′, H-6, J=7.7 Hz). Found: C, 64.20; H, 3.33; S, 10.86%. Calcd for $C_{16}H_{10}O_4S$: C, 64.42; H, 3.38; S, 10.75%.

6-Methoxy-2-phenylsulfonyl-1,4-naphthoquinone (3b): This compound was obtained from **1b** in a similar manner as described for **3a**; Yellow needles from methanol, mp 201—203 °C (decomp). IR: 1670, 1660, 1595, 1340, and 1155 cm^{-1}. ^1H NMR (400 MHz) δ=3.95 (s, 3H, OMe), 7.22 (dd, 1H, H-7, J=8.8 and 2.6 Hz), 7.48 (d, 1H, H-5, J=2.6 Hz), 7.59 (near t, 2H, H-3′, H-5′, J=ca. 7.5 Hz), 7.68 (near t, 1H, H-4′, J=ca. 7.5 Hz), 7.80 (s, 1H, H-3), 7.97 (d, 1H, H-8, J=8.8 Hz), and 8.15 (d, 2H, H-2′, J=7.7 Hz). Found: C, 62.20; H, 3.68; S, 9.82%. Calcd for $C_{17}H_{12}O_5S$: C, 62.19; H, 3.68; S, 9.77%.

5,7-Dimethoxy-3-phenylsulfonyl-1,4-naphthoquinone (3c): To a warm solution of 326 mg (1.00 mmol) of **3a** in 30 ml of acetic acid was added 0.45 ml (4.0 mmol) of 30% hydrogen peroxide solution. The mixture was kept at 80 °C for 4 h, and evaporated to dryness. The residue was recrystallized from dichloromethane-ethanol giving 235 mg (66%) of orange needles of **3c**. Mp 230—234.5 °C (decomp) was measured in a sealed capillary. IR: 1690, 1660, 1595, 1550, 1340, 1325, and 1160 cm^{-1}. ^1H NMR (400 MHz) δ=3.92 (s, 3H, OMe), 3.95 (s, 3H, OMe), 6.73 (d, 1H, H-6, J=2.2 Hz), 7.20 (d, 1H, H-8, J=2.2 Hz), 7.56 (near t, 2H, H-3′, H-5′, J=ca. 7.5 Hz), 7.64 (near t, 1H, H-4′, J=ca. 7.5 Hz), 7.76 (s, 1H, H-2), and 8.15 (d, 2H, H-2′, H-6′, J=7.7 Hz). Found: C, 60.17; H, 3.78; S, 9.16%. Calcd for $C_{18}H_{14}O_6S$: C, 60.33; H, 3.94; S, 8.95%.

2,3-Epoxy-2-phenylsulfonyl-1,4-naphthoquinone (4): Under ice-cooling, 4.50 g (21 mmol) of 80% MCPBA was added all at once to a stirred solution of 1.85 g (7.0 mmol) of **1a** in 170 ml of chloroform. The mixture was stirred for 2 h at 0 °C and left overnight at room temperature. An additional 0.20 g (0.9 mmol) of 80% MCPBA was added, and the mixture was stirred for further 8 h. The chloroform solution was washed with sodium hydrogencarbonate solution, dried over sodium sulfate and evaporated. The residual oil was crystallized by trituration with ether and the crystals were collected by filtration to give 2.01 g (92%) of **4**. Recrystallization from dichloromethane-ether (charcoal) afforded colorless prisms, mp 151.5—153.5 °C. MS m/z=314 (M^+). IR: 1695, 1585, 1575, 1345, 1335, 1165, and 1145 cm^{-1}. ^1H NMR (400 MHz) δ=4.80 (s, 1H, H-3), 7.64 (near t, 2H, H-3′, H-5′, J=ca. 7.5 Hz), 7.75 (near t, 1H, H-4′, J=ca. 7.5 Hz), 7.78 (m, 2H, H-6, H-7), 7.94 (dd, 1H, H-5 or H-8, J=7.0 and 1.8 Hz), 8.02 (dd, 1H, H-8 or H-5, J=7.5 and 1.5 Hz), and 8.19 (d, 2H, H-2′, H-6′, J=7.3 Hz). Found: C, 61.38; H, 3.07; S, 10.33%. Calcd for $C_{16}H_{10}O_5S$: C, 61.14; H, 3.21; S, 10.20%.

Diels-Alder Reaction of the Naphthoquinones 1a—c, 2a—c, and 3a—c with the Vinylketene Acetals 5, 6, and 26; General Procedure: Under nitrogen atmosphere, 2.0 mmol of the vinylketene acetal was added to a solution or suspension of 1.0 mmol of the naphthoquinone in 50 ml of dry toluene or benzene. After completion of the Diels-Alder reaction, 1.0 ml of triethylamine was added and the aromatization reaction was conducted. The reaction conditions for both the Diels-Alder and aromatization reactions were shown in Table 1 or 2 for each cases. When the Diels-Alder reaction was slow (Table 1: Entries 6,9,12), small portions of additional vinylketene acetal were added until the starting quinone had disappeared (TLC analysis) (Entry 6: 2 equiv of the vinylketene acetal for the quinone; Entry 9: 25 equiv; Entry 12: 3 equiv). When the reaction was completed, the reaction mixture was evaporated to dryness under reduced pressure. The residue was washed with methanol and filtered giving the quinonoid products, which were chromatographed on silica gel using dichloromethane or a mixture of dichloromethane and acetone (20:1) as eluents. From the first yellow band, the hydroxy quinone was obtained, and its *O*-alkylated derivative was obtained from the next yellow band. The yield of each compound is shown in Table 1 or 2. The following quinones were obtained in this manner.

1-Hydroxy-3-methylanthraquinone (Pachybasin) (8): Yellow needles from ethanol; mp 176.5—177.5 °C (lit,[16,17] mp 176—177 °C; lit,[1j] mp 179—180 °C). IR: 1670, 1635, 1585, and 1570 cm^{-1}. ^1H NMR (400 MHz) δ=2.47 (s, 3H, Me), 7.11 (s, 1H, H-2), 7.64 (s, 1H, H-4), 7.80 (m, 2H, H-6, H-7), 8.29 (m, 2H, H-5, H-8), and 12.57 (s, 1H, OH). Found: C, 75.70; H, 4.16%. Calcd for $C_{15}H_{10}O_3$: C, 75.62; H, 4.23%.

1-Methoxy-3-methylanthraquinone (9): Yellow needles from methanol; mp 190—191 °C (lit,[16] mp 187—188 °C; lit,[17] mp 185—187 °C. IR: 1670, 1655, 1595, and 1590 cm^{-1}. ^1H NMR (400 MHz) δ=2.50 (s, 3H, Me), 4.04 (s, 3H, OMe), 7.14 (s, 1H, H-2), 7.7—7.8 (m, 2H, H-6, H-7), 7.77 (s, 1H, H-4), 8.21 (dd, 1H, H-8 or H-5, J=7.6 and 1.4 Hz), and 8.27 (dd, 1H, H-5 or H-8, J=7.5 and 1.4 Hz). Found: C, 76.04; H, 4.67%. Calcd for $C_{16}H_{12}O_3$: C, 76.18; H, 4.79%.

1-Hydroxy-6-methoxy-3-methylanthraquinone (Phomarin 6-Methyl Ether) (10): Yellow needles from ethanol; mp 188.5—189 °C (lit,[1f] mp 187.0—187.5 °C; lit,[18] mp 193 °C). R_f (TLC-benzene)=0.41. IR: 1670, 1630, and 1590 cm^{-1}. UV: 267.5 (log ε 4.61), 292sh (4.25), and 411 nm (3.93). ^1H NMR (400 MHz) δ=2.46 (s, 3H, Me), 3.99 (s, 3H, OMe), 7.10 (s, 1H, H-2), 7.26 (dd, 1H, H-7, J=8.4 and 2.8 Hz), 7.63 (s, 1H, H-4), 7.71 (d, 1H, H-5, J=2.8 Hz), 8.24 (d, 1H, H-8, J=8.8 Hz), and 12.71 (s, 1H, OH). Found: C, 71.85; H, 4.39%. Calcd for $C_{16}H_{12}O_4$: C, 71.64; H, 4.51%.

1,6-Dimethoxy-3-methylanthraquinone (11): Yellow needles from methanol; mp 189.5—190 °C. IR: 1665, 1650, 1600, 1575, and 1560 cm^{-1}. ^1H NMR (400 MHz) δ=2.50 (s, 3H, Me), 3.96 (s, 3H, OMe), 4.03 (s, 3H, OMe), 7.13 (s, 1H, H-2), 7.25 (dd, 1H, J=8.4 and 2.6 Hz), 7.63 (d, 1H, H-5, J=2.6 Hz), 7.76 (s, 1H, H-4), and 8.21 (d, 1H, H-8, J=8.4 Hz). Found: C, 72.36; H, 5.04%. Calcd for $C_{17}H_{14}O_4$: C, 72.33; H, 5.00%.

1-Hydroxy-6,8-dimethoxy-3-methylanthraquinone (Emodin 6,8-Dimethyl Ether) (12): Orange needles from ethanol; mp 211.5—213 °C (lit,[19] mp 211.0 °C; lit,[1e] mp 204—205 °C). IR: 1665, 1625, 1590, and 1550 cm^{-1}. ^1H NMR (400 MHz) δ=2.43 (s, 3H, Me), 3.99 (s, 3H, OMe), 4.02 (s, 3H, OMe), 6.78 (d, 1H, H-7, J=2.3 Hz), 7.07 (s, 1H, H-2), 7.45 (d, 1H, H-5, J=2.8 Hz), 7.56 (s, 1H, H-4), and 13.09 (s, 1H, OH). Found: C, 68.55; H, 4.64%. Calcd for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73%.

1,3,8-Trimethoxy-6-methylanthraquinone (13): Hygroscopic yellow needles from methanol; mp 228.5—229.5 °C (lit,[20] mp 227—228 °C; lit,[11] mp 229 °C). IR: 1650, 1600,

and 1555 cm^{-1}. ^{1}H NMR (400 MHz) δ=2.47 (s, 3H, Me), 3.95 (s, 3H, OMe), 3.96 (s, 3H, OMe), 3.99 (s, 3H, OMe), 6.77 (d, 1H, H-2, J=2.6 Hz), 7.10 (s, 1H, H-7), 7.32 (d, 1H, H-4, J=2.6 Hz), and 7.64 (s, 1H, H-5). This compound was shown to be identical with an authentic sample[11] by spectroscopic and TLC comparisons.

1-Hydroxy-3-methoxyanthraquinone (Xanthopurprine 3-Methyl Ether) (14): Yellow needles from ethanol; mp 195—196.5 °C (lit,[21] mp 193—194 °C; lit,[1d] mp 193.5—194.5 °C). IR: 1675, 1630, 1590, and 1565 cm^{-1}. ^{1}H NMR (400 MHz) δ=3.93 (s, 3H, OMe), 6.68 (d, 1H, H-2, J=2.3 Hz), 7.34 (d, 1H, H-4, J=2.3 Hz), 7.77 (m, 2H, H-6, H-7), 8.26 (m, 2H, H-5, H-8), and 12.86 (s, 1H, OH). Found: C, 70.75; H, 3.85%. Calcd for $C_{15}H_{10}O_4$: C, 70.86; H, 3.96%.

1,3-Dimethoxyanthraquinone (15): Yellow needles from methanol; mp 163.5—164 °C (lit,[22] mp 163 °C; lit,[21] mp 154—155 °C). IR: 1665, 1655, 1590, 1580, and 1555 cm^{-1}. ^{1}H NMR (400 MHz) δ=3.99 (s, 3H, OMe), 4.02 (s, 3H, OMe), 6.79 (d, 1H, H-2, J=2.3 Hz), 7.46 (d, 1H, H-4, J=2.3 Hz), 7.71 (dt, 1H, H-6 or H-7, J=7.8 and 1.4 Hz), 7.77 (dt, 1H, H-7 or H-6, J=7.3 and 1.4 Hz), 8.21 (dd, 1H, H-8 or H-5, J=7.8 and 0.9 Hz), and 8.27 (dd, 1H, H-5 or H-8, J=7.8 and 0.9 Hz). Found: C, 71.50; H, 4.52%. Calcd for $C_{16}H_{12}O_4$: C, 71.64; H, 4.51%.

1-Hydroxy-3,6-dimethoxyanthraquinone (16): Orange needles from ethanol; mp 220—221 °C. IR: 1675, 1620, and 1585 cm^{-1}. ^{1}H NMR (400 MHz) δ=3.94 (s, 3H, OMe), 3.98 (s, 3H, OMe), 6.71 (d, 1H, H-2, J=2.3 Hz), 7.27 (dd, 1H, H-7, J=8.8 and 2.8 Hz), 7.36 (d, 1H, H-4, J=2.8 Hz), 7.70 (d, 1H, H-5, J=2.3 Hz), 8.23 (d, 1H, H-8, J=8.8 Hz), and 13.01 (s, 1H, OH). Found: C, 67.63; H, 4.21%. Calcd for $C_{16}H_{12}O_5$: C, 67.60; H, 4.25%.

1,3,6-Trimethoxyanthraquinone (17): Yellow microcrystals from ethanol; mp 242—243 °C (lit,[23] mp 240—241.5 °C). IR: 1655, 1645, 1595, 1575, and 1560 cm^{-1}. ^{1}H NMR (400 MHz) δ=3.96 (s, 3H, OMe), 3.98 (s, 3H, OMe), 4.01 (s, 3H, OMe), 6.79 (d, 1H, H-2, J=2.6 Hz), 7.25 (dd, 1H, H-7, J=8.8 and 2.6 Hz), 7.45 (d, 1H, H-4, J=2.6 Hz), 7.63 (d, 1H, H-5, J=2.6 Hz), and 8.22 (d, 1H, H-8, J=8.8 Hz). Found: C, 68.54; H, 4.70%. Calcd for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73%.

1-Hydroxy-3,6,8-trimethoxyanthraquinone (18): Orange microcrystals from chloroform-ethanol; mp 257—258 °C. IR: 1620, 1590, and 1550 cm^{-1}. ^{1}H NMR (400 MHz) δ=3.92 (s, 3H, OMe), 3.99 (s, 3H, OMe), 4.03 (s, 3H, OMe), 6.71 (d, 1H, H-2, J=2.3 Hz), 6.80 (d, 1H, H-7, J=2.3 Hz), 7.30 (d, 1H, H-4, J=2.8 Hz), 7.47 (d, 1H, H-5, J=2.3 Hz), and 13.40 (s, 1H, OH). Found: C, 65.12; H, 4.44%. Calcd for $C_{17}H_{14}O_6$: C, 64.97; H, 4.49%.

1,3,6,8-Tetramethoxyanthraquinone (19): Hygroscopic yellow microcrystals from ethanol, mp 222—223 °C (lit,[22] mp 220—221 °C, lit,[24] mp 224—225 °C). IR: 1655, 1600, and 1560 cm^{-1}. ^{1}H NMR (400 MHz) δ=3.96 (s, 6H, OMe), 3.99 (s, 6H, OMe), 6.76 (d, 2H, H-2, H-7, J=2.6 Hz), and 7.31 (d, 2H, H-4, H-5, J=2.6 Hz). An analytical sample was obtained by sublimation at 150—180 °C/0.15 mmHg (1 mmHg=133.322 Pa). Found: C, 65.66; H, 4.88%. Calcd for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%.

6-Hydroxy-9-methoxy-7,8-dihydro-5,12-naphthacenedione (27): Orange needles from dichloromethane; mp 243—244 °C. MS m/z=306 (M$^+$). IR: 1665, 1615, 1590, 1570, and 1550 cm^{-1}. ^{1}H NMR (400 MHz) δ=2.49 (near t, 2H, H-8, J=ca. 8.5 Hz), 3.03 (near t, 2H, H-7, J=ca. 8.5 Hz), 3.78 (s, 3H, OMe), 5.65 (s, 1H, H-10), 7.45 (s, 1H, H-11), 7.77 (m, 2H, H-2, H-3), 8.27 (m, H-1, H-4), and 12.99 (s, 1H, OH). Found: C, 74.42; H, 4.52%. Calcd for $C_{19}H_{14}O_4$: C, 74.45; H, 4.60%.

6-Ethoxy-9-methoxy-7,8-dihydro-5,12-naphthacenedione (28): Yellow needles from dichloromethane–hexane, mp 203.5—204.5 °C. MS m/z=334 (M$^+$). IR: 1670, 1630, 1575, and 1540 cm^{-1}. ^{1}H NMR (400 MHz) δ=1.53 (t, 3H, CH_3 of OEt, J=7.0 Hz), 2.46 (near t, 2H, H-8, J=ca. 8 Hz), 3.08 (near t, 2H, H-7, J=ca. 8 Hz), 3.78 (s, 3H, OMe), 4.03 (q, 2H, CH_2 of OEt, J=7.0 Hz), 5.71 (s, 1H, H-10), 7.72 (s, 1H, H-11), 7.7—7.8 (m, 2H, H-2, H-3), 8.21 (dd, 1H, H-4 or H-1, J=7.3 and 1.5 Hz), and 8.26 (dd, 1H, H-1 or H-4, J=7.7 and 1.5 Hz). Found: C, 75.37; H, 5.42%. Calcd for $C_{21}H_{18}O_4$: C, 75.43; H, 5.43%.

6-Hydroxy-2,9-dimethoxy-7,8-dihydro-5,12-naphthacenedione (29): Orange needles from dichloromethane–hexane; mp 232—233 °C. MS m/z=336 (M$^+$). IR: 1670, 1630, 1615, 1595, 1560, and 1550 cm^{-1}. ^{1}H NMR (400 MHz) δ=2.49 (near t, 2H, H-8, J=ca. 8.5 Hz), 3.02 (near t, 2H, H-7, J=ca. 8.5 Hz), 3.78 (s, 3H, OMe), 3.98 (s, 3H, OMe), 5.64 (s, 1H, H-10), 7.23 (dd, 1H, H-3, J=8.8 and 2.9 Hz), 7.43 (s, 1H, H-11), 7.68 (d, 1H, H-1, J=2.9 Hz), 8.21 (d, 1H, H-4, J=8.8 Hz), and 13.10 (s, 1H, OH). Found: C, 71.36; H, 4.75%. Calcd for $C_{20}H_{16}O_5$: C, 71.42; H, 4,79%.

6-Ethoxy-2,9-dimethoxy-7,8-dihydro-5,12-naphthacenedione (30): Yellow needles from dichloromethane–ether–hexane; mp 224—225 °C. MS m/z=364 (M$^+$). IR: 1670, 1630, 1600, 1570, and 1540 cm^{-1}. ^{1}H NMR (400 MHz) δ=1.52 (t, 3H, CH_3 of OEt, J=7.0 Hz), 2.45 (near t, 2H, H-8, J=ca. 8 Hz), 3.07 (near t, 2H, H-7, J=ca. 8 Hz), 3.77 (s, 3H, OMe), 3.96 (s, 3H, OMe), 4.02 (q, 2H, CH_2 of OEt, J=7.0 Hz), 5.69 (s, 1H, H-10), 7.23 (dd, 1H, H-3, J=8.8 and 2.6 Hz), 7.63 (d, 1H, H-1, J=2.6 Hz), 7.69 (s, 1H, H-11), and 8.20 (d, 1H, H-4, J=8.8 Hz). Found: C, 72.61; H, 5.50%. Calcd for $C_{22}H_{20}O_5$: C, 72.51; H, 5.53%.

6-Hydroxy-2,4,9-trimethoxy-7,8-dihydro-5,12-naphthacenedione (31): Orange needles from dichloromethane–ether–hexane; mp 257—259 °C (decomp). MS m/z=366 (M$^+$). IR: 1670, 1630, 1615, 1595, and 1550 cm^{-1}. ^{1}H NMR (400 MHz) δ=2.47 (near t, 2H, H-8, J=ca. 8.5 Hz), 3.02 (near t, 2H, H-7, J=ca. 8.5 Hz), 3.77 (s, 3H, OMe), 3.98 (s, 3H, OMe), 4.03 (s, 3H, OMe), 5.62 (s, 1H, H-10), 6.78 (d, 1H, H-3, J=2.3 Hz), 7.39 (s, 1H, H-11), 7.46 (d, 1H, H-1, J=2.3 Hz), and 13.48 (s, 1H, OH). Found: C, 68.57; H, 4.92%. Calcd for $C_{21}H_{18}O_6$: C, 68.85; H, 4.95%.

6-Ethoxy-2,4,9-trimethoxy-7,8-dihydro-5,12-naphthacenedione (32): Yellow needles from dichloromethane–ether; mp 207.5—209.5 °C. MS m/z=394 (M$^+$). IR: 1665, 1635, 1595, 1580, and 1565 cm^{-1}. ^{1}H NMR (400 MHz) δ=1.50 (t, 3H, CH_3 of OEt, J=7.0 Hz), 2.43 (near t, 2H, H-8, J=ca. 8 Hz), 3.06 (near t, 2H, H-7, J=ca. 8 Hz), 3.76 (s, 3H, OMe), 3.95 (s, 3H, OMe), 3.97 (s, 3H, OMe), 4.07 (q, 2H, CH_2 of OEt, J=7.0 Hz), 5.67 (s, 1H, H-10), 6.76 (d, 1H, H-3, J=2.2 Hz), 7.34 (d, 1H, H-1, J=2.6 Hz), and 7.60 (s, 1H, H-11). Found: C, 69.89; H, 5.64%. Calcd for $C_{23}H_{22}O_6$: C, 70.04; H, 5.62%.

***N,N*-Diethyl-2-methoxy-4-methylbenzamide (20):** This amide was prepared under standard conditions[10] from the corresponding acid via the acid chloride and purified by Kugelrohr distillation, bp 130 °C/0.1 mmHg. Colorless solid, mp 60—62 °C. IR: 1610, 1575, and 1510 cm^{-1}. ^{1}H NMR (400 MHz) δ=1.02 (near t, 3H, CH_3 of NEt_2, J=ca. 7 Hz), 1.23 (near t, 3H, CH_3 of NEt_2, J=ca. 7 Hz), 2.35 (s, 3H,

Me), 3.15 (q, 2H, CH_2 of NEt_2, J=ca. 7 Hz), 3.56 (br s, 2H, CH_2 of NEt_2), 3.79 (s, 3H, OMe), 6.71 (s, 1H, H-3), 6.77 (d, 1H, H-5, J=7.3 Hz), and 7.06 (d, 1H, H-6, J=7.7 Hz). Found: C, 70.66; H, 8.69; N, 6.15%. Calcd for $C_{13}H_{19}NO_2$: C, 70.56; H, 8.65; N, 6.33%.

7-Methoxy-3-(4-methoxyphenyl)-5-methyl-1(3*H*)-isobenzofuranone (21): A solution of 13.8 ml (16.5 mmol) of *s*-BuLi (1.20 M in cyclohexane (1 M=1 mol dm^{-3})) was slowly injected into a stirred solution of 3320 mg (15 mmol) of **20** and 2.5 ml of TMEDA in 250 ml of anhydrous ether at −78 °C under nitrogen atmosphere. After stirring for 1 h, a solution of 2246 mg (16.5 mmol) of *p*-anisaldehyde in ether was injected. After 1 h, Dry Ice-acetone bath was removed and the solution was stirred overnight. The reaction mixture was quenched by saturated ammonium chloride solution, washed successively with water and brine solution, dried over sodium sulfate and evaporated to give an oily residue. A solution of this material and 1 g of *p*-toluenesulfonic acid in 200 ml of benzene was refluxed for 6 h. The reaction mixture was washed twice with sodium hydrogencarbonate solution, dried over sodium sulfate and evaporated. The residual oil was dissolved in ether and the mixture was left overnight. The precipitate was collected by filtration giving 1167 mg of **21**. An additional 765 mg of **21** was obtained from the mother liquor after silica-gel chromatography using dichloromethane as eluent. The total yield was 1932 mg (45%). An analytical sample was obtained by recrystallization from dichloromethane-ether-hexane to give colorless needles; mp 118—118.5 °C. IR: 1750 and 1605 cm^{-1}. ^1H NMR (400 MHz) δ=2.40 (s, 3H, Me), 3.80 (s, 3H, OMe), 4.00 (s, 3H, OMe), 6.21 (s, 1H, H-3), 6.62 (s, 1H, H-6), 6.73 (s, 1H, H-4), 6.89 (d, 2H, H-3′, H-5′, J=8.4 Hz), and 7.18 (d, H-2′, H-6′, J=8.8 Hz). Found: C, 72.10; H, 5.55%. Calcd for $C_{17}H_{16}O_4$: C, 71.82; H, 5.67%.

1,7-Dimethoxy-3-methylanthraquinone (23): A mixture of 1008 mg (3.55 mmol) of **21** and 370 mg of 5% palladium on charcoal in 100 ml of glacial acetic acid was stirred at 80 °C overnight under an atmosphere of hydrogen. The catalyst was removed by filtration, and the filtrate was evaporated under reduced pressure giving an oily residue. In order to remove acetic acid contaminant, toluene was added and the whole was evaporated. The residual crude acid **22** was dissolved in 150 ml of dry dichloromethane, and 3 ml of trifluoroacetic anhydride was added at 0 °C. The mixture was stirred at room temperature for 5 h and evaporated. Methanol was added to the residue and the whole was evaporated. The residue was dissolved in dichloromethane and the solution was washed with sodium hydrogencarbonate solution, dried over sodium sulfate and evaporated to give a dark oil. A mixture of this oil, 0.4 g of chromium trioxide and a few drops of water in 90 ml of acetic acid was stirred at room temperature for 3.5 h. The mixture was evaporated to dryness, and the residue was dissolved in dichloromethane. The solution was washed with sodium hydrogencarbonate solution, filtered through celite, dried over sodium sulfate and evaporated. The residue was chromatographed over silica gel using a mixture of dichloromethane and ether (20:1) giving 294 mg (29%) of **23**. An analytical sample was obtained by recrystallization from methanol to give yellow needles; mp 181—182 °C (lit,[25] mp 183—184 °C). IR: 1665, 1650, 1595, and 1555 cm^{-1}. ^1H NMR δ=2.50 (s, 3H, Me), 3.97 (s, 3H, OMe), 4.04 (s, 3H, OMe), 7.11 (s, 1H, H-2), 7.20 (dd, 1H, H-6, J=8.8 and 2.6 Hz), 7.70 (d, 1H, H-8, J=2.6 Hz), 7.77 (s, 1H, H-4), and 8.17 (d, 1H, H-5, J=8.8 Hz). Found: C, 72.61; 4.85%. Calcd for $C_{17}H_{14}O_4$: C, 72.33; H, 5.00%.

1-Hydroxy-7-methoxy-3-methylanthraquinone (24): A solution of 85 mg (0.34 mmol) of boron tribromide in 5 ml of dichloromethane was added to a stirred solution of 80 mg (0.28 mmol) of **23** in 40 ml of dry dichloromethane at −78 °C. After 1 h, Dry Ice-acetone bath was removed and the mixture was stirred for 1.5 h. The mixture was washed with 5% sodium carbonate solution, dried over sodium sulfate and evaporated. The residue was purified by silica-gel chromatography using benzene as eluent giving 65 mg (86%) of **24**. An analytical sample was obtained by recrystallization from ethanol to give yellow needles; mp 191—192 °C and 201—201.5 °C (double melting point) (lit,[25] mp 198—199 °C). R_f (TLC-benzene)=0.37. IR: 1670, 1630, 1590, and 1565 cm^{-1}. UV: 272.5 (log ε 4.59), 295 (4.29), and 390 nm (3.90). ^1H NMR (400 MHz) δ=2.46 (s, 3H, Me), 3.99 (s, 3H, OMe), 7.08 (s, 1H, H-2), 7.26 (dd, 1H, H-6, J=8.7 and 2.8 Hz), 7.64 (s, 1H, H-4), 7.72 (d, 1H, H-8, J=2.8 Hz), 8.23 (d, 1H, H-5, J=8.7 Hz), and 12.52 (s, 1H, OH). Found: C, 71.41: H, 4.37%. Calcd for $C_{16}H_{12}O_4$: C, 71.64; H, 4.51%.

Diels-Alder Reaction of 6-Methoxynaphthoquinone (25) and the Vinylketene Acetal 5: A solution of 188 mg (1.0 mmol) of **25**[4,26] and 373 mg (2.0 mmol) of **5** in 50 ml of benzene was refluxed for 20 h, and evaporated to dryness. The residual oil was dissolved in a mixture of 10 ml each of THF and ethanol, 10 ml of 5% aqueous sodium hydroxide was added, and oxygen was bubbled through the resulting solution for 3 h. The mixture was acidified with hydrochloric acid and diluted with water. The yellow precipitate was collected by filtration and washed with water. Chromatography of the precipitate over silica gel using dichloromethane as eluent afforded 210 mg (78%) of a 3.1:1 mixture of the hydroxy quinones **24** and **10**, and 39 mg (14%) of a mixture of the methoxy quinones **23** and **11**. The ratio of **24** to **10** was determined by integration of the absorptions of the hydroxyl proton of each isomer by 400 MHz NMR. The ratio of **23** to **11** could not be estimated correctly by 400 MHz NMR because of the similarity of the spectra of the two isomers. However, it was apparent that **23** was a major product (**23**/**11**>5) from the comparison of the spectrum (aromatic region) of the mixture with those of authentic samples. Attempts to separate the mixture of **23** and **11** by GC or analytical HPLC were not successful.

Diels-Alder Reaction of 2b or 3b with Isoprene (33): A mixture of 156 mg (0.5 mmol) of **2b** and 1.0 ml (10 mmol) of isoprene in 20 ml of benzene was refluxed for 4 h, and evaporated to dryness. The residue was dissolved in a mixture of 5 ml each of THF and ethanol, and 5 ml of 5% aqueous sodium hydroxide was added. Oxygen was bubbled through this solution for 2 h. The mixture was diluted with water, and the precipitate was collected by filtration giving 77 mg (61%) of slightly colored fine needles of a 7:3 mixture of 2-methoxy-7-methylanthraquinone (**34**) and 2-methoxy-6-methylanthraquinone (**35**). The ratio was estimated by gas chromatography (2.5% BBBT/2 m×2.6 mm I.D./230 °C). Spectral data of the mixture were as follows. MS m/z=252 (M^+). ^1H NMR (400 MHz) δ=2.53 (s, Me of **34** and **35**), 3.99 (s, OMe of **34** and **35**), 7.25 (partially overlapped dd, H-3 of **34** and **35**), 7.56 (d, H-7 of **35**, J=8.1 Hz), 7.58 (d, H-6 of **34**, J=8.1 Hz), 7.72 (d, H-1 of **34** and **35**, J=2.6 Hz), 8.08 (s, H-8 of **34** and H-5 of **35**), 8.18 (d, H-8 of **35**, J=8.1 Hz), 8.19 (d,

H-5 of **34**, J=7.7 Hz), and 8.24 (d, H-4 of **34** and **35**, J=8.8 Hz). These values of the chemical shifts and coupling constants are almost identical with the reported values[4] for **34** and **35**. In a similar manner **2b** was treated with isoprene giving a 8:2 mixture of **34** and **35** in 84% combined yield.

The Mechanism of the Reaction of (Arylthio)trimethylgermanes with Benzyl Bromides Giving Aryl Benzyl Sulfides. A Kinetic Study

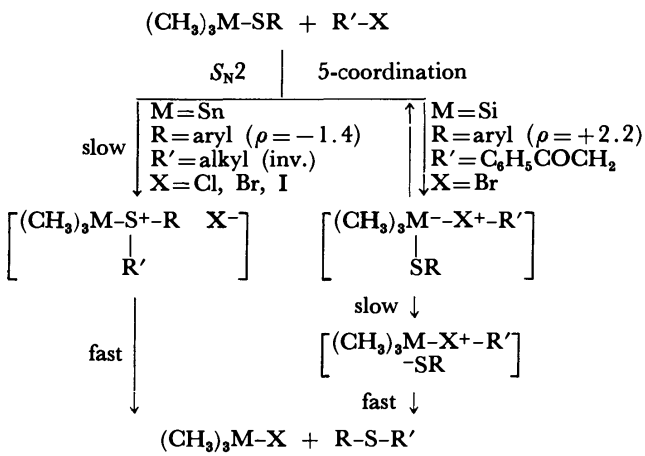
Seizi KOZUKA,* Shoji TAMURA, Satoshi ISHIBASHI, Sadamu OHYA, and Waichiro TAGAKI

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto 3-Chome, Sumiyoshi, Osaka 558

(Received May 29, 1987)

A kinetic study has been conducted on the reaction of (arylthio)trimethylgermanes with benzyl bromides. The reaction was found to be second order and the rate was largely accelerated in polar solvents. Both ρ values due to substituents on arylthio and benzyl groups revealed nucleophilic attack of the sulfur atom on benzylic carbon atom as the reaction mechanism. Rates of the reactions of trimethyl(*p*-tolylthio)stannane with substituted benzyl chlorides were also examined to compare the substituent effects. Steric crowd around the sulfur atom has been found as an important factor to control the reaction mechanism.

Different kinetic aspects have been observed for the reactions of aroyl chlorides with a series of organometallic sulfur compounds. Individually different mechanisms have been suggested for the reactions of (arylthio)trimethylstannanes,[1] germanes,[2] and silanes,[3] regardless of quite similar outcomes of the reaction products. The difference has also been observed between the reactions of haloalkanes with (arylthio)trimethylstannanes[4] and analogous silanes.[5] Namely, a negative ρ value due to the substituents on the arylthio group and inversion of the carbon atom of the haloalkane were observed for the reaction of the arylthiostannanes. Accordingly, a nucleophilic attack of the sulfur atom has been suggested for the reaction. Relative reactivity of the haloalkanes also supported the mechanism.[4] On the other hand, a large positive ρ value was observed for the reaction of (arylthio)trimethylsilanes with a reactive haloalkane of phenacyl bromide.[5] Initial formation of a 5-coordinated intermediate followed by rate-determining cleavage of the silicon–sulfur bond has been claimed for the reaction (Scheme 1). In this connection, a kinetic study is of interest on the reaction of germanium analogue with haloalkanes.



Scheme 1.

We have conducted a kinetic study on the reaction of (arylthio)trimethylgermanes with benzyl bromides.

Results and Discussion

The reaction of trimethyl(phenylthio)germane with benzyl bromide was found to give bromotrimethylgermane and benzyl phenyl sulfide in quantitative yields. No other product was found in the reaction mixture. Products were isolated and characterized.

$$(CH_3)_3Ge\text{-}SC_6H_5 + C_6H_5CH_2\text{-}Br \xrightarrow{100\,^\circ C,\ 30\ h} (CH_3)_3Ge\text{-}Br + C_6H_5S\text{-}CH_2C_6H_5$$

The reaction was monitored by observing ^1H NMR trimethyl signals of the starting germane (δ=0.47) and the product (δ=0.85). The rate constant, k_2, was obtained by least-squares calculation of relative intensities of the trimethyl signal at time intervals. The reaction was found to obey second order rate equation. Kinetic experiments were done at various temperatures in several solvents to observe activation parameters and solvent effect. The results are given in Table 1.

Dichloromethane used as a solvent was observed to react with the arylthiogermane. However, the rate of this reaction was found to be much smaller than that of the reaction with benzyl bromide under the same reaction conditions and the solvent reaction can be neglected. No reaction was found with the other solvents.

Activation parameters given in Table 1 are quite similar to those of the analogous reactions which proceed by ionic processes.[4,5] Solvent effect on the rate of the reaction also supports ionic mechanism for the present reaction since large acceleration in polar solvent was observed.

Effects of the substituents both in the arylthio (X) and the benzyl (Y) moieties were examined to clarify the reaction mechanism. The results are shown in Tables 2 and 3. A clear negative ρ value due to the substituents of the arylthio moiety (ρ_X=−1.41) was

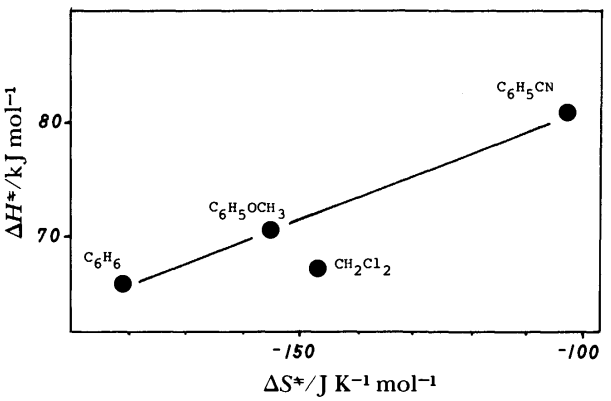

Fig. 1. Plot of $\Delta H^{\ddagger}$ vs. $\Delta S^{\ddagger}$ in various solvents.

observed in benzene solution. This result together with the large solvent effect supports a nucleophilic attack of the sulfur atom as the mechanism for the reaction carried out even in a nonpolar solvent. The effect, on the other hand, appeared substantially smaller in a polar solvent like benzonitrile (ρ_X= −0.76). However, it does not necessarily suggest another mechanism for the reaction in benzonitrile. Rather, the observed linear isokinetic relationship shown in Fig. 1 suggests similarity in the mechanism for the reactions in these solvents, although the plot for the reaction in dichloromethane appeared somewhat deviated. One possible explanation for the small absolute ρ value observed in benzonitrile is to consider the greater stabilization of the polar transition state in the polar solvent and hence stabilization or destabilization by the substituent becomes less important. This interpretation, however, contradicts with the results observed for the analogous reaction in which an enhanced substituent effect was observed in a polar solvent.[6] Thus, the smaller negative ρ value observed in benzonitrile is difficult to explain but it is clearly negative anyway in accordance with the nucleophilic mechanism.

The substituent (Y) effect due to the benzyl group (ρ_Y) appeared somewhat obscure. Rate acceleration by electron donating substituent was observed in all the solvents examined. Almost no effect, on the other

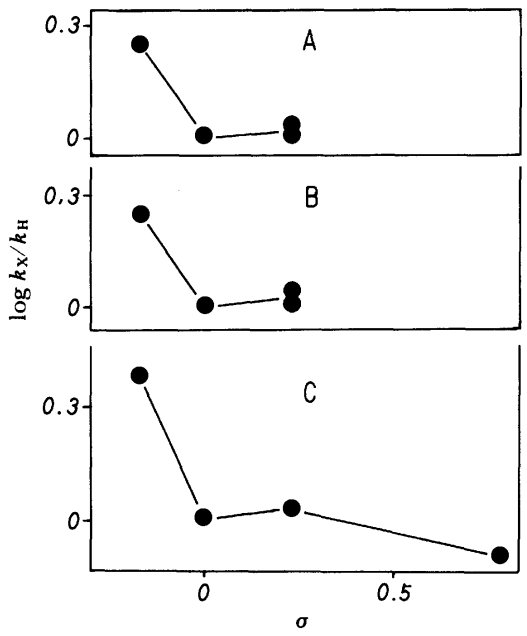

Fig. 2. Hammett plots for the reactions of $(CH_3)_3GeSC_6H_5$+$YC_6H_4CH_2Br$: A, in C_6H_6; B, in C_6H_5CN and $(CH_3)_3SnSC_6H_4CH_3$-*p*+$YC_6H_4CH_2Cl$: C, in $CHCl_3$.

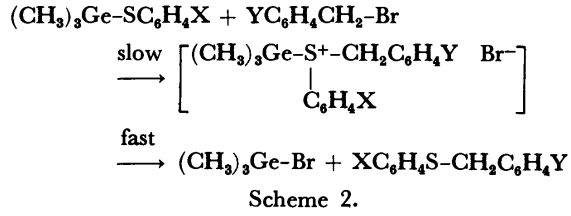
hand, was observed by electron-withdrawing substituents. Thus, bent or curved Hammett plots were obtained as shown in Fig. 2. The bent plots do not contradict with the nucleophilic mechanism. Indeed, a quite similar bent plot has also been reported for the nucleophilic reaction of benzenethiol with substituted benzyl bromides.[7]

Moreover, rate of the reaction of trimethyl(*p*-tolylthio)stannane with substituted benzyl chlorides was measured in order to make sure the mechanism, since a nucleophilic mechanism has been accepted conclusively for such reaction by many evidences.[4] The plot is shown in Fig. 2. A similar bent plot was obtained. The observed bent or curved plot is quite common for the nucleophilic reactions with the substituted benzyl halides.

Thus, all the results obtained by the present study support a mechanism involving nucleophilic attack of the sulfur atom on the benzylic carbon atom (Scheme 2). The formation of the sulfonium intermediate would be the rate-determining step and the salt would decompose rapidly. Neither any precipitation was formed even in a nonpolar solvent nor signals corresponding to the salt were observed during the reaction. A stannylsulfonium salt of this type had once been reported as an isolable product[8] but we later found that the structure of the isolated product was wrong and concluded that the salt cannot be isolated.[9]

The mechanism for the present reaction which has thus been suggested, is quite different from that of the reaction of the same arylthiogermanes with benzoyl



Scheme 2.

chloride.[2] The kinetic aspects observed in the present study are quite similar with those of the reaction of the arylthiostannanes with haloalkanes[4] and different from those of the reaction of the arylthiosilanes with phenacyl bromide.[5]

There are several factors which may control the course of the reaction. Nucleophilicity of the sulfur atom and 5-coordination ability of the germanium atom might be important factors. However, the difference in the mechanisms of the present reaction and that of the reaction with benzoyl chloride[2] cannot be explained in terms of those factors since the same arylthiogermanes were used.

On inspection of the present results and those of the previously reported, the reactivity of benzoyl chloride[2] is appeared smaller than expected.[10] In other words the reactivity of the arylthiogermanes seems to be restricted toward aroyl chlorides and the restriction may change the mechanism. Namely, the reaction of the arylthiogermanes with benzoyl chloride proceeds only slightly faster than the reaction with benzyl bromide and these two reactions proceed by different mechanisms. Aroyl chlorides would be expected to have much higher reactivity than benzyl bromides for the reaction with nucleophiles. In fact, much faster reaction of benzoyl chloride was observed than that of benzyl bromide with the arylthiostannanes and the reactions have been known to proceed by a common mechanism i.e., nucleophilic attack of the sulfur atom.[11]

The restricted reactivity of the arylthiogermanes toward benzoyl chloride can also be recognized by comparing the rates of the reactions of the arylthiogermanes and the stannanes with these two halides.[1,2,4] The arylthiogermanes are substantially less reactive than the arylthiostannanes for the reactions with benzoyl chloride. On the other hand, no such substantial difference in their reactivities was observed for the reactions with benzyl bromide.[12] Only the reaction of the arylthiogermanes with benzoyl chloride, among these four reactions, has been known to involve a 5-coordinated intermediate.[2]

There should be a special factor to restrict the reactivity of the arylthiogermanes toward aroyl chlorides. The mechanism of the reaction seems to be closely related to the reactivity as has hither been discussed. The facile reaction involves a nucleophilic attack of the sulfur atom, while 5-coordinated intermediate is formed when the nucleophilic reaction

was disturbed. The factor to control the reactivity together with the mechanism would be a steric effect. The aroyl halides may have more steric requirements than that of benzyl halides upon nucleophilic attacks. Thus, benzyl bromide accepts a facile nucleophilic attack even by a bulky nucleophile like the arylthiogermanes. On the other hand, benzoyl chloride cannot be attacked by a bulky nucleophile and the reaction proceeds by forming a 5-coordinated intermediate when forced to proceed.[2]

The same concept can also be applied to the other reactions of this type. The loger metal–sulfur bond would reduce the steric crowd around the sulfur atom and hence allows the sulfur atom to act as a nucleophile. The reaction of the arylthiostannanes of the longer metal–sulfur bond, with aroyl chlorides has been known to proceed by the nucleophilic process.[1] On the other hand, the shorter metal–sulfur bond increases the steric crowd and restricts the nucleophilic attack. The reaction of the arylthiogermanes with benzoyl chloride proceeds via 5-coordinated intermediate as mentioned above.[2] In this connection, it is quite natural that the reaction of the arylthiosilanes having the shortest metal–sulfur bond with benzoyl chloride involves 5-coordinated intermediate.[3] The borderline bond length lies between the tin–sulfur and the germanium–sulfur bonds for the reaction with aroyl chlorides in changing the mechanism from nucleophilic reaction to the 5-coordination process.

The difference in the mechanisms of the reactions of a series of metal–sulfur compounds with benzyl bromide can also be rationalized by their different bond lengthes. The reaction of the arylthiostannanes with benzyl bromide undergoes by a nucleophilic attack of the sulfur atom on the benzylic carbon.[4] In the present study, the shorter metal–sulfur bond like the arylthiogermanes has been found to attack on the benzyl bromide in a similar way due to less steric requirements of the halide. The 5-coordination process suggested for the reaction of the arylthiosilanes with phenacyl bromide[5] can be understood in terms of the steric crowd due to the shortest metal–sulfur bond length. Among the reactions with primary haloalkanes, only the reaction of the arylthiosilanes would involve a 5-coordinated intermediate although any kinetic evidence with a common haloalkane like benzyl bromide has not been obtained yet.[13]

The steric effect has thus been found to be an important factor to control the course of the reaction. Other factors such as the nucleophilicity and the 5-coordination ability dependent on the individual metals cannot be ruled out but seem to be not important at least for the reactions discussed here.

Experimental

Materials. Solvents were dried and distilled. Substituted benzyl bromides and chlorides were purified by distillation or recrystallization before use. The preparations of (arylthio)trimethylgermanes were reported previously.[2]

Product Analysis. Trimethyl(phenylthio)germane (1.10 g, 5.6×10^{-3} mol) was heated with an equimolar amount of benzyl bromide (0.94 g) in a sealed tube at 100 °C for 30 h. ^{1}H NMR analysis of the reaction mixture showed only signals due to bromotrimethylgermane and benzyl phenyl sulfide. Bromotrimethylgermane was isolated by distillation (bp 113—114 °C, 65%). Benzyl phenyl sulfide was obtained from the residue and was purified by recrystallization, mp 41—43 °C (from hexane, 98%, lit,[14] 41—43.5 °C).

Kinetics. The rates of the reactions of the arylthiogermanes (0.262 mol dm^{-3}) with benzyl bromides (0.318 mol dm^{-3}) were measured by the procedure reported recently.[2] The rates of the reactions of trimethyl(*p*-tolylthio)stannane (0.06 mol dm^{-3}) with benzyl chlorides (0.6 mol dm^{-3}) were measured by the previous method.[4] Pseudo-first-order rate constants k_1 for the reactions of $(CH_3)_3SnSC_6H_4CH_3$-*p* with $ClCH_2C_6H_4Y$-*p* in chloroform at 130 °C are as follows: Y=CH_3, 2.36×10^{-5} s^{-1}; H, 9.96×10^{-6} s^{-1}; Cl, 1.05×10^{-5} s^{-1}; NO_2, 7.86×10^{-6} s^{-1}.

The Reaction of (Arylthio)trimethylgermanes with the Solvents. Dichloromethane solution of trimethyl(phenylthio)germane (0.262 mol dm^{-3}) was heated at 150 °C for 110 min. The reaction conditions correspond to more than 75% completion of the reaction of the germane with benzyl bromide. Small amount of chlorotrimethylgermane was found in the mixture by ^{1}H NMR analysis (δ=0.72). Pseudo-first-order rate constant was estimated based on the conversion: $k_1=1.2\times1.0^{-5}$ s^{-1}. Thus, the reaction with the solvent was negligible under the conditions used for the kinetics. No reaction was found with the other solvents.

9) S. Kozuka and S. Ohya, *J. Organomet. Chem.*, **149**, 191 (1978).

10) For instance, extrapolation of the present result and comparing with that reported[2] gives $k_2(C_6H_5COCl)/k_2(C_6H_5CH_2Br)$ is only 9 in CH_2Cl_2 at 100 °C.

11) The reaction of $(CH_3)_3SnSC_6H_4CH_3$-*p* with benzyl

bromide in nonpolar solvent proceeds only at elevated temperatures (k_1=2.65×10^{-4} s^{-1} at 115 °C in $CHCl_3$)[4] while that with benzoyl chloride proceeds at around room temperature (k_2=4.5×10^{-5} mol^{-1} dm^{3}s^{-1} at 34 °C in CCl_4).[1] These reactions proceed by nucleophilic mechanisms.

12) The retes of the reactions are as follows: $(CH_3)_3GeSC_6H_5+C_6H_5COCl$; k_2=3.45×10^{-4} dm^3 s^{-1} at 130 °C in CCl_4,[2] and $(CH_3)_3SnSC_6H_5+C_6H_5COCl$; k_2=5.2×10^{-5} dm^3 mol^{-1} s^{-1} at 43 °C in CCl_4.[1] Extraporations of their Arrhenius plots gave relative reactivity of the phenylthiogermane and the phenylthiostannane with benzoyl chloride: k_2(GeS)/k_2(SnS)=ca. 0.025 at 100 °C in CCl_4. On the other hand, direct comparison of their reactivity toward benzyl bromide is difficult due to difference in their reaction conditions. However the rate of the reaction of $(CH_3)_3SnSC_6H_4CH_3$-*p* + $C_6H_5CH_2Br$[4,11] is only slightly faster than that in nonpolar solvents as shown in Table 1.

13) Kinetic study on the reaction of the arylthiosilanes with benzyl halides was failed due to facile decomposition of the reactant.[5] However, the reaction with phenacyl bromide has been found to proceed via 5-coordinated intermediate.[5]

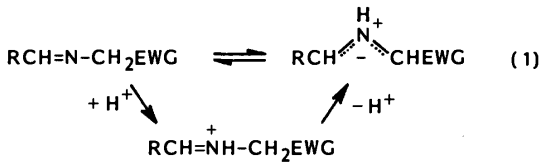
(Received May 30, 1987)

Condensation of 2-amino esters with carbonyl compounds leads to simple generation of ester-stabilized azomethine ylides which are trapped by olefinic dipolarophiles as cycloadducts. Anti ylides are exclusively involved in the cycloadditions when *N*-substituted 2-amino esters are employed for the ylide generation, while syn ylides from *N*-unsubstituted 2-amino esters. Relative stability among all possible ylide isomers has been inspected and the selective involvement of particular ylidic forms has been explained on the ground of 1,5-dipole interaction or hydrogen bonding stabilization. Endo- and exo-selectivity of the cycloadditions is also discussed.

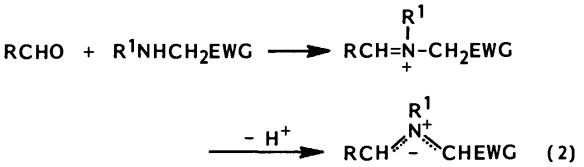
Cycloaddition of azomethine ylides with olefinic and acetylenic dipolarophiles affords pyrrolidines, pyrrolines, and pyrroles. The importance of azomethine ylide chemistry is being increased more than ever as a tool for constructing the nitrogen-containing five-membered heterocycles which are often central ring systems of numerous natural products. Its synthetic application was encouraged by the recent discovery of new generation methods of azomethine ylides, including wide range of stabilized to nonstabilized azomethine ylides. Two typical methods involve the desilylation route[1] discovered by Vedejs; the imine route[2] by Grigg, Joucla, and Tsuge, separatedly.

Griggs' method of generating azomethine ylides is based upon a thermal tautomerization of imine (Eq. 1). The acidic hydrogen adjacent to both the imine



(1)

nitrogen and ester moiety migrates onto the nitrogen (1,2-proton migration). This imine–azomethine ylide tautomerization is known to be catalyzed by an acid which facilitates the reaction by the rapid formation of an iminium intermediate.[3] It is therefore envisaged that the iminium compounds which will be produced from the condensation of *N*-substituted 2-amino esters with carbonyl compounds would allow ready deprotonation to lead to the generation of ester-stabilized azomethine ylides (Eq. 2). This process has been



(2)

recently realized by several groups,[4-6] while the reaction examples were quite limited so that no details of this promising azomethine ylide generation are known.

The present article describes full details of the 2-amino ester route as a simple and general generation method of ester-stabilized azomethine ylides. Stereochemical features of the cycloaddition of ester-stabilized azomethine ylides with olefins have been figured out. The origin of anti- and syn-selectivity with respect to the ylides as well as the endo-, exo, and regioselectivity of the cycloaddition is discussed.[7]

Results and Discussion

Generation and Cycloaddition of *N*-Substituted Azomethine Ylides of Ester-Stabilized Types. According to the Eq. 2, benzaldehyde and ethyl *N*-methylaminoacetate (**1**) were heated under reflux in toluene. The water eliminated was removed by the aid of a Dien-Stark trap and the azomethine ylide **A** (R=Ph, R^1=Me, EWG=COOEt) generated was captured by *N*-(*p*-tolyl)maleimide to give three stereoisomers of **1**:**1** cycloadducts **4a**, **5a**, and **6a** in 93% of total yield (Scheme 1 and Table 1).

Their structures are readily assigned as 3a,4-trans-6,6a-cis- (**4a**, 69%), 3a,4-cis-6,6a-trans- (**5a**, 20%), and 3a,4-cis-6,6a-cis-isomer (**6a**, 4%) on the basis of the vicinal coupling constants as well as other spectral and analytical data: **4a**: $J_{3a,4}$=0.8 and $J_{6,6a}$=9.4 Hz; **5a**: $J_{3a,4}$=8.8 and $J_{6,6a}$=5.7 Hz; **6a**: $J_{3,3a}$=8.8 and $J_{6,6a}$=7.0 Hz. Thus, **4a** and **5a** are cycloadducts to the anti form of ylide **A** and **6a** to the syn ylide.

Aliphatic aldehydes can be used as carbonyl compounds albeit low yield formation of the cycloadducts. The azomethine ylide **A** (R=Et, R^1=Me, EWG=COOEt) derived from propanal reacted with the maleimide to produce 48% yield of two stereoisomeric cycloadducts **4b** and **5b** to the anti

ylide together with the third product **10** which was assigned as 4,6-dimethyl-2-(*p*-tolyl)-1,3,3a,4-tetrahydro-2*H*-isoindole-1,3-dione. When ethanal was employed, no trace of the cycloadducts of methyl-substituted azomethine ylide **A** (R=Me) was even detected but two stereoisomeric cycloadducts **8**+**9** to 1-propenyl-substituted ylide were obtained. Isoindoledione **11** was again accompanied.

Formation of **8** to **11** was not surprising since we have already experienced a similar reaction pattern in the reaction of aminoacetonitrile with aliphatic aldehydes.[3b] As illustrated in Scheme 1, an aliphatic aldehyde undergoes condensation with ethyl *N*-methylaminoacetate **1** to generate the expected azomethine ylide which is in equilibrium with an enamine isomer. The enamine then adds to the second molecule of the aldehyde to form 1-alkenyl-substituted azomethine ylide which is also equilibrating with the dienamine. 1,3-Dipolar cycloaddition of the ylide leads to **8** and **9**, while Diels–Alder reaction of the latter gives **10** and **11** after the elimination of amino ester **1**.

The condensation of **1** with paraformaldehyde generated the azomethine ylide **A** (R=H, R[1]=Me, EWG=COOEt) bearing an ester as the only *C*-substituent. It was captured by *N*-(*p*-tolyl)maleimide to give two stereoisomeric cycloadducts **4c** and **5c** in an excellent combined yield.

Reactions of methyl *N*-phenylaminoacetate (**2**) with benzaldehyde, propanal, and paraformaldehyde generated azomethine ylides **A** (R[1]=Ph, EWG=COOMe) whose cycloadditions with *N*-(*p*-tolyl)maleimide afforded mixtures of endo- and exo-cycloadducts to the anti forms of ylides **A** (**4d**+**5d** to **4f**+**5f**, Scheme 1 and Table 1).

The exclusive involvement of the anti form of *N*-substituted azomethine ylides **A** (EWG=COOR[2]) bearing a ylide-stabilizing ester in their cycloadditions contrasts with the extremely poor selectivity of cyano-stabilized azomethine ylide **A** (EWG=CN), with respect to both the ylide configuration and cycloaddition approach. For instance, reaction of *N*-methylaminoacetonitrile (**3**) with benzaldehyde in the presence of *N*-(*p*-tolyl)maleimide gave a mixture of four stereoisomeric cycloadducts **4g**, **5g**, **6g**, and **7g**, all possible stereoisomers, in a comparable ratio (Table 1).

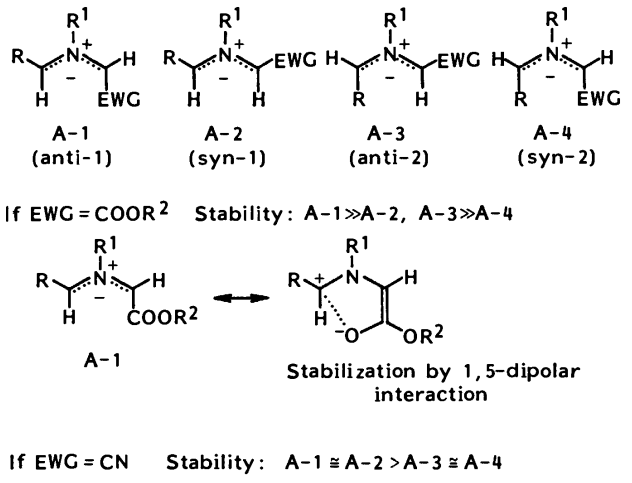

Fig. .1. Stable configuration of *N*-substituted azomethine ylides of ester- and cyano-stabilized types.

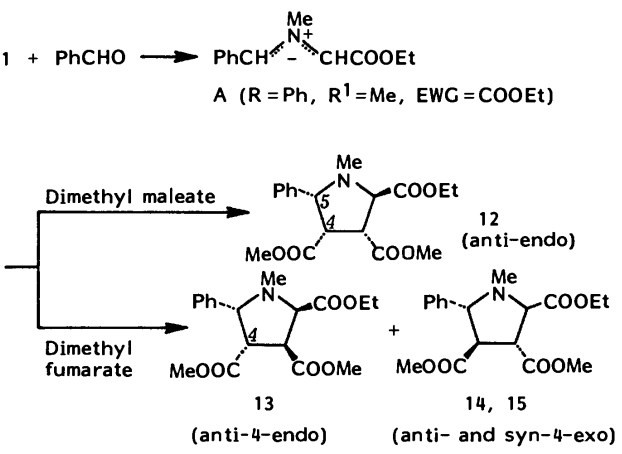
Each two anti (**A-1** and **A-3**) and syn configurations (**A-2** and **A-4**) are possible for the *N*-substituted azomethine ylide **A** with an ester or a cyano stabilizing substituent (Fig. 1). Their relative stability may be estimated on the ground of steric and electronic interactions among the substituents.

The U-shaped syn ylide **A-4** of ester-stabilized type is first discarded as the concerned species because it is too congested to exist as a stable form. Although the other three ylides seem equally stable from a sterical standpoint, only the S-shaped anti ylide **A-1** with the ester group opposite to the *N*-substituent R[1] has an additional stabilization by 1,5-dipole interaction.[8,9] In the end the relative stability of ester-stabilized ylides (EWG=COOR[2]) becomes as follows: **A-1**≫**A-2**≅**A-3**≫**A-4**. Accordingly the anti ylide **A-1** must have been selectively involved in its cycloaddition.

On the other hand such stabilization by an extended dipole is impossible in the case of cyano-stabilized azomethine ylide **A** (EWG=CN). Cyano moiety is only slightly bulkier than hydrogen so that the difference of steric stability between **A-1** and **A-2**, and also **A-3** and **A-4**, is negligible. Thus the relative stability becomes in the following order: **A-1**≅**A-2**>**A-3**≅**A-4**. Poor stereoselectivity will be unavoidable in the cycloadditions of *N*-substituted azomethine ylides **A** of cyano-stabilized types.

Exclusively stereospecific cycloadditions of the azomethine ylide **A** (R=Ph, R[1]=Me, EWG=COOEt) derived from **1** and benzaldehyde is shown in Scheme 2 and Table 2. Contrary to the poor stereoselectivity observed in the cycloaddition to *N*-(*p*-tolyl)maleimide



Scheme 2.

(Entry 1 of Table 1), the reaction with dimethyl maleate was highly endo-selective leading to **12**. With dimethyl fumarate, three stereoisomeric cycloadducts **13**—**15** were produced. Similar dramatic change of stereoselectivity has been recently reported by Joucla.[5] 4,5-Cis structure of **12** and **13** was assigned on the basis of the intense shielding of 4-ester moiety by the adjacent phenyl (5-Ph).

With unsymmetrically substituted olefins such as methyl acrylate and (*E*)-β-nitrostyrene, the above ylide **A** (R=Ph, R^1=Me, EWG=COOEt) as well as its *N*-phenyl analog **A** (R=R^1=Ph, EWG=COOMe) underwent highly endo- and regioselective cycloadditions giving 2,3-cis-3,4-trans-4,5-cis-cycloadducts **16a**—**16d** as single isomers (Scheme 3 and Table 2). As will be realized soon, these high regio- and stereoselectivities can not be achieved without the phenyl substituent.

The azomethine ylide bearing an ester moiety as the only *C*-substituent was previously generated by thermolysis of aziridine-2-carboxylates,[6a,b] deprotonation of *N*-(phenylthiomethyl)aminoacetates,[6c] or desilylation of *N*-(trimethylsilylmethyl)iminoacetates.[6d] This ylide **A** (R=H, R^1=Me, EWG=COOEt) which was more simply generated from **1** and paraformaldehyde under reflux in toluene undergoes cycloadditions to unsymmetrically substituted olefins, but both the regio- and stereoselectivities are very poor like the precedents. Thus a mixture of two regioisomeric cycloadducts **17a** or **17b** was produced with methyl acrylate or phenyl vinyl sulfone, respectively (Scheme 3). It is noteworthy that this ylide showed high reactivity toward styrene as an aryl-substituted olefin to give the regioselective cycloadduct **17c**. This is the first example for the cycloaddition of ester-stabilized azomethine ylide to such an aryl-substituted olefin as styrene.[10,11]

As some incorrect structural assignments are contained in the previous work,[13] our structural

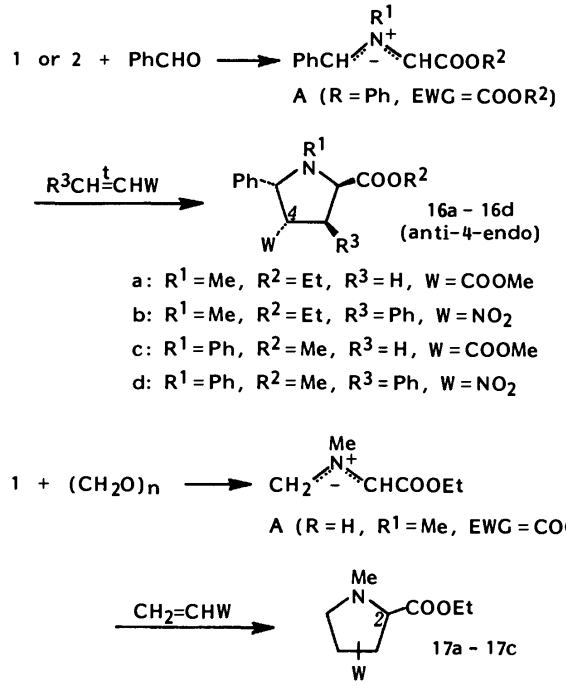
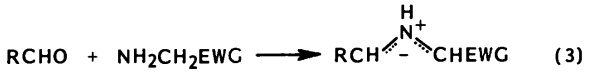
a) A: Under reflux in toluene, B: Uuder reflux in toluene together with *N*,*N*-diisopropylethylamine, C: At 180 °C in a sealed tube together with anhydrous potassium carbonate, D: At room temperature in acetonitrile in the presence of acetic acid (10 mol%), E: Under reflux in chloroform. b) Yield of isolated products. c) Determined by ^{1}H NMR. d) Only **15** was separated from the other two. e) Inseparable mixture of two regioisomers. f) 2,3-Isomer : 2,4-isomer=6 : 5 (^{1}H NMR). g) Stereostructure remains unsolved. h) 2,3-Isomer : 2,4-isomer=1 : 4 (^{1}H NMR). i) Inseparable mixture of two stereoisomers. j) Both 2,3-isomers.

analysis on **17a—17c** based upon the ^{13}C NMR is summarized in Table 3. Adjacent substitution with an ester brings about a downfield ^{13}C shift by 3—5 ppm, and with a phenyl by 7—10 ppm. Substitution with a sulfonyl makes no significant shift to the adjacent carbon. Thus **17a** and **17b** were assigned as mixtures of two regioisomers, while their stereostructures could not be determined. Also apparent is the 2,3-disubstituted structure of **17c**. A 6:5 ratio of 2,3- to 2,4-substitution of **17a** is opposite to the reported one (1:3),[6c] indicating that regioselectivity in the azomethine ylide cycloadditions strongly depends upon the generation method or reaction medium.



Scheme 3.

Generation and Cycloaddition of *N*-Unsubstituted (or *N*-Protonated) Azomethine Ylides of Ester-Stabilized Types. As shown with Eq. 1 *N*-(alkoxycarbonylmethyl)imines undergo a ready thermal tautomerization and this reaction is one of the most useful generation methods of *N*-unsubstituted azomethine ylides of ester-stabilized types.[2] This procedure may be simplified by omitting the isolation step of the imines and this modified method would be especially useful when imine esters as ylide precursors are labile.[3b] Our procedure consists of heating a mixture of 2-amino ester and carbonyl compound under continuous removal of water (Eq. 3).[14]



(3)

N-Unsubstituted azomethine ylides **B** of ester-stabilized types were directly generated by similar reactions of methyl aminoacetate (**18**) with carbonyl compounds and trapped with *N*-methylmaleimide to provide the exclusive formation of endo-cycloadducts **19a—19c** and **21** to the syn form of **B** (Scheme 4 and

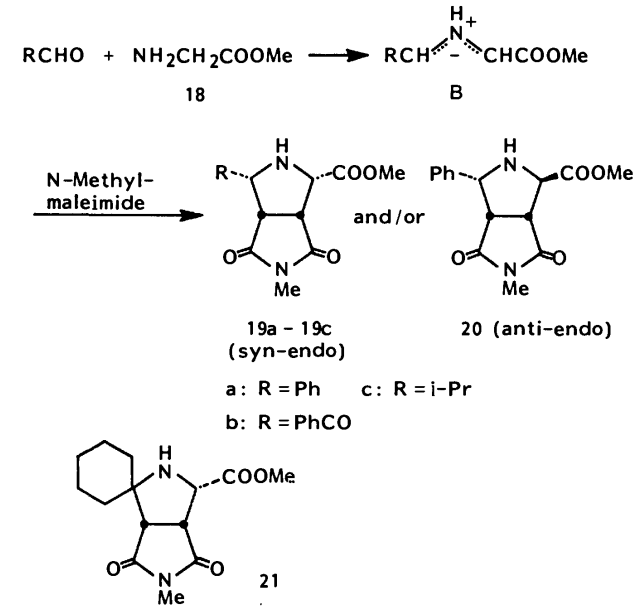
a) All recorded in $CDCl_3$. b) See Ref. 12.

Table 2). Benzaldehyde and cyclohexanone form relatively stable imines so that the thermal tautomerization method could be also applied to these imines. Although the imines of **18** with phenylglyoxal and 2-methylpropanal are too unstable to be isolated, our method worked well in both cases. However a serious limitation appeared when such aldehydes as propanal and cinnamaldehyde were employed. No corresponding azomethine ylides were trapped by a maleimide dipolarophile.

As shown above the imine derived from **18** and benzaldehyde tautomerized into a syn form of azomethine ylide **B** (R=Ph) on heating in toluene. To our surprise the stereoselectivity with respect to the ylide was extremely decreased when the same imine was heated in acetonitrile in the presence of acetic acid (10 mol%). Thus a 1:2 mixture of the syn and anti ylide cycloadducts **19a**+**20** was obtained. This will be discussed later.



Scheme 4.

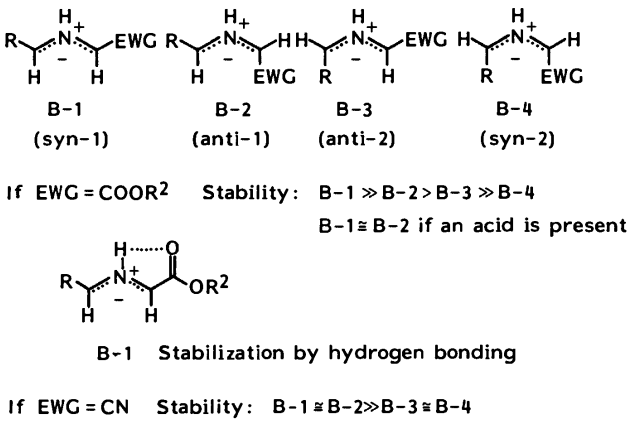


Fig. 2. Stable configuration of *N*-protonated azomethine ylides of ester- and cyano-stabilized types.

Four configurations including each two syn (**B-1** and **B-4**) and anti ylidic forms (**B-2** and **B-3**) are also possible for the *N*-unsubstituted azomethine ylide **B** of ester- or cyano-stabilized type (Fig. 2). In all the cycloaddition examples described in Scheme 4 with an exception the syn form of ester-stabilized ylide **B** (EWG=COOMe) was exclusively incorporated in the cycloadducts, indicating higher stability of the syn ylide. This makes a striking contrast to the case of *N*-substituted ylide **A** where anti form has predominated. It is quite easy to understand that ylide **B-1** is much more stabilized than the other syn ylide **B-4** on the basis of both steric consideration and the hydrogen bonding between the ester carbonyl and NH hydrogen. In a polar or protic solvent this hydrogen bonding becomes fragile, and the positively charged ylide nitrogen is stabilized through the coordination of the solvent molecules nearby. In this case syn configuration **B-1** is no longer the most stable.

In the case of *N*-protonated azomethine ylide **B** (EWG=CN) of cyano-stabilized type, syn ylide **B-1** and anti ylide **B-2** would have an identical stability. Poor stereoselectivity with respect to the ylidic carbon bearing a CN substituent has been previously demonstrated.[3b]

Stereochemical Aspects of Cycloaddition of Ester-Stabilized Azomethine Ylides. The predominant participation in cycloaddition of the anti ylide **A-1** of *N*-substituted azomethine ylide (Fig. 1) and of the syn ylide **B-1** of *N*-unsubstituted ylide has been discussed above (Fig. 2). Table 1 summarizes the endo–exo ratios of cycloadducts derived from *N*-substituted azomethine ylides **A** (EWG=COOEt or COOMe) bearing a variety of *C*-substituents and *N*-(*p*-tolyl)-maleimide, and Entries 10—14 of Table 2 show the exclusive formation of endo cycloadducts from *N*-unsubstituted azomethine ylides **B** and the maleimide. Apparently the endo–exo selectivity depends upon the *N*-substituents.

Endo and exo approaches of maleimide to an azomethine ylide 1,3-dipole is illustrated in Fig. 3 with Approach I and II, respectively (either A or B is an ester moiety). In Approach II (exo) there exist four sets of near-eclipsed repulsion (H/CO, A/CO, R/H, B/H), and in Approach I (endo) steric repulsion

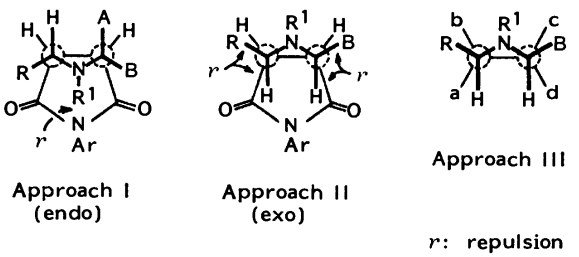

Fig. 3. Approaches between azomethine ylide $RCH{=}\overset{+}{N}(R^1)\text{-}\underline{C}AB$ and olefinic dipolarophiles.

between both the *N*-substituents (R^1 and Ar) is the only barrier. Accordingly it is readily understood that cycloaddition becomes highly endo-selective if the *N*-substituent R^1 is small in size, for instance a hydrogen. On the other hand this steric repulsion is critical when R^1 is bulky, the endo selectivity becoming lowered.

The small bond angle of CO–CH=CH and the planer geometry make maleimides a very special dipolarophile. The *N*-substituent repulsion of Approach I and the eclipsed repulsion of Approach II are both amplified compared with other acyclic dipolarophiles whose approach is illustrated with Approach III (Fig. 3). Now the substituents a and d are not bonded so that the steric repulsion toward the *N*-substituent R^1 is reduced. This may be the main reason why the cycloaddition of ylide **A** (R=Ph, R^1=Me, EWG=COOEt) to dimethyl maleate was absolutely endo-selective to lead to **12** (Entry 1 of Table 2). Attractive interaction working between the phenyl substituent and the ester group, each is on either the ylide or olefin, is also responsible for the high endo selection as shown with Entries 3—6 of Table 2.

The present generation method of ester-stabilized azomethine ylides is valuable because of 1) simple procedure using readily available 2-amino esters and carbonyl compounds, 2) high yield formation of a variety of ylides, 3) no need of the isolation of ylide precursors, 4) mild generation conditions. As the aziridine route leading to ester-stabilized azomethine ylides with no other ylide-stabilizing substituent requires the pyrolysis at an elevated temperature,[6a] the ylide trapping with olefins are not so effective as the present case.

Experimental

General. Melting points were determined on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-40 (90 MHz) or a JEOL FX-100 instrument (100 MHz) and ^{13}C NMR on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra were measured with a JEOL-01SG-2 spectrometer at 70 eV of ionization energy. High resolution mass spectra were also obtained on the same instrument. Elemental analyses were performed on a Hitachi 026 CHN analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck). Visualization was made with ultraviolet light (254 and 365 nm), iodine, molybdophosphoric acid (5% in ethanol), or *p*-anisaldehyde (5% in ethanol containing 5% of sulfuric acid). For preparative column chromatography, Wakogel C-200, C-300 (Wako), and Silicagel 60 (Merck) were employed. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silicagel 60 (Merck, size: 0.04—0.063 mm). Gas liquid chromatography (GLC) was accomplished on a Yanaco G-2800 gas chromatograph with an ionization flame detector using a glass column (SE-30, 3×2000 mm) or a glass capillary column (Silicone GE, SE-30, 0.25×50000 mm). Micro vacuum distillation was carried out on a Sibata GTO-250R Kugelrohr distilling apparatus. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type-V at about 50 °C unless otherwise stated.

General Procedure for the Azomethine Ylide Generation from the Condensation of 1—3 with Carbonyl Compounds. An amine (**1**, **2**, or **3**) and an aldehyde were heated under reflux in dry toluene (5 ml for 1 mmol of the amine) in the presence of *N*-(*p*-tolyl)maleimide. The water formed was continuously removed by the aid of a Dean-Stark trap. Equimolar amounts of the amine and *N*-(*p*-tolyl)maleimide were used, while the aldehydes were employed in excess: Benzaldehyde and propanal: 1.5 equivalent. Acetaldehyde and paraformaldehyde: 5 equivalents. The reaction conditions as well as the results are all summarized in Table 1.

4a+5a+6a: This mixture was chromatographed over silica gel with hexane–ethyl acetate (10:1 vol/vol) to give **4a** (63%), **5a** (21%), and then **6a** (7%). **4a**: Colorless needles (benzene–hexane); mp 151—152 °C; IR (KBr) 1720 and 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.35 (3H, t, COOEt), 2.28 2.32 (each 3H, s, NMe and *p*-Me), 3.47 (1H, dd, J=8.0 and 0.8 Hz, 3a-H), 3.75 (1H, dd, J=9.4 and 8.0 Hz, 6a-H), 4.25 (2H, q, COOEt), 4.40 (1H, br s, 4-H), 4.49 (1H, d, J=9.4 Hz, 6-H), and 6.8—7.4 (9H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=14.47 (q, COOEt), 21.18 (q, *p*-Me), 35.56 (q, NMe), 48.65 (d, 3a-C), 50.42 (d, 6a-C), 61.00 (t, COOEt), 67.53 (d, 4-C), 69.06 (d, 6-C), 128.00 128.10, 128.54, 128.77, 129.83 (each d), 129.48, 137.19, 138.54 (each s), 171.01 (s, COOEt), 174.84, and 176.54 (each s, CON); MS *m/z* (rel intensity, %) 393 (M^+, 1), 320 (25), 319 (base peak), and 158 (42). Generation of Azomethine Ylide A (R=Ph, R^1=Me, EWG=COOEt) from 1 and Benzaldehyde, and Ylide Trapping with Dimethyl Maleate or Fumarate Leading to 12—15. A mixture of **1** (0.22 g, 1.66 mmol), benzaldehyde (0.24 g, 2.26 mmol), and dimethyl maleate or fumarate (0.24 g, 1.66 mmol) in dry toluene (15 ml) was heated under reflux under the reaction conditions listed in Table 2. The water formed was removed by the aid of a Dean–Stark trap. The solvent was evaporated in vacuo and the residue was chromatographed over silica gel. Elution of the maleate mixture with hexane–ethyl acetate (10:1 vol/vol) afforded **12** (0.368 g, 62%). Elution of the fumarate mixture (**13**:**14**:**15**= 3:3:2 (^{1}H NMR)) with hexane–ethyl acetate (20:1 vol/vol) gave **15** (0.194 g, 33%) and then **13+14** (0.323 g, 54%, **13**:**14**=1:1 (^{1}H NMR)).

12: Colorless needles (benzene–hexane); mp 93—94 °C; IR (KBr) 1740 and 1722 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.31 (3H, t, COOEt), 2.20 (3H, s, NMe), 3.17 (3H, s, 4-COOMe), 3.64 (3H, s, 3-COOMe), 3.5—3.7, 4.1—4.5 (2H+3H, m, 2-, 3-, 4-H, and COOEt), 4.60 (1H, d, J=6.5 Hz, 5-H), and 7.24 (5H, s, Ph); ^{13}C NMR ($CDCl_3$) δ=14.35 (q, COOEt), 34.53 (q, NMe), 48.77 (d, 3-C), 51.24, 53.18 (each q, COOMe), 52.12 (d, 4-C), 61.00 (t, COOEt), 65.71 (d, 2-C), 70.83 (d, 5-C), 127.83, 128.18, 128.42, 128.72 (each d), 137.71 (s), 171.31, and 173.43 (each s, COOMe and COOEt); MS m/z (rel intensity, %) 349 (M^+, 11) and 276 (base peak). Found: C, 61.81; H, 6.63; N, 4.13%. Calcd for $C_{18}H_{23}NO_6$: C, 61.88; H, 6.64; N, 4.01%.

13+14: Colorless viscous liquid; IR (neat) 1725 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.30, 1.31 (each 1/2×3H, t, COOEt), 2.16, 2.20 (each 1/2×3H, s, NMe), 3.03 (1/2×3H, s, 4-COOMe of **13**), 3.4—3.7 (1H, m, CH), 3.65 (3H, s, COOMe), 3.77 (1/2×3H, s, COOMe), 3.9—4.4 (3H, m, CH), 4.24, 4.25 (each 1/2×2H, COOEt), and 7.2—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.41 (q, COOEt), 34.88, 35.71 (each q, NMe), 47.77, 48.77 (each d, 3-C), 51.18, 51.47, 52.24, 52.77 (each q, COOMe), 54.65 (d, 4-C), 60.65, 60.89 (each t, COOEt), 67.65, 68.42 (each d, 2-C), 69.18, 70.01 (each d, 5-C), 128.18, 128.72

(each d), 141.24 (s), 171.48, 171.78, 172.36, and 172.95 (each s, COOMe and COOEt); MS *m/z* (rel intensity, %) 349 (M^+, 16), 276 (base peak), 244 (63), 216 (54), and 184 (22). HRMS Found: *m/z* 349.1593. Calcd for $C_{18}H_{23}NO_6$: M, 349.1524.

15: Colorless liquid; IR (neat) 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.29 (3H, t, COOEt), 2.24 (3H, s, NMe), 3.3—4.0 (4H, m, 2-, 3-, 4-, and 5-H), 3.59, 3.66 (each 3H, s, COOMe), 4.20 (2H, q, COOEt), and 7.2—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.24 (q, COOEt), 39.36 (q, NMe), 48.53 (d, 3-C), 52.18, 52.18 (each q, COOMe), 54.12 (d, 4-C), 61.12 (t, COOEt), 68.71 (d, 2-C), 74.01 (d, 5-C), 128.01, 128.36, 128.72 (each d), 139.83 (s), 171.01, 171.36, and 172.95 (each s, COOEt and COOMe); MS *m/z* (rel intensity, %) 349 (M^+, 9), 276 (base peak), 244 (65), 216 (73), 184 (30), and 158 (25). HRMS Found: *m/z* 349.1519. Calcd for $C_{18}H_{23}NO_6$: M, 349.1524.

Capture of the Ester-Stabilized Azomethine Ylides A (R=Ph, EWG=COOR[2]) with Methyl Acrylate or (*E*)-β-Nitrostyrene Leading to 16. An identical procedure was applied to a mixture of **1** or **2** (0.93 mmol), benzaldehyde (1.32 mmol, 1.5 equiv), and methyl acrylate (4.67 mmol, 5 equiv) in dry toluene (10 ml) or a mixture of **1** or **2** (0.94 mmol), benzaldehyde (0.94 mmol), and (*E*)-β-nitrostyrene (0.87 mmol) in toluene (8 ml). When **2**·HCl was used, and equimolar amount of *N,N*-diisopropylethylamine was added to the mixture. The reaction conditions as well as the results are summarized in Table 2. Products were purified through column chromatography over silica gel with hexane–ethyl acetate (10:1 vol/vol).

16a: Colorless liquid; IR (neat) 1730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.30 (3H, t, COOEt), 2.04 (1H, ddd, *J*=13.1, 8.7, and 1.7 Hz, one of 3-H), 2.26 (3H, s, NMe), 2.72 (1H, ddd, *J*=13.1, 9.0, and 8.0 Hz, the other of 3-H), 3.04 (3H, s, COOMe), 3.62 (1H, ddd, *J*=10.0, 9.0, and 8.7 Hz, 4-H), 3.97 (1H, dd, *J*=8.0 and 1.7 Hz, 2-H), 4.18 (2H, q, COOEt), 4.38 (1H, d, *J*=10.0 Hz, 5-H), and 7.22 (5H, s, Ph); ^{13}C NMR ($CDCl_3$) δ=14.47 (q, COOEt), 30.59 (t, 3-C), 35.47 (q, NMe), 48.89 (d, 4-C), 51.06 (q, COOMe), 60.30 (t, COOEt), 65.77 (d, 2-C), 69.36 (d, 5-C), 127.66, 128.01, 128.54 (each d), 139.89 (s), 173.01, and 173.71 (each s, COOEt and COOMe); MS *m/z* (rel intensity, %) 291 (M^+, 5), 219 (15), 218 (base peak), and 158 (15). Found: C, 66.16; H, 7.26; N, 4.96%. Calcd for $C_{16}H_{21}NO_4$: C. 65.94; H, 7.28; N, 4.81%.

16b: Colorless viscous liquid; IR (neat) 1720, 1540, and 1365 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.94 (3H, t, COOEt), 2.30 (3H, s, NMe), 3.92 (2H, q, COOEt), 4.30 (1H, d, *J*=7.3 Hz, 2-H), 4.70 (1H, dd, *J*=10.0 and 7.3 Hz, 3-H), 4.88 (1H, d, *J*=10.0 Hz, 5-H), 6.03 (1H, t, *J*=10.0 Hz, 4-H), and 7.2—7.4 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=13.88 (q, COOEt), 35.77 (q, NMe), 49.53 (d, 2-C), 60.48 (t, COOEt), 69.95 (d, 3-C), 70.95 (d, 5-C), 91.95 (d, 4-C), 127.66, 128.06, 128.36, 128.65, 128.89 (each d), 134.36, 139.89 (s), 171.31 (s, COOEt); MS *m/z* (rel intensity, %) 354 (M^+, 1), 308 (14), 281 (38), 235 (22), 234 (base peak), 115 (17), and 91 (20). Found: C, 67.89; H, 6.30; N, 7.98%. Calcd for $C_{20}H_{22}N_2O_4$: C, 67.78; H, 6.27; N, 7.91%.

16c: Colorless needles (benzene–hexane); mp 174—176 °C; IR (KBr) 1730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.16 (1H, ddd, *J*=13.5, 6.8, and 0.8 Hz, one of 3-H), 2.88 (1H, dt, *J*=13.5, 13.5, and 9.0 Hz, the other of 3-H), 3.36 (3H, s, 4-COOMe), 3.72 (3H, s, 2-COOMe), 3.90 (1H, ddd, *J*=13.5, 9.0, and 6.8 Hz, 4-H), 4.73 (1H, dd, *J*=9.0 and 0.8 Hz, 2-H), 5.26 (1H, d, *J*=9.0 Hz, 5-H), and 6.3—7.2 (10H, m, Ph); MS *m/z* (rel intensity, %) 339 (M^+, 28), 281 (17), 280 (base peak), 220 (16), and 77 (15). Found: C, 70.77; H, 6.26; N, 4.29%. Calcd for $C_{20}H_{21}NO_4$: C, 70.78; H, 6.24; N, 4.13%.

16d: Colorless needles (benzene–hexane); mp 205—207 °C; IR (KBr) 1730, 1550, and 1360 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.33 (3H, s, COOMe), 4.70 (1H, dd, *J*=11.8 and 8.6 Hz, 3-H), 5.04 (1H, d, *J*=8.6 Hz, 2-H), 5.64 (1H, d, *J*=9.2 Hz, 5-H), 6.28 (1H, dd, *J*=11.8 and 9.2 Hz, 4-H), and 6.4—7.3 (15H, m, Ph); MS *m/z* (rel intensity, %) 402 (M^+, 44), 356 (23), 343 (29), 297 (25), 296 (base peak), 115 (15), 104 (21), and 77 (23). Found: C, 71.52; H, 5.60; N, 7.06%. Calcd for $C_{24}H_{22}N_2O_4$: C, 71.62; H, 5.51; N, 6.96%.

Capture of the Ester-Stabilized Azomethine Ylide A (R=H, R[1]=Me, EWG=COOEt) with Unsymmetrically Substituted Olefins Leading to 17. A similar procedure employing **1** (2 mmol), paraformaldehyde (10 mmol, 5 equiv), and an olefin (methyl acrylate and styrene: 3 mmol, 1.5 equiv phenyl vinyl sulfone: 2 mmol, 1 equiv) afforded **17**. The reaction conditions and results are listed in Table 2. Purification of the products was carried out through column chromatography over silica gel with the following eluents: **17a** and **17c**: hexane–ethyl acetate (10:1 vol/vol), **17b**: hexane–ethyl acetate (1:1 vol/vol).

17a (a 6:5 mixture of 2,3- and 2,4-diesters (^1H NMR)): Pale yellow liquid; IR (neat) 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.27 (3H, t, COOEt), 2.40 (5/11×3H, s, NMe), 2.42 (6/11×3H, s, NMe), 2.0—2.7, 3.0—3.5 (each 3H, m, CH_2 and CH), 3.68, 3.70 (3H, each s, COOMe), 4.20, and 4.22 (2H, each, q, COOEt); ^{13}C NMR ($CDCl_3$) 2,3-isomer: δ=14.30 (q, COOEt), 27.83 (t, 4-C), 40.36 (q, NMe), 47.12 (d, 3-C), 51.88 (q, COOMe), 55.77 (t, 5-C), 60.65 (t, COOEt), 70.24 (d, 2-C), 172.07, and 174.19 (each s, COOEt and COOMe). 2,4-isomer: δ=14.30 (q, COOEt), 32.77 (t, 3-C), 40.71 (q, NMe), 41.47 (d, 4-C), 52.06 (q, COOMe), 58.83 (t, 5-C), 60.89 (t, COOEt), 66.83 (d, 2-C), 172.65, and 174.37 (each s, COOEt and COOMe); MS *m/z* (rel intensity, %) 215 (M^+, 4), 156 (11), 142 (base peak), 83 (13), and 82 (42). HRMS Found: *m/z* 215.1146. Calcd for $C_{10}H_{17}NO_4$: M, 215.1157.

17b (a 1:4 mixture of 2,3- and 2,4-isomers (^1H NMR)): Pale yellow liquid; IR (neat) 1741, 1308, and 1149 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.25 (3H, t, COOEt), 2.39 (3H, s, NMe), 2.0—3.5, 3.6—4.1 (5H+1H, m, CH_2 and CH), 4.16 (2H, q, COOEt), 7.4—7.7, and 7.8—8.0 (3H+2H, m, Ph); ^{13}C NMR ($CDCl_3$) 2,3-isomer: δ=13.29 (q, COOEt), 24.71 (t, 4-C), 38.94 (q, NMe), 54.94 (t, 5-C), 59.89 (t, COOEt), 65.71 (d, 3-C), 66.95 (d, 2-C), 127.89, 128.72, 133.24 (each d), 137.36 (s), and 169.66 (s, COOEt). 2,4-isomer: δ=13.29 (q, COOEt), 29.59 (t, 3-C), 38.94 (q, NMe), 54.24 (t, 5-C), 59.89 (t, COOEt), 60.30 (d, 4-C), 65.36 (d, 2-C), 127.60, 128.72, 133.24 (each d), 137.66 (s), and 170.84 (s, COOEt). MS *m/z* (rel intensity, %) 297 (M^+, 3), 224 (84), 82 (41), and 81 (base peak). HRMS Found: *m/z* 297.1034. Calcd for $C_{14}H_{19}NO_4S$: M, 297.1034.

17c (a 1:1 mixture of 2,3-cis and 2,3-trans isomers (GLC)): Pale yellow liquid; IR (neat) 1745 and 1730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.78 (3H, t, COOEt), 2.40 (3H, s, NMe), 2.0—2.7, 3.1—4.2 (2H+5H, m, CH_2 and CH), and 7.15 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=13.65, 14.24 (each q, COOEt), 31.94, 32.71 (each t, 4-C), 40.71, 40.83 (each q, NMe), 47.94, 49.65 (each d, 3-C (cis, trans)), 56.12, 55.83 (each t, 5-C), 60.24, 60.77 (each t, COOEt), 73.01, 76.01 (each d, 2-C (cis, trans)), 126.65, 126.95, 127.66, 128.25, 128.65 (each d), 141.48, 143.13 (each s), 171.13, and 172.72 (each s, COOEt); MS *m/z* (rel intensity, %) 233 (M^+, 2), 161 (12), 160 (base peak), and 43

(12). HRMS Found: m/z 233.1395. Calcd for $C_{14}H_{19}NO_2$: M, 233.1415.

Generation of Azomethine Ylides B from Methyl Aminoacetate (18) and Carbonyl Compounds, and Ylide Trapping with *N*-Methylmaleimide Leading to 19—21. A mixture of methyl aminoacetate (**18**) (0.178 g, 2 mmol), *N*-methylmaleimide (0.222 g, 2 mmol), and a carbonyl compound (benzaldehyde, cyclohexanone: 2 mmol in toluene (20 ml); phenylglyoxal: 2 mmol in chloroform (20 ml); 2-methylpropanal: 6 mmol in toluene (20 ml)) was heated under reflux. The reaction time is summarized in Table 2. The solvent was evaporated in vacuo. The residue was chromatographed over silica gel with diethyl ether to give **19—21**.

19a: Colorless prisms (benzene–hexane); mp 215—216 °C; IR (KBr) 3300, 1740, and 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.41 (1H, br t, NH), 2.85 (3H, s, NMe), 3.40 (1H, dd, J=8.0 and 7.5 Hz, 6a-H), 3.66 (1H, dd, J=7.5 and 6.8 Hz, 3a-H), 3.85 (3H, s, COOMe), 4.04 (1H, dd, J=6.8 and 5.5 Hz, 4-H), 4.47 (1H, dd, J=8.0 and 5.5 Hz, 6-H), 7.30 (5H, br s, Ph); MS m/z (rel intensity, %) 288 (M^+, 23), 229 (86), 177 (79), 144 (59), 117 (base peak), and 115 (21). Found: C, 62.37; H, 5.53; N, 9.54%. Calcd for $C_{15}H_{16}N_2O_4$: C, 62.49; H, 5.59; N, 9.72%.

19b: Colorless prisms (acetonitrile); mp 228—230 °C; IR (KBr) 3310, 1775, 1740, and 1695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.67 (3H, s, NMe), 2.92 (1H, t, J=11.0 Hz, NH), 3.68 (1H, dd, J=8.1 and 7.7 Hz, 3a-H), 3.70 (3H, s, COOMe), 3.91 (1H, t, J=7.7 Hz, 6a-H), 4.04 (1H, dd, J=11.0 and 8.1 Hz, 4-H), 4.98 (1H, dd, J=11.0 and 7.7 Hz, 6-H), 7.4—7.8 (3H, m, Ph), and 7.9—8.1 (2H, m, Ph); MS m/z (rel intensity, %) 257 (M^+−59, 8), 211 (base peak), 179 (32), 151 (56), 105 (36), 97 (15), 95 (18), 94 (94), 91 (31), and 76 (50). Found: C, 60.82; H, 5.09; N, 8.87. Calcd for $C_{16}H_{16}N_2O_5$: C, 60.75; H, 5.10; N, 8.86%.

19c: Colorless needles (benzene–hexane); mp 166—167 °C; IR (KBr) 3360, 1750, and 1680 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.03, 1.20 (each 3H, d, J=6.9 Hz, *i*-Pr), 1.6—2.2 (2H, m, NH and *i*-Pr), 2.80 (1H, dd, J=10.1 and 7.2 Hz, 6a-H), 2.94 (3H, s, NMe), 3.29 (1H, t, J=7.2 Hz, 3a-H), 3.50 (1H, t, J=7.2 Hz, 6-H), 3.81 (3H, s, COOMe), and 3.88 (1H, d, J=7.2 Hz, 4-H); ^{13}C NMR ($CDCl_3$) δ=20.94, 21.06 (each q, *i*-Pr), 25.12 (q, NMe), 29.36 (d, *i*-Pr), 47.47, 49.18 (each d, 3a- and 6a-C), 52.42 (q, COOMe), 62.59 (d, 6-C), 69.18 (d, 4-C), 170.71 (s, COOMe), 175.78, and 176.13 (each s, CON); MS m/z (rel intensity, %) 254 (M^+, 3), 211 (base peak), 195 (45), 179 (32), 151 (55), 110 (31), 94 (60), 68 (32), 67 (36), 40 (36), and 38 (28). Found: C, 56.65; H, 7.07; N, 10.87%. Calcd for $C_{12}H_{18}N_2O_4$: C, 56.68; H, 7.13; N, 11.02%.

20: A mixture of **18** (0.178 g, 2 mmol) and benzaldehyde (0.212 g, 2 mmol) in dry dichloromethane (20 ml) was heated under reflux for 2 h. The dichloromethane was dried over magnesium sulfate and evaporated in vacuo. The residue was dissolved in acetonitrile (10 ml) containing acetic acid (0.024 g, 10 mol%). After *N*-methylmaleimide (0.222 g, 2 mmol) was added the mixture was stirred at room temperature for 13 h. A similar separation procedure gave **19a** and **20**. **20**: Colorless prisms (benzene–hexane); mp 141—142 °C; IR (KBr) 3300, 1740, and 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.59 (1H, br, NH), 2.88 (3H, s, NMe), 3.35 (1H, dd, J=8.5 and 7.8 Hz, 6a-H), 3.66 (1H, d, J=7.8 Hz, 3a-H), 3.78 (3H, s, COOMe), 4.39 (1H, s, 4-H), 4.59 (1H, dd, J=8.5 and 4.0 Hz, 6-H), and 7.30 (5H, br s, Ph); MS m/z (rel intensity, %) 288 (M^+, 21), 229 (96), 228 (21), 144 (base peak), 143 (28), 117 (76), and 115 (30). Found: C, 62.64; H, 5.62; N, 9.58%. Calcd for $C_{15}H_{16}N_2O_4$: C, 62.49; H, 5.59; N, 9.72%.

21: Colorless prisms (benzene–hexane); mp 120.5—121 °C; IR (KBr) 3400, 2990, 1755, 1725, and 1680 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.1—2.2 (10H, m, *c*-Hex), 1.96 (1H, br, NH), 2.91 (3H, s, NMe), 2.96 (1H, d, J=7.8 Hz, 6a-H), 3.52 (1H, t, J=7.8 Hz, 3a-H), 3.80 (3H, s, COOMe), and 4.02 (1H, d, J=7.8 Hz, 4-H); ^{13}C NMR ($CDCl_3$) δ=22.41, 23.18, 25.94, 34.93, 37.12 (each t, *c*-Hex), 24.94 (q, NMe), 50.53 (d, 6a-C), 52.42 (q, COOMe), 55.18 (d, 3a-C), 60.42 (d, 4-C), 65.36 (s, 6-C), 171.24 (s, COOMe), 176.13, and 176.42 (each s, CON); MS m/z (rel intensity, %) 280 (M^+, 20), 237 (66), 221 (54), 177 (72), 165 (25), 136 (40), 93 (22), 80 (base peak), 79 (21), 53 (26), 41 (33), and 39 (21). Found: C, 59.79; H, 7.15; H, 9.75%. Calcd for $C_{14}H_{20}N_2O_4$: C, 59.99; H, 7.19; N, 9.99%.

12) Our unpublished data which will be published as a following article in this journal.

13) It has been reported that the reactions of A (R=H, R^1=*p*-$MeOC_6H_4$ or $PhCH_2$, EWG=COOMe) with *t*-butyl acrylate or phenyl vinyl sulfone lead to a mixture of stereoisomers of 2,4-substituted pyrrolidines (Ref. 6a).

14) It is not clear whether the *N*-protonated azomethine ylide is formed directly by the 1,3-elimination of an intermediary hemiacetal (or iminium salt) or via an imine.

Simple Generation of Nonstabilized Azomethine Ylides through Decarboxylative Condensation of α-Amino Acids with Carbonyl Compounds via 5-Oxazolidinone Intermediates

Otohiko TSUGE,* Shuji KANEMASA, Masayuki OHE, and Shigeori TAKENAKA

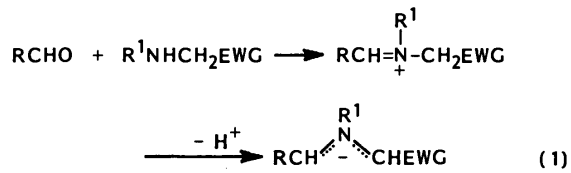
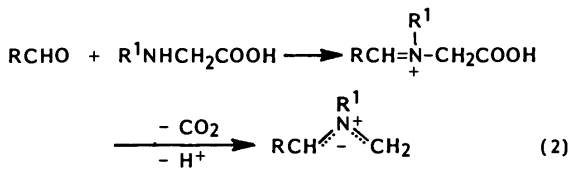
(Received May 30, 1987)

Heating α-amino acids with a variety of carbonyl compounds generates *N*-unsubstituted or *N*-substituted azomethine ylides of nonstabilized types through the elimination of water and carbon dioxide. The ylides are captured by olefinic, acetylenic, and carbonyl dipolarophiles producing pyrrolidines, pyrrolines, and oxazolidines. The reaction involves intermediary 5-oxazolidinones which can be sometimes isolated. Some synthetic equivalents of parent azomethine ylide, methaniminium methylide, are accessible by this route.

In the previous paper a simple generation method of ester- or cyano-stabilized azomethine ylides was reported.[1a] This method is a modification of imine-azomethine ylide tautomerism[2] and involves the condensation of α-amino esters or nitriles with aldehydes leading to iminium compounds, which spontaneously deprotonate at the position adjacent to the electron-withdrawing group (EWG) to generate the ylides (Eq. 1).



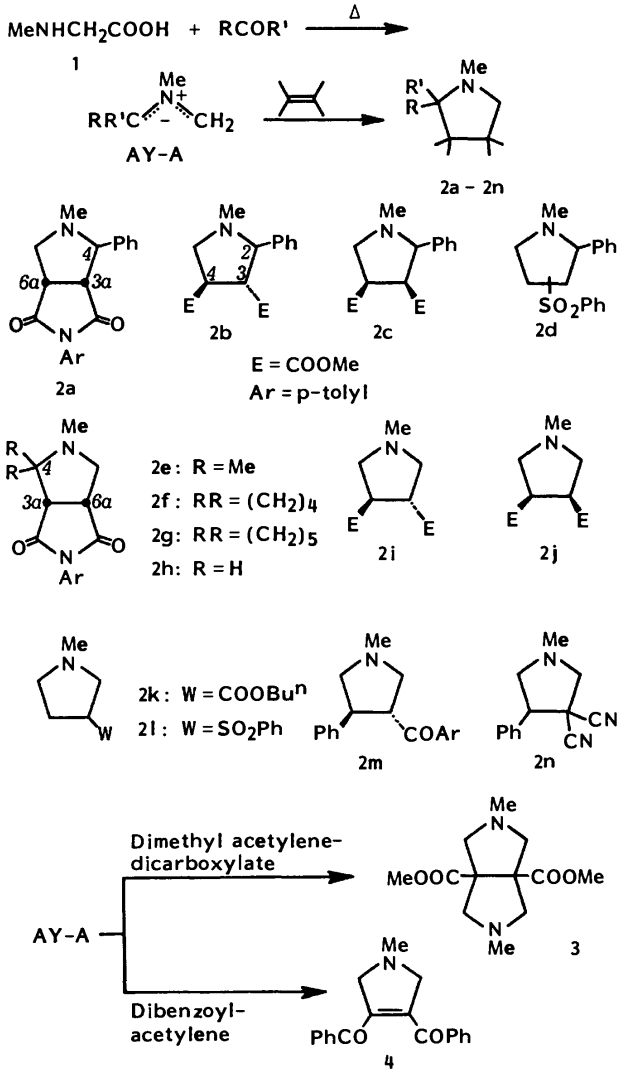
During this investigation we noticed that the condensation of α-amino acids with carbonyl compounds would afford a general route to azomethine ylides bearing no stabilizing substituent.[3] As shown in Eq. 2 the intermediates expected to be formed in this condensation are iminium acids which will then undergo ready decarboxylation leading to azomethine ylides.[4]



In the present article, we will present a general and practical generation method of nonstabilized azomethine ylides via the decarboxylative condensation route and the scope and limitation of the method will be discussed.[1b]

Results and Discussion

Benzaldehyde and a slightly excess of *N*-methylaminoacetic acid (sarcosine, **1**) were heated to reflux in toluene in the presence of electron-deficient olefins to give cycloadducts **2a—2d** (Scheme 1 and Table 1), indicating the formation of azomethine ylide **AY-A** (R=Ph, R′=H). poor endo- and exo-selectivity of these reactions is consistent with the reported results on the related ylides derived from *N*-benzylidene-(trimethylsilyl)methylamine.[5,6] The reaction with dimethyl maleate gave two cycloadducts, 3,4-cis-adduct **2c** in a poorer yield (11%) and 3,4-trans-adduct



Scheme 1.

2b (71%) as a major product. Under the reaction conditions, the 3,4-cis-adduct **2c** does not epimerize into the 3,4-trans-adduct **2b**, and the isomerization of dimethyl maleate into fumarate does not proceed at an appreciable rate. Catalysis of benzaldehyde in the isomerization was not observed.

The poor stereospecificity is not due to the isomerization of dimethyl maleate into fumarate prior to its cycloaddition trapping, consequently.[7] A stepwise mechanism is responsible for the nonstereospecific cycloaddition of ylide **AY-A** (R=Ph, R′=H).

Azomethine ylides **AY-A** (R, R′=alkyl) with two substituents at the same carbon are available by similar reactions of **1** with ketones. The cycloadducts **2e—2g** to *N*-(*p*-tolyl)maleimide were obtained in high yields (Scheme 1 and Table 1).

Azomethine ylide **AY-A** (R=R′=H) carrying no *C*-substituent is also accessible by the condensation of **1** with paraformaldehyde under reflux in toluene. 2,5-Unsubstituted pyrrolidines **2h—2l** were produced by trapping ylide **AY-A** with a variety of olefinic dipolarophiles. Both the cycloadditions to dimethyl fumarate and maleate were exclusively stereospecific to give **2i** and **2j**, respectively. This high stereospecificity makes a striking contrast to the previous cycloadditions of **AY-A** (R=Ph, R′=H) leading to **2b** and **2c**. With dimethyl acetylenedicarboxylate two molecules of the ylide **AY-A** (R=R′=H) were incorporated in the reaction to give perhydropyrrolo-[3,4-*c*]pyrrole-3a,6a-dicarboxylate **3**.

Azomethine ylides **AY-A** (R=R′=H) bearing no *C*-substituent have been previously generated by several routes, all of which have utilized *N*-silylmethyl amine reagents.[8] Our method has some advantages over these precedents: 1) Our ylide generation starts with readily available chemicals, paraformaldehyde and sarcosine (**1**). 2) Reaction can be performed by a simple operation under almost neutral conditions. 3) Cycloaddition takes place with a variety of dipolarophiles producing high yields of cycloadducts.

The above decarboxylative ylide generation utilizing paraformaldehyde was further applied to cyclic α-amino acids such as 2-pyrrolidinecarboxylic acid (proline, **5**) and 4-thiazolidinecarboxylic acid (**7**). Cyclic azomethine ylides **AY-B** and **AY-C** generated were captured with *N*-(*p*-tolyl)maleimide or dimethyl maleate to give **6**, **8**, and **9**, all as mixtures of stereoisomers (Scheme 2 and Table 2). Each two stereoisomers of the maleimide cycloadducts **6** and **8** could be separated through column chromatography, while **9** was a 5:4 mixture (GLC) of two inseparable stereoisomers.

It was surprising to know that 3-phenyl-5-oxazolidinone (**11**) was isolated in a quantitative yield in the reaction of *N*-phenylaminoacetic acid (**10**) with paraformaldehyde under reflux in toluene for 15 min. The azalactone **11** readily eliminated carbon dioxide by heating to generate azomethine ylide **AY-D**, which was in situ trapped with olefinic dipolarophiles to give **12a—12c** (Scheme 3 and Table 2).

Table 1. Generation and Cycloaddition of Azomethine Ylides **AY-A** Generated from Sarcosine **1** and Carbonyl Compounds

Entry	Carbonyl compound	Type of ylide[a]	Dipolarophile	Condition[b]	Product (yield/%)[c]	Isomer ratio[d]
1	Benzaldehyde	A1	*N*-(*p*-Tolyl)maleimide	A, 1 h	**2a** (86)	5 : 2
2	Benzaldehyde	A1	Dimethyl fumarate	A, 1 h	**2b** (86)	1 : 1

4	Benzaldehyde	A1	Phenyl vinyl sulfone	A, 2 h	**2d** (29)[e,f]	
5	Acetone	A2	*N*-(*p*-Tolyl)maleimide	A, 9 h	**2e** (85)	
6	Cyclopentanone	A3	*N*-(*p*-Tolyl)maleimide	A, 5 h	**2f** (79)	
7	Cyclohexanone	A4	*N*-(*p*-Tolyl)maleimide	A, 3 h	**2g** (91)	
8	Paraformaldehyde	A5	*N*-(*p*-Tolyl)maleimide	B, 15 min	**2h** (89)	
9	Paraformaldehyde	A5	Dimethyl fumarate	B, 15 min	**2i** (80)	
10	Paraformaldehyde	A5	Dimethyl maleate	B, 15 min	**2j** (84)	
11	Paraformaldehyde	A5	Butyl acrylate	B, 15 min	**2k** (79)	
12	Paraformaldehyde	A5	Phenyl vinyl sulfone	B, 15 min	**2l** (84)	
13	Paraformaldehyde	A5	2-Benzylidene-4′-methylacetophenone	A, 1 h	**2m** (93)	
14	Paraformaldehyde	A5	Benzylidenemalononitrile	A, 1 h	**2n** (94)	
15	Paraformaldehyde	A5	Dimethyl acetylenedicarboxylate	B, 15 min	**3** (68)	
16	Paraformaldehyde	A5	Dibenzoylacetylene	B, 15 min	**4** (36)	

a) A1: R=Ph, R′=H, A2: R=R′=Me, A3: RR′=$(CH_2)_4$, A4: RR′=$(CH_2)_5$, A5: R=R′=H. b) A: Under reflux in toluene with *N*,*N*-diisopropylethylamine (1.5 equiv), B: Under reflux in toluene. c) Yield of isolated products. d) Mixture of stereoisomers whose ratio was based on ^{1}H NMR. e) 2-(Dimethylamino)ethyl phenyl sulfone was obtained in 55% yield. f) Mixture of two regioisomers.

Successful isolation of the azomethine ylide precursor **11** enabled the use of some activated aldehydes as dipolarophiles. Thus heating **11** with *p*-nitrobenzaldehyde or phenylglyoxal gave the oxazolidine cycloadduct **13a** or **13b**, respectively. Pyruvaldehyde was incorporated into 5-oxazolidinone skeleton through an acetal-exchange reaction of **11**. The resulting acetyl-substituted 5-oxazolidinone **A** underwent the decarboxylative generation of azomethine ylide **AY-E**, which was captured by the same aldehyde to give cycloadduct **13c** (Scheme 3).

It is now apparent that the condensation of *N*-substituted α-amino acids with carbonyl compounds offers a simple and versatile generation route to a variety of nonstabilized azomethine ylides **AY-A** to **AY-D**, presumably via 5-oxazolidinone intermediates.[9] Extension of this method to the generation of *N*-unsubstituted azomethine ylides of nonstabilized types is worthy to be tested. This may be achieved by the reaction of *N*-unsubstituted α-amino acids with carbonyl compounds (Eq. 3).

$$RCHO + NH_2CH_2COOH \longrightarrow RCH^{\overset{H}{N^+}}{}^{-}CH_2 \qquad (3)$$

According to Eq. 3, glycine (**14**) was allowed to react with carbonyl compounds under reflux in toluene to

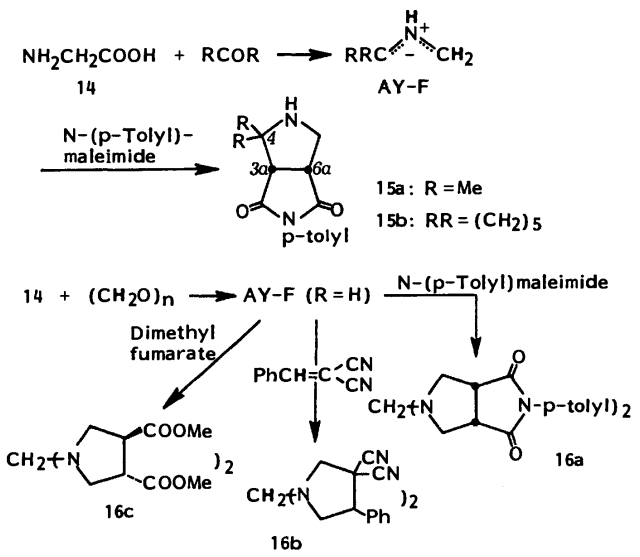
a) A: Under reflux in toluene, B: 3-Phenyl-1,3-oxazolidin-5-one (**11**) was first prepared by heating **10** with paraformaldehyde (0.5 h in toluene), and its decarboxylation was conducted in the presence of a dipolarophile under reflux in toluene. b) Yield of isolated products. c) Mixture of stereoisomers. d) Determined by ^{1}H NMR. e) Yield of isolated isomers. f) Determined by GLC.

generate *N*-unsubstituted azomethine ylides **AY-F**. The use of acetone and cyclopentanone as carbonyl compounds afforded the maleimide cycloadducts **15a** and **15b**, but the yields were unsatisfactory (Scheme 4 and Table 3).

The decarboxylative condensation of **14** with formaldehyde was expected to offer a direct generation method of parent azomethine ylide **AY-F** (R=H), methaniminium methylide, whose preparation is so far unknown. The ylide generation from **14** and paraformaldehyde under reflux in toluene was followed by the cycloaddition trapping with *N*-(*p*-tolyl)maleimide, benzylidenemalononitrile, or dimethyl fumarate. The cycloadducts obtained were not the expected 1,2,5-unsubstituted pyrrolidines but their *N*-methylene-bridged dimers **16a—16c**.[10] Use of less than one equivalent of paraformaldehyde was not effective, and the identical products **16** were only afforded in poorer yields.

Similar reactions of paraformaldehyde with 2-aminopropanoic acid (alanine) or 2-amino-3-hydroxypropanoic acid (serine) in the presence of *N*-(*p*-tolyl)maleimide under reflux in toluene led to the formation of complex mixture of products.

Two routes are possible for the formation of *N*-methylene-bridged pyrrolidines **16a—16c**: participation of either the parent azomethine ylide **AY-F** (R=H) or *N*,*N*′-methylenebis(azomethine ylide) **AY-**



Scheme 4.

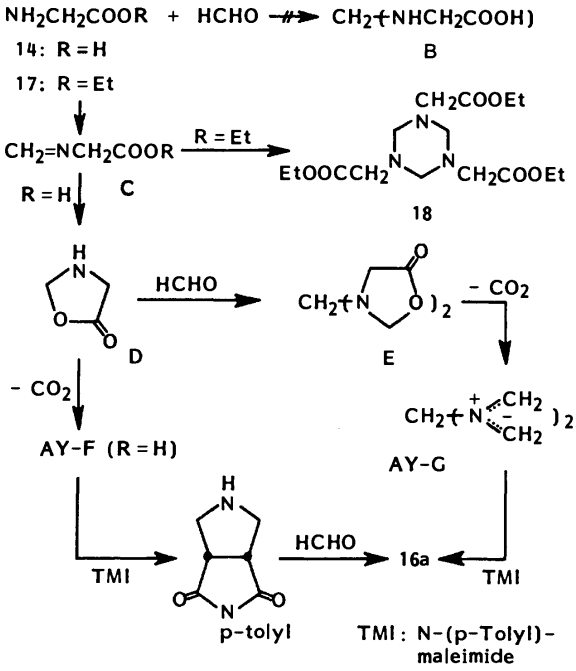


Fig. 1. Two possible routes to **16a**.

13	**26**	Paraformaldehyde	I	Butyl acrylate	A, 15 min	**27d** (38)

a) F1: **AY-F** (R=Me), F2: **AY-F** (RR=$(CH_2)_5$), F3: **AY-F** (R=H). b) A: Under reflux in toluene, B: Under reflux in DMF, C: Under reflux in toluene with potassium carbonate (excess), D: Under reflux in toluene using **20**. c) Yield of isolated product.

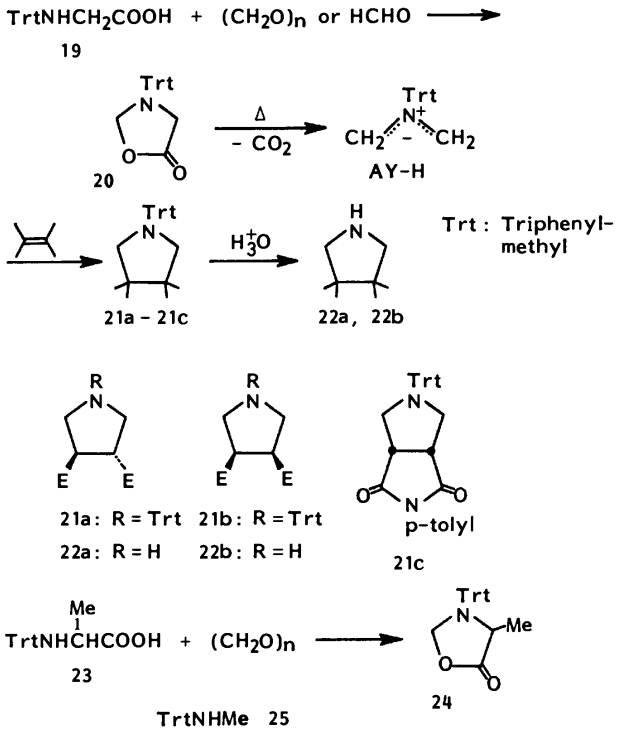
G. The initial methylene bridging of glycine (**14**) leading to methylenediamine-*N*,*N*′-diacetic acid (**B**) is unlikely to happen since the reaction of ethyl aminoacetate (**16**) with paraformaldehyde forms 1,3,5-tris(ethoxycarbonylmethyl)-1,3,5-triazine **18**, a trimer of ethyl *N*-methyleneaminoacetate **C** (R=Et) (Fig. 1). *N*-Methyleneaminoacetic acid **C** (R=H) cyclizes into labile 5-oxazolidinone (**D**).[11] This heterocycle **D** loses carbon dioxide generating the parent azomethine ylide **AY-F** (R=H) whose cycloaddition to *N*-(*p*-tolyl)maleimide and subsequent reaction with formaldehyde gives **16a**.[12] Another route to **16a** is the initial bridging of **D** forming *N*,*N*′-methylenebis(5-oxazolidinone) (**E**), elimination of carbon dioxide generating *N*,*N*′-methylenebis(azomethine ylide) **AY-G**, and the final cycloaddition. Discrimination of the both routes depends upon the stability of intermediary 5-oxazolidinone **D**.

One of the synthetic equivalents of the parent azomethine ylide **AY-F** (R=H) will be *N*-triphenylmethyl azomethine ylide **AY-H**. Reaction of *N*-(triphenylmethyl)aminoacetic acid (**19**) with aqueous formaldehyde in ethanol or with paraformaldehyde under reflux in toluene gave 3-(triphenylmethyl)-5-oxazolidinone (**20**) as a stable compound, both in quantitative yields (Scheme 5). When heated under reflux in toluene, **20** gradually eliminated carbon dioxide to generate the parent ylide equivalent **AY-H**, which was captured by *N*-(*p*-tolyl)maleimide, dimethyl fumarate, or maleate leading to cycloadducts **21a—21c** (Scheme 5 and Table 3). The triphenylmethyl moiety of **21a** and **21b** was readily removed on treatment with hydrochloric acid in dichloromethane at room temperature to give **22a—22c**.

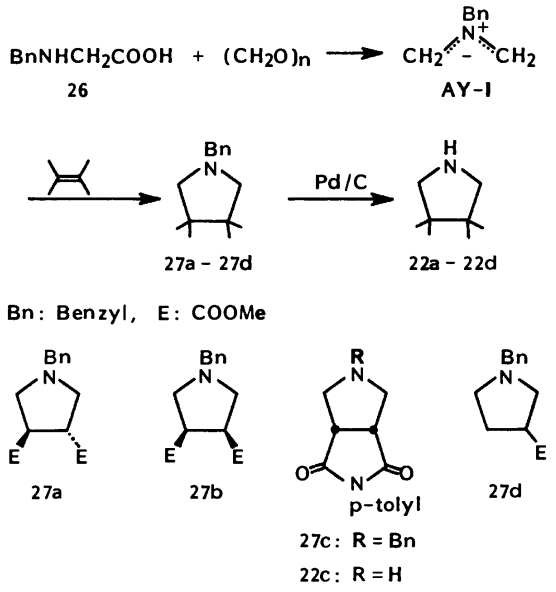
In contrast with the ready formation of 5-oxazolidinone **20** from **19** and paraformaldehyde, similar reactions of **19** with acetaldehyde or benzaldehyde all resulted in the quantitative recovery of **19**. The bulky triphenylmethyl group of **19** may have inhibited its attack to these aldehydes. On the other hand, 3-triphenylmethyl-4-methyl-5-oxazolidinone (**24**) was obtained in a high yield from *N*-(triphenylmethyl)-2-aminopropanoic acid (**23**) and paraformaldehyde. However heating **24** in the presence of a variety of dipolarophiles yielded no cycloadducts. *N*-(Methyl)triphenylmethylamine **25** was the only product.[13]

There are some problems in the employment of 3-(triphenylmethyl)-5-oxazolidinone **20** as a synthetic equivalent of parent azomethine ylide **AY-F** (R=H). Table 3 indicates that 1) the decarboxylative ylide generation takes many hours (48 h), 2) the yields of cycloadducts **21** remain to be improved (63—74%), and 3) removal of the triphenylmethyl moiety is not a high-yield reaction. Since the thermal stability of 5-oxazolidinones seems to decrease with the decreased steric size of the 3-substituent, a 5-oxazolidinone bearing a smaller 3-substituent, which should be readily removable after the cycloaddition, is needed.

We chose *N*-benzylaminoacetic acid (**26**) as the parent ylide equivalent. Although all attempts to isolate the corresponding 5-oxazolidinone failed, the reaction of **26** with paraformaldehyde was completed in 15 min under reflux in toluene. The azomethine ylide **AY-I** generated was captured by *N*-(*p*-tolyl)-maleimide, dimethyl maleate, fumarate, and butyl acrylate to give excellent yields of cycloadducts **27a—**



Scheme 5.



Scheme 6.

27d (Scheme 6 and Table 3). Debenzylation of **27c** by Pd/C proceeded smoothly under reflux in xylene to produce a quantitative yield of **22c**. However, similar debenzylation of ester-substituted pyrrolidines **27a—27b** and **27d** led to a complex mixture of many products. In these cases also the debenzylation was completed, but subsequent condensation of the resulting secondary amine moiety with the esters would be a main reason for the complex results.

Experimental

General. Melting points were determined on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-40 (90 MHz) or a JEOL FX-100 instrument (100 MHz) and ^{13}C NMR on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra as well as high resolution mass spectra were measured with a JEOL-01SG-2 spectrometer at 70 eV of ionization energy. Elemental analyses were performed on a Hitachi 026 CHN analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60 F-254 (Merck) or of aluminum oxide 60 F-254 type-E (Merck). Visualization was made with ultraviolet light (254 and 365 nm), iodine, molybdophosphoric acid (5% in ethanol), or *p*-anisaldehyde (5% in ethanol containing 5% of sulfuric acid). For preparative column chromatography, Wakogel C-200, C-300 (Wako), and Silicagel 60 (Merck) were employed. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silicagel 60 (Merck, size: 0.04—0.063 mm). Micro vacuum distillation was carried out on a Sibata GTO-250R Kugelrohr distilling apparatus. Solvents were evaporated with a Tokyo Rikakikai rotary evaporator type-V at about 50 °C unless otherwise stated.

General Procedure for the Generation of Azomethine Ylide AY-A from Sarcosine (1) and Carbonyl Compounds, and Subsequent Ylide Trapping with Olefins Leading to 2—4. A mixture of sarcosine **1**, carbonyl compound, and olefin was heated under reflux in toluene (10—15 ml for 1 mmol of the dipolarophile). A mixture of sarcosine hydrochloride and *N,N*-diisopropylethylamine (1.5 equiv of the hydrochloride) may be employed instead of **1**. The water formed was removed by the aid of a Dean-Stark trap. The reaction conditions are listed in Table 1. The molar equivalents of **1** and carbonyl compounds are based on dipolarophiles as follows: **1** (2 equiv)+benzaldehyde (1.5 equiv); **1** (2 equiv)+acetone (10 equiv); **1** (2 equiv)+cycloalkanones (1.5 equiv); **1** (2 equiv)+paraformaldehyde (5 equiv). After the completion of reaction the solvent was evaporated in vacuo. The residue was chromatographed over silica gel by using hexane–ethyl acetate (3:1 to 1:1 vol/vol) to give **2—4**. All the results are summarized in Table 1 in which yields are based on the dipolarophiles.

2a: This cycloadduct **2a** consists of two stereoisomers (3a,4-trans:3a,4-cis=2:5 (^{1}H NMR)). The 3a,4-trans isomer could be separated from the 3a,4-cis isomer by washing the mixture with diethyl ether (3a,4-trans isomer is less soluble) and through column chromatography over silica gel (hexane–diethyl ether=3:1 vol/vol). 3a,4-*trans*-**2a**: Colorless prisms (diethyl ether); mp 153—154 °C; IR (KBr) 1765 and 1695 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.15 (3H, s, *p*-Me), 2.36 (3H, s, NMe), 2.70 (1H, ddd, J=9.6, 8.2, and 5.8 Hz, 6a-H), 3.3—3.8 (2H, m, 3a-H and 6-H), and 7.0-7.4 (9H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=21.00 (q, *p*-Me), 38.53 (q, NMe), 44.06 (d, 6a-C), 53.42 (d, 3a-C), 57.18 (t, 6-C), 72.42 (d, 4-C), 126.24, 127.83, 127.95, 128.65, 129.30, 129.66 (each d), 138.42, 139.07 (each s), 176.54, and 177.12 (each s, CON); MS *m/z* (rel intensity, %) 320 (M^+, 21), 158 (28), 132 (100), 118 (26), 115 (28), 91 (46), 82 (62), 77 (35), and 43 (28). 2c: (An inseparable mixture of 2,3-cis and 2,3-trans isomers (1:2)): Colorless liquid; IR (neat) 1745 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.18 (2/3×3H, s, NMe), 2.23 (1/3×3H, s, NMe), 2.5—4.1 (5H, m, 2-, 3-, 4-, and 5-H), 3.20, 3.65 (each 1/3×3H, s, COOMe of 2,3-cis isomer), 3.60, 3.67 (each 2/3×3H, s, COOMe of 2,3-trans isomer), and 7.2—7.4 (5H, m, Ph); MS *m/z* (rel intensity, %) 277 (M^+, 30), 262 (44), 246 (21), 218 (21), 158 (37), 133 (31), 132 (95), 115 (base peak), 91 (22), 82 (28), and 42 (23). HRMS Found: *m/z* 277.1329. Calcd for $C_{15}H_{19}NO_4$: M, 277.1313.

2d: (An inseparable mixture of two regioisomers): Colorless liquid; IR (neat) 1295 and 1135 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.14 (3H, s, NMe), 2.3—2.9 (3H, 3- and 4-H), 3.1—3.8 (3H, m, 2- and 5-H), and 7.0—7.8 (10H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=25.88 (t, 4-C of 2,3-isomer), 36.00 (t, 3-C of 2,4-isomer), 39.77 (q, NMe), 55.53, 56.24 (each t, 5-C), 61.00 (d, 4-C of 2,4-isomer), 70.24 (d, 3-C of 2,3-isomer), 70.83 (each d, 2-C), 127.36, 127.54, 127.89, 128.07, 128.48, 128.65, 128.95, 129.24, 129.36, 129.53 (each d), 133.71, 134.01, 140.60, and 141.01 (each s); MS *m/z* (rel intensity, %) 301 (M^+, 3), 159 (base peak), 158 (32), and 91 (22). HRMS Found: *m/z* 301.1136. Calcd for $C_{17}H_{19}NO_2S$: M, 301.1142.

This compound **2d** was accompanied by 2-(dimethyl-

amino)ethyl phenyl sulfone: Pale yellow liquid; IR (neat) 1319, 1306, and 1149 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.16 (6H, s, NMe_2), 2.5—2.8 (2H, m, NCH_2), 3.1—3.4 (2H, m, CH_2), 7.4—7.7 (3H, m, Ph), and 7.8—8.0 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=44.89 (q, NMe_2), 52.24, 53.83 (each t, CH_2), 128.01, 129.36, 133.83 (each d), and 139.66 (s); MS *m/z* (rel intensity, %) 213 (M^+, 4), 77 (64), 71 (98), 58 (base peak), 56 (28), 51 (29), and 42 (55). Found: C, 56.50; H, 7.05; N, 6.57%. Calcd for $C_{10}H_{15}NO_2S$: C, 56.31; H, 7.10; N, 6.57%.

2e: Colorless needles (benzene–hexane); mp 153—154 °C; IR (KBr) 1770 and 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.06, 1.24 (each 3H, s, 4-Me), 2.20 (3H, s, *p*-Me), 2.35 (3H, s, NMe), 2.90 (1H, dd, *J*=9.9 and 8.0 Hz, one of 6-H (exo)), 2.94 (1H, d, *J*=7.3 Hz, 3a-H), 3.26 (1H, ddd, *J*=8.0, 7.3, and 1.7 Hz, 6a-H), 3.30 (1H, dd, *J*=9.9 and 1.7 Hz, the other of 6-H (endo)), and 7.0—7.3 (4H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=18.77, 20.65 (each q, 4-Me), 22.41 (*p*-Me), 32.77 (q, NMe), 42.77 (d, 6a-C), 54.42 (d, 3a-C), 54.42 (t, 6-C), 62.30 (s, 4-C), 126.01, 129.24 (each d), 129.42, 137.89 (each s), 176.01, and 178.42 (each s, CON); MS *m/z* (rel intensity, %) 272 (M^+, 2), 257 (33), and 96 (base peak). Found: C, 70.53; H, 7.33; N, 9.96%. Calcd for $C_{16}H_{20}N_2O_2$: C, 70.56; H, 7.40; N, 10.29%.

2f: Colorless needles (diethyl ether); mp 145.5—147 °C; IR (KBr) 1770 and 1705 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.2—2.2 (8H, m, *c*-Pen), 2.22 (3H, s, *p*-Me), 2.35 (3H, s, NMe), 2.75 (1H, dd, *J*=10.2 and 8.2 Hz, one of 6-H (exo)), 2.97 (1H, d, *J*=7.9 Hz, 3a-H), 3.25 (1H, ddd, *J*=8.2, 7.9, and 1.2 Hz, 6a-H), 3.28 (1H, dd, *J*=10.2 and 1.2 Hz, the other of 6-H (endo)), and 7.0—7.3 (4H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=20.82 (q, *p*-Me), 23.12, 23.35, 27.24, 29.83 (each t, *c*-Pen), 33.30 (q, NMe), 42.89 (d, 6a-C), 53.47 (d, 3a-C), 56.00 (t, 6-C), 74.71 (s, 4-C), 126.13, 129.30 (each d), 129.66, 137.95 (each s), 176.42, and 178.66 (each s, CON); MS m/z (rel intensity, %) 298 (M^+, 14), 269 (70), 256 (base peak), 108 (31), and 94 (29). Found: C, 72.54; H, 7.46; N, 9.08%. Calcd for $C_{18}H_{22}N_2O_2$: C, 72.45; H, 7.43; N, 9.39%.

2g: Colorless grains (benzene–hexane); mp 119—120 °C; IR (KBr) 1770 and 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.1—1.9 (10H, m, *c*-Hex), 2.24 (3H, s, *p*-Me), 2.35 (3H, s, NMe), 2.8—3.4 (4H, m, 3a-, 6-, and 6a-H), and 7.0—7.3 (4H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=21.12 (q, *p*-Me), 23.30, 23.71, 25.30, 26.00, 32.36 (each t, *c*-Hex), 33.12 (q, NMe), 43.00 (d, 6a-C), 50.42 (d, 3a-C), 54.77 (t, 6-C), 66.83 (s, 4-C), 126.48, 129.71 (each d), 129.83, 138.42 (each s), 176.72, and 179.07 (each s, CON); MS *m/z* (rel intensity, %) 312 (M^+, 34), 270 (22), 269 (base peak), and 256 (28). Found: C, 73.12; H, 7.69; N, 8.89%. Calcd for $C_{19}H_{24}N_2O_2$: C, 73.04; H, 7.74; N, 8.97%.

2h: Colorless prisms (benzene–hexane); mp 138—139 °C; IR (KBr) 1770 and 1708 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.24 (3H, s, *p*-Me), 2.35 (3H, s, NMe), 2.2—2.4, 3.1—3.4 (2H+4H, m, 3a-, 4-, 6-, and 6a-H), 7.04 (2H, d, Ar), and 7.26 (2H, d, Ar); ^{13}C NMR ($CDCl_3$) δ=21.00 (q, *p*-Me), 40.71 (q, NMe), 44.94 (d, 3a- and 6a-C), 58.83 (t, 4- and 6-C), 126.36, 129.66 (each d), 129.83, 138.36 (each s), and 178.66 (CON); MS *m/z* (rel intensity, %) 244 (M^+, 40), 82 (55), 57 (base peak), and 41 (24). Found: C, 68.93; H, 6.61; N, 11.33%. Calcd for $C_{14}H_{16}N_2O_2$: C, 68.83; H, 6.60; N, 11.47%.

2i: Colorless liquid; IR (neat) 1736 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.31 (3H, s, NMe), 2.6—3.0, 3.3—3.6 (4H+2H, m, 2-, 3-, 4-, and 5-H), and 3.70 (6H, s, COOMe); ^{13}C NMR ($CDCl_3$) δ=41.53 (q, NMe), 45.94 (d, 3- and 4-C), 59.06 (t, 2- and 5-C), 52.24 (q, COOMe), and 174.01 (s, COOMe); MS *m/z* (rel intensity, %) 201 (M^+, 7), 142 (13), 140 (27), 82 (base peak), 59 (21), 58 (33), and 42 (57). HRMS Found: *m/z* 201.0991. Calcd for $C_9H_{15}NO_4$: M, 201.1000.

2j: Colorless liquid; IR (neat) 1741 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.37 (3H, s, NMe), 2.6—2.8, 2.9—3.2, 3.2—3.4 (each 2H, m, 2-, 3-, 4-, and 5-H), and 3.65 (6H, s, COOMe); ^{13}C NMR ($CDCl_3$) δ=41.85 (q, NMe), 45.85 (d, 3- and 4-C), 51.81 (q, COOMe), 58.35 (d, 2- and 5-C), and 172.99 (s, COOMe); MS *m/z* (rel intensity, %) 201 (M^+, 7), 81 (base peak), 59 (25), 57 (27), and 41 (54); HRMS Found: *m/z* 201.1003. Calcd for $C_9H_{15}NO_4$: M, 201.1000.

2k: Colorless liquid; IR (neat) 2960, 2939, 2875 2779, and 1736 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.93 (3H, t, *n*-Bu), 1.2—1.8 (4H, m, *n*-Bu), 2.0—3.2 (7H, m, 2-, 3-, 4-, and 5-H), 2.35 (3H, s, NMe), and 4.08 (2H, t, *n*-Bu); ^{13}C NMR ($CDCl_3$) δ=12.94 (q, *n*-Bu), 18.41, 30.06 (each t, *n*-Bu), 27.47 (t, 4-C), 41.06 (q, NMe), 41.94 (d, 3-C), 55.30 (t, 5-C), 58.24 (t, 2-C), 63.65 (t, *n*-Bu), and 174.19 (s, COOBu-*n*); MS *m/z* (rel intensity, %) 185 (M^+, 7), 128 (56), 84 (24), 83 (28), 82 (57), 58 (42), 43 (base peak), 42 (67), and 40 (30). HRMS Found: *m/z* 185.1455. Calcd for $C_{10}H_{19}NO_2$: M, 185.1415.

2l: Pale yellow liquid; IR (neat) 1308 and 1147 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.0—2.9 (6H, m, 2-, 4-, and 5-H), 2.31 (3H, s, NMe), 3.5—3.9 (1H, m, 3-H), 7.4—7.7 (3H, m, Ph) and 7.8—8.0 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=25.94 (t, 4-C), 41.30 (q, NMe), 55.30, 55.47 (each t, 2- and 5-C), 62.48 (d, 3-C), 128.13, 129.13 (each d), 133.60, and 138.36 (each s); MS *m/z* (rel intensity, %) 225 (M^+, 3), 83 (base peak), 82 (45), and 41 (37). Found: C, 58.36; H, 6.76; N, 6.21%. Calcd for $C_{11}H_{15}NO_2S$: C, 58.63; H, 6.72; N, 6.22%.

2m: Colorless liquid; IR (neat) 1675 and 1605 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.34, 2.40 (each 3H, s, NMe and *p*-Me), 2.6—3.2, 3.7—4.1 (4H+2H, m, 2-, 3-, 4-, and 5-H), 7.12 (2H, d, COPh), 7.25 (5H, s, Ph), and 7.66 (2H, d, COPh); ^{13}C NMR ($CDCl_3$) δ=21.47 (q, *p*-Me), 42.00 (q, NMe), 46.65 (d, 4-C), 55.30 (d, 3-C), 60.36 (t, 2-C), 64.36 (t, 5-C), 126.60, 127.71, 128.72, 128.89. 129.30 (each d), 134.07, 143.83, 144.60 (each d), and 199.13 (s, CO); MS *m/z* (rel intensity, %) 279 (M^+, 42), 175 (51), 174 (base peak), 133 (59), 119 (20), 117 (26), 91 (28), 58 (32), 44 (22), and 43 (23). Found: C, 81.58; H, 7.58; N, 5.15%. Calcd for $C_{19}H_{21}NO$: C, 81.68; H, 7.58; N, 5.01%.

2n: Colorless needles (hexane); mp 78—80 °C; IR (KBr) 2250 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.49 (3H, s, NMe), 3.13 (2H, d, *J*=8.0 Hz, 5-H), 3.35 (2H, s, 2-H), 3.97 (1H, t, *J*=8.0 Hz, 4-H), and 7.37 (5H, s, Ph); ^{13}C NMR ($CDCl_3$) δ=40.48 (q, NMe), 40.67 (s, 3-C), 54.35 (d, 4-C), 58.79 (t, 2-C), 64.89 (t, 5-C), 113.87, 115.62 (each s, CN), 128.17, 128.76 (each d), and 135.01 (s); MS *m/z* (rel intensity, %) 211 (M^+, 3), 57 (88), and 41 (base peak). Found: C, 73.66; H, 6.20; N, 19.64%. Calcd for $C_{13}H_{13}N_3$: C, 73.90; H, 6.20; N, 19.89%.

3: Colorless prisms (benzene–hexane); mp 72—74 °C; IR (KBr) 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.34 (6H, s, NMe), 2.71, 3.04 (each 4H, d, *J*=9.5 Hz, 2-, 3-, 5-, and 6-H), and 3.65 (6H, s, COOMe); ^{13}C NMR ($CDCl_3$) δ=41.75 (q, NMe), 52.29 (q, COOMe), 63.87 (s, 3a- and 6a-C), 65.62 (t, 1-, 3-, 4-, and 6-C), and 173.92 (s, COOMe); MS *m/z* (rel intensity, %) 256 (M^+, 32), 180 (34), 94 (22), 58 (base peak), and 43 (25). Found: C, 56.30; H, 7.76; N, 10.70%. Calcd for $C_{12}H_{20}N_2O_4$: C, 56.23; H, 7.87; N, 10.93%.

4: Pale yellow grains (benzene–hexane); mp 157—158 °C; IR (KBr) 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.55 (3H, s, NMe), 4.03 (4H, s, 2- and 5-H), and 7.0—7.5 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=42.30 (q, NMe), 64.48 (t, 2- and 5-C), 128.24, 128.54, 128.65 (each d), 133.24 (d), 137.66 (s), 143.95

(s, 3- and 4-C), and 193.12 (s, CO); MS *m/z* (rel intensity, %) 291 (M^+, 5), 105 (52), 77 (base peak), and 51 (25). HRMS Found: *m/z* 291.1204. Calcd for $C_{19}H_{17}NO_2$: M, 291.1258.

Generation of Azomethine Ylide AY-B or AY-C by the Reaction of Proline (5) or 4-Thiazolidinecarboxylic Acid (7) with Paraformaldehyde and Subsequent Ylide Trapping with Olefins Leading to 6, 8, and 9. As a typical procedure, the reaction of **5** with paraformaldehyde in the presence of a maleimide is described: A mixture of **5** (0.3 g, 2.61 mmol), paraformaldehyde (0.2 g, 6.7 mmol), and *N*-(*p*-tolyl)maleimide (0.25 g, 1.32 mmol) was heated under reflux in toluene (15 ml) for 15 min. The water formed was removed by an azeotropic distillation. The mixture was evaporated in vacuo and the residue (0.36 g, 100%, 3:2 by ^{1}H NMR) was chromatographed over silica gel by using hexane–ethyl acetate (1:1 vol/vol) to give two stereoisomers of **6**. The results are summarized in Table 2.

8a,8b-*trans*-6: Colorless prisms (benzene–hexane); mp 150—152 °C; IR (KBr) 1775 and 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.5—2.2 (4H, m, 7- and 8-H), 2.36 (3H, s, *p*-Me), 2.7—3.1, 3.2—3.8 (3H+4H, m, 3a-, 4-, 6-, 8a-, and 8b-H), and 7.0—7.3 (4H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=21.12 (q, *p*-Me), 23.59 (t, 7-C), 29.65 (t, 8-C), 45.94 (d, 3a-C), 50.06 (d, 8b-C), 51.95 (t, 6-C), 55.00 (t, 4-C), 69.12 (d, 8a-C), 126.48, 129.77 (each d), 129.77, 138.60 (each s), 177.83, and 178.37 (each s, CON); MS *m/z* (rel intensity, %) 270 (M^+, 15), 133 (31), 132 (28), 108 (27), 104 (26), 83 (base peak), 82 (23), 81 (59), 80 (54), 78 (21), and 77 (31). Found: C, 71.15; H, 6.72; N, 10.22%. Calcd for $C_{16}H_{18}N_2O_2$: C, 71.09; H, 6.71; N, 10.36%. **8a,8b-*cis*-6:** Colorless solid; mp 138—140 °C; IR (KBr) 1770 and 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.6—3.9 (11H, m, CH_2 and CH), 2.16 (3H, s, *p*-Me), and 7.0—7.3 (4H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=21.06 (q, *p*-Me), 24.83 (t, 7-C), 25.18 (t, 8-C), 48.24 (d, 3a-C), 48.42 (d, 8b-C), 52.95 (t, 6-C), 54.65 (t, 4-C), 68.42 (d, 8a-C), 125.95, 129.66 (each d), 129.83 (s), 177.12, and 179.01 (each s, CON); MS *m/z* (rel intensity, %) 270 (M^+, 13), 108 (21), 83 (base peak), 81 (39), 80 (35), 77 (21), 68 (21), 56 (49), 42 (23), and 40 (24). Anal. Found: C, 70.65; H, 6.75; N, 10.18%. Calcd for $C_{16}H_{18}N_2O_2$: C, 71. 09; H, 6.71; N, 10.36%.

8: A similar procedure employing **7** (0.2 g, 1.5 mmol), paraformaldehyde (0.2 g, 6.7 mmol), and *N*-(*p*-tolyl)maleimide (0.25 g, 1.32 mmol) in toluene (18 ml) followed by silica-gel chromatography gave **8a,8b-*trans*-8** (0.156 g, 41%, from the elution with hexane–ethyl acetate (2:1 vol/vol)) and **8a,8b-*cis*-8** (0.153 g, 40%, from the elution with ethyl acetate). **8a,8b-*trans*-8:** Colorless needles (benzene–hexane); mp 213-215 °C; IR (KBr) 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.34 (3H, s, *p*-Me), 2.62 (1H, t, *J*=10.0 Hz, one of 1-H (exo)), 2.8—3.5 (5H, m), 3.78 (1H, dd, *J*=10.0 and 7.5 Hz, 8b-H), 4.10, 4.26 (each d, *J*=9.8 Hz, 3-H), and 7.0—7.3 (4H, m, Ar); MS *m/z* (rel intensity, %) 288 (M^+, 53), 242 (74), 101 (26), 81 (base peak), and 80 (24). Found: C, 62.53; H, 5.62; N, 9.53%. Calcd for $C_{15}H_{16}N_2O_2S$: C, 62.48; H, 5.59; N, 9.71%. **8a,8b-*cis*-8:** Colorless prisms (benzene–hexane); mp 162—164 °C; IR (KBr) 1775 and 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.34 (3H, s, *p*-Me), 2.5—3.9 (7H, m), 4.04, 4.20 (each 1H, d, *J*=9.8 Hz, 3-H), 7.07 (2H, d, Ar), and 7.23 (2H, d, Ar); ^{13}C NMR ($CDCl_3$) δ=21.18 (q, *p*-Me), 30.71 (t, 1-C), 46.12 (d, 5a-C), 47.89 (d, 8a-C), 52.06 (t, 5-C), 57.18 (t, 3-C), 70.48 (d, 8b-C), 126.36, 129.19 (each d), 130.01, 139.07 (each s), 175.36, and 177.07 (each s, CON); MS *m/z* (rel intensity, %) 288 (M^+, 73), 242 (53), 101 (22), 100 (46), 81 (base peak), 80 (23), and 55 (22). Found: C, 62.72; H, 5.63; N, 9.70%. Calcd for $C_{15}H_{16}N_2O_2S$: C, 62.48; H, 5.59; N, 9.71%.

9: A similar procedure using **7** (0.2 g, 1.5 mmol), paraformaldehyde (0.2 g, 6.7 mmol), and dimethyl maleate (0.2 g, 1.39 mmol) in toluene (15 ml) followed by silica-gel chromatography gave **9** as a mixture of **7,7a-*trans*-9** and **7,7a-*cis*-9** (5:4 by GLC, 0.207 g, 77%, eluent: hexane–ethyl acetate (5:1 vol/vol)). The separation of either isomer was unsuccessful. **9:** Colorless liquid; IR (neat) 1735 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.6—4.3 (9H, m), 3.65, and 3.68 (each 3H, s, COOMe); ^{13}C NMR ($CDCl_3$) δ=32.65, 39.71 (each t, 4:5, 1-C), 44.71, 45.83 (each d, 4:5, 6-C), 48.60, 51.36 (each d, 4:5, 7-C), 51.89, 52.06, 52.18 (each q, COOMe), 53.30, .56.18 (each t, 4:5, 5-C), 58.00, 61.42 (each t, 4:5, 3-C), 68.48, 70.65 (each d, 5:4, 7a-C), 171.01, 171.66, 172.96, and 173.36 (each s, COOMe); MS *m/z* (rel intensity, %) 245 (M^+, 57), 214 (38), 212 (25), 199 (38), 140 (base peak), 101 (26), 81 (25), 80 (46), 59 (26), 55 (27), 41 (40), and 40 (24). HRMS Found: *m/z* 245.0731. Calcd for $C_{10}H_{15}NO_4S$: M, 245.0721.

General Procedure for the Generation of Azomethine Ylide AY-D by Thermolysis of 5-Oxazolidinone 11 and Subsequent Ylide Trapping with Olefins or Aldehydes Leading to 12 or 13. A mixture of *N*-phenylglycine (10, 0.2 g, 1.32 mmol) and paraformaldehyde (0.207 g, 6.9 mmol) was heated under reflux in toluene (10 ml). The water formed was removed by the aid of Dean-Stark trap. After 20 min the toluene was evaporated to dryness in vacuo to give almost pure **11** (0.215 g, 100%) as a labile solid: ^{1}H NMR ($CDCl_3$) δ=3.83 (2H, s, 4-H), 5.24 (2H, s, 2-H), 6.3—6.5 (2H, m, Ph), 6.7—6.9 (1H, m, Ph), and 7.0—7.3 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=46.18 (t, 4-C), 81.54 (t, 2-C), 112.60, 119.89, 129.42 (each d), 144.07 (s), and 171.42 (s, COO). The generation of ylide **AY-D** was conducted without isolation of the precursor **11** as follows: A mixture of **10** (0.2 g, 1.32 mmol) and paraformaldehyde (0.207 g, 6.9 mmol) was heated under reflux in toluene (10 ml) for 30 min under continuous removal of the water formed and then an olefin or an aldehyde (1.32 mmol) was added. The resulting mixture was heated under reflux. The residue obtained by evaporation of the solvent in vacuo was chromatographed over silica gel by using hexane–ethyl acetate to give **12** or **13**. The reaction conditions as well as the results are all summarized in Table 2.

12a: Colorless needles (ethyl acetate–hexane); mp 214—216 °C; IR (KBr) 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.35 (3H, s, *p*-Me), 3.1—3.4, 3.4—3.7 (each 2H, m), 4.07 (2H, d, *J*=8.9 Hz, 4- and 6-H), 6.6—6.9 (3H, m, Ar), and 7.0—7.4 (6H, m, Ar); MS *m/z* (rel intensity, %) 306 (M^+, base peak), 144 (74), 119 (37), 105 (26), 104 (36), 91 (62), and 77 (46). Found: C, 74.61; H, 5.89; N, 8.90%. Calcd for $C_{19}H_{18}N_2O_2$: C, 74.49; H, 5.92; N, 9.14%.

12b: Colorless needles (hexane); mp 104—106 °C; IR (KBr) 1725 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.4—3.7 (6H, m, 2-, 3-, 4-, and 5-H), 3.72 (6H, s, COOMe), 6.4—6.8 (3H, m, Ph), and 7.1—7.3 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=45.53 (d, 3- and 4-C), 50.30 (t, 2- and 5-C), 52.36 (q, COOMe), 112.42, 117.12, 129.36 (each d), 147.31 (s), and 172.83 (s, COOMe); MS *m/z* (rel intensity, %) 263 (M^+, base peak), 202 (31), 145 (37), 144 (74), 119 (21), 104 (32), 91 (42), and 77 (41). Found: C, 64.17; H, 6.60; N, 5.39%. Calcd for $C_{14}H_{17}NO_4$: C, 63.87; H, 6.51; N, 5.32%.

12c: Colorless needles (hexane); mp 78—80 °C; IR (KBr) 1725 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.2—3.7 (6H, m, 2-, 3-, 4-, and 5-H), H), 3.65 (6H, s, COOMe), 6.4—6.8 (3H, m, Ph),

and 7.0—7.3 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=45.06 (d, 3- and 4-C), 49.06 (t, 2- and 5-C), 52.12 (q, COOMe), 111.95, 116.65, 129.36 (each d), 147.24 (s), and 172.31 (s, COOMe); MS *m/z* (rel intensity, %) 263 (M^+, 77), 204 (21), 145 (56), 144 (base peak), 104 (32), 91 (38), and 77 (49). Found: C, 63.94; H, 6.50; N, 5.58%. Calcd for $C_{14}H_{17}NO_4$: C, 63.87; H, 6.51; N, 5.32%.

13a: Yellow prisms (benzene–hexane); mp 118—120 °C; IR (KBr) 1595 and 1345 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.27 (1H, dd, *J*=8.6 and 7.5 Hz, one of 4-H), 3.86 (1H, dd, *J*=8.6 and 6.5 Hz, the other of 4-H), 5.05, 5.17 (each 1H, d, *J*=2.3 Hz, 2-H), 5.33 (1H, dd, *J*=7.5 and 6.5 Hz, 5-H), 6.4—6.6 (2H, m, Ph), 6.7—6.9 (1H, m, Ph), 7.1—7.3 (2H, m, Ph), 7.55 (1H, d, *J*=8.8 Hz, Ar), and 8.20 (1H, d, *J*=8.8 Hz, Ar); ^{13}C NMR ($CDCl_3$) δ=53.59 (t, 4-C), 78.88 (d, 5-C), 82.18 (t, 2-C), 113.07, 118.54, 123.95, 126.89, 129.60 (each d), 145.48, 147.31, and 147.89 (each s); MS *m/z* (rel intensity, %) 270 (M^+, 32), 119 (92), 91 (base peak), and 77 (35). Found: C, 67.00; H, 5.30; N, 10.17%. Calcd for $C_{15}H_{14}N_2O_3$: C, 66.66; H, 5.22; N, 10.36%.

13b: Pale yellow liquid; IR (neat) 1690 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.6—3.8 (2H, m, 4-H), 5.01, 5.04 (each 1H, d, *J*=2.1 Hz, 2-H), 5.50 (1H, dd, *J*=6.8 and 6.1 Hz, 5-H), 6.4—6.6 (2H, m, Ph), 6.7—6.9 (1H, m, Ph), 7.1—7.3 (2H, m, Ph), 7.3—7.6 (3H, m, PhCO), and 7.9—8.1 (2H, m, PhCO); ^{13}C NMR ($CDCl_3$) δ=48.36 (t, 4-C), 79.24 (d, 5-C), 82.06 (t, 2-C), 113.30, 118.42, 128.83, 128.95, 129.42 (each d), 133.83, 134.72, 145.42 (each s), 196.31 (s, CO); MS *m/z* (rel intensity, %) 253 (M^+, 39), 222 (23), 149 (30), 122 (49), 121 (56), 120 (34), 106 (40), 105 (base peak), 93 (26), 91 (29), 77 (77), 58 (29), 51 (25), and 43 (76). HRMS Found: *m/z* 253.1099. Calcd for $C_{16}H_{15}NO_2$: M, 253.1102.

13c: Pale yellow liquid; IR (neat) 1715 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.20, 2.23, (each 3H, s, COMe), 4.40 (1H, d, *J*=3.2 Hz, 4-H), 4.61 (1H, d, *J*=3.2 Hz, 5-H), 5.07, 5.18 (each 1H, d, *J*=2.5 Hz, 2-H), 6.4—6.5 (2H, m, Ph), 6.7—6.9 (1H, m, Ph), and 7.1—7.3 (2H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=25.94, 26.41 (each q, COMe), 67.36 (d, 4-C), 82.71 (t, 2-C), 84.77 (d, 5-C), 113.19, 119.60, 129.89 (each d), 144.19 (s), 206.25, and 208.72 (each s, COMe); MS *m/z* (rel intensity, %) 233 (M^+, 21), 190 (base peak), 162 (25), 149 (50), 146 (32), 91 (22), 77 (25), and 43 (40). HRMS Found: *m/z* 233.1055. Calcd for $C_{13}H_{15}NO_3$: M, 233.1051.

General Procedure for the Generation of Azomethine Ylides AY-F from Glycine (14) and Carbonyl Compounds and Subsequent Ylide Trapping with Olefins Leading to 15 and 16. A mixture of **14** (0.2 g, 2.66 mmol), paraformaldehyde (0.2 g, 6.67 mmol), and an olefin (1.32 mmol) was heated under reflux in toluene or DMF (15 ml). The solvent as well as the reaction conditions is listed in Table 3 (Entries 1—6). After the completion of reaction the solvent was evaporated in vacuo and the residue was chromatographed over silica gel with ethyl acetate as an eluent to give **15** or **16**. The results are summarized in Table 3. Elemental analyses for **16a—16c** were not available because of the absence of parent ion peaks in their mass spectra.

15a: Colorless grains (benzene–hexane); mp 159—161 °C; IR (KBr) 3330 and 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.31, 1.36 (each 3H, s, Me), 1.99 (1H, br s, NH), 2.35 (3H, s, *p*-Me), 2.9—3.1, 3.3—3.6 (1H+3H, m, 3a-, 6-, and 6a-H), and 7.0—7.3 (4H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=21.12 (q, *p*-Me), 25.12, 28.83 (each q, Me), 47.94 (t, 6-C), 48.47 (d, 6a-C), 54.89 (d, 3a-C), 63.12 (s, 4-C), 126.30, 129.48 (each d), 129.83, 138.66 (each s), 176.36, and 178.66 (each s, CON); MS *m/z* (rel intensity, %) 258 (M^+, 2), 82 (base peak), and 67 (19). Found: C, 69.56; H, 7.03; N, 10.53%. Calcd for $C_{15}H_{18}N_2O_2$: C, 69.73; H, 7.04; N, 10.85%.

15b: Colorless grains (benzene–hexane); mp 148—150 °C; IR (KBr) 3300 and 1700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.2—2.0 (10H, m, *c*-Hex), 2.35 (3H, s, *p*-Me), 2.96 (1H, br, NH), 3.1—3.6 (4H, m, 3a-, 6-, and 6a-H), and 7.0—7.3 (4H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=22.71, 23.24, 25.59, 34.71, 36.36 (each t, *c*-Hex), 21.24 (q, *p*-Me), 47.53 (d, 6a-C), 47.83 (t, 6-C), 54.65 (d, 3a-C), 126.42, 129.54, 129.95 (each d), 138.77 (s), 176.36, and 179.01 (each s, CON); MS *m/z* (rel intensity, %) 258 (M^+, 2), 82 (base peak), and 67 (19). Found: C, 69.56; H, 7.03; N, 10.53%. Calcd for $C_{15}H_{18}N_2O_2$: C, 69.73; H, 7.04; N, 10.85%.

16a: Colorless needles (benzene–hexane); mp 102—104 °C; IR (KBr) 1705 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.32 (6H, s, *p*-Me), 2.3—2.6 (4H, m, CH), 3.1—3.5 (10H, m, CH_2), and 7.0—7.3 (8H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=21.18 (q, *p*-Me), 44.24 (d, CH), 55.24 (t, CH_2), 72.01 (t, NCH_2N), 126.42, 129.95 (each d), 138.77 (s), and 178.66 (s, CON); MS *m/z* (rel intensity, %) 244 (M^+—228, 18), 243 (base peak) 96 (24), 81 (43), 80 (20), 68 (88), 55 (37), 43 (42), 42 (29), and 41 (25).

16b: Pale yellow liquid; IR (neat) 2250 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.2—4.1 (12H, m, CH_2 and CH) and 7.40 (10H, s, Ph); ^{13}C NMR ($CDCl_3$) δ=40.59 (s, q-C), 53.95 (d, CH), 54.89, 61.42 (each t, CH_2), 73.18 (t, NCH_2N), 114.01, 115.42 (each s, CN), 128.42, 129.30 (each d), and 134.36 (s); MS *m/z* (rel intensity, %) 211 (M^+—195, 17), 210 (base peak), 132 (36), 105 (32), 103 (23), 91 (34), and 42 (77).

16c: Colorless liquid; IR (neat) 1735 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.8—3.7 (14H, m, CH_2 and CH) and 3.68 (12H, s, COOMe); ^{13}C NMR ($CDCl_3$) δ=45.24 (d, CH), 52.24 (q, COOMe), 55.06 (t, CH_2), 74.36 (t, NCH_2N), and 174.07 (s, COOMe); MS *m/z* (rel intensity, %) 343 (M^+—43, 12), 312 (15), 200 (93), 140 (33), 82 (27), 68 (21), 59 (base peak), 41 (27), and 33 (44).

Triethyl Perhydro-1,3,5-triazine-1,3,5-triacetate (18): To a solution of aqueous formaldehyde (37%, 0.39 g, 4.85 mmol) in ethanol (0.5 ml) was added at 0 °C ethyl aminoacetate (**17**) (0.35 g, 3.39 mmol). The mixture was stirred at 0 °C for 10 h, diluted with dichloromethane (30 ml), and then dried over magnesium sulfate. The residue obtained by evaporating the solvent in vacuo was chromatographed over silica gel with hexane–ethyl acetate (1:1 vol/vol) to give **18** (0.208 g, 53%): Colorless liquid; IR (neat) 1735 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.24 (9H, t, COOEt), 3.39 (6H, NCH_2), 3.67 (6H, NCH_2N), and 4.13 (6H, q, COOEt); ^{13}C NMR ($CDCl_3$) δ=14.24 (q, COOEt), 54.06 (t, NCH_2), 60.71 (t, NCH_2N), 73.18 (t, COOEt), and 170.84 (s, COOEt).

3-(Triphenylmethyl)-5-oxazolidinone (20). This compound was prepared according to either of the following two methods: (1) A mixture of *N*-(triphenylmethyl)aminoacetic acid (**19**) (0.203 g, 0.64 mmol) and paraformaldehyde (0.1 g, 3.3 mmol) was heated under reflux in toluene (10 ml) for 15 min during which time the water formed was removed by the aid of a Dean-Stark trap. The residue, obtained by evaporation of the solvent, was dissolved in dichloromethane (30 ml). The dichloromethane was washed with water, dried over magnesium sulfate, and evaporated in vacuo to give colorless solid of **20** (0.189 g, 90%). (2) To a solution of **19** (0.205 g, 0.65 mmol) in ethanol (15 ml) was added at room temperature aqueous formaldehyde (37%, 0.3 ml). The mixture was stirred at room temperature for 2 h

and evaporated in vacuo. The residue was dissolved in dichloromethane (30 ml). This solution was dried over magnesium sulfate and evaporated in vacuo to give **20** (0.211 g, 99%). **20**: Colorless needles (benzene-hexane); mp 153—155 °C; IR (KBr) 1775 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.55 (2H, s, 4-H), 5.09 (2H, s, 2-H), and 7.0—7.5 (15H, m, Trt); ^{13}C NMR ($CDCl_3$) δ=48.77 (t, 4-C), 76.01 (s, Trt), 83.54 (t, 2-C), 127.42, 128.48, 128.89 (each d), and 142.66 (s); MS *m/z* (rel intensity, %) 244 (M^+−86, 24), 243 (base peak), and 165 (27). Found: C, 80.01; H, 5.87; N, 4.40%. Calcd for $C_{22}H_{19}NO_2$: C, 80.22; H, 5.81; N, 4.25%.

Generation of Azomethine Ylide AY-H by Thermolysis of 20 and Subsequent Ylide Trapping with Olefins Leading to 21. A mixture of **20** (0.396 g, 1.2 mmol) and an olefin (1 mmol) in dry toluene (20 ml) was heated under reflux for the period shown in Table 3 (Entries 7—9). The mixture was evaporated in vacuo and the residue was chromatographed over silica gel by using hexane-ethyl acetate (1:1 vol/vol) to give **21**. The results are listed in Table 3.

21a: Colorless prisms (benzene-hexane); mp 137—138.5 °C; IR (KBr) 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.4—2.8, 3.2—3.4 (4H+2H, m, 2-, 3-, 4-, and 5-H), 3.65 (6H, s, COOMe), and 7.0—7.5 (15H, m, Trt); ^{13}C NMR ($CDCl_3$) δ=44.07 (d, 3- and 4-C), 49.83 (t, 2- and 5-C), 52.12 (q, COOMe), 73.95 (s, Trt), 126.48, 127.71, 129.30 (each d), 142.13 (s), 174.24 (s, COOMe); MS (at 40 eV) *m/z* (rel intensity, %) 429 (M^+, 1), 244 (21), 243 (base peak), and 165 (37). Found: C, 75.31; H, 6.43; N, 3.49%. Calcd for $C_{27}H_{27}NO_4$: C, 75.50; H, 6.34; N, 3.26%.

21b: Colorless needles (benzene-hexane); mp 140—141 °C; IR (KBr) 1735 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.5—2.8, 2.9—3.1 (2H+4H, m, 2-, 3-, 4-, and 5-H), 3.60 (6H, s, COOMe), and 7.0—7.6 (15H, m, Trt); ^{13}C NMR ($CDCl_3$) δ=44.18 (d, 3- and 4-C), 48.94 (t, 2- and 5-C), 51.71 (q, COOMe), 74.48 (s, Trt), 126.42, 127.66, 129.36 (each d), 142.42 (s), and 173.07 (s, COOMe); MS *m/z* (rel intensity, %) 429 (M^+, 1), 244 (33), 243 (base peak), and 165 (23). Found: C, 75.52; H, 6.43; N, 3.50%. Calcd for $C_{27}H_{27}NO_4$: C, 75.50; H, 6.34; N, 3.26%.

21c: Colorless prisms (benzene-hexane); mp 276—279 °C; IR (KBr) 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.7—2.0 (2H, m, 3a- and 6a-H), 2.41 (3H, s, *p*-Me), 3.0—3.2, 3.5—3.7 (each 2H, m, 4- and 6-H), and 7.1—7.4 (19H, m, Ar); MS *m/z* (rel intensity, %) 473 (M^+, 1), 243 (base peak), 244 (22), and 165 (39). HRMS Found: *m/z* 472.2144. Calcd for $C_{32}H_{28}N_2O_2$: M, 472.2149.

General Procedure for the Elimination of Trityl Group of 21 Leading to 22. To a solution of **21a** or **21b** (0.1 g, 0.232 mmol) in dichloromethane (1 ml) was added concd HCl (0.05 ml). The mixture was stirred at room temperature for 0.5 h. Another portion of dichloromethane (30 ml) and then saturated aqueous sodium carbonate (30 ml) were added. The dichloromethane was dried over magnesium sulfate and evaporated in vacuo to give **22a** (0.023 g, 53%) or **22b** (0.022 g, 50%).

22a: Colorless liquid; IR (neat) 3330 and 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.17 (1H, s, NH, D_2O exchangeable), 3.0—3.5 (6H, m, 2-, 3-, 4-, and 5-H), and 3.67 (6H, s, COOMe); ^{13}C NMR ($CDCl_3$) δ=48.18 (d, 3- and 4-C), 52.12 (t, 2- and 5-C), 52.30 (q, COOMe), and 174.54 (s, COOMe); MS *m/z* (rel intensity, %) 187 (M^+, 3), 68 (base peak), 59 (21), 43 (44), 42 (22), 41 (35), and 39 (31). HRMS Found: *m/z* 187.0861. Calcd for $C_8H_{13}NO_4$: M, 187.0844.

22b: Colorless liquid; IR (neat) 3300 and 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.47 (1H, s, NH, D_2O exchangeable), 3.1—3.4 (6H, m, 2-, 3-, 4-, and 5-H), and 3.63 (6H, s, COOMe); ^{13}C NMR ($CDCl_3$) δ=47.71 (d, 3- and 4-C), 50.65 (t, 2- and 5-C), 52.00 (q, COOMe), and 173.54 (s, COOMe); MS *m/z* (rel intensity, %) 187 (M^+, 2), 68 (base peak), 59 (25), 43 (27), 42 (22), 41 (39), and 39 (33). HRMS Found: *m/z* 187.0843. Calcd for $C_8H_{13}NO_4$: M, 187.0844.

4-Methyl-3-triphenylmethyl-5-oxazolidinone (24): A mixture of *N*-triphenylmethyl-2-aminopropanoic acid (**23**) (1.12 g, 3.37 mmol) and paraformaldehyde (0.5 g, 16.7 mmol) was heated in toluene (30 ml) for 0.5 h. The water formed was removed by the aid of a Dean-Stark trap. The toluene was removed by evaporation in vacuo, the residue was dissolved in dichloromethane (30 ml). The dichloromethane was washed with water, dried over magnesium sulfate, and then evaporated to give **24** (1.01 g, 91%): Colorless needles (benzene-hexane); mp 174—177 °C; IR (KBr) 1775 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.52 (3H, d, *J*=7.2 Hz, 4-Me), 3.72 (q, 1H, *J*=7.2 Hz, 4-H), 5.15, 5.32 (each 1H, d, *J*=8.0 Hz, 2-H), and 7.1—7.5. (15H, m, Trt); ^{13}C NMR ($CDCl_3$) δ=15.41 (q, 4-Me), 55.42 (d, 4-C), 77.24 (s, Trt), 82.36 (t, 2-C), 127.24, 128.42, 128.77 (each d), 143.31 (s), and 177.01 (5-C); Ms *m/z* (rel intensity, %) 343 (M^+, 1), 266 (3), 244 (27), 243 (base peak), 241 (5), 239 (5), 166 (base peak), 165 (32), 91 (3), 78 (4), and 77 (4). Found: C, 80.43; H, 6.18; N, 4.20%. Calcd for $C_{23}H_{21}NO_2$: C, 80.44; H, 6.16; N, 4.08%.

***N*-(Triphenylmethyl)methylamine (25):** Colorless liquid; IR (neat) 3330, 1598, 1485, 1450, 900, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.5—1.7 (1H, br, NH), 2.03 (3H, s, NMe), and 7.0—7.5 (15H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=30.59 (q, NMe), 71.42 (s, q-C), 126.36, 127.89 128.91 (each d), and 146.01 (s); MS *m/z* (rel intensity, %) 273 (M^+, 13), 243 (33), 196 (base peak), 165 (28), and 77 (22). HRMS Found: *m/z* 273.1515. Calcd for $C_{20}H_{19}N$: M, 273.1517.

Generation of Azomethine Ylide AY-I and Ylide Trapping with Olefins Leading to 27. A mixture of *N*-benzylaminoacetic acid (**26**) (0.33 g, 2 mmol), paraformaldehyde (0.18 g, 6 mmol), and an olefin (1 mmol) in dry toluene (10 ml) was refluxed for 15 min. The water formed was continuously removed. The toluene was evaporated in vacuo and the residue was chromatographed over silica gel with hexane-ethyl acetate (3:1 to 1:1 vl/vol) to give **27a**—**27d**. The results are summarized in Table 3. Cycloadducts **27a** and **27b** are known and their structures were confirmed by comparison of the spectral data with the reported ones.[8]

27c: Colorless plates (benzene-hexane); mp 129—130 °C; IR (KBr) 1770 and 1695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.2—2.5 (2H, m, 3a- and 6a-H), 2.31 (3H, s, *p*-Me), 3.0—3.4 (4H, m, 4- and 6-H), 3.51 (2H, s, $PhCH_2$), and 7.0—7.2 (9H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=21.12 (q, *p*-Me), 44.24 (d, 3a- and 6a-C), 56.47 (t, 4- and 6-C), 58.12 (t, $PhCH_2$), 126.36, 127.24, 128.30, 128.48, 129.83 (each d), 138.01, 138.60 (each s), and 178.66 (s, CON); MS *m/z* (rel intensity, %) 320 (M^+, 80), 319 (25), 243 (23), 229 (73), 133 (22), 92 (28), 91 (base peak), 42 (30), and 32 (28). Found: C, 74.95; H, 6.29; N, 8.75%. Calcd for $C_{20}H_{20}N_2O_2$: C, 74.98; H, 6.29; N, 8.74%.

27d: Colorless liquid; IR (neat) 1730 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.92 (3H, t, *n*-Bu), 1.2—1.8, 1.9—2.2, 2.3—3.1 (4H+2H+5H, m, *n*-Bu and CH_2), 3.60 (2H, s, $PhCH_2$), 4.06 (2H, t, *n*-Bu), and 7.1—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=13.71 (q, *n*-Bu), 19.12, 27.71, 30.71 (each t, *n*-Bu and 4-C), 42.24 (d, 3-C), 53.77, 56.77, 60.12, 64.48 (each t, *n*-Bu, 2-, and

5-C), 127.07, 128.36, 128.83 each d), 139.13 (s), and 175.19 (s, COOBu-*n*); MS *m/z* (rel intensity, %) 261 (M^+, 6), 170 (30), 91 (base peak), 72 (30), and 42 (39). HRMS Found: *m/z* 261.1751. Calcd for $C_{16}H_{23}NO_2$: M, 261.1728.

Debenzylation of 27c by Pd/C Leading to 22c. A mixture of **27c** (0.16 g, 0.5 mmol) and palladium on charcoal (5%, 0.15 g) in dry xylene (1.5 ml) was refluxed under an atmosphere of hydrogen (ca. 1 atm) for 3 h. The catalyst was filtered off and washed with dichloromethane (5 ml). The filtrate and washing were combined and evaporated in vacuo to give **22c** (0.11g, 96%): Colorless viscous liquid; IR (neat) 3300, 1770, and 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.7—2.0 (1H, m, D_2O exchangeable, NH), 2.38 (3H, s, *p*-Me), 2.9—3.7 (4H, m, 3a-, 4-, 6, and 6a-H), and 7.0—7.4 (4H, m, Ar); MS *m/z* (rel intensity, %) 230 (M^+, 70), 188 (24), 107 (18), 96 (31), 91 (19), 68 (base peak), and 43 (78). HRMS Found: *m/z* 230.1050. Calcd for $C_{13}H_{14}N_2O_2$: M, 230.1054.

Horner-Emmons Olefination of 4-Hydroxy-2-oxoalkylphosphonates and Related Compounds: Applications to the Syntheses of (±)-Gingerol, (±)-Yashabushiketol, and (±)-Dihydroyashabushiketol

Otohiko Tsuge,* Shuji Kanemasa, Norihiko Nakagawa, and Hiroyuki Suga
Institute of Advanced Material Study, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816
(Received June 19, 1987)

Horner–Emmons olefination of 4-hydroxy-2-oxoalkylphosphonates, readily available by hydrogenation of 5-substituted 3-phosphinylmethyl-2-isoxazolines, gives mainly E-isomers of 1-hydroxy-4-alken-3-ones bearing a variety of substituents at the 1-position. Use of the combination of triethylamine (or DBU)+lithium bromide as a weak base on the *O*-unprotected phosphonates is favored. Similar olefinations on the isoxazolines, 2-oxo-3-alkenylphosphonates, and 4-alkoxy-2-oxoalkylphosphonates have been also examined. Their synthetic applications to (±)-Gingerol, (±)-Yashabushiketol, and (±)-Dihydroyashabushiketol are described.

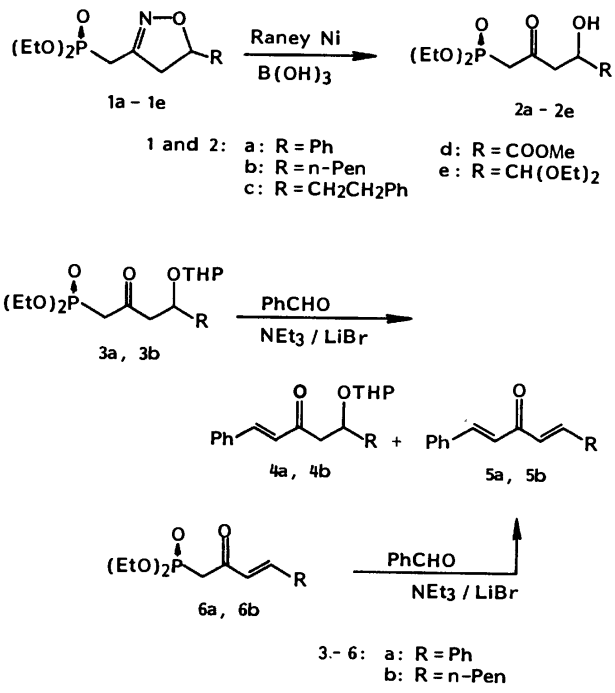
Regioselective 1,3-dipolar cycloaddition reactions of α-(diethoxyphosphinyl)acetonitrile oxide, a phosphorus-functionalized nitrile oxide, with unsymmetrically substituted olefins lead to 5-substituted 3-[(diethoxyphosphinyl)methyl]-2-isoxazolines (**1**).[1] Deprotonation occurs regioselectively at the side chain of **1** to form phosphorus-stabilized carbanions, which can be effectively utilized for the subsequent olefination, alkylation, or acylation to produce 3-substituted 2-isoxazolines. Hydrogenation of **1** on Raney Ni provides 4-hydroxy-2-oxoalkylphosphonates which are further dehydrated into 2-oxo-3-alkenylphosphonates.[1b]

The 4-hydroxy-2-oxoalkylphosphonates must be important as synthetic building blocks since they correspond to phosphorus-functionalized aldols. Their Horner–Emmons olefination leading to 1-hydroxy-4-alken-3-ones is therefore attractive. However 4-hydroxy-2-oxoalkylphosphonates and their *O*-protected derivatives are both base-sensitive so that the olefination may be only achieved under extremely mild and less basic conditions.[2]

With an aim of examining the synthetic utility of our phosphorus-functionalized nitrile oxide, α-(diethoxyphosphinyl)acetonitrile oxide,[1a] Horner–Emmons olefinations have been applied to 4-hydroxy-2-oxoalkylphosphonates and the related derivatives. The present article describes the details of these intractable olefinations which finally succeeded by the use of triethylamine (or 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU)) + lithium bromide. Furthermore it should be noted that protection of the hydroxyl group has to be avoided. These olefination conditions were applied to the syntheses of some natural products such as (±)-Gingerol, (±)-Yashabushiketol, and (±)-Dihydroyashabushiketol.

Results and Discussion

4-Hydroxy-2-oxoalkylphosphonates **2a—e** are readily prepared by the cycloadditions of α-(diethoxyphosphinyl)acetonitrile oxide with monosubstituted olefins followed by hydrogenation of the cycloadducts **1a—e** on Raney Ni (Scheme 1).[1b] Initially two derivatives **2a,b** were protected as tetrahydropyranyl ethers **3a,b** and then subjected to the olefination reactions with benzaldehyde under various conditions. Deprotonation of **3a,b** with butyllithium or lithium diisopropylamide (LDA) in tetrahydrofuran (THF) at −78 °C and subsequent trapping with benzaldehyde, the usual reaction conditions frequently employed for the olefination of phosphoryl-stabilized carbanions,[3] resulted in the complex mixture of many products. After some efforts had been made to improve the reaction, a satisfactory result was obtained when a mixture of triethylamine (1.2 equiv) and lithium bromide (1.5 equiv) was used for the carbanion



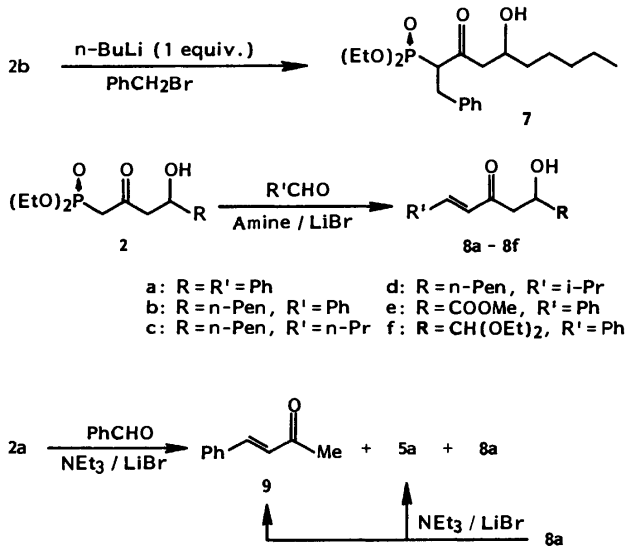
Scheme 1.

generation[4] and when the condensation with benzaldehyde was carried out at 0 °C in THF. However the desired olefins **4a,b** (**4a**: 64%, E only; **4b**: 54%, E only)[5] were accompanied by dienones **5a,b** (**5a**: 20%, E,E:E,Z=6:1; **5b**: 13%, 1E,4E:1Z,4E=8:1) as the elimination products of **4**. Several attempts to exclude the formation of dienones **5a,b** were not successful.

The dienones **5a,b** could be prepared, but in unsatisfactory yields (**5a**: 54%, E,E only; **5b**: 31%, 1E,4E:1Z,4E=9:1 as our best results[6]), by olefinations of 2-oxo-3-alkenylphosphonates **6a,b** (both E isomers) with benzaldehyde in the presence of lithium bromide and triethylamine, which were quantitatively and stereoselectively available by dehydration of **2a,b**.[1b]

Thus olefinations of either 4-alkoxy-2-oxoalkylphosphonates **3** or 2-oxo-3-alkenylphosphonates **6** could not provide a fruitful synthetic conversion.

To our surprise, not *O*-benzylated but *C*-benzylated product **7** was obtained (73% as a mixture of two diastereomers) when 4-hydroxy-2-oxononylphosphonate (**2b**) was treated with one equivalent of butyllithium followed by benzyl bromide (Scheme 2). In this reaction no elimination product **6b** was detected. The selective deprotonation adjacent to the phosphinyl moiety, not at the hydroxyl moiety, would be a result from high stabilization of the anionic center by the lithium chelation. These results indicate that *O*-unprotected 4-hydroxy-2-oxoalkylphosphonates **2** may undergo a successful olefination by the use of one equivalent of base and that the elimination as a major side reaction may be sufficiently suppressed when *O*-unprotected **2** is employed.[7]



Scheme 2.

O-Unprotected 4-hydroxy-2-oxoalkylphosphonates **2** underwent smooth and E-selective olefinations with both aromatic and aliphatic aldehydes to give 1-hydroxy-4-alken-3-ones **8** (Scheme 2 and Table 1). Olefination of **2b** bearing an alkyl substituent (R=*n*-Pen) was effected by NEt_3+LiBr producing high yields of **8b—d** (Entries 3—5), while phenyl-substituted **2a** gave only very poor yield (21%) of **8a** under identical conditions (Entry 1). Beside the elimination reaction leading to **5a** (9%), the major side reaction in this case was retro aldol condensation giving **9** (31%). Formation of both **5a** and **9** was apparently due to the instability of **8a** under the reaction conditions: A 1:2 mixture of **5a** and **9** was yielded on treatment of **8a** with NEt_3+LiBr in THF at room temperature, while **8a** was inert without LiBr.

When DBU was used instead of triethylamine, the olefination reaction was significantly accelerated. The olefination reaction could be carried out at a lower temperature (0 °C) so that the side reactions were relatively suppressed. Thus the reaction of **2a** with benzaldehyde in the presence of DBU+LiBr (both 1 equiv) was very clean to give **8a** in 56% yield.[8,9] The unsatisfactory yield of **8a** was fully complemented by the recovery of the starting phosphonate **2a** (29%) and no formation of the side products **5a** and **9** (Entry 2).

It should be emphasized that 1-hydroxy-4-alken-3-ones **8e,f** bearing an ester or an acetal functionality

Table 1. Horner-Emmons Olefination of 4-Hydroxy-2-oxoalkylphosphonates **2a—e** Leading to 1-Hydroxy-4-alken-3-ones **8a—g**[a]

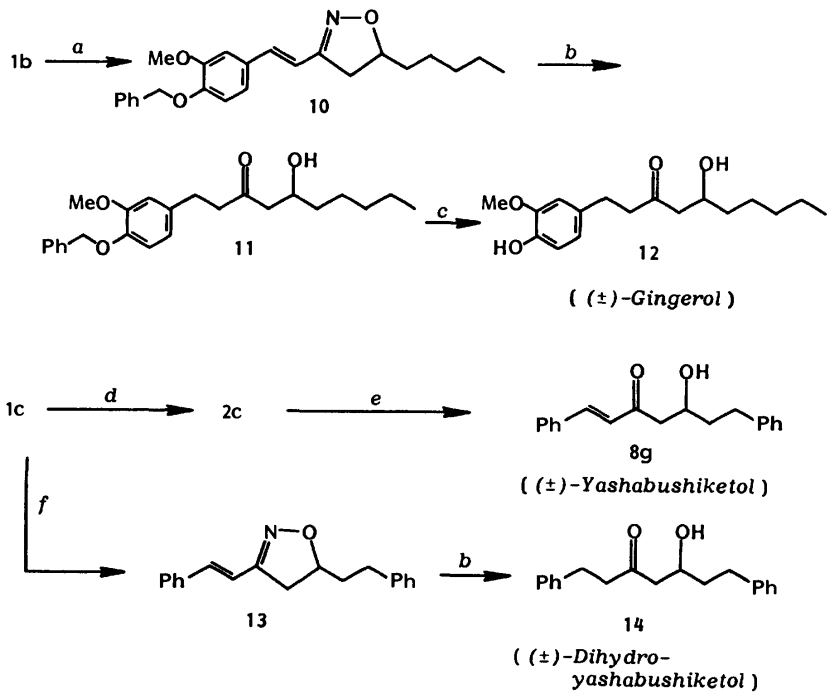
a) All reactions were carried out in dry THF in the presence of LiBr (1.5 equivalent). b) Yield of isolated products. c) One equivalent of LiBr was used. d) Recovered **2a**: 29%. e) Recovered **2d**: 21%. f) Recovered **2e**: 13%. g) Recovered **2c**: 18%.



a: 1) *n*-BuLi in THF, −78 °C, 2) 4-benzyloxy-3-methoxybenzaldehyde, rt. *b*: Raney Ni/$B(OH)_3$ in aqueous EtOH/dichloromethane, rt. *c*: H_2/5% Pd–C in MeOH, rt. *d*: Raney Ni/$B(OH)_3$ in aqueous EtOH, rt. *e*: 1) DBU/LiBr in THF, 0 °C, 2) benzaldehyde, 0 °C. *f*: 1) *n*-BuLi in THF, −78 °C, 2) benzaldehyde, rt.

Scheme 3.

could be available by these olefinations (Entries 6—8).

Synthetic applications of the diethoxyphosphinyl moieties of **1** and **2** were next examined (Scheme 3). 3-[(Diethoxyphosphinyl)-methyl]-5-pentyl-2-isoxazoline (**1b**) was condensed with 4-benzyloxy-3-methoxybenzaldehyde (*n*-BuLi, in THF at −78 °C) giving **10** (only E-isomer) in 79% yield. The N–O bond cleavage as well as the C–C double bond hydrogenation was carried out with Raney Ni (W-2) producing **11** (68%). Dichloromethane was employed as a co-solvent which increased the solubility of **10** in ethanol.[10] Debenzylation of **11** with palladium on charcoal gave a quantitative yield of (±)-Gingerol (**12**).

The Raney Ni reduction of 3-[(diethoxyphosphinyl)methyl]-5-(2-phenylethyl)-2-isoxazoline (**1c**) gave diethyl 4-hydroxy-2-oxo-6-phenylhexylphosphonate (**2c**) in 74% yield. The Horner–Emmons olefination of **2c** with benzaldehyde in the presence of DBU-LiBr at 0 °C led to (±)-Yashabushiketol (**8g**) as a single E-isomer. Reverse operation of the above procedure on **1c** gave (±)-Dihydroyashabushiketol (**14**) via 3-styryl-2-isoxazoline **13** (only E-isomer).

Experimental

General. Melting points were determined on a Yanagimoto melting point apparatus and are not corrected. IR spectra were taken with a JASCO IRA-1 or a JASCO A-702 spectrometer. ^1H NMR spectra were recorded on a Hitachi R-40 (90 MHz) or a JEOL FX-100 instrument (100 MHz) and ^{13}C NMR on a JEOL FX-100 spectrometer at 25.05 MHz. Chemical shifts are expressed in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra as well as high resolution mass spectra were measured with a JEOL-01SG-2 spectrometer at 70 eV of ionization energy. Elemental analyses were performed on a Hitachi 026 CHN analyzer. Thin-layer chromatography (TLC) was accomplished on 0.2 mm precoated plates of silica gel 60F-254 (Merck). Visualization was made with ultraviolet light (254 and 365 nm), iodine, molybdophosphoric acid (5% in ethanol), or *p*-anisaldehyde (5% in ethanol containing 5% of sulfuric acid). For preparative column chromatography, Wakogel C-200, C-300 (Wako), and Silicagel 60 (Merck) were employed. Micro vacuum distillation was carried out on a Sibata GTO-250R Kugelrohr distilling apparatus. Solvents were evaporated at about 50 °C unless otherwise stated.

Materials. 3-[(Diethoxyphosphinyl)methyl]-2-isoxazolines **1a,b** and **1d,e** were prepared by the cycloaddition reactions of α-(diethoxyphosphinyl)acetonitrile oxide to the corresponding olefins.[1b] Diethyl 4-hydroxy-2-oxoalkylphosphonates **2a,b** and **2d,e** were obtained by the Raney Ni reduction of **1** in the presence of boric acid.[1b] The preparation of **1c** and **2c** is presented in the synthetic procedure of Yashabushiketol **8g** and Dihydroyashabushiketol **14**.

Diethyl 2-Oxo-4-phenyl-4-(2-tetrahydropyranyloxy)butylphosphonate (3a). To a solution of **1a** (0.977 g, 3.25 mmol) in dry dichloromethane (10 ml) was added 3,4-dihydro-2*H*-

pyran (0.821 g, 9.76 mmol) and then pyridinium *p*-toluenesulfonate (PPTS, 0.245 g, 0.976 mmol). The mixture was stirred under nitrogen at room temperature for 17 h and poured into water. The products were extracted with diethyl ether (15 ml×2). The combined ether was washed with brine, dried over anhydrous magnesium sulfate, and evaporated in vacuo. The residue was chromatographed over silica gel by using ethyl acetate to give **3a** (1.092 g, 87%): Colorless liquid (a mixture of two diastereomers); IR (neat) 1710, 1240, 1020, and 790 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.28, 1.30 (6H, each t, J=7.0 Hz, OEt), 1.1—1.9 (6H, m, THP), 2.8—3.4 (2H, m, $COCH_2$), 3.0—4.0 (2H, m, THP), 3.04, 3.18 (2H, each d, $^2J_{HP}$=22.0 Hz, PCH_2), 4.07, 4.09 (4H, each dq, $^3J_{HP}$=9.0 and J=7.0 Hz, OEt), 4.36, 4.85 (1H, each br, THP), 5.04, 5.20 (1H, each dd, J=8.5 and 4.5 Hz, CHOTHP), and 7.1—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=16.32 (qd, $^3J_{CP}$=7.4 Hz, OEt), 19.18, 19.35, 25.35, 30.59 (each t, THP), 43.34 (td, $^1J_{CP}$=126,5 Hz, PCH_2), 51.95 (t, $COCH_2$), 62.12 (t, THP), 62.62 (td, $^2J_{CP}$=7.4 Hz, OEt), 73.42, 75.42 (each d, CHOTHP), 95.30, 99.18 (each d, THP), 126.60, 127.13, 127.66, 128.18, 128.48, 128.77 (each d), 140.89, 142.60 (each s), and 200.19 (d, $^2J_{CP}$=5.9 Hz, CO); MS *m/z* (rel intensity, %) 299 (8, M^+ − 85), 283 (11), 194 (18), 179 (50), 167 (15), 152 (50), 151 (42), 131 (36), 125 (39), 123 (89), 109 (75), 105 (61), 104 (base peak), 103 (70), 97 (35), 91 (41), 85 (84), 81 (76), 78 (51), and 77 (90). This compound **3a** was used for the following reaction without further purification.

Diethyl 2-Oxo-4-(2-tetrahydropyranyloxy)nonylphosphonate (3b). A similar procedure using **2b** (0.806 g, 2.74 mmol), 3,4-dihydro-2*H*-pyran (0.691 g, 0.75 mmol), and PPTS (0.206 g, 0.82 mmol) in dichloromethane (15 ml) for 15 h at room temperature gave **3b** (0.869 g, 84%) after column chromatography over silica gel with diethyl ether: Colorless liquid (a mixture of two diastereomers); IR (neat) 1710, 1250, 1020, and 780 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.7—1.8 (17H, m, *n*-Pen and THP), 1.32 (6H, t, J=7.0 Hz, OEt), 2.6—3.0 (2H, m, $COCH_2$), 3.10, 3.16 (2H, each d, $^2J_{HP}$=22.5 Hz PCH_2), 3.3—4.3 (3H, m, THP), 4.12 (4H, dq, $^3J_{HP}$=8.0 and J=7.0 Hz, OEt), and 4.4—4.7 (1H, m, CHOTHP); ^{13}C NMR ($CDCl_3$) δ=13.65 (q, *n*-Pen), 16.00 (qd, $^3J_{CP}$=5.9 Hz, OEt), 19.59, 20.06, 22.24, 24.47, 24.71, 25.18, 30.77, 30.88, 31.47, 34.12, 35.30 (each t, THP and *n*-Pen), 42.83, 43.00 (each td, $^1J_{CP}$=126.5 Hz, PCH_2), 48.30, 49.59 (each t, $COCH_2$), 62.18 (td, $^2J_{CP}$=5.9 Hz, OEt), 62.42, 63.00 (each t, THP), 73.36, 73.71 (each d, CHOTHP), 98.30, 98.89 (each d, THP), 200.72, and 200.84 (each d, $^2J_{CP}$=5.9 Hz, CO); MS *m/z* (rel intensity, %) 293 (M^+ −85, 16), 278 (39), 277 (base peak), 223 (77), 195 (27), 194 (45), 179 (26), and 85 (27). This compound **3b** was used for the following reaction without further purification.

General Procedure for the Horner–Emmons Olefinations of 3 Leading to 4 and 5. As a typical procedure the olefination of **4a** with benzaldehyde is described as follows: To a solution of lithium bromide (0.109 g, 1.25 mmol) in dry THF (1 ml) was added **3a** (0.402 g, 1.05 mmol in THF (4 ml)). The mixture was stirred under nitrogen at room temperature for 10 min and triethylamine (0.16 ml, 1.15 mmol) was added at 0 °C. The resulting mixture was stirred at 0 °C for 30 min. Addition of benzaldehyde (0.133 g, 1.25 mmol) was followed by the stirring at 0 °C for 18 h. The mixture was poured into ice water and extracted with dichloromethane (20 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using hexane–ethyl acetate (7:1 vol/vol) to give **4a** (0.226 g, 64%) and **5a** (0.049 g, 20%).

A similar procedure employing lithium bromide (0.102 g, 1.18 mmol) in dry THF (1 ml), **3b** (0.372 g, 0.983 mmol) in THF (4 ml), triethylamine (0.109g, 1.08 mmol), and benzaldehyde (0.125 g, 1.18 mmol) at 0 °C for 20 h gave **4b** (0.174 g, 54%) and **5b** (0.029 g, 13%) after the same chromatographic separation as shown above.

4a: (only E-isomer by ^1H NMR): Pale yellow liquid; IR (neat) 1660, 1610, 1580, and 1500 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.2—1.9 (6H, m, THP), 2.83 (1H, dd, J=16.0 and 4.5 Hz, one of $COCH_2$), 3.1—4.0 (2H, m, THP), 3.32 (1H, dd, J=16.0 and 9.5 Hz, the other of $COCH_2$), 4.3—4.4, 4.8—5.0 (1H, each m, THP), 5.16, 5.28 (1H, each dd, J=9.5 and 4.5 Hz, CHOTHP), 6.67, 6.76 (1H, each d, J=16.0 Hz, COCH=), 7.0—7.7 (10H, m, Ph), and 7.48, 7.52 (1H, each d, J=16.0 Hz, PhCH=); ^{13}C NMR ($CDCl_3$) δ=19.18, 25.35, 30.53 (each t, THP), 49.12 (t, $COCH_2$), 61.71, 62.06 (each t, THP), 73.48, 76.01 (each d, CHOTHP), 94.71, 99.24 (each d, THP), 126.48, 126.83, 127.07, 127.48, 128.01, 128.42, 128.72, 129.07 (each d), 130.65, 134.60 (each s), 141.42, 143.19 (each d), and 197.95 (s, CO); MS *m/z* (rel intensity, %) 336 (M^+, 3), 252 (15), 251 (24), 131 (base peak), 104 (16), 103 (23), and 85 (92). HRMS Found: *m/z* 336.1722. Calcd for $C_{22}H_{24}O_3$: M, 336.1724.

4b: (only E-isomer by ^1H NMR): Pale yellow liquid; IR (neat) 1650, 1610, 1580, and 1490 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.7—2.0 (17H, m, *n*-Pen and THP), 2.65, 2.71 (1H, each dd, J=15.5, 5.2 and J=15.5, 5.8 Hz, one of $COCH_2$), 2.97, 3.13 (1H, each dd, J=15.5, 7.3 and J=15.5, 6.2 Hz, the other of $COCH_2$), 3.3—4.3 (3H, m, THP and CHOTHP), 4.5—4.7 (1H, m, THP), 6.72, 6.74 (1H, each d, J=16.4 Hz, COCH=), and 7.2—7.6 (6H, Ph and =CH); ^{13}C NMR ($CDCl_3$) δ=14.06 (q, *n*-Pen), 20.00, 20.24, 22.59, 24.94, 25.18, 25.41, 31.24, 31.88, 34.65, 36.06, 45.89, 47.18, 62.95, 63.12 (each t, THP and *n*-Pen), 74.65, 76.01 (each d, CHOTHP), 98.83, 99.24 (each d, THP), 127.01, 127.24, 128.42, 129.07, 130.48, 130.65 (each d), 134.77, 134.95 (each s), 142.66, 143.01 (each d), 199.01, and 199.24 (each s, CO); MS *m/z* (rel intensity, %) 330 (M^+, 5), 131 (73), 103 (17), and 85 (base peak). HRMS Found: *m/z* 330.2171. Calcd for $C_{21}H_{30}O_3$: M, 330.2193.

5a: (a 6:1 mixture of E,E- and E,Z-isomers by ^1H NMR): Colorless solid; ^1H NMR ($CDCl_3$) E,E-isomer δ=7.00 (2H, d, J=15.6 Hz, COCH=), 7.1—7.7 (10H, m, Ph), and 7.65 (2H, d, J=15.6 Hz, PhCH=). E,Z-isomer δ=6.28 (1H, d, J=12.0 Hz, COCH=(Z)), 6.61 (1H, d, J=15.6 Hz, COCH=(E)), 6.90 (1H, d, J=12.0 Hz, PhCH=(Z)), and 7.1—7.7 (11H, m, Ph and PhCH= (E)). The major isomer of **5a** was identified to be (*E,E*)-1,5-diphenyl-1,4-pentadien-3-one by comparison with the authentic sample prepared from acetone and benzaldehyde.[11]

5b: (an 8:1 mixture of 1E,4E- and 1Z,4E-isomers by ^1H NMR): Pale yellow liquid; IR (neat) 1670, 1630, 1610, 1580, and 1500 cm^{-1}; ^1H NMR ($CDCl_3$) 1E,4E-isomer δ= 0.90 (3H, t, *n*-Pen), 1.0—1.8 (6H, m, *n*-Pen), 2.26 (2H, q, J=7.0 Hz, =$CHCH_2$), 6.40 (1H, dt, J=16.0 and 1.3 Hz, $COCH$=$CHCH_2$), 6.97 (1H, dt, J=16.0 and 7.0 Hz, =$CHCH_2$), 7.2—7.7 (5H, m, Ph), and 7.62 (1H, d, J=16.0 Hz, =CHPh); 1Z,4E-isomer δ=2.09 (2H, qd, J=7.0 and 1.5 Hz, =$CHCH_2$), 6.05 (1H, dt, J=16.0 and 1.5 Hz, $COCH$=$CHCH_2$), 6.20 (1H, d, J=12.8 Hz, PhCH=), 6.84 (1H, dt, J=16.0 and 7.0 Hz, =$CHCH_2$), 6.86 (1H, d, J=16.0 Hz, $COCH$=CHPh), and

7.2—7.7 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.00 (q, *n*-Pen), 22.53, 27.65, 27.94, 31.30, 31.47, 32.47, 32.77 (each t, *n*-Pen), 125.07, 128.48, 129.13, 129.54, 129.71, 130.54, 130.89 (each d), 135.13, 135.71 (each s), 138.89, 143.13, 148.60, 149.95 (each d), and 222.72 (s, CO); MS *m/z* (rel intensity, %) 228 (M^+, 20), 227 (34), 131 (25), 128 (37), 127 (20), 103 (59), 102 (22), 91 (22), 76 (66), 57 (32), 55 (37), 53 (22), 51 (27), 42 (25), and 40 (base peak). Found: C, 83.93; H, 8.76%. Calcd for $C_{16}H_{20}O$: C, 84.16; H, 8.83%.

A 2:1 mixture of 1E,4E- and 1Z,4E-isomers of **5b** was obtained in 30% yield when the reaction of **6b** with benzaldehyde was carried out at room temperature for 16 h in the presence of LiBr +NEt_3 (See Ref. 6). Their structures were clearly assigned on the basis of the ^{1}H NMR of this mixture, which was shown above.

General Procedure for the Olefination of 6 Leading to 5. As a typical procedure the olefination of **6b** with benzaldehyde is described below: To a solution of E-isomer of **6b** (0.197 g, 0.713 mmol) in dry THF (2 ml) was added lithium bromide (0.074 g, 0.856 mmol) under nitrogen. After 10 min at room temperature, the mixture was cooled to −20 °C. Benzaldehyde (0.076 g, 0.713 mmol) and then triethylamine (0.081 g, 0.11 ml, 0.799 mmol) were added. The resulting mixture was stirred for 2 h at −20 °C and then for 3 h at room temperature, poured into ice water, and extracted with diethyl ether (20 ml). The extract was washed with aqueous HCl, saturated aqueous sodium carbonate, and finally water. The organic layer was dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel to give **5b** (0.052 g, 31%, a 9:1 mixture of E- and Z-isomers by ^{1}H NMR) and recovered **6b** (13%).

A similar procedure using **6a** (0.223 g, 0.79 mmol), lithium bromide (0.082 g, 0.948 mmol), triethylamine (0.088 g, 0.12 ml, 0.869 mmol), and benzaldehyde (0.168 g, 1.58 mmol) at room temperature for 21 h gave **5a** (0.097 g, 52%, a 6:1 mixture of E- and Z-isomers by ^{1}H NMR).

Diethyl 1-Benzyl-4-hydroxy-2-oxononylphosphonate (7). To a solution of **2b** (0.326 g, 1.11 mmol) in dry THF (2 ml) was added dropwise, at −78 °C under nitrogen, butyllithium (15% solution in hexane, 0.69 ml, 1.11 mmol). After 10 min, benzyl bromide (0.379 g, 2.22 mmol) and then dry hexamethylphosphoric triamide (HMPA, 2 ml) were added slowly. The resulting mixture was warmed to room temperature, stirred for 6 h, and then poured into ice water. The products were extracted in diethyl ether (20 ml×3), the combined extracts were washed with water (50 ml×5), dried over magnesium sulfate, and finally evaporated in vacuo. The residue was chromatographed over silica gel by using hexane-ethyl acetate (3:2 vol/vol) to give **7** (0.312 g, 73%): Pale yellow liquid; IR (neat) 3400, 1700, 1600, 1490, 1240, 1020, and 790 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.7—1.6 (11H, m, *n*-Pen), 1.32 (6H, t, *J*=7.0 Hz, OEt), 2.2—3.5 (6H, m, CH_2, PCH, and OH), 3.5—4.3 (1H, m, CHOH), 4.12 (4H, dq, $^3J_{HP}$=8.0 and *J*=7.0 Hz, OEt), and 7.0—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.06 (q, *n*-Pen), 16.41 (qd, $^3J_{CP}$=5.9 Hz, OEt), 22.65, 25.12, 31.77 (each t, *n*-Pen), 32.48 (td, $^2J_{CP}$=3.0 Hz, $PhCH_2$), 36.59 (t, *n*-Pen), 52.18, 52.30 (each t, $COCH_2$), 55.00, 55.42 (each dd, $^1J_{CP}$=123.5 Hz, PCH), 62.77 (td, $^2J_{CP}$=5.9 Hz, OEt), 63.12, 63.42 (each d, CHOH), 126.95, 128.83 (each d), and 206.22 (d, $^2J_{CP}$=4.4 Hz, CO); MS *m/z* (rel intensity, %) 384 (M^+, 8), 313 (28), 241 (base peak), and 91 (25). HRMS Found: *m/z* 384.2066. Calcd for $C_{20}H_{33}O_5P$: M, 384.2064.

General Procedure for the Horner-Emmons Olefination of 2a—e Leading to 8a—g. As a typical procedure the reaction of **2a** with benzaldehyde leading to **8a** is described as follows: To a solution of lithium bromide (0.044 g, 0.503 mmol) in dry THF was added **2a** (0.151 g, 0.503 mmol). This mixture was stirred at room temperature under nitrogen for 10 min and cooled down to 0 °C. After DBU (0.076 g, 0.503 mmol) was added the stirring was continued for 30 min. Benzaldehyde (0.107 g, 1.01 mmol) was added dropwise. The mixture was stirred at 0 °C for 24 h, poured into ice water, and then extracted with dichloromethane (20 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel with hexane-ethyl acetate (5:1 vol/vol) to give **8a** (0.071 g, 56%). The continued elution with ethyl acetate afforded **2a** (0.044 g, 29%).

The reactions of other phosphonates **2** with aldehydes were similarly carried out under the reaction conditions shown in Table 1 which also summarizes the results of the reactions.

8a: (a 20:1 mixture of E- and Z-isomers by ^{1}H NMR): Pale yellow liquid; IR (neat) 3400, 1650, 1600, 1580, and 1490 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.01, (1H, d, *J*=5.0 Hz, one of $COCH_2$), 3.02 (1H, d, *J*=7.0 Hz, the other of $COCH_2$), 3.74 (1H, br s, OH), 5.21 (1H, dd, *J*=7.0 and 5.5 Hz, CHOH), 6.65, 7.49 (each 1H, d, *J*=16.5 Hz, PhC<u>H</u>=C<u>H</u>), and 7.0—7.6 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=49.12 (t, $COCH_2$), 70.18 (d, CHOH), 125.89, 126.48, 127.71, 128.60, 129.13, 130.89 (each d), 134.36, 143.42 (each s), 143.95 (d), and 200.18 (s, CO); MS *m/z* (rel intensity, %) 252 (M^+, 59), 146 (31), 145 (34), 131 (95), 120 (68), 106 (23), 105 (base peak), 104 (33), 103 (77), 91 (21), 79 (33), and 78 (21). HRMS Found: *m/z* 252.1143. Calcd for $C_{17}H_{16}O_2$: M, 252.1149. Z-Isomer of **8a**: ^{1}H NMR ($CDCl_3$) δ=6.10 (d, *J*=12.7 Hz, COCH=(Z)).

8b: (a 23:1 mixture of E- and Z-isomers by ^{1}H NMR): Colorless prisms (hexane); mp 38—39 °C; IR (KBr) 3350 and 1630 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.6—1.7 (11H, m, *n*-Pen), 2.77 (2H, d, *J*=8.0 Hz, one of $COCH_2$), 2.80 (1H, d, *J*=4.0 Hz, the other of $COCH_2$), 3.24 (1H, br s, OH), 3.8—4.3 (1H, m, CHOH), 6.68, 7.53 (each 1H, d, *J*=16.0 Hz, PhC<u>H</u>=C<u>H</u>), and 7.0—7.6 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.06 (q, *n*-Pen), 22.65, 25.30, 31.83, 36.77 (each t, *n*-Pen), 47.24 (t, $COCH_2$), 68.01 (d, CHOH), 126.65, 128.60, 129.13, 130.83 (each d), 134.48 (s), 143.54 (d), and 201.01 (s, CO); MS *m/z* (rel intensity, %) 246 (M^+, 7), 146 (22), 131 (base peak), and 103 (29). Found: C, 78.10; H, 8.99%. Calcd for $C_{16}H_{22}O_2$: C, 78.01; H, 9.00%. Z-Isomer of **8b**: ^{1}H NMR ($CDCl_3$) δ=6.14 (d, *J*=12.6 Hz, COCH=(Z)).

8c: (Only E-isomer by ^{1}H NMR): Colorless liquid; IR (neat) 3400, 1650, and 1620 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.7—1.8 (16H, m, *n*-Pen and *n*-Pr), 2.20 (2H, dt, *J*=8.0 and 7.0 Hz, *n*-Pr), 2.64 (1H, d, *J*=8.0 Hz, one of $COCH_2$), 2.68 (1H, d, *J*=4.0 Hz, the other of $COCH_2$), 3.20 (1H, br s, OH), 3.8—4.2 (1H, m, CHOH), 6.04 (1H, dt, *J*=16.0 and 1.5 Hz, COCH=), and 6.84 (1H, dt, *J*=16.0 and 7.0 Hz, CH_2C<u>H</u>=); ^{13}C NMR ($CDCl_3$) δ=13.71, 14.06 (each q, *n*-Pen and *n*-Pr), 21.41, 22.71, 25.35, 31.94, 34.59, 36.77 (each t, *n*-Pen and *n*-Pr), 46.42 (t, $COCH_2$), 68.01 (d, CHOH), 131.13, 148.66 (each d, CH=CH), and 201.36 (s, CO); MS *m/z* (rel intensity, %) 212 (M^+, 1), 141 (55), 97 (base peak), 55 (89), 43 (35), and 41 (59). HRMS Found: *m/z* 212.1750. Calcd for $C_{13}H_{24}O_2$: M, 212.1775.

8d: (Only E-isomer by ^{1}H NMR): Colorless liquid; IR (neat) 3400, 1660, and 1625 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.7—1.8 (11H, m, *n*-Pen), 1.07 (6H, d, J=7.0 Hz, *i*-Pr), 2.1—2.7 (1H, m, *i*-Pr), 2.66 (1H, d, J=8.0 Hz, one of $COCH_2$), 2.70 (1H, d, J=4.0 Hz, $COCH_2$), 3.28 (1H, br s, OH), 3.9—4.2 (1H, m, CHOH), 6.03 (1H, dd, J=16.0 and 1.0 Hz, COCH=), and 6.83 (1H, dd, J=16.0 and 6.5 Hz, *i*-PrCH=); ^{13}C NMR ($CDCl_3$) δ=14.06 (q, *n*-Pen), 21.30 (q, *i*-Pr), 22.65, 25.30 (each t, *n*-Pen), 31.24 (d, *i*-Pr), 31.88, 36.71 (each t, *n*-Pen), 46.42 (t, $COCH_2$), 67.89 (d, CHOH), 128.13, 154.84 (each d), and 201.72 (s, CO); MS *m/z* (rel intensity, %) 212 (M^+, 3), 141 (31), 97 (base peak), 69 (21), 56 (24), 43 (44), and 41 (80). HRMS Found: *m/z* 212.1765. Calcd for $C_{13}H_{24}O_2$: M, 212.1775.

8e: (only E-isomer by ^{1}H NMR): Pale yellow liquid; IR (neat) 3500, 1730, 1660, and 1620 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.20 (2H, d, J=5.0 Hz, $COCH_2$), 3.5—3.8 (1H, m, OH), 3.76 (3H, s, COOMe), 4.64 (1H, q, J=5.5 Hz, CHOH), 6.71, 7.56 (each 1H, d, J=16.0 Hz, PhCH=CH), and 7.2—7.7 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=43.94 (t, $COCH_2$), 52.59 (q, COOMe), 67.30 (d, CHOH), 126.07, 128.60, 129.13, 130.95 (each d), 134.36 (s), 144.13 (d), 174.37 (s, COOMe), and 197.72 (s, CO); MS *m/z* (rel intensity, %) 234 (M^+, 11), 131 (base peak), 103 (76), 102 (21), 77 (63), and 52 (23); HRMS Found: *m/z* 234.0886. Calcd for $C_{13}H_{14}O_4$: M, 234.0891.

8f: (only E-isomer by ^{1}H NMR): Pale yellow liquid; IR (neat) 3450, 1650, 1610, 1580, and 1490 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.22 (6H, t, J=7.0 Hz, OEt), 2.8—3.0 (3H, m, $COCH_2$ and OH), 3.4—3.9 (4H, m, OEt), 4.20 (1H, ddd, J=9.0, 7.0, and 4.5 Hz, CHOH), 6.72, 7.57 (each 1H, d, J=16.5 Hz, PhCH=CH), and 7.2—7.7 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=15.06 (q, OEt), 41.77 (t, $COCH_2$), 63.12, 63.65 (each t, OEt), 68.71 (d, CHOH), 104.01 (d, $CH(OEt)_2$), 126.54, 128.18, 128.77, 130.36 (each d), 134.30 (s), 142.95 (d), and 199.60 (s, CO); MS *m/z* (rel intensity, %) 233 (M^+—45, 4), 131 (42), 103 (base peak), 77 (30), 75 (40), and 48 (45). Found: C, 68.88; H, 7.95%. Calcd for $C_{16}H_{22}O_4$: C, 69.04; H, 7.97%.

8g: All data will be presented below (in the synthesis of Yashabushiketol **8g**).

Synthesis of (±)-Gingerol 12. Butyllithium (15% in hexane, 3.69 ml, 6 mmol) was added at −78 °C to a solution of **1b** (1.748 g, 6 mmol) in dry THF (12 ml) and stirred under nitrogen for 30 min. After 4-benzyloxy-3-methoxybenzaldehyde (1.599 g, 6.6 mmol) was added, the resulting mixture was stirred at −78 °C for 1 h, at room temperature for 4 h, poured into cold aqueous ammonium chloride solution, and extracted with diethyl ether (30 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using dichloromethane to give **10** (1.802 g, 79%) as a single E-isomer (^{1}H NMR): Colorless prisms (diethyl ether-hexane); mp 112—113 °C; IR (KBr) 1600, 1580, and 1500 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.8—2.0 (11H, m, *n*-Pen), 2.74 (1H, d, J=16.0 and 8.5 Hz, one of 4-H), 3.19 (1H, d, J=16.0 and 10.0 Hz, the other of 4-H), 3.86 (3H, s, OMe), 4.4—4.8 (1H, m, 5-H), 5.12 (2H, s, CH_2Ph), 6.59, 6.94 (each 1H, J=16.0 Hz, ArCH=CH), 6.8—7.1 (3H, m, Ar), and 7.2—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=13.98 (q, *n*-Pen), 22.52, 25.18, 31.60, 35.23 (each t, *n*-Pen), 38.50 (t, 4-C), 55.90 (q, OMe), 70.92 (t, OCH_2Ph), 81.49 (d, 5-C), 109.49, 113.79, 116.47, 120.63, 127.24, 127.89, 128.51 (each d), 129.46 (s), 135.72 (d), 136.81, 149.04, 149.87 (each s), and 157.66 (s, 3-C); MS *m/z* (rel intensity, %) 379 (M^+, 3), 288 (7), 92 (8), 91 (base peak), and 66 (14). Found: C, 75.96; H, 7.67; N, 3.74%. Calcd for $C_{24}H_{29}NO_3$: C, 75.96; H, 7.70; N, 3.69%. The mixture of **10** (0.38 g, 1 mmol), Raney Ni (W-2, suspension in ethanol, 0.14 ml), and boric acid (0.135 g, 2.1 mmol) in ethanol (5 ml, containing dichloromethane (2 ml) and water (1 ml)) was stirred at room temperature at an ordinary atmospheric pressure of hydrogen for 48 h. Insoluble materials were filtered off by the aid of celite. The filtrate was mixed with dichloromethane (30 ml), the dichloromethane was washed with water, dried over magnesium sulfate, and evaporated in vacuo. The residue was chromatographed over silica gel with hexane-ethyl acetate (3:1 vol/vol) to give **11** (0.261 g, 68%): Colorless prisms (diethyl ether-hexane); mp 52—53 °C (lit,[12] mp 53—54 °C); IR (KBr) 3400, 1700, and 1590 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.9—1.6 (11H, m, *n*-Pen), 2.4—2.6, 2.6—3.0 (2H+5H, m, CH_2 and OH), 3.84 (3H, s, OMe), 3.8—4.1 (1H, m, CHOH), 5.08 (2H, s, CH_2Ph), 6.5—6.9 (3H, m, Ar), and 7.1—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.06 (q, *n*-Pr), 22.59, 25.18, 29.18, 31.77, 36.65, 45.24, 49.53 (each t, CH_2), 56.00 (q, OMe), 62.77 (d, CHOH), 71.30 (t, OCH_2Ph), 112.60, 114.65, 120.30, 127.48, 127.89, 128.65 (each d), 134.36, 137.54, 146.83, 149.95 (each s), and 211.31 (s, CO); MS *m/z* (rel intensity, %) 384 (M^+, 14), 151 (15), 149 (19), 137 (19), and 91 (base peak). Found: C, 75.15; H, 8.43%. Calcd for $C_{24}H_{32}O_4$: C, 74.97; H, 8.39%. A mixture of **11** (0.038 g, 0.1 mmol) and palladium on charcoal (5%, 0.07 g) in methanol (3 ml) was stirred at room temperature at an ordinary atmospheric pressure of hydrogen for 7 h and then filtered by the aid of celite. The filtrate was evaporated in vacuo. The residue was purified through column chromatography over silica gel with hexane-ethyl acetate (3:1 vol/vol) to give (±)-Gingerol **12** (0.029 g, 100%): Colorless liquid; IR (neat) 3420, 1710, and 1600 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.88 (3H, t, J=5.5 Hz, *n*-Pen), 1.0—1.8 (8H, m, *n*-Pen), 2.4—2.6, 2.6—3.2 (2H+5H, m, CH_2), 3.83 (3H, s, OMe), 3.7—4.2 (2H, m, CHOH and OH), and 6.4—6.9 (3H, m, Ar); MS *m/z* (rel intensity, %) 294 (M^+), 151 (16), 150 (55), 138 (13), and 137 (base peak). HRMS Found: *m/z* 294.1835. Calcd for $C_{17}H_{26}O_4$: M, 294.1830.

Synthesis of (±)-Yashabushiketol 8g. To a solution of *N*-2-(diethoxyphosphinyl)ethylidene hydroxylamine (0.625 g, 3.2 mmol) in dry *N*,*N*-dimethylformamide (DMF, 7 ml) was added at −20 °C *N*-bromosuccinimide (NBS, 1.139 g, 6.4 mmol in DMF (6.4 ml)). After 1 h at −20 °C and 30 min at 0 °C, dry diethyl ether (7 ml) was added. A mixture of triethylamine (0.324 g, 0.45 ml, 3.2 mmol) and 4-phenyl-1-butene (0.846 g, 6.4 mmol) in diethyl ether (7 ml) was added dropwise. The mixture was stirred at room temperaure for 18 h, poured into ice water, and extracted with dichloromethane (20 ml×2). The combined extracts were washed with water three times, dried over magnesium sulfate, and evaporated in vacuo. The residue was chromatographed over silica gel by using ethyl acetate to give **1c** (0.6 g, 58%): Pale yellow liquid; IR (neat) 1620, 1600, 1500, 1260, and 1025 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.32 (6H, t, J=7.0 Hz, OEt), 1.7—2.2, 2.4—3.3 (2H+4H, m, CH_2 and 4-H), 2.93 (2H, d, $^2J_{HP}$=22.0 Hz, PCH_2), 4.11 (4H, qd, J=7.0 and $^3J_{HP}$=8.0 Hz, OEt), 4.4—4.8 (1H, m, 5-H), and 7.0—7.4 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=16.00 (q, $^3J_{CP}$=5.9 Hz, OEt), 26.00 (td, $^1J_{CP}$=141.2 Hz, PCH_2), 31.30, 36.53 (each t, CH_2), 42.00 (t, 4-C), 62.27 (td, $^2J_{CP}$=7.4 Hz, OEt), 80.01 (d, 5-C), 125.83, 128.25, 141.01 (each d), and 151.16 (d, $^2J_{CP}$=10.3 Hz, 3-C); MS *m/z* (rel intensity, %) 325 (M^+, 21), 220 (base peak), 192 (22),

164 (39), and 91 (40). HRMS Found: *m/z* 325.1443. Calcd for $C_{16}H_{24}NO_4P$: M, 325.1442. The mixture of **1c** (0.461 g, 1.42 mmol), boric acid (0.191 g, 2.976 mmol), and Raney Ni (W-2, 0.2 ml) in ethanol (7.8 ml, containing water (1.3 ml) was stirred at room temperature at an ordinary pressure of hydrogen for 13 h. The reaction mixture was filtered through celite and the filtrate was treated with dichloromethane (25 ml). The dichloromethane was dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel by using ethyl acetate to give **2c** (0.343 g, 74%): Colorless liquid; IR (neat) 3400, 1700, 1600, 1490, 1240, 1020, and 790 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.30 (6H, t, J=7.0 Hz, OEt), 1.6—2.0, 2.5—3.2 (2H+6H, m, CH_2), 3.52 (1H, br s, OH), 4.12 (4H, qd, J=7.0 and $^3J_{HP}$=8.0 Hz, OEt), and 3.9—4.2 (1H, m, CHOH); ^{13}C NMR ($CDCl_3$) δ=16.29 (qd, $^3J_{CP}$=5.9 Hz, OEt), 31.83, 38.59 (CH_2), 43.03 (td, $^1J_{CP}$=128.0 Hz, PCH_2), 51.36 (CH_2), 62.77 (td, $^2J_{CP}$=5.9 Hz, OEt), 67.01 (d, CHOH), 125.95, 128.54, 128.65 (each d), 142.13 (s), and 202.72 (d, $^2J_{CP}$=5.9 Hz, CO); MS *m/z* (rel intensity, %) 328 (M^+, 16), 310(43), 277 (22), 223 (47), 220 (29), 195 (34), 194 (23), 179 (34), 172 (20), 167 (26), 152 (50), 151 (25), 139 (39), 125 (37), 123 (45), 109 (21), 105 (21), 97 (30), and 91 (base peak). HRMS Found: *m/z* 328.1446. Calcd for $C_{16}H_{25}O_5P$: M, 328.1438. To a solution of lithium bromide (0.065 g, 0.75 mmol) in dry THF (0.5 ml) was added **2c** (0.165 g, 0.5 mmol, in THF (1.5 ml)) and stirred at room temperature for 10 min. After addition of DBU (0.076 g, 0.5 mmol, in THF (0.5 ml)) at 0 °C the stirring was continued for 1 h. Benzaldehyde (0.107 g, 1 mmol) was added and the mixture was stirred at 0 °C for 24 h. It was then poured into ice water and extracted with dichloromethane (20 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed over silica gel with hexane-ethyl acetate (5:1 vol/vol) to give (±)-Yashabushiketol **8g** (0.084 g, 60%) as a single E-isomer (^1H NMR). Further eluent with ethyl acetate gave **2c** (0.029 g, 18%). **8g**: Colorless needles (hexane); mp 82—83 °C (lit,[13] mp 59.5—60.5 °C); IR (KBr) 3300, 1650, 1610, 1580, and 1490 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.6—1.9 (2H, m, $C\underline{H}_2CH_2Ph$), 2.4—2.9 (4H, m, $COCH_2$ and $CH_2C\underline{H}_2Ph$), 3.45 (1H, br s, OH), 3.9—4.3 (1H, m, CHOH), 6.65, 7.50 (each 1H, J=16.5 Hz, $PhC\underline{H}$=$C\underline{H}$), and 6.9—7.6 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=31.83, 38.30 (each t, CH_2CH_2Ph), 47.00 (t, $COCH_2$), 67.30 (d, CHOH), 126.01, 126.48, 128.54, 129.13, 130.89 (each d), 134.36, 142.13 (each s), 143.71 (d), and 200.89 (s, CO); MS *m/z* (rel intensity, %) 280 (M^+, 32), 175 (22), 131 (base peak), 103(38), 91 (41), 77 (20), and 32 (21). Found: C, 81.52; H, 7.12%. Calcd for $C_{19}H_{20}O_2$: C, 81.40; H, 7.19%.

