* Hydrogen pressure: 5.06 bar; nitro compound concentration: 0.5 M; Total volume: 20 mL; reaction temperature: 300 K; solvent: methanol.

By analogy with the mechanism proposed by these authors, we may think that the presence of electron releasing groups would slow down stage (1') and hence inhibit the formation of the nitrene, thus giving rise to lower conversion than nitrobenzene. Conversely, the presence of electron withdrawing substituents would stabilize the intermediate nitrene and speed up stage (2') with respect to nitrobenzene.

According to Carturan et al.,[24] the tentative formulation of dimeric or oligomeric R-N-O- intermediates is consistent with nitrene reactivity. On the other hand, the deoxygenation of nitro groups by metal catalysts via intermediate nitrenes is similar to the process described by Cadogan, who uses homogeneous phosphine catalysts.[37] The occurrence of nitrenes has also been proposed by Watanabe et al.[38] as intermediates in the reduction of nitroarenes to aminoarenes with carbon monoxide and water.

This study has been carried out with a grant from the "Consejería de Educación y Ciencia de la Junta de Andalucía".

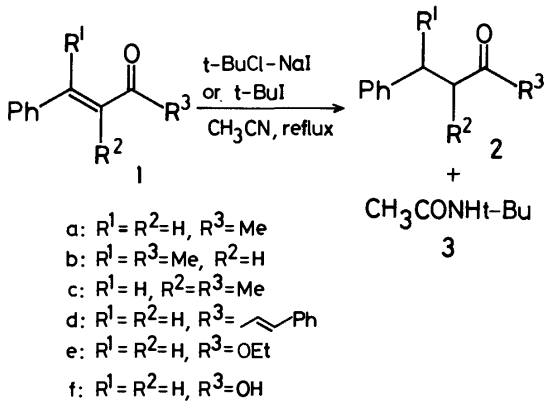
(Received March 24, 1987)

Synopsis. β-Phenyl α,β-unsaturated carbonyl compounds were conveniently reduced to the corresponding saturated aromatic compounds by heating with t-BuCl-NaI in acetonitrile.

We recently disclosed that the Me_3SiCl-NaI-ROH reagent was useful for the selective reduction of olefinic double bond of β-phenyl α,β-unsaturated carbonyl compounds and that the reduction was explained by the 1,4-addition of HI and subsequent attack of an iodide anion to the resulting β-iodo carbonyl intermediate.[1] In this paper, we report that t-BuCl-NaI was found to be effective for a similar reduction (Scheme 1). The applicability of the reaction was examined by using the same substrates **1a-f** as those employed in the preceeding paper.[1] The present method has advantages that the reagent is readily available and can be handled without a special care to moisture. Yields of the reduction products **2a—f** shown in Table 1 were comparable with those observed for the reaction with Me_3SiCl-NaI-ROH reagent.[1]



Scheme 1.

The reaction simply involves heating of the substrates **1a—f** with a six-molar excess of the reagent in acetonitrile for 24 h, giving **2a—f** together with a small amount of *N*-*t*-butylacetamide[2] (**3**) in every case. The reaction mixture was colored dark purple gradually due to liberation of iodine. In a typical reduction with **1a**, shortening of the reaction time to 5 h decreased the yield of **2a** and the starting **1a** was recovered in a considerable amount. Unfortunately, the present reaction is not suitable for aliphatic conjugated enones. For example, mesityl oxide was recovered unchanged.

Table 1. Reduction of β-Phenyl α,β-Unsaturated Carbonyl Compounds with t-BuCl-NaI Reagent[a]

	Substrate 1			Method[b]	Product 2
	R^1	R^2	R^3		Yield/%[c]
1a	H	H	Me	A	74[d]
				A	34[e]
				B	80[f]

				B	49
1c	H	Me	Me	A	46
1d	H	H	-CH=CHPh	A	51
1e	H	H	OEt	A	86[g]
1f	H	H	OH	A	72
				B	59[f]

a) The reaction was usually done for 24 h under refluxing unless otherwise noted. b) A: t-BuCl-NaI in CH_3CN; B: t-BuI in CH_3CN. c) Yield after purification by preparative TLC. d) Reaction time of 12 h. e) Reaction time of 5 h. Thirtytwo per cent of **1a** was recovered. f) Reaction time of 7 h. g) A 65:35 mixture of the ester **2e** and its acid.

The present reduction would be caused by the in situ generated HI in a manner similar to that described previously.[1] The handling of gaseous HI is not easy, because it readily decompose to iodine and hydrogen molecules.[3] The t-BuCl-NaI reagent is suitable for generation of HI in a reaction vessel. The liberation of isobutene[4] was detected by GLPC analysis.[5] The minor by-product **3** may be formed by the reaction of acetonitrile either with isobutene[2a] or t-BuCl.[2b] Furthermore, the applicability of t-BuI to the reaction was ascertained, although it is far more expensive than t-BuCl.

The present reaction is the first example utilizing t-BuCl-NaI as a reagent for the selective reduction of conjugated olefin of β-phenyl α,β-unsaturated carbonyl compounds.

Experimental

General. IR spectra were taken on a JASCO A-102 spectrometer. ^1H NMR spectra (60 MHz) were measured with a JEOL JNM-60 SI spectrometer using Me_4Si as an internal standard. GLPC analysis was done with a Hitachi 163 gas chromatograph.

General Procedure for the Reduction of 1a—f. Sodium iodide (1.80 g, 12 mmol) was placed in a reaction vessel and the atmosphere is replaced by nitrogen. To this was added a

solution of the substrate **1** (2 mmol) and *t*-butyl chloride (1.11 g, 12 mmol) in acetonitrile (2 ml). The mixture was stirred for the time indicated in Table 1 under refluxing. After addition of water, the ether extract was washed with aqueous sodium thiosulfate to remove liberated iodine and then with water, dried ($MgSO_4$), and concentrated. The residual oil was purified by preparative TLC (Merck, Kieselgel 60, PF_{254}, hexane–ether, 3:1) to give the reduction product **2** and *N*-*t*-butylacetamide[2] (60—70 mg).

Reduction of 1a with *t*-BuI. A mixture of **1a** (73 mg, 0.5 mmol), *t*-BuI (0.35 ml, 3.0 mmol), and acetonitrile (1 ml) was heated under reflux for 7 h. The reaction mixture was treated in a similar manner. The yield of **2a** by GLPC analysis of the crude product was 80%.

Selective 1,2-Reduction of α,β-Unsaturated Carbonyl Compounds with $LnCpCl_2(THF)_3/NaBH_4$

Sanshiro KOMIYA* and Osamu TSUTSUMI
Department of Applied Chemistry for Resources, Tokyo University of Agriculture and Technology, 2-24-16 Nakamachi, Koganei, Tokyo 184
(Received March 27, 1987)

Synopsis. Highly selective 1,2-reduction of conjugated α,β-unsaturated carbonyl compounds such as enones and unsaturated aldehydes has been achieved by $NaBH_4$/$LnCpCl_2(THF)_3$ (Ln=Sm and Er) in MeOH under ambient conditions.

Utilization of organolanthanoid reagents to organic reactions has been recently attracting growing attention.[1] Although lanthanoid compounds are now available in large quantities and in very pure form, their chemical uses are still very limited. Luche et al. reported lanthanoid ion-promoted reduction of enones to allylic alcohol with $NaBH_4$,[2] which is of interest, since the regio- and chemoselectivity is in sharp contrast to the reduction promoted by $NaBH_4$ in the presence of late transition metal complexes as well as to the reduction with $NaBH_4$ in pyridine.[2,3] We now report the highly chemo- and regioselective 1,2-reduction of conjugated unsaturated carbonyl compounds with $NaBH_4$ assisted by organolanthanide complexes, $LnCpCl_2(THF)_3$ (Ln=Sm and Er)[4] in methanol.

Table 1 summarizes the results of selective reduction of α,β-unsaturated carbonyl compounds with $NaBH_4/LnCpCl_2(THF)_3$. When a half-molar amount of $NaBH_4$ per substrate was added into a 4:1 mixture of crotonaldehyde and $SmCpCl_2(THF)_3$ (**1**) in methanol at room temperature, crotyl alcohol was selectively obtained in an almost quantitative yield. Cinnamaldehyde was also reduced cleanly to cinnamyl alcohol. Only slight amounts of saturated alcohols and 1,4-reduction products were formed in these reactions. The present selective reduction is also applicable to various alicyclic and cyclic enones such as methyl vinyl ketone, cyclopentenone and cyclohexenone, to give corresponding allylic alcohols in

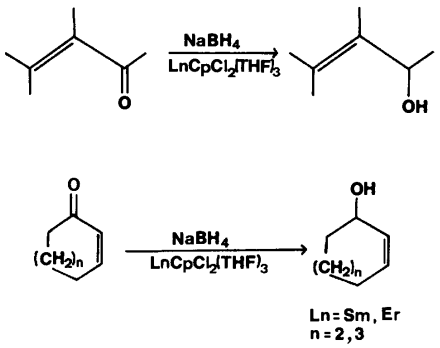
a) In methanol (1.0 cm^3) at room temperature for 6 h. The ratio of substrate, $NaBH_4$, and $LnCpCl_2(THF)_3$ used was 4.4:2.2:1. b) Yields are based on the starting substrates by GLC. c) A: Allylic alcohol, B: saturated ketone, C: saturated alcohol.

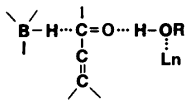


high yields as well as in high selectivity.

Although the reaction products were determined after 6 h, the reduction was actually completed after 5 min. On the other hand, reduction of 2,3,4,5-tetramethylcyclopentenone failed. Selectivity and the yields of 1,2-reduction products decrease when methyl and methoxycarbonyl substituents are placed on the cyclic enone ring. Steric effect may be important in these reduction process. Similar selective 1,2-reduction of α,β-unsaturated carbonyl compounds was also performed by using $ErCpCl_2(THF)_3$ (**2**).

Limitation of the present reduction to other organic substances was determined. Reductions of allyl phenyl ether, cyclohexene oxide, cyclohexene, allyl bromide, methyl acrylate, and crotonic acid have failed. The results demonstrate the high chemoselectivity of the reaction. Thus, the reduction of citral (neral:geranial=37:63) with **1** or **2** gave quantitative yields of a mixture of nerol and geraniol in 37:63 ratio.

Table 2 shows the reduction of 2-cyclohexen-1-one in various solvents. Polar and protonic solvent such as methanol seems to be the best for the reduction. A considerable amount of dimethoxymethane (31.2 mol%/Sm) was detected in the reduction of crotonaldehyde, suggesting participation of methanol during the reduction. An analogous mechanism proposed by Luche[2] involving solvent assisted intermediate seems to be operative.



Present results are considered to be complement to the Luche's selective reduction of enones with lanthanoid metal salts.[2]

Table 2. Solvent Effect on the Reduction of 2-Cyclohexen-1-one with $NaBH_4/SmCpCl_2(THF)_3$[a]

a) Solvent=1.0 cm^3. At room temperature for 6 h. Yields are based on 2-cyclohexen-1-one. The ratio of substrate, $NaBH_4$, and **1** was 4.4:2.2:1. b) A: 2-Cyclohexen-1-ol, B: cyclohexanone, C: cyclohexanol.

Experimental

General. All the reactions were carried out under nitrogen. Solvents were dried by usual procedure, distilled, and stored under nitrogen. Enones and unsaturated aldehydes were used after distillation of commercially available materials. $SmCpCl_2(THF)_3$ were prepared according to the literature methods.[4]

Reduction of α,β-Unsaturated Carbonyl Compounds. Typical procedure of the reduction is described below: To a homogeneous solution of a mixture of 2-cyclohexen-1-one (0.240 mmol) and $SmCpCl_2(THF)_3$ (0.057 mmol) in methanol(1.0 cm^3), $NaBH_4$ (0.120 mmol) was added at room temperature. After 6 h a quantitative yield of 2-cyclohexenol (0.232 mmol) was detected by GLC analysis. A small amount of 2-cyclohexan-1-ol (0.005 mmol) was also formed. Other experiments were carried out similarly and the results are listed in Tables 1 and 2.

Preparation of 2-Nitromethyl-2-cycloalkenol and 2-Nitromethyl-2-cycloalkenone

Tohru SAKAKIBARA, Mangala devi MANANDHAR,*,† Noriaki OHKITA, and Yoshiharu ISHIDO*
Department of Chemistry, Yokohama City University, Seto, Kanazawa-ku, Yokohama 236
*Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received April 11, 1987)

Synopsis. Oxidation of 1-nitromethylcycloalkenes with *m*-chloroperbenzoic acid afforded the corresponding 2-nitromethyl-2-cycloalkenols, which were further converted into 2-nitromethyl-2-cycloalkenones.

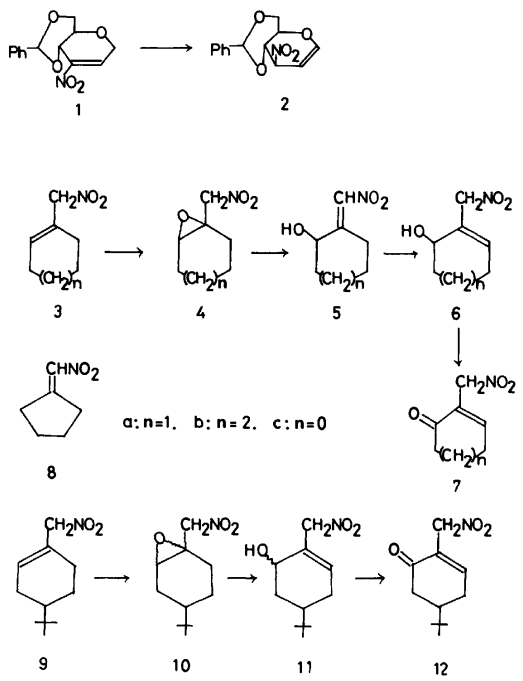
We found that the double bond of α-nitro alkene **1** migrated to give the β-nitro alkene **2** on treatment with triethylamine.[1] In order to clarify if such a facile double bond migration is caused by the conjugation of the double bond formed with the ring oxygen atom, we performed the epoxidation of 1-nitromethylcycloalkenes[2] and subsequent ring opening, anticipating that an exo double bond formed should migrate to the corresponding endo isomer.

Epoxidation of 1-nitromethylcyclohexene (**3a**) with *m*-chloroperbenzoic acid (MCPBA) afforded the epoxide **4a** in 96% yield. As suggested by Takamoto et al. in oxidation of α,β-epoxy ketone oximes,[3] the epoxide ring readily opened by treatment with sodium carbonate to give a mixture of the exo **5a** and endo isomers **6a**. Although complete purification of **5a** was not accomplished, its IR [3500 (OH), 1635 and 1505 cm^{-1} (C=C-NO_2)] and ^1H NMR spectra (olefinic proton at δ=7.17) made us possible to assign the exo structure. In the case of cycloheptene derivative **4b**, the exo isomer **5b** was isolated. Treatment of **4a** with triethylamine afforded **6a** in 83% yield, indicating that, among the hydrogen atoms activated by the nitro alkene moiety, H-1 which attached to the carbon atom having the hydroxyl group is less acidic than the alternative one (H-3). This may be partly attributable to the formation of alkoxide, which should deactivate H-1 and suppress an approach of a base by electrostatic repulsion. Compound **6a** thus formed has potential utility for synthetic purposes, since nitromethyl group thus introduced should be convertible into formyl,[4] nitrile,[5] nitrile oxide,[6] and the nitro group into arylthio,[7] arylsulfonyl groups,[7] and active methylene compounds.[8] Oxidation of **6a** with pyridinium chlorochromate (PCC) afforded the ketone **7a** in 58% yield.

Similar epoxidation of the cycloheptene **3b** gave the epoxide **4b** in 84% yield, of which ring opening with sodium carbonate and triethylamine gave **5b** and **6b** in 60 and 78% yield, respectively. Oxidation of **6b** with PCC afforded the ketone **7b** in 67% yield.

Contrary to the cases of other cycloalkanones, nitromethane condensation of cyclopentanone according to the method described by Eckstein et al.[9] gave a mixture of the exo **8** and endo isomers **3c**. The mixture, without separation, was oxidized with MCPBA to afford the epoxide **4c** and unchanged exo isomer **8**. Epoxide ring opening with triethylamine gave the alcohol **6c** (60%), of which oxidation with PCC gave the ketone **7c** in 41% yield.

Unfortunately, stereoselectivity of epoxidation was low; oxidation of 1-nitromethyl-4-*t*-butylcyclohexene (**9**) with MCPBA afforded a 3:1 mixture of the epoxides **10** (based on ^1H NMR spectroscopy) in 90% yield. Without separation of the mixture, it was treated with triethylamine to afford the allyl alcohol **11** in 97% yield and subsequent oxidation gave the ketone **12** (53% overall yield from **9**).



Experimental

IR spectra were recorded with a Hitachi 285 Infrared Spectrophotometer on sodium chloride plate. ^1H NMR spectra were determined in chloroform-*d* with tetramethylsilane as an internal standard with a Varian EM360A NMR Spectrometer. Column chromatography was carried out on silica gel (Wakogel, C-300). Analytical samples except for **12** were prepared by bulb to bulb distillation at the oven temperature as described.

General Procedure for the Epoxidation of 1-Nitromethylcycloalkene. To a solution of **3b** (1.55 g, 10 mmol) in dichloromethane (20 ml) was added MCPBA (1.9 g, 11 mmol), and the mixture was stirred until the starting material **3b** had disappeared in TLC (ca. 1 h) and then

† UNESCO Student, 1981—1982.

diluted with water. The aqueous layer was extracted with dichloromethane and the combined organic layers were successively washed with saturated aqueous sodium hydrogen carbonate, aqueous sodium hypochlorite, and saturated aqueous sodium chloride, dried, and evaporated to a syrup. It was purified by flash column chromatography with 3:1 (v/v) cyclohexane-benzene to give 1.44 g (84%) of 1-nitromethylcycloheptene oxide (**4b**): bp 117 °C (0.35 Torr, 1 Torr=133.322 Pa); IR 1540 cm^{-1} (NO_2); ^1H NMR δ=4.38 (2H, s, CH_2NO_2), 3.07 (1H, t, $J_{2,3}=J_{2,3'}=4.5$ Hz, H-2); Found: C, 55.76; H, 7.40; N, 7.81%. Calcd for $C_8H_{13}NO_3$: C, 56.12; H, 7.65; N, 8.18%.

1-Nitromethylcyclohexene Oxide (4a): Yield 96%, bp 78—80 °C (0.2 Torr); IR 1545 cm^{-1} (NO_2); ^1H NMR δ=4.38 (2H, s, CH_2NO_2), 3.13 (1H, t, $J_{2,3}=J_{2,3'}=2.0$ Hz, H-2); Anal. ($C_7H_{11}NO_3$) C, H, N.

1-Nitromethylcyclopentene Oxide (4c). Similar treatment of cyclopentenone (1 mmol) with nitromethane (1.5 mmol) and piperidine (0.2 ml) for 10 h gave a mixture of exo- and endo-products in the ratio of 1:2. Epoxidation of the crude product, followed by column chromatography with 9:1 (v/v) cyclohexane-benzene, gave successively the unreacted exo isomer (900 mg) and 1.05 g (72% yield, based on the starting endo isomer) of **4c**. Compound **4c**: bp 100 °C (0.35 Torr); IR 1550 cm^{-1} (NO_2); ^1H NMR δ=5.08, 4.61, 4.58, 4.11 (2H, AB type, CH_2NO_2), 3.40 (br. s, 1H, H-2); Anal. ($C_6H_9NO_3$) C, H, N.

2-Nitromethylene-1-cycloheptanol (5b). A mixture of **3b** (325.5 mg, 2.1 mmol), MCPBA (725 mg, 4.2 mmol), and dichloromethane (20 ml) was stirred for 1 h. To the mixture was added saturated aqueous sodium carbonate (20 ml) and the mixture was stirred for 8 h. Conventional work up gave a syrup, which was chromatographed with 3:1 (v/v) benzene-cyclohexane to give **6b** (8%) and **5b** (60%) in turn. Compound **5b**: bp 122 °C (0.35 Torr); IR 3450 (broad OH), 1635 and 1515 cm^{-1} (C=C-NO_2); ^1H NMR δ=7.29 (1H, s, $CHNO_2$), ca. 4.45 (1H, m, H-1); Anal. ($C_8H_{13}NO_3$) C, H, N.

General Procedure for Preparation of 2-Nitromethyl-2-cycloalkenol (6b). A solution of the epoxide **4b** (1.52 g, 8.9 mmol) in chloroform (10 ml) in the presence of triethylamine (0.1 ml) was kept at room temperature for 0.5 h. Conventional work up afforded a syrup. It was chromatographed with 3:1 (v/v) benzene-cyclohexane to give 1.19 g (78%) of the alcohol (**6b**), which was pure as judged from TLC and ^1H NMR spectroscopy: bp 125 °C (0.35 Torr); IR 3450 (broad OH), 1540 cm^{-1} (NO_2); ^1H NMR δ=6.05 (1H, br. t, $J_{3,4}=J_{3,4'}=6.5$ Hz, H-3), 4.99 (2H, s, CH_2NO_2), 4.55 (1H, m, H-1), 2.97 (1H, s, OH); Anal. ($C_8H_{13}NO_3$) C, H, N.

2-Nitromethyl-2-cyclohexenol (6a): Yield 83%, bp 125 °C (0.35 Torr); IR 3350 (OH), 1550 cm^{-1} (NO_2); ^1H NMR δ=6.03 (1H, br. t, $J_{3,4}=J_{3,4'}=3.3$ Hz, H-3), 5.16 (1H, d, J=14 Hz, $CHNO_2$), 4.76 (1H, d, $CHNO_2$), 4.25 (1H, br. t, $J_{1,6}=J_{1,6'}=4.0$ Hz, H-1), 3.20 (1H, br. s, OH); Anal. ($C_7H_{11}NO_3$) C, H, N.

2-Nitromethyl-2-cyclopentenol (6c): Yield 60%, bp 115 °C (0.35 Torr); IR 3370 (OH), 1550 cm^{-1} (NO_2); ^1H NMR δ=6.05 (1H, br. s, H-3), 5.04 (2H, s, CH_2NO_2), 4.81 (1H, m, H-1), 2.80 (1H, s, OH); Anal. ($C_6H_9NO_3$) C, H, N.

General Procedure for Preparation of 2-Nitromethyl-2-cycloalkenone (7b). To an ice-cooled solution of PCC (500 mg, 2.3 mmol) in dichloromethane (20 ml) was added dropwise a solution of the alcohol **6b** (164 mg, 0.96 mmol) in dichloromethane (2 ml) under a nitrogen atmosphere and the mixture was stirred for additional 3 h at ambient temperature and diluted with diethyl ether. After removal of a solid material by filtration, the filtrate was evaporated and the residue was chromatographed with 9:1 (v/v) benzene-ethyl acetate to give 109 mg (67%) of the ketone **7b**, which was pure as judged from TLC and ^1H NMR spectroscopy: bp 120 °C (0.35 Torr); IR 1670 (CO), 1550 cm^{-1} (NO_2); ^1H NMR δ=6.77 (t, 1H, $J_{3,4}=J_{3,4'}=6.0$ Hz, H-3), 5.03 (s, 2H, CH_2NO_2); Anal. ($C_8H_{11}NO_3$) C, H, N.

2-Nitromethyl-2-cyclohexenone (7a): Yield 58%, bp 120 °C (0.35 Torr); IR 1680 (CO), 1550 cm^{-1} (NO_2); ^1H NMR δ=7.09 (1H, t, $J_{3,4}=J_{3,4'}=4.0$ Hz, H-3), 4.95 (2H, s, CH_2NO_2); Anal. ($C_7H_9NO_3$) C, H, N.

2-Nitromethyl-2-cylopentenone (7c): Yield 41%, bp 95 °C (0.35 Torr); IR 1705 (CO), 1550 cm^{-1} (NO_2); ^1H NMR δ=7.81 (1H, br. s, H-3), 5.06 (2H, s, CH_2NO_2); Anal. ($C_6H_7NO_3$) C, H, N.

5-*t*-Butyl-2-nitromethyl-2-cyclohexenone (12): According to the method described by Eckstein et al.[9] **9** was obtained in 60% yield from 4-*t*-butylcyclohexanone; bp 115 °C (0.45 Torr); IR 1550 cm^{-1} (NO_2); ^1H NMR δ=5.89 (1H, br.s, H-2) and 4.77 (2H, s, CH_2NO_2); Anal. ($C_{11}H_{19}NO_2$) C, H, N.

Similar epoxidation of **9** afforded a 3:1 mixture of **10** as judged from its ^1H NMR spectrum, the epoxide ring of which was opened by treatment with triethylamine, followed by oxidation with PCC, to give **12** in 53% overall yield (from **9**); syrup, purified by column chromatography without distillation; IR 1675 (CO), 1550 cm^{-1} (NO_2); ^1H NMR δ=7.1 (1H, m, H-3), 4.98 (2H, s, CH_2NO_2); Found: C, 62.82; H, 8.08; N, 6.28%. Calcd for $C_{11}H_{17}NO_3$: C, 62.54; H, 8.11; N, 6.63%.

Tin-Promoted Electrochemical Hydrodimerization of Ionones

Kenji UNEYAMA, Takumi TOKUNAGA, and Sigeru TORII*
Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700
(Received April 23, 1987)

Synopsis. Electrochemical hydrodimerization of α and β-ionones in the presence of metal tin provides the corresponding hydrodimers in 77 and 60% yields, respectively.

Reductive hydrodimerization of carbonyl compounds is important for the carbon-carbon bond formation. Especially, hydrodimerization of polyenyl carbonyl compounds is useful for the carotenoid synthesis. The electrochemical hydrodimerization would be usable for the purpose. In fact, the electroreductive hydrodimerization is successfully employed for the saturated carbonyl compounds.[1] On the other hand, the hydrodimerization of α, β-unsaturated carbonyl compounds has not been studied in details. 3-Methyl-2-butenal,[2] citral,[3] ionone,[4] and retinal[4] have been electrochemically hydrodimerized by the use of a mercury electrode, but the isolated yields are unsatisfactory. Moreover, the electrolysis has been mostly conducted by the use of a mercury electrode and very few electrodes have been examined for the purpose. On these backgrounds and in connection with our recent study on the electrochemical generation and recycle of the reactive tin reagent,[5] this paper describes a tin-promoted electroreductive hydrodimerization of ionones by the use of platinum electrodes.

Results and Discussion

The electrolysis of α-ionone **1a** was conducted in a methanol-acetic acid-water-1 M (1.M=1 mol dm^{-3}) sulfuric acid solution containing metal tin. Constant current was supplied using two platinum foils as electrodes in a beaker type undivided cell. The result is summarized in Table 1. The reaction at around 40 °C gave the hydrodimer **2a**[6] in more than 70% yield. The reaction at the lower temperature resulted in the increase of the recovered **1** (**2a**; 46% and **1a**; 33%).

Table 1. Electrochemical Hydrodimerization of Ionones

Substrate	Sn/mol%	F mol^{-1}	**2a** or (**2b**)/%
1a[a]	5	8.6	69
	10	7.5	73
	50	6.6	74
	100	5.8	77
	0	2.5	46
1b[b]	20	3.0	(60)

a) **1a** (1 mmol), MeOH (1.5 cm^3), AcOH (0.5 cm^3), H_2O (0.5 cm^3), 1 M H_2SO_4 (0.03 cm^3). b) **1b** (1 mmol), MeOH (2.0 cm^3), H_2O (1.0 cm^3), Et_4NOTs (0.1 mmol).

The increase of metal tin amount led to a slight increase of the yield of **2a**. On the other hand, only 46% of **2a** was obtained in the absence of metal tin after 2.5 F mol^{-1} (1F=96480 C) of current passage. The prolonged electrolysis in the absence of metal tin lost the product **2a** since **2a** was in part converted into the pinacolone **3a**[6] via the pinacol-pinacolone rearrangement in the electrolysis conditions.

The action of metal tin in the same electrolysis solution under no current passage did not induce the hydrodimerization, clearly suggesting that the metal tin is not a reducing agent. Presumably, di- or tetravalent tin generated in situ would chelate the 1,2-diol to suppress the rearrangement. Another role of tin ion would associate the reductively generated anion radical from **1a** as proposed for chromium(III)[7] to promote an effective dimerization of the metal-associated anion radical **4**. In fact, **2a**(54%) and **3a**(36%) were obtained by the electrolysis in the presence of tin(II) sulfate ($SnSO_4$). The electrolysis of **1b** in a methanol-acetic acid-water-1 M sulfuric acid solution containing metal tin as employed for **1a** provided a trace of **2b**.[4] The pinacol **2b** is so acid-sensitive that it smoothly undergoes the pinacol-pinacolone rearrangement. The electrolysis at −7 °C gave **2b** in 46% yield. Therefore, the electrolysis was conducted in a neutral solution such as in an MeOH-H_2O-Et_4NOTs system, affording **2b** in 60% yield.

Experimental

Electrolysis of 1a. A mixture of **1a** (1.0 mmol) and tin powder (0.1 mmol) dissolved in methanol (1.5 cm^3), water (0.5 cm^3), acetic acid (0.5 cm^3), and 1 M sulfuric acid (0.03 cm^3) was electrolyzed in an undivided beaker type cell at 40 °C using platinum foil electrodes (1×1.5 cm^2) under a constant current (20 mA for 10.5 h, 7.5 F mol^{-1}, Metronix

543B DC power supply). After neutralization with saturated sodium hydrogencarbonate, methanol was removed under reduced pressure. Then, the mixture was extracted with ethyl acetate several times. The combined extracts were washed with brine, dried over sodium sulfate, and concentrated in vacuo. The residue was chromatographed on silica gel (hexane–AcOEt) to give **2a**[6] in 73% yield (141 mg).

This work was supported in part by a Grant-in-Aid (No. 61550640) from the Ministry of Education, Science and Culture.

The Reaction of Calcium Atoms with Group 4B Catenates, Me_3E-E'Me_2R (E, E'=Si, Ge, Sn; R=Me, Cl)

Kunio MOCHIDA* and Takayuki YAMANISHI
Department of Chemistry, Faculty of Sciences, Gakushuin University,
1-5-1 Mejiro, Tokyo 171
(Received March 20, 1987)

Synopsis. Calcium atoms are thought to be inserted into E-E' bonds of group 4B catenates, Me_3E-E'Me_2R (E, E'=Si, Ge, Sn; R=Me, Cl) to give the corresponding Me_3E-Ca-E'Me_2R compounds.

The activation of metal-metal bonds of group 4B catenates by metals and metal complexes has received considerable attention in a variety of synthetic organic procedures and catalytic processes.[1-7] In this activation, the oxidation addition of metals or metal complexes into metal-metal bonds of group 4B catenates is generally thought to be the most important process. However, there has been no definite report on insertion reactions of the metal-metal bonds of group 4B catenates by metals.

On the other hand, the study of metal-vapor reactions is of considerable interest in organometallic chemistry since by these methods it is possible to synthesize organometallic compounds which would be difficult, if not impossible, to prepare by other methods, and to study their reactive intermediates.[8]

In this report, we first describe the insertion reactions of metal-metal bonds of group 4B catenates by calcium atoms.

Results and Discussion

Calcium atoms were generated by evaporation from a tungsten filament using essentially the same apparatus and conditions as have been described in the literature (ca. 900 °C and 5×10^{-3} Torr, 1 Torr=133.322 Pa).[9-11] Calcium metal was evaporated at a rate of ca. 20 mg min^{-1}, while an excess of the group 4B catenate compound was co-condensed on the walls of a quartz reaction flask containing a crucible and a perforated inlet tube through which the group 4B catenate compound was admitted. The reaction flask was immersed in liquid nitrogen during calcium evaporation. The color of the co-condensation product of calcium atoms-group 4B catenate compound vapor at 77 K is deep blue, probably due to a weak σ complex.[12] After the calcium evaporation and admission of the group 4B catenate was completed, the reaction flask was warmed to room temperature. The co-condensation product of calcium atoms-group 4B catenate compound vapor turns black. Then, an excess of the organic substrate was admitted as vapor and the reaction flask was left to stand for 1 h. After removing the reaction flask from the vacuum line, the reaction mixture was slowly hydrolyzed with water. The organic layer was extracted with ether.

All products were identified by comparing their GC-MASS and retention times on GLC with those of authentic samples. The results are summarized in Table 1.

Group 4B element-centered anions react with organic halides to give the corresponding substitution products; unreacted anions are converted to the hydrides by hydrolysis.[13]

As shown in Tbale 1, the reaction products of calcium atoms/hexamethyldisilane ($Me_3SiSiMe_3$) and pentamethylchlorodisilane ($Me_3SiSiMe_2Cl$) vapors when treated with phenyl bromide or hydrolyzed gave hexamethylsiloxane. Blank experiments of $Me_3SiSiMe_3$ and $Me_3SiSiMe_2Cl$ in the absence of calcium metal were carried out under identical conditions to give no hexamethylsiloxane ($M_3SiOSiMe_3$). The compound $Me_3SiOSiMe_3$ is probably formed by the insertion of Si-Si bonds by calcium atoms to give Si-Ca-Si followed by hydrolysis in a basic medium.[14] Silylcalcium compounds, thus formed,may be inactive toward phenyl bromide under these conditions.[10]

The reaction products of calcium atoms/(trimethylgermyl)trimethylsilane vapor when treated with phenyl bromide gave phenyltrimethylgermane ($PhGeMe_3$), as expected, besides $Me_3SiOSiMe_3$.

The reaction products of calcium atoms/hexamethyldigermane vapor with phenyl bromide afforded trimethylgermane (Me_3GeH) and $PhGeMe_3$ (Table 1). The formations of $PhGeMe_3$ and Me_3GeH provide strong evidence of the insertion of a Ge-Ge bond of $Me_3GeGeMe_3$ by calcium atoms.

Table 1. Reactions of Calcium Atoms/Group 4B Catenate Compound Vapors with Substrates[a]

Compound	Substrate	Product (Yield/%)[b]
$Me_3SiSiMe_3$	H_2O or PhBr/H_2O	$Me_3SiOSiMe_3$ (5.0)
$Me_3SiSiMe_2Cl$	H_2O	$Me_3SiOSiMe_3$ (15.0)
$Me_3SiGeMe_3$	PhBr/H_2O	$Me_3SiOSiMe_3$ (1.0)
		$PhGeMe_3$ (trace)
$Me_3GeGeMe_3$	PhBr/H_2O	$PhGeMe_3$ (6.0)
		Me_3GeH (0.5)
$Me_3SiSnMe_3$	PhBr/H_2O	$Me_3SiOSiMe_3$ (36.0)
		$PhSnMe_3$ (2.0)
		Me_3SnH (42.0)
		$Me_3SnSnMe_3$ (8.0)
		Me_3SnOH (10.0)

a) Reactions were performed at room temperature for 1 h. b) Yields of products were based on the calcium metals consumed.

The reaction products of calcium atoms/(trimethylsilyl)trimethylstannane vapor when treated with phenyl bromide afforded $Me_3SiOSiMe_3$, phenyltrimethylstannane ($PhSnMe_3$), trimethylstannane (Me_3SnH), hexamethyldistannane ($Me_3SnSnMe_3$), and trimethylstannol (Me_3SnOH) shown in Table 1. A blank experiment of $Me_3SiSnMe_3$ in the absence of calcium metal was carried out under identical conditions. $Me_3SiOSiMe_3$, $Me_3SnSnMe_3$, and Me_3SnOH were produced in the ratio of 1:1:2. Taking the experimental results into consideration, most of the $Me_3SiOSiMe_3$, $PhSnMe_3$, and Me_3SnH may be derived from the insertion of a Si–Sn bond by a calcium atom.

The degree of insertion of metal–metal bonds of group 4B catenates by calcium atoms increased in the order Si–Si<Ge–Ge<Si–Sn in accord with the metal–metal bond dissociation energy.

The yields of the products shown in Table 1 are very low. The yields of these products were determined on the basis of the amount of calcium metal consumed on the assumption that all of the vaporized calcium metal completely reacted with the substrate.

Experimental

GLC analyses were performed on a Shimazu GC-6A and 8A gas chromatograph with 2 m 20% SE-30 and 2 m 30% Apiezon L columns. GC-MASS spectra were obtained with a JEOL JMS-DX 303 mass spectrometer. NMR spectra were obtained with a Varian FT-80A spectrometer using $CDCl_3$ as the solvent and TMS as the internal standard.

Materials. Calcium metal (granule, 99% pure, Wako chemicals) was commercially available. $Me_3SiGeMe_3$,[15] $Me_3GeGeMe_3$,[16] $Me_3SiSnMe_3$,[17] $PhGeMe_3$,[18] Me_3GeH,[19] $PhSnMe_3$,[20] Me_3SnH,[21] $Me_3SnSnMe_3$,[22] and Me_3SnOH[23] were prepared as described in the cited references.

Reactions of Calcium Atoms/Group 4B Catenate Compound Vapors with Substrate. As a typical example, the reaction of calcium atoms/hexamethyldigermane vapor with phenyl bromide is described. Calcium metal (500 mg, 12.5 mmol) was vaporized at a temperature of ca. 900 °C using a filament of tungsten in vacuo (ca. 5×10^{-3} Torr), at a rate of ca. 20 mg min^{-1}. During the vaporization of calcium metal, digermane (12 g, 51.3 mmol) was introduced into the quartz reaction flask as vapor. Calcium atoms/digermane vapor condensed on the walls of the reaction vessel, which was cooled to 77 K with liquid nitrogen. The initial product at 77 K was a deep blue. The reaction vessel was warmed to room temperature and an excess of phenyl bromide was then admitted as vapor. The reaction vessel was left to stand for 1 h. After removing the reaction vessel from a vacuum line, the reaction mixture was slowly hydrolyzed with water. The organic layer was extracted with ether. The products were identified by comparing their GC-MASS and retention times on GLC with those of authentic samples. The yields of the products were determined by an internal-standard method.

The authors thank Professor Hideki Sakurai and Dr. Kenkichi Sakamoto of Tohoku University for a gift of organosilyl compounds. Partial financial support of this research by the Saneyoshi Scholarship Foundation is greatly acknowledged (1984).

Titanium Oxide-Supported Carbonylmolybdenum Catalyst in Liquid Phase: Application to Allylic Alkylation of Methyl *p*-Tolylsulfonylacetate

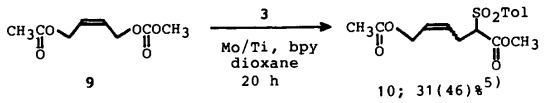
Yoshiro MASUYAMA,* Yutaka MITSUNAGA, Yasuhiko KURUSU, and Koh-ichi SEGAWA
Department of Chemistry, Faculty of Science and Technology, Sophia University,
7-1 Kioicho, Chiyoda-Ku, Tokyo 102
(Received March 26, 1987)

Synopsis Titanium oxide-supported carbonylmolybdenum catalyst was applied to selective monoallylation of methyl *p*-tolylsulfonylacetate using allylic acetates or carbonates in refluxing dioxane. This reaction required both 2,2′-bipyridyl as a ligand and sodium hydride as a base for preparation of the salt of methyl *p*-tolylsulfonylacetate.

We have applied metal oxide-supported carbonylmolybdenum [$Mo(CO)_3$–metal oxide] catalyst to allylic alkylation of carbon nucleophiles using allylic acetates.[1] The $Mo(CO)_3$–TiO_2 catalytic system is superior to others, and exhibits desirable characteristics as regards 1) long life and easy separation of the catalyst and 2) regio- and stereochemistry. Application of sulfones which stabilize an adjacent carbanion as carbon nucleophiles, instead of diethyl malonate or ethyl 2-oxocyclopentanecarboxylate, should further enhance the desirability of the $Mo(CO)_3$–TiO_2 catalyst in the allylic alkylation.[2] Homogeneous $Mo(CO)_6$ catalyst did not catalyze any reactions of allylic acetates with sulfones, whereas allylic carbonates did serve as allylating agents.[3] Here, we report the selective monoallylation of methyl *p*-tolylsulfonylacetate with several allylic acetates or carbonates by means of the $Mo(CO)_3$–TiO_2 catalytic system.

The reactions of 2-butenyl acetate (**1a**) or 2-butenyl methyl carbonate (**2b**) with the salt **3**, derived from methyl *p*-tolylsulfonylacetate and sodium hydride, were investigated under various conditions. The reaction proceeded in the presence of both the $Mo(CO)_3$–TiO_2 catalyst and 2,2′-bipyridyl (bpy) in refluxing dioxane. Some examples are shown in the Table 1. Neither **1a** nor **2b** reacted with **3** in refluxing toluene, which is a common solvent.[1,4] Allylic acetates could be utilized in this reaction, which was not the case with the homogeneous $Mo(CO)_6$ system (Entries 1—3).[3] However, the reactivity of the allylic acetates was less than that of the corresponding allylic carbonates. Monoallylation occurred selectively without diallylation. *p*-Tolylsulfonylacetonitrile, which was a good nucleophile in the homogeneous system, did not react under these conditions.[3]

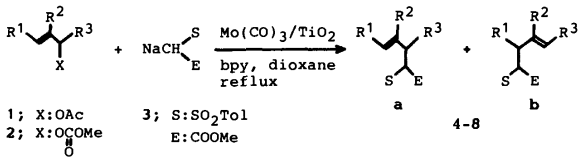
The reaction of **3** with **9**, containing both an allylic acetate moiety and an allylic carbonate moiety, occurred chemoselectively at the carbonate moiety and regioselectively at the less substituted end of the allyl unit (Eq. 1).



(1)

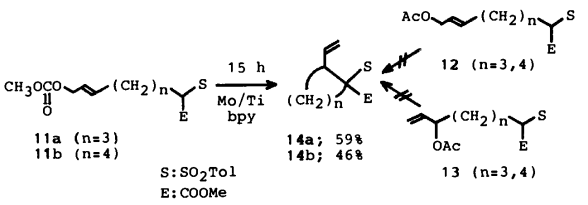
In order to extend this allylic alkylation to a cyclization, several intramolecular reactions were investigated under the same conditions.[6] The sodium salts of carbonates **11a** and **11b** reacted regioselectively to afford five- and six-membered ring compounds **14a** and **14b** respectively. No cyclizations occurred in the case of sodium salts of acetates **12** and **13** under the same conditions (Scheme 1).

Table 1. Allylic Alkylation of **3**



Entry	Allylic compd.		Time / h	Product R¹	R²	R³		Yield[a] / %	Ratio[b] a : b
1		**1a**	15	CH_3	H	H	**4**	33	42 : 58
2		**1b**	31	H	H	n-C_5H_{11}	**5**	36	11 : 89
3		**1c**	24	H	-$(CH_2)_4$-		**6**	40	81 : 19
4		**2a**	19	H	H	H	**7**	67	—
5		**2b**	17	CH_3	H	H	**4**	72	40 : 60
6		**2c**	15	Ph	H	H	**8**	76	33 : 67

a) Isolated yields. b) The ratio was determined by ^1H NMR. Diastereomer ratios: **4a** (60/40), **5a** (60/40), **6a** (71/29), and **8b** (58/42).



Scheme 1.

As mentioned above, the heterogeneous $Mo(CO)_3$–TiO_2 catalyst enabled us to use allylic acetates as allylating agents, and was found to show higher selectivity of monoallylation of **3** than that for homogeneous $Mo(CO)_6$ catalyst and higher chemoselectivity to allylic carbonates than acetates.

Experimental

Reaction of Allylic Acetates 1 or Carbonates 2 with Methyl *p*-Tolylsulfonylacetate. 4: To a solution of salt **3** derived from methyl *p*-tolylsulfonylacetate (0.23 g, 1.0 mmol) with sodium hydride (27 mg, 1.1 mmol) in dioxane (10 ml) were added 2-butenyl acetate (**1a**) (0.11 g, 1.0 mmol) and bpy (8.0 mg, 0.05 mmol) under argon atmosphere. The solution was added to a vessel, in which $Mo(CO)_3$–TiO_2 catalyst, prepared from TiO_2 (0.50 g) and $Mo(CO)_6$ (13 mg, 0.05 mmol),[1] had been placed. This mixture was refluxed for 15 h under argon atmosphere. The reaction mixture was diluted with ether (50 ml) and the catalyst was removed by filtration. Evaporation of solvents followed by purification of the residue by column chromatography (silica gel, hexane-ethyl acetate=3/1) gave the monoallylated product **4** as colorless oil in 33% yield (93 mg). The structure was confirmed by IR and ^1H NMR spectral comparison with an authentic sample.[3]

5: IR (neat) 1735 (C=O), 1320 and 1140 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ=0.85 (t, J=7.0 Hz, 3H), 1.12—1.36 (m, 6.2H), 1.87—2.00 (m, 1.8H), 2.46 (s, 3H), 2.50—2.77 (m, 1.8H), 2.80—2.94 (m, 0.1H), 3.51 (s, 0.12H), 3.64 (s, 0.18H), 3.66 (s, 2.7H), 3.96 (dd, J=4.0, 11.4 Hz, 0.9H), 3.98, 4.01 (2d, J=2.6 Hz, 0.1H), 5.02—5.10 (m, 0.2H), 5.12—5.31 (m, 0.9H), 5.44—5.57 (m, 0.9H), 5.58—5.66 (m, 0.1H), 7.30—7.40 (m, 2H), and 7.71—7.81 (m, 2H); MS (70 ev) m/z (rel intensity) 338 (M^+, 1), 183 (100), 182 (39), 123 (34), 111 (30), 91 (46), 81 (39), and 67 (33). Found: m/z 338.1546. Calcd for $C_{18}H_{26}O_4S$: M, 338.1550.

6: IR (neat) 1735 (C=O), 1320 and 1140 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ=1.34—1.97 (m, 5.6H), 2.02—2.17 (m, 1.8H), 2.23—2.35 (m, 0.6H), 2.44(s, 3H), 2.60 (br, 0.4H), 3.06—3.17 (m, 0.8H), 3.43 (s, 1.7H), 3.63 (s, 0.7H), 3.65 (s, 0.6H), 4.11 (dd, J=4.6, 10.8 Hz, 0.2H), 4.43 (d, J=11.7 Hz, 0.56H), 4.49 (d, J=9.8 Hz, 0.24H), 4.61 (s, 0.56H), 4.68 (s, 0.56H), 4.82 (s, 0.24H), 4.84 (s, 0.24H), 5.41 (br, 0.2H), 7.29—7.40 (m, 2H), and 7.72—7.82 (m, 2H); MS (70 ev) m/z (rel intensity) 322 (M^+, 0.7), 167 (82), 166 (100), 138 (26), 135 (50), 107 (46), 94 (40), 91 (58), and 79 (35). Found: m/z 322.1229. Calcd for $C_{17}H_{22}O_4S$: M, 322.1238.

7: The structure was confirmed by IR and ^1H NMR spectral comparison with an authentic sample.[3]

8: IR (neat) 1735 (C=O), 1320 and 1140 cm^{-1} (SO_2); ^1H NMR ($CDCl_3$) δ=2.41 (s, 3H), 2.75—2.98 (m, 0.66H), 3.62 (s, 1H), 3.68 (s, 0.8H), 3.70 (s, 1.2H), 4.07 (dd, J=8.5, 12.1 Hz, 0.4H), 4.08 (dd, J=4.3, 10.7 Hz,0.33H), 4.18 (dd, J=8.5, 10.1 Hz, 0.27H), 4.50 (d, J=8.5 Hz, 0.4H), 4.54 (d, J=8.5 Hz, 0.27H), 4.99—5.20 (m, 1.34H), 5.80—6.04 (m, 0.67H), 6.23 (dt, J=6.9, 15.9 Hz, 0.33H), 6.47 (d, J=15.9 Hz, 0.33H), 7.02—7.36 (m, 7H), and 7.71—7.82 (m, 2H); MS (70 eV) m/z (rel intensity) 344 (M^+, 0.3), 189 (100), 188 (33), 157 (38), 130 (35), 129 (99), 128 (32), 117 (42), and 91 (41). Found: m/z 344.1080. Calcd for $C_{19}H_{20}O_4S$: M, 344.1081.

10: IR (neat) 1740 (C=O), 1320 and 1140 cm^{-1} (SO_2); ^1H NMR (CCl_4) δ=1.93 (s, 3H), 2.40 (s, 3H), 2.58—2.82 (m, 2H), 3.56 (s, 3H), 3, 88 (dd, J=7,9 Hz,1H), 4.38—4.60 (m, 2H), 5.22—5.71 (m, 2H), 7.29 (d, J=7.5 Hz, 2H), and 7.67 (d, J=7.5 Hz, 2H); MS (70 eV) m/z (rel intensity) 340 (M^+, 0.3), 185 (72), 184 (100), 141 (36), 125 (22), and 91 (23). Found: m/z 340.0976. Calcd for $C_{16}H_{20}O_6S$: M, 340.0979.

Intramolecular Cyclization of 11. 14a: A solution of **11a** (0.19 g, 0.5 mmol) in dioxane (5 ml) was added to the suspension of sodium hydride (17 mg, 0.7 mmol) in dioxane (5 ml) at room temperature under argon atmosphere. The solution followed by bpy (8.0 mg, 0.05 mmol) were added to a vessel, in which $Mo(CO)_3$–TiO_2 catalyst, prepared from TiO_2 (0.50 g) and Mo $(CO)_6$ (13 mg, 0.05 mmol),[1] had been placed. After refluxing for 15 h under argon atmosphere, the mixture was diluted with ether (50 ml) and the catalyst was removed by filtration. Evaporation of solvents followed by purification of the residue by column chromatography (silica gel, hexane-ethyl acetate=2:1) gave the cyclic product **14a** as colorless oil in 59% yield (91 mg). IR (neat) 1735 (C=O), 1310, and 1140 cm^{-1} (SO_2); ^1H NMR (CCl_4) δ=1.44—2.73 (m, 6H), 2.41 (s, 3H), 3.09—3.44 (m, 1H), 3.51 (s, >2.85H), 3.59 (s, <0.15H), 4.84 (d, J=10 Hz, 1H), 4.87 (d, J=16 Hz, 1H), 5.53 (ddd, J=7,10, 16 Hz, 1H), 7.21 (d, J=8 Hz, 2H), and 7.71 (d, J=8 Hz, 2H); MS (70 ev) m/z (rel intensity) 308 (M^+, 0.3), 153 (57), 152 (50), 121 (31), 93 (100), and 91 (39). Found: m/z 308.1082. Calcd for $C_{16}H_{20}O_4S$: M, 308.1081.

14b: IR (neat) 1735 (C=O), 1320, and 1140 cm^{-1} (SO_2); ^1H NMR (CCl_4) δ=0.91—2.36 (m, 8H), 2.40 (s, 3H), 2.60—2.93 (m, 0.6H), 3.04—3.31 (m, 0.4H), 3.51 (s, 1.2H), 3.62 (s, 1.8H), 4.84—5.20 (m, 2H), 6.02—6.51 (m, 1H), 7.07—7.28 (m, 2H), and 7.42—7.64 (m, 2H); MS (70 ev) m/z (rel intensity) 322 (M^+, 0.3), 167 (58), 121 (32), 119 (97), 117 (100), 107 (78), and 91 (23). Found: m/z 322.1236. Calcd for $C_{17}H_{22}O_4S$: M, 322.1237.

Ordering of Cations in $Ba(Mg_{1/3}Nb_{2/3})O_3$ and $Ba(Zn_{1/3}Nb_{2/3})O_3$

Hideki YOSHIOKA
Industrial Research Institute of Hyogo Prefecture, Yukihira-cho 3-1-12, Suma-ku, Kobe 654
(Received March 16, 1987)

Synopsis. The ordering of B-site cations in $Ba(Mg_{1/3}Nb_{2/3})O_3$ (BMN) and $Ba(Zn_{1/3}Nb_{2/3})O_3$ (BZN) was studied from superlattice reflections in X-ray diffraction patterns. The degree of ordering in BMN increases with increasing sintering temperature. While in BZN an ordered structure was observed up to 1673 K, and an order-disorder phase transition was found below 1773 K.

The ordering of B-site cations has been studied by Galasso et al.[1] for a number of $A(B'B'')O_3$ type complex perovskite oxides. $Ba(Mg_{1/3}Nb_{2/3})O_3$ (BMN) and $Ba(Zn_{1/3}Nb_{2/3})O_3$ (BZN) were also synthesized by Galasso et al.[2] and their ordering properties were investigated by X-ray powder diffraction analysis. They reported that Mg^{2+} and Nb^{5+} in BMN are hexagonally ordered, while BZN has a disordered structure in terms of its B-site Zn^{2+} and Nb^{5+} cations.

It was considered that the ordering of B-site cations depends upon the defferences in their ionic charges and ionic radii.[2] Since the differences in the ionic charges are equal for BMN and BZN, their ordering properties may depend upon the differences in the ionic radii of B-site cations. As the ionic radii of Mg^{2+}, Zn^{2+}, and Nb^{5+} are 0.066, 0.074, and 0.069 nm, respectively,[3] the differences are 0.003 nm for BMN and 0.005 nm for BZN, which are also very close. Therefore, it is considered that the ordering properties of these compounds are located near the boundary of stability between order and disorder, and that the possibility of changing the degree of ordering by a heat treatment exists for these compounds. In this study the ordering of B-site cations for BMN and BZN under various heat treatments was investigated using superlattice reflections in the X-ray powder diffraction patterns.

BMN and BZN were prepared by solid state reactions. The mixtures of stoichiometric proportions of $BaCO_3$, MgO or ZnO, and Nb_2O_5 (purity>99.99%) were calcined at 1273 K for 8 h. The obtained powders gave X-ray patterns of a cubic perovskite structure. After pressing into pellets, these were sintered under various conditions, as shown in Table 1. The ordering of B-site cations produces superlattice reflections such as (1/3 1/3 1/3) and (2/3 1/3 1/3) with an original perovskite unit cell in the X-ray powder diffraction patterns. If B-site cations are completely ordered, the unit cell can be described as a hexagonal lattice and the superlattice reflections, (1/3 1/3 1/3) and (2/3 1/3 1/3), can be indexed as (001) and (100), respectively, with this hexagonal unit cell.

Table 1. Sintering Conditions of BMN and BZN

BMN	T/K	t/h	BZN	T/K	t/h
1	1473	16	1	1473	16
2	1573	4	2	1573	16
3	1673	4	3	1573	4
4	1773	4	4	1673	4
5	1833	4	5	1773	4

X-Ray diffraction patterns of the superlattice reflections (001) and (100) in BMN with Cu $K\alpha$ radiation are shown in Fig. 1. In all samples, (100) reflections are about twice as large in peak heights as the (001) reflections. The lattice spacings of (001) and (100) obtained from the diffraction angles are 0.71 and 0.50 nm, respectively; these are constant among samples under various sintering conditions. However, with increasing sintering temperature, the increase in peak heights and the sharpening of peaks are evident in Fig. 1. The degree of ordering can be represented by the intensity of the superlattice peak, while the ordered domain size can be calculated from the broadening of the peak. To estimate the degree of ordering in samples, the intensity ratio of the (100) reflection, which is the strongest superlattice reflection, to (110) and (102) reflections, which are overlapped and the strongest of all reflections, was calculated. The ordered domain sizes were obtained from the half widths of the superlattice reflections. The results are listed in Table 2. An increase in the degree of ordering was observed for a sample sintered at more than 1773 K; this is attributed to an enhancement of the rate of ordering with increasing temperature. Since the intensity ratio in a sample sintered at 1833 K is comparable with the theoretical value calculated from the completely ordered arrangement, the ordering of Mg^{2+} and Nb^{5+} in BMN is almost achieved by sintering at 1883 K for 4 h. The

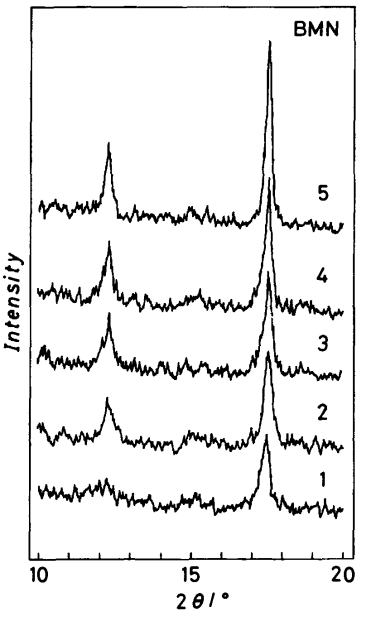

Fig. 1. X-Ray diffraction patterns of superlattice reflections for BMN.

Table 2. Intensity Ratio of Superlattice Peak and Size of Ordered Domains for BMN

	$(I_{100}/I_{110,102}) \times 100$	L/nm
1	2.18	62
2	2.38	73
3	2.28	75
4	2.78	>100
5	3.27	>100

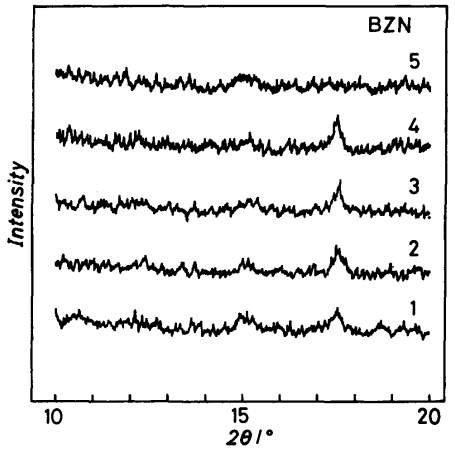

Fig. 2. X-Ray diffraction patterns of superlattice reflections for BZN.

ordered domain sizes increase steadily with increasing sintering temperature, reaching more than 100 nm at 1773 K.

Superlattice peaks of (100) reflections were detected for BZN sintered at less than 1673 K (Fig. 2), corresponding to the cation ordering, although Galasso et al.[2] reported that BZN was a disordered perovskite. Scattering factors of Zn^{2+} and Nb^{5+} are so close that the (100) reflections are much smaller than those in BMN and that the (001) reflections, which are considered to be about half as much as the (100) reflections in intensities like in BMN, are invisible. Since no significant difference with sintering time was observed between the diffraction patterns of samples 2 and 3 in Fig. 3, it seems that sintering for 4 h is sufficient for investigating the ordering property of BZN. One characteristic is the fact that the peak intensities increase with increasing sintering temperature for a sample sintered at less than 1673 K, and that no superlattice reflection could be observed for a sample sintered at 1773 K. This indicates that below 1673 K the ordered arrangement is stable, but above 1773 K the disordered arrangement is stable for BZN. This could be confirmed by X-ray diffraction patterns of the samples subjected to two-step heat treatments. In Fig. 3, the diffraction pattern of a sample sintered at 1573 K for 4 h (labeled as 3) in which the (100) reflection can be clearly observed. After sintering this sample again at 1773 K for 4 h (represented by 3 R in Fig. 3), the (100) reflection could no longer be detected. Though the sample first sintered at 1773 K for 4 h showed no superlattice reflection (labeled as 5 in Fig. 3), a weak superlattice reflection was detected

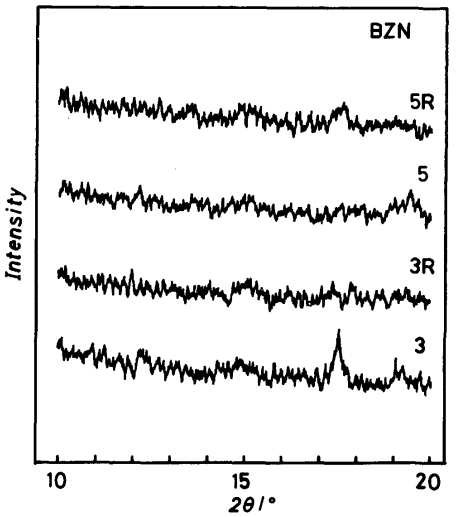

Fig. 3. Superlattice reflections of BZN subjected to two-step heat treatments.

when reheated to 1573 K for 4 h (5 R in Fig. 3). This result clearly indicates that the ordered structure is stable up to 1573 K, but that the disordered structure is stable above 1773 K. Also, there is a reversible phase transition between the ordered and disordered structures in the temperature range from 1573 to 1773 K.

Few of the complex perovskite oxides, which show an order-disorder phase transition like BZN, are known except for $Pb(Sc_{1/2}Ta_{1/2})O_3$ (PST) studied by N. Setter et al.[4] They found that the degree of Sc^{3+} and Ta^{5+} ordering in PST sintered at 1833 K increases from 0.37 to more than 0.80 after annealing at 1273 K for 4 h; this strongly suggests that there is an order-disorder phase transition between 1273 and 1833 K.

The appearance of the order-disorder phase transition can be explained in terms of an increase in the entropy contribution to the free energy at high temperatures. The free energy of the ordered structure in BMN is lower than that of the disorderd structure (up to 1833 K); however, in BZN that of the disordered structure is lower than that of the ordered structure in 1773 K. The free energies of these materials mainly consist of the Madelung energy, due to an electrostatical interaction, and the entopy contribution which increases at high temperatures. Both are very close between BMN and BZN at the same temperature. Thus, it is noted that as G. Patrat et al.[5] pointed out for $Sr(Fe_{1/2}Ta_{1/2})O_3$, that the polarization energy and the displacement energy, which are caused by the size and the polarizability of the constituent ions, must be included in calculations of their free energies.

Synopsis. Hydrogen molybdenum bronze, $H_{0.3}MoO_3$, heated in vacuo was studied by FT-IR spectroscopy. The spectrum near 1000 cm^{-1} analyzed by a microcomputer system was confirmed to be composed of three bands. Among them, bands at 1005 and 990 cm^{-1} correspond to the Mo=O bonds of orthorhombic bronze and rhombic MoO_3, respectively.

It is well-known that by insertion of atomic hydrogen into MoO_3, the rhombic MoO_3 structure turns to the orthorhombic bronze structure.[1] This structural change is expected to effect strongly on the Mo=O stretching vibration. It is confirmed by thermogravimetry[2] and TPD method[3] that orthorhombic hydrogen molybdenum bronze, $H_{0.3}MoO_3$, is decomposed into $MoO_{2.86}$, a nonstoichiometric compound with the rhombic MoO_3 structure, by heating in vacuo with evolution of H_2O. The change in IR spectra has also been studied on samples heated in vacuo, but no quantitative analysis has been made for the bands in the region 1000—800 cm^{-1} which can be assigned to the Mo=O or Mo–O stretching vibration in molybdenum oxide.[4,5] Because of low infrared transmittance of the samples, IR spectra obtained by a conventional grating IR spectrophotometer were not able to be analyzed quantitatively. In the present work, the authors have studied the dehydrogenation process of hydrogen molybdenum bronzes by using a Fourier transform infrared spectrophotometer directly connected with a microcomputer systems and analyzed in detail how dehydrogenation influenced on changes in the structure and composition. This paper mainly deals with the behavior of the bands near 1000 cm^{-1} assigned to the Mo=O stretching vibration of the samples heated in vacuo.

Experimental

The preparation and identification of orthorhombic hydrogen molybdenum bronze, $H_{0.3}MoO_3$, were described previously.[2,3,6] Samples having various hydrogen contents (formulated as H_xMoO_y) were prepared by heating the bronze at various temperatures in vacuo and in air. The composition was determined by thermogravimetry[2] and by Choain and Marion's method.[7] The samples after heating were pressed into disks (ca. 0.5 wt% in KBr). All spectra were recorded in dry air by a Fourier transform infrared spectrophotometer (SHIMADZU, FTIR-4000: with 2 cm^{-1} resolution) directly connected with the microcomputer system (NEC, PC-9801 F2).

Results and Discussion

The hydrogen molybdenum bronze, $H_{0.3}MoO_3$, with the orthorhombic structure was decomposed to a nonstoichiometric compound with the rhombic MoO_3 structure as follows;[6]

$$H_{0.30}MoO_3 \rightarrow H_{0.21}MoO_{2.95} \rightarrow H_{0.06}MoO_{2.88} \rightarrow MoO_{2.85}.$$

This was confirmed to the dehydration process by mass spectrometry. Atomic hydrogens in samples reacted with lattice oxygens and the water was liberated. At the same time, vacancies were produced.

Figure 1 shows the FT-IR spectra of the samples heated in vacuo. The bands at 999, 650, 590, and 430 cm^{-1} of orthorhombic bronze, $H_{0.30}MoO_3$, are almost the same as those reported by Schroder and Weizel.[8] The intensities of the bands at 999, 650, and 430 cm^{-1} gradually reduced with the decrease in hydrogen content of the samples. On the other hand, new bands appeared in the region 900—800 cm^{-1} and the band at 590 cm^{-1} was intensified as dehydration process proceeded. Figure 1 also shows that the band at 999 cm^{-1} was split into two bands at 1004 and 990 cm^{-1} in the case of the samples with lower hydrogen contents than the lowest limit (x=0.21) of

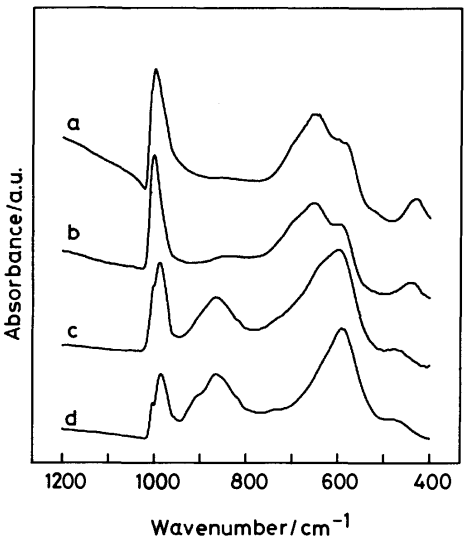

Fig. 1. FT-IR spectra of the samples, H_xMoO_y. a, $H_{0.30}MoO_3$; b, $H_{0.21}MoO_{2.95}$; c, $H_{0.080}MoO_{2.89}$; d, $MoO_{2.85}$.

the orthorhombic structure. This behavior could not be observed clearly by using the grating IR spectrophotometer. It is well-known that the bands near 1000 cm^{-1} can be assigned to the Mo=O stretching vibration in molybdenum oxide.[4,5] The results suggest that samples with lower hydrogen contents than x=0.21 give at least two kinds of the Mo=O stretching vibration. While in the case of the bronze heated in air, only the bands due to MoO_3 appeared at 993, 878, and 820 cm^{-1}, though a small amount of hydrogen remained. By thermogravimetry and mass spectrometry, atomic hydrogens inserted in the sample were removed easily as hydrogen molecules in this case. The samples gave immediately the rhombic MoO_3 structure. Therefore, the bands also appeared at the same frequencies with those of MoO_3.

In the previous work,[6] the authors observed the band at 1004 cm^{-1} due to the Mo=O stretching vibration of the orthorhombic bronze and the one at 998 cm^{-1} for the rhombic MoO_3. This suggests that the band shifts of Mo=O stretching vibration was caused by a structural change. As shown in Fig. 1, the band near 1000 cm^{-1} was at least composed of two peaks. Therefore, the band shape analysis has been carried out to obtain further information of the Mo=O bonds by a microcomputer system using the same techniques described previously.[9,10] Although there exists no theoretical justification for IR bands of solid to fit any specific functional form, the Gaussian form was applied.[9] One of the results in the region 1050—950 cm^{-1} is shown in Fig. 2. The band was confirmed to be overlapped by three bands with peaks at 1005, 990, and 972 cm^{-1}, although the original band has two peak maxima. The convoluted curve of these separated bands fits in well with the original spectrum. Thus all spectra of the samples gave three bands with the peaks at nearly the same frequencies in the region 1050—950 cm^{-1}. These results led to the conclusion that the band near 1000 cm^{-1} of each sample is composed of three kinds of Mo=O stretching vibration which shows the peaks at 1005, 990, and 972 cm^{-1}, respectively.

The intensity of each band calculated for unit weight of the samples in disks is plotted against the hydrogen content of the sample as shown in Fig. 3. From this result the intensity ratio of each band to the sum of three bands is calculated at the same hydrogen content as shown in Fig. 4. The value of 1005 cm^{-1} band decreases monotonously, while that of 990 cm^{-1} increases, as hydrogen content decreases. The intensity ratio of the band at 1005 cm^{-1} to that of the

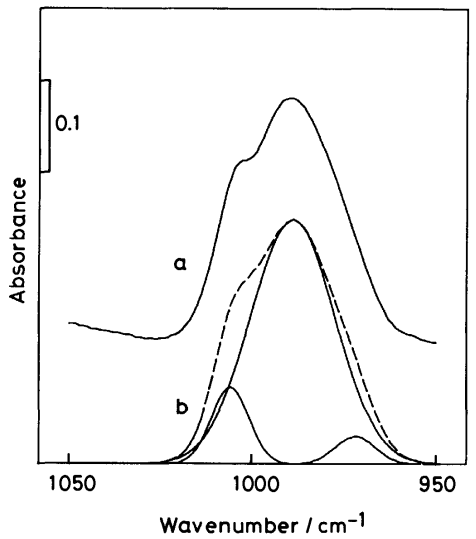

Fig. 2. An example of band shape analysis in the region 1050—950 cm^{-1} (sample: $H_{0.080}MoO_{2.89}$). a, original spectrum; b, separating peaks (——) and convoluted curve (----).

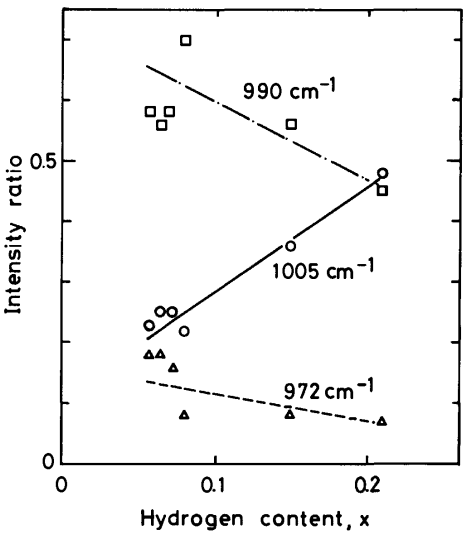

Fig. 4. Relationship between intensity ratio of each band to the sum of three bands and hydrogen content, x, of the samples; 1005 cm^{-1} (○), 990 cm^{-1} (□), 972 cm^{-1} (△).

band at 990 cm^{-1} is calculated from the values in Fig. 4. The ratio is 0.48/0.45=0.52/0.48 at x=0.21, 0.36/0.56=0.39/0.61 at x=0.15, and 0.22/0.70=0.24/0.76 at x=0.08, respectively. These values are in close agreement with the ratios of the orthorhombic to rhombic components obtained from the X-ray and thermogravimetric data.[6] Thus, it is concluded that the band at 1005 cm^{-1} is assigned to the Mo=O stretching vibration of the orthorhombic bronze formed by the insertion of hydrogen atom and that at 990 cm^{-1} is assigned to that of the oxide with rhombic MoO_3 structure. It is clear that existence of the atomic hydrogen induced the change of crystal structure which is strongly correlated with the mode of Mo=O bond as described previously (see Fig. 3 in Ref. 6). On the other hand, the ratio of band at 972 cm^{-1} is small in the whole region and gradually increased as the hydrogen content decreased. It is not sure that this band can be assigned to another kind of Mo=O stretching vibration of polymolybdate such as Mo_4O_{11}, Mo_9O_{26}, and so forth.

Irreversible Nature of the Stacked β-Pleated Sheets of a Model Polypeptide

Hiroshi MAEDA
Department of Chemistry, Faculty of Science, Nagoya University,
Chikusa-ku, Nagoya 464
(Received April 15, 1987)

Synopsis. A mode of association of β-sheets, most probably the stacking of the pleated sheets, has been studied by circular dichroism and light scattering on the 5×10^{-2} mol dm^{-3} NaCl solutions of poly(*S*-carboxymethyl-L-cysteine). It was found that the association is highly irreversible with respect to concentration change at constant pH. Relevance of the study of synthetic polypeptides is discussed in relation to the association mode found in proteins.

It has been frequently reported that aggregation of polypeptide chains takes place when the β-structure is formed.[1-10] Association of extended chains, observed on short chains,[2,11-14] couples with the formation of the β-structure. In this case, the β-content from circular dichroism (CD) parallels the aggregation number. In low ionic strength media, dissociation of β-aggregates occurs very slowly.[11,12,14] On addition of a salt, however, reversible association-dissociation takes place depending on the concentration of the salt.[12,13] Another well-defined association process was found recently,[15] in which the extent of aggregation incerases with concentration accompanied by a negligible change of the β-content, as indicated by a nearly constant residue ellipticity. An edge-to-edge association of the folded-chain-pleated sheets was suggested for this process,[15] mediated by hydrogen bonds between peptide groups of different chains. This edge-to-edge association of β-sheets has been proposed for the monomer-monomer interface within a dimer of concanavalin A.[16]

There are many facts concerning the aggregation of the β-structure of synthetic polypeptides which cannot be understood consistently in terms of these two types of association and their mixtures. Different lines of evidence have been accumulated for different polypeptides that a face-to-face association, or stacking, of the pleated sheets also occurs in addition to the above edge-to-edge association of pleated sheets. Various diagnostic means have been used for the detection of the stacking, including fluorescence (hydrophobic probe),[3,17-19] hydrodynamic properties,[6,7] potentiometric titration,[7,20,21] counterion activity,[20] and isodichroic point associated with the β-coil conversion.[10] Recently, it was indicated that increase of aggregation number is enormous when stacking occurs and hence this could be used as another diagnostic tool for the detection of the stacking.[15]

In the present study, circular dichroism (CD) and aggregation number by light scattering were measured on 5×10^{-2} M (mol dm^{-3}) NaCl solutions of different concentrations of poly(*S*-carboxymethyl-L-cysteine)-(poly[Cys(CH_2COOH)]) at a constant pH of 4.86±0.02 with special reference to the reversibility of the association. The aggregation is expected of face-to-face type according to the results from the above mentioned diagnostic means.

Experimental

The weight average molecular weight ($\bar{M}_w$) and degree of polymerization (DP_w) of the sample were 5.8×10^4 and 360, respectively. Light scattering was measured on a Chromatix low-angle light scattering photometer KMX-6 at room tmperature (24±2 °C). A value of 0.220 was used for the refractive index increment,[15] since it could not be measured at the pH used (4.86±0.02) due to the low solubility of the polypeptide in the β-structure. Apparent aggregation number m was evaluated at each concentration, assuming nonideal contribution to be negligible. CD spectra were taken on a Jasco J-40A Circular Dichrograph at 25±0.1 °C using cells of 0.5, 1, 2, 5, 10, and 20 mm light paths. Four to eight scans were accumulated. Measurements were made on the solutions about 24 hours after their preparation.

Results and Discussion

In Fig. 1, the concentration dependence of the apparent aggregation number m is shown on a double logarithmic plot. At the lowest polypeptide concentration C_p of about 1×10^{-4} residue M, aggregation already occurs for the chain of DP_w=360, which is consistent with the previous result on the

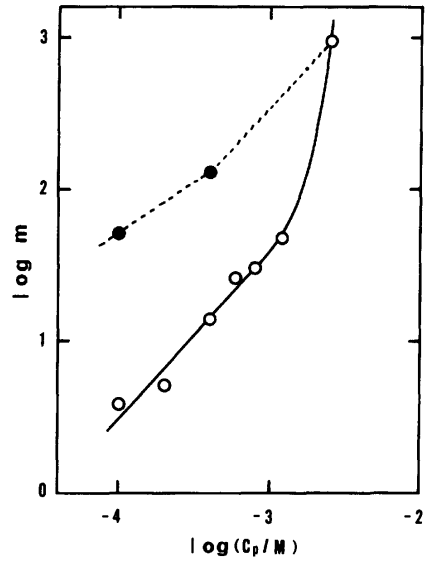

Fig. 1. Concentration dependence of apparent aggregation number m. Filled circles refer to solutions prepared by diluting the solution of the highest concentration.

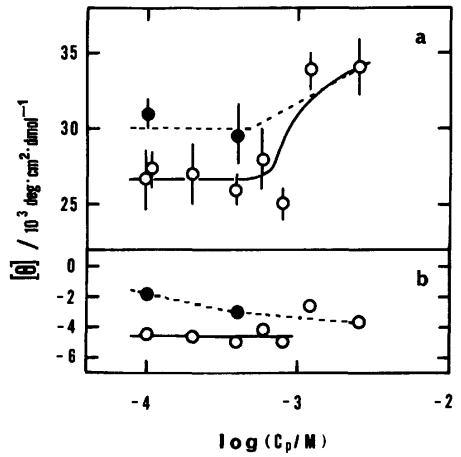

Fig. 2. Concentration dependence of residue ellipticities at 200 nm (a) and 218 nm (b). Filled circles refer to the solutions prepared by diluting the solution of the highest concentration.

same sample[15] but is in contrast with the previous result on a sample of DP_w=630 that approximately unassociated folded-chain β-structure exists at this concentration.[15] Upon increasing the concentration, the aggregation increases steadily. At C_p=2.48×10^{-3} M, however, the aggregation number increases enormously, suggesting that the stacking of pleated sheets occurs. Each solution corresponding to an open circle was prepared from each solution of the same concentration at neutral pH by the addition of HCl. At neutral pH, polypeptides were molecularly dispersed as random coils irrespective of the concentration.

In Fig. 2(a), the concentration dependence of the residue ellipticity at 200 nm, $[\theta]_{200}$, is given as a measure of the β-content. In a concentration range below about 1×10^{-3} M, $[\theta]_{200}$ remains nearly unchanged in spite of the increase of the aggregation number m. It is likely that edge-to-edge association of pleated sheets occurs in this concentration range, consistent with previous result.[15] When C_p exceeds about 1×10^{-3} M, $[\theta]_{200}$ increases sharply, which seems to correspond to the stacking process, although the correspondence between m and $[\theta]_{200}$ is not complete enough.

It has been shown that an isodichroic point around 218 nm, associated with the β-coil conversion of poly[Cys(CH_2COOH)], disappeared when the stacking of pleated sheets was expected to occur.[10] In Fig. 2(b), values of $[\theta]_{218}$ are plotted against log C_p. The presence of an isodichroic point around 218 nm is suggested in the concentration range lower than about 1×10^{-3} M. Disappearance of the isodichroic point is clear at C_p=1.2×10^{-3} M.

Two solutions were prepared by diluting the solution at C_p=2.48×10^{-3} M. The results on these two solutions are indicated by filled circles in Figs. 1 and 2. In Fig. 1, aggregation numbers found on these solutions are greater by nearly an order of magnitude than those found on the corresponding solutions of the same concentration prepared by the addition of HCl to the solution of neutral pH. On dilution, values of $[\theta]_{200}$ decrease but remain significantly greater than those of the solutions containing negligible amount of stacked aggregates. The observed slight decrease of $[\theta]_{200}$ may indicate the dissociation of either a small amount of stacked aggregates or unstacked portion of aggregates. A clearer indication of irreversible change at $[\theta]_{200}$ than shown here was reported previously. (Figure 5 of Ref. 11). Disappearance of the isodichroic point is clearly indicated for the solutions prepared by dilution. Therefore, dissociation of stacked aggregates by dilution is largely inhibited even in the presence of excess salt in the present case.

It is to be stated that essentially identical behavior to that is shown in Figs. 1 and 2 was obtained in three independent sets of experiments. However, all these results could not be put together into a single figure, since residue ellipticities differed appreciably for different sets due to slight differences in pH (smaller than 0.04) among them.

In conclusion, a mode of association which most likely corresponds to face-to-face association, or stacking, of pleated sheets is shown to be irreversible in the present study. It is to be noted that the (assumed) stacked aggregates can be easily dissociated by charging the side chains, i.e., by raising pH in the present case.

It is pertinent to ask whether this face-to-face association of β-sheets occurs in proteins. A good counterpart is found in the dimer of Streptomyces subtilisin inhibitor (SSI), which has been indicated to be formed by the stacking of two β-sheets belonging to each subunit.[22] Consistent with the present result, dimeric SSI does not dissociate into monomer on dilution, showing strong adhesive interaction.[23] The dissociation rate constant was obtained recently by clever means.[24]

The auther thank Mr. Kohei Kadono for his help in some CD measurements.

(Received January 7, 1987)

Synopsis. The crystal and molecular structures of the titled scandium(III) (**1**) and yttrium(III) chloroacetates (**2**) were determined by the single-crystal X-ray diffraction method. **1** is monoclinic, with the space group $P2_1/n$, a=12.148(4), b=8.860(5), c=11.028(4) Å, and β=103.31(3)°. In **1**, the metal atom has the hexa-coordinated octahedral geometry, and any pair of the neighboring metal atoms are bridged by three bidentate carboxylate ions, forming an infinite chain. **2** is isomorphous with the heavy lanthanoid salts, $[Ln_3(ClCH_2CO_2)_9(H_2O)_4]_n \cdot nH_2O$ (Ln=Gd—Yb), and its crystal structure closely resembles that of the erbium(III) complex.

We have previously reported on the complicated structures of the series of light and heavy lanthanoid-(III) chloroacetates.[1,2] Although it is well-known that the properties of the scandium(III) and yttrium(III) complexes resemble those of the lanthanoids(III)[3,4] there are not much structural data about their carboxylates; moreover, the data regarding complexes synthesized under the same conditions as those for the corresponding lanthanoid complexes are rare.

The structural data of scandium(III) formate is the sole example;[5] its metal atoms are in the hexa-coordinated octahedral geometry, and are bridged by the anions forming a two-dimensional polymeric form. Therefore, it is desirable to obtain more structural data concerning the scandium complexes in order to clarify whether their coordination numbers are always six or not, and to determine its polymeric form.

The yttrium(III) formate dihydrate[6,7] and yttrium-(III) acetate tetrahydrate[8] are known to be isomorphous with the corresponding heavy lanthanoid salts.[6,9,10,11] If the yttrium and heavy lanthanoids always give complexes isomorphous with each other, the high coordination number and the complicated bridging found in the lanthanoid complexes should not be due to the 4f-orbitals of the latters.

Therefore, we have synthesized the scandium(III) and yttrium(III) chloroacetates, $Sc(ClCH_2CO_2)_3$ (**1**) and $[Y_3(ClCH_2CO_2)_3(H_2O)_4]_n \cdot nH_2O$ (**2**), under synthetic conditions almost the same as that for the lanthanoid salts.

Experimental

Syntheses of the Scandium(III) and Yttrium(III) Chloroacetates. Scandium(III) hydroxide (obtained from 0.193 g (1.0 mmol) of Sc_2O_3) was dissolved into an aqueous solution of chloroacetic acid (0.59 g (6.2 mmol) into 10 cm^3 of water). The solution was filtered off, left standing in a silica-gel desiccator for several days until 2/3 of the water was evaporated off; crystals of **1** were deposited. Yield: 0.33 g (51%). The yttrium salt, **2**, was obtained almost in the same way starting from 0.229 g (1.0 mmol) of Y_2O_3 and chloroacetic acid (0.59 g, 6.2 mmol). Yield, 0.61 g (75%). Found; Sc, 13.77; C, 22.11; H, 1.58%; Calcd for $ScC_6H_6O_6Cl_3$, Sc, 13.81; C, 22.15; H, 1.86%. Found; Y, 22.15; C, 17.50; H, 2.31%; Calcd for $Y_3C_{18}H_{28}O_{23}Cl_9$; Y, 22.26; C, 18.04; H, 2.36%.

X-Ray Structure Analysis. Crystallographic data and some experimental conditions for obtaining their intensities are tabulated in Table 1. The intensities were collected on a Rigaku AFC-6A automated 4-circle X-ray diffractometer with graphite monochromated Mo $K\alpha$ radiation, a ω—2θ scan technique being employed (the scan speed was 4° min^{-1} (θ)).

The structure of the scandium complex was solved by the heavy-atom method. In the case of the yttrium salt, the structure was solved starting with the final parameters of the erbium complex, $[Er_3(ClCH_2CO_2)_9(H_2O)_4]_n \cdot nH_2O$,[2] and were refined as usual.

In both cases, all the hydrogen atoms were fixed at the calculated positions (C-H=1.08 Å), B_{iso}=8.00 $Å^2$ being given.

All the calculations were carried out on a HITAC M-682H

Results and Discussion

The final parameters and their equivalent thermal parameters of **1** are listed in Table 2.[14]

In **1**, the metal atom has an octahedral coordination by six oxygen atoms of six different anions (Fig. 1); the octahedral geometry is not much deformed.[15] The mean Sc–O distance is 2.075 Å (Table 3), not far from the sum of the Shannon's ionic radii of Sc and O, 2.10 Å.[16] The metal atoms are laid along the b-axis in a zig-zag way, and any pair of side-by-side metal atoms are bridged by three carboxylate ions, where all carboxylate ions act as *Z,Z*-type bidentate (Fig. 2).[17] Such a type of the triple carboxylate ion bridging is rarely found, even in any other metal complexes. The three oxygen atoms (O(**11**), O(**21**), and O(31)) of the respective three carboxylate ions bridging to the one side next metal atom are in an *fac*-configuration (Fig. 1). The carboxylato carbon and oxygen atoms (C(**n1**), O(**n1**), and O(**n2**)) of each carboxylato bridge, together with the metal atoms Sc and Sc^{ii},[18] are approximately on each plane. The average deviations of the atoms from the respective planes are: **11**, 0.065; **21**, 0.131; and **31**, 0.027 Å. The dihedral angles between them are: **11**—**21**, 114.2; **11**—**31**, 56.7; **21**—**31**, 57.5°.[19] Although all of the bridging ions are approximately the *Z,Z*-type, angles C(**11**)-O(12)-Sc^{ii} (164.1(5)°) and C(31)-O(31)-Sc (171.6(7)°) are larger than, and C(**11**)-O(**11**)-Sc (133.8(5)°) and C(31)-O(32)-Sc^{ii} (131.8(6)°) are smaller than the standard value (145—150°) of the type of bridge[14,17] On the other hand, although ion **21** has almost a normal C–O–Sc angle, the planarity of the Sc-O-C-O-Sc^{ii} plane is not good. Relatively short Sc-O(12^{i}) and Sc-O(31) bonds are found where

Key to the symmetry operations: i, $-x$, $-y$, $-z$; ii, $1-x$, $1-y$, $1-z$.

the C-O-Sc angles of the oxygen atoms are large.[18,19] Therefore, in the case of the chloroacetate, scandium makes a polymeric complex like the heavier IIIA elements; however, its coordination number is six, not so high as yttrium and the lanthanoids. This fact is probably due to its small ionic radius.

The structure of **2** is isomorphous with heavy lanthanoid salts, $[Ln_3(ClCH_2CO_2)_9(H_2O)_4]_n \cdot nH_2O$, (Ln=Gd—Yb).[2] The Shannon's ionic radius of the yttrium ion resemble those of holmium and erbium.[16] The bond lengths and angles of the yttrium salt (Table 4) are not so much different from the corresponding values of the latter salts.[2] The average of the 25 Y-O bond lengths of **2** is 0.012 Å longer than that of the Er-O bonds of the erbium complex,[2] reflecting a longer ionic radius, Y(1.019 Å), than that of Er(1.004 Å) (where the valence of the metal atoms is 3+, and the coordination number is 8).[16]

Therefore, we deduce from these results that both yttrium and the lanthanoids form the same complicated polimeric-type carboxylate complexes; 4f electrons are not greatly related with the characteristic structures.

In the infrared spectrum of **1**, the ν_{as}(COO) and ν_s(COO) bands appear as singlets at 1565 and 1442 cm^{-1}, and do not split as those of the lanthanoid salts. These peaks probably correspond with bands of the *Z,Z*-type bridging carboxylate ion.[17] The general feature as well as the wavenumbers of the ν_{as}(COO) and ν_s(COO) bands of **2**(which appear at 1662, 1627, 1595, 1572 (strongest); and 1442 and 1399 cm^{-1}, respectively) are approximately similar to those of the erbium salt.[2]

The authors wish to thank the Shin-Etsu Chemical Ind. Co., Ltd., for presenting us with the highly pure lanthanoid oxides.

Solid-Phase Thermal Reactions of Chromium(III) and Copper(II) Complexes Containing Pentadentate Ethylenediaminetetraacetate and 1,2-Propanediaminetetraacetate Ions

Goutam De, Masatatsu Suzuki, and Akira Uehara*
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920
(Received March 5, 1987)

Synopsis. Thermal reactions of the solid complexes [Cr{Hedta or (*RS*)-Hpdta}(H_2O)] and [Cu{H_2edta or (*RS*)-H_2pdta(H_2O)] were investigated under quasi-isothermal and -isobaric conditions (Q-conditions) and under open dynamic conditions (D-conditions), where Hedta and H_2edta, and Hpdta and H_2pdta denote mono- and diprotonated ethylenediaminetetraacetate and 1,2-propanediaminetetraacetate ions, respectively.

We previously reported the thermal deaquation of the chromium(III) complex [Cr{Hedta or (*RS*)-Hpdta}(H_2O)][1] and thermal dehydrohalogenation of the cobalt(III) complex Na[CoX{Hedta or (*RS*)-Hpdta}] (X=Cl or Br) under D-conditions, where Hedta and Hpdta are monoprotonated ethylenediaminetetraacetate and 1,2-propanediaminetetraacetate ions, respectively.[2] In the latter case, pentadentate edta or pdta changed to hexadentate ligand after dehydrohalogenation, but in the former case we failed to isolate hexadentate edta and pdta chromium(III) complexes by deaquation because the reaction was accompanied by a subsequent decomposition. Quasi-isothermal and -isobaric conditions (Q-conditions) are fundamentally different from D-conditions.[3] The present study was therefore undertaken to investigate the thermal reactions of [Cr{Hedta or (*RS*)-Hpdta}-(H_2O)]·nH_2O (n is 0 for the Hedta and 1 for the Hpdta complexes) under Q-conditions. Thermal reactions of [Cu{(*RS*)-H_2pdta}(H_2O)]·1/2H_2O and their optical antipodes are not yet known. The optical pairs $(+)_D$- and $(-)_D$-[Cu{(*S*)- and (*R*)-H_2pdta}]·1/2H_2O were newly prepared in this study, of which thermal reactions were also investigated.

Experimental

Preparation of Complexes. [Cr(Hedta)(H_2O)] (**1**),[4] [Cr{(*RS*)-Hpdta}(H_2O)]·H_2O (**2**),[4] [Cu(H_2edta)(H_2O)] (**3**),[5] and [Cu(*RS*)-H_2pdta(H_2O)]·1/2H_2O (**4**)[6] were prepared according to the respective methods of literatures.

$(+)_D$-[Cu{(*S*)-H_2pdta}]·1/2H_2O (**5**) was prepared from $(-)_D$-Ba[Cu{(*S*)-pdta}(H_2O)]·2H_2O.[6] The barium salt (2.78 g) in hot water (45 cm^3) was treated with exactly one equivalent of sulfuric acid (10 cm^3, 0.5 mol dm^{-3}), and the mixture was heated to boiling. The $BaSO_4$ thus formed was removed by filtration, the filtrate was evaporated to 10 cm^3 and cooled in refrigerator. The light blue colored compound was collected by filtration and washed with ethanol and then ether. Found: C, 34.94; H, 4.53; N, 7.60%. Calcd for $C_{11}H_{17}N_2O_{8.5}Cu$: C, 35.05; H, 4.51; N, 7.43%.

$(-)_D$-[Cu{(*R*)-H_2pdta}]·1/2H_2O (**6**) was prepared by the same method as that described for complex **5** except that $(+)_D$-Ba[Cu{(*R*)-pdta}(H_2O)]·2H_2O was used as the starting material. Found: C, 34.86; H, 4.40; N, 7.10%. Calcd for $C_{11}H_{17}N_2O_{8.5}Cu$: C, 35.05; H, 4.51; N, 7.43%.

Thermal Measurements. The thermal reactions of the complexes were carried out under Q-conditions and D-conditions by using Q-derivatograph[3,7] and a Seiko SSC/580 TG/DTA-30 thermal analyzer, respectively. The measurements under D-conditions were carried out under a constant flow of nitrogen at the heating rate of 2 °C min^{-1}.

Spectral Measurements. The electronic spectra of the samples in aqueous solution were monitored on a Jasco UVIDEC-505 UV/VIS recording digital spectrophotometer, and those in powder state on a Hitachi EPU-2A spectrophotometer equipped with a standard Hitachi reflection attachment (Type R-3). IR spectra of the samples were measured by a KBr-disk method with a Jasco A-3 infrared spectrophotometer.

Specific Rotation Measurement. All rotations were measured in 1 dm tube in aqueous solution at 15 °C by a Jasco DIP—181 digital polarimeter. An 18.0 mg sample in 10 cm^3 of water was used for each measurement.

Results and Discussion

Figure 1 shows the TG curves of complexes **1** and **2** measured under Q-conditions. The TG curve of [Cr(Hedta)(H_2O)] (**1**) is essentially similar to that of D-derivatogram reported earlier[1] except that the deaquation temperature under Q-conditions is higher (302 °C) than that under D-conditions (280 °C), and it suggests a slim possibility of synthesizing the deaquated hexadentate complex H[Cr(edta)]. Thermal behavior of [Cr{(*RS*)-Hpdta}(H_2O)]·H_2O (**2**) under Q-conditions is different from that under D-conditions. Under Q-conditions, the complex starts to lose water molecule slowly at 171 °C, then a sharp mass loss can be seen at 235—247 °C and a clear plateau is obtained. The weight loss (9.0%) is close to that (9.2%) calculated for 2 mol of water. The product isolated at 250 °C under Q-conditions is pure H[Cr{(*RS*)-pdta}], where pdta functions as hexadent-

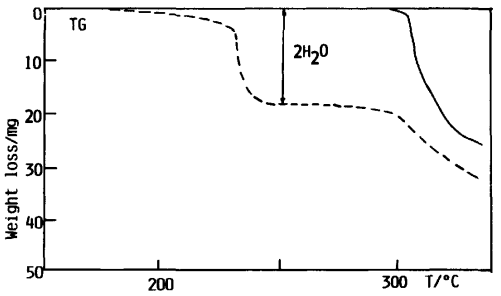

Fig. 1. Q-Derivatoggrams of [Cr(Hedta)(H_2O)] (**1**) (——) and [Cr{(*RS*)-Hpdta}(H_2O)]·H_2O (**2**) (----). Sample weight: **1**, 205 mg; **2**, 210 mg.

ate ligand. It is interesting to note that the lattice and coordinated waters are evolved simultaneously. The complex before heating shows two IR bands at 1738 and 1610 cm^{-1} which are due to free -COOH and coordinated $-COO^-$ groups, respectively. The product, however, does not give the band due to free -COOH group. It is thus clear that the non-coordinated -COOH group comes into coordination toward chromium(III) ion after the elimination of the coordinated water molecule.

The crystal structure of $[Cu(H_2edta)(H_2O)]$ (**3**) is known.[8] The potentially hexadentate edta ligand acts as pentadentate with a water molecule taking up the sixth position, giving rise to a six-coordinated environment about copper(II) ion. The IR (in the carbonyl region) and electronic reflectance spectra of complex **3** and $[Cu\{(RS)\text{-}H_2pdta\}(H_2O)]\cdot 1/2H_2O$ (**4**) are essentially similar to each other. These results suggest that the stereochemistry around the copper(II) ion in complex **4** must be the same as that of complex **3**.

Figure 2 shows the TG and DTA curves (D-conditions) and TG curve of complex **4** under Q-conditions. Under D-conditions, the complex loses its lattice water (Found: 2.23%, Calcd: 2.28%) and coordinated water (Found: 4.57%; Calcd: 4.56%) in the temperature range of 75—90 °C and 150—175 °C respectively, and then a clear plateau is obtained. The corresponding DTA curve shows initially an endothermic peak due to the elimination of lattice water then two overlapping endothermic peaks for the evolution of coordinated water molecule. The elimination of the coordinated water takes place in two steps, but details thereof are still unknown.

$$\underset{\text{light blue}}{[Cu\{(RS)\text{-}H_2pdta\}(H_2O)]\cdot 1/2H_2O} \xrightarrow[\Delta]{-1/2H_2O}$$

$$\underset{\text{light greenish blue}}{[Cu\{(RS)\text{-}H_2pdta\}(H_2O)]} \xrightarrow[\Delta]{-H_2O} \underset{\text{deep blue}}{[Cu\{(RS)\text{-}H_2pdta\}]}$$

The IR spectrum of complex **4** shows a medium strong band at 1740 cm^{-1} due to free -COOH group and a very strong broad peak at 1590 cm^{-1} due to coordinated COO^- group. As the dehydrated complex has a tendency to absorb water molecule, the IR spectrum of **4** has been recorded at 125 and 190 °C in nitrogen atmosphere. The peak due to free -COOH group was always observed. This suggests that the non-coordinated -COOH group remains free even after the elimination of the coordinated water molecule, and pdta still functions as pentadentate ligand. Consequently, Cu^{II} ion is penta-coordinated in the dehydrated complex. The solid state reflectance spectra (350—850 nm) of complex **4** and its dehydrated form show bands at about 740 and about 710 nm. The shifting of the absorption band toward the shorter wavelength region also suggests the formation of penta-coordinated Cu^{II} complex.[9] The dehydrated complex may be either trigonal bipyramidal or square pyramidal in structure, but the decision could not be made.

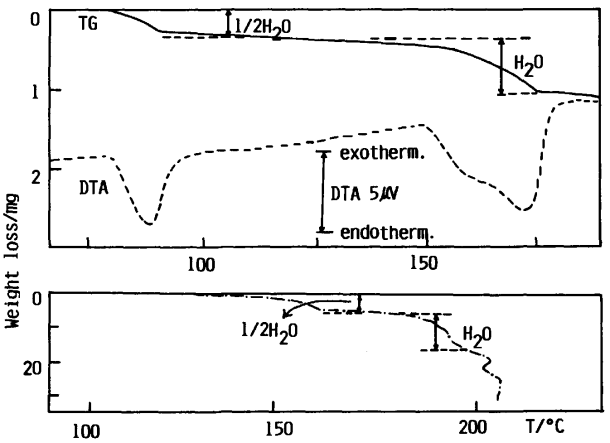

Fig. 2. TG (——) and DTA (----) curves (D-conditions), and TG (—·—) curve (Q-conditions) of $[Cu\{(RS)\text{-}H_2pdta\}(H_2O)]\cdot 1/2H_2O$ (**4**). Sample weight: for TG-DTA (D-conditions), 15.6 mg; for TG (Q-conditions), 199 mg.

Under Q-conditions, the thermal reaction of complex **4** is unusual. The complex evolves its lattice water in the temperature range of 124—163 °C, and above 163 °C evolution of coordinated water molecule takes place upto 195 °C. The product isolated in this stage is violet in color. The product shows a broad absorption band at 561 nm and its analytical composition nicely fits with $[Cu(H_2pdta)]$ (Found: C, 35.10; H, 4.39; N, 7.46%. Calcd for $C_{11}H_{16}N_2O_8Cu$: C, 35.19; H, 4.35; N, 7.61%). The IR spectrum of the product shows two peaks of comparable intensity at 1733 and 1718 cm^{-1} due to free -COOH group and a broad peak at 1610 cm^{-1} due to coordinated carboxylato groups. The two peaks at 1733 and 1718 cm^{-1} indicate the presence of two free -COOH groups in the product.[10] From the spectral and analytical data, it is conceivable that pdta functions as tetradentate ligand toward Cu^{II} ion.

We attempted to get a pair of optical antipodes of complex **4** from $(-)_D$-$Ba[Cu\{(S)\text{-pdta}\}(H_2O)]\cdot 2H_2O$ ($[\alpha]_D$: −126°) and $(+)_D$-$Ba[Cu\{(R)\text{-pdta}\}(H_2O)]\cdot 2H_2O$ ($[\alpha]_D$: +128°)[6]. However, complexes **5** and **6** were always isolated which do not contain any coordinated water molecule. The specific rotations of complexes **5** and **6** are $[\alpha]_D$=+136.4° and −133.7°, respectively. It is interesting to note that pure complexes **5** and **6** can be obtained from the respective barium complexes. Appearance of a medium strong band at 1738 cm^{-1} in the IR spectra of complexes **5** and **6** does not support the full coordination of pdta. Therefore, Cu^{II} ion is probably pentacoordinated in the isomers. The electronic spectra of complex **6** in water and in the solid state (reflectance) were not identical, suggesting that the structure in water is different from that in the solid state. The electronic spectra of the racemic complex **4** and optical pairs **5** and **6** in water were identical. Thus, in water the optical pairs possess similar structure to that of the racemic complex **4**.

TGA runs of the optical isomers (under both Q- and D-conditions) show that dehydration occurs soom

after heating is begun (30—35 °C). Anhydrous weight levels are attained at 140—190 °C (amounting to 2.4% of the total weight). As the temperature is raised further, there is a slow loss of weight resulting from the decomposition of the complexes. The dehydrated complexes **5** and **6** show $[\alpha]_D$=+138.3° and −137.3°, respectively. The increase of rotations are due to the loss of molecular weight resulting from the elimination of lattice water.

One (G. De) of the authors is indebted to the Japan Society for the Promotion of Science (JSPS) for awarding him a Long Term JSPS Research Fellowship for the 1986 fiscal year.

Syntheses of New Multi-Sulfur 1,2-Dithiolene Complexes. Ni- and Pd-Complexes of 1,4-Dithiin-2,3-dithiolate

Tadashi NAKAMURA, Takashi NOGAMI,* and Yasuhiko SHIROTA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565
(Received March 13, 1987)

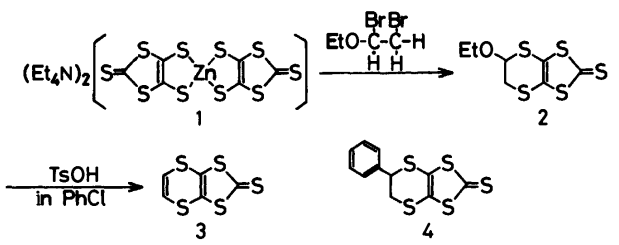
Synopsis. The title dithiolene complexes possessing eight sulfur atoms were synthesized. They are expected to give highly conductive organic salts. The improved synthesis of 4,5-(vinylenedithio)-1,3-dithiole-2-thione is also reported.

Studies on highly conductive organic materials have progressed greatly since the discovery of the low-dimensional metallic behavior of TTF·TCNQ.[1] The one-dimensional metallic system is susceptible to a metal-insulator transition due to Peierls distortion. Therefore, increase in the dimensionality was pursued. One of the most successful results along this line was achieved for BEDT-TTF salts,[2] which have a sulfur-sulfur network in the solid and exhibit two-dimensional electrical properties. BEDT-TTF salts possessing trihalide anions were found to be organic superconductors without applying pressure.[3] TTF-[Ni(dmit)$_2$]$_2$ was found to be a new type of organic superconductor last year.[4] Cassoux et al. postulated that this material has a three-dimensional property due to the sulfur-sulfur network in the solid.[4] Multi-sulfur 1,2-dithiolene complexes like M(dmit)$_2$ salts[5] have been postulated as promising candidates for highly conductive organic materials.[6] However, reports on the syntheses of such complexes are surprisingly few, and have appeared in recent years.[7] We have synthesized a new type of multi-sulfur dithiolene complexes (Ni- and Pd-complexes of 1,4-dithiin-2,3-dithiolate), which are also expected to give highly conductive organic complexes. The improved synthesis of 4,5-(vinylenedithio)-1,3-dithiole-2-thione, which is a starting material for the above new complexes, is also reported.

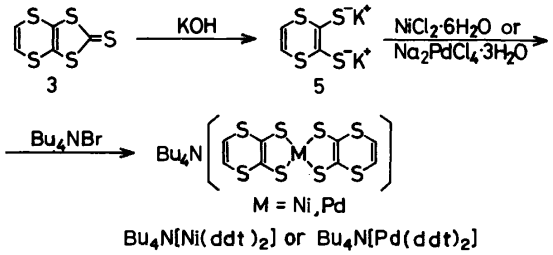
Results and Discussion

Improved Synthesis of 4,5-(Vinylenedithio)-1,3-dithiole-2-thione. 4,5-(Vinylenedithio)-1,3-dithiole-2-thione (**3**) was synthesized as a precursor to bis(vinylenedithio)tetrathiafulvalene (VT).[8] We have now found an improved synthetic method for **3**, and it is shown in Scheme 1. $(Et_4N)_2[Zn(dmit)_2]$ (**1**) was reacted with 1,2-dibromoethyl ethyl ether in acetone at room temperature, and 4,5-(ethoxyethylenedithio)-1,3-dithiole-2-thione (**2**) was obtained. Elimination of ethanol from **2** was achieved by heating the chlorobenzene solution of **2** with anhydrous *p*-toluenesulfonic acid (TsOH) to afford **3**. The currently accepted method[8] has the following drawbacks; (1) it requires expensive 1,2-dichloroethyl ethyl ether in the first step of the reaction; (2) 4,5-(phenylethylenedithio)-1,3-dithiole-2-thione (**4**) was found as a by-product in the second step of the reaction. It was produced by an electrophilic attack of the intermediate carbenium ion (resulting from the elimination of ethanol from **2**) to benzene (solvent).[9] The first drawback was overcome by using 1,2-dibromoethyl ethyl ether which can easily be synthesized on a large scale.[10] The reaction time was shortened from 24 h for the previous method to 10 h for the present method. Moreover, the reaction can be conducted at room temperature, whereas the previous method requires refluxing conditions. The second drawback was overcome by using chlorobenzene as a solvent. The reaction time was also shortened from 24 h for the previous method to 1.5 h for the present method, and the yield of **3** was improved from 23.7% to 32% owing to the absence of the side reaction. This is because the electrophilic attack of the carbenium ion[9] on chlorobenzene is suppressed as a result of the presence of the electron-withdrawing chloride group. Purification of **2** and **3** in the present method was simpler than that of the previous method. Thus, the method shown in Scheme 1 should also be used for the synthesis of VT.

Syntheses of Ni- and Pd-Complexes of 1,4-Dithiin-2,3-dithiolate. The synthetic route of Ni- and Pd-complexes of 1,4-dithiin-2,3-dithiolate is shown in Scheme 2. 4,5-(Vinylenedithio)-1,3-dithiole-2-thione (**3**) was reacted with KOH in ethanol to give a potassium salt (**5**) The salt was then reacted with $NiCl_2 \cdot 6H_2O$ or $Na_2PdCl_4 \cdot 3H_2O$; the product was oxidized by air, and subsequently reacted with

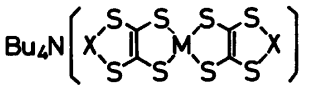


Scheme 1.



Scheme 2.

Table 1. Electrochemical Data for $Bu_4N[Ni(ddt)_2]$ and $Bu_4N[Pd(ddt)_2]$, Together with Those of the 1,2-Dithiolene Complexes Reported



Complex	M	X	E_1 V vs. SCE	E_2 V vs. SCE	$\Delta E(E_1-E_2)$ V
$Ni(ddt)_2$	Ni	-CH=CH-	0.06	−0.51	0.57
$Pd(ddt)_2$	Pd	-CH=CH-	0.11	−0.37	0.43
a	Ni	$-CH_2CH_2-$	0.06	−0.69	0.75
b	Ni	$-CH_2CH_2CH_2-$	0.16	−0.71	0.87
c	Ni	$-CH_2SCH_2-$	0.28	−0.59	0.87
$Ni(dmit)_2$	Ni	C=S	0.22	−0.13	0.35
$Pt(dmit)_2$	Pt	C=S	0.19	−0.13	0.32

tetrabutylammonium bromide to give the new multi-sulfur dithiolene complexes ($Bu_4N[Ni(ddt)_2]$, $Bu_4N[Pd(ddt)_2]$). Here, the ligand portion (1,4-dithiin-2,3-dithiolate) is abbreviated as ddt as shown in Scheme 2. The synthetic approach to $Bu_4N[Pt(ddt)_2]$ by using K_2PtCl_4[7] was unsuccessful. The redox potentials of the dithiolene complexes obtained by the cyclic voltammograms vs. SCE in acetonitrile are shown in Table 1, together with those of the other multi-sulfur 1,2-dithiolene complexes reported[7] for the sake of comparison. The redox waves in the negative potential range were reversible. However, those in the positive potential range were irreversible. In spite of this, E_1 and E_2 of the present complexes were defined as the middle points between the redox peak potentials. The $\Delta E(=E_1-E_2)$ values of the present complexes are 0.43—0.57 V, while those for **a**—**c**, and $M(dmit)_2$ complexes in Table 1 are 0.75—0.87 V and 0.32—0.35 V respectively. This suggests that in the case of the present complexes the intermolecular Coulomb repulsion energy in the conducting state lies between that of $M(dmit)_2$ complexes and other 1,2-dithiolene complexes **a**—**c**.[11]

Experimental

4,5-(Ethoxyethylenedithio)-1,3-dithiole-2-thione (2). To the acetone solution (1.8 L) of $(Et_4N)_2[Zn(dmit)_2]$ (**1**) (25 g) was added dropwise an acetone solution (200 cm³) of 1,2-dibromoethyl ethyl ether (17 g) for a 6-h period with stirring at room temperature, and the mixture was stirred for another 4 h. The orange powder was filtered off, and the solvent removed to obtain an orange solid. It was extracted with benzene, washed with aqueous sodium hydrogencarbonate, and then with water. After drying over Na_2SO_4, the benzene was evaporated, and the residue recrystallized from a mixed solvent of hexane and chloroform (1 : 1) to give **2** (51% yield based on **1**). Its ^1H NMR, mass spectrum, and melting point were identical to those reported previously.[8] Elemental analyses gave satisfactory results.

4,5-(Vinylenedithio)-1,3-dithiole-2-thione (3). The reaction was conducted under nitrogen atmosphere. *p*-Toluenesulfonic acid monohydrate ($TsOH\cdot H_2O$, 7.09 g) was added to a mixed solvent of chlorobenzene (100 cm³) and benzene (100 cm³). Water in the solution was eliminated by azeotropic distillation of benzene. The above solution was heated to 120 °C and chlorobenzene solution (200 cm³) of **2** (5 g) was added. The mixture was stirred for 1.5 h at 110 °C. After filtering off TsOH, the filtrate was washed with aqueous sodium hydrogencarbonate, and then with water. After drying over Na_2SO_4, the solvent was distilled under vacuum. The black solid was chromatographed on silica gel using hexane and chloroform (4:1) as eluent, and the first reddish yellow fraction gave **3** (32% yield). Its ^1HNMR, mass spectrum, and melting point were identical to those reported previously.[8] Elemental analyses gave satisfactory results.

Preparation of Complexes. $Bu_4N[Ni(ddt)_2]$. An ethanol solution (20 cm³) of **3** (1 g) and KOH (2 g) was stirred at 40—45 °C for 2 h under nitrogen atmosphere. The potassium salt **5** precipitated was collected in a hurry, washed with ethanol under nitrogen atmosphere, and dried in vacuum. It was then dissolved in methanol (10 cm³), and a methanol solution (20 cm³) of $NiCl_2\cdot 6H_2O$ (0.4 g) was added. The solution was stirred for 2 h at room temperature under a nitrogen atmosphere. After air-bubbling for 15 min, tetrabutylammonium bromide (2 g) was added to the solution. The dark purple precipitate was collected, washed with methanol, dissolved into acetone (65 cm³), and the solution filtered. To the filtrate was added isopropyl alcohol (65 cm³), the solution was concentrated by rotary evaporator, and $Bu_4N[Ni(ddt)_2]$ was crystallized out. It was collected, washed with methanol and diethyl ether, and dried in vacuum (0.45 g, 73% yield). 135 °C (decomp). Found: C, 43.42; H, 6.08; N, 2.02; S, 38.92%. Calcd for $C_{24}H_{40}NNiS_8$: C, 43.82; H, 6.13; N, 2.13; S, 38.99%. $\lambda_{max}^{CH_3CN}$ ($\log\varepsilon$): 252 nm (4.42); 316 nm (4.40); 564 nm (3.11).

$Bu_4N[Pd(ddt)_2]$. Using $Na_2PdCl_4\cdot 3H_2O$ (0.6 g) instead of $NiCl_2\cdot 6H_2O$ in the above reaction, $Bu_4N[Pd(ddt)_2]$ was obtained as black needles (32% yield). 133 °C (decomp). Found: C, 40.30; H, 5.72; N, 1.86; S, 35.88%. Calcd for $C_{24}H_{40}NPdS_8$: C, 40.86; H, 5.72; N, 1.99; S, 36.33%. $\lambda_{max}^{CH_3CN}$ ($\log\varepsilon$): 258 nm (4.57); 289 nm (4.55); 549 nm (3.16).

(Received February 17, 1987)

Synopsis. The diastereoselective alkylation of chiral diamides derived from chiral piperazines afforded optically active alcohols and acids in moderate enantiomeric excesses (up to 68% e.e.).

The diastereoselective alkylation of enolates derived from chiral amides is an important method for the synthesis of chiral acids.[1] However, in these reactions one mole is the maximum quantity of the product that can be obtained from one mole of the chiral auxiliary.

In this paper, we report a diastereoselective alkylation of chiral diamides derived from chiral piperazines. In the present system, one mole of chiral diamide affords (in principle) two moles of the product. Chiral 2,5-disubstituted piperazines(**2a,b**)[2] were synthesized by a reduction of the corresponding 2,5-piperazinediones(**1a,b**)[3] with sodium borohydride-titanium tetrachloride[4] (Scheme 1). Chiral diamides(**3a—c**) were obtained in good yields from **2a,b** by the *N*-acylation using the corresponding acid chloride and triethylamine.

The diamides(**3a—c**) were deprotonated and treated with various alkyl halides. The reduction of the alkylated diamides(**4a—c**) with lithium hydrotriethylborate($LiBHEt_3$) removed the chiral auxiliary to afford the corresponding optically active 2-substituted alcohols(**5a,b**). Results are shown in Table 1.

Lithium enolate was formed from **3a** by lithium diisopropylamide (LDA), and was alkylated with methyl iodide. The reductive removal of the chiral auxiliary afforded (*S*)-2-methyl-3-phenyl-1-propanol (**5a**, S:R=71:29) (Entry 1). In diastereoselective alkylation, additives to the enolates had a considerable effect on the degree of diastereoselectivity and the sense of the asymmetric induction. Diastereoselectivities increased in the presence of hexamethylphosphoric triamide(HMPA). Thus, (*S*)-**5a** (S:R=81:19) was obtained from the methylation of lithium enolate of **3a** in the presence of HMPA (LDA:HMPA=1:1) (Entry 3). Butylation under the same conditions showed better diastereoselectivity, and (*S*)-2-benzylhexanoic acid(**6**, S:R=84:16, 68% e.e., Entry 9) was obtained after the oxidation of alcohol(**5b**) (Eq. 1). Meanwhile, the benzylation of **3b** using LDA without any additive afforded (*R*)-**5a**. However, (*S*)-**5a** was obtained from the reaction in the presence of HMPA or *N,N,N′,N′*-tetramethylethylenediamine (TMEDA). This shows that the sense of the asymmetric induction in benzylation was reversed by these additives. Crown ethers as additives showed

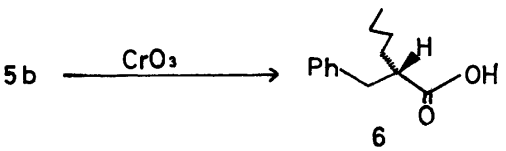
a) Determined by the measurement of the optical rotation. Literature value of **5a**; $[\alpha]_{578}^{22}$ −11.5° (*c* 0.5, C_6H_6). M. M. Leclercq, J. Billed, and J. Jacques, *Mol. Cryst. Liq. Cryst.*, **8**, 367 (1969). b) Observed $[\alpha]_{577}^{28}$ −7.07° (*c* 0.99, C_6H_6). c) Alcohol **5b** was oxidized to the acid **6**, and the optical rotation of **6** was measured. Lit value; $[\alpha]_D^{20}$ −22.8° (*c* 2.06, C_6H_6), M. B. Atson and G. W. Youngson, *J. Chem. Soc. C*, **1968**, 258. d) Observed $[\alpha]_D^{23}$ +15.5° (*c* 0.69, C_6H_6). e) Observed $[\alpha]_{577}^{24}$ −4.58° (*c* 1.02, C_6H_6); $[\alpha]_D^{22}$ −4.29° (*c* 0.63, C_6H_6), 39% e.e. based on lit value for 74% e.e., $[\alpha]_D^{24}$ −8.2° (*c* 4.63, C_6H_6), S. Terashima and S. Yamada, *Chem. Pharm. Bull.*, **16**, 1953 (1968).

relatively little effect. The addition of 12-crown-4 (1 molar equiv) to lithium enolate of **3a** gave **5a** (S:R=70:30, Entry 7).



6 (1)

Lithium enolate was more effective than sodium and zirconium enolates. Sodium enolate was formed using sodium disilazane, and was alkylated by methyl iodide at room temperature to give **5a** (S:R=65:35, Entry 19). The addition of 18-crown-6 (1 molar equiv) to sodium enolate gave **5a** (S:R=70:30, Entry 20). The desired product was not obtained in an attempted methylation of zirconium enolate, which had been prepared from lithium enolate using dicyclopentadienylzirconium dichloride.[1a]

Experimental

(2*S*,5*S*)-2,5-Dibenzylpiperazine (2a) was synthesized by the reduction of *cyclo*-L-Phe-L-Phe (**1a**) with sodium borohydride–titanium tetrachloride ($NaBH_4$–$TiCl_4$) according to a previously reported procedure.[2]

(2*S*,5*S*)-2,5-Diisopropylpiperazine (2b): Compound **2b** was synthesized from *cyclo*-L-Val-L-Val (**1b**) by the same procedure as above (64% yield); mp as dihydrochloride, 265.5—267.0 °C (decomp), $[\alpha]_D^{25}$ −21.1° (*c* 1, H_2O). ^1H NMR (CCl_4) δ=0.90 (dd, 12H), 1.30 (s, 2H), 2.09 (m, 4H), 2.65 (s, H, NH), 2.72 (m, 2H); IR (neat) 3000, 1540, 920 cm^{-1}; Found: *m/z* 170.1779. Calcd for $C_{10}H_{22}N_2$: M, 170.1785.

(2*S*,5*S*)-2,5-Dibenzyl-1,4-bis(3-phenylpropanoyl)piperazine (3a): To a solution of **2a** (1.697g, 5mmol) in 20ml of CH_2Cl_2 in ice-cooling bath, triethylamine (Et_3N, 1.012g, 10mmol) was added. Then, 3-phenylpropanoyl chloride (2.023g, 12mmol) in 10ml of CH_2Cl_2 and Et_3N (1.214g 12mmol) were added successively. The mixture was stirred for 1h. The cooling bath was removed and the mixture was stirred for 12h. The mixture was filtered, and the filtrate was evaporated under reduced pressure. The residue was dissolved in ethyl acetate and was washed successively with 1 M† HCl, H_2O, satd. aq $NaHCO_3$. Purification by silica-gel column chromatography (eluent EtOAc–hexane=1:2) gave **3a** as an oil in 82% yield; ^1H NMR (CCl_4) δ=2.3—2.7 (m, 14H), 4.1 (broad, 4H), 7.0 (m, 20H); IR (neat) 3050, 1640, 1420, 740 cm^{-1}; Found: *m/z* 530.2906. Calcd for $C_{36}H_{38}N_2O_2$: M, 530.2935; $[\alpha]_D^{22}$ +55.0° (*c* 1.073, EtOH).

(2*S*,5*S*)-2,5-Dibenzyl-1,4-dipropanoylpiperazine (3b): Compound **3b** was prepared by the same procedure as described above in 62% yield as an oil; ^1H NMR (CCl_4) δ=1.0 (t, 6H), 1.95 (m, 4H), 2.7 (m, 6H), 4.2 (m, 4H), 7.05 (s, 10H);

† 1 M=1 mol dm^{-3}.

IR (neat) 3000, 1640, 1430 cm^{-1}; Found: *m/z* 378.2278. Calcd for $C_{24}H_{30}N_2O_2$: M, 378.2309; $[\alpha]_D^{27}$ +64.0° (*c*1.00, EtOH).

(2*S*,5*S*)-2,5-Diisopropyl-1,4-bis(3-phenylpropanoyl)piperazine (3c): Compound **3c** was prepared by the same procedure as described for **3a** in 95% yield; ^1H NMR (CCl_4) δ=0.90 (dd, 12H), 1.68 (m, 2H), 2.45—2.83 (m, 10H), 4.05 (m, 4H), 7.05 (s, 10H); IR (neat) 2950, 1640, 1420 cm^{-1}; MS (70 eV) *m/z* 434(M^+), 391, 259, 127, 91; $[\alpha]_D^{22}$ +100.3° (*c* 1.00, EtOH).

Diastereoselective Alkylation of the Lithium Enolate Derived from 3a in the Presence of HMPA. Typical Procedure: A THF solution of lithium diisopropylamide-(LDA)[5] (0.50 M, 2.3 mmol) was added slowly to diamide (**3a**, 0.512 g, 0.96 mmol) dissolved in THF (6 ml) at −78 °C under an argon atmosphere; the mixture was stirred for 30 min at −30 °C and HMPA (0.412 g, 2.3 mmol) was added. Then, the mixture was cooled again to −78 °C. Methyl iodide (0.545 g, 3.84 mmol) was added and the mixture was stirred for 3 h, quenched with phosphoric acid buffer (pH 7), and 1 M HCl was added. The mixture was extracted with $CHCl_3$, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. The purification by silica-gel TLC (developing solvent EtOAc–hexane=1 : 2) gave dialkylated diamide **4a** in 65% yield as an oil; ^1H NMR (CCl_4) δ=1.00 (s, 6H), 2.40—2.67 (m, 12H), 4.02(broad, 4H), 7.05 (s, 20H); IR (neat) 3000, 1640, 1420 cm^{-1}.

Diastereoselective Methylation of Sodium Enolate of 3a in the Presence of 18-Crown-6 (Table 1, Entry 20): A solution of sodium disilazane (1.0 M, 2.0 mmol) was slowly added to the mixture of diamide **3a** (0.264 g, 0.5 mmol) and 18-crown-6(0.529 g 2.0 mmol) dissolved in THF (3.0 ml) at room temperature under an argon atmosphere; the mixture was stirred for 30 min at room temperature. Methyl iodide (0.426 g, 3.0 mmol) was added and the mixture was then stirred over night at room temperature and worked up in the same manner as described above. Compound **4a** was obtained in 82% yield.

Preparation of Optically Active Alcohols 5a, b by the Reductive Cleavage of the Alkylated Diamide 4a—c with Lithium Hydrotriethylborate: $LiBHEt_3$ (1.0 M solution in THF, 5 ml) was added to **4** and stirred for 24 h at 35 °C; it and was then quenched with a careful addition of H_2O. The mixture was made acid with 1 M HCl. The mixture was extracted with $CHCl_3$, evaporated under reduced pressure. The residue was purified on silica gel TLC (developing solvent $CHCl_3$) followed by bulb-to-bulb distillation to afford 2-methyl-3-phenyl-1-propanol (**5a**) or 2-benzyl-1-hexanol (**5b**), respectively. The enantiomeric excess of **5a** was determined by the optical rotation of the sample. The enantiomeric excess of **5b** was determined by optical rotation after **5b** was oxidized to **6**.

(*S*)-2-Benzylhexanoic Acid (6): Chromium(VI) oxide[6] (2.32 g) in sulfuric acid (4M, 5 ml) was added to an acetone solution (2.0 ml) of **5b** in an ice cooled bath. After the mixture was stirred for 1 h, sodium sulfite (4.0 ml of 10% aq solution) was added; extraction was performed using ether. The extract was dried over anhydrous sodium sulfate, evaporated under reduced pressure. The residue was purified on silica-gel TLC (developing solvent EtOAc–hexane=1 : 1). (*S*)-**6** was obtained in 64% yield.

(Received March 24, 1987)

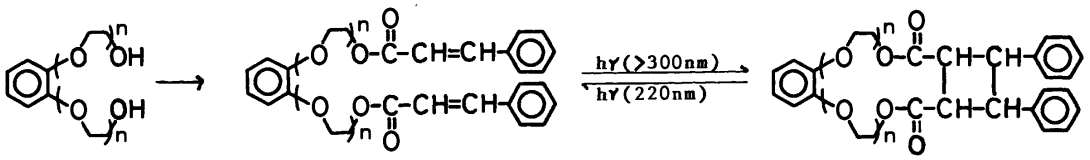
Synopsis. Irradiation of a solution of dicinnamates of *o*-bis(3-hydroxy-1-oxapropyl)benzene and *o*-bis(6-hydroxy-1,4-dioxahexyl)benzene in methanol by Pyrex-filtered UV light gave the corresponding intramolecular pseudophotodimerized crown ethers, and irradiation of the crown ethers in methanol by 220 nm UV light gave the open chain starting dicinnamates in reverse. The structures of the isolated crown ethers were confirmed to be δ-form by the ^{1}H NMR spectra and X-ray analysis.

It is well-known[1] that crown ethers can be complexed with alkali, alkaline earth, and other metal cations, despite the poor complexing abilities of the corresponding open chain polyethers. Recently, several kinds of photoresponsive crown ethers have been reported by Shinkai et al.[2] and Osa et al.[3] For example, the alkali cation-binding abilities of benzocrown ethers containing azo group were enhanced by photoirradiation.[2] There are many reports on the photodimerization of cinnamic acid and its derivatives.[4] Furthermore, intramolecular photocycloaddition has received attention from the synthetic viewpoints of crown ethers. For example, Mizuno et al.[5] obtained cyclobutanocrown ethers (cyclobutane-fused crown ethers) by intramolecular photocycloaddition of the bis(vinyloxy) compounds using a sensitizer. Recently, Egerton et al.[6] have suggested that photodimerization of the ethyl cinnamate in solution gives a cyclodimer in high yield. It was further reported that, on irradiation of 210 nm UV light, the cyclodimer regenerated the starting monomer. In connection with the above results, the preparation of polymers having both crown ether moiety as a cation binding site and a cinnamic acid ester moiety as a photodimerizable pendant group has been recently reported by Shirai et al.[7] They showed that, in 310 nm UV light, the cinnamoyl groups of these polymers caused dimerization in a dilute solution and the cation extraction abilities of the photoreacted polymers were higher than those of the original polymers. Also, Kimura et al.[8] and Hiratani et al.[9] reported the preparation of the cyclobutanocrown ethers by photoirradiation of the dicinnamates of the polyethylene glycol derivatives. These findings suggest that dicinnamates of polyethylene glycol and their homologs in solution could be cyclized by intramolecular additions in 310 nm light; then, in 210 nm UV light, the cyclized crown ethers could possibly give the corresponding open chain dicinnamates in reverse. Therefore, the extraction abilities of the crown ether could be controlled by photoaddition. However, these authors did not describe the reversible photocleavage of the cyclobutanocrown ethers. We therefore in this paper report on the syntheses of cyclobutanocrown ethers by intramolecular photocycloaddition of the polyethylene glycol derivatives and their photoreversible reaction.

Catechol (**1a**) reacted with cinnamoyl chloride in the presence of pyridine in benzene to give **2a** in 57.3% yield. Also, the dicinnamates **2b** and **2c** were obtained in 61% yields, respectively by the reaction of cinnamic acid with **1b** and **1c** in the presence of a catalytic amount of *p*-toluenesulfonic acid in benzene.

Irradation of methanol solutions (1 dm^3) of **2b** and **2c** (4×10^{-4} mol) with a 450W high-pressure mercury lamp through a Pyrex filter gave **3b** and **3c** in 27 and 41% yields, respectively. However, **3a** could not be isolated from the photoirradiated products. The thin-layer chromatography of the reaction mixture of **2a** or **2c** showed the presence of several products. However, in both cases, the products, which may be isomers of **3a** or **3c**, could not be separated because of their negligible amounts.

Template-typed photoreaction was also determined, however the yields of **3** were not improved. In the ^{1}H NMR spectra of **3b** and **3c**, the aromatic protons caused by the phenyl moieties shifted upfield (ca. 0.11 ppm), compared with those of the starting materials. Kuzuya et al.[10] reported that the signals of the phenyl protons in the δ-truxinate of polymethylene dicinnamates were shifted upfield about 0.13 and 0.35 ppm, compared with those of the starting dicinnamates, respectively. Therefore, there was an upfield shift of ca. 0.11 ppm of the signal of the phenyl moieties when going from the dicinnamates



1a: n=0 **2a**: n=0 **3a**: n=0
1b: n=1 **2b**: n=1 **3b**: n=1
1c: n=2 **2c**: n=2 **3c**: n=2

(**2b** and **2c**) to the crown ethers (**3b** and **3c**). Furthermore, the discovery of the coupling constant (ca. 5.7 Hz) between the Ha and Hb in the cyclobutane ring of **3b** and **3c** is also supported by the above results. Also, the hydrolysis of **3b** and **3c** with dil hydrochloric acid gave δ-truxinic acid quantitatively.[8] In addition, irradiation of **3b** and **3c** with 220 nm UV light gave the starting dicinnamates quantitatively.

In order to investigate in more detail, photocycloaddition was carried out at a concentration of 4×10^{-5} mol dm^{-3} of **2a—c** in methanol. These results showed the relationship between the lengths of oxyethylene units and formation rates of photocycloaddition. In specific results, the rate of the decrease of the absorption at 275 nm of the dicinnamates was in the following order (min): **2b**(98.7)>**2c**(105.9)>**2a** (590.7). This finding is explicable when the length of the oxyethylene units in the dicinnamates is considered, because the overlapping of two cinnamoyl groups in **2b** could easily occur due to their suitable bond lengths compared with the longer and shorter chain units of **2c** and **2a**, respectively, although other influences cannot be ruled out.

Photocleavage of **3b** and **3c** was carried out in acetonitrile under irradiation at 220nm UV light using a grating monochromator with a 500W xenon lamp. The solution was measured by UV-VS spectra at appropriate intervals. The absorption band at 275 nm increased with UV irradiation of the solution and a steady state was attained within 7 h. The photoreversible cleavage of **3b** and **3c** proceeded to give **2b** and **2c** in 40 and 60% yields, respectively.

Measurement of the extraction ability was carried out by the method described in a previous paper.[11] The extraction abilities of the compounds **2a—c**, **3b**, and **3c** toward alkali metal cations were very low or negligible in values. Also, the differences in the extraction abilities between the **2** and **3** could not be observed in all cases. The low extraction ability of the dicinnamates **2** is explicable by the large steric repulsion between the two terminal cinnamoyl groups when a guest cation is surrounded by the oxygen atoms of the host molecule. Also, the distortion of the structure of the macrocyclic moiety as well as the presence of the ester moiety in **3** seems to be the reason for their low extraction abilities. Therefore, **3b** was further characterized by X-ray crystallographic study.

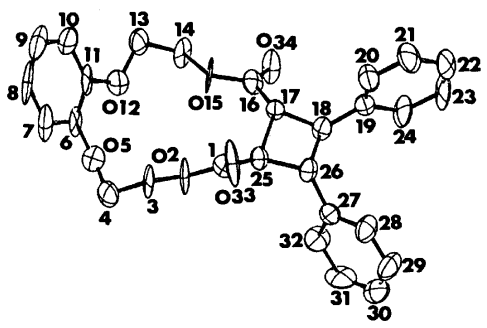


Fig. 1. ORTEP drowing of the molecular structure of **3b**.

The conformation of **3b** is illustrated in Fig. 1, which also shows the atom labels used. The result confirmed the δ-configuration of the toluxinate moiety in **3b**, indicating that the cyclobutane structure bearing two ester groups largely distorts the macrocyclic structure as shown in Fig. 1. The distances between O(5)-O(15), O(2)-O(15), and O(2)-O(12) are 3.819(5), 3.515(4) and 4.379(4) Å, respectively, although the distances between O(2)-O(5) (2.844(5) Å), O(12)-O(15) (2.740(4) Å) are better located to form the complex. The conformation and the long distances (3.819, 3.515, and 4.379 Å) between those oxgen atoms of the macrocyclic moiety are disadvantageous for forming the complex with a guest cation.

In conclusion, the complexing abilities of the cyclobutanocrown ether **3b** with alkali metal cation were decreased by the two factors of long distances between the oxygen atoms of the ether linkage and the presence of the ester moieties in the macrocyclic polyether part. However, the photoreversible reaction between **2** and **3** suggests the possibility of its use as photoresponsive crown ether.

Experimental

The melting points are uncorrected. The ^{1}H NMR spectra were obtained on Hitachi R-90 and GEOL GX400 spectrometers, with TMS as an internal standard. The UV spectra were obtained on a Hitachi 330 Spectrometer. The IR spectra were measured on a JASCO IRA-2 Diffraction Grating Infrared Spectrometer. For irradiation of **2** on a preparative scale, a solution charged in a vessel fitted with a Pyrex cooling jacket was purged with dry nitrogen for 10 min and internally irradiated with an Ushio High-pressure mercury lamp (HPL) (UM-452). Also, photocleavage of **3** to **2** was carried out by means of a 220 nm UV light using a grating monochromater (Model JASCO CT-10) with a 500 W xenon lamp(JASCO PS-X500) and 0.5 nm band width.

2a. Dry pyridine (40 cm^3) was added dropwise to a solution of chatechol (1.65 g, 15 mmol) and cinnamoyl chloride (5.0 g, 30 mmol) in benzene (100 cm^3) and the mixture was stirred for 3 h at room temperature. Water (100 cm^3) was then added dropwise to the mixture, and an aqueous layer was separated. The organic layer was then washed with dil hydrochloric acid, water, 10% aq sodium hydrogencarbonate solution and water, and then dried over anhyd. sodium sulfate. After evaporation of the solvent under reduced pressure, the residue was recrystallized from ethanol to give **2a** as colorless crystals in 57.3% yield. Mp 123.5—124.5 °C. Found: C, 77.80, H, 4.99%. Calcd for $C_{24}H_{18}O_4$: C, 77.82, H, 4.90%. MS (70 eV) *m/z* 370 (M^+). IR(KBr) 1720 cm^{-1} (C=O). UV (in MeOH) 275 nm (ε 9000). ^{1}H NMR ($CDCl_3$) δ=6.58 (d, *J*=16.0 Hz, 2H, C_α-H), 7.86(d, *J*=16.0 Hz, 2H, C_β-H), 7.58—7.31 (m, 10H, aromatic H), and 7.31(s, 4H, aromatic H).

2b. A solution of **1b** (0.68 g, 3.5 mmol), cinnamic acid (2.1 g, 14 mmol), and a trace of *p*-toluenesulfonic acid in toluene (80 cm^3) was refluxed for 26 h. The reaction mixture was cooled to room temperature and washed with a 0.01% aq sodium hydroxide solution and water, and then evaporated. The residual solid was recrystallized from hexane to give **2b** as colorless needles in 61% yield. Mp 59.0—59.5 °C. Found: C, 73.03, H, 5.86%. Calcd for $C_{28}H_{26}O_6$: C, 73.35, H, 5.72%. MS (70 eV) *m/z* 458 (M^+). UV (in MeOH) 277 (ε 49000). IR (KBr) 1720 cm^{-1} (C=O). ^{1}H NMR ($CDCl_3$) δ=4.64—4.25 (m, 8H, CH_2), 6.45 (d, *J*=16.0 Hz, 2H, C_α-H), 7.69 (d, *J*=16.0 Hz,

2H, C_β-H), 7.48—7.32 (m, 10H, aromatic H), 6.98 (s, 4H, aromatic H).

2c. A solution of lc (1.03 g, 3.64 mmol), cinnamic acid (2.16 g, 15 mmol) and a trace of *p*-toluenesulfonic acid in toluene (80 cm^3) was refluxed for 44 h. The reaction mixture was cooled, evaporated in vacuo and the residue was dissolved in chloroform. The solution was washed with a 10% aq sodium hydrogencarbonate solution and water, and evaporated. The residue was chromatographed on silica gel using a benzene-acetone (12:1) solution as an eluent. The evaporation of the second fraction gave **2c** as pale yellow viscous oil in 61.0% yield. Found: C, 70.12, H, 6.33%. Calcd for $C_{32}H_{34}O_8$: C, 70.31, H, 6.27%. MS (70 eV) *m/z* 546 (M^+). IR (KBr) 1720 cm^{-1} (C=O). UV (in MeOH) 277 nm (ε 49000). ^{1}H NMR ($CDCl_3$) δ=4.45—4.10 (m, 8H, CH_2), 3.95—3.72 (m, 8H, CH_2), 6.45 (d, *J*=16.0 Hz, 2H, C_α-H), 7.70 (d, *J*=16.0 Hz, 2H, C_β-H), 7.52—7.32 (m, 10H, aromatic H), 6.92(s, 4H, aromatic H).

Irradiation of 2b. Dicinnamate **2b** (0.137 g, 0.3 mmol) dissolved in methanol (1 dm^3) was irradiated internally with HPL (450 W) through a Pyrex filter at running water temperature for 5 h. The solvent was evaporated and the residue was recrystallized from methanol resulting in **3b** as colorless crystals. Yield 20%, Mp 142.0—143.0 °C. Found: C, 73.05, H, 5.68%. Calcd for $C_{28}H_{26}O_6$: C, 73.33, H, 5.72%. MS (70 eV) *m/z* 458(M^+). UV (in MeOH) 275 nm (ε 2300); ^{1}H NMR ($CDCl_3$) δ=7.29 (s, 10H), 6.97 (s, 4H), 4.92—4.50(m, 2H), 4.50—4.03 (m, 6H), 4.00—3.80 (m, 2H), 3.50—3.31 (m, 2H).

Irradiation of 2c. Dicinnamate **2c** (0.109 g, 0.2 mmol) dissolved in methanol (1 dm^3) was irradiated as described above. After irradiation, the solvent was evaporated. An oily residue was chromatographed on silica gel. Elution with benzene-ethyl acetate (4:1) gave pure **3c** as an oily product. Yield 24%. Found: C, 69.93, H, 6.40%. Calcd for $C_{32}H_{34}O_8$; C, 70.30, H, 6.28%. MS (70 eV) *m/z* 546 (M^+). UV (in MeOH) 275 nm (ε 2400), ^{1}H NMR($CDCl_3$) δ=7.28 (s, 10H), 6.91 (s, 4H), 4.57—4.01 (m, 8H), 4.01—3.58 (m, 10H), 3.53—3.36 (m, 2H).

Irradiation of 3b and 3c. An acetonitrile solution of **3** (ca. 2.0×10^{-5} mol dm^{-3}) was placed in a quartz cell (1×1×4 cm) and was irradiated at room temperature with a 220 nm UV light for 6—7 h. The UV spectra during irradiation were recorded with a Hitachi 330 spectrometer. The photoreversible yields of **2b** and **2c** were calculated from the intensity of the absorption band at 275 nm in the stead state. After irradiation, the solvent was evaporated in vacuo and the residue was chromatographed on silica-gel TLC using chloroform as an eluent. The main fraction was extracted with chloroform and the solution was then evaporated in vacuo to give **2c** or **2b**. The structures of **2b** and **2c** were confirmed by comparison with R_f values of TLC, the melting point (for **2b**) and spectral data of the authentic samples.

Hydrolysis of 3b and 3c. A solution of **3b** (0.107 g, 0.23 mmol) in methanol (20 cm^3) containing dil hydrochloric acid (10 cm^3) was refluxed for 4.5 h. After the solution has been cooled to room temperature, aq sodium hydroxide solution was added. The resulting alkaline solution was extracted with chloroform. To the aqueous solution was added dil hydrochloric acid until it became acidic and then the solution was extracted with chloroform. The extract was dried over anhyd. sodium sulfate and concentrated. To the residue was added an ether solution (50 cm^3) of diazomethane. Evaporation of the solvent gave dimethyl δ-toluxinate in 33% yield. Mp 78.0—79.5 °C(lit,[12] 77 °C). ^{1}H NMR (in $CDCl_3$) δ=7.24 (s, 10H), 3.94—3.29 (m, A_2B_2 pattern, 4H), 3.82 (s, 6H).

δ-Toluxinate was also obtained from **3c** by the same method.

X-Ray Crystallography. Crystal of dimensions 0.4×0.2×0.1 mm was used for the X-ray crystallography. Crystal data are as follows: $C_{28}H_{26}O_6$, Mw=450.5. Monoclinic, $P2_1/n$, a=19.325(5), b=5.323(1), c=22.838(5)Å, β=95.14(2)°, U=2339.9 $Å^3$, Z=4, Dx=1.30 g cm^{-3}, ν(Cu Kα)=7.6 cm^{-1}. Intensity data for $2\theta\leqslant128°$ were recorded on a Rigaku AFC-5R with graphite monochromatized CuKα radiation. A total of 3898 independent reflections were corrected for Lorentz and polarization factors but not for absorption. The structure was solved by direct methods using MULTAN84,[13] and refined by block diagonal least-squares methods. The positions of the hydrogen atoms were estimated using standard geometry. The final refinements with anisotropic temperature factors for the non-hydrogen atoms and isotropic temperature factors for the hydrogen atoms were lowered R values 0.079 (R_w=0.050, $w=1/\sigma^2(F_o)$, 2646 observed reflections with $F_o\geqslant2\sigma(F_o)$). Parameters for bond lengths, angles and structure factors (observed and calculated) are kept at the Chemical Society of Japan (Document No.8751).

The present work was partially supported by a Grant-in-Aid for Scientific Research (No. 6154038) from the Ministry of Education, Science and Culture.

Ruthenium Complex-Catalyzed N-Heterocyclization. Syntheses of *N*-Substituted Pyrroles and Pyrrolidines from 1,4-Diols and Primary Amines

Yasushi TSUJI, Yasuharu YOKOYAMA, Keun-Tae HUH, and Yoshihisa WATANABE*
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received March 26, 1987)

Synopsis. 2-Butyne-1,4-diol reacts with aliphatic amines in the presence of a catalytic amount of [$RuCl_2(PPh_3)_3$] at 150 °C to give *N*-alkylpyrroles in good yields. 1,4-Butanediol reacts with aromatic or aliphatic amines to give *N*-substituted pyrrolidines in excellent yields; [$RuCl_2(PPh_3)_3$] and [$RuCl_3 \cdot nH_2O$-3PBu_3] are the best catalysts for aromatic and aliphatic amines, respectively. The reaction of 2-butene-1,4-diol with alkyl amines gives a 1:1 mixture of *N*-substituted pyrroles and pyrrolidines in high yield.

Pyrroles and pyrrolidines, well-known and very important compounds in organic syntheses and in many other fields, are prepared by various methods[1] including inter- and intramolecular cyclization of tetramethylene dibromides,[2] 4-halo-1-butanamines,[3] α-amino ketones,[4] α-halo ketones,[5] and 1,4-diketones.[6] Recently, transition metal-catalyzed synthetic methods of pyrrole derivatives have been developed.[7,8] In the course of our studies on the ruthenium complex-catalyzed *N*-heterocyclization using alcohols[9] we found a novel synthetic method of *N*-substituted pyrroles and pyrrolidines from readily availabe 1,4-diols and primary amines.

Experimental

General Reaction Procedure. All boiling points and melting points were uncorrected. The ^1H and ^{13}C NMR spectra were recorded in $CDCl_3$ at 100 and 25.05 MHz, respectively, with a JEOL JNM FX-100 spectrometer. Elemental analyses were performed at the Microanalytical Center of Kyoto University. The GLC analyses were made using Shimadzu GC-4CM with a column (3 mm×3 m) packed with Apiezon Grease L (10%) on Neopack 1A, 60—80 mesh. Gel-permeation chromatograms (GPC) were recorded on a Waters ALC/GPC 244 system equipped with a Shodex GPC H-2002 column. Typical reaction conditions were as follows. A stainless-steel reactor (50 ml Taiatsu Glass Industry, TVS-1 type) containing a glass liner was used. Under an argon stream, dioxane (5 ml), amine (2 mmol), 2-butyne-1,4-diol (3 mmol), and [$RuCl_2(PPh_3)_3$] (0.02 mmol, 1 mol% based on the amines used) were added into the glass liner. After the reactor was flushed with argon (10 atm) four times, the reactor was held at 150 °C for 5 h. The products were isolated by vacuum distillation or medium-pressure column chromatography (hexane or benzene–aluminum oxide 90, Merck, No. 1076). Spectral data of unreported compounds are as follows.

(±)-1-(2-Ethylhexyl)pyrrole: Colorless oil; Kugelrohr pot temp. 60 °C (0.04 mmHg†); ^1H NMR δ=0.80—0.93 (6H, m, $2CH_3$), 1.14—1.34 (8H, m, $4CH_2$), 1.48—1.86 (1H, m, CH), 3.71 (2H, d, CH_2), 6.09 (2H, t), 6.60 (2H, t); ^{13}C NMR δ=10.6 (q, CH_3), 14.0 (q, CH_3), 23.0 (m, CH_2), 23.8 (m, CH_2), 28.7 (m, CH_2), 30.6 (m, CH_2), 41.3 (d, CH), 53.1 (t, CH_2), 107.6 (d), 120.9 (d). Results and Discussion

Synthesis of *N*-Substituted Pyrroles from 2-Butyne-1,4-diol and Amines. The reaction between 2-butyne-1,4-diol (**1**) and aliphatic primary amines **4** at 150 °C in dioxane in the presence of catalytic amounts of a ruthenium complex afforded *N*-substituted pyrroles **5** (Eq. 1, Table 1). When [$RuCl_2(PPh_3)_3$] was

$$\underset{\mathbf{1}}{HOCH_2C{\equiv}CCH_2OH} + \underset{\mathbf{4}}{RNH_2} \xrightarrow[-2H_2O]{RuL_n} \underset{\mathbf{5}}{R\text{-}N\!\!\begin{array}{l}\diagup\!=\\ \diagdown\!=\end{array}} \qquad (1)$$

used as a catalyst, the reaction of octylamine with 2-butyne-1,4-diol gave 1-octylpyrrole in 63% yield. The catalytic activity was little affected by the phosphorus ligands; [$RuCl_2(PPh_3)_3$], [$RuCl_3 \cdot nH_2O$-3PBu_3], and [$RuCl_3 \cdot nH_2O$] showed high catalytic activity (63, 52, and 57% yield of **5**, respectively) and other ruthenium complexes such as [$RuHCl(CO)(PPh_3)_3$] and [$RuBr_2(PPh_3)_3$] were also effective (58 and 53% yield of **5**, respectively). Addition of bis(diphenylphosphino)-ethane (dppe) as a bidentate phosphorus ligand or a bulky PCy_3 suppressed the catalytic activity considerably (4 and 1% yield, respectively). No satisfactory results were obtained in case of aromatic amines. When 2-butyne-1,4-diol (**1**) was treated with a

† 1 mmHg=133.322 Pa.

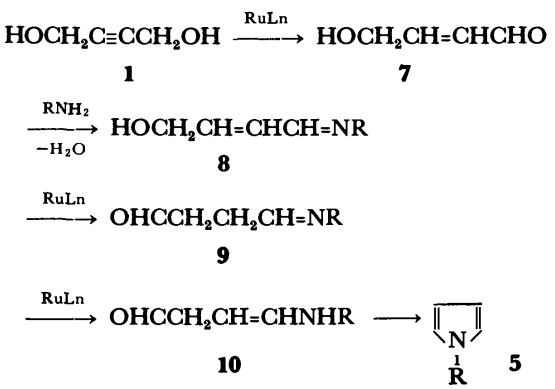
2		$HOCH_2C{\equiv}CCH_2OH$		(49)
3		$HOCH_2C{\equiv}CCH_2OH$		49 (24)
4		$HOCH_2C{\equiv}CCH_2OH$		(27)
5[b)]	$n\text{-}C_8H_{17}NH_2$	$HO(CH_3)CHC{\equiv}CCH(CH_3)OH$		(47)

a) Amine (2.0 mmol), 1,4-diol (3.0 mmol), $RuCl_2(PPh_3)_3$ (0.02 mmol), dioxane (5 mL), at 150 °C for 5 h. b) Amine (10 mmol), 1,4-diol (15 mmol), $RuCl_2(PPh_3)_3$ (0.10 mmol). c) Determined by GLC based on the amine and figures in the parentheses are isolated yields.

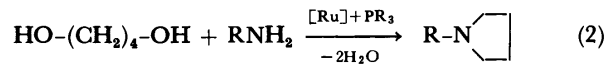


Scheme 1.

catalytic amount of $[RuCl_2(PPh_3)_3]$ in dioxane at 150 °C, the diol was converted into an oligomeric intractable mixture (conversion 100%, molecular weight 200—1000 by GPC). The ruthenium complexes are well-known catalysts for the isomerization of olefins[10] and of allyl alcohol to aldehyde.[11] Therefore, we postulate a reaction route (shown in Scheme 1) including the isomerization of 2-butyne-1,4-diol (**1**) to γ-hydroxy-α,β-unsaturated aldehyde (**7**),[12] which reacts with amines **3** to give imine intermediates **8**. An allylic alcohol moiety of **8** isomerizes again to an imino aldehyde species **9**, which subsequently gives **10** via imine-enamine isomerization.[13] *N*-Substituted pyrroles **5** would be produced by intramolecular cyclization of **10**.

The N-heterocyclization to the pyrroles seems to compete with the oligomerization of **7**, since α,β-unsaturated aldehydes are reported to be easy to oligomerize.[14] When more basic aliphatic amines are employed as the substrate, most of **7** is trapped with them to give **8**. On the other hand, with less basic aromatic amines, a considerable amount of **7** is consumed by the oligomerization.

Synthesis of *N*-Substituted Pyrrolidines from 1,4-Butanediol and Amines. The reaction of 1,4-butanediol (**2**) with primary amines **4** in the presence of a catalytic amount of a ruthenium complex to give *N*-substituted pyrrolidines **6** in excellent yields (Eq. 2,



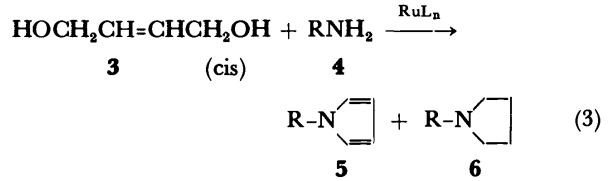
(2)

Table 2). The reaction is drastically affected by the nature of the phosphorus ligand employed, and the most suitable phosphorus ligand depends on the basicity of the amine.[15]

Dichlorotris(triphenylphosphine)ruthenium ($[RuCl_2(PPh_3)_3]$) was the most effective catalyst for less basic amines (Runs 6—11), while $[RuCl_3 \cdot nH_2O\text{–}3PBu_3]$ was highly effective for the amines with high basicity (Runs 12—15). Methoxy, chloro, trifluoromethyl, and methylenedioxy groups did not affect the catalysis appreciably (Runs 7, 9—11). Amines containing an *N*-hetero ring such as 3-picolylamine and tryptamine also afforded the desired *N*-substituted pyrrolidines in good yields (Runs 14 and 15).

The reaction would proceed via a route analogous to that proposed in the previous paper.[9]

The Reaction of *cis*-2-Butene-1,4-diol with Amines. *cis*-2-Butene-1,4-diol (**3**) reacted with octylamine in the presence of 1.0 mol% of $[RuCl_3 \cdot nH_2O\text{–}3PBu_3]$ to afford a mixture of 1-octylpyrrole (**5**; R=n-C_8H_{17}) and 1-octylpyrrolidine (**6**; R=n-$C_{18}H_{17}$) in 1:1 molar ratio (Eq. 3). Their combined yields were 69% at 150 °C and



(3)

73% at 180°C. On the other hand, aniline reacted with cis-2-butene-1,4-diol (**3**) to afford 1-phenylpyrrole (**5**; R=Ph) and 1-phenylpyrrolidine (**6**; R=Ph) in only 4—9% yields (**5**:**6**=1:9).

Table 2. *N*-Substituted Pyrrolidine Synthesis[a)]

Run	Amine	Catalyst[c)]	Temp/°C	Time/h	Product	Yield[d)]/%

(Received April 7, 1987)

Synopsis. Crystal structure of the title salt was determined by the X-ray analysis. Segregated columnar stacks of anion radicals are formed along the c axis, in which quinone molecules are not spaced equally but forming dyads with short contacts between sulfur atoms.

We have recently found that the quinones fused with sulfur heterocycles such as 1,3-dithiole rings possess strong electron affinities to give highly conductive CT complexes with tetrathianaphthacene (TTN) or tetrathiafulvalene (TTF) derivatives.[1] For example, quinone **1** formed CT complexes with TTN and tetramethyltetraselenafulvalene (TMTSF) whose electrical resistivities measured on compaction samples at room temperature are 9.9 Ω cm and 2.4 Ω cm, respectively. It is expected in these highly conductive complexes that the quinone molecules may form segregated columnar stacks with some interheteroatom interactions which can stabilize the metallic state by forming two-dimensional networks. However, unfortunately the crystallization of these complexes have still been unsuccessful. On the other hand, the anion radicals of quinone **1** have been isolated as stable salts.[1] To investigate the possible interheteroatom interactions in the negatively charged quinone molecules, we carried out the X-ray structural analysis of the title salt which was obtained as suitable single crystals. The role of the 1,3-dithiole rings which enhance the electron affinity of the quinone skeleton is discussed from the view point of the molecular structure.

Experimental

Material. Quinone **1** was prepared according to the literature.[2] The title 1:1 anion radical salt was prepared by the reaction of quinone **1** (64 mg) with tetraethylammonium iodide (514 mg, 10 equivalents) in hot dry acetonitrile (40 ml). Black needles of the salt thus obtained (85 mg, decomp. 240—241 °C) show the following analytical values, Calcd for $C_{16}H_{20}NS_6O_2$: C, 42.64; H, 4.47; N, 3.11%. Found: C, 42.43; H, 4.43; N, 3.11%. Its electrical resistivity (ρ_{RT}) measured on a compaction sample at room temperature was 1.2×10^7 Ω cm. Single crystals were obtained when the hot acetonitrile solution was cooled slowly. When four equivalents of the iodide were used, green-black needles (mp > 400 °C) were obtained whose molar ratio was determined to be 1:2 on the basis of the elemental analysis. Calcd for $C_{24}H_{20}NS_{12}O_4$: C, 37.38; H, 2.61; N, 1.82%. Found: C, 37.30; H, 2.54; N, 1.93%. The resistivity (ρ_{RT}) of the 1:2 salt was 8.7×10^3 Ω cm.

a) $B_{eqv}=(4/3)\sum_{ij}\beta_{ij}(a_i\cdot a_j)$.

Structural Analysis. A needle-like crystal with the dimensions of 0.15×0.15×0.25 mm³ was used for the data collection on a Rigaku AFC-5R automated four-circle diffractometer. A total of 4366 reflections within $2\theta=52°$ was collected using graphite monochromated Mo $K\alpha$ radiation ($\lambda=0.71069$ Å). Crystal data are as follows: MF $C_{16}H_{20}NS_6O_2$, MW 450.72, triclinic, $P\bar{1}$, $a=14.300(1)$, $b=13.243(1)$, $c=7.251(1)$ Å, $\alpha=69.58(1)$, $\beta=86.73(1)$, $\gamma=124.56(1)°$, $V=1000.2(3)$ Å³, $Z=2$, $D_{calcd}=1.50$ g cm⁻³. The structure was solved by the direct method using RANTAN 81[3] with some modification whereby only quinone molecule appeared in the Fourier map. After the block-diagonal least-squares refinement for these atoms, the remaining atoms of the ammonium ion were located in the difference Fourier map. After the refinement with anisotropic temperature factors, all the hydrogen atoms were successively picked up from the difference Fourier

map. The final R value is 4.36% for the 2636 reflections with $|F_o|>3\sigma|F_o|$. The final atomic coordinates are given in Table 1.

The atomic scattering factors from the International Tables for X-Ray Crystallography[4] were used. All the computation were carried out by an ACOS 1000 computer at Tohoku University using the applied library programs of UNICS III system.[5]

Results and Discussion

The crystal structure viewed along the b axis and the c axis are shown in Figs. 1 and 2. The quinone molecules form segregated columnar stacks along the c axis. These columns are linearly arranged to the a axis and separated by the ammonium ions along the b axis. In the column, the anion radicals are not equally spaced but pairing to form dyads. So there are two different modes of overlapping, and the quinone molecules are stacked parallel to each other in both overlapping. In the dyad, the overlapping is a well-known "ring-double bond" type[6] of a high symmetry with the short interplanar distance of 3.21 Å. There exist some short contacts such as C(7)-C(7) (3.13 Å) and O(2)-C(8) (3.11 Å) in this dyad, and particularly the S(4)-S(5) contact (3.42 Å) is quite shorter than the sum of van der Waals radii (3.70 Å)[7], indicating the strong interactions between sulfur atoms which may contribute to the dyad formation with "ring-double bond" type overlapping. Although the quinone molecule is nearly planar, slight deviations of atoms from the molecular plane are observed. These deviations afford the dihedral angles of 4.5° for the planes containing S(1)-S(3)-S(5) and C(3)-S(3)-S(5)-C(5), 2.5° for the planes containing C(3)-C(5)-C(4)-C(6) and O(2)-C(4)-C(5), and 2.3° for the planes containing C(4)-C(6)-(8)-C(7) and C(3)-C(5)-C(7)-C(8). Since molecules bow in the opposite direction in the dyad, this slight molecular defomation is considered to be accompanied by the short interplanar distance in the dyad which is formed in the crystal. Between the dyads, the interplanar distance (molecule C and D in Fig. 1) is 3.65 Å which is much longer than that in the dyad (molecule A and B), and the distances among the inner sulfur atoms are also long [S(3)-S(4) 3.90 Å, S(5)-S(6) 3.91 Å]. This type of segregated stack accompanied by the dyad formation is also observed in

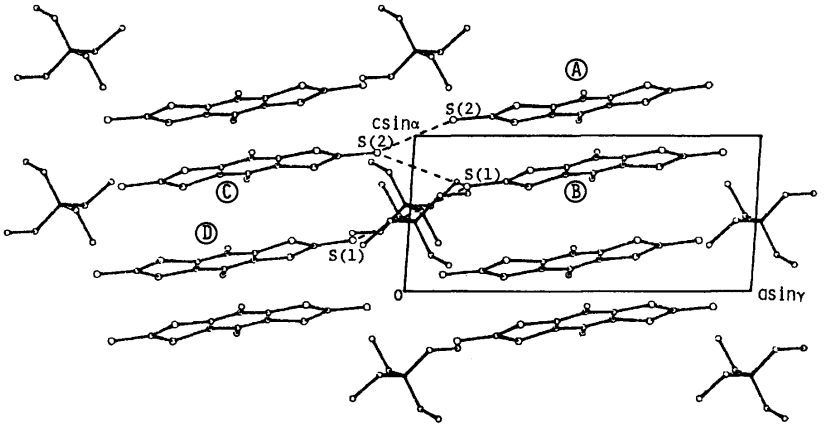

Fig. 1. Crystal structure viewed along the b axis. Molecules A—D are related by the following symmetry operations: A (x, y, z), B ($1-x$, $-y$, $-z$), C ($-x$, $-y$, $-z$), D ($-1+x$, y, $-1+z$). Intercolumn S-S contacts are indicated by broken line: 3.95 Å for molecule A and C, 4.04 Å for molecule B and C, 5.21 Å for molecule B and D.

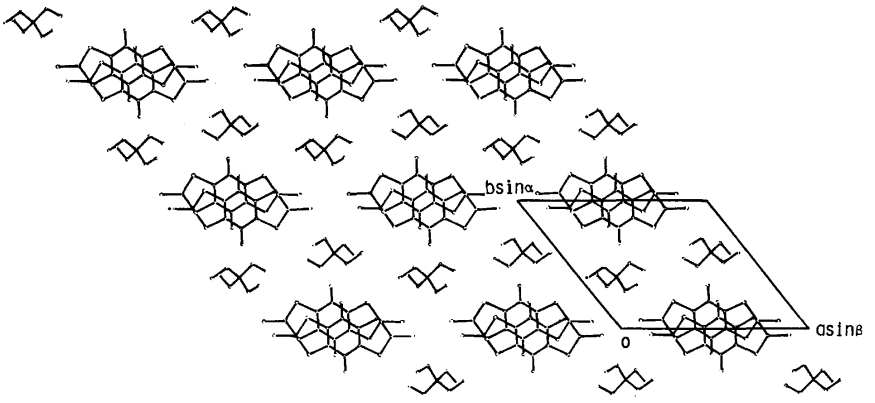

Fig. 2. Crystal structure viewed along the stacking c axis. Nitrogen atom of the ammonium ion is located on the same plane of the quinone molecule.

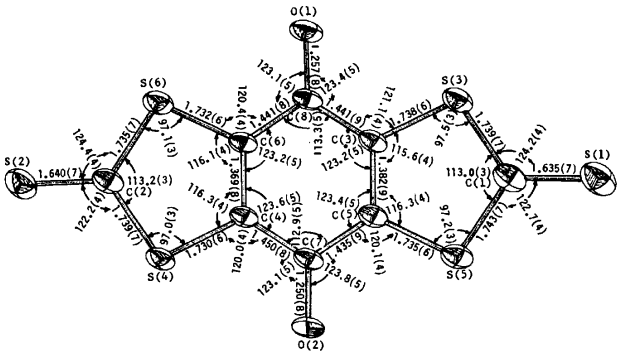

Fig. 3. Molecular geometry of quinone anion radical with bond lengths and angles.

the Et_4N^+ $(BTDA\text{-}TCNQ)_2^-$ anion radical salt which shows low electrical conductivity.[8] Therefore, the low conductivity of the present salt is accounted for by this dyad formation. However, it is noted that the segregated columnar stacks are formed with "ring-double bond" type overlapping, and this stacking motif is facilitated by the interaction between the sulfur atoms. This finding suggests that the highly conductive CT complexes of quinone **1** may have the segregated columnar stacks[9] which are facilitated by the S-S contacts observed here. Although the intercolumn interactions were also expected by the contacts between the terminal sulfur atoms, the distances among S(1) and S(2) are too long (3.95—5.21 Å, Fig. 1) to undergo such interactions.

The molecular geometry of the quinone anion radical is shown in Fig. 3. It is apparent that the C(8)=O(1) (1.257 Å) and C(7)=O(2) (1.250 Å) bonds are elongated than the corresponding bonds of ordinary neutral quinones (ca. 1.22 Å)[10] although those for the quinone **1** are not available. This means that the negative charge is largely localized on the carbonyl moieties, indicating that the anion radical mainly exists as the semiquinone form **2a**. The possibility of **2c** was excluded by considering the molecular overlapping in the dyad and the location of counter cation which may reflect the charge density of the anion radical species. However, the six-membered ring of **1** takes a quinoid structure and the bond lengths of S(1)=C(1) (1.635 Å) and S(2)=C(2) (1.640 Å) are longer than those of ordinary thiocarbonyl bonds (1.61 Å). This fact can be attributed to the contribution of the structure **2b**, in which aromatic 1,3-dithiolium cations are formed. This result leads to the conclusion that the electron affinity of the quinone **1** fused with 1,3-dithiole units is enhanced inductively by the contribution of the polarized form in the 1,3-dithiol-2-ylidene moieties.

Tables of observed and calculated structure factors, atomic positional parameters, anisotropic temperature factors, and bond lengths and angles are kept at the Chemical Society of Japan, Document No. 8755.

9) Generally, CT complexes of quinones tend to form mixed stacks with alternated overlapping of donors and acceptors which leads to low electrical conductivity.

10) The C=O bond lengths of quinones are as follows: 1.218 Å for benzoquinone (J. Trotter, *Acta Crystallogr.*, **13**, 86 (1960); 1.21 and 1.22 Å for naphthoquinone (J. Gaultier and C. Hauw, *Acta Crystallogr.*, **18**, 604 (1965)); 1.213 Å for anthraquinone (A. Prakash, *Acta Crystallogr.*, **22**, 439 (1967)).

Preparation and Some Properties of Acyltin Compounds

Masanori KOSUGI,* Hiroyuki NAKA, Hiroshi SANO, and Toshihiko MIGITA*
Department of Chemistry, Faculty of Technology, Gunma University,
Kiryu, Gunma 376
(Received April 14, 1987)

Synopsis. According to Quintard's method, acyltin compounds were prepared by the reaction of tributylstannylmagnesium chloride with an excess of aldehyde, and their physical data were described. These compounds were sensitive to oxygen air to give the corresponding tributyltin carboxylates. Free radical chain mechanism was suggested.

For lack of a suitable synthetic method, acyltin compounds have been virtually unkown and are believed to be very labile compounds.[1,2] Recently, the acyltins have been reported by Quintard et al. to form through the reaction of tributylstannylmagnesium chloride prepared in situ from isopropylmagnesium chloride and tributyltin hydride, with an excess of aldehyde.[3]

$$Bu_3SnMgCl+2\ RCHO \rightarrow Bu_3SnCOR+RCH_2OMgCl$$

However, physical data of the acyltins thus formed were not fully provided.[3] In this note, several trials of the syntheses of acyltins, and some of their physical data were described.

The reaction presented by Quintard et al. is interesting and thought to be a kind of Cannizzaro reaction of aldehyde involving Grignard reagent instead of a base. In 1925, the reaction of Grignard reagent with benzaldehyde giving benzyl alcohol was reported.[4] We re-examined the reaction of some ordinary Grignard reagents with excess of aldehydes,

$$RMgBr + 2PhCHO \rightarrow \rightarrow PhCOR + PhCH_2OH$$

R=Et, Ph: Et; 77%, Et; 83%; Ph; 60%, Ph; 61%

$$EtMgCl + 2PhCH_2CH_2CHO \rightarrow \rightarrow EtCOCH_2CH_2Ph + PhCH_2CH_2CH_2OH$$

44% 49%

and found that Cannizzaro type reactions between the Grignard reagent and an excess of aldehyde actually occurred to give the corresponding ketones and alcohols in moderate to good yields, even with aldehydes bearing α-hydrogen atoms.[5]

Based on the above results, the reactions of various tributylstannylmetal compounds (Bu_3Sn–M) with an excess of propanal were carried out, expecting to give the propanoyltributyltin. Tributylstannylmagnesium chloride was the best reagent which reacted with an excess of aldehyde to give the acyltins in 84% yield. The reaction with diethyl(tributylstannyl)aluminum also gave the acyltins, although the yields were low (18%). The reaction with other reagents, Bu_3Sn–M (M: Li, ZnCl, $ZnSnBu_3$, $SiMe_3$, $SnBu_3$ etc.) did not give the acyltins.

The following two coupling reactions were also carried out for the purpose of preparation of acyltins.

$$Bu_3SnLi + EtCOBr \longrightarrow Bu_3SnCOEt + LiBr$$

$$Bu_3SnSnBu_3 + EtCOCl \xrightarrow{[Pd]} Bu_3SnCOEt + Bu_3SnCl$$

These two reactions gave the propanoyltributyltin, although the yields (12 and 15% yields, respectively) were not satisfactory.[6] At present, Quintard's method was found to be the best for the preparation of acyltins.

Table 1 shows the physical properties of acyltins thus obtained. Propanoyl- and 2-methylpropanoyltributyltin were greenish yellow liquid with the absorption at ca. 380nm and could be distilled under reduced pressure. Their GC–MS(CI) showed the parent peak with the reasonable isotopic patterns. ^1H NMR, ^{13}C NMR, and IR spectrum were also reasonable. On the other hand, benzoyltributyltin was thermally unstable and decomposed to give the white solid on distillation under reduced pressure. Its GC–MS showed the pattern quite different from that of GLC and benzil was detected, showing that the

a) 1 mmHg=133.322 Pa. b) Peak at 360 was not detected. c) Decomposition was occurred in the MS chamber and benzil was detected.

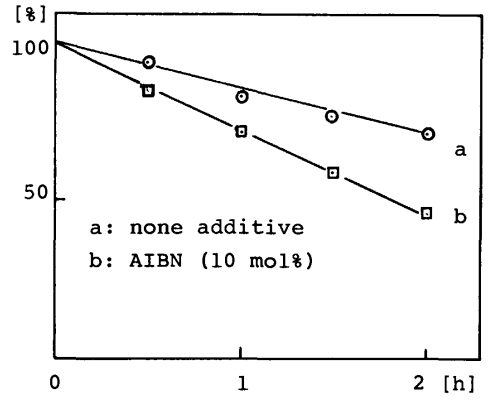

Fig. 1. Effect of AIBN on the disappearance of $Bu_3SnCOEt$ at 60 °C.

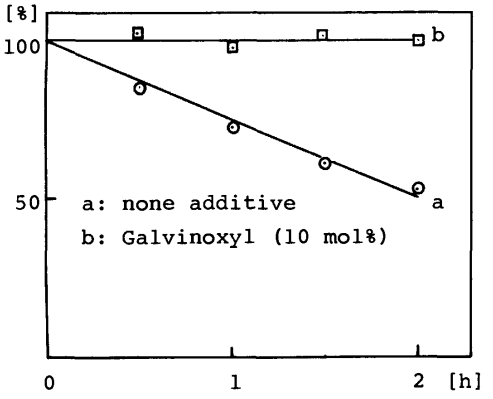

Fig. 2. Effect of Galvinoxyl on the disappearance of $Bu_3SnCOEt$ at room temperature.

benzoyltin decomposed in the GC-MS chamber. However, the product before distillation showed the reasonable spectroscopic data.

The acyltins were fairly stable under dark and inert atmosphere, being capable to be kept more than a month. One of the most characteristic reactions of acyltin was oxidation by molecular oxygen, giving the corresponding tributyltin carboxylates quantitatively. As Figs. 1 and 2 show, the autoxidation was completely inhibited in the presence of galvinoxyl (10 mol%) and was slightly accelerated by addition of AIBN (azobisisobutyronitrile). Based on these observations, free radical chain mechanism involving attack of acylperoxyl radical to a tin atom, followed by Baeyer-Villiger type oxidation, may be suggested.

$$Bu_3SnCOR \longrightarrow Bu_3Sn\cdot + R\dot{C}O$$

$$R\dot{C}O + O_2 \longrightarrow RCOOO\cdot$$

$$RCOOO\cdot + Bu_3SnCOR \longrightarrow RCOOOSnBu_3 + R\dot{C}O$$

$$RCOOOSnBu_3 + Bu_3SnCOR \longrightarrow 2RCOOSnBu_3$$

Moreover, propanoyltributyltin was found to reduce Tollens reagent. Thus, acyltin shows chemical behavior quite similar to aldehyde.

Experimental

Infrared spectra were recorded on a JASCO Model A-100 infrared spectrometer. ^1H NMR spectra (in carbon tetrachloride with tetramethylsilane internal standard) were run on a Varian Associates Model EM-360 spectrometer. ^{13}C NMR spectra (in deuteriochloroform with tetramethylsilane internal standard) were taken on a Hitach Model R-90H spectrometer. GC-MS spectra (Chemical Ionization) were recorded on a Shimadzu Model QP-1000 spectrometer. UV spectra (in hexane) were taken on a Hitachi Model 200-10 spectrophotometer. GLC analyses (10% of SF-96 on Celite 545) were performed by Ohkura Model 202 instrument.

Materials. Ethyl- and phenylmagnesium bromide were prepared by a standard method. Benzaldehyde, propanal, 2-methylpropanal, 3-phenyl-1-propanal, propanoyl chloride and bromide, propiophenone, benzophenone, benzyl alcohol, 1-phenyl-3-pentanone, 3-phenylpropanol, galvinoxyl, and AIBN were commercially available and used without further purification. Bu_3SnLi,[7] $Bu_3SnZnCl$,[8] $Bu_3SnZnBr$,[8] $(Bu_3Sn)_2Zn$,[8] $Bu_3SnSiMe_3$,[7] $Bu_3SnSnBu_3$,[7] $Bu_3SnAlEt_2$,[8] $Bu_3SnMgCl$,[4] $Bu_3SnOCOEt$,[9] $Bu_3SnOCOCHMe_2$,[9] and $Bu_3SnOCOPh$[9] were prepared from the method described in the literatures.

Cannizzaro Type Reaction of Aldehyde with Grignard and Stannylmetal Reagents. After dropwise addition of benzaldehyde into an ethereal solution of ethyl Grignard reagent, the solution was refluxed for 2 h. The resulting reaction mixture was hydrolyzed with aqueous saturated ammonium chloride, and extracted with ether. The extracts were analyzed by GLC and ethyl phenyl ketone and benzyl alcohol were detected as products. Other reactions with Grignard reagents and the reactions of propanal with various stannylmetals were also carried out similarly.

Preparation of Acyltributyltins. Tributyltin hydride (45 g, 0.15mmol) was added to a solution of the Grignard reagent prepared from 14.1 g of isopropyl chloride (0.18 mol) and 4.4 g of magnesium (0.18 mol). The solution was then refluxed for an hour. The flask was cooled with an ice bath and 26.1 g of propanal (0.45 mol) was added into the solution dropwisely, which was further refluxing for an hour. Subsequent treatment of the resulting reaction mixture with aqueous ammonium chloride was carried out. Distillation under reduced pressure gave 32 g of propanoyltributyltin (62% yield). 2-Methylpropanoyltin (59%) and crude benzoyltin (64% yield) were obtained similarly. However, the latter was decomposed on heating under reduced pressure. Physical data of acyltins are shown in Table 1.

Reaction of Propanoyltributyltin with Oxygen. The disappearance of propanoyltributyltin in the presence of Galvinoxyl or AIBN was followed by GLC. The results are shown in Figs. 1 and 2.

The gift of tributyltin oxide by Hokkoh Kagaku Kogyo Co. Ltd. is gratefully acknowledged. The present work was partially supported by a Grant-in-Aid for Special Project Research No. 61225002 from the Ministry of Education, Science and Culture.

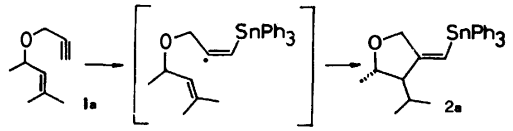
Synthesis of α-Methylene-γ-butyrolactones via Addition of Tin Hydride to Enynes Induced by Triethylborane

Kyoko NOZAKI, Koichiro OSHIMA,* and Kiitiro UTIMOTO
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606
(Received April 25, 1987)

Synopsis. Et_3B induced addition of Ph_3SnH to suitably constituted enynes provides (triphenylstannylmethylene) oxolanes stereoselectively in one pot. Destannylation followed by oxidation affords α-methylene-γ-butyrolactones in fair yields.

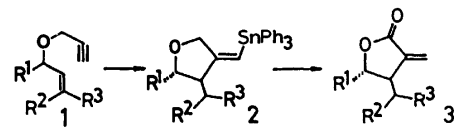
We have recently shown[1] that triphenyltin hydride adds easily to acetylenes regioselectively in the presence of Et_3B under mild conditions. The reaction has been found to be effective for vinyl-radical cyclization[2] of suitably constituted acetylenic olefins.[1,3] Here we wish to report the applicaton of this new method to the stereoselective synthesis of α-methylene-γ-butyrolactones, which represent a major class of known natural products and possess wide-ranging biological activities.[4]

A hexane solution of Et_3B was added to a solution of Ph_3SnH and enyne, 1,3-dimethyl-2-butenyl propargyl ether (**1a**) in toluene at 25 °C under an argon atmosphere. The mixture was stirred for 3 h at 25 °C and workup followed by preparative tlc purification gave cyclized product **2a** in 84% yield.



The results are summarized in Table 1. The yields of cyclized products depend on the concentration of the substrate and Ph_3SnH. High dilution favors the formation of the desired cyclized product **2**. On the other hand, without solvent or high concentration provided uncyclized product along with **2**.[5] It is worth noting that the cyclized products, **2a—d**, consist of only (Z)-trans-isomer independently of the stereochemistry of the double bond in the starting enynes (**1c** and **1d**). In contrast, treatment of **1e** with Ph_3SnH gave cis-fused oxolane **2e** exclusively which is thermodynamically more stable than trans-isomer.

Table 1. Synthesis of α-Methylene-γ-butyrolactone



1	R^1	R^2	R^3	Yield/%	
				2	3[a]
a	Me	Me	Me	84	57
b	Ph	Me	Me	70	39

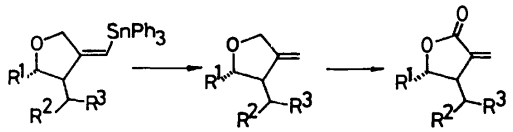
d	Me	*n*-Bu	H	75	59
e	$-(CH_2)_4-$		H	71[b]	31

a) Overall yield from **2**. b) Cis product was obtained. See experimental part.

Destannylation[6] (*n*-BuLi/THF and H_2O) followed by oxidation[7] with $CrO_3 \cdot 2py$ gave the desired α-methylene-γ-butyrolactones.[8]



Experimental

The IR spectra were determined on a JASCO IR-810 spectrometer, the mass spectra on a Hitachi M-80 machine, the ^1H NMR spectra were recorded on a Varian EM-390H and XL-200 spectrometers, and the ^{119}Sn NMR spectra on a JEOL JNM-FX 90Q spectrometer. The chemical shifts of the proton NMR are given in δ with TMS as an internal standard, and those of the ^{119}Sn NMR are given in δ with Me_4Sn as an internal standard. The analyses were performed at the Elemental Analyses Center of Kyoto University. Tetrahydrofuran was dried in benzophenone ketyl and distilled. All the experiments were carried out under an argon atmosphere.

Preparation of Alkenyl Propargyl Ether. Generation of (*E*)-1-butyl-2-hexenyl propargyl ether (**1c**) is representative. A hexane solution of butyllithium (1.5 M, 1 M=1 mol dm^{-3}, 13.3 ml, 20.0 mmol) was added to a solution of (*E*)-2-hexenal (1.96 g, 20.0 mmol) in THF (30 ml) at 0 °C. After stirring for 15 min, HMPA (5 ml) and propargyl bromide (1.87 ml, 21.0 mmol) was added. The resulting mixture was stirred at 0 °C for 15 min, then at 25 °C for 3 h. Workup (AcOEt, 1 M HCl) followed by purification by silica-gel column chromatography and distillation gave **1c** (2.6 g, 67% yield) as a colorless oil: Bp 120 °C (20 Torr, 1 Torr=133.322 Pa); IR (neat) 3308, 2956, 2928, 2860, 1655, 1638, 1459, 1076 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.84—0.97 (m, 6H), 1.27—1.70 (m, 8H), 2.00—2.12 (m, 2H), 2.37 (dd, *J*=2.0, 2.0 Hz, 1H), 3.75—3.87 (m, 1H), 4.01 (dd, *J*=16.0, 2.0 Hz, 1H), 4.18 (dd, *J*=16.0, 2.0 Hz, 1H), 5.25 (dd, *J*=15.5, 9.0 Hz, 1H), 5.65 (dt, *J*=15.5, 6.5 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=13.6, 14.0, 22.3, 22.6, 27.6, 34.2, 35.2, 54.6, 73.4, 79.8, 80.5, 129.9, 135.1. Found: C, 80.34; H, 11.64%. Calcd for $C_{13}H_{22}O$: C, 80.35; H, 11.41%.

1,3-Dimethyl-2-butenyl Propargyl Ether (1a): Bp 120 °C (760 Torr); IR (neat) 3300, 2972, 2928, 1671, 1445, 1376, 1265, 1208, 1150, 1104, 1077, 1037, 844 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.20 (d, *J*=7.0 Hz, 3H), 1.69 (s, 3H), 1.72 (s, 3H), 2.38 (bs, 1H), 4.02 (d, *J*=15.0 Hz, 1H), 4.13 (d, *J*=15.0 Hz, 1H), 4.40 (dq, *J*=10.0, 7.0 Hz, 1H), 5.02 (d, *J*=10.0 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=18.0, 21.2, 25.27, 54.4, 70.5, 73.3, 80.6, 126.2, 136.3.

1-Phenyl-3-methyl-2-butenyl Propargyl Ether (1b): Bp

160 °C (20 Torr); IR (neat) 3290, 2968, 2916, 2852, 1451, 1376, 1066, 1027, 755, 698 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.76 (s, 3H), 1.83 (s, 3H), 2.42 (dd, J=2.4, 2.4 Hz, 1H), 4.07 (dd, J=17.0, 2.4 Hz, 1H), 4.20 (dd, J=17.0, 2.4 Hz, 1H), 5.33 (s, 2H PhCH-OCH_2+Me_2C=CH), 7.35 (m, 5H), ^{13}C NMR ($CDCl_3$) δ 18.4, 26.0, 54.8, 74.0, 76.5, 80.4, 125.2, 126.8, 127.6, 128.5, 137.1, 142.1. Found: C, 67.36; H, 6.52%. Calcd for $C_{29}H_{34}OSn$: C, 67.34; H, 6.63%.

(*Z*)-*cis*-Hexahydro-3-(triphenylstannylmethylene)benzofuran (2e): Mp 85 °C (hexane); IR (neat, before crystallization) 3060, 2928, 2825, 1623, 1480, 1428, 1074, 1052, 727, 697 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.20—1.83 (m, 8H), 2.63—2.77 (m, 1H), 4.00—4.33 (m, 3H), 6.06 (s, 1H), 7.35—7.80 (m, 15H); ^{13}C NMR ($CDCl_3$) δ=21.4, 23.0, 27.2, 27.8, 46.8, 71.3, 78.0, 110.3, 128.6, 129.0, 136.8, 138.2, 166.4; ^{119}Sn NMR ($CDCl_3$) δ=−143.01. Found: C, 66.36; H, 5.77%. Calcd for $C_{27}H_{28}OSn$: C, 66.56; H, 5.79%.

Typical Procedure for Destannylation. Butyllithium (1.5 M hexane solution, 2.7 ml, 4.0 mmol) was added to a soluton of (triphenylstannylmethylene)oxolane (**2a**) (0.49 g, 1.0 mmol) in THF (5 ml) at −78 °C. After stirring for 15 min, MeOH (1.0 ml) was added and the resulting mixture was allowed to warm to 25 °C. The mixture was poured into 1 M HCl solution and extracted with ethyl acetate. The organic extracts were washed with brine, dried (Na_2SO_4), and concentrated. The crude product was purified by preparative TLC (silica gel, hexane-ethyl acetate=20:1) to give (*Z*)-*trans*-3-isopropyl-2-methyl-4-methyleneoxolane (IR (neat) 3064, 2956, 2924, 2872, 1659, 1459, 1371, 1090, 1048 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.94 (d, J=6.8 Hz, 3H), 0.96 (d, J=6.9 Hz, 3H), 1.24 (d, J=6.2 Hz, 3H), 1.68—1.97 (m, 1H), 2.08—2.20 (m, 1H), 3.98—4.17 (m, 1H), 4.24 (d, J=12.5 Hz, 1H), 4.36 (d, J=12.5 Hz, 1H), 4.96 (bs, 1H), 5.01 (bs, 1H)) which was contaminated by unidentified compounds and converted into α-methylene-γ-butyrolactone without further purification.

Transformation of Methyleneoxolane to α-Methylene-γ-butyrolactone. According to the procedure described in the literature,[7] methyleneoxolane derived from **2a** was oxidized with Collins reagent to give *trans*-4,5-dihydro-4-isopropyl-5-methyl-3-methylene-2(3*H*)-furanone (**3a**, 88 mg, 57% yield): Bp 90 °C (bath temp, 20 Torr); IR (neat) 2962, 2928, 2874, 1762, 1654, 1459, 1275, 1126, 1099, 1033 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.94 (d J=6.7 Hz, 3H), 0.95 (d, J=6.9 Hz, 3H), 1.37 (d, J=6.4 Hz, 3H), 1.84—2.05 (m, 1H), 2.52—2.61 (m, 1H), 4.47 (dq, J=3.3, 6.4 Hz, 1H), 5.62 (d, J=2.1 Hz, 1H), 6.35 (d, J=2.1 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=18.2, 19.0, 22.7, 31.4, 52.1, 76.8, 123.5, 137.6, 170.7. Found: m/z 154.0831, 139.0744. Calcd for $C_9H_{14}O_2$: M, 154.0992, M−CH_3, 139.0758.

***trans*-4,5-Dihydro-4-isopropyl-3-methylene-5-phenyl-2(3*H*)-furanone (3b)**: Bp 120 °C (bath temp, 20 Torr); IR (neat) 2960, 2872, 1765, 1656 1458, 1401, 1390, 1270, 1126, 1021, 1001, 964 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.01 (d, J=5.7 Hz, 3H), 1.05 (d, J=5.6 Hz, 3H), 1.95—2.13 (m, 1H), 2.85—2.93 (m, 1H), 5.31 (d, J=2.9 Hz, 1H), 5.65 (d, J=2.2 Hz, 1H), 6.41 (d, J=2.2 Hz, 1H), 7.49—7.70 (m, 5H); ^{13}C NMR ($CDCl_3$) δ=18.5, 18.9, 32.2, 53.6, 81.1, 123.9, 125.3, 128.3, 128.8, 136.8, 140.6, 170.6. Found: C, 77.47; H, 7.65%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

***trans*-4,5-Dibutyl-4,5-dihydro-3-methylene-2(3*H*)-furanone (3c)**:[9] Bp 155 °C (bath temp, 20 Torr); IR (neat) 2954, 2928, 2860, 1763, 1467, 1459, 1268, 1151, 1110 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.90—1.01 (m, 6H), 1.33—1.76 (m, 12H), 2.60—2.75 (m, 1H), 4.22 (dt, J=4.1, 6.2 Hz, 1H), 5.59 (d, J=2.4 Hz, 1H), 6.26 (d, J=2.4 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=13.9, 22.4, 22.6, 27.2, 28.5, 33.9, 35.9, 44.5, 83.5, 122.0, 139.5, 170.3.

***trans*-4,5-Dihydro-5-methyl-4-pentyl-3-methylene-2(3*H*)-furanone (3d)**: Bp 150 °C (bath temp, 20 Torr); IR (neat) 2956, 2928, 2856, 1764, 1664, 1459, 1402, 1382, 1271, 1162, 1126, 1102, 1053, 948, 815 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.90 (t, J=5.0 Hz, 3H), 1.33—1.74 (m, 9H), 1.41 (d, J=6.3 Hz, 3H), 2.56—2.70 (m, 1H), 4.37 (dq, J=4.8, 6.3 Hz, 1H), 5.59 (d, J=2.6 Hz, 1H), 6.26 (d, J=2.6 Hz, 1H); ^{13}C NMR ($CDCl_3$)

δ=13.9, 21.7, 22.4, 26.1, 31.7, 33.5, 46.3, 79.8, 121.9, 139.6, 170.3. Found: C, 72.55; H, 10.24%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.95%.

***cis*-Hexahydro-3-methylene-2(3*H*)-benzofuranone (3e)**: The compound was obtained from **1e** in similar fashion described for the conversion of **1a** into **3a**. The physical deta of **3e** were identical with those in the literature.[10]

Financial support by the Ministry of Education, Science, and Culture, (Grant-in-Aid for Special Project Research No. 61211016) is acknowledged.

Palladium Catalyzed Hydrostannylation and Hydrogermylation of Acetylenes

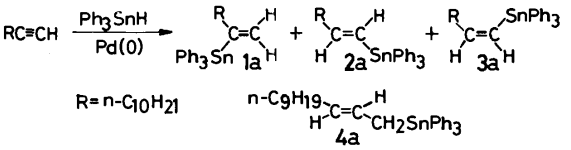
Yoshifumi ICHINOSE, Hiroji ODA, Koichiro OSHIMA,* and Kiitiro UTIMOTO
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606
(Received April 27, 1987)

Synopsis. Treatment of acetylenes with Ph_3SnH or Ph_3GeH in the presence of a catalytic amount of $Pd(PPh_3)_4$ provides the corresponding alkenyltriphenylstannanes or alkenyltriphenylgermanes in good yields.

Transition-metal-catalyzed hydrosilylation reaction has been extensively developed.[1] On the other hand, hydrostannylation[2] and hydrogermylation[3] have not been well-established. Here we wish to disclose the hydrostannylation and hydrogermylation of acetylenic compounds in the presence of a palladium catalyst to give the corresponding alkenyltriphenylstannanes and alkenyltriphenylgermanes.

The hydrostannylation or hydrogermylation of acetylenes takes place readily in the presence of a catalytic amount of free radical initiator such as azobisisobutyronitrile (AIBN) to give the corresponding alkenylstannanes or alkenylgermanes in good yields.[4] The reaction is regioselective but nonstereoselective. Thus, terminal acetylenes give 1-stannyl-1-alkenes or 1-germyl-1-alkenes as stereoisomeric mixtures (E and Z) upon treatment with R_3SnH or R_3GeH.

On the other hand, triphenylstannane adds to acetylenes in the presence of a catalytic amount of $Pd(PPh_3)_4$ to give a mixture of three isomeric alkenyltriphenylstannanes. The representative results are summarized in Table 1. (E)-Isomer **2** (cis addition products) predominates and (Z)-isomers **3** and its regio isomers **1** are obtained as minor products. Solvents (CH_2Cl_2, THF, and benzene) did not affect the isomeric ratios of the products. Palladium complexes such as $PdCl_2(PPh_3)_2$, $PdCl_2(CH_3CN)_2$, and $Pd(OAc)_2$ are equally effective as $Pd(PPh_3)_4$. Distribution of the isomeric products depends on the ligand on palladium. For instance, the reaction of 1-dodecyne with Ph_3SnH in the presence of $PdCl_2(n\text{-}Bu_3P)_2$ or $Pd(OAc)_2$-$(p\text{-}MeOC_6H_4)_3P$ combination[5] provided a mixture of **1a**, **2a**, and **3a** (**1a**:**2a**:**3a**=10:80:10) as $Pd(PPh_3)_4$. Meanwhile, $PdCl_2[P(o\text{-}MeC_6H_4)_3]_2$-catalyzed reaction gave (*E*)-1-triphenylstannyl-2-dodecene (**4a**) in 42% yield along with **1a** (3%), **2a** (24%), and **3a** (2%).[6] Catalysts such as $Pd(OAc)_2$ and $PdCl_2(CH_3CN)_2$ without phosphine compounds were also effective for the addition of Ph_3SnH to acetylenes to give allylic stannane as a major product. For instance, 1-dodecyne gave a mixture of **4a** and **2a** (**4a**:**2a**=7:3, combined yield 65—75%) upon treatment with Ph_3SnH in the presence of these palladium salts.



Hydrogermylation reaction could also be catalyzed by $Pd(PPh_3)_4$. The use of $Pd(PPh_3)_4$ was essential for the successful reaction. Triphenylgermane is less reactive hydrogen donor than Ph_3SnH and can not

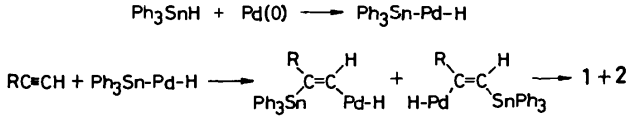
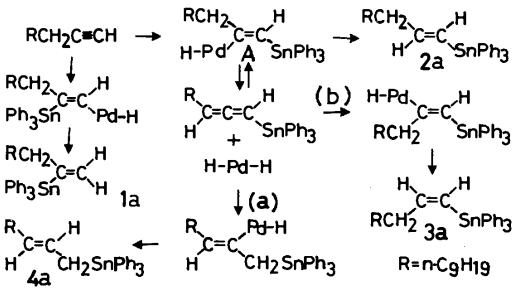
a) (*E*)-6-Triphenylgermyl-6-dodecene (**5a**) and (*E*)-7-triphenylgermyl-5-dodecene (**8**) were obtained (**5a**:**8**=1:2).

reduce $PdCl_2(PPh_3)_2$, $PdCl_2(CH_3CN)_2$, and $Pd(OAc)_2$ to zerovalent palladium which is an active catalyst for the reaction. Thus, these palladium complexes were not effective for the hydrogermylation. In contrast to hydrostannylation, the reaction of terminal acetylenes proceeds stereoselectively[7] and no (Z)-isomers are formed (Table 1). 6-Dodecyne gave a mixture of alkenylgermane **5e** and allylic germane, (*E*)-7-triphenylgermyl-5-dodecene (**8**).

We are tempted to assume following reaction mechanism: (1) Oxidative addition of Ph_3SnH (Ph_3GeH) to Pd(0), (2) stannylpalladation (cis addition),



and (3) reductive elimination to produce alkenylstannanes (alkenylgermanes) and regenerate the palladium(0) complex. The formation of allylic stannane **4a** and allylic germane **8** presumably is explained by elimination of a palladium hydride from vinylpalladium species **A** and subsequent readdition in the opposite end of the 1,2-diene system followed by reductive elimination (path (a) in Scheme 1). The path (b) in Scheme 1 (readdition followed by reductive elimination) may explain the formation of (Z)-isomer **3**.[8]



Scheme 1.

Experimental

General Procedure for the Reaction of Acetylenic Compounds with Triphenylstannane in the Presence of $Pd(PPh_3)_4$. The reaction of 1-dodecyne with Ph_3SnH is representative. $Pd(PPh_3)_4$ (58 mg, 0.05 mmol) was added to a solution of 1-dodecyne (0.17 g, 1.0 mmol) and Ph_3SnH (0.43 g, 1.2 mmol) in CH_2Cl_2 (10 ml) under an argon atmosphere. The reaction mixture was stirred at 25 °C for 5 h, then poured into water, and extracted with 3 portions of ethyl acetate. The organic extracts were dried (Na_2SO_4) and evaporated. Purification by preparative TLC on silica gel provided a mixture of 2-triphenylstannyl-1-dodecene (**1a**), (*E*)-1-triphenylstannyl-1-dodecene (**2a**), and (Z)-isomer **3a** in 77% combined yield (**1a**:**2a**:**3a**=11:82:7, the isomeric ratio was determined by its ^1H NMR spectrum). The spectral data were identical with those reported in the literature.[9] Phenylacetylene and 4-benzyloxy-1-butyne were treated with Ph_3SnH under the same reaction conditions to give the corresponding mixture of alkenylstannanes whose IR, ^1H NMR, and ^{119}Sn NMR spectra were identical with those reported.[9]

(*E*)-1-Trimethylsilyl-2-triphenylstannylethane: Mp 74 °C (hexane); IR (Nujol) 2950, 1482, 1428, 1246, 1160, 1077, 1016, 861, 838, 724, 696 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.01 (s, 9H), 6.91 (d, J=22.5 Hz, 1H), 7.14 (d, J=22.5 Hz, 1H), 7.30—7.50 (m, 9H), 7.50—7.81 (m, 6H); ^{119}Sn NMR ($CDCl_3$) δ=−147.0. Found: C, 61.09; H, 5.75%. Calcd for $C_{23}H_{26}SiSn$: C, 61.49; H, 5.83%.

(*E*)-6-Triphenylstannyl-6-dodecene: Bp 170 °C (bath temp, 0.3 Torr, 1 Torr=133.322 Pa); IR (neat) 3060, 3012, 2953, 2922, 2852, 1480, 1465, 1458, 1428, 1074, 725, 697 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.72—0.84 (m, 6H), 0.85—1.55 (m, 12H), 2.01 (dt, J=7.2, 7.2 Hz, 2H), 2.28 (t, J=7.1 Hz, 2H), 6.32 (t, J=7.2 Hz, 1H), 7.3—7.8 (m, 15H); ^{119}Sn NMR ($CDCl_3$) δ=−139.4. Found: C, 69.66; H, 7.51%. Calcd for $C_{30}H_{38}Sn$: C, 69.65; H, 7.40%.

General Procedure for the Hydrogermylation of Acetylenes. 1-Dodecyne (0.17 g, 1.0 mmol) and Ph_3GeH (0.36 g, 1.2 mmol) were combined in THF (10 ml). $Pd(PPh_3)_4$ (58 mg, 0.05 mmol) was added to the solution and the resulting mixture was stirred at 25 °C for 5 h under an argon atmosphere. Workup (AcOEt, brine) followed by silica-gel TLC purification gave alkenyltriphenylgermane (0.46 g, 97% combined yield) as a 14:86 (**5a**:**6a**) mixture of regioisomers as determined by the integrations of the olefinic protons in the ^1H NMR spectrum: Bp 120 °C (bath temp, 0.1 Torr); IR (neat) 2880, 2820, 1425, 1085, 730, 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.8—0.98 (m, 3H), 1.04—1.51 (bm, 16H), 2.18—2.35 (m, 2H), 5.39 (m, 0.14H), 5.90 (m, 0.14H), 6.12—6.23 (m, 1.72H), 7.32—7.65 (m, 15H). Found: C, 76.23; H, 8.15%. Calcd for $C_{30}H_{38}Ge$: C, 76.47; H, 8.13%.

2-Tripropylgermyl-1-dodecene (5c′) and (*E*)-1-Tripropylgermyl-1-dodecene (6c′) (5c′:6c′=20:80): Bp 88 °C (bath temp, 0.08 Torr); IR (neat) 2890, 2820, 1455, 1065, 690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.67—1.02 (m, 24H), 1.17—1.51 (bm, 16H), 2.03—2.19 (m, 2H), 5.12 (m, 0.2H), 5.54 (m, 0.2H), 5.68 Found: C, 68.46; H, 11.94%. Calcd for $C_{21}H_{44}Ge$: C, 68.32; H, 12.01%.

1-Phenyl-1-triphenylgermylethene (5b) and (*E*)-1-Phenyl-2-triphenylgermylethene (6b) (5b:6b=9:91): Mp 144—146 °C (benzene-hexane(1:1)); IR (CCl_4) 3020, 1480, 1425, 1085, 985, 710, 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.61 (d, J=2.3 Hz, 0.09 H), 6.30 (d, J=2.3 Hz, 0.09 H), 6.95 (d, J=18.9 Hz, 0.91H), 7.05 (d, J=18.9 Hz, 0.91H), 7.25—7.63 (m, 20H). Found; C, 76.55; H, 5.39%. Calcd for $C_{26}H_{22}Ge$: C, 76.72; H, 5.45%.

2-Triphenylgermyl-4-benzyloxy-1-butene (5c) and (*E*)-1-Triphenylgermyl-4-benzyloxy-1-butene (6c) (5c:6c:7c=7:91:<2): Bp 129 °C (bath temp, 0.08 Torr); IR (neat) 1425, 1090, 735, 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.57 (dt, J=6.7, 6.0 Hz, 2H), 3.59 (t, J=6.7 Hz, 2H), 4.52 (s, 2H), 5.50 (bs, 0.07H), 6.01 (bs, 0.07H), 6.14 (dt, J=18.2, 6.0 Hz, 0.91H), 6.31 (d, J=18.2 Hz, 0.91H), 7.28—7.62 (m, 20H). (*E*)-2-Triphenylgermyl-1-buten-4-ol (6f): Mp 111—113 °C (hexane-CH_2Cl_2); IR (KBr) 3318, 1638, 1484, 1430, 1091, 1039, 999, 983, 735, 698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.55 (s, 1H), 2.49 (dt, J=6.3, 6.4 Hz, 2H), 3.69 (dt, J=6.4 Hz, 2H), 6.09 (dt, J=18.3, 6.3 Hz, 1H), 6.35 (d, J=18.3 Hz, 1H), 7.44—7.62 (m, 9H), 7.62—7.87 (m, 6H); ^{13}C NMR ($CDCl_3$) δ=39.9, 61.4, 127.3, 128.1, 128.9, 134.9, 136.4, 146.1. Found: C, 70.35; H, 5.82%. Calcd for $C_{22}H_{22}OGe$: C, 70.46; H, 5.81%.

(*E*)-1-Trimethylsilyl-2-triphenylgermylethene (6d): Mp 92—94 °C (hexane); IR (KBr) 1430, 1245, 1092, 870, 834, 735, 694 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.14 (s, 9H), 6.78 (d, J=21.8 Hz, 1H), 7.14 (d, J=21.8 Hz, 1H), 7.32—7.47 (m, 9H), 7.47—7.67 (m, 6H); ^{13}C NMR ($CDCl_3$) δ=−1.5, 128.2, 128.9, 135.4, 136.5, 143.1, 155.2. Found: C, 68.41; H, 6.51%. Calcd for $C_{23}H_{26}SiGe$: C, 68.52; H, 6.50%.

(*E*)-6-Triphenylgermyl-6-dodecene (6d) and (*E*)-7-Tri-

phenylgermyl-5-dodecene (8): Bp 165 °C (bath temp, 0.2 Torr); IR (neat) 3048, 2922, 2852, 1430, 1090, 733, 697 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.69—1.01 (m, 6H), 1.01—1.51 (m, 10H), 1.89—2.10 (m, 2H), 2.15—2.37 (m, 2H), 2.58—2.73 (m, 1.33H), 5.24—5.50 (m, 1.33H), 5.80 (t, J=7.0 Hz, 0.33H), 7.05—7.23 (m, 9H), 7.23—7.42 (m, 6H). Found: C, 76.31; H, 8.14%. Calcd for $C_{30}H_{38}Ge$: C, 76.46; H, 8.13%.

Reaction of 1-Dodecyne with Ph_3SnH in the Presence of $PdCl_2[P(o\text{-}MeC_6H_4)_3]_2$. A catalytic amount of $PdCl_2[P(o\text{-}MeC_6H_4)_3]_2$ (35 mg, 0.05 mmol) was added to a solution of 1-dodecyne (0.17 g, 1.0 mmol) and Ph_3SnH (0.42 g, 1.2 mmol) at 25 °C under an argon atmosphere. The resulting mixture was stirred at 25 °C for 6 h. The mixture was poured into water and extracted with ethyl acetate. The organic layers were dried (Na_2SO_4) and concentrated. The residual oil was submitted to preparative TLC (hexane as eluant) gave a mixture of **1a** (15 mg, 3%), **2a** (0.12 g, 24%), **3a**, (10 mg, 2%), and (*E*)-1-triphenylstannyl-2-dodecene (**4a**) (0.22 g, 42%). **4a**: ^1H NMR ($CDCl_3$) δ=2.38 (d, J=6.0 Hz, 2H), 5.40 (dt, J=15.0, 8.0 Hz, 1H), 5.51 (dt, J=15.0, 7.0 Hz, 1H).

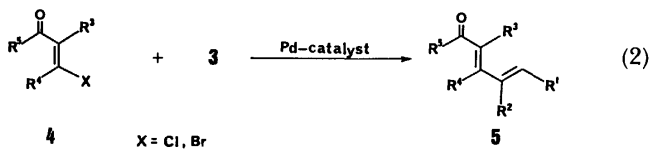
Stereoselective Synthesis of Conjugated Dienones via the Palladium-Catalyzed Cross-Coupling Reaction of 1-Alkenylboronates with 3-Halo-2-alken-1-ones

Naoyuki SATOH, Tatsuo ISHIYAMA, Norio MIYAURA, and Akira SUZUKI*
Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received April 27, 1987)

Synopsis. The synthesis of conjugated dienones by means of palladium-catalyzed cross-coupling reaction between (*E*)-1-alkenyl-1,3,2-benzodioxaboroles or diisopropyl (*Z*)-1-hexenylboronate with 3-halo-2-alken-1-ones is described.

In our recent papers,[1-3] we reported a stereoselective synthesis of (*E,E*)-, (*E,Z*)-, (*Z,E*)-, and (*Z,Z*)-alkadienes and trienes by the palladium-catalyzed cross-coupling reaction of (*E*)- or (*Z*)-1-alkenylboronates and (*E*)- or (*Z*)-1-halo-1-alkenes. In this paper, we describe the development of reaction for the synthesis of conjugated dienones **5** as shown in Eqs. 1 and 2.

Since 1-alkenylboronates are quite inert toward many functional groups including carbonyl, the coupling reaction can be carried out without any protection of these groups. On the other hand, the reaction proceeds in the presence of bases such as sodium alkoxides and hydroxide. Consequently, vinylic halides with functional groups sensitive to base, such as halo enones **4** may cause difficulties.



(*E*)-1-Hexenyl-1,3,2-benzodioxaborole (**3**, R^1=*n*-Bu, R^2=H) was initially chosen, and its reaction with 3-bromo-5,5-dimethyl-2-cyclohexen-1-one (**4**, R^3=H, R^4, R^5=CH_2–CMe_2–CH_2) was investigated under various different conditions as shown in Table 1.

Unlike our earlier palladium-catalyzed reactions,[1-3] relatively weak bases such as sodium acetate and triethylamine are effective in obtaining high yields of the coupling product **6**. The solvent also appears to play a critical role in determining the yield of **6**. Comparison of THF, DMF, and MeOH as solvents under various conditions demonstrates that the higher yields of dienone **6** are obtained in a methanol solution. When THF and DMF are employed as solvents, a substantial amount of the head-to-tail coupling product **7**[4] was prepared as a by-product. The solvent effect seems to be concerned with the mechanism of cross-coupling. We previously proposed a mechanism[1] which involves the intermediacy of alkoxopalladium(II) complexes for the cross-coupling reaction of 1-alkenylboronates with 1-halo-1-alkenes. The present reaction should also involve a methoxopalladium(II) **9**, prior to the transmetalation with 1-alkenylboronates. Such an exchange reaction of ligand in **8** can be accelerated by the trans effect[5] of electron-withdrowing carbonyl group, which may be a major reason to explain the difference between the present and former results.[1-3] All of the palladium complexes studied were proved to be used in catalytic amounts. Both palladium(II) acetate and dichlorobis(triphenylphosphine)palladium(II) appear to be more effective than tetrakis(triphenylphosphine)palladium(0). Thus, we used $PdCl_2(PPh_3)_2$ and sodium acetate in refluxing methanol as a general procedure for the reaction. Under these conditions, the coupling with 1-alkenylboronates is fortunately faster than the nucleophilic displacement of halogen in **4** with sodium acetate or other side reactions such as aldol condensation. The full scope of this cross-coupling reaction has been investigated by using a variety of 1-alkenylboronates **3** and halo enones **4**. The results are summarized in Table 2.

Table 1. Effects of Reaction Conditions for Cross-Coupling of (*E*)-1-Hexenyl-1,3,2-benzodioxaborole with 3-Bromo-5,5-dimethyl-2-cyclohexen-1-one[a]

Catalyst	Base	Solvent	Yield/%[b]	(**6**:**7**)
$Pd(OAc)_2$	NaOAc	MeOH	91	(100: 0)
$Pd(OAc)_2$	NaOAc	DMF	65	(41:59)
$Pd(OAc)_2$	Et_3N	DMF	37	(37:63)
$Pd(OAc)_2$	Et_3N	THF	23	(60:40)
$Pd(OAc)_2$	Et_3N	MeOH	97	(100: 0)
$Cl_2Pd(PPh_3)_2$	NaOAc	MeOH	98	(100: 0)
$Pd(PPh_3)_4$	NaOAc	MeOH	33	(100: 0)

a) Reactions were carried out under conditions described in the text. b) Yields are based on the haloenone used.

Diisopropyl (*Z*)-1-hexenylboronate **10a**[13] prepared by the hydroboration of 1-bromo-1-hexyne with dibromoborane, followed by the reaction with 2-propanol and potassium hydrotriisopropoxyborate also gave the dienone **11a** preserving the stereochemistry of (Z)-double bond, Z>96% (Eq. 3). The reaction of diisopropyl (*E*)-(1-methyl-1-hexenyl)boronate (**10b**) with 3-chloro-5,5-dimethyl-2-cyclohexen-1-

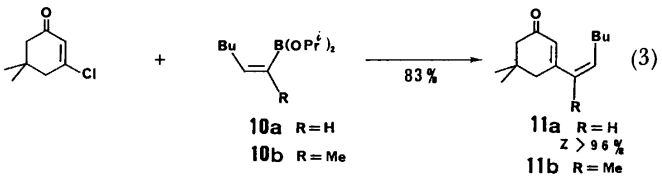
one was reported elsewhere.[3]



(3)

Conjugated dienones and polyenones are promising versatile intermediates for the synthesis of naturally occurring compounds. Most recently, we reported a stereoselective synthesis of a fungal prohormone (±)trisporol B[6] by means of such a crosscoupling reaction of 1-alkenylboronates. The present reaction affords an alternative and general procedure of obtaining stereodefined conjugated dienones and trienones.

Experimental

All reactions were carried out under nitrogen atmosphere. 1-Hexyne, 3,3-dimethyl-1-butyne, phenylethyne, and 3-hexyne are commercial products and purified by distillation before use. 1-Cyclohexenylethyne was prepared according to the method reported by Brandsma.[7] 3-Halo-2-cycloalkene-1-ones[8,9] were prepared from the corresponding 1,3-cycloalkadienones.

The IR spectra were recorded on a Hitachi-Perkin Elmer Model 125 spectrometer. The ^{1}H NMR spectra were taken on a Hitachi R-22 spectrometer (90 MHz, TMS as the internal reference). The measurement of mass spectra was carried out on a JEOL JMS-D 300 spectrometer (70 eV).

Palladium Complexes. Palladium(II) acetate was commercial. Dichlorobis(triphenyphosphine)palladium(II)[10] and tetrakis(triphenylphosphine)palladium(0)[11] were prepared according to the reported procedures.

1-Alkenylboronate 3. 1-Alkenyl-1,3,2-benzodioxaboroles were prepared by the Brown's method[1,12] from 1,3,2-benzodioxaborole (catecholborane) and 1-alkynes, and they were purified by distillation before use; **3a** (R^1=*n*-Bu, R^2=H): Bp 86—87 °C/ 0.3 mmHg (1 mmHg=133.322 Pa) (lit,[12] 82 °C/0.25 mmHg); **3b** (R^1=*t*-Bu, R^2=H): Bp 128 °C/ 12 mmHg; **3c** (R^1=Et, R^2=Et): Bp 63 °C/0.1 mmHg (lit,[12] 81 °C/0.2 mmHg); **3d** (R^1=phenyl, R^2=H): Mp 78 °C (lit,[12] 78—78.5 °C); **3e** (R^1=cyclohexenyl, R^2=H): Bp 135—149 °C/0.1 mmHg, Mp 76—79 °C. 1-Alkenylboronates except **3e** are stable toward air and can be handled by the usual method.

Reaction Conditions (Table 1). The best conditions for the formation of conjugated dienone **6** were determined by the following general procedure. The palladium complex (0.03 mmol), an appropriate solvent (3.5 ml of MeOH, DMF, or THF), base (1.5 mmol of NaOAc or Et_3N), and 3-bromo-5,5-dimethyl-2-cyclohexen-1-one (1.0 mmol) were placed in a 25 ml-flask, and flushed with nitrogen. (*E*)-1-Hexenyl-1,3,2-benzodioxaborole (1.1 mmol) was then added by means of a hypodermic syringe through the septum inlet, and the resultant mixture was heated under reflux for 3 h. In the case of DMF, the reaction temperature was controlled at 80 °C for 3 h. After the completion of reaction, the mixture was cooled to room temperature and the residual organoborane was oxidized with an aqueous solution (3 M (1 M=1 mol dm^{-3}), 0.2 ml) of NaOH-H_2O_2 (30% solution, 0.2 ml) for 1 h. The product was extracted with benzene, washed with brine, dried over $MgSO_4$, and analyzed directly by GLC (15% SE-30 on Uniport B, 2 m). The product was isolated by column chromatography over silica gel with hexane/ether. **6**: Bp 90—93 °C/0.1 mmHg; n^{22}=1.5149; IR

(film) 3040, 1670, 1635, 1595, and 975 cm^{-1}; ^1H NMR (CCl_4) δ=0.93 (t, 3H, J=6.5 Hz), 1.08 (s, 6H), 1.2—1.7 (m, 4H), 2.0—2.3 (m, 6H), 5.78 (broad s, 1H), 6.0 (dt, 1H, J=6.5 and 16 Hz) and 6.26 (d, 1H, J=16 Hz); Found:C 81.27; H, 10.55%. Calcd for $C_{14}H_{22}O$: C, 81.50; H, 10.75%.

Standard Procedure for the Synthesis of Dienone 5c (Table 2). In a dry 100 ml-flask equipped with a septum inlet and a magnetic stirring bar were placed $PdCl_2(PPh_3)_2$ (0.21 g, 0.3 mmol) and NaOAc (1.23g, 15 mmol). The flask was flushed with nitrogen and charged with 15 ml anhydrous methanol, 3-halo-2-alken-1-one (10 mmol), and 1-alkenyl-1,3,2-benzodioxaborole (11 mmol). The reaction mixture was then refluxed for 3 h. After completion of the reaction, aqueous NaOH (0.5 ml of a 3 M solution) and 30%-H_2O_2 (0.5 ml) were added at room temperature in order to oxidize the unreacted borane. The product was extracted with benzene, washed with brine and dried over $MgSO_4$. The extracts thus obtained were analyzed by GLC (15% SE-30 on Uniport B, 2 m, or fused silica capillary colum, 20 m). Analytically pure samples were obtained by chromatography over silica gel with hexane-ether or distillation under reduced pressure.

The dienones prepared by the above procedure are as follows.

5a: Mp 54 °C; IR (film) 3040, 1670, 1635, 1595, and 975 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.07 (s, 6H), 1.09 (s, 9H), 2.26 (s, 2H), 2.32 (broad s, 2H), 5.91 (t, 1H, J=1.3 Hz), 6.24 (d, 1H, J=16 Hz), and 6.26 (d, 1H, J=16 Hz); MS m/z (rel intensity) 107 (100), 191 (83) and 206 (47); Found: m/z 206.16711. Calcd for $C_{14}H_{22}O$: M, 206.16711.

5b: Bp 68—69 °C/0.05 mmHg; n^{21}=1.5217; IR (film) 3040, 1660, 1615, and 1580 cm^{-1}; ^1H NMR (CCl_4) δ=0.9—1.2 (m, 6H), 1.07 (s, 6H), 2.12 (s, 2H), 2.3 (s, 2H), 2.0—2.5 (m, 4H), 5.85 (t, 1H, J=7 Hz), and 5.96 (s, 1H); Found: C, 81.30; H, 10.55%. Calcd for $C_{14}H_{22}O$: C, 81.50; H, 10.75%.

Synthesis of (*Z*)-1-Hexenylboronate 10a and Its Reaction with Halo Enone (Eq. 3). To a solution of diisopropyl (*Z*)-(1-bromo-1-hexenyl)boronate[12,13] (1.1 mmol) in ether (2 ml) was added a solution of potassium hydrotriisopropoxyborate in THF (1 M solution, 1.2 mmol) at 0 °C. The mixture was stirred for 15 min at 0 °C. The cooling bath was removed, and stirring was continued for 30 min at room temperature. The solvent was evaporated under reduced pressure (0.01 mmHg) and then diisopropyl (*Z*)-1-hexenylboronate **10a** thus obtained was dissolved in methanol (4 ml). Sodium acetate (1.5 mmol), $PdCl_2(PPh_3)_2$ (0.03 mmol), and 3-chloro-5,5-dimethyl-2-cyclohexen-1-one (1.0 mmol) were added, and the mixture was refluxed for 5 h. The reaction mixture was diluted with benzene-hexane(1/1) (30 ml), washed with water, and dried over $MgSO_4$. Chromatography over silica gel with hexane-ether gave **11a** (0.17 g, 83%). Analysis by GLC (fused silica capillary column, OV-101, 20 m) indicated that E/Z is 4/96. **11a:** IR (film) 3020, 1670, and 1630 cm^{-1}; ^1H NMR (CCl_4) δ=0.90 (t, 3H, J=6.5 Hz), 1.07 (s, 6H), 1.2—1.5 (m, 4H), 2.1—2.4 (m, 6H), 5.7 (dt, 1H, J=6.5 and 12 Hz), 5.9 (d, 1H, J=12 Hz), and 5.93 (broad s, 1H); MS m/z (rel intensity) 206 (76), 191 (10), 177 (15), 163 (15), 149 (30), 121 (39), and 108 (100); Found: C, 81.27; H, 10.55%. Calcd for $C_{14}H_{22}O$: C, 81.50; H, 10.75%.

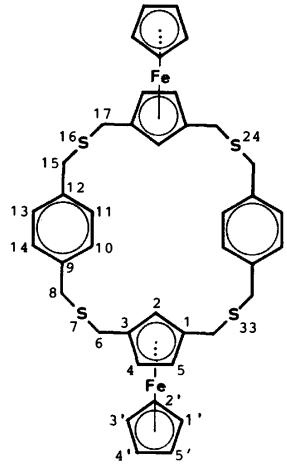
(Received May 2, 1987)

Synopsis. The crystal structure of the title compound, a macrocyclic thioether containing two 1,3-ferrocene and two 1,4-benzene moieties, has been determined by X-ray diffraction. The compound is in a chair-like conformation in the crystal and solvated with one molecule of benzene which was used for crystallization.

Czech and Ratajczak[2)] reported on the synthesis of ferrocene polythioethers by coupling reaction of 1,1′-bis(hydroxyalkyl)ferrocenes and alkanedithiols with trifluoroacetic acid (TFA) in dichloromethane. We applied the reaction to the synthesis of dithia[3]-benzeno[3]ferrocenophanes, which were used as synthetic intermediates of [2]benzeno[2]ferrocenophanes.[3,4)] In these reactions of 1,3-bis(hydroxymethyl)ferrocene with TFA, an oligomeric compound **1** was the main product in coupling with 1,4-bis(mercaptomethyl)benzene, whereas reaction with 1,3-bis(mercaptomethyl)benzene gave mononuclear coupling product, 7,14-dithia[3]metacyclo[3](1,3)ferrocenophane (**3**),[5,6)] in a good yield. The yield of **1** was always higher than that of mononuclear coupling product, 7,14-dithia[3]paracyclo[3](1,3)ferrocenophane (**2**), even though in high dilution conditions (10^{-3} mol dm^{-3}).



1

The molecular structure of **1** could not unequivocally confirmed by spectroscopy. The mass spectrum by means of electron impact ionization showed the same spectral pattern as that of **2**. The peak corresponding to the molecular weight of binuclear coupling product (*m/z* 760) was detected by field desorption (FD) ionizing technique. Furthemore, treatment of **1** or **2** with TFA in dichloromethane gave an equilibrium mixture of **1** and **2** (formation ratio, 3:1). These facts suggest that formation of **1** and **2** is thermodynamically controlled. Accordingly, it was not certain whether the peak observed in the FD mass spectrum indicates the exact molecular weight of **1**. On the other hand, there is no paper on the X-ray crystal structure of macrocyclic thioether containing metallocenes except for 1,1′-substituted metallocenes.[7,8)] Therefore, determination of the crystal structure of **1** was carried out by X-ray diffraction.

Experimental

Material: Coupling reaction of 1,3-bis(hydroxymethyl)-ferrocene and 1,4-di(mercaptomethyl)ferrocene with trifluoroacetic acid gave **1** (67%) and **2** (21%). The reaction conditions and the procedure were previously described.[4)]

Table 1. Atomic Coordinates ($\times 10^5$ for Fe; $\times 10^4$ for C and S) and Isotropic Equivalent Thermal Parameters (in Å^2 Unit) of **1** with Estimated Standard Deviations in Parentheses

Crystals of **1** were grown in a benzene–ethyl acetate solution as orange yellow plates of irregular shape.

X-Ray Crystallography: A crystal of approximate dimensions 0.1×0.2×0.3 mm was chosen for X-ray diffraction work. The cell dimensions and intensity data were collected on a Philips PW 1100 diffractometer using Mo $K\alpha$ radiation monochromated by a graphite plate. A total of 2588 reflections out of 3560 theoretically possible ones were measured as above the $2\sigma(I)$ level in a 2θ range of 6—50°. Intensities were corrected for Lorentz and polarization factors but not for absorption.

(Crystal Data): 7,16,24,33-Tetrathia[3]paracyclo[3](1,3)ferroceno[3]paracyclo[3](1,3)ferrocenophane (**1**) benzene solvate; $C_{40}H_{40}S_4Fe_2 \cdot C_6H_6$; FW=838.8; triclinic; space group $P\bar{1}$; a=9.123(5), b=11.598(6), c=10.109(5) Å, α=96.10(5), β=97.95(5), γ=104.42(5)°; U=1014.9 Å^3; D_{calc}=1.372 g cm^{-3}; Z=1.

The molecule posseses a center of symmetry which lies on a crystallographic symmetry center. The presence of one molecule of benzene in a unit cell laying on another symmetry center was noticed during the refinement. The structure was solved by the heavy atom method and refined by the method of block-diagonal least-squares. The present R factor is 0.06 for 2588 reflections including anisotropic temperature factors for all atoms but hydrogen atoms are not included.

The atomic coordinates are listed in Table 1.[9]

Results and Discussion

The perspective ORTEP drawings are shown in Fig. 1. The compound **1** is a macrocyclic thioether containing two ferrocene and two benzene moieties, as expected by FD mass spectrometry. The thioether **1** is the first example of macrocyclic 1,3-substituted ferrocenophane of which the structure was established by X-ray crystal analysis.

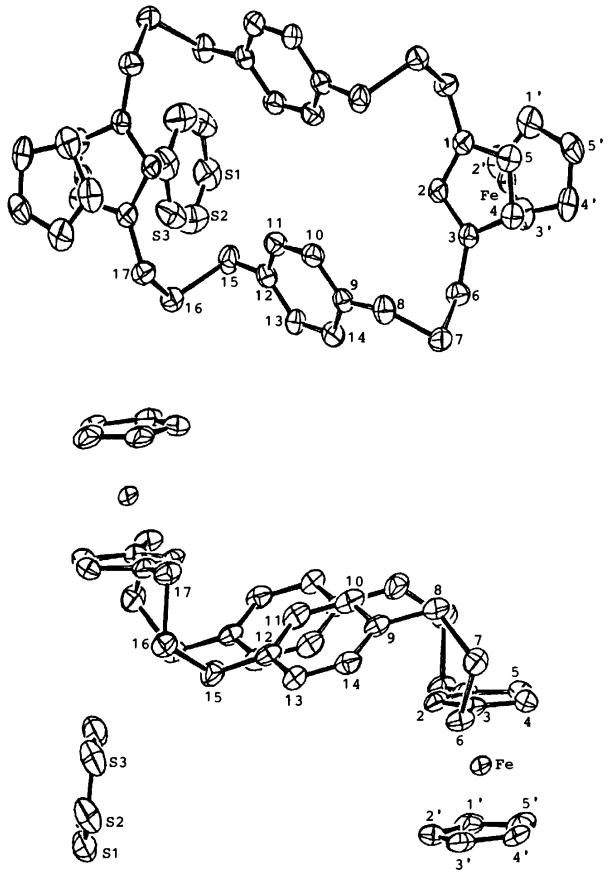

Fig. 1. ORTEP drawings (30% probability thermal ellipsoids) of **1**.