Synthesis of (±)-Dihydroyashabushiketol 14. To a solution of **1c** (0.16 g, 0.492 mmol) in dry THF (1 ml) was added at −78 °C butyllithium (15% in hexane, 0.37 ml, 0.59 mmol) and stirred for 1 h under nitrogen. Benzaldehyde (0.104 g, 0.984 mmol) was added, the mixture was stirred at room temperature for 24 h, poured into aqueous ammonium chloride, and finally extracted with dichloromethane (20 ml×2). The combined extracts were washed with water, dried over magnesium sulfate, and evaporated in vacuo. The residue was chromatographed over silica gel by using hexane-ethyl acetate (5:1 vol/vol) to give **13** (0.102 g, 75%) as a single E-isomer (^1H NMR): Colorless needles (diethyl ether-hexane); mp 104—105 °C; IR (KBr) 1600 and 1490 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.6—2.3, 2.6—3.4 (2H+4H, m, CH_2 and 4-H), 4.5—4.9 (1H, m, 5-H), 6.64, 7.07 (each 1H, d, J=17.0 Hz, $PhC\underline{H}$=$C\underline{H}$), and 7.0—7.6 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=31.77, 37.00, 38.53 (each t, CH_2 and 4-C), 80.65 (d, 5-C), 118.36, 126.18, 127.07, 128.69, 129.01 (each d), 136.01 (s), 136.25 (d), 141.30 (s), and 157.77 (s, 3-C); MS *m/z* (rel intensity, %) 277 (M^+, 65), 276 (base peak), 143 (26), 115 (23), 103 (39), 91 (72), and 77 (44). Found: C, 82.35; H, 6.91; N, 5.05%. Calcd for $C_{19}H_{19}NO$: C, 82.28; H, 6.90; N, 5.05%. The mixture of **13** (0.166 g, 0.6 mmol) and Raney Ni (W-2, suspension in ethanol, 0.16 ml) in ethanol (6 ml, containing dichloromethane (2.4 ml) and water (1.2 ml)) was stirred at room temperature under hydrogen for 14 h. All insoluble materials were filtered off and the filtrate was treated with dichloromethane (30 ml). The mixture was washed with water, dried over magnesium sulfate, and evaporated in vacuo. The residue was chromatographed over silica gel with hexane-ethyl acetate (5:1 vol/vol) to give (±)-Dihydroyashabushiketol **14** (0.136 g, 80%): Colorless needles (hexane); mp 71—72 °C (lit,[14] mp 69—70.5 °C); IR (KBr) 3350, 1700, 1600, and 1500 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.4—1.9, 2.3—3.0 (2H+9H, m, CH_2 and OH), 3.8—4.2 (1H, m, CHOH), and 6.9—7.2 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=29.41, 31.71, 38.24, 44.89, 49.42 (each t), 66.89 (d, CHOH), 125.95, 126.24, 128.54 (each d), 140.95, 142.01 (each s), and 210.77 (s, CO); MS *m/z* (rel intensity, %) 282 (M^+, 6), 264 (19), 133 (19), 105 (48), 104 (base peak), 92 (15), 91 (base peak), and 77 (19). Found: C, 81.02; H, 7.95%. Calcd for $C_{19}H_{22}O_2$: C, 80.82; H, 7.85%.

(Received June 5, 1987)

The title hydroxylamine (NT) undergoes pyrene-sensitized photodecomposition to give rearrangement and fragmentation products. An analysis of linear Stern-Volmer plots, both for the sensitized photolysis of NT and for the fluorescence quenching of pyrene by NT, indicates the involvement of singlet pyrene in this photolysis. The observation of negligible effects of 1,3-cyclohexadiene and *trans*-stilbene as a triplet quencher on the reaction provides further supporting evidence for a singlet-pathway mechanism. A comparison of the relative state energies of NT and the sensitizer suggests the existence of a reactive singlet-exciplex intermediate formed between the singlet-state sensitizer and the ground-state NT. The results of solvent and micellar effects on the sensitized photolysis establish that electron transfer in the exciplex predominates in a polar solvent, and that in a nonpolar solvent energy transfer in this exciplex plays a major role in the reaction.

Our recent observation that the triplet-sensitized photolysis of *N*-(1-naphthoyl)-*O*-(*p*-toluoyl)-*N*-phenylhydroxylamine (NT) and related *N,O*-diacylhydroxylamines gives no rearranged products provided additional supporting evidence for the suggestion that "photoacyloxyl" migration proceeds mainly through the excited singlet state.[1,2] Furthermore, the results of micellar and solvent viscosity effects on the quantum yields for the direct photolysis of NT allowed us to conclude that the "in-cage" products are not derived from the reaction that occurs within the identical solvent cage but from recombination of two distinct spin-correlated radical pairs.[2] On the other hand, diaroyl peroxides have been known to undergo aromatic hydrocarbon-sensitized decompositions whose mechanism involves a reactive and nonemissive singlet-exciplex intermediate.[3-5] These works of Tokumaru and his co-workers on the mechanism of sensitized photolyses of the peroxides stimulated mechanistic investigation of the singlet-sensitized photolysis of our *N,O*-diacylhydroxylamines. NT was selected for the present study because we have already obtained detailed information regarding the mechanism of the direct and triplet-sensitized photolysis of this hydroxylamine.[2] We chose pyrene as a singlet sensitizer and investigated solvent and micellar effects on the pyrene-sensitized photolysis of NT in order to gain more definitive evidence for the reactive state (singlet or triplet state) from which "photoacyloxyl" migration takes place. We also hoped to clarify the mechanism of this sensitized photolysis.

Results

Pyrene-Sensitized Photolysis of NT (1). Irradiation of a N_2-purged benzene solution of NT (2.50—10.0×10^{-3} M, 1 M=1 mol dm^{-3}) in the presence of pyrene (3.00×10^{-3} M) with 366-nm light resulted in the sensitized decomposition of NT giving rearrangement (**2** and **3**) and fragmentation (**4** and **5**) products along with small amounts of unknown products.[6] These photoproducts undergo no sensitized decomposition under the same conditions as above. Pyrene

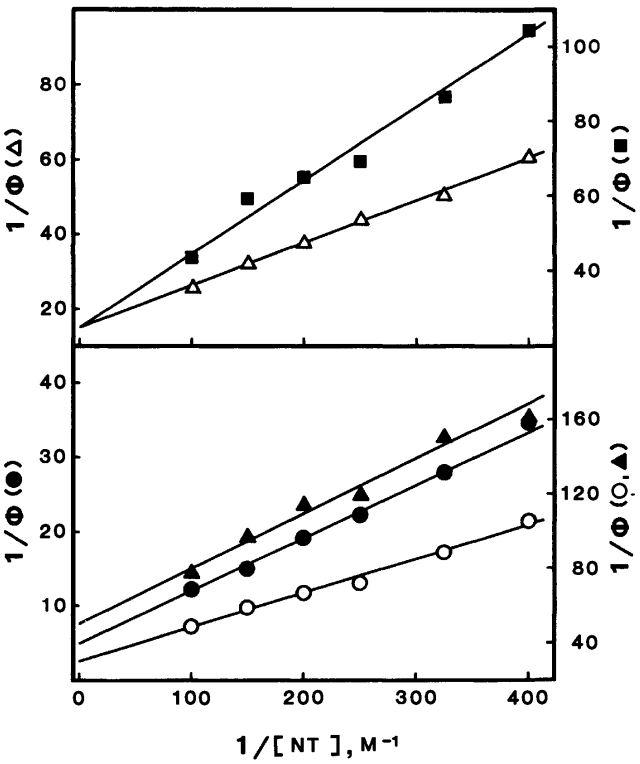

Fig. 1. Stern-Volmer plots of $1/\Phi_{-NT}$ (●), $1/\Phi_2$ (○), $1/\Phi_3$ (▲), $1/\Phi_4$ (△), and $1/\Phi_5$ (■) vs. 1/[NT] for pyrene (3.00×10^{-3} M)-sensitized photolysis of NT with 366-nm light in benzene under nitrogen at room temperature (25±3 °C).

was found to decompose to a negligible extent during the irradiation within the experimental errors of HPLC analysis. In addition, no NT was photolyzed to yield these products without the sensitizer. On the other hand, NT is not subjected to the sensitized decomposition to a measurable extent in the presence of relatively low concentrations of pyrene (less than 10^{-4} M).

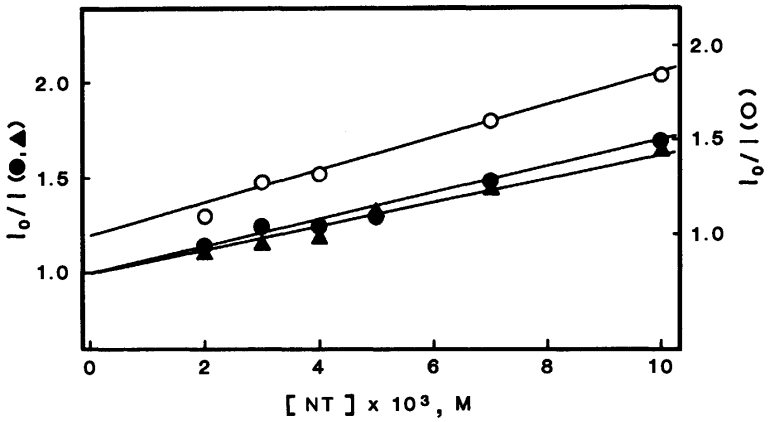

Fig. 2. Stern-Volmer plots for monomer-fluorescence quenching of pyrene (3.00×10^{-3} M) by NT in benzene (●), 1,2-dichloroethane (▲), and acetonitrile (○) under nitrogen at room temperature (23±1 °C). Excitation wavelength=366 nm. I and I_0 refer to fluorescence intensity at 390 nm of pyrene with and without NT, respectively.

A potassium trioxalatoferrate(III) actinometry was applied to determine quantum yields for the disappearance of NT (Φ_{-NT}) and for the appearance of photoproducts (Φ_{2-5}) at low conversions (5—10%) of starting NT.[7] Stern-Volmer plots of the reciprocal of NT concentration against the reciprocal of quantum yields for the sensitized photolysis measured in the presence of a constant concentration of pyrene (3.00×10^{-3} M) gave a straight line for any plot from which we are able to obtain the limiting quantum yields (Φ_{lim}), i.e., the quantum yields extrapolated to the infinite concentration of NT. Typical double reciprocal plots are shown in Fig. 1. Similar linear plots are observed also in 1,2-dichloroethane and acetonitrile.

Quenching of the Fluorescence of Pyrene by NT. Pyrene (3.00×10^{-3} M) in any solvent employed for the sensitization experiments exhibits a monomer fluorescence at 390 nm and an excimer one at 470 nm under nitrogen at room temperature (23±1 °C). The intensity ratio of monomer- to excimer-fluorescence is in the range of 0.6 to 0.9. These fluorescences were quenched by NT following linear Stern-Volmer relationships, as shown in Fig. 2. The quenching constants ($k_t\tau_S$ where k_t and τ_S refer to the rate constant for singlet energy transfer and the lifetime of singlet pyrene without NT, respectively) for the monomer and excimer fluorescences of this sensitizer have not much different values as seen from Table 1, indicating that the monomer and excimer species are in dynamic equilibrium with each other at photostationary state. A consideration of the relative state energies of pyrene-monomer (77 kcal mol^{-1}) and -excimer (≈60 kcal mol^{-1}) species responsible for the dual fluorescence allows us to assume that NT quenches the monomer fluorescence under our experimental conditions.[8] Measurements of monomer-fluorescence lifetimes under the same conditions as those for the sensitized photolysis permit estimations of the k_t values as 1.0×10^9, 0.8×10^9, and 1.7×10^9 M^{-1} s^{-1} in benzene, 1,2-dichloroethane, and acetonitrile, respectively (Table 1). These k_t values reveal that the pyrene fluorescence is quenched by NT at a rate which is close to the diffusion-controlled one.

Discussion

Solvent Effects on the Pyrene-Sensitization. Much higher singlet and triplet states of NT (the first singlet excitation energy, E_{S_1}=90; the first triplet excitation energy, E_{T_1}=59 kcal mol^{-1}; 1 kcal=4.184 kJ) in comparison with those of pyrene (E_{S_1}=77, E_{T_1}=48 kcal mol^{-1})[9] make singlet-singlet energy transfer from pyrene to NT endothermic and, hence, it very unlikely. It is known that dibenzoyl peroxide, whose structure is similar to that of NT, quenches the

Scheme 1.

fluorescence of pyrene through the formation of an nonemissive exciplex with a charge-transfer character.[4] This fact suggests the existence of a similar exciplex produced between the singlet-state pyrene monomer and the ground-state NT. The fluorescence from such an exciplex intermediate could not be detected under the present experimental conditions.

If the pyrene-sensitized decomposition of NT proceeds according to Scheme 1, then the following linear Stern-Volmer relationships can be derived between the reciprocals of quantum yields ($1/\Phi_{-NT}$ and $1/\Phi_{2-5}$) and the reciprocals of varying concentrations of NT (1/[NT]) under the steady-state approximation:

$$1/\Phi_{-NT} = C_1(1+k_R/(k_s+k_2))(1+1/k_t\tau_S[NT]), \quad (1)$$

$$1/\Phi_2 = C_1(1+(k_s+k_R)/k_2)(1+1/k_t\tau_S[NT]), \quad (2)$$

$$1/\Phi_3 = C_1C_2(1+(k_{-s}+k_D)/k_3)(1+1/k_t\tau_S[NT]), \quad (3)$$

$$1/\Phi_4 = C_1C_2C_3(1+k_u^N/k_4)(1+1/k_t\tau_S[NT]), \quad (4)$$

and

$$1/\Phi_5 = C_1C_2C_3(1+(k_6+k_u^T)/k_5)(1+1/k_t\tau_S[NT]), \quad (5)$$

where $C_1=1+k_d/k_r$, $C_2=1+(k_2+k_R)/k_s$, and $C_3=1+(k_3+k_{-s})/k_D$. In this Scheme processes for the formation and deactivation of the pyrene excimer were omitted because we presumed no participation of this excimer in the sensitized photolysis. As shown typically in Fig. 2 the observation of linear plots of $1/\Phi$ against 1/[NT] provides a supporting evidence for the mechanism given in Scheme 1. These linear plots allow for the estimation of the values of Φ_{lim}, $k_t\tau_S$, and $k_d/k_r+k_R(1+k_d/k_r)/(k_s+k_2)$ summarized in Table 1. The $k_t\tau_S$ values, thus evaluated, correspond well to those determined from the fluorescence quenching in any solvent employed, giving an additional evidence in support of Scheme 1.

To confirm that the pyrene-sensitized photolysis of NT occurs undoubtedly from the excited singlet state, we tried to quench the reaction by 1,3-cyclohexadiene (E_{S_i}=97, E_{T_i}=52.4 kcal mol^{-1})[9] and *trans*-stilbene (E_{S_i}=94, E_{T_i}<50 kcal mol^{-1})[9]. 1,3-Cyclohexadiene has previously been found to quench the NT phosphorescence efficiently,[1] while triplet pyrene sensitizes the isomerization of *trans*-stilbene.[10] These facts indicate that 1,3-cyclohexadiene and *trans*-stilbene become good quenchers for the NT and pyrene triplets, respectively. We assume here that intersystem crossing of the singlet exciplex Py·NT(S_1) produces these two triplets, NT(T_1) and Py(T_1), but not the triplet exciplex Py·NT(T_1). Triplet pyrene is also formed by intersystem crossing of the singlet pyrene-monomer and -excimer.[8] This assumption allows us to predict that both the compounds quench the triplet-derived reaction. Figure 3 clearly shows that neither 1,3-cyclohexadiene nor *trans*-stilbene exerts their quenching effects on the disappearance of NT and the appearance of any product **2**—**5**.[11] This finding provides a strong piece of evidence for a singlet-pathway mechanism depicted in Scheme 1. The fact that "photoacyloxyl" migration is also observed by the singlet sensitization, therefore, demonstrates that the rearrangement products **2** and **3** come from the singlet-state reaction but not from the triplet-state one.

As evident from Table 1, the singlet-sensitized photolysis gives the same product distribution as that derived from direct photolysis. Interestingly, the quantum yields for the formation of **2** and **3** (Φ_2 and Φ_3) are fairly small, especially in acetonitrile, compared with those for the direct photolysis. On the contrary, the quantum yield for the formation of **5** (Φ_5) in acetonitrile becomes larger in the sensitized photolysis than in the direct photolysis. In addition, Φ_5 decreases with decreasing the polarity of solvents. Although the sum of Φ_2 and Φ_5 for the direct photolysis undergoes negligible solvent polarity effects,[2] the decreased polarity of solvents increases this sum for the sensitized photolysis. Quantum yields Φ_2, Φ_3, and Φ_5 in benzene are comparable to Φ_2,

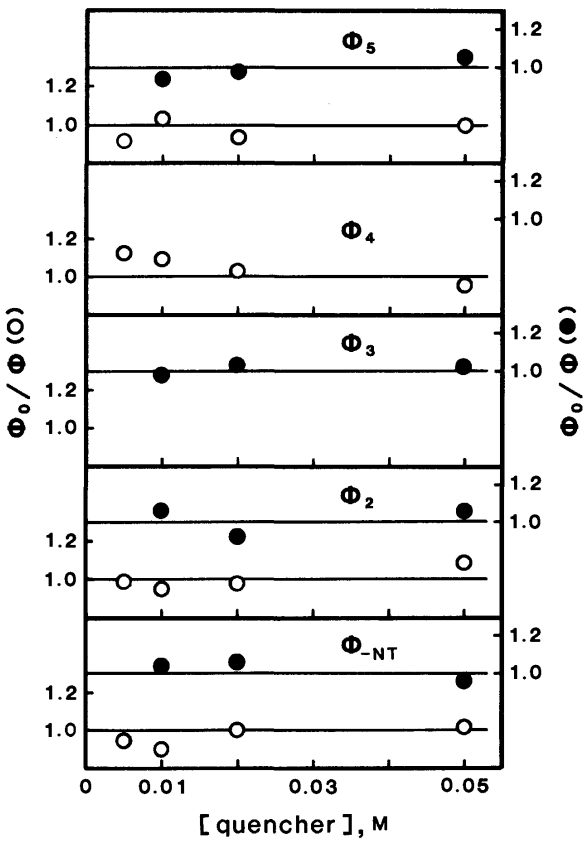

Fig. 3. Stern-Volmer plots for quenching of pyrene (3.00×10^{-3} M)-sensitized reaction of NT (6.67×10^{-3} M) with 366-nm light by 1,3-cyclohexadiene (●) and *trans*-stilbene (○) in 1,2-dichloroethane under nitrogen at room temperature (25±3 °C). Φ and Φ_0 are quantum yield for the reaction of NT with and without the quencher, respectively.

Scheme 2.

Φ_3, and Φ_5 for the direct photolysis, respectively. As previously discussed we used here Φ_5 as a measure of the extent of an "out-of-cage" reaction, owing both to a complicated fragmentation of the amido radical and to a minor decarboxylation process of the toluoyloxyl radical.[2]

As shown in Scheme 1, an energy transfer in the singlet exciplex intermediate causes a homolytic cleavage of the N-O bond in a NT molecule and the reactivities of the resulting geminate-radical pair should be affected to a lesser extent by the polarity of solvents based on our previous results.[1,2] Accordingly, Scheme 1 cannot explain the observed solvent polarity effects on $\Phi_2+\Phi_3$ and Φ_5 for the sensitized reaction. Because exciplexes with a charge-transfer character are well known to have a tendency to dissociate into radical ion pairs in polar solvents,[5,12] solvent polarity effects on the quantum yields ($\Phi_2+\Phi_3$ and Φ_5) for the reaction can be accounted for in terms of Scheme 2. In this Scheme an energy transfer in the singlet exciplex (path a) competes with electron transfer in this exciplex (path b). Path a gives the singlet geminate-radical pair from which the products **2**—**5** and starting NT are derived as already indicated in Scheme 1. On the other hand, electron transfer from pyrene to NT in the exciplex intermediate (path b) generates a NT anion radical and a pyrene cation radical. Polar solvents stabilize this radical ion pair but nonpolar solvents do not.[12] A NT anion radical, thus formed, may readily decompose to afford the amido radical and *p*-methylbenzoate which is oxidized by a pyrene cation radical to give the toluoyloxyl radical and pyrene. The amido and toluoyloxyl radicals abstract hydrogen atom from solvent molecules to yield the fragmentation products **4** and **5**. The exclusive participation of path b in the reaction makes the value of $\Phi_2+\Phi_3$ negligibly small. If path a predominates, then the quantum yields for the sensitized photolysis are expected to be comparable to those for the direct photolysis. Therefore the polar solvent, acetonitrile, prefers electron transfer to energy transfer in the exciplex intermediate to reduce $\Phi_2+\Phi_3$ accompanied by an increase in Φ_5, whereas energy transfer predominates in the nonpolar solvent, benzene. Both energy- and electron-transfer pathways may be important in 1,2-dichloroethane.

In order to examine whether or not electron transfer in the exciplex intermediate is thermodynamically possible, the free energy change ΔG in electron transfer was calculated by using the simplified Weller equation[13]

$$\Delta G \text{ (kcal mol}^{-1}\text{)} = 23.06[E(Py^{\cdot+}/Py) - E(NT/NT^{\cdot-})] - E_{S_1},$$

where $E(Py^{\cdot+}/Py)$ is the oxidation potential of pyrene (1.16 V vs. SCE in acetonitrile),[14] $E(NT/NT^{\cdot-})$ is the reduction potential of NT (−1.86 V vs. SCE in acetonitrile), and E_{S_1} is the first singlet excitation energy of pyrene (77 kcal mol^{-1}). The calculation of the free energy change gives ΔG=−7.4 kcal mol^{-1}, strongly indicating electron transfer from the singlet-state pyrene to the ground-state NT to be thermodynamically very favorable process. Although the participation of both energy- and electron-transfer mechanisms in the singlet-sensitized photolysis modifies Eqs. 1—5 slightly, a linear relationship between $1/\Phi$ and 1/[NT] remains unaltered and the intercept/slope ratio of double reciprocal plots still give the same $k_t\tau_S$ values.

Micellar Effects on the Singlet Sensitization. Our previous study of micellar effects on the direct photolysis of NT provided us two interesting findings.[2] One is that diffusive separation of the singlet radical pair generated in hexadecyltrimethylammonium chloride (HTAC) micelles must be slow enough to allow efficient micellar cage reaction to yield exclusively **2**, **3**, and starting NT accompanying negligible formation of **4** and **5**. The other is that the appearance of the secondary cage-reaction product **3** is suppressed within the micelles owing to the high intramicellar viscosity. Based on these findings we expect that the micelle cage of HTAC can be used to distinguish between an energy- and an electron-transfer mechanisms both of which work in the pyrene-sensitized photolysis of NT depending on the polarity of solvents employed.

If the singlet-sensitized photolysis in HTAC micelles proceeds by an energy-transfer mechanism to result in the homolytic cleavage of the N-O bond in a NT molecule, then we expect negligibly small quantum yields for the formation of **4** and **5** compared to those of **2** and **3**. Thus the appearance of **4** and **5** in the micelles can be taken as indication for an electron-transfer mechanism. The sensitized decomposition of NT (3.00×10^{-3} M) by pyrene (1.00×10^{-3} M) in HTAC micelles (1.30×10^{-3} M) under nitrogen at room temperature (23±1 °C) gave the following results: Φ_{-NT}=0.051, Φ_2=0.005, Φ_3<0.001, Φ_4=0.012, and Φ_5=0.045. These results strongly suggest a dominant

electron-transfer mechanism for the reaction in HTAC micelles. Since hydrophobic nature of the amido and toluoyloxyl radicals should retard escape of these radicals from the micelle cage into the water phase,[15] we cannot offer a clear answer to the question of whether the rearranged products **2** is derived from recombination of the singlet geminate-radical pair or from recombination of the radical pair reencountered within the micelles after a NT anion radical decomposed to give the amido and toluoyloxyl radicals. The fact that the micelle surface has a polarity corresponding to that of alcohols seems to indicate minor contribution of an energy-transfer mechanism.[16,17]

Experimental

General Methods. Hitachi 638-50 HPLC apparatus with a 2.6×500-mm ODS (Hitachi gel #3050) column was used to accurately determine the concentrations of the starting materials that disappeared and of the photoproducts that appeared from linear calibration curves for each compound. Fluorescence spectra of pyrene with and without a quencher were taken under nitrogen on a Shimadzu RF-500 spectrophotofluorimeter. UV spectra were obtained with a Shimadzu UV-210A spectrophotometer. Fluorescence lifetimes of pyrene were measured under nitrogen on a Horiba NAES-1100 time-resolved spectrophotofluorimeter.

Materials and Solvents. *N*-(1-Naphthoyl)-*O*-(*p*-toluoyl)-*N*-phenylhydroxylamine (NT) and independently prepared authentic compounds **2**—**5** were the same as in previous studies.[2] Benzene and 1,2-dichloroethane (spectrograde from Dojin Chemical Co.) were used as received. Highly-purified acetonitrile was obtained by the modified procedure of Walden and Birr.[18] 1,3-Cyclohexadiene (Aldrich) was fractionally distilled just before its use and stored under nitrogen in a refrigerator. *trans*-Stilbene (reagent grade, Wako) was recrystallized twice from ethanol. Pyrene (reagent grade, Wako) was purified by repeated recrystallization from ethanol followed by sublimation at reduced pressure. Mobile phase for HPLC analysis consisted of acetonitrile (62 vol%) and water (38 vol%) (HPLC grade from Wako). Hexadecyltrimethylammonium chloride (HTAC, Wako) was recrystallized twice from acetone–methanol and sodium dodecyl sulfate (SDS, specially pure from Wako) was used as supplied.

Quantum Yields. The same methods as before was applied to determine the quantum yields for the pyrene-sensitized photolysis of NT.[2] The 366-nm light from a 450W high-pressure Hg lamp was isolated with Corning 0-52, Corning 7-37, and Toshiba IRA-25S glass filters (Transmittance=19% at 366 nm). Molar absorption coefficients of pyrene were determined to be 220, 190, and 130 ($M^{-1}\,cm^{-1}$) in benzene, 1,2-dichloroethane, and acetonitrile, respectively, so that more than 95% of the incident light is absorbed by pyrene in the sensitized decomposition of NT. All the quantum yields are average of more than three determinations. Quantum yields for the sensitized photolysis in HTAC micelles were measured at a pyrene concentration such that the [pyrene]/[micelle] ratio nearly equals unity. The micelle concentration was estimated based on the equation [micelle]=([HTAC surfactant] $-$cmc)/N, where [HTAC surfactant]=0.15 M, critical micelle concentration, cmc=1.3×10^{-3} M, and aggregation number, N=113.[19]

Fluorescence Lifetimes and Reduction Potential. Prior to fluorescence lifetime measurements, solutions were purged with oxygen-free nitrogen for about 10 min for deoxygenation. Fluorescence decay was traced by the use of a single photon counting technique for deconvolution of the data obtained with a computer attached to the apparatus. The reduction potential of NT was measured by cyclic voltametry in acetonitrile. For this purpose we used saturated calomel electrode (SCE) as a reference electrode and tetrabutylammonium bromide (0.1 M) as a supporting electrolyte.

We thank Dr. Kazuo Ohta, Faculty of Engineering, Tokyo Institute of Polytechnics, for determining fluorescence lifetimes.

6) In the sensitized photolysis of NT in benzene there is a possibility of the formation of biphenyl whose chemical yield may be comparable to that of **4** and **5**. But it was impossible to check this possibility because we could not detect HPLC peak of biphenyl whose concentration was adjusted so as to become the same as that of **4** and **5** obtained by the photolysis under our analytical conditions. Additionally HPLC peak of any unknown product observed was not consistent with that of biphenyl.

17) Recent studies on the solubilization of pyrene in cationic HTAC micelles suggest a micelle surface as the solubilization site of pyrene in this micelle.[19,20] An interaction between the surfactant head group and pyrene has been shown to be major driving force for the solubilization. This interaction also seems to be responsible for the solubilization of NT in HTAC micelles since the solubility of NT in anionic SDS micelles was found to be much low compared to that in cationic HTAC micelles. Thus it is likely that both pyrene and NT are preferentially solubilized at the surface of HTAC micelles.

Total Syntheses of Indicine *N*-Oxide, Intermedine *N*-Oxide, and Their Enantiomers Using Carbohydrate as a Chiral Educt

Yoshio NISHIMURA,* Shinichi KONDO, Tomio TAKEUCHI, and (the late) Hamao UMEZAWA
Institute of Microbial Chemistry, 3-14-23 Kamiosaki, Shinagawa-ku, Tokyo 141
(Received June 10, 1987)

The first completely enantioselective syntheses of indicine *N*-oxide, intermedine *N*-oxide, and their enantiomers have been achieved stereospecifically. A synthetic analogue modeled on indicine *N*-oxide showed the superior activity to indicine *N*-oxide itself against cancer cell in vitro test.

The pyrrolizidine alkaloids constitute an exceptionally large class of naturally occurring materials which possess in common the 1-azabicyclo[3.3.0]-octane skelton often functionalized by hydroxyl or stereochemically complex carboxylic ester moieties at a variety of structural sites. The pyrrolizidine alkaloids containing $\Delta^{1,2}$-unsaturated subgroup are associated with wide range of potent biological effects.[1] Indicine *N*-oxide (**1**)[2] shows marked antitumor effects without the hepatotoxicity normally associated with this class of compounds, while the very similar heliotrine (**2**)[1a,3] is an established carcinogen. Due to their intriguing chemical structures and their pharmacological activities, the $\Delta^{1,2}$-unsaturated pyrrolizidine alkaloids have attracted the synthetic attention in recent years.[4]

In order to investigate the relationships between structure and antitumor activity, we undertook the syntheses of **1** and three possible diastereomer (**3**—**5**)[5] of **1** by coupling of (+) and (−)-retronecine (**18** and **19**) with (+) and (−)-trachelanthic acid (**13** and **16**). Although the formal and relay syntheses of indicine (**23**)[6] and intermedine (**21**),[6,7] and the synthesis of inseparable four diastereomeric mixture of **22** by the combination of racemic retronecine and racemic trachelanthic acid[8] have been reported, little is known about the completely enantioselective syntheses of **21**, **22** and their enantiomers. Recently, we succeeded in the enantioselective synthesis of retronecine and its enantiomer.[9] In this paper we wish to report the first enantioselective syntheses of **1**, **3**, **4**, and **5** in a totally stereospecific fashion via the enantioselective synthesis of (+) and (−)-trachelanthic acid. Compounds **1** and **4** are enantiomers of compounds **3** and **5**, respectively. Here we also wish to present the synthesis of active analogue **26** of **1** against cancer cells in vitro test by the regioselective esterification of retronecine with (*S*)-(−)-α-methoxy-α-(trifluoromethyl)-phenylacetic acid (**24**).

Results and Discussion

Synthesis of (+) and (−)-Trachelanthic Acid. The hitherto-known syntheses of trachelanthic acid are all of racemic form,[10] and **13** and **16** have been prepared via its optical resolution. Our approach to **13** and **16** involves, as the key step, the synthesis of a specific branched-chain sugar having a hydroxyl group and a isopropyl group at the branched position. Recently, a route to a branched-chain sugar having such asymmetric center by several steps have been described by Redlich.[11] The simple construction of such asymmetric center by one step sequence has been examined by Grignard reaction using isopropylmagnesium halide with a ulose having the desired stereochemistry.

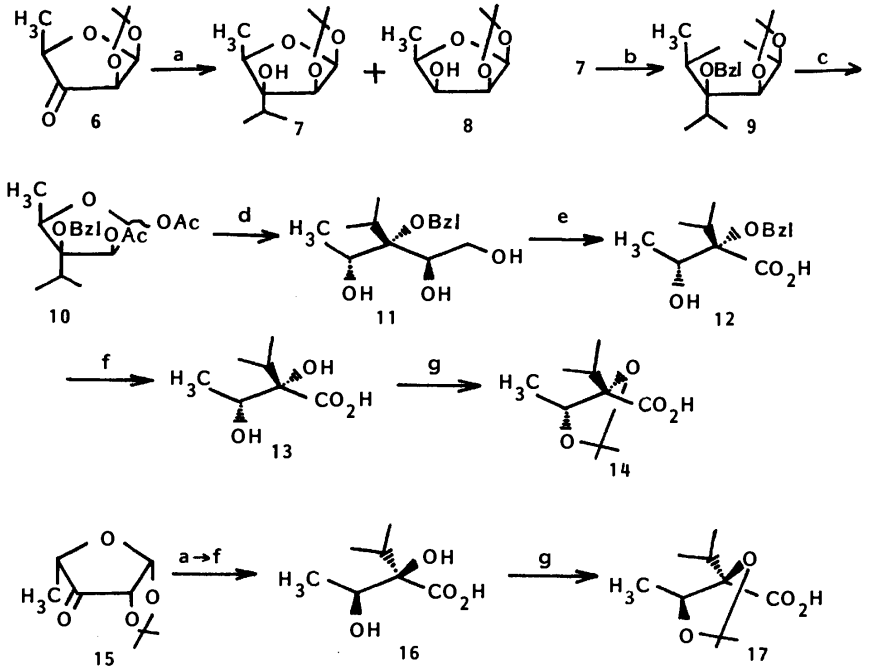
Grignard reaction of **6** with 3 equiv of isopropylmagnesium bromide occurred stereospecifically to afford 1,2-*O*-isopropylidene-5-deoxy-3-*C*-isopropyl-β-D-lyxofuranose (**7**) and 1,2-*O*-isopropylidene-5-deoxy-β-D-lyxofuranose (**8**) in a yield of 52 and 35%, respectively. Stereospecific addition and reduction were caused by the attack of the bulky Grignard reagent to the carbonyl group from less sterically

hindered side. The configuration of branched chain at C-3 is assigned on the observation of NOE between 3-C-isopropyl and the protons at C-2 and C-4, and between 3-OH and the methyl groups of 1,2-*O*-isopropylidene and C-4. This is also confirmed by successful transformation to natural (+)-trachelanthic acid (**13**). Swern oxidation[12] of by-product **8** was effectively recycled to **6**. Benzylation of tertiary alcohol of **7** gave a corresponding benzyl ether **9** in a yield of 94%. Acid hydrolysis of **9** followed by acetylation produced an anomeric mixture **10** (α: 84%, β: 6% yield). Borohydride reduction of **10** afforded the tetrol **11** in a yield of 72%. Lemieux-von Rudloff oxidation[13] of **11** yielded the carboxylic acid **12** in a yield of 81%. Removal of protected group of **12** by hydrogenolysis afforded (+)-trachelanthic acid (**13**), whose structure was also supported by ^{1}H NMR and ^{13}C NMR spectra. The resulting acid **13** was converted to the acetonide **14** by treatment of 20 equiv of 2,2-dimethoxypropane and a trace amount of concd hydrochloric acid in a yield of 90%. (−)-Trachelanthic acid (**16**) was synthesized from **15** by the same sequence used for the synthesis of (+)-trachelanthic acid. Compound **16** was identical in all respects with **13** except for the sign of the specific rotation. The acid **16** was transformed into the acetonide **17** by a similar treatment mentioned above. The first enantioselective syntheses of **13** and **16** have thus been achieved by the convergent method employing D- and L-arabinose as a chiral source.

Total Syntheses of Indicine *N*-Oxide, Intermedine *N*-Oxide, Their Enantiomers, and Their Analogues. The first synthesis of hepatotoxic pyrrolizidine alkaloid was reported in the reconstruction of intermedine (**22**) by coupling 1-(chloromethyl)-1,2-dehydro-7β-hydroxy-8α-pyrrolizidine and (+)-trachelanthic acid sodium salt obtained from natural source in a low yield.[7]

For syntheses of **1**, **3**, **4**, and **5**, the coupling each of **18** and **19** with each of **14** and **17** was examined by regioselective esterification. The synthetic approaches to monoester pyrrolizidine alkaloids have been described by use of combinations of 1,1′-carbonyldiimidazole (CDI) and imidazoylsodium in tetrahydrofuran,[14] dicyclohexylcarbodiimide (DCC) and catalytic amount of 4-(dimethylamino)pyridine (DMAP) in toluene,[15] and CDI and a catalytic amount of imdiazoylsodium in *N*,*N*-dimethylformamide.[6] These studies suggested that the combination of DCC and DMAP was most suitable for our synthesis.

Treatment of **14** and **19** with DCC and DMAP in toluene followed by hydrolysis with 0.6 M hydrochloric acid afforded foamy (−)-indicine (**20**) (71% yield), identical in all respects with natural indicine[16] except for the sign of the specific rotation. Oxidation of **20** with *m*-chloroperbenzoic acid (MCPBA) in dry acetone gave **3** (84% yield), whose spectral properties were superimposable with those of natural indicine



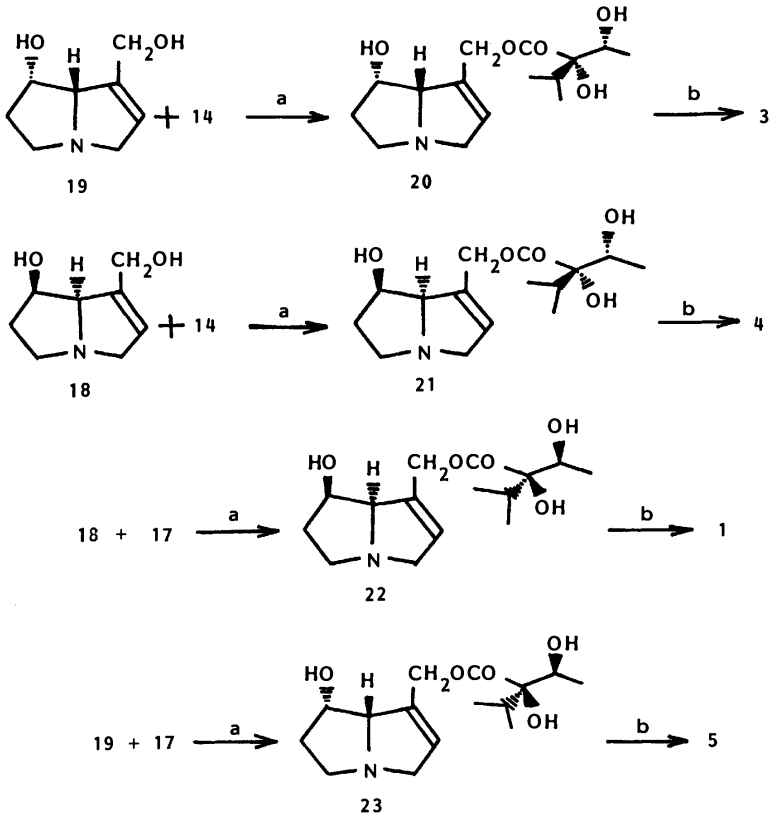
a) $(CH_3)_2CHMgBr/Et_2O$ (52%); b) NaH/DMF, then BzlCl (94%); c) i) 6 M HCl–AcOH (1:3); ii) Ac_2O/Py (90%); d) $NaBH_4$/EtOH, Δ (72%); e) $NaIO_4/KMnO_4/Na_2CO_3$/*t*-BuOH–H_2O (81%); f) H_2/10% Pd-C/MeOH (90%); g) $(CH_3)_2C(OCH_3)_2$/trace concd HCl (90%)

Scheme 1.

N-oxide.[16]

The synthesis of intermedine *N*-oxide (**4**) was achieved through the same sequence used for the synthesis of (−)-indicine *N*-oxide. Esterification of **18** with **14** followed by acid hydrolysis produced intermedine (**21**) (76% yield), identical in all respects with natural intermedine.[17] Oxidation of **21** with MCPBA in dry acetone afforded hygroscopic **4** quantitatively, whose structure was confirmed by ^{1}H NMR, ^{13}C NMR, IR, and mass spectra.

The synthesis of indicine *N*-oxide (**1**) from **18** and **17**, and the synthesis of (−)-intermedine *N*-oxide (**5**) from **19** and **17** were accomplished via indicine (**22**) and (−)-intermedine (**23**) by the same sequence used for the syntheses of **3** and **4**, respectively. The spectral properties of all of synthesized compounds were superimposable with those of natural specimens.[16,17] Thus, the diastereomeric set, which is composed of



a) DCC/DMAP/PhCH$_3$, then 0.6 M HCl (71%);
b) mCPBA/CH$_3$COCH$_3$ (84%)

two enantiomeric pairs related to **1**, has successfully been synthesized.

In relation to these syntheses, we were interested in the synthesis of new analogue modeled on **1**. The antitumor activity of four diastereomers and indicine *N*-oxide derivatives[3b,18] suggested that the electronic and steric factor around α-carbon of necic acid esterified to (+)-retronecine played an important role in increasing antitumor activity. In view of these facts, we undertook to synthesize **26**. Treatment of **18** and **24** with DCC and DMAP in toluene gave 9-*O*-[(*S*)-(−)-2-methoxy-2-phenyl-3,3,3-trifluoropropionyl]retronecine (**25**) in a yield of 68%. Oxidation of **25** resulted in **26** (90% yield).

The antitumor activity of synthesized compounds is shown in Table 1. Among four diastereomers synthesized, **1** showed the best antitumor activity. Interestingly, the synthesized analogue **26** was found to have the superior activity to **1**.

Experimental

General Methods. Melting points were determined with a Yamato apparatus and were uncorrected. IR spectra were determined on a Hitachi Model 260-10 spectrophotometer. Optical rotations were measured with a Parkin-Elmer Model 241 polarimeter. The ^{1}H NMR spectra were recorded with Varian XL-100, Varian EM-390, Bruker WM250, and Jeol GX-400 spectrometers. Chemical shifts were expressed in values (ppm) with tetramethylsilane as an internal standard. Proton noise decoupled FT ^{13}C NMR spectra were taken at 100.4 MHz on a Jeol GX-400 spectrometer using tetramethylsilane as a reference. The mass spectra were taken by a Hitachi RMU-6M mass spectrometer for electron-impact ionization or RMU-7M for field-desorption and for secondary ionization.

1,2-*O*-Isopropylidene-5-deoxy-3-*C*-isopropyl-β-D-lyxofuranose (7). To a solution of **6** (1.3 g) in diethyl ether (26 ml) was added isopropylmagnesium bromide in ether (1 mol dm^{-3}, 13 ml) at −78 °C, and the mixture was stirred from −78 °C to room temperature, and then the mixture was stirred at room temp overnight. After addition of water, the reaction mixture was extracted with ether. The extract was washed with NaCl-saturated aqueous solution, dried over $MgSO_4$, and filtered. Evaporation of the filtrate to give a solid, which was subjected to the column chromatography on silic gel. Elution with toluene–acetone (10:1) gave solids of **7** (849 mg, 52%) and **8** (572 mg, 35%). **7**: mp 37.5—38.5 °C; $[\alpha]_D^{20}$ +9.8° (*c* 1.0, $CHCl_3$); IR ($CHCl_3$) 3540, 3000, 2970, 2940, 2880, 1470, 1460, 1390, 1380 cm^{-1}; ^{1}H NMR ($CDCl_3$, 400 MHz) δ=0.96 (6H, d, *J*=6.7 Hz, CH_3 of 3-C-isopropyl), 1.31 (3H d, *J*=6.7 Hz, 4-CH_3), 1.40 and 1.62 (3H each S, isopropylidene), 1.77 (1H heptet, *J*=6.7 Hz, CH of 3-C-isopropyl), 2.92 (1H, s, 3-OH), 4.08 (1H q, *J*=6.7 Hz, H-4), 4.32 (1H d, *J*=4.0 Hz, H-2) and 5.65 (1H d, *J*=4.0 Hz, H-1); MS (EI) *m/z* 217 (M^++1), 261, 215, 183.

1,2-*O*-Isopropylidene-3-*O*-benzyl-5-deoxy-3-*C*-isopropyl-β-D-lyxofuranose (9). To a solution of **7** (680 mg) in dry *N*,*N*-dimethylformamide (6.8 ml) was added NaH (50% in oil, 375 mg) at 0 °C. After the mixture was stirred at room temperature for 30 min, benzyl chloride (1.08 ml) was added to the mixture. Then the resulting mixture was stirred at room temperature overnight. After being quenched with water, evaporation of the solvent gave an oil. The oil was dissolved in chloroform, and the chloroform solution was washed with water, dried over $MgSO_4$, and filtered. Evaporation of the solvent gave an oil, which was subjected to the column chromatography on silica gel. Elution with toluene–acetone (10:1) gave an oil of **9** (906 mg, 94%): $[\alpha]_D^{25}$ +15.9° (*c* 0.79, $CHCl_3$); IR ($CHCl_3$) 3000, 2960, 1460, 1390, 1380 cm^{-1}; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=0.90 and 0.93 (3H each d, *J*=6.7 Hz, CH_3 of 3-C-isopropyl), 1.27 and 1.57 (3H each s, isopropylidene), 1.37 (3H d, *J*=6.7 Hz, 4-CH_3), 2.27 (1H heptet, *J*=6.7 Hz, CH of 3-C-isopropyl), 4.17 (1H q, *J*=6.7 Hz, H-4), 4.43 (1H, d, *J*=4.4 Hz, H-2), 4.43 and 4.67 (2H ABq, CH_2-φ), 5.68 (1H, d, *J*=4.4 Hz, H-1) and 7.2—7.6 (5H m, phenyl); MS (SIMS) *m/z* 329 (M^++Na), 249, 143, 59, 43; (EI) *m/z* 305 (M^+−1), 291, 261, 248.

1,2-Di-*O*-acetyl-3-*O*-benzyl-5-deoxy-3-*C*-isopropyl-D-lyxofuranose (10). Compound **9** (840 mg) was dissolved in a mixture of 70% acetic acid–6 M† hydrochloric acid (4:1, 10 ml), and the mixture was allowed to stand at room temp for 2 h. After being neutralized with solid Na_2CO_3, the mixture was filtered, and the residue was washed with

† 1 M=1 mol dm^{-3}.

acetone. The filtrate and washings were combined, and evaporated to dryness to give an oil. To a solution of the oil in pyridine (12 ml) was added acetic anhydride (4 ml), and the mixture was allowed to stand at room temperature overnight. After being quenched with water, evaporation of the solvent gave a solid, which was dissolved in chloroform. The solution was washed with water, and dried over $MgSO_4$. Evaporation of the solvent gave an oil. The oil was subjected to the column chromatography on silica gel. Elution with toluene–acetone (10:1) gave the α-acetate of **10** (807 mg, 84%) and the β-acetate of **10** (58 mg, 6%). α-Acetate of **10**: $[\alpha]_D^{27}$ +62.7° (*c* 0.73, $CHCl_3$); IR ($CHCl_3$) 3030, 2980, 2950, 2880, 1750, 1375, 1250 (sh) cm^{-1}; ^1H NMR ($CDCl_3$, 90 MHz) δ=1.00 and 1.03 (3H each d, *J*=6.7 Hz, CH_3 of 3-C-isopropyl), 1.38 (3H d, *J*=6.7 Hz, 4-CH_3), 1.97 and 2.10 (3H each s, isopropylidene), 4.38 (1H q, *J*=6.7 Hz, H-4), 4.73 and 4.90 (2H ABq, *J*=12 Hz, CH_2-ϕ), 5.53 (1H d, *J*=3 Hz, H-2), 6.18 (1H d, *J*=3 Hz, H-1) and 7.2—7.6 (5H m, phenyl), MS (SIMS) *m/z* 373 (M^++Na), 291, 185, 142, 91, 84, 43.

β-Acetate of **10**: $[\alpha]_D^{27}$ +3.9° (*c* 0.55, $CHCl_3$); IR ($CHCl_3$) 3030, 2975, 2950, 2880, 1750, 1380, 1250 (sh) cm^{-1}; ^1H NMR ($CDCl_3$, 90 MHz) δ=1.00 and 1.05 (3H each d, *J*=7.0 Hz, CH_3 of 3-C-isopropyl), 1.40 (3H d, *J*=6.7 Hz, 4-CH_3), 1.97 and 2.0 (3H each s, -$COCH_3$), 2.37 (1H heptet, *J*=7.0 Hz, CH of 3-C-isopropyl), 4.23 (1H q, *J*=6.7 Hz, H-4), 4.62 and 4.83 (2H ABq, CH_2-ϕ), 5.42 (1H d, *J*=5.1 Hz, H-2), 6.26 (1H d, *J*=5.1 Hz, H-1) and 7.1—7.6 (5H m, phenyl), MS (SIMS) *m/z* 373 (M^++Na), 291, 185, 142, 91, 84.

(2*R*,3*S*,4*R*)-3-Benzyloxy-3-isopropyl-1,2,3,4-pentanetetrol (11). To a solution of **10** (816 mg) in ethanol (15 ml) was added $NaBH_4$ (2.64 g), and the mixture was stirred at room temperature overnight, and then refluxed under stirring for 20 h. After being quenched with acetic acid, evaporation of the solvent gave a solid. The solid was extracted with warm ethyl acetate, and the extract was evaporated to give an oil. The oil was subjected to the column chromatography on silica gel to give an oil of **11** (450 mg, 72%): $[\alpha]_D^{25}$ +6.8° (*c* 0.8, $CHCl_3$); IR ($CHCl_3$) 3560, 3420, 2970, 2940, 2880, 1460, 1380 (sh) cm^{-1}; ^1H NMR ($CDCl_3$, 400 MHz) δ=1.08 and 1.17 (3H each d, *J*=7.2 Hz, CH_3 of isopropyl), 1.39 (3H d, *J*=6.8 Hz, H-5), 2.25 (3H heptet, *J*=7.2 Hz, CH of isopropyl), 3.78 (1H dd, *J*=7.0 and 12 Hz, H-1), 3.91 (1H dd, *J*=3.6 and 12 Hz, H-1′), 4.13 (1H dd, *J*=3.6 and 7.0 Hz, H-2), 4.16 (1H q, *J*=6.8 Hz, H-4), 4.67 and 4.81 (2H ABq, *J*=11.2 Hz, CH_2-ϕ); MS (FD) *m/z* 268 (M^+), 223, 207, 149, 91, 61, 58, 32.

2-*O*-Benzyl-(+)-trachelanthic Acid (12). To a solution of **11** (330 mg) in *t*-butyl alcohol (5 ml) was added a solution of mixture of $NaIO_4$ (610 mg) and $KMnO_4$ (41 mg) in water (14 ml) and K_2CO_3, and the mixture was stirred at room temperature for 1 h. After being acidified with 1 M sulfuric acid, the mixture was extracted with dichloromethane. The extract was dried over $MgSO_4$, and filtered. The filtrate was evaporated to give an oil. The oil was subjected to the preparative thin-layer chromatography on silica gel developed with chloroform–methanol (9:1) to give an oil of **12** (252 mg, 81%): $[\alpha]_D^{25}$ −16.47° (*c* 0.87, $CHCl_3$); IR ($CHCl_3$) 3350, 2980, 2940, 2880, 1600, 1460, 1400 (sh) cm^{-1}; ^1H NMR ($CDCl_3$, 400 MHz) δ=0.96 and 1.02 (3H each d, *J*=7 Hz, CH_3 of isopropyl), 1.15 (3H d, *J*=7.0 Hz, H-4), 2.0—2.2 (1H broad m, CH of isopropyl), 4.17 (1H q, *J*=7.0 Hz, H-3), 4.59 and 4.74 (2H ABq, *J*=11.6 Hz, CH_2-ϕ); ^{13}C NMR ($CDCl_3$) δ=18.112, 18.629, 18.825 (3×CH_3), 31.903 (CH of isopropyl), 67.195 (CH_2-ϕ), 69.517 (C-3), 88.176 (C-2) and 178.509 (C-1); MS (FD) *m/z* 253 (M^+), 159, 58, 23.

(+)-Trachelanthic Acid (13). Compound **12** (173 mg) in methanol (17 ml) was stirred with 10% Pd/C (50 mg) under bubbling hydrogen gas at room temperature for 3 h. The catalyst was filtered off, and the filtrate was evaporated to give an oil. The oil was dissolved in 1 M hydrochloric acid, and the solution was extracted with ether. The extract was washed with NaCl-saturated aqueous solution, dried over $MgSO_4$, and filtered. The filtrate was evaporated to give a solid. The solid was crystallized from benzene–hexane to yield a crystal of **13** (100 mg, 90%): mp 89.5—90 °C; $[\alpha]_D^{25}$ +4.0° (*c* 0.85, EtOH); IR ($CHCl_3$) 3500, 3040, 2980, 2950, 2890, 1720, 1475, 1460 cm^{-1}; ^1H NMR ($CDCl_3$, 400 MHz) δ=0.96 and 0.99 (3H each d, *J*=7 Hz, CH_3 of isopropyl), 1.26 (3H d, *J*=6.5 Hz, CH_3), 2.01 (1H heptet, *J*=7 Hz, CH of isopropyl) and 2.24 (1H q, *J*=6.5 Hz, H-3); ^{13}C NMR ($CDCl_3$) δ=16.741, 16.825 and 16.881 (3×CH_3), 32.771 (CH of isopropyl), 69.656 (C-3), 82.567 (C-2) and 177.348 (C-1); MS (SIMS) *m/z* 163 (M^++1), 75, 57, 45.

2,3-*O*-Isopropylidene-(+)-trachelanthic Acid (14). To a solution of **13** (89 mg) in 2,2-dimethoxypropane (1.78 ml) was added concd hydrochloric acid (14 μl), and the mixture was allowed to stand at room temperature ovenight. Evaporation of the solvent gave an oil, which was solidified with ether. The solid was subjected to the preparative thin-layer chromatography developed with chloroform–methanol (3:1) to give a solid. The sublimation of the solid gave a crystal of **14** (100 mg, 90%): mp 54.5—55.5 °C; $[\alpha]_D^{25}$ −34.2° (*c* 0.35, EtOH); IR ($CHCl_3$) 2980, 2940, 2875, 1770, 1720, 1460, 1390, 1380, 1260 cm^{-1}; ^1H NMR ($CDCl_3$, 400 MHz) δ=0.91 and 1.02 (3H each d, *J*=6.7 Hz, CH_3 of isopropyl), 1.50 (3H d, *J*=6.5 Hz, CH_3), 2.20 (1H heptet, *J*=6.7 Hz, CH of isopropyl) and 4.36 (1H q, *J*=6.5 Hz, H-3); MS (SIMS) *m/z* 203 (M^++1) 162, 75, 57, 45.

(−)-Trachelanthic Acid (16). Procedures used for the synthesis from **15** were similar to those used for the preparation of **13** from **6**; the yield 93%: mp 89.5—90 °C; $[\alpha]_D^{25}$ −4.8° (*c* 0.51, EtOH).

2,3-*O*-Isopropylidene-(+)-trachelanthic Acid (17). Procedure employed was similar to that used for the preparation of **14** from **13** described above; the yield 88%: mp 55—56 °C; $[\alpha]_D^{25}$ +36° (*c* 0.31, EtOH).

(−)-Indicine (20). To a solution of mixture of (+)-retronecine (**18**, 21.5 mg) and **14** (46 mg) in toluene (3 ml) was added DCC (46.6 mg) and DMAP (3.35 mg), and the mixture was stirred at room temperature for 3 d. The precipitate was filtered off, and the residue was washed with a small amount of toluene. The filtrate was extracted with 0.6 M hydrochloric acid. The extract was allowed to stand at room temperature for 8 h. After being made basic by treatment with 28% NH_4OH solution, the mixture was treated with solid NaCl until saturation, and then the mixture was extracted with ether. The extract was dried over $MgSO_4$, and filtered. The filtrate was evaporated to give a foamy glass, which was subjected to the preparative thin-layer chromatography on silica gel developed with chloroform–methanol–concd aqueous ammonia (10:3:0.1) to give a foamy glass of **20** (29.4 mg, 71%): $[\alpha]_D^{23}$ −19° (*c* 2.6, EtOH); IR ($CHCl_3$) 3500 (br), 2975, 2950, 2875, 1730, 1475, 1460, 1390, 1380, 1325, 1305, 1230 (sho), 1180, 1160, 1110, 1080, 1035, 1005, 975, 890, 840 cm^{-1}; ^1H NMR ($CDCl_3$, 400 MHz) δ=0.92 and 0.97 (3H each d, *J*=7 Hz, CH_3 of isopropyl), 1.17 (3H d, *J*=6.7 Hz, H-13), 1.85—2.05 (2H m,

H-6,6'), 2.15 (1H heptet, J=7 Hz, CH of isopropyl), 2.65—2.85 (1H m, H-5), 3.2—3.35 (1H m, H-5'), 3.42 (1H dd, J=5.2 and 15.6 Hz, H-3), 3.96 (1H d, J=15.6 Hz, H-3'), 4.04 (1H q, J=6.7 Hz, H-12), 4.16 (1H broad s, H-8), 4.28 (1H broad s, H-7), 4.59 and 5.09 (2H ABq, J=12.4 Hz, H-9) and 5.91 (1H s, H-2); ^{13}C NMR ($CDCl_3$) δ=16.564, 17.166, 17.543 (3×CH_3), 32.345 (CH of isopropyl), 36.248 (C-6), 53.777 (C-5), 62.885 (C-3), 63.011 (C-9), 69.194 (C-12(?)), 71.321 (C-8), 78,679 (C-7(?)), 82.764 (C-11), 130.428 (C-2), 132.806 (C-1) and 175.364 (C-10); MS (SIMS) m/z 300 (M^++1), 138, 94, 80, 43: (FD) 299 (M^+), 262, 220, 186, 99, 58.

(−)-Indicine *N*-Oxide (3). To a solution of **20** (25 mg) in dry acetone (1.5 ml) was added MCPBA (18 mg), and the mixture was stirred at room temperature for 1 h. The mixture was directly subjected to the preparative thin-layer chromatography on silica gel to give a solid. The solid was crystallized from a mixture of acetone-methanol to yield a crystal of **3** (22.2 mg, 84%): mp 119—121 °C; $[\alpha]_D^{21}$ −34.7° (c 1.44, EtOH); IR ($CHCl_3$) 3300 (br), 2980, 2950 (sh), 1740, 1460 (sh), 1380, 1310 (sh), 1230 (br), 1185, 1165, 1145, 1100, 1060, 1025, 1010, 990, 950, 890, 835 cm^{-1}; ^{1}H NMR ($CDCl_3$, 400 MHz) δ=0.90 and 0.94 (3H each d, J=7 Hz, CH_3 of isopropyl), 1.15 (3H d, J=6.7 Hz, H-13), 1.88 (1H heptet, J=7 Hz, CH of isopropyl), 2.00 (1H broad m, H-6), 2.59 (1H m, H-6'), 3.65—3.80 (2H m, H-5,5'), 4.08 (1H q, J=6.7 Hz, H-12), 4.42 (1H s, H-3,3'), 4.62 (1H broad s, H-8 (?)), 4.68 (1H s, H-7(?)), 4.70 and 5.05 (2H ABq, J=12.4 Hz, H-9) and 5.81 (1H s, H-2); MS (SIMS) m/z 316 (M^++1), 136, 93, 75, 57, 45.

Intermedine (21). Procedure used was similar to that used for the preparation of **20** from **14** and **19**; the yield 76%: mp 140—141 °C; $[\alpha]_D^{23}$ +6.3 (c 1.2, EtOH); IR ($CHCl_3$) 3500, 2970, 2930, 2850, 1720, 1460 (sh), 1370 (sh), 1320 (sh), 1220 (broad), 1160, 1110, 1080, 1030, 1000, 970, 950, 910, 890, 840 cm^{-1}; ^{1}H NMR ($CDCl_3$, 400 MHz) δ=0.93 and 0.94 (3H each d, J=7 Hz, CH_3 of isopropyl), 1.21 (3H d, J=6.7 Hz, H-13), 1.9—2.1 (3H m, H-6,6' and CH of isopropyl), 2.65—2.85 (1H m, H-5), 3.30 (1H t, J=8.4 Hz, H-5'), 3.44 (1H dd, J=6 and 15.4 Hz, H-3), 3.96 (1H d, J=15.4 Hz, H-3'), 4.11 (1H q, J=6.7 Hz, H-12), 4.20 (1H broad s, H-8(?)), 4.27 (1H broad s, H-7(?)), 4.76 and 4.86 (2H ABq, J=12 Hz, H-9) and 5.96 (1H s, H-2); ^{13}C NMR ($CDCl_3$) δ=16.881, 17.118 and 17.244 (3×CH_3), 33.008 (CH of isopropyl), 36.254 (C-6), 53.822 (C-5), 62.537 (C-9), 62.872 (C-3), 69.293 (C-12), 70.901 (C-8), 78.734 (C-7), 83.015 (C-11), 131.203 (C-2), 132.531 (C-1) and 175.278 (C-10).

Intermedine *N*-Oxide (4). Procedure used was similar to that used for the preparation of **3** from **20**: the yield is 98%; $[\alpha]_D^{20}$ +8.6° (c 0.98, EtOH); IR ($CHCl_3$) 3200, 2980 (sh), 1740, 1460 (sh), 1380 (sh), 1310 (sh), 1230 (broad), 1185, 1170, 1145, 1100, 1060, 1025, 1010 cm^{-1}; ^{1}H NMR ($CDCl_3$, 400 MHz) δ=0.91 and 0.97 (3H each d, J=7 Hz, CH_3 of isopropyl), 1.16 (3H d, J=7 Hz, H-13), 1.85 (1H q, J=6.7 Hz, CH of isopropyl), 2.01 (1H broad d, J=11 Hz, H-6), 2.45—2.65 (1H m, H-6'), 3.75—3.85 (2H m, H-5,5'), 4.11 (1H q, J=6.7 Hz, H-12), 4.44 (2H broad t, J=18 Hz, H-3,3'(?)), 4.67 (1H broad s, H-8(?)), 4.75 (1H broad s, H-7(?)), 4.85 (2H broad t, J=14 Hz, H-9,9'(?)) and 5.81 (1H s, H-2); ^{13}C NMR ($CDCl_3$) δ=16.741, 17.174 and 17.636 (3×CH_3), 33.722 (CH of isopropyl), 34.701 (C-6), 61.292 (C-5), 69.223 (C-9(?)), 69.559 (C-12(?)), 69.908 (C-8(?)), 77.993 (C-3), 84.064 (C-11), 95.883 (C-7), 122.125 (C-2), 132.811 (C-1) and 174.802 (C-10).

Indicine (22) and Indicine *N*-Oxide (1). Procedures used were similar to those used for the preparations of **3** via **20** from **14** and **19**. **22**: $[\alpha]_D^{22}$ +19.5° (c 1.2, EtOH) [natural indicine[16]: $[\alpha]_D^{22}$ +20° (EtOH)]. **1**: mp 118—119 °C, $[\alpha]_D^{22}$ +35° (c 0.9, EtOH) [natural indicine *N*-oxide:[16] mp 119—120 °C, $[\alpha]_D^{21}$ +34.8° (EtOH)]. Synthetic **22** and **1** were identical in all respects with natural specimens.

(−)-Intermedine (23) and (−)-Intermedine *N*-Oxide (5). Procedures used were similar to those used for the preparation of **4** via **21** from **14** and **18**. **23**: mp 138—139 °C, $[\alpha]_D^{23}$ −7.1° (c 1.1, EtOH). **5**: $[\alpha]_D^{22}$ −9.1° (c 0.88, EtOH).

9-*O*-[(*S*)-(−)-2-Methoxy-2-phenyl-3,3,3-trifluoropropionyl]retronecine (25). To a solution of mixture of (+)-retronecine (**18**, 100 mg) and (*S*)-(−)-α-methoxy-α-(trifluoromethyl)phenylacetic acid (**24**, Aldrich Chem. Co., 302 mg) in dry toluene (10 ml) was added DCC (240 mg) and DMAP (18 mg), and the mixture was stirred at room temprature overnight. The precipitate was filtered off, and the filtrate was quenched with water. Evaporation of the solvent gave a solid, which was dissolved in dichloromethane. The solution was washed with NaCl-saturated aqueous solution, dried over $MgSO_4$, and filtered. The filtrate was evaporated to give a foamy glass, which was subjected to the preparative thin-layer chromatography on silica gel to give a foamy glass of **25** (169 mg, 68%): $[\alpha]_D^{21}$ −1.9° (c 0.95, $CHCl_3$); IR ($CHCl_3$) 3000, 2950, 2850, 1750, 1460, 1440, 1280, 1250, 1210, 1175 (sh), 1115 (sh), 1085, 1000 (sh), 840 cm^{-1}; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=1.6—2.1 (2H m, H-6,6'), 2.4—3.0 (1H m, H-5), 3.1—3.4 (1H m, H-5'), 3.40 (1H dd, J=5.2 and 15.6 Hz, H-3), 3.53 (3H s, OCH_3), 3.93 (1H d, J=15.6 Hz, H-3'), 4.17 (1H broad s, H-7 and H-8), 4.93 (2H broad t, J=14.3 Hz, H-9,9'), 5.85 (1H s, H-2) and 7.2—7.7 (5H m, phenyl); MS (SIMS) m/z 386 (M^++1), 189, 136, 93, 80, 43.

9-*O*-[(*S*)-(−)-2-Methoxy-2-phenyl-3,3,3-trifluoropropionyl]retronecine *N*-Oxide (26). Procedure used was similar to that used for the preparation of **3** from **20**; the yield 90%: $[\alpha]_D^{20}$ +6.0° (c 1.45, $CHCl_3$); IR ($CHCl_3$) 2975 (sh), 1760, 1460, 1280, 1250, 1180 (sh), 1130 (sh), 1020, 1010, 840 cm^{-1}; ^{1}H NMR ($CDCl_3$, 90 MHz) δ=2.0 (1H broad d with a small coupling, J=12.6 Hz, H-6), 2.3—2.8 (1H m, H-6'), 3.53 (3H s, OCH_3), 3.5—3.9 (2H m, H-5,5'), 4.42 (2H broad s, H-3,3'), 4.53 (2H broad s, H-7 and H-8), 5.00 (2H broad s, H-9,9'), 5.70 (1H s, H-2) and 7.3—7.7 (5H m, phenyl); MS (SIMS) m/z 388 (M^++1), 189, 136, 93, 80.

We are very grateful to Dr. Mathew Suffness, National Cancer Institute and Dr. Leslie W. Smith, CSIRO for generous gifts of the authentic samples. We wish also thank to Mrs. Mieko Nagasawa, Pharmaceutical Research Laboratories, Meiji Seika Kaisha Ltd. for antitumor tests. This work was supported in part by a Contract NO1-CM-47593 with the Division of Cancer Treatment, National Cancer Institute, U.S.A., and by a Grant-in-Aid for Cancer Research from the Ministry of Education, Science and Culture, Japan (No. 62010013), and from the Ministry of Health and Welfare, Japan (No. 61-21).

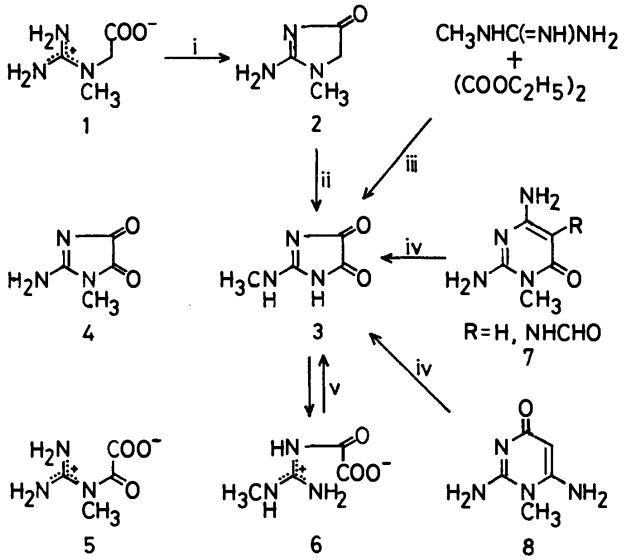
(Received June 15, 1987)

Treatment of creatinine with BOC-ON gave 2-*t*-butoxycarbonylamino-1-methyl-1,5-dihydro-4*H*-imidazol-4-one, which was oxidized with mercury(II) acetate to the corresponding 1*H*-imidazole-4,5-dione. Deprotection of the amino group of this dione afforded the title compound **4**, which in turn was shown to undergo a facile, Dimroth-type rearrangement under weakly acidic conditions to give creatone, thus proving **4** to be the key intermediate in the formation of creatone from various starting materials. The equilibria among these compounds are discussed.

Creatine (**1**) and its dehydrated form creatinine (**2**) are present in the muscular tissue of many vertebrates and play important roles in energy transfer and storage.[1,2] We reported[3] that the oxidation product (creatone) of **1** and **2** with mercury(II) acetate possessed the structure **3** (2-methylamino-1*H*-imidazole-4,5-dione) rather than the previously presented ring-open formula **5**[4,5] (Scheme 1). Furthermore, it was suggested[3] that the previous structures **4** and **6** which had been respectively presented for the condensation product[6] of methylguanidine with diethyl oxalate and for the peroxyacid oxidation product[7] of 2,6-diamino-3-methyl-4(3*H*)-pyrimidones **7** or 2,6-diamino-1-methyl-4(1*H*)-pyrimidone (**8**) ought to be replaced by the revised formulation **3**, because all of these products were found to be identical with creatone (Scheme 1). It was also confirmed[8] that the acyclic compound **6** prepared from **3** reverted to **3** without producing any other isomers **4** and **5**. We have now prepared **4** (2-amino-1-methyl-1*H*-imidazole-4,5-dione) and confirmed a facile, Dimroth-type rearrangement of **4** to **3**, thus proving that **4** is the key intermediate in the formation of **3** from various precursors.

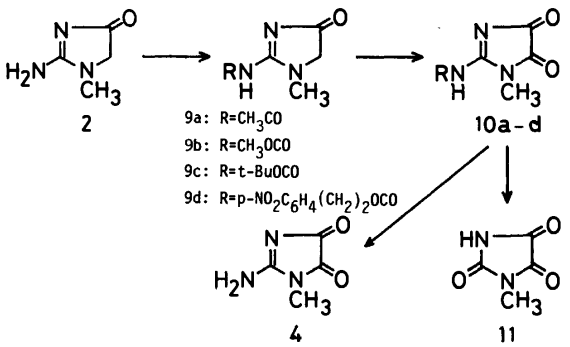


Scheme 1. Formation of creatone **3** from various starting materials, i. H^+, Ref. 21. ii. $Hg(OAc)_2$, Refs. 3—5. iii. reflux in EtOH, Ref. 6. iv. H_2O_2–HCOOH, Ref. 7. v. H_2O, Ref. 8.

Results and Discussion

As the oxidation of **1** and **2** with mercury(II) acetate resulted[3,8] in the exclusive formation of **3** without affording any of the postulated intermediates such as **4** and **5**, we had to devise a new scheme for preparing **4** by an alternative route: namely, the protection of the 2-amino group of creatinine (**2**), followed by the oxidation and then deprotection of the amino group of the resulting imidazoledione. Thus, in order to find a suitable protecting group, **2** was led to various kinds of NH(2)-substituted derivatives (see Scheme 2): 2-acetamido- (**9a**,[9] with acetic anhydride, 74% yield), 2-methoxycarbonylamino- (**9b**, with 1-methoxycarbonyl-3-methylimidazolium chloride, 71%), 2-*t*-butoxycarbonylamino- (**9c**, with 2-(*t*-butoxycarbonyloxyimino)-2-phenylacetonitrile (BOC-ON),[10] 75%), and 2-[2-(*p*-nitrophenyl)ethoxycarbonylamino]-1-methyl-1,5-dihydro-4*H*-imidazol-4-one (**9d**, with 1-methyl-3-[2-(*p*-nitrophenyl)ethoxycarbonyl]imidazolium chloride,[11] 95%).

The structures of these compounds were readily verified by the spectral data and the elemental analyses



Scheme 2. Preparation of **4**.

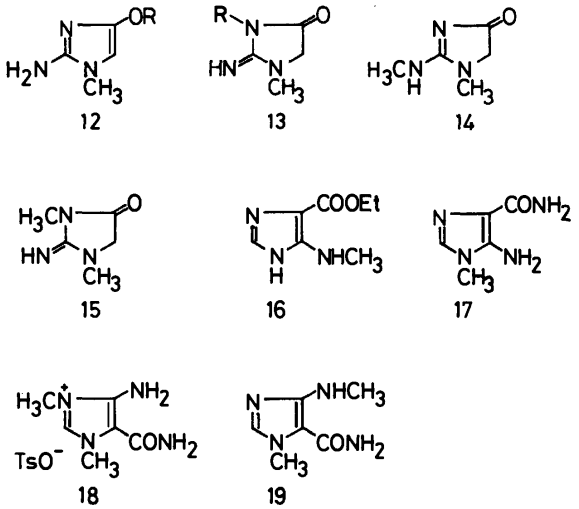
a) δ values (at 60 MHz unless otherwise specified): s, singlet; d, doublet; t, triplet; m, multiplet; br, broad. b) Solvent: C, $CDCl_3$; D, D_2O; T, TFA. c) At 250 MHz. d) From Ref. 3. e) J=5 Hz. f) J=7 Hz, $ArCH_2$-CH_2OOC. g) J=9 Hz, O_2N-C_6H_4C. h) Species: monocation (+), neutral species (0), monoanion (−). i) From Ref. 22. j) From Ref. 23. k) Extrapolated value since the species gradually decomposes during the measurement. l) Likely for the ring-open species **6a**.

(see Table 1 for ^{1}H NMR and UV spectra as well as pK_a values, and the Experimental section for other data). The presence of a singlet (2H) at δ 3.9—4.0 (due to H_2-5) in the ^{1}H NMR spectra of **9a—d** eliminated the possibility of the enolated O(4)-substituted structure **12** for these compounds. Also the rather low, basic pK_a values (3.4—2.0) of **9a—d** were in agreement with the 2-amino-4-oxo form rather than the 2-imino-3-substituted form **13** which would be expected to have much higher pK_a values by analogy with those of related compounds (e.g. acetylguanidine, pK_a 8.26).[2b,12,13]

The 2-carbonyamino derivatives **9a—d** were then subjected to the oxidation with mercury(II) acetate. However, the oxidation conducted in water (as in the case of **1** and **2**)[3-5] gave no satisfactory results in general but appeared to cause decomposition into smaller fragments. After various attempts, the oxidation of **9b** and **9c** was accomplished by employing a two-layer system ($CHCl_3$–water), thus giving the 4,5-dioxo compounds **10b** (80% yield) and **10c** (50%), respectively (Scheme 2). Compound **9a**, however, did not give the expected product **10a** but yielded creatone (**3**) and a low yield of 1-methylparabanic acid (**11**)[14] under these conditions, whereas the



oxidation of **9d** gave only a low yield of unstable **10d** which was contaminated by a small amount of the inseparable starting material. The structures of these 4,5-dioxo compounds **10b—d** were established on the evidences of the spectral data (see Experimental section).

Deprotection of the 2-amino group of **10b—d** was

then examined under various conditions. Acid hydrolysis of **10b** (in 2 M†† HCl) resulted in the formation of a 60% yield of **11**, whereas treatment of **10b** with sodium benzenethiolate in HMPA caused profound decomposition. The desired compound **4** was, however, obtained in a 67% yield on heating **10c** in anhydrous trifluoroacetic acid (TFA) at 60 °C. A less satisfactory deprotection to obtain **4** was also accomplished by the treatment of **10d** with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in pyridine.[11]

The IR spectrum of **4** showed absorptions due to NH and C=O groups (3200, 3000, 1793, 1720, and 1700 cm^{-1}) but apparently differed from that[3] of **3** particularly in the fingerprint regions. Compound **4** showed a singlet at δ 3.22 due to N-Me and a broad multiplet at 7.4 due to NH_2 groups in $CDCl_3$; the N-Me singlet signal appeared at δ 3.57 and 3.21 in TFA and in D_2O, respectively. As the high-resolution MS confirmed the molecular formula $C_4H_5N_3O_2$, the 2-amino-1-methyl-1*H*-imidazole-4,5-dione structure was unequivocally assigned to **4**. It should be noted that the Me-1 signal of **4** appears at a slightly down-field when compared with the N-Me signals of **2** and **3** in the same solvent system; the conclusive N-Me parameters of **2** and **3** for the additional structural proof have been obtained for the first time in the present study in $CDCl_3$ (and D_2O) (see Table 1).

The UV spectra of the neutral and monocationic species of **4** are shown in Fig. 1; for their absorption maxima, see Table 1. It was found that **4** possessed a low, basic pK_a value (1.89) similar to that of **3** (0.6).[3] These figures indicate that the neutral species of **4** exists exclusively in the 2-amino-1*H*-imidazol-4-one form rather than in the 2-imino-2,3-dihydro-1*H*-imidazol-4-one form **4a** (Scheme 3) in water, taking into account the notable difference of the known pK_a values between the 2-amino-4-oxo and the 2-imino-4-oxo forms of such related compounds as **14** (4.55) and **15** (8.07),[2b] respectively.

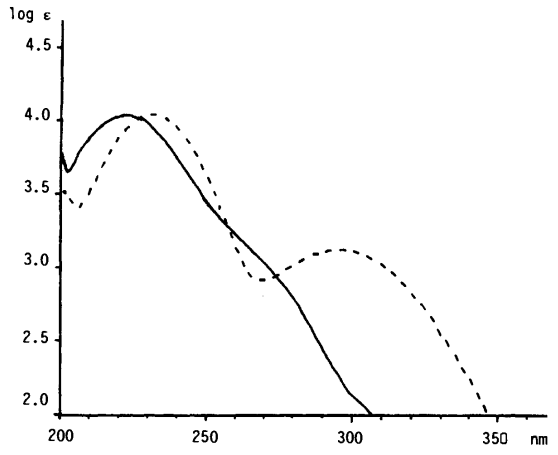


Fig. 1. UV Spectra of **4**: ——, pH 0; ------, pH 4.

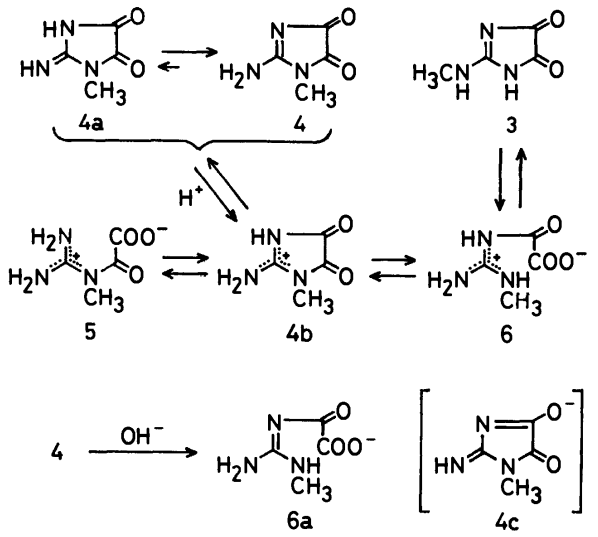
†† 1 M=1 mol dm^{-3}.

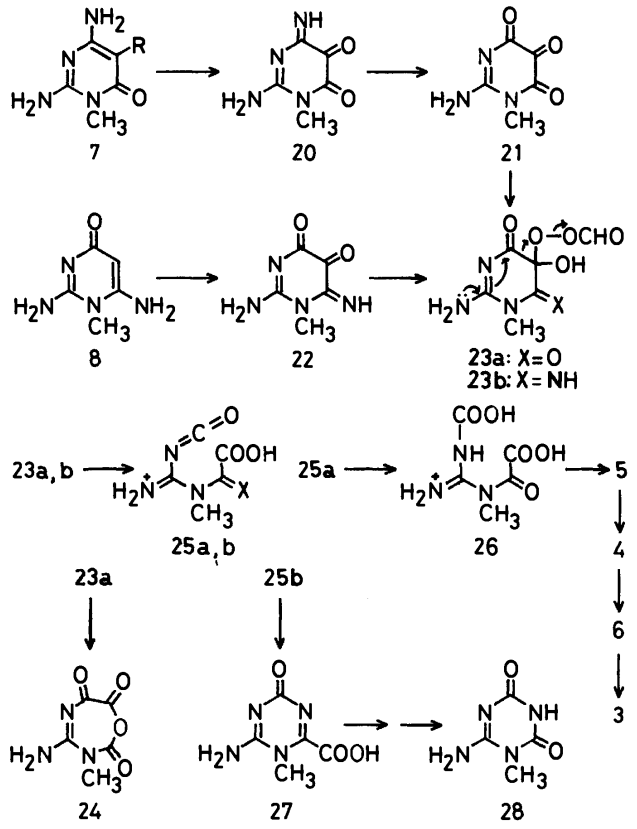
Although **4** remained stable as solid or in anhydrous aprotic solvents, it was found to undergo rearrangement rapidly in aqueous acid ($t_{1/2}$ ca. 5 min at pH 4) and more slowly even at pH 7 ($t_{1/2}$ ca. 30 min), giving creatone **3** exclusively; it was possible to follow this rearrangement either by ^1H NMR in D_2O or by UV spectrometry in various pH buffer solns.[15] Thus, the protonation of an equilibrium mixture of the neutral species **4** and **4a** affords the resonance-stabilized monocation **4b** in acid, which in turn is readily transformed into an equilibrium with the ring-open forms **5** and **6**. Recyclization of the latter provides apparently the thermodynamically more stable product **3** in a manner similar to the Dimroth rearrangement[16] as illustrated in Scheme 3.

Even in weak alkaline regions, **4** was found to change into a transient species which showed a UV absorption maximum at 237 nm (at pH 10, with an apparent pK_a value of 8.0) but underwent a gradual decomposition into smaller fragments exhibiting virtually no UV absorptions ($t_{1/2}$=ca. 60 min). On the grounds of these spectral data and the pK_a value, the short-lived intermediate is presumed to be a ring-open, anionic species such as **6a** rather than the equilibrated 2,5-dihydro-2-imino-5-oxo-1*H*-imidazol-4-olate form **4c** which is expected normally to have a much higher pK_a value.

It has now become obvious that compound **4** is the initially formed key intermediate by the oxidation of creatine (**1**) and creatinine (**2**) to give creatone (**3**), the reaction of which proceeds at ca. pH 3.[3] The oxidized pyrimidone intermediates **20**—**23a** (Scheme 4) and then the seven-membered ring intermediate **24** derived by a Baeyer–Villiger reaction were previously suggested[3] for the possible reaction pathways for the



Scheme 3. Tautomeric forms and equilibria of **4** and the rearrangement to **3**.



Scheme 4. Revised reaction pathways for the formation of **3** from 2,6-diamino-3-methyl-4(3*H*)-pyrimidones **7** and the 1-methyl-4(1*H*) isomer **8**.

oxidative ring-contraction of **7** and **8** to **3**. We now present here a slightly modified common, ring-open intermediates **25a** (instead of **24**) and **26** as illustrated in Scheme 4. Decarboxylation from **26** would afford **5** which subsequently is converted into **3** through the equilibrium shown in Scheme 3, while in the case of the peroxyacid oxidation of **8** the major product 1,3,5-triazine **28** is produced by the oxidative rearrangement through the previously presented intermediates[3] **22**, **23b**, **25b**, and then **27** (Scheme 4).

Many rearrangements have been known[17] involving the fission of a heterocyclic ring and ring closure in the alternate direction catalyzed by acid, base, heat, light, or miscellaneous reagents. As for the imidazole ring system, only a few examples of such rearrangements have been reported, to the best of our knowledge: i.e. **15**→**14** (in boiling methanol),[2b] **16**→**17** (in aq ammonia at 120 °C),[18] and **18**→**19** (with a basic ion-exchange resin).[19] The present rearrangement which takes place extremely fast under such mild conditions is certainly a unique example of the thermodynamically controlled ring transformation. Moreover, as creatone **3** has been isolated[20] from beef and regarded as a constituent of muscle tissue, the present findings are believed to be of value in connection with a biological implication, particularly in clarifying the possibility and mechanism of the reversible reaction between creatine and creatone (or an intermediate shown above), participating in an oxido-reductive process of organism.

Experimental

Melting points were determined with a Yanagimoto MP-S3 instrument and are uncorrected. All reactions were monitored by TLC (Merck silica gel 60F, 0.25 mm) with 2-propanol–AcOEt–water (5:3:1) or MeOH–$CHCl_3$ (1:9) as eluant. Column chromatography was performed with Wako C-200 silica gel. The IR spectra were taken with a Hitachi 215 spectrometer (as KBr disk). The ^1H NMR spectra were measured in $CDCl_3$ (unless otherwise stated) with a Hitachi R-600 (60 MHz, FT) or Bruker AM-250 cryospectrometer (250 MHz) at 27 °C. Chemical shifts (at 60 MHz unless otherwise specified) are recorded as δ values relative to tetramethylsilane [or sodium 3-(trimethylsilyl)-1-propanesulfonate in D_2O] as internal standard. The mass spectra were taken on a Shimadzu LKB-9000 low resolution or a JEOL JMX-HX100 high-resolution instrument, and are given in terms of *m/z* (rel intensity) compared with the base peak. The microanalyses were performed at University of Konstanz. The measurements of the ionization constants were carried out spectrophotometrically at 25 °C in 0.01 M buffers by the usual method.[12]

2-Acetamido-1-methyl-1,5-dihydro-4*H*-imidazol-4-one (9a). A better yield of **9a** was obtained by employing a slightly modified procedure of Ing.[9] Thus, a mixture of **2**[21] (0.50 g) and acetic anhydride (1 cm^3) was heated at 70 °C (oil bath) with swirling until the white suspension became a pale yellow soln (ca. 5 min), and then, after cooling with water, diluted with diethyl ether (10 cm^3). The mixture was allowed to stand overnight at 5 °C. The ppt was filtered and recrystd from EtOH/ether, giving **9a** as colorless needles (0.51 g, 74%): mp 124—125 °C (Ref. 9, 124—125 °C); IR 3170 (NH), 1770, 1740, and 1615 cm^{-1} (C=O, C=N); MS *m/z* 155 (M^+; 4.4), 154 (37.8), 140 (75.3), 113 (27.0), and 44 (100).

2-Methoxycarbonylamino-1-methyl-1,5-dihydro-4*H*-imidazol-4-one (9b). To a soln of 1-methylimidazole (0.44 cm^3) in dry ether (8 cm^3) was added methyl chloroformate (0.43 cm^3, 1.0 equiv) at 0 °C under nitrogen. After 5 min, the solvent was evaporated in vacuo and the white viscous tar (1-methoxycarbonyl-3-methylimidazolium chloride) was dissolved in dry DMF (7 cm^3) with stirring at 0 °C under nitrogen. To this soln was added **2** (0.50 g, 1.0 equiv) and the mixture was stirred at 20 °C under nitrogen. After 2 h, water (1 cm^3) was added. The solvent was evaporated in vacuo and the residue was triturated with AcOEt. The combined organic layers were dried (Na_2SO_4) and evaporated in vacuo. The residue was recrystd from AcOEt–ether, giving **9b** as pale yellow crystals (0.53 g, 71%): mp 132—133 °C; IR 3230 (NH), 1780, 1750, 1660, and 1620 cm^{-1} (C=O, C=N); MS *m/z* 171 (M^+; 45.9), 140 (63.8), 112 (24.7), 69 (33.9), 44 (100), and 42 (52.9).

Found: C, 42.07; H, 5.35; N, 24.25%. Calcd for $C_6H_9N_3O_3$: C, 42.10; H, 5.30; N, 24.55%.

2-*t*-Butoxycarbonylamino-1-methyl-1,5-dihydro-4*H*-imidazol-4-one (9c). A soln of **2** (240 mg), triethylamine (0.45 cm^3, 1.6 equiv), and BOC-ON (260 mg, 0.5 equiv) in dry DMF (16 cm^3) was heated at 60 °C for 4 d with stirring

under argon; more BOC-ON (3×260 mg) was added every 1 d. The solvent was evaporated in vacuo and the residue was triturated with $CHCl_3$. The combined organic layers were dried (Na_2SO_4) and evaporated in vacuo. The residue was chromatographed in a column of silica gel with AcOEt–hexane, giving **9c** as a pale yellow syrup (338 mg, 75%), which became colorless needles on recrystallization from ether-light petroleum: mp 33—34 °C; IR 3230 (NH), 1760, and 1655 cm^{-1} (C=O); MS *m/z* 213 (M^+; 0.7), 158 (100), 140 (57.1), 57 (57.0), 44 (20.7), and 18 (51.9).

Found: *m/z* 158.0562. Calcd for $C_5H_8N_3O_3$: M−C_4H_7, 158.0566.

1-Methyl-2-[2-(*p*-nitrophenyl)ethoxycarbonylamino]-1,5-dihydro-4*H*-imidazol-4-one (9d). To a suspension of **2** (23 mg) in dry DMF (0.5 cm^3) was added 1-methyl-3-[2-(*p*-nitrophenyl)ethoxycarbonyl]imidazolium chloride[11] (69 mg, 1.1 equiv) in one portion at 20 °C with stirring. After 45 min, cold water (3 cm^3) was added to the mixture at 5 °C. The resultant suspension was extracted with $CHCl_3$. The combined organic layers were dried (Na_2SO_4) and evaporated in vacuo and the residue was recrystd from AcOEt to give **9d** as almost colorless needles (60 mg, 95%): mp 146—147 °C; IR 3220 (NH), 1755, 1710, 1650, and 1620 cm^{-1} (C=O); MS *m/z* 307 (M+1; 4.53), 306 (M^+; 2.39), 260 (2.87), 167 (4.07), 157 (42.7), 149 (19.3), 140 (83.7), 139 (13.7), 137 (11.3), 112 (20.6), 91 (7.7), 69 (18), 44 (100), 43 (43.7), 42 (52.2), 31 (40.2), 30 (43.8), and 18 (28).

Found: C, 50.87; H, 5.02; N, 18.16%. Calcd for $C_{13}H_{14}N_4O_5$: C, 50.98; H, 4.61; N, 18.29%.

Oxidation of 9a. To a soln of **9a** (31 mg) in water (2 cm^3) was added mercury(II) acetate (128 mg, 2.0 equiv). The resultant mixture was set aside at 20—25 °C for 3 d. The ppt was filtered off and washed with a small amount of water. The combined filtrate and washings were saturated with H_2S (gas). The ppt was filtered off and washed with water. The combined filtrate and washings were once more filtered (with gravity) and evaporated in vacuo to give a white solid, which was triturated with $CHCl_3$ to give crude **11**; the solid which remained undissolved in $CHCl_3$ was identified by chromatography and spectroscopy (NMR, IR, and MS) to be mostly creatone **3** (10 mg, 39%). The former product **11** was chromatographed in a column of silica gel with 2% MeOH–$CHCl_3$, giving pure **11** as colorless needles (2 mg, 8%): mp 151—152 °C (from AcOEt–hexane, Ref. 14, 150—152 °C); pK_a 5.99±0.1; UV λ_{max} (pH 2) 213 nm (log ε 3.88), (pH 8) 221 and 285 nm (log ε 3.95 and 2.50); IR 3220, 1790, 1745, 1715, and 1660 cm^{-1}; ^1H NMR (250-MHz) δ=3.21 (3H, s, Me-1) and 7.98 (1H, brm, NH), (in D_2O) 3.11 (s, Me-1); MS *m/z* 128 (M^+; 48.6), 100 (44.3), 72 (21.9), 57 (83.6), 56 (100), 44 (25.0), 43 (26.6), 29 (51.1), and 28 (69.6). (Found: *m/z* 128.0235).

Even by employing the two-layer system (see below), oxidation of **9a** with $Hg(OAc)_2$ resulted in the formation of **3** and **11** only; no desired compound **10a** was obtained.

2-Methoxycarbonylamino-1-methyl-1*H*-imidazole-4,5-dione (10b). To a soln of **9b** (105 mg) in water (10 cm^3) was added $CHCl_3$ (20 cm^3) and then mercury(II) acetate (395 mg, 2.0 equiv). The mixture was stirred at 20 °C under the protection of light. After 90 min, it was separated and the aq layer was extracted with $CHCl_3$. The combined organic layers were dried (Na_2SO_4) and evaporated in vacuo. The residue was chromatographed in a column of silica gel with 5% MeOH–CH_2Cl_2, giving crude **10b** as a pale yellow solid. This was dissolved in CH_2Cl_2 (50 cm^3), washed with cold 0.5 M HCl (20 cm^3), dried (Na_2SO_4), and evaporated in vacuo. The residue was recrystd from CH_2Cl_2–hexane to give pure **10b** as colorless needles (89 mg, 80%): mp 192—193 °C; IR 3280, 1790, 1690, and 1650 cm^{-1}; ^1H NMR 3.26 (s, Me-1) and 3.84 (s, MeO); MS *m/z* 185 (M^+; 50.0), 157 (85.4), 155 (36.5), 126 (100), 99 (26.5), 83 (81.0), 69 (45.5), and 59 (19.6).

Found: *m/z* 185.0464. Calcd for $C_6H_7N_3O_4$: M, 185.0446.

2-*t*-Butoxycarbonylamino-1-methyl-1*H*-imidazole-4,5-dione (10c). A mixture of **9c** (68 mg) and mercury(II) acetate (225 mg, 2.2 equiv) in $CHCl_3$ (15 cm^3) and water (15 cm^3) was stirred at 20 °C for 6 h in the dark. After separation the aq layer was extracted with $CHCl_3$. The combined organic layers were washed with aq $NaHCO_3$, dried (Na_2SO_4), and evaporated in vacuo. The residue was chromatographed in a column of silica gel with AcOEt–hexane, giving **10c** as pale yellow needles (37 mg, 50%): mp 157—159 °C (from AcOEt–hexane); IR 3290, 1800, 1790, 1770, 1690, 1670, and 1650 cm^{-1}; ^1H NMR 1.55 (s, *t*-BuO) and 3.27 (s, Me-1); MS *m/z* 227 (M^+; ≃0), 212 (1.5), 172 (47.8), 154 (50.4), and 57 (100).

Found: *m/z* 172.0388. Calcd for $C_5H_6N_3O_4$: M−C_4H_7, 172.0357.

1-Methyl-2-[2-(*p*-nitrophenyl)ethoxycarbonylamino]-1*H*-imidazole-4,5-dione (10d). To a suspension of **9d** (32 mg) in water (30 cm^3) was added mercury(II) acetate (90 mg, 2.5 equiv), and the mixture was stirred at 20 °C for 3 d. Then more mercury(II) acetate (50 mg, 1.5 equiv) and water (10 cm^3) were added, and stirring was continued for 7 d (total). The pale yellow precipitate was filtered off and triturated with 5% MeOH–$CHCl_3$; the above filtrate was extracted with $CHCl_3$. The combined organic layers were evaporated in vacuo and the residue was chromatographed in a column of silica gel with $CHCl_3$→5% MeOH–$CHCl_3$, giving **10d** as pale yellow crystals (10 mg, 30%) (which, however, contained a small amount of inseparable **9d**): mp 182—184 °C (from $CHCl_3$–hexane); IR 3300, 1789, 1740, 1685, 1635 cm^{-1}; ^1H NMR (250-MHz) 3.17 (2H, t, *J*=6.8 Hz, $ArCH_2$), 3.27 (3H, s, Me-1), 4.49 (2H, t, *J*=6.8 Hz, CH_2OOC), 7.44 (2H, brd, *J*=8.9 Hz, H-2′,6′), 8.20 (2H, brd, *J*=8.9 Hz, H-3′,5′), and 10.29 (1H, brm, NH-2); MS *m/z* 320 (M^+; ≃0), 167 (4.0), 154 (47.3), 149 (100), 137 (17.7), 126 (27.8), 103 (17.0), 83 (67.3), and 28 (100). Compound **10d** was liable to decompose (presumably by hydrolysis or methanolysis) during the purification.

Found: C, 49.16; H, 4.12; N, 17.76%. Calcd for $C_{13}H_{12}N_4O_6$: C, 48.75; H, 3.78; N, 17.50%.

Attempted Deprotection of 10b. A soln of **10b** (22 mg) in 2 M HCl (10 cm^3) was stirred at 20 °C for 10 min, and then extracted with CH_2Cl_2. The organic layers were combined, dried (Na_2SO_4), and evaporated in vacuo. The residue was chromatographed in a column of silica gel with 10% ether–CH_2Cl_2, giving **11** (by IR, ^1H NMR, and TLC) as colorless plates (10 mg, 66%), mp 153—154 °C (Ref. 14, 150—152 °C).

2-Amino-1-methyl-1*H*-imidazole-4,5-dione (4). A. A soln of **10c** (4.5 mg) in anhyd TFA (1 cm^3) was heated at 60 °C for 1 h with stirring under argon. The mixture was diluted with dry $CHCl_3$ and then evaporated in vacuo to remove TFA, which was repeated several times. The residue

was washed with dry $CHCl_3$ and then with a small amount of dry AcOEt, giving **4** as a colorless crystalline powder (2.0 mg, 67%): mp 208—209 °C decomp; IR 3200, 3000, 1793, 1720, and 1700 cm^{-1}; MS *m/z* 127 (M^+; 88.0), 99 (M−CO, 87,7), 71 (M−2CO, 44.8), 56 (61.0), 42 (59.8), and 28 (100).

Found: *m/z* 127.0418. Calcd for $C_4H_5N_3O_2$: M, 127.0382.

B. A soln of **10d** (9 mg) and DBU (15 mg) in dry pyridine was stirred at 20 °C for 12 h under argon. The solvent was evaporated in vacuo below 20 °C (pump) and the residue was washed with dry cyclohexane, and then with a small amount of dry $CHCl_3$, giving crude **4** (by IR, ^1H NMR, and TLC) as a colorless powder (1 mg, ca. 25%), mp 205—208 °C decomp.

Rearrangement of 4 to 3. A soln of **4** (2.6 mg) in 1 M acetic acid (0.15 cm^3) was allowed to stand at 20 °C for 20 h. The ppt was filtered off and washed with cold water, giving colorless crystals which were identified by IR and ^1H NMR to be **3** (1.6 mg, 62%), mp 198—201 °C decomp (Ref. 3, 197—199 °C decomp).

The rearrangement of **4** (0.8 mg) in D_2O (0.6 cm^3) was pursued by ^1H NMR measurement (following a gradual decrease of the singlet signal of **4** at δ 3.21 with a simulaneous increase of the singlet of **3** at δ 2.98; $t_{1/2}$ ca. 14 min at pH 5).

On of us (H. Y.) is very grateful to the Alxander von Humboldt Foundation (F. R. Germany) for providing a research scholarship to him (in 1984). We are greatly indebted to Ms. Margarette Bischler (Univ. Konstanz) for the measurements of some of the pK_a values and UV spectra and to Mr. Shin-ichi Takekuma (Kinki University) for the mass spectra.

Asymmetric Induction in the Base-Catalyzed Reactions Using Polymer-Supported Quinines with Spacer Groups

Minoru INAGAKI, Jun HIRATAKE, Yukio YAMAMOTO, and Jun'ichi ODA*
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received June 23, 1987)

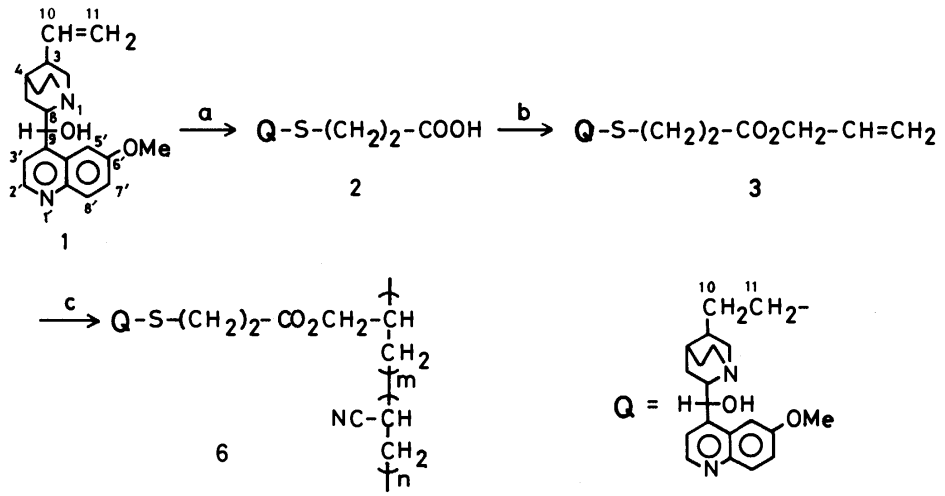
New polymer-supported quinines having the spacer groups were synthesized and utilized for three types of base-catalyzed asymmetric reactions. Insertion of the spacer groups leads to improve the stereoselectivity in comparison with the polymer-catalyst with no spacer groups.

Cinchona alkaloid and its derivertives have been used as chiral catalysts in asymmetric reactions because of their unique stereochemical properties.[1-3] We also investigated the methanolysis of cyclic anhydrides using cinchona alkaloids as catalysts.[4] In order to obtain more easy-to-handle catalysts, many workers[5-9] have prepared polymer-supported cinchona alkaloids. In particular, Kobayashi et al. synthesized chiral functionalized polymers having relatively higher stereoselectivity by copolymerization with acrylonitrile and the vinyl group of the alkaloids.[7] But the utilization of a Kobayashi's polymers for the methanolysis of *cis*-2,4-dimethylglutaric anhydride resulted in low steroselectivity.

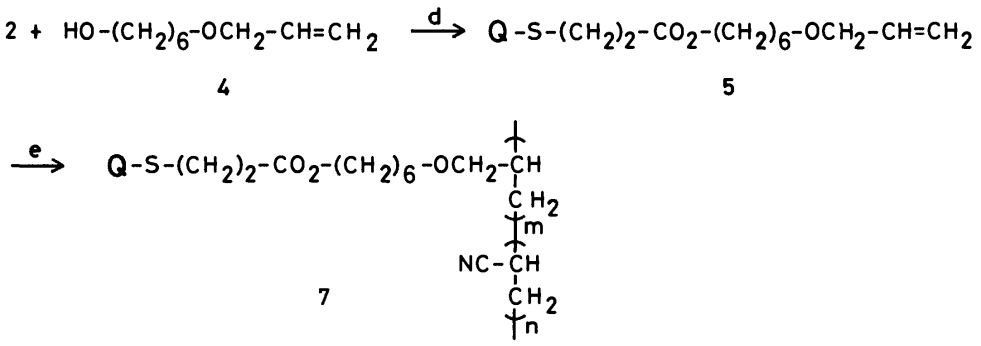
It has been found that the reactivity of catalyst or reagent is often reduced by being polymer-supported. One approach to overcome this drawback is introduction of spacer group between catalytic center and polymer matrix. By inserting a spacer group, the reactivity[10-13] and/or selectivity[14] can be improved. This also holds the case with immobilized enzymes.[15] Thus we prepared the polymer-supported quinine derivatives with spacer groups of various length, and applied them for three types of asymmetric base-catalyzed reactions.

Results and Discussion

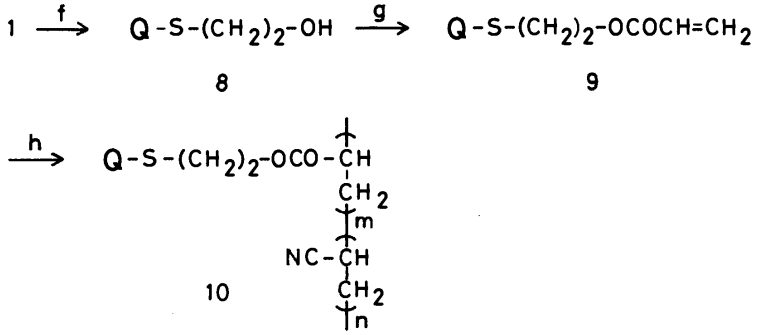
Preparation of Polymer-Supported Quinines with Spacer Groups. The synthetic strategy is shown in Schemes 1—3. Our first attempt to submit methyl 3-mercaptopropionate to the reaction with quinine (**1**) was unsuccessful. But 3-mercaptopropionic acid easily reacted with **1** in the presence of 2,2′-azobisisobutyronitrile (AIBN) as a radical initiator to give the carboxylic acid derivative **2** as a colorless powder in 91% yield. In order to introduce a polymerizable double bond, esterification of **2** with allyl alcohol by the use of thionyl chloride afforded **3** having a spacer group as long as 8-atoms from the quinuclidine ring of quinine in 72% chemical yield. The carboxylic acid **2** was also esterified by the Mitsunobu reaction with the alcohol **4** derived from 6-chloro-1-hexanol to give the ester **5** having a spacer group of 15-atoms length in 94% yield. Copolymerization of quinine derivatives **3** and **5** with acrylonitrile in dry DMF afforded the polymers **6** and **7**, respectively. The crude polymers were reprecipitated and Soxhlet-extracted to remove unreacted monomers. The alkaloid content of **6** and **7** were determined by elemental analyses to be 1.10 and 1.24 mol%, respectively. These values were lower than



Scheme 1. (a): $HSCH_2CH_2COOH$, AIBN; 91%, (b): $HOCH_2CH{=}CH_2$, $SOCl_2$; 72%, (c): $CH_2{=}CHCN$. AIBN; 57%.



Scheme 2. (d): Diethyl azodicarboxylate, PPh_3; 94%, (e): CH_2=CHCN, AIBN; 43%.



Scheme 3. (f): $HSCH_2CH_2OH$, AIBN; 77%, (g): diethyl azodicarboxylate, CH_2=CHCOOH, PPh_3; 67%, (h): CH_2=CHCN, AIBN; 57%.

Table 1. Physical Properties of Polymer-Supported Quinines with Spacer Groups

Polymer-catalyst	Spacer length	Initial molar ratio[a]	$[\alpha]_D$[b]/°	Elemental analysis/%			Alkaloid content/mol%
				C	H	N	
6	8	1 : 19	−5.6[c]	67.41	5.78	24.44	1.10
7	15	1 : 19	−6.5	67.62	5.95	23.81	1.24
10	7	1 : 9	−26.0	65.82	6.15	17.69	8.04
11	0	1 : 19	−10.4[d]	68.33	5.93	24.39	1.99

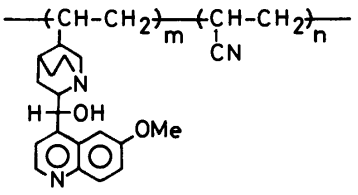
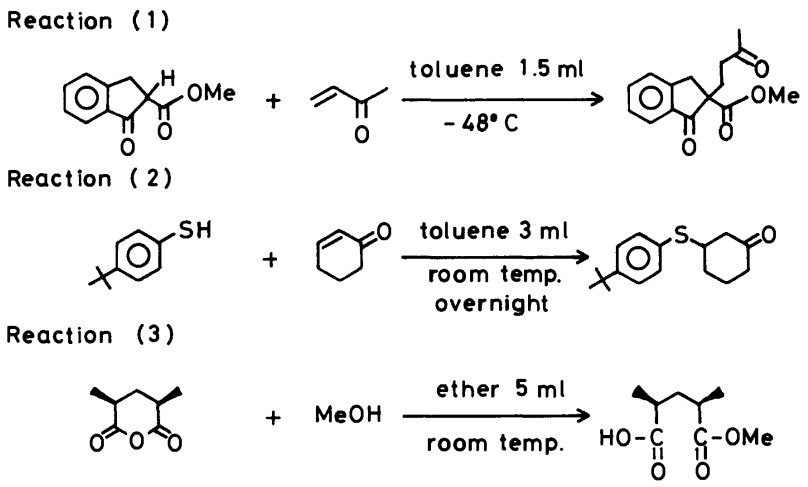
that expected from the initial alkaloid concentration (5 mol%) in the reaction mixture. Therefore we synthesized another copolymer with higher alkaloid content. The monomer having an acryloyl group was prepared which can polymerize with acrylonitrile more easily than simple terminal double bond.[16] Then, **1** was allowed to react with 2-mercaptoethanol to give **8**.[17] The compound **8** was converted to the acrylic ester **9** by the selective esterification of the primary hydroxyl group by the Mitsunobu reaction. It is worth noting that the secondary hydroxyl group of quinine moiety was exclusively esterified when **8** was treated with acryloyl chloride. Copolymerization of **9** with acrylonitrile (1:9 molar ratio) afforded the copolymer **10** having an alkaloid content of 8.04 mol%, which agreed with the initial molar ratio in the reaction mixture. To evaluate the spacer effect, we also synthesized the polymer **11** having no spacer group according to the Kobayashi's method.[18] The



11

conditions employed in polymerizations and some properties of the polymers **6**, **7**, **10**, and **11** are compiled in Table 1.

Asymmetric Reactions Catalyzed by Polymer-Supported Quinine with Spacer Groups. Polymers **6**, **7**, **10**, and **11** were used as catalysts for three types of



Scheme 4.

base-catalyzed reactions including the Michael addition of methyl 1-oxo-2-indancarboxylate to 3-buten-2-one (Reaction (1)),[1] the conjugated addition of *p-t*-butylbenzenethiol to 2-cyclohexenone (Reaction (2)),[2] and the methanolysis of *cis*-2,4-dimethylglutaric anhydride (Reaction (3)).[4]

The results of the Reaction (1) catalyzed by polymers **6**, **7**, **10**, and **11** are shown in Table 2. The reaction was also effected using monomeric alkaloids **1**, **3**, **5**, and **9** for comparison. The monomers **3**, **5**, and **9**, as well as **1**, promoted the reaction to give the adduct quantitatively with 75—76% optical purity. Elongation of spacer arms from the (C)-3 vinyl group of quinine did not reduce the stereoselectivity (Table 2, Entries 5—8). In other words, the conformation of the catalytic center of quinine, around the hydroxyl group and nitrogen atom of quinuclidine moiety, was kept unaltered. Polymer-catalysts **6**, **7**, and **11** on the other hand, gave the product with 88—99% yield, and somewhat lower asymmetric yields than the corresponding monomers. The polymers **6** and **7** with spacer groups showed higher stereoselectivity 62 and 65% than **11** with no spacer 49% (Table 2, Entries **1**, 2 vs. 4).

The results of the Reaction (2) are shown in Table 3. The monomers **1**, **3**, **5**, and **9**, gave the addition product in high chemical yield with 25—45% e.e. Polymers **6**, **7**, and **11** also catalyzed the reaction with 89—98% chemical yield. But the optical purities were extremely reduced in comparison with their monomeric counterparts **1**, **3**, **5**, and **9**, respectively. The reason for this phenomena is unclear at present, but at least the result can not be attributed to spontaneous reaction in the presence of polymer matrix, since poly(acrylonitrile) itself has no catalytic activity (Table 3, Entry 5). Thus the polymer-catalysts, with or without spacer group, were found to be unsuitable so far as this asymmetric reaction.

On the other hand, polymers **6**, **7**, **10**, and **11** were good catalysts for the Reaction (3) as shown in Table 4. Although they showed lower stereoselectivity than the corresponding monomers **1**, **3**, **5**, and **9**,

a) Conversion = >95%. b) Determined by HPLC after converting the product to the diastereometric amide ester. c) We define the selectivity as *R*-side when the caboxyl group next to the asymmetric center with *R*-configuration was attacked preferentially by the nucleophile. d) The reaction was worked up at a conversion of ca. 40% and the e.e. was determined. e) Reuse of catalyst.

respectively, the effect of the spacer group was also observed clearly. The stereoselectivity of the reaction was improved from 14 to 22% e.e. by inserting a spacer group with 8-atoms length, moreover by inserting a 15-atoms-spacer the steroselectivity was raised up to 32% (Table 4, Entries 1, 2, and 4).

The polymer **10**, having another type of spacer group containing acryloyl moiety had a lower activity as to all the three Reactions (1)—(3). However, when the reaction was carried out at room temperature, the polymer **10** slowly catalyzed the Reaction (1) to give the *S* enantiomer of methyl 2-(3-oxobutyl)-1-oxo-2-indancarboxylate with 45% e.e. (Table 2, Entry 9). The similar feature was also observed for the Reaction (3) (Table 4, Entry 3). This indicates that configurational environment of the alkaloid moieties in polymer **10** was retained after the copolymerization in spite of their low catalytic activity.

One of the advantage of polymer-catalysts is that they can be recovered by filtration and reused. Thus the recovered polymers **6** and **7** were reused as the catalysts in the Reaction (3). As shown in Table 4, although the recovered **6** and **7** exhibited lower catalytic activity, the stereoselectivities were comparable with the first usages. (Table 4, Entries 9 and 10 vs. 1 and 2).

In summary, polymer-supported quinines were prepared in which the spacer arms was elongated to remote the catalytic center from polymer chain. Those polymers were found to be good catalysts for the three types of asymmetric reactions as well, and by inserting spacer groups, enantioselectivities were approached to those of the corresponding non-immobilized catalysts.

Experimental

General Procedure. The spectroscopic and analytical instruments were: ^1H NMR, Varian EM-360 (60 MHz), VXR-200 (200 MHz), and JEOL GX-400 (400 MHz); ^{13}C NMR, Varian VXR-200 (50 MHz) and JEOL GX-400 (100 MHz); IR, Hitachi 215; Elemental Analysis, Yanaco MT-3; MS, JEOL JMS-DX-300; Optical Rotation, Perkin-Elmer 241; GLC, Shimadzu GC-4B; HPLC, JASCO BIP-I. NMR spectra were measured in $CDCl_3$ with TMS as internal standard throughout unless otherwise specified. Toluene and methanol were distilled over CaH_2. Diethyl ether and THF were distilled from benzophenone ketyl before use. Acrylonitrile was distilled and immediately used for polymerization.

11-(2-Carboxyethylthio)-10,11-dihydroquinine (2): A mixture of **1** (9.73 g, 30 mmol), 3-mercaptopropionic acid (31.67 g, 300 mmol), and 2,2′-azobisisobutyronitrile (AIBN) (0.99 g, 6 mmol) in benzene (80 ml) was heated at 70 °C for 17 h under Ar atmosphere. The reaction mixture was extracted with 2 M† HCl (3×50 ml). The combined extracts were washed with ether (2×50 ml) and made alkaline (pH 8)

† 1 M=1 mol dm^{-3}.

with Na_2CO_3 powder to afford **2** as viscous semisolid. It became powder by cooling at 4 °C overnight. The powder was collected and dried, and used for the next step without further purification; 10.55 g (82%): $[\alpha]_D^{25}$ 211° (*c* 1.022, 0.1 M HCl); ^{1}H NMR (200 MHz, DMSO-d_6) δ=1.30—3.55 (19H, m, H of quinuclidine ring and spacer arms), 3.91 (3H, s, CH_3O), 5.54 (1H, d, *J*=4.4 Hz, H-9), 6.15 (3H, br s, OH and COOH), 7.37 (1H, dd, *J*=9.2 and 2.5 Hz, H-7′), 7.50 (1H, d, *J*=2.5 Hz, H-5′), 7.54 (1H, d, *J*=4.7 Hz, H-3′), 7.92 (1H, d, *J*=9.2 Hz, H-8′), 8.68 (1H, d, *J*=4.7 Hz, H-2′); ^{13}C NMR (50 MHz, DMSO-d_6) δ=21.427, 24.991, 26.705, 26.972, 28.969, 33.537, 33.592, 35.724, 41.844, 55.652, 56.051, 59.605, 68.936, 102,143, 118.958, 121.119, 126.501, 131.106, 143.768, 147.363, 148.007, 157.073, 174.080; MS (30 eV) *m/z* (rel intensity) 430 (M^+; 6), 242 (8), 44 (100); Found: *m/z* 430.1927. Calcd for $C_{23}H_{30}N_2O_4S$: M, 430.1927; IR (KBr) 3410 (OH), 1620 cm^{-1} (C=O).

11-[2-(Allyloxycarbonyl)ethylthio]-10,11-dihydroquinine (3): To a suspension of **2** (2.50 g, 5.81 mmol) in allyl alcohol (40 ml), was added thionyl chloride (1.45 g, 12.16 mmol) at 0 °C with stirring. Then the mixture was stirred at room temperature for 3 h. The resulting mixture was evaporated and quenched with 1 M NaOH at 0 °C, followed by extraction with CH_2Cl_2 (4×25 ml). The extracts were washed with brine and dried (Na_2SO_4). Evaporation followed by column chromatography on silica gel (eluent, $CHCl_3$(70)–MeOH(2)–NEt_3(1)) and concentration gave **3** as a syrup; 1.96 g (72%): $[\alpha]_D^{28}$ −122° (*c* 0.968, EtOH); ^{1}H NMR (400 MHz) δ=1.35—1.82, 2.32, 2.58, 2.99—3.05, and 3.47 (13H, m, H of quinuclidine ring and H-10), 2.41 (2H, m, H-11), 2.57 (2H, m, $C\underline{H}_2CO_2$), 2.71 (2H, m, $SC\underline{H}_2CH_2CO_2$), 3.90 (3H, s, CH_3O), 4.56 (2H, m, *J*=5.9 and 1.5 Hz, allyl H), 5.21 (1H, m, *J*=10.3, 2.5, and 1.5 Hz, (*Z*)-vinyl H), 5.29 (1H, m, *J*=17.1, 3.2, and 1.5 Hz, (*E*)-vinyl H), 5.36 (1H, br s, OH), 5.50 (1H, d, *J*=3.4 Hz, H-9), 5.88 (1H, m, *J*=17.1, 10.3, and 5.9 Hz, =CH), 7.21 (1H, d, *J*=2.4 Hz, H-3′), 7.25 (1H, dd, *J*=9.3, and 2.9 Hz, H-7′), 7.44 (1H, d, *J*=4.4 Hz, H-5′), 7.87 (1H, d, *J*=9.3 Hz, H-8′), 8.43 (1H, d, *J*=4.9 Hz, H-2′); ^{13}C NMR (100 MHz) δ=20.959, 25.512, 26.987, 27.483, 30.022, 34.182, 34.255, 34.678, 43.144, 55.681, 57.739, 59.695, 65.036, 70.670, 100.839, 117.798, 117.973, 120.980, 125.899, 130.905, 131.416, 143.530, 146.493, 146.741, 157.162, 170.662; MS (30 eV) *m/z* (rel intensity) 470 (M^+; 27), 282 (42), 32 (100); Found: *m/z* 470.2235. Calcd for $C_{26}H_{34}N_2O_4S$: M, 470.2239; IR (liquid) 3080 (OH), 1735 cm^{-1} (C=O).

6-Allyloxy-1-hexanol (4): The allyl ether **4** was prepared from 6-chloro-1-hexanol and allyl alcohol through its THP ether; 2.20 g (37% from 6-chloro-1-hexanol): bp (bath) 142—148 °C/13 mmHg††; ^{1}H NMR (200 MHz) δ=1.20—1.60 (8H, m, CH_2×4), 2.65 (1H, s, OH), 3.22—3.68 (4H, m, OCH_2×2), 4.83—4.92 (2H, m, allyl H), 5.05—5.26 (2H, m, CH_2=), 5.70—5.95 (1H, m, =CH).

11-[2-[6-(Allyloxy)hexyloxycarbonyl]ethylthio]-10,11-dihydroquinine (5): The carboxylic acid **2** (2.50 g, 5.81 mmol), **4** (1.10 g, 6.98 mmol), and triphenylphosphine (1.83 g, 6.98 mmol) were suspended in dry THF (60 ml), and diethyl azodicarboxylate (1.21 g, 6.98 mmol) was added dropwise to the mixture at 0 °C with stirring over a period of 15 min. The mixture was stirred overnight at room temperature and evaporated to dryness, and extracted with 2 M HCl (4×25 ml). The combined acid extract was washed with ether (6×35 ml) and made alkaline with NaOH pellet, and extracted with CH_2Cl_2 (4×25 ml). The extract was washed with brine and dried (Na_2SO_4). Evaporation gave **5**; 3.12 g (94%): $[\alpha]_D^{24}$ −101° (*c* 1.156, EtOH); ^{1}H NMR (400 MHz) δ=1.30—1.85, 2.35, 2.61, 3.02—3.08, and 3.47 (21H, m, H of quinuclidine ring, H-10, and CH_2×4), 2.42 (2H, t, *J*=7.3 Hz, H-11), 2.53 (2H, t, *J*=7.3 Hz, $C\underline{H}_2CO_2$), 2.70 (2H, t, *J*=7.3 Hz, $SC\underline{H}_2CH_2CO_2$), 3.40 (2H, t, *J*=6.4 Hz, $C\underline{H}_2OCH_2$–CH=), 3.87 (3H, s, CH_3O), 3.94 (2H, m, *J*=5.4 and 1.5 Hz, allyl H), 4.05 (2H, t, *J*=6.8 Hz, $CO_2OC\underline{H}_2$), 4.88 (1H, br s, OH), 5.16 (1H, m, *J*=10.3 and 1.5 Hz, (*Z*)-vinyl H), 5.25 (1H, m, *J*=17.1, 3.4, and 1.5 Hz, (*E*)-vinyl H), 5.52 (1H, m, H-9), 5.90 (1H, m, *J*=17.1, 10.3, and 5.4 Hz, =CH), 7.22 (1H, d, *J*=2.4 Hz, H-5′), 7.27 (1H, dd, *J*=9.3, and 2.4 Hz, H-7′), 7.46 (1H, d, *J*=4.4 Hz, H-3′), 7.90 (1H, d, *J*=9.3 Hz, H-8′), 8.51 (1H, d, *J*=4.4 Hz, H-2′); ^{13}C NMR (50 MHz) δ=21.404, 25.688, 25.835, 25.908, 27.157, 28.013, 28.586, 29.683, 30.196, 34.452, 34.631, 34.882, 43.627, 55.805, 58.202, 59.876, 64.770, 70.242, 71.580, 71.811, 101.370, 116.688, 118.423, 121.382, 126.527, 131.343, 134.941, 144.029, 147.326, 147.725, 157.657, 171.846; MS (70 eV) *m/z* (rel intensity) 570 (M^+; 4), 382 (5), 32 (100); Found: *m/z* 570.31328. Calcd for $C_{32}H_{46}N_2O_5S$: M, 570.31278; IR (liquid) 3150 (OH), 1740 cm^{-1} (C=O).

Alkaloid 3–Acrylonitrile Copolymer (6): The alkaloid **3** (1.91 g, 4.06 mmol), acrylonitrile (4.09 g, 77.14 mmol), and AIBN (0.018 g, 0.11 mmol) in dry DMF (14.8 ml) were heated at 60 °C for 21 h under Ar atmosphere. The reaction mixture was poured into boiling MeOH (1000 ml). Precipitated polymer was filtered, reprecipitated twice and Soxhlet-extracted with MeOH (5 h) to remove unreacted monomers. The residue was dried (over P_2O_5 in vacuo at 70 °C (4 h)), to give the polymer **6**; 3.39 g (57%): $[\alpha]_D^{27}$ −5.6° (*c* 1.022, DMF); Elemental analysis. Found: C, 67.41; H, 5.78; N, 24.44%; Alkaloid content 1.10 mol%.

Alkaloid 5–Acrylonitrile Copolymer (7): The alkaloid **5** (2.58 g, 4.52 mmol), acrylonitrile (4.56 g, 85.89 mmol), and AIBN (0.021 g, 0.13 mmol) in dry DMF (17.5 ml) were heated at 60 °C for 22 h under Ar atmosphere. The same purification process described above afforded the polymer **7**; 3.08 g (43%): $[\alpha]_D^{25}$ −6.5° (*c* 1.086, DMF); Elemental analysis. Found: C, 67.62; H, 5.95; N, 23.81%; Alkaloid content 1.24 mol%.

11-(2-Hydroxyethylthio)-10,11-dihydroquinine (8): Quinine (**1**) (9.73 g, 30 mmol), 2-mercaptoethanol (18.75 g, 240 mmol), and AIBN (0.99 g, 6 mmol) in benzene (80 ml) were heated at 70 °C for 28 h under Ar atmosphere. The reaction mixture was extracted with 2 M HCl (2×50 ml). The extracts were washed with ether (2×50 ml), and made alkaline with NaOH pellet. The liberated oil was taken up with CH_2Cl_2 (3×50 ml). The combined extracts were washed with brine and dried (Na_2SO_4). Evaporation and chromatography on silica gel (eluent $CHCl_3$(70)–MeOH-(2)–NEt_3(1)) afforded **8** as a syrup; 9.25 g (77%): $[\alpha]_D^{25}$ −108° (*c* 1.030, EtOH), (Ref. 17 $[\alpha]_D^{25}$ −140.6° (EtOH)); ^{1}H NMR (400 MHz) δ=1.22—1.80, 2.26, 2.52, 2.90—3.00, and 3.48 (13H, m, H of quinuclidine ring and H-10), 2.37 (2H, m, H-11), 2.59 (2H, t, *J*=6.4 Hz, SCH_2), 3.63 (2H, t, *J*=6.4 Hz, CH_2O), 3.83 (3H, s, CH_3O), 4.36 (1H, br s, OH), 5.49 (1H, m, H-9), 5.59 (1H, br s, OH), 7.13—7.26, 7.43, 8.79, and 8.42 (5H, m, H of quinoline ring); ^{13}C NMR (50 MHz) δ=20.880,

†† 1 mmHg=133.322 Pa.

25.633, 27.945, 29.956, 34.586, 35.154, 43.189, 55.742, 58.157, 59.681, 60.700, 68.403, 71.322, 101.509, 118.476, 121.377, 126.532, 130.996, 143.709, 147.110, 148.461, 157.733; MS (70 eV) *m/z* (rel intensity) 402 (M^+; 57), 357 (49), 214 (100).

11-[2-(Acryloyloxy)ethylthio]-10,11-dihydroquinine (9): To a suspension of **8** (4.00 g, 9.94 mmol), acrylic acid (0.745 g, 10.33 mmol), and triphenylphosphine (2.71 g, 10.33 mmol) in dry THF (100 ml), was added dropwise a solution of diethyl azodicarboxylate (1.80 g, 10.33 mmol) in dry THF (5 ml) with stirring at 0 °C over a period of 15 min. The mixture was stirred at 0 °C for 30 min and then at room temperature overnight. The reaction mixture was evaporated to dryness. The residue was dissolved in 2 M HCl (80 ml). Aqueous layer was washed with ether (6×30 ml), made alkaline with Na_2CO_3 powder and extracted with CH_2Cl_2 (2×50 ml). The extracts were washed with brine and dried (Na_2SO_4), and the solvent was evaporated. The residue was flush chromatographed on silica gel (eluent $CHCl_3$-(50)-MeOH(2)-NEt_3(1)) to afford **9**; 3.02 g (67%): $[\alpha]_D^{25}$ −105° (*c* 1.044, EtOH); ^1H NMR (400 MHz) δ=1.34—1.83, 2.38, 2.61, 3.02—3.08, and 3.53 (13H, m, H of quinuclidine ring and H-10), 2.45 (2H, t, *J*=7.3 Hz, H-11), 2.70 (2H, t, *J*=6.8 Hz, SCH_2), 3.84 (3H, s, CH_3O), 4.23 (2H, a, *J*=6.8 Hz, CH_2O), 5.56 (2H, m, H-9 and OH), 5.80 (1H, m, *J*=10.3, 2.4, and 1.5 Hz, (*Z*)-vinyl H), 6.07 (1H, m, *J*=17.1 and 10.3 Hz, =CH), 6.34 (1H, m, *J*=17.1 and 1.5 Hz, (*E*)-vinyl H), 7.21 (1H, d, *J*=2.9 Hz, H-5′), 7.23 (1H, dd, *J*=9.3 and 2.4 Hz, H-7′), 7.46 (1H, d, *J*=4.4 Hz, H-3′), 7.86 (1H, d, *J*=9.3 Hz, H-8′), 8.45 (1H, d, *J*=4.4 Hz, H-2′); ^{13}C NMR (50 MHz), δ=20.931, 25.543, 27.738, 30.221, 30.403, 33.723, 34.431, 43.182, 55.699, 58.008, 59.781, 63.433, 71.111, 101.338, 118.456, 121.338, 126.457, 128.059, 131.142, 131.142, 143.832, 147.202, 148.059, 157.676, 165.846; MS (70 eV) *m/z* (rel intensity) 456 (M^+; 87), 357 (99), 268 (100); Found: *m/z* 456.20527. Calcd for $C_{25}H_{32}N_2O_4S$: M, 456.20817; IR (liquid) 3160 (OH), 1725 cm^{-1} (C=O).

Alkaloid 9-Acrylonitrile Copolymer (10): A solution of the alkaloid **9** (1.95 g, 4.27 mmol), acrylonitrile (2.04 g, 38.40 mmol), and AIBN (0.012 g, 0.07 mmol) in dry DMF (10.0 ml) was heated at 65 °C for 42 h under Ar atmosphere. The same purification process described for the polymer **5** gave the polymer **10**; 2.29 g (57%): $[\alpha]_D^{25}$ −26.0° (*c* 1.008, DMF); Elemental analysis. Found: C, 65.82; H, 6.15; N, 17.69%; Alkaloid content 8.04 mol%.

Quinine-Acrylonitrile Copolymer (11): According to reported procedure,[18] a mixture of **1** and acrylonitrile (1:19) was copolymerized in dry DMF. The crude polymer was purified as above to give the polymer **11** having no spacer; 8.09 g (29%): $[\alpha]_D^{28}$ −10.4° (*c* 1.00, DMF); Elemental analysis. Found: C, 68.33; H, 5.93; N, 24.39%; Alkaloid content 1.99 mol%.

Asymmetric Addition of Methyl 1-Oxo-2-indancarboxylate Catalyzed by 7. Typical Procedure for the Reaction (1): A mixture of the polymer-catalyst **7** (59.0 mg, 0.0125 mmol of alkaloid), methyl 1-oxo-2-indancarboxylate (47.5 mg, 0.25 mmol), and freshly distilled 3-buten-2-one (35.0 mg, 0.50 mmol) in dry toluene (1.5 ml) was stirred at −48 °C. The conversion was monitored by HPLC (hexane(100)-*i*-PrOH(5), detect at 280 nm). Evaporation of the filtrate afforded the pure adduct and its optical rotation was measured at 578 nm (25 °C) in benzene. The purity and structural integrity were certified by ^1H NMR and TLC.

Asymmetric Addition of the Thiol Catalyzed by 6. Typical Procedure for the Reaction (2): A mixture of the polymer catalyst **6** (80.0 mg, 0.015 mmol), *p-t*-butylbenzenethiol (301 mg, 1.81 mmol), and 2-cyclohexenone (150 mg, 1.56 mmol) in dry toluene (3 ml) was stirred overnight at room temperature. The reaction mixture was washed successively with 2 M HCl (2×10 ml), 2 M KOH (2×10 ml), and brine (1×10 ml) followed by drying over Na_2SO_4. Then the optical rotation was measured at 578 nm (25 °C) in CCl_4.

Asymmetric Methanolysis of the Acid Anhydride Catalyzed by 6. Typical Procedure for the Reaction (3): The polymer-catalyst **6** (52.6 mg, 0.01 mmol of alkaloid), *cis*-2,4-dimethylglutaric anhydride (14.2 mg, 1.0 mmol), and dry methanol (32.0 mg, 1.0 mmol) in dry ether (5 ml) were allowed to react at room temperature. The conversion was monitored by GLC (2% XE-60, 2 m, 160 °C). After removing polymer-catalyst by filtration, the half-ester obtained was converted to the diastereomeric amide ester using (*R*)-1-(1-naphthyl)ethylamine.[4] The diastereomeric ratio of the amide ester was determined by HPLC (hexane(100)-*i*-PrOH(6), detection at 280 nm).

The Study on Peptide and Protein Syntheses. Infrared Spectroscopic Conformational Analysis of Oligo-L-leucines Containing Only One D-Amino Acid Residue[1)]

Mitsuaki NARITA,* Shinya HONDA, and Hiroshi UMEYAMA
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei 184
(Received July 1, 1987)

In order to investigate the influence of a D-amino acid residue on the conformational behavior of peptides and proteins, IR spectroscopic conformational analysis of oligo-L-Leus containing only one D-Ala or D-Val residue was performed in the solid state. For the estimation of their structures, a CPK model and Ramachandran map were very helpful. The D-amino acid residue is clearly inhibited to take the values of the backbone dihedral angles ϕ and ψ for β-sheet structures formed by L-amino acid residues, while it is allowed for the D-amino acid residue to take the values ϕ and ψ for helical structures formed by L-amino acid residues. The IR absorption spectroscopic analysis of samples after application of strong shear stress was also useful for the investigation. The effect of shear stress on β-sheet-like structure→helix conformational change is larger for oligo-L-Leus containing a D-Ala residue than those containing a D-Val residue, indicating that the D-Ala residue is more favorable in a helical structure than the D-Val residue. This tendency can be also easily confirmed using CPK model. The significance of this study was discussed in relation to protein synthesis and design of three-dimensional structures of peptides using D-amino acid residues.

In our recent papers,[2-8)] we have demonstrated that a β-sheet aggregation plays an important role in the insolubility of oligopeptides larger than octa- or nonapeptide levels and that replacement of an L-amino acid residue with an Aib residue promotes helical folding in an oligopeptide to improve its solubility to a remarkable extent. The solubility improvement was clearly explained by the fact that the values of the backbone dihedral angles ϕ and ψ of the Aib residue were restricted to helical regions.[4)] The Aid residue in an oligopeptide is inhibited to take the values of ϕ and ψ corresponding to a β-sheet region, and a β-sheet structure of the oligopeptide containing the Aib residue is destroyed due to steric hindrance of the Aib residue. A D-Ala residue has the structure that the C_L^β methyl group in the Aib residue is replaced by a hydrogen atom, and the D-Ala residue in oligo-L-Leus is also inhibited to take the values of ϕ and ψ corresponding to a β-sheet structure formed by oligo-L-Leus. Therefore, it is interesting to investigate the conformational behavior of oligo-L-Leus containing only one D-Ala residue.

The concern in this paper is to investigate the influence of a D-amino acid residue on the conformational behavior of oligo-L-Leus containing only one D-Ala or D-Val residue in the solid state. The investigation is significant in the study on peptide and protein syntheses since racemization during coupling reaction is inevitable. It also gives information for the design of three-dimensional structures, especially β-turn structures, of peptides using D-amino acid residues.

Experimental

Materials. The peptides used in this study are in the following: Boc-L-Leu$_3$-D-X-L-Leu$_3$-OBzl: X=Ala **1a**, X=Val **1b**; Boc-L-Leu$_4$-D-X-L-Leu$_4$-OBzl: X=Ala **2a**, X=Val **2b**; Boc-L-Leu$_5$-D-X-L-Leu$_3$-OBzl: X=Ala **3a**, X=Val **3b**; Boc-L-Leu$_4$-L-X-L-Leu$_4$-OBzl: X=Ala **4a**, X=Val **4b**. Preparation and solubility properties of the peptides **1**—**4** will be reported elsewhere.[9)] The peptides **1a** and **3a** are soluble in dichloromethane, tetrahydrofuran, and highly polar solvents such as *N*,*N*-dimethylformamide and dimethyl sulfoxide. The peptides **1b** and **3b** are less soluble in dichloromethane and tetrahydrofuran and soluble in the highly polar solvents. The peptides **2** and **4** are insoluble even in the highly polar solvents. The solid samples of the peptides **1a** and **3a** were obtained by repeated recrystallization from aqueous ethanol and the solid sample of the peptide **1b**, from methanol. Those of the peptides **2**, **3b**, and **4** were obtained by repeated washing with hot methanol. The purity of the peptides was confirmed by elemental and amino acid analyses. The peptides soluble in *N*,*N*-dimethylformamide gave a single peak on high-performance liquid chromatography.

IR Measurements. The IR absorption spectra of the solid samples were recorded with a JEOL Model JIR-100 FT-IR spectrometer in a Nujol mull. The IR absorption spectra (Fig. 1) of the peptides **1**—**4** under slight shear stress were obtained after the solid samples were pulverized with Nujol by weak shear stress.[8,13)] The IR absorption spectra (Fig. 2) of the peptides **1**—**4** after application of shear stress were also obtained in a Nujol mull after the solid samples were pulverized without Nujol by strong shear stress.[8,13)]

Results

IR Absorption Spectra of the Peptides 1—4 in the Solid State. Figure 1 shows the IR absorption spectra of the peptides **1**—**4** in the most significant spectral regions for the conformational assignments (3500—3100 cm^{-1}, amide A; 1800—1600 cm^{-1}, amide I). All of the peptides show a strong band at 3280—3270 cm^{-1} and a negligible small band around 3425 cm^{-1} in the amide A region, suggesting that the Boc-urethane

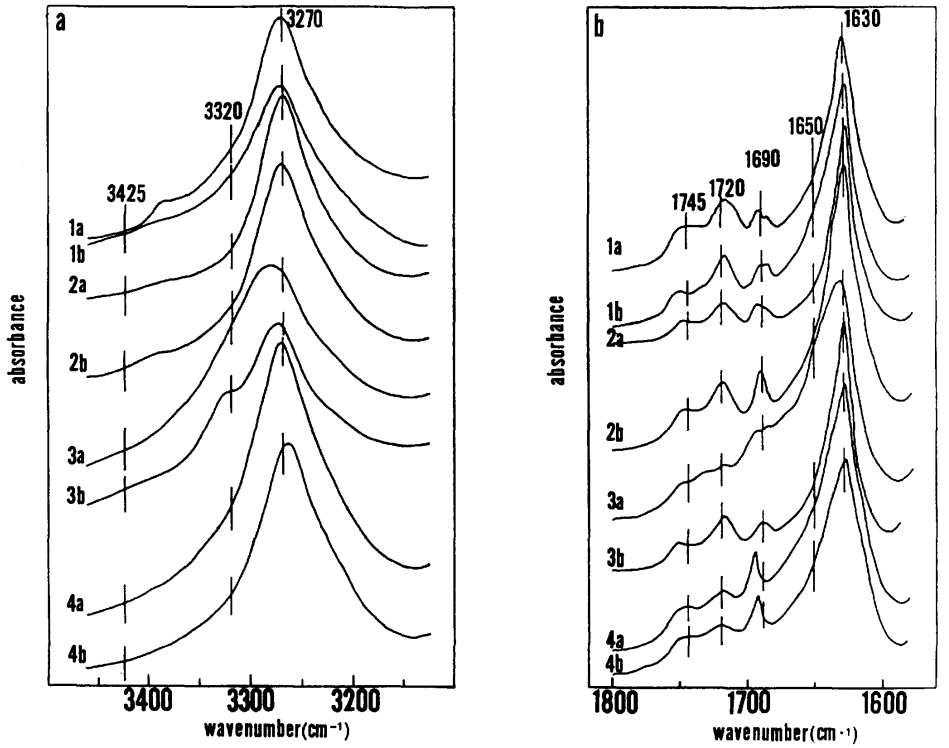

Fig. 1. IR absorption spectra of the peptides **1**—**4** in the solid state under slight shear stress. a: The amide A region; b: the amide I region.

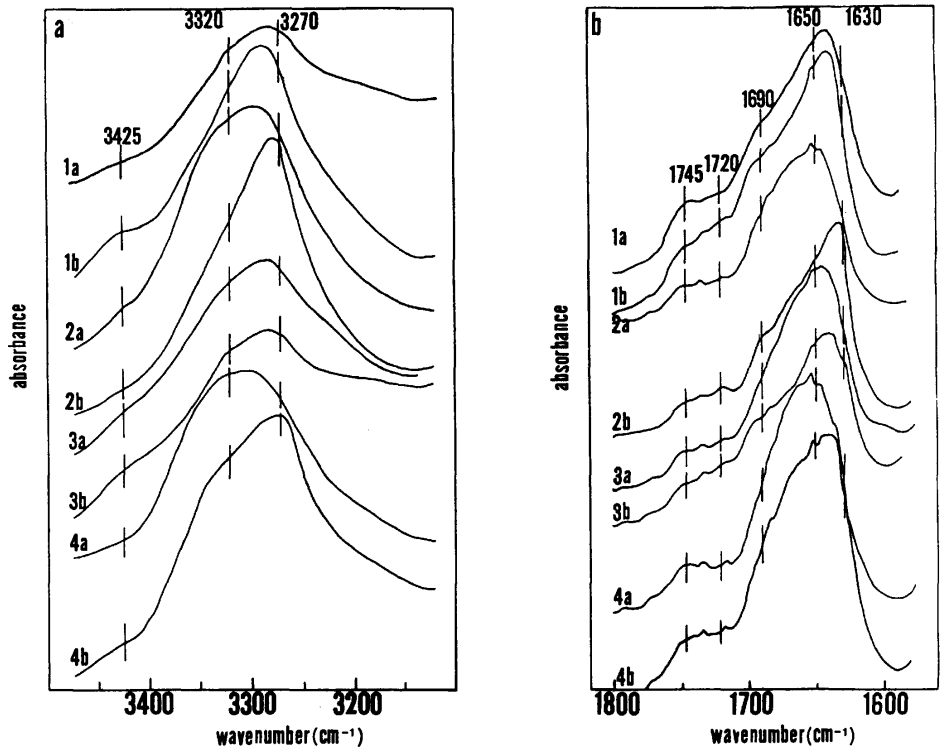

Fig. 2. IR absorption spectra of the peptides **1**—**4** in the solid state after application of strong shear stress. a: The amide A region. b: the amide I region.

N-H bond and peptide N-H bonds are mostly subjected to hydrogen bonding in the solid state. The bands around 1745 cm^{-1} and 1720 cm^{-1} are assigned to the Bzl-ester carbonyl group and the Boc-urethane carbonyl group, respectively, and the bands at 1690—1625 cm^{-1}, mainly to hydrogen-bonded amide-carbonyl groups. The strong bands at 3280—3270 cm^{-1} in the amide A region and at 1635—1625 cm^{-1} in the amide I region and the weak band at 1690 cm^{-1} in the amide I region suggest that the peptides **1—3** have an antiparallel β-sheet-like structure, while those of the peptides **4a** and **4b** containing only L-amino acid residues are indicative of an antiparallel β-sheet (β_A-sheet) structure.[10-12] The peptides **3a** and **3b** are accompanied by a shoulder band around 3320 cm^{-1}, indicating a contribution of other conformations.

The Influence of Shear Stress on Peptide Conformations in the Solid State. It has been reported that β-sheet→helix conformational change in the solid state brings about by application of shear stress.[8,13] Figure 2 shows the IR absorption spectra of the peptides **1—4** after application of strong shear stress. These spectra indicate the influence of shear stress on peptide conformations to a small or considerable extent. The increase in intensities of 3320-cm^{-1} and 1655-cm^{-1} shoulder bands of the peptides strongly suggests the onset of a helical structure although the increase in intensity of a 3425-cm^{-1} shoulder band is not negligible, which is assigned to N-H bonds free from hydrogen bonding.

Discussion

The IR absorption spectra (Fig. 1) of the peptides **1—4** under a slight influence of shear stress are reproducibly obtained when solid samples are pulverized with Nujol by weak shear stress, indicating that the peptides **1—3** have a β_A-sheet-like structure, while the peptides **4a** and **4b** have a β_A-sheet structure. The solubility of the nonapeptides **2a** and **2b** is as low as that of Boc-(L-Leu)$_9$-OBzl and the nonapeptides **4a** and **4b**, also suggesting that they have successive-strong intermolecular hydrogen bonds like β-sheet aggregation. The solubility of peptides forming successive-intermolecular hydrogen bonds is strongly dependent on peptide chain length,[2-7] and the heptapeptides **1a** and **1b** is actually more soluble than the nonapeptides **2a** and **2b**.

For the estimation of the structures of the peptides **1—3**, a CPK model and Ramachandran map[14] are quite helpful. The values of the backbone dihedral angles ϕ and ψ of an L-amino acid residue are allowed in the regions outlined by solid lines in Fig. 3a, and those of a D-amino acid residue, in the regions outlined by solid lines in Fig. 3b. The restriction of the values ϕ and ψ in Fig. 3 results entirely from the steric repulsion of $C^{\beta}_{L,i}$ and $C^{\beta}_{D,i}$ with O_{i-1}, N_{i+1}, and H_{i+1} (Fig. 4). Therefore, the D-Ala and D-Val residues in the peptides **1** and **2** clearly can not exist in β_A-sheet and parallel β-sheet (β_P-sheet) structures formed by L-amino acid residues. Furthermore, Fig. 3 suggests three possibilities of the conformation of the peptides **1** and **2**. The first one is the right handed helical (H_R) structure, where the L-Leu, D-Ala, and D-Val residues should have the values of ϕ and ψ corresponding to the H_R region. The second one is the segment-separated structure, where β-sheet structures are separated by the D-Ala or D-Val residue into two peptide segments as proposed previously for tertiary peptide bond-containing polypeptides.[2,15] The last one is the β_P- or β_A-sheet-like structure as shown in Fig. 5. In the β_P-sheet-like structure shown in Fig. 5a, the L-Leu residues have the values of ϕ and ψ corresponding to the β_P region in the L-configuration:

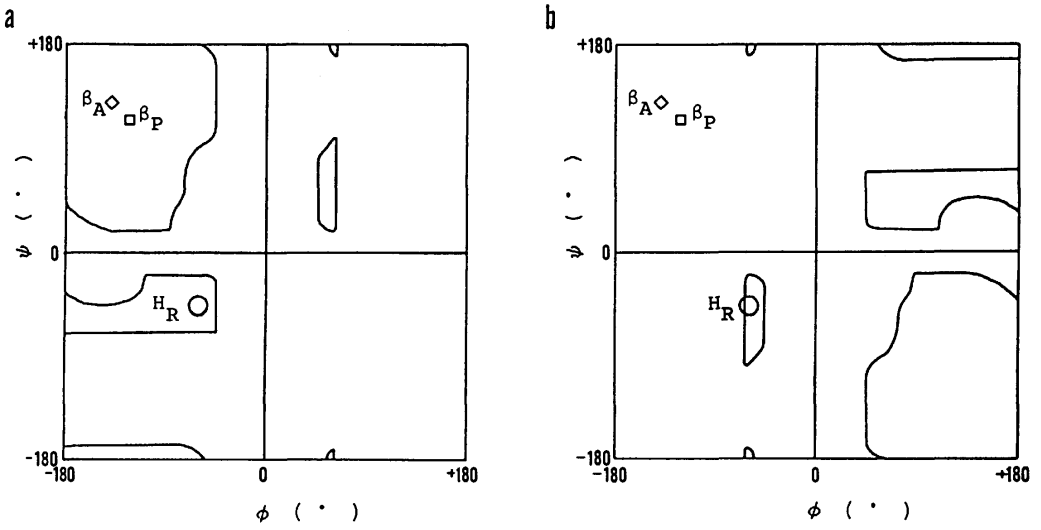

Fig. 3. Ramachandran map of amino acid residues except for glycine and proline residues. a: L-Amino acid residues; b: D-amino acid residues.

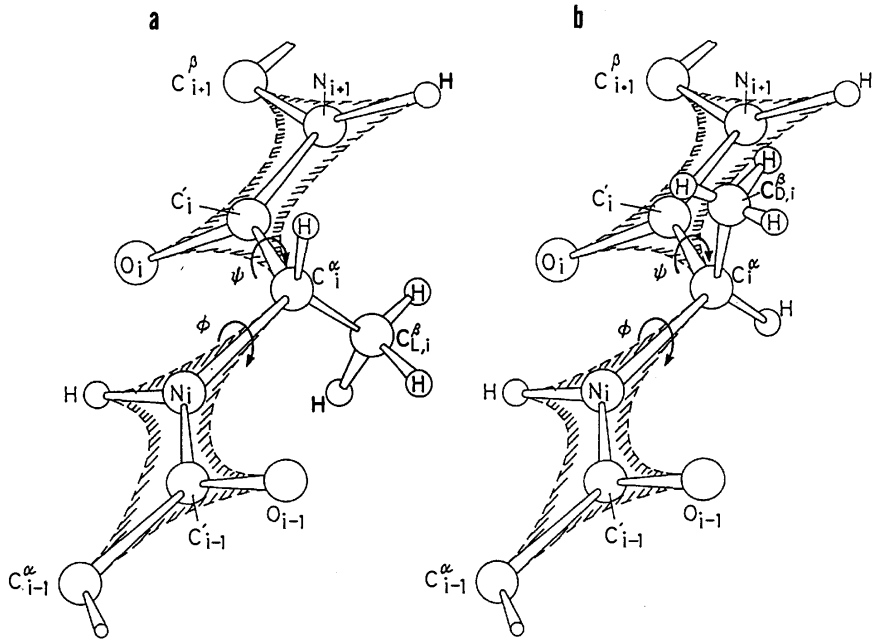

Fig. 4. The structure of peptide backbone and the backbone dihedral angles ϕ and ψ. a: L-Amino acid residues; b: D-amino acid residues.

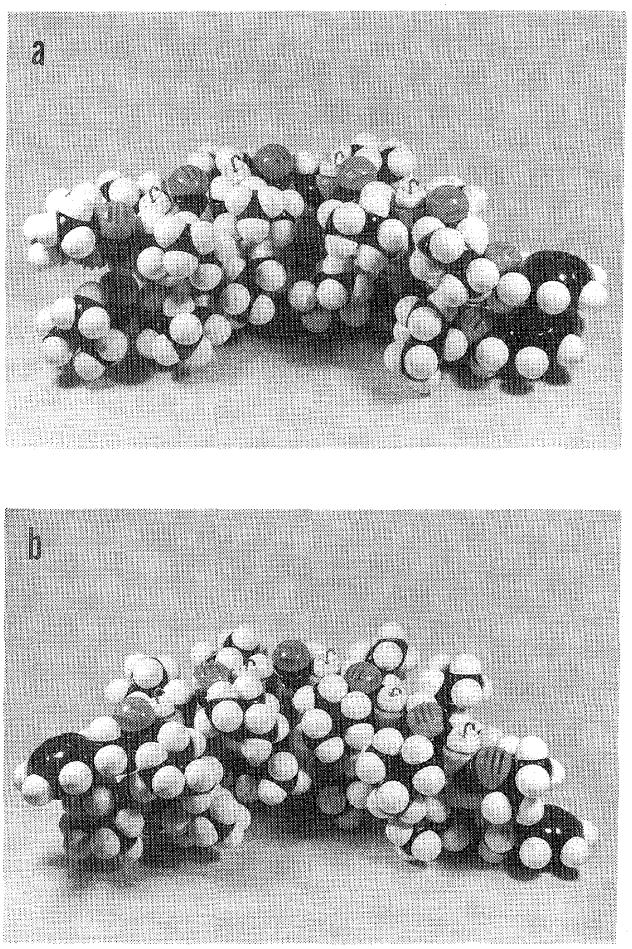

Fig. 5. The CPK model of theβ_P- and β_A-sheet-like structures of the peptide **2a**. a: The β_P-sheep-like structure; b: the β_A-sheet-like structure.

ϕ=−119° and ψ=+120°, while the D-Ala and D-Val residue have the other values in the regions outlined by solid lines in Fig. 3b. In the β_A-sheet-like structure shown in Fig. 5b, the L-Leu residues have the values of ϕ and ψ corresponding to the β_A region in the L-configuration: ϕ=−139° and ψ=+135°, and the D-Ala and D-Val residue have the other values in Fig. 3b. The solubility of peptides having the helical or segment-separated structure is expected to be easily soluble in organic solvents.[2,4,15] In addition to the above consideration, the IR absorption spectra (Fig. 1) and solubility properties of the peptides **1** and **2** strongly suggest that they have the β_A-sheet-like structure shown in Fig. 5b although an L-Leu residue is favorable in both β_A- and β_P-sheet structures.[16] The β_A-sheet-like structure of the peptides **1** and **2** is also supported by the solubility behavior and IR absorption spectrum (Fig. 1) of the peptide **3a**. When the peptide **3a** is favorable in a β_P-sheet-like structure having successive-intermolecular hydrogen bonds, it will be insoluble in highly polar solvents. However, the peptide **3a** is easily soluble even in medium-polar solvents such as dichloromethane and tetrahydrofuran, and its IR absorption spectrum (Fig. 1) rather suggestes the β_A-sheet-like structure containing other conformational contribution.

The IR absorption spectra (Fig. 2) of the peptides **1**—**4** after application of shear stress are also useful for investigating the influence of a D-amino acid residue on the conformational behavior of oligo-L-Leus containing only one D-amino acid residue. They are reproducibly obtained when solid samples are pulverized without Nujol by strong shear stress. The

effect of shear stress on β-sheet-like structure→helix conformational change is larger for oligo-L-Leus containing a D-Ala residue, **1a—3a**, than those containing a D-Val residue, **1b—3b**. This result indicates that the D-Ala residue is more favorable in a helical structure than the D-Val residue. In fact, this tendency can be easily confirmed using a CPK model. The difference of conformational preference in the D-Ala and D-Val residues subsequently brings about the solubility difference of the peptides **3a** and **3b**. The peptide **3a** is easily soluble in dichloromethane, while the peptide **3b** is nearly insoluble. The peptide **3a** is indeed estimated to have a helical structure in dichloromethane solution as well as Boc-(L-Leu)$_4$-Aib- (L-Leu)$_4$-OBzl and the peptide **1a**.[4,17] The same tendency of conformational transformation is observed in the peptides **4a** and **4b** having a typical β_A-sheet structure. The effect of shear stress on β-sheet→helix conformational change is also larger for the peptide **4a** having an L-Ala residue than the peptide **4b** having an L-Val residue (Fig. 2), but both peptides are insoluble even in highly polar solvents such as *N*,*N*-dimethylformamide and dimethyl sulfoxide. The conformational behavior and solubility properties of the peptides **3** and **4** clearly suggest that, in the case of oligopeptides containing a D-Ala residue, the inhibition of the values ϕ and ψ in the β-sheet region and the allowance of the values ϕ and ψ in the helical region promote helical folding to improve their solubility as pointed out for oligopeptides containing an Aib residue.[4]

The conformational behavior of the peptides **1—3** is significant in the study on peptide and protein syntheses. The results obtained indicate that a D-amino acid residue resulted in inevitable racemization in coupling reactions can not exist in β_A- and β_P-sheet structures of peptides and proteins and brings about remarkable conformational change shown in Fig. 5 at least in the β-sheet regions. On the other hand, Fig. 3 suggests that, due to steric hindrance, β-turn structures can be kept stable using a D-amino acid residue in the position $i+1$ or $i+2$ of β-turn structures. We are now working on the design of β-turn structures using a D-amino acid residue.

The authors wish to thank Ajinomoto Co., Ltd., for the generous gift of various amino acids. We also wish to thank Mitsubishi Kasei Co., Ltd., for the generous gift of Boc-S reagents.

Enzyme Sensors Based on Coated-Wire Electrode. Use of Carboxyl-Substituted Poly(vinyl chloride) as a Support for Immobilizing Penicillinase

Jun-ichi Anzai, Masahiko Shimada, Tetsuo Osa,* and Chien-wu Chen†
Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980
†Department of Pharmacy, Kao-Hsiung Medical College, Kao-Hsiung, Taiwan, Republic of China
(Received April 23, 1987)

A poly(vinyl chloride) derivative which contained 1.8% carboxyl residue was used to prepare a potentiometric sensor sensitive to penicillin G. A pH-sensitive base electrode was fabricated by covering an Ag wire electrode with the membrane composed of the carboxyl-substituted poly(vinyl chloride), *o*-nitrophenyl octyl ether, and tridodecylamine. The sensitive layer of the pH-sensitive electrode was modified with penicillinase to make a penicillin-sensitive electrode. Penicillinase was adsorbed to the surface of the polymer membrane by immersing the sensitive layer of the electrode in the penicillinase solution. Treatment of the pH-sensitive electrode with ca. 0.3% penicillinase solution at pH 6.7 (1 mM†† phosphate buffer) resulted in favorable performance of the penicillin sensor. The long-term stability of the penicillin sensor thus prepared was satisfactorily good.

Enzyme sensors have been considered to have great potential as analytical tools for sensing precursors and metabolites in biological fluids, some kinds of drugs, and other biologically important compounds. To data, many kinds of electric and optical devices, including ion- and gas-sensitive conventional types of electrodes, semiconductor electrodes, thermistors, and optical fibers, coupled with enzymes have been employed for developing enzyme sensors.[1-10]

Many researchers have used potentiometric pH-sensitive devices as base electrodes on which enzyme is immobilized. Mosbach et al. reported that a pH glass electrode can be used as a base electrode to construct enzyme sensors sensitive to glucose, urea, and penicillin by covering the electrode surface with glucose oxidase, urease, and penicillinase membranes, respectively.[11] The principle of operation of the sensors was that the changes in H^+ concentration arising from the enzymatic reaction in the enzyme membrane were detected as local pH change by the pH glass electrode.

Recently, metal electrodes coated with metal oxide layer (IrO_2 or RuO_2), which can serve as pH sensors, have been utilized as base electrodes for preparing potentiometric enzyme sensors.[12-15] The metal oxide electrodes are of considerable interest due to their mechanical strength as well as ease of miniaturization as compared with the conventional type of glass electrode.

We have used an ion-sensitive field effect transistor (ISFET) as a pH-sensitive base electrode for developing micro enzyme sensors.[16-19] In the course of our study on the ISFET-based enzyme sensors, it has become obvious that high-performance enzyme sensors can be prepared by covering the ISFET gate with the enzymes which catalyze the reactions resulting in pH changes of the medium. Another interesting device for preparing potentiometric enzyme sensors is a pH-sensitive metal electrode coated with solvent polymeric membrane containing neutral carrier sensitive to H^+. The membrane-coated Ag electrode has a merit in miniaturizing the sensor body due to the absence of internal reference solution. We have already reported that urea and penicillin sensors can be prepared based on the Ag electrode which is coated with poly(vinyl chloride)–tridodecylamine composite membrane coupled with the enzyme–albumin crosslinked membrane.[20,21] However, the life time of the enzyme–albumin crosslinked membrane was not long. A poor surface adhesion between the polymer membrane and the enzyme membrane was also a drawback.

In this paper, we report that the poly(vinyl chloride) derivative which contains 1.8 wt% carboxyl residue can be used as a polymer matrix of pH-sensitive coated-wire electrode and that, using the coated-wire electrode, penicillin-sensitive electrode can be prepared by immobilizing penicillinase on the polymer surface mainly through electrostatic interaction. The present technique would provide a facile method to make enzyme sensors by the use of polymer-coated electrode.

Experimental

Materials. The carboxyl-substituted poly(vinyl chloride) (PVC-COOH), nominally 1.8 wt% carboxyl residue, was used as received from Aldrich Chemical Co. Poly(vinyl chloride) (PVC) was purchased from Wako Chemical Co. Sodium tetraphenylborate (NaTPB), tridodecylamine (TDA), and *o*-nitrophenyl octyl ether (NPOE) were of extra pure reagent grade. Penicillinase was purchased from Miles Chemical Co. Penicillin G potassium salt was obtained from Wako Chemical Co.

Electrode Preparation. Figure 1 shows the schematic representation of the electrode. The top of Ag wire (0.5 mm

†† (M=mol·dm^{-3}).

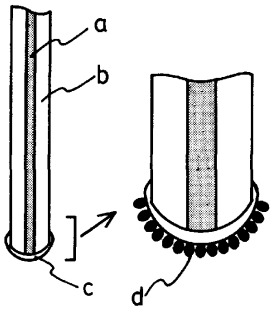

Fig. 1. Schematic representation of the penicillin-sensitive electrode.
a: Ag wire; b: Teflon rod; c: PVC-COOH-TDA membrane; d: penicillinase.

diameter) mounted in a Teflon rod was coated with a pH-sensitive solvent polymeric membrane composed of PVC-COOH (31%), NPOE (63%), TDA (5.5%), and NaTPB (0.5%). The polymer membrane was prepared by dip-coating method using tetrahydrofuran solution of the materials. The thickness of the polymer membrane thus prepared was about 0.2 mm. Prior to enzyme immobilization, the pH response of the coated-wire electrode was checked. Then, the polymer layer of the electrode was further modified with penicillinase by immersing the top of the electrode in the penicillinase solution. After treatment for about 15 h at 5—10 °C, the probe was rinsed adequately with the working buffer.

Measurements. All potentiometric measurements were carried out at 23 °C, using a digital multimeter (TR 6843, Takeda Riken Co.) and a saturated calomel electrode (SCE). Solutions were not stirred during the measurements, and the probe was rinsed with the working buffer after each measurement. The electrode was stored in a refrigerator at about 4 °C when not in use.

Results and Discussion

PVC-TDA-Coated Electrode. It has been demonstrated previously that the PVC-TDA composite membrane can serve as a pH sensor.[22,23] A metal electrode coated with the PVC-TDA membrane was also examined.[24] The use of PVC-COOH for preparing coated-wire electrode has been first reported by Satchwill and Harrison.[25] They have demonstrated that the potentiometric response of K^+-sensitive electrode coated with the PVC-COOH-valinomycin membrane is comparable to that of the parent PVC-based device.

The pH response of the PVC-COOH-TDA-coated electrode was checked using 50 mM KH_2PO_4 solutions containing varying amounts of NaOH (Fig. 2). The electrode potential depended linearly on the solution pH over the range of pH 4.3—10.2. The pH sensitivity was about 50 mV/decade, and the response was satisfactorily fast (20—30 s). The pH response of the electrode is almost the same as that of the PVC-TDA-based electrode.[22-24] These results suggest that the PVC-COOH can be used as a polymer matrix

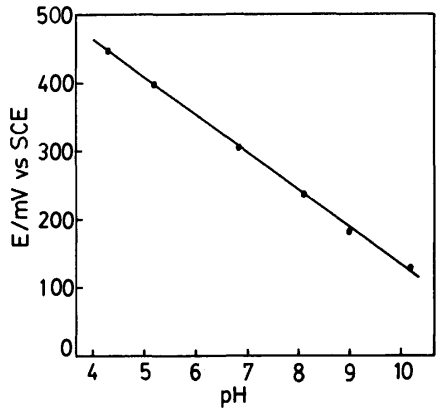

Fig. 2. pH response of the PVC-COOH-TDA-coated electrode. The pH values of the solutions were adjusted by adding varying amounts of NaOH to 50 mM KH_2PO_4.

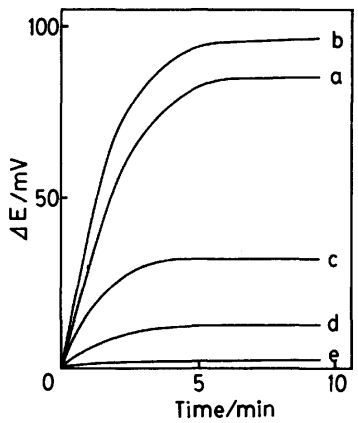

Fig. 3. Typical response curves of the penicillin sensor for penicillin G solutions in 5 mM phosphate buffer at pH 7.0.

of the pH-sensitive membrane for constructing enzyme sensors.

Penicillin-Sensitive Electrode. The PVC-COOH-TDA-coated electrode was modified with penicillinase for making penicillin-sensitive electrode, by treating the sensitive layer with 0.3% penicillinase solution which was prepared in 1 mM phosphate buffer at pH 7.0. The potentiometric response of the penicillin sensor thus prepared was examined for 0.1—30 mM penicillin G in 5 mM phosphate buffer of pH 7.0 (Figs. 3 and 4). When the electrode was immersed in the penicillin G solution, the electrode potential shifted in the positive direction and reached steady-state value after 4—6 min. The positive shift of the potential means that the pH value around the PVC-COOH-TDA membrane decreased (cf. Fig. 2). This is reasonably explained based on the enzymatic reaction of penicillinase (1), where H^+ is liberated from

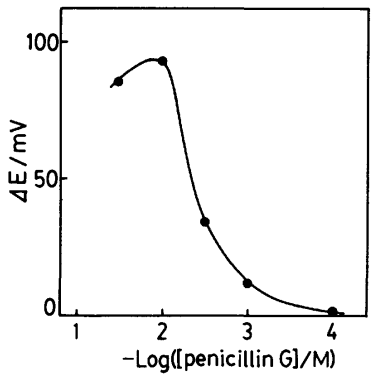

Fig. 4. Calibration graph of the penicillin sensor in 5 mM phosphate buffer at pH 7.0.

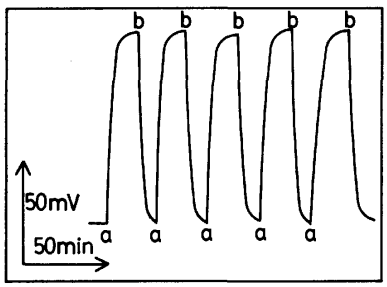

Fig. 5. Reproducibility of the penicillin sensor. Sample solution was 10 mM penicillin G in 5 mM phosphate buffer at pH 7.0. The sensor was immersed in the sample solution (a) and rinsed with the working buffer (b).

penicilloic acid produced. The value of the potential shift, ΔE, depended on the concentration of penicillin G in the solution. It is clear that penicillinase was adsorbed irreversibly to the surface of the PVC-COOH-TDA membrane without inactivation. The reduced response of the sensor for 30 mM penicillin G solution may be explained based on the fact that, as a result of the progress of the enzymatic reaction, the pH value around the polymer surface shifted down to ca. pH 5 at which penicillinase lost its catalytic activity to some degree.[26]

The reproducibility of response of the penicillin sensor was checked by repeatedly immersing the probe in 10 mM penicillin G in 5 mM phosphate buffer at pH 7.0 (Fig. 5). The reproducibility of the sensor was satisfactorily good. After the electrode potential had reached a steady-state value in the sample solution, the original potential was recovered in 10—15 min by immersing the probe in the working buffer. Potential drift during the series of measurements was small.

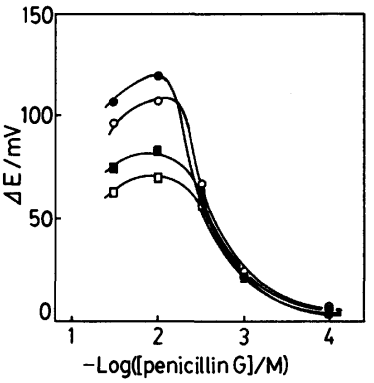

Fig. 6. Effects of pH of penicillinase solution on the response of the sensor.
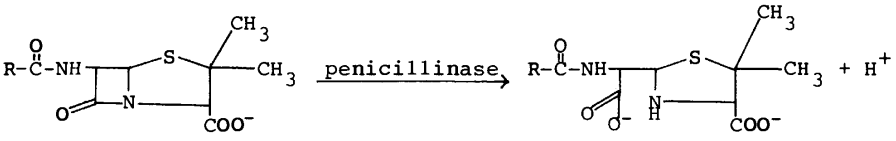
The pH values of the penicillinase solutions were 5.2 (—□—), 6.0 (—○—), 6.7 (—●—), and 7.8 (—■—). The penicillin G solutions were prepared in 5 mM phosphate buffer at pH 7.0.

We also tried to immobilize penicillinase to the pH-sensitive electrode prepared by the use of parent PVC-TDA membrane under the same conditions. After treatment with penicillinase solution, the PVC-TDA-coated electrode responded to penicillin G to some extent, but the response disappeared after repeated measurements of the sample. This is presumably due to the desorption of penicillinase from the surface of PVC-TDA membrane. These results suggest that the carboxyl groups in PVC-COOH serve as ionic sites for binding penicillinase by the electrostatic force of attraction.

In order to establish the optimum conditions of enzyme solution in which the pH-sensitive electrode is treated, the effects of pH and ionic concentration of the enzyme solution, as well as the enzyme concentration, on the potentiometric response were examined. Figure 6 illustrates the calibration graphs for the enzyme sensors prepared by treating the probe in 0.3% penicillinase solutions at pH 5.2, 6.0, 6.7, and 7.8. At all pH tested, penicillinase was adsorbed to the membrane surface. The penicillin G sensors prepared at pH 6.0 and 6.7 showed relatively higher response as compared with those prepared at pH 5.2 and 7.8. These results imply that the electrode surface binds penicillinase efficiently in the pH region where PVC-COOH and penicillinase are charged negatively and positively, respectively.

Figure 7 shows the effects of buffer strength of the penicillinase solutions in which the PVC-COOH-TDA-coated electrode was treated for immobilizing penicillinase. The concentration of penicillinase was



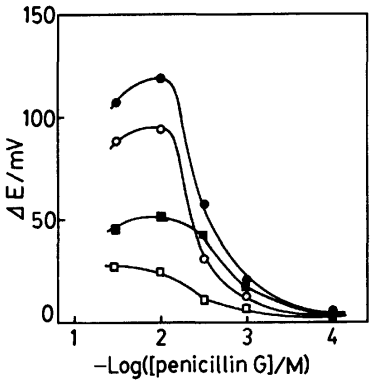


Fig. 7. Effects of buffer strength of penicillinase solution on the response of the sensor.
The buffer concentrations of penicillinase solutions were 1 (—●—), 5 (—○—), 20 (—■—), and 50 mM (—□—).
The penicillin G solutions were the same as used for Fig. 6.

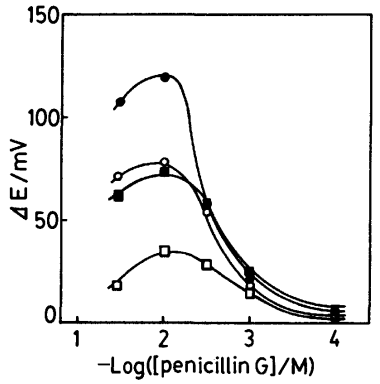

Fig. 8. Effects of penicillinase concentration on the response of the sensor.
The penicillinase concentrations were 0.07% (—■—), 0.3% (—●—), 0.7% (—○—), and 1.3% (—□—).
The penicillinase solutions were prepared in 1 mM phosphate buffer at pH 6.7.
The penicillin G solutions were the same as used for Fig. 6.

0.3% and the pH of the solutions was adjusted at 6.7. The results clearly demonstrate that the penicillin sensors prepared in the lower strength buffers exhibit higher response. This should arise from the difference in the enzyme load on the electrode. In other words, the penicillinase solution of lower buffer concentration favors the binding of penicillinase to the membrane, which situation agrees with the fact that the main force of attraction between penicillinase and PVC-COOH-TDA membrane is electrostatic one. Mitz et al. reported a similar effect of salt concentration, which was observed in immobilizing enzymes onto some cellulose ion exchangers.[27]

In Fig. 8 are shown the effects of penicillinase

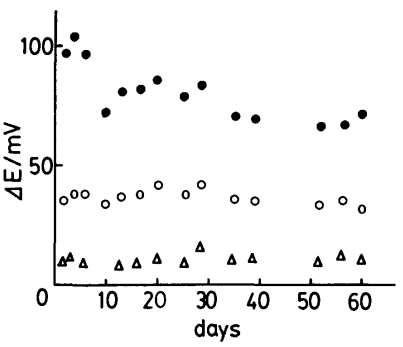

Fig. 9. The long-term stability of the penicillin sensor. The ΔE values were recorded for 10 (—●—), 3 (—○—), and 1 mM (—Δ—) penicillin G in 5 mM phosphate buffer at pH 7.0.

concentration in the solutions from which penicillinase was adsorbed to the electrode. The pH values of the solutions were kept constant at 6.7 by 1 mM phosphate buffer. The penicillin sensor prepared in 0.3% penicillinase solution exhibited the highest response. Unexpectedly, the sensor prepared in 1.3% penicillinase solution showed a decreased response, which may result from the enhanced ionic strength in the 1.3% penicillinase solution. From the results shown in Figs. 6, 7, and 8, it is recommended that, to construct high-performance penicillin sensor, the PVC-COOH-TDA-coated electrode is treated with 0.3% penicillinase solution prepared in 1 mM phosphate buffer at pH 6.7.

The long-term stability of the sensor was examined. The ΔE values of the sensor for 0.1, 3, and 10 mM penicillin G solutions were plotted in Fig. 9. Though the response of the sensor for 10 mM penicillin G solution slightly reduced after 10 days, the sensor can be used for more than 2 months.

Thus, it has been demonstrated that PVC-COOH membrane can be used for immobilizing penicillinase on its surface, as well as for the polymer matrix for making a pH-sensitive base electrode.

The present work was supported in part by a Grant-in-Aid for Special Project Research (No. 61127003) from Ministry of Education, Science and Culture.

(Received May 20, 1987)

Synopsis. A new method for determining the optical purity based on enthalpy of transition in solid-solid phase transition was introduced. The enthalpy of transition of norleucine recovered by an optical resolution procedure was measured by means of DSC. The magnitude of optical purity based on enthalpy of transition was in agreement with that based on specific rotation.

For the products obtained by optical resolution procedure or asymmetric synthesis, it is necessary to determine the magnitude of optical purity. The method for the determination of optical purity based on specific rotation has frequently been used.[1] A large amount of sample (about 0.1 g) is required to measure its specific rotation with dissolution procedure, whereas only small amount of sample (a few mg) is required to measure its enthalpy of transition by DSC without dissolution procedure.

In the course of thermoanalytical and calorimetric studies on polymorphic behaviors of crystalline modification for aliphatic α-amino acids with normal alkyl chains, we have found that the α-form DL-norleucine (DL-NL) is transformed into the γ-form DL-NL at 390 K with the enthalpy of transition of 4.4 kJ mol^{-1} by DSC[3] and that the α-γ transition of DL-NL is of the first order.[4]

In this report, a new method for the determination of optical purity based on enthalpy of transition is introduced. The enthalpy of transition of norleucine recovered by optical resolution procedure was measured by means of DSC. The magnitude of optical purity based on enthalpy of transition was compared with that based on specific rotation.

Experimental

L-Phenylalanine (L-Phe) and L-tryptophan (L-Try) were purchased from Tokyo Kasei Co., and DL-norleucine (DL-NL) and D-norleucine (D-NL) from Sigma Chemical Co. All the samples used were the purest reagents commercially available: The purity of the compounds was guaranteed by each manufacturers to be more than 98%. These samples were further purified by recrystallization from aqueous solution. Active carbon, which was purchased from Wako Chemical Co., was G. R. grade. The procedure of optical resolution was based on the method described by Shiraiwa et al.[5] The measurement of enthalpy of transition was carried out by means of DSC. The apparatus and procedure were tha same as described in the previous works.[3,4] The specific rotation was determined by Japan Spectroscopic Co. Model J-20 for 5 mol dm^{-3} HCl solution by using a 0.1 dm path-length quartz cell.

DL-NL (0.02 mol) and L-Phe (0.01 mol) were dissolved in 35 cm^3 of 1 mol dm^{-3} sodium hydroxide solution and to the alkaline solution containing DL-NL was added 70 cm^3 of water. By adding 1 mol dm^{-3} HCl to the above solution, the pH was adjusted to 5—6 (isoelectric point). Precipitates obtained by stirring the solution for 10 min at 0 °C were collected by filtration. The similar procedure was performed in the case of DL-NL and L-Try. The precipitates were then dissolved in 50 cm^3 of water and active carbon (ten times of samples by weight) was added to the solution. The mixture was shaken at room temperature for 3 h and carbon powders were filtered off. The filtrate was evaporated to dryness at 40 °C under reduced pressure and then the residure was collected. The samples obtained by this procedure were dried in a desiccator and used (denoted as samples NL-A and NL-B) Other procedure for evaporating water from aqueous solution containing DL-NL was also performed. For example, a solution containing equimolar amounts (0.02 mol) of DL-NL and L-Phe in 350 cm^3 of water was concentrated to 180 cm^3 at 60 °C and the precipitates formed were collected by filtration (sample NL-C). A filtrate was again concentrated to 90 cm^3 at 60 °C and the resulting precipitates were collected by filtration (sample NL-D). Separation of free NL from the adduct was based on the adsorption difference between NL and Phe on active carbon.[6]

Results and Discussion

The DSC method for determining optical purity, which is equal to enantiomeric purity is based on phase diagrams.[7] Since α-amino acids, in general have no melting point and enthalpy of fusion, this method is not applicable to the amino acid samples.

In this study, we assume that crystalline amino acid that is racemic compound shows a solid-solid phase transition and that there is no interaction between DL- and D- or L-isomer in crystalline state. The magnitude of optical purity by thermal method, p_{th}, is defined as

$$p_{th} = \frac{\Delta H_t^{DL} - \Delta H_t^{obs}}{\Delta H_t^{DL}}, \quad (1)$$

where ΔH_t^{DL} and ΔH_t^{obs} are the enthalpy of transition of racemic compound and the observed enthalpy of transition of mixture of DL-and D- or L-isomer in amino acids, respectively. The observed enthalpy of transition of amino acid recovered by optical resolution procedure, ΔH_t^{obs}, is expressed as

$$\Delta H_t^{obs} = (1-y)\Delta H_t^{DL}, \quad (2)$$

where y is enantiomer excess.
Equation 2 can be rewritten as

$$\Delta H_t^{obs} = 2x\,\Delta H_t^{DL} \text{ for } 0 \leqslant x \leqslant 0.5, \quad (3)$$

$$\Delta H_t^{obs} = 2(1-x)\Delta H_t^{DL} \text{ for } 0.5 \leqslant x \leqslant 1.0, \quad (4)$$

where x is mole fraction of D- or L-isomer of the amino acid. The correlation between ΔH_t^{obs} and x is schematically shown in Fig. 1.

In fact there is an example of racemic compound

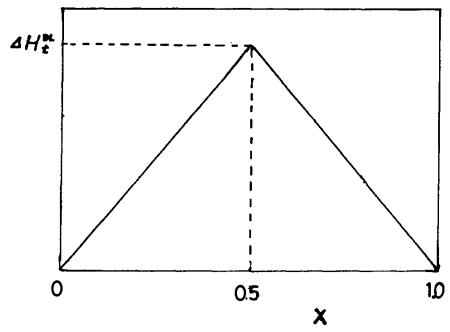

Fig. 1. The correlation between enthalpy of transition, ΔH_t^{obs} and mole fraction of D- or L-isomer, x.

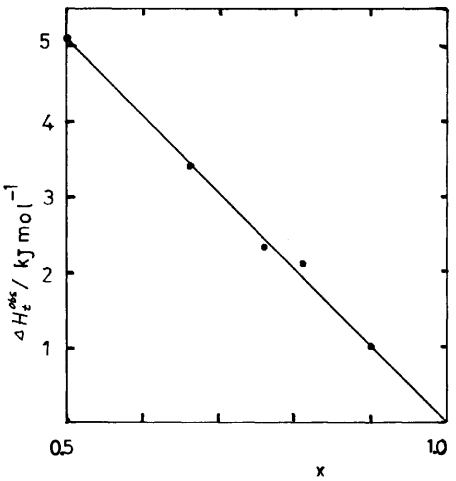

Fig. 2 A plot of enthalpy of transition, ΔH_t^{obs} against mole fraction of D-isomer.

with a solid-solid phase transition.[2,3] The α-form DL-NL is transformed into the γ- form DL-NL at 390 K with the enthalpy of transition of 4.4 kJ mol^{-1} at null heating rate by DSC.[4] To confirm whether Eq. 4 holds in the case of NL, the enthalpy of transition by DSC was determined in the range of mole fraction of D-isomer between 0.5 and 1.0 at a heating rate of 5 K min^{-1}. The results obtained are summarized in Table 1. As is shown in Fig. 2, a plot of ΔH_t^{obs} against mole fraction of D-isomer was found to be linear. We can accordingly calculate the magnitude of optical purity of NL recovered by optical resolution from the enthalpy data obtained for mixtures of known mole fractions without dissolution procedure.

An attempt to resolve aliphatic amino acids by using L-phenylalanine as resolving agent has been introduced by Shiraiwa et al.[5] The results of optical resolution by their method are summarized in Table 2, in which the magnitudes of optical purity by DSC are compared with those by specific rotation. The samples of NL-A and NL-B in Table 2 were recovered by using L-Phe and L-Try as resolving agents, respectively. The samples of NL-C and NL-D were obtained by evaporating water from aqueous solution. The optical purity in Table 2 is the percent optical

purity. As is shown in Table 2, the values of optical purity by DSC agree fairly well with those by specific rotation. Therefore, it is concluded that the method for determining the optical purity based on enthalpy of transition is applicable to the sample of norleucine.

We are grateful to Dr. Kazuko S. Kunihisa of National Chemical Laboratory for Industry for advice in DSC measurements and to Dr. Tadashi Shiraiwa of Kansai University for useful suggestion on optical resolution by adduct formation between aliphatic and aromatic amino acid.

[2π+2σ] and [4π+2σ] Type Cycloaddition Reactions of Furan and Benzofurans with Benzocyclopropene

Katsuhiro SAITO,* Hiraku ISHIHARA, and Shinzo KAGABU†
Department of Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
†Department of Chemistry, Faculty of Education, Gifu University, Yanagido, Gifu 501-11
(Received May 15, 1987)

Synopsis. Reactions of benzocyclopropene with furan and benzofuran afforded [2π+2σ]-type cycloaddition products, where the furans act as 2π-components and benzocyclopropene acts as a 2σ-component. A similar reaction with 1,3-diphenylisobenzofuran gave a [4π+2σ]-type cycloaddition product using the furan as a 4π-component.

It is known that benzocyclopropene (**1**) is a highly strained and reactive species, which is likely to behave as a 6π-donator in [6π+4π]-type cycloaddition reactions,[1] except a reaction with butadiene, where **1** reacts as a 2σ-donator affording a [2π+2σ]-type cycloadduct among many product mixtures.[1b]

While the addition reactions of **1** with various kinds of olefins have been extensively investigated,[1,2] only a few reactions with heterocyclic partners are known. As one part of our research on the cycloaddition reactions of heterocyclic compounds, we investigated cycloaddition reactions of furan derivatives with **1**.[3] Here, the results of these reactions will be reported.

A chloroform solution of furan **2** and an equimolar amount of **1** was allowed to stand at room temperature for 6 days. The separation and purification of the reaction mixture by thin-layer chromatography on silica gel afforded a [2π+2σ]-type cycloadduct **3** in a 39% yield. The reaction of **1** with benzofuran **4**, also gave [2π+2σ]-type cycloadducts **5** in a yield of 25%. On the other hand, the reaction of **1** with 1,3-diphenylisobenzofuran **6** gave a [4π+2σ]-type cycloadduct **7** in a 71% yield.

The structure of **3** was determined on the basis of its spectral, especially ^{1}H NMR spectral properties. The good resemblance of the ^{1}H NMR spectral properties of **3** to those of the analogous compound such as **8** supports the structure of **3**.[4] The orientation of the dihydrofuran moiety in **3** was determined on the basis of the coupling constants in its ^{1}H NMR spectrum as follows. The coupling pattern of the signal of the methine proton H_e shows that the neighbouring protons of H_e are only two methylene protons (H_a and H_b) and a methine proton (H_c). The structure which satisfies the above terms is **3**. Another possible structure such as **9** can not explain the NMR spectral properties. The stereochemistry of **3** was deduced on the basis of the coupling constants in the ^{1}H NMR spectrum as shown in the figure. The structure of **5** was also determined on the basis of its spectral properties, comparing them to those of **3**.

The molecular ion peak in the high-resolution Mass spectrum indicates that **7** is a 1:1 adduct of **1** and **6**. The NMR spectrum shows that **7** is an unsymmetrical compound that has geminal protons. The IR spectrum designates that **7** has no carbonyl or hydroxyl groups, showing that the oxygen atom of **7** is an ether oxygen. These considerations lead to the structure shown in the figure.

The reaction is most likely initiated by the cleavage of a cyclopropene bond in a homolytic fashion to give a diradical intermediate **10**, which attacks the furans to produce the cycloadducts via a diradical inter-

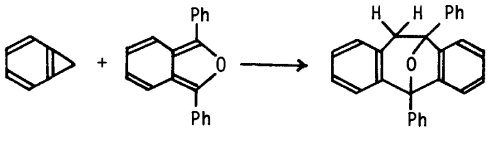
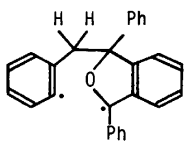
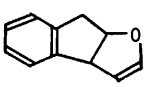
1 10 11



1 6 7



13



12

mediate **11**.[1b] The stabilization of **11** by the delocalization of the radical electron is considered to determine the orientation of the dihydrofuran moiety in the final cycloadduct **12**. The reaction of **1** with **6** is also considered to proceed via the diradical intermediate **10**, which attacks the 1-position of **6** to produce the benzyl radical-type intermediate **13**. The cyclization of **13** keeping the benzene structure in the isobenzofuran moiety, affords **7**.

The same type of reactions of **1** with pyrrole derivatives such as 1-methyl-, 1-phenyl-, and 1-(methoxycarbonyl)pyrrole resulted in a recovery of the starting materials. The difference between the reactivities of furans and pyrroles are considered to be attributable to the difference in the degree of the aromaticity of these two kinds of compounds. It is known that furans are less aromatic than pyrroles because of a strong electronegativity of oxygen atom comparing to that of nitrogen atom.[5] Thus, it is cocluded that less aromatic compounds, furans, react with **1**; on the other hand, the more aromatic compounds, pyrroles, are electronically too stable to react with **1**.

Experimental

NMR spectra were measured with Varian XL 200 or Hitachi R-20B spectrometers with tetramethylsilane as an internal standard. IR spectra were measured with DS-701G spectrometer. Mass spectra were measured with Hitachi M-52 or JMS-DX300 spectrometers. Wako gel B5F was used for thin-layer chromatography.

Reaction of 1 with 2. A mixture of **1** (90 mg, 1 mmol) and **2** (70 mg, 1 mmol) in chloroform (0.3 ml) was allowed to stand at room temperature for 6 days. The reaction mixture was separated by thin-layer chromatography on silica gel using benzene as a developing solvent to give an oil **3** (65 mg, 39%, R_f=0.70).

Oxidation of Aliphatic Secondary and Benzylic Alcohols to Carbonyl Compounds by Peracetic Acid in the Presence of Sodium Bromide in Acetic Acid

Takashi MORIMOTO,* Masao HIRANO, Hiroyuki ASHIYA, Hidetaka EGASHIRA, and Xiumin ZHUANG
Department of Industrial Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received June 10, 1987)

Synopsis. Alcohols were smoothly oxidized by peracetic acid in the presence of sodium bromide to give the corresponding carbonyl compounds in good yields.

The conversion of hydroxyl groups to the corresponding carbonyl groups is one of the most important methods for synthetic chemistry and many procedures have been developed. Many of them are the oxidation using metallic oxidants in amounts ranging from stoichiometric to large excess. However, these oxidants are environmentally hazardous and rather expensive. Thus, a number of catalytic systems including [$RuCl_2(PPh_3)_3$]-*t*-BuOOH,[1] pyridinium dichromate-$Me_3SiOOSiMe_3$,[2] $R_4N^+Br_4MoO^-$-*t*-BuOOH,[3] 2,4-dimethyl-2,4-pentanediol-CrO_3-peracetic acid,[4] and sodium bromate-hydrogen bromide[5] have recently been reported for this purpose. In this paper we report that aliphatic secondary and benzylic alcohols can be smoothly converted to carbonyl compounds in good yields by peracetic acid in the presence of sodium bromide.

Results and Discussion

The reaction of peracetic acid with alcohols was conducted in acetic acid in the presence of sodium bromide. GLC analysis showed that only carbonyl compound and starting material were involved in the product mixture under suitable conditions. Thus, a small excess of the oxidant was used for the completion of the reaction. The results were summarized in Table 1.

$$\text{CHOH} + \text{AcOOH} \xrightarrow[\text{AcOH}]{\text{NaBr}} \text{C=O} + \text{AcOH} + H_2O$$

Benzylic and aliphatic secondary alcohols (Entries 1—8) were converted smoothly to the corresponding carbonyl compounds in good yields by using 10—20% excess of peracetic acid and 0.5—1 equivalent of sodium bromide. The oxidation of hindered aliphatic secondary alcohols was slow and thus the oxidation of terpenoid alcohols (Entries 9—11) required 1.5 equivalent of sodium bromide as promoter and 50% excess of peracetic acid as an oxidant in order to get good yields of the products. Aliphatic primary alcohols were much slowly oxidized to give aldehydes in poor yields. The oxidation in raised temperature was unsuccessful, perhaps due to the self-decomposition of peracetic acid.

In order to clarify a real active species and reaction path of the present reaction, the independent oxidations of benzyl alcohol with peracetic acid, with bromine and also with the combination of these two reagents were carried out, since peracetic acid is a strong oxidant and bromine, which may be formed during the reaction, is also an oxidant. Peracetic acid, itself, could not oxidize the alcohol to benzaldehyde but converted it to benzyl acetate in the absence of sodium bromide. Indeed bromine itself also oxidized the alcohol, but the reaction was considerably slow and resulted in lower yield of benzaldehyde. The combination of peracetic acid with bromine gave the better results (60—70% yield by GLC analysis) but the

Table 1. The Oxidation of Alcohols by Peracetic Acid-Sodium Bromide in Acetic Acid

a) Ca. 0.5 g of substrates were used in every run. b) Isolated yields.

yield was inferior to those by the combination of peracetic acid and sodium bromide. These results may show that the true oxidant for alcohol is acetyl hypobromite which comes from the reaction of peracetic acid with bromide ion or bromine. Acetyl hypobromite has been suggested to be a reacting species for the bromination[6] of aromatic compounds and bromoacetoxylation[7] of olefins by peracetic acid–bromine or bromide ion. Thus, the acetyl hypobromite might be a real active oxidant.

$$AcOOH + AcOH + NaBr \longrightarrow AcOBr + AcONa + H_2O$$

$$AcOBr + \begin{array}{c}\diagdown\\ CHOH\\ \diagup\end{array} \longrightarrow AcOH + HBr + \begin{array}{c}\diagdown\\ C{=}O\\ \diagup\end{array}$$

$$AcONa + HBr \longrightarrow AcOH + NaBr$$

The present reaction may be a useful process of synthesizing simple ketones from the economical and environmental points of view, since the reagents used are cheap, the yields are good and nothing except water and acetic acid is formed.

Experimental

^{1}H NMR spectra were measured for solutions in CCl_4 on a JEOL model PMX-60 spectrometer. IR spectra were recorded for thin film or KBr disk on a JASCO DS-403G spectrophotometer. GLC was carried out on a Shimadzu GC-6A instrument with a 2-m glass column packed with 5% PEG-20M on Chromosorb WAW-DMCS or on a Shimadzu GC-4C instrument with a 2-m glass column packed with 1.5% Silicone OV-17 on Chromosorb WAW-DMCS, with temperature programming.

All reagents were commercially available and were used without purification. Peracetic acid was prepared from 60% hydrogen peroxide and acetic anhydride[7] and the concentration was determined by the iodometry.

Oxidation Procedures. A typical procedure is as follows. Sodium bromide (ca. 0.5 g), alcohol (0.5 g), and acetic acid (3 ml) were placed in a two naked round-bottomed flask, equipped with a dropping funnel and a condenser, the top of which was connected to the argon-filled balloon. After flashing with argon, peracetic acid (2—3 mol dm^{-3}) was added dropwise to the magnetically stirred mixture for a given period and the stirring was continued for an another hour. The reaction mixture was poured into brine (30 ml) and the product was extracted with ether (15 ml×3). Combined ethereal solution was washed with brine, 10% aq Na_2CO_3, and brine and then dried (Na_2SO_4). After filtration, the ether was removed on a rotary evaporator under a reduced pressure to give colorless to pale-yellow oil or solid, which was purified by flash chromatography (silica GLC and hexane–ethyl acetate). Products were identified by ^{1}H NMR and IR spectra. GLC analyses showed that the purities of products were satisfactory.

(Received April 1, 1987)

Synopsis. The conventional solubility parameter was modified so that it could be applied to supercritical fluids. It was found that the parameters could correlate the experimental solubility data of some hydrophobic solutes in carbon dioxide, ethylene, and carbon dioxide-entrainer systems.

Supercritical fluids have the capacity to dissolve nonvolatile and thermolabile materials without denaturalization by several orders of magnitude greater than gases in the standard state.[1-4] However, since the dissolving power is widely variable from one supercritical solvent to another, a supercritical fluid (SCF) method has been a considerable trial-and-error process and, consequently, has required much expenses and time. With the addition of a proper entrainer to supercritical solvents, the extraction efficiency can be enhanced compared to SCF alone in many extraction processes;[5-9] particular attention has been drawn to the effect of entrainer. However, the solubility significantly varies with the entrainer. Therefore, recently a parameter for representing the effect of the entrainer has been desired. The solubility parameter concept[10] has widely been used for many years for interpreting and predicting the thermodynamic behavior of a solution. In recent years, the SCF extraction method has been remarkably noted; for supercritical fluids a similar solubility parameter is expected to be presented.[11]

The purpose of this paper is to extend the conventional solubility parameter concept to SCF with an assumption of random mixing of the spieces present in the mixture and to examine its usefulness in selecting a suitable supercritical solvent and entrainer in the SCF extraction process.

Solubility Parameter for Supercritical State. The basic assumption in the solubility parameter concept is that there is a correlattion between the cohesive energy and mutual solubility. The definition of the solubility parameter δ is in terms of the square root of the molecular cohesive energy, $(-E)$, per unit volume.

$$\delta = (-E/V)^{1/2} \tag{1}$$

$-E$ is the energy of a liquid relative to its ideal vapor at the same temperature. It can, therefore, be considered that $-E$ consists of the energy required to vaporize the liquid to its saturated vapor and, then, to isothermally expand it to infinite volume.

$$-E = \Delta U_v + \int_{v=v}^{v=\infty} (\partial U/\partial V)_T dV, \tag{2}$$

where ΔU_v is the energy to vaparize liquid to saturated vapor. At the critical temperature, the first term in Eq. 2 is zero, and $-E$ can be represented as

$$-E = \int_{v=v}^{v=\infty} (\partial U/\partial V)_T dV. \tag{3}$$

Equation 3 can be modified to express δ more conveniently:

$$-E = (H^*-H) - RT(1-z) = \Delta H - RT(1-z) \tag{4}$$

and

$$\delta = [(\Delta H - RT(1-z))/V]^{1/2}, \tag{5}$$

where H^*, H, z, and R are the standard enthalpy, molar enthalpy, compressibility factor, and gas constant, respectively. ΔH is represented from the thermodynamic relations as follows:

$$\Delta H = RT_c T_r^2 \int_0^{P_r} (\partial z/\partial T_r)_{P_r} dP_r/P_r. \tag{6}$$

ΔH can be also determined using:

$$\Delta E/T_c = \Delta H/T_c - (1-z)RT_r, \tag{7}$$

where T_c, T_r, and P_r are the critical temperature, reduced temperature, and reduced pressure, respectively. Here, the function $\Delta E/T_c$ is available in the literature as functions of T_r and P_r.[12] In addition, to make δ applicable to any solvent, the solubility parameter is expressed in terms of reduced parameters. Thus,

$$\delta_r = [P_r/z(T_r \int_0^{P_r} (\partial z/\partial T_r)_{P_r} dP_r/P_r - 1 + z)]^{1/2}, \tag{8}$$

where δ_r is the modified solubility parameter, $(\delta/P_c^{1/2})$.

Application of Solubility Parameter. Next, we turn to the application of δ_r and examine how δ_r values fit experimental data well. Kurnik[13] has

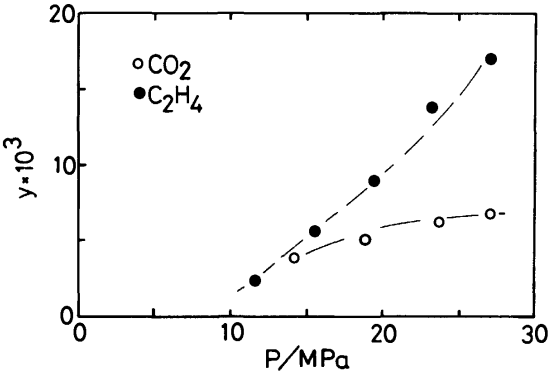

Fig. 1. Experimental solubilities for 2,6-dimethylnaphthalene in supercritical carbon dioxide and ethylene at 318 K.[13]

studied the solubility of 2,6-dimethylnaphthalene in different kinds of supercritical fluids at the same temperature. Figure 1 shows its solubility in supercritical carbon dioxide and ethylene at pressures of 11.6—27.0 MPa and 318 K. This reveals a great difference between carbon dioxide and ethylene in the power of dissolving the solute. The solubility curves for carbon dioxide and ethylene are separated over the range of the pressures examined. The solubility for ethylene increases more rapidly with the pressure than does that for carbon dioxide. These two curves scarcely imply a similarlity to each other.

Figure 2 shows the same solubility data using the modified solubility parameter (δ_r). The data for these two solvents fall on a single line. We have obtained a good correlation between the experimental data and the δ_r. The δ_r was found to be a good parameter for the solubility of 2,6-dimethylnaphthalene.

Recently, higher fatty acids have been noted in terms of their medicinal purposes and their utility as precursors of prostaglandins.[14,15] Therefore, we have examined the extration efficiency of *dl*-α-tocopherol,[16] triolein,[7,8] mixtures of triglycerides,[7,8] higher fatty acid methyl esters[17] on the addition of entrainers to the CO_2. Further, Sako et al. reported[9] the extraction of lipid, which contained γ-linolenic acid(γ-C_{18-3}), from fungi using hexane as an entrainer. Table 1 indicates the enhancement factors in the solubility on the extraction of *dl*-α-tocopherol, triolein, lipid in fungi, mixtures of tristearin and triolein, and stearic-(C_{18-0}), oleic-(C_{18-1}), linoleic-(C_{18-2}), and linolenic (C_{18-3}) acid methyl esters with the addition of several entrainers to the CO_2 at 19.6 MPa. The enhancement factor α is definited as

$$\alpha = C_2/C_2^*, \tag{9}$$

where C_2 and C_2^* are the solubility on the extraction with and without entrainer, respectively. The concentrations of each entrainer in CO_2 are 4 or 10 per cent by weight. As entrainers, ethyl acetate, ethanol, aceone, ether, dichloromethane, and hexane were sued. On the extraction of lipid such as glycerides and fatty acid methyl esters with supercritical carbon dioxide (SC-CO_2), the addition of ethanol and ether decrease the extraction efficiency, but ethyl acetate, hexane, and dichloromethane enhance it.

We think that these effects of the entrainer could be due to a difference in the cohesive energy before and after mixing the CO_2 with the entrainer. The difference is given as energy of dissolution, ΔE_M, using the solubility parameter:

$$\Delta E_M = n_1V_1n_2V_2(\delta_1-\delta_2)^2/(n_1V_1+n_2V), \tag{10}$$

where subscripts of 1 and 2 indicate the solvent and entrainer, respectively, and n is the amount of them fed into the extractor. Furthermore, we modify ΔE_M to make it applicable to any entrainer in the following way. Thus,

$$\Delta E_M' = [n_1V_1n_2V_2/(n_1V_1+n_2V_2)][(\delta_1-\delta_2)^2/(P_{1c}P_{2c})^{1/2}]. \tag{11}$$

The energy per mole of an entrainer is given as $\Delta E_2'$.

$$(\partial\Delta E_M'/\partial n_2) = \Delta E_2' = V_2\phi_1^2(\delta_1-\delta_2)^2/(P_{1c}P_{2c})^{1/2}, \tag{12}$$

where ϕ_1 stands for the volume fraction of solvent. The concentration of an entrainer in the CO_2 is low, and $\phi_1 \simeq 1$.

We use the $\Delta E_2'$ as a parameter for expressing the effect of the entrainer. Figure 3 shows the relation between the enhancement factor α and the $\Delta E_2'$. The values of the α and $\Delta E_2'$ are indicated in Tables 1 and 2, respectively. The $\Delta E_2'$ of these entrainers is found to conveniently express the solubility data under conditions examined. The less $\Delta E_2'$ an entrainer has, the more it can enhance the extraction efficiency. Namely, when the solubility parameter of an entrainer is closed to that of the CO_2, the $\Delta E_2'$ is decreased and the solubility is increased.

On the extraction of lipid such as glycerides or fatty acids with SC-CO_2 under constant experimental

$C_2H_5OC_2H_5$	3.7

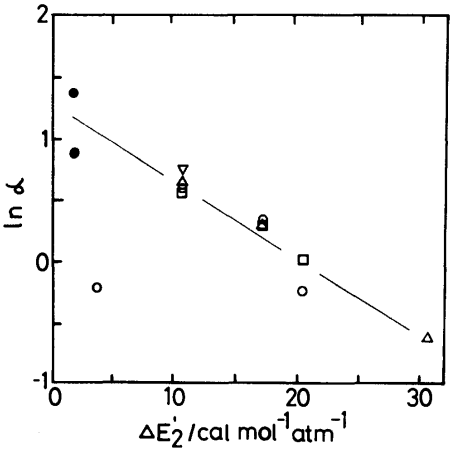

Fig. 3. Relationship between $\Delta E_2'$ and solubilities of lipids and *dl*-α-tocopherol with carbon dioxide-entrainer.[7-9,16,17] (□): A mixture of C_{18-0}, C_{18-1}, C_{18-2}, and C_{18-3} acid methyl esters, (●): lipid containing γ-C_{18-3} acid, (○): triolein, (▽): a mixture of tristearin and triolein, (△): *dl*-α-tocopherol.

conditions, if only we calculate the $\Delta E_2'$ value of the entrainer used, we can determine how much entrainer can enhance the extraction efficiency compared to the CO_2 alone. Furthermore, as shown in Table 1, in such a case that *dl*-α-tocopherol is extracted with the CO_2-ethyl acetate or CO_2-dichloromethane, the extraction efficiency is increased similarly to that of the lipid; a plot of the α against the $\Delta E_2'$ of ethyl acetate or dichloromethane is in agreement with that of the lipid. Therefore, parameter $\Delta E_2'$ might be applicable to the solubility data of not only the lipid but, also other hydrophobic materials. However, at present, the number of the solubility data using entrainers is few; we do not have any distinct evidence whether $\Delta E_2'$ could represent the solubility data using other materials as solutes or in the ranges of other pressures and temperatures. Further, on using ether as an entrainer for the extraction of triolein (Fig. 3), the $\Delta E_2'$ of ether can not represent the solubility data well. A possible reason for this is that there may be some association between ethyl ether and methyl ester molecules, causing the random-mixing assumption to be invalid in this case. We are further examining the adaptability of the parameters for the other extraction systems.

The Influence of Ureas on the Phase-Transition Behavior of the Dipalmitoylphosphatidylcholine Vesicle Membrane

Tohru INOUE,* Kenji MIYAKAWA,† and Ryosuke SHIMOZAWA
Department of Chemistry, Faculty of Science, Fukuoka University, Nanakuma, Jonan-ku, Fukuoka 814-01
†Department of Applied Physics, Faculty of Science, Fukuoka University, Nanakuma, Jonan-ku, Fukuoka 814-01
(Received April 13, 1987)

Synopsis. The gel-to-liquid-crystalline phase transition of the dipalmitoylphosphatidylcholine vesicle membrane was observed in the presence of urea, ethylurea, and butylurea by monitoring the scattered light intensity of the vesicle suspension. Urea showed no significant effect on either the transition temperature, T_m, or the transition width, W, whereas ethylurea and butylurea depressed T_m without affecting W.

In a previous work,[1] we studied the gel-to-liquid-crystalline phase transition of the dipalmitoylphosphatidylcholine (DPPC) vesicle membrane in the presence of surfactants with several types of head group and different hydrocarbon chain lengths. It was found that all the surfactants examined induced the depression of the phase-transition temperature, depending on the surfactant concentration. This depression of the transition temperature was interpreted in terms of the partitioning of the surfactant molecule into the lipid membrane.

In addition to the transition temperature, the transition width was also affected by the addition of surfactants. It was observed that surfactants other than the series of alkanoyl-*N*-methylglucamides (MEGA)[††] increased the transition width and that the extent of the widening depended on the type of head group, but not on the hydrocarbon-chain length in a homologous series of surfactants.

The transition width is a measure of the cooperativity of the phase transition. The widening of the transition width induced by the addition of surfactants was interpreted as resulting from the fact that the surfactant molecules incorporated in the membrane tend to disrupt the interaction between lipid molecules responsible for the cooperativity. The origin of the cooperativity in the phase transition of the lipid bilayer has been attributed to the excluded volume interaction between hydrocarbon chains of lipid molecules.[2] However, the strong dependence of the transition width on the type of hydrophilic group of surfactants added suggests that the inter-head group interaction between lipid molecules also contributes to the cooperativity. Along the lines of this interpretation, it is of interest that MEGA's retain the transition width unaltered; i.e., MEGA's do not perturb the cooperativity. This feature may be attributed not to the electrical neutrality, but to the unique structure of the hydrophilic head group of these surfactants, because hexaethylene glycol monododecyl ether (nonionic surfactant),[1] 1-alkanols,[3,4] and uncharged anesthetic molecules[5,6] also exhibit a broadening effect on the phase transition. The hydrophilic group of MEGA contains both hydrogen-bond-donating and -accepting groups, which are lacking in other additives affecting the transition width. This led to the speculation that the hydrogen bond may play some role in the interaction associated with the cooperativity of the transition.

In order to test the above hypothesis, we have now studied the effects of urea and alkylurea on the phase-transition behavior of the DPPC vesicle membrane. These compounds are typical protein denaturants and have a strong tendency to form hydrogen bonds.

Experimental

The synthetic dipalmitoylphosphatidylcholine (DPPC) was obtained from Sigma. The ultrapure urea and reagent-grade ethylurea (Wako Pure Chemical Industries) and butylurea (99%, Aldrich) were used without further purification. The water was deionized and doubly distilled, once from an alkaline potassium permanganate solution.

The vesicle suspension of DPPC in water was prepared by sonication in the cup-horn of a Branson Sonifier, Model 185, at 45 °C (above the gel-to-liquid-crystalline phase-transition temperature) for about 30 min. The size of the vesicles thus prepared was estimated from the quasielastic light-scattering measurements to be about 160 nm in diameter; considering the size and the phase-transition pattern, these vesicles may be regarded as multilamellar. The sample suspension was prepared by mixing the stock DPPC suspension with the additive solution to give the desired additive concentration and by then sonicating it again at 45 °C for about 5 min. The DPPC concentration was kept at about 5×10^{-4} M[†††] throughout the experiments.

The gel-to-liquid-crystalline phase transition of the DPPC vesicle membrane was followed by means of the scattered light intensity. The details of the procedure were described elsewhere.[1] The measurements were repeated at least three times with a given sample; a good reproducibility was obtained for the transition temperature and the transition width.

Results and Discussion

The transition temperature, T_m, and the transition width, W, of the gel-to-liquid-crystalline phase transition of the DPPC vesicle membrane were measured as functions of the additive concentration. The transition temperature was expressed in terms of

†† 
††† 1 M=1 mol dm^{-3}.

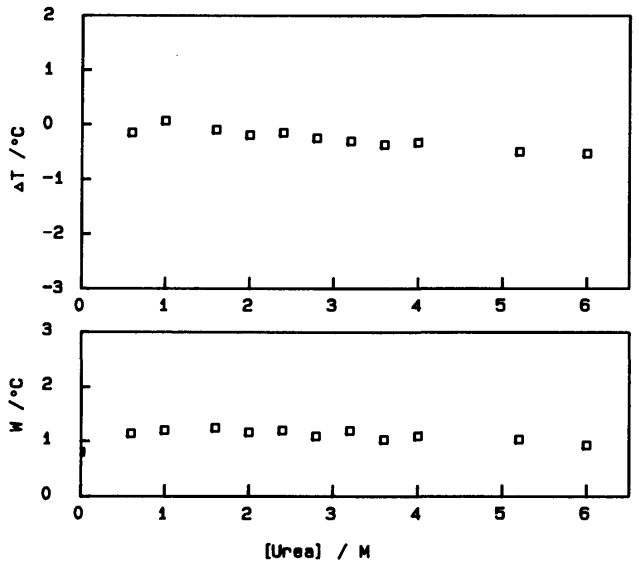

Fig. 1. Effect of urea on the transition temperature, ΔT, and transition width, W, of the gel to liquid-crystalline phase transition of DPPC vesicle membrane. $\Delta T=T_m-T_{m,0}$ where T_m and $T_{m,0}$ are the transition temperatures with and without additives, respectively.

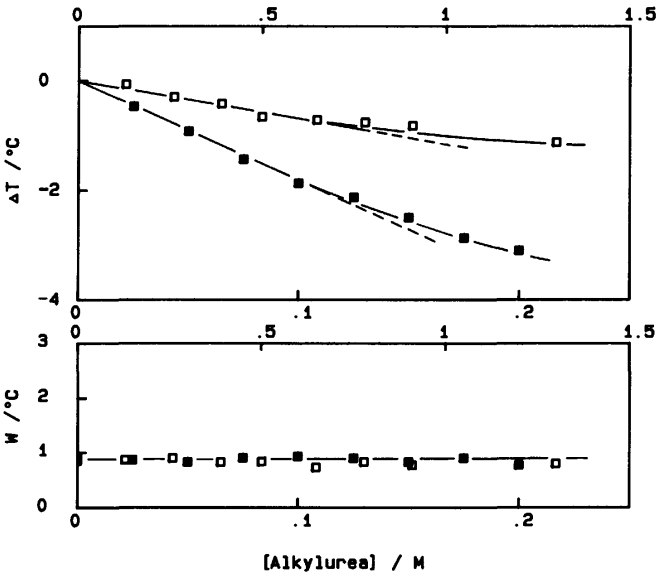

Fig. 2. Effect of alkylureas on ΔT and W of the gel to liquid-crystalline phase transition of DPPC vesicle membrane. □; ethylurea (upper scale) and ■; butylurea (lower scale).

the difference between $T_{m,0}$ (without additives) and T_m (with additives); i.e., $\Delta T=T_m-T_{m,0}$. The results obtained with urea are shown in Fig. 1. Neither T_m nor W is significantly affected by the presence of urea over a wide range of concentrations up to 6 M, although a slight decrease in T_m and a slight increase in W are seen. It is well-known that T_m is generally depressed by the dissolution of small molecular additives in the membrane as a result of an effect analogous to the freezing-point depression. The unaltered T_m suggests that urea is not incorporated into the lipid membrane.

It is believed that urea induces the breakdown of the water structure because of its strong tendency to form hydrogen bonds. Hammes and Schimmel[7] have demonstrated, on the basis of the ultrasonic absorption data in an aqueous urea solution, that the bulk water structure is broken down continuously with an increase in the urea concentration. The almost constant T_m and W values observed in DPPC-urea system indicate that the nature of the vesicle membrane is insensitive to the structure of bulk water with regard to the gel-to-liquid-crystalline phase transition.

The effects of ethylurea and butylurea on the phase-transition behavior are shown in Fig. 2. ΔT decreases linearly with an increase in the concentrations of the additives with the deviation from the linearity in the high-concentration region. On the other hand, W is unchanged by the presence of the additives. This behavior is just the same as that observed in studying the effects of the MEGA-series surfactants.[1]

Previously,[1] we have studied the effects of various surfactant molecules on the phase-transition behavior of the DPPC vesicle membrane; it was found that the transition width was dependent on the type of head group rather than on the hydrocarbon-chain length of the added surfactant. On the basis of this observation, and taking into account the fact that the head groups of surfactants may be located between head groups of DPPC when incorporated in the membrane, it was suggested that, in addition to the excluded volume interaction between hydrocarbon chains,[2] some other interaction between lipid head groups may participate in the cooperativity of the transition. MEGA series surfactants (Ref. 1) and alkylurea (this work) do not affect the transition width (or perturb the cooperativity). The common feature of both types of additives is that the hydrophilic group has a hydrogen-bond-donating group and -accepting group, which is lacking in other types of additives broadening the transition width (or weakening the cooperativity). If we assume that lipid head groups are connected throughout the membrane by the intermolecular hydrogen-bond-donating-accepting system, and that this system is responsible for the cooperativity of the transition, then it is plausible that the connection is broken and, hence, the cooperativity is weakened by introducing additives other than MEGA's or alkylureas. MEGA's and alkylureas may retain the hydrogen-bond system because of their hydrogen-bond-donating and -accepting nature. This may imply that the interaction between lipid head groups in the membrane is not disturbed by the presence of these additives and that, hence, the cooperativity is unaffected by the addition. A hydrogen bond associated with phosphatidylcholine has been reported recently,[8] where it was shown that hydrogen-bonding long-chain compounds form 2:1 complexes with DPPC when both hydrogen-bond-donating and -accepting groups are present.

The direct hydrogen bond between lipid head

groups is unlikely, considering the structure of phosphatidylcholine. It may be speculated that the hydrogen-bond interaction is mediated by water molecules present at the membrane surface. Indeed, it is regarded that the lipid head group in the bilayer dispersed in an aqueous media is fairly strongly hydrated:[9,10] 10—20 water molecules per lecithin molecule.

This work was supported in part by funds from the Central Research Institute of Fukuoka University.

Surface Tensions of Molten Binary $PrCl_3$-NaCl, $PrCl_3$-KCl, and $PrCl_3$-$CaCl_2$ Systems

Kazuo IGARASHI* and Junichi MOCHINAGA
Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Chiba-shi, Chiba 260
(Received April 23, 1987)

Synopsis. The surface tensions of molten binary $PrCl_3$-NaCl, $PrCl_3$-KCl, and $PrCl_3$-$CaCl_2$ systems were measured by a maximum bubble pressure method, and the results were expressed as linear functions of the temperature. The isotherms of surface tension of the $PrCl_3$-MCl (M=Na and K) systems had minimum; however, such behavior was not observed in the isotherm of the $PrCl_3$-$CaCl_2$ system.

An investigation of the surface tension of molten salts is of interest in understanding the characteristics of the melts. The surface tensions of some molten binary RCl_3-MCl (M=alkali metal) mixtures containing rare earth chlorides RCl_3 have been measured by Smirnov and Stepanov,[1] Kurmaev et al.,[2] and Igarashi et al.,[3] but those of molten binary systems containing $PrCl_3$ have not yet been reported. We have already measured the densities,[4] refractive indexes,[5] and electrical conductivities[6] of molten $PrCl_3$-alkali and -alkaline earth chloride mixtures in order to elucidate the physical properties of charge-asymmetric melts. In the present study the surface tensions of molten binary $PrCl_3$-NaCl, $PrCl_3$-KCl, and $PrCl_3$-$CaCl_2$ mixtures were measured.

Experimental

Chemicals. $PrCl_3$ was prepared and purified in the same way as that previously reported.[5] Impurities in the purified $PrCl_3$ were analyzed, their contents being less than 100 ppm.[6] The chemicals NaCl, KCl, and $CaCl_2$ were of analytical reagent grade, and dried with conventional techniques.[7] The prepared mole ratios of mixtures were checked by chelate titration.

Measurement Procedure. In the present study the maximum bubble pressure method was applied for determining the surface tension of melts because of the precision of the measurement at the elevated temperature. As working gas argon was used, which was purified by passing through chemical traps filled with molecular sieves 4A and titanium sponges at 900 °C to remove possible H_2O, N_2, and O_2 contaminations. A manometer filled with *n*-butyl phthalate colored red by a dyestuff was used to measure the pressure of the working gas bubble, which was kept at 30.4±0.1 °C by a circulation of thermostatted water. The temperature of a furnace was raised above the liquidus temperature of the sample according to the phase diagrams[8,9] and kept constant. The temperature of the melts was maintained within ±1 °C with a temperature controller, and measured with a C.A. thermocouple sheathed with a fused silica tube. Pt-10%Rh alloy capillary was used for a creation of bubble. The accurate inside diameter of the capillary tip was determined by the surface tension of distilled water at room temperature. The diameter of the capillary at elevated temperature was corrected by use of the coefficient of thermal expansion for the alloy.[10] The surface tensions of the melts were calculated using Schrödinger's equation[11] giving the relation between bubble pressure and surface tension.

Results and Discussion

The surface tensions of molten pure NaCl, KCl, and $CaCl_2$ obtained were compared with the values recommended by Janz et al.[12,13] Our results yield smaller values than the recommended ones, but the departures are within 1%. There are no data on the surface tension of molten $PrCl_3$ except our data.[3]

The surface tensions of these binary systems in the liquid state were represented as linear functions of temperature, $\gamma=a-bt$, (t/°C). The parameters a and b obtained by the method of least squares are summarized in Table 1. The isotherms of surface tension for the molten $PrCl_3$-NaCl, $PrCl_3$-KCl, and $PrCl_3$-$CaCl_2$ systems at 850, 900, and 950 °C are shown in Figs. 1, 2, and 3, respectively. The isotherm at each temperature of the $PrCl_3$-NaCl system had a minimum at about 60 mol% $PrCl_3$. The minimum was also observed in the isotherm of the $PrCl_3$-KCl system, but the composition in the minimum was recognized to shift to low concentration of $PrCl_3$, i.e., about 30 mol% $PrCl_3$. On the other hand, as can be seen in Fig. 3, the isotherms of the $PrCl_3$-$CaCl_2$ system showed quite different behavior, i.e., the surface tension decreased curvilinearly with a increase of

Table 1. Surface Tensions of Molten Binary $PrCl_3$-NaCl, $PrCl_3$-KCl, and $PrCl_3$-$CaCl_2$ Systems

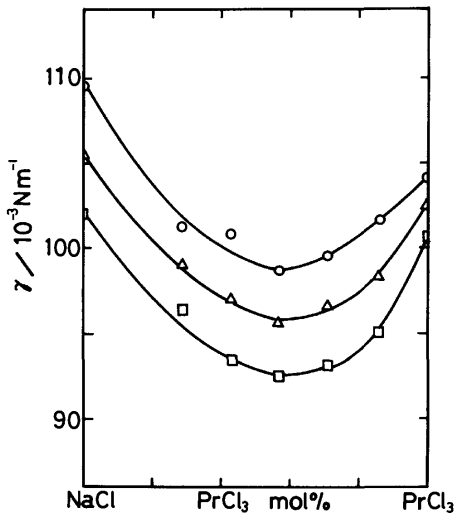

Fig. 1. Isotherms of surface tension of molten $PrCl_3$–NaCl system at 850(○), 900(△), and 950(□)°C.

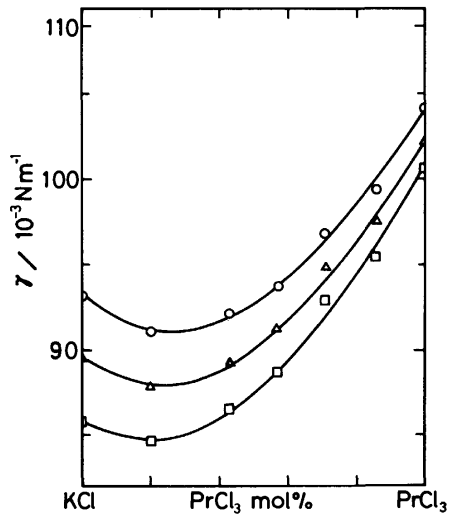

Fig. 2. Isotherms of surface tension of molten $PrCl_3$–KCl system at 850(○), 900(△), and 950(□)°C.