All bond lengths and angles[9] are in almost normal ranges; the C–C distances of the cyclopentadienyl (Cp) rings, 1.413(12)—1.452(10) Å; the C–C distances of the benzene ring, 1.381(9)—1.410(9) Å; the C–S bond lengths, 1.812(7)—1.832(8) Å. The average distance of the substituted Cp ring carbons from the iron (2.046 Å) is almost similar to that of the unsubstituted ring carbons (2.054 Å). These results indicate that the macrocyclic ring is strain-free. On the other hand, inspection of mononuclear coupling product **2** with a Dreiding molecular model reveals its strained molecular structure, because the distance between the benzene and Cp ring planes in the most stable conformation is 2.5—2.7 Å, which would be enough space to cause mutual repulsion between the two rings. Therefore, the macrocyclic compound **1** is more thermodynamically stable than **2**. The experimental result that the macrocyclic compound **1** was formed in preference to [3.3]phane **2** in the synthetic reaction and under an equilibrium condition with TFA, as mentioned above, can be reasonably explained on the basis of the stabilities of their structures.

The conformation of **1** is in an interesting chair-like shape as a whole. The size of the macrocyclic cavity is about 3×6 Å. The planes of the two benzene rings of the phane are faced each other with a little inclination. The two ferrocene nucleus take an "anti" direction parallel to one another about the Cp–Fe–Cp axes. The rotational conformation about the Cp–Fe–Cp axis of each ferrocene moiety is almost eclipsed.

One molecule of benzene is packed in a unit cell as a solvent of crystallization. Attempted preparations of single crystals with other some solvents were unsuccessful. Accordingly, the benzene molecule would play an important role to the packing of the macrocyclic ring in crystallization.

Studies of Collectors. IX. The Flotation of a Trace Amount of Uranium by Using 2-(Alkylamino)propionohydroxamic Acid and Cotelomer-Type Surfactants Bearing Hydroxyaminocarbonyl and Pyridyl Groups

Yoshifumi KOIDE,* Masazumi UCHINO, and Kimiho YAMADA
Department of Applied Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860
(Received February 23, 1987)

Chelating surfactants bearing hydroxyaminocarbonyl and amino groups (R_nAHx) and cotelomer-type surfactants bearing hydroxyaminocarbonyl and pyridyl groups (Ls-VP-Q-Hx) were prepared and applied as flotation collectors for a trace amount of uranium. The uranium in an aqueous solution of pH 4—8 and in seawater was floated more effectively by ion flotation using R_nAHx or by foam fractionation using Ls-VP-Q-Hx, compared with alkylhydroxamic acid (R_nHx) and telomers bearing hydroxyaminocarbonyl groups (Lo-Hx). The effective flotation was concluded to be due to the chelate effects between the two groups on the complex formation and to the HLB of the resulting complex. Furthermore, the uranium recoveries were examined by using a hydroxamic acid polymer (62Hx), a *N*-methylhydroxamic acid telomer (Ls5.6MHx), and its cotelomer (Ls3.2VP4.5MHx).

Hydroxyaminocarbonyl group (hydroxamic acid),[1] N^2-hydroxyamidino group (amidoxime),[2] and the pyridyl group[3] are known as affinity groups for uranium ions, and chelating resins bearing such selective functional groups were applied to uranium recovery from seawater. On the other hand, uranium flotation has been studied by using decanedioic acid,[4] hexadecyltrimethylammonium chloride,[4] and sodium dodecyl sulfate-sodium 9-octadecenate in the presence of Fe^{3+} and Al^{3+}.[5] However, there are few reports on a flotation for a trace amount of uranium by using a surfactant bearing selective functional groups. Amidoxime-type surfactants were, though, applied as uranium-floating collectors in a previous paper.[6] Furthermore, surfactants bearing hydroxyaminocarbonyl and amino groups can be expected to be excellent ion-flotation and foam-fractionation collectors for uranium, because surfactants bearing the two groups are considered to exert chelate effects on the complex formation of uranium. This paper will describe the examinations of 2-(alkylamino)propionohydroxamic acid (R_nAHx n= 10, 12, 16) and of cotelomer-type surfactants bearing hydroxyaminocarbonyl and pyridyl groups (Ls-VP-Q-Hx) as flotation collectors for uranium, compared with the hydroxamic acid derivatives (alkanehydroxamic acid: R_nHx n=10, 12, 14, telomer-type surfactants bearing hydroxyaminocarbonyl groups: Lo-Hx, and polymer: 62Hx). No study of an uranium flotation using R_nAHx and Ls-VP-Q-Hx has yet been reported as far as the present authors are aware.

Experimental

Synthesis of Surfactants. Decanehydroxamic acid ($R_{10}Hx$), Dodecanehydroxamic acid ($R_{12}Hx$), and tetradecanehydroxamic acid ($R_{14}Hx$) were prepared by the reaction of equimolar amounts of corresponding alkanoyl chloride and hydroxylamine,[7] and then 2-(decylamino)propionohydroxamic acid ($R_{10}AHx$), 2-(dodecylamino)propionohydroxamic acid ($R_{12}AHx$), and 2-(hexadecylamino)propionohydroxamic acid ($R_{16}AHx$) were prepared by the reaction of the synthesized methyl 2-(alkylamino)propionate with hydroxylamine, which had themselves been prepared by the esterification of the corresponding 2-(alkylamino)propionic acid[8] with methanol. The yields were $R_{10}Hx$ 53%, $R_{12}Hx$ 48%, $R_{14}Hx$ 45%, $R_{10}AHx$ 54%, $R_{12}AHx$ 38%, and $R_{16}AHx$ 44%. The structures were confirmed by means of their IR spectra (Shimadzu IR-408), NMR spectra (JEOL JMN-MH-100), and elementary analyses (Yanako CHN Corder MT-3). Mp: $R_{10}Hx$ 86.2—88.8 °C, $R_{12}Hx$ 97.0—98.6 °C, $R_{14}Hx$ 93—95 °C, $R_{10}AHx$ 158.5—160.4 °C, $R_{12}AHx$ 155.9—157.2 °C, $R_{16}AHx$ 143—145 °C. IR (KBr): ν_{N-H} 3220 cm^{-1}, ν_{C-H} 2890, 2820 cm^{-1}, $\nu_{C=O}$ 1630—1650 cm^{-1}, δ_{N-H} 1610 cm^{-1}. ^1H NMR (CF_3COOH): δ=0.9 (3H, t, CH_3CC-), 1.3—1.4 (methylene in alkane), 1.8 {3H, t, -CNC(CH_3)CO-}, 2.7 (2H, t, -CCH_2CO-), 3.3 (2H, t, -CCH_2NC<), 4.2 {1H, -CNCH(Me)CO-}, 7.4 {1H, -CNHC(Me)CO-}. $R_{10}Hx$ Found: C, 63.37; H, 11.30; N, 7.38%; Calcd for $C_{10}H_{21}O_2N$: C, 64.13; H, 11.30; N, 7.48%. $R_{12}Hx$ Found: C, 66.15; H, 11.47; N, 6.20%; Calcd for $C_{12}H_{25}O_2N$: C, 66.95; H, 11.70; N, 6.51%. $R_{14}Hx$ Found: C, 68.44; H, 11.83; N, 5.80%; Calcd for $C_{14}H_{29}O_2N$: C, 69.08; H, 12.00; N, 5.75%. $R_{10}AHx$ Found: C, 64.07; H, 11.66; N, 11.41%; Calcd for $C_{13}H_{28}O_2N_2$: C, 63.89; H, 11.55; N, 11.46%. $R_{12}AHx$ Found: C, 65.92; H, 11.89; N, 10.50%; Calcd for $C_{15}H_{32}O_2N_2$: C, 66.13; H, 11.84; N, 10.28%. $R_{16}AHx$ Found: C, 68.73; H, 12.24; N, 8.50%; Calcd for $C_{19}H_{40}O_2N_2$: C, 69.46; H, 12.27; N, 8.52%.

The cotelomer-type surfactants used in this study were obtained as described in a previous paper:[9] The mixed monomers of 4-vinylpyridine and methyl acrylate were polymerized by using 2,2′-azobisisobutyronitrile as an initiator in a 1-dodecanethiol solvent of a chain-transfer agent, and the products were treated with benzyl chloride in order to quaternize them. The degree of polymerization and the composition were determined by means of the elementary analyses, the molecular weight (Corona 114 vapor-pressure osmometer), and the ^1H NMR spectra. In order to obtain the *N*-methylhydroxamic acid derivative, the more reactive *p*-nitrophenyl acrylate was also introduced to the cotelomer instead of the methyl acrylate;[10] it had been prepared by the reaction of acrylic chloride with *p*-nitrophenol. Then, the methyl and *p*-nitrophenyl esters were converted into hydroxamic acid or *N*-methylhydroxamic acid by treatment with a 5-fold amount of hydroxylamine or *N*-methylhydroxylamine.

The formation of the hydroxamic acid derivatives was confirmed by the strong broad absorption of hydroxamic acid at $\nu_{C=O}$ 1660 cm^{-1} in the IR spectrum and by that of the hydroxamate anion (pH 12) at 285 nm in the UV spectrum, but the conversion of the esters into the hydroxamic acid was incomplete; the resulting compounds exhibited the weak absorption of carboxylic acid, $\nu_{C=O}$ 1730—1750 cm^{-1}, in the IR spectrum. The ratios of the hydroxyaminocarbonyl and *N*-methylhydroxyaminocarbonyl groups were calculated from the absorbance to be about 80% of the methyl ester groups in the starting cotelomer and about 70% of the *p*-nitrophenyl ester groups.

Benzohydroxamic acid (BHx), *o*-aminobenzohydroxamic acid (BAHx), and the telomer (Lo-Hx), were prepared according to the methods described in the literature.[6,11,12] The chemical formulas and the abbreviations are shown in Fig. 1.

Apparatus and Procedures. The flotation apparatus was the same as that previously reported.[6] A uranium solution was prepared by dissolving $UO_2(NO_3)_2$ in an aqueous solution, while seawater was taken at the seacoast of Akase, Utogun, Kumamoto, in January 1983. The surfactant was added to 500 cm^3 of the uranium solution or the seawater in the flotation vessel, and air was introduced into the solution through the sintered-glass disk (No. 4) at the bottom of the vessel at the rate of 30—40 $cm^3 min^{-1}$ for 20 min. The amount of uranium in the aqueous solution or the seawater was determined from the absorbance of the uranium-arsenazo III complex (660 nm).[13] The floatabilities of uranium in ion flotation and foam fractionation were calculated using this formula:

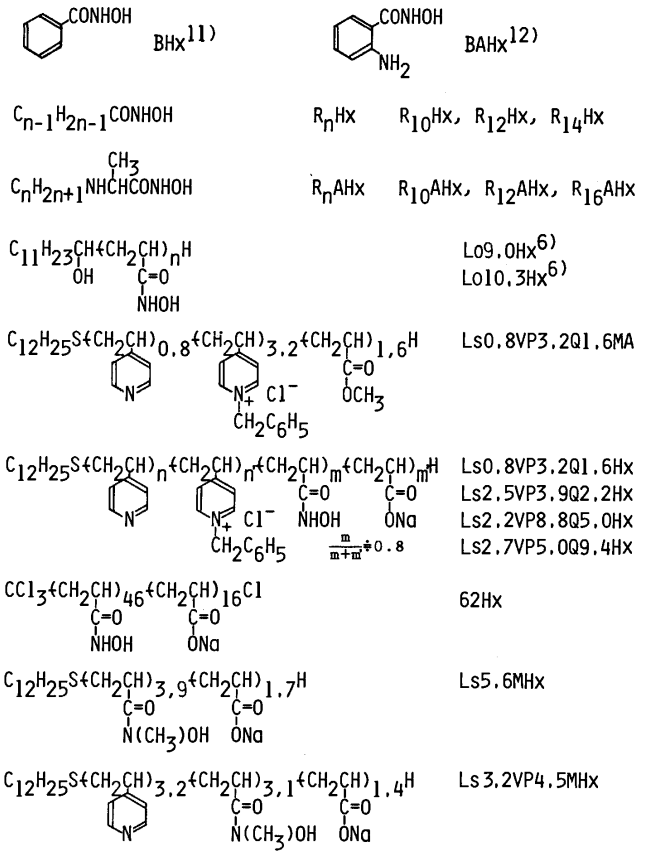

Fig. 1. Chemical formulas and abbreviations.

$$F(\%)=\frac{a_0-a_1}{a_0}\times 100$$

where a_0 and a_1 denote the initial and the final uranium concentrations.

Results and Discussion

Surface Activity. Chelating surfactants used as ion-flotation and foam-fractionation collectors should be surface-active, as was mentioned in a previous paper.[6] The surface tensions of these surfactant solutions were measured by means of a Du Noüy surface-tension balance. The values at their critical micellar concentration (cmc) are 53 dyn cm^{-1} (1 dyn=1×10^{-5} N) for 5×10^{-4} M (1M=1 mol dm^{-3}) $R_{10}Hx$ (pH 10), 61 dyn cm^{-1} for 1.5×10^{-4} M $R_{12}Hx$ (pH 10), 48 dyn cm^{-1} for 8×10^{-5} M $R_{10}AHx$ (pH 10), 62 dyn cm^{-1} for 5×10^{-5} M $R_{12}AHx$ (pH 10), 34 dyn cm^{-1} for 10^{-2} M $R_{10}AHx$ (pH 4), 40 dyn cm^{-1} for 10^{-2} M $R_{12}AHx$ (pH 4), 37 dyn cm^{-1} for 0.4 wt% Ls5.6MHx (pH 8.0), and 47 dyn cm^{-1} for 0.2wt% Ls3.2VP4.5MHx (pH 8.0). The cmc of R_nAHx at pH 10 was lower than that at pH 4, and a milky turbidity appeared at pH 4—11.5. The acid dissociations were pk_a 9.29 for BAHx,[14] and pk_{a_1} 3.52, pk_{a_2} 6.33, pk_{a_3} 8.00, and pk_{a_4} 9.07 for *N,N'*-ethylenediaminediacetic-*N,N'*-diacethydroxamic acid.[15] Therefore, the acid dissociations of R_nAHx may be assumed to be pk_{a_1} about 6 and pk_{a_2} 9.1—9.3, while R_nAHx at pH 10 would still have weakly nonionic properties because of its free amine and undissociated hydroxamic acid. The surface tensions of the Lo9.0Hx and Lo10.3Hx solutions were 38—40 dyn cm^{-1} in pH 7—10, as was mentioned in a previous paper.[16] Therefore, these surfactants were used as ion-flotation and foam-fractionation collectors because they have surface-active properties.

----: BHx, ——: BAHx.

uranium solution was examined by using R_nHx and R_nAHx. Figure 2 shows the pH-dependent floatabilities. R_nHx were effective in pH 4—10, while R_nAHx were effective in pH 4—8. The most effective collectors among them were $R_{12}AHx$ in pH 4—6 and $R_{12}Hx$ in pH 8—12. The floatabilities were naturally affected by the concentration of the collector, as is shown in Fig. 3. R_nAHx were clearly more effective than R_nHx at pH 4 and slightly more so in pH 6—8. However, the floatabilities at pH 10 achieved by using R_nAHx were less effective than those achieved by using R_nHx.

The uranium ions in an aqueous solution exist in the forms of free cation and hydroxo complexes, and the species changes with the pH. The stability constants of the BHx and hydroxouranium complexes are $\log K_{MBHx}$ 9.03, $\log K_{M(BHx)_2}$ 8.91,[17] $\log K_{MOH}$ 9.0, $\log K_{M(OH)_2}$ 7.8, and $\log K_{M(OH)_3}$ 8.1.[18] The ratios of the hydroxo-, BHx-, chloro-, and carbonato species calculated under the same conditions as seawater are shown in Table 1. The formation of the R_nHx-uranium complex could be explained by assuming its stability constant to be close to that of BHx. Most of the complexes in the 10-ppb uranium solution were BHx species in pH 4—8 and hydroxo species in pH 10—12. The long-alkylated R_nHx would form the floatable uranium complexes more in pH 4—8 because the surfactant was concentrated at the gas-liquid interface of the bubble, and then the R_nHx would make the colloidal hydroxo species float in pH 10—12. Ligand-

Table 2. Uranium Flotation from a 10-ppb Uranium Solution of pH 8

Condition of flotation[a]		Uranium-floated	
Collector	mg	Floatability %	Amount mg/g-collector
$R_{10}Hx$	5	30	0.30
$R_{12}Hx$	5	30	0.30
$R_{10}AHx$	3	23	0.38
$R_{12}AHx$	3	49	0.82
R_8Hx	3+N[b]	50	0.19
Lo9.0Hx	3+N[b]	64	0.24
Ls2.2VP8.8Q5.0Hx	30	93	0.16

a) 500 cm³ of a 10-ppb uranium solution (pH 8.0). R_8Hx, Lo9.0Hx, Ls2.2VP8.8Q5.0Hx: foam fractionation. b) 10 mg of a nonionic surfactant (Nissan nonion O-6).

bearing hydroxyaminocarbonyl and amino groups may be expected to exhibit a higher stability. However, the stability constants for the UO_2^{2+} complex of *o*-hydroxybenzohydroxamic acid (BHHx), a ligand-bearing hydroxyaminocarbonyl and hydroxyl group, is not higher than those for the UO_2^{2+}-BHx complex: log $K_{M\cdot BHHx}$ 7.71, log $K_{M(BHHx)_2}$ 6.80.[17] In order to examine the chelate effect of R_nAHx between hydroxyaminocarbonyl and amino groups, pH titrations for the BAHx-UO_2^{2+} and BHx-UO_2^{2+} complexes were carried out because of the low solubilities of R_nHx and R_nAHx. It can be seen from Fig. 4 that the BAHx complex is more stable than the BHx complex. The long-alkylated R_nAHx is also considered to be more stable than the R_nHx. Therefore, the enhancement when R_nAHx was used in pH 4—6 was considered to be due to the chelate effect between hydroxyaminocarbonyl and amino groups on the uranium-complex formation. Therefore, the HLB values of the floatable metal complexes should be in the range of 4—14, as was mentioned in a previous paper.[6] The six alkyl chains in the R_nAHx and R_nHx series were used in order to examine the hydrophobic variation in HLB; they were all surface-active collectors. The HLB values of the uranium complexes (2 : 1) were calculated according to the Oda equation:[19] $R_{10}Hx$ 6 (collector 15), $R_{12}Hx$ 5 (13), $R_{14}Hx$ 4 (11), $R_{10}AHx$ 6 (14), $R_{12}AHx$ 5 (12), and $R_{16}AHx$ 4 (10). Therefore, R_nAHx-UO_2-$(R_nAHx)_2$ and R_nHx-$UO_2(R_nHx)_2$ would float simultaneously, and the collectors would make the colloidal $UO_2(OH)_3^-$ species float.

Uranium Flotation from Seawater. Seawater is pH 8.0, and the concentration of uranium is 3 ppb. The flotation for a 10-ppb uranium solution of pH 8.0 is shown in Table 2. Among those collectors, $R_{12}AHx$ was the most effective; the floated amount of the uranium was 0.82 mg/g-$R_{12}AHx$. $R_{16}AHx$ was useful as an ion-flotation collector, but was only slightly soluble in water. R_8Hx and the telomer, Lo9.0Hx, were not useful because of their rich solubilities, whereas the foamy sublate was formed by the addition of a nonionic surfactant. Therefore, the uranium recoveries using the latter collectors were carried out by means of foam fractionation. The apparatus and the procedures in the foam fractionation were the same as those in the ion flotation, except for the continuous removal of the resulting foam.[6] The floatabilities became 50% by using the R_8Hx-nonionic surfactant and 64% by using the LoHx-nonionic surfactant. The cotelomer-type surfactant, Ls2.2VP8.8Q5.0Hx, exhibited an excellent foaming ability and the floatabilities by using Ls2.2VP8.8Q5.0Hx became more effective. A cationic surfactant, hexadecyltrimethylammonium bromide(HTABr), made the uranium float highly:[4] There was a 99%-floatability with 20 mg of HTABr, which is not indicated in Table 2. It was considered that the uranium could be floated because of the electrostatic force of attraction between the cationic HTABr and the anionic $[UO_2(OH)_3]^-$. However, HTABr did not make the uranium float from seawater: There was only a 3% floatability with 20 mg of HTABr. Many salts are highly dissolved in seawater, so that recovery from seawater is usually difficult. Figure 5 shows the ion flotation using R_nAHx and R_nHx for the uranium in seawater. The uranium floatabilties in pH 4—6 were similar to those for the 10-ppb uranium solution, whereas the floatabilities in pH 8—10

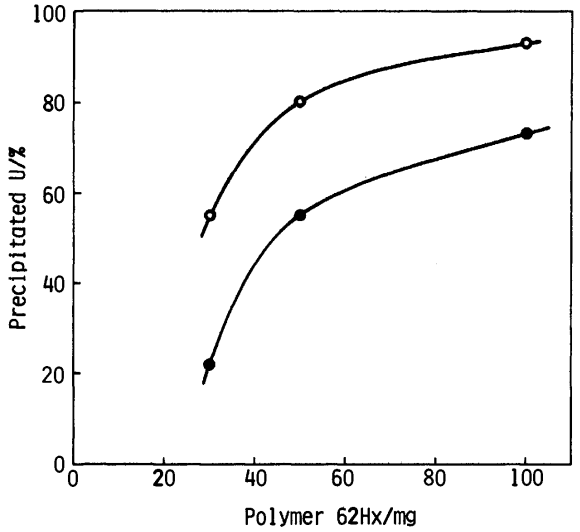

Fig. 7. Precipitated U with polymer 62Hx.
Seawater: 500 cm³. Precipitated U: Ratios of precipitated U to initial amount. Precipitated U was calcd from the differences between the initial and the final concns after the filtration of the resulting ppt(U-62Hx); ○: Dissolved the polymer 62Hx in a 50 cm³ of seawater on heating and then the hot seawater was added to a 450 cm³ of seawater with stirring: ●: Dispersed the fine particles of the polymer 62Hx into a 500 cm³ of seawater for 2 h with stirring.

differed considerably from these. The distribution of uranium complexes in Table 1 shows that most of them are carbonato species in pH 8—10. Therefore, the low floatability at pH 10 is probably due to the difficulty of the complex formation with the collectors. Therefore, the uranium flotation from natural seawater and seawater adjusted to pH 4 or 6 with HNO_3 was examined. The floatabilities depended on the R_nAHx and R_nHx concentrations, as is shown in Fig. 6. The flotation from natural seawater was not so effective, but the floatabilities in pH 4—6 were high. R_nAHx was far more effective than R_nHx was at pH 4, while it was only a little effective at pH 6. $R_{12}AHx$ became most effective because of its excellent chelating ability and the lower HLB value ($R_{16}AHx$ was slightly soluble in seawater).

Foam Fractionation Using Cotelomer-Type Surfactants. The uranium in an aqueous solution was floated by foam fractionation using the telomer (Lo9.0Hx)-nonionic surfactant.[6] In this section, the recoveries of uranium from seawater will be examined by depositing uranium ions with a polymer-bearing hydroxamic acid, 62Hx, and by foam fractionation using the cotelomer, Ls-VP-Q-Hx.

The polymer 62Hx was dissolved in 50 cm³ of seawater on heating, and the hot seawater was stirred into 450 cm³ of seawater. The other polymer, 62Hx, was dispersed in 500 cm³ of seawater for 2 h with stirring so that the uranium could be adsorbed to the 62Hx particles. After the filtration of the resulting 62Hx-uranium precipitate, the concentration of the uranium in the seawater was determined. The results are shown in Fig. 7. The affinity of the hydroxyaminocarbonyl group for uranium was evident. The recovery by the dissolution method using 62Hx was more effective than that by the dispersion method. However, the polymer precipitant was still difficult to keep in contact with the bulk solution and to collect from the solution.

Then, the foam fractionation of uranium from seawater was carried out by using Ls-VP-Q-Hx; the results are shown in Table 3, together with those obtained by using Lo-Hx, R_nAHx(ion flotation: the largest amounts of uranium floated was at 0.07 mg/g-$R_{12}AHx$), and R_nHx(ion flotation). The uranium in seawater was floated a little by foam fractionation

Table 3. Uranium Recovery from Seawater

Condition of flotation[a] Collector	mg	Uranium-floated Floatability %	Amount mg/g-collector

Ls2.5VP3.9Q2.2Hx	30	63	0.03
Ls2.5VP3.9Q2.2Hx	40	45	0.02
Ls2.2VP8.8Q5.0Hx	30	73	0.04
Ls2.7VP5.0Q9.4Hx	30	80	0.04

a) 500 cm^3 of seawater. R_nHx, R_nAHx: Ion flotation. Lo-Hx, Ls-VP-Hx, Lo-VP-Q-Hx: Foam fractionation.
b) 10 mg of a nonionic surfactant (Nissan nonion O-6).

using the Lo9.0Hx and a nonionic surfactant. The cationic Ls-VP-Q-MA, quarternized for dissolving it into seawater, was expected to be useful as a foam-fractionation collector for the anionic uranyl carbonate. However, Ls0.8VP3.2Q1.6MA (unsubstituted by hydroxamic acid) was ineffective for the foam-fractionation of uranium. The hydroxamic acid derivatives (Ls-VP-Q-Hx) from the cationic Ls-VP-Q-MA made the uranium float highly; e.g., the floatabilities were 81% with 30 mg of Ls0.8VP3.2Q-1.6Hx and 80% with 30 mg of Ls2.7VP5.0Q9.4Hx. The HLB values of the cotelomer-type surfactants were calculated to be Lo9.0Hx 36, Lo10.3Hx 37, Ls1.4VP7.2Hx 23 (Hx/VP=1.4: the ratio of hydroxyaminocarbonyl groups to pyridyl groups), Ls0.8VP3.2Q1.6MA 11 (0), Ls0.8VP3.2Q1.6Hx 14 (1.6), Ls2.5VP3.9Q2.2Hx 14 (0.7), Ls2.2VP8.8Q5.0Hx 16 (1.8), and Ls2.7VP5.0Q-9.4Hx 19 (2.8). The HLB values for the effective Ls-VP-Q-Hx in foam fractionation were 14—19; these values were near to those in a previously reported foam-fractionation (HLB 21).[20] The ratio of hydroxyaminocarbonyl groups to pyridyl groups was also a cause of the variation in the floatability. The most useful ratios were 1—2.8, so that the complex formation based on the chelate effects between the two groups were considered. In addition to the chelate effects, the cationic Ls-VP-Q-Hx would be more favorable for the attraction of the anionic uranyl carbonate.

N-Methylhydroxamic Acid Derivatives. The hydroxamic acid derivatives are apt upon *N*-deprotonation on heating, to decompose to isocyanates or to amines in an aqueous solution.[21] Therefore, *N*-methylhydroxamic acid derivatives were prepared, and their resistance to decomposition was periodically examined in acidic and alkaline solutions. *N*-Methylhydroxamic acid derivatives, Ls5.6MHx and Ls3.2VP4.5MHx, were stable for a week at pH 1 and 12, whereas Ls-VP-Q-Hx in an alkaline solution of pH 12 decomposed within 20 h, as is shown in Fig. 8. Therefore, the foam fractionation of uranium was examined by using

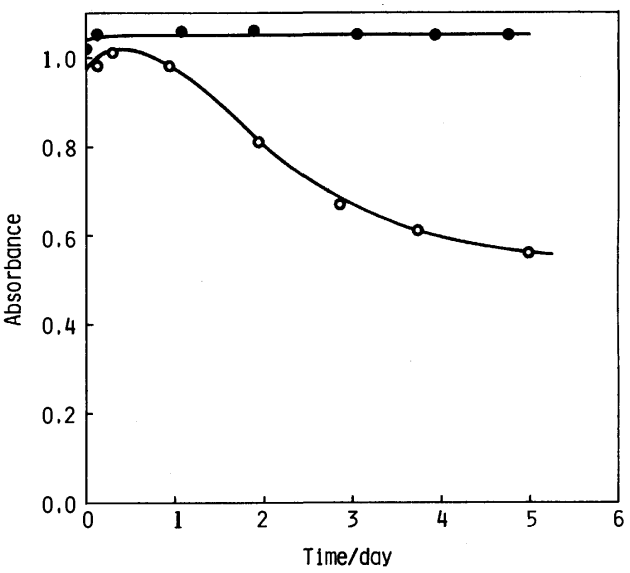

Fig. 8. Stability of hydroxamic acid derivatives at pH 12.
●: Ls3.2VP4.5MHx, ○: Ls2.5VP3.9Q2.2Hx.

Table 4. Foam Fractionation of Uranium by Using Ls-VP-MHx

Condition of flotation[a]		Uranium-floated	
Collector	mg	Floatability	Amount
		%	mg/g-collector
Ls5.6MHx	10	16	0.02
Ls5.6MHx	40	41	0.02
Ls3.2VP4.5MHx	10	27	0.04
Ls3.2VP4.5MHx	40	56	0.02

a) 500 cm^3 of seawater.

Ls5.6MHx and Ls3.2VP4.5MHx. The uranium floatabilities from seawater are shown in Table 4. Ls5.6MHx and Ls3.2VP4.5MHx showed the foam-fractionation effects on the uranium in seawater, the Ls3.2VP4.5MHx being more effective than the Ls5.6MHx. The high floatability is considered to be due to the chelate effects between the *N*-methylhydroxyaminocarbonyl and pyridyl groups and to the surface activities (HLB: Ls5.6MHx 21, Ls3.2VP4.5MHx 14).

Thus, the effects of the chelating surfactants bearing hydroxyaminocarbonyl and amino groups or hydroxyaminocarbonyl and pyridyl groups on uranium flo tation have been established as a result of one investigation.

The present authors are indebted to Mr. Kuniaki Jinnai for his help in the foam fractionation using cotelomer-type surfactants.

An NMR Study of Phenyl- and Diphenylphosphine Alkali Metal Salts

Yukihiro YOKOYAMA and Kensuke TAKAHASHI*
Department of Applied Chemistry, Nagoya Institute of Technology,
Gokiso-cho, Showa-ku, Nagoya 466
(Received February 25, 1987)

The ^{1}H, ^{13}C, and ^{31}P NMR spectra were observed for the title salts in several solvents. The formation of the salts by the deprotonation of the neutral precursors causes significant changes in their NMR parameters. First, the delocalization of the excess charges into the phenyl ring of the salts was confirmed from the ^{1}H and ^{13}C chemical-shift data. Second, the parameters concerned with the center of the anions are dependent on the circumstances of the center atom, phosphorus, such as the hybridization. The results are discussed in terms of the effects of the counter cations and the solvents. Third, a strong polar solvent, HMPA, exerts significant effects on the chemical shifts and the one-bond ^{13}C-^{31}P coupling constants. These parameter changes are explained in terms of an equilibrium between two kinds of ion-pairs (contact ion-pairs and solvent-separated ion-pairs). The parameters obtained in this solvent, HMPA, correspond to those of the solvent-separated ion-pairs or the free anions.

The NMR technique is a useful and efficient technique for investigating many aspects of the anionic species of organic compounds in solutions. Among such species, the carbanions are the most investigated species; they have a carbon atom as an anionic center.[1,2] Recently, there have appeared several articles concerned with the anionic species with heteroatoms as anionic centers.[3,4] However, there has not yet been sufficient discussion on the accumulation of enough data about the problems of these anions, such as their structures, electron distributions, bondings, and counter cations.

In this article we wish to report our measurements of the ^{1}H, ^{13}C, and ^{31}P chemical shifts for the anionic species produced from phenyl- and diphenylphosphines, whose sodium salts were reported previously.[3a] The results are discussed in terms of the structures of the anions, solvents, and counter cations, and the temperature.

Experimental

The phenylphosphine and chlorodiphenylphosphine used as starting materials were commercially available and were used without further purification. These starting materials were dried and distilled over calcium hydride, and then degassed and stored in sealed vessels with a break seal.

The tetrahydrofuran (THF), 1,2-dimethoxyethane (DME), and 2-methyltetrahydrofuran (2MTHF) were refluxed and distilled over sodium metal and then stored over sodium-potassium alloy. The hexamethylphosphoric triamide (HMPA) and tetrahydrofuran-d_8 (THF-d_8) were dried and distilled over calcium hydride, and then degassed and stored in sealed vessels with a break seal.

The phenylphosphine was allowed to react with butyllithium in hexane under a vacuum. Then, after all volatile materials had been distilled off in a vacuum, the residue was dissolved in a solvent (THF, DME, 2MTHF, HMPA, or THF-d_8). The solution of the resulting lithium salt was filtered into an NMR tube, which was then sealed under a vacuum.

Diphenylphosphine alkali metal salts were generated from chlorodiphenylphosphine by means of a halogen-metal exchange reaction. The reaction was carried out so that the starting material was in contact with lithium, sodium, or potassium metal flakes in a solvent at room temperature in a reaction vessel under a vacuum. The solution was kept in the vessel with stirring for a day for the reaction to be completed. Then, the resulting solution was filtered into an NMR tube, which was then sealed under a vacuum. All the NMR samples were prepared as approximately 1M solutions sealed in 5- or 10-mm o.d. tubes.

All the NMR spectra were measured on a Varian XL-200 Fourier transform spectrometer at the ambient temperature (ca. 25 °C). The ^{1}H and ^{13}C chemical shifts were referred to the more (or most) shielded peaks of the solvents, and then converted to the values from TMS by taking 1.79 and 26.40 (or 1.75 and 25.40) for δ_H and δ_C of THF(or THF-d_8), and 21.20, 37.00, and 58.80 for δ_C of 2MTHF, HMPA, and DME respectively. The ^{31}P chemical shifts were measured externally relative to a 1 wt% H_3PO_4 solution dissolved in D_2O.

Results and Discussion

^{1}H Chemical Shifts. The ^{1}H chemical-shift data for the compounds measured in THF-d_8 are summarized in Table 1, together with the citation numbers of the compounds. The ^{1}H chemical shifts of the anionic

Table 1. ^{1}H Chemical Shifts of Phenyl- and Diphenylphosphines and Their Anions in ppm[a)]

No.	Compound	P-H	H-2	H-3	H-4
1	$PhPH_2$	3.97	7.51	7.28[b)]	7.28[b)]
1a	PhPHLi	2.13	7.09	6.56	6.27
1b	PhPHNa[c)]	2.23	7.16	6.58	6.29
2	Ph_2PH	5.24	7.51	7.31[b)]	7.31[b)]
2a	Ph_2PLi	—	7.46	6.79	6.50
2b	Ph_2PNa	—	7.53	6.84	6.57
2c	Ph_2PK	—	7.48	6.80	6.48

a) Chemical shifts are measured for ca. 1M (1M=1 mol dm^{-3}) solutions in THF-d_8 relative to the more shielded residual solvent peak, which is taken as 1.75 ppm from TMS. b) The values are not determined precisely because of the signal overlapping. c) The values are cited from Ref. 3a.

compounds from **1a** to **2c** are more shielded than those of the corresponding neutral molecules, **1** and **2**, except that the ortho-proton shifts of the diphenylphosphine alkali metal salts are slightly deshielded. The shift changes of the P-H protons from phenylphosphines to their anionic molecules are ca. 1.7 ppm because of an increased shielding caused by the negative charge on the phosphorus atom. There is a small but significant downfield shift of the P-H proton on going from **1a** to **1b** (0.10 ppm), in accord with a greater charge density in this position in the former species.

The changes in the ^{1}H chemical shifts of the phenyl-ring protons are in the ranges from −0.42 to 0.02, from −0.72 to −0.47, and from −1.01 to −0.83 ppm for the ortho, meta, and para protons respectively. The ring-proton shifts are influenced by various factors. The ortho-proton shift is affected by inductive, resonance, magnetic anisotropy, and electric-field effects from the phosphorus atom as an anionic center. These effects, however, are much smaller for the meta-proton shift, and probably only the resonance effect is important for the para proton shift.[5] This is why the upfield shifts of the para-protons are regarded as a rough estimation of the charge delocalization.

The reason that the ortho-proton shifts have smaller changes than those expected from the resonance effect of the substituent is presumably attributable to some electronic effects caused by the excess charge and the lone-pair electrons on the phosphorus atom.

^{13}C Chemical Shifts. The ^{13}C chemical-shift data for the compounds studied in several solvents are presented in Table 2. The general trends that are apparent in the table are as follows: The formation of the anion species from the corresponding neutral molecules causes the ipso carbon to be significantly deshielded (21 to 42 ppm) and the para carbon to be shielded (9 to 18 ppm), while the ortho and meta carbons show small upfield shifts (2 to 7 ppm).

a) Chemical shifts are measured for ca. 1M solutions relative to the more or most shielded peak of the solvent used. See text. b) The values are cited from Ref. 3a.

The ipso-carbon resonances shift clearly towards the downfield direction, contrary to what would be expected from the excess charge delocalization into the phenyl rings, corresponding to a decrease in the electron density at that position. However, such downfield shifts are observed as a general trend for monosubstituted benzenes, in which the substituent is an anionic center, like phenylmethyl carbanions and so on.[3,4,6,7]

The ortho-carbon shifts are affected by various factors because their position is near, second only to the ipso position, to the substituent. However, the ortho- and meta-carbon shifts are indeed of similar magnitudes. This is also a characteristic feature of these anions.[3,4]

It has been considered that para-carbon chemical shifts provide a good measure of charge delocalization, just as para-proton shifts do. It is found that the changes in the para-carbon shifts in the anions produced from **1** and **2** are slightly smaller than those of the phenylmethyl carbanions,[7] but there are significant upfield shifts. Therefore, these upfield shifts show that the degree of charge delocalization into the phenyl ring is relatively large.

^{31}P Chemical Shifts. The ^{31}P NMR data for the compounds studied in several solvents are summarized in Table 3. The trends of the ^{31}P chemical shifts are in agreement with the previously published data.[3a] It is known that the formation of the anions from PH_3 causes the phosphorus atoms to be shielded (16 to 58 ppm).[3a] This is in agreement with the general tendency for the increase in the electron density to result in more shielding on an atom. However, the ^{31}P chemical-shift changes of the anions in Table 3 are in the direction opposite to that expected from the increasing electron density on the phosphorus atoms (5 to 36 ppm downfield shifts).

Batchlor and Birchall have mentioned that the downfield shifts of the phenyl- and diphenylphosphines upon deprotonation might be attributed to a $p\pi$-$p\pi$ interaction between the phenyl ring and the phosphorus atom.[3a] However, such downfield shifts have been observed for the carbons in some carbanions due to the rehybridization of the α-carbon atom.[7] Considering the changes in the ^{31}P-^{13}C coupling constants that will be mentioned later, it seems that the effects of rehybridization (resulting in downfield shifts) and electron density (resulting in upfield shifts) play significant roles in the ^{31}P shifts.

It is found that the solvents with a stronger polarity result in more downfield ^{31}P chemical shifts of the anions as well as more ^{13}C chemical shifts of the

anions. The ^{31}P chemical shifts of the anions in HMPA are ca.30 to 40 ppm more deshielded than those of the same anions in 2MTHF, whereas the neutral molecules have similar chemical shifts in several solvents.

^{31}P-^{13}C and ^{31}P-^1H Coupling Constants. The phosphorus-carbon and phosphorus-proton coupling constants are summarized in Table 3. It may be pointed out that the values of $^1J_{PC}$ of the anions (34—63 Hz) are significantly larger than those of the neutral molecules (7—12 Hz) and that the solvents with a stronger polarity result in larger values in the $^1J_{PC}$ of the anions. It has been known that the $^1J_{PC}$ are very sensitive to the hybridization of the phosphorus atom and the substituents attached to the atom.[8] The change in the $^1J_{PC}$ of the anions, therefore, may be attributed to the rehybridization of the phosphorus atom in the anions.

On the other hand, the values of $^2J_{PC}$ and $^3J_{PC}$ of the anions are almost like the values of the neutral molecules. The effects of both the counter cations and the solvents scarcely influence the two- and three-bond phosphorus-carbon coupling constants.

The trend of the change in the one-bond phosphorus-proton coupling constants is in agreement with the previously reported values for sodium salts.[3a] That is, it is found that the magnitude of $^1J_{PH}$ of the anions (144—172 Hz) is significantly smaller than that of the neutral molecule (ca. 200 Hz). If the signs of the $^1J_{PH}$ are considered to be positive, as has been reported for other systems,[8] the reduction of the $^1J_{PH}$ in the salts corresponds to a decrease in the s character of the hybridized orbital directed to the hydrogen from the phosphorus atom in the salts as compared with that in **1** or **2**. Further, the increase in the magnitude of the $^1J_{PC}$ in the salts corresponds to the greater conjugation between the p-π orbitals of the two atoms forming the P-C bond as compared with those of the phenylphosphines, **1** and **2**. Additionally, the signs of the $^1J_{PC}$ of several alkylphosphines were noted to be the opposite of those of their phosphonium salts.[8] Therefore, studies along this line are in progress for several related phosphines and their salts.

It is of interest to point out that the solvents with a stronger polarity result in smaller values of the $^1J_{PH}$ of the anions. The changes in $^1J_{PH}$ are clearly towards the direction opposite to those of $^1J_{PC}$; therefore, the sum of the $^1J_{PH}$ and $^1J_{PC}$ is approximately constant in each species, although the reasons for this are not well understood.

Counter-Cation and Solvent Effects on NMR Parameters. The ^1H chemical shifts of P-H and ortho protons for the phenylphosphine alkali metal salts are slightly affected by the counter cation, but the ring-proton shifts of the anions produced from diphenylphosphines are scarcely affected by the cation, except for the shifts of the sodium salt, which behave differently from the lithium and potassium salts. The counter-cation effects on the carbon and phosphorus chemical shifts are illustrated schematically in Figs. 1 and 2 respectively. According to the variation in the cations from lithium to potassium, the resonance lines of the ipso-carbon and phosphorus atoms move downfield, while the lines of the para-carbons move upfield. However, the ortho and meta carbons scarcely shift at all. These trends can be explained by the fact that carbon and phosphorus chemical shifts show differences, accompanied by changes in the cation size, that reflect the electron-distribution changes in the ion-pairs, like those observed for phenylmethyl carban-

ions.[6,7] However, the chemical shifts of the ipso carbon and phosphorus atoms of the sodium salts behave curiously, unlike the general expected trend, as is shown in Figs. 1 and 2. For example, the ^{31}P chemical shifts of the sodium salts **2b** are the most shielded among the three salts, **2a**—**c**. Especially, the characteristic feature of the sodium salts is significant in moderately polar solvents, such as 2MTHF and THF. Therefore, it seems that this phenomenon is connected with an equilibrium between contact ion-pairs and solvent-separated ion-pairs in the anionic solutions. In more polar solvents such as HMPA, therefore, the counter cations do not affect the chemical shifts, because in such solvents the ion-pairs exist only a form of solvent-separated ion-pairs or free ions. It must be noted that the chemical shifts measured in HMPA are quite different from those measured in THF, which is mostly used in carbanion chemistry.[6] Therefore, it is recommended to use HMPA as a solvent for obtaining the chemical-shift values for the solvent-separated ion-pairs in the ion-pair equilibrium. Further, such solvent effects are not observed in the chemical shifts of the neutral molecules, **1** and **2**.

One of the molecular theoretical parameters that gives the degree of solvation consists of Gutmann's donor and acceptor numbers (DN and AN).[9] In view of the concepts of DN and AN, the different behavior of the sodium salts can be explained by saying that, in solvents with a medium DN (20) value, such as 2MTHF and THF, the sodium ion is solvated less than the lithium one because of its smaller AN. Therefore, the sodium salts have an equilibrium with more contact ion-pairs in the ion-pair equilibrium. Therefore, the negative charge is localized more on the anionic-center atom. Therefore, the ^{31}P chemical shifts of **2b** tend to shift towards a more shielded direction than those of the other salts, **2a** and **2c**. Further, the slightly smaller changes in the C_i and C_p chemical shifts of **2b** show that the delocalization of the excess charges into the phenyl ring is less than those of **2a** and **2c**. The solvent effects on the ^{13}C chemical shifts of **1a** are given in Fig. 3. The solvent effects for the shifts of these salts are larger than their counter cation effects. The former effects increase in the order of 2MTHF,DME,THF, and HMPA. As may be seen in Tables 2 and 3, however, the effects for the salts from **2a** to **2c** increase in a slightly different order. The order of DME≳THF>2MTHF is consistent with that found for the alkali

metal salts of diphenylmethane.[6] O'Brien et al. stated several reasons for the solvent effects. Their explanation is essentially the same as the concepts of DN and AN. The correlation between such DN and the ^{13}C chemical shifts in several solvents is shown in Fig .4. This shows that the ^{13}C chemical shifts largely reflect the equilibrium between two kinds of ion-pairs. On the other hand, the ^{31}P chemical shifts are not correlated with such DN. This may be because the ^{31}P chemical shifts are not affected by only ion-pair equilibrium, but also by polarization as an anionic center and by rehybridization.

The solvent and counter-cation effects for the $^1J(^{13}C-^{31}P)$ are given in Fig. 5. In the cases of **1** and **2** the coupling constants have a magnitude of about 10 Hz, similar to that of trimethylphosphine. On the other hand, for the alkali metal salts the values tend to increase to a magnitude of about 50 Hz, although their signs were not determined. These values are similar to that of phospharine.[10] The changes in the values are the largest for **2a** (34 to 60) and the least for **2c** (44 to 60 Hz). Further, the effect of the counter cations appears with the largest range in 2MTHF and the least in HMPA. Perhaps the value of 60 Hz is characteristic of the anionic species of **2**. The change in the $^1J_{PC}$ values is affected by the equilibrium between the contact ion-pairs and solvent-separated ion-pairs. The hybridization of the phosphorus atom as an anionic center is similar to that of phospharine.

Recently, two research groups have reported that **2a** exists in a dimeric state in ether at a lower temperature or in a polymeric state in the solid crystal with a covalent bonding between the phosphorus atom and the counter cation.[11,12]

No splitting of the ^7Li NMR signal of **2a** was observed in a THF solution in the temperature range from 25 to −110 °C, although the signal moved slightly upfield (0.4 ppm). This may be considered to indicate that the nature of the bonding between phosphorus and lithium atoms of **2a** is essentially ionic or that there exists some other mechanism of signal narrowing in **2a**.

An Ab Initio Molecular Orbital Study on Infrared Absorption Spectrum of ν_1 Vibration in Chloroform Vapor

Tomoaki HAYANO,* Hisao TAKEUCHI,† and Tomoo MIYAZAKI
Department of Applied Chemistry, Faculty of Science and Engineering, Waseda University, Ohkubo Shinjuku-ku, Tokyo 160
†Mitsubishi Chemical Industry, Kamoshida-cho Midori-ku, Yokohama-shi 227
(Received February 25, 1987)

The infrared absorption frequency and intensity of the ν_1 vibration, referring to the C-H stretching of chloroform vapor, have been calculated from the theoretical potential energy and dipole-moment functions determined by an ab initio molecular orbital calculation. The selection effect of a Gaussian basis set in the ab initio MO method on the calculated frequency and intensity has been studied. It has been pointed out that the theoretical dipole-moment function is sensitive to a slight displacement of the chlorine in the ν_1 vibrational mode.

In two earlier papers,[1,2] the abnormal absorption intensity of the ν_1 vibration band in chloroform vapor was discussed on the basis of results calculated by the semi-empirical molecular orbital (MO) method (CNDO/2).[3] From the result it was confirmed that the abnormal absorption intensity of the C-H stretching vibration band in chloroform vapor arises from the electrical properties of a vibrating bond and that the 3d orbitals on chlorine play an important role in determining the molecular properties by the CNDO/2 method.

In the previous study we assumed that the normal mode of ν_1 vibration is approximately equivalent to the pure C-H stretching mode. Since the mass of chlorine is much heavier than those of other atoms, it seemed reasonable to assume that a slight displacement of the chlorine in the ν_1 vibration is negligible. From the results of a recent preliminary investigation, however, it was found that the theoretical infrared absorption intensity is affected by a slight displacement of the chlorine in the ν_1 vibration. Then, by employing an ab initio MO calculation, the effects of this approximation for the ν_1 vibrational mode on the theoretical potential energy and dipole-moment functions are discussed in detail. Also, the infrared absorption frequencies and intensities of the fundamental and first overtone of the ν_1 vibration, calculated on the basis of these functions, are compared with the experimental values. In an effort to determine the selection effect of the basis set in the ab initio MO method on the theoretical frequency and intensity, the results calculated from five kinds of Gaussian basis sets are compared with one another.

Computational Procedure

All ab initio MO calculations were performed by employing the Gaussian 80 program provided by the QCPE, and HITAC M-680H system of the Computer Center in the University of Tokyo.

The theoretical equilibrium geometry of chloroform has been determined by the use of an energy gradient method. The basis sets employed in this work are the 4-31G, 4-31G*, 6-31G*,[4] 6-31G**[4] and Dunning contraction to [6s4p/4s2p/2s] basis[5,6] from the Huzinaga (11s7p/9s5p/4s) primitive set,[7,8] augmented by a set of d-type polarization functions on carbon and chlorine. For the exponent of the polarization function, the values recorded in the Gaussian 80 program were adopted, except for the cases described below. The exponent values of chlorine in 4-31G* (0.47) and the Huzinaga-Dunning (0.65) basis sets were evaluated on the condition of minimizing the total energy at the equilibrium structure, determined without the polarization function in question, the exponent of carbon in the latter case following the value (0.75) adopted by Kato.[11] For the exponent of the chlorine polarization function in 6-31G* and 6-31G**, the value (0.70) selected by Pople et al. was employed.[9,10]

The quadratic force constants with respect to the internal symmetry coordinates were evaluated by a numerical second differentiation of the potential energy of chloroform. By using these force constants, a normal coordinate analysis could be carried out with the Wilson's GF matrix method.[12] In the next step, the derivatives of the detailed potential energy function, $V(Q)$, with respect to the normal coordinate Q_1 were determined from the increment of total energy of the molecule distorted along the normal mode in question. The derivatives of another potential energy function, $V'(Q)$, were obtained in the same way, except that the molecule was distorted under a local-mode approximation: the normal mode ν_1 is equal to the C-H stretching mode. These two types of potential energy functions, $V(Q)$ and $V'(Q)$, have been determined by calculations with five kinds of basis sets.

From the same treatment, the derivatives of the dipole-moment functions, $\mu^z(Q)$ and $\mu^{z\prime}(Q)$, with respect to the normal coordinate Q_1 were determined from the variation of the dipole moment calculated under the two types of vibrational modes, i.e. the normal mode and the local mode. In determining these potential energy and dipole-moment functions, the cross terms between normal coordinates were neglected. By the use of these potential energy functions, the variation method has been adopted in order to obtain the vibrational energy levels in view of the mechanical anhar-

monicity of the vibration.[13] The wave functions, ψ_i, of the molecular vibration were described as a linear combination of the harmonic oscillator wave functions, ϕ_k. By employing the vibrational wave function, ψ_i, and the dipole-moment function, $\mu^z(Q)$, the infrared absorption intensities of the fundamental and first overtone with respect to the ν_1 vibration have been determined in view of the mechanical and electrical

anharmonicities of the vibrating bond. Details of above the treatments were reported in a previous paper.[13)]

Another series of calculations have been performed in order to consider this problem on the basis of a variation of the dipole moment in the vicinity of the experimental equilibrium geometry.[14)] The treatment in this calculation is the same as that described above except for the calculation of the force constants. We adopted the force constants[15)] determined from the experimental absorption frequencies since there is a difference between the experimental and theoretical geometries, the latter being determined by minimizing the total energy.

Results and Discussion

The theoretical equilibrium geometries, dipole moments and total energies calculated by each basis set are shown in Table 1. These values are generally in good agreement with the experimental values; in detail, the results calculated by the high-level basis set are more improved than those by other basis sets.

Table 2 indicates the force constants with respect to the internal symmetry coordinates, which are used in Wilson's GF matrix method.[12)] These theoretical force constants, F_{ii}, are slightly overestimated. This is the general tendency in the result of a Hartree-Fock level calculation.

The displacements of atoms for a unit of normal coordinate, referring to the C-H stretching mode, are summarized in Table 3. It can be seen from the table that the displacements of chlorine in the normal mode are quite small in comparison with those of other atoms. Therefore, it seems reasonable to assume that the ν_1 normal mode of chloroform can be replaced by the pure C-H stretching mode. Practically, the derivatives of $V(Q)$ and $V'(Q)$, calculated from any basis set, are in almost good agreement with each other (Table 4). As indicated in Fig. 1, the profiles of the respective potential energy functions obtained by different basis set are drawn as a thick curve together, since there has a close resemblance regarding their shapes.

The fundamental and first-overtone frequencies calculated by the variation method are indicated in Table 5. These results make clear the delicate differences between the potential energy functions. In the table, the values in parentheses are the results obtained under a local-mode approximation. The absolute deviations of the theoretical frequencies from their mean value are within 1.8%, and the frequencies calculated under the local-mode approximation coincide with those calculated under the normal-mode treatment without an approximation. This fact shows that the potential energy function with respect to the ν_1 vibration is little affected by the motion of chlorine in the normal mode and the selection of the basis set in the ab initio MO calculation.

The agreement between the theoretical and experimental frequencies is generally unsatisfactory and a calculation with a high-level basis set does not always produce a better result. However, by the variation method, the frequencies are improved by 3—4% in comparison with the harmonic results which are given in italics in Table 5. These results indicate the effect of the mechanical anharmonicity on the fundamental and first-overtone frequencies of the ν_1 vibration. Table 6 indicates an example of the energy levels and wave functions of the ν_1 vibration calculated by the

variation method. From these results, the high anharmonicity of the C-H stretching mode can be obviously recognized. In this calculation, the cross terms between ν_1 and other vibrational modes in the potential energy function have been neglected.

In a previous paper, the CNDO/2 method was adopted for the molecular orbital calculation. Also, the calculated potential energy function was scaled in order to obtain the appropriate energy levels, since the force constants of stretching vibration calculated by

the CNDO/2 method is much larger than those generally found. In this work, however, such a treatment has not been performed since the results from the ab initio MO calculation are much more favourable than those from the CNDO/2 calculation.

Table 7-1 records the derivatives of the dipole-moment functions calculated by each basis set with regard to a normal-mode treatment and a local-mode approximation. In the relation between $\mu^z(Q)$ and $\mu^{z\prime}(Q)$, a different tendency can be found in comparison with the case of the potential energy functions, $V(Q)$ and $V'(Q)$. The corresponding derivatives of $\mu^z(Q)$ and $\mu^{z\prime}(Q)$ are different from each other, except for the μ_0^z values.

Especially, the M_1^z values are sensitive to the type of vibrational mode as well as the basis set in the MO calculation, although they are generally small. The $\mu^z(Q)$ and $\mu^{z\prime}(Q)$ calculated from each basis set are displayed in Fig. 2. By the use of the high-level basis set, the extremum of $\mu^z(Q)$ is generally shifted to the direction of short interatomic distance. The values of M_1^z in all cases are close to zero; in other words, the dipole-moment function has an extremum in the vicinity of the equilibrium structure of chloroform.

As generally pointed out, the absorption intensities of the fundamental and first overtone mainly depend on the magnitude of the absolute values of M_1^z and M_2^z, respectively. It is noteworthy, however, that the absorption intensities are affected by the mechanical and electrical anharmonicities of vibration. Especially, these effect in the case of the ν_1 vibration cannot be neglected since the C-H stretching mode is considerably anharmonic, as shown in Table 6.

The fundamental and first-overtone intensities calculated in view of the mechanical and electrical anharmonicities are listed in Table 8-1. Also, the intensities calculated under the harmonic approximation are summarized in Table 8-2. By a comparison between the results in Table 8-1 and those in Table 8-2, the effects of the mechanical and electrical anharmonicities on the infrared absorption intensities can be easily estimated as follows: the fundamental intensity is increased and the first-overtone intensity decreased.

The infrared absorption intensities calculated by using the 6-31G* and 6-31G** basis sets under the local-mode approximation are in agreement with the experimental results. However, from a comparison between these results and those from the normal-mode

treatment, in which a slight displacement of chlorine in the normal mode is considered, it is found that the treatment under the local-mode approximation requires circumspection in determining the dipole-moment function.

In the present work, we did not obtain satisfactory results by employing the high-level basis set under the normal-mode treatment. However, reasonable results would be obtained if we introduced the following treatments: a configuration interaction treatment in the MO calculation, an appropriate exponent for polarization functions, and cross terms between ν_1 and other vibrational modes in the potential energy function. These are subjects for future studies.

The theoretical dipole moment is affected by the charge distribution and equilibrium geometry of a molecule. In order to investigate the effect of the charge distribution calculated by different basis sets, the dipole-moment functions have been determined by each basis set under the same equilibrium geometry. In this treatment, the experimental geometry[14] has been adopted and the force constants determined on the basis of the experimental data[15] have been employed. The normal coordinates of the ν_1 vibration can be determined by the use of these force constants, however, the potential energy function $V(Q)$ cannot be obtained since the experimental equilibrium geometry is not generally in agreement with the theoretical equilibrium geometry, which are determined by minimizing the total energy.

Table 7-2 indicates the derivatives of the dipole-moment functions calculated by using the experimental equilibrium geometry. These results are similar to those displayed in Fig. 2, in which the results were obtained by using the theoretical equilibrium geometry. Therefore, the graphical representation of Table 7-2 have not been provided. The fundamental and first-overtone intensities calculated from these dipole-

moment functions and harmonic wave functions are listed in Table 8-3, the harmonic wave function being determined on the basis of the experimental results. These results from high-level basis sets are similar to those in Table 8-2 which are derived from the harmonic approximation at the theoretical equilibrium geometry.

The results of an ab initio MO calculation at the 6-31G* level for the dipole-moment function, referring to the ν_1 vibration of chloroform, were published by Tamagake et al.[16,17] It was reported in their papers that the first- and second-order coefficients of a dipole-moment function $\mu(R)$ were -0.08 and -1.0, respectively. For convenience, these values have been transformed to the coefficients of a function $\mu^z(Q)$. The values are -0.60 and -5.60, respectively, while the corresponding values obtained in this work are -0.252 and -9.022. They also reported that the dipole-moment function has an extremum at a distance smaller (-0.04 Å) than the theoretical equilibrium structure. Our corresponding result is -0.0109 Å. The cause of these differences between Tamagake's results and ours for the coefficients and extremum of the dipole-moment function cannot be discussed here since their report does not mention details regarding the following points: the equilibrium geometry and the exponent value of the polarization function on chlorine.

The absorption intensities based on Tamagake's results can be calculated only in the case of the harmonic approximation; however, a detailed treatment cannot be performed since a potential energy function is not published in their paper. The calculated intensities reproduce the experimental results as indicated in Table 8-2. However, if the mechanical anharmonicity is considered, it is expected that the fundamental intensity will be increased and the first-overtone intensity decreased in a similar manner (as our results indicated in Table 8-1).

Conclusion

The infrared absorption frequencies of the chloroform ν_1 vibration calculated by the ab initio MO method under the Hartree-Fock level treatment were larger than the experimental values (by about 10%). The potential energy function was insensitive to a slight displacement of the chlorine in the normal mode ν_1. Also, the selection effect of a Gaussian basis set in the ab initio MO method for the potential energy function was smaller than we have expected.

The theoretical infrared absorption intensities calculated by the 6-31G* and 6-31G** basis sets under the local-mode approximation reproduced the experimental results for the ν_1 vibration. However, satisfactory results could not be obtained by the high-level basis sets, including 6-31G* and 6-31G**, under the normal-mode treatment, which is faithful to the theoretical vibrational mode. The dipole-moment function was sensitive to a displacement of the chlorine in the normal mode ν_1 and to the selection of a Gaussian basis set in the ab initio MO method. It has been found that the local-mode treatment for ν_1 vibration requires circumspection in determining the dipole-moment function.

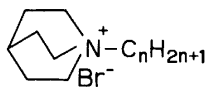
The Phase Transitions of 1-Alkyl-1-azoniabicyclo[2.2.2]octane Bromides, C_n-ABCO-Br ($10 \leqq n \leqq 22$)

Kengo IMAMURA, Takashi NOGAMI,* and Yasuhiko SHIROTA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565
(Received March 25, 1987)

The phase transitions of a series of 1-alkyl-1-azoniabicyclo[2.2.2]octane bromides were studied on the basis of DSC, the measurements of the ionic conductivities of the bromide anion, and Raman spectroscopy. Most of the materials exhibited three endothermic signals at T_{c1}, T_{c2}, and T_{c3} ($T_{c1}<T_{c2}<T_{c3}$) when they were heated. The temperature dependence of the ionic conductivities of the bromide anion showed conductivity jumps by a factor of 2—4 at around T_{c3}. In order to clarify the phase transition, the temperature dependences of the Raman spectra were measured. It was found that the phase transition at T_{c1} is caused by the molecular rearrangement in the solid, while the transitions at T_{c2} and T_{c3} are caused by both the conformational change in the alkyl chain and the rotational motion of the ABCO portion.

In a series of papers,[1-6] the phase transitions of bis(quaternary alkyl halides) of 1,4-diazabicyclo[2.2.2]octane (DABCO) and mono(quaternary alkyl bromides) of DABCO were studied on the basis of DSC, the measurements of the ionic conductivities of the halide anion, and IR and Raman spectroscopy. All of the symmetric bis(quaternary salts) of DABCO exhibited one transition, which was accompanied by abrupt increases in the ionic conductivities of the halide anion by two to three orders of magnitude.[1,2] The temperature dependence of the IR spectra showed abrupt disappearance of the band progressions at the transition temperature. This fact shows that the motion of the alkyl chain involving conformational change is excited above the transition temperature. On the other hand, unsymmetric bis(quaternary alkyl bromide salts) of DABCO exhibited somewhat different phenomena.[3-5] Although they also showed abrupt increases in the ionic conductivities of the halide anion at the transition temperatures, they were converted to the metastable state after they had been heated above the transition temperature and then cooled to room temperature. The thermodynamic properties of the unsymmetric DABCO salts could be explained on the basis of the free energy-temperature relation. Interesting correlations were found between the difference in the two alkyl-chain lengths of the unsymmetric DABCO salts and the phase transitions, the thermodynamic properties, and the ionic conductivities of the bromide anion.

As an extension of the above studies, we have now studied the phase transitions of a series of 1-alkyl-1-azoniabicyclo[2.2.2]octane bromides, which have only one nitrogen. We have found that most of the salts exhibited three transitions, and that the conductivity jumps of the bromide anion occurred at the highest transition temperature of the three. The phase transition could be analysed on the basis of the temperature dependence of the Raman spectra. In this paper, 1-azabicyclo[2.2.2]octane is abbreviated as ABCO. The materials studied are abbreviated by the numbers of the alkyl-carbons attached to ABCO nitrogen, shown in Fig. 1. For example, 1-decyl-1-azoniabicyclo[2.2.2]octane bromide is abbreviated as C_{10}-ABCO-Br. Thus, the materials in Fig. 1 are generally abbreviated as C_n-ABCO-Br ($10 \leqq n \leqq 22$).



C_n-ABCO-Br
(n = 10, 11, 12, 13, 14
15, 16, 17, 18, 22)

Fig. 1. Quaternary alkyl bromide salts of ABCO.

Experimental

Syntheses of C_n-ABCO-Br. Equimolar amounts (5 mmol) of ABCO and alkyl bromide were dissolved into methanol (20 ml), and the solution was refluxed for 10 h. In the cases of C_n-ABCO-Br (n=10, 11, 12, 13, 15, 17, 22), the methanol was evaporated to dryness, and the white residue was recrystallized three times from a mixed solvent of ethyl acetate and ethanol. In the cases of C_n-ABCO-Br (n=14, 16, 18), the methanol solution of the reaction was poured directly into diethyl ether (300—400 ml), the white precipitate was collected and recrystallized three times from the mixed solvent of ethyl acetate and ethanol. All the products were somewhat hygroscopic, and they were dried under a vacuum after recrystallization. They gave good analytical agreement; the residual solvent and moisture were negligible.

Measurements. A portion of 3—5 mg of the sample, dried beforehand under vacuum, was used for the measurement of the DSC. The details of the DSC and the measurements of the ionic conductivities of the bromide anion were described previously.[1,2] The Raman spectra were measured for the powdered sample by a method which will be reported elsewhere.[6]

Results and Discussion

DSC Measurements. The DSC measurements were

made in order to gain insight into the phase transition. Since all samples decomposed above 200 °C, their DSC measurements were made from room temperature to just above the highest transition temperature. Part of Table 1 shows the materials, the transition temperatures, the transition enthalpies, and the transition entropies. The transition temperature was obtained by the onset of the DSC signal. C_n-ABCO-Br (n=13, 14, 15, 16, 17, 18) showed three transitions. C_n-ABCO-Br (n=11, 12) and C_n-ABCO-Br (n=10, 22) showed two and four transitions respectively. Figure 2 shows the DSC thermogram of C_{13}-ABCO-Br as a typical example. When the sample was heated from room temperature, three endothermic signals were observed at T_{c1}, T_{c2}, and T_{c3} ($T_{c1} < T_{c2} < T_{c3}$). The corresponding exothermic signals were observed in the temperature region lower than T_{c1}, T_{c2}, and T_{c3} when the samples were cooled after they had been heated above T_{c3}; the hysteresis between the endothermic and exothermic signals was especially large for the transitions at T_{c1} and T_{c2}. In the second heating cycle, all of the materials showed endothermic signals identical to those of the first cycle. The transition temperatures of C_n-ABCO-Br ($11 \leqq n \leqq 22$) were classified into T_{c1}, T_{c2}, and T_{c3} in Table 1 for the following reasons. Almost iden-

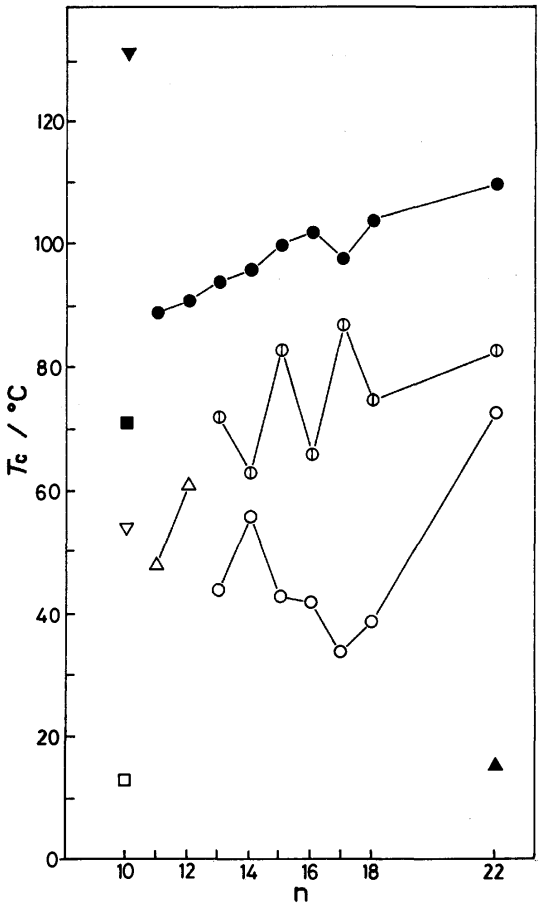

Fig. 3. The plot of the transition temperatures against carbon numbers of alkyl groups in C_n-ABCO-Br.
○ T_{c1}; ⦶ T_{c2}; ● T_{c3}; □▽■▼ transition temperatures of C_{10}-ABCO-Br; △ T_{c1} of C_n-ABCO-Br (n=11, 12); ▲ the lowest transition temperature of C_{22}-ABCO-Br.

tical structural changes seem to occur at T_{c1}, as will be discussed later in connection with the Raman spectroscopy. Regarding the transitions at T_{c2}, another type of structural change, which was also clarified by Raman spectroscopy, occurs for these materials. Since the conductivity jumps of the bromide anion occur at the highest transition temperatures (T_{c3}) for C_n-ABCO-Br ($n \geqq 11$), as will be described later, these transitions seem to be caused by the common structural change in the solid. On the other hand, the transitions of C_{10}-ABCO-Br seem to be different from those of the other ABCO salts.[7] Thus, its thermodynamic data are shown in the footnote of Table 1. The first transition of C_n-ABCO-Br (n=11, 12) is tentatively assigned to T_{c1}, for it has two transition temperatures, in contrast to the three transition temperatures of most of the other salts.

Figure 3 plots the transition temperatures (T_{c1}, T_{c2}, and T_{c3}) of C_n-ABCO-Br ($n \geqq 11$) and the four transition temperatures of C_{10}-ABCO-Br against the carbon numbers of the alkyl group attached to ABCO-nitrogen. Although T_{c1} showed a complex behavior, a distinct even-odd number effect of the alkyl carbons was observed for T_{c2}. T_{c3} increased gradually with the increase in the alkyl-chain lengths except for C_{17}-ABCO-Br. Figure 4 plots the transition enthalpies (ΔH_1, ΔH_2, ΔH_3) against the carbon numbers of the alkyl groups attached to ABCO nitrogen. Here, ΔH_1, ΔH_2, and ΔH_3 correspond to the values of the endothermic heats at T_{c1}, T_{c2}, and T_{c3} respectively. The values of ΔH_1 and ΔH_2 are not so different, being about 10 kJ mol^{-1} or less. An even-odd number effect of the alkyl carbons was observed for ΔH_2 (C_n-ABCO-Br, $n \geqq 13$). On the other hand, ΔH_3 increased with the increase in the alkyl-chain lengths. The transition temperatures (T_{c1} and T_{c2}) for C_n-ABCO-Br ($n \geqq 13$) seem to coalesce to a single transition temperature (T_{c1}) for C_n-ABCO-Br (n=11, 12), because the sum of ΔH_1 and ΔH_2 for the former salts gives values similar to those of ΔH_1 for the latter salts (see Fig. 4). This point will be discussed later in connection with the Raman spectroscopy. The above characteristics of the transition enthalpies were also applicable to the cases of transition entropies ($\Delta S_1 = \Delta H_1/T_{c1}$, $\Delta S_2 = \Delta H_2/T_{c2}$, $\Delta S_3 = \Delta H_3/T_{c3}$).

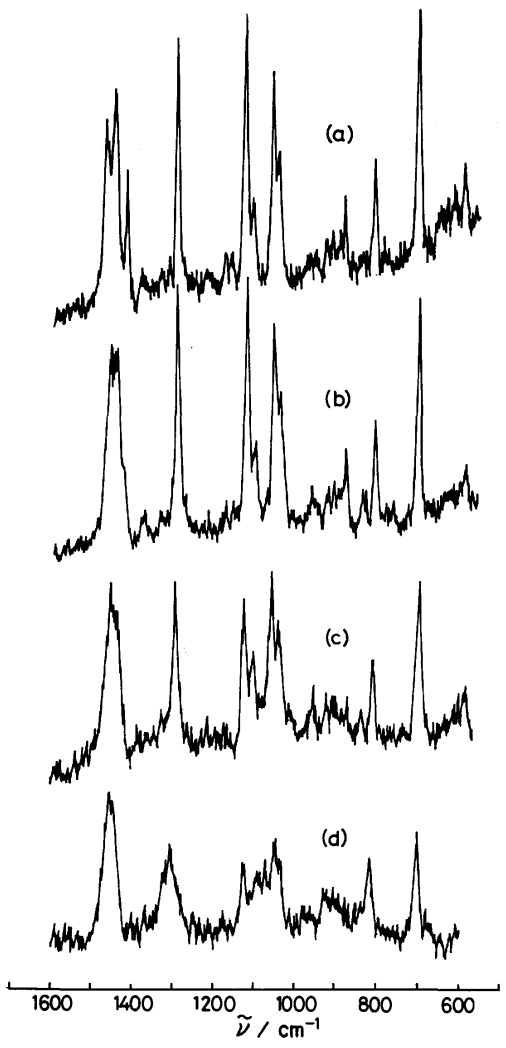

Fig. 5. Temperature dependence of the Raman spectra of C_{18}-ABCO-Br. (a) 17°C, (b) 50°C, (c) 80°C, (d) 110°C.

Raman Spectroscopy. In order to clarify the phase transitions at T_{c1}, T_{c2}, and T_{c3} in more detail, the temperature dependence of the Raman spectra was measured. Figure 5 shows the result observed for C_{18}-ABCO-Br as a typical example. Below T_{c1} (39 °C), crystal-field splitting[8] was observed at 1419 and 1450 cm^{-1} (see the spectrum at 17 °C). This fact shows that the zigzag planes of the nearest neighboring alkyl chains are packed nearly perpendicular to each other.[8] The crystal-field splitting disappeared above T_{c1} (see the spectrum at 50 °C). In view of the small value of ΔH_1 (2.7 kJ mol^{-1}), the transition at T_{c1} seems not to be caused by the onset of a rotator phase.[9] The lack of the crystal-field splitting above T_{c1} shows that a reorientation of the molecules takes place in the solid. No appreciable decreases in the Raman intensities were observed for the C-C skeletal vibration (1061, 1130 cm^{-1}) and the CH_2 twisting mode (1297 cm^{-1}) in the temperature range of $T_{c1} < T < T_{c2}$. In this context, Kobayashi et al. investigated the correlation between the Raman intensities and the length of the *trans*-zigzag structure in polyethylene.[10] They found that the Raman intensities decreased with the decrease in the length of the *trans*-zigzag portion, and that the Raman bands were broadened by the onset of vigorous reorientational motion of the molecule. Taking these results into account, the present findings suggest that no conformational change of the alkyl group occurs between T_{c1} and T_{c2}.[10] Above T_{c2} (75 °C), the intensities of these vibrational modes decreased significantly (see the spectrum at 80 °C). This fact shows that the conformational change in the alkyl group occurs above T_{c2}. Since the Raman intensities of the NC_4 symmetric stretching mode (706 cm^{-1}) also decreased to some extent above T_{c2}, the rotational motion of ABCO seems to be excited.[10] All of the Raman signals decreased in their intensities and were considerably broadened above T_{c3} (see the spectrum at 110 °C). This fact shows that the alkyl chain seems to be "melt" from the dynamical point of view and that a vigorous rotational motion of ABCO occurs in this temperature range. The coalescence of T_{c1} and T_{c2} observed for C_n-ABCO-Br ($n \geqq 13$) into T_{c1} for C_n-ABCO-Br ($n=11$, 12) was clearly demonstrated by the fact that both the disappearance of the crystal-field splitting and the decrease in the Raman intensities at 1064, 1130, and 1297 cm^{-1} were simultaneously observed above T_{c1} for the latter materials; the former observation corresponds to the rearrangement of the molecule in the solid, and the latter, to the conformational change in the alkyl group. Thus, the structural changes observed at T_{c1} and T_{c2} for C_n-ABCO-Br ($n \geqq 13$) occurred simultaneously at T_{c1} for C_n-ABCO-Br ($n=11$, 12).

Ionic Conductivities of the Bromide Anion. The temperature dependences of the ionic conductivities of the bromide anion were measured for the compressed pellet samples by an AC impedance method.[1,2] Figure

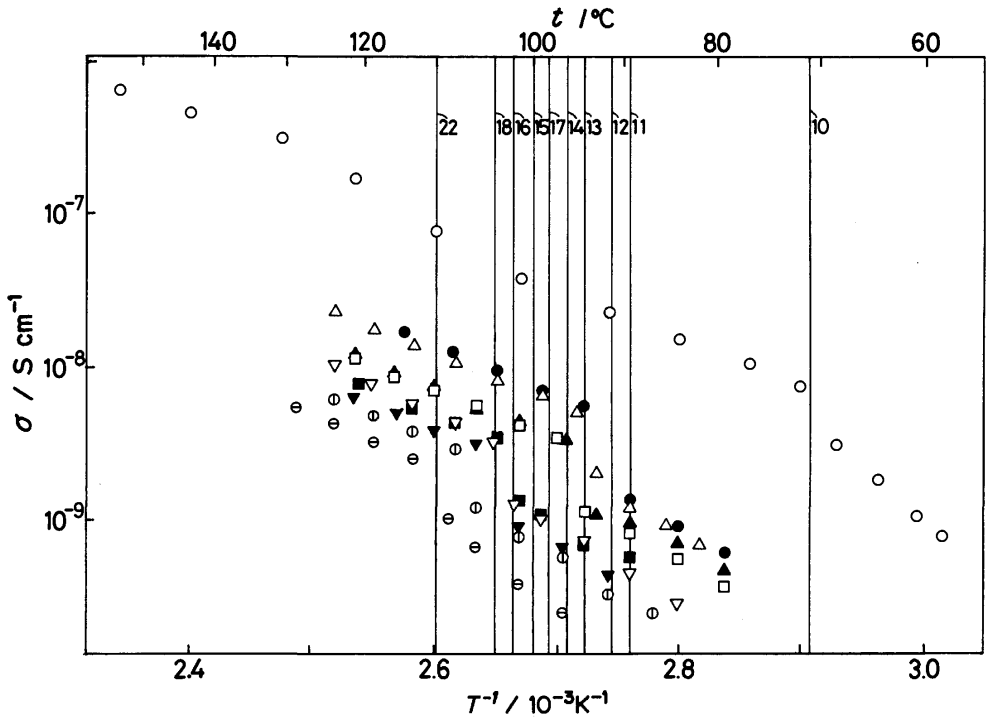

Fig. 6. Temperature dependence of the ionic conductivities of bromide anion of C_n-ABCO-Br. ○ $n=10$; ● $n=11$; △ $n=12$; ▲ $n=13$; □ $n=14$; ■ $n=15$; ▽ $n=16$; ▼ $n=17$; ⦶ $n=18$; ⊖ $n=22$. The vertical solid lines and the numbers nearby represent T_{c3} and n respectively.

6 shows the observed results. All of the materials exhibited conductivity jumps, and the ratios of the ionic conductivities of the bromide anion before (σ_l) and after (σ_h) the transitions were found to be in the range of 2—4 (see Table 1). These values are much smaller than those of the bis(quaternary alkyl bromide salts) of DABCO,[1-5] but are almost identical with those of the mono(quaternary alkyl bromide salts) of DABCO.[6] In order to correlate the conductivity jumps with the transition temperatures, T_{c3}'s are also shown as vertical solid lines in this figure. The numbers near these lines represent the numbers of the alkyl carbons attached to ABCO nitrogen. From Fig. 6, the following characteristics can be seen: (1) The conductivity jump occurs at around T_{c3} by a factor of 2—4. (2) The shorter the alkyl-chain lengths, the higher the ionic conductivities of the bromide anion. (3) The activation energies of the conduction above T_{c3} are lower than those below T_{c3}.

The first characteristic shows that no appreciable conductivity jump occurs at T_{c1}, where molecular rearrangement takes place, or at T_{c2}, where the conformational motion of the alkyl chain and the rotational motion of ABCO are excited to some extent. Only at T_{c3} where vigorous molecular motion sets in, does the conductivity jump take place. The values of the conductivity jump seem to be related with the degree of the molecular motion for the following reason. The temperature dependence of the Raman spectra of the symmetric bis(quaternary alkyl bromides) of DABCO exhibited an almost complete disappearance of the C-C skeletal modes above the transition temperature.[11] This fact shows that the molecular motion of the alkyl group is too vigorous to be regarded as if it were "liquid." As a result, the conductivity jumps of these materials were large. On the other hand, the molecular motion of the present materials are retarded to some extent, in view of the presence of the C-C skeletal mode even above T_{c3} (see Fig. 6); this gives rise to the small conductivity jump. The second characteristic above can be explained by the fact that the distance between the hopping sites of the bromide anion becomes shorter as the alkyl-chain lengths decrease. The third characteristic above can be explained by the fact that the bromide anion can move more easily in the high-temperature range ($T > T_{c3}$) than in the low temperature range ($T < T_{c3}$) because of the presence of a large number of voids which are produced by the vigorous motion of the alkyl group and the ABCO portion.

Summary. The phase transitions of C_n-ABCO-Br ($10 \leqq n \leqq 22$) were studied on the basis of the DSC, the Raman spectroscopy, and the measurements of the ionic conductivities of the bromide anion. Concluding a series of the studies,[1-6] three characteristic points (the numbers of the transitions, the existence of a metastable state, and the conductivity ratios of the bromide anion before and after the transition) were compared: The results are summarized in Table 2. Here, C_n-DABCO-C_n-Br_2,[1,2] C_n-DABCO-C_m-Br_2,[3-5] and C_n-DABCO-Br[6] denote symmetric bis(quaternary alkyl bromides) of DABCO, unsymmetric bis(quaternary alkyl bromides) of DABCO, and mono(quaternary alkyl bromides) of DABCO respectively; n and m denote the numbers of alkyl carbons. As to the numbers of the transitions, C_n-DABCO-C_n-Br_2, C_n-DABCO-C_m-Br_2, C_n-DABCO-Br, and C_n-ABCO-Br exhibited one, one, two, and three transitions respectively. Regarding the thermodynamic properties, no metastable state was observed for C_n-DABCO-C_n-Br_2, C_n-DABCO-Br, or C_n-ABCO-Br. In the case of the unsymmetric bis(quaternary alkyl bromide salts) of DABCO (C_n-DABCO-C_m-Br_2), however, the low-temperature phase was converted to the metastable state after they had been heated above the transition temperature and then cooled. All of the quaternary salts studied up to now showed conductivity jumps of the bromide anion. The conductivity jumps (the σ_h/σ_l values) are found to be in the range of 100—6000 for the bis(quaternary alkyl bromides) of DABCO. On the other hand, they are small (2—10) for the mono(quaternary alkyl bromides) of DABCO and of ABCO. In the cases of C_n-DABCO-C_n-Cl_2 and C_n-DABCO-C_n-I_2, the conductivity jumps of the chloride anion and iodide anion by a factor of 150—190 and 140—350 respectively were also observed.[2]

We are grateful to Professor Masamichi Kobayashi and Dr. Tsutomu Ishioka, Faculty of Science, Osaka University, for their fruitful discussions with regard to the analysis of the Raman spectra. We are also grateful to Professor Shigekazu Kusabayashi and Dr. Shunsuke

Fluorescence Quenching of *N*-Phenyl-1-naphthylamine by Nitriles, Esters, and Amines

Sanyo HAMAI
Department of Physics, Miyazaki Medical College, Kiyotake, Miyazaki 889-16
(Received April 2, 1987)

The equilibrium constants for the hydrogen bonding between *N*-phenyl-1-naphthylamine (NPNA) and proton acceptors (1,4-dioxane, nitriles, esters, and amines) in cyclohexane and the corresponding thermodynamic parameters have been determined. The fluorescence of NPNA is quenched by nitriles, esters, and amines. In the cases of nitriles and esters, the quenching is caused by compounds in which a cyano or carboxyl group is conjugated with a double bond. The rate constants for quenching of the NPNA fluorescence by methyl tiglate, methyl 3,4,5-trimethoxybenzoate, and 2,4,6-trimethylpyridine are 81, 73, and 69% of those by methyl acrylate, methyl benzoate, and pyridine, respectively. These findings can be interpreted in terms of the charge-transfer interaction through the hydrogen bond between NPNA (an electron donor) and the proton acceptors (electron acceptors) except for the amines, for which a mechanism different from the charge-transfer mechanism may be important in explaining the fluorescence quenching.

It is well-known that 1- or 2-naphthylamine is hydrogen-bonded to pyridine etc.[1-3] It has been shown that when two conjugated π-electronic systems are directly combined by the hydrogen-bonding interaction, the fluorescence of 1- or 2-naphthylamine is quenched.[1-4] As the quenching mechanism in these cases, a charge-transfer interaction between a proton donor and a proton acceptor through the hydrogen bond has been suggested.[1-5]

Derivatives of *N*-phenyl-1-naphthylamine (NPNA), 1,8-ANS (8-anilino-1-naphthalenesulfonate) etc., are frequently used as fluorescent probes in the areas of biochemistry and biology.[6,7] However, the hydrogen-bonding interaction between a fluorescent probe and substrates has not been noted, although these probes may be hydrogen bonded to substrates. Thus, we studied the quenching behavior of the fluorescence of NPNA in cyclohexane by using additives forming a hydrogen bond with NPNA.

Experimental

N-Phenyl-1-naphthylamine (NPNA) was recrystallized from cyclohexane three times. Ethers, nitriles, esters, and amines were distilled under atmospheric or reduced pressure except for methyl 3,4,5-trimethoxybenzoate and 1,4-diazabicyclo[2.2.2]octane (DABCO) which were recrystallized twice from ethanol and hexane, respectively. Cyclohexane was purified by percolation through a silica-gel column. Absorption spectra were recorded with a Shimadzu UV-260 spectrophotometer. Fluorescence spectra were taken with a Shimadzu RF-501 spectrofluorometer. Fluorescence spectra were corrected for the spectral response of the spectrofluorometer.[8] The fluorescence lifetime of NPNA was measured with an Ortec 9200 nanosecond decay time fluorimeter equipped with a Horiba NFL-111A ns lamp. Fluorescence quantum yields were determined relative to a quantum yield of 0.90 of 9,10-diphenylanthracene in nitrogenated cyclohexane.[9] The concentrations of NPNA for the measurement of absorption and fluorescence were 10^{-4} and 3×10^{-5} mol dm^{-3}, respectively. Sample solutions for the fluorescence measurement were nitrogen bubbled. Unless otherwise stated, all the measurements were made at 25±0.1 °C.

Results and Discussion

Figure 1 shows the absorption spectra of NPNA in cyclohexane in the absence and presence of 1,4-dioxane. The absorption maximum of NPNA is shifted to the red with isosbestic points at 284 and 332 nm. These spectral changes indicate a hydrogen bonding between NPNA and 1,4-dioxane. In the hydrogen-bonding complex with 1,4-dioxane, a proton donor is NPNA and a proton acceptor 1,4-dioxane. From the spectral changes of NPNA in Fig. 1, an equilibrium constant (K_g) for the hydrogen bonding in the ground state could be evaluated, and its value is shown in Table 1 together with the enthalpy change (ΔH) and the entropy change (ΔS) of K_g which were determined from the temperature dependence of K_g.[10] For nitriles, esters, and amines, similar changes to those for 1,4-dioxane in the absorption spectra of NPNA were observed, indicating a hydrogen bonding with NPNA.

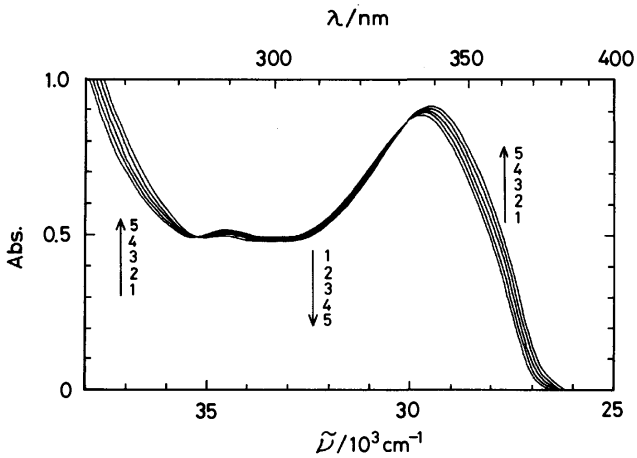

Fig. 1. Absorption spectra of NPNA (10^{-4} mol dm^{-3}) in cyclohexane in the presence of 1,4-dioxane. Concentration of 1,4-dioxane: (1) 0 mol dm^{-3}; (2) 0.117 mol dm^{-3}; (3) 0.234 mol dm^{-3}; (4) 0.585 mol dm^{-3}; (5) 1.17 mol dm^{-3}.

Table 1. Equilibrium Constants for Hydrogen Bonding of NPNA in the Ground State at 25 °C (K_g), Enthalpy Changes (ΔH), and Entropy Changes (ΔS)

	K_g/mol^{-1} dm^3	ΔH/kJ mol^{-1}	ΔS/J K^{-1} mol^{-1}
1,4-Dioxane	1.8	−26	−84
Propionitrile	2.5	−10	−27
Acrylonitrile	1.6	−12	−38
Benzonitrile	2.0	−12	−33
Ethyl acetate	1.8	−17	−50

Methyl tiglate	1.4	−22	−72
Dibutyl oxalate	2.5	−21	−63
Dibutyl maleate	4.1	−21	−60
Methyl benzoate	1.4	−20	−63
Methyl 3,4,5-trimethoxybenzoate	6.3	−17	−42
Pyridine	3.2	−8.8	−20
2,4,6-Trimethylpyridine	5	—	—
Triethylamine	0.3	−35	−130
DABCO	2	−42	−130

The compounds are proton acceptors like 1,4-dioxane for NPNA. The values of K_g, ΔH, and ΔS for these esters, nitriles, and amines are also given in Table 1. As can be seen from Table 1, similar values of K_g are obtained for each group of proton acceptors except for dibutyl oxalate, dibutyl maleate, methyl 3,4,5-trimethoxybenzoate, and triethylamine. About twofold larger values of K_g for dibutyl oxalate and dibutyl maleate than those for monocarboxylates (ethyl acetate, etc.) can be explained by the fact that two carboxyl groups are involved in one molecule. The large difference in K_g between triethylamine and DABCO may be partly due to the difference of the number of the amino nitrogen. The larger value of K_g for methyl 3,4,5-trimethoxybenzoate or 2,4,6-trimethylpyridine than that for methyl benzoate or pyridine can be interpreted in terms of an increase of the electron density on a carboxyl oxygen atom or a nitrogen atom caused by an electron-donating substituent (methoxy or methyl group). The values for ΔH and ΔS are not too different within the same groups of acceptors.

The fluorescence spectra of NPNA in cyclohexane in the presence of 1,4-dioxane are shown in Fig. 2. When 1,4-dioxane is added to an NPNA solution, the fluorescence maximum of NPNA is shifted to longer wavelengths with an isoemissive point at 388 nm. An enhancement of the integrated fluorescence intensity is also observed. These spectral changes can be ascribed to the hydrogen bonding between NPNA and 1,4-dioxane. The enhancement of the NPNA fluorescence indicates that the fluorescence quantum yield (ϕ_f) is larger in a hydrogen-bonding form of NPNA than in a free form.

We examined the solvent dependence of ϕ_f and the fluorescence maximum position of NPNA. The values of ϕ_f in cyclohexane (ε=2.02), 1,4-dioxane (ε=2.21), ethyl acetate (ε=6.02), propionitrile (ε=27.2),

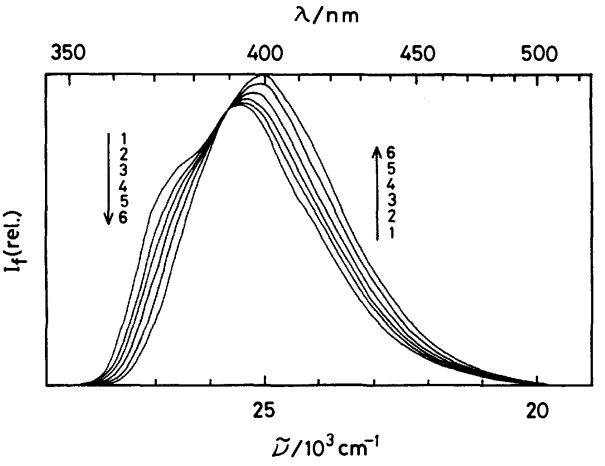

Fig. 2. Fluorescence spectra of NPNA (3×10^{-5} mol dm^{-3}) in cyclohexane in the presence of 1,4-dioxane. Concentration of 1,4-dioxane: (1) 0 mol dm^{-3}; (2) 0.059 mol dm^{-3}; (3) 0.117 mol dm^{-3}; (4) 0.234 mol dm^{-3}; (5) 0.585 mol dm^{-3}; (6) 1.17 mol dm^{-3}. λ(exc.)=332 nm.

and water (ε=78.5) were 0.68, 0.72, 0.63, 0.54, and 0.029, respectively. The larger the dielectric constant of the solvent, the smaller ϕ_f of NPNA except for 1,4-dioxane. The dielectric constant of 1,4-dioxane (2.21) is very close to that of cyclohexane (2.02). In the case of 1,4-dioxane, therefore, the effect of the hydrogen bonding, which enhances the fluorescence intensity, prevails over the effect of the solvent polarity. The fluorescence maximum in cyclohexane, 1,4-dioxane, ethyl acetate, propionitrile, and water are at 393, 413, 420, and 485 nm, respectively. The maximum position is red-shifted as the solvent polarity is increased. Such characteristics of both ϕ_f and the fluorescence peak have been reported for other naphthylamine derivatives.[11,12]

Figure 3 shows the fluorescence spectra of NPNA solutions containing varying concentrations of propionitrile. Below ≈0.07 mol dm^{-3} of propionitrile, the spectral change, with an isoemissive point at 389 nm, is similar to that for 1,4-dioxane (Fig. 2). Although the dielectric constant of propionitrile (27.2) is very large compared with that of cyclohexane (2.02), the polarity of the cyclohexane solution containing such a low concentration of propionitrile is not too different from that of neat cyclohexane. Above ≈0.14 mol dm^{-3} of propionitrile, the fluorescence intensity is reduced, accompanied by a red shift of the fluorescence maximum; also, the isoemissive point at 389 nm disappears. In the high-concentration range of propionitrile, the solvent polarity becomes fairly high. Thus, the effect of solvent polarity which decreases the fluorescence intensity overcomes the effect of the hydrogen bonding to decrease the fluorescence intensity.

In Table 2 are summarized the proton acceptors by which the fluorescence quenching of NPNA is caused (O) or not caused (X). The ethers examined in this study show no fluorescence quenching. In the nitrile series, acrylonitrile and benzonitrile quench the NPNA fluorescence, while acetonitrile and propionitrile do not quench. Acrylonitrile and benzonitrile have a double bond which is conjugated with a cyano group although in benzonitrile a conjugated double bond belongs to a benzene ring. For the fluorescence quenching of naphthylamines, quenchers forming a hydrogen bond are pyridine and quinoline whose conjugated double bond is present as a part of an aromatic ring.[1-3] In the case of acrylonitrile, however, a cyano group is conjugated with a nonaromatic double bond. In the ester series, ethyl acetate and vinyl acetate do not quench the NPNA fluorescence. However, the

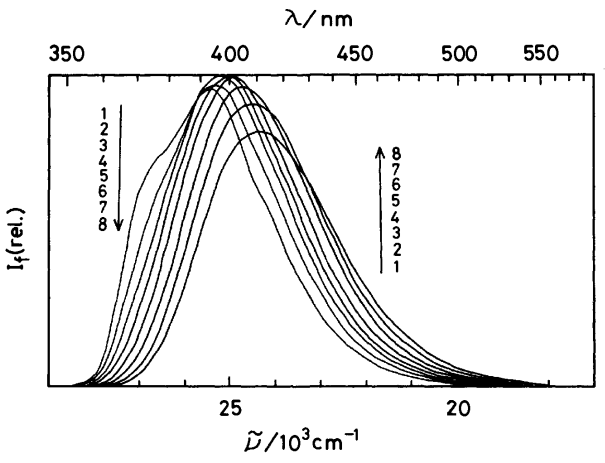

Fig. 3. Fluorescence spectra of NPNA (3×10^{-5} mol dm^{-3}) in cyclohexane in the presence of propionitrile. Concentration of propionitrile: (1) 0 mol dm^{-3}; (2) 0.028 mol dm^{-3}; (3) 0.071 mol dm^{-3}; (4) 0.142 mol dm^{-3}; (5) 0.284 mol dm^{-3}; (6) 0.710 mol dm^{-3}; (7) 1.42 mol dm^{-3}; (8) 2.84 mol dm^{-3}. λ(exc.)=326 nm.

Table 2. Proton Acceptors Which Exhibit Quenching (O) or No Quenching (X) for the NPNA Fluorescence

Proton acceptor	Result
1,4-Dioxane	X
Ethyl vinyl ether	X
Furan	X

2,4,6-Trimethylpyridine	O
Triethylamine	O
DABCO	O

fluorescence quenching takes place by methyl acrylate, methyl tiglate, dibutyl oxalate, dibutyl maleate, methyl benzoate, and methyl 3,4,5-trimethoxybenzoate. These esters also possess a double bond which is conjugated with a carboxyl group. For methyl acrylate, methyl tiglate, dibutyl oxalate, and dibutyl maleate, the double bonds are nonaromatic ones. In the case of amines, pyridine and 2,4,6-trimethylpyridine are effective quenchers for the NPNA fluorescence. Besides pyridine and 2,4,6-trimethylpyridine, aliphatic amines (triethylamine and DABCO) were found to quench the fluorescence.

All the quenchers shown in Table 2 are hydrogen bonded to NPNA in the ground state. Because the K_g values for these quenchers are not so large (1.2—6.3 mol^{-1} dm^3), the concentration of a hydrogen-bonding complex can be neglected in the low-concentration range of the quencher. Thus, the fluorescence quenching by these proton acceptors was analyzed according to the Stern-Volmer plot. From the Stern-Volmer quenching constants and the fluorescence lifetime of NPNA (3.9 ns), the rate constants for fluorescence quenching could be determined and are listed in Table 3.[13] These values in Table 3 represent the rate constants for the dynamic quenching in the excited state of NPNA. Almost diffusion-controlled rate constants are obtained for the nitriles. Although the quenchers shown in Table 3 can be hydrogen bonded to excited NPNA, the nonfluorescent exciplex formation may be possible for benzonitrile, methyl benzoate, and methyl 3,4,5-trimethoxybenzoate. Thus, we investigated the fluorescence quenching of *N*,*N*-dimethyl-1-naphthyl-

Table 3. Rate Constants for Fluorescence Quenching of NPNA (k_q)

Proton acceptor	$k_q/10^{10}$ mol^{-1} dm^3 s^{-1}
Acrylonitrile	1.60
Benzonitrile	1.53
Methyl acrylate	1.17
Methyl tiglate	0.95
Dibutyl oxalate	1.08
Dibutyl maleate	1.42
Methyl benzoate	1.14
Methyl 3,4,5-trimethoxybenzoate	0.83
Pyridine	1.19
2,4,6-Trimethylpyridine	0.82
Triethylamine	0.28
DABCO	1.00

amine (DMNA) by these proton acceptors. Its oxidation potential (0.46 V), estimated from the fluorescence maximum position of the perylene exciplexes with DMNA, *N*,*N*-diethylaniline, and *N*-ethylcarbazole, is much smaller than that of NPNA estimated in a similar fashion (0.89 V).[14,15] In addition, DMNA cannot be hydrogen bonded to proton acceptors in contrast to NPNA. It was found that no fluorescence quenching of DMNA took place by the above proton acceptors which quenched the NPNA fluorescence. From this finding, it is clearly evident that NPNA does not form a nonfluorescent exciplex with the above proton acceptors. Therefore, the hydrogen bonding in the excited state of NPNA is responsible for the fluorescence quenching. As shown in Table 3, the quenching constants of methyl tiglate, methyl 3,4,5-trimethoxybenzoate, and 2,4,6-trimethylpyridine are about 81, 73, and 69% of those for methyl acrylate, methyl benzoate, and pyridine, respectively, indicating a reduction of the quenching constant by the substitution of an electron-donating group (methyl or methoxy group) in a proton acceptor. Therefore, the quenching is caused by the charge-transfer interaction between NPNA and proton acceptors through the hydrogen bond. In these cases, NPNA is an electron donor and the proton acceptors electron acceptors.

For a 2-naphthylamine-pyridine system, Ikeda et al. has successfully detected a transient absorption of a charge-transfer state from excited 2-naphthylamine to hydrogen-bonded pyridine.[5] Our results that the fluorescence of NPNA is quenched only by the proton acceptors possessing a double bond which is conjugated with a functional group and that NPNA acts as an electron donor in the fluorescence quenching are consistent with the observations for the 2-naphthylamine-pyridine system. The findings that ethers, nonconjugated nitriles and esters do not quench the NPNA fluorescence can also be interpreted in terms of the charge-transfer interaction through a hydrogen bond.

Since the aliphatic amines (triethylamine and DABCO) were found to quench the perylene fluorescence to a smaller extent than NPNA does, they seem to be weaker electron donors than NPNA. If so, it is difficult to attribute the fluorescence quenching of NPNA by these amines to their electron donating nature. Other mechanisms, such as a proton transfer or a hydrogen atom transfer, may be responsible for the fluorescence quenching by the aliphatic amines.

The author wishes to thank Professor Fumio Hirayama for his valuable discussion.

Photocatalytic Oxidative Dehydrogenation of 2-Propanol with Niobium Oxide Supported on Porous Vycor Glass

Yuji WADA* and Akira MORIKAWA
Department of Chemical Engineering, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152
(Received April 22, 1987)

2-Propanol was catalytically converted to acetone on niobium oxide supported on porous Vycor glass in the presence of oxygen or nitrogen monoxide under UV irradiation. The light of wavelength shorter than 300 nm was effective for the reaction. The VIS-UV absorption measurements showed that niobium oxide was reduced by 2-propanol under the irradiation and Nb^{4+} formed by the photoreduction was reoxidized by oxygen. The kinetics of the reoxidation was investigated by means of spectroscopic measurements. The redox mechanism is proposed for the photocatalytic oxidation of 2-propanol.

In the periodic table, niobium belongs to 5A group and is located closely to Ti, Mo, and V. The catalytic activity of these oxides effective for chemical processes assisted by visible or ultraviolet irradiation has been well-investigated.[1] Similarity of niobium oxide in chemical and physical properties, such as crystal structure[2] and a semiconducting property,[3] to the oxides of the elements mentioned above suggests that the oxide can be a candidate of a catalyst for photoassisted chemical processes.

Photoactivation of niobium oxide catalyst has been reported.[4] Niobium oxide, which is catalytically inactive for ethylene dimerization, becomes active for the reaction by irradiation with ultraviolet light in the presence of ethylene. The catalyst once activated by the irradiation maintains its activity after the irradiation is ceased. This phenomenon has been attributed to the formation of Nb^{4+} ions, which are active sites for the reaction, by the reduction of Nb^{5+} ions with ethylene under the irradiation. If Nb^{4+} ions are readily oxidized by a proper oxidant, this photo-system can be designed as a photo-redox cycle.

The authors have found that 2-propanol is continuously converted to acetone in the presence of oxygen gas on niobium oxide supported on porous Vycor glass under irradiation with ultraviolet light. This paper deals with kinetic and spectroscopic investigations of this photocatalysis system to clarify the role of the niobium species in the photo-redox cycle.

Experimental

Materials. Porous Vycor glass was purchased from Corning Glass Works. Niobium pentachloride was kindly supplied from Professor M. Nangyo at Tohoku University. Its purity of 99.96% has been guaranteed. 2-Propanol purchased from Wako Chemical Co. was dried with molecular sieve 5A and thoroughly degassed before use.

Preparation of Catalyst. Porous Vycor glass of ca. 1 mm thickness was calcined at 550 °C in oxygen gas and then soaked at room temperature into a solution of niobium pentachloride in concentrated hydrochloric acid (0.5 mol-Nb l-HCl_{aq}^{-1}). After 12 h, the glass was washed with deionized water and stored in the water for 12 h to ensure hydrolysis of niobium chloride in the pore system of the Vycor glass. The amount of supported Nb, determined by radioactivation analysis, was 3 wt%-Nb_2O_5. The weights of the catalyst used were 0.356 and 0.482 g for the reaction experiments and the spectroscopic measurements, respectively. The catalyst is denoted by Nb_2O_5/PVG hereafter.

Apparatus. The reaction was carried out in a conventional gas-circulating system with a reaction volume of 149 ml, connected to a vacuum system. A reactor (Fig. 1-a) was made of quartz glass whose bottom was a flat, transparent quartz plate. The catalyst was laid on the bottom, through which the catalyst was irradiated by the light of a medium-pressure mercury lamp. The reaction temperature was controlled by an electric furnace whose bottom was open for the irradiation.

For measurements of visible and ultraviolet absorption spectra, a quartz-made rectangular cell was used, where the catalyst could be treated in the same way as in the reaction experiments. A small room is attached at the top of the cell for admitting oxygen gas onto the catalyst during the measurements. The catalyst was placed as shown in Fig. 1-b. A spectrometer, Shimadzu UV-200, was employed for light absorption measurements.

Procedures. The catalyst, Nb_2O_5/PVG, was treated with oxygen in the reactor at 500 °C for 1 h and degassed at the same temperature for 1 h before the reaction. The reaction was initiated by the irradiation after 2-propanol and oxygen gas were introduced into the reaction system. A portion of a

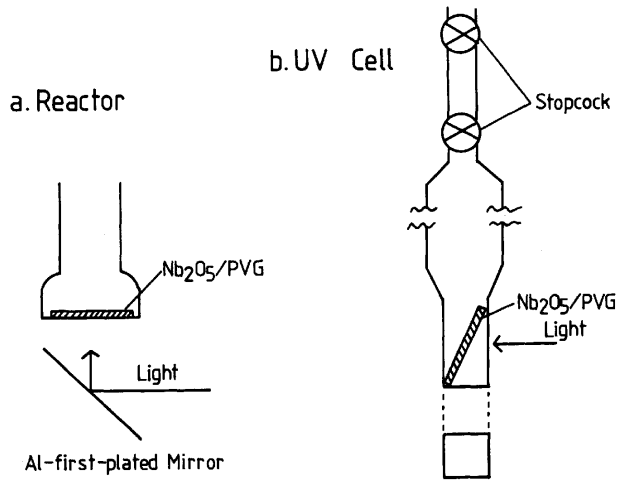

Fig. 1. Reactor and container of catalysts for VIS-UV absorption measurements.

reaction mixture was taken at appropriate time interval and analyzed by gas chromatography. A column (2 m) with packing, PEG 20M on Chromosorb W/AW, was used at 80 °C for the chromatography.

Results

It has been found that acetone was produced from the mixture of 2-propanol and oxygen gas on niobium oxide supported on porous Vycor glass under the irradiation at room temperature. No acetone was detected without the irradiation even at 100 °C. Propene, acetaldehyde, and CO_2 were observed beside acetone. They were less than 1% in yield even after the reaction was performed for 3 h. Figure 2 shows the formation of acetone along the irradiation time on Nb_2O_5/PVG, at room temperature (23—26 °C). Acetone was produced proportionally to the duration of the irradiation.

When no oxygen was present in the reaction system, the formation of only a small amount of acetone was observed within 60 min of the reaction time and its amount was not increased further (see Fig. 2). The acetone formation started again by the addition of oxygen and its rate was the same as that in the presence of oxygen gas. The catalyst was turned to black in color with a bluish cast after the reaction without oxygen gas, suggesting that niobium ion (IV) was produced during the reaction. The catalyst returned to transparent immediately by the addition of oxygen gas.

Figure 3 is a dependence of the rate of the acetone formation on a pressure of oxygen gas. A curve fits to the Langmuir-Hinshelwood type rate equation where the rate follows the first order of the amount of adsorbed oxygen (Eq. 1).

$$r = \mathrm{d(acetone)}/\mathrm{d}t = kKP(O_2)/\{1 + KP(O_2)\} \quad (1)$$

where k and K are constants and $P(O_2)$ denotes a pressure of oxygen gas.

The effect of the reaction temperature was examined in the range of the temperature, 75—150 °C. Rather large amount of propene was produced at these temperatures. This type of dehydration of 2-propanol took place in a dark in the same rate as in the irradiation. Figure 4 shows an Arrhenius type plot of the acetone formation rate. The apparent activation energy of 23 kJ mol^{-1} was estimated from the linear line of the plot.

In order to reveal an effective region of the wavelength to the dehydrogenation, light filters were inserted in between the reactor and the light source. Figure 5 shows that the light of wavelength shorter than 300 nm was effective for the reaction.

Oxidants other than oxygen, such as NO and N_2O, were tested. NO acted as an oxidant, but, the reaction rate was slower by a factor of 3 than when oxygen gas was used. When N_2O was used, the amount of acetone and its change along the irradiation time were the same as those observed in the absence of any oxidant as mentioned above.

UV-Absorption Analysis. As described in the previous section, the color of the catalyst turned to black

with bluish cast by UV irradiation in the presence of 2-propanol alone. This change in color suggests the formation of Nb^{4+} ion.

Figure 6 shows VIS-UV absorption spectra of the catalyst observed before and after the irradiation. The sample strongly absorbed UV light of wavelength shorter than 300 nm. After the irradiation in the presence of only 2-propanol, a broad absorption band appeared in the region from UV to visible light, corresponding to the color change of the catalyst observed when the reaction was carried out without oxygen gas.

An absorption maximum is distinguished at 450 nm in the spectra shown in Fig. 6. It has been reported that Nb^{4+} in an aqueous oxalic-acid solution has an absorption maximum at around 450 nm.[5] Compared to the latter absorption spectrum, the absorption band observed for the oxide supported on the glass was very broad. The broadening of absorption bands observed for a condensed phase is rather general phenomenon in the observation of electronic spectra. Therefore, the absorption band of the Nb_2O_5/PVG observed after the irradiation in the presence of only 2-propanol is attributed to Nb^{4+} ion which is situated on the surface of the porous glass in its rather strong interaction with either the silica network of the glass or the niobia framework supported on the glass. It is suggested that the Nb^{4+} ion must be produced through reduction of Nb_2O_5 by 2-propanol, being converted to acetone at the same time. Figure 7 represents a relation between the amount of acetone formed during the various irradiation times and the absorbance at 450 nm of the catalyst measured after the irradiation. Acetone was collected by degassing the catalyst after a certain irradiation time of the catalyst with UV light in the presence of only 2-propanol. A proportional relationship between the two values rationalized the above suggestion for the path of the Nb^{4+} ion production.

Transient Analysis of Reoxidation of Catalyst. Figure 8 shows a change in the spectrum of the photoreduced catalyst by its exposure to oxygen gas. The

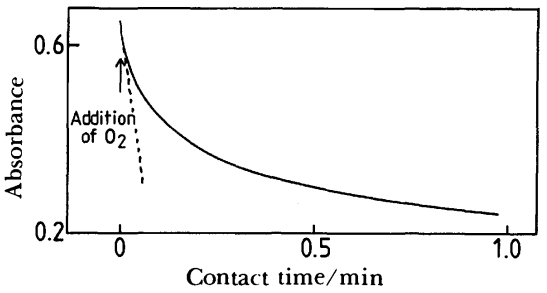

Fig. 9. Decrease of the absorbance at 450 nm by the admission of oxygen.

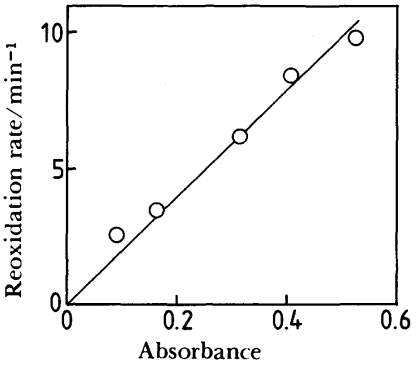

Fig. 10. Dependence of the Nb^{4+} reoxidation rate on the absorbance at 450 nm.

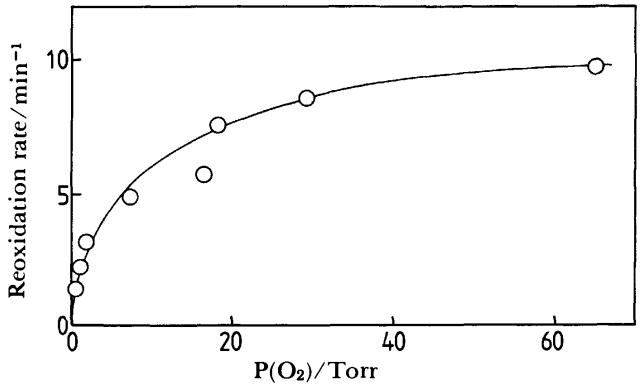

Fig. 11. Dependence of the Nb^{4+} reoxidation rate on the pressure of oxygen.

absorption band disappeared immediately by the exposure, indicating that Nb^{4+} was reoxidized easily by oxygen gas. The spectrum measured after the exposure was almost coincident with that observed before the reduction. The change of the absorbance at 450 nm could be recorded continuously by admitting oxygen gas onto the photoreduced catalyst (Fig. 9). Since the absorbance corresponds to the concentration of Nb^{4+} species, the result in Fig. 9 shows that the rate of the oxidation of the Nb^{4+} species decreases with increasing the exposure time, but the oxidation completed 80% within 1 min. This method allowed kinetic investigation of the reoxidation of the catalyst. The initial rate of the oxidation was evaluated from the slope of the dotted line drawn in Fig. 9 at the contact time, 0 min. Figures 10 and 11 show the dependencies of the initial rate on the initial absorbance of Nb^{4+} species and on the pressure of oxygen admitted on the catalyst showing a constant, initial absorbance of Nb^{4+} species, respectively. It is concluded from the two figures that the oxidation rate follows the first order kinetics on the concentration of Nb^{4+} on the surface and depends upon the concentration of oxygen molecules in a Langmuir-Hinshelwood type of equation as follows.

$$r = k[Nb^{4+}]KP(O_2)/\{1 + KP(O_2)\} \quad (2)$$

Discussion

Photoreduction. The present spectroscopic investigation has shown that the irradiation causes photoreduction of Nb^{5+} in the oxide to Nb^{4+} in the presence of 2-propanol. Visible and ultraviolet absorption spectrum of thin film of niobium oxide has shown the light absorption below 400 nm,[6] which overlaps to the same region (<300 nm) effective for the reaction of 2-propanol photooxidation. The linear relationship between the amount of formed acetone and the absorbance of Nb^{4+} on the catalyst (Fig. 7) shows that alcohol reacts with Nb^{5+} to produce acetone and Nb^{4+} according to the stoichiometry described in the Reaction i.

$$Nb^{5+}\text{-}O^{2-}\text{-}Nb^{5+} + CH_3CH(OH)CH_3 \rightarrow 2Nb^{4+} + CH_3COCH_3 + H_2O \quad (i)$$

As far as the homogeneous character of Nb^{4+} species formed in the Reaction i is supposed, its absorption coefficient at 450 nm was evaluated to be 1.5×10^6 mol^{-1} g-cat. cm^{-1} from the slope of the line in Fig. 7 and the thickness of the catalyst, 1 mm. Nb^{4+} formed by photoreduction must be present only on the surface and cannot migrate into the bulk of the niobium oxide, since the reduction occurs at room temperature. The amount of Nb^{4+} estimated from the stoichiometry of the Reaction i is 3.4×10^{-6} mol g-cat.$^{-1}$ for the catalyst photoreduced for 15 min. This amount corresponds to 1.3% of the total Nb^{5+} ions supported on the glass.

When titanium oxide was irradiated in the presence of alcohol, the color of the oxide turned to purple, showing that the photoreduction occurred.[7] This is essentially the same phenomenon as was observed for the present Nb_2O_5/PVG system.

Photoactivation of niobium oxide observed for the dimerization of ethylene has been explained by the photoreduction of the niobium oxide, which results in the formation of Nb^{4+} species by the photoreduction, which acts as an active site for ethylene dimerization.[4] Thus the niobium oxide is generally photoreduced in the presence of an organic reductant such as alcohols or olefins to give Nb^{4+} species.

Reoxidation. Nb^{4+} formed by the photoreduction is readily reoxidized by oxygen gas at room tempera-

ture as shown in Fig. 8. The oxidation curve in Fig. 9 fits to Elovich equation, suggesting that Nb^{4+} ions are heterogeneous in their reactivity for oxygen.

The rate equation for the reoxidation, obtained as shown by Eq. 2, indicates that Nb^{4+} species disappears through a reaction of adsorbed molecular oxygen, $O_2(a)$, with Nb^{4+}, as follows.

$$O_2 \rightleftarrows O_2(a) \quad \text{(ii)}$$

$$Nb^{4+} + O_2(a) \rightarrow Nb^{5+} - O_2^- \quad \text{(iii)}$$

It is plausible that O_2^- oxygen species must be formed at the first step of the reoxidation as shown in the Reaction iii. This is supported by the ESR observation that O_2^- is formed by oxygen admission on the silica-niobia which has been preliminarily reduced by hydrogen gas.[8] The O_2^- must be successively oxidized and finally converted to lattice oxygen (O^{2-}).

Catalytic Oxidation of 2-Propanol. The photooxidation of 2-propanol on Nb_2O_5/PVG proceeds via a redox mechanism of the oxide. The whole reaction steps are in the following.

$$Nb^{5+}\text{-}O^{2-}\text{-}Nb^{5+} + h\nu \rightarrow (Nb^{4+}\ O^-\text{-}Nb^{5+})^* \quad \text{(iv)}$$

$$(Nb^{4+}\ O^-\text{-}Nb^{5+})^* + \text{2-PrOH} \rightarrow 2Nb^{4+} + CH_3COCH_3 + H_2O \quad \text{(v)}$$

$$2Nb^{4+} + O_2 \rightarrow (Nb^{5+}\text{-}O_2^-\ Nb^{4+}) \quad \text{(vi)}$$

$$(Nb^{5+}\text{-}O_2^-\ Nb^{4+}) + 2Nb^{4+} \rightarrow 2(Nb^{5+}\text{-}O^{2-}\text{-}Nb^{5+}) \quad \text{(vii)}$$

This redox mechanism contains the photoreduction and the reoxidation discussed in the previous sections.

Yoshida et al. have proposed a redox mechanism for the photooxidation of CO and propene on V_2O_5 supported on silica.[9,10] The lattice oxygen of the oxide is responsible for the oxidation reaction in this mechanism.

Formenti et al. have proposed a mechanism of photooxidation of paraffin on TiO_2, where alcohols are formed from paraffins at first, and then the alcohols are converted to olefins, which are oxidized to ketones finally.[11] Since a small amount of propene was detected for the Nb_2O_5/PVG system, olefin can be an intermediate in the Reaction v.

A similarity of the rate equations of the acetone formation, Eq. 1, and of the reoxidation of the catalyst, Eq. 2, leads us to assume that the reoxidation, either of the reactions, vi or vii, is rate determining. In the mechanism of photodehydrogenation of alcohol on metal-supported titania proposed by Pichat et al.[7] and Herrmann et al.,[12] the abstraction of α-hydrogen from alcohol is rate determining. However the abstraction of hydrogen does not seem to be rate determining for the Nb_2O_5 system, because no isotope effect was observed when $CD_3CD(OD)CD_3$ was used as a reactant.

To get a general idea of 2-propanol photooxidation on metal oxides, literature data were compared as follows. The rate of the acetone formation in the present system was 4.0×10^{-7} mol s^{-1} for 1g of Nb_2O_5 at room temperature. Cunningham et al. have reported that the rates of the same reaction on irradiated TiO_2 and ZnO were 3×10^{-8} and 8×10^{-9} mol s^{-1} g^{-1}, respectively.[13] The rate calculated from the data for TiO_2 in the report by Bickley et al. was 1.2×10^{-10} mol s^{-1} g^{-1}.[14] The formation of acetaldehyde on TiO_2 has been 10 times slower than that of acetone.[13] On ZnO the two products were formed almost at the same rate.[13] The amount of acetaldehyde formed during the reaction on niobium oxide supported on porous Vycor glass was less than 1/50 of acetone. Although comparison in experimental procedures and conditions, i.e., a shape of a reactor, intensity and energy distribution of light, and a form of a catalyst, must be taken into account among these photocatalytic systems, the difference between the photocatalytic performances of TiO_2 or ZnO and that of niobium oxide is so large that it can be mentioned that niobium oxide is more active than TiO_2 and ZnO in the photooxidation of 2-propanol and far more selective for the formation of acetone.

The present research was supported by a Grant of the Asahi Glass Foundation for Industrial Technology.

New Discogenic Compounds: *N,N'*-Dialkanoyl-2,3,5,6-tetrakis-(alkanoyloxy)-1,4-benzenediamines

Yukio KOBAYASHI and Yoshio MATSUNAGA*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received April 18, 1987)

A series of *N,N'*-dialkanoyl-2,3,5,6-tetrakis(alkanoyloxy)-1,4-benzenediamines has been prepared and found to be mesogenic over a wide temperature range. The transformation into an isotropic liquid at a temperature between 189 and 209 °C is followed by thermal decomposition. The X-ray diffraction pattern of unoriented specimens in the mesophase consists of two sharp inner peaks and a broad outer one assignable to 100, 110, and 001 reflections respectively, indicating that the phase is hexagonal columnar.

A number of single compounds composed not only of elongated molecules but also of disk-like molecules are known to form stable or metastable thermotropic liquid crystals.[1,2] The first series of the latter group was discovered by Chandrasekhar et al. in 1977.[3,4] The compounds examined by them were hexakis(alkanoyloxy)benzenes (**1**), which were synthesized forty years earlier by Backer and van der Baan.[5] The discotic mesophase is observable only when n=6, 7, and 8. The temperature ranges are 5.8 and 3.6 °C in the first and the second members respectively. The mesophase appearing in the last member is metastable. In these mesophases, the disk-like molecules are stacked one on top of the other in columns forming a hexagonal arrangement but the spacing between the molecules in each column is irregular. As the substituent $NHCOC_nH_{2n+1}$ is efficient to promote the thermal stability of nematic and smectic phases,[6,7] the partial replacement of $OCOC_nH_{2n+1}$ groups in the above-mentioned hexasubstituted benzenes by $NHCOC_nH_{2n+1}$ groups might also stabilize discotic phases. Therefore, we have undertaken a study of *N,N'*-dialkanoyl-2,3,5,6-tetrakis(alkanoyloxy)-1,4-benzenediamines (**2**). A discotic mesophase was found over temperature ranges as wide as 140 °C when n=4 to 15.

Experimental

Materials. The sodium salt of 2,5-dihydroxy-3,6-dinitro-*p*-benzoquinone prepared by starting from *p*-chloranil was reduced to 3,6-diamino-1,2,4,5-benzenetetrol according to Nietzki and Benckiser.[8] The acylation was carried out employing acyl chloride in the presence of pyridine. For example, Found: C, 68.09; H, 9.61; N, 3,31%. Calcd for $C_6(NHCOC_6H_{13})_2(OCOC_6H_{13})_4$: C, 68.21; H, 9.54; N, 3.31%. Found: C, 73.90; H, 11.24; N, 2.33%. Calcd for $C_6(NHCOC_{11}H_{23})_2(OCOC_{11}H_{23})_4$: C, 74.00; H, 11.15; N, 2.21%. Hexakis(heptanoyloxy)benzene to be used as a reference discogen was prepared by the reaction between heptanoic anhydride and benzenehexol.[5] The latter compound was derived from the diaminobenzenetetrol.[8]

Measurements. Calorimetric curves up to the transition to isotropic liquids were recorded on a Rigaku Thermoflex differential scanning calorimeter at a heating rate of 5 K min^{-1}. The enthalpy changes were estimated by comparing the peak areas with that due to the melting of indium, 3.26 kJ mol^{-1}. The phase diagram was determined by the calorimetric curves of mixtures at every ten mol%. X-Ray diffractions were measured with a Rigaku auto-diffractometer, model RAD IVB, using filtered copper radiation. Proton NMR spectra were recorded as the first derivatives at 40 MHz, using a JEOL model JES-ME-3X spectrometer with a broad-line NMR attachment, model JES-BE-1, which employs a crossed-coil system.

Results and Discussion

The thermal properties of *N,N'*-dialkanoyl-2,3,5,6-tetrakis(alkanoyloxy)-1,4-benzenediamines are summarized in Table 1. Here, K, D, and I stand for crystalline, discotic, and isotropic phases respectively. No solid-solid transition is observed above room temperature for any member. The valeryl derivative (n=4)

forms a viscous birefringent fluid upon the transition located at 134 °C. All the higher homologous members melt below 100 °C. It is noted that the melting (K-D transition) points of the heptanoyl, octanoyl, and nonanoyl derivatives (n=6, 7, and 8) are not far from those of the compounds **1** with the same alkyl groups, 81, 80, and 80 °C respectively. On the other hand, the clearing (D-I transition) point is at a temperature higher than 200 °C in the case of the valeryl to nonanoyl derivatives and gradually lowers as the series is ascended. Thus, the temperature range of the mesophase is so expanded upwards by the replacement that the D-I transition of compound **2** is followed by thermal decomposition. The enthalpy of the D-I transition decreases with the increase of the alkyl chain length as is known for discotic hexasubstituted triphenylenes by the work of Destrade et al.[9] The same tendency may be noted also for the short series of compounds **1**. However, the value in the present compound is larger almost by a factor of two than that of the corresponding member in the series **1**. For example, 40 kJ mol^{-1} versus 22.2 kJ mol^{-1} when n=6.

The X-ray diffraction patterns of unoriented liquid crystals were measured at temperatures 10 to 15 °C below the clearing point. The major feature resembles that known for smectic A or C phase. The innermost peak is sharp and strong and is often accompanied by the second order reflection. An additional weak sharp peak is found in all the diffraction patterns. The spacing given by the former peak increases linearly within the limits of our experimental errors from 1.36 nm of the valeryl derivative to 2.37 nm of the hexadecanoyl derivative (n=15) and that given by the latter from 0.79 to 1.37 nm (see Fig. 1). These two spacings are in a ratio of about $1/\sqrt{3}$ characteristic of a hexagonal lattice. Therefore, the strong inner peak may be assigned to 100 reflection and the weak one to 110 reflection. This observation is interpreted by the presence of lamellar order with hexagonal symmetry in two dimensions in agreement with that reported for compounds **1**.[3,4] The diffuseness of the outer peak assignable to the 001 reflection must be evidence of the liquid-like disorder in the third dimension. The mean intermolecular spacing calculated using the formula $2d_{001}=\lambda/\sin\theta$ is 0.47 nm throughout the series **2** and essentially agrees with the values reported for compounds **1**, namely, 0.46 nm.

The identification of the mesophase is supported by an uninterrupted miscibility between the phases of compounds **1** and **2**. Figure 2 presents the diagram of the binary system composed of *N*,*N*′-dinonanoyl-2,3,5,6-tetrakis(nonanoyloxy)-1,4-benzenediamine (n=8) and hexakis(heptanoyloxy)benzene (n=6) as the reference discogenic compound. The open and shaded circles on the reference compound-rich side (the right-hand side) show the transitions recorded on the calorimetric curves during the processes of heating and cooling respectively, while recording during cooling on the other side was not made because of the thermal instability of compound **2** at high temperatures. The D-I transition does not occur sharply and the curve exhibits a minimum around 72.5 °C and 60 mol% of the reference compound. The destabilization of the mesophase by mixing may account for the differences in the geometrical, chemical, and mechanical properties of the component molecules. The estimated ratio of spacings is about 1.3. Such a value is known to be large

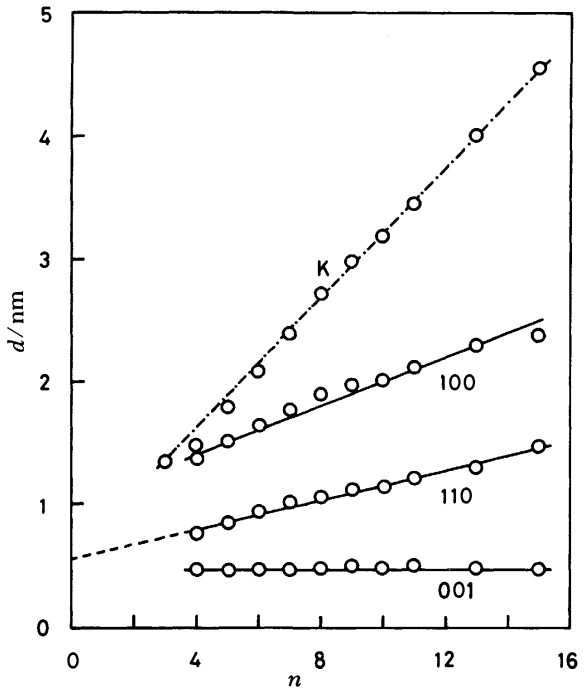

Fig. 1. Plot of spacings against the number of carbon atoms in the alkyl group for compounds **2**.

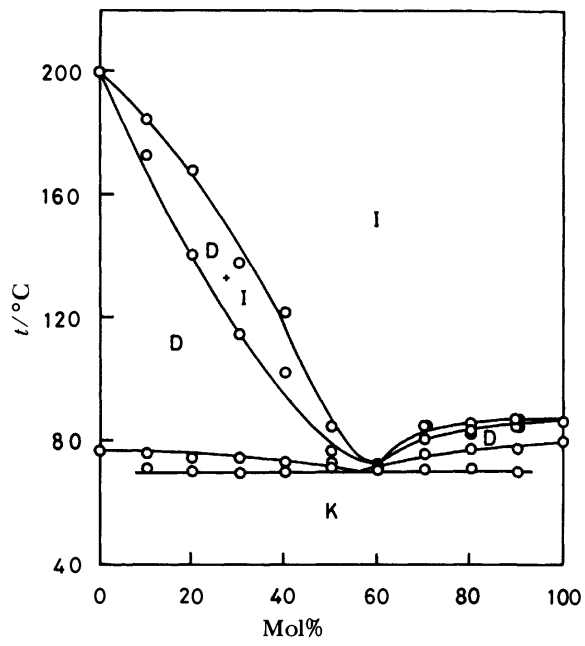

Fig. 2. Phase diagram of the compound **2** (n=8)–compound **1** (n=6) system. The former compound is located on the left-hand side.

enough to produce a marked deviation from a straight line even when the monomolecular smectic A phases of two homologous members are mixed.[10] Although this minimum lies close to the eutectic point, these two are readily distinguished from each other in the process of cooling because the I-D transition is never delayed but the discotic phase is markedly supercooled.

The spacing d_{100} in the mesophase of compound **1** reported by Chandrasekhar et al. is 1.50 nm for the octanoyl derivative and 1.59 nm for the nonanoyl derivative. The corresponding values for compounds **2** are appreciably longer; that is, 1.77 and 1.89 nm. The paraffinic chains in the present compounds are apparently more stretched and conformationally less disordered than those in compounds **1**. Such a dissimilarity is well indicated by the much larger enthalpy and entropy changes at the clearing point shown by compounds **2**. As is seen in Fig. 1, a linear relationship is found between n and the longest spacing in the crystalline phase, suggesting that the crystal structure is similar throughout this homologous series. The spacing shrinks only slightly upon melting when n=4 but by a factor of more than two when n=15. This behavior is not contradictory to the thermal data since the enthalpy change at the melting point increases remarkably with the increase of the alkyl chain length; for example 18 kJ mol^{-1} in the hexanoyl derivative and 115 kJ mol^{-1} in the hexadecanoyl derivative.

It may be added that the d_{110} value obtained by the extrapolation to n=0, 0.55 nm, is in good agreement with the radius estimated for the core structure, $C_6(NHCHO)_2(OCHO)_4$. Although rotation of the whole molecule about the normal to the molecular plane and the fluctuations of this axis around the preferred aromatic director are conceivable in the discotic phase,[11] the coincidence may be considered as an indication that the disk planes are, on an average, perpendicular to the columns in which the molecules are stacked.

The increment of spacing d_{110} per methylene group in the mesophase is merely 0.05 nm and is much shorter than that expected for the all-trans configuration of alkyl chains, 0.128 nm. Therefore, the longer the alkyl groups the faster on the NMR time scale, conformational changes of the alkyl groups are more extensive, resulting in more significant softening of the paraffinic crown. This proposition is in accordance with the considerable decrease of enthalpy change upon the D-I transition as the series is ascended. The change in the extent of liquid-like characteristic in the mesophase by the alkyl chain length is also manifested by the following proton second moments (the mean-square widths of the resonance lines), $\langle \Delta H^2 \rangle$, above the melting point; 0.3 G^2 (G=10^{-4} T) in the case of the octanoyl derivative and 0.03 G^2 in the case of the hexadecanoyl derivative. As is shown in Fig. 3, the moment measured at room temperature is as large as

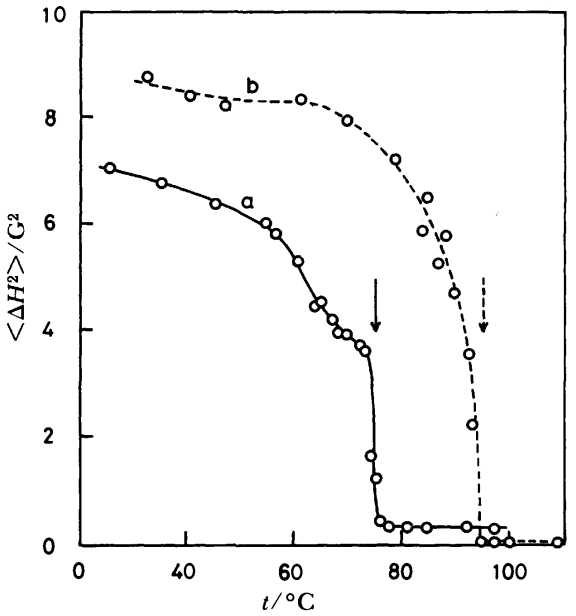

Fig. 3. Second moments of the broad-line proton NMR spectrum of compound **2**, (a) n=7 and (b) n=15. The vertical arrow indicates the melting point determined by calorimetry.

about 7 G^2 for the former compound and about 9 G^2 for the latter. It decreases gradually as the temperature is raised and then sharply near the transition temperature. The vertical arrows in this figure indicate the transition points determined by calorimetry.

In conclusion, the substituent $NHCOC_nH_{2n+1}$ is an efficient group to promote the thermal stability of hexagonal columnar mesophase. As noted by Gray in his reasoning why the nematic and smectic efficiencies of $NHCOCH_3$ group are high,[12] the polarizable substituent employed by us has a strong dipole and can form hydrogen bonds. The dipole-dipole interaction and intermolecular hydrogen bonding operating across the molecular plane appear to contribute greatly to the enhancement of thermal stability of the discotic mesophase.

Unimolecular Decomposition of Silane in Shock Waves

Hitoshi TANAKA, Mitsuo KOSHI,* and Hiroyuki MATSUI
Department of Reaction Chemistry, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received May 2, 1987)

Thermal decomposition of silane highly diluted in argon was studied behind incident shock waves at the temperatures ranging from 1250 to 1600 K. The decomposition course was followed by monitoring the infrared emission of silane at 4.4 μm. It was confirmed that the effects of consecutive reactions on the decay rate of silane were negligible under our experimental conditions. The unimolecular rate constants obtained directly from the decay curve of silane were found to be smaller than previous experimental values but consistent with the result of the recent trajectory-RRK calculation. It was also found that the addition of molecular hydrogen or nitrogen monoxide to the reactant mixtures had no effect on the decomposition rate of silane.

The homogeneous gas-phase decomposition of silane has already been investigated by several groups of workers. Various methods including static pyrolysis,[1-4] single pulse shock tube technique[5,6] and IR laser powered homogeneous pyrolysis[7,8] have been used to investigate the mechanistic detail of silane pyrolysis. Although some ambiguities on the role of the inhomogeneous production of hydrogen atoms are still remained,[9,10] the primary step of the homogeneous gas-phase decomposition has been now well established. At low temperature this step is the elimination of molecular hydrogen to form silylene.

$$SiH_4 \rightarrow SiH_2 + H_2 \qquad (1)$$

The homolytic cleavage of one SiH bond only becomes important at internal silane energies in excess of about 106 kcal mol^{-1} [11] (1 cal=4.184J). The conclusion has been supported by a consideration of symmetry of the reaction,[12] a calculation of the potential energy surface[13] and a trajectory-RRK calculation.[11]

Rate constants for the unimolecular decomposition of the Reaction 1 have already been measured by several investigators[1,2,5,6] and it was found that the reaction was in its pressure fall-off region at the atmospheric pressure and below. Purnell and Walsh[1] found that the rate constant of Reaction 1 was proportional to the square root of the total pressure. White et al.[3] observed the same pressure dependence in the similar pressure and temperature range and this pressure dependence was well explained by their RRKM calculations. However, the mechanism of the consecutive reactions of silylene is rather complex. Rate inhibition of the silane decay by molecular hydrogen which was attributed to the reverse process of the Reaction 1 was observed.[3] Also the reaction of silylene with silane would play a significant role on the silane loss rate.

It should be noted that all of these previous studies were based on the products analysis. If the decomposition process of silane has the induction period, as suggested by Newman et al.,[6] it might be difficult to get precise rate constant for the initiation reaction by the products analysis only. Time resolved measurement of silane concentration is desirable to investigate the mechanism of silane decomposition in details. Moreover, the published experimental works have been done for relatively high concentrations of silane, which made the roles of the consecutive reactions unclear, and the temperatures covered in these works have been limited to a relatively low range.

In the present study, we derived the unimolecular rate constant for the Reaction 1 directly from the time history of silane highly diluted in argon by monitoring infrared emission. The present study was performed for high temperatures up to 1600 K. The results were compared with those of the previous experimental and theoretical studies.

Experimental

A diaphragmless stainless-steel shock tube of 5 cm diameter was used. The driven section was 4 m in length and was evacuated to less than 2×10^{-6} Torr (1 Torr=133.322Pa) before charging it with a sample gas. The shock tube window (CaF_2) was located at 3.0 m downstream from the driver section. Highly diluted mixtures of silane (500 ppm) in argon were heated behind incident shock waves. The temperature, pressure and density of shocked gas were calculated from the shock velocity measured by piezo electric pressure gauges. The temperature and pressure of the reaction zone varied from 1250 to 1600 K and from 0.25 to 1.3 atm, respectively.

The intensity of the infrared emission at 4.4 μm, which could be attributed to the ν_3 fundamental band of silane, was monitored by an interference band pass filter (0.19 μm FWHM) and an InSb detector. The time response of the detection system was estimated to be less than 8 μs.

The gas mixtures were prepared manometrically with a calibrated diaphragm-type pressure gauge. Commercially available ultra-high purity gases (SiH_4: 99.9999%, Ar: 99.9995%, H_2: 99.9999%, and NO: 99.8%) were used without further purification.

Results and Discussion

An example of the time profile of 4.4 μm emission intensity is shown in Fig. 1. The intensity decreases exponentially behind the shock front and increases slowly near the contact surface of the shock wave. According to the recent ab initio calculation on the Si-containing species,[14] many of Si_2H_x and Si_3H_x

molecules have fundamental vibration-rotation bands in 4.5—4.7 μm region. For example, SiH_4, Si_2H_4, Si_2H_6, and Si_3H_8 have the fundamental bands at 4.56, 4.5, 4.63—4.66, and 4.63—4.69 μm respectively. Therefore it is possible that the observed emission is caused by not only SiH_4 but also other species like Si_2H_4. However, for the IR emission at initial decay this possibility is rejected by the following observations. 1) The decay of the emission intensity is described by a single exponential function as shown in Fig. 1. This implies that any product species which increase with time may not have significant contributions to the emission intensity, since the intensity goes down to the ground line before it shows gradual increase near the contact surface. 2) The solution of the simultaneous kinetic equations, which is discussed later in detail, predicts that the main reaction intermediates or products during the course of the silane decomposition under our experimental conditions are H_2, Si_2, Si, Si_2H_2, Si_3, and SiH_2. These species do not emit at 4.4 μm. 3) We also observed the emission at 4.87 μm with an interference band pass filter. The time profile of 4.87 μm emission intensity was the same as that of 4.4 μm intensity. No emission was observed at 5.22 μm. Therefore there is no significant contribution of the emission from SiH (4.88 μm), SiH_3 (5.0 μm), and SiH_2 (4.95 μm) to the emission at 4.4 μm.

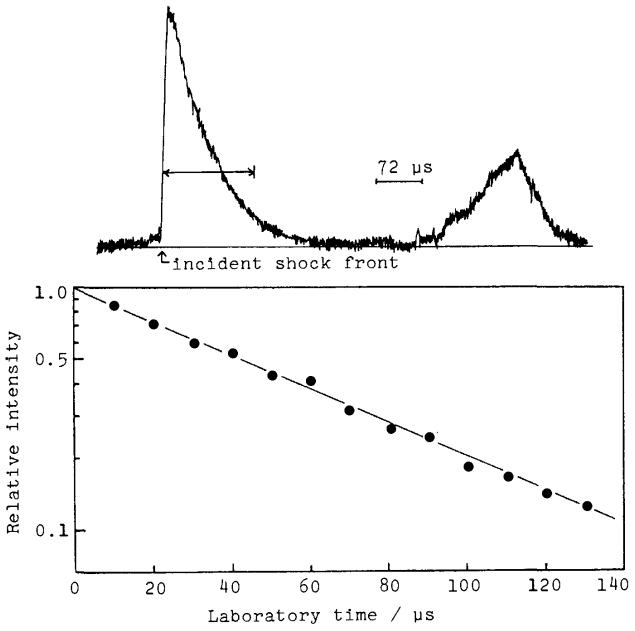

Fig. 1. Time history of the emission intensity at 4.4 μm. Upper panel: An example of the oscillogram trace. Lower panel: A log plot of the normarized intensity. T=1380 K, P=0.28 atm, 500 ppm SiH_4 in Ar. The region indicated by an arrow in the upper panel is plotted in the lower panel.

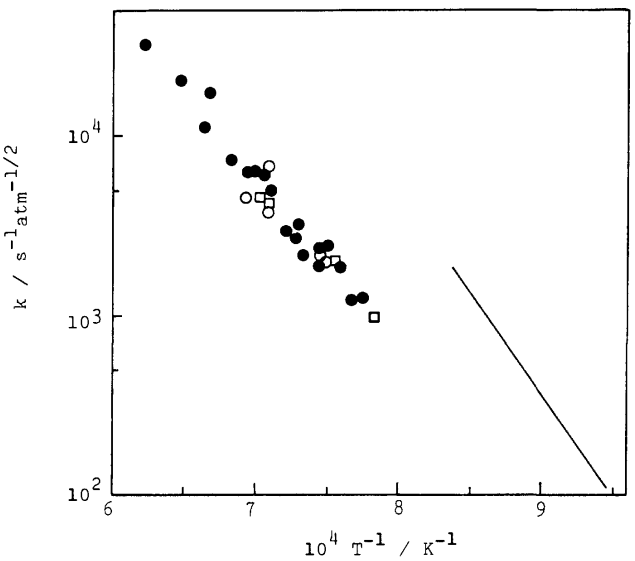

Fig. 2. Arrhenius plots of the pressure independent rate constants for the unimolecular decomposition of silane. k is defined by Eq. I in the text. Pressures of the experimental data are in the range of 0.25—1.2 atm. Closed circle: 500 ppm SiH_4 in Ar, open circle: 500 ppm SiH_4 in Ar with 1.1% H_2, open square: 500 ppm SiH_4 in Ar with 0.31% NO, line: from Ref. 6 (P=5.26 atm, 0.96% SiH_4 in Ar).

The origin of the slowly rising part of the emission profile near the contact surface is not clear. Only the decaying part of the emission intensity which was concluded to be proportional to the concentration of silane is analyzed in the present study. It was found that the first-order rate constants for the silane decay, k_{obs}, were proportional to a square root of the total pressure. Figure 2 shows Arrhenius plots of the pressure independent rate constants, k, which are defined by

$$k=k_{obs}P^{-1/2}, \quad \text{(I)}$$

where P is the total pressure. Irrespective of the total pressure ranging from 0.25 to 1.3 atm, all the experimental points can be very well represented by a single straight line. The least-squares analysis of the data gave the following Arrhenius expression:

$$k=10^{11.1\pm0.8}\exp(-(48.1\pm0.7)\ \text{kcal mol}^{-1}/RT)\ \text{atm}^{-1/2}\,\text{s}^{-1} \quad \text{(II)}$$

A square root pressure dependence of the rate of molecular hydrogen production and of silane decay was also found in static pyrolysis studies at low temperatures.[1,6] This pressure dependence has been well explained by the pressure fall-off behavior of the Reaction 1.[6] However, it is not obvious if the measured rate constants in the present study can be attributed to the rate constant of Reaction 1, because the overall reaction mechanism of the silane decomposition is rather complicated. White et al.[3] proposed the following reaction mechanism for the consecutive reactions of the homogeneous decomposition of silane at static system reaction temperatures.

$$SiH_2+SiH_4 \rightarrow Si_2H_6 \quad (2)$$

$$Si_2H_6 \rightarrow Si_2H_4+H_2 \quad (4)$$

Table 1. Reaction Mechanism

a) Arrhenius parameters for the rate constants in the forward direction written in the form $k=A\exp(-E/RT)$. The units of A depend on the reaction order, but are given in terms of moles, cubic centimeters and seconds. E is in kcal mol^{-1}. b) See text for discussion of the pressure dependence. Listed value is for P=1 atm.

They suggested that the rate acceleration by these reactions might occur when silane conversion was less than 30%. Consequently the induction period on the silane loss was expected. At conversions greater than 40%, a gradual rate deceleration with increasing deviations from first-order kinetics was observed.[3] This rate inhibition was attributed to the contribution of the back reaction of hydrogen and silylene.

$$SiH_2+H_2\rightarrow SiH_4 \qquad (-1)$$

White et al.[3] further suggested that the silylene dimerization-decomposition reactions, 3, −3, and 7, might play a significant role on the silane decay rate over the temperature range of the single pulse shock tube experiments by Newman et al.[5,6]

$$SiH_2+SiH_2 \rightarrow Si_2H_4 \qquad (3)$$

$$Si_2H_4 \rightarrow Si_2H_2+H_2 \qquad (7)$$

In the present study, the induction period on the silane decay was not observed. Moreover, no effect of the addition of molecular hydrogen to the reactant mixtures was observed. This is evident in Fig. 2 in which the pressure independent rate constants obtained with the addition of 1.1% molecular hydrogen are shown. This is consistent with the single exponential decay of sliane during the entire course of the decomposition. This behavior of the silane decay can be explained if the Reaction 3 is much faster than the Reactions 2 and −1 in our experimental conditions. If this is the case, the rate constants for the initial decay observed in the present study correspond directly to the rate constants for the Reaction 1 only. In order to confirm the validity of this prediction, the simultaneous kinetic equations for the various species were numerically solved based on the reaction mechanism and the rate constants listed in Table 1. Each of the reactions listed in the table is reversible. The rate constants for the reverse reactions can be obtained from the reaction thermochemistry. Thermochemical

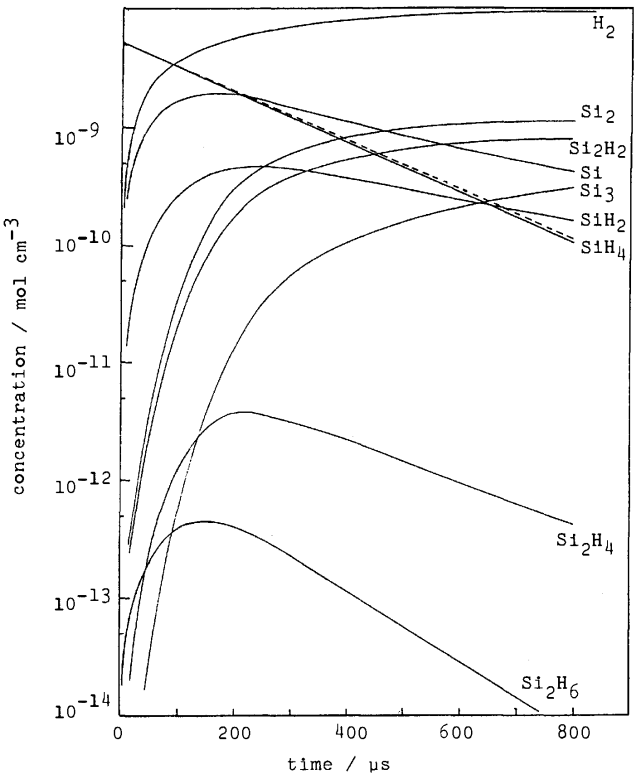

Fig. 3. Calculated concentrations for the mixture of 500 ppm SiH_4 in Ar at T=1400 K and P=1.24 atm.

data for each species involved in the reaction mechanism are taken from the work by Coltrin et al.[15] Although there are no reliable data for the Reactions 9 through 14, these reactions have no sensitivity for the silane loss rate. The rate constants estimated by Coltrin et al.[15] were used for these reactions. An example of the calculated time-concentration profiles of the various species involved in the model is shown in Fig. 3. The dashed curve in the figure represents the analytical solution for the silane concentration calculated by using Reaction 1 only. This curve agrees very well

with that obtained by the numerical integrations of the full kinetic equations. Therefore it is confirmed that the silane decay rate in our experimental conditions is determined by the unimolecular decomposition of silane without any significant contribution of other consecutive reactions.

Another possible silane loss mechanism that is not involved in our model is Si-chain mechanism:

$$SiH_2 (+M) \rightarrow Si + H_2 (+M) \quad (-9)$$
$$Si + SiH_4 \rightarrow SiH_2 + SiH_2 \quad (15)$$

There have been no experimental and theoretical works on the Reaction 15. If we include this reaction with the rate constant estimated by Coltrin et al.[15] in our model, the rate of the silane loss is greatly accelerated and a single exponential decay of silane is no longer obtained. To clarify the contribution of the Si-chain reactions to the rate of the silane decay, nitrogen monoxide was added to the mixtures. Because of the extremely fast reaction between nitrogen monoxide and silicon atom,[16] the silane loss rate might be considerably decelerated if the Si-chain reactions could play an important role. The pressure independent rate constants with the addition of 0.31% nitrogen monoxide are also included in Fig. 2. It was found that the single exponential decay of the silane concentration was not affected by the addition of nitrogen monoxide. No significant deviation of the rate constants from those obtained without the addition of nitrogen monoxide is evident in the figure. The absence of an induction period and the fact that the addition of nitrogen monoxide has no effect on the silane decay provide good evidence that the Si-chain reactions are not responsible for the rate of the silane decay.

The unimolecular rate constants obtained by the single pulse shock tube experiments of Newman et al.[6] are also shown in Fig. 2, where the square root dependence of the rate constants on the total pressure is assumed. The extrapolation of their values to our experimental temperatures gives much higher values than those obtained in this work. Under the conditions of their single pulse shock tube experiments (T=1000—1200 K, P=5.25 atm with 0.96—0.12% SiH_4 in argon), the rate of Reaction 1 is slower than the rates of Reactions 2 and 3. As a result, the decay rate of silane can be accelerated by these consecutive reactions even in a very early stage of the decomposition. If we consider only Reactions 1—3 with an assumption of the steady state concentration of silylene, the following expressions for the initial decay rate of silane are obtained.

$$-d[SiH_4]/dt = k_1[SiH_4](1+F) \quad (III)$$
$$F = g(1+2/g)^{1/2},\ g = (k_2^2/4k_1k_3)[SiH_4] \quad (IV)$$

Using the rate constants listed in Table 1, the value of F is estimated to be equal to 4.2 at T=1100 K and P=5.26 atm for 0.96% SiH_4 in argon. In contrast, F-values in our experimental conditions are always less than 0.14. Although the realistic reaction mechanism is much more complicated because of the reverse process of Reaction 2 and other consecutive reactions, the discrepancy shown in Fig. 2 is caused by the contributions of the consecutive reactions of silylene in the single pulse shock tube experiment.

Recently the rate constant of Reaction 1 has been calculated by Viswanathan et al.[11] They obtained the dissociation rate coefficient at internal energy E, $k(E)$, by means of the Monte-Carlo trajectory calculations. The values of $k(E)$ were fitted to a RRK form:

$$k(E) = \nu[(E-E_0)/E]^{s-1} \quad (V)$$

The values of the RRK parameters obtained by Viswanathan et al. were ν=1.08×10^{13} s^{-1}, E_0=49.6 kcal mol^{-1} and s=2.7. It is interesting to compare the results of their calculations with those of this study. The unimolecular rate coefficient was calculated with the following classical RRK formula.

$$k_1 = \int_{E_0}^{\infty} [f(E)k_d k(E)]dE/[k_d + k(E)], \quad (VI)$$
$$k_d = \lambda zp,$$
$$f(E) = (kT)^{-s}E^{s-1}\exp(-E/kT)/\Gamma(s),$$

where z is the hard-sphere collision frequency, p is the pressure, λ is the deactivation probability upon collision and $\Gamma(s)$ is the Gamma function. In the calculation, hard-sphere collision diameters of 5.76 Å for silane and 3.47 Å for argon were used with a strong collision assumption (λ=1). The pressure dependence of the rate coefficients is compared in Fig. 4. The calculated rate constants with parameters given by Viswanathan et al. show steeper pressure dependence (curve A in Fig. 4) compared with the experimental values. We have searched a new set of RRK parameters

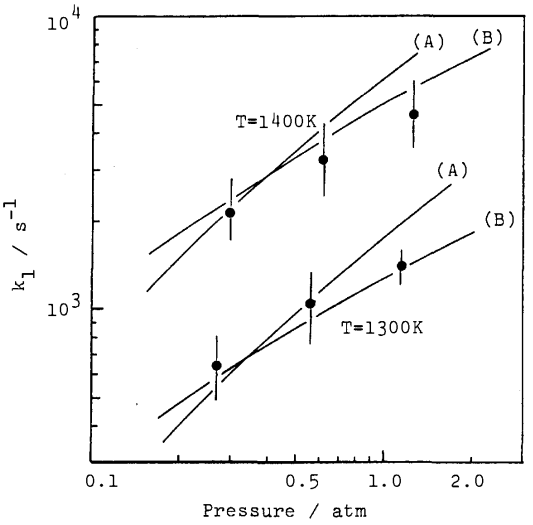

Fig. 4. Pressure dependence of the unimolecular decomposition of silane. Shaded circle with an error bar: Present experimental value, curves A and B: RRK calculations. See text for the RRK parameters used.

which can give better agreement with our experimental results. Although the limited range of the pressure and rather large scatter of the data points prevent the precise determination of parameters, the following set of parameters seems to be reasonable; E_0=55 kcal mol^{-1}, ν=1×10^{13} s^{-1}, and s=4.2. The calculated rate constants with these parameters are shown in Fig. 4 (curve B). The new value for a critical threshold energy is in good agreement with the result of the recent ab initio calculation.[13] The activation energy, E_a, of the unimolecular reaction in the low pressure region will be given by the following equation.[17]

$$E_a = E_0 - (s - 1.5)RT \quad \text{(VII)}$$

Using the RRK parameters obtained in this work, the values of E_a were estimated to be equal to 49.6 kcal mol^{-1} at T=1000 K and 46.7 kcal mol^{-1} at T=1500 K. The observed activation energy in Eq. II agrees well with these estimated values.

Conclusion

In order to obtain the unimolecular rate coefficient for the silane decomposition without any effect of the consecutive reactions, highly diluted silane in argon was decomposed behind shock waves at the temperatures ranging from 1250—1600 K and the intensity of the infrared emission at 4.4 μm which was proportional to the concentration of silane was monitored. The conclusions obtained in the present study are summarized as follows.

(1) In our experimental conditions, the decay of silane is exclusively caused by the unimolocular decomposition of silane. The rate constants for this reaction were determined directly from the time resolved measurements on the silane concentration. (2) No effect on the silane decay rate was observed with the addition of molecular hydrogen nor nitrogen monoxide. (3) The observed pressure fall-off behavior of the rate constant for the silane decomposition is reasonably well explained by a RRK theory with appropriate parameters.

Formation of Molecular Complexes of Water-Soluble Porphyrin with Cation-18-Crown-6 Complexes

Masaaki TABATA* and Isao YAMADA
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840
(Received May 11, 1987)

The formation of molecular complexes of 5,10,15,20-tetrakis(4-sulfonatophenyl)porphine (H_2tspp) with cation-18-crown-6 (M(18C6)) has been studied spectrophotometrically at I=0.1 mol dm^{-3} (MX and MX_2, M: Na^+, K^+, Cs^+, NH_4^+, Ca^{2+}, Sr^{2+}, Ba^{2+}, X: NO_3^-, Cl^-, Br^-, I^-, SCN^-), and pH 7.0 (*N,N'*-bis(2-sulfonatoethyl)piperazine: PIPES buffer, 2.0×10^{-3} mol dm^{-3}). The absorption spectrum of H_2tspp considerably changed in the presence of both cation and 18-crown-6, but not in the absence of either of them. The formation constants (log K) of the molecular complexes (M(18C6)·H_2tspp) were found to be 2.17±0.05, 2.31±0.03, 2.45±0.03, 2.58±0.02, 1.94±0.03, 2.07±0.02, and 2.12±0.02 for Na^+, K^+, Cs^+, NH_4^+, Ca^{2+}, Sr^{2+}, and Ba^{2+}, respectively at 25.0±0.5 °C and I=0 mol dm^{-3}. Thermodynamic parameters ΔH/(kJ mol^{-1}) and ΔS/(J K^{-1} mol^{-1}) are −19.9, −25.0; −33.0, −66.0; −29.3, −50.8; −48.5, −113.7; −21.9, −34.2 and −32.5, −68.0 for Na^+, K^+, Cs^+, NH_4^+, Sr^{2+}, and Ba^{2+}. The enthalpy changes are linearly correlated to the entropy changes. The equilibrium studies show that charge transfer between M(18C6) and porphyrin π-system is a driving force for the formation of the molecular complex (M(18C6)·H_2tspp) as well as hydrophobic interaction.

The interaction of porphyrins or metalloporphyrins with aromatic ligands such as methyl viologen,[1] 1,10-phenanthrolines,[2] anthraquinones,[3] or DNA[4,5] has been the subject of a number of investigations. The basis for these studies in part is related to the observation that porphyrins can serve as photocatalysts[6] for photoproduction of H_2 and O_2 in water and photosensitizer for destruction of tumor cells[7] (i.e., phototeraphy). The thermodynamic, optical, and physicochemical evidences have suggested the formation of molecular complex by π-π interaction between aromatic donors or acceptors and porphyrin plane. Shelnutt has demonstrated that charge-transfer interaction is a binding force for complexation of metal uroporphyrins with 1,10-phenanthrolines on the basis of the results of resonance Raman differential spectroscopy.[2] Kano et al., concluded that a van der Waals interaction is the predominant binding force and hydrophobic interaction assists the stabilization of the molecular complexes in the reaction of anionic porphyrin with anionic aromatics.[3]

In this studies we describe the formation of molecular complex of 5,10,15,20-tetrakis(4-sulfonatophenyl)-porphine (H_2tspp) with cation-18-crown-6 (M(18C6)), where M is Na^+, K^+, Cs^+, NH_4^+, Ca^{2+}, Sr^{2+}, and Ba^{2+}. 18-Crown-6, of course, does not have π-system. The thermodynamic studies suggest that the formation of the molecular complex ((M(18C6)·H_2tspp)) results from charge transfer between cation-18-crown-6 and π-system of porphyrin as well as hydrophobic interaction of ethylene group of 18-crown-6 with porphyrin. The desolvation of both cation and 18-crown-6 caused by formation of cation-18-crown-6 enables hydrophobic interaction of porphyrin with cation-18-crown-6 and the positive charge in M(18C6) stabilizes the molecular complex.

Experimental

18-Crown-6 (Tokyo Kasei Co. Ltd., Japan) was dried in vacuo at room temperature for 3 days. The inorganic compounds were analytical reagent grade. Porphyrin (H_2tspp) was synthesized and its sodium salt was purified as described previously.[8] The purity was checked by thin-layer chromatography and NMR spectroscopy. Concentrations of calcium(II), strontium(II), and barium(II) in the stock solutions were determined complexometrically. Other stock solutions were prepared by weighing the reagents. Water redistilled in the presence of permanganate was used for all solutions.

The formation constant of the molecular complex was determined spectrophotometrically at pH 7.0 (*N,N'*-bis(2-sulfonatoethyl)piperazine: PIPES buffer) and at given temperatures (20, 25, 30, and 35 °C). Ionic strength was adjusted to 0.1 mol dm^{-1} by cation salts of which molecular complex was studied. Sample solution was prepared by addition of 1 cm^3 H_2tspp (5×10^{-5} mol dm^{-3}) to a solution containing 18C6, PIPES buffer (2.0×10^{-3} mol cm^{-3}) and cation in a 25 cm^3 flask, followed by addition of water to the mark. The solution was kept in a thermostated bath for about 30 min. The absorption spectra were recorded by a Hitachi 323 UV-VIS spectrophotomerter in a 1 cm cell with a thermostated water jacket.

Results

Formation of Molecular Complex of H_2tspp with M(18C6). Absorption spectrum of H_2tspp changed considerably in the presence of both 18-crown-6 and cation as shown in Fig. 1(a), but not in the absence of either of them. The absorption maximum at 413 nm decreased with increasing of 18-crown-6. The isosbestic points were 388 and 420 nm. Similar absorption spectra of porphyrins were also observed in the reaction of H_2tspp with 1,10-phenanthroline[9] and that of 5,10,15,20-tetrakis(4-*N*-methylpyridyl)porphine (H_2tmpyp) with DNA[5] at soret bands.

Under the present experimental conditions (pH 7.0) porphyrin is free base form, because the protonation constants of H_2tspp to form H_3tspp and H_4tspp are $10^{4.99}$ and $10^{4.76}$, respectively (charges on porphyrin are omitted for the simplicity).[10] The formation of the molecular complex decreased at pH lower than 5.

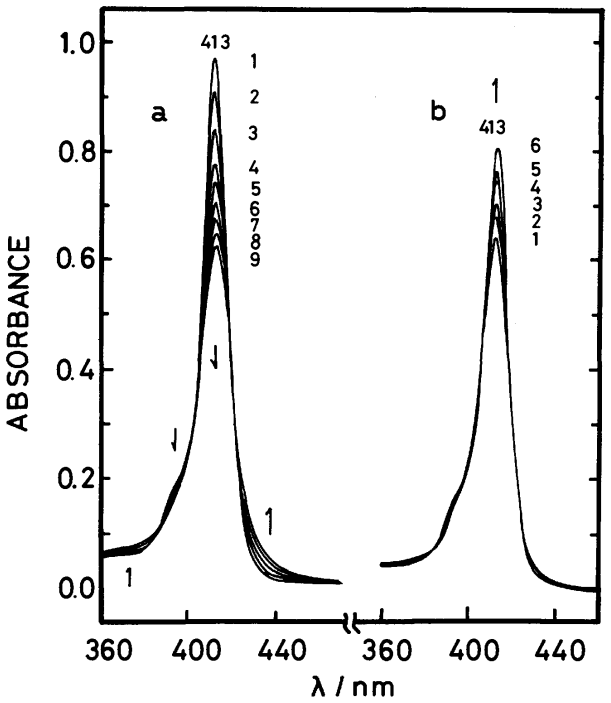

Fig. 1. (a), Absorption spectra of H_2tspp (2.11×10^{-6} mol dm^{-3}) with increasing of 18-crown-6 ((1), 0.000; (2), 1.09×10^{-3}; (3), 2.18×10^{-3}; (4), 3.63×10^{-3}; (5), 5.44×10^{-3}; (6), 7.25×10^{-3}; (7), 1.09×10^{-2}; (8), 1.45×10^{-2}; (9), 1.81×10^{-2}, (unit= mol dm^{-3}) in the presence of K^+ (0.1 mol dm^{-3}) at pH 7.0, and (b) the spectral change of H_2tspp (1.99×10^{-6} mol dm^{-3}) with increasing of ethanol ((1), 0; (2), 2; (3), 4; (4), 6; (5), 8; (6), 10% (v/v)) in the presence of 18-crown-6 (1.97×10^{-2} mol dm^{-3}) and Ba^{2+} (3.47×10^{-2} mol dm^{-3}) at pH 7.0.

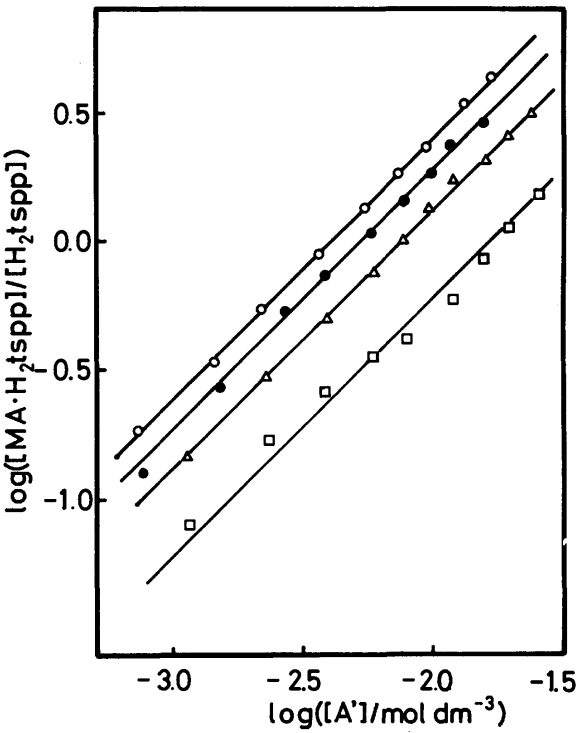

Fig. 2. Plot of $\log([MA\cdot H_2tspp]/[H_2tspp])$ vs. $\log([A']/\text{mol dm}^{-3})$ in the reaction of H_2tspp with NH_4^+ (○), K^+ (●), Ba^{2+} (△), and Na^+ (□) at 25 °C and I=0.1 mol dm^{-3}, where [A'] is the concentration of 18-crown-6 unbound to H_2tspp. $C_{H_2tspp}=2.00\times10^{-6}$ mol dm^{-3}, and pH 7.0.

Cation (M) reacts with 18-crown-6 (A) to form cation-18-crown-6 (MA) as

$$M + A \underset{}{\overset{K_{MA}}{\rightleftharpoons}} MA, \quad (1)$$

and the equilibrium constant is defined by

$$K_{MA}=[MA][M]^{-1}[A]^{-1}. \quad (2)$$

Thus the reaction of H_2tspp with 18-crown-6 in the presence of cation may be given by

$$MA + H_2tspp \overset{K}{\rightleftharpoons} MA\cdot H_2tspp, \quad (3)$$

and the equilibrium constant is written by

$$K=[MA\cdot H_2tspp][MA]^{-1}[H_2tspp]^{-1} \quad (4)$$

From the Eqs. 2 and 4 we obtain Eqs. 5—7:

$$K=[MA\cdot H_2tspp][H_2tspp]^{-1} ([MA]+[A])^{-1}(1+K_{MA}{}^{-1}[M]^{-1}) \quad (5)$$

and

$$K=[MA\cdot H_2tspp][H_2tspp]^{-1}[A']^{-1}\alpha_{MA} \quad (6)$$

$$=\alpha_{MA}K', \quad (7)$$

where A' and α_{MA} denote the total concentration of 18-crown-6 unbound to H_2tspp and side-reaction coefficient of MA, respectively, and they are defined as follows:

$$[A']=[MA]+[A] \quad (8)$$

and

$$\alpha_{MA}=1+K_{MA}{}^{-1}[M]^{-1} \quad (9)$$

Conditional formation constant (K') of the molecular complex can be rearranged in logarithmic form from Eqs. 6 and 7 as follows:

$$\log K'=\log([MA\cdot H_2tspp]/[H_2tspp])-\log[A']. \quad (10)$$

The first term in right-hand side of Eq. 10 was determined from the absorbances in the various concentrations of 18-crown-6, and is plotted against logarithmic concentration of 18-crown-6 in Fig. 2. The plot gives a straight line with a slope of unity and shows that one molecule of MA reacts with an H_2tspp. Thus the formation constants of molecular complexes (K) were calculated from Eqs. 7 and 9, where the logarithmic values of K_{MA} in Eq. 9 were taken from literatures:[11] 0.84, 2.03, 1.01, 1.23, 1.8, 2.71, and 3.83 for Na^+, K^+, Cs^+, NH_4^+, Ca^{2+}, Sr^{2+}, and Ba^{2+}, respectively at I=0.1 mol dm^{-3} and at 25 °C. Table 1 summarizes the formation constants of molecular complexes.

Dependence of the Formation Constant on the Temperature. The formation constants of the molecular complexes for Na^+, K^+, Cs^+, NH_4^+, Ba^{2+}, and Sr^{2+}

Table 1. Formation Constants of Molecular Complexes of MA·H_2tspp at I=0.1 mol dm^{-3} and at 25 °C (A=18-crown-6)

Cation salt	log K / mol^{-1} dm^3	Cation salt	log K / mol^{-1} dm^3
KNO_3	2.31±0.03	NH_4NO_3	2.58±0.02
KCl	2.28±0.03	CsCl	2.45±0.05
KBr	2.40±0.06	$Ca(NO_3)_2$	1.94±0.03
KI	2.32±0.05	$Sr(NO_3)_2$	2.07±0.02
KSCN	2.37±0.04	$Ba(NO_3)_2$	2.12±0.02
$NaNO_3$	2.17±0.05		

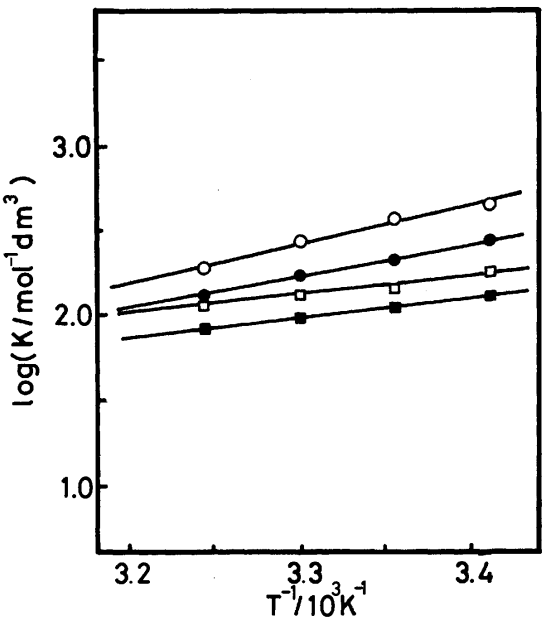

Fig. 3. Temperature dependence of the formation constant of molecular complex between H_2tspp and cations of NH_4^+ (○), K^+ (●), Na^+ (□), and Sr^{2+} (■) at I=0.1 mol dm^{-3}. C_{H_2tspp}=2.00×10^{-6} mol dm^{-3}, and pH 7.0.

were determined at temperatures of 20, 25, 30, and 35 °C. The thermodynamic parameters of enthalpy change (ΔH) and entropy change (ΔS) were calculated from van't Hoff plots of $R\ln K$ vs. T^{-1} and ΔG vs. T, respectively (Fig. 3). The thermodynamic parameters of the formation of the molecular complexes (MA·H_2tspp) are listed in Table 2.

Dependence of the Formation of the Molecular Complex on Ethanol. Addition of ethanol to a solution containing Ba^{2+}, 18-crown-6, and H_2tspp increased the absorbance at 413 nm. At high concentration of ethanol the absorption spectrum is the same as that of H_2tspp in the absence of cation and 18C6 (Fig. 1(b)). The spectral change indicates the dissociation of the molecular complex by addition of ethanol. Since the increase of ethanol decreases dielectric constant of the aqueous solution, the interaction between M(18C6) and H_2tspp does not arise from ion-pair formation. If the molecular complex is ion pair, the formation of the molecular complex may become easier with the decrease of dielectric constant.

Table. 2. Thermodynamic Parameters in the Formation of Molecular Complexes of MA·H_2tspp (A=18-crown-6)

Cation	$-\Delta G$[a)] / kJ mol^{-1}	$-\Delta H$ / kJ mol^{-1}	ΔS / J K^{-1} mol^{-1}
Na^+	12.4	19.9	−25.0
K^+	13.2	33.0	−66.0
Cs^+	14.0	29.3	−50.8
NH_4^+	14.7	48.5	−113.7
Sr^{2+}	11.8	21.9	−34.2
Ba^{2+}	12.1	32.5	−68.0

a) Value at 25 °C.

Discussion

The formation constant of molecular complex is independent of anionic species (Table 1). This shows that anion is not involved in the formation of molecular complex. The formation constants increase in the following order: $Na^+ < K^+ < Cs^+ < NH_4^+$ for univalent and $Ca^{2+} < Sr^{2+} < Ba^{2+}$ for bivalent cations. Comparison of the formation constants of the molecular complexes with those of cation-18-crown-6 shows that the formation of molecular complex is not so affected for different cations as the formation of cation-18-crown-6. Cation size and cavity radius of 18-crown-6 are factors affecting the stability of cation-18-crown-6.[11,12] On the other hand, the molecular complex formation is a weak interaction between porphyrin plane and crown ether complex, and is not so much influenced by the cation size and cavity size of 18-crown-6. As shown in Table 1, the formation constants for bivalent cations are smaller than those for univalent cations. This is the opposite situation compared with the formation of crown ether complex. Since porphyrins trend to associate with organic ligands such as 1,10-phenanthrolines,[2] anthraquinones,[3] and DNA,[4,5] porphyrin plane may be hydrophobic. Thus the large hydration in cation-18-crown-6 may make difficult the interaction between cation-18-crown-6 with porphyrin plane. The hydration free energies ($-\Delta G_h$/(kJ mol^{-1})) are 411.3, 338, 297, 1593, 1447, and 1318 for Na^+, K^+, Cs^+, Ca^{2+}, Sr^{2+}, and Ba^{2+}, respectively.[13] The hydration free energies imply the following relative order for the stabilities of the molecular complexes: $Cs^+ > K^+ > Na^+ > Ba^{2+} > Sr^{2+} > Ca^{2+}$. The hydration enthalpies of

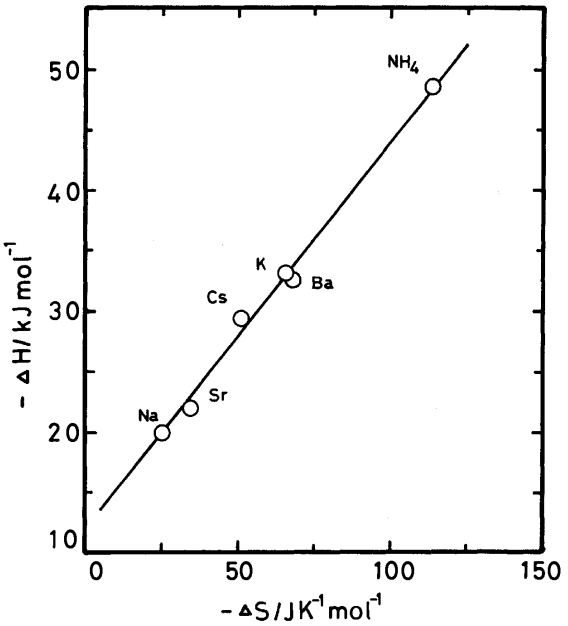

Fig. 4. Plot of $-\Delta H/(\mathrm{kJ\,mol^{-1}})$ vs. $-\Delta S/(\mathrm{J\,K^{-1}\,mol^{-1}})$ for the formation of the molecular complexes of MA·H_2tspp (M=Na^+, K^+, Cs^+, Sr^{2+}, Ba^{2+}, and NH_4^+).

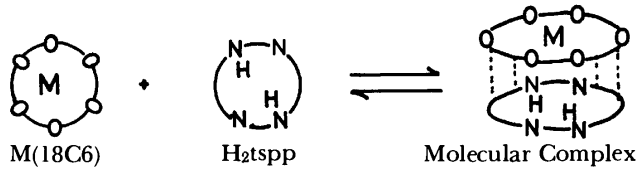
cations also suggest the same order for the formation of the molecular complexes, because the hydration enthalpy is much higher than the hydration entropy.[13] The observed formation constants of the molecular complexes decrease with the order as expected above. This is a reason why the molecular complex of bivalent cation-18-crown-6 is unstabler than that of univalent cation-18C6. Other contribution of cation in the formation of molecular complex is charge-transfer interaction between cation-18-crown-6 and porphyrin π-system.

In Fig. 4, the enthalpy change is plotted against the entropy change in the formation of the molecular complex. The plots give a good straight line. The correlation was generally observed for the charge-transfer complexes such as iodine-aromatic ligands.[14] The enthalpy change is compensated with the entropy change and shows Barcley-Buttler rule. The large contribution of enthalpy change indicates the charge-transfer interaction between cation of M(18C6) and porphyrin π-system. Hydrophobic interaction also contributes to the molecular complex formation. Crown ether does not interact with porphyrin in the absence of cation. Coordination of cation to crown ether releases water molecules from both crown ether and metal ion. The desolvation from 18-crown-6 may increase the hydrophobicity of 18C6, and water around M(18C6) may be structured. In fact the negative entropy change was observed in the reaction of cation with 18-crown-6.[11] The negative enthalpy change in the formation of the molecular complex suggests that water may be structured between cation-18-crown-6 and porphyrin plane. The positive charge in 18-crown-6 complex stabilizes the molecular complex by the charge transfer through porphyrin π-system.

A possible reaction scheme in the formation of molecular complex is given in Scheme 1, in which cation-



Scheme 1.

18-crown-6 may be parallel to porphyrin plane like "crowned porphyrin."[15] The present studies show, for the first time, the formation of molecular complex of porphyrin with non-aromatic ligands.

The authors thank professor Motoharu Tanaka of Nagoya University, for helpful discussions and gratefully acknowledge the financial support of this study by a Grant-in-Aid from the Ministry of Education, Science and Culture (No. 61540450).

†Department of Pharmaceutical Sciences, Nagoya City University, Mizuho-ku, Nagoya 467
(Received May 12, 1987)

The synthesis and molecular structure of the title complex was investigated as part of our work into the chemical significance of atropisomerism in porphyrin compounds. The complex crystallizes in the triclinic system, space group $P\bar{1}$, a=11.707 (2) Å, b=12.744 (5) Å, c=9.521 (2) Å, α=102.60 (3)°, β=101.31 (2)°, and γ=100.29 (2)°, Z=1. A total of 3737 reflections (average of two forms) were considered observed and used in the solution and refinement of the structure. The structure was refined to a final R=0.081. The molecule, with a crystallographically imposed inversion center, has disordered nicotinamide side chains. This disorder leads to some ambiguity in defining the relative substitution pattern of the phenyl rings. Independent of the assumptions used to define the disorder, the nicotinamide side chains are found to coordinate the zinc ions of adjacent molecules to form a polymeric, linear chain containing six-coordinate zinc ions. The average equatorial Zn-N bond distance is 2.052 (3) Å and the unique axial bond distance is 2.432 (5) Å.

We and others[1-3] have been exploring strategies for introducing asymmetry in porphyrin species by appropriate substitution of tetraarylporphyrin derivatives. Such asymmetric species could, under appropriate circumstances, be utilized to control reactivity. One such series of asymmetric molecules are *o*-substituted tetraphenylporphyrin complexes in which an adjacent pair of phenyl groups are substituted on opposite sides of the porphyrin plane. The synthesis of one such example, 5α,10β-bis(*o*-aminophenyl)-15,20-diphenylporphyrin has been recently reported.[4] Measurements of the atropisomerization rates of tetrakis(*o*-aminophenyl)porphyrin[5] suggested that such a disubstituted derivative could be manipulated without significant loss of chirality. However, a crystal structure determination[6] of the above diamino derivative showed that the material was profoundly disordered, and suggested that substituents larger than amino groups are required for lattice (solid state) discrimination.

We report in this paper the preparation of a porphyrin derivative bearing much larger *o*-substituents on adjacent phenyls, a bis(nicotinamidophenyl) derivative. We also report the crystal structure of the zinc(II) complex of this porphyrin. Much to our surprise, this derivative also suffers from disorder. However, the disordered porphyrinate species has an interesting structural feature, namely, a six-coordinate zinc(II) ion that results from extended interaction in the solid state. The present complex, like the earlier reported [Zn(TPP)(THF)$_2$],[7] appears to achieve six-coordination purely as a result of solid-state effects. There remain no credible reports for six-coordinate zinc porphyrinates in solution.

Experimental

Syntheses. The preparation and isolation of 5α,10β-bis(*o*-aminophenyl)-15,20-diphenylporphyrin (H_2BADPP) has been described previously.[4] Nicotinoyl chloride hydrochloride (0.3 g, Tokyo Kasei Chem. Co.) was added to a H_2BADPP solution (0.5 g, 50 cm^3 of CH_2Cl_2 and 1 cm^3 pyridine) at room temperature. The resulting green solution was magnetically stirred for 1 h. Aqueous ammonia (8%, 25 cm^3) was poured into the solution and vigorously stirred for 30 min. The solution was then transferred to a separatory funnel and the CH_2Cl_2 layer was washed several times with water and then evaporated to dryness. The resulting solid porphyrin was dissolved in 15 cm^3 of $CHCl_3$ and crystallized by addition of petroleum ether. Yield 520 mg (78%). The product 5α,10β-bis(*o*-nicotinamidophenyl)-15,20-diphenylporphyrin(H_2BNDPP) (250 mg) was reacted with 0.5 g zinc acetate in 25 cm^3 of DMF in a temperature-controlled oil bath (35 °C) for 16 h. TLC of the reaction products confirmed that these conditions led to complete metallation and minimal rotational isomerization.[5] Zn(BNDPP) was obtained by addition of 50 cm^3 of water, followed by filtration of the resulting precipitate. Crystals of Zn(BNDPP) suitable for X-ray analysis were obtained by diffusing pentane into a pyridine-chloroform solution. Found: C, 72.88; H, 3.68; N, 12.06%. Calcd for $C_{66}H_{44}N_{10}O_2Zn$: C, 73.78; H, 4.13; N, 13.04%.

Structure Determination. A single crystal of Zn(BNDPP) with approximate dimensions of 0.35×0.35×0.45 mm was mounted in a thin-walled glass capillary. Preliminary examination on a CAD4 diffractometer established a one-molecule triclinic unit cell. Refined cell constants, a=11.707(2) Å, b=12.744(5) Å, c=9.521(2) Å, α=102.60(3)°, β=101.31(2)°, and γ=100.29(2)°, came from the least-squares refinement of the setting angles of 25 reflections. For a cell content of Zn(BNDPP)·2py (or $ZnO_2N_{10}C_{66}H_{44}$) (F.W.=1074.5), the calculated density is 1.35 g cm^{-3} and the observed density of freshly prepared crystals is 1.36 g cm^{-3}. Intensity data were measured with graphite-monochromated Mo $K\alpha$ radiation at 21±1 °C. Since a completely ordered structure would require that the correct space group be $P1$, the entire triclinic sphere (to 2θ=52.9°) was measured. A total of 10833 reflections were measured. The linear absorption coefficient is 0.52 mm^{-1} and an empirical absorption correction was applied to the entire data set. Relative transmission coefficients ranged from 0.761 to 1.000.

The structure was solved by direct methods (MULTAN):[8] A total of 46 atoms (out of 79) were found in the initially chosen noncentrosymmetric space group $P1$. A few cycles of difference Fourier syntheses located the remaining atoms (except for the solvent molecules). Despite this initial success in the noncentrosymmetric space group, isotropic least-squares refinement led to a number of unsatisfactory interatomic distances and other features more consistent with the presence of inversion centers. Refinement was thus shifted into the centrosymmetric space group $P\bar{1}$. The triclinic data were first averaged assuming Friedel's Law, yielding 3737 observed[9] and averaged reflections (R_{int}=0.019). A certain amount of crystallographic disorder is required in order to describe the Zn(BNDPP) molecule in space group $P\bar{1}$ with Z=1. The zinc atom of the complex was shifted to the inversion center at 0,0,0; this necessarily leads to disorder for the two phenyl substituents. This disorder unfortunately leads to some ambiguity in defining the relative orientations for the two nicotinamide residues. Our analysis assumed the basic molecular structure shown in Fig. 1. The complete structure analysis shows that the terminal pyridine ring of each nicotinamide group coordinates to the zinc atom of an adjacent molecule translated along the c axis. One phenyl ring, C(7)—C(12), had rather large anisotropic thermal parameters and was described by two overlapping rigid groups, a and b. The two rigid groups are almost coplanar but with a C(7a)-C(m2)-C(7b) angle of 17.6°. The occupancy factors of individual atoms of the rigid phenyl groups and amide arms were held fixed at 0.5. The two pyridine solvates (per cell) were found near two separate inversion centers at 1/2,1/2,1/2 and 0,1/2,1/2. Each pyridine ring was close to but disordered around the inversion center. The pyridine near 0,1/2,1/2 was described in terms of two rigid groups. The nitrogen atoms were not conclusively identified and thus the pyridine rings were included in the refinement as three separate, partial occupancy (uniform occupancy factors of 0.25 for each atom) C_6 rigid groups with D_{6h} symmetry. All rigid group refinements were carried out with a locally modified version of ORFLS following the rigid-group description of Scheringer.[10] The hydrogen atoms of the porphyrin ligand were found in difference Fourier maps and were included in fixed idealized positions in the final cycles of least-squares refinement. The final model utilized anisotropic thermal parameters for all non-hydrogen atoms except those of rigid groups. Final values for the discrepancy indices were R_1=0.081 and R_2=0.111.[11] A final differ-

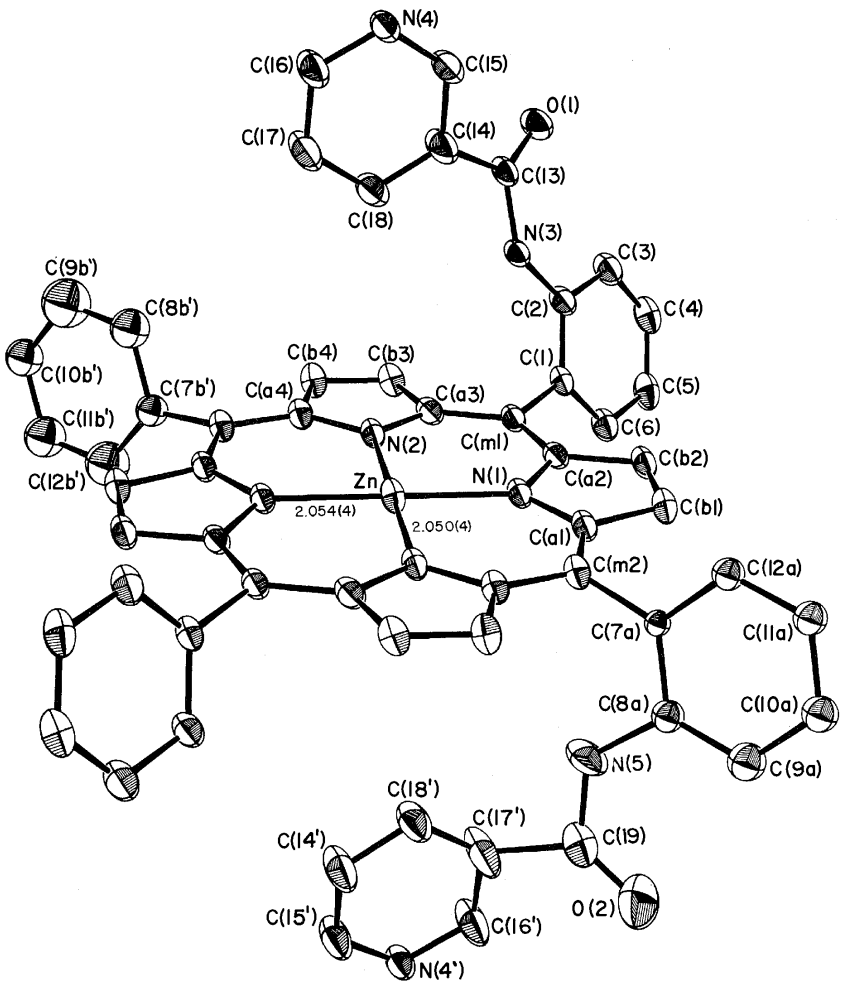

Fig. 1. ORTEP plot (50% ellipsoids) of the Zn(BNDPP) molecule as it exists in the crystal. The atom-labeling scheme for the crystallographically unique atoms are given. Primed (′) atoms are related to unprimed atoms by the inversion center located at the zinc atom.

ence Fourier synthesis had its highest peak (0.9 e Å^{-3}) near one of the solvate rigid groups. The atomic coordinates are given in Table 1. Final values for the fixed atoms, rigid group descriptions and anisotropic thermal parameters are available.[12]

Results and Discussion

The molecular structure of Zn(BNDPP) is displayed in Fig. 1 along with the atom labeling scheme. Each nicotinamide pyridine ring is coordinated to a zinc ion above or below its porphyrin plane to create a linear chain along the c axis. Three molecules of the resulting chain of six-coordinate zinc porphyrinates is illustrated in Fig. 2. Bond distances and angles (with estimated standard deviations) in the unique half of the porphinato core are given in Fig. 3. Complete tables of individual bond distances and angles are available.[12] Figure 3 also displays the deviations (in units of 0.01 Å) of each atom from the least-squares plane of the porphinato core. Deviations from exact planarity are unremarkable. The zinc(II) ion is precisely centered in the porphinato plane, as required by the molecular (and crystallographic) inversion center.

The two unique Zn-N_p bond distances are 2.050 (4) and 2.054 (4) Å. This 2.052 (3) Å-average value is larger than the 2.037 Å-average value found for three[13-15] different four-coordinate zinc porphyrinates and significantly shorter than the 2.059 (10) to 2.079 (8) Å range observed in a variety[16-21] of five-coordinate zinc porphyrinates. The 2.052 Å distance is comparable to the 2.057 (1) Å-value observed[7] in the only other known six-coordinate porphinatozinc(II) derivative. In both species, the six-coordinate zinc(II) ion is accommodated by substantial radial expansion of the porphinato central hole.

The axial Zn-N(py) bond distance in Zn(BNDPP) is 2.432 (5) Å. This distance is substantially longer than the Zn-N(ax) distance observed[16-23] in any of the five-coordinate species where the axial distances vary from 2.106 (4) to 2.200 (3) Å. The axial distance is even longer than the 2.380 (2) Å Zn-O distance found in [Zn(TPP)(THF)$_2$].[7] This long distance is consistent with quite weak axial bonding, although the observed porphinate core expansion makes evident that a real axial interaction exists. The coordinated pyridine ring plane makes an 88.2° dihedral angle with the porphinato plane. The dihedral angle between the N(1)-Zn-N(4)′ coordinate plane and the pyridine plane is 5.9°.

The structural analysis of this molecule is like the

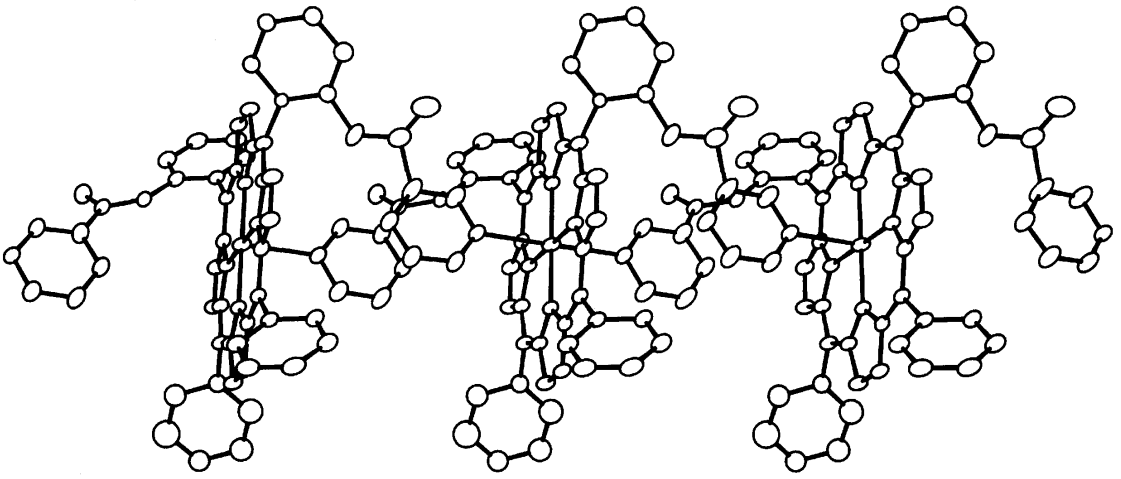

Fig. 2. Computer-drawn plot of the extended structure in crystals of Zn(BNDPP) showing the coordination of the pyridines of the nicotinamide residues on adjacent zinc atoms (c-axis). Only three molecules of the infinite chain are illustrated.

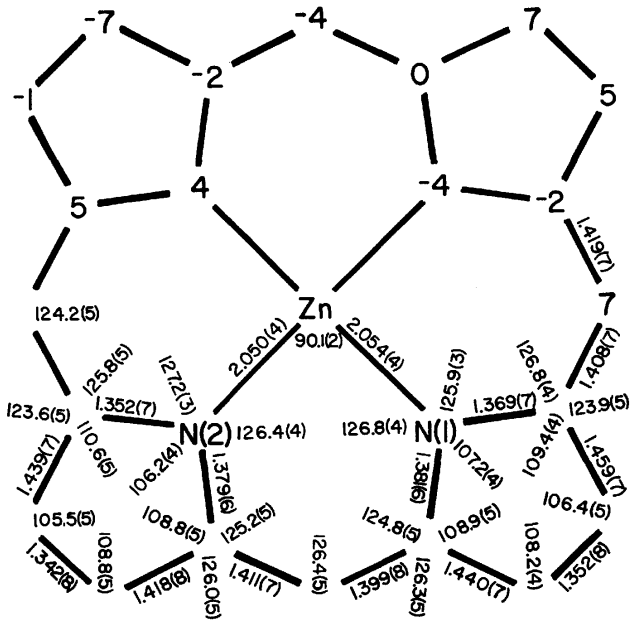

Fig. 3. Formal diagram of the porphinato core illustrating on the top half the displacement of the unique atoms from the mean plane of the 24-atom core. The centrosymmetrically related atoms in the lower half of the diagram have displacements of the same magnitude but opposite sign. All displacement values are in units of 0.01 Å. On the lower half of the diagram are entered the individual values of the bond distances (Å) and angles (°) in the core of the molecule.

resolution of a small puzzle ring. As noted in the Experimental section, the presence of inversion symmetry in the crystal requires a disordered solid-state structure. Unfortunately, this leads to some ambiguity in the complete definition of the molecular structure. However, unless the unlikely assumption—that both amido arms join the porphyrin core to the same pyridine ring—is allowed, the structure determination provides direct evidence that the phenyl substituents are on opposite sides of the porphyrin plane, i.e. the conformation is $\alpha\beta$. Further, unless the assumption that the disorder in the crystal includes two 90° rotational positions (i.e., relative right and left turns) of porphyrin core (in addition to the inversion required disorder), then the structural analysis leads to the conclusion that the substituted phenyl rings on a given molecule must be adjacent. Finally, the six-coordinate nature of the zinc ion is most consistent with this $\alpha\beta$-adjacent substitution of the porphyrin derivative. The disorder in the crystal lattice involves both the chains and the pyridine groups of the nicotinamides, and leads to the enantiomeric disorder. However, although the disorder in the crystal lattice is complex, the $\alpha\beta$-adjacent molecular structure seems to hold in the crystal.

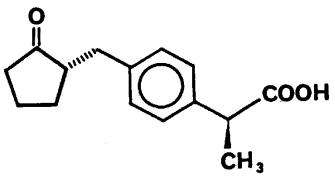
(Received May 26, 1987)

The crystal structure of the title compound was determined by X-ray diffraction techniques. The final *R* index was found to be 0.072 for 1187 reflections. The torsional angles of the 2-phenylpropionic acid moiety were comparable to those in other antiinflammatory arylpropionic acids. Force-field energy calculations suggested that the α-methyl substituent to the carboxyl group restricts the rotation of the benzene ring about the C_α-phenyl bond. This restricted conformation may be related to the antiinflammatory activity.

In the search for non-steroidal antiinflammatory drugs, a number of (cycloalkylmethyl)phenylacetic and -propionic acids have been synthesized.[1] Among them, 2-[4-(2-oxocyclopentylmethyl)phenyl]propionic acid (loxoprofen), exhibited particularly potent anti-inflamatory and analgesic activities.[2] This derivative is a mixture of two racemic diastereoisomers having melting points of 102 and 114 °C, respectively. The title compound **1** is the isomer of the lower melting



1

point and structure analysis has established the relative configuration.

The potentiating effect of an α-(*S*)-methyl substituent to the carboxyl group has been observed for many antiinflammatory arylacetic acids.[3,4] On the other hand, the substitution of an (*R*)-methyl or two methyls results in manyfold reduction of activity.[5] This must be due to a steric effect at the enzyme surface. It is interesting to compare the conformation of (*S*)-2-phenylpropionic acids with those of phenylacetic and 2-methyl-2-phenylpropionic acids. The present paper deals with the crystal and molecular structure of **1** and the results of empirical force-field calculations for the related molecules based on the crystal structure of **1**.

Experimental

X-Ray Structure Determination of 1. Colorless prisms were grown by slow evaporation of an ether–hexane solution of **1** at room temperature. Diffraction experiments were performed with a crystal, 0.1×0.1×0.6 mm, on a Rigaku AFC-5 diffractometer; monochromated Cu $K\alpha$ radiation being used. The cell parameters were determined from the 2θ values of forty-four reflections in the range with $21° < 2\theta < 49°$. Space group was assigned from systematic absences. The crystal data are as follows; $C_{15}H_{18}O_3$, Mr=246.3, monoclinic, $I2/c$, a=18.276 (1), b=7.5164 (4), c=19.539 (2) Å, β=93.063 (2)°, V=2680.2 (2) Å^3, Z=8, Dc=1.22 g cm^{-3}, μ(Cu $K\alpha$)=6.9 cm^{-1}. An ω-2θ scanning mode was employed up to 2θ=130°. A total of 1842 reflections were measured, of which 1188 unique reflections with $F \geqq 3\sigma(F)$ were used for the analysis. Three references measured every 100 reflections showed no significant variation in intensity. Correction was made for Lorentz and polarization factors, but not for absorption. The structure was solved by the direct method using MULTAN78,[6] and refined by the full-matrix least-squares method with anisotropic thermal parameters. Hydrogen atoms were located on a difference Fourier synthesis and their coordinates were refined with isotropic thermal parameters. One intense low-angle reflection (2,0,−4) seemed to suffer secondary extinction and excluded from the data set. The final refinement converged at R=0.072 and Rw=0.040. The weighting scheme was $w=1/\sigma^2$ (F). Atomic scattering factors were taken from Ref. 7. The final fractional coordinates and equivalent isotropic thermal parameters are given in Table 1.[8]

††Present address: Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo.

Force-Field Calculations. The force-field calculations were performed on the model compounds of (*S*)-2-phenylpropionic acid which was constructed based on the crystal structure of **1**, using the MM2′ program.[9] The two torsional angles of τ_1 and τ_2, which correspond to C(10)-C(11)-C(14)-C(16) and C(11)-C(14)-C(16)-O(17) of **1**, were simultaneously varied at intervals of 10 degrees and the conformational energy map for double rotation was calculated. In order to evaluate the effect of the α-methyl group, conformation energy calculations for the two model compounds of phenylacetic acid and 2-methyl-2-phenylpropionic acid which have no and two methyl groups, respectively, were also performed in the same manner as for (*S*)-2-phenylpropionic acid.

Results and Discussion

The Crystal and Molecular Structure of 1. The atom labelling and the thermal ellipsoids are shown in Fig. 1. This racemate crystal of mp 102°C contains molecules with (S, S) and (R, R) configurations. Bond lengths and angles are all normal within the limits of experimental error.

The torsional angles of τ_1[C(12)-C(11)-C(14)-C(16)] and τ_2[C(11)-C(14)-C(16)-O(17)] of the propionic acid side chain are 95.5 (6) and 93.5 (6)°, respectively. These values are compatible with those of other antiinflammatory drugs; 96.4 and 89.3° in ibuprofen,[10] 107.7 and 77.3° in flurbiprofen,[11] 111.7 and 90.2° in naproxen.[12] The torsional angles of other 2-phenylpropionic acids such as 2-(2-isopropyl-5-indanyl)propionic acid (IPIP)[13] and the four racemic diasteroisomers of 2-[4-(2-hydroxycyclopentylmethyl)phenyl]propionic acid (HOPP)[14–16] are listed in Table 2. The corresponding angles of phenylacetic and 2-methyl-2-phenylpropionic acids[17–21] are also included in Table 2. As shown in Table 2, τ_1 and τ_2 of the 2-phenylpropionic acid are localized around angles of 110 and 90°, respectively, with a few exceptions. The corresponding angles for the phenylacetic acid side chain, on the other hand, are 24.4—112.6° and −128.6—25.7°. Therefore, the α-methyl group of the 2-phenylpropionic acid moiety restricts the conformation of this moiety, which should be related to the antiinflammatory activity.

The cyclopentanone ring adopts a half-chair form with the equatorial hydroxyl and methylphenyl groups, in which the C (4) and C (5) atoms are dis-

placed by −0.22 (9) and 0.30 (9) Å from the plane through C (3), C (2) and C (6). The torsional angles of C(2)-C(6)-C(7)-C(8) and C(5)-C(6)-C(7)-C(8) are −72.5 (7) and 49.2 (8)°, respectively.

The molecules form centrosymmetric dimers by the hydrogen-bonds between the carboxyl groups. The O (18) atom donates a hydrogen to O(17^{i}) [(i) $1/2-x$, $1/2-y$, $3/2-z$]; the hydrogen bond distance being 2.619 (5) Å.

Force-Field Calculations. The conformational energy map for double rotation, τ_1 and τ_2, of the acetic acid residue in phenylacetic acid is given in Fig. 2. The map is cyclic with a period of 180° in τ_1 owing to the two-fold rotation symmetry of the benzene ring and also the two-fold rotation axis at τ_1=180°, τ_2=180° owing to the two equivalent hydrogen atoms at the α-carbon of acetic acid, resulting in four global minima A, A′, A″, and A‴. The rotation around the C_α-phenyl bond is somewhat hindered by a barrier of 5.0 kJ mol^{-1} (between A and A′), whereas the rotation barrier between the global minima A and A″ is only 2.9 kJ mol^{-1}. The values of τ_1 and τ_2 in the crystals of phenylacetic acids, which are plotted by the symbol X in Fig. 2, scatter owing to the low energy barriers. It is suggested that the side chain of acetic acid is freely rotated about the C_α-phenyl and C_α-COOH bonds.

The energy surface of 2-phenylpropionic acid as a function of τ_1 and τ_2 is shown in Fig. 3. Because of the two-fold rotation symmetry of the benzene ring, the map is cyclic with a period of 180° in τ_1, resulting in two global minima A and A′. Local minima B and B′ are 5.9 kJ mol^{-1} higher in energy. The rotation around the C_α-phenyl bond is somewhat hindered by a barrier of 11.3 kJ mol^{-1} (between A and A′), whereas the rotation barrier between the global minimum A and local minimum B is 8.4 kJ mol^{-1}. These values are appreciably higher than those of 5.0 and 2.9 kJ mol^{-1} in 2-phenylacetic acid; 2-phenylpropionic acid has more tendency to take the definite conformation than phenylacetic acid. Smeyer et al.[22] have reported that 2-(4-isobutylphenyl)propionic acid (ibuprofen) presents a preferred conformation with torsional angle τ_1 between 90 and 120°, or between 270 and 300° from CNDO/2 molecular orbital calculations. These coincide with the present global minimum A or A′.

The τ_1 and τ_2 torsional angles in the crystals of some derivatives of 2-phenylpropionic acid are given in Table 2 and plotted by the small circles in Fig. 3. In contrast with phenylacetic acid, these are crowded around τ_1=110° and τ_2=90°, which slightly deviates from the point A. This fact, combined with the higher rotation barrier of the side chain in 2-phenylpropionic acid, indicates that the α-methyl substituent to the carboxyl group restricts rotations about the C_α-phenyl and C_α-COOH bonds. The potentiating effect of α-(*S*)-methyl substituent in many antiinflammatory arylacetic acids may be related to such restricted conformation of propionic acid.

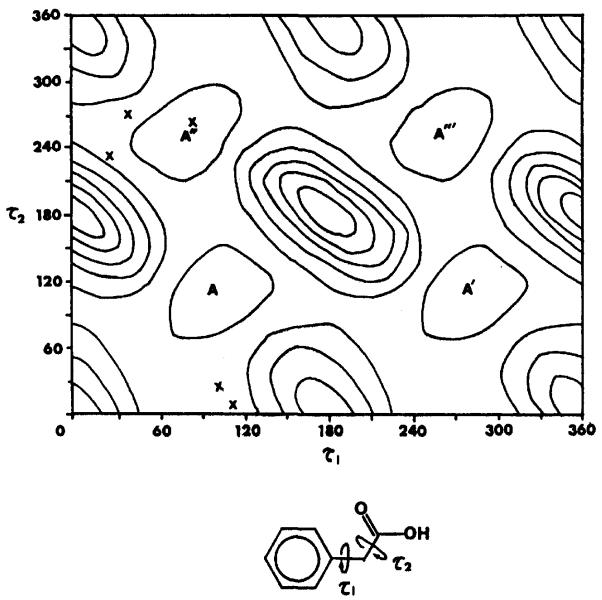

Fig. 2. The conformational energy map for the acetic acid residue in phenylacetic acid by MM2′ calculations. Isobars are drawn at 4.2 kJ mol^{-1} intervals. Four global minimum energy points are A, A′, A″, and A‴. The observed point in the crystal of phenylacetic acids are denoted by the symbol x.

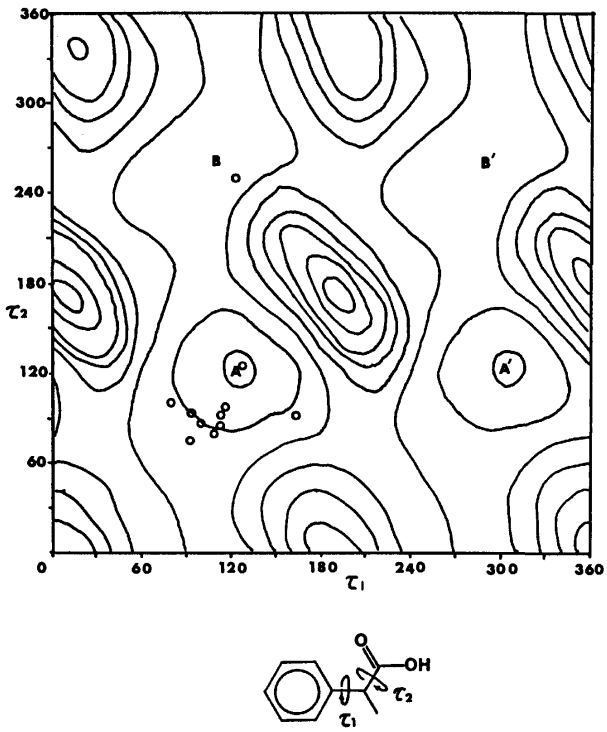

Fig. 3. The conformational energy map for double rotation of the propionic acid residue in 2-phenylpropionic acid by MM2′ calculations. Contours are drawn at 4.2 kJ mol^{-1} intervals. The global minimum points are A and A′ and local ones are B and B′. The observed crystal conformations of 2-phenylpropionic acids are plotted by the small circles.

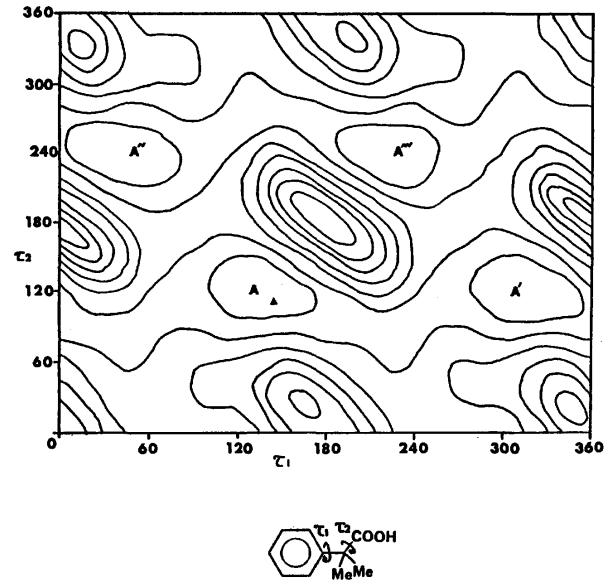

Fig. 4. MM2′ calculated rotational energy surface for the side chain of 2-methyl-2-phenylpropionic acid. Contours are drawn at 4.2 kJ mol^{-1} intervals. The global minimum points are A, A′, A″, and A‴. The observed point of 2-methylpropionic acids in the crystal is denoted by the symbol ▲.

(b) The global minimum energy conformation of 2-methyl-2-phenylpropionic acid. (c) The global minimum energy conformation of (*R*)-2-phenylpropionic acid. (d) The conformation of (*R*)-2-phenylpropionic acid with torsional angles of τ_1=120° and τ_2=120° corresponding to the global minimum energy conformation of the (S)-isomer.

In order to evaluate the effect of one more methyl group, empirical force-field energy calculations have been performed for 2-methyl-2-phenylpropionic acid. The conformational energy map for double rotation of the 2-methyl-2-phenylpropionic acid is given in Fig. 4. This energy surface map has the four global minima A, A′, A″, and A‴, as in phenylacetic acid. The rotation barriers between the global minima A and A′ and between A″ and A‴ are 7.1 and 9.2 kJ mol^{-1}, respectively. The former is lower by 4.2 kJ mol^{-1} than that in 2-phenylpropionic acid and the latter is higher by 0.8 kJ mol^{-1}. The conformation analysis of 2-methyl-2-phenylpropionic acid has been performed by CNDO/2 molecular orbital calculations.[22] Its results show that the τ_1 torsional angle in the preferred conformation is around 0 or 180° which is different from the global minimum points indicated by the MM2′ calculations. The values of τ_1 and τ_2 in crystals of 2-(2-isopropyl-5-indanyl)-2-methylpropionic acid (IPIMP) are plotted by the symbol ▲ in Fig. 4, close to the global minimum A. It is noted that the bulkier the α-substituent to the carboxyl group is, the larger the value of τ_1 for the global minimum; the τ_1 valules of phenylacetic acid, 2-phenylpropionic acid, and 2-methyl-2-phenylpropionic acid being 100, 120, and 130°, respectively.

The most stable conformations of (*S*)-2-phenylpropionic acid and 2-methyl-2-phenylpropionic acid projected along the C_α-phenyl axis are shown in Fig. 5. For the former the α-hydrogen atom lies in the phenyl plane and one of the two methyl groups of the latter is also located approximately on the phenyl plane. On the other hand, (*R*)-2-phenylpropionic acid presents a preferred conformation with τ_1=60° and τ_2=−120°, which is a mirror image of the structure of the (S)-isomer at the global minimum as shown in Fig. 5. These differences in the torsional angles of the global minimum energy conformation of (*R*)-2-phenylpropionic acids may contribute to the lowering of the antiinflammatory activity of the (R)-isomer. However, in the crystal of the antiinflammatory agent, (*S*)-6-chloro-5-cyclohexyl-1-indancarboxylic acid (clidanac), where the carboxyl group is constrained by attachment to a five-membered ring, the τ_1 torsional angle has been found[23] to be 61.8°, compatible with the value of 60° in the global minimum energy conformation of the (R)-isomer molecule. Therefore, conformations with a τ_1 torsional angle of 60° should be able to exhibit some antiinflammatory activity.

The conformation of the (R)-isomer (τ_1=120° and τ_2=120°) corresponding to the preferred conformation of the (S)-isomer is higher by 7.5 kJ mol^{-1} in energy than the global minimum and the projection is also given in Fig. 5. In this conformation (τ_1=120°), not the α-hydrogen atom but the α-methyl group is approximately in the phenyl ring plane just as 2-

methyl-2-phenylpropionic acid. These projecting methyl groups of both compounds, (*R*)-2-phenylpropionic acid and 2-methyl-2-phenylpropionic acid, may point into the receptor site to prevent binding, giving rise to the manyfold reduction in antiinflammatory activity.

We wish to thank Professor Eiji Ōsawa of Hokkaido University for kindly supplying the MM2′ program and Dr. Atsusuke Terada of The Chemical Research Laboratories of our company for providing samples.

Surface Properties and Catalytic Activities of Niobic Acid Treated with Diluted Phosphoric Acid

Akito KUROSAKI, Tetsuhiro OKUYAMA, and Susumu OKAZAKI*
Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Nakanarusawa-cho, Hitachi 316
(Received February 2, 1987)

A surface treatment of niobic acid using about 1 mol dm^{-3} of phosphoric acid was effective for the enhancement of the surface acidity and the catalytic activity for some acid-catalyzed reactions such as cyclohexanol dehydration and alkylation of benzene with methanol. However, a treatment with phosphoric acid of higher concentration might form a deposit on the surface, which would prevent the penetration of reactants and/or products and, thus, decreased the catalytic activity of niobic acid. The P component added to the niobic acid was hardly removed by steaming at 400 °C, although it could be taken off by soaking in water at room temperature for twelve hours.

Niobic acid is known to exhibit a considerably high acid strength even in the presence of steam and, hence, to be available as an effective catalyst for hydration,[1] esterification,[2] or condensation,[3] which are to be performed in the presence of steam.[4] However, surface acidity of niobic acid remarkably decreases when it is heat-treated at temperatures higher than 400°C, possibly due to the crystallization which is known to be taken place above 435°C.[5] It was previously found that the decrease in the surface acidity lowered the catalytic activity of niobic acid for ethylene hydration and methanol conversion.[6] This limitation on the temperature restricts reaction conditions and the possibility for the reactivation of used catalysts. It was also found in a previous study[6] that the addition of a small amount of phosphoric acid is effective for preventing decreases in the surface acidity and the catalytic activity of niobic acid due to a heat treatment at temperatures higher than 400 °C. Furthermore, the phosphoric acid addition is even effective for increasing the surface acidity or enhancing the catalytic activity of the niobic acid heat-treated at lower temperatures. For uses of niobic acid as an industrial catalyst, the increase in the amount of acid sites seems essential; hence, the effects of a phosphoric acid addition on the surface acidity and on the catalytic activity for an acid-catalyzed reaction were investigated in more detail in this study. Especially, the durability of the P component was examined in terms of the change of the P content in the phosphoric acid-treated sample during a high-temperature (400 °C) steam treatment.

Experimental

Catalyst Preparation. Niobic acid (AD-135) supplied by CBMM was dried in air at 120 °C for 6 h. This material (10 g) was immersed in 30 ml of a phosphoric acid solution prepared so as to have a given concentration (0.05, 0.25, 0.5, 1, 3, or 5 mol dm^{-3} of H_3PO_4). The suspension of niobic acid was allowed to stand for 48 h; the sample was then evaporated to dryness in air at 120 °C. The dried sample was calcined at various temperatures ranging from 200 to 800 °C.

Surface Acidity and Specific Surface Area. The acidity of niobic acid before and after the acid-treatment was determined by adsorptions of ammonia and pyridine at various temperatures. The BET method was applied in order to measure the specific surface area. Constant-volume adsorption of N_2 was carried out at 78 K for samples having sizes of 14—20 mesh.

XRD and XPS Measurements. The XRD measurement was carried out using Geigerflex Diffractometer(Rigaku Denki) (target: Cu; filter: Ni). Some catalyst samples were heat-treated at 400 °C and then subjected to an XPS measurement (using Shimadzu ESCA 750) for the surface composition analysis. Also, ICP (Induction Combined Argon Plasma Emission Spectroscopy) was used to determine the change in the P content during a steam treatment.

Dehydration of Cyclohexanol and Alkylation of Benzene with Methanol. The dehydration of cyclohexanol was performed by using as a catalyst untreated niobic acid as well as niobic acid treated with 1 mol dm^{-3} phosphoric acid. The reaction was carried out at 180 °C under normal pressure using a conventional flow reactor. W/F was kept at 31.0 $g \cdot h \cdot mol^{-1}$ for the catalytic dehydration. The alkylation of benzene with methanol was performed at 400 °C, using a pulse reactor. The pulse size and the catalyst weight were 2 μl and 50 mg, respectively. The molar ratio of methanol/benzene was adjusted at 3 for all the pulse reactions.

Results and Discussion

Surface Area. The surface area of niobic acid sharply dropped when the sample was heat-treated at temperatures above 400 °C, owing to the crystallization which should take place above 435 °C.[5] This decrease in the surface area was prevented by a treatment with 0.5—1.0 mol dm^{-3} of phosphoric acid, similarly to that observed previously.[6] However, treatments with phosphoric acid of higher concentrations were ineffective for the prevention of a decrease in the surface area, (Fig. 1). Especially, a treatment with 5 mol dm^{-3} phosphoric acid decreased rather than increased the surface area of the niobic acid heat-treated at 600 °C. It was possible that some niobium compound, such as niobium phosphate, was formed on the surface of niobic acid, although the XRD measurement did not show any peak ascribable to a newly formed compound on this sample.

Surface Acidity. The acidity changes of phos-

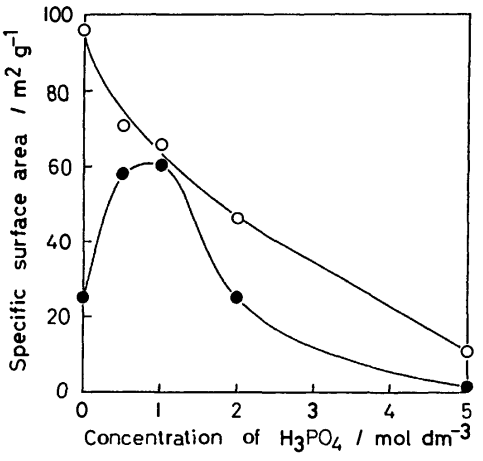

Fig. 1. Effect of H_3PO_4 concentration on specific surface area of niobic acid. Heat treatment temperature; ○: 400 °C, ●: 600 °C.

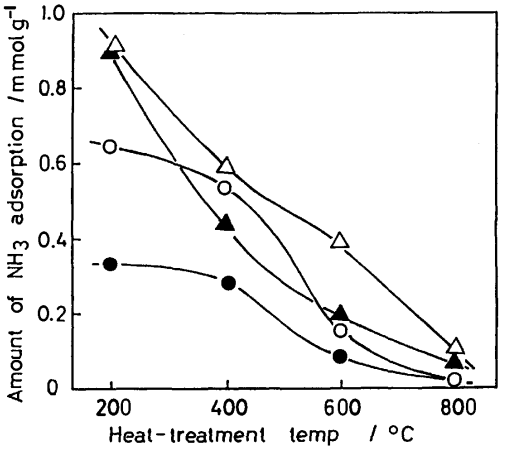

Fig. 2. Effect of heat treatment temperature on surface acidity of niobic acid before and after H_3PO_4 treatment. Concentration of H_3PO_4: 1.0 mol dm^{-3}; ○: adsorption at 100 °C on niobic acid before H_3PO_4 treatment; △: adsorption at 100 °C after treatment; ●: adsorption at 200 °C before treatment; ▲: adsorption at 200 °C after treatment.

phoric acid-treated and untreated niobic acid after heating at various temperatures were determined by the NH_3 adsorptions at 100 and 200 °C. As is shown in Fig. 2, the amount of NH_3 adsorbed at 100 and 200 °C on the acid-treated sample was larger than that adsorbed at a respective temperature on the untreated sample for all the heat-treatment temperatures ranging from 200 to 800 °C. Thus, the phosphoric acid treatment was effective irrespective of the heat-treatment temperature. Especially, adsorption amount of NH_3 at 200 °C was nearly equal to that of NH_3 adsorbed at 100 °C for the sample heat-treated at 200 °C. The evidence suggested that relatively strong acid sites were formed on the sample when the acid-treated sample was heated at a lower temperature such as 200 °C.

To determine the effect of the concentration of phosphoric acid used for the acid treatment on the

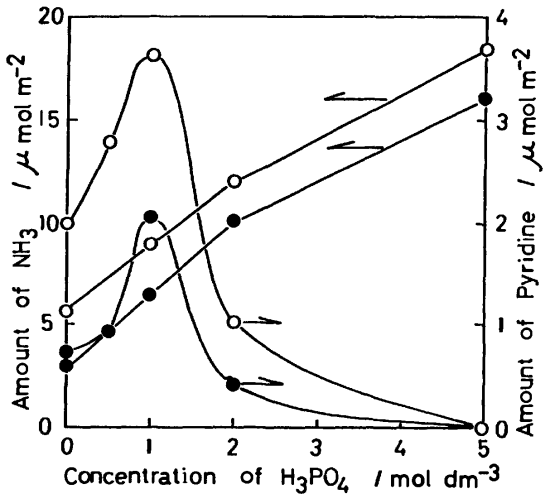

Fig. 3. Effect of H_3PO_4 concentration on surface acidity determined by NH_3 or pyridine adsorption. Ammonia and pyridine adsorptions were carried out by volumetric and gravimetric methods, respectively. Heat treatment temperature: 400 °C. Adsorption temperature: 100 °C (○) or 200 °C (●).

surface acidity of niobic acid, the adsorptions of NH_3 and pyridine on both treated and untreated niobic acid were attempted. The relationship between the amounts of NH_3 and pyridine per unit surface area and the concentration of used phosphoric acid is shown in Fig. 3. The amount of adsorption was similarly changed by changing the heat-treatment temperature, irrespective of the difference of the adsorption temperature. When the determination was carried out by the NH_3 adsorption, both the amounts per unit surface or densities, calculated for the adsorption temperatures of 100 and 200 °C on the niobic acid surface monotonously increased with the phosphoric acid concentration. On the other hand, the densities determined by the pyridine adsorption presented a maximum at a concentration of 1 mol dm^{-3}. This difference between acid site amounts (or densities) determined by NH_3 and pyridine adsorptions may be resulted from the difference in the molecular size of these bases. That is, the smaller molecules of NH_3 may penetrate through the micro pores of the surface layer formed by the phosphoric acid treatment on niobic acid, whereas the larger molecules of pyridine may be unable to penetrate. A similar phenomenon was observed by Itoh and Tada in their study on double adsorption of NH_3 and pyridine on Al_2O_3.[7] The surface possibly came to be covered more compactly as the concentration of the phosphoric acid used for the treatment became higher. On the other hand, the surface of niobic acid treated with less concentrated phosphoric acid might not be fully or less compactly covered by the compound newly formed on the surface. In such a state, the adsorption amount of pyridine was larger than that of NH_3 for the sample treated with phosphoric acid of lower concentration (0.5 and 1

mol dm^{-3}), since the basic strength of pyridine is higher than that of NH_3.[7-8] As a result of the two opposing effects, regarding the basic strength and the molecular size, respectively, a maximum was observed at a 1 mol dm^{-3} concentration of phosphoric acid for the adsorbed amount of pyridine (shown in Fig. 3).