$PrCl_3$ concentration without the minimum. We have measured the surface tensions of molten $LaCl_3$–MCl (M=Na[14] and K[15]) and –$CaCl_2$[14] systems. A similar behavior to the isotherms of surface tension of the $PrCl_3$ systems observed in this work has also been found in the corresponding three $LaCl_3$ mixtures. There are no data available on the structure of molten chloride mixtures containing $PrCl_3$. Fortunately, the structure of molten $LaCl_3$–MCl(M=Na[16] and K[16–18]) and –$CaCl_2$[16] systems has been investigated by Raman spectroscopy. The ionic radius of Pr^{3+} ion is 0.099 nm, which is almost equal to that of La^{3+} ion, viz., 0.1032 nm.[19] From the similarity of the density in valence and the very small difference in ionic radii, 0.004 nm, the structures of the molten $PrCl_3$ systems are expected to be extremely close to those of the corresponding molten $LaCl_3$ systems. In the alkali chloride-rich $PrCl_3$–NaCl and $PrCl_3$–KCl melts, a $PrCl_6^{3-}$ octahedron is thought to be a predominant

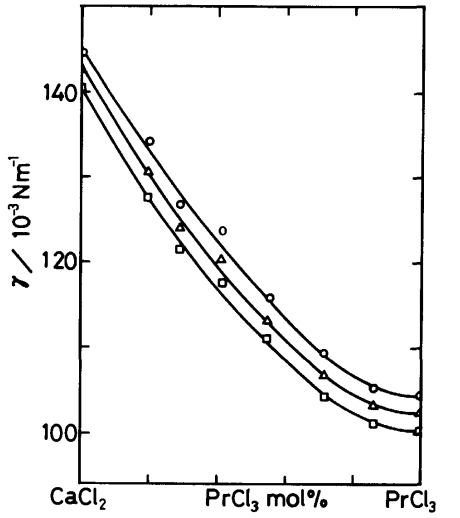

Fig. 3. Isotherms of surface tension of molten $PrCl_3$–$CaCl_2$ system at 850(○), 900(△), and 950(□)°C.

configuration since a similar species is found in the alkali chloride-rich $LaCl_3$–NaCl and $LaCl_3$–KCl melts.[16–18] The complex behavior of the isotherms of the surface tension in both systems seems to be due to such complex species formed in the melts. It has been reported that there exists little such octahedral complex species in the $LaCl_3$–$CaCl_2$ system.[16] The fact implies that the $PrCl_3$–$CaCl_2$ system does not deviate significantly from a cation random mixture. A simple composition change of the surface tension in this system seems to be attributable to such mixing of the melt.

The authors would like to express their sincere gratitude to Mr. Yasuo Saito for assistance in measuring the surface tensions.

First ESR Spectrum of a Selenoaminyl Radical[1)]

Yozo MIURA* and Osamu TSUMORI
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558
(Received May 11, 1987)

Synopsis. *N*-(*o*-Nitrophenylseleno)-3,5-di-*t*-butylphenylaminyl radical, generated by photolysis of *N*-(3,5-di-*t*-butylphenyl)-*o*-nitrobenzeneselenenamide in the presence of di-*t*-butyl peroxide, has been studied by ESR spectroscopy. The ESR parameters are compared with those for the corresponding sulfur analogue.

Thioaminyl radicals (RNSR′) have an interesting structure in which a divalent sulfur attaches directly to the radical center. Our ESR spectroscopic studies on a variety of thioaminyls have shown that they are electronically substantially stabilized by conjugative delocalization of the unpaired electron from the nitrogen to the sulfur,[2)] and that some thioaminyls can be isolated as pure radical crystals or bydrazine-like dimers.[3–5)]

In the extension of these ESR studies our interest was focused on electronically related selenoaminyls (RNSeR′). However, in contrast to a wide ESR study on thioaminyls, there has appeared no ESR report on selenoaminyls in the literature. In this paper we report the first ESR spectrum of a selenoaminyl.

Results and Discussion

Selenenamides are known to be relatively labile owing to the weak N–Se bonds sensitive to hydrolysis;[6)] in particular, the compounds of the type RNHSeR′ are much more labile. This was shown by the repeated failures in obtaining the desired RNHSePh compounds from benzeneselenenyl chloride and RNH_2 (R: alkyl or aryl). However, *o*-nitrobenzeneselenenamide derivatives ($RNHSeC_6H_4NO_2$-*o*) exhibited high stabilities.[6)] That is, the reactions of *o*-nitrobenzeneselenenyl chloride with RNH_2 gave the desired *N*-alkyl- and *N*-aryl-*o*-nitrobenzeneselenenamides (**1**) in 53—67% yields.[7)]

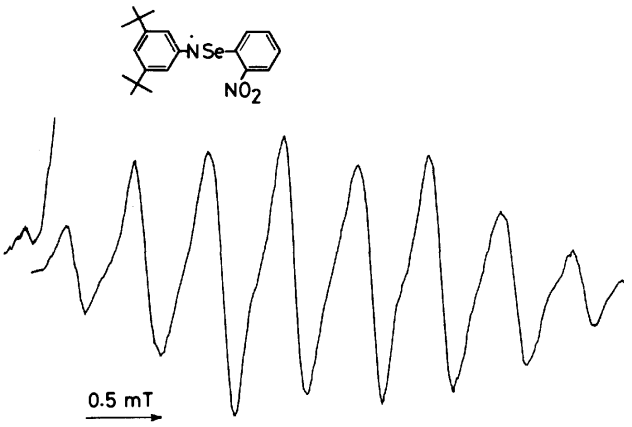

Fig. 1. ESR spectrum of **2a** recorded during photolysis of a solution of **1a** in 1:4 (v/v) di-*t*-butyl peroxide–benzene at 20 °C. The left wing is shown at high gain (5 times), and a satellite line due to ^{77}Se is seen.

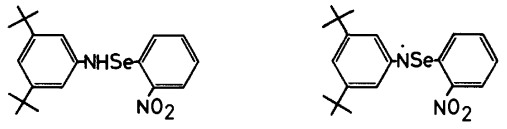
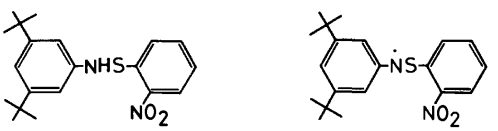


1a **2a**

The generation of selenoaminyl radicals was performed by the photolysis of solutions of **1** in the presence of di-*t*-butyl peroxide. When being irradiated in the cavity of an ESR instrument using a 1 kW xenon lamp, a solution of **1a** gave a 1:3:4:4:4:4:3:1 octet ESR spectrum with a relatively broad line width (peak-to-peak width, ca. 0.14 mT) as illustrated in Fig. 1. This signal, upon interruption of the UV-irradiation, disappeared immediately. In cases of other *o*-nitrobenzeneselenenamides,[7)] no ESR spectra attributable to the corresponding selenoaminyls were found for the solutions in the temperature range −50—20 °C.

The hyperfine splitting (hfs) constants for **2a**, determined by computer simulation, are a_N: 0.972 (1N), a_H: 0.453 (2H) and 0.525 mT (1H). On the basis of the numbers of the equivalent protons we could readily assign these three protons to the anilino ortho (2H) and para (1H) benzene ring protons. Interestingly, upon recording at higher gain a satellite line due to ^{77}Se (I=1/2, natural abundance 7.6%) was found in the left (low field) wing of the parent spectrum (see, Fig. 1). The assignment of this satellite line was made by its intensity ratio to the parent spectrum (experimental value ca. 3%, theoretical 3.8%). The ESR parameters are listed in Table 1.

For a comparison of the ESR parameters, we also prepared *N*-(*o*-nitrophenylthio)-3,5-di-*t*-butylphenylaminyl (**4**), the corresponding sulfur analogue, by oxidation of *N*-(3,5-di-*t*-butylphenyl)-*o*-nitrobenzenesulfenamide (**3**) with PbO_2. The ESR spectrum is illustrated in Fig. 2. This aminyl, in contrast to the very short-lived **2a** radical, persisted over a long period (> a day) in benzene at room temperature and the radical solution showed a green color [λ_{max} (benzene) 590 nm].[3)]



3 **4**

As found in Fig. 1, there is no splitting due to the phenylseleno benzene ring protons. However, the

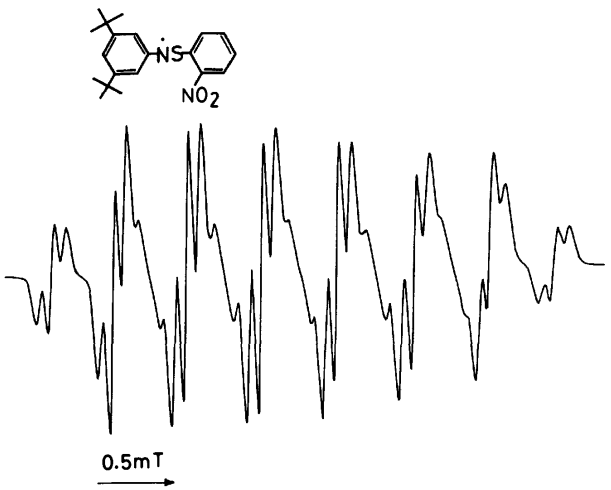

Fig. 2. ESR spectrum of **4** in benzene at 20 °C, generated by oxidation of **3** with PbO_2.

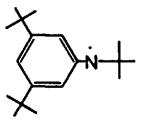
unusually high g value (2.011), as well as the relatively high $a_{^{77}Se}$ value (0.61 mT), is strongly suggestive of a considerable delocalization of the unpaired electron onto the selenium. Because of the large spin-orbit coupling parameter for selenium (1688 cm^{-1}; 382 cm^{-1} for sulfur),[8,9] the delocalization will cause the ESR lines to be considerably broadened.[10] Accordingly, small hfs's will have no effect on the spectrum other than to broaden the ESR lines.

When comparing the ESR parameters for **2a** with those for **4**, one will find some interesting differences in the ESR parameters between them. First, in the spectrum of **4** the hfs's of 0.074 and 0.088 mT due to the phenylthio benzene ring protons are found. On the other hand, in that of **2a** no splitting due to the phenylseleno benzene ring protons was detected. Second, the hfs constants for the anilino benzene ring protons of **2a** are 0.045—0.047 mT higher than those for **4**. These differences in hfs constants strongly suggest the lower ability of the selenium to delocalize the unpaired electron. That is, the dipolar canonical structure **B** seems to contribute less to the resonance hybride of **2a** than does the corresponding dipolar canonical structure **D** to the hybrid of **4**.

A B

C D

On the other hand, when comparing the ESR parameters for **2a** with those for 3,5,*N*-tri-*t*-butylphenylaminyl (**5**)[11] which is substituted at the nitrogen by a *t*-butyl group that has a negligibly small ability to delocalize the unpaired electron, one will note that the anilino benzene ring proton hfs constants for **2a** are substantially lower (0.112—0.188 mT) than those for **5** (see: Table 1). The sums of the spin densities on the ortho and para carbons of each anilino benzene ring ($\sum\rho_{o\text{-and }p\text{-}C}$) of **2a**, **4**, and **5**, derived from Table 1 using Q_H^{CH}=−2.7 mT, are 0.530 (**2a**), 0.479 (**4**), and 0.683 (**5**), these magnitudes being strongly suggestive



5

of the order: sulfur>selenium>*t*-Bu for the ability to delocalize the unpaired electron. This order, however, is not in agreement with the report of Gilbert et al.,[8,10] in which they showed the opposite order: ρ_{Se}^{π} (0.085)>ρ_S^{π} (0.076) based on the Hückel MO calculations with McLachlan's perturbation treatment on phenothiazine and phenoselenazine neutral radicals. The discrepancy seemed to come from the choice of parameters used in their calculations. To confirm this point calculations were performed using the same set of parameters as in the literature[8,10] ($\alpha_N=\alpha+0.8\beta$, $\alpha_S=\alpha+1.25\beta$, $\alpha_{Se}=\alpha+1.21\beta$, $\alpha_{NO_2\text{-}C}=\alpha+0.1\beta$, $\beta_{CN}=1.0\beta$, $\beta_{NS}=\beta_{CS}=\beta_{NSe}=\beta_{CSe}=0.57\beta$, and λ=0.7). In the present calculations the molecules are assumed to be planar. The results of the calculations certainly showed the same order as that of Gilbert, et al.: ρ_{Se}^{π} (0.138)>ρ_S^{π} (0.127). Although, in the above calculations the magnitude of β_{NS} is taken to be the same as that β_{NSe} and the magnitude of β_{CS} is taken to be the same as that of β_{CSe}, these are not physically realistic because of the loss of overlap due to extension of orbitals in the selenium. We think that k_{NS} and k_{CS} (for $\beta_x=k_x\beta$) should be larger than k_{NSe} and k_{CSe}, respectively. From this viewpoint, the magnitudes of β_{NS} and β_{CS} were changed from 0.57β to 0.65β.[12] Recalculations using these modified parameters afforded the order ρ_S^{π} (0.158)>ρ_{Se}^{π} (0.138), which is in agreement with the experimental results. Consequently, we wish to

conclude that the ability of selenium to delocalize the unaired electron is lower than sulfur.

Experimental

Melting points were determined on a Yanagimoto micro melting point apparatus and are uncorrected. IR spectra were run on a JASCO A-202 spectrophotometer. ^{1}H NMR spectra were recorded on a JEOL JNM-PS-100 spectrometer and chemical shifts (δ) are expressed in ppm relative to internal tetramethylsilane.

3,5-Di-*t*-butylaniline[13] and *o*-nitrobenzeneselenenyl chloride[14] were prepared by the reported procedures.

***N*-(3,5-Di-*t*-butylphenyl)-*o*-nitrobenzeneselenenamide (1a).** To a stirred solution of 1.00 g (4.87 mmol) of 3,5-di-*t*-butylaniline and 0.73 g (7.2 mmol) of triethylamine in 200 ml of dry ether was added dropwise at 0 °C a solution of 1.00 g (4.23 mmol) of *o*-nitrobenzeneselenenyl chloride in 50 ml of dry ether. After being stirred at the same temperature for 2 h, the reaction mixture was filtered and evaporated under reduced pressure. The residual red solid mass was crystallized from hexane to afford red prisms: mp 160—162 °C; yield 1.11 g (65%); IR (KBr) 3360 cm^{-1} (NH); ^{1}H NMR ($CDCl_3$) δ=1.25 (s, *t*-Bu, 18H), 5.10 (s, NH, 1H), 6.73—8.40 (m, aromatic, 7H). Found: C, 59.44; H, 6.66; N, 6.92%. Calcd for $C_{20}H_{26}N_2O_2Se$: C, 59.25; H, 6.47; N, 6.91%.

***N*-(3,5-Di-*t*-butylphenyl)-*o*-nitrobenzenesulfenamide (3).** To a stirred solution of 2.00 g (9.74 mmol) of 3,5-di-*t*-butylaniline and 1.5 g (15 mmol) of triethylamine in 100 ml of dry ether was added dropwise at 0 °C a solution of 2.2 g (12 mmol) of *o*-nitrobenzenesulfenyl chloride in 100 ml of dry ether. After being stirred at the same temperature for 2 h, the reaction mixture was filtered and evaporated under reduced pressure. The residual orange powdery solid was subjected to column chromatography (alumina, Merck art 1097) using benzene as eluant, and crystallization from benzene–hexane gave yellow prisms: mp 138—140 °C; yield 2.61 g (75%); IR (KBr) 3400 cm^{-1} (NH); ^{1}H NMR ($CDCl_3$) δ=1.26 (s, *t*-Bu, 18H), 5.09 (s, NH, 1H), 6.78—8.37 (m, aromatic, 7H). Found: C, 66.96; H, 7.28; N, 7.54%. Calcd for $C_{20}H_{26}N_2O_2S$: C, 67.01; H, 7.31; N, 7.81%.

ESR Measurements. Radicals **2** were generated by the photolysis of solutions of 10—25 mg of **1** in 0.20 ml of 1:4 (v/v) di-*t*-butyl peroxide–benzene (or toluene) using a 1 kW xenon lamp. Aminyl **4** was generated by treating 50 mg of **3** in 3 ml of benzene with 2 g of PbO_2. All the solutions were degassed by three freeze-pump-thaw cycles using a high vacuum system. ESR spectra were recorded on a JEOL JES-FE-2XG spectrometer equipped with an X-band microwave unit and 100 kHz field modulation. Hyperfine splitting constants and g values were determined by a comparison with Fremy's salt in an aqueous K_2CO_3 solution (a_N=1.309 mT, g=2.0057). Estimated accuracy for the hfs constants, ±0.01 mT.

We thank Prof. Tadatoshi Ohta and Dr. Hitoshi Tanaka of Tokushima University for making it possible to use the JEOL JES-FE-2XG ESR spectrometer at Tokushima University and for valuable suggestions on the ESR spectra.

Prediction of Mutual Solubility Curve for *t*-Butyl Alcohol-Water System Utilizing Salting Out Phenomenon

Zhang QING-ZHI,* Wang JIAN-JI, Lu YAN, Lu JIN-SUO, and Tadashi KATO†
Department of Chemistry, Henan Teacher's University, Henan, China
†Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158
(Received May 22, 1987)

Synopsis. The consolute temperatures (T_s) for ternary solutions of water-tetrahydrofuran-salt and water-*t*-butyl alcohol (TBA)-salt (salt: ammonium chloride or potassium chloride) were measured. From a plot of T_s against the salt concentration, the mutual solubility curve for the water-TBA system was predicted. The critical solution temperature and the critical composition were estimated to be about 200 °C and 0.15—0.2 (mole fraction of TBA), respectively.

Although *t*-butyl alcohol (TBA) is completely miscible with water, some experimental results suggest the existence of the lower critical solution temperature (LCST) above the boiling pont.[1-4] As is well-known, one of the criteria for an LCST is the relation $T|\Delta S^E| > |\Delta H^E|$, where ΔS^E and ΔH^E are the excess entropy and excess enthalpy, respectively. This relation holds for the TBA-water system.[1,5] Iwasaki and Fujiyama[2] have shown that the concentration fluctuations obtained from light scattering intensities increase rapidly with increasing temperature. This indicates that the system approaches the critical point as the temperature increases. However, the mutual solubility curve itself has not yet been predicted. In the present work, we have attempted to obtain a mutual solubility curve indirectly by utilizing the salting-out phenomenon for the water-TBA system. For a comparison, we have also studied a water-tetrahydrofuran (THF) system whose solubility curve can be measured directly under ordinary conditions.

Experimental

All the reagents used in this work were analytically pure reagent grade and were purified by the conventional method. Water was triply distilled in an all-Pyrex still.

The experimental procedures are summerized as follows.[6,7] Weighed ammounts of water, organic reagent (TBA or THF), and salt were sealed in ampoules. These ampoules were then put into a temperature-controlled water bath whose temperature was increased at a constant rate (about 0.2 °C per minute). The consolute temperature was determined by visual observation.

Results and Discussion

Figures 1—3 show semilogarithmic plots of the consolute temperature (T_s) against the mole fraction of salt (x_3) for ternary solutions of water-THF-ammonium chloride, water-THF-potassium chloride, and water-TBA-potassium chloride, respectively. In each series of measurements, the mole fraction of nonelctrolyte before adding salt,

$$x_2' = \frac{n_2}{n_1+n_2}, \quad (1)$$

was kept constant. Here, n_1 and n_2 are the number of moles of water and nonelectrolyte (THF or TBA), respectively. It can be seen from the figure that T_s^0 decreases with an increase in the salt concentration.

In the water-THF system, the consolute temperature for the salt-free system, T_s^0, can be observed directly under an atmosphere, as is illustrated in Fig. 1. Although the water-TBA system does not have the

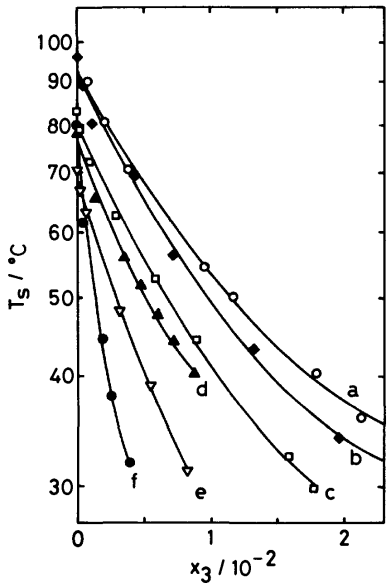

Fig. 1. A semilogarithmic plot of the consolute temperature against the mole fraction of salt for water-THF-ammonium chloride system. a: x_2'= 0.082, b: 0.095, c: 0.116, d: 0.136, e: 0.195, f: 0.364.

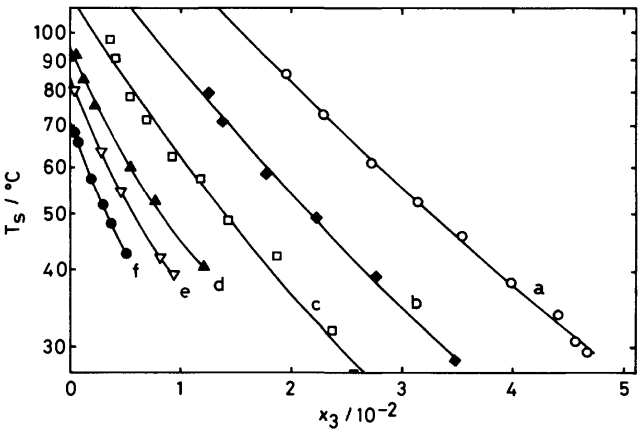

Fig. 2. A semilogarithmic plot of the consolute temperature against the mole fraction of salt for water-THF-potassium chloride system. a: x_2'= 0.035, b: 0.047, c: 0.065 d: 0.087, e: 0.097, f: 0.141.

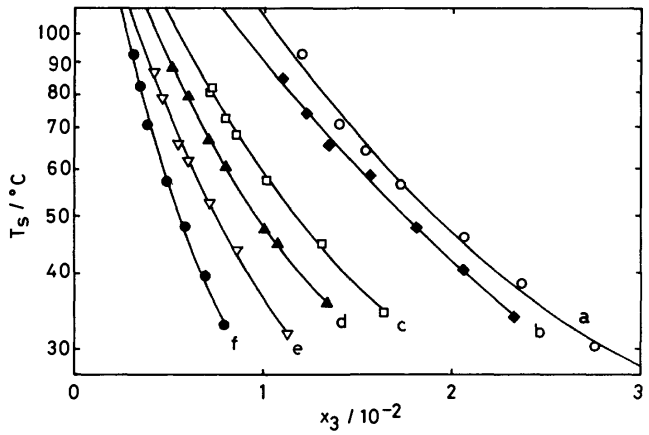

Fig. 3. A semilogarithmic plot of the consolute temperature against the mole fraction of salt for water-TBA-potassium chloride system. a: x_2'= 0.049, b: 0.055, c: 0.097, d: 0.135, e: 0.190, f: 0.267.

LCST under ordinary conditions, the limiting value of T_s as $x_3 \to 0$ may be regarded as the consolute temperature for the salt-free system. As can be seen from Fig. 3, however, it seems difficult to obtain the limiting value uniquely. We therefore have tried to determine an empirical formula for describing the relation between T_s and X_s. It has been found that all the present data can be fitted to the equation

$$\log T_s = a + bx_3 + cx_3^2, \quad (2)$$

where a, b, and c are the fitting parameters. The solid lines in Figs. 1—3 represent the best-fit curves obtained by the least-squares method. The T_s^0 values for the water-THF and water-TBA systems have been calculated from the parameter a (=log T_s^0). It should be noted that the validity of this procedure depends on the applicability of Eq. 2 in the low x_3 region.

In Figs. 4 and 5, the T_s^0 values, thus obtained, are plotted against the mole fraction of THF and TBA (x_2), respectively.[8] The closed circles in Fig. 4 represent T_s^0 values directly observed. It can be seen from the figure that the T_s^0 values obtained from the fitting procedure coinside with the observed values, at least in the range $0.08 < x_2 < 0.4$. This indicates that Eq. 2 can be applied to the THF system at least in the range $x_3 < 0.02$ (see Figs. 1 and 2). We have assumed that the same holds true for the TBA system.[9]

Figure 5 suggests the existence of a minimum in the solubility curve. The LCST and the critical composition are thus estimated to be 200 °C and 0.15—0.2, respectively. Bender and Pecora[10] have obtained concentration dependence of the correlation length by means of dynamic light scattering. They have shown that the correlation length takes a maximum at x_2=0.15 in the temperature range 10—40 °C. The Kirkwood-Buff integral G_{ij} (i, j=1 or 2 for a binary solution composed of 1 and 2) for the water-TBA system have been reported by several authors.[3,11,12] According to these data, G_{12} also takes a minimum at x_2=0.15. These x_2 values are closed to the critical composition estimated in the present work.

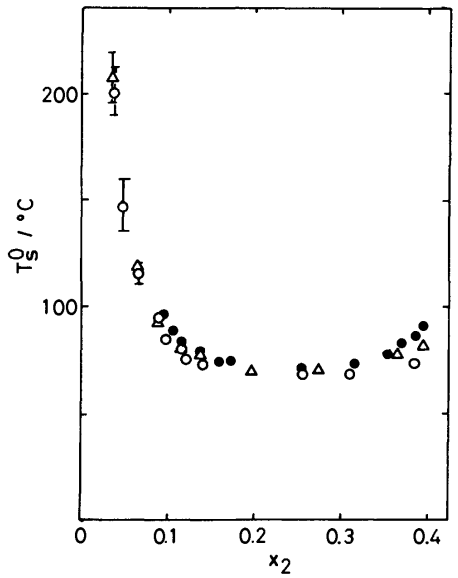

Fig. 4. Mutual solubility curve for water-THF system calculated from log T_s—x_3 plots for water-THF-potassium chloride(○) and water-THF-ammonium chloride(△) systems. Closed circles represent observed values.

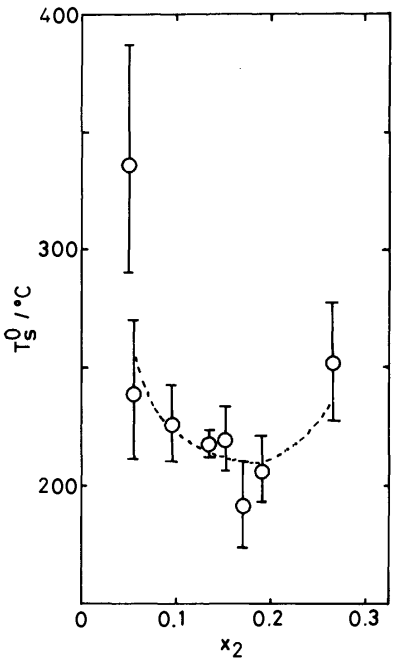

Fig. 5. Mutual solubility curve for water-TBA system calculated from log T_s—x_3 plots for water-TBA-potassium chloride system.

This suggests that the critical phenomenon of demixing dominates the mixing states, even at temperatures some 150—200 °C below the critical consolute temperature.

8) Measurements of T_s were made also at compositions other than those shown in Figs. 1—3.

9) The slight difference between calculated and observed T_s^0 values for the potassium chloride system arises from the lack of data in the low x_3 region. This may cause serious error in the estimation of T_s^0 for the water-TBA system because T_s cannot be observed up to much higher concentration of salt than the THF system. At present, however, it seems difficult to confirm the validity of Eq. 2 for the TBA system.

Re-extraction Behavior of Nitrosyl Ruthenium Complex in Tributyl Phosphate-Dodecane Solvent System

Akira SASAHIRA,* Tatsuo IZUMIDA,* and Fumio KAWAMURA*
Energy Research Laboratory, Hitachi, Ltd., Moriyama-cho, Hitachi, Ibaraki 316
(Received February 10, 1987)

Synopsis. A re-extraction of the nitrosyl ruthenium complex from a tributyl phosphate-dodecane solvent system to a nitric acid solution was carried out. A longer aging of the organic phase before re-extraction lowered the re-extraction yield, while nitric acid extracted into the organic phase increased it. These results could be explained using a model with two organic species.

The extraction behavior of nitrosyl ruthenium has been studied for the past few years[1-7] owing to its presence in spent nuclear fuel. Ruthenium is distributed between the organic and aqueous phases and is a contamination during fuel reprocessing. Tributyl phosphate (TBP) is a common extraction reagent in nuclear fuel reprocessing. The extraction reaction in the system, nitrosyl ruthenium–nitric acid–TBP, was originally proposed as [8]

$$RuNO^{3+}(w.) + mNO_3^-(w.) + nTBP(w.) \rightleftarrows RuNO(NO_3)_m^{(3-m)+}\cdot(TBP)_n(o.), \quad (1)$$

where (w.) and (o.) denote aqueous and organic phases. However, since it was pointed out that complex formation and deformation are very slow,[9] studies concerning the partition coefficients and formation-deformation reaction rate of each complex were necessary. The extraction reaction can be described in the following reaction scheme:

$$RuNO(NO_3)_m^{(3-m)+}(w.) + (m-x)NO_3^-(w.) \rightleftarrows RuNO(NO_3)_x^{(3-x)+}(w.), \quad (2)$$

$$RuNO(NO_3)_x^{(3-x)+}(w.) + yTBP(w.) \rightleftarrows RuNO(NO_3)_x(TBP)_y^{(3-x)+}(w.), \quad (3)$$

and

$$RuNO(NO_3)_x(TBP)_y^{(3-x)+}(w.) \rightleftarrows RuNO(NO_3)_x(TBP)_y^{(3-x)+}(o.). \quad (4)$$

However the only important species is RuNO $(NO_3)_3$, since other anionic or cationic species are less extractable. Further, Prurtt[1] examined the extraction rate of mixtures of nitrosyl ruthenium nitrate complexes and found that the extraction was not completed within 4 hours. It was suggested that the slow extraction is due to a slow conversion of ruthenium complexes in the organic phase, but not the conversion of ruthenium species in the aqueous phase.[2] On the other hand, re-extraction behavior of nitrosyl ruthenium was not examined except for Maya's report.[2] In this paper we report on the effects of the re-extraction period, aging period of the organic phase before re-extraction, and acid concentration of the aqueous phase on the re-extraction rate.

Experimental

Preparation. An acid solution of nitrosyl ruthenium complexes was prepared by dissolving RuNO $(NO_3)_3$ (α-products) in a 3 mol·dm^{-3} nitric acid solution. The acid solution was aged in a dark box for 6 months in order to equilibrate the reactions between the ruthenium complexes, such as in Eq. 2.[4] The acid solution contained 15.7×10^{-3} mol·dm^{-3} of the complexes. A solvent containing TBP was prepared by mixing 3:7 volume of reagent grade TBP and reagent grade dodecane (both Wako Chemical Co.).

Re-extraction. An organic phase containing ruthenium was obtained by the extraction of ruthenium from 20 cm^3 of the aged acid solution using 200 cm^3 of TBP solvent. The extraction was carried out for 5 min in a separatory funnel. The concentration of extracted ruthenium was about 1×10^{-3} mol·dm^{-3}. Then, the organic phase was aged from 5 min to 7 d before re-extraction. Ruthenium was re-extracted from 5 cm^3 of aged organic phase using 5 to 20 cm^3 of fresh aqueous phase containing 1 to 6 mol·dm^{-3} of nitric acid.

Analytical Method. Ruthenium concentration in the aqueous phase was measured by colorimetry.[10] The ruthenium in the organic phase was re-extracted into Na_2SO_3 solution (0.5 mol·dm^{-3}) and measured by colorimetry.

Results and Discussion

First of all, the prepared organic phase was aged from 5 min to 24 h before a 2 min re-extraction into nitric acid solution. Since the nitric acid concentration in the aqueous phase after the extraction was 1 mol·dm^{-3}, ruthenium was re-extracted into nitric acid of the same concentration to avoid changing the acid concentration in the organic phase. The concentration ratio of ruthenium in the organic phase to the aqueous phase is plotted against the aging period before re-extraction in Fig. 1. The ratio increased with the aging period and depended on the volume ratio of organic and aqueous phases. However, a residual factor, R, defined as

$$R = \frac{\text{Organic Ru concentration after re-extraction}}{\text{Organic Ru concentration before re-extraction}}, \quad (5)$$

did not depend on the volume ratio (Fig. 2). This behavior was expected from the two species model.[2] The reaction is written as

$$Ru(s) \underset{k_2}{\overset{k_1}{\rightleftarrows}} Ru(r), \quad (6)$$

where Ru(s) and Ru(r) denote strippable and retained ruthenium species in the organic phase; k_1 and k_2 are rate constants. If the re-extraction period was

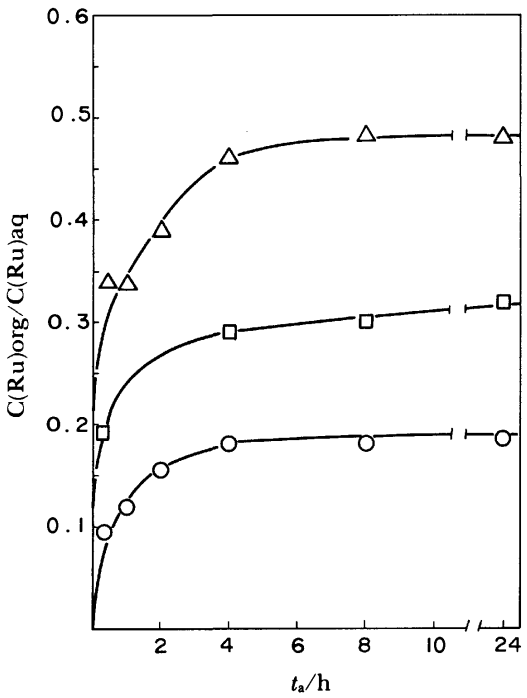

Fig. 1. Variation of ruthenium concentration ratio with organic phase aging period after 5 min extraction denoted as ta.
Aqueous volume/organic volume; △: 1, □: 2, ○: 4. Concentration of aqueous nitric acid was 1 mol·dm^{-3} and re-extraction period was 2 min.

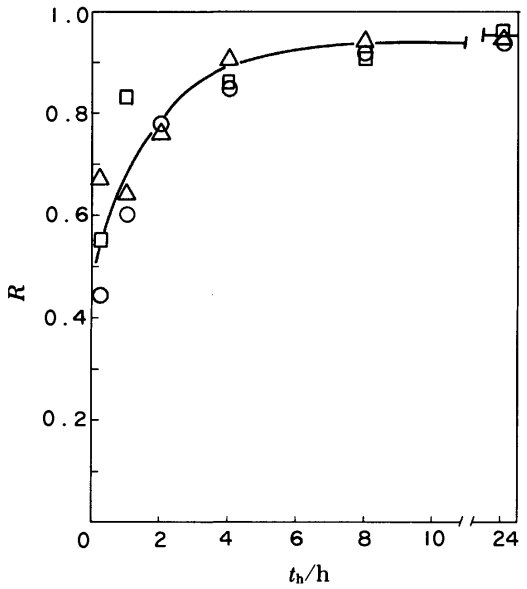

Fig. 2. Variation of ruthenium residual factor in organic phase with organic phase aging period.
Aqueous volume/organic volume; △: 1, □: 2, ○: 4. Concentration of aqueous nitric acid was 1 mol·dm^{-3} and re-extraction period was 2 min.

sufficiently short to avoid conversion between Ru(r) and Ru(s) during re-extraction, the residual factor was equal to the mole ratio of Ru(r) to Ru(s) at the end of

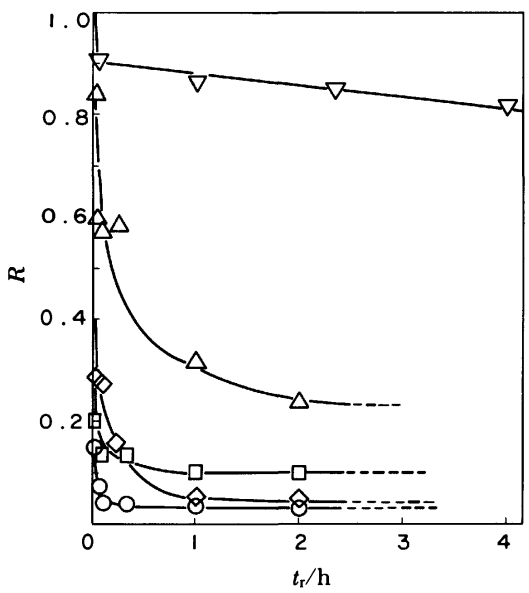

Fig. 3. Variation of ruthenium residual factor in organic phase, aged for 7 d, with re-extraction period denoted as t_r. Concentrations of aqueous nitric acid were ▽: 1, △: 2, □: 3, ◇: 4, ○: 6 mol·dm^{-3}, respectively.

aging. Then, the residual factor was expected to be independent of the volume ratio. On the other hand, the Ru concentration in the aqueous phase was expected to decrease with increasing aqueous phase volume upon dilution. These predictions from this model agreed with the experimental results given in Figs. 1 and 2. Rate constants k_1 and k_2 were calculated from the dependency of residual factor on the aging period by using the rate equation of an "Opposing Reaction."[11] The estimated values of k_1 and k_2 were 5×10^{-1} and 4×10^{-2} h^{-1}, respectively.

Next, the effect of the re-extraction period on the residual factor was measured. The used organic phase was aged for 7 d to equilibrate reaction 6. For a 2 min re-extraction into 1 mol·dm^{-3} nitric acid, the residual factor was equal to that of the organic phase aged 24 h, within the experimental error. The residual factor for re-extraction into 1 to 6 mol·dm^{-3} nitric acid is plotted against the re-extraction period in Fig. 3. For re-extraction into 1 mol·dm^{-3} nitric acid, it was observed that a rapid transfer of ruthenium into the aqueous phase was followed by a slow transfer. The former must be a stripping of species Ru(s) initially existing in the aged organic phase. The latter must be a stripping of Ru(s) formed from Ru(r) during re-extraction. The formation rate constant of Ru(s) calculated from the slope of slow transfer is shown in Table 1 as k(obs.). The calculated value agreed well with the value of k_2. For re-extraction into 2 mol·dm^{-3} nitric acid, ruthenium was transferred much more rapidly. For re-extraction into 3—6 mol·dm^{-3}, the partition equilibrium of ruthenium seemed to be established quickly. The nitric acid, extracted into the organic phase, would enhance the formation reaction of Ru(s) from Ru(r). The rate

Table 1. Rate Constant of Ru(s) Formation Reaction, k(obs.), Estimated from Re-extraction Rate

HNO_3 / mol·dm^{-3}	k(obs.) / h^{-1}
1.0	4×10^{-2}
2.0	9×10^{0}
3.0	$\geqq9\times10^{1}$
4.0	$\geqq8\times10^{1}$
6.0	$\geqq1\times10^{2}$

constants of the formation reaction of Ru(s) on the re-extraction into 2—6 mol·dm^{-3} nitric acid were calculated from the initial slopes of the residual factor versus the re-extraction period, and are shown in Table 1.

The two species model seemed to be a reasonable mechanism for the re-extraction of nitrosyl ruthenium complexes. However, further experiments would be required to clarify the mechanism of the conversion reaction between the two species of ruthenium in the organic phase.

The Magnetic Field Effects on Electrolysis. II.[1] The Anodic Surface Oxidation of Gold

Takeshi WATANABE,† Yoshifumi TANIMOTO,*,†† Ryoichi NAKAGAKI, Mitsuo HIRAMATSU,†††
Tadayoshi SAKATA, and Saburo NAGAKURA
Institute for Molecular Science, Myodaiji, Okazaki 444
(Received April 2, 1987)

Synopsis. In the anodic oxidation of gold in an acidic solution, the electrode surface is covered with a black deposit. It dissolves immediately after the application of an external magnetic field (1 T). The results are discussed in terms of a magnetohydrodynamic mechanism.

In previous work,[1] the magnetic field effects on the electrochemical reduction of hexacyanoferrate(II) and oxidation of hexacyanoferrate(III) were studied by means of potentiometry. It was shown that the magnetic field effects on these redox reactions can be interpreted in terms of a magnetohydrodynamic (MHD) mechanism in which an electrolyte flow near the electrode is affected by an external magnetic field.

In the present paper we report on magnetic field effects on the anodic surface oxidation of gold in an acidic solution.

Experimental

The experimental set-up was essentially the same as that described previously.[1] An electrolytic cell and electrodes were placed between the pole pieces of an electromagnet (Tokin SEE-15). A magnetic field did not affect the potential of a saturated calomel electrode (SCE) used as a reference. One side of a gold plate electrode (5×10 mm) was covered with an epoxide glue. The electrode plate was always kept parallel to the magnetic flux.

Electrolysis was carried out by using a potentio/galvano stat (Hokuto Denko, HA-102). The purest grade sulfuric acid, sodium sulfate, and sodium chloride were used as received. Water was distilled twice before use.

Results and Discussion

Figure 1 shows the potential–current curves of a gold electrode in an acidic solution observed in the absence and the presence of a magnetic field (1 T). An electric current increases with the increasing electric potential and reaches a maximum at 1.2 V, a sudden drop of the current appearing at 1.23 V. By increasing the potential, however, the current again increases. Gas (probably O_2) evolves at higher potentials (>1.4 V).

The anodic behavior of Au in chloride solutions has been reported by several research groups.[2-5] Concerning anodic oxidation of gold in NaCl–H_2SO_4 and KCl–$HClO_4$ solutions,[4,5] the current increase with increasing potential in the range of 1.0—1.4 V was reported to be due to the dissolution of Au:

$$Au + 4Cl^- \longrightarrow AuCl_4^- + 3e^-. \quad (1)$$

Thus, the current increase in the range of 1.0—1.2 V shown in Fig. 1, can be attributable to the Reaction 1 mentioned above. A sudden drop at 1.23 V is due to the formation of a passive oxide and/or adsorbed oxygen film on the Au electrode. In the presence of a magnetic field, the electrolytic current at 1.1—1.2 V increases by about 300% compared with the one in the zero field, as shown in Fig. 1. Judging from the results in a previous paper,[1] this current increase is attributable to the MHD mechanism, since the MHD force is expected to affect the mass transfer near the electrode surface.

Upon electrolysis at an electric potential of about 1.2 V, the surface is covered with a black deposit in the absence of a magnetic field, as reported in the literature.[4] By applying a magnetic field, the black deposit on the surface was found to dissolve, suggesting that the MHD mechanism is operative in the present reaction. In order to make this point clearer, the influence of the orientation of electrode

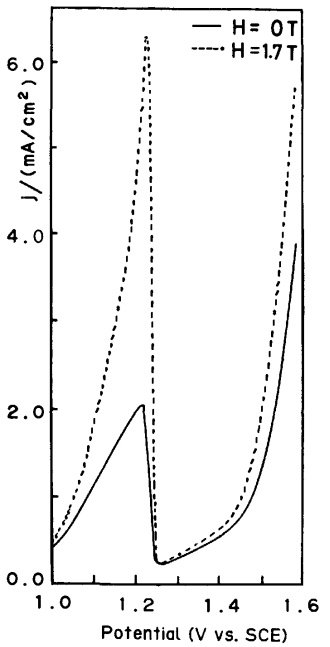

Fig.1 Mangetic field effects on the potential–current curves of the anodic surface oxidation of gold. Concentrations of Na_2SO_4, H_2SO_4, and NaCl are 0.1, 0.05, and 0.01 mol dm^{-3}, respectively.

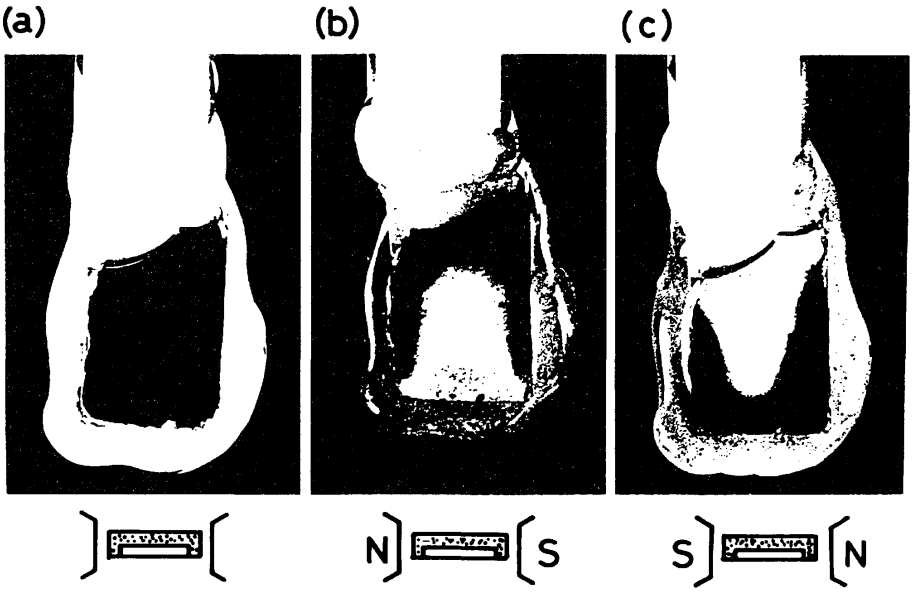

Fig. 2. Magnetic field effects on the deposit on a gold electrode in the absence (a) and in the presence ((b) and (c)) of a magnetic field (1 T). Electrolysis is carried out at 1.2 V vs SCE. Concentrations of Na_2SO_4, H_2SO_4, and NaCl are 0.1, 0.05, and 0.2 mol dm^{-3}, respectively. Top views of two magnetic field orientations with respect to the electrode are also illustrated in the figure. Dotted area indicates the epoxide glue and the rest is the gold electrode.

with respect to a magnetic field on the dissolution of the black deposit was examined.

Figure 2 shows the effects of a magnetic field (1 T) on the black deposit on the Au electrode. In the absence of a magnetic field, the surface of the Au electrode is covered with a black deposit 2—3 min after the start of electrolysis (a). Then, a magnetic field is applied in the direction shown in (b). The deposit immediately starts to dissolve from the bottom of the electrode. On the other hand, when a magnetic field is applied in the opposite direction, as shown in (c), after the electrolysis at zero field, dissolution of the deposit occurs from the top of the electrode.

Electrochemical corrosion and passivation of metal electrodes are affected by various experimental factors such as composition and concentration of electrolyte, current density, pH, and temperature. Taking into account the reports on the deposit on an Au electrode[2,4,6] and others,[7] the black deposit observed in the present study may be a hydrated oxide of Au, though its chemical composition has not yet been determined. According to the literature,[8-10] halogen ions, such as Cl^- and Br^-, attack the oxide film on metal electrodes, resulting in a dissolution of the oxide film. Therefore, the magnetic field effects on the dissolution of the black deposit can be interpreted in terms of the MHD mechanism as described below.

The MHD force $\boldsymbol{F}$ to the electrolytic current $\boldsymbol{j}$ in the magnetic field $\boldsymbol{H}$ can be given by

$$\boldsymbol{F} = \boldsymbol{j} \times (\mu \boldsymbol{H}), \quad (2)$$

where μ is the magnetic permeability. In the orientation of the electrode with respect to the magnetic field shown in Fig. 2 (b), the MHD flow of the electrolyte occurs upward. This means an increasing supply of Cl^- from the bulk solution to the electrode surface, leading to an upward dissolution of the hydrated oxide deposit on the electrode. Similarly, in the orientation shown in (c), the electrolyte flows downward, resulting in a downward dissolution of the deposit.

In the absence of a magnetic field, Cl^- ions are supplied from a bulk solution to the electrode surface by such mass-transport processes as diffusion, convection, and electrophoretic migration. In the presence of a magnetic field, they are further supplied by the MHD flow. This efficient and orientation-dependent mass-transport process is observed as a dissolution of the black deposit (Fig. 2). Furthermore, an enhanced dissolution of the deposit by the MHD flow was also observed as an increase in the electrolytic current in the potential–current curve (Fig. 1).

It is noteworthy that the MHD flow of the electrolyte has no influence on the electrolytic current in the passive state around 1.35 V (Fig. 1). This fact suggests that bonding of the passive oxide film to the metal surface is probably strong, as the passive film might be quite thin.[11,12] On the other hand, the black (hydrated oxide) deposit appearing arround 1.2 V may loosely cover the electrode surface. Therefore, we may conclude that the external magnetic field significantly affects the mass-transport processes near the electrode surface, while it seldom influences those inside the surface. Thus, the present results *visually* demonstrate the importance of the MHD-induced flow for the mass-transport process near the electrode, though quite a few are reported for the magnetic field effects on the electrolytic current.[13]

The Magnetic Field Effects on Electrolysis. III.[1] The Anodic Oxidation of Phenylacetate Ion

Takeshi WATANABE,† Yoshifumi TANIMOTO,*,†† Ryoichi NAKAGAKI, Mitsuo HIRAMATSU,††† and Saburo NAGAKURA

Institute for Molecular Science, Myodaiji, Okazaki 444

(Received April 2, 1987)

Synopsis. In anodic oxidation of the phenylacetate ion, the formation yield of benzaldehyde increases by about 40% in the presence of a magnetic field (0.67 T), while 1,2-diphenylethane is insensitive to the field. The results are interpreted in terms of the magnetohydrodynamic mechanism.

In previous studies,[1,2] we have investigated external magnetic field effects on inorganic electrochemical processes and demonstrated that the magnetohydrodynamic (MHD) effect plays an important role in redox reactions. In the MHD mechanism, a flow of electrons and ions is affected by an external magnetic field, resulting in the perturbation on the mass-transport process near the electrode. As an extention of the above-mentioned investigation, we have studied the magnetic field effects on organic electrochemical processes.

In the present paper, we report on the magnetic field effects on the electrolysis of the phenylacetate ion, as an example of the Kolbe reaction, which may be preparatively useful.

Experimental

Phenylacetic acid was prepared by the hydrolysis of ethyl phenylacetate,[3] and was purified by recrystallization. Solvents for high-performance liquid chromatography (HPLC) grade, methanol, dioxane and water, were used as received.

The electrolysis was carried out using a potentio/galvano stat (Hokuto Denko, HA-102). An aerated methanol-dioxane solution (50 ml), containing phenylacetic acid (0.05 mol dm^{-3}) and its potassium salt (0.05 mol dm^{-3}), was electrolyzed between two platinum plate electrodes (5 mm×10 mm) at a constant density of 9 mA cm^{-2} for about 90 min (0.1 F mol^{-1}). Argon or oxygen gas was bubbled through the solution during the electrolysis, when necessary. A magnetic field was applied with an electromagnet (Tokin SEE-10).

The reaction products were analyzed on an HPLC apparatus (Waters model 590 liquid chromatograph) and a UV detector (Waters 481 LC-spectrophotometer). The products were identified from the agreement of their UV absorption spectra and retention times with those of authentic samples, by monitoring the absorbance at 260 nm.

Results and Discussion

Figure 1a shows a typical chromatogram of the reaction mixture obtained by electrolysis in the absence of a magnetic field. The five peaks in the chromatogram have been identified as benzaldehyde (PhCHO), benzyl methyl ether ($PhCH_2OCH_3$), toluene ($PhCH_3$), benzyl phenylacetate ($PhCH_2COOCH_2Ph$), and 1,2-diphenylethane ($PhCH_2CH_2Ph$), though the other two peaks with retention times of 10.2 and 16.8 min remain unidentified. Figure 1b shows the effects of a magnetic field (0.67 T) on the product yields. In the presence of a magnetic field, the yield of benzaldehyde increases by about 40%, while those of 1,2-diphenylethane and others are insensitive to the magnetic field (summarized in Table 1).

The electrolysis of substituted phenylacetate ions in methanol was studied in detail by Coleman et al.[4] According to their proposed mechanism, the plausible

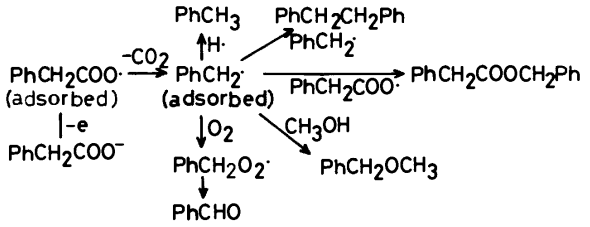
pathways of the present reaction could be summarized as follows:



The benzyl radical generated via the phenylacetoxy radical by the one-electron oxidation of phenylacetate ion, undergoes the following reactions: coupling of radicals and an addition of molecular oxygen. Benzaldehyde could result from the addition of oxygen to the benzyl radical.[5)] The oxygen involved in the reaction could be either dissolved oxygen or oxygen produced electrochemically from the hydroxide ion.

In order to clarify the role of molecular oxygen in the benzaldehyde formation, electrolysis was carried out under two extreme conditions. In the electrolysis under the argon bubbling, the yield of benzaldehyde slightly decreased (≈15%), while that of 1,2-diphenylethane remained unchanged on the removal of dissolved oxygen by argon. On the other hand, in a reaction under oxygen bubbling, a significant increase (≈20 times) in the yield of benzaldehyde was observed in a concomitant decrease (70—80%) in that of 1,2-diphenylethane. These observations indicate that the dissolved molecular oxygen is responsible for the formation of benzaldehyde in aerated solutions. In argon-bubbled solutions, the molecular oxygen produced electrochemically from the hydroxide ion could be a major source of molecular oxygen in benzaldehyde formation.

In a previous study,[1)] the external magnetic field effects on electrolytic currents in hexacyanoferrate(II) and hexacyanoferrate(III) solutions were investigated under various conditions by means of potentiometry. All the results were interpreted in terms of the MHD mechanism, in which a flow of electrolyte is affected by a MHD force $\boldsymbol{F}$ with the relation $\boldsymbol{F}=j\times(\mu\boldsymbol{H})$, j, μ, and $\boldsymbol{H}$ being the electrolytic current density, the magnetic permeability, and the magnetic field, respectively. Furthermore, it was demonstrated that, in electrochemical oxidation of gold, a MHD-induced flow even causes a visual change in the color of the electrode surface, in addition to that in the potential-current curve.[2)] Taking the above-mentioned observations into account, the magnetic field effects on the present oxidation reaction can mostly be interpreted in terms of the MHD mechanism. The mass-transport from the bulk solution to the electrode surface occurs via diffusion, convection, and electrophoretic migration in the absence of a magnetic field. In the presence of a magnetic field, a MHD-induced flow of electrolyte opens a new and efficient process of mass-transport from the bulk solution to the electrode. In the present electrolysis of phenylacetate ion, the reaction between benzyl radical and dissolved molecular oxygen is responsible for the formation of benzaldehyde. Thus, in a presence of a magnetic field, the supply of molecular oxygen from the bulk solution to the electrode surface can be improved because of the MHD flow. This results in the acceleration on the reaction of benzyl radical and molecular oxygen to yield benzaldehyde on the electrode surface. An effort to measure the magnetic field effects on the potential-current curve of the present solution was failed because of its high impedance (typically ≈20 V cm^{-1}).

An external magnetic field is expected to decrease the yields of the coupling products, which are formed via the competing paths with the benzaldehyde formation. However, no effects were detected concerning the yield of 1,2-diphenylethane and other coupling products, as shown in Table 1. In the present current conditions (9 mA cm^{-2}), benzaldehyde could be a minor product, since the relative yields of 1,2-diphenylethane, benzyl methyl ether, and benzaldehyde were reported to be 1:0.48:0.12 at the current density of about 7 mA cm^{-2}.[4)] Therefore, magnetic-field-induced change of benzaldehyde yield does not influence appreciably those of the coupling products because of the material balance.

The external magnetic field effects on photochemical and thermal reactions have been interpreted in terms of the radical pair model, in which triplet and singlet intersystem crossing of a radical pair, a short-lived intermediate, is affected by a magnetic field.[6)] Magnetic field effects due to a radical pair mechanism might be effective in the present reaction, since the coupling reaction of radicals, such as benzyl radicals, on the electrode could proceed via the radical-pair intermediate. However, we could not observe any appreciable magnetic field effects on the yield of 1,2-diphenylethane. The rate-determining step for the present coupling of radicals adsorbed on the electrode might not be the intersystem crossing in the radical pair, since the diffusion of adsorbed radicals on the electrode could be quite slow. Otherwise, the intersystem crossing might be accelerated by a magnetic-field-independent path, i.e., the spin-orbit interaction,[7,8)] since the radical pairs (radicals) are strongly adsorbed on the platinum electrode.

To our knowledge, this is the first report of the

magnetic field effect in organic electrochemistry, though a large number of papars have been concerned with inorganic electrochemistry.[1,2,9-11] We believe that the present finding demonstrates the applicability of an external magnetic field effect to the mechanistic study of organic electrochemistry.

(Received May 23, 1987)

Synopsis. The stoichiometries of alkali and alkaline earth metal complexes with macrocyclic ligands were determined in a water-containing nitrobenzene solution by means of ^{1}H NMR. The chemical shift of the water protons was more sensitive to the complexation than that of the methylene protons of the ligands.

In early papers,[1-5] we showed that alkali and alkaline earth metal cations exist as hydrated state in a water-containing nitrobenzene solution and, when these cations undergo complexation with macrocyclic ligands, the water molecules attached to the cations are partially or almost fully released. These findings suggest that the equivalence point of the complexation may be detected by observing the chemical shift of the water protons as a function of the ligand concentration. The stoichiometries of unsubstituted 12- to 18-membered crown ether complexes with the alkali and alkaline earth metal cations have been determined by means of ^{1}H NMR.[6] In this paper, the usefulness of the method was confirmed with macrocyclic ligands, such as 21-crown-7 (21C7), 24-crown-8 (24C8), 4,7,13,16-tetraoxa-1,10-diazacyclooctadecane (C22) and 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane (C222).

Experimental

Materials. 21C7 was synthesized according to the method of Dale and Kristiansen.[7] The crude product was adsorbed on a cation-exchange column (Amberlite CG 120) connected to an anion-exchange column (Amberlite IRA-400, Rohm & Haas) and then eluted by water. Colored impurities were also removed by the deionization process. Evaporation of the solvent under reduced pressure left a viscous residue. The substance was dissolved in a small quantity of acetonitrile and then cooled in a refrigerator. The resulting crystalline 21C7-acetonitrile complex was decomposed under vacuum for at least 12 h at room temperature. The 21C7 thus obtained was ^{1}H NMR spectroscopically pure. 24C8 was synthesized in the same way. C22 and C222 (Merck) were used without further purification.

The alkali and alkaline earth metal salts with 2,2′,4,4′,6,6′-hexanitrodiphenylamine (HND) were prepared as described previously.[6] The Li, Sr, and Ba salts contained 4 molecules of water of crystallization, the Ca salt 11, and the K, Rb, and Cs salts contained none.

For ^{1}H NMR measurements, solutions were prepared by dissolving weighed ligands and salts into deuterated nitrobenzene (99%, Merck), the water content being adjusted by adding a certain amount of water-saturated nitrobenzene. The K, Rb, and Cs salts were made $(2.5—4.0)\times10^{-2}$ mol dm^{-3} solutions and the others $(1.5—5.0)\times10^{-3}$ mol dm^{-3} solutions. The ligands were made about 0.8 or 0.04 mol dm^{-3} solutions; the concentrated solutions were used for the titration of the concentrated salt solution.

NMR Measurements. To an NMR tube, 400 μl of the salt solution was transferred and the chemical shift of the water proton was measured on a Hitachi FT-NMR R600 (60 MHz) spectrometer. A 5 μl-aliquot of a ligand solution was added to the solution and mixed well on a vibrator-type mixer. The chemical shifts of both the water proton and the ligand protons were measured. The measurements were repeated until the ligand/cation mole ratio increased to about 2 or 3. Tetramethylsilane was used as internal standard. The chemical shifts were reproduceced within 0.4 Hz. All the measurements were carried out at 25 °C.

Results and Discussion

^{1}H NMR Spectra. The chemical shift spectra for Ca^{2+}–C222 at different ligand/cation mole ratios are shown in Fig. 1. The spectrum of the free ligand (**0**) consisted of a triplet due to $-OCH_2-$ (about δ 3.6), a triplet for $-NCH_2-$ (about δ 2.6), and a singlet for $-OCH_2CH_2O-$ (δ 3.7). A peak at δ 2.5 may be due to residual water in the solvent. Resonance signals centered at about δ 8 are due to the aromatic protons of undeuterated nitrobenzene. The spectrum of a water-containing ligand-free $Ca(HND)_2$ solution (**1**) consisted of two singlets (water and aromatic protons of HND at δ 3.2 and 8.8, respectively). Addition of the ligand to this solution resulted in a strong upfield shift of the water protons (from δ 3.2 in **1** to 3.0 in **2**

([C222]/[Ca^{2+}]=0.5)) and a strong downfield shift of the methylene signals due to complexation (from δ 2.6 and 3.6 in **0** to δ 3.2 (weak) and 4.2 in **2**, respectively). As the titration proceeded, the water signal continued to shift upfield until the equivalence point (**3**, [C222]/[Ca^{2+}]=1) was reached, but the signals of the complexed ligand showed virtually no shift. The further addition of the ligand caused a downfield shift of the water signal and a slight upfield shift of the signals of the complexed ligand (**4**, [C222]/[Ca^{2+}]=2). It was noted that, in spectrum **4**, the free ligand signals reappeared at δ 2.6 (not clear) and 3.6; the reappearance of the free ligand signals in the presence of excess ligand, however, was observed only with Sr^{2+}- and Ba^{2+}-15C5.

The spectral changes for C22 complexes were quite similar to those of C222. Uncomplexed 21C7 and 24C8 each gave a sharp singlet at δ 3.7 and their signal-shift patterns due to complexation were almost identical with those of 12- to 18-membered crown ethers.[6] Concerning the shift patterns, we found no fundamental difference between the 12- to 24-membered crown ethers and the nitrogen-containing macrocycles.

The magnitude and direction of the signal shifts for Ca^{2+}–C222 can clearly be seen from Fig. 2a, where curve W denotes the shift of the water signal and curve L, that of the ligand signal (-OCH_2CH_2O-). Hereafter, the signal shift measurements for C22 and C222 were made on this signal because of the ease of the measurements. Some typical shift patterns are shown in Figs. 2 (b,c) and 3 (a,b,c).

Curves W always exhibited a single break point at [L]/[M]=1, indicating the formation of 1:1 (M:L) complexes in the solution. There were, however, a few cases in which curves L lacked a break point. The curve W for Ca^{2+}–21C7 exhibited two break points at [L]/[M]=1 and 2 (Fig. 2b); the curve L, however, showed no break point at [L]/[M]=2. The curve L for Rb^{+}–C22 (Fig. 2c) lacked a break point. The same observation was true for K^{+}–C222 (Fig. 3b). The C222 signal (Fig. 3a) shifted upfield as the titration proceeded. The upfield shift was characteristic of all the complexes formed between small cations and ligands having a relatively large cavity. The water signal in Fig. 3c exhibited no shift until the equivalence point was reached; this was the case with Cs^{+}–C222 alone.

Chemical Shift of Water Protons. The complexation between hydrated cations and macrocyclic ligands can simply be represented as follows:

$$M(H_2O)_i + L \rightleftharpoons M(H_2O)_jL + (i-j)H_2O \quad (1)$$

$$kH_2O + L \rightleftharpoons L(H_2O)_k \quad (2)$$

where $i>j$. Two types of water molecules, i.e., cation- or ligand-bound and free, are present during the course of the titration. Based on the fast proton exchange between the bound and free water molecules, the water signal gave only one population-averaged peak. The population of the free water increases with the ligand concentration (Eq. 1). The characteristic upfield shift of water protons before the equivalence point can be explained by taking into account that the free water resonates at a higher field than the bound water. The downfield shift beyond the equivalence point can likewise be accounted for by a decrease in the free water (Eq. 2).

Table 1. [L]/[M] Values at the Break Points for the Alkali Metal Complexes

Ligand	Signal	Li^+	Na^+		K^+	Rb^+	Cs^+
12C4[a]	L[b]	1.00	0.88	2.02	0.96	0.97	1.03

	W	0.98		0.99		0.96	
C22	L	—		1.09		0.97	
	W	0.99		0.99		0.98	
C222	L	1.02		0.99		1.05	
	W	1.00		1.00		0.99	

a) Revised from the data in Ref. 7; a few were redetermined. b) Ligand signal. c) Water signal. d) The symbol "—" indicates the lack of a break point.

It follows from the above discussion that the [L]/[M] ratio at the break point represents the stoichiometry of the complex in solution.

Usefulness of the Water Signal. The curves W were always V-shaped, exhibiting at least one break point; this has enabled sensitive and accurate stoichiometry determination. On the other hand, the curves L were mostly less sensitive and, for some complexes, completely insensitive to the complexation. It can, therefore, be concluded that the water signal is used to advantage in determining the stoichiometries of macrocyclic complexes.

Stoichiometries of the Complexes. The [L]/[M] ratios at the break points are summarized in Tables 1 and 2, together with the revised ones for 12C4, 15C5, and 18C6. The data obtained were all consistent with those reported by others.[8] As regards the present experiments, 1:1 complexes were found for all complexation systems. 1:2 complex was found only for Ca^{2+}–21C7.

Crystal and Molecular Structure of Bis(benzylamine)bis(thiocyanato)-cadmium(II), $[Cd(SCN)_2(C_6H_5CH_2NH_2)_2]$

Masahiro TANIGUCHI* and Akira OUCHI
Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received May 23, 1987)

Synopsis. The crystal and molecular structure of the title complex was determined by means of a single-crystal X-ray diffraction method. A crystal of $CdC_{16}H_{18}N_4S_2$, F. W. 442.8, is monoclinic, with the space group of $P2_1/n$, a=27.390(19), b=5.7709(8), c=5.8733(9) Å, β=90.35(3)°, U=928.3(7) Å^3, Z=2, D_m=1.57(3), D_x=1.58 Mg m^{-3}, and μ(Mo $K\alpha$)=1.59 mm^{-1}. The cadmium(II) atom is hexa-coordinated being ligated with two thiocyanato (SCN) sulfur atoms, as well as with two SCN and two benzylamine nitrogen atoms, where the respective pairs of the same kinds of atoms are all in trans-configuration. Each cadmium atom is at the center of symmetry, and the coordination structure around the atom is symmetric. The metal atoms are lined along c-axis, and the pair of the neighboring metal atoms are doubly bridged by SCN ions, although the bridges are a little weaker than the other same type adducts.

There are already several structural reports about the Lewis-base (L) adducts of cadmium(II) thiocyanate, $Cd(SCN)_2L_2$, where L is 1-, 2-, or 3-methylpyridine,[1,2] dibenzylamine,[3] 2-imidazolidinethione,[4] or 1*H*-1,2,4-triazole.[5] In all of them, the octahedrally coordinated cadmium(II) complex cores are laid linearly, and each pair of the neighboring metal atoms are doubly bridged by the thiocyanate (SCN) ions.

This time, we could obtain the same type adduct of benzylamine (bza), $Cd(SCN)_2(bza)_2$, and it was thought to be interesting to clarify its structure due to the reasons as follows. First, how is the direction of the benzene rings of the ligands in the crystal? Although their benzene rings can rotate around the methylene-carbon atom, even in the complex molecule, they must be laid regularly in the crystal to attain the closest packing in it. Therefore, what kind of the arrangement of the rings is adopted there, or whether the π-electron interaction due to the overlapping of the benzene rings exists or not, are interesting problems. Secondly, a preliminary test has shown that the crystal has a unit cell in which only the a-axis is very long, while the other two axes are short; why such long and short periodicities in the crystal take place? Thirdly, to better clarify the character of this type of the double SCN bridging, it is necessary to add more data about the complexes with the bridge.

From these points of view, we determined its crystal and molecular structures by the single-crystal X-ray diffraction method.

Experimental

Synthesis of Bis(benzylamine)bis(thiocyanato)cadmium-(II). Cadmium(II) thiocyanate (0.57 g, 2.5 mmol) was dissolved into 20 cm^3 of methanol; benzylamine (0.53 g, 5 mmol) dissolved into 10 cm^3 of methanol was added to it, and mixed. The mixed solution gradually became turbid and precipitation started soon. After being left standing about 30 min at ambient temperature, the deposited crystals were filtered off, washed with acetone, and dried in open air. Yield, 1.0 g (90%). Found; Cd, 25.37; C, 43.07; H, 4.03; N, 12.57%. Calcd for ($CdC_{16}H_{18}N_4S_2$) Cd, 25.38; C, 43.39; H, 4.10; N, 12.65%.

Single Crystal X-Ray Structure Analysis. The colorless crystal used for the structure determination was 0.3×0.3×0.15 mm^3 in size, and was used without shaping. The intensities in the range of $3<2\theta<60°$ (2θ) were collected on a Rigaku AFC-6A automated four-circle X-ray diffractometer using graphite monochromated Mo $K\alpha$ radiation (λ=0.71073 Å), by means of ω-scan technique (scan speed 4° min^{-1}; scan width 1.08° (θ)). The intensities were corrected for Lorentz and polarization factors, but no corrections were made for absorption and extinction. Of 3667 independent intensities collected, 2273 with $|F_o|>3\sigma(|F_o|)$ were used for the structure determination.

All the calculations were carried out on a HITAC M-680H computer at the Computer Center of the University of Tokyo, using UNICS III.[6] The scattering factors were taken from Ref. 7.

The structure was solved by the heavy-atom method. The positions of the metal and some sulfur atoms were deduced from a three dimensional Patterson map: other non-hydrogen atoms were succesively located by means of the Fourier syntheses. The positional, isotropic and then anisotropic thermal parameters were refined by a block-diagonal least-squares method. At the final step, all hydrogen atoms were added in the refinement, fixing at the calculated positions (C–H=1.08 Å for the benzene-ring hydrogen atoms, and 1.09 Å for the methylene ones, β_{iso}=8.0 Å^2 being given). The final R and R_w values[8] thus obtained were 0.042 and 0.052, respectively.

Results and Discussion

The selected bond lengths and bond angles are shown in Table 1. A perspective drawing of the complex together with the numbering scheme of the atoms, except the benzene rings of the ligands, is shown in Fig. 1.[9] The projections of the unit cell along b- and c-axes are shown in Figs. 2 and 3, respectively.[10]

The cadmium atoms are lined along c-axis and the respective pair of the side-by-side metal atoms are bridged by two SCN ions as in the case of the other $Cd(SCN)_2L_2$ type adducts.[1-5]

As shown in Fig. 1, around one cadmium(II) atom, two SCN sulfur, two SCN nitrogen, and two bza nitrogen atoms are coordinated, where each pair of the same kinds of the ligating atoms are in trans-configurations. The bond lengths are; Cd–S is 2.7540(15), Cd–N(SCN) is 2.372(3), and Cd–N(bza) is 2.294(3) Å, respectively. The Cd–N(bza) bond length is shorter than, and the Cd–N(SCN) length is longer than, the corresponding bonds of the other Cd-

$(SCN)_2L_2$ type Lewis base adducts, although their Cd-S(SCN) bond lengths are not much different from each other.[1-5] It is noteworthy that the Cd-N(base) bonds are stronger than the Cd-N(SCN) bonds in this complex; reverse to the other base adducts.

The Cd-N-C(SCN) angle, 145.2(3)°, is much smaller than the other thiocyanato complexes: commonly in the range of 180—160°.[11] However, S-C-N angle, 177.3(4)°, as well as Cd-S-C, 99.15(14)°, are not much different from the corresponding values of the type of cadmium(II) thiocyanate adducts ($Cd(SCN)_2L_2$).[1-5]

An eight-membered ring consisting of the two metal atoms and two SCN ions bridging them is in the chair form. The metal atom deviates 1.063 Å from the least-squares plane by six atoms of the two SCN ions (the average deviation of the six atoms are 0.010 Å); the deviation is much larger than the other adducts of this type.[1-5]

From these data, we deduce that the ring is quite deformed and the bridging of the double SCN chains in this complex is weaker than those in the other complexes of this type: The Cd···Cd distance, 5.8733(9) Å (the same as the c-axis length) is longer than the corresponding distances of the latters.[1-5]

As shown in Figs. 2 and 3, no bridgings are found between the complex chains. Respective chains are parallel to the bc-plane. They are intercalated by the parallel hydrophobic layers consisting of the ligand benzene-rings of both side complexes; the rings from both side complexes are not interposed with each other, and the rings from one side metal complexes are not parallel with those of the other side metal complexes. There is no overlapping between the neighboring parallel benzene-ring planes,[12] and no π-electron interaction between the benzene rings are expected. However, such short structural periodicities found in the directions of the b- and c-axes are probably due to the quite regular and closely packed arrangement of the benzene rings in the crystal as above mentioned.

Terpenoids. IX.[1] Permanganate Oxidation of Thujopsene. 2.[2] Neutral Products

Shizuo NAGAHAMA* and Masato TAZAKI
The Kumamoto Institute of Technology, Ikeda 4-22-1, Kumamoto 860
(Received April 10, 1987)

Synopsis. Permanganate oxidation of thujopsene **1** in dry and aqueous acetone was reexamined with a careful separation of the neutral part of the products. In dry acetone, the major products were Δ^9-thujopsen-8β- and 8α-ols (**2** and **3**) which easily decomposed to thujopsadiene **6**. In aqueous acetone, **1** gave 8β-hydroxythujopsan-9-one **8** and thujopsane-8α,9α-diol **11** as main products, besides 8β,9β-diol **10**, 8α-hydroxythujopsan-9-one **9**, and epimeric allyl alcohols **2** and **3**. The hydroxy ketone **8** was isomerized to a ring contracted compound, 4α-acetyl-4β-hydroxy-6α,10,10-trimethyltricyclo[4.4.0.0^{1,3}]decane **4** during alumina chromatography. 8β,9-Epoxy-10-thujopsanone **5** was isolated as a minor product. Kawamura's glycol was an eutectic mixture of **10** and **11**.

For the structural elucidation of thujopsene **1**, permanganate oxidation of this compound in dry acetone has been studied.[2,3] From the neutral part of the products, a considerable amount of "isomerized hydrocarbon" was isolated by distillation[2] and identified later as thujopsadiene **6** by the author.[4] The formation of such a diene **6** by permanganate oxidation is interesting and a reexamination was undertaken.

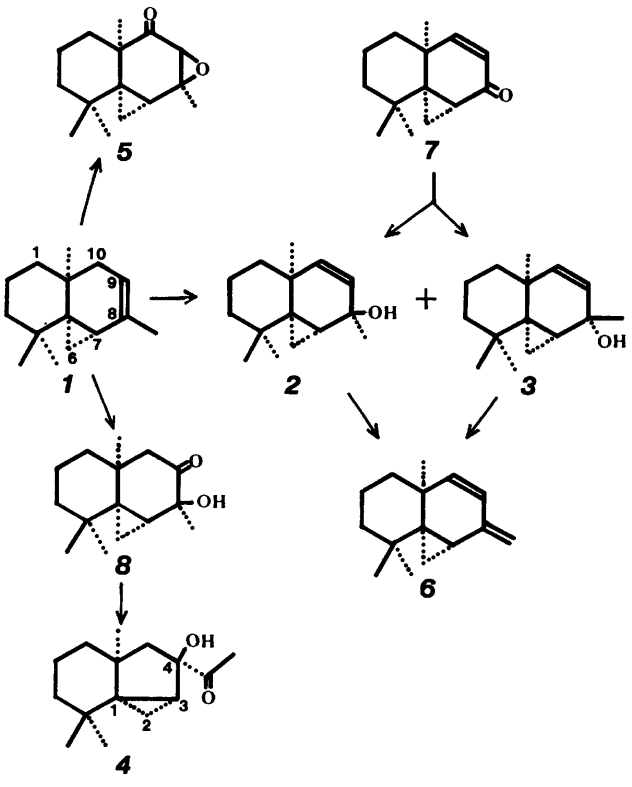
Kawamura[5] obtained a glycol, mp 92—3 °C, from thujopsene by permanganate oxidation in aqueous acetone. Later Traas et al.[6] obtained thujopsane-8β,9β-diol **10** (mp was not announced) and 8α,9α-diol **11**, mp 79—80 °C, from thujopsene by osmium tetraoxide oxidation. To clarify the relation of these products, permanganate oxidation in aqueous acetone (Kawamura's conditions) has also been carried out.

Results and Discussion

Oxidation in Dry Acetone: The neutral products showed two main peaks on GLC analysis (PEG-HT), in a ratio of about 2:1, accompanying at least 8 minor peaks, besides unchanged hydrocarbon **1**. The mixture was chromatographed on an alumina column and the main product isolated as an oil. The IR spectrum of the oil showed the presence of an OH group. The NMR spectrum showed four tertiary methyl groups, two vinyl protons and some protons on a cyclopropane ring. The structure was considered to be Δ^9-thujopsen-8β-ol **2**.

The second main product **3** (produced in about half the amount of **2**) crystallized and was identified as Δ^9-thujopsen-8α-ol, mp 110—2 °C (lit, mp 110—2 °C).[7] It was unstable and decomposed, on standing, to a liquid from which thujopsadiene **6** and mayurone **7** could be separated. The amount of **6** in the neutral product was estimated as about 1% from the analysis of the hydrocarbon fraction separated by column chromatography. Therefore most of **6** previously obtained[2] was considered to be a secondary product from these allyl alcohols by dehydration during distillation.

Two major by-products were separated as crystals. One was previously described as "oxyketone," $C_{15}H_{24}O_2$, mp 68—70.5 °C.[3] The NMR data showed one acetyl group at 2.31 ppm as well as three tertiary methyl groups and some protons on the cyclopropane ring. Thus a ring contracted structure, 4α-acetyl-4β-hydroxy-6α,10,10-trimethyltricyclo[4.4.0.0^{1,3}]-decane **4** was proposed for this compound. The β-hydroxy configuration was based on a high field shift of Hα-C(2) upon $NaBH_4$ reduction of **4** to the corresponding glycols. The NMR analysis of the initial mixture showed the absence of **4** and the presence of 8β-hydroxy-9-thujopsanone **8** (see below). Thus **4** was formed from **8** by α-ketol rearrangement during separation on the alumina column. Another by-product mp 75—7 °C possessed an IR band at 1690 cm^{-1} which is characteristic of a C=O group adjacent to a three membered ring. NMR data showed one singlet proton on an epoxy ring at δ 3.14, four tertiary methyl groups and cyclopropane protons. Thus, the 8β,9-epoxy-10-thujopsanone **5** structure was assigned to this compound. The β-configuration of the epoxy ring was proposed, based on the high magnetic field shift of Hα-C(6).



Since the formation of allyl alcohols on permanganate oxidation of alkenes is unfamiliar to our knowledge, further study of the structure of **2** and **3** was required. Grignard methylation of mayurone **7** gave **2** and **3** in a ratio of 1:9. Relative values of the lanthanoide-induced shift (LIS) using $Eu(fod)_3$ and $Pr(fod)_3$ are summarized in Table 1. The data show that the OH group of **3** is closer to the cyclopropane ring than that of **2**. Thus, the OH group in **3** must be in an α-configuration, and that in **2** in a β-configuration. Interestingly, all of the three tertiary methyl groups remote from the OH group in the epimers **2** and **3** showed the same chemical shifts. The difference in the LIS values of the bridge head proton, H-C(7), in **2** and **3** is small. These results show that the epimers have the same ring conformation in which the cyclohexene ring has a boat form with a flag pole of a C(1) atom. The LIS data observed for two vinyl protons and two methylene protons on the cyclopropane ring are consistent with this conformation.

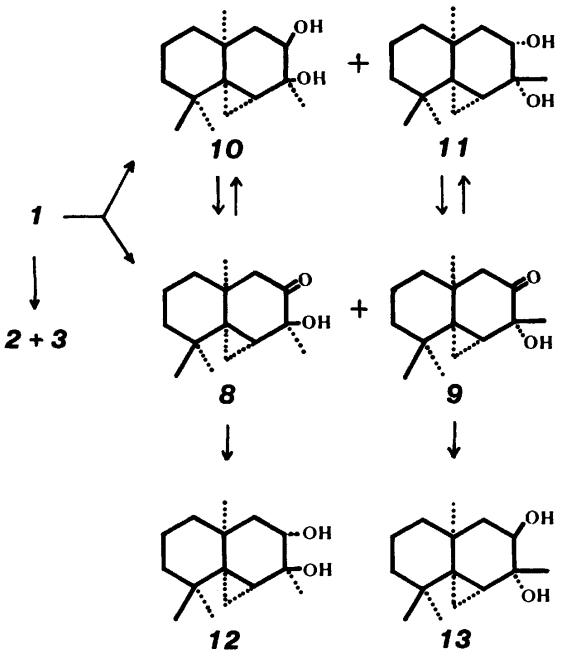


Table 1. Lanthanoide-Induced Shift (LIS) of **2** and **3**

Proton	Chemical shift δ/ppm		Relative LIS	
	2	**3**	**2**	**3**
(Cyclopropane)				
Hα on C(6)	0.02	0.22	0.449	0.754
Hβ on C(6)	0.44	0.39	0.321	0.465

Me	1.17	1.15	0.216	0.216

Oxidation in Aqueous Acetone: Gas chromatographic analysis of the neutral product obtained under Kawamura's conditions showed two main peaks besides more than 12 minor peaks. Chromatographic separation with silica gel gave a mixture of *cis*-8,9-diols **10** and **11** as one of the main products. The mixture of **10** and **11** showed a single peak on gas chromatography. The ratio of **10** to **11** was about 1:4 by NMR analysis. Further chromatography of the mixture on neutral alumina gave 8β,9β-diol **10**, mp 68—71 °C and 8α,9α-diol **11**, mp 71—3 °C. Repeated recrystallization of a mixture of **10** and **11** from hexane gave binary eutectic crystals of mp 92 °C corresponding to Kawamura's glycol.

Another main product **8** was separated as an oil. IR showed the presence of OH and C=O groups. NMR showed an isolated CH_2-(C=O) group, four tertiary methyl groups and a cyclopropane ring. $NaBH_4$ reduction of **8** gave **10** and a *trans*-diol **12**, mp 62—3 °C in a ratio of 2:1. CrO_3 oxidation of **10** in pyridine gave **8**. Thus **8** was 8β-hydroxythujopsan-9-one. Semicarbazone, mp 230 °C.

The epimeric 8α-hydroxythujopsan-9-one **9** was obtained as a crystalline minor product, mp 97—8 °C. $NaBH_4$ reduction of **9** gave **11** and a *trans*-diol **13**, mp 76—8 °C in a ratio of about 2:3. CrO_3 oxidation of **11** gave **9**. α-Ketol rearrangement of **8** was easy as described above. However, the rearrangement of **9** was found to be slow.

Δ^9-Thujopsen-8β-ol (**2**) and -8α-ol (**3**), the main products under nonaqueous conditions, became minor products.

Experimental

The ^1H NMR spectra were measured with JEOL JNM-PMX 60si in $CDCl_3$ solution. GLC analyses were performed on a Shimadzu GC-5A gas chromatograph with PEG-HT glass column 1.0 or 1.5 m. The column temperature was elevated from 100 to 220 °C at a rate of 5 °C min^{-1}.

Thujopsene **1** was separated from Hiba wood neutral oil perchased from Soda Aromatic Co., by a spinning band distillation with Tokyo Kagaku Seiki Co., Model SB 818 (1.8 m height) and the fraction of bp 124—6 °C/10 mmHg† (purity 95% up) was used immediately after passing through a silica-gel column to eliminate some autoxidation products.

Oxidation in Dry Acetone: Thujopsene **1** 30.4 g (0.149 mol) was dissolved in 250 ml of dry acetone and 47 g (0.30 mol) of $KMnO_4$ was added portionwise below 6 °C under nitrogen atmosphere. The mixture was stirred for 12 h and MnO_2 was filtered off. Evaporation of the acetone left 11.8 g of residue. The MnO_2 was washed twice with acetone and additional 7.7 g of extract was obtained. The combined residue was dissolved in hexane and shaken with aqueous Na_2CO_3 solution and NaOH solution successively, giving 14 g of neutral products. Gas chromatography showed unreacted hydrocarbon **1** 33.5%, thujopsadiene **6** 2%, **2** 28.5%, **3** 14.5%, **8** 6.5% and **5** 5%. Extraction of MnO_2 with hot water gave neutral product 1.1 g. Gas chromatography showed 67% of thujopsane-8,9-diol.

† 1 mmHg=133.322 Pa.

Separation by Column Chromatography: The separation was accomplished by passage through an alumina column (320 g). Hexane eluted hydrocarbons and **5** successively. Hexane-CH_2Cl_2 (4:1) eluted **2**, hexane-CH_2Cl_2 (1:1) eluted **3** and CH_2Cl_2 eluted **4**. Δ^9-Thujopsen-8β-ol (**2**): Oil. IR (neat) 3400 (OH), 3060, 1665, 1100, 910, and 760 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.02 (1H, dd, J=5 and 4 Hz), 0.44 (1H, dd, J=9 and 4 Hz), 0.66 (3H, s), 1.07 (3H, s), 1.17 (3H, s), 1.28 (3H, s), 1.0—1.7 (6H, m), 1.55 (1H, ddd, J=9, 5 and 2 Hz), 5.15 (1H, d, J=10 Hz), and 5.24 (1H, dd, J=10 and 2 Hz). Δ^9-Thujopsen-8α-ol (**3**): mp 110—2 °C. IR (KBr) 3300 (OH), 3060, 1660, 1125, 1090, 940, 750, and 738 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.29 (1H, dd, J=5 and 4 Hz), 0.39 (1H, dd, J=9 and 4 Hz), 0.65 (3H, s), 1.0—1.7 (6H, m), 1.06 (3H, s), 1.15 (3H, s), 1.40 (3H, s), 1.48 (1H, ddd, J=9, 5 and 2 Hz), 4.92 (1H, d, J=10 Hz), and 5.10 (1H, dd, J=10 and 2 Hz). Ring contracted hydroxy ketone **4**: mp 69—70 °C. IR (KBr) 3450, 3370, 3200, 1698, 1350, 1235, and 1048 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.35—0.82 (2H, m), 0.60 (3H, s), 1.03 (3H, s), 1.13 (3H, s), 1.3—2.3 (7H, m, broad), 1.33 (1H, d, J=14 Hz), 1.72 (1H, d, J=14 Hz), 2.31 (3H, s), and 3.75 (1H, broad). 8β,9-Epoxy-10-thujopsanone (**5**): mp 75—7 °C. IR (KBr) 3050, 3025, 1690 (C=O), 1372, 1250, 1090, 850, and 818 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.00 (1H, dd, J=6 and 5.5 Hz), 0.78 (1H, dd, J=8.5 and 6 Hz), 0.67 (3H, s), 1.05 (3H, s), 1.33 (3H, s), 1.52 (3H, s), 1.3—2.3 (6H, m), 1.77 (1H, dd, J=8.5 and 5.5 Hz) and 3.14 (1H, s).

Isomerization of 8-Hydroxy-9-thujopsanone 8 to 4 by Alumina: Eighty three mg of **8** was dissolved in hexane and loaded on a column containing 10.5 g alumina deactivated with 1.05 ml of water. After one day, 82 mg of **4** was eluted with ether as the sole product.

Synthesis of 2 and 3 from Mayurone (7): To a Grignard reagent from 0.080 ml of methyl iodide in 3 ml ether was added dropwise 21 mg of mayurone in 1 ml ether. After 15 min at 0 °C, the mixture was cooled on a Dry Ice methanol bath, hydrolyzed with aqueous ammonium acetate, and extracted with hexane-ether (1:1). The extract was washed twice with saturated sodium chloride, dried over sodium sulfate and evaporated to give 21 mg of residue. GLC of the residue showed 7% of **2**, and 63% of **3** besides 11% of **6** and 12% of an unidentifiable product.

Lanthanoide-Induced Shift (LIS) of 2 and 3: ^1H NMR spectra were measured for ca. 20 mg of **2** and **3** in 0.35 ml $CDCl_3$ by adding stepwise $Eu(fod)_3$ and $Pr(fod)_3$ (3—5 mg for each measurement). The LIS values of CH_3-C(8) were from +2.4 to −8.0 ppm for **2** and from +3.4 to −5.5 ppm for **3**. A good straight line was obtained when the chemical shift values of each proton at various concentrations of the shift reagents were plotted against the corresponding values of CH_3-C(8). The relative value of LIS (1.00 for CH_3-C(8)) was obtained from the slope. The chemical shift values of cyclopropane ring protons were also obtained by extrapolating the concentration of the shift reagents to zero. The results are summarized in Table 1.

Oxidation in Aqueous Acetone: Potassium permanganate 14.0 g (88.6 mmol) was added portionwise to a mixture of thujopsene 14.0 g (68.5 mmol) in 140 ml of acetone and 14 ml of water under ice water cooling. The mixture was stirred overnight and filtered. The filtrate was evaporated under reduced pressure, and the residue was dissolved in hexane. The MnO_2 was extracted with hot water several times. The oil which separated from the water layer was extracted with hexane. The hexane solutions were combined and extracted with aqueous sodium carbonate solution. They afforded 13.4 g of neutral product and 1.7 g of acidic product. Gas chromatography of the neutral product yielded unreacted hydrocarbon **1** 26%, thujopsadiene **6** 0.4%, **2** 8.0%, **3** 4.0%, **8** 22.1%, **9** 4.5% and cis-diols (**10** and **11**) 25.1%.

Separation: The neutral product 27 g was chromatographed on a column (45 mm i.d. ×49 cm) packed with 350 g of Fuji gel CQ-3 silica gel. The eluent was fed with a Chemco Low Prep Pump Model 81-M-2. Hexane eluted hydrocarbons. Most of **2** and **3** were dehydrated to **6** on a SiO_2 column. Hydroxy ketone **8**, 5.86 g was eluted with hexane -CH_2Cl_2 (4:1). Hydroxy ketone **9**, 0.95 g was eluted with hexane-CH_2Cl_2 (1:1). Then, a mixture of *cis*-diols, **10** and **11**, 6.95 g was eluted with CH_2Cl_2. A similar oxidation product was chromatographed on alumina containing 10% H_2O gave **4** instead of **8**. **8**: oil. IR(neat) 3480, 3050, 1715, 1140, 1090, and 958 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.43—0.86 (2H, m), 0.62 (3H, s), 1.06 (3H, s), 1.1—1.66 (7H, m), 1.20 (3H, s), 1.28 (3H, s), 1.66 (1H, d, J=14 Hz), 2.35 (1H, d, J=14 Hz), and 3.37 (1H, broad). **9**: mp 97—8 °C. IR(KBr) 3480, 3070, 3050, 1704, 1168, and 1106 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.44—0.80 (2H, m), 0.70 (3H, s), 1.06 (3H, s), 1.18 (3H, s), 1.4—1.75 (7H, m), 1.52 (3H, s), 2.10 (1H, d, J=16.5 Hz), 2.31 (1H, d, J=16.5 Hz) and 2.92 (1H, broad).

Reduction of 8 and 9: **8** (385 mg) was dissolved in methanol (20 ml) and reduced with excess $NaBH_4$. The product (319 mg) was chromatographed on a silica-gel column (10 g). Methylene chloride eluted 175 mg of **10**, mp 68—71 °C. Ether eluted 85 mg of 8β,9α-diol **12**. **12**: mp 61—3 °C (recrystallized from hexane). IR (Nujol) 3440, 3150, 1170, 1140, 1103, 1080, and 1035 cm^{-1}. ^1H NMR ($CDCl_3$) δ=−0.01—0.57 (2H, m), 0.55 (3H, s), 0.9—1.9 (9H, m), 0.96 (3H, s), 1.07 (3H, s), 1.18 (3H, s), 2.47 (2H, broad), and 3.75 (1H, X part of ABX, $J_{AX}+J_{BX}$=16.5 Hz).

Hydroxy ketone **9**, 387 mg was reduced similarly, to give 53 mg of **11**, mp 72—3 °C and 82 mg of 8α,9β-diol **13**. **13**: mp 76—8 °C (from hexane). IR (Nujol) 3300, 1145, 1106, and 1082 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.29—0.66 (2H, m), 0.79 (6H, s), 1.09 (3H, s), 1.1—1.7 (9H, m), 1.33 (3H, s), 2.25—2.57 (3H, m, broad), and 3.51 (1H, X part of ABX, $J_{AX}+J_{BX}$=16.5 Hz).

The Thermally-Controlled Chemoselective Reduction of 5*H*-Pyrrolo[3,4-*b*]pyridine-5,7(6*H*)-dione with Sodium Borohydride

Takehiko GOTO,* Minoru SAITO, and Ryu SATO
Department of Resource Chemistry, Faculty of Engineering, University of Iwate, Ueda, Morioka 020
(Received April 22, 1987)

Synopsis. The title reaction produced either 2-(hydroxymethyl)nicotinamide or 6,7-dihydro-7-hydroxy-5*H*-pyrrolo[3,4-*b*]pyridin-5-one as the major product at room temperature or −20 °C, respectively, along with the corresponding regioisomers as minor products. These novel compounds were converted to known compounds in order to establish their isomeric structures.

Although the reduction of phthalimide with metal borohydride to 2-(hydroxymethyl)benzamide or 2,3-dihydro-3-hydroxy-1*H*-isoindol-1-one has been well-known,[1] there has been few studies on the application of this reduction to the aza-analogs, for instance 5*H*-pyrrolo[3,4-*b*]pyridine-5,7(6*H*)-dione(quinolinimide **1**). Recently, Cotrel et al.[2] have reported in a patent the reduction of 6-substituted quinolinimides with potassium borohydride to 6-substituted 6,7-dihydro-7-hydroxy-5*H*-pyrrolo[3,4-*b*]pyridin-5-one and the corresponding 5-hydroxy-7-oxo isomer in low yields, which were transformed to pharmacologically active compounds. The isomeric structures and the spectroscopic characterizations of these isomers, however, have not been established. In conjunction with our ongoing studies on the synthesis of 2,3-dihydro-3-(substituted amino)-1*H*-isoindol-1-ones[3a] and their 2-alkyl derivatives[3b] of which the anti-inflammatory activity has been observed,[4] our attention has been focused on the synthesis of their aza-analogs. First, we envisioned the synthesis of 6,7-dihydro-7-hydroxy-5*H*-pyrrolo[3,4-*b*]pyridin-5-one (**2**) by the reduction of quinolinimide (**1**) with sodium borohydride ($NaBH_4$) because of the easy availability of both the substrate and the reducing agent, and the feasibility of converting the hydroxyl group to various functional groups. Surprisingly, there has been no report on **2** and the corresponding regioisomer **3** in the literature to our knowledges. We wish to report in this paper the temperature-controlled chemoselective reduction of quinolinimide (**1**) with $NaBH_4$ to give the mixture either of **2** and **3** at −20 °C, or of 2-(hydroxymethyl)nicotinamide (**4**) and 3-hydroxymethyl-2-pyridinecarboxamide (**5**) at ambient temperature. The present reaction provides a convenient method for the synthesis of the novel heterocycle **2** or **4**, both of which can be easily separated from the corresponding minor regioisomer **3** or **5**.

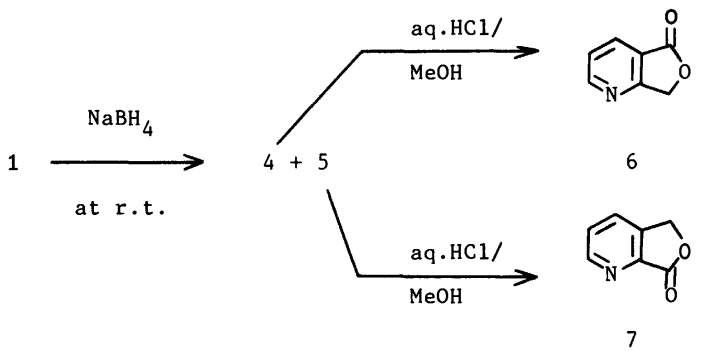
Results and Discussion

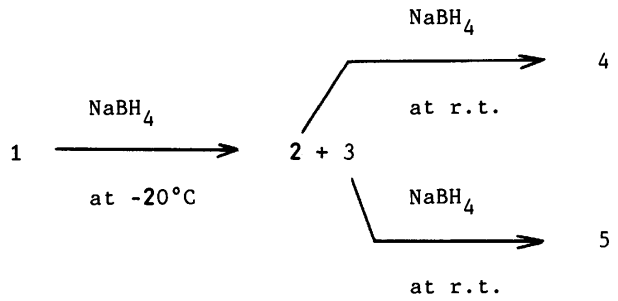
Reduction at Room Temperature. Quinolinimide (**1**) was smoothly reduced with an excess amount of $NaBH_4$ in methanol–chloroform (1 : 1 v/v) to yield two products which exhibited much different chromatographic behaviors on TLC. After the usual work-up, these components were easily separated on a silica-gel column. The analytical data of these materials indicated either chemical structure **4** or **5**; however, we could not assign the isomeric structure of each hydroxymethylcarbamoylpyridine because of their very similar spectral character. Although a description of **5** could not be found in the literature, there was only one report as to the formation of **4** from furo[3,4-



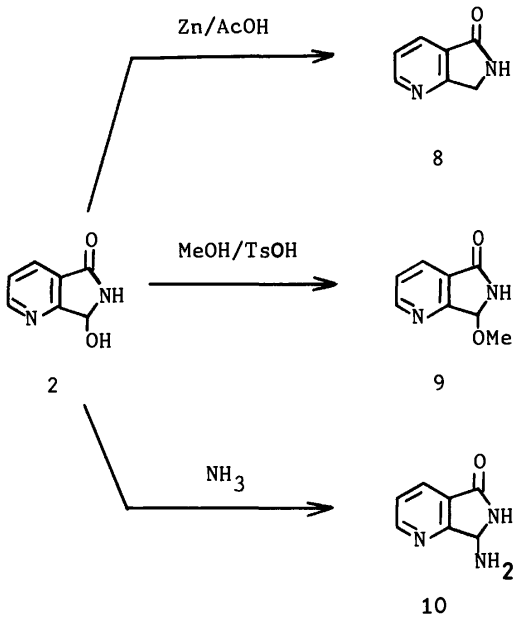
Scheme 1.

b]pyridin-5(7*H*)-one (**6**) with ammonia by Sato et al.[5] The melting point and IR spectra reported by them were identical with those of our sample of **4**. In order to obtain a further confirmation of the assignment, we achieved the transformations of **4** and **5** to the known azaphthalide **6** and **7**,[6] respectively (Scheme 1). Thus, **4** and **5** were smoothly hydrolyzed and cyclized in hot acidic methanol to produce **6** and **7** in 74 and 78% yield, respectively. Consequently, it was revealed that the yields of **4** and **5** were 50 and 23%, respectively, from quinolinimide (**1**). The moderate yield of **4** might be synthetically acceptable in view of the availability of the substrate **1** and reducing agent, and the simple, one-step procedure starting from **1**.

Reduction at −20 °C. The reduction of **1** with $NaBH_4$ also proceeded smoothly at −20 °C to lead a mixture involving two components, **2** and **3**, quantitatively. The ^1H NMR of the mixture showed that the ratio of **2** and **3** was 3:1; the cleanly chemoselective formation of **2** and **3** without the contamination of **4** and **5** was achieved. Fortunately, isomerically pure **2** was obtained by recrystallization of the mixture two times in a moderate yield (53%), in spite of the very similar chromatographic property of **2** and **3**. Isomerically pure **3** was obtained from the mother liquor after recrystallization only in very low yield. Since **2** and **3** were novel compounds, as far as we know, their chemical structures were determined by elemental analysis and spectral data. Isomeric assignments were easily achieved by the transformation of **2** and **3** to **4** and **5**, respectively, with $NaBH_4$ at room temperature in good yields (Scheme 2).



Scheme 2.



Scheme 3.

Since the hydroxy lactam **2** has been available in multigram scale through the procedure described above, we preliminarily tried to convert the hydroxyl group to other functional groups, as shown in Scheme 3. Thus, the reduction of **2** with zinc powder in acetic acid gave 6,7-dihydro-5*H*-pyrrolo[3,4-*b*]pyridin-5-one (**8**)[7] in good yield (71%). The treatment of **2** with methanol in the presence of a catalytic amount of *p*-toluenesulfonic acid[8] afforded **9** in excellent yield (94%). Finally, the desired 7-amino derivative **10** was obtained by the amination of **2** with liquid ammonia in high yield (83%). The chemical structures of these novel compounds, **9** and **10**, were confirmed by elemental analysis and spectral data.

In summary, we achieved the chemoselective synthesis of either **2** or **4**, along with **3** or **5**, which are interesting intermediates for the synthesis of some biologically active compounds, and some of their fundamental derivations. Further applications of these compounds will soon be reported elsewhere.

Experimental

Melting points were uncorrected. NMR, IR, and mass spectra were recorded with HITACH R-22, HITACH 295, and HITACH RUM-6M, respectively. Elemental analyses were determined with YANAGIMOTO MT-3.

5*H*-Pyrrolo[3,4-*b*]pyridine-5,7(6*H*)-dione (1) was prepared from commercially available 2,3-pyridinedicarboxylic acid and acetamide according to a procedure in a literature.[7]

6,7-Dihydro-7-hydroxy-5*H*-pyrrolo[3,4-*b*]pyridin-5-one (2) and 5,6-Dihydro-5-hydroxy-7*H*-pyrrolo[3,4-*b*]pyridin-7-one (3) by the Reduction of 1 with $NaBH_4$. Into a solution of **1** (2.96 g, 20 mmol) in 200 ml of methanol–chloroform (1:1 v/v) cooled at −20 °C under agron was added $NaBH_4$-powder (1.13 g, 30 mmol). After 30 min, the reaction mixture was acidified with aqueous HCl approximately to pH 3. The resulting mixture was stirred for 10 min and basified with aqueous NaOH approximately to pH 9. Throughout the procedure the reaction mixture was kept at about −20 °C. After being warmed up to room temperature, the mixture was concentrated in vacuo to give a solid. This material was purified over a short silica-gel column (methanol–chloroform, 1:5 v/v) to give the mixture of **2** and **3** (2.9 g, 96%). The mixture was recrystallized from ethanol two times to give isomerically pure **2** as white crystals (1.59 g, 53%): mp 201 °C (decomp); ^1H NMR (DMSO-d_6) δ=5.82 (1H, d, J=9 Hz, H-7), 6.49 (1H, d, J=9 Hz, OH), 7.50 (1H, dd, J=7 and 5 Hz, H-3), 8.03 (1H, dd, J=7 and 2 Hz, H-4), 8.75 (1H, dd, J=5 and 2 Hz, H-2), and 9.04 (1H, br s, NH); IR (KBr) 1740 (C=O), 3000 and 3270 (NH and OH) cm^{-1}; MS (70 eV) m/z 150 (M^+); Found: C, 56.39; H, 4.08; N, 18.72%. Calcd for $C_7H_6N_2O_2$: C, 56.00; H, 4.03; N, 18.66%.

The solid residue (1.05 g) from the mother liquor was triturated in hot methanol–chloroform (1:5 v/v, 30 ml) for 1 h. Then, the unsoluble material was filtered, washed with the same solvent, and recrystallized from methanol–ether to give isomerically pure **3** as white crystals (0.23 g). Decomp

185 °C; ^{1}H NMR (DMSO-d_6) δ=5.94 (1H, d, J=9 Hz, H-5), 6.53 (1H, d, J=9 Hz, OH), 7.57 (1H, dd, J=9 and 6 Hz, H-3), 8.01 (1H, dd, J=9 and 2 Hz, H-4), 8.74 (1H, dd, J=6 and 2 Hz, H-2), and 9.24 (1H, br s, NH); IR (KBr) 1710 (C=O), 3230 (NH and OH) cm^{-1}; MS (70 eV) m/z 150 (M^+); Found: C, 56.35; H, 4.02; N, 18.41%. Calcd for $C_7H_6N_2O_2$: C, 56.00; H, 4.03; N, 18.66%.

2-(Hydroxymethyl)nicotinamide (4) and 3-Hydroxymethyl-2-pyridinecarboxamide (5) by the Reduction of 1. Compound **1** (1.48 g, 10 mmol) in 100 ml of methanol–chloroform (1 : 1 v/v) was reduced with $NaBH_4$ (0.76 g, 20 mmol) at room temperature (about 20 °C) for 1 h by a procedure similar to that described above. When the crude product was chromatographed (silica gel, MeOH–$CHCl_3$ (1 : 5 v/v)), **5** was obtained from the first fraction as white crystals (0.36 g, 23%): mp 154 °C (from ethanol); ^{1}H NMR (DMSO-d_6) δ=4.89 (2H, d, J=6 Hz, CH_2), 5.31 (1H, t, J=5 Hz, OH), 7.50 (1H, br s, NH), 7.54 (1H, dd, J=9 and 5 Hz, H-5), 8.02 (1H, br s, NH), 8.10 (1H, dd, J=9 and 1 Hz, H-4), and 8.46 (1H, dd, J=5 and 2 Hz, H-6); IR (KBr) 1710 (C=O), 3100 and 3350 (NH and OH) cm^{-1}; MS (70 eV) m/z 152 (M^+); Found: C, 55.54; H, 5.28; N, 18.45%. Calcd for $C_7H_8N_2O_2$: C, 55.26; H, 5.30; N, 18.41%.

The second fraction gave **4** (0.76 g, 50%) as white crystals: mp 148 °C (from ethanol, lit,[5] 146—147 °C); ^{1}H NMR (DMSO-d_6) δ=4.68 (2H, d, J=5 Hz, CH_2), 5.22 (1H, t, J=5 Hz, OH), 7.35 (1H, dd, J=8 and 5 Hz, H-5), 7.58 (1H, br s, NH), 7.89 (1H, dd, J=8 and 2 Hz, H-4), 8.00 (1H, br s, NH), and 8.54 (1H, dd, J=5 and 2 Hz, H-6); IR (KBr) 1640, 1680 (C=O), 3150 and 3340 (NH and OH) cm^{-1}; MS (70 eV) m/z 152 (M^+); Found: C, 55.04; H, 5.26; N, 18.49%. Calcd for $C_7H_8N_2O_2$: C, 55.26; H, 5.30; N, 18.41%.

Starting with **2** or **3** (0.15 g, 1 mmol), a similar reduction gave the same products, **4** or **5**, in 78 or 99% yield, respectively.

Furo[3,4-*b*]pyridin-5(7*H*)-one (6). Into a solution of **4** (0.46 g, 3 mmol) in 15 ml of methanol was added 6 ml of concd HCl and the mixture was heated at 80 °C for 1.5 h. The reaction mixture was neutralized with aqueous NaOH, and concentrated in vacuo. After the residue was extracted with chloroform (10 ml×3), the combined extracts were washed with water, dried with sodium sulfate, and concentrated in vacuo to afford spectroscopically pure **6** (0.30 g, 74%) as white crystals (mp 144 °C, from chloroform–hexane, lit,[6] 142 °C; Found: C, 62.46; H, 3.71; N, 10.39%. Calcd for $C_7H_5NO_2$: C, 62.22, H, 3.73, N, 10.37%).

Furo[3,4-*b*]pyridin-7(5*H*)-one (7) was obtained from **5** with the same procedure for **6** in 72% yield as white crystals (mp 164 °C, from chloroform–ether, lit,[6b] 162 °C; Found: C, 62.40; H, 3.69; N, 10.37%. Calcd for $C_7H_5NO_2$: C, 62.22, H, 3.73, N, 10.37%).

6,7-Dihydro-5*H*-pyrrolo[3,4-*b*]pyridin-5-one (8) was obtained from **2** with zinc powder in acetic acid according to von Dobeneck's procedure[7] in 71% yield as white crystals (mp 204 °C, from ethanol, lit,[7] 204—206 °C; ^{1}H NMR (DMSO-d_6) δ=4.44 (2H, s, H-7), 7.50 (1H, dd, J=8 and 5 Hz, H-3), 8.10 (1H, dd, J=8 and 2 Hz, H-4), and 8.75 (2H, dd+br s, J=5 and 2 Hz, H-2+NH).

6,7-Dihydro-7-methoxy-5*H*-pyrrolo[3,4-*b*]pyridin-5-one (9). A solution of **2** (1.50 g, 10 mmol) and *p*-toluenesulfonic acid (0.04 g, 0.2 mmol) in 50 ml of methanol was refluxed for 24 h. After the reaction mixture was concentrated in vacuo, aqueous $NaHCO_3$ was added to the residue, and the resulting mixture was sufficiently extracted with chloroform. The combined organic layers were dried with sodium sulfate and concentrated in vacuo to give practically pure **9** (1.5 g, 94%) as white crystals: mp 150 °C (from chloroform–hexane); ^{1}H NMR (DMSO-d_6) δ=3.43 (3H, s, CH_3), 5.88 (1H, s, H-7), 7.46 (1H, dd, J=8 and 6 Hz, H-3), 8.10 (1H, br s, NH), 8.13 (1H, dd, J=8 and 2 Hz, H-4), and 8.79 (1H, dd, J=6 and 2 Hz, H-2); IR (KBr) 1720 (C=O), 3100 and 3180 (NH) cm^{-1}; MS (70 eV) m/z 164 (M^+); Found: C, 58.88; H, 4.91; N, 17.12%. Calcd for $C_8H_8N_2O_2$: C, 58.53; 4.91; N, 17.06%.

6,7-Dihydro-7-amino-5*H*-pyrrolo[3,4-*b*]pyridin-5-one (10). A solution of **2** (0.30 g, 2 mmol) in 20 ml of liquid ammonia was heated in an autoclave at 110 °C for 48 h. After the evaporation of ammonia at room temperature, the residue was chromatographed over silica gel (methanol–chloroform, 1 : 5 v/v) to afford **10** (0.25 g, 83%) as white crystals: decomp 160 °C (from methanol); ^{1}H NMR (DMSO-d_6) δ=2.44 (2H, br s, NH_2), 5.32 (1H, s, H-7), 7.47 (1H, dd, J=8 and 5 Hz, H-3), 7.99 (1H, dd, J=8 and 2 Hz, H-4), and 8.72 (2H, dd+br s, J=5 and 2 Hz, H-2+NH); IR (KBr) 1720 (C=O) and 3160 (NH and NH_2) cm^{-1}; Found: C, 56.40; H, 4.74; N, 27.84%. Calcd for $C_7H_7N_3O$: C, 56.37; H, 4.73; N, 28.17%.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 60740263 from the Ministry of Education, Science and Culture.

Synthesis of Novel Bis-Crown and Double-Armed Crown Ethers Having the 18-Crown-6 Residue

Koichiro NAEMURA,* Hiroshi IWASAKA, and Hiroaki CHIKAMATSU
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received May 8, 1987)

Synopsis. The 18-crown-6 derivative possessing two hydroxyl groups was prepared from the Diels–Alder adduct of 1,7-(1,2-ethanediylidene)-18-crown-6 with dimethyl 2-butynedioate. By using the crown ether as the key intermediate, novel bis-crown and double-armed crown ethers having the 18-crown-6 residue were synthesized, and their abilities to extract metal picrates were investigated.

Since Smid and co-workers first prepared the bis-crown ether,[1] a variety of bis-crown ethers have been synthesized and their complexing properties have been investigated, because of interests in their unique binding properties. Here we report the syntheses of novel bis-crown and double-armed crown ethers having the 18-crown-6 residue and the solvent extraction of metal picrates with these crown ethers. Bis-crown ethers are divided into several groups according to a variation of the linkage holding two macrorings[2] together and bis-crown ethers described in this paper may be classified into a group which is referred to as a "hinged" bis-crown ether.[2,3]

We chose the crown ether **8** possessing two hydroxyl groups as well as the 18-crown-6 residue as the key intermediate for the preparation of bis-crown and double-armed crown ethers having the 18-crown-6 residue. Treatment of **1**[4] with dimethyl 2-butynedioate in refluxing toluene gave the adduct **4** in 71% yield. Catalytic hydrogenation of **4** over 10% Pd/C in methanol afforded the diester **7** in 79% yield. The diester **9** containing the 15-crown-5 residue was obtained from **2**[5] in 52% overall yield via the adduct **5**.

Assignment of the configuration of **7** and **9** was based on their ^{1}H NMR spectra with those of **11** and **12** with known configurations.[6] Chemical shifts on endo- and exo-protons on the ethano bridge in **7**, **9**, **11**, and **12** are summarized in Table 1. The endo-protons in **11** are shifted considerably downfield due to a deshieding effect of the endo-carbonyl groups on C2 and C3, and the endo-protons in **7** and **9** are also shifted to downfield. From the data described above, we assigned the endo-configuration to **7** and **9** as shown in their structural formulas.

Table 1. Chemical Shifts of Endo- and Exo-Protons on the Ethano Bridge

	endo-proton	exo-proton
7	1.9—2.2	1.4—1.7
9	1.9—2.2	1.4—1.7
11	1.9—2.1	1.6—1.8
12	1.4—1.6	1.7—1.9

Reduction of **7** and **9** with $LiAlH_4$ in tetrahydrofuran (THF) gave **8** (81%) and **10** (78%), respectively. High dilution condensation of **8** with triethylene glycol, tetraethylene glycol, and pentaethylene glycol ditosylate in dimethyl sulfoxide (DMSO)–1,2-dimethoxyethane (DME) in the presence of NaH gave **15** (22%), **16** (26%), and **17** (45%), respectively. Treatment of **10** with pentaethylene glycol ditosylate in high dilution conditions afforded **18** in 42% yield. The structures of these crown ethers were confirmed on the basis of their ^{1}H NMR and mass spectra as well as elemental analyses.

Double-armed crown ethers **19** and **20** containing the 18-crown-6 residue were also prepared from **8**. Treatment of **8** with 3,6-dioxaheptyl and 3,6,9-trioxadecyl *p*-toluenesulfonate in *N*,*N*-dimethylformamide (DMF) in the presence of NaH provided **19** (68%) and **20** (20%), respectively. Our attempts to prepare directly **19** from **1** by the Diels–Alder reaction of **1** with 2,5,8,13,16,19-hexaoxa-10-icosyne, prepared by condensation of 2-butyne-1,4-diol with 3,6-dioxaheptyl *p*-toluenesulfonate and KOBu^t in THF,

were unsuccessful, because the reaction did not give any Diels-Alder adduct.

We next turned our attention to the preparation of the other type of polyether that is O_7-monopodand[7] bound to a crown ether framework by two single bonds. A similar set of reactions described for **8** transformed the monopodand **3** into the key intermediate **14** (25% overall yield) via **6** and **13**. The structure of **13** was confirmed by its ^{1}H NMR spectrum exhibiting signals of the endo-protons at C5 and C6 at δ 2.0—2.2 and the exo-protons at δ 1.5—1.7. High dilution condensation of **14** with tetraethylene glycol and pentaethylene glycol ditosylate gave **21** (47%) and **22** (37%), respectively.

The cation-binding ability of these crown ethers was estimated by solvent extraction of aqueous solution of metal picrate with a chloroform solution containing crown ether, and the results are given in Table 2.

Among crown ethers described here, the bis-crown ether **16** containing the 18-crown-6 and the 17-crown-5 residue possesses the highest extractability towards all cations examined in this study, and both double-armed crown ethers **19** and **20** also exhibit higher extractabilities towards all cations than the parent 18-crown-6. However, in the case of the bis-crown ethers **15** and **17**, both of which contain also the 18-crown-6 residue, the additional crown ether framework contributes hardly to raise the extractability of the bis-crown ether.

Table 2. Extraction of Metal Picrates[a]

Host	Extractability/%

a) The solvent extraction was carried out according to the procedure reported in our preceding paper.[8]

Experimental

2,5-Bis(2,5,8-trioxanonyl)furan (3). To a suspension of potassium *t*-butoxide (11.2 g, 0.100 mol) in dry THF (300 mL) was added 2,5-bis(hydroxymethyl)furan[4] (3.84 g, 0.0300 mol) and then a solution of 3,6-dioxaheptyl *p*-toluenesulfonate (27.4 g, 0.100 mol) in dry THF (100 mL) was added to the reaction mixture. After the mixture was refluxed for 12 h, a solid was filtered off and the filtrate was condensed in vacuo. The residue was chromatographed on alumina (benzene eluent) to give **3** (4.06 g, 41% yield): bp 160—162 °C (0.02 mmHg (1 mmHg=133.322 Pa)). Found: C, 57.50; H, 8.41%. Calcd for $C_{16}H_{28}O_7$: C, 57.81; H, 8.49%.

18,19-Bis(methoxycarbonyl)-3,6,9,12,15,22-hexaoxatricyclo-[15.2.2.1^{1,17}]docosa-18,20-diene (4). A solution of **1**[4] (1.00 g, 3.50 mmol) and dimethyl 2-butynedioate (5.82 g, 41.0 mmol) in toluene (20 mL) was refluxed for 15 h. After evaporation of volatile materials, the residue was chromatographed on alumina ($CHCl_3$) to give **4** (1.06 g, 71%): mp 84—86 °C (lit,[4] mp 55—60 °C); ^{1}H NMR ($CDCl_3$) δ=3.5—3.9 (16H, m), 3.75 (6H, s), 4.15 (2H, d J=12 Hz), 4.31 (2H, d J=12 Hz), 6.99 (2H, s). Found: C, 55.88; H, 6.50%. Calcd for $C_{20}H_{28}O_{10}$: C, 56.07; H, 6.59%.

15,16-Bis(methoxycarbonyl)-3,6,9,12,19-pentaoxatricyclo-[12.2.2.1^{1,14}]nonadeca-15,17-diene (5). The diester **5** (1.31 g, 69%) was prepared from **2**[5] (1.20 g, 4.95 mmol) and dimethyl 2-butynedioate (7.10 g, 50.0 mmol) as an oil: ^{1}H NMR ($CDCl_3$) δ=3.5—3.9 (12H, m), 3.82 (6H, s), 4.08 (2H, d J=12 Hz), 4.42 (2H, d J=12 Hz), 7.03 (2H, s). Found: C, 55.92; H, 5.97%. Calcd for $C_{18}H_{24}O_9$: C, 56.24; H, 6.29%.

2,3-Bis(methoxycarbonyl)-1,4-bis(2,5,8-trioxanonyl)-7-oxabicyclo[2.2.1]hepta-2,5-diene (6). The diester **6** (1.68 g, 41%) was prepared from **3** (2.86 g, 8.61 mmol) and dimethyl 2-butynedioate (12.2 g, 86.1 mmol) as an oil: ^{1}H NMR ($CDCl_3$) δ=3.35 (6H, s), 3.5—3.7 (16H, m), 3.75 (6H, s), 4.20 (4H, s), 7.03 (2H, s). Found: C, 55.05; H, 7.30%. Calcd for $C_{22}H_{34}O_{11}$: C, 55.68; H, 7.22%.

***cis*-18,19-Bis(methoxycarbonyl)-3,6,9,12,15,22-hexaoxatricyclo[15.2.2.1^{1,17}]docosane (7).** A mixture of **4** (2.85 g, 6.65 mmol) and methanol (70 mL) was shaken at room temperature with 10% Pd/C (390 mg) at 1 atm of hydrogen. After a usual workup, chromatography (Al_2O_3, benzene-$CHCl_3$ 1:1) gave **7** (2.27 g, 79%): mp 62—63 °C (hexane-benzene) ^{1}H NMR ($CDCl_3$) δ=1.4—1.7 (2H, m), 1.9—2.2 (2H, m), 3.5—3.7 (22H, m), 3.62 (6H, s). 2,5,8,11,14,19,22,25,28,33-Decaoxatetracyclo[15.14.2.$1^{1,16}$.$0^{17,30}$]-tritriacontane (15). To a suspension of NaH (96 mg, 4.0 mmol) in 30 mL of DMSO–DME (1:3) was added **8** (486 mg, 1.30 mmol) and then the mixture was heated at 50 °C for 1 h. A solution of triethylene glycol ditosylate (595 mg, 1.30 mmol) in 60 mL of DMSO–DME (1:3) was added to the mixture at 50±5 °C over a 10 h period and the reaction mixture was heated at this temperature for an additional 30 h. After a small amount of water was added to the chilled reaction mixture, the solvent was evaporated in vacuo. The residue was extracted with $CHCl_3$. After a usual workup, chromatography on alumina ($CHCl_3$) gave **15** (140 mg, 22%) as an oil: ^1H NMR ($CDCl_3$) δ=1.68 (4H, br s), 2.50 (2H, br s), 3.4—3.8 (36H, m); MS *m/z* 490 (M^+). Found: C, 58.25; H, 8.49%. Calcd for $C_{24}H_{42}O_{10}$: C, 58.75; H, 8.63%.

4,7,10,13,16,21,24,27,30,33,37-Undecaoxatetracyclo-[17.15.2.$1^{1,19}$.$0^{2,18}$]heptatriacontane (16). Compound **16** (144 mg, 26%) was prepared from **8** (400 mg, 1.06 mmol) and tetraethylene glycol ditosylate (530 mg, 1.06 mmol) as an oil after chromatography (Al_2O_3, $CHCl_3$–methanol 50:1): ^1H NMR ($CDCl_3$) δ=1.73 (4H, br s), 2.23 (2H, br s), 3.3—3.9 (40H, m); MS *m/z* 534 (M^+). Found: C, 58.02; H, 8.60%. Calcd for $C_{26}H_{46}O_{11}$: C, 58.41; H, 8.67%.

4,7,10,13,16,19,24,27,30,33,36,40-Dodecaoxatetracyclo[20.15.2.$1^{1,22}$.$0^{2,21}$]tetracontane (17). Compound **17** (230 mg, 45%) was obtained from **8** (330 mg, 0.877 mmol) and pentaethylene glycol ditosylate (480 mg, 0.877 mmol) as an oil: ^1H NMR ($CDCl_3$) δ=1.67 (4H, br s), 2.44 (2H, br s), 3.3—3.9 (44H, m); MS *m/z* 578 (M^+). Found: C, 57.58; H, 8.65%. Calcd for $C_{28}H_{50}O_{12}$: C, 58.11; H, 8.71%.

4,7,10,13,16,19,24,27,30,33,37-Undecaoxatetracyclo[20.12.2.$1^{1,22}$.$0^{2,21}$]heptatriacontane (18). Compound **18** (204 mg, 42%) was obtained from **10** (300 mg, 0.903 mmol) and pentaethylene glycol ditosylate (500 mg, 0.914 mmol) as an oil: ^1H NMR ($CDCl_3$) δ 1.72 (4H, br s), 2.50 (2H, br s), 3.4—3.8 (40H, m); MS *m/z* 534 (M^+). Found: C, 57.72; H, 8.79%. Calcd for $C_{26}H_{46}O_{11}$: C, 58.41; H, 8.67%.

18,19-Bis(2,5,8-trioxanonyl)-3,6,9,12,15,22-hexaoxatricyclo[15.2.2.$1^{1,17}$]docosane (19). To a suspension of NaH (40 mg, 1.7 mmol) in dry DMF (10 mL) was added a solution of **8** (200 mg, 0.532 mmol) in dry DMF (10 mL). After the mixture was heated at 50±5 °C for 1 h, a solution of 3,6-dioxaheptyl *p*-toluenesulfonate (320 mg, 1.17 mmol) in DMF (10 mL) was added to the mixture and then it was heated at 50±5 °C for an additional 30 h. After a similar workup described for the preparation of **15**, chromatography (Al_2O_3, benzene–$CHCl_3$) provided **19** (210 mg, 68%) as an oil: ^1H NMR ($CDCl_3$) δ=1.70 (4H, br s), 2.48 (2H, br s), 3.36 (6H, s), 3.4-3.8 (40H, m); MS *m/z* 580 (M^+). Found: C, 57.47; H, 9.09%. Calcd for $C_{28}H_{52}O_{12}$: C, 57.91 H, 9.03%.

18,19-Bis(2,5,8,11-tetraoxadodecyl)-3,6,9,12,15,22-hexaoxatricyclo[15.2.2.$1^{1,17}$]docosane (20). Compound **20** (135 mg, 20%) was obtained from **8** (376 mg, 1.00 mmol) and 3,6,9-trioxadecyl *p*-toluenesulfonate (795 mg, 2.50 mmol) as an oil: ^1H NMR ($CDCl_3$) δ=1.68 (4H, br s), 2.45 (2H, br s), 3.32 (6H, s), 3.4—3.8 (48H, m); MS *m/z* 668 (M^+). Found: C, 56.72; H, 9.08%. Calcd for $C_{32}H_{60}O_{14}$: C, 57.46; H, 9.04%.

1,19-Bis(2,5,8-trioxanonyl)-4,7,10,13,16,22-hexaoxatricyclo-[17.2.1.$0^{2,18}$]docosane (21). Compound **21** (160 mg, 47%) was prepared from **14** (250 mg, 0.592 mmol) and tetraethylene glycol ditosylate (300 mg, 0.597 mmol) as an oil: ^1H NMR ($CDCl_3$) δ=1.70 (4H, br s), 2.50 (2H, br s), 3.38 (6H, s), 3.5—3.9 (40H, m); MS *m/z* 580 (M^+). Found: C, 57.06; H, 9.10%. Calcd for $C_{28}H_{52}O_{12}$: C, 57.91; H, 9.03%.

1,22-Bis(2,5,8-trioxanonyl)-4,7,10,13,16,19,25-heptaoxatricyclo[20.2.1.$0^{2,22}$]pentacosane (22). Compound **22** (164 mg, 37%) was obtained from **14** (300 mg, 0.710 mmol) and pentaethylene glycol ditosylate (390 mg, 0.710 mmol) as an oil: ^1H NMR ($CDCl_3$) δ=1.69 (4H, br s), 2.50 (2H, br s), 3.37 (6H, s), 3.5—3.9 (44H, m); MS *m/z* 624 (M^+). Found: C, 57.08; H, 8.97%. Calcd for $C_{30}H_{56}O_{13}$: C, 57.67; H, 9.04%.

Synopsis. Sulfuryl chloride has been shown to be useful activator for sulfides in the selective preparation of ortho-alkylated phenols via [2,3]sigmatropic rearrangement. By this process, ortho-alkylated phenols have been prepared with various symmetric sulfides in good yields. The rearrangement products having 3-chloropropyl or 3-methyl-3-butenyl moiety have been converted into 2*H*-1-benzopyran derivatives.

We reported previously ortho-selective alkylation of phenols with sulfoxides and thionyl chloride via a [2,3]sigmatropic rearrangement.[1-3] However, in general, sulfoxides are hygroscopic and accessible by the oxidation of the corresponding sulfides. Therefore, we hoped that phenoxysulfonium salts **3** could be prepared from sulfides,[4] which are easier to handle than sulfoxides. Since the intermediates in the formation of phenoxysulfonium salts **3** with sulfoxides and thionyl chloride seem to be chlorosulfonium salts, we anticipated that the same sulfonium salts could be generated when sulfuryl chloride was used as an activator of sulfides. In this paper, we report a new method of selective ortho-alkylation of phenols using dialkyl sulfides and sulfuryl chloride, and also the facile preparation of 2*H*-1-benzopyrans by the cyclization of the resulting *o*-alkylphenols.

When sulfide was used, the operation of the alkylation of phenol could be simplified compared to the use of sulfoxides. Namely, sulfuryl chloride was added to a mixture of phenol **2** and sulfide **1** in dichloromethane at low temperature, followed by addition of triethylamine and then the reaction mixture was warmed to room temperature before work-up. We found that both the temperature and the period of the reaction of a sulfide with sulfuryl chloride affected the yield of **5**. The yield of *o*-alkylated phenol **5** decreased when the reaction time was prolonged at the same temperature. This tendency is enhanced at higher temperature, because of the thermolability of phenoxysulfonium salts **3**.

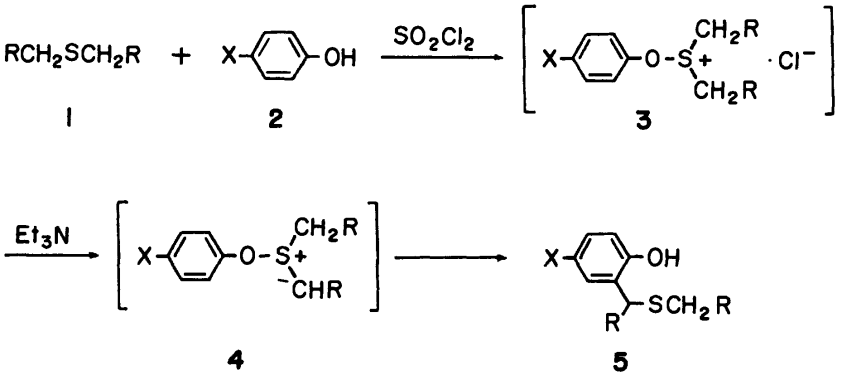
We investigated the alkylation of phenol **2** with various symmetric dialkyl sulfides **1** (Scheme 1). These results are summarized in the Table 1. Reaction of phenol (**2**; X=H) and sulfides **1** afforded the corresponding *o*-alkylated phenols **5** in good yields. Also, we investigated the reaction of para-substituted phenols **2** (X=Me, Cl, Ph, CO_2Et) with bis(2-acetoxyethyl) sulfide (**1**; R=CH_2OAc). In these cases, the expected products **5f—i** were obtained in good yields, except in the case of **5i**.

Next we studied the conversion of the rearrangement products **5j** and **5m** into 2*H*-1-benzopyran derivatives. We reported previously a facile synthesis of coumarin

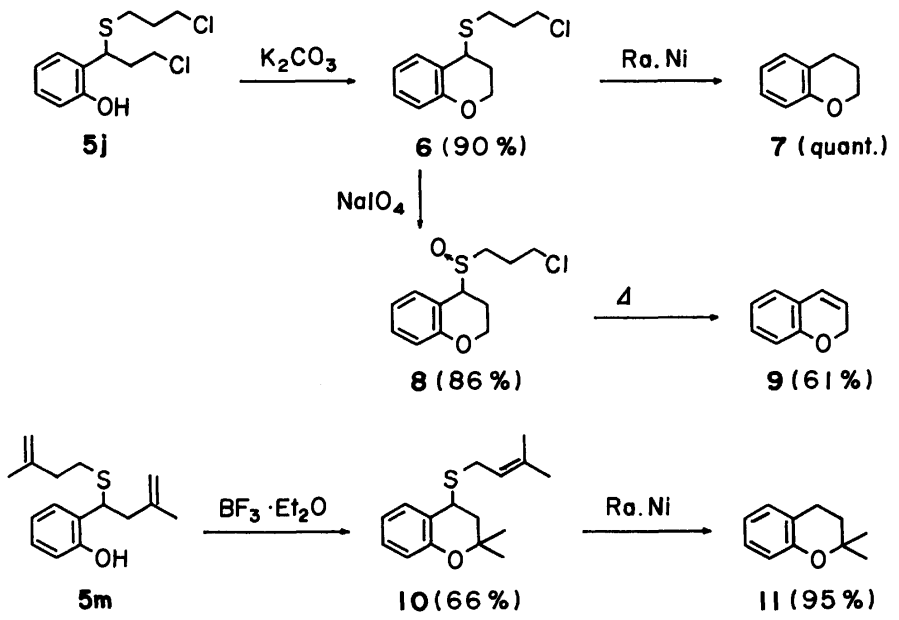
Table 1. Ortho-Selective Alkylation of Phenols with Symmetric Sulfides and Sulfuryl Chloride

Product	R	X	Yield/%[a]
5a	H	H	72 (78)
5b	Me	H	67 (69)
5c	Ph	H	56 (68)
5d	CH_2CO_2Me	H	70 (80)
5e	CH_2OAc	H	77
5f	CH_2OAc	Me	73
5g	CH_2OAc	Cl	61
5h	CH_2OAc	Ph	76[b]
5i	CH_2OAc	CO_2Et	31[b]
5j	CH_2CH_2Cl	H	83 (61)
5k	CH_2CMe_2Cl	H	67
5l	CH_2CMe_2OAc	H	77
5m	$CH_2CMe{=}CH_2$	H	63

a) Yields from the corresponding sulfoxides are given in parentheses. see Ref. 2. b) Dichloromethane-*N*,*N*-dimethylformamide (10:1) was used as a solvent.



Scheme 1.



Scheme 2.

from **5d**.[2] Herein, we report the preparation of chromene and chromane derivatives. The results are illustrated in Scheme 2. Thus, the treatment of **5j** with potassium carbonate followed by Raney nickel afforded chromane (**7**). Also, chromene (**9**) was prepared by sodium periodate oxidation of **6**, followed by β-elimination of sulfoxide **8**. Cyclization of **5m** with boron trifluoride etherate gave chromane derivative **10**, which possessed a 3-methyl-2-butenylthio group as the result of migration of carbon-carbon double bond. Then desulfurization of **10** with Raney nickel gave 2,2-dimethylchromane (**11**) in 95% yield. These results demonstrate that the terminally functionalized *o*-alkylphenols **5d**, **5j**, and **5m**, which are readily obtained by the present [2,3]sigmatropic rearrangement, are very useful for the synthesis of 2*H*-1-benzopyran derivatives.

Experimental

Melting points are uncorrected. IR spectra were measured on either a Hitachi 215 or a Hitachi 260-50 spectrometer. ^{1}H NMR spectra were obtained with a JEOL JNM-C-60M or a JEOL FT-90Q with tetramethylsilane as an internal standard. The known compounds were established on the basis of spectroscopic properties of itself and of the description of literature. Column chromatography was normally effected with Wakogel C-200 (Wako Pure Chemical Industries).

General Procedure. Sulfuryl chloride (2.2 ml, 22 mmol) was added dropwise to the mixture of sulfide **1** (22 mmol) and phenol **2** (66 mmol) in dry dichloromethane (200 ml) at −40 °C. After the reaction mixture was stirred for 20 min at −40 °C, triethylamine (20 ml) was added to the reaction mixture at −30 °C. The solution was allowed to warm to room temperature, and it was then poured into dilute hydrochloric acid. The organic layer was separated and the aqueous solution was extracted with ether. The combined organic layers were washed with water and brine, dried ($MgSO_4$), and then evaporated. The residue was chromatographed on a column to give the ortho-alkylated phenol **5**.

The following new compounds were prepared using the above procedure. The other compounds were established on the basis of spectroscopic properties of itself and of the products prepared from phenol and the corresponding sulfoxides.[2]

2-[2-Acetoxy-1-(2-acetoxyethylthio)ethyl]phenol (5e): Yield 77%. IR (neat) 3370, 2940, 1730, 1710, 1240, and 1220 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.03 (6H, s), 2.71 (2H, t, J=6), 4.18 (2H, t, J=6), 4.3—4.7 (3H, m), and 6.7—7.5 (5H, m). Found: C, 56.58; H, 6.03%. Calcd for $C_{14}H_{18}O_5S$: C, 56.36; H, 6.08%.

2-[2-Acetoxy-1-(2-acetoxyethylthio)ethyl]-4-methylphenol (5f): Yield 73%. Mp 64—65 °C. IR (KBr) 3280, 2920, 1730, 1700, 1270, and 1240 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.03 (6H, s), 2.23 (3H, s), 2.68 (2H, t, J=6), 4.15 (2H, t, J=6), 4.42 (3H, s), and 6.5—7.1 (4H, m). Found: C, 57.59; H, 6.43%. Calcd for $C_{15}H_{20}O_5S$: C, 57.68; H, 6.45%.

2-[2-Acetoxy-1-(2-acetoxyethylthio)ethyl]-4-chlorophenol (5g): Yield 61%. Mp 95—96.5 °C. IR (KBr) 3230, 2930, 1730, 1695, 1270, and 1245 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.07 (6H, s), 2.6—2.8 (2H, m), 4.20 (2H, t, J=6), 4.2—4.3 (3H, m), and 6.7—7.3 (4H, m). Found: C, 50.66; H, 5.11%. Calcd for $C_{14}H_{17}ClO_5S$: C, 50.53; H, 5.15%.

2-[2-Acetoxy-1-(2-acetoxyethylthio)ethyl]-4-phenylphenol (5h): Yield 76%. IR (neat) 3400, 2950, 1735, 1710, and 1230 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.05 (6H, s), 2.7—2.9 (2H, m), 4.22 (2H, t, J=6), 4.5—4.7 (3H, m), and 6.8—7.6 (9H, m). Found: C, 64.30; H, 5.90%. Calcd for $C_{20}H_{22}O_5S$: C, 64.15; H, 5.92%.

Ethyl 3-[2-Acetoxy-1-(2-acetoxyethylthio)ethyl]-4-hydroxybenzoate (5i): Yield 31%. IR (neat) 3230, 2970, 1740, 1710, 1270, and 1230 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=1.39 (3H, t, J=7), 2.06 (6H, s), 2.77 (2H, t, J=7), 4.1—4.7 (7H, m), 6.92 (1H, d, J=8), 7.92 (1H, dd, J=2, 8), 8.04 (1H, d, J=2), and 8.34 (1H, bs). Found: C, 55.54; H, 6.02%. Calcd for $C_{17}H_{22}O_7S$: C, 55.12; H, 5.99%.

2-[3-Chloro-1-(3-chloro-3-methylbutylthio)-3-methylbutyl]phenol (5k): Yield 67%. IR (neat) 3350, 1580, 1490, 1450, 1370, and 1230 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=1.43, 1.57 (12H, each s), 1.7—2.0 (4H, m), 2.2—2.6 (2H, m), 4.42 (1H, t, J=7), 6.20 (1H, bs), and 6.6—7.3 (4H, m). Found: C, 57.53; H,

7.21%. Calcd for $C_{16}H_{24}Cl_2OS$: C, 57.31; H, 7.21%.

2-[3-Acetoxy-1-(3-acetoxy-3-methylbutylthio)-3-methylbutyl]phenol (5l): Yield 77%. IR (neat) 3300, 2970, 1720, and 1250 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.32 (6H, s), 1.42, 1.46 (6H, each s), 1.67 (3H, s), 1.88 (3H, s), 2.0—3.2 (6H, m), 4.50 (1H, dd, J=4, 8), 6.7—7.3 (4H, m), and 7.87 (1H, bs). Found: C, 62.50; H, 7.77%. Calcd for $C_{20}H_{30}O_5S$: C, 62.80; H, 7.90%.

2-[3-Methyl-1-(3-methyl-3-butenylthio)-3-butenyl]phenol (5m): Yield 63%. IR (neat) 3320, 3075, 2925, 1645, and 750 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.60, 1.67 (6H, each s), 2.2—2.4 (4H, m), 2.57 (2H, d, J=8), 4.17 (1H, t, J=8), 4.67 (4H, bs), and 6.6—7.3 (5H, m). Found: C, 73.53; H, 8.44%. Calcd for $C_{16}H_{22}OS$: C, 73.24; H, 8.45%.

4-(3-Chloropropylthio)-3,4-dihydro-2*H*-1-benzopyran (6). Potassium carbonate (2.76 g, 20 mmol) was added to a solution of **5j** (0.51 g, 1.83 mmol) in acetone (30 ml). After the mixture was refluxed for 3 h, it was filtered. The filtrate was concentrated. The residue was chromatographed on a column (benzene) to give **6** (0.40 g, 90%). IR (neat) 1580, 1480, 1260, and 750 cm^{-1}. ^1H NMR (CCl_4) δ=1.8—2.3 (4H, m), 2.57 (2H, t, J=7), 3.55 (2H, t, J=6), 3.95 (1H, t, J=4), 4.1—4.6 (2H, m), and 6.6—7.3 (4H, m). Found: C, 59.07; H, 6.17%. Calcd for $C_{12}H_{15}ClOS$: C, 59.37; H, 6.23%.

3,4-Dihydro-2*H*-1-benzopyran (7). The mixture of **6** (60 mg, 0.25 mmol) and Raney nickel (W4) (ca. 4 g) in ethanol (5 ml) was refluxed for 1 h. After the mixture was filtered, the filtrate was concentrated. The residual oil was chromatographed on a column (5% AcOEt–hexane) to give **7** (33 mg, quant.)

4-(3-Chloropropylsulfinyl)-3,4-dihydro-2*H*-1-benzopyran (8). A solution of sodium periodate (0.396 g, 1.85 mmol) in water (2 ml) was added dropwise to a solution of **6** (0.383 g, 1.58 mmol) in ethanol (6 ml) at 0 °C. The solution was stirred for 24 h at 0 °C. After the precipitate was filtered, the filtrate was poured into water. The aqueous solution was extracted with chloroform. The organic layer was washed with brine, dried ($MgSO_4$), and then evaporated. The residue was chromatographed on a column (13% AcOEt–benzene) to afford **8** (0.354 g, 86%). IR (neat) 3400, 1580, 1485, 1220, and 1030 cm^{-1}. ^1H NMR (CCl_4) δ=1.6—2.5 (4H, m), 2.5—3.0 (2H, m), 3.60 (2H, t, J=7), 3.8—3.9 (1H, m), 4.0—4.4 (2H, m), and 6.7—7.2 (4H, m). Found: C, 55.61; H, 5.83%. Calcd for $C_{12}H_{15}ClO_2S$: C, 55.70; H, 5.84%.

2*H*-1-Benzopyran (9). A solution of **8** (0.20 g, 0.774 mmol) in toluene (100 ml) was refluxed for 3 h and then concentrated. The residual oil was chromatographed on a column (30% benzene–hexane) to give **9** (0.062 g, 61%).

3,4-Dihydro-2,2-dimethyl-4-(3-methyl-2-butenylthio)-2*H*-1-benzopyran (10). Boron trifluoride etherate (0.1 ml, 0.8 mmol) was added to a solution of **5m** (100 mg, 0.8 mmol) in dichloromethane (3 ml) at room temperature under nitrogen atmosphere. After the mixture was stirred for 90 min, it was washed with water. The organic layer was dried and then evaporated. The residual oil was chromatographed on a column (2% AcOEt–hexane) to afford **10** (66 mg, 66%). IR (neat) 2980, 1605, and 760 cm^{-1}. ^1H NMR (CCl_4) δ=1.23, 1.43 (6H, each s), 2.07 (2H, d, J=8.2), 5.20 (1H, t, J=8). Found: C, 73.60; H, 8.53%. Calcd for $C_{16}H_{22}OS$: C, 73.24; H, 8.45%.

3,4-Dihydro-2,2-dimethyl-2*H*-1-benzopyran (11). The mixture of **10** (60 mg, 0.23 mmol) and Raney nickel (W4) (ca. 4 g) in ethanol (5 ml) was refluxed for 1.5 h. After the mixture was filtered, the filtrate was concentrated. The residual oil was chromatographed on a column (5% AcOEt–hexane) to give **11** (35 mg, 95%).

We are indebted to Mr. Shuichi Sato and Mr. Norimichi Iwase for valuable technical help and to Mrs. Hiroko Suesawa for measuring some of the NMR spectra.

Synopsis. Reaction of phenols with calculated amounts of benzyltrimethylammonium tribromide or tetrabutylammonium tribromide in dichloromethane–methanol for 0.5—1 h under mild conditions gave, selectively, the objective mono-, di-, or tribromophenols in good yields.

Previous work in this series[2] has shown that the reaction of phenols (**1**) with benzyltrimethylammonium tribromide (BTMA Br_3) (**2a**) in dichloromethane–methanol at room temperature readily gave bromophenols (**3**). In this paper, we wish to report a selective bromination of **1** by use of tetraalkylammonium tribromides (**2**), such as **2a** or tetrabutylammonium tribromide (TBA Br_3) (**2b**).

Results and Discussion

In general, it is difficult to carry out a step-by-step bromination of **1** with bromine since **1** reacts very rapidly with the reagent and leads to the polybromo-substituted phenols. For the purpose of the syntheses of monobromophenols from **1**, some technique in which the position of the substrate is blocked by an appropriate substituent group has frequently been employed.[3,4]

The well-known method for preparing pure monobromophenols is a diazotization of the corresponding aromatic amines and a subsequent heating with water. However, sometimes this method requires a tediously long synthetic pathway to obtain the bromophenols.

We have recently found that the reaction of **1** with calculated amounts of **2a** or **2b** in dichloromethane–methanol at room temperature gives the desirable mono-, di-, or tribromophenols in good yields. For instance, reactions of phenol (**1a**) with 1.0 equiv of **2b** gave *p*-bromophenol (**3a-1**), and with 2.0 equiv of **2a** gave 2,4-dibromophenol (**3a-2**); furthermore, reactions with 3.0 equiv of **2a** gave 2,4,6-tribromophenol[2] in good yields, respectively. Especially, we emphasize that our procedure is a highly useful method for synthesizing monobromophenols. The results are summarized in the Table 1. (The results for an exhaustive bromination of several **1** with sufficient amounts of **2a** are already shown by us[2]).

Compounds 2,4-dibromophenol[6] (**3a-2**), 2-bromo-4-*t*-butylphenol[12] (**3e-1**) and 2,4,6-tribromo-1,3-benzenediol[24] (**3m-2**) have been prepared by special methods. Our method easily gave these compounds in good yields, respectively. However, as a limitation of this method, attempts at the monobromination of less reactive **1**, such as nitrophenols, were unsuccessful.[28]

Experimental

4-Bromo-3,5-dimethylphenol (3i-1): Typical Procedure (1). To a solution of 3,5-dimethylphenol (**1i**) (0.50 g, 4.09 mmol) in dichloromethane (30 ml)–methanol (20 ml) was added dropwise **2b** (2.0 g, 4.13 mmol) under stirring at room temperature. The mixture was stirred for 30 min until a decoloration of the orange solution took place. The solvent was distilled and to the obtained residue was added water (30 ml). The mixture was extracted with ether (40 ml×4). The ether layer was then dried with magnesium sulfate and evaporated in vacuo to give a residue which was recrystallized from methanol–water (1:3) affording **3i-1** as colorless crystals; yield 0.77 g (93%); mp 115—116 °C (lit,[18] mp 115—116 °C).

2,4-Dibromo-3,5-dimethylphenol (3i-2): Typical Procedure (2). To a solution of **1i** (0.50 g, 4.09 mmol) in dichloromethane (30 ml)–methanol (20 ml) was added dropwise **2a** (3.2 g, 8.23 mmol) under stirring at room temperature. The mixture was stirred for 30 min until a decoloration of the orange solution took place. A subsequent same work-up as above gave **3i-2** as colorless crystals; yield 1.07 g (93%); mp 72—73 °C (lit,[18] mp 72—73 °C).

2,4,6-Tribromo-3,5-dimethylphenol (3i-3): Typical Procedure (3). A mixture of **1i** (0.50 g, 4.09 mmol) and **2a** (4.95 g, 12.70 mmol) in dichloromethane (50 ml)–methanol (20 ml) was stirred for 1 h at room temperature until a discoloration of the orange solution took place. A subsequent same work-up as above gave **3i-3** as colorless crystals; yield 1.63 g (90%); mp 166—169 °C (lit,[19] mp 166 °C).

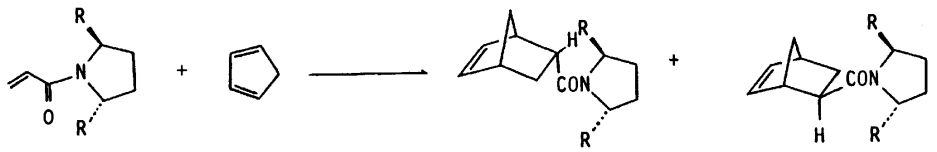
(Received June 2, 1987)

Synopsis. The asymmetric Diels-lder reaction between chiral acrylamides derived from (2R,5R)-2,5-disubstituted pyrrolidines and cyclopentadiene gave (1*R*,2*R*,4*R*)-5-norbornene-2-carboxylic acid amides **3a—c** with excellent diastereoface selectivity. The amides **3a—c** were converted into the corresponding carboxylic acid by an iodolactonization-reduction sequence and 2,5-disubstituted pyrrolidines were recovered intact.

The Diels-Alder reaction[1] provides one of the useful methods of creating new chiral centers and some highly diastereoselective examples employing different types of optically active dienophiles have been reported in the last few years.[2-4] Recently, we have developed chiral auxiliaries, *trans*-2,5-disubstituted pyrrolidines,[5] which were quite effective for asymmetric α-alkylations,[5] α-acylation,[6] aldol reaction,[7] and [2,3]-Wittig rearrangement[8] of carboxylic acids through their amides. In this note, we wish to describe the asymmetric Diels-Alder reaction of acrylamides **1a—c** bearing the same chiral auxiliaries with cyclopentadiene under Lewis acid catalyzed and uncatalyzed conditions.



1a; R=COOMe
1b; R=CH_2OMe
1c; R=CH_2OCH_2OMe

2

The dienophiles **1a—c** were prepared by the acylation of the corresponding (2R,5R)-2,5-disubstituted pyrrolidines[5] with acryloyl chloride and Et_3N in CH_2Cl_2 at 0 °C. Then, **1a—c** were submitted to Diels-Alder reaction with cyclopentadiene in toluene under various conditions. The reaction proceeded smoothly to give (1*R*,2*R*,4*R*)-5-norbornene-2-carboxylic acid amides **3a—c** as major isomers. The results obtained were summarized in Table 1. Aluminum trichloride among Lewis acids examined afforded the highest *endo*- and almost quantitative diastereoface selectivity (Entries 5 and 8). Diethylaluminum chloride also gave the same degree of diastereomeric excess as aluminum trichloride but the *endo*

a) Reactions were carried out in 0.2—0.5 mol dm^{-3} toluene solution of **1**. b) Isolated yield. c) Ratios were determined after column chromatography separation. Each compound gave satisfactory ^1H NMR analysis. d) Determined by ^1H NMR spectra in the presence of Eu(fod)$_3$ and/or ^{13}C NMR spectra. e) Configurations of the adducts were deduced to be 2'R from the configuration of (+)-(1*R*,2*R*,4*R*)-5-norbornene-2-carboxylic acid. f) MOM=CH_2OMe. g) Acrylamide derived from (*S*)-*O*-methoxymethylprolinol. h) Absolute configuration was determined to be 2'S.

selectivity suffered a small loss (Entry 9). In the reactions in the absence of catalyst, the diastereoface selectivity depended on the substituent on the pyrrolidine ring and the best result (90% de) was obtained when the amide **1c** was used (Entry 6). This result is noteworthy because highly diastereoselective Diels-Alder reactions with one exception[2] have usually been attained in the presence of Lewis acid catalysts.[1] An acrylamide **1d** derived from (*S*)-*O*-methoxymethylprolinol, was examined for comparison and only moderate diastereoface selectivity (73% de) was obtained under aluminum trichloride-catalyzed conditions, though high *endo* selectivity was also observed (Entry 10).

The major *endo*-adducts **3** were converted to (+)-(1*R*,2*R*,4*R*)-5-norbornene-2-carboxylic acid[2,9] by the sequence, i) iodolactonization to a iodo lactone using iodine in H_2O-DME[10] and ii) reduction of the iodo lactone by zinc in methanol. Chiral auxiliaries were also recovered by this iodolactonization process.

Although the exact steric cource of the reaction is not clear at present, absolute configurations of cycloaddition products and a CPK-model examination suggest that the acrylamide exists as a cisoid conformer due to the severe repulsion between the *cis*-vinylic hydrogen on the β-carbon atom and one of the C_2-symmetrically placed substituents on the pyrrolidine ring and that the amide is attacked by cyclopentadiene on its less hindered side (*si*-face). Further work on the reaction of other combinations of dienophiles and dienes is under way.

Experimental

Melting points were uncorrected. ^{1}H NMR and ^{13}C NMR spectra were obtained at 90 MHz in $CDCl_3$ with TMS as an internal standard.

(2*R*,5*R*)-*N*-Acryloyl-*trans*-2,5-bis(methoxycarbonyl)pyrrolidine (1a). Acryloyl chloride (0.21 ml, 2.58 mmol) was added to a solution of (2*R*,5*R*)-*trans*-2,5-bis(methoxycarbonyl)pyrrolidine (242 mg, 1.29 mmol) and triethylamine (0.36 ml, 2.58 mmol) in dichloromethane (4 ml) at 0 °C and the mixture was stirred for 1 h. The reaction mixture was diluted with ether and filtered through Celite. The filtrate was concentrated and chromatographed on silica gel (hexane-acetone, 10:3) to give **1a** (172 mg, 58%): $[\alpha]_D^{23}$ +118° (*c* 1.14, EtOH); UV (EtOH) 206 nm (ε 4065); IR (neat) 1740, 1650, and 1615 cm^{-1}; ^{1}H NMR δ=1.92—2.63 (4H, m), 3.73 (3H, s), 3.75 (3H, s), 4.6—4.8 (2H, m), 5.70 (1H, dd, *J*=9.5 and 4.0 Hz), 6.06—6.55 (2H, m); Found: C, 54.98; H, 6.16; N, 5.54%. Representative Procedure for Diels-Alder Reaction of Acrylamides with Cyclopentadiene. Aluminum trichloride (122 mg, 0.904 mmol) was added to a solution of **1c** (206 mg, 0.753 mmol) in toluene (3.7 ml) at 0 °C. After 5 min, freshly distilled cyclopentadiene (0.5 ml, 6 mmol) was added to the solution. The mixture was stirred for 1 h, quenched with saturated aqueous $NaHCO_3$ solution, and extracted with ethyl acetate. The organic layer was washed with brine, dried over $MgSO_4$, and concentrated in vacuo. The concentrate was chromatographed on silica gel (hexane-acetone, 5:2) to give the less polar *exo*-isomer (**4c**, 10 mg, 4%) and the more polar *endo*-isomer (**3c**, 185 mg, 72%).

4c: IR (neat) 1635 cm^{-1}; ^{1}H NMR δ=1.1—1.4 (2H, m), 1.78—2.50 (7H, m), 2.75 (1H, m), 2.92 (1H, m), 3.32 (3H, s), 3.35 (3H, s), 3.2—3.8 (4H, m), 3.93—4.32 (2H, m), 4.56 (2H, s), 4.60 (2H, s), 6.15 (2H, m).

3c: $[\alpha]_D^{23}$ +161.8° (*c* 1.23, EtOH); IR (neat) 1640 cm^{-1}; ^{1}H NMR δ=1.15—2.40 (8H, m), 2.82—3.72 (7H, m), 3.35 (6H, s), 4.20 (2H, m), 4.60 (4H, s), 5.76 (1H, dd, *J*=2.6 and 5.6 Hz), 6.25 (1H, dd, *J*=3.1 and 5.6 Hz); ^{13}C NMR δ=25.1, 27.5, 29.2, 42.0, 43.2, 46.6, 50.2, 55.1, 55.2, 56.8, 57.3, 67.0, 69.4, 96.5, 96.6, 130.3, 137.3, 173.0; Found: C, 63.49; H, 8.79; N, 4.17%. Calcd for $C_{18}H_{29}NO_5$: C, 63.69; H, 8.61; N, 4.13%.

(2*R*,5*R*)-*N*-[(1*R*,2*R*,4*R*)-5-Norbornene-2-carbonyl]-*trans*-2,5-bis(methoxycarbonyl)pyrrolidine (3a): $[\alpha]_D^{23}$ +212.6° (*c* 1.98, EtOH); IR (neat) 1735 and 1650 cm^{-1}; ^{1}H NMR δ=1.16—2.98 (10H, m), 3.17 (1H, m), 3.70 (3H, s), 3.77 (3H, s), 4.61 (1H, m) 4.79 (1H, d, *J*=7.4 Hz), 5.89 (1H, dd, *J*=6.0 and 3.0 Hz), 6.19 (1H, dd, *J*=6.0 and 3.0 Hz); ^{13}C NMR δ=26.9, 29.6, 30.1, 42.3, 42.8, 45.9, 49.8, 52.0, 52.6, 59.3, 131.5, 136.7, 172.3, 172.5, 173.0; Found: C, 62.52; H, 6.93; N, 4.58%. Calcd for $C_{16}H_{21}NO_5$: C, 62.53; H, 6.89; N, 4.56%.

(2*R*,5*R*)-*N*-[(1*R*,2*R*,4*R*)-5-Norbornene-2-carbonyl]-*trans*-2,5-bis(methoxymethyl)pyrrolidine (3b): $[\alpha]_D^{23}$ +213° (*c* 1.0, EtOH); IR (neat) 1640 cm^{-1}; ^{1}H NMR δ=1.15—2.55 (9H, m), 2.82—3.68 (6H, m), 3.32 (3H, s), 3.35 (3H, s), 4.15 (2H, m), 5.74 (1H, m), 6.24 (1H, m); ^{13}C NMR δ=25.0, 27.3, 29.0, 42.0, 43.0, 46.6, 50.2, 56.5, 57.1, 58.6, 59.0, 71.4, 74.5, 130.3, 137.4, 173.0; Found: C, 68.54; H, 9.27; N, 5.00%. Calcd for $C_{16}H_{25}NO_3$: C, 68.79; H, 9.02; N, 5.01%.

Conversion of (+)-3c to (+)-(1*R*,2*R*,4*R*)-5-Norbornene-2-carboxylic Acid. Iodine (57.8 mg, 0.228 mmol) was added to a solution of **3c** (70.3 mg, 0.207 mmol) in H_2O-DME (1:1, 0.6 ml) at room temperature and the mixture was stirred for 1 day. The resultant solution was diluted with ethyl acetate and washed with saturated $Na_2S_2O_3$ and with 0.5 mol dm^{-3} HCl. The organic layer was further washed with saturated $NaHCO_3$ and with brine, dried over $MgSO_4$, and concentrated. The residue was subjected to preparative TLC (hexane-acetone, 10:3) to give the iodo lactone (**5**, 34.6 mg, 63%): ^{1}H NMR δ=1.59—2.80 (6H, m), 3.20 (1H, m), 3.89 (1H, d, *J*=2.6 Hz), 5.13 (1H, d, *J*=5.3 Hz). The whole aqueous solution was made basic with $NaHCO_3$ and extracted with chloroform-ethanol (3:1). The extract was dried over $MgSO_4$ and concentrated to recover (2*R*,5*R*)-2,5-bis(methoxymethoxymethyl)pyrrolidine (63%). The iodo lactone **5** was then treated with zinc (120 mg, 1.84 mmol) and CuBr (40 mg, 0.279 mmol) in methanol at room temperature for 2 h. The mixture was filtered through Celite and concentrated. The residue was submitted to bulb-to-bulb distillation (130—140 °C/2133 Pa, bath temperature) to give (+)-5-norbornene-2-carboxylic acid (12.3 mg, 68%); $[\alpha]_D^{23}$ +146° (*c* 0.615, EtOH) [lit,[2] $[\alpha]_D^{23}$ −147.14° (*c* 0.49, EtOH) for (*S*)-acid].

The compounds [(+)-**3a** and (+)-**3b**] were also converted into the same (+)-norbornene-2-carboxylic acid in a similar manner.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 61740306 from the Ministry of Education, Science and Culture.

Electroreduction of *m*-Hydroxybenzoic Acid.[1] Preparation of *m*-Phenoxybenzyl Alcohol for the New Insecticide Ethofenprox

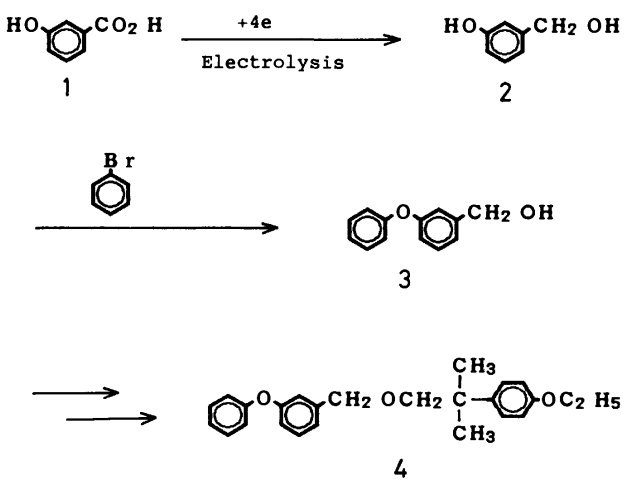
Ryu Oi, Chitoshi Shimakawa, Yasushi Shimokawa, and Shinji Takenaka*
Research Dept. Omuta Factory, Mitsui Toatsu Chemicals, Inc., Omuta, Fukuoka 836
(Received June 5, 1987)

Synopsis. The electroreduction of *m*-hydroxybenzoic acid was examined from both mechanistic and technical points of view, and a practical route to *m*-phenoxybenzyl alcohol has been developed.

Recently, various kinds of artificial pyrethroids having *m*-phenoxybenzyloxy group have been developed and their characteristic features have received much attention in the insecticide chemistry. Among these pyrethroids, due to low toxicity to fish as well as to mammals and excellent pesticidal activity, the exceptional potency of ethofenprox (**4**)[2] has opened up an important market, especially in agriculture for pest control. In our research project on the development of a commercially feasible procedure for the synthesis of **4**, we needed an efficient procedure for producing *m*-phenoxybenzyl alcohol (**3**) (Scheme 1).

Many attempts have been made to prepare **3**; majority of the hitherto disclosed procedures relies upon partial oxidation of *m*-phenoxytoluene (**5**). For example, the halogenation of **5** followed by hydrolysis[3] has been intensively investigated, but the product selectivity is not necessarily satisfactory. On the other hand, alternative route to **3** has been performed by the air-oxidation of **5** followed by the electroreduction.[4] However, there still remain some difficulties in operating in the industrial practice, since the air-oxidation requires vigorous conditions, e.g., high temperature and high pressure, and the substrate concentration in the electrolysis is impractically low.

Herewith, we describe a new efficient procedure for the synthesis of **3** (Scheme 1) involving electroreduction of *m*-hydroxybenzoic acid (**1**), which is easily available on a commercial basis, and subsequent condensation of hydroxybenzyl alcohol **2** with bromobenzene.[5]



Scheme 1.

The merit of this approach strongly depends upon ease of the operation and high yield of the electrochemical reduction step (**1**→**2**). Reduction of the carboxylic acid **1** to alcohol **2** has been performed by the chemical reduction with borane–dimethyl sulfide,[6] but the use of a stoichiometric amount of the expensive reduction agent is impractical. As a potential tool for the catalytic hydrogenation of **1**, electroreduction has received some attention.[7] The yield of **2** reported so far, however, is insufficient (44%), and the commercial application of the electrolysis procedure has been out of consideration.

In order to improve the yield of **2** sufficient for practical use, we reinvestigated the electrochemical reduction of **1** from both mechanistic and technical points of view.

Electroreduction was carried out with two lead electrodes using an H-shaped two compartment cell divided by ion-exchange membrane in aqueous H_2SO_4 solution. The results under various electrolysis conditions are summarized in Table 1. Satisfactory current efficiency was attained in the aqueous acidic media (Entries 1—4), while in neutral conditions (Entry 8), the reduction was very slow, and no appreciable amount of **2** was detected in basic conditions (Entry 9). A lead cathode gave better results than mercury one (Entries 3 and 6). Attempts were made to assess the relative importance of acids in this reduction by influences of current efficiency upon several different H_2SO_4 concentrations (Table 1, Entries 1—4). Better results were obtained at higher H^+ concentrations, but decomposition of product **2** was promoted at the same time.

Next, we studied this phenomenon from voltammetric viewpoint. In the acidic electrolysis systems, reduction of **1** competes with the hydrogen evolution reaction. Therefore, particular attention should be paid to the relative reduction potential of **1** against hydrogen overvoltage. It is of interest to note that in spite of the fact that no appreciable shifts of hydrogen overvoltage of lead electrode were observed with the variation of H_2SO_4 concentration (−1.73—1.75 V vs. Hg/Hg_2SO_4), reduction wave of **1** appeared more clearly at higher H_2SO_4 concentrations. The reduction wave shifts to ca. −1.66 V from −1.71 V by increasing the H_2SO_4 concentration from 5% up to 17.5%, while no appreciable change of the potential was observed over 17.5% (Table 1, Entries 1—4). These results are good in accordance with the variation of the current efficiency. These remarkable effects of the concentration of H_2SO_4 are well understood by assuming the four electron reduction mechanism[8] involving protonated aromatic carboxylic acid as a

Table 1. Electroreduction of *m*-Hydroxybenzoic Acid (**1**)[a]

Entry	Solvent electrolyte	Conversion of **1**[b,c] %	Current efficiency[c] %	Yield of **2**[c] %	Reduction potential of **1**[d]
1	5% aq H_2SO_4	10.5	4.2	8.7	−1.71
2	10% aq H_2SO_4	51.0	20.4	48.1	−1.69
3	17.5% aq H_2SO_4	99.9	40.0	91.5(90)[h]	−1.66
4	25% aq H_2SO_4	100.0	40.0	86.4(85)[h]	−1.66
5[e]	17.5% aq H_2SO_4	25.1	10.0	21.4	
6[f]	17.5% aq H_2SO_4	81.2	32.5	75.1	
7[g]	17.5% aq H_2SO_4	99.9	40.0	31.6	
8	15% aq Et_4NOTs	3.3	1.3	2.9	
9	15% aq NaOH	—	—	—	

a) The electroreduction was curried out under constant current of 16 A dm^{-2} with an H-shaped devided cell fitted with two lead electrodes at 50 °C. The amount of each 15% of **1**(vs. solvent) was added portionwise. b) Electricity was passed up to 10 F mol^{-1}. c) Analyzed by HPLC based on **1**. d) V vs. Hg/Hg_2SO_4. e) **1** was added all at once at the beginning. f) A Hg pool cathode was used. g) Carried out at 80 °C. h) Isolated yield based on **1**.

reactive species. Thus, in more acidic solutions, a greater proportion of activated **1** by protonation may contribute to move the reduction potential in positive direction and to improve the current efficiency.

In a practical sense, it is important to operate the electrolysis at a high substrate concentration, since the concentration is directly related to the production efficiency and economy. Unfortunately, carboxylic acid **1** has a low solubility in the water, and when **1** was added beyond its solubility, deposits of insoluble parts of **1** covered the surface of the cathode to disturb the desired reduction (Table 1, Entry 5). In order to obtain a 10% homogeneous solubility of **1**, reaction temperature must be raised above 80 °C. However, product **2** is easily decomposed in the acidic solution, and the decomposition rate undesirably increases as the temperature rises. Lower yield of **2** at 80 °C (Table 1, Entry 7) compared with that at 50 °C (Entry 3) seems to be ascribed to thermal decomposition of **2**.

The contradictory problems can be solved by portionwise addition of **1**. When the electrolysis was carried out at 50 °C by adding **1** little by little during the course of electrolysis with a gradual generation of the product, reduction of significant amount of the carboxylic acid could be achieved and finally concentration of the product reached to 15%. This can be ascribed to the fact that in contrast to the poor solubility of starting **1**, product **2** is very soluble in the water, and the presence of **2** improves the solubility of **1** significantly. Due to these investigations, this electrochemical reduction has successfully gone through pilot plant test and is being studied for the commercial production.

Experimental

Melting points are uncorrected and were determined in open-ended capillaries. IR spectra were recorded on a Hitachi 285 grating spectrometer, and ^1H NMR spectra were measured at 90 MHz with a Nippon Denshi FX-90Q spectrometer. Chemical shifts are quoted in parts par million downfield from Me_4Si used as an internal reference. Cyclic voltammetric experiments were performed by using Hokuto Denko Ltd. Model HA-303 potentio-galvanostat, HB-104 function generator and Riken Denshi Co., Ltd. Model F-3 X-Y plotter.

Consumption of the starting material and purity of products were checked on a Shimazu HPLC system (Model LC-5A pump, SPD-2A spectrophotometric detector) using *p*-nitrophenol as an internal standard. For reverse-phase chromatography, Dupont Zorvax ODS column (a 4.6 mm diameter, 25 cm length stainless steel) was used. An eluent solvent of 40/60 MeCN–H_2O was buffered with 0.3 mmol dm^{-3} AcOH and 3 mmol dm^{-3} AcONa. The flow rate was 0.5 ml min^{-1} and fixed-wavelength detection (266 nm) was used.

Materials. *m*-Hydroxybenzoic acid (**1**) was available as a commercial product of our company. *m*-Hydroxybenzyl alcohol (**2**) was purchased from Aldrich Chemicals Co. as authentic sample.

Apparatus. An H-shaped cell divided with ion-exchange membrane (Asahi Glass Co., Ltd. Selemion CMV) was used, which was equipped with two lead plate electrodes (50 cm^2, 12 cm apart), stirring bars, and a thermometer. A vessel was immersed in a hot water bath at 50 °C and regulated dc power was supplied by Kikusui Electronics Co. Model PAD 35—60L.LP.

General Procedures. Electrochemical Reduction of *m*-Hydroxybenzoic Acid (1). Into both the anode and cathode compartments was placed a 17.5% water solution of H_2SO_4 (200 g each). After regulated dc power (16 A dm^{-2}) was supplied at 50 °C, to the catholytes was portionwise added *m*-hydroxybenzoic acid (**1**; 6.85 g h^{-1}, total 35.0 g, 0.253 mol) during the first 6 F mol^{-1} (5.1 h). After being electrolyzed (10 F mol^{-1}, 8.5 h) at 50 °C, the catholytes were extracted with diethyl ether. The extract was washed with brine, dried (Na_2SO_4) and concentrated in vacuo, giving a brown oil (29.3 g). The rapidly crystallized at room temperature, giving tan crystals, mp 68—70 °C (lit,[7] mp 73 °C), with IR and ^1H NMR spectrums identical with that reported for the authentic material.[9] The crystals were checked on HPLC and purity of *m*-hydroxybenzyl alcohol (**2**) was 96.5% (90.0% yield based on **1**), along with 0.1% of starting material **1** by using an internal standard.

We thank Prof. Sigeru Torii, Dr. Hideo Tanaka (Okayama University, Jpn.), and Dr. Akihiro Tamaki (General Manager of Research Dept., Omuta Factory, Mitsui Toatsu Chemicals, Inc., Jpn.) for many helpful

discussions as this work progressed. We thank Morihiko Hoshioka (Director of Omuta Factory, Mitsui Toatsu Chemicals, Inc., Jpn.) for giving us an opportunity to present this work.

$AlBr_3$ Group Reorientation in $NaAl_2Br_7$ and KAl_2Br_7 Studied by Means of ^{81}Br, ^{27}Al NQR and ^{27}Al NMR

Koji YAMADA,* Tsutomu OKUDA, and Sumio ICHIBA
Department of Chemistry, Faculty of Science, Hiroshima University, Naka-ku, Hiroshima 730
(Received February 27, 1987)

^{81}Br NQR spin-lattice relaxation times for MAl_2Br_7 (M=Na and K) were measured from 77 to 373 K and the reorientational activation energies of the $AlBr_3$ groups about Al-Br(bridge) axes were determined. In the case of $NaAl_2Br_7$, the reorientation of the $AlBr_3$ group was also confirmed by a motional narrowing effect of the ^{27}Al NMR using a single crystal. In order to examine the effect of the reorientation on the Al site, ^{27}Al NQR frequencies in $NaAl_2Br_7$ were observed as a function of temperature by a SEDOR technique. The asymmetry parameter (η) of the electric field gradient (efg) tensor was found to increase at one of the two Al sites with the onset of the reorientation.

NQR spin-lattice relaxation times (T_1) have been measured in order to study reorientation of molecules or molecular fragments[1,2] and also molecular motions in the vicinity of phase transitions.[3] This is due to the fact that the NQR relaxation rate increases because of the large fluctuation of its efg tensor induced by molecular motions. The dynamical properties of the compounds containing reorientationable groups such as $-CCl_3$, $-PCl_3$, and $=PCl_3$ have been studied by ^{35}Cl NQR T_1.[4-9] In contrast to proton NMR experiment in the solid state, the measurements of the NQR relaxation times give dynamical information at each crystallographically different site. This advantage was clearly shown for p-$CCl_3C_6H_4Cl$[4] and $AlBr_3 \cdot 2CH_3CN$ which has the ionic structure $AlBr(CH_3CN)_5^{2+} \cdot 2AlBr_4^- \cdot CH_3CN$.[10]

According to the crystal structures of KAl_2Br_7 and $NH_4Al_2Br_7$, the $Al_2Br_7^-$ anion consists of two $AlBr_4$ tetrahedra sharing one Br atom. The Al-Br-Al bridge angle is close to regular tetrahedral one and the two $AlBr_3$ groups are arranged in a staggered configuration to minimize halogen-halogen repulsions.[11,12] In our previous paper it was shown from the ^{27}Al NMR experiments, using a single crystal of KAl_2Br_7, that the angle between efg z-axes of the ^{27}Al was by about 9 degrees larger than that of ∠Al-Br-Al.[13] Similarly the angle between approximate C_3 axes of $AlBr_3$ groups, which were determined as a geometrical means of the three efg z-axes of the terminal Br atoms, is larger than ∠Al-Br-Al and almost consistent with the angle deduced from the ^{27}Al NMR. Accordingly, the approximate C_3 axis of the $AlBr_3$ group is not parallel to the Al-Br(bridge) direction and hence the bridging bond forms a "bent bond" or "banana bond" similar to the Al-Br-Al bond that occurs in the dimeric Al_2Br_6 molecule.[14,15] The steric hindrance of the two $AlBr_3$ groups seems to be the reason for the "bent bond." Therefore, these two $AlBr_3$ groups may affect each other in the activation process of their reorientations. In this paper we report the dynamical property of the two $AlBr_3$ groups in the $Al_2Br_7^-$ anion by means of ^{81}Br NQR and ^{27}Al NMR. Furthermore, the effect of the $AlBr_3$ reorientation on the ^{27}Al NQR parameters was investigated as a function of temperature.

Experimental

The compounds $NaAl_2Br_7$ and KAl_2Br_7 were obtained by crystallizing the molten mixture containing $AlBr_3$ and relevant alkali bromides by the Bridgman method. About 5% excess of $AlBr_3$ was added above the stoichiometric ratio because of the incongruent melting property of the compounds.[11,16]

The ^{81}Br NQR relaxation time T_1 was measured by the 90°-90° pulse method using a Matec pulse spectrometer. A typical pulse length for the 90° pulse was about 5 μs with a coil diameter of 12 mm. ^{27}Al and ^{23}Na NQR signals were detected by the ^{81}Br-^{27}Al and ^{81}Br-^{23}Na spin echo double resonance (SEDOR) method respectively, where a strong ^{81}Br NQR echo signal was monitored. The relative positions of the Br atoms within the anion were also determined, because the sensitivity of the SEDOR method depends upon the dipole-dipole interaction under study.[17] The experimental procedure has been described elsewhere.[18]

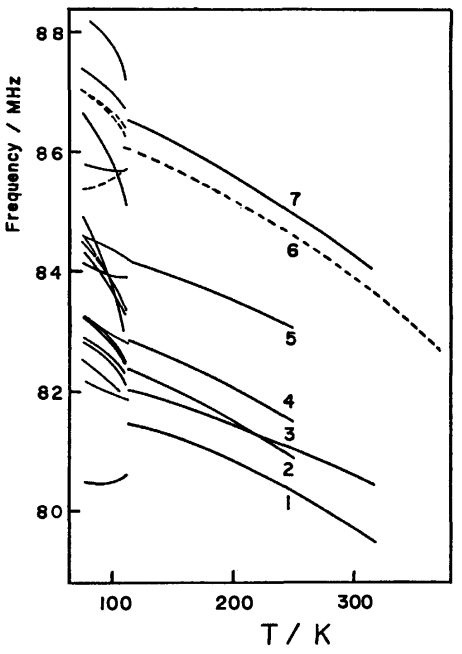

Fig. 1. Temperature dependence of the ^{81}Br NQR frequency in $NaAl_2Br_7$. The dotted curve Br(6) was assigned to the bridging atom.

Table 1. ^{27}Al and ^{23}Na NQR Parameters in $NaAl_2Br_7$ at Selected Temperature[a)]

Nucleus	Temp/K	Assignment[b)]	ν_1/MHz	ν_2/MHz	η	e^2Qqh^{-1}/MHz
^{27}Al	90	Al(1)′	1.306	2.561	0.039	8.692

a) Estimated error in ν is ±0.003 MHz. b) Below 113±1 K, Al(1) and Al(2) lines split into three lines Al(1)′ and Al(2)′ respectively.

Results and Discussion

$NaAl_2Br_7$. Figure 1 shows the temperature dependence of the ^{81}Br NQR frequencies. Above the phase transition temperature (T_c=113±1K) seven ^{81}Br NQR lines were observed as reported previously.[13] Below T_c, however, the spectrum was very complicated and totally 21 ^{81}Br NQR lines could be detected suggesting three nonequivalent $NaAl_2Br_7$ units in the low temperature phase. This ^{81}Br NQR spectrum is consistent with ^{27}Al and ^{23}Na NQR spectra which have the six pairs of ν_1 (1/2↔3/2) and ν_2 (3/2↔5/2) and three lines respectively, as shown in Table 1. Above T_c two sets of three ^{81}Br NQR lines disappeared at about 250K and 320K respectively, but the remaining single line could be detected up to near the decomposition temperature of 370K. The relative positions of all the Br atoms in the $Al_2Br_7^-$ anion were determined by the SEDOR technique as described above. Then, the sets of three resonance lines which disappeared at almost the same temperatures could be assigned to the same $AlBr_3$ group and the remaining line to the bridging atom. There was no significant difference in the T_1 vs. temperature behavior among the three lines assigned to the same $AlBr_3$ group. Therefore, the temperature dependence of the ^{81}Br NQR spin-lattice relaxation times (T_1) were measured precisely only for three Br(1), Br (2), and Br (6) sites as shown in Fig. 2 together with their assignment. A small dip was observed near T_c for each line. The feature above 160 K is similar to that found in the compounds containing such reorientational groups as CCl_3 or PCl_3. The drastic decrease of the T_1 for Br (1) and Br (2) at high temperature may come from the $AlBr_3$ group reorientation about its approximate C_3 axis for the following reasons; (1) there was no significant difference in the T_1 vs. temperature curves which were assigned to the same $AlBr_3$ group, (2) the bridging atom Br (6) showed no drastic decrease of T_1 with temperature and (3) a line width transition of the ^{27}Al NMR was observed as described later. In this case the ^{81}Br NQR relaxation rate $(1/T_1)_{obs}$ may be described as a sum of the two mechanisms, lattice vibration $(1/T_1)_{vib}$ and reorientation of

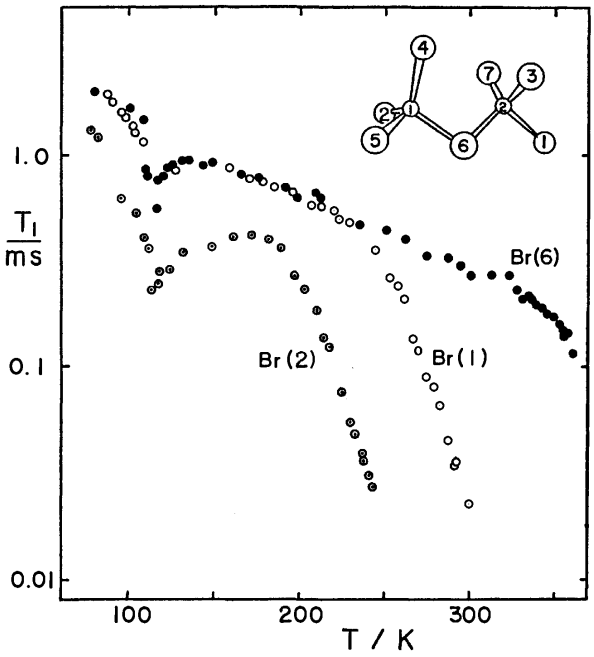

Fig. 2. Temperature dependence of the ^{81}Br NQR spin-lattice relaxation times T_1 in $NaAl_2Br_7$.

the $AlBr_3$ group $(1/T_1)_{reo}$ as follows,

$$(1/T_1)_{obs} = (1/T_1)_{vib} + (1/T_1)_{reo} = a\,T^n + b\exp(-V/RT), \quad (1)$$

where V is the activation energy of the reorientation motion of the $AlBr_3$ group and the parameters a, n, and b are determined experimentally. Table 2 shows these parameters determined by a non-linear least squares method. Joes et al. showed that if the librational fluctuation governs the relaxation, n is equal to 2 for I=3/2 nuclei.[19] The value of n obtained for the Br (1) is smaller than the theoretical one. This is probably due to the additional contribution to T_1 near the phase transition point, because the parameter n for the bridging Br (6) shows a value close to the theoretical one in the temperature range from 180 to 350K as shown in Table 2.

The $AlBr_3$ group reorientation could also be detected as a motional narrowing phenomena of the

Table 2. Best Fit Parameters of Eq. 1

Compound	Assignment	$a/10^{-2}$ s	n	$b/10^{12}$ s	V/kJ mol^{-1}	Temp/K

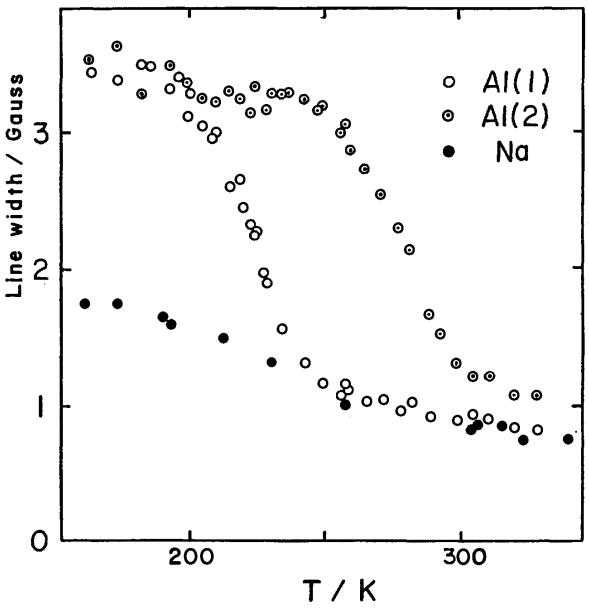

Fig. 3. ^{27}Al and ^{23}Na NMR line widths are plotted against temperature for $NaAl_2Br_7$ using single crystal.

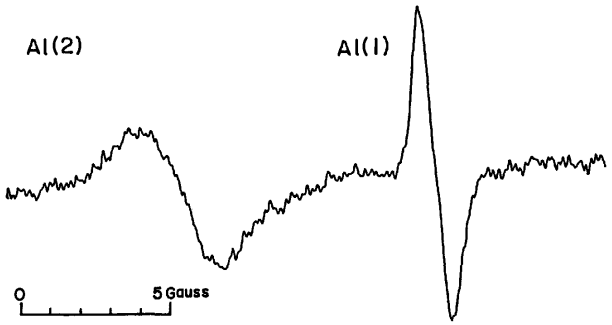

Fig. 4. Typical ^{27}Al NMR spectra for $(1/2\leftrightarrow -1/2)$ transitions at 271 K. A motional narrowing is completed for the Al(1) site at this temperature. The modulation width was chosen to be about 1/3 of each absorption line.

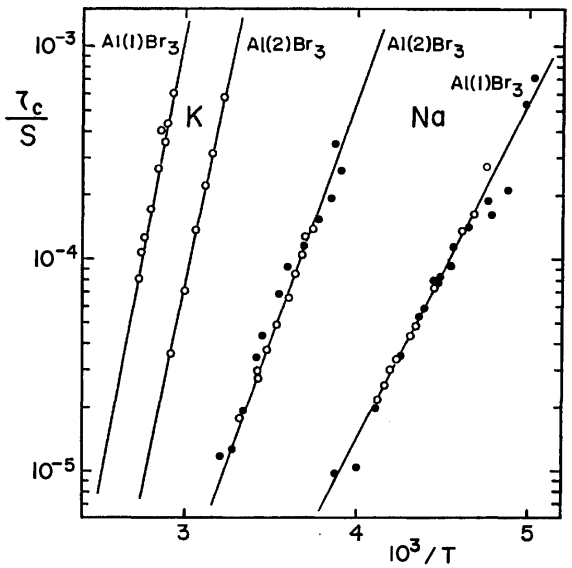

Fig. 5. Temperature dependence of the correlation times, τ_c, of the $AlBr_3$ reorientation for $NaAl_2Br_7$ and KAl_2Br_7. The lines were calculated from the second term of the Eq. 1 using the parameters in Table 1. O: from ^{81}Br NQR T_1 data, ●: from ^{27}Al NMR line width data.

^{27}Al NMR using a single crystal at 16 MHz. Figure 3 plots the line width against temperature together with that of the ^{23}Na NMR, where the line width is defined as the separation between the maximum and the minimum of the derivative curve. Because of the large quadrupole coupling constant at the Al site, central transitions $(-1/2\leftrightarrow 1/2)$ were shifted as a function of the crystal orientation with respect to the external magnetic field in terms of the second order quadrupole effect. Thus, the line width of the ^{27}Al NMR was observed at each site separately as a function of temperature. A precise analysis and assignment of the quadrupole splitting lines was reported previously.[13] Figure 4 shows a typical ^{27}Al NMR spectrum recorded at 271 K at a certain crystal orientation with respect to the external magnetic field, where Al (1) and Al (2) sites are in a motional narrowing and a rigid state in the NMR time scale, respectively. In general at the temperature where a line width transition takes places the following relation holds between the reorientational correlation time, τ_c, and the line width.

$$\tau_c=(1/H\alpha\gamma)\tan[\pi(H^2-B^2)/2(C^2-B^2)], \quad (2)$$

where B, H, and C are the line width above, within and below the transition region respectively, γ is the gyromagnetic ratio and α is a numerical constant. On the other hand, the correlation time of the $AlBr_3$ reorientation is calculated from the $(T_1)_{reo}$ data using a simple relation, $(T_1)_{reo}=(3/4)\tau_c$.[20] The correlation times from the ^{81}Br NQR data are plotted against temperature in Fig. 5. If $\alpha=3.1\pm0.1$ is adopted as a numerical constant in Eq. 2 the correlation times from the ^{27}Al NMR agree well with those of the ^{81}Br NQR as shown in Fig. 5. This finding suggests that both the abrupt decrease in the NQR T_1 and the motional nar-

rowing of the ^{27}Al NMR are governed by the same mechanism, i.e., $AlBr_3$ reorientation about the C_3 axis.

In view of the low potential barrier of the $AlBr_3$ reorientation, the diffusion of the Na^+ cation was suspected to occur in the same manner as a Li^+ in $LiAlCl_4$.[21] The ^{23}Na line width was also measured as a function of temperature as shown in Fig. 3. Two central transitions ($-1/2 \leftrightarrow 1/2$) resulted from the monoclinic system were shifted by the second order quadrupole effect because of the large quadrupole coupling constant. The line width was observed at a certain orientation of the crystal where two central transitions separated from each other. The line width decreases from 1.8 to 0.8 Gauss. However, the narrowing limit of 0.8 Gauss is too large as a result of the diffusion and the narrowing temperature range is almost the same as that of the ^{27}Al NMR. Therefore, the ^{23}Na NMR narrowing probably results from the $AlBr_3$ groups reorientation and not from the diffusion of the Na^+ cation.

Figure 6 shows the temperature dependence of the ^{27}Al and ^{23}Na NQR frequencies above 113 K. The quadrupole coupling constants (e^2Qq/h) and asymmetry parameters (η) for the ^{27}Al are calculated using an exact formula for nuclear spin $I=5/2$[22] as is shown in Fig 7. If the reorientational frequency is much higher than that of NQR, the asymmetry parameter of the ^{27}Al reduces to zero due to the motional averaging of the

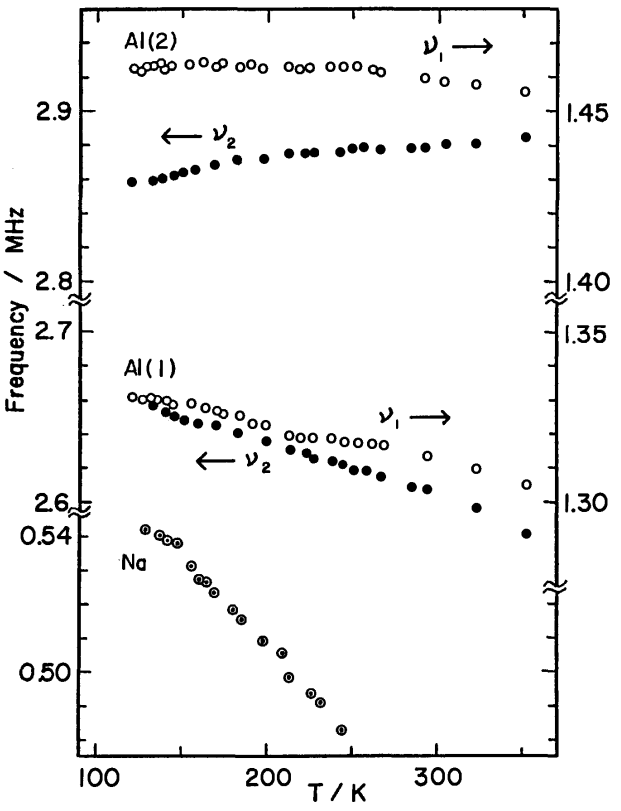

Fig. 6. Temperature dependence of the ^{27}Al and ^{23}Na NQR frequencies for $NaAl_2Br_7$. In the case of the ^{27}Al ν_1 and ν_2 correspond to ($1/2 \leftrightarrow 3/2$) and ($3/2 \leftrightarrow 5/2$) transitions, respectively.

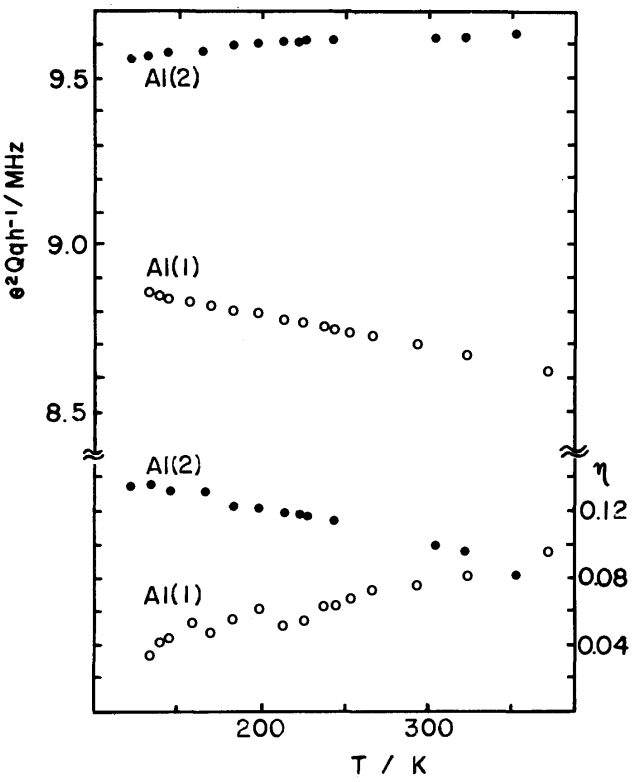

Fig. 7. Quadrupole coupling constant (e^2Qq/h) and asymmetry parameter (η) for the ^{27}Al NQR are plotted against temperature for $NaAl_2Br_7$.

$AlBr_3$ group. This is not the case, as is also expected from the temperature dependence of the correlation time in Fig. 5. However, it is interesting to note that at the Al (1) site the value of η increases with the onset of the $AlBr_3$ group reorientation. If the asymmetry parameter of the Al site is assumed to increase with the extent of the "bend bond" for the Al-Br (bridge) bond, the increase of the asymmetry parameter with the onset of the reorientation would be understandable because the activation energy for the reorientation is expected to decrease with the extent of the "bent bond."

KAl_2Br_7. The temperature dependence of the seven ^{81}Br NQR lines and their assignment for KAl_2Br_7 have been reported previously;[13,23] three lines belonging to the same $AlBr_3$ group disappeared at a temperature about 30 degrees below the decomposition temperature. Accordingly the reorientation of the $AlBr_3$ group was predicted from the fade out phenomena. Figure 8 shows the temperature dependence of the spin-lattice relaxation times for the ^{81}Br NQR lines which were assigned to the different $AlBr_3$ groups. Because of the overlapping of the NQR lines over the wide temperature range, the T_1 vs. temperature curve for the bridging Br could not be obtained. Table 1 shows the best fit parameters to Eq. 1. The values of b for these two sites are much larger than the values expected from the classical rotator approximation. A possible reason is the temperature dependency of the activation energy as suggested by the NMR experiment for ammonium sul-

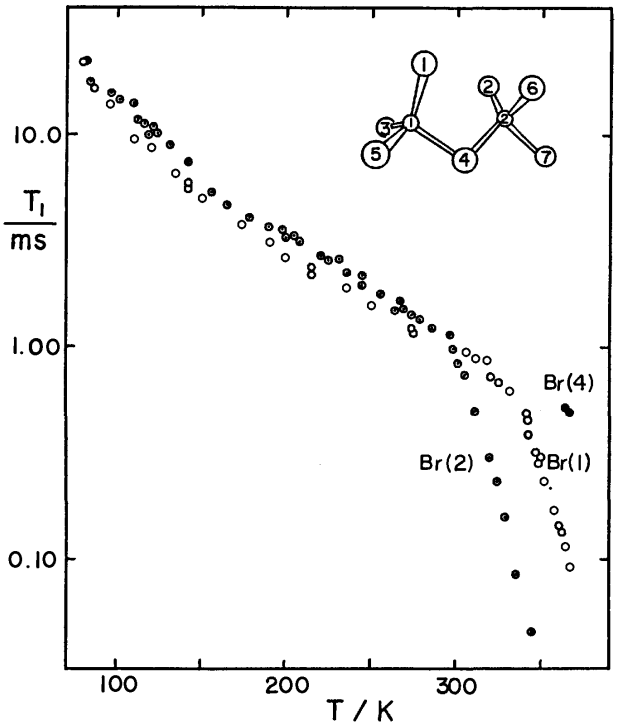

Fig. 8. Temperature dependence of the ^{81}Br NQR spin-lattice relaxation times T_1 in KAl_2Br_7.

fate.[24] For simplicity we assume that the activation energy V decreases linearly with increasing temperature as

$$V = V_0 - CT, \tag{3}$$

where V_0 is an activation energy extrapolated to 0 K and where C is a temperature coefficient. The Eq. 1 then becomes

$$1/T_1 = a\,T^n + 10^{12} \exp(-(V_0 - CT)/RT), \tag{4}$$

$$= a\,T^n + b_0 \exp(-V_0/RT), \tag{5}$$

where $b_0 = 10^{12} \exp(C/R)$. In these equations $b = 10^{12}$ s was assumed as a pre-exponent factor from the classical rotator model. Eq. 5 is the same as that of Eq. 1. Therefore, only from the measurements in the narrow temperature range is it impossible to deduce whether the activation energy has a temperature dependence or not. Using the values of Table 2 the temperature coefficient C were calculated to be 0.068 and 0.072 kJ mol^{-1} K^{-1} for the Br (1) and Br (2) sites, respectively. Accordingly activation energies fall down to about 70% of the values listed in Table 1, at the temperature where the NQR signals disappear. At present we have no other experimental evidence for the temperature dependence of the activation energy. However it may be reasonable because the two $AlBr_3$ groups have large steric repulsions and affect each other in the activation process of the reorientation.

^{81}Br NQR and ^{119}Sn Mössbauer Spectra for $SnBr_3^-$ Anions

Koji YAMADA,* Tomoko HAYASHI, Takako UMEHARA, Tsutomu OKUDA, and Sumio ICHIBA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received April 30, 1987)

The structures of the $SnBr_3^-$ anions in $MSnBr_3$ (M=$(CH_3)_2NH_2$, $(CH_3)_3NH$) and $MSnBr_3 \cdot H_2O$ (M=K, NH_4) were deduced by means of ^{81}Br NQR spectroscopy. The former compounds have three ^{81}Br NQR lines in the frequency range 73—80 MHz at 77 K, indicating the presence of pyramidal $SnBr_3^-$ anions. The anion structure of the latter hydrate, on the other hand, was presumed to be square-pyramid with one terminal and two bridging Br atoms, because two of the ^{81}Br NQR frequencies were considerably low compared with that of the terminal atom. Phase transitions were observed for the latter hydrates. Associated with these, drastic increases of the NQR frequencies were observed only for the bridging atoms, suggesting significant changes in the bridging network.

The trihalostannate(II) anion, SnX_3^- (X=Cl and Br), in the solid state still provides us with interesting structural subjects. Two quite different structures for the SnX_3^- anions have been reported for $CsSnCl_3$[1] and $CsSnBr_3$:[2] The former contains a discrete anion with bond angles ∠XSnX, close to 90°, like an isoelectronic $SbCl_3$; however the latter contains a regular octahedron with six bridging bromines. The latter is a typical example of a hypervalent state of Sn(II). In this case the available orbitals of the tin atom are mainly 5p orbitals, since both the participation of the outer 5d orbitals to the bond may be small and the 5s orbital is full. On account of the orbital deficiency of the Sn(II) state, the trans Br-Sn-Br bond is regarded as being a three-center four-electrons bond (abbreviated as a 3c-4e bond) and each Sn-Br bond is weaker than that of a normal two-center two-electron bond (2c-2e). Some interesting phenomena associated with the 3c-4e bond have been observed for anions such as $SbBr_4^-$,[3] $SbBr_6^{3-}$,[4] and I_3^-.[5] For these structural and bonding subjects, halogen NQR is a useful technique owing to the high sensitivity of the NQR frequency to the bond nature.

Halogen NQR studies for trihalostannate(II) anions were only reported for $CsSnX_3$ (X=Cl, Br, and I).[6] In this paper the structure and bonding of $SnBr_3^-$ anions are discussed on the basis of ^{81}Br NQR and ^{119}Sn Mössbauer data. Furthermore, a possible model of a structural change accompanied by a phase transition is proposed for $MSnBr_3 \cdot H_2O$ (M=K, NH_4) utilizing the 3c-4e bond.

Experimental

All compounds, except for $NH_4SnBr_3 \cdot H_2O$, were crystallized from aqueous solutions containing stoichiometric amounts of $SnBr_2$ and relevant alkali bromide or alkylammonium bromide. $NH_4SnBr_3 \cdot H_2O$ was obtained from an aqueous solution containing about twice the stoichiometric amount of NH_4Br. H_2O and Br were analyzed by means of TG and potentiometric titration with $AgNO_3$, respectively. Anal. for $(CH_3)_3NHSnBr_3$. Found: C, 8.23; H, 2.42; N, 3.051; Br, 57.31%. Calcd for $C_3H_{10}NSnBr_3$: C, 8.61; H, 2.41; N, 3.35; Br, 57.28%. Anal. for $(CH_3)_2NH_2SnBr_3$. Found: C, 5.73; H, 2.07; N, 3.27; Br, 59.34%. Calcd for $C_2H_8NSnBr_3$: C, 5.94; H, 1.99; N, 3.46; Br, 59.26%. Anal. for $KSnBr_3 \cdot H_2O$. Found: Br, 56.4; H_2O, 4.22%. Calcd for $KSnBr_3 \cdot H_2O$: Br, 57.7; H_2O, 4.34%. Anal. for $NH_4SnBr_3 \cdot H_2O$. Found: H, 1.24; N, 3.72; Br, 60.77; H_2O, 4.18%. Calcd for $NH_4SnBr_3 \cdot H_2O$; H, 1.53; N, 3.55; Br, 60.77; H_2O, 4.31%.

^{81,79}Br NQR were searched in the frequency range from 20 to 100 MHz with a super-regenerative spectrometer or a pulsed spectrometer (Matec model 5100+525). The former was sensitive, even near the phase transition temperature (T_c) or at high temperature where the relaxation time (T_1) was short, T_1<100 μs. On the other hand, a pulse spectrometer was applied at low temperature where only the spin echo signal was detected due to its large line width. NQR lines were assigned with the aid of the quadrupole moment ratio, $(Q(^{79}Br)/(Q(^{81}Br)=1.1971)$.

^{119}Sn Mössbauer spectra were recorded by means of a constant acceleration-type spectrometer.

Results

^{81}Br NQR for $MSnBr_3$ (M=$(CH_3)_2NH_2$ and $(CH_3)_3NH$). Table 1 shows the ^{81}Br NQR frequencies for tribromostannate(II) anions. Three ^{81}Br NQR were detected in the frequency range of 73—80 MHz at 77 K for these two compounds. This frequency range is consistent with that expected from the ^{35}Cl NQR frequency for $CsSnCl_3$, where three NQR lines were observed at about 10.8 MHz for the pyramidal $SnCl_3^-$ anion.[6] Accordingly, it is thought that these compounds contain discrete $SnBr_3^-$ anions and, therefore, a frequency of about 73—80 MHz at 77 K corresponds to the normal 2c-2e bond for this anion.

^{81}Br NQR for $MSnBr_3 \cdot H_2O$ (M=K and NH_4). Although there has been no crystal structure determination for both compounds, it was suggested by means of IR spectra that the water molecule associates with the cation for the chloride analog.[7] As Table 1 shows, ^{81}Br NQR lines were detected over the wide frequency region 35—83 MHz, suggesting the existence of both terminal and bridging Br atoms. Figure 1 shows the temperature dependence of the ^{81}Br NQR frequencies. The disappearance of NQR signals was observed just below and above the phase-transition temperature (T_c). The highest NQR signal is exceptional and shows a small dip in the corresponding temperature range (Fig. 2). From this figure the phase-transition temperature was determined to be T_c=273±0.5 K.

Table 1. ^{81}Br NQR Frequencies for $MSnBr_3$ and $MSnBr_3 \cdot H_2O$

Compound	Temperature/K	Frequency/MHz
$(CH_3)_2NH_2SnBr_3$	77	78.06, 77.76, 72.92
	293	74.90, 74.28, 71.65
$(CH_3)_3NHSnBr_3$	77	80.11, 79.77, 79.29
$KSnBr_3 \cdot H_2O$	77	78.25, 78.07, 58.25, 56.33, 55.09, 52.23
	298	75.96, 40.45, 37.25
$NH_4SnBr_3 \cdot H_2O$	77	84.40, 79.79, 59.09, 58.12, 53.18, 51.62
	300	79.89, 38.56, 37.63

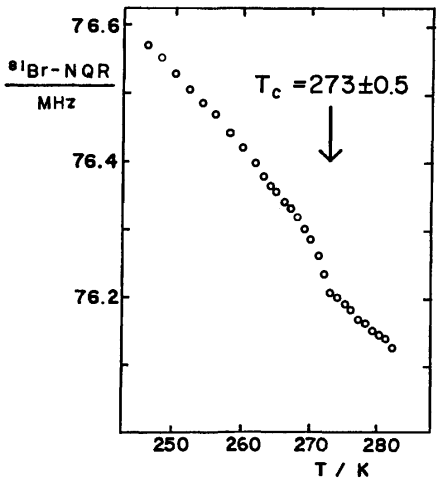

Fig. 2. Temperature dependence of the highest ^{81}Br NQR frequency in $KSnBr_3 \cdot H_2O$ near phase transition temperature.

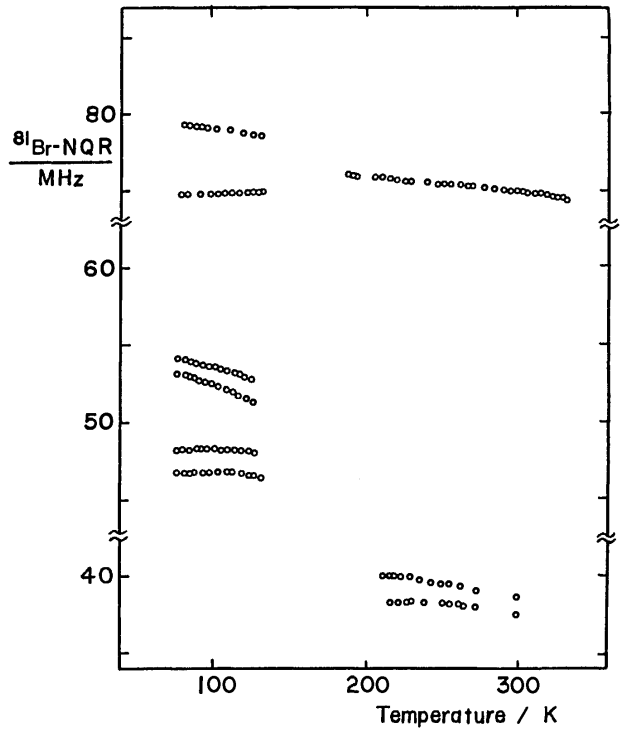

Fig. 3. Temperature dependence of the ^{81}Br NQR frequencies for $NH_4SnBr_3 \cdot H_2O$.

Because of the continuity of the highest ^{81}Br NQR frequency, this phase transition was supposed to be second-order type. Below T_c each line split into two, but the highest frequency line could not be resolved into two until about 90 degrees below T_c. This is due to its very small splitting compared with the line width. A phase transition was also observed for M=NH_4 (Fig. 3); unfortunately, the transition temperature was not determined owing to the disappearance of the NQR signals between 130 and 190 K. According to our preliminary T_1 measurements for both compounds, these disappearances of the NQR signals arise from their very short relaxation times (T_1) and also from the large line width ($1/T_2^*$) near T_c to detect NQR signals. Below T_c three NQR lines split into six lines for both compounds, suggesting at least two Sn sites. In connection with these phase transitions the most interesting feature is that the drastic increases of the NQR frequencies for the lower four lines with decreasing temperature. At 77 K the NQR frequencies

Table 2. ^{119}Sn Mössbauer Parameters for $MSnBr_3$ and $MSnBr_3 \cdot H_2O$ at 93 K[a)]

$CsSnBr_3$[b)]	0.84	3.96	0

a) Estimated error $\pm 0.05\ mms^{-1}$. b) Ref. 2.

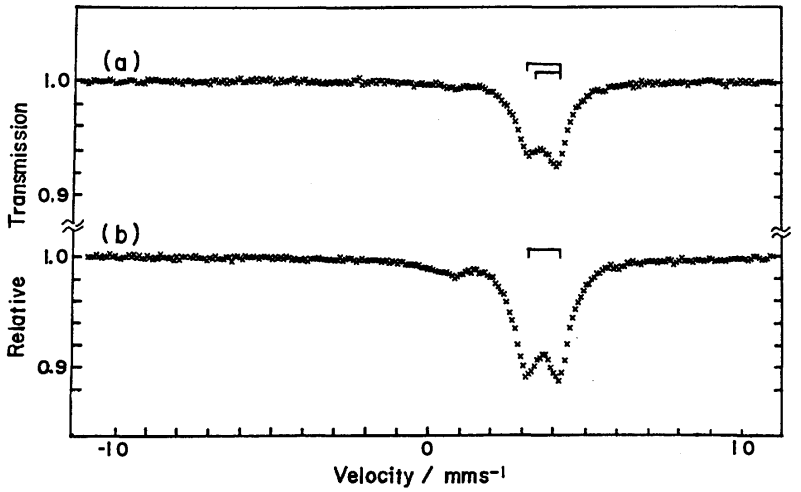

Fig. 4. ^{119}Sn Mössbauer spectra for $KSnBr_3 \cdot H_2O$ (a) and $(NH_4)SnBr_3 \cdot H_2O$ (b) at 93 K.

increased about 40% more than those of the high-temperature phase. These finding were not understandable only from the change of the crystal fields. No anomalous peak associated with these phase transitions was detected for $MSnBr_3 \cdot H_2O$ from the DTA measurements in the corresponding temperature.

^{119}Sn Mössbauer Effect. Table 2 shows the Mössbauer parameters of $MSnBr_3$(M=$(CH_3)_2NH_2$, $(CH_3)_3NH$) and $MSnBr_3 \cdot H_2O$ (M=K, NH_4). All these compounds showed quadrupole doublets. In the latter hydrates, however, the doublets are slightly asymmetric, even for powdered samples (Fig. 4). This is consistent with the NQR result; that is, there are at least two crystallographically different Sn sites at 93 K. In the potassium salt the spectrum was analyzed as two quadrupole doublets (Table 2).

Discussion

Structures of $SnBr_3^-$ Anions Based on the 3c-4e Bond Model. Figure 5 shows three structural models for the SnX_3^- anions based on the 3c-4e bonds. Model **A** exists in the perovskite $CsSnBr_3$, in which the Sn forms regular octahedron with six bridging Br atoms. In this case typical 3c-4e bonds are formed in the three orthogonal directions. While model **C** exists in $CsSnCl_3$,[1)] in which the Sn forms distorted octahedron with three short Sn-Cl bonds and three interanionic

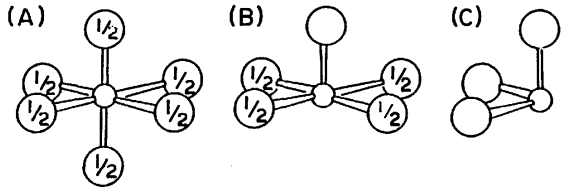

Fig. 5. Structural models for SnX_3^- anion, where 1/2 denotes bridging halogen.

interactions Sn··· Cl (not shown in this figure). In this structure it is also possible to consider that the Sn atom in $CsSnCl_3$ forms extremely unsymmetrical 3c-4e bonds along the three orthogonal directions. If one of the three 3c-4e bonds in the model **A** structure becomes asymmetric, it changes to model **B**. Several structural changes associated with the symmetric-asymmetric 3c-4e bond have been observed for Sb(III) compounds when the temperature or the counter cation was changed.[3,4)]

The anion structures in $MSnBr_3$(M=$(CH_3)_2NH_2$, $(CH_3)_3NH$) can be expressed as model **C**, since three ^{81}Br NQR lines were detected in a narrow frequency region of 73—80 MHz. On the other hand, $MSnBr_3 \cdot H_2O$ (M=K, NH_4) yielded only one NQR signal assigned to a terminal atom at room temperature. Two more signals were detected at about one half of the terminal NQR frequency. Therefore, model **B** is

most plausible for the anion structure in these hydrates from their NQR spectra. Then, the NQR frequency for the bridging Br was estimated as confirming this model on the basis of the Townes-Dailey method under following conditions: (1) The net charge on the Br atom does not change as the result of a structural change from model **A** to **C** and (2) the bridging bond angle is close to 90°; hence, the bond is formed using only p orbitals. The population of the p_z orbital, N_z, for the terminal atom could be estimated assuming $\eta=0$ using following equation:

$$(e^2Qq_{obs}/h)/(e^2Qq_p/h)=2\,\nu_{obs}/(e^2Qq_p/h)=(2-N_z), \quad (1)$$

where $(e^2Qq_p/h)=643$ MHz. Since ν_{obs} for the terminal atom is on average 78 MHz at 77 K, the populations were determined to be $N_z=1.76$ and $N_y=N_x=2$ for p_z, p_y and p_x orbitals, respectively. On the other hand, in the case of symmetrical bridge using the p_z and p_x orbitals, the p electron populations change to $N_z=N_x=1.88$ and $N_y=2$, since the net charge on the Br atom is assumed to be constant. Between these two extremes the populations can be expressed using parameter b as

$$N_z=1.76+b,$$
$$N_y=2, \quad (2)$$

and

$$N_x=2-b.$$

Then, the NQR frequency for the bridging atom is calculated as a function of b using following equations:

$$(e^2Qq_{obs}/h)/(e^2Qq_p/h)=|N_z-(N_x+N_y)/2| \quad (3)$$

$$\eta=3(N_y-N_x)/(2N_z-N_y-N_x), \quad \text{for } 0<b<0.08 \quad (4)$$

$$\eta=3(N_z-N_x)/(2N_y-N_z-N_x), \quad \text{for } 0.08<b<0.12 \quad (5)$$

$$\nu_{obs}=(1/4)(e^2Qq_{obs}/h)(1+\eta^2/3)^{-2/1} \quad (6)$$

Figure 6 shows the calculated NQR frequency as a function of b. This figure shows that the NQR frequency decreases drastically in forming a bridging bond and that the principal z- and y-axes of the efg tensor change their orientations with each other in the range $0.08<b<0.12$. The observed NQR frequencies, ν_{obs}, for two hydrates are about 38.5 MHz, which are in good agreement with that obtained with this model in the range $b=0.07$—0.12. One NQR line was observed for the perovskite $CsSnBr_3$ near 63 MHz,[6] which is about 50% higher than that expected from this model. This is probably due to the fact that the bridging bond Sn-Br-Sn in the perovskite structure is linear in contrast to this model.

According to the recent crystal structure analysis for $CsSnI_3$, the SnI_3^- anion was proved to exist in the form of model **B**.[8] The SnI_3^- anion forms a distorted octahedron in which one pair of short and long Sn-I bonds at the trans position and four Sn-I bonds with intermediate lengths exist.

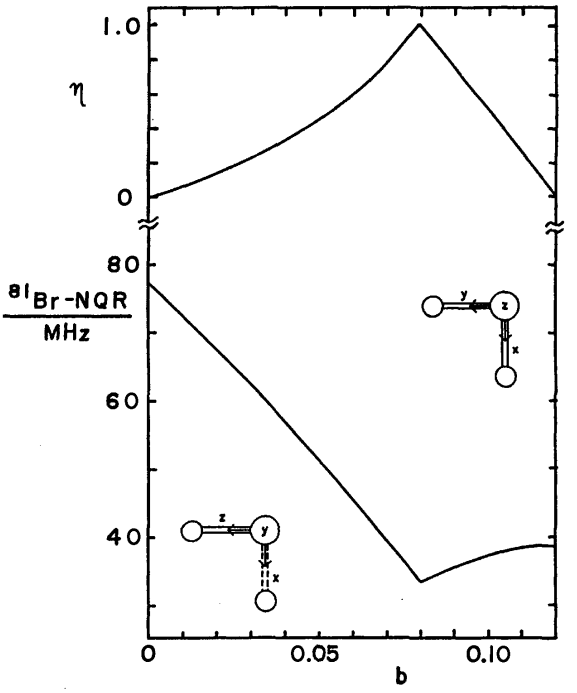

Fig. 6. Calculated ^{81}Br NQR frequencies for the bridging Br atom are plotted as a function of parameter b, where $b=0$ and $b=0.12$ correspond to terminal and symmetric bridge Br, respectively. At $b=0.08$ the efg z and y axes change their orientations each other.

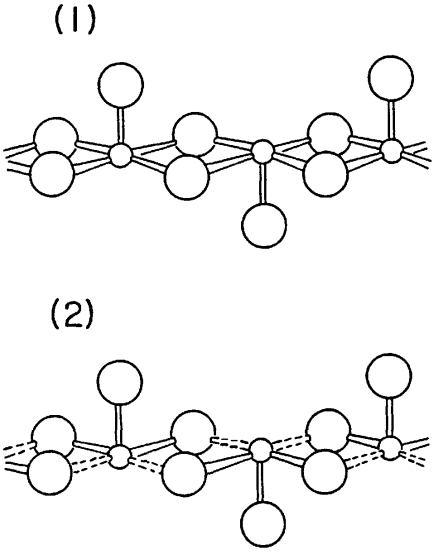

Fig. 7. Proposed structural models for high (1) and low (2) temperature phases.

Proposed Structural Changes for $MSnBr_3\cdot H_2O$ (M=K, NH_4) below Phase Transition Temperatures. The temperature dependence of the ^{81}Br NQR for these compounds differs from each other, especially near T_c. However, the spectra at 77 K and room temperature resemble each other, suggesting similar changes take place around the Sn environments associated with the phase transitions. The drastic increases of NQR

frequencies can be easily explained in terms of the slight change in the bridging Sn-Br-Sn bond, as shown in Fig. 6. That is, at high temperature the bridging Sn-Br-Sn bond is formed almost symmetrically, whereas at lower temperature one side of the bridging bond becomes weaker than the other. This change is more understandable by applying a 3c-4e bond model for the trans Br-Sn-Br as shown in Fig. 7. At temperatures above T_c the trans Br-Sn-Br bond is regarded as being a symmetrical 3c-4e bond. Below T_c, however, it becomes asymmetric Br-Sn$\cdots$Br and increases its NQR frequency (Fig. 6) owing to a decrease in parameter b. This type of structural change was also observed for $(C_5H_5NH)SbBr_4$, where the axial Br-Sb-Br bond is symmetric or asymmetric above and below T_c and, finally, the anion structure is more reasonably expressed as $SbBr_3 \cdot Br^-$ at 77 K.[3]

Correlation between ^{119}Sn Mössbauer Parameters and Structure. As Table 2 shows, the change of the isomer shifts is considerably large compared with that of $Sn^{IV}Cl_6^{2-}$ anions.[9] This is probably due to the fact that the SnX_3^- anion changes drastically its structure with a change in the counter cation as well as with temperature (as described above). In spite of their quit different ^{81}Br NQR spectra, the ^{119}Sn quadrupole coupling constant changes only slightly. However, the observed feature was consistent with structural models of the anion which were proposed by the ^{81}Br NQR. That is, the magnitude of the quadrupole coupling constant is expected from the point charge model as **B>C>A**. For a more satisfactory interpretation of these Mössbauer parameters, an X-ray structural determination may be required for each compound.

The Influence of Molecular Conformation on the Electronic Relaxation Processes. Complex Formation in the Ground State and Triple Fluorescences of 6-Acetoxyspiro[aceanthyrylene-2(1*H*),9′(10′*H*)-anthracene]-10′-one

(Received March 26, 1987)

The absorption spectra of 6-acetoxyspiro[aceanthyrylene-2(1*H*),9′(10′*H*)-anthracene]-10′-one(**2**) in cyclohexane, dichloromethane, and chloroform have been observed. The absorption spectra have been also observed as a function of concentration of chlorinated methanes in mixtures with cyclohexane. It was revealed that **2** forms a ground state complex with chlorinated methanes. The equilibrium constants for the ground-state complex formation with dichloromethane and chloroform were determined to be 0.14 and 0.17 $mol^{-1}dm^3$, respectively. The fluorescence and fluorescence excitation spectra of **2** have been obtained as a function of excitation wavelengths and emission wavelengths in cyclohexane and chlorinated methanes. The spiro compound emits structured fluorescence(FM) in cyclohexane. On the other hand, three types of fluorescence bands (FM, FC, and FE) were observed in chlorinated methanes. The FC and FE bands are both structureless and their peak wavenumbers are 20800 and 18700 cm^{-1}. The quenching of fluorescence quantum yield and lifetime were treated by Stern-Volmer kinetics considering the complex formation in both the ground and the excited states of the system. Based on the experimental findings, the origins of FM, FC, and FE bands are explained by the complex formation between **2** and chlorinated methanes in the ground state and exciplex formation in the excited state.

The emission spectra of molecules which have somewhat specific molecular geometry in the ground and excited states are interesting problem from the stand point of the relation between the electronic structure and the geometrical specificity of the molecules. In previous papers the authors presented the influence of molecular conformation on the electronic relaxation processes of biphenyl[1] and *m*-terphenyl[2] which have conformational flexibility. Becker and Sandross[3] found dual fluorescences for 1′2′-dihydrospiro[anthracene-9(10*H*),3′-[3*H*]benz[*de*]anthracene]-10-one(**1**, Diagram 1) in various solvents. **1** has a six-membered ring containing a spiro carbon atom and has two possible conformations. The anthracene ring is not perpendicular to the anthrone ring in **1**. Photoexcitation of the anthracene chromophore in **1** in chloroform and other solvents gives rise to two types of fluorescences. One is an anthracene-like fluorescence and its assigned to the anthracene moiety. The other fluorescence is a structureless emission (σ_{max}=18700 cm^{-1}). They attributed this fluorescence band to radiative deactivation of an excited intramolecular charge-transfer complex between the electron-donating anthracene moiety and the electron-withdrawing anthrone moiety.

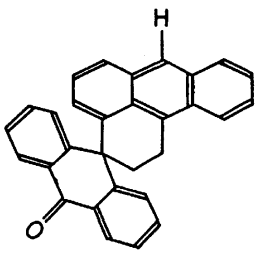

Diagram 1. 1′,2′-Dihydrospiro[anthracene-9(10*H*), 3′-[3*H*]benz[*de*]anthracene]-10-one.

In this paper, the absorption, fluorescence, and fluorescence excitation spectra of 6-acetoxyspiro[aceanthyrylene-2(1*H*), 9′(10′*H*)-anthracene]-10′-one(**2**, Diagram 2) in cyclohexane, dichloromethane, chloroform, and cyclohexane-chlorinated methane mixtures are reported. In contrast to the case of **1**, **2** has a five-membered ring containing a spiro carbon atom and has a rigid geometry. The anthracene position is connected to the anthrone ring though the five-membered ring. The two rings are precisely perpendicular.

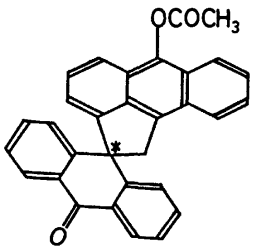

Diagram 2. 6-Acetoxyspiro[aceanthyrylene-2(1*H*), 9′(10′*H*)-anthracene]-10′-one.

The fluorescence spectrum of **2** has an anthracene-like structure in cyclohexane. In the mixtures of cyclohexane and chlorinated methanes shows a remarkable excitation-wavenumber dependence. In chlorinated-methanes, however, two broad fluorescence

††Present address: Central Research Institute, Taiyo Yuden Co., Ltd., Hongo, Haruna, Gunma, Gunma 370-33.

bands are observed and anthracene-like fluorescence spectrum is strongly quenched in the solvents. This remarkable fluorescence change of **2** suggests that **2** may specifically interact with chlorinated methanes in an energetically favourable conformation.