Surface Composition and Structure. The atomic ratio of P/Nb in the surface layer of the catalyst determined by XPS linearly increased with increasing the concentration of phosphoric acid used for the treatment as shown in Fig. 4. The P/Nb ratio shown in the figure was considerably higher than the value calculated from the amount of phosphoric acid added to the niobic acid sample; for example, the value is calculated to be about 0.5 for the treatment with phosphoric acid of 1 mol dm^{-3}, but the experimental value is roughly 1. The evidence again indicated that the P component was concentrated in the surface layer. In spite of the concentration in the surface layer, the P component was slightly removed by a steam treatment at 400°C for 3 h (Fig. 5). The P component was partially removed by soaking in water with vigorous stirring at room temperature for 12 h.

XPS spectra regarding O, Nb, and P components in the surface layer of niobic acid samples containing various amounts of P component is shown in Fig. 6. The numbers in the parentheses indicate the atomic ratio of

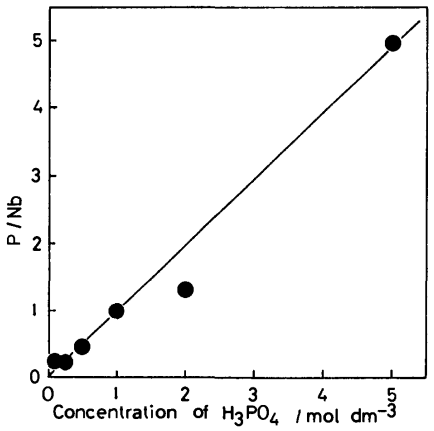

Fig. 4. Effect of H_3PO_4 concentration on atomic ratio P/Nb in surface layer of H_3PO_4-treated niobic acid.

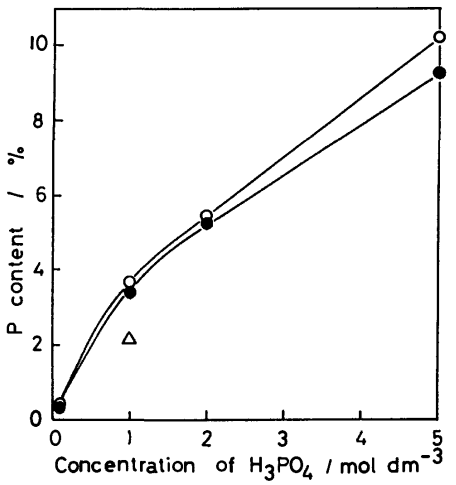

Fig. 5. Change of the P content of the acid treated sample during treatment with steam or water. ○: Untreated; ●: treated with steam. △: Treated with water at room temperature for 12 h. The steam treatment was carried out at 400°C for 3 h by using 106 m mol of steam per g of the niobic acid sample.

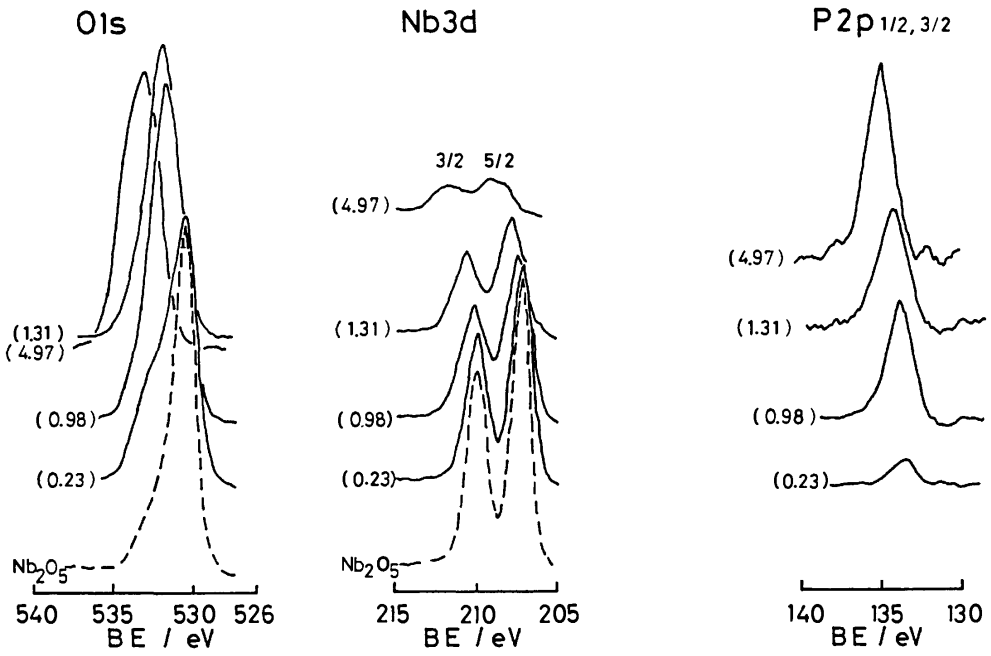

Fig. 6. XPS spectra for niobic acid before and after treatment with phosphoric acid. BE values shown here were obtained by assuming the Cls peak position due to contaminant carbon as 285 eV.

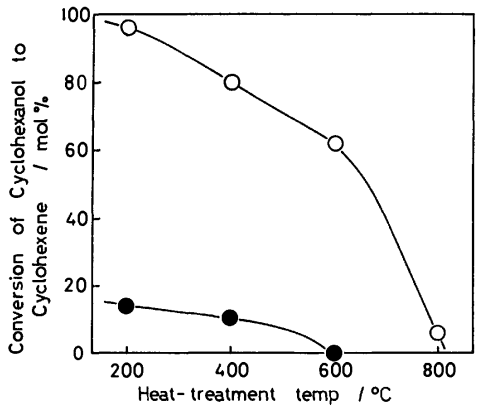

Fig. 7. Catalytic dehydration of cyclohexanol over niobic acid before and after treatment with H_3PO_4. Reaction temperature: 180°C; W/F: 31.0 g·h·mol^{-1}. ●: Before treatment; ○: after treatment with 1.0 mol dm^{-3} H_3PO_4.

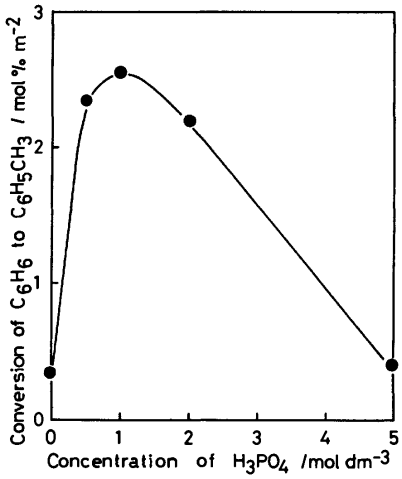

Fig. 8. Catalytic alkylation of benzene with methanol. Reaction temperature: 400°C; molar ratio of MeOH/benzene=0.3; heat treatment temperature of catalyst: 400°C; pulse size: 2 μl; catalyst weight 50 mg.

P/Nb determined by an analysis using XPS. The peak position of P2s for the sample treated with phosphoric acid was, in general, shifted to the lower BE side compared to that observed for P_2O_5 (135.8 eV, which was determined by taking Cls peak position of contaminant C as 285 eV).[9] The extent of the shift increased with decreasing the P content. Thus, the peak positions of samples having various atomic ratios of P/Nb are as follows: 135.8 (P_2O_5), 134.4 (P/Nb=4.97), 134.1 (1.31), 134.0 (0.98), and 133.7 (0.23) eV. The values for samples containing small amounts of the P component almost coincided with that for P^{3+} (134 eV).[9] The evidence suggests that P atoms might contribute to the withdrawal of electrons from the neighbouring Nb atoms; the contribution of individual P atoms might become more remarkable as the amount of phosphoric acid addition decreases. On the other hand, the peak due to Nb3d gradually shifted to the higher bonding energy side upon increasing the amount of the phosphoric acid addition. The result again suggested a withdrawal of electrons from Nb atoms by the phosphoric acid molecules added for the treatment. Thus, the electrons of the Nb atoms surrounded by a larger amount of phosphate molecules might be drawn out to a greater extent; the largest shift to the higher energy side was observed for niobic acid containing the largest amount of the P component (P/Nb=5). However, further details of the induction of electrons of Nb atoms, or the enhancement of the surface acidity due to Nb atoms are not clear at the present stage of this study.

Catalytic Activity in Cyclohexanol Dehydration. Similar to the surface acidity shown in Fig. 2, the catalytic activity of niobic acid in cyclohexanol dehydration, increased with a treatment using phosphoric acid, and gradually decreased upon increasing the heat-treatment temperature (Fig. 7). The change of the catalytic activity described above could be ascribed to a change in the surface acidity. Therefore, the addition of P component should contribute to an increase in the surface acidity, resulting in an enhancement in the catalytic activity in cyclohexanol dehydration.

Catalytic Activity in Alkylation of Benzene with Methanol. The conversion of the alkylation of benzene with methanol over niobic acid before and after a treatment with phosphoric acid of various concentrations is shown in Fig. 8. The catalytic activity of niobic acid, which was shown by the conversion of benzene to toluene, showed a maximum when the sample was treated with 0,5—1.0 mol dm^{-3} of phosphoric acid. As already shown in Fig. 3, a similar maximum value was also obtained for the amount of surface acidity, determined by pyridine adsorption, of H_3PO_4-treated niobic acid, when the phosphoric acid concentration was 1.0 mol dm^{-3}. This fact again suggests that the surface layers formed by the deposition of a phosphorus compound should absorb only small molecules such as N_2 (critical dimension: 3.0 Å[10]) and NH_3 (3.8 Å[10]). On the other hand, larger molecules such as benzene (6.8 Å[10]) might not be able to penetrate through the micro pores of the deposited compound and are, thus, little adsorbed on the H_3PO_4-treated niobic acid. Although the accurate molecular dimension of pyridine is not known, it is considered to be close to that of benzene. This seems to be the reason for obtaining a maximum at about the same concentration of the phosphoric acid to enhance the catalytic activity in the alkylation of benzene with methanol (Fig. 8) and to increase the surface acidity determined by pyridine adsorption (Fig. 3).

The authors are grateful to Mr. Osamu Horie and Mr. Atsushi Uetake for the assistance to perform the catalytic reactions. In addition, we are much obliged to CBMM for the financial support of this study.

Dinuclear iron(II, II) complexes, $[Fe_2(L\text{-}py)(RCOO)_2]BF_4 \cdot nH_2O$ (RCOO: CH_3COO (**1a**) and C_6H_5COO (**2a**)), and two types of dinuclear mixed valence iron(II, III) complexes $[Fe_2(L\text{-}py)(RCOO)_2](BF_4)_2 \cdot nH_2O$ (RCOO: CH_3COO (**1b**) and C_6H_5COO (**2b**)) and $[Fe_2(L\text{-}py)(CH_3COO)(OH)](BF_4)_2 \cdot 2H_2O$ (**3**) were prepared, where L-py represents 2,6-bis[bis(2-pyridylmethyl)aminomethyl]-4-methyl-phenolate(1−). Only one of the two iron(II) ions in the iron(II, II) complexes is easily oxidized with molecular oxygen in methanol to form the mixed valence complexes, $[Fe_2(L\text{-}py)(RCOO)_2](BF_4)_2 \cdot nH_2O$, which were characterized by chemical analyses and Mössbauer measurements. Magnetic susceptibility measurements over the temperature range 80—300 K revealed that high-spin iron(II) and iron(III) ions are antiferromagnetically coupled with the spin-exchange coupling constants J=−3—−8 cm^{-1}. The complexes exhibited an ESR signal of $g_{av} \approx 1.7$ near liquid helium temperature. Such an ESR signal arises from an antiferromagnetically spin-coupled high-spin iron(II, III) dimer. An intervalence charge-transfer transition was observed in the region 7000—8500 cm^{-1}. The electron delocalization parameter α is estimated to be ca. 0.08, which corresponds to the class II mixed valence type in the classification of Robin and Day. Cyclic voltammogram of the complex **2b** in acetonitrile showed two reversible couples at +0.05 and +0.73 V (vs. SCE), which were assigned to the redox reactions of Fe(II, III)/Fe(II, II) and Fe(III, III)/Fe(II, III), respectively. The comproportionation constants of **1b** and **2b** at 20 °C are 1.6×10^{12} and 5.0×10^{11}, respectively, implying that the present mixed valence complexes are significantly stabilized.

Dinuclear iron(II, III) mixed valence centers have been found to exist in iron proteins such as *semi-met*hemerythrin,[1-3] pink uteroferrin,[4-8] and the reduced form of bovine spleen acid phosphatase.[4,5,9] They exhibited an ESR signal with g_{av}<2.0 observable only near liquid helium temperature. Such an ESR signal has been interpreted in terms of antiferromagnetic superexchange interaction between high-spin iron(II) and high-spin iron(III) ions.[10] Spin-exchange coupling constants for pink uteroferrin[6,7] and the reduced form of bovine spleen acid phosphatase[9] are ≈−10 and ≈−50 cm^{-1}, respectively. From these data, it was suggested that the former protein had μ-hydroxo bridge[6] and the latter μ-oxo bridge[9]. Recent EXAFS study of the latter protein also suggested the presence of additional bridges such as carboxylato group.[11] For these proteins, phenolato and imidazole groups of tyrosine and histidine residues were proposed as additional coordinating groups;[6,12] possible ligating groups for irons in *semi-met*hemerythrin are imidazole group of histidine residue, and carboxylato groups of aspartic and glutamic acid residues. However, details of structure and function of metal center of these proteins still remain ambiguous.

Synthetic dinuclear mixed valence iron(II, III) complexes with biologically relevant ligands such as imidazole group, carboxylato, and phenolato groups are useful for further elucidation of structure and function of the iron(II, III) centers in the above proteins. In the previous communication, we reported the synthesis and characterization of a mixed valence complex $[Fe_2(L\text{-}Bzim)(C_6H_5COO)_2](BF_4)_2 \cdot 2H_2O$ (L-Bzim=2,6-bis[bis(2-benzimidazolylmethyl)aminomethyl]-4-methylphenolate (1-)) and proposed a dinuclear structure of iron(II) and iron(III) bridged triply by a phenolate and a couple of carboxylato groups.[13] Recently we found a similar triply bridging unit in an analogous dinuclear mixed valence manganese(II, III) complex $[Mn_2(L\text{-}py)(C_6H_5COO)_2](ClO_4)_2 \cdot H_2O$,[14] where L-py is 2,6-bis[bis(2-pyridylmethyl)aminomethyl]-4-methyl-phenolate(1−) (Fig. 1). Reported herein are the syntheses and various physicochemical properties of the two types of dinuclear mixed valence complexes with the dinucleating ligand, L-py, and carboxylate ion(s), $[Fe_2(L\text{-}py)(RCOO)_2](BF_4)_2 \cdot nH_2O$ (RCOO=CH_3COO or C_6H_5COO) and $[Fe_2(L\text{-}py)(CH_3COO)(OH)](BF_4)_2 \cdot 2H_2O$. The L-Bzim and L-py complexes are the first examples of synthetic dinuclear mixed valence high-spin iron(II, III) complexes.

Dinuclear metal complexes with metal ions in sterically and electronically controlled environment are expected to reversibly bind molecular oxygen.

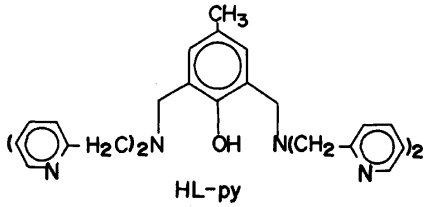

Fig. 1. Dinucleating ligand (HL-py): 2,6-bis[bis(2-pyridylmethyl)aminomethyl]-4-methylphenol.

Recently, we have demonstrated that dinuclear cobalt(II, II) complexes $[Co_2(L\text{-}py)(RCOO)_2]^+$ and $[Co_2(L\text{-}py)(RCOO)]^{2+}$ react reversibly with molecular oxygen to form μ-peroxo complexes $[Co_2(L\text{-}py)(RCOO)(O_2)]^{2+}$.[15] The irreversible oxidation of cobalt ion was much suppressed in the above dioxygen complexes. Such stabilty of the dioxygen complexes must stem from a geometry and donor properties of the ligands. In this study, we also prepared the dinuclear iron(II, II) complexes with L-py and carboxylate ions, $[Fe_2(L\text{-}py)(RCOO)_2]BF_4 \cdot nH_2O$, and their reaction with molecular oxygen was investigated.

Experimental

Materials. HL-py was synthesized as previously described.[15] Iron(II) tetrafluoroborate hexahydrate was prepared according to the method of literature.[16] Other chemicals used were of reagent grade.

Preparation of Iron(II, II) Complexes. $[Fe_2(L\text{-}py)(RCOO)_2]BF_4 \cdot nH_2O$ (RCOO: CH_3COO (1a) or C_6H_5COO (2a)): The complexes were prepared by ordinary Schlenk techniques in an inert atmosphere. A solution of $Fe(BF_4)_2 \cdot 6H_2O$ (1 mmol) in 20 cm^3 of ethanol was added to a solution of HL-py (0.5 mmol), RCOOH (1 mmol), and triethylamine (1 mmol) in 20 cm^3 of ethanol with stirring. The reddish yellow solution was concentrated to a half of the original volume by vacuum evaporation and allowed to stand overnight at 0 °C. Orange-yellow crystals formed were collected by filtration, washed with ethanol and ether, and dried in vacuo.

Preparation of Iron(II, III) Complexes. $[Fe_2(L\text{-}py)RCOO)_2](BF_4)_2 \cdot nH_2O$ (RCOO: CH_3COO (1b) or C_6H_5COO (2b)): A solution of $Fe(BF_4)_2 \cdot 6H_2O$ (1 mmol) in 40 cm^3 of ethanol was added to a mixture of HL-py (0.5 mmol), RCOOH (1 mmol), and triethylamine (1 mmol) in 20 cm^3 of methanol with stirring under a nitrogen atmosphere. The reddish yellow solution was then exposed to an oxygen atmosphere at 10 °C with stirring to cause an instanteneous color change to dark green. The solution was kept at 0 °C for several hours. Dark green crystals thus obtained were collected by filtration, washed with ethanol and ether, and dried in vacuo; they were recrystallized from methanol under a nitrogen atmosphere. The crystals are stable in the open atmosphere. Single crystals suitable for X-ray analysis have not yet been obtained.

$[Fe_2(L\text{-}py)(CH_3COO)(OH)](BF_4)_2 \cdot 2H_2O$ (3): A solution of $Fe(BF_4)_2 \cdot 6H_2O$ (1 mmol) in 20 cm^3 of ethanol was added to a solution of HL-py (0.5 mmol), CH_3COOH (0.5 mmol), and triethylamine (1 mmol) in 20 cm^3 of ethanol under a nitrogen atmosphere. The resulting pale yellow solution was exposed to an oxygen atmosphere with stirring at 10 °C to cause an instanteneous color change to dark blue. The dark blue solution was cooled to 0 °C and allowed to stand for one hour to yield dark blue microcrystalline powders. They were collected by filtration, washed with ethanol and ether, and dried in vacuo. The product is stable in the open atmosphere.

Measurements. The electronic spectra in acetonitrile solution were measured on a Jasco UVIDEC 505 UV/VIS recording digital spectrophotometer and a Hitachi 323 recording spectrophotometer. Infrared spectra were obtained by a KBr-disk method and a Nujol mull method with a Jasco A-3 infrared spectrophotometer. Magnetic susceptibilities were measured with a Shimadzu torsion magnetometer MB-2. The apparatus was calibrated by the use of Hg-$[Co(NCS)_4]$. Diamagnetic corrections were made by using Pascal's constants.[17] Molar conductivities were measured in *N,N*-dimethylformamide or acetonitrile solution (1×10^{-3} mol dm^{-3}) at 25 °C with a Yokogawa Universal Bridge Type BUZ-10A. Mössbauer spectra were measured at 77 K against a $^{57}Co(Pt)$ source moving in a mode of constant acceleration at room temperature. Velocity calibration was carried out by the resonance lines of metallic iron, and isomer shifts were given relative to iron metal at room temperature. Cyclic voltammograms were measured with a Yanagimoto P-900 in a cell containing a glassy carbon working electrode, auxiliary electrode, and a saturated calomel electrode. Applied voltage was measured with a Takeda Riken TR-8651 electrometer. Acetonitrile was used as the solvent and tetrabutylammonium perchlorate as the supporting electrolyte. Ferrocene was added for an internal check on redox potential and reversibility. $E_{1/2}$ of ferrocene was 0.39 V (vs. SCE) with a peak-to-peak separation of 70 mV. ESR spectra above 10 K were measured on a JEOL JES-FE2XG ESR spectrometer (X-band microwave unit, 100 kHz field modulation) equipped with an Air Product LTD-3-110 liquid helium transfer system. The microwave frequency was measured with a Takeda Riken TR5212 microwave counter, and the resonance magnetic field values of the signals were measured with an NMR field meter (ECHO Electronics Co., Ltd.). ESR spectra at 6 K were recorded on a Varian E-112 spectrometer (X-band microwave unit, 100 kHz modulation) equipped with an Oxford cryostat.

Analyses of Iron(II) and Iron(III) Ions. The contents of iron(II) and iron(III) ions in the mixed valence complexes were determined colorimetrically.[18] A weighted quantity of the complex (ca. 40 mg) was dissolved into a solution of 1,10-phenanthroline (200 mg) in 20 cm^3 *N,N*-dimethylformamide under nitrogen atmosphere. The solution was stirred for 1 min and treated with an aqueous suspension (20 cm^3) of excess H_4edta (ca. 100 mg) for preventing the reduction of the iron(III) and masking iron(III)-phenolato complexes.[19] The mixture was diluted to ca. 250 cm^3 with water and the pH of the solution was adjusted to ca. 4 with acetic acid. The volume of the resulting solution was adjusted to 500 cm^3. After filtration, the iron(II) content was determined spectrophotometrically at 510 nm as $[Fe(phen)_3]^{2+}$ (ε=11300 $mol^{-1}\,dm^3\,cm^{-1}$). Total content of iron(II) and iron(III) ions was determined in a similar way after the iron(III) ion had been reduced to divalent state. The iron(III) content was known from the difference. The analytical data are given in Table 1 together with the magnetic moments.

Results and Discussion

Characterization of Complexes. The effective magnetic moments of **1b** and **2b** are 7.7 and 7.3 B. M./Fe_2, respectively, indicating that both iron(II) and iron(III) ions are in high-spin state. The infrared spectra of the complexes in the region of 600—4000 cm^{-1} are almost the same as those of the corresponding manganese(II,III) complexes $[Mn_2(L\text{-}py)(RCOO)_2](ClO_4)_2 \cdot nH_2O$,[14] except for the stretching vibration region of perchlorate and tetrafluoroborate ions.

Table 1. Analytical Data and Effective Magnetic Moments of Complexes

No.	Complex	Found (Calcd)/%					μ_{eff}/B.M.[a]
		C	H	N	Fe(II)	Fe(III)	
1a	$[Fe_2(L\text{-}py)(CH_3COO)_2]$-$BF_4\cdot 0.5H_2O$	52.02 (51.92)	4.62 (4.71)	9.65 (9.82)			7.4
2a	$[Fe_2(L\text{-}py)(C_6H_5COO)_2]$-$BF_4\cdot 3H_2O$	54.99 (55.10)	4.47 (4.82)	8.20 (8.20)			7.2
1b	$[Fe_2(L\text{-}py)(CH_3COO)_2]$-$(BF_4)_2\cdot H_2O$	47.10 (46.70)	4.32 (4.34)	8.90 (8.84)	5.6 (5.87)	5.9 (5.87)	7.7
2b	$[Fe_2(L\text{-}py)(C_6H_5COO)_2]$-$(BF_4)_2\cdot 2H_2O$	51.73 (52.07)	4.13 (4.28)	7.60 (7.75)	4.9 (5.11)	5.2 (5.11)	7.3
3	$[Fe_2(L\text{-}py)(CH_3COO)(OH)]$-$(BF_4)_2\cdot 2H_2O$	44.89 (45.35)	4.22 (4.46)	9.16 (9.07)	5.9 (6.03)	6.0 (6.03)	7.4

a) At room temperature.

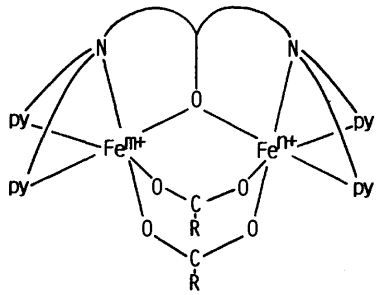

Fig. 2. Possible structure of $[Fe_2(L\text{-}py)(RCOO)_2]^+$ (m=2 and n=2) and $[Fe_2(L\text{-}py)(RCOO)_2]^{2+}$ (m=2 and n=3).

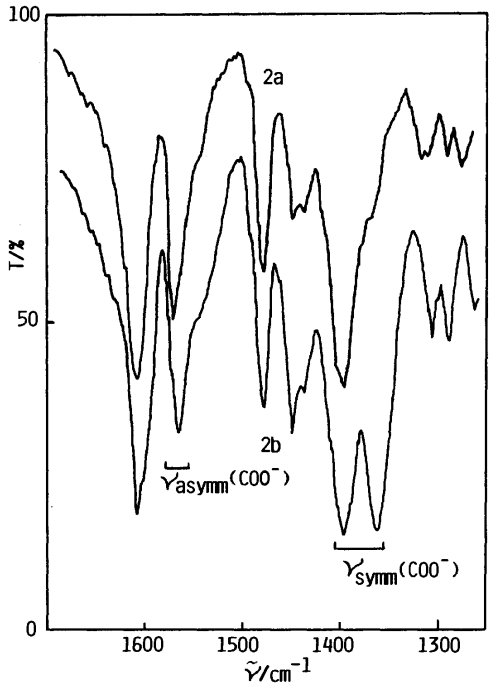

Fig. 3. Infrared spectra of $[Fe_2(L\text{-}py)(C_6H_5COO)_2]$-$BF_4\cdot 3H_2O$ (**2a**) and $[Fe_2(L\text{-}py)(C_6H_5COO)_2](BF_4)_2\cdot 2H_2O$ (**2b**).

From the IR spectral data, both the mixed valence iron and manganese complexes seem to have the same structure. The crystal structure of $[Mn_2(L\text{-}py)(C_6H_5\text{-}COO)_2](ClO_4)_2\cdot H_2O$[14b] showed that manganese(II) and (III) ions are bridged by phenolate and two carboxylate oxygens to form a cofacial bi-octahedral structure. Such triply bridging structure has been found for some dinuclear manganese and iron complexes with bridging groups composed of two carboxylato groups and oxo, hydroxo, or phenolato group.[20-23] A possible structure of **1b** and **2b** is shown in Fig. 2.

Infrared spectra of **2a** and **2b** in the $\nu(COO^-)$ stretching vibration region (Fig. 3) showed that the ν_{symm} (COO^-) of **2b** splits into two bands at 1395 and 1362 cm^{-1}, suggesting the presence of two types of carboxylato groups. A similar splitting of ν_{symm} (COO^-) was also observed in manganese(II,III) complex $[Mn_2(L\text{-}py)(C_6H_5COO)_2](ClO_4)_2\cdot H_2O$[14b] in which two bridging benzoato groups are not equivalent: one symmetrically bridges manganese(II) and (III) ions, and the other unsymmetrically. The Mn(III)-O and Mn(II)-O bond distances, and two C-O bond distances of unsymmetrically bridging benzoato group considerably differ from each other. It has been suggested that $\Delta\tilde{\nu}$ (COO^-) value ($\tilde{\nu}_{asymm}$ (COO^-) $-$ $\tilde{\nu}_{symm}$ (COO^-)) is diagnostically useful for elucidating coordination mode of carboxylato group; a symmetrically bridging carboxylato group gives $\Delta\tilde{\nu}$ smaller than 200 cm^{-1}, whereas an unsymmetrically bridging group a larger $\Delta\tilde{\nu}$.[24] The $\Delta\tilde{\nu}$ values are 150 and 200 cm^{-1} for **1b**, and 173 and 206 cm^{-1} for **2b**. Thus the larger $\Delta\tilde{\nu}$ values correspond to an unsymmetrically bridging carboxylato group and the smaller values to a symmetrically bridging one.

The complex **3** is air-stable in the solid state, but easily oxidized with molecular oxygen in various solvents at room temperature. Its effective magnetic moment is 7.4 B.M./Fe_2 at room temperature, indicating that iron(II) and iron(III) ions are in high-spin state. The molar conductivity (137 Ω^{-1} cm^2 mol^{-1}) in DMF indicates that the complex is a 2:1 electrolyte. From the molar conductivity measurement and elemental analysis, the coordination of hydroxide ion is

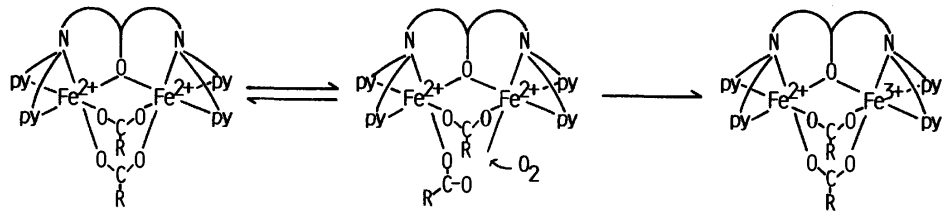

Fig. 4. A possible reaction scheme of oxidation of $[Fe_2(L\text{-}py)(RCOO)_2]^+$ (**1a** and **2a**).

plausible and the complex **3** may be formulated as $[Fe_2(L\text{-}py)(CH_3COO)(OH)](BF_4)_2 \cdot 2H_2O$.

The effective magnetic moments of **1a** and **2a** are 7.4 and 7.2 B.M./Fe_2, respectively, indicating that iron(II) ions are in high-spin state. The infrared spectra of **1a** and **2a** are almost identical to those of the corresponding Co^{II}-Co^{II} complexes, $[Co_2(L\text{-}py)(RCOO)_2]BF_4 \cdot nH_2O$,[15] in which cobalt ions were shown to adopt a six-coordinated structure on the basis of their reflectance spectra. On the analogy with the cobalt complexes, the present complexes seem to have six-coordinated structure. This may also be supported by the reactivity of the complexes with molecular oxygen in various solvents (vide infra). A possible structure is shown in Fig. 2.

The complexes **1a** and **2a** are relatively stable for a day in acetonitrile and dichloromethane under an oxygen atmosphere, whereas they rapidly react with molecular oxygen in methanol and *N,N*-dimethylformamide to form dark brown solution. Addition of tetraethylammonium tetrafluoroborate and ethanol to the above dark brown solution gave the mixed valence complexes **1b** and **2b**.

Reactivity of the Iron(II,II) Complexes with Molecular Oxygen. The effect of solvents on the reactivity of the dinuclear iron(II,II) complexes **1a** and **2a** with molecular oxgyen is quite similar to that of the corresponding cobalt(II,II) complexes $[Co_2(L\text{-}py)(RCOO)_2]^+$.[15] Both cobalt and iron complexes readily react with molecular oxygen in methanol and *N,N*-dimethylformamide but to a much lesser extent in acetonitrile and dichloromethane. The cobalt complexes give reversible oxygenation in the former two solvents to give μ-peroxo complexes, whereas the iron complexes form the mixed valence complexes **1b** and **2b** as mentioned in the preceding section. We suggested that the oxygenation of the cobalt complexes proceeds via a five-coordinated species: one of two carboxylato groups dissociates in the former solvents, but not in the latters. In fact, the five-coordinated complexes $[Co_2(L\text{-}py)(RCOO)]^{2+}$ react reversibly with molecular oxygen both in methanol and acetonitrile as well as in the solid state. This is also the case for the oxidation of iron(II,II) complexes: the oxidation of iron complexes seems to take place in a five-coordinated species. A possible reaction scheme is given in Fig. 4. It is probable that one of two bridging carboxylato groups (a in Fig. 4) dissociates to form a species containing five-and six-coordinated irons and then five-coordinated moiety reacts with molecular oxygen to form a hyperoxo complex as a transient intermediate. This hyperoxo complex is unstable and irreversibly oxidized to form mixed valence complex. In the cobalt complex, however, the hyperoxo complex is relatively stable and the coordinated hyperoxide ion displaces the unidentate carboxylate ion to form a μ-peroxo complex.

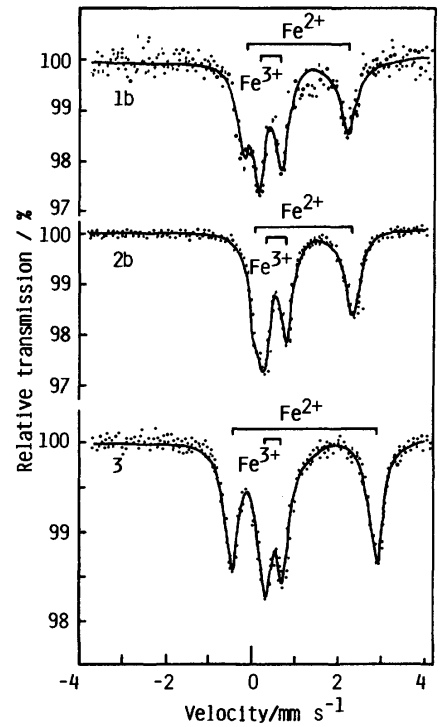

Fig. 5. Mössbauer spectra of $[Fe_2(L\text{-}py)(CH_3COO)_2](BF_4)_2 \cdot H_2O$ (**1b**), $[Fe_2(L\text{-}py)(C_6H_5COO)_2](BF_4)_2 \cdot 2H_2O$ (**2b**), and $[Fe_2(L\text{-}py)(CH_3COO)(OH)](BF_4)_2 \cdot 2H_2O$ (**3**) at 77 K.

Mössbauer Spectra. Mössbauer spectra of the mixed valence complexes are shown in Fig. 5 and their parameters are listed in Table 2. All the spectra were analyzed with a least square fitting program of Lorenztian functions into two sets of quadrupole doublets, each of which was fitted with an equal line width and intensity. The calculated quadrupole splittings ΔE (isomer shifts δ) in mm s^{-1} are 2.06—3.38

a) All data in mm s^{-1} except for A(Fe(III)/(Fe(II)). b) Isomer shift, δ, relative to iron metal. c) Ratios of areas of Fe(III) to Fe(II). d) Data at 60 K from Ref. 8.

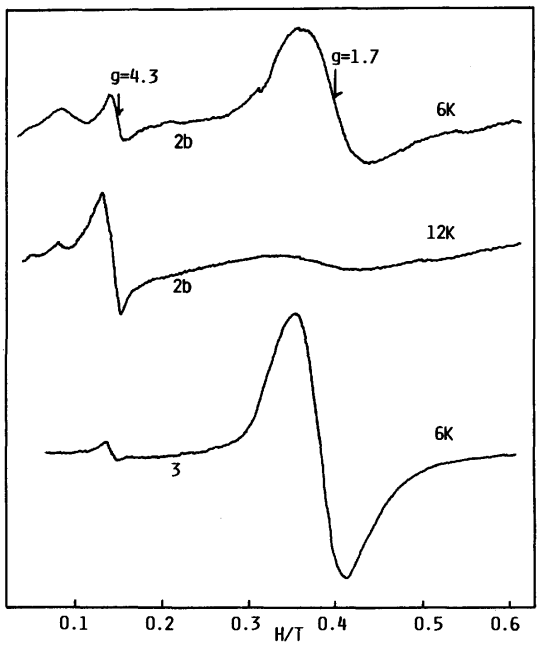

Fig. 6. ESR spectra of $[Fe_2(L\text{-}py)(C_6H_5COO)_2]^{2+}$ (**2b**) and $[Fe_2(L\text{-}py)(CH_3COO)(OH)]^{2+}$ (**3**) in acetonitrile at 6 and 12 K.

(1.16—1.19) and 0.42—0.51 (0.47—0.56), which are assigned to those arising from the high-spin iron(II) and iron(III) moieties, respectively.[25] The presence of iron(II) and iron(III) ions in equimolar ratio is evidenced from the fact that the ratios of areas of two sets of quadrupole doublets are nearly unity (the last columm in Table 2), which is in good agreement with the results of the chemical analyses as described in the Experimental section.

Pink uteroferrin[8] also shows two sets of quadrupole doublets. The reported values are listed in Table 2. The quadrupole splitting of the iron(III) moiety in pink uteroferrin is much larger than those of the present complexes. This fact reflects a remarkable structural difference in iron(III) moieties between the protein and the present complexes. It is well-known that μ-oxo dinuclear iron(III,III) complexes tend to exhibit larger quadrupole splittings.[25,26] However, μ-oxo bridging seems unlikely to occur in pink uteroferrin from its magnetism.[7] Therefore, iron(III) moiety in pink uteroferrin may have a distorted five-coordinated structure which shows a larger quadrupole splitting because of the larger electric field gradient at nucleus.[25,27]

ESR Spectra. ESR spectra of **2b** and **3** at 6 and 12 K are shown in Fig. 6. Both complexes exhibit two signals centered at g=1.7 and 4.3, which are quite similar to those observed in the mixed valence iron proteins such as bovine spleen acid phosphatase.[9] The g=4.3 signal can be assigned to that arising from mononuclear rhombic high-spin iron(III) ion present as impurity which may be produced by a slight decomposition of the complex. The g=1.7 signal is observable only near liquid helium temperature and almost disappears above 12 K as shown in Fig. 6. Such an ESR signal with $g_{av}<2.0$ has been interpreted in terms of antiferromagnetic superexchange interaction between high-spin iron(II) (S=2) and high-spin iron(III) (S=5/2) ions.[10] In contrast to the iron proteins, the present complexes exhibited only a broad isotropic signal even at 6 K, which suggests a rapid electron spin-lattice relaxation.

Magnetic Susceptibilities. The antiferromagnetic interaction was confirmed by the temperature dependence of magnetic susceptibilities. Magnetic susceptibilities of the mixed valence complexes were measured over the temperature range 80—300 K. The results were analyzed by the usual spin-spin interaction model based on the exchange Hamiltonian $H=-2JS_1\cdot S_2$. The molar susceptibility (χ_A) of S_1=2—S_2=5/2 spin exchange coupling dimer is given by Eq. 1,

$$\chi_A=\frac{N\beta^2g^2}{4\kappa T}\times\frac{x^{24}+10x^{21}+35x^{16}+84x^9+165}{x^{24}+2x^{21}+3x^{16}+4x^9+5}+N\alpha \qquad (1)$$

where $x=\exp(-J/\kappa T)$ and the symbols have their usual meanings. The magnetic susceptibilities of the complexes were well interpreted in terms of the above equation. Figure 7 shows temperature dependence of magnetic susceptibilities of **2b**. The solid line is the calculated curve by using the parameters listed in Table 3. The g value used in the fit for magnetic susceptibilities is 2.10, which differs significantly from

Table 3. Magnetic Parameters of the Mixed Valence Complexes

No.	Complex	J/cm^{-1}	g	$N\alpha/10^{-6}$ cgs mol^{-1}

that derived from ESR measurement ($g\approx 1.7$). These two g values are not necessarily the same: the former is the average value derived from the energy separations ($g\beta H$) in the five spin states (S=1/2, 3/2, 5/2, 7/2, 9/2), whereas the latter is that in the S=1/2 ground state. The results indicate that high-spin iron(II) and high-spin iron(III) ions are antiferromagnetically coupled to yield the S=1/2 ground state. The corresponding manganese complexes $[Mn_2(L\text{-}py)(RCOO)_2](ClO_4)_2\cdot nH_2O$ also exhibited weak antiferromagnetic interaction ($J\approx -6$ cm^{-1}).[14] Recently such triply bridging units consisting of two carboxylato groups and oxo, hydroxo, or phenolato group have been found for several iron and manganese complexes.[20-23] The magnitude of spin-exchange interaction in dinuclear iron(III,III) complexes having a triply bridging unit is highly dependent on the nature of the bridging groups. In general, μ-oxo bridged complexes exhibit much stronger antiferromagnetic interaction than μ-hydroxo and μ-phenolato bridged ones.[20,22,28]

The J values of the present complexes are comparable to that for pink uteroferrin ($J\approx -10$ cm^{-1}),[6,7] but much smaller than that for the reduced form of bovine spleen acid phosphatase ($J\approx -50$ cm^{-1}).[9] The oxidized forms of both proteins have been suggested to have a μ-oxo bridge on the basis of their strong antiferromagnetic interactions. The presence of μ-oxo bridge is also suggested in the reduced form of bovine spleen acid phosphatase. A much weaker exchange coupling for pink uteroferrin as compared with that for the reduced form of bovine spleen acid phosphatase may reflect a change in the bridging groups. Lauffer et al.[7] proposed a possibility of hydroxo bridge in pink uteroferrin. It is needed to study extensively the dinuclear iron(II,III) complexes with a μ-oxo or μ-hydroxo bridge for further elucidation of the structure of these proteins.

Electronic Spectra. All the mixed valence complexes exhibit absorption band in the near infrared region (ε=300—100 mol^{-1} dm^3 cm^{-1}/Fe_2) in acetonitrile (Fig. 8 and Table 4). Neither iron(II) nor iron(III) complexes in high-spin state has such intense band in this region,[29] and the band is undoubtedly assigned to

the intervalence charge transfer transition (IT) of the type

$$[Fe^{II}\text{-}Fe^{III}] \xrightarrow{h\nu} [Fe^{III}\text{-}Fe^{II}]^*$$

The complexes also give an band in the visible region (ε=700—1000 mol^{-1} dm^3 cm^{-1}/Fe^{III}). This is the band characteristic of iron(III)-phenolato complexes[30] and is assigned to charge transfer transition from pπ orbital of bridging phenolato group to half filled dπ^* orbital of iron(III) ion. The ligand field bands may be obscured under the above CT band.

According to Hush,[31] the delocalization coefficient, α^2, a measure of mixing of oxidation states, can be calculated by using Eq. 2

$$\alpha^2 = \frac{(4.24\times10^{-4})\cdot\varepsilon_{max}\cdot\Delta\tilde{\nu}_{1/2}}{\tilde{\nu}_{max}\cdot d^2} \quad (2)$$

The α^2 value calculated for **2b** is 6.8×10^{-3} assuming $\tilde{\nu}_{max}$=7300 cm^{-1}, $\Delta\tilde{\nu}_{1/2}$=5000 cm^{-1}, ε_{max}=290 mol^{-1} dm^3 cm^{-1} and d=3.5 Å. The metal-metal distance (d) is estimated from the corresponding manganese(II, III) complex.[14b] The α^2 value implies that delocalization of electron between iron(II) and iron(III) moieties is relatively small and the complex belongs to so-called class II mixed valence system.[32] This is compatible with the results of Mössbauer spectra: all the mixed valence complexes show two sets of quadrupole doublets arising from iron(II) and iron(III) moieties (Fig. 5 and Table 2), indicating that the thermal electron-transfer rate between iron(II) and iron(III) ions are slower than 10^7 s^{-1} (Mössbauer life time).

Loehr et al.[29] reported the electronic spectrum of *semi-met*hemerythrin (*semi-met*)$_R$Hr, where no IT band is detected in the visible and near infrared regions. The absence of IT band in the visible and near infrared regions implies that delocalization of electron in (*semi-met*)$_R$Hr is less than that in the present complexes, and that iron(II) and iron(III) valences in (*semi-met*)$_R$Hr are firmly trapped. It has been suggested that two iron moeities are not equivalent in *deoxy*- and *met*Hr.[33] Such an unsymmetry of two coordination moieties may be responsible for this trapped valence state.

Cyclic Voltammograms. Cyclic voltammograms of the mixed valence complexes **2b** and **3** in acetonitrile at 20 °C are illustrated in Fig. 9 (Table 5). The complex **1b** exhibits two redox couples at 0.68 and −0.03 V (vs. SCE). The constant potential coulometry revealed that these two redox couples correspond to one-electron redox reactions attributable to Fe^{III}-Fe^{III}/Fe^{II}-Fe^{III} (+0.68 V) and Fe^{II}-Fe^{III}/Fe^{II}-Fe^{II} (−0.03 V). Peak-to-peak separations of these two waves are 70 mV at a scan rate of 100 mV s^{-1} and the ratios of the oxidation currents (i_{pa}) for the forward scan to the reduction currents (i_{pc}) for the reverse scan are close to unity for the both couples. These two couples are fairly reversible since ferrocene present in this system as an internal standard showed a peak-to-peak separation of 70 mV. A similar cyclic voltammogram was observed for **1b**. The complex **3** also exhibits two redox couples at ca. +0.7 and −0.1 V (vs. SCE). However, these two couples are not reversible (Fig. 9). This irreversibility suggests a significant structural change upon electron transfer.

Stability of Mixed Valence Complexes. From the separation of the redox potentials of E_1([II, III]/[II, II])

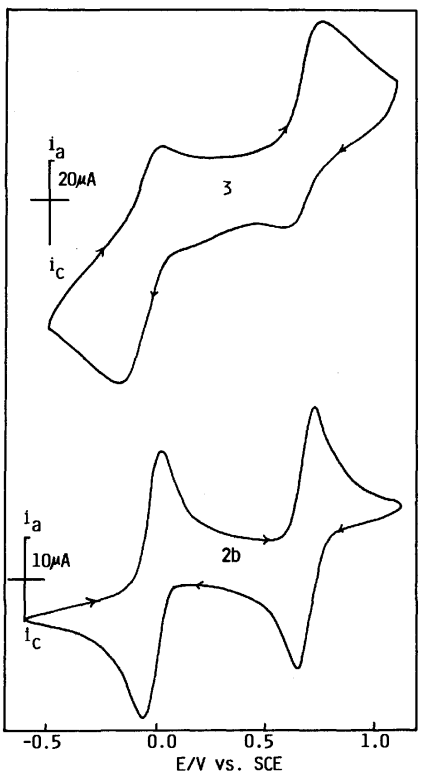

Fig. 9. Cyclic voltammograms of [Fe_2(L-py)-($CH_3COO)_2$]($BF_4)_2\cdot H_2O$ (**1b**) and [Fe_2(L-py)-(CH_3COO)(OH)]($BF_4)_2\cdot 2H_2O$ (**3**) in acetonitrile. The scan rate is 100 mV s^{-1}.

Table 5. Cyclic Voltammetric Data of the Mixed Valence Complexes

No.	Complex	$E_{1/2}$[a] E/V (vs. SCE)	$E_{1/2}$[b] E/V (vs. SCE)	(i_{pa}/i_{pc})[a]	(i_{pa}/i_{pc})[b]	K_c[c]
1b	[Fe_2(L-py)($CH_3COO)_2$]($BF_4)_2\cdot H_2O$	−0.03	+0.68	1.0	1.0	1.6×10^{12}
2b	[Fe_2(L-py)($C_6H_5COO)_2$]($BF_4)_2\cdot 2H_2O$	+0.05	+0.73	1.0	1.0	5.0×10^{11}
3	[Fe_2(L-py)(CH_3COO)(OH)]($BF_4)_2\cdot 2H_2O$	−0.08[d]	+0.67[d]			

a) For Fe(II, III)/Fe(II, II) redox couple. b) For Fe(III, III)/Fe(II, III) redox couple. c) Comproportionation constant at 20 °C. d) Irreversible.

and E_2([III, III])/[II, III]), comproportionation constants (K at 20 °C) of the following reaction are calculated by Eq. 3.

$$(Fe^{III}\text{-}Fe^{III})+(Fe^{II}\text{-}Fe^{II}) \rightleftharpoons 2(Fe^{III}\text{-}Fe^{II})$$
$$E_2-E_1=RT/F\cdot\ln K \quad (3)$$

The values obtained for **1b** and **2b** are 1.6×10^{12} and 5.0×10^{11} (ΔG=−68 and −66 kJ mol^{-1}) respectively, indicating that the present mixed valence complexes are highly stabilized. Others have suggested that factors such as electron delocalization, electrostatic interaction, and steric interaction can contribute to the magnitude of K.[34] The electron delocalization energy (E_e) can be estimated by an analysis of the IT band. The value was calculated to be 600 J mol^{-1} for **2b** by using Eq. 4.

$$E_e=\alpha^2\cdot\tilde{\nu}_{IT}.^{34a)} \quad (4)$$

Thus the electron delocalization energy for the present system is too small to contribute significantly to its stability. When the metal ions are in close proximity, electrostatic interaction may play an important role. A dinuclear metal(II, II) complex will be more readily oxidized than a metal(II, III) species from electrostatic point of view. This will lead to a greater separation of redox potentials and increase of stability of the mixed valence state. In addition, a steric requirement arising from binucleating ligand L-py and two bridging carboxylato groups seems to be important.

Very recently we found that the reaction of an equimolar mixture of iron(III) and manganese(II) ions with L-py and carboxylate ions yields a dinuclear heterometal manganese(II)-iron(III) complex [MnFe(L-py)(RCOO)$_2$]$^{2+}$ in more than 70% yieid.[35] The reaction of iron(III) ion with a dinuclear manganese(II, II) complex [Mn$_2$(L-py)(RCOO)$_2$]$^+$ also resulted in the formation of the above dinuclear heterometal complex with a slight contamination of dinuclear homometal complexes.[35] Thus the present ligand system affords a favorable coordination sites for dinuclear metal(II, III) complexes.

Inhibition of Dimerization of Copper(II) Carboxylates by Cyclohexane Ring in Extraction of Copper(II) with Cyclohexanecarboxylic Acid

Hiromichi YAMADA,* Miyuki ITŌ, and Masateru MIZUTA
Faculty of Engineering, Gifu University, 1-1 Yanagido, Gifu 501-11
(Received April 9, 1987)

The extraction of copper(II) with cyclohexanecarboxylic acid in benzene was carried out at 25 °C and at the aqueous ionic strength of 0.1 mol dm^{-3} ($NaClO_4$). The partition constant, $K_{D,HA}$ of cyclohexanecarboxylic acid between benzene and water, and the dimerization constant, $K_{2,HA}$ of cyclohexanecarboxylic acid in benzene were determined: $\log K_{D,HA}=0.90$ and $\log K_{2,HA}=1.54$, respectively. The monomeric and dimeric copper(II) cyclohexanecarboxylates were responsible for the extraction:

$$Cu^{2+}+(HA)_{2,o} \rightleftharpoons (CuA_2)_o+2H^+$$
$$Cu^{2+}+2(HA)_{2,o} \rightleftharpoons (CuA_2(HA)_2)_o+2H^+$$
$$2Cu^{2+}+2(HA)_{2,o} \rightleftharpoons (Cu_2A_4)_o+4H^+$$
$$2Cu^{2+}+3(HA)_{2,o} \rightleftharpoons (Cu_2A_4(HA)_2)_o+4H^+$$

with the extraction constants, $\log K_{ex(10)}=-8.34$, $\log K_{ex(12)}=-7.33$, $\log K_{ex(20)}=-12.47$, and $\log K_{ex(22)}=-11.73$, respectively. By comparing the overall formation constant of the dimeric copper(II) cyclohexanecarboxylate, $Cu_2A_4(HA)_2$ in the aqueous phase with that of copper(II) decanoate and lipoate, the cyclohexane ring was found to inhibit the formation of the dimeric copper(II) carboxylate.

The stability of the dimeric copper(II) carboxylate is so high that no appreciable amount of monomer can be detected in most nonsolvating solvents.[1,2] In the extraction of copper(II) with some sterically crowded carboxylic acids such as trimethylacetic acid,[3] cyclohexanecarboxylic acid,[4] and cyclopentylacetic acid,[5] it was suggested that the monomeric copper(II) species is extracted together with the dimer. But, in the first reference[3] presented by Haffenden and Lawson, they didn't mention the composition of the monomeric copper(II) trimethylacetate. And although the other references[4,5] reported by Brzozka and Rozycki will be later described in detail, there are some doubts about their results. In the previous reports, it has been shown that the monomeric and dimeric copper(II) decanoates are in equilibrium in alcohols[6,7] and ketones,[8] and it has been interpreted according to the regular solution theory that the extraction of the monomeric copper(II) decanoates as well as the dimeric ones can be attributed to the stabilization of the monomeric copper(II) species by the extensive solvation of alcohols or ketones molecules.

The present paper deals with the extraction of copper(II) with cyclohexanecarboxylic acid in benzene, and it was found that the cyclohexane ring at 2-position in cyclohexanecarboxylic acid inhibited the formation of the dimeric copper(II) carboxylate.

Experimental

Reagents. Cyclohexanecarboxylic Acid: Commercial cyclohexanecarboxylic acid (purity: over 97%, Aldrich Chemical Company, Inc.) was dissolved in benzene just before its use. Copper(II) perchlorate,[6] sodium perchlorate,[6] and benzene[9] were the same as employed as previously. All other reagents were reagent grade and used without further purification.

Procedure. Partition was carried out in the same manner as was stated in the previous paper.[10] In the partition of cyclohexanecarboxylic acid between benzene and water, the concentration of the acid in the aqueous phase was determined by potentiometric titration.

Apparatus. Taiyo Incubator M-100^N(Taiyokagaku-Kogyo Co., Tokyo) was used for mechanical shaking in a thermostat. The pH measurements and potentiometric titrations were performed with a Horiba pH Analyzer F-80 (Horiba Seisakusho Ltd., Kyoto). A swing type centrifuge model CD-50SR (Tomy Seiko Co. Ltd., Tokyo) was used for centrifugation.

Results and Discussion

Partition of Cyclohexanecarboxylic Acid. The following equilibria on cyclohexanecarboxylic acid (HA) should be considered: (a) The dissociation of HA in the aqueous phase ($K_a=[H^+][A^-]/[HA]$), (b) the partition of HA into benzene ($K_{D,HA}=[HA]_o/[HA]$), and (c) the dimerization of HA in the organic phase ($K_{2,HA}=[(HA)_2]_o/[HA]_o^2$), where the subscript o refers to the organic phase and $[(HA)_2]_o$ denotes the concentration of the dimeric acid in the organic phase. Then, the distribution ratio of the acid between benzene and water can be written as:

$$D=C_{HA,o}/C_{HA,w}$$
$$=K_{D,HA}(1+2K_{2,HA}K_{D,HA}[HA])/(1+K_a[H^+]^{-1}). \quad (1)$$

In the lower pH region where the dissociation of the acid in the aqueous phase can be neglected, that is, $1 \gg K_a[H^+]^{-1}$, the following equation can be obtained:

$$\log D=\log K_{D,HA}+\log(1+2K_{2,HA}K_{D,HA}[HA]). \quad (2)$$

According to Eq. 2, by comparing the plots of log D against log [HA] with the normalized curve, log $(1+X)$ vs. log X, the dimerization constant in the organic phase and the partition constant can be determined. Benzene solutions of cyclohexanecarboxylic acid ranging from 0.024 to 0.96 mol dm^{-3} were equilibrated with 0.01 mol dm^{-3} perchloric acid solution (ionic strength: 0.1 mol dm^{-3} H, $NaClO_4$). From the plots shown in Fig. 1, the following constants of cyclohexanecarboxylic acid were determined by the curve-fitting method: log $K_{D,HA}$=0.90 and log $K_{2,HA}$=1.54, respectively.

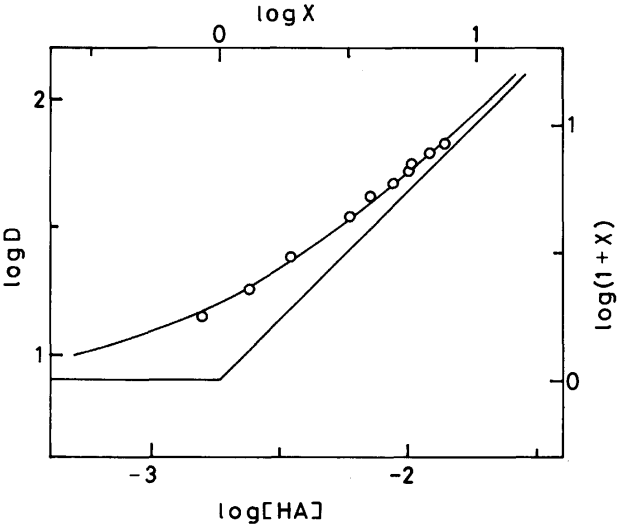

Fig. 1. Determination of the dimerization constant in benzene and the partition constant between benzene and water of cyclohexanecarboxylic acid. Solid curve is the normalized curve, log $(1+X)$ vs. log X. Solid lines are the asymptotes of the normalized curve.

Under the present experimental conditions, the dissociation of cyclohexanecarboxylic acid in the aqueous phase can being neglected, the concentration of the dimeric acid in the organic phase can be written as follows:

$$[(HA)_2]_o = 0.5\,(C_{HA} - [HA]_o - [HA]) \qquad (3)$$

where C_{HA} denotes the total concentration of the acid. Then, the concentration of the dimeric cyclohexanecarboxylic acid in the organic phase was calculated by substituting the dimerization and partition constants of the acid in Eq. 3.

Extraction of Copper(II) with Cyclohexanecarboxylic Acid. If a j-merized copper(II) carboxylate, $Cu_jA_{2j}(HA)_a$ is extracted, the following equilibrium is relevant to the extraction:

$$j\mathrm{Cu}^{2+} + 0.5\,(2j+a)\,(HA)_{2,o} \rightleftharpoons (Cu_jA_{2j}(HA)_a)_o + 2\mathrm{jH}^+$$

with

$$K_{ex(ja)} = [Cu_jA_{2j}(HA)_a]_o[H^+]^{2j}[Cu^{2+}]^{-j}[(HA)_2]_o^{-0.5(2j+a)}. \qquad (4)$$

The following relation can hold for the total concentration of copper in the organic phase, $C_{Cu,o}$:

$$\log C_{Cu,o} = \log \sum_j \sum_a \{jK_{ex(ja)}([Cu^{2+}][H^+]^{-2})^j[(HA)_2]_o^{0.5(2j+a)}\}. \qquad (5)$$

According to Eq. 5, the degree of polymerization of the extracted species can be found from the slope of the plot of log $C_{Cu,o}$ against $(\log[Cu^{2+}] - 2\log[H^+])$ at constant $[(HA)_2]_o$. If two or more species with different degree of polymerization are responsible for the extraction, the plot should give rise to a curve. The results are shown in Fig. 2. The slope lies between unity and two, and tends to approach to two with increasing copper concentration in the organic phase. Therefore, it is expected that the monomeric and dimeric copper(II) carboxylates are responsible for the extraction. Then, the total concentration of copper(II) in the organic phase is expressed as follows:

$$C_{Cu,o} = [CuA_2(HA)_a]_o + 2[Cu_2A_4(HA)_b]_o. \qquad (6)$$

By substituting the extraction constants $K_{ex(1a)}$ and $K_{ex(2b)}$ in Eq. 6, the following expression can be derived:

$$\log C_{Cu,o} - \log[Cu^{2+}] + 2\log[H^+] = 0.5\,(2+a)\log[(HA)_2]_o + \log K_{ex(1a)} + \log\left(1 + \frac{2K_{ex(2b)}}{K_{ex(1a)}}[(HA)_2]_o^{0.5(2+b-a)}[Cu^{2+}][H^+]^{-2}\right). \qquad (7)$$

According to Eq. 7, by comparing the plots of the left-hand side of Eq. 7 against $(\log[Cu^{2+}] - 2\log[H^+])$ at constant $[(HA)_2]_o$ with the normalized curve, log $(1+X)$ vs. log X, the degree of polymerization of cop-

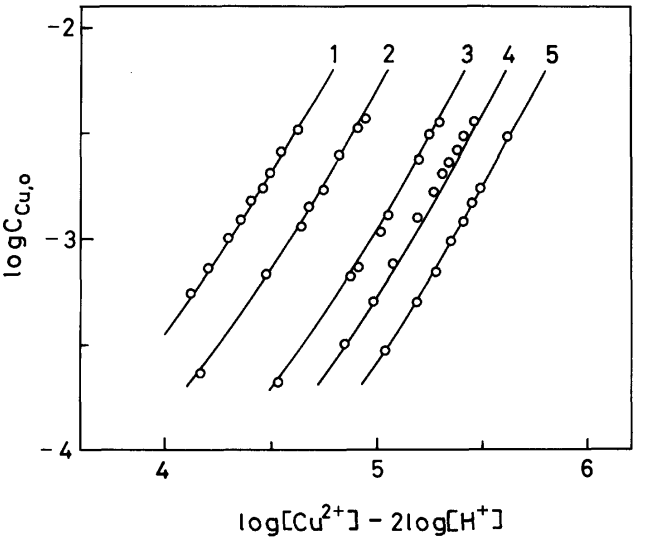

Fig. 2. Determination of the degree of polymerization of copper(II) carboxylate. C_{HA}; 1: 1.47, 2: 0.98, 3: 0.55, 4: 0.40, 5: 0.29 mol dm^{-3}. Solid lines are calculated curves based on the results obtained in this work.

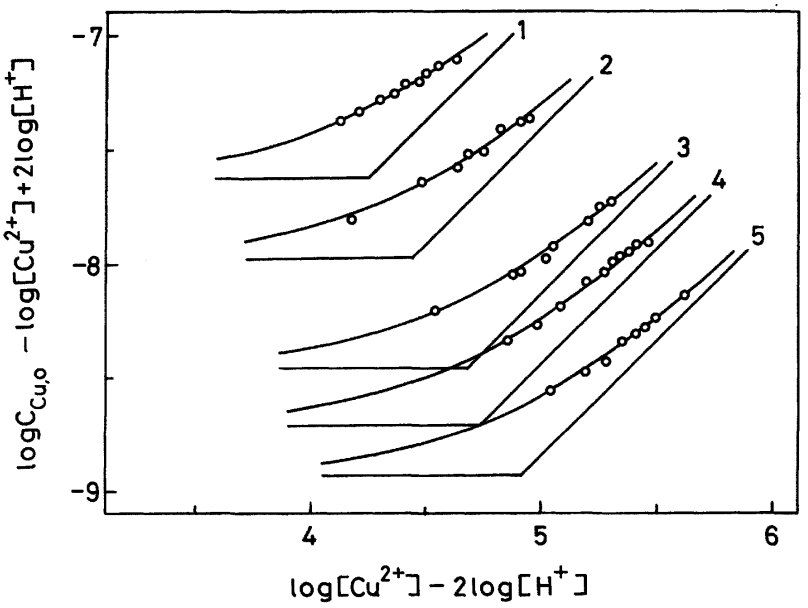

Fig. 3. Identification of the degree of polymerization of copper(II) carboxylate. Solid curves are the normalized curves, $\log(1+X)$ vs. $\log X$. Solid lines are the asymptotes of the normalized curves. Numbers are the same as in Fig. 2.

per(II) species can be identified. As shown in Fig. 3, the plots fit well the normalized curve. Therefore, it was proved that both the dimeric and monomeric copper(II) carboxylates are responsible for the extraction.

In the region, where the plots in Fig. 3 fall along the horizontal asymptotes, the predominant extracted species is the monomer. Then the total concentration of copper(II) in the organic phase can be written as:

$$\log C_{Cu,o} = \log \sum_a (K_{ex(1a)}[Cu^{2+}][H^+]^{-2}[(HA)_2]_o^{0.5(2+a)}). \quad (8)$$

According to Eq. 8, the number of cyclohexanecarboxylic acid molecules involved in the monomeric copper(II) species can be obtained from the slope of the plot of $(\log C_{Cu,o} - \log[Cu^{2+}] + 2\log[H^+])$ against $\log[(HA)_2]_o$. As shown in Fig. 4, the plot deviates upward from the straight line with a slope of two with decreasing $[(HA)_2]_o$. This fact suggests that the two monomeric species are responsible for the extraction in the lower concentration of copper in the organic phase: One of them is $CuA_2(HA)_2$ and the other $CuA_2(HA)_a$ ($a<2$). Under these conditions the total copper concentration in the organic phase can be written as follows:

$$\log C_{Cu,o} - \log[Cu^{2+}] + 2\log[H^+] - 2\log[(HA)_2]_o$$
$$= \log\left(1 + \frac{K_{ex(1a)}}{K_{ex(12)}}[(HA)_2]_o^{-0.5(2-a)}\right) + \log K_{ex(12)}. \quad (9)$$

Comparing the plot of the left-hand side of Eq. 9 against $-\log[(HA)_2]_o$ with the normalized curves, $\log(1+X^n)$ vs. $\log X$, another monomeric species can be determined. As evident from Fig. 5, the plot fits well the normalized curve with $n=1$, $\log(1+X)$ vs. $\log X$, that is, $0.5(2-a)=1$ or $a=0$. Then the monomeric species are CuA_2 and $CuA_2(HA)_2$. By the curve-fitting method from Fig. 5, the respective extraction constants $K_{ex(10)}$ and $K_{ex(12)}$ can be determined: $\log K_{ex(10)} = -8.34 \pm 0.03$, $\log K_{ex(12)} = -7.33 \pm 0.03$, respectively.

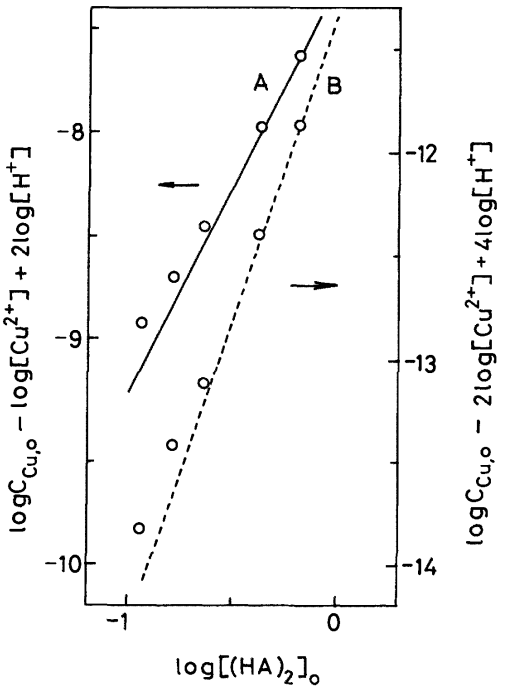

Fig. 4. Determination of the number of carboxylic acid molecules involved in the monomeric and dimeric copper(II) species. A: Monomeric copper(II) carboxylate. B: Dimeric copper(II) carboxylate. Solid and dotted lines are the straight lines with a slope of 2.0 and 3.0, respectively.

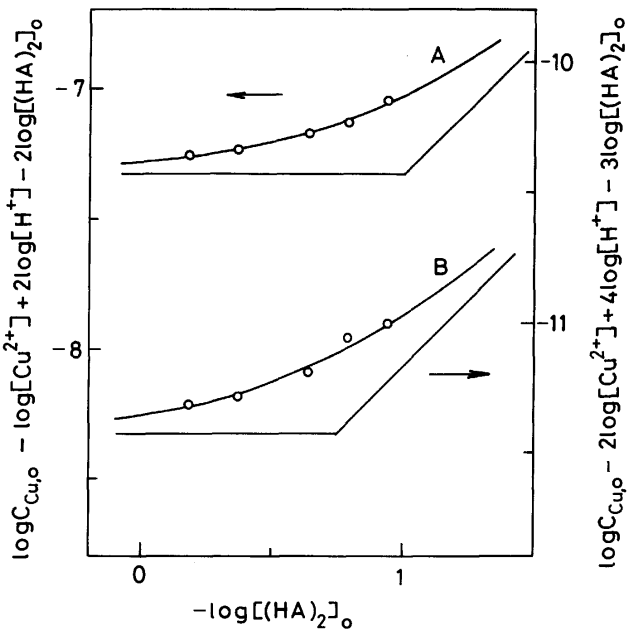

Fig. 5. Determination of the number of carboxylic acid molecules involved in the copper(II) species by curve-fitting method. A and B are the same as in Fig. 4. Solid curves are the normalized curves, $\log(1+X)$ vs. $\log X$. Both solid lines are the asymptotes of the normalized curves.

On the other hand, in the region, where the dimeric copper(II) species is predominant, that is, the plots shown in Fig. 3 fall along the straight line asymptotes with a slope of unity, the total concentration of copper(II) in the organic phase can be represented as:

$$\log C_{Cu,o} = \log(2[Cu^{2+}]^2[H^+]^{-4}) + \log\left(\sum_b (K_{ex(2b)}[(HA)_2]_o^{0.5(4+b)})\right). \quad (10)$$

According to Eq. 10, the number of cyclohexanecarboxylic acid molecules involved in the dimer can be obtained from the slope of ($\log C_{Cu,o} - 2\log[Cu^{2+}] + 4\log[H^+]$) against $\log[(HA)_2]_o$. As shown in Fig. 4, the plot gets to approach the straight line with a slope of 3.0 with increasing the concentration of dimeric cyclohexanecarboxylic acid in the organic phase. As judged from this tendency, the two dimeric species, $Cu_2A_4(HA)_2$ and $Cu_2A_4(HA)_b$ ($b<2$) exist in the higher concentration of copper in the organic phase. Therefore, the following relation can be expected to hold for the total concentration of copper in the organic phase:

$$\log C_{Cu,o} - 2\log[Cu^{2+}] + 4\log[H^+] - 3\log[(HA)_2]_o = \log\left(1 + \frac{K_{ex(2b)}}{K_{ex(22)}}[(HA)_2]_o^{-0.5(2-b)}\right) + \log 2 + \log K_{ex(22)}. \quad (11)$$

In the similar manner as the monomeric species, another dimeric species can be determined. As shown in Fig. 5, the plot of the left-hand side of Eq. 11 against $-\log[(HA)_2]_o$ fits with the normalized curve, $\log(1+X)$ vs. $\log X$, that is, $0.5(2-b)=1$ or $b=0$. Then, Cu_2A_4 is also involved in the extraction together with $Cu_2A_4(HA)_2$ under the present conditions. In addition we can determine the extraction constants $K_{ex(20)}$ and $K_{ex(22)}$ in the similar manner as the monomer: $\log K_{ex(20)} = -12.47 \pm 0.03$ and $\log K_{ex(22)} = -11.73 \pm 0.03$, respectively.

Consequently, in the present extraction system, the corresponding extraction equilibria are described as follows:

$$Cu^{2+} + (HA)_{2,o} \overset{K_{ex(10)}}{\rightleftharpoons} (CuA_2)_o + 2H^+$$

$$Cu^{2+} + 2(HA)_{2,o} \overset{K_{ex(12)}}{\rightleftharpoons} (CuA_2(HA)_2)_o + 2H^+$$

$$2Cu^{2+} + 2(HA)_{2,o} \overset{K_{ex(20)}}{\rightleftharpoons} (Cu_2A_4)_o + 4H^+$$

$$2Cu^{2+} + 3(HA)_{2,o} \overset{K_{ex(22)}}{\rightleftharpoons} (Cu_2A_4(HA)_2)_o + 4H^+.$$

Brzozka and Rozycki found the monomer $CuA_2(HA)_4$ and dimer $Cu_2A_4(HA)_4$ in the extraction of copper(II) with cyclohexanecarboxylic acid in benzene.[4] Judging from the coordination number of copper(II), both extracted species seem unlikely. Because they estimated the composition of the extracted species under the region where both copper(II) species with different degree of polymerization coexist, erroneous results seem to be drawn. In addition, Rozycki reported that only the monomeric species $CuA_2(HA)_2$ was responsible for the extraction of copper(II) with cyclopentylacetic acid in benzene.[5] According to his data, the slope of the plot of $\log C_{Cu,o}$ against ($\log C_{Cu,w} + 2pH$) at constant $[(HA)_2]_o$ (Fig. 1 in Ref. 5) is greater than unity. This suggests that the dimeric copper(II) species is expected to be involved in the extraction. Owing to take no account of a dimeric copper(II) species for analysis of extraction equilibrium, they failed to notice not only dimeric species but also another monomeric species CuA_2.

Recently, the dimeric copper(II) carboxylate $Cu_2A_4(HA)_2$ has been reported to be extracted with 2-bromopentanoic acid in benzene.[11] On the other hand, Bold and Balusescu proposed the monomeric copper(II) carboxylate, $CuA_2(HA)_2$ in the extraction of copper(II) with 2-bromooctadecanoic acid in benzene.[12] Their results appear doubtful. Because recalculation[11] of their data led us to the dimeric species, $Cu_2A_4(HA)_2$. Therefore, it seems likely that bromine at 2-position in the respective carboxylic acid does not inhibit the formation of a dimeric copper(II) carboxylate.

In contrast with these instances, the extraction of monomeric copper(II) species in the present extraction system indicate that the dimerization of copper(II) carboxylate is hindered by the cyclohexane moiety at 2-position in cyclohexanecarboxylic acid.

Effect of Cyclohexane Ring on Dimerization of Carboxylic Acid and Copper(II) Carboxylate in Benzene. The dissociation constant of cyclohexanecar-

Table 1. Comparison of Cyclohexanecarboxylic with Other Carboxylic Acids

	(12.72)	(16.04)	(16.28)	(16.39)

a) Ref. 13. b) Ref. 14. c) Ref. 17. d) Ref. 18. e) Ref. 15. f) Ref. 9. g) Ref. 16. h) Ref. 1. i) Ref. 2. j) Calculated by Eq. 10 in Ref. 9. The values in the parentheses are evaluated by taking into account the electro-striction of ligands in the complex (Eq. 11 in Ref. 9).

boxylic acid in the aqueous solution is reported to be pK_a=4.89[13] at 25 °C. This value is agreement with that of heptanoic acid[14] with the same carbon number as cyclohexanecarboxylic acid. This implies that the cyclohexane ring has no inductive effect on the carboxylate group. The partition constant of heptanoic acid between benzene and water, and its dimerization constant in benzene can be established from the constants of its homologs as follows: $\log K_{D,HA}$=0.78[15] and $\log K_{2,HA}$=2.61,[16] respectively. Judging from no inductive effect of the cyclohexane moiety, the similar constants for cyclohexanecarboxylic acid as those of heptanoic acid can be expected to be obtained. As expected, the value of the partition constant of cyclohexanecarboxylic acid was found to be close to that of heptanoic acid (see: Table 1). On the other hand, it was proved that the value of its dimerization constant in benzene is smaller by about one order of magnitude than that of heptanoic acid. This fact suggests that the cyclohexane ring would interfere in the dimerization of cyclohexanecarboxylic acid in benzene.

As stated previously,[9] the extraction constant of dimeric copper(II) species, $Cu_2A_4(HA)_2$ can be written as follows:

$$K_{ex(22)}=K_{D,Cu_2A_4(HA)_2}K_{D,HA}^{-6}K_{2,HA}^{-3}\beta_{Cu_2A_4(HA)_2}K_a^4 \quad (12)$$

where $K_{D,Cu_2A_4(HA)_2}$ and $\beta_{Cu_2A_4(HA)_2}$ denote the partition constant of $Cu_2A_4(HA)_2$ between benzene and water, and the overall formation constant of this complex in the aqueous phase, respectively. Then, the overall formation constant can be approximated by Eq. 12. The value is summarized in Table 1 together with other constants. As shown in Table 1, each of these acids has a similar dissociation constant. On the other hand, the overall formation constant of a dimeric copper(II) species, $Cu_2A_4(HA)_2$ for cyclohexanecarboxylic acid are decreased about three orders of magnitude under that for other three acids. It has been shown that the formation of copper(II) cyclohexanecarboxylate is inhibited by cyclohexane ring in the same manner as the dimerization of cyclohexanecarboxylic acid.

It is well-known that the copper(II) carboxylates have dimeric structure not only in the crystalline state but also in various organic solvents. Then, in the extraction of copper(II) carboxylates, only the dimeric copper(II) carboxylate, $Cu_2A_4(HA)_2$ has been widely proved to be responsible for the extraction by numerous investigators.[19] A few studies on the extraction of the monomeric copper(II) carboxylate have been merely published in the extraction systems presented below. In the extraction of copper(II) with decanoic acid in some alcohols[6,7] and ketones,[8] monomeric and dimeric copper(II) species are in equilibrium in these solvents, because of the extensive solvation by these solvents. In addition, the dimerization of copper(II) benzoate does not occur to any appreciable extent in the extraction of copper(II) with benzoic acid.[10] It is reasonable to imagine that the conjugated system in benzoic acid inhibits the dimerization of copper(II) benzoate.

On the other hand, the extraction of the monomeric copper(II) cyclohexanecarboxylates in the present extraction system can be due to the steric hindrance of the cyclohexane moiety on the dimerization of copper(II) carboxylate. The present result is contrast to the facts that "bromine" at 2-position in pentanoic[11] and octadecanoic[12] acids does not inhibit the dimerization of the respective copper(II) carboxylates.

The polymeric metal carboxylates are often involved in the extraction of metal carboxylates.[19] And the polymerization of metal carboxylate can be regarded as a kind of synergistic effect, and would contribute to a good extractability. According to the result obtained from this work, it can be anticipated that the introduction of the more bulky moiety at 2-position in carboxylic acid will also interfere with the polymerization of other metal carboxylates, and will lead to a lowering of the extractability, particularly in the extraction of metal carboxylates into nonsolvating solvents, for which the formation of polymerized species is essential. Therefore, it can be expected that the more crowded substituent at 2-position in carboxylic acid will result in a more favorable selectivity for the extraction of metal carboxylate.

†Department of Industrial Chemistry, Tottori University, Koyama-cho, Tottori 680
(Received April 23, 1987)

Neutral and cationic 1-3-η-(2-methylallyl) complexes of Pd and Pt containing tris(2,6-dimethoxyphenyl)-phosphine (abbreviated as $P(2,6)_3$), $M(1\text{-}3\text{-}\eta\text{-}CH_2CMeCH_2)Cl\{P(2,6)_3\}$ and $[M(1\text{-}3\text{-}\eta\text{-}CH_2CMeCH_2)\{P(2,6)_3\}]BF_4$, were prepared. The latter contained a weakly coordinated OMe group of $P(2,6)_3$ which was readily replaced by carbon monoxide to afford $[M(1\text{-}3\text{-}\eta\text{-}CH_2CMeCH_2)(CO)\{P(2,6)_3\}]BF_4$. Owing to large steric bulk and high nucleophilicity of $P(2,6)_3$, addition of $P(2,6)_3$ to these complexes did not result in coordination of the second molecule of the phosphine to the metal atom but ready attack at the metal-bound 2-methylallyl and methoxyl carbon atoms to give the corresponding (2-methylallyl)phosphonium and methylphosphonium ions. From these reactions were isolated a neutral 1-3-η-(2-methylallyl)platinum(II) complex involving chelate coordination of a tertiary phosphine ligand which was derived from the loss of methyl of one methoxyl group in $P(2,6)_3$ and the resulting phenoxo ligand, and a cationic, binuclear Pt(I) carbonyl complex bridged by the 2-methylallyl group. Also prepared in this study were 1-3-η-(2-methylallyl)(acetylacetonato) complexes of Pd and Pt, $M(1\text{-}3\text{-}\eta\text{-}CH_2CMeCH_2)(acac)\{P(2,6)_3\}$. In the platinum analog, the acetylacetonato ligand was suggested to coordinate to the metal in a monodentate fashion via the central carbon atom. Both complexes afforded moderate yields of $CH_2{=}CMeCH_2CH(COMe)_2$ upon treatment with carbon monoxide, while the reaction of $M(1\text{-}3\text{-}\eta\text{-}CH_2CMeCH_2)(CO)\{P(2,6)_3\}^+$ with sodium acetylacetonate failed to give the same coupling product.

A new tertiary phosphine, tris(2,6-dimethoxyphenyl)-phosphine (abbreviated as $P(2,6)_3$) was shown to exhibit unusually high basicity and great nucleophilicity toward some organic electrophiles (e.g. alkyl halides, oxiranes).[1] This electronic property, together with its considerable steric bulk (cone angle= 184°),[1b] prompted us to examine coordination chemistry and catalytic activity of metal complexes containing $P(2,6)_3$ as a ligand. A brief synthesis of two-coordinated complexes, $[M\{P(2,6)_3\}_2]^+$ (M=Cu, Ag) has been reported before.[1b] We describe here synthesis and properties of 1-3-η-(2-methylallyl)palladium(II) and platinum(II) complexes containing $P(2,6)_3$.

Results and Discussion

Coordination and Nucleophilic Attack of $P(2,6)_3$. Dimeric complexes, 1-3-η-(2-methylallyl)(chloro)palladium and platinum reacted with 1 molar quantity of $P(2,6)_3$ to give **1** (see Scheme 1). Treatment of **1** with $AgBF_4$ in acetone gave acetone-free cationic complexes **2**. The very large spin coupling constant between ^{195}Pt and the anti allyl proton cis to the phosphine (H^1) in the ^1H NMR spectrum of **2b** (Table 1) is consistent with coordination of the 2-OMe group having a weak trans influence to Pt.

It seems of particular note that the second molecule of $P(2,6)_3$ did not show any tendency to coordinate to the metal atom of **1**. Thus, when free $P(2,6)_3$ was added to a $CDCl_3$ solution of **1** at room temperature, we could observe no change in ^1H NMR spectra of **1** except for occurrence of a slow attack of $P(2,6)_3$ not on the metal atom but on the different sites, as described below. In the corresponding reaction of $M(1\text{-}3\text{-}\eta\text{-allyl})Cl(PPh_3)$ with PPh_3, there occurred quite ready formation of *trans*-$M(\sigma\text{-allyl})Cl(PPh_3)_2$ or $[M(1\text{-}3\text{-}\eta\text{-allyl})(PPh_3)_2]Cl$.[2] The mixture of **1a** and $P(2,6)_3$ in $CDCl_3$ caused formation of $[P(CH_3)(2,6)_3]Cl$ and $[P(CH_2CMe{=}CH_2)(2,6)_3]Cl$ (each ca. 10%) when kept to stand at room temperature for 12 h. **1b** and $P(2,6)_3$ afforded $[P(CH_3)(2,6)_3]Cl$ still more slowly.

The reaction of $P(2,6)_3$ with **2b** occurred much faster to give $[P(CH_3)(2,6)_3]BF_4$ and a neutral complex **3**. The corresponding reaction of **2a** resulted in rapid, high-yield formation of a mixture of $[P(CH_3)(2,6)_3]BF_4$ and $[P(CH_2CMe{=}CH_2)(2,6)_3]BF_4$ (ca. 1 : 1), but isolation of any palladium-containing product was not successful. Again there was no tendency of the coordination of two molecules of $P(2,6)_3$ to the metal atom in the cationic complexes.

The ready phosphonium ion formation in the reaction of $P(2,6)_3$ with **1** and **2** may have been induced by both steric and electronic causes. The large size of $P(2,6)_3$ would make coordination of two molecules of this ligand highly unfavorable. In addition, its high nucleophilicity facilitates attack at the carbon atom of the OMe and 2-methylallyl groups bound to the metal, with particular ease in the case of the cationic complexes. The methyl abstraction by $P(2,6)_3$ from the OMe group of the coordinated $P(2,6)_3$ ligand in **1** would have occurred via transient coordination of the OMe group to the metal. A quite similar result has been observed in the reaction of MCl_2L_2 (L=PhCN, 1/2COD; M=Pd, Pt) with $P(2,6)_3$ in unsuccessful attempts to prepare $MCl_2\{P(2,6)_3\}_2$.[3]

2 reacted with carbon monoxide to form **4**. **4a** is fairly stable in the solid state for a cationic carbonyl complex of Pd,[4] but reverts to **2a** in $CDCl_3$ in the absence of carbon monoxide. The lower ν(CO) value (2075 cm^{-1}) of **4b** than that[5] (2120 cm^{-1}) of $[Pt(1\text{-}3\text{-}\eta\text{-}$

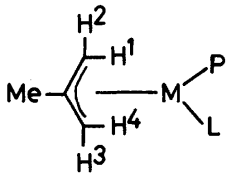
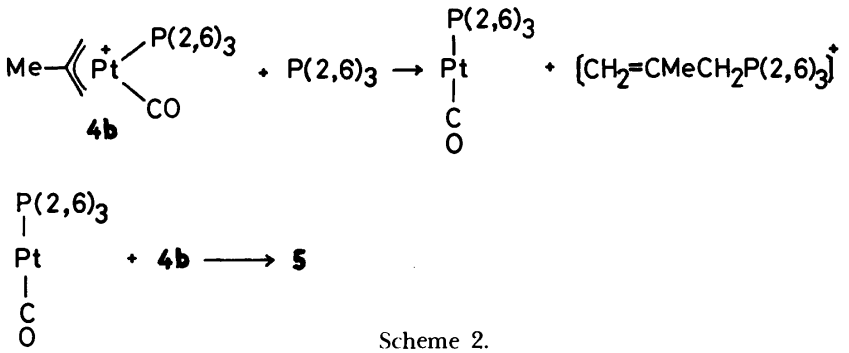
a) In $CDCl_3$ at room temperature except as noted. Chemical shifts in ppm, J in Hz. Abbreviations: s=singlet, d=doublet, t=triplet, dd=doublets of doublet, b=broad, m=multiplet. For proton numbering scheme, see below.

b) At −10 °C. c) Obscured by the OMe peak. d) CH_3CO: 1.73^s (J_{Pt}=10) and 1.95^s (J_{Pt}=7). -CH(: 4.43^d (J_P=9, J_{Pt}=115).





Scheme 2.

$CH_2CMeCH_2)(CO)(PPh_3)]^+$ reflects the more basic nature of $P(2,6)_3$ than PPh_3.

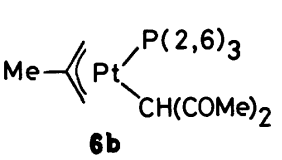
4a rapidly reacted with $P(2,6)_3$ in $CDCl_3$ containing free carbon monoxide to give almost quantitative yield of $[P(CH_2CMe{=}CH_2)(2,6)_3]BF_4$ and palladium metal. In converting **4a** to this phosphonium ion, there was no need to use equimolar amount of $P(2,6)_3$; addition of 10 mol% of $P(2,6)_3$ to **4a** caused formation of the phosphonium ion in ca. 80% yield.

4b also reacted with $P(2,6)_3$ very rapidly in 2 : 1 mole ratio to give a binuclear complex **5** and $[P(CH_2CMe{=}CH_2)(2,6)_3]BF_4$. The structure of **5** was deduced by the following spectral data. The IR spectrum showed ν(CO) bands at 2010 and 2040 cm^{-1} which are in the region expected for the Pt(I)-coordinated carbonyl ligand.[6] In the ^1H NMR spectrum, the 2-methyl proton resonance appeared as a triplet due to coupling with two equivalent ^{31}P nuclei (J_P=2.5 Hz). Furthermore, the resonances of the protons at 3- and 5-positions of $P(2,6)_3$ and the allylic syn protons appeared as double triplets ($1/2[J_P+J_P']$=2 Hz, J_H=8.5 Hz) and a triplet ($1/2[J_P+J_P']$=12 Hz), respectively, owing to virtual coupling arising from strong P-P' coupling, as observed in complexes having the P-M-M-P framework bridged by the allyl group.[7] The structure **5** should also require in ^1H NMR spectra a satellite set of the methyl signal associated with a ^{195}Pt-^{195}Pt framework which is composed of a 1 : 2 : 1 triplet with the central peak overlapping with the main peak. However, we could not observe this set due to low solubility.

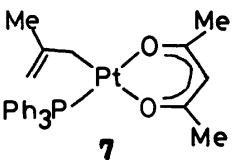
A possible route to **5** is shown in Scheme 2. The nucleophilic attack of $P(2,6)_3$ at the 2-methylallyl group of **4b** produces the phosphonium ion and $Pt(CO)\{P(2,6)_3\}$ which subsequently attacks the metal atom of another **4b** to form **5** eventually. The initial step in the corresponding reaction of **4a** with $P(2,6)_3$ may be the same as that shown in Scheme 2, but $Pd(CO)\{P(2,6)_3\}$ formed would be much less stable, releasing free $P(2,6)_3$. It seems of further interest to note that the 2-methylallyl group of **5** underwent no further nucleophilic attack of $P(2,6)_3$ even when excess $P(2,6)_3$ was added to the solution of **5**.

Preparation and Reaction of 1-3-η-(2-Methylallyl)-metal Complexes Containing $P(2,6)_3$ and Acetylacetonato Ligands. Palladium and platinum complexes of PPh_3 are known to be good catalysts for coupling reaction of allylic electrophiles and acetylacetonate anion.[8] However, the $P(2,6)_3$ complexes **1** did not show very good catalytic activity in the reaction of 2-methylallyl acetate with sodium acetylacetonate in acetone where each complex was used either by itself or in combination with free $P(2,6)_3$. Next we looked into stoichiometric reactions of 1-3-η-(2-methylallyl) complexes containing $P(2,6)_3$ with acetylacetonate anion.

The reaction of **1** with thallium acetylacetonate in benzene gave a complex of the formula, $M(C_4H_7)(acac)\{P(2,6)_3\}$ **6**. In the platinum analog, the acetylacetonato ligand may coordinate to the metal via the central carbon atom (see **6b**), as deduced by the following IR and ^1H NMR spectral data. The absence of any IR absorption at 1500—1600 cm^{-1} may exclude the chelating acetylacetonato ligand. Instead, medium to strong absorption bands appeared at 1600—1650 cm^{-1}. In the ^1H NMR spectrum of **6b** (Table 1), the methine proton of the acetylacetonato ligand resonated in the chemical shift region (δ 4.43) considerably higher than where this proton in the bidentate and monodentate oxygen-bonded ligand resonates ($\delta \geqslant$ 5.1).[9] Also, it exhibited a ^{31}P coupling of magnitude similar to those in *cis*-$ML_2(acac\text{-}C)(PR_3)$ (M=Pd, Pt)[9] and a large ^{195}Pt coupling. Moreover, the resonance of the allylic anti proton trans to the acetylacetonato ligand showed a relatively small ^{195}Pt coupling when compared to those in **2b** and **3** containing the oxygen donor, in accord with the presence of a ligand of strong trans influence.



6b



7

It seems notable that the triphenylphosphine analog of **6b** was reported to have the structure **7** having the *O,O*-chelate and the σ-bonded 2-methylallyl group.[8c] It is not certain how the electronic effect of the phosphine ligand controls the mode of the

metal-allyl and -acetylacetonato bonding in these complexes. Adoption of the structure **6b** in the $P(2,6)_3$ analog appears reasonable in terms of the steric cause. Thus, in spite of the presence of the secondary alkyl group ($CH(COMe)_2$), **6b** would contain more room for the bulky $P(2,6)_3$ to coordinate than a structure in which PPh_3 in **7** is replaced by $P(2,6)_3$, primarily due to the smaller bite angle of the 1-3-η-allyl chelate ($\leqslant 70°$)[10] than that of the acetylacetonato chelate (90°).

The IR spectrum of the palladium analog **6a** was much the same as that of **6b**. However, **6a** decomposed relatively rapidly when dissolved in chloroform and dichloromethane (see below), so that the ^1H NMR spectral data were not obtained in these solvents. The spectrum in toluene-d_8 was very broad at room temperature, and the spectra at the lower temperatures (down to −70°C) indicated the presence of free $P(2,6)_3$ and Pd(1-3-η-CH_2CMeCH_2)(acac) in ca. 30% amount. However, the remaining parts of the spectra were still very broad and no definitive structural assignment could be made.

Attempts to isolate a triphenylphosphine analog of **6a** were unsuccessful owing to fast decomposition to give good yields of the coupling product, CH_2=$CMeCH_2CH(COMe)_2$ **8**. Interestingly, however, decomposition of **6a** in methanol or chloroform gave only low yields of **8** (up to ca. 30%). The ^1H NMR spectra of the CD_3OD or $CDCl_3$ solution of **6a** after being kept at room temperature for one day showed the presence of the $[P(CH_2CMe{=}CH_2)(2,6)_3]^+$ ion (ca. 30—50%), although the nature of its counter anion remains to be identified. **6b** is fairly stable in solutions under the similar conditions.

It was reported before[11,12] that addition of phosphine or carbonyl ligand to otherwise stable 1-3-η-allyl (acetylacetonato) complexes of Pd and Pt greatly accelerates the formation of the C-C coupling products. Adding $P(2,6)_3$ to **6a** did not result in the increase of the formation of **8**, but bubbling carbon monoxide through a $CDCl_3$ solution of **6a** somewhat raised the amount of **8** (46%). Addition of $P(2,6)_3$ to **6b** caused no change. On the contrary, it was reported[8c] that **7** reacts with PPh_3 very rapidly to give **8** in good yields. However, **6b** did afford **8** (55—60%) rapidly when carbon monoxide was bubbled through its methanol or chloroform solution. Formation of some 30% amount of the ion, $[P(CH_2CMe{=}CH_2)(2,6)_3]^+$ was also confirmed by ^1H NMR spectroscopy.

When thallium or sodium acetylacetonate was added to **4a** in methanol-chloroform mixture under an atmospheric pressure of carbon monoxide, immediate decomposition of **4a** occurred. However, to our surprise, **8** was obtained in only 3% yields, the major product being $[P(CH_2CMe{=}CH_2)(2,6)_3]BF_4$ (92%). Surprisingly again, in the reaction of **4b** and sodium acetylacetonate in methanol-dichloromethane, **8** was not obtained so efficiently as in the reaction of **6b** with carbon monoxide.

It is possible that the reaction of **6** with carbon monoxide to give **8** does not take a pathway proceeding via an ion pair, $[M(1\text{-}3\text{-}\eta\text{-}CH_2CMeCH_2)(CO)\{P(2,6)_3\}]^+CH(COMe)_2^-$, **9**, as was often postulated in analogous reactions of platinum and palladium complexes.[8c,11b,12] One possible alternative pathway would be intramolecular reductive elimination of **8** from **6** assisted by coordination of carbon monoxide. Or it is also conceivable that the reaction of **6** with carbon monoxide does proceed via **9**, a kind of built-in ion pair, but in the reaction of **4** with sodium acetylacetonate the presence of the counter anion and cation (BF_4^-, Na^+) prohibits close contact of two reacting ions. Evidently, more works are necessary before any definitive conclusion on the mechanistic pathway is attained.

Experimental

Preparation of Complexes. **1a** and **1b** were obtained from the reaction of $[M(1\text{-}3\text{-}\eta\text{-}CH_2CMeCH_2)Cl]_2$ with $P(2,6)_3$ (1 : 1) in chloroform at 0 °C, and recrystallized from dichloromethane-hexane. As for the preparation of **2a**, an acetone solution (1 cm^3) of $AgBF_4$ (1 mmol) was added dropwise to **1a** (1 mmol) in the same solvent (100 cm^3). White precipitates of AgCl obtained immediately were filtered off, and the solution was concentrated to about a half volume by evaporation under vacuum. Hexane was added to cause precipitation of pale-yellow solids. These were recrystallized from dichloromethane-hexane. **2b** was prepared in a similar manner.

4a and **4b** were prepared by passing carbon monoxide through a dichloromethane solution of **2a** or **2b** at 0 °C for 10 min. To the resulting solution was added diethyl ether to give pale-pink **4a** or colorless **4b** precipitates. **4b** was recrystallized from dichloromethane-hexane, but **4a** was used without recrystallization for analysis, spectroscopy, and further reactions. IR (Nujol): **4a** 2098 cm^{-1}; **4b** 2075 cm^{-1}.

6a and **6b** were prepared from the reaction of **1a** and **1b** with thallium acetylacetonate, respectively, in manners similar to that for obtaining **7** described before.[8c] IR (Nujol): **6a** 1610 and 1630 cm^{-1}; **6b** 1624 and 1653 cm^{-1}. The ^1H NMR spectrum of **6a** in toluene-d_8 at −30 °C showed, other than the resonances due to $P(2,6)_3$ and Pd(1-3-η-CH_2CMeCH_2)(acac),[13] broad peaks at δ=1.53, 1.89, and 3.15 and very broad, weak peaks at δ=2.4, 3.9, and 4.6.

Reaction of 2b with $P(2,6)_3$. A chloroform solution (5 cm^3) of **2b** (0.26 mmol) was added to $P(2,6)_3$ (0.26 mmol) at room temperature. The resulting pale-yellow solution was concentrated under vacuum, and hexane was added to cause precipitation of pale-yellow solids. These were extracted with benzene (100 cm^3). Benzene insoluble materials were identified as $[P(CH_3)(2,6)_3]BF_4$ by ^1H NMR spectra ($CDCl_3$). The benzene extract was passed through a short Florisil column. After adding hexane, **3** was obtained as pale-yellow solids (37%). The same reaction as well as the analogous one between **2a** and $P(2,6)_3$ in $CDCl_3$ were also followed by ^1H NMR spectroscopy.

Reaction of 4b with $P(2,6)_3$. A chloroform solution (5 cm^3) of **4b** (0.25 mmol) was added to $P(2,6)_3$ (0.13 mmol) at room temperature. After concentrating the pale-yellow solution by evaporation under vacuum, diethyl ether was added

Table 2. Analytical Data of Complexes

to cause precipitation of pale-yellow solids. These were dissolved in 20 cm^3 of ethanol, and this solution was kept at −30 °C overnight to give pale-yellow crystals of **5** (36%). This was further recrystallized from dichloromethane-hexane kept in a refrigerator. IR (Nujol): 2010 and 2040 cm^{-1}. ^1H NMR ($CDCl_3$) δ=1.32 (t, J_P=2.5 Hz, J_{Pt}=60 Hz, Me); 1.47 (br s, anti-H); 2.88 (br t, $1/2[J_P+J_P']$=12 Hz, syn-H); 3.51 (s, OMe); 6.45 (dt, $1/2[J_P+J_P']$=2 Hz, J_H=8.5 Hz, 3- and 5-H); 7.25 (t, J_H=8 Hz, 4-H). The stoichiometry of this reaction was also followed by ^1H NMR spectroscopy, and found very clean.

Analytical data of new complexes thus obtained are summarized in Table 2.

Reactions of Other Complexes. The reactions involving **4a** were run in deuterated solvents which had been saturated with an atmospheric pressure of carbon monoxide. The proceeding of all the reactions was followed by ^1H NMR spectroscopy. The reactions of **6**, and those of **4** with sodium acetylacetonate, were also followed by GLC analysis for the determination of the coupling product **8** (SE30, 2 m×3 mm, internal reference, tridecane).

GLC analysis was run on a Hitachi 163 gas chromatograph. ^1H NMR spectra were measured on a JEOL JNM-PS-100 spectrometer, and IR spectra on a Hitachi 215 grating spectrophotometer.

Partial support of this work by a Grant-in-Aid for Special Project Research, Ministry of Education, Science and Culture (No. 61225016) is gratefully acknowledged.

Synthesis and Chromotropic Behavior of Nickel(II) Complexes with 1,4-Diazacycloheptane-*N,N'*-dicarboxylates in Solution

Yutaka FUKUDA,* Keiko YAMAGATA, and Thomas A. KADEN†
Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112
†Institute of Inorganic Chemistry, University of Basel, Spitalstr. 51, CH-4056 Basel, Switzerland
(Received April 28, 1987)

A new series of nickel(II) complexes containing 1,4-diazacycloheptane-*N,N'*-dicarboxylates (dachdx, where x=a means the acetate derivative, x=m, e, and p are the α-methyl, α-ethyl, and α-propyl substituents of the carboxyl side chain, respectively) were prepared as solids, Ni(dachdx)L_n (L=H_2O or pyridine, n=0, 1, or 2). These complexes can be classified according to their geometry into three types: (1) Octahedral [Ni(dachda)-$(H_2O)_2$], (2) square planar [Ni(dachdx)](x=m, p, or e) and (3) penta-coordinate [Ni(dachdm)(py)]. In the solid state the strength of the bonds between the metal ion and the carboxylate groups increases in the order: Octahedral < penta-coordinate < square planar. In solution, some of these compounds show chromotropic behavior, e.g. solvatochromism, thermochromism, and inert salt or active salt effects. The stability constants of the Ni^{2+} complexes were determined by pH-titrations and spectrophotometry. The following equilibria were found:

$$[Ni(aq)]^{2+} + dachdx^{2-} \rightleftharpoons [Ni(dachdx)];$$

$$[Ni(dachdx)] + X^- \rightleftharpoons [Ni(dachdx)X]^-;$$

where X^-=NCS^-, Cl^-, or Br^-. It is shown that the substituent of the carboxylate side chain plays an important steric role, thus determining the value of the stability constant of [Ni(dachdx)].

The chemistry of Ni^{2+} complexes with diamino-dicarboxylates is interesting and manifold, since different structures and properties were found. For example the nickel(II) complex of ethylenediamine-*N,N'*-diacetate(edda), [Ni(edda)$(H_2O)_2$], has an octahedral hexa-coordinate geometry in aqueous solution,[1] whereas the nickel(II) complex of 1,5-diazacyclo-octane-*N,N'*-diacetate(dacoda), [Ni(dacoda)(H_2O)], is penta-coordinate.[2] However, there are not many studies on the solution behavior of cyclic diamine-*N,N'*-dicarboxylate complexes (Scheme 1), because of difficulties encountered in the synthesis of such ligands and in the crystallization of their complexes. In particular there is no report about nickel(II) complexes of 1,4-diazacycloheptane-*N,N'*-dicarboxylates except our preliminary communication.[3] In continuation of such studies we describe now several nickel(II) complexes with the ligands dachdx. They show some interesting phenomena in solution, such as solvatochromism, thermochromism and inert salt ($NaClO_4$) or active salt (NCS^-) effects on the electronic spectra. In addition the stability constants of the following two equilibria were determined by means of potentiometric (Eq. 1, in aqueous media) and spectrophotometric methods (Eq. 2, in DMSO solutions):

$$[Ni(aq)^{2+}] + dachdx \rightleftharpoons [Ni(dachdx)(H_2O)_n];\ K_{NiL} \quad (1)$$

$$[Ni(dachdx)] + X^- \rightleftharpoons [Ni(dachdx)X]^-;\ K_{NiLX} \quad (2)$$

Experimental

Syntheses. The synthetic route of the ligands and their Ni^{2+} complexes are shown in Scheme 2.

Ni(dachdm)py	50.56(50.53)	6.10(5.88)	11.06(11.07)	Green	3.22

a) Calculated values are shown in parentheses. b) In B.M., dia.=diamagnetic.

Potentiometric Titrations. To prepare standard solutions of the ligands the recrystallized barium salts of dachdx were treated with a slight excess of 0.1 M H_2SO_4 (1M=1 mol dm^{-3}) to precipitate $BaSO_4$. After centrifugation the clear solutions were diluted to the desired volume and the exact concentration of the ligands was determined acidimetrically with 0.4 M NaOH. Typical concentrations: 2.4×10^{-3} M ligand with no metal addition or with 2.0×10^{-3} M $Ni(NO_3)_2$. The ionic strength was kept constant with KNO_3 to I=0.5 M and the temperature was controlled to 25 °C. The titrations with 0.4 M NaOH were run using the previously described titration unit.[4] The electrode was calibrated with two buffers and checked by titrating a standard mixture of HNO_3 and CH_3COOH in 0.5 M KNO_3. The calculation of the protonation and stability constants was done on a Hewlett-Packard HP 9835 computer using the program TITFIT.[5]

Spectral Measurements. Electronic spectra of solutions were obtained with a Hitachi 340 recording spectrophotometer using 10 mm quartz cells. The procedure for determining the stability constants of the complexes [Ni(dachdx)] with NCS^- ion in DMSO was that reported in the literature.[6] Powder reflectance spectra were recorded with the same instrument, attached with an integrating sphere, using $BaSO_4$ as a reference. Infrared spectra were recorded for Nujol mulls using a JASCO IR-A3 Grating spectrophotometer (5000—400 cm^{-1}).

Results and Discussion

Analytical data, magnetic moments and colors of the Ni^{2+} complexes are shown in Table 1. Since [Ni(dachda)$(H_2O)_2$] is very difficult to crystallize and only a small amount of crystals was obtained, they were used for the determination of the elemental analysis, the magnetic moment and the IR spectrum. For visible spectral measurements we prepared solutions of equimolar amounts of dachda and $[Ni(aq)]^{2+}$, starting from Ba(dachda) and $NiSO_4\cdot6H_2O$ as described previously.[3]

From the analytical data of Table 1 and other data such as magnetic moments, IR and electronic spectra (see later), one can classify the solid nickel(II) complexes according to the coordination geometries into three types. The type 1 complex, [Ni(dachda)$(H_2O)_2$], is a green paramagnetic octahedral complex. The type 2 complex, [Ni(dachdx)] where x=m, e, or p, are orange, diamagnetic and have square planar structure. The type 3 complex, [Ni(dachdm)py] which contains one pyridine, is pentacoordinate, green and paramagnetic.

Because of the different coordination geometries of these complexes, it is interesting to look at the stretching frequencies of the carboxyl groups in the region 1700—1300 cm^{-1}. Table 2 gives the $\nu_{C=O}$ (I) and ν_{C-O} (II) bands of our complexes together with other data reported earlier,[7] as well as the difference between these two bands ($\Delta\nu_{I,II}$). From these data one can see that octahedral nickel(II) complexes with diaminedicarboxylate have $\Delta\nu_{I,II}$ values in the range 168—190 cm^{-1}, the pentacoordinate complex [Ni(dachdm)py] has $\Delta\nu_{I,II}$=246 cm^{-1} and those with square planar geometry have $\Delta\nu_{I,II}$ in the range of 296—373 cm^{-1}. [Ni(dachda)$(H_2O)_2$] and [Ni(dachdm)py] both show a similar IR change, when the complexes are heated. Before heating, the separation $\Delta\nu_{I,II}$ between the two peaks is relatively small, whereas after heating rather large one is observed (Eqs. 3 and 4) as follows (observed values shown in cm^{-1}).

Table 2. Carbonyl Stretching Modes (cm^{-1}) for the Ni(II) Complexes

a) Values taken from Ref. 8.

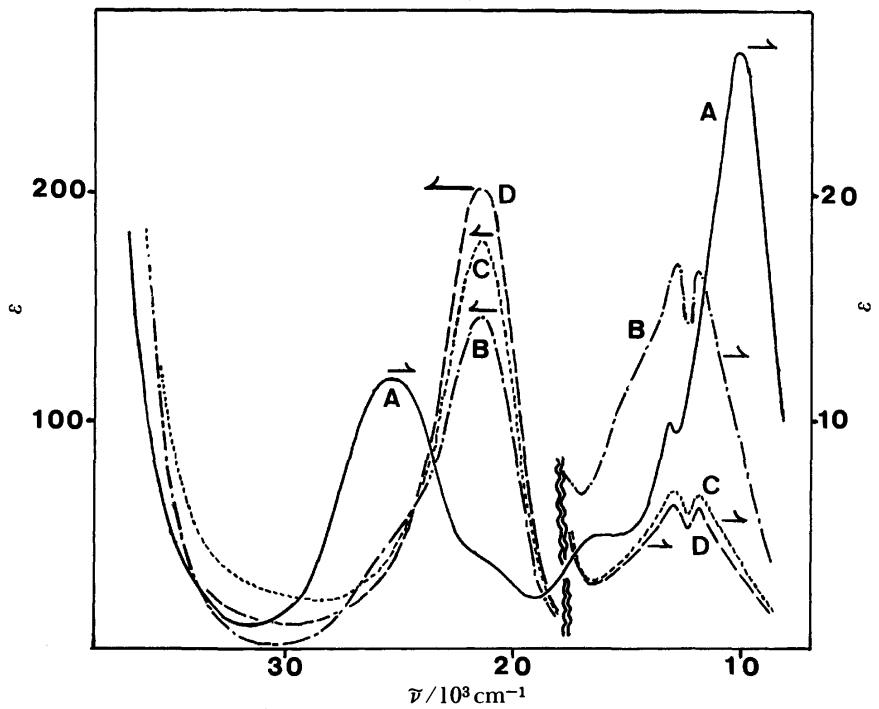

Fig. 1. Electronic absorption spectra of Ni(dachdx) in H_2O at room temperature. A: [Ni(dachda)(H_2O)$_2$] (5.0×10^{-2} M) (——), B: [Ni(dachdm)] (5.2×10^{-3} M) (-·-·-), C: [Ni(dachde)] (5.0×10^{-3} M) (·····), D: [Ni(dachdp)] (4.9×10^{-3} M) (----).

The $\Delta\nu_{I,II}$ values might reflect the strength of the coordinative bond between the metal ion and the carboxylate group. In square planar chelates the metal-ligand bonds are stronger than those in the other two geometries, whereas the bonds in the octahedral structure are the weakest. Since the carboxylate groups in the square planar complex are coordinated more covalently to the metal ion, they become more asymmetrical, whereas the ones in complexes with octahedral geometry being more ionic are less asymmetrical. Consequently the $\Delta\nu_{I,II}$ values reflecting this asymmetry are large for square planar complexes and small for octahedral ones.

The protonation and formation constants of the ligands are given in Table 3. The protonation constants are typical for diamine-*N*,*N*′-dicarboxylates as a comparison with EDDA shows.[8] With Ni^{2+} complexes of the stoichiometry NiL are formed, the stability of which is described by K_{NiL} (Eq. 1). The ligands with small substituent groups, dachda and dachdm, give more stable complexes than dachde and dachdp indicating that steric effects are important (Table 3). However, as we shall discuss later, the complexes NiL formed by these ligands differ from each other, being a mixture of species with different geometies, and this steric effect could play also an important role for determining the predominant species in solution.

The electronic spectra of the Ni^{2+} complexes in aqueous solution are shown in Fig. 1 and the values are given in Table 4. The shapes of the spectra of the complexes with dachdm, dachde, and dachdp (the type 2 complexes) are very similar to each other. Since the peak intensities at 21×10^3 cm^{-1} decrease in the order: [Ni(dachdp)]>[Ni(dachde)]>[Ni(dachdm)], the amount of the square planar species also decreases in the same order. On the other hand, the weak shoulder at 25×10^3 cm^{-1}, which is observed only in the case of dachdm, and the band at ca. 13×10^3 cm^{-1} are due to a pentacoordinate species. This latter species, with an absorption at 13×10^3 cm^{-1} which was also observed more or less distinctly for the complexes of dachde or dachdp, has a spectrum quite similar to that of [Ni-

	(12.6)	(1.9)	(4.2)	(7.2)	
Ni(dacoda)(H_2O)[a]	12.3	13.1	15.8	26.4	
	(21.4)	(25.3)	(28.0)	(86.5)	

a) Values taken from Ref. 2.

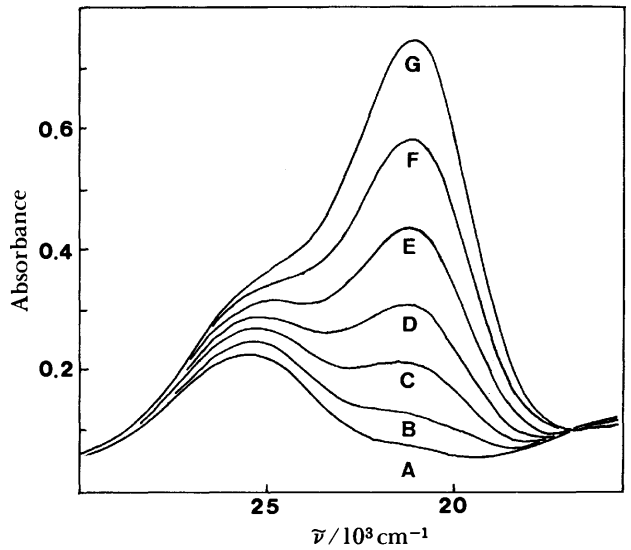

Fig. 2. Temperature effect on the electronic absorption spectra of [Ni(dachda)$(H_2O)_2$] (2.3×10^{-2} M) in H_2O. Curves A to G are the spectra measured at A (293 K), B (313), C (323), D (333), E (343), F (353), and G (363), respectively.

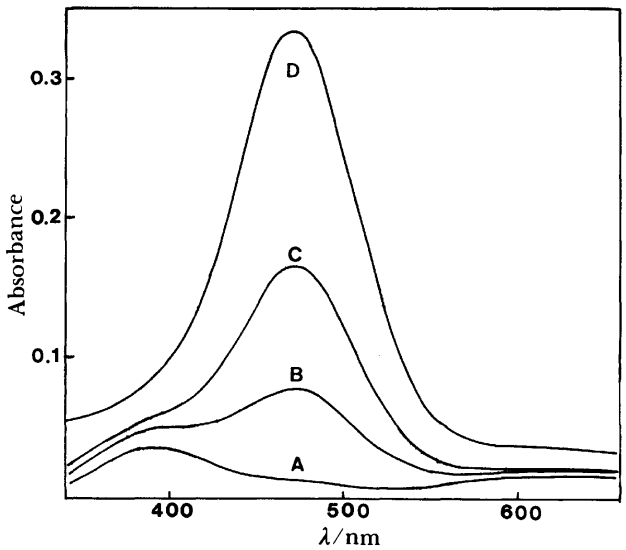

Fig. 3. Inert salt effect on the absorption spectra of [Ni(dachda)$(H_2O)_2$] (4.6×10^{-3} M) in H_2O at room temperature. Concentration of $NaClO_4$ added; A=0.0 M, B=2.0 M, C=3.0 M, and D=large excess amounts of $NaClO_4$.

(dacoda)(H_2O)] in aqueous solution.[2] The order of the amount of penta-coordinate species is the reverse of that for the square planar species given above. The type 2 complexes form equilibrium mixtures of the planar and the penta-coordinate species in aqueous solution, in which the square planar form is predominant. For example, in the case of [Ni(dachdm)] we have Eq. 5.

$$[\text{Ni(dachdm)}] + H_2O \rightleftharpoons [\text{Ni(dachdm)}(H_2O)] \quad (5)$$

Finally, the spectrum of [Ni(dachda)$(H_2O)_2$] is rather different from the other ones. A comparison of this spectrum (Fig. 1) with those typical for planar, penta-coordinate and hexa-coordinate species (Table 4) indicates that in aqueous solution the dachda complex is predominantly a mixture of penta-coordinate and hexa-coordinate species, whereas the square planar form is only present in a minor amount ([Ni(dachda)$(H_2O)_2$] $\rightleftarrows$ [Ni(dachda)(H_2O)]+H_2O). The peak at 17×10^3 cm^{-1} is the second transition expected in octahedral geometry $^3A_{1g} \rightarrow {}^3T_{1g}(F)$,[9] whereas the other two peaks $^3A_{1g} \rightarrow {}^3T_{2g}$, $^3A_{1g} \rightarrow {}^3T_{1g}(P)$ are obscured under the strong bands of the penta-coordinate species.

In addition, the above solutions are thermochromic: The color of the aqueous solution of [Ni(dachda)$(H_2O)_2$] changes from blue-green to orange when the temperature of the solution is raised (Fig. 2). The peak intensity at 21×10^3 cm^{-1} gradually increases as the temperature increases, indicating that Eq. 6 is shifted to the right hand side (where n=1 or 2).

$$\underset{\text{Blue-green (room temp)}}{[\text{Ni(dachda)}(H_2O)_n]} \underset{\text{cool}}{\overset{\text{heat}}{\rightleftharpoons}} \underset{\text{Orange (high temp)}}{[\text{Ni(dachda)}] + nH_2O} \quad (6)$$

Addition of an inert salt such as $NaClO_4$ to an aqueous solution of [Ni(dachda)$(H_2O)_2$] gives rise to this phenomenon more easily. Finally, when a large

excess of $NaClO_4$ is added to this solution, the color of the solution changes already at room temperature from blue-green to orange (Eq. 7, see Fig. 3). This color change (inert salt effect) is explained by decreasing of coordination ability of solvent molecules due to the solvation of large amounts of the inert salt in solution.

$$\underset{\text{Blue-green (room temp)}}{[\text{Ni(dachda)}\,(H_2O)_n]} \xrightarrow{\text{excess } NaClO_4} \underset{\text{Orange(room temp)}}{[\text{Ni(dachda)}]} + nH_2O \quad (7)$$

On the other hand, aqueous solutions of the type 2 compounds show a color change from orange to green when the temperature decreases, e.g. Eq. 8.

$$\underset{\text{Orange (room temp)}}{[\text{Ni(dachdm)}] + H_2O} \xrightarrow{\text{cooling}} \underset{\text{Green (low temp)}}{[\text{Ni(dachdm)}(H_2O)]} \quad (8)$$

We have also noticed that the type 2 complexes, especially the complex [Ni(dachdm)], show solvatochromism. The spectra of this complex in DMSO and H_2O are shown in Fig. 4. The spectrum in DMSO is typical for a planar species, whereas in H_2O there is a mixture of square planar and penta-coordinate species. This is rather strange since from the donor strength of DMSO and H_2O one would expect the opposite.[10] That the species in DMSO solution is square planar and there is no solvent coordination, is probably due to (1) steric effects in solvent coordination, DMSO being larger than H_2O and also (2) the hydrogen bond between carboxylato groups in dachdm and solvent molecules. In other words, the C=O groups can interact with H_2O molecules but not with DMSO molecules, so that H_2O can approach to the central metal ion more easily than DMSO.

The type 2 compounds show an "active salt effect," which means that, when a coordinating anion such as NCS^- is added to the solution, Equilibrium 9 is shifted to the right, i.e. from a square planar species a penta-coordinate one is formed.

$$\underset{\text{Orange, planar}}{[\text{Ni(dachdx)}] + NCS^-} \rightleftharpoons \underset{\text{Green, 5-coordinate}}{[\text{Ni(dachdx)(NCS)}]^-} \quad (9)$$

A typical penta-coordinate spectrum of [Ni(dachdm)-(NCS)]$^-$ is shown in Fig. 5, which was obtained from the DMSO solution with a large excess of NH_4NCS. The formation constants of the penta-coordinate complexes [Ni(dachdx)X]$^-$ (Eq. 2) with three coordinating anions X^-=NCS^-, Br^-, and Cl^- were determined spectrophotometrically in DMSO solutions by the Hildebrand-Benesi method[6] at room temperature (Table 5). The anion coordination decreases in the

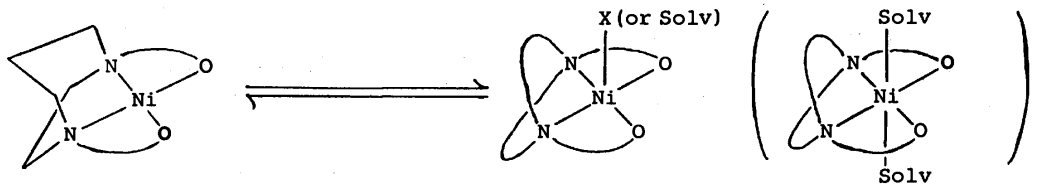
Conclusion: Some Chromotropic Phenomena of the Chelates, [Ni(dachdx)$(H_2O)_n$]



Structure: Square Planar (Sq. Pl.) ⟷ 5-Coord. (or 6-Coord.)
Substituent Effect (R): C_3H_7–, C_2H_5–, CH_3– ⟷ (H–)
Solvent Effect: DMSO ⟷ H_2O
Temperature Effect: High Temp ⟷ Low Temp
Inert Salt Effect ($NaClO_4$ in H_2O): Higher Concn ⟷ Lower Concn
Active Salt Effect (NR_4X in DMSO): Lower Concn ⟷ Higher Concn
Active Salt Effect (Anion Coordination): Br^- ⟷ NCS^- ⟷ Cl^-

Scheme 3.

order $Cl^- > NCS^- > Br^-$, whereas the order of increasing stability of the penta-coordinate species is the following:

[Ni(dachdm)] > [Ni(dachde)] > [Ni(dachdp)].

It is concluded that the substituent at the carboxylate side chain of these ligands plays a very important role in the determination of the structure and the solution behavior of the Ni^{2+} complexes.

Finally, we can summarize the observed chromotropic phenomena due to the structural change between square planar and 5-coordinate structure (or 6-coordinate octahedral one) as shown in Scheme 3.

The authors wish to express their thanks to Professor Kozo Sone of Ochanomizu University for his helpful discussion.

Cobalt(III) Complexes of Salen Analog with Thioether Pendant Group. X-Ray Structure Analysis and Thioether Coordination Effects

Kaoru HORIUCHI, Masahiro MIKURIYA,†,§ Hisashi ŌKAWA,* and Sigeo KIDA†
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashiku, Fukuoka 812

(Received May 29, 1987)

A pentadentate salen analog with a pendant thioether group, *N,N'*-disalicylidene-2-methyl-4-ethylthio-1,2-butanediamine (H_2L), formed two types of cobalt(III) complexes, $[Co(L)]ClO_4 \cdot H_2O$ (**1**) and $[Co(L)NH_3]PF_6 \cdot H_2O$ (**2**). Based on infrared and electronic spectra, the complex **1** was revealed to have a square-pyramidal configuration with the pendant sulfur coordination at the apex. The structure of the complex **2** was determined by single-crystal X-ray analysis. The molecule has a six-cooridnate structure with the coordination of the pendant sulfur and the ammonia molecule at the apical sites, the Co-S and Co-N(NH_3) distances being ca. 2.25 and 2.0 Å, respectively. Electrochemical measurements (CV and DPP) for **2** and $[Co(salen)(R\text{-}NH_2)_2]PF_6$ as the reference have revealed that the substitution of thioether sulfur for one of the apical amine ligands results in a positive shift of the Co^{III}/Co^{II} redox potential. It is also found that the Co^{III}/Co^{II} reduction of five-coordinate **1** occurs at a significantly high potential compared with six-coordinate **2** and $[Co(salen)(R\text{-}NH_2)_2]PF_6$.

Pentadentate salen analogs (H_2 salen=*N,N'*-disalicylidenethylenediamine) with a pendant group capable of axial coordination are of current interest because their metal complexes show some characteristics relevant to biological systems, such as formation of reversible oxygen-adducts[1-11] or alkylcobalt(III) complexes[12,13] and catalytic functions in substrate oxidation.[14-18] In a hope to elucidate the effect of the pendant donor atom on the electronic states and the reactivities of the complexes, pentadentate salen analogs with a pendant group of various kinds have been synthesized so far.[19-23] Salen analogs with a thioether in the pendant group, *N,N'*-disalicylidene-2-methyl-4-alkylthio-1,2-butanediamine and *N,N'*-disalicylidene-2-methyl-4-phenylthio-1,2-butanediamine (Fig. 1), were prepared in our laboratory.[22,23] It was shown that the cobalt(II) complexes of these ligands form dioxygen adducts in which the pendant thioether group is coordinated to the trans position to the dioxygen.[22] Further, these ligands form novel μ-oxodiiron(III,IV) complexes composed of high-spin iron(III) and low-spin iron(IV).[23] The unusual low-spin state of the iron(IV) presumably stems from the coordination of the pendant sulfur atom. These findings prompted us to examine the sulfur coordination effect in cobalt(III) complexes of these sulfur-containing salen analogs. This paper deals with synthesis, characterization, structure, and properties of five-coordinate cobalt(III) complex $[Co(L)]ClO_4 \cdot H_2O$ and six-coordinate complex $[Co(L)NH_3]PF_6 \cdot H_2O$ of *N,N'*-disalicylidene-2-methyl-4-ethylthio-1,2-butanediamine (H_2L: Fig. 1, R=C_2H_5).

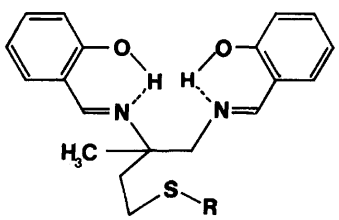

Fig. 1.

Experimental

Preparations. Synthesis of the ligand (H_2L) was described in the preceding paper.[23]

$[Co(L)]ClO_4 \cdot H_2O$ (**1**). Cobalt(II) perchlorate hexahydrate (0.25 g) and H_2L (0.25 g) were dissolved in methanol (30 cm^3), and the mixture was refluxed for 30 minutes to form brownish green solution. It was filtered and the filtrate was left stand in a refrigerator to give a dark green mass. It was crystallized from a chloroform–methanol (1:1) mixture.

Found: C, 46.03; H, 4.99; N, 5.13%. Calcd for $C_{21}H_{26}ClCoN_2O_7S$: C, 46.29; H, 4.81; N, 5.14%.

$[Co(L)NH_3]PF_6 \cdot H_2O$ (**2**). A methanolic solution of cobalt(II) acetate tetrahydrate (0.17 g) and H_2L (0.25 g) was refluxed for two hours. To the resulted deep brown solution was added a methanolic solution of ammonium hexafluorophosphate (excess) to give brown crystals. They were recrystallized from methanol.

Found: C, 41.28; H, 5.00; N, 6.65%. Calcd for $C_{21}H_{29}CoF_6N_3O_3PS$: C, 41.52; H, 4.81; N, 6.92%.

Single-Crystal X-Ray Analysis of 2. On prolonged standing the filtrate of the recrystallization of the complex **2**, the second crop of the complexes was obtained as crystals. From this crop a crystal was picked up and used for the X-ray analysis.

$[Co(L)NH_3]PF_6 \cdot H_2O = C_{21}H_{29}CoSPF_6O_3N_3$, M=607.44, dark brown plates, crystal dimensions 0.15×0.29×0.54 mm, triclinic, a=17.001(2), b=21.388(3), c=11.280(2) Å, α=102.57(1), β=96.71(1), γ=94.38(1)°, V=3954 Å^3, space group $P\bar{1}$ (C_i, No. 2), Z=6, D_m (floatation)=1.53, D_c=1.53 g cm^{-3}, μ(Mo $K\alpha$)=8.52 cm^{-1}, F(000)=1872.

Data collection and processing: RIGAKU AFC-5 diffractometer, $\omega/2\theta$ mode with ω scan width=1.1+0.5 tanθ, ω scan speed 3 deg min^{-1} graphite-monochromated Mo $K\alpha$ radia-

a) Occupancy factor.

tion; 14641 reflections measured ($2.0 \leqq 2\theta \leqq 50.0°$), giving 7623 with $F > 3\sigma(F)$.

The structure was solved by direct method and Fourier technique, and refined by block-diagonal least-squares method. This gave the positions of six $[Co(L)NH_3]^+$ cations, five PF_6^- anions, and six lattice water molecules in the unit cell. At this stage, no remaining peaks as intense as those of a PF_6^- anion could be found. The remaining peaks were eventually assigned to five sites for disordered PF_6^- ion. It was not possible to locate the fluorine atoms of the PF_6^- ion. No attempts were made to locate hydrogen atoms. The weighting scheme was $w=[\sigma_{count}^2+(0.015|F_o|)^2]^{-1}$. Final R and R_w values are 0.093 and 0.167, respectively. The final difference Fourier synthesis showed no peaks higher than 1.3

e Å^{-3}. All the calculations were performed on HITAC M-680H computer of the Computer Centre of the Institute for Molecular Science with the UNICS-III, MULTAN 78, and ORTEP programs. The final atomic parameters are given in Table 1. The anisotropic thermal parameters and the F_o—F_c tables have been deposited as a Document No. 8759 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Other Physical Measurements. Electronic spectra were recorded on a Shimadzu Multipurpose Spectrometer Model MPS-5000 in acetonitrile. Infrared spectra were recorded on a JASCO Infrared Spectrometer Model IR-810 on KBr disks or Nujol mulls. Cyclic voltammograms and differential pulse polarograms were obtained with a Yanagimoto P-1000 voltammetric analyzer in freshly distilled dichloromethane, using a three-electrode cell equipped with a glassy-carbon working electrode, a platinum coil auxiliary electrode, and a calomel electrode as the reference electrode. Tetrabutylammonium perchlorate (0.1 mol dm^{-3}) was added as the supporting electrode. All the potentials were normalized relative to the ferrocenium/ferrocene potential[24] added as the internal standard.

Results and Discussion

Electronic spectra of the complexes in acetonitrile are shown in Fig. 2. The spectrum of **1** is characterized by an absorption ($\varepsilon \approx 700$ dm^3 mol^{-1} cm^{-1}) at 16.9×10^3 cm^{-1}. A similar absorption is observed for five-coordinated salen-cobalt(III) complexes with a soft donor group such as an alkyl anion,[12,25-27] cyanide ion,[18] or triphenylphosphine[28] at the apical site. The spectrum, therefore, suggests the configuration of this complex to be of square-pyramid with the coordination of the pendant sulfur at the apex. The infrared spectrum of the complex indicates non-coordination of the perchlorate ion to the metal ($\nu(ClO_4) \approx 1100$ cm^{-1}).[29] The O-H stretching mode appears near 3400 cm^{-1} when measured on Nujol mulls. This implies that the water molecule is not coordinated but combined in the crystal lattice.[30] It is evident that the complex **1** retains the five-coordinate structure in solid state.

The crystal structure of **2** was determined by single crystal X-ray structure analysis in this study. The crystal contains three crystallographically independent $[Co(L)NH_3]^+$ cations (represented as **A**, **B**, and **C**) which show the essentially same structure. The molecular structure of A is shown in Fig. 3. Selected interatomic distances and bond angles of the cations are given in Table 2. The coordination geometry around the cobalt ion is a distorted octahedron with the thioether sulfur and the ammonia molecule at the apical positions. The in-plane Co-N and Co-O distances are in the range 1.880—1.917 Å, and are comparable to those of salen-complexes.[31] The ethylene chain of the salen skeleton adopts a gauche conformation with the pendant group at the axial orientation so as to allow the sulfur coordination to the metal ion with the Co-S distance of 2.244—2.268 Å. The S-Co-O(1), S-Co-O(2), S-Co-N(1), and S-Co-N(2) angles all are close to 90°, demonstrating that the Co-S bond

is nearly perpendicular to the least-squares plane defined by the Co, O(1), O(2), N(1), and N(2) atoms (N_2O_2 plane). The Co atom resides on the equatorial plane, the deviation of the cobalt atom from the N_2O_2 least square plane being less than 0.03 Å. The Co-N (NH_3) distance (1.987—2.012 Å) is essentially equivalent to the Co-N (pyridine) distance (2.031 Å) of $[CH_3OCo(salen)py]$[32] and Co-N (amine) distance (2.01 Å) of $[Co(salen)(n\text{-}BuNH_2)_2]^+$ (n-$BuNH_2$=butylamine),[33] but significantly short compared with the Co-N (pyridine) bond (2.15 Å) of [Co(salen)py].[34]

In the related cobalt(II)[20,35] and iron(II)[35] complexes of *N,N'*-disalicylidene-4-(2-pyridyl)-1,2-butanediamine, the coordination of the pendant pyridyl group induces distortions of the MN_2O_2 moiety from square-plane to trigonal bipyramid. Because of this distortion the cobalt complex is high-spin. The cobalt(II) complex of H_2L ([Co(L)]), on the other hand, was revealed to be low-spin based on EPR spectra.[22] In the six-coordinate O_2-adduct, [*N,N'*-disalicylidene-4-(2-pyridyl)-1,2-butanediaminato]superoxocobalt(III),[36] the cobalt atom is still displaced towards the pendant pyridyl nitrogen from the equatorial plane. All these facts suggest that in metal complexes of H_2L the pendant sulfur can occupy the apical position without any significant strain when the salen skeleton coordinates to a metal in the usual planar manner.[31]

Cyclic voltammograms (CV) and differential pulse polarograms (DPP) of **1** and **2** were obtained in order to examine the sulfur coordination effect on their electrochemical properties. Both complexes showed two reduction waves but no oxidation wave up to +1.0 V (see Fig. 4). It is reasonable to assign the reduction

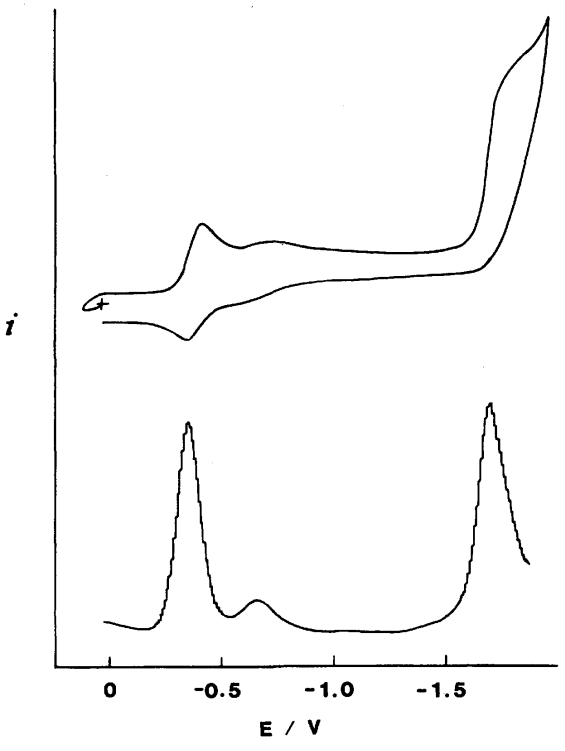

Fig. 4. Cyclic voltammogram (above) and differential pulse polarogram (below) of [Co(L)]$ClO_4 \cdot H_2O$ in dichloromethane ($\approx 1\times10^{-3}$ mol dm^{-3}); scan rate 0.1 V s^{-1} for both CV and DPP.

waves to the Co^{III}/Co^{II} and Co^{II}/Co^{I} processes, respectively.[37] The reduction potentials determined by DPP are given in Table 3. The Co^{III}/Co^{II} process of **1** is quasi-reversible: The separation between the anodic and cathodic peaks is 65 mV. On the other hand, the

Table 3. Redox Potentials of Cobalt(III) Complexes

	Co^{III}/Co^{II}	Co^{II}/Co^{I}
$[Co(L)]ClO_4$	−0.36	−1.70

Determined by DPP in dichloromethane and given by V vs. $E(F_c^+/F_c)$.

corresponding process of **2** is irreversible where only anodic peak was observed in the CV spectrum. The Co^{II}/Co^{I} process is irreversible for both **1** and **2**. Esr investigations[2,7] have revealed that the cobalt(II) complexes of salen and its homologs adopt five-coordinate structure even in donative solvents such as pyridine. Such five-coordination has been proved for [Co(salen)py] by single-crystal X-ray analysis.[34] In the case of five-coordinate **1**, no structural change is necessitated to be reduced to the cobalt(II) species [Co(L)]. On the other hand, one of the apical donors (NH_3 or thioether) should be removed in the case of the reduction of **2** to the cobalt(II) species,[38] and such a structural change must be associated with the irreversible Co^{III}/Co^{II} process. The structure of the cobalt(I) species is presumably square planar because of its d^8-electronic configuration. Agin, the structural change on going from the five-coordinate cobalt(II) species to the four-coordinate cobalt(I) species must be the reason for the irreversibility of the Co^{II}/Co^{I} process. It is seen that the Co^{III}/Co^{II} potential of five-coordinate **1** is considerably high relative to the corresponding potential of six-coordinate **2**.

For comparison electrochemical measurements were also made for diamine(*N,N'*-disalicylideneethylenediaminato)cobalt(III) hexafluorophosphate, $[Co(salen)(R\text{-}NH_2)_2]PF_6$,[33] whose structures were shown to be pseudo-octahedral with the coordination of the amine molecules at the apical sites. They also showed two irreversible reductions waves. The reduction potentials determined by DPP are included in Table 3. Inspection of the electrochemical data of **2** and $[Co(salen)(R\text{-}NH_2)_2]PF_6$ indicates that the substitution of the thioether sulfur for the axial amine gives rise to a significant positive shift of the Co^{III}/Co^{II} potential. This is particularily interesting in view of redox potentials of cytochromes, where axial donor groups play an important role in controlling the redox potential required for the enzymes. It is generally known that the redox potential of cytochromes with two histidinyl residues as axial ligands is lower than that of cytochromes with one histidinyl and one methionyl axial ligands.[39]

Possible Fluorescence from the Polycyclic Aromatic Hydrocarbons in the Interstellar Medium

Jun-ichi AIHARA
Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422
(Received June 1, 1987)

Large compact polycyclic aromatic hydrocarbons (PAHs) are photochemically very stable. These PAHs have been considered as excellent candidates for explaining the interstellar infrared emission lines. Since the large compact PAHs exhibit the first electronic absorption band in a rather low-energy region, it is possible and very probable that fluorescence from such PAHs are responsible for the red emission humps of several nebulae such as the Red Rectangle, a nebula surrounding the binary star HD 44179.

The Red Rectangle is a symmetric biconical nebula centered at the bright binary star HD 44179.[1] Since its discovery in 1975, it has been a target of various spectroscopic observations.[1-4] The visible emission spectrum of the Red Rectangle consists of two major components.[2] They are: (1) The scattered stellar light, which is fairly uniform in intensity over the visible region, and (2) a broad emission hump, which spreads in the wavenumber range 13000—18600 cm^{-1} with a maximum around 15700 cm^{-1}. The latter component gives the red color to the nebula. The rough contour of this red emission hump is reproduced in Fig. 1. Recently several other nebulae were found to exhibit extended red emission similar to that from the Red Rectangle.[5,6]

Duley proposed that the red emission hump of the Red Rectangle could be due to fluorescence from small particles of hydrogenated amorphous carbon (HAC).[7,8] An argument for this hypothesis is the similarity to the observed fluorescence from the HAC particles.[9] Wdowiak attributed the red emission hump to the PAHs clumped together on the surfaces or interiors of grain mantles.[10] He inferred that excimers are formed on the surfaces of grains, and that excimer fluorescence might be responsible for the hump. These explanations require that the molecules responsible for the emission hump must be aggregated on grains.

Discrete infrared lines are emitted coincidentally from the Red Rectange and the like nebulae.[1,5] Léger and Puget and Allamandola et al. ascribed these infrared lines to polycyclic aromatic hydrocarbons (PAHs) in the gas phase, but not in the condensed phase.[11-14] If infrared and red emissions arise from the same source, it must be these PAHs in the gaseous state. In 1986 d'Hendecourt et al. stressed that isolated PAHs can provide broad emission spectra.[15] They suggested that phosphorescence, rather than fluorescence, might be responsible for the red emission hump of the Red Rectangle. Chlewicki and Laureijs also proposed that the most likely source of the red emission hump is phosphorescence from aromatic molecules.[16]

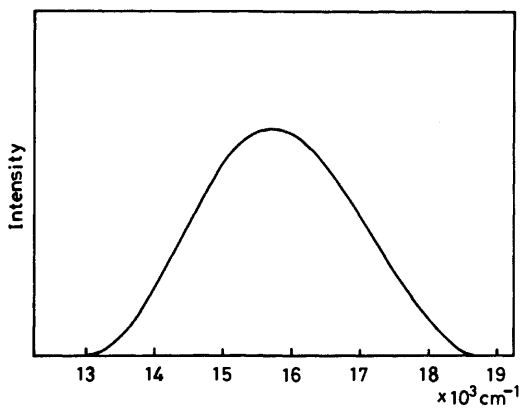

Fig. 1. Rough contour of the red emission hump of the Red Rectangle.

Since the light-emitting interstellar PAHs, if any, are placed in the intense radiation field, they must be fairly resistant to the field. Therefore, photochemically stable PAHs are qualified for explaining the interstellar infrared spectra. In a previous paper,[17] we showed that it is very probable that many of large compact PAHs are stable in the radiation field. They have large percent resonance energies (%REs)[18-20] in the excited state. In this paper, the peculiar red emission hump is interpreted with this characteristic of large compact PAHs in mind. The Hückel molecular orbital model is used throughout this paper.

Results and Discussion

We have developed the graph theory of aromaticity.[18-23] The %RE of a molecule is given as 100 times the graph-theoretically defined resonance energy, divided by the π-electron energy of the olefinic reference structure.[18-20] The %RE can be defined for any conjugated system in any electronic state. It has been established that most of the conjugated molecules with large %REs are stable or fairly unreactive. In the case of polyacenes, naphthalene, anthracene, and naphthacene are relatively stable, but pentacene and higher members are not stable. In general, PAHs with %RE$>$2.15 are stable in our chemical sense.[17]

We previously calculated %REs of a variety of PAHs both in the ground and excited states.[17] As shown in Table 1, **1—14** have the %REs larger than 2.15 both in the ground and excited states. Many large compact

PAHs have large %REs both in the ground and excited states.[17] This implies that these PAHs are possibly stable not only at high temperature but also in the strong radiation field in the interstellar medium. As pointed out by Léger and Puget and Allamandola et al.,[11-14] the PAHs having not a few solo hydrogens are consistent with the infrared emission spectra of the interstellar medium. Therefore, large compact PAHs are the best candidates conceivable for explaining the infrared emission from the interstellar medium.

Fully benzenoid hydrocarbons are the PAHs whose Clar structures consist of aromatic sextets only.[24] There are no formal double bonds in them. This type of PAHs are indeed extremely stable. d'Hendecourt et al. found that the phosphorescence spectrum of hexabenzocoronene (**15**), a typical fully benzenoid hydrocarbon, resembles the red emission hump of the Red Rectangle.[15] However, we previously pointed out that fully benzenoid hydrocarbons are greatly destabilized in the excited state.[17] At present, there is no spectroscopic evidence for the presence of this type of PAHs in the interstellar medium. Compact fully benzenoid hydrocarbons do not have solo hydrogens.[17]

For PAHs having very large %REs or very large resonance energies per π electron in the ground state, the highest occupied molecular orbital (HOMO) is very low in energy,[21,25] and the lowest unoccupied molecular orbital (LUMO) is necessarily very high in energy. This implies that, in general, the energy of the first electronic transition of a fully benzenoid hydrocarbon is too large to exhibit red fluorescence. In other words, fluorescence from such PAHs as **15** cannot reproduce the red emission hump. A situation is essentially the same for relatively small PAHs. It is probably for this reason that Wdowiak and d'Hendecourt et al. were forced to fit excimer fluorescence or phosphorescence to the red emission hump.[10,15] Both excimer fluorescence and phosphorescence are much lower in energy than the fluorescence band of an isolated molecule.

In general, the first electronic absorption band of a PAH can be assigned to the transition from the HOMO to the LUMO. According to Streitwieser,[26] the energy of the first allowed transition (i.e, the p band in Clar's terminology[24]) is linearly related to the energy of the HOMO:

$$\nu_p/\mathrm{cm}^{-1} = 38040\, m_{\mathrm{HOMO}} + 10520 \quad (1)$$

where ν_p is the wavenumber of the p band, and m_{HOMO} is the energy coefficient of the HOMO or the energy of the HOMO given in units of β. This relationship holds for alternant hydrocarbons such as PAHs, for which m_{LUMO} is the negative of m_{HOMO}. It is useful for estimating the absorption edge of an unknown PAH. A p band is sometimes preceded by an α band assignable to a very weak electronic transition.[26] An α band sometimes shifts the absorption edge to a lower-energy side.

In a previous paper, a photochemically stable PAH was defined as the one whose %RE is greater than 2.15 in the excited states.[17] In this sense, **1**—**14** are thermodynamically and photochemically stable. The m_{HOMO} value is less than 0.28 for these PAHs. It follows that the HOMOs of these PAHs are relatively high in energy, as compared with those of fully benzenoid hydrocarbons. Then, photochemically stable PAHs must have the first absorption band in a relatively low-energy region. The m_{HOMO} values of **1**—**14** are listed in Table 1.

For example, m_{HOMO}=0.213 for circumanthracene (**8**).[27] This PAH has been regarded as one of the best candidates for the interstellar molecular species.[17] From Eq. 1 this PAH is predicted to have a p band around 18600 cm^{-1}. Clar et al. devised the relationship between the π-electron ionization potentials and the absorption maximum of the p band,[27] and predicted the location of this band at 2.24 eV or 18100 cm^{-1} in the gas phase. For **8** the p band is the lowest-energy band in the electronic absorption spectrum.[27] The red emission hump appears to give a mirror image of this absorption band. Therefore, it is highly probable that fluorescence from **8** constitutes a part of the red emission hump. Phosphorescence from this PAH is not responsible for it because it is too low in energy.

The wavenumbers of the p bands estimated using Eq. 1 are also presented in Table 1. Fluorescence from **1**—**3**, **6**—**8**, and **11**—**13** might appear in the energy region covered by the red emission hump, and can in principle reproduce the whole or a part of the red emission hump. Thus, there are many qualified large compact PAHs. It is noteworthy that **7** is an exceptionally non-compact PAH with no solo hydrogen. Since these photochemically stable PAHs are expected to exhibit fluorescence in a rather low-energy region, neither phosphorescence nor excimer fluorescence is necessary to explain the red emission hump of the Red Rectangle and other nebulae.

Other PAHs with somewhat larger m_{HOMO} values may also contribute to the red emission hump. If these PAHs coexist with those given in Table 1, the high-energy part of the fluorescence from the former PAHs are absorbed by the latter ones. On the other hand, the PAHs having very small m_{HOMO} values, such as **4**, **5**, **9**, **10**, and **14**, are not desirable as the candidates for explaining the red emission hump. Their fluorescence bands must be located in the infrared region. Among the PAHs in Table 1, these ones have relatively small %REs in the ground state. This might indicate that the ground-state stability is still very important in the interstellar medium.

Aromatic molecules typically have high fluorescence yields.[28] In general, PAHs are much more fluorescent than phosphorescent. Measurements of fluorescence from jet-cooled naphthalene, anthracene, and naphthacene have been made.[29–32] No one has reported the observation of phosphorescence from these PAHs in a supersonic jet. Phosphorescence must follow the intersystem crossing, which is formally a forbidden electronic process for most organic molecules.[28] Therefore, fluorescence is likely to be a much more natural electronic process than phosphorescence even in the interstellar medium. This may further support the assignment of the red emission hump to fluorescence from a group of PAHs.

Concluding Remarks

Large compact PAHs are rich in carbon atoms. If PAHs are formed in a carbon-rich environment, they must be large and compact in shape. Most of them happened to be photochemically very stable.[17] Interestingly, rather large compact PAHs are formed by combustion of light oil in a Diesel engine.[33] This fact might suggest possible formation mechanisms of PAHs in the interstellar medium. As has been seen above, if we accept the existence of abundant large compact PAHs in the interstellar medium, we can rationalize both discrete infrared and broad red emission bands of the Red Rectange and other nebulae in terms of fluorescence spectroscopy. It is very true that most PAHs are more fluorescent than phosphorescent, at least in solution.[28] PAHs emit exclusively from the first excited state.

Hexabenzocoronene (**15**) is a yellow fully benzenoid hydrocarbon of extreme stability.[34,35] Clar reported that this PAH shows an orange-red phosphorescence of very long life at low temperature.[24] If it is generally ture that a large compact PAH tends to undergo intersystem crossing from the singlet excited state to the lowest triplet state at high temperature, the contribution of phosphorescence to the red emission hump must be taken into consideration. At present, it is not at all clear whether there are large compact or fully benzenoid PAHs which are very phosphorescent at high temperature in the gaseous state. This question can only be answered by detailed laboratory measure-

ments of the appropriate materials and processes.

Studies on the Interaction of Molybdate Ion and Magnesium Ion Observed in the Raman Spectra of the Mixture Solutions

Toru OZEKI,* Kazuko MURATA, Hiroshi KIHARA, and Seiichiro HIKIME
Hyogo University of Teacher Education, 942-1 Shimokume, Yashiro-cho, Kato-gun, Hyogo 673-14
(Received March 9, 1987)

When alkali metal or alkaline earth metal chloride, (except magnesium chloride) was added to a solution of sodium molybdate, similar Raman spectra were observed. When magnesium chloride was added to the molybdate solution, however, the intensity of the peak (ν_1) based on the symmetric stretching vibration of the tetrahedral molybdate decreased and a new peak (ν_x) appeared at a higher wavenumber than ν_1. The wavenumber of the new peak is almost equal to that observed for solid magnesium molybdate. This suggests that the new peak can be ascribed to the molybdates of the distorted octahedral structure, since the molybdate ion exists as an octahedral in the solid state of magnesium molybdate. The tetrahedral and the octahedral molybdates seem to be in equilibrium in the solution.

The molybdate ion is a typical oxoanion, having a tetrahedral structure in an alkaline or neutral solution.[1,2] The dissolved states of the molybdate ion have been studied under various experimental conditions, e.g., pH, ionic strength, coexisting salt etc.,[2-10] and their typical Raman peaks, based on the fundamental vibrations, have been assigned.[5] However, the number of studies regarding the effect of the coexisting salts on the Raman spectra of the solution have been few. In this study, a change in the Raman spectra was studied, especially when alkaline earth chloride was added to a solution of molybdates.

When magnesium ion was added to a molybdate ion solution, the appearance of a new peak was found in the Raman spectra. This peak seemed to be the result of interaction of these ions in solution.

Experimental

Reagents. Molybdate solutions were prepared using sodium molybdate ($Na_2MoO_4 \cdot 2H_2O$). All reagents used were analytical reagent grade chemicals and were used without further purification.

Equipments. Raman spectra were measured with a laser Raman spectrometer with double monochromators (JASCO R800); the 514.5 nm line of an Ar^+ laser was used as the excitation light source. One ml of sample solution was used for each measurement. The slit widths of the spectrometer for the entrance, intermediate and exit were 300, 500, and 300 μm, respectively.

Results and Discussion

The Effect of Magnesium Ion. The Raman spectra of two 0.1M (1M=1 mol dm^{-3}) sodium molybdate solutions in which lithium chloride and magnesium chloride were added, respectively, are shown in Fig. 1. The Raman spectrum of a magnesium chloride solution is also shown for a reference. In the case of lithium chloride, only the peaks ascribed to the free molybdate were observed. The molybdate ion generally exists as a tetrahedral ion in alkaline or neutral solutions and four peaks characterizing tetrahedral structure have been observed at 900, 850, 310, and 270 cm^{-1} in the Raman spectra. The peak at 900 cm^{-1} (denoted by ν_1) has been assigned to the totally symmetric stretching vibration and the peaks at 850 cm^{-1} (ν_3) to an antisymmetric stretching vibration.[5] When magnesium chloride was added to the molybdate solution, a noticeable change was observed, namely the peak near 900 cm^{-1} decreased and the shape of the peak was deformed. A more detailed change in the shape is indicated by the dotted lines in Fig.2. As the magnesium concentration increased from 0.5 to 4.5M, the intensity of the peak at 900 cm^{-1} (ν_1) decreased, and a new peak (denoted by ν_x) appeared in the region 910 to 930 cm^{-1}. In order to separate the peaks, a nonlinear least-squares wave analysis was applied assuming Lorentz-Gauss sum functions. An algorithm of the calculation was taken from the work of Edgell et al.[11-13] Three peaks were obtained, as shown by the solid lines in Fig. 2. All spectra in Fig. 2 were normalized so that the highest peak in the spectrum had the same intensity. The dependence of the wavenumbers of each peak and that of the area fraction, $\nu_1/(\nu_1+\nu_x)$, upon magnesium concentration are shown in Fig. 3. The area fraction of ν_1 decreased against an increase in the magnesium concentration. This implies a decrease in the concentration of the free molybdate ion and an

increase in a new species (ν_x). The peak ν_x appeared at a higher wavenumber than ν_1 and its wavenumber moved to a higher value, accompaning an increase in the magnesium concentration.

In acidic molybdate solutions, the presence of such isopolymolybdates as heptamer and octamer had been known.[14-16] The pH of the solution studied in this work changed from 7.0 (0.1M Na_2MoO_4) to 5.0 (0.1M Na_2MoO_4, 4M $MgCl_2$). Thus, the possibility that the new species might be the isopolymolybdate, was suspected. A study concerning the dissolved states of the isopolymolybdate ions, however, has shown that the peak wavenumbers of the isopolymolybdates are not consistent with ν_x : ν_x=910-930, cf. $\nu(Mo_7O_{24}^{6-})$=945, $\nu(HMo_7O_{24}^{5-})$=957, and $\nu(Mo_8O_{26}^{4-})$=970 cm^{-1}.[17] The new species observed here is not the isopolymolybdate ion, but other species.

The Raman spectra of the solutions in which the concentration of the sodium molybdate was varied and that of magnesium chloride was kept 3M, were shown in Fig. 4. Almost the same spectra were obtained independently of the molybdate concentration, i.e., the peak wavenumbers of each spectra were almost the same and the fraction of the peak areas was nearly constant.

Raman Spectra of Powdered Alkaline Earth Salts of Molybdate. The solubility of calcium, strontium, and barium molybdates are very small, but that of magnesium molybdate is fairly large in water. A precipitate of magnesium molybdate was obtained by concentrating a mixed solution of sodium molybdate and magnesium chloride. The compositions of these freshly prepared precipitates were all 1 : 1 as for the ratio of the

alkaline earth metal ion against the molybdate as a result of a quantitative analysis. After drying them in a desiccator with concentrated sulfuric acid, their Raman spectra were measured. The obtained spectra are shown in Fig. 5. Calcium, strontium, and barium molybdates gave similar Raman spectra. Only magnesium salt gave a different spectrum from the others. From this fact, it is supposed that these alkaline earth salts, except magnesium salt, have a similar crystal structure. In Fig. 6, the X-ray diffraction pattern of these salts are shown. The same analogy was observed among the calcium, strontium and barium molybdates. However, only the pattern of the magnesium molybdate was complex and was different from the others. The crystal salts were divided to two groups. The crystals, except magnesium salt, are all ascribed to Scheelite and only magnesium salt is ascribed to Wolframite.[18-20]

If the salt of molybdate is expressed as XYO_4, the Y atom in Scheelite is surrounded by four oxygen atoms in a tetrahedral structure. On the other hand, the Y atom of XYO_4 in Wolframite type lies in the center of a distorted octahedral structure and is surrounded by six oxygen atoms.[19,21] This suggests that the peak, which is observed in the Raman spectra of magnesium molybdate in solid state, should be ascribed to the molybdate species in a distorted octahedral structure. Even in a such isopolymolybdate ions as heptamer and octamer, it has been reported that each molybdenum atom lies in a center of the octahedral unit.[22,23] The octahedral structure might be a stable structure for molybdate. Figure 3 shows that the wavenumber of the new peak ν_x observed in a mixed solution approaches the peak (930 cm^{-1}) of the solid state magnesium molybdate (Fig. 5) upon increasing the concentration of magnesium chloride. From these facts, it is suggested that both peaks, one for the solid and the other for the solution, must be based on a similar structure; the distorted octahedral structure. Thus, tetrahedral and distorted octahedral ions must be in equilibrium in the solutions.

On the other hand, if the new species formed in the mixture solution is a stoichiometric compound and its shape is constant, then its concentration only depends upon the magnesium concentration and its wavenumber will not shift. However, a shift of ν_x was observed with an increase in the magnesium concentration. This fact implies that the structure of the new species, itself, depends upon the composition. Thus, the formation reaction equation can not be strictly expressed.

However, suppose the stoichiometry and assume the following reaction for the qualitative explanation of the experimental results:

$$Mg^{2+} + Mo(T) = Mg\text{-}Mo(O), \quad (1)$$

where Mo(T) is the free tetrahedral molybdate, and Mg-Mo(O) the distorted octahedral molybdate inte-

racting with magnesium ions. Then, the equilibrium constant K is

$$K=[\text{Mg-Mo(O)}]/[\text{Mg}^{2+}][\text{Mo(T)}]. \quad (2)$$

This equation can be rewritten as

$$[\text{Mg-Mo(O)}]/[\text{Mo(T)}]=K[\text{Mg}^{2+}]. \quad (3)$$

This equation indicates that the ratio of the concentration of the new species Mg-Mo(O) against that of free molybdate Mo(T) is in proportion to the total concentration of the magnesium ions, since the latter concentration is in large excess against that of molybdate and is almost identical to the free magnesium ion concentration. If the amount of magnesium is constant and that of molybdate is varied, the fraction of Eq. 3 remains constant. Thus, the results shown in Figs. 2 to 4 are well explained qualitatively by Eq. 3.

Spectroscopic Analysis of the Interaction at Low Concentration Solution. It was expected that the ultraviolet absorption spectra of the molybdate solution would change by the formation of molybdate octahedral species. The absorption spectra of 0.1 mM sodium molybdate solutions in which various concentrations of magnesium chloride were added, were measured; no noticeable change was observed. On the other hand, 3 mg of four kinds of molybdate compounds (sodium molybdate: Na_2MoO_4, magnesium molybdate: $MgMoO_4$, ammonium paramolybdate: $(NH_4)_6Mo_7O_{24}$, and ammonium tetramolybdate: $(NH_4)_4Mo_8O_{26}$), were each mixed with the 0.3 g KCl ground powder, respectively, and their sample disks were prepared by pressing each mixture powders into the disks (1 cm diameter and 1mm thickness) in a vacuum chamber. The measured ultraviolet absorption spectra of these disks are shown in Fig. 7. Two kinds of isopolymolybdates gave different spectra from that of sodium molybdate disk: The former had a definite absorption intensity at 250 nm, but the latter had no absorption there. However, the spectrum of a disk of magnesium molybdate was almost the same as that of sodium molybdate. This indicates that a noticeable difference will not be observed between the absorption spectra of the molybdate tetrahedral ion and that of the octahedral deformed ion. Namely, the fact that the ultraviolet spectra observed in the mixture solutions were almost same as that of free molybdate, does not rule out the presence of the octahedral molybdate species. On the other hand, the fact that the ultraviolet absorption spectra of any isopolymolybdates were shifted to the longer wavelength region, suggests the possibility that the new species is essentially a monomer and, thus, has no direct bonding between each molybdenum atom.

Conclusion

When magnesium chloride is added in greater concentrations than 4.5 M to a 0.1 M sodium molybdate solution, magnesium molybdate precipitates. In the Raman spectra of the mixture solution, a ν_x peak similar to that of a precipitate crystal was already observed, even in a solution of 0.5M $MgCl_2$. This peak shifted to a higher wavenumber. These facts suggest that a crystal-like structure is already formed in a mixture solution of such low concentrations and grows. The new peak was ascribed to the molybdates in the distorted octahedral structure, resulting in the interaction of molybdate and magnesium ions.

We believe that in a precipitation reaction, the ions are all present as free ions before saturation and that they change in structure when the composition reaches a saturated state. Namely, the transformation of the structure occurrs at a saturated composition. However this model is not adequate for explaining the system studied above. This study suggests that before saturation (even in the low concentration solutions) there exists an ion having a structure similar to that of the precipitate crystal. Also, not the free tetrahedral molybdate but, rather, the distorted octahedral molybdates precipitates through a formation reaction of the latter species. This phenomenon was observed for the first time, since the structure of the free molybdate ion in solution happened to be different from that of molybdate ion of magnesium molybdate precipitate. We expect that this is not a unique case but that a similar phenomenon will also be found in the other systems.

Interaction of Cationic Drugs with Nafion on Electrode Surfaces and Its Applicability to Determination of Electroinactive Drugs

Tomokazu MATSUE,* Atsushi AOKI, Isamu UCHIDA,* and Tetsuo OSA†
Department of Applied Chemistry, Faculty of Engineering, and
†Pharmaceutical Institute, Tohoku University, Aramaki Aoba, Sendai 980
(Received May 6, 1987)

The interaction of several electroinactive cationic drugs (hexamethonium, quinidine, neostigmine, nicotine and acetylcholine) with Nafion and the applicability of Nafion-coated electrodes to determination of the drugs have been investigated. The addition of a drug to an electrolyte solution containing (ferrocenylmethyl)trimethylammonium (FA^+) induced a decrease in the peak current and a shift in the apparent half-wave potential of a cyclic voltammogram for FA^+. The decrease in the peak current has been used for determination of the drugs at low concentrations less than 10^{-3} mol dm^{-3}. The ion-selectivity coefficients of Nafion for the drugs have been determined by an electrochemical method. These drugs showed quite large values and the values seemed to be dependent on the hydrophobicity of the drugs.

Du Pont's Nafion, a perfluoro sulfonated ion-exchange polymer, has been receiving a great deal of attention as a modifier for polymer-coated electrodes mainly because of its outstanding chemical stability and excellent ionic conductivity. Among extensive studies[1] dealing with mechanisms of charge and mass transportation as well as catalytic properties, some attempts[2-4] have recently been made to use the Nafion-coated electrodes for determination of electroactive compounds.

Nafion has two important aspects which are useful for electroanalytical purposes. One is its preconcentrating ability[5,6] of cations by electrostatic interaction between the cations and negatively charged sulfonato group in Nafion. Thus, amperometric determination of quite low concentration of electroactive materials becomes possible on the preconcentrated electrodes. Szentirmay and Martin[2] demonstrated that 10^{-8} mol dm^{-3} of methyl viologen could be detected on the Nafion-coated electrode by cyclic voltammetry. This detection limit is about three orders lower than that observed on a bare electrode. The lowering of the effective diffusion coefficient in the Nafion matrix is apparently unfavorable for the electroanalytical purpose, but the favorable preconcentrating effect more than compensates the unfavorable lowering. The other is ionic selectivity. Previous investigations[7,8] have proved that Nafion favors hydrophobic organic cations as compared with hydrophilic inorganic cations. This phenomenon is caused by hydrophobic interaction between fluorocarbon network of the polymer and substrates. There is a possibility for selective determination of organic cations in the presence of hydrophilic cations.

The important advantage of the electrochemical determination over the spectroscopic one widely used currently is that only the vicinity of the electrode surface is necessary in the former method. Therefore, the preconcentrated layer can be very thin; in extreme case, a monolayer is enough to detect the adsorbed species.[9-11] This situation is usually difficult in the spectroscopic method. We report here the indirect determination of electroinactive cationic drugs with Nafion-coated electrodes, taking advantages of the strong interaction of such drugs with Nafion. Indirect electrochemical determination[12,13] is one of the attractive methods since it removes the limitation of direct electrochemical determination. The present method is based on the competitive partitioning effect between an electroactive compound and cationic drugs into Nafion layer, and has been applied to several ammonium drugs using (ferrocenylmethyl)trimethylammonium ion (FA^+) as an electroactive chemical agent. Since the drugs have shown strong affinity with Nafion, the electroinactive drugs less than 10^{-3} mol dm^{-3} level have been determined by voltammetry.

Eperimental

A Nafion solution (Nafion 117, 1100 EW, 5% solution) was obtained from Aldrich Co. and was diluted with methanol to give a 0.025% solution. (Ferrocenylmethyl)trimethylammonium (FA^+) perchlorate was prepared from the iodide salt of FA^+ (Tokyo Kasei Co.) by using aqueous solution of $NaClO_4$ and was recrystallized three times from water. Five drugs were obtained from the commercial sources: hexamethonium chloride (*N*,*N*′-hexamethylenebis(trimethylammonium chloride), autonomic ganglionic blocking drug), Wako chemicals; acetylcholine chloride (parasympathomimetic drug), Kanto Chemicals; neostigmine bromide ([3-(dimethylcarbamoyloxy)phenyl]trimethylammonium-bromide, parasympathomimetic drug), Wako Chemicals; nicotine (autonomic ganglionic blocking drug), Kanto Chemicals; quinidine sulfate (antiarrhythmic drug), Nakarai Chemicals. The structures of these drugs are shown drugs are shown in Fig. 1.

Cyclic voltammetry was carried out with a PAR model 273. The cell was a water-jacket type and kept at 25 °C. The working electrode was a 3 mm diameter glassy carbon (GC) disk (GC-20, Tokai Carbon Co.) mounted in a Teflon rod and was polished finally with alumina powder (50 nm average particle size, Buehler Co.) to give a mirror-like surface. A

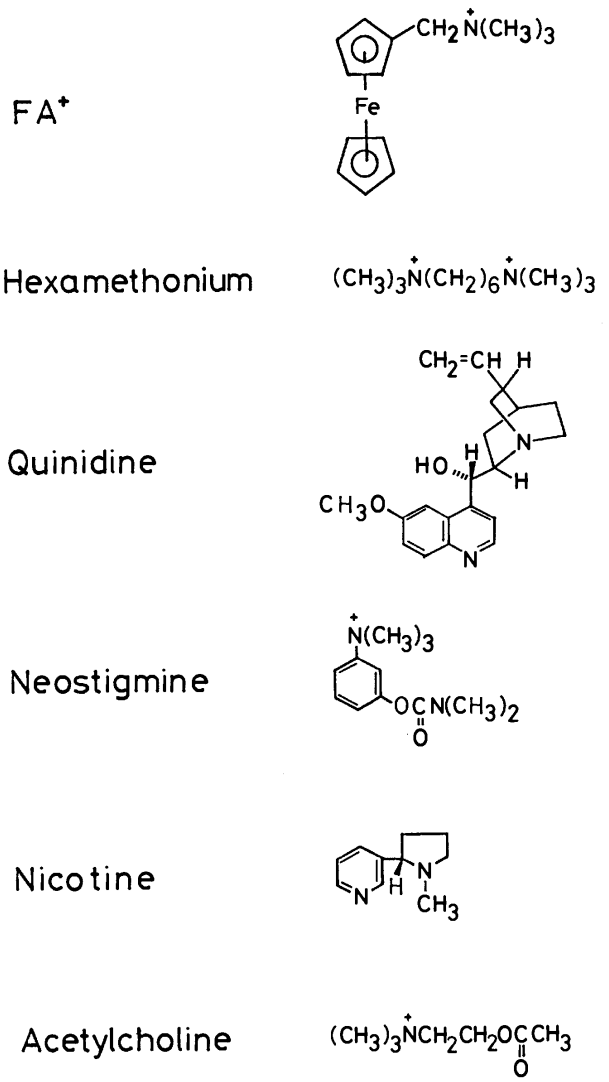

Fig. 1. Structures of drugs.

Pt wire was used as a counter electrode and the potentials were referenced to a saturated calomel electrode (SCE). Nafion coating was prepared by pipetting 2 mm^3 of the 0.025% Nafion solution onto a clean GC surface and allowing the solvent to evaporate at a room temperature. This process was repeated several times using methanol without Nafion to avoid island-like surface coatings. These procedures are important to obtain stable coatings and reproducible results.

Results and Discussion

Voltammetry of FA^+ on the Nafion-Coated Electrode. Figure 2A shows the cyclic voltammograms for FA^+ on the Nafion-coated electrode at different scan rates. The shape indicates near-ideal behavior of a thin film.[14] The peaks are almost symmetrical with very little diffusional tails at the anodic region. The peak current is clearly proportional to the scan rates when the scan rate is less than 200 mV s^{-1} as shown in Fig. 2B. The peak width at half-peak height is 120 mV which is larger than the theoretical value, 90 mV,[14] predicted for a surface species, which may indicate that

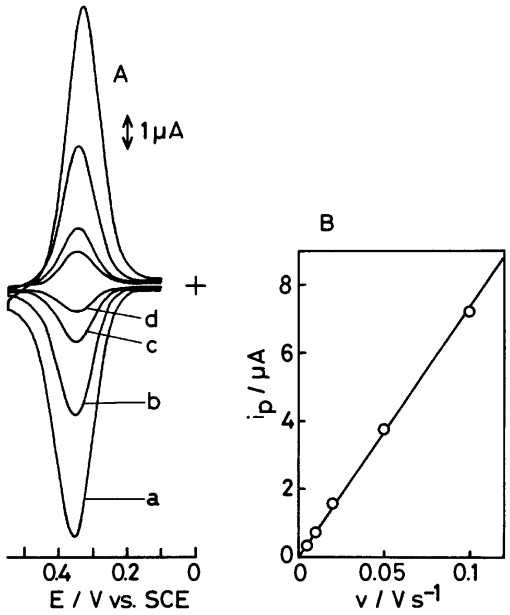

Fig. 2. (A) Cyclic voltammograms of FA^+ on the Nafion-coated GC in 0.1 mol dm^{-3} Na_2SO_4. Scan rate: a, 0.1; b, 0.05; c, 0.02; d, 0.01 V s^{-1}. Concentration of FA^+ in the solution: 7.2×10^{-6} mol dm^{-3}. (B) Relationship between the anodic peak current (i_p) and scan rate (v).

the entrapped FA^+ exists under various circumstances. The small separation between the anodic and cathodic peaks (ca. 15 mV at 50 mV s^{-1}) would be mainly caused by the residual resistance of the polymer film.

The surface concentration of $-SO_3^-$ sites on the electrode is estimated to be 3.4×10^{-9} mol equivalent cm^{-2} from the loading amount of FA^+ entrapped in the Nafion and ion-exchange selectivity coefficient for FA^+.[2] Thus, the average thickness of the film is calculated to be ca. 24 nm by using the density of wet Nafion (1.58 g cm^{-3}) in Na^+ form.[15] This value agrees reasonably with the value (ca. 40 nm) estimated from the amount of the Nafion on the surface. Although the thickness of the Nafion film on the GC surface might be uneven, FA^+ in the outside solution equilibrates fairly rapidly. It takes only ca. 10 min to reach near equilibrium for the cationic exchange between Na^+ and FA^+ after the Nafion-coated electrode is dipped into the electrolyte solution containing 7.2×10^{-6} mol dm^{-3} FA^+. This can be compared with the results reported by Szentirmay and Martin[2] with a 1 μm thick Nafion film. Almost a day was necessary to reach ion-exchange equilibrium between Na^+ and methyl viologen.

The apparent half-wave potential of FA^+ observed on the Nafion-coated electrode is 0.34 V vs. SEC, which is ca. 50 mV negative from the value on a bare GC electrode. This difference in the half-wave potential indicates the stabilization[16-19] of the oxidized species by electrostatic interaction with the negativity charged sulfonato group. This phenomenon contrasts well

with that observed on a perfluorinated carboxylic acid polymer.[17]

Determination of Cationic Drugs on the Nafion-Coated Electrode. The concentration of FA^+ inside the Nafion membrane is susceptible to the presence of cations. Figure 3 shows the cyclic voltammograms observed on the Nafion-coated GC electrode with 7.2×10^{-6} mol dm^{-3} FA^+ and different concentrations of hexamethonium in the electrolyte solution. The addition of hexamethonium resulted in a decrease in the peak current for FA^+. This phenomenon clearly demonstrates that some amount of FA^+ initially trapped inside the Nafion membrane is replaced by hexamethonium added to the electrolyte solution. The extent of the decrease in the peak current is dependent on the concentration of hexamethonium in the solution and thus the determination of the concentration becomes possible by using this phenomenon. As shown in Fig. 3, the presence of 1.0×10^{-6} mol dm^{-3} hexamethonium in solution induces a clear decrease in the peak current for FA^+. We have used several other cationic drugs (acetylcholine, neostigmine, nicotine and quinidine) to clarify the influence of these drugs on the voltammetric response of FA^+ and to investigate the applicability of the Nafion-coated electrodes for determination of these drugs. The drugs induced the decrease in the oxidation peak current for FA^+ as was observed for hexamethonium. Figure 4 demonstrates the relationship between the $i_p/i_{p,o}$ value (where i_p and $i_{p,o}$ are the peak currents with and without drugs, respectively) and the concentration of the several drugs in the electrolyte solution. All drugs investigated here show a clear increase in the $i_p/i_{p,o}$ value in the fairly low concentration ranges of the drugs. Therefore, the concentration of a drug can be determined by using these curves. The detection limits of the drugs in the present procedure are as follows: hexamethonium, 2×10^{-7}; quinidine, 5×10^{-7}; neostigmine, 2×10^{-6}; nicotine, 1×10^{-5}; acetylcholine, 5×10^{-5} mol dm^{-3}.

In these measurements, the cyclic voltammograms were recorded after 5 min of immersion of the Nafion-coated electrode into the sample solution containing a specific amount of a drug. Hexamethonium, acetylcholine and neostigmine equilibrated fairly rapidly and a near equilibrium state was obtained after 5 min of immersion. Only small changes in the voltammetric peak current were observed on the subsequent scans. However, ca. 30 min was necessary to reach a near equilibrium state for quinidine. These differences in the equibration time seem to be mainly dependent on the size of the cation. For analytical purposes it is not necessary to obtain equilibrium response. The same measurements were carried out using a number of Nafion-coated GC electrodes. The results were quite reproducible and the variations of the relative peak current under different runs were within 5%. When the Nafion-coated GC electrode used for these measurements was transferred to the electrolyte solution containing 7.2×10^{-6} mol dm^{-3} FA^+ without any drug, the anodic peak current recovered to its original value. The Nafion film on the GC surface seems to be quite stable and the electrode can be used at least for several times.

Influence of the Added Drugs on the Apparent Half-wave Potentials and Voltammetric Shapes. The apparent half-wave potential ($E_{1/2,app}$) of FA^+ on the Nafion-coated GC is dependent on the loading level of

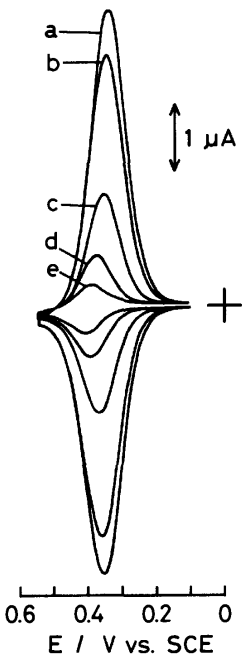

Fig. 3. Cyclic voltammograms of FA^+ in the presence of hexamethonium on the Nafion coated GC in 0.1 mol dm^{-3} Na_2SO_4. Concentration of FA^+ in the solution: 7.2×10^{-6} mol dm^{-3}. Concentration of hexamethonium in the electrolyte solution: a, 0; b, 1.0×10^{-6}; c, 1.0×10^{-5}; d, 1.0×10^{-4}; e, 1.0×10^{-3} mol dm^{-3}. Scan rate: 0.05 V s^{-1}.

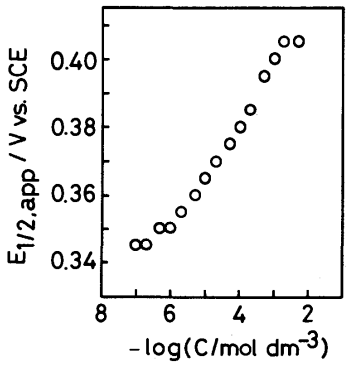

Fig. 5. Relationship between $E_{1/2,app}$ and concentration of hexamethonium in the electrolyte solution.

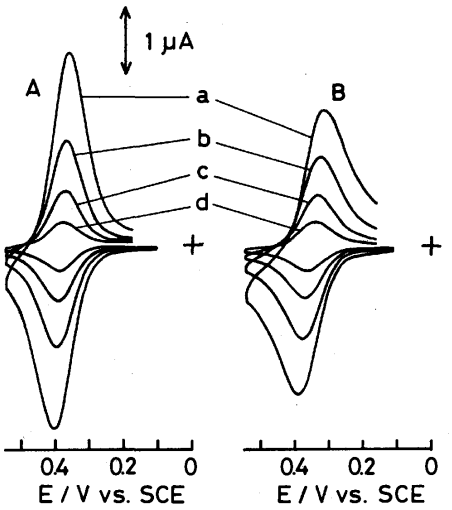

Fig. 6. Cyclic voltammograms of FA^+ on the Nafion coated GC in the presence of 2.0×10^{-4} mol dm^{-3} hexamethonium (A) and 2.0×10^{-5} mol dm^{-3} quinidine (B) in pH 7.0 phosphate buffer. Scan rate: a, 0.2; b, 0.1; c, 0.05; d, 0.02 V s^{-1}. Concentration of FA^+ in the solution: 7.2×10^{-6} mol dm^{-3}.

hexamethonium. Figure 5 shows the relationship between the $E_{1/2,app}$ value and the concentration of hexamethonium in the electrolyte solution. This concentration dependence corresponds well to that of the relative peak current shown in Fig. 4. The half-wave potential (0.34 V vs. SCE) observed on the Nafion-coated GC without hexamethonium is negative compared with the value on a bare GC (0.392 V vs. SCE). The $E_{1/2,app}$ value shifts to positive potentials with increasing concentration of hexamethonium and surpasses the value on a bare GC at hexamethonium concentration higher than 10^{-3} mol dm^{-3}. At the low concentration of hexamethonium, the $E_{1/2,app}$ value is governed by the stabilization[15-19] of the oxidized FA^+ by the favorable electrostatic interaction of the divalent cation (FA^{2+}) with the sulfonato groups in Nafion film. However, the incorporation of hexamethonium into the hydrophilic phase in the Nafion film provides a more hydrophobic environment relative to the original state.[19] This environmental change obviously destabilizes the highly charged species, which implies a positive shift of the $E_{1/2,app}$ of FA^+ entrapped in the Nafion film. Therefore, the shift in $E_{1/2,app}$ is caused by the compensation of extra stability due to electrostatic interaction by the increasing hydrophobicity of the ionic cluster.[19] This trend was also observed for other drugs.

The incorporation of bulky drugs also caused changes in the cyclic voltammetric shapes of FA^+. In Fig. 6 are shown the cyclic voltammograms of FA^+ on the Nafion-coated GC electrodes in the presence of hexamethonium (2.0×10^{-4} mol dm^{-3}) and quinidine (2.0×10^{-5} mol dm^{-3}). The peak heights at 50 mV s^{-1} are about two-tenth of those in the absence of the drugs. A significant difference in the cyclic voltammetric shape was observed. The voltammogram in the presence of quinidine in solution shows obvious diffusional tails after the anodic and cathodic peaks. In addition, the peak separation in this case was ca. 50 mV at 100 mV s^{-1}, which can be compared to ca. 20 mV observed in the original voltammogram. The peak separation gradually increased with increasing concentration of quinidine. These changes in the voltammetric shape are probably caused by the decrease in the apparent diffusion coefficient of FA^+ in the Nafion film since the anodic peak current is no longer linearly dependent on the scan rate. The incorporation of bulky quinidine into the ionic cluster will decrease the hydrodynamic mobility of FA^+ in the hydrophilic region.[19] Therefore, the cyclic voltammetric shape alters from the thin-layer behavior to the diffusion-controlled situation. On the other hand, such an effect on the cyclic voltammetric shape in the presence of hexamethonium in solution is small, suggesting no severe influence of entrapped hexamethonium on the ionic movement of FA^+ in the hydrophilic region. Similarly only small changes in the shape were observed when acetylcholine, neostigmine and nicotine were added to the electrolyte solution. The above may be a reason for the difference in curvature for quinidine in Fig. 4 as compared with those for other drugs.

Ion-Selectivity Coefficient for the Drugs. The present procedure for determination of cationic drugs is based on the competitive partitioning effect between FA^+ and the drug into Nafion, and thus the detection limits are largely dependent on the strength of the interaction. In order to obtain quantitative feature of the drug-Nafion interaction, the determination of steady-state concentration was also carried out. The strength of the interaction can be expressed by the ion-exchange selectivity coefficient, K^D_{Na},[2] which is the equilibrium constant for the following ion-exchange reaction:

$$D^{n+} + n(SO_3^-Na^+)_{Naf} \rightleftharpoons [(SO_3^-)_nD^{n+}]_{Naf} + nNa^+ \quad (1)$$

and given by

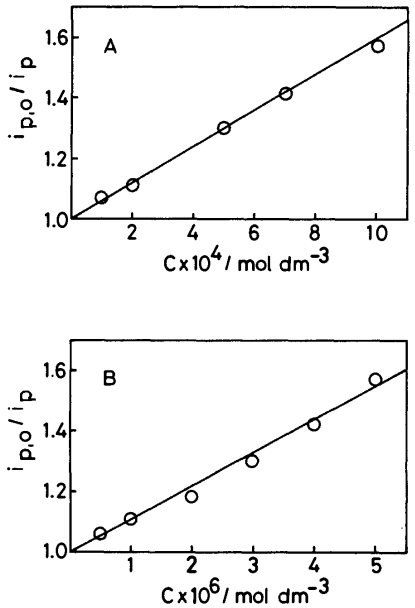

Fig. 7. Relationship between the $i_{p,o}/i_p$ value and concentration of acetylcholine (A) and quinidine (B) in pH 7.0 phosphate buffer. Concentration of FA^+ in the electrolyte solution: 1.0×10^{-5} mol dm^{-3}. Scan rate: 0.05 V s^{-1}.

Table 1. Ion-Selectivity Coefficients for Ammonium Drugs

Drug	Ion-selectivity coefficient
Acethylcholine	5.6×10^2
Hexamethonium	2.0×10^5
Qunidine	1.0×10^5
Neostigmine	2.8×10^4
Nicotine	3.7×10^3
FA^+	$7.3\times10^{4a)}$

a) From Ref. 2.

$$K^D_{Na}=x_D(C_{Na})^n/(x_{Na})^nC_D \quad (2)$$

where C_{Na} and C_D are the concentrations of Na^+ and a drug in an aqueous solution and x_{Na} and x_M are the equilibrium ionic fractions of $-SO_3^-$ sites occupied by each ion, respectively. Thus, for monocationic drugs the following simple equation is derivated:

$$x_{FA,o}/x_{FA}=K^D_{Na}C_D/(C_{Na}+K^{FA}_{Na}C_{FA})+1 \quad (3)$$

where $x_{FA,o}$ and x_{FA} represent the x values for FA^+ without and with a drug, respectively. The $x_{FA,o}/x_{FA}$ value is directly proportional to the ratio of the peak current, $i_{p,o}/i_p$ observed at a steady-state. Figure 7 shows the plots for $i_{p,o}/i_p$ vs. concentrations of quinidine and acetylcholine at low concentration ranges. The plots show quite good linearity and the K^D_{Na} values can be determined from the slopes of the plots by using the K^{FA}_{Na} value (7.3×10^4) reported by Szentirmay and Martin.[2] Since the experimental points deviated from the line at high concentration ranges, the measurements were restricted in the relatively low concentration ranges. The deviation may be indicative of a structural change of Nafion. Hexamethonium is a dicationic drug and the plot does not show a linear relationship. The K^D_{Na} value in this case has been determined by a curve fitting between the experimental and theoretical current ratios. Table 1 shows the ion-selectivity coefficients. It is obvious that these drugs have strong affinity with Nafion. The K^D_{Na} value seems to be related with the hydrophobicity of the drugs. In a series of monocationic drugs, relatively hydrophobic quinidine shows a large value, whereas hydrophilic actylcholine shows a small value.

Since all of these drugs employed here are electroinactive in a practical potential range, the determination by a direct electrochemical method is difficult. In addition, neither acetylcholine nor hexamethonium has a chromophore in the molecule and thus the determination by absorption spectroscopy will also be difficult. It should be emphasized that the simple method proposed here can be used for determination of these drugs and will be applicable to many cationic drugs.

Alkaline Hydrolysis of *N*-Methyl-2,4-dinitroacetanilide and *N*-Alkyl-*N*-(5-nitro-2-pyridyl)acetamides

Atsushi KIJIMA and Shizen SEKIGUCHI*
Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Kiryu, Gunma 376
(Received November 21, 1986)

The kinetics of the alkaline hydrolysis of *N*-methyl-2,4-dinitroacetanilide (**2**), *N*-ethyl- (**3**), and *N*-methyl-*N*-(5-nitro-2-pyridyl)acetamide (**4**) was carried out. The reaction path consists of two stages: the first one is the rate-limiting formation of the first tetrahedral intermediate (monoanionic) and the second one the fast decomposition of the intermediate. The latter fast decomposition of the intermediate (monoanionic) involves two processes: one is the direct decomposition of the intermediate to the products and the other is a proton abstraction of the hydroxyl group of the intermediate by $^-$OH giving the second tetrahedral intermediate (dianionic), followed by its deconposition to the products. For the alkaline hydrolysis of **2**—**4**, the decomposition of the first intermediate occurred predominantly via the latter process.

Many reports and reviews have so far appeared on the alkaline hydrolysis of amides.[1] In particular the alkaline hydrolysis of acetanilides has been extensively studied by Schowen et al.,[2-6] Pollack and Bender,[7] Dewolfe and Newcomb,[8] and Eriksson et al.[9] The alkaline hydrolysis of amides is generally considered to be sensitive to both polar and steric effects of acyl substituents. We have already reported the alkaline hydrolysis of *N*-ethyl-2,4-dinitroacetanilide (**1**) and found that the substituents on the amido nitrogen atom and on the phenyl moiety considerably affect its rate of hydrolysis.[10] Although previous studies involved the effects of substituents on the amido nitrogen atom and ring carbon atom of acetanilides, there have been few cases in which both effects are considered[2-9] simultaneously.

This paper reports the effects of substituents of the following acetanilide and *N*-pyridylacetamides on their rates of alkaline hydrolyses to elucidate the nature of these effects (inductive or steric).

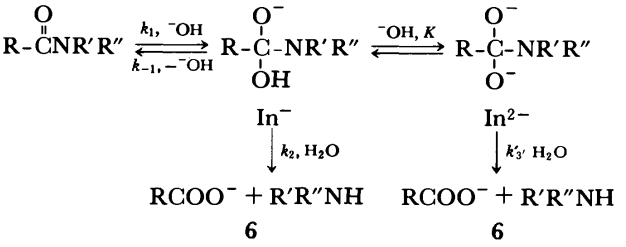
Results and Discussion

Absorption Spectra. The time-dependent spectral changes were measured in the reactions of **2** with excess NaOH (Fig. 1). The spectral change was found to be moderate for the reaction rate to be measured, where the absorption (d) was due to *N*-methyl-2,4-dinitroaniline (Fig. 1). For **3** and **4**, similar changes were observed (not shown).

From these results and much information obtained so far,[1-10] the reaction sequence is shown in Scheme 1 in unbuffered solutions.

Order of Reaction. The kinetic order with respect to [NaOH] is important for considering the reaction



Scheme 1.

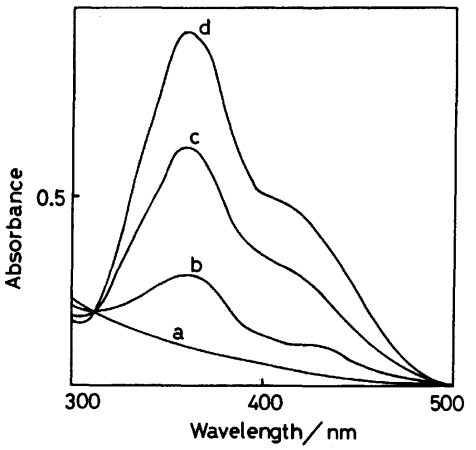


Fig. 1. Time-dependent spectral change in the alkaline hydrolysis of *N*-methyl-2,4-dinitroacetanilide (**2**) at 30°C {[$^-$OH] 0.1 M}: a **2** (3.0×10^{-5} M); b 10 min after addition of NaOH; c 45 min; d 19 h.

mechanism. The relationships between log k_ψ (pseudo first-order rate constant) and log[$^-$OH] (Table 1), therefore, are shown in Fig. 2, together with those of **1** and 4-nitroacetanilide (**7**).[7]

For **7**, the slope varied from ca. 2 at log [$^-$OH] $\leqslant$ ca. -1.0 to ca. 1 at log [$^-$OH] $\geqslant$ ca. -1.0, which shows that at lower log [$^-$OH] the decomposition of In^- to In^{2-} is rate-limiting, whereas at higher log [$^-$OH] the addition of $^-$OH to the carbonyl carbon atom of an amido group is rate-limiting (refer to Eq. 1).

On the other hand, for **1**—**4** the slope was ca. 1 in the

a) [Substrate]$_0$ 2.5×10^{-5} M; μ 0.8 M (NaCl); solvent H_2O–CH_3CN (99.95/0.05 v/y). b) Estimated limit of error ±0.5% for observed k_ψ. c) These k_ψ values were calculated by substituting the data in Table 2 into Eq. 1.

range of [⁻OH] studied, indicating the addition of ⁻OH to the carbonyl carbon atom to be rate-limiting. As will be discussed later, **1**—**4** have an alkyl group on the amide nitrogen atom. This is also expected to exert steric hindrance, in addition to the inductive effect, toward the carbonyl carbon atom in the transition state for formation of In⁻. These effects, therefore, would be expected to make In⁻ less stable.

Rate Constants. According to Scheme 1, the alkaline hydrolysis is catalyzed by ⁻OH to produce the tetrahedral intermediate (In⁻), followed by its decomposition to the products. By applying the steady-state approximation to the concentration of In⁻, the mechanism leads to Eq. 1 for the observed pseudo first-order rate constant, k_ψ, for alkaline hydrolysis (Table 1). In Eq. 1, k_3 (Table 2) means Kk_3'. At present, it is not clear whether the K and k_3' steps are stepwise or simultaneous. Eq. 2 is derived by dividing both sides of Eq. 1 by [⁻OH]. Therefore, the relationship between k_ψ/[⁻OH] and [⁻OH] should be convex upward (not shown),

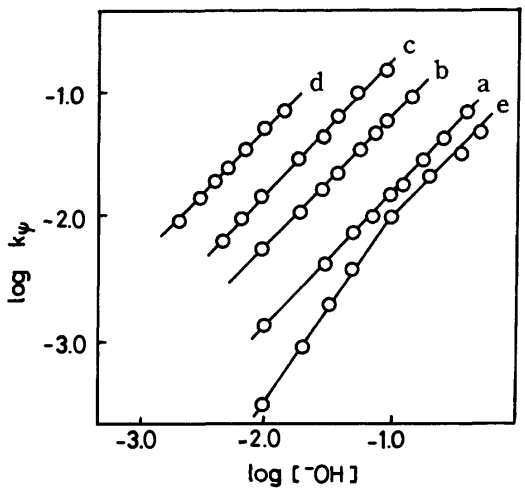

Fig. 2. Relationship between log k_ψ and log[$^-$OH] in the alkaline hydrolyses of acetanilides and pyridylacetamides; a **1** (20 °C); b **2** (60 °C); c **3** (50 °C); d **4** (60 °C); e **7** (25 °C).

which shows the validity of Scheme 1. As a result, k_1 can be obtained as $k_\psi/[^-OH]$ ($=k_1$), when [$^-$OH] is much higher in Eq. 1. Eq. 2 is further derived by rearranging

$$k_\psi = k_1[^-OH]\cdot\frac{k_2+k_3[^-OH]}{k_{-1}+k_2+k_3[^-OH]} \quad (1)$$

$$\frac{k_\psi}{[^-OH]} = k_1\cdot\frac{a+b[^-OH]}{1+a+b[^-OH]} \quad (2)$$

$$a=\frac{k_2}{k_{-1}};\ b=\frac{k_3}{k_{-1}};\ k_3=Kk_3'$$

Eq. 1. Then, the relationship between $k_\psi/(k_1[^-OH]-k_\psi)$ and [$^-$OH] is expected to be linear (Fig. 3). By substituting the k_1 value determined above into Eq. 2, a and b can be estimated from the intercept and slope of the straight line. These k_1, a, and b values were used as the initial ones to calculate k_1, a, and b more accurately. The k_1, a, and b values in Table 2 were derived from Eq. 2 by using the initial values (k_1, a, and b), obtained above, and the non-linear least squares method (Program: SALT Model-F[11]).

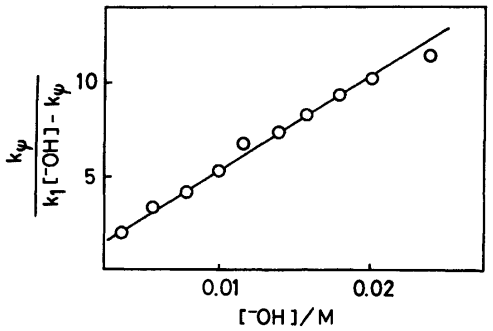

Fig. 3. Relationship between $k_\psi/(k_1[^-OH]-k_\psi)$ and [$^-$OH] in the alkaline hydrolysis of *N*-methyl-2,4-dinitroacetanilide (**2**) at 60 °C [μ 0.8 M (NaCl)].

By applying a similar method to **3** and **4**, the rate constants were determined.

(1) k_1 Values. The k_1 ratio (**2**/**1**) is ca. 2.8, being comparable to ca. 3.3 for that (**4**/**3**) (Run 1, 3, 5, and 6), from which it was found that on changing from an ethyl to a methyl group on the amido nitrogen atom the extent of release of steric compression is similar in both the *N*-pyridylacetamide and the acetanilide. These values are close to the $k_1^{CH_3}/k_1^{C_2H_5}$ values for the alkaline hydrolysis of methyl and ethyl acetates (ca. 2.3 at 0.6—20 °C in 62% acetone-H_2O[12]) and of methyl and ethyl lactates (2.4 at 0 °C in H_2O).[13] These rate ratios are due almost entirely to the inductive effect of the alkyl groups.[12]

As for the k_1 ratio due to the change in the acyl component of esters, Evans et al.[14] showed the $k_1^{CH_3}/k_1^{C_2H_5}$ values of ca. 1.6—1.7 for the alkaline hydrolyses of ethyl acetate and propanoate, and Taft[15] reported 2.0 as a statistical value for the rate ratio of the same esters, which are a little smaller than those described above.

From Table 2 the k_1 value for acetanilide is smaller than that for the corresponding *N*-pyridylacetamide: the k_1 ratio is 7.0 (**3**/**1**) and 8.3 (**4**/**2**) (Run 5 and 1, and 6 and 3). These rate ratios are clearly due to the steric hindrance of 2-substituent toward the steric crowding in the transition state for formation of In$^-$.[10]

On the other hand, Pratt[16] has reported the k_1 value for the alkaline hydrolysis of *N*-methyl-4-nitroacet-

Table 2. Rate Constants and Rate Ratios for the Alkaline Hydrolyses of *N*-Methyl-2,4-dinitroacetanilide (**2**) and *N*-Alkyl-*N*-(5-nitro-2-pyridyl)acetamide (**3** and **4**)

Run No.	Substrate	Temp °C	k_1[a] $M^{-1}min^{-1}$	$a(k_2/k_{-1})$[a]	$b(k_3/k_{-1})$[a] M^{-1}
1	**1**[b]	60	0.460	2.03	5.25
2	**2**	50	0.649	6.95	209
3		60	1.28	0.255	459
		70	2.11	—	—
4	**3**[c]	50	1.71	6.12	238
5		60	3.26	3.22	376
6	**4**[d]	60	10.7	2.23	3484

a) Estimated limit of error ±1.0% for k_1; ±1.3% for a and b. b) *N*-Ethyl-2,4-dinitroacetanilide; cited from Ref. 10. c) *N*-Ethyl-*N*-(5-nitro-2-pyridyl)acetamide. d) *N*-Mehyl-*N*-(5-nitro-2-pyridyl)acetamide.

anilide (**8**) to be 0.0408 M^{-1} min^{-1} ($l\,m^{-1}$ $mol\,dm^{-3}$) at 25 °C, which is smaller than the k_1 value (0.119 M^{-1} min^{-1} at 25 °C) for **2**, derived from the temperature-dependence of log k_1 (E_a=54.8 kJ mol^{-1}).

These results show that the inductive effect (accelerating effect) of 2-NO_2 group is superior to its steric hindrance (retarding effect).

(2) *a* and *b* Values. The b/a value (k_3/k_2) is 2.5 (60 °C) for **1**, and 30 (50 °C) and 1800 (60 °C) for **2**. It is 39 (50 °C) and 117 (60 °C) for **3**, and 1562 (60 °C) for **4**.

From these results, the decomposition of In^- is seen to take place predominantly via the K and k_3' stages, together by considering the b/a value (138 at 30 °C in H_2O) of 4-nitroacetanilide (**7**)[8] and other related acetanilides with electron-withdrawing 4-substituents.[17]

In the case of acetanilide or *N*-pyridylacetamides with electron-withdrawing substituents on the aniline or pyridine moiety, the acidity of the hydroxyl group of In^- becomes stronger,[6] which would make In^- decompose via the K and k_3' stages more often than via the k_2 stage.

Further, on changing from an ethyl to a methyl group on the amido nitrogen atom, the k_3/k_2 (b/a) value increases (2.5 for **1** to 1800 for **2**, and 117 for **3** to 1562 for **4** at 60 °C).

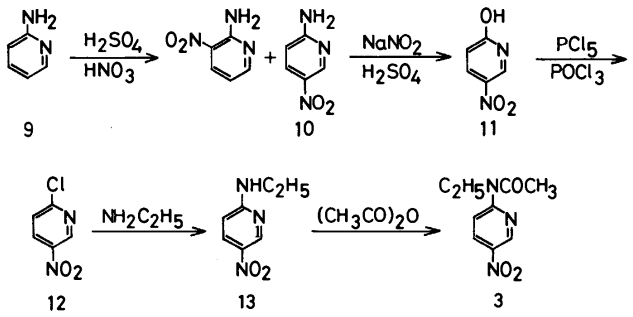
These results indicate that In^- of the substrate with an *N*-methyl group is more stable than In^- of the one with an *N*-ethyl group, because in the former the steric compression is less. Then, proton abstraction of In^- by ^-OH could occur more frequently, that is, the possibility that In^- decomposes to products via the K and k_3' stages would increase.

In conclusion it is found that in the alkaline hydrolysis of nitro-substituted acetanilides or *N*-pyridylacetamides the substituents on the amido nitrogen atom electronically affect the rate of hydrolysis, and those at the 2-position of a ring do so sterically, as well as electronically.

Experimental

Materials. *N*-Methyl-2,4-dinitroacetanilide (2). *N*-Methyl-2,4-dinitroaniline (NMDA) was synthesized from 2,4-dinitrochlorobenzene and methylamine according to the method of Bogoslovskii and Tsil'man[18] (yield 75.1%; recryst. solvent ethanol), mp 174—175 °C (lit,[18] 176—177 °C). The compound **2** was synthesized from NMDA and acetic anhydride in the presence of a small amount of concd. H_2SO_4 (three or four drops) as described in the literature:[10] Yield 63.4%; mp 75—76 °C; ^1H NMR (DMSO-d_6, 60 MHz) δ= 2.17 (3H, s, acetyl CH_3), 3.48 (3H, s, N-CH_3), 7.07 (1H, d, J=4 Hz, ring H^6), and 8.70 (2H, m, ring H^3 and H^5 overlapped). Anal. ($C_9H_9N_3O_5$) C, H, N.

***N*-Ethyl-*N*-(5-nitro-2-pyridyl)acetamide (3).** The synthetic sequence was shown in Scheme 2.



Scheme 2.

9 → 10. Into a 120 ml solution of concd H_2SO_4 was dissolved 2-aminopyridine (27 g, 0.29 mol) by portions under stirring below 90 °C, and the solution was cooled to 0 °C. Then, into this stirred solution was added the cooled mixed acid (concd HNO_3 19.5 ml and concd H_2SO_4 21 ml) at 10 to 20 °C. Stirring was continued and the temperature rose to 65 °C. The mixture was then poured onto 500 ml of ice water and neutralized with Na_2CO_3, giving the precipitate (raw **10**). It was separated by filtration and dried. Althogh it included a small amount of 2-amino-3-nitropyridine, it was used in the next procedure without purification.

10 → 11. To a solution of 24.9 ml of concd. H_2SO_4 in 358 ml of H_2O was added 23.1 g (0.166 mol) of crude **10**, into which 98 g of ice was added. Subsequently a solution of 12.8 g (0.186 mol) of $NaNO_2$ in 40 ml of H_2O was added dropwise under stirring at 0 °C, the solution was stirred for an additional 30 min, and filtered. Recrystallization of the precipitates from H_2O gave 11.9 g (51.2%) of pure **11**: mp 182.5—183.5 °C. Anal. ($C_5H_4N_2O_3$) C, H, N.

11 → 12. To a mixture of 11.9 g (0.085 mol) of **11** and 35 g (0.168 mol) of PCl_5 was added sufficient $POCl_3$ to just cover the mixture. After the mixture was refluxed (at 110 °C) for 3 h, the $POCl_3$ was distilled off under reduced pressure. To the residue was added 144 ml of cooled H_2O, and it was neutralized with NaOH. After the mixture was filtered off, recrystallization of the precipitate from ethanol gave 12.0 g (89.1%) of pure **12**: mp 106—108 °C. Anal. ($C_5H_3ClN_2O_2$) C, H, N.

12 → 13. A solution of 7.9 g (0.05 mol) of **12** in 150 ml of DMSO was added dropwise to a stirred solution of 120 ml $C_2H_5NH_2$ (0.725 mol) in 82.8 ml of DMSO. After the mixture was stirred for 5 h at room temperature, it was neutralized by pouring into a cooled aqueous solution of dilute H_2SO_4 and filtered. Recrystallization of the precipitate from ethanol gave 5.9 g (71.1%) of pure **13**: mp 117—119 °C. Anal. ($C_7H_9N_2O_2$) C, H, N.

13 → 3. After a mixture of 1.5 g (0.009 mol) of **13**, 2 ml of acetic anhydride, and 2 ml of gracial acetic acid was refluxed for 9.5 h, and then the solvent was distilled off under reduced pressure. Recrystallization of the residue from ethanol gave 1.55 g (93%) of **3**: mp 60—61 °C; ^1H NMR (DMSO-d_6, 60 MHz) δ=1.17 (3H, t, *N*-ethyl CH_3), 2.27 (3H, s, acetyl CH_3), 4.05 (2H, q, *N*-ethyl CH_2), 7.87 (1H, d, $J_{H^3\text{-}H^4}$=7.0 Hz, ring H_3), 8.66 (1H, d with each peak finely and doubly split, $J_{H^3\text{-}H^4}$=7.0 Hz, ring H^4), and 9.28 (1H, finely-split d, $J_{H^4\text{-}H^6}$=2 Hz, ring H^6). Anal. ($C_9H_{11}N_3O_3$) C, H, N.

***N*-Methyl-*N*-(5-nitro-2-pyridyl)acetamide (4).** According to the similar method to **3**, **4** was synthesized: mp 96.5—97 °C; ^1H NMR (DMSO-d_6, 60 MHz) δ=2.25 (3H, s, acetyl CH_3), 3.30 (3H, s, N-CH_3), 7.70 (1H, d, $J_{H^3\text{-}H^4}$=7.0 Hz, ring H^3), 8.51 (1H, d with each peak finely and doubly split, $J_{H^3\text{-}H^4}$=7.0 Hz, ring H^4), and 9.11 (1H, finely-split d, $J_{H^4\text{-}H^6}$=2 Hz, ring H^6). Anal. ($C_8H_9N_3O_3$) C, H, N.

Rate Measurements. A sample solution was prepared as follows: After 1.5 μl of an acetonitrile solution of an amide

(0.1 M) was added to a quartz cell containing 3 ml of the prescribed concentration of an aqueous sodium hydroxide solution kept at the constant ionic strength (0.8 M NaCl), the time-dependent increase in the absorption maximum of the corresponding aniline formed were measured with a Hitachi 124 spectrophotometer.

Rate constants were calculated by the Guggenheim method.[19]

Synthesis and Structural Studies of Remirol

Seiji YAMAGUCHI, Mayumi TAKAI, Isao HANAZOME, Yûko OKADA, and Yoshiyuki KAWASE*
Department of Chemistry, Faculty of Science, Toyama University, Gofuku 3190, Toyama 930
(Received January 21, 1987)

One step cyclization of 2′,4′,6′-trihydroxyacetophenone with 1,4-dibromo-2-methyl-2-butene gave two 2-isopropenyl-2,3-dihydrobenzofuran-4,6-diols and a new 3-methyl-2,5-dihydro-1-benzoxepin-6,8-diol. The structure of natural remirol was confirmed by comparison with monomethylated compounds of the former products. Racemic remirol was synthesized from 3,5-dimethoxyphenol in three steps.

In 1969, Allan et al. isolated a new dihydrobenzofuran from *Remiria maritima* and proposed a structure of 5-acetyl-2-isopropenyl-6-methoxy-2,3-dihydrobenzofuran-4-ol (**1**).[1] A positive Gibbs test was the only reason to propose the structure, and so some possibilities of other structure, 5-acetyl-2-isopropenyl-4-methoxy-2,3-dihydrobenzofuran-6-ol (**2**) or 7-acetyl-2-isopropenyl-4-methoxy-2,3-dihydrobenzofuran-6-ol (**3**), remained for remirol. In this paper, we describe a synthesis and structural reconsideration of remirol.

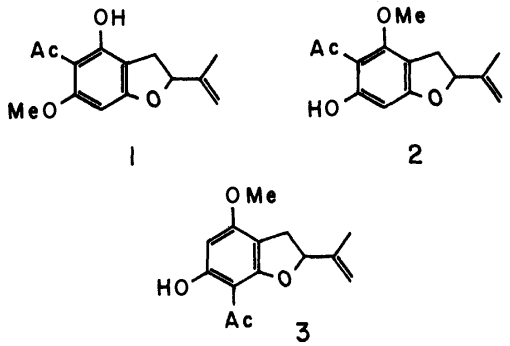

Chart 1.

Cyclization of 2′,4′,6′-trihydroxyacetophenone with 1,4-dibromo-2-methyl-2-butene was already reported by two groups.[2,3] Nickl obtained 7-acetyl-2-isopropenyl-2,3-dihydrobenzofuran-4,6-diol (**5**) in cyclization of the sodium salt of the phenol in cold methanol.[2] Bigi et al. isolated two dihydrobenzofurans, 5-acetyl-2-isopropenyl-2,3-dihydrobenzofuran-4,6-diol (**4**) and **5**, in cyclization of the potassium salt in refluxing toluene.[3] We have reinvestigated these two methods and found that Nickl's method gave a mixture, different from Bigi's, containing 9-acetyl-3-methyl-2,5-dihydro-1-benzoxepin-6,8-diol (**6**). This evidence shows that a different cyclization proceed in a different solvent; the cyclization in nonpolar toluene occurred at 2′- and 4′-hydroxyl groups, while the cyclization in polar methanol occurred mainly at the 2′-hydroxyl group. We have already reported that a similar cyclization of 2′,6′-dihydroxyacetophenone gave a mixture of corresponding dihydrobenzofuran and dihydrobenzoxepin in nonpolar toluene.[4] In these two cases dihydrobenzoxepin derivatives were obtained. Further studies are necessary to establish the formation mechanism of the dihydrobenzoxepin derivatives. In the ^{1}H NMR spectra, two isopropenyldihydrobenzofurans **4** and **5** showed ABX coupling patterns due to protons in their dihydrofuran ring, while **6** showed another coupling mode of the oxepin ring part. The spectral mode of **6** was similar to those of some natural 3-methyl-2,5-dihydro-1-benzoxepin derivatives.[5] Hydrogenation of **6** gave a mixture of 9-acetyl-3-methyl-2,3,4,5-tetrahydro-1-benzoxepin-6,8-diol (**7**) (mp 117—118 °C) and 2′,4′,6′-trihydroxy-3′-(3-methylbutyl)acetophenone (**8**). Nickl already reported that hydrogenation of **5** gave a dihydro compound (mp 153—156 °C) and **8**. The dihydro compound **7** derived from **6** showed only one doublet methyl at δ 0.94 in ^{1}H NMR sectrum. This evidence shows that **6** was not a dihydrobenzofuran derivative but a 3-methyl-2,5-dihydro-1-benzoxepin derivative. In their methylation with diazomethane, **4** gave two mono-methylated

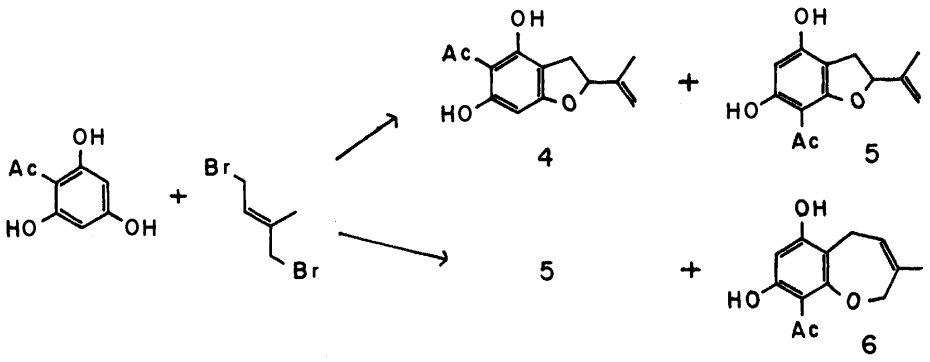

Chart 2.

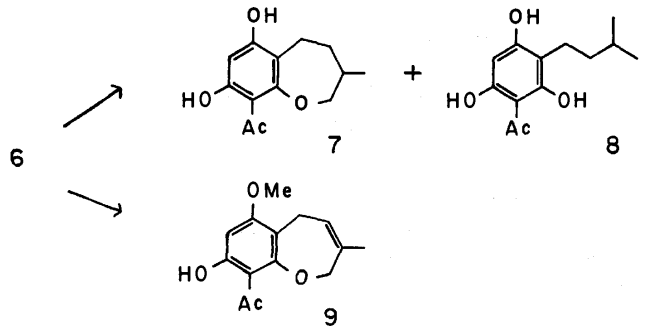

Chart 3.

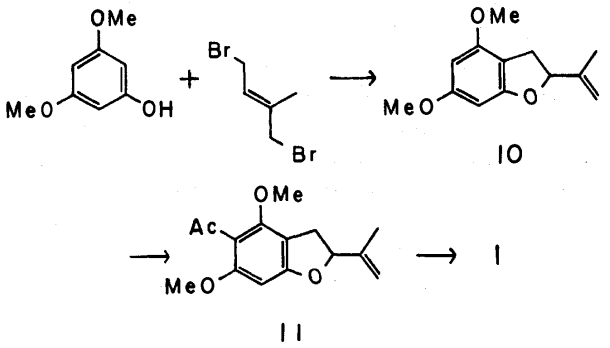

Chart 4.

compounds **1** and **2**, while **5** gave only one monomethylated compound **3**. The methylation of a dihydrobenzoxepin **6** gave one monomethylated compound, 9-acetyl-6-methoxy-3-methyl-2,5-dihydro-1-benzoxepin-8-ol (**9**). Each structure of these monomethylated dihydrobenzofurans **1**—**3** was confirmed by NOE measurements in their ^{1}H NMR spectra. In irradiations at methoxy protons, **1** and **3** showed 39 and 35% area increases, respectively, in their aromatic proton signals (7-H in **1** and 5-H in **3**), but **2** showed only +3 and +4% increases in the two methylene proton signals (3-H). In the UV spectra, **1** and **2** were comparable with 5-acetyl-2-isopropenyl-2,3-dihydrobenzofuran-4-ol and 5-acetyl-2-isopropenyl-2,3-dihydrobenzofuran-6-ol, respectively, while **3** and **9** were comparable with 7-acetyl-2-isopropenyl-2,3-dihydrobenzofuran-6-ol.[4,6] Thus, each structure of the four monomethylated compounds **1**—**3** and **9** was confirmed. The structure of natural remirol whose spectral data were identical with those of **1**, was confirmed to be 5-acetyl-2-isopropenyl-6-methoxy-2,3-dihydrobenzofuran-4-ol.

By a similar procedure,[7] 2-isopropenyl-4,6-dimethoxy-2,3-dihydrobenzofuran (**10**) was prepared from 3,5-dimethoxyphenol and 1,4-dibromo-2-methyl-2-butene. Acylation of **10** with acetic acid and trifluoroacetic anhydride gave only one acylated product, 5-acetyl-2-isopropenyl-4,6-dimethoxy-2,3-dihydrobenzofuran (**11**). Demethylation of **11** with magnesium iodide etherate gave only one demethylated product, the spectrum of which was identical with **1** and natural remirol. This shows that the acylation of **10** occurred only at the 5-position and the demethylation of **11** occurred only at the 4-methoxyl group. It is interesting that the demethylation of **11** occurred only at the 4-methoxyl group, while monomethylation of **4** occurred at two hydroxyl groups with almost equal probability. By this way, racemic remirol was effectively synthesized from 3,5-dimethoxyphenol in three steps.

Experimental

The boiling points (1 mmHg=133.322pa) and melting points are uncorrected. The IR spectra were measured on a Hitachi EPI-S2 spectrophotometer in KBr disks or liquid films, and UV spectra were taken on a Hitachi 220A spectrophotometer in ethanol. The ^{1}H NMR spectra were recorded on a JEOL JNM-MH-60 NMR spectrometer, a JEOL JNM-FX90Q FT NMR spectrometer, or Varian XL-200 FT NMR spectrometer, Mass spectra were determined on a JEOL JMS-OISG-2 mass spectrometer.

Cyclization of 2′,4′,6′-Trihydroxyacetophenone with 1,4-Dibromo-2-methyl-2-butene by Nickl's Procedure.[2] A solution of the sodium salts was prepared by mixing 2′,4′,6′-trihydroxyacetophenone monohydrate (9.95 g, 53.5 mmol) and sodium methoxide (prepared from 2.78 g, 121 mmol of sodium metal) in methanol (200 mL). To the solution , 1,4-dibromo-2-methyl-2-butene (15.5 g, 64.3 mmol) was added and the mixture was stirred at room temperature for 20 h. After removal of the methanol under reduced pressure, the mixture was acidified with 10% hydrochloric acid and extracted with ether. The ethereal layer was extracted with 10% sodium hydroxide solution. The sodium hydroxide solution was acidified with 10% hydrochloric acid and extracted with ether. After removal of the ether, the residue was chromatographed on a silica-gel column to give 7-acetyl-2-isopropenyl-2,3-dihydrobenzofuran-4,6-diol (**5**) (0.90 g, 7.2%) and 9-acetyl-3-methyl-2,5-dihydro-1-benzoxepin-6,8-diol (**6**) (1.48 g, 11.8%). The compounds isolated showed the following data. **5**: mp 185—186 °C (from benzene)(lit,[3] 178—182 °C); IR 1640 cm^{-1}; UV 228.5 (log ε=4.07), 286 (4.26), 327 nm (3.58); ^{1}H NMR (acetone-d_6) δ=1.8 (3H, broad s), 2.6 (3H, s), 3.0 (1H, dd, J=15 and 8 Hz), 3.2 (1H, dd, J=15 and 9.5 Hz), 5.0 (1H, broad s), 5.2 (1H, broad s), 5.5 (1H, dd, J=9.5 and 8 Hz), 6.0 (1H, s), 13.4 (1H, s); all spectra were identical with Bigi's. **6**: mp 192—193 °C (from benzene); IR 1630 cm^{-1}; UV 223.5 (log ε=4.05), 284 (4.11), 328 nm (3.66); ^{1}H NMR (acetone-d_6) δ=1.6 (3H, broad s), 2.7 (3H, s), 3.4 (2H, broad m), 4.6 (1H, broad s), 5.7 (1H, broad m), 6.3 (1H, s), 13.6 (1H, s); MS m/z 234 (M^+), 219, 201. Found: C, 66.56, H, 6.11%. Calcd for $C_{13}H_{14}O_4$: C, 66.65, H, 6.02%.

Hydrogenation of 6. A solution of **6** (330 mg, 1.41 mmol) in ethyl acetate (20 mL) was stirred with Adams catalyst (100 mg) under a hydrogen atmosphere. After the absorption of hydrogen ceased, the catalyst was filtered off. After removal of the ethyl acetate, the residue was chromatographed on a silica-gel column to give 9-acetyl-3-methyl-2,3,4,5-tetrahydro-1-benzoxepin-6,8-diol (**7**) (106 mg, 32%) and 2′,4′,6′-trihydroxy-3′-(3-methylbutyl)acetophenone (**8**) (84 mg, 25%). These two compounds showed following data. **7**: mp 117—118.5 °C (from cyclohexane-benzene); IR 1620 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.94 (3H, d, 3-CH_3), 1.22 (1H, m, 4-Hax), 1.96 (1H, m, 4-Heq), 2.18 (1H, m, 3-Hax), 2.50 (1H, dd, 5-Hax), 2.66 (3H, s, -$COCH_3$), 3.05 (1H, dd, 5-Heq), 3.38 (1H, dd,

2-Hax), 4.29 (1H, dd, 2-Heq), 6.14 (1H, s, 7-H), 6.96 (1H, broad s, 6-OH), 13.54 (1H, s, 8-OH), J=15 (5a-5e), 14 (4a-4e), 12 (2a-2e, 3a-4a, 4a-5a), 9 (2a-3a), 7 (3a-Me, 4e-5e), 4 (2a-3a, 3a-4e), 2 (4a-5e, 4e-5a), 1 Hz (2e-4e); MS m/z 236 (M^+), 221, 181, 165. Found: C, 66.37, H, 6.77%. Calcd for $C_{13}H_{16}O_4$: C, 66.08, H, 6.38%. **8**: mp 190—192 °C (from benzene lit,[2] 185 °C); IR 1640 cm^{-1}; ^1H NMR (acetone-d_6) δ=0.95 (6H, d, J= 6 Hz), 1.2—1.7 (3H, m), 2.57 (2H, t, J=7 Hz), 2.58 (3H, s), 6.00 (1H, s), 8.83 (1H, s), 9.30 (1H, broad s), 13.8 (1H, s).

Methylation of 4—6 with Diazomethane. A solution of **4**, **5**, or **6** in methanol was treated with an ethereal solution containing excess diazomethane at room temperature for one night. After removal of the solvents and the excess of diazomethane, the residual oil was chromatographed. Methylation of **4** gave two monomethyl ether **1** and **2** in 21 and 24%, respectively. 5-Acetyl-2-isopropenyl-6-methoxy-2,3-dihydrobenzofuran-4-ol (racemic remirol) (**1**): mp 72—72.5 °C (from hexane) (natural remirol:[1] 76.5—77 °C); IR 1635 cm^{-1}; UV 238 (log ε=4.11), 293 nm (4.28), (natural remirol:[1] 239 and 294 nm); ^1H NMR ($CDCl_3$) δ=1.76 (3H, s), 2.60 (3H, s), 2.95 (1H, dd, J=15, 8 Hz), 3.30 (1H, dd, J=15, 10 Hz), 3.86 (3H, s), 4.92 (1H, broad s), 5.07 (1H, broad s), 5.29 (1H, broad dd, J=10, 8), 5.97 (1H, s), 14.08 (1H, s); MS m/z 248 (M^+), 233. Found: C, 67.50, H, 6.63%. Calcd for $C_{14}H_{16}O_4$: C, 67.73, H, 6.50% **2**: mp 70.5—71 °C (from hexane); IR 1625 cm^{-1}; UV 233 (log ε=4.12), 241 sh (4.01), 288 (4.20), 323 sh nm. (3.67); ^1H NMR ($CDCl_3$) δ=1.77 (3H, s), 2.62 (3H, s), 3.09 (1H, J=15, 7 Hz), 3.46 (1H, dd, J=15, 9 Hz), 3.94 (3H, s), 4.95 (1H, broad s), 5.08 (1H, broad s), 5.22 (1H, dd, J=9, 7 Hz), 6.15 (1H, s), 13.86 (1H, s); MS m/z 248 (M^+), 233. Found: C, 67.81, H, 6.50%. Calcd for $C_{14}H_{16}O_4$: C, 67.73, H, 6.50%. Methylation of **5** and **6** gave corresponding monomethyl ethers **3** and **9** in 75.4 and 27.6%, respectively. 7-Acetyl-2-isopropenyl-4-methoxy-2,3-dihydrobenzofuran-6-ol (**3**): mp 61—62 °C (from hexane); IR 1640 cm^{-1}; UV 230 (log ε=4.14), 283.5 (4.30), 337 nm (3.52); ^1H NMR ($CDCl_3$) δ=1.82 (3H, s), 2.58 (3H, s), 2.92 (1H, dd, J=15, 8 Hz), 3.17 (1H, dd, J=15, 9 Hz), 3.88 (3H, s), 5.02 (1H, braod s), 5.18 (1H, broad s), 5.38 (1H, dd, J=9, 8 Hz), 6.00 (1H, s), 13.57 ppm (1H, s); MS m/z 248 (M^+), 233. Found: C, 67.90, H, 6.61%. Calcd for $C_{14}H_{16}O_4$: C, 67.73, H, 6.50%. 9-Acetyl-6-methoxy-3-methyl-2,5-dihydro-1-benzoxepin-8-ol (**9**): mp 152—153 °C (from hexane) IR 1630 cm^{-1}. UV 230.5 (log ε=3.99), 280 (4.06), 328 nm (3.84); ^1H NMR ($CDCl_3$) δ=1.55 (3H, broad s), 2.68 (3H, s), 3.37 (2H, broad m), 3.83 (3H, s), 4.45 (2H, broad m), 5.65 (1H, broad m), 6.27 (1H, s), 13.67 (1H, s); MS m/z 248 (M^+), 233. Found: C, 67.93, H, 6.44%. Calcd for $C_{14}H_{16}O_4$: C, 67.73, H, 6.50%.