Fluorescence quenching is discussed based on the data of quantum yield and lifetime. It is shown that **2** forms a ground state complex with chlorinated methanes and emits three types of fluorescence. Fluorescence quenching by added chlorinated methanes is interpreted by Stern-Volmer kinetics. The origins of the triple fluorescences are explained by the complex formation between **2** and chlorinated methanes in the ground and excited states.

Experimental

2 was synthesized according to the method given in the literature.[4] Cyclohexane and dichloromethane (Wako Pure Chemical Industries Inc., Luminasol grade), chloroform (Wako, Spectrosol grade), ethanol (Wako, S. G. S. grade), and sulfuric acid (Wako, S grade) were used without further purification. The absorption and emission spectra were observed at room temperature using a Hitachi 220 recording spectrophotometer and a Hitachi MPF-2A fluorescence spectrophotometer. The data were transferred to an NEC PC-8001 microcomputer for processing. The fluorescence quantum yields were determined with reference to those of anthracene in cyclohexane,[5] 9,10-diphenylanthracene in ethanol,[6] and quinine sulfate in sulfuric acid.[7] Fluorescence lifetimes were determined with a single-photon fluorescence lifetime instrument arranged in this laboratory. The fluorescence lifetimes obtained by the instrument were found to agree well with the widely accepted literature values.[8] The sample solutions were prepared just prior to measurements and stored in the dark. The solutions were degassed when necessary.

Results and Discussion

Absorption Spectra and Complex Formation in the Ground State. The absorption spectra of **2** in cyclohexane and dichloromethane are shown in Fig. 1. Although the spectrum in dichloromethane shifts to the red compared with that in cyclohexane, the spectral difference between these spectra is small, except that a very weak absorption band appears between 23500 and 21500 cm^{-1} in chlorinated methanes (see next).

The absorption spectrum at high concentration of **2** in chloroform is shown in Fig. 2. It is seen from Fig. 2 that a very weak and broad band exists around 22700 cm^{-1}. This frequency region coincides with a new fluorescence excitation band for FC emission (see below). Almost the same spectral feature was obtained in **2** and dichloromethane system.

The spectrum observed in chloroform is similar to that observed in dichloromethane. These spectral features were unchanged after a week. The band with fine structure which appears between 23800 and 31200

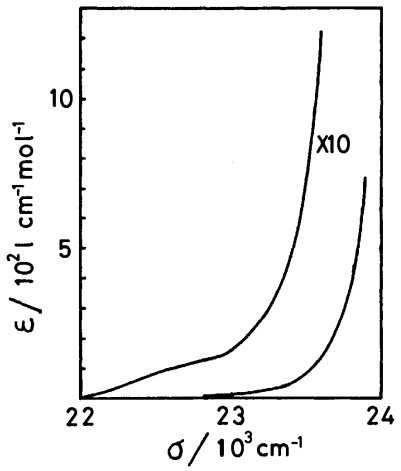

Fig. 2. The absorption spectrum of **2** in dichloromethane at higher concentration.

cm^{-1} and the intense band which appears between 35700 and 43500 cm^{-1} closely resemble the ^1L_a and ^1B_b transitions of anthracene. The band which appears between 31200 and 35700 cm^{-1} can be assigned to the local transition of the anthrone chromophore in **2**. Therefore the whole absorption spectrum of **2** is composed of the absorption spectrum of the anthracene chromophore and that of the anthrone chromophore except for an band in the lowest frequency region that appears in chlorinated methanes. Note that the strong ^1L_a transition due to the anthracene chromophore obscures the weak n-π^* transition of anthrone around 25000 cm^{-1}.[9]

To make clear the origin of the very weak absorption band which appears in chlorinated methanes, the absorption spectra of **2** in cyclohexane-dichloromethane and cyclohexane-chloroform mixed solvents are shown in Figs. 3 and 4 respectively as a function of the

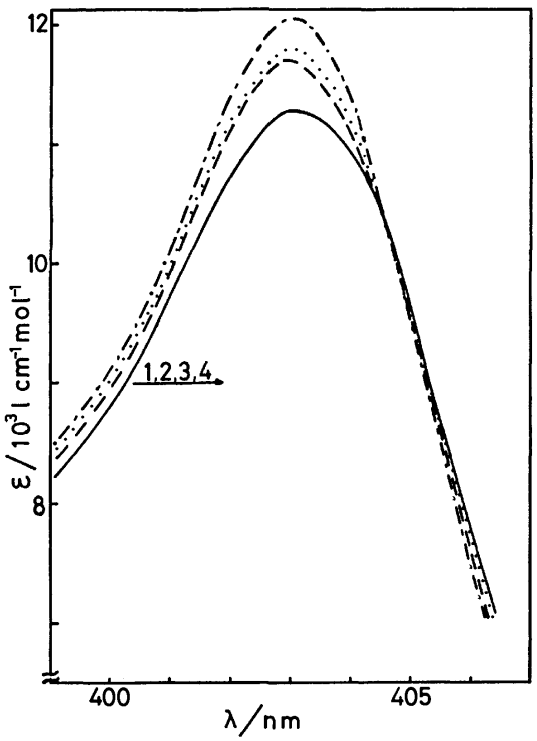

Fig. 3. The absorption spectra of **2** in cyclohexane-dichloromethane mixed solvent. Concentrations for dichloromethane are 1: 0, 2: 0.20, 3: 0.31, 4: 1.01 mol dm^{-3}.

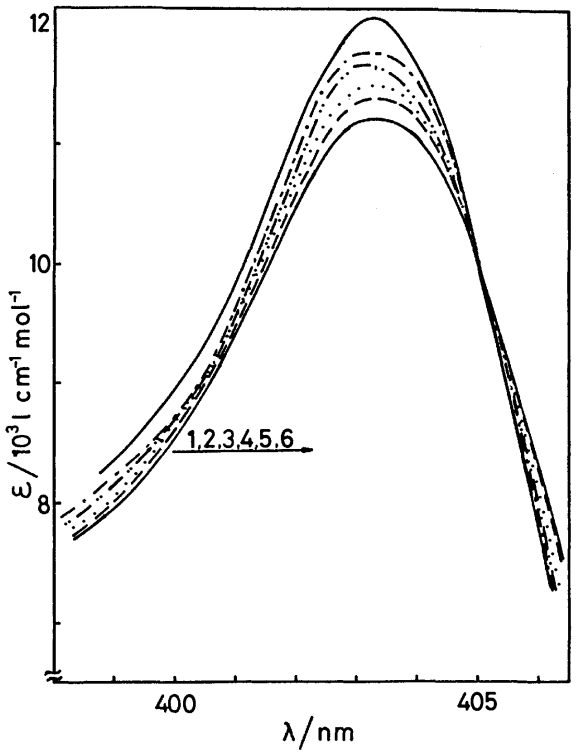

Fig. 4. The absorption spectra of **2** in cyclohexane-chloroform mixed solvent. Concentrations for chloroform are 1: 0, 2: 0.10, 3: 0.20, 4: 0.40, 5: 0.70, 6: 1.0 mol dm^{-3}.

concentration of chlorinated methanes. As the concentration of dichloromethane increases, the peak intensity of vibrational bands decreases (Fig. 3). An isosbestic point appears in the spectra. These observations indicate that an equilibrium between two species occurs in the ground state of this system. A similar spectral feature is also seen in the cyclohexane-chloroform mixed solvents (Fig. 4). The spectral feature was unchanged after a week unless the solutions were stored in the light. Therefore it is safely concluded that a complex is formed between chlorinated methanes and **2** in its ground state. The equilibrium constant of the ground state complex, K_C, can be determined by the usual procedure.[10] The K_C values were 0.14 and 0.17 mol dm^{-3} for the ground state complex between **2** and dichloromethane and between **2** and chloroform, respectively.

It is noted that the K_C value in **2** and chloroform system is larger than that in **2** and dichloromethane system. This difference between two K_C values may be attributable to the difference of the numbers of chlorine atoms in dichloromethane and chloroform.

The formation of ground-state complexes between aromatic molecules and halomethanes has been established for anthracene.[11,12] In the ground-state complexes of anthracene, halomethanes are located on the plane of anthracene ring. Ware and Lewis showed that there are higher complexes of carbon tetrachloride with anthracene and this higher complexes are responsible for the origin of wavelength effects in the fluorescence quenching of anthracene.[12]

There are two possible configurations for a complex between **2** and chlorinated methanes. One is the configuration in which chlorinated methanes are located on the anthracene ring, similar to complexes between anthracene and halomethanes. The other is the configuration in which chlorinated methanes are connected to the C=O group of **2** through hydrogen bonding between **2** and chlorinated methanes. Baba and Takemura found that anthrone forms a ground-state complex with triethylamine.[13] They also reported that a very weak n-π^* absorption band appears in the red edge side of a stronger absorption band due to the formation of a complex between anthrone and triethylamine in the ground state. This situation is similar to what we observe for **2** and chlorinated methanes. Therefore it is safely concluded that chlorinated methanes are either connected to the C=O group of **2** through a hydrogen bond or are located on the plane of **2** in the ground state.

This very weak absorption band is not obvious in cyclohexane solution. Taking into account the discussion in the previous section, one possible interpretation for the appearance of the band is an n-π^* band in anthrone, normally around 25000 cm^{-1}, shifted to the red due to a ground-state complex formation between **2** and chlorinated methanes. Another possible interpretation of this band is that the n-π^* band shifts to

the red due to the distortion of the anthrone ring system in **2**.

Fluorescence and Fluorescence Excitation Spectra. The fluorescence and fluorescence excitation spectra of **2** in cyclohexane are given in Fig. 5. Although it is not shown in Fig. 5, there are no excitation-wavenumber and no emission-wavenumber dependent changes in the fluorescence emission or fluorescence excitation spectra of **2** in cyclohexane. The fluorescence spectrum of **2** has an anthracene-like structure and the fluorescence excitation spectrum of **2** also has an anthracene-like structure. Hereafter the anthracene-like structured band is referred to as FM fluorescence band, meaning "molecular fluorescence." It is noted that the FM band is a similar emission band observed in cyclohexane for **1**.[3]

Figure 6 shows the excitation-wavenumber dependence of fluorescence spectra of **2** in dichloromethane. When **2** is excited at 33330 and 25000 cm^{-1}, it exhibits an anthracene-like fluorescence band on the higher wavenumber side and a broad band on the lower wavenumber side (σ_{max}=18700 cm^{-1}). On the other hand, when **2** is excited at 23800 cm^{-1}, it has only one broad and structureless fluorescence band (σ_{max}=20800 cm^{-1}). Similar characteristics are seen in the excitation-wavenumber dependence of fluorescence spectra of **2** in chloroform (Fig. 7). Hereafter the broad bands which show peaks at 20800 and 18700 cm^{-1} are referred to as FC and FE fluorescence bands, respectively. They will be assigned below to "complex fluorescence" and "exciplex fluorescence." It is noted that the FE band has seen in some solvents for **1** but the FE band was not seen in the fluorescence spectra of **1**.[3]

Figure 8 shows the observation-wavenumber dependence of the fluorescence spectra of **2** compound in dichloromethane. When the spectrum is observed at a wavenumber of 22730 cm^{-1}, which corresponds to a peak of the FM band, the spectrum is similar to the fluorescence excitation spectrum observed in cyclohexane. With decreasing the observation wavenumber below 22730 cm^{-1}, a shoulder appears on the red side of the anthracene-like band. When the spectrum is observed at 20830 cm^{-1}, which corresponds to the peak of the FC band, a new excitation band appears around 22700 cm^{-1}. A mirror symmetry relation is found

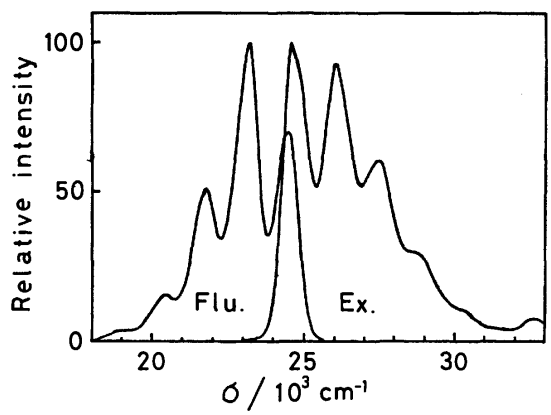

Fig. 5. The fluorescence and fluorescence excitation spectra of **2** in cyclohexane.

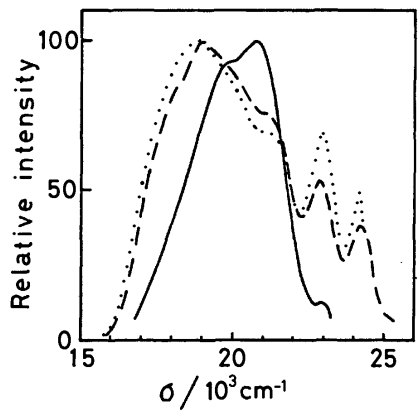

Fig. 6. The fluorescence spectra of **2** in dichloromethane. Excitation wavenumbers are as follows, 1(----): 33300, 2(·····): 25000, 3(——): 23800 cm^{-1}.

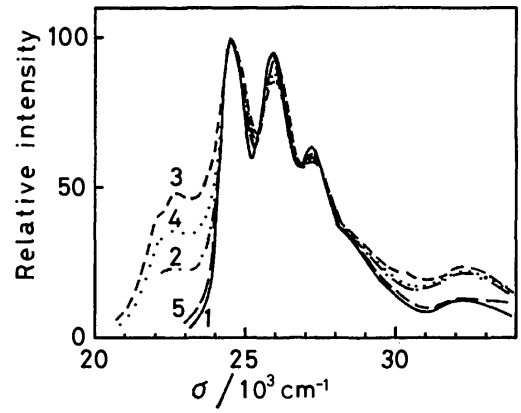

Fig. 8. The fluorescence excitation spectra of **2** in dichloromethane. Emission wavenumbers are as follows, 1(——): 22730, 2(-·-·-): 21740, 3(----): 20330, 4(·····): 20000, 5(——): 17860 cm^{-1}.

between this broad band and the FC band. When the spectrum is observed at around 18000 cm^{-1}, which corresponds to the peak of the FE band, the spectrum is similar to the fluorescence excitation spectrum observed in cyclohexane.

The observation-wavenumber dependence of fluorescence excitation spectra of the compound in chloroform is given in Fig. 9. It is seen from Fig. 9 that the spectral features in chloroform are almost the same as in dichloromethane, but the spectral characteristics in chloroform are not so obvious as in dichloromethane.

These results indicate that the FM and FE bands originate from the same ground-state species which show the anthracene-like fluorescence excitation spectra. On the other hand, the FC band originates from a ground state species which shows a broad fluorescence excitation spectrum around 22700 cm^{-1} in chlorinated methanes.

The data in Figs. 1 to 9 indicate the origins of the

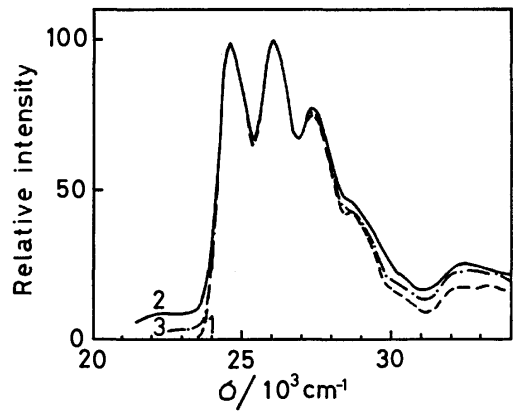

Fig. 9. The fluorescence excitation spectra of **2** in chloroform. Emission wavenumbers are as follows, 1(----): 22730, 2(——): 20830, 3(-·-·-): 18180 cm^{-1}.

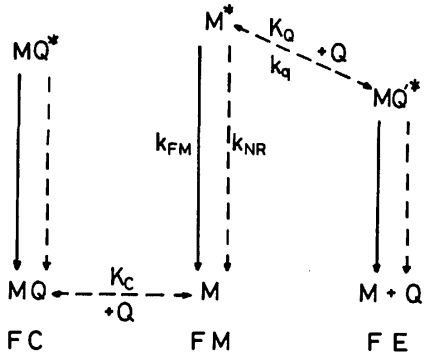

Fig. 10. Reaction scheme of **2**. M is **2**, Q is chlorinated methanes, MQ is a ground-state complex between **2** and chlorinated methanes, M* and MQ* are an excited-state species of M and MQ, MQ'* is an exciplex between M* and chlorinated methanes, K_C is equilibrium constant of complex formation in the ground state. K_Q is defined in the text and k's are rate constants. When the initial concentration of quencher, [C], is enough larger than that of **2**, then we can put [Q]=[C].

fluorescence bands, FM, FC, and FE may be summarized as follows: The FM band can be assigned to a fluorescence of the anthracene chromophore from the excited **2**. The FC band originates from excitation of a complex which is formed between **2** and chlorinated methanes in the ground state. The FE band is an emission from an exciplex which is formed between excited **2** and chlorinated methanes.

Kinetic Consideration. The reaction scheme for the interaction of **2** with chlorinated methanes discussed in the above section is illustrated in Fig. 10. If initial concentration of quencher, initial concentration of **2**, equilibrium concentration of **2**, equilibrium concentration of quencher, and equilibrium concentration of the complex are denoted by [C], [B], [M], [Q], and [MQ], respectively, then

$$[B] = [M] + [MQ], \tag{1}$$

$$[C] = [Q] + [MQ]. \tag{2}$$

Equilibrium constant of complex formation among M, Q, and MQ is

$$K_C = \frac{[MQ]}{[M][Q]} \tag{3}$$

Therefore [MQ] is represented as

$$[MQ] = K_C \times [M] \times [Q]. \tag{4}$$

The fraction of the incident light intensity absorbed by M is given by[5]

$$a = \frac{\varepsilon_M[M]}{\varepsilon_M[M] + \varepsilon_{MQ}[MQ]} \tag{5}$$

$$= \frac{1}{1 + a \times K_C \times [Q]}, \tag{6}$$

where ε_M and ε_{MQ} represent the molar absorption coefficients for M and MQ and a is equal to $\varepsilon_{MQ}/\varepsilon_M$.

The fluorescence intensity of the FM band in the absence of quenchers is written as

$$F_0 = \frac{k_{FM}}{k_{FM} + k_{NR}} \times [M^*]_{[Q]=0} \tag{7}$$

where $[M^*]_{[Q]=0}$ indicates excited concentration of **2** at equilibrium concentration ([Q]) of chlorinated methanes is equal to 0. When [Q] is not equal to 0, the fluorescence intensity of **2** can be written as

$$F_Q = \frac{k_{FM}}{k_{FM} + k_{NR} + k_q[Q]} \times [M^*]_{[Q]}, \tag{8}$$

where $[M^*]_{[Q]}$ represents excited concentration of **2** where equilibrium concentration of chlorinated methanes is [Q]. $[M^*]_{[Q]}$ can be rewritten as

$$[M^*]_{[Q]} = [M^*]_{[Q]=0} \times a. \tag{9}$$

Then Stern-Volmer equations for the ratio of the fluorescence intensity (RQY) and for the ratio of the

fluorescence lifetime (RTF) for the FM band can be rewritten as

$$\mathrm{RQY} = \frac{F_0}{F_Q} = \frac{k_{FM} + k_{NR} + k_q[Q]}{k_{FM} + k_{NR}} \times \frac{[M^*]_{[Q]=0}}{[M^*]_{[Q]}}$$

$$= (1 + a \times K_C \times [Q]) \times (1 + K_Q \times [Q]), \quad (10)$$

$$\mathrm{RTF} = \frac{k_{FM} + k_{NR} + k_q[Q]}{k_{FM} + k_{NR}} = 1 + K_Q \times [Q], \quad (11)$$

where

$$K_Q = \frac{k_q}{k_{FM} + k_{NR}}$$

Under the condition that the initial concentration of quencher, [C], is much larger than that of **2**, [B], Eqs. 10 and 11 can be written as

$$\mathrm{RQY} = (1 + a \times K_C \times [C]) \times (1 + K_Q \times [C]) \quad (10a)$$

$$\mathrm{RTF} = 1 + K_Q \times [C]. \quad (11a)$$

Figure 11 plots the RQY for the FM band of **2** as a function of [C], a concentration of dichloromethane or chloroform, in cyclohexane-dichloromethane or cyclohexane-chloroform mixed solvents. It is seen from Fig. 11 that the plots are nonlinear. This nonlinearity is attributed to the decrease of concentration of free **2** at higher concentration of chlorinated methanes due to the formation of the ground-state complex between **2** and chlorinated methanes. The nonlinearity is also attributed to exciplex formation between the excited **2** and chlorinated methanes. The experimental curves are well represented by Eq. 10a. The Stern-Volmer constant for deexcitation processes, K_Q, can be determined by Eq. 10a. The K_Q values of 0.20 and 0.09 $\mathrm{mol^{-1}\,dm^3}$ were obtained for the deexcitation processes between the excited compound and chloroform and between the compound and dichloromethane, respectively.

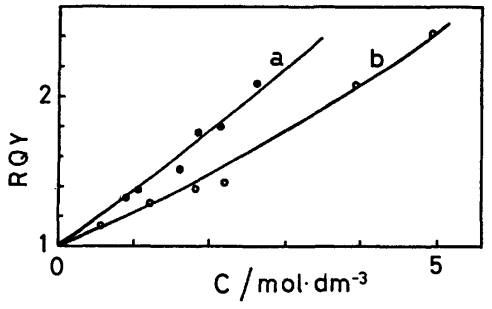

Fig. 11. Stern-Volmer plots of fluorescence quantum yield of **2** in cyclohexane-dichloromethane(a) and cyclohexane-chloroform(b). Since the excitation wavelength corresponds to an isosbestic point, a=1 in Eq. 10a. The solutions are not degassed.

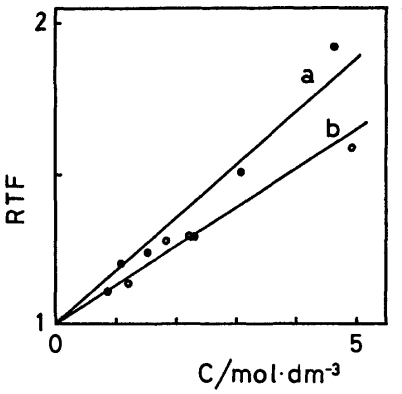

Fig. 12. Stern-Volmer plots of fluorescence lifetime of **2** in cyclohexane-dichloromethane(a) and cyclohexane-chloroform(b). The solutions are not degassed.

Figure 12 plots the RTF of **2** as a function of [C] in cyclohexane-dichloromethane and cyclohexane-chloroform mixed solvents. Figure 12 shows that the plots are linear within the experimental error and experimental results are well represented by Eq. 11a. The K_Q values obtained from the RTF plots are 0.18 and 0.12 $\mathrm{mol^{-1}\,dm^3}$ for chloroform and dichloromethane system, respectively.

The K_Q values obtained from the quenching of fluorescence quantum yields agree well with those obtained from the decrease in fluorescence lifetimes. These results confirm that the FM band originates from an excited **2**, the FC band originates from a complex formed in the ground state, and the FE band originates from an exciplex between excited **2** and chlorinated methanes.

Comparison of 2 with 1.[3] **1** and **2** are similar compounds. **1** emits only the FM and FE bands. Becker and Sandross has assigned the FM band to a fluorescence of the anthracene chromophore and the FE band to an exciplex fluorescence which originates from a solvent-assisted intramolecular charge-transfer interaction between the ground-state anthrone and excited-state anthracene. On the other hand, **2** emits the FM, FC, and FE fluorescences.

This difference may be attributable to the difference of molecular geometries between **1** and **2**. The geometry of **1** and that of **2** are similar but not identical. **1** has the six-membered ring containing a spiro carbon atom and has two possible conformations. Furthermore, the twisted angle between anthracene and anthrone rings are not perpendicular. **2**, however, has the five-membered ring containing a spiro carbon atom and has a rigid conformation. The anthracene ring is precisely perpendicular to the anthrone ring in **2**.

The assignment about the origin of the FM band by Becker and Sandross agrees with our conclusion. On the origin of the FE band, our conclusion is not in conflict with Becker and Sandross since the formation of an intermolecular complex may be responsible for an excited-intramolecular charge-transfer complex. Although it is difficult at present to presume what type geometry is acceptable for the exciplex geometry, there are possible geometries for the exciplex between **2** and chlorinated methanes. One is a similar conformation to the ground-state complex between anthracene and halogenated methanes where halogenated methanes are located on the plane of anthracene ring.[10] The other is a conformation where halogenated methanes are located surrounding the anthrone ring. In this case anthrone ring has geometrical distortion due to the connection through the five-membered ring with the anthracene ring. The electronic structure of the exciplex would resemble that of a σ-π complex suggested by Becker and Sandross for **1**.[3] The study of the more detailed kinetic consideration including similar compounds as **1** and **2** will be the object of further work.

The authors are much indebted to Professor Takeshi Takemura of Hokkaido University for his helpful suggestion about the possible structures of the ground-state complex between **2** and chlorinated methanes.

Effects of NH_3 on ^{13}C-Selective Infrared Multiple Photon Decomposition of CF_2HCl by a CO_2 Laser

Kyoko SUGITA* and Shigeyoshi ARAI
The Institute of Physical and Chemical Research, Wako-shi, Saitama 351-01
(Received March 30, 1987)

The effects of NH_3 on product yields and ^{13}C enrichment factors have been examined for the IRMPD of CF_2HCl using a CO_2 TEA laser. The IRMPD of neat CF_2HCl yields only C_2F_4 and HCl as final products. The addition of NH_3 resulted in the formation of CF_3H and NH_4Cl in addition to C_2F_4, and enhanced significantly the decomposition of CF_2HCl. The enrichment factors of ^{13}C in C_2F_4 and CF_3H decreased with increasing NH_3, but the decreases were relatively small. The mechanism of the IRMPD in the presence of NH_3 is discussed on the basis of the observed results.

It has been well-established that four-atom or larger molecules absorb numerous photons and undergo unimolecular decomposition when their resonant vibration modes are irradiated with high-fluence radiation from infrared lasers.[1] The photochemical phenomenon is called infrared multiple photon decomposition (IRMPD in abbreviation). IRMPD frequently exhibits remarkable isotope effects, reflecting the relatively large isotope shifts on infrared absorption. A number of studies have been already published on isotope separation of elements from hydrogen to uranium.[1-3] However, it is not easy to obtain practical amounts of enriched products in laser isotope separation by use of IRMPD, although selectivities are high. Recently, Kamioka et al. have succeeded in producing silicon isotopes on a practical scale using the IRMPD of Si_2F_6.[4,5]

Natural carbon consists of two isotopes, i.e., 98.9% of ^{12}C and 1.1% of ^{13}C. The IRMPD of CF_2Cl_2, CF_3X (X=Cl, Br, or I), and CF_2HCl has been extensively studied with the intention of ^{13}C separation; most of the studies have been succinctly reviewed in the introductory section of the paper by Outhouse et al.[6] The IRMPD of CF_3Br was found to produce C_2F_6 with a ^{13}C content of 80%, and that of CF_2HCl to produce C_2F_4 with 90—96% under selected irradiation conditions.[7-9] However, the enrichment of ^{13}C above 70% is attainable only with a great sacrifice of the yield. Outhouse et al. have demonstrated production rates of 0.23 $g\,h^{-1}$ for 50% ^{13}C and of 0.011 $g\,h^{-1}$ for 72% ^{13}C using a high power CO_2 TEA laser (10 J, 10 Hz)[6]. Therefore, there is general agreement that practical ^{13}C separation requires a two-stage process. For example, the first process is intended to increase a ^{13}C content from 1.1% to 20—50% (enrichment factor, 23—90) and the following second process is the production of ^{13}C above 90% (enrichment factor, 9—36). Since a high selectivity is not needed in each step, one can obtain a relatively large production rate of ^{13}C by such a two-stage process.

Abdushelishvili et al. have proposed the IRMPD of CF_3Br or CF_3I in the presence of NO, where NO scavenged CF_3 radicals produced from the first ^{13}C-selective IRMPD.[10] The resulting product, i.e., CF_3NO was presumed to be converted into CF_3Br or CF_3I for the second IRMPD, where the chemical conversion could be easily achieved by heating CF_3NO in Br_2 or I_2 vapor. Arai and his coworkers found that the IRMPD of C_2F_6 in the presence of Br_2 formed CF_3Br with 20—30% ^{13}C.[11] The further IRMPD of the enriched CF_3Br resulted in the production of C_2F_6 with 90% ^{13}C. On the other hand, Hackett et al. showed that the production of C_2F_4 with 95—99% ^{13}C from equimolar mixtures of 50% $^{12}CF_2HCl$ and 50% $^{13}CF_2HCl$ was very efficient in energy expenditure.[6,12] They predicted the production rate of 1.7 $g\,h^{-1}$ for 99% ^{13}C, assuming that equimolar mixtures were irradiated in a flow system with 10 J pulses at a repetition rate of 10 Hz. However, enriched CF_2HCl must be provided from other enrichment process. Recently, Ma et al. proposed the two-stage IRMPD of CF_2Cl_2-HI or CF_2ClBr-HI mixtures, where the first process was the production of CF_2HCl with ^{13}C content of 30% and the second process was the further enrichment by the selective decomposition of the CF_2HCl.[13] In view of the efficient decomposition of CF_2ClBr at low fluences, the IRMPD of CF_2ClBr-HI mixtures could be one of the most effective two-stage processes to the practical enrichment of ^{13}C.

IRMPD of several fluorocarbons has been examined in our group for the development of a practical two-stage ^{13}C enrichment. In the course of the study we found that NH_3 significantly enhanced the decomposition yield in the IRMPD of CF_2HCl. The effect could be applied to an improvement of a ^{13}C yield in separation processes involving IRMPD of CF_2HCl. The present paper describes detailed experimental results and decomposition mechanisms.

Experimental

The experimental apparatus and procedures are essentially the same as were described elsewhere.[14,15]

Laser beams from a Lumonics 103-2 CO_2 TEA laser were focussed on the center of a reaction cell by a BaF_2 lens with a focal length of 60 cm, where the resulting focus area was about 0.045 cm^2. The laser was operated without nitrogen gas at a repetition rate of 0.7 Hz. A typical pulse had a half width of about 80 ns and a triangle profile without a tail.

Output energies were measured with a Scientech 362 energy power meter and a Scientech 360001 detector. The reaction cell was a 113 cm long and 2.0 cm diameter cylindrical Pyrex tube equipped with KBr windows at both ends. In addition, the cell has KBr side windows for infrared spectrophotometric analysis, where the optical path length was 5.0 cm. The total volume was 393 cm^3.

Formation amounts and isotopic compositions of products were determined by using a Shimadzu GC-7A gas chromatograph coupled with a NEVA quadrapole mass spectrometer, where a 3 mm ϕ and 3 m long VZ-10 column was mainly employed under programmed temperature variations. CF_2HCl purchased from Nitto Fluorochemical Co. was distilled repeatedly at low temperatures and the middle fractions were used as irradiation samples. We could not detect impurities such as C_2F_4 and CF_3H except for a trace amount of CF_2Cl_2. NH_3 from Suzuki Shokan Co. was also distilled repeatedly at low temperatures.

Results

The infrared absorption spectra of natural CF_2HCl and NH_3 are shown in Fig. 1. The bands centered at 1105 and 1120 cm^{-1} in CF_2HCl are assigned to CF_2 symmetric and antisymmetric stretching vibration modes, respectively. The bands at 932 and 968 cm^{-1} in NH_3 are due to degenerate symmetric deformation modes, where their R branches are extending on the higher wavenumber side. A ^{13}C isotope shift has been reported to be nearly 30 cm^{-1} for CF_2HCl.[16] In comparison to usual infrared absorption spectra, the band shapes become broader and the peaks shift to the red side in multiple-photon absorption spectra, depending on a laser fluence. The previous study of the IRMPD of CF_2HCl has shown that the decomposition probability of ^{13}C bearing molecules is considerably larger than that of ^{12}C bearing molecules in a wavenumber region from 1030 cm^{-1} to 1060 cm^{-1}.[9] Since this study was concerned with ^{13}C enrichment, we employed mainly the 9P (20) line at 1046.85 cm^{-1} and the 9P (22) line at 1045.02 cm^{-1} for irradiation of the mixtures. Although NH_3 also absorbed some of the laser radiation, neat NH_3 did not decompose at all under the present irradiation conditions, probably because of insufficient fluences for decomposition of a simple four-atom molecule.[17]

The IRMPD of neat CF_2HCl gives only C_2F_4 and HCl as stable final products; these are the same products as in homogeneous gas-phase thermolysis.[18,19] The addition of NH_3 causes the formation of a new product, which can be definitely identified as CF_3H on the basis of its retention time on gas chromatography, a peak wavenumber in infrared spectroscopy, and a cracking pattern in mass spectrometry. In addition, we observed thick deposition of a white solid on the cell walls. The element analysis of the solid showed C, 1.04; H, 7.39; N, 25.7% in weight; the composition was consistent with NH_4Cl. No fluorocarbons containing Cl, (for example, CFH_2Cl, $CFHCl_2$, $C_2F_2Cl_2$) were detected on gas chromatography.

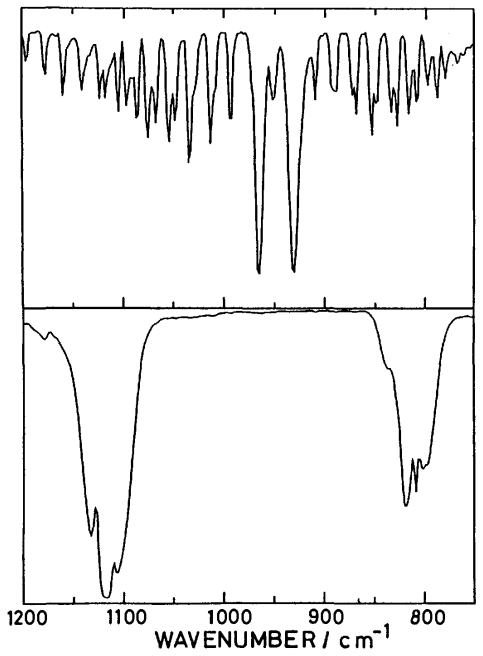

Fig. 1. Infrared absorption spectra of CF_2HCl (lower) and NH_3 (upper).

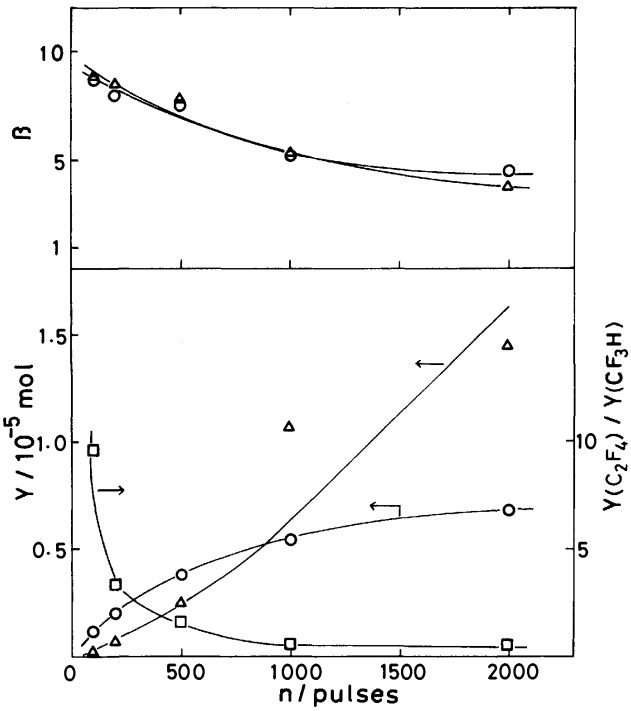

Fig. 2. Effects of pulse number n on yields Y (lower) and enrichment factors β (upper) for IRMPD of CF_2HCl-NH_3 mixtures at 5 Torr and 5 Torr.
○, $Y(C_2F_4)$ or $\beta(C_2F_4)$; △, $Y(CF_3H)$ or $\beta(CF_3H)$; □, $Y(C_2F_4)/Y(CF_3H)$. Laser wavenumber, 1046.85 cm^{-1}; laser fluence at focus, about 27 J cm^{-2}.

Figure 2 shows the effects of pulse number on yields and enrichment factors for the IRMPD of CF_2HCl-NH_3 mixtures at 5 Torr plus 5 Torr (1 Torr=133.322 Pa). The yield for C_2F_4, $Y(C_2F_4)$ is defined as a total amount of C_2F_4 produced, while that for CF_3H,

$Y(CF_3H)$ has a similar definition. The enrichment factors for C_2F_4 and CF_3H are as follows.

$\beta(C_2F_4)=\{[^{13}C]/[^{12}C]$ in $C_2F_4\}/\{[^{13}C]/[^{12}C]$ in natural$\}$

$\beta(CF_3H)=\{[^{13}C]/[^{12}C]$ in $CF_3H\}/\{[^{13}C]/[^{12}C]$ in natural$\}$

Ratios of $[^{13}C]$ to $[^{12}C]$ in C_2F_4 were determined from ion intensities of $^{12}CF_2^+$ at m/z=50 and those of $^{13}CF_2^+$ at m/z=51 for the C_2F_4 peak in GC-MS. On the other hand, we obtained similar ratios in CF_3H from ion intensities at m/z=50 ($^{12}CF_2^+$), m/z=51 ($^{12}CF_2H^+$ and $^{13}CF_2^+$), and m/z=52 ($^{13}CF_2H^+$), taking the cracking pattern of CF_3H into consideration. Figure 2 includes plots of $Y(C_2F_4)/Y(CF_3H)$ vs. number of pulses. $Y(C_2F_4)$ predominates over $Y(CF_3H)$ at small pulse numbers, but $Y(C_2F_4)$ decreases to about a half of $Y(CF_3H)$ at 2000 pulses. For pulse numbers less than 1000, logarithmic plots of $[CF_2HCl]_n/[CF_2HCl]_0$ vs. number of pulses give a good straight line, as shown in Fig. 3, where $[CF_2HCl]_0$ and $[CF_2HCl]_n$ are the amounts of CF_2HCl before and after n-pulse irradiation, respectively. The slope corresponds to a so-called specific decomposition rate in IRMPD, which is 2.1×10^{-4} pulse^{-1} in this case.

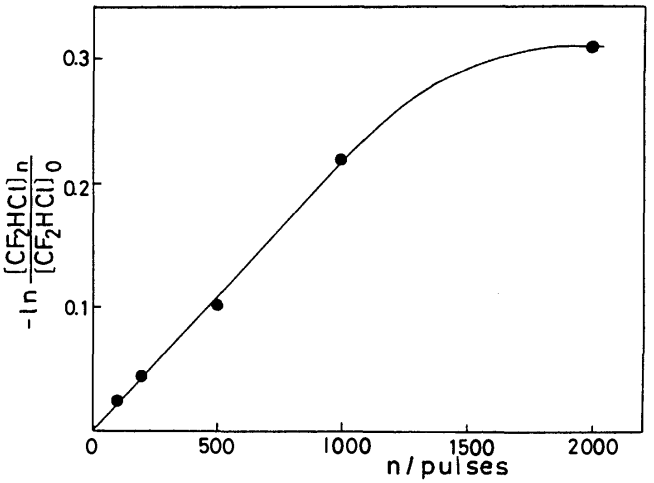

Fig. 3. Logarithmic plots of $[CF_2HCl]_n/[CF_2HCl]_0$ vs. number of pulses for IRMPD of CF_2HCl–NH_3 mixtures at 5 Torr and 5 Torr. $[CF_2HCl]_n$ and $[CF_2HCl]_0$, see text. Laser wavenumber, 1046.85 cm^{-1}; laser fluence at focus, about 27 J cm^{-2}.

Figure 4 shows the laser line dependences of yields and enrichment factors for the IRMPD of 10 Torr CF_2HCl and 10 Torr NH_3, where the number of laser pulses is 1000 at each line. In these irradiations, fluences at the focus were adjusted to fall within 20.8±2.8 J cm^{-2} by inserting polyethylene films into the beam path. However, that for the 9P(34) line at 1033.49 cm^{-1} was 12.5 J cm^{-2} at a maximum output. Although $Y(C_2F_4)$ and $Y(CF_3H)$ decrease with decreasing wavenumber, $\beta(C_2F_4)$ and $\beta(CF_3H)$ have maxima at the 9P (26) line, i.e., 1041.28 cm^{-1} and the 9P (30) line, i.e., 1037.43 cm^{-1}. In addition, the parallel relations between C_2F_4 and CF_3H in yield and enrichment factor suggest that both compounds have the same origin, which must be a CF_2 radical produced in the ^{13}C selective IRMPD of mixtures. There seems to be a structure in the wavenumber dependences of $\beta(C_2F_4)$ and $\beta(CF_3H)$. The structure may originate from the nar-

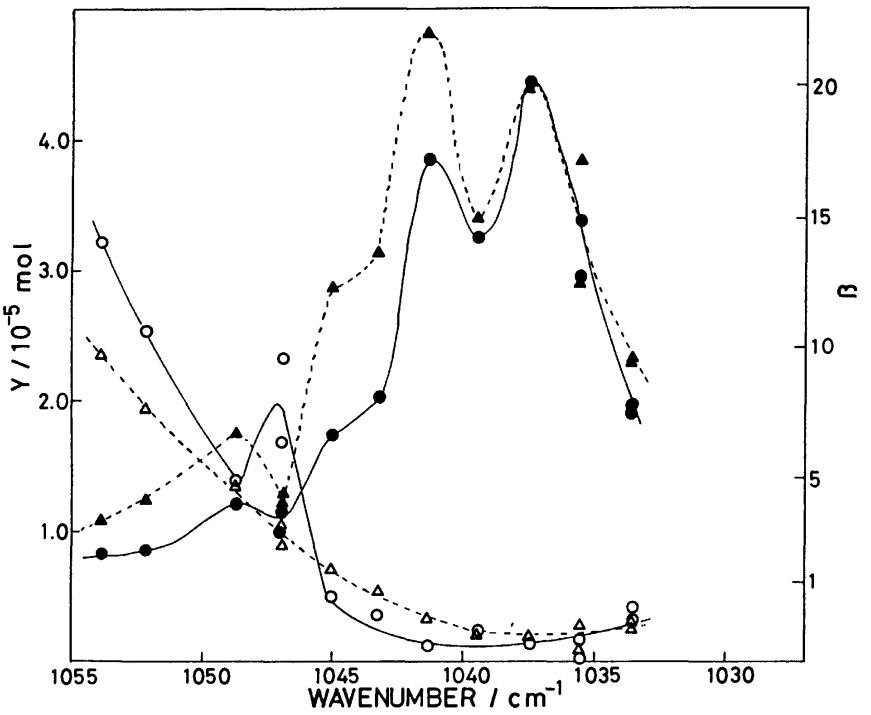

Fig. 4. Laser line dependences of yields Y and enrichment factors β for IRMPD of CF_2HCl–NH_3 mixtures at 10 Torr and 10 Torr. ○, $Y(C_2F_4)$; △, $Y(CF_3H)$; ●, $\beta(C_2F_4)$; ▲, $\beta(CF_3H)$; pulse number, 1000. Fluences, see text.

row resonance of the laser radiation with rotation-vibration transition energy in the discrete energy-level region.[1] In the IRMPD of neat CF_2HCl for different irradiation frequencies at 1053.92, 1046.85, 1041.28, and 1035.47 cm^{-1}, the enrichment factor increased rapidly with decreasing wavenumber. We consider that a non-selective thermal process may contributes to the formation of both C_2F_4 and CF_3H in mixtures of 10 Torr CF_2HCl and 10 Torr NH_3. The contribution becomes more significant with decreasing wavenumber, resulting in a rapid decrease in $\beta(C_2F_4)$ or $\beta(CF_3H)$ below 1035 cm^{-1}.

In order to obtain standard data for comparison, we examined briefly the IRMPD of neat CF_2HCl under the same experimental conditions as the CF_2HCl-NH_3 mixtures. Figure 5 shows the pressure dependences of $Y(C_2F_4)$ and $\beta(C_2F_4)$, where the laser was adjusted to the 9P (22) line and the fluences were set at about 30 J cm^{-2}. As NH_3 is added to 1.0 Torr CF_2HCl, $Y(C_2F_4)$ decreases rapidly and, after passing through a minimum, increases gradually with increasing NH_3 (see Fig. 6). $Y(CF_3H)$ increases simply with increasing NH_3, while both $\beta(C_2F_4)$ and $\beta(CF_3H)$ decrease. Hereafter, we define a total carbon yield, $Y(C)$ as 2 $Y(C_2F_4)$ for neat CF_2HCl or $Y(CF_3H)+2\ Y(C_2F_4)$ for

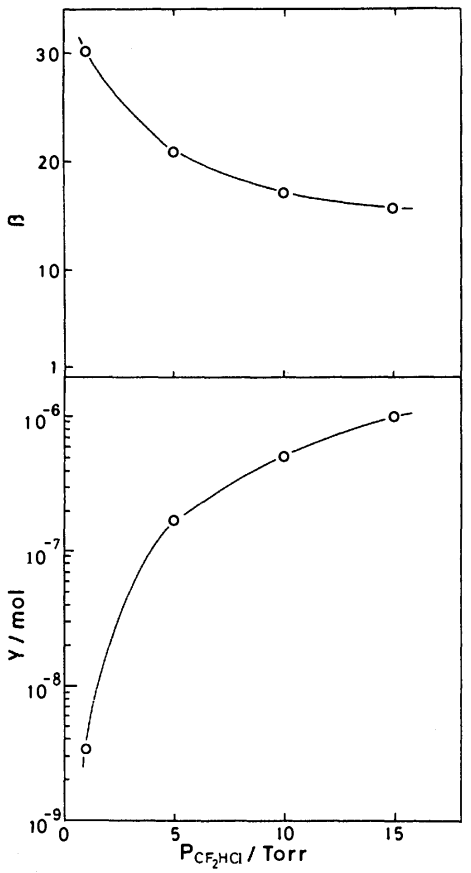

Fig. 5. Pressure dependences of $Y(C_2F_4)$ and $\beta(C_2F_4)$ for IRMPD of neat CF_2HCl. Laser wavenumber, 1045.02 cm^{-1}; laser fluence at focus, about 29 J cm^{-2}; pulse number, 1000.

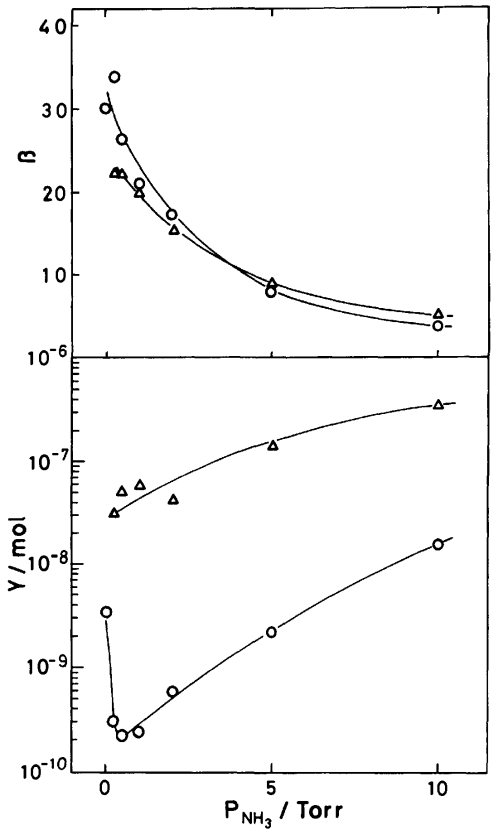

Fig. 6. Effects of NH_3 pressure on yields Y and enrichment factors β for IRMPD of CF_2HCl (1.0 Torr)-NH_3 mixtures. O, $Y(C_2F_4)$ or $\beta(C_2F_4)$; Δ, $Y(CF_3H)$ or $\beta(CF_3H)$. Laser wavenumber, 1045.02 cm^{-1}; laser fluence at focus, about 29 J cm^{-2}; pulse number, 1000.

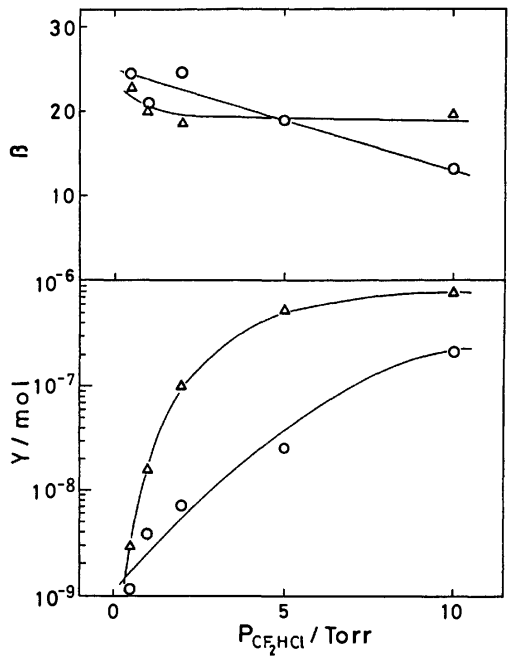

Fig. 7. Effects of CF_2HCl pressure on yields Y and enrichment factors β for IRMPD of CF_2HCl-NH_3 (1.0 Torr) mixtures. O, $Y(C_2F_4)$ or $\beta(C_2F_4)$; Δ, $Y(CF_3H)$ or $\beta(CF_3H)$. Laser wavenumber, 1045.02 cm^{-1}; laser fluence at focus, about 29 J cm^{-2}; pulse number, 1000.

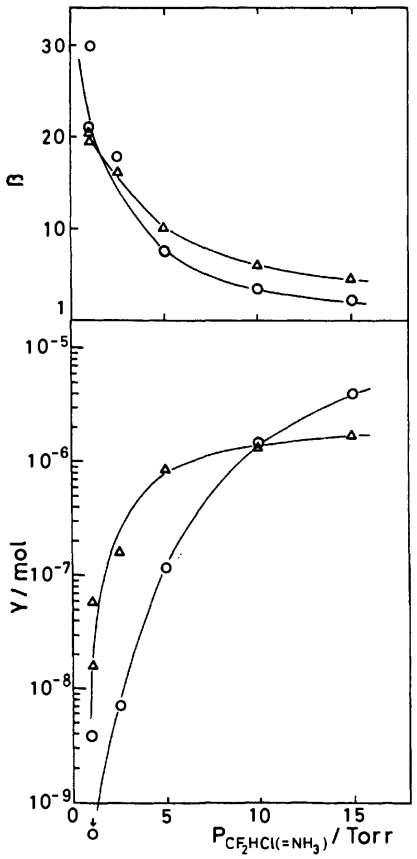

Fig. 8. Effects of total pressure on yields Y and enrichment factors β for IRMPD of equimolar CF_2HCl–NH_3 mixtures. ○, $Y(C_2F_4)$ or $\beta(C_2F_4)$; △, $Y(CF_3H)$ or $\beta(CF_3H)$. Laser wavenumber, 1045.02 cm^{-1}; laser fluence at focus, about 28 J cm^{-2}; pulse number, 1000.

mixtures. $Y(C)$ for the mixture of 1.0 Torr CF_2HCl and 1.0 Torr NH_3 was found to be 5.8×10^{-7} mol, while $Y(C)$ for 1.0 Torr neat CF_2HCl was only 6.8×10^{-8} mol; the former yield is about 8 times as large as the latter. The corresponding enrichment factors were $\beta(CF_3H)$= 20 for the mixture and $\beta(C_2F_4)$=30 for the neat CF_2HCl.

Fluence effects on yields and enrichment factors were examined for mixtures of 1.0 Torr CF_2HCl and 5.0 Torr NH_3 in the range from 12 to 30 J cm^{-2}. For examples, $Y(CF_3H)$ and β (CF_3H) at 12 J cm^{-2} were 1.96×10^{-7} mol and 26, respectively, while those at 30 J cm^{-2} were 1.40×10^{-6} mol and 9.0, respectively. $Y(C_2F_4)$ was much less than $Y(CF_3H)$ at either fluence. An increase in fluence enhances product yields and reduces enrichment factors. When CF_2HCl was added to 1.0 Torr NH_3, we observed an increase in $Y(C_2F_4)$ or $Y(CF_3H)$ and a decrease in $\beta(C_2F_4)$ or $\beta(CF_3H)$ with increasing CF_2HCl, as shown in Fig. 7. Similar results were also obtained with total pressure effects on equimolar mixtures of CF_2HCl and NH_3, as shown in Fig. 8.

Discussion

The IRMPD of neat CF_2HCl has been explained satisfactorily in terms of the initial photochemical decomposition of CF_2HCl into CF_2 and HCl, and the subsequent combination between two carbene radicals.[9,18]

$$CF_2HCl + nh\nu \rightarrow CF_2 + HCl \quad (1)$$

$$2\,CF_2 \rightarrow C_2F_4 \quad (2)$$

The same products, i.e., C_2F_4 and HCl have been obtained with the thermal decomposition of CF_2HCl, and the activation energy for the initial decomposition has been found to be 56 kcal mol^{-1} (1 cal=4.184 J) at pressures above 100 Torr.[19] Since the addition of HCl results in a decrease in decomposition rate, the following back reaction is considered to occur in thermolysis.

$$HCl + CF_2 \rightarrow CF_2HCl \quad (3)$$

The heat of formation for CF_2, $\Delta H_f(CF_2)$ show large divergence among several determinations.[19,20] The enthalpy change of the initial decomposition is calculated to be 41 kcal mol^{-1} on the basis of $\Delta H_f(CF_2)$= −49.5 kcal mol^{-1}.[19]

In the presence of NH_3, one can consider the following bimolecular decomposition with an enthalpy change much less than that of Reaction 1.

$$CF_2HCl + nh\nu \rightarrow CF_2HCl^* \quad (4)$$

$$CF_2HCl^* + NH_3 \rightarrow CF_2 + NH_4Cl \quad \Delta H = -1 \text{ kcal mol}^{-1} \quad (5)$$

Therefore, the activation energy of Reaction 5 may be considerably smaller than the 56 kcal mol^{-1} observed for Reaction 1. The reduction in activation energy means that a certain fraction of the excited molecules, which cannot decompose without NH_3, undergo Reaction 5 in the IRMPD of mixtures, where excited CF_2HCl originates from ^{13}C-selective multiple-photon absorption. We conclude that the observed large increases in product yields are caused by the contribution of such excited parent molecules into laser-induced decomposition via Reaction 5.

The formation of C_2F_4 is explained simply by dimerization of two CF_2 radicals in mixtures. However, the rapid decrease of $Y(C_2F_4)$ by adding NH_3 suggests that CF_2 radicals react directly with NH_3 to form a key product, which is responsible for the formation of CF_3H via some subsequent process. The reaction and subsequent process may be as follows.

$$CF_2 + NH_3 \rightarrow HCF_2NH_2 \quad (6)$$

$$CF_2 + HCF_2NH_2 \rightarrow CF_3H + HCFNH \quad (7)$$

A further reaction of CF_2 with HCFNH will give CF_3H and HCN.

$$CF_2 + HCFNH \rightarrow CF_3H + HCN$$

The relative yield of CF_3H to the yield of C_2F_4 tends to increase with increasing pulse number, as shown in

Table 1. IRMPD of CF_2HCl-NH_3 Mixtures

CF_2HCl Torr	NH_3 torr	Pulse number	Fluence[a] J cm^{-2}	$Y(C_2F_4)$	$Y(CF_3H)$	$\beta(C_2F_4)$	$\beta(CF_3H)$	Y(C) per pulse
1.0	0	1000	31	3.4×10^{-8}	0	30	—	6.8×10^{-11}
1.0	1.0	200	25	4.2×10^{-8}	Small	19	b)	4.2×10^{-10}
5.0	0	1000	30	1.7×10^{-6}	0	21	—	3.4×10^{-9}
5.0	5.0	100	28	4.0×10^{-7}	3.5×10^{-8}	18	b)	8.4×10^{-9}
10.0	0	1000	26	5.0×10^{-6}	0	17	—	1.0×10^{-8}
10.0	10.0	30	19	4.9×10^{-7}	2.6×10^{-7}	12	9	4.2×10^{-8}
10.0	10.0	100	26	2.1×10^{-6}	9.8×10^{-7}	8	8	5.1×10^{-8}
10.0	10.0	200	27	3.9×10^{-6}	2.1×10^{-6}	7	8	5.0×10^{-8}

a) Fluence at focus. b) Selectivity could not be determined because of a small yield of CF_3H.

Fig. 2. This fact seems to indicate that the accumulation of a certain compound during pulse irradiation causes the observed preferential formation of CF_3H in a late period. However, we failed to detect directly HCF_2NH_2 by gas chromatography.

CF_2HCl is one of the most promising working molecules in ^{13}C separation by IRMPD. Gauthier et al. have reported that the irradiation of 100 Torr natural CF_2HCl with the CO_2 laser radiation at 1046.9 cm^{-1} and 3.5 J cm^{-2} yields C_2F_4 containing 50% ^{13}C at the efficiency that an absorption of 140 photons produces one carbon atom.[9] Therefore, a 100-watt CO_2 TEA laser can produce carbon at rate of 1.3 g h^{-1}, if 50% of the laser radiation is absorbed by CF_2HCl. Although the production rate is sufficiently high in their experiment, the ^{13}C content must be increased to 90% or higher for practical purposes. In the previous paper we have proposed the two-stage IRMPD separation of ^{13}C using CF_2Cl_2-HI and CF_2ClBr-HI mixtures, where the first IRMPD gives CF_2HCl with a ^{13}C content of about 30% and the second IRMPD of the CF_2HCl is expected to result in the production of highly enriched ^{13}C. Since CF_2ClBr decomposes at low laser fluences, one can obtain a relatively high yield of CF_2HCl in the CF_2ClBr-HI mixture. The production of 90% ^{13}C from the CF_2HCl with a ^{13}C content of about 30% corresponds to a separation process with an enrichment factor of only 21.

Table 1 tabulates yields and enrichment factors for the IRMPD of CF_2HCl in the presence of NH_3. The results clearly demonstrate that a total carbon yield per pulse increases significantly by adding NH_3 without a large loss of selectivity. The effect may be useful for the second stage in the IRMPD separation of ^{13}C using a CF_2ClBr-HI mixture.

(Received April 27, 1987)

Double layer capacitance of the polarized nitrobenzene-water interface has been measured in the presence of the adsorption of L-α-dilauroylphosphatidylcholine (DLPC). The double layer capacitance was lowered with the increase of the DLPC concentration in the negative branch of the potential range where the aqueous phase was in negative potential with respect to the nitrobenzene phase. A saturated monolayer of DLPC was formed at a concentration of DLPC above 20 $\mu mol\,dm^{-3}$. The area occupied by a DLPC molecule at the saturated monolayer was 0.73 nm^2 which was estimated by comparing the capacitance data with those obtained from a spread monolayer of DLPC at the interface. In the negative branch the monolayer was stable over 100 mV of the applied potential across the monolayer. The adsorption was described by the Frumkin adsorption isotherm. The interaction between the adsorbed DLPC molecule was weak, corresponding to the penetration of nitrobenzene molecules and, possibly, ions between the hydrocarbon chains of DLPC. This penetration also explains the high capacitance value of 11 $\mu F\,cm^{-2}$ for the saturation monolayer. In the potential range where the aqueous phase is positive, the capacitance increased with the DLPC concentration.

Recent advances in electrochemistry of the oil-water interface have established the basic experimental methods and the relevant theories for studying the ion-transfer processes taking place at the interface.[1-4] Based on this recent achievement a quantitative study of the effect of an adsorbed monolayer of phospholipids and related compounds on ion transfer processes across the oil-water interface has now become possible. It is expected to provide fundamental information for a better understanding of the mass-transfer processes occurring at biological as well as artificial membranes. Koryta et al.[5] have reported that the ion-transfer reaction at the nitrobenzene-water interface became irreversible in the presence of lecithin in the nitrobenzene phase. Similar retardation of ion-transfer reaction has also been found for the tetraethylammonium ion transfer across the 1,2-dichloroethane-water interface in the presence of egg yolk lecithin.[6] However, in these studies the state of the adsorbed lecithins at the interface was not characterized enough to investigate in depth the mechanism of the retardation of the ion-transfer rate. Even the formation of a monolayer at the interface has not been confirmed. The purpose of the present communication is to establish the condition of the monolayer formation of phosphatidylcholine at the nitrobenzene-water interface, which is essential to the detailed study of the double layer structure and ion-transfer processes across lipid monolayers. We have studied the monolayer formation using L-α-dilauroylphosphatidylcholine (DLPC). This phospholipid monolayer is also expected to serve as a model particularly useful for studying ion-phospholipid interactions, since at polarized oil-water interfaces the structure of the electrical double layer can be studied in detail by electrocapillary measurements. Watanabe et al. have studied the adsorption of phospholipids at the methyl isobutyl ketone-water interface and have elucidated interesting qualitative features of phospholipid adsorption including the effect of pH on the aqueous solution side.[7-9] Their studies are mainly concerned with the effect of foreign substances as well as solution pH rather than the adsorption properties of the phospholipid monolayer itself. Recently, Girault and Schiffrin[10] have reported the adsorption behavior of phosphatidylcholine and phosphatidylethanolamine at the polarized 1,2-dichloroethane-water interface by measuring electrocapillary curves. In the present study, we have measured the differential capacitance of the polarized nitrobenzene-water interface in the presence of phosphatidylcholine monolayers formed by the two methods: i.e. adsorbed monolayer and spread monolayer.

Experimental

DLPC was obtained from Sigma Ltd. and was used without further purification. Tetrapentylammonium tetraphenylborate (TPnATPB) was prepared from tetrapentylammonium iodide and sodium tetraphenylborate and was twice recrystallized from acetone-ethanol mixture. Aqueous solution of reagent grade tetrapentylammonium chloride (TPnACl) was treated with silver chloride to remove trace iodide ion. Lithium chloride monohydrate (a Merck's Spurapur grade) was dissolved in water to prepare the stock solution. The concentration of TPnACl and LiCl solutions were determined by potentiometric titration with a standard silver nitrate solution. Nitrobenzene was distilled under reduced pressure. The middle 60% of the distillate was shaken with active alumina and then equilibrated with water after filtrating off the precipitates. Triply distilled water was used throughout the measurements. All other chemicals used were of reagent grade.

The electrochemical cell is represented by:

I	II	III	IV	V	VI	VII
		50 mmol dm^{-3}	0.1 mol dm^{-3}	0.1 mol dm^{-3}		(I)
Ag	AgCl	TPnACl	TPnATPB	LiCl	AgCl	Ag
		(W)	(NB)	(W)		

The interface between Phases IV and V is the polarized nitrobenzene-water interface. The potential of the right-hand side of the cell with respect to the left is denoted as E_{O+}^{W-}, where super- and subscripts, W− and O+, indicate that the right-hand and left-hand side reference electrodes are reversible to an anion, Cl^- ion in Phase V, and a cation, $TPnA^+$ ion in Phase IV, respectively.

A flat polarized nitrobenzene-water interface was formed at the orifice of a glass tube of 0.548 cm inner diameter. Other details of the measuring cell have been described elsewhere.[11] The double layer capacitance was measured by phase-selective ac polarography. The principle of the method and the type of measuring cell have been described previously.[11] An ac voltage of 50.0 Hz and 5 mV^{p-p} was superimposed on the dc voltage. In the adsorption method ac polarograms were usually recorded with a scan rate of 5 $mV\,s^{-1}$ from E_{O+}^{W-}=0.15 to 0.48 V. No change was observed in the shape of the polarogram if recorded with a scan rate of 0.5 $mV\,s^{-1}$ or if the sweep direction was reversed. In the spread method, the impedance was measured at a fixed potential as a function of time. All measurements were made at 25.0±0.5 °C.

A monolayer of DLPC at the interface between Phases IV and V was made in two ways: The formation of the monolayer by adsorption of DLPC from nitrobenzene phase (the adsorption method) and by placing a known amount of DLPC as a toluene-chloroform solution on the interface (the spread method). In the adsorption method a nitrobenzene solution of DLPC was prepared by adding a needed amount of 10 $mmol\,dm^{-3}$ chloroform solution of DLPC to 0.1 $mol\,dm^{-3}$ TPnATPB nitrobenzene solution with a micro syringe. The mixture was then sonicated at 27 °C to dissolve the added DLPC completely. Without this sonication treatment small particles persisted in the solution and sometimes gave rise to a characteristic peak in the far positive potential range in a capacitance vs. potential curve. In the spread method phosphatidylcholine was first dissolved in 3:2 (v/v) toluene-chloroform mixture to prepare the stock solutions of various concentrations. The 3:2 toluene-chloroform mixture has a density of 1.1, which is smaller than that of the nitrobenzene solution, 1.18, and larger than that of the aqueous solution, 1.0, and was used as a spreading solvent to avoid undesirable mixing due to density difference. This mixed solvent itself introduced no detectable change in the double layer capacitance. The DLPC solutions for the spreading method were stored in a decicator containing the solvent of the same composition in the bottom compartment. On spreading DLPC at the interface the solution of 1×10^{-6} dm^3 was applied through an L-shaped fine glass capillary of 0.55 mm inner diameter which was connected to a 1×10^{-5} dm^3 micro syringe mounted on a micro manipulator. The tip of the capillary was drawn out to a sharp conical shape with an orifice of 0.15 mm inner diameter. First the capillary was inserted in the nitrobenzene solution beneath the interface. Then the tip was brought up through the interface into the aqueous solution side just above the interface and a few tenths of 1×10^{-6} dm^3 DLPC solution were squeezed out of the tip of a micro syringe to form a small "bubble" at the tip. The tip was then brought down slowly to a position just beneath the interface. The "bubble" spontaneously spread away over the interface while the tip was passing through the interface. This procedure was repeated several times to complete the spreading of 1×10^{-6} dm^3 DLPC solution. The time needed for the spreading procedure was typically 30 s. The time at the completion of the final spreading was taken as t=0 for the later analysis of the data. After the spreading, the interface was brought down in close proximity to the glass frit of the reference electrode compartment. The shape of the interface was then readjusted to obtain a flat interface. The solution resistance was then measured promptly. This resistance measurement was made every time before an impedance measurement. Usually it took 0.5—1.5 min from the completion of the spreading to the start of the impedance measurement.

Results and Discussion

Adsorbed Monolayer. The double layer capacitance of the interface was measured in the potential range between E_{O+}^{W-}=0.15 and 0.48 V for ten different concentrations of DLPC from c=0.1 to 100 $\mu mol\,dm^{-3}$. The time required to attain adsorption equilibrium was checked by measuring the capacitance as a function of time. Figure 1 illustrates the time dependence of the capacitance at c=5 $\mu mol\,dm^{-3}$ and at E_{O+}^{W-}=0.20 V after the formation of a new nitrobenzene-water interface at the orifice of the glass tube. In this case, Fig. 1 shows that at least 60 min was needed to reach a time invariant value. We recorded ac polarograms to obtain the capacitance (C) vs. potential (E_{O+}^{W-}) curves after a sufficiently long time, usually 60 min, had elapsed. Some of the results are shown in Fig. 2. The vertical bars in the figure show the standard errors for the triplicate measurements. The capacitance decreased with the concentration of DLPC in the range of E_{O+}^{W-} between 0.15 and 0.35 V as shown in Fig. 2, indicating the strong adsorption of DLPC at the interface. At a concentration higher than 20 $\mu mol\,dm^{-3}$, the capacitance showed no further decrease. This probably corresponds to the formation of a saturated monolayer in this potential range. The minimum capacitance value for this saturated monolyer was 11 $\mu F\,cm^{-2}$ at E_{O+}^{W-}=0.24 V. This is significantly higher than the value, ca. 1 $\mu F\,cm^{-2}$ found in bilayer lipid membrane.[12] If the monolayer is only a half of a bilayer lipid membrane, the capacitance would be at least one fifth of the measured value. The observed high capac-

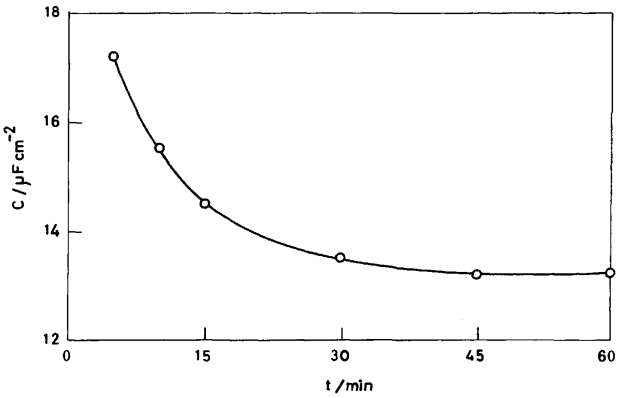

Fig. 1. Change of the double layer capacitance with time for 5 $\mu mol\,dm^{-3}$ DLPC at E_{O+}^{W-}=0.20 V.

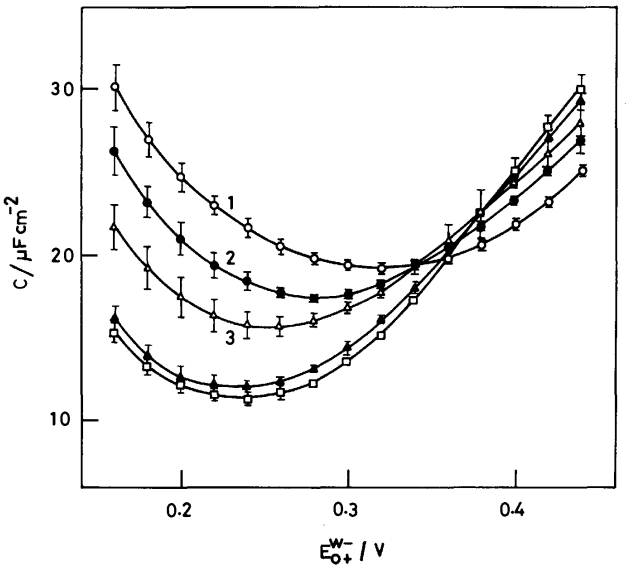

Fig. 2. Equilibrium double layer capacitance vs. applied potential curves recorded by the adsorption method for a given concentration of DLPC: 0(○), 1(●), 2(△), 10(▲), and 50(□) μmol dm^{-3} in nitrobenzene.

itance presumably reflects the penetration of solvent nitrobenzene molecules and, possibly, $TPnA^+$ and TPB^- ions into the hydrocarbon chain part of the monolayer, resulting in the higher effective dielectric constant of the monolayer.

At potentials positive to 0.35 V, the capacitance increased with the DLPC concentration. Since the potential of zero charge for the base solutions, $E^{W-}_{O+,pzc}$, is 0.34 V,[13] the results in Fig. 2 indicate that DLPC exhibits asymmetrical adsorption behavior with respect to the potential drop across the interface. There is a decrease of the capacitance with increasing concentration of DLPC in the negative branch, that is, at $E^{W-}_{O+} < E^{W-}_{O+,pzc}$, but an increase of the capacitance with DLPC concentration in the positive branch, that is at $E^{W-}_{O+} > E^{W-}_{O+,pzc}$ Such a dependence of the adsorption of phospholipid at the oil-water interface may be of importance in relevance to the dependence of physicochemical properties of biological and artificial membranes on the trans-membrane potential. Change of the adsorbed state of phosphatidylcholines with the applied voltage has also been observed at the mercury-solution interface.[14,15]

Spread Monolayer. To confirm the formation of a DLPC monolayer at the interface, we have measured the double layer capacitance after spreading a known amount of DLPC at the interface. After the spreading of the DLPC solution, the capacitance in the negative branch continuously increased with time owing to the desorption of DLPC molecules from the interface to the nitrobenzene phase. The capacitance value at E^{W-}_{O+}=0.24 V is plotted against the square root of time in Fig. 3. The straight line in Fig. 3 up to 900 s indicates that the desorption of DLPC is diffusion

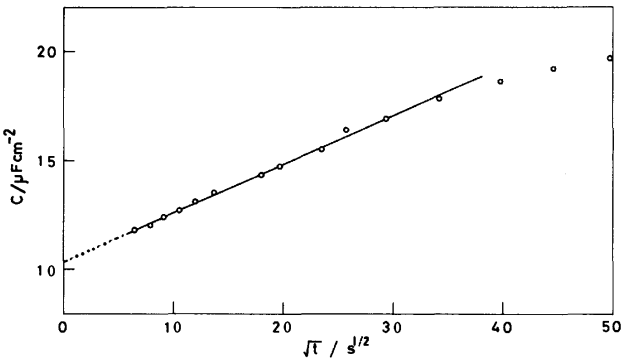

Fig. 3. Change of the double layer capacitance with time at E^{W-}_{O+}=0.240 V after spreading 1×10^{-6} dm^3 of 80 μmol dm^{-3} DLPC in 3:2 toluene-chloroform mixture.

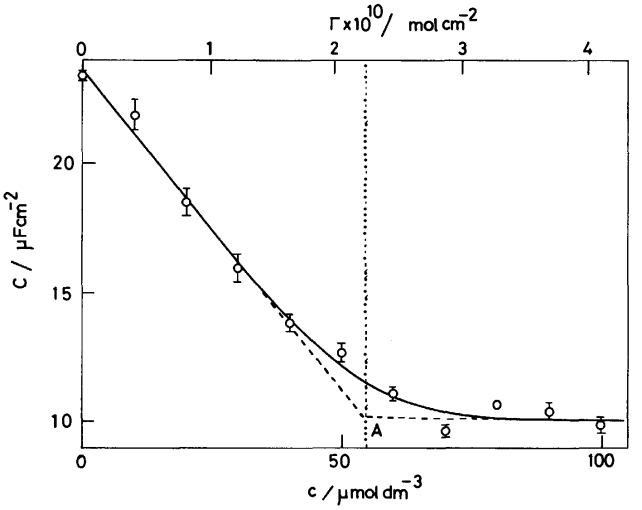

Fig. 4. Extrapolated double layer capacitance at t=0 and at E^{W-}_{O+}=0.240 V as a function of the concentration of DLPC in spreading solution at the interface. Upper scale indicates the calculated amount of DLPC to be present at the interface.

limited.[16] By extrapolating the initial straight line in Fig. 3 to t=0 we obtained the capacitance value at which a known amount of DLPC was supposed to be spread at the interface. The capacitance at t=0 thus obtained at E^{W-}_{O+}=0.24 V is plotted in Fig. 4 as a function of the DLPC concentration in the spreading solution. The upper scale in Fig. 4 indicates the spread amount of DLPC, Γ, in mol cm^{-2} unit calculated by assuming that the whole DLPC molecules contained in the spreading solution participated in the monolayer formation. The vertical bars show the standard errors for the triplicate measurements. The capacitance first decreased linearly with Γ and then reached a saturation value of 10.5 μF cm^{-2} at c=80 μmol dm^{-3} of the spreading solution. This linear change of the capacitance is in accord with Eq. 1,[17] which is based on the Frumkin's parallel plate condenser model:

$$C = C'\theta + (1-\theta)C^0 \quad (1)$$

where C^0 and C' are the C values at θ=0 and 1, respec-

tively, and θ is the surface coverage. At the concentrations of DLPC in the spreading solution above 80 μmol dm^{-3} there was no further decrease in the capacitance, indicating the formation of a saturated DLPC monolayer at the interface. If Eq. 1 holds at any value of θ, the two straight parts of the curve in Fig. 4 should cross each other at Point A. The deviation of the experimental curve from Point A indicates that at higher coverage certain portion of the spread DLPC molecules escaped from the interface and did not take part in the monolayer formation. Only after an excess of DLPC was applied, did the surface seem fully covered with the DLPC molecules as envisaged by the saturation of the capacitance value in Fig. 4. Hence, it would be reasonable to adopt a value of Γ at Point A in Fig. 4 for estimating the packing density of the saturated monolayer. The Γ value at Point A is 2.3×10^{-10} mol cm^{-2}, which corresponds to the area occupied by a DLPC molecule being 0.73 nm^2. This value is close to that for a lecithin bilayer in a liquid crystal phase. In the case of a bilayer composed of dipalmitoylphosphatidylcholine in the presence of excess water, the area was found to be 0.7 nm^2 at temperatures above the critical temparature, T_c=41 °C, whereas the area becomes 0.48 nm^2 at temperatures below T_c.[18] On the other hand, when the area per molecule in the monolayer at the air-water interface is 0.70 nm^2/molecule, didecanoyl- and dimyristoylphosphatidylcholines take on a liquid-expanded state at 25 °C.[19] The present result, therefore, indicates that the saturated DLPC monolayer formed at the nitrobenzene-water interface is in the liquid-expanded state and the DLPC molecules in the monolayer are as dense as the packing of the phosphatidylcholine molecules in the bilayer above T_c. It has been established that in a mesomorphic lamellar phase above T_c, the hydrocarbon chains are in a melted and liquid-like state.[20] This is in harmony with the interpretation for the high capacitance value of DLPC monolayer described above. In the liquid-expanded monolayer the hydrocarbon chains are melted and in a highly fluid and mobile state.[20] In contrast, a more dense liquid-condensed or solid monolayer would give a much lower capacitance value, since in such a membrane the solvent molecules and ions can not be accommodated in the hydrocarbon part which is in a crystaline state. Phillips[21] has recommended the phosphatidylcholine monolayer at the air-water interface occuping 0.70 nm^2/molecule as the most appropriate for membrane-oriented experiments using the monolayer. In this respect, the DLPC monolayer at the polarized nitrobenzene water interface can be used to study the properties, e.g., transfer of ions across the lipid-water interface, of biological as well as artificial lipid membranes.

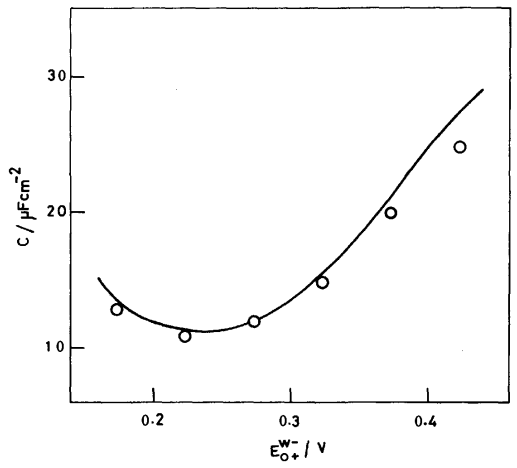

Fig. 5. Comparison of the capacitance data obtained from the adsorption method (—) at 20 μmol dm^{-3} DLPC and the spread method (O). For the spread method, 1×10^{-6} dm^3 of 100 μmol dm^{-3} DLPC was applied to the interface.

In order to check if the monolayer formed by the spread method is the same as that formed in the adsorption method at the higher concentration of DLPC, we compared in Fig. 5 the C vs. E^{W-}_{O+} curve at c=20 μmol dm^{-3} recorded by the adsorption method with the C values at several E^{W-}_{O+} obtained by extrapolating C values to t=0 for the spread monolayer when a DLPC molecule has an area of 0.73 nm^2. The agreement between the values from the two methods is excellent except at the positive extreme of E^{W-}_{O+}. It is clear from this figure that the saturated monolayer formed in the adsorption method is essentially the same as that formed in the spread method. Consequently, a condensed monolayer of DLPC whose occupied area is 0.73 nm^2 can be formed also by the adsorption method, provided that the concentration of DLPC in nitrobenzene is sufficiently high.

Adsorption Isotherm in the Negative Branch. The surface coverage can be estimated using Eq. 1, though this equation is strictly valid only when the change of θ with the electrical potential is negligible,[22] which we assume in the present analysis. This assumption would become inadequate in the positive branch where $d\theta/dE^{W-}_{O+}$ is relatively large. The adsorption isotherm obtained at E^{W-}_{O+}=0.24 V is shown with error bars in Fig. 6. In the calculation of θ we took the C values

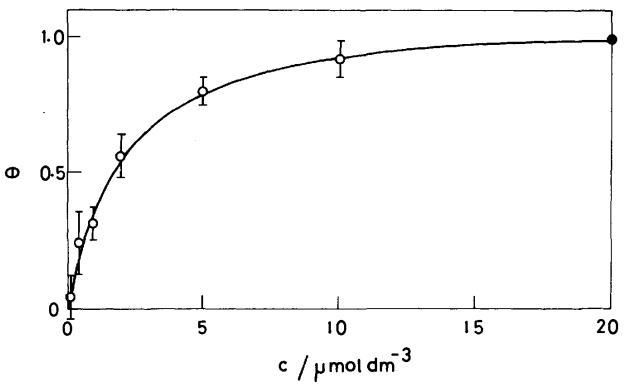

Fig. 6. Adsorption isotherm for DLPC at E^{W-}_{O+}= 0.24 V.

for c=20 mol dm^{-3} as C' in Eq. 1. Similarly, isotherms were obtained at the potentials between E^{W-}_{O+}=0.18 and 0.26 V. These isotherms were analyzed by using the Frumkin isotherm of the form:[17]

$$\beta c = \frac{\theta}{1-\theta}\exp(-2a\theta) \qquad (2)$$

where β is the adsorption coefficient, c is the concentration of phosphatidylcholine, and a is the interaction parameter. Figure 7 illustrates $\ln[\theta/\{c(1-\theta)\}]$ vs. θ plot at E^{W-}_{O+}=0.24 V to test this isotherm. Vertical bars in the figure show the standard error which was calculated from the experimental error in the capacitance measurements taking account of the error propagation. The solid line in Fig. 7 is the curve calculated through the weighted linear regression. The experimental isotherm can thus be fitted well to the Frumkin isotherm. From the intercept and the slope of this regression curve, $\ln\beta$ and the interaction parameter were found to be -1.1 ± 0.3 and -0.28 ± 0.05, respectively, where the intervals designate standard errors. Similar fittings were obtained for the data between E^{W-}_{O+}=0.18 and 0.26 V. The $\ln\beta$ and a values are plotted in Fig. 8 as a function of E^{W-}_{O+}. The vertical bars in the figure indicate the standard errors. In the potential range examined, neither $\ln\beta$ nor a depend strongly on the potential. In other words, DLPC forms a stable monolayer in the potential range of about 100 mV between E^{W-}_{O+}=0.18 and 0.26 V, irrespective of the change of the electrical potential difference across the interface. This greatly simplifies the interpretation of the data when studying the ion-transfer reaction across the DLPC monolayer in this potential range. The average value of $\ln\beta$, -1.1, is equivalent to the standard adsorption energy of 37 kJ mol^{-1}, if we choose 1 mol dm^{-3} and θ=1 for the standard states in the nitrobenzene and in the adsorption layer, respectively. This value of the standard adsorption energy is approximately four times greater than that for the adsorption of hexadecyltrimethylammonium ion at the nitrobenzene-water interface in similar polarization potential range.[23] The small α value, 0.25 on average, means a weak attractive interaction between the adsorbed DLPC molecules. The observed weak interaction is probably due to the penetration of nitrobenzen molecules between the hydrocarbon chains of the phosphatidylcholine molecules resulting in reduced cohesion between the chains. The reduced interaction between hydrocarbon chain is manifested by the behavior of phosphatidylcholines at the oil-water interface: Mingins et. al.[24] have found that diacylphosphatidylcholines having hydrocarbon chains shorter than C_{14} do not show a characteristic phase transition at the heptane-water interface between 5 and 20 °C.

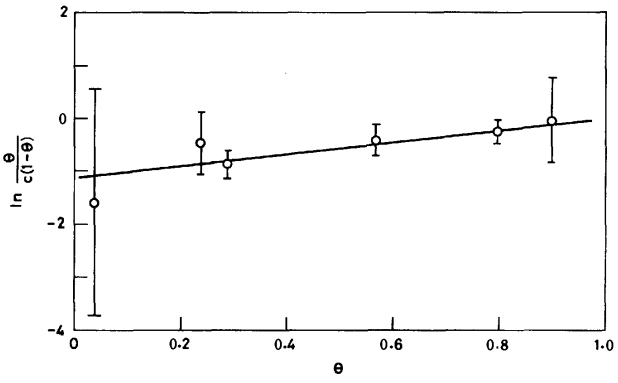

Fig. 7. Test of the Frumkin isotherm for the adsorption of DLPC at E^{W-}_{O+}=0.24 V.

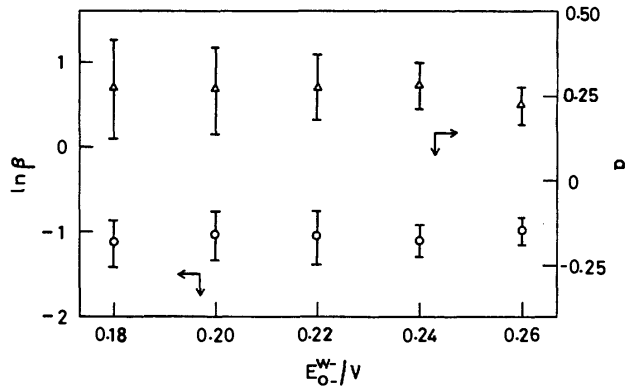

Fig. 8. Logarithm of the adsorption coefficient (○) and the interaction parameter (△) of the Frumkin isotherm for the adsorption of DLPC as a function of the electrical potential.

Adsorption in the Positive Branch. According to our prelimimary results of the interfacial tension measurements, the interfacial tension in this potential region showed a tendency to recover from the extremely low value in the more negative potential range, but still remains lower than the interfacial tension for the base solution. A similar change of the interfacial tension with the applied potential has been observed by Girault and Schiffrin[6,10] at the 1,2-dichloroethane-water interface. Consequently, the observed increase of the capacitance in Fig. 2 may be ascribed to the change of the orientation of adsorbed DLPC molecules, possibly accompanied by a partial desorption with the change of the electrical potential difference across the interface. The concomitant increase of the real part of the addmittance was observed in the positive branch, suggesting the presence of non-equilibrium processes at the interface.

The authors thank Masatoshi Nakanishi for his assistance in part of the capacitance measurements.

Shock Tube Studies of the Oxidation of Acetylene in Fuel-Rich Mixtures

Tohru KOIKE* and Kihei MORINAGA
Department of Chemistry, National Defense Academy, Hashirimizu, Yokosuka 239
(Received May 16, 1987)

The oxidation of C_2H_2 in fuel-rich mixtures was studied in the temperature range 1600—2500 K by a shock-tube technique combined with UV absorption spectroscopy. The absorption profile, attributed to both an increase of C_4H_2 and a decrease of C_2H_2, could be modeled with a reaction mechanism comprising 38 elementary reactions. The progress of the oxidation was found to be greatly influenced by the pyrolysis steps of C_2H_2.

The kinetics of C_2H_2 oxidation at high temperatures above 1000 K has been studied in shock waves and flames. The progress of the oxidation was monitored by various measuring techniques and the obtained results have been subjected to discussion concerning the reaction mechanism.

White and Gardiner[1] did a literature survey for C_2H_2 oxidation in shock waves and carried out extensive computer modeling for a reaction employing the reported experimental results. The reaction mechanism adopted was one devised by Olson and Gardiner[2,3] to model CH_4 oxidation in shock waves. The reaction mechanism includes various reaction steps involving the primary products of C_2H_2, C_2H_4, C_2H_6 and CH_2O appearing in CH_4 oxidation. Therefore, it was considered that the reaction mechanism devised for CH_4 oxidation could be applicable to C_2H_2 oxidation. The consequences were not satisfactory for C_2H_2 oxidation nor for other three species oxidations. A completely different reaction mechanism appropriate to each oxidation had to be devised.

Such a conclusion has also been derived from modeling studies of C_2H_2 oxidation in flames by Levy,[4] in which a modified reaction mechanism based on that by Olson and Gardiner[2] was used. One of difficulties in using their reaction mechanism is that the concentration of CH_4 is modeled too large in comparison with the measured value. To improve on these difficulties, he included ketene as an intermediate species produced by a reaction between C_2H_2 and OH,

$$C_2H_2 + OH = C_2H_2O + H \quad (7)$$

$$C_2H_2O + OH = CH_2O + CHO$$

instead of

$$C_2H_2 + OH = CH_3 + CO,$$

where the elementary reactions with numbers exhibit the reactions adopted in the present reaction mechanism of Table 1. His intention is that the two-step decay of C_2H_2 by OH does not give a CH_n group directly and the concentration of CH_4 given by computer modeling does not become as large as modeled above.

Recently, Gardiner's group[5] further studied C_2H_2 oxidation in shock waves by computer modeling for the reported data concerning the ignition delay, including their own data for a laser-schlieren experiment, and the exponential growth. In the derived reaction mechanism, ketene as well as the ketene radical were taken into account:

$$C_2H_2O + OH = C_2HO + H_2O. \quad (9)$$

The assumed product of this reaction is different from the above, i.e., the formyl groups are not produced.

All of the experimental results concerning C_2H_2 oxidation in shock waves reported so far are for fuel-lean mixtures. The role of pyrolysis steps in C_2H_2 oxidation must be small in these experiments. We carried out oxidation in rich mixtures and measured the concentration of C_4H_2 through UV absorption spectroscopy at 216 nm. The obtained absorption profile was subjected to computer modeling using the above-mentioned reaction mechanism. The applicability of the mechanism to the present case was examined.

Experimental

The rectangular shock-tube and optical set-up used were fully described in a previous paper.[6]

Briefly, the light from a D_2-lamp (Hanau, D200F) was detected by a photomultiplier (Hamamatsu, R208) with a monochromator (Jarrell-Ash, JE25) after passing through two shock-tube windows. The test gas compositions used were $C_2H_2/O_2/Ar$=3/1/96 and 5/1/94 prepared from 99.6% pure C_2H_2, 99.99% pure O_2 and 99.999% pure Ar. Hereafter, and in the figure captions, the former mixture is abbreviated as a 3/1 mixture and the latter as a 5/1 mixture. The shock velocity was measured with a universal counter (Takeda-Riken, TR5002) by detecting signals from 4 piezo-gauges (International Transducer, PK16-13) mounted on the shock-tube with a 10-cm spacing. The shock temperature was calculated from the measured shock velocity by assuming a full relaxation and no chemical reaction.

Results and Discussion

Figure 1 shows a representative oscillogram obtained in this study. It can be seen that absorption increases to a maximum value after showing shock front absorption by C_2H_2, and then decreases. The decrease was not observed for C_2H_2/Ar mixtures without O_2.[6] We estimated the absorption A from the oscillogram according to the equation $A=\ln(I_o/(I_o-\Delta I_t))$, where I_o is the incident light intensity and ΔI_t the absorbed

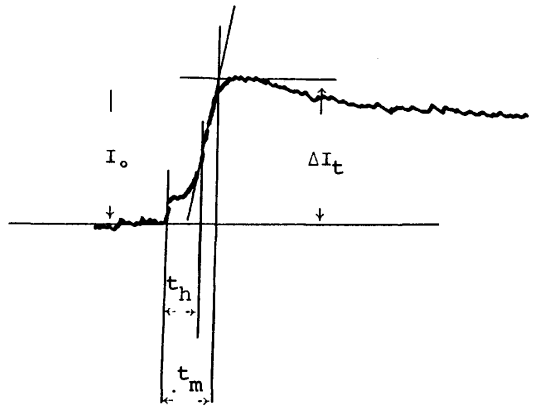

Fig. 1. A sample oscillogram for the 3/1 mixture. P_1=10 Torr and T_2=2114 K. Parameters t_h and t_m used in computer modeling are shown schematically.

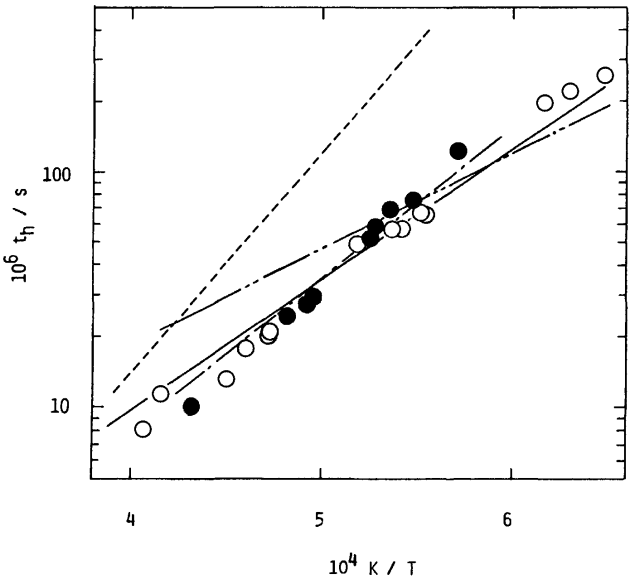

Fig. 2. Relation between t_h and $10^4/T$. Symbols used are: ○ for the 3/1 mixture. ● for the 5/1 mixture. Lines are by computer modeling: (——) for the 3/1 mixture, (–·–·–) for the 5/1 mixture, (– – – –) for the C_2H_2/Ar mixture without O_2.[6] These three lines are modeled using Table 1 reaction mechanism. (–·–··–) for the 3/1 mixture. Ref. 5 reaction mechanism is used.

intensity at reaction time t (laboratory time). The parameter t_h used for computer modeling was derived from this A and defined to be the time when A reaches half of its maximum value. The maximum A are further divided by $[C_2H_2]_0$, the shock front concentration of C_2H_2, so as to be able to compare the values of A directly in different test gas mixtures. These values of t_h and A are plotted vs. $10^4/T$ in Figs. 2 and 3, respectively. In the figures, the values of t_h and A evaluated for the C_2H_2 mixture without O_2 (C_2H_2/Ar= 3.2/96.8) are shown for a comparison.[6] It can be seen that the A for a 3/1 mixture is smaller than that for a 5/1 mixture. This tendency can also be seen in the t_h value. The values for a C_2H_2 mixture without O_2 are

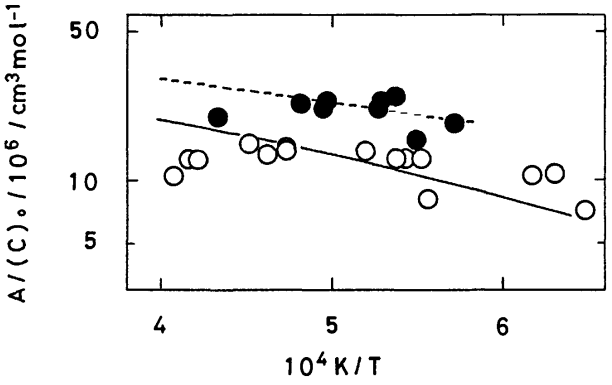

Fig. 3. Relation between A and $10^4/T$. Symbols and lines are the same as in Fig. 2. For the 5/1 mixture, the values are almost the same as those for the C_2H_2/Ar mixture.[6]

much larger than those for 3/1 and 5/1 mixtures.

We adopted computer modeling in order to interpret the measured profile of the absorption more quantitatively and to obtain a reasonable reaction mechanism. We tried it first using the reaction mechanism of Gardiner's group,[5] since the experiments were done under similar conditions to the present. Their mechanism is composed of 23 elementary reactions (Reactions 1—23 in Table 1); the only exception is that k_2 is 1/5 of that in Table 1.[8,9]

It is well-known that absorption is an aggregate by the species present in the reaction region. As for the species in C_2H_2 oxidation. C_2H_2, C_4H_2, CO_2, O_2, C_6H_2, and C_2H_2O are expected to absorb 216-nm light. The absorptions by C_6H_2 and C_2H_2O were, however, neglected in the computer modeling, since absorption data at such high temperatures as the present were not available for these two species. From a former study of C_2H_2 pyrolysis,[6] it is expected that $[C_6H_2]$ only reaches a value less than 1/10 of $[C_4H_2]$. As for the growth of C_2H_2O, it is expected to be small due to the rich mixtures investigated. Thus, ignoring absorptions by these two species does not seem to greatly influence the computer modeling results. The absorptivities of the first 4 species obtained by several workers[6,7] are shown vs. $10^4/T$ in Fig. 4. These absorptivities were incorporated into the present computer program[6] and computations were carried out. The absorption given by $A=\sum a_i[C_i]d$ was evaluated, where a_i and $[C_i]$ are the absorptivity and the concentration of species i, respectively,and d is the light-path length. From the absorption modeling, the two parameters corresponding to the above t_h and A were evaluated. Only the t_h values are plotted in Fig. 2, since the values of A are not very much dependent on the kinetic parameters. It was found that the t_h values by computer modeling are not in accordance with the experimental results.

It is important to determine whether a proposed reaction mechanism can reproduce other experimental results. We carried this out further using one mechanism by Levy[4] and another one by Miller et al.[10] in

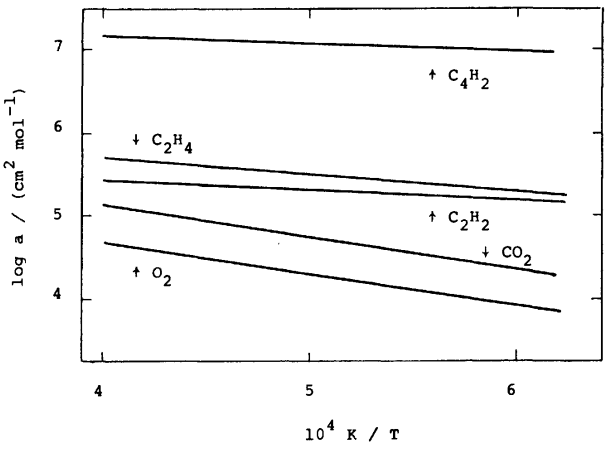

Fig. 4. Absorptivities used in computer modeling.

addition to that by Gardiner's group as above. All of the reaction mechanisms by these three groups include the chemistry of ketene groups. As for the case by Miller et al., they derived the reaction mechanism so as to be able to reproduce both of the experimental results by shock waves and flames. The shock-tube data investigated by them were, however, not adopted in the work by Gardiner's group. Thus, the present modeling plays roles in making up for such a deficiency. As for the modeling results, these two mechanisms by Levy and by Miller et al. were not appropriate for reproducing the present results. The t_h values by Levy's mechanism is larger, like the results by Gardiner's group, whereas the values by the mechanism by Miller et al. is smaller than that from the experiment.

There are two other mechanisms proposed by Jachimowski[11] and by Shaub and Bauer,[12] in which the chemistry of ketene groups is not included. These mechanisms were found not to be appropriate for reproducing the present experimental results.

One of the reasons of such failures in computer modeling could be given as follows. Acetylene in rich mixtures as in the present is expected to decay primarily through pyrolysis steps. Therefore, the k values of the reactions concerning such steps must be adopted with care. We showed in a previous paper[6] that the k_3 value largely depends on the absorption profile and proposed a smaller value than those previously reported. The k_3 value adopted in the three mechanisms by Jachimowski, by Shaub and Bauer and by Miller et al.[10] is the same as proposed by Browne et al.[14] This k_3 value is almost one order larger than the value accepted in the previous paper.[6]

As for the mechanisms by Gardiner's group and by Levy, a reasonable k_3 value is adopted. Therefore, the failure in computer modeling seems to be due to the absence of any important decaying processes of C_2H_2 necessary for rich mixtures. We added Reactions 24—38 to the reaction mechanism by Gardiner's group[5] so as to be appropriate to the present mixtures. This

Table 1. Reaction Mechanism and Rate Constants $k=A\exp(-E/RT)$ (mol, cm, s, and kcal units)

No.	Reaction	log A	E
1	$C_2H_2+M=C_2H+H+M$	16.62	107.00
2	$C_2H_2+C_2H_2=C_4H_3+H$	13.0	45.9
3	$C_2H+H_2=H+C_2H_2$	12.9	2.63
4	$C_2H_2+C_2H=C_4H_2+H$	13.6	0.0
5	$C_2H_2+O=CH_2+CO$	8.61+1.5 log T	1.7
6	$C_2H_2+O=C_2HO+H$	14.63	12.1

21	$HO_2+H=H_2+O_2$	13.4	0.7
22	$HO_2+OH=H_2O+O_2$	13.7	1.0
23	$CO+OH=CO_2+H$	12.6	8.0
24	$C_4H_2+O=C_3H_2+CO$	13.43	1.72
25	$C_4H_2+OH=C_3H_2+CHO$	13.48	0.0
26	$C_3H_2+O=C_2H+CHO$	13.83	0.0
27	$C_3H_2+OH=C_2H_2+CHO$	13.83	0.0
28	$C_4H_3+M=C_4H_2+H+M$	16.0	60.0
29	$C_4H_2+M=C_4H+H+M$	17.53	80.0
30	$C_2H_2+C_4H=C_6H_2+H$	13.6	0.0
31	$C_4H_2+C_2H=C_6H_2+H$	13.6	0.0
32	$C_6H_2+M=C_6H+H+M$	16.7	80.0
33	$H+C_4H_2=H_2+C_4H$	13.3	0.0
34	$H+C_6H_2=H_2+C_6H$	13.3	0.0
35	$C_2H_2+OH=C_2H+H_2O$	12.78	7.0
36	$C_2H_2+O=C_2H+OH$	15.5−0.6 log T	15.0
37	$C_4H_2+O=C_4H+OH$	13.0	0.0
38	$C_4H_2+OH=C_4H+H_2O$	13.0	0.0

extended mechanism is the final one determined in this study. By computer modeling with this reaction mechanism, we could reproduce the experimental t_h data shown in Fig. 2.

From the obtained oscillograms, parameters t_m, corresponding to the time when the absorption A reaches a maximum value, were also evaluated and are plotted in Fig. 5 vs. $10^4/T$. The t_m values found by modeling are also shown in the figure for a comparison. This value for t_m has been used as a parameter in previous modeling studies.[6,13] A good agreement between experiment and modeling could be obtained for a 3/1 mixture. For a 5/1 mixture, however, the values by modeling are larger than those by experiment. This incompatibility could not be diminished without greatly disordering the mechanism by Gardiner's group;[5] thus, the k_3 value had to be increased by more than two times. In this case, however, we could not reproduce the other parameter t_h and the t_m in the 3/1 mixture. Therefore, it can be said that the t_m in the 5/1 mixture does not accord with the reaction mechanism

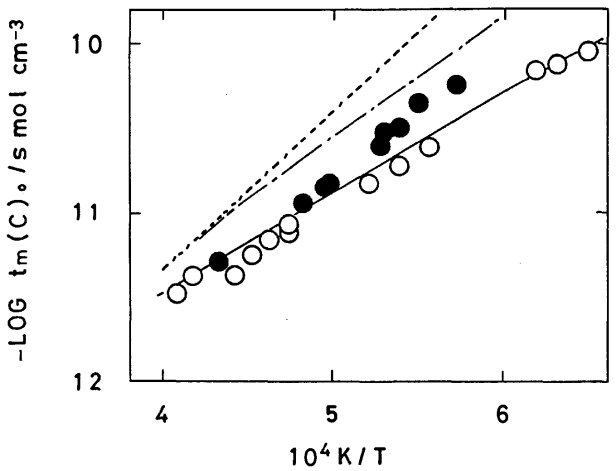

Fig. 5. Relation between t_m and $10^4/T$. Symbols and lines are the same as in Fig. 2.

in Table 1 and remains uninterpretable.

The features of the mechanism shown in Table 1, except for Reactions 1—23, can be described as follows. Reactions 24—27 show the degradation process of C_4H_2 by oxides to smaller hydrocarbons.[15] These reactions, as well as Reactions 37 and 38, seem to be concerned with a decrease in the absorption after exhibiting a maximum value. This can be an evidence to support the idea that the absorption measured in the C_2H_2 mixtures without O_2 did not show a decrease. There have been, however, only a few studies in which the oxidation of C_4H_2 were measured directly. We did not go into this point further and only adopted Reactions 24—27, 37, and 38 as such reactions for the decay of C_4H_2. Reactions 28—34 are concerned with polyacetylenes and polyacetylene radicals. Since the concentrations of these species are modeled to be large, these reactions must be important under the present fuel-rich conditions, as in the pyrolysis of C_2H_2. Abstraction reactions of H atom, 35—38, by an O atom and an OH radical produce acetylene radicals. The number of reaction channels to produce acetylene radicals is larger in the present experiment than that in C_2H_2 pyrolysis. Since the acetylene radicals play roles as chain carriers, the overall reaction rate is expected to become larger in the present experiment. This is in accordance with the measured results of the overall reaction rate given by the reciprocals of t_h and t_m in Figs. 2 and 5. Gardiner's group ignored these reactions as not being important.

As for the reaction mechanism of the oxidation of C_2H_2, Shaub and Bauer[12] referred to two important points differring from the present treatment. One is that the ketene and the ketene radical produced as intermediates were presumed to decompose via unimolecular steps very rapidly. Reactions of the ketene groups were not considered explicitely in their reaction mechanism. The mechanism shown in Table 1 includes not only such steps but also the H atom abstraction reactions by an O atom and an OH radical. The other different point is that they considered reactions involving the CH_2 radical to be unimportant. In Table 1, however, the reaction between CH_2 radical and O_2 was assumed to be the main route to produce CO_2.[5] Reaction 23 has been known as a primary step in producing CO_2 in hydrocarbon oxidation.

In conclusion, the present experimental results could be explained with an extended reaction mechanism based upon that by Gardiner's group.[5] All of the rate constants used were obtained from the existing literature.

Application of the SPE Method to Organic Electrochemistry. VIII. The Incorporation of an Iron Redox Couple into Pt-Nafion and Its Behavior as a Mediator

Zempachi OGUMI,* Toshiyuki MIZOE, Naoki YOSHIDA, and Zen-ichiro TAKEHARA
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received 26 May, 1987)

Fe^{2+} and Fe^{3+} were incorporated into Pt-Nafion. The full incorporation of Fe^{2+} into H^+-type Nafion was attained beyond 0.3 M† $FeSO_4$. The ion-exchange selectivity of Fe^{2+} was estimated to about 2 to H^+. The incorporated ions exhibited diffusional behavior inside the composite electrode. The formal potential of the incorporated iron(III/II) redox couple was dependent on both the H_2SO_4 and the Fe^{3+} and Fe^{2+} concentrations. The potential shift was, however, not so large as that reported on some redox systems on polymer-coated electrodes. The incorporated redox couple was revealed to behave as a mediator in the oxidation of L-ascorbic acid.

The present authors have investigated the application of the SPE method to organic electrochemistry[1,2] using Nafion as an SPE material. Electroorganic syntheses mediated by a redox system are very attractive and have been investigated by many workers. The present authors also attempted to utilize some redox mediators in an SPE electrolyzer, though only mediators dissolved in a solution were used.[3,4] The fixing of a mediator system into an SPE composite electrode would facilitate the separation process after an electrolysis and would demand only a small amount of the mediator. These advantages enable one to use an expensive mediator. In this work, the use of a redox mediator fixed in an SPE composite electrode prepared by the electroless deposition of Pt on Nafion (Pt-Nafion) was preliminarily examined using an iron-redox system.

Pt-Nafion has inherently the structure of a Nafion-coated electrode. Many workers have investigated Nafion-coated electrodes prepared by the casting of a Nafion solution.[5,6] A solution-cast Nafion film does not, however, have the well-known structure of Nafion without curing above 120 °C.[7] On the other hand, nobody would hesitate to accept the reported structure model of Nafion on Pt-Nafion prepared by the electroless plating method under the mild conditions adopted in this work. Pt-Nafion, therefore, may serve as a typical model of an electrode coated with Nafion with a better defined structure. The electrochemical behavior of an iron-redox couple in Pt-Nafion will also be briefly examined.

Experimental

Chemicals. Commercially available chemicals of a reagent grade were used without further purification.

Pt-Nafion Composite Electrodes. Nafion 125, a perfluorinated cation-exchange membrane, was used as an SPE material. Platinum was deposited on one side of the Nafion from chloroplatinic(VI) acid employing an electroless plating method described peviously,[8] using $NaBH_4$ as a reductant. After electroless plating, platinum was further electrolytically deposited in order to decrease the surface ohmic resistivity to less than 0.7 Ω between the two ends of the deposit (3 cm in diameter).

Electrolysis Cell. The SPE composite electrode, with an effective geometric surface area of 3.1 cm^2, was placed in a glass cell described elsewhere.[2] The electrode potential was set vs. the Ag/AgCl reference electrode via a Luggin capillary inserted in a counter-electrode compartment using a potentiostat (Hokuto Denko HA-301). During experiments, argon was introduced into the working-electrode compartment. In all cases, the set potential contained a junction potential at the interface between Nafion and the contacting solution and a fairly large ohmic drop through the Nafion.

Incorporation of Fe^{2+} and Fe^{3+} into Pt-Nafion. After platinum deposition, the Pt-Nafion was immersed in 1M H_2SO_4 for more than 2h in order to change the counter ion into H^+. This H^+-type Pt-Nafion was then immersed in a $FeSO_4$ or $Fe_2(SO_4)_3$ solution of different concentrations under argon purging into the solution.

Amounts of Fe^{3+} and Fe^{2+} Incorporated in Pt-Nafion. A chronoamperometry technique was first used to measure the amount of iron ions in the Pt-Nafion. The decaying current after potential stepping with and without incorporation was integrated. The difference in values with and without the incorporation gave the amount of Fe^{2+} or Fe^{3+} in Pt-Nafion.

Pt-Nafion incorporated with Fe^{2+} or Fe^{3+} was immersed in 2M H_2SO_4 or 0.3M EDTA so that the incorporated Fe^{2+} or Fe^{3+} could be extracted into the solution. The amount of iron ions in the extract was measured by a fluorescent X-ray analysis method using Kelex Ultra-Trace 0600. In some experiments, iron(II) or iron(III) ion was oxidized by H_2O_2 or reduced by L-ascorbic acid[AH_2] respectively during immersion in order to fix the ionic form at Fe^{3+} or Fe^{2+}.

Mediation by Iron-Redox Couple Incorporated in Pt-Nafion. Using a 25 mM AH_2 aqueous solution, the capability of mediation by the iron-redox couple was examined by means of the cyclic voltammetry and potential pulse electrolysis techniques. An AH_2 solution was introduced into either the working or counter-electrode compartment.

Results and Discussion

The Incorporation of Iron Ions into Pt-Nafion. The amounts of Fe^{2+} incorporated into Pt-Nafion from aqueous $FeSO_4$ in various concentrations were

† 1M=1 mol dm^{-3}.

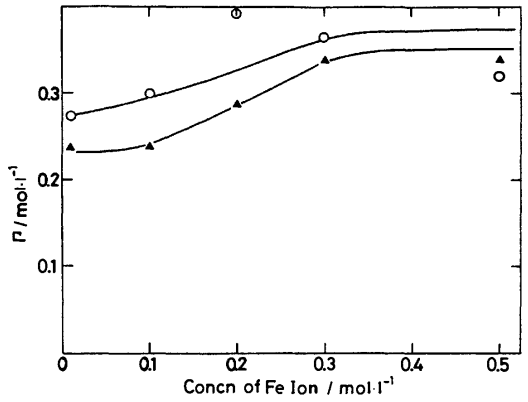

Fig. 1. The amount of Fe^{2+} up-taken into Nafion 125, Γ, by X-ray fluorescence (○) and chronoamperometric (▲) measurements.

measured by means of a chronoamperometry technique and fluorescent X-ray analysis. The incorporated Fe^{3+}/Fe^{2+} showed diffusional behavior, which allowed us to use a chronoamperometry technique in order to estimate the amount of Fe^{2+} in Pt-Nafion. As Fig. 1 shows, the results obtained by the two methods agreed fairly well. The amount reached the ceiling value of about 0.34—0.37 mol dm^{-3}-whole wet resin in a 0.30 M $FeSO_4$ soaking solution. The exchange site concentration of Nafion 125 after standard boiling-water treatment in the H^+ form was estimated as ca. 1 equivalent dm^{-3}-whole wet resin, ca. 3 equivalent dm^{-3}-dry resin. The results obtained here correspond to ca. 0.7 equivalent dm^{-3}-whole wet resin, which is about 70% of the estimated value of a full exchange.

Redox Behavior of Incorporated Fe^{3+} and Fe^{2+} Ions. Incorporated iron ions showed redox behavior on cyclic voltammetry measurements. After a decrease in the current during several initial sweeps, steady voltammograms were obtained. Changing a potential sweep rate, the peak currents were examined on Pt-Nafion placed in contact with 0.025 M H_2SO_4, which had precedingly been equilibrated with 0.25 M $Fe_2(SO_4)_3$. The anodic and cathodic peak currents exhibited a linear dependence on the square root of the sweep rate, suggesting the usual diffusional properties of the redox species existing in the Pt-Nafion and a negligible contribution from a migration effect. On the other hand, a linear dependence of the peak currents on the sweep rate has been reported on many polymer-coated electrodes, including a Nafion coated electrode, and an electron-hopping conduction process has been reported to take place in a Nafion-coating film on electrodes.[6,10] In the present case, however, we need not consider this process, because the Nafion keeps its structure as an ion-exchange membrane in which the conduction is exclusively sustained by the diffusional and migrational movements of ionic species, and so electronic conduction must be insignificant.

The Exchange Selectivity of Fe^{2+}. The increase in the H_2SO_4 concentration at 0.05 M $FeSO_4$ caused a decrease in the anodic peak current on Pt-Nafion incorporated with iron ions. This decrease implies the exchange of H^+ with Fe^{2+} or Fe^{3+} in Pt-Nafion. The exchange selectivity, K, of ion exchange membranes was calculated. Assuming the activity coefficient of Fe^{2+} $\gamma_{Fe}=1$ and using a mean activity coefficient of H_2SO_4 for γ_H, the molar fraction of Fe^{2+} in Pt-Nafion, $\bar{x}$, was calculated. $\bar{x}$ is shown in Fig. 2. Since the $\bar{x}$ calculated assuming $K=2.0$ agrees well with the experimental results, we obtained the selectivity constant of 2.0 for Fe^{2+} in Nafion. The value of $K=2.0$ is acceptable in view of the reported values of 0.97, 1.24, 3.60, and 2.30 for Zn^{2+}, Co^{2+}, Cu^{2+}, and Mg^{2+} respectively.[11]

Formal Potential of the Iron-Redox Couple Incorporated in Pt-Nafion. The formal potential of the iron-redox couple incorporated in Pt-Nafion, E_p^f, was obtained by means of cyclic voltammetry measure-

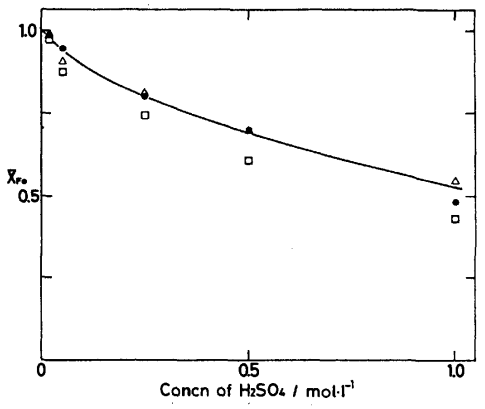

Fig. 2. The dependence of Fe^{2+} molar fraction inside Pt-Nafion, $\bar{x}$, on H_2SO_4 concentration at 0.05 M $FeSO_4$. Solid line; experimental result, Calculated values assuming $K=2.0$ (△) and $K=1.4$ (□).

ments; a set of values are listed in Tables 1 and 2, together with the values in an aqueous solution on a conventional bare Pt electrode, E_s^f. The values were calculated as a middle point between the anodic and cathodic peak potentials. As shown in the tables, the potential difference, $\Delta E^f = E_p^f - E_s^f$, changes from a negative to a positive value with an increase in the H_2SO_4 or Fe_2SO_4 concentration. Some authors have previously noticed a systematic shift of the formal potential of some redox couples incorporated in the polymer coating on electrodes. Braun et al.,[12] for instance, reported a very big potential shift of $[Fe(CN)_6]^{3-/4-}$ (over 200 mV) incorporated in an anion-exchange layer on glassy carbon. Tsou and Anson[13] examined the shift of the formal potential of some redox couples using pyrolytic graphite electrodes covered with Nafion or a polymerized perfluorinated calboxylic acid type cation exchanger. They observed a negative ΔE^f for the more hydrophobic redox couples, $[Ru(NH_3)_6]^{3+/2+}$ and positive ΔE^f for the more hydrophobic redox couple, $[Os(bpy)_3]^{3+/2+}$. They explained this as follows. In the case of hydrophilic redox couples, the oxidized redox half is stabilized more by the electrostatic interaction with a coating polyelectrolyte than is the reduced redox half. In the case of hydrophobic redox couples, on the other hand, the reduced redox half is stabilized more by the hydrophobic interaction with the coating polyelectrolyte than is the oxidized redox half. They also explained the dependence of the potential shift on the ionic strength as the result of a combination of two interactions in the opposite direction, increased electrostatic interactions at a lower ionic strength, and stronger hydrophobic interactions at a higher ionic strength.

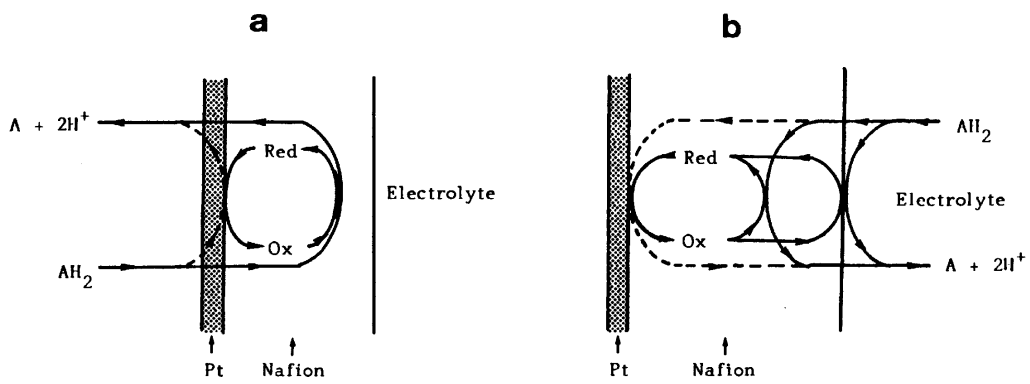
In the present results shown in Tables 1 and 2, however, neither the potential shift nor the change in ΔE^f with the concentration of the outer solution were so large as the value observed by Tsou and Anson. Iron(III) and iron(II) ions are so hydrophilic that the contribution of the hydrophobic interaction with Nafion is insignificant. The change in E^f with the concentration could be ascribed to the change in the Donnan potential, which was not estimated here. The characteristic ionomer structure of Nafion,[11] which is widely accepted, can be directly adopted in the case of Pt-Nafion, while the structure of Nafion on a polymer-coated electrode prepared from liquid Nafion should be dependent on the treatment after coating and might be different from the structure of the membrane Nafion. The ionomer structure of Nafion renders the behavior of the hydrophilic species inside the Nafion similar to that in the homogeneous aqueous phase. This leads to the smaller ΔE^f value on Pt-Nafion than on polymer-coated electrodes prepared from the liquid Nafion.

The redox potential of Fe(III)/Fe(II) is well-known to be affected by an anion in solution. In the present case, some direct effects of a $-SO_3^-$ group of Nafion, such as coordinating to and ion-pairing with redox cations, must be taken into consideration in any further discussion.

Indirect Oxidation of AH_2. From the above results, it seems that the redox potential of Fe(III)/Fe(II) in Nafion dose not differ much from the value in a usual aqueous system; the Fe(III) ion in Nafion can, therefore, be expected to oxidize AH_2 to dehydroascorbic acid.[14]

In the use of SPE composite electrodes incorporated with a redox mediator, two different configurations in the electrolysis system are possible, as is shown in Fig. 3. Case a is a distinguishing configuration for an SPE electrolyzer. In this case, a substrate solution is not required to contain any electrolyte; even neat substrate fluid can be used. Case b is the same configuration as in a usual polymer-coated electrode, though the coating polymer layer is much thicker than on the latter. In Case a, the substrate must be transferred to the reaction site through a thin, porous metal electrode layer. In Case b, the mediator or substrate must pass through a coating Nafion layer.

In the configuration of Case b, the electrode poten-



AH_2 : L-ascorbic acid, A : dehydroascorbic acid, Red : Fe^{2+}, Ox : Fe^{3+}

Fig. 3. Schematic diagrams of a mediation reaction by a redox couple incorporated in an SPE composite electrode. a: a substrate is introduced in a working electrode compartment, b: a substrate is introduced in a counter electrode compartment.

tial was stepped from 0.4 to 0.75 V, where the Fe(II) ion was oxidized to the Fe(III) ion. As is shown in Fig. 3 (b), AH_2 can be oxidized by two different courses: The direct oxidation of AH_2 on the Pt electrode bound to Nafion and indirect oxidation by the Fe(III) ion produced by the oxidation of the Fe(II) ion on the Pt electrode at the surface or inside the layer of the Nafion film. In the former, AH_2 has to penetrate through the Nafion layer and so reach the Pt electrode (the broken line in Fig. 3 (b)). In the latter, the Fe(III) ion has to move from the Pt electrode to the Nafion surface and so come in contact with the solution containing AH_2. If the Fe(III) ion meets with AH_2, which comes into the Nafion layer from the solution on the way to the Pt surface, it will oxidize the AH_2 there (the solid line in Fig. 3 (b)). The current due to the direct oxidation was estimated from measurements of the current after the potential stepping described above, without any incorporation of the iron-redox couple. Line a in Fig. 4 shows the direct oxidation current, the values of which increase linearly with the increase in the concentration of AH_2 in the counter-electrode compartment, as can be predicted from its simple diffusional mass-transfer through the Nafion layer. The incorporation of the iron-redox couple enhances the oxidation current after the potential stepping. The oxidation current should contain the oxidation of the Fe(II) ion incorporated in the Nafion layer. The latter would, however, fall off to zero after the consumption of the whole Fe(II) ion if Fe(II) was not regenerated by the reaction with AH_2. Therefore, the increase in the current should be ascribed to the indirect oxidation mediated by the iron redox couple, because the current was measured under steady-state conditions. The increase in current upon the incorporation of the iron-redox couple is shown by line b in Fig. 4. The increment was calculated by subtracting the values shown by line a from the values

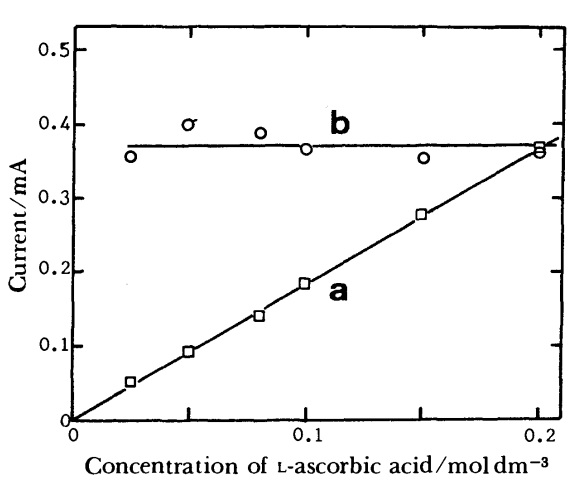


Fig. 4. Oxidation current of AH_2 in 25 mM H_2SO_4 in a counter electrode compartment of Pt-Nafion without incorporation of the redox couple (a), and with incorporation of Fe^{3+} and Fe^{2+} after subtraction of the direct oxidation current of AH_2 (b).

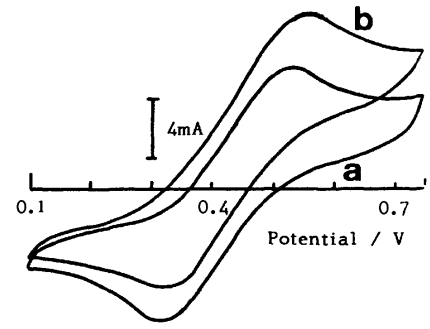

Fig. 5. Cyclic voltammograms on Pt-Nafion incorporated with Fe^{3+} and Fe^{2+} containing with water (a), and 25 mM AH_2 (b) in a working electrode compartment.

obtained with the incorporation. The subtraction does not give the correct value of the indirect oxidation in an exact sense, because the simple diffusional mass-transfer is no longer valid when diffusing AH_2 reacts with the Fe(III) ion on the way. However, the increment still gives evidence of the contribution of the indirect oxidation process. Details of the rate of the indirect oxidation relative to the direct oxidation will be discussed in successive papers, together with problems in the mass-transfer and reaction zone in the Nafion layer.

Figure 5 shows cyclic voltammograms obtained in the configuration of Case a in Fig. 3. Curves a and b were obtained without and with 25 mM AH_2 respectively in the working-electrode compartment. The current increases to the positive direction throughout the potential range of the potential sweep. It has been reported that AH_2 is oxidized directly at the potential examined here in the low pH region.[14] Therefore, it seems that the increase observed here was caused by both the direct oxidation of AH_2 on Pt and its indirect oxidation mediated by the iron-redox couple. The increase is more remarkable at the positive potential, where the Fe(II) ion is oxidized to the Fe(III) ion, than at the negative potential where the Fe(II) ion is stable. These phenomena suggest qualitatively that the indirect oxidation process takes place in the configuration of a in Fig.3. It is difficult to separate the contributions to the current-increase from the two courses of oxidation in this configuration. The increase in the current upon a mediatory action of the redox couple was, however, larger in the configuration of Case a than in that of Case b (cf. Fig. 3. This means that the former configuration is preferable. The results in Figs. 4 and 5 show the applicability of the redox couples incorporated in an SPE composite electrode as mediators for the electrochemical reactions of organic substances.

We wish to thank Dr. Masanobu Kitamura for his help in the fluorescent X-ray measurement.

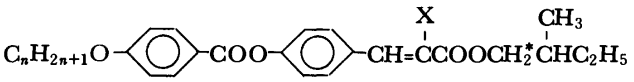
Thermal and Ferroelectric Properties of (*S*)-2-Methylbutyl Esters of α-Substituted 4-(4-Alkoxybenzoyloxy)cinnamic Acid

Jun NAKAUCHI,* Yoshitaka KAGEYAMA, Mioko UEMATU, and Shunsuke MINAMI
Tokyo Research Laboratory, Mitsubishi Rayon Co. Ltd., Noborito, Tama-ku, Kawasaki, Kanagawa 214
(Received May 26, 1987)

Three homologous series of (*S*)-2-methylbutyl esters of α-substituted 4-(4-alkoxybenzoyloxy)cinnamic acid **Ia** (α-H), **Ib** (α-CH_3), and **Ic** (α-CN) have been synthesized and their thermal and ferroelectric properties have been investigated. The mesomorphic transition temperatures for the homologous series (**Ia**, **Ib**, and **Ic**) depend on the α-substituents as well as the terminal alkoxyl chain length. In comparison with Schiff base analogues, the transition temperatures from the isotropic phase to smectic A for all the homologous series are a little lower; however, their transition temperatures from the smectic A phase to chiral smectic C show significantly different features. The thermal stability of the chiral smectic C phase has been discussed from the view point of the local intermolecular dipole-dipole interaction in the homologous series (**Ia**, **Ib**, and **Ic**) and the Schiff base analogues. The spontaneous polarization for the homologous series is in the order of the homologues: **Ib** > **Ia** > **Ic** and their polarity is negative for **Ia** and **Ib** and positive for **Ic** homologues, respectively. These results have also been discussed in terms of the α-substituent effect on the spontaneous polarization.

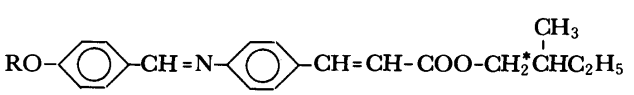
Since the discovery of ferroelectricity in smectic liquid crystals containing a chiral group in the molecular structure (Sm*C phase),[1] extensive studies have been carried out not only from a fundamental point of view, but for practical applications as well. However, the relation between the ferroelectricity in the Sm*C phase and the molecular structure has not been well understood so far. Two plausible reasons are the limited number of compounds which have been investigated regarding their physical properties and the drastic change of the thermal stability in the mesophase frequently caused by altering the molecular structure slightly. Thererofe, the synthesis of various novel compounds with the Sm*C phase and the measurement of their fundamental physical propertries are necessary in order to elucidate the relationship between the ferroelectricity and the molecular structure.

From this point of view, the following homologous series (**Ia**, **Ib**, and **Ic**) of general formula:



(**Ia** : X = -H, $n = 5—16$; **Ib** : X = -CH_3, $n = 5—16$; **Ic** : X = -CN, $n = 7—12$)

have been synthesized and their thermal and ferroelectric properties have been investigated. These compounds have a characteristic molecular structure in the sense that the -CH=N- linkage of well-known Schiff base analogues ((*S*)-2-methylbuthyl 4-(4-alkoxybenzylideneamino)cinnamate)



is replaced with a -COO- linkage. Such a mesogen unit was reported to be a suitable structure for the Sm*C phase,[2] and some compounds shown in the above formula (**Ia** : n=5—14, **Ic** : n=5—12) have already been synthesized; their thermal porperties and polarity were reported by Goodby et al.[3-5] However, the effect of the α-substituents on the mesomorphic thermal stability and other ferroelectric properties have not been discussed so far.

In the present paper, we compare the physical properties of the homologous series (**Ia**, **Ib**, and **Ic**) with those of the Schiff base analogues reported by P. Keller et al.[6] and Ph. Martinot-Lagarde et al.,[7,8] and discuss the effect of the molecular structure on the thermal stabilty in the mesophase and the ferroelectricity in the Sm*C phase.

Experimental

Preparation of Materials. All the reagents purchased from Tokyo Kasei Co. Ltd. were used without further purification. *p*-Hydroxy-α-methylcinnamic acid was prepared by a Perkin reaction according to the literature.[9] (*S*)-2-Methylbutyl esters of α-substituted *p*-hydroxycinnamic acid were synthesized by an esterification reaction of *p*-hydroxy-α-substituted cinnamic acid with (*S*)-2-methyl-1-butanol using a Soxhlet extractor. Their specific rotations ($[\alpha]_D$) measured in diethyl ether at 23 °C were +5.35°, +3.59°, and +8.16° for α-H, α-CH_3, and α-CN derivatives, respectively. (*S*)-2-Methylbutyl esters of α-substituted 4-(4-alkoxybenzoyloxy)cinnamic acid were synthesized by a reaction of (*S*)-2-methylbutyl esters of α-substituted *p*-hydroxycinnamic acid with *p*-alkoxybenzoyl chloride and triethylamine in the diethyl ether solution. The crude products obtained were purified twice by recrystallization from their solution with diethyl ether and pentane. Their elementary analysis data are listed in Table 1.

Measurements of Physical Properties. An identification of the mesophase was carried out using a Nikon polarizing microscope equipped with a Mettler FP-52 heating stage. Transition temperatures were measured using a Daini Seikosha SSC-560 differential scanning calorimeter (DSC) at a scanning rate of 2.5 °C min^{-1} under an N_2 atomsphere.

The spontaneous polarization (*P*s) was determined by a triangular-wave method reported by Miyasato et al.[10] The frequency, the maximum amplitude and the cell thickness were 1.0 Hz, ±70 V and 50 μm, respectively.

The tilt angle (θ/°) and the polarity (the direction of *P*s)

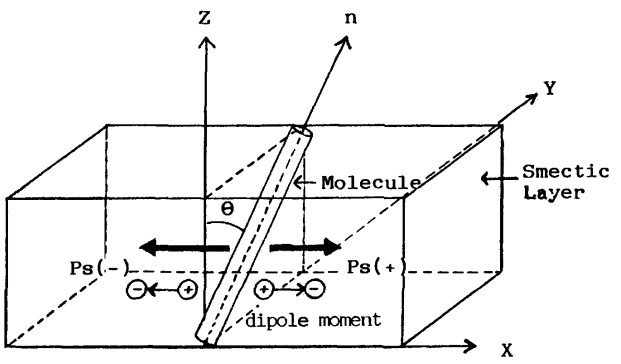
were determined by applying a *D.C.* field to a specimen placed between crossed polarizers and by observing the direction of extinction by rotating the stage. The polarity is defined by the direction that the molecules are tilted with respect to the layer normal, as shown in following picture.



Results and Discussion

Figures 1, 2, and 3 show the mesomorphic trends of each homologous series (**Ia**, **Ib**, and **Ic**). A normal

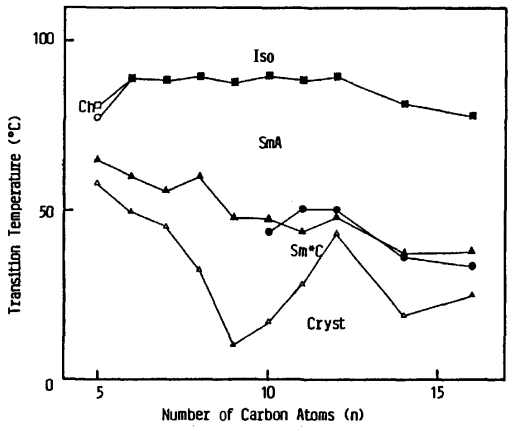


Fig. 1. Plots of the transition temperatures against the number of carbon atoms (n) in the n-alkoxyl chain of (*S*)-2-methylbutyl 4-(4-alkoxybenzoyloxy)-cinnamates (**Ia** homologues): Iso-Ch (-□-); Iso-SmA (-■-); Ch-SmA (-○-); SmA-Sm*C (-●-); SmA-Cryst or Sm*C-Cryst (-△-); melting point (-▲-).

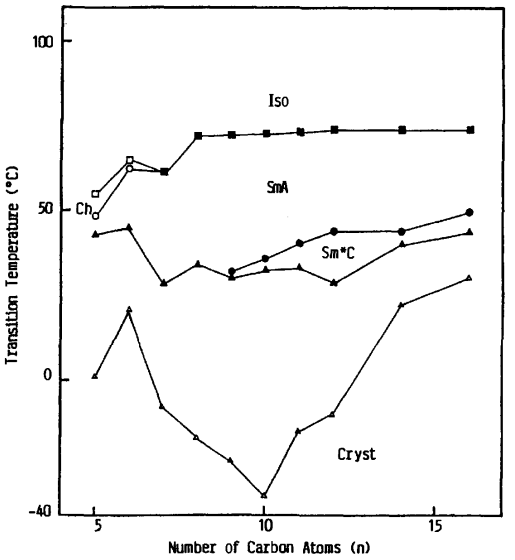

Fig. 2. Plots of the transition temperatures against the number of carbon atoms (n) in the n-alkoxyl chain of (*S*)-2-methylbutyl 4-(4-n-alkoxybenzoyloxy)-α-methylcinnamates (**Ib** homologues): Iso-Ch (-□-); Iso-SmA (-■-); Ch-SmA (-○-); SmA-Sm*C (-●-); SmA-Cryst or Sm*C-Cryst (-△-); melting point (-▲-).

odd-even alternation for the isotropic (Iso) to smectic A (SmA) and for SmA to chiral smectic C (Sm*C) can clearly be seen in **Ia** homologues, though it is ambiguous in **Ib** and **Ic** homologues. In all the homologous series investigated, cholesteric (Ch) appears in the lower alkoxyl chain homologues, whose number of the carbon in terminal alkoxyl chain are n=5, n=6, and n=9 for **Ia**, **Ib**, and **Ic** homologues, respectively. The Sm*C phase of **Ia** and **Ic** homologues injected at decyloxy and heptyloxy derivatives appears as a monotropic transition from SmA, except for enantiotropic undecyloxy and dodecyloxy derivatives of **Ia** homologues. On the other hand, the Sm*C phase of **Ib** homologues

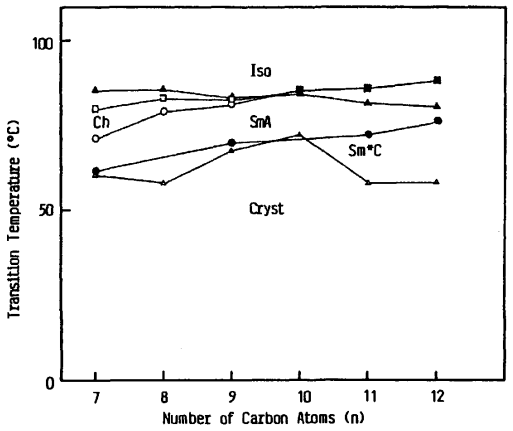

Fig. 3. Plots of the transition temperatures against the number of carbon atoms (n) in the n-alkoxyl chain of (S)-2-methylbutyl 4-(4-n-alkoxybenzoyloxy)-α-cyanocinnamates (**Ic** homologues): Iso-Ch (-□-); Iso-SmA (-■-); Ch-SmA (-○-); SmA-Sm*C (-●-); SmA-Cryst or Sm*C-Cryst (-△-); melting point (-▲-).

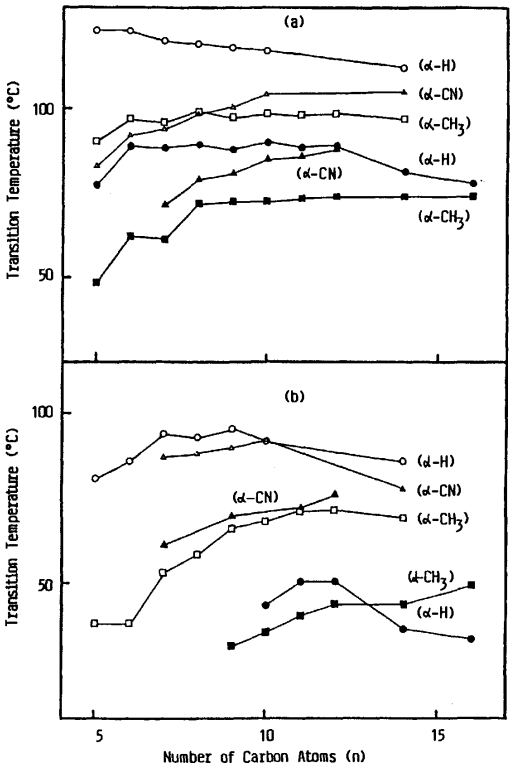
injected at nonyloxy derivative appears as an enantiotropic one from SmA with a wider temperature range than those of **Ia** and **Ic** homologues. Plots of the transition temperatures from SmA to Sm*C against the number of carbon atoms in the alkoxyl chain in **Ia** homologues are "parabolic" as Goodby et al. referred to;[11] however, this trend was not seen in **Ib** and **Ic** homologues.

In order to compare the thermal stability of SmA and Sm*C phase for homologous series (**Ia**, **Ib**, and **Ic**) with those for the Schiff base analogues reported by Keller et al.,[6] the transition temperatures from Iso to SmA and from SmA to Sm*C against the carbon number of the terminal alkoxyl chain are plotted in Figs. 4a and 4b, respectively. As is evident from Fig. 4a, the transition temperatures from the Iso phase to SmA for each homologues with different α-substituents are a little lower than those for the Schiff base analogues. This trend is attributed to the effect of replacing the -CH=N- linkage in the core with the -COO- linkage on the thermal stability for SmA phase.[12]

On the other hand, the thermal stability of the Sm*C phase for the homologous series (**Ia**, **Ib**, and **Ic**) is significantly different from those for the Schiff base analogues. That is, the transiton temperatures from SmA phase to Sm*C for the Schiff base analogues decrease in the order of the analogues: α-H > α-CN > α-CH_3. However, those for the homologous series decrease in the order of the homologues (α-CN > α-H ≈ α-CH_3 (**Ic** > **Ia** ≈ **Ib**)), respectively.

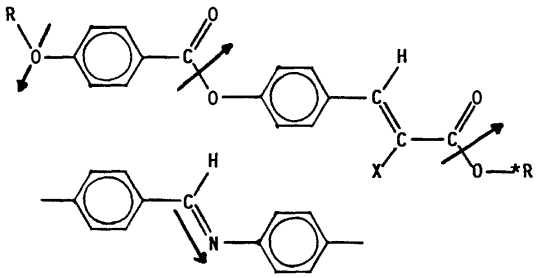
According to McMillan's theory,[13] if a molecule has both central and out-board dipole moments, the transition temperature from SmA to Sm*C depends on the local intermolecular dipole-dipole interaction among these dipole moments.

In the homologous series (**Ia**, **Ib**, and **Ic**), the central dipole corresponds to the dipole of the ester linkage of



Figs. 4a and 4b. Plots of the transition temperatures from Iso phase to SmA (4a) and from SmA phase to Sm*C (4b) against the number of carbon atoms in the n-alkoxyl chain of the homologous series **Ia** (-●-), **Ib** (-■-), and **Ic** (-▲-), and those of the Schiff base analogues α-H (-○-), α-CH_3 (-□-), and α-CN (-△-).

the core (6.34×10^{-30} C m)[14] and the out-board dipoles correspond to dipoles of the ether linkage (4.27×10^{-30} C m)[14] and the ester linkage of the cinnamoyl moiety including the α-substituent. It is noteworthy that the direction of the dipole moment of the homologous series (-COO-: 6.34×10^{-30} C m) to the molecular axis is quite defferent from that of the Schiff base analogues (-CH=N-: 5.24×10^{-30} C m),[14] if the molecule has the all trans configulation, as shown in the following schemes



These facts indicate that the different dependence of the SmA-Sm*C transition temperature on the α-substitution between the homologous series (**Ia**, **Ib**, and **Ic**) and the Schiff base analogues can be attributed to a difference in the local intermolecular dipole-dipole interaction caused by replacing the central link-

age -CH=N- with -COO-.

The temperature dependence of the spontaneous polarization in the Sm*C of the homologous series **Ia**, **Ib**, and **Ic** are shown in Figs. 5, 6, and 7, respectively. As is evident from the figures, the spontaneous polarization of the homologous series is in the order of the homologues (**Ib**>**Ia**>**Ic**) and shows a maximum at certain alkoxyl chain length in each homologues. The maximum value was observed in the **Ib** homologue with a terminal dodecyloxyl chain (60 $\mu C\,m^{-2}$). These facts show that spontaneous polarization strongly depends on the α-substituents in the cinnamoyl moiety as well as the terminal alkoxyl chain length.

The polarities of the spontaneous polarization in the homologous series are negative for **Ia** and **Ib** homologues and positive for **Ic** homologues, respectively. The alternation of polarity between **Ia**, **Ib**, and **Ic**, which was observed in the Schiff base analogues,[8] has already been reported and interpreted as tilt variations between the core and the terminal chain by Goodby et al.[5] To confirm the tilt variations among the homologous series, the tilt angles for the dodecyloxy homologues for **Ia**, **Ib**, and **Ic** were measured. Figure 8 shows the temperature dependence of the tilt angle in the Sm*C phase for **Ia**, **Ib**, and **Ic** homologues. The tilt angle measured by the optical method corresponds to the angle of the core in the molecule tilted to the smectic layer. Therefore, the core of the **Ic** homologue has the most tilted structure among three homologues. This result seems to be in conflict with the speculation of Goodby et al. However, in the present study, the thickness of the smectic layer has not been measured yet; hence, the tilt variations between the core and the terminal chain are not clear at this stage.

According to Meyer et al.,[1] the spontaneous polari-

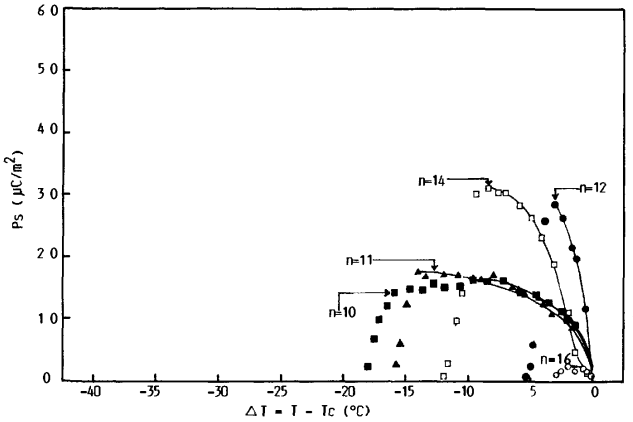


Fig. 5. Temperature dependence of the spontaneous polarization of **Ia** homologues. The cell thickness, the frequency and the maximum amplitude of applied voltage are 50 μm, 1.0 Hz, and ±70 V, respectively.

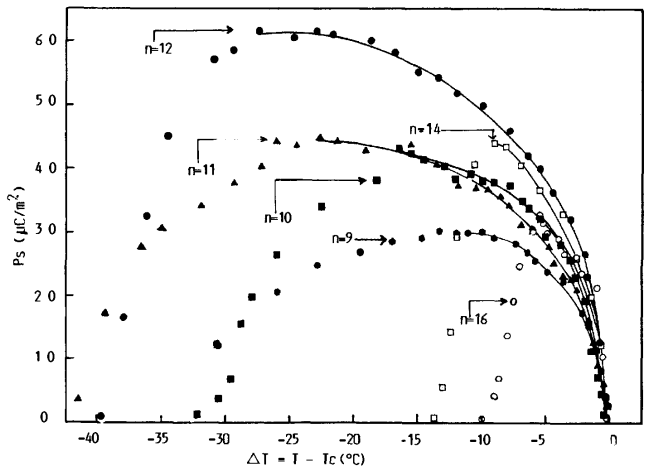

Fig. 6. Temperature dependence of the spontaneous polarization of **Ib** homologues. The cell thickness, the frequency and the maximum amplitude of applied voltage are 50 μm, 1.0 Hz, and ±70 V, respectively. The deviation of the plots from the curve satisfied the relation: $Ps \propto (\Delta T)^{\beta}$ at the lower temperature side is probably due to the applied voltage not enough to reverse the spontaneous polarization completely.

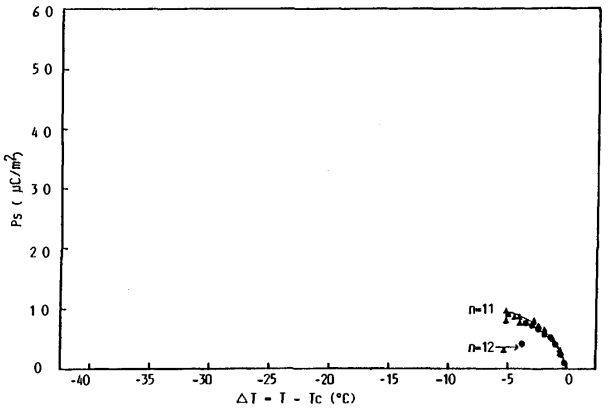

Fig. 7. Temperature dependence of the spontaneous polarization of **Ic** homologues. The cell thickness, the frequency and the maximum amplitude of applied voltage are 50 μm, 1.0 Hz, and ±70 V, respectively.

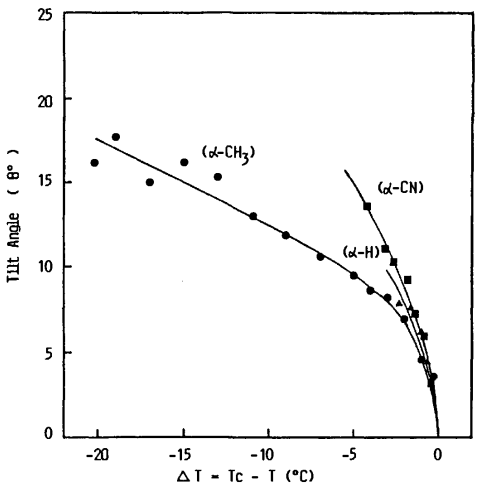

Fig. 8. Temperature dependence of the tilt angle for the homologous series **Ia** (-▲-), **Ib** (-●-), and **Ic** (-■-).

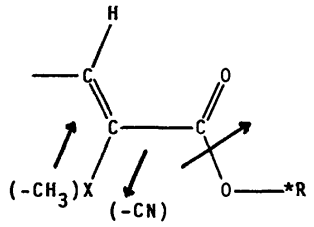
zation originates from the perpendicular component of the dipole moment in the polar group attached to the asymmetric carbon atom. The structure of the cinnamoyl moiety adjecent to the asymmetric carbon for the homologous series (**Ia**, **Ib**, and **Ic**) are schematically pictured as follows.



The contribution of the α-substituent to the dipole moment or the 2-methylbutoxycarbonyl group is inverse between **Ib** and **Ic** homologues. In comparison with the unsubstituted homologues **Ia**, **Ib** homologues have an electron-releasing methyl group so that the dipole moment of the ester group in the cinnamoyl moiety is enhanced, thus leading to the increase of spontaneous polarization. On the other hand, **Ic** homologues have a strong electron-withdrawing cyano group (13.01×10^{-30} Cm)[15] with the opposite direction of the dipole moment to that of the dipole moment of the ester group in the cinnamoyl moiety (6.34×10^{-30} Cm); hence the perpendicular component of the net dipole moment to the molecular axis decreases and has the opposite direction to those of **Ia** and **Ib** homologues. The **Ic** homologues have a smaller spontaneous polarization with opposite polarity.

The authors thank Dr. Toshio Yoshihara for his helpful discussion.

(Received June 4, 1987)

Excited state dipole moments of 9-(4-dimethylaminophenyl)-10-cyanoanthracene determined from the electric field effect on solutions in several solvents as well as fluorescence spectra, ground state absorption and S_n-S_1 transient absorption spectra show that this molecule most probably fluoresces from two excited states in nonpolar and medium polar solvents, whereas only one highly polar excited state emits in polar solvents.

The spectroscopic and kinetic behaviour of 4-(9-anthryl)-*N*,*N*-dimethylaniline (ADMA) and some derivatives has been investigated in several papers.[1-15] In particular, the fluorescence at least in sufficiently polar solvents originates from a polar state which is stabilized in polar solvents through solvent-solute interaction and/or formation of a twisted conformer so that its energy, originally higher than the less polar first Frank-Condon (FC) excited singlet state, becomes the energetically lowest. From electro-optical absorption and emission measurements[7,12] it has been shown that polarizability effects due to mere solvent solute interaction can describe the observed effects, but also a description of the experimental material assuming mere twisting to a so-called "twisted intramolecular charge-transfer (TICT) state" was shown to be possible.[9,12] A crucial point is the interpretation of the electro-optical absorption measurement in the long wavelength shoulder. Here, Herzberg-Teller coupling between two nearby electronic states as discussed with the related compound *p*-dimethylaminobenzonitril (DMABN) and some of its derivatives[16] could cause problems in the interpretation of the measured quantities. Hence, the molecule 9-(4-dimethylaminophenyl)-10-cyanoanthracene (10-CN-ADMA) was synthesized[17] in order to study the effect of a larger charge transfer present already in the ground state on the solvent dependence of the fluorescence. Also there was some hope that the long wavelength shoulder in the absorption spectrum would be broader at least in polar solvents than this is the case with ADMA. Then, electro-optical absorption measurements could be performed with less inherent systematic error than with ADMA.[7]

Experimental

Outline of Electro Optical Absorption (EOAM) and Integral Electro Optical Emission (IEOEM) Measurements. With EOAM, the effect of an external electric field E_a on the absorption $A^E(\tilde{\nu}, \chi)$ of solute molecules is measured dependent on the wavenumber $\tilde{\nu}$ and the angle χ between the direction of E_a and the polarization direction of the linearly polarized light used to measure $A^E(\tilde{\nu}, \chi)$. The method has been worked out extensively by Liptay and co-workers.[18] From a suitable experiment,[19] the experimental quantity $L(\tilde{\nu}, \chi)$ is determined as defined by the following Eq. 1,

$$A^E(\tilde{\nu}, \chi) = A(\tilde{\nu}, \chi)[1 + L(\tilde{\nu}, \chi) E_a^2] \quad (1)$$

From the measured wavenumber and angular dependence of $L(\tilde{\nu}, \chi)$ the terms ${}^aE$ to ${}^aI$ can be determined as shown in Ref. 18. With the transitions considered in this paper, they are related to the molecular dipole moments through the following Eqs. 2 to 4, if only explicit dipole terms have to be taken into account

$${}^aE = 2\beta^2 f_e^2 \mu_g^2 \quad (2)$$

$${}^aF = {}^aG = \beta f_e^2 \mu_g \Delta^a\mu \quad (3)$$

$${}^aH = {}^aI = f_e^2 (\Delta^a\mu)^2 \quad (4)$$

For further definitions see below. Integral electro optical emission measurement (IEOEM)[12,20] are a modified (an integral) version of spectrally resolved electro optical emission measurements (EOEM).[21] With IEOEM the effect of E_a on the fluorescence photon flux $p_1^E(\phi)$ from the whole fluorescence band is measured without spectral resolution in an optical broad band experiment, dependent on the angle ϕ between the direction of E_a and the polarization direction given by an analyzing polarizer in the fluorescence light beam. The method has been described and checked with various systems in refs.[20-23] Equation 5 defines the experimental quantity $\chi_1(\phi)$

$$p_1^E(\phi) = p_1[1 + \chi_1(\phi) E_a^2] \quad (5)$$

From the angular dependence of χ_1, two experimental terms ${}^iD$ and ${}^iE$ can be derived. As is shown elsewhere,[20,22] a linear combination of these quantities is related to the dipole moment of the fluorescent state

$${}^eE = {}^iE - 4{}^iD = 2\beta^2 f_e^2 \mu_e^2 \quad (6)$$

$$\beta = (kT)^{-1} \quad (7)$$

with Boltzmann's constant k and the temperature T.

$$\Delta^a\mu = (1 - f'\alpha_e^{oFC})^{-1} (1 - f\alpha_e^{oFC}) (1 - f\alpha_g^{o})^{-1} (1 - f'\alpha_g^{o}) (\mu_e^{FC} - \mu_g) \quad (8)$$

$$\mu_g = (1 - f\alpha_g^{o})^{-1} \mu_g^{o} \quad (9)$$

$$\mu_e^{FC} = (1 - f\alpha_e^{oFC})^{-1} \mu_e^{oFC} \quad (10)$$

$$\mu_e = (1 - f\alpha_e^{o})^{-1} \mu_e^{o} \quad (11)$$

$$\mu_g^{FC} = (1 - f\alpha_g^{oFC})^{-1} \mu_g^{oFC} \quad (12)$$

μ^o are the dipole moments of the considered equilibrium and Frank-Condon (FC) states of the free solute and α^o their polarizabilities. Subscripts e and g indicate excited state and ground state properties, respectively.

$$f_e = 3\varepsilon/(2\varepsilon + 1) \cdot 1 \quad (13)$$

$$f = [(\varepsilon - 1)/(2\varepsilon + 1)]/(2\pi\varepsilon_o a^3) \cdot 1 \quad (14)$$

$$f' = [(n^2 - 1)/(2n^2 + 1)]/(2\pi\varepsilon_o a^3) \cdot 1 \quad (15)$$

In the used model,[18,21] the solute dipole is approximated by a point dipole in the center of a sphere with radius a, determined by the solute's size. f_e then connects the field in the empty sphere to the externally applied field E_a and f and f' describe the effect of the reaction field due to polarization of the solvent shell around the solute dipole ε_0 is the permittivity of the vacuum. Equation 8 reduces to

$$\Delta^a\mu = \mu_e^{FC} - \mu_g \qquad (16)$$

in nonpolar solvents are used.

Conventional Absorption and Fluorescence Spectra. Ground-state absorption spectra have been measured using a Perkin Elmer-Hitachi model 340 spectral photometer with data handler, connected to a Digital Equipment LSI 13/2 computer with Watanabe WX4671 plotter. Spectral bandwidth was 0.4 nm. The quanta-corrected fluorescence spectra have been recorded using a Farrand MK II fluorometer connected to the mentioned computer system. Quanta calibration of the emission channel was performed using an EG&G 1000 Watts quartz-halogen lamp, calibrated to an NBS-standard. Spectral bandwidth was 2 nm, excitation wavelength was 400 nm.

Transient Absorption Spectra. Picosecond time-resolved transient absorption spectra were measured by means of a microcomputer-controlled, mode-locked Nd^{3+}: YAG laser photolysis system described elsewhere.[24] The third harmonic of a single picosecond pulse was used for excitation.

Compounds. 10-CN-ADMA has been prepared and carefully purified as described else where.[17] All solvents have been purified using standard procedures[25] and were dried under reflux conditions over Na-K-alloy or where this was impossible by chromatography over alumina, immediately before preparing the solutions, undre Ar protective overpressure.

Results and Discussion

Results from EOAM. The long wavelength shoulder of the absorption spectrum of 10-CN-ADMA[17] in dioxane is represented in Fig. 1 and is compared with 9-cyanoanthracene. EOAM investigations have been performed at 298 K in cyclohexane and dioxane solutions. The results are given in Table 1 together with the calculated dipole moments.

The effective ground state dipole moment μ_g does not show a solvent dependence that could be due to a

reaction field induced part and what could be separated using Eq. 9. Hence, $\mu_g=(21\pm2)10^{-30}$ Cm is used as an upper limit for μ_g°. This value agrees well with the sum of μ_g° of *N,N*-dimethylaniline and of 9-cyanoanthracene[26] which amounts to $19.1\cdot10^{-30}$ Cm.

The change of the effective dipole moment with excitation is found to be solvent dependent, even if the very large experimental error of $\Delta^a\mu$ is taken into account. This is due to the fact that the measurement is done in a slope which is a small part only of the whole absorption to the polar FC-state. Nevertheless, the effective dipole moment μ_e^{FC} is found to be very large in both solvents, although the value of μ_e^{FC} found in dioxane must be discussed as an approximation, since Eq. 16 is not valid in dioxane where reaction field induced terms cannot be neglected. Referring to Eq. 10, obviously μ_e^{FC} in cyclohexane is an upper limit for μ_e^{oFC}.

The values found for $\Delta^a\mu$ are larger than those reported in Table 5 of Ref. 7, which would be in agreement with the model of an intramolecular charge-transfer excited state where the charge centers would be further apart in 10-CN-ADMA than in ADMA itself.

Results from IEOEM. Table 2 represents the experimental quantities ${}^iD$ and ${}^iE$.

Discussion Assuming One Emitting Species or State. If one emitting species or state is assumed, μ_e can be calculated using Eq. 6. The values are given in Table 3. They show a strong solvent dependence which might be interpreted as reaction field induced amounts to the total effective dipole moment μ_e. Then with Eq. 17 from a regression analysis of μ_e^{-1} on $(\varepsilon-1)/(2\varepsilon+1)$, μ_e° as well as the polarizability density

Table 3. Some Results from IEOEM on 10-CN-ADMA Assuming a One State System. Errors of μ_e Are about 5%, Those of μ_e^0 and α_e^0/a^3 Are Derived from the Standard Error of the Regression Coefficients

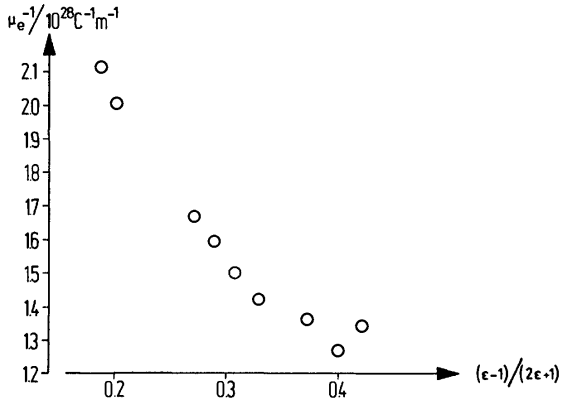

Fig. 2. Plot of μ_e^{-1} of 10-CN-ADMA versus $(\varepsilon-1)/(2\varepsilon+1)$.

α_e^0/a^3 can be derived.

$$\mu_e^{-1}=(\mu_e^0)^{-1}-(\alpha_e^0/(\mu_e^0 2\pi\varepsilon_0 a^3))(\varepsilon-1)/(2\varepsilon+1) \quad (17)$$

Fig. 2 shows a plot according to Eq. 17, which hardly could be interpreted as a straight line. A better interpretation seems to be a curve that levels off to a horizontal line at μ_e around $80\cdot10^{-30}$ C m, at high solvent polarity. Table 3 displays the results from a respective linear regression analysis, too. The permanent dipole moment μ_e^0 seems to be pretty small. Contrasting this, the polarizability density α_e^0/a^3 is pretty large, in the order of what had been reported in Ref. 7 with ADMA. This unusual finding is based on the assumption that only one state or species emits. On the other hand, from investigations on ADMA and some other derivatives[6] as well as from the bent curve of Fig. 2 and from the disagreement between μ_e determined in cyclohexane and μ_e^{FC}, it might follow that perhaps two emitting species or states determine the spectroscopic behavior of 10-CN-ADMA. This idea is also supported by the change of the spectral shape of the fluorescence of 10-CN-ADMA, when going from nonpolar to polar solvents, as shown in Fig. 3.

Discussion Assuming Two Emitting Species or States. For the considerations in this section, terms like $f\alpha_e^0$ are assumed to be much smaller than 1, in all

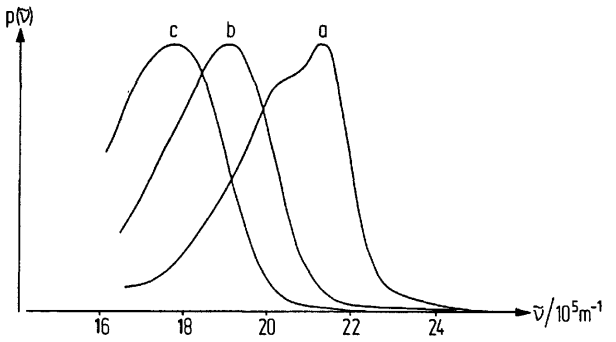

Fig. 3. Fluorescence spectrum of 10-CN-ADMA, a: in methylcyclopentane; b: in diisopropyl ether; c: in fluorobenzene, at 298 K, Excitation wavelength was 400 nm, sample concentration $1\cdot10^{-5}$ mol dm^{-3}.

solvents, that is induced amounts to μ_e are assumed to be negligible, and hence $\mu_e=\mu_e^0$, with the two-state model. Also it is assumed as the working hypothesis in this section, that there are a polar fluorescent species or state A and a less polar fluorescent species or state B which emit simultaneously to give the observed broad fluorescence band. State A may be the intramolecular charge transfer state just discussed and state B probably a locally excited 9-cyanoanthracene like state with some admixture of the dimethylaniline→cyanoanthracene charge transfer character. No assumption is made with respect to the conformation of 10-CN-ADMA in these two states, as to whether the two states are to be considered as conformers. With this model, the solvent dependence of the dipole moment μ_e shown in Table 3 and in Fig. 3 is due to a change of the ratio q of the fluorecence intensities of B and A

$$q=p_{1B}/p_{1A} \quad (18)$$

Consequently, the value of μ_e in polar solvents that gets constant around $\mu_e^0=80\cdot10^{-30}$ C m would be due to almost only the A state emission and $\mu_e^0=47.4\cdot10^{-30}$ C m in heptane might be assumed as due to almost pure B-state emission. Then q can be calculated according to Eq. 19, which is taken from[20]

$${}^cE_A={}^cE_M(1+q)-{}^cE_B q. \quad (19)$$

The values of q are given in Table 4. They are founded on the assumed values for $\mu_e^0(A)=80\cdot10^{-30}$ C m and $\mu_e^0(B)=47\cdot10^{-30}$ C m or alternatively $\mu_e^0(B)=35\cdot10^{-30}$ C m, by which ${}^cE_A$ and ${}^cE_B$ have been calculated according to Eq. 6. In principle, q can be used for the kinetic interpretation of the activation barrier between the two states. A quantitative discussion will be given together with respective data of other related molecules in a forthcoming communication.[27]

S_n-S_1 Absorption Spectra. S_n-S_1 absorption spectra have been measured at 298K in cyclohexame, fluorobenzene, tetrahydrofuran, 1-butanol, and acetonitrile. The measurements suffered from the very low solubility of 10-CN-ADMA in all solvents-which is the reason for the noisy spectra. Figure 4 shows these spectra at

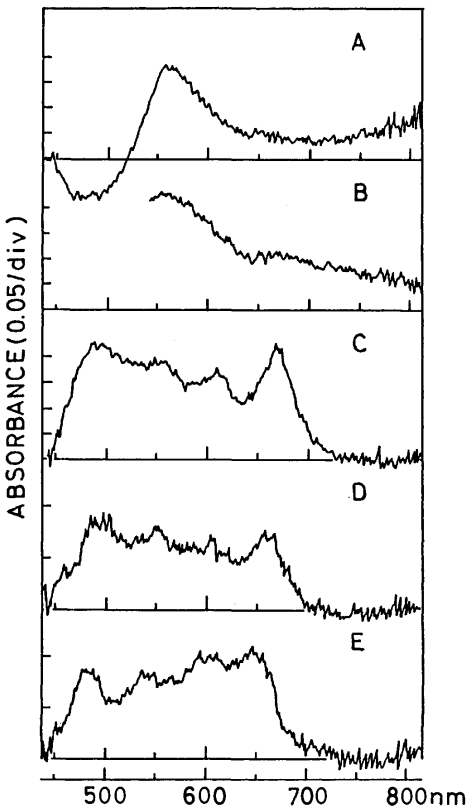

Fig. 4. S_n–S_1 transient absorption spectra of 10-CN-ADMA in some solvents, taken at 298 K, A: in cyclohexane, 100 ps after the 355 nm excitation pulse; B: in fluorobenzene, after 100 ps; C: in tetrahydrofuran, after 200 ps; D: in 1-butanol, after 200 ps; E: in acetonitrile, after 100 ps.

100 ps delay time after the excitation with the laser pulse of about 25 ps duration. The spectral band shape has not indicated any change depending on the delay time except in 1-butanol. Even in 1-butanol the spectral shape has reached its steady state within this time interval. The spectra change considerably when passing from nonpolar to polar solutions. In cyclohexane, an absorption band with peak around 570 nm and broad absorption without distinct peak in 600—800 nm region are observed. This transient absorption spectrum is somewhat similar to that of 9-cyanoanthracene (9-CA) (Fig. 5) as well as that of ADMA

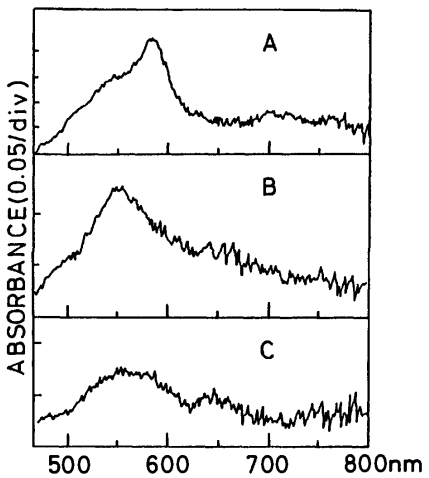

Fig. 5. S_n–S_1 transient absorption spectra, taken at 298 K, of A: 9-CA in cyclohexane, 100 ps after the 355 nm excitation pulse; B: 9-CA+DMA(ca. 0.1 M) in acetonitrile, after 66 ps; C: 9-CA+DMA(ca. 0.1 M) in acetonitrile, after 300 ps.

in cyclohexane solutions.

In tetrahydrofuran, 1-butanol and acetonitrile (Fig. 4), the spectra are very similar to each other, but quite different from that in cyclohexane. The spectral shape in these polar solvents with peaks at 550, 610, and 660 nm is very similar to those of some derivatives of and compounds related to ADMA,[28] where the anthryl moiety is quite isolated from the other part of these compounds, except that the spectra of 10-CN—ADMA are ca. 70—80 nm bule-shifted compared with those of ADMA. It had been emphasized there that the S_n-S_1 spectra of the latter compounds in polar solvents resemble the anthracene anion.[28] In Fig. 5, the transient absorption spectra of 9-CA in cyclohexane (A, at 100 ps delay time) and 9-CA+*N*,*N*-dimethylaniline (DMA) in acetonitrile (B and C, at 66 and 300 ps delay times, respectively) are indicated. The spectrum B is mainly due to the S_1 state of 9-CA because of the relative low concentration of DMA (ca. 0.1 M), while the spectrum C is mainly due to the $(9\text{-CA})^-\cdots DMA^+$ ion pair which shows decay due to back electron transfer within 1 ns. Although this absorption spectrum of the $(9\text{-CA})^-\cdots DMA^+$ ion pair is much broader compared with the spectra of 10-CN-ADMA in polar solvents given in Fig. 4, its wavelength region agrees very well with those of 10-CN-ADMA in polar solvents, which suggests strongly that the excited 10-CN-AMDA in polar solvents should be characterized by a large intramolecular charge separation between the 9-CA and DMA moieties. The broadening of the spectrum in Fig. 5C compared to those of Fig. 4C, D, E, could be ascribed to the difference in the ion-pair structures. Namely, the π-electronic systems of 9-CN^- and DMA^+ of the ion pair in the case of Fig. 5C might be in a closer contact (presumably face to face?) than in the case of the intramolecular charge-transfer state of 10-CN-ADMA in polar solvents. This is exactly what was

derived experimentally from IEOEM, where a dipole moment in between 70 and $80 \cdot 10^{-30}$ C m has been found, which is equivalent to a charge transfer over 0.5 nm.

The band at 660 nm which is quite intense in the polar solvents, tetrahydrofuran, 1-butanol, and acetonitrile, is also contained in the spectra in cyclohexane and fluorobenzene solutions, although quite weakly. Hence, these spectra might be considered as a superposition of a 9-CA anion spectrum from a locally excited 9-CA like state. In this case, the dipole moment of the excited 10-CN-ADMA determined in cyclohexane ought to be represented very roughly by the sum of the first singlet excited state dipole moment of 9-CA[22] and of the ground state dipole moment of dimethylaniline,[26] which would amount to about $35 \cdot 10^{-30}$ C m. This value was used as an alternative value for calculating q in Table 4. It is considerably less than the experimental value reported for heptane solutions (Table 3). The difference could either be ascribed to the fact that the two molecular subunits cannot be considered isolated, or that even in heptane there is some amount of A-state emission.

The large value for μ_e in Table 3 found for fluorobenzene indicates that there is almost a full charge transfer in fluorobenzene although the S_n-S_1 spectrum is not yet the one of the ion-pair like state, as revealed in the polar solvents tetrahydrofuran, 1-butanol and acetonitrile. This means that such an ion pair like state is not yet reached in fluorobenzene, i.e. the electronic structure of the excited state is still slightly less polar.

The two state interpretation of the S_n-S_1 spectra is also in agreement with the ground state absorption spectrum, which shows a long wavelength shoulder fronting the 9-CA like first absorption band. From EOAM in this shoulder, the highyl polar ICT character of the respective FC-state was derived as described already. Figure 6 shows the ground state absorption spectrum in cyclohexane between 20 and $40 \cdot 10^5$ m^{-1}. The absorption bands around 32 and $38 \cdot 10^5$ m^{-1} might be due to transitions to the same excited states as those reached by the S_n-S_1 absorption processes in cyclohexane at 570 nm ($17.5 \cdot 10^5$ m^{-1}) and 870 nm ($11.5 \cdot 10^5$ m^{-1}), which can be seen if a small stabilization of about 1 to $1.5 \cdot 10^5$ m^{-1} of the equilibrium excited state with respect to the first FC-excited state at $22.5 \cdot 10^5$ m^{-1} is taken into account.

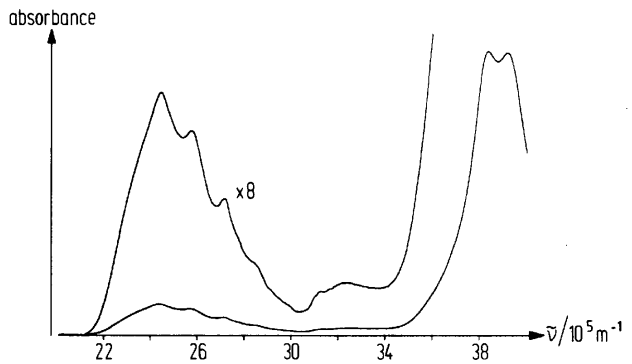

Fig. 6. Ground state absorption spectrum of 10-CN-ADMA in cyclohexane at 298 K. Concentration was 1.2 10^{-5} mol dm^{-3}.

Concluding Remarks. The absorption and fluorescence behavior of 10-CN-ADMA can be well-understood assuming two nearby electronic states, a very polar state A and a less polar state B. From the electric field dependence of these spectra, equilibrium excited state dipole moments μ_e as well as Franck-Condon excited state dipole moments μ_e^{FC} could be determined. The values from these measurements fit well to the results from solvent shift measurements of the fluorescence[17] and to those from the solvent dependent S_n-S_1 spectra. The very solvent dependent S_n-S_1 spectra as well as the levelling off of the μ_e^{-1} values discussed above (Discussion Assuming Two Emitting Species or States) make the two state model strongly favoured.

The observed dipole moment μ_e°(A) of about $80 \cdot 10^{-30}$ C m is in agreement with the picture of about one-electron charge transfer between the 9-cyanoanthracene and the dimethylaniline moieties.

The agreement between μ_e° and μ_e^{oFC} although within large errors, shows that there does not occur any dramatic change of the dipole moment after excitation, as had been one of the working hypotheses at the beginning of the application of the TICT model[29,30] to various compounds. Hence, no decision can be made whether there is a conformational change of 10-CN—ADMA after excitation to a TICT state, or whether there is simply an intramolecular charge transfer state.

(Received June 15, 1987)

Polarized reflectance spectra were measured on the single crystals of α-(BEDT-TTF)$_3$(ReO$_4$)$_2$ and α-(BEDT-TTF)$_2$I$_3$. The optical spectra of these materials were interpreted on the basis of a simple semimetallic band model, and the anisotropic character of the intermolecular interaction in these crystals was quantitatively examined by analyzing the observed spectra. The observed temperature dependence of reflectance spectrum reflects the change of the electronic structure accompanying the metal-insulator phase transition, and is consistent with our interpretation of the spectra.

In the charge-transfer salts of BEDT-TTF(bis(ethylenedithio)tetrathiafulvalene), the Peierls instability is expected to be suppressed by the introduction of a relatively strong interchain interaction through sulfur atoms.[1,2] In fact studies on the crystal structures of BEDT-TTF salts revealed a presence of the two-dimensional network of short S-S contacts.[3] The optical experiment on (BEDT-TTF)$_4$(ClO$_4$)$_2$(TCE)$_{1.0}$ proved that a strong charge-transfer interaction between donor molecules takes place through these S-S contacts.[4] Some of the trihalide salts of BEDT-TTF remain metallic down to low temperature and exhibit a superconducting transition at ambient pressure.[5-8] However. a large majority of BEDT-TTF salts undergo a metal-insulator transition at low temperature. The nature of this metal-insulator transition has not been well characterized so far. α-(BEDT-TTF)$_3$(ReO$_4$)$_2$[9,10] and α-(BEDT-TTF)$_2$I$_3$[11-13] belong to this kind of BEDT-TTF salt, showing the metal-insulator transition at 88 and 135 K, respectively. The phase transitions of these materials have been studied by means of the electrical[9,11] and magnetic[10,12,13] experiments. These experiments are sensitive to a small change near a Fermi surface, whereas the optical experiment probes the overall band structure. Furthermore, the optical experiment is a powerful tool to inspect the effect of an electron-electron correlation. We have conducted a systematic study on the metallic BEDT-TTF salts and analyzed the optical spectra on the basis of a simple one-electron band model.[14-18] In this paper we present the experimental results of the temperature dependence of the reflectance spectra of α-(BEDT-TTF)$_3$(ReO$_4$)$_2$ and α-(BEDT-TTF)$_2$I$_3$, and discuss the change of the electronic structure accompanying the metal-insulator phase transition.

Experimental

Single crystals of α-(BEDT-TTF)$_3$(ReO$_4$)$_2$ and α-(BEDT-TTF)$_2$I$_3$ were prepared by using an electrochemical method from the tetrahydrofuran and benzonitrile solutions, respectively. The dimensions of the crystal used in this experiment were 1×2 mm^2 for α-(BEDT-TTF)$_2$I$_3$ and 1.5×1.5 mm^2 for α-(BEDT-TTF)$_2$I$_3$. Polarized reflectance spectra were measured from 720 cm^{-1} to 25000 cm^{-1} by using the two types of microspectrophotometers, the one for the visible and near-infrared regions and the other for the infrared region, both of which were designed in our laboratory (Department of Chemistry, the University of Tokyo) to measure the reflectivity of a tiny crystal.[13,19] A polarized reflectance spectrum was measured for the two polarization directions parallel to the optical axes projected onto the crystal face. These axes were searched by using the light of 3330 cm^{-1}, because the dispersion of reflectivity around this wavenumber was strongest in the spectral region concerned with the present experiment. The optical axes are mutually perpendicular and give the maximum and minimum reflectivities. The crystallographic axes which correspond to these directions were identified by means of X-ray diffraction. As cryostats to cool the sample crystal, Oxford CF104A was used for the infrared spectrometer and CTi SPECTRIM^{tm} for the visible spectrometer. The sample crystal was fixed with vacuum grease on a Si single crystal plate, the surface of which was painted by carbon paint to remove a stray light, and was transferred from one cryostat to another. The Si plate was glued with silver paint onto the goniometer head which was fixed to the cold stage of the cryostat. A thermocouple, Au(Fe)/Chromel, was attached near the sample on the goniometer head. The electrical resistivity of α-(BEDT-TTF)$_3$(ReO$_4$)$_2$ were measured along the c-axis by using a low-frequency four-probe method. The electrical contacts to the 10 μm gold wires were made by carbon paint.

Results and Discussion

α-(BEDT-TTF)$_3$(ReO$_4$)$_2$. The crystal of α-(BEDT-TTF)$_3$(ReO$_4$)$_2$ belongs to the monoclinic system, six BEDT-TTF molecules being contained in the unit cell.[20] Figure 1 shows the polarized reflectance spectrum measured on the (010) crystal face, the arrangement of BEDT-TTF molecules in one of the two crystallographically equivalent molecular sheets being also shown there. The maximum dispersion was found for the light polarization parallel to the [102] axis. This axis coincides with the direction of the maximum overlap integral between the neighboring

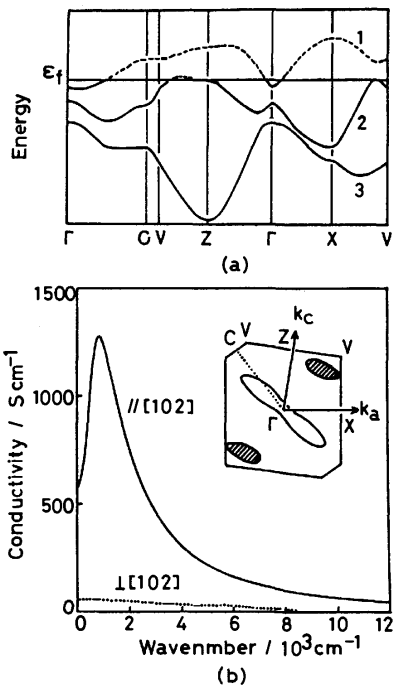

Fig. 3. (a) Band structure of α-(BEDT-TTF)$_3$(ReO$_4$)$_2$. (b) Conductivity spectrum of α-(BEDT-TTF)$_3$(ReO$_4$)$_2$ calculated by assuming the point charge approximation. The inset shows the names of special points and the Fermi surface in the Brillouin zone.

BEDT-TTF molecules. Therefore, this material is essentially composed of the molecular chains along the [102] axis, although the molecules are stacking along the [$\bar{1}$01] axis. However, a weak dispersion was also observed in the low-wavenumber region of the ⊥[102] spectrum. This dispersion clearly indicates the existence of a significant magnitude of interchain interaction. Figure 2 shows the optical conductivity spectrum obtained through the Kramers-Kronig transformation of the reflectance spectrum illustrated in Fig. 1. The integrated intensity of the electronic transition in the infrared region is related to the magnitude of the intermolecular interaction along the polarization direction. In order to obtain a quantitative measure for the anisotropy of the intermolecular interaction, we calculated the average transfer integrals in the hypothetical reduced unit cell drawn in the inset of Fig. 2. The method of calculation is the same as the one used by Jacobsen in the analysis of β-(BEDT-TTF)$_2$I$_3$.[21] We calculated the plasma frequency by the following equation,

$$\omega_p^2 = 8\int_0^{10\times10^3\,\mathrm{cm}^{-1}} \sigma(\omega)\,\mathrm{d}\omega$$

and obtained $\omega_{p//}$=9.5×10^3 cm^{-1} and $\omega_{p\perp}$=4.8×10^3 cm^{-1}. Then, the transfer integrals were calculated to be $t_{//}$=0.10 eV and $t_\perp$=0.07 eV by using $d_{//}$=6.0 Å (//[102]) and $d_\perp$=4.4 Å (⊥[102]). The ratio, $t_{//}/t_\perp$=1.4, is much smaller than the corresponding value, 10, found for (TMTSF)$_2$PF$_6$.[22] This fact indicates the strong two dimensionality of α-(BEDT-TTF)$_3$(ReO$_4$)$_2$.

The conductivity spectrum of the //[102] polarization exhibits a broad peak around 2000 cm^{-1} and a sharp peak at 1250 cm^{-1}. The feature that the conductivity falls down at low wavenumber showing a peak around 2000 cm^{-1} is not dependent on the method of extrapolation of the reflectivity which has to be assumed in the Kramers-Kronig transformation. This spectral shape inevitably comes from the low reflectivity in the low-wavenumber region. The presence of the peak is also supported by the comparison with the DC electrical conductivity which corresponds to the

optical conductivity at zero wavenumber. The DC conductivity measured at room temperature along the c-axis is about 20 $S\,cm^{-1}$, which is much smaller than the maximum conductivity, 600 $\Omega^{-1}\,cm^{-1}$ at 2000 cm^{-1}. The observed shape of the conductivity spectrum is significantly different from that predicted from a Drude model. For organic conductors, the deviation from the Drude-like line shape in conductivity spectrum has been often interpreted as the one associated with a strong Coulomb interaction between conduction electrons. This kind of interpretation was given for the spectrum of $(TMTTF)_2X$ salts.[23,24] If this is the case, the optical transition across a Hubbard gap or equivalently the charge-transfer transition between the BEDT-TTF cations should be observed around 5×10^3 cm^{-1}[25] in the //[102] spectrum, since two of the three BEDT-TTF molecules are formally cations, and in this situation the probability for the neighboring BEDT-TTF molecules to be the cation state is quite large. In fact, the corresponding charge-transfer band was observed in the case of the radical salts of TTF halides[26] which have a similar situation. However, we could not find any dispersion corresponding to the charge-transfer between neighboring cations in the near infrared region of the //[102] spectrum. Therefore, we adopted another standpoint, that is to consider the effect of the interband transition on the basis of one-electron model. For example, the optical spectrum of graphite is considerably deviated from a Drude model due to the presence of the interband transition

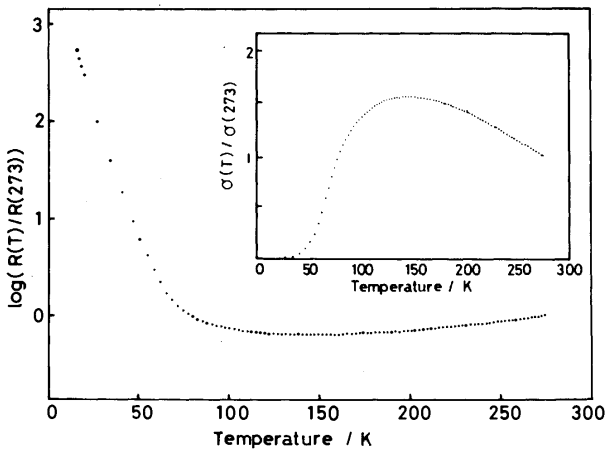

Fig. 4. Temperature dependence of the electrical resistivity and conductivity (inset) of α-(BEDT-TTF)$_3$(ReO$_4$)$_2$.

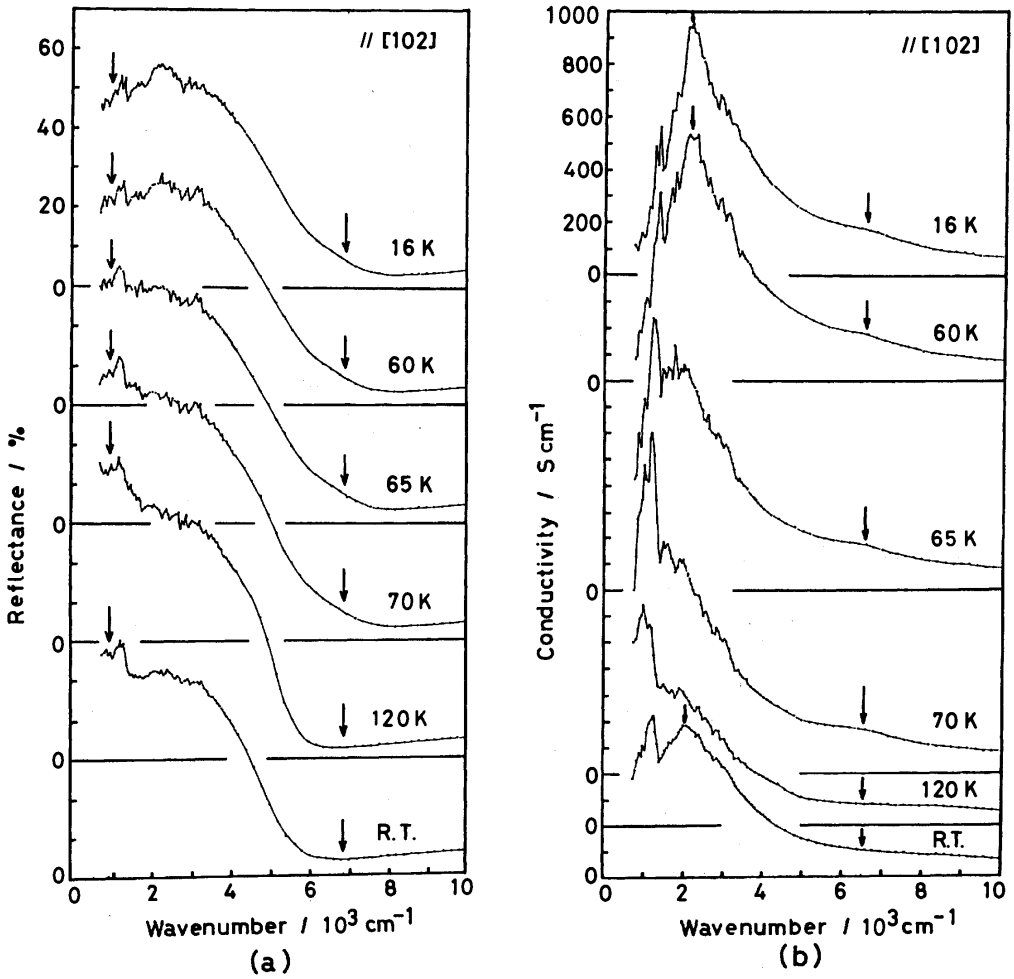

Fig. 5. Temperature dependence of (a) reflectance spectrum and (b) conductivity spectrum of α-(BEDT-TTF)$_3$(ReO$_4$)$_2$.

near the plasma edge.[27] To examine the effect of the interband transition we calculated the two-dimensional band structure in the (010) plane using the tight binding approximation within the framework of the extended Huckel method. The π-band produced from the HOMO's of BEDT-TTF splits into three, among which the lower two bands were nearly filled as shown in Fig. 3a, since the two-dimensional unit cell contains three BEDT-TTF molecules and two of them is oxidized. Therefore, this material is predicted to have a semimetallic small Fermi surface. Figure 3b shows the conductivity spectrum calculated by the point charge approximation on the basis of this band structure.[16] This spectrum contains the contribution of the intraband transition associated with the conduction electrons at the small Fermi surface, and the contribution of the interband transition from the bands 2 and 3 to the band 1. The agreement with the observed spectrum shown in Fig. 2 is qualitatively good.

Parkin et al. found a metal-insulator transition in the experiment on the electrical resistivity of α-$(BEDT\text{-}TTF)_3(ReO_4)_2$: The resistivity showed a shallow minimum at about 150 K and steeply increased at about 115 K.[9] On the other hand, Carneiro et al. reported a gentle phase transition at about 88 K in the ESR expriment.[10] Our result of the electrical resistivity measured along the c-axis was illustrated in Fig. 4. The shallow minimum appeared at almost the same temperature as that of Parkin et al., but this sample showed a steeper slope at about 85 K. No hysteresis was observed in the cooling and heating cycle. This metal-insulator transition is very gentle and is similar to the temperature dependence of the magnetic susceptibility. Figure 5a shows the temperature dependence of the //[102] reflectance spectrum. On lowering temperature, salient changes were observed typically around 900 and 6800 cm^{-1} as shown by arrows in Fig. 5a. Let us first discuss the change observed in the low-wavenumber region. The temperature dependence of the reflectivity at 900 cm^{-1} were plotted in Fig. 6a. A gentle but remarkable change of reflectivity takes place around the phase-transition temperature. The increase of the reflectivity from room temperature to 120 K is probably related to the increase of the relaxation time of the conduction electrons, and the decrease below 70 K corresponds to the disappearance of the conduction electrons probably due to the some structural change. The temperature dependence of the optical conductivity spectra were shown in Fig. 5b. The peak of the interband transition shifts to the low-wavenumber side on lowering the temperature from room temperature to 120 K, then shifts to the high wavenumber side from 70 K to 60 K, and remains at the same position below 60 K down to 16 K. The reason for the gradual shift of the interband transition below 70 K is not clear at present. Since the peak position of the interband transition at 16 K is almost the same as that of room temperature spectrum, we consider that the metal-insulator transition brings about a minor change to the overall structure of the energy band, although it gradually introduces a small band gap at low temperature. In contrast to the temperature dependence of reflectivity around 900 cm^{-1}, the reflectivity change at 6800 cm^{-1} abruptly increases on going

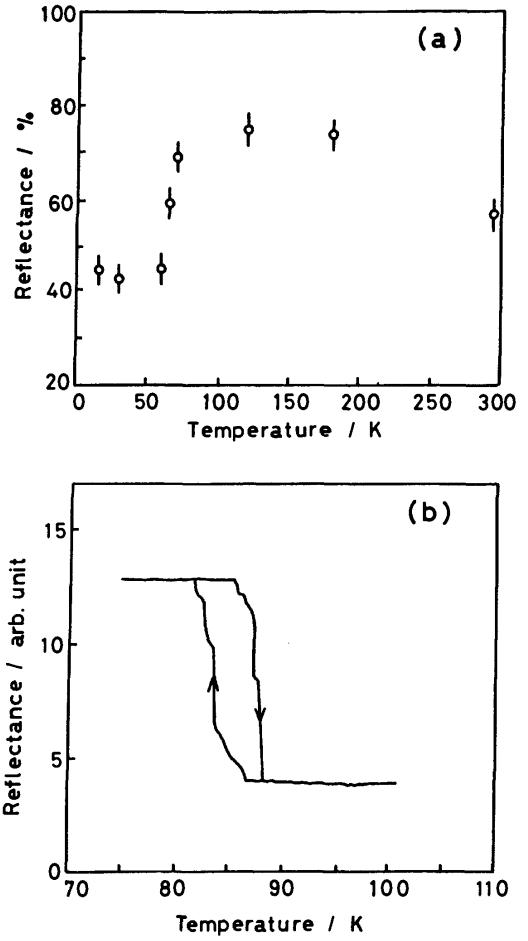

Fig. 6. Temperature dependence of the reflectivity of α-$(BEDT\text{-}TTF)_3(ReO_4)_2$ at (a) 900 cm^{-1} and (b) 6800 cm^{-1}.

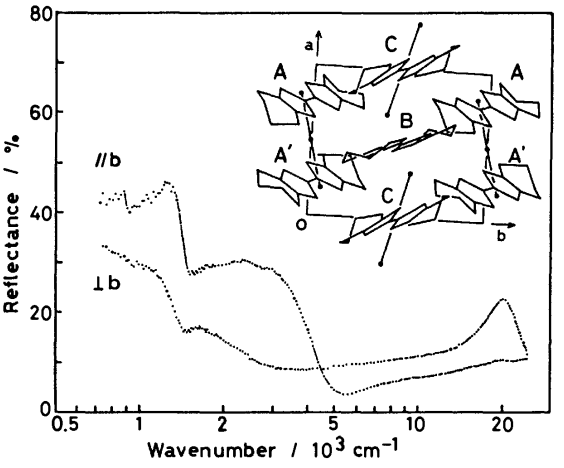

Fig. 7. Reflectance spectrum of α-$(BEDT\text{-}TTF)_2I_3$. The inset shows the crystal structure projected onto the (001) plane.

from the metallic phase to the semiconductive phase, as shown in Fig. 5a. The details of the temperature dependence were examined at 6000 cm^{-1} by changing the sample temperature at the rate of 2° min^{-1}. The results are shown in Fig. 6b, which clearly indicates the abrupt reflectivity change around the phase transition temperature reported by Carneiro et al. The increase of the reflectivity is reflected on appearance of a hump at about 6500 cm^{-1} in the conductivity spectrum as shown in Fig. 5b. This new hump may be associated with the transition from the band 3 to the band 1 which is introduced by a small structural change on the phase transition. Another possible assignment is that this weak hump corresponds to the charge-transfer band between BEDT-TTF^{+} which appears as the result of the reduction of the screening effect in the semiconductive phase.

α-(BEDT-TTF)$_2I_3$. The crystal of α-(BEDT-TTF)$_2I_3$ belongs to triclinic system and the unit cell contains four BEDT-TTF molecules as shown in Fig. 7.[10] The structure is composed of two crystallographically independent stacks along the a-axis. However, the maximum reflectivity at 3330 cm^{-1} was found in the polarization direction parallel to the b-axis. Figure 7 shows the polarized reflectance spectra measured on the (001) crystal face. The reflectivity and the anisotropy of the reflectance spectrum are much smaller

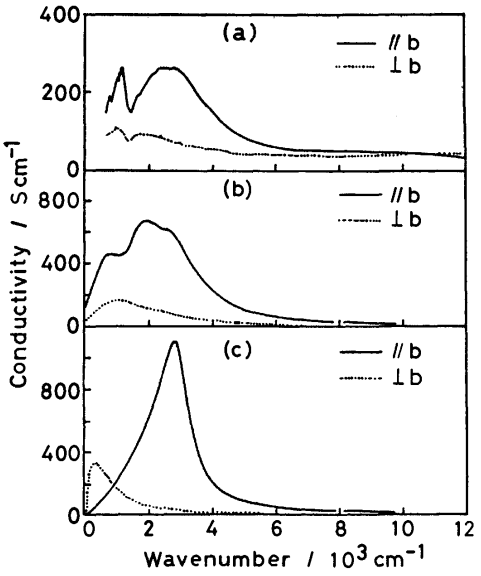

Fig. 8. Conductivity spectrum of α-(BEDT-TTF)$_2I_3$. (a) The observed spectrum (b) calculated spectrum based on the two-dimensional model (c) calculated spectrum based on the one-dimensional model.

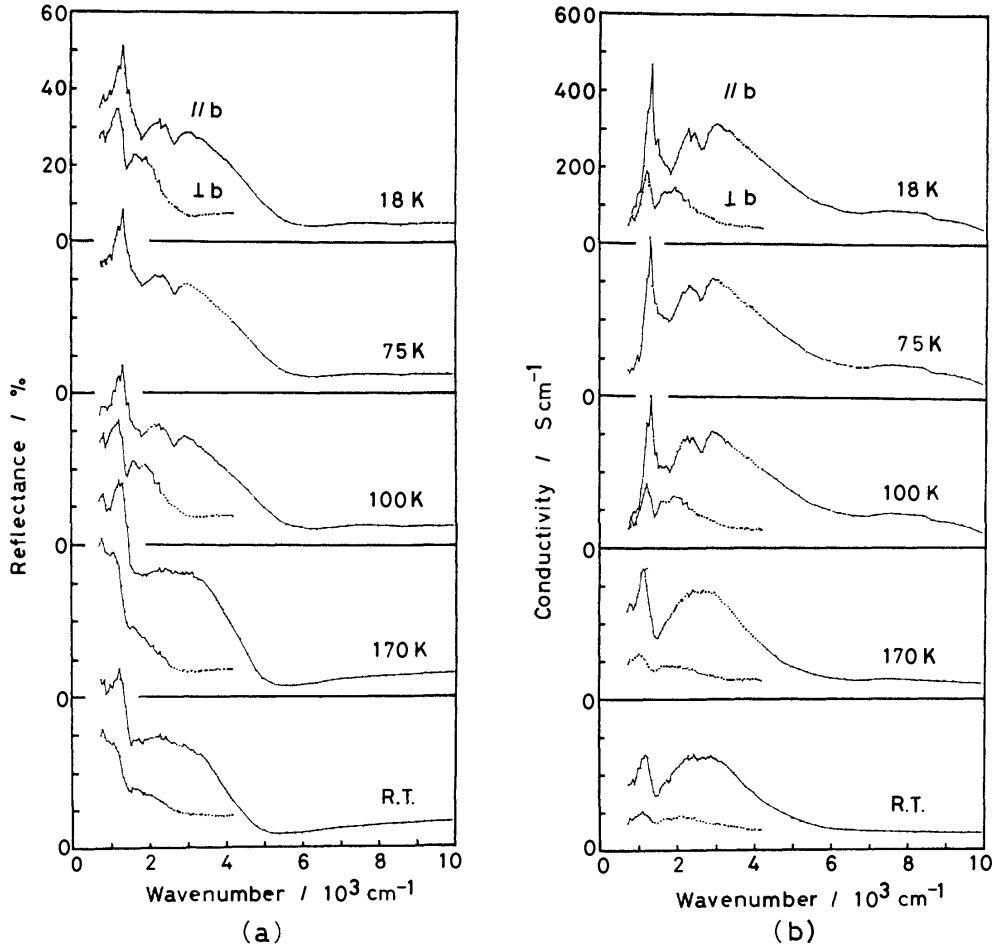

Fig. 9. Temperature dependence of (a) reflectance spectrum and (b) conductivity spectrum of α-(BEDT-TTF)$_2I_3$.

than those of α-(BEDT-TTF)$_3$(ReO$_4$)$_2$. The conductivity spectrum was shown in Fig. 8a. The average transfer integrals obtained by the same method mentioned in the previous section were $t_{//}$=0.07 eV and $t_{\perp}$=0.06 eV, the ratio being 1.2, where we used the anisotropic plasma frequencies $\omega_{p//}$=6.5×10^3 cm^{-1} and $\omega_{p\perp}$=4.6×10^3 cm^{-1} and the reduced unit cell parameters, $d_{//}$=5.4 Å (//b) and $d_{\perp}$=4.6 Å ($\perp$b). The small anisotropy of transfer integrals is in accord with the almost isotropic electrical resistivity.[10] We calculated the conductivity spectra of the intraband and interband transitions based on the semi-metallic band structure reported by Mori et al.[28] The calculated result shown in Fig. 8b coincides qualitatively with the observed spectra: The transition probability for the //b polarization is larger than that for the $\perp$b polarization, and the //b transition appears at the higher wavenumber region than the $\perp$b transition. According to the overlap integral calculated by Mori et al., the largest two integrals which are those between C and A′ and between A′and B are markedly larger as compared with the remaining integrals. If we neglect the latters, the electronic structure becomes one-dimensional along the zigzag chain through C-A′-B-A-C. The conductivity spectra calculated by this model are shown in Fig. 8c. We wish to emphasize that the interchain interaction is quite important to reproduce the line shape of the observed spectrumm.

α-(BEDT-TTF)$_2$I$_3$ is metallic at room temperature and exhibits a metal-insulator transition at 135 K, according to the experiment of the electrical resistivity.[10] It was also reported that the intensity and the line width of ESR signal suddenly decreased at about 135 K.[11,12] The study by X-ray diffraction elucidated the structural change that the inversion symmetry, which exists in the high-temperature phase, is lost in the low-temperature phase.[29] The change of the infrared spectrum also indicated the symmetry breaking at low temperature.[30] All these experiment suggest that the phase change is of the first order. Figures 9a and 9b show the temperature dependence of the reflectance spectrum and the conductivity spectrum. The spectra at different temperatures in the metallic phase are essentially the same with each other, and those in the semiconductive phase are also the same with each other. To examine the temperature dependence in detail, we conducted the same experiment as that we have done on α-(BEDT-TTF)$_3$(ReO$_4$)$_2$, at the wavenumber of 5600 cm^{-1}. The reflectivity change took place abruptly and no hysteresis was observed as shown in Fig. 10. These optical results are consistent with the results of other experiments. The remarkable features found for the spectrum of the semiconductive phase are (1) the decrease of the reflectivity and therefore the decrease of the conductivity in the low-wavenumber region, (2) the splitting (2350 and 2950 cm^{-1}) of the broad interband transition at 2600 cm^{-1}, and (3) the increase of the reflectivity around the tail of

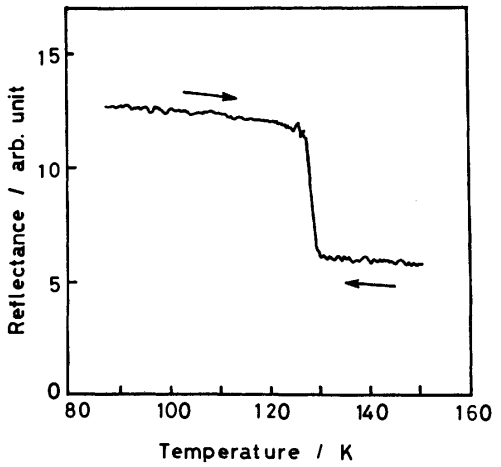

Fig. 10. Temperature dependence of the reflectivity of α-(BEDT-TTF)$_2$I$_3$ at 5600 cm^{-1}.

the interband transition at about 5000 cm^{-1}. The first one corresponds to the disappearance of the conduction electrons. The second and the third are probably related to a small change of the band structure arising from the slight structural change. Incidentally, it is worth to be noted that the spectral change observed at 5000 cm^{-1} on α-(BEDT-TTF)$_2$I$_3$ is very much similar to that observed for the semiconductive phase of α-(BEDT-TTF)$_3$(ReO$_4$)$_2$.

Summary and Conclusion

The anisotropic character of intermolecular interaction was examined by determining the average transfer integrals from the observed reflectance data. We conclude that the two-dimensional interaction of α-(BEDT-TTF)$_3$(ReO$_4$)$_2$ is weaker than that of α-(BEDT-TTF)$_2$I$_3$ but significantly stronger than that of Bechgaard salts. The observed electronic transition of the BEDT-TTF salts in the infrared region was interpreted to be an overlap between the strong interband transition and the weak intraband transition. We found two common features on the temperature dependence of the reflectance spectra of the two salts. The one is the decrease of the reflectance at low wavenumber on lowering temperature in the semiconductive phase due to the decrease of the density of conduction electrons, the other is the appearance of a new hump at high-wavenumber region. A curious phenomenon was found in the temperature dependence of the hump of α-(BEDT-TTF)$_3$(ReO$_4$)$_2$: This hump appeared abruptly near the phase transition temperature although the phase transition takes place rather gradually. Finally it should be noted that the optical conductivity spectra did not change drastically between the metallic and semiconductive phases. This fact further support that the electronic transition of the infrared region is attributable mainly to the interband transition.

A High-Resolution Solid-State ^{13}C NMR Study of the Secondary Structure of Linear (1→3)-β-D-Glucans: A Conformational Elucidation of Noncrystalline and Crystalline Forms by Means of Conformation-Dependent ^{13}C Chemical Shifts

Hazime SAITÔ,* Ryoko TABETA, Motoko YOKOI, and Tomoki ERATA†
Biophysics Division, National Cancer Center Research Institute, Tsukiji 5-chome, Chuo-ku, Tokyo 104
†Bruker Japan Co., Ltd., 21-5, Ninomiya, Yatabe, Tsukuba, Ibaraki 305
(Received June 19, 1987)

The high-resolution solid-state ^{13}C NMR spectra of annealed curdlan, a (1→3)-β-D-glucan, were recorded in order to obtain reference data on the ^{13}C chemical shifts of the triple helix form, which would be useful for the conformational elucidation of two distinct noncrystalline forms, curdlan- and laminaran-types. It was found that the C-3 peak of crystalline annealed glucan is substantially displaced from that of noncrystalline starting powder, reflecting the conformational change. The laminaran-type conformation, which is found in either laminaran or a number of fungal branched glucans, was identical with the triple helix, judging from the similarity in the ^{13}C NMR spectra, although the linewidths of the former are much larger than those of the latter. The curdlan-type form, on the other hand, was ascribed to the single helix form on the basis of the previous data on high-resolution ^{13}C NMR. In addition, the ^{13}C NMR spectra of crystalline paramylon showed a number of additional signals other than the peaks of triple-helical annealed curdlan, in spite of the similarity in the X-ray diffraction patterns.

It has been previously shown that the solution properties, including the gelation behavior, of a number of (1→3)-β-D-glucans vary greatly with various parameters, such as the degree of branching, the molecular weight, and the manner of annealing.[1,2] Undoubtedly, such properties might be closely related to the secondary or tertiary structures of these polysaccharides in the solid, fully or partially hydrated, and unhydrated portions of gels, and a (fully hydrated) aqueous solution.

A fully hydrated aqueous solution of a linear (1→3)-β-D-glucan (Fig. 1) is achieved either at a higher alkaline solution (>0.2 M NaOH (1 M=1 mol dm^{-3})) or at neutral pH for lower molecular-weight glucan[3,4] and the relevant molecular conformation of this state is effectively random-coiled, as may be seen from the displacements of the ^{13}C chemical shifts as well as the relaxation parameters. The molecular architecture of the gel state formed by a linear (1→3)-β-D-glucan (curdlan) (Fig. 1) is , however, very complicated. It is considered to consist of the following two or three regions: fully or partially hydrated and unhydrated portions. In particular, the former, which is not detected by X-ray diffraction, gives rise to well-resolved isotropic ^{13}C NMR signals.[2-5] The rest of the immobilized unhydrated region, which is not detected by means of high-resolution NMR, can be characterized by the triple[7-10] or single helices[11] and their dehydrated aggregates by means of X-ray diffraction.

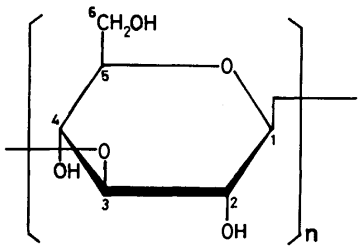

Fig. 1. Primary structure of a linear (1→3)-β-D-glucan. Curdlan (from *Alcaligenes faecalis*), n=540; laminaran (from *Porio cocos*), n=38; paramylon (from *Euglena gracila*).

The conformational feature of curdlan powder used as the starting material of gel formation or of the lyophilized sample from the gel cannot, however, be analyzed by the use of the X-ray diffraction method because of its extremely poor crystallinity: alternative means must be utilized. In fact, only 30% of the former is crystalline.[12] Nevertheless, our previous finding, based on the ^{13}C NMR data, showed that spray-dried or lyophilized (1→3)-β-D-glucans from various sources in the solid state do not necessarily take a disordered conformation,[13,14] but two kinds of distinct, regular secondary structures, curdlan-type and laminaran-type forms, as revealed by the conformation-dependent ^{13}C chemical shifts.[15,16] This finding is based on the fact that the ^{13}C chemical shifts of the C-1 and C-X carbons at the glycosidic linkage of various types of glucans are closely related to the torsion angles of C-1-O$_{gly}$ (ϕ) and C-X-O$_{gly}$ (ψ), respectively.[17-19] Hence, the conformation of the noncrystalline region can be as well characterized by this NMR technique as that of the crystalline portion.

In the present paper, we recorded the ^{13}C NMR spectra of several types of curdlan samples annealed at various temperatures, together with two additional linear (1→3)-β-D-glucans, laminaran and paramylon (Fig. 1), in order to clarify these conformations further. As a result, we were able to ascribe the curdlan- and laminaran-type conformations[14] of a variety of noncrystalline (1→3)-β-D-glucans to the single- and triple-helical conformations, respectively. It was further

shown, on the basis of the ^{13}C spin-lattice relaxation data, that the molecular organization of the noncrystalline portion was not dynamically disordered as compared with that of the crystalline samples.

Experimental

Materials. Curdlan powder was provided by Takeda Chemical Industries Co., Ltd., Osaka. Laminaran was purchased from Nutritional Biochemistry Corporation, Ohio, USA. Paramylon was a generous gift from Professor B. A. Stone of La Trobe University, Australia. The annealed curdlan samples were prepared by a manner similar to that described previously.[7] That is, an aqueous suspension of curdlan powder was heated at various temperatures (80—180 °C) in a sealed bomb. The resulting gel samples were cooled either slowly or rapidly, together with dehydration by means of air-drying or immersion in a methanol solution. The densities of the resultant samples were measured by means of floatation in a xylene-carbon tetrachloride. The crystallinities were estimated from the X-ray powder patterns at room humidity (40% r. h.) by the use of a Rigaku Geigerflex X-ray diffractometer RAD IIIA, employing Ni-filtered Cu $K\alpha$ radiation generated at 40 kV and 30 mA.

Method. The high-resolution solid state ^{13}C NMR spectra at 75.46 MHz were recorded on a Bruker CXP-300 spectrometer by means of the cross polarization-magic angle spinning (CP-MAS) method. Powdered samples were placed in an alumina rotor used for the double air-bearing-type MAS system and spun as fast as 3—3.5 kHz. The duration of the 90° pulse was 4 μs. The contact, sampling and repetition times were 1 ms, 20—30 ms, and 4 s, respectively. The ^{13}C chemical shifts were referred to TMS through the peak position of the glycine carboxyl group (176.0 ppm). The ^{13}C spin-lattice relaxation times (T_{1C}'s) were measured by the method of cross polarization enhancement, with an inversion of the proton-spin temperature.[20]

Results

Figures 2 and 3 show the ^{13}C CP-MAS NMR spectra of annealed curdlan at various temperatures, together with those of laminaran, curdlan powder, and paramylon. Figures 4A and B illustrate some X-ray powder diffraction patterns of annealed curdlan under different conditions (Table 1) and of laminaran, respectively. The powder X-ray diffraction patterns of Samples 1 and 2 and of paramylon[9] (data not shown) exhibit high crystallinity and coincide with that of the triple-helical conformation, previously analyzed.[7-9] On the other hand, the diffraction patterns of Samples 3, 5, and 6 and also of laminaran were very diffusive because of their lower crystallinity. The extent of crystallinity from the X-ray diffraction is parallel with the magnitude of the density, as is summarized in Table 1.

It is noteworthy that Samples 1 and 2 gave the narrowest NMR signals (about 1 ppm linewidths) among all the samples examined herein except for paramylon. In parallel with this observation, the crystallinity of these two samples is found to be significantly improved by the annealing, as is shown by the X-ray powder diffraction (Fig. 4A) and density data (Table 1). The ^{13}C NMR peaks of C-3 and C-2/C-5 carbons are also displaced from those of the starting curdlan powder (Table 2).

a) The peak assignment may be interchangeable.

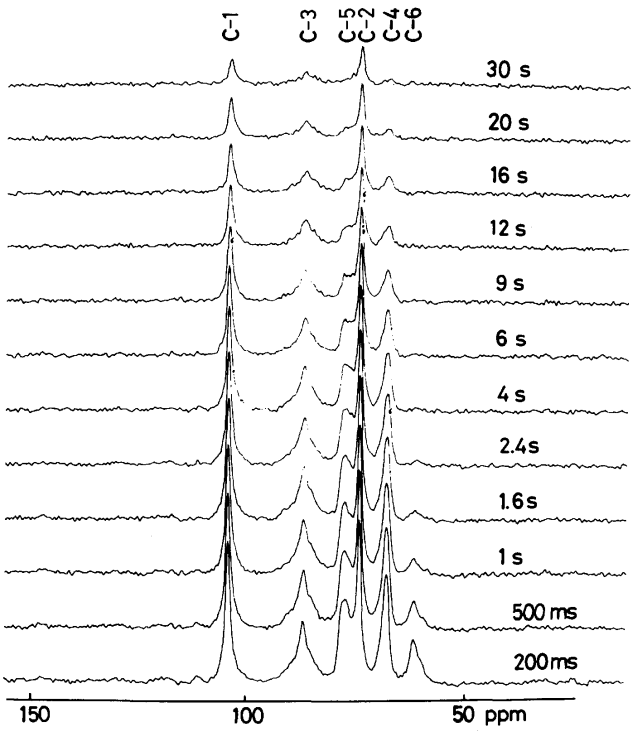

Fig. 5. Stacked plot of ^{13}C NMR peak intensities of annealed curdlan obtained by cross polarization for the T_{1C} measurements. Delay times between two 90° pulses are indicated in the right-hand side. Number of transients is 100.

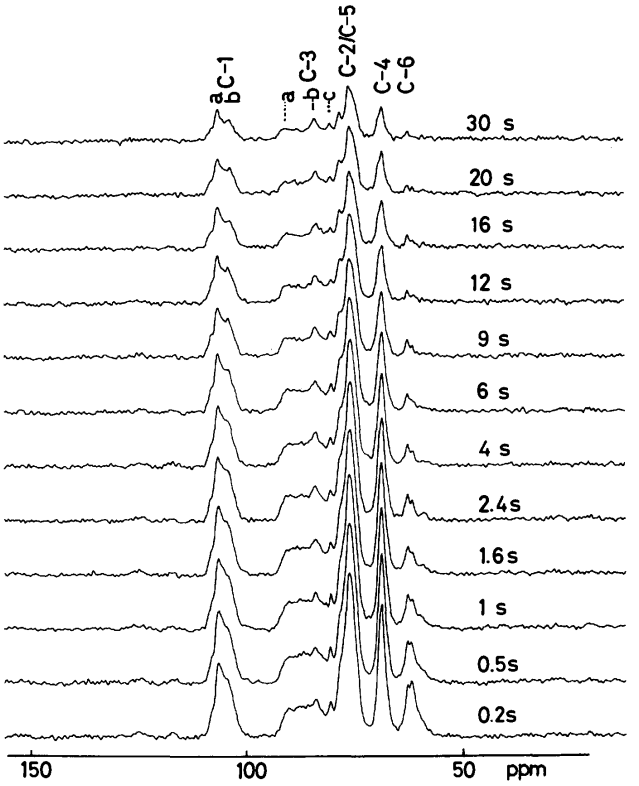

Fig. 6. Stacked plot of ^{13}C NMR peak intensities of paramylon obtained by cross polarization for the T_{1C} measurements. Delay times between two 90° pulses are indicated in the right-hand side. Number of transients is 100.

Surprisingly, the ^{13}C NMR pattern of laminaran is very similar to that of the annealed curdlan (Samples 1 and 2) in spite of its poor crystallinity, as may be seen from the X-ray diffraction data (Fig. 4B). The conformational change in curdlan from the noncrystalline to the crystalline form, however, is not complete when annealed samples at 150 and 120 °C were cooled rapidly (Samples 3 and 5). As a result, the C-3 NMR peak consists of two kinds of contributions: the peak from unconverted noncrystalline powder (C-3a) and that from converted crystalline species (C-3b). Further, it is interesting to note that the high-field shoulder of the C-3 peak in Sample 4 is resonated at 83.8 ppm, much higher than that of most annealed samples (86—87 ppm). In addition, the C-1 peaks appear to be split into doublet, 105.6 and 103.5 ppm. These data show that the ^{13}C NMR spectral pattern of Sample 4 resembles that of paramylon. Crystallinity and density of Sample 4 are found to be very high in spite of the broadened linewidths of its ^{13}C NMR pattern.

Figures 5 and 6 illustrate some typical examples of a stacked plot of the ^{13}C NMR spectra of annealed curdlan and paramylon, respectively, for measurements of the ^{13}C spin-lattice relaxation times (T_{1C}'s) by cross-polarization.[20] In this pulse sequence, the peak intensity at the delay time t after turning off the ^{13}C H_1 field, $M_{net}(t)$, decays exponentially from its initial value, $2M_{cp}(0)$, as is shown by Eq. 1,

Table 3. ^{13}C Spin-Lattice Relaxation Times of Some (1→3)-β-Glucans (s)[a]

	Curdlan		Laminaran	Paramylon
	Powder	Annealed[b]		
C-1	14	16	26	31(a),[c] 30(b)[c]
C-2	10[d]	18	24	22[d]
C-3	11	16	20	26(a),[c] 34(b),[c] 32(c)[c]
C-4	7.8	8.2	13	12
C-5	10[d]	9.3	10	22[d]
C-6	1.0	1.2	1.7	6.3

a) Estimated error ±15%. b) Sample 2 (see Table 1). c) Letters in parentheses denote the peak indicated in Fig. 6. d) Not distinguishable.

$$M_{net}(t) = 2M_{cp}(0)\exp(-t/T_{1C}) \quad (1)$$

Thus, the T_{1C} values were obtained from a plot of log $M_{net}(t)$ vs. t, as is summarized in Table 3. Interestingly, it appears that the T_{1C} values of the annealed curdlan and laminaran can be classified into the following three groups: peaks with short (1.2—1.7 s for C-6), intermediate (8—13 s for C-4 and C-5), and long (16—26 s for C-1, C-2, and C-3) relaxation times. The existence of such a step in the relaxation times could be related to the ease of spin diffusion process with the hydroxymethyl group which undergoes rapid internal reorientation process. There appears to be no signifi-

cant differences in the T_{1C} values of curdlan between the noncrystalline and crystalline forms. The T_{1C} values of laminaran and paramylon are, however, significantly longer than those of curdlan. In particular, the C-6 T_{1C} of paramylon is 5—6 times as long as those of the curdlan samples (Table 3). Further, we found that the T_{1C} values differ among the three peaks, C-3a, b and c (see Fig. 6 and Table 3).

Discussion

Triple Helix: Laminaran-Type Form. The sharp ^{13}C NMR pattern of annealed curdlan at 150—180 °C (Figs. 2D and E) is straightforwardly ascribed to the triple-helical conformation,[7-9] in view of its characteristic X-ray powder-diffraction patterns (Fig. 4A). The above-mentioned pronounced peak narrowing (ca. 1 ppm) is obviously caused by the improved crystallinity of samples due to annealing in the presence of water, as is consistent with our previous observation of annealed chitosan.[21] The achievement of peak-narrowing as well as conformational change is not sufficient when annealed samples at 120—180 °C are cooled rapidly (Samples 3 and 5, see Fig. 3). In fact, the magnitude of the conformational change to the triple helix is, at most, 50% at the time of annealing (150—180 °C); additonal conversion was achieved by a slow crystallization process, together with concomitant dehydration during the course of the slow cooling.

Subsequently, we found that the laminaran-type conformation[14] found in laminaran and fungal branched glucans is identified with the same triple-helical conformation in view of the similarity in ^{13}C NMR patterns between laminaran and annealed curdlan (Samples 1 and 2) (Fig. 2C—E). This finding is in contrast to the observation by means of X-ray diffraction: laminaran exhibits a poor crystallinity, judging from the X-ray diffraction (Fig. 4B), whereas annealed curdlan (Samples 1 and 2) exhibits a high crystallinity and its diffraction pattern is obviously different from that of laminaran (Fig. 3A). Nevertheless, the present ^{13}C NMR data show that the overall conformation of noncrystalline laminaran is the same as that of the triple-helix form of annealed curdlan, but the presence of conformations whose torsion angles are slightly deviated from those of the most stable triple-helical conformation results in line-broadening. In addition, it is pointed out that a number of fungal branched (1→3)-β-D-glucans take a triple-helical conformation similar to that of laminaran, judging from the similarity of the ^{13}C NMR spectra, as discussed in the previous[14] and subsequent papers.[22]

Single Helix: Curdlan-Type Form. No information is available from X-ray diffraction as to the conformation of the curdlan-type form arising from the noncrystalline portion of the powder sample. In fact, curdlan powder accounts for only about 30% crystalline portion as estimated from density-measurements.[12] Nevertheless, the conformation of the remaining major portion (about 70%) is not always completely disordered, because the C-3 ^{13}C NMR peaks of this form from various samples are always resonated at the same position (89.6±0.5 ppm), which is clearly distinguishable from that of the above-mentioned triple-helix conformation (86.4±0.5 ppm). It should be emphasized that this form corresponds to the *native* conformation of curdlan, directly isolated from solid cultures of *Alcaligenes faecalis*.[13] In a similar manner, we previously showed, on the basis of the ^{13}C chemical shifts, that the molecular conformation of the disordered or random-coiled form, as judged by the X-ray diffraction, of silk fibroin is very similar to that of the crystalline silk I form.[23,24] This discrepancy may arise from the fact that conformational analysis by means of X-ray diffraction requires regular arrangement of the molecules under consideration with the neighboring molecules or interstrands, whereas the present ^{13}C NMR approach is able to afford the conformational characterization of individual molecules, irrespective of the manner of the arrangement of the neighboring molecules.