4,6-Dimethoxy-2-isopropenyl-2,3-dihydroxybenzofuran (10). By a method described in our previous paper,[7] **10** was obtained from 3,5-dimethoxyphenol (25.0 g, 163 mmol) and 1,4-dibromo-2-methyl-2-butene (37.3 g, 163 mmol) in the presence of sodium hydride (7.8 g, 326 mmol) in dry ether (300 mL). After distillation and chromatography, **10** was obtained in pure state in 27% yield. **10**: bp 138—140 °C (3 mmHg); mp 53.5—54.5 °C (from hexane); UV 234 sh (log ε=3.86), 273 nm (3.20); ^1H NMR (CCl_4) δ=1.72 (3H, s), 2.80 (1H, dd, J=15, 8 Hz), 3.03 (1H, dd, J=15, 9 Hz), 3.62 (3H, s), 3.65 (3H, s), 4.73 (1H, broad s), 4.92 (1H, broad s), 4.98 (1H, dd, J=9, 8 Hz), 5.72 (1H, d, J=2 Hz), 5.80 (1H, d, J=2 Hz); MS m/z 220 (M^+), 205. Found: C, 71.15, H, 7.52%. Calcd for $C_{13}H_{16}O_3$: C, 70.89, H, 7.32%.

5-Acetyl-2-isopropenyl-4,6-dimethoxy-2,3-dihydrobenzofuran (11). By the method described in our previous paper,[7] **10** (3.45 g, 15.7 mmol) was acylated with acetic acid (1.90 g, 31.7 mmol) and trifluoroacetic anhydride (6.60 g, 31.4 mmol) to give **11** (1.19 g, 28.3%); bp 225—240 °C (16 mmHg); IR 1685 cm^{-1}; UV 234 sh: 4.02), 274 nm (3.70); ^1H NMR (CCl_4) δ=1.78 (3H, s), 2.33 (3H, s), 3.03 (1H, dd, J=16, 8 Hz), 3.27 (1H, dd, J=16, 9 Hz), 3.78 (6H, s), 4.87 (1H, broad s), 5.05 (1H, broad s), 5.12 (1H, dd, J=8,9 Hz), 6.10 (1H, s); MS m/z 262 (M^+), 245. Found: C, 68.77, H, 6.88%. alcd for $C_{15}H_{18}O_4$: C, 68.68, H, 6.92%.

Demethylation of 11 to Racemic Remirol (1). By the method described in our previous paper,[6] **11** (1.00 g 3.83 mmol) was demethylated with magnesium iodide etherate in refluxing benzene. After purification by silica-gel column chromatography, fractions eluted with hexane-benzene (8:2) gave **1** (431 mg, 42.7%) as colorless crystals (mp 72—72.5 °C). All spectral data were identical with those of **1** obtained from monomethylation of **4** and natural remirol reported by Allan et al.[1]

We wish to thank Dr. Franca Bigi for providing some copies of the spectra of **4** and **5** and also thank Dr. Takashi Tokuyama (Osaka City University) for measuring the NOE data.

^{13}C and ^{1}H NMR of Arylnitrones. Substituent Effects of α-Phenyl-*N*-(*p*-substituted phenyl)nitrones

Kohji SUDA,* Toshio TSUJIMOTO, and Masashige YAMAUCHI†
Department of Physical Chemistry, Meiji College of Pharmacy, 1-35-23, Nozawa, Setagaya-ku, Tokyo 154
†Faculty of Pharmaceutical Sciences, Josai University, Keyakidai, Sakado, Saitama 350-02
(Received February 2, 1987)

Substituent effects on the chemical shifts of the conjugation sites in α-phenyl-*N*-arylnitrones (**2**) have been investigated. Resonance effects predominate at these positions. The electronic effects of the substituents should be treated separately between electron-donating groups and electron-withdrawing ones. A plausible mechanism for the transmission of the substituent effects in **2** has been proposed.

Recently, the substituent effects of α,*N*-diarylnitrones (**1** and **2**) were investigated by means of ^{13}C and ^{1}H NMR spectroscopy.[1] The analyses, however, seem to be insufficient with regard to the mechanisms of the transmission of the substituent effects. For example, the previous investigators have reported that, while the chemical shifts of C-4′ in α-aryl-*N*-phenylnitrones (**1**) and those of C_α in α-phenyl-*N*-arylnitrones (**2**) are properly correlated with the Hammett σ_p or the Swain-Lupton *F* and *R* parameters, there are poor correlations between these parameters and the chemical shifts of C_α in **1** and those of C-4 in **2**. These results obtained for the conjugation sites of **1** and **2** are inconsistent with their explanation that there are through-resonance effects between the α- and *N*-phenyl rings via the nitrone function; thus, some reasonable explanations of the mechanisms are required.

In a previous paper,[2] the present authors have systematically investigated the substituent effects of **1** and α-aryl-*N*-alkylnitrones, especially the effect of the 4-substituents on the α-position, by means of ^{13}C and ^{1}H NMR spectroscopy. From the good correlations obtained in correlation analyses, we have concluded that 1) inductive effects are predominant at the α-carbon, and 2) a "back-polarized" structure of nitrones is responsible for the anomalous upfield shift of the C_α signals.

The aim of the present work is to understand the nature of the nitrone function and to give an appropriate explanation of the mechanism of the transmission of the substituent effects by assessing the substituent effects of **2**.

Experimental

Materials. α-Phenyl-*N*-(*p*-substituted phenyl)nitrones (**2**): Nitrones **2a**[3] and **2b**[3,4] were synthesized from the corresponding nitrosobenzenes and *N*-benzylpyridinium chloride; they were purified by recrystallization from ethanol-hexane and then from benzene-hexane. Nitrones, **2c—k**, were prepared by the condensation of the appropriate phenylhydrox-

ylamines (**3**)[5,6] with benzaldehyde in ethanol and were purified by recrystallization from ethanol-hexane or benzene-hexane. To our knowledge, although nitrones **2a—g**, **2i**, and **2k** are known,[1,7] the physical constants of the following nitrones have not been reported: **2b**, mp 129—130 °C (uncorrected), **2e**, 173—175 °C, **2i**, 130—131 °C, **2k**, 191.5—192 °C. Nitrones **2h** and **2j** are new compounds: **2h** mp 195 °C, Found: C, 70.40; H, 4.94; N, 5.49%. Calcd for $C_{15}H_{13}O_3N$: C, 70.58; H, 5.13; N, 5.49%. **2j** mp 164.5—165 °C, Found: C, 75.47; H, 4.25; N, 12.85%. Calcd for $C_{14}H_{10}ON_2$: C, 75.65; H, 4.54; N, 12.61%. All the compounds obtained were characterized as *Z*-isomers by means of their physical constants and spectral data.[2]

NMR Measurement. The ^{13}C NMR spectra of **2a—d** were measured at 100.4 MHz on a JEOL GX-400 spectrometer under a pulse Fourier transform mode. A spectral width of 25000 Hz was used with 64 K (digital resolution 0.76 Hz) data points. The ^{13}C NMR spectra of **2c—k** were measured at 67.8 MHz on a JEOL GX-270 spectrometer under a pulse Fourier transform mode. A spectral width of 18000 Hz was used with 32 K (digital resolution 1.10 Hz) data points. The ^1H NMR spectra were obtained on the JEOL GX-400 NMR spectrometer operating at 400 MHz for **2a—d** and on the JEOL GX-270 NMR spectrometer for **2c—k** at 270 MHz.

Sample solutions were prepared in a concentration of 0.4 M (mol dm^{-3}), except for **2f—h** and **2k** (0.16 M), with $CDCl_3$ (99.8%, Merck) containing 1% TMS (tetramethylsilane) as the internal standard. Sample tubes with a 5-mm diameter were used, and the probe temperature was 20—25 °C. The chemical shifts were independent of the concentrations of the compounds used within a range of 0.15 to 0.5 M (with a deviation smaller than 5 and 3% in ppm for the ^{13}C and ^1H spectra respectively). The ^{13}C and $^1H_\alpha$ signals of **2** were assigned in a similar manner as described in the previous paper.[2]

Results and Discussion

It is well-accepted that the nitrone function is flush with the two phenyl rings in **1** and **2**.[7a,b] Since C-1′, C_α, and C-4 in **2** are, in contrast to the case of **1**, conjugation sites of the 4′-substituents, we will mainly discuss the substituent effects on these sites. The chemical shifts and substituent-induced chemical shifts (SCS) for C_α, C-1, C-4, C-1′, C-4′, and H_α in **2** are shown in Table 1. All the C_α chemical shifts appear ca. 25 ppm upfield and ca. 20 ppm downfield from the corresponding carbon chemical shifts of imines **4**[8] and styrenes **5**[9] respectively, while they are very close to the corresponding carbon chemical shifts of *trans*-stilbenes **6**.[10] Table 1 reveals that the C_α, C-4, C-1′, and H_α signals of **2** shift downfield as the electron-withdrawing ability of the substituents increases, whereas the C-1 signals shift upfield, showing a reverse substituent effect. This behavior at C-1 is, however, not the characteristic of the nitrone alone; it is also observed in the ^{13}C NMR spectra of **4** and **6**.[8,10]

To ascertain the mechanisms and the extent of the transmission of the substituent effects in **2**, the SCS values for the requisite positions were compared with those for the corresponding sites of **4**, **5**, **6**, and mono-

a) n: The number of data, SD: standard deviations, and r: correlation coefficients. The SCS values for the reference systems were obtained from the reported δ values.[8-11] b) Correlations with the $^{13}C_{para}$ SCS of monosubstituted benzenes. c) Correlations with the $^{13}C_{ipso}$ SCS of monosubstituted benzenes.

substituted benzenes.[11] As is shown in Table 2, the SCS-SCS plots gave fairly good correlations with the correlation coefficients of $r>0.960$ at these positions.

However, the slopes, ρ_{Bz}, ρ_{Im}, and ρ_{Sb}, are small, especially at C_α, C-4, and a nonconjugation site, C-1, with the exception of the ρ_{Im} at C-4. Since the magnitude of the rho values is a measure of the relative sensitivity of substituent effects, such smaller values than unity in **2** can be explained by the lower double-bond order of the nitrone function compared with the corresponding side-chain double bonds in **4**, **5**, and **6**.[2] Furthermore, among the SCS-SCS correlations at C_α, the correlation between **2** and a non-planar system **4**,[8a-c] in which the *N*-phenyl ring is twisted from the molecular plane containing the C=N bond, is much better (r=0.994) than the correlations between **2** and the comparable planar molecules, such as monosubstituted benzenes, **5**, and **6** (r=0.965—0.976). In the latter correlations, electron-donating and electron-withdrawing groups have apparently different slopes, as is illustrated in Fig. 1. These findings suggest that the mechanisms of the transmission of substituent effects through the side-chain double bond in **2** are considerably different from those for **5** and **6**.

In the analysis of the substituent effects of **2**, the previous investigators have reported[1] that 1) there is an excellent correlation between the chemical shifts at C_α and Hammett σ_p or Swain-Lupton F and R parameters, 2) the chemical shifts at C-1′ have a poor correlation with the σ_p, but a fair correlation with the σ^+, parameters, and 3) there is no correlation between the chemical shifts at C-4 and these parameters. The

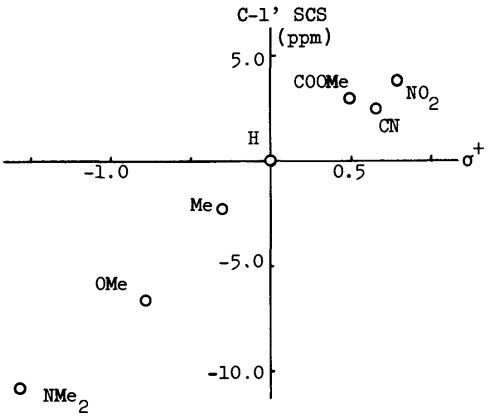

Fig. 3. Plot of C-1′ SCS vs. Hammett σ^+ constants in **2**.

present analyses by the use of our own spectral data are, however, inconsistent with their results at these positions in **2**. As is illustrated in Fig. 2, the SCS values at C_α show an excellent linear relationship with the σ^+ constants, with a correlation coefficient of 0.991, whereas the correlation coefficient with σ_p constants is, at most, 0.976. This can be best interpreted in terms of an enhanced electron density at C_α caused by the electron-donating groups. This also means that the nitrone function is capable of acting either as an electron-donating group or as an electron-withdrawing group, depending on the nature of the substituents on the *N*-phenyl ring, i.e., the electronically amphoteric character of the nitrone function being ascertained. The deviation of halogens from the correlation shown in Fig. 2 might be caused by the well-known electronically amphoteric character of these atoms. Indeed, a principal component analysis of the ^{13}C SCS of monosubstituted benzenes has recently shown that the substituents cluster into four groups: alkyl, halogens, donors, and acceptors; thus, the omission of halogens might be appropriate in the correlation analyses of nitrones.[12]

Although the SCS values at C-1′ in **2** can be correlated fairly well with the σ_p constants (r=0.937), the correlation with the σ^+ constants is much better (r=0.971), and the best correlation coefficient (0.990) is obtained when halogen atoms are omitted from the consideration (Fig. 3). Accordingly, the SCS-SCS correlation between C-1′ and C_α also gives a good linear relationship (r=0.978) when halogens are omitted from the plot.

The SCS values of C-4 in **2** showed a good correlation with σ_p. This supports the idea that the electronic effects of the 4′-substituents are virtually transmitted from the *N*-phenyl ring to the *C*-phenyl ring through the whole conjugation system in **2**. The low sensitivity to resonance effects at C-4 is probably responsible for the lower double bond-order of the nitrone function compared with those of the reference systems, **5** and **6**.[2] The SCS-SCS correlation between C_α and C-4 in **2**, however, gave different slopes between electron-

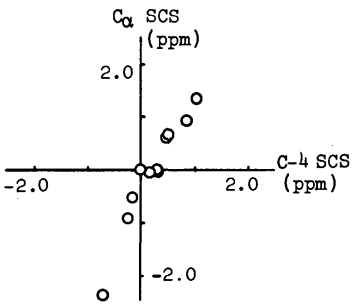

Fig. 4. Plot of C_α SCS vs. C-4 SCS in **2**.

donating and electron-withdrawing substituents (Fig. 4), reflecting different substituent effects at the two sites. Hence, dual parameter analyses will be a better approach to give quantitative information on the balance of electronic substituent effects.

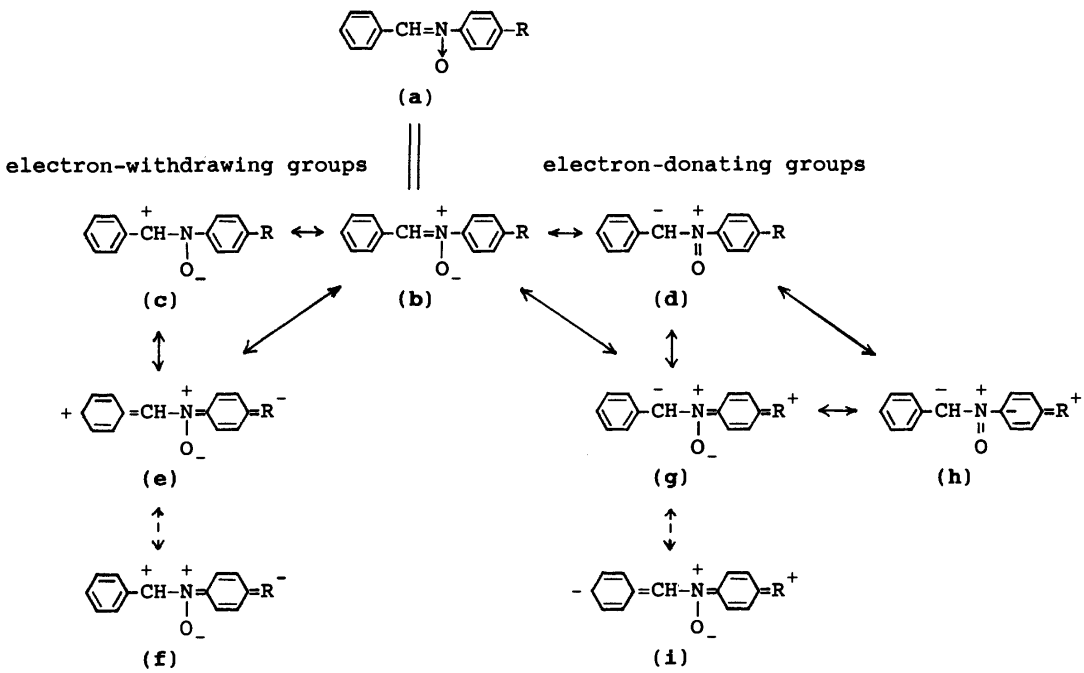
Excellent correlations were obtained between the SCS values and the Yukawa-Tsuno σ_i and σ_π[13] parameters at the positions in **2** being discussed (Table 3).[††] The resonance effects are, as was expected, predominant at the conjugation sites, C-1′ and C_α, except in the case of C-4. The inductive effects can essentially be ignored at C-1′. It should be noticed that the slopes (ρ_π^+) for the electron-donating substituents are much larger than those (ρ_π^-) for the electron-withdrawing substituents at the two positions: ρ_π^+/ρ_π^-=1.5 and 2 at C-1′ and C_α respectively.

The resonance effects are, however, depressed at C-4 and are comparable to inductive effects. Since the ρ_π/ρ_i ratio will be a measure of the relative contribution of resonance effects to inductive effects, we next compared these ratios at C_α and C-4 in **2** with those for the corresponding sites in a reference system **6**. For **6**, the ρ_π^+/ρ_i and ρ_π^-/ρ_i values are nearly constant; i.e., they are 2.3 and 2.5 at C_α, and 1.8 and 2.2 at C-4, respectively. On the other hand, these values in **2** are 3.4 and 1.8 at C_α, and 1.3 and 1.0 at C-4, respectively. It is thus obvious that the resonance effects in **2** are anomalously enhanced at C_α by the electron-donating groups (but depressed by the electron-withdrawing groups), while at C-4 they are much more depressed, especially by electron-withdrawing groups. Therefore, the electronic effects of the 4′-substituents are transmitted to C_α and C-4 in a different fashion in **2**.

On the basis of the above observations of the electronic substituent effects at C-1′, C_α, C-1, and C-4 in **2**, we may propose the mechanisms shown in Scheme 2.

The nitrone function takes a coplanar conformation with the two phenyl groups in **2**, and the double-bond order is lower than those of the corresponding double bonds in **5** and **6**. The observed large shielding at C_α in **2** is best attributable to a "back-polarized" structure, **d**, which predominates over the alternative canonical form, **c**; thus, the positive charge on the nitrone function should be localized mainly on the nitrogen atom. In such situations, resonance effects caused by the electron-donating substituents on the *N*-phenyl ring will be important. The effects are illustrated by the structures shown in the right column of Scheme 2. Among the resonance structures, **g** and **h**, in which a negative charge donated by the substituent R is located on the carbons (i.e., C_α and/or C-1′) next to the positive nitrogen, electrically predominate over such a structure as **i**, in which the negative charge donated by R is delocalized over all the conjugation sites of the molecule (i.e., normal resonance effects are to be expected at the sites). On the other hand, among the resonance structures caused by electron-withdrawing groups, such as **e** and **f**, the **f** structure will show a negligible contribution because of the repulsion between the two neighboring positive charges on the

††A combined treatment of the σ_π^+ and σ_π^- parameters, such as was attempted in the previous paper,[2] is inappropriate in a situation such as this where resonance effects are predominant. Our data also give an excellent correlation with the Swain-Lupton F and R parameters: r=0.993 at C-1; r=0.991 at C_α; and r=0.995 at C-4.



Scheme 2.

carbon and nitrogen atoms; thus, a positive charge is, as is shown by the canonical structure **e**, delocalized over all the conjugation sites of the molecule according to the electron demand of the electron-withdrawing substituents on the C-4′. Resonance effects caused by electron-withdrawing substituents are, hence, normal but depressed at C_α and C-4.

The H_α chemical shifts of **2** appear between the corresponding proton chemical shifts of **4** and **6**. This also supports the idea that the canonical structure **d** predominates over the alternative structure **c** in **2**. The SCS values at H_α also show a fairly good correlation (r=0.935) with the σ_p constants, and a better correlation coefficient of r=0.990 can be estimated when halogens are omitted from the correlation. The resonance effects of the substituents are, therefore, predominant at H_α. However, the sensitivity of H_α SCS is much lower than that of C_α SCS; therefore, correlation analysis based on H_α SCS seems to be less valuable for discussing the precise mechanism of the transmission of substituent effects.

Enzymatic Reactions in Aqueous-Organic Media. II.[1] Effects of Reaction Conditions and Selectivity in the Esterification of Aromatic Amino Acids by α-Chymotrypsin in Alcohols

Hideo KISE,* Hitoshi SHIRATO, and Hidetaka NORITOMI
Institute of Materials Science, University of Tsukuba, Sakura, Niihari, Ibaraki 305
(Received February 5, 1987)

N-Acetylated aromatic amino acids were esterified by α-chymotrypsin suspended in alcohols. The reaction rate and the yields of the esters depended primarily on the amount of the aqueous buffer solution in which α-chymotrypsin was dissolved. The reaction rate increased but the equilibrium yield of the esters decreased with increasing concentration of water. High substrate selectivity and stereospecificity were observed for L-aromatic amino acids; and therefore, in this system α-chymotrypsin was considered to be an effective catalyst which maintains its native conformation. When the amount of the substrate was increased, the present reactions gave higher yields of the esters than the reactions in chloroform (two-phase method).

Recently, the area of enzymatic reactions in the presence of organic solvents, either miscible or immiscible with water, is rapidly growing and is drawing much attention. These reactions are of great interest in view of both basic studies on the medium effects on enzyme catalysis and the application of enzymatic reactions to organic synthesis. For example, hydrolytic enzymes, such as α-chymotrypsin (CT), have been employed as catalysts for various ester syntheses in aqueous-organic two-phase systems.[2-12] It has been considered that in this system the decreased amount of water and the low solubility of the products in the aqueous phase shift the reaction equilibrium to the synthesis of esters. However, when a hydrophobic (water-immiscible) organic solvent is used, the main drawback of the method is that if one of the reactants RCOOH such as amino acids is hardly soluble in the organic phase, it would be concentrated in the aqueous phase (Fig. 1a). This often causes a substrate inhibition of the enzyme, leading to low yields of the esters.[7,13]

The synthetic reactions by hydrolytic enzymes in water-hydrophilic (water-miscible) organic solvents have also been reported.[9,14-16] By using limited amounts of water in solvents, the equilibrium of the reaction can be shifted to favor the synthesis. However, the catalytic activity of the enzymes is often impaired at high concentrations of organic solvents, and the yields of products have been rather limited. For example, it has been reported that *N*-acetyl-L-tyrosine ethyl ester was obtained in 25—30% yields by CT-catalyzed reactions of *N*-acetyl-L-tyrosine with ethanol in 50—60% water, but that CT was inactivated at lower concentrations of water.[14]

The present study concerns with the esterification of *N*-acetylated aromatic amino acids by CT at very high concentrations of alcohols. The reaction system is heterogeneous containing suspended CT which can be easily separated by filtration like immobilized enzymes. The results for the effects of various reaction conditions on the reaction rate and the yield of the esters, as well as substrate selectivity and stereospecificity of the reaction, are reported.

Experimental

Materials. Bovine pancreatic α-chymotrypsin (CT) (EC 3.4.21.1) having a specific proteinase activity, with *N*-benzoyl-L-tyrosine ethyl ester (BTEE), of 50 units (μmol-min^{-1}) mg^{-1} of protein (pH 7.8 at 25 °C) was purchased from Sigma Chemical Co. *N*-Acetyl-L-tyrosine (ATy), its ethyl ester (ATyE), *N*-acetyl-D-tryptophan, -D-phenylalanine, and -L-alanine were also purchased from Sigma. *N*-Acetyl-L-tryptophan (AT), -L-phenylalanine (AP), their ethyl esters (ATE and APE), and *N*-acetyl-L-leucine were obtained from Nakarai Chemical Co. Alcohols and chloroform of guaranteed grade were also obtained from Nakarai and used without further purification.

Reactions and Measurements. Typically, a solution of CT (0.01 g) in 0.5 ml of phosphate buffer (0.1 M (1M=1 mol dm^{-3}), pH 6.8) was added to a solution of AT (0.05 g, 0.20 mmol) in 20 ml of ethanol. The mixture was incubated with constant reciprocal shaking (140 cycle per min) at 30 °C for 24 h (method A). Unless otherwise stated method A was used throughout this study. Alternatively, AT was first dissolved into the CT solution and then ethanol was added (method B). When chloroform was used as a solvent (two-phase method), the total volume of the organic solution was also 20 ml. In all the methods, after the reaction the solvents were evaporated with a rotary evaporator, and the amounts of AT and ATE in the residue were determined by a HPLC (JASCO Tri Rotar SR-1) using a JASCO Finepak SIL C18 column eluted with water-acetonitrile (50/50 by volume). Acetanilide was used as an internal standard.

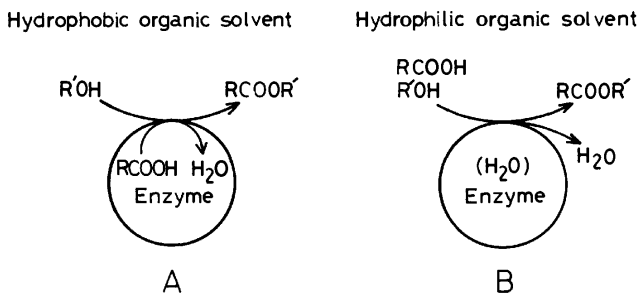

Fig. 1. Schematic representation of enzymatic ester synthesis in two-phase (A) and the present (B) systems.

The initial rate of esterification was measured by a determination of the amounts of AT and ATE in the reaction mixtures at intervals. A 4 μl aliquat of the reaction mixture, from which CT had been removed by filtration with a regenerated cellulose type membrane filter, was injected directly inot HPLC and analyzed under the same conditions as described above.

The CD spectra of CT solutions in ethanol or water were obtained with a JASCO spectropolarimeter model J-20.

Results and Discussion

Ester Synthesis in Chloroform (Two-Phase Method). In order to elucidate the effect of a water-immiscible organic solvent we at first investigated the esterification of AT by CT in chloroform.[1] Figure 2 shows the time courses of esterification with 1 M ethanol in chloroform and with different amounts of buffer solution in which CT was dissolved. It can be seen that the conversion (yield) of ATE at equilibrium increases with the decrease in the amount of the buffer. Although longer reaction time was required to attain the equilibrium with 0.25 ml of the buffer solution, more than 90% conversion was obtained after 24 h. Without water, however, the reaction was totally inhibited, indicating that a minimum amount of water is essential to the catalytic activity of CT. Furthermore, no reaction occurred without CT under the same conditions, ruling out the possibility of catalysis by ionic species in the buffer solutions.

The dependency of the equilibrium conversion on water content may be explained simply by a mass action law which predicts that with decreasing amounts of water the equilibrium shifts to ester synthesis. It is considered that the reaction occurs in the water droplets in which CT is dissolved. With lower water contents the amount of free water available for hydrolysis may be small enough to suppress the hydrolysis.

When the concentration of ethanol in chloroform was increased with a constant total volume of the organic phase (20 ml), the change in ATE yield was found to be rather small (less than 10%); the data are presented in Table 1. It had been considered that high concentration of water-miscible solvents such as ethanol would impair the enzyme activity and for this reason two-phase method has been employed. However, the above result indicates that chloroform can be replaced as a solvent by ethanol without any serious inactivation of CT. In neat ethanol the reaction mixture is a suspension of hydrated CT which can be separated by filtration with a glass or a membrane filter. Since the reactions in alcohols are clean and easy to work up, and, as will be mentioned later, the substrate inhibition is much less than in two-phase method, most of the reactions were carried out in alcohols.

Ester Synthesis in Ethanol. The effects of the reaction conditions on the ester yield were extensively studied in order to obtain optimum conditions. Figures 3 to 5 exhibit plots of the yields of ethyl esters of AT, ATy, and AP after 24 h reactions in ethanol against the volume-% of aqueous buffer solutions in which CT

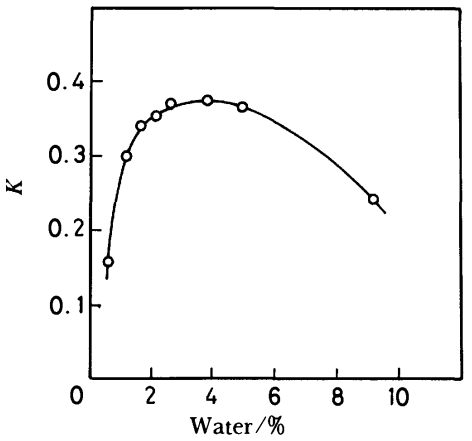

Fig. 7. Change in K with water content. K=[ATE]-[water]/[AT][EtOH].

was dissolved. The results for the two methods (method A and B, see Experimental) are compared in each Figure. The yields of the three esters exhibit a similar dependency on the water content, although the water contents which gave maximum yields are different. Like the reactions in chloroform mentioned above, the decrease in the yield with increasing amount of water may be explained by the shift of the equilibrium to hydrolysis. Alternatively, the increase in the solubility of CT in ethanol-water may be responsible for the decrease in the yield, since, as will be mentioned later, CT loses activity by dissolving in the mixed solvent.

The marked decrease in the yields at lower water concentrations may be the consequence of the slower reaction rate due to the decrease in the degree of hydration of CT which is considered to be essential to the catalytic activity of CT. This consideration may be supported by the fact that, as shown in Fig. 6, the rate of ATE synthesis decreased with a decreasing amount of water. Furthermore, the yield of ATE at prolonged reaction times up to 15 days which were considered to be enough to attain the equilibrium shows quite different dependency on water content from those shown in Fig. 3. In the lower range of water content, a prolonged reaction time gave much higher yields than those for 24 h reactions shown in Fig. 3. This suggests that the amount of active enzyme decreases with the decrease in water content for probably not only ATE but also ATyE and APE synthetic reactions. As in the

reaction in chloroform, in the absence of water the reaction was totally inhibited.

Figure 7 shows a plot of the calculated equilibrium constant K for ATE synthesis against water content. The K value may be affected by several factors, such as the dielectric constant of the medium; however, much slower reactions at very low concentrations of water are probably responsible for the sharp decrease in K in this region. It was found that CT loses activity at 50 °C, probably due to denaturation; the optimum temperatures for the ester synthesis were between 10 and 35 °C (Table 2).

Effect of the Amount of the Substrate. It was found that an increase in the initial amount of AT caused a decrease in the yield of ATE after 24 h reaction. However, in ethanol the yield of ATE increased upon increasing the reaction time, whereas in chloroform the yield was largely suppressed regardless of the reaction time and pH of the buffer solution. The results are summarized in Table 3.

These results imply that, when the initial amount of AT was increased, for example 0.2 g of AT in 20 ml of

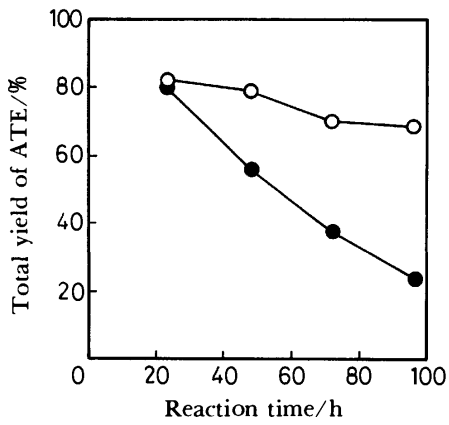

Fig. 8. Change in the yield of ATE in consecutive reactions. 0.05 g each of AT was added every 24 h. CT 0.01 g, EtOH (○) or chloroform (●) 20 ml, phosphate buffer (0.1 M, pH 6.8) 0.5 ml, 30 °C.

solvent, the reaction in ethanol is under kinetic control, but other factors must be taken into consideration for the reactions in chloroform, since the yields were very low even after prolonged reactions (below 5% after 96 h, Table 3). No distinct conclusion can be drawn from the present study, but it is probable that excess AT, which is considered to be concentrated in water phase, hinders CT activity.

Stability of Chymotrypsin. One of the most important aspects of enzymatic reactions is the stability of enzymes in the reaction media. Figure 8 shows the change in the total ATE yield in the course of successive reactions in which an equal amount of AT (0.05 g) was added every 24 h to the reaction mixtures containing constant amounts of CT and water. The total yield in ethanol decreased from 82 to 68% in going from the first reaction with 0.05 g AT for 24 h to the fourth reaction with total 0.20 g AT for 96 h. The yield decreased more rapidly in chloroform than in ethanol. The above result can not be attributed only to the instability of CT in chloroform, since the accumulation of AT may impair CT activity as mentioned above. The result, however, again exhibits the preference of the reaction in ethanol to that in chloroform when larger amounts of AT were employed.

Selectivity in Ester Synthesis. *N*-Acetylated L-alanine and L-leucine could not be esterified under the same conditions as those for aromatic amino acids. Also the yields of ethyl esters of *N*-acetylated D-tryptophan and D-phenylalanine were negligibly low. These results clearly indicate that substrate selectivity, stereospecificity, and therefore the native conformation of CT were strictly maintained in the present reaction system.

Klibanov et al.[17] reported that porcine pancreatic lipase maintained a high stability in various alcohols and that at very low water concentrations the enzyme exhibited a high activity, even at 100 °C. It seems from these results that enzymes require only small amounts

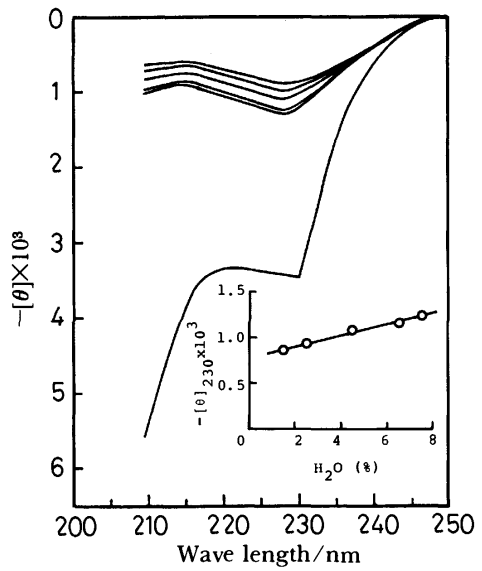

Fig. 9. CD spectra of CT in EtOH. From upper to lower water contents (%) are 1.5, 2.5, 4.5, 6.5, 7.5, and in neat water (pH 6.8). Insertion is the plot of $-[\theta]$ at 230 nm against water content.

Table 4. Effect of Alcohol Structure on AT Ester Synthesis[a)]

Alcohol	$v\times10^2$	Ester yield/%	
	μmol min^{-1} mg^{-1}	24 h	48 h
Methanol	0	0	0
Ethanol	12	81	81
1-Propanol	21	83	82
2-Propanol	17	78	79
1-Butanol	21	83	84
2-Butanol	12	65	78
2-Methyl-1-propanol	17	80	83
2-Methyl-2-propanol	0	0	0
1-Hexanol	0	40	61

a) AT 0.05 g, CT 0.01 g, alcohol 20 ml, phosphate buffer (0.1 M, pH 6.8) 0.5 ml, 30 °C.

of water for the maintenance of their native conformation in alcoholic solutions.

It was found that in the present system about 85% of added CT is suspended in ethanol and the rest of CT which is solubilized in ethanol is inactive. It has been reported that the content of α-helix in CT can be evaluated by the CD band at 230 nm, and the intensity of this band can be correlated with the enzyme activity.[18-20] Our data in ethanol is presented in Fig. 9. The CD spectrum in a phosphate buffer (pH 6.8) is also given in the Figure. It can be clearly seen that the intensity ($-[\theta]$) at 230 nm in ethanol decreases with a decrease in the water content, and is much lower than that in a buffer solution. Thus, the inactivity of solubilized CT in ethanol-water may be interpreted by the change in its conformation, probably due to a hydrophobic interaction between the enzyme and ethanol.

The results for the reactions of AT with different alcohols are summarized in Table 4. It is interesting that methanol and 2-methyl-2-propanol (*t*-butyl alcohol) are specifically inactive, while other alcohols gave esters in fairly good yields. Although no definite conclusion can be derived on the structure-reactivity relationship for the alcohols, it seems that CT exhibits rather a loose selectivity for the structure of alcohols as in the case of peptide synthesis in water where the amine components to some extent affect the reaction rate.[21]

Conclusion

The esterification of *N*-acetylated aromatic amino acids was realized in alcohols containing small amounts of water. The reaction mixture is considered to contain hydrated α-chymotrypsin (CT) suspended in alcohols which catalyzes the reaction, while CT in solution was found to be inactive. The reaction rate and the yield of the esters depended primarily on the water content in the reaction mixtures. The optimum reaction temperatures were between 10 and 35 °C. When the initial amount of AT was increased, CT suffered less of a substrate inhibition in ethanol than in chloroform. From the study of substrate selectivity, CT is considered to maintain its native conformation in this reaction system.

(Received February 16, 1987)

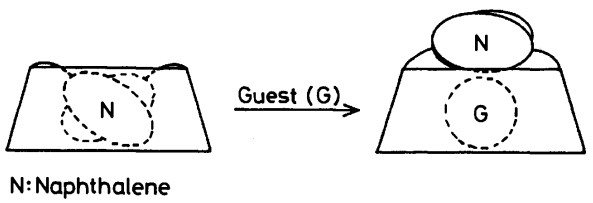
Host-guest complexation of β-Cyclodextrin bearing two naphthyl moieties (**1**) has been studied by circular dichroism and fluorescence spectroscopic methods. The circular dichroism spectrum exhibits a positive band around 225 nm while the fluorescence spectrum exhibits a predominant monomer peak with a shoulder of excimer emission. These data suggest that **1** can take two forms, one of two naphthyl moieties being included in the cavity of the predominant form (A) while both naphthyl moieties being located outside of the cavity in another form (B). With increasing concentration of guests, the dichroism intensity diminishes but the excimer intensity increases. This result indicates that **1** moves the included naphthyl moiety outward from the interior of the cavity during guest binding and then the two naphthyl moieties act as hydrophobic caps. The binding of **1** was stronger for cyclohexanol and 1-adamantanecarboxylic acid but weaker for cyclododecanol than that of the corresponding γ-cyclodextrin derivative in correspondence with size-fitting between the guests and hosts.

Cycloamyloses (Cyclodextrins, CDs) are water-soluble receptors and have been extensively studied as enzyme models, catalysts, miracle additives in pharmacy and food processing, and others.[1] The number of glucopyranose unit is designated by a Greek letter: α for six, β for seven, γ for eight, and so on. The smaller α- and β-CDs have been widely used because of their appropriate cavity sizes for forming 1:1 inclusion complexes with usual organic molecules.[1] However, recently, γ-CD has excited much attention because of the inclusion of two guest molecules in its large cavity.[2-5] As an extension of the works on the two guest accommodation by γ-CD, inclusion phenomena of some γ-CD derivatives have been studied,[6-8] and the γ-CD derivative bearing two naphthyl moieties (**2**) was found to act as a flexible host in which the two naphthyl moieties move outward from the interior of the cavity during guest binding to act as hydrophobic caps (Scheme 1).

In this report, we describe the binding behavior of β-CD bearing two naphthyl moieties **1** in which simultaneous accommodation of the two naphthyl moieties seems impossible because of its smaller cavity size. The guest-dependent excimer formation as well as the solvent-induced conformational changes of **1** will also be shown.

Results

Compound **2** was prepared by the procedure reported previously.[7b] Compound **1** was synthesized in the same manner as that of **2** via azobenzene-capped β-CD (**3**). Figure 1 shows the absorption and circular dichroism spectra of **1** in aqueous 10% ethylene glycol (EG) solutions at various concentrations of 1-adamantanecarboxylic acid (1-ACA). The solvent composition used is due to the poor solubility of **1** in pure



Scheme 1.

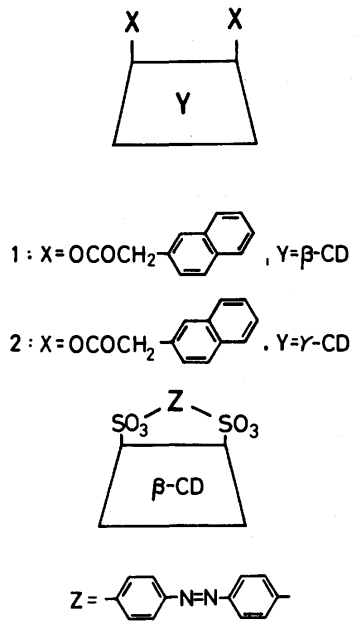

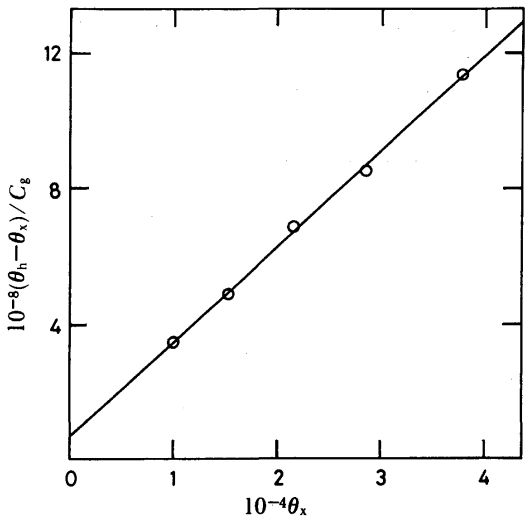

Fig. 2. The plot of $(\theta_h-\theta_x)/C_g$ as a function of θ_x in the system of **1** and 1-ACA.

water. Here, circular dichroism measurements were performed only in the naphthalene ^1B_b transition region. No reliable data in the ^1L_a transition region was obtained due to the limited solubility of **1** and the small circular dichroism ellipticity of the band. The circular dichroism spectrum in the absence of 1-ACA reveals a positive peak around 225 nm with the molar ellipticity of 110000 associated with the naphthalene ^1B_b transition. The intensity of the positive peak diminished with increasing 1-ACA concentration. When (−)-borneol and cyclohexanol were used as guest molecules, similar phenomena were observed. The guest-induced variations in the molar ellipticity were analyzed to obtain binding constants (K) of **1**, by using Eq. 1 which can be used in the presence of large excess

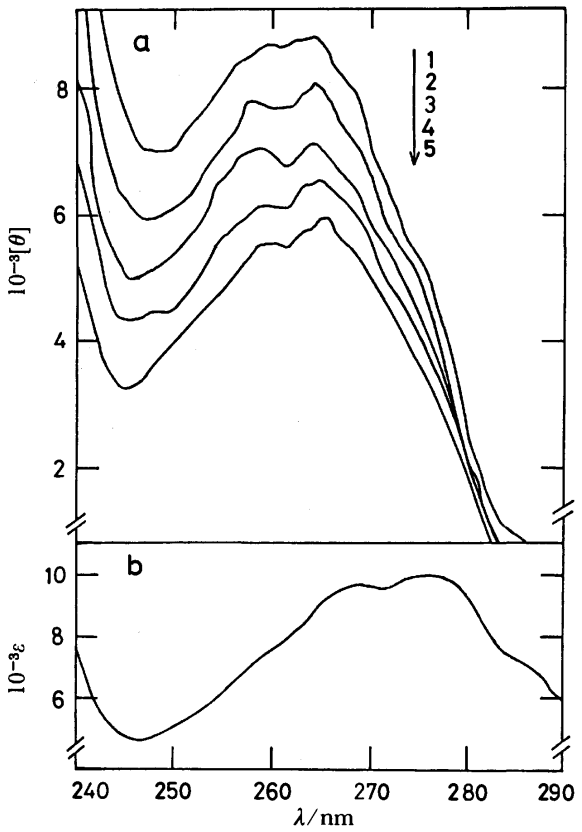

Fig. 3. Circular dichroism (a) and absorption (b) spectra of **1** in aqueous 10% DMSO solutions (6.5×10^{-5} mol dm^{-3}) at various cyclododecanol concentrations (a, 1, 0.0; 2, 3.3×10^{-5}; 3, 6.7×10^{-5}; 4, 1.3×10^{-4}; 5, 2.0×10^{-4} mol dm^{-3}; b, 0.0 mol dm^{-3}).

of guest.[9]

$$\frac{\theta_h-\theta_x}{C_g}=k\theta_x-k\theta_c \qquad (1)$$

Figure 2 shows the plot of $(\theta_h-\theta_x)/C_g$ against θ_x in the case of 1-ACA. Here, θ is molar ellipticity (the molar ellipticity at 225 nm in this study), θ_x for sample, θ_h for host alone, θ_c for complex, and C_g is total guest concentration. Cyclododecanol was also used as a guest molecule. In the case of cyclododecanol, aqueous 10% dimethyl sulfoxide (DMSO) was used as a solvent instead of aqueous 10% EG, because of the poor solubility of cyclododecanol in aqueous 10% EG. Circular dichroism measurements of the aqueous 10% DMSO solutions of **1** were performed in the naphthalene ^1L_a transition region since the measurements in the shorter wavelengths could not be achieved due to the absorption of DMSO. It is noted that the solubility of **1** in aqueous 10% DMSO was large enough to perform the circular dichroism measurements in the naphthalene ^1L_a transition region. The guest-induced variation of the molar ellipticity at 265 nm (Fig. 3) was analyzed by using the curve-fitting method because, in this case, the guest is not in large excess and Eq. 1 cannot be applicable.[7b] The binding constants of **2** for

Table 1. Binding Constants of **1** and **2** at 25 °C[a)]

Guest	Solvent	K/mol^{-1}dm^{3}[b)]	
		1	**2**
1-ACA	10% EG	28000	1000
(−)-Borneol	10% EG	1900	1800
Cyclododecanol	10% DMSO	4600	26000[c)]
Cyclohexanol	10% EG	90	32

a) Values were obtained by the plot of $(\theta_h-\theta_x)/C_g$ vs. θ_x except for the value for cyclododecanol which was obtained by the curve-fitting method. b) Errors are within ±9%. c) Reported in Ref. 7b.

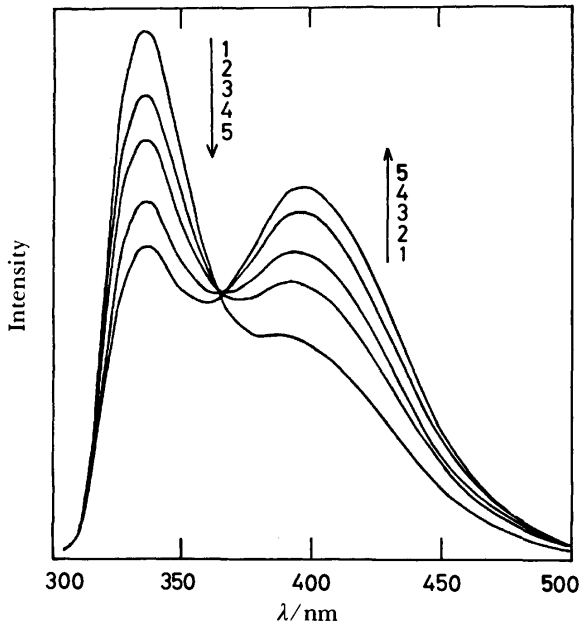

Fig. 4. Fluorescence spectra of **1** in aqueous 10% EG solutions (6.5×10^{-6} mol dm^{-3}) at various 1-ACA concentrations (1, 0.0; 2, 3.3×10^{-5}; 3, 6.7×10^{-5}; 4, 1.3×10^{-4}; 5, 2.3×10^{-4} mol dm^{-3}). Excitation wavelength is 290 nm.

1-ACA, cyclohexanol, and (−)-borneol were also obtained to be compared with those of **1** by the analysis (Eq. 1) of the circular dichroism variations at 215 nm of **2** (6.5×10^{-6} mol dm^{-3}) in aqueous 10% EG solutions. The binding constant of **2** for cyclododecanol in aqueous 10% DMSO solution was reported previously.[7b)] The obtained binding constants are listed in Table 1.

Figure 4 shows the fluorescence spectra of **1** in aqueous 10% EG solutions at various 1-ACA concentrations. The spectrum in the absence of 1-ACA exhibits a predominant monomer fluorescence around 336 nm and a shoulder of excimer emission around 394 nm. With increasing 1-ACA concentration, the intensity of the monomer fluorescence decreases while that of the excimer emission increases. When (−)-borneol and cyclohexanol were used in place of 1-ACA as guests, similar phenomena were observed.

It was found that EG content in the solutions of **1** markedly influences the circular dichroism and fluorescence patterns. The circular dichroism intensity of the positive peak around 225 nm decreased with increasing EG content. The EG-dependency of the fluorescence pattern was more complicated, that is, the intensity of the monomer fluorescence increases monotonously while the intensity of the excimer emission reaches a maximum around 50% of EG and then decreases with increasing EG content (Fig. 5).

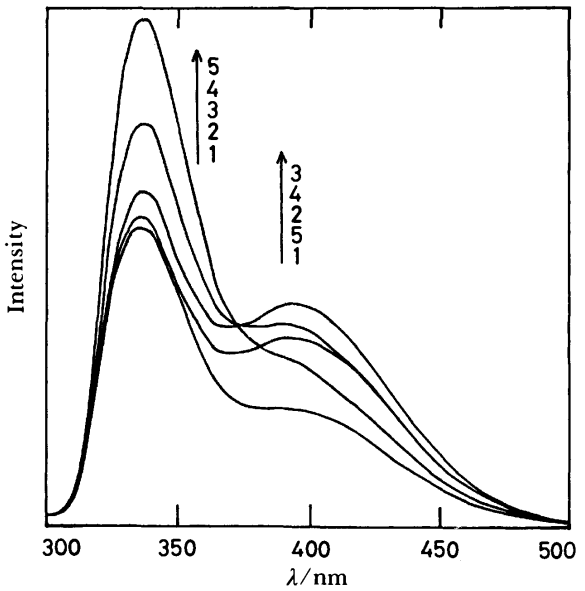

Fig. 5. Fluorescence spectra of **1** (5.4×10^{-6} mol dm^{-3}) at various EG content (1, 10; 2, 30; 3, 50; 4, 80; 5, 100%).

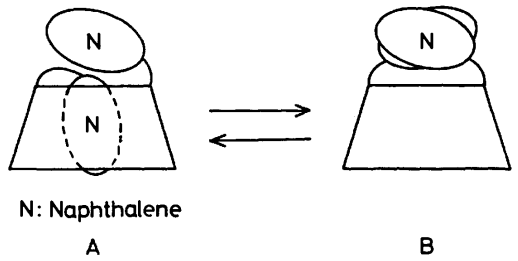
Discussion

The synthesis of **1** was performed via β-CD capped by azobenzene-4,4′-disulfonate moiety (**3**). Therefore, the positions of the two naphthyl moieties are those of primary hydroxyls sulfonated by azobenzene-4,4′-disulfonyl dichloride. When glucose units of CD ring are denoted by A, B, C, D, etc., in the order, primary hydroxyl groups of A and D glucose units of β-CD were reported to be selectively sulfonated by stilbene-4,4′-disulfonyl dichloride.[10)] Similar selectivity may be expected with azobenzene-4,4′-disulfonyl dichloride. The determination of the modified positions of **3** was performed by the reversed-phase high-performance liquid chromatography (HPLC). The diazido-β-CD, which was prepared by the reaction of **3** with sodium azide, was assigned to the AD-isomer by comparing its retention time with those of the AB-, AC-, AD-diazido-β-CD.[11)] Consequently, the modified positions of **1** and **3** are A and D of primary hydroxyls of β-CD.

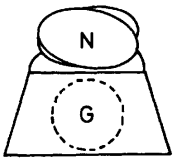
The circular dichroism and fluorescence spectra of **1** may be used for determing the location of the two naphthyl moieties. By using the spectroscopic data, we first discuss the structural features of **1** in the absence of any guest. Considering the fact that **1** cannot include the two naphthyl moieties simultaneously



Scheme 2.

because of its small cavity size, the positive peak observed in the region of ^1B_b transition, which is longitudinally polarized, may arise from the form A (Scheme 2), in which one of the two naphthyl moieties is included axially.[12] Since face-to-face interaction between the two naphthyl moieties is not allowed for such a geometry, it is obvious that excimer formation should not occur in the A form. However, excimer emission was observed as shoulder of the main peak of monomer fluorescence; therefore **1** can be either in A or B form as shown in Scheme 2. In the B form, the two naphthyl moieties are both out of the CD cavity, interacting with each other.

The guest-induced decreases in the molar ellipticity suggest that **1** moves one of its pendant naphthyl moieties outward from the interior of the cavity during guest binding. The guest-induced decreases in the monomer fluorescence and increases in the excimer emission suggest that the two naphthyl moieties are close in the complexes. The two naphthyl moieties are likely to contact with the included guest molecule as flexible caps, as illustrated below. It is noted that the



excimer formation in the complex may be compared with the reported base-base interactions in the complexes of β-CD derivatives, which have two nucleobases.[13] The binding constants of **1** and **2** are listed in Table 1. It is noted that the guest-induced circular dichroism variations of **2** as well as those of **1** could be analyzed based on a simple 1 : 1 stoichiometry.[7b] The binding constants of **1** for 1-ACA and cyclohexanol are larger than those of **2**. These results suggest that **1** is a better host for these guests than **2**, in accordance with the fact that the cavity size of **2** is too large to include these guests tightly. The binding constants of **1** and **2** for (−)-borneol are similar in spite of the difference of their cavity sizes. The binding constant of **1** for cyclododecanol is smaller than that of **2**. This result may arise from the fact that **2** has an appropriate cavity to include cyclododecanol while **1** has the cavity too small to include the guest completely. The examination of the Corey-Pauling-Koltun models supports this argument. Consequently, γ-CD derivative **2** seems to exhibit the better binding ability than β-CD derivative **1**, for large guests such as cyclododecanol. This is in contrast with the fact that β-CD derivative **1** is better host than **2** for small guests.

Figure 6 shows the plots of excimer-monomer ratio and circular dichroism intensity at 225 nm against EG content. The solvent-induced decrease in the circular dichroism intensity suggests that EG tends to convert the intramolecular complex form of A into the relaxed form of B (Scheme 2). It is frequently seen that fluorescence of aromatic compounds is solvent-dependent, usually with greater intensity in apolar solvents than in polar solvents. In this case, the monomer fluorescence seems basically to be stronger in EG-rich solutions than in EG-poor solutions. However, the complicated result that there is a maximum ratio of excimer emission around 50% of EG requires an additional explanation. One possible explanation is that the face-to-face interaction needed for excimer formation is attained only in one of three forms of **1** (B in Scheme 3). It is noted that 50% EG is the solvent in

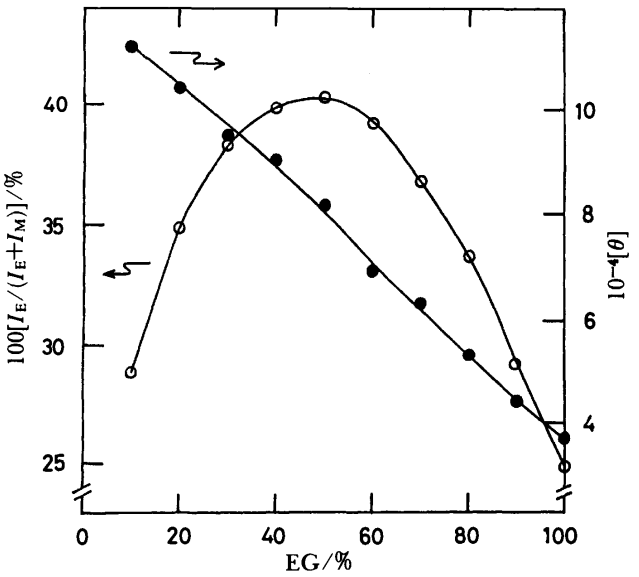


Fig. 6. Plots of excimer-monomer fluorescence ratio (I_M and I_E are intensities at 336 and 394 nm, respectively) and the molar ellipticity at 225 nm of **1** (5.4×10^{-6} mol dm^{-3}) as a function of EG content.

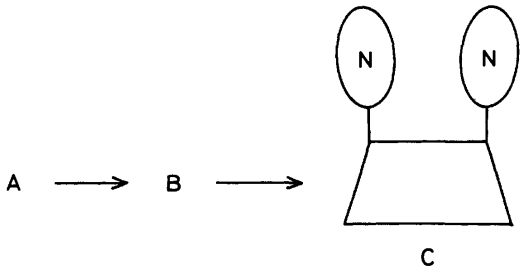

Scheme 3.

which hydrophobic interaction is still important; so two naphthyl moieties tend to interact with each other by the hydrophobic driving force. In the solutions with higher EG contents, the driving force becomes weaker and the two naphthyl moieties are likely to be located apart at the opposite sides of β-CD rim (C in Scheme 3). In the form of A, which mainly exists in the solutions with lower EG contents, excimer formation is stereochemically impossible. Consequently, A converts to C via B with increasing EG content.

Experimental

Materials. The following commercially available reagents (guaranteed grade) were used without further purification, β-CD, 1-ACA, (−)-borneol, cyclododecanol, cyclohexanol, and EG. DMSO was Dotite-spectrosol grade. Azobenzene-4,4′-disulfonyl dichloride and bis(2-naphthylacetyl)-γ-CD (**2**) were prepared by the same methods previously reported.[7b] Isomers of diazido-β-CD were prepared as the standard samples by the method of Fujita et al.[11]

Measurements. HPLC was performed analytically on a JASCO 800 series with a TSKgel ODS 120A column (4.6 ×250 mm, 5 μm, Toyo Soda, Japan). A linear gradient elution of 10% aqueous CH_3CN-25% aqueous CH_3CN was applied, and the diazido-β-CD was detected by monitoring the UV absorption at 210 nm. The circular dichroism, UV and fluorescence spectra were measured at 25 °C using a JASCO J-400X spectrodichrometer, a Shimadzu UV-250 spectrophotometer and a Shimadzu RF-500 spectrofluorophotometer, respectively. The circular dichroism intensities were expressed as molar ellipticity (in degree cm^2 $dmol^{-1}$) on the basis of the total concentration of **1** or **2**.

***trans*-Azobenzene-4,4′-disulfonyl-β-CD (3).** To a stirred solution of dry β-CD (4.0 g, 3.5 mmol) in dry pyridine (100 ml), azobenzene-4,4′-disulfonyl dichloride (1.3 g, 4.1 mmol) was added, and then heated at 60 °C for 1 h. After cooling the reaction mixture, pyridine was removed by evaporation under reduced pressure. Water addition to the residue followed by evaporation was repeated several times until no pyridine odor was detected. The resultant oily residue was dissolved in a small amount of water and subjected to Sephadex G-15 column chromatography. Recrystallization from methanol afforded the product (0.54 g, 10%): R_f=0.33 (5:1 CH_3CN-H_2O); Found: C, 43.47; H, 5.54; N, 1.97; S, 4.47%. Calcd for $C_{54}H_{76}N_2O_{39}S_2 \cdot 3H_2O$: C, 43.37; H, 5.53; N, 1.87; S, 4.29%.

Bis(2-naphthylacetyl)-β-CD (1). A mixture of **3** (0.54 g, 0.36 mmol), sodium 2-naphthyl acetate (0.31 g, 1.5 mmol) and DMSO (10 ml) was stirred at 80 °C for 6 h. After cooling, the reaction mixture was poured into 500 ml acetone. The precipitates were collected by filtration and subjected to column chromatography on silica gel (8:1 CH_3CN-H_2O). Recrystallization from water gave the desired product (0.15 g, 26%): R_f=0.50 (5:1 CH_3CN-H_2O). ^1H NMR (DMSO-d_6, 25 °C) δ=3.2—4.0 (42H, m, CD protons other than C_1H and OH), 4.2—4.6 (9H, m, O_6H and CH_2Ar), 4.7—4.9 (7H, m, C_1H), 5.6—5.9 (14H, m, O_2H and O_3H), 7.4—7.9 (14H, m, ArH); UV (9:1 H_2O-EG) (ε) 224 nm (150000); IR (KBr) 1720 cm^{-1} (CO). Found: C, 48.81; H, 6.01%. Calcd for $C_{66}H_{86}O_{37} \cdot 8H_2O$: C, 49.07; H, 6.36%.

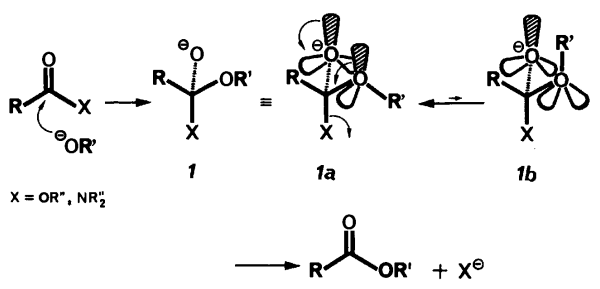
(Received February 23, 1987)

Ab initio molecular orbital calculations have been performed on the reaction profile for the addition/elimination reaction between ammonia and formic acid, proceeding via a tetrahedral intermediate: $NH_3+HCO_2H\rightarrow H_2NCH(OH)_2\rightarrow NH_2CHO+H_2O$. For the addition of ammonia two transition state conformations, of which one possesses a lone pair, on the hydroxyl oxygen of formic acid, antiperiplanar to the attacking nitrogen (T1 conformer) and the other possesses a hydrogen atom, of the OH group, antiperiplanar to the nucleophile ammonia (T1′ conformer), have been identified as characteristic transition state structures. Calculated transition state energies for the first addition step of the reaction revealed that a lone pair on the oxygen of the OH group, which is antiperiplanar to the attacking nitrogen (T1 conformer), stabilized the transition state by 7.4 kcal mol^{-1} compared to the T1′ conformer. Similarly, for the second water elimination step of the reaction, two conformers (T2 and T2′) have been identified as transition state structures, of which the T2 conformer possesses a lone pair on the nitrogen, antiperiplanar (app) to the leaving water and the T2′ conformer possesses a hydrogen atom, of the NH_2 group, app to the leaving water molecule. Again, calculated transition state energies for the T2 and T2′ structures revealed that a lone pair on the nitrogen of the NH_2 group, which is app to the scissile C–O bond (T2 conformer), stabilized the transition state by 3.1 kcal mol^{-1}, thus supporting the hypothesis of stereoelectronic control for this reaction. The significance of these stereoelectronic effects for the mechanism of action of serine proteases is discussed and a novel mechanism is proposed.

Stereoelectronic control, or the role of orbital orientation in organic and enzymatic reactions, has been of considerable interest over the last decade.[1–31] Deslongchamps and cowokers[2] in studying tetracovalent carbon species have demonstrated selective cleavage of bonds which are *trans*-antiperiplanar (app) to lone pair on directly bonded oxygen and/or nitrogen atoms. There has been a growing recognition that conformationally-dependent orbital interactions can play a significant role in the structure and reactivity of biomolecules.

Thus, as shown in the reaction below, addition of alkoxide to the acyl carbon, will yield the tetrahedral intermediate **1**. In the stereoelectronic theory, breakdown of this intermediate with cleavage of the C–X bond is facilitated by two non-bonded electron pairs oriented app (shaded) to the C–X bond in conformation **1a**. In conformation **1b** only one non-bonded electron lone pair is oriented app to the scissile C–X bond. In the stereoelectronic theory, cleavage of the C–X bond of the tetrahedral intermediate **1** is presumed to be controlled by the number of *app* lone pairs and thus should proceed through conformation **1a** rather than **1b** (two app paris in **1a** vs. one app pair in **1b**).



Research groups of Lehn,[5–9] Pople,[10] Gorenstein,[11–17] and others have provided theoretical justification for these stereoelectronic effects in tetracovalent carbon species and phosphates and pentacovalent phosphoranes. We have recently suggested that this stereoelectronic effect has a major impact on the relative energies of transition states, much more so than on ground states or intermediates.[14,15] It is thus important to use calculated transition state energies as a guide in the evaluation of the stereoelectronic effect. Although earlier calculations[1–13] supported the existence of the operation of stereoelectronic effects in tetracovalent species, these comparisons were based only on stable molecular structures that, again, would tend to minimize the stereoelectronic effect. Following the detailed quantum mechanical studies by Oie et al.,[32,33] for the addition-elimination reaction profile between ammonia and formic acid proceeding via a tetrahedral intermediate, we have recently initiated

$$NH_3+HCO_2H\rightarrow H_2NCH(OH)_2\rightarrow NH_2CHO+H_2O \quad (1)$$

an examination of the stereoelectronic effect in the well-characterized transition states.[16] Separate transition states were observed for the first addition step and the second elimination step, with a metastable tetrahedral intermediate.[16,32,33] Related molecular orbital calculations on acyl addition reactions have characterized only a single transition state, failing to find any stabilization of a metastable tetrahedral intermediate.[32,34] Although we could identify for the first

addition step two transition state structures (T1 and T1′) which were important for the stereoelectronic effect comparison, only one conformer (T2) could be characterized for the second elimination step as a real transition state structure, thus making our work half complete.[16] We report here a complete characterization of all four of the transition state conformers (T1, T1′, T2, and T2′) which are ideal for testing the stereoelectronic theory.

Methods of Calculation

In our original study,[16] the SCF LCAO-MO ab initio molecular orbital calculations utilized the GAUSSIAN 70 series of programs with a STO-3G minimal basis set.[35] Initial structures for the addition-elimination transition states of reaction 1, as shown in Fig. 1, were partially taken from the optimized structures of Oie et al.[32] The geometries for different conformations about the C-N and C-O-H bonds for both transition states were then optimized by sequentially varying all bond lengths, bond angles, and torsional angles until the total energy has been effectively minimized when it was clear that only very small (<0.02 kcal mol^{-1}) decreases in energy were possible by further calculation. For optimization of parameter χ, the following Eq. 2 was used, by calculating three energies (E_1—E_3) around the previously increment of dχ, which assumes a parabolic harmonic vibration function:

$$\chi_{OPT} = \chi_0 - \frac{(E_2 - E_3)d\chi}{2(E_2 + E_3 - 2E_1)} \quad (2)$$

where $E_1 = a\chi_0^2 + b\chi_0 + c$

$E_2 = a(\chi_0 + d\chi)^2 + b(\chi_0 + d\chi) + c$

$E_3 = a(\chi_0 - d\chi)^2 + b(\chi_0 - d\chi) + c$

Since $a=(E_2+E_3-2E_1)/2d\chi^2$, the force constant is negative when the numerator of coefficient a is negative. In those structures (T1, T1′, and T2) identified as transition states (a saddle point with only one negative force constant), the reported energy was maximized with respect to this single geometric parameter defining the reaction coordinate, and all other geometric parameters were relaxed to their minimum energy values.[16] Although this procedure is feasible for calculating stable intermediates or ground state structures, it may not be the best choice for calculations of transition state structures unless one geometric parameter can clearly be identified as the reaction coordinate. In general, however, the reaction coordinate consists of the translating bond coupled with other vibrations. A newer optimization routine of the GAUSSIAN 80 program[36] can now automatically search for the transition state. The initially optimized geometries[16] obtained from the GAUSSIAN 70 program were utilized in the full transition state optimization with the GAUSSIAN 80 program. All four transition state structures (T1, T1′, T2, T2′; see Fig. 1) are now optimized and the final geometries are given in Table 1.

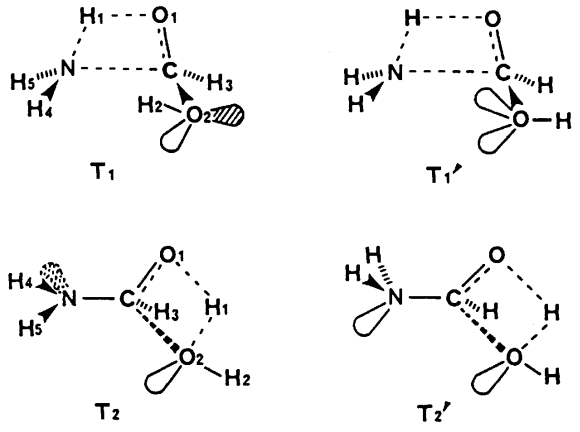

Fig. 1. Structures for different conformations of tetrahedral transition states in the acyl addition-elimination reaction 1.

Results

Shown in Fig. 1 are the four optimized transition state structures of which T1 and T1′ correspond to the first addition step of the reaction and T2 and T2′ to the second elimination step. T1 possesses a lone pair on oxygen (shaded), which is antiperiplanar (app) or trans to the attacking nitrogen (nucleophile). Similarly, T2 possesses a lone pair on nitrogen (shaded), which is trans-app to the leaving water molecule. On the other hand, both T1′ and T2′ do not have an app lone pair with respect to the nucleophile (ammonia) or the leaving group (water). Instead they possess a hydrogen atom which is app to the translating bond.

Shown in Fig. 2 are the reaction profiles for formation of the amide bond in the reaction of ammonia and formic acid. The profiles differ with respect to the conformations about the C-N and C-OH bonds. The relative T1 and T2 transition state energies (Table 2) and geometries (Table 1) calculated in the present study agree well with the earlier calculations.[32] The lowest reaction pathway (solid line in Fig. 2) proceeds via T1 and T2 transition states, with T1 being 1.9 kcal mol^{-1} more stable than T2. It is important to note that both T1 and T2 possess a lone pair (shaded), which is app to the translating bond, in agreement with the stereoelectronic theory.[14,15] For the first addition transition state (formation of the C-N bond), the conformation T1 with an oxygen lone pair on $O_{(2)}H$ app to the C-N bond is 7.4 kcal mol^{-1} lower in energy than T1′, which has no lone pair orbital on $O_{(2)}$ app to the C-N bond. We have previously reported[16] that the energy difference between T1 and T1′ is 3.9 kcal mol^{-1}, which is much smaller than the present 7.4 kcal mol^{-1}, indicating the limitation of the stepwise optimization procedure for the characterization of transition state structures. Similarly, for the second elimination transition state, the conformation T2 with a nitrogen lone pair app to the scissile C-$O_{(2)}$ is 3.1 kcal mol^{-1} lower in energy than T2′, which has no lone pair on nitrogen app to the breaking C-$O_{(2)}$ bond. In our previous study,[16] we failed to locate the T2′ transition state when we assumed that we could approximate the 3N-6

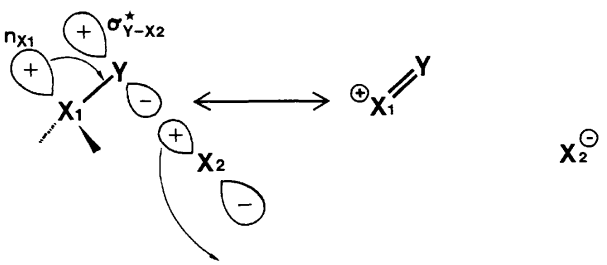
eigenvectors and eigenvalues of the quadratic force constant matrix by treating them as classical vibrational modes (bond stretches, bends, etc.) and force constants. For a col point or transition state, only one of the eigenvalues (force constant) can be negative, and this corresponds to the imaginary vibration frequency defined as the reaction coordinate. In reality, however, it is an oversimplification to assign a single classical vibrational mode to the reaction coordinate eigenvector, although it has the advantage of giving us better chemical intuition for the nature of chemical reactivity. Apparently, the geometric parameters of T2′ were strongly coupled and thus could not be treated in a classical fashion.[16]

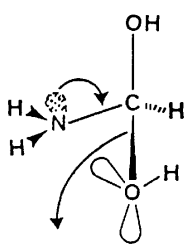
Oie et al. have established that the relative stabilities of the various species were generally unaffected by using more extensive basis sets and inclusion of correlation effects.[32] Because we are only interested in relative energies of transition states differing only in conformation (not atomic bonding), any errors resulting from neglect of correlation and polarization in our study should essentially cancel.[32] The STO-3G optimized geometries, population analyses, and energies for various transition state conformations are shown in Tables 1 and 2.

The stereoelectronic effect is believed to arise from the interaction of an app lone pair (n_{X_1}) on X_1 (oxygen or nitrogen) with the σ^* antibonding Y–X_2 orbital (Scheme 1).[1-28]

In terms of a simple resonance picture for the stereoelectronic effect, stabilization of the structure is thought to derive from an anomeric type, double bond–no bond resonance contribution. The bond opposite to the app lone pair has some no bond character and the bond containing an app lone pair has some double bond character. The overlap population analysis[37] of Table 2 confirms this general picture. As expected, the overlap population of a bond that is app to a lone pair is smaller than the overlap populaton of a bond that is not app to a lone pair (assuming we are comparing otherwise identical structures). Thus the C–N overlap population is 0.264e in the T1′ conformation, whereas it is 0.229e in the T1 conformation (Table 2). The presence of an app lone pair to the scissile C–N bond in T1 conformation weakens this bond (reduces the overlap population). As expected from the double bond–no bond resonance description of the stereoelectronic effect, the C–$O_{(2)}$ overlap population in T1 (0.540e) is larger than in T1′ (0.490). The app lone pair on $O_{(2)}$ to the C–N bond in T1 imparts some double bond character to the C–$O_{(2)}$ bond. Similar overlap population stereoelectronic effects are observed for the T2 and T2′ conformation. T2, with an app lone pair on nitrogen to the scissile C–$O_{(2)}$ bond, has a lower C–$O_{(2)}$ bond overlap population (0.186e) than T2′ (0.213e), and also has a higher C–N bond population (0.675e) than T2′ (0.605e), in accordance with the double bond–no bond resonance structure of Scheme 1.



Scheme 1.



Scheme 2.

Discussion

We have earlier established that the kinetic stereoelectronic effect will largely be manifested in energy differences at the transition state.[14,15,17] On the basis of one-electron molecular orbital theory,[38] the two-electron stabilization from the interaction of a doubly occupied MO(n) with a vacant nondegenerate MO(σ^*) may be approximated as being inversely proportional to the energy separation of the two MO's and directly proportional to the square of their overlap.

$$SE(\mathrm{n},\sigma^*) \propto \frac{S^2_{n\sigma^*}}{\Delta E_{n\sigma^*}} \qquad (3)$$

In the above example, $S_{n\sigma^*}$ is the overlap integral between the app lone-pair orbital(n) on oxygen or nitrogen and the vacant antibonding orbital(σ^*) of the translating bond, and $\Delta E_{n\sigma^*}$ is the energy difference between these orbitals. The app lone-pair stereoelectronic effect presumably derives from this orbital interaction since maximal overlap between n and σ^* is found for the app orientation. Of course, if the stereoelectronic effect does not have its major impact in the transition state, little activation energy differences and no kinetic acceleration will result from these interactions.

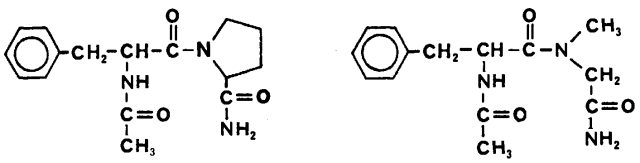
By microscopic reversibility, it should be easier to break or make the bond that possesses no bond character (Scheme 1), and indeed as shown in Fig. 2 and Table 2, this has been confirmed in these calculations of transition state structures. For the addition transition state, the conformation T1 with an oxygen lone pair that is app to the translating C–N bond is 7.4 kcal mol^{-1} lower in energy than T1′, which has no lone pair app to the C–N bond. A similar stereoelectronic effect operates on the second water elimination step:

T2 with a nitrogen lone pair app to the scissile C-$O_{(2)}$ bond is 3.1 kcal mol^{-1} lower in energy than T2′, which has no lone pair app to the C-$O_{(2)}$ bond. Note in our discussion we ignore the lone pair orbitals on $O_{(1)}$, which also are app to the C-N or C-$O_{(2)}$ bonds and hence stereoelectronically facilitate C-N or C-$O_{(2)}$ bond translation. Considering also the counterbalancing stereoelectronic effect,[16] the most favored tetrahedral carbon transition state is one that possesses a lone-pair app to the adjacent scissile bond while at the same time does not have a lone pair on the cleaving atom, which is app to a polar adjacent bond (bond which possesses double bond character; see Scheme 2).

This stereoelectronically most favored structure, derived from the comparisons of transition state conformations, supports Lehn and Wipff's similar conclusions[5-9] based upon overlap population and energy differences in stable tetrahedral intermediates.

Reversing the addition-elimination reaction of Eq. 1 (going from right to left in Fig. 2), one can consider this reverse reaction to be a model study of serine proteases, the water molecule representing a serine hydroxyl group and ultimately hydrolyzing a peptide bond. Although enzymic catalysis is believed to derive from the enzyme's special capacity to stabilize (and hence lower the energy of) the transition state of the reaction,[39-41] it is important to recognize that for most enzymatic reactions, and certainly including peptide bond hydrolysis, there is probably no one unique transition state. Thus, as Albery and Knowles[42] have argued, in the "evolutionary perfection" of an enzyme catalyst in facilitating a multistep reaction, eventually the enzyme must find a mechanism that lowers the barrier to each elementary step. Chymotrypsin and most likely all other serine proteases proceed via an acyl enzyme intermediate in which formation of the acyl enzyme intermediate and hydrolysis of the intermediate in turn proceed via tetrahedral intermediates.[43] Concentrating only on the reaction path between Michaelis comple and acyl enzyme, the enzyme must catalyze formation and breakdown of the tetrahedral intermediate in a minimum two-step reaction. If chymotrypsin is "evolutionarily perfect," then each of these steps is partially rate limiting. The enzyme must thus be sufficiently conformationally flexible at its active site to stabilize both transition states in the formation (T2) and breakdown (T1) of the tetrahedral intermediate. If stereoelectronic effects operate for one transition state, they will likely operate for both. Since the optimal stereoelectronic conformation for formation of the tetrahedral intermediate (T2 conformation) must be different from the optimal stereoelectronic conformation for breakdown of the intermediate (T1 conformation), passage from one transition state to the other will require single-bond rotation about C-O and C-N in the tetrahedral intermediate. Although recent papers have addressed the importance of stereoelectronic effects in the mechanism of action of the serine proteases, such as α-chymotrypsin,[29-31] no mention has been made to the important C-O bond rotation, which is required by an additional counterbalancing stereoelectronic effect.[16] We argue that a most important function of the enzyme is to provide for these conformational changes in the tetrahedral intermediate complex.

Experimental support for the stereoelectronic effects in the mechanism of action of α-chymotrypsin is provided by the elegant work of Bizzozero and coworkers.[29-31] Although peptide bonds involving the carbonyl group of amino acid residues with large hydrophobic side chains are known to be easily hydrolyzed by α-chymotrypsin, if the amide nitrogen is contributed by a proline residue, the peptide bond is resistant to chymotryptic cleavage. This finding has led Bizzozero and Zweifel to examine the reactivity of dipeptides, possessing an alkyl substituent on the leaving group nitrogen, such as *N*-acetyl-L-phenylalanyl-L-prolinamide and *N*-acetyl-L-phenylalanyl-sarcosinamide (Scheme 3). Both dipeptides were found to be unreactive but proved to be good competitive inhibitors, indicating that they form enzyme-dipeptide complexes and their unreactivity must be due to some factors arising during the transformation leading to or from the acyl-enzyme intermediate.



Scheme 3.

Shown in Fig. 3 is our modified description of the catalytic events in the acylation reaction as presented by Dugas and Penny.[31] This modified description is equivalent to Figs. 5 and 6 in our previous article[16] and also to Fig. 4.7 of Deslongchamps' proposal,[31] and this Fig. 3 contains the important C-O bond rotation, in addition to the nitrogen inversion. For the nucleophilic attack by the hydroxyl group of Ser-195, the most stereoelectronically favored transition state is E-T2, which possesses a nitrogen lone pair app to the developing SerO-C_α bond while at the same time does not have a lone pair on the nucleophile serine-oxygen, which is app to a polar N-C_α bond (see also Scheme 2). The important point to be considered here is that the app lone-pair orbital on nitrogen points toward the solvent (backside of the page) and the N-H′ bond toward the inside of the enzyme active site. The distance between the nitrogen and the imidazole ring of His-57 in the E-T2 conformation is only 3.5 Å (based upon model building derived from analogous X-ray crystal structures), and is just sufficient to accommodate a hydrogen atom. When the N-H′ hydrogen is

replaced by an alkyl group, as in the case of a proline residue, this substituent would come too close to the imidazole ring of His-57. Hence it can be argued that a dipeptide containing an alkyl substituent on nitrogen is inactive toward α-chymotrypsin hydrolysis because the steric hindrance prevents formation of the tetrahedral intermediate in the stereoelectronically required E-T2 conformation: In Fig. 3, H′ on nitrogen must be replaced by an alkyl group. The E-T2 conformation is not possible because the distance between the nitrogen and the imidazole ring is only 3.5 Å. Then when H′ is replaced by an alkyl group, the lone pair orbital on the nitrogen can never be app to the nucleophile (Ser-OH), corresponding to the T2′ conformation in Fig. 2-this prevents the nucleophilic attack by Ser-OH.

Note in Fig. 2 that the energy difference between T2 and T2′ is 3.1 kcal mol^{-1}. However, this is the minimum estimate of the corresponding energy difference between E-T2 and E-T2′ (H′ in Fig. 3 is replaced by an alkyl group and rotated to be app to Ser-OH as in the T2′ conformation) since the energy different between T2 and T2′ would have been greater if methyl groups (any alkyl groups) had been used in place of hydrogen on the amide nitrogen. This originates from the expectation that SE (n,σ^*)>SE($\sigma_{O\text{-}H}$,σ^*); SE(n,σ^*)>SE ($\sigma_{C\text{-}H}$,σ^*)>SE ($\sigma_{C\text{-}C}$,σ^*); and SE (n,σ^*)>SE ($\sigma_{N\text{-}C}$, σ^*)>SE ($\sigma_{N\text{-}H}$,n*)[44] in Eq. 3. This implies that electron donation from the $\sigma_{N\text{-}H}$ bond into the σ^* bond is better than the $\sigma_{N\text{-}C}$ bond, resulting in a stabilization of the T2′ conformation compared to the corresponding alkyl substituted counterpart, such as E-T2′ with the replacement of H′ by an alkyl group.

If the E-T2 conformation is stereoelectronically best for lowering the energy of the transition state for SerO-C_α bond formation, as discussed above, it must be the worst for N-C_α bond cleavage. For the cleavage of the N-C_α bond, stereoelectronically the lone pair on the serine oxygen must be app to the translating (scissile) N-C_α bond and no lone pair on the N should be app to the adjacent SerO-C_α bond (E-T1 conformation). This E-T1 conformation is achieved by N-inversion[30] accompanied by torsion about the Ser-195 bonds. The equilibrium between the two intermediates, E-T2 and E-T1 in Fig. 3, is likely to be largely on the side of the E-T1 conformer since E-T2 is destabilized by the unfavorable dipole-dipole repulsion between the N-H group of His-57 and the N-H′ group of the nitrogen. In E-T1 this unfavorable interaction is replaced by a favorable hydrogen bond interaction between the N-H group of His-57 and the lone pair orbital of the nitrogen. It is interesting to note[30] that due to this particular equilibrium position the tetrahedral intermediate is now locked into a conformation (E-T1) where reversion to the enzyme-substrate complex is no longer feasible, since the SerO-C_α bond no longer has an app lone pair on N. Recall that an app lone pair on N is responsible for stabilizing the transition state for C-O cleavage by 3.1 kcal mol^{-1}. This N-inversion step implies that the leaving nitrogen acts as a switch controlling which of the two critical bonds of the tetrahedral intermediate, the C-O bond or the C-N bond, is broken.[30] In the switch position of E-T2, where the lone pair on N points toward the solvent (backside), C-O bond formation is allowed by the stereoelectronic principle, whereas C-N bond cleavage is prevented by lack of an app lone pair on serine oxygen and also by lack of N-protonation by the imidazole. In the other switch position of E-T1, where the lone pair on N points toward the inside of the enzyme active site, C-O bond cleavage is forbidden by the stereoelectronic principle, whereas C-N bond cleavage is facilitated by the app lone pair on the serine oxygen as well as by the N-protonation.

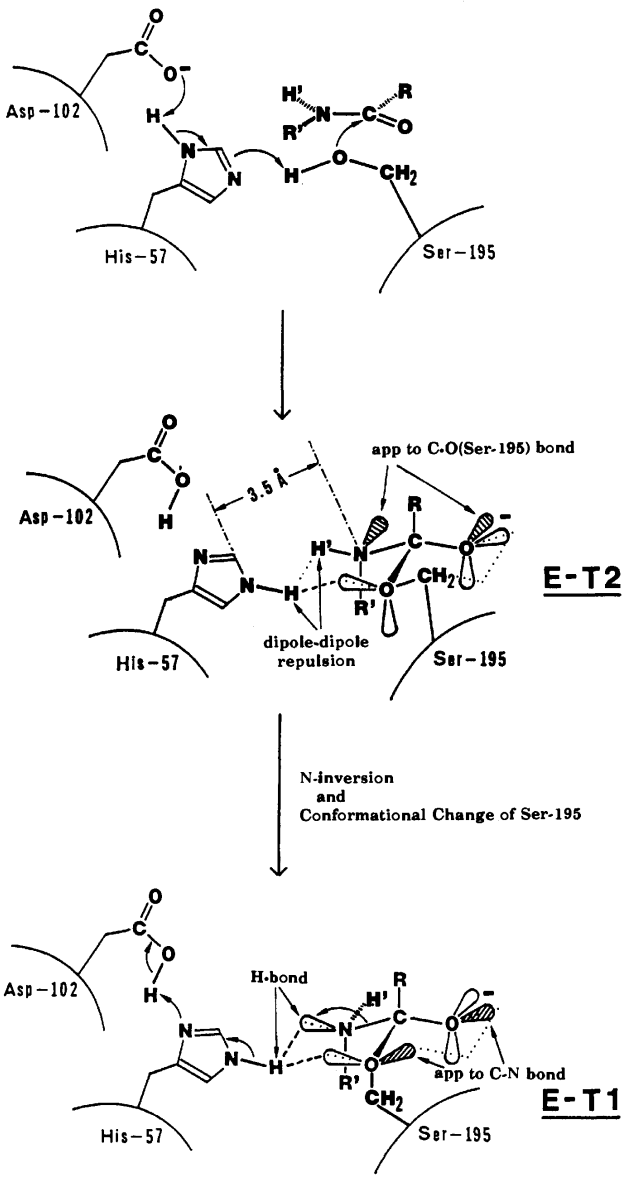


Fig. 3. Schematic drawing of steps in acylation reaction of α-chymotrypsin partially taken from Dugas and Penny.[31] Antiperiplanar lone pairs to the scissile bond are shaded.

Since the tetrahedral intermediate is more stable in E-T1 than in E-T2 (even without considering the dipole-dipole interaction, the T1 transition state is 1.9 kcal mol^{-1} more stable than the T2 transition state; see Table 2), the breakdown of the amide bond (forward direction) is favored over that in the backward direction. Note also the additional important conformational change of Ser-195, going from E-T2 to E-T1, to gain 7.4 kcal mol^{-1} stabilization (Fig. 2) for C-N bond cleavage, which has been missed in the previously recognized literature (actually, the counterbalancing stereoelectronic effect[16] in E-T2 has been ignored in the literature).

The important mobility of the imidazole, to swing between a position allowing formation of a hydrogen bond with the serine oxygen, and one allowing formation of a hydrogen bond with the leaving nitrogen, has been discussed.[16,30] Detailed experimental support for the movement of important atoms has also been given in our earlier publication.[16] Together with the mechanistically required nitrogen inversion, conformational change of the Ser-195, and the observed flexibility of the imidazole group, it would appear as though the serine protease is designed to provide the stereoelectronically optimal transition states for both the acyl addition and elimination steps. These stereoelectronic effects should now be included in a more detailed quantum mechanical calculation of the reaction profile for the serine proteases.

Support by NSF (Chem 83K0098), NIH GM36281 and the John Simon Guggenheim Memorial Foundation for a fellowship (to D.G.G.) and by FRI (to K.T.) is acknowledged. The generous allocation of computing time by the Computer Center, University of Illinois at Chicago, and the help of Dr. Shigeyuki Urano (UIC) with the implementation of GAUSSIAN 80 is also appreciated.

(Received March 13, 1987)

Thermal reactions of tropone with furan and 2-methoxyfuran mainly gave the endo-[4+2] cycloadducts, the kinetically controlled products, at 3000 bar. In the latter case, the product further reacted with tropone to yield 2:1-adducts. On the other hand, the reaction with 3,4-dimethoxyfuran under similar conditions yielded mainly the exo-[4+2] adducts, the thermodynamically controlled products. The predominant formation of the endo-Diels-Alder adducts with furans under the high-pressure conditions may be valuable from a synthetic point of view.

We have recently reported the high-pressure kinetic analysis of the electrocyclic reactions of tropone (**1**) to show the normal volume profiles for the cycloadditions of **1**.[1,2] Accordingly, the ordinary pressure effect should apply to **1**, and under the high-pressure conditions, even the hitherto unsuccessful Diels-Alder reaction of **1** with furans, due to a facile cycloreversion, may occur.[3] Here, we describe the reaction of **1** with furan (**2**), 2-methoxyfuran (**3**), and 3,4-dimethoxyfuran (**4**).

Results and Discussion

Thermal Cycloaddition of 1 with Furans. Heating of an isopropylbenzene (IB) solution of **1** and **2** in a Teflon ampule placed in a pressure vessel (3000 bar)[4] at 130 °C for 10 h yielded, after silica-gel column chromatography, two 1:1-adducts (**5** and **6**). A similar treatment of **1** and **3** yielded three 1:1-adducts **7**—**9**, together with six 2:1-adducts **10**—**15**, which were derived from further cycloaddition of **1** to **7a** or **8a**, proto-adducts leading to **7** or **8**. With **4**, **1** afforded two 1:1-adducts **16** and **17** in 8 and 28% yields, respectively. The results are summarized in Table 1.

In comparison with these high-pressure cycloadditions, the reaction of **1** under ordinary pressure yielded inferior results; heating **1** and **2** in a sealed tube at 130 °C caused no reaction, while under similar conditions, **1** and **3** yielded only **7** and **8**, and **1** and **4** yielded a mixture of products too complicated to permit further investigation.

Table 1. High-Pressure Cycloaddition Reactions of Tropone with Furans

Yield/%	endo-[4+2]	exo-[4+2]	endo/exo
1+2	6 (0)[a]	5 (0)	1.2 (—)
1+3	35 (13)	13 (3)	2.7 (4.3)
	45[b]	18[b]	
1+4	8 (0.5)	28 (0.5)	0.29 (1)

a) Figures in parenthesis are yields at room temperature. b) These values are yields including 2:1-cycloadducts.

a) Not observable. b) No change in signal shape. c) Appreciable sharpening occurred. d) Figures indicate the confirmed coupling values by NMDR.

Structures of 1 : 1-Adducts. The 1 : 1-adducts from **3** (**7**—**9**) exhibited no methoxyl signals in the ^{1}H NMR spectra to indicate a hydrolytic removal of the methoxyl group under the chromatographic conditions to form γ-lactone functions. Other structural features were parallel with the other adducts from **2** and **4**. The structures of these 1 : 1-adducts were clarified by mutual comparisons of the ^{1}H NMR analysis.[5] Namely, the ^{1}H NMR spectra[6] of all 1 : 1-adducts revealed signals of the α,β-unsaturated keto groups at δ=6.8—7.1 and 5.8—6.2 with the coupling constant of ca. 11 Hz, and the latter signals long-range-coupled with the bridge-head methine protons, being characteristic for the [4+2] adducts from **1**.[5] In addition, the ^{1}H NMR of **5**, **7**, and **16** exhibited the smaller J_{fg} (2.5 Hz for **5** and 2 Hz for **7** and **16**), while those of **6**, **8**, and **17** did larger J_{fg} (7 Hz for **6**, 7.5 Hz for **8**, and 6.5 Hz for **17**). Therefore, endo-[4+2][7] structures could be assigned for the formers and exo-[4+2] ones for the latter.[8]

The remaining **9** was another endo-[4+2] cycloadducts; its spin-spin splitting patterns (J_{gh}=7.5 and J_{ch}=2 Hz) ascribable to the lactonic proton indicated to be a regioisomer of **7**.

Structures of 2 : 1-Adducts. Structures of 2 : 1-adducts from **1** and **3** were determined by detailed 400 MHz-decoupled NMR analysis (NMDR) or measurements of the nuclear Overhauser effect (NOE). The **10** and **11**, having two carbonyl carbon signals in the ^{13}C NMR spectra, were [4+2]-[4+2] cycloadducts. The ^{1}H NMR spectra of **10** and **11** revealed J_{gh}=8.5, J_{fg}=1.5, and J_{jr}=0 Hz for **10** and J_{gh}=8.5, J_{fg}=6.5, and J_{jr}=0 Hz for **11**, and clarified their structures to be endo-[4+2]-endo-[4+2] and exo-[4+2]-endo-[4+2] cycloadducts, respectively. The regiochemistry of the second addition step to tropone was confirmed by NMDR; irradiation of the bridge-head protons (H_r) of **10** and **11** changed the broad doublet of H_j to sharp doublets, respectively. While, H_n of **10** and **11**, spin-coupled with the β-protons (H_m) of α,β-unsaturated keto group, was irradiated, the splitting patterns of H_j did not change at all. Hence, H_j and H_r of **10** and **11** are mutually coupled and their structures are unambiguously clarified as was shown in Scheme 1. The changes in shape of the signals caused by intensive NMDR experiments are tabulated in Tables 2 and 3.

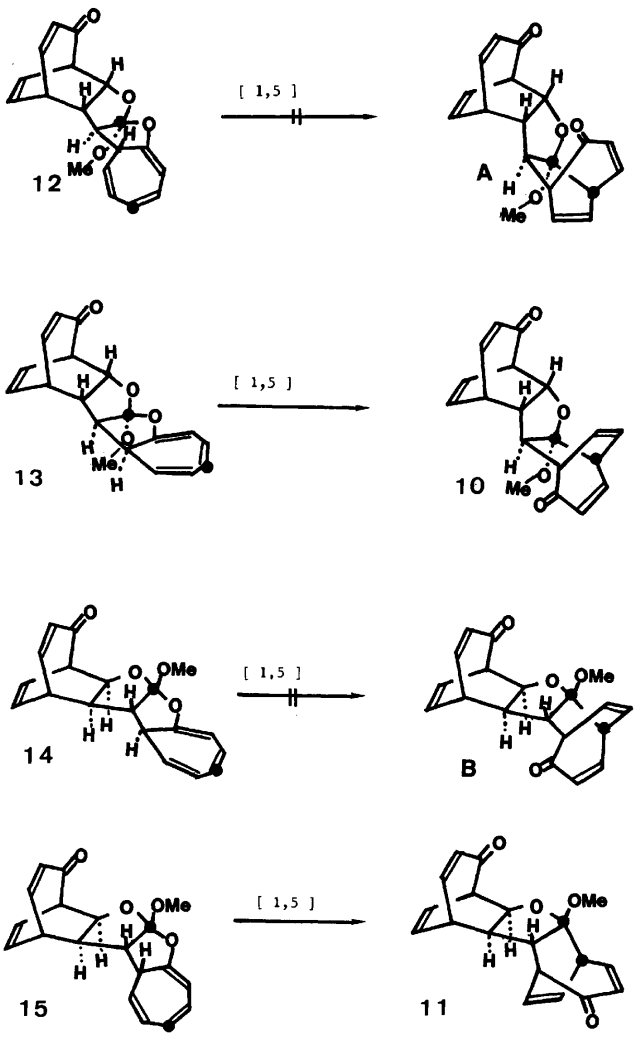
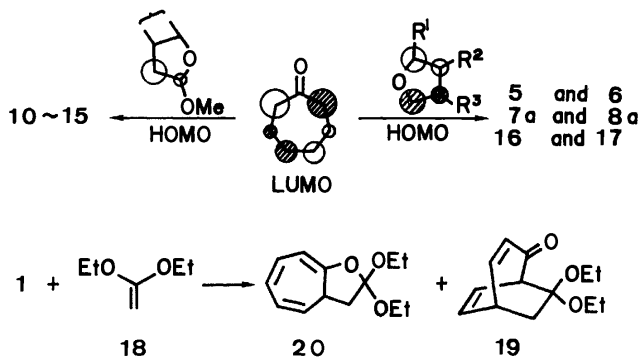
a) Not observable. b) No change in signal shape. c) Figures indicate the confirmed coupling values by NMDR. d) Appreciable sharpening occurred.

On the other hand, **12**—**15** each revealed only one carbonyl carbon ^{13}C NMR spectrum; one of the tropone molecules had thus reacted as the 8π-cycloaddend. Therefore, they are [4+2]-[8+2] cycloadducts. The observed coupling sequences of the methine protons clarified the stereochemistry, and particularly for analyses of [8+2] adducts, there are good model compounds already investigated;[9,10] e.g., **12** [J_{fg}=2, J_{gh}=8.5, J_{jk}=0, J_{hj}=7, and J_{ch}=2 Hz] and **13** [J_{fg}=2, J_{gh}=8.5, J_{jk}=7.5, and J_{hj}=7.5 Hz] are derived from **7a**, while **14** [J_{fg}=7, J_{gh}=8.5, J_{jk}=1, and J_{hj}=5 Hz] and **15** [J_{fg}=7, J_{gh}=8.5, J_{jk}=7.5, J_{hj}=6, and J_{ch}=5 Hz] are from **8a**. The assignments were supported by NOE observations; i.e., an irradiation with the frequency of H_h-signal of **12** enhanced its H_g- and H_k-signals, and similar irradiations with the frequencies of H_h- and H_j-signals of **14** enhanced the H_g- and H_m-signals. When the isomeric **12**—**15** were separately heated in a sealed NMR tube respectively, although the isolated yields were not sufficiently high due to the instability towards air, stereospecific formation of **10** from **13** and **11** from **15** was confirmed and the identities with



Scheme 2.



Scheme 3.

authentic **10** and **11** were established by the ^{1}H NMR spectral comparison. Moreover, the stereospecific isomerization without formation of fragmented 1 : 1-adducts eliminated the dissociation-recombination process. Therefore, considering these structural relationships, **13** and **15** were deduced to have endo-[4+2]-cis-[8+2] and exo-[4+2]-cis-[8+2] structures,[11] respectively.

Mechanism of the Cycloaddition. As shown in Table 1, furans only gave [4+2] cycloadducts with **1**, being parallel to cyclopentadiene at 145 °C,[8] but not to 2,5-dimethyl-3,4-diphenylcyclopentadienone, which gave a [4+2] cycloadduct above 100 °C and predominantly a [6+4] cycloadduct at 60 °C.[12] Among 1 : 1-adducts of **1** with furans, there was no [2+4] or [6+4] cycloadduct formed at all, and a predominant occurrence of the endo-[4+2] cycloadducts is noteworthy. In parallel to the previous study of 3,4-dialkoxyfuran with alkyl coumalates,[13] **4** reacted solely as the 2π-component, a dienophile, throughout.

The regioselectivities of these reactions can be explained by consideration of the LUMO(**1**)-HOMO(furans) interactions, where the largest coefficients are at the C-2(7) positions of **1**, the C-2 positions of **2** and **4**, and the C-5 position of **3**.[14]

The reaction of **1** with **3** yielded six 2 : 1-adducts. The second step of tropone incorporation occurred at a dialkoxyethene part of **7a** and **8a** in two different fashions with a high regioselectivity; one is a [4+2] adduct and the other an [8+2] ([8+2]/[4+2]=3.4).[15]

The predominant formation of [8+2] adducts is parallel to the previous result of the reaction of **1** with 1,1-diethoxyethene(**18**).[10] The high regioselectivity in the second step could be reasonably explained by Frontier Orbital interactions.[16] The energies of the HOMO of the dialkoxyethene part in **7a** and **8a** are estimated to be around −7.5 eV, and those of the LUMO around −4.5 eV.[14] Therefore, considering Frontier Orbitals of **1**,[17] the LUMO(**1**)-HOMO(**7a** and **8a**) interactions[16] are primarily important to 2 : 1-adducts formation. However, these could not explain the periselectivity of the second step of cycloaddition; i.e., the LUMO of **1** has the largest coefficient at the C-2 and the next at the C-5, and the coefficient of the carbonyl oxygen is null.[17] Furthermore, the regiochemistry of the second step of the [4+2]-[4+2] addition is opposite to that of the reported [4+2] adduct (**19**) from **1** and **18**.[10,18] Therefore, the [4+2]-[8+2] adducts may be the thermodynamically stable products accumulated by mutual isomerization with the [4+2]-[4+2] adducts via a [1,5] bond migration. As has been stated, **13** and **15** indeed rearranged to **10** and **11**. A failure to isolate the corresponding [4+2]-[4+2] products (**A** and **B**) from **12** or **14**, however, did not contradict but supported the results of the reaction of **1** with **3**. Since the isomerization occurred only with the stereomers having the cis-geometry, the difference in the thermodynamic stability should be critical; as the molecular model suggests, both **12** and **14** possess the stable trans-trans-geometry for H_h-H_j-H_k and as a result, the equilibria could not produce detectable amounts of **A** and **B** while heating.

In addition, although a stepwise rearrangement was unlikely on the basis of the observed stereospecificity, the mechanism should be analyzed carefully. If the [1,5] sigmatropy is operative in this particular case, the trans-cis system present in the reactive diene site of the

molecule forces the migrating group to flight for long distance,[19] but, the doubly-allylic methine hydrogen was inert against the Woodward-Hoffmann rule-allowed [1,5] sigmatropy. At present, due to the instability of our [8+2] adducts,[20] no further study is possible.

Furthermore, the endo/exo ratio is dependent on the substituents on furans, and under higher pressures, the amount of the exo-isomer which is the thermodynamically controlled product increased in the reaction of **1** with **4**.

Finally, although the present pressure, 3000 bar, being a limit of our apparatus, is not high enough in a preparative point of view, yet, the observed pressure effect was significant, and under higher pressures, the yields and the endo/exo-selectivity of the reaction can be improved.[21,22]

Experimental

Elemental analyses were performed by Miss S. Hirashima, of the Research Institute of Industrial Science, Kyushu University. The NMR spectra were recorded either on a JEOL GX 400 Model or on a JEOL FX 100 Model Spectrometer in $CDCl_3$ solution; the chemical shifts were expressed in δ units. The IR spectra were taken in KBr disks or in $CHCl_3$ solution using a Jasco IR-A 102 Spectrometer. The mass spectra were measured on a JEOL OISG-2 Spectrometer. The UV spectra were measured by means of a Hitachi U-3200 Spectrophotometer.

Diels-Alder Reaction of 1 with 2. **a)** An IB solution (3 cm^3) of **1** (103 mg) and **2** (672 mg) was heated at 130 °C for 10 h in a Teflon ampule under 3000 bar. After cooling to room temperature, the mixture was decompressed and chromatographed on a silica-gel column to give unreacted **1** [61.9 mg; 60%] and the mixture of adducts, which was purified via high-pressure liquid chromatography (HPLC; Micropolasil with hexane-AcOEt) to give **5** [a colorless oil, 4.2 mg; 6%. Found: m/z, 174.0682 (M^+). Calcd for $C_{11}H_{10}O_2$: M, 174.0682. ^1H NMR δ=3.28 (H_c,[6] tdm, J=8.5, 2.5 Hz), 3.67 (H_h, dtd, J=10, 2.5, 2 Hz), 3.95 (H_f, dm, J=7 Hz), 4.70 (H_j, td, J=2.5, 1 Hz), 5.00 (H_g, ddd, J=10, 2.5, 1 Hz), 5.72 (H_a, ddd, J=11, 2, 1 Hz), 6.07 (H_e, ddt, J=8.5, 7, 1 Hz), 6.27 (H_k, dd, J=2.5, 2 Hz), 6.40 (H_d, tm, J=8.5 Hz), and 7.10 (H_b, dd, J=11, 8.5 Hz). ^{13}C NMR δ=40.7, 50.4, 59.9, 81.5, 102.9, 125.2, 129.8, 136.7, 148.5, 154.2, and 194.4. IR ν 1670 cm^{-1}. UV λ_{max}^{MeOH} 209 nm (ε=7600)] and **6** [colorless needles, mp 70—72 °C, 3.1 mg; 5%. Found: m/z, 174.0681 (M^+). ^1H NMR δ=3.3—3.5 (H_c and H_h, m), 4.07 (H_f, tm, J=7 Hz), 4.82 (H_j, t, J=2.5 Hz), 5.11 (H_g, dd, J=11, 7 Hz), 5.88 (H_a, dd, J=11, 2 Hz), 5.99 (H_e, ddd, J=8.5, 7, 1 Hz), 6.29 (H_k, dd, J=2.5, 1.5 Hz), 6.53 (H_d, ddd, J=8.5, 7, 1 Hz), and 6.81 (H_b, dd, J=11, 9 Hz). ^{13}C NMR δ=40.9, 49.9, 56.7, 81.9, 102.2, 125.3, 131.6, 139.5, 148.2, 151.4, and 193.9. IR ν 1680 cm^{-1}. UV λ_{max}^{MeOH} 212 nm (ε=7400)].

b) An IB solution (1 cm^3) of **1** (44.4 mg) and **2** (307 mg) was heated at 130 °C for 10 h in a sealed tube. After removal of the volatile material, no compound was isolated other than the recovered **1**.

Diels-Alder Reaction of 1 with 3. **a)** An IB solution (51 cm^3) of **1** (768 mg) and **3** (6.93 g) was heated at 130 °C for 10 h under 3000 bar. Silica-gel column chromatography of the mixture afforded **7** [colorless needles, mp 138—140 °C, 474 mg; 35%. Found: C, 69.35; H, 5.33%; m/z, 190.0627 (M^+). Calcd for $C_{11}H_{10}O_3$: C, 69.45; H, 5.31%; M, 190.0629. ^1H NMR δ=2.28 (H_j, dd, J=18, 5 Hz), 2.88 (H_k, dd, J=18, 11 Hz), 3.26 (H_h, ddddd, J=11, 8, 5, 2, 1 Hz), 3.36 (H_c, ddm, J=8.5, 7 Hz), 3.90 (H_f, dtd, J=7, 2, 1 Hz), 5.04 (H_g, ddd, J=8, 2, 1 Hz), 5.78 (H_a, ddd, J=11, 2, 1 Hz), 6.18 (H_e, ddt, J=8.5, 7, 1 Hz), 6.60 (H_d, ddt, J=8.5, 7, 1 Hz), and 7.14 (H_b, dd, J=11, 8.5 Hz). ^{13}C NMR δ=34.7, 38.9, 39.9, 59.1, 79.7, 127.2, 130.4, 136.2, 152.7, 175.9, and 192.7. IR ν 1780 and 1670 cm^{-1}. UV λ_{max}^{MeOH} 228 nm (ε=7500)], **8** [colorless needles, mp 137—139 °C, 175 mg; 13%. Found: C, 69.39; H, 5.36%; m/z, 190.0628 (M^+). ^1H NMR δ=2.2—3.1 (H_h, H_j, and H_k, m), 3.46 (H_c, ddd, J=8.5, 7, 4 Hz), 4.10 (H_f, tdd, J=7.5, 2, 1 Hz), 5.04 (H_g, dd, J=8, 7.5 Hz), 5.94 (H_a, ddd, J=11, 2, 1 Hz), 6.04 (H_e, ddd, J=8.5, 7.5, 1 Hz), 6.64 (H_d, ddd, J=8.5, 7, 1 Hz), and 6.94 (H_b, dd, J=11, 8.5 Hz). ^{13}C NMR δ=32.6, 39.7, 40.4, 56.3, 78.5, 124.5, 133.5, 140.2, 148.6, 176.0, and 192.7. b) An IB solution (5 cm^3) of **1** (67 mg) and **3** (613 mg) was heated at 130 °C for 10 h in a sealed tube. Silica-gel column chromatography of the mixture afforded recovered **1** [14.6 mg; 22%], **7** [11.8 mg; 13%], and **8** [2.6 mg; 3%].

Diels-Alder Reaction of 1 with 4. a) An IB solution (5 cm^3) of **1** (94 mg) and **4** (126 mg) was heated at 130 °C for 10 h under 3000 bar. The silica-gel column chromatography afforded, together with the recovered **1** [59.2 mg; 63%], a mixture of products, whose HPLC purification gave **16** [colorless crystals, mp 82—84 °C, 6.4 mg; 8%. Found: m/z, 234.0897 (M^+). Calcd for $C_{13}H_{14}O_4$: M, 234.0892. ^{1}H NMR δ=3.24 (3H, s), 3.54 (3H, s), 3.69 (1H, t, J=8.5 Hz), 3.77 (1H, dtd, J=7, 2, 1.5 Hz), 4.58 (1H, d, J=2 Hz), 5.82 (1H, dd, J=11, 2 Hz), 6.06 (1H, tt, J=7, 1 Hz), 6.09 (1H, s), 6.36 (1H, ddd, J=8.5, 7, 1.5 Hz), and 7.00 (1H, dd, J=11, 8.5 Hz). ^{13}C NMR δ=42.2, 51.6, 57.9, 60.4, 81.4, 94.1, 125.8, 128.2, 130.7, 136.1, 140.5, 152.5, and 193.5. IR ν 1660 and 1090 cm^{-1}. UV λ_{max}^{MeOH} 220 nm (ε=8800) and 302 (850)] and **17** [colorless crystals, mp 126—128 °C, 21.2 mg; 28%. Found: C, 66.25; H, 5.97%; m/z, 234.0922. Calcd for $C_{13}H_{14}O_4$: C, 66.65; H, 6.04%. ^{1}H NMR δ=3.23 (3H, s), 3.52 (3H, s), 3.52 (1H, dddt, J=9, 7, 1.5, 1 Hz), 3.95 (1H, dddd, J=7.5, 6.5, 2, 1 Hz), 4.58 (1H, dd, J=6.5, 1.5 Hz), 5.80 (1H, ddd, J=11, 2, 1 Hz), 5.97 (1H, ddd, J=8.5, 7.5, 1 Hz), 6.03 (1H, s), 6.59 (1H, ddd, J=8.5, 7, 1 Hz), and 6.89 (1H, dd, J=11, 9 Hz). ^{13}C NMR δ=44.5, 51.9, 56.0, 57.8, 81.5, 92.8, 123.0, 127.4, 131.7, 137.8, 140.8, 148.8, and 193.7. IR ν 1665 and 1080 cm^{-1}. UV λ_{max}^{MeOH} 221 nm (ε=7600) and 316 (250)].

b) An IB solution (1 cm^3) of **1** (31.6 mg) and **4** (38.9 mg) was heated at 130 °C in a sealed tube. Silica-gel column chromatography of the mixture afforded, other than the recovered **1** [21.3 mg; 67%] and **4** [19 mg; 49%], a complicated mixture of products, 3.8 mg, whose HPLC revealed more than ten compounds.

Thermal Rearrangement of 13. A benzene-d_6 (C_6D_6) solution (0.3 cm^3) of **13** (13 mg) was heated in a sealed NMR tube at 100 °C for 5 d. The HPLC of the mixture afforded **10** [0.3 mg; 3%], which was identical with the authentic sample prepared directly from **1** and **3**.