As has been demonstrated previously, intense high-resolution ^{13}C NMR signals of curdlan gel are visible (70—80%)[5] at the temperature of swelling (54 °C; low-set gel), but the peak-intensities are substantially decreased by annealing at temperatures higher than 54 °C, together with the development of the turbidity. Obviously, the portion which gives rise to the high-resolution NMR signals corresponds with the fully hydrated region, so as to give freedom of isotropic molecular motion with the correlation times of an order of 10^{-9} s.[2-4] This portion turned out to be an ordered conformation by the characteristic displacement of the C-3 ^{13}C chemical shifts[3,4] as well as by optical rotatary dispersion, intrinsic viscosity, flow birefringence, and shift of absorption maximum with Congo Red.[25-27] We previously ascribed this ordered conformation to a single helix, in view of the ease of swelling in aqueous media, resulting in the formation of a fully hydrated region able to give high-resolution ^{13}C NMR signals.[2-4,28] The relative proportion of such a fully hydrated portion (65—80%),[2] as observed by high-resolution ^{13}C NMR, at the temperature of swelling, is very close to the estimated proportion of the noncrystalline region (about 70% by density measurement[12]). Thus, it is natural to consider that the conformation of the noncrystalline portion of curdlan powder arises from this single helix. This view is based on premise that the conformation achieved in aqueous media could be preserved in lyophilized samples, because no further heat treatment required for conformational transition is given. In supporting this view, we previously found that the conformations of silk I and (L-Ala-Gly)$_n$ II achieved in an aqueous solution are also retained in lyophilized solids, judging

from the ^{13}C NMR data.[23] In addition, we showed previously that lyophilized (1→3)-β-D-glucans gave the same peak positions, depending on their molecular weight or on the solvents used.[36] In this connection, it should be taken into account that the single helix form, which is an energetically favored conformation in the fully hydrated state, is not always favored in the solid. For this reason, the conformation achieved in a lyophilized or spray-dried sample should not be considered to be the most stable conformation, as established by the calculation of the conformational energy.[12]

Interestingly, the ^{13}C NMR spectra of Samples 3, 5, and 6 (Figs. 3A, C, and D, respectively) are very similar to those of the acid-degraded lower-molecular-weight fraction (DP_n 14—131) of curdlan (see Fig. 4 of Ref. 14). Obviously, in these samples the relative proportion of the triple-helix form is increased to about 50%, as compared with that (about 10% from the peak area) of the starting curdlan powder.[12] These samples do not any longer possess gel-forming ability, because there are very few portions left able to swell because of the increased proportion of the triple helix. These results clearly show that gel-forming ability of (1→3)-β-D-glucan is simply related to the relative proportion of the triple helix. As for the gelation behavior of branched (1→3)-β-D-glulcans, however, we will discuss it in more detail in the subsequent paper.[22]

Paramylon. It has been shown that the X-ray powder diffraction pattern of paramylon is very similar to that of the hydrate triple helix of curdlan.[9] Unexpectedly, however, the ^{13}C NMR spectrum of paramylon can not be explained simply by the peak profile of the triple-helical curdlan alone, although the presence of the ^{13}C NMR peaks from the latter can easily be recognized. Instead, the presence of the conformational heterogeneity of this paramylon is well demonstrated by the spreads of several C-3 carbon signals, ranging from 89.5 to 80.4 ppm, their maximum separation being 9.1 ppm, in addition to the observation of the doublet C-1 peaks. This view is also confirmed by the observation of the differential behavior of the ^{13}C spin-lattice relaxation times among the peaks ascribed to the same carbons (C-3 or C-5/C-2 peaks) of paramylon (see Fig. 6 and Table 3). Further, it appears that the C-2/C-5 peaks consist of the superposition of several kinds of peaks, indicating the presence of a conformational heterogeneity. It is obvious that Fig. 2 also contains peaks from the curdlan-type form. Therefore, it is conceivable that highly crystalline paramylon (see the density data in Table 1) contains conformers which are essential for relaxing conformational strain, in addition to the usual triple helix. In this connection, it is interesting that a paramylon-like conformation was produced by annealing at 150 °C, followed by rapid cooling (Sample 4; Table 1 and Fig. 3B), although the crystalline packing of paramylon which is produced at the time of biosynthesis can not be well reproduced by a simple annealing procedure.

^{13}C Spin-Lattice Relaxation Data. The observed relaxation times, ranging from 8 to 34 s, indicate that these polysaccharides lack molecular motion whose correlation time of an order of 10^{-8} s effective in shortening the T_{1C} values. Instead, the spin-lattice relaxation of this magnitude may be mainly affected by the ^{13}C spin diffusion.[37] The presence of the fast rotational motion of the hydroxymethyl group leads to the effective ^{13}C T_{1C} relaxation pathways coupled with spin exchange. Then, it is expected that the ^{13}C T_{1C}'s of the C-4 and C-5 carbons are subsequently reduced as a result of the spin exchange with the C-6 hydroxylmethyl group, because the rate of the spin exchange is proportional to r^{-6} where r is the interatomic distance. On the contrary, longer T_{1C} values observed in paramylon could be interpreted in terms of lack of efficient relaxation pathways due to plausible restricted rotation of the hydroxymethyl group. This is an additional piece of evidence which suggests that the conformation of paramylon is different from that of the triple-helical curdlan.

Therefore, it appears that these ^{13}C T_{1C} values reflect the manner of crystalline packing, effective in the spin diffusion process. In fact, the present ^{13}C T_{1C} values of (1→3)-β-D-glucans are much shorter than those of the crystalline component of cellulose[38,39] but longer than those of the noncrystalline component.[38] No such a distinction can, however, be observed in the present cases. In fact, noncrystalline samples characterized by X-ray diffraction are not necessarily motionally disordered. On the contrary, it has been shown that the T_{1C}'s of the amorphous portion of polyethylene or polyoxymethylene (50—200 ms) are much shorter than those of crystalline portion (20—2000 s).[40-42] The observed reduction of the former can be explained mainly in terms of the presence of segmental motions in the solid.

Concluding Remarks. The molecular conformations of noncrystalline polysaccharides do not necessarily take a disordered form, although this view cannot be clarified by X-ray diffraction study. Nevertheless, we previously showed that two distinct types of conformations of (1→3)-β-D-glucans, the curdlan- and laminaran-type forms, are distinguishable for a number of noncrystalline solid samples by an examination of the characteristic displacements of the C-3 ^{13}C chemical shifts. As an illustrative example, we attempted to reveal the conformations of these two forms with the aid of a high-resolution NMR study of curdlan gel and a high-resolution solid-state ^{13}C NMR study of annealed curdlan. Thus, the curdlan- and laminaran-type forms were ascribed to single and triple helix conformations, respectively. Finally, we pointed out that the conformation of paramylon can not be accounted for simply by the presence of the triple helix of annealed curdlan alone, in view of the

spreads of the ^{13}C chemical shifts and differences in the spin-lattice relaxation times.

The authors wish to thank Dr. Kozo Ogawa, Radiation Center of Osaka Prefecture, for his preparation of the annealed samples, and measurements of the density and the X-ray diffraction, and for his stimulating discussion. The authors are also grateful to Professor B. A. Stone for a generous gift of paramylon.

5) In the gel state, ^{13}C NMR peaks are usually suppressed to some extent because of the restricted molecular motions caused by the presence of cross links. The observed maximum peak intensities of swollen gels were 65—80% as referred to the peak intensities of fully hydrated 0.22M NaOH solution (Ref. 2). Further heating of the gel sample (80 °C) resulted in the subsequent reduction of the peak intensities to about 20% in parallel with the development of turbidity and a shrinkage of the gel sample. A similar extent of peak intensities (20—50%) was noted at an ambient temperature. In this connection, it is worthwhile to recall that the introduction of 0.1 and 1 mol% cross links in a chemically cross-linked synthetic polymer resulted in the reduction of peak intensities to 55 and 35%, respectively (Ref. 6).

28) A decade ago,[3,4] we proposed that the ^{13}C NMR observation in gels is solely limited to the rather flexible *single* helical portion (the correlation time being in the order of 10^{-8} s) where molecular chains are fully exposed to the diluent and the peak areas of the triple-helical portion are lost under high-resolution NMR conditions. In fact, it is very difficult to account for the presence of the peak arising from the triple helix (86.4±0.4 ppm) in the ^{13}C NMR signal of elastic gel (88.7 ppm). Furthermore, we found that all of peak-areas were suppressed[29,30] when high-resolution ^{13}C NMR spectra of branched (1→3)-β-D-glucans taking the triple-helix conformation[31-33] were recorded in aqeuous media. Undoubtedly, such a suppression of peaks arose from an insufficient averaging of the C-H dipolar and/or chemical shift anisotropy interactions due to the presence of a slow tumbling motion of the stiff, rod-like molecules of the triple helix. In this connection, Yanaki et al. showed that the triple helix of schizophyllan, a branched (1→3)-β-D-glucan, is stiffer than that of native collagen, for the persistent chain length of the former (200±30 nm) is larger than that of the collagen triple helix (130 nm).[32,33] The preservation of chemical shift anisotropy as large as 50—140 ppm in native collagen[34,35] makes impossible the observation of the ^{13}C NMR spectra by means of high-resolution spectrometer. It may also be pointed out that the ease of the aggregation of the rod-like triple helix of curdlan, as manifested by syneris or dehydration, which are not seen in the triple helices of branched glucans, leads to an additional suppression of the NMR peaks.

A High-Resolution Solid-State ^{13}C NMR Study of the Secondary Structure of Branched (1→3)-β-D-Glucans from Fungi: Evidence of Two Kinds of Conformers, Curdlan-Type Single-Helix and Laminaran-Type Triple-Helix Forms, as Manifested from the Conformation-Dependent ^{13}C Chemical Shifts

(Received June 19, 1987)

The high-resolution ^{13}C NMR spectra of a variety of fungal branched (1→3)-β-D-glucans were recorded in a DMSO solution and a lyophilized solid in order to gain an insight into the primary and secondary structures in relation to their gel-forming property. We found that all the five lyophilized branched (1→3)-β-D-glucans examined so far, except lentinan, exhibit the laminaran-type triple-helix form, as established by the close resemblance of the ^{13}C NMR spectra among them. On the contrary, lentinan taking the curdlan-type single-helix conformation was readily converted to the triple-helix form by lyophilization after having been dissolved in a 8M urea solution (1M=1 mol dm^{-3}) and dialysis against distilled water. This finding should be compared with the similar conformational change of curdlan: the conversion by this procedure was at most 50%; annealing at 150°C, followed by slow cooling, was essential for a complete conversion. This treatment did not induce the reverse conformational change from the triple helix to the single helix. The differential behavior of gel-formation between the linear and branched (1→3)-β-D-glucans was explained in terms of the molecular conformations in the solid and gel states.

The molecular conformation or polymorphs of crystalline polysaccharides have previously been analyzed by means of X-ray diffraction studies.[1] No information, however, is provided by this diffraction method as to the conformational feature of noncrystalline polymers or such region in crystalline samples. Nevertheless, the conformations of such portions are not necessarily the completely randomly coiled form. Instead, we have previously shown that a variety of biological macromolecules, such as polypeptides, fibrous proteins,[2-6] and polysaccharides,[7-10] obtained by lyophilization take regular conformation, as is shown by the characteristic displacements of ^{13}C chemical shifts. Thus, high-resolution solid-state ^{13}C NMR spectroscopy offers an excellent means for the conformational characterization of noncrystalline as well as crystalline samples. In particular, the ^{13}C chemical shifts vary significantly (up to 8 ppm) with the respective conformation as characterized by the glycosidic torsion angles (ϕ, ψ).[11-13] Thus, this approach has been used for the conformational characterization of a number of polysaccharides, including cellulose[12-19] chitin, chitosan,[9,20,21] amylose,[7,11] starch,[22-25] and (1→3)-β-D-glucans.[8,10,26-32]

The crystallinity of (1→3)-β-D-glucans is, in many instances, low so as to give a halo X-ray diffraction pattern, unless otherwise examined samples are extensively annealed. However, this treatment could severely alter the molecular conformation. Therefore, the development of a method for the in situ conformational characterization of a starting material is essential for better understanding of the conformational feature of these glucans in relation to their physical properties. For this purpose, we previously demonstrated[10] that at least four kinds of secondary structures could be distinguished by means of solid-state ^{13}C NMR spectra. In particular, two major forms, the curdlan- or laminaran-type forms, can readily be distinguished by means of the conformation-dependent ^{13}C chemical shifts when these samples are obtained either by lyophilization or spray-drying.[10] In the preceding paper, these curdlan- and laminaran-type forms were identified as having the single- and triple-helix conformation, respectively.[33]

Previously, we found that the gel-forming ability of linear (1→3)-β-D-glucans is related to the presence of a single helix as the major conformer, and swelling does not occur from samples taking the triple helix as the major conformation. In this connection, it is surprising to note that the two kinds of branched glucans previously studied, HA-β-glucan and lentinan, take the two different above-mentioned conformations, in spite of exhibiting a similar gel-forming property.[10] Therefore, it seems to be very important to clarify the stability and ease of conformational changes in branched (1→3)-β-D-glucans.

In the present paper, we will examine the ^{13}C NMR spectra of four additional branched (1→3)-β-D-glucans in order to clarify their conformations in the solid state. We noted that all five (1→3)-β-D-glucans assume the laminaran-type triple-helix. The curdlan-type single-helical conformation of lentinan was converted to the laminaran-type triple-helix when dialyzed after dissolving in 8M urea solution.

Table 1. Characteristics of Branched (1→3)-β-D-Glucans Used

Trivial name	Physical property	Chemical analysis		Source	Ref.
		m-(m'-)res./ b-res.[a]	1.6-linkage		
T-5-N	Soft gel	2.5(1.4)[b]	0.06	*Dictyophora industiata*	36
T-4-N	Highly viscous soln.	1.5	0	*Dictyophora industiata*	35
Schizophyllan	Extremely viscous	2	0	*Schizophyllum commune*	38
Scleroglucan		2	0	*Sclerotium rolfsii*	39
HA-β-Glucan	Non-elastic gel	3	0	*Pleurotus ostreatus*	34
Lentinan	Non-elastic gel	3.4—1.5	0.2	*Lentinus edodes*	37

a) m- and m'-residues stand for 3-mono-*O*-substituted glucosyl residues, while b-residue stands for the 3,6-di-*O*-substituted glucosyl residue. b) Data in parentheses are from enzymatic analysis (C. Hara, T. Kiho, and S. Ukai, *Carbohydr. Res.*, **117**, 201 (1983)).

Experimental

Table 1 summarizes the trivial names, physical properties, degrees of branching, and sources of isolation for the variety of fungal branched (1→3)-β-D-glucans used in this study. The isolation of HA-β-glucan[34] (from *P. ostreatus* (Fr.) Quél), T-4-N[35] and T-5-N[36] (from *Dictyophora indusiata* FISH.) was described previously. Lentinan[37] (from *Lentinus edodes*) was a generous gift from Dr. G. Chihara of the National Cancer Center Research Institute. Schizophyllan[38] and its partially depolymerized sample by sonication (from *Schizophyllum commune*) were donated by Kaken Pharmaceutical Co. Ltd., Tokyo, Japan. Scleroglucan[39] (from *Sclerotium rolfsii*) was provided by Taito Co. Ltd., Tokyo, Japan. These samples were first used as received, for the measurements of the high-resolution solid-state ^{13}C NMR spectra. Then, they (200 mg) were dissolved in an 8M urea solution (5 ml), dialyzed against distilled water, and lyophilized for use for further measurements of the solid-state-NMR. Curdlan (Takeda Chemical Industries, Osaka, Japan) and GE-3[40] (by courtesy of Dr. Y. Nishikawa of Kanazawa University) were used as reference compounds for the ^{13}C NMR spectra of (1→3)-β-D- and (1→6)-β-D-glucans, respectively.

The high resolution ^{13}C NMR spectra were recorded on a Bruker CXP-300 spectrometer operated at 75.46 MHz. These samples (30 mg) were dissolved in DMSO-d_6 (1.5 ml) and contained in a 10 mm NMR tube. Single-contact 75.46 MHz ^{13}C cross polarization-magic angle spinning (CP-MAS) NMR spectra were recorded on a Bruker CXP-300 spectrometer equipped with a CP-MAS accessory. Solid lyophilized samples were placed in an Andrew-Beams type rotor machined from perdeuterated poly(methyl methacrylate), and then spun as fast as 3 kHz. 90° Pulse width was 5 μs and repetition time was 4 s. Spectra were usually accumulated 1000—2000 times. Chemical shifts were calibrated indirectly from the signal of liquid benzene (118.5 ppm) and then converted to the value from tetramethylsilane.

Results and Discussion

Primary Structure. Figure 1 illustrates the ^{13}C NMR spectra of a variety of (1→3)-β-D-glucans with different degrees of branching (see Table 1) in a DMSO-d_6 solution. As has previously been described,[31] the ^{13}C NMR spectra recorded in a DMSO solution can be ascribed to glucans taking the random-coil form and the displacements of the peaks can be considered to arise mainly from the primary sequence of the glucans. Obviously, none of these branched

Table 2. The Assignment of the Peaks in the ^{13}C NMR Spectra of Various Branched (1→3)-β-D-Glucans

Peak	Chemical shift ppm	m- (or m'-) Residue	b-Residue	t-Residue
C-1	103.7	C-1	C-1′	C-1″
a	87.7	C-3 m′		
C-3	87.0	C-3 m		
b	86.4		C-3′	
c	77.4			C-3″
C-5	77.0	C-5		
d	76.7	C-5		C-5″
e	75.4		C-5′	
f	74.5			C-2″
C-2	73.8	C-2		
	73.6	C-2	C-2′	
g	70.9			C-4″
C-4	69.3	C-4	C-4′, C-6′	
C-6	61.8	C-6		C-6″

Table 3. Relative Peak Intensities of the ^{13}C NMR Spectra of Branched (1→3)-β-D-Glucans in a DMSO Solution

	Relative-peak intensity		
	C-4[a])/g	C-2[b])/f	C-3[c])/c
T-5-N	2.4	1.5	1.5
Schizophyllan	3.1	2.6	2.2
Scleroglucan	2.9	2.1	2.2
T-4-N	2.9	2.1	2.0
Lentinan	2.7	1.9	2.3
HA-β-glucan	3.2	3.1	2.6

a) The C-4 and g peaks contain C-4, C-4′, and C-6′, and C-4″, respectively. b) The C-2 and f peaks contain C-2 and C-2′, and C-2″, respectively. c) The C-3 and c peaks contain C-3 and C-3′, and C-3″, respectively.

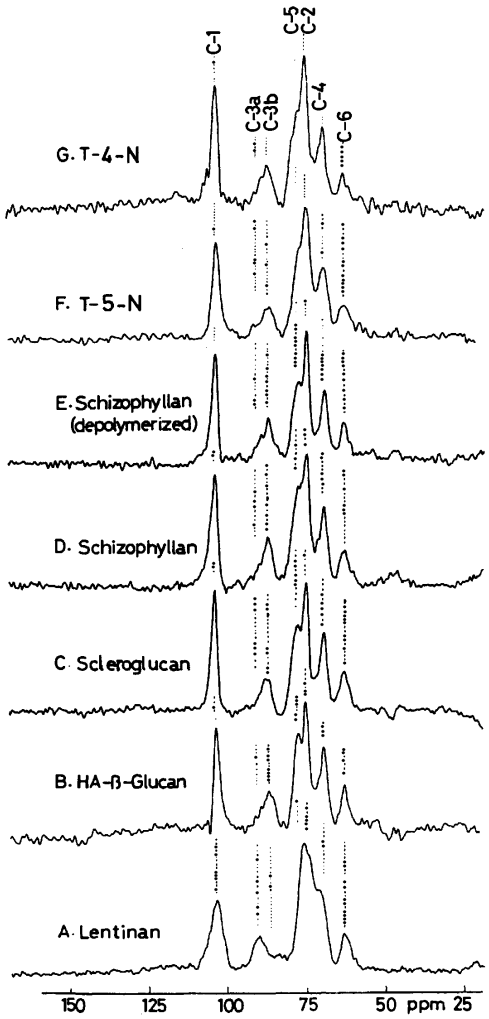

Fig. 3. 75.46 MHz High-resolution solid-state ^{13}C NMR spectra of a variety of branched (1→3)-β-D-glucans.

(1→3)-β-D-glucans possesses longer β-1,6 sequence, because no such signals can be seen as inferred from the peak-position of (1→6)-β-D-glucan (GE-3). The individual ^{13}C NMR signals were assigned to the carbons of the b-, m-(m'-), and t-residues (Fig. 2 and Table 2) on the basis of our previous assignment of the peaks for HA-β-glucan.[34] Further, it appears that two kinds of signals can be distinguished in the m- and m'-residues, as manifested by the C-3, C-5, and C-2 peaks. Further, the distinction of the peaks between m- and m'-residues is based on the data of Takeo and Tei[41] who synthesized some repeating units of branched (1→3)-β-D-glucans. The inspection of the ^{13}C NMR spectral profile leads to the classification of these polysaccharides into the following three regions: (1) HA-β-glucan, lentinan, and T-4-N, (2) scleroglucan and schizophyllan, and (3) T-5-N. In fact, the relative intensities of C-4, C-2, and C-3 with respect to those of the g, f, and c peaks (C-4″, C-2″, and C-3″, respectively, of the t-residue (side-group)), respectively, decrease in this order (Table 3). Undoubtedly, this is consistent with the degree of branching determined by the previous chemical analysis, as is summarized in Table 1.

Secondary Structure in the Solid State. Figure 3 summarizes the ^{13}C CP-MAS NMR spectra of a variety

of (1→3)-β-D-glucans in the solid state. Interestingly, all of the branched glucans, except for lentinan, give rise to a spectral pattern similar to that of laminaran and annealed curdlan adopting the triple helix (see Fig. 2 of Ref. 33), in spite of the differences in the degree of branching. This finding indicates that the manner of side-chain orientation does not affect the resulting back-bone conformation. The characteristic feature of the ^{13}C NMR pattern arising from the triple helix is that the C-3 peak is resonated at 86.4±0.5 ppm (C-3b). On the contrary, the C-3 peak of lentinan is resonated at 89.6±0.5 ppm (C-3a), characteristic of the presence of the single-helical curdlan-type form. This observation is in contrast to that of the previous X-ray diffraction study of lentinan, which suggests the presence of the triple helix.[42] This discrepancy might be, however, ascribed to the difference in the manner of sample preparation: the specimen for X-ray diffraction was obtained by fiber prepared from gel, whereas a spray-dried powder sample was used for the NMR study. In this connection, it is important to examine a plausible conformational change between spray-dried powder and lyophilized solid.

To confirm this point, we examined the conditions of the conformational change of branched (1→3)-β-D-glucans. We first dissolved these glucans in an 8M urea solution and then dialyzed it against distilled water and lyophilized to obtain solid samples. It was essential to utilize 8M urea to achieve a clear aqueous solution of branched glucans, corresponding to the completely random- coiled state, because these glucans take an ordered conformation (see Table 4). Figures 4 and 5 illustrate how the ^{13}C NMR spectra of (1→3)-β-D-glucans, taking the curdlan-type (single-helix) and laminaran-type (triple-helix) forms, respectively, are changed by treatment with 8M urea.

Interestingly, the lyophilization of lentinan resulted in a significant conformational change from the single helix to the triple-helix forms, as manifested by the displacements of the peaks from the C-3a to C-3b peak, as is indicated by the arrows, together with the characteristic change in the relative peak intensities in the C-2/C-5 peaks (Figs. 4A and B). On the contrary, the

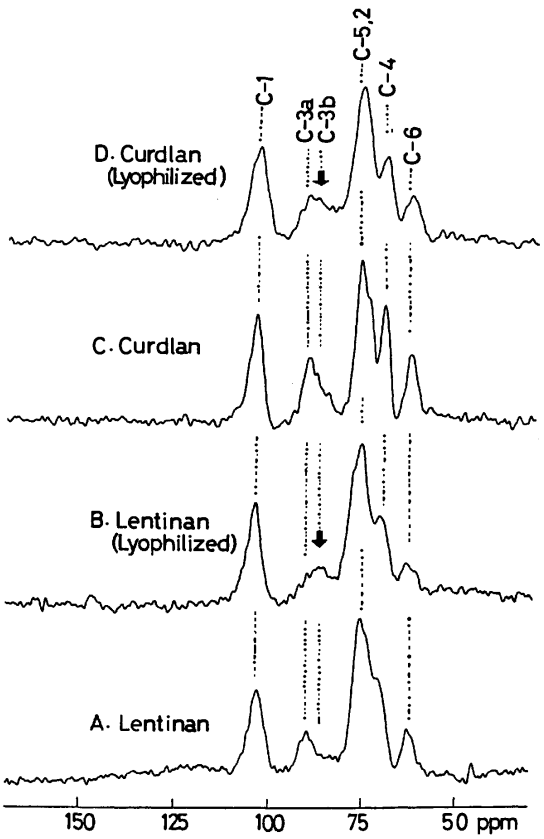

Fig. 4. Variation of high-resolution solid-state ^{13}C NMR spectra of lentinan (A and B) and curdlan (C and D) before and after treatment with 8 M urea and lyophilization. The peaks indicated by the arrows denote the peaks whose peak-intensities are varied.

extent of the conversion of curdlan is 50% at most, as judged from the relative peak-intensities between the C-3a and C-3b peaks. In fact, annealing of the sample at 150 °C, followed by slow cooling, is required for a complete conversion from the single to the triple helix, in the case of curdlan, a linear (1→3)-β-D-glucan.[33] Therefore, this distinction implies that the potential barrier to the converison from the single to the triple helix form in the linear glucan is much higher than that in the branched glucans. Accordingly, it may be

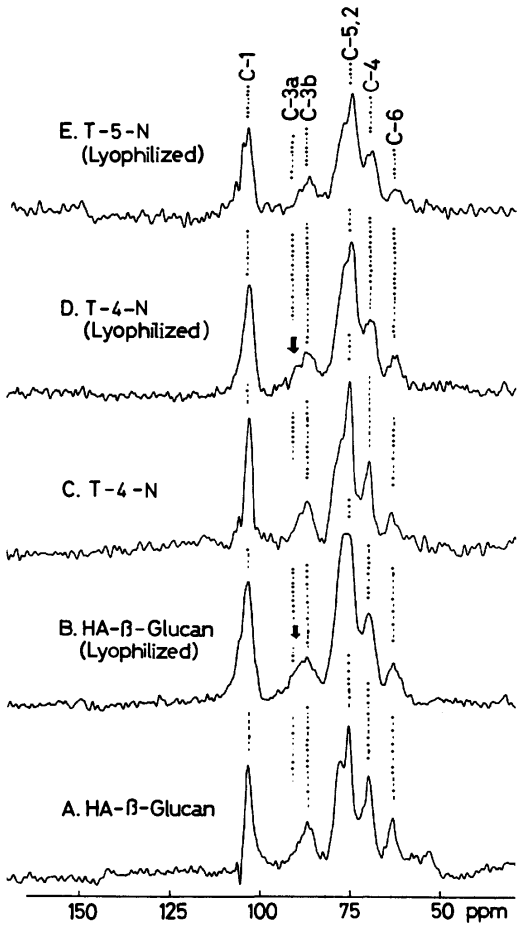

Fig. 5. Variation of high-resolution solid-state ^{13}CNMR spectra of HA-β-glucan (A and B), T-4-N (C and D) and T-5-N by treatment with 8 M urea.

concluded that the branched glucans obtained by lyophilization from the gel state take the triple-helix conformation. This result is reasonable, for branched glucans such as schizophyllan and scleroglucan take the triple helix in aqueous media[43-47] and any conformation achieved in aqueous media is usually preserved in a lyophilized solid, as has been discussed in the preceding paper.[33]

The two types of the above-mentioned conformations were also observed by Yadomae et al.[41] for branched (1→3)-β-D-glucans from *Grifora frodosa* and from *Sclerotinia sclerotiorum* IFO 9395.[48,49] Their terms of the two forms, "helix" and "native," correspond to the single and triple helix conformations, respectively, in view of the characteristic ^{13}CNMR peak-positions. They showed that milder and drastic conditions for isolation resulted in the conformations of the triple helix and single helix forms, respectively. This view seems generally to be correct in view of the presence of the triple helix in aqueous media. However, they also showed a conversion from the triple-helix conformations to the single-helix conformation by treatment with 8M urea. This finding was supported by the observation of an increased proportion of Congo Red bound to the glucans.[49] As pointed out previously, Congo Red is bound to the single-helical portion.[50]

It is now clear that the triple-helix form is the major form for lyophilized solid of the branched (1→3)-β-D-glucans, reflecting their major conformations in the gel state. On the contrary, curdlan powder contains the triple-helical region of less than 10%, as estimated from the ^{13}C NMR peak-intensity of the C-3 region.[33] This contradiction may be ascribed to apparent differences in the organization of the gel network between the linear and branched (1→3)-β-D-glucans. In the former, the major form is the single helix; the triple helix and its aggregates serve as portions of the cross-links.[28-30,33] Molecular chains other than the cross-links are sufficiently flexible, for high-resolution ^{13}C NMR signals are visible from the gel sample. In fact, the amount of the triple helix in lyophilized curdlan is less than 50%, even if the elastic gel has been annealed at 150 °C.[33]

On the contrary, gel from the branched glucan is not elastic and forms a viscous solution when the concentration is low. In addition, the ^{13}C NMR signals from the gel network are completely suppressed: the rate of molecular tumbling is longer than 10^{-6} s, for rod-like chains of the triple helix are stiffer than the native collagen fibril.[43,45] We previously pointed out that high-resolution ^{13}C NMR signals were made visible by a partial disruption of the triple helix to the single helix by adding NaOH (0.06—0.2 M).[27,28] Thus, the gel network of the branched (1→3)-β-D-glucans at a neutral pH arises mainly from the triple helix.

Concluding Remark. We have analyzed the two kinds of conformations of noncrystalline branched (1→3)-β-D-glucans in the solid state by means of the high-resolution solid-state ^{13}CNMR spectroscopy. The major conformation of the branched (1→3)-β-D-glucans is found to be the laminaran-type triple-helix on the basis of an examination of the conformation-dependent displacements of the ^{13}C chemical shifts. This obsevation is in contrast to that for the linear (1→3)-β-D-glucans, reported previously.[33] The curdlan-type single-helix conformation of spray-dried lentinan was easily converted to the laminaran-type triple helix, by the treatment with 8 M urea, followed by dialysis and lyophilization.

The authors wish to thank Dr. Goro Chihara and Dr. Takuma Sasaki of National Cancer Center Research Institute for their donation of samples and helpful discussion. They are also grateful to Kaken Pharmaceutical Co., Ltd. and Taito Co., Ltd. for their generous gifts of schizophyllan and scleroglucan, respectively.

Mutarotation of α-D-Glucose over Several Al_2O_3 Catalysts

Sentaro OZAWA, Jiro NAKATANI, Masanori SATO, and Yoshisada OGINO*
Department of Chemical Engineering, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980
(Received July 3, 1987)

The mutarotation of α-D-glucose to β-D-glucose has been studied at 25±0.1 °C using five kinds of alumina as catalysts. Two kinds of alumina with measurable surface basicities have exhibited high catalytic activities while the others with little surface basicities have exhibited low activities. Thus, the surface basic sites have been considered to be responsible for the catalytic activity observed. Any of crystal structures, surface areas, pore structures, and surface elemental compositions have no relation to the catalytic activity. It has also been revealed that the kinetics of the reaction is explained by a surface reaction mechanism

$$\alpha + 1 \underset{K_\alpha}{\rightleftharpoons} \alpha_{ad} \overset{k_1}{\underset{k_2}{\rightleftharpoons}} \beta_{ad} \underset{K_\beta}{\rightleftharpoons} \beta + 1,$$

where 1, K_α, K_β, k_1, and k_2 denote the active site, the adsorption equilibrium constant for α, the adsorption equilibrium constant for β, the rate constant for the surface forward reaction, and the rate constant for the surface backward reaction, respectively, and the subscript ad denotes an adsorbed state. The result of kinetic analysis has revealed that $K_\beta > K_\alpha$, indicating that the adsorption of β-glucose is stronger than that of α-glucose. This also supports the view that the surface basic sites are responsible for the catalytic activity.

Although abundant information about the mutarotation of α-D-glucose (an optical rotation change brought about by the rearrangement of α-D-glucose to β-D-glucose) catalyzed by acids and bases in homogeneous solutions is available in literature,[1-3] we have only scanty information[4,5] about this reaction over heterogeneous catalysts. The mutarotation of α-D-glucose has been regarded as one of fundamental reactions related to enzymic biochemical reactions,[2] and heterogeneous catalyses in this field have been lately calling the attention of world scientists. It appears worthwhile, therefore, to accumulate basic knowledge about the heterogeneous catalysis of the glucose mutarotation reaction.

The present paper reports the results of a catalysis study on the mutarotation of α-D-glucose over several alumina catalysts at 25 °C. The kinetics of the reaction has been established and the activities of the alumina catalysts are compared with respect to their properties.

Experimental

Catalyst. Five kinds of alumina used as catalysts in the present study have been commercially obtained, and their main properties are shown in Table 1. Each of these catalysts was pulverized in a mortar for 30 min, and then dried in an oven at 120 °C for 24 h before use.

Catalyst Characterization. The following characterization experiments were carried out for each catalyst; crystal structure (powder X-ray diffraction; Rigaku Geigerflex 2320 instrument; Cu $K\alpha$ radiation at 30 kV and 15 mA), surface elemental composition (XP spectra; Shimazu ESCA 750 instrument; Mg $K\alpha$ radiation), surface area and pore structure (nitrogen adsorption at 77 K), surface basicity (benzoic acid titration method[6]).

Catalytic Activity. Anhydrous α-D-glucose (Nakarai Kagaku) was dried for 24 h in a desiccator containing P_2O_5 under a pressure of ca. 1 Pa and at a temperature of 60 °C. Dimethyl sulfoxide used as a solvent was dried for 24 h using calcium hydride and then followed by a vacuum distillation (ca. 10^3 Pa at 72 °C). The middle distillate, thus obtained, was kept in a bottle flashed with dry nitrogen.

The reaction was carried out in the following manner using a three-neck flask (300 cm^3). Firstly, 100 cm^3 of the dry solvent and 0.005 mol of α-D-glucose were taken into the flask flashed with dry nitrogen, and the flask was immersed in a water bath kept at a constant temperature of 25±0.1 °C. Then, the reactant solution was stirred with a magnetic stirrer and the catalyst powder was added to initiate the reaction. At appropriate time intervals, ca. 3 cm^3 of the reacting solution was withdrawn from the flask using a syringe equipped with a catalyst filter. The sample solution was analyzed using an automatic digital polarimeter (Union Giken PM-101 instrument). Such measurements as mentioned above were continued until no change in the optical

Table 1. Properties of Alumina Catalysts

Catalyst	Crystal from	Surface area	Pore volume	Pore size	Surface composition/atom %				
		$m^2 g^{-1}$	$cm^3 g^{-1}$	Å	Al	O	C	Si	Na

rotation (r) was observed (usually over 24 h).

Adsorption of Glucose. The amount of adsorption onto the catalyst was measured by a separate experiment. The experimental procedures were almost the same as those used in the activity measurement, except for the method of the glucose analysis. Namely, in this case, the sample solution taken out of the reaction system was analyzed to determine the total glucose using the anthrone colorimetric method;[7,8] an absorption intensity at 620 nm was measured using a Hitachi 330 spectrophotometer.

Results and Discussion

Mutarotation Activity. Part of the experimental results obtained in this work are shown in Fig. 1. The figure shows changes in the optical rotation (r) as a function of the reaction period (t). High activities of the catalysts Al-1 and Al-5 as well as low activities of the catalysts Al-2, Al-3, and Al-4 are evident in the figure. The dotted line in the figure represents the result of a repeated run over the Al-1 catalyst and demonstrates a good reproducibility of the measurement. The figure also contains part of the results of the adsorption measurements. It can be seen that the adsorption of glucose reaches equilibrium within 30 min while the mutarotation reaction is still continuing.

Kinetics. A homogeneous reaction model: As reported in literature,[1,2] the rearrangement of α-D-glucose to β-D-glucose accompanies a reduction of the optical rotation of the reacting solution until the reaction reaches equilibrium. In an homogeneous reaction, this change in the optical rotation obeys the first order reversible reaction kinetics.[1] Thus, the apparent rate

constant defined by

$$\alpha \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \beta \qquad (1)$$

can be obtained from

$$k_1 + k_2 = -(1/t)\ln[(r_t - r_\infty)/(r_0 - r_\infty)], \qquad (2)$$

where r_t, r_0, and r_∞ denote the optical rotation r at a reaction period t, r at $t=0$ ($r_0=r_\alpha$), and r at equilibrium ($t=\infty$), respectively.

Although the rate equation, Eq. 2, is very simple and has been employed by Pincock et al.[4] in analyzing their catalysis data over alumina catalysts, it appears to be an oversimplification to assume that fine catalyst powder suspended in a reaction solution can be regarded as a homogeneous molecular or an ionic catalyst similar to H_3O^+ or OH^-. Indeed, as can be seen in Fig. 2, plots of $\ln[(r_t-r_\infty)/(r_0-r_\infty)]$ against the reaction period t have been nonlinear. Pincock et al.[4] have attributed the deviation of the first order plot from the linearity to a catalyst poisoning and have infered that the poisoning is due to glucose.

The present authors consider that the oversimplification adopted in applying Eq. 2 has caused the disagreement between the theory and experiments. It is more likely that α-glucose and β-glucose are competing in adsorption onto active sites. It is reasonable to consider that the β-glucose produced by the reaction would occupy part of the active sites and retard the reaction.

Heterogeneous reaction models: On the basis of the above-mentioned discussion, the present authors have adopted the following heterogeneous reaction model:

$$\alpha + 1 \rightleftharpoons \alpha_{ad} \rightleftharpoons \beta_{ad} \rightleftharpoons \beta + 1, \qquad (3)$$

where 1 denotes an active site on the catalyst surface.

Although Pincock et al.[4] have considered that the adsorption characteristics of α-glucose is identical with those of β-glucose, the present study assumes that the Langmuir type adsorption properties of α- and β-glucose are different from each other.

It must be pointed out that we have three different cases, even when the overall reaction is expressed by Eq. 3. Namely, there are three possible rate-determining steps, i.e. the surface reaction step, the adsorption step of α-glucose, and the desorption step of β-glucose. Each of these three cases yields its own rate equation, as can be seen below.

(1) When the surface reaction is the rate-determining step, the rate of decreasing of α-D-glucose concentration is expressed by

$$-\mathrm{d}[\alpha]/\mathrm{d}t = k_1[\alpha_{\mathrm{ad}}] - k_2[\beta_{\mathrm{ad}}], \tag{4}$$

where square bracket denotes the concentration, k_1 denotes the rate constant of the surface forward reaction, and k_2 denotes the rate constant of the surface backward reaction. If we define L_o, [G], K_α, and K_β as the total concentration of active sites, the total concentration of glucose $[\alpha]+[\beta]$, the adsorption equilibrium constants for α-glucose and β-glucose, respectively, Eq. 4 becomes

$$-\mathrm{d}X/\mathrm{d}t=[(1/(a+bX)][(\vec{k}_1+\overleftarrow{k}_2)/[\mathrm{G}]](X-k''), \tag{5}$$

where $X=[\alpha]/[\mathrm{G}]$, $a=(1/[\mathrm{G}])+K_\beta$, $b=K_\alpha-K_\beta$, $\vec{k}_1=k_1K_\alpha L_o$, $\overleftarrow{k}_2=k_2K_\beta L_o$, and $k''=\overleftarrow{k}_2/(\vec{k}_1+\overleftarrow{k}_2)$. An integration of Eq. 5 under the conditions that $X=1$ at $t=0$ and $X=X_\infty$ at $t=\infty$ gives

$$[1/(1-X)]\ln[(X-X_\infty)/(1-X_\infty)] = -At/(1-X)+B, \tag{6}$$

where $A=(\vec{k}_1+\overleftarrow{k}_2)/(a+bX_\infty)$, and $B=b/(a+bX_\infty)$. It must be noted here that the relation $X_\infty=\overleftarrow{k}_2/(\vec{k}_1+\overleftarrow{k}_2)$ also results from the integration process. Now we can convert the variable X into the optical rotations r_t, r_o, and r_∞, i.e. $X=(r_t-r_\beta)/(r_\alpha-r_\beta)=(r_t-r_\beta)/(r_o-r_\beta)$ and obtain a final expression of the integral rate equation:

$$[(r_o-r_\beta)/(r_o-r_t)]\ln[(r_t-r_\infty)/(r_o-r_\infty)] = -At[(r_o-r_\beta)/(r_o-r_t)]+B. \tag{7}$$

The rate equation, Eq. 7, can easily be compared with the experimental data. The value of the left hand side of Eq. 7 should have a linear relation with $(r_o-r_\beta)t/(r_o-r_t)$, and the straight line enables us to obtain the values of A and B. It must be pointed out that A should be positive because A has been defined by

$$A=(\vec{k}_1+\overleftarrow{k}_2)/[1+\{K_\alpha X_\infty+K_\beta(1-X_\infty)\}[\mathrm{G}]], \tag{8}$$

and $1-X_\infty>0$. On the other hand, B can be either positive or negative depending on the sign of $K_\alpha-K_\beta$, because B has been defined by

$$B=[\mathrm{G}](K_\alpha-K_\beta)/[1+\{K_\alpha X_\infty+K_\beta(1-X_\infty)\}[\mathrm{G}]]. \tag{9}$$

(2) When the adsorption of α-glucose is the rate-determining step, a rate equation with a form identical with that of Eq. 7 can easily be derived. In this case, however, the definition of A and B are different from those for the case (1), as we can see in Table 2.

(3) When the desorption of β-glucose is the rate-determining step, again a rate equation with the same form as Eq. 7 can be derived. The definition of A and B are, however, different from those for Eq. 7, as we can see in Table 2.

Comparison with experimental results: Plots of experimental values for $[(r_o-r_\beta)/(r_o-r_t)]\ln[(r_t-r_\infty)/(r_o-r_\infty)]$ against $(r_o-r_\beta)t/(r_o-r_t)$ values are exemplified in Figs. 3 and 4. Linear relations between the two quantities mentioned above are evident. This informs the validity of the heterogeneous reaction model discussed above. It must be pointed out that the linear plots shown in the figures reveal that $A>0$ and $B<0$. This implies that either the surface reaction mechanism (1) or the adsorption mechanism (2) is actually the case. The desorption mechanism (3) has to be excluded because this mechanism requires positive values of B (Table 2).

Although which of (1) and (2) is the true reaction mechanism can not be determined, from the kinetic treatments mentioned above, the adsorption data exemplified in Fig. 1 clearly indicate that the surface reaction mechanism is most probable. As already pointed out, the adsorption reaches equilibrium while the mutarotation reaction is still continuing (Fig. 1). If the adsorption of glucose controles the reaction rate,

Table 2. Properties of Kinetic Equations for Different Mechanisms

Rate-determining step	Definitions and properties of A and B	Notation
1. Surface reaction	$A=(\vec{k}_1+\overleftarrow{k}_2)/[1+\{K_\alpha X_\infty+K_\beta(1-X_\infty)\}[\mathrm{G}]]>0$ $B=[\mathrm{G}](K_\alpha-K_\beta)/[1+\{K_\alpha X_\infty+K_\beta(1-X_\infty)\}[\mathrm{G}]]>0$, or$<0$	$\vec{k}_1=L_oK_\alpha k_1$ and $\overleftarrow{k}_2=L_oK_\beta k_2$.
2. Adsorption of α-glucose[a]	$A=(\vec{k}_1+\overleftarrow{k}_2)/[1+\tilde{K}(1-X_\infty)[\mathrm{G}]]>0$ $B=-\tilde{K}[\mathrm{G}]/[1+\tilde{K}(1-X_\infty)[\mathrm{G}]]<0$	$\vec{k}_1=L_o\tilde{k}_1$, $\overleftarrow{k}_2=L_o(K_\beta/K)\tilde{k}_2$, and $\tilde{K}=[(K_\beta/K)+K_\beta]$.
3. Desorption of β-glucose[a]	$A=(\vec{k}_1+\overleftarrow{k}_2)/[1+\tilde{K}X_\infty[\mathrm{G}]]>0$ $B=[\mathrm{G}]\tilde{K}/[1+\tilde{K}X_\infty[\mathrm{G}]]>0$	$\vec{k}_1=L_oKK_\alpha\tilde{k}_1$, $\overleftarrow{k}_2=L_o\tilde{k}_2$, and $\tilde{K}=K_\alpha(1+K)$.

a) $\tilde{k}_1$ and $\tilde{k}_2$ denote the rate constants for the forward reaction and the backward reaction in the rate-determining step, respectively, and K denotes the equilibrium constant of the surface reaction $\alpha_{\mathrm{ad}} \rightleftarrows \beta_{\mathrm{ad}}$.

the reaction should reach equilibrium as soon as the adsorption reaches equilibrium. Thus, the mechanism (2) has to be discarded and we can conclude that the surface reaction mechanism (1) is most pertinent.

On the basis of the above-mentioned discussion, we can evaluate the kinetic parameters $\vec{k}_1$, $\vec{k}_2$, K_α, and K_β. For this purpose, linear relations between ($1/A$) and [G] and between ([G]/B) and [G] together with the relation $\vec{k}_2/(\vec{k}_1+\vec{k}_2)=X_\infty$ are available.[9] Part of the linear relationships mentioned above are shown in Fig. 5

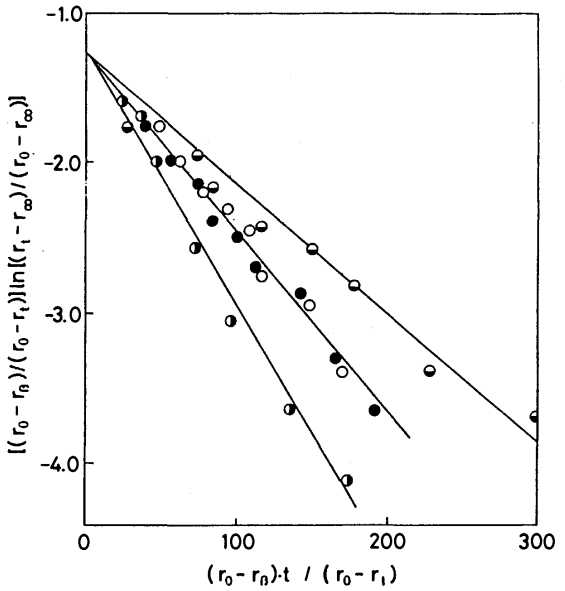

Fig. 3. Linear plots proving the applicability of the rate equation derived from a heterogeneous reaction model. ○: Al-1 (2.5 g), ◒: Al-5 (2.0 g), ●: Al-5 (2.5 g), ◑: Al-5 (4.0 g); initial concentration of glucose=0.05—0.056 mol·l^{-1}.

and kinetic parameters obtained are summarized in Table 3.

Activity and Property of Catalyst. As already pointed out, the Al-1 catalyst and the Al-5 catalyst exhibited approximately equal activities while crystal structures of these two catalysts were different from each other, i.e. γ-type for Al-1 and χ-type for Al-5 (Table 1). Furthermore, all of the less active Al-2, Al-3, and Al-4 catalysts were found to be the χ-type as the Al-5 catalyst while only the Al-5 catalyst exhibited a high catalytic activity. These facts inform that the crystal structures are not directly related to the catalytic activity. It has been reported by Pincock et al.[5] that α-alumina also exhibits a high catalytic activity for the glucose mutarotation.

Likewise, the surface areas, the pore sizes, and the surface elemental compositions shown in Table 1 did not influence the catalytic activities of the catalysts used in the present study. Insignificant relations between the catalytic activity and the pore structures shown in Table 1 and in Fig. 6 are particularly important, because this denies the pore diffusion controlling reaction mechanism. Pincock et al.[4] have also proven that the pore diffusion does not control the reaction rate by changing the size of the catalyst particle. An activation energy measurement would provide us with further support for the view mentioned above.

It appears most probable that the surface basic sites are responsible for the catalytic activity observed, though weak Brönsted acid sites have been postulated as the active sites over ordinary alumina catalysts.[4] As can be seen in Table 4, the Al-1 and Al-5 catalysts both exhibited high catalytic activities have been found to possess considerable amounts of surface basicity. On the other hand, the other catalysts (Al-2, Al-3, and Al-

4) which have exhibited low catalytic activities possess little surface basicities. Adsorbed water or surface hydroxyl groups might have been weak catalytic sites over these three catalysts.

More important information suggested by the basicity data shown in Table 4 is that the total basic sites ($H_- \geqq 7.3$) are considered to catalyze the reaction. As we can see in the table, the total basicity of the Al-1 catalyst is approximately equal to that of the Al-5 catalyst. This corresponds well with the experimental result, i.e. almost identical activities of these catalysts. On the other hand, the contents of stronger basic sites with H_- values larger that 9.3 is larger for the Al-5 catalyst than for the Al-1 catalyst. If we assume that the strong basic sites are responsible for the catalytic

Table 4. Surface Basicities of Catalysts

Catalyst	Surface basicity/m mol g^{-1}		
	$9.3 > H_- > 7.3$	$H_- > 9.3$	Total
Al-1	0.036	0.009	0.045
Al-2	0	0	0
Al-3	0	0	0
Al-4	0	0	0
Al-5	0.025	0.025	0.05

activity, the activity of the Al-5 catalyst must be much larger than that of the Al-1 catalyst. This does not agree with the experimental result.

The surface reaction model coupled with the basic catalytic sites model is most probable in view of the different acidic properties of α- and β-glucose. Since the acid strength of β-glucose is about two times larger than that of α-glucose,[2] a stronger adsorption of β-glucose onto the basic sites can be expected, and the relation $K_\beta > K_\alpha$ obtained by the kinetic analysis is quite reasonable. Thus, the rate constants, k_1 and k_2, have been evaluated by assuming that L_o represents the basic sites concentration in the reaction system. The results are also included in Table 3.

Reaction of Allyl Phenyl Ether over Various Liquid Metal Catalysts

Sentaro Ozawa,* Yoshiki Sasaki, and Yoshisada Ogino
Department of Chemical Engineering, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980
(Received July 8, 1987)

Allyl phenyl ether has been reacted over various kinds of liquid metal catalysts (Sn, Ga, In, Tl, Pb, Cd, Bi, Zn) and without catalysts in the temperature range of 320—500 °C. Phenol (PN), 1,5-hexadiene (HD), benzofuran (BF), and *o*-allylphenol (*o*-AP) together with small amounts of unknown compounds have been found in the condensable products. The results of correlation among the conversion for PN, HD, and BF as well as the results of kinetic simulation of the products distribution have revealed that only the *o*-AP formation is catalyzed by the liquid metal. A clear compensation effect between the frequency factor and the activation energy has been found for the *o*-AP formation reaction, suggesting that a radicalic high energy and high entropy transition state is involved in the catalysis. A good correlation between the methyl group-catalyst metal bond energy and kinetic parameters of the *o*-AP formation reaction has also supported the radicalic transition state model.

Although much information about the catalysis of liquid metals has been accumulated by one of the present authors,[1,2] there remain many problems to be clarified. For instance, characteristics of reactions involving free radicals over liquid metals are not fully investigated. This kind of reaction is interesting not only from the scientific point of view but also from the practical point of view;[3-5] e.g. as model compounds reactions for coal liquefaction and heavy oils up grading reactions.

In the present study, the reaction of allyl phenyl ether which models ether linkages in coal structures has been examined using several liquid metals as catalysts. The experimental results have revealed that the reaction consists of noncatalytic decomposition reactions and a catalytic rearrangement reaction. This reaction scheme has been utilized to derive kinetic equations available for simulating the observed product distribution curves. The purpose of this paper is to report on details regarding the experimental results and to discuss the characteristic features of liquid metal catalysis.

Experimental

Materials. Tin (Sn), indium (In), gallium (Ga), thallium (Tl), cadmium (Cd), lead (Pb), bismuth (Bi), and zinc (Zn) were commercially obtained and used as catalysts in their molten states. Prior to the activity measurement, each catalyst metal was purified by the method reported earlier.[1] Ally phenyl ether (APE) was commercially obtained (reagent grade) and used as a reactant without further purification; benzene was used as a solvent of the reactant (2.5 wt% APE in benzene). Hydrogen was used as a carrier gas of the reactant and as a catalyst purification gas, after a deoxygenation with a Pd-catalyst at 250 °C and a drying with a liquid nitrogen trap.

Procedures. A bubbling type reactor[1,2] made from Pyrex glass was used in the activity measurements. Since details of the experimental method with a reactor of this type have already been reported elsewhere,[1,2] the precedures are only briefly described below.

After purification, the catalyst liquid metal was transferred from the catalyst preparatory tube to the reactor tube through a glass line connecting both tubes under a streaming of purified hydrogen which prevented the catalyst from contamination due to oxidation. Then the reactant solution and hydrogen were fed to the reaction system; the feed rate of the reactant solution was 5.25 $cm^3 h^{-1}$ and that of hydrogen was 82.5 $cm^3 min^{-1}$. The reactant solution was evaporated in a preheater and a gaseous mixture of allyl phenyl ether, benzene, and hydrogen was led to the bottom of the reactor. The mixture was then forced to bubble into the liquid metal catalyst (ca. 10 cm^3) kept at a predetermined reaction temperature. The effluents from the reactor were cooled and condensable materials were separated from gaseous materials. The products, thus obtained, were analyzed by means of a gaschromatography. The instrument used was a Hitachi-163 gaschromatographic apparatus equipped with a capillary column (Hewllet-Packard 19091A-105; 50 m) and a FI detector. The conditions of the analysis were as follows; sample size=1 μl for condensed samples, 1 cm^3 for gaseous samples; injection temperature=260 °C; flow rate=144 $cm^3 min^{-1}$; column temperature=keeping at 50 °C for 9 min followed by a raising at a rate of 10 °C min^{-1}. In addition to the above mentioned analysis, a gas chromatographic mass spectrometry was carried out in identifying important products (JEOL JMS-D300 instrument).

Results and Discussion

Products Distributions. The main products obtained were 1,5-hexadiene (HD), phenol (PN), benzofuran (BF), and *o*-allylphenol (*o*-AP). Methane and a small amount of propene were also found in the gaseous products. A few unknown products were observed. The amounts of these byproducts were estimated by gas chromatography using an averaged calibration curve obtained from the curves of known products. Part of the byproducts probably contain the C_3-group since the ratio of HD/PN was less than 1/2 (mole ratio). Another cause of the deficient HD formation would be polymerization of C_3-radicals; a contaminaion of the outlet of reactor suggested this. Uncertainties due to hydrogenation would be insignificant because the liquid metal little catalyzes the hydrogenation and the residence time is very short. This view is supported by the small amount of observed propene.

The temperature dependences of the above-men-

tioned liquid products are shown in Figs. 1—3; data points representing concentrations estimated for unknown products were not shown, in order to avoid confusion. The first figure, Fig. 1, shows the two most typical cases observed in the present study. It is seen in Fig. 1 (a) that the reaction over the liquid tin (Sn) catalyst has produced a significant amount of *o*-AP. On the other hand Fig. 1 (b) shows that *o*-AP formation is insignificant and, instead, PN formation is significant in the noncatalytic reaction. This informs us of a difference between the catalytic reaction and the noncatalytic reaction, i.e. the former reaction favors the *o*-AP formation while the latter reaction favors the PN formation. The experimental results shown in Figs. 2 and 3 inform us of an existence of wide differences in the *o*-AP forming activity among the catalyst metals. Concentrations of other products (HD, PN, and BF) also vary upon changing the catalyst metal; however, the extent of variation is smaller compared with that observed for the *o*-AP concentration. This

suggests a mechanistic difference between the *o*-AP formation reaction and the other reactions forming HD, PN, and BF.

Relations among Conversions. The relations shown in Fig. 4 (a)—(c) reveal an important aspect of the reaction of allyl phenyl ether (APE). The abscissa of this figure represents the sum of conversions ($\sum X_j$; j=HD, PN, BF) and the ordinate represents the conversion for individual product, i.e. X_{HD}, X_{PN}, or X_{BF}. It can be seen in Fig. 4 (a) that a linear relation exists between $\sum X_j$ and X_{PN}. Furthermore, the straight line represents every data point, irrespective of the catalyst species and conditions used in taking the experimental data; data obtained with different catalysts, data obtained without catalysts, and the data obtained at different temperatures are represented by a single straight line. These facts indicate that the PN formation reaction is essentially noncatalytic, i.e. the catalysts have little affected the PN formation rate. Relations similar to that observed in Fig. 4 (a) can be seen both in Fig. 4 (b) and in Fig. 4 (c), though data points somewhat scatter around the correlation lines. It is possible, therefore, to consider that both the HD formation and BF formation are essentially noncatalytic. The temperature independences of the correlation lines mentioned above suggest that the temperature dependences of X_{HD}, X_{PN}, and X_{BF} are almost identical with each other.

Reaction Scheme and Kinetic Treatments. On the basis of the above-mentioned discussion, the reaction scheme shown in Fig. 5 has been assumed. The reaction scheme consists of five elementary steps. The steps forming HD, PN, and BF are noncatalytic while the step forming *o*-AP is catalytic. A noncatalytic step where *o*-AP decomposes to unknown product (UN) has been added in order to account for the decreasing of the *o*-AP concentration at high temperatures (Figs. 1—3). The symbols k_j (j=1—5) shown in the reaction scheme are the first-order rate constant of the j-th elementary step.

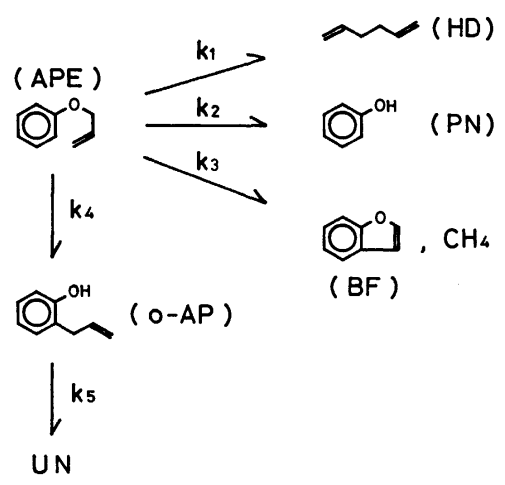

Fig. 5. Reaction scheme of allyl phenyl ether transformation.

If we assume that every step obeys irreversible first-order kinetics, the following relations can easily be derived:

$$1-X_{APE} = \exp(-kt), \quad (1)$$

$$X_{HD} = (k_1/k)[1-\exp(-kt)], \quad (2)$$

$$X_{PN} = (k_2/k)[1-\exp(-kt)], \quad (3)$$

$$X_{BF} = (k_3/k)[1-\exp(-kt)], \quad (4)$$

$$X_{o\text{-}AP} = \exp(-k_5 t)[k_4/(k-k_5)][1-\exp(k_5-k)t], \quad (5)$$

where $k=k_1+k_2+k_3+k_4$ and t denotes the reaction period (residence time).

From Eqs. 2—4 we can derive the following relations:

$$X_{HD}/(X_{HD}+X_{PN}+X_{BF}) = k_1/(k_1+k_2+k_3), \quad (6)$$

$$X_{PN}/(X_{HD}+X_{PN}+X_{BF}) = k_2/(k_1+k_2+k_3), \quad (7)$$

$$X_{BF}/(X_{HD}+X_{PN}+X_{BF}) = k_3/(k_1+k_2+k_3). \quad (8)$$

It is evident from these equations that, if activation energies for k_1, k_2, and k_3 are identical with each other, the right hand side of each equation becomes constant and the experimental results shown in Fig. 4 (a)—(c) can be explained. This result indicates that the kinetic treatment mentioned above is promissing. The extent of the constancy of the activation energies will be shown in the following section.

Simulation of Experimental Results. The validity of the reaction scheme and the kinetic treatment mentioned above has been proved by simulating experimentally observed products distribution curves. For this purpose, every rate constants (k_1—k_5) have been converted to the Arrhenius form, i.e. $k_j=a_j\exp(-E_j/RT)$; a_j is the frequecy factor, E_j is the activation energy, R is the gas constant, and T is the absolute temperature. With this expression and with Eqs. 1—5, the experimental results shown in Figs. 1—3 have been simulated and the most probable values for a_j and E_j have been determined; the residence time t has been estimated to be 0.1 s[6] from the reactant flow rate and the reactor volume, and a_j as well as E_j have been determined by trials. The results of simulation are shown in Figs. 1—3 by solid lines and the values of a_j and E_j are summarized in Table 1. The figures show that the experimental results have been well simulated by the calculated lines.

The values of kinetic parameters a_j and E_j (Table 1) deserve special comments. As can be seen in the table, the kinetic parameters (in particular the frequency factor) for the *o*-AP formation reaction, a_4, varies very widely upon changing the catalyst species. On the other hand, the extents of variation of kinetic parameters for other reactions are limited within small ranges compared with that of the *o*-AP formation step. These facts confirm that only the *o*-AP formation step has been catalyzed and the other steps have been little catalyzed by the liquid metal. It must also be pointed out that each value for E_1, E_2, and E_3 does not differ much from the average value of 142 kJ mol^{-1}. The deviations

Table 1. Values of Kinetic Parameters for Different Catalysts and for Noncatalytic Reaction

Catalyst	Frequency factor/s^{-1}					Activation energy/kJ mol^{-1}				
	$a_1/10^{10}$	$a_2/10^{10}$	$a_3/10^{12}$	a_4	$a_5/10^{12}$	E_1	E_2	E_3	E_4	E_5
Pb	1.3	0.8	1.8	2.7×10^5	0.5	135	124	167	65	163
Bi	1.5	1.0	2.0	8.5×10^1	—	135	124	165	24	—
Ga	1.5	6.0	3.0	9.5×10^7	4.0	135	134	165	95	163
Sn	1.3	0.9	2.0	1.8×10^8	0.7	135	126	165	98	162
In	1.5	2.0	2.5	2.2×10^7	0.5	135	128	163	86	146
Cd	1.5	1.1	2.0	5.0×10^3	—	135	126	165	43	—
Tl	1.5	4.5	2.0	3.5×10^7	3.0	134	134	165	91	159
Non	1.1	2.0	1.9	3.7×10^2	—	128	126	163	33	—

of every E_j values (j=1—3) from this average value inform us of the extent of approximation of the constant activation energy, i.e. E_j=constant, discussed in the preceding section.

Catalysis over Liquid Metals. As proved in the above mentioned discussion, only the *o*-AP formation step is regarded as a catalytic reaction. It must be pointed out here that this reaction is a well-known Claisen rearrangement reaction.[7,8] According to literature,[8] the rearrangement proceeds at low temperatures (190—220 °C) without catalysts, though a residence time of several hours is required to obtain a conversion of ca. 85%. Such a homogeneous noncatalytic Claisen rearrangement at low temperatures has been explained in terms of a [3,3]sigmatropic mechanism[8] which requires a highly ordered cyclic transition state. It is unlikely that this mechanism is applicable to explain the results obtained in the present study. The reaction temperature adopted in the present study is much higher and the residence time is much shorter than the respective values mentioned above. Furthermore, the experimental results have shown that the rearrangement is almost inhibited and decompositions prevail in the temperature range studied in this work, if the catalyst is not used. Thus, under the high-temperature conditions adopted in the present study, a homolytic cleavage of the allyl group-oxygen bond is considered to be predominant. It is not unlikely, therefore, that the rearrangement of APE to *o*-AP over the liquid metal proceeds through another mechanism similar to that proposed for the photo-Claisen rearrangement,[9,10] i.e. a radicals recombination mechanism.

In this connection, the relation shown in Fig. 6 reveals an important aspect of the catalysis. The figure shows the existence of a clear compensation effect between the frequency factor a_4 and the activation energy E_4. Qualitatively speaking, this relation indicates that the activation entropy increases with the increase in the activation enthalpy. Thus we can infer from Fig. 6 that a high activation entropy and a high activation enthalpy are associated with the rearrangement reaction over a high activity catalyst, e.g. Sn. In other words, the transition state over the catalyst is expected to have a loosened and unstable structure.

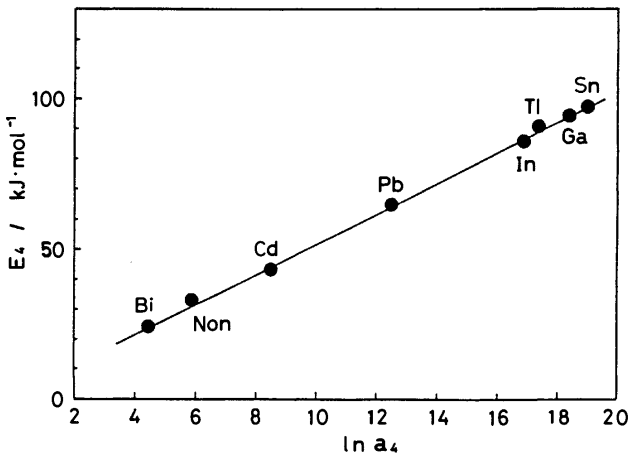

Fig. 6. A compensation effect between the frequency factor and activation energy for the rearrangement reaction.

Thus, a radicalic mechanism in which a phenoxyl radical and an allyl radical pair interaction is involved appears plausible. The cyclic transition state model proposed for the low-temperature homogeneous Claisen rearrangement is unprobable because this model should require a small activation entropy.[8]

If we assume the above-mentioned radicalic mechanism, the result shown in Fig. 6 suggests that the decreasing order of the radical-catalyst interaction energy would be Sn>Ga>Tl>In>Pb>Cd>Bi. This view is indirectly, but strongly, supported by the relation shown in Fig. 7. This figure informs us of that both a_4 and E_4 can be well correlated with the bond energy $Q_{C\text{-}Me}$, the bond energy per one carbon-metal linkage in $(CH_3)_n$-Me (Me=metal, n=an integer).[11-13] It is not unlikely that the $Q_{C\text{-}Me}$ value approximates the interaction energy between the reacting radical and the catalyst metal.

It appears worth reporting that the correlation shown in Fig. 7 enables us to discuss the catalytic activity of liquid zinc (Zn). Since this metal melts at ca. 420 °C, its activity can not be measured at low temperatures and, hence, kinetic parameters for this metal are unknown. It is possible, however, to expect that the activity of Zn would approximately be equal to that of In because $Q_{C\text{-}Zn}$ is 175.7 kJ mol^{-1} which lies

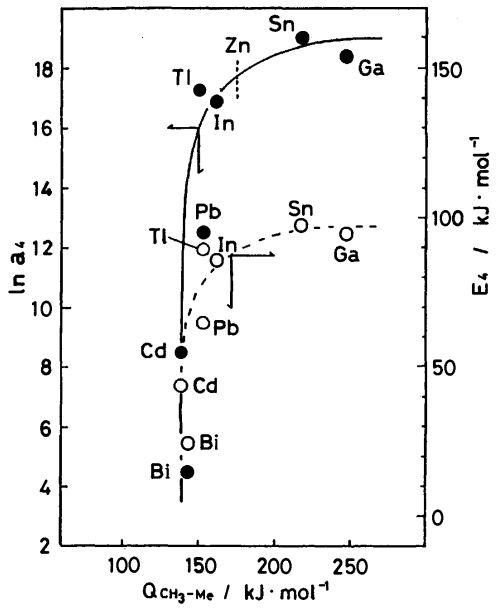

Fig. 7. Correlations between methyl group-metal bond energy and kinetic parameters for the rearrangement reaction. —●—: frequency factor, --○--: activation energy. The bond energy for Tl was taken from CRC "Handbook of Chemistry and Physics," 62nd ed, CRC Press Inc. (1981—1982, F-195. Other values were taken from H. A. Skinner, *Adv. Organomet. Chem.*, **2**, 49 (1964) and "Kagaku Binran; Kisohen II," ed by Chem. Soc. Jpn., Maruzen, Tokyo (1975), pp. 959—978.

close to the value of $Q_{C\text{-}In}$, as we can see in Fig. 7. Indeed, the experimental results shown in Fig. 2 (d; ⊕) inform that the catalytic activities observed for Zn at 430 and 455 °C are close to the line representing the *o*-AP formation activity of In.

6) The residence time t of 0.1 s is not so accurate but this never affects the value of the activation energy obtained. Instead, the error (Δt) in the residence time brings about a shift of logarithm of the frequency factor by $\ln(1+\Delta t/t)$ or ca. $\Delta t/t$ if $-1<\Delta t/t<1$. However the extent of this shift is expected to be almost identical for every catalysts used. Thus the relative magnitudes of frequency factors obtained would not vary. For the understanding of above mentioned description, it must be noted that the following relation has been used in evaluating, for instance, E_1 and a_1;

$$\ln(a_1 t)-E_1/RT= \ln(C_B/C_{A_o})+\ln[\ln(C_{A_o}/C_A)] -\ln[1-(C_A/C_{A_o})].$$

Methods similar to this were used in evaluating other E_j and a_j.

Structural Retention of Decatungstates upon Photoreduction

Yoh SASAKI, Toshihiro YAMASE,* Yuji OHASHI,†,†† and Yoshio SASADA†
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta 4259, Midori-ku, Yokohama 227
†Department of Life Science, Tokyo Institute of Technology, Nagatsuta 4259, Midori-ku, Yokohama 227
(Received January 26, 1987)

The crystal structures of oxidized and photoreduced decatungstates are compared. Three specimens of decatungstate complexes were prepared in mixed solvents of H_2O-CH_3CN and were characterized by X-ray diffraction. Unit cell parameters are as follows: $(C_6H_{16}N)_4[W_{10}O_{32}]\cdot 2CH_3CN$; DECA M_r=2841.4, monoclinic, $P2_1/n$, a=14.617(2), b=17.783(3), c=11.755(2) Å, β=100.27(2)°, V=3006.5(9) Å^3, Z=2; $(C_6H_{16}N)_4[H_{1.5}W_{10}O_{32}]\cdot 8H_2O$; RED1 M_r=2905.4, monoclinic, $P2_1/n$, a=15.902(3), b=12.233(2), c=15.673(4) Å, β=93.76(2)°, V=3042(1) Å^3, Z=2; $Na_4[H_{1.8}W_{10}O_{32}]\cdot 14H_2O$; RED2 M_r=2696.7, monoclinic, $C2/m$, a=16.123(5), b=12.636(3), c=12.168(4) Å, β=117.40(2)°, V=2202(1) Å^3, Z=2; There is no obvious change in the anion frame among the three decatungstate complexes. Photoreduced decatungstates may coordinate protons which neutralize excess charge injected into anions. It is concluded that the structure of $W_{10}O_{32}$ is not largely altered up to two-electron reduction.

The photochemical properties of polyoxometalates in both solutions and solid states have been investigated.[1,2] To characterize the reduced polyoxometalates produced as a results of a photoredox reaction, it was decided to carry out a study of the crystal structure of photoreduced polyoxometalates. There have been only a few reports on the crystal structures of such reduced polyoxometalates as $(C_3H_{10}N)_4[Mo_{13}O_{40}]_{0.33}[H_4Mo_{12}O_{40}]_{0.67}$, $Rb_4H_8[H_2W_{12}O_{40}]\cdot 18H_2O$, and $Ca_{0.5}H_6PMo_{12}O_{40}\cdot 18H_2O$.[3-5] This paper describes the crystal structures of photoreduced decatungstates which are useful for catalytic H_2 production from water and organic substances.

The decatungstate anions, $[W_{10}O_{32}]^{4-}$[6] are stable in an acidic media and exhibit electrochemically reversible oxidation-reduction steps.[7] We prepared single crystals of two specimens of photoreduced decatungstates from H_2O-CH_3CN mixed solvents, and carried out X-ray diffraction studies.

Experimental

$(C_6H_{16}N)_4[W_{10}O_{32}]\cdot 2CH_3CN$; DECA. 3 g of $Na_2WO_4\cdot 2H_2O$ was dissolved in 40 cm^3 of water. The solution pH was adjusted to 1 using $HClO_4$. The solution was stirred at 80 °C for 30 min. Pale-yellow precipitates were obtained upon adding 20 cm^3 of a 2 mol dm^{-3} diisopropylammonium perchlorate aqueous solution and filtering. The precipitates were washed with water and diethyl ether and then recrystallized from a mixed solvent of H_2O-CH_3CN (1 : 4 v/v (pH 2)). Pale-yellow crystals were grown after 1—2 days.

$(C_6H_{16}N)_4[H_{1.5}W_{10}O_{32}]\cdot 8H_2O$; RED1. 1.8 g of the DECA powder was dissolved in 20 cm^3 mixed solvent of H_2O-CH_3CN (1 : 4 v/v (pH 2)). The solution was irradiated for 20 h by a use of a 500-W superhigh pressure mercury lamp in combination of a cut filter (λ>300 nm) under an argon atmosphere. Dark-blue crystals were grown from the photolyte at 5 °C within 2—3 days. The analysis of W^v in the blue crystals was achieved by $KMnO_4$ titration under an argon atmosphere and gave the composition of 1.5-electron reduction.

$Na_4[H_{1.8}W_{10}O_{32}]\cdot 14H_2O$; RED2. 5 g of $Na_2WO_4\cdot 2H_2O$ was dissolved in 20 cm^3 of H_2O. The solution pH was adjusted to 1 using $HClO_4$. The solution was stirred at 80 °C for 60 min and then 20 cm^3 of 2 mol dm^{-3} monoisopropylammonium perchlorate aqueous solution and 160 cm^3 of CH_3CN were added together. After cooling at room temperature, the solution was irradiated for 20 h in the same manner with RED1. Dark-blue platelike crystals were obtained from the solution at room temperature. The $KMnO_4$-titration analysis yielded a composition of 1.8 electron reduction per molecule.

X-Ray Structure Analysis. [DECA] The preliminary unit-cell dimensions and the space group were obtained from the oscillation and Weissenberg photographs. Systematic absences were $k=2n+1$ for $0k0$ and $h+l=2n+1$ for $h0l$. The cell parameters were refined by least-squares on the basis of 15 independent 2θ values in the range $22° < 2\theta < 29°$. Crystallographic data are summarized in Table 1.

A crystal of 0.2×0.2×0.3 mm, sealed in a glass capillary, was mounted on a Rigaku AFC-4 diffractometer. Intensity data were collected up to 2θ=55° using Mo $K\alpha$ radiation monochromated by graphite. The ω—2θ scan technique was applied with a scan rate of 8° (2θ) min^{-1}. Three standard reflections, measured every 50 reflections, showed a variation in intensity of less than 2%. A total of 6898 reflections were measured, of which 5776 with $|F_o| > 3\sigma(F_o)$ were used for the analysis. Correction was made for Lorentz and polarization factors, but neither for absorption nor extinction. The positions of the W atoms were obtained by a direct method using

MULTAN78.[8] Other C, N, and O atoms appeared on successive Fourier maps. The structure was refined by using a the block diagonal least-squares program called HBLS.[9] Anisotropic temperature factors were applied to all the atoms except O (15) and C (42), whose factors turned out to non-positive definite. No hydrogen atoms were found on the difference map and, thus, not included in the calculation. The weighting scheme was $w=\{\sigma^2(|F_o|)+(C|F_o|)^2\}^{-1}$, where C was 0.06. In the final difference map, maximum and minimum electron densities were 5.2 and 4.3 e Å^{-3} within 1.5 Å around a W atom. The final R and R_w values became 0.090 and 0.110 for 5776 reflections. Final positional and thermal parameters are given in Table 2. The atomic scattering factors, including anomalous dispersion terms, were taken from International Tables for X-Ray Crystallography.[10] Calculations were carried out on the FACOM-HITAC system M-180 and M-280 computer at this Institute.

[RED1]: Experimental details were similar to those for [DECA]. Systematic absences were $k=2n+1$ for $0k0$ and $h+l=2n+1$ for $h0l$. The cell parameters were refined using 18 independent 2θ values in the range $18°<2\theta<29°$. A crystal of 0.3×0.3×0.2 mm was used for data collection. A total of 6980 reflection were obtained, of which 6001 were $|F_o|>3\sigma(F_o)$. In a least-squares refinement with the program HBLS, the anisotropic temperature factors of 15 non-W atoms was shown to be non-positive definite. These atoms were refined with isotropic temperature factors. The C value in the weighting scheme was 0.08. A considerably high residual peak of 11.4 e Å^{-3} appeared near one of the W atoms (ca. 0.9 Å) and ±3.6 e Å^{-3} around the other W atoms. A refinement based on a disordered model was unsuccessful. The final R and R_w were 0.127 and 0.159 for 6001 reflections, respectively. Final positional and thermal parameters are shown in Table 3.

[RED 2]: Experimental detailes were similar to those for

[DECA]. Systematic absences were at $h+k=2n+1$. The space group was assigned to be $C2m$ or $C2/m$. The refinement of the structure on the latter gave a reasonable result. The cell parameters were refined with 15 reflections of $18°<2\theta<30°$. A crystal of 0.35×0.25×0.12 mm was used for data collection. The intensities were gradually decrease to 92% in the data collection. An absorption correction was made using the program DABEX.[11] The correction factors were from 1.421 to 1.817. The positions of W atoms were obtained by a direct method with MULTAN 78. The Na and O atoms appeared on the successive Fourier maps. The structure was refined by a full-matrix least-squares method with the SHELX 76 program.[12] Two oxygen atoms, O(4) and O(7), revealed non-positive definite and refined isotropically. The weighting scheme employed was $w=\{\sigma^2(|F_o|)+0.002869\times(|F_o|)^2\}^{-1}$. In the final difference map, a maximum and minimum height of 11.0 and −7.4 e $Å^{-3}$, respectively, appeared around one of the W atoms for distances of less than 1.4 Å. Final R and R_w became 0.084 and 0.098 for 2499 reflections, respectively. Final positional and thermal parameters are given in Table 4.†††

Results

Structure of Decatungstate. The approximate geometries of the decatungstate anions in the three crystals (DECA, RED1 and RED2) are similar to one another and to that found in the crystal of tributylammonium salts.[6] Figure 1 shows the numbering of the atoms.

It is composed of ten WO_6 octahedra sharing edges

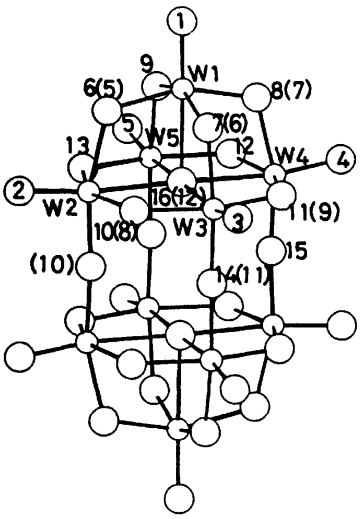

Fig. 1. The molecular structure of the decatungstate (DECA, RED1, and RED2) anions with the numbering on the atoms. Numbers in the bracket were given to RED2.

†††The complete F_o-F_c data, anisotropic thermal parameters, bond distances of diisopropylammonium cations and acetonitrile in DECA and of the diisopropylammonium cations of RED1 and bond angles are deposited as Document No. 8756 at the Office of the Editor of Bull. Chem. Soc. Jpn.

and corners and has a pseudo point symmetry D_{4h}. Bond distances of the decatungstate in the three crystals are given in Table 5.

The corresponding bonds agreed with one another within the three crystals. There are three types of W-O bonds; terminal, bridging and central bonds. The terminal W-O bond, in which an oxygen atom has only one bond with a W atom, has a distance of 1.68—1.78 Å. The bridging W-O bond distance ranges from 1.84 to 2.07 Å, since the oxygen atom makes bonds with two W atoms. The central O atom has five bonds with the surrounding W atoms and the central W-O bond distances are 2.25—2.38 Å.

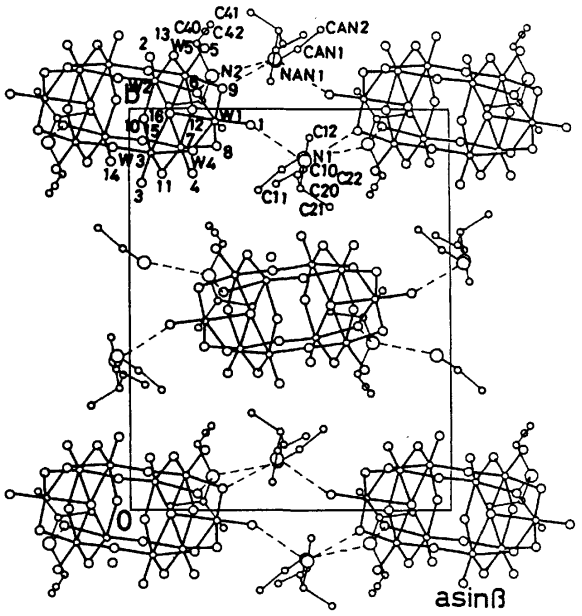

Fig. 2. The crystal structure of DECA viewed along the c axis. The hydrogen bonds are drawn with broken lines.

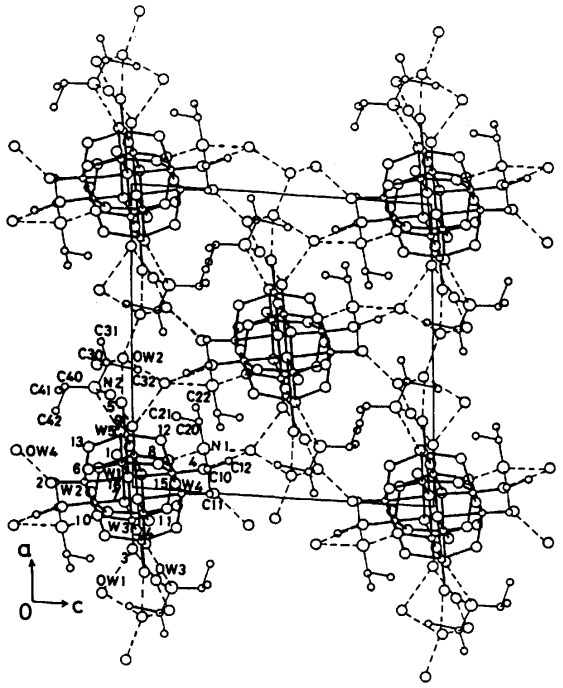

Fig. 3. The crystal structure of RED1 viewed along the b axis. The hydrogen bonds are drawn with broken lines.

Crystal Structure and Hydrogen-Bonding Scheme. The crystal structure of DECA viewed along the c axis is shown in Fig. 2.

The decatungstate anion in DECA is located at a center of symmetry. There are two diisopropylammonium cations and one CH_3CN solvent molecule per half an anion. One of the cations, N(1), makes two hydrogen bonds with O(1) and O(9) and links the anions along the *a*-axis. Another cation, N(2), has two hydrogen bonds with O(6) and the CH_3CN molecule. The distances of the hydrogen bonds are listed in Table 6. Figure 3 shows the crystal structure of RED1 viwed along the b-axis.

The decatungstate anion in RED1 also lies at a center of symmetry. Two cations and four water molecules take part in the three-dimensional hydrogen network; N(1) makes two hydrogen bonds with O(8) and O(W1), and N(2) has two bonds with O(9) and O(W3). Each water molecule has three or four hydrogen bonds with the anions and cations and with other water molecules.

Figure 4 shows the crystal structure of RED2 viewed along the b-axis. The decatungstate anion is at the position of symmetry 2/*m*.

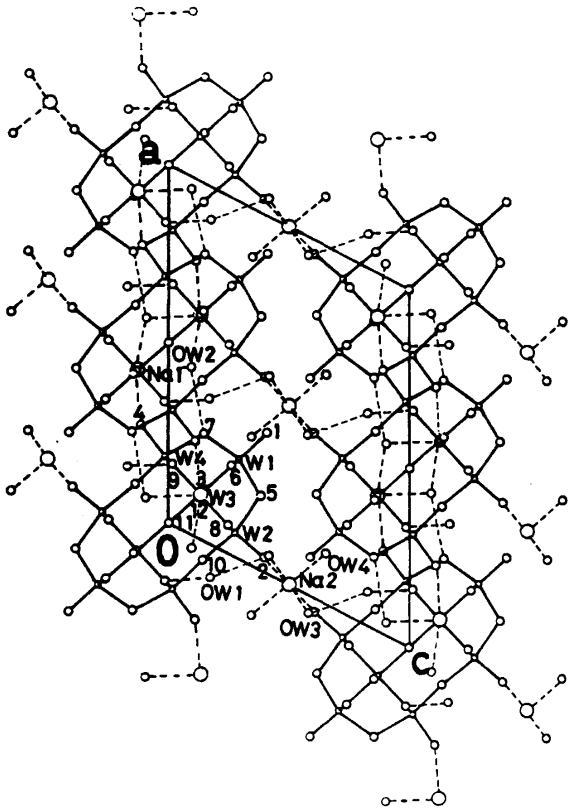

Fig. 4. The crystal structure of RED2 viewed along the b axis. Interactions among the oxygen atoms of the polyanions, water molecules and Na are shown with broken lines.

The Na(1) cation interacts with O(3), O(4), and O(W2). The two Na(1) cations are bridged by the two O(W2) atoms and they make a tetragon. This tetragon unit connects the anion along the a- and b-axes. The Na(2) cation has octahedral interaction with O(2), O(W3), and O(W4). The two Na(2) cations are also bridged by two O(2) atoms of the neighboring anions. These octahedral units are stacked and make a column along the b-axis. This column connects the anions along the b- and c-axes. The intermolecular distances are given in Table 6.

Discussion

The structure of the decatungstate anion is not obviously changed by two-electron photoreduction. Electrochemical six-electron reduction of metatungstate $[H_2W_{12}O_{40}]^{6-}$ yields dark-brown crystals and the structural frame of the metatungstate anion is retained during the reduction.[4] However, the W-O bond distances are obviously changed by a six-electron reduction: each of the tungsten atoms in the WO_6 octahedra of a certain W_3O_{13} group is positioned with a shifting to a cavity center of the anion, resulting in a longer bond length between terminal oxygen and tungsten atoms compared to these of the WO_6 sites of other W_3O_{13} groups. Such a structural distortion induced by the six-electron reduction has been explained by a localization of six electrons within the specific edge-shared W_3O_{13} group of the metatungstate frame which consists of four W_3O_{13} groups with corner-shared bonding.

The photoreduced decatungstates of RED1 and RED2 consist of a mixture of protonated one- and two-electron reduced species, since flash photolysis of $[(C_4H_9)_4N]_4[W_{10}O_{32}]$ in CH_3CN, revealed that $[W_{10}O_{32}]^{5-}$ is produced by electron transfer from $[(C_4H_9)_4N]^+$ to $[W_{10}O_{32}]^{4-}$ and that upon protonation $[HW_{10}O_{32}]^{4-}$ (with $pK_a \approx 3.7$ in CH_3CN-H_2O of 9:1 v/v) suffers from the disproportionation to a protonated two-electron reduced species, $[H_2W_{10}O_{32}]^{4-}$, as summarized by Eqs. 1—3:[13,14]

$$[W_{10}O_{32}]^{4-} + [(C_4H_9)_4N]^+ \xrightarrow{h\nu} [W_{10}O_{32}]^{5-} + [N(C_4H_9)_3\cdot]^+ + H^+ + \text{1-butene}, \quad (1)$$

$$[W_{10}O_{32}]^{5-} + H^+ \rightleftarrows [HW_{10}O_{32}]^{4-}, \quad (2)$$

and

$$2[HW_{10}O_{32}]^{4-} \rightarrow [H_2W_{10}O_{32}]^{4-} + [W_{10}O_{32}]^{4-}. \quad (3)$$

Furthermore, it has been reported that the paramagnetic electron in the photoreduced decatungstate solid is delocalized over the anion by a large extent, compared with the six-electron reduced metatungstate.[2] The large degree of the electron-delocalization results in a decrease in the structural distortion due to a decrease in the formal electron density on a single WO_6 octahedron, leading to no obvious difference of the anion frame between the oxidized and photoreduced decatungstates (up to two-electron reduction). An X-ray structural analysis of the photoreduced decatungstates reveals the presence of four $[((CH_3)_2CH)_2NH_2]^+$ or Na^+ cations per decatungstate anion. This provides the compositions $(C_6H_{16}N)_4[H_xW_{10}O_{32}]\cdot 8H_2O$ and $Na_4[H_xW_{10}O_{32}]\cdot 14H_2O$. In conjunction with the result of the W^V analysis, in order to maintain electrical neutrality, therefore, the photoreduced species can be formulated as $(C_6H_{16}N)_4[H_{1.5}W_{10}O_{32}]\cdot 8H_2O$ and $Na_4[H_{1.8}W_{10}O_{32}]\cdot 14H_2O$, respectively. It must be recalled that the structure of $[(C_2H_5)_3NH]_3(H_3O)[Mo_8O_{26}]$ revealed the presence of one oxonium in addition to three $[(C_2H_5)_3NH]^+$, as cations.[15] The crystals of complexes of RED1 and RED2 incorporate several water molecules to form a complicated hydrogen-bonding network among the anions and water molecules. This enabled us to deduce the presence of aquahydrogen cations in the crystal; from the fact that the oxidized decatungstate has no water molecule in the crystal, it is inferred that the photoreduction of the decatungstates accompanies the incorporation of aquahydrogen cations for a conpensation of excess charges injected into the anion.

Equilibrium Studies on the Species Formed in the Extraction of Divalent Transition Metal Ions with 8-Quinolinethiol and Its 2-Methyl Derivative

Akio YUCHI,* Kiminari SUGIURA, Hiroko WADA, and Genkichi NAKAGAWA
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received March 25, 1987)

The equilibria were studied in the extraction of divalent transition metal ions (M^{2+}: Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}) with 8-quinolinethiol(Hqt) and its 2-methyl derivative (Hmqt). Precipitates form in the Cd-Hqt and Cu-Hmqt systems. In other systems except the Co-Hqt, ML_2(L^-: qt^- or mqt^-) is responsible for the extraction. Effects of anions and solvents were examined in the Zn-Hqt system. The $Ni(qt)_2$, $Ni(mqt)_2$, and $Co(mqt)_2$ complexes hold the capacity to form the adduct with 1,10-phenanthroline. A mixture of diamagnetic Co(III) complexes is extracted in the Co-Hqt system. The main species was assigned as *mer(S)*-$Co(qt)_3$ by the ^{13}C NMR spectrum. The structures of other complexes are also discussed.

8-Quinolinethiol(Hqt), the sulfur-containing analogue of 8-quinolinol(Hq), has been used as a reagent having a preference for soft metal ions.[1] Several equilibrium studies on this reagent have been published.[2-9] The bis chelate, $M(qt)_2$ was assigned to the extracted species for common divalent transition metal ions (M^{2+}: Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}), whereas $Co(qt)_2(Hqt)$ or $Co(qt)_2(Hqt)_2$ to that for Co^{2+}.[5,9] The cobalt complex prepared, on the other hand, was characterized as $Co(qt)_2$ by IR and mass spectrometry,[10,11] or as $Co(qt)_3$ by polarography.[12]

Recently, we have made a systematic study on the extraction of divalent transition metal ions with 8-quinolinol.[13] Remarkable effects of solvents and anions (X^-) on the extraction were found, and were reasonably ascribed to the change in the contribution of three extracted species, $M_2q_3(Hq)_3X$, $Mq_2(Hq)$, and $M_2q_4(Hq)_2$.

In this work, we likewise studied the extraction equilibria of divalent transition metal ions with 8-quinolinethiol and its 2-methyl derivative (Hmqt) in detail. Complexes corresponding to the extracted species were prepared and their physicochemical properties as well as their capacities to form the adduct with 1,10-phenanthroline (phen) were investigated. Their structures are discussed through comparisons with the 8-quinolinol complexes.

Experimental

Reagents. 8-Quinolinethiol and its 2-methyl derivative were prepared as described in the literature,[14] and were stored as their disulfides or sodium salts.[15] Solutions of the thiols in organic solvents were prepared by extraction after the reduction of disulfides with phosphinic acid and neutralization with ammonia under a nitrogen atmosphere.

Metal(II) solutions were prepared from the sulfates and standardized against a Na_2H_2edta solution. Sodium perchlorate was recrystallized twice. Organic solvents were shaken, successively, three times with concd sulfuric acid, 4 mol dm^{-3} potassium hydroxide solution and distilled water.

Preparation of the Metal Complexes. The complexes of transition metal ions (Co, Ni, Cu, Zn, Cd) with Hqt and Hmqt were prepared by the reaction of a metal ion with a sodium salt of the thiols at the molar ratio of 1:2 in an aqueous solution. After being collected and washed with ethanol, these complexes were recrystallized from chloroform or benzene. The Cd-Hqt complex was not recrystallized because it is insoluble in common organic solvents. The precipitates obtained in the Co-Hqt and Cu-Hmqt systems were mixtures of chloroform-soluble and -insoluble species.

Determination of the metal content after decomposition of the complex with hydrogen peroxide and sulfuric acid showed the metal : ligand ratio of 1 : 2 except for the Co-Hqt and Cu-Hmqt complexes.[16] Chloroform-insoluble species in the Cu-Hmqt system has the ratio close to 1 : 1 (results for the Co-Hqt complexes are described below). Infrared spectra of Hqt complexes were in good agreement with those reported previously.[10]

Procedure. All the solutions used for the extraction were purged for 30 min with nitrogen gas. Details of the distribution measurement were the same as described previously.[13,17] A 1×10^{-4} mol dm^{-3} metal solution of the ionic strength 0.1 was shaken with an equal volume of an organic solvent containing 7.5×10^{-4} to 6.0×10^{-3} mol dm^{-3} thiol at 250 strokes min^{-1}. After phase separation, $-\log[H^+]$ higher than 2 was measured with a Radiometer pH METER 26. A solution containing 1.00×10^{-2} mol dm^{-3} perchloric acid and 9.00×10^{-2} mol dm^{-3} sodium perchlorate was used as a $-\log[H^+]$ standard. Below $-\log[H^+]$ 2, the analytical concentration of hydrogen ion was used as $-\log[H^+]$. Change in the activity coefficient is not so serious in the $-\log[H^+]$ range used.[18] Visible absorption spectra of the organic phase were recorded on a Union spectrophotometer SM-401 with a quartz cell of 10 mm. All the measurements were carried out with a thermoelectric circulating bath at 25±0.5 °C.

The adduct-formation constants were spectrophotometrically determined by adding various amounts of 1,10-phenanthroline to the complex solution (1×10^{-4} mol dm^{-3}) in the presence of excess ligand.

^{13}C NMR spectra were recorded on a Varian XL-200 Fourier transform spectrophotometer at a frequency of 50.3 MHz. The magnetic moment was measured by Faraday method with a torsion balance. JASCO chromatographic system MULTI-320 with a silica-ODS column was used for the separation of cobalt complexes.

Results and Discussion

Protonation Equilibria of 8-Quinolinethiolates. Protonation equilibria given by Eqs. 1 and 2 were spectrophotometrically studied (L^-: qt^- or mqt^-).

$$L^- + H^+ \overset{K_1}{\rightleftharpoons} HL \quad (1)$$

$$HL + H^+ \overset{K_2}{\rightleftharpoons} H_2L^+ \quad (2)$$

The protonation constants obtained and those in the literatures are as follows: log K_1=8.20 (8.38,[3] 8.36,[19] 8.39[20]) for Hqt and 9.03 (9.06[3]) for Hmqt, log K_2=2.08 (2.16,[3] 2.05[20]) for Hqt and 2.28 (2.28[3]) for Hmqt.

Partition of 8-Quinolinethiols. Distribution equilibria of 8-quinolinethiols between water and some organic solvents were studied at $-\log[H^+]$ around 5. The distribution constants obtained are as follows: K_D=325 (324[21]) for Hqt into chloroform, 166 (160[21]) for Hqt into benzene, 128 for Hqt into chlorobenzene, 353 for Hmqt into chloroform.

In neutral aqueous solutions, these thiols exist in both the molecular and the zwitter-ionic forms, which are related by

$$(\text{molecular}) \overset{K_t}{\rightleftharpoons} (\text{zwitter-ionic}), \quad (3)$$

where K_t is the tautomeric constant. The constants have been estimated for a series of substituted 8-quinolinethiols;[22] for example, $10^{1.43}$ for Hqt and $10^{1.79}$ for Hmqt. In nonpolar solvents, on the other hand, the equilibrium is shifted far to the left side, irrespective of the substituent. Thiols with tautomerism are expected to be distributed less into nonpolar solvents by a factor of $(1+K_t)$.

In a homologous series of organic extractants such as carboxylic acids and alkylamines, values of logK_D increase with increasing the carbon number. The increment of logK_D for an added methylene group, $\Delta\log K_D/CH_2$, ranges from 0.56 to 0.64.[23] The difference in logK_D between 8-quinolinol and its 2-methyl derivative is 0.64. The enhancement in partition must also operate on the molecular form of Hmqt, but may be compensated by the tautomeric effect. Thus, the K_D values for 8-quinolinethiol and its 2-methyl derivative do not differ so much (0.04 in logarithmic unit).

Extraction Time and Absorption Spectra of Extracted Species. Preliminary experiments showed the precipitate formation in the extraction systems of Cd-Hqt and Cu-Hmqt. In the other systems, approximate time required for equilibration was studied by measuring the absorbance of the organic phase during the extraction (Table 1). In the Ni-Hmqt system, the spectral change was very complicated. At $-\log[H^+]$ 4, the species with an absorption maximum at 472 nm, which agreed with that of $Ni(mqt)_2$ prepared, was first extracted within a day. It changed to the other species with a maximum at 390 nm over several days. At lower $-\log[H^+]$, the latter species was directly extracted in a shorter period. These reactions could not be identified at this stage. The slow extraction in the Ni-Hqt system is just expected from inert character of Ni^{2+}. The Co-Hqt system took an abnormally long time for equilibration in spite of labile character of Co^{2+}, which was actually exemplified by the Co-Hmqt system. In the other systems, equilibria were reached relatively fast. Shaking longer than 5 days caused the decrease in the absorbance together with the formation of precipitates, which did not contain metal ions. Quinolinethiols are supposed to be slowly decomposed under these conditions.

Spectral characteristics of the extracted species are summarized in Table 1. Absorption maxima of any system lie at longer wavelengths than those of 1:1 complexes, which have been previously reported.[2,3] Molar absorption coefficients range from 6000 to 9000, whereas that of the species in the Co-Hqt system is definitely large.

Treatment of Extraction Equilibria. Distribution

Table 1. Extraction of Divalent Transition Metal Ions with Hqt and Hmqt at 25 °C

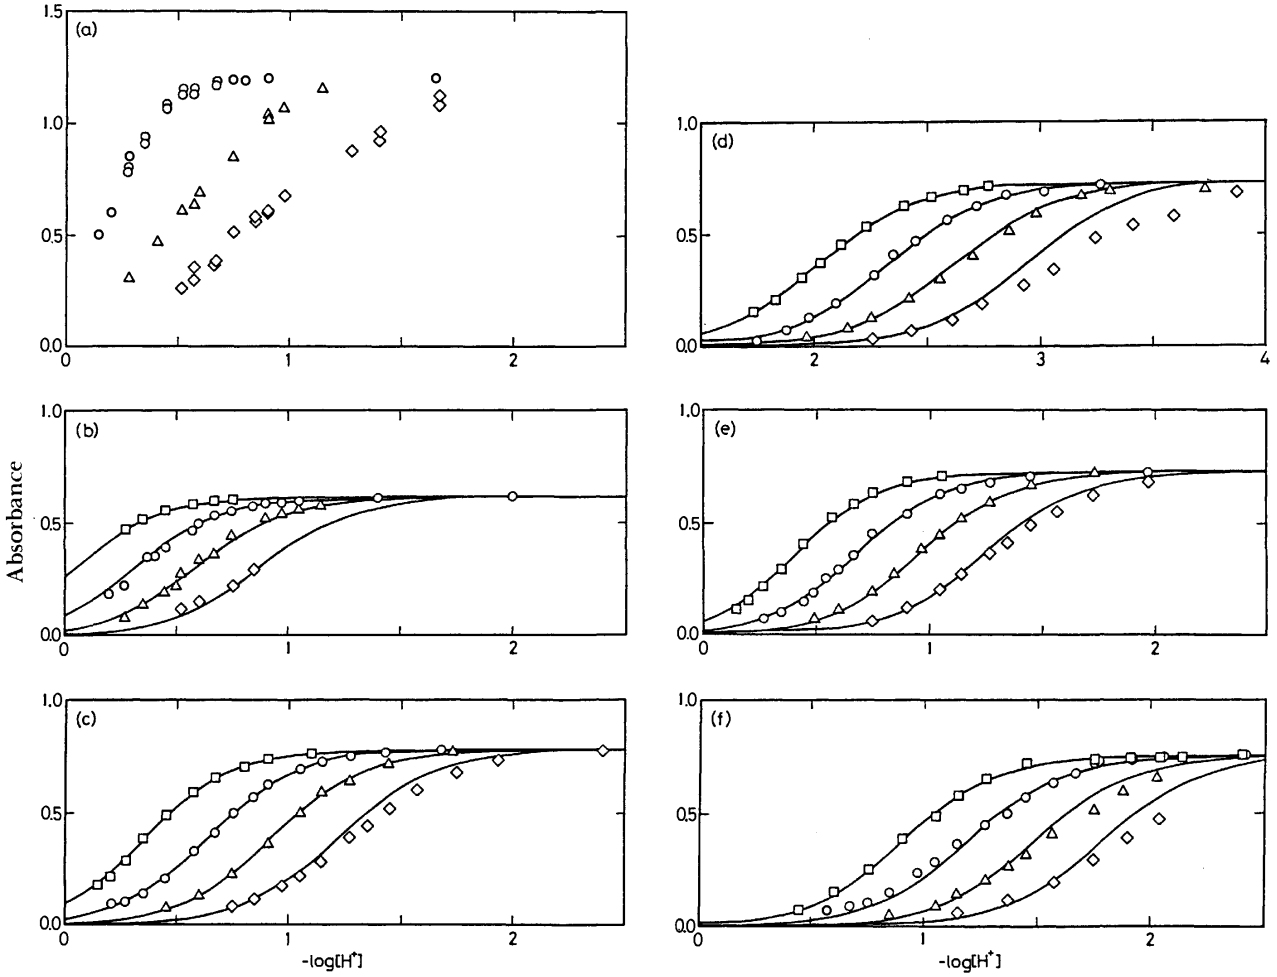

Fig. 1. Plot of absorbance vs. $-\log[H^+]$. Aqueous phase: $C_M=1\times10^{-4}$ mol dm^{-3}; 0.1 mol dm^{-3} $NaClO_4$. Organic phase: chloroform. C_{Hqt} or $C_{Hmqt}/10^{-3}$ mol dm^{-3}: (□) 6.0; (○) 3.0; (△) 1.5; (◇) 0.75. System, wavelength/nm: (a) Co^{2+}-Hqt, 467; (b) Ni^{2+}-Hqt, 537; (c) Zn^{2+}-Hqt, 403; (d) Co^{2+}-Hmqt, 454; (e) Zn^{2+}-Hmqt, 403; (f) Cd^{2+}-Hmqt, 410. Solid lines: calculated curves with constants in Table 1.

data were collected under various conditions in each system. Some of the results were shown as absorbance vs. $-\log[H^+]$ diagrams in Fig. 1.

With these extracting reagents, metal ions start to be extracted at low $-\log[H^+]$. As the concentration of H_2qt^+ or H_2mqt^+ in the aqueous phase is not negligible in this $-\log[H^+]$ range, the prominent equilibrium treatment assuming a general species $(M_jL_{2j}(HL)_m)_o$ could not be applied.[24] The composition of the solid complex prepared under the same conditions is taken into account, and the extracted species is assumed to be a neutral j-meric complex of the composition M_jL_{2j},[13]

$$jM^{2+}+2j(HL)_o \overset{K_{ex}}{\rightleftharpoons} (M_jL_{2j})_o+2jH^+, \quad (4)$$

where K_{ex} represents the extraction constant. The total concentration of metal(II) in the organic phase, $C_{M,o}$ is expressed as a logarithmic form by

$$\log C_{M,o}=j(\log C_{M,w}-2\log[H^+]+2\log[HL]_o)+\log jK_{ex}, \quad (5)$$

where $[HL]_o$ is calculated from the total concentration of the extracting reagent, C_{HL}, as follows:

$$[HL]_o=K_D\cdot C_{HL}/(K_D+1+[H^+]/K_2). \quad (6)$$

If the j-meric species is responsible for the extraction, the plot of $\log C_{M,o}$ vs. $(\log C_{M,w}-2\log[H^+]+2\log[HL]_o)$ would yield a straight line of slope j.

The results are shown in Fig. 2. Only a simple monomeric species, ML_2 is extracted except for the Co-Hqt system.

$$M^{2+}+2(HL)_o \rightleftharpoons (ML_2)_o+2H^+ \quad (7)$$

The extraction constants obtained are summarized in Table 1 together with literature values, which have been recalculated with the K_1 and K_D values used in the paper.[5]

Effects of Anions, Organic Solvents, and Central Metal Ions. In the extraction of divalent transition metal ions with 8-quinolinol, $M_2q_3(Hq)_3X$, $Mq_2(Hq)$, and $M_2q_4(Hq)_2$ are responsible for the extraction.[13] In the systems containing a hydrophobic anion and a polar solvent, metal ions start to be extracted at lower $-\log[H^+]$ because of the larger contribution of

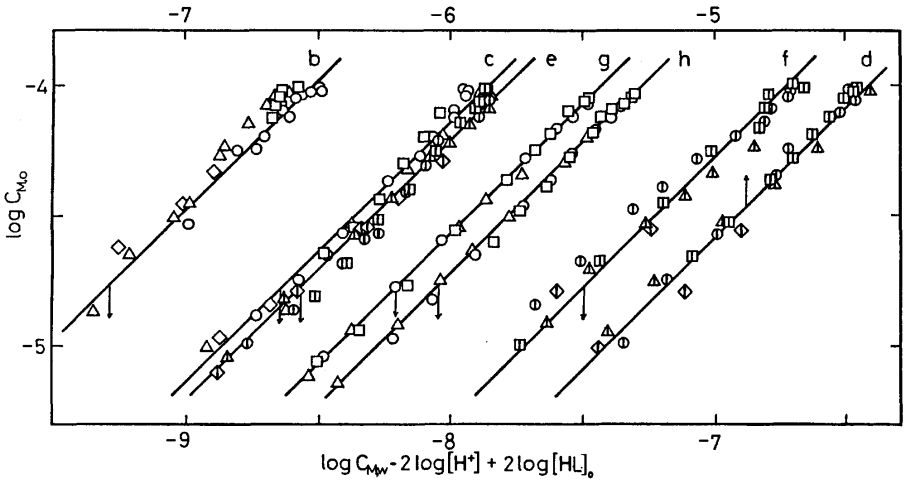

Fig. 2. Determination of the polymerization degree of metal(II) 8-quinolinethiolate according to Eq. 5. System: (b)—(f) same with Fig. 1; (g) Zn^{2+}-ClO_4^--Hqt-chlorobenzene; (h) Zn^{2+}-SO_4^{2-}-Hqt-chloroform. Solid lines: straight lines with a slope of unity.

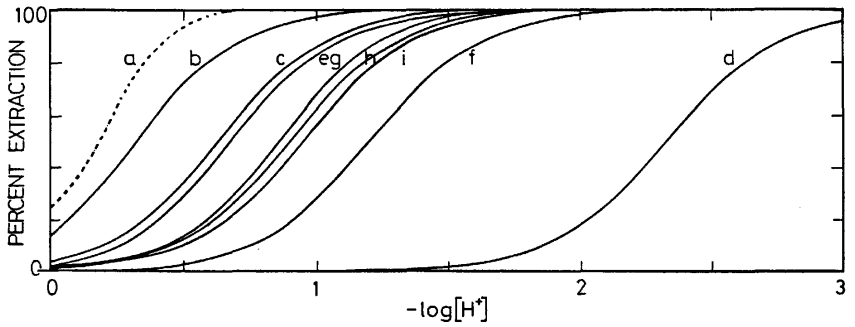

Fig. 3. Extraction curve for various systems. C_{Hqt} or C_{Hmqt}= 3.0×10^{-3} mol dm^{-3}. System: (a)—(h) same with Fig. 1 and 2; (i) Zn^{2+}-ClO_4^--Hqt-benzene. Curve (a) does not show the equilibrated state (see text for details).

$M_2q_3(Hq)_3X$. In the extraction with 8-quinolinethiol, on the other hand, the extraction curves do not change so much by solvents and anions (Fig. 3). This agrees with that only the neutral species $M(qt)_2$ is found as an extracted species.

Zinc ion has a stronger interaction with sulfate than with perchlorate in aqueous solutions.

$$Zn^{2+} + SO_4^{2-} \overset{K}{\rightleftharpoons} ZnSO_4 \qquad (8)$$

The constant, K at the ionic strength of 0.1 is estimated to be $10^{1.6}$ from the constant at infinite dilution ($10^{2.4}$) and the activity coefficient for divalent ions ($10^{-0.4}$). The side reaction coefficient of zinc with sulfate, $\alpha=1+K[SO_4^{2-}]$, is $10^{0.4}$, which is comparable to the difference in the extraction constant ($10^{0.56}$) between perchlorate and sulfate media.

The extraction constant for the Ni-Hqt system is larger than the literature value by 1.1 in logarithmic unit.[5] Care must be taken of slow equilibration in this system.

The data obtained in the Co-Hqt system (Fig. 1(a)) are not those expected for the equilibria expressed by Eq. 4. Moreover, species once extracted into chloroform could hardly be back-extracted. These, together with some findings mentioned above, indicate the formation of Co(III) complexes. This type of oxidation was suggested when abnormally large enthalpy change was found for the formation of the 1 : 1 complex with Hqt in 50v/v% aqueous dioxane.[4]

Adduct Formation. The complex solution (1×10^{-4} mol dm^{-3}) in chloroform was mixed with various amounts of 1,10-phenanthroline (4×10^{-5}—4×10^{-1} mol dm^{-3}) in the presence of excess thiol (3—6×10^{-3} mol dm^{-3}). Spectral change having isosbestic points was found with an absorption maximum shifted from 537 to 432 for $Ni(qt)_2$, and from 472 to 425 nm for $Ni(mqt)_2$. The $Co(mqt)_2$ complex also gave indication of the same reaction. This is ascribed to the formation of the 1 : 1 adduct,[25,26]

$$ML_2 + phen \overset{K_{add}}{\rightleftharpoons} ML_2(phen), \qquad (9)$$

where K_{add} denotes the adduct formation constant. From the absorbance change shown in Fig. 4, this constant was determined by the conventional method:

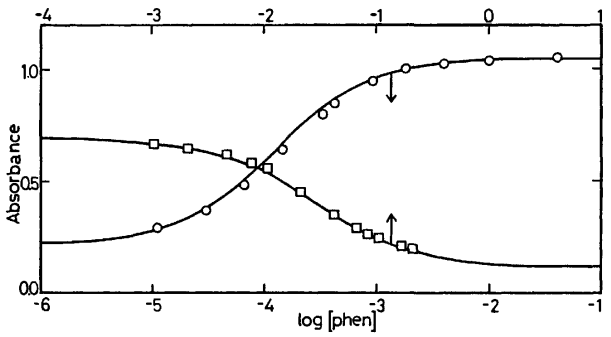

Fig. 4. Plot of absorbance vs. log[phen]. $C_{complex}$= 1×10^{-4} mol dm^{-3}; C_{Hqt} or C_{Hmqt}=3–6×10^{-3} mol dm^{-3}. Complex, wavelength/nm: (○) $Ni(qt)_2$, 432; (□) $Ni(mqt)_2$, 480. Solid lines: calculated curves with constants obtained.

Table 2. Analytical Data for the Co-Hqt Complexes Prepared under Various Conditions

Compound	Found (%)				
	Co	C	H	N	Cl
Prepared in aqueous ClO_4^- medium	9.47	53.5	3.0	6.7	6.0
Prepared in ethanol	10.66	55.0	3.1	7.8	
Extracted from SO_4^{2-} medium into benzene	10.70	60.3	3.2	7.6	
Calculated for $Co(qt)_2$	15.53	56.98	3.19	7.39	
Calculated for $Co(qt)_3$	10.92	60.10	3.37	7.79	

$\log K_{add}$=3.92 (3.97)[25] for $Ni(qt)_2$, 1.55 for $Ni(mqt)_2$, and <0 for $Co(mqt)_2$. On the other hand, no change was observed for $Cu(qt)_2$, $Zn(mqt)_2$, and $Cd(mqt)_2$ as well as $Zn(qt)_2$.[6,27] Some effects of phen on the extraction of Co^{2+} with Hqt have been reported,[26] but the Co-Hqt complex prepared does not show any spectral change. The Cd-Hqt and Cu-Hmqt complexes prepared are insoluble in chloroform. In the presence of phen, however, the adducts of these complexes are extracted without precipitate formation (see below).

Structures of Co-Hqt and Co-Hmqt Complexes. Analytical data for the Co-Hqt complexes prepared in aqueous perchlorate and ethanolic media are shown in Table 2. Neither gave a definite composition. Especially, the complex obtained from perchlorate medium contained chlorine, and consisted of at least 4 species as shown by chromatogram in Fig. 5(a). Since this mixture is diamagnetic in contrast to the Co-Hmqt, the cobalt in these complexes is oxidized to Co(III).

The extracts from a sulfate medium into benzene, on the other hand, had a composition close to $Co(qt)_3$. Although two geometrical isomers are possible for $Co(qt)_3$, only one species was practically found in chromatogram of Fig. 5(b). The ^{13}C NMR spectrum of this species given by Fig. 6 showed very complicated resonances (more than 19). Thus the complex is assigned as the *mer*(*S*) isomer, because only nine signals are expected for the *fac*(*S*) geometry.[28]

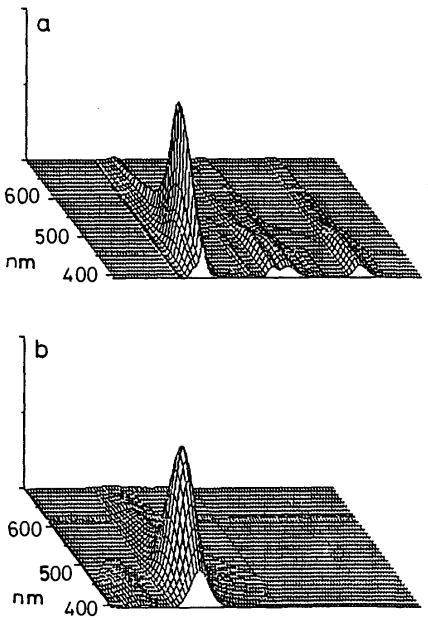

Fig. 5. Chromatograms of Co-Hqt complexes. (a) Complex prepared in perchlorate medium. (b) Complex extracted from sulfate medium into benzene. Column: CIG pre-packed column CPO-042-10 (200 mm×4-mm i.d.). Mobile phase: methanol-water (80:20 v/v).

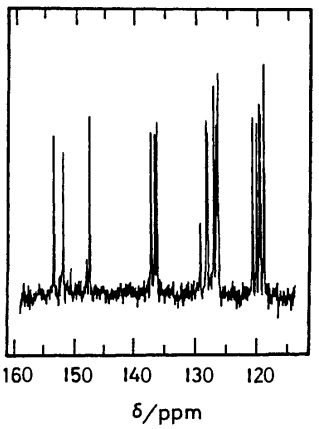

Fig. 6. ^{13}C NMR spectrum of $Co(qt)_3$ in $CDCl_3$ containing TMS as an internal standard.

The Co-Hmqt complex, on the other hand, is a simple 1 : 2 complex and is expected to have tetrahedral configuration judged from the magnetic moment (4.9 B.M.). The methyl group adjacent to the donor atom sometimes shows striking effect on the properties of the complex. In this case, steric hindrance in the formation of the tris chelate suppresses the oxidation of cobalt.

Structures of Other Complexes. The structure of $Cu(qt)_2$, which has the same composition with copper 8-quinolinolate, Cuq_2, was determined to be square-planar in solution by ESR spectra,[29,30] and in solid by X-ray crystallography.[31] This structure is stable and even phen cannot change the configuration to

octahedron. On the other hand, the Cu-Hmqt prepared, which is insoluble in organic solvents, has a metal : ligand ratio close to 1 : 1 and is expected to be a copper(I) complex. Coordinated water molecules, which are identified by the IR spectrum, can be replaced by phen to make the complex soluble in organic solvents. The 2-methyl substituent makes the planar structure unfavorable and increases the reducibility of the copper complex.

With 8-quinolinol, zinc is precipitated as $Znq_2 \cdot 2H_2O$ and is extracted as $Znq_2(Hq)$ or $Znq_2(phen)$. With thiols, on the other hand, $Zn(qt)_2$ or $Zn(mqt)_2$ is precipitated or extracted, and neither thiol nor phen can change the configuration to octahedron. By the change of the donor atom from O to S, tetrahedral structure is relatively stabilized for zinc. Since the 2-methyl group does not hinder the coordination of the second mqt^- with this configuration, $Zn(qt)_2$ and $Zn(mqt)_2$ have similar characteristics.

The structure of $Cd(mqt)_2$ was determined to be tetrahedral by X-ray crystallography.[32] Although $Cd(qt)_2$ prepared also has a metal : ligand ratio of 1 : 2 without coordinated waters, the behavior is fairly different from those of $Zn(qt)_2$ and $Cd(mqt)_2$; for example, $Zn(qt)_2$ has a solubility of 4.8×10^{-2} mol dm^{-3} in chloroform, whereas $Cd(qt)_2$ is insoluble but is solubilized in the presence of phen. Since cadmium ion has a larger ionic radius than zinc ion, $Cd(qt)_2$ may change the configuration to octahedron.

From the magnetic susceptibility measurements, $Ni(qt)_2$ (3.32 B.M.) was estimated to have a polymeric square planar structure,[33] whereas $Ni(mqt)_2$ (3.14 B.M.) a distorted tetrahedron.[34] These structures were confirmed by X-ray crystallographic studies.[35,36] In solution, on the other hand, a monomeric planar structure was proposed for $Ni(qt)_2$ from a kinetic study on its reaction with alkyl halide,[37] and from the equilibrium study on the adduct formation reaction.[25] $Ni(mqt)_2$ differs from $Ni(qt)_2$ in the absorption spectra and in the solubilities in chloroform,[34] and is believed to have the same structure in solution with that in the solid.

The planar $Ni(qt)_2$ keeps some capacity to be coordinated. A configurational change does not occur with weak ligands such as water as found in the precipitation of $Niq_2 \cdot 2H_2O$, but it does occur with stronger ligands such as phen. The 2-methyl substituent hinders the structural change to octahedron to make K_{add} of $Ni(mqt)_2$ small.

The authors wish to express their thanks to Dr. Tetsuo Asaji of Nagoya University for the measurement of magnetic susceptibility.

(Received May 22, 1987)

Ammonium *cyclo*-hexaphosphate 1.5-hydrate $(NH_4)_6P_6O_{18} \cdot 1.5H_2O$ was prepared. Under conditions similar to those in the thermal analysis (TG-DTA), the hydrate was heated in an electric furnace. The atmospheres used then were streams of humid air, dried air and dry ammonia gas. The products were characterized by the X-ray diffraction method and by HPLC-flow injection analysis (HPLC-FIA). The thermal decomposition of anhydrous ammonium *cyclo*-tetraphosphate $(NH_4)_4P_4O_{12}$ was also investigated. From each ammonium *cyclo*-phosphate, very analogous ammonium polyphosphate was produced. Its formation was considered to result from the polymerization of some lower-condenced phosphate radicals, which were generated on the cleavage of the ring anions of the *cyclo*-phosphates. The radicals incorporated water molecules in the atmosphere, which causes less formation of the ammonium polyphosphate and exhibited a TG gain and an exothermal DTA break. The exotherm could be attributed theoretically to the incorporation in case of the *cyclo*-tetraphosphate. Moreover, the release of ammonia from the starting material was supposed to be a trigger for the cleavage of the ring anions.

The ammonium *cyclo*-tri- and *cyclo*-tetraphosphates have been studied in regard to several properties by many authors.[1-10] Especially Coates and Woodard summarized the preparations, stability, and X-ray diffraction data of ammonium lower-condenced phosphates containing ammonium *cyclo*-tetraphosphate, but the thermal stability of the *cyclo*-tetraphosphate was mentioned a little.[10] As with the *cyclo*-tetraphosphate, the thermal stability of the ammonium salt of *cyclo*-hexaphosphate with a twelve-membered ring anion has not been reported. Therefore, it seemed that it would be of interest to obtain detailed informations on the thermal stability of the ammonium salt of these *cyclo*-phosphates.

The purpose of the present work was to study the thermal decomposition of ammonium *cyclo*-hexaphosphate, mainly in connection with the effect of humidity in the atmosphere; its preparation was established. In addition, by comparison with that of the *cyclo*-hexaphosphate, the pyrolysis of ammonium *cyclo*-tetraphosphate was investigated more closely.

Experimental

Chemicals, and Analyses of Phosphorus and Nitrogen. Chemicals: Unless otherwise stated, guaranteed-grade reagents were used without further purification.

Analyses of Phosphorus and Nitrogen: With a HPLC-flow injection system, the total phosphorus was determined colorimetrically. The nitrogen content was obtained by means of an ammonia-distillation method.

X-Ray Diffraction Analysis. The X-ray powder diffraction patterns were measured with a Rigaku Denki diffractometer, using nickel-filtered Cu $K\alpha$ radiation.

Thermal Analysis. The thermal analyses (TG-DTA) were carried out at the rate of 2.5° min^{-1} by means of a Rigaku 8002 SD Thermal Analyser. The measurements were performed in stationary air or in a stream of dry N_2 gas at a rate of 100 $cm^3 min^{-1}$, which did not influence the temperatures assigned to DTA breaks. If required, an atmosphere of stationary N_2 gas was also used. It was attained by the evacuation of the furnace of the TG-DTA device, followed by the introduction of dry N_2 gas. This procedure was repeated three times.

HPLC-Flow Injection Analysis (HPLC-FIA). A JASCO TRIROTER V Liquid Chromatograph was used. The system was equipped with two injection ports called "loop-valve sampler." One loop-valve sampler, placed ahead of a column, is used for the separation and determination of phosphates. The other, for the total phosphorus analysis, is situated after the column. A polystyrene-based anion exchanger (TSK gel SAX, d_p=10 μm, Toyo Soda) was packed in the column.

The eluent was flowed through at 1.0 $cm^3 min^{-1}$. It was prepared from appropriate concentrations of an aq. potassium chloride soln. and an aq. 0.1% (w/v) EDTA-4Na soln. The Mo(V)-Mo(VI) reagent for the colorimetric analysis was the 10-fold-diluted aq. solution of the reagent prepared by Lucena-Conde and Prat.[11] At a flow rate of 0.8 $cm^3 min^{-1}$ it was introduced continuously into the stream of the effluent. Then the mixed solution was heated up to 140 °C by passing it through 10 m of 2.0×0.5 mm (O.D.×I.D.) PTFE tubing in an oil bath. The heteropoly blue thus formed was measured at 830 nm in a flow cell.

Thirty-mg portions of a sample were dissolved in water and diluted to 25 cm^3. When they were dissolved inadequately or not, 1—4 cm^3 of 10% (w/w) sodium chloride aq. soln. was then added. A two-cm^3 portion of this solution was transferred into a 50-cm^3 volumetric flask to be diluted. One hundred-μl portions of it were then analyzed.

When this solution contained many polyphosphates and/or their chain length became longer, the above-mentioned technique of analyzing the solution was not enough to produce the heteropoly blue completely. Consequently, the amount of the polyphosphates was estimated at less than the true value. To prevent this, a 2-cm^3 portion of 2-mol dm^{-3} hydrochloric acid was added to a 10-cm^3 portion of the preceding HPLC-FIA sample solution, and they were mixed well. It was allowed to stand at 70 °C for 1 h, cooled to room temperature, and then neutralized with ca. 2 cm^3 of

2-mol dm^{-3} sodium hydroxide aq. soln. This solution was subsequently diluted 5-fold and then injected into the loop-valve sampler located after the column in order to determine its total phosphorus content. The amount of the polyphosphates was calculated by subtracting the amount of phosphorus of all the phosphates (except for the polyphosphates) from the total phosphorus content.

Preparation of Ammonium *cyclo*-Hexa- and Ammonium *cyclo*-Tetraphosphates. Ammonium *cyclo*-Hexaphosphate $(NH_4)_6P_6O_{18} \cdot 1.5H_2O$: Ammonium *cyclo*-hexaphosphate could be prepared from sodium *cyclo*-hexaphosphate $Na_6P_6O_{18} \cdot 6H_2O$ by means of a cation exchanger. $Na_6P_6O_{18} \cdot 6H_2O$ was obtained in a way similar to the method reported by Griffith and Buxton.[12] A cation-exchange procedure was performed in accordance with the work by Coates and Woodard.[10]

The *cyclo*-hexaphosphate anion was contained at least 98.5% as phosphorus in the product. The impurities were mainly highly-condensed phosphates. The X-ray powder diffraction pattern did not agree with that of ammonium *cyclo*-hexaphosphate monohydrate prepared by Vol'fkovich et al.[13] (Table 1). Analyses of phosphorus and nitrogen: P, 30.55; N, 13.87%. The water content could be calculated based on the phosphorus value, as the molar ratio of phosphorus to nitrogen was 1.00:1.00. The formula was $(NH_4)_6P_6O_{18} \cdot 1.5H_2O$. Yield: about 11 g for 15 g of $Na_6P_6O_{18} \cdot 6H_2O$.

Ammonium *cyclo*-Tetraphosphate $(NH_4)_4P_4O_{12}$: Anhydrous ammonium *cyclo*-tetraphosphate was prepared by means of a cation-exchange method similar to that used for the *cyclo*-hexaphosphate. Sodium *cyclo*-tetraphosphate tetrahydrate[14] was used as the starting material. The ammonium *cyclo*-tetraphosphate was identified X-ray diffractometrically.[10]

Thermal-Decomposition Processes. The ammonium *cyclo*-phosphate (0.2 g) was spread on a porcelain boat in a layer less than 1 mm thick, so as to get the desired atmosphere instantly. The boat was placed in a quartz tube, which had been set in a cylindrical electric furnace (I.D.×L: 35×350 mm) beforehand. The sample was heated at the same rate (2.5° min^{-1}) as in the TG-DTA measurements. As soon as it reached at the required temperature, it was taken out and cooled to room temperature in a desiccator.

The humidity of the air entering at 50 cm^3 min^{-1} into the quartz tube was controlled by means of a Heatless Air Drier HF 200-9-30 (Nippon Pure Gas Co., Ltd.) or an Ace Constant-humidity Generator Model AHC-1 (Ace Scientific Laboratory Co., Ltd.). The amounts of water vapor in the quartz tube were nearly 0 and 1.04 mg per minute respectively. These two atmospheres should be considered to show the effect of humidity on the thermal decomposition more obviously than in the corresponding TG-DTA measurements. In addition, a stream of NH_3 gas (purity: 99.9%) was also used by introducing it directly from the cylinder at 50 cm^3 min^{-1}.

Results and Discussion

Thermal Decomposition of Ammonium *cyclo*-Hexaphosphate 1.5-Hydrate $(NH_4)_6P_6O_{18} \cdot 1.5H_2O$. The results of the thermal analyses (TG-DTA) of ammonium *cyclo*-hexaphosphate 1.5-hydrate (P_{6m}) in stationary air and in a stream of dry N_2 gas are shown in Fig. 1, (a) and (b) respectively. Three endothermic breaks — at about 180, 195 and around 300 °C—are observed in both atmospheres. Exothermal breaks are shown at 205 °C. As P_{6m} has 1.5 moles of water of crystallization and is considered to bring humidity to the atmosphere on heating, it is supposed that hardly any difference in the DTA curves is recognized. The endothermic break at around 300 °C was apparently attributable to the melting of the product.

In the N_2 gas stream, no increase in weight is found in the temperature range measured, but in the stationary air there is an increase from 195 to 205 °C (Fig. 1, (b) and (a)).

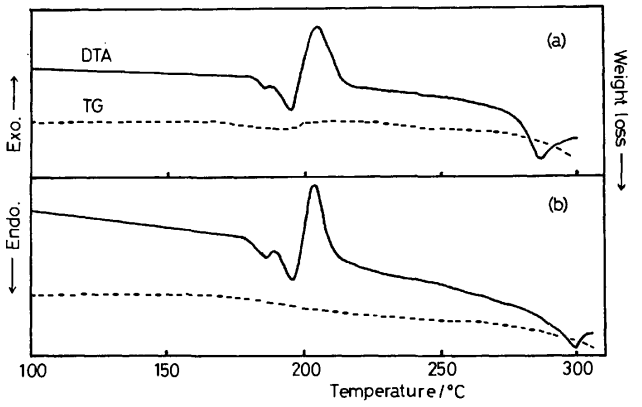

Fig. 1. TG-DTA analyses of ammonium *cyclo*-hexaphosphate in the two different atmospheres. (a): Performed in stationary air, (b): in a stream of N_2 gas.

In order to investigate the decomposition processes causing the DTA breaks in the range from 100 to 215 °C, many studies were carried out with a cylindrical electric furnace. The amount of P_{6m} and polyphosphates in the samples heated up to 100, 150, 180, 195, 205, and 215 °C are illustrated in Fig. 2.

Thilo and Grunze reported that the tetra- and octaphosphates were formed selectively in the course of the thermal decomposition of lithium *cyclo*-tetraphosphate tetrahydrate. They supposed that their formation was attributable to the polymerization of the "radicals," which had been produced thermally.[1] The same paper described that the radicals incorporated water molecules from the atmosphere. As the decomposition of P_{6m} is scarcely affected by the humidity (Fig. 2), the P_{6m} rings do not disappear upon hydrolysis, but decompose to "radicals." The TG-increase from 195 to 205 °C is probably due to the incorporation of water molecules. The polyphosphates form less in the presence of water vapor than in its absence (Fig. 2). Figure 3 shows that the total amount of oligophosphates is larger under the humid condition than under the dried condition. Thus, the incorporation of water molecules inhibits the polymerization of the radicals.

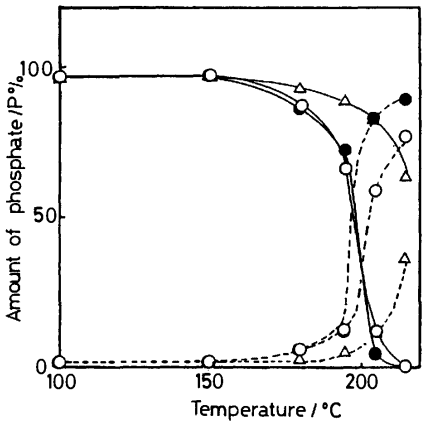

Fig. 2. Amounts of the *cyclo*-hexaphosphate and the polyphosphates in the products heated up to the required temperatures in the three different atmospheres. ——: *cyclo*-Hexaphosphate, ----: polyphosphates, ○: in a stream of humid air, ●: in a stream of dried air, △: in a stream of NH_3 gas.

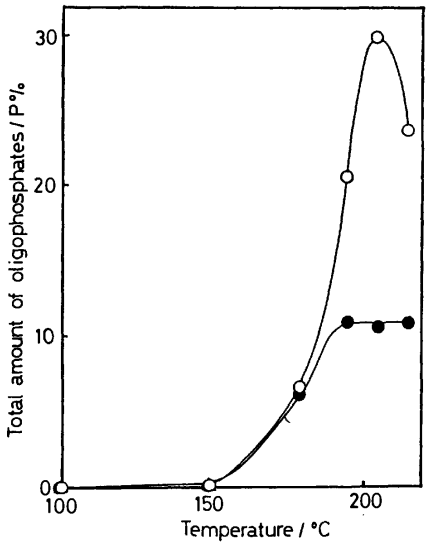

Fig. 3. Total amounts of oligophosphates in the humid and the dried atmospheres. ○: In a stream of humid air, ●: in a stream of dried air.

Among the oligophosphates contained in the samples, di-(P_2) and monophosphate(P_1) were more abundant than the others. This shows that the P_{6m} ring decomposed into three or six parts to produce the P_2 or the P_1 radicals.

At any rate, the endothermic break at 195 °C, regardless of humidity, probably corresponds to the cleavage of the P_{6m} rings. The following exothermal break at 205 °C must be caused by the bonding of the water molecules with the radicals (see the next subsection, for an analogous exothermal reaction is explained there thermodynamically).

In a stream of NH_3 gas, P_{6m} remained more abundantly than in the humid and dried atmospheres (Fig. 2). The departure of ammonia molecules from P_{6m} is thought to be the trigger for the cleavage of P_{6m} to the P_1 and the P_2 radicals.

Thermal Decomposition of Ammonium *cyclo*-Tetraphosphate $(NH_4)_4P_4O_{12}$. Since the ammonium *cyclo*-tetraphosphate (P_{4m}) used was an anhydrous salt, it was expected that the humidity effect on the thermal decomposition would be more obvious than in the case of *cyclo*-hexaphosphate(P_{6m}), which has 1.5 moles of water of crystallization.

Thermal analyses of P_{4m} were carried out in three atmospheres: in stationary air, in a stream of dry N_2 gas, and in stationary dry N_2 gas. Contrary to the case

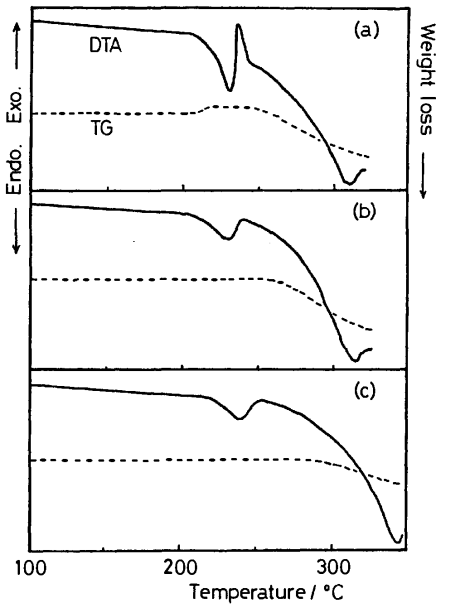

Fig. 4. TG-DTA analyses of ammonium *cyclo*-tetraphosphate in the three different atmospheres. (a): Performed in stationary air, (b): in a stream of N_2 gas, (c): in stationary N_2 gas.

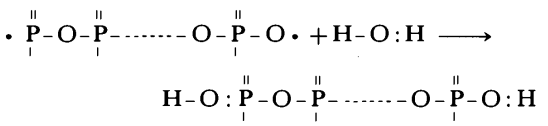
of P_{6m}, the DTA curve in the humid atmosphere has an exothermal break at 238 °C (Fig. 4, (a)), while that in the dried atmosphere has no exotherm (Fig. 4, (b)). These DTA curves show endothermic processes at 233 and 230 °C respectively. On the DTA chart measured in the stationary dry N_2 gas, there is an endothermic break at the rather high temperature of 240 °C (Fig. 4, (c)).

P_{4m} was also heated up to 150, 200, 233, 238, and 244 °C (and sometimes 258 °C as well) in a cylindrical electric furnace. Figure 5 shows that the amount of P_{4m} in the products decreases rapidly between 200 and 238 °C in the humid and dried atmospheres. The decrease is independent of the humidity in the atmosphere. Therefore, the P_{4m} rings are not hydrolyzed.

If the polyphosphates are produced by the condensation of acidic ammonium oligophosphates, the thermogravimetric analysis will show a weight loss. However, in the dried atmosphere, the TG curve indicates no weight change (Fig. 4, (b)), and the amount of the polyphosphates increases rapidly in the range from 200 to 238 °C (Fig. 5). Consequently, the polyphosphates do not arise by the condensation, but are produced by the polymerization of the "radicals" which result from the cleavage of P_{4m}.

Only in the humid atmosphere is there an exothermal break, as is shown in Fig. 4, (a). Corresponding to this exotherm, a TG gain is observed. Therefore the exotherm at 238 °C may be attributed to the binding of the radicals with water molecules. The heat of the formation of the phosphate molecules brought about by the binding of the radicals with water molecules (ΔH; kJ mol^{-1}) can be calculated by means of the following scheme. In this scheme, ΔH should be



obtained by means of this equation; $\Delta H=(\text{O-H})_{H_2O}+[-\{(\text{O-H})+(\text{P-O})\}]\approx-(\text{P-O})$, where $(\text{O-H})_{H_2O}$ is the oxygen-hydrogen bond energy of water molecules, (O-H) is the oxygen-hydrogen bond energy of the phosphates produced, and (P-O) is the phosphorus-oxygen bond energy of the phosphates ca. 359.8 kJ mol^{-1}.[15] Consequently, the heat of the formation of the phosphates (ΔH) is the negative value of −359.8 kJ mol^{-1}. This value accounts for the exothermal reaction at 238 °C very well.

The radicals are considered to combine with water molecules in the atmosphere, so the water molecules can be expected to inhibit the radical polymerization. Practically, indeed, compared with the dried atmosphere, in the humid atmosphere the amount of the polyphosphates was poor, as is indicated in Fig. 5, while the total amount of the oligophosphates was rich.

Figure 6 represents the amount of the individual oligophosphate plotted against its chain length. Under the humid condition, mono-(P_1) and diphosphate (P_2) are present in larger quantities (Fig. 6, (a)). Only P_1 is detected in the dried atmosphere (Fig. 6, (b)). As a trace of water vapor may be found in the dried atmosphere, P_1 is thought to result from the P_1 radicals, trapping of the water molecules. Accordingly, it is concluded that the P_{4m} ring decomposes into four parts, thus producing the P_1 radicals, or perhaps into two parts, thus producing the P_2 radicals, as is revealed by the abundance of P_2 (Fig. 6, (a)). Moreover, the decomposition of the P_{4m} rings seems to cause the endothermic break at about 230 °C.

In a stream of ammonia gas, P_{4m} was very stable in the range from 150 to 244 °C (Fig. 5). The release of ammonia from the starting material of P_{4m}, must be a

"trigger" for the cleavage of the P_{4m} anions, accompanied by the exotherm at about 230 °C. The shift of the exotherm to a higher temperature in the stationary N_2 gas (Fig. 5, (c)) is attributable to an enhanced partial pressure of ammonia by evacuation and may be thought to prove the "trigger reaction."

Characterization of the Polyphosphate. The X-ray diffraction data for the decomposition products of P_{6m} and P_{4m} are indicated in Table 2. The diffraction lines of the respective products are similar to each other, except for those of the starting materials. They also agree closely with the diffraction lines of ammonium polyphosphates reported by Shen et al.[16] and Frazier et al.[17] In addition, we observed that there was always a water-insoluble material, which must be ammonium polyphosphate,[16] in the product of P_{4m} heated above 233 °C.

Syntheses and Characterization of Dinuclear Manganese(II,II) and Manganese(II,III) Complexes with Phenolate and Two Carboxylate Bridges

Masatatsu SUZUKI, Masahiro MIKURIYA,† Shuji MURATA, Akira UEHARA,* Hiroki OSHIO,† Sigeo KIDA,† and Kazuo SAITO†

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
†Coordination Chemistry Laboratories, Institute for Molecular Science, Okazaki 444

(Received May 27, 1987)

Dinuclear manganese(II,II) and (II,III) complexes, $[Mn_2(L\text{-}py)(RCOO)_2]ClO_4 \cdot nH_2O$ and $[Mn_2(L\text{-}py)(RCOO)_2](ClO_4)_2 \cdot nH_2O$, were prepared, where L-py is 2,6-bis[bis(2-pyridylmethyl)aminomethyl]-4-methylphenolate(1−) and RCOO denotes CH_3COO or C_6H_5COO. X-Ray structure analysis of the mixed valence complex $[Mn_2(L\text{-}py)(C_6H_5COO)_2](ClO_4)_2 \cdot H_2O$ revealed that the complex cation involves octahedral manganese(II) and manganese(III) centers with N_3O_3 donor sets and that the two metal ions are linked by phenolato and two benzoato groups. Magnetic susceptibility measurements over temperature range 80—300 K indicated that both manganese(II,II) and (II,III) complexes exhibit weak antiferromagnetic interaction with spin-exchange coupling constant, J=−5—−7 cm^{-1}. Cyclic voltammograms of the mixed valence complexes showed two quasi-reversible redox couples at ca. 0.5 and ca. 1.0 V (vs. SCE), assignable to the redox reactions of Mn^{II}-Mn^{III}/Mn^{II}-Mn^{II} and Mn^{III}-Mn^{III}/Mn^{II}-Mn^{III}, respectively. The comproportionation constants for the reaction $(Mn^{III}\text{-}Mn^{III})+(Mn^{II}\text{-}Mn^{II}) \rightleftarrows 2(Mn^{II}\text{-}Mn^{III})$ at 20 °C were estimated as $2\text{—}3\times10^9$.

It has been pointed out that the manganese ions in the water oxidizing system of photosystem II in green plants are present as dinuclear or tetranulclear cluster, in which the di-, tri-, and/or tetravalent manganese ions are involved in the catalytic cycle of water oxidation.[1,2] Although many efforts have been devoted to understanding the role of the manganese ions operating in the cycle, little is known on the structure of the manganese site and the reaction mechanism of water oxidation.

It has been suggested that a mixed valence dinuclear manganese(II,III) center exists in chloroplasts in the dark.[3,4] For further elucidation of the above manganese site, it is needed to study in more detail the coordination chemistry of dinuclear mixed valence manganese(II,III) complexes with biologically relevant ligands such as 2- or 4-imidazolyl group, carboxylato and phenolato groups, etc. However, only a few suitable model complexes have been devised for this purpose.[5,6]

In the previous paper, we shortly communicated the synthesis and characterization of a mixed valence manganese(II, III) complex $[Mn_2(L\text{-}py)(CH_3COO)_2](ClO_4)_2 \cdot H_2O$, and proposed a dinuclear structure in which manganese(II) and manganese(III) ions are bridged by the phenolato and two acetato groups.[7] Reported herein are syntheses and the physicochemial properties of the dinuclear manganese(II, II) and (II, III) complexes with a dinucleating ligand (L-py) and a carboxylate ion, $[Mn_2(L\text{-}py)(RCOO)_2]ClO_4 \cdot nH_2O$ and $[Mn_2(L\text{-}py)(RCOO)_2](ClO_4)_2 \cdot nH_2O$ (RCOO=CH_3COO or C_6H_5COO), where L-py represents 2,6-bis[bis(2-pyridylmethyl)aminomethyl]-4-methylphenolate(1−) ion. The crystal structure of $[Mn_2(L\text{-}py)(C_6H_5COO)_2](ClO_4)_2 \cdot H_2O$ is also described, which is the first example of a mixed valence manganese(II, III) complex whose structure was determined by X-ray structure analysis.

Experimental

Materials. HL-py was synthesized as previously described.[8] $[Mn(dmso)_6](ClO_4)_3$ was prepared according to the method of literature.[9] The other chemicals were of reagent grade.

Preparation of Manganese(II, II) Complexes. $[Mn_2(L\text{-}py)(CH_3COO)_2]ClO_4 \cdot 0.5H_2O$ (**1a**): A solution of $Mn(CH_3COO)_2 \cdot 4H_2O$ (1 mmol) in 20 cm^3 of methanol was added with stirring to a solution of HL-py (0.5 mmol), triethylamine (1 mmol), and $NaClO_4$ (2 mmol) in 20 cm^3 of methanol. White crystals formed were filtered off, washed with ethanol and ether, and dried in vacuo.

$[Mn_2(L\text{-}py)(C_6H_5COO)_2]ClO_4 \cdot 2H_2O$ (**2a**): A solution of $Mn(ClO_4)_2 \cdot 6H_2O$ (1 mmol) in 20 cm^3 of methanol was added to a methanol solution (20 cm^3) of HL-py (0.5 mmol), C_6H_5COOH (1 mmol), and triethylamine (1.5 mmol) with stirring. White crystals obtained were filtered off, washed with ethanol and ether, and dried in vacuo.

Preparation of Manganese(II, III) Complexes. $[Mn_2(L\text{-}py)(CH_3COO)_2](ClO_4)_2 \cdot H_2O$ (**1b**): A solution of $Mn(CH_3COO)_3 \cdot 2H_2O$ (1 mmol) in 30 cm^3 of methanol was mixed with a solution of HL-py (0.5 mmol) in 20 cm^3 of methanol with stirring. To the resulting solution was added a methanol solution (20 cm^3) of $NaClO_4$ (4 mmol) to give dark green crystals, which were filtered off, washed with ethanol and ether, and dried in vacuo. Recrystallization was carried out from acetonitrile.

$[Mn_2(L\text{-}py)(C_6H_5COO)_2](ClO_4)_2 \cdot H_2O$ (**2b**): A solution of HL-py (0.5 mmol), C_6H_5COOH (1 mmol), and triethylamine (1.5 mmol) in 20 cm^3 of methanol was added to a suspension of $[Mn(dmso)_6](ClO_4)_3$ (1 mmol) in 30 cm^3 of acetone with stirring. The mixture was strirred for 30 min and filtered to remove the unreacted dmso complex. The filtrate was allowed to stand overnight to produce dark green crystals. They were recrystallized from acetonitrile.

Measurements. The electronic spectra in acetonitrile solution were measured on a Jasco UVIDEC 505 UV/VIS recording digital spectrophotometer and a Hitachi 323 recording spectrophotometer.

Infrared spectra were obtained by a KBr-disk method and a nujol mull method with a Jasco A-3 infrared spectrophotometer.

Magnetic susceptibilities were measured with a Shimazu torsion magnetometer MB-2 which was calibrated with $Hg[Co(NCS)_4]$. Diamagnetic correction was made by using Pascal's constants.

Cyclic voltammograms were obtained with a Yanagimoto P-900 in a cell containing a glassy carbon working electrode, a platinum-coil auxiliary electrode, and a saturated calomel electrode as reference electrode. Applied voltage was measured with a Takeda Riken TR-8651 electrometer. Acetonitrile was used as the solvent and tetrabutylammonium perchlorate as the supporting electrolyte. Ferrocene was added for an internal check on redox potential and reversibility. $E_{1/2}$ of ferrocene was 0.39 V (vs. SCE) with a peak-to-peak separation (ΔE) of 70 mV. For constant-potential electrolyses, Hokuto Denko HA-301 potentiostat/galvanostat was used to control the potentials. Current-time curves were recorded with a Rikenn Denshi SP-K1V recorder. Integration of current was carried out by integrating the area under the current vs. time curves. A two compartmental H-type cell with a glass frit containing a platinum gauze working electrode, platinum plate auxiliary electrode, and a saturated caromel electrode was used. For the reduction and oxidation of **1b**, applied potentials were +0.35 and +1.15 V (vs. SCE), respectively.

ESR spectra were measured on a JEOL JES-FE2XG ESR spectrometer (X-band microwave unit, 100 KHz field modulation) equipped with an Air Product LTD-3-110 liquid helium transfer system. The microwave frequency was monitored with a Takeda Riken TR5212 microwave counter, and the resonance magnetic field values of the signals were measured with an NMR field meter (ECHO Electronics Co., Ltd.)

Analyses of Manganese(II) and Manganese(III) Ions. Analysis of manganese(III) ion was carried out by iodometry and by the method described in the literature.[10] Total amount of manganese ion was determined colorimetrically.[11] The results are listed in Table 1.

X-Ray Crystal Structure Analysis of $[Mn_2(L\text{-}py)(C_6H_5COO)_2](ClO_4)_2 \cdot H_2O$. Crystal data: $[Mn_2(C_{33}H_{33}N_6O)(C_6H_5COO)_2](ClO_4)_2 \cdot H_2O$; $F.W.$=1098.69, monoclinic; $P2_1/c$; a=23.979 (4), b=11.357(1), and c=18.502(2) Å; β=97.29(1)°; V=4997.8(12) Å^3; Graphite monochromated Mo$K\alpha$ (λ=0.71073 Å); D_m=1.50, D_c=1.46 g cm^{-3}; Z=4; μ (Mo$K\alpha$)=6.60 cm^{-1}; A dark green crystal with dimensions of 0.10×0.18×0.37 mm.

Data Collection and Processing: The unit-cell parameters and intensities were measured on a Rigaku AFC-5 automated four-circle diffractometer by the 2θ-ω scan technique with a scan rate of 3° min^{-1}. A total of 9543 reflections with $2\theta < 50°$ was collected. Three standard reflections were monitored every 50 reflections. The intensities of two standard reflections showed a good stability, although one reflection underwent a significant decay: the intensities decreased to ca. 35% of initial intensity at the end of measurement. All attempts to obtain better single crystals were in vain, because the crystals were very fragile and not suitable for measurement. Therefore we used the above intensity data for analysis without correction for the intensity decay. The intensity data were corrected for the Lorentz-polarization effects and for absorption. Independent 3590 reflections with $|F_o| > 3\sigma(|F_o|)$ were considered as "observed" and were used for the structure analysis.

The structure was solved by the direct method. Refinement was carried out by the block-diagonal least-squares method. Oxygen atom of water molecule was found to be statistically distributed at two positions with occupancy factor of 0.5. All the non-hydrogen atoms were refined with isotropic thermal parameters. Hydrogen atoms were not included in the calculation. The weighting scheme $w=[\sigma^2_{count}+(0.015|F_o|)^2]^{-1}$ was employed. The final discrepancy factors were $R=\sum||F_o|-|F_c||/\sum|F_o|=0.116$ and $R_w=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}=0.118$.

The atomic scattering factors and the anomalous dispersion corrections, $\Delta f'$ and $\Delta f''$, for Mn, Cl, O, N, and C, were taken from the International Tables for X-Ray Crystallography.[12] All the calculations were carried out on the HITAC M-680H computer at the Computer Center of the Institute for Molecular Science by the use of the UNICS-III,[13] MULTAN 78,[14] and ORTEP[15] programs. The final positional and thermal parameters of non-hydrogen atoms with their estimated standard deviations are given in Table 2. Observed and Calculated structure factors have been deposited as a Document No. 8773 at the office of the Editor.

Results and Discussion

Structure Description of $[Mn_2(L\text{-}py)(C_6H_5COO)_2](ClO_4)_2 \cdot H_2O$. Figure 1 shows a perspective view of the complex cation and the numbering system of

a) Ocuppancy factor of 0.5.

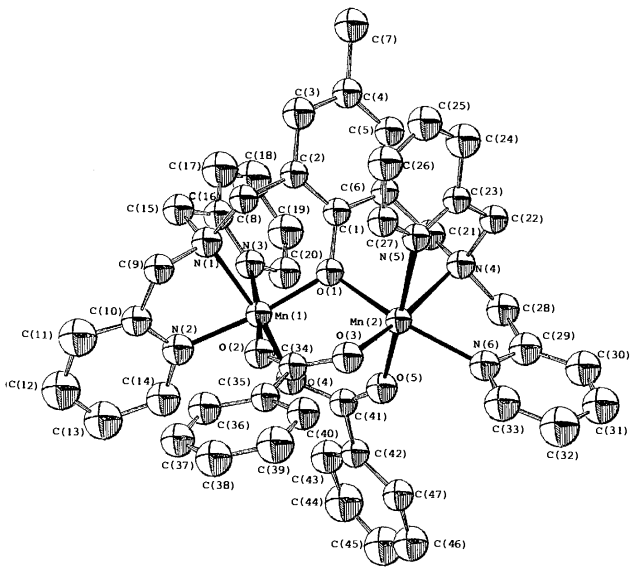

Fig. 1. Crystal structure of the complex cation $[Mn_2(L\text{-}py)(C_6H_5COO)_2]^{2+}$ showing the 50% probability thermal ellipsoids and the atom-labeling scheme.

atoms. The selected bond distances and anlges are listed in Table 3. The crystal structure consists of a discrete dinuclear cation $[Mn_2(L\text{-}py)(C_6H_5COO)_2]^{2+}$, two perchlorate anions, and a water molecule which is statistically distributed to the two positions. Each manganese atom is in a distorted octahedral coordination with a cis,cis-N_3O_3 configuration. The bond distances around the Mn(1) and Mn(2) moieties significantly differ from each other. The bond distances of Mn(1)-O and Mn(1)-N are in the ranges of 1.905(10)—2.147(11) Å and 2.022(14)—2.217(12) Å, respectively, while those of Mn(2)-O and Mn(2)-N are in the ranges of 2.123(11)—2.184(9) Å and 2.224(12)—2.304(13) Å, respectively. The Mn(1)-O and Mn(1)-N distances are comparable to those reported for manganese(III) complexes[16,17] and the Mn(2)-O and Mn(2)-N ones to those reported for manganese(II) complexes.[18] In the Mn(1) moiety, the Mn(1)-O(2) and Mn(1)-N(3) distances are much longer than Mn(1)-O(1), Mn(1)-O(4), Mn(1)-N(1), and Mn(1)-N(2) ones. The O(1), O(4), N(1), and N(2) atoms form an approximate square

plane involving Mn(1) atom at its center. The coordination geometry around Mn(1) is best described as an elongated octahedron, which is attributable to the Jahn-Teller effect of high spin d^4 ion (vide infra). Thus, the molecular structure clearly shows that the present complex consists of manganese(II) and manganese(III) ions whose valence states are firmly trapped.

The intramolecular Mn(1)-Mn(2) distance is 3.484 (3) Å. The manganese atoms are triply bridged by phenolate oxygen and two benzoate oxygens to form a cofacial bioctahedral structure. Such triply bridging structures have been found for some dinuclear manganese and iron complexes with bridging groups composed of two carboxylate and one oxide (hydroxide, or phenolate) ions.[19-22]

Two benzoato groups bridge the manganese atoms in syn-syn configuration. However, the bridging benzoato groups are not equivalent: one symmetrically bridges the manganese atoms, whereas the other does unsymmetrically. The Mn(1)-O(2) (2.147(11) Å) and Mn(2)-O(3) (2.123(11) Å) bonds of symmetrically bridging benzoato group are close to each other in length. However, the Mn(1)-O(4) (1.947(10) Å) and Mn(2)-O(5) (2.162(11) Å) bond lengths of unsymmetrically bridging benzoato group significantly differ from each other.

IR Spectra. The infrared spectrum of **2b** shows one $\nu_{asymm}(COO^-)$ at 1567 cm^{-1} and two $\nu_{symm}(COO^-)$ at 1407 and 1370 cm^{-1} (Fig. 2), indicating the presence of two types of benzoato groups, which is compatible with the result of X-ray structural analysis mentioned above. The $\Delta\nu$ value ($\nu_{asymm}(COO^-)-\nu_{symm}(COO^-)$) is useful for the diagnosis of coordination mode of carboxylato group, i.e., a symmetrically bridging carboxylato group gives $\Delta\nu$ value smaller than 200 cm^{-1}, whereas an unsymmetrically bridging one and monodentate one larger $\Delta\nu$ values.[23] Thus, the larger $\Delta\nu$ (197 cm^{-1}) of **2b** is assigned to that of the unsymmetrically bridging carboxylato group and the smaller value (160 cm^{-1}) to that of the symmetrically bridging one. On the other hand, the dinuclear manganese(II, II) complex **2a** shows one $\nu_{asymm}(COO^-)$ and one $\nu_{symm}(COO^-)$ at 1570 and 1400 cm^{-1} ($\Delta\nu$=170 cm^{-1}), respectively, indicating that the two carboxylato groups are equivalent and symmetrically bridge two manganese(II) ions. The complex **2a** seems to have a triply bridging structure similar to that of **2b**.

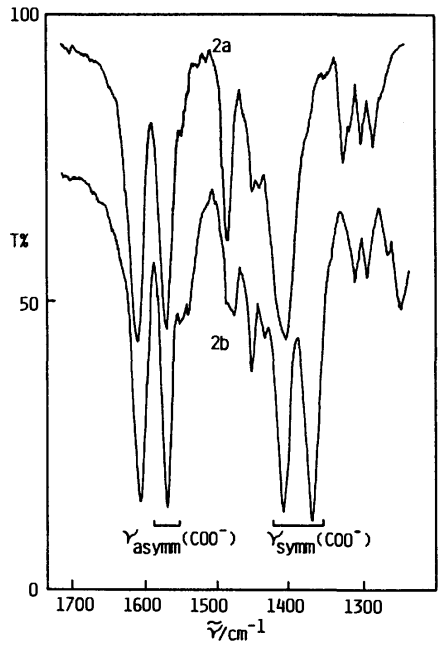

Fig. 2. Infrared spectra of $[Mn_2(L\text{-}py)(C_6H_5COO)_2]ClO_4\cdot 2H_2O$ (**2a**) and $[Mn_2(L\text{-}py)(C_6H_5COO)_2](ClO_4)_2\cdot H_2O$ (**2b**).

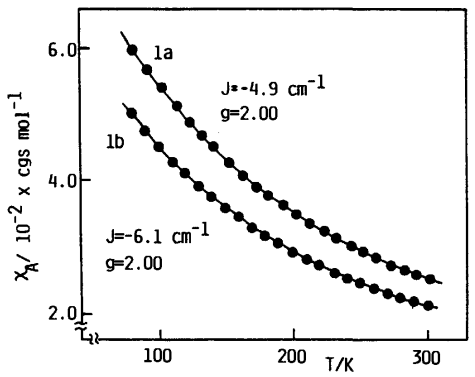

Fig. 3. Temperature dependence of magnetic susceptibilities of $[Mn_2(L\text{-}py)(CH_3COO)_2]ClO_4\cdot 0.5H_2O$ (**1a**) and $[Mn_2(L\text{-}py)(CH_3COO)_2](ClO_4)_2\cdot H_2O$ (**1b**).

Magnetic Susceptibilities. The effective magnetic moments of **1a** and **2a** at room temperature are 7.8 and 7.7 B.M./Mn_2, and those of **1b** and **2b** are 7.1 and 7.1 B.M./Mn_2, respectively, indicating that all the manganese(II) and (III) ions in the above complexes are of high spin. Magnetic susceptibilities of the complexes were measured in the temperature range from 80 to 300 K. The results were analyzed by the usual spin-spin interaction model based on exchange Hamiltonian $H=-2JS_1\cdot S_2$. The molar magnetic susceptibility of (χ_A) of an $S_1=5/2\cdot S_2=5/2$ spin exchange coupling dimer is given in Eq. 1, and that of an $S_1=2\cdot S_2=5/2$ spin exchange coupling dimer by Eq. 2,

$$\chi_A=\frac{2N\beta^2g^2}{\kappa T}\cdot\frac{x^{28}+5x^{24}+14x^{18}+30x^{10}+55}{x^{30}+3x^{28}+5x^{24}+7x^{18}+9x^{10}+11}+N\alpha \quad (1)$$

$$\chi_A=\frac{N\beta^2g^2}{4\kappa T}\cdot\frac{x^{24}+10x^{21}+35x^{16}+84x^{9}+165}{x^{24}+2x^{21}+3x^{16}+4x^{9}+5}+N\alpha \quad (2)$$

where $x=\exp(-J/\kappa T)$ and the symbols have their usual meanings. Figure 3 shows temperature dependence of the magnetic susceptibilities of **1a** and **1b**. The solid lines are the calculated curves by using the paremeters listed in Table 4. Both dinuclear manganese(II, II) and (II, III) complexes exhibit weak antiferromagnetic interaction (J=−4.9—−6.3 cm^{-1}: Table 4). The corresponding dinuclear mixed valence iron(II, III) complexes $[Fe_2(L\text{-}py)(RCOO)_2](BF_4)_2\cdot nH_2O$ and $[Fe_2(L\text{-}py)(CH_3COO)(OH)](BF_4)_2\cdot 2H_2O$ exhibited comparable magnitude of antiferromagnetic interaction (J=−3—−8 cm^{-1}).[24] These results suggest that the triply bridging unit consisting of phenolate and two carboxylate ions provides an weak antiferromagnetic interaction, regardless of the species (Fe or Mn ion) and oxidation state of metal ion.

Electronic Spectra. The aborption spectra of **1a** and **1b** are shown in Fig. 4. The complex **1a** shows no appreciable absorption in the region below 25000

Table 4. Magnetic Parameters of the Complexes

	Complex	J/cm^{-1}	g	Nα/10^{-6} cgs mol^{-1}
1a	$[Mn_2(L\text{-}py)(CH_3COO)_2]ClO_4\cdot 0.5H_2O$	−4.9	2.00	0
2a	$[Mn_2(L\text{-}py)(C_6H_5COO)_2]ClO_4\cdot 2H_2O$	−5.5	2.00	0
1b	$[Mn_2(L\text{-}py)(CH_3COO)_2](ClO_4)_2\cdot H_2O$	−6.1	2.00	0
2b	$[Mn_2(L\text{-}py)(C_6H_5COO)_2](ClO_4)_2\cdot H_2O$	−6.3	2.00	0

		21.6(1180)^s	23.4(1290)^s	25.9(1490)

s: Shoulder.

cm^{-1}, indicating the electronic configuration of manganese(II) ion to be of high spin. The mixed valence complex **1b** exhibits six absorption bands including shoulders in the visible and near ultraviolet regions (Fig. 4 and Table 5). In general, six-coordinated manganese(III) complex displays one or two d-d bands (^5E_g to $^5T_{2g}$ electronic transitions in octahedral symmetry) in these regions.[17,25] The molar extinction coefficients of **1b** and **2b** are 800—1500 mol^{-1} dm^3cm^{-1}, which are considerably larger than those of d-d transitions of manganese(III) complexes. Judging from the numbers of absorption bands and their intensities, all the six bands can not be ascribed to the d-d transitions. Charge transfer transitions from $p\pi$ orbital of bridging phenolato group to half filled $d\pi^*$ orbitals of manganese(III) ion may appear in these regions as was observed for iron(III)-phenolato complexes.[26] It is also possible that intervalence charge transfer transition(IT) from Mn^{II} moiety to Mn^{III} moiety appears in these regions. More detailed assignment is not possible at the present stage.

It should be noted that the present mixed valence complexes exhibit no IT bands in the near infrared region, whereas the iron complexes $[Fe_2(L)(RCOO)_2]^{2+}$ (L=L-py or L-Bzim) (L-Bzim=2,6-bis[bis(2-benzimidazolylmethyl)aminomethyl]-4-methylphenolate-(1−) ion) showed an intense IT band at that region.[24,27] This fact might be due to a smaller extent of electron delocalization in the manganese complexes than that in the iron complexes.

Cyclic Voltammogram. Figure 5 illustrates the cyclic voltammogram of **1b** in acetonitrile at 20 °C. This complex shows two quasi-reversible redox couples at +1.02 and +0.47 V (vs. SCE). Controlled potential electrolysis of the complex **1b** was carried out in order to determine the number of electrons (n) transferred in the above two processes. The oxidation of the complex at +1.15 V and reduction at +0.35 V (vs. SCE) gave n values of 1.1±0.1 and 0.9±0.1, respectively, indicating that those two redox couples correspond to one-electron redox reactions assignable to $E_{1/2}{}^a$ (Mn^{III}-Mn^{III}/Mn^{II}-Mn^{III} (+1.02 V)) and $E_{1/2}{}^b$ (Mn^{II}-Mn^{III}/Mn^{II}-Mn^{II} (+0.47 V)). The complex **2b** also showed a similar cyclic voltammogram (Table 6).

From the separation of the redox potentials, $E_{1/2}{}^a$ and $E_{1/2}{}^b$, comproportionation constant (K at 20 °C) of the following reaction can be calculated by Eq. 3.

$$(Mn^{III}\text{-}Mn^{III})+(Mn^{II}\text{-}Mn^{II}) \rightleftarrows 2(Mn^{III}\text{-}Mn^{II})$$
$$E_{1/2}{}^a - E_{1/2}{}^b = RT/F \ln K \quad (3)$$

The values for **1b** and **2b** are 2.9×10^9 (ΔG=−53 kJ mol^{-1}) and 1.9×10^9 (ΔG=−52 kJ mol^{-1}), respectively, indicating that the mixed valence complexes are considerably stabilized. A dinuclear metal(II, II) complex must be more easily oxidized than a metal(II, III)

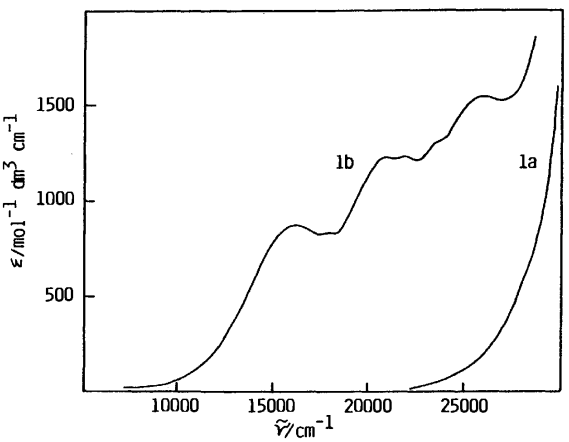

Fig. 4. Electronic spectra of $[Mn_2(L\text{-py})(CH_3COO)_2]$-$ClO_4\cdot0.5H_2O$ (**1a**) and $[Mn_2(L\text{-py})(CH_3COO)_2]$-$(ClO_4)_2\cdot H_2O$ (**1b**) in acetonitrile.

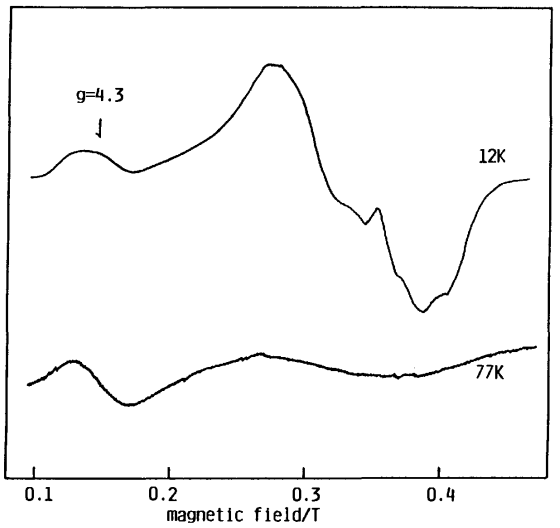

Fig. 6. ESR spectra of $[Mn_2(L\text{-}py)(CH_3COO)_2](ClO_4)_2 \cdot H_2O$ (**1b**) in acetonitrile at 12 and 77 K. Spectral conditions: microwave power, 1 mW at 12 K and 2 mW at 77 K; microwave frequency, 9.036 GHz at 12 K and 9.041 GHz at 77 K; modulation amplitude, 0.25 mT at 12 K and 0.32 mT at 77 K at 100 kHz; receiver gain, 6.5×100 at 12 K and 3×1000 at 77 K.

one from electrostatic point of view. The electrostatic effect seems to be important, but a steric requirement of dinucleating ligand L-py and two bridging carboxylate ions may also play an important role. Actually, the reaction of an equimolar mixture of Fe^{3+} and Mn^{2+} ions with L-py and carboxylate ions afforded a dinuclear heterometal (II, III) complex $[FeMn(L\text{-}py)(RCOO)_2]^{2+}$ with a slight contamination of homometal dinuclear complexes.[28] Thus, the present ligand system provides favorable coordination sites to M^{2+} and M^{3+} ions to form a mixed valence complex in the trapped valence state.

ESR Spectra. The ESR spectra of **1b** in acetonitrile were measured at 12 and 77 K. The spectrum at 12 K shows several resonances (Fig. 6). However, the signals almost disappear at 77K except for a signal at g=4.3. The g=4.3 signal may be ascribed to a distorted octahedral mononuclear manganese(II) complex with D and $E<0.1$ cm^{-1}, and $E/D \approx 1/3$[18] which is present as impurity formed by slight decomposition of the dinuclear complex. Such a temperature dependence of the signals suggests that the signals arise from the spin ground state of S=1/2. Mabad et al.[6] reported that the ESR of antiferromagnetically coupled dinuclear mixed valence manganese(II, III) complex shows a 16-hyperfine line ESR spectrum. As can be seen in Fig. 6, however, the present complexes show only broad signals.[29]

Treatment of Tetraalkoxysilanes with Amberlyst 15 Cation-Exchange Resin in Presence of Hexamethyldisiloxane

Isao HASEGAWA† and Sumio SAKKA*,†
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
†Division of Molecular Engineering, Graduate School of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received June 11, 1987)

Tetraalkoxysilanes were treated with Amberlyst 15 cation-exchange resin in hexamethyldisiloxane at 40 °C in order to substitute the trimethylsilyl group for the alkyl group in a tetraalkoxysilane partially. Tetramethoxy-, ethoxy-, propoxy-, and butoxysilanes were used for the experiments. After the treatment, $SiO_4R_{4-n}X_n$ ($1 \leqq n \leqq 4$, R=CH_3, C_2H_5, n-C_3H_7, and n-C_4H_9, X=$Si(CH_3)_3$) were detected by gas chromatography and were identified by combined gas chromatography-mass spectrometry. The degree of trimethylsilylation of tetraalkoxysilane changed with the molar ratio of hexamethyldisiloxane to tetraalkoxysilane and quantities of the reaction products in the system depended mainly on the ratio.

Tetraalkoxysilanes (TAOS) are promising materials as a source of silica for the synthesis of inorganic or organosilicon compounds. Hydrolysis and polycondensation of TAOS in the system of TAOS-ethanol-H_2O-HCl produce a variety of silicate species, however, even if the amount of added water for the hydrolysis is little.[1] This random polymerization would be caused by the tetra-functionality of TAOS. In other words, all four alkoxyl groups on a silicon atom have the same reactivity, making it difficult to control the reaction of a TAOS. In order to synthesize the compounds with controlled structures in their silicate skeletons from TAOS, it will be necessary to substitute functional groups of low reactivity, such as trimethylsilyl groups (-$Si(CH_3)_3$), for some of the functional groups of TAOS. Trimethylsilylation of silicates, originated by Lentz in 1964,[2] has been developed into several characteristic methods.[3] When the method of Götz and Masson[4] is applied to silicate minerals, such as hemimorphite, trimethylsilyl mono-, di-, and trialkoxy derivatives of silicate anions are formed by the side reaction of esterification of the silanol group with an alcohol used in the trimethylsilylating reagent.[5-8] On the basis of this esterification reaction, Kuroda et al. synthesized silicate-organic copolymer from hemimorphite and ethylene glycol in the reaction mixture for trimethylsilylation.[9] On the other hand, post-treatment with Amberlyst 15 cation-exchange resin in the presence of an excess of hexamethyldisiloxane ($(CH_3)_3Si$-O-$Si(CH_3)_3$) is necessary for the completion of trimethylsilylation. Such treatment would promote the exchange of the residual silanol groups or alcohol-esterified sites in the silicate skeleton with the trimethylsilyl groups, although there might be some other side reactions.[10-12]

It is expected that such partially trimethylsilylated alkoxysilanes might be more readily produced from TAOS as a silica source than silicate minerals. In this study, it is aimed to produce partially trimethylsilylated derivatives from 4 TAOS; tetramethoxy-, ethoxy-, propoxy-, and butoxysilanes (abbreviated to TMOS, TEOS, TPOS and TBOS, respectively) by treatment with Amberlyst 15 in hexamethyldisiloxane (HMDS). The effects of the molar ratio of HMDS to TAOS (abbreviated to the HMDS/TAOS ratio) and the time of the treatment on the distribution of the reaction products were studied by gas-liquid chromatography.

Experimental

Materials. Reagent grade tetramethoxy-, ethoxy-, propoxy-, and butoxysilanes were used. Hexamethyldisiloxane was used after a single distillation (bp 100—101 °C). Amberlyst 15 cation-exchange resin was used after heating in an oven at 80 °C for 4 h and cooling in a desiccator for standardization, as was suggested by Garzó et al.[12]

Preparation of Solutions. The solutions with the HMDS/TAOS ratios from 0.5 to 10.0 were prepared by mixing given amounts of TAOS and HMDS. After stirring for 5 min for homogeneity of the solution, ca. 0.5 g of Amberlyst 15 cation-exchange resin was added to the mixture (20 cm^3) and the vessel was sealed. After keeping standing the vessels in an oven at 40 °C for 85 h, the samples were analyzed by means of gas-liquid chromatography. The effect of the time of treatment was investigated by analyzing the sample with the HMDS/TEOS ratio of 4.0 at various time intervals.

Analytical Procedure. The solutions were analyzed by a Shimadzu GC-12A gas-liquid chromatograph equipped with a hydrogen flame-ionization detector and a CLH-702 split sample injection for capillary gas chromatography. The capillary column (length 25 m, i.d. 0.25 mm) of fused silica cross-linked immovable layer (ULBON HR-101, similar polarity to OV-101) as a stationary phase was used. The injection temperature was 330 °C. The column temperature was programmed to rise at 4 °C min^{-1} from 100 to 330 °C. The carrier gas was nitrogen and its flow rate was 0.34 cm^3 min^{-1} at the split rate of 1 : 104. Standard solutions of the mixed derivatives were not prepared, and so the results of gas-liquid chromatography are expressed in terms of percentages of total peak area. Although it is impossible to elucidate the distribution of the products quantitatively, the main product in the system can be determined from the peak area ratio.

Identification of the peaks on the gas chromatograms was made by conducting combined gas chromatograph-mass spectrometric analyses with a JEOL JMS-DX 300 gas chromatograph-mass spectrometer using an ionizing energy of 70 eV. The ion source block was maintained at 200 °C and the molecular separator at 230 °C. The column consisted of 1 m coiled glass packed with SE-30. The column was oper-

ated isothermally. The carrier gas was He (15 cm^3 min^{-1}).

Results and Discussion

Gas chromatograms of the products obtained by treating the TAOS-HMDS solutions at the HMDS/TAOS ratio of 4.0 with Amberlyst 15 for 85 h in an oven at 40 °C are shown in Fig. 1(a)—(d). Five peaks are seen in each gas chromatogram.

These peaks were identified by a combined gas chromatography-mass spectrometry. It is known from the mass spectra of trimethylsilylated derivatives of silicates[13] that the molecular ion is either of very low abundance or below detection limit and the most structurally informative ion is the one produced by the loss of a methyl radical from the molecular ion, $[M-15]^+$. Moreover, substitution of a trimethylsilyl group for an alkyl group is indicated by the difference in the mass numbers of $[M-15]^+$, in regard to neighboring peaks on the gas chromatogram. This difference corresponds to the difference between $-Si(CH_3)_3$ and $-C_nH_{2n+1}$ (n=1—4), an alkyl group in a TAOS.[5,6] These characteristics of the mass spectra were confirmed on four of the five peaks on the gas chromatogram. The mass number for the molecular ion corresponding to the other peak is that of TAOS used for preparation of the sample. Actually, the retention time of the peak corresponded to that of pure TAOS. Table 1 shows the assignments of peaks in each gas

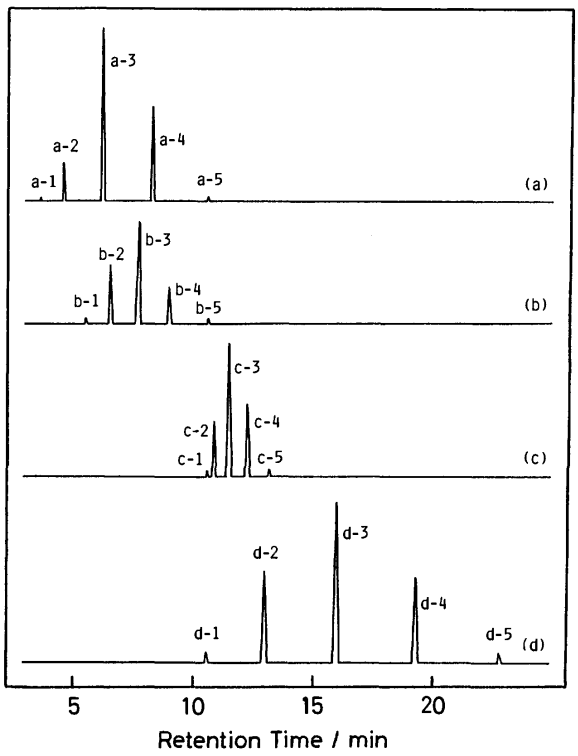

Fig. 1. Gas chromatograms of the products obtained by treating the TAOS-HMDS solutions at the HMDS/TAOS ratio of 4.0 with Amberlyst 15 at 40 °C for 85 h. TAOS: (a) TMOS, (b) TEOS, (c) TPOS, and (d) TBOS.

Table 1. Identification of the Peaks on the Gas Chromatograms in Fig. 1

TAOS	Peak	Formula
TMOS	a-1	$SiO_4(CH_3)_4$
	a-2	$SiO_4(CH_3)_3[Si(CH_3)_3]$
	a-3	$SiO_4(CH_3)_2[Si(CH_3)_3]_2$
	a-4	$SiO_4(CH_3)[Si(CH_3)_3]_3$
	a-5	$SiO_4[Si(CH_3)_3]_4$
TEOS	b-1	$SiO_4(C_2H_5)_4$
	b-2	$SiO_4(C_2H_5)_3[Si(CH_3)_3]$
	b-3	$SiO_4(C_2H_5)_2[Si(CH_3)_3]_2$
	b-4	$SiO_4(C_2H_5)[Si(CH_3)_3]_3$
	b-5	$SiO_4[Si(CH_3)_3]_4$
TPOS	c-1	$SiO_4[Si(CH_3)_3]_4$
	c-2	$SiO_4(C_3H_7)[Si(CH_3)_3]_3$
	c-3	$SiO_4(C_3H_7)_2[Si(CH_3)_3]_2$
	c-4	$SiO_4(C_3H_7)_3[Si(CH_3)_3]$
	c-5	$SiO_4(C_3H_7)_4$
TBOS	d-1	$SiO_4[Si(CH_3)_3]_4$
	d-2	$SiO_4(C_4H_9)[Si(CH_3)_3]_3$
	d-3	$SiO_4(C_4H_9)_2[Si(CH_3)_3]_2$
	d-4	$SiO_4(C_4H_9)_3[Si(CH_3)_3]$
	d-5	$SiO_4(C_4H_9)_4$

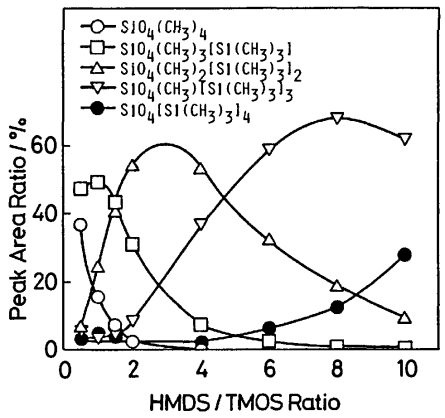

Fig. 2. Effect of the HMDS/TMOS ratio on the peak area ratios of the derivatives from TMOS ($SiO_4(CH_3)_4$) by Amberlyst treatment at 40 °C for 85 h.

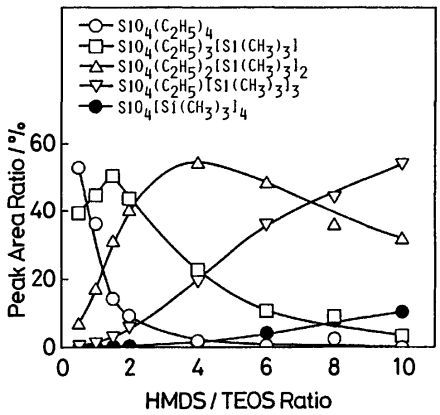

Fig. 3. Effect of the HMDS/TEOS ratio on the peak area ratios of the derivatives from TEOS ($SiO_4(C_2H_5)_4$) by Amberlyst treatment at 40 °C for 85 h.

chromatogram. It is seen that TAOS is partially or fully trimethylsilylated by Amberlyst treatment in HMDS.

Figures 2 and 3 show the effect of the HMDS/TAOS ratio on the distribution of the products in the TMOS- and TEOS- HMDS systems, respectively. The main product of the derivatives from TAOS varies with the HMDS/TAOS ratio, indicating that the degree of trimethylsilylation of TAOS is governed mainly by the HMDS/TAOS ratio. The tendencies of the variations in the distribution of products with the ratio in the TPOS- and TBOS-HMDS systems are almost the same as that in the TEOS-HMDS system. In the TEOS-, TPOS-, and TBOS-HMDS systems, the optimum conditions for partial trimethylsilylation are determined, regardless of the type of alkyl group, as follows; the HMDS/TAOS ratio of 1.5 for monosubstitution, the ratio of 4.0 for disubstitution and the ratio of 10.0 for trisubstitution. In the TMOS-HMDS system, however, the optimum ratios for the substitutions are slightly lower than those noted above.

On the other hand, a few peaks are slightly traced at longer retention time on the gas chromatograms. These peaks appear more clearly at lower HMDS/TAOS ratios or longer treating times. A typical gas chromatogram is shown in Fig. 4. This is the chromatogram for the sample at the HMDS/TEOS ratio of 1.0 treated with Amberlyst 15 for ca. 7 months at room temperature. Around the retention time from 14 to 17 min, three peaks (labeled a, b, and c in Fig. 4) appear, which can not be detected in such large peak areas when treated for 85 h at 40 °C.

In the combined gas chromatograph-mass spectrometric analyses, the peak a is assigned to $Si_2O_5(C_2H_5)_6$, which has the dimeric structure in the silicate skeleton. Also, from the rule on mass spectra of trimethylsilylated derivatives of silicates described above, it is considered that the peaks b and c are identified as $Si_2O_5(C_2H_5)_5[Si(CH_3)_3]$, whose molecular weight is 386 and $[M-15]^+$ is 371 (The mass spectrum of this compound is shown in Fig. 5.), and $Si_2O_5(C_2H_5)_4[Si(CH_3)_3]_2$, whose molecular weight is 430 and $[M-15]^+$ is 415. These compounds are also in the dimeric state of silicate structure. This dimerization might be caused by high TAOS concentrations in low HMDS/TAOS ratios. Moreover, these facts suggest that a long treatment time with Amberlyst 15 is not required for substitution of the trimethylsilyl group for the alkyl group in a TAOS, and makes the reactions between TAOS or partially trimethylsilylated alkoxysilanes proceed.

In order to clarify the effect of treatment time, the variation in the distribution of derivatives from TEOS at the HMDS/TEOS ratio of 4.0 with treatment time at 40 °C was investigated and the result is shown in Fig. 6. The main product at this ratio is $SiO_4(C_2H_5)_2[Si(CH_3)_3]_2$, as shown in Fig. 3. In initial ten hours, the less the degree of trimethylsilylation of the species is, the larger the peak area ratio is. However, $SiO_4(C_2H_5)_2[Si(CH_3)_3]_2$ becomes the main product after 14 h treatment. Although the peak area ratios of $SiO_4(C_2H_5)_3[Si(CH_3)_3]$ and $SiO_4(C_2H_5)[Si(CH_3)_3]_3$ vary further with the time of treatment, that of $SiO_4(C_2H_5)_2[Si(CH_3)_3]_2$ hardly varies on and after 48 h

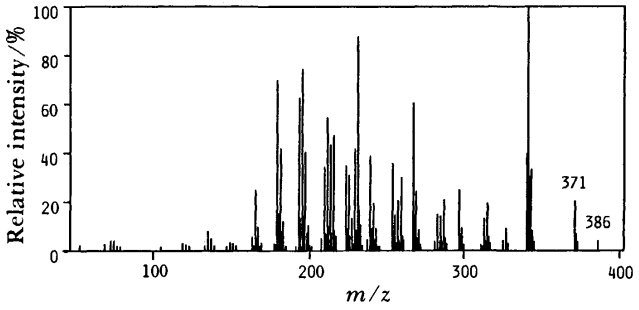

Fig. 5. Mass spectrum of $Si_2O_5(C_2H_5)_5[Si(CH_3)_3]$.

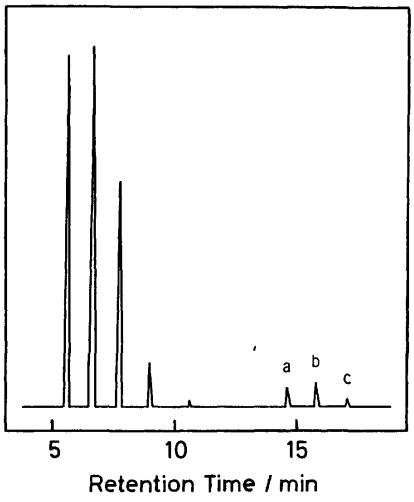

Fig. 4. Gas chromatogram of the TEOS-HMDS solution at the HMDS/TEOS ratio of 1.0 treated with Amberlyst 15 for ca. 7 months at room temperature.

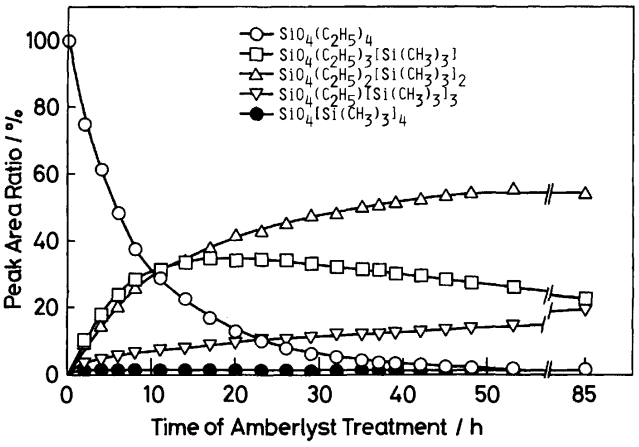

Fig. 6. Effect of the time of Amberlyst treatment on the peak area ratios of the derivatives formed in the TEOS-HMDS solution at the HMDS/TEOS ratio of 4.0 at 40 °C.

treatment at 40 °C. This indicates that the distribution of the derivatives varies with the time of treatment and the equilibrium relating to the formation of $SiO_4(C_2H_5)_2[Si(CH_3)_3]_2$ appears to be established on and after 48 h treatment at 40 °C.

In addition, the peaks at longer retention times on the gas chromatograms are traced in very small peak areas, indicating that the reactions between TEOS or partially trimethylsilylated ethoxysilanes hardly occur and only the substitution occurs in 85 h treatment.

From these results, it is concluded that TAOS is partially or fully trimethylsilylated by treating in HMDS with Amberlyst 15 cation-exchange resin. The degree of trimethylsilylation is governed by the HMDS/TAOS ratio. Within the treatment time of 85 h, reactions between TAOS or between partially trimethylsilylated alkoxysilanes scarcely occur and only substitution by the trimethylsilyl group proceeds. At lower HMDS/TAOS ratios, however, not only the substitution but also the dimerization occurs because of high concentrations of TAOS in the systems.

The present work was supported by a Grant-in-Aid for Scientific Research on Priority Areas, New Functionality Materials-Design, Preparation and Control, The Ministry of Education, Science and Culture, No. 62604011. The authors wish to express their sincere thanks to Dr. Kazuyuki Kuroda at Department of Applied Chemistry, Waseda University for useful discussions. Thanks are also due to Mr. Nakashi Nakamura at Science and Engineering Research Laboratory, Waseda University for measuring mass spectra.

Stereospecific and Nucleophilic Additions of 2- and 3-Thienylmethylene. Reactions of 2- and 3-Thienylmethylene with *cis*- and *trans*-Stilbene, Dimethyl Maleate, Dimethyl Fumarate, and Styrene Derivatives

Katsuhiro SAITO,* Hiraku ISHIHARA, Toyonobu MURASE, Yoichi HORIE, and Etsuro MAEKAWA
Department of Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received February 16, 1987)

The addition reactions of 2-thienylmethylene with *cis*- and *tarns*-stilbene afforded stereospecific adducts, respectively, indicating that the multiplicity of the carbene is singlet. The nucleophilicity of the carbenes was elucidated by an investigation of the relative rate ratio of the reactions of the carbene with various styrenes. An analogous result was afforded by reactions of 3-thienylmethylene with the same olefins mentioned above.

Much attention has been paid to the chemistry of carbenes from the view point of their electronic natures and chemical reactivities.[1] It is known that the reactivities of carbenes are influenced by substituents and especially by conjugation with olefinic groups.[1] However, the number of papers concerning the chemistry of carbenes conjugated with heterocyclic moieties seem to be few.[1,2]

Thiophene (**1**) is known to have an aromaticity due to the contribution of the ionic canonical formula (**1a**).[3] The reactivities of 2-thienylmeythylene (**2**) and 3-thienylmethylene (**3**) are considered to reflect conjugation with a thiophene ring. While Shechter has documented the chemical behaviors of **2** and **3**,[2] nothing is known concerning the addition reactions of these carbenes to olefins. As a part of our research on the reactivity of carbenes,[1] we investigated the addition reactions of **2** and **3** with olefins. Here we wish to report the results of these reactions.

Results and Discussion

The reaction of sodium salt of 2-thiophenecarbaldehyde tosylhydrazone (**4**) and 4 molar equivalents of *trans*-stilbene (**6**) in anhydrous diglyme gave the adduct (**7**) in a 12.1% yield. The same reaction using *cis*-stilbene (**8**) afforded adducts **9** and **10** in 4.4 and 2.2% yields, respectively. The reaction of **4** with dimethyl fumarate (**11**) and dimethyl maleate (**12**) yielded the same adduct **13** in the yields of 41.3 and 36.7%, respectively. Similar reactions of **5** with **6** and **8** gave adducts **14**, **15**, and **16** in the yields of 14.9, 11.3, and 5.5%, respectively. The reactions of **5** with **11** and **12** afforded the same adduct **17** in 38.5 and 31.0% yields, respectively.

The structures of the adducts were deduced on the basis of their spectral properties and were confirmed by comparisons of these spectral properties with those of analogous compounds.[4] The assignment of the structures of **9** and **10** are based on the chemical shifts of the cyclopropane proton H_b. Comparing the chemical shifts of the proton H_b of **9** and **10**, the chemical shift of the proton H_b of **9** should appear at lower field because of the paramagnetic anisotropic effect of the two phenyl groups located in the same side of the cyclopropane moiety as that of the proton H_b. The same consideration is applicable for **15** and **16**.

Reactions of the carbenes **2**, **3** with stilbenes **6**, **8** proceed in a strereospecific manner, indicating that the multiplicity of these carbenes are singlet.[1] On the

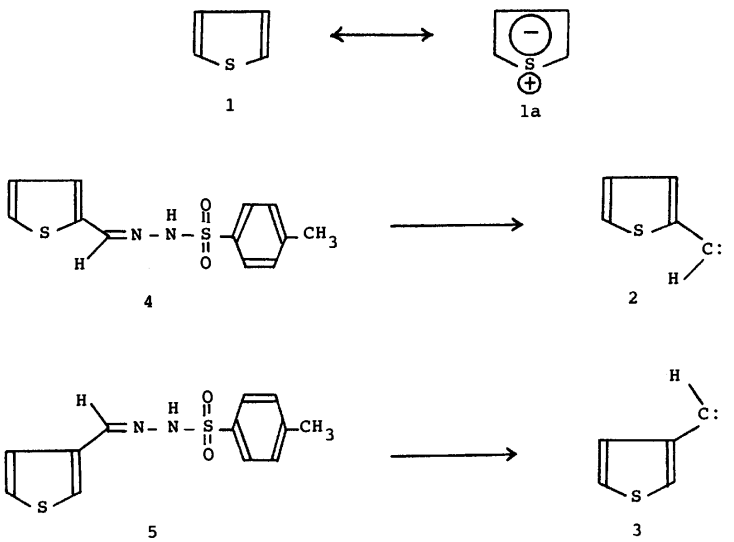

Fig. 1.

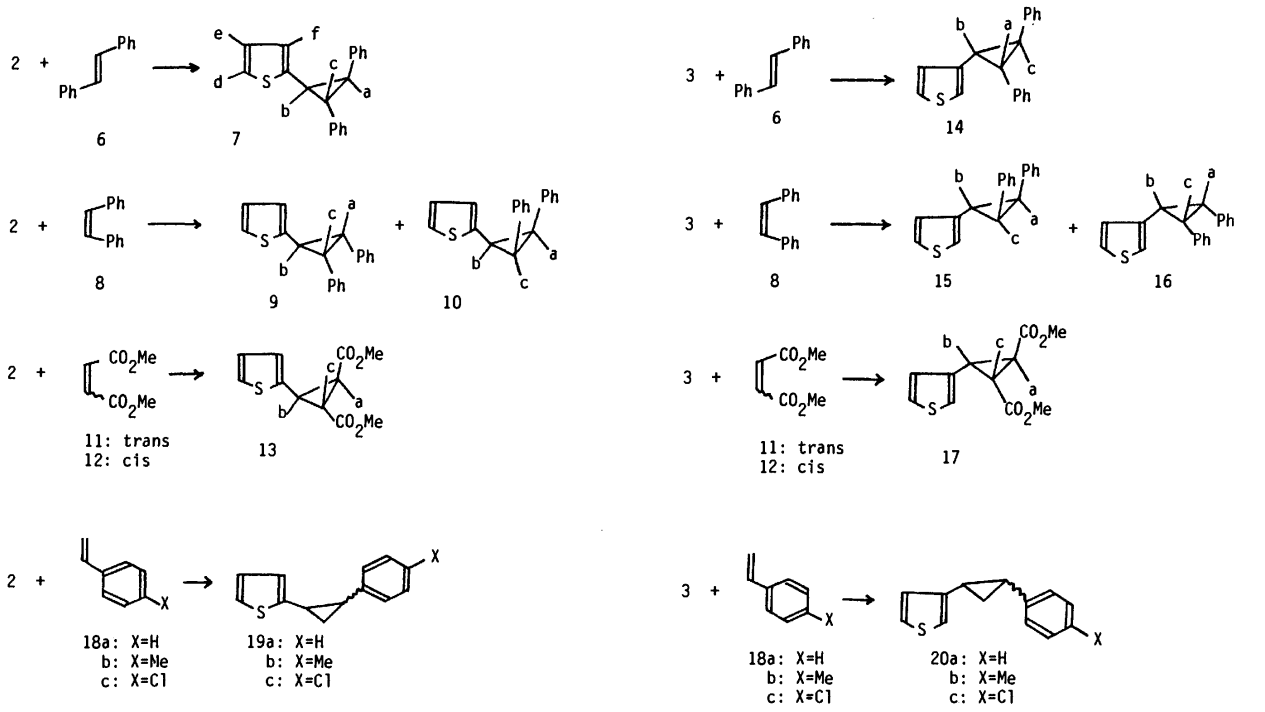

Fig. 2.

other hand, reactions of the carbenes **2**, **3** with the esters **11**, **12** do not seem to be stereospecific additions. It is known, however, that under the reaction conditions **12** isomerizes to **11**,[5] and that the reactivity of **11** to carbenes is higher than that of **12**.[6] Considering the above facts, the loss of stereospecificity of the present reactions is thought to be attributable to the isomerization of **12** to **11**.

There is a considerable difference in the product yields between reactions of the carbenes **2**, **3** with the stilbenes **6**, **8** and the esters **11**, **12**. Considering that the phenyl group of stilbenes is a very week electron-attracting group and, on the other hand, the ester group is a strong electron-attracting group, the above fact is thought to show the nucleophilicity of the carbenes.

In order to confirm the nucleophilicity of the carbenes, substituent effects on the addition reactions were investigated with styrene derivatives **18a**—c. Reactions of **2** with **18** gave the corresponding addition products **19a**—c in yields of 33.2, 38.0, and 48.5%, respectively. Similar reactions of **3** with **18** also afforded adducts **20a**—c in yields of 34.4, 32.7, and 33.0%, respectively. The relative rate ratios of **2** to the substituted styrenes was measured with the addition reactions of **2** to a mixture of **18a** and **18b** and a mixture of **18a** and **18c**[7] and found to be **18b** : **18a** : **18c** is 0.8 : 1.0 : 1.3. The relative rate ratios of **3** to the styrenes was also measured in the same manner to be **18b** : **18a** : **18c** is 0.8 : 1.0 : 1.6. This result is considered to demonstrate the nucleophilicity of **2** and **3**.

The electronic natures of **2** and **3** are considered to be as shown in **21** and **23**, respectively. The carbenic carbons have two carbenic electrons in the sp^2 orbital and leave a vacant 2p orbital, which delocalizes to the π-orbital system of the thienyl group. Consequently, the carbenic carbon atom shares the negative charge on the ring part of the thienyl group while forming a nucleophilic singlet carbenes, as shown in **22** and **24**, respectively.

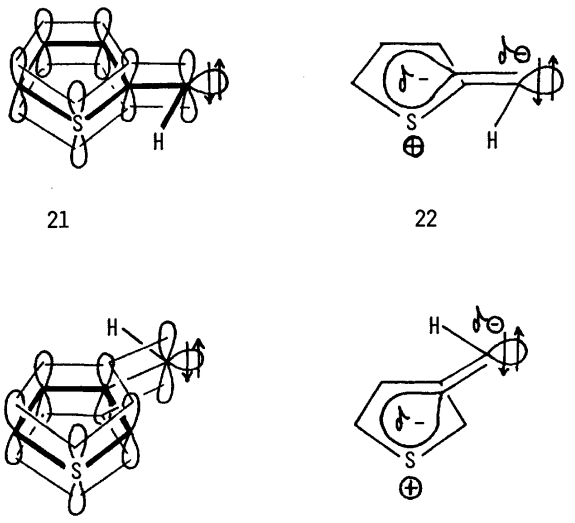

Fig. 3.

Experimental

Melting points were recorded on a Yanagimoto micro melting point apparatus and are uncorrected. NMR spectra were measured with a Varian XL 200 or Hitachi R-20B spec-

trometers with tetramethylsilane as an internal standard. IR sprectra were measured with a DS-701G spectrometer. Mass spectra were measured with a Hitachi M-52 or JMS-DX300 spectrometers. Wako gel C 200 and Wako gel B5F were used for column and thin-layer chromatography, respectively. Diglyme was dried over Molecular Sieves 3A 1/16. In all reactions, quantitative amounts of nitrogen gas and sodium *p*-toluenesulfinate were generated.

Reaction of 2 with 6. To a solution of **4** (2.52 g, 9 mmol) in diglyme (40 ml) was added sodium hydride (230 mg, 9 mmol), and **6** (6.48 g, 36 mmol); the reaction mixture was heated at 105 °C for 10 min to evolve a quantitative amount of nitrogen gas. After separating of a quantitative amount of sodium *p*-toluenesulfinate by filtration, the filtrate was poured into water, extracted with ether, washed with water and dried over anhydrous sodium sulfate. After removing of the solvent on a rotary evaporator, the oily residue was chromatographed on silica gel to give crystals **7** (300 mg, 12.1%) by the use of pet ether-benzene 9 : 1. The crystals were recrystallized from cyclohexane to give pure **7**. **7**: Mp 51—52 °C. Found: C, 82.46; H, 5.79%. Calcd for $C_{19}H_{16}S$: C, 82.60; H, 5.80%. Reaction of 2 with 18b. A mixture of **4** (2.52 g, 9 mmol), sodium hydride (230 mg, 9 mmol), and **18b** (4.25 g, 36 mmol) in diglyme (30 ml) was reacted at 105 °C for 10 min. A thin-layer chromatographic separation of the reaction mixture using pet. ether-ether 9 : 1 as a developing solvent gave **19b** (617 mg, 40.7%, R_f=0.60).

19b: Found: *m/z* 214.0826. Calcd for $C_{14}H_{14}S$: M, 214.0826. MS *m/z* (rel intensity): 214 (M^+, 100), 199 (43), 150 (30). IR (oil): 3100, 3030, 2930, 1520 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.26 (m, 2H), 2.23 (m, 2H), 2.24 (s, 3H), 6.5—7.2 (m, 7H).

Reaction of 2 with 18c. A mixture of **4** (2.52 g, 9 mmol), sodium hydride (230 mg, 9 mmol), and **18c** (4.99 g, 36 mmol) in diglyme (30 ml) was reacted at 105 °C for 10 min. A thin-layer chromatographic separation of the reaction mixture using cyclohexane-ethyl acetate 4 : 1 as a developing solvent gave an oil **19c** (802 mg, 38.1%, R_f=0.60).

19c: Found: *m/z* 234.0251. Calcd for $C_{13}H_{11}SCl$: M, 234.0270. MS *m/z* (rel intensity) 236 (M^+, 45), 234 (M^+, 100), 199 (55), 191 (41). IR (oil): 3080, 2920, 1493 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.30 (m, 2H), 2.18 (m, 2H), 6.4—7.3 (m, 7H).

Relative Rate Ratios of the Reaction of 2 to 18a—c.

Tosylhydrazone (**4**) was reacted with a 1 : 1 mixture of **18a** and **18b** as usual. The integrations of the signals of the cyclopropane carbons of **19a** and **19b** in ^{13}CNMR spectra show that the ratio of **19a** and **19b**, which indicates the relative rate ratios of **2** to **18a** and **18b** to be 1.0 and 0.8, respectively.[7] The same procedure as above using a 1 : 1 mixture of **18a** and **18c** gave the relative rate ratio of the reaction of **2** to **18a** and **18c** to be 1.0 and 1.3, respectively.

Reaction of 3 with 18a. A mixture of **5** (2.52 g, 9 mmol), sodium hydride (230 mg, 9 mmol), and **18a** (3.75 g, 36 mmol) in diglyme (30 ml) was reacted at 140 °C for 30 min. A thin-layer chromatographic separation of the reaction mixture using pet. ether-benzene 4 : 1 as a developing solvent gave **20a** (618 mg, 34.4%, R_f=0.50).

20a: Found: *m/z* 200.0667. Calcd for $C_{13}H_{12}S$: M, 200.0660. MS *m/z* (rel intensity): 200 (M^+, 100), 185 (25), 167 (25). IR (oil): 3030, 2930, 1603, 1500 cm^{-1} ^1H NMR ($CDCl_3$) δ=1.34 (m, 2H), 2.20 (m, 2H), 6.5—7.4 (m, 8H).

Reaction of 3 with 18b. A mixture of **5** (2.52 g, 9 mmol), sodium hydride (230 mg, 9 mmol), and **18b** (4.25 g, 36 mol), in diglyme (30 ml) was reacted at 140 °C for 60 min. A thin-layer chromatographic separation of the reaction mixture using pet. ether-benzene 4 : 1 as a developing solvent gave **20b** (630 mg, 32.7%, R_f=0.57).

20b: Found: *m/z* 214.0798. Calcd for $C_{14}H_{14}S$: M, 214.0817. MS *m/z* (rel intensity) 214 (M^+, 100), 200 (37), 181 (9). IR (oil): 3010, 2920, 1518 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.28 (m, 2H), 2.20 (m, 2H), 2.29 (s, 3H), 6.6—7.2 (m, 7H).

Reaction of 3 with 18c. A mixture of **5** (2.52 g, 9 mol), sodium hydride (230 mg, 9 mmol), and **18c** (4.25 g, 36 mmol) in diglyme (30 ml) was reacted at 140 °C for 60 min. A thin-layer chromatographic separation of the reaction mixture using pet. ether-benzene 4 : 1 as a developing solvent gave **20c** (697 mg, 33.0%, R_f=0.57).

20c: Found: *m/z* 234.0268. Calcd for $C_{13}H_{11}SCl$: M, 214.0270. MS *m/z* (rel intensity) 234 (M^+, 100), 199 (44), 183 (12). IR (oil): 3080, 2920, 1492 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.30 (m, 2H), 2.31 (m, 2H), 6.5—7.2 (m, 7H).

Relative Rate Ratios of the Reaction of 3 to 18a—c. Tosylhydrazone (**5**) was reacted with 1 : 1 mixtures of **18a** and **18b** or **18a** and **18c** as usual. The ratios of products **20a**, **20b**, and **20c** were measured by the same method as that employed in the case of reactions of **4** to be 1.0, 0.8, and 1.6, respectively.

(Received March 27, 1987)

A practical method for the production of D-*p*-hydroxyphenylglycine, useful as a starting material for preparing semisynthetic penicillins or cephalosporins, has been developed. The diastereomeric salts of DL-*p*-hydroxyphenylglycine with (+)-1-phenylethanesulfonic acid as a resolving agent, were efficiently resolved into less soluble D-*p*-hydroxyphenylglycine (+)-1-phenylethanesulfonate [D-HPG·(+)-PES] and soluble L-HPG·(+)-PES by the fractional crystallization of its salts in aqueous solution. The soluble L-HPG·(+)-PES could be easily epimerized into DL-HPG·(+)-PES by heating it with water containing a 0.1 molar equivalent of free DL-HPG in an autoclave. When the fractional crystallization of DL-HPG with (+)-PES was simultaneously carried out under the epimerizing conditions, the DL-HPG·(+)-PES was transformed into D-HPG·(+)-PES in up to 90% yield. The present asymmetric transformation should be a suitable method for preparing D-HPG in a large scale.

It is well-known that D-*p*-hydroxyphenylglycine is useful as a side chain of semisynthetic penicillins or cephalosporins.[1] Thus far, we have presented several methods for the production of D-*p*-hydroxyphenylglycine.[2-5] Our previous paper[5] showed that (+)-1-phenylethanesulfonic acid [(+)-PES] was a favorable resolving agent for the diastereomeric resolution of DL-*p*-hydroxyphenylglycine (DL-HPG) and, for the asymmetric transformation of DL-HPG: a combination of the fractional crystallization of the less soluble D-*p*-hydroxyphenylglycine (+)-1-phenylethanesulfonate [D-HPG·(+)-PES] and the epimerization of the soluble L-*p*-hydroxyphenylglycine (+)-1-phenylethanesulfonate [L-HPG·(+)-PES] in a system. In the previous work, the asymmetric transformation of DL-HPG·(+)-PES was performed in acetic acid in the presence of salicylaldehyde. In the course of our further studies, it has been found that the asymmetric transformation of DL-HPG·(+)-PES could be achieved merely by heating a mixture of DL-HPG, (+)-PES, and water in an autoclave. The present paper describes a simple method for the asymmetric transformation of DL-HPG by the use of (+)-PES as a resolving agent.

The advantages of asymmetric transformation have been described in our previous reports[4-6] and the literature.[7-9] An asymmetric transformation between two diastereomers by a combination of fractional crystallization of the less soluble diastereomer and the epimerization of the soluble diastereomer is known as a second-order asymmetric transformation. In order to perform such an asymmetric transformation, we must search for the conditions under which both fractional crystallization and epimerization can be carried out simultaneously, and for which the resolving agent is chemically and optically stable.

The solubility of L-HPG·(+)-PES in water at 20 °C is about 80 times greater than that of D-HPG·(+)-PES as was noted in our previous paper.[5] Consequently, the fractional crystallization of the less soluble D-HPG·(+)-PES from the solution consisting DL-HPG, (+)-PES, and water occurred efficiently. On the other hand, we previously reported that the salt of L-HPG with achiral sulfonic acid (*o*-toluenesulfonic acid) was readily racemized by heating it in water at 140 °C.[2] To combine this racemization method and the optical resolution method of DL-HPG with (+)-PES, we have studied the epimerization of the soluble L-HPG·(+)-PES in water; this study was carried out by using

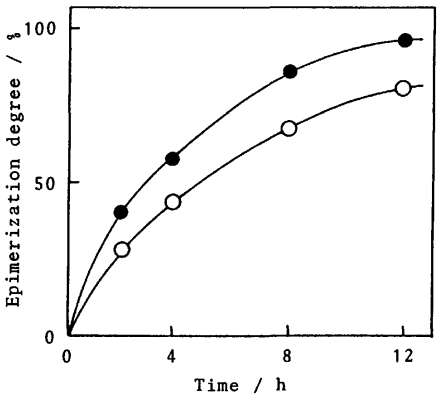

Fig. 1. Time course on epimerization of L-HPG·(±)-PES. The reactions were carried out at 140 °C in aqueous solution containing L-HPG·(±)-PES in a sealed tube. Additives: none (○), a 0.1 molar equivalent of DL-HPG (●).

L-HPG·(±)-PES instead of L-HPG·(+)-PES to aim at accurately determining the racemization degree of the L-HPG moiety.

When L-HPG·(±)-PES was heated in water at 140 °C in a sealed tube, the epimerization of L-HPG·(±)-PES occurred as well as the racemization of L-HPG *o*-toluenesulfonate.[2] In Fig. 1, the time course of the epimerization of L-HPG·(±)-PES is shown together with that of adding a 0.1 molar equivalent of free DL-HPG. The presence of free DL-HPG considerably accelerated the rate of the epimerization. Under such epimerizing conditions, (+)-PES was confirmed to be chemically and optically stable in the manner described in our previous report.[5] Furthermore, the crystals of D-HPG·(+)-PES precipitated from the epimerizing solution were also detected to accumulate without redissolving into its solution. Thus the essential requirements for the intended asymmetric transformation were fulfilled.

In this kind of the asymmetric transformation (the second order), the composition of two diastereomers in the whole system is displaced to the one component by the crystallization. The yield of the desired diastereomer [D-HPG·(+)-PES] therefore is dependent on how much of the precipitate of the diastereomer crystallized in the reaction system. To increase the amount of the precipitate under the above conditions for epimerization, the amount of the solvent (in this case, water) must be minimized.

When the amount of water used as a solvent was almost equal to that of the ammonium (+)-1-phenylethanesulfonate [(+)-PES·NH_4, was used because it was easier to handle than (+)-PES (free acid: syrup or pasty crystals[5])], a good yield was obtained and the stirring state of the reaction mixture was satisfactory. A typical experiment of the resulting asymmetric transformation was performed by heating a slurry consisting of DL-HPG (35.3 g, 0.19 mol×1.1), (+)-PES·NH_4 (39.0 g, 0.19 mol), sulfuric acid (9.4 g, 0.19 mol×0.5), and water (40 ml) with stirring in a glass autoclave. This reaction proceeded in the slurry state of the solid-liquid heterogeneous system. In order to achieve a high yield in the above experiment, the optimal conditions of the reaction were examined in further detail. Figure 2 shows the yield of D-HPG·(+)-PES as a function of the reaction time for three different temperatures. The excessive heating resulted in a lowering of yield of D-HPG·(+)-PES owing to the decomposition of HPG although the (+)-PES was stable. The highest yield (91.2% based on the DL-HPG·(+)-PES) was obtained in the reaction at 125 °C for 20 h. The change in the composition of both diastereomeric salts during the period of the reaction is illustrated in Fig. 3.

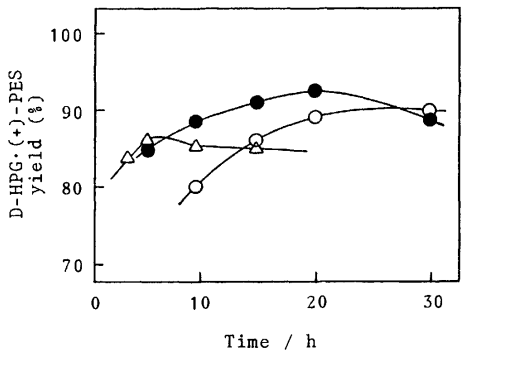

Fig. 2. Effect of temperature and time on asymmetric transformation of DL-HPG·(+)-PES. A mixture of DL-HPG (35.3 g), (+)-PES·NH_4 (39.0 g), sulfuric acid (9.4 g), and water (40 ml) was stirred at a temperature (○; 118 °C, ●; 125 °C, △; 135 °C) in an autoclave.

Since the D-HPG·(+)-PES obtained above was optically pure, it could be decomposed to optically pure D-HPG by neutralization with aqueous ammonia without further purification. The (+)-PES·NH_4 contained in the mother liquor after the separation of D-HPG could be reused as the resolving agent for the

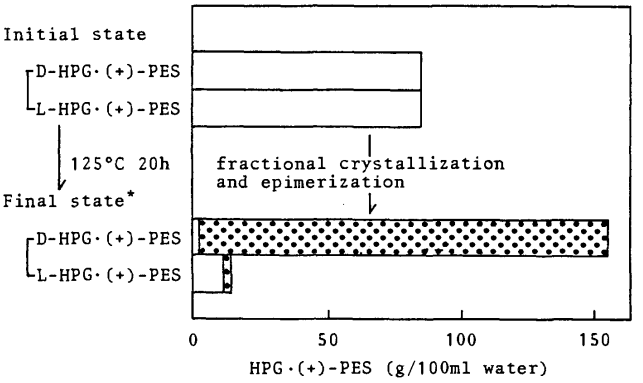

Fig. 3. The change in the composition of diastereomeric salts by asymmetric transformation. *: ▨, crystals of (+)-PES salt; □, (+)-PES salt in solution.

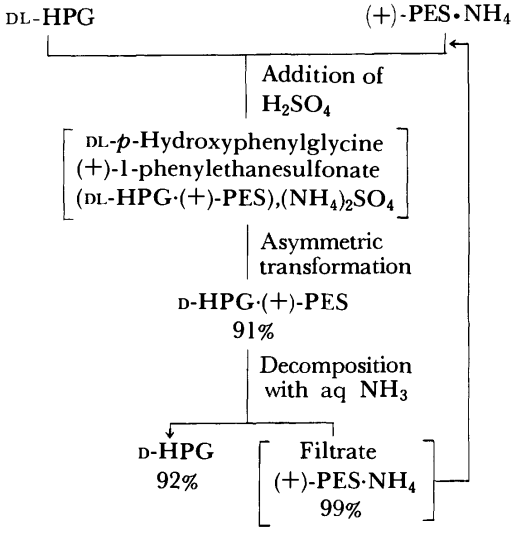

Scheme 1. Flowsheet for preparation of D-*p*-hydroxyphenylglycine by asymmetric transformation. [ ] were used in the next process without separation.

next asymmetric transformation without isolation. Our proposed repetitive process for preparing D-HPG is shown in Scheme 1. The asymmetric transformation presented here proceeds in a slurry state containing a large amount of solid and gives a high degree of transformation and a high yield of D-HPG·(+)-PES per a unit volume of water solvent (Fig. 3). This method for the preparation of D-HPG, therefore, has a definite advantage and is suitable for industrial application.

Experimental

Materials and Analyses. Optically active and racemic HPG manufactured by our company, Tanabe Seiyaku Co., Ltd., were used. (+)-1-Phenylethanesulfonic acid [(+)-PES] was prepared in a manner described in our previous report.[5] Optical rotations were measured with a Perkin-Elmer 141 automatic polarimeter. IR spectra were recorded on a Shimadzu IR-420 spectrophotometer. ^{1}H NMR spectra were measured with a Hitachi Perkin-Elmer R-40 spectrometer using tetramethylsilane as an internal standard. A glass autoclave TEM-U300 (Taiatsu Glass Industry Co., Ltd., Japan) was used. The temperature control for asymmetric transformation was carried out by a Thermo-mate oil bath BZ-21 (Yamato Scientific Co., Ltd., Japan).

Epimerization of L-HPG·(+)-PES. The experiments aimed at the epimerization of the diastereomeric salt were carried out using the 1 : 1 molar ratio salt of L-HPG with (±)-PES [L-HPG·(±)-PES]. The epimerization degree, i.e., the racemization degree of the L-HPG moiety was evaluated by measurement of the optical rotation. A mixture of L-HPG·(±)-PES (50 mg), DL-HPG (2.4 mg), and water (0.6 ml) was heated in a sealed tube at 140 °C. After heating for the prescribed time, the reaction mixture was diluted with water (10 ml), and the optical rotation was measured. The epimerization degree was evaluated from the change in the optical rotation. The results together with those without free DL-HPG are shown in Fig. 1.

Preparation of Ammonium (+)-1-Phenylethanesulfonate. A solution of (+)-PES [40.0 g; $[\alpha]_D^{25}$ +20.9 ° (*c* 3, DMSO)] in water was adjusted to pH 7 with 28% aqueous ammonia (14.5 ml). The aqueous solution was concentrated to dryness under reduced pressure. To the residue was added acetone (150 ml), and the resulting crystals were filtered, and dried at 90 °C to give (+)-PES·NH_4 (41.5 g; $[\alpha]_D^{25}$ +15.2 ° (*c* 1, MeOH); mp 208—209 °C; IR (Nujol) 3200, 1600, 1410, 1020, and 700 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=1.46 (3H, d, J=7 Hz, CH_3), 3.67 (1H, q, J=7Hz, CH), and 6.9—7.3 (5H, m, aromatic H).

Asymmetric Transformation of DL-HPG. A mixture of DL-HPG (35.3 g), (+)-PES·NH_4 (39.0 g), sulfuric acid (9.4 g), and water (40 ml) was heated at a prescribed temperature (118, 125, and 135 °C) in an autoclave fitted with a mechanical stirrer. The reaction system was a thick slurry during the reaction. After heating for a required time, into the heterogeneous reaction mixture were added water (40 ml) and sulfuric acid (0.9 g). The mixture was cooled to 5 °C and then stirred for 2 h. The crystals which precipitated were collected by filtration, washed with a small amount of cold water, and dried to give almost optically pure D-HPG·(+)-PES (yield, 54.4—61.9 g). The relationships between the yield of D-HPG·(+)-PES and the reaction time at each reaction temperature are shown in Fig. 2. The highest yield was obtained when the reaction mixture was treated at 125 °C for 20 h; yield of D-HPG·(+)-PES 61.9 g (91.2% based on the DL-HPG·(+)-PES); $[\alpha]_D^{25}$ −76.8° (*c* 1, MeOH); optical purity, 97.6%. The change in the composition of both diastereomeric salts during the reaction is shown in Fig. 3.

Preparation of D-HPG. A mixture of D-HPG·(+)-PES (60.0 g; optical purity, 97.6%) and water (60 ml) was heated at 60 °C with stirring. The suspended mixture was adjusted to pH 6.0 with 6 mol dm^{-3} aqueous ammonia. After stirring for 1 h at the same temperature, the mixture was stirred for 2 h at 5 °C. The reaction proceeded in a thick slurry. The crystals which precipitated were collected by filtration, washed with a small amount of cold water, and dried to give D-HPG (26.0 g) in a 91.6% yield; $[\alpha]_D^{25}$ −158.0° (*c* 1, 1 mol dm^{-3} HCl).

Found : C, 57.43 ; H, 5.40 ; N, 8.41%. Calcd for $C_8H_9NO_3$: C, 57.48 ; H, 5.43 ; N, 8.38%.

The mother liquor obtained after the separation of D-HPG was the aqueous solution containing (+)-PES·NH_4, which could be reused for the next asymmetric transformation in the form of the solution without isolating the (+)-PES·NH_4.

The authors wish to thank Dr. C. Hongo for his valuable advice during this work.

(Received April 24, 1987)

Di-, tri-, and tetrahydroxytropolones were prepared in good yields by the acetolysis of corresponding halotropones or polyhalotropolones with acetyl trifluoroacetate followed by acetic acid hydrolysis. However, using the same treatment to obtain hexaacetoxytropone with fully substituted acetoxyhalotropones predominantly yielded fewer substituted acetoxytropones than expected; the mechanism of formation was shown to involve an acetic acid-mediated reduction of intermediary formed acetoxy-*p*-tropoquinone equivalents. A couple of 2,7-unsubstituted 3,4-diacetoxytropones were deduced to have cyclized 1,3-dioxole structures, 2-acetoxy-2-methyl-5*H*-cyclohepta-1,3-dioxol-5-ones. An acetolysis of the brominated 5-isopropyltropolones furnished an acetylated by-product, 2,3,7-triacetoxy-5-(1,1-dimethyl-2-oxopropyl)tropone, which might be formed by the acylation of an intermediate, 3,4,5,6-tetraacetoxy-8,8-dimethylheptafulvene.

It is well-known that polyhydroxytropolones are physiologically active; in the 1930's several carboxylic acid derivatives, stipitatic acid,[1] stipitatonic acid,[2] puberulic acid,[3] and puberulonic acid,[3] which all possessed additional hydroxyl groups, had already been isolated from microorganisms such as *Penicillium stipitatum Thom.* and *P. puberulum Bainier.* Even 3-hydroxytropolone (**1**) was recognized to be an antibiotic.[4]

Therefore, a systematic method for synthesizing polyhydroxylic tropolones is desirable; recently, we have demonstrated the facile preparation of **1** from 7-bromo-2-methoxytropone (**2**) by treatment with acetyl trifluoroacetate (ATA) prepared in situ from acetic anhydride and trifluoroacetic acid, with or without sodium acetate.[5]

In order to detemine its a versatility, we have extended this method to prepare 3- (**1**),[6] 4- (**3**),[7] and 5-hydroxytropolones (**4**),[8,9] along with several further hydroxylated tropolones, such as di-, tri-, tetra-, and pentahydroxytropolones. It is true that, to date, there has been no efficient method for the preparation of such fundamental derivatives, **1** and **3**; for the hydrochloric acid-hydrolysis of 3-bromotropolone (**5**) to **1** it was necessary to heat at 160—180 °C,[6] while an alkali fusion of **5** gave **3** instead of **1**. However, its yield was at most 17%.[7]

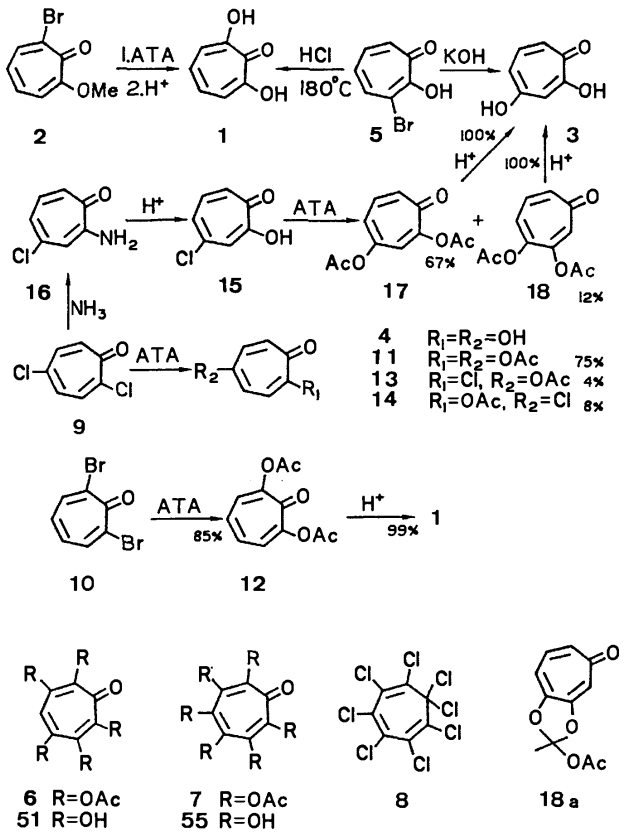
The attempted formation of pentaacetoxytropone (**6**) and hexaacetoxytropone (**7**) from corresponding halotroponoids by this method, however, yielded fewer substituted derivatives than predicted. After all, octachlorocycloheptatriene (**8**)[10] was converted to **7** in low yield together with some intermediary acetoxychlorotropones. Herein, we will show the results.

Results and Discussion

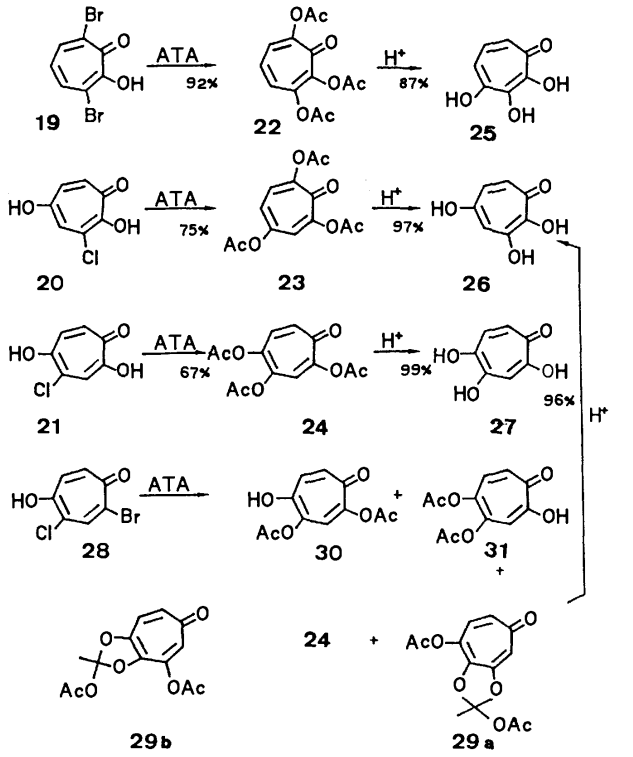
Acetolysis of Dihalotropones. First of all, in order to prepare fundamental hydroxytropolones, when 2,5-dichlorotropone (**9**)[11] and 2,7-dibromotropone (**10**)[12] were treated with ATA at 85 °C, a neat reaction occurred to form the halogen-free compounds, 2,5-diacetoxytropone (**11**)[8] and 2,7-diacetoxytropone (**12**),[8] 75 and 85%, respectively. Both **11** and **12** were identical with the authentic samples, as confirmed by direct comparisons. Under the conditions, **9** formed two intermediary chlorine-containing compounds, 5-acetoxy-2-chlorotropone (**13**)[13] and 2-acetoxy-5-chlorotropone (**14**), in 4 and 8% yields, respectively. Heating at a higher temperature, 100 °C, or for a prolonged period smoothly resulted in the replacement of all of the halogen atoms. In all cases, there was no ring-contracted benzene derivative. A mild hydrolysis of **11** and **12** with aqueous acetic acid gave, after evaporation of the solvent, **4** and **1** in nearly quantitative yields. Therefore, this may be applicable for preparing hydroxytropolones from corresponding halotropones.

Similarly, 4-chlorotropolone (**15**),[14] prepared from **9** via 2-amino-4-chlorotropone (**16**) by sequential reactions, was converted via 2,4-diacetoxytropone (**17**) and 3,4-diacetoxytropone (**18**) to 4-hydroxytropolone (**3**) as the sole product. An attempted hydrolysis of **15** with concentrated hydrochloric acid or acetolysis of **16** with the present reagent has been unsuccessful. Noteworthy was the structure of **18**. Namely, the ^{13}C NMR spectrum of **17** indicated an operating acetotropy[15,16] at room temperature, but that of **18** did not. In addition, its ^{1}H NMR showed another aspect of anomaly; the acetoxyl methyl signals on the troponoid rings generally appeared at δ=2.2 to 2.3; however, the acetoxyl signals of **18** were at a much higher region, i.e., one at 2.00, and the other at 2.08. These would not be ascribable to those on the aromatic ring. Moreover its ^{13}C NMR revealed a quarternary carbon signal at δ=124.3; this value has no analogy in any of the other

acetoxytropones that have been studied. Taking all these observations into account, **18** should be formulated as a cyclized 1,3-dioxole (**18a**) as depicted in Scheme 1. The formation of such a cyclized structure



Scheme 1.

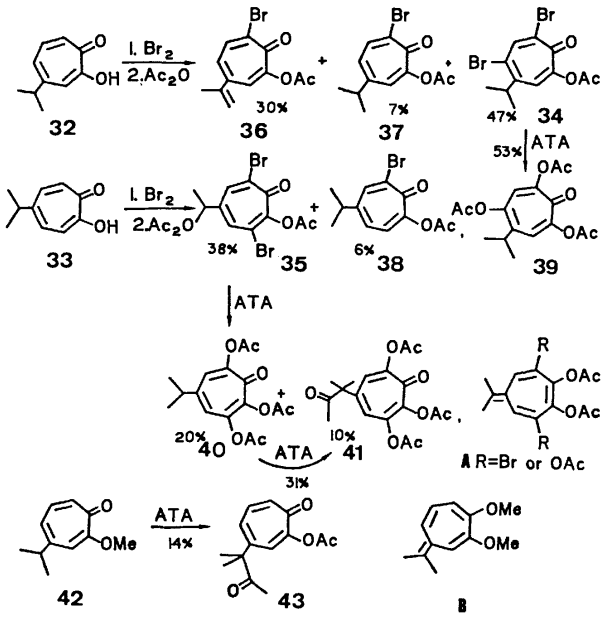


Scheme 2.

should be attributable to severe steric and repulsive non-bonding interactions of the *vic*-diacetoxyl groups on the seven-membered ring.[17]

Acetolysis of Dihalotropolones. By a similar acetolysis, 3,7-dibromotropolone (**19**),[18] 3-chloro-5-hydroxytropolone (**20**),[19] and 4-chloro-5-hydroxytropolone (**21**)[20] were respectively converted to triacetoxytropones, 2,3,7-triacetoxytropone (**22**), 2,4,7-triacetoxytropone (**23**),[21,22] and 2,4,5-triacetoxytropone (**24**), and further to dihydroxytropolones, 3,4-dihydroxytropolone (**25**),[3] 3,5-dihydroxytropolone (**26**),[19] and 4,5-dihydroxytropolone (**27**). From 2-bromo-4-chloro-5-hydroxytropone (**28**), four halogen-free products (**24**, **29**, **30**, and **31**) were isolated via silica-gel column chromatography; the major product obtained after elutions of **29** was the expected **24**. The ^{1}H NMR spectrum of **29** was identical with the "3,4,5-triacetoxytropone" already prepared by Itô et al., and its aqueous acetic acid hydrolysis indeed yielded **26**.[21,22] However, the ^{1}H NMR chemical shifts of the acetoxyl methyl signals again suggested a 1,3-dioxole derivative; the two methyl singlets at δ=2.01 and 2.08 were incompatible with the acetoxyl signals on the aromatic ring and were, therefore, tentatively assigned to be 2,8-diacetoxy-2-methyl-5*H*-cyclohepta-1,3-dioxol-5-one (**29a**), as depicted.[23,24] The formation of **29a** from **28** must involve a substitution at a remote position of the leaving group. More polar compounds, **30** and **31**, were partially-hydrolyzed diacetoxyhydroxytropones and the ^{1}H and ^{13}C NMR spectra distinguished the structures; **30**, showing a symmetry element, is therefore 2,4-diacetoxy-5-hydroxytropone.

Acetolysis of Bromo Derivatives Prepared from 4-, and 5-Isopropyltropolones. To extend the applicability of the reaction to alkyl derivatives, the acetolysis of dibromo derivatives of hinokitiol (**32**) and γ-



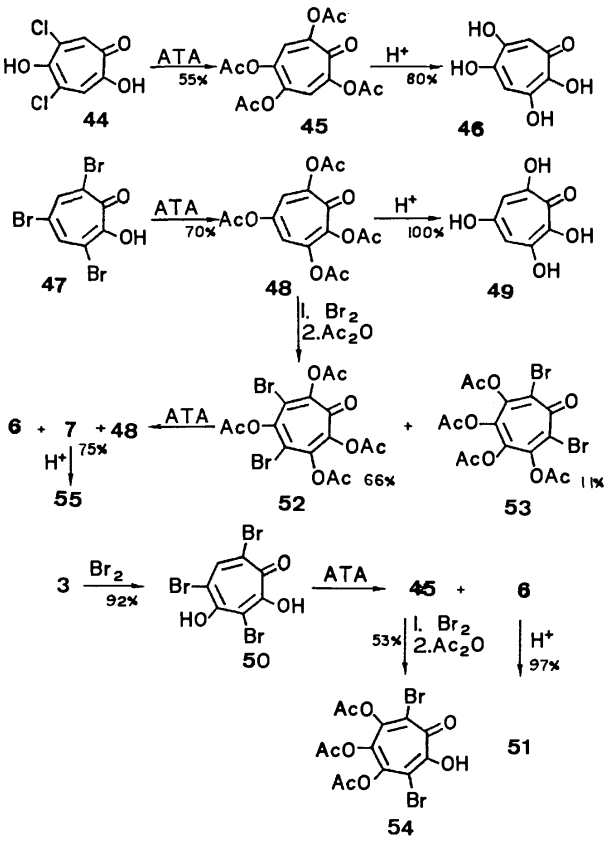
Scheme 3.

thujaplicin (**33**), 2-acetoxy-5,7-dibromo-4-isopropyltropone (**34**) and 2-acetoxy-3,7-dibromo-5-isopropyltropone (**35**),[25,26] was carried out. Through brominations, we have identified by-products, 2-acetoxy-7-bromo-4-isopropenyltropone (**36**) and 2-acetoxy-7-bromo-4-isopropyltropone (**37**) from **32** and 2-acetoxy-7-bromo-5-isopropyltropone (**38**) from **33**;[27] however, this is not further discussed.

The acetolysis of **34** and **35**, respectively, gave triacetoxytropones, 2,4,7-triacetoxy-5-isopropyltropone (**39**) and 2,3,7-triacetoxy-5-isopropyltropone (**40**) in good yields. A notable by-product in the acetolysis of **35** was the acylation product, 2,3,7-triacetoxy-5-(1,1-dimethyl-2-oxopropyl)tropone (**41**). An independent treatment of **40** gave **41** in a better yield, 31%. Evidently, **41** must be produced via a heptafulvene intermediate (**A**). The fact that such an acylated product from **34** did not appear might be due to the presence of an acetoxyl group at the vicinity of the isopropyl group, C-4. Indeed, acylation also occurred with a halogen-free heptafulvene (**B**) from 4-isopropyl-2-methoxytropone (**42**); a similar treatment of **42**, indeed, afforded 14% of the acylation product, 2-acetoxy-4-(1,1-dimethyl-2-oxopropyl)tropone (**43**). It has been emphasized that the Friedel-Crafts-type acylation and alkylation were not applicable to troponoids because of their insoluble metal chelate formation with the catalysts or easy protonation to form a delocalized stable cationic 6 π species by acid. The present example must constitute an overcoming of a deactivated reactivity towards the Friedel-Crafts acylation of the non-benzenoid aromatics. The electrophilic substitution of heptafulvenes has been successfully carried out only with some 8-monosubstituted heptafulvenes, such as 8-cyanoheptafulvene, showing that the reaction site is exclusively C-8.[28] The present examples are in that line.

Acetolysis of Polyhalo Troponoids: Occurrence of Reduction Process. Subsequently, when 4,6-dichloro-5-hydroxytropolone (**44**)[19] was treated with ATA, 2,4,5,7-tetraacetoxytropone (**45**) was obtained in 55% yield, and its mild hydrolysis gave 3,5,6-trihydroxytropolone (**46**) in 80% yield. On the other hand, 3,5,7-tribromotropolone (**47**) afforded 2,3,5,7-tetraacetoxytropone (**48**) and 3,4,6-trihydroxytropolone (**49**) in good yields.

However, the same treatment of 3,5,7-tribromo-4-hydroxytropolone (**50**), obtained from the bromination of **3**, afforded a small amount of pentaacetoxytropone (**6**). The hydrolysis of **6** gave tetrahydroxytropolone (**51**). Even more surprising was the predominant formation of **6** from 2,3,5,7-tetraacetoxy-4,6-dibromotropone (**52**), which was prepared together with 3,4,5,6-tetraacetoxy-2,7-dibromotropone (**53**) by a further bromination and acetylation of **48**;[29] the yield of the expected **7** was around 0.5%. Several other attempts to make **7** from fully-substituted acetoxyhalotropones always resulted in the formation of **6**. Although the yields for the acetolysis products in the polysubstituted derivatives could be improved by the addition of sodium acetate to the mixture, yields of the reduction products became more predominant. For example, **50** gave the expected **6** in 11% yield together with **45** in 60% yield, whose bromination and acetylation afforded 4,5,6-triacetoxy-3,7-dibromotropolone (**54**). On the other hand, **52** yielded **48** in 48% and **6** in 12% yield. Particularly, the formation of **48** from **52** indicates an occurrence of two-fold reduction.[30] Thus, in the acetolysis of the polyhalotropones, the yields of the substitution product could not be improved by the addition of sodium acetate. The results are summarized in Table 1. As a whole, in spite of intensive attempts, the formation of **7** from fully substituted polyacetoxyhalotropones was not reproducible. A mild hydrolysis of **7** gave pentahydroxytropolone (**55**) in 75% yield.



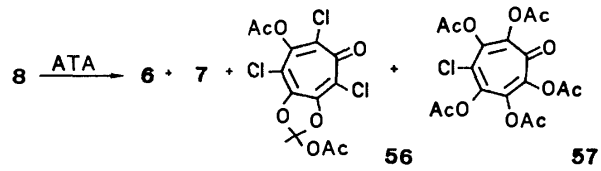
Scheme 4.

Table 1. Acetolysis of **50**, **52**, and **8** with ATA

Substrate	Condition	Addition	Yield/% of Product			
			6	**45**	**7**	**48**
50	85 °C, 9 h	—	11	—	—	—
50	125 °C, 2 d	NaOAc	11	60	—	—
52	110 °C, 5 d	—	2.6	—	0.5	—
52	110 °C, 5 d	NaOAc	12	—	—	48
8[a]	115 °C, 5 d[b]	NaOAc	3	—	0.6	—

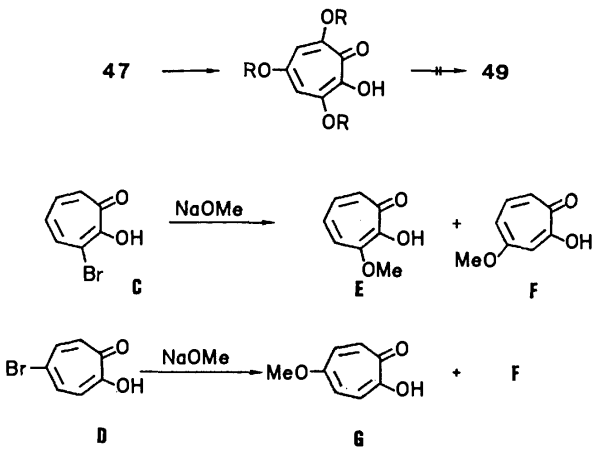
a) Acetolyses of **8** under other conditions were cited in Experimental. b) These were followed by further heating at 160 °C for 2 d.

Nevertheless, ATA-acetolysis of **8** always gave **6** and **7** in low yields together with a mixture of intermediary trichloro and monochloro derivatives (**56** and **57**). The structure of an intermediate product, **56**, was of interest. Its elemental analysis was compatible to triacetoxytrichlorotropone, and the ^{1}H and ^{13}C NMR spectra suggested 1,3-dioxole, since two of the three acetoxymethyl signals appeared at δ=2.09 and 2.12 together with a signal at 124.1. This signal is ascribable to the ortho-acetate carbon, being parallel to "3,4-diacetoxytropone" (**18a**) and "3,4,5-triacetoxytropone" (**29a**), which exist as a cyclized 1,3-dioxole form. These observations, together with a low-field signal at 2.38, an acetoxyl group between two chlorine atoms, indicated the structure to be 2,7-diacetoxy-4,6,8-trichloro-2-methyl-5*H*-cyclohepta-1,3-dioxol-5-one, a cyclisate from 3,4,6-triacetoxy-2,5,7-trichlorotropone.



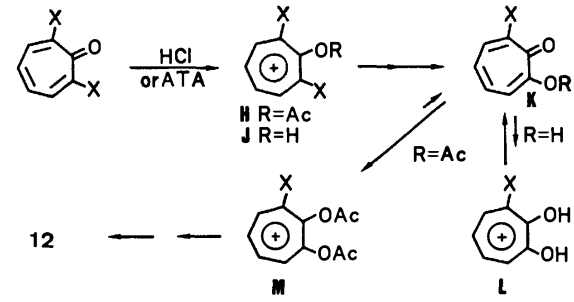
Scheme 5.

As far as we know, the previously known methods of hydrolyzing polyhalotropones have several limitations. Namely, an acid-hydrolysis of 2,7-dihalotropones to 3-halotropolones is rapid, but the second step of the substitution is very slow.[6] While 3,5,7-tribromotropolone (**47**) could be converted to 3,5,7-trialkoxytropolones together with several by-products, its hydrolysis to **49** was unsuccessful.[21] In addition to the above, a mechanistically-interesting elimination-addition reaction of 3- and 5-bromotropolones (**C** and **D**) with sodium methoxide is known to form, via benzyne-type intermediates, 3-, 4-, and 5-methoxytropolones (**E**, **F**, and **G**). However, this procedure should not be applicable to the displacement of *vic*-dihalo derivatives to alkoxyl groups.[31] Furthermore, the previously-studied sulfuric acid-hydrolysis of **8** gave structure-unidentified tetrachlorodihydroxytropones.[10] Thus, the utility of the present method for preparation of halogen-free derivatives is outstanding.



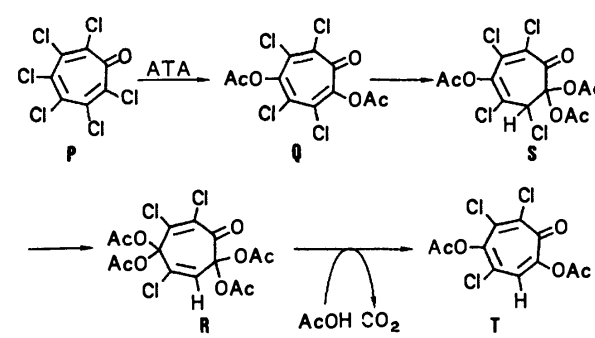
Scheme 6.

Since intermediates in the displacement of halogens, halogenated acetoxycycloheptatrienylium ions (**H**) should be formed, their further acetoxylation might be equally easy. To the contrary, the intermediate formed in the first step in an ordinary acid hydrolysis of polyhalotropones should be halogenated dihydroxycycloheptatrienylium salt (**L**), which can be deprotonated easily to tropolones (**K**). This is the reason why ordinary acid hydrolysis gives halogenated monohydroxylic tropones. In addition, this ATA acetolysis was inapplicable to the benzenoid compounds.[5] Therefore, this exhaustive displacement of acetoxyl group proceeded to the advantage of the formation of **H**.



Scheme 7.

Mechanism of Formation of Reduction Products. Now, the reaction mechanism leading to reduced products should be explained. In the later steps of the acetolysis in polysubstituted troponoids (**P**), the acetolysates may become halogenated 2,5-diacetoxytropone derivatives (**Q**). In case of sterically hindered **Q**, the base, sodium acetate, may facilitate an elimination of acetyl halide (or hydrogen halide) rather than a substitution to form the *p*-tropoquinone (**R**) via an intermediate (**S**). Under these conditions, *p*-tropoquinones should be reduced by acetic acid to 2,5-diacetoxytropone derivative (**T**), being parallel to the previously described parent *p*-tropoquinone and other derivatives.[19,32]

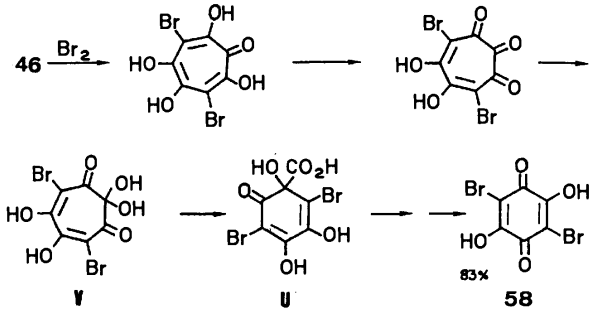


Scheme 8.

Conclusion

Before concluding, results of the bromination reac-

tion of polyhydroxytropolones must be mentioned. When **46** was treated with bromine in acetic acid at room temperature, a rapid decoloration of bromine was observed. The product after heating at 95 °C was, however, 2,5-dibromo-3,6-dihydroxy-*p*-benzoquinone (**58**);[33] evidently, a benzil-benzilic acid rearrangement product (**U**) of an intermediate, an *o*-tropoquinone hydrate derivative (**V**), was further decarboxylated to **58**, and a protection of free hydroxyl group must be essential to avoid the ring contraction.



Scheme 9.

Finally, up to pentaacetoxytropone, the present procedure is satisfactory; but for fully oxygenated hexaacetoxytropone, the reduction process was predominant. Still, no ring-contraction to the benzenoid derivative occurred. This is the scope and limitation of this method. The ^{1}H- and ^{13}C NMR spectra of hexaacetoxytropone, a potential C_7-oxo carbon precursor, has disclosed a degenerated acetyl migration operative at room temperature, and the kinetic features of this rearrangement will be a subject of an independent publication.[16]

Experimental

Elemental analyses were carried out by Miss S. Hirashima, of the Research Institute of Industrial Science, Kyushu University. The NMR spectra were measured by a JEOL FX 100 Spectrometer in $CDCl_3$ solution, unless otherwise specified, and the chemical shifts expressed were in δ unit. The mass spectra were measured with a JEOL OISG-2 Spectrometer. The IR spectra were taken as KBr disks or as a liquid film inserted between NaCl plates using a Jasco IR-A 102 Spectrometer. The UV spectra were measured by a Hitachi U-3200 Spectrophotometer.

Preparation of Acetyl Trifluoroacetate (ATA). Ac_2O (50 cm^3) was mixed with CF_3COOH (5 cm^3) and AcOH (2.5 cm^3) at room temperature. The whole operation should be carefully undertaken in a good ventilated hood. Each time, a portion of the solution was taken out by pipette.

Acetolysis of 2,5-Dichlorotropone (9). An ATA solution[34] (5.6 cm^3) of **9** (100 mg) was sealed in an autoclave and heated at 85 °C for 10 h. After removal of the solvent in vacuo, the residue was chromatographed on a silica-gel column to give **14** [colorless crystals, mp 70.5—73.5 °C, 9 mg; 8%. Found: C, 54.17; H, 3.58%; *m/z* 198.0068 and 200.0023 (M^+). Calcd for $C_9H_7O_3Cl$: C, 54.41; H, 3.53%; M, 198.0081 and 200.0053. ^{1}H NMR δ=2.33 (3H, s), 7.05 (2H, dd, *J*=11, 1.5 Hz), and 7.24 (2H, dd, *J*=11, 1.5 Hz). ^{13}C NMR δ=20.6, 132.4, 132.8, 134.0 (2C), 140.2, and 168.0 (3C). IR ν: 1765, 1630, 1580, 1200, 1075, and 860 cm^{-1}], **13** [colorless crystals, mp 102—103 °C (lit,[12] 101.5—102 °C), 4 mg; 4%. ^{1}H NMR δ=2.29 (3H, s), 6.68 (1H, ddd, *J*=10.5, 2.5, 0.5 Hz), 6.97 (1H, dd, *J*=13, 2.5 Hz), 7.21 (1H, dd, *J*=13, 0.5 Hz), and 7.71 (1H, d, *J*=10.5 Hz). ^{13}C NMR δ=20.9, 122.2, 133.9, 134.2, 138.2, 147.4, 154.5, 168.9, and 179.4], and **11** [pale yellow needles, mp 93—95 °C (lit,[8] 91—92 °C), 95 mg; 75%. ^{1}H NMR δ=2.26 (3H, s), 2.31 (3H, s), 6.88 (2H, dd, *J*=10.5, 1.5 Hz), and 7.17 (2H, dd, *J*=10.5, 1.5 Hz). ^{13}C NMR δ=20.6, 20.9, 128.2 (2C), 133.0 (2C), 153.5, 167.9 (2C), and 168.7 (2C). IR ν: 1755, 1585, 1365, 1140, and 920 cm^{-1}].

Acetolysis of 2,7-Dibromotropone (10). An ATA solution (8 cm^3) of **10** (64.2 mg) and NaOAc (101 mg) was heated in a sealed tube at 100 °C for 24 h. The mixture was then heated in vacuo, and the residue was chromatographed on a silica-gel column to give **12** [a colorless crystals, mp 90—91 °C (lit,[5] 86—87 °C), 45.6 mg; 85%].

Hydrolysis of 12 to 1. An aqueous AcOH (50%, 10 cm^3) of **12** (490 mg) was heated at 100 °C for 16 h to give **1** [orange needles, mp 179—181 °C, 248 mg; 99%].

Attempted Acetolysis of 2-Amino-4-chlorotropone (16). An ATA solution (2 cm^3) of **16** (40 mg) was heated in a sealed tube at 100 °C for 6 h. After evaporation of the solvent in vacuo, the residue was chromatographed on a silica-gel column, but no identifiable compound was obtained.

Acetolysis of 4-Chlorotropolone (15). An ATA solution (50 cm^3) of **15** (1.197 g) was heated in an autoclave at 100 °C for 14 h. The mixture was then heated in vacuo to remove the solvent, and the residue was chromatographed on a silica-gel column to give **17** [colorless crystals, mp 101—102.5 °C, 1.138 g; 67%. Found: C, 59.72; H, 4.48%. Calcd for $C_{11}H_{10}O_5$: C, 59.46; H, 4.54%. ^{1}H NMR δ=2.22 (3H, s), 2.28 (3H, s), 6.79 (1H, ddd, *J*=9, 3, 2 Hz), 6.96 (1H, d, *J*=2 Hz), 7.00 (1H, dd, *J*=10, 9 Hz), and 7.13 (1H, dd, *J*=10, 3 Hz). ^{13}C NMR δ=20.5, 20.8, 129.5, 129.7, 130.0, 131.9, 156.0, 164.2, 167.8, 168.5, and 170.9. IR ν: 2940, 1740, 1580, 1515, 1365, 1185, 1100, 1005, and 915 cm^{-1}] and **18** [pale yellow crystals, mp 89—91 °C, 212 mg; 12%. Found: C, 59.39; H, 4.53%. ^{1}H NMR δ=2.00 (3H, s), 2.08 (3H, s), 6.44 (1H, dd, *J*=8, 2 Hz), and 6.65—7.05 (3H, m). ^{13}C NMR δ=21.5, 24.0, 107.0, 115.6, 124.3, 133.4, 136.7, 154.2, 157.0, 167.3, and 184.7. IR ν: 1775, 1680, 1400, 1110, 955, and 880 cm^{-1}. UV λ_{max}^{MeOH}: 239 nm (ε=23200), 246 (22600, sh), 257 (18900, sh), 271 (5400, sh), 301 (6200, sh), and 312 (7100)].

Hydrolysis of 2,4-Diacetoxytropone (17). An aqueous AcOH solution (50%, 20 cm^3) of **17** (1.22 g) was heated at 100 °C for 5 h. After removal of the solvent in vacuo, the residue was washed with AcOEt, and recrystallized from MeOH to give **3** [colorless crystals, mp 229—230 °C (lit,[1] 230—231 °C), 761 mg; 100%. ^{1}H NMR (CD_3OD) δ=6.72 (1H, ddd, *J*=10.7, 2.5, 1 Hz), 6.87 (1H, d, *J*=2.5 Hz), 6.92 (1H, dd, *J*=10.3, 1 Hz), and 7.24 (1H, dd, *J*=10.7, 10.3 Hz). ^{13}C NMR (CD_3OD) δ=114.7, 115.8, 121.5, 138.1, 168.4, 169.8, and 174.7. IR ν: 3210, 2930, 1590, 1420, 1210, and 730 cm^{-1}].

Hydrolysis of 18 to 3. An aqueous AcOH solution (3 cm^3) of **18** (100 mg) was heated at 100 °C for 5 h. The same work up as above yielded **3** [62 mg; 100%].

Acetolysis of 3,7-Dibromotropolone (19) to 2,3,7-Triacetoxytropone (22). An ATA solution (10 cm^3) of **19** (117.4 mg) and NaOAc (168 mg) was similarly heated in a sealed tube at 100 °C for 4 d. The mixture was then heated in vacuo to

remove the volatile material and the residue was chromatographed on a silica-gel column to give **22** [a pale yellow oil, 107.9 mg; 92%. Found: m/z[35] 280.0551 (M^+). Calcd for $C_{13}H_{12}O_7$: M, 280.0581. ^{1}H NMR δ=2.30 (6H, s), 2.32 (3H, s), and 6.9—7.2 (3H, m). ^{13}C NMR δ=20.3, 20.5 (2C), 128.8, 129.2 (2C), 154.4 (2C), 166.9 (2C), and 167.8 (3C). IR ν: 1770, 1740, 1600, 1370, 1150, 1010, and 875 cm^{-1}].

Acetolysis of 3-Chloro-5-hydroxytropolone (20) to 2,4,7-Triacetoxytropone (23). An ATA solution (10 cm^3) of **20** (50 mg) was similarly heated in a sealed tube at 90 °C for 7 h. The mixture was then heated to remove the solvent and the residue was chromatographed on a silica-gel column to give **23** [colorless crystals, mp 110—111 °C (lit,[21,22] 111—112 °C), 61 mg; 75%. ^{1}H NMR δ=2.26 (3H, s), 2.31 (6H, s), 6.84 (1H, dd, J=10.5, 2.5 Hz), 7.12 (1H, d, J=2.5 Hz), and 7.21 (1H, d, J=10.5 Hz). ^{13}C NMR δ=20.4 (2C), 20.6, 122.8, 127.6, 127.8, 151.9, 155.8, 158.5, 167.3, 167.6 (2C), and 168.3].

Acetolysis of 4-Chloro-5-hydroxytropolone (21) to 2,4,5-Triacetoxytropone (24). An ATA solution (2 cm^3) of **21** (120 mg) was heated in a sealed tube at 80 °C for 4 h. The mixture was then heated to remove the solvent and the residue was chromatographed on a silica-gel column to give **24** [colorless needles, mp 126.5—128 °C, 130 mg; 67%. Found: C, 55.69; H, 4.31%. Calcd for $C_{13}H_{12}O_7$: C, 55.72; H, 4.32%. ^{1}H NMR δ=2.26 (6H, s), 2.32 (3H, s), 6.89 (1H, d, J=11.5 Hz), 7.06 (1H, s), and 7.11 (1H, d, J=11.5 Hz). ^{13}C NMR δ=20.4, 20.6, 20.8, 121.9, 123.5, 129.9, 146.5, 153.6, 153.8, 166.1, 167.2, 167.5, and 167.8. IR ν: 3050, 1770, 1595, 1370, 1070 and 910 cm^{-1}. UV λ_{max}^{MeOH}: 235 nm (ε=24400), 280 (6800), 318 (8400), and 384 (2000, sh)].

Hydrolysis of 22 to 3,4-Dihydroxytropolone (25). An aqueous AcOH solution (50%, 2 cm^3) of **22** (40.7 mg) was heated at 100 °C for 7 h. After cooling the solution to room temperature, the separated crystals were collected by filtration to give **25** [colorless plates, mp 230 °C (decomp) (lit,[3] mp 237—238 °C), 19.4 mg; 87%. ^{1}H NMR (CD_3OD) δ=7.04 (3H, s). ^{13}C NMR (CD_3OD) δ=119.3 (2C), 129.4, 158.4 (2C), and 159.1 (2C)].

Hydrolysis of 23 to 3,5-Dihydroxytropolone (26). An aqueous AcOH solution (50%, 6 cm^3) of **23** (61 mg) was heated at 100 °C for 24 h. After cooling, the mixture was heated in vacuo to remove the volatile material, and the residue was recrystallized from MeOH and AcOEt to give **26** [colorless crystals, mp 219—222 °C (lit,[20] 223—224 °C, 30 mg; 97%. ^{1}H NMR (CD_3OD) δ=6.93 (1H, s), 6.99 (1H, d, J=12 Hz), and 7.31 (1H, d, J=12 Hz). ^{13}C NMR (CD_3OD) δ=116.4, 116.7 (2C), 126.5, 127.9, 156.4, and 167.7.].

Hydrolysis of 24 to 4,5-Dihydroxytropolone (27). An aqueous AcOH solution (50%, 6 cm^3) of **24** (130 mg) was heated at 100 °C for 24 h. After evaporation of the mixture in vacuo, the residue was washed with AcOEt and recrystallized from MeOH and AcOEt to give **27** [pale yellow needles, mp 285—289 °C. 70 mg; 99%. Found: C, 54.48; H, 3.93%. Calcd for $C_7H_6O_4$: C, 54.54; H, 3.93%. ^{1}H NMR (CD_3OD) δ=6.92 (2H, s) and 7.04 (1H, s). ^{13}C NMR (CD_3OD) δ=116.2 (2C), 126.3, 156.0 (2C), and 167.5 (2C). IR ν: 3250, 2950, 1405, 1210, and 1090 cm^{-1}].

Acetolysis of 2-Bromo-4-chloro-5-hydroxytropone (28). a) An ATA solution (50 cm^3) of **28** (703 mg) was heated in a sealed tube at 85 °C for 15 h. The mixture was then heated in vacuo to remove the volatile material, and the residue was chromatographed on a silica-gel column to give [29] [colorless prisms, mp 127—128.5 °C, 86 mg; 10%. Found: C, 55.87; H, 4.32%. Calcd for $C_{13}H_{12}O_7$: C, 55.72; H, 4.32%. ^{1}H NMR δ=2.01 (3H, s), 2.08 (3H, s), 2.29 (3H, s), 6.42 (1H, d, J=10 Hz), 6.82 (1H, s), and 6.96 (1H, d, J=10 Hz). ^{13}C NMR δ=20.6, 21.5, 24.0, 103.8, 115.0, 124.4, 124.8, 152.9, 153.6, 156.8, 167.3, 168.6, and 176.0. IR ν: 1765, 1595, 1440, 1200, 1115, and 945 cm^{-1}. UV λ_{max}^{MeOH}: 240 nm (ε=26600), 258 (18100, sh), 310 (7500, sh), and 320 (8150)], **24** [380 mg; 45%], and **30** [colorless crystals, mp 131.5—132.5 °C, 37 mg; 5%. Found: C, 55.31; H, 4.31%. Calcd for $C_{11}H_{10}O_6$: C, 55.46; H, 4.23%. ^{1}H NMR δ=2.23 (6H, s), 6.93 (1H, s), and 7.02 (2H, s). ^{13}C NMR δ=20.6 (2C), 122.3, 124.6 (2C), 155.0 (2C), and 166—172 (4C). IR ν: 3600—3300, 1765, 1750, 1555, 1535, 1155 and 910 cm^{-1}. UV λ_{max}^{MeOH}: 252 nm (ε=30400), 263 (27000, sh), 332 (8200), and 367 (6700, sh)].

b) A similar treatment of **28** (50 mg) in an ATA solution (5 cm^3) at 85 °C for 10 h gave **24** [23 mg; 39%] and **31** [colorless crystals, mp 131—132.5 °C, 11 mg; 22%. Found: C, 55.18; H, 4.17%. Calcd for $C_{11}H_{10}O_6$: C, 55.46; H, 4.23%. ^{1}H NMR δ=2.27 (3H, s), 2.29 (3H, s), 6.88 (1H, d, J=11.2 Hz), 6.91 (1H, s), and 7.10 (1H, d, J=11.2 Hz). IR ν: 3050, 1770, 1560, 1370, 1155, and 915 cm^{-1}. UV λ_{max}^{MeOH}: 252 nm (ε=29100), 337 (7200), 358 (6700, sh), and 371 (5500, sh)].

Hydrolysis of 29 to 26. Similarly, an aqueous AcOH solution (6 cm^3) of **29** (86 mg) was heated at 100 °C for 4 h to yield **26** [45 mg; 96%], whose identity with the authentic **26** was confirmed by direct comparisons.

Bromination of Hinokitiol (32).[25] An AcOH solution (50 cm^3) of **32** (1.20 g) was treated with Br_2 (3.2 g) dissolved in AcOH (32 cm^3) at 5 °C. The mixture was then heated at 95 °C for 3 h and kept for further 15 h at room temperature. After removal of the solvent in vacuo, the residue was acetylated with Ac_2O (2 cm^3) by heating at 100 °C for 4 h. After evaporation of the solvent, the residue was chromatographed on a silica-gel column to give **34** [a yellow oil, 1.25 g; 47%. Found: C, 39.40; H, 3.32%. Calcd for $C_{12}H_{12}O_3Br_2$: C, 39.59; H, 3.32%. ^{1}H NMR δ=1.21 (6H, d, J=7 Hz), 2.34 (3H, s), 3.53 (1H, sept, J=7 Hz), 7.13 (1H, s), and 8.59 (1H, s). ^{13}C NMR δ=20.6, 21.6 (2C), 38.4, 126.4, 137.0, 144.9 (2C), 150.8, 153.7, and 167.9 (2C). IR ν: 2980, 1780, 1630, 1470, 1370, 1175, 1115, and 755 cm^{-1}. UV λ_{max}^{MeOH}: 241 nm (ε=16600), 259 (24000), 264 (23400, sh), 340 (10600), and 416 (1450)], **36** [colorless crystals, mp 99—101.5 °C, 625 mg; 30%. Found: C, 50.94; H, 3.93%. Calcd for $C_{12}H_{11}O_3Br$: C, 50.91; H, 3.92%. ^{1}H NMR δ=2.13 (3H, dd, J=1.5, 0.5 Hz), 2.35 (3H, s), 5.33 (1H, q, J=1.5 Hz), 5.42 (1H, br s), 6.91 (1H, dd, J=10.5, 2 Hz), 7.45 (1H, d, J=2 Hz), and 8.12 (1H, d, J=10.5 Hz). ^{13}C NMR δ=20.6, 21.8, 118.7, 127.6, 128.0, 139.1, 139.9, 143.8, 146.0, 155.2, 168.3, and 171.7. IR ν: 3600—3300, 1770, 1610, 1500, 1375, 1200, 1090, 920, and 860 cm^{-1}. UV λ_{max}^{MeOH}: 241 nm (ε=12300), 247 (16300), 256 (15800, sh), 345 (12300), 358 (10500, sh), and 377 (4850, sh)], and **37** [a yellow oil, 149 mg; 7%. Found: m/z 284.0106 and 286.0071 (M^+). Calcd for $C_{12}H_{13}O_3Br$: M, 284.0048 and 286.0028. ^{1}H NMR δ=1.24 (6H, d, J=7 Hz), 2.36 (3H, s), 2.82 (1H, sept, J=7 Hz), 6.76 (1H, dd, J=10, 1.5 Hz), 7.19 (1H, d, J=1.5 Hz), 8.04 (1H, d, J=10 Hz). ^{13}C NMR δ=20.7, 22.9 (2C), 38.1, 128.2, 130.1, 138.3, 140.1, 154.4, 157.7, and 168.3 (2C). IR ν: 2930, 1775, 1605, 1365, 1190, 1160, and 1080 cm^{-1}. UV λ_{max}^{MeOH}: 226 nm (ε=14500), 248 (20200), 254 (18900, sh), and 331 (9100)].

Bromination of γ-Thujaplicin (33).[26] An AcOH solution (40 cm^3) of **33** (0.80 g) was similarly treated with Br_2 (2.2 g) in AcOH (22 cm^3) at 5 °C. The mixture was then heated at 95 °C for 3 h. After the removal of the volatile materials in

vacuo, the residue was treated with Ac_2O at 100 °C for 4 h. The mixture was then heated again in vacuo to remove the solvent, and the residue was chromatographed on a silica-gel column to give **35** [pale yellow crystals, mp 60—64 °C, 669 mg; 38%. Found: C, 39.80; H, 3.44%. Calcd for $C_{12}H_{12}O_3Br_2$: C, 39.59; H, 3.32%. ^{1}H NMR δ=1.25 (6H, d, J=7 Hz), 2.36 (3H, s), 2.79 (1H, sept, J=7 Hz), and 7.67 (2H, s). ^{13}C NMR δ=20.5, 22.9 (2C), 38.2, 135.2 (2C), 137.6 (2C), 149.9, and 167.0 (3C). IR ν: 3600—3300, 2960, 1770, 1610, 1590, 1175, 1130, 1090, and 810 cm^{-1}. UV λ_{max}^{MeOH}: 259 nm (ε=27000), 265 (26800), and 329 (7800)] and **38** [a yellow oil, 100 mg; 6%. Found: m/z 284.0137 and 286.0007 (M^+). Calcd for $C_{12}H_{13}O_3Br$: M, 284.0048 and 286.0028. ^{1}H NMR δ=1.25 (6H, d, J=7 Hz), 2.35 (3H, s), 2.83 (1H, sept, J=7 Hz), 6.92 (1H, d, J=10.5 Hz), 7.18 (1H, d, J=10.5 Hz), and 8.04 (1H, s). ^{13}C NMR δ=20.6, 23.1 (2C), 38.1, 129.1, 129.8, 135.8, 140.7, 152.8, and 168.4 (3C). IR ν: 2930, 1770, 1695, 1590, 1365, and 1175 cm^{-1}. UV λ_{max}^{MeOH}: 228 nm (ε=13000), 250 (21700), and 330 (8900)]. Several other products were detected on TLC, but no further fractionation was carried out.[27]

Acetolysis of 2-Acetoxy-5,7-dibromo-4-isopropyltropone (34). An ATA solution (50 cm^3) of **34** (1.157 g) was heated in an autoclave at 100 °C for 3 d. Then, the solvent was removed in vacuo, and the residue was chromatographed on a silica-gel column to give **39** [colorless crystals, mp 122—123 °C, 538 mg; 53%. Found: C, 59.71; H, 5.59%. Calcd for $C_{16}H_{18}O_7$: C, 59.62; H, 5.63%. ^{1}H NMR δ=1.18 (6H, d, J=7 Hz), 2.31 (6H, s), 2.33 (3H, s), 3.14 (1H, sept, J=7 Hz), 7.07 (1H, s), and 7.25 (1H, s). ^{13}C NMR δ=20.5 (3C), 22.0 (2C), 29.8, 127.7, 128.5, 142.3, 147.6, I55.1, 155.8, 167.9, 168.2, and 169.0 (2C). IR ν: 1765, 1630, 1600, 1510, 1370, 1200, 1125, 1050 and 940 cm^{-1}. UV λ_{max}^{MeOH}: 236 nm (ε=27100), 325 (9750), and 396 (390)].

Acetolysis of 2-Acetoxy-3,7-dibromo-5-isopropyltropone (35). An ATA solution (30 cm^3) of **35** (413 mg) was heated in an autoclave at 100 °C for 3 d. The mixture was then heated in vacuo to remove the solvent and the residue was chromatographed on a silica-gel column to give **40** [colorless crystals, mp 91—93 °C, 73 mg; 20%. Found: C, 59.36; H, 5.61%. Calcd for $C_{16}H_{18}O_7$: C, 59.62; H, 5.63%. MS m/z 322 (M^+). ^{1}H NMR δ=1.24 (6H, d, J=7 Hz), 2.30 (9H, s), 2.80 (1H, sept, J=7 Hz), and 6.97 (2H, s). ^{13}C NMR δ=20.4, 20.6 (2C), 22.8 (2C), 38.4, 128.0 (2C), 150.5, 154.1 (2C), 167.0 (2C), and 167.9 (3C). IR ν: 1780, 1610, 1375, 1200, 1165, and 1020 cm^{-1}. UV λ_{max}^{MeOH}: 238 nm (ε=26800), 322 (8400), and 391 (520, sh)] and **41** [colorless needles, mp 182—184 °C, 40 mg; 10%. Found: C, 59.35; H, 5.56%. Calcd for $C_{18}H_{20}O_8$: C, 59.33; H, 5.53%. ^{1}H NMR δ=1.45 (6H, s), 2.05 (3H, s), 2.31 (9H, s), and 6.92 (2H, s) ^{13}C NMR δ=20.4, 20.6 (2C), 24.7 (2C), 26.0, 55.5, 127.3 (2C), 145.5, 152.4, 153.5, 166.9 (2C), 167.8 (3C), and 208.8. IR ν: 3500—3300, 1775, 1710, 1605, 1365, 1200, 1160, and 1020 cm^{-1}. UV λ_{max}^{MeOH}: 240 nm (ε=26000), 321 (8000), and 400 (400)].

Acylation of 40 to 41. An ATA solution (3 cm^3) of **40** (50 mg) was heated at 100 °C for 3 d. After evaporation of the solvent in vacuo, the residue was chromatographed on a silica-gel column to give, after elution of the recovered **40** [19 mg; 38%], **41** [11 mg; 31%] whose identity with the authentic sample was confirmed by direct comparisons.

Acylation of 2-Methoxy-4-isopropyltropone (42). An ATA solution (7 cm^3) of **42** (57 mg) was heated in an autoclave at 95 °C for 2 d. A similar workup afforded **43** [a yellow oil, 11 mg; 14%. Found: m/z 248.1005 (M^+). Calcd for $C_{14}H_{16}O_4$: M, 248.1048. ^{1}H NMR δ=1.83 (6H, s), 2.01 (3H, s), 2.33 (3H, s), 6.7—7.2 (3H, m), and 7.13 (1H, d, J=0.5 Hz). ^{13}C NMR δ=20.7, 24.8 (2C), 25.9, 55.8, 131.7, 132.5 (2C), 133.4, 151.0, 168.4 (3C), and 209.5. IR ν: 2950, 1770, 1715, 1605, 1365, 1195, and 1145 cm^{-1}. UV λ_{max}^{MeOH}: 233 nm (ε=19000), 316 (6660), and 442 (790)].

Acetolysis of 4,6-Dichloro-5-hydroxytropolone (44) to 45 with ATA. An ATA solution (4 cm^3) of **44** (152 mg) was heated in a sealed tube at 80 °C for 2 d. After removal of the solvent in vacuo, the residue was chromatographed on a silica-gel column to give **45** [colorless needles, mp 166—167 °C, 136 mg; 55%. Found: C, 53.43; H, 4.11%. Calcd for $C_{15}H_{14}O_9$: C, 53.26; H, 4.17%. ^{1}H NMR δ=2.27 (6H, s), 2.32 (6H, s), and 7.16 (2H, s). ^{13}C NMR δ=20.5 (4C), 126.4 (2C), 142.5 (2C), 155.2 (2C), 167.1 (2C), and 167.3 (3C). IR ν: 1775, 1600, 1500, 1360, 1135, 1100, and 935 cm^{-1}].

Acid Hydrolysis of 45 to 46. An aqueous AcOH solution (33%, 9 cm^3) of **45** (150 mg) was heated at 100 °C for 4 h. The mixture was then heated in vacuo to remove the solvent, and the residue was washed with AcOEt to obtain insoluble product, **46** [pale yellow needles, mp 269—271 °C (decomp), 60 mg; 80%. Found: C, 49.12; H, 3.59%. Calcd for $C_7H_6O_5$: C, 49.42; H, 3.56%. ^{1}H NMR (CD_3OD) δ=6.98 (2H, s). ^{13}C NMR (CD_3OD) δ=112.0 (2C), 158.1 (2C), and 158.4 (3C). IR ν: 3600—3200, 1395, 1365, 1190, and 900 cm^{-1}. UV λ_{max}^{MeOH}: 256 nm (ε=25600), 281 (3700, sh), 332 (5400, sh), 353 (6500), and 329 (2900, sh)].

Acetolysis of 3,5,7-Tribromotropolone (47) to 48. a) An ATA solution (4 cm^3) of **47** (500 mg) was sealed in a pressure bottle and heated at 100 °C for 2 d. After cooling the mixture to room temperature, volatile materials were evaporated in vacuo, and the residue was chromatographed on a silica-gel column to give **48** [colorless needles, mp 133—134 °C, 326 mg; 70%. Found: C, 52.99; H, 4.13%. Calcd for $C_{15}H_{14}O_9$: C, 53.25; H, 4.18%. ^{1}H NMR δ=2.28 (3H, s), 2.31 (6H, s), 2.32 (3H, s), and 6.95 (2H, s). ^{13}C NMR δ=20.2, 20.5 (2C), 20.8, 124.0 (2C), 150.0, 153.4 (2C), 166.5, 167.2 (3C), and 168.2 (2C). IR ν: 3050, 1770, 1605, 1515, 1375, 1360, and 1020 cm^{-1}. UV λ_{max}^{MeOH}: 222 nm (ε=19500), 238 (29100), 280 (4600), and 322 (8500)].

b) Similarly, an ATA solution (16 cm^3) of **47** (500 mg) and NaOAc (330 mg) was heated at 110 °C for 2 d. The mixture was then heated in vacuo to remove the solvent and the residue was chromatographed on a silica-gel column to give **48** [356 mg; 76%].

Acid Hydrolysis of 2,3,5,7-Tetraacetoxytropone (48) to 49. An aqueous AcOH solution (50%, 5 cm^3) of **48** (326 mg) was heated at 100 °C for 24 h. After evaporation in vacuo, the mixture was washed with AcOEt, and the residue was collected by filtration to give **49** [pale yellow crystals, mp 263—266 °C (decomp), 164 mg; 100%. Found: C, 49.13; H, 3.55%. Calcd for $C_7H_6O_5$: C, 49.42; H, 3.56%. ^{1}H NMR (CD_3OD) δ=6.63 (2H, s). ^{13}C NMR (CD_3OD) δ=107.8 (2C), 151.5, 161.9 (2C), and 163.0 (2C). IR ν: 3370, 3300, 1580, 1480, 1400, 1010, and 850 cm^{-1}].

Bromination of 4-Hydroxytropolone (3) to 3,5,7-Tribromo-4-hydroxytropolone (50). An AcOH solution (13 cm^3) of **3** (440 mg), NaOAc (780 mg) was treated with bromine (1550 mg) in AcOH (15.5 cm^3) at 5 °C. The mixture was then heated at 95 °C for 1.5 h, and the mixture was heated in vacuo to remove the solvent. The residue was extracted with $CHCl_3$ and the organic extract was evaporated in vacuo to leave a crude product which was purified by recrystalliza-

tions from MeOH to yield **50** [pale green needles, mp 149—151 °C (lit,[7] 151 °C), 1.102 g; 92%. ^{1}H NMR (CD_3OD) δ=8.39 (1H, s). ^{13}C NMR (CD_3OD) δ=112.6, 113.8, 118.6, 142.9, 160.4, 161.5, and 167.3. IR ν: 3330, 1600, 1350, 1260, 1170, 1110, and 795 cm^{-1}].

Acetolysis of 3,5,7-Tribromo-4-hydroxytropolone (50) to 6. An ATA solution (50 cm^3) of **50** (343 mg) was heated in an autoclave at 85 °C for 9 h. The mixture was evaporated in vacuo to remove the solvent and the residue was chromatographed on a silica-gel column to give **6** [colorless crystals, mp 183.5—185 °C, 39 mg; 11%. Found: C, 51.28; H, 3.95%. Calcd for $C_{17}H_{16}O_{11}$: C, 51.52; H, 4.07%. ^{1}H NMR δ=2.28 (6H, s), 2.30 (9H, s), and 6.95 (1H, s). ^{13}C NMR (DMF-d_7) δ=20.1, 20.4, 123.5, 123.8, 147.4, 167.5, 167.7, and 168.6. IR ν: 1780, 1600, 1365, 1180, and 995 cm^{-1}. UV λ_{max}^{MeOH}: 218 nm (ε=18000), 240 (29900), 292 (6500), and 319 (7800)] together with a mixture of 2,4-diacetoxy-3,5,7-tribromotropone and a tetraacetoxybromotropone [283 mg].

Acetolysis of 50 to 45 and 6 in the Presence of NaOAc. An ATA solution (15 cm^3) of **50** (150 mg) and NaOAc (99 mg) was heated in an autoclave at 125 °C for 2 d. The solvent was then removed by heating the mixture in vacuo and the residue was chromatographed on a silica-gel column to give, from hexane-AcOEt (1 : 1), **45** [81 mg; 60%], identical with the authentic sample, and **6** [18 mg; 11%].

Acid Hydrolysis of 6. An aqueous AcOH solution (60%, 5 cm^3) of **6** (129 mg) was heated at 100 °C for 5 h. After removal of the solvent, the residue was recrystallized from MeOH-AcOEt to give **51** [brown crystals, mp>300 °C (decomp), 59 mg; 97%. Found: C, 44.78; H, 3.32%; m/z, 186.0158 (M$^+$). Calcd for $C_7H_6O_6$: C, 45.17; H, 3.25%; M, 186.0163. ^{1}H NMR (DMF-d_7) δ=6.77 (1H, s). ^{13}C NMR (DMF-d_7) δ=104.9, 142.0 (2C), 150.3 (2C), and 154.3 (2C). IR ν: 3510, 3400—3000, 1600, 1380, 1305, 1205, and 1030 cm^{-1}. UV λ_{max}^{MeOH}: 268 nm (ε=31500), 317 (2800, sh), 332 (3500, sh), 340 (3600, sh), and 360 (3000, sh)].

Bromination of 2,4,5,7-Tetraacetoxytropone (45) to 4,5,6-Triacetoxy-3,7-dibromotropolone (54). A $CHCl_3$ solution of **45** (90 mg) was treated with Br_2 (100 mg) in $CHCl_3$ (1 cm^3) at room temperature. Then, the mixture was heated at 60 °C for 4 h, and the mixture was heated in vacuo to remove the solvent, and the residue was acetylated with Ac_2O (2 cm^3) at 110 °C for 6 h. After removal of the solvent in vacuo, the residue was chromatographed on a silica-gel column to give **54** [a yellow oil, 28 mg; 53%. Found: C, 34.23; H, 2.34%; Calcd for $C_{13}H_{10}O_8Br_2$: C, 34.39; H, 2.22%. ^{1}H NMR δ=2.33 (9H, s). ^{13}C NMR δ=20.4 (2C), 166.0, and 166.2. IR ν: 3600—3300, 1790, 1610, 1375, 1165, 1010, and 960 cm^{-1}. UV λ_{max}^{MeOH}: 212 nm (ε=9900), 250 (20200, sh), 259 (23200, sh), 266 (22800, sh), 341 (6700), and 419 (800)] together with the recovered **45** [51 mg; 57%].

Bromination of 2,3,5,7-Tetraacetoxytropone (48) to 2,3,5,7-Tetraacetoxy-4,6-dibromotropone (52) and 3,4,5,6-Tetraacetoxy-2,7-dibromotropone (53). A $CHCl_3$ solution (25 cm^3) of **48** (356 mg) was treated with Br_2 (400 mg) in $CHCl_3$ (4 cm^3) at room temperature. The mixture was then heated to 60 °C for 4 h, and evaporated to remove the solvent. The residue was acetylated by Ac_2O (2 cm^3) at 95 °C for 6 h, and again evaporated in vacuo. The residue was chromatographed on a silica-gel column to give **52** [colorless needles, mp 140.5—142.5 °C, 342 mg; 66%. Found: C, 36.55; H, 2.55%. Calcd for $C_{15}H_{12}O_9Br_2$: C, 36.32; H, 2.44%. MS m/z 495 (M$^+$+1), 410, 368, 330, 328, 326 (1 : 2 : 1), 298. ^{1}H NMR δ=2.30 (3H, s), 2.32 (6H, s), and 2.37 (3H, s). ^{13}C NMR δ=20.2, 20.3 (2C), 20.7, 166.1, and 166.3. IR ν: 3600—3300, 1795, 1625, 1375, 1285, 1170, 1035, and 900 cm^{-1}. UV λ_{max}^{MeOH}: 257 nm (ε=25800) and 335 (7700)], and **53** [colorless crystals, mp 145—147 °C, 60 mg; 11%. Found: C, 36.18; H, 2.57%. ^{1}H NMR δ=2.27 (6H, s) and 2.33 (6H, s). ^{13}C NMR δ=20.0 (2C), 20.5 (2C), 130.6 (2C), 149.1 (4C), 165.8 (2C), and 166.1 (3C). IR ν: 1790, 1625, 1380, 1285, 1165, 1015, and 840 cm^{-1}. UV λ_{max}^{MeOH}: 232 nm (ε=16100), 268 (19300), and 332 (6900)].

Acetolysis of 2,3,5,7-Tetraacetoxy-4,6-dibromotropone (52). An ATA solution (15 cm^3) of **52** (311 mg) was sealed in an autoclave and heated at 100 °C for 5 d. After removal of the solvent in vacuo, the residue was chromatographed on a silica-gel column to give **6** [6.4 mg; 2.6%] and **7** [colorless crystals, mp 173—175 °C, 1.3 mg; 0.5%. Found: C, 50.16; H, 4.06%. Calcd for $C_{19}H_{18}O_{13}$: C, 50.23; H, 3.99%. (Calcd for $C_{17}H_{16}O_{12}$, as a pentaacetoxytropolone: C, 49.52; H, 3.91%). ^{1}H NMR δ=2.29 (18H, s). ^{13}C NMR δ=20.1 (6C) and 165.9 (6C). IR ν: 3600—3300, 1800, 1785, 1615, 1370, and 1175 cm^{-1}. MS m/z 412 (M$^+$−42), 370, 328, 286, 244, 202, and 176. UV λ_{max}^{MeOH}: 243 nm (ε=29700) and 320 (7300)].

Acetolysis of 52 in the Presence of NaOAc. Formation of 2,3,5,7-Tetraacetoxytropone (48) and Pentaacetoxytropone (6). An ATA solution (16 cm^3) of **52** (513 mg) and NaOAc (180 mg) was heated at 110 °C for 5 d. The mixture was then heated in vacuo to remove the solvent, and the residue was chromatographed on a silica-gel column to give **48** [168 mg; 48%] and **6** [49 mg; 12%].

Acetolysis of Octachlorocycloheptatriene (8). a) An ATA solution (15 cm^3) of NaOAc (200 mg) and **8** (200 mg) was sealed in a pressure bottle, and heated at 85 °C in an autoclave for 12 d. The solvent was then removed in vacuo, and the residue was chromatographed on a silica-gel column to give **56** [green needles, mp 128.5—130.5 °C, 20 mg; 10%. Found: C, 40.95; H, 2.64%. Calcd for $C_{13}H_9O_7Cl_3$: C, 40.71; H, 2.36%. ^{1}H NMR δ=2.09 (3H, s), 2.12 (3H, s), and 2.38 (3H, s). ^{13}C NMR δ=20.3, 21.6, 24.6, 111.9, 124.1 (2C), 134.8, 147.4, 148.9, 151.8, 166.1, 166.7, and 170.0. IR ν: 1780, 1595, 1360, 1170, 1120, and 995 cm^{-1}. UV λ_{max}^{MeOH}: 245 nm (ε=22100), 262 (31600), 271 (25500, sh), 328 (7200, sh), 340 (7800), 353 (6700, sh), and 372 (3500, sh)]. The rest of fractions were complex mixture of products, and no further fractionation was carried out.

b) An ATA solution (100 cm^3) of **8** (950 mg) and NaOAc (1.6 g) was sealed in a pressure bottle and heated in an autoclave at 130 °C for 5 d. The solvent was then removed in vacuo, and the residue was chromatographed on a silica-gel column to give **57** [20 mg; 2%. MS m/z 431 (M$^+$+1). ^{1}H NMR δ=2.31 (3H, s), 2.32 (6H, s), and 2.36 (6H, s). ^{13}C NMR δ=20.1 (5C) and 165.9 (5C). UV λ_{max}^{MeOH}: 248 nm (ε=22600), 278 (5400, sh), 295 (4900), and 325 (6100)], and a mixture consisted of pentaacetoxychlorotropone, triacetoxytrichlorotropones, and diacetoxytetrachlorotropones (ca. 70%).

c) An ATA solution (41 cm^3) of NaOAc (1.3 g) and **8** (750 mg) was heated similarly in an autoclave at 115 °C for 5 d, then 160 °C for 2 d. After removal of the solvent in vacuo, the residue was chromatographed on a silica-gel column to give **6** [23 mg; 3%], which was identical with the sample prepared from **50**, and **7** [colorless crystals, mp 173—175 °C, 6 mg; 0.6%.].

Acid Hydrolysis of Hexaacetoxytropone (7). An aqueous AcOH solution (50%, 4 cm^3) of **7** (3 mg) was heated at 95 °C

for 10 h. Removal of the volatile material left **55** [pale brown crystals, mp >300 °C, 1 mg; 75%. UV λ_{max}^{MeOH}: 226, 272, and 292 nm].

Bromination of 46 in AcOH. An AcOH solution (5 cm^3) of **46** (11 mg) and NaOAc (9 mg) was treated with Br_2 (20 mg) at room temperature. The mixture was then heated at 95 °C for 2 h, and evaporated the solvent in vacuo. The residue was extracted with $CHCl_3$, and again evaporated to give **58** [orange crystals, mp 222 °C (decomp) (lit,[33] mp 270 °C (decomp)), 16 mg; 83%. ^{13}C NMR (CD_3OD) δ=102.5 (2C) and 167.1 (4C). MS *m/z* 300, 298, 296 (M^+, 1:2:1)].

We wish to thank the Ministry of Education, Science and Culture for a financial assistance through the Grant-in-Aid for Scientific Research to A. M. (No. 60470025). We are also grateful to Mr. Kazushi Tomiyasu who prepared some of the starting materials.

17) During our kinetic studies on the acetoxytropones, we noticed that a thermal isomerization of *o*-diacetoxytropones to 1,3-dioxoles occurred gradually. The acetotropy was no longer operative in the latter molecule. This is also incompatible to the view that the 1,3-dioxole might be an intermediate of the acetoxyl migration.

23) Formations of these dioxoles, **18a** and **29a**, were supposed to be a secondary products due to a thermal elimination. Indeed, we frequently noticed an increasing of the peaks around δ=124 by heating. This means that the other vicinally diacetoxylated tropones may also form the dioxoles.

24) Between the two possibilities, **29a** is favored over **29b** on the basis of the chemical shift; the singlet signal ascribable to the C-2 proton at 6.82 was lower than estimated for that of 3-alkoxytropones.

(Received May 11, 1987)

"The acetotropy" of 2-acetoxytropones was shown to be a concerted [1,9] sigmatropic process on the basis of a kinetic analysis. A little substituent effect for the activation free energy of the acetyl migration was recognized. Preferred tautomers of polyacetoxytropones were those having the carbonyl group at inner positions. As an extreme case, a "Merry-Go-Round"-type rearrangement was operative in hexaacetoxytropone.

Currently, we have developed a preparation method for polyacetoxytropones from polyhalotropones.[1] By this method, we have synthesized several polyacetoxytropones, including hexaacetoxytropone (**1**). The ^{1}H NMR of **1** revealed only one methyl signal in the ^{1}H NMR spectrum at room temperature, indicating the operation of a seven-fold symmetric degenerated [1,9] acetyl migration. This paper deals with a kinetic analysis with variable temperature ^{13}C NMR spectra of **1** and its related derivatives in order to ascertain the concerted nature of this rearrangement. The term, [1,9] sigmatropy, was first introduced in the literature by Harrison et al.[2] for a benzyl group migration in the isomerization of 2-benzyloxy-3-bromotropone to 2-benzyloxy-7-bromotropone.[3]

The acetyl migration in the 2-acetoxytropones was previously reported by Masamune et al.[4] and by Minkin et al.[5] Masamune et al. proposed an ionic mechanism which is assisted by the polarization of tropone carbonyl to form a delocalized 6π system in a seven-membered ring; however, at the same time, they inconsistently mentioned a small medium effect for the reaction rates. When we noticed a formation of the same thermolysates in the same product distribution[6] in the thermal homolytic rearrangement of 2-(2-furylmethoxy)-4-isopropyltropone and 2-(2-furylmethoxy)-6-isopropyltropone, we thought that prior to rearrangement, these ethers mutually isomerized via an electrocyclic process, a further example of the [1,9] alkyl shift process.[2] In view of the similarity, the acetotropy, the rearrangement of the acyl groups between two oxygens of C-1 and C-2 positions of tropolones, may well be concerted, too. Herein, we will show unequivocal evidence for the concerted mechanism of the acetotropy, that is the [1,9] sigmatropy.[7]

Chart 1.

Results and Discussion

Acetotropy of 2-Acetoxytropone and Its Acetoxy Derivatives. At first, the kinetics of the acetotropy of 2-acetoxytropone (**2**) were analyzed in order to make a comparison with the reported data.[4] Table 1 shows that both data were in accord within experimental error. Unexpectedly, 2,7-diacetoxytropone (**3**)[9] did not operate the acetotropy and its ^{1}H NMR signals retained their sharpness at a temperature between −50 and +100 °C, while 2,5-diacetoxytropone (**4**)[9] showed smooth acetotropy. Therefore, the acetyl migration is operative only between tautomers having the same degree of thermodynamic stability. In other words, in the case of **3**, a symmetrical 2,7-diacetoxy structure is much more stable than the unsymmetrical 2,3-diacetoxy structure. As will be shown in later, this applies to consecutively substituted polyacetoxytropones; the predominant tautomers in that category possess the carbonyl carbon as such having two adjacent acetoxyl groups (the "inner positions"). Further examples of acetotropy were obtained from 2-acetoxy-5-methoxytropone (**5**), 2-acetoxy-3,7-dibromo-5-isopropyltropone (**6**),[1] 2,3,7-triacetoxy-5-isopropyltropone (**7**),[1] 2,3,5,7-tetraacetoxytropone (**8**),[1] pentaacetoxytropone (**9**),[1] and 2,3,7-triacetoxy-5-(1,1-dimethyl-2-oxopropyl)tropone (**10**):[1] From the NMR spectros-

Chart 2.

copy, the acetotropy of **7** or **10** is operative only with an acetyl group between C-1 and C-2 oxygens, while **8** mainly exists as a tautomeric 1 : 1-mixture of **8b** and **8c**, and **9** was a mixture of **9b**, **9c**, **9d**, and **9e** (13 : 37 : 37 : 13). The absence of tautomers having the carbonyl carbon at the "outer position" in these polyacetoxytropones simplified the kinetic analyses. A notable case was that of 2,4,5,7-tetraacetoxytropone (**11**)[1] which showed no acetotropy at all.

Acetotropy of Hexaacetoxytropone. Now, it is noteworthy that **1**[1,10] exhibited a seven-fold symmetric, "Merry-Go-Round"-type degenerated acetotropy; at +50.2 °C, **1** exhibited only one methyl signal (20.05) and one carbonyl signal (167.47). However, the signals of tropone ring carbons were undetectable due to the broadenings by the chemical exchange. At −0.5 °C, these tropone ring signals were still undetectable, while the methyl signal (20.02) and the acetyl carbonyl signals (167.74 and 168.02) became broadened. At −15.4 °C, the spectrum changed to show three acetyl carbonyl signals (167.79, 168.03, and 168.35), three tropone ring signals (140.59, 145.61, and 149.17), and an unresolved methyl signal (20.14). At −60.1 °C, the exchange ceased; i.e., the methyls (20.13, 20.22, and 20.44), tropone ring signals (140.91, 146.17, and 149.45), the tropone carbonyl (169.00), and acetyl carbonyl signals (168.56, 168.82, and 169.18).

Kinetic Analyses of the Acetotropy. The kinetic data of these acetoxytropones are compiled in Table 1. In all cases, the activation free energies ($\Delta G^{\neq}$) were not much different, in spite of the different polarity and electronic effect of the substituents and different solvent polarity. Should an ionic intermediate be involved, the $\Delta G^{\neq}$ must become smaller to large extent by increasing the number of electron-releasing acetoxyl groups, and even by the polarity of the solvents. Consequently, the figures obtained by the present experiments were not consistent with an ionic mechanism. Previously, Harrison et al. proposed that the

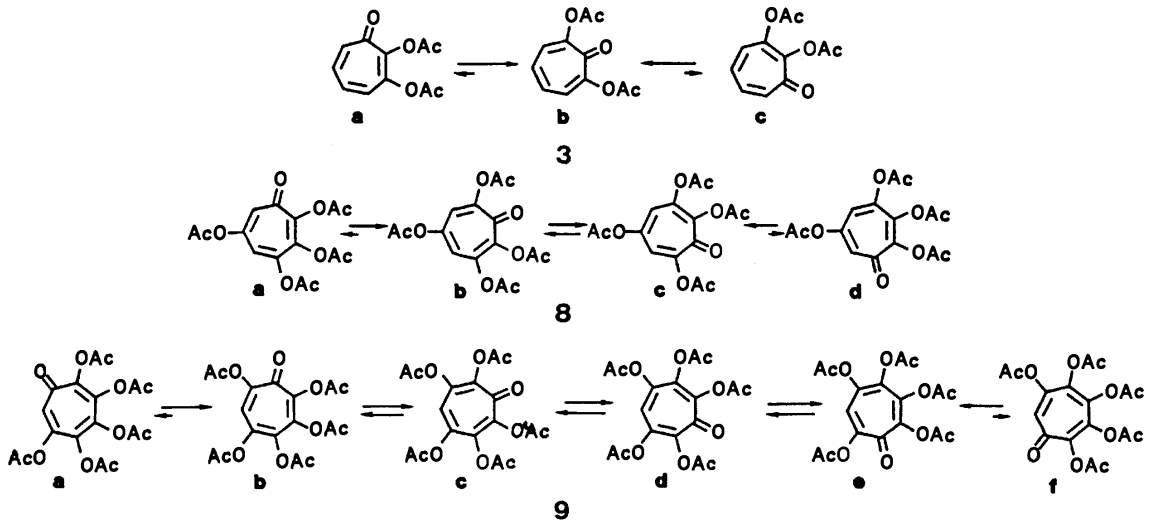
Equilibrium of Polyacetoxytropones



Scheme 1.

acetotropy of 2-acetoxytropones proceeds via an ionic intermediate in view of its small $\Delta G^{\neq}$;[2] however, their proposal seems to lack a sound basis. The figures of $\Delta G^{\neq}$ for [1,5] sigmatropies determined to date are in very wide range (27 to 210 kJ mol^{-1}),[11] and no definite conclusion should be drawn only from the $\Delta G^{\neq}$.

On the other hand, the activation entropies ($\Delta S^{\neq}$) should provide available information; the negative and small $\Delta S^{\neq}$ for the present acetotropies are in the range of many precedent figures of [1,5] sigmatropies;[11] also, the migration of the acetyl group must proceed via a concerted mechanism, i.e., [1,9] sigmatropy, but not via a radical mechanism which should show the positive $\Delta S^{\neq}$.

Further, an introduction of the oxygen functions into 5-position made the $\Delta S^{\neq}$ significantly larger negative in DMF (ε=36.7); if one looks at **2** and **4**, which showed most reliable parameters, $\Delta S^{\neq}$ are −16 J mol^{-1} K^{-1} for the former and −42 J mol^{-1} K^{-1} for the latter. Unfortunately, errors for other substrates are quite large, and it is not suitable for intensive discussions. However, if each compound could be classified as in Table 1, a very interesting tendency would be noticed. An average $\Delta S^{\neq}$ of **2**, **6**, **7**, and **10** (Group I) is −9 J mol^{-1} K^{-1}, the other hand, −45 J mol^{-1} K^{-1} in the case of other derivatives (Group II). All 2-acetoxytropones have the large negative $\Delta S^{\neq}$ (−42 to −57 J mol^{-1} K^{-1}) in chloroform (ε=4.70). This means that as far as the 2-acetoxytropones concern, the transition state of the acetotropy is less polar than the initial state. Particularly, the initial state of Group II compounds is less polar and less solvated than the initial state of Group I derivatives. The same classification might be true for $\Delta H^{\neq}$, owing to the results of compensation effect between $\Delta S^{\neq}$ and $\Delta H^{\neq}$.

Namely, polarized 6π contribution stabilizes the initial state in respect of tight solvation, but does not stabilize the transition state; therefore, polarized carbonyl oxygen does not assist but retard the rearrangement. This invalidates the Masamune's mechanism.

It will be interesting to compare these kinetic features to those of the isomerization of 2-benzyloxy-3-bromotropone to 2-benzyloxy-7-bromotropone, for which, we have recently established the concerted nature, the [1,9] sigmatropy, by an intensive high-pressure kinetic analysis.[3] Namely, in that rearrangement, the $\Delta S^{\neq}$, (−47 and −92 J mol^{-1} K^{-1} in isopropylbenzene (IP, ε=2.4) and 1-hexanol (ε=13.3), respectively), showed a weak, but not negligible, polarized contribution at the transition state. The value of $\Delta S^{\neq}$ of the present acetotropy in less polar chloroform is in the same range with the $\Delta S^{\neq}$ of that [1,9] sigmatropy in IP. These similarities did not contradict the view of a concerted mechanism for the acetotropy, i.e., the [1,9] sigmatropy. However, the $\Delta S^{\neq}$ in polar solvents were considerably different; $\Delta S^{\neq}$ of that benzyl migration (−92 J mol^{-1} K^{-1}) was more negative than the $\Delta S^{\neq}$ of the present acetotropy (−9 J mol^{-1} K^{-1}). The difference is surely attributable to a solvation effect in the transition states for the former and the initial states for the latter.[3]

All the findings supported the rearrangement of the acetyl group in the 2-acetoxytropones being the [1,9] sigmatropy, which could not be expected in benzenoid derivatives such as 2-acetoxybenzaldehyde.

Experimental

The compounds studied in this paper were prepared by means of reported procedures as indicated, except for 2-acetoxy-5-methoxytropone. Kinetic analysis of this process was performed by variable temperature ^{13}C NMR measurements at 100 MHz and 25 MHz in *N*,*N*-dimethylformamide-d_7 (DMF-d_7) or $CDCl_3$: Rate constants of the chemical exchange process were determined by broadened line-widths

of the exchangeable signals at the half height. Natural line widths were obtained from the signals of C-5 or the narrowest signal for each compound.[8] The ^{13}C NMR spectra were measured with JMN GX 400 Model and FX 100 Model Spectrometers, JEOL. The chemical shifts (δ unit) were from the internal Me_4Si.

Preparation of 2-Acetoxy-5-methoxytropone (5). A mixture of Ac_2O (10 cm^3) and 5-methoxytropolone (214 mg)[9] was heated at 90 °C for 3.5 h. The solvent was removed in vacuo and the residue was chromatographed on a silica-gel column to give **5** [colorless crystals, mp 90—91 °C, 269 mg; 99%. Found: *m/z* 194.0576 (M^+). Calcd for $C_{10}H_{10}O_4$: M, 194.0578. ^1H NMR δ=2.29 (3H, s), 3.77 (3H, s), 6.4—6.6 (2H, dm, J=12 Hz), and 7.0—7.2 (2H, dm, J=12 Hz). ^{13}C NMR δ=20.9, 56.1, 105.6, 129.5, 134.7, 140.1, 151.1, 163.7, 169.4, and 178.1].

The starting material, tropolone, was provided by Sankyo Co. Ltd., Tokyo, to whom our thanks are due. Also, we thank the Ministry of Education, Science and Culture for a financial support, a Grant-in-Aid for Scientific Research to A. M. (No. 60470025).

10) It should be emphasized that the species involved in this acetotropy was not pentaacetoxytropolone (**A**), but **1**. Although, the difference for calculated carbon content, 0.71%, is larger than the experimental error, a discrimination of **A** and **1** on the basis of elemental analyses alone seems to be unconvincing. The ^{13}C NMR spectra at −60 °C firmly eliminated the possibility of **A**; three separated methyl signals were nearly 1:1:1 in peak heights.

The Solid-Phase ^{13}C NMR Spectra of Several Tropolone Derivatives

Akira MORI,* Shigeru SUGIYAMA, Hiroaki MAMETSUKA,† Kazushi TOMIYASU, and Hitoshi TAKESHITA*
Institute of Advanced Material Study, 86, Kyushu University, Kasuga-koen, Kasuga, Fukuoka 816

(Received June 8, 1987)

The solid-phase ^{13}C NMR spectra of *o*-, *m*-, and *p*-hydroxytropolones were measured. In the solid state, the hydrogen shift between the C-1 and C-2 oxygens was frozen under the NMR time-scale; the major tautomer of the *o*-hydroxytropolone was shown to the 2,7-dihydroxytropone form, which was parallel to the previous assignment deduced from the IR spectroscopy. In addition, the solid-phase ^{13}C NMR of *o*-bromotropolone showed it to be 7-bromo-2-hydroxytropone.

It is well-known that the tropolones undergo rapid tautomerism in solution and their ^{13}C NMR spectra usually reveal averaged signals. However, in the solid state, this tautomerism is inhibited, e.g., parent tropolone exhibited six resolved lines.[1,2]

Recently, we have investigated the [1,9] sigmatropic acetoxyl migration of several polyacetoxytropones, including hexaacetoxytropone (**1**) and 2,3-diacetoxytropone (**2**), and elucidated the concerted nature of the process by means of a kinetic analysis.[3] In the case of **2**, apparently no acetotropic rearrangement has been detected in respect of high-temperature ^{13}C NMR; this was explained in terms of the thermodynamic stability of the symmetrical 2,7-diacetoxytropone structure (**2a**) over 2,3-diacetoxy isomer (**2b**). Even tri-, tetra-, and pentaacetoxytropones, the acetotropic equilibria were operative between tautomers having the carbonyl group at the inner positions. In this connection, the prototropy in the tropolone system seems to be worth investigating by means of solid-phase NMR measurement, since the NMR in solution represent the equilibrated structures by hydrogen exchange.

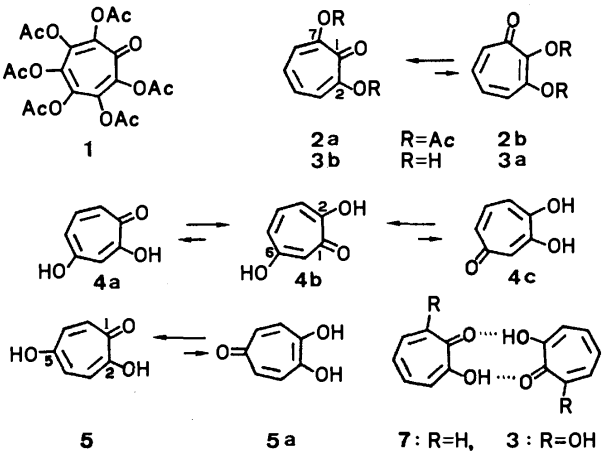
We wish to describe the investigations with *o*-hydroxytropolone (**3**), *m*-hydroxytropolone (**4**), and *p*-hydroxytropolone (**5**); these dihydroxytropones may constitute interesting tautomeric systems. Additionally included are the solid state and solution NMR behaviors of *o*-bromotropolone (**6**), being a point in dispute with its major tautomer in solution.

Experimental

The solid-phase ^{13}C NMR spectra were measured with a JEOL GX 270 spectrometer at 67.8 MHz, using the technique of high-power ^{1}H decoupling CP/MAS with a cross-polarization time of 2 ms. Chemical shifts were expressed by external reference to the Me_4Si. The actual reference compound was adamantame (methine carbon signal at δ=29.5). The samples, *o*-hydroxytropolone,[4] *m*-hydroxytropolone,[5] and *p*-hydroxytropolone,[6] *o*-bromotropolone[7] and their methyl ethers were prepared by known methods.

Results and Discussion

The ^{13}C NMR Spectra of *o*-, *m*-, and *p*-Hydroxytropolones. In the NMR of **3**, six lines appeared; its lowest signal at δ=168.1 was ascribable to a carbon having a pronounced carbonyl nature and the next two low-field signals, at δ=160.8 and 159.8, to carbons having the hydroxy nature. Superficially, the appearance of two separated hydroxy-bearing carbon signals together with exhibiting six lines favored the unsymmetrical 2,3-dihydroxytropone structure (**3a**), but the chemical shift of the lowest signal was considerably higher than that of tropolone (**7**), δ=177.5. If the magnetic non-equivalence arises from the arrangement in crystals, an alternative symmetrical 2,7-dihydroxytropone structure (**3b**) should be equally probable. This was the case from the ^{13}C NMR chemical shift comparisons between **3** and 2,3-dimethoxytropone (**8**) and 2,7-dimethoxytropone (**9**).[8] Thus, the solid-state ^{13}C NMR of **9** disclosed two separated methoxy carbon signals as well as six aromatic carbon signals, of which the magnetic non-equivalence should come from the molecular arrangement in the lattice. According to the X-ray crystallograhic analysis,[9] the tropolones are known to exist in the dimeric form with intermolecular hydrogen bondings between the α-hydroxyenone moiety; in the case of **3**, such a dimeric structure makes two kinds of hydroxyl groups, one is intermolecularly hydrogen-bonded and another isolated. The chemical shifts of **3** resembled those of **9** more closely than those of **8**. Therefore, the predominant tautomer of **3** must be 2,7-dihydroxytropone (**3b**), as being parallel to the previous result of the IR spec-



Scheme 1.

troscopy by Ikegami.[10] From these results, the signals of **3** were assigned as shown in Table 1 and the substituent effect of a hydroxyl group at C-7 was obtained to be +26.1. Furthermore, the solid-state NMR of its diacetate, *o*-diacetoxytropone (**2**),[3] exists as the symmetrical 2,7-diacetoxytropone (**2a**), which was also an exclusive tautomer in solution. Under similar conditions 2-acetoxytropones generally exist as equilibrated mixtures resulting from the [1,9] sigmatropic acetyl migration.[3]

In the case of **5**, separated seven line signals and the chemical shift of the carbonyl carbon, 173.5, eliminated the alternative 4,5-dihydroxytropone structure (**5a**).[11] From this result, the substituent effect of a hydroxyl group at C-5 was estimated to be 29.6, which was similar to the value (+26.1) obtained in **3** and that reported for a hydroxyl group of the benzenoid.[12]

On the other hand, the NMR spectrum of **4** showed considerably low-field shifted carbon signals for enolic carbons, at 164.6 and 170.3, together with a carbonyl carbon signal at 176.1. The appearance of a signal at 164.6, being appropriate for C-2 of the tropolone ring and the chemical shift of the carbonyl carbon, 176.1 eliminated the 3,4-dihydroxytropone structure (**4c**). While the substituent effect of a hydroxyl group was estimated to be +37.6 for **4a** and +28.6 for **4b**, the latter was in accord to those obtained for **3** and **5**. Thus, the major isomer of *m*-hydroxytropolone was assigned to be 6-hydroxytropolone (**4b**). The data were shown in Table 1. Consequently, α-hydroxy keto structures must be a more favorable contribution than others, and all of **3**, **4**, and **5** exist as frozen forms under the conditions for solid-phase NMR measurements.

The Tautomeric Form of *o*-Bromotropolone. According to the solid-state ^{13}C NMR spectra, the major tautomer of *o*-bromotropolone (**6**) in the solid state is indeed 7-bromo-2-hydroxytropone (**6b**). The spectrum of **6** disclosed five lines, among which, the

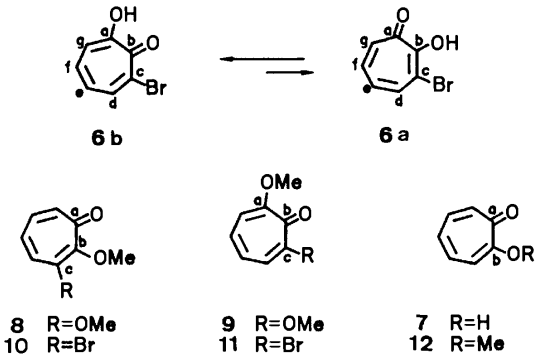

Scheme 2.

highest signal at δ=119.5 could be ascribable to the α-carbon of the hydroxyl group. This fact clarified its stable tautomer to be **6b** in the solid state.

To date, the major tautomer of **6** has been disputed; 3-bromo-2-hydroxytropone form (**6a**) was proposed by H. Sugiyama et al. on the basis of ^{1}H NMR chemical shift considerations in terms of the anisotropic effect from the bromine substituent in $CDCl_3$;[13] later, however, Bagli et al. claimed it to be **6b** on the basis of observing the triplet carbonyl carbon signal which spin-coupled to two β-protons in the ^{13}C NMR spectrum.[2] When the ^{1}H NMR spectrum of **6** was compared with isomeric 3-bromo-2-methoxytropone (**10**) and 7-bromo-2-methoxytropone (**11**), much better resemblance was observed between **6** and **10**, in favor of the H. Sugiyama's conclusion. However, the ^{13}C NMR of **6** in solution resembled **11** rather than **10**. This apparent contradiction called further careful investigation for the predominant tautomer of **6** in solution: Table 2 shows the solid-phase ^{13}C NMR of **6**, its two methyl ethers, **10** and **11**, together with reference compounds, unsubstituted tropolone, **7** and 2-methoxytropone (**12**). For the ^{13}C NMR spectra of **6**, **10**, and **11**, the chemical shifts measured in $CDCl_3$ solutions and as the solid state were parallel and showed agreement within 3.5 ppm in each other. In addition, the chemical shift of carbonyl carbon of **6** is closely related to that of **11**. By extending this to all carbons, the summations of the absolute values of the chemical shift differences for each carbon signals gave smaller $|\Delta\delta|$ in **6**—**11** (21.3) than **6**—**10** (32.5). The $|\Delta\delta|$ between **7** and **12** is 13.6. Furthermore, when we observed multiplicities of the carbonyl carbon signals, following the Bagli's procedure, **10** showed a doublet signal (J=11 Hz) while **11** showed a triplet signal (J=9.5 Hz). Consequently, **6** must predominantly exist as **6b**, 7-bromo-2-hydroxytropone form in solution and in the solid phase.

(Received May 14, 1987)

In order to elucidate the contribution of the N-terminal moiety (Phe[1] or Met[2]) of FMRFamide to the activity, 16 kinds of FMRFamide analogs were synthesized and their structure-activity relations are discussed. From the results, it was found that hydrophobic or bulky group in N-terminal contributes to the contractile effect, while the precise length of the side chain of amino acid at 2-position is due to a relaxing effect.

Previously, we reported that (*p*-hydroxyphenyl)dimethylsulfonium methyl sulfate(HODMSP · $MeSO_4^-$) active ester[1] enabled the formation of a peptide bond in aqueous solution and was applicable for the synthesis of a molluscan neuropeptide, FMRFamide (Phe-Met-Arg-Phe-NH_2),[2] which was isolated from the ganglia of the clam *Macrocallista nimbosa* by Price and Greenberg.[3] Particularly, this active ester method was recognized as an effective process for the coupling reaction with a peptide containing Arg, which has the free guanidine group. As a further utility of this method, we next tried to apply it to a synthetic study of the structure-activity relations of FMRFamide. FMRFamide is known to have diverse effects on molluscan muscles and neurons. In the anterior byssus retractor muscle of *Mytilus*, FMRFamide relaxes catch tension induced by acetylcholine at concentrations 10^{-8}—10^{-7} M[4] (1M=1 mol dm^{-3}) and elicits a contraction by a direct action on the muscle fibers at concentrations higher than 10^{-7} M,[5] as shown in Fig. 1.

With regard to the structure-activity relations of this peptide for these actions, Muneoka and Saitoh[6] tested a number of FMRFamide analogs and other peptide with biological actions in mammals, arthropods, and molluscans. From their report, we can draw an interesting conclusion that at least the structure of Arg^3-Phe^4-NH_2 moiety of FMRFamide is necessary for the production of both contraction and relaxation. Probably, this moiety will act as the binding unit to FMRFamide receptor. However, the role of the Phe^1 or Met^2 residue of N-terminal moiety in FMRFamide to these productions was not fully characterized.

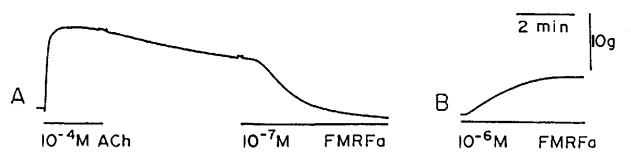

Fig. 1. Contractions and Relaxtations Produced by FMRFamide. A: Relaxing action of FMRFamide on ACh-induced catch tension. B: Contractile action of FMRFamide. ACH: Acetylcholine, FMRFa: FMRFamide.

In order to elucidate the contribution of Phe^1 or Met^2 to the activity, we synthesized 16 kinds of

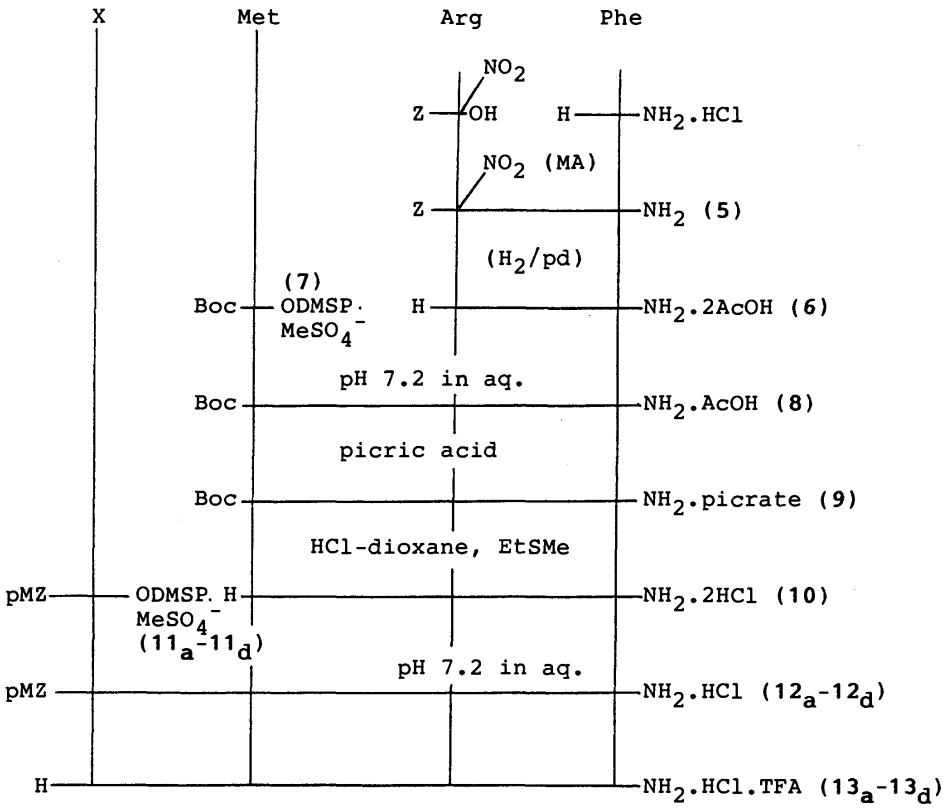
a) The contractile effect of this peptide was stronger than that of FMRFamide.

FMRFamide analogs shown in Table 1 and Table 2 and discussed their structure-activity relations of FMRFamide on a molluscan muscle.

The synthetic route for the FMRFamide analogs for Phe[1] is shown in Fig. 2. Z-Arg(NO_2)-OH was coupled with H-Phe-NH_2·HCl by means of mixed anhydride (MA) method to yield Z-Arg-(NO_2)-Phe-NH_2 (**5**). Removal of Z-group and NO_2-group from **5** by catalytic hydrogenation afforded the corresponding dipeptide amide (**6**). Boc-Met-OH was esterified by DCC and HODMSP·$MeSO_4^-$ to afford the water-soluble active ester (**7**). In aqueous solution, **7** was allowed to react with **6** in the presence of 1 M Na_2CO_3 at pH 7.2. To the reaction mixture containing the Boc-tripeptide amide (**8**), 1% picric acid was added and then the resulting Boc-tripeptide amide picrate (**9**) was isolated by extraction with ethyl acetate. The Boc-group was removed from **9** with trifluoroacetic acid and then hydrogen chloride in the presence of ethyl methyl sulfide to yield tripeptide amide (**10**). N-protected amino acid or peptide, which was prepared by the usual method, was esterified by DCC and HODMSP·$MeSO_4^-$ to afford the water-soluble active ester (**11**$_a$—**11**$_c$), which was allowed to react with **10** in the same manner as described for **8** to yield N-protected peptide amide (**12**$_a$—**12**$_c$). Finally the *p*-methoxybenzyloxycarbonyl group (pMZ-group) was removed with trifluoroacetic acid and then hydrogen chloride respectively, to yield desired peptides (**13**$_a$—**13**$_c$).

The synthetic route to **14**, **15**, and **17** is shown in Fig. 3. **14** or **15** was prepared by the coupling reaction of **10** and Ac-Phe-ODMSP·$MeSO_4^-$ or Bz-Phe-ODMSP·$MeSO_4^-$ in aqueous solution at pH 7.2, respectively. In the synthesis of **17**, pMZ-Phe-ODMSP·$MeSO_4^-$ was coupled with FMRFamide (**13**$_c$) in aqueous solution at pH 7.2 to yield **16**. The pMZ-group was removed from **16** with trifluoroacetic acid and then hydrogen chloride in the presence of ethyl methyl sulfide to yield **17**.

FMRFamide analogs for Met[2] were synthesized by the synthetic route, as shown in Fig. 4. The desired tetrapeptides (**23**$_a$—**23**$_i$) were prepared by stepwise



X: Phe(a), Gly(b), Gly-Gly(c), Phe-Gly(d), Phe-Phe-Gly(e).

-ODMSP.$MeSO_4^-$:

elongation from the C-terminal. Details of the synthetic route to those peptides is described in the experimental part.

In the synthesis of **23a**, Z-Phe-Gly-OH was coupled with **19** to yield **22a**. **22a** was then hydrogenated to give **23a**. The purity of synthetic peptides and their intermediates was confirmed by TLC with two solvent systems and by elemental analysis. The homogeneity of the final products was also confirmed by amino acid analysis.

Contractile effects and catch-relaxing effects of synthetic peptides on the anterior byssus retractor muscle of Mytilus were determined,[7] as shown in Tables 1 and 2. All the synthesized analogs of FMRFamide for Phe[1] producted only contraction and had no relaxing activity, as shown in Table 1. In the contractile activity, substitution of Gly for N-terminal Phe ($\mathbf{13_b}$) showed a decrease in contractile potency. But, extension of $\mathbf{13_b}$ by attaching Gly ($\mathbf{13_c}$) was almost equipotent to FMRFamide. When N-terminal Phe was separated from Met[2] by inserting a Gly residue and was replaced with Phe-Phe or Phe-Phe-Gly residue in FMRFamide, these peptides ($\mathbf{13_d}$, **17**, and $\mathbf{13_e}$) did not substantially change contractile activity. N-terminal acylation of FMRFamide with acetyl group or benzoyl group was slightly more active. These results indicate that hydrophobic or bulky group in N-terminal clearly contributes to the contractile effect of the peptide and the precise structure is not required for contractile activity.

In the analogs of FMRFamide for Met[2], Muneoka and Saitoh already reported that Nle can be substituted for Met[2].[6] We also recognized that this analog ($\mathbf{23_g}$) had both contractile and relaxing activity and each activity was comparable with that of FMRFamide, as shown in Table 2. Substitution of Leu for Met[2] showed a slight decrease in contractile and relaxing potency. In contrast, Gly, Ala, Abu, Ile, Phe, and Pro could not be substituted for Met[2]; these peptides had no relaxing activity. The most remarkable fact was that the peptide ($\mathbf{23_d}$), in which Val was substituted for Met[2], had only a relaxing activity. The results described above indicate that the precise length of the side chain of amino acid at 2-position, in addition to the hydrophobic group of N-terminal, contributes to the relaxing activity. In conclusion, we could biologicaly synthesize active peptides, which produced a contraction or a relaxation separately. From the viewpoint of pharmacology, we expect that these findings give an important clue to the designing effective relaxing peptides. For the structure-activity relations of FMRFamide, further studies are now in progress.

Experimental

All the melting points were uncorrected. The optical rotations were measured on a Union PM-101 polarimeter. TLC was carried out on Merck Silicagel G: R_{f_1}, 1-butanol-acetic acid-pyridine-water (4:1:1:2, v/v), R_{f_2}, $CHCl_3$-methanol (5:1, v/v), R_{f_3}, 1-butanol-acetic acid-water (3:3:2, v/v). Spots of materials possessing free amino group on TLC plate were detected by spraying with ninhydrin, and those of amino group blocked materials by spraying with 25% HBr in acetic acid and then ninhydrin. Amino acid analysis was performed by HPLC using JASCO TRI ROTAR-V and UVIDEC-100V apparatus.

Synthesis of Analogs for Phe[1]. Z-Arg(NO_2)-Phe-NH_2 (5): A solution of Z-Arg(NO_2)-OH (3.53g, 10 mmol) and NMM (1.1ml, 10 mmol) in THF (20 ml) was chilled to −5 °C, then ECF (1 ml, 10 mmol) was added to it. After 10 min, a precooled solution of H-Phe-NH_2·HCl (2.00 g, 10 mmol) and Et_3N (1.4 ml, 10 mmol) in $CHCl_3$ (20 ml) was added. The reaction mixture was refrigerated for 1 h and then allowed to stand overnight at room temperature. The mixture was concentrated in vacuo, and the solid was suspended in hot methanol (50 ml). The solid was filtered and washed with methanol; Yield 4.24g (85%); mp 218—221 °C; $[\alpha]_D^{20}$ −14° (*c* 0.5, DMF); R_{f_1} 0.91; R_{f_2} 0.41; Found: C, 55.56; H, 5.70; N, 19.38%; Calcd for $C_{23}H_{29}O_6N_7$: C, 55.34; H, 5.81; N, 19.63%.

H-Arg-Phe-NH_2·2AcOH (6): Compound **5** (2.5g, 5 mmol) in acetic acid (10 ml) was hydrogenated in the presence of palladium black. The filtrate was concentrated in vacuo and the residue was crystallized from ether as hygroscopic crystals; Yield 1.08 g (98%); $[\alpha]_D^{20}$ +9° (*c*1, H_2O); R_{f_1} 0.41; R_{f_3} 0.75.

Boc-Met-ODMSP·$MeSO_4^-$ (7) (Water-Soluble Active Ester): To a chilled solution of Boc-Met-OH (2.49g, 10 mmol) and HODMSP·$MeSO_4^-$ (2.66 g, 10 mmol) in CH_3CN (80 ml), DCC (2.06 g. 10 mmol) was added. The reaction mixture was held overnight at 0 °C and the DCurea which formed was filtered off. The filtrate was concentrated in vacuo, and the residual oil was washed with ether by decantation; Yield 3.93 g (80%); $[\alpha]_D^{20}$ −30° (*c*1, MeOH); R_{f_1} 0.82; R_{f_2} 0.34.

Boc-Met-Arg-Phe-$N\bar{H}_2$·Picrate (9): Compound **6** (0.88 g, 2 mmol) was dissolved in H_2O and the pH of the solution was adjusted to 7.2 by addition of Et_3N. Boc-Met-ODMSP·$MeSO_4^-$ (**7**) (0.99 g, 2 mmol) was added to the stirred solution below 20 °C, the pH being maintained automatically at 7.2 with Et_3N. After 12 h, 1% picric acid was added to the solution and the pH of the solution was adjusted to 5.6. A yellow precipitate was filtered off and it was dissolved in ethyl acetate (100 ml). The solution was washed successively with 4% sodium hydrogencarbonate, 4% citric acid and water, and then dried over anhydrous sodium sulfate. The solution was concentrated to an oily residue which was crystallized by addition of ether. It was recrystallized from $CHCl_3$; Yield 0.75 g (45%); mp 110 °C (decomp); $[\alpha]_D^{20}$ −14° (*c* 0.5, DMF); R_{f_1} 0.83; R_{f_2} 0.32; Found C, 46.84; H, 5.81; N, 17.95%; Calcd for $C_{25}H_{41}O_5N_7S \cdot C_6H_3N_3O_7 \cdot 1/2H_2O$; C, 47.17; H, 5.70; N, 17.74%; Amino acid ratios in acid hydrolyzate: Arg 0.94, Met 0.89, Phe 1.00.

H-Met-Arg-Phe-NH_2·2HCl (10): To a solution of **27** (0.78g, 1 mmol) and ethyl methyl sulfide, 4M HCl in dioxane (5 ml) was added. The solution was allowed to stand for 1 h at room temperature, and then concentrated in vacuo. The residue was crystallized with ether; Yield 0.47 g (90%); mp 140 °C (decomp); $[\alpha]_D^{20}$ +10° (*c* 0.5, H_2O); R_{f_1} 0.52; R_{f_3} 0.74; Found: C, 49.03; H, 6.87; N, 20.01%; Calcd for $C_{20}H_{33}O_3N_7S \cdot 2HCl$; C, 49.25; H, 6.97; N, 20.09%; Amino acid ratios in acid hydrolyzate: Arg 0.96, Met 0.84, Phe 1.00.

pMZ-X-ODMSP·$MeSO_4^-$ ($\mathbf{11_a}$—$\mathbf{11_d}$) (Water-Soluble Active Ester): pMZ-Phe-ODMSP·$MeSO_4^-$ ($\mathbf{11_a}$), pMZ-Gly-ODMSP·$MeSO_4^-$ ($\mathbf{11_b}$), pMZ-Gly-Gly-ODMSP·$MeSO_4^-$ ($\mathbf{11_c}$), pMZ-Phe-Gly-ODMSP·$MeSO_4^-$ ($\mathbf{11_d}$), pMZ-Phe-Phe-Gly-ODMSP·$MeSO_4^-$ ($\mathbf{11_e}$), Ac-Phe-ODMSP·$MeSO_4^-$, and Bz-Phe-ODMSP·$MeSO_4^-$ were also prepared from the corresponding carboxyl components and HODMSP·$MeSO_4^-$ by the same method as **7**.

$\mathbf{11_a}$: Yield 90%; R_{f_1} 0.85; R_{f_2} 0.51.

$\mathbf{11_b}$: Yield 85%; R_{f_1} 0.70; R_{f_2} 0.39.

$\mathbf{11_c}$: Yield 90%; R_{f_1} 0.72; R_{f_2} 0.38.

11_d : Yield 88%; R_{f_1} 0.82; R_{f_2} 0.45.

11_e : Yield 80%; R_{f_1} 0.85; R_{f_2} 0.51.

Ac-Phe-ODMSP · $MeSO_4^-$: Yield 82%; R_{f_1} 0.81; R_{f_2} 0.42.

Bz-Phe-ODMSP · $MeSO_4^-$: Yield 88%; R_{f_1} 0.88; R_{f_2} 0.55.

Since these compounds were obtained as the oily products, they were soon employed for the next reactions.

pMZ-X-Met-Arg-Phe-NH_2 · HCl (12_a—12_d and 14—16): The synthesis of pMZ-Gly-Met-Arg-Phe-NH_2 · HCl (**12_b**) is as follows. Compound **10** (0.52 g, 1 mmol) was dissolved in H_2O (10 ml) and the pH of the solution was adjusted to 7.2 by addition of 1M Na_2CO_3. pMZ-Gly-ODMSP · $MeSO_4^-$ (**11_b**) (0.59 g, 1.2 mmol) was added to the stirred solution below 20 °C, the pH being maintained automatically at 7.2 with 1M Na_2CO_3. After 12 h, the crude product was precipitated from the reaction mixture. It was filtered and then washed with 4% sodium hydrogencarbonate and water. It was recrystallized from methanol; Yield 0.23 g (32%); mp 146 °C (decomp); $[\alpha]_D^{20}$ −20° (*c* 0.5, DMF); R_{f_1} 0.75; R_{f_3} 0.81; Found: C, 50.72; H, 6.53; N, 15.21%; Calcd for $C_{31}H_{44}O_7N_8S$ · HCl · H_2O: C, 51.23; H, 6.47; N, 15.41%; Amino acid ratios in acid hydrolyzate: Arg 0.95, Gly 0.93, Met 0.87, Phe 1.00.

pMZ-Phe-Met-Arg-Phe-NH_2 (**12_a**), pMZ-Gly-Gly-Met-Arg-Phe-NH_2 · HCl (**12_c**), pMZ-Phe-Gly-Met-Arg-Phe-NH_2 · HCl (**12_d**), pMZ-Phe-Phe-Gly-Met-Arg-Phe-NH_2 · HCl (**12_e**), pMZ-Phe-Phe-Met-Arg-Phe-NH_2 · HCl (**16**), Ac-Phe-Met-Arg-Phe-NH_2 · HCl (**14**), Bz-Phe-Met-Arg-Phe-NH_2 · HCl (**15**) were prepared from the corresponding HODMSP.$MeSO_4^-$ active ester and **28** by the same method described for the preparation of **12_b**.

12_a: Yield 41%; mp 190 °C (decomp); $[\alpha]_D^{20}$ −20° (*c* 0.5, DMF); R_{f_1} 0.80; R_{f_3} 0.91; Found: C, 55.91; H, 6.31; N, 13.47%; Calcd for $C_{38}H_{50}O_7N_8S$ · HCl · H_2O: C, 55.87; H, 6.49; N, 13.71%; Amino acid ratios in acid hydrolyzate: Arg 0.95, Met 0.87, Phe 2.00.

(Received May 14, 1987)

In order to investigate the role of C-terminal Phe^4-NH_2 of FMRFamide (Phe-Met-Arg-Phe-NH_2) to the biological activity, 30 kinds of cyclohexylamide derivatives of peptides related to FMRFamide were synthesized and their FMRFamide-like activity was measured. From the results, it was found that the peptide which was placed at C-terminal Phe^4-NH_2 by D-Ala-CHA showed only a relaxing activity. Furthermore, it was recognized that Met-Arg-Asp-diCHA inhibited FMRFamide contraction selectively.

The molluscan neuropeptide FMRFamide(Phe-Met-Arg-Phe-NH_2)[1] which was isolated from the ganglia of the clam *Macrocallista nimbosa* by Price and Greenberg,[2] causes a relaxation or a contraction, depending on its concentration, in the anterior byssus retractor muscle of *Mytilus*. Low concentrations of this peptide(10^{-8}—10^{-7}M, 1M=1mol dm^{-3}) relax acetylcholine-induced catch-tension,[3] whereas high concentrations(higher than 10^{-7}M) cause contraction.[4] In a previous paper,[5] we reported the synthesis of FMRFamide analogs for N-terminal moiety and discussed their structure-activity relations. Consequently, it was found that the precise structure of the N-terminal moiety is indispensable for the FMRFamide-like activity. However, we did not deal with the structure-activity relations of the C-terminal moiety in that paper. Muneoka and Saitoh[6] already reported that the substitution of D-Arg or Lys for Arg,[3] the substitution of D-Phe for C-terminal Phe, and the removal of the C-terminal amide eliminated contractile activity and greatly reduced relaxing activity in the relations of the C-terminal moiety. From their report, it is assumed that the C-terminal moiety (Arg^3-Phe^4-NH_2) of this peptide serves as a binding unit to the FMRFamide receptor, so that it gives rise to a FMRFamide-like activity.

To learn more about the role of C-terminal Phe^4-NH_2 to the activity, we designed FMRFamide analogs and fragments, which possess the fundamental structure shown in Fig. 1. Since the substitution of cyclohexylamide of D-amino acid for C-terminal Phe^4-NH_2 seems to substantially keep the molecular structure of FMRFamide, we expected that these peptides were designed to exhibit the same activity as the FMRFamide one.

In this paper, for the first step of this study, about thirty kinds of cyclohexylamide derivatives of di-, tri-, and tetrapeptide were synthesized and the FMRFamide-like activity of these peptides were measured. Further, antagonistic effects of these peptides to FMRFamide- or acetylcholine-induced contractions were examined in order to determine the interaction of FMRFamide and its receptor.

The synthetic route to the cyclohexylamide deriva-

tives of di-, tri-, and tetrapeptide is shown in Fig. 2. For the synthesis of FMRFamide, the method of selective acylation to Arg residue in aqueous solution was employed.[7] Boc-X-OH(X; Gly, D/L-Ala, Abu, D/L-Asn, Gln, Asp, or Gln was coupled with cyclohexylamide by the mixed anhydride(MA) method to yield $\mathbf{2_a}$—$\mathbf{2_i}$. The N-terminal protecting group of $\mathbf{2_a}$—$\mathbf{2_i}$ was removed by the action of hydrogen chloride in dioxane to yield $\mathbf{3_a}$—$\mathbf{3_i}$, and then Z-Arg-(NO_2)-OH and $\mathbf{3_a}$—$\mathbf{3_i}$ were condensed to yield $\mathbf{4_a}$—$\mathbf{4_i}$. The removal of the Z-group and NO_2-group from $\mathbf{4_a}$—$\mathbf{4_i}$ by hydrogenation afforded the free dipeptide cyclohexylamide($\mathbf{5_a}$—$\mathbf{5_i}$). Boc-Met-OH was esterified by DCC and *p*-(hydroxyphenyl)dimethylsulfonium methyl sulfate (HODMSP·$MeSO_4^-$) to afford the water-soluble active ester (**6**). In an aqueous solution, compound **6** was allowed to react with $\mathbf{5_a}$—$\mathbf{5_i}$ in the presence of 1M Na_2CO_3 (1M=1 mol dm^{-3}) at pH 7.2. To the reaction

mixture containing the Boc-tripeptide cyclohexylamide acetate, 1% picric acid was added and then the resulting Boc-tripeptide cyclohexylamide picrate(**7a**—**7i**) was isolated by extraction with ethyl acetate. The Boc-group was removed from **7a**—**7i** with hydrogen chloride in the presence of ethyl methyl sulfide to yield tripeptide cyclohexylamide(**8a**—**8i**). pMZ-Phe-OH was esterified by DCC and HODMSP·$MeSO_4^-$ to afford the water-soluble active ester(**9**), which was allowed to react with **8a**—**8i** in the same manner as described for the preparation of Boc-tripeptide cyclohexylamide to yield pMZ-tetrapeptide cyclohexylamide(**10a**—**10i**). Finally, the pMZ-group was removed from **10a**—**10i** with trifluoroacetic acid to yield free tetrapeptide cyclohexylamide(**11a**—**11i**).

The purity of the synthetic peptides was confirmed by TLC in two solvent systems and by elemental analysis. The homogeneity of the tri- or tetrapeptides were confirmed by amino acid analysis.

The FMRFamide-like activity of these synthesized peptides on the anterior byssus retractor muscle was determined,[8] as shown in Table 1. All of the cyclohexylamide derivatives of di- or tripeptide synthesized showed neither contractile activity nor relaxing activity between 10^{-8} and 10^{-4} M. In the tetrapeptides, the

peptide which was replaced at C-terminal Phe^4-NH_2 by D-Ala-CHA showed only a relaxing activity. Its potency was one tenth as compared with that of FMRFamide, but the fact that this peptide had only a relaxing activity is noteworthy from the viewpoint of pharmacology.

Muneoka and Saitoh[6] reported that Phe-Met-Arg-D-Phe-NH_2 antagonized strongly FMRFamide contraction. It is very important to determine the antagonists

of FMRFamide for the elucidation of the mechanism of its biological actions. Therefore, these synthesized peptides were tested regarding their abilities to block FMRFamide-induced contractions or the contractions produced by other actions.[8] The results of antagonistic activity tests are shown in Tables 2—4. As shown in Table 2, Arg-Asp-diCHA(**5h**) and Arg-Glu-diCHA(**5i**) antagonized FMRFamide contrations and acetylcholine contractions. From Table 3, it was found that Met-Arg-Asp-diCHA(**8h**) and Met-Arg-Glu-diCHA(**8i**) exhibit higher activities than the corresponding dipeptides to block FMRFamide-induced contractions, respectively. In particular, Met-Arg-Asp-diCHA(**8h**) inhibited FMRFamide contraction selectively and had no effects upon acetylcholine contractions, as shown in Fig. 3. Most of the synthesized tetrapeptides antagonized FMRFamide contraction and acetylcholine contraction. The ability of the inhibition generally enhanced with the increasing of the hydrophobicity of C-terminal, but the selective inhibition observed in Met-Arg-Asp-diCHA(**8h**) was not observed.

From the results described above, we could synthesize a relaxing peptide by the subsutitution of cyclohexylamide derivatives for C-terminal Phe^4-NH_2. This fact will lead us to design more useful relaxing peptide. Furthermore, the result that the synthesized peptide possessing high hydrophobicity at C-terminal antagonized FMRFamide contraction, was compatible with the hypothesis that the hydrophobic C-terminal of FMRFamide serves as a binding unit to the receptor.

Experimental

All the melting points were uncorrected. The optical rotations were measured on a Union PM-101 polarimeter. TLC was carried out on Merck Silicagel G: R_{f_1}, 1-butanol-acetic acid-pyridine-water(4 : 1 : 1 : 2, v/v), R_{f_2}, $CHCl_3$-methanol (5 : 1, v/v). Spots of material possessing free amino group on TLC plate were detected by spraying with ninhydrin, and those of amino group blocked materials by spraying with 25% HBr in acetic acid and then ninhydrin. Amino acid analysis was performed by HPLC using JASCO TRI ROTAR-V and UVIDEC-100 V apparatus.

Synthesis of Cyclohexylamide Derivatives of Peptides. Z-Arg(NO_2)-X-CHA(4a—4i): To a solution of Z-Arg(NO_2)-OH in THF and equimolar NMM, equimolar ECF was added at −5 °C. After 10 min, a solution of equimolar H-X-CHA·HCl(**3a—3i**) and NMM in $CHCl_3$ was added. The reaction mixture was stirred in an ice bath for 1 h and then at room temperature overnight. The mixture was evaporated in vacuo, and the oily residue was dissolved in ethyl acetate. The solution was washed with water, 4% sodium hydrogencarbonate, 0.5M hydrochloric acid, and water, successively, and then dried over anhydrous sodium

sulfate. The filtrate was evaporated in vacuo. The oily residue was crystallized with ether. In the case of peptides containing D/L-Asn, Gln, Asp, and Glu, the reaction mixture was evaporated in vacuo, and the resulting residue was poured into ice-water. The solid was filtered and the filter cake was washed with 4% sodium hydrogencarbonate, 0.5M hydrochloric acid, and water, successively. The product thus obtained was recrystallized from ethyl acetate. These results were summarized in Table 5.

H-Arg-X-CHA · 2AcOH(5_a—5_i): A solution of Z-Arg-(NO_2)-X-CHA(4_a—4_i) in acetic acid was hydrogenated in the presence of palladium black at room temperature for 21 h. The catalyst was removed by filtration, and the filtrate was evaporated in vacuo. The residue was crystallized with ether. These results are summarized in Table 5.

Boc-Met-ODMSP · $MeSO_4^-$(6)(Water-Soluble Active Ester): To a chilled solution of Boc-Met-OH (2.49g, 10 mmol) and HODMSP · $MeSO_4^-$(2.66g, 10 mmol) in CH_3CN (80 ml), DCC (2.06g, 10 mmol) was added. The reaction mixture was held overnight at 0 °C and the DCurea which formed was filtered off. The filtrate was concentrated in vacuo, and the residual oil was washed with ether by decantation; Yield 3.93g (80%); $[\alpha]_D^{20}$ −30° (*c* 1, MeOH); R_{f_1} 0.82; R_{f_2} 0.34.

Boc-Met-Arg-X-CHA(7_a—7_i): H-Arg-X-CHA · 2AcOH (5_a—5_i) was dissolved in H_2O and the pH of the solution was adjusted to 7.3 by addition of 1M Na_2CO_3. Equimolar Boc-Met-ODMSP · $MeSO_4^-$ was added to the stirred solution below 20 °C, the pH being maintained automatically at 7.2 with 1M Na_2CO_3. After 12 h, 1% picric acid was added to the solution and the pH of the solution was adjusted to 5.6. Yellow precipitate was filtered off and it was dissolved in ethyl acetate. The solution was washed successively with 4% sodium hydrogencarbonate, 4% citric acid and water, and then dried over anhydrous sodium sulfate. The solution was concentrated to an oily residue which was crystallized by addition of ether. It was recrystallized from $CHCl_3$. These results are summarized in Table 6.

H-Met-Arg-X-CHA · 2HCl(8_a—8_i): To a solution of Boc-Met-Arg-X-CHA(7_a—7_i), TFA and ethyl methyl sulfide was added. The reaction mixture was concentrated in vacuo. To a residue, 4M HCl in dioxane was added and then the resulting hydrochloride salt was solidified with acetone. These results are summarized in Table 6.

pMZ-Phe-ODMSP · $MeSO_4^-$(9)(Water-Soluble Active Ester): pMZ-Phe-OH (3.29g, 10 mmol) and HODMSP · $MeSO_4^-$ (2.66g, 10 mmol) were coupled by the same method as **6**. It was an oily product; Yield of the oily product 5.20 g

pMZ-Phe-Met-Arg-X-CHA · HCl(10$_a$—10$_i$): H-Met-Arg-X-CHA (**8$_a$—8$_i$**) was dissolved in H_2O and the pH of the solution was adjusted to 7.2 by addition of 1M Na_2CO_3. A slight excess of pMZ-Phe-ODMSP · $MeSO_4^-$ was added to the stirred solution below 20 °C, the pH being maintained automatically at 7.2 with 1M Na_2CO_3. After 12 h, the crude product was precipitated from the reaction mixture. It was filtered and then washed with 4% sodium hydrogencarbonate and water. After removal of moisture by drying, it was recrystallized from methanol or ethyl acetate. These results are summarized in Table 7.

H-Phe-Met-Arg-X-CHA · HCl · TFA(11$_a$—11$_i$): pMZ-Phe-Met-Arg-X-CHA · HCl (**10$_a$—10$_i$**) and ethyl methyl sulfide were dissolved in TFA. The reaction mixture was allowed to stand at room temperature. After 2 h, the solution was concentrated in vacuo. The residue was crystallized with ether. These results were summarized in Table 7.

We wish to thank Professor Yojiro Muneoka of Hiroshima University for biological assays and helpful discussions.

Quantitative Analysis of Partition Behavior of Substituted Phenols from Aqueous Phase into Liposomes Made of Lecithin and Various Lipids

Hideto MIYOSHI,* Hiroaki MAEDA, Nobuya TOKUTAKE, and Toshio FUJITA
Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606
(Received May 25, 1987)

The partition coefficient of a series of substituted phenols in lecithin-liposome-water systems, P(L/W), was quantitatively analyzed by use of physicochemical molecular and substituent parameters. The effects on the P(L/W) value of the incorporation of cholesterol and charged lipids such as cardiolipin or stearylamine into the liposomal membranes were examined with the perturbation of the bilayered membrane structure induced by these lipids being taken into account. The partition behavior of phenols was primarily decided by the hydrophobicity, represented in terms of the 1-octanol-water partition coefficient, P(O/W). The partitioned phenols seemed to be in membrane close to the interface. The steric and electronic effects of substituents on the partitioning into liposomes varied significantly depending upon the type of lipids incorporated. The variations in these effects reflect differences in the structure of the interfacial region of the lecithin bilayer modified by the incorporation of various lipids.

The partition behavior of a variety of medicinal and agricultural chemicals has been studied extensively with the use of artificial lipid membranes as models of biomembranes.[1-5] In most of these studies, the effects of lipid composition,[1,2] temperature,[3,4] or the pH of the bulk aqueous phase[5] on the partition coefficient have been examined for a limited series of compounds. Only a few investigations have dealt with effects of physicochemical characteristics on the partition behavior of a series of systematically selected chemicals.[6,7]

We have quantitatively analyzed various physicochemical factors that decide the partition coefficient, P(L/W), of a series of substituted phenols in the nonionized form in a lecithin-liposome-water system.[8] The partition was governed most strongly by molecular hydrophobicity represented in terms of the partition coefficient in the 1-octanol-water system, P(O/W), as a reference. It was also affected by the acidity of phenols: The higher the electron-withdrawing ability of the substituent, the easier was the partitioning into the liposomal membrane. The basicity of the hydrogen-bond acceptor in the liposomal membrane seemed to be greater than that of the oxygen of 1-octanol used as the reference phase for the partitioning. The steric bulkiness of substituents was more unfavorable to partitioning into the liposomes than into 1-octanol. The 2,6-disubstitution showed the most unfavorable steric effect. The steric bulkiness of substituents at the meta or para position was less unfavorable. That of monoortho substitution was negligible. From these results, we assumed that the partitioned phenol molecules would be oriented with the benzene ring in the apolar interior and the phenolic OH group in the polar interfacial region of the membrane.

In this study, we measured the P(L/W) values for a number of substituted phenols including newly synthesized compounds to continue examinations of the partition behavior of phenols in artificial membranes. The substitution pattern was varied so that the steric effect of substituents specific for their positions could be analyzed in more detail than in our previous study. The effects of the incorporation of various kinds of lipids, such as cardiolipin (negatively charged), stearylamine (positively charged) and cholesterol, into bilayered lecithin liposomes on the partition behavior of substituted phenols were analyzed by comparison of quantitative structure-partitioning relationships derived with these partitioning systems.

Here, we report details of these analyses and discuss differences in physicochemical factors that govern the partitioning behavior of substituted phenols in various kinds of membranes.

Experimental

Materials. Lecithin was prepared from fresh egg yolk and purified by the method of Singleton et al.[9] Most of the phenols were the same as those studied before.[8,10] Additional phenols were purchased from Nakarai Chemicals, Ltd., except for 2-alkyl-4,6-dinitrophenols, which were synthesized by the nitration of 2-alkylphenols.[11] The structures of newly synthesized phenols were confirmed by elementary analysis and spectra. Phenols were purified by either distillation or silica-gel column chromatography before use. Reagent-grade stearylamine, cardiolipin, *N*-dansylhexadecylamine (DSHA), and anthroylstearic acid (AS) were obtained from the Sigma Chemical Co. Cholesterol was of reagent grade and was further purified by recrystallization from ethanol.

Preparation of Liposome. Lecithin bilayered liposome was prepared by a procedure slightly different from that reported previously.[8] Dry lecithin (100 mg) was suspended in 20 ml of an aspartate buffer (0.04 M† sodium aspartate, 0.25 M Na_2SO_4, and 0.2 mM EDTA), adjusted to pH 6.0 by the addition of NaOH, and sonicated in an ice-cooled bath under Ar gas. Bilayered liposome was separated from the undispersed lecithin by centrifugation and from multilayered liposome by gel filtration on Sepharose 4B at 4 °C. Cholesterol-lecithin liposome (1 : 10, m/m), cardiolipin-lecithin liposome (1 : 5, m/m), and stearylamine-lecithin

† 1 M=1 mol dm^{-3}.

liposome (1 : 5, m/m) were prepared from the corresponding dry lipid mixture in a similar way. The amount of lecithin in the liposome suspension was estimated from that of phosphorus by a modification of the Bartlett method.[12]

Measurement of Partition Coefficient. The partition coefficient, P(L/W), of each substituted phenol between the liposomal membrane and the external aqueous phase was measured by equilibrium dialysis at pH 6.0.[8] A solution of phenols, the concentration range of which is from 10^{-5} to 10^{-4} M, was prepared in the same pH 6.0 aspartate buffer as for the preparation of liposome. At this pH, all of these compounds except for 2,4,6-trichlorophenol and 2,4-dinitro derivatives exist almost completely as the nonionized form. In an equilibrium dialysis cell (ten 1-ml chambers, Sanko Plastic Co.), the liposome suspension (1 ml) was equilibrated with the phenol solution (1 ml) through a cellophane dialysis membrane at 25 °C for 12 h. The partition coefficient, P(L/W), was calculated by Eq. 1,

$$P(\mathrm{L/W}) = \frac{2(C_0 - C)}{C \times C_L} \quad \left[\frac{\text{mol phenols/kg lipids}}{\text{mol phenols/l buffer}}\right] \qquad (1)$$

where C is the concentration at equilibrium of the phenol in the liposome-free chamber, C_0 is that of the phenol in a control experiment without liposome, and C_L is the concentration of lecithin (kg l^{-1}) in the liposome suspension. The total amount of lecithin in 1 ml of the liposome suspension was about 1 mg. The concentration of the phenol was measured spectrophotometrically on a Shimadzu UV-360 spectrophotometer. For the 2,4-dinitro derivatives, the P(L/W) value was measured at pH 3.0. Since the dinitro derivatives exist as an equilibrated mixture of ionized and nonionized species even at this pH (3—8% ionized), this gave the apparent value. Using lecithin-liposome, we examined the effect of variations in the pH of the bulk aqueous phase on the apparent P(L/W) value for 2,4,6-trichloro- and 2,4-dinitrophenols.

Measurement of Polarity of Liposomal Membrane. Variations in the polarity of interfacial and interior regions of the liposome membrane were estimated from the change in λ_{max} of the emission spectrum of DSHA and AS, respectively, incorporated in liposomes.[13] DSHA or AS was mixed with lecithin at the molar ratio of 1 : 50 in chloroform. After removal of the chloroform, liposomes containing the fluorescent probe were prepared in a similar way. All fluorescent measurements were made on a Shimadzu RF-503A spectrophotometer equipped with a thermoregulated cell compartment at 25 °C. The emission λ_{max} of DSHA- and AS-liposome was observed at around 520 and 450 nm, respectively, with excitation at 330 nm and with the slit width of 5 nm for both excitation and emission sides. As an index of polarity, the emission λ_{max} value of DSHA and AS in various organic solvents was also measured.

Results

pH Dependence of Log P(L/W). For 2,4,6-trichloro- and 2,4-dinitrophenols, the effect of variations in pH on the apparent log P(L/W) was examined (Fig. 1). These phenols were partitioned into the liposome membrane even from the bulk aqueous phase, where they are invariably in the ionized form.[8]

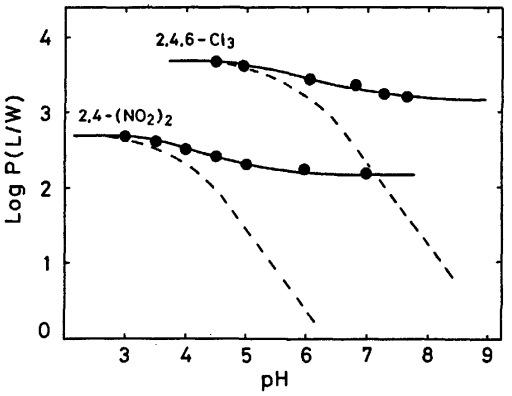

Fig. 1. Dependence on pH of the apparent log P(L/W) value for 2,4,6-trichloro- and 2,4-dinitrophenols. The dotted line is for the dependence of the log P(L/W) value according to the pH-partition model.[14]

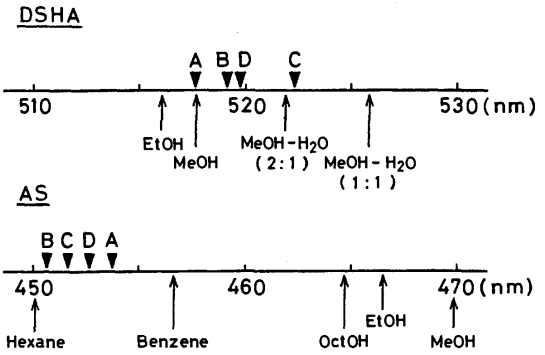

Fig. 2. Positions of the fluorescence emission maximum of DSHA and AS in lecithin liposome (A), cholesterol-lecithin liposome (B), cardiolipin-lecithin liposome (C), and stearyamine-lecithin liposome (D), together with those of various solvents.

Judging from the differences in the apparent log P(L/W) value in regions of lower to higher pH, the partition of the phenolate anions was lower than that of the neutral phenols, although the difference was not large. The partition behavior of 2,4,6-trichloro- and 2,4-dinitrophenols did not obey the pH-partition model,[14] in which the partition of ionized species from aqueous to organic phases such as 1-octanol can be neglected.

Polarity of Liposome Membrane. The emission λ_{max} values of DSHA and AS incorporated in various kinds of liposomes are shown in Fig. 2 together with those measured in various organic solvents. The fluorescent moieties of DSHA and AS have been said to be in the aqueous interface and the hydrophobic fattyacid regions of artificial membranes, respectively.[13] The λ_{max} of DSHA in the genuine lecithin bilayer was 518 nm, which corresponds to that in methanol. That of AS was between those in hexane and benzene. The λ_{max} of DSHA increased after the incorporation of cholesterol, stearylamine, or cardiolipin toward the λ_{max} in

aqueous alcohol, indicating that the polarity of the membrane surface region increased. The incorporation of cardiolipin had the strongest effect. The λ_{max} of AS decreased after the incorporation of one of these lipids, suggesting that the polarity was lowered in the membrane interior.

Analysis of Log *P*(L/W). The log P(L/W) values in four different liposome-water systems are listed in Table 1, where P(L/W), P(L/W)^C, P(L/W)$^+$, and P(L/W)$^-$ represent the partition coefficients measured with liposomes of genuine lecithin, cholesterol-lecithin, stearylamine-lecithin, and cardiolipin-lecithin, respectively. As shown in Fig. 1, the log P(L/W) of 2,4-dinitrophenol ionized by 7.5% at pH 3.0 did not seem to differ much from that of the nonionized form. Along with previous data on 2-*s*-butyl-4,6-dinitrophenol,[8] the log P(L/W) values measured at pH 3.0 for 2,4-dinitrophenol and its 6-substituted derivatives were used without further correction for the following analyses, as approximate values for their nonionized form.

We previously measured the log P(L/W) values of nonionized phenols in the lecithin-liposome-water system using Tris-HCl buffer (10 mM Tris, 50 mM NaCl, 0.2 mM EDTA).[8] The previous relationship between log P(L/W) and log P(O/W) was analyzed by regression analysis with the steric and electronic effects of substituents taken into account, as shown in Eq. 2:

$$\log P(\mathrm{L/W}) = \underset{(0.070)}{0.870}\log P(\mathrm{O/W}) + \underset{(0.029)}{0.064}\,\Delta\log K_A$$
$$\underset{(0.042)}{-0.111}\,\Delta V\mathrm{w(di\text{-}ortho)} \underset{(0.033)}{-0.074}\,\Delta V\mathrm{w(m,p)} + \underset{(0.182)}{0.629} \quad (2)$$
$$(n=26,\ s=0.117,\ r=0.986)$$

In this and the following equations, n is the number of phenols, s is the standard deviation, and r is the correlation coefficient. The figures in parentheses are the 95% confidence interval. As a steric parameter, the relative van der Waals volume of substituents, ΔVw, was used. The ΔVw is the Vw value of substituents relative to that of H and multiplied by 0.1 to make the magnitude similar to other parameters according to Eq. 3.[15]

$$\Delta V\mathrm{w} = [V\mathrm{w(X)} - V\mathrm{w(H)}] \times 0.1 \quad (3)$$

ΔVw(di-ortho) is the sum of the parameters of both ortho substituents for di-ortho substituted phenols. ΔVw(m,p) is such a sum for meta and para substituents. The $\Delta\log K_A$ value [$\log K_A$(substituted phenols)$-\log K_A$(unsubstituted phenol)] is used as the electron-withdrawing index of substituents. Here, the possible relationship between the newly measured log P(L/W) and log P(O/W) values was also analyzed in a similar way. Equations 4—7 gave the best correlation for the various liposome-water systems.

$$\log P(\mathrm{L/W}) = \underset{(0.064)}{0.820}\log P(\mathrm{O/W}) + \underset{(0.025)}{0.079}\,\Delta\log K_A$$
$$\underset{(0.037)}{-0.124}\,\Delta V\mathrm{w(di\text{-}ortho)} \underset{(0.029)}{-0.050}\,\Delta V\mathrm{w(m,p)} + \underset{(0.168)}{0.821} \quad (4)$$
$$(n=34,\ s=0.114,\ r=0.981)$$

$$\log P(\mathrm{L/W})^c = \underset{(0.063)}{0.750}\log P(\mathrm{O/W}) + \underset{(0.026)}{0.064}\,\Delta\log K_A$$
$$\underset{(0.037)}{-0.122}\,\Delta V\mathrm{w(di\text{-}ortho)} + \underset{(0.174)}{0.854} \quad (5)$$
$$(n=34,\ s=0.119,\ r=0.976)$$

$$\log P(\mathrm{L/W})^- = \underset{(0.059)}{0.714}\log P(\mathrm{O/W}) + \underset{(0.024)}{0.053}\,\Delta\log K_A$$
$$\underset{(0.034)}{-0.076}\,\Delta V\mathrm{w(di\text{-}ortho)} + \underset{(0.162)}{1.015} \quad (6)$$
$$(n=34,\ s=0.111,\ r=0.978)$$

$$\log P(\mathrm{L/W})^+ = \underset{(0.052)}{0.756}\log P(\mathrm{O/W}) + \underset{(0.021)}{0.031}\,\Delta\log K_A$$
$$\underset{(0.030)}{-0.057}\,\Delta V\mathrm{w(di\text{-}ortho)} + \underset{(0.144)}{0.859} \quad (7)$$
$$(n=34,\ s=0.099,\ r=0.985)$$

Each of the terms is significant at a level higher than 99.5% except for the $\Delta\log K_A$ in Eq. 7, which is significant at the 99% level. The addition of the ΔVw(m,p) term to Eqs. 5—7 was not justified over the 95% level. In each correlation, the regression coefficients of the $\Delta\log K_A$ and ΔVw terms were much lower than that for the log P(O/W) value. This does not mean that the steric and electronic effects of substituents were not important. In general, the variations in log P(O/W) values were much lower than those in $\Delta\log K_A$ and ΔVw values throughout the series of compounds. The lower regression coefficients for the $\Delta\log K_A$ and ΔVw terms were attributable to a range of variations much higher than that for the log P(O/W) term.

Discussion

Yeagle et al.[16] showed that the choline moiety of the lecithin head groups is oriented almost parallel to the surface plane of bilayered liposomes and that the positively charged trimethylammonio groups are associated electrostatically with the negatively charged phosphates of neighboring lipids. Here, we examined the polarity of the interfacial region of various kinds of liposomes in terms of the shift in the emission maximum of DSHA. The polarity increased with the incorporation of negatively as well as positively charged lipid, suggesting that the inter-head group interactions of the kind studied by Yeagle et al. were weakened and that the interfacial structure was loosened so that the binding of water molecules with the charged head groups on the membrane surface was enhanced. The effects of the cardiolipin molecule, with a large polar head group, were particularly strong. This molecule could perturb the membrane surface structure markedly, increasing the surface polarity very much.

According to Sunamoto et al.[17] the addition of cholesterol molecules to the lecithin bilayer allows closer molecular packing and reduces the mobility of the fatty acid chain of the lecithin above the phase transition temperature of lipids (that of the egg yolk lecithin is approx. -7 to -15 °C[18]). The emission maximum of AS was shifted toward a shorter wavelength. The polarity of the interior region of the liposome was decreased by the incorporation of cholesterol, consistent with the highly packed structure (Fig. 2). However, the addition of cholesterol caused an increase in the polarity around the fluorescent moiety of DSHA. This suggests that the inter-head group interactions were also weak in the cholesterol-lecithin liposome. Our result is consistent with the ^{31}P NMR studies[19] demonstrating that the inter-polar head interactions of phospholipid bilayered membranes are slightly weakened by the addition of cholesterol molecules.

Phenolate anions were partitioned into the liposome membrane, although the extent of partitioning is lower than that of neutral phenols.[8] Generally, the partitioning of charged species into the hydrophobic interior of a lipid membrane is energetically unfavorable.[3] Thus, the phenol molecules, regardless of their dissociation conditions, would be in a region close to the surface of the membrane holding the polar OH group toward the external aqueous phase. Colly and Metcalfe[20] studied the partition behavior of benzyl alcohol in liposomes using NMR spectroscopy and showed that the hydroxyl group projects toward the

aqueous phase. Their observation would be consistent with the model stated above for the orientation of phenols.

The coefficient of the log P(O/W) term in Eqs. 4—7 was from 0.71 to 0.82, which suggests that the partitioning of phenols occurs mainly into a phase less hydrophobic than 1-octanol.[3] Although the variations in the slope were not great, they seemed to correspond to those in the polarity of the membrane surface region; the slope decreased as the polarity increased. This would also suggest that the partitioned phenol molecules are mainly in the region of the membrane surface rather than the more hydrophobic interior.

The significance of the $\Delta \log K_A$ term would be that the basicity of the hydrogen-bond acceptor in the membrane surface region is higher than that of the oxygen of 1-octanol. We have suggested that the phenolic OH group interacts with the phosphate group of the neighboring lecithin.[8] This suggestion may need revision because this type of the interaction seems to be energetically unfavorable from the ^{31}P NMR studies of the lecithin-cholesterol interaction by Yeagle et al.[16] They have shown that the hydrogen bonding of the OH group of the incorporated cholesterol with the carbonyl group of the ester moiety of the lecithin molecule is energetically more favorable than that with the phosphate. If the hydrogen bonding occurs with the phosphate group, a part of nonpolar steroid ring should be exposed in the polar aqueous phase that is energetically less favorable. Thus, the interaction of the OH group of phenols with the carbonyl moiety of lecithin may also be more favorable although the acidity of the OH group in phenols is higher than that in cholesterol (Fig. 3-A). Incorporation of stearylamine (a positively charged lipid) to lecithin liposome reduced the coefficient of $\Delta \log K_A$ term, as shown by Eq. 7, suggesting a reduction in the hydrogen-bonding effect. It is probable that the positively charged amino groups compete with the phenols for the above kind of hydrogen-bonding interaction with hydrogen acceptors.

As shown in Eqs. 2 and 4, the bulkiness of meta and para substituents but not of the mono-ortho substituent was unfavorable to partition into the liposome. We have suggested[8] that the substituted phenols are incorporated from the side of the benzene ring, with the polar OH group projecting toward the external aqueous phase. In this situation, meta and para substituents would have an unfavorable effect on packing in the lecithin molecules, the effect depending upon their volume (Fig. 3-B). For ortho substituted derivatives, both the OH group and the single ortho substituent would be close to the outside of the membrane, with little steric effect on the packing structure of the membrane.[8] Such positional specificity in the steric effect was, however, not observed in Eqs. 5—7. Steric demands for the meta and para substituents were apparently made less strict in the partitioning into the mixed lipid liposomes. These findings are in accord with the partitioning model where the partitioned phenol molecules are close to the surface region of the membrane. With incorporation of lipids other than lecithin, the structure of the membrane surface was loosened even in regions corresponding to the meta and para positions of phenols.

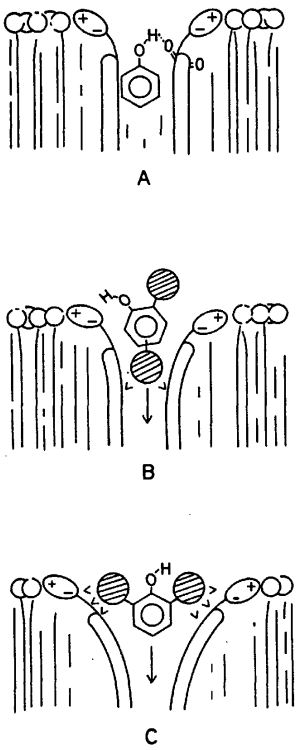

Fig. 3. Partition model of substituted phenols in liposome membrane. 3-A) The OH group of unsubstituted phenol interacts with the carbonyl moiety of lecithin. 3-B) Insertion of meta and para substituents into packed fatty acid chains is unfavorable, whereas that of the ortho substitution into phenols shows negligible effect. 3-C) Di-ortho substituents act as a wedge against the parallel arrangement of lecithin molecules and hinder the hydrogen bond of the OH group.

The steric bulkiness of di-ortho substituents lowered the partitioning into liposome in each of the liposome-water systems. Di-ortho substituents probably act as a wedge against the parallel arrangement of lecithin molecules and hinder the interaction of OH groups with hydrogen-acceptor groups (Fig. 3-C).[8] This kind of steric hindrance is somewhat reduced by the addition of charged lipids to liposome (Eqs. 6 and 7). The conformation of the head groups was more perturbed by the charged lipids more than by cholesterol, as observed by fluorescent probe studies, which is consistent with the above difference in the steric effect of di-ortho substituents.

Equation 4 for log P(L/W) measured in the genuine lecithin liposome was essentially equivalent to Eq. 2 published previously[8] except for the intercept. The higher intercept value for Eq. 4 is probably due to the

Table 2. Log P(L/W) of 2,6-Dialkyl-4-(2,2-dicyanovinyl)phenols

higher ionic strength in the aqueous phase used here. The higher the ionic strength, the higher would be the partitioning into the lipid phase. Although the ionic strength would affect the membrane structure, the perturbation may be not so significant since the other terms, which decide the partitioning behavior of phenols, in two equations are almost equal.

To confirm the validity of Eq. 4 for the partition coefficient in the lecithin-liposome-water system, we measured the log P(L/W) value for structurally complex 2,6-dialkyl-4-(2,2-dicyanovinyl)phenols, and compared the observed values with the ones calculated by Eq. 4 (Table 2). The fact that observed values for the three dicyanovinyl phenols agreed with those calculated by Eq. 4 indicates the applicability of the equation to a wide range of phenols to predict their partition coefficient in the lecithin-liposome-water system.

The accumulation of this kind of knowledge on partition behavior of series of systematically selected compounds into various artificial membrane systems from aqueous media should provide reliable means for explanation of their mode of interactions with various biomembranes.

The calculations were done with a FACOM M382 computer at the Data Processing Center of this university. We thank Dr. Takaaki Nishioka, Institute for Chemical Research, Kyoto University for invaluable discussion.

Reactions of Aryl Ketones and Coumarins with Iodine(III) Tris(trifluoroacetate)

Norihiro FUKUYAMA, Hiroshi NISHINO, and Kazu KUROSAWA*
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received June 15, 1987)

The reaction of acetophenones with iodine(III) tris(trifluoroacetate) yields 3′- and/or 2-iodo derivatives, depending upon the substituent on the aromatic ring and the reaction conditions. The reaction was examined by changing the molar ratio of acetophenone versus the reagent, reaction temperature, and solvent. In similar reactions flavanones and coumarins gave iodo derivatives in which iodine is incorporated at various positions orientated by the oxygen functions. 1,2-Diphenylethanone yields 2-hydroxy-2-(2-iodophenyl)-1-phenylethanone and 1-(2-iodophenyl)-2-phenylethanedione. The reactions of other aromatic ketones such as 9-xanthenone, 9-fluorenone, and anthrone also give iodo derivatives in moderate to good yields. The mechanisms for the iodination at the α-carbon to the carbonyl group have been discussed.

Although several iodination reactions of aromatic hydrocarbons and ketones have been investigated,[1,2] it is still desirable to seek a better method for iodination. The reaction of iodine(III) tris(trifluoroacetate) (ITT), which is readily prepared by the oxidation of iodine with fuming nitric acid in trifluoroacetic anhydride,[3] has been carried out only with a limited number of aromatic substrates such as benzene, toluene, and chlorobenzene by Maletina et al.[4] In Maletina's procedure, iodination products were obtained when a reaction intermediate, bis(trifluoroacetoxy) derivative, was treated with aqueous sodium iodide (Scheme 1).

Scheme 1.

We have studied the reaction for its applicability to a wide variety of compounds. We chose acetophenones, 1,2-diphenylethanone, flavanones, coumarins, 9-xanthenone, 9-fluorenone, and anthrone as the substrate, because they were polyfunctionalized compounds, and some biological activity is expected for their iodination products.[5] At first, the iodination of several acetophenone derivatives **1a—e** was examined in order to understand the dependency of yields on the reaction time, reaction temperature, solvents and substituent effects.

Results

A mixture of acetophenone (**1a**) and ITT in a molar ratio of 1 : 1 was stirred in dichloromethane at 23 °C and the reaction mixture was treated with aqueous sodium iodide, giving 3′-iodoacetophenone (**2a**) in a 41% yield (Table 1, Entry 2). The reaction of **1a** with ITT in a molar ratio of 1 : 2 gave 92% yield of **2a** after 24h (Entry 4). At 0 °C or at the refluxing temperature of dichloromethane, yields of **2a** became lower (Entries 1 and 3). A remarkable change in the products was demonstrated by reaction media. In chloroform, in which ITT is readily soluble, the reaction yielded only 2-iodoacetophenone (**3a**) and 2-hydroxyacetophenone

a) Substrate: $I(OCOCF_3)_3$. b) Yields based on the substrate added.

(**4a**) in a shorter reaction time (Entry 5). In carbon tetrachloride **2a** was again found to be the main product, but in poor yields (Entries 7 and 8). 4′-Methylacetophenone (**1b**) or 4′-methoxyacetophenone (**1c**) in dichloromethane gave the corresponding 3′-iodo derivatives **2b** and **2c** in excellent yields (Entries 9 and 11). On the other hand, 4′-nitroacetophenone (**1d**) yielded 2-iodo-4′-nitroacetophenone (**3d**) in poor yield (Entry 13). Propiophenone (**1f**) gave 3′-iodo derivative **2f** (Entry 16). The reactions of **1b**, **1c**, **1d**, and 4′-chloroacetophenone (**1e**) in chloroform resulted in 2-iodo derivatives **3b**, **3c**, **3d**, and **3e** in moderate to good yields (Entries 10, 12, 14, and 15). In the case of **1c** diiodo compound **5** was also isolated (Entry 12). The reaction of 1,2-diphenylethanone (**6**) with ITT yielded two products, **7** and **8**. The structure of **7** was concluded to be 2-hydroxy-2-(2-iodophenyl)-1-phenylethanone since an AB spin system due to a methine proton and a hydroxy proton appeared at δ 4.50 and 5.20 with J value of 6.0 Hz in the ^{1}H NMR spectrum. One of the doublets at δ 4.50 disappeared upon deutration and the other collapsed to a singlet. The spectral data for **8** indicated that it is an iodine-substituted benzil. The ^{1}H NMR spectrum showed the presence of nine aromatic hydrogen atoms, three of which appeared at a slightly lower field. Therefore, the structure of **8** is assigned to be 1-(2-iodophenyl)-2-phenylethanedione. Benzoin **7** could be oxidized to **8** by iodine in a 73% yield.

Flavanones. The reaction of flavanone (**9a**) yielded 6-iodoflavanone (**10a**) (Table 2, Entry 18). With increasing the amount of the reagent (ITT) the yield of **10a** increased slightly (Entry 19). When 4′-methoxyflavanone (**9b**) was treated with ITT, it gave 3′-iodo (**11**) and 3′,6-diiodo derivative (**12**) (Entry 20). 7-Methoxyflavanone (**9c**) similarly yielded 6-iodo

Table 3. Physical, Spectral, and Analytical Data for the New Compounds

derivative **10c** and 6,8-diiodo derivative **13** (Entry 21). The repeated iodination of **10c** with ITT gave 4′,6,8-triiodo-7-methoxyflavanone (**14**) (Entry 22).

Coumarins. The reaction of coumarin (**15a**) with ITT yielded 6-iodo (**16a**) and 3-iodocoumarin (**17a**) (Entry 23). The ^{1}H NMR spectrum of **16a** showed an AB quartet with a J value of 9.6 Hz due to H-3 and H-4, and three aromatic hydrogen atoms. The

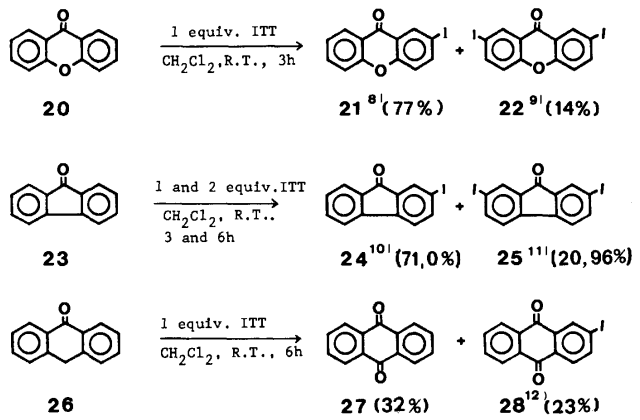

Fig. 2.

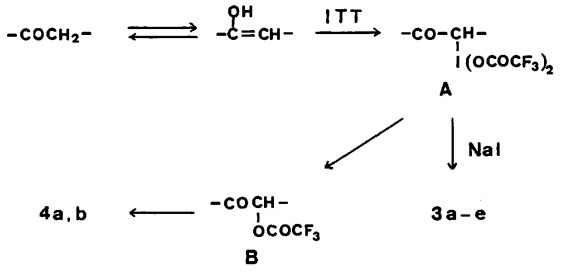
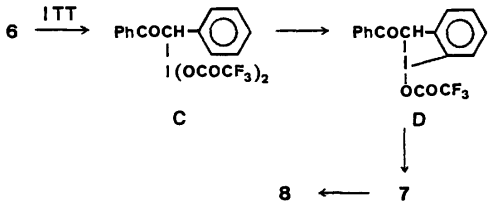


Scheme 2.



Scheme 3.

^{1}H NMR spectrum of **17a** exhibited a multiplet at the aromatic region corresponding to four hydrogen atoms, H-5—H-8, and a singlet at δ 8.31, indicating the presence of H-4. 3,6-Diiodocoumarin (**18a**) was obtained in a reaction at a molar ratio of 1 : 1.5 and the yield increased remarkably in the reaction at a molar ratio of 1 : 2 (Entries 24 and 25). Introduction of a methoxy group at the C-4 yielded 3-iodo derivative **17b** as the sole product in the reaction of **15b** (Entry 26), while that of a methoxy group at the C-6 in **15c** changes the site of the reaction to the C-5. A methoxy group at the C-7 in **15d** activated the C-3 as well as the C-6, giving **16d**, **17d**, and **18d** (Entry 28).

Other Aromatic Ketones. The reactions of 9-xanthenone (**20**), 9-fluorenone (**23**), and anthrone (**26**) with ITT in dichloromethane were examined and it was found that **20** and **23** gave monoiodo and diiodo derivatives, respectively, and **26** gave anthraquinone (**27**) and 2-iodoanthraquinone (**28**) in moderate yields (Fig. 2).

Discussion

The reaction of ITT with simple aromatic compounds has been reported by Maletina et al.[4] Our study revealed that the electron-donating groups, such as methyl and methoxy groups in acetophenones, enhance the reactivity as shown in Entries 9 and 11. The electron-withdrawing substituents, such as the nitro group, deactivate the aromatic ring and, thus, the reaction occurs at the α-carbon atom to the carbonyl group. The reaction at the aromatic ring can be interpreted as an electrophilic aromatic substitution[4] as shown in Scheme 1. The reaction of acetophenone (**1a**) with ITT in chloroform showed quite different products from those in dichloromethane. 2-Hydroxyacetophenone (**4a**) was obtained along with **3a** and the reaction took much shorter time. A mechanism for the iodination of acetophenone (**1a**) at the C-2 is depicted in Scheme 2. A keto-enol equilibrium and the subsequent addition of ITT to the double bond gave an alkyliodine(III) intermediate **A** which is then decomposed to **3a—e** and **4a,b** during work-up with aqueous sodium iodide. It may be also possible that in the reaction the intermediate **A** could partially be converted to 2-(trifluoroacetoxy)acetophenone (**B**), which may give rise to **4a** during the work-up. In fact, the analogue of **B** prepared from 2-bromoacetophenone with sodium trifluoroacetate was readily hydrolyzed on TLC to give **4a**. It should be noted that iodine is incorporated regiospecifically into the ortho-position in benzyl moiety and a hydroxyl group is introduced onto the methylene group in the reaction of **6** with ITT in dichloromethane. The formation of **7** could be accounted for by modifying the mechanism which has been described for the reaction of acetophenones with ITT in chloroform (as shown in Scheme 3). The reaction intermediate **C** may form an iodine(III)-containing cyclic compound **D** which could be decomposed during work-up to give **7**. The oxidation of benzoin to benzil has precedence.[6]

The orientation in the reaction of coumarins with ITT is quite similar to the orientation in the nitration and the sulfonation of coumarin (**15a**) in which the aromatic ring and the pyrone ring undergo the electrophilic aromatic substitution.[7] The reaction of 4-methoxycoumarin (**15b**) and 7-methoxycoumarin (**15d**) with ITT yielded 3-iodo derivatives **17b** and **17d** that are expected from the consideration of the electron-donating effect of the methoxy group. The reaction of 9-xanthenone (**20**) and 9-fluorenone (**23**) gave 2-iodo derivatives as the major product and diiodo derivatives. These iodo derivatives have been previously prepared by various methods.[8-12] However, the ease of operation in the iodination with ITT made the latter better for the preparation of these compounds. The formation of 2-iodoanthracene (**28**) deserves comments. Anthraquinone (**27**) could not give **28** on treatment with ITT. It therefore follows that anthrone (**26**) was iodinated at the 2-position and then oxidized to **28**.

Conclusion

The reaction of ITT proved to be useful for the iodination of aromatic ketones, particularly for those activated by oxygen functions. The fact that **10c** gave triiodo derivative **14** would also indicate the synthetic utility of the reaction for the preparation of periodinated aromatic compounds. The regiospecific iodination that was observed in the reaction of **6** may suggest that iodine could be incorporated at the ortho-position of a vinyl group in aromatic substrates.

Experimental

Measurements. All the ^{1}H NMR spectra were taken in deuteriochloroform solutions with a Hitachi Perkin-Elmer R-24 NMR spectrometer (60 MHz) with tetramethylsilane as the internal standard. The IR spectra were measured in chloroform solutions on a JASCO A-102 IR spectrometer. The MS sperctra were obtained with a JMS-O1SG-2 and a JMS DX300 instrument. The melting points were determined with a Yanagimoto micromelting point apparatus and were not corrected. The HPLC analysis were performed on an ALTEX model 330/110A/153 isocratic liquid chromatograph equipped with an UNSIL Pack 5C18 250A column, eluting with methanol or 80% aqueous methanol.

Materials. Iodine(III) tris(trifluoroacetate),[3] 4′-methoxyacetophenone[25](**1c**), 1,2-diphenylethanone[26] (**6**), flavanone[27] (**9a**), 4′-methoxyflavanone[28] (**9b**), 7-methoxyflavanone[29] (**9c**), 4-methoxycoumarin[30] (**15b**), 6-methoxycoumarin[31] (**15c**), and 7-methoxycoumarin[32] (**15d**) were prepared by the methods described in the literature. The other 4′-substituted acetophenones **1b**, **d**, and **e**, propiophenone (**1f**), coumarin (**15a**), 9-xanthenone (**20**), 9-fluorenone (**23**), and anthrone (**26**) were purchased from Wako Pure chemical Industries, Ltd. Acetophenone (**1a**) was commercially available from Katayama chemical Industries, Ltd.

Reaction of Iodine(III) Tris(trifluoroacetate). The general procedure for the reaction of ITT was follows. To a solution of a substrate (1 mmol) in a solvent (20 cm^3), iodine(III) tris(trifluoroacetate) (1—2 mmol as shown in Tables 1 and 2, and in Fig. 2) was added under an atmosphere of nitrogen. The solution was stirred with the undissolved ITT at 23 °C. A high-pressure liquid chromatographic analysis was performed on aliquots which were withdrawn periodically from the reaction mixture with the aid of a pipet. There appeared several peaks due to the substrate and products in the chromatogram. When one of the product peaks became maximum (the time is shown in the Tables 1 and 2, and in Fig. 2), the reaction mixture was treated with 20% aqueous sodium iodide solution (20 cm^3) with stirring for 30 min and extracted with dichloromethane or chloroform. The organic layer was washed with a saturated sodium hydrogencarbonate solution, 5% sodium thiosulfonate solution, and water. The solvent was removed under reduced pressure. The products were separated on TLC with benzene or chloroform as the developing solvent. The yields on reasonably pure products are summarized in Tables 1 and 2, and in Fig. 2. Analytical samples were further purified by distillation or recrystallization. The known compounds were identified by comparing them with spectral data and/or the melting points found in the literature. The physical, spectral, and analytical data for the new compounds are listed in Table 3.

A Typical Procedure for the Reaction of Acetophenone (1a) with ITT. To a solution of **1a** (1 mmol) in calcium chloride-dried chloroform (20 cm^3) was added iodine(III) tris(trifluoroacetate) (1 mmol) under an atmosphere of nitrogen. The solution was stirred for 6h at 23 °C. After adding 20% aqueous sodium iodide solution (20 cm^3), the mixture was stirred for 30 min. The chloroform layer was washed with a saturated sodium hydrogencarbonate solution, 5% aqueous sodium thiosulfonate solution, and water. After the removal of the chloroform, the resulting liquid was fractionated on a silica-gel plate eluting with benzene, giving **3a** and **4a** in yields shown in Table 1 (Entry 5). 2-Iodoacetophenone (**3a**): Light-brown liquid;[14] IR ($CHCl_3$) ν/cm^{-1}=3012, 1676, 1600, 1581, 1492, 1449, 1418, 1316, 1303, 1271, 1181, 1169, 1004, 983, 697; ^{1}H NMR ($CDCl_3$) δ=4.32 (2H, s), 7.3—7.6 (3H, m), 7.8—8.0 (2H, m); MS *m/z* (rel intensity) 246 (55, M$^+$), 141 (6), 127 (23), 105 (100), 77 (51). 2-Hydroxyacetophenone (**4a**): Colorless needles; mp 85—86 °C (sublimed) (lit,[15] mp 86—87 °C); IR ($CHCl_3$) ν/cm^{-1}=3484, 3012, 1597, 1448, 1285, 1202, 1091, 972, 661; ^{1}H NMR ($CDCl_3$) δ=3.7 (1H, br. s), 4.90 (2H, s), 7.3—7.7 (3H, m), 7.8—8.1 (2H, m); MS *m/z* (rel intensity) 136 (6, M$^+$), 105 (100), 77 (55).

2-(Trifluoroacetoxy)acetophenone (B). A mixture of 2-bromoacetophenone (2.0 g), sodium trifluoroacetate (1.36 g), and 2-butanone (20 cm^3) was heated under reflux for 24 h. After the removal of the 2-butanone under reduced pressure, the resulting semisolid was extracted with chloroform. The chloroform solution evaporated to give a light-brown liquid (2.1 g, 90%). IR ($CHCl_3$) ν/cm^{-1}=1685 (>C=O) and 1783 ($OCOCF_3$); ^{1}H NMR ($CDCl_3$) δ=4.88 (2H, s, -OCH_2-) and 7.3—8.0 (5H, m, Ph). **B** could not be purified and was hydrolyzed to give **4a** on a silica-gel plate eluting with benzene.

Oxidation of 2-Hydroxy-2-(2-iodophenyl)-1-phenylethanone (7) with Iodine. A mixture of **7** (100 mg), sodium methoxide which prepared by dissolving metallic sodium (13.6 mg) in methanol (5 cm^3), and iodine (150 mg) was heated under reflux for 30 min. After the removal of the methanol, the resulting mixture was triturated with water and then extracted with benzene. The benzene solution evaporated and the product was purified on a silica-gel plate with chloroform as developing solvent, giving light-yellow liquid (72.4 mg, 73%). The IR and ^{1}H NMR spectra were identical with those of **8** obtained by the ITT oxidation of **6**.

We wish to thank Professor Hitoshi Takeshita and Associate Professor Akira Mori of the Research Institute of Industrial Science, Kyushu University, and Dr. Teruyoshi Marunaka of Taiho Pharmaceutical Co. Ltd., Tokushima, for their kind assistance in obtaining the mass spectra.

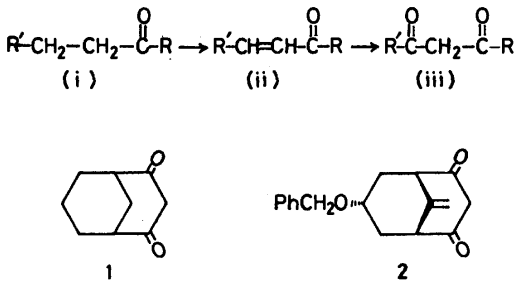
Bicyclo[3.3.1]nonane-2,4-dione and 7-*endo*-benzyloxy-9-methylenebicyclo[3.3.1]nonane-2,4-dione were prepared starting from bicyclo[3.3.1]nonan-2-one and 7-*endo*-benzyloxybicyclo[3.3.1]nonane-2,9-dione, respectively. The key reaction was the NCS oxidation of the 2,2-ethylenedioxy-4-phenylthiobicyclo[3.3.1]nonanes, derived from the corresponding bicyclo[3.3.1]non-3-en-2-ones.

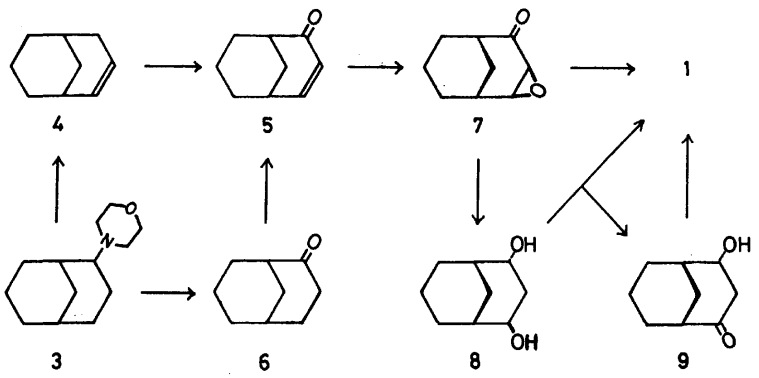
In the course of our study on the synthesis of the taxane framework,[1] we investigated the preparation of bicyclo[3.3.1]nonane-2,4-dione derivatives. Such systems had been reported by several workers,[2] but methodologies had limited application to the preparation of poly functionalized bicyclic derivatives. We chose the transformation from a ketone(**i**) to a 1,3-diketone(**iii**) via an α,β-unsaturated ketone(**ii**) (Scheme 1) because carbonyl compounds are easy to prepare and several efficient methods to their transformation have recently been developed. However, as shown later, there exists clear differences in a bicyclic ring system as compared to an acyclic or a monocyclic one; especially, the conformation of the ring is frequently fixed in the former system and the methods applicable to the latter are not always suitable in the bicyclic system. In this report, we wish to describe our results concerning the preparation of bicyclo[3.3.1]nonane-2,4-dione (**1**) and 7-*endo*-benzyloxy-9-methylenebicyclo-[3.3.1]nonane-2,4-dione (**2**) starting from bicyclo[3.3.1]-nonan-2-ones via α,β-unsaturated carbonyl compounds. The bicyclic diketone **1** have been successfully converted to the 3β-trinortaxane derivative.[1]



Scheme 1.

A. Bicyclo[3.3.1]nonane-2,4-dione (1). As the parent bicyclo[3.3.1]nonane-2,4-dione (**1**) had been unknown, our initial efforts were focused on the preparation of **1**. The reaction of a cyclohexanone enamine with acrylaldehyde[3] or acryloyl chloride[4] is one of the useful methods for constructing a bicyclo[3.3.1]-nonane framework. Schaefer and co-workers[5] prepared bicyclo[3.3.1]non-3-en-2-one (**5**) via **4** by starting from the amine **3** derived from the reaction of 1-morpholinocyclohexene and acrylaldehyde followed by Wolff-Kishner reduction. We followed the reaction and could improve the total yield up to 28% (lit,[5] 23%) by changing the oxidizing agent of the nitrogen from H_2O_2 to purified *m*-chloroperbenzoic acid (MCPBA). However, the yield was still low and a short-step synthesis of **5** was then examined. When **3** was oxidized with $Hg(OAc)_2$[6] in 5% acetic acid in water bicyclo-[3.3.1]nonan-2-one (**6**) was obtained in 61% yield after the hydrolysis of the iminium salt produced. A usual bromination-dehydrobromination[7] smoothly afforded the desired enone **5** in 88% yield.

A direct oxidation of the enone **5** with H_2O_2 or with *t*-butyl hydroperoxide catalyzed by Pd(II)[8] resulted in the recovery of the starting enone. The reaction of the epoxy ketone **7**, prepared by treating **5** with alkaline H_2O_2 in methanol, with tetrakis(triphenylphosphine)-palladium and 1,2-bis(trimethylphosphino)ethane[9] in



Scheme 2.

toluene gave a target diketone **1** but in only 20% yield with several concomitant. Although the above two procedures[8,9] have been found to be effective to acyclic or monocyclic analogues, the present results were considered to be due to a facile β-elimination of the axial hydroxyl (or corresponding oxygen) group. Lithium aluminium hydride reduction of **7** afforded a 2-*endo*,4-*exo*-diol **8**, one hydroxyl of which was equatorial and the other axial. As the axial hydroxyl group is known to be liable to oxidation with Cr(VI) and the equatorial hydroxyl is less eliminable, the oxidation of **8** would proceed via an equatorial hydroxy ketone **9**. Among various chromium reagents, chromium etherate[10] at low temperature was proved to be most suitable to afford **1**. Treatment of the diol **8** with an equimolar amount of $CrO_3 \cdot Et_2O$ in dichloromethane over Celite at −60—−40 °C gave **1** in 30% yield accompanied with **9** (34%) and the starting diol (20%). The equatorial hydroxy ketone **9** was also converted to **1** under the same conditions in 50% yield with 41% recovery.

The structure of **1** was confirmed to be β-diketones by the typical behavior of the absorption maximum in the UV spectra: λ_{max} at 255 nm (log ε=4.13) in ethanol shifted to 281 nm (4.31) with the addition of a base. The IR spectra of **1** in KBr (1625 and 1590 cm^{-1}) and in chloroform (1730sh, 1705, 1630sh, and 1600br cm^{-1}) suggest that the β-diketone **1** exists in a monoketo monoenol form when it is solid, but in a mixture of a monoketo monoenol and a diketo forms in solution.

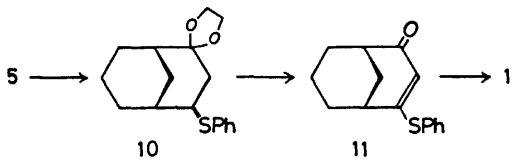
Recently, Fetizon and co-workers[11] reported the preparation of bicyclo[3.3.1]nonane-2,4-dione derivatives under a similar reaction sequences in a comparable yield.

Although the target β-diketone **1** was obtained, the low overall yield and complexity at the last oxidation stage of the reaction sequences required us to search for other approaches. We utilized a sulfur group in place of the oxygen since the sulfur group is easy to introduce to an enone[12,13] and since the sulfur is less apt to eliminate that an alkoxyl group under acidic conditions. The sulfide may be converted into a ketone by the oxidation either to a corresponding sulfoxide followed by a Pummerer rearrangement[14] or to a chloro sulfide followed by hydrolysis.[15] Heating a mixture of the enone **5**, ethylene glycol, and thiophenol in benzene in the presence of a catalytic amount of *p*-toluenesulfonic acid (*p*-TsOH) afforded a 4-phenylthio acetal **10** in good yield. The treatment of **10** with 1.05 equimolar amount of *N*-chlorosuccinimide (NCS) in purified (dried) carbon tetrachloride[13] at room temperature gave a new spot on TLC in 3 h, but filtration of the mixture through a silica-gel column gave two spots. The R_f value of the second was identical with that of a vinyl sulfide **11**. It was suggested that the initially formed intermediate was hydrolyzed with the water present in the column. Thus, the NCS oxidation of **10** under the addition of water resulted in one-pot conversion of **10** into **11**. The subsequent hydrolysis of the vinyl sulfide **11** into **1** was quantitatively accomplished under either acidic or basic conditions (see Experimental).

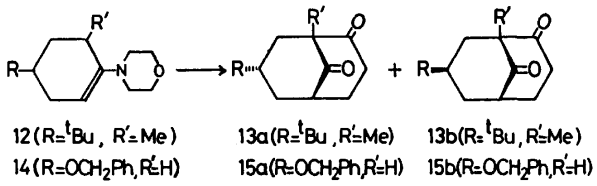
In the present method, **1** was obtained in 40% overall yield from the amine **3**.

B. 7-Benzyloxy-9-methylenebicyclo[3.3.1]nonane-2,4-dione(2). The successful preparation of **1** prompted us next to examine whether this method is applicable to a more functionalized bicyclo[3.3.1]nonan-2-one. The starting ketone chosen was 7-substituted 2,9-dione (e.g., **15**), which has functional groups at both rings and the bridged carbon. **15** can be prepared by the reaction of 4-benzyloxy-1-morpholinocyclohexene with acryloyl chloride.[4] The stereochemistry of the 7-substituent had been proven only in the case of 4-*t*-butyl-6-methyl-1-morpholinocyclohexene(**12**); the major isomer (**13b**/**13a**=4/1) was subjected to X-ray crystal analysis to establish the syn relation between the *t*-butyl group and the bridge C=O group.[16] We used 4-benzyloxy-1-morpholinocyclohexene(**14**) as a starting material. After a reexamination of several reaction conditions,[6,18,19] we found that the addition of hydroquinone to the procedure reported by Aredova and co-workers[19] improved the yield up to 80%. From an ^1H NMR study, **15** was found to consist of two stereoisomers (**15a**/**15b**=2.2/1.0). The characteristic features of the two isomers in ^1H NMR spectra are the shape of the signal of C_7-H — a broad singlet at δ=3.72 in **15a** and a triplet of triplet at 3.89 (J=10.8 and 5.4 Hz) in **15b**, and that of the benzylic protons — an AB quartet at 4.20 and 4.50 with J=11.6 Hz in **15a** and a sharp singlet at 4.50 in **15b**. These properties suggested that the benzyloxyl group of the major isomer **15a** was anti to the bridged C=O group and existed in axial in contrast to the *t*-butyl group of **13b**. This was unequivocally confirmed by an X-ray crystal analysis[20] of **20a** (vide infra).

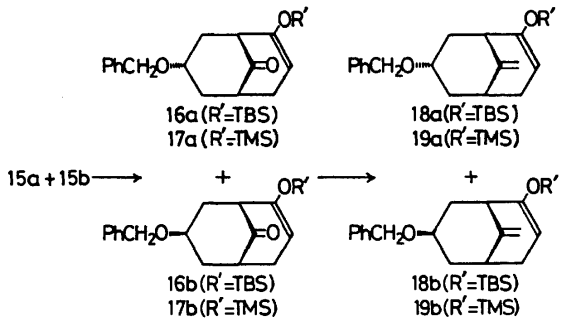
As the β-diketones **15** was unstable to alkali, the enolizable C_2-carbonyl group was protected by treating **15a** and **15b** with t-butyldimethylsilyl or trimethylsilyl triflate as silyl enol ether **16** (R′=$SiBu^tMe_2$; TBS) or **17**



Scheme 3.



Scheme 4.



Scheme 5.

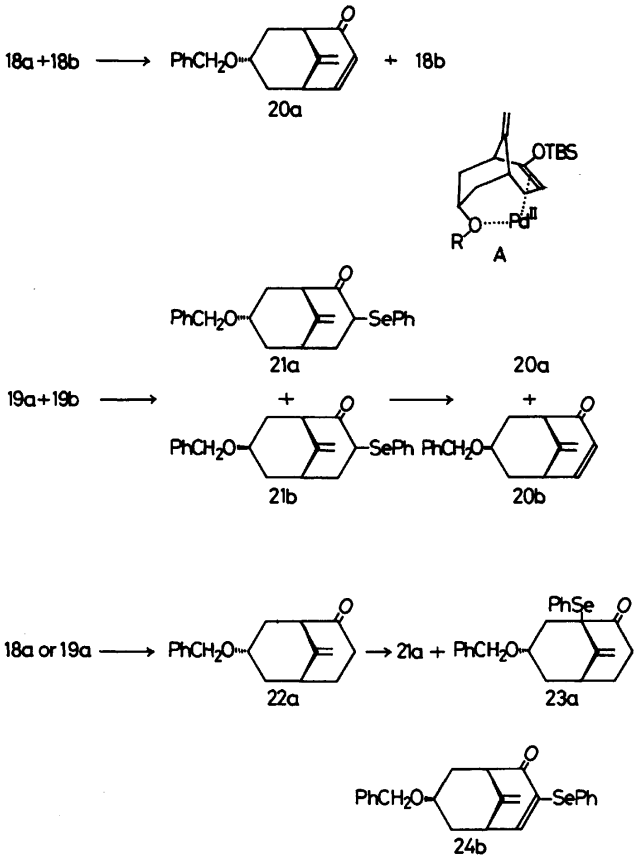
(R′=$SiMe_3$; TMS), respectively. These silyl enol ethers were then converted into 9-methylene derivatives **18** (R′=TBS) or **19** (R′=TMS), respectively, by treating with methylenetriphenylphosphorane. The ratio of **18a** to **18b** (or **19a** to **19b**) remained unchanged during these transformations.

The conversion of the silyl enol ether into an α,β-unsaturated carbonyl compound **20** was achieved either oxidation with palladium acetate or benzeneselenenylation followed by oxidation-elimination of the phenylseleno group. The stable TBS enolates (**18a**+**18b**) were treated with palladium acetate in acetonitrile.[21] Of interest, only **18a** was converted into an anticipated **20a** (99% based on the amount of **18a** in the mixture) but **18b** recovered almost quantitatively. The coordination of Pd(II) with both the oxygen of the benzyloxyl group and the olefin as shown in **A** may accelerate the reaction.

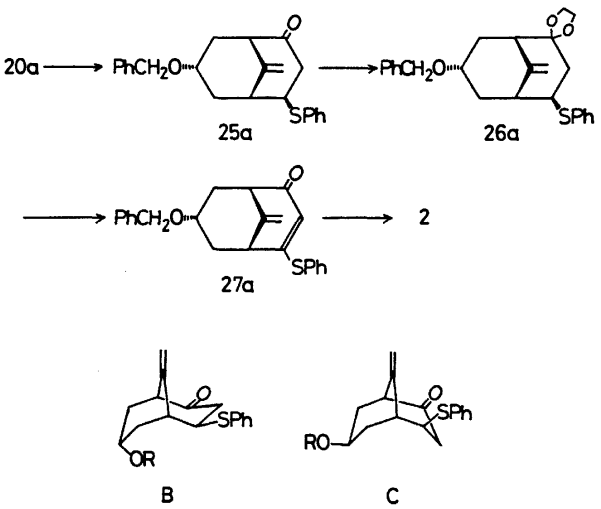
On the other hand, benzeneselenenylation[22,23] was successfully carried out with unstable TMS enolates (**19a**+**19b**). The reaction with one equivalent of benzeneselenenyl chloride in THF gave a mixture of phenylseleno ketones **21a** and **21b**, which without a further purification was oxidized with H_2O_2 in dichloromethane-pyridine[23] to give a mixture of **20a** and **20b** in 46% yield. In the large scale preparation of **20**, the TMS enolates (**17a** and **17b**) were successively treated with methylenetriphenylphosphorane, benzeneselenenyl chloride, and H_2O_2 to give **20** (**20a**/**20b**=9.6/1.0)[24] in 50% overall yield.

The benzeneselenenylation of 7-benzyloxy-9-methylenebicyclo[3.3.1]nonan-2-one (**22a**), obtained by the hydrolysis of **18a** or **19a**, gave a 2-phenylseleno ketone **21a** in 43% yield accompanied with 11% of a bridgehead seleno ketone **23a**; while the reaction of TMS enol ethers (**19a** and **19b**) with two equivalent benzeneselenenyl chloride afforded, besides **21a** (24%), an α-phenylseleno α,β-unsaturated ketone **24b** in 18% yield.

Conversion from the α,β-unsaturated ketone **20a** into β-dicarbonyl compound **2** was achieved under a similar process to that used in the preparation of **1**, except for a slight modification of the reaction conditions. A direct conversion of **20a** to an acetal **26a** was unsuccessful. The addition of thiophenol to **20a** in the presence of a catalytic amount of triethylamine



Scheme 6.



Scheme 7.

afforded a 4-phenylthio ketone **25a** in quantitative yield. On the other hand, **20b** did not react at all. Thus, when the mixture of **20a** and **20b** was subjected to the thiophenol addition, **25a** and unreacted **20b** were obtained; they were separable by chromatography. The difference in the reactivity of **20a** and **20b** toward thiophenol can be rationalized by comparing their conformations: In **20a** the axial benzyloxyl group distorts the other ring to the boat form resulting the phenylthio group being equatorial (**B**), while in **20b**,

the axial phenylthio group (**C**), if produced, is eliminated easily to revert to the starting **20b**.[25]

The acetalization of **25a** was employed by 1,2-bis(trimethylsiloxy)ethane to give **26a** in high yield.[26] The oxidation of **26a** with NCS in the presence of water gave a vinyl sulfide **27a**, which was hydrolyzed to the target β-diketone **2** in good yield. The diketone **2** exists almost in a ketonic form, even in solution (cf. **1**).

A successful preparation of **1** and **2** proved that the present method has wide applications to the preparation of a bicyclic β-diketone.

Experimental

Melting points are uncorrected. Column chromatography was performed with Wako C-300 silica gel unless otherwise stated. IR and UV spectra were recorded on a Hitachi 215 grating and a Hitachi 340 spectrophotometers, respectively. ^1H and ^{13}C NMR spectra were measured in $CDCl_3$ on a JEOL LMN-FX90Q spectrometer using TMS as the internal standard unless otherwise stated. High-resolution mass spectra were performed at Nippon Roche Research Center, Kamakura.

Bicyclo[3.3.1]non-2-ene (4). A solution of 825 mg of MCPBA (100% activity: washed three times with KH_2PO_4-NaH_2PO_4 buffer, pH=7.50, and dried under reduced pressure) in 40 ml of $CHCl_3$ was added gradually to an ice-cooled and stirred solution of 1.00 g of 2-morpholinobicyclo[3.3.1]-nonane (**3**)[5] in 20 ml of $CHCl_3$. Stirring was continued for 3 h, during which the mixture was allowed to come to room temperature. Removing of the solvent under reduced pressure and chromatography (alumina, $CHCl_3$) of the residue gave 1.02 g (95%) of an *N*-oxide. The flask containing 1.02 g of the *N*-oxide equipped with a distillation set and tandem Dry Ice traps, was heated slowly to 110 °C under reduced pressure. After 1 h, the temperature was raised to 145 °C and kept for 5 h. In the first trap, 370 mg (65%) of **4** was collected. Mp, 96—98 °C (purified by sublimation, lit,[5] 96.5—98.5 °C).

Bicyclo[3.3.1]non-3-en-2-one (5). A) From **4**. According to the known procedure,[5] **5** was obtained from **4** in a comparable yield. Mp 97—98 °C (from pentane) (lit,[5] 97.5—98.5 °C).

B) From **6**. To a solution of 22.8 g of phenyltrimethylammonium tribromide[27] in 400 ml of THF, was added a solution of 8.38 g of **6** in 40 ml of THF at a once at 0 °C. The mixture was stirred for 30 min at that temperature and then was poured into a solution of saturated aqueous NaCl and 0.1 M (1 M=1 mol dm^{-3}) aqueous $Na_2S_2O_3$ (1 : 1) through a filter paper. The solids were washed with ether, and the filtrate was extracted with CH_2Cl_2. The combined organic solution was washed with water, brine, and dried over $MgSO_4$. Evaporation of the solvent and recrystallization of the crude product from pentane gave 10.4 g of 3-bromobicyclo[3.3.1]nonan-2-one. Chromatography of the mother liquid with CH_2Cl_2 gave further 1.86 g of the product. The total yield was 12.3 g (93%). Mp 115—116 °C (from benzene); IR ($CHCl_3$) 2940, 2860, and 1715 cm^{-1}; ^1H NMR δ=1.00—3.32 (12H, m), and 4.87 (1H, dd, *J*=12 and 9 Hz).

Found: C, 49.76; H, 6.02%. Calcd for $C_9H_{13}OBr$: C, 49.79: H, 6.03%.

A mixture of 4.71 g of the bromo ketone, 14.2 g of freshly dried LiBr (heated at 120 °C for 20 h under reduced pressure), 8.70 g of anhyd Li_2CO_3 (dried under reduced pressure prior to use) and 80 ml of DMF was heated at 110 °C for 5 h. The cooled mixture was poured into 500 ml of ice-cooled 10% AcOH-H_2O by filtration and the solids were washed with CH_2Cl_2. The combined organic solution was shaken with saturated $NaHCO_3$, water, brine, and dried over $MgSO_4$. Distillation of the solvent at the ordinary pressure and chromatography of the residue with CH_2Cl_2-pentane (10 : 2) gave 2.82 g (95%) of **5**.

Bicyclo[3.3.1]nonan-2-one (6). A mixture of 10.0 g of **3** and 15.3 g of $Hg(OAc)_2$ in 100 ml of 5% AcOH-H_2O was heated at 90 °C for 2 h. After cooling to room temperature, 250 ml of brine was added to the mixture. The precipitates were filtered off and washed with ether. The filtrate was extracted with ether and the combined organic solution was washed with 1 M HCl, water, and dried over anhyd Na_2SO_4. Evaporation of the solvent at the ordinary pressure and sublimation of the residue gave 4.0 g (61%) of **6** as crystals; mp 131—134 °C (lit,[5] mp 134—137 °C); IR ($CHCl_3$) 2930, 2860, 1690, and 1450 cm^{-1}.

3,4-*exo*-Epoxybicyclo[3.3.1]nonan-2-one (7). To a solution of 243 mg of **5** in 50 ml of MeOH, was added 0.56 ml of 30% H_2O_2 and then was added drop by drop 0.88 ml of 6 M NaOH solution over a period of 2 h at 0 °C. The whole was allowed to warm and kept in the range of 15—20 °C for 4 h. The products were extracted with ether and the extract was washed with water, brine, and dried over $MgSO_4$. Careful concentration of the solution under 30 mmHg (1 mmHg= 133.32Pa) and filtration of the residue through a silica-gel layer with CH_2Cl_2-pentane (1 : 1) gave 248 mg (91%) of **7**; mp 94—96 °C (from pentane); IR ($CHCl_3$) 2950, 1700, 1080, and 1000 cm^{-1}; ^1H NMR δ=2.37—2.67 (2H, m), 3.26 (1H, d, *J*=3.5 Hz), and 3.37 (1H, t, *J*=3.5 Hz).

Found: C, 70.91; H, 7.96%. Calcd for $C_9H_{10}O_2$: C, 71.02; H, 7.94%.

Bicyclo[3.3.1]nonane-2-*endo*, 4-*exo*-diol (8). A mixture of 614 mg of **7**, 240 mg of $LiAlH_4$, and 100 ml of dry ether was refluxed for 5 h. Work up as usual and chromatography with ether gave 603 mg (97%) of **8** accompanied with 13 mg (2.1%) of a 1,2-diol.

8; Mp 205—206 °C (from hexane); IR ($CHCl_3$) 3600, 3400br, 2950, and 2905 cm^{-1}; ^1H NMR δ=1.20—2.30 (12H, m), 3.88 (1H, m, $W_{1/2}$=7 Hz), 4.00 (1H, m, $W_{1/2}$=12 Hz), and 4.66 (2H, s).

Found: C, 68.87; H, 10.28%. Calcd for $C_9H_{16}O_2$: C, 69.19; H,10.33%.

Bycyclo[3.3.1]nonane-2,4-dione (1). A) From **11**. Procedure (i). A mixture of 176 mg of **11**, 25 ml of 25% KOH solution and 25 ml of water was refluxed for 2 h. To the resulted solution, 90 ml of CH_2Cl_2 and 90 ml of 2M HCl solution were added. The layers were separated and the aqueous layer was extracted with CH_2Cl_2. The combined organic solution was washed with water, brine, and dried over anhyd Na_2SO_4. Evaporation of the solvent and recrystallization of the residue gave 109 mg (99%) of **1**.

1; Mp 136—138 °C (from benzene); UV (EtOH) 255 nm (log ε=4.13); UV (EtOH-OH^-) 281 nm (4.31); IR (KBr) 3400br, 1625, 1590, 1185, and 1145 cm^{-1}; IR ($CHCl_3$) 3200br, 1730sh, 1705, 1630sh, 1600br, 1185, and 1145 cm^{-1}; ^1H NMR δ=1.20—2.83 (10H, m), 3.37 (2H×1/3, br. AB, *J*=12 Hz), 5.62 (1H×2/3, s), and 6.82 (1H×2/3, br. s.).

Found: C, 70.74; H, 7.89%. Calcd for $C_9H_{12}O_2$: C, 71.02; H,

7.94%.

Procedure (ii). A mixture of 120 mg of **11**, 15 ml of concd HCl and 11 ml of dioxane was refluxed for 6 h. The resulting mixture was poured into 50 ml of water and was extracted with CH_2Cl_2. The extract was washed with 5% $NaHCO_3$ solution, water, brine, and dried over $MgSO_4$. Evaporation of the solvent and recrystallization of the residue gave 74 mg (99%) of **1**.

B) From **7**. A mixture of 249 mg of the epoxy ketone **7**, 7.7 mg of 1,2-bis(diphenylphosphino)ethane, and 24.8 mg of tetrakis(triphenylphosphine)palladium (prepared[28] prior to use) in 1 ml of degassed toluene was placed in a sealed tube under argon and heated at 80 °C for 24 h. Chromatography of the residue with CH_2Cl_2-ether (1 : 1) afforded 48 mg (20%) of **1** and 20 mg (10%) of the starting **7**.

C) From **8**. To a solution of 408 mg of **8** in CH_2Cl_2 (12.3 ml) and ether (4.1 ml), were added 523 mg of celite and 523 mg of CrO_3 successively at −60 °C. The temperature was kept in the range of −60—−40 °C for 6 h. To the mixture were added 82 ml of ether and 500 mg of Celite, and after 15 min, the suspension was filtered through a Celite pad. Removal of the solvent and chromatography on silica gel gave 118 mg (30%) of **1**, 139 mg (34%) of 4-*endo*-hydroxybicyclo-[3.3.1]nonan-2-one (**9**) and 81 mg (20%) of the starting diol **8**.

9; Oil; IR (CCl_4) 3600, 3460, 2940, 2855, and 1700 cm^{-1}; ^1H NMR δ=1.36—2.90 (12H, m), 3.25 (1H, br. s), and 4.17 (1H, br. t, J=4.5 Hz).

2,2-Ethylenedioxy-4-*exo*-phenylthiobicyclo[3.3.1]nonane (10). A mixture of 3.40 g of **5**, 3.30 g of thiophenol, 3.10 g of ethylene glycol, 70 mg of *p*-TsOH, and 300 ml of benzene was refluxed through a water separator for 10 h. After the solvent had been removed, the residue was dissolved in 100 ml of CH_2Cl_2. The solution was washed with a 1M NaOH solution, water, brine, and dried over anhyd Na_2SO_4. Evaporation of the solvent afforded 5.86 g (81%) of **10** as crystals; mp 107.5—108.5 °C (from hexane); IR (KBr) 1585, 1115, 1080, 1050, 1035, 745, and 690 cm^{-1}; ^1H NMR δ=1.25—2.04 (10H, m), 2.06 (1H, br. d, J=16.3 Hz), 2.39 (1H, dd, J=16.3 and 7.3 Hz), 3.62 (1H, br. d, J=7.3 Hz), 3.98 (4H, m), and 7.18—7.50 (5H, m).

Found: C, 70.32; H, 7.60%. Calcd for $C_{17}H_{22}O_2S$: C, 70.30; H, 7.63%.

4-Phenylthiobicyclo[3.3.1]non-3-en-2-one (11). To a solution of 4.56 g of **10** in 1 L of CCl_4, was added successively 2.36 g of NCS (98% activity) and 1 ml of water. After vigorous stirring for 5 h, the resulted white crystals were removed by filtration. Evaporation of the solvent and chromatography of the residue with benzene-AcOEt (92 : 8) gave 3.42 g (89%) of **11** as an oil; IR ($CHCl_3$) 1635, 1560, 1345, 1290, 1150, 1085, 1055, 980, and 875 cm^{-1}; ^1H NMR δ=1.40—2.00 (7H, m), 2.12—2.78 (3H, m), 5.61 (1H, s), and 7.43 (5H, br. s.)

Found: m/z 244.0920. Calcd for $C_{15}H_{16}OS$: M, 244.0921.

7-*endo*-Benzyloxybicyclo[3.3.1]nonane-2,9-dione(15a) and 7-*exo*-Benzyloxybicyclo[3.3.1]nonane-2,9-dione(15b). A mixture of 4-benzyloxycyclohexanone[17] (40 g), 17 g of morpholine, 400 mg of TsOH in 400 ml of benzene-toluene (1 : 1) was refluxed through a Dean-Stark trap until no more water separated (ca. 36 h). Evaporation of the solvent and excess morpholine gave a crystalline enamine (52 g). To a boiling mixture of 20 g of the crude enamine, 500 mg of hydroquinone, and 1 L of dry benzene, a solution of acryloyl chloride (16.7 g) in 250 ml of dry benzene was added drop by drop over a period of 2 h. The whole was vigorously stirred at that temperature for an additional 18 h. The precipitates were collected by filtration, washed with dry hexane and then dissolved in 500 ml of ice-cooled water. The solution was kept at 0 °C for 4 h and then was extracted with CH_2Cl_2 (100 ml×5). The combined extracts were dried over $MgSO_4$ and were evaporated. The residue was distilled (bath temp 180 °C/0.03 mmHg) to give 15.1 g (80%) of a bicyclic dione **15** as an epimeric mixture of the 7-benzyloxyl group (**15a**/**15b**=2.2/1.0). The each epimer could be separable by preparative TLC.

15a: Oil; IR (CCl_4) 1730, 1705, 1140, 1090, 1070, and 695 cm^{-1}; ^1H NMR δ=1.50—3.20 (10H, m), 3.72 (1H, br. s, $W_{1/2}$=8 Hz), 4.20 and 4.50 (2H, AB, J=11.6 Hz), and 7.30 (5H, s); ^{13}C NMR δ=22.7(t), 37.5(t), 38.2(t), 40.8(t), 43.2(d), 60.0(d), 70.0(t), 72.0(d), 127.6(d), 128.4(d), 137.7(s), 209.0(s), and 212.0(s).

Found: C, 73.82; H, 7.03%. Calcd for $C_{16}H_{18}O_3$: C, 74.39; H, 7.02%.

15b: Oil; IR (CCl_4) 1735, 1705, 1090br and 695 cm^{-1}; ^1H NMR δ=1.50—2.95 (9H, m), 3.18 (1H, m), 3.89 (1H, tt, J=10.4 and 5.8 Hz), 4.50 (2H, s), and 7.30 (5H, s); ^{13}C NMR δ=23.0(t), 38.1(t), 38.6(t), 40.0(t), 42.7(d), 62.3(d), 69.9(d), 71.0(t), 127.5(d), 127.8(d), 129.6(d), 137.9(s), 208.4(s), and 209.3(s).

7-Benzyloxy-1-(*t*-butyldimethylsiloxy)-9-methylenebicyclo-[3.3.1]non-2-ene (18). To an ice-cooled mixture of 30 g of **15** (**15a**/**15b**=2.2/1.0), 32.4 ml of triethylamine, and 1 L of carbon tetrachloride, was added 46 g of TBSOTf drop by drop, and the solution was stirred at room temperature for 6 h. The triethylammonium trifluoromethanesulfonate produced was removed through a short alumina column. Concentrating the filtrate gave a crude oily **16** (43 g, 100%), IR (CCl_4): 1720, 1660, 1190, 1175, and 1090 cm^{-1}, which was employed for the next reaction without a further purification.

To a suspension of 48.5 g of methyltriphenylphosphonium bromide in 300 ml of dry tetrahydrofuran at 0 °C under argon was added drop by drop 97.5 ml (1.50 mol) of butyllithium-hexane solution. The mixture was stirred for 1.5 h at room temperature. To the resulting Wittig reagent, a solution of 43 g of the TBS enol ethers **16** in 500 ml of THF was added at a once and the whole was stirred for 1.5 h. After most of the solvent had been evaporated below 40 °C, 30 ml of benzene was added and the solution was filtered through a short alumina column. Evaporating the solvent gave 43.7 g (100%) of a mixture of **18a** and **18b** (**18a**/**18b**=2.2/1.0); IR (CCl_4) 1660, 1190sh, 1175, 1095, and 890 cm^{-1}.

7-*endo*-Benzyloxy-9-methylenebicyclo[3.3.1]non-3-en-2-one (20a) and 7-*exo*-Benzyloxy-9-methylenebicyclo[3.3.1]non-3-en-2-one(20b). A) From **18**. To a vigorously stirred solution of **18** (512 mg) in 10 ml of dry acetonitrile, was added 273 mg of $Pd(OAc)_2$ under argon at 0 °C, and the whole was stirred at room temperature for 8 h. Chromatography of the mixture with benzene and $CHCl_3$ gave 271 mg (99% based on **18a**) of **20a** and 110 mg of the recovered **18b**.

20a: Mp 88.5—89.5 °C (from hexane); IR (KBr) 1670, 1650, 900, and 695 cm^{-1}; ^1H NMR δ=1.5—3.2 (6H, m), 3.77 (1H, br. s), 4.23 and 4.30 (2H, AB, J=11.6 Hz) 4.73 (1H, s) 4.77 (1H, s), 5.98 (1H, d, J=9.7 Hz), 7.14 (1H, dd, J=9.7 and 6.5 Hz), and 7.30 (5H, br. s); ^{13}C NMR δ=34.7(t), 36.7(t), 39.8(d), 52.2(d), 70.3(t), 72.9(d), 104.8(t), 127.3(d), 128.3(d), 130.0(d), 138.5(s), 150.2(s), 152.0(d), 153.1(d), and 202.1(s).

Found: C, 80.42; H, 7.23%. Calcd for $C_{17}H_{18}O_2$: C, 80.28; H, 7.13%.

B) From **19** via **21**. To an ice-cooled solution of 9.23 g of **15** (**15a**/**15b**=2.2/1.0) and 5.97 ml of triethylamine in 90 ml of CCl_4, 6.91 ml of TMSOTf was added drop by drop and the mixture was stirred at room temperature for 6 h. The whole was filtered through an anhyd K_2CO_3 column with CCl_4 and concentration of the solvent gave 11.8 g (100%) of **17**; ^{1}H NMR δ=0.1 (9H, s), 1.7—2.5 (8H, m), 3.4 (1H, m), 4.2 and 4.4 (2H, AB, J=13 Hz), 4.7 (1H, m), and 7.2 (5H, s).

To a suspension of 1.26 g of methyltriphenylphosphonium bromide in 20 ml of THF, 2.99 ml of 1.3 M butyllithium-hexane solution was added at 0 °C and the whole was stirred at room temperature for 30 min. A solution of 1.06 g of **17** in 20 ml of THF was added and the stirring was continued for 1 h. The TMS enol ethers **19** were unstable and were used immediately to a subsequent reaction without a further purification.

A solution of 615 mg (1 molar equivalent) of benzeneselenenyl chloride in 10 ml of THF was added to the mixture and the whole was stirred for 1 h when **19** disappeared (TLC check). After evaporating the solvent, the oily residue (1.28 g) containing a crude **21** was dissolved in 10 ml of CH_2Cl_2, 0.5 ml of pyridine was added and 1.9 ml of 15% aqueous H_2O_2 was added drop by drop under vigorous stirring at room temperature. After 25 min, 5 ml of CH_2Cl_2 and 6.2 ml of saturated $NaHCO_3$ were added and the mixture was stirred for 30 min. An organic layer was separated and the aqueous layer was extracted with CH_2Cl_2. The combined organic extract was washed with 3M HCl, water, saline, and dried over anhyd Na_2SO_4. After the solvent had been evaporated, the residue was chromatographed with hexane-AcOEt (5 : 1) to give 404 mg of **20a** and **20b** (**20a**/**20b**=9.6/1.0). **20b**: ^{1}H NMR δ=4.38 (2H, s) and 6.00 (1H, d, J=9.6 Hz).

When 2 molar equivalents of benzeneselenenyl chloride were used, 18% of **24b** was obtained accompanied with 24% of a mixture of **21a** and **21b**, and 30% of unknown materials.

24b; Oil; ^{1}H NMR δ=1.2—2.7 (4H, m), 3.0—3.35 (1H, m), 3.35—3.55 (1H, m), 3.67 (1H, tt, J=11.0 and 5.0 Hz), 4.48 (2H, br. s), 4.76 (2H, s), 6.50 (1H, d, J=6.6 Hz), and 7.2—7.8 (10H, m); ^{13}C NMR δ=34.4(t), 37.0(t), 42.4(d), 53.9(d), 70.7(t), 71.1(d), 106.6(t), 126.5(s), 127.5(d), 128.3(d), 128.8(d), 129.6(d), 136.6(d), 136.9(s), 138.4(s), 146.1(d), 147.5(s), and 196.8(s).

Found: m/z 410.0787. Calcd for $C_{23}H_{22}O_2Se$: M, 410.0783.

7-*endo*-Benzyloxy-9-methylenebicyclo[3.3.1]nonan-2-one (22a). The TMS (**18**) or TBS (**19**) enolates were hydrolyzed by a usual method to give a mixture of saturated ketones **22a** and **22b**. From those 7-*endo*-benzyloxy-9-methylenebicyclo-[3.3.1]nonan-2-one (**22a**) was obtained by chromatography with benzene.

22a; Oil; ^{1}H NMR δ=2.5—3.1 (10H, m), 3.65 (1H, quint, J=3.0 Hz), 4.13 and 4.41 (2H, AB, J=11.4), 4.70 and 4.78 (2H, AB, J=2.0 Hz), and 7.25 (5H, s).

Found: m/z 256.1458. Calcd for $C_{17}H_{20}O_2$: M, 256.1462.

Benzeneselenenylation of 22a. To a solution of 0.25 mmol of LDA in 4 ml of THF, was added a solution of 64 mg of **22a** in 5 ml of THF at −78 °C and the mixture was stirred at room temperature for 30 min. Benzeneselenenyl chloride (54 mg) was added to the cooled (−78 °C) solution and the mixture was stirred at that temperature for 5 h. After had been warmed to 0 °C, a piece of ice was added and the solution was acidified, extracted with ether. The ether layer was washed with water, saline, and dried over anhyd Na_2SO_4. Evaporating the solvent and the chromatography of the residue with benzene-AcOEt (7 : 1) gave 44 mg (43%) of **21a** and 11 mg (11%) of **23a**.

21a; Oil; IR ($CHCl_3$) 1685, 1650, 1080br, and 895 cm^{-1}; ^{1}H NMR δ=1.5—3.0 (7H, m), 3.25 (1H, m), 3.65 (1H, m), 3.79 (1H, dd, J=7.6 and 2.0 Hz), 4.05 and 4.39 (2H, AB, J=12.0 Hz), 4.79 and 4.90 (2H, AB, J=1.8 Hz), and 7.1—7.6 (10 H, m).

23a; Mp 85—86 °C (from hexane); IR ($CHCl_3$) 1715 and 900 cm^{-1}; ^{1}H NMR δ=1.5—3.2 (9H, m), 3.72 (1H, m), 4.05 and 4.45 (2H, AB, J=12.0 Hz), 5.15 and 5.61 (2H, AB, J=1.8 Hz), and 7.1—7.8 (10H, m); ^{13}C NMR δ=25.1(t), 37.9(d), 39.1(t), 40.4(t), 42.5(t), 61.4(s), 69.7(t), 74.7(d), 112.0(t), 127.3—138.5 (Ph-×2), 150.1(s), and 210.2(s).

Found: C, 67.33; H, 5.94%. Calcd for $C_{17}H_{24}O_2Se$: C, 67.14; H, 5.88%.

7-*endo*-Benzyloxy-9-methylene-4-*exo*-phenylthiobicyclo-[3.3.1]nonan-2-one (25a). A) From **20a**. To a solution of 825 mg of the enone **20a** and 358 mg of thiophenol in 5 ml of chloroform at 0 °C was added 0.02 µl of triethylamine. The solution was stirred at room temperature for 6 h and was filtered through a short silica-gel column. The solvent was removed and the residue was recrystallized from hexane to give 1.11 g (94%) of a sulfide **25a**, mp 82.5—83 °C; IR (KBr) 1710, 1075, 1040, 915, 750, 735, 730, 695, and 685 cm^{-1}; ^{1}H NMR δ=1.54—1.98 (2H, m), 2.20 (1H, dd, J=16 and 8 Hz), 2.50—3.00 (4H, m), 2.73 (1H, dd, J=16 and 6 Hz). 3.69 (1H, br. s), 4.06 (1H, ddd, J=8, 6, and 1 Hz), 4.13 and 4.45 (2H, AB, J=11.6 Hz), 4.84 and 4.89 (2H, AB J=1.8 Hz), and 7.30 (5H, br. s).

Found: C, 75.85; H, 6.63%. Calcd for $C_{23}H_{24}O_2S$: C, 75.78; H, 6.63%.

B) From the mixture of **20a** and **20b**. Triethylamine (0.0035 µl) was added to the solution of 144 mg of **20** (**20a**/**20b**=3.5/1.0) and 0.064 ml of thiophenol in 1 ml of $CHCl_3$ and the mixture was stirred at room temperature for 6 h. The solvent was removed and the residue was chromatographed with hexane-AcOEt (5 : 1) and recrystallized from hexane to give 200 mg (97%) of **25a**. **20b** was recovered from the mother liquid.

7-*endo*-Benzyloxy-2,2-ethylenedioxy-9-methylene-4-*exo*-phenylthiobicyclo[3.3.1]nonane(26a). To a solution of 80 mg of TBSOTf in 40 ml of dichloromethane was added at −78 °C 934 mg of 1,2-bis(trimethylsiloxy)ethane[26] and 1.04 g of the sulfide **25a** successively. The solution was stirred for 4 h at −10 °C, and filtered through a short silica-gel column. The solvent was removed and chromatography of the residue with hexane-AcOEt (6 : 1) gave 1.07 g (93%) of an acetal **26a** as an oil: IR ($CHCl_3$) 1655, 1580, 1355, and 900 cm^{-1}; ^{1}H NMR δ=1.4—2.7 (5H, m), 3.05 (1H, dd, J=14.8 and 6.8 Hz), 3.4—3.7 (2H, m), 3.53 (1H, d, J=6.8 Hz), 3.6 (1H, m), 3.94 (4H, m), 4.31 and 4.58 (2H, AB, J=11.6 Hz), 4.84 and 4.97 (2H, AB, J=2.2 Hz), and 7.32 (10H, br. s.)

Found: m/z 408.1763. Calcd for $C_{25}H_{28}O_3S$: M, 408.1758.

7-*endo*-Benzyloxy-9-methylene-4-phenylthiobicyclo[3.3.1]-non-3-en-2-one(27a). To a solution of 680 mg of **26a** in 30 ml of CCl_4 was added 234 mg of NCS and 0.5 ml of water at a once and the suspension was stirred for 3 h. Filtration of the precipitates at room tempertature, evaporation of the solvent and chromatography of the residue with hexane-AcOEt (7 : 1) gave 537 mg (89%) of a vinyl sulfide **27a** as an oil; IR (CCl_4) 1660sh, 1650, 1580, 1080, and 900 cm^{-1}; ^{1}H NMR δ=1.8—2.2 (2H, m), 2.4—2.8 (2H, m), 3.17 (2H, br. s), 3.89 (1H, br. s), 4.37 and 4.47 (2H, AB, J=10.8 Hz), 4.84 (1H, s), 5.45 (1H, s), and 7.3 (10H, br. s).

Found: *m/z* 362.1346. Calcd for $C_{23}H_{22}O_2S$: M, 362.1339.

7-*endo*-Benzyloxy-9-methylenebicyclo[3.3.1]nonane-2,4-dione(2). To a solution of 500 mg of **27a** in 15 ml of ethanol, was added 15 ml of 25% aqueous KOH solution under argon and the solution was heated to reflux for 12 h. After had been cooled to room temperature, the whole was poured into ice-water. The solution was acidified, extracted with ether (100 ml×3). The extracts were dried over anhyd Na_2SO_4 and was concentrated to give a crude diketone **2** as crystals. Recrystallization from hexane-benzene (10:1) gave 343 mg (92%) of pure **2**; mp 91—91.5 °C; IR (CCl_4) 1720sh, 1710, 1235, 1080, 905, and 690 cm^{-1}; ^1H NMR δ=1.94 (2H, br. d, J=16.1 Hz), 2.65 (2H, br. d, J=15.2 Hz), 3.12 and 3.28 (2H, AB, J=17.9 Hz), 3.69 (1H, quint, J=5.4 Hz), 4.27 (2H, s), 5.02 (2H, s), and 7.25 (5H, br. s); ^{13}C NMR δ=38.8(t), 51.7(d), 55.3(t), 69.8(t), 72.2(d), 111.3(t), 127.4(d), 127.6(d), 128.5(d), 137.5(s), 145.2(s), and 205.1(s).

Found: C, 75.48; H, 6.68%. Calcd for $C_{17}H_{18}O_3$: C, 75.53; H, 6.71%.

The authors are deeply indebted to Dr. Noboru Nakayama, Nippon Roche Research Center, for the measurement of the high-resolution mass spectra. The present work was supported in part by a Grant-in-Aid from university of Tsukuba Project Research (1986).

Efficient Carbonyl Addition of Polyfluorochloroethyl, -ethylidene, and -ethenyl Units by Means of 1,1,1-Trichloro-2,2,2-trifluoroethane and Zinc

Makoto FUJITA and Tamejiro HIYAMA*
Sagami Chemical Research Center, 4-4-1 Nishiohnuma, Sagamihara, Kanagawa 229
(Received July 22, 1987)

Thermally stable zinc carbenoid CF_3CCl_2ZnCl was prepared from 1,1,1-trichloro-2,2,2-trifluoroethane and zinc powder in *N,N*-dimethylformamide and was allowed to add to carbonyls of aldehydes and α-keto esters in excellent yields to give 1-substituted 2,2-dichloro-3,3,3-trifluoro-1-propanols. Employment of excess zinc induced further reductive β-elimination to afford 1-substituted 2-chloro-3,3,3-trifluoropropenes (**3**) and 1-substituted 2-chloro-3,3-difluoro-2-propen-1-ols (**4**). Exclusive formation of **3** was achieved by use of acetic anhydride as the co-reagent, whereas **4** was produced with an aluminium chloride catalyst highly selectively.

Introduction of fluorine to biologically active compounds often results in remarkable modification of their activity owing to increased stability and lipophilicity as well as to mimic and block effect of fluorine atom.[1] Therefore, various methods have been developed recently for the introduction of fluorinated groups to organic molecules.[2] Readily accessible fluorohalocarbons such as CF_2Br_2, $CFCl_3$, and HCF_2Cl are frequently utilized for this purpose as fluorine-containing building blocks.[3] However, 1,1,1-trifluoro-2,2,2-trihaloethanes (CF_3CX_3, X=Cl, Br) have scarecely been employed as the fluorine source,[4] though they are also commercially available. A carbenoid reagent of type CF_3CX_2-Mtl which might be derived from CF_3CX_3 attracted our interest, as it should provide us a facile way for the nucleophilic introduction of CF_3CX_2 group. In striking contrast to extensive studies on perfluoroalkylmetals,[5] the chemistry of the organo-metallics of the formula CF_3CX_2Mtl remained unexplored at the outset of our study. Only the Grignard reagent CF_3CX_2MgX[6] was recorded which, however, are labile and does not achieve carbonyl addition even at low temperatures. Thus, we searched for a practically stable reagent of this type and found that 1,1-dichloro-2,2,2-trifluoroethylzinc chloride fulfils our criteria.[7] Its preparation and carbonyl addition are described herein.

Results and Discussion

Preparation of CF_3CCl_2ZnCl. When 1,1,1-trichloro-2,2,2-trifluoroethane was added to a suspension of small excess of zinc powder in *N,N*-dimethylformamide (DMF) in the presence of copper(I) chloride catalyst[8] at room temperature, exothermic reaction took place, and most of the zinc was consumed within 1 h. At the expense of the peak of CCl_3CF_3(δ=−81.1), a new peak appeared at δ=−72.3, which was assigned as that of CF_3CCl_2ZnCl.[9] Upon hydrolysis CF_3CCl_2H was produced quantitatively. The reaction with carbon dioxide gave 2,2-dichloro-3,3,3-trifluoropropanoic acid (18% yield)[10] (Scheme 1). Thermal stability of the zinc carbenoid deserves particular attention: No decomposition was observed in DMF solution after several days at room temperature. The zinc reagent could be prepared in tetrahydrofuran (THF) solution also in a similar manner.

Aldehyde Addition of CF_3CCl_2ZnCl. The synthetic utility of the zinc reagent is demonstrated by an aldehyde addition. Although the pre-prepared reagent does undergo addition to aldehyde carbonyl, the Barbier-type conditions were found more efficient. Treatment of aldehydes (**1**) with 1,1,1-trichloro-2,2,2-trifluoroethane (1.2—1.5 mol) and zinc powder (1.0—1.2 mol) in DMF afforded CF_3CCl_2 adducts **2** (Eq. 1). Results are summarized in Table 1. The reaction with aromatic aldehydes proceeded smoothly in good yields. Though the carbonyl addition to some aliphatic and α,β-unsaturated aldehydes were sluggish, the addition of copper(I) chloride, dichlorobis(triphenylphosphine)palladium(II), or dichlorobis(triphenylphosphine)nickel(II) catalyst or ultrasonic irradiation[5c] improved the yields significantly (Runs 9—12,

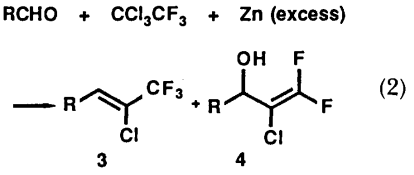
a) All the reactions were carried out in DMF (1 ml $mmol^{-1}$). b) Molar ratio of CCl_3CF_3, Zn, and Ac_2O. Single step procedure corresponds to Procedure A, whereas the two-step procedure means Procedure B. c) The values in the brackets are Z/E ratio of **3**. d) Accompanied by **2a** (17—19% yields). e) Titanium-(IV) chloride (0.12 ml, 1.0 mmol) was employed in lieu of acetic anhydride. f) Acetic anhydride was replaced by $SiCl_4$ (0.3 mmol). g) Boron trifluoride etherate (0.3 mmol) was used in place of acetic anhydride. h) Acetyl chloride (0.1 ml, 1.6 mmol) was employed instead of acetic anhydride. i) $NiCl_2(PPh_3)_2$ (2 mol%) was employed as the catalyst.

and 15). Other 1,1,1-trifluoro-2,2,2-trihaloethanes e.g. CBr_2ClCF_3 and CBr_3CF_3 also were applicable, thouth the yields were inferior (Runs 2 and 3). No ketone adducts were isolated under the reaction conditions. Lewis acids such as $AlCl_3$ and $TiCl_4$ were totally ineffective for the ketone addition. DMF solvent is essential to the carbonyl reaction, as in THF the aldehyde addition did not take place.

Attempted reaction of the zinc carbenoid with benzoyl chloride failed. Although benzoyl chloride was consumed immediately in DMF, benzoic acid was isolated after workup with trifluoroacetic acid. Possibly the zinc reagent promoted the reaction of PhCOCl with DMF to give rise to a Vilsmeier reagent $[Me_2N{=}CHOCOPh]^+Cl^-$ or $[Me_2N{=}CHCl]^+PhCOO^-$. Parallel experiment in THF induced ring-opening of the THF ring to yield 4-chlorobutyl benzoate. Thus, strong acid character as well as low nucleophilicity of the zinc carbenoid is now revealed.

Transformation of RCHO (1) into RCH=C(Cl)CF_3 (3). When excess zinc is applied to the aldehyde addition, further reductive β-elimination is expected to afford 2-chloro-1,1,1-trifluoro-2-alkene (**3**) and/or 2-chloro-1,1-difluoro-1-alken-3-ol (**4**) (Eq. 2). Actually, treatment of benzaldehyde with CCl_3CF_3 (1.5 mol) and

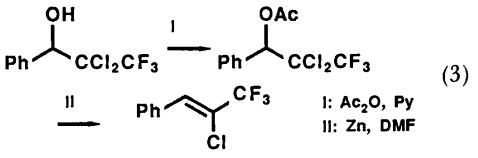


(2)

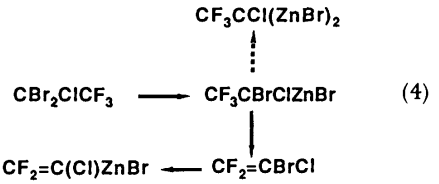
zinc (3.0 mol) afforded a mixture of **3a** (14%) and **4a** (57%) (Table 2, Run 1). In order to control the two pathways, the effect of various additives was studied.

By use of excess acetic anhydride (1.5—1.6 mol) as the additive, conversion of RCHO into **3** was achieved highly selectively. Various aldehydes including aromatic, aliphatic, and α,β-unsaturated ones were successfully converted into **3**, and the results are summarized in Table 2. Employment of 2 mol of CCl_3CF_3 and large excess of zinc (5 mol) was desirable for giving **3** in satisfactory yields (Procedure A). The amount of zinc could be reduced to 3.1 mol without decrease of the yield by a modified two-step but one-pot procedure (Procdure B): i) Formation of C-C bond with CCl_3CF_3 (1.2 mol) and zinc (1.1 mol) and ii) reduction with zinc (2 mol) and acetic anhydride (1.5 mol). Such Lewis acids as $TiCl_4$ and $SiCl_4$[11] were also effective for exclusive transformation of benzaldehyde into **3a**, whereas boron trifluoride etherate did not significantly affect the selectivity (Runs 6 and 7). Acetyl chloride also could be used in lieu of acetic anhydride for the Procedure B (Run 10).

The reaction pathway should involve formation of an acetate of **2** as the intermediate, since the acetate of **2a** was produced (79% yield) when zinc (1.2 mol), CCl_3CF_3 (1.2 mol), and acetic anhydride (1.2 mol) were employed. Actually, treatment of the acetate with zinc in DMF produced **3a** in good yields (Eq. 3).[14] In order to check an alternative route which goes through a *gem*-dimetallic species like $CF_3CCl(ZnBr)_2$, we allowed CBr_2ClCF_3 to react with zinc at 50 °C and observed a β-elimination to give $CF_2{=}CClBr$. This was successively converted into $CF_2{=}CClZnBr$ under the reaction conditions (Eq. 4). These results contrast sharply to the carbonyl methylenation with $CH_2X_2/Zn/TiCl_4$



(3)



(4)

which involves $CH_2(ZnX)_2$ as the intermediate.[11a]

Synthetic utility of this reaction was demonstrated by a one-pot synthesis of 2-chloro-1,1,1-trifluoro-5-methyl-2,4-hexadiene (**3f**)[12b,c] which is one of key synthetic precursors for artificial pyrethroids containing $CH{=}C(Cl)CF_3$ moiety in common.[12,13] Although the same transformation can be effected with $CCl_3CF_3/PPh_3/Zn$ reagent,[4b] this Wittig type olefination method requires use of 2 mol of triphenylphosphine and tedious separation of triphenylphosphine oxide contaminated in the products and thus is apparently unpractical.

Transformation of RCHO (1) into RCH(OH)CCl=CF_2 (4). In striking contrast, aluminium chloride catalyst promoted highly selective transformation to **4**. For example, in the presence of 10 mol% of aluminium chloride, benzaldehyde was converted into **4a** in 86% yield accompanied by a trace amount of **3a** (<5%). With the increase of the proportion of $AlCl_3$ to 30 mol%, both yield and selectivity decreased considerably. **4a** was no longer produced on employment of 1 mol of $AlCl_3$: A mixture of 2,2-dichloro-3,3,3-trifluoro-1-phenyl-1-propanol (**2a**) (37%) and **3a** (11%) resulted. The effect of $AlCl_3$ may be explained as follows. Catalytic amount of $AlCl_3$ can interact with CF_3 group of the primary adduct and direct the reductive elimination to produce **4**, whereas an equimolar amount of $AlCl_3$ substitutes ZnCl of the primary adduct to weaken the C-O bond of the primary adduct. The $AlCl_3$-catalyzed method was applied to various aldehydes. Results summarized in Table 3 show that 1-substituted 2-chloro-3,3-difluoro-2-propen-1-ols of various kinds are readily accessible through the methodology disclosed herein.

The reaction was monitored by ^{19}F NMR which

Table 3. Transformation of **1** to **4**[a]

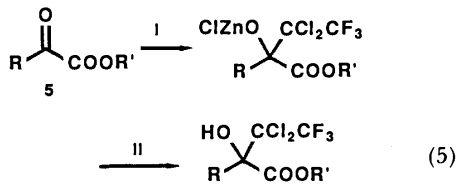
9	**1k**	0.3	18 h	**4k** (41)

a) All the reactions were carried out in DMF (1 ml $mmol^{-1}$) at 50 °C with **1**, CCl_3CF_3, and Zn in a molar ratio of 1 : 1.5 : 3.0. b) Molar equivalents to aldehyde. c) Roughly 1:1 diastereoisomeric mixture. d) Copper(I) chloride catalyst (5 mol%) was used.

showed formation of an aldehyde adduct of CF_3CCl_2ZnCl at the early stage of the reaction. The observation clearly eliminates the possibility of the intermediacy of CF_2=C(Cl)ZnCl.

The achievement of the practical transformation of aldehydes to **4** is of great value from synthetic viewpoint, as the aldehyde adducts of CX=CF_2 group (X=F, Cl) are key intermediates for a number of fluorine containing carbonyl compounds.[14] Whereas the carbonyl addition is usually carried out with labile LiCX=CF_2[15,16] below −100 °C, the $CX_3CF_3/Zn/AlCl_3$ (cat) reagent can do the same transformation at 50 °C.[17]

Addition of CF_3CCl_2ZnCl to α-Keto Esters and DMF. Although the zinc carbenoid did not add across ketone carbonyls, the reagent reacted with α-keto esters **5** (Eq. 5). The yields of the aducts **6** were moderate even in the presence of large excess of the reagent. The conversion-based yields were quantitative, though. Possibly the intermediate adduct is in equilibrium between **5** and the zinc reagent which gradually decomposes to shift the equilibrium to the starting material.



(5)

Attempted Reaction with Chlorosilanes. In the presence of chlorosilanes, the CF_3CCl_2ZnCl reagent reacted with DMF to give α-silyloxy *N,N*-dimethylamines **7** in good yields (Eq. 6). As CF_3CCl_2ZnCl alone does not interact with DMF, **7** may be derived from a Vilsmeier type reagent $[Me_2N^+=CHOSiR_3]Cl^-$ generated in situ from R_3SiCl and DMF.

$$HCONMe_2 + R_3SiCl + CCl_3CF_3 \longrightarrow CF_3CCl_2CH(NMe_2)OSiR_3 \quad (6)$$

7

a: $SiR_3 = SiMe_2t\text{-}Bu$
b: $SiR_3 = SiEt_3$

A new zinc carbenoid reagent CF_3CCl_2ZnCl is readily prepared from commercially available CCl_3CF_3 and zinc and is shown to undergo carbonyl addition. Although it did not exhibit enough reactivity to achieve coupling with a wide variety of electrophiles, the zinc reagent allowed us to introduce three kinds of C_2 units containing both chlorine and flourine atoms. Synthetic application to artificial pyrethroids is disclosed in following article.[18]

Experimental

Melting points and boiling points are uncorrected. Bulb-to-bulb distillation was carried out by use of Büchi Kugelrohr or Glass Tube Oven (Shibata GTO 250R). ^1H NMR spectra (tetramethylsilane as an internal standard) were obtained with a Varian EM-390, Varian XL-100A, Hitachi R-90H, or Bruker AM-400 spectrometer, chemical shifts being given in ppm units, ^{19}F NMR spectra (trichlorofluoromethane as an internal standard) with a Hitachi R-20B or Varian XL-100A spectrometer, ^{13}C NMR spectra with a Bruker AM-400. IR data of neat liquid film samples (unless otherwise noted) were recorded with a JASCO A-202. Mass spectra (70 eV unless otherwise noted) were recorded with a RMU-6MG, high mass with a Hitachi M-80A spectrometer. GLC analyses were performed with a Shimadzu GC-7A chromatograph (FID detector). Preparative GLC were carried out with a Shimadzu GC-3Bt chromatograph (TCD detector). TLC analyses were performed by means of Merck Silica Gel 60 F_{254} (0.25 mm thick). Preparative TLC plates were prepared with Merck Kiesel-Gel PF_{254}. Column chromatography was carried out with silica-gel (Wakogel C-200) at atmospheric pressure. Ultrasonic irradiation was performed with a Wakenyaku UW-10 (250 W, 28 KHz) cleaner. DMF was distilled over calcium hydride and stored over Molecular Sieve 4A. Zinc powder purchased from Wako Pure Chemical Industries, Ltd. was washed successively with dil hydrochloric acid, water, ethanol, diethyl ether and finally with absolute diethyl ether, and dried under reduced pressure. 1,1,1-Trichloro-2,2,2-trifluoroethane was purchased from Tokyo Kasei Kogyo Co. and used directly.

A Typical Procedure for Generation of CF_3CCl_2ZnCl and Its Aldehyde Addition. To a solution of benzaldehyde (**1a**) (2.12 g, 20.0 mmol) in DMF (20 ml) were added 1,1,1-trichloro-2,2,2-trifluoroethane (4.52 g, 24.1 mmol) and zinc powder (1.44 g, 22.1 mmol), and the resulting mixture was stirred for 3 h at room temperature and for 2 h at 50 °C before treatment with sat aq ammonium chloride solution (30 ml). Extraction with diethyl ether (2×30 ml), drying the ethereal extract over magnesium sulfate, concentration, followed by distillation, gave 2,2-dichloro-3,3,3-trifluoro-1-phenyl-1-propanol (**2a**) (4.49 g, 86% yield) as a colorless oil. Bp 100 °C (bath temp)/1 Torr;† ^1H NMR ($CDCl_3$) δ=2.90 (d, *J*=5 Hz, 1H), 5.20 (d, *J*=5 Hz, 1H), 7.25—7.55 (m 5 H); ^{19}F NMR

4,4-Dichloro-5,5,5-trifluoro-1-phenyl-1-penten-3-ol (2e): A colorless oil. ^1H NMR ($CDCl_3$) δ=2.53 (br s, 1 H), 4.80 (d, *J*=5 Hz, 1 H), 6.27 (dd, *J*=5 and 16 Hz, 1H), 6.82 (d, *J*=16 Hz, 1H), 7.20—7.50 (m, 5 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−73.9 (s); IR 3450, 1257, 1195, 969, 870, 751, 722, 694 cm^{-1}; MS *m/z* (rel intensity) 286 (M^++2, trace), 284 (M^+, 2), 134 (11), 133 (100), 115 (22), 103 (10), 77 (15), 55 (37).

Found: C, 46.35; H, 3.02%. Calcd for $C_{11}H_9Cl_2F_3O$: C, 46.34; H, 3.18%.

2,2-Dichloro-1,1,1-trifluoro-5-methyl-4-hexen-3-ol (2f). Zinc powder (1.50 g, 24 mmol) and copper(I) chloride (99 mg, 1.00 mmol) were suspended in DMF (20 ml) at room temperature. After 5 min, 1,1,1-trichlorotrifluoroethane (4.75 ml, 40 mmol) was added, and the whole was stirred for 20 min at room temperature. Exothermic reaction soon took place, and the vessel was occasionally cooled with ice-water bath. Then, 3-methyl-2-butenal (**1f**) (1.81 g, 21.5 mmol) was added over 10 min to this mixture at 60 °C. Workup and purification by column chromatography (CH_2Cl_2-hexane 1 : 2 to 2 : 1) gave **2f** (3.0 g, 60% yield) as a colorless oil, bp 65—67 °C/0.6 Torr. ^1H NMR ($CDCl_3$) δ=1.77(d, *J*=1.4 Hz, 3 H), 1.81 (d, *J*=1.4 Hz, 3 H), 2.08 (br s, 1 H), 4.80 (d, *J*=9.1 Hz, 1 H), 5.33 (d, *J*=9.1Hz, 1H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−74.6 (s); IR 3420, 1258, 1204, 1052, 872, 724 cm^{-1}; MS *m/z* (rel intensity) 221 (trace), 219 (trace), 85 (100), 55 (10), 41 (29), 39 (12), 29 (15).

Found: C, 35.30; H, 3.83%. Calcd for $C_7H_9Cl_2F_3O$: C, 35.47; H, 3.83%.

A control experiment in the absence of copper(I) chloride catalyst gave **2f** in 16% yield.

An experiment which employed dichloro[bis(triphenylphosphine)]palladium was carried out by adding 1,1,1-trichloro-2,2,2-trifluoroethane (0.18 ml, 1.5 mmol), $PdCl_2(PPh_3)_2$ (7.5 mg, 0.011 mmol) and zinc powder (78 mg, 1.2 mmol) to a solution of **1f** (86 mg, 1.0 mmol) in DMF (1 ml) and by stirring the reaction mixture at room temperature for 1 h and at 50 °C for 8 h. The yield of **2f** was estimated to be 61% by GLC assay (internal standard: tridecane; column: 5% silicone SE-30 on Uniport HP, 2 m; carrier gas: N_2, 50 ml min^{-1}): R_t 2.97 min.

The adduct **2f** was alternatively prepared by ultrasonic irradiation. To a solution of **1f** (84 mg, 1.0 mmol) in DMF (1 ml) was added 1,1,1-trichloro-2,2,2-trifluoroethane (0.18 ml, 1.5 mmol) and zinc powder (78 mg, 1.2 mmol), and the mixture was allowed to warm gradually to 50 °C under ultrasoic irradiation which was continued for 2 h at 50 °C. The yield was estimated by GLC.

2,2-Dichloro-1,1,1-trifluoro-4-phenyl-3-pentanol (2g): A colorless oil. ^1H NMR ($CDCl_3$), δ=1.46 (d, *J*=7.0, Hz, 3 H), 2.37 (d, *J*=8.1 Hz, 1 H), 3.52 (dq, *J*=2.1 and 7.0 Hz, 1 H), 4.31 (dd, *J*=2.1 and 8.1 Hz, 1 H), 7.33 (s, 5 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−74.8 (s); IR 3550, 1250, 1194, 870, 704 cm^{-1}; MS *m/z* (rel intensity) 288 (M^++2, trace), 286 (M^+, trace), 106 (10), 105 (100), 103 (5), 79 (9), 77 (7).

Found: C, 46.02; H, 3.97%. Calcd for $C_{11}H_{11}Cl_2F_3O$: C, 46.02; H, 3.86%.

2,2-Dichloro-1-cyclohexyl-3,3,3-trifluoro-1-propanol (2h). Cyclohexanecarbaldehyde (**1h**) (112 mg, 1.00 mmol) and 1,1,1-trichloro-2,2,2-trifluoroethane (0.18 ml, 1.5 mmol) were added to a suspension of zinc powder (78 mg, 1.20 mmol) and copper(I) chloride (5 mg, 0.05 mmol) in DMF (1 ml), and then the reaction mixture was stirred for 5 h at 50 °C. Workup followed by preparative TLC (CH_2Cl_2) gave **2h** (156 mg, 61% yield) as a colorless oil. ^1H NMR ($CDCl_3$) δ=1.0—2.3 (m, 12H), 3.94 (br s, 1H); ^{19}F NMR ($CDCl_3$-$CFCl_3$): δ=−75.1 (s); IR 3490, 2950, 2875, 1252, 1200 cm^{-1}; MS *m/z* (rel intensity) 245 (M^+−19, trace), 113 (19), 95 (60), 83 (100), 82 (18), 67 (17), 55 (84), 41 (39).

Found: C, 40.90; H, 5.08%. Cacld for $C_9H_{13}Cl_2F_3O$: C, 40.78; H, 4.94%.

In the absence of the copper catalyst, the yield of **2h** was 16%.

2,2-Dichloro-3,3,3-trifluoro-1-phenylpropyl Acetate. A solution of 2,2-dichloro-3,3,3-trifluoro-1-phenyl-1-propanol (0.62 g, 2.4 mmol) in pyridine (1 ml) and acetic anhydride (1

ml) was allowed to react for 4 h at room temperature. Work-up and purification by preparative TLC (CH_2Cl_2-hexane 1:2) gave the desired acetate (0.69 g, 96% yield) as a colorless oil. ^1H NMR ($CDCl_3$) δ=2.15 (s, 3 H), 6.35 (s, 1 H), 7.3—7.6 (m, 5 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−74.7 (s); IR 1767, 1373, 1248, 1204, 1040,1028, 938, 840, and 699 cm^{-1}; MS *m/z* (rel intensity) 302 (M^++2, trace), 300 (M^+, trace), 149 (27), 107 (87), 79 (14), 77 (13), 43 (100).

Found: C, 43.79; H, 2.79%. Calcd for $C_{11}H_9Cl_2F_3O_2$: C, 43.88; H, 3.01%.

Zinc Reduction of 2,2-Dichloro-3,3,3-trifluoro-1-phenyl-1-propyl Acetate. Zinc powder (40 mg, 0.61 mmol) was added to a DMF (0.5 ml) solution of the acetate (0.150 g, 0.50 mmol), and the mixture was stirred for 2 h at 50 °C. GLC assay (dodecane as the internal standard; 5% SE-30, 2 m; 120 °C; N_2 50 ml min^{-1}, R_t 5.81 min for **3a** and 12.0 min for the standard) revealed **3a** was produced in 88% yield.

Transformation of 1c to 3c. A Typical Procedure A for the Preparation of 3. To a solution of 4-chlorobenzaldehyde (**1c**) (139 mg, 0.99 mmol) in DMF (1 ml) was added 1,1,1-trichloro-2,2,2-trifluoroethane (0.24 ml, 2.0 mmol) and zinc powder (0.33 g, 5.0 mmol), and the mixture was stirred for 10 min at 0 °C and for 4 h at 50 °C. Water (10 ml) was added, and the resulting mixture was extracted with diethyl ether (3×10 ml). The ethereal extract was dried over anhydrous magnesium sulfate and concentrated under reduced pressure. Purification by preparative TLC (CH_2Cl_2-hexane 1:2) afforded 2-chloro-1-(4-chlorophenyl)-3,3,3-trifluoropropene (**3c**) (175 mg, a mixture of (Z)- and (E)-isomers, 73% yield) as a colorless oil. Bp 75 °C (bath temp)/1 Torr. ^1H NMR ($CDCl_3$) δ=7.25 (s, 1 H), 7.40 (d, *J*=10 Hz, 2 H), 7.67 (d, *J*=10 Hz, 2 H) were attributed to the (Z) isomer. ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−69.1 (s, for (Z)-isomer) and −61.7 (s, for (E)-isomer) with the intensity ratio of 88:12. IR 1495, 1307, 1288, 1173, 1140, 1106, 962 cm^{-1}; MS *m/z* (rel intensity) 244 (M^++4, 11), 242 (M^++2, 66), 241 (M^++1, 10), 240 (M^+, 100), 207 (10), 205 (28), 187 (13), 185 (38), 170 (14), 169 (23), 136 (15), 75 (16), 74 (10), 50 (12).

Procedure B Exemplified by the Preparation of 3a. To a solution of benzaldehyde (**1a**, 105 mg, 0.99 mmol) in DMF (1 ml) were added 1,1,1-trichlorotrifluoroethane (0.142 ml, 1.2 mmol) and zinc powder (72 mg, 1.1 mmol). The mixture was stirred for 1 h at room temperature and for 24 h at 50 °C before the addition of acetic anhydride (0.15 ml) and zinc powder (131 mg, 2.0 mmol). Stirring was continued for 4 h at 50 °C. Water (1 ml) and 5 drops of conc hydrochloric acid were added to quench the reaction. Extraction with diethyl ether (3×3 ml), concentration, followed by ^{19}F NMR assay ($CDCl_3$-$CFCl_3$, internal standard: 1,3,5-trichloro-2,4,6-trifluorobenzene), showed two doublets at δ=−69.9 (d, *J*=0.8 Hz) and −62.1 (s) attributed to (*Z*)- and (*E*)-**3a** respectively in a ratio of 87:13 and 87% yield. ^1H NMR ($CDCl_3$) δ=7.2—7.5 (m, 4 H), 7.5—7.8 (m, 2 H); IR 1287, 1216, 1176, 1140, 692 cm^{-1}; MS *m/z* (rel intensity) 208 (M^++2, 34), 207 (M^++1, 10), 206 (M^+, 100), 171 (39), 151 (59), 102 (16), 75 (11), 51 (15), 50 (10).

Reaction of CF_3CCl_2ZnCl with DMF and Chlorotrialkylsilanes. A Typical Procedure. Zinc powder (0.78 g, 12 mmol) and 1,1,1-trichloro-2,2,2-trifluoroethane (1.42 ml, 12 mmol) were added slowly to a solution of t-butylchlorodimethylsilane (1.52 ml, 10 mmol) in DMF (10 ml) under cooling with water bath. The mixture was stirred for 1 h at room temperature. The whole was charged on a short silica gel (20 g) column and eluted with hexane (ca. 100 ml). The eluate was concentrated and again subjected to colum chromatography (silica gel, 10 g, hexane). Concentration of the hexane eluate and distillation gave 1-(t-butyldimethylsiloxy)-2,2-dichloro-3,3,3-trifluoro-1-dimethyl-1-propanamine (**7a**, 2.02 g, 60% yield) as a colorless oil, bp 50 °C (bath temp)/0.15 Torr. ^1H NMR ($CDCl_3$) δ=0.16 (s, 6 H), 0.98 (s, 9 H), 2.53 (s, 6 H), 4.71 (s, 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−75.2 (s); IR 1257, 1198, 1184, 1088, 1061, 840, 783 cm^{-1}; MS m/z (rel intensity) 324 (M^+−Me, trace), 208 (29), 188 (68), 131 (45), 130 (23), 116 (26), 102 (39), 85 (37), 83 (54), 75 (32), 74 (22), 73 (100), 59 (28).

Found: C, 38.83; H, 6.52; N, 4.12%. Calcd for $C_{11}H_{22}Cl_2F_3NOSi$: C, 38.93; H, 6.58; N, 4.07%.

2,2-Dichloro-1-triethylsiloxy-3,3,3-trifluoro-*N*,*N*-dimethyl-1-propanamine (7b): Bp 95 °C (bath temp)/0.3 Torr. ^1H NMR ($CDCl_3$) δ=0.2—1.2 (m, 15 H), 2.50 (s, 6 H), 4.70 (s, 1 H); IR 2975, 2899, 1260, 1196, 1182, 1068, 1008, 942, 902, 812, 742 cm^{-1}.

This work was partially supported by a Grant-in-Aid for Special Research on Organochemical Resources (Nos. 61111001 and 62101001) from the Ministry of Education, Science and Culture. We thank Ms. Tomoe Morita and Mr. Masanori Ueno for their experimental assistance.

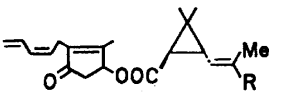
Practical, Stereocontrolled Synthesis of Polyfluorinated Artificial Pyrethroids

Makoto FUJITA, Kiyosi KONDO, and Tamejiro HIYAMA*
Sagami Chemical Research Center, 4-4-1 Nishiohnuma, Sagamihara, Kanagawa 229
(Received July 22, 1987)

Practical and stereocontrolled approaches to polyfluorinated synthetic pyrethroids based on aldehyde addition of CF_3CCl_2ZnCl are described. The zinc reagent was allowed to react with 3-formyl-2,2-dimethylcyclopropanecarboxylates (**6**) to give the corresponding adducts. These were acetylated and then reduced again with zinc to afford (1*R**, 3*S**)-3-(2-chloro-3,3,3-trifluoro-1-propenyl)-2,2-dimethylcyclopropanecarboxylates (**12**). The (1R*, 3R*)-isomer was derived from 2,2-dichloro-1,1,1-trifluoro-5-methyl-4-hexen-3-ol by diazoacetylation, Cu(II)-catalyzed intramolecular carbene addition, and finally by the zinc reduction. An alternative access to **12** and its halogen homologues of the (*Z*)-pyrethroids involves addition of 1-halo-2,2-difluoroethenyl group across the CHO group of **6** and subsequent regio- and stereoselective halogenation.

In spite of high insecticidal activity and low mammalian toxicity, use of such natural pyrethroids as pyrethrin I and pyrethrin II has been limited owing to rapid biological degradation and poor photo-oxidative stability.[1] Since the discovery of a photo-stable and more potent analogue permethrin (**1a**), a great deal of effort has been made in search for new highly potent artificial pyrethroids, and a number of derivatives including cypermethrin (**1b**) and deltamethrin (**1c**) have been developed and used currently.



R = Me : Pyrethrin I

R = COOMe : Pyrethrin II

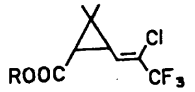
a : X = Cl, R = H (permethrin)

b : X = Cl, R = CN (cypermethrin)

c : X = Br, R = CN (deltamethrin)

New fluorinated analogues having a $CH=C(Cl)CF_3$ group commonly in place of $CH=CCl_2$ moiety are found recently to exhibit remarkably enhanced activity: Typical examples are cyhalothrin (**2a**)[2] and bifenthrin (**2b**),[3] which show, in addition to intensified insecticidal activity, 50 to 100 fold acaricidal activity as compared to **1**. Although several synthetic methods for **2** are reported to date,[2-4] the stereochemical control yet remained unsettled. Described herein is practical and stereocontrolled synthesis of **2** based on aldehyde-addition of CF_3CCl_2ZnCl reagent.[5]

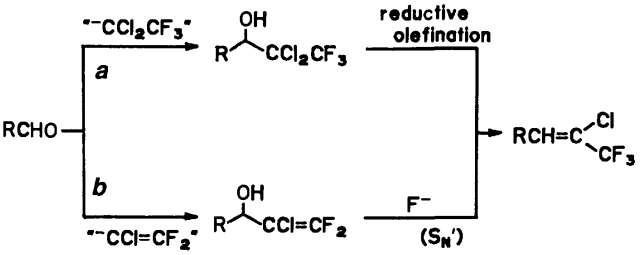


2

a: R =  (cyhalothrin)

b: R =  (bifenthrin)

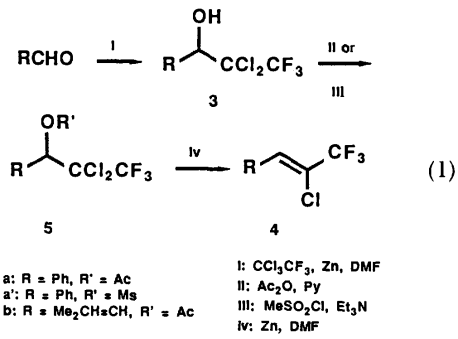
Retrosynthetic analysis of **2** led us to a new strategy (Scheme 1) which is characterized by a new transformation of CHO group to $CH=C(Cl)CF_3$ moiety through two routes as summarized in Scheme 1. The one involves the addition of $^-CCl_2CF_3$ to an aldehyde carbonyl and subsequent reductive β-elimination (route *a*). The other will be realized by the addition of $^-CCl=CF_2$ followed by S_N'-type fluorination (route *b*).



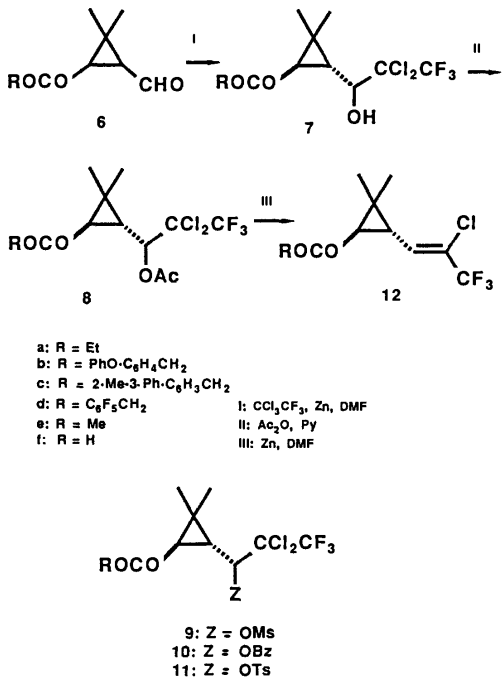
Scheme 1.

Results and Discussion

Stereocontrolled Synthesis of 2. The first step of the route *a* is now readily achieved by the recently found zinc carbenoid reagent CF_3CCl_2ZnCl.[6] The second step was studied benzaldehyde-CCl_2CF_3 adduct **3a** as the model. Reduction of **3a** under the standard conditions (zinc in acetic acid) gave the desired olefin **4a** in only 33% yield in contrast to the related reduction in permethrin synthesis.[1] The yield of **4a** was improved to 84% by the reduction of the acetate **5a** in *N*,*N*-dimethylformamide (DMF). The mesylate **5a'** equally underwent the reductive olefination to give **4a** in 65% yield. Similarly, the acetate **5b** derived from 3-methyl-2-butenal was reduced to a diene **4b**, another precursor of our target compound **2**.



These findings were successfully applied to 3-formyl-2,2-dimethylcyclopropanecarboxylates **6**[7] which were readily prepared by ozonolysis[8] of the corresponding chrysanthemates (81—89% yield). The addition of CF_3CCl_2ZnCl to **6** took place in good yields (Scheme 2 and Table 1). The adducts **7** were acetylated, and the resulting acetates **8** were transformed to **12** whose stereochemistry was proved to be uniform (1R*, 3S*) with the Z/E ratio of 86 : 14 to 93 : 7. As the alcohols **7** consisted of ca. 1 : 1 mixture of two diastereomers, each isomer was separated by column chromatography. To check the stereochemical course of the reductive olefination, each diastereomer was converted into **12**, whose Z/E ratios were almost the same and thus totally independent of the configuration of the OH group in **7**. The mesylate (**9**), benzoate (**10**), and tosylate (**11**) of **7** also are potential precursors of **12**. Results are summarized in Table 1.



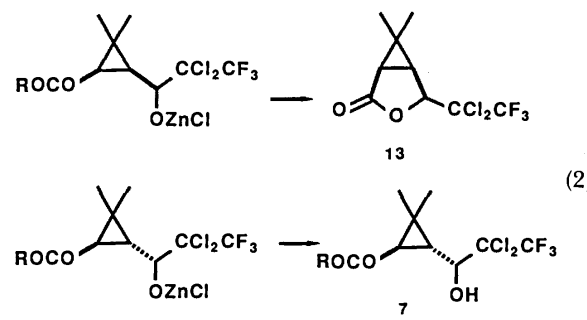
Scheme 2.

Table 1. Transformation of **6** to **12**

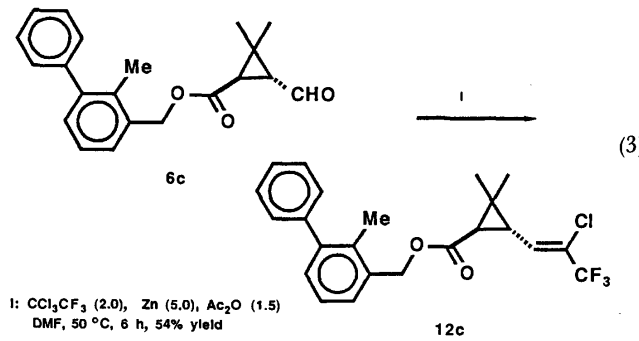
Aldehyde	**7** (yield/%)	**8** (yield/%)	**12** (yield/%)
6a[a]	58	93	86[d]
6b[b]	74	98	74[d]
6c[b]	86	100	95[e]
6d[b]	71	—	—
6e[c]	75	—	—

a) Trans/cis=4 : 1. b) Trans/cis=6 : 1. c) Trans/cis=100 : 0. d) Z/E=6 : 1. e) Z/E=8 : 1.

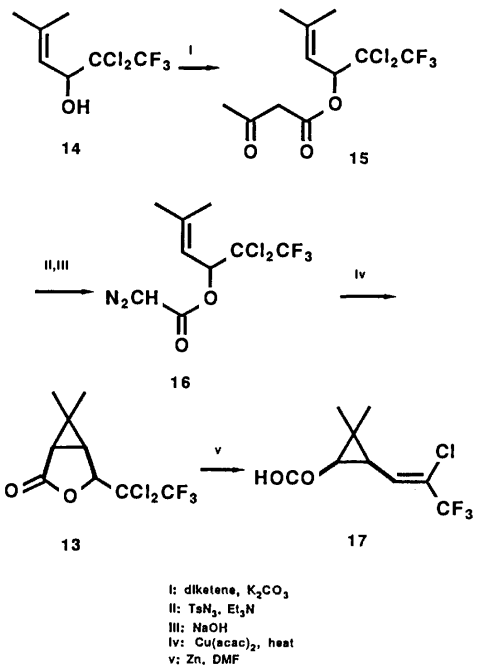
It should be noted that, though trans/cis isomeric mixture (4 to 6 : 1) of **6** was employed, only *trans*-**6** gave the adduct **7**. The CF_3CCl_2 adducts of the *cis*-**6** apparently underwent lactonization under the reaction conditions to give a bicyclic lactone **13** (<10% yield) which was isolated in some cases. The lactone **13** was not produced from pure *trans*-**6e**. Thus, the correlation of *trans*-**6**→**7** and *cis*-**6**→**13** is disclosed. Since *cis*-**6** is easily epimerized to the trans-isomer under the basic conditions,[9] a method is now established for control of the trans-configuration on the cyclopropane ring.



A one-step transformation of **6c** to **12c** (*trans*-bifenthrin) was effected with the $CF_3CCl_3/Zn/Ac_2O$ reagent (Eq. 3)[10] Although the same transformation was previously carried out by the Wittig type olefination using 1,1,1-trichloro-2,2,2-trifluoroethane, triphenylphosphine (2 mol), and zinc,[4c] the method disclosed herein is apparently more practical in view of low cost of reagents and much simpler separation technique.



The (1R*,3R*)-isomer of **2** was synthesized stereospecifically according to Scheme 3.[11] The alcohol **14**[6] was treated with diketene in the presence of potassium carbonate to give the acetylacetate **15** (88% yield), which was converted into the diazoacetate **16** by treatment with a slight excess of *p*-toluenesulfonyl (tosyl) azide and triethylamine followed by alkaline hydrolysis (82% yield from **15**). Intramolecular cyclopropanation of **16** was successfully performed with copper(II) acetylacetonate catalyst to give the lactone **13** in 75%



Scheme 3.

yield. Finally, reduction with zinc afforded the cis-acid **17** in 84% yield.

Regio- and Stereocontrolled Halogenation of 1-Substituted 2-Chloro-3,3-difluoro-2-propen-1-ols. In order to effect the transformation of route *b* in Scheme 1, we studied fluorination of the adducts **18** which are readily accessible by the reaction of aldehydes with $CCl_3CF_3/Zn/AlCl_3$ (cat) reagent[10] or by polyfluoroethenylsilane/F^- (catalyst) reagent.[12] Although several reagents for fluorinating alcohols have been developed,[13] the reaction applied to allylic alcohols is problematic due to side reactions like dehydration and lack of regioselectivity.[13a,14] In contrast, polyfluoroallylic alcohols **18** are found to be fluorinated with diethylaminosulfur trifluoride (DAST) under high regio- and stereocontrol (Eq. 4). When 1,1,2-trifluoro-1-tridecen-3-ol (**18a**) was treated with DAST, quantitative formation of 1,1,1,2-tetrafluoro-2-tridecene (**19a**) free of any stereo- or regioisomers was demonstrated by ^{19}F NMR. The configuration of **19a** was confirmed to be Z as judged by $^3J_{H-F}$ value (33 Hz).[15] The fluoride attack at the difluoromethylene carbon is particularly facilitated by highly electronegative fluorine substituent, and thus smooth and regioselective nucleophilic attack by fluoride ion is achieved under concomitant

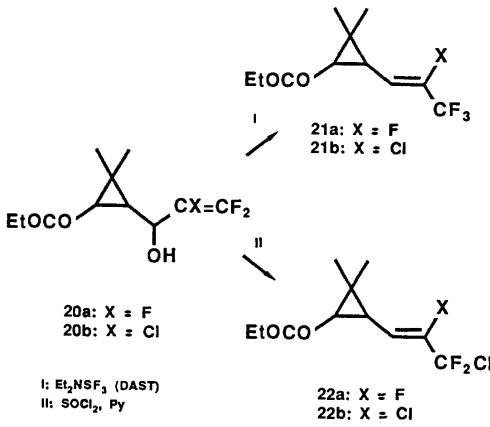
Table 2. Halogenation of **18**

Alcohol	Reagent[a] Solvent	Condition	Product[b] (yield/%)[c]
18a	DAST (1.0)/CH_2Cl_2	−78 °C—r.t., 0.2 h	**19a** (90)
18a	$SOCl_2$ (1.0)/Et_2O[e]	r.t., 3 h	**19a'** (85)
18b	DAST (1.0)/CH_2Cl_2	−78 °C—r.t., 0.3 h	**19b** (70)
18b	$SOCl_2$ (1.4)/Et_2O	50 °C, 13 h[d]	**19b'** (90)
18b	$SOBr_2$ (1.2)/Et_2O	50 °C, 4 h[d]	**19b''** (84)
18b	PBr_3 (1.05)/Et_2O	r.t., 1.5 h; 35 °C, 13 h	**19b''** (67)
18c	$SOCl_2$ (1.0)/Et_2O	50 °C, 18 h[d]	**19c'** (75)
18d	$SOCl_2$ (1.1)/Et_2O	50 °C, 12 h[d]	**19d'** (79)

a) Values in the parentheses refer to molar ratio to **18**. b) Only (Z)-isomers were isolated. c) Isolated yields. d) Carried out in a sealed tube. e) Pyridine (2.0 mol) was added.

deoxygenation.[16] Chlorination and bromination of the allylic alcohols **18** also proceeded with high regio- and stereoselectivity to allord (Z)-2-alkenes **19'** and **19''**, which should have been yielded by a cyclic S_Ni'-mechanism. The stereochemistry was determined again by ^1H and/or ^{13}C NMR spectrometry.[17] Results are summarized in Table 2. Thus, halogen analogues of **3** grew readily accessible by the two-step strategy which involves the aldehyde addition of $^-CCl=CF_2$ group and subsequent regio- and stereoselective halogenation.

Halogen analogues of **2** such as **21** and **22** were also shown to have high insecticidal activity.[2a,4f] The regio- and stereocontrolled halogenation disclosed above was applied successfully to the synthesis of these halogen analogues as well. The $CX=CF_2$ adducts **20** were prepared from **6** by the addition of trifluoroethenyllithium[18] or by the fluoride ion mediated addition of polyfluoroethenylsilanes[12] followed by acid hydrolysis. Fluorination or chlorination of **20** afforded respectively **21** or **22** under high regiocontrol (Eq. 5).



(5)

In summary, the method reported in this paper provides facile ways to polyfluorinated artificial pyrethroids under high stereocontrol. Practicability of these processes deserves particular emphasis: Most of reagents are commercially available, and the reaction conditions of each step are mild enough.

Experimental

Experimental apparatus and instrumental facilities are the same as those of the preceding paper.

2,2-Dichloro-3,3,3-trifluoro-1-phenylpropyl Methanesulfonate (5a′). Triethylamine (0.42 ml, 3 mmol) and methanesulfonyl chloride (0.155 ml, 2.0 mmol) were successively added to an ethereal solution (10 ml) of 2,2-dichloro-3,3,3-trifluoro-1-phenyl-1-propanol (**3a**, 0.26 g, 1.0 mmol) at 0 °C, and the resulting mixture was stirred for 2 h at 0 °C and for 1 h at room temperature. Workup and purification by preparative TLC (CH_2Cl_2-hexane 1 : 1) gave **5a′** (0.29 g, 85% yield) as a viscous colorless oil. ^{1}H NMR ($CDCl_3$) δ=2.65 (s, 3 H), 6.00 (s, 1 H), 7.2—7.9 (m, 5 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−75.0 (s); IR 1369, 1191, 962, 900, 819, 740, 701 cm^{-1}; MS *m/z* (rel intensity) 338 (M^++2, trace), 336 (M^+, 4), 185 (51), 107 (100), 79 (26), 77 (22), 51 (13).

Found: C, 35.56; H, 2.70%. Calcd for $C_{10}H_9Cl_2F_3O_3S$: C, 35.63; H, 2.69%.

4-Acetoxy-5,5-dichloro-6,6,6-trifluoro-2-methyl-2-hexene (5b). A mixture of 5,5-dichloro-6,6,6-trifluoro-2-methyl-2-hexen-4-ol (**3b**, 0.116 g, 0.49 mmol), acetic anhydride (0.2 ml), and pyridine (0.2 ml) was stirred for 8 h at room temperature. Concentration in vacuo followed by preparative TLC (CH_2Cl_2-hexane 1 : 1) gave **5b** (0.131 g, 96% yield) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ=1.83 (s, 6 H), 2.10 (s, 3 H), 5.28 (d, *J*=9.3 Hz, 1 H), 6.08 (d, *J*=9.3 Hz, 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−75.1 (s); IR 1767, 1254, 1208, 1190, 1024 cm^{-1}; MS *m/z* (rel intensity) 280 (M^++2, trace), 278 (M^+, trace), 183 (10), 85 (100), 43 (88), 41 (10).

Found: C, 38.73; H, 3.94%. Calcd for $C_9H_{11}Cl_2F_3O_2$: C, 38.73; H, 3.97%.

2-Chloro-1,1,1-trifluoro-5-methyl-2,4-hexadiene (4b). Zinc powder (36 mg, 0.55 mmol) and copper(I) chloride (1 mg) were added to a solution of **5b** (0.142 g, 0.51 mmol), and the whole was stirred for 6 h at 50 °C before quenching with water (2 ml) and 3 drops of conc hydrochloric acid. Extraction with pentane (4×3 ml), drying over magnesium sulfate, followed by careful concentration at 0 °C under reduced pressure gave **4b** (77 mg, 82% yield) as a colorless oil which consisted of (Z)- and (E)-isomers in a ratio of 85 : 15. ^{1}H NMR ($CDCl_3$) δ=1.87 (s, 3 H), 1.96 (s, 3 H), 6.13 (d, *J*=11.1 Hz, 1 H), 7.01 (d, *J*=11.1 Hz, 1 H) for the (Z)-isomer, δ=6.83 (d, *J*=11.1 Hz, 1 H) for the (E)-isomer, ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−69.0 (s) for the (Z)-isomer and −62.1 (s) for the (E)-isomer.

A Typical Procedure for the Preparation of 2,2-Dimethyl-3-(2-methyl-1-propenyl)cyclopropanecarboxylates. To an ethereal solution (10 ml) of 2,2-dimethyl-3-(2-methyl-1-propenyl)cyclopropanecarbonyl chloride[8] (2.80 g, 15.0 mmol) was added (2-methyl-3-phenylphenyl)methanol (2.97 g, 15.0 mmol) dissolved in pyridine (1.5 ml) and diethyl ether (10 ml), and the whole was stirred for 3 h at room temperature. Workup and purification by column chromatography (CH_2Cl_2-hexane 1 : 2) gave (2-methyl-3-phenylphenyl)methyl 2,2-dimethyl-3-(2-methyl-1-propenyl)cyclopropanecarboxylate (0.29 g, 85% yield) as a colorless viscous oil. ^{1}H NMR ($CDCl_3$) δ=1.14 (s, 3 H), 1.29 (s, 3 H), 1.54 (d, *J*=5 Hz, 1 H), 1.71 (s, 6 H), 2.17 (dd, *J*=5 and 8 Hz, 1 H), 2.22 (s, 3 H), 4.94 (d, *J*=8 Hz, 1 H), 5.20 (s, 3 H); IR 1733, 1160, 764, 707 cm^{-1}; MS *m/z* (rel intensity) 348 (trace, M^+), 182 (21), 181 (94), 166 (35), 165 (28), 123 (100), 81 (23).

Found: C, 82.52; H, 8.14%. Calcd for $C_{24}H_{28}O_2$: C, 82.72; H, 8.10%.

According to the similar procedure, following esters were prepared and characterized spectrometrically.

(3-Phenoxyphenyl)methyl 2,2-Dimethyl-3-(2-methyl-1-propenyl)cyclopropanecarboxylate: 98% yield as a trans/cis mixture. ^{1}H NMR ($CDCl_3$) δ=1.12 (s, 3 H), 1.24 (s, 3 H), 1.42 (d, *J*=5 Hz, 1 H), 1.69 (s, 6 H), 2.04 (dd, *J*=5 and 8 Hz, 1 H), 4.85 (d, *J*=8 Hz, 1H), 5.04 (s, 2 H), 6.8—7.4 (m, 9 H) for the trans isomer, δ=1.18 (s, 3 H), 1.23 (s, 3 H), 1.69 (s, 6 H), 5.03 (s, 2 H), 5.33 (d, *J*=8 Hz, 1 H), 6.8—7.4 (m, 9 H) for the cis isomer. IR 1732, 1591, 1492, 1260, 1219, 1160, 694 cm^{-1}.

(Pentafluorophenyl)methyl 2,2-Dimethyl-3-(2-methyl-1-propenyl)cyclopropanecarboxylate: 85% yield. ^{1}H NMR ($CDCl_3$) δ=1.13, 1.19, 1.25, 1.26 (s, totally 6 H), 1.37 (d, *J*=5 Hz, 1 H), 2.05 (dd, *J*=5 and 8 Hz, 1 H), 4.85 and 5.27 (br d, *J*=8 Hz, totally 1 H), 6.32 and 6.33 (s, totally 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−142 (m, 2 F), −153 (m, 1 F), −162 (m, 2 F); IR 1736, 1527, 1509, 1153, 1133 cm^{-1}.

A Typical Procedure for the Preparation of 3-Formyl-2,2-dimethylcyclopropanecarboxylates. Ozone was bubbled into an ethyl acetate (10 ml) solution of (2-methyl-3-phenylphenyl)methyl 2,2-dimethyl-3-(2-methyl-1-propenyl)-cyclopropanecarboxylate (0.70 g, 2.0 mmol) at −78 °C until the solution became pale blue. Excess ozone and the ozonide were reduced by addition of dimethyl sulfide (1 ml), and the reaction mixture was allowed to warm to room temperature. Concentration under reduced pressure followed by purification by column chromatography (CH_2Cl_2-hexane 1 : 1) afforded (2-methyl-3-phenylphenyl)methyl 3-formyl-2,2-dimethylcyclopropanecarboxylate **6c** (0.59 g, 92% yield) as a colorless viscous oil. The trans/cis ratio was estimated to be 6 : 1 by ^{1}H NMR analysis. ^{1}H NMR (400 MHz, $CDCl_3$) δ=1.31 (s, 3 H), 1.36 (s, 3 H), 2.22 (s, 3 H), 2.53 (d, *J*=1.5 Hz, 1 H), 2.53 (s, 1 H), 5.23 (s, 2 H), 7.23—7.44 (m, 8 H), 9.59 (dd, *J*=1.1 and 2.5 Hz, 1 H) for the trans-isomer. δ=1.27 (s, 3 H), 1.58 (s, 3 H), 1.88 (dd, *J*=6.5 and 8.6 Hz, 1 H), 2.20 (d, *J*=8.6 Hz, 1 H), 2.23 (s, 3 H), 5.28 (s, 3 H), 7.23—7.44 (m, 8 H), 9.79 (d, *J*=6.5 Hz, 1 H) for the cis-isomer. IR 1730, 1710, 1233, 1164, 1112, 763, 704 cm^{-1}; MS *m/z* (rel intensity) 322 (M^+, trace), 182 (18), 181 (100), 180 (74), 179 (16), 178 (12), 167 (11), 166 (56), 165 (67), 152 (10), 97 (61), 43 (12), 41 (36).

Found: C, 77.97; H,6.92%. Calcd for $C_{21}H_{22}O_3$: C, 78.23; H, 6.88%.

By the similar procedure, **6b** and **6d** were prepared.

(3-Phenoxyphenyl)methyl 3-Formyl-2,2-dimethylcyclopropanecarboxylate (6b): 82% yield. ^{1}H NMR ($CDCl_3$) δ=1.29 (s, 3 H), 1.32 (s, 3 H), 2.46 (ABq, 2 H), 5.06 (s, 2 H), 6.8—7.5 (m, 9 H), 9.56 (dd, *J*=1.8 and 1.8 Hz, 1 H) for the trans isomer, δ=1.8—2.3 (m, 2H), 9.73 (d, *J*=6.7 Hz, 1 H) for the cis isomer. IR 1732, 1711, 1588, 1492, 1258, 1215, 1167, 693 cm^{-1}; MS *m/z* (rel intensity) 325 (M^++1, 2), 324 (M^+, 21), 184 (20), 183 (100), 97 (40), 77 (10), 41 (10).

(Pentafluorophenyl)methyl 3-Formyl-2,2-dimethylcyclopropanecarboxylate (6d): 89% yield. ^{1}H NMR ($CDCl_3$) δ=1.30 (s, 3 H), 1.36 (s, 3 H), 2.4—2.6 (m, 2 H), 5.15—5.25 (m, 2 H), 9.58 (d, *J*=3.0 Hz, 1 H) for the trans isomer, δ=1.55 (s, 3 H), 1.86 (dd, *J*=6.0 and 8.5 Hz, 1 H), 2.11 (d, *J*=8.5 Hz, 1H), 9.72 (d, *J*=6.0 Hz, 1 H) for the cis isomer. ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−141.8 (m, 2 F), −152.2 (m, 1 F), −161.3 (m, 2 F); IR 1740, 1712, 1528, 1512, 1160, 1133, 1056, 946 cm^{-1}; MS *m/z* (rel intensity) 294 (M^++1, 2), 293 (M^+, 11), 181

(100), 113 (11), 97 (90), 69 (10), 67 (14), 43 (17), 41 (37).

Ethyl (1*R,3*S**)-3-(2,2-Dichloro-3,3,3-trifluoro-1-hydroxypropyl)-2,2-dimethylcyclopropanecarboxylate (7a). A Typical Procedure for the Reaction of 6 with a CCl_3CF_3/Zn Reagent.** To a DMF (1 ml) solution of **6a** (trans/cis 4 : 1 mixture, 0.174 g, 1.0 mmol) were added zinc powder (96 mg, 1.47 mmol) and 1,1,1-trichloro-2,2,2-trifluoroethane (0.36 ml, 3.0 mmol) at 0 °C. The solution was stirred for 2 h at 0 °C and for 10 h at 50 °C, then treated with sat ammonium chloride aq solution (2 ml), and extracted with diethyl ether (3×2 ml). The combined ethereal extract was dried over magnesium sulfate and concentrated under reduced pressure to give a crude product. Purification by preparative TLC (CH_2Cl_2–hexane 1 : 1) afforded **7a** (54: 46 diastereomeric mixture, 0.188 g, 58% yield) as a viscous colorless oil. ^1H NMR (400 MHz, $CDCl_3$) δ=1.22 (s, 3 H), 1.25 (s, 3 H), 1.29 (t, J=7.2 Hz, 3 H), 1.69 (d, J=5.8 Hz, 1 H), 1.94 (dd, J=5.8 and 8.9 Hz, 1H), 2.63 (br s, 1 H), 3.82 (br d, J=8.9 Hz, 1 H), 4.10—4.20 (m, 2 H) for the major isomer, δ=1.26 (t, J=7.2 Hz, 3 H), 1.30 (s, 3 H), 1.33 (s, 3 H), 1.70 (d, J=5.4 Hz, 1 H), 1.82 (dd, J=5.4 and 9.6 Hz, 1 H), 2.43 (br d, 1 H), 3.82 (br d, J=9.6 Hz, 1 H), 4.10—4.20 (m, 2 H) for the minor isomer; ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−74.3 (s) for the major isomer, −74.7 (s) for the minor isomer. IR 3465, 1710, 1260, 1200 cm^{-1}; MS m/z (rel intensity) 277 (11), 197 (13), 142 (11), 141 (100), 125 (16), 113 (59), 98 (20), 97 (18), 95 (30), 69 (18), 67 (22), 59 (29), 55 (41), 53 (10), 43 (30).

(2-Methyl-3-phenylphenyl)methyl 3-[2,2-Dichloro-3,3,3-trifluoro-1-(*p*-tolylsulfonyloxy)propyl]-2,2-dimethylcyclopropanecarboxylate (11c). Sodium hydride (50% in oil, 12 mg, 0.25 mmol) and *p*-toluenesulfonyl chloride (39 mg, 0.20 mmol) were added to **7c** (97 mg, 0.20 mmol) dissolved in diethyl ether (0.5 ml) and DMF (0.5 ml), and the mixture was stirred for 12 h at room temperature. Workup and purification by preparative TLC (CH_2Cl_2-hexane 1 : 1) gave **11c** (83 mg, 65% yield) as a viscous oil. ^{1}H NMR ($CDCl_3$) δ=1.23, 1.33, 1.37 (s, totally 3 H), 1.9—2.3 (m, 2 H), 2.19, 2.21 (s, totally 3 H), 2.37, 2.43 (s, totally 3 H), 4.85—5.05 (m, 1 H), 5.15, 5.16 (s, totally 2 H), 7.1—7.4 (m, 10 H), 7.6—7.9 (m, 2 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−74.6 (s) and −73.3 (s); IR 1730, 1600, 1360, 1387, 1114, 1096, 560 cm^{-1}; MS m/z (rel intensity) 630 (M^++2, trace), 628 (M^+, trace), 182 (15), 181 (100), 180 (74), 166 (30), 165 (28).

Found: C, 57.23; H, 4.70%. Calcd for $C_{30}H_{29}Cl_2F_3O_5S$: C, 57.24; H, 4.64%.

Reduction of 8a with Zinc. Zinc powder (35 mg, 0.54 mmol) was added to a DMF (0.5 ml) solution of **8a** (0.183 g, 0.50 mmol) and the mixture was stirred for 4 h at 50 °C before quenching by addition of sat ammonium chloride aq solution (1 ml). Extraction with diethyl ether (5×1 ml), drying the ethereal extract over magnesium sulfate, concentration in vacuo, followed by preparative TLC (CH_2Cl_2-hexane

1 : 1) gave ethyl (1*R**,3*S**)-3-(2-chloro-3,3,3-trifluoro-1-propenyl)-2,2-dimethylcyclopropanecarboxylate (**12a**) as a Z/E=6 : 1 mixture (0.116 g, 86% yield, a colorless oil). ^{1}H NMR (400 MHz, $CDCl_3$) δ=1.24 (s, 3 H), 1.28 (t, J=7.1 Hz, 3 H), 1.33 (s, 3 H), 1.77 (d, J=5.3 Hz, 1 H), 2.40 (ddq, J=5.3, 9.3, and 1.0 Hz, 1 H), 4.10—4.22 (m, 2 H), 6.15 (dq, J=9.3 and 1.0 Hz, 1 H) for the (Z)-isomer, δ=1.21 (s, 3 H), 1.27 (t, J=7.1 Hz, 3 H), 1.28 (s, 3 H), 1.69 (d, J=5.4 Hz, 1 H), 2.38—2.44 (m, 2 H), 4.10—4.22 (m, 2 H), 5.89 (d, J=9.4 Hz, 1 H) for the (E)-isomer; ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−68.9 (s) for the (Z)-isomer, −62.5 (d, J=3.2 Hz) for the (E)-isomer; IR 1731, 1286, 1229, 1176, 1142 cm^{-1}.

(3-Phenoxyphenyl)methyl 3-(2-Chloro-3,3,3-trifluoro-1-propenyl)-2,2-dimethylcyclopropanecarboxylate (12b): A colorless oil. ^{1}H NMR ($CDCl_3$) δ=1.21 (s, 3 H), 1.30 (s, 3 H), 1.76 (d, J=5.4 Hz, 1 H), 2.37 (dd, J=5.4 and 9.0 Hz, 1 H), 5.06 (s, 2 H), 6.08 (d, J=9.0 Hz, 1 H), 6.8—7.4 (m, 8 H) for the (Z)-isomer, δ=1.22 (s, 3 H), 1.70 (d, J=5.4 Hz, 1 H), 5.82 (d, J=9.0 Hz, 1 H) for the (E)-isomer; ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−69.2 (s), −62.9 (s) for the (E)-isomer; IR 1732, 1588, 1492, 1283, 1256, 1221, 1167, 1140, 1113, 693 cm^{-1}.

When **8b** (49 mg, 0.094 mmol) was treated with zinc (9 mg, 0.13 mmol) in THF (0.2 ml) for 23 h at 50 °C, **12b** was obtained in 88% isolation yield. Z/E=77 : 23.

(2-Methyl-3-phenylphenyl)methyl 3-(2-Chloro-3,3,3-trifluoro-1-propenyl)-2,2-dimethylcyclopropanecarboxylate (12c): A colorless oil, Z/E=89 : 11 from the less polar isomer of **8c**. ^{1}H NMR ($CDCl_3$) δ=1.23 (s, 3 H), 1.35 (s, 3 H), 1.82 (d, J=5 Hz, 1 H), 2.22 (s, 3 H), 2.42 (dd, J=5 and 9 Hz, 1 H), 5.20 (s, 2 H), 6.10 (dq, J=10 and 1 Hz, 1 H), 7.15—7.5 (m, 8 H) for the (Z)-isomer, δ=1.23 (s, 3 H), 1.29 (s, 3 H), 5.85 (d, J=9.1 Hz, 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−68.7 (s) for the (Z)-isomer, −62.5 (s) for the (E)-isomer.

The more polar isomer of **8c** gave **12c** of Z/E=93 : 7 in a similar yield.

One-Pot Conversion of 6c into 12c. To a DMF (1 ml) solution of **6c** (0.28 g, 0.87 mmol) were added 1,1,1-trichloro-2,2,2-trifluoroethane (0.21 ml, 1.7 mmol), zinc powder (0.29 g, 4.4 mmol) and acetic anhydride (0.12 ml), and the mixture was stirred for 6 h at 50 °C. After quenching with water (2 ml) and 2 drops of conc hydrochloric acid, the reaction mixture was extracted with diethyl ether (3×3 ml). The ethereal extract was dried over anhydrous magnesium sulfate and concentrated in vacuo. Purification by column chromatography (dichloromethane-hexane 1 : 3 to 1 : 2) gave **12c** (0.20 g, 54% yield) as a colorless oil which consisted of 6 : 1 (Z)- and (E)-isomers.

By applying **9c** and **10c** to the reduction with zinc, we obtained **12c** in 95% (Z/E=88 : 12) and 98% (Z/E=86 : 14) yield respectively.

4-(2,4-Dioxobutoxy)-5,5-dichloro-6,6,6-trifluoro-2-methyl-2-hexene (15). A mixture of **14** (0.95 g, 4.0 mmol), sodium acetate (50 ml), and diketene (0.5 ml) was heated at 80 °C for 4 h under stirring and then charged on a silica-gel column. Elution with dichloromethane-hexane 1 : 1 gave **15** (1.13 g, 88% yield) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ=1.83 (s, 6 H), 2.26 (s, 3 H), 3.46 (s, 2 H), 5.28 (d, J=9.6 Hz, 1 H), 6.08 (d, J=9.6 Hz, 1 H) for the keto form, δ=1.97 (s, 3 H), 5.03 (s, 1 H), 6.17 (d, J=9.6 Hz, 1 H) for the enol tautomer; ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−75.0 (s); IR 3480, 1756, 1728, 1255, 1210, 1188, 1149 cm^{-1}; MS m/z (rel intensity) 285 (2), 183 (9), 127 (5), 86 (6), 85 (100), 84 (5), 83 (5), 69 (6), 67 (7), 58 (5), 55 (9), 44 (12), 43 (48), 41 (24).

Found: C, 40.89; H, 3.96%. Calcd for $C_{11}H_{13}Cl_2F_3O_3$: C, 41.14; H, 4.08%.

4-Diazoacetoxy-5,5-dichloro-6,6,6-trifluoro-2-methyl-2-hexene (16). Triethylamine (0.060 ml, 0.43 mmol) and *p*-toluenesulfonyl azide (80 mg, 0.41 mmol) were added to an acetonitrile (1 ml) solution of **15** (0.128 g, 0.40 mmol), and the mixture was stirred for 0.5 h at room temperature. At this point, all of **15** was converted into the diazo compound as assayed by TLC. Sodium hydroxide (1,2 M† aq solution, 1 ml) was added, and stirring was continued for 1 h at room temperature. Extraction with diethyl ether (3×2 ml) and then with dichloromethane (2 ml), drying the combined organic extract over magnesium sulfate, concentration in vacuo, and finally purification by column chromatography (CH_2Cl_2-hexane 1 : 1) gave **16** (0.100 g, 82% yield) as a pale yellow oil. ^{1}H NMR ($CDCl_3$) δ=1.85 (s, 6 H), 4.77 (s, 1 H), 5.03 (d, J=9.6 Hz, 1 H), 6.13 (d. J=9.6 Hz, 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−75.0 (s); IR 2120, 1710, 1376, 1210, 1188, 1163 cm^{-1}; MS m/z (rel intensity) 278 (11), 221 (20), 219 (33), 213 (47), 185 (25), 184 (20), 183 (64), 147 (30), 143 (44), 127 (49), 125 (54), 97 (25), 79 (21), 77 (24), 70 (69), 53 (26), 51 (20), 43 (31), 42 (69), 41 (100).

4-(1,1-Dichloro-2,2,2-trifluoroethyl)-6,6-dimethyl-3-oxabicyclo[3.1.0]hexan-2-one (13). An dioxane (0.5 ml) solution of **12** (38 mg, 0.12 mmol) was added over 0.5 h to a refluxing suspension of copper(II) acetylacetonate (1 mg) in dioxane (3 ml), and the heating and stirring were continued for additional 2.5 h. The reaction mixture was treated with water (5 ml) and extracted with diethyl ether (2×10 ml). The extract was dried over magnesium sulfate and concentrated under reduced pressure to afford a crude product which was purified by column chromatography (CH_2Cl_2-hexane 1 : 2) to give **13** (26 mg, 75% yield) as colorless crystals, mp 49—60 °C. ^{1}H NMR ($CDCl_3$) δ=1.25 (s, 6 H), 2.11 (d, J=5.7 Hz, 1 H), 2.36 (d, J=5.7 Hz, 1 H), 4.61 (s, 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−75.2 (s); IR (KBr) 1802, 1260, 1212, 1194, 1070, 1012, 908 cm^{-1}. MS m/z (rel intensity) 278 (M^++2, 2), 276 (M^+, 3), 243 (32), 241 (92), 205 (10), 199 (23), 197 (64), 161 (34), 159 (11), 141 (47), 126 (11), 125 (100), 97 (86), 96 (16), 95 (12), 91 (14), 81 (63), 79 (35), 77 (12), 69 (31), 67 (39), 65 (14), 63 (11), 55 (12), 53 (48), 51 (16), 43 (51), 42 (13).

(1*R,3*R**)-3-(2-Chloro-3,3,3-trifluoro-1-propenyl)-2,2-dimethylcyclopropanecarboxylic Acid (17).** Zinc powder (6 mg, 0.09 mmol) was added to a DMF (0.1 ml) solution of **13** (23 mg, 0.083 mmol), and the resulting mixture was stirred for 3 h at 60 °C before quenching by addition of water (1 ml) and conc hydrochloric acid (0.5 ml). Extraction with diethyl ether (4×3 ml), drying the ethereal extract over magensium suflate, and concentration in vacuo gave rise to **17** (17 mg, 84% yield, Z/E=93 : 7) as colorless crystals, mp 103—105 °C (sublime).[19] ^{1}H NMR ($CDCl_3$) δ=1.33 (s, 6 H), 1.96 (d, J=8 Hz, 1 H), 2.22 (dd, J=8 and 9 Hz, 1 H), 6.81 (d, J=9 Hz, 1 H) for the (Z)-isomer, 6.52 (d, J=9 Hz, 1 H) attributed to the (E)-isomer. ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−68.8 (s) for the (Z)-isomer, −62.0 (s) for the (E)-isomer; IR 1708, 1437, 1293, 1272, 1194, 1146, 1128 cm^{-1}.

Ethyl 3-(2,3,3-Trifluoro-1-hydroxy-2-propenyl)-2,2-di-

†1 M=1 mol dm^{-3}.

methylcyclopropanecarboxylate (**20a**). Gaseous chlorotrifluoroethene (240 ml at room temperature, 10 mmol) was dissolved in a mixture of THF (10 ml), hexane (1 ml), and diethyl ether (1 ml) at −78 °C. The solution was cooled at −130 °C. Butyllithium (1.67 M hexane solution, 6.0 ml, 10 mmol) was added dropwise to the solution, and the mixture was stirred for 1 h at −130 °C. To this solution was added **6a** (2.0 g, 12 mmol) dissolved in the trap solvent mixture composed of THF (10 ml), hexane (1 ml) and diethyl ether (1 ml) at −130 °C drop by drop over a period of 5 min. The reaction mixture was allowed to warm gradually to −40 °C over 7 h. Workup and purification by column chromatography (CH_2Cl_2-AcOEt 1 : 0 to 1 : 1) gave **20a** (0.63 g, 25% yield) as a colorless viscous oil. ^{1}H NMR ($CDCl_3$) δ=1.1—1.4 (m, 9 H), 1.65 (d, J=6 Hz, 1 H), 1.84 (dd, J=6 and 10 Hz, 1 H), 3.76—4.1 (m, 2 H), 4.10 (q, J=7 Hz, 2 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−102 (ddd, J=6, 33, and 81 Hz, 1 F), −120 (ddd, J=1, 37, and 47 Hz, 1 F), −188 (m, 1 F); IR 3440, 2970, 1791, 1730, 1709, 1306, 1256, 1213, 1175, 1114, 1100, 1072, 1032, 1018 cm^{-1}; MS m/z (rel intensity) 207 (6), 142 (17), 141 (100), 114 (12), 113 (78), 111 (27), 109 (12), 96 (11), 95 (55), 69 (17), 67 (36), 59 (39), 55 (19), 53 (11), 43 (31), 41 (38).

Found: m/z 207.0673. Calcd for $C_{11}H_{15}F_3O_3$: M, 207.0632.

The adduct **20a** was alternatively prepared by the reaction of **6a** with triethyl(trifluoroethenyl)silane. A THF solution of tris(diethylamino)sulfonium difluorotrimethylsilicate (TASF) (1.0 M solution 0.1 ml, 0.1 mmol) was added to a mixture of **6a** (0.175 g, 1.0 mmol), triethyl(trifluoroethenyl)-silane (0.24 g, 1.2 mmol) and THF (2 ml) at 0 °C. The reaction mixture was stirred for 1 h at 0 °C and for 10 h at room temperature. Workup followed preparative TLC (hexane-dichloromethane 1 : 1) afforded ethyl (1*R**,3*R**)-3-(1-triethylsiloxy-2,3,3-trifluoro-2-propenyl)-2,2-dimethylcyclopropanecarboxylate (22 mg) and its (1R*,3R*)-isomer (75 mg). Total yield was 39%. The (1R*,3R*)-isomer exhibited ^{1}H NMR consistent to the structure (J=8.7 Hz for the coupling constant of the ring proton, 2.58: 1 diastereomeric mixture); IR 1795, 1730 cm^{-1}; Found: m/z 337.1415. Calcd for $C_{15}H_{24}F_3O_3Si$: M−Et, 337.1444. The (1R*,3R*)-isomer exhibited J=5.52 Hz for the coupling constant of the ring proton (ca. 1 : 1 diastereomeric mixture); IR 1790, 1735 cm^{-1}; Found: m/z 337.1431. Calcd for $C_{15}H_{24}F_3O_3Si$: M−Et, 337.1445.

Desilylation was effected by treating the silyl ether with 0.2 M hydrochloric acid (0.5 ml) and THF (0.5 ml) at room temperature for 0.5 h. Workup and TLC purification gave **20a** quantitatively.

Ethyl 3-(2-Chloro-3,3-difluoro-1-hydroxy-2-propenyl)-2,2-dimethylcyclopropanecarboxylate (20b). A THF solution (1.0 M, 0.1 ml) of TASF (0.1 mmol) was added to a mixture of **6a** (0.34 g, 2.0 mmol), (1-chloro-2,2-difluoroethenyl)-triethylsilane (0.21 g, 1.0 mmol) and THF (2 ml) at room temperature. The reaction mixture was stirred for 16 h, and then worked up. Preparative TLC (dichloromethane-hexane 1 : 1) afforded **20b** (27 mg), its triethylsilyl ether (49 mg) and the recovered **6a** (101 mg). The silyl ether (39 mg out of the 49 mg sample) was dissolved in 0.2 M hydrochloric acid-THF 1 : 1 mixture (1 ml), and the solution was stirred for 1 h at room temperature. Work-up and preparative TLC afforded **21b** (27 mg, 99% yield) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ=1.1—1.4 (m, 9 H), 1.67 (d, J=5 Hz, 1 H). 1.87 (d, J=5 and 10 Hz, 1 H), 2.29 (br s, 1 H), 3.95—4.3 (m, 3 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−87 (dd, J=4 and 40 Hz, 1 F), −91 (dd, J=9 and 40 Hz, 1 F); MS m/z (rel intensity) 223 (5), 142 (24), 141 (100), 127 (32), 125 (12), 114 (19), 113 (92), 96 (14), 95 (53), 69 (19), 67 (38), 61 (14), 59 (37), 55 (14), 53 (13), 43 (33), 41 (39).

Found: m/z 223.0349. Calcd for $C_9H_{10}ClF_2O_2$: M−OEt, 223.0336.

2-Chloro-1,1-difluoro-1-tridecen-3-ol (18b). The silyl ether of **18b** was prepared by the similar procedure as above, starting from undecanal (0.93 ml, 4.5 mmol), 1-chloro-2,2-difluoroethenyltriethylsilane (0.53 g, 3.0 mmol), THF (6 ml), and TASF (0.3 mmol). TLC purification using dichloromethane-hexane 1 : 2 gave 2-chloro-1,1-difluoro-3-triethylsilyloxy-1-tridecene (0.33 g, 39% yield) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ=0.45—0.8 (m, 6 H), 0.8—1.15 (m, 12 H), 1.30 (s, 16 H), 1.45—1.85 (m, 2 H), 4.35—4.65 (m, 1 H), ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−88 (d, J=44 Hz, 1 F), −92 (d, J=44 Hz, 1 F); IR 2950, 1747, 1470, 1286, 1100, 1002, 750, 730 cm^{-1}; MS m/z (rel intensity) 355 (38), 354 (25), 353 (M$^+$−Et, 96), 241 (27), 115 (36), 109 (16), 105 (72), 104 (11), 103 (100), 97 (35), 95 (37), 91 (15), 89 (35), 87 (38), 83 (42), 81 (33), 77 (63), 75 (85), 71 (15), 69 (43), 67 (28), 59 (27), 57 (32), 55 (58), 47 (26), 43 (59), 41 (35).

Found: C, 60.02; H, 9.44%. Calcd for $C_{19}H_{37}ClF_2OSi$: C, 59.58; H, 9.74%.

Acid-catalyzed desilylation was effected in 0.2 M hydrochloric acid and THF in 83% yield to give **18b** as a colorless oil. ^{1}H NMR ($CDCl_3$) δ=0.7—1.0 (m, 3 H), 1.25 (s, 16 H), 1.45—1.9 (m, 2 H), 1.77 (br s, 1 H), 4.35—4.6 (m, 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−87 (dd, J=39 and 2 Hz, 1 F), −91 (dd, J=39 and 3 Hz, 1F); IR 3380, 2945, 2875, 1747, 1288 cm^{-1}; MS m/z (rel intensity) 250 (M$^+$−H_2O, trace), 129 (34), 127 (100), 57 (2), 55 (14), 43 (39), 41 (25).

Found: m/z 250.1326. Calcd for $C_{13}H_{21}ClF_2$: M−H_2O, 250.1299.

Fluorination of 18a. A Typical Fluorination Procedure. To a solution of DAST (82 mg, 0.50 mmol) dissolved in dichloromethane (5 ml) was added dropwise 1,1,2-trifluoro-1-tridecen-3-ol (**18a**, 0.123 g, 0.49 mmol) at −78 °C, and the solution was allowed to warm to room temperature over 10 min. The solution was concentrated under reduced pressure, and the residue was subjected to column chromatography (dichloromethane-haxane 1 : 9) to afford 1,1,1,2-tetrafluoro-2-tridecene (**19a**, 0.112 g, 90% yield) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ=0.8—1.0 (m, 3 H), 1.1—1.6 (m, 16 H), 2.1—2.4 (m, 2 H), 5.53 (dt J=33 and 7.8 Hz, 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−72 (d, J=12 Hz, 3 F), −137 (dq, J=33 and 12 Hz, 1F); IR 2940, 2870, 1833, 1470, 1362, 1194, 1148, 1050 cm^{-1}; MS m/z (rel intensity) 254 (M$^+$, trace), 97 (12), 85 (12), 84 (16), 83 (15), 71 (23), 70 (31), 69 (30), 57 (54), 56 (47), 55 (34), 43 (100), 42 (16), 41 (46).

Found: m/z 254.1647. Calcd for $C_{13}H_{22}F_4$: M, 254.1659.

2-Chloro-1,1,1-trifluoro-2-tridecene (19b): ^{1}H NMR ($CDCl_3$) δ=0.7—1.0 (m, 3 H), 2.27 (s, 16 H), 2.1—2.4 (m, 2 H), 6.43 (tq, J=7 and 1 Hz, 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−69 (m), IR 2940, 2865, 1307, 1186, 1148 cm^{-1}; MS m/z (rel intensity) 270 (M$^+$, trace), 111 (10), 98 (12), 97 (18), 85 (14), 84 (28), 83 (25), 71 (32), 70 (64), 69 (56), 57 (77), 56 (97), 55(55), 43 (100), 42 (25), 41 (66).

Found: C, 57.95; H, 8.17%. Calcd for $C_{13}H_{22}ClF_3$: C, 57.67; H, 8.19%.

Ethyl 3-(2,3,3,3-Tetrafluoro-1-propenyl)-2,2-dimethylcyclopropanecarboxylate (21a): A colorless oil. ^{1}H NMR ($CDCl_3$) δ=1.21 (s, 3 H), 1.27 (t, J=7.1 Hz, 3 H), 1.30 (s, 3 H),

1.67 (d, J=5.3 Hz, 1 H), 2.32 (dd, J=5.3 and 9.8 Hz, 1 H), 4.15 (q, J=7.1 Hz, 1 H), 5.30 (dd, J=9.8 and 31.5 Hz, 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−72.8 (d, J=11.8 Hz, 3 F), −136.9 (dq, J=31.5 and 11.8 Hz, 1 F); MS m/z (rel intensity) 254 (M^+, 3), 209 (24), 182 (10), 181 (92), 141 (18), 115 (11), 97 (12), 77 (11), 59 (10), 47 (21), 41 (21).

Found: m/z 254.0936. Calcd for $C_{11}H_{14}F_4O_2$: M, 254.0929.

Ethyl 3-(2-Chloro-3,3,3-trifluoro-1-propenyl)-2,2-dimethylcyclopropanecarboxylate (21b): A colorless oil. ^{1}H NMR ($CDCl_3$) δ=1.22 (s, 3 H), 1.27 (t, J=7 Hz, 3 H), 1.33 (s, 3 H), 1.74 (d, J=5.1 Hz, 1 H), 2.37 (dd, J=5 and 10 Hz, 1 H), 4.13 (m, 2 H), 6.13 (d, J=10 Hz, 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−69 (s); IR 1733, 1724, 1304, 1286, 1228, 1176, 1144 cm^{-1}; MS m/z (rel intensity) 270 (M^+, 1), 225 (18), 119 (24), 197 (68), 161 (20), 141 (27), 41 (18).

Chlorination of 18a. A Typical Chlorination Procedure. Pyridine (0.081 ml, 1.0 mmol) and thionyl chloride (0.038 ml, 0.50 mmol) were added to an ethereal solution (1 ml) of **18a** (0.126 g, 0.50 mmol) at 0 °C, and the mixture was stirred for 3 h at room temperature. The precipitated material was filtered off, and the filtrate was concentrated under reduced pressure. Preparative TLC (dichloromethane-hexane 1 : 5) afforded 1-chloro-1,1,2-trifluoro-2-tridecene (**19a'**, 0.115 g, 85% yield) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ=0.7—1.0 (m, 3 H), 1.1—1.6 (m, 16 H), 2.0—2.4 (m, 2 H), 5.47 (dt, J=33 and 8 Hz, 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−59 (dt, J=17 and 3 Hz, 2 F), −131 (ddt, J=33, 17, and 4 Hz, 1 F); IR 2940, 2870, 1470, 1146, 1052, 928 cm^{-1}; MS m/z (rel intensity) 243 (trace), 97 (14), 85 (12), 84 (18), 83 (20), 71 (24), 70 (36), 69 (34), 57 (57), 56 (52), 55 (38), 43 (100), 42 (16).

1,2-Dichloro-1,1-difluoro-2-tridecene (19b'). Thionyl chloride (0.020 ml, 0.27 mmol) was added to **18b** (54 mg, 0.20 mmol) dissolved in diethyl ether (0.4 ml), and the solution was stirred for 2 h at room temperature and for 15 h at 50 °C. Workup and purification by preparative TLC (dichloromethane-hexane 1 : 10) afforded **19b'** (52 mg, 90% yield) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ=0.7—1.0 (m, 3 H), 1.26 (s, 16 H), 2.1—2.4 (m, 2 H), 6.40 (t, J=7 Hz, 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−54.1 (s): IR 2950, 2880, 1244, 1142, 1128, 1008, 825 cm^{-1}; MS m/z (rel intensity) 288 (M^++2, 3), 286 (M^+, 4) 124 (12), 111 (11), 98 (13), 97 (20), 85 (14), 84 (28), 83 (26), 71 (28), 70 (55), 69 (50), 57 (66), 56 (72), 55 (49), 43 (100), 42 (18), 41 (64).

Found: C, 54.37; H, 7.82%. Calcd for $C_{13}H_{22}Cl_2F_2$: C, 54.36; H, 7.72%.

1-Cyclohexyl-2,3-dichloro-3,3-difluoropropene (19c'). This was prepared by the procedure applied to the synthesis of **19b'** and obtained as a colorless oil, bp 75—80 °C (bath temp)/12 Torr (1 Torr=133.322 Pa). ^{1}H NMR ($CDCl_3$) δ=0.8—2.0 (m, 10 H), 2.2—2.8 (m, 1 H), 6.26 (d, J=9.3 Hz, 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−54.0 (s); IR 2945, 2870, 1449, 1246, 1212, 1129, 1096, 996, 828 cm^{-1}; MS m/z (rel intensity) 228 (M^+, 1), 137 (13), 115 (5), 101 (5), 83 (8), 82 (100), 81 (21), 69 (9), 68 (5), 67 (69), 55 (10), 54 (16), 41 (25).

Found: C, 47.00; H, 5.36%. Calcd for $C_9H_{12}Cl_2F_2$: C, 47.19; H, 5.28%.

Ethyl 3-(3-Chloro-2,3,3-trifluoro-1-propenyl)-2,2-dimethylcyclopropanecarboxylate (22a). This was obtained as a colorless oil which consisted of ca. 1 : 1 stereoisomers. ^{1}H NMR ($CDCl_3$) δ=1.21 (s, 3 H), 1.27 (t, J=7.2 Hz, 3 H), 1.31 (s, 3 H), 1.67 (d, J=5.5 Hz, 1 H), 2.30 (ddd, J=5.5, 9.7, and 0.9 Hz, 1 H), 4.18 (m, 2 H), 5.26 (dd, J=9.7 and 31 Hz, 1 H) for the (1R*,3R*)-isomer, δ=1.27 (s, 3 H), 1.27 (t, J=7.2 Hz, 3 H), 1.89 (d, J=8.6 Hz, 1 H), 2.11 (dd, J=8.6 and 9.8 Hz, 1 H), 4.18 (m, 2 H), 6.10 (dd, J=9.8 and 33 Hz, 1H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−58.5 (d, J=17 Hz, 2 F), −58.8 (d, J=17 Hz, 2 F), −131 (dt, J=31 and 17 Hz, 1 F); IR 1733, 1221, 1190, 1152, 1136, 1091, 1062, 1050, 934 cm^{-1}; MS m/z (rel intensity) 270 (M^+, 3), 225 (17), 199 (19), 197 (58), 162 (11), 161 (14), 141 (20), 97 (11), 65 (15), 59 (10), 41 (19).

Found: m/z 270.0643. Calcd for $C_{11}H_{14}F_3ClO_2$: M, 270.0633.

Ethyl 3-(2,3-Dichloro-3,3-difluoro-1-propenyl)-2,2-dimethylcyclopropanecarboxylate (22b): A colorless oil. ^{1}H NMR ($CDCl_3$) δ=1.23 (s, 3 H), 1.28 (t, J=7.2 Hz, 3 H), 1.33 (s, 3 H), 1.75 (d, J=5.3 Hz, 1 H), 2.39 (dd, J=5.3 and 9.2 Hz, 1 H), 4.14 (q, J=7.2 Hz, 1 H), 6.23 (d, J=9.2 Hz, 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−54 (s); MS m/z (rel intensity) 286 (M^+, trace), 241 (10), 215 (25), 213 (37), 177 (12), 141 (17), 77 (10), 61 (15), 41 (17).

Found: m/z 286.0358. Calcd for $C_{11}H_{14}Cl_2F_2O$: M, 286.0338.

1-Bromo-2-chloro-1,1-difluoro-2-tridecene (19b''). Thionyl bromide (33 mg, 0.16 mmol) was added to **18b** (24 mg, 0.13 mmol) dissolved in diethyl ether (0.5 ml), and the mixture was stirred for 4 h at 40 °C in a sealed tube. Workup and preparative TLC (dichloromethane-hexane 1 : 10) afforded **19b''** (36 mg, 84% yield) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ=0.8—1.0 (m, 3 H), 1.1—1.7 (m, 16 H), 2.1—2.4 (m, 2 H), 6.40 (t, J=7.2 Hz, 1 H); ^{19}F NMR ($CDCl_3$-$CFCl_3$) δ=−48.8 (s); IR 2945, 2875, 1824, 1470, 1233, 1141, 1128, 990, 802 cm^{-1}; MS m/z (rel intensity) 330 (M^+, trace), 124 (11), 97 (7), 85 (11), 84 (6), 83 (10), 71 (21), 70 (11), 69 (15), 57 (53), 56 (16), 55 (27), 43 (100), 42 (11), 41 (57).

Found: m/z 330.0554. Calcd for $C_{13}H_{22}BrClF_2$: M, 330.0560.

The compound **19b''** was alternatively prepared in 67% yield by treatment of **18b** with an equimolar amount of phosphorus tribromide at 0 °C in ether and stirring the reaction mixture at room temperature for 1.5 h and at 35 °C for 13 h.

This work was partially supported by a Grant-in-Aid for Special Research on Organochemical Resources (Nos. 61111001 and 62101001) from the Ministry of Education, Science and Culture. We thank Ms. Tomoe Morita and Mr. Masanori Ueno for their experimental assistance. We also thank FMC Corporation and Kuraray Co. Ltd., for their generous gift of (2-methyl-3-phenylphenyl)methanol and 3-methyl-2-butenal respectively.

(Received September 26, 1986)

The kinetics of oxidation of pyridoxine (PRX) by chloramine-T (CAT) in the presence of hydrochloric acid (0.04—0.14 M) have been studied over the temperature range of 303—323 K. The rate of the reaction shows first-order dependence on each of CAT, PRX, and chloride ion concentrations. The reaction rate is independent of hydrogen ion concentration. Variations of ionic strength and dielectric constant of the medium have negligible effect on the rate. Addition of the reaction product, *p*-toluenesulfonamide, decreases the rate showing a negative first order dependence. The solvent isotope effect has been studied by using heavy water. The activation parameters, E_a, ΔH^*, and ΔS^* are computed from the reaction rates at various temperatures. The mechanism of PRX oxidation proposed and the rate law derived are consistent with the observed kinetics.

Considerable progress has been made on the chemistry of *N*-haloamines.[1] The diverse nature of the chemistry of these compounds is due to their ability to act as sources of halonium cations, hypohalite species, and nitrogen anions; as a result they interact with a wide range of functional groups, effecting an array of molecular transformations. Sodium *N*-chloro-*p*-toluenesulfonamide, p-$CH_3C_6H_4SO_2NClNa \cdot 3H_2O$, commonly known as chloramine-T (CAT), is a very prominent member of this series of organic *N*-haloamines. CAT behaves both as oxidizing and chlorinating agent in acidic and alkaline media. Normally, CAT undergoes a two-electron change in its reaction giving the products, *p*-toluenesulfonamide (RNH_2) and sodium chloride. The redox potential of a CAT-RNH_2 couple depends on the pH and decreases with increase in pH of the solution. CAT furnishes different types of reactive species, depending on the pH of the medium.[3] In the acid solution monochloramine-T (RNHCl, where R=p-$CH_3C_6H_4SO_2$), dichloramine-T ($RNCl_2$), HOCl, and H_2OCl^+ are the reactive species while $RNCl^-$ and OCl^- ions are formed in alkaline medium. CAT forms free chlorine in acid solutions containing chloride. An extensive review of the literature on the chemistry of CAT and its analogs has been reported.[1,5] Although, the oxidative capacity of CAT has been widely used in the assay of a large number of chemical compounds,[6-9] only a little information is available about the kinetics of reactions.[10-12]

Pyridoxine (PRX) finds applications in pharmaceutical industries. Pyridoxine, pyridoxal, and pyridoxamine are collectively known as vitamine B_6 complex. In the biological system they are converted into pyridoxal phosphate which is the coenzyme for amino acid decarboxylase and for transaminase. PRX has been oxidized[13] to pyridoxal by acidic MnO_2 and by alkaline $KMnO_4$ solutions.[14] Least information is available in literature on the kinetics of oxidation of pharmaceuticals with organic haloamines which may throw some light on the mechanisms of metabolic conversions of the former in the biological system. Therefore, as a part of our broad program on mechanistic studies of haloaminometric reactions in generel and medicinal compounds in particular, we have studied the kinetics and mechanism of oxidation of pyridoxine by chloramine-T in acid medium.

Experimental

Pyridoxine hydrochloride (Fluka Chemical Corp., Hauppauga, N.Y.) was assayed by a spectrophotometric[15] method before use and found to be 99.8% pure. An aqueous concentrated solution of the compound was prepared and used as a stock solution. CAT (E. Merck) was purified by the method of Morris et al.[16] Chlorine solution was prepared by passing chlorine into distilled water. Aqueous solutions of CAT and chlorine were standardized by the iodometric method and preserved in brown bottles. Heavy water (D_2O) was obtained from Bhabha Atomic Research Centre, Bombay, India. The ionic strength of the medium was maintained constant using a concentrated solution of sodium perchlorate. Doubly distilled water was used throughout the investigations. All other reagents used were of Analar grade.

Stoichiometry. Reaction mixtures containing varying ratios of CAT to PRX were kept at room temperature (300±2 K) in the presence of 0.1 M (1 M=1 mol dm^{-3}) HCl for 24 h. The determination of the unreacted CAT showed that one mole of PRX could consume one mole of CAT:

$$C_8H_{11}NO_3+RNClNa \rightarrow C_8H_9NO_3+RNH_2+Na^++Cl^-$$

where R=p-$CH_3C_6H_4SO_2$

This stoichiometry is in agreement with the one reported in the literature.[17]

Product Analysis. The reduction product of CAT, *p*-toluenesolfonamide (RNH_2) was detected by paper chromatography[18] with benzyl alcohol saturated with water as the solvent and 0.5% vanillin in 1% HCl (in ethanol) as spraying reagent (R_f=0.90). The oxidation product of PRX, pyridoxal ($C_8H_9NO_3$), was identified[19] as semicarbazone (melting point 509 K).

Kinetic Measurements. The reaction was carried out in glass stoppered Pyrex boiling tubes whose outer surface was coated black to eliminate photochemical effects. Requisite amounts of PRX, acid, sodium perchlorate, and water (to keep the total volume constant for all runs) were taken in the

††Present address: Department of Chemistry, Western Illinois University Macomb, Illinois 61455, U.S.A.

tube and thermostated at 313 K for 30 min for thermal equilibrium. A measured amount of CAT or chlorine solution, also thermostated at the same temperature, was rapidly added to the mixture in the boiling tube. The progress of the reaction was monitored by the iodometric estimation of the unreacted CAT or chlorine present in known aliquots of the mixture withdrawn at different intervals of time. The course of the reaction was studied for over two half-lives. The rate constants calculated were reproducible within ±3% error.

Results

The kinetic runs for the reaction between PRX and CAT were performed at 313 K in the presence of several initial concentrations of mineral acids. The reaction was found to be moderate only in acidic chloride solution. Hence, a detailed study was made on the kinetics of oxidation of PRX by CAT in HCl medium.

Effcet of Varying Reactant Concentrations. For varying concentrations of CAT with constant [HCl] (0.1M) and a known excess of the substrate, plots of log titre vs. time were linear with the same slope indicating a first order dependence of the reaction rate on [CAT]. Values of the pseudo-first order rate constants, k, are presented in Table 1. The kinetics performed with varying concentrations of chlorine (where the molar concentration range of chlorine was the same as that of CAT) under identical experimental conditions gave k values comparable to that of CAT; this showed a first order dependence of the rate on chlorine concentration also (Table 5).

Table 1. Effects of Reactant Concentrations on the Rate[a)]

5.0	10.0	10.03
5.0	5.0	5.21[b)]
5.0	5.0	5.14[c)]

a) [HCl]=0.1 M; temp: 313 K. b) 0.5 M $NaClO_4$. c) In D_2O medium.

Table 2. Dependence of Reaction Rate on Hydrogen Ion and Chloride Ion Concentrations[a)]

[HCl]/M	[NaCl]/M	$10^4\times k/s^{-1}$
0.06	0.08	7.98
0.08	0.06	7.99
0.10	0.04	7.98
0.12	0.02	7.97
0.14	—	7.97
0.08	—	4.52
0.08	0.02	5.83
0.08	0.04	6.92
0.08	0.06	7.99
0.08	0.08	8.93

a) [CAT]=5.0×10^{-4} M; [PRX]=5.0×10^{-3} M; temp: 313 K. When $[H^+]$ is varied, constant total $[Cl^-]$= 0.14 M; When $[Cl^-]$ is varied, constant $[H^+]$=0.08 M.

An increase in [PRX], at constant [CAT] and [HCl], increased the rate. A plot of log k vs. log [PRX] gave a straight line with unit slope, showing a first-order dependence of the rate on [PRX]. The values of k obtained for different [PRX] are presented in Table 1.

Effect of Varying $[Cl^-]$ and $[H^+]$. At constant concentrations of H^+ (0.08 M), PRX (5×10^{-3} M), and CAT (5×10^{-4} M), addition of NaCl increased the reaction rate (Table 2). A plot of log k vs. log $[Cl^-]$ was linear with unit slope showing a first-order dependence of rate on $[Cl^-]$. Similarly, the influence of H^+ was studied by varying suitably the concentrations of both HCl and NaCl (Table 2), keeping Cl^- (0.14 M), PRX (5×10^{-3} M), and CAT (5×10^{-4} M) concentrations constant. It is observed that the rate is independent of $[H^+]$ showing a zero-order.

Effects of Varying Ionic Strength and Addition of Toluenesulfonamide. The change in ionic strength of the medium affected by adding sodium perchlorate at constant concentrations of PRX (5×10^{-3} M), CAT (5×10^{-4}), and HCl (0.1 M) had no significant influence on the rate of reaction (Table 1). The influence of the reaction product on the rate was studied by carrying out the reaction in presence of various concentrations of the product, *p*-toluenesulfonamide. The reaction rate decreased (Table 3) with the increase in the product concentration. A plot of log k vs. log $[RNH_2]$ gave a straight line with unit negative slope indicating a first order retardation of rate by $[RNH_2]$.

Effect of Solvent Isotope. The reaction was also studied using D_2O, instead of H_2O, as the solvent keeping other factors constant (Table 1). The solvent isotope effect (k_{H_2O}/k_{D_2O}) was found to be 1.01, indicating a negligible effect of the solvent isotope on the reaction rate.

Effects of Dielectric Constant and Temperature. The reaction was studied at 313 K by adding methanol to the reaction mixture at constant concentrations of PRX (5×10^{-3} M), CAT (5×10^{-4} M), and HCl (0.1 M). The reaction rate increased with decrease in dielectric constant (D) or with increase in methanol content of the medium (Table 4). A plot of log k vs. $1/D$ gave a straight line with a positive slope. The effect of temperature on the rate was studied by performing the kinetics at various temperetures (303—323 K) (Table 4) keeping [PRX], [CAT], and [HCl] constant. From the

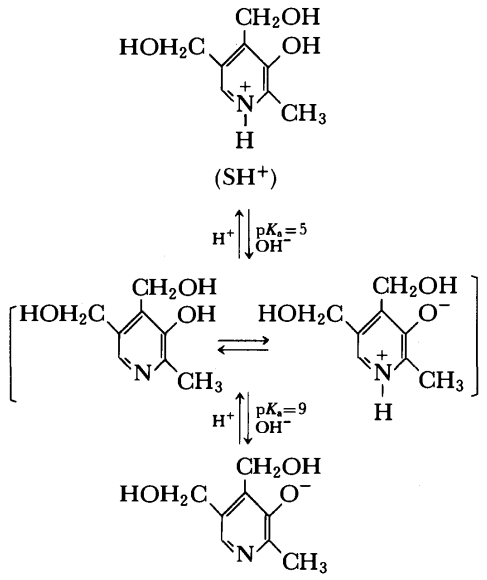
a) [CAT]=5.0×10^{-4} M; [PRX]=5.0×10^{-3} M; [HCl]= 0.10 M. b) Ref. 24, average of D values at 308 and 318 K. c) Temp: 313 K. d) Calculation based on energy of activation equals 84.51 kJ mol^{-1}; ΔH^*: enthalpy of activation; ΔS^*: entropy of activation.

Arrhenius plot of log k vs. $1/T$, the energy of activation and then the thermodynamic parameters, enthalpy of activation (ΔH^*) and entropy of activation (ΔS^*), were evaluated in a standard manner (Table 4).[20)]

Discussion

The substrate pyridoxine exhibits several equilibria[21)] depending on the pH of the solution:



(1)

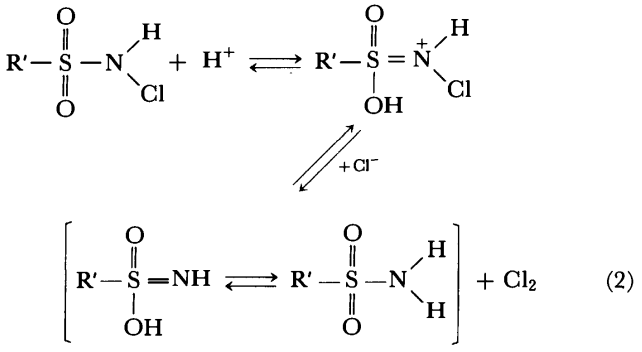
In the acidic conditions employed in the present investigations, the substrate (S) exists in the protonated form (SH^+).

Acidified CAT solutions contain RNHCl, $RNCl_2$, and HOCl as the oxidizing species.[3)] The observed first-order dependence of rate on [CAT] shows that $RNCl_2$ is not the oxidizing species in the reaction sequence. In acidic chloride solution, HOCl or monochloramine-T forms molecular chlorine. The formation of free chlorine[4)] from the acid form of CAT is presumed to occur through the following steps:

Table 5. Effect of Chlorine Concentration on the Rate[a)]

$10^4 \times$[Chlorine]/M	$10^3 \times$[PRX]/M	$10^4 \times k/s^{-1}$
3.0	5.0	5.20
4.0	5.0	5.20
4.8	5.0	5.11
5.6	5.0	5.13
6.6	5.0	5.15

a) [HCl]=0.10 m; temp: 313 K.



(2)

where R′=CH_3-C_6H_4.

Therefore, in the present system one can expect RNHCl or Cl_2 to be the effective oxidizing species. To verify this possibility, some experiments were carried out with chlorine water under identical experimental conditions. It is found that kinetic data with Cl_2 (Table 5) are almost identical with those with CAT (Table 1). The first order retardation of the rate by p-toluenesulfonamide ($R'SO_2NH_2$ or RNH_2) supports the involvement of Cl_2 in the oxidation sequence.

Based on these and other facts the reaction mechanism, Scheme 1, has been proposed. Scheme 1 involves the equilibrium reaction forming the protonated RNHCl species, RN^+H_2Cl, which on interaction with Cl^- forms Cl_2. The free chlorine formed interacts with the protonated substrate, SH^+, in a slowest and rate determining step to form an intermediate X. The intermediate then interacts with a solvent molecule, in a fast step, to form the end-products of the reaction.

$$RNHCl + H^+ \overset{K_1}{\rightleftharpoons} RN^+H_2Cl \quad (3)\ (\text{slow})$$

$$RN^+H_2Cl + Cl^- \overset{K_2}{\rightleftharpoons} RNH_2 + Cl_2 \quad (4)\ (\text{slow})$$

$$Cl_2 + SH^+ \xrightarrow{k_3} X \quad (5)$$

(slowest and rate determining)

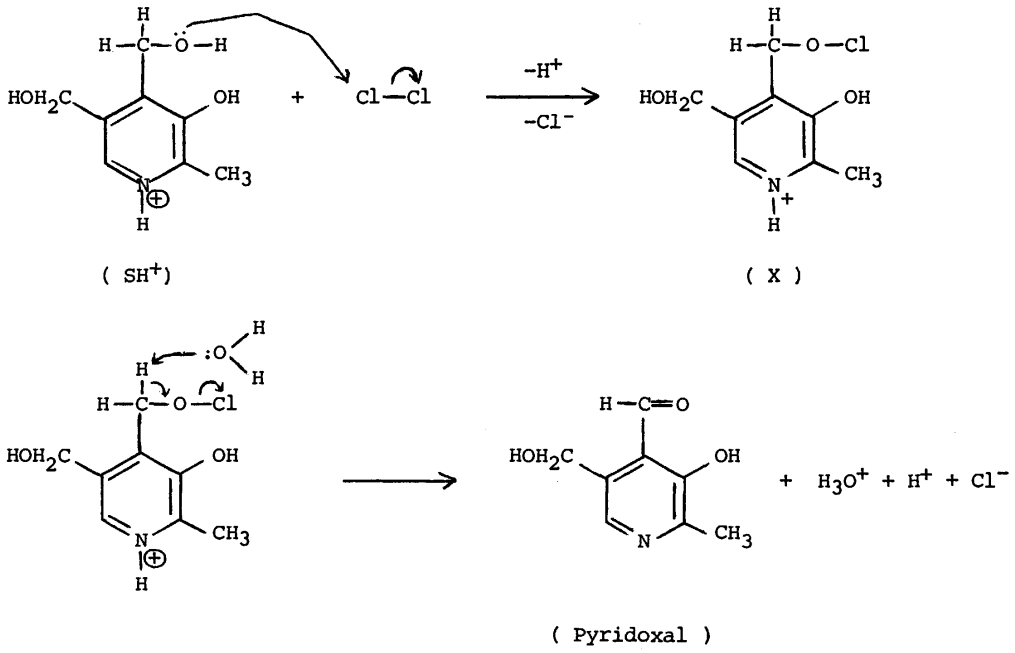
$$X + H_2O \xrightarrow{k_4} \text{Products} \quad (6)\ (\text{fast})$$

Scheme 1.

Based on the above scheme, the total CAT concentration is given by

$$[CAT]_T=[RNHCl]+[RN^+H_2Cl]+[Cl_2] \quad (7)$$

By making the appropriate substitutions in Eq. 7



Scheme 2.

using the equilibria of Scheme 1, the Eq. 8 for $[Cl_2]$ can be obtained.

$$[Cl_2] = \frac{K_1K_2[CAT]_T[H^+][Cl^-]}{K_1[H^+][RNH_2] + [RNH_2] + K_1K_2[H^+][Cl^-]} \quad (8)$$

From Scheme 1, the reaction rate is

$$\text{Rate} = -d[CAT]_T/dt = k_3[Cl_2][SH^+] \quad (9)$$

The substitution for $[Cl_2]$ in the above equation leads to the rate expression as follows:

$$\frac{-d[CAT]_T}{dt} = \frac{K_1K_2k_3[CAT]_T[SH^+][H^+][Cl^-]}{K_1[H^+][RNH_2] + [RNH_2] + K_1K_2[H^+][Cl^-]} \quad (10)$$

If $K_1[H^+][RNH_2] \gg [RNH_2] + K_1K_2[H^+][Cl^-]$, the last two terms can be neglected.

$$\frac{-d[CAT]_T}{dt} = \frac{K_2k_3[CAT]_T[SH^+][Cl^-]}{[RNH_2]} \quad (11)$$

By rearranging the rate expression 11, we get

$$k_{obsd} = \frac{-d\ln[CAT]_T}{dt} = \frac{-d[CAT]_T}{[CAT]_T} \cdot \frac{1}{dt} = \frac{K_2k_3[SH^+][Cl^-]}{[RNH_2]} \quad (12)$$

This rate law 11 is in agreement with the experimentally observed unit orders in [CAT], $[SH^+]$, and $[Cl^-]$, zero order in $[H^+]$, and inverse first order in $[RNH_2]$ (Tables 1—3). The plots, k_{obsd} vs. $[SH^+]$ or $[Cl^-]$ or $1/[RNH_2]$, were all linear passing through the origin in conformity with the rate law 12.

A possible mechanistic pathway for the PRX oxidation is shown in Scheme 2. A mechanism involving the formation of the intermediate (X), hypochlorite ester of PRX, due to the electrophilic attack of Cl_2 on one of the primary alcohol groups of the protonated substrate (SH^+) in the important rate determining step has been suggested. In the mechanism of bromine oxidation of alcohols, hypobromite ester is considered to be a possible intermediate. Kruse et al.[21,22] have proposed that the primary or secondary alcohol forms a hypobromite ester as the intermediate which then readily loses hydrogen bromide to form the carbonyl product. Our proposed mechanism involving hypochlorite ester as the intermediate is in agreement with that of Kruse et al. The observed absence of solvent isotope effect (Table 1) does not rule out the possibility of the hydride transfer. It does, however, show that the proton transfer in the rate-determining step may be ruled out; this may not always be the case. The nucleophilic attack by the water molecule may facilitate the cleavage of the weak O-Cl bond of the hypochlorite to form the aldehyde, pyridoxal, as the oxidation product of PRX.

The proposed mechanism is supported by the observed thermodynamic parameters (Table 4). The negative entropy of activation indicates formation of the compact transition state, hypochlorite species.[20] The positive effect of dielectric constant of the medium on the rate (Table 4) supports the involvement of positive ion-dipole interaction in the rate determining step which is in agreement with the kinetic theories.[20,23,24] The negligible effect of ionic strength of the medium (Table 1) conforms to the ion-neutral molecule interaction in the rate determining step. The negligible solvent isotope effect and the negative effect of the reaction product, *p*-toluenesulfonamide, on the rate (Table 3) are also in conformity with the proposed mechanism.

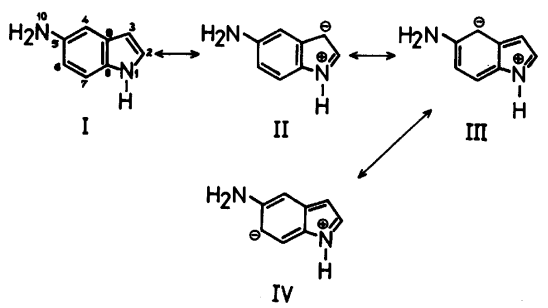
Dual fluorescence emissions are observed when the electron-donating group ($-NH_2$) is present at the position 5 of indole moiety. From the study of solvent effect and the large blue shift observed in the fluorescence spectra at 77 K, it is concluded that the long wavelength fluorescence band (480 nm) is assigned to the more polar state and the short wavelength band (350 nm) to the less polar state of 5-aminoindole (AI). Monocation is formed by protonating the amino group and no proton-induced fluorescence quenching of the neutral species is observed prior to its being protonated. This is mainly due to the shorter life of the conjugated acid-base pair. CNDO/S calculations indicate that dication is formed by protonating the C-3 position of the monocation of AI in the S_0 state but position 4 of monocation of AI in the S_1 state. Monoanion is formed by the deprotonation of >NH group in the S_0 state, but from the deprotonation of $-NH_2$ group in the S_1 state.

It is now well-established that the monocation of 5-hydroxy derivatives of indole fluoresces at ≈520 nm[1-5] and this band is used as an analytical tool for the diagonosis as well as for the estimation purposes. Unlike the other prototropic reactions of indole and indole derivatives,[6] the proton is added either at position 6 or at position 4[3-5] (the latter is preferred) of the 5-hydroxy derivatives, rather than at position 3 in the former compounds. The fluorescence band of the monocations of 5-hydroxy derivatives is very large red shifted (520 nm) as compared to that of the neutral molecules (≈360 nm) and no explanation is available in literature.

Recently, we have reinvestigated the spectral characteristics of some of the indole derivatives (mostly the carboxylic acids)[7-9] in different solvents and at various pH. It has been found that a new weak fluorescence band (≈460 nm) has been observed only in the compounds where 5-OH or 5-OCH_3 group is present in the indole moiety.[5] For example, in the fluorescence spectrum of 5-hydroxy-3-indoleacetic acid the ≈460 nm band is observed in the neutral species as well as in the case of monoanion formed by the deprotonation of -COOH group, but this band is absent if the deprotonation takes place from the -OH group. It has been further shown[4,5] that the charge densities in S_0 and S_1 states are maximum at position 6 or 4 in the case when -OH or -OMe group is present at position 5 of indole, and this leads to cannonical structure III or IV rather than II (Scheme 1) which is generally present in the other indole derivatives. If this phenomenon is due to the presence of electron-donating groups at position 5, the fluorescence band at ≈480 nm should also be observed in the case of amino group. The present study has been undertaken to see whether the observation of two fluorescence bands is due to the characteristic feature of the presence of electron-donating groups at position 5. The effects of solvents and pH on the spectral characteristics have also been studied. The ground state and excited-state pK_a values have been determined and discussed.



Scheme 1. Various cannonical forms of 5-aminoindole.

Method and Material

5-Aminoindole (AI) was obtained from Aldrich and was recrystallized from ethanol. The purity of the compound was checked by noting the sharp mp, absorption spectrum, and getting the similar fluorescence spectra when excited at different wavelengths. Spectrograde methanol, analytical grade sulfuric acid, sodium hydroxide, and phosphoric acid (BDH) were used. Analytical grade acetonitrile (E. Merck), cyclohexane (IDPL), ether, and ethanol were further purified by the procedures, as described in literature.[10] Triply distilled water was used for aqueous solutions. pH of the solutions in the range of 3—12 were adjusted by adding appropriate amount of sodium hydroxide and phosphoric acid, as phosphate buffers do not quench the fluorescence. A modified Hammett's acidity scale[11] for H_2SO_4-H_2O mixtures and Yagil's basicity scale[12] for NaOH-H_2O mixtures were used for aqueous solutions of pH less than 1 and pH greater than 13 respectively.

The absorption spectra were recorded on a Shimadzu spectrophotometer model UV 190, equipped with a chart recorder model U 135. The fluorescence measurements were carried out on the laboratory made scanning spectrofluorimeter, details were available elsewhere.[13] Both monochromators were calibrated with a low-pressure mercury lamp from time to time and the band width used for excitation was 8 nm. Fluorescence quantum yields were determined with the solutions having absorbance less than 0.1 and from the corrected fluorescence spectra, using quinine sulfate in 0.05 M (1 M=1 mol dm^{-3}) H_2SO_4 as a reference.[14] For absorptiometric and fluorimetric titrations, the solutions were prepared just before taking measurements. Isosbestic wavelengths were used as exciting wavelengths to measure the

fluorescence intensity. The concentrations of the solutions were of the order of 10^{-4}—10^{-5} mol dm^{-3}.

Both Pariser-Parr-Pople (PPP)[15,16] and CNDO/S[17] methods were employed to calculate the transitions energies, ground and excited state charge densities at various centres of the molecule and its prototropic species. All configurations obtained by single electron excitation from occupied molecular orbital to unoccupied molecular orbital were considered in all configuration interaction calculations. The species were assumed to be planar and the rings were taken as regular pentagon and hexagon. All ring C-C, C-N, and C-NH_2 bond lengths were taken as 1.40 Å.

Results and Discussion

Effect of Solvents. Table 1 lists the absorption maxima, log ε_{max} and Table 2 the fluorescence band maxima and quantum yields of AI in different solvents. The data in Table 1 clearly indicate that the absorption band maxima of AI are large red-shifted as compared to indole[6] or even 5-hydroxyindole (HI).[5] All band maxima are red-shifted as the polarity or the proton accepting nature of the solvents increases while a blue shift is noticed if the proton donor capacity of the solvents increases. Similar to 5-hydroxy derivatives, AI also exhibits dual fluorescence band systems, one at ≈350 nm and the other at ≈480 nm. The fluorescence intensity of the latter band system is much less than that of the former. The ratio of the band intensities remains the same value in different solvents as well as with the 100 fold change in the concentration of AI. The fluorescence maxima of both bands are red-shifted with change of solvents from cyclohexane to water, where the red shift observed in the shorter wavelength band is less than that in the longer wavelength band. In the measurements of fluorescence spectra at 77 K, the blue shift observed in the long wavelength fluorescence band (≈80 nm) is very large compared to that in the shorter wavelength band (≈30 nm). These data are compiled in Table 2 and the spectra are depicted in Fig. 2. The fluorescence quantum yield decreases under the above environments, such that we are unable to detect the long wavelength emission in water.

a) Values underlined are at 77 K.

It is now well-established that the long wavelength absorption band of indole is a mixture of ^1L_b and ^1L_a bands[15-18] i.e., the absorption band near 285 nm is due to the transition from the ground state to the ^1L_b state, around 272 nm to the ^1L_a state, whereas the band maximum near 220 nm is due to the ^1B state. The larger red shift observed in the 285 nm band system of AI as compared to that in 272 nm band system, is consistent with the earlier results that the former transition is polarised along the longer axis and the latter along the shorter axis. The -NH_2 group situated along the longer axis may perturb the ^1L_b state more than the ^1L_a state. The larger red shift observed in the absorption maximum is because of the fact that the lone-pair electrons on the amino group perturb the π cloud of the aromatic moiety much better than those on the hydroxyl group.

The fluorescence spectrum of indole and its derivatives in polar solvents has been proposed as the combination of two emission bands[18-22] i.e., due to the emission from the two closed lying ^1L_a and ^1L_b states. The assignment of the fluorescence spectrum as a combination of two bands is based on the results of polarized fluorescence excitation, fluorescencspectra,

and the fluorescence decay times of indoles. The present study also suggests the presence of two closed lying excited electronic states, because the absorption spectrum and the excitation spectra recorded at both fluorescence maxima resemble each other. The large difference in the fluorescence band maxima is due to the increased polarity in one of the electronic states, that is, one of them is much more stablished. This phenomenon has been further confirmed from the study of fluorescence spectra recorded at 77 K. The blue shift observed in the case of long wavelength band is much larger (≈80 nm) than that in the shorter wavelength band (≈30 nm). Further, stability of the states depends upon the nature, orientation and position of the substituent in the parent molecule. Similar to 5-hydroxyindole,[4] spectral data and charge densities at various atomic centres have been carried out on AI by the semiemperical-SCF MO-CI method (PPP) and by CNDO/S methods. The data are listed in Table 3 and 4 respectively. The data in Table 3 indicate that values of λ_{max} predicted by the CNDO/s method agree nicely with those observed for various species and the result proves the validity of the method. The data in Table 4 have clearly indicated that, similar to those of 5-hydroxyindole, the charge densities increase at the positions 4 and 6 (preferably at latter center) in comparison to position 3, normally observed in the case of indole. This suggests that charge migration takes place from heterocyclic to homocyclic ring leading to polarize the indole molecule. Cannonical structures arising from this intramolecular charge transfer are given in Scheme 1. Thus 480 nm band represents the fluorescence band may be due to more polarized cannonical structure II or IV of AI. This band cannot be assigned to the excimer or exciplex emission as the I_{480}/I_{350} ratio remains the same even when the concentration of AI is varied by 100 fold or the solvent is changed. The long wavelength emission is due to the presence of electron-donating group because on protonation of $-NH_2$ group to produce $-NH_3^+$ (see later) the 480 nm band disappears. Lastly this 480 nm band also cannot be assigned to the phosphorescence spectra on the basis of no effect of dissolved oxygen on the emission intensity. Oxygen from the solutions was removed by bubbling nitrogen and no phosphorescence was observed at 298 K, using an Amino-Bowman

The values in the parentheses are the excited state charge densities. The numbering of the atomic centers are shown in Scheme 1.

phosphorescope. The similar kind of behavior has been observed in the case of monocations of benzimidazole and methyl-substituted benzimidazoles.[23-25]

The dependence of the shifts of absorption and fluorescence band maxima of AI upon solvent polarity or hydrogen-bond-formation capacity of solvents is consistent with the earlier findings on the similar groups that proton-donating nature of solute leads to red shift and that proton-accepting nature of solute to blue shift. Thus ether and acetonitrile are acting as proton-accepting solvents, whereas methanol and water as proton-donating ones in the S_0 state. Since the intramolecular charge transfer from $-NH_2$ group to the ring is more effective in the S_1 state than in S_0, this group acts as a better proton donor in S_1 state. The decrease in the fluorescence quantum yield with increase in the solvent polarity or hydrogen-bonding power of solvents is due to interactions between the S_1 state and solvent molecules resulting in an increase of the rates of radiationless processes. This is further manifested by an increase in the Stokes shift under similar conditions.

Effect of pH. The absorption and fluorescence spectra of AI have been investigated in the H_0/pH/H_- range of −10 to 17. The relevant data are compiled in Tables 1 and 2 respectively. The absorption and fluorescence spectra of the various prototropic species are shown in Figs. 1 and 2. The spectral changes observed in the absorption spectrum of AI are consistent with the earlier results of the compounds containing amino groups. The neutral AI exists over the range of pH 14 to 3. With a decrease in pH, the absorption spectrum of AI is blue-shifted and the blue shift observed in the long wavelength band is so large that it is merged with the ^1L_a band system, resembling with that of indole molecule.[6] This clearly indicates that the monocation is formed by protonating the

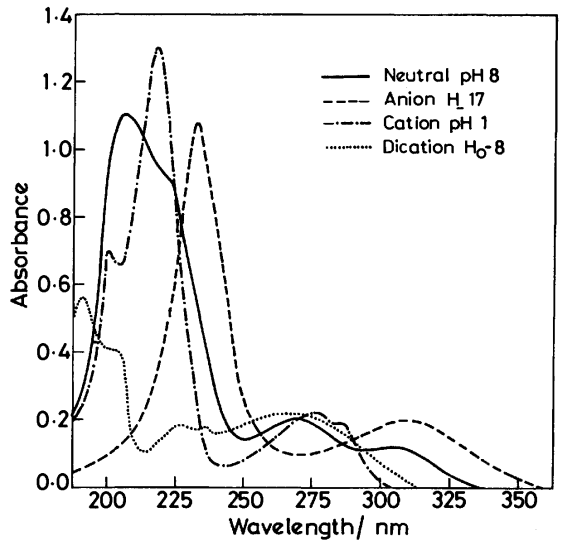

Fig. 1. Absorption spectra of various prototropic forms of AI at 298 K.

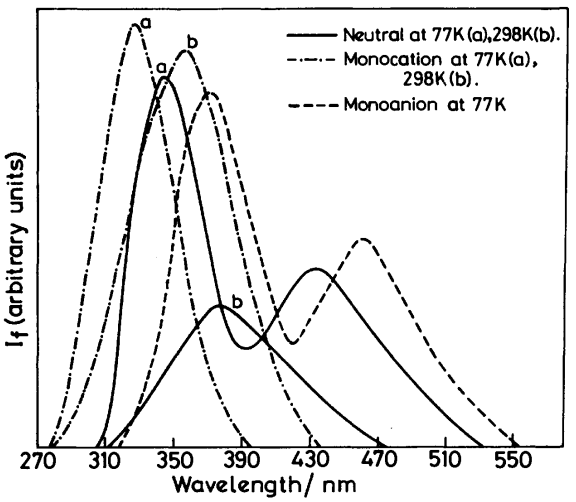

Fig. 2. Fluorescence spectra of AI in different solvents and at different pH at 298 K.

amino group in the S_0 state. Further increase in the acid strength, does not involve much change in the long wavelength band, except the vibrational structures, however, the intensity of 218 nm band system decreases and it is replaced by the two band systems, one at 236 and the other at 204 nm. This is a characteristic feature of the ring carbon atom of indole moiety.[6] Since there is already a presence of positive charge on the carbocyclic ring due to the presence of $-NH_3^+$ group, it is proposed that the protonation will take place at C-3 position normally observed for the indole molecule. This is further confirmed from calculated data of Table 4 that the charge density at position 3 is the maximum in the ground state of AI monocation (AI^+). With an increase in the basic strength, the absorption spectrum of AI is red-shifted and indicates the formation of monoanion. The monoanion can be formed by the deprotonation of either >NH group or $-NH_2$ group leading to the red shift. Further the pK_a values of both deprotonation reactions fall in the same range of basic strength.[12,26] The charge-density calculations, as shown in Table 4, have clearly indicated that the formal charge at the nitrogen atom of >NH group of indole molecule does not change due to the presence of amino group at position 5. Further the charge density at the nitrogen atom of >NH group is less than that at the nitrogen atom of $-NH_2$ group. This indicates that monoanion (AI^-) is formed by the deprotonation of imino group rather than amino group.

Thefluorescence spectrum of AI also follows the similar changes as observed in the absorption spectrum, within the same acidic and basic range i.e., the neutral species exists in the pH range of 7 to 14, monocation starts appearing below pH 6. Only one fluorescence band, similar to indole, has been observed for AI^+, indicating that the presence of electron-donating group is necessary at the position 5 for the emission of long wavelength fluorescence band. Dication of AI is nonfluorescent and this behaviour is similar to the

monocation of indole or other indole derivatives. Although the charge density is maximum at position 3 of AI^+ in the ground state, the charge density is maximum at position 4 of AI^+ in the first excited singlet state, similar to the neutral AI molecule and actually it decreases at position 3 in the S_1 state in comparison to S_0 (Table 4). The driving force behind this intramolecular charge migration from the heterocyclic to the carbocyclic ring is due to the presence of positive charge on the latter ring. On the basis of charge densities at the various atomic centers, it is concluded that the dication in the S_1 state is formed by protonating the carbon center at position 4 rather than at position 3. Similar to dication, the monoanion of AI is also nonfluorescent. Literature data show that monoanion formed by the deprotonation of >NH group of indole and some of its derivatives as well as the monoanions formed by the deprotonation of similar group in indazoles and benzimidazoles[2,13,27-29] are fluorescent, whereas that formed by the deprotonation of $-NH_2$ group is nonfluorescent,[30-32] with few exceptions.[33] Our data suggest that, though the ground state prototropic reaction is from the >NH group, but in the excited state, it is from the $-NH_2$ group.

Further charge density data at the two nitrogen centres do not point out clearly but the decrease in the formal charges at the nitrogen atom of $-NH_2$ (0.09) is larger than that at the nitrogen atom of >NH group (0.01). So the deprotonation in the excited singlet state, most probably is from the $-NH_2$ group. This is confirmed from the fluorescence spectral study at 77 K. Since at such a low temperature and in the frozen state, the species is present in the ground state environments, even when excited. The observation of two fluorescence bands at H_ 16 and at 77 K, clearly indicate that the electron-donating group at position 5 is not disturbed in the highly basic conditions and confirming that the deprotonation in the S_0 state takes place from the >NH group. Similar behavior has been observed in the case of 2-aminobenzimidazoles[34] and aminoindazoles.[35-37]

pK_a Values. The pK_a values for the different prototropic reactions have been determined absorptiometrically and are listed in Table 5. The values of pK_a's obtained for neutral-monoanion[12] and monocation-neutral[26] equilibria are in the range of pK_a's for similar reactions. The pK_a for the protonation of indole-ring carbon atom is less than that of indole (3.5)[6] and it is due to the presence of positive charge on the carbocyclic ring.

The pK_a^* values have been determined with the help of fluorimetric titration method (Fig. 3) and Förster cycle method,[37] using absorption and fluorescence data, wherever applicable. For example, pK_a^* for the neutral-monoanion equilibrium can not be calculated by the latter method as the equilibrium involved in S_0 and S_1 states are different. Similarly pK_a^* for dication-monocation equilibrium, because the protonation involves change in the structure of indole moiety as well as the dication is non-fluorescent. The

results of fluorimetric titrations have indicated that the $-NH_2$ group becomes strong acid and carbon centre of indole more basic on excitation. These results are consistent with the earlier findings. Only ground state pK_a is obtained from the fluorimetric titrations for monocation-neutral equilibrium, which is little unusual for this kind of prototropic reaction, because in general, proton-induced fluorescence quenching[30,31,38] is observed before $-NH_2$ group gets protonated. Since the Förster cycle method has clearly indicated that $-NH_3^+$ group becomes stronger acid on excitation, it is concluded that the radiative lifetimes of the neutral and singly protonated species must be too short for proton exchange to occur appreciably within these lifetimes of conjugated species at pH≈5. Therefore, a prototropic equilibrium is not established within the lifetimes of the lowest excited singlet states of these molecules and thus fluorescence intensities measured at pH≈5 reflect the relative ground state concentrations of AI and AI^+. Hence, the ground-state pK_a is determined by fluorimetric titration in this case. Similar behavior has been observed in the prototropic reaction of 4-(9-anthryl)-*N*,*N*-dimethylaniline.[39] The difference between the pK_a^* values obtained by the Förster cycle method and absorption and fluorescence data is due to the different solvent relaxation for the conjugated species in S_0 and S_1 states. All the prototropic reactions are mentioned in Scheme 2.

Conclusion

The presence of electron-donor group at the position 5 of indole molecule, leads to the dual fluorescence, one nearly at≈360 nm and the other at≈480 nm. The latter one is because of more polar electronic state than that of the former. Monocation is formed by protonating the $-NH_2$ group and the dication further protonating the C-3 position in S_0 state but the position 4 of indole moiety in the S_1 state. The deprotonation of >NH group takes place in the S_0 state but of $-NH_2$ group in the S_1 state to form the monoanion. No proton-induced fluorescence quenching is observed before protonating amino group, and fluorimetric titrations have given the ground state pK_a value, indicating that the lifetimes of the conjugate species are very small to achieve the prototropic equilibrium in S_1 state.

Spectral Characteristics of Phenylenediamines and Their Various Protonated Species

R. MANOHARAN and Sneh Kumar DOGRA*
Department of Chemistry, Indian Institute of Technology, Kanpur 208016, India
(Received November 25, 1986)

Increase in the Stokes shift [$\bar{\nu}_{abs}(max)-\bar{\nu}_{flu}$ (max)] with an increase in the polarity and hydrogen-bonding capacity of the solvents is the maximum for *p*-phenylenediamine and the minimum for *m*-phenylenediamine. These studies have indicated that the two amino groups in *o*- and *p*-phenylenediamines are not in the same plane of the benzene ring. Spectral characteristics of monocations and dications resemble to those of aniline and benzene respectively. pK_a values for the dication-monocation and monocation-neutral equilibria have been determined, both in S_0 and S_1 states, and discussed.

If $\pi\rightarrow\pi^*$ is the lowest energy transition, the protonation at the tertiary nitrogen atom leads to the red shift in the absorption and fluorescence spectra of the molecule.[1] Schulman et al.[2] in their study of prototropic reactions of 1,10-phenanthroline have revealed that the spectral changes, observed in the absorption spectrum on protonation, followed the normal trend, but the emitting state of the monocation, formed by protonating one of the tertiary nitrogen atom is of lower energy than that of the dication, formed by protonating the second tertiary nitrogen atom i.e., red shift is followed by the blue shift in the above prototropic reactions. This anomalous behavior has been attributed to the very large solvent relaxation in the S_1 state of monocation and this has been further confirmed when the similar study was carried out in nonpolar medium, where the solvent relaxation is negligible. The similar behavior has been observed in our earlier study on 2,7-fluorenediamine,[3] where the two amino groups are symmetrical, like the two tertiary nitrogen atoms of 1,10-phenanthroline.

The aim of the present study is to see whether 1,2-, 1,3-, 1,4-phenylenediamines follow the similar trend or these molecules behave in a different fashion. Secondly, most of the prototropic studies carried out on the disubstituted benzenes are on the donor-acceptor substituents.[4-7] This kind of study, carried on the donor-donor substituents is very rare.[8-11] Since amino groups are electron donating, we have undertaken this study to see the effect of solvents and pH on the spectral changes of these three isomers of phenylenediamines.

Method and Material

o-Phenylenediamine (*o*PA) and *p*-phenylenediamine (*p*PA) were obtained from Aldrich Chemical Co. and *m*-phenylenediamine (*m*PA) was prepared by the reduction of *m*-nitroaniline as suggested in literature.[12] *o*PA was recrystallized from water, *m*PA from benzene, and *p*PA from diethyl ether repeatedly.[13] The purity of these compounds was checked by their sharp mp, absorption data and getting the similar fluorescence spectra when excited with different wavelengths. Spectrograde BDH methanol, analytical grade sulfuric acid, orthophosphoric acid, and sodium hydroxide (BDH) were used without further purification. Cyclohexane (IDPL), ether (BDH), and acetonitrile (E. Merck) were further purified by the procedures, as suggested in literature.[14] Triply distilled water was used for the aqueous study. Modified Hammett's acidity scale[15] for aqueous H_2SO_4 and Yagil's basicity scale[16] for aqueous NaOH were used for solutions below pH 1 and above pH 13 respectively. pH of the solutions in the range of 3 to 11 was adjusted by the addition of appropriate amount of NaOH and H_3PO_4.

Absorption spectra were recorded on a Shimadzu spectrophotometer, model UV 190, equipped with a chart recorder, model U 135. Fluorescence measurements were carried out on a scanning spectrofluorimeter, fabricated in our laboratory, the details of which were available elsewhere.[17] Both monochromators were calibrated from time to time with low-pressure mercury lamp and the band width of the excitation monochromator was 8 nm. pH of the solutions in the range of 1—13 was measured on a Toshniwal's pH meter, model CL-44A. Fluorescence quantum yields were measured on the solutions, having absorbance less than 0.1, fluorescence spectra were corrected and quinine sulfate in 0.05M H_2SO_4 (1M=1 mol dm^{-3}) was used as a standard.[18] The excitation wavelengths (λ_{exc}) used for *o*PA, *m*PA, and *p*PA were 275, 285, and 288 nm respectively. For absorptiometric and fluorimetric titrations, the solutions were prepared just before taking measurements and the concentrations of the solutions were of the order of 1×10^{-4} M (1M=1 mol dm^{-3}). To measure the fluorescence intensity at any analytical wavelength, isosbestic wavelengths were used for excitation. For dication-monocation equilibria of all diamines, a mercury-xenon lamp was used instead of a xenon lamp, normally used in the spectrofluorimeter. This is because of the low intensity of the xenon arc lamp below 270 nm.

Results and Discussion

Effect of Solvents. Table 1 depicts the absorption maxima, log ε_{max}, fluorescence maxima, and quantum yields of *o*PA, *m*PA, and *p*PA in the solvents of different polarity and hydrogen bond forming tendency, as well as at different proton concentrations. Figures 1—3 show the fluorescence spectra of these three diamines under the above environments. Data in Table 1 clearly indicate that the absorption spectra of all isomers are largely red shifted and the vibrational structure of the long wavelength band is completely lost in any one of the solvents compared to those of benzene. The intensity of each band of benzene is increased. The above results are quite consistent with

the presence of amino groups in the ring, because it completely destroys the hexagonal symmetry of the benzene ring. Therefore the symmetry forbidden selection rule is reduced resulting in an increase in the value of the transition dipole moment. The large red shift in λ_{max} and loss in the vibrational structure of the absorption spectrum are due to the strong interactions of the amino group with the π cloud of the benzene ring.

The absorption maxima of all bands of diamines are red-shifted with an increase in the polarity of aprotic solvents but are blue-shifted with an increase in the

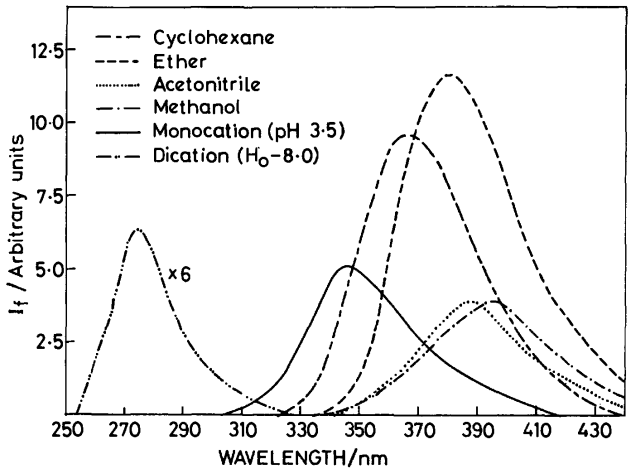

Fig. 3. Fluorescence spectra of *p*PA in different solvents and pH at 298 K. Concd $=5.0\times10^{-4}$ M.

proton-donor capacity of solvents. On the other hand, the fluorescence maxima of all diamines are regularly red-shifted under the above environments. The fluorescence quantum yield is quite small and further decreases in going from cyclohexane to water, where it is completely nonfluorescent at room temperature. The effect of solvents on the absorption and fluorescent maxima is agreeing with results observed earlier in the case of amino groups[19] i.e., the dispersive interactions and proton-donor nature of the solute lead to red shift and the proton-acceptor of solute leads to the blue shift in the absorption and fluorescence spectra of molecule if $\pi\rightarrow\pi^*$ is the lowest energy transition. Our data clearly indicate that in S_0 state, all diamines are acting as a proton donor in ether and acetonitrile, whereas a proton acceptor in methanol and water. The results of fluorescence spectra can be explained on the ground that charge migration from the amino group towards the benzene ring increases on excitation, thereby decreasing the charge density on the nitrogen atom and increasing the proton-donor capacity of the amino group. The decrease in the fluorescence quantum yield of all diamines, under the above environments is due to their strong interactions with the solvents and thus increasing the rates of radiationless processes. This is further manifested from the Stokes shift, which increases with the increase in the polarity of the solvents.

The Stokes shift $[\bar{\nu}_{abs}(max)-\bar{\nu}_{flu}(max)]$ observed for three amines is minimum for *m*PA (2630 cm^{-1}) and nearly same for *o*PA and *p*PA (4180, 4200 cm^{-1}) in cyclohexane. But an increase in the Stokes shift with an increase in the solvent polarity is the maximum for *p*PA and the minimum for *m*PA (See Table 2). Although no data is available for the polarity or dipole moment of these molecules in the excited states but it is quite clear from the data that the polarity and dipole moment of these molecules increase upon excitation. Our data further suggest that two amino groups present at the para position are not in the plane

Table 2. Stokes Shifts (cm^{-1}) Observed for Phenylenediamines in Different Solvents

of benzene ring. Had these groups been planar to the benzene ring, the dipole moment of *p*PA would have been zero, and thus the molecule would have been nonpolar in both S_0 and S_1 states. The dipole moment data of these molecules, available in the ground state,[20] do indicate that $-NH_2$ groups in the cases of *o*PA and *p*PA are not in the same plane of the benzene ring whereas in the case of *m*PA these groups are in the same plane of benzene. These conclusions are based on the fact that the calculated dipole moments of diamines (based on the vector addition of amino groups) do not agree with the observed ones. We, also, conclude from our data that the similar geometries of these molecules are present in the first excited singlet state.

Effect of Proton Concentration. The absorption and fluorescence spectra of all diamines have been studied in the H_0/pH/H_- range of -10 to 17. The relavent data are compiled in Table 1 and the fluorescence spectra of the various prototropic species of these amines are also shown in Fig. 1—3 respectively. The results observed are on the right track. With the decrease of pH (from≈8, depending on the particular diamine) the absorption spectra of all diamines are blue shifted and the absorption spectra so obtained resemble to that of aniline.[21] This clearly suggests that the species so formed is a monocation, obtained by protonating one of the amino groups. With the further increase of proton concentration, the absorption spectra are further blue-shifted and the long wavelength broad band is replaced by a structured spectrum, in each case. This spectrum resembles to that of benzene molecule.[22] This is further manifested from the similar vibrational frequencies as observed in the case of benzene coupled with the electronic transition, as well as from a decrease in the molecular extinction coefficient of the absorption bands of this species, resembling more closely to that of ^1L_b transition in benzene. The above results clearly indicate that the latter species is a dication, formed by protonating the second amino group. The above behavior clearly resembles to that of the aromatic compounds containing the amino group.[19,23-25]

The absorption spectra of ortho- and metadiamines do not change till pH 14 but after and at H_- 15, a small but a regular red shift is noticed and it continued even upto H_- 17, the highest basic conditions used and the

band maxima is observed at the same wavelength (295 nm). On the other hand, the absorption spectrum of *p*PA starts getting red shifted at pH $\geqslant$13 and is continuously red-shifted even at H_- 17, with a band peak at 313 nm. The above results are consistent with the results that deprotonation of the amino group leads to a red shift in the spectra.

The behavior of fluorescence spectra of the various species formed in these acid region is the same as observed in the ground state, i.e., around pH 4, the fluorescence spectrum of each amine is blue-shifted and resembles to the fluorescence spectrum of aniline ($\approx$340 nm in ethanol).[21] Around H_0 −8, the fluorescence spectrum is further largely blue-shifted in each case, with the band maximum at 275 nm and this resembles more closely to the fluorescence spectrum of benzene, without the band structure.[21] The above results clearly suggest that the former species is a monocation formed by the protonation of the amino group and the second species is a dication, formed by the protonation of the second amino group. The loss in the structure of the second species in the fluorescence spectrum, as compared to that in the ground state, is due to the stronger interactions in such a highly ionic medium. The assignment of the species is further confirmed by getting the fluorescence band maximum of the monocation nearly at the same wavelength and that of dication exactly at the same point in cases of the diamines studied. This is because, during these prototropic reactions, the species formed in the first case is close to aniline and in the second case, it is close to benzene, as the lone pairs are mopped by protons.

No fluorescence emission is observed from the neutral species as well as from the monoanions of these amines at room temperature and even upto H_- 17, the highest basic conditions used. This is consistent with the earlier results that monoanions formed by the deprotonation of aromatic amines, in general, are non-fluorescent, with few exceptions.[27,28]

Equilibrium Constants in the Ground and Excited States. pK_a values of dication-monocation and monocation-neutral equilibria have been calculated spectrophotometrically and are compiled in Table 3. The values of pK_a's obtained agree with literature values within experimental errors.[29] The pK_a for the neutral-monoanion cannot be determined because the absorption maxima in each case was constantly red-shifted even at the highest basic conditions used but one thing is certain that the pK_a value of neutral-monoanion equilibrium of *p*PA is smaller than that of *o*PA and *m*PA. The difference in the pK_a values of monocation-neutral equilibria between *o*PA and *m*PA is quite small but it is quite large in the case of *p*PA. Further the pK_a values for *o*PA (4.50) and *m*PA (4.80) are not very different from that of aniline (4.66).[30] Since the amino group is an electron donating group and it is ortho- and para-directing, it will not change the charge densities at the nitrogen atom of the other $-NH_2$ group in case of *m*PA. Thus the pK_a value for *m*PA will be close to that of aniline, as observed. For *o*PA, it was expected that its value should be greater than that of aniline. However the small decrease in the pK_a value of *o*PA was observed. This may be due to the steric hindrance of the two amino groups adjacent to each other. The high pK_a value for monocation-neutral equilibrium of *p*PA can be explained as follows: Because of the symmetry of the amino groups, the average charge densities at both nitrogen atoms will be same. But at any particular instant, if one of the nitrogen atom becomes more acidic, the other will

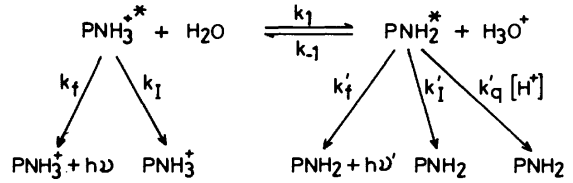
become more basic and since the steric hindrance is minimum for *p*PA, the pK_a value for the monocation-neutral equilibrium would be the highest, whereas it would be the lowest for neutral-monoanion equilibrium among the diamines.

pK_a^* values for all equilibria have been calculated fluorimetrically (Fig. 4) as well as using the Förster cycle method[27] wherever it is applicable, except for the neutral-monoanion case where both species are nonfluorescent. All values have been compiled in Table 3. For the monocation-neutral equilibrium, the formation curves of the monocations are plotted only because the neutral species are nonfluorescent in aqueous medium. It is clear from Fig. 4 that the fluorimetric titration curves have given only the ground state pK_a values for the monocation-neutral equilibria. Whereas the Förster cycle method, using absorption data only, have shown that the amino group becomes stronger acid on excitation to the first excited singlet state. It is thus concluded that the radiative lifetimes of the neutral and singly protonated species must be too short for proton exchange to occur appreciably within these lifetimes at pH 4—6. Due to this reason the prototropic equilibrium is not established within the lifetimes of the lowest excited singlet states of these molecules. Thus the fluorescence intensities measured at pH ≈4—6 reflect the ground-state concentrations of neutral and monocation species. Consequently, the ground-state pK_a is determined by fluoremetric titrations in this case. Secondly, though the neutral molecules are nonfluorescent, the fluorimetric curves by giving the ground state pK_a values have clearly shown that the proton-induced fluorescence quenching is not observed for the neutral species, before forming the monocations. Otherwise one would have observed a different pK_a value from the formation curve of monocation, if the proton-induced fluorescence quenching of the neutral species had been observed. This behavior is very similar to that observed for 4-(9-anthryl)-*N*,*N*-dimethylaniline by Shizuka et al.[31] Shizuka et al. have clearly shown from their time dependence fluorescence study that the lifetimes of the conjugate acid-base pair is very short, even though the intramolecular charge-transfer state $^1A^*_{CT}$ is very rapidly produced via $^1A^*$. Similar explanation can be offered in the cases of all diamine derivatives of benzene.

In the dication-monocation equilibrium the fluorescence of monocation is quenched in the pH region where the dication is present in the ground state but not fluorescent in the S_1 state. The dications start emitting only below H_0 −4. This behavior is similar to the prototropic reactions of aromatic monoamines and decreases in the fluorescence intensity of monocations is attributed to the proton-induced fluorescence quenching. Thus the pK_a^* values have been calculated from the formation curves of the dications and the values are listed in Table 3. The data of Table 3 clearly indicate that the $-NH_3^+$ group is a stronger acid in the S_1 state than in the S_0 state, consistent with the earlier results.[19,23-26] The pK_a^* values calculated with the help of the Förster cycle method and using absorption and fluorescence data do not agree with each other. This is because: (i) The long wavelength absorption band of monocation is broad whereas that of dication is structured. On the other hand the fluorescence spectrum of both species are broad and structureless, (ii) the solvent relaxation for monocation in the S_1 state is very large in comparison to that observed for dication. This can be seen from the Stokes shift observed for the monocation (≈5960 cm^{-1}) and for the dication (≈1900 cm^{-1}). Thus it can be concluded that pK_a^* values determined by fluorimetric titrations will be more close to the actual values. The pK_a^* values for neutral-monoanion equilibrium cannot be calculated because neither neutral species nor monoanion is emitting.

Proton-Induced Fluorescence Quenching. As said earlier no correspondence is observed between the decrease in the fluorescence intensities of the monocations and the increase in the fluorescence intensities of the dications. This has been attributed to proton-induced fluorescence quenching in the pH range of 1 to 4. This is because the SO_4^{2-} ion concentration (produced by adding K_2SO_4) equivalent to that obtained by the addition of H_2SO_4, do not quench the fluorescence of monocations. The model suggested by Shizuka et al.[32-34] can be transformed to simple Stern-Volmer plot under the conditions that the lifetimes of the



P=Monocations of phenylenediamines

monocations are short in comparison to those of dications and concentration of H^+ are small to have any backward reaction, dipicted in Scheme I. i.e.

$$\frac{I_0}{I} = 1 + k_q\tau[H^+]$$

where I and I_0 are the fluorescence intensities with and without the quencher respectively, k_q is the proton-induced fluorescence quenching constant and τ is the lifetime of the basic species. I_0/I vs. $[H^+]$ is plotted in Fig. 5 and the $k_q\tau$ values obtained for all three monocations are listed in Table 4. The natural radiative lifetimes of monocation of three diamines are estimated from the corrected fluorescence spectra, using Strickler and Berg's relations.[37] The actual lifetimes are determined from the relation $\tau=\tau_{FM}\,\phi$ where ϕ is the quantum yield of the respective monocation. These values for three species are listed in Table 4. To the first approximation, assuming that the monocations of the three diamines will behave like aniline, the results obtained about the τ_{FM} of monocations of *o*-, *m*-, and *p*- diamines [35, 39, 45 ns respectively] are not very far off from the experimentally determined τ_{FM} of aniline in ethanol (34 ns). The difference in τ is due to the difference in the quantum yields of these species. The smallest lifetime of the para species is due to the larger interactions with solvent molecules which is further manifested by the greater Stoke's shift observed for this species. From our study it is difficult to offer any exact explanation for the large increase in the $k_q\tau$ value in going from the monocation of *o*PA to *p*PA. It may be speculated that steric factor may be playing the major role in the proton-induced fluorescence quenching, although the Stokes shift observed for the monocation of *p*PA is the maximum but do not differ so much from those of other amines if energy of the state has to do anything for this quenching.

Conclusion

Large spectral changes, both in the absorption and fluorescence spectra of *o*PA and *p*PA have clearly indicated that the two amino groups in *p*PA are not in the same plane of the benzene ring. Larger pK_a value for the monocation-neutral equilibrium of *p*PA as compared to *o*PA and *m*PA, indicates that the charge density at the nitrogen atom of amino group is larger than that at the respective atom of other two compounds. In case of *o*PA, the steric hindrance plays the role in having the minimum pK_a value for this equilibrium. Fluorimetric titration curves have indicated that the lifetimes of the monocation-neutral conjugate acid-base pair are quite short to allow the acid-base equilibria in the excited singlet state.

The authors are thankful to the Department of Science and Technology, for the financial support to the project entitled "Proton Transfer reactions in the excited states."

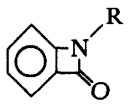
Mass Spectral and Pyrolytic Studies of Some 4,4-Disubstituted 1,4-Dihydro-2*H*-3,1-benzoxazin-2-ones

Baman Prasad ACHARYA, Bijaya Kumar MISRA, and Yerramalli Ramachandra RAO*
Regional Research Laboratory, Bhubaneswar-751013, India
(Received August 21, 1986)

Pyrolysis of 4,4-diaryl-1,4-dihydro-2*H*-3,1-benzoxazin-2-ones at 230—240 °C gives 9-arylacridines and (2-aminophenyl)diarylmethanes. Their formation correlates well with the mass fragmentation of the respective parent compounds.

Benzazetin-2(1*H*)-ones (**1**) have been postulated as reactive intermediates in the pyrolysis and photolysis of isatoic anhydride and 3-substituted 1,2,3-benzotriazin-



1

4(3*H*)-ones;[1,2] their formation during the mass fragmentation has also been observed. We had prepared some 4,4-diaryl-1,4-dihydro-2*H*-3,1-benzoxazin-2-ones (**2**) by Friedel-Crafts acylation of arenes with 2-isocyanatobenzoyl chlorides.[3,4] Their mass spectra show appearance of peaks at *m/z* M^+-44 and M^+-45 which are characteristic of these benzoxazinones **2**. In Table 1 are given prominent fragment ions with relative abundances and the fragmentation pattern is depicted in Chart 1.

It is observed that these benzoxazinones decompose at their melting points and in view of the known corre-

lation of pyrolytic and electron impact reactions of some of the closely related compounds viz isatoic anhydride and 3-substituted 1,2,3-benzotriazin-4(3*H*)-ones, it is of interest to study the pyrolysis and photolysis of these 4,4-disubstituted benzoxazinones **2**; we report here the results of these investigations.

When the benzoxazinones (**2a, b, f**) are pyrolyzed at 230—240 °C without solvent, 9-arylacridines (**3a, b,** f) are obtained in 45—60% yield along with (2-aminophenyl) diarylmethanes (**4a, b,** f†) in 10—25% yield. These are separated by column chromatography and identified through their spectral data and comparison with authentic samples[6,7] wherever possible. The formation of **3** and **4** from the above pyrolysis reaction is depicted in Scheme 1.

It is likely that the two hydrogen atoms lost in the final step of formation of **3** add to the intermediate **5**. In order to verify this, the benzoxazinone (**2a**) is pyrolyzed in presence of hydrogen donors such as sodium borohydride and hydroquinone; however, no improvement in the yield of **4** is observed and products with the same relative distribution are obtained. Pyrolysis carried out in the presence of nucleophile e.g. methyl anthranilate also did not produce any additional product.

When 4-methoxy-4-phenyl-1,4-dihydro-2*H*-3,1-benzoxazin-2-one (**2g**) is pyrolyzed at 230 °C, it afforded 2-aminobenzophenone (**6**, 49%) and 6,12-diphenyldibenzo(*b,f*)(1,5)diazocine (**7**, 8.5%). The formation of dibenzodiazocine **7** seems to be through the dimerization of the

† **4f** was not isolated, but observed on TLC only.

intermediate **5g** (Scheme 2) similar to the dimerization observed in the pyrolysis of isatoic anhydride and 1,2,3-benzotriazin-4(3*H*)-one reported earlier.[1,2]

Although these benzoxazinones **2** afforded the expected products on pyrolysis, they are found to be quite stable to photolysis and are recovered back unchanged after irradiation in a Hanovia reactor with a 400 W lamp for 24 h.

In the case of **2a, b, f**, no dimerization product is obtained, whereas dimerization products are invariably obtained in the reactions of isatoic anhydride and 3-substituted 1,2,3-benzotriazin-4(3*H*)-ones. This is probably due to the stabilization of the intermediate **5** by extended mesomeric interaction with the aromatic residue. No evidence for either the free radical or ionic mechanisms could be obtained as the product composition did not change when the pyrolysis is carried out in the presence of hydroquinone, a known free radical trap or sodium borohydride. However, in view of the correlation with the mass fragmentations, the free radical mechanism is preffered.[5] Formation of no other additional product in the presence of methylanthranilate supports this view. In the case of **2g** however, the intermediate **5g** dimerises to some extent and dibenzodiazocine **7** is obtained (Scheme 2).

Experimental

4,4-Disubstituted 1,4-dihydro-2*H*-3,1-benzoxazin-2-ones (**2**) are prepared according to the known procedure.[3,4] Yields are given after crystallization. Melting points reported are not corrected.

General Procedure of the Pyrolysis of 4,4-Disubstituted 1,4-Dihydro-2*H*-3,1-benzoxazin-2-ones (2): 4,4-Disubstituted 1,4-dihydro-2*H*-3,1-benzoxazin-2-ones (**2**) were pyrolyzed without solvent in an open mouth round bottomed flask at 230—240 °C for 3 h. After cooling, the mass was taken up in benzene (10 ml), filtered to remove the unreacted **2**, which remained insoluble and the filtrate was subjected to column chromatography on silica gel by successively eluting with benzene-hexane (1 : 1), benzene, and benzene-ethyl acetate (9 : 1) when (2-aminophenyl)diarylmethanes (**4**), 9-arylacridines (**3**) and some unreacted **2** were obtained in the same order of elution. These compounds were further purified by recrystallization.

Pyrolysis of 4,4-Diphenyl-1,2-dihydro-2*H*-3,1-benzoxazin-2-one (2a): The captioned compound **2a** (750 mg) was pyrolyzed as above; the following compounds were obtained:

(i) (2-Aminophenyl)diphenylmethane (**4a**) (180 mg, 28%), mp 127 °C (benzene-hexane), lit,[6] 126—128 °C; IR (Nujol) ν_{max} 3470, 3375, and 1610 cm^{-1}; MS *m/z* (rel intensity) 259 (M^+, 100), 258 (19), 182 (37), 181 (8), 180 (28), 167 (9), 91 (3). Found: C, 88.096; H, 6.552; N, 5.13%. Calcd for $C_{19}H_{17}N$: C, 88.031; H, 6.564; N, 5.405%.

(ii) 9-Phenylacridine (**3a**) (280 mg, 44%), mp 184 °C (benzene-hexane), lit,[7] 185 °C; MS *m/z* (rel intensity) 255.3 (M^+, 100), 254.3 (86.6), 253.3 (17.7), 252.3 (11.5), 251.2 (6.4), 227.2 (6.8), 226.2 (11.1), 127.2 (20.8), 126.2 (20.2), 113.2 (12.4). Found: C, 89.412; H, 5.098; N, 5.49%. No absorptions in the NH and carbonyl region are observed in the IR spectrum.

(iii) Unreacted **2a**. (130 mg).

Pyrolysis of 4,4-Di-*p*-tolyl-1,4-dihydro-2*H*-3,1-benzoxazin-2-one (2b): Analogously, pyrolysis of **2b** (350 mg) yielded.

(i) (2-Aminophenyl)di-*p*-tolylmethane (**4b**) (20 mg, 7%), semisolid, purified by passing over a short column of silica gel; IR (Nujol) ν_{max} 3450, 3360, 1610 cm^{-1}; MS *m/z* 287 (M^+, 100), 286 (11), 196 (40), 195 (19), 194 (57), 91 (49). Found: C, 87.52; H, 7.262; N, 4.87%. Calcd for $C_{21}H_{21}N$: C, 88.05; H, 7.317; N, 4.88%.

(ii) 2-*p*-Tolyl-3-methylacridine (**3b**) (210 mg, 70%), mp 143 °C (methanol); MS *m/z* (rel intensity) 283.3 (M^+, 100), 282.3 (18.2), 281.3 (5), 280.3 (4), 279.3 (1.6), 254.2 (2.4), 141.2 (29), 140.2 (2.7), 127.1 (19). Found: C, 89.049; H, 6.06; N, 4.8%. Calcd for $C_{21}H_{17}N$: C, 89.049; H, 6.007; N, 4.94%. IR spectrum shows no absorptions in the NH or carbonyl regions.

(iii) Unreacted **2b** (80 mg).

Pyrolysis of 6-Chloro-4,4-diphenyl-1,4-dihydro-2*H*-3,1-benzoxazin-2-one (2f): From the pyrolysis of the captioned compound **2f** (400 mg), were obtained 2-chloro-9-phenylacridine (**3f**) (210 mg, 64.5%), mp 133 °C (methanol); MS *m/z*

(rel intensity) 289.3 (M^+, 100), 288.3 (18.7), 254.3 (52), 253.3 (23.2), 252.3 (11.7), 251.3 (10), 227.2 (5), 144.8 (2.6), 127.2 (16.6), 125.8 (20.8). Found : C, 78.78; H, 4.087; N, 4.79%. Calcd for $C_{19}H_{12}ClN$: C, 78.893; H; 4.152; N, 4.847%. Its IR spectrum has no absorptions in the carbonyl or NH regions.

Unreacted **2f** (130 mg) from the column was recovered.

Pyrolysis of 4-Methoxy-4-phenyl-1,4-dihydro-2*H*-3,1-benzoxazin-2-one (2g): The above compound **2g** (500 mg) when pyrolyzed at 235 °C yielded.

(i) 6,12-Diphenyldibenzo[*b,f*][1,5]diazocine (**7**) (30 mg, 8.5%), mp 188 °C (methanol). Lit,[3] 186—188 °C, found to be identical with an authentic sample by mixed mp and superimposable IR spectrum.

(ii) 2-Aminobenzophenone (**6**) (190 mg, 49%), mp and mixed mp 106 °C (methanol).

(iii) Unreacted **2g** (75 mg).

Pyrolysis of 2a in Presence of Hydroquinone or Sodium Borohydride: The compound **2a** (300 mg, 0.001 mol) was pyrolyzed in presence of hydroquinone (1.1 g, 0.01 mol) at 235 °C for 3 h. After usual work up, were isolated **4a** (75 mg, 27%), **3a** (110 mg, 43%) and unreacted **2a** (50 mg).

Similar result wes obtained when the reaction is carried out in the presence of sodium borohydride also.

Pyrolysis of 2a in Presence of Methyl Anthranilate: A mixture of **2a** (300 mg, 0.001 mol) and methyl anthranilate (1.51 g, 0.01 mol) was heated for 3 h at 235 °C. After usual workup, was obtained **3a** (120 mg, 47%). **4a** was observed on TLC but could not be separated from the unreacted methyl anthranilate.

Photochemical Reaction of 4,4-Diphenyl-1,4-dihydro-2*H*-3,1-benzoxazin-2-one (2a): A solution of **2a** (300 mg) in methanol (400 ml) was irradiated with 400 W ultraviolet lamp in s Hanovia photochemical reactor, with Pyrex filter for 6 h. After one hour, the color of the solution changed to yellow. However, TLC at the end of 6 h showed no change, it was further irradiated for additional 18 h. Even then, no change was observed and the parent compound **2a** (275 mg, 90%) was recovered back after removal of solvent by distillation.

Similar observation of stability to UV irradiation was observed in the case of **2g** also.

We thank Dr. M. Bapuji for his help in recording the mass spectra at the Technical University, West Berlin and Professor P. K. Jena, Director, Reginal Research Laboratory, Bhubaneswar for awarding a fellowship to BPA.

Conformations of Some Monosubstituted *N*-Benzylideneanilines

Lalit N. PATNAIK* and Sarojini DAS
Department of Chemistry, Ravenshaw College, Cuttack 753003, India
(Received August 23, 1986)

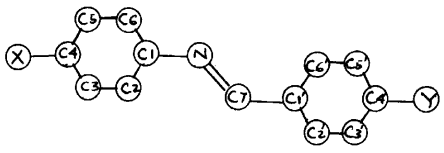
Theoretical computations , using quantum mechanical PCILO method, have been carried out on the conformations of four monosubstituted *N*-benzylideneanilines—*N*-benzylidene-4-nitroaniline (**1a**), *N*-benzylidene-4-dimethylaminoaniline, *N*-(4-nitrobenzylidene)aniline, and *N*-(4-dimethylaminobenzylidene)-aniline. The aniline ring is found to be most twisted (60°) in **1a**, while in all other cases , the twist angle is 30°. The results have been compared with earlier experimental findings and rationalized in terms of two factors contributing to nonplanarity , namely , the overlapping of bridge nitrogen lone pair with the π-system of the aniline ring and a steric interaction between the azomethine hydrogen and one of the ortho hydrogens in the aniline ring.

Experimental and theoretical studies on the molecular conformation of *N*-benzylideneanilines have been reported by a number of workers.[1-5] These studies were initially meant to account for the marked dissimilarity in the electronic absorption spectra of *N*-benzylideneanilines (**BA**) and the isoelectronic molecules stilbene (**S**) and azobenzene (**AB**). It is now generally agreed that the difference arises on account of nonplanar conformation of *N*-benzylideneaniline in contrast to the nearly planar structure of azobenzene and stilbene.

We have reported earlier the results of theoretical (perturbative configuration interaction over localized orbitals, PCILO) computations on the conformation of *N*-(4-dimethylaminobenzylidene)-4-nitroaniline (**1e**), *N*-(4-nitrobenzylidene)-4-dimethylaminoaniline (**1f**), and the corresponding stilbene (**2**) and azobenzene (**3**) derivatives.[6] The computed conformations were rationalized in terms of two factors that facilitate the nonplanar structure: i) An interaction of the nitrogen lone pair and the aromatic system (CT-2)[7] and ii) repulsion between the hydrogen in -CH=N- and one of the ortho hydrogens of the aniling ring, which is released by the twisting of the *N*-phenyl bond. On the other hand there could also be intramolecular charge transfer between the substituents (CT-1). Smaller the twist angle, larger is the contribution of CT-1.[7]

Recently, Akaba et al. have reported the results of their NMR (Proton and ^{13}C) studies on mono- and di-(in the two aromatic rings) substituted *N*-benzylideneanilines.[4,5] The nonadditivity of substituent effect observed for **1** (X=NMe_2) and **1** (Y=NO_2) is interpreted in terms of substituent-substituent interactions (synonimous with CT-1, described earlier) accompanied by conformational changes with substituents in these *N*-benzylideneanilines. It was found that for *N*-benzylideneanilines carrying the variable substituent X on the anilinobenzene ring, the azomethine protons undergo upfield shifts with increasing electron-withdrawing property of X, whereas those for *N*-benzylideneanilines carrying the variable substituent Y on the benzylidene benzene ring exhibited the expected low field shifts with increasing electron-withdrawing property of Y. This anomalous upfield shift of the azomethine proton has been attributed to the increase in the twist angle of the aniline ring from the molecular plane containing -C=N- bond.

The theoretical and experimental facts accumulated so far indicate that the substitution in the rings is an important factor in determining the twist angles Φ and θ. Most spectroscopists, however, seem to emphasize that the origin of nonplanarity can be attributed to the



1a: X=NO_2; Y=H
1b: X=NMe_2; Y=H
1c: X=H; Y=NO_2

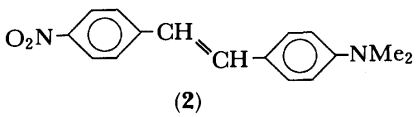
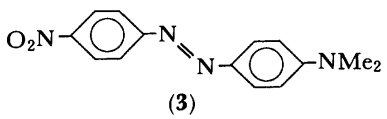
(**AB**)



(**2**)



(**3**)

delocalization of the azomethine lone pair. We report here the theoretical computations of the conformations of four monosubstituted *N*-benzylideneanilines (**1a—d**). A preliminary communication of this work was made earlier[6] as corroborating evidence in favour of our contention that *N*-benzylideneaniline conformations depend both, on the delocalization of the bridge nitrogen lone pair and ortho hydrogen interactions. The present paper deals with a detailed report on the conformational energetics of these molecules and a comparison of the computed results with earlier findings that illustrates an interesting interplay between theory and experiment.

Procedure

Among the more recently developed theoretical methods for all-valence electrons, PCILO is extensively used in conformational studies, because of its proven success with quite diverse types of molecules.[8-14] This method was therefore chosen for present work. It may, however, be mentioned that the PCILO method requires the choice of definite pattern of localized chemical bonds. The investigation under report deals with molecules involving delocalized bonds. Difficulties, that may arise in the calculations on such molecules within the PCILO framework have been discussed in some detail in our earlier communications.[6,15]

The torsion angles have been indicated in the structures **1** and are defined as

$$\Phi = C_2\text{-}C_1\text{-}N\text{-}C_7$$
$$\theta = N\text{-}C_7\text{-}C_{1'}\text{-}C_{2'}$$

the clockwise direction being positive. The cis and trans dihedral angles have been taken as 0 and 180°, respectively.

Since it is considered that the theoretical equilibrium geometry in the gas phase is closer to the standard geometry rather than X-ray values, we have adopted the standard geometries from People and Beveridge.[16] All bond angles involving sp^2 and sp^3 hybrid orbitals, have been taken as 120 and 109.47°, respectively.

The PCILO energies have been computed as a function of Φ and θ at 30° intervals with preselected values of the other geometrical parameter.

Results and Discussion

***N*-Benzylidene-4-nitroaniline (1a):** There are four reports on the conformation of **1a**. Skrabal and collaborators[17] from a comparison of its electronic absorption spectra with *N*-benzylideneaniline, have proposed that the twist angle of the aniline ring (Φ) should be of the same order as that in case of *N*-benzylideneaniline, which is 55°. Theoretical calculations (CNDO/s) and UV spectral studies by Akaba et al. indicate Φ=70—85° and that the twist of the aniline ring in soln and gas phase is more than *N*-benzylideneaniline itself.[1] This contention was further confirmed from the photoelectron spectra.[2] From NMR measurements on substituted *N*-benzylideneanilines, it was proposed that the introduction of the electron-withdrawing nitro group at the 4-position of the aniline ring enhances the delocalization of nitrogen (of -N=CH-) lone pair electrons into the ring that leads to an increase in the value of Φ in solution which in turn changes the ring current effect by the aniline ring exerted on HC (7) resulting in an anomalous upfield shift.[5]

Results of the present computations show that the aniline ring in **1a** is twisted by 60° in either directions. The rotational energy barrier with respect to the planar conformation is 1.96 kcal mol^{-1} (1 cal=4.184J). It is seen from the results described in Table 1, Φ=30 to 90° through 60°, represents low energy regions indicating that the molecule has a good deal of conformational flexibility in this region. This situation is sim-

Table 1. Preferred Conformations of Monosubstituted *N*-Benzylideneanilines

Molecule	Energy of the planar conformation	Global minimum		Low-energy regions		
	kcal mol^{-1}	Φ/deg	θ/deg	Φ/deg	θ/deg	Energy kcal mol^{-1}
1a		60	0	30	0	0.28
	1.96	−60	0	−30	0	0.28
				90	0	0.53
				−90	0	0.53
1b	1.53	30	0	60	0	0.82
		−30	0	−60	0	0.82
1c	1.51	30	0	60	0	0.06
		−30	0	−60	0	0.06
				90	0	0.78
				−90	0	0.78
1d	1.54	30	0	60	0	0.16
		−30	0	−60	0	0.16

ilar to the value of Φ=70—85°, proposed by Akaba et al.[1] PCILO calculations on *N*-benzylideneaniline itself give value of 36° of Φ.[12] Thus, it is seen that theoretical computations and spectral measurements (UV, PES, and NMR) lead to the same conclusion that the aniline ring in **1a** is more twisted than *N*-benzylideneaniline.

***N*-Benzylidene-4-dimethylaminoaniline (1b)**: UV absorption spectra by Skrabal et al.[17] reveal only a small torsion angle for the aniline ring in **1b**. Although the NMR work is not very explicit about the conformational state of this particular molecule, it appears by implication that two opposite factors will operate here (a) in the absence of any electron-attracting substituent at the 4-position on the benzylidene ring, the through-conjugative interaction is obviously impaired leading to less planarity and (b) on the other hand, presence of the electron-donating dimethylamino group would lead to a smaller twist angle, Φ.

The present computational results indicate the aniline ring to be twisted out of plane by ±30°. This conformation is of 1.53 kcal mol^{-1} higher energy than the planar conformation. The low energy region is confined to ±60° with an energy barrier of 0.82 kcal mol^{-1}. These results clearly indicate that there must, at least, be one more factor contributing to nonplanarity, besides the delocalization of the nitrogen lone pair. As described in our earlier work,[6] we identify the factor as the interaction between HC(2) and HC(7).

***N*-(4-Nitrobenzylidene)aniline (1c)**: For **1c**, a torsion angle similar to BA is predicted from UV results,[17] which means $\Phi\approx$55°. HMO calculations by Minkin[18] give Φ=44°. We find the value of Φ=±30° from present calculations. The energy barrier with respect to the planar structure is 1.51 kcal mol^{-1}. However, it is seen from Table 1 that the region Φ=±60° is only of 0.06 kcal mol^{-1} higher energy. Since an energy barrier of this magnitude can easily be overcome in the solution or solid state, it may be concluded that the experimental (UV) and the theoretical conformations lead to the same result.

***N*-(4-Dimethylaminobenzylidene)aniline (1d)**: From the UV spectral study, **1d** is found to be more or less planar. The results are, however, not unambiguous. The present calculation shows that the aniline ring is twisted out of plane by ±30° with a rotational energy barrier of 1.54 kcal mol^{-1}. The low energy region is indicated by Φ=±60°, which is only of 0.16 kcal mol^{-1} higher energy.

It can be seen from Table 1 that the results with respect to **1b—d** are strikingly similar. This implies that perhaps there is a common mechanism that determines the conformational characteristics of these molecules and it appears most rational that this mechanism is the interaction between the ortho hydrogen HC(2) and HC(7), since in all the three cases, CT 1 (π-electron delocalization between the substituents) and CT 2 (delocalization of the nitrogen lone pair to the substituent in the aniline ring) will either be extremely weak or altogether absent. This hypothesis is supported by the results obtained with respect to **Ia**. In this molecule there can be a substantial overlapping of the *N*-lone pair with the aniline ring bearing the strongly electron-withdrawing NO_2 group (CT 2) which reinforces the nonplanar structure due to ortho hydrogen interaction leading to a greater twist angle Φ (=60°).

The authors are grateful to Dr. Anil Saran of the Tata Institute of Fundamental Research, Bombay, for many helpful discussions and to the Department of Atomic Energy, Government of India for the award of a research grant for computation and fellowship to one of them (S.D.).

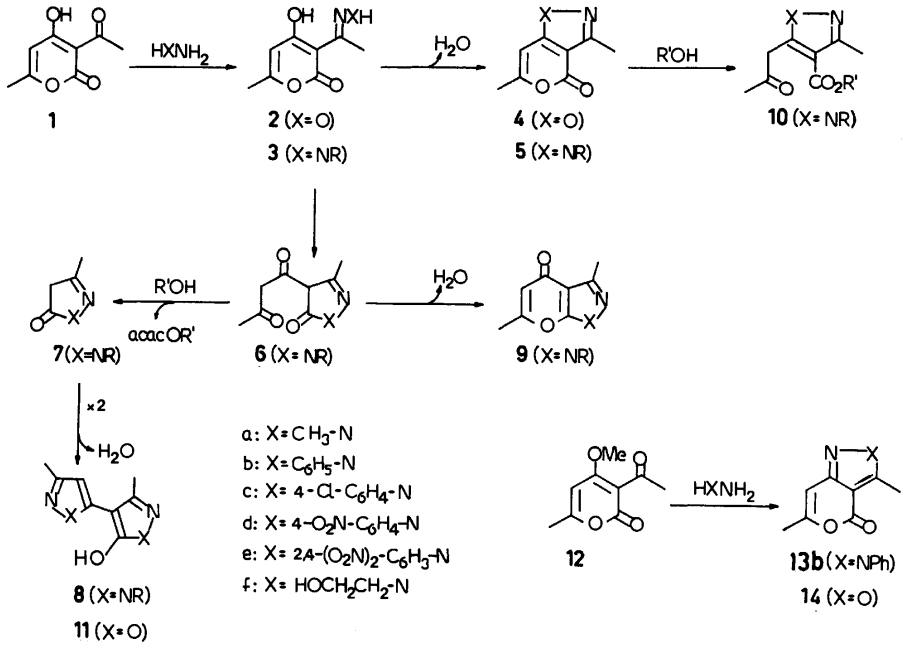
Synthesis of Pyrano[4,3-*c*]pyrazol-4(1*H*)-ones and -4(2*H*)-ones from Dehydroacetic Acid. Homo- and Heteronuclear Selective NOE Measurements for Unambiguous Structure Assignment

Albert CANTOS, Pedro de MARCH, Marcial MORENO-MAÑAS,* Anna PLA, Francisco SANCHEZ-FERRANDO,* and Albert VIRGILI
Departament de Química. Universitat Autnoma de Barcelona, Campus de Bellaterra, 08193 Barcelona, Spain
(Received October 20, 1986)

Cyclization of dehydroacetic acid *N*-substituted hydrazones furnished 1-substituted 3,6-dimethylpyrano-[4,3-*c*]pyrazol-4(1*H*)-ones, together with varying amounts of *N*,*N*'-disubstituted 5-hydroxy-3-methyl-4-(3-methyl-1*H*-pyrazol-5-yl)-1*H*-pyrazoles. The same pyranopyrazolones were obtained regioselectively without side reactions from *N*-alkylhydrazines and 4-chloro-3-(1-chlorovinyl)-6-methyl-2*H*-pyran-2-one, ("Dehydroacetchlorid"), while *N*-arylhydrazines gave the 2-aryl-3,6-dimethylpyrano[4,3-*c*]pyrazol-4(2*H*)-ones. NMR NOE methods, including long-range selective heteronuclear $^{13}C\{^1H\}$ NOE enhancement measurements, allowed unambiguous distinction between -4(1*H*)-ones and -4(2*H*)-ones.

The reactions of dehydroacetic acid **1** and derivatives with hydroxylamine or hydrazines are a rich source of several types of heterocycles[1] (Scheme 1). Thus, the initially formed oxime **2** or hydrazones **3** have been converted into 3,6-dimethyl-4*H*-pyrano[3,4-*d*]isoxazol-4-one (**4**)[2] or into pyrano[4,3-*c*]pyrazol-4(1*H*)-ones (**5**),[3] 4-acetoacetyl-2,4-dihydro-5-methyl-3*H*-pyrazol-3-ones (**6**),[4] 2,4-dihydro-5-methyl-3*H*-pyrazol-3-ones (**7**)[5] or their formal condensation dimers 5-hydroxy-3-methyl-4-(3-methyl-1*H*-pyrazol-5-yl)-1*H*-pyrazoles (**8**),[3,4] pyrano[2,3-*c*]pyrazol-4(1*H*)-ones (**9**),[4] and 5-(2-oxopropyl)-1*H*-pyrazole-4-carboxylates (**10**).[3b,c] 4-(5-Isoxazolyl)isoxazole (**11**) has also been reported[6] from reaction of **1** with hydroxylamine. Even the formation of 5-anilino-1,5-dihydro-3,6-dimethyl-1-phenyl-4*H*-pyrazolo[4,3-*c*]pyridin-4-one from **1** and phenylhydrazine was once claimed,[7] although this reaction was later shown[4] to afford only **8b**. Depending upon the reaction conditions, most compounds **5**—**10** can be obtained directly from **1** and hydrazines, usually as mixtures with the corresponding hydrazones **3**.[3c] Furthermore, reaction of the methyl ether of dehydroacetic acid (**12**) with phenylhydrazine or hydroxylamine gives 3,6-dimethyl-2-phenylpyrano[4,3-*c*]pyrazol-4(2*H*)-one (**13b**)[3c,8] or 3,6-dimethyl-4*H*-pyrano[4,3-*c*]isoxazol-4-one (**14**)[3c,8] while Oppenheim's "Dehydroacetchlorid,"[9] of hitherto-unknown constitution, has long been known[9b] to react with phenylhydrazine giving an as yet unidentified isomer, mp 203 °C, of **5b**.

Clearly, some sort of control on regioselectivity is desirable for this manifold of reactions and in general in pyrazole and isoxazole syntheses. Thus, in the related case of β-substituted enones, the treatment with hydroxylamine under carefully controlled conditions has been reported to afford regioselectively the isomeric 3,5-disubstituted isoxazoles through pH control of the more nucleophilic center in hydroxylamine.[10a] Also, a regioselective synthesis of 3,5-disubstituted



Scheme 1.

isoxazoles based on the reactivity of 3-methylthio-2-buten-1-ones has been recently reported.[10b]

We herein report on: i) The synthesis of several new hydrazones **3**, their cyclization to pyranopyrazolones **5**, and their conversion to pyrazolylpyrazoles **8**; ii) the identification of Oppenheim's "Dehydroacetchlorid" as 4-chloro-3-(1-chlorovinyl)-6-methyl-2*H*-pyran-2-one (**15**) and its regioselective conversion into pyranopyrazolones **5** or **13**; iii) an NMR study of some of these compounds, mainly based on NOE measurements, which allows unambiguous structure assignment between pairs of possible isomers.[11]

Results and Discussion

Reaction of **1** with hydrazines in methanol yielded the corresponding hydrazones **3a—e** in fair to good yields (Table 1). The configuration of the C=N double bond was not determined. Nevertheless, hydrazones **3a—c** were cyclized to the corresponding pyrano[4,3-*c*]pyrazol-4(1*H*)-ones **5a—c** (Table 2), although the very insoluble hydrazones **3d—e** could not be cyclized, due to the very low nucleophilicity of the aryl-bound nitrogen atom.

Formation of pyrazolylpyrazole **8c** upon treatment of hydrazone **3c** with aqueous HCl in DME under reflux has precedent in the known[3a] formation of **8b**, together with **5b**, when **1** is reacted with two equivalents of phenylhydrazine hydrochloride. Thus, a possible mechanism through **6c** can be envisaged (Scheme 2, path b). However, we have been unable to find the 3,4′-bipyrazoles **16**. (Scheme 2, path a). Therefore, an alternative mechanism through pyrazolone **7c** cannot be excluded, since its formation from **6c** involves a simple retro-Claisen condensation and the closely related compound **7b** (Ar=C_6H_5) is known[13] to yield **8b** upon heating.

In the present work, reaction or **1** with two equivalents of either methylhydrazine or (2-hydroxyethyl)-hydrazine also gave the corresponding pyrazolylpyrazoles **8a** and **8f** (Table 3).

NMR experiments, summarized below, showed convincingly, that the product from the first reaction of Table 3 was indeed **8a**, rather than **16a**. The 80 MHz ^{1}H NMR spectrum of **8a** in $CDCl_3$ showed the presence of several unresolved long range couplings, which were uncovered by resolution enhancement via gaussian multiplication and zero-filling of the FID prior to Fourier transformation.[14] In this way, the assignments shown in Table 4 were made. Double irradiation experiments, also shown in Table 4, confirmed these assignments.

In order to complete the characterization of **8a**, a homonuclear ^{1}H{^{1}H} NOE experiment was performed, using the NOE difference technique.[15] Irradiation of the $N_{1'}$-methyl at δ 3.51 gave about 1% increase in the signals of the C-methyl groups, a result which rules out constitution **16a**, for which a much more significant (≃15%) increase of the adjacent C-methyl group, at δ 2.06, was expected. The only clear increase from this NOE difference experiment was a 10% enhancement of the 5-hydroxyl proton, at δ 8.5—9.5, thus showing that the conformation of **8a** is *seqcis*, and not *seqtrans* (Scheme 3), possibly due to steric hindrance between both methyl groups in the latter.

A similar conclusion was drawn for compound **8c**,

Table 1. Preparation of Oxime **2** and Substituted Hydrazones **3** of Dehydroacetic Acid[a]

Product	X	Molar ratio $HXNH_2$/**1**	Condition	Yield %	Mp θ_m/°C
2	O	2.1[b]	R.t., 17 h	76	171—173[f]
3a	CH_3N	1.1[c]	R.t., 25 h[d]	50[e]	100—102

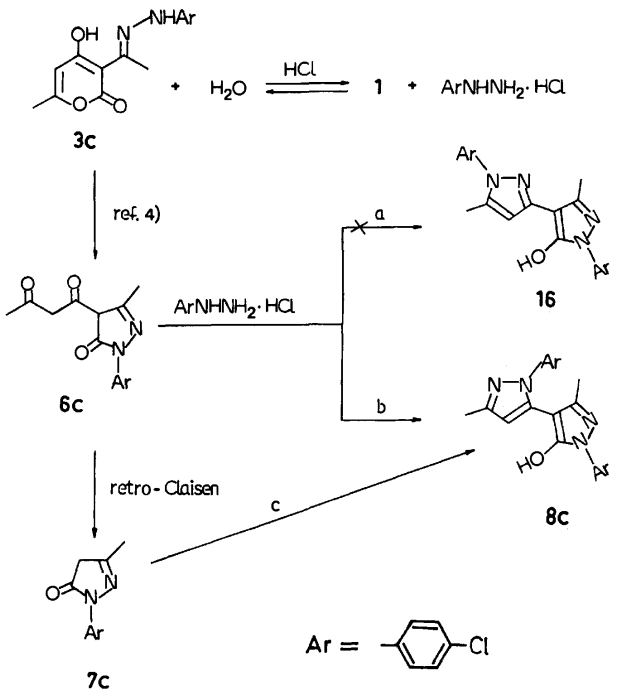
3e	2,4-$(NO_2)_2C_6H_3N$	1.2[c]	Refl., 21 h	35	228—231

a) A 0.1 M (1 M=1 mol dm^{-3}) solution of **1** in MeOH was used, unless otherwise stated. b) A mixture of $HXNH_2$·HCl and 10% excess sodium acetate trihydrate was used. c) Free $HXNH_2$ was used. d) Solvent: DME. e) Pyrazolylpyrazole **8a** was detected in the mother liquor. f) Lit, 171—173°C (Ref. 6). g) Lit, 211—212°C (Ref. 12).

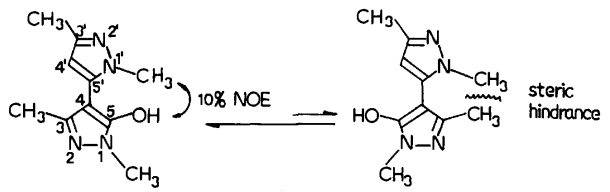
Table 2. Cyclization of Hydrazones **3**

Starting material	Reagent	Reaction condition	Product	Yield/%	Mp θ_m/°C
3a	1 equiv 1M HCl	DME, r.t., 23 h	**5a**	73	152—154
3b	Cat. TsOH	Xylene, reflux, 12 h	**5b**[a,b]	33	156—157[d]
3c	1.2 equiv 1M HCl	DME, reflux, 49 h	**5c**[c]	18	220—222

a) Neither Mitsunobu's reagent (EtO_2CN=NCO_2Et/PPh_3) nor $POCl_3$ under reflux achieved the desired increase in the yield of **5b** and/or decrease in by-product **9b**. b) Also obtained was a second product, in 30% yield, identified as 3,6-dimethyl-1-phenylpyrano[2,3-*c*]pyrazol-4(1*H*)-one, **9b**, mp 150°C (lit, 150°C (Ref. 4)). c) Also obtained was pyrazolylpyrazolone **8c**, mp 272—275°C, in 17% yield. See text for characterization. d) Lit, 156—157°C (Ref. 3b).



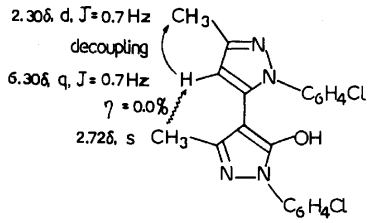
Scheme 2.



Scheme 3.

in which irradiation of the C_3-methyl protons at δ 2.72 gave no significant increase for any of the *p*-chlorophenyl singlets. The results are summarized in Scheme 4.

(2-Hydroxyethyl)hydrazine-derived pyrazolylpyrazole **8f** could not be structurally assigned by NOE measurements. However, the close similarity between its spectra and those of **8a** points to a common structural type for both compounds (See experimental). In particular, the UV spectrum of **8a** shows peaks at 210, 226, and 260 nm, while **8f** shows 207, 226, and 258 nm. Also, the aromatic carbons exhibit very similar chemical shifts in the ^{13}C NMR spectra of both compounds.



Scheme 4.

Identification and Reactions of Oppenheim's "Dehydroacetchlorid": Preparation of 1-Alkyl-3,6-dimethylpyrano[4,3-*c*]pyrazol-4(1*H*)-ones (5), and 2-Aryl-3,6-dimethylpyrano[4,3-*c*]pyrazol-4(2*H*)-ones (13). As early as 1876, Oppenheim and Precht reported[9a] that reaction of **1** with phosphoryl chloride and phosphorus pentachloride gave a compound, $C_8H_6O_2Cl_2$, mp 101 °C, which they named "Dehydroacetchlorid." We have now found, that reaction of **1** with phosphoryl chloride gives 4-chloro-3-(1-chlorovinyl)-6-methyl-2*H*-pyran-2-one (**15**), mp 100 °C, and therefore we propose this constitution for "Dehydroacetchlorid." Constitution **15** is clear from elemental analysis and spectral data (see Experimental). Furthermore, in 1890 Feist reported[9b] that reaction of **15** with phenylhydrazine gave an unidentified compound, mp 203 °C, isomeric with **5b**. We have repeated this reaction and, in our hands, the resulting compound showed mp 209—210 °C. This compound was identical with **13b**, previously obtained by a Russian group[3c,8] from reaction of 3-acetyl-4-methoxy-6-methyl-2*H*-pyran-2-one (**12**) with phenylhydrazine. A comparison between the

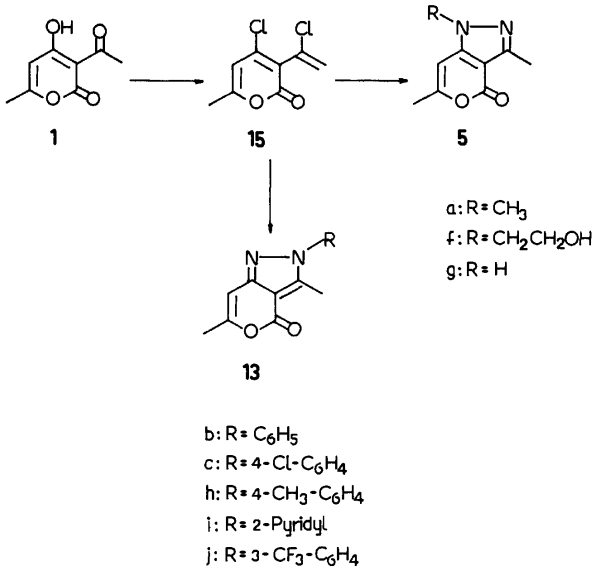
Table 4. The Assigned 80 MHz ^1H NMR Spectrum of **8a**, 50 mM in $CDCl_3$[a]

Proton	δ/ppm	Mult.	J/Hz	Decouplin and NOE
N_1-Me	3.63	q	0.3	
C_3-Me	2.01	q	0.3	Note[b]
C_5-OH	8.5—9.5	broad	—	Note[c]
$N_{1'}$-Me	3.51	q	0.3	
$C_{3'}$-Me	2.06	dq	0.6; 0.3	Note[d,e]
$C_{4'}$-H	5.78	q	0.6	

a) See Scheme 3 for numbering. b) Upon irradiation at δ 3.63 collapses to a singlet. c) Upon low power presaturation at δ 3.51 under NOE difference conditions, this signal shows a 10% enhancement in its integrated area. d) Collapses to a quartet, J=0.3 Hz, when decoupling from $C_{4'}$-H at δ 5.78. e) Collapses to a doublet, J=0.6 Hz, when decoupling from $N_{1'}$-Me at δ 3.51.

reactions of **1**, **12**, and **15** with hydroxylamine or phenylhydrazine is worth here. Thus, **1** gives only products derived from initial attack on the side-chain carbonyl group, and therefore **1** can be converted into the fused heterocycles **4** and **5**, but not into the isomeric **13** and **14**. However, the increased electrophilicity of C-4 in both **12** and **15** opens up the way to **13** and **14** via initial attack of the nucleophile on the now more reactive C-4. This point was confirmed by reaction of **15** with several arylhydrazines (Scheme 5), which furnished the expected 3,6-dimethyl-2-arylpyrano[4,3-*c*]pyrazol-4(2*H*)-ones (**13**) in fair to good yields (Table 5). Furthermore, reaction of **15** with alkylhydrazines gave the 3,6-dimethyl-1-alkylpyrano[4,3-*c*]pyrazol-4(1*H*)-ones (**5**) (Table 5), i.e., the products also expected from initial attack of the now more nucleophilic, substituted nitrogen of the hydrazine on C-4 of the pyrone ring of **15**.



Scheme 5.

Distinguishing between 1-Substituted 5 and 2-Substituted Pyranopyrazoles 13: NOE Measurements. Throughout the present work, we felt the need for a quick and reliable method for ascertaining the constitution of new pyranopyrazolones as **5** or **13** in an unambiguous way. Since the new compounds were crystalline solids, X-ray diffraction analysis was one possibility, but we were seeking for a faster, more versatile method. The new 2-D NMR techniques[16] were also out of question, because usually they require large amounts of sample and long measuring times. Hopefully, homonuclear $^1H\{^1H\}$ NOE measurements[17] particularly in the useful NOE difference mode,[18] are very helpful for the constitutional assignment of simple fused heterocycles.[15] Thus, in 3,6-dimethylpyrano[4,3-*c*]pyrazol-4(1*H*)-ones (**5**), the group bound to N-1 has

Table 5. Reactions of **15** with Hydrazines, $RNHNH_2$

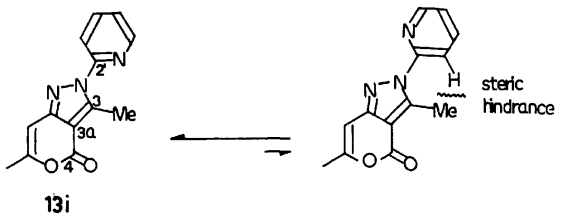
a) Determined on 10 mM solutions in $CDCl_3$, using the NOE difference technique.



Scheme 6.

its protons close to H-7, while in the isomeric -4(2*H*)-ones the N-2 bound group is close to the C-3 methyl group. A series of homonuclear $^1H\{^1H\}$NOE difference experiments, summarized in Table 6, confirmed this expectations, and provided clear-cut proof for structures **5** and **13**. One exception was compound **13i**, for which no homonuclear NOE enhancements were found besides the trivial C_6-Me{H_7}. The lack of NOE on any pyridine proton upon irradiation at the C-3 methyl protons was taken as evidence for conformation *seqtrans*, rather than *seqcis* (Scheme 6).

Finally, proof for constitution **13i** rather than **5i** was obtained by means of the recently reported technique[19,20] of long range, selective heteronuclear $^{13}C\{^1H\}$NOE measurements. Thus, the assigned ^{13}C NMR spectrum of **13i** is given in Table 7. As shown in Scheme 6, the C-3 methyl protons are close to four quaternary carbons, namely C-3, C-3a, and C-4 of the pyranopyrazole nucleus, as well as, to the C-2′ carbon of the pyridine substituent. Therefore, low power preirradiation of the C-3 methyl protons should result in a NOE enhancement of these four quaternary carbons.[19,20]

As shown in Table 7, this was indeed the case. This result, which proves constitution **13i**, rules out the alternative constitution **5i**, in which the pyridine C-2′ carbon atom is too far apart from the C-3 methyl protons to undergo any NOE enhancement.

On the other hand, the doubt between constitutions **5g** or **13g** for the product obtained from reaction of **15** with unsubstituted hydrazine could not be solved by NOE methods. However, its constitution was unambiguously determined as **5g** by comparison of its UV spectrum (215 nm, log ε=4.33 and 255 nm, log ε=3.79) with those of **5a** (218 nm, log ε=4.40 and 258 nm, log ε=4.01) and **5g** (218 nm, log ε=4.38 and 259 nm, log ε=3.80).

Experimental

General. Mp's have been determined on a Kofler block (Reichert, Wien). UV spectra were run in a Perkin-Elmer 550 instrument. IR spectra were measured on a Perkin-Elmer 1310 instrument. 80 MHz ^{1}H and 20 MHz ^{13}C NMR spectra were recorded in the FT mode on a Bruker WP80SY instrument. MS were taken under EI (70 eV) using a Hewlett-Packard 5985-B instrument.

General preparation procedures, yields and melting points are given in Tables 1—3 and 5. Separations were carried out by column chromatography on silica gel Merck 7754. Special NMR procedures have been described in detail elsewhere: Gaussian resolution enhancement-zero filling,[14] measurement of $^1H\{^1H\}$NOEs by the NOE difference technique,[15] assignment of carbon spectra by selective proton decoupling[19] and measurement of long range, selective heteronuclear NOE enhancements.[20]

Dehydroacetic Acid Oxime (2). Prepared according to the described procedure.[6] IR (KBr) 3400—2500, 1660 cm^{-1}; ^{1}H NMR (d_6-DMSO) δ=2.15 (3H, s), 2.35 (3H, s), 4.7—6.2 (1H, broad absorption), 6.05 (1H, s); ^{13}C NMR (d_6-DMSO) δ=13.3, 19.2, 95.1, 102.0, 158.7, 161.9, 163.0, 173.4; MS *m/z* (%) 183 (M^+, 44), 166 (33), 139 (21), 126 (38), 85 (36), 69 (33), 67 (35), 43 (100).

Preparation of Substituted Dehydroacetic Acid Hydrazones 3. The reaction conditions are summarized in Table 1.

Dehydroacetic Acid Methylhydrazone (3a). IR (KBr) 3300, 1690, 1570 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.2 (3H, s), 2.7 (3H, s), 2.8 (3H, s), 5.7 (1H, s); ^{13}C NMR ($CDCl_3$) δ=15.9, 19.5, 38.3, 94.8, 106.6, 162.2, 163.6, 172.2, 182.8; MS *m/z* (%) 196 (M^+, 35), 181 (18), 154 (22), 139 (100), 111 (25), 85 (38), 69 (40), 43 (82). This compound did not give a correct elemen-

4-Chloro-3-(1-chlorovinyl)-6-methyl-2*H*-pyran-2-one (15). A solution of **1** (4.02 g, 24 mmol) in 30 ml of phosphoryl chloride was refluxed for 4.5 h. The cooled mixture was poured very slowly and with stirring over 200 g of ice. This water solution was extracted with chloroform and the organic phase was washed with sodium hydrogenocarbonate. This extract was dried over magnesium sulfate and removal of the solvent left 3.6 g of a black residue. This crude was purified by sublimation at 85 °C/0.2 mmHg (1 mmHg=133.322Pa) affording 1.827 g (33% yield) of a white solid identified as **15**: Mp 100 °C (lit: 101 °C (Ref. 9a)); IR (KBr) 3070, 1700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.2 (3H, s), 5.55 (1H, d, *J*=2 Hz), 5.85 (1H, d, *J*=2 Hz), 6.2 (1H, s); ^{13}C NMR ($CDCl_3$) δ=19.6, 106.5, 121.0, 121.2, 130.0, 149.5, 158.9, 162.1; MS *m/z* (%) 208 (5), 206 (32), 204 (M^+, 46), 178 (20), 176 (33), 171 (24), 169 (72), 143 (32), 141 (100), 137 (3), 135 (21), 133 (33), 77 (25), 63 (53) ,43 (47); Found: C, 46.65; H, 2.98%. Calcd for $C_8H_6Cl_2O_2$: C, 46.87; H, 2.95%.

Financial support from "Comisión Asesora de Investigación Cientifica y Técnica" through project No. 2014/83 and a generous gift of dehydroacetic acid from LONZA A.G. (Basel) are gratefully acknowledged. We also thank generous funding from "Fundación María Francisca de Roviralta", which allowed the purchase of the NMR spectrometer and "Direcció General d'Ensenyament Universitari", Generalitat de Catalunya, for the NMR data system.

Photochemical Reactions of the Natural Furocoumarin, Imperatorin

M. M. Abou-Elzahab,* M. A. Metwally, A. M. Dawidar, M. Abdel-Mogib, and E. A. Abu-Mustafa†
Chemistry Department, Faculty of Science, Mansoura University, Mansoura, A. R. Egypt
†Lab. of Natural Products, National Research Centre, Dokki, Cairo, Egypt
(Received November 17, 1986)

Photochemical behavior of imperatorin was investigated including photolysis and sigmatropic effects in different solvents and photodimerization. The structures of the photoproducts obtained were determined by chemical and spectral methods.

Natural and synthetic coumarins are important due to their biological activities, e.g. photosensitizing effect of xanthotoxin and trimethylpsorolene.[1] Behavior of coumarins and furocoumarins (xanthotoxin only) under irradiation with ultraviolet light has been studied previously.[2-9]

Imperatorin (**1**), known also as ammidin is a natural furocoumarin and occurs in the fruits of *Ammi majus* (Umbelliferea).[10] No previous studies on the photolysis of imperatorin are reported. This paper deals with the behaviour of imperatorin towards:

a) Photolysis and sigmatropic reactions in different solvents. b) Photodimerization.

Results and Discussion

Photolysis and Sigmatropic Reactions in Different Solvents. Irradiation of **1** in different solvents (cf. Experimental) at room temperature resulted in the formation of two furocoumarins (R_f 0.28 and 0.36) in all the tried solvents, but with different yields (Table 1). IR spectrum of the first product, R_f 0.28, $C_{11}H_6O_4$, M^+ 202, showed bands at 1720 and 3340 cm^{-1} characteristics for δ-lactone and associated OH groups (phenolic, from iron(III) chloride test) respectively. It was thought to be xanthotoxol (**2**) from MS (Chart 1). The ^1H NMR of its acetate derivative in $CDCl_3$ solution showed two singlet peaks at δ 2.50 and 7.53 for -OCOC<u>H</u>$_3$ and aromatic proton at C-5 respectively, two doublets at δ 6.35 and 7.76 (J=10 Hz) for two α-pyrone protons, and other two furan protons. The mass spectrum showed molecular ion at m/z 202, and only one mode of fragmentation (Chart 1). Final confirmation was obtained by mixed melting point with an authentic sample (mp and mixed mp 240 °C) and also by its transformation to xanthotoxin, a natural furocoumarin, mp and mixed mp 145 °C (cf. Experimental).

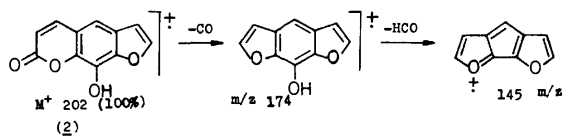

Chart 1.

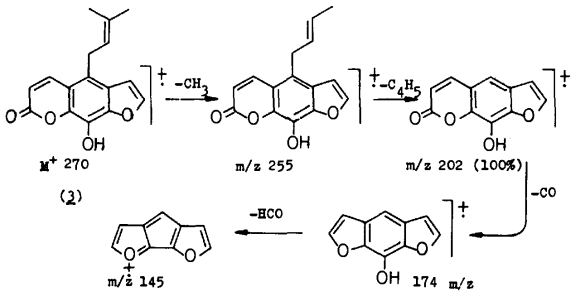

Chart 2.

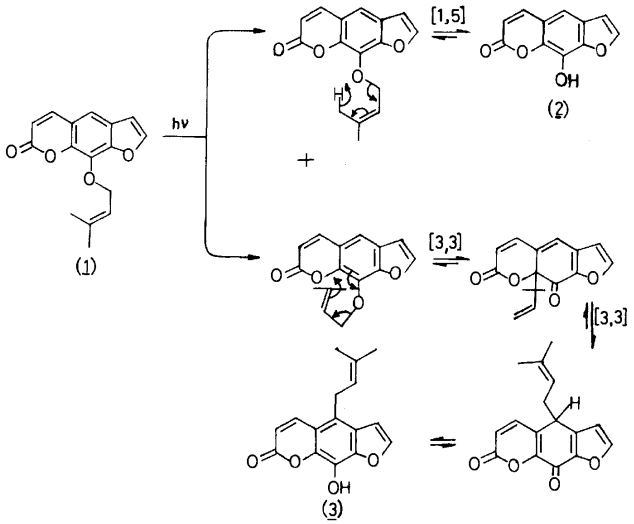
IR spectrum of the second product, R_f 0.36, $C_{16}H_{14}O_4$, M^+ 270, mp 228 °C indicated the presence of a hydroxyl group and δ-lactone. It was thought to be *allo*-imperatorin (**3**) from its fragmentation behavior (Chart 2) in the mass spectrum.

The ^1H NMR spectrum of its acetate derivative supported the above identification as *allo*-imperatorin where it displayed a singlet at δ 2.5 for -OCOC<u>H</u>$_3$. The isoprenyl group attached at C-5 showed signals at δ 4.15 and 4.29 due to C<u>H</u>$_2$, H-9 (both doublet of doublets J=12.5) 4.22 due to H-10 (doublet of doublets J=5), and 2.2 singlet for 2C<u>H</u>$_3$. Final confirmation was achieved by preparing *allo*-imperatorin followed by mixed mp where no depression occurred. (cf. Experimental).

Table 1. Yields with Different Solvents

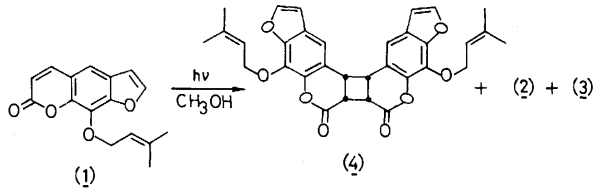
Solvent	Xanthotoxol (**2**)	*allo*-Imperatorin (**3**)	Imperatorin dimer (**4**)
	mg	mg	mg
Benzene	25	16	—
1,4-Dioxane	18	19	—
Tetrahydrofuran	13	16	—
Ethyl acetate	4	4	—
Acetone	26	25	—
Acetonitrile	15	5	—
Dimethyl sulfoxide	46	17	—
Acetic acid	246	23	—
Methanol	73	22	11

The mechanism of photolysis of imperatorin (**1**) to produce these products **2** and **3** may be illustrated as in Scheme 1 where xanthotoxol (**2**) is produced via antrafacial [1,5] hydrogen shift, whereas, *allo*-imperatorin (**3**) is most likely formed through aromatic Claisen rearrangement, where the isoprenyl group underwent one inversion to give an ortho-isomer and another to give the para-isomer via [3,3] sigmatropic rearrangement.



Scheme 1.

Photodimerization Reaction. Imperatorin (**1**) was irradiated in methanolic solution where the dimeric product head-to-head syn (**4**) was formed via [2+2] photo-cycloaddition in addition to xanthotoxol (**2**) and *allo*-imperatorin (**3**).



Formulation of the photo-dimer (**4**) was based on analytical and spectral data. IR spectrum showed a band at 1750 cm^{-1} characteristic of δ-lactone. The mass spectrum showed the expected molecular ion at

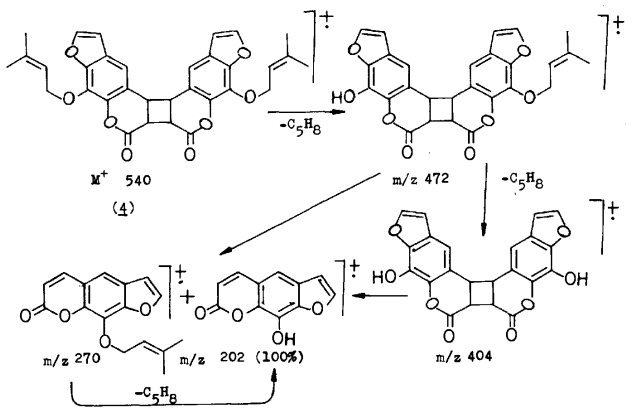


Chart 3.

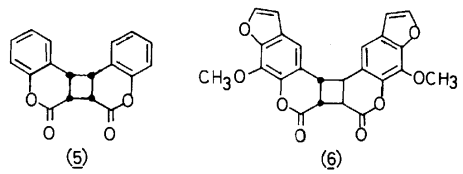
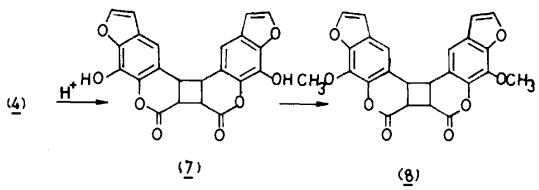
m/z 540, and only one mode of fragmentation (Chart 3).

This result is in agreement with the work of Anet[8] who reported that photo-irradiation of coumarin in ethanol solution produced a dimer **5**, having the head-to-head syn structure. In contrast, Kruch and Farid[7] found that irradiation of xanthotoxin in non-polar solvents led to formation of the dimer **6**, having the head-to-head anti structure.



The weight loss due to the acid hydrolysis of the dimer **4** afforded other support to the structure, where it was found that the calculated value (12.6 mg) is in good agreement with the observed value (12.1 mg). The acid hydrolysis of the dimer **4** gave a gray dimer **7**, containing hydroxyl groups as shown from IR spectrum (3500 cm^{-1}). The dimer **7** was methylated with methyl iodide in the presence of anhydrous potassium carbonate to give the dimer **8**. The IR spectrum showed absence of any OH group.



The difference in melting points and solubilities of xanthotoxin dimer (**8**) and that of Krauch and Farid[7] showed that the configuration of the two dimers is different, i.e. the dimer is not head-to-head anti **8**. The abnormally high melting point of the dimer **8** will not be surprising when we know that the melting point of the head-to-head syn coumarin dimer **5** is 100 °C higher than the head-to-head anti dimer.[11]

Experimental

Imperatorin was supplied by Memphis Chemical Co., Cairo, Egypt. All melting points (°C) are uncorrected and were taken in a Fischer electric melting point apparatus. Infrared spectra were recorded on a Unicam SP 2000 infrared Spectrophotometer using KBr pellet technique. ^1H NMR spectra were obtained in $CDCl_3$ on a Brucker 400 MHz apparatus. Mass spectra were measured on a Varian Mat 711, direct inlet at 70 eV. The photolysis apparatus used is a 500 W medium pressure wide spectrum mercury lamp (Hanovia TQ 718) supported in a water cooled quartz tube.

Irradiation of Imperatorin (1): A solution of imperatorin (**1**) (675 mg, 0.0025 mole) in different solvents (10 ml) (except methanol) (Table 1), was irradiated in the corning glass test tubes which were degassed, sealed in vacuo. The irradiation was carried out without filter at 25—30 °C, for 100 h. The tubes were opened and the solution was evaporated to dryness to give gummy material, which was further separated by

TLC (silica gel, benzene-ethyl acetate 9 : 1) to give xanthotoxol (**2**) (R_f 0.28, mp 240 °C) and *allo*-imperatorin (**3**) (R_f 0.36, mp 228 °C) (cf. Table 1).

Xanthotoxol (2): IR 3340 (OH), 3000 (CH, CH_2 str.), 1720 (δ-lactone), and 1600 (C=C) cm^{-1}. MS *m/z* (rel intensity) 202 (M^+, 100) ($C_{11}H_6O_4$), 174 (48, M-CO), 145 (10, $M-C_2HO_2$), 118 (10), 90 (16), 75 (22), and 61 (52).

***allo*-Imperatorin (3)** IR: 3330 (OH), 3000 (CH_2, CH_3 str.), 1720 (δ-lactone), and 1600 (C=C) cm^{-1}. MS *m/z* (rel intensity) 270 (M^+, 0.6, $C_{16}H_{14}O_4$), 255 (0.8, $M-CH_3$), 202 (100, $M-C_5H_8$), 174 (48, $M-C_6H_8O$), 144 (5, $M-C_7H_9O_2$), 118 (4), 90 (18), 75 (8), and 61 (52).

Acetylation of Xanthotoxol (2): A solution of xanthotoxol (**2**) (0.5 g) in acetic anhydride (10 ml) was refluxed for 2 h. The reaction mixture was diluted with water (10 ml). The solvent was evaporated under reduced pressure to dryness and the residue was washed with toluene, then petroleum ether 40—60 °C, to give a solid material which was recrystallized from ethanol to give *O*-acetylxanthotoxol as pale yellow crystals; mp 175 °C (lit,[12] 175 °C). IR 1750 ($OCOCH_3$), 1720 (δ-lactone), 1630 and 1600 (C=C) cm^{-1}. ^1H NMR δ=2.5 (s, 3H, $OCOCH_3$), 6.35 (d, 1H, H-3, *J*=10 Hz), 7.77 (d, 1H, H-4, *J*=10 Hz), 7.53 (s, 1H, H-5), 6.83 (d, 1H, H-6, *J*=2.5 Hz), and 7.67 (d, 1H, H-7, *J*=2.5 Hz).

Methylation of Xanthotoxol (2): A solution of xanthotoxol (**2**) (0.5 g), methyl iodide (1 ml) in acetone (10 ml) in the presence of potassium carbonate (2 g) as base catalyst was refluxed on water bath for 6 h. Potassium iodide was separated and filtered off. The acetone solution was evaporated under reduced pressure to give xanthotoxin which was recrystallized from ethanol to give colourless crystals; mp 145 °C (lit,[13] 146 °C). IR 3120 (CH_2, CH_3 str.), 1730 (δ-lactone), and 1600 (C=C) cm^{-1}. ^1H NMR δ=4.3 (s, 3H, OCH_3), 6.37 (d, 1H, H-3, *J*=10 Hz), 7.77 (d, 1H, H-4, *J*=10 Hz), 7.34 (s, 1H, H-5), 6.8 (d, 1H, H-6, *J*=2.5 Hz), and 7.69 (d, 1H, H-7, *J*=2.5 Hz). MS *m/z* (rel intensity) 216 (M^+, 100, $C_{12}H_8O_4$), 201 (23, $M-CH_3$), 173 (32, $M-C_2H_3O$), 145 (10, $M-C_3H_3O_2$), 117 (2), 89 (12) and 63 (10).

Acetylation of *allo*-Imperatorin (3): *allo*-Imperatorin (**3**) (0.5 g) was acetylated according to method used for xanthotoxol acetate to give *allo*-imperatorin acetate, colourless crystals, mp 126 °C. (lit,[15] 108 °C) IR 1750 ($OCOCH_3$), 1720 (δ-lactone), 1630, and 1600 (C=C) cm^{-1}. ^1H NMR δ=2.5 (s, 3H, $OCOCH_3$), 6.38 (d, 1H, H-3, *J*=10 Hz), 7.77 (d, 1H, H-4, *J*=10 Hz), 6.83 (d, 1H, H-6, *J*=2.5 Hz), 7.79 (d, 1H, H-7, *J*=2.5 Hz), 4.15 (d, 1H, CH_2, H-9, *J*=12.5 Hz), 4.29 (d, 1H, CH_2, H-9, *J*=12.5 Hz), 4.22 (dd, 1H, H-10, *J*=5 Hz), and 2.2 (s, 6H, $2CH_3$, H-12 and H-13).

Rearrangement of Imperatorin (1) to *allo*-Imperatorin (3): Imperatorin (**1**) (1 g) was fused at 200 °C, for 25 min. under reduced pressure. The melted product changes to solid. The solid product was washed with CH_2Cl_2, and then recrystallized from ethanol to give the colourless crystals of *allo*-imperatorin (**3**); mp 228 °C (lit,[14,15] 228 °C).

Irradiation of Imperatorin (1) in Methanol Solution: Irradiation of imperatorin (**1**) (675 mg, 0.0025 mol) in methanol for 100 h gave a solid material which was washed with hot methanol to give 11 mg of the dimeric product (**4**) (mp above 360 °C). Evaporation of the filtrate afforded a mixture of two compounds. Further separation with TLC (silica gel, benzene-ethyl acetate 9 : 1) afforded xanthotoxol (**2**) (R_f 0.28, mp 240 °C) and *allo*-imperatorin (**3**) (R_f 0.36, mp 228 °C).

Imperatorin Dimer (4): IR: 3000 (CH_2, CH_3 str.), 1750 (δ-lactone), and 1610 (C=C) cm^{-1}. MS *m/z* (rel intensity) 540 (M^+, 3, $C_{32}H_{24}O_8$), 472 (6, $M-C_5H_8$), 404 (0.8, $M-C_{10}H_{16}$), 270 (20, ½M), 202 (100, ½M−C_5H_8), 174 (20, ½M−C_6H_8O), 149 (20), 89 (10), and 69 (20).

Acid Hydrolysis of Imperatorin Dimer (4) into Xanthotoxol Dimer (7); A mixture of imperatorin dimer (**4**) (0.05 g), ethanol (10 ml) and a mixture of concentrated sulfuric acid and ethanol (1.5 ml: 12.5 ml), was refluxed with stirring for 6 h. The initial white precipitate was converted into a gray precipitate (0.0379 g) which was filtered off and washed with ethanol mp>360 °C. IR (Nujol) 3500 (OH), 1750 (α-pyrone) and 1610 (C=C) cm^{-1}.

Methylation of Xanthotoxol Dimer (7) into Xanthotoxin Dimer (8): A mixture of xanthotoxol dimer (**7**) (0.026 g), methyl iodide (1 ml), anhydrous potassium carbonate (2 g) and acetone (10 ml) was refluxed on a water bath for 6 h. The inorganic salt with the insoluble faint brown product were filtered off, washed with diluted hydrochloric acid, distilled water then methanol to give the methylated dimer (**8**), mp>360 °C. IR(Nujole) 3000 (CH_3 str.), 1730 (α-pyrone), and 1600 (C=C) cm^{-1}.

We are indebted to Professor Dr. F. Bohlmann, TU Berlin, West Germany for spectral measurements.

Protection of Functional Groups and Stannylation of Phenylalanine

S. A. METWALLY,*,† H. H. COENEN, and G. STÖCKLIN
Institut für Chemie 1 (Nuklearchemie), Kernforschungsanlage Jülich GmbH, D-5170 Jülich, Federal Republic of Germany
(Received December 8, 1986)

The protection of both amino and carboxylic acid groups in *p*-halogenated phenylalanine was done by using different reagents. The protected amino acid was stannylated by using hexamethyldistannane in the presence of tetrakis(triphenylphosphine)palladium as catalyst.

Substituted especially halogenated aromatic amino acids are generally prepared from appropriate, already substituted aryl derivatives, for example benzaldehydes.[1] Radiohalogenation with short lived isotopes, however, necessitates a fast introduction of the halogen, if possible in the last reaction step. *p*-Fluoro-L-phenylalanine labelled with the positron emitter fluorine-18 ($T_{1/2}$=110 min) was recently suggested as a potential tracer for measuring cerebral protein synthesis in vivo in man using positron emission tomography.[2] The direct electrophilic fluorination of L-phenylalanine leads to *p*-fluorophenylalanine, but only in low yields and the ortho- and meta-product which are also formed are difficult to separate.[2] Fluorodemetallation reactions on suitably metallated phenylalanine derivatives can provide a way to regioselective halogenation.

There are not many examples of complex biomolecules which were labelled by fluorodemetallation reactions.[3] However, a recent systematic study on simple aryltrimethyl compounds of group IVB showed that tin derivatives are most suitable for fluorodemetallation.[4] There are ample precedences in the literature for cleavage of aryl-tin bonds by halogens and interhalogens (I_2, Br_2, Cl_2, ICl, IBr). Given these facts, and the ease with which aromatic substrates can be metallated, and subsequently stannylated,[5,6] it occurred to us that such substances might be ideal substrates for fluorination using elemental fluorine.

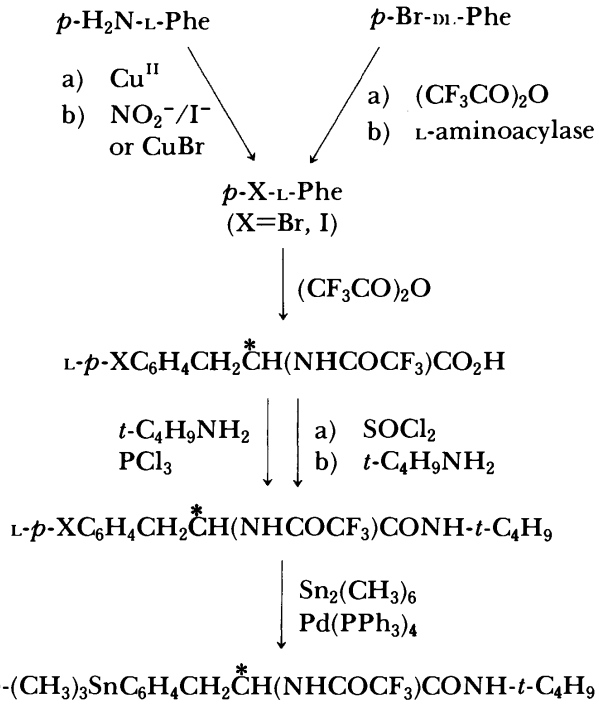
The aim of this work is the preparation of a suitable stannylated phenylalanines to be used for ^{18}F-fluorination. The need of a variety of amino- and carboxyl protecting groups which can be cleaved under relatively mild conditions to the corresponding amino acids is well recognized. The protection groups have to meet the following requirements in our specific case: The condensation and cleavage reactions have to proceed without racemization and the cleavage has to be fast with respect to the half life of fluorine-18. The protecting groups should not hinder the stannylation and fluorination.

Results and Discussion

The need of a *p*-stannylated derivative of phenylalanine for the direct regiospecific radiofluorination stimulated a search for suitable halogenated precursors with appropriate protecting groups for the metallation. In view of the necessary regiospecific labelling with fluorine-18, *p*-iodo- and *p*-bromo-L-phenylalanine were found useful intermediates which were prepared according to Scheme 1.

p-Iodo-L-phenylalanine was prepared from the commercially available L-*p*-aminophenylalanine by chelating the α-amino and the carboxyl group using copper(II) ions to form a stable copper complex[7] in which the aromatic amino group is free to react with appropriate reagents. The latter was diazotized by sodium nitrite-hydrochloric acid mixture to form the corresponding diazotized phenylalanine copper complex. The diazonium salt was transformed into the corresponding *p*-iodo-L-phenylalanine.

A less expensive way is the *N*-acylation of *p*-bromo-DL-phenylalanine with subsequent enzymatic deacylation of the L-enantiomer. The stereochemical purity of the *p*-halo-L-phenylalanines was tested by chiral TLC



L-Phe is a notation for L-phenylalanine.

L indicates the configuration of $\overset{*}{C}$ atom.

Scheme 1.

†On leave from Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt.

plates and chiral HPLC (see Experimental).

We have protected both the two functional groups by different types of blocking moieties: the carboxyl group was blocked by *t*-butylamide[8] or *t*-butyl ester[9] while the protecting groups for the amino function were trifluoroacetyl,[10] acetyl,[11] trityl,[12] and *o*-nitrobenzenesulfenyl groups.[11] Under the reaction conditions used, trifluoroacetyl and acetyl for the amino group and the conversion into *t*-butylamide for the carboxyl group proved to be the best protecting groups with respect to the requirements stated above (cf. Scheme 1). Hydrolysis of the protected amino acids was tested under various conditions, where hydroiodic acid (56% super pure) was found to be very suitable since the reaction was completed in the course of 15 min. Hydrochloric acid at different concentrations and temperatures failed to achieve such hydrolysis. The effect of protection for L-phenylalanine functional groups and also of the succeeding stannylation step on racemisation were tested after hydrolysis to the corresponding free L-phenylalanine. In this way the hydrolysis conditions were also checked for racemisation. It was noted that the amidation with *t*-butyl amine and PCl_3, given as an alternative in Scheme 1, was not as stated in the literature[8] and up to 10% of D-isomer was formed in some preparations.

Stannylation of the protected *p*-halophenylalanine was tried using different routes: a) Grignard reaction: Stannylation via Grignard reaction, using the known technique[13] did not give rise to stannylated products. b) Stannylation using an aryllithium intermediate:[14] The interaction of protected *p*-halophenylalanine with butyllithium followed by the reaction with trimethylstannyl chloride resulted in the formation of *p*-butylphenylalanine derivatives. c) Stannylation with Pd(0) catalysts: The stannylation was successful using hexamethyldistannane and protected *p*-iodo- or *p*-bromophenylalanine in presence of tetrakis(triphenylphosphine)palladium(0) as catalyst. This method was tested according to the wide application of this palladium catalyst in stannylation of simple organic compounds.[15-17] No stannylation for complex molecules such as protected phenylalanine was found in the literature. The features of this reaction can be summarized as follows:

a) *p*-Iodo-DL-phenylalanine (protected at both amino and carboxy group) behaves like simple iodo aromatic compounds[16] and gave a distinctly better yield than the *p*-bromo derivative.

b) The cleavage of hexamethyldistannane by the *p*-chloro-DL-phenylalanine derivative did not proceed even at 135 °C and 35 bar to any significant extent, and more drastic conditions led to decomposition of the catalyst.[18]

c) The completion of the reaction is clearly visualized since the catalyst serves as an indicator; as soon as *p*-halogenated-DL-phenylalanine derivative is consumed, Pd metal precipitates and the brown solution turns colorless.

Ph=phenyl
Phe'=protected phenylalanine

Scheme 2.

It can be assumed that the first step in the stannylation reaction is the dissociation of the catalyst (I) into bis(triphenylphosphine)palladium (II) possibly complexed with the solvent. Oxidative addition of (II) to the protected *p*-iodo- or *p*-bromo-DL-phenylalanine (III) gives iodo- or bromo-DL-phenylalanine bis(triphenylphosphine)palladium (IV). This complex interacts with hexamethyldistannane (V) under substitution of the halogen substituent by the trimethylstannyl group to yield Phe' $Pd(PPh_3)_2SnMe_3$ (VI) which dissociates to the *p*-stannylated phenylalanine derivative (VII) and the bis(triphenylphosphin)palladium (II). The reaction cycle is shown in Scheme 2 and is similar to the selective ketone synthesis from acid chlorides and tetraalkylstannane catalysed by $[PdCl(PhCH_2)(PPh_3)_2]$.[19]

Dichlorobis(triphenylphosphine)palladium also was found to initiate the reaction of hexamethyldistannane (V) with *p*-iodo- or *p*-bromo-DL-phenylalanine derivatives, but the catalyst was not active as Pd(0) complex. This is implied by the fact that with the divalent complex the reaction went to only 20% completion at 115 °C in 20 h. The present system thus may furnish the only convenient method for aromatic amino acid stannylation.

Experimental

Melting points are uncorrected. The ^1H NMR measurements were performed on an 80 MHz Brucker spectrometer (WP 80), using TMS as internal standard and $CDCl_3$ or D_2O as solvents. Mass spectra were recorded at 70 eV on an AEI MS 12 mass spectrometer using a direct insertion technique and a probe temperature ranging between 150 and 200 °C. IR spectra were recorded in KBr on a Perkin-Elmer model 20

spectrophotometer. Hexamethyldistannane was prepared according to published procedures.[20] The substituted phenylalanines and the palladium catalyst were from Aldrich (Steinheim, FRG). Other solvents and reagents were from Merck (Darmstadt, FRG), unless otherwise noted.

Synthesis of *p*-Iodo-L-phenylalanine: *p*-Amino-L-phenylalanine hydrochloride hydrate (0.5 g) was dissolved in water (15 ml) and boiled under reflux for 45 min with an excess (1 g) of black copper oxide. The excess copper oxide was filtered off and the solution was concentrated and cooled to give green crystals of the *p*-amino-L-phenylalanine copper complex (0.45 g). It was dissolved in dilute hydrochloric acid (20 ml) and cooled to 0 °C. Cold soldium nitrite solution (0.06 g in 5 ml of water) was added and the resulting diazonium salt was kept in ice for 30 min. The solution was boiled under reflux with potassium iodide (0.2 g) and the copper complex was decomposed by hydrogen sulphide and the precipitated copper sulphide was removed by filtration. *p*-Iodo-L-phenylalanine was isolated by the addition of sodium acetate and identified by TLC.

Synthesis of *p*-Bromo-L-phenylalanine: *N*-Trifluoroacetyl-*p*-bromo-DL-phenylalanine was prepared as described below and 0.5 g was dissolved in phosphate buffer (pH 7—7.2) and 12 mg $CaCl_2$ and 1 ml aminoacylase solution (*N*-acylamino acid amidohydrolase EC 3.5.1.14, 3.2 mol dm^{-3}, 25 U mg^{-1}) added. The solution was kept at 38 °C for 20 h then acidified (pH 3). The precipitated enzyme was separated by centrifugation. The supernatant is adjusted to pH 5.5—6 and concentrated until the free L-amino acid starts to crystalize. After cooling for several hours the *p*-bromo-L-phenylalanine is filtered off, washed with H_2O and ethanol, and identified by TLC.

Protection of *p*-Halo-DL-phenylalanines: *N*-Trifluoroacetyl-*p*-halo-DL-phenylalanine. The following is a representative and modified procedure to that known in the literature.[11] Dry *p*-bromo-DL-phenylalanine (0.96 g) was dissolved in a 10—15 fold amount of dry trifluoroacetic acid (warming if necessary). The solution was cooled in an ice-salt bath to −10 °C. Trifluoroacetic anhydride (1.2 mol) (0.929 g; 0.61 ml) was added gradually in the course of a few minutes. The temperature was increased to 10 °C and left for 30 min. The reaction mixture was dried under vacuum at a maximum temperature of 30 °C using a well cooled receiver. The nonreacted amino acid was removed by dissolving the residue in dry ether followed by filtration and evaporation of ether. The solid was recrystallized from benzene to give colorless needles of *N*-trifluoroacetyl-*p*-bromo-DL-phenylalanine, mp 152 °C yield 1.25g. IR 1680—1730 (-COOH, C=C) 3100 cm^{-1} (sec. amide), ^1H NMR ($CDCl_3$) δ=7.3—7.8 (q, 4 aromatic H); MS M^+: 329 and 331. Calcd for $C_{11}H_9NO_3BrF_3$: C, 38.82; H, 2.64; N, 4.11%. Found: C, 38.85; H, 2.71; N, 4.32%.

***N*-Trifluoroacetyl-*p*-chloro-DL-phenylalanine.** Colorless needles from benzene, mp 114 °C, yield 90%. Found: C, 44.82; H, 3.26; N, 4.64%. Calcd for $C_{11}H_9NO_3F_3Cl$: C, 44.74; H, 3.05; N, 4.74%.

***N*-Trifluoroacetyl-*p*-iodo-DL-phenylalanine.** Colorless needles from benzene, mp 148 °C, yield 83%. Found: C, 34.28; H, 2.64; N, 3.75%. Calcd for $C_{11}H_9NO_3F_3I$: C, 34.10; H, 2.32; N, 3.61%.

***N*-Trifluoroacetyl-*p*-bromo-DL-phenylalanine *t*-Butylamide:** The following are typical general procedures: a) *N*-Trifluoroacetyl-*p*-bromo-DL-phenylalanine (1 g) is dissolved in dry pyridine (10 ml) by warming if necessary. *t*-Butylamine (1.31 ml) is added and the mixture is cooled in an ice bath. Phosphorus trichloride (0.13 ml) in 5 ml dry pyridine is added gradually to the cold reaction mixture. The solution is heated under reflux for 3 h, followed by concentration to one third and poured on ice-cold water. The solid product was filtered, washed with water until pyridine free and dried. It was crystallized from ethanol into colorless needles of *N*-trifluoroacetyl-*p*-bromo-DL-phenylalanine *t*-butylamide, mp 127 °C, yield 0.5 g. b) Alternatively: 25 ml $SOCl_2$ were added to *N*-trifluoroacetyl-*p*-bromo-L-phenylalanine (4.75 g) and kept for 3 h at 40 °C. Subsequently, the excess of $SOCl_2$ was evaporated. The residual acid chloride was dissolved in 30 ml CH_2Cl_2 and *t*-butylamine added dropwise until alkaline reaction (2.2 ml). The CH_2Cl_2 solution was extracted 4 times with water and then dried over Na_2SO_4. After evaporation to dryness the residue was recrystallized from ethanol. Yield 1.4 g, 26%.

***N*-Trifluoroacetyl-*p*-chloro-DL-phenylalanine *t*-Butylamide:** Colorless needles from ethanol mp 132 °C, yield 55%. ^1H NMR ($CDCl_3$) δ=1.17 (s, 9H), 4.25 (d, 2H), 5.25 (t, 1H), 7.37—7.75 (q, 4 aromatic H). Found: C, 51.84; H, 4.66; N, 8.12%. Calcd for $C_{15}H_{16}ClN_2O_2F_3$: C, 51.72; H, 4.59; N, 8.04%.

***N*-Trifluoroacetyl-*p*-iodo-L-phenylalanine *t*-Butylamide:** Colorless needles from ethanol mp 129 °C, yield 50%. ^1H NMR ($CDCl_3$) δ=1.15 (s, 9H), 4.25 (d, 2H), 5.31 (t, 1H), 7.35—7.70 (q, 4 aromatic H). Found: C, 34.28; H, 2.68; N, 3.82%. Calcd for $C_{15}H_{16}IN_2O_2$: C, 34.10; H, 2.32; N, 3.61%.

***p*-Halogeno-DL-phenylalanine *t*-Butyl Ester:** The following is a typical procedure: A large amount of concentrated sulfuric acid (about 1 ml per 1 g of amino acid) is added to a suspension of the amino acid in diethylene glycol dimethyl ether (5 to 10 ml per 1 g of amino acid), an equal volume of liquid isobutene (liquified by passing the gaseous isobutene in a wide glass tube immersed in Dry Ice-acetone mixture) was added and the mixture was shaken overnight in a pressure gold-lined steal bottle. The solution was cautiously poured into excess 2 M (1 M=1 mol dm^{-3}) sodium hydroxide and the ester was extracted under vacuum to leave an oil (all of the three *p*-halogenophenylalanines). Addition of dilute hydrochloric acid resulted in the immediate precipitation of the ester hydrochloride. The nonreacted amino acid precipitates soon after extraction from the aqueous layer. The yield was almost quantitative and 5 g of *p*-chloro-DL-phenylalanine, for example, gave 5.9 g of the *t*-butyl ester hydrochloride and 0.7 g of *p*-chlorophenylalanine was isolated from the aqueous layer. Trials to carry the reaction in presence of concentrated sulfuric acid without solvent failed.

***p*-Chloro-DL-phenylalanine *t*-Butyl Ester Hydrochloride:** Colorless flakes from water mp 221 °C (decomp) ^1H NMR (D_2O) δ=1.38 (s, 9H), 4.5 (d, 2H), 5.25 (t, 1H), 7.25—7.8 (q, 4 aromatic H). Found: C, 53.74; H, 6.68; N, 4.88%. Calcd for $C_{13}H_{19}NCl_2O_2$: C, 53.60; H, 6.52; N, 4.81%.

***p*-Bromo-DL-phenylalanine *t*-Butyl Ester Hydrochloride:** Colorless flakes from dil ethanol mp 214 °C (decomp). ^1H NMR (D_2O) δ=1.35 (s, 9H), 4.57 (d, 2H), 5.3 (t, 1H), 7.25—7.75 (q, 4 aromatic H). Found: C, 46.64; H, 5.76; N, 4.22%. Calcd for $C_{13}H_{19}BrClNO_2$; C, 46.42; H, 5.65; N, 4.16%.

***p*-Iodo-DL-phenylalanine *t*-Butyl Ester Hydrochloride:** Colorless flakes from water mp 233 °C (decomp) ^1H NMR (D_2O) δ=1.38 (s, 9H), 4.55 (d, 2H), 5.3 (t, 1H), 7.3—7.8 (q, 4 aromatic H). Found: C, 40.86; H, 5.12; N, 3.78%. Calcd for

$C_{13}H_{19}NClIO_2$: C, 40.73; H, 4.96; N, 3.95%.

***t*-Butyl Esters of *N*-Acetyl-, *N*-Nitrobenzesulfenyl, and *N*-Trityl-*p*-halogeno-DL-phenylalanine**: The following is a general method: Either 0.01 mol of acetyl chloride, *o*-nitrobenzenesulfenyl chloride or trityl bromide was added to a solution of 0.01 mol of *p*-halogeno-DL-phenylalanine *t*-butyl ester hydrochloride in 25 ml of dry chloroform and 2.8 ml of triethylamine. After being left at room temperature for 6 h, the solution was successively washed with water, dilute acetic acid, aqueous potassium hydrogencarbonate solution, and again with water. It was dried over sodium sulfate and evaporated under vacuum to dryness. The crude products were usually crystallized from ethanol, methanol, or ethyl acetate-petroleum ether.

***N*-Acetyl-*p*-chloro-DL-phenylalanine *t*-Butyl Ester**: Colorless needles from toluene, mp 123 °C, yield 47%. ^{1}H NMR ($CDCl_3$) δ=1.38 (s, 9H), 2.1 (s, 3H), 4.87 (d, 2H), 5.18 (t, 1H), 7.25—7.75 (q, 4 aromatic H). Found: C, 60.58; H, 6.82; N, 4.64%. Calcd for $C_{15}H_{20}ClNO_3$: C, 60.6; H, 6.73; N, 4.71%.

***N*-Acetyl-*p*-bromo-DL-phenylalanine *t*-Butyl Ester**. Colorless needles from benzene, mp 138 °C, yield 55%. ^{1}H NMR ($CDCl_3$) δ=1.37 (s, 9H), 2.2 (s, 3H), 4.82 (d, 2H), 5.2 (t, 1H), 7.32—7.75 (q, 4 aromatic H). Found: C, 56.78; H, 6.36; N, 4.48%. Calcd for $C_{15}H_{20}BrNO_3$: C, 56.60; H, 6.28; N, 4.40%.

***N*-Acetyl-*p*-iodo-DL-phenylalanine *t*-Butyl Ester**: Colorless needles from benzene, mp 127 °C, yield 63%. ^{1}H NMR ($CDCl_3$) δ=1.38 (s, 9H), 2.3 (s, 3H), 4.86 (d, 2H), 5.2 (t, 1H), 7.32—7.8 (q, 4 aromatic H). Found: C, 46.52; H, 5.28; N, 3.64%. Calcd for $C_{15}H_{20}NO_3I$: C, 46.27; H, 5.14; N, 3.59%.

Stannylation of *p*-Halo-*N*-acetyl- or *N*-Trifluoroacetyl-L-phenylalanine *t*-Butylamide: The following is a general procedure for the stannylation of protected *p*-halophenylalanines: A mixture of hexamethyldistannane (39 mmol), *p*-bromo- or *p*-iodo-*N*-trifluoro- or *N*-acetyl-L-phenylalanine *t*-butylamide (2.5 mmol), tetrakis(triphenylphosphine)palladium(0) (1.3×10^{-4} mol) and dioxane (50 ml) was heated under reflux for 5 h whereby palladium metal was precipitated as fine black powder. The mixture was cooled and filtered, and the filtrate was evaporated under vacuum to a residue. This was taken up in ether or benzene and the solution was washed several times with water and dried over $MgSO_4$. The solvent was removed to leave the product which was crystallized from benzene.

***N*-Acetyl-*B*-[4-(trimethylstannyl)phenyl]-L-alaine *t*-Butylamide**. White crystals, yield 15—20%. ^{1}H NMR ($CDCl_3$) δ=7.6 (p, 4H, aryl H), 0.34 (s, with Sn satellites, 9H, $SnMe_3$), 1.18 (s, 9H, *t*-butyl H), 2.06 (s, 3H), 2.06 (s, 3H). The mass spectrum showed the expected parent ion at *m/z* 410. Found: C, 52.74; H, 7.54; N, 3.48; Sn, 28.94%. Calcd for $C_{18}H_{30}O_2N_2Sn$: C, 52.68; H, 7.31; N, 3.41; Sn, 28.78%.

***N*-Trifluoroacetyl-*B*-[4-(trimethylstannyl)phenyl]-L-alanine *t*-Butylamide**. White crystals, yield 15—20%. ^{1}H NMR ($CDCl_3$) δ=7.8 (q, 4H, aryl H), 0.32 (s, with Sn satellites, 9H, $SnMe_3$), 1.18 (s, 9H, *t*-butyl H), the mass spectrum indicated the expected parent ion at *m/z* 464. Found: C, 46.64; H, 5.88; N, 3.14; Sn, 25.86%. Calcd for $C_{18}H_{27}O_2NSnF_3$: C, 46.55; H, 5.81; N, 3.01; Sn, 25.43%.

Chromatographich Analysis of Enantiomeric Purity: The enantiomeric purity of all phenylalanine derivatives prepared were checked in form of the free amino acid on chiral TLC plates or by means of chiral HPLC. In the case of protected compounds blocking groups were previously hydrolised. Typically 5 to 10 mg of the compound were heated for 20 min in 2 ml 56% pure HI at 140 °C in a closed reaction vial. The chiral TLC plates from Macherey-Nagel (Düren, FRG) were developed with methanol-H_2O-acetonitrile 50 : 50 : 200 (v/v/v). For chiral HPLC a column from serva (Heidelberg, FRG) (Si-100 Polyol, Chrial Pro Cu, 5 µm, 4×250 mm) was used with a 1 mM $CuSO_4$ solution as eluant and a flow of 4 ml min^{-1}.

The authors thank Mr. M. Wutz for valuable experimental assistance and Dipl. Chem. K. Reisinger for the performance of mass spectra.

The Control of the Particles of Magnetite

Keizo MATSUDA,* Masami SUMIDA, Kazumi FUJITA, and Shunmei MITSUZAWA
Department of Chemistry, Faculty of Science, Tokai University, Kitakaname Hiratsuka-shi 259-12
(Received March 24, 1987)

Synopsis. Fine particles of magnetite were prepared by the hydrolysis of urea.[1] The effects of the amount of urea on the particles were investigated. The expected particles were prepared in the range 0.8 to 2.2 μm in size by controlling the amount of urea. Fine particles of magnetite of 0.8 μm in size were prepared from a solution with R=60 (R=urea/iron(III) mol ratio).

For the synthesis of magnetite by the wet method, there are four methods: (1) The coprecipitation method adding a strong alkalline solution to a solution containing Fe^{2+} and Fe^{3+} ions;[2] (2) the air-oxidation method bubbling air into a suspension solution of green rust;[3] (3) the reaction of iron(III) hydroxide sol and Fe metal;[4] and (4) the method adding the non-ion surface active agent to mixed iron(III) hydroxide sol and Fe metal.[5]

In the first three methods, the obtained particles were ultrafine particles under 0.06 μm and the particles in the latter were 5 μm. It was clear that magnetite was prepared by the hydrolysis of urea from the solution containing Fe^{2+} and Fe^{3+} ions,[1] or from the aqueous suspension of β-FeOOH containing Fe^{2+} ions.[6] The fine particles of the crystalline magnetite were obtained by these methods. The pH of the solution dissolved Fe^{2+}, Fe^{3+}, ions and urea increased with the hydrolysis of urea. It increased rapidly by the hydrolysis of a great amount of urea; then, the particles of obtained magnetite became small. The change of the pH of each solution with various R values and the particle size of magnetite precipitated from each solution were measured. From these results, the relation between the distribution of particle sizes of magnetite and amount of urea (R=6—60) was discussed.

Experimental

Magnetite was synthesized by heating a solution containing urea, iron(II) chloride, and iron(III) chloride at 98 °C. A reaction apparatus, already described,[6] was used. Zero point zero five mol of iron(III) chloride and the prescribed amount of urea (the range of R=6 to 60) were dissolved in 0.3 dm^3 of distilled water; and the solution was transfered into three neck flask of 1 dm^3. Iron(II) chloride of 0.025 mol was dissolved with bubbling N_2 gas in the solution at the rate of 1 $dm^3\,min^{-1}$. The time required to raise the temperature up to 98 °C from temperature was 5 min and the reaction time was measured from the time when up to 98 °C was reached. After the programed reaction time, the products were filtered, washed with a large amount of boiling water until iron(II) ion could not be detected. They were then dried in a vacuum desiccator on P_2O_5 powder and were stored. In measurement of particle size of magnetite, centrifugal particles size analyzer (Shimazu CP-50) were used. Sodium hexametaphosphate (0.3%) was used as disparse medium.

Results and Discussion

The change of the pH of each solution with R=6, 10, 20, and 60 with reaction time are shown in Fig. 1. The rate of the pH rise increased rapidly with an increase in R and the final pH of the solution became high. The rate of the pH rise slowed down at pH 4—5 in the solution with R=6 and 10. These phenomena were not observed in the solutions with R=20 and 60.

On the other hand, the changes of the intensities of X-ray diffraction patterns of the products obtained from the solution with R=6 with reaction time are shown in Fig. 2. From the results of measurements of pH and X-ray diffraction patterns of products, β-FeOOH was produced at pH 1—2 and magnetite was produced at pH 4—5. α-FeOOH was recognized from the solutions with R=6 and 10. Magnetite and α-FeOOH were produced at the same time; after that, α-FeOOH gradually decreased and α-FeOOH was finally transformed into magnetite.[6] α-FeOOH was not observed from the solutions with R=20 and 60. The relation between the intensities of the X-ray diffraction (311) plane of magnetite produced from solutions R=6, 10, and 20 and the reaction time is shown in Fig. 2. Magnetite precipitated rapidly, since the rate of the rise of pH was quick with an increase in R.

The average particle sizes of magnetite produced from the solutions with R=6—60 were determined by a centrifugal particle size analyzer. The relation between the average particle sizes and R is shown in Fig. 3. The average particle sizes of magnetite became small with the increase in R. The average particle sizes

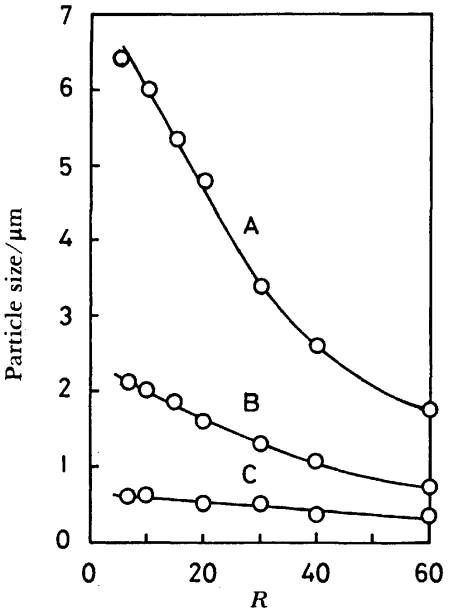

Fig. 3. Plots of average particle size of magnetite and width of distribution of particles. Conditions: A: Upper limit of distribution of particles. B: Average particles. C: Lower limit of distribution of particles.

of magnetite produced from the solutions R=6 and 60 were 2.2 and 0.8 μm, respectively. The widths of the distribution of particle size of magnetite prepared under the various conditions are shown in Fig. 3. The width of distribution was small with the increase of R.

When R value (as R=6) was small, the rate of the rise of pH was slow and the hydrolysis of urea was a rate-determining step in the formation of magnetite, and the pH of the solution was kept at constant of pH about 4.6 during precipitation magnetite. Therefore, nucleation of magnetite took place slightly compared with R=60; the particles precipitated in the first stage were aged for longer periods and the particles became large; however, the particles precipitated in the latter stage were small because of no aging. It was considered that the particle size of β-FeOOH formed in the initial stage of the reaction became large, when R value was small,[7] and that effected the particle size of magnetite. The average size, as a whole, was large. The distribution of particle size was widespread.

When the R value was large, the rate of the rise of pH was rapid and the pH value quickly reached 7—8. Therefore, a high nucleation of magnetite also quickly took place (at a breath). The particles of magnetite produced were small, the width of distribution in particle size narrowed.

It was clear that the R value was large, the average particle size was smaller and that the distribution of particle size was uniformed. When the R value was small, the particles of magnetite precipitated in the initial stage were aged and became large; however, the particles precipitated in the latter stage increased with increasing pH, and were small. Therefore, it was considered that this distribution was not normal; the large particles were a little but the distribution was widespread. When R value was large, the particles precipitated in the first stage were small and amount of particles was much. Therefore, it was considered that the particles were not aged and the particles were small, and that the distribution of particle size was uniformed.

On the ground of these facts, it was elucidated that the magnetite particles of the expected size in the range of 0.8 to 2.2 μm were prepared by hydrolysis of urea easily. The average particle size of 0.8 μm was obtained from the solution with R=60, and the particles were distribution in the range of 0.3—1.75 μm.

Adsorption of Uranium from Nitric Acid Solutions Using Crystalline Hydrous Titanium Dioxide Fibers

Yū KOMATSU,* Yoshinori FUJIKI, and Takayoshi SASAKI
National Institute for Research in Inorganic Materials, 1-1 Namiki, Sakura-mura, Niihari-gun, Ibaraki 305
(Received May 2, 1987)

Synopsis. The adsorption of uranium on an ion exchanger of crystalline hydrous titanium dioxide fibers from nitric acid solutions has been studied. The rate of the adsorption of uranium was much higher than that of alkaline earth metal ions. The adsorption behavior of uranium was well explained by their ion exchange with hydrogen ions in the fibers.

Hydrous titanium dioxides have been mentioned for use in the extraction of uranium from seawater.[1,2] However, conventional hydrous titanium dioxide has been prepared of a fine particle powder and is not very suitable for column operations. Recently, Ohta and Fujiki have reported[3] a new type of hydrous titanium dioxide, crystalline hydrous titanium dioxide fibers, which is a derivative of potassium tetratitanate ($K_2Ti_4O_9$) fibers. The adsorption of alkali metal ions,[4,5] alkaline earth metal ions,[6-9] and bivalent transition metal ions[10] from weakly acidic solutions on the fibers has been studied by the authors. In the present work, the adsorption properties of crystalline hydrous titanium dioxide fibers for uranium are studied in order to obtain further information on the fibers.

Experimental

The titanium dioxide used was of 99.9% purity. Potassium tetratitanate fibers, $K_2Ti_4O_9$, were grown by the slow-cooling method in a K_2MoO_4 flux melt.[3] The fiber of about 10 g was filled in a glass column and converted to the protonated form, $H_2Ti_4O_9 \cdot nH_2O$, by passing 1 mol dm^{-3} hydrochloric acid until detection limit of potassium ion in the effluent by an atomic absorption method(Hitachi Polarized Zeeman Atomic Absorption Spectrophotometer 180-80). The weight of uranyl nitrate was measured as unhydrated state. All the other reagents used were of analytical grade. The measurements of the ion-exchange equilibria were made in a similar way to that in the previous study,[7] except that the fiber and the aqueous solution were agitated 50 times a day by hand.

The distribution coefficient K_d of uranium was obtained by mixing 0.1 g of the fiber with 10 cm^3 of the aqueous solution containing various concentrations of uranium and calculated as:

$$K_d = \frac{\text{(amount of uranium of sorbed per 1 g of the fiber)}}{\text{(amount of uranium per 1 cm}^3\text{ of solution)}} \quad (1)$$

Here, the weight of the solid was measured in the air-dried state.

The pH values of the solutions were controlled with nitric acid and were measured by a TOA pH meter(model HM-20E). The uranium contents in the supernatant solution was determined with a Daini Seikosha Inductively Coupled Plasma Optical Emission Spectrophotometer(model SPS-1100).

Results and Discussion

Figure 1 gives the percent adsorption values for uranium between fibers and aqueous solution as a function of the contact time. Although 10—14 days were required to attain equilibrium for alkaline earth metal ions[7] and bivalent transition metal ions,[10] the equilibrium of uranium was attained within three days.

Crystalline hydrous titanium dioxide fibers have two exchangeable protons in the chemical formula. When alkali metal ions are incorporated in the hydrated fibers, one of these protons may be replaced with an alkali metal ion by ion exchange. An alkaline earth metal ion or a bivalent transition metal ion can replace the two protons in the fiber. As can be seen in Fig. 2, the distribution coefficient of uranium is first-

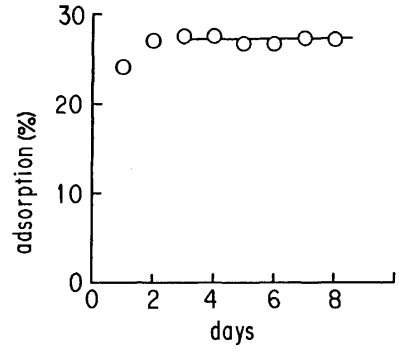

Fig. 1. The percent absorption of the uranium as a function of contact time at 298 K. Ion exchanger: $H_2Ti_4O_9 \cdot nH_2O$ (0.1 g). Aqueous phase: nitric acid containing 1×10^{-4} mol dm^{-3} uranyl nitrate at initial time (10 cm^3).

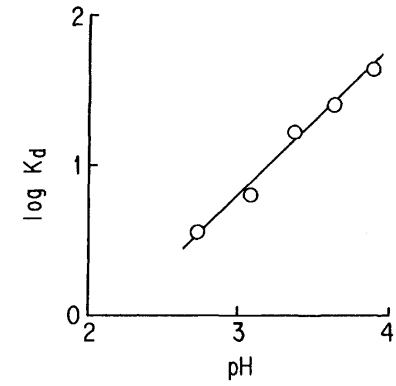

Fig. 2. The distribution coefficient of the uranium as a function of pH in the aqueous solution at 298 K. Ion exchanger: $H_2Ti_4O_9 \cdot nH_2O$ (0.1 g). Aqueous phase: nitric acid containing 1×10^{-4} mol dm^{-3} uranyl nitrate at initial time (10 cm^3).

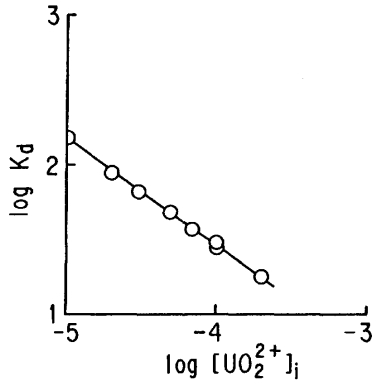

Fig. 3. The distribution coefficient of the uranium as a function of initial uranium concentration in the aqueous phase at 298 K. Ion exchanger: $H_2Ti_4O_9 \cdot nH_2O$ (0.1 g). Aqueous phase: uranyl nitrate solution of various concentrations (10 cm^3).

order with respect to pH value under the substantially constant concentration of the hydrogen ion in the solid. Furthermore, the rate of ion-exchange reaction for uranium is as fast as that for alkali metal ions.[5] These facts may indicate that uranium acts as a univalent metal complex ion on adsorption. The two kinds of univalent uranium complex ions exist in the solution as $[UO_2NO_3]^+$ [11] or $[UO_2OH]^+$.[12] However, since the stability constant for $[UO_2NO_3]^+$($\log K_{(UO_2NO_3^+)} = -0.3$)[11] is extremely larger than that for $[UO_2OH]^+$ ($\log K_{(UO_2OH^+)} = -5.0$)[12] in the aqueous solution, the adsorption reaction of uranium in this system can be written as

$$m[UO_2NO_3]^+ (aq) + H_2Ti_4O_9 \cdot nH_2O (s) \longrightarrow [UO_2NO_3]_mH_{(2-m)}Ti_4O_9 \cdot nH_2O (s) + mH^+ (aq) \quad (0<m<2), \qquad (2)$$

where the subscripts "aq" and "s" denote the aqueous and solid phase.

Figure 3 gives the log K_d values as a function of the initial uranium concentration in the aqueous solution. The K_d increases with a decrease of the uranium concentration. Accordingly, this result is to be expected for the recovery of uranium in seawater since these ions are contained only about 3 ppb in sea water.

The authors are very grateful to Professor Tatsuya Sekine and Mr.Kazuho Inaba of Science University of Tokyo for their valuable discussions during the work, and to Professor Mitsuo Abe of Tokyo Institute of Technology who encouraged us during this work.

The Magnetic Properties of the Copper(II) (Disubstituted Acetate) Adducts with Ammonium Chloride

Shuji EMORI,* Yayoi TOHYAMA, and Yoneichiro MUTO
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840
(Received June 16, 1987)

Synopsis. Various copper(II) (disubstituted acetate) adducts with ammonium chloride have been prepared and characterized by magnetic susceptibility and IR spectroscopy measurements. Factors affecting the magnetic moments of the dinuclear copper(II) alkanoates are discussed.

Previously, we have shown that in a series of dinuclear copper(II) (monosubstituted acetate)s with coordinated chloride ions in the axial positions their room-temperature magnetic moments tend to increase as the pK_a values of their parent carboxylic acids decrease,[1] being approximated well by a linear equation:

$$\mu_{eff} = -0.052(pK_a - 4.56) + 1.31_8. \quad (1)$$

This empirical relationship has been explained in terms of the inductive effect of the carboxylato substituents, and is supported by molecular orbital analyses,[2,3] However, it seems likely that other factors also contribute to the magnetic properties of copper(II) carboxylates, since several modes of interaction concern the spin-exchange coupling in these dinuclear compounds.[3] Actually, the magnetic moments of the copper(II) salts of acetic acid and fluoroacetic acid deviate from the above trend,[1,4] Thus, in order to obtain more information concerning α-substitution effects in dinuclear copper(II) alkanoates, we have studied copper(II) difluoroacetate, dichloroacetate, *dl*-2-chloropropionate, *dl*-2-bromopropionate, and isobutyrate adducts with the following ammonium chlorides: methylammonium, dimethylammonium, trimethylammonium, tetramethylammonium, *N*-ethylpiperidinium, and quinuclidinium chlorides.

All compounds, apart from the isobutyrates, were prepared by leaving the aqueous solution containing appropriate ammonium chloride and copper(II) carboxylate for a few days in a refrigerator at ca. 5 °C.[4] The isobutyrates were prepared by evaporating the ethanolic solutions under reduced pressure at room temperature.

The effective magnetic moments of these compounds (Table 1) were evaluated from the room-temperature magnetic susceptibilities, which were corrected for the diamagnetic contribution of the constituent atoms using Pascal constants,[6] and a value of $N\alpha = 60\times10^{-6}$ emu mol^{-1} (1 emu$=4\pi\times10^{-6}$ m^3) was used throughout the present study. For the dimethylammonium chloride adducts of copper(II) 2-chloropropionate and copper(II) isobutyrate, the temperature dependence of their magnetic susceptibilities was measured in the temperature range of 80—300 K in order to confirm their dinuclear structures. The results agreed well with the Bleaney-Bowers equation,[7] using the following parameters: $g=2.18$ and $2J=-309$ cm^{-1} for the 2-chloropropionate and $g=2.17$ and $2J=-331$ cm^{-1} for the isobutyrate, respectively. The IR spectra of the solid compounds show characteristic bands in the ranges of 1680—1595 and 1465—1460 cm^{-1} connected with symmetric and unsymmetric COO stretching vibrations of the carboxyl groups.[8] The magnetic and IR spectral data indicate that the

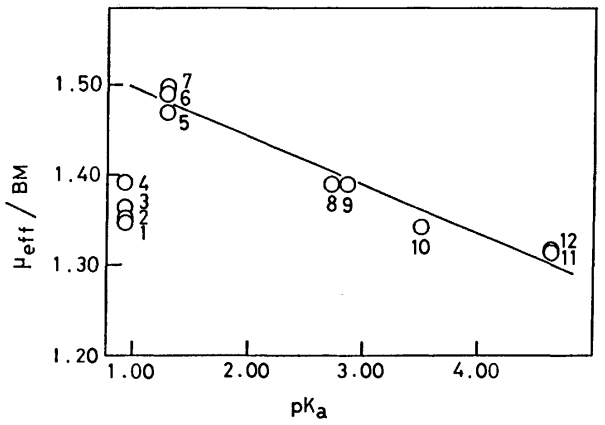

Fig. 1. The magnetic moment at 20°C plotted against the pK_a value of the parent carboxylic acid for the copper(II) salts of disubstituted acetic acids containing coordinated chloride ions in the axial positions; the difluoroacetates (**1—4**), the dichloroacetates (**5—7**), the 2-chloropropionate (**8**), the 2-bromopropionate (**9**), the (3-piperidinio)-formate (**10**),[11] and the isobutyrates (**11**, **12**).

present compounds have a bridged dinuclear structure similar to copper(II) acetate monohydrate,[9,10] The ammonium cations in these compounds may affect the dinuclear structure due to packing effects and the hydrogen bonds; however, no marked difference was observed in the magnetic moments for the respective copper(II) carboxylates.

A plot (Fig. 1) of the room-temperature magnetic moment vs. the pK_a value of the parent alkanoic acid for the present compounds, except difluoroacetates, confirms the correlation between these quantities,[1] with the best least-squares fit yielding

$$\mu_{eff} = -0.052\,(pK_a - 4.56) + 1.30_5. \quad (2)$$

The obtained slope agrees satisfactorily with that for the corresponding series of monosubstituted acetates. The variation of singlet-triplet separation values (e.g. $-2J$=271,[5] 309, and 331 cm^{-1} for the dimethylammonium chloride adducts of copper(II) dichloroacetate, 2-chloropropionate, and isobutyrate compounds, respectively) indicates that the smaller magnetic moment is accompanied by the strong magnetic interaction between copper(II) ions. On the other hand, the slight difference observed between the intercepts for the series of mono- and disubstituted acetates, indicates that some decrease in the magnetic moment (ca. −0.01 BM) is accompanied, probably due to an increase in the steric strain and a decrease of hyperconjugation by the substitution of the methyl group of acetic acid. However, the substantially small magnetic moments of the fluoro- and difluoroacetates can not be explained in terms of the inductive effect of the fluoro substituent. From a study of the ^{19}F NMR in the series of fluoromethanes, Gutowsky and Hoffman have suggested the use of higher energy orbitals in the hybridized orbitals of atoms attached to fluorine atoms.[12] On the other hand, Roberts and Carboni have pointed out that, in the transmission of the electrical influence of the dipolar substituents, the inductive and field effects are of comparable importance.[13] For an explanation of the magnetic moments for the fluoro- and difluoroacetates, it is necessary to consider these effects. The higher magnetic moments of the copper(II) salts of acetic acid[4] may also be explained by the mechanism described above.

Reactions of Tropone Tosylhydrazone Sodium Salt with 2-Pyrone Derivatives: Nucleophilic Addition of 1,2,4,6-Cycloheptatetraene to 2-Pyrone Derivatives

Katsuhiro SAITO* and Hiraku ISHIHARA
Department of Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received June 1, 1987)

Synopsis. The reaction of tropone tosylhydrazone sodium salt with 3- or 5-methoxycarbonyl-2-pyrones afforded benzotropilidene derivatives. These products are considered to be formed via addition reactions of the 2-pyrone derivatives with 1,2,4,6-cycloheptatetraene derived from cycloheptatrienylidene, which is the initial product of the decomposition of tropone tosylhydrazone sodium salt.

It has been reported that upon heating or irradiation tropone tosylhydrazone sodium salt (**1**) generates cycloheptatrienylidene (**2**), which is considered to be a nucleophilic singlet carbene because of a contribution of a 6π-electrons type aromatic structure (**2a**).[1] The possibility of a rearrangement of the carbene (**2**) to an allene, 1,2,4,6-cycloheptatetraene (**3**) has been pointed out by Unch et al.[2] The present authors[3] have documented some experimental examples of the rearrangement and Alder et al.[4] have reported a theoretical investigation of the rearrangement.

Recently, Waali et al. documented that **2** is actually a planar transition state for the interconversion of chiral, nonplanar allenes (**3**), which could have nucleophilicity because the strained cyclic allene, 1,2-cyclohexadiene, had a nucleophilicity.[5] As one part of our research on the reactivities of **2** and **3**,[3] we invesitigated the reactions of **1** with 3- (**4a**) or 5-methoxycarbonyl-2-pyrone (**4b**). Here, the results of these reactions will be discussed.

A mixture of **1** and three molar equivalents of **4a** in anhydrous diglyme was heated at 120 °C for 15 min. The separation and purification of the reaction mixture by chromatography afforded 2-methoxycar-

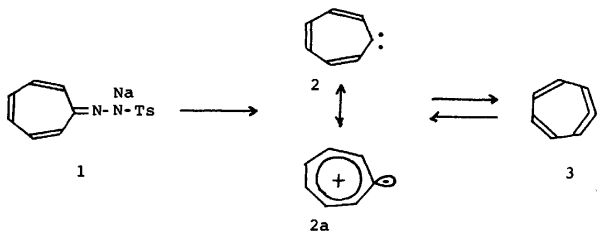

Fig. 1.

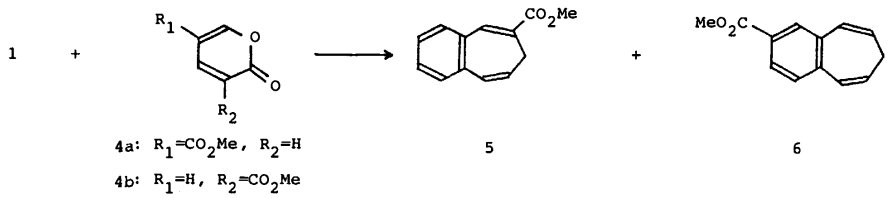

Fig. 2.

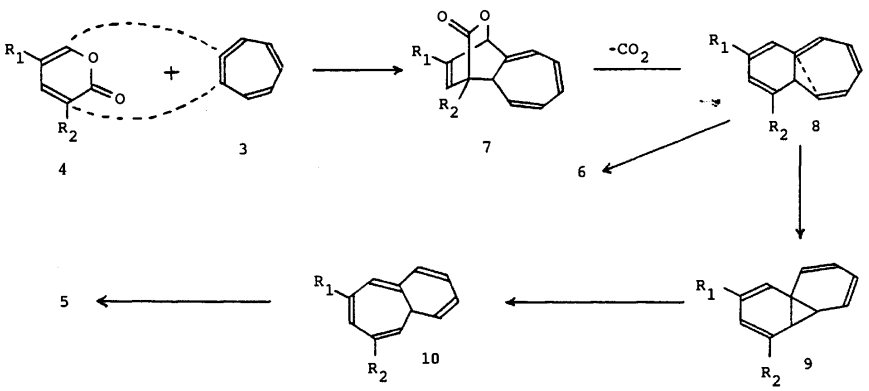

Fig. 3.

bonylbenzo[*f*]-1,4,5a-cycloheptatriene (**5**) and 8-methoxycarbonylbenzo[*f*]-1,4,5*a*-cycloheptatriene (**6**) in 8.1 and 15% yields, respectively. The same reaction, but using **4b**, gave **5** in 2.8% yield. The structures of **5** and **6** were deduced on the basis of their spectral properties, especially from their NMR spectral properties, and confirmed by comparisons of these spectral properties with those of analogous compounds.[3,6]

The products are considered to be formed via a reaction mechanism resembling that of the reaction of **1** with cyclopentadienone derivatives.[1e,3c] A [$4\pi + 2\pi$]-type cycloaddition of **3** with **4** gives **7**, which generates **8** via an elimenation of carbon dioxide. A hydrogen migration in **8** gives **6**. On the other hand, a valence tautomerization of **8** yields a norcaradiene form **9**,[7] which again undergoes a valence tautomerization to tropilidene form **10**. A hydrogen migration of **10** affords **5**. The reaction of **3** with **4b** proceeds via almost the same mechanism as above. The low product yield from the reaction of **4b** is due to a steric hindrance of the methoxycarbonyl group.

The electron densities on carbon atoms of **4a** and **4b** are known to be as shown in Fig. 3.[8] The 2-position carbons bear the smallest electron densities in both **4a** and **4b**. Considering the above fact, the experimental result that the allenic carbon atom of **3** attacks the 2-position carbon atoms of both **4a** and **4b**, seems to prove the nucleophilicity of the allene **3**.

Experimental

NMR spectra were measured with Varian XL 200 or Hitachi R 20B spectrometers with tetramethylsilane as an internal standard. IR spectra were measured with a DS 701G spectrometer. Mass spectra were measured with Hitachi M-52 or JMS DX300 spectrometers. Diglyme was dried over Molecular Sieves 3A, 1/16. Wako gel C 200 and Wako gel B5F were used for column and thin-layer chromatography, respectively.

Reaction of 1 with 4a. A mixture of **1** (8.40 g, 28.4 mmol), and **4a** (13.20 g, 85.7 mmol) in diglyme (100 ml) was heated at 120 °C for 15 min. The reaction mixture was poured into water, extracted with ethyl acetate, washed with water and brine, and dried over anhydrous sodium sulfate. After evaporation of the solvent, the oily residue was column chromatographed to give an oily mixture of **5** and **6** (1.10 g) by the use of pet. ether (bp 35—60 °C)-benzene 1 : 4 and crystals of tropone tosylhydrazone (2.63 g, 31%) by the use of benzene-ether 9 : 1. The NMR spectrum of the mixture of **5** and **6** showed that the mixture contained 35% of **5** (8.1% yield)[9] and 65% of **6** (15.0% yield).[9] Each compound was separated by thin-layer chromatgraphy using benzene-ether 3 : 1 as a developing solvent (**5**, R_f=0.60; **6**, R_f=0.55). 2-Methoxycarbonylbenzo[*f*]-1,4,5a-cycloheptatriene (**5**): Found: *m/z* 200.0819. Calcd for $C_{13}H_{12}O_2$: M, 200.0836. MS *m/z* (rel intensity): 200 (M^+, 29), 186 (25), 155 (57), 127,(100). IR (oil): 3030, 2950, 1720, 1440 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.80 (d, 2H, *J*=7 Hz), 3.90 (s, 3H), 5.6—6.8 (m, 3H), 7.1—8.0 (m, 4H).

8-Methoxycarbonylbenzo[*f*]-1,4,5a-cycloheptatriene (**6**): Found: *m/z* 200.0864. Calcd for $C_{13}H_{12}O_2$: M, 200.0836. MS *m/z* (rel intensity): 200 (M^+, 100), 169 (95), 139 (43), 127 (53). IR (oil): 3030, 2970, 1725, 1440 cm^{-1}. ^1H NMR ($CDCl_3$) δ=2.50 (t, 2H, *J*=7 Hz), 3.80 (s, 3H), 5.6—6.8 (m, 4H), 7.2—8.0 (m, 3H).

Reaction of 1 with 4b. A mixture of **1** (8.88 g, 30 mmol) and **4b** (13.86 g, 90 mmol) in diglyme (100 ml) was heated at 120 °C for 20 min. The same procedure as above using column chromatography gave an oil **5** (0.12 g, 2.8%,[9] benzene-ether 17 : 3) and crystals of tropone tosylhydrazone (2.28 g, 27.8%, benzene-ether 9 : 1).

The authors are indebeted to Professor Toshio Mukai of Tohoku University for his fruitfull suggestions. The present work was supported by a Grant-in-Aid for Science Research No. 61540367 from the Ministry of Education, Science and Culture.

Effect of Catalyst on the Oxygenation of Styrene with BH_4^- and Molecular Oxygen[1)]

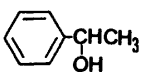
Tadashi OKAMOTO,* Yoshihiro SASAKI, Ken SASAKI, and Shinzaburo OKA
Institute for Chemical Research, Kyoto University, Uji 611
(Received June 4, 1987)

Synopsis. The effects of equatorial ligands and central metals on the catalytic conversion of styrene to 1-phenylethanol were examined. Accompanying hydrogenation and hydrodimerization of the substrate to ethylbenzene and 2,3-diphenylbutane, respectively, was facilitated in the presence of a catalyst ligated with an electron-releasing ligand such as 1,4,8,11-tetraazacyclotetradecane or sulfur-containing ligands.

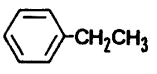
Previously we reported the catalytic conversion of aryl-conjugated olefins to the derivatives of benzyl alcohol by molecular oxygen and tetrahydroborate ion at room temperature.[2,3)] The reaction proceeded with high reio- and chemoselectivities affording the corresponding alcohols in high yields. A related reaction by using nitrogen monoxide in place of molecular oxygen also presented a new process for preparation of oximes under mild reaction conditions.[4)] As for the catalyst of these reactions, successful results were reported with cobalt complexes of the monoanion of 2,3-butanedione dioxime (DMG)[2)] and tetraphenylporphyrin (TPP).[3)] The catalytic effects of some other transition metal complexes in the oxygenation of styrene was examined in the present study to reveal a distinctive effects of equatorial ligands and the central metals on the distribution of the products.

Results and Discussion

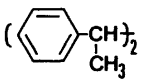
In the transition metal-catalyzed oxygenation of styrene with tetrahydroborate and molecular oxygen, the main product of 1-phenylethanol (**1**) was occasionally accompanied by three by-products. Two of them were ethylbenzene (**2**) and 2,3-diphenylbutane (**3**) which



1



2



3

were produced by hydrogenation and hydrodimerization of styrene, respectively. The other was acetophenone, a compound formally produced by dehydrogenation of the alcohol **1**. The relative yields of these products were dependent on the various reaction conditions. Typically, the yields of products via hydrogenation, **2** and **3**, increased at the high concentration of tetrahydroborate ion. On the other hand, the yield of acetophenone increased when the low concentration of BH_4^- was used. At low reaction temperature the yield of acetophenone increased relative to the alcohol. The contribution of bimolecular process affording **3** was important at the high concentration of the catalyst.

Except for these general phenomena, the product distribution was dependent on the metal complex used as the catalyst. The effect of equatorial ligand was compared with eight cobalt complexes having the equatorial coordinating atoms of nitrogen, oxygen, and sulfur such as **4**—**11**. The effect of central metal ion was also examined for complexes with a nitrogen

a) Reaction conditions: styrene/catalyst=10, in 50% 1,2-dimethoxyethane/isopropyl alcohol at room temperature, 25 h. b) Yields were calculated on the basis of the amounts of consumed substrate. c) DMG: monoanion of 2,3-butanedione dioxime. d) At −60 °C; optical yield, 2%.

ligand such as DMG (Co and Fe complexes) or TPP (Co, Fe, and Mn complexes). The results are summarized in Table 1.

The effect of metal ion is characterized by the tendency that the activity for hydrogenation increases in the order of the periodic table, Mn(III)<Fe(III)< Co(II). In the case of TPP complex, nearly one tenth of the total products was converted to hydrogenation and hydrodimerization products, **2** and **3** by using Co(tpp), while the corresponding value by the use of Fe(tpp)Cl was less than 5%. For the catalysis by Mn(tpp)(OAc), no hydrogenation to **2** and **3** proceeded and the main product was acetophenone instead of **1**. Thus hydrogenation is not a favorable process by the use of Mn(tpp)(OAc) as the catalyst. The related tendency was observed in the catalysis by DMG complexes; the relative amount of hydrogenation product increased in the order, Fe<Co.

The effect of equatorial ligand also showed a distinct tendency. A cobalt complex of a chelating ligand bearing four coordination sites with two nitrogen and two oxygen atoms **4** gave quite similar results with the DMG complex. The change of carbon framework of the ligand has minor importance. The results show that the oxygen and nitrogen atoms have similar effect on the catalytic reaction. However, when two coordinating oxygen atoms of the ligand were substituted by sulfur atoms such as **5** and **6**, the yields of **2** and **3** increased significantly at the expense of oxygenation product **1**. Again, the change of organic substituents, Y, from phenyl to methyl group had little effect compared with the ligating atoms. Related result was obtained with the complex of saturated cyclic ligand **11**. In the reaction by the catalysis of this electron-rich complex, the formation of the oxygenation product **1** was almost inhibited. The results of Schiff base complexes **7** and **8** were not straightfoward. The low conversion and low yields of products as well as its distribution should be accounted for by the instability of the Schiff bases under the reaction conditions. In fact, almost quantitative amount of salicylaldehyde was found after the reaction by the catalysis of **7**. The effect of equatorial ligand are thus interpreted that the cobalt complex ligiated with an electron-releasing ligand promotes hydrogenation and hydrodimerization relative to oxygenation. Electron-releasing ligand increases the electron density of the central cobalt ion and stabilizes the alkyl-cobalt bond against homolytic dissociation to cobalt(Il) and alkyl radical.[5] In this context the observed tendency supports the mechanism of a free radical combination process for the oxygenation step. As the catalyst of oxygenation, rigid cyclic tetraaza ligands such as porphyrin and phthalocyanine gave the best results with respect to both stability of the catalyst and the selectivity of the product alcohol. An attempt for the asymmmetric catalysis by using complex (1*R*,2*R*)-**12** at −60 °C resulted in only the isolation of **1** with optical yield of 2% (S) in 50% 1,2-dimethoxyethane-isopropyl alcohol. Intermediate formation of π-type free radical might be a possible explanation of the low optical yield.

Experimental

Complexes **4**—**11** were prepared according to the methods in literature.[6-10] Styrene was distilled before use. Other chemicals were commercial products and used as received. Experimental procedure of catalytic oxygenation was similar as the previous study. Reaction conditions were; Catalyst, 0.05 mmol; styrene, 0.5 mmol; tetraethylammonium tetrahydroborate, 1 mmol; in 5 ml of 50% 1,2-dimethoxyethane-isopropyl alcohol under atmospheric pressure of oxygen at room temperature. The yields of the reaction products were determined by Yanaco G2800 gas chromatography fitted with OV 101 packed column and calculated on the basis of the consumed amounts of the substrate.

The authors acknowledge Prof. Masafumi Goto of Nagoya City University for a gift of complex 12.

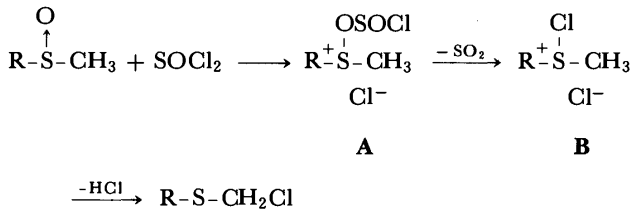
Formation of Chlorosulfonium Salt of 1,5-Dithiacyclooctane and Transannular Sulfur-Sulfur Interaction in Hydrolysis of Its Salt

Hisashi FUJIHARA, Ryouichi AKAISHI, and Naomichi FURUKAWA*
Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 305
(Received June 11, 1987)

Synopsis. The reaction of 1,5-dithiacyclooctane 1-oxide (**2**) with thionyl chloride afforded the corresponding chlorosulfonium chloride as a stable salt and an evidence for the intermediary formation of the bis-sulfide dication with an equilibrium mixture of the chlorosulfonium salt was found. In contrast to **2**, 1,4-dithiacyclohexane 1-oxide (**6**) reacts with thionyl chloride like a simple sulfoxide.

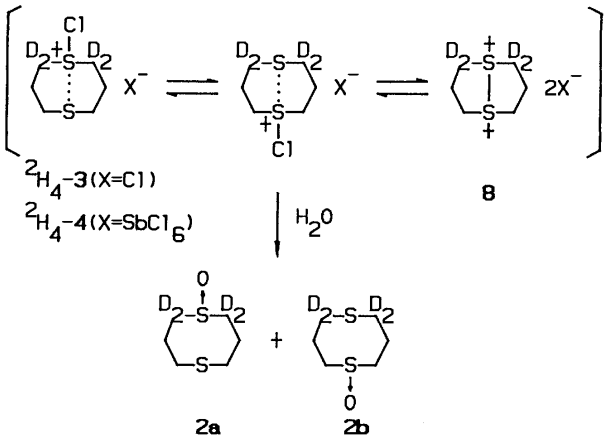
Normally, the sulfoxides bearing α-protons react with thionyl chloride ($SOCl_2$) to form initially a (chlorosulfinyloxy)sulfonium cation (**A**) which then decomposes to give a chlorosulfonium chloride (**B**) and sulfur dioxide.[1a,b] Finally chlorosulfonium salts generated are easily converted to α-chloro sulfides[1c] as shown below.



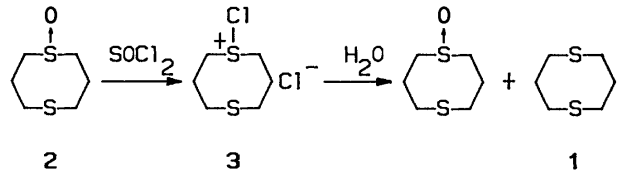
An intermediacy of the bis-sulfide dication of 1,5-dithiacyclooctane (**1**) has been confirmed kinetically by Musker et al. in the reduction of the corresponding sulfoxide with HI.[2] Recently, we reported that the bis-sulfide dication of **1** is formed in either the reaction of the corresponding sulfoxide with concd H_2SO_4 or the Pummerer reaction with acetic anhydride.[3,4] These results indicate that when a positive charge is induced on the one sulfur atom in the cyclic bis-sulfide, the remote second sulfur atom participates transannularly to stabilize the charge via formation of the S-S bond. We present here the formation of chlorosulfonium salt of **1** and the transannular sulfur-sulfur interaction in the hydrolysis of its salt, and the distinct difference between **1** and 1,4-dithiacyclohexane (**5**) in the reaction mode of the corresponding sulfoxides with thionyl chloride.

The reaction of 1,5-dithiacyclooctane 1-oxide (**2**) with thionyl chloride in anhydrous dichloromethane at 0°C gave the corresponding chlorosulfonium chloride **3** as a stable salt in 74% isolated yield. Secondary ion mass spectrum (SIMS) of **3** indicates the peaks at *m/z* 185 and 183 (base peak) which correspond to $C_6H_{12}S_2Cl^+$. This salt could be stabilized by transannular interaction of the second sulfur atom even in the absence of antimony pentachloride ($SbCl_5$). Treatment of **3** with H_2O and work-up led to sulfoxide **2** in 70% yield and sulfide **1** in 15% yield (Scheme 1). The sulfide was presumably formed by reduction of the halosulfonium ion by the second halide ion as a counterpart of the cation. 2,2,8,8-Tetradeuterated 1,5-dithiacyclooctane 1-oxide (**2a**) was treated similarly with thionyl chloride to afford the chlorosulfonium salt [$^2H_4$]-**3** in 75% yield. Hydrolysis of the salt [$^2H_4$]-**3** led to the sulfoxide in 69% yield and the tetradeuterated sulfide **1a** in 17% yield. The ^1H NMR spectra of the recovered sulfoxide indicate that it is a 1:1 mixture of 2,2,8,8- and 4,4,6,6-tetradeuterated sulfoxides (**2a**) and (**2b**) (Scheme 2). Furthermore, sulfoxide **2** was treated with thionyl chloride in the presence of antimony pentachloride in anhydrous dichloromethane to give 1-chloro-5-thia-1-thioniacyclooctane hexachloroantimonate (**4**) in 75% yield. The ^1H NMR spectrum of salt **4** in CD_3CN showed signals at δ 4.16—3.58 [m, 4H, $S(Cl)CH_2$], 3.52—2.71 (m, 4H, SCH_2), and 2.60—2.32 (m, 4H, CH_2). Hydrolysis of salt **4** gave only sulfoxide **2** in 67% yield. The tetradeuterated hexachloroantimonate salt [$^2H_4$]-**4**[5] gave a similar result to [$^2H_4$]-**3**. These results suggest the intermediary formation of bis-sulfide dication **8** with an equilibrium mixture of the chlorosulfonium salt ([$^2H_4$]-**3** or **4**) (Scheme 2).

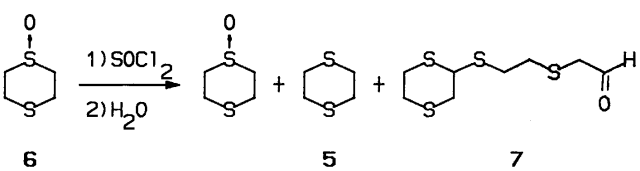
Meanwhile, 1,4-dithiacyclohexane 1-oxide (**6**) in which transannular interaction of the sulfur atoms is



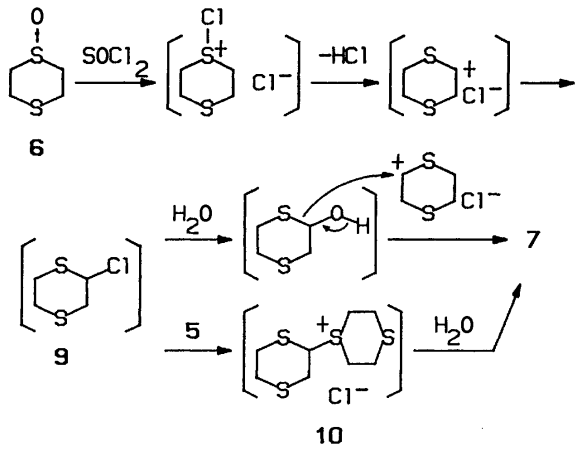
Scheme 2.



Scheme 1.



Scheme 3.



Scheme 4.

minimal, was treated similarly with thionyl chloride as described in **2**. The chlorosulfonium chloride of **5** could not be isolated as a salt in the reaction of **6** with thionyl chloride in the absence of antimony pentachloride. Hydrolysis of the reaction mixture in situ gave sulfoxide **6** in 9%, sulfide **5** in 20%, and aldehyde **7** in 41% yields (Scheme 3). This reaction may have proceeded through the formation of the Pummerer product such as α-chloro sulfide **9** which subsequently is converted into **7** by hydrolysis of **9** as illustrated in Scheme 4. However, an alternative process involving the formation of the sulfonium salt **10** by the reaction of **9** with **5** cannot be excluded (Scheme 4). The structure of **7** was confirmed by the formation of 2,4-dinitrophenyl hydrazone **11**. Thus, this distinct difference of reactivity between **2** and **6** should depend on the degree of the transannular S-S interaction in the six- and eight-membered rings.

Experimental

^{1}H NMR spectra were measured on a Hitachi R-600 FT-NMR spectrometer. The IR spectra were obtained on JASCO A-3 spectrometer. Secondary ion mass spectra were taken by Hitachi M-80B mass spectrometer. Elemental analyses were carried out by the Chemical Analytical Center at this University.

1,5-Dithiacyclooctane was synthesized by a modification of the method of Meadow and Reid.[6] 1,4-Dithiacyclohexane was obtained from Wako Pure Chemical Industries, Ltd.

Cyclic Bis-Sulfide Monosulfoxides. The monosulfoxides were obtained by general oxidation using *m*-chloroperbenzoic acid.

1,5-Dithiacyclooctane 1-Oxide (2): Yield 76%; mp 27—29 °C; IR (neat) 1010 cm^{-1} (S=O); ^{1}H NMR ($CDCl_3$) δ=2.18—2.43 (m, 4H, CH_2), 2.54—2.76 (m, 4H, SCH_2), and 3.04—3.23 [m, 4H, $S(O)CH_2$].

1,4-Dithiacyclohexane 1-Oxide (6): Yield 36%; mp 125.5—127.0 °C; IR (KBr) 1020 cm^{-1} (S=O); ^{1}H NMR ($CDCl_3$) δ=2.40—2.70 (m, 2H, SCH_2-*e*), 2.91—3.22 [m, 4H, $S(O)CH_2$], and 3.43—3.77 (m, 2H, SCH_2-*a*).

Preparation of 2,2,8,8-Tetradeuterated 1,5-Dithiacyclooctane 1-Oxide (2a). Deuteration of sulfoixde **2** was carried out in NaOD-D_2O under nitrogen atmosphere at 100 °C for 24 h. After usual work-up the tetradeuterated sulfoxide **2a** was obtained in 91% yield; the deuterium content of **2a** was more than 95 atom% by ^{1}H NMR spectroscopy.

Isolation of Chlorosulfonium Chloride 3. Addition of pure thionyl chloride (1 mmol) in anhydrous dichloromethane (1 ml) to a solution of 1,5-dithiacyclooctane 1-oxide (**2**) (1 mmol) in anhydrous dichloromethane (1 ml) under N_2 atmosphere at 0 °C resulted in a white crystalline precipitate. Upon filtration in a dry box under rigorously anhydrous conditions, 1-chloro-5-thia-1-thioniacyclooctane chloride (**3**) was obtained in 74% yield as stable hygroscopic crystalline salt: Mp 80°C; SIMS *m/z* (rel intensity) 185(42), 183(100) 151(17), 107(44), and 73(23).

Reactions of Sulfoxide 2 with Thionyl Chloride in the Presence of Antimony Pentachloride. To a stirred solution of sulfoxide **2** (1 mmol) and antimony pentachloride (1 mmol) in anhydrous dichloromethane (1 ml) was added thionyl chloride (1 mmol) in anhydrous dichloromethane under nitrogen at 0 °C. 1-Chloro-5-thia-1-thioniacyclooctane hexachloroantimonate (**4**) was obtained in 75% yield as stable hygroscopic crystalline salt: Mp 106—107 °C (decomp); ^{1}H NMR (CD_3CN) δ=2.32—2.60 (m, 4H, CH_2), 2.71—3.52 (m, 4H, SCH_2), and 3.58—4.16 [m, 4H, $S(Cl)CH_2$]; MS *m/z* 183 (M^+-SbCl_6).

Hydrolysis of Chlorosulfonium Salt 3. The salt **3** was treated with aqueous $NaHCO_3$ on ice bath. The mixture was extracted with dichloromethane. The combined organic phase was dried over $MgSO_4$, filtered, and concentrated under vacuum to give sulfoxide **2** in 70% and sulfide **1** in 15% yields. The salt **4** was hydrolyzed by the same procedure as **3**.

Reaction of Sulfoxide 6 with Thionyl Chloride. To a stirred solution of 1,4-dithiacyclohexane 1-oxide (**6**) (1 mmol) in anhydrous dichloromethane (1 ml) was added thionyl chloride (1 mmol) in anhydrous dichloromethane (1 ml) under nitrogen at 0 °C. Then the reaction mixture was treated with aqueous $NaHCO_3$ to afford sulfide **5** in 20%, sulfoxide **6** in 9%, and aldehyde **7** in 41% yields. The hydrazone of **7** was prepared as follows. To a solution of aldehyde **7** (19 mg) in ethanol (3 ml) was added 2,4-dinitrophenylhydrazine (50 mg, 0.1%-HCl solution). The reaction mixture was stirred at room temperature for 2 h. The solution was extracted with carbon tetrachloride, and the extract was dried over Na_2SO_4. After removal of the solvent, hydrazone **11** was purified by silica-gel column chromatography. **11**: Mp 125—126 °C; IR (KBr) 1610 (C=N), 1504 and 1321 cm^{-1} (NO_2); ^{1}H NMR ($CDCl_3$) δ=2.70—3.19 (m, 10H), 3.47 (d, *J*=6Hz, 2H, SCH_2CH=N), 4.10 (m, 1H, SCHS), 7.47 (t, *J*=6 Hz, 1H, CH=N), 7.92 (d, *J*=9 Hz, 1H, ArH), 8.36 (dd, *J*=9, 3 Hz, 1H, ArH), 9.13 (d, *J*=3 Hz, 1H, ArH), and 11.11 (br s, 1H, NH). Found: C, 38.69; H, 4.17; N, 12.89%. Calcd for $C_{14}H_{18}N_4O_4S_4$: C, 38.38; H, 4.14; N, 12.85%.

Terpenoids. X.[1] Natural Autoxidation of Thujopsene

Shizuo NAGAHAMA* and Masato TAZAKI
The Kumamoto Institute of Technology, Ikeda 4-22-1, Kumamoto 860
(Received June 22, 1987)

Synopsis. The natural autoxidation of thujopsene **1** afforded three dimeric peroxides (**14**, **15**, and **16**) as the major products. 9α,10-Epoxy-8α-thujopsanol **17** was separated as a minor product besides other known compounds, allylic alcohols **2** and **3**, mayurone **7**, thujopsane-8α,9α-diol **11**, and thujopsan-9-ones **19** and **20**.

Kawamura[2] described in his first report the instability of thujopsene **1** towards exposure to air or sunlight; i.e., **1** suffers autoxidation very easily. The photosensitized[3,4] and catalytic[5] autoxidations were examined extensively; however, the oxidation occuring naturally with atmospheric oxygen has not been studied so far, in which the reaction can proceed under extremely mild conditions. In this paper, we will show the products from the natural autoxidation of **1**, as analyzed by chromatographic separation.

Results and Discussion

Three crystalline bis(Δ^9-thujopsen-8-yl) peroxides were separated by repeated alumina chromatography in the order of elution: **14** mp 100—102 °C, **15** mp 62—68 °C, and **16** mp 136—138 °C. Upon the reduction by $LiAlH_4$, the peroxide **14** gave only Δ^9-thujopsen-8β-ol[1] **2**, whearas the peroxide **16** gave Δ^9-thujopsen-8α-ol[1] **3**. The peroxide **15** gave a 1 : 1 mixture of **2** and **3**. The gas chromatography of peroxides showed a broad peak accompanied with the peaks of thujopsadiene[1] **6** and mayurone[1] **7** as decomposition products.

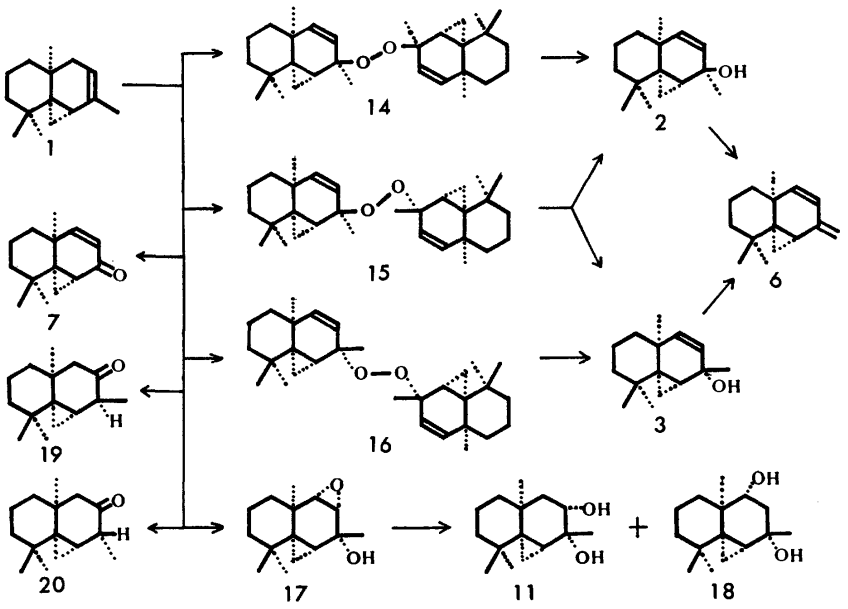
A crystalline compound **17** mp 106—107 °C was isolated as a minor product. The IR spectrum of **17** showed the presence of an OH group. The ^1H NMR spectrum showed two protons on an epoxy ring, one of which showed a long-range coupling constant of 1.8 Hz. The reductive cleavage of the epoxy ring in **17** with $LiAlH_4$ resulted in the formation of thujopsane-8α,9α-diol[1] **11** as a minor product. Thus, 9α,10-epoxy-8α-thujopsanol was assigned to **17**. The major reduction product was 8α,10α-diol **18**.

As the known compounds, **2**, **3**, thujopsan-9-ones[6] **19** and **20**, **7** and **11** were also separated from the natural autoxidation products.

Experimental

A thujopsene fraction (23.8 g) obtained by spinning band column distillation of Hiba wood neutral oil was allowed to stand for 6 years. The viscous oil afforded by repeated chromatography on alumina following fractions: hydrocarbons 24%, peroxides (**14**—**16**) 25%, a 1 : 1 mixture of thujopsan-9-ones (**19** and **20**) 6%, allylic alcohols **2** and **3**, 2%, mayurone **7**, 6%, epoxy alcohol **17**, 5% and 8α,9α-diol **11**, 0.6%. The structures of the known compounds, **2**, **3**, **7**, **11**, **19**, and **20**, were confirmed by the comparison of their ^1H NMR and IR spectra with those reported earlier.[1,6] **17**: Mp 106—107 °C. IR (KBr) 3500 (OH), 3050, 2970, 2930, 1459, 1378, 1306, 1177, 1159, 1129, 1074, 1040, 1022, 1004, 922, 919, 910, 864, 830, and 809 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.18 (1H, dd, J=8.8, 4.0 Hz), 0.54 (3H, s), 1.00 (3H, s), 1.34 (3H, s), 1.41 (3H, s), 0.93—1.81 (8H, m), 2.05 (1H, broad), 2.74 (1H, d, J=4.0 Hz), and 3.02 (1H, dd, J=4.0, 1.8 Hz).

Separation of 14, 15, and 16: A later part of the peroxide fraction obtained above crystallized. Recrystallization from hexane gave peroxide **16** (1.05 g) mp 136—138 °C. Found: C, 81.73; H, 10.51%. Calcd for $C_{30}H_{46}O_2$: C, 81.63; H, 10.87%. IR (KBr) 3080, 2950, 1389, 1371, 1360, 1159, 1103, 1082, 770, 756,



Scheme 1.

and 740 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.33—0.72 (4H, m), 0.65 (6H, s), 1.06 (6H, s), 1.15 (6H, s), 1.44 (6H, s), 1.0—1.7 (14H, m), 5.02 (2H, d, J=10.4 Hz), and 5.42 (2H, dd, J=10.4, 1.8 Hz).

The intermediate fraction between hydrocarbons and **16** was re-chromatographed. The fast-running fraction crystallized and afforded peroxide **14** (0.15 g) mp 100—102 °C (from hexane). IR (KBr) 3055, 3010, 1466, 1381, 1371, 1160, 1100, 1091, 1080, 901, 882, 764, and 741 cm^{-1}. ^1H NMR ($CDCl_3$) δ=−0.03 (2H, dd, J=5.6, 4.6 Hz), 0.39 (2H, dd, J=9.6, 4.6 Hz), 0.63 (6H, s), 1.04 (6H, s), 1.13 (6H, s), 1.28 (6H, s), 1.1—1.7 (14H, m), and 4.93—5.38 (4H, m).

Repeated chromatography of the middle fractions of **14** and **16** finally gave crystalline peroxide **15** (0.11 g) mp 62—68 °C. IR (neat) 3060, 2920, 1386, 1371, 1360, 1158, 1171, 1132, 1083, 1032, 952, 903, 881, 770, 751, and 740 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.00 (1H, dd, J=5.4, 4.6 Hz), 0.29—0.70 (3H, m), 0.64 (6H, s), 1.05 (6H, s), 1.14 (6H, s), 1.31 (3H, s), 1.44 (3H, s), 1.0—1.7 (14H, m), 5.08 (1H, d, J=10.4 Hz), 5.16 (2H, s), and 5.52 (1H, dd, J=10.4, 1.8 Hz).

Reduction of Peroxides 14—16: Peroxide **14** (120 mg) dissolved in 2 ml of dioxane was refluxed for 10 hrs with excess $LiAlH_4$. The usual work-up gave an oil (85.7 mg), identical to **2**, obtained by $KMnO_4$ oxidation of thujopsene.[1] Peroxide **16** (157 mg) was reduced as above, and gave 128 mg of **3**. The similar reduction product of peroxide **15** was a 1 : 1 mixture of **2** and **3** by gas chromatography.

Reductive Cleavage of Epoxy Ring in 17: Epoxy alcohol **17** (283 mg) in 10 ml dioxane was refluxed with $LiAlH_4$ for 1 day. The product (290 mg) was recrystallized from ether-hexane gave diol **18** mp 128—129.5 °C (98 mg). The residue from the mother liquor (160 mg) was chromatographed on an alumina column (6 g) and eluted with ether. **18** (54 mg) was recovered and 8α,9α-diol **11** (28 mg) was obtained. **18**: IR (KBr) 3260(broad, OH), 3010, 1370, 1252, 1141, 1091, 1048, 1002, 911, 888, 859, 838, and 741 cm^{-1}. ^1H NMR ($CDCl_3$) δ=0.43 (1H, dd, J=10.6, 5.0 Hz), 0.57 (3H, s), 1.01 (3H, s), 1.26 (3H, s), 1.42 (3H, s), 0.80—1.8 (8H, m), 1.69 (2H, d, J=3.4 Hz), 2.79 (1H, broad), 2.96 (1H, d, J=5.2 Hz), and 3.30 (1H, dt, J=5.2, 3.4 Hz).

Reaction between Copper(II) Chloride and Active Carbon for the Formation of Solid Carbon Monoxide Adsorbent

Makoto KOMIYAMA,*,† Hiroaki ANDO, and Hidefumi HIRAI††
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, 7-3-1, Hongo, Bunkyo-ku, Tokyo 113
(Received April 24, 1987)

Synopsis Evolution of hydrochloric acid on the preparation of carbon monoxide adsorbents from copper(II) chloride and active carbon has been experimentally confirmed. Relationship between the amount of hydrochloric acid evolved and the adsorbing capacity shows that the efficient adsorption by the adsorbents is attributable to the function of the copper(I) chloride, which is formed during the preparation by the reaction between copper(II) chloride and active carbon.

In industry, carbon monoxide is usually obtained as gas mixtures with nitrogen, hydrogen, methane, and carbon dioxide. Thus carbon monoxide must be separated from gas mixtures for the effective utilization.[1)]

Previously,[2)] the present authors have reported that solid adsorbents, prepared from copper(II) chloride and active carbon, adsorb carbon monoxide efficiently and reversibly under mild conditions. These adsorbents have an advantage from the viewpoint of practical application that both of the starting materials are stable against oxygen and thus the preparations are successfully achieved even under air. The adsorbing capacities of the adsorbents are much larger than the sum of the values for copper(II) chloride and active carbon. Thus it has been proposed that copper(II) chloride ($CuCl_2$) and active carbon (AC-H) react during the preparation as shown by Eq. 1, resulting in the formation of copper(I) chloride (CuCl).[2)] The resultant copper(I) chloride supported on the active carbon effectively adsorbs carbon monoxide.[3)]

$$\text{AC-H} + 2\,CuCl_2 \rightarrow \text{AC-Cl} + 2\,CuCl + HCl \qquad (1)$$

In this article, evolution of hydrogen chloride during the preparation of the adsorbents from copper(II) chloride and active carbon are quantitatively analyzed. The relationship between the amounts of hydrogen chloride evolved and the adsorbing capacities of the adsorbents is described.

Experimental

Active carbon (Kureha Chemical Industry Co., BAC G-70R, Lot. No. 810117) was subjected to a reduced pressure (5 mmHg (1 mmHg=133.322 Pa)) at 200 °C for 5 h prior to use.

The adsorbents were prepared by refluxing 20 g of the active carbon and 30 mmol of copper(II) chloride in 30 cm^3 of water, followed by removal of the liquid phase under 5 mmHg. Here, hydrogen chloride evolved was trapped with the use of liquid nitrogen traps, and was titrated with 1.0 mol dm^{-3} aqueous solution of sodium hydroxide. The amount of copper atoms, which were supported onto the active carbon, was 28.2 g-atoms as determined by atomic absorption spectroscopy.

Results and Discussion

When aqueous solution of silver nitrate was added to the contents obtained in the liquid nitrogen traps on the preparation of the adsorbents from copper(II) chloride and the active carbon, white precipitates (AgCl) were immediately formed. This result definitely shows that the reaction of Eq. 1 in fact takes place, yielding hydrogen chloride.

No hydrogen chloride was trapped, when only water-active carbon mixtures were evaporated at 180 °C under 2.5 mmHg. On evaporation of 30 cm^3 of aqueous solution of copper(II) chloride (1.0 mol dm^{-3}), the amount of hydrogen chloride was only 0.2 mmol.

Table 1 shows the amounts of hydrogen chloride trapped in the liquid nitrogen traps under various preparation conditions, together with the carbon monoxide adsorbing capacities of the resultant adsorbents. When the adsorbent is prepared by refluxing copper(II) chloride and the active carbon in water for 6 h, followed by the evaporation of the liquid phase at 180 °C, the amount of hydrogen chloride trapped is 13.5 mmol. The adsorbing capacity of the adsorbent is 19.3 mmol. On increase of the evaporation temperature from 180 to 200 °C, the amount of hydrogen chloride trapped is slightly increased to 14.1 mmol.

According to Eq. 1, 28.2 mmol of copper(I) chloride should be formed during the preparation of the adsorbent, when 14.1 mmol of hydrogen chloride is evolved. The molar ratio (0.68) of the adsorbing capacity (19.3

Table 1. Carbon Monoxide Adsorbing Capacities of the Adsorbents Prepared from the Active Carbon and Copper(II) Chloride as well as the Amounts of Hydrogen Chloride Trapped on Their Preparation

Preparation condition		Adsorbing capacity/ mmol	Amount of HCl/ mmol[c)]
Refluxing[a)] period/h	Evaporation[b)] temp/°C

mmol) of the adsorbent to the estimated amount (28.2 mmol) of copper(I) chloride formed is almost identical with the corresponding value (0.64)[3] for the adsorbent, which is prepared directly from copper(I) chloride and active carbon in water. Thus the carbon monoxide adsorbing activity of the present adsorbent is ascribed to the function of the copper(I) chloride, which is formed during the preparation and is supported on the active carbon.

The adsorbent, prepared by the removal of the liquid phase at 180 °C without refluxing the mixture in water, shows a smaller adsorbing capacity (16.5 mmol). The amount (9.5 mmol) of hydrogen chloride trapped during the preparation is about 2/3 of the value (13.5 mmol) for the adsorbent obtained by the evaporation at 180 °C after refluxing.

These results indicate that the reaction of Eq. 1 occurs both during the refluxing and during the evaporation of the liquid phase. Refluxing of the reaction mixture in water probably facilitates the dissolution of hydrogen chloride, which is formed in the micropores of the active carbon and is adsorbed there, into aqueous phase.

The reaction of Eq. 1 proceeds in a similar way as electrophilic chlorination of anthracene by copper(II) chloride,[4] in which 9,10-dichloroanthracene and copper(I) chloride are formed. Active carbons have many reaction sites for this reaction, since they are composed of conjugated aromatic rings.

In conclusion, it has been experimentally established that the reaction of Eq. 1 occurs during the preparation of carbon monoxide adsorbents from copper(II) chloride and active carbon. The resultant copper(I) chloride supported on the active carbon is responsible for the efficient adsorption of carbon monoxide by the adsorbents.

Low Temperature Synthesis of Dispersed Fine Particle of Cobalt Aluminate—A New Application of Zeolite

Tatsuo OHGUSHI* and Shigeru UMENO
School of Materials Science, Toyohashi University of Technology, Tempaku-cho, Toyohashi 440
(Received May 11, 1987)

Synopsis. $CoAl_2O_4$, with the spinel structure in a dispersed form, was synthesized at 400 °C by using zeolite A as a starting material. A specific surface area of the products was measured by adsorption of $(CH_3)_2CHCH_3$ gas at −110 °C and the mean size of the product particles was estimated to be about 14 nm.

Zeolites have been used as catalysts, adsorbent or ion exchangers owing to their porous structure. In these applications, the zeolitic structure is, of course, preserved. In the present work, zeolite A was used as a source of aluminium for the synthesis of cobalt aluminate. The methods of synthesis and characterization of the product are described in the following.

Experimental

The starting material, Na-A zeolite, was treated several times with 0.1 mol dm^{-3} $CaCl_2$ solution, and $Ca_{5.7}Na_{0.2}H_{0.3}(AlO_2)_{11.9}(SiO_2)_{12.1}$ was obtained. This zeolite (abbreviated as Ca_6-A) was further ion-exchanged, at 80±1 °C for 3 days, with solutions of $CoCl_2$ or mixed solutions of $CoCl_2$ and $CaCl_2$ of 0.1 (or 0.01) mol dm^{-3}. The pH value of the solution was not strictly controlled during the ion exchange, and the values before and after the ion exchange were in a range of 6.5—5.5 at room temperature, irrespective of the concentration of the solution (0.1 or 0.01 mol dm^{-3}). The composition Co_xCa_{6-x}-A was calculated from the composition of the solution and the material balance. The composition of the solution was determined by spectrophotometry. All chemical reagents used were S.P. grade, and the adsorbate gases used, oxygen and $(CH_3)_2CHCH_3$, had nominal purities better than 99.99 and 99.9%, respectively.

The amount of gas adsorbed was measured by the volumetric method in a clean vacuum system. A vacuum of 10^{-5} Pa was easily attained. Prior to adsorption experiments, the adsorbents were dehydrated at room temperature for 5 h and carefully baked out by raising the temperature stepwise. The samples were finally kept at 400 °C for 6 h in a vacuum of 10^{-5} Pa.

Results and Discussion

$Co_{5.5}Ca_{0.5}$-A zeolite (prepared in 0.1 mol dm^{-3} solution) was heated under various conditions (specified as (a), (b), ···) and rehydrated at 20 °C. Its color changed as follows (P denotes pink and B blue),

$Co_{5.5}Ca_{0.5}$-A (P)
- →(a) 20 °C in vac.(B)→20 °C rehy.(P)
- →(b) 20 °C in vac.(B)→400 °C in vac.(B)→20 °C rehy.(B)
- →(c) 400 °C in vac.(B)→20 °C rehy.(B)
- →(d) 400 °C in Ar(B)→20 °C rehy.(B)
- →(e) 1000 °C in Ar(deep B)→20 °C rehy.(deep B)
- →(f) 1000 °C in air(deep B)→20 °C rehy.(deep B)
- →(g) 400 °C in air(gray-brown)→20 °C rehy.(gray-brown).

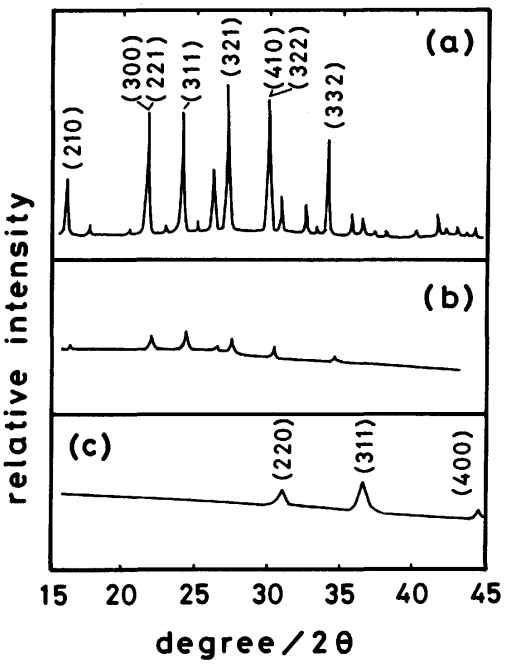

Fig. 1. X-Ray diffraction patterns of Co_xCa_{6-x}-A zeolites heat-treated. Copper radiation ($K\alpha$, λ=0.154 nm) was used. The patterns in (a) and (c) are characteristic to zeolite A and $CoAl_2O_4$, respectively. The pattern in (b) is characteristic to zeolite A but each peak is much weaker than that in (a). Representative indices of planes are shown in parenthesis. (a) x=0, heated at 400 °C in vacuum (b) x=4.1, heated at 400 °C in vacuum (c) x=5.5, heated at 1000 °C in air.

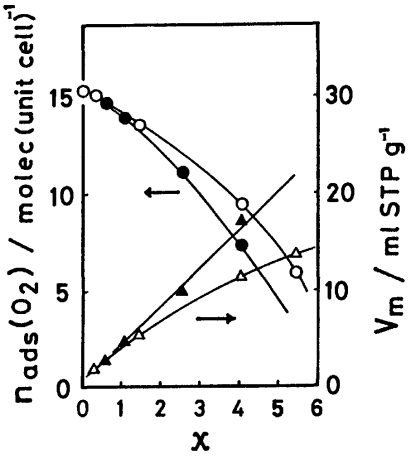

Fig. 2. Adsorptive capacities of Co_xCa_{6-x}-A zeolite heat-treated at 400 °C in vacuum. $n_{ads}(O_2)$; amount of O_2 adsorbed at −196 °C and 2000 Pa, v_m; monolayer capacity of $(CH_3)_2CHCH_3$ at −110 °C. ○△; zeolite prepared in 0.1 mol dm^{-3} solution, ●▲; zeolite prepared in 0.01 mol dm^{-3} solution.

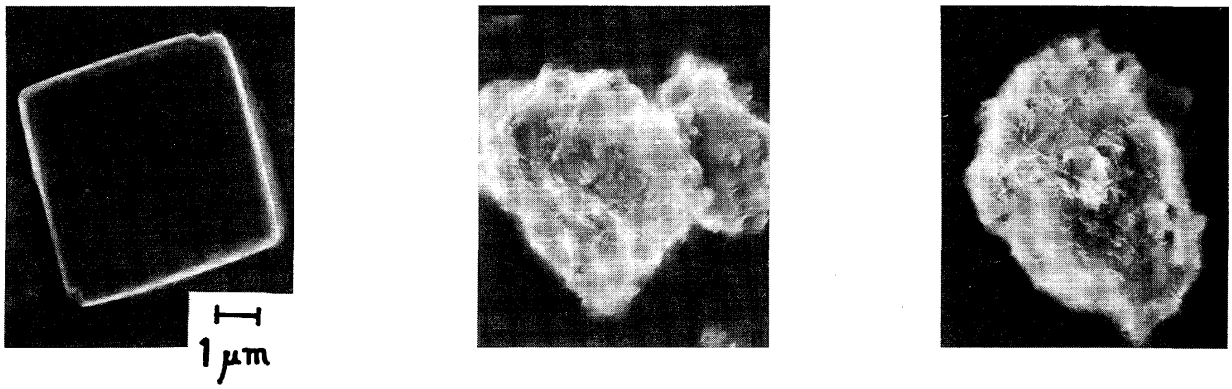

Fig. 3. Electron micrographs of Co_xCa_{6-x}-A zeolite, ion-exchanged with 0.1 mol dm^{-3} solution and then heat-treated at 400 °C in vacuum. (a) x=0, (b) x=4.1, (c) x=5.5.

With samples of $x<5.5$, the same changes were observed, though the color became thin with decreasing x-values. In $Co_{5.5}Ca_{0.5}$-A, heat treatments at 400 °C or higher always caused irreversible changes. All substances produced in treatments (b)—(g) were dipped in water, but did not return to the original color, pink. X-Ray diffractions of heat-treated zeolites were measured, and representative patterns are shown in Fig. 1. All peaks in the diffraction pattern of $Co_{4.1}Ca_{1.9}$-A, in Fig. 1(b), are assigned to zeolite A.[1] The same is the case with zeolites containing less Co than this. The peaks became weak with increasing x and vanished at x=5.5. The products in the treatments (e) and (f) contained $CoAl_2O_4$ as judged from their X-ray diffraction patterns[2] (Fig. 1(c)). The products in the treatment (g) gave no X-ray diffraction peaks but gave electron diffraction spots, which could not be assigned to any crystal. Products obtained in the treatments (b)—(d) contained $CoAl_2O_4$ as judged from electron diffraction patterns. The fraction of zeolite decomposed was estimated from the decrease in the adsorption capacity of O_2 which can penetrate into the zeolite cavity.[3,4] The amount of O_2 adsorbed was measured at −196 °C, and is given in Fig. 2. Representative scanning electron micrographs are shown in Fig. 3. In Fig. 3(c), the products are fine flakes. It was observed with the scanning electron microscope that the surface of Co_x. Ca_{6-x}-A became increasingly rough with the increasing x-value. Their surface became much rougher on heating. From the above results, it is concluded that the fraction of Co_xCa_{6-x}-A decomposed, by heating at 400 °C in vacuum or Ar atmosphere, increases with increasing x and becomes 0.7—0.8† at x=5.5, and the degradation products contain $CoAl_2O_4$.

The outer-surface area (BET area) of the degradation products was measured by the adsorption of $(CH_3)_2CHCH_3$ at −110 °C, which cannot penetrate into the zeolite cage.[4,5] Monolayer capacities of the products are shown in Fig. 2. The surface area of $CoAl_2O_4$ powder can not be deduced with confidence from this BET area. Now, let us roughly estimate the mean particle size of the products by assuming that the products contain $CoAl_2O_4$, SiO_2, Al_2O_3, and Ca_2SiO_4, all components have a cubic form of the same size, and the cross sectional area of $(CH_3)_2CHCH_3$ molecule at −110 °C is 0.29 nm^2. The edge of the products obtained from $Co_{5.5}Ca_{0.5}$-A was about 14 nm. The size, however, depended upon the ion-exchange condition, as shown in Fig. 2.

$CoAl_2O_4$ with the spinel structure is usually synthesized from CoO and Al_2O_3 at temperatures higher than 1000 °C.[6] In the present work, $CoAl_2O_4$ was obtained at such a low temperature as 400 °C by using (Co,Ca)-A zeolite as a precursor. The precursor method has frequently been used in the synthesis of some spinel compounds.[7-9] The use of zeolite material as a precursor is a new development and further investigations may open a new way of techniques for the synthesis.

The present authors wish to thank Prof. Tetsuo Takaishi of Toyohashi University of Technology, for useful discussions and language correction, and Mr. Keiji Itabashi of Toyo Soda Co., who kindly supplied zeolite materials.

†Oxygen gas adsorbs into the zeolite cage, and onto the outer surface of the zeolite and degradation products. In three kinds of adsorptions, the amount of O_2 adsorbed onto the zeolite outer surface is negligible at all x-values. Hence, the fraction of zeolite decomposed is obtained by correcting for the amount adsorbed on the degradation products.

Hydrates of Organic Compounds. XIV. The Formation of Clathrate-Like Hydrates of Tetrabutylammonium Amino Carboxylates

Haruo NAKAYAMA,* Hideyuki USUI, and Hiroshi MATSUI†
Department of Chemistry, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240
†The Radio Isotope Center, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240
(Received March 24, 1987)

Synopsis. The solid-liquid phase diagrams of binary mixtures of water with a series of tetrabutylammonium α-amino carboxylates, $(n\text{-}C_4H_9)_4NOOCCH(NH_2)R$ (R=H, CH_3, C_2H_5, $n\text{-}C_3H_7$, and $(CH_3)_2CH$), were examined. It was found that all the salts examined could form hydrates with hydration numbers either around 30 or around 39.

A series of tetrabutylammonium carboxylates has been known to form a clathrate-like hydrate[1] similar to the so-called gas hydrate.[2] According to a crystal structural analysis by Jeffrey et al. on a tetrabutylammonium benzoate hydrate,[3] oxygen atoms of the benzoate anion are incorporated into the water lattice, making an anionic host structure. The characteristics found for the tetrabutylammonium carboxylate hydrates are summarized as follows: (1) Two types of hydrates exist; group I which has fairly high melting points and hydration numbers around 30 and group II which has relatively low melting points and hydration numbers around 39; and (2) a methyl group attached to the carbon atom of the α-position of the carboxylate anion pronouncely lowers the stability of the hydrate due to a deformation effect imposed on the host structure.[1]

In this study, the solid-liquid phase diagrams for binary mixtures of a series of tetrabutylammonium α-amino carboxylates with water were examined in order to determine (1) whether these amino carboxylates can form similar types of clathrate-like hydrates and (2) the degree of distortion effect of a NH_2 group attached to the carbon atom of α-position on the stability of the hydrate.

Experimental

An aqueous solution of tetrabutylammonium amino carboxylates was prepared by the neutralization of a tetrabutylammonium hydroxide solution with each amino acid. The hydroxide solution was prepared by the same procedure as described in previous papers.[1,4] All amino acids were purchased from Tokyo Kasei Kogyo Co. Ltd., and were purified by a conventional method: A hot aqueous solution of an amino acid was added dropwise to 95 v/v% ethyl alcohol with stirring, followed by filtration of a solid phase and by washing the solid with 95 v/v% ethyl alcohol.

Solid-liquid phase diagrams for the binary systems of water-tetrabutylammonium amino carboxylates were determined in the same manner as described in the previous papers[1,4] (an ampoule method).

Results and Discussion

The solid-liquid phase diagrams for binary systems of tetrabutylammonium aminoacetate (glycine salt)-water and of tetrabutylammonium DL-α-aminopropionate (alanine salt)-water are shown in Fig. 1. Similar phase diagrams for binary systems of tetrabutylammonium DL-α-aminoisobutyrate (valine salt)-water and of tetrabutylammonium DL-α-aminopentanoate (norvaline salt)-water are shown in Fig. 2. In these figures the logarithm of the concentration expressed in the mole fraction, X, is plotted against the reciprocal of the absolute temperature. The temperature, expressed in ordinary Celcius units, is shown on the upper side of the figure. Because of the similarity of the phase diagram of tetrabutylammonium DL-α-aminobutyrate-water system with that of the tetrabutylammonium DL-α-aminopropionate-water system, the phase diagram of the former system is excluded from Fig. 1.

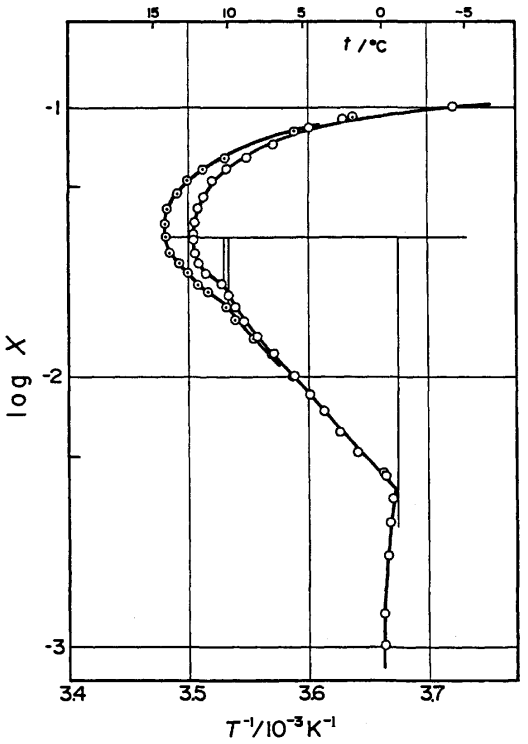

Fig. 1. Solid-liquid phase diagrams for the tetrabutylammonium aminoacetate-water system (◉) and for the tetrabutylammonium DL-α-aminopropionate-water system (○).

The existence of congruent melting points at $X\simeq0.032$ in Fig. 1 and at $X\simeq0.025$ in Fig. 2 clearly indicates that these salts form a hydrate which has large hydration numbers: the congruent composition of $X\simeq0.032$ corresponds to a hydrate whose hydration numbers are around 30 and of $X\simeq0.025$ to the one with hydration numbers around 39. Judging from such large hydration numbers, these hydrates seem to be

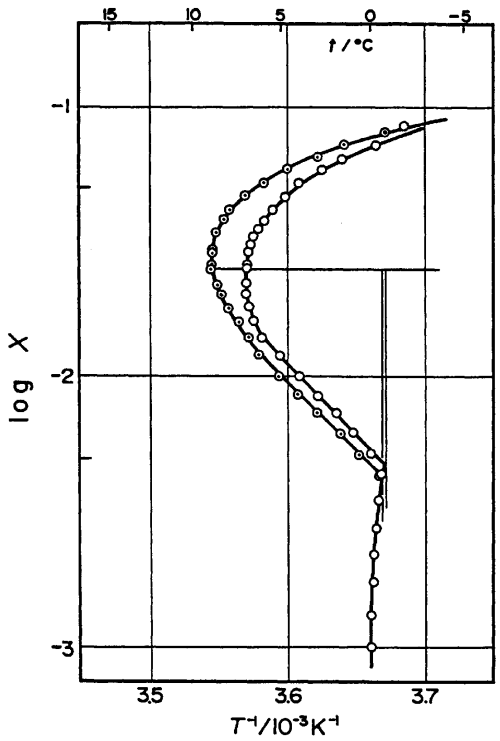

Fig. 2. Solid-liquid phase diagrams for the tetrabutylammonium DL-α-aminoisobutyrate-water system (○) and for the tetrabutylammonium DL-α-aminopentanoate-water system (◉).

clathrate-like hydrates, similar to $(n\text{-}C_4H_9)_4NF \cdot 30H_2O$[5] and $(n\text{-}C_4H_9)_4NOOCC_6H_5 \cdot 39.5H_2O$[3] hydrates. The presence of tetrabutylammonium amino carboxylate hydrates has never been known before. As can be seen in Fig. 1, phase diagrams of the tetrabutylammonium aminoacetate-water system and the tetrabutylammonium DL-α-aminopropionate-water system show an incongruent melting point of 10.1 °C at $X \simeq 0.018$ and of 10.4 °C at $X \simeq 0.022$, respectively. The exact hydration numbers of the hydrates formed in the concentration range between eutectic composition ($X \simeq 0.004$) and the concentration corresponding to the incongruent point are not obvious at present.

All the melting points and hydration numbers, determined from each congruent melting point and congruent composition are summarized in Table 1. From these results the clathrate-like hydrates of tetrabutylammonium DL-α-amino carboxylates can be classified into two groups, group I and group II, just as in the case of tetrabutylammonium carboxylate hydrates.[1] The classification of group I and II is also given in Table 1. The group I hydrate, whose hydration numbers are around 30, has fairly high melting points and is formed by amino carboxylates with small alkyl groups. The group II hydrate, whose hydration numbers are around 39, has relatively low melting points and is formed by amino carboxylates with relatively large alkyl groups.

In previous studies[1,4,6] it became clear that the melting point of tetrabutylammonium salt hydrate is largely dependent upon the molar volume of the anion

Table 1. Melting Points and Hydration Numbers of Clathrate-Like Hydrates of Tetrabutylammonium DL-α-Amino Carboxylates $(n\text{-}C_4H_9)_4NOOCCH(NH_2)R$

R	Mp θ_m/°C	Hydration number	Group
H	14.2	30±1	I
CH_3	12.3	30±2	I

The same relationships for tetrabutylammonium carboxylate hydrates[1] and tetrabutylammonium alkanesulfonate hydrates[4] are also shown.

of the salt. This relation is represented in Fig. 3, in which the melting point of each hydrate is plotted against the conventional partial molar anionic volume at 25 °C as an indication of the effective volume of the anion within the hydrate solid.[6] The conventional partial molar volume of each amino carboxylate anion was obtained from the literature.[7] In Fig. 3 the same relationships for a series of tetrabutylammonium carboxylate hydrates[1] and of tetrabutylammonium alkanesulfonate hydrates[4] are also shown. Although the dependence of the melting point of the amino carboxylate hydrates upon the anionic volume is not so marked as compared with the other two series of hydrates, the region in which either the group I hydrate or the group II hydrate is formed is essentially identical for the three types of hydrates. For this reason, concerning the crystal structure of the amino carboxylate hydrates, the same speculation as was done regarding both the carboxylate hydrates and the alkanesulfonate hydrates may be made: The group I hydrate is iso-structural with $(n\text{-}C_4H_9)_4NF$ hydrate[5] and a vacant pentagonal dodecahedron is occupied by a small alkyl group, such as CH_3 and C_2H_5, of the amino carboxylate anion; and the group II hydrate is iso-structural with $(n\text{-}C_4H_9)_4NOOCC_6H_5$ hydrate[3] and the amino carboxylate anion like $CH_3(CH_2)_2CH(NH_2)$-

Table 2. Melting Points of Clathrate-Like Hydrates of Three Types of Tetrabutylammonium Carboxylates

COO^- and $(CH_3)_2CHCH(NH_2)COO^-$ is enclathrated within a large polyhedron, such as tetrakaidecahedron and pentakaidecahedron.

In Table 2 the melting points of the hydrates of three types of tetrabutylammonium carboxylates (ordinary carboxylates,[1] DL-α-amino carboxylates and α-methyl carboxylates[1]) are compared with each other. This table clearly indicates that the effect of a NH_2 group upon the melting points of the hydrate is generally intermediate between that of a H group and of a CH_3 group. However, it is interesting to note that (1) the melting point of the tetrabutylammonium aminoacetate hydrate (14.2 °C) is almost the same as that (14.8 °C) of the tetrabutylammonium acetate hydrate, in spite of the situation that a slightly bulky $CH_2(NH_2)$ group is expected to be more suitable for being intercalated within a pentagonal dodecahedron than a CH_3 group; and (2) the melting point of the valine salt hydrate (6.9 °C) is lower than that of the norvaline salt hydrate (8.9 °C), in contrast to the slightly higher melting point (11.3 °C) of tetrabutylammonium isovalerate hydrate as compared with that of tetrabutylammonium pentanoate hydrate (10.6 °C). These phenomena may be explained by the formation of hydrogen bonding between the NH_2 group and water lattice since the configuration of the group attached to the carbon atom of α-position is restricted if both the COO^- group and the NH_2 group make hydrogen bonding with water lattice at the same time. Though the effect of the formation of a hydrogen bonding between the NH_2 group and water lattice upon the stability of the hydrates is not so eminent, this effect will lead to the anticipation that there will be some difference in the melting points of the hydrates between a D-amino carboxylate and of a L-amino carboxylate. Preliminary experiments for α-aminopropionate and α-aminoisobutyrate hydrates showed that the melting points of the hydrates were slightly different between the D and the L isomers. Precise investigations are now in progress.

Excited-State Reactions of Coumarins in Aqueous Solutions. V. Fluorescence Lifetimes of 7-Ethoxycoumarin in Acidic Solutions

Tetsuo MORIYA
Electrotechnical Laboratory, 1-1-4 Umezono, Sakura-mura, Niihari-gun, Ibaraki 305
(Received May 11,1987)

Synopsis. The fluorescence lifetime of 7-ethoxycoumarin (7EC) was measured in acidic aqueous solutions while varying the concentration of Cl^- as a fluorescence quencher. The subsequent analysis of the two-component fluorescence decay curves indicated that the protonated species in the excited state led to the fluorescence quenching; this result was quantitatively consistent with the fluorescence-yield study under steady-state conditions.

Since the extensive study of the photophysics of aromatic compounds was carried out by Ware and his co-workers,[1] it has been confirmed that steady-state and time-dependent analyses provide complementary information on various reaction processes and kinetic rate constants. The main concern of this report is to clarify the relation between the fluorescence lifetime and the steady-state quenching measurements of 7-ethoxycoumarin (7EC), which exhibits very interesting excited-state reactions, as has been extensively studied in previous papers.[2,3] Coumarin derivatives are heterocyclic compounds with a ring oxygen and a carbonyl group. Usually they have a very efficient fluorescing ability and show a variety of protonation or deprotonation reactions in the excited state, depending on the solvent conditions. To know the detailed mechanisms of such reactions, we must determine several rate constants which correspond to phenomena in a nanosecond region.

The transient spectroscopy of aqueous 7EC solutions has been conducted as a function of the quencher concentration, and the results have been compared with those of the steady state measurement. Assuming that two reacting species exist in the excited state, only one of which can cause a fluorescence-quenching reaction, the dependence of the lifetimes on the quencher concentration has been analyzed. The proposed model can consistently explain the results of both steady-state and transient studies.

Experimental

The high-purity-grade reagent of 7-ethoxycoumarin (7EC) was obtained from Molecular Probes, Inc., and was used without further purification; mp 84.8 °C. The hydrochloric acid and perchloric acid were of a pure quality and were obtained from Wako Pure Chemical Ind. The water was permeated and distilled.

The usual UV absorption and fluorescence spectra of the aqueous 7EC solution of $\approx 5\times10^{-5}$ mol dm^{-3} were measured at 20 °C. The pH of the solution was controlled with HCl and $HClO_4$, the chloride-ion concentration being adjusted by changing their ratio. The fluorescence lifetime measurements were performed by means of a time-correlated single-photon-counting fluorometer similar to the one described in Ref. 4. Since the lifetime of the fluorescer was close to the decay time of a repetitive short-pulsed light at 337 nm from an air-flash lamp, the result was deconvoluted in order to ascertain the true decay character, unaffected by the response function of the measurement system; the typical accuracy of this procedure was ±0.05 ns.

Results

The fluorescence quenching phenomenon of 7EC by chloride ions in acidic aqueous solutions has already been investigated under steady-state light illumination.[3] When $[H^+]$ was set at 0.5 mol dm^{-3} by the addition of HCl or $HClO_4$, the absorption maximum was at 324 nm, which corresponded to the neutral form (N) of 7EC. On the other hand, the fluorescence spectrum was composed of the emission from the neutral form of excited molecules ($\overset{*}{N}$), peaking at 390 nm, and the weak component from the protonated form ($\overset{*}{C}^+$), peaking at 423 nm. The general scheme of the excited state reaction and the fluorescence quenching process was given by:[3]

$$\begin{array}{ccccc} & & \overset{*}{N} & + H^+ \underset{k_2}{\overset{k_1}{\rightleftharpoons}} & \overset{*}{C}^+ \\ G \nearrow & & \searrow \tau^{-1} & & \downarrow \tau'^{-1} \\ h\nu_A & & h\nu_F & & h\nu_F' \end{array} \qquad (1)$$

$$\overset{*}{C}^+ + Cl^- \xrightarrow{k_q} C^+ + Cl^- \qquad (2)$$

The excited neutral species ($\overset{*}{N}$) is generated by a continuous UV-light illumination at the rate of G, and it is rapidly equilibrated with the excited protonated species ($\overset{*}{C}^+$) in the acidic solution. Then, $\overset{*}{C}^+$ interacts with the chloride ions and is deactivated to the ground state (C^+). k_1 and k_2 are the forward and backward rate constants for equilibration; τ and τ' are the fluorescence lifetimes of the neutral and protonated species respectively. k_q is the quenching rate constant caused by the collisional interaction between $\overset{*}{C}^+$ and Cl^-. By the analysis of the relative fluorescence intensity, I_0/I, depending on $[Cl^-]$ (I_0 and I are the fluorescence intensities in the absence and in the presence of chloride ions), the various rate constants in Eqs. 1 and 2 have already been determined, as cited in Table 1.[3] The ClO_4^- ion showed no observable quenching ability.

Under the pulsed-light excitation at 337 nm which

generates $\overset{*}{N}$, the decay characteristic of fluorescence from the neutral fluorescer has been measured at 390 nm in the acidic aqueous solution while varying the concentration of Cl^-. The pH is kept constant by satisfying $[HClO_4]+[HCl]=0.5\,mol\,dm^{-3}$, and $[Cl^-]$ is controlled by the amount of the HCl component added. The time-dependent light intesity, $i^N(t)$, of $\overset{*}{N}$ could be analysed by means of a decay curve of a double exponential character:

$$i^N(t) \propto \exp(-t/\tau_+) + C\cdot\exp(-t/\tau_-) \quad (3)$$

The best-fitted values for τ_+, τ_-, and C are shown in Table 2. The typical decay profiles of a light source, a fluorescence response, and the fitted curve are shown in Fig. 1. The total fluorescence spectrum of 7EC at $[H^+]\approx0.5\,mol\,dm^{-3}$ includes two components which

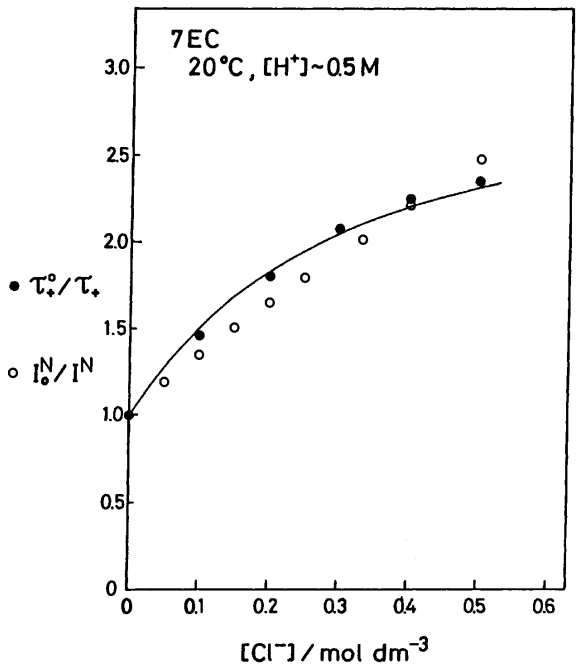

Fig. 2. Dependences of the relative fluorescence intensity, I_0^N/I^N (○), and the relative lifetime, τ_+^0/τ_+ (●), of 7EC on $[Cl^-]$ in the acidic aqueous solution at 20 °C. The solid line shows the theoretical prediction for τ_+^0/τ_+ vs. $[Cl^-]$ presented in the text.

result from the $\overset{*}{N}$ and $\overset{*}{C}^+$ in the solution. Since the concentration of $\overset{*}{C}^+$ is lower than that of $\overset{*}{N}$ by about one order of magnitude at $[H^+]\approx0.5\,mol\,dm^{-3}$, the fluorescence contribution of $\overset{*}{C}^+$ at 390 nm is negligible in the lifetime measurement. Equation 2 describes how the fluorescence quenching by Cl^- is operative only for $\overset{*}{C}^+$, as was proved previously.[3] This has been reaffirmed by the fact that the time-variation in the $\overset{*}{N}$ fluorescence in a simple neutral solution, where no $\overset{*}{C}^+$ is formed, is not changed by the further addition of 0.5 mol dm^{-3} NaCl.

In Fig. 2, the dependences of the relative fluorescence intensity, I_0^N/I^N, and the relative lifetime, τ_+^0/τ_+, on $[Cl^-]$ are shown, where τ_+^0 is a slow-decay component of the fluorescence lifetime of $\overset{*}{N}$ in the absence of Cl^-. These plots do not obey the linear Stern-Volmer relationship. The nonlinear dependency of the steady state result (I_0^N/I^N vs. $[Cl^-]$) was clearly explained in a previous paper.[3]

Discussion

Based on the scheme described by Eqs. 1 and 2, the time-dependent rate equation of the excited species can be derived. Subsequently, the response of $i^N(t)$ for a light pulse with an ideal δ-function is easily obtained:

$$\tau_\pm^{-1} = \frac{1}{2}\left[\tau^{-1} + \tau'^{-1} + k_1[H^+] + k_2 + k_q[Cl^-] \mp \sqrt{\{(\tau^{-1}+k_1[H^+]) - (\tau'^{-1}+k_2+k_q[Cl^-])\}^2 + 4k_1[H^+]k_2}\right] \quad (4)$$

$$C = -\frac{\tau'^{-1} + k_2 + k_q[Cl^-] - \tau_-^{-1}}{\tau'^{-1} + k_2 + k_q[Cl^-] - \tau_+^{-1}} \quad (5)$$

From Eqs. 4 and 5, τ_+, τ_-, and C are theoretically predictable using the constants given in Table 1. The calculated values are shown in the last three columns of Table 2; the dependence of $\tau_\Phi^{cal}/\tau_+^{cal}$ on $[Cl^-]$ is drawn in Fig. 2 with a solid line. The quencher-concentration dependence of τ_Φ/τ_+ agrees very well with the theoretical prediction. It is possible in principle to determine the rate constants, k_1, k_2, and k_q, from the obtained set of τ_+, τ_-, and C values by using $1/\tau_+ + 1/\tau_- \propto$ const.$+k_q[Cl^-]$, etc. Because of the relatively low accuracy of deconvolution for the fast-decay component (τ_- and C, ±10—30%) compared with that of τ_+ (±2—5%), the rate constants to be determined are less reliable than those given by steady-state measurements (±1%). The lifetime analysis based on observing the fluorescence component from $\overset{*}{N}$ of 7EC is analogous to the lifetime measurement of a monomer form in aromatic compound-quencher molecule systems, where an exciplex is generated to result in fluorescence quenching.[1] The excited-state reaction of coumarin derivatives is classified essentially as an acid-base reaction and has time constants of a nanosecond order because of the very high mobilties of the participating species, such as H^+ and Cl^-, whereas the exciplex-formation reaction is a usually slower phenomenon by one or more orders.

The fluorescence-lifetime study of the aqueous solution of 7EC is characteristic in that the instantaneous or 'static' quenching process, which makes the steady state analysis complex, does not appear in the first approximation if the quencher concentration is not very high. A similar example has been presented by Efftink and Ghiron,[5] who have shown experimentally, in an indole-quencher system, that τ^0/τ is independent of the $W=\exp(-V[Q])$ factor, in contrast to I_0/I, where V is the static quenching constant. After pulsed-light illumination, the fraction, W, of the generated excited state, $\overset{*}{C}^+$, is actually quenched by the collisional mechanism corresponding to the rate constant, k_q. The remaining fraction, $1-W$, is deactivated almost instantaneously after being formed because the quencher, Cl^-, is accidentally positioned in the proximity of $\overset{*}{C}^+$ and interacts directly with it. Including such a static quenching mechanism, the fluorescence-yield decrease of 7-ethoxycoumarins by Cl^- in acidic solutions under steady state conditions has been successfully explained.[3] In the rate equations for the time-variations of $[\overset{*}{N}]$ and $[\overset{*}{C}^+]$ under pulsed excitation, the fraction of excited species that never give fluorescence over an observing interval of, typically, 50 nanoseconds and which result in the static quenching must be treated separately from a reaction system described with time-independent rate constants. That is, the generation rate, G, of $\overset{*}{N}$ should be reduced effectively to $G\cdot\{(\tau^{-1}+Wk_1[H^+])/(\tau^{-1}+k_1[H^+])\}$, maintaining the same equational form as $W=1$.[3] Such an approximation is valid for a weak static quenching case ($V \ll k_q\tau'$) and for rapid protonation and deprotonation reactions. A more rigorous treatment has appeared in the serial works of Ware et al.[1] and Weller,[6] who formulate the transient nature of the diffusing reactants by introducing a time-dependent rate constant into the rate equation and who show that the static quenching mentioned here is essentially equivalent to the transient effect. The replacement of the quenching-reaction term with $k_q(t)[Cl^-][\overset{*}{C}^+]$ will be required in the present problem, where $k_q(t)$ decreases to the usual constant k_q at a large t. However, except for a very short interval after pulsed excitation, the two different ways of analysis which utilize W and $k_q(t)$ as the key parameters give approximately the same results for the case of a weak transient effect.[1,5,6] It may be concluded that, under appropriately chosen conditions, the normalized intensity for $i^N(t)$ is given by Eq. 3—5, even if $W \neq 1$, whereas the integrated yield of the fluorescence is not correctly derived without taking account of the static quenching effect.

It has been made clear that, in the steady state study, the static quenching parameter, W, is a very important factor in analyzing the nonlinear behavior of I_0/I vs. $[Cl^-]$, but, in the transient study, W is less important for the time variation in the fluorescence from $\overset{*}{N}$. Experimentally, the quencher dependence of τ_Φ/τ_+ behaves very differently from I_0^N/I^N, as is shown in Fig. 2. The parameters determined by the steady state measurement could consistently reproduce the data from the transient spectroscopy, although these two methods differ in the treatment of the static quenching factor, W. Therefore, the validity of the fundamental scheme of Eqs. 1 and 2 for the excited state reactions of 7EC has been well confirmed by independent experiments.

Preparation of Noble Metal Organosols Containing Polyethylene Glycol Mono-*p*-nonylphenyl Ether

Yukimichi NAKAO* and Kyoji KAERIYAMA
Research Institute for Polymers and Textiles, Yatabe-Higashi, Tsukuba, Ibaraki 305
(Received June 26, 1987)

Synopsis. Stable organosols of ruthenium, rhodium, palladium, and platinum were prepared by evaporating the corresponding noble metal hydrosols containing nonionic surfactant, polyethylene glycol mono-*p*-nonylphenyl ether, followed by dissolving the resulting residues in organic solvents such as chloroform. The organosol of the noble metals was exclusively yielded at a definite range of the surfactant concentration. A mechanism for the formation of the organosols is proposed.

There are fewer reports on the organosols of metals than those on their hydrosols. Svedberg's method is known to be applicable to the preparation of a variety of metal organosols which are somewhat unstable and polydispersed.[1] Thomas[2] reported that the pyrolytic decomposition of organometallic compounds such as dicobaltoctacarbonyl in organic media gave monodispersed organosols of the corresponding metals. Hirai et al.[3] prepared extremely fine colloidal rhodium dispersed in methanol by reducing $RhCl_3 \cdot 3H_2O$ with the methanol in the presence of NaOH. More recently, Boutonnet et al.[4] proposed a preparative method for colloidal metals in organic solvents from microemulsion. On the other hand, Meguro and Kondo[5] found that colloidal Fe_2O_3 having positive charge coagulated on addition of sodium dodecylbenzenesulfonate and that the resulting coagulum was redispersed in organic solvents to give an organosol.

In the preceding paper[6] are reported a variety of noble metal hydrosols stabilized by cationic, anionic, or nonionic surfactant. We have succeeded in converting the hydrosols of noble metals stabilized by nonionic surfactant, polyethylene glycol mono-*p*-nonylphenyl ether, into their organosols. In this paper, preparative procedures and adaptable noble metals and dispersion media are described.

Experimental

Materials. Noble metal salts used as starting materials were reagent grade $RuCl_3 \cdot 3H_2O$, $RhCl_3 \cdot 3H_2O$, $PdCl_2$, and $H_2PtCl_6 \cdot 6H_2O$. Polyethylene glycol mono-*p*-nonylphenyl ether (degree of polymerization=10, PN) as a protecting agent and sodium borohydride ($NaBH_4$) as a reductant were also of reagent grade. Water was deionized and distilled before use.

Preparation of Noble Metal Organosols. Noble metal organosols were prepared via the corresponding hydrosols previously reported.[5]

A typical procedure for the preparation of a rhodium organosol is as follows. $RhCl_3 \cdot 3H_2O$ (0.05 mmol) and PN (10 mg) were dissolved in water (95 cm^3). Then, an aqueous solution (5 cm^3) of $NaBH_4$ (0.2 mmol) was poured into the mixture with vigorous stirring. At that time, rhodium ion was rapidly reduced to result in the formation of a clear dark-brown hydrosol of rhodium. The hydrosol was then placed into a Petri dish and heated to evaporate to dryness on a hot plate of a temperature of about 150 °C. A tarry residue left after evaporation was redissolved in chloroform (100

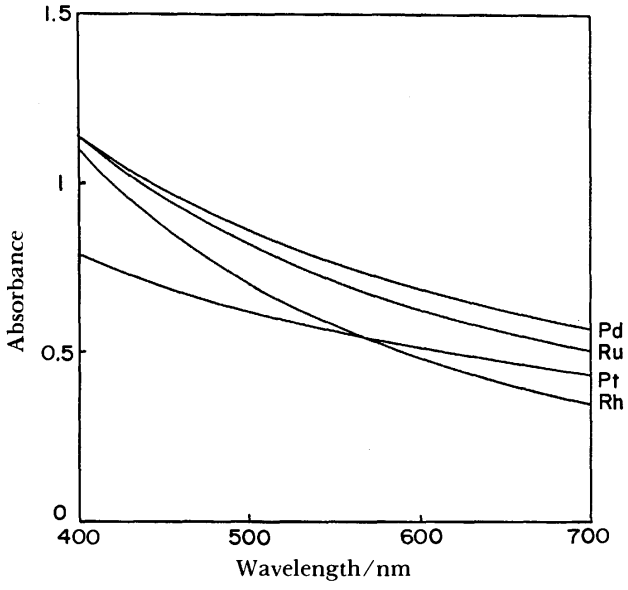

Fig. 1. Visible absorption spectra of noble metal organosols in chloroform (PN conc. in starting hydrosols; 0.01% for Ru and Rh, 0.05% for Pd and Pt).

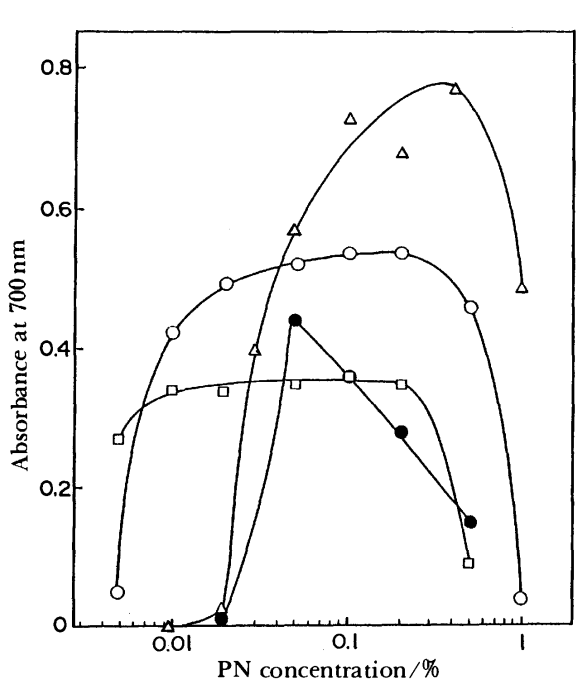

Fig. 2. Absorbance at 700 nm by noble metal organosols in chloroform (○: Ru, □: Rh, △: Pd, ●: Pt).

cm^3) to yield a clear dark-brown sol of rhodium. A small amount of insolble colorless part of the residue was then removed by decantation.

According to a similar precedure, ruthenium, palladium, and platinum sols dispersed in chloroform were obtained. In the case of palladium, NaCl (0.25 mmol) was added to dissolve $PdCl_2$.

Visible Spectroscopy. The visible spectra of the noble metal sols in chloroform were measured on a Shimadzu Model UV-240 spectrophotometer using a cell of a light-path length of 1 cm.

Electron Microscopy. A very small amount of a noble metal sol in chloroform was evaporated to dryness on a thin carbon film supported by Cu-mesh and observed with a Hitachi Model H-800 electron microscope at a magnification of 200000.

Results and Discussion

Hydrosols of ruthenium, rhodium, palladium, and platinum were prepared with varying amounts of PN, and the formation of noble metal organosols from the hydrosols was examined. Thus, the hydrosols were evaporated to dryness and chloroform was added to the residues to dissolve them. In Fig. 1 are shown the typical visible absorption spectra of the supernatant solutions, that is, noble metal organosols. Figure 2 shows the absorbance at 700 nm of the organosols.

Table 1. Solubility of Residues from Noble Metal Hydrosols Left after Evaporation

++ Completely soluble, + partly soluble, − insoluble.

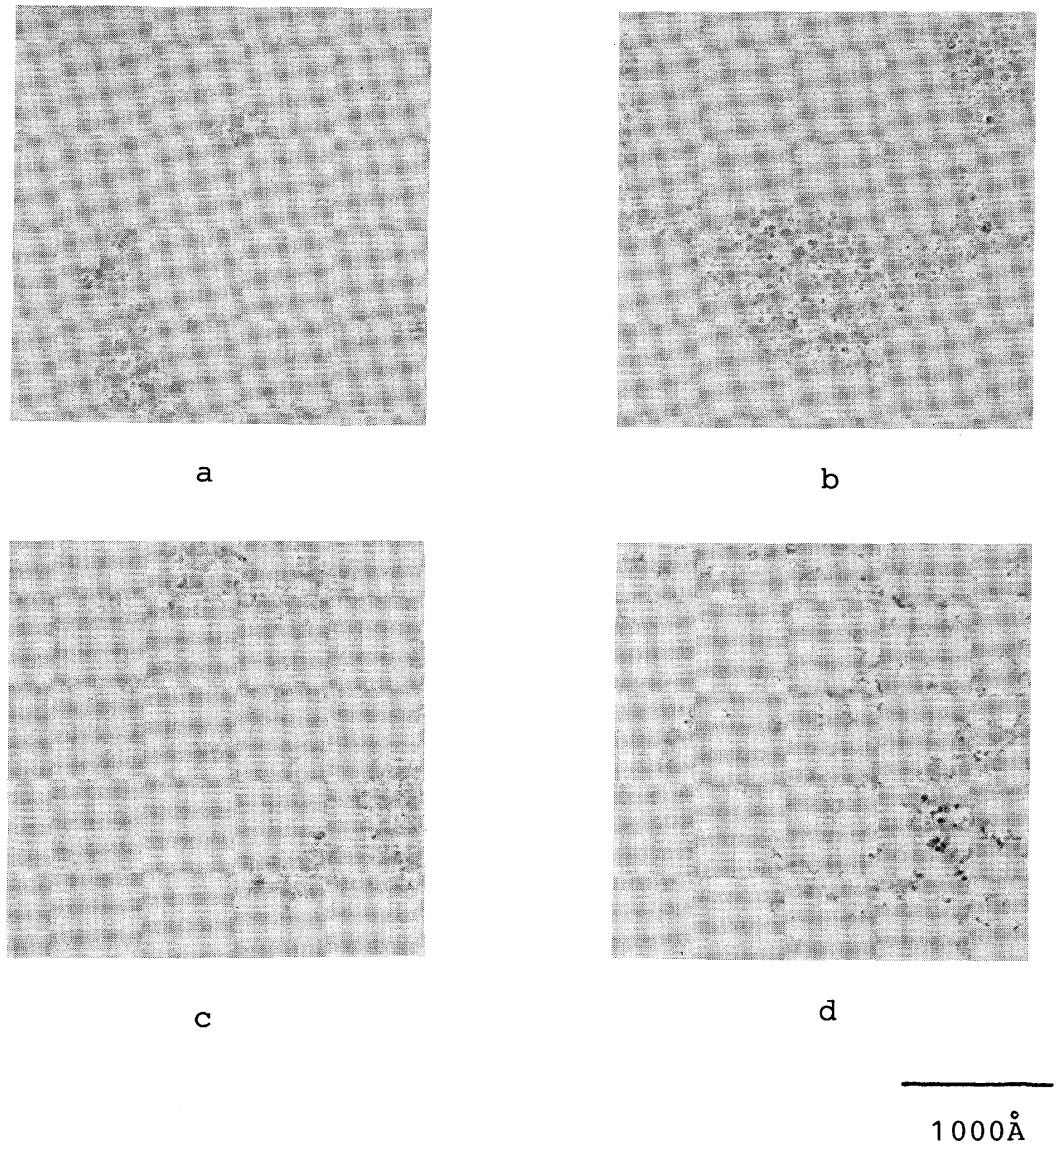

Fig. 3. Electron micrographs of colloidal ruthenium (a), rhodium (b), palladium (c), and platinum (d) from the organosols in chloroform.

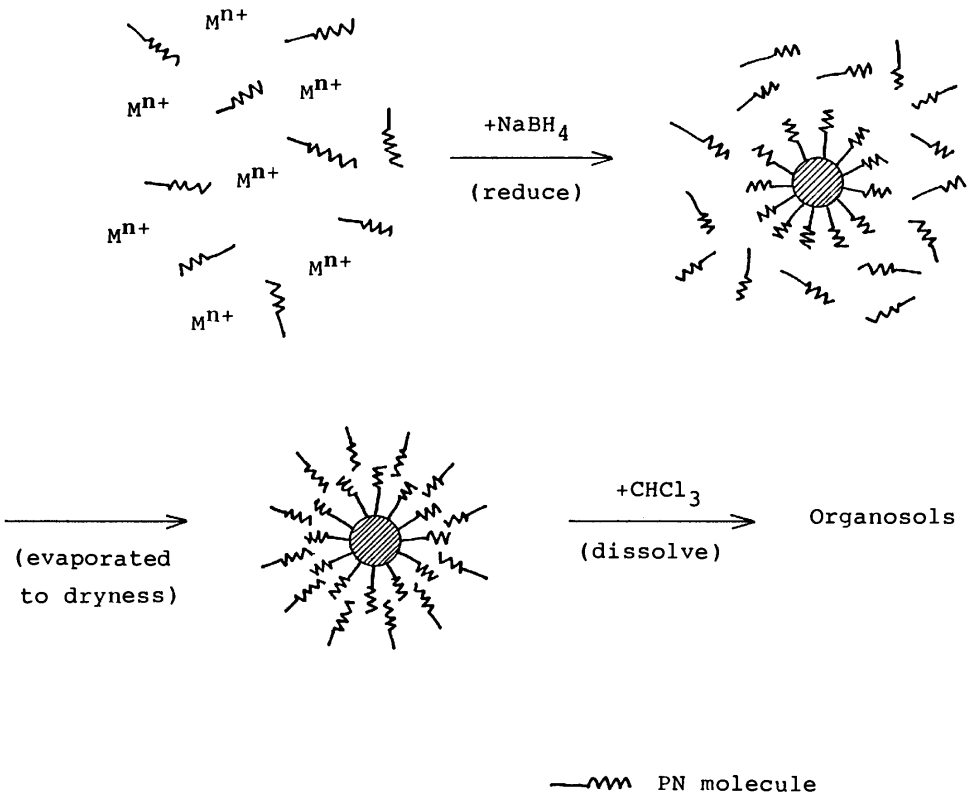

Fig. 4. Mechanism for the formation of noble metal organosols in the presence of PN (∧∧∧∨ and —— designate the hydrophilic and hydrophobic moieties of PN molecules, respectively).

The absorbance is presumed to be an indication of the amounts of colloidal noble metals in the organosols.[7] This figure indicates that noble metal organosols in chloroform were successfully yielded at a definite range of PN concentration. In other cases, all or a part of colloidal noble metal particles remained in the insoluble residues. Rhodium organosols were obtained at PN concentration of 0.01—0.2% with good reproducibility and were quite similar in color to each other. Ruthenium organosols were also yielded at a wide range of PN concentration. In the case of palladium, larger amounts of PN were required for organosol formation. Among residues from platinum hydrosols, only that from a sol containing 0.05% PN was completely dissolved in chloroform to give an organosol.

In Table 1 are shown the solubilities of the residues from the noble metal hydrosols in a variety of organic solvents. This indicates that chloroform was the most useful dispersion medium for organosols.

Colloidal noble metal particles in the organosols observed by an electron microscope are shown in Fig. 3. Two-dimensional aggregation of the colloidal particles appeared in the electron micrographs might be occurred in the course of evaporation. Such two-dimensional aggregations were also observed in the electron micrographs of the noble metal hydrosols,[6] and the colloidal particles had almost equal dimensions as those in the precursor hydrosols. Narrow spaces lain between the colloidal particles in the aggregates are presumed to correspond to PN layers on the surface of the particles.

A possible mechanism for the formation of noble metal organosols is shown in Fig. 4. At the first step, noble metal ions are reduced with $NaBH_4$ to yield colloidal metal particles. Then the surface of the particles may be immediately covered with PN molecules, of which the hydrophobic moiety orients to the surface. At the second step, excess PN molecules, which exist apart from the surface of the particles, are forced to be attached on the first-adsorbed layers of PN as the evaporation proceeds, and form themselves into the second layer with hydrophobic outer surface. Thus, the colloidal particles could be dispersed in organic solvents.

Synopsis. Rates of the dehydrogenation of 2′-substituted flavanones with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone were measured by means of HPLC analyses. All substituents at the ortho position of the side-chain phenyl group of flavanones showed a retarding effect on the reaction. A correlation analysis for the ortho effect using the linear combination model has led to a conclusion that the inductive effect is much more important than the steric and the resonance effect, and that the steric effect is slightly greater than the resonance effect.

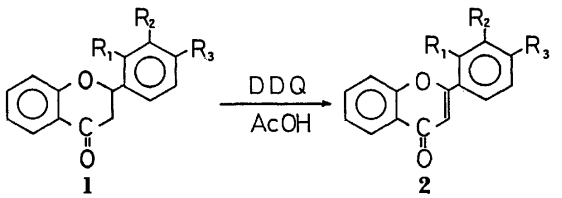
We previously examined the rate of dehydrogenation of flavanones (**1**) with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) in dry benzene in the presence of acetic acid.[1] The following conclusions were drawn: (1) the reaction is first-order in both concentrations of substrate and DDQ; (2) the reaction proceeds along a path of the two-step ionic mechanism and its rate-determining step is a hydride abstraction by quinol cation of DDQ (Scheme 2); (3) the rate is increased by introduction of an electron-donating group at the meta or para position of the side-chain phenyl group, and decreased by introduction an electron-withdrawing one; (4) the apparent second order rate constant, $k_{2,a}$, is proportional directly to the square root of the initial concentration of acetic acid.

On the other hand, it is generally considered that the ortho substituent effect on the reactivity results in various kinds of influences depending upon the sort and condition of reaction. Namely, the steric and proximity effects may participate complicatedly in addition to the normal inductive and resonance ones. Thus, it is general to analyse the ortho substituent effect independently of the meta and/or para substituent ones.

Now, for the purpose of examination of the ortho substituent effect on the dehydrogenation of flavanones, reactions of 2′-substituted flavanones (**1b—f**) with DDQ were conducted under the same reaction conditions as those in the previous work.[1] All analyses of rates of reaction were continued for ten hours after the beginning of reaction (percentages of reaction were ca. 15—33%) by means of HPLC analyses. In this series also, all reactions for five flavanone derivatives followed the second rate law (Eq. 1):

$$dx/dt = k_{2,a}(a-x)(b-x) \quad (1)$$

where a and b are the initial concentrations of substrate and DDQ, respectively, and x is the concentration of product. Rates were determined by the calibration method from the peak area ratio vs. the concentration ratio. Values of $k_{2,a}$, which are the mean of three runs for each sample, are summarized in Table



1 **2**

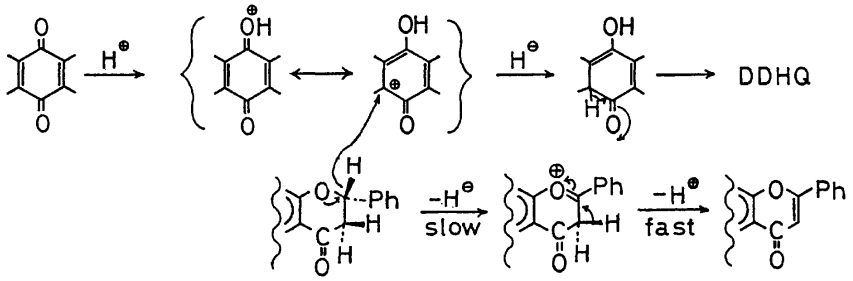
a $R_1=R_2=R_3=H$ **d** $R_1=OCH_3$, $R_2=R_3=H$
b $R_1=Cl$, $R_2=R_3=H$ **e** $R_1=R_3=CH_3$, $R_2=H$
c $R_1=CH_3$, $R_2=R_3=H$ **f** $R_1=R_2=OCH_3$, $R_3=H$

Scheme 1.

Table 1. Apparent Second Order Rate Constants and Relative Rates of Dehydrogenation of 2′-Substituted Flavanones with DDQ[a] at 80.0±0.2 °C

Substrate	Product	$k_{2,a}\times10^3$ / 1 mol^{-1} s^{-1}	k_{rel}[b]
1a	**2a**	1.43[c]	1.00
1b	**2b**	0.472	0.330
1c	**2c**	1.18	0.825
1d	**2d**	0.706	0.494
1e	**2e**	1.49	1.04
1f	**2f**	0.881	0.616

a) Initial concentrations: $[Substrate]_0=[DDQ]_0=1.0\times10^{-2}$ mol l^{-1}; $[CH_3COOH]_0=0.920$ mol l^{-1}. b) k_{rel} relative to $k_{2,a}$ for **1a**. c) From Ref. 1.

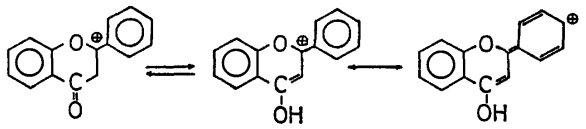


Scheme 2.

1. In the table, k_{rel} is the value relative to $k_{2,a}$ of **1a**. When the reaction proceeded above ca. 50%, correct analysis of the rate was no longer possible because of the precipitation of 2,3-dichloro-5,6-dicyanohydroquinone (DDHQ).

From the results in Table 1, it is clear that all the reaction rates decrease as compared with **1a**, except for **1e**. In contrast with the previous results (conclusion (3)), it is suggested that all the ortho substituents function with a retarding effect on this reaction regardless of their electronic properties. Although the reaction rate of **1e** is slightly greater than that of **1a**, it should be considered that an acceleration effect of the para-methyl group on the rate is comparatively canceled by the ortho-methyl group, because the relative rate of dehydrogenation of 4'-methylflavanone is 1.10.[1)]

A transition state of this reaction is a carbonium cation having a positive charge on the C_2-atom (conclusion (2) and Scheme 3). This carbocation corresponds to a flavylium cation (Scheme 3). In our work



Scheme 3.

on the basicity of flavones,[2)] it has been revealed that the side-chain phenyl group would be planar with the benzopyrylium ring in the state where the proton is added at the carbonyl oxygen atom. When a substituent is present at the ortho position of the side-chain phenyl group, the above-mentioned coplanarity seems to be prohibited in the transition state of this reaction. Thus the resonance effect of the substituent on the phenyl group is inhibited for such a steric reason. Furthermore, the reaction center, the C_2-position, might be blocked by the ortho substituent for the approach of an attacking species, and the rate of reaction decreases consequently. The values of **1b** and **1d** suggest that the inductive effect appears more eminent than the resonance one, because the former effect of the chlorine atom and methoxyl group functions in a retarding way for this reaction; the relative rates of the corresponding para-isomers are 0.923 and 1.37, respectively.[1)]

Taft[3)] and Charton[4)] represented the ortho effect as a linear combination of the inductive, resonance, and steric effects as Eq. 2:

$$\log (k_{rel})_{ortho} = \rho_I \sigma_I + \rho_R \sigma_R + \delta E_s \quad (2)$$

where σ_I, σ_R, and E_s are the inductive, resonance, and steric substituent constants, and ρ_I, ρ_R, and δ are the inductive, resonance, and steric reaction constants, respectively. In the present work, **1e** and **1f** have a meta or para substituent in addition to the ortho one. Then the relation obtained in the previous work[1)] for the meta or para substituted derivatives is added to both sides of Eq. 2 to give Eq. 3:

$$\log (k_{rel})_{o,m,p} = \rho_I \sigma_I + \rho_R \sigma_R^+ + \delta E_s - 0.190 \sigma_{(m,p)}^+ \quad (3)$$

where σ_R^+ is used instead of σ_R because of the introduction of Brown-Okamoto's electrophilic substituent constants, $\sigma_{(m,p)}^+$. According to Eq. 3, ρ_I, ρ_R, and δ were calculated by means of multiple least squares, where the values proposed by Ehrenson et al.[5)] were used for σ_I and σ_R^+ and those by Taft[3)] and Kutter and Hansch[6,7)] were used for E_s (Table 2). The reason for the adoption of these values is their popularity. Particularly, values of constant E_s were derived for heteroatom substituents and for symmetrical-top groups such as H and CX_3 (X=H, halogen, or CH_3). Consequently Eq. 4 was obtained as a linear free energy relationship for the substituent effect on the side-chain phenyl group in this reaction:

$$\log (k_{rel})_{o,m,p} = -0.893\sigma_I - 0.042\sigma_R^+ + 0.088E_s - 0.190\sigma_{(m,p)}^+ \quad (4)$$

The correlation coefficient of Eq. 4, 0.999, was obtained on the basis of a slope of the relation between the observed and the calculated values of the logarithmic relative rate (Fig. 1).

Table 2. Ortho Substituent Parameters for the Correlation Using the Linear Combination Model

Substituent	ρ_I[a)]	σ_R^+[b)]	E_S[c)]
H	0	0	0
Cl	0.46	−0.36	−0.97
CH_3	−0.04	−0.25	−1.24
OCH_3	0.27	−1.02	−0.55

a) Inductive substituent constant cited from Ref. 5.
b) Resonance substituent constant cited from Ref. 5.
c) Steric substituent constant cited from Refs. 3, 6, and 7.

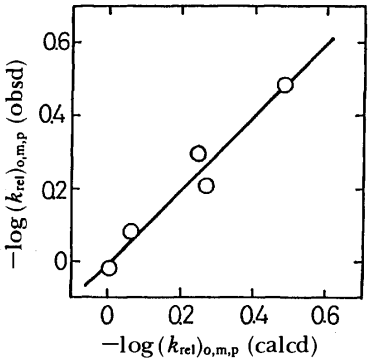


Fig. 1. Correlation between the calculated and the observed logarithmic relative rate.

From the results in Table 1 and Eq. 4, it can be concluded that, in the ortho substituent effect on the side-chain phenyl group for the dehydrogenation of flavanones with DDQ, the inductive effect (ρ_I= −0.893±0.05) is much more important than the steric and resonance effects, of which the steric one is somewhat influential, whereas the latter one is negligibly small. This conclusion is in accord with our recently proposed stepwise mechanism[1)] via the benzopyrylium type cationic intermediate for the DDQ dehydrogenation.

Experimental

All melting points were uncorrected. ^{1}H NMR spectra

were obtained with a Hitachi R-22 (90 MHz) spectrometer by using tetramethylsilane as an internal standard. HPLC analyses were conducted with a Yanagimoto High Speed Liquid Chromatograph L-2000 under the following conditions:

Stationary phase: Yanapak-SA-1

Mobile phase: Hexane-EtOH=10/1 (v/v) for **1d** and **1f**, and 40/1 (v/v) for **1b**, **1c**, and **1e**.

Detector: Yanagimoto U-212 Spectrometer (240 and 300 nm) Estimation: Yanagimoto Computing Integrator-SYSTEM 1000.

Materials. Benzene, acetic acid, and DDQ were of the same grade as those used in the previous work.[1] Flavanones were synthesized from the corresponding 2'-hydroxychalcones by the known procedures,[8] and identified by melting points, ^{1}H NMR, and elemental analyses.

2'-Chloroflavanone (1b): Mp 100—101 °C: ^{1}H NMR (CCl_4) δ=2.52—3.72 (2H, m, C_3-H_{ax}, H_{eq}), 5.75 (1H, d·d, C_2-H_{ax}, $J_{ax\cdot ax}$=12.0 Hz, $J_{ax\cdot eq}$=3.5Hz), 6.89—7.55 (7H, m, Aromatic), and 7.83 (1H, d·d, C_5-H, J_{ortho}=7.5Hz, J_{meta}=2.4 Hz). Found: C, 69.65; H, 4.13; Cl, 13.72%. Calcd for $C_{15}H_{11}O_2Cl$: C, 69.64; H, 4.29; Cl, 13.70%.

2'-Methylflavanone (1c): Mp 68.5—70.0 °C; ^{1}H NMR (CCl_4) δ=2.39 (3H, s, 2'-CH_3), 2.58—3.11 (2H, m, C_3-H_{ax}, H_{eq}), 5.58 (1H, d·d, C_2-H_{ax}, $J_{ax\cdot ax}$=12.2 Hz, $J_{ax\cdot eq}$=5.0 Hz), 6.89—7.56 (7H, m, Aromatic), and 7.85 (1H, d·d, C_5-H, J_{ortho}=8.4 Hz, J_{meta}=2.3 Hz). Found: C, 80.61; H, 6.03%. Calcd for $C_{16}H_{14}O_2$: C, 80.65; H, 6.03%.

2'-Methoxyflavanone (1d): Mp 61.0—62.0 °C; ^{1}H NMR (CCl_4) δ=2.53—3.11 (2H, m, C_3-H_{ax}, H_{eq}), 3.83 (3H, s, 2'-OCH_3), 5.76 (1H, d·d, C_2-H_{ax}, $J_{ax\cdot ax}$=11.0 Hz, $J_{ax\cdot eq}$=6.4 Hz), 6.78—7.60 (7H, m, Aromatic), and 7.85 (1H, d·d, C_5-H, J_{ortho}=8.0 Hz, J_{meta}=1.6 Hz). Found: C, 75.50; H, 5.62%. Calcd for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55%.

2',4'-Dimethylflavanone (1e): Mp 88—89 °C; ^{1}H NMR (CCl_4) δ=2.33 and 2.36 (3H, 3H, s, s, 2' and 4'-CH_3), 2.56—3.12 (2H, m, C_3-H_{ax}, H_{eq}), 5.56 (1H, d·d, C_2-H_{ax}, $J_{ax\cdot ax}$=12.5 Hz, $J_{ax\cdot eq}$=4.6 Hz), 6.92—7.53 (6H, m, Aromatic), and 7.88 (1H, d·d, C_5-H, J_{ortho}=7.8 Hz, J_{meta}=2.2 Hz). Found: C, 81.31; H, 6.55%. Calcd for $C_{17}H_{16}O_2$: C, 81.25; H, 6.42%.

2',3'-Dimethoxyflavanone (1f): Mp 96.0—96.5 °C; ^{1}H NMR (CCl_4) δ=2.64—3.08 (2H, m, C_3-H_{ax}, H_{eq}), 3.87 (6H, s, 2' and 3'-OCH_3), 5.74 (1H, d·d, C_2-H_{ax}, $J_{ax\cdot ax}$=10.5 Hz, $J_{ax\cdot eq}$=6.8 Hz), 6.79—7.52 (6H, m, Aromatic), and 7.88 (1H, d·d, C_5-H, J_{ortho}=8.5 Hz, J_{meta}=2.0 Hz). Found: C, 72.20; H, 5.74%. Calcd for $C_{17}H_{16}O_4$: C, 71.82; H, 5.67%.

Flavones as authentic samples for HPLC analyses were prepared by the same reaction as carried out in the kinetic experiment, and were isolated and purified by the known procedures.[9] Their physical data are as follows, except for **2c** which was identified by the value in literature.[10]

2'-Chloroflavone (2b): Mp 117.0—117.5 °C; ^{1}H NMR (CCl_4) δ=6.48 (1H, s, C_3-H), 7.27—7.75 (7H, m, Aromatic), and 8.14 (1H, d·d, C_5-H, J_{ortho}=8.3 Hz, J_{meta}=2.3 Hz). Found: C, 70.40; H, 3.47; Cl, 13.71%. Calcd for $C_{15}H_9O_2Cl$: C, 70.19; H, 3.53; Cl, 13.76%.

2'-Methylflavone (2c): Mp 46.0—47.5 °C (lit, 47.5 °C[10]).

2'-Methoxyflavone (2d): Mp 98.5—100 °C; ^{1}H NMR (CCl_4) δ=3.93 (3H, s, 2'-OCH_3), 6.84 (1H, s, C_3-H), 6.92—7.83 (7H, m, Aromatic), and 8.11 (1H, d·d, C_5-H, J_{ortho}=8.2 Hz, J_{meta}=2.0 Hz). Found: C, 76.09; H, 4.80%. Calcd for $C_{16}H_{12}O_3$: C, 76.18; H, 4.79%.

2',4'-Dimethylflavone (2e): Mp 64.5—66.0 °C; ^{1}H NMR (CCl_4) δ=2.34 (3H, s, 4'-CH_3), 2.43 (3H, s, 2'-CH_3), 6.24 (1H, s, C_3-H), 6.96—7.66 (6H, m, Aromatic), and 8.12 (1H, d·d, C_5-H, J_{ortho}=8.5 Hz, J_{meta}=2.0 Hz). Found: C, 81.50: H, 5.71%. Calcd for $C_{17}H_{14}O_2$: C, 81.58; H, 5.64%.

2',3'-Dimethoxyflavone (2f): Mp 85.5—87.5 °C; ^{1}H NMR (CCl_4) δ=3.91 and 3.94 (3H, 3H, s, s, 2' and 3'-OCH_3), 6.98 (1H, s, C_3-H), 7.05—7.80 (6H, m, Aromatic), and 8.25 (1H, d·d, C_5-H, J_{ortho}=7.6 Hz, J_{meta}=1.5 Hz). Found: C, 67.64; H, 4.77%. Calcd for $C_{17}H_{14}O_4$: C, 67.55; H, 4.67%.

Procedures. Reactions and kinetic analyses were carried out in almost the same conditions and procedures as in the previous work.[1] Some comments are given in the footnote of Table 1.

Fluorinated Tertiary Thio- and Selenoethers from the Reaction of Sulfenyl or Selenenyl Chloride with Perfluoropropene Dimers in the Presence of Alkali Fluoride

Hitomi SUZUKI,* Hiroshi SATAKE, Hidemitsu UNO, and Hiroaki SHIMIZU†

(Received April 13, 1987)

Synopsis. Perfluoro(1,1-dimethylbutanide) anion generated from hexafluoropropene dimers and alkali fluorides in dry *N,N*-dimethylformamide, reacts with arenesulfenyl or areneselenenyl chloride to give the corresponding aryl perfluoro(1,1-dimethylbutyl) sulfides or selenides in low to good yields.

Fluorinated organic sulfides find uses as fungicides, insecticides, and surface-active agents. The usual procedures for the preparation of aryl perfluoroalkyl sulfides involve the alkylation of arenethiolates with perfluoroalkyl iodides,[1] reaction of aryl iodides[2] or arenediazonium salts[3] with metal perfluoroalkanethiolates, and photochemical reaction of arenethiols[4] or diaryl disulfides[5] with perfluoroalkyl iodides. Thermal decomposition of trifluoromethylazosulfonylarenes in the presence of diaryl disulfides[6] and reaction of aryl perfluoroalkyliodonium compounds with sodium arenethiolates[7] also lead to aryl perfluoroalkyl sulfides. In most of these cases, however, reactions are limited to the synthesis of fluorinated sulfides of short or straight alkyl chains. The synthesis of tertiary perfluoroalkyl sulfides is quite difficult, because the nucleophilic displacement of halogen atom from tertiary carbon is not feasible with perfluoro compounds.

In the present paper, we wish to report that aryl perfluoroalkyl sulfides of branched side chains can be easily obtained by the reaction of arenesulfenyl chlorides with perfluoroalkenes in the presence of alkali fluorides.[8] We used perfluoro(2-methyl-2-pentene) (**1a**) and perfluoro(4-methyl-2-pentene) (**1b**) as perfluoroalkenes, since these are inexpensive commercial products obtained by the dimerization of hexafluoropropene.[9]

When alkene **1a** or **1b** is stirred with potassium fluoride in dry *N,N*-dimethylformamide (DMF) at 50—60 °C, perfluoro(1,1-dimethylbutanide) anion is generated and smoothly reacts with arenesulfenyl chloride (**2**) to afford the corresponding aryl perfluoro (1,1-dimethylbutyl) sulfides (**3**) in 58—86% yields, which are of interest as additives to some organic fluids.[10]

Although **1a** appears to react more smoothly than **1b**, the yields of the common product **3** do not differ appreciably after appropriate duration of time. Tertiary structures of perfluoroalkyl chains are confirmed by ^{19}F NMR spectrum ($CFCl_3$) of **3a**, which exhibits absorptions due to CF_3 groups at δ 61.1 and 80.2 and those due to CF_2 groups at δ 104.3 and 121.3 with an intensity ratio of 6:3:2:2. Cesium fluoride is excellent as a source of fluoride ion, but it can be replaced by cheaper potassium fluoride without significant decrease in yields. Perfluoroalkene **1b** is known to isomerize into the thermodynamically more stable isomer **1a** in the presence of fluoride ion.[11] Both **1a** and **1b** are known to react with arenethiolates to give a complicated mixture of fluorinated vinylic sulfides.[12]

The present procedure is extended to the preparation of phenyl perfluoro(1,1-dimethylbutyl) selenide (**5**). Benzeneselenenyl chloride (**4**), generated in situ by the chlorinolysis of diphenyl diselenide with sulfuryl chloride, reacted with perfluoro(1,1-dimethylbutanide) anion in DMF at room temperature to give the expected selenide **5** in a low yield. incomplete even after prolonged reaction time. The product **5** is a photo-labile oil, which slowly decomposes on storage, even in a refrigerator, to form diphenyl diselenide. Reaction of **1a** with 2,4,6-trimethylbenzeneselenenyl chloride in the presence of an alkali fluoride also affords the corresponding selenide in a similar yield, but the product is unstable and soon begins to decompose on standing at room temperature. Introduction of methyl groups into aromatic rings appears to lower the stability of fluorinated tertiary selenoethers. Literature so far contains only few descriptions on the preparation of aryl perfluoroalkyl selenides; they are obtained either by photochemical reaction of areneselenols with trifluoromethyl iodide[13] or by treatment of trifluoromethaneselenenyl chloride with arylmagnesium bromides.[14]

In summary, the present method is a simple, efficient, and straightforward procedure for the preparation of various ring-substituted aryl tertiary perfluoroalkyl sulfides from readily accessible diaryl disulfides and commercially available perfluoroolefins.

Experimental

Perfluoro(2-methyl-2-pentene) (**1a**) and perfluoro(4-methyl-2-pentene) (**1b**) are commercial products available from NEOS Co. Ltd. (Kano-cho, Chuo-ku, Kobe 650, Japan). Diaryl disulfides are prepared by heating aryl iodides with copper(I) thiocyanate in hexamethylphosphoric triamide.[15] Diaryl diselenides are obtained by the alkaline decomposition of aryl selenocyanates.[16] Potassium fluoride is dried over phosphorus pentaoxide under reduced pressure at 100—120 °C prior to use.

Arenesulfenyl Chloride (2); General Procedure: To a stirred solution of diaryl disulfide (1 mmol) in dichloromethane (1 ml) is added dropwise sulfuryl chloride (1 mmol) at room temperature. Stirring is continued for 30 min to afford arenesulfenyl chloride **2** as a red solution, which is immediately used for the following reaction.

Aryl Perfluoro(1,1-dimethylbutyl) Sulfide (3); General Procedure: A mixture of perfluoro(2-methyl-2-pentene) **1a** (3.0 g; 10 mmol) and potassium fluoride (0.23 g; 4 mmol) in dry DMF (5 ml) is stirred at 50—60 °C for 3 h under nitrogen. Color gradually turns deep yellow. Then arenesulfenyl chloride **2** (2 mmol) is added dropwise and stirring is continued at this temperature for 1—2 h. After cooling the mixture is diluted with water and extracted with ether (3×10 ml). The organic extract is washed with brine, dried with sodium sulfate, and evaporated. The residual oil is chromatographed on silica gel (Wako Gel C-200) using hexane as eluent to give **3** in the yields given in the Table.

Perfluoro(1,1-dimethylbutyl) Phenyl Selenide (5): A mixture of perfluoroalkene **1a** (3.0 g; 10 mmol), potassium fluoride (0.23 g; 4 mmol) and DMF (5 ml) is stirred at 50—60 °C for 3 h under nitrogen. The resulting yellow liquid is cooled to room temperature and diphenyl diselenide (0.31 g; 1 mmol) followed by sulfuryl chloride (0.134 g; 1 mmol) is added with vigorous stirring. After stirring for 1 h, the reaction is quenched by the addition of water and the product is extracted with ether (3×10 ml). The combined extract is washed with brine, dried with sodium sulfate, and evaporated to leave an oily residue, which is chromatographed on silica gel (Wako Gel C-200) using hexane as eluent to give **5** as a pale yellow oil; yield, 0.195 g (21%). MS (20 eV) m/z (rel intensity) 476 (M^+, 3), 281 (8), 181 (46), and 157 (100); ^{1}H NMR (CCl_4): δ 7.33—7.50 (m, 3H) and 7.76—7.89 (m, 2H); IR (KBr) 3070, 1250—1210 (vs), 1150, 1100, 960, 820, 750, 730, and 710 cm^{-1}. Found: C, 30.12; H, 0.98%. Calcd for $C_{12}H_5F_{13}Se$: C, 30.34; H, 1.06%.

On standing, **5** gradually decomposes to separate diphenyl diselenide as yellow needles, mp 60—61 °C (lit,[17] mp 63 °C).

(Received July 1, 1987)

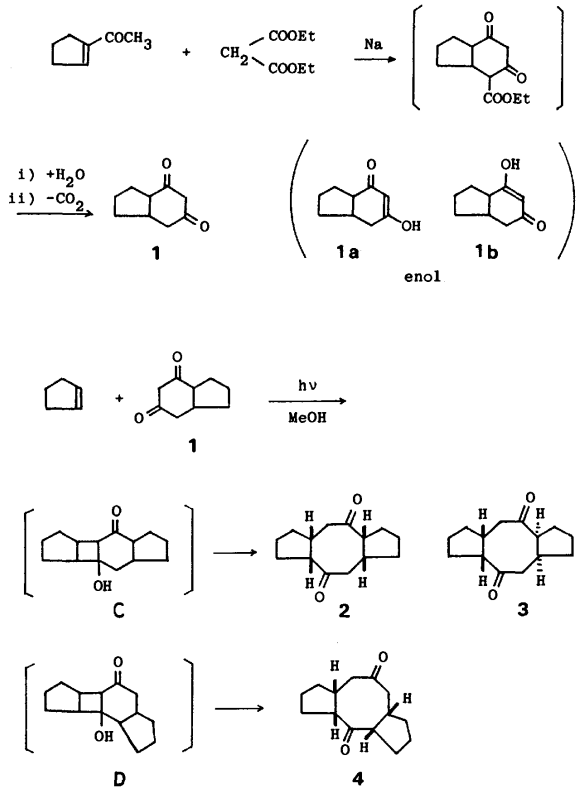
Synopsis. The isomers, *cis-cisoid-cis-* and *cis-transoid-cis*-tricyclo[9.3.0.0^{4,8}]tetradecane-2,9-dione (**2** and **3**) and *cis-cisoid-cis*-tricyclo[9.3.0.0^{3,7}]tetradecane-2,9-dione (**4**) were synthesized by the photocycloaddition of bicyclo[4.3.0]nonane-2,4-dione (**1**) to cyclopentene. X-Ray analyses of those compounds revealed that the conformations of the eight-membered rings are twist-boat in **2**, chair in **3**, and boat-chair form in **4**.

The 5-8-5 fused tricyclic systems have been found as the carbon skeletons of ophiobolin[1] sesterterpenes, and fusicoccin[2] and basmane[3] diterpenes. Although several reports[4] have appeared concerning the syntheses of 5-8-5 fused ring compounds, the synthetic and conformational studies on such compounds are still insufficient. In this paper we report the syntheses of some 5-8-5 fused ring compounds via the photocycloaddition of bicyclo[4.3.0]nonane-2,4-dione (**1**) to cyclopentene and their molecular structures and conformations.

The starting material, bicyclo[4.3.0]nonane-2,4-dione (**1**), was synthesized by Michael condensation between 1-acetylcyclopentene and diethyl malonate, accompanied by intramolecular cyclization and followed by decarboxylation, in an analogous synthetic procedure of dimedone.[5] The enolization of β-diketone (**1**) is feasible in two forms, **1a** and **1b**. For the photoadducts, therefore, two structural isomers (**C** and **D**) are possible.

The photocycloaddition was carried out in a methanol solution of **1** and cyclopentene by high-pressure mercury lamp, and yielded directly 5-8-5 fused ring compounds; *cis-cisoid-cis-* and *cis-transoid-cis*-tricyclo[9.3.0.0^{4,8}]tetradecane-2,9-dione (**2** and **3**) and *cis-cisoid-cis*-tricyclo[9.3.0.0^{3,7}]tetradecane-2,9-dione (**4**). The latter compound (**4**) has the same carbon ring skeleton as that of ophiobolin and fusicoccin. The ratio of **2**, **3**, and **4** was approximately 4 : 1 : 2.

The molecular structures of **2**, **3**, and **4** were determined by X-ray analyses.[6] Figure 1 shows perspective views of the molecules and Fig. 2 shows the side views of eight-membered rings. Molecules **3** has a center of symmetry. In these compounds, two five-membered rings are fused to eight-membered ring in a *cis-*



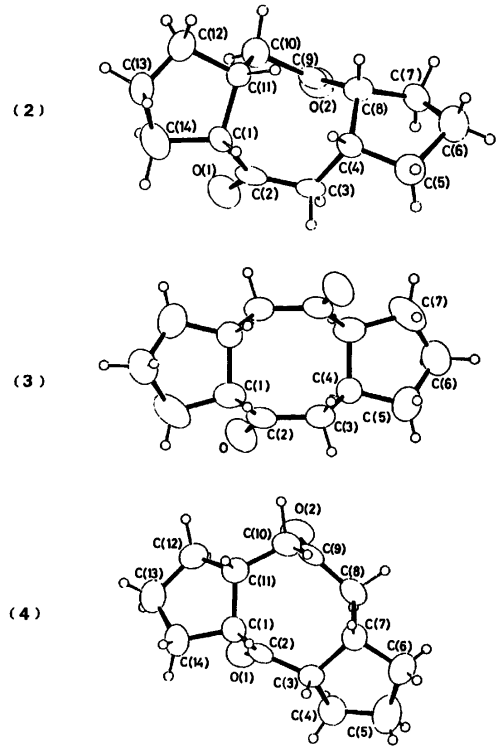


Fig. 1. Perspective views of the molecules **2**, **3**, and **4**.

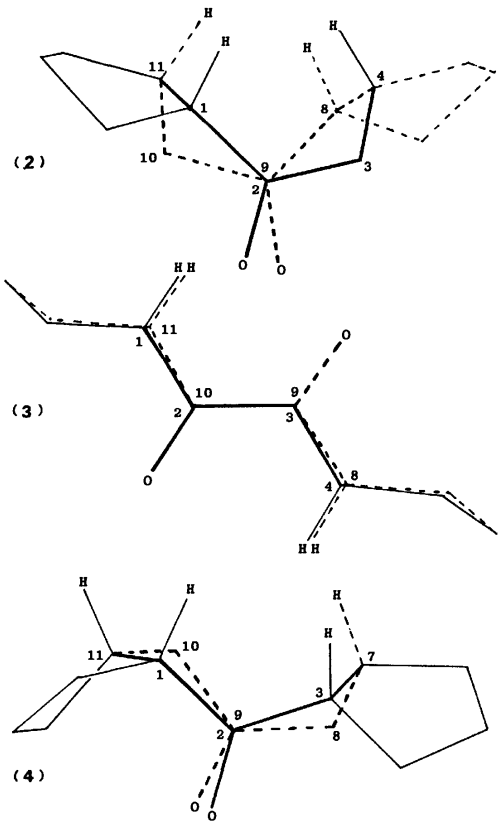

Fig. 2. The side views of the molecules **2**, **3**, and **4**. **2** and **4**: Projections along the C(2)···C(9) vectors. **3**: Projection along the C(2)···C(10) and C(3)···C(9) vectors.

configuration. Consequently, **2** and **4** have a *cis-cisoid-cis* configuration and **3** has a *cis-transoid-cis* configuration. Broadly speaking, two carbonyl groups in **2** and **4** are arranged in parallel orientation, whereas those in **3** take antiparallel orientation.

Cyclooctane, its simple derivatives, and 1,5-cyclooctanedione have been shown to exist predominantly in boat-chair(BC) form,[7] which is the most stable conformation predicted by the molecular mechanics calculations.[8] The X-ray analysis of *trans*-7-bromo-4,4-dimethylbicyclo[6.3.0]undecane-2,6-dione[9] and *trans*-5-bromobicyclo[6.3.0]undecane-2,6-dione[10] revealed that their eight-membered rings in the molecules are BC form. In this study the central eight-membered ring of **4** takes considerably distorted BC form. In contrast the conformations in **2** and **3** are a twist-boat and a chair forms, respectively, and these two conformations are quite unique in 5-8-5 fused ring systems.

Experimental

The IR spectra were recorded on a JASCO IR-G spectrometer. The mass spectra were measured with a Hitachi M-80B mass spectrometer. The GC-analyses were carried out on a 263-50 Hitach gas chromatograph.

Bicyclo[4.3.0]nonane-2,4-dione (1). Sodium (5 g) was dissolved in absolute ethanol (85 ml) with stirring under reflux. To the solution diethyl malonate (36 g) was added; then 1-acetylcyclopentene (22 g) was added dropwise. After being refluxed with stirring for 2 h., a solution of KOH (25 g) in water (140 ml) was added to the reaction mixture, which was refluxed with stirring for 8 h. The hot mixture was acidified with dilute HCl (4 M (1M=1 mol dm^{-3})), and then ethanol was evaporated. The residue was boiled with charcoal (3 g) until no more carbon dioxide was evolved, then again acidified with dil. HCl, and again boiled with charcoal (3 g). The hot mixture was finally acidified (pH<3) with dil. HCl, and boiled for a few minutes. In order to dissolve the resulting oily phase, acetone was added to the mixture, and then boiled and filtered. The filtrate was evaporated under reduced pressure and the residue was crystallized from carbon tetrachloride to give **1** (66% yield): Mp 95—96 °C (from CCl_4); IR (Nujol) 2600 (broad, enol OH), 1610 cm^{-1} (β-diketone C=O); MS *m/z* (rel intensity) 152 (M^+, 64), 124 (19), 111 (30), 95 (28), 83 (45), 82 (42), 67 (100), 54 (22), 43 (30). ***cis-cisoid-cis*- and *cis-transoid-cis*-Tricyclo[9.3.0.0^{4,8}]-tetradecane-2,9-dione (2 and 3) and *cis-cisoid-cis*-Tricyclo-[9.3.0.0^{3,7}]tetradecane-2,9-dione (4).** A solution of **1** (1 g) in methanol (150 ml) and cyclopentene (20 ml) was irradiated for 10 h.[11] through quartz filter[11] with a 100 W high-pressure mercury lamp at 5 °C in a nitrogen atmosphere. After the irradiation, the solvent was removed under reduced pressure, and a small amount of ether was added in the residue. Immediately, the photoadduct (**2**) was isolated as a crystalline solid, sparingly soluble in ether. **2** was recrystallized from ether-acetone. Subjecting to silica-gel column chromatography of the residual ether solution (eluted with hexane-ether), **3**, **4**, additional amount of **2** and also unreacted starting material (**1**) were obtained. Compounds of **3** and **4** were crystallized from ether-hexane. In a GC-analysis of the reaction mixture the ratio of **2**, **3**, **4**, and **1** was approximately 4:1:2:6. The yield of the photoadducts mixture (**2**, **3**, and **4**) was 40%, based on the starting material consumed. Mp, IR, and MS; (see Table 1).

(Received June 1, 1987)

Synopsis. The structure of the title compound has been determined by an X-ray method. The dinuclear complex is composed of two Cu(dien) units which are bridged by pyrazolate and Br^- anions. The geometry around each copper(II) may be described as a square pyramid. The antiferromagnetic interaction within the dinuclear complex has been observed ($J=-14\,cm^{-1}$, $H=-2JS_1\cdot S_2$).

A number of studies have been conducted on magneto-structural correlation of dinuclear copper(II) complexes bridged by imidazolate anion (im), in view of their importance as structural models for the active site of bovine erythrocyte superoxide dismutase.[1] On the other hand, there has been continuing interest in the magnetic properties of dinuclear copper(II) complexes bridged by pyrazolate anion (pz) which is similar to im.[2-4] Few such studies, however, have been appeared. We report here on the structure and magnetism of $[Cu_2(dien)_2(pz)(Br)](ClO_4)_2\cdot H_2O$ (**1**) (dien= diethylenetriamine).

Experimental

Preparation of $[Cu_2(dien)_2(pz)(Br)](ClO_4)_2\cdot H_2O$ (1). An aqueous solution of $AgClO_4$ (0.38 g, 1.8 mmol) was added to an aqueous solution of $[Cu_2(dien)_2(pz)]Br_3\cdot H_2O$[4] (0.60 g, 0.92 mmol), and the mixture was stirred for 15 min. After removing precipitated AgBr, the filtrate was evaporated to dryness. The violet-blue solids obtained were recrystallized from ethanol containing a small quantity of water. Found: C, 18.86; H, 4.38; N, 16.03%. Calcd for $C_{11}H_{29}O_8N_8Cl_2Cu_2Br\cdot H_2O$: C, 18.94; H, 4.49; N, 16.07%.

Crystal Data. $C_{11}H_{31}O_9N_8Cl_2Cu_2Br$, $F.W.=697.4$, triclinic, space group $P\bar{1}$, $a=23.294(10)$ Å, $b=14.084(5)$ Å, $c=7.750(2)$ Å, $\alpha=92.50(2)°$, $\beta=92.07(2)°$, $\gamma=90.98(2)°$, $Z=4$, $D_m=1.80\,g\,cm^{-3}$, $D_c=1.82$, $\mu(MoK\alpha)=36.8\,cm^{-1}$, $\lambda(MoK\alpha)=0.71069$ Å, $U=2538.1(15)$ Å^3.

X-Ray Data Collection. The crystal chosen for data collection and lattice constants determination had dimensions of $0.12\times0.30\times0.38$ mm^3. It was mounted in an arbitrary orientation on a Philips PW1100 automated diffractometer. The PW1100 program obtained 23 centered reflections and an orientation matrix, and then identified the triclinic cell. The space group $P\bar{1}$ was assumed throughout the structure analysis and confirmed by the successful refinement of the structure. The unit cell dimensions with standard deviations were derived from a least-squares fit from the angular positions of 25 centered reflections. The intensity data ($4°\leqq2\theta\leqq50°$) were collected at room temperature by the use of graphite monochromated Mo$K\alpha$ radiation. The ω-scan method was employed. The scan range was $(1.0+0.3\,\tan\theta)°$ and the scan speed $0.05°\,s^{-1}$; the background was counted for 10 s at each side of the scan range. During the data collection, intensities of 3 standard reflections were monitored every 4 h in order to check the orientation and stability of the crystal. The compound remained quite stable. A total of 3635 reflections [$F_o^2\geqq3\sigma(F_o^2)$] were considered as observed. The intensities were corrected for Lorenz-polarization effects,[5] but not for absorption.

Structure Solution and Refinement. MULTAN 78[6] provided the positions of the copper and bromine atoms. Subsequent least-squares refinement followed by difference Fourier syntheses revealed the positions of all non-hydrogen atoms. The least-squares refinement with anisotropic temperature factors for the non-hydrogen atoms gave $R=0.068$ and $R'=(\sum w\Delta F^2/\sum wF_o^2)^{1/2}=0.092$. The hydrogen atoms were located on calculated positions (N-H, C-H= 1.0 Å). In the final cycles of refinement, the hydrogen atoms, except for the water hydrogen atoms, were included with a common isotropic temperature factor $B=5.0$ Å^2, but their parameters were not refined. The function minimized was $\sum w(F_o-|F_c|)^2$, where $w=1/(\sigma^2(F_o)+0.005\,F_o^2)$ was used. All the parameter shifts were less than 0.5σ. The atomic scattering factors for Cu, Br, O, N, C, and H atoms were taken from Ref. 7, with corrections for anomalous scattering for the Cu and Br atoms. The final difference Fourier map was featureless and showed no peaks greater than 0.8 e Å^{-3}. Observed and calculated structure factors, thermal parameters, and hydrogen atom coordinates are preserved by the Chemical Society of Japan (Document No. 8763). Final atomic coordinates for non-hydrogen atoms are given in Table 1. The computer programs used in the calculations were a local version of the UNICS.[8] Figure 1 was drawn by the use of ORTEP.[9] Calculations were performed on a FACOM M 180II AD computer at Osaka City University.

Measurement. The Faraday method was applied for the measurement of magnetic susceptibility over the range from liquid helium temperature to room temperature.

Results and Discussion

Figure 1 gives a perspective view of the complex cation of **1**. There are two crystallographically independent complexes in a cell and their structures are similar to each other. Each complex is composed of two Cu(dien) units which are bridged by pyrazolate and bromine anions, forming a dimeric $[Cu_2(dien)_2(pz)(Br)]^{2-}$. The complexes are described as an intermediate between a trigonal bipyramid and a square pyramid. From the trigonal bipyramidal view point, N(1)[N(9)], N(3)[N(11)], and Br(1)[Br(2)] atoms, and N(4)[N(12)], N(6)[N(14)], and Br(1)[Br(2)] atoms form the equitorial planes and, N(2)[N(10)] and N(7)[N(15)], and N(5)[N(13)] and N(8)[N(16)] atoms occupy the apical positions. In the square pyramidal approximation, Br(1) and Br(2) occupy the apical positions. N(1)[N(9)], N(2)[N(10)], N(3)[N(11)], and N(7)[N(15)] atoms, and N(4)[N(12)], N(5)[N(13)], N(6)[N(14)] and N(8)[N(16)] atoms form the basal planes. The intermediate coordination geometry has been characterized by the structural index parameter $\tau=(\beta-\alpha)/60$,[10] where α and β are the two largest metal ligand bond angles in the complex. Application of the formula to the present complex gives the τ values of 0.33, 0.31, 0.29, and 0.35, indicating that the complex lies closer

Table 1. Fractional Coordinates and Temperature Factors for **1**

The magnetic moment(μ_{eff} value) for **1** was found to be 1.83 B.M. at 291.5 K using a Gouy magnetic apparatus. Figure 2 gives the temperature-dependence of the magnetic susceptibility for **1**. The magnetic data show a peak near 25 K and a rapid decrease to zero at lower temperatures, indicating an antiferromagnetic interaction within the dinuclear complex. The magnetic parameters are estimated as g=2.15, $N\alpha$=60×10^{-6} cgs emu mol^{-1}, and J=−14 cm^{-1} from the best fit of the χ_a values to the Bleaney-Bowers equation.[11] In 1, the pyrazolate anion bridges two basal planes of the two square pyramids, while the bridging Br atom shares the common apical position of the two square pyramids. It appears that the present complex has the $d_{x^2-y^2}$ ground state. The coordination geometries around the two copper(II) ions in **1** are unfavorable for exchanging two unpaired electrons through the bridging Br$^-$ ion. Accordingly, the antiferromagnetic exchange interaction of the two magnetic orbitals through pz seems to be more important than that through Br

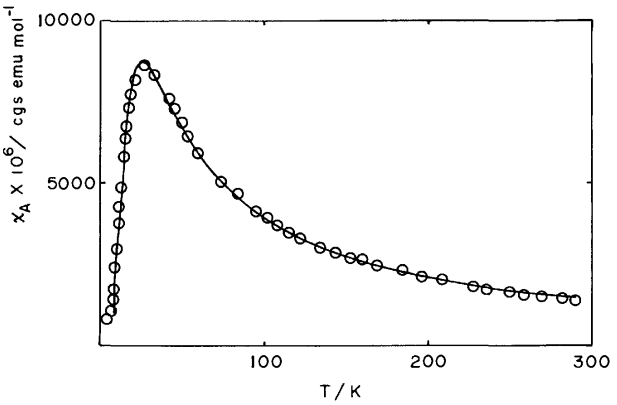

Fig. 2. Temperature dependence of the magnetic susceptibility of **1**. The open circles indicate observed susceptibility. The solid line shows the theoretical susceptibility calculated by the Bleaney-Bowers equation.

atom. The antiferromagnetic interaction is also observed in some complexes which are bridged by pz and J values range from −35.0 to −12.3 cm^{-1}.[2,4,12,13] Since no detailed stereochemistry around copper(II) in other pz-bridged copper(II) complexes[2,4,12,13] except **1** is available, a discussion concerning the relationship between the structure and the magnetism in these compounds is difficult at present. The exchange interaction in pz-bridged complexes, however, seems to be weaker than those in the dinuclear copper(II) complexes connected by imidazolate anion.[1]

We wish to thank Mr. Junichi Gohda for elemental analyses.

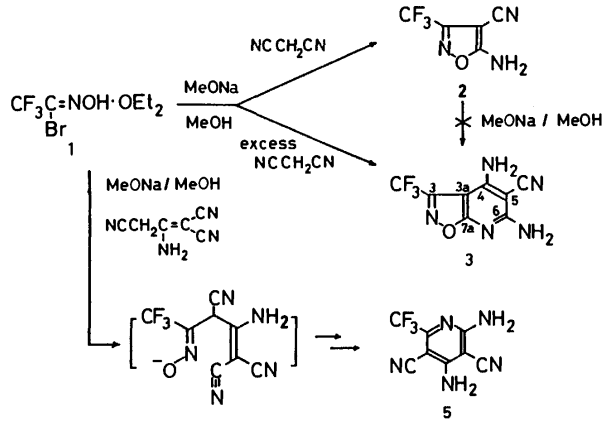
An Unusual Cyclization of Trifluoroacetohydroximoyl and -hydrazonoyl Bromides with Malononitrile[1)]

Kiyoshi TANAKA,* Takashi SUZUKI, Seiji MAENO, and Keiryo MITSUHASHI
Department of Industrial Chemistry, College of Technology, Seikei University, Musashino, Tokyo 180
(Received June 23, 1987)

Synopsis. Trifluoroacetohydroximoyl bromide etherate (**1**) reacted with an excess of malononitrile in the presence of sodium methoxide, giving a fused isoxazolopyridine **3**, participated by two molecules of malononitrile, along with the conventional isoxazole **2**. Similar concomitant formation of **7** and the fused pyrazolopyridines **8** was also recognized from the hydrazonoyl bromides **6** and their product ratio was found to depend on the reaction conditions, particularly on the concentration of malononitrile used.

It has been well explored that nitrile oxides and nitrilimines offer a wide variey of isoxazoles and pyrazoles, respectively, through the reaction with the doubly activated methylene compounds.[2-4)] So far, we have demonstrated the successful synthetic routes to 3-trifluoromethylisoxazoles and -pyrazoles by the reactions of trifluoroacetohydroximoyl bromide etherate (**1**) and *N*-aryltrifluoroacetohydrazonoyl bromides (**6**), respectively, with various active methylene compounds such as β-keto esters,[5)] β-diketones, and cyanoacetates.[6)] As an extension of this study, we now wish to describe an unusual cyclization of **1** and **6** with two molecules of malononitrile other than the conventional cyclization giving 5-amino-4-cyanoazole derivatives.



Scheme 1.

The bromide **1** reacted with an equimolar malononitrile in the presence of sodium methoxide to give 5-amino-4-cyano-3-trifluoromethylisoxazole (**2**) in 45% yield (Table 1). The orientation of the cycloaddition was deduced by the chemical shifts of its 4-and 5-carbons compared with those of 4-methoxycarbonyl analogue **2'**[6)] (Table 2). However, the treatment with an excess of malononitrile resulted in the formation of brown tarry matter, from which 4,6-diamino-5-cyano-3-trifluoromethylisoxazolo[5,4-*b*]pyridine (**3**) could be isolated in 18% yield. Thus obtained bicyclic product **3** was converted into the 6-chloro analogue, 4-amino-6-chloro-5-cyano-3-trifluoromethylisoxazolo[5,4-*b*]pyridine (**4**), by diazotization followed by chlorination with hydrochloric acid. The structure of **3** and **4** was supported by their elemental analysis and spectral data, particularly by ^{13}C NMR analysis (Table 2). The similar behavior producing the fused pyridine was also recognized in case of the hydrazonoyl bromides **6**. Thus, the reaction of **6a** with three times of malononitrile afforded a mixture of 5-amino-4-cyano-1-phenyl-3-trifluoromethylpyrazole (**7a**) (38%) and 4,6-diamino-

a) Measured in deuteriochloroform.

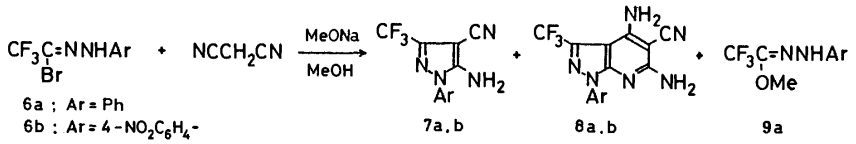
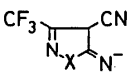


Scheme 2.

5-cyano-1-phenyl-3-trifluoromethylpyrazolo[5,4-*b*]-pyridine (**8a**) (3%) along with 20% of methyl *N*-phenyltrifluoroacetohydrazonate (**9a**).[7] The structure of **7a** was confirmed by a comparison of its ^{13}C NMR spectra with those of 4-methoxycarbonyl analogue **7a′**[6] (Table 2). The pyrazolopyridine **8a** was similarly converted into 4-amino-6-chloro-5-cyano-1-phenyl-3-trifluoromethylpyrazolo[5,4-*b*]pyridine (**10**). *N*-(4-Nitrophenyl)hydrazonoyl bromide **6b** also afforded a mixture of **7b** and **8b** in 64 and 7% yields, respectively, with no appreciable formation of the corresponding hydrazonate **9b**. It should be noted that the product ratio of **8a** increased remarkably with increase in malononitrile used.

The formation of the fused pyridines **3** and **8** is characteristic of the trifluoromethylated bromides **1** and **6** and three plausible reaction paths could be considered. These paths involve 1) the process where the initially formed **2** and **7** cyclized subsequently with another molecule of malononitrile, 2) the reaction of **1** and **6** with dimeric malononitrile, formed under the used reaction conditions, as reported in the literature on the formation of an isoxazolopyridine analogue from benzohydroximoyl chloride and dimeric malononitrile,[8] or 3) the cycloaddition of a certain reactive intermediate with another molecule of malononitrile. Out of these, the paths 1) and 2) can be both ruled out from the following results. First, the isolated **2** and **7** were subjected to the further reaction with malononitrile under similar conditions, the former giving a tarry matter with no appreciable amount of **3** and the latter being recovered almost. Second, the treatment of **6a** with the commercially available dimeric malononitrile did not give **8a**, resulting in substitution into **9a**, whereas that of **1** afforded an unexpected product, 2,4-diamino-3,5-dicyano-6-trifluoromethylpyridine (**5**) in 9% yield. Elemental analysis and MS spectra of **5** strongly support the absence of oxygen, and ^1H NMR and IR spectra features the characteristic pattern of diaminodicyanopyridine.[9] From the fact that the product ratio of **8a** depends on the reaction conditions, particularly on the concentration of malononitrile, the intervention of the reactive anions **3′** and **8′** seems to be reasonable, where the anions attack another molecule of malononitrile to give **3** and **8**, respectively.



3′ : X = O
8′ : X = NAr

Experimental

The IR spectra were recorded on a JASCO A-100 spectrometer. Samples were run as potassium bromide pellets. The ^1H and ^{13}C NMR spectra were measured with a JEOL

JNM-GX270 spectrometer using tetramethylsilane as an internal standard, the chemical shifts being given in δ ppm downfield. Samples were prepared by dissolving in deuteriochloroform-bis(deuteriomethyl) sulfoxide unless otherwise noted. The UV spectra were observed with a Hitachi 340 spectrometer. The MS spectra were obtained on a Finnigan 4023 GC-MS DS spectrometer. The bromides **1** and **6** were prepared by the methods reported in our previous paper.[6]

Reaction of 1 with Malononitrile. (A) A solution of **1** (3.65 g, 13.7 mmol) in 20 cm^3 of methanol was rapidly added dropwise to a solution of malononitrile (0.91 g, 13.8 mmol) and sodium methoxide (0.75 g, 13.9 mmol) in 25 cm^3 of methanol. After stirring at room temperature for 2 h, the solvent was removed to leave a residue which was extracted with diethyl ether. The extracts were washed with water and brine, dried over magnesium sulfate, and evaporated. The resulting residue was chromatographed on silica gel with chloroform to give 1.10 g (45%) of the isoxazole **2**, mp 149—150 °C (recrystallized from hexane-chloroform).

(B) Three times of malononitrile was reacted on a similar procedure to the above and the solvent was removed. The resulting mixture was washed with chloroform and extracted with acetone. The extracts were evaporated and the residual solid was sublimed, giving 0.60 g (18%) of **3** which was further purified by recrystallization from chloroform-acetone (sublimed at around 200 °C).

Reaction of 6a with Malononitrile. (A) To a solution of malononitrile (0.89 g, 13.5 mmol) and sodium methoxide (0.73 g, 13.5 mmol) in 20 cm^3 of methanol was added a solution of **6a** (1.20 g, 4.5 mmol) in 10 cm^3 of methanol. After the mixture was refluxed for 2 h, the solvent was removed to leave a residue which was extracted with diethyl ether. The extracts were dried over magnesium sulfate and evaporated under reduced pressure. To the residue was added excess hexane and the deposited solid was collected on a filter to give 0.05 g (3%) of **8a** which was recrystallized from acetone-methanol, mp 249.5—250.5 °C. On the other hand, hexane-extracts were evaporated and the resulting mixture was chromatographed (silica gel, hexane-chloroform, 4:1) to give 0.43 g (38%) of **7a**, which was further purified by recrystallization from hexane-chloroform, mp 115—116 °C, along with 0.20 g (20%) of oily **9a**. The spectral data of **9a** are consistent with those of our authentic sample.[7]

(B) A solution of **6a** (4.80 g, 18.0 mmol) in 20 cm^3 of methanol was added to a solution of malononitrile (3.56 g, 53.9 mmol) and sodium methoxide (2.92 g, 54.1 mmol) in 40 cm^3 of methanol and the mixture was heated under reflux for 2 h. Usual work-up yielded 1.01 g (22%) of **7a** and 2.27 g (40%) of **8a**.

Reaction of 6b with Malononitrile. A mixture of malononitrile (0.76 g, 11.5 mmol), sodium methoxide (0.62 g, 11.5 mmol), and **6b** (1.20 g, 3.8 mmol) in 30 cm^3 of methanol was stirred at room temperature for 15 h. The formed solid was collected on a filter, washed with water, and dried at the pump to give 0.10 g (7%) of **8b** which was recrystallized from chloroform-ethyl acetate, mp 309 °C (decomp). On the other hand, the filtrate was concentrated and chromatographed (silica gel, hexane-ethyl acetate, 1:1) to give 0.72 g (64%) of **7b** which was further purified by recrystallization from chloroform-ethyl acetate, mp 213—214 °C.

Chlorination of 3 into 4. Isoxazolopyridine **3** (0.40 g, 1.6 mmol) was dissolved in 50 cm^3 of 6 mol dm^{-3} hydrochloric acid under reflux. To this solution was added dropwise a solution of 0.40 g of sodium nitrite in 5 cm^3 of water at the same temperature. The mixture was refluxed for 2 h and cooled overnight in a refrigerator. The deposited solid was collected on a filter and passed through a short column (silica gel, hexane-ethyl acetate, 3:1) to give 0.09 g (21%) of **4**, which was recrystallized from hexane-diethyl ether, mp 165—166 °C.

Chlorination of 8a into 10. In a similar manner to the above, diazotization of 0.25 g of **8a** was carried out at the same temperature for 10 min, giving 0.13 g (49%) of **10**, mp 221—222 °C (recrystallized from hexane-ethanol).

Reaction of 1 with Dimeric Malononitrile. A mixture of 2.40 g (18.2 mmol) of dimeric malononitrile and 1.00 g (18.5 mmol) of sodium methoxide in 30 cm^3 of methanol was stirred for 40 min. And to this mixture was added dropwise a solution of 4.00 g (15.0 mmol) of **1** in 10 cm^3 of methanol over a period of 30 min. After stirring at room temperature for 25 h, the solvent was removed to leave a residue which was extracted with acetone and evaporated under reduced pressure. The resulting mixture was chromatographed (silica gel, hexane-ethyl acetate, 4:1) to give 0.32 g (9%) of **5** which was further purified by recrystallization from hexane-ethanol, mp 290—291.5 °C (decomp), IR 3460, 3330, 3230, 3160 (NH_2), 2210 (C≡N), 1630 cm^{-1} (C=N, C=C), ^{1}H NMR δ=7.1 (br.s, 2H), 7.4 (br.s, 2H), ^{13}C NMR δ=159.6, 157.3, 150.8 (J_{CCF}=33.3 Hz), 118.5 (J_{CF}=277.8 Hz), 112.4, 111.4, 78.5, 72.2, MS (CI, *m/z*) 228 $(M+H)^+$, 208 $(M+H-HF)^+$, UV λ_{max}^{EtOH} (ε) 238 (4.143×10^4), 324 (5.516×10^3), 328 (5.600×10^3).

Found: C, 42.19; H, 1.49; N, 30.64%. Calcd for $C_8H_4F_3N_5$: C, 42.30; H, 1.77; N, 30.83%.

Some Applications of Thermodynamic Equations on the Pressure Effect of the Chemical Reactions

Jong-Gi JEE
Department of Chemistry, Teacher's College, Kyungpook National University, Taegu 635, Korea
(Received August 24, 1985)

Synopsis. This paper is concerned with the theoretical derivation of the linear relationship between enthalpy and entropy for pressure change in chemical equilibria, and its application to the dissociation equilibria of some 4-substituted 1-methylpyridinium iodides in water-ethanol mixture. The isoequilibrium temperature, $\bar{\beta}$, for this system was derived to be 322 K.

In the studies of chemical equilibria and reaction kinetics in gas and liquid phases, it is better to measure the pressure effect on the system, because pressure is the conjugated thermodynamic variable of the volume which is more direct parameter than entropy conjugated to temperature. We have found experimentally the interesting fact that a linearity between enthalpy and entropy for pressure change exists in chemical equilibria and reaction rates.[1,2] B. S. El'yanov and E. M. Vasylvistskaya[3] have proved the same relationship theoretically and defined the isoequilibrium temperature, $\bar{\beta}$, under high pressure.

Theory

From the Maxwell relation of thermodynamic, we get the following equation;

$$(\partial S/\partial P)_T = -(\partial V/\partial T)_P = -V\alpha, \tag{1}$$

where α is the isobaric volume expansivity.

From the first and second laws of thermodynamics, $dH = TdS + VdP$, we obtain directly Eq. 2,

$$V = (\partial H/\partial P)_T - T(\partial S/\partial P)_T. \tag{2}$$

Substituting V in Eq. 2 into Eq. 1, we get Eq. 3,

$$(\partial H/\partial P)_T = \frac{T\alpha - 1}{\alpha}(\partial S/\partial P)_T. \tag{3}$$

On the other hand, we can define volume as

$$V = -\frac{1}{\beta}(\partial V/\partial P)_T, \tag{4}$$

where β is the isothermal compressibility. Inserting Eq. 4 into Eq. 1 leads to

$$(\partial V/\partial P)_T = \frac{\beta}{\alpha}(\partial S/\partial P)_T. \tag{5}$$

From Eqs. 3 and 5, we obtain the following result.

$$(\partial H/\partial P)_T = \frac{T\alpha - 1}{\beta}(\partial V/\partial P)_T \tag{6}$$

Experimental

The experiments were performed in the 5 ml conductance cell which had been made to use under high pressure. A detailed explanation of the equipment and the procedures has been given in the previous papers.[4-7]

The equilibria of several 4-substituted 1-methylpyridinium iodides in ehanol-water mixture (95/5 vol%) were measured by monitoring the conductance in the range over 25—40 °C (±0.01 °C) and 1—20000 bar (±10 bar), and also by monitoring UV absorbance at the wavelength of the absorption maximum in the same range of temperature.[8,9] Purified 4-substituted 1-methylpyridinium iodides were diluted to

about 9.10×10^{-5}—5.10×10^{-4} mol dm^{-3} by the use of the water-ethanol mixture.

The association constants (K) of the sample determined in this way are shown in Table 1. The values of K were evaluated as the average value obtained from four measurements. Their absolute errors were about ±3%.

The values of ΔH, ΔS, and ΔV were calculated from the following equations;

$$\Delta H = -R(\partial \ln K/\partial(\frac{1}{T}))_P, \quad (7)$$

$$\Delta S = (\Delta H - \Delta G)/T, \quad (8)$$

$$\Delta V = -RT(\partial \ln K/\partial P)_T. \quad (9)$$

The values of these thermodynamic parameters were shown in Table 2.

Results and Discussion

A form of $\delta\Delta H=\bar{\beta}\delta\Delta S$ with $\bar{\beta}\geqq 0$ is called an isoequilibrium relationship. A corresponding expression between the kinetcic quantities is called an isokinetic relationship.[10-12] The reason for this nomenclature is clear from the following equation;

$$\delta\Delta G = \delta\Delta H - T\delta\Delta S,$$
$$= (\bar{\beta}-T)\delta\Delta S \quad (10)$$

where the parameter, $\bar{\beta}$, has the unit of absolute temperature. If the value of $\bar{\beta}$ approaches to the experimental temperature (T), all the differences in the rate or equilibrium constants will vanish;

$$\lim_{T\to\beta}(\partial\Delta G) = 0 \quad (11)$$

To illustrate the pressure dependence of $\delta\Delta H=\bar{\beta}\delta\Delta S$, we integrated Eq. 3 in the range from 1 to P bars assuming that the pressure dependence of $(T\alpha-1)/\alpha$ is negligible as shown in Fig. 1, although α is slightly dependent on pressure in the liquid phase reaction;

$$(\Delta H_P-\Delta H_0) = \frac{T\alpha-1}{\alpha}(\Delta S_P-\Delta S_0), \quad (12)$$

where subscripts 0 and P represent 1 and P bars respectively. Its slope is defined as the isokinetic (isoequilibrium) temperature, $\bar{\beta}$, which is independent of pressure. This equation is consistent with the B. S. El'yanov and E. M. Vasylvitskaya's result;[3]

$$(\Delta H_P-\Delta H_0) = (\Delta S_P-\Delta S_0) = -(n/m)(\Delta S_P-\Delta S_0), \quad (13)$$

where m and n represent R ln $10(\partial V_0/\partial T)$ and R ln $10(\Delta V_0-T\cdot\partial V_0/\partial T)$, respectively. The method of derivation in this paper is simpler than their method because this method derives the equation from the basic thermodynamic equation whereas their derivation required a complicated procedure by the use of a linear free energy relationship.[13]

Similarly, integrating Eqs. 5 and 6, we have the following two equations;

$$(\Delta V_P-\Delta V_0) = \frac{\beta}{\alpha}(\Delta S_P-\Delta S_0) \quad (14)$$

$$(\Delta H_P-\Delta H_0) = \frac{T\alpha-1}{\beta}(\Delta V_P-\Delta V_0) \quad (15)$$

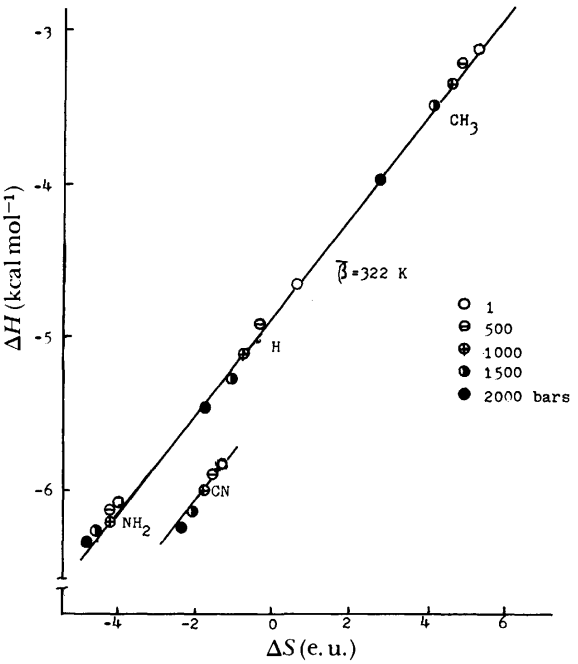

Fig. 1. The plot of ΔH vs. ΔS for changing pressure.

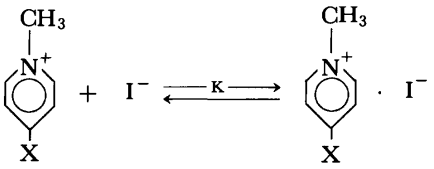
From Eq. 12 and either one of these two equations, the values of α and β can be obtained.

Replacing Eq. 12, on the other hand, with the values of ΔH and ΔS listed in Table 2, we obtained the iso-equilibrium relationship of the following reaction as shown Fig. 1.



The figure shows a satisfactory linearity as expected from Eq. 12. The slope, $\bar{\beta}$, is 322 K. The value of $\bar{\beta}$ deduced from Fig. 1 is independent of both substituent change and pressure change. It is very interesting and important for us to determine the mechanism of chemical reaction under high pressure. The $\bar{\beta}$ value is larger than the experimental temperature, 303.15 K, and hence the contribution to ΔG from ΔH is larger than that from ΔS. Accordingly, we could suggest the equilibrium of the above raction is enthalpy-controlled.

The present study was supported by the Basic Science Research Institute Program, Ministry of Education, Korea, 1985.

Nitriles in Heterocyclic Synthesis. Novel Synthesis of Pyridazine Derivatives

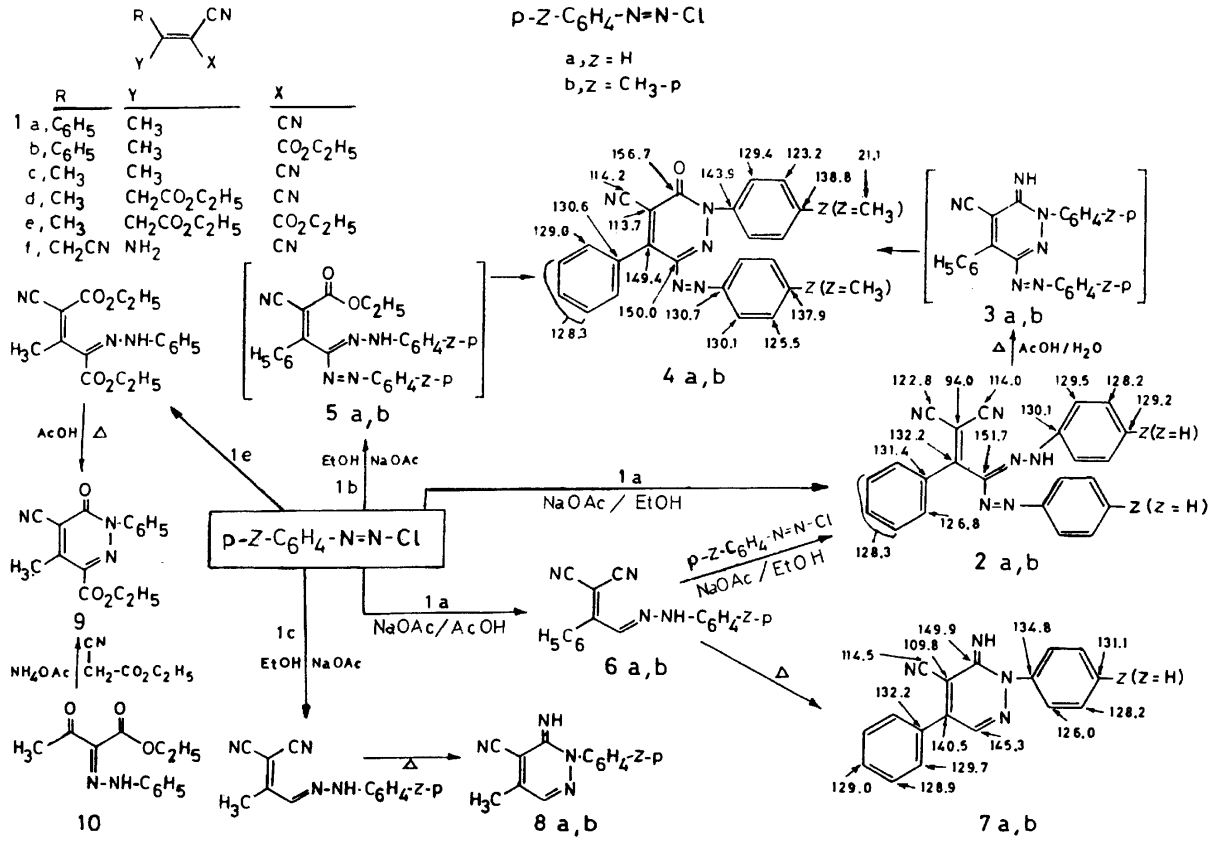
Nadia Sobhy IBRAHIM,* Fathy Mohamed ABDEL-GALIL, Ramadan Maawad ABDEL-MOTALEB, and Mohamed Hilmy ELNAGDI*

Department of Chemistry, Faculty of Science, Cairo University, Giza, A. R. Egypt

(Received February 3, 1986)

Synopsis. The crotononitriles **1a—c** coupled with arenediazonium salts to yield either the acyclic mono- or dihydrazones depending on coupling reaction conditions. Both mono- and dihydrazones could be cyclized to the corresponding pyridazine derivatives. Direct formation of pyridazines on coupling **1b** and **1c** with arenediazonium salts was observed. Structures of reaction products are confirmed by spectral and analytical data.

Nitriles are versatile reagents and their utility in organic synthesis is now receiving considerable interest.[1-3] In the last few years we have been involved in a program aiming to develop new efficient procedures for the synthesis of polyfunctionally substituted heterocycles utilizing simple laboratory available functionally substituted nitriles as starting materials.[4-6] As a part of this work we have investigated the possible utility of crotononitrile derivatives **1a—c** for synthesis of pyridazines. The methyl function in 1-phenylethylidenemalononitrile (**1a**) and isopropylidenemalononitrile (**1c**) has been reported to react readily with a variety of nucleophiles.[7] However, it has been reported[8] that this function does not couple with aromatic diazonium salts. Reaction of **1a**, c with arenediazonium salts afforded arylhydrazonomesoxalonitrile through a suggested complicated mechanism. Inspection of the literature experimental procedure indicated that the author has utilized methanolic sodium hydroxide as a medium for the coupling reaction. We have recently provided evidence that ylidenemalononitrile decomposes in basic medium into its constituents. Thus it was believed that in Coenen experiment malononitrile was the realy reacting species. We have thus investigated the behavior of **1a, b** towards arenediazonium salts under conditions that do not allow hydrolysis of the ylidenemalononitriles. The nature of the coupling products was found to be dependent on the applied coupling reaction conditions and the nature of the substituents on **1**. Acetic acid-sodium acetate and ethanolic sodium acetate were selected as media that fulfil requirements. The first medium affords weak basic conditions while the second allows more basic medium. Thus, **1a** coupled with arenediazonium salts in ethanolic sodium acetate solution to yield brown coupling products. ^{13}CNMR of these products revealed that they are the acyclic hydrazones **2a, b** and not the isomeric **3a, b** as they revealed signals for two C=N carbons. When **2a, b** were refluxed for 2 h in aqueous acetic acid the 3(2*H*)-pyridazinones **4a, b** were obtained in almost quantitative yields. Compounds **4a, b** are assumed to be formed via intermediacy of the imines **3a, b**. Attempted isolation of the imines **3a, b** were unsuccessfull. Compounds **4a, b** were also



formed on coupling **1b** with arenediazonium salts. Again the arenehydrazones **5a, b** are the assumed reaction intermediates. Trials to obtain a pure form of **5a, b** were unsuccessful, and they were converted to **4a, b** even on attempted chromatographing. However the crude product showed MS and IR in accordance with proposed structure but ^{13}C NMR revealed a pattern for a mixture. In contrast to the behavior of **1a** towards arenediazonium salts in ethanolic sodium acetate solutions, **1a** coupled with arenediazonium salts in acetic acid in the presence of sodium acetate to yield the hydrazones **6a, b**, which afforded the 3(2*H*)-pyridazinimines

Table 1. List of Synthesized Compounds

7a, b on heating above their melting points. No trial was made to convert **7a, b** into the corrresponding pyridazinones. Compounds **6a, b** could be converted into **2a, b** on coupling with arenediazonium salts in ethanolic sodium acetate solutions. Compound **1c** also coupled with arenediazonium salts to yield hydrazones which could not be isolated in pure form but the 3(2*H*)-pyridazinimines **8a, b** were isolated on short reflux of the hydrazones in acetic acid. Compounds **1b, c** failed to couple with arenediazonium salts in acetic acid-sodium acetate. The formation of hydrazones on coupling of **1a, b** with arenediazonium salts finds a parallism to the reported[9-11] coupling of **1d—f** with arenediazonium salts and the cyclization of the formed coupling products. The results, however, reveal that the presence of electron-withdrawing substituent on the methyl group in **1** is not necessary for coupling reaction to take place. The methyl group adjacent to activated double bond with two cyano or cyano and ester function on the β-carbon is sufficiently acidic to react with arenediazonium salts.

Although **1e** was reported[12] to afford **9** on coupling with benzene-diazonium salt and cyclization of the formed hydrazone, trials to repeat these results in our laboratories revealed that this synthetic route is highly inefficient as **1e** is obtainable only in low yield and polymerizes quickly on storage. Thus we developed more efficient synthesis of **9** via condensation of the readily obtainable hydrazone **10** with ethyl cyanoacetate in the presence of ammonium acetate.

Experimental

All melting points are uncorrected. IR spectra (KBr) were recorded on a Pye Unicam SP-1100 spectrophotometer. ^1H and ^{13}C NMR spectra were obtained in $(CD_3)_2SO$ with a Varian EM 390 and Bruker Wm 300 spectrometer with $SiMe_4$ as internal standard and chemical shifts are expressed as δ values. Mass spectra were recorded on mass spectrometer MS 30 and MS 9 (AEI) 70 eV. Microanalytical data were performed by the microanalytical centre at Cairo University.

(2-Arylazo-2-arylhydrazono-1-phenylethylidene)malononitriles 2a, b. Method A: A solution of **1a** (0.01 mol) in ethanol (30 ml) containing sodium acetate (6.0 g) was cooled to 0 °C, stirred and treated gradually with a cooled solution of the appropriate diazonium salt (prepared from 0.02 mol of the aromatic amine and the appropriate quantities of hydrochloric acid and sodium nitrite). The solid products formed on standing were collected by filtration and crystallized from the proper solvent.

Method B: A solution of either **6a** or **6b** (0.01 mol) in ethanol (30 ml) containing sodium acetate (6.0 g) was cooled to 0 °C, stirred and treated gradually with a cooled diazonium salt (prepared as described above). The solid product formed was collected by filtration and crystallized from the proper solvent.

2-Arly-6-arylazo-4-cyano-5-phenyl-3(2*H*)-pyridazinones 4a, b. Method A: A solution of either **2a** or **2b** (0.01 mol) in aqueous acetic acid (30 ml; 70%) was refluxed for 2 h and then left to cool. The solid products so formed were collected by filtration and crystallized from the proper solvent.

Method B: An ice-cold solution of arenediazonium solid prepared from 0.02 mol of the aromatic amine and the appropriate amounts of sodium nitrite and hydrochloric acid was added to a solution of 0.01 mol of **1b** in ethanol (30 ml) containing sodium acetate (6.0 g). The products formed on standing were refluxed in acetic acid (20 ml) for 15 min and the reaction mixture was left to cool. The solid products formed were collected by filtration and crystallized from the proper solvent.

(2-Arylhydrazono-1-phenylethylidene)malononitriles 6a, b. A solution of **1a** (0.01 mol) in glacial acetic acid (50 ml) was treated with anhydrous sodium acetate (3.0 g), then with a solution of the appropriate diazonium salt (prepared as described above). The reaction mixture was left in a refrigerator for 24 h, then left to warm to room temperature. The solid products so formed were collected by filtration and crystallized from the proper solvent.

2-Aryl-4-cyano-5-phenyl-3(2*H*)-pyridazinimines 7a, b. Compounds **6a, b** (0.01 mol) were heated at 160 °C (bath temperature) for 30 min, then left to cool to room temperature. The products so formed were triturated with ethanol, collected by filtration and crystallized from the ptoper solvent.

2-Aryl-4-cyano-5-methyl-3(2*H*)-pyridazinimines 8a, b. A solution of **1c** (0.01 mol) in ethanol (30 ml) containing sodium acetate (6.0 g) was coupled with an ice-cold solution of the appropriate arenediazonium salt (prepared as described above). The products formed on standing were separated and refluxed in acetic acid (30 ml) for 15 min, then poured onto water. The solid products formed were filtered off and crystallized from glacial acetic acid.

4-Cyano-6-ethoxycarbonyl-5-methyl-2-phenyl-3(2*H*)-pyridazinone 9. Method A: Compound **9** was prepared in 65% yield from coupling **1e** with an ice-cold benzenediazonium salt using the procedure recently described by Gewald and Hain.[12] The product reveals analytical and spectral data consistent with those reported in literature.

Method B: Equimolecular amounts of **10** and ethyl cyanoacetate (0.01 mol) were heated in presence of ammonium acetate at 160 °C (bath temperature) for 1 h. The formed solid product was crystallized from acetic acid. Compound **9** was identical with authentic speciment (identity was made by mp and mixed mp).

We are deeply indebted to Prof. Dr. W. Steglich, Institut fur Organische Chemie und Biochemie, Universitat Bonn, F.R.G. for facilities that enabled measurements of MS and ^{13}C NMR.

The Effect of the Carbonyl Group, Phenyl Ring, and Ring Size of α-Iodo Cycloketones on the Nature of the Photochemical Carbon-Iodine Bond Cleavage

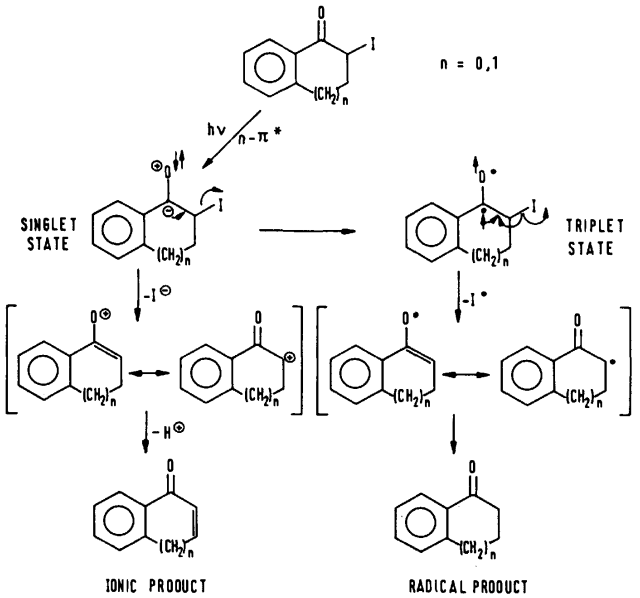
Boris Šket* and Marko Zupan
Department of Chemistry and Jožef Stefan Institute, Edvard Kardelj University, Ljubljana, Yugoslavia
(Received October 7, 1986)

Synopsis. UV irradiation of 2-iodo-3,4-dihydro-1(2*H*)-naphthalenone and 2-iodo-1-indanone has been found to involve competing radical and ionic photoprocesses. The carbonyl group, phenyl ring and ring size of cycloketones have an influence on the nature of the photochemical carbon-iodine bond cleavage.

The photochemistry of alkyl halides[1] and cycloalkanones[2] has been extensively studied, but little attention has been paid to the study of α-halo cycloalkanones. There are a few reports on the study of the photochemistry of α-halo cycloalkanones which include different types of photoprocesses, such as α-cleavage,[3] photoelimination,[4] hydrogen abstraction by α-keto radicals,[5] and rearrangement.[6] The nature of the photochemical carbon-halogen bond cleavage mainly depends on the hybridization of the carbon atom, on the type of the halogen bonded, the solvent polarity and the used wavelength. It has been generally observed that by the irradiation of alkyl halides, the ratio of ionic to radical products is substantially larger for iodides than for bromides,[1] while this tendency becomes reversed when the halogen atom is bonded to an olefinic carbon.[7,8]

It is known from literature that the irradiation of iodocyclohexane[9] in nonpolar solvents, or even in methanol, resulted in the formation of cyclohexene as the product derived from the carbocationic intermediate and only a low percentage of cyclohexane as the radical product was observed. On the other hand, the irradiation of 2-iodocyclohexanone[5] undergoes both ionic and radical photoprocesses, with the ratio between radical to ionic products 3.16:1. The mentioned results show that the photochemistry of carbon-iodine bond is greatly influenced by the α-keto group.

As the formation of α-keto carbonium ions depends on the α-halogen atom, the ring size of the ketone and the other functional groups present in the molecule, we found it reasonable to study the influence of another chromophore (phenyl ring), which is in conjugate position with the carbonyl group as also the



n	Solvent	λ/nm	% Conversion	Radical : Ionic Product

Scheme 1. The effect of the ring size on the nature of the carbon-iodine bond cleavage.

influence of the ring size of cycloketone on the behavior of excited states of α-iodo cycloalkanones.

Irradiation of 2-iodo-3,4-dihydro-1(2*H*)-naphthalenone[10] in cyclohexane solution resulted in two products: 3,4-Dihydro-1(2*H*)-naphthalenone and 1-naphthol in the ratio 1 : 1.32 (Scheme 1). The formation of the reduction product corresponds to the radical reaction pathway, while 1-naphthol formation can be explained as a tautomer of the initially formed ionic product. On irradiation, iodine atom liberated on homolytic fission of C-I bond prefers to combine with another iodine atom than to undergo hydrogen abstraction, which is known to be extremely slow.[11] The quantity of liberated iodine corresponds to the quantity of the radical products formed, which was determined by iodine titration. 3,4-Dihydro-1(2*H*)-naphthalenone is, in the presence of iodine, under the same reaction conditions photostable and does not undergo phototransformation to 1-naphthol. Irradiation at λ=300 nm only slightly influenced the ratio of the products formed (Scheme 1). A comparison of the ratio of the radical to the ionic products formed by irradiation of 2-iodocyclohexanone (3.1 : 1) and 2-iodo-3,4-dihydro-1(2*H*)-naphthalenone (1.32 : 1) in cyclohexane solution shows that the conjugation of the carbonyl group with the phenyl ring lowers this ratio.

To understand the nature of the excited states involved, we carried out the reaction in acetone, which is a triplet sensitizer, and noted a significant change in the ratio of the radical to the ionic products (4.26 : 1). This result indicates that the solvent acetone strongly favoured the formation of the radical product. The quenching studies carried out, using oxygen as the triplet quencher, show a slight decrease in the radical product formation and a lower conversion of the starting α-iodo ketone was observed (Scheme 1).

In order to compare the influence of the phenyl group and the ring size of the cycloketone, we carried out the photoreaction of 2-iodo-1-indanone. Fifteen-hours irradiation of the indanone at λ=253.7 nm in cyclohexane resulted in a crude reaction mixture containing two products: 1-Indanone as the radical product and 2-inden-1-one[12] as the ionic product in a ratio of 2.1 : 1, while irradiation of the acetone solution under the same reaction conditions led to a complete conversion of the starting material with only 1-indanone formation (Scheme 1). On the other hand, irradiation of 2-iodo-1-indanone in methanol at λ=300 nm resulted in the formation of 2-methoxy-1-indanone (27%)[13] as ionic and 1-indanone (73%) as the radical product. The photoprocess in cyclohexane using triethylamine resulted in a marked decrease of conversion of the starting α-iodo ketone (26% conversion).

From the above results several conclusions can be derived: (i) The photochemistry of the carbon-iodine bond is greatly influenced by the α-keto group. (ii) The phenyl ring in a conjugate position with the carbonyl group has an influence on the excited states of the α-iodo cycloalkanones. (iii) The ratio between the radical and the ionic products depends on the ring size of cycloketone; the five-membered ring favours the expulsion of the iodine atom, while in the six-membered ring the expulsion of the halide anion is preferential, which can be explained by the geometry of the excited state, being, by its partially negative charge on the carbonyl carbon atom, more stabilized in the conformation of the six-membered ring[14] than in the nearly planar five-membered[15] system in α-indanone. (iv) Reaction rate of the six-membered cycloalkanone in a cyclohexane solution is larger than that of the five-membered compound. (v) The results of the quenching and sensitizing experiments indicate that the radical processes may occurr mostly through n-π^* triplet states and the ionic through singlet states, which clearly supports the Wagner model.[16]

Experimental

Irradiation was carried out in a Rayonet Photochemical Chamber, Reactor Model RPR-100 with RPR 253.7 nm and RPR 300 nm lamps. IR spectra (KBr disc) were recorded by using a Perkin-Elmer 257 spectrometer, ^{1}H NMR spectra were determined by a JEOL JNM-PS-100 in CCl_4 solution with Me_4Si as an internal standard and mass spectra were recorded on a CEC 21-110 spectrometer. Gas liquid chromatography was carried out on a Varian Aerograph Model 1800 and preparative TLC on Merck-PSC-Fertigplatten Kieselgel F 254. Melting points were determined on a Kofler apparatus and are uncorrected.

2-Iodo-1-indanone and 2-iodo-3,4-dihydro-1(2*H*)-naphthalenone[10] were prepared by iodination of the 1-indanone and 3,4-dihydro-1(2*H*)-naphthalenone in acetic acid using poly[styrene-co-4-vinylpyridinium dichloroiodate (I)].

2-Iodo-1-indanone: IR 710, 1260, 1600, 1710 cm^{-1}, ^{1}H NMR (CCl_4) δ=3.45 (1H, dd, J_{AB}=18 Hz, $J_{2,3A}$=3 Hz, H-3A), 3.90 (1H, dd, J_{AB}=18 Hz, $J_{2,3B}$=7.5 Hz, H-3B), 4.92 (1H, dd, $J_{2,3B}$=7.5 Hz, $J_{2,3A}$=3 Hz, H-2), 7.50 (4H, m, aromatic H's), mass spectra *m/z* (relative intensity): M^+ 258 (100), 131 (88), 127 (23), 103 (84), 102 (35), 77 (61). Found: *m/z* 257.9550, Calcd for C_9H_7IO: M, 257.9544. Mp 68—70 °C (from ethanol).

General Procedures: An 18-ml, 0.028 M (1M=1 mol dm^{-3}) solution of the 2-iodo-1-indanone or 2-iodo-3,4-dihydro-1(2*H*)-naphthalenone was irradiated in a quartz tube for 15 h, the solvent was evaporated in vacuo, the crude reaction mixture was analyzed by ^{1}H NMR and the products from irradiations outlined in Scheme 1 were isolated by preparative gas chromatography (FFAP 30% on Chromosorb AW) or preparative TLC (SiO_2, benzene), whose spectral properties agreed with those of authentic samples.

To measure the reactivity difference, 18 ml of 0.028 M cyclohexane solution of the 2-iodo-1-indanone or 2-iodo-3,4-dihydro-1(2*H*)-naphthalenone was irradiated at λ=253.7 nm and 25 °C in a quartz tube for 3 and 5 h and the degree of conversion of the starting α-halo ketone determined from the ^{1}H NMR spectrum of the crude reaction mixture.

Reduction of Nitrostyrenes to Nitroalkanes with a NADH Grafted Model

Thierry TRÉFOUEL, Patrik TINTILLIER, Georges DUPAS,
Jean BOURGUIGNON,* and Guy QUÉGUINER
Laboratoire de Chimie Organique Fine et Hétérocyclique-INSA-BP 08, Mont Saint Aignan 76130, France
(Received December 1, 1986)

Synopsis. Grafting of the 1,4-dihydronicotinamide structure on a Merrifield type resin is described. With this reagent, arylnitroethanes have been obtained by regioselective reduction of β-nitrostyrenes. The yields are good and no dimeric compounds are formed. The role of magnesium ions in these reductions is different from that observed with classical NADH models.

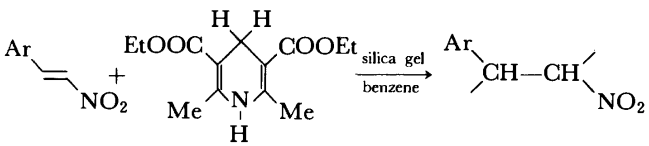
Arylnitroethanes are compounds of special interest since they are useful synthetic intermediates. The nitro group can be converted to other functional groups such as carbonyl, nitrile oxides, or amino group.

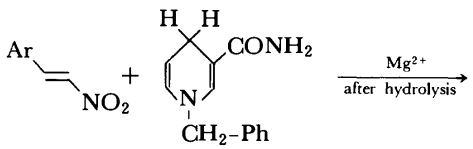
A widely used method to obtain 2-aryl-1-nitroethanes involves reduction of nitrostyrenes. Selective reduction of the ethylene double bound is rather difficult: borohydride reduction under various conditions often leads to contamination of the desired product by side reactions: for example a dimeric compound can be formed by Michael addition of the nitronate intermediate to the starting nitroalkene.[1]

$$ArCH{=}CH\text{-}NO_2 \xrightarrow{NaBH_4} ArCH_2CH_2NO_2 + Ar\text{-}CH_2\text{-}\underset{\displaystyle Ar\text{-}CH\text{-}CH_2\text{-}NO_2}{\underset{|}{CH}}\text{-}NO_2$$

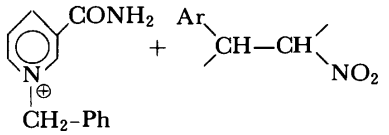
Recently some improvements to the usual procedure led the authors to better results.[2]

Other reagents have been used to ensure selective reduction of the ethylenic double bond of nitrostyrenes, for example NADH models such as 1,4-dihydronicotinamide derivatives or Hantzsch ester. With this last reagent good results in the reduction of various nitroolefins in the presence or silica gel have been reported.[3]





BNAH



$BNA^{\oplus}$

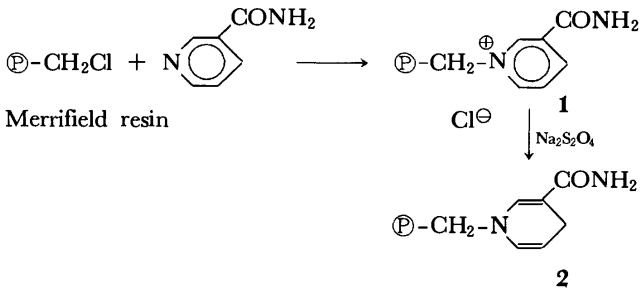
With 1,4-dihydronicotinamide derivatives there are few examples of such reductions[4] and the yields are rather poor. Moreover it was established that β-nitrostyrene is not reduced in the absence of magnesium ions.[4a]

The work-up of reactions performed with BNAH is not easy. It is rather difficult to isolate the desired product from starting reagents or other products formed during the reduction.

Grafting reagents on to an insoluble matrix can constitute an elegant way of resolving the practical problems encountered with free reagents.[5] A few NADH grafted models have been studied.[6] In our laboratory we have synthesized the first truly reactive polymer-bound NADH model.[7] With this reagent excellent results are obtained in the reduction of activated carbonyl compounds.[7]

In this publication we describe the optimisation of the synthesis of the grafted reagent on a Merrifield type resin and its use in the reduction of aryl nitro olefins.

Preparation of Grafted Reagent. The reagent is obtained by reaction of the halomethylated copolymer styrene and divinylbenzene resin with nicotinamide (Scheme 1). The pyridinium salt is just filtered, not dried, before being subjected to regioselective 1,4-reduction with $Na_2S_2O_4$. If the polymer-bonded pyridinium salt **1** is quite free of the solvent used during the quaternarization (CH_3CN), wetting of the polymer does not occur and reaction of $Na_2S_2O_4$ becomes impossible.



The reduction of **1** is complete as shown by the absence of chlorine in the analysis of **2**.

Reduction of Nitrostyrenes. With BNAH, reduction of a substrate in the presence of magnesium ions usually occurs in acetonitrile as solvent. With the reagent **2** we observed that in this solvent the polymer matrix did not swell and consequently no reduction occured. The access to the active site of the polymer bonded reagent is probably impossible. A swelling cosolvent is needed which also ensures the solubility of Mg^{2+} ions. Finally the best results were obtained in a benzene-acetonitrile (1/1) mixture. In typical conditions [grafted NADH model 1.2 milliequivalent, $Mg(ClO_4)_2$ 1 mmol, nitrostyrene 1 mmol, solvents 14 ml, 5 d, 80 °C] the results were as follows:

$$\underset{\mathbf{3}}{ArCH{=}CHNO_2} + \mathbf{2} \longrightarrow \underset{\mathbf{4}}{ArCH_2CH_2NO_2} + \mathbf{1}$$

Table 1. Reduction of β-Nitrostyrenes

Ar in starting nitrostyrene **3**		Yield in **4**	Ar in starting nitrostyrene **3**		Yield in **4**
Phenyl	**3a**	100	3,4-(Methylenedioxy)phenyl	**3e**	72
2-Naphtyl	**3b**	98	3-Pyridyl	**3f**	60
p-Methoxyphenyl	**3c**	77	2-Thienyl	**3g**	70
3,4-Dichlorophenyl	**3d**	90			

$ArCH_2\text{-}CH_2\text{-}NO_2$ **4**
β α

Ar=			NMR (Chemical shift)
4a	Phenyl	Oil (2b)	3.17 (t) $CH_2\beta$; 4.45 (t) $CH_2\alpha$; 6.93—7.4 (m) H arom.
4b	2-Naphthyl	Oil $C_{12}H_{11}NO_2$	3.42 (t) $CH_2\beta$; 4.65 (t) $CH_2\alpha$; 7.50 (m) H arom.
4c	*p*-Methoxyphenyl	Oil (2b)	3.21 (t) $CH_2\beta$; 4.53 (t) $CH_2\alpha$; 3.75 (s) CH_3O; 6.84 and 7.12 H arom.
4d	3,4-Dichlorophenyl	Oil $C_8H_7Cl_2NO_2$	3.30 (t) $CH_2\beta$; 4.60 (t) $CH_2\alpha$; 7.30 (m) H arom.
4e	3,4-(Methylenedioxy)phenyl	F=55 (2b)	3.20 (t) $CH_2\beta$; 4.52 (t) $CH_2\alpha$; 6.56—6.80 (m) H arom.
4f	3-Pyridyl	Oil $C_7H_8N_2O_2$	3.30 (t) $CH_2\beta$; 4.60 (t) $CH_2\alpha$; 7.10—7.60 (m) H_4 and H_5 arom.; 8.43 (m) H_2 and H_6 arom.
4g	2-Thienyl	Oil (3)	3.43 (t) $CH_2\beta$; 4.50 (t) $CH_2\alpha$; 6.70—7.20 (m) H arom.

The most interesting features of these reductions are: (i) Yields are good to quantitative. (ii) The work-up is easy; filtration followed by evaporation of the solvents gives the pure arylnitroethanes. Some of them (**3b**, **3d**, and **3f**) are new compounds. They have been identified by the usual spectroscopic methods. (iii) No dimeric compound was detected in the final product [absence of signals near δ 5.0 in the ^1H NMR spectra[1]].

Role of Magnesium Ions. The role of magnesium ions in BNAH reduction is to ensure an interaction between the substrate and the model through a ternary complex.[8] In the case of free models in the absence of Mg^{2+}, generally no reaction occurs. However the reduction of (α-methylbenzylidene)malonitrile with a BNAH derivative affords different product depending upon the presence or not of Mg^{2+} (9). We have performed the reduction of **3a** in the typical conditions described above but without the magnesium ion. A large quantity of polymeric compounds is obtained but after chromatographic purification we could isolate 10% of **4a**. To our knowledge it is the first partial reduction of 1-phenyl-2-nitroethene observed with a 1,4-dihydronicotinamide reagent in the absence of magnesium ions. We think that a "polymer effect" occurs: the redox potential of the reactants are changed and the transition state becomes different to that ocurring with a free model. The medium used (CH_3CN-C_6H_6) is less polar and the polymeric matrix contains numerous phenyl rings. The micro environment in the neighbourhood of the active site is less favorable to solvatation of the dihydronicotinamide by CH_3CN. So the interaction between the reagent and the substrate is forced. This phenomenon could be sufficient to induce a partial reduction.

Experimental

Nitrostyrenes derivatives were prepared according to the literature.[10] Merrifield resin was purchased from Merck (Art. 818178). NMR spectra were recorded with a Varian EM 360 L spectrometer (solvent $CDCl_3$, internal reference HMDS). Analyses have been performed with a Carlo Erba 1106 apparatus).

Grafted Reagent. Merrifield resin (50 g) nicotinamide (20 g) in 300 ml of dry acetonitrile were stirred at 90 °C during 6 d. The pyridinium derivative **1** was filtered, washed with acetonitrile then with hot water. The product was suitable for the next step.

Analysis of a dried sample gave the following typical values. C: 79.9; H: 7.0; N: 3.6; Cl: 5.0%.

The wet quaternarized resin (about 20 g) was treated with a mixture of $Na_2CO_3 \cdot 10H_2O$ (20 g) and $Na_2S_2O_4$ (40 g) in 200 ml of water. The mixture was stirred for 6 h at room temperature. The color of the resin turned from red-orange to yellow. After filtration the resin was dried for 2 d (40 °C/0.5 Torr (1 Torr=133.322 Pa)). The grafted NADH model was storred under argon in the refrigerator.

Typical analysis is as follows. C: 83.5; H: 3.5; N: 3.8% (absence of chlorine).

This corresponds to 1.3 meq of the 1,4-dihydronicotinamide moiety pergram (based on N percentage).

Reduction of Nitrostyrenes. In a dry glass tube 1.2 meq of grafted reagent **2**, 250 mg of $Mg(ClO_4)_2$ (1 mmol), 1 mmol of nitrostyrene, 7 ml of hyperdry benzene and 7 ml of hyperdry acetonitrile were introduced under an argon

atmosphere. The tube was sealed, then heated at 80 °C for 5 d. After cooling the tube was broken. The resin is discarded, washed with acetonitrile, and water (1 ml) was added. The solvents were evaporated. The residue was extracted with water, then extrated with chloroform. After evaporation of the solvent the pure arylnitroethanes were recovered.

The aryl-2-nitroalkanes have the characteristics given on the precedent page.