Thermal Rearrangement of 15. A C_6D_6 solution (0.3 cm^3) of **15** (9 mg) was similarly heated in a sealed tube at 100 °C for 5 d. The HPLC of the mixture afforded **11** [0.1 mg; 1%], identical with the authentic sample.

Attempted Thermal Rearrangement of 12 and 14. An each C_6D_6 solution (0.3 cm^3) of **12** (17 mg) and **14** (27 mg) was heated in a sealed NMR tube at 100 °C for 5 d. Despite a careful NMR inspection, every chromatographic fraction gave no identifiable product.

We thank The Ministry of Education, Science and Culture for a Grant-in-Aid for Scientific Research given to S. S. (No. 61740294).

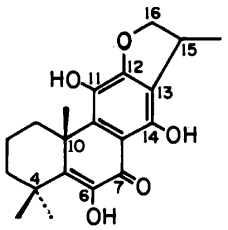
The Synthesis of Lycoxanthol and Its C-15 Epimer

Takashi MATSUMOTO,* Sachihiko IMAI, and Takashi YOSHINARI
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Naka-ku, Hiroshima 730
(Received March 28, 1987)

In order to elucidate the absolute configuration of C-15 in natural lycoxanthol, (15*R*)-11,16-dihydroxy-12-methoxymethoxy-8,11,13-abietatrien-7-one and its (15*S*)-epimer were transformed into (15*R*)-12,16-epoxy-6,11,14-trihydroxy-5,8,11,13-abietatetraen-7-one (**1a**) and its (15*S*)-epimer, respectively. The synthetic **1a** was identical with natural lycoxanthol. Thus, the stereochemistry of C-15 in the natural compound was conclusively assigned as R-configuration.

Lycoxanthol, a highly oxygenated abietane-type diterpene possessing a dihydrofuran moiety, has been isolated from *Lycopodium lucidulum* by Burnell et al.[1,2] On the basis of chemical and spectroscopic studies, they deduced the structure of lycoxanthol to be 12,16-epoxy-6,11,14-trihydroxy-5,8,11,13-abietatetraen-7-one (**1**). However, the absolute configuration of C-15 in the natural compound remained unsettled. In order to elucidate the unknown stereochemistry at C-15, we have now attempted the syntheses of (15*R*)-12,16-epoxy-6,11,14-trihydroxy-5,8,11,13-abietatetraen-7-one (**1a**) and its (15*S*)-epimer (**1b**). For this purpose, (15*R*)-11,16-dihydroxy-12-methoxymethoxy-8,11,13-abietatrien-7-one (**2a**)[3] and its (15*S*)-epimer (**2b**)[3] were chosen as convenient relay intermediates, because these compounds have recently been synthesized in our laboratory by an unambiguous method starting from (+)-dehydroabietic acid.



1

Mesylation of the 12-methoxymethyl ether **2a** with methanesulfonyl chloride in pyridine afforded a mesylate **3a** which was converted into 12,16-epoxy-11-hydroxy-8,11,13-abietatrien-7-one (**4a**) by refluxing with sodium iodide in ethyl methyl ketone and then with anhydrous potassium carbonate in ethyl methyl ketone in 87.2% yield from **2a**. The ^{1}H NMR spectrum of **4a** showed signals at δ 1.30 (3H, doublet), ca. 3.5 (1H, multiplet), 4.13 (1H, double doublet), and 4.75 ppm (1H, triplet) due to a dihydrofuran moiety. For the protection of the hydroxyl group, the dihydrobenzofuran derivative **4a** was acetylated with acetic anhydride in pyridine to give an acetate **5a** in 95.0% yield. This was reduced with sodium borohydride in a mixture of ether and methanol at room temperature, and the resulting crude product was immediately refluxed with *p*-toluenesulfonic acid in benzene to give 11-acetoxy-12,16-epoxy-6,8,11,13-abietatetraene (**6a**) in 93.1% yield. Epoxidation of **6a** with *m*-chloroperbenzoic acid in dichloromethane followed by treatment with *p*-toluenesulfonic acid in refluxing benzene afforded 11-acetoxy-12,16-epoxy-8,11,13-abietatrien-6-one (**7a**) in 63.1% yield. To introduce an oxygen function at the C-14 position, the 6-oxo compound **7a** was reduced with lithium aluminium hydride in ether and the resulting 6β,11-diol (**8a**: 94.5%) was then oxidized with *m*-chloroperbenzoic acid in tetrahydrofuran at room temperature to give a *p*-quinone, 12,16-epoxy-6β-hydroxy-8,12-abietadiene-11,14-dione (**9a**) in 19% yield.[4] In the ^{1}H NMR spectrum of **8a**, the downfield shift of a signal (δ 1.70) due to the methyl group at C-10 relative to the corresponding signal (δ 1.33) for **7a** suggested a 1,3-diaxial-*cis*-relationship between the methyl group and the hydroxyl group at C-6. For the protection of the *p*-quinone moiety, the hydroxy quinone **9a** was subjected to reductive acetylation with zinc powder and acetic anhydride in pyridine, and the resulting crude product was immediately oxidized with Jones reagent at 0—5 °C to give 11,14-diacetoxy-12,16-epoxy-8,11,13-abietatrien-6-one (**10a**) in 20% yield. To introduce a final oxygen function at the C-7 position, the diacetate **10a** was further oxidized with Jones reagent at room temperature and the crude product, without purification, was hydrolyzed with dilute hydrochloric acid in refluxing ethanol to give the desired (15*R*)-12,16-epoxy-6,11,14-trihydroxy-5,8,11,13-abietatetraen-7-one (**1a**), mp 250—251 °C, in 31% yield. The synthetic **1a** was identical with natural lycoxanthol (mp 249 °C).

For direct comparison with **1a**, the synthesis of (15*S*)-12,16-epoxy-6,11,14-trihydroxy-5,8,11,13-abietatetraen-7-one (**1b**) was also carried out in the same manner to that described for the preparation of **1a**. Mesylation of (15*S*)-11,16-dihydroxy-12-methoxymethoxy-8,11,13-abietatrien-7-one (**2b**) with methanesulfonyl chloride in pyridine, followed by treatment of the resulting mesylate **3b** with sodium iodide in refluxing ethyl methyl ketone and then with anhydrous potassium carbonate in refluxing ethyl methyl ketone afforded 12,16-epoxy-11-hydroxy-8,11,13-abietatrien-7-one (**4b**) in 97.8% yield from **2b**. The 11-

hydroxy compound **4b** was acetylated with acetic anhydride in pyridine and the acetate (**5b**: 94.8%) was then transformed into 11-acetoxy-12,16-epoxy-6,8,11,13-abietatetraene (**6b**: 83.0%) by sodium borohydride reduction and acid-catalyzed dehydration. Oxidation of **6b** with *m*-chloroperbenzoic acid followed by treatment with *p*-toluenesulfonic acid led to 11-acetoxy-12,16-epoxy-8,11,13-abietatrien-6-one (**7b**) in 58.0% yield. This was reduced with lithium aluminium hydride to give the corresponding 6β,11-diol (**8b**: 99.2%) which was then converted into 12,16-epoxy-6β-hydroxy-8,12-abietadiene-11,14-dione (**9b**: 16.4%[4]) by oxidation with *m*-chloroperbenzoic acid. Reductive acetylation of **9b** with zinc powder and acetic anhydride in pyridine, followed by oxidation with Jones reagent at 0—5 °C produced 11,14-diacetoxy-12,16-epoxy-8,11,13-abietatrien-6-one (**10b**) in 28.7% yield. Further oxidation of **10b** with Jones reagent at room temperature and subsequent hydrolysis with dilute hydrochloric acid afforded the desired **1b** (40%), mp 219—220 °C, which was not identical with natural lycoxanthol.

From the present study, the stereochemistry of C-15 in natural lycoxanthol was conclusively assigned as R-configuration.

Experimental

All melting points are uncorrected. The IR spectra and optical rotations were measured in chloroform, and the ^1H NMR spectra in deuteriochloroform at 60 MHz, with tetramethylsilane as an internal standard, unless otherwise stated; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, t: triplet, m: multiplet. The column chromatography was performed using Merck silica gel (0.063 mm).

(15*R*)-12,16-Epoxy-11-hydroxy-8,11,13-abietatrien-7-one (4a) and Its (15*S*)-Epimer (4b). a) A mixture of (15*R*)-11,16-dihydroxy-12-methoxymethoxy-8,11,13-abietatrien-7-one (**2a**)[3] (4.485 g) and methanesulfonyl chloride (1.1 ml) in pyridine (10 ml) was allowed to stand at room temperature for 15 h and then poured into a mixture of ice and dilute hydrochloric acid. The mixture was extracted with ether.

The ether extract was washed with brine, dried over sodium sulfate, and evaporated in vacuo to give a crude mesylate (**3a**), IR 3490—3325, 1670, 1360, and 1170 cm^{-1}; ^1H NMR δ=0.95 (3H, s) and 0.98 (3H, s) (-C(CH$_3$)$_2$), 1.32 (3H, d, J=7 Hz, C_{15}-CH$_3$), 1.41 (3H, s, C_{10}-CH$_3$), 2.91 (3H, s, -OSO$_2$-CH$_3$), 3.67 (3H, s, -OCH$_3$), 4.22 (2H, bd, J=7 Hz, -CH$_2$-OSO$_2$CH$_3$), 5.03 (2H, s, -OCH$_2$O-), 7.45 (1H, s) and 7.51 (1H, s) (C_{11}-OH and C_{14}-H).

A stirred mixture of the above crude **3a** and sodium iodide (3.572 g) in ethyl methyl ketone (40 ml) was refluxed for 4 h. After cooling, the mixture was poured into water and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine. The dried solution was evaporated in vacuo. The residue was further refluxed with anhydrous potassium carbonate (3.5 g) in ethyl methyl ketone (20 ml) for 2.5 h. After cooling, the mixture was poured into dilute hydrochloric acid and extracted with ether. The ether extract was washed successively with aqueous sodium thiosulfate and brine, dried, and evaporated in vacuo. The crude product was purified by column chromatography on silica gel (100 g), using ether-benzene (1 : 99) as eluent, to give an oily **4a** (3.268 g: 87.2% yield from **2a**), $[\alpha]_D$ +17.1° (*c* 12.35), IR 3560, 3320, and 1668 cm^{-1}; ^1H NMR δ=0.94 (3H, s) and 0.97 (3H, s) (-C(CH$_3$)$_2$), 1.30 (3H, d, J=7 Hz, C_{15}-CH$_3$), 1.39 (3H, s, C_{10}-CH$_3$), ca. 3.5 (1H, m, C_{15}-H), 4.13 (1H, dd, J=7 and 8 Hz) and 4.75 (1H, t, J=7 Hz) (-OCH$_2$-), 5.36 (1H, s, C_{11}-OH), 7.60 (1H, bs, C_{14}-H). Found: C, 76.54; H, 8.64%. Calcd for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34%.

b): A mixture of (15*S*)-11,16-dihydroxy-12-methoxy-methoxy-8,11,13-abietatrien-7-one (**2b**)[3] (4.104 g) and methanesulfonyl chloride (0.93 ml) in pyridine (10 ml) was treated as described in **a**) to give a crude mesylate **3b**, IR 3490—3325, 1678, 1360, and 1170 cm^{-1}; ^1H NMR δ=0.96 (3H, s) and 0.99 (3H, s) (-C(CH$_3$)$_2$), 1.29 (3H, d, J=7 Hz, C_{15}-CH$_3$), 1.42 (3H, s, C_{10}-CH$_3$), 2.93 (3H, s, -OSO$_2$CH$_3$), 3.68 (3H, s, -OCH$_3$), 4.26 (2H, bd, J=7 Hz, -CH$_2$OSO$_2$CH$_3$), 5.04 (2H, s, -OCH$_2$O-), 7.48 (1H, s) and 7.53 (1H, s) (C_{11}-OH and C_{14}-H).

A stirred mixture of the above crude **3b** and sodium iodide (3.268 g) in ethyl methyl ketone (40 ml) was refluxed for 4 h. After the work-up as described in **a**), the crude product was further refluxed with anhydrous potassium carbonate (3.0 g) in ethyl methyl ketone (20 ml) for 2.5 h. The crude product was purified by column chromatography on silica gel (100 g), using ether-benzene (1 : 99) as eluent, to give an oily **4b** (3.352 g: 97.8% yield from **2b**), $[\alpha]_D$ +33.3° (*c* 8.95), IR 3560, 3320, and 1669 cm^{-1}; ^1H NMR δ=0.95 (3H, s) and 0.97 (3H, s) (-C(CH$_3$)$_2$), 1.33 (3H, d, J=7 Hz, C_{15}-CH$_3$), 1.40 (3H, s, C_{10}-CH$_3$), *ca.* 3.5 (1H, m, C_{15}-H), 4.14 (1H, dd, J=7 and 8 Hz) and 4.78 (1H, t, J=8 Hz) (-OCH$_2$-), 5.33 (1H, s, C_{11}-OH), 7.62 (1H, bs, C_{14}-H). Found: C, 76.13; H, 8.54%. Calcd for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34%.

(15*R*)-11-Acetoxy-12,16-epoxy-8,11,13-abietatrien-7-one (5a) and Its (15*S*)-Epimer (5b). **a**): A mixture of **4a** (1.403 g) and acetic anhydride (3.0 ml) in pyridine (4.0 ml) was heated at 75—80 °C for 2.5 h. After the usual work-up, the crude product was chromatographed on silica gel (50 g), using ether-benzene (1 : 99 and then 5 : 95) as eluents, to give **5a** (1.511 g: 95.0%) which was recrystallized from hexane, mp 165—166.5 °C, IR 1770 and 1668 cm^{-1}, ^1H NMR δ=0.94 (3H, s) and 0.97 (3H, s) (-C(CH$_3$)$_2$), 1.32 (3H, d, J=7 Hz, C_{15}-CH$_3$), 1.33 (3H, s, C_{10}-CH$_3$), 2.32 (3H, s, -OCOCH$_3$), ca. 3.5 (1H, m, C_{15}-H), 4.13 (1H, dd, J=7 and 9 Hz) and 4.73 (1H, t, J=9 Hz) (-OCH$_2$-), 7.88 (1H, d, J=1 Hz, C_{14}-H). Found: C, 74.33 H, 8.18%. Calcd for $C_{22}H_{28}O_4$: C, 74.13; H, 7.92%.

b): A mixture of **4b** (3.047 g) and acetic anhydride (7.0 ml) in pyridine (7.0 ml) was heated at 75—80 °C for 2 h. After the usual work-up, the crude product was chromatographed on silica gel (100 g), using ether-benzene (1 : 99 and then 5 : 95) as eluents, to give **5b** (3.273 g: 94.8%) which was recrystallized from hexane, mp 156.5—158 °C, $[\alpha]_D$ +64.4° (*c* 4.64), IR 1770 and 1668 cm^{-1}, ^1H NMR δ=0.99 (6H, s, -C(CH$_3$)$_2$), 1.36 (3H, s, C_{10}-CH$_3$), 1.36 (3H, d, J=7 Hz, C_{15}-CH$_3$), 2.33 (3H, s, -OCOCH$_3$), *ca.* 3.5 (1H, m, C_{15}-H), 4.12 (1H, dd, J=7 and 9 Hz) and 4.79 (1H, t, J=9 Hz) (-OCH$_2$-), 7.91 (1H, d, J=1 Hz, C_{14}-H). Found: C, 74.26; H, 8.17%. Calcd for $C_{22}H_{28}O_4$: C, 74.13; H, 7.92%.

(15*R*)-11-Acetoxy-12,16-epoxy-6,8,11,13-abietatetraene (6a) and Its (15*S*)-Epimer (6b). **a**): A suspension of **5a** (648 mg) and sodium borohydride (69 mg) in ether-methanol (2 : 1) (9.0 ml) was stirred at 0—5 °C for 15 min and at room temperature for 1 h. The mixture was acidified with dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried, and evaporated in vacuo. The residue was refluxed with *p*-toluenesulfonic acid (50 mg) in dry benzene (10 ml) for 1 h, cooled, and diluted with ether. The ether solution was washed with water, dried, and evaporated in vacuo. The crude product was chromatographed on silica gel (50 g), using benzene as eluent, to give an oily **6a** (576 mg: 93.1%), $[\alpha]_D$ −55.9° (*c* 1.67), IR 1750 cm^{-1}, ^1H NMR δ=0.95 (3H, s), 1.01 (3H, s), and 1.10 (3H, s) (-C(CH$_3$)$_2$ and C_{10}-CH$_3$), 1.27 (3H, d, J=6.5 Hz, C_{15}-CH$_3$), 2.28 (3H, s, -OCOCH$_3$), ca. 3.5 (1H, m, C_{15}-H), 4.03 (1H, dd, J=7 and 9 Hz) and 4.63 (1H, t, J=9 Hz) (-OCH$_2$-), 5.79 (1H, dd, J=3 and 9.5 Hz, C_6-H), 6.42 (1H, dd, J=3 and 9.5 Hz, C_7-H), 6.72 (1H, s, C_{14}-H). Found: C, 77.91; H, 8.56%. Calcd for $C_{22}H_{28}O_3$: C, 77.61; H, 8.29%

b): A suspension of **5b** (3.273 g) and sodium borohydride (348 mg) in ether-methanol (2 : 1) (15 ml) was stirred at 0—5 °C for 15 min and at room temperature for 2 h. After the work-up as described in **a**), the crude product was refluxed with *p*-toluenesulfonic acid (200 mg) in dry benzene (30 ml) for 1 h. The mixture was cooled and diluted with ether. The ether solution was washed with water, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (60 g), using benzene as eluent, to give an oily **6b** (2.594 g: 83.0%), $[\alpha]_D$ −102.8° (*c* 6.48), IR 1752 cm^{-1}, ^1H NMR δ=0.96 (3H, s), 1.01 (3H, s), and 1.11 (3H, s) (-C(CH$_3$)$_2$ and C_{10}-CH$_3$), 1.30 (3H, d, J=6.5 Hz, C_{15}-CH$_3$), 2.29 (3H, s, -OCOCH$_3$), ca. 3.5 (1H, m, C_{15}-H), 4.02 (1H, t, J=9 Hz) and 4.69 (1H, t, J=9 Hz) (-OCH$_2$-), 5.81 (1H, dd, J=3 and 9.5 Hz, C_6-H), 6.44 (1H, dd, J=3 and 9.5 Hz, C_7-H), 6.72 (1H, s, C_{14}-H). Found: C, 77.41; H, 8.52%. Calcd for $C_{22}H_{28}O_3$: C, 77.61; H, 8.29%.

(15*R*)-11-Acetoxy-12,16-epoxy-8,11,13-abietatrien-6-one (7a) and Its (15*S*)-Epimer (7b). **a**): A mixture of **6a** (508 mg) and *m*-chloroperbenzoic acid (80%: 483 mg) in dichloromethane (5.0 ml) was stirred at 0—5 °C for 30 min and at room temperature for 17 h. The mixture was diluted with ether and washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated in vacuo. The residual oil was refluxed with *p*-toluenesulfonic acid (50 mg) in dry benzene (5.0 ml) for 1 h,

cooled, and diluted with ether. The ether solution was washed successively with water, aqueous sodium hydrogencarbonate, and water. The dried solution was evaporated in vacuo. The crude product was chromatographed on silica gel (50 g), using ether-benzene (1 : 99) as eluent, to give an oily **7a** (332 mg: 63.1%), $[\alpha]_D$ +44.8° (*c* 4.58), IR 1763 and 1716cm^{-1}, ^{1}H NMR δ=1.03 (3H, s) and 1.22 (3H, s) (-C(CH$_3$)$_2$), 1.29 (3H, d, *J*=7 Hz, C_{15}-CH$_3$), 1.33 (3H, s, C_{10}-CH$_3$), 2.32 (3H, s, -OCOCH$_3$), 2.60 (1H, s, C_5-H), 3.34 (1H, bd, *J*=21 Hz) and 3.76 (1H, d, *J*=21 Hz) (-COCH$_2$-), 4.08 (1H, dd, *J*=7 and 9 Hz) and 4.67 (1H, t, *J*=9 Hz) (-OCH$_2$-), 6.72 (1H, s, C_{14}-H). Found: C, 73.92; H, 8.09%. Calcd for $C_{22}H_{28}O_4$: C, 74.13; H, 7.92%.

b): A mixture of **6b** (2.820 g) and *m*-chloroperbenzoic acid (80%: 2.680 g) in dichloromethane (20 ml) was stirred at 0—5 °C for 30 min and at room temperature for 13 h. After the work-up as described in **a**), the crude product was refluxed with *p*-toluenesulfonic acid (100 mg) in dry benzene (20 ml) for 1 h. The mixture was cooled, diluted with ether, and washed successively with water, aqueous sodium hydrogencarbonate, and water. The dried solution was evaporated in vacuo. The residue was chromatographed on silica gel (50 g), using ether-benzene (1 : 99) as eluent, to give an oily **7b** (1.712 g: 58.0%), $[\alpha]_D$ +54.6° (*c* 6.54), IR 1761 and 1712 cm^{-1}, ^{1}H NMR δ=1.02 (3H, s) and 1.22 (3H, s) (-C(CH$_3$)$_2$), 1.29 (3H, d, *J*=7 Hz, C_{15}-CH$_3$), 1.31 (3H, s, C_{10}-CH$_3$), 2.28 (3H, s, -OCOCH$_3$), 2.55 (1H, s, C_5-H), 3.31 (1H, d, *J*=21 Hz) and 3.71 (1H, d, *J*=21 Hz) (-COCH$_2$-), 4.00 (1H, t, *J*=8 Hz) and 4.68 (1H, t, *J*=8 Hz) (-OCH$_2$-), 6.66 (1H, s, C_{14}-H). Found: C, 74.26; H, 7.79%. Calcd for $C_{22}H_{28}O_4$: C, 74.13; H, 7.92%.

(15*R*)-12,16-Epoxy-8,11,13-abietatriene-6β,11-diol (8a) and Its (15*S*)-Epimer (8b). **a**): A mixture of **7a** (434.0 mg) and lithium aluminium hydride (69.3 mg) in dry ether (7.0 ml) was refluxed for 1.5 h. The mixture was poured into ice-dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried, and evaporated in vacuo to give a crude **8a** as a solid (364.3 mg: 94.5%) which was recrystallized from acetone-hexane, mp 216—218 °C, IR (KBr) 3580 and 3380 cm^{-1}, ^{1}H NMR δ=1.03 (3H, s) and 1.27 (3H, s) (-C(CH$_3$)$_2$), 1.28 (3H, d, *J*=7 Hz, C_{15}-CH$_3$), 1.70 (3H, s, C_{10}-CH$_3$), 4.02 (1H, t, *J*=8 Hz) and 4.63 (1H, t, *J*=8 Hz) (-OCH$_2$-), 4.55 (1H, overlap, C_6-H), 5.03 (1H, s, C_{11}-OH), 6.42 (1H, s, C_{14}-H). Found: C, 76.16; H, 9.13%. Calcd for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92%.

b): A mixture of **7b** (1.252 g) and lithium aluminium hydride (133 mg) in dry ether (10 ml) was refluxed for 1.5 h to give a crude **8b** as a solid (1.102 g: 99.2%). This was recrystallized from acetone-hexane, mp 212—214.5 °C, IR (KBr) 3490 and 3230 cm^{-1} ^{1}H NMR δ=1.03 (3H, s) and 1.27 (3H, s) (-C(CH$_3$)$_2$), 1.27 (3H, d, *J*=7 Hz, C_{15}-CH$_3$), 1.70 (3H, s, C_{10}-CH$_3$), 4.00 (1H, t, *J*=8 Hz) and 4.66 (1H, t, *J*=8 Hz) (-OCH$_2$-), 4.55 (1H, overlap, C_6-H), 5.01 (1H, s, C_{11}-OH), 6.42 (1H, s, C_{14}-H). Found: C, 76.20; H, 9.15%. Calcd for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92%.

(15*R*)-12,16-Epoxy-6β-hydroxy-8,12-abietadiene-11,14-dione (9a) and Its (15*S*)-Epimer (9b). **a**): A mixture of the above crude **8a** (56.2 mg) and *m*-chloroperbenzoic acid (80%: 42.1 mg) in tetrahydrofuran (2.0 ml) was stirred at room temperature for 18 h. The mixture was diluted with ether and washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated in vacuo. The residue was chromatographed on silica gel (7.0 g), using chloroform as eluent, to give the starting **8a** (19.1 mg) and a *p*-quinone **9a** (7.2 mg: 12%). The *p*-quinone **9a** was recrystallized from acetone-hexane, mp 224—225 °C, $[\alpha]_D$ +39° (*c* 0.51), IR 3620, 3530, 1669sh, 1652, and 1636 cm^{-1}; ^{1}H NMR δ=1.00 (3H, s) and 1.25 (3H, s) (-C(CH$_3$)$_2$), 1.29 (3H, d, *J*=7 Hz, C_{15}-CH$_3$), 1.63 (3H, s, C_{10}-CH$_3$), 4.17 (1H, dd, *J*=6 and 9.5 Hz) and 4.72 (1H, t, *J*=9.5 Hz) (-OCH$_2$-), ca. 4.6 (1H, overlap, C_6-H). Found: C, 72.47; H, 7.69%. Calcd for $C_{20}H_{26}O_4$: C, 72.70; H, 7.93%.

b): A mixture of the crude **8b** (880 mg) and *m*-chloroperbenzoic acid (80%: 660 mg) in tetrahydrofuran (5.0 ml) was stirred at room temperature for 17.5 h. After the work-up as described in **a**), the crude product was chromatographed on silica gel (30 g), using chloroform as eluent, to give the starting **8b** (144 mg) and a *p*-quinone **9b** (126 mg: 13.7%). The *p*-quinone **9b** was recrystallized from acetone-hexane, mp 225—226.5 °C, $[\alpha]_D$ +20.6° (*c* 1.41), IR 3615, 3540, 1670 sh, 1650, and 1637 cm^{-1}; ^{1}H NMR δ=1.01 (3H, s) and 1.26 (3H, s) (-C(CH$_3$)$_2$), 1.29 (3H, d, *J*=7 Hz, C_{15}-CH$_3$), 1.66 (3H, s, C_{10}-CH$_3$), 4.18 (1H, dd, *J*=6 and 9.5 Hz) and 4.70 (1H, t, *J*=9.5 Hz) (-OCH$_2$-), ca. 4.6 (1H, overlap, C_6-H). Found: C, 72.58; H, 7.79%. Calcd for $C_{20}H_{26}O_4$: C, 72.70; H, 7.93%.

(15*R*)-11,14-Diacetoxy-12,16-epoxy-8,11,13-abietatrien-6-one (10a) and Its (15*S*)-Epimer (10b). **a**): A mixture of **9a** (33.3 mg), acetic anhydride (1.0 ml), and zinc powder (50 mg) in pyridine (1.0 ml) was stirred at 0—5 °C for 1 h. After the addition of ether, the zinc powder was removed and the organic solution was washed successively with dilute hydrochloric acid, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated in vacuo. The residue was oxidized with Jones reagent (2.5 mol dm^{-3}: 0.06 ml) in acetone (2.0 ml) with cooling in an ice-water bath for 3 min. After the addition of ether, the mixture was washed with water, dried, and evaporated in vacuo. The crude product was chromatographed on silica gel (5.0 g), using ether-benzene (3 : 97) as eluent, to give an oily **10a** (8.5 mg: 20%), IR 1763 and 1718 cm^{-1}, ^{1}H NMR (90 MHz) δ=1.01 (3H, s), 1.21 (3H, s), and 1.32 (3H, s) (-C(CH$_3$)$_2$ and C_{10}-CH$_3$), 1.23 (3H, d, *J*=7 Hz, C_{15}-CH$_3$), 2.29 (6H, s, C_{11}-OCOCH$_3$ and C_{14}-OCOCH$_3$), 2.62 (1H, s, C_5-H), 3.08 (1H, d, *J*=21 Hz) and 3.47 (1H, d, *J*=21 Hz) (-COCH$_2$-), 3.57 (1H, m, C_{15}-H), 4.13 (1H, dd, *J*=6.5 and 9 Hz) and 4.66 (1H, t, *J*=9 Hz) (-OCH$_2$-). Found: C, 69.25; H, 7.11%. Calcd for $C_{24}H_{30}O_6$: C, 69.54; H, 7.30%.

b): A mixture of **9b** (81.8 mg), acetic anhydride (1.0 ml), and zinc powder (30 mg) in pyridine (1.0 ml) was stirred at 0—5 °C for 1 h. After the work-up as described in **a**), the crude product was oxidized with Jones reagent (2.5 mol dm^{-3}: 0.15 ml) in acetone (1.0 ml) with cooling in an ice-water bath for 3 min. After the addition of ether, the mixture was washed with water, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (10 g), using ether-benzene (3 : 97) as eluent, to give an oily **10b** (29.4 mg: 28.7%), $[\alpha]_D$ +48.2° (*c* 1.23), IR 1761 and 1718 cm^{-1}, ^{1}H NMR (90 MHz) δ=1.00 (3H, s), 1.21 (3H, s), and 1.31 (3H, s) (-C(CH$_3$)$_2$ and C_{10}-CH$_3$), 1.23 (3H, d, *J*=7 Hz, C_{15}-CH$_3$), 2.28 (6H, s, C_{11}-OCOCH$_3$ and C_{14}-OCOCH$_3$), 2.61 (1H, s, C_5-H), 3.15 (1H, d, *J*=21 Hz) and 3.42 (1H, d, *J*=21 Hz) (-COCH$_2$-), 3.57 (1H, m, C_{15}-H), 4.09 (1H, dd, *J*=6.5 and 9 Hz) and 4.69 (1H, t, *J*=9 Hz) (-OCH$_2$-). Found: C, 69.81; H, 7.59%. Calcd for $C_{24}H_{30}O_6$: C, 69.54; H, 7.30%.

(15*R*)-12,16-Epoxy-6,11,14-trihydroxy-5,8,11,13-abietate-

traen-7-one (Lycoxanthol) (1a) and Its (15*S*)-Epimer (1b). **a**): A stirred solution of **10a** (8.5 mg) in acetone (1.0 ml) was oxidized with Jones reagent (1 mol dm^{-3}: 0.1 ml) at room temperature for 2 h. The mixture was diluted with ether, washed with water, and evaporated in vacuo. The residue was dissolved in ethanol (1.0 ml) containing dilute hydrochloric acid (15%: 0.1 ml). The solution was refluxed for 5 h, cooled, and then diluted with ether. The ether solution was washed with water, dried, and evaporated in vacuo. The crude product was chromatographed on silica gel (Mallinckrodt CC-4, 7 g), using hexane-chloroform (1 : 2) as eluent, to give **1a** (2.2 mg: 31%) which was recrystallized from acetone-hexane, mp 250—251 °C, IR (KBr) 3485, 1640, and 1615 cm^{-1}; ^{1}H NMR (90 MHz) δ=1.40 (3H, d, J=7 Hz, C_{15}-CH_3), 1.44 (6H, s, -C(CH$_3$)$_2$), 1.65 (3H, s, C_{10}-CH_3), 3.80 (1H, m, C_{15}-H), 4.28 (1H, dd, J=9 and 6 Hz) and 4.81 (1H, t, J=9 Hz) (-OCH_2-), 12.55 (1H, s, C_{14}-OH); MS m/z 344 (M^+). The synthetic **1a** was identical with natural lycoxanthol (mp 249 °C).

b): A stirred solution of **10b** (29.4 mg) in acetone (2.0 ml) was oxidized with Jones reagent (2.5 mol dm^{-3}: 0.14 ml) at room temperature for 2 h. The crude product was hydrolyzed with dilute hydrochloric acid (15%: 0.1 ml) in refluxing ethanol (1.0 ml) for 5 h. After the work-up as described in **a**), the crude product was chromatographed on silica gel (Mallinckrodt CC-4, 7 g), using hexane-chloroform (1 : 2) as eluent, to give **1b** (9.8 mg: 40%). This was recrystallized from acetone-hexane, mp 219—220 °C, IR (KBr) 3395, 1637, and 1611 cm^{-1}; ^{1}H NMR (90 MHz) δ=1.42 (3H, d, J=7 Hz, C_{15}-CH_3), 1.44 (6H, s, -C(CH$_3$)$_2$), 1.66 (3H, s, C_{10}-CH_3), 3.75 (1H, m, C_{15}-H), 4.28 (1H, dd, J=9 and 6 Hz) and 4.80 (1H, t, J=9 Hz) (-OCH_2-), 12.55 (1H, s, C_{14}-OH); MS m/z 344 (M^+).

(Received April 1, 1987)

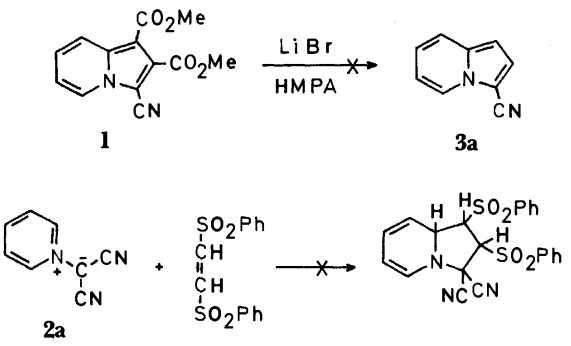
Pyridinium and diazinium dicyanomethylides underwent 1,3-dipolar cycloaddition-extrusion reactions with phenylsulfinylethene, producing the corresponding 3-cyanoindolizines in moderate to good yields. 1,3-Dipolar cycloadditions of these ylides with bis(trimethylsilyl)ethyne gave either the 1,2-bis(trimethylsilyl)-3-cyanoindolizines or the 1-trimethylsilyl-3-cyanoindolizines, or mixtures of these, depending on the substituents and the presence of another nitrogen atom in the pyridine ring. 1,2-Bis(trimethylsilyl)-3-cyanoindolizines underwent regiospecific protodesilylation at the 2-position upon a treatment with silica gel in refluxing chloroform, yielding 1-trimethylsilyl-3-cyanoindolizines. The 1,2-bis(trimethylsilyl)-, and 1-trimethylsilyl-3-cyanoindolizines suffered from quantitative protodesilylation under catalysis by tetrabutylammonium fluoride to afford 1,2-unsubstituted 3-cyanoindolizines.

The preparation of indolizines and their aza analogues[1] has been the subject of considerable interest from physical, chemical, and biological points of view.[2] Controlled reductions of appropriate indolizines would provide a stereospecific and general route to indolizidine alkaloids that comprise a large family of naturally occuring molecules with important medicinal and agricultural properties.[3] In the course of our studies on cycl[3.2.2]azine derivatives, it became necessary to know whether 1,2-unsubstituted 3-cyanoindolizines could serve as key intermediates in cycl[3.2.2]azine synthesis.[4] Unfortunately, however, there are few precedents for 3-substituted indolizines substituted only in the pyridine ring.[5]

In this paper we wish to report in full detail on the simple preparation of 1,2-unsubstituted 3-cyanoindolizines by 1,3-dipolar cycloaddition of heteroaromatic dicyanomethylides with phenylsulfinylethene and bis(trimethylsilyl)ethyne, followed by protodesilylation in the latter case.[6]

Results and Discussion

Although a wide variety of acetylene equivalents in cycloaddition reactions have been devised,[7] only few are suitable for the preparation of nitrogen heterocycles since most of the acetylene equivalents require either an oxidative or reductive procedure after cycloaddition in order to remove the functional groups. For example, in the case of 1,2-bis(methoxycarbonyl)-3-cyanoindolizine (**1**) that was prepared in good yield by a reaction of bis(methoxycarbonyl)ethyne with pyridinium dicyanomethylide (**2a**), a procedure employing LiBr/HMPA that is amenable to the demethoxycarbonylation of tetraheterafulvalenes[8] was unsuccessful, resulting in the formation of a complex reaction mixture. On the other hand, the reaction



of (*Z*)- and (*E*)-1,2-bis(phenylsulfonyl)ethenes, excellent acetylene equivalents in cycloadditions of acyclic compounds[7,9] with pyridinium dicyanomethylide was extremely sluggish, producing a complex mixture after 4 days in refluxing toluene.

We have found that both phenylsulfinylethene (PVSO) and bis(trimethylsilyl)ethyne (BTMSA) serve as reliable acetylene equivalents in 1,3-dipolar cycloadditions. The reaction of pyridinium dicyanomethylide (**2a**) with PVSO[10] produced 3-cyanoindolizine (**3a**) in 43% yield. The elemental and mass spectral analyses as well as IR, ^{1}H and ^{13}CNMR spectra are in agreement with structure **3a** (Tables 2 and 3). The generality of this cycloaddition-extrusion reaction follows from Table 1; the yields are moderate to good. These 3-cyanoindolizines are highly fluorescent in solution. Those possessing an electron-withdrawing group in the pyridine moiety are pale yellow and stable, whereas indolizines like **3a** and **3b** form colorless crystals which turn dark brown on standing.

A comparison of the NMR data of **3** with those of the parent indolizine (**4**)[11,12] deserves to be mentioned. In general, δ(H-2) and δ(H-5) appear in a lower field than those of **4** due to conjugation with the electron-withdrawing 3-CN. Similar to the cyano-substituted

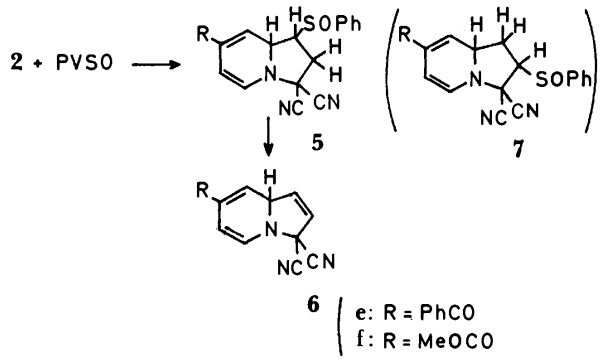
4(^{1}H NMR: δ & J)



The reaction of pyridinium dicyanomethylide (**2a**) with BTMSA in refluxing toluene afforded a mixture of 1,2-bis(trimethylsilyl)-3-cyanoindolizine (**8a**) and 1-trimethylsilyl-3-cyanoindolizine (**9a**) each in 2% yield (^{1}H NMR analysis). They could be separated by medium-pressure liquid chromatography (MPLC), though accompanied by some protodesilylation, **8a**→**9a**. One run (Entry 2, Table 4) gave a 1 : 5 mixture of **8a** and **9a** in 24 % yield (^{1}H NMR analysis). The MPLC separation of crude **8a** afforded a mixture of **8a** and **9a** in the ratio of 1 : 8; the ratio did not change appreciably upon refluxing the mixture in xylene. 4-Methyl- and 4-(*t*-butyl)pyridinium dicyanomethylide, (**2b**) and (**2l**), reacted sluggishly with BTMSA in refluxing toluene, giving **9b** and a mixture of **8l** and **9l** respectively (Table 4). The low yield could be improved when the reaction was performed in refluxing xylene (Entry 9). In contrast, the pyridinium dicyanomethylides (**2e, f, g, m**) having an electron-withdrawing substituent gave better yields of the indolizines (**8e, f, g, m**) and (**9e**). For instance, heating of 4-cyanopyridinium dicyanomethylide (**2g**) with BTMSA in refluxing toluene produced 1,2-bis(trimethylsilyl)-3-cyanoindolizine (**8g**) in 65% isolated yield. Diazinium ylides (**2k, n, o**) that are more π-deficient than the pyridinium analogues reacted smoothly with BTMSA affording the

benzene series, the cyano causes higher field shifts of δ(C-3) by 14—18 ppm (16 ppm in benzonitrile). The ^{13}C resonances at the 6-, 7-, and 8-positions appear lower than those of **4**.

Although no initial adducts **5** have been isolated, a probable mechanism for the formation of **3** involves a 1,3-dipolar cycloaddition of **2** to PVSO to give a primary adduct **5** followed by the elimination of benzenesulfenic acid and hydrogen cyanide. Indeed, the intermediates **6e, f** were isolated in reactions of 4-benzoyl- and 4-methoxycarbonylpyridinium dicyanomethylides (**2e, f**) in yields as poor as 4 and 3%, respectively. The regioisomeric structure **7** might be unlikely, both on steric and electronic grounds (see discussion below).

Although silylacetylenes could be employed as an acetylene equivalent,[7] they usually do not exceed the unsilylated acetylenes in reactivity.[13]

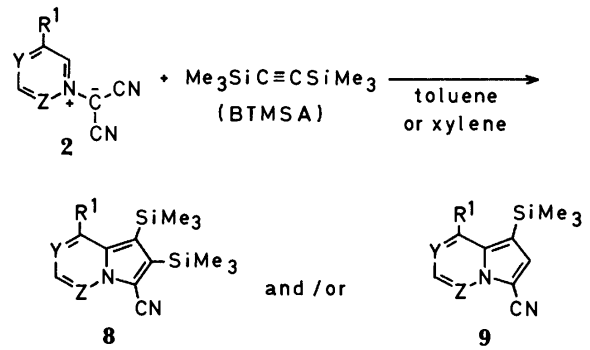
azaindolizines (**8k**, **n**, **o**) and (**9n**); e.g., pyridazinium dicyanomethylide (**2k**) with BTMSA in refluxing toluene gave 92% of **8k**.

In some cases (Entries 5, 6, 7, and 10), protodesilylation was not observed (Table 4). The higher temperature improved the yield, but also promoted protodesilylation, as exemplified with Entry **11**.

The structures of **8** and, partially, **9** were confirmed by elemental (see Experimental) and mass analyses as well as ^{1}H and ^{13}C NMR data (Tables 5 and 6). However, the spectral data did not permit an unambiguous determination of the position of the trimethylsilyl group in **9**. The 1,2-bis(trimethylsilyl)-3-cyanoindolizines (**8**) underwent regiospecific protodesilylation in refluxing chloroform with suspended silica gel yielding **9**; as an exception, **8k** did not undergo protodesilylation under these conditions. The regiochemistry of **9a** was mainly based on the probable regioselectivity in the reaction of **2a** with trimethylsilylethyne (see below). Attempts to convert **8a** to the known 1-methoxycarbonyl-3-cyanoindolizine (**10**)[14] with



2, **8**, and **9**:

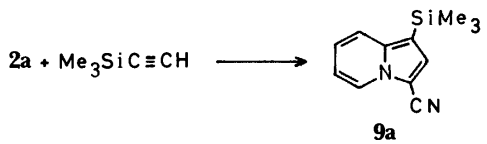
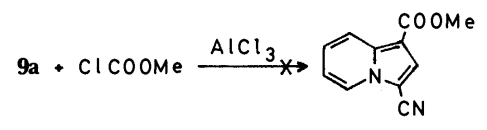
a) δ in $CDCl_3$. b) Coupling constants; Hz. c) $J_{6\text{-}7}$. d) For convenience, the numberings are formally based upon indolizine system.



9a



10

methyl chloroformate catalyzed either by aluminium (III) chloride[15] or by potassium fluoride/18-crown-6[16] were unsuccessful, resulting in the formation of 3-cyanoindolizine (**3a**) in low yields. 7-(*t*-Butyl)-1,2-bis(trimethylsilyl)-3-cyanoindolizine (**8l**) readily lost the trimethylsilyl moiety at 2-position in deuteriochloroform even at room temperature. The reaction is presumably acid-catalyzed.

Tetrabutylammonium fluoride catalyzed the protodesilylation of the trimethylsilylindolizines **8** and/or **9** to give the 3-cyanoindolizines **3** in excellent yields (see Experimental).

The ^{29}Si NMR chemical shifts of **8** reveal a mutual deshielding of the ortho trimethylsilyl groups, as established in the benzene analogues.[17a] the magnitude (0.2—0.3 ppm) is here slightly smaller than in the benzene analogues (ca. 0.6 ppm).[17]

It is now well-documented that, to a more or less extent, most 1,3-dipolar cycloadditions[18] receive

a) Calculated by the CNDO/2 method.

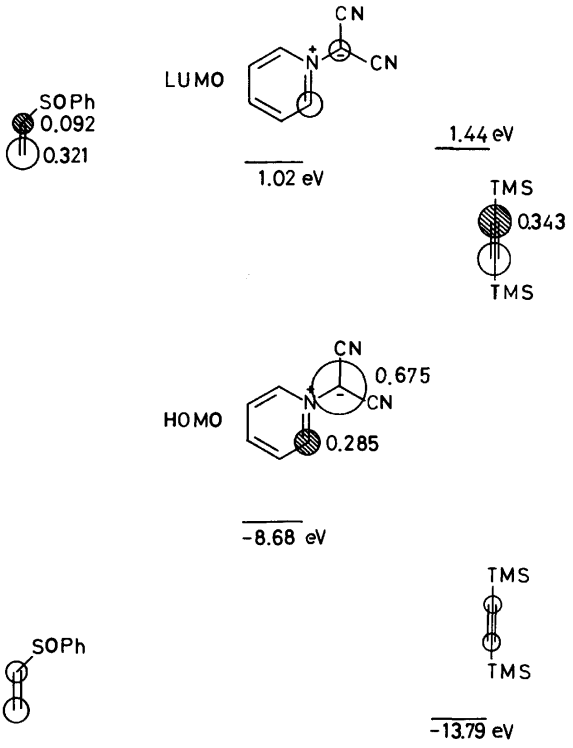

Fig. 1. Frontier molecular orbital interactions in 1,3-dipolar cycloadditions of **2a** with PVSO and BTMSA.

contributions from HOMO-LUMO interactions.[19] Clearly, cycloadditions of highly electron-deficient PVSO with **2** are predominantly HOMO (1,3-dipole)-LUMO(dipolarophile) controlled [type I in Sustmann's classification],[20] whereas those of BTMSA with **2** tend to be under major HOMO(1,3-dipole) control and partial LUMO(1,3-dipole) control when an electron-withdrawing group is introduced in the pyridine ring of **2** (Fig. 1);[21] CNDO/2 calculations of some ylides **2** show that LUMO energy levels are highly affected by a 4-substituent of **2**, while HOMO energy levels vary much less (Table 8).

A consideration of the LUMO-HOMO coefficient would lead to the regioselective formation of **9a** in a reaction of **2a** with trimethylsilylethyne when this reaction is HOMO(1,3-dipole)-LUMO(dipolarophile) controlled, as depicted in Fig. 2.[21]

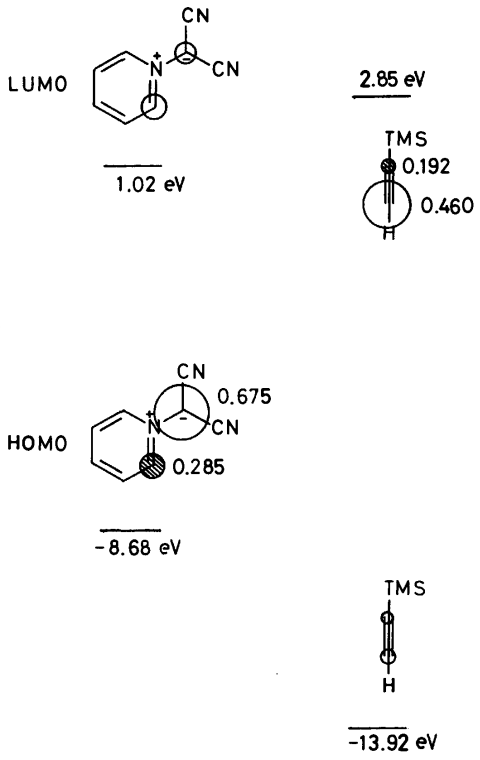

Fig. 2. Frontier molecular orbital interactions in 1,3-dipolar cycloaddition of **2a** with trimethylsilylethyne.

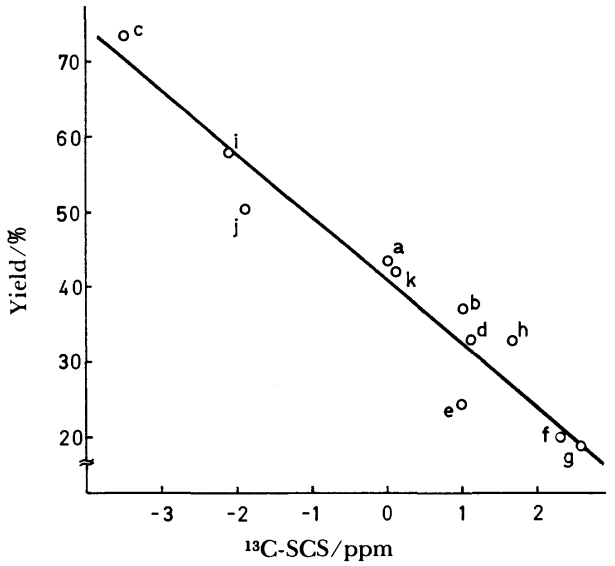

Fig. 3. Plot of the isolated yields of **3** vs ^{13}C-SCS of C-2 of **2**. Yields=−8.26(^{13}C-SCS)+40.91 (r=0.959).

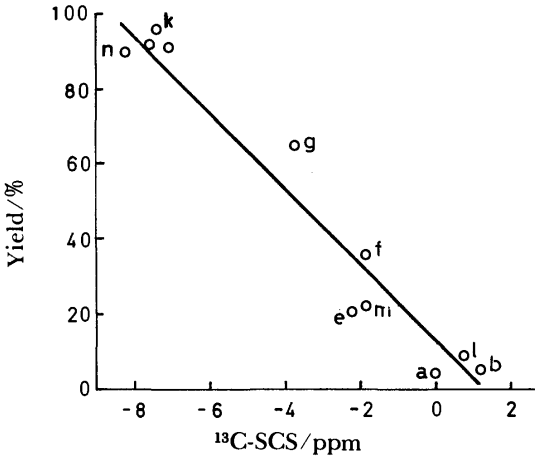

Fig. 4. Plot of the total yields of **8** and **9** (in refluxing toluene) vs. ^{13}C-SCS of the ylidic carbons of **2**. Yields=−10.42(^{13}C-SCS)+11.63 (r=0.971).

Surprisingly, linear correlations have been observed between the yields of **3** and (**8**+**9**) with the ^{13}C-SCS of the C-2 and ylidic carbons, respectively (Figs. 3 and 4). Yields are just determined by the rate ratio of the desired and undesired reactions. Only if the rate of all the side reactions remains constant upon substituent variation, yields may reflect the rate constants. The linear correlations (Figs. 3 and 4) give examples that are amusing, although we do not ascribe much value to them.

In view of the ready availability of cycloiminium ylides, PVSO, and BTMSA, the present two methods for the preparation of 1,2-unsubstituted 3-cyanoindolizines that are otherwise difficult to obtain directly, seem to be practical even in those cases in which only moderate yields are realized. Thus, both PVSO and BTMSA constitute reliable and complementary acetylene equivalents in 1,3-dipolar cycloadditions.

Experimental

General. Melting points were taken on a Yanagimoto micro melting point apparatus and uncorrected. IR spectra were obtained on a Jasco IR-G or a Hitachi EPI-G spectrometer. ^{1}H NMR spectra were measured on a JEOL JNM-C-60HL (60 MHz) or Hitachi R40 (90 MHz) instrument. ^{13}C and ^{29}Si NMR spectra were recorded on a JEOL FX-90Q pulsed Fourier-transform spectrometer operating at 22.49 and 17.75 MHz, respectively. Chemical shifts are expressed in parts per million downfield from internal tetramethylsilane. Partial proton decoupling was used to distinguish between individual carbon atoms. Mass spectra were obtained on a JEOL 01SG-2 spectrometer at 75 eV of ionization energy. Thin-layer chromatography (TLC) was performed on Kiessel-gel PF-254 (0.25 mm; Merck). Preparative medium-pressure liquid chromatography (MPLC) was carried out using a column (25×310 mm) pre-packed with silica gel (Lobar; LiChroprep Si 60; Merck).

Toluene and xylene were dried over sodium or Drierite. The dicyanomethylides **2** were prepared according to the method of Linn et al.[22]

Action of Lithium Bromide on 1. A magnetically stirred mixture of **1** (0.10 g; 0.4 mmol), lithium bromide (0.53 g; 6 mmol), and HMPA (12 ml) was heated to about 100 °C for 1.5 h. The resultant mixture was poured into cold water (15 ml) and extracted with two portions of cyclohexane containing five percent benzene (total 50 ml). The combined organic layer was dried over anhydrous magnesium sulfate and evaporated, leaving an oil which was fractionated by MPLC (elution with hexane-ethyl acetate (1 : 1)). With the

recovered **1** (20 %), many other fractions were obtained, the amounts of which were too small to determine their structures.

Reaction of 2a with (*Z*)- and (*E*)-1,2-Bis(phenylsulfonyl)-ethenes. A solution of **2a** (118 mg; 0.83 mmol) and the ethenes (254 mg; 0.83 mmol) in dry toluene (20 ml) was heated at reflux for 95 h. The solvent was evaporated and the residue was fractionated by MPLC (elution with hexane-ethyl acetate (2 : 1)) to give very complex fractions. A 20 % of **2a** was recovered.

General Procedure for the Reactions of 2 with PVSO. A solution of **2** (6 mmol) and PVSO (9—12 mmol) in dry toluene (35—50 ml) was refluxed under nitrogen with stirring for the time periods given in Table 1. The resulting mixture was concentrated and chromatographed on silica gel (Wako-gel C-100). Elution with hexane and hexane-benzene (1 : 1) gave diphenyl disulfide in the first fraction. Further elution of the column with benzene or hexane-ethyl acetate (2 : 1) gave the 3-cyanoindolizines **3**, which was purified by recrystallization from hexane containing a small portion of ethanol. Yields of the reactions and the physical properties of **3** are shown in Tables 1—3. The analytical data are tabulated in Table 9. In the cases of the reactions of **2e** and **2f** with PVSO, the third elution of the column with benzene-ethyl acetate (1 : 1) gave **6e** and **6f**, respectively. **6e** (4%): Dark red needles (ethanol-ethyl acetate); mp 182—183 °C; IR (KBr) 2200, 1647, 1605 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.22 (d, J=7 Hz, H-8a), 7.1—7.9 (m, 9H, Ph-H+H-1, -2, -5, -6), 9.32 (d, J=7 Hz, 1H, H-8); ^{13}C NMR ($CDCl_3$) δ=93.6 (s, C-3), 101.7 (d, C-8a), 114.2 (d, C-1), 117.8 (s, CN), 127.9 (d, C-2), 128.9 (d, C-ortho), 129.8 (d, C-meta), 133.9 (d, C-para), 135.4 (s, C-ipso), 139.5 (d, C-6), 140.2 (s, C-7), 144.4 (d, C-8), 154.6 (d, C-5), 192.7 (CO); MS m/z (rel intensity, %) 273 (M^+, 100), 237 (32, M^+—HCN). Found: C, 75.04; H, 4.20; N, 15.43%. Calcd for $C_{17}H_{11}N_3O$: C, 74.73; H, 4.03; N, 15.38%. **6f** (3%): Dark brown crystals (hexane-benzene); mp 184—186 °C; IR (KBr) 2205, 2150, 1725 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.01 (s, 3H, OCH_3), 6.31 (br d, J=8 Hz, 1H, H-8a), 7.41 (dd, J=7.5 and 1.5 Hz, 1H, H-1), 7.53 (d, J=7.5 Hz, 1H, H-2), 8.04 (d, J=8 Hz, 1H, H-6), 8.45 (d, J=8 Hz, 1H, H-5), 9.34 (d, J=8 Hz, 1H, H-8); MS m/z (rel intensity, %), 227 (M^+, 100), 200 (58, M^+—HCN), 169 (40, M^+—HCN—OMe) (MW=227.2; Calcd for $C_{12}H_9N_3O_2$).

General Procedure for the Reactions of 2 with BTMSA. A solution of **2** (5 mmol) and BTMSA (50 mmol) in dry toluene or xylene (40 ml) was refluxed with stirring for the time periods stated in Table 4. The solvent and the excess BTMSA were removed in vacuo giving a dark-brown residue, which was subjected to chromatography on Florisil (Wako; 100—200 mesh). Elution with hexane, benzene, and then benzene-ethyl acetate (10 : 1) gave **8** or a mixture of **8** and **9** as pale-yellow crystals. In the cases of Entries 1, 2, 8, and 11, **8** and **9** were isolated by MPLC (elution with hexane-ethyl acetate (9 : 1)) and purified by recrystallization from hexane. The results of the reactions and physical properties are given in Tables 4—6. The analytical data are tabulated in Table 9. In the cases of the reactions of **2a** and **2m** with BTMSA in xylene, the addition of paradium/carbon

Table 9. Analytical Data of Indolizines **3**, **8**, and **9**

a) A mixture of 6,7- and 7,8-dimethyl-3-cyanoindolizine.

(10%; the same weight to the ylide) raised the yields as follows: **8a** (15%) and **9a** (34%); **8m** (58%) and **9m** (27%).

Reaction of 2a with Trimethylsilylethyne. A mixture of **2a** (0.36 g; 2.5 mmol) and trimethylsilylethyne (1.3 g; 14 mmol) in dry toluene (40 ml) was refluxed with stirring for 50 h. The reaction mixture was allowed to stand at room temperature and filtered to recover **2a** (75%). The solids were rinsed with a small portion of toluene and the combined filtrate was concentrated and chromatographed on silica gel (Wakogel C-100; elution with hexane-ethyl acetate (1 : 9)) to give the crude product, which was purified by MPLC (elution with hexane-ethyl acetate (1 : 9)) to afford **9a** (53 mg; 42% based upon the consumed ylide).

Attempts to Transform 9a to 10. 1. To an ice-cold mixture of anhydrous aluminium chloride (53 mg; 0.4 mmol) in dry tetrachloromethane (10 ml) were added methyl chloroformate (38 mg; 0.4 mmol) and **9a** (43 mg; 0.2 mmol). After 20 min, the reaction mixture was heated at the reflux temperature for 4 d and poured into cold water (20 ml). The aqueous phase was extracted with dichloromethane (total 40 ml). The combined organic layers were dried over anhydrous magnesium sulfate and evaporated to leave a dark brown oil that was fractionated by MPLC (elution with hexane-ethyl acetate (4 : 1)). There was isolated a small amount of crude **3a** (ca. 6 mg).

2. A mixture of **9a** (22 mg; 0.1 mmol), methyl chloroformate (19 mg; 0.2 mmol), potassium fluoride (5.8 mg; 0.1 mmol), 18-crown-6 (1,4,7,10,13,16-hexaoxacyclooctadecane) (26 mg; 0.1 mmol) in dry tetrahydrofuran (4 ml) was stirred at room temperature for 51 h and then refluxed for 6 h under a nitrogen atmosphere. There was no detectable product by TLC of the reaction mixture.

3. A mixture of **9a** (22 mg; 0.1 mmol), methyl chloroformate (19 mg; 0.2 mmol), anhydrous zinc chloride (27 mg; 0.2 mmol) in dry dichloromethane (5 ml) was reacted with stirring at room temperature for 22 h and heated to the reflux temperature under a nitrogen atmosphere. The expected product was not detected by TLC of the solution.

Regioselective Protodesilylations of 8. A magnetically stirred mixture of **8** (1.5 mmol) and silica gel (Wakogel C-100; 0.5 g) in trichloromethane (5 ml) was heated at the reflux temperature for 14 h, filtered, and rinsed with dichloromethane. The combined organic solutions were purified by recrystallizations from hexane. The yields of each reaction and various physical properties are given as follows: **9a** (100%), **9f** (93%): mp 124—125 °C; IR (KBr) 2250, 1720 cm^{-1}, **9g** (89%): mp 133—134 °C; IR (KBr) 2225 cm^{-1}, **9m** (95%), **9n** (83%). The other spectral data and analytical data are shown in Tables 5, 6, and 9.

Complete Protodesilylations of 8 with Tetrabutylammonium Fluoride. A cold (0 °C) solution of **8** (1.0 mmol) in dry tetrahydrofuran (7 ml) was treated with tetrabutylammonium fluoride (0.5 ml of 1.0 mol dm^{-3} in tetrahydrofuran). The mixture was stirred at room temperature for 1 d and treated with cold water (20 ml). The aqueous layer was extracted with benzene (total 80 ml), and the combined organic layers were dried over anhydrous sodium sulfate and evaporated to give the crude products **3**, which were identified as **3** by the ^1H NMR and IR spectroscopic data except **3m** and **3n**. The yields of each reactions and some physical properties are given as follows: **3f** (100%), **3k** (86%), **3m** (93%): mp 149—150 °C; IR (KBr) 2240, 1655, 1620 cm^{-1}; ^1H NMR (δ; $CDCl_3$) 2.62 (s, 3H, Me), 6.75 (d, J=4.5 Hz, 1H, H-2), 7.33 (d, J=4.5 Hz, 1H, H-1), 7.35 (dd, J=7.2, 2.7 Hz, 1H, H-6), 8.09 (d, J=2.7 Hz, 1H, H-8), 8.22 (d, J=7.2 Hz 1H, H-5); ^{13}C NMR (ppm from TMS; $CDCl_3$) 26.0 (q, Me), 97.9 (s, C-3), 106.1 (d, C-1), 110.8 (d, C-2), 113.0 (s, CN), 121.7 (d, C-6), 123.4 (d, C-8), 124.9 (d, C-5), 130.3 (s, C-7), 134.8 (s, C-8a), 195.1 (s, CO). **3n** (100 %): mp 158—159 °C; IR (KBr) 2250 cm^{-1}; ^1H NMR (δ; $CDCl_3$) 6.87 (d, J=4.8 Hz, 1H, H-2), 7.25 (d, J=4.8 Hz, 1H, H-1), 7.5—8.1 (m, 4H, Ar-H), 8.54 (bs, 1H, H-6); ^{13}C NMR (ppm from TMS; $CDCl_3$) 99.8 (d, C-1), 101.2 (s, C-3), 112.9 (s, CN), 119.8 (d, C-2), 120.6 (s, C-7), 127.0 (s, C-8), 130.9 (s, C-8a), 145.5 (d, C-6), 122.2, 128.1, 128.3, 133.2 (each d, Ar-C).

Molecular Orbital Calculations. Molecular orbitals were calculated by the CNDO/2 method.[23] The geometry of **2a** was approximated using data for the crystalline state[24] with a slight modification involving a reforming of the molecule planar. Regarding the substituted compounds, the geometries were assumed by means of standard geometrical models,[25] except for the ylide structure which was kept unchanged. The HMO calculations were performed according to the established method.[26]

The authors wish to thank Professor Rolf Huisgen (University of Munich, West Germany) for his kind and helpful comments. They also extend their gratitude to the Institute for Molecular Science for allotment of CPU time on the HITAC M-680H Computer. This work was supported by Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture (Nos. 61840017 and 62540377).

(Received April 9, 1987)

The Crystal structures of (+)-1-phenylethylamine·cinnamic acid salt and (+)-1-(4-isopropylphenyl)-ethylamine·cinnamic acid salt were determined by X-ray analysis. The crystal structures of these two salts provided for the first time some insights into the mechanism of the formation of a conglomerate crystal. In each crytal, two amine components and two acid components form a helical column by hydrogen bonds. On the basis of this similarity in the molecular arrangements, the role of cinnamic acid, an achiral acid, is discussed, and the criteria for the choice of an achiral acid in the transformation of the racemic modification of an amine into a conglomerate crystal is proposed.

The optical resolution of the racemic modification of an amine or a carboxylic acid is usually carried out by the diastereomeric salt method.[1] But, in this resolution, a stoichiometric amount of an optically pure enantiomer is required as a resolving agent, and it is difficult to get both enantiomers of the racemic modification by a simple operation. This difficulty can be solved by the preferential crystallization method. Despite the practical importance, the technique is known to be applicable for the optical resolution of only about 300 racemic modifications, since only conglomerates can be resolved by the method.[1] Moreover, rational explanation has not been proposed for the experimental results. Then, the successful resolution by the preferential crystallization method can only be achieved by a time-consuming trial-and-error procedure.

In the previous papers, we reported that the cinnamic acid salts of α-substituted benzylamine derivatives such as 1-phenylethylamine,[2] 1-phenyl-2-(*p*-tolyl)ethylamine,[2] *erythro*-2-amino-1,2-diphenylethanol,[3] and 1-(4-isopropylphenyl)ethylamine[4] are conglomerates and that these salts can be resolved into pairs of enantiomers by the preferential crystallization. These results seem to suggest the presence of some structural relationship between the chiral amines and the achiral acid. We report here the crystal structures of two conglomerates, 1-phenylethylamine·cinnamic acid salt and 1-(4-isopropylphenyl)ethylamine·cinnamic acid salt that provide considerable insight into the mechanism of the formation of a conglomerate.

significant intensity change. Of unique reflections measured, those as observed with $I > 3\sigma(I)$ were used. The intensities were corrected for Lorentz, polarization, and extinction but not for absorption. The structure was solved by the direct method (MULTAN 11/82) and was refined by the full-matrix least-squares. Scattering factors were taken from "International Tables for X-Ray Crystallography (1974)." Computations were performed by using Enraf-Nonius SDP v3.0. Crystal data and details of refinement are summarized in Table 1.

Results and Discussion

Fractional coordinates for the crystals of (+)-1-phenylethylamine · cinnamic acid salt (**1**) and (+)-1-(4-isopropylphenyl)ethylamine · cinnamic acid salt (**2**) are given in Tables 2 and 3, respectively.[5] Labeled stereoscopic drawings of cinnamic acid and (+)-1-phenylethylamine in the crystal of **1** and those of cinnamic acid and (+)-1-(4-isopropylphenyl)ethylamine in the crystal of **2** are given in Figs. 1 and 2, respectively. Bond distances of **1** and **2** are given in Table 4.

In the crystal of **1**, two amine components and two acid components form a helical column by hydrogen bonds along the *c* axis (Fig. 3). The lengths of the hydrogen bonds are 2.727(2) Å for $O(2)^{i} \cdots N(1)^{i}$, 2.709(2) Å for $N(1)^{i} \cdots O(1)^{ii}$, and 2.785(2) Å for $O(2)^{i} \cdots N(1)^{ii}$. But, no hydrogen bond exists between the columns. Excluding the hydrogen bonds, the shortest intermolecular distance is 3.618(1) Å which is a little larger than the sum of ordinary van der Waals radii.

In the crystal of **2**, two amine components and two acid components are also arranged to form a helical column by hydrogen bonds along the *c* axis (Fig. 4). The lengths of the hydrogen bonds are 2.743(2) Å for $O(2)^{i} \cdots N(1)^{i}$, 2.741(3) Å for $N(1)^{i} \cdots O(1)^{ii}$, and 2.787(3) Å for $O(2)^{i} \cdots N(1)^{ii}$. There is no hydrogen bond between the columns. Other than the hydrogen bonds,

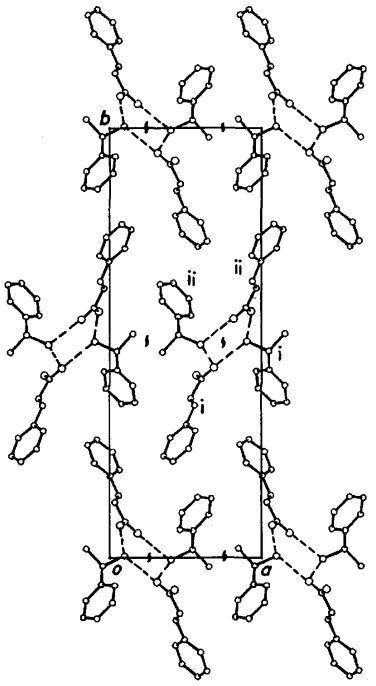

Fig. 3. The Crystal Structure of **1** viewed along the *c* axis. Hydrogen bonds are shown by dashed lines. The numbers i, ii denote the operations, i: *x*, *y*, *z*; ii: 3/2−*x*, 1−*y*, 1/2+*z*.

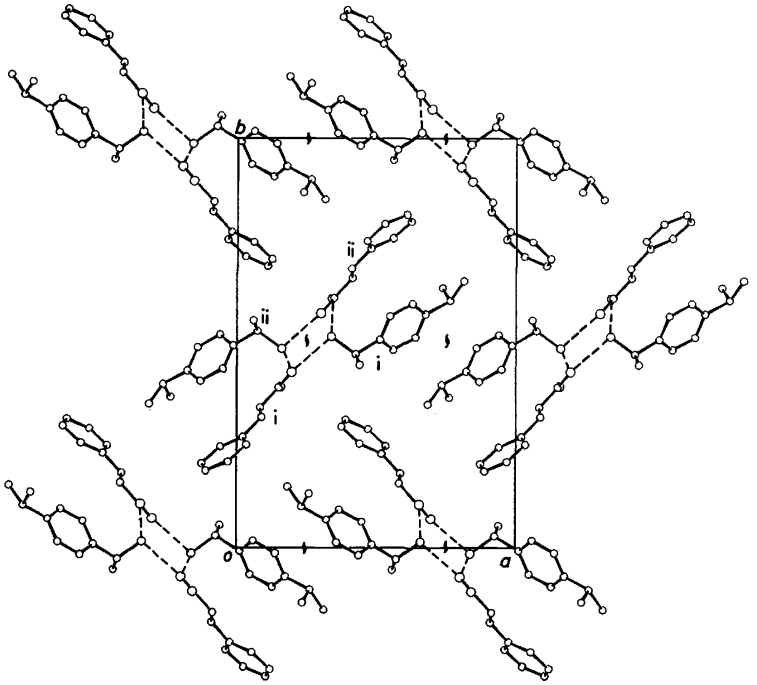

Fig. 4. The Crystal Structure of **2** viewed along the *c* axis. Hydrogen bonds are shown by dashed lines. The numbers i, ii denote the operations, i: *x*, *y*, *z*; ii: 1/2−*x*, 1−*y*, 1/2+*z*.

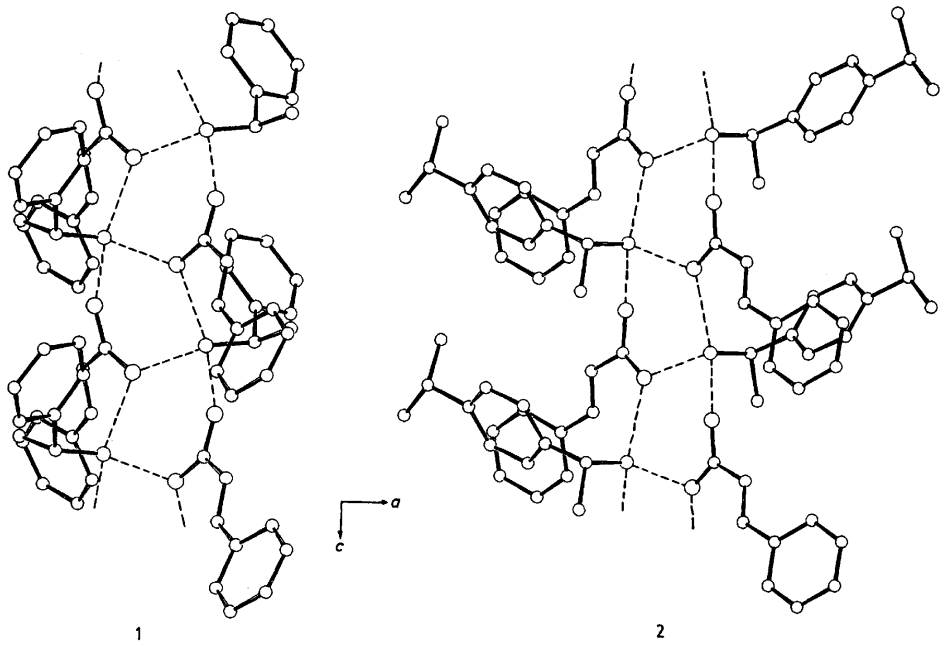

Fig. 5. The Crystal Structures of **1** and **2** viewed along the *b* axis. Hydrogen bonds are shown by dashed lines.

the short intermolecular distances are 3.432(1) Å for C(3)^{i}–C(13)^{ii} and 3.489(0) Å for C(4)^{i}–C(14)^{ii}, which are nearly equal to the sum of van der Waals radii.

As mentioned above, the crystal structures of **1** and **2** are very close. Namely, the crystals of **1** and **2** are built up by the hydrogen bonds between two amine components and two acid components to form columns along the *c* axis. Figure 5 shows the hydrogen bond columns in **1** and **2**. The arrangements of the acid components are very similar to each other in the two columns, whereas those of the amine components are differed from one another. In the structure of **1**, the phenyl group of (+)-**1**-phenylethylamine is parallel to the axis of the column, whereas in the structure of **2** the isopropylphenyl group of (+)-**1**-(4-isopropylphenyl)ethylamine is nearly perpendicular to the column axis. Such different arrangements may be interpreted by steric requirement. The parallel arrangement of isopropylphenyl group would be unfavorable for the formation of the hydrogen bonds. In other words, unusually short contacts less than 2 Å appear between the isopropyl group and the methyl group of the neighboring amine in the hydrogen bond columns, if the phenyl group is replaced by the isopropylphenyl one. The formation of these rigid hydrogen bonds would result in the high selectivity for only one enantiomer of the chiral amine in the course of crystallization. On the other hand, the phenyl group and double bond of cinnamic acid play a significant role for crystal packing to offer suitable space for the amine molecules and to fix it well. In addition, a similar size between the molecules of the amine and cinnamic acid seems to be very important in order to form the column by the hydrogen bonds and to make it rigid.

On the basis of structural similarity of the two conglomerates it is suggested that an achiral acid satisfying the following structural requirement is favorable for the transformation of a racemic modification of an amine into a conglomerate crystal: (a) The achiral acid can form a helical column by hydrogen bonds with the amine; (b) the acid should be rigid and flat to limit the orientation of the amine; (c) the sizes of the amine and the acid are similar to each other.

These working hypotheses are the first insights for the structure of a conglomerate crystal, and they are regarded at the first step for the prediction of the transformation from a racemic modification into a conglomerate crystal.

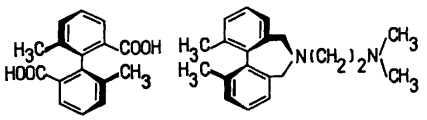
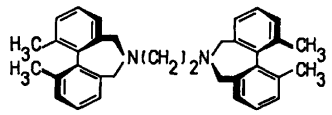
Practical Method for the Synthesis and Optical Resolution of Axially Dissymmetric 6,6′-Dimethylbiphenyl-2,2′-dicarboxylic Acid

Shigeyoshi KANOH, Hiroki MURAMOTO, Natsumi KOBAYASHI, Masatoshi MOTOI, and Hiroshi SUDA*
Department of Chemistry and Chemical Engineering, Faculty of Technology, Kanazawa University, 2-40-20 Kodatsuno, Kanazawa 920
(Received April 9, 1987)

Racemic 6,6′-dimethylbiphenyl-2,2′-dicarboxylic acid (**1**) could be conveniently synthesized and efficiently resolved by the recrystallization of the brucine salts in satisfactory yields. Each enantiomer, thus obtained, was confirmed to be optically pure from a high-performance liquid chromatographic (HPLC) analysis on an optically active column.

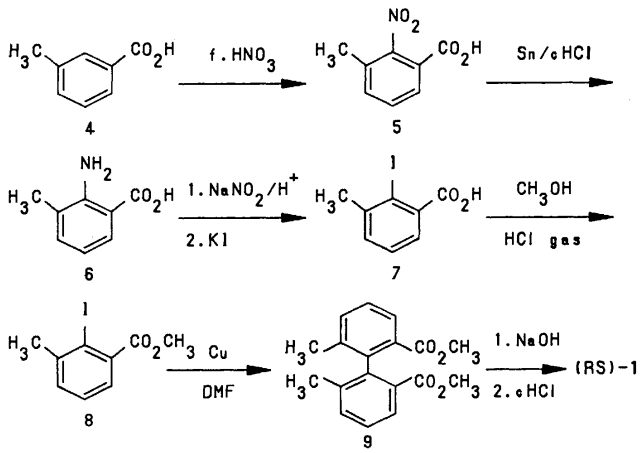
N,N- and *N,N*:*N′,N′*-[(Axially dissymmetric biphenyl-2,2′-diyl)dimethylene]-substituted ethylenediamines, such as **2** and **3**, have been found to serve as very efficient chiral ligands for organolithium compounds in the asymmetric polymerization of triphenylmethyl methacrylate[1,2] and the enantioface-differentiating alkylation of aldehydes.[3] A highly asymmetric induction in these reactions is considered to be due to a complementary effect between the high ability of the biphenyl unit for chiral recognition[4] and the flexibility of the tetramethylethylenediamine sidearm for chelation with organolithium compounds.[5] The key intermediate in the syntheses of ligands **2** and **3** is axially dissymmetric 6,6′-dimethylbiphenyl-2,2′-dicarboxylic acid (**1**) as optically pure forms. Therefore, the development of a convenient method for the synthesis and optical resolution of the diacid is practically important from the viewpoint of a ready application of such ligands to asymmetric reactions.





Recently, we have reported asymmetric polymerizations of triphenylmethyl methacrylate by using chiral complexes of organolithium with **2** or **3**.[1,2] During the course of these investigations, we intended to develop a more convenient preparation of the chiral ligands. In this paper, we wish to describe a facile synthesis of (*RS*)-**1** and its efficient optical resolution through the recrystallization of the brucine salt. The resolved acids were confirmed to be optically pure by means of a high-performance liquid chromatography (HPLC) with an optically active column.

The synthesis of (*RS*)-**1** has been outlined briefly by two research groups.[6,7] However, these papers failed



Scheme 1.

to give the detailed procedures. Our approach to (*RS*)-**1** is represented in the above scheme; details are described in Experimental. The first stage of the synthesis is the nitration of *m*-toluic acid. Even after the optimization of the reaction conditions, the yield was as low as 49%, owing to an inevitable formation of nitrated isomers. However, the poor solubility of 2-nitro-3-methylbenzoic acid (**5**) in cold fuming nitric acid facilitated the separation of **5** from undesirable isomers by a simple suction-filtration. The subsequent steps were conducted in a combination of common procedures, resulting in satisfactory yields.

The first optical resolution of (*RS*)-**1** was carried out with morphine by Bell.[7] Since then, this method has been followed essentially by later investigators.[8,9] However, different specific rotations ranging from +15 to +25° in methanol at 589 nm have been reported for the (+)-acid resolved.[7-9] Moreover, it has been very difficult to obtain optically pure (−)-enantiomer, since the recrystallization of morphine salt of (−)-**1** was not successful.[7]

Bell[7] also reported that an attempt to resolve (*RS*)-**1** with brucine was unsuccessful. We succeeded to resolve the diacid by using this alkaloid.[1] Details of the procedure is as follows. A reaction of (*RS*)-**1** with an equimolar amount of brucine gave a mixture of the diastereomeric salts. In order to effectively separate

this mixture into each salt, it was found that solvent systems for recrystallization were extremely important. One recrystallization of the diastereomeric salts from a mixture of methanol–acetone (7/3 v/v) gave levorotatory brucine salt of (*S*)-**1**, the yield of which was 40% based on (*RS*)-**1** used. The optical purity of this salt seemed to be nearly 100%, since further recrystallization did not cause any noticeable change in the optical rotation. Subsequently, when the solvents of the mother liquor were replaced with acetone alone, crystallization of another diastereomeric salt started. The (+)-salt obtained was recrystallized from acetone containing a small amount of methanol to give pure brucine salt of (*R*)-**1** in 43% yield. Further recrystallizations of the last residue remaining in the acetone solution led to additional yields of the individual salts. The decomposition of each salt with diluted hydrochloric acid gave (*S*)- and (*R*)-**1** in 43 and 42% overall yields, respectively; the absolute configuration has been established.[9] As a matter of course, most of the resolving agent was recovered.

Optical purities of (+)- and (−)-**1**, thus resolved, were determined from HPLC analyses of the dimethyl esters **9** derived from the diacids. The column used was an optically active column, **CHIRALCEL OC**, which is commercially available from *Daicel Chemical Industries Ltd.*; the packing material is cellulose tris-(phenylcarbamate) coated on a macroporous silica gel.[10] Base-line resolution of racemic **9** was accomplished with this column, using hexane–2-propanol (9/1 v/v) as an eluent.[11] Figure 1 shows the chromatograms of (+)- and (−)-**9** under the same operation conditions as those for the racemate. Each major peak in the curves appeared at a different retention volume,

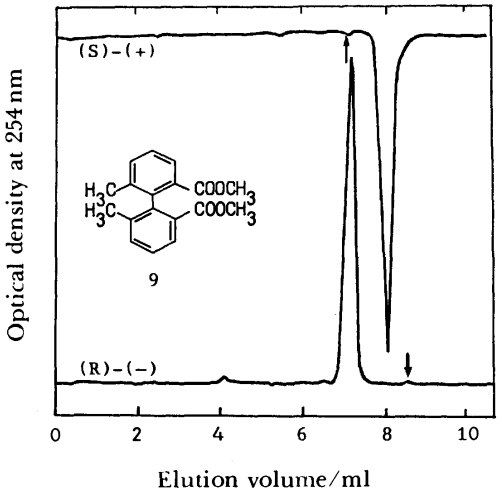


Fig. 1. Chromatograms of the dimethyl esters **9** derived from optically resolved **1**. The peaks marked with arrows are probably due to the minor enantiomers. Column: **CHIRALCEL OC** (*Daicel Chemical Industries Ltd.*), 25×0.46 (i.d.) cm; eluent: hexane–2-propanol (9/1 v/v); flow rate: 0.2 ml min^{-1} at 25 °C; detector: UV at 254 nm.

which is nearly in agreement with that of either two peaks in the enantiomeric separation observed for the racemate. An inspection of the curves reveals that each of the samples probably contains a very small amount of the opposite enantiomer. Based on the relative peak area, the optical purities of (+)- and (−)-diesters were estimated to be 99.1 and 99.6%, respectively. From the chromatographic results, each of the diacids **1** resolved in the present study may be regarded as almost optically pure. The completely pure enantiomers, if required, are obtainable by a recrystallization from benzene.

The present procedure for the optical resolution of (*RS*)-**1** seems advantageous regarding the use of cheaper brucine, an easy access of nicely recrystallizable salts with both enantiomers and, above all, an operational simplicity and high efficiency of the resolution.

Experimental

Melting points are uncorrected. IR and ^{1}H NMR spectra were recorded on a JASCO A-202 and a JEOL JNM-FX-100S (100 MHz) spectrometer, respectively. Optical rotations were measured on a JASCO DIP-360 digital polarimeter. A determination of the optical purities of (+)- and (−)-**9** was performed by using an HPLC on an optically active column, **CHIRALCEL OC** (*Daicel Chemical Industries Ltd.*; 25×0.46 (i.d.) cm). Resolution was carried out with hexane–2-propanol (9/1 v/v) at a flow rate of 0.2 ml min^{-1} at 25 °C.

Preparation of (*RS*)-2,2′-Dimethylbiphenyl-6,6′-dicarboxylic Acid (1). 2-Nitro-3-methylbenzoic Acid (5): *m*-Toluic acid (**4**) (200 g, 1.47 mol) was added in small portions to 500 ml of fuming nitric acid (d=1.52) with stirring at −10 °C. Stirring was continued for an additional 1 h at this temperature. The precipitate was collected by a suction-filtration with a large sintered-glass filter as quickly as possible, and thoroughly washed with water. Recrystallization from ethanol yielded 130 g (49%) of **5**. Mp 218—219 °C (lit,[12] 219 °C); IR (KBr) 3200—2400, 1690, 1550, 1375, and 1300 cm^{-1}; ^{1}H NMR (DMSO-d_6/D_2O) δ=2.32 (s, 3H), 7.5—7.9 (m, 3H).

2-Amino-3-methylbenzoic Acid (6): Tin powder (220 g, 1.85 mol) was suspended in a solution of **5** (120 g, 0.66 mol) in ethanol (500 ml). To the stirred mixture was added dropwise 1.3 l of 9 mol dm^{-3} hydrochloric acid at 50—60 °C. The resulting solution was stirred for 1.5 h at 70 °C, cooled, and then made alkaline by the addition of concd. aqueous NH_3. Inorganic precipitates were removed and the filtrate was freed from ethanol by evaporation under reduced pressure. The resulting solution was acidified with acetic acid (pH=5). The precipitate was collected and dissolved in acetone. After the removal of insoluble materials and then the solvent, recrystallization of the residue from ethanol gave 89 g (89%) of **6**. Mp 174—175 °C (lit,[12] 172 °C); IR (KBr) 3500, 3380, 3200—2400, 1670, 1575, and 1240 cm^{-1}; ^{1}H NMR ($CDCl_3$/D_2O) δ=2.18 (s, 3H), 6.5—7.9 (m, 3H).

2-Iodo-3-methylbenzoic Acid (7): A suspension of **6** (75 g, 0.5 mol) in a mixture of concd. H_2SO_4 (300 ml) and water (600 ml) was stirred for 1 h at room temperature, and then a solution of $NaNO_2$ (45 g, 0.65 mol) in 75 ml of water was

added drop by drop at 10 °C. The excess nitrite was decomposed with urea. To the solution were added in one portion a saturated aqueous solution of KI (420 g, 2.5 mol) and a small amount of copper powder,[13] which was prepared by the reduction of copper(II) sulfate with zinc powder. Vigorous stirring was continued for 3 h at about 30 °C, and the mixture was allowed to stand overnight. The supernatant solution was decanted and a brownish precipitate was dissolved in benzene. The benzene solution was decolorized with aqueous $NaHSO_3$, followed by evaporation under reduced pressure. Recrystallization from aqueous ethanol yielded 106 g (81%) of **7**. Mp 143—144 °C (lit,[6] 145—146 °C); IR (KBr) 3200—2400, 1700, and 1290 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.56 (s, 3H), 7.2—7.7 (m, 3H), 9.5 (br s).

Methyl 2-Iodo-3-methylbenzoate (8): A solution of **7** (129 g, 0.49 mol) in 650 ml of methanol was saturated with hydrogen chloride; the gas was then passed through the refluxing solution for 1 h. The usual extractive work-up, followed by distillation under reduced pressure, gave 128 g (94%) of **8**. Bp 130—140 °C (5 mmHg (1 mmHg=133.322 Pa)) (lit,[8] 156.5—157.5 °C (13 mmHg)); IR (liquid film) 1730, 1295, and 1145 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.50 (s, 3H), 3.92 (s, 3H), 7.2—7.4 (m, 3H).

Methyl 6,6′-Dimethylbiphenyl-2,2′-dicarboxylate (9): A solution of **8** (209 g, 0.76 mol) in 210 ml of *N*,*N*-dimethylformamide was mixed with activated copper powder[14] (100 g), and gently refluxed for 5 h. The copper was filtered off and thoroughly washed with hot benzene. The combined filtrates were washed with water, 1 mol dm^{-3} HCl, aqueous $NaHCO_3$, and then brine. After the solvents were removed, distillation under reduced pressure gave 91 g (80%) of **9**. Bp 150—160 °C (0.05 mmHg) (lit,[8] 197—198 °C (13 mmHg)); IR (liquid film) 1735, 1280, and 1150 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.91 (s, 6H), 3.57 (s, 6H), 7.2—7.9 (m, 6H).

6,6′-Dimethylbiphenyl-2,2′-dicarboxylic Acid (1): The diester **9** (116 g, 0.39 mol) was refluxed in a solution of 150 g of NaOH in 800 ml of water for 5 h. The mixture was acidified by the addition of concd. HCl with cooling and the precipitate was collected. Recrystallization from aqueous ethanol yielded 100 g (95%) of **1**. Mp 240—241 °C (lit,[9] 236—237.5 °C); IR (KBr) 3300—2400, 1700, and 1280 cm^{-1}; ^1H NMR (DMSO-d_6/D_2O) δ=1.81 (s, 6H), 7.3—7.8 (s, 6H). Found: C, 71.06; H, 5.05%. Calcd for $C_{16}H_{14}O_4$: C, 71.10; H, 5.22%.

Optical Resolution of (*RS*)-1. Brucine (100 g, 0.26 mol) and (*RS*)-**1** (69 g, 0.26 mol) were dissolved in a refluxing mixture of methanol (420 ml) and acetone (180 ml). After the solution was cooled at room temperature overnight, the colorless needles deposited were collected by filtration and washed with cold methanol: Brucine salt of (*S*)-**1**, 68 g (40% yield); $[\alpha]_D^{25}$ −39.2° (*c* 1.0, methanol). When a part of the first crop was recrystallized from acetone, the resulting salt showed a similar rotation of $[\alpha]_D^{25}$ −38.9°. The solvents of the mother liquor were evaporated under reduced pressure and the oily residue was dissolved in 200 ml of acetone on heating. Cooling the solution in a refrigerator overnight gave 78 g of colorless cubics, which showed $[\alpha]_D^{25}$ +37.1° (*c* 1.0, methanol). After the recrystallization of the (+)-salt from acetone containing a small amount of methanol, the resulting (+)-salt showed a slightly higher rotation of $[\alpha]_D^{25}$ +38.1 (*c* 1.0, methanol), and the rotation was not changed by further recrystallization. The yield of brucine salt of (*R*)-**1** was 43% (73 g). Additional recrystallizations of the last residue, in turn from methanol–acetone (7/3 v/v) and acetone alone, gave small amounts of the (−)- and (+)-salts in 5 and 2%, respectively.

The combined (−)-salts (77 g, 0.12 mol) were decomposed in 250 ml of 1 mol dm^{-3} HCl and the equal volume of ethyl acetate with stirring at 50 °C. The organic extracts were washed with 1 mol dm^{-3} HCl and brine, dried over Na_2SO_4, and evaporated under reduced pressure. The residual oil, which gradually solidified, was dried under reduced pressure to give 30 g of (*S*)-**1** (43% yield based on (*RS*)-**1** used).[15] It was possible to recrystallize the diacid from benzene. Mp 211—212 °C (lit,[9] 211.5—213.5 °C); $[\alpha]_D^{25}$ +22.1° (*c* 1.0, methanol) (lit,[9] $[\alpha]_D^{25}$ +25° (*c* 1.2)).

The (+)-salt (76 g, 0.11 mol) was similarly converted back to (*R*)-**1** in 42% yield.[15] Mp 213—214 °C (lit,[9] 207—211 °C); $[\alpha]_D^{25}$ −21.3° (*c* 1.0, methanol) (lit,[9] $[\alpha]_D^{23}$ −22° (*c* 1.0)). More than 90% of brucine used were recovered from the acid extracts combined, by the recrystallization from ethanol.

In order to determine the optical purity of the resolved **1**, it was converted to the dimethyl ester **9**. Thus, an ethereal suspension of optically active **1** before recrystallization was treated with a large excess of diazomethane in tetrahydrofuran at room temperature; then, the solvents were removed. The chromatographic sample was purified by a simple distillation of the residue under reduced pressure. The yield of **9** was nearly quantitative. (*R*)-**9**, $[\alpha]_D^{25}$ −55.3° (*c* 2.0, benzene) (lit,[8] $[\alpha]_D^{25}$ −45.1° (*c* 1.3)). (*S*)-**9**, $[\alpha]_D^{25}$ +55.8° (*c* 2.0, benzene) (lit,[8] $[\alpha]_D^{25}$ +55.2° (*c* 2.0)).

The authors are indebted to Dr. Akito Ichida of Daicel Chemical Industries Ltd. for the chromatographic resolution of **9** on the optically active column. This work was supported in part by a Grant-in-Aid for Scientific Research No. 61470105 from the Ministry of Education.

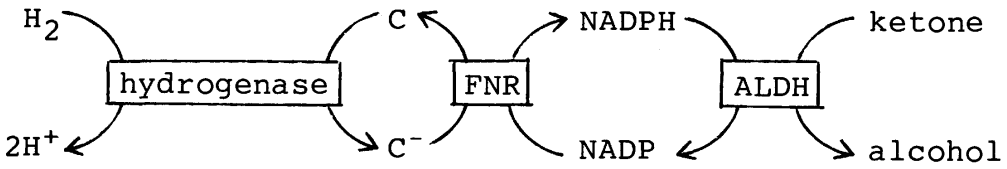
Regeneration of NADPH and Hydrogenation of Ketones to Alcohols with the Combination of Hydrogenase, Ferredoxin-NADP Reductase, and Alcohol Dehydrogenase

Ichiro Okura,* Katsumi Kurabayashi, and Shigetoshi Aono
Department of Bioengineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152
(Received April 14, 1987)

The regeneration of nicotinamide-adenine dinucleotide phosphate (reduced form, NADPH) by the reduction of NADP by hydrogen gas was carried out with the [hydrogenase-ferredoxin-NADP reductase (FNR)] system. Ketone hydrogenation was tried by the combination of the above system and alcohol dehydrogenase (ALDH), as shown in the following scheme:



C: electron carrier

Scheme 1.

In the [hydrogenase-FNR] system, NADP was easily reduced by hydrogen to form NADPH. By adding ALDH to the above system, the hydrogenation of ketone to alcohol was observed. The ketones used in this study were 2-butanone, 2-pentanone, and 2-hexanone. After 8 h, the turnover number of NADP was 13 for 2-butanone, 15 for 2-pentanone, and 10 for 2-hexanone, showing a recurrence of NADP by hydrogen gas.

Some photochemical,[1-3] electrochemical,[4-7] and enzymatic[7-9] systems for NAD(P)H regeneration have been reported. Among these systems, enzymatic systems are of great advantage to produce compounds with a high optical purity, and to the simplicity of the systems.

In this study the [hydrogenase-FNR] system for the regeneration of NADPH from NADP was established by using hydrogen gas as a reducing agent; ketone hydrogenation was tried by a combination of the system with ALDH as shown in Scheme 1.

Experimental

The bipyridinium compounds used in this experiment are listed in Fig. 1. Compounds **A**, **B**, and **C** were synthesized according to the literature.[10,11] The hydrogenase from *Desulfovibrio vulgaris* (Miyazaki type, IAM 12604) was purified according to Yagi's method.[12] The activity (1 unit) of hydrogenase used was to reduce 1 μmol of methyl viologen for 1 min in the system containing hydrogenase and methyl viologen (3.7×10^{-2} mol dm^{-3}) in 5.0 ml of a 0.02 mol dm^{-3} Tris-HCl buffer (pH 7.0) under 1 atmospheric pressure of hydrogen at 30 °C. FNR from spinach leaves was purified by Shin's method.[13] The concentration of FNR is not known but it had the ability to reduce 0.37 μmol of 2,6-dichlorophenol-indophenol (DPIP) in the following system: NADPH (1.2×10^{-4} mol dm^{-3})-DPIP (7.4×10^{-5} mol dm^{-3})-FNR (2.0%) in 5.0 ml of 0.05 mol dm^{-3} Tris-HCl buffer (pH 7.0) at 30 °C for 1 min. ALDH from *Thermoanaerobium brockii* was obtained from SIGMA Co.

The sample solution, which consisted of hydrogenase, bipyridinium salt, FNR, NADP, and ketone (if included) in a Tris-HCl buffer (pH 7.0), was deaerated by repeated freeze-pump-thaw cycles. The reaction was carried out at 30 °C by the introduction of hydrogen gas into the above system.

Ketones and alcohols were analyzed by gas chromatography with a 3-m long column of PEG 6000 at 80 °C by using nitrogen as a carrier gas. The electronic spectra were measured using a Shimadzu MPS 5000 spectrometer, and the concentration of NADPH was determined from the absorbance at 340 nm.

Results and Discussion

Reduction of Bipyridinium Compounds by Hydrogen. When hydrogen gas was introduced into a system containing hydrogenase and methyl viologen, a

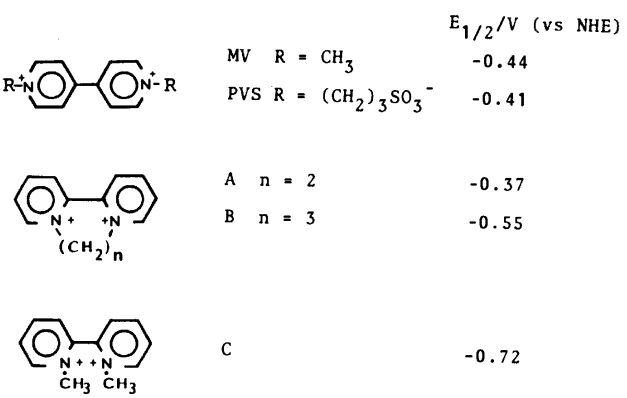


Fig. 1. Bipyridinium salts as electron carriers.

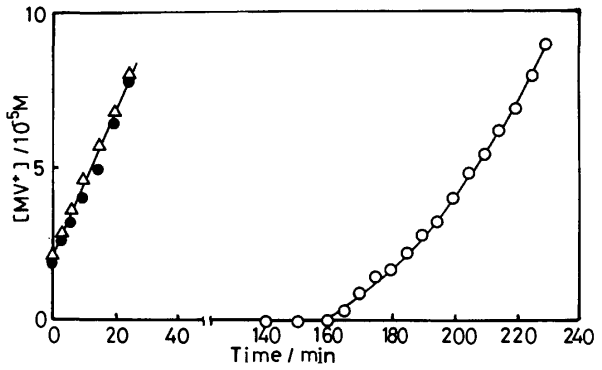

Fig. 2. Reduction of methyl viologen by hydrogen gas with hydrogenase. Reaction conditions: Methyl viologen, 3.7×10^{-2} mol dm^{-3}; hydrogenase, 4.9 units dm^{-3}; hydrogen, 0.97 atm; Tris-HCl buffer, 0.4 mol dm^{-3}, pH 7.0; reaction temp, 30°C. a (○): No pretreatment, b (△): pretreated with RSH (2.0×10^{-4} mol dm^{-3}) for 1 h, c (●): pretreated with $Na_2S_2O_4$ (5.0×10^{-4} mol dm^{-3}) for 1 h.

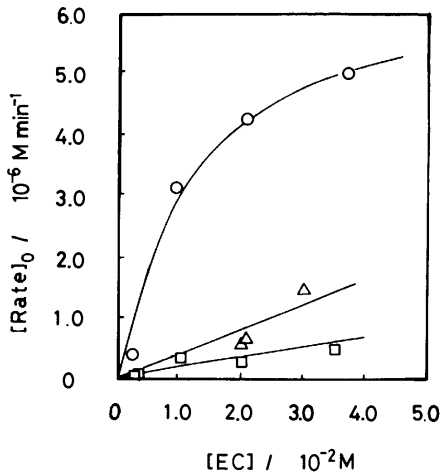

Fig. 3. Initial reduction rate vs. bipyridinium salt concentration. Reaction conditions: Hydrogenase pretreated with RSH, 4.9 units dm^{-3}, hydrogen, 0.97 atm; Tris-HCl buffer, 0.4 mol dm^{-3}, pH 7.0; reaction temp, 30°C. ○: Methyl viologen; △: A; □: PVS.

reduced type of methyl viologen was detected as shown in Fig. 2-(a). The induction period, ca. 150 min, was observed for the reduction. When the hydrogenase was pretreated with $Na_2S_2O_4$ or 2-mercaptoethanol, the induction period disappeared and a reduced form of methyl viologen was detected, as shown in Fig. 2-(b) and (c). As $Na_2S_2O_4$ and 2-mercaptoethanol are well-known reducing agents, the hydrogenase may be activated by reduction. The hydrogenase, sensitive to oxygen,[12,14] may be inactivated during the purification of the enzyme. The inactivated hydrogenase, however, may be re-activated by treatment with a reducing agent. Though hydrogen is also a reducing agent, it takes time to re-activate the hydrogenase. A long induction time appeared when hydrogen was used, as shown in Fig. 2-(a). In the following experiments, the hydrogenase pretreated by 2-mercaptoethanol was used.

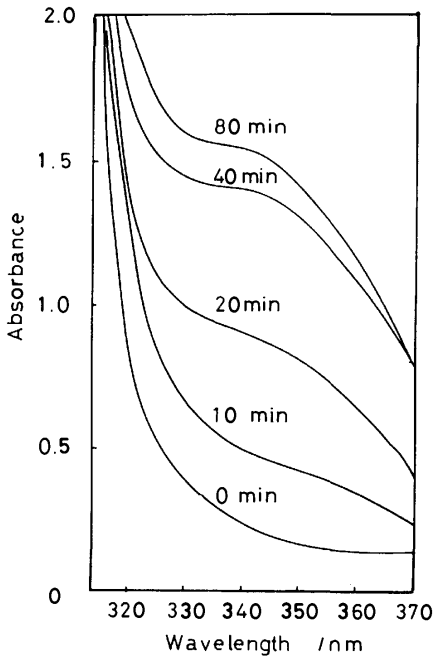

Fig. 4. Typical spectrum change during the reaction. Reaction conditions: Methyl viologen, 3.7×10^{-2} mol dm^{-3}; hydrogenase pretreated with RSH, 20.2 units dm^{-3}, hydrogen, 0.97 atm; FNR, 1.0 ml; NADP, 9.7×10^{-4} mol dm^{-3}; Tris-HCl buffer, 0.4 mol dm^{-3}, pH 7.0; reaction temp, 30°C.

When 3-sulfonatopropyl viologen (PVS) or compound A was used in place of methyl viologen, these compounds were also reduced by hydrogen with hydrogenase. The dependence of the initial reduction rate on the concentration of these compounds is shown in Fig. 3. The order of the reduction rate does not coincide with that of the redox potential (see Fig. 1) of these compounds, suggesting that methyl viologen is the most effective substrate of the hydrogenase among these compounds.

Reduction of NADP by Hydrogen. When hydrogen gas was introduced to a system containing hydrogenase, FNR, and NADPH, the spectrum of the solution changed with reaction time (Fig. 4). The characteristic absorption band of the reduced form (NADPH) of NADP was observed at 340 nm.

As shown in Fig. 5, the NADPH concentration increased linearly with the reaction time at low NADP conversion; then, the NADPH formation rate decreased. The rate decrease was caused by a decrease in the concentration of the starting material, NADP. When 4.5×10^{-3}, 9.7×10^{-4}, and 4.9×10^{-4} mol dm^{-3} of NADP were used, the conversion of NADP after 1 h was 26, 67, and 70%, respectively. In the case of the system shown in Fig. 5-(a), NADPH formed with the reaction time and no deactivation of the enzymes was observed within the reaction time.

The time dependence of the amount of NADPH

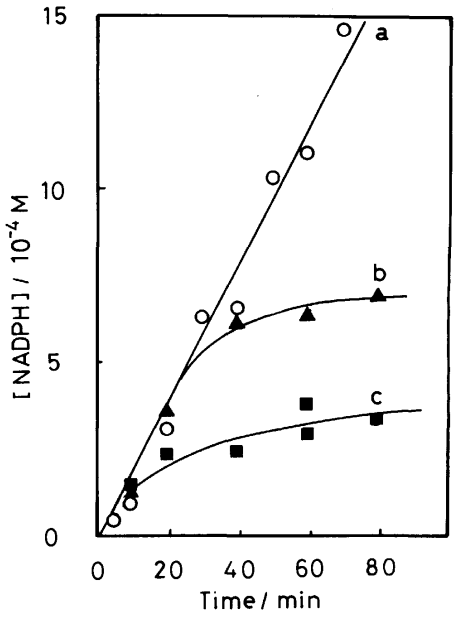

Fig. 5. Time dependence of NADPH formation. Reaction conditions: Methyl viologen, 3.7×10^{-2} mol dm^{-3}; hydrogenase pretreated with RSH, 20.2 units dm^{-3}, hydrogen, 0.97 atm; FNR, 1.0 ml; NADP, 4.5×10^{-3} mol dm^{-3} (○), 9.7×10^{-4} mol dm^{-3} (▲), 4.9×10^{-4} mol dm^{-3} (■); Tris-HCl buffer, 0.4 mol dm^{-3}, pH 7.0; reaction temp, 30°C.

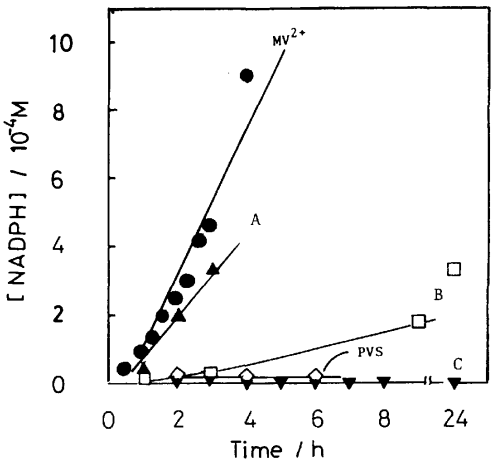

Fig. 6. Time dependence of NADPH formation. Reaction conditions: Bipyridinium salt 1.9×10^{-3} mol dm^{-3}; hydrogenase pretreated with RSH, 7.4 units dm^{-3}, hydrogen, 0.97 atm; FNR, 1.0 ml; NADP, 3.3×10^{-2} mol dm^{-3}; Tris-HCl buffer, 0.4 mol dm^{-3}, pH 7.0; reaction temp, 30°C. ●: Methyl viologen, ▲: A, □: B, ▼: C, ◇: PVS.

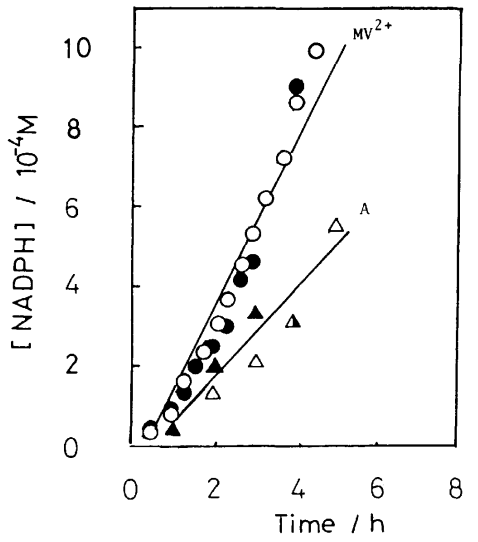

Fig. 7. Time dependence of NADPH formation. Reaction conditions: Same as the caption of Fig. 6 except for the amount of FNR. FNR: 1 ml (●,▲), 2 ml (○,△), 3 ml (▲).

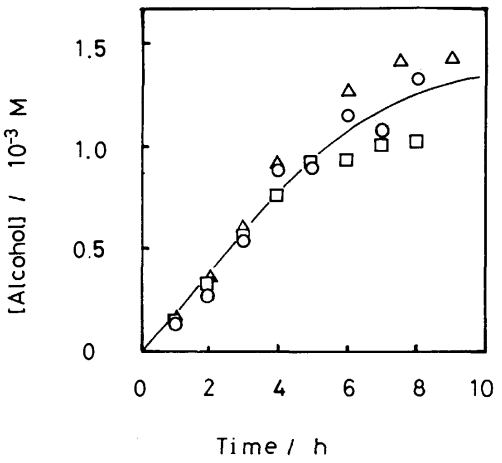

Fig. 8. Time dependence of alcohol formation. Reaction conditions: Methyl viologen, 3.7×10^{-2} mol dm^{-3}; hydrogenase pretreated with RSH, 5.25 units dm^{-3}, hydrogen, 0.97 atm; FNR, 2.0 ml; NADP, 1.0×10^{-4} mol dm^{-3}; NADP, 1.0×10^{-4} mol dm^{-3}; ALDH, 500 units dm^{-3}; Tris-HCl buffer, 0.4 mol dm^{-3}, pH 7.0; reaction temp, 30°C. ○: 2-Butanone (3.15×10^{-2} mol dm^{-3}), △: 2-pentanone (1.24×10^{-2} mol dm^{-3}), □: 2-hexanone (3.6×10^{-3} mol dm^{-3}).

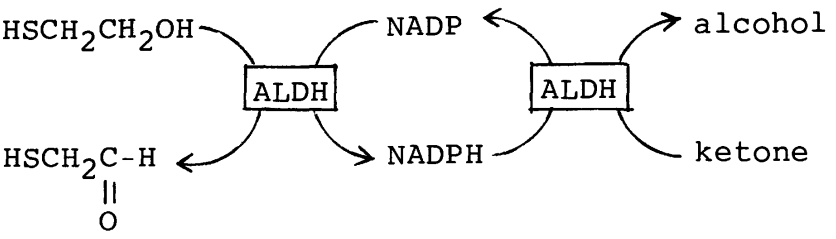
formation is shown in Fig. 6, when various bipyridinium compounds were used as electron carriers. Among these compounds, methyl viologen, compounds **A** and **B**, were effective for NADPH formation. PVS and compound **C** were inactive. As PVS was easily reduced by hydrogen with hydrogenase and its reduced form has a sufficient redox potential (see Fig. 1) to reduce NADP, it is apparent that PVS cannot be a substrate of FNR.

When other concentrations of methyl viologen and compound **A** were used, no change in the reduction rate of NADP was observed (Fig. 7). From the above results, it can be seen that the rate determining step of NADPH formation by hydrogen is not the reduction step of NADP with FNR, but the reduction step of a bipyridinium compound by hydrogen with hydrogenase.

Reduction of Ketone by Hydrogen. When NADP is reduced in a [hydrogenase-FNR] system, the



Scheme 2.

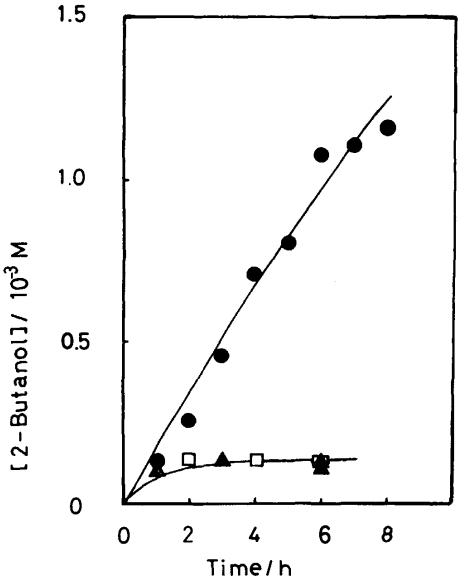


Fig. 9. Effect of RSH for alcohol formation. The system (shown by ●) contains methyl viologen (3.7×10^{-2} mol dm^{-3}), hydrogenase (5.25 units dm^{-3}), RSH (1.0×10^{-2} mol dm^{-3}), hydrogen (0.97 atm), FNR (2.0 ml), NADP (1.0×10^{-4} mol dm^{-3}), ALDH (500 units dm^{-3}), 2-butanone (0.18 mol dm^{-3}), Tris-HCl buffer (0.4 mol dm^{-3}, pH 7.0); reaction temp, 30°C. The systems (shown by ▲,□) contain RSH (1.0×10^{-2} mol dm^{-3}), hydrogen (0.97 atm), FNR (2.0 ml), NADP (3.0×10^{-3} mol dm^{-3}, (▲), 1.6×10^{-3} mol dm^{-3} (□)); ALDH (500 units dm^{-3}), 2-butanone (0.18 mol dm^{-3}), Tris-HCl buffer (0.4 mol dm^{-3}, pH 7.0); reaction temp, 30°C.

hydrogenation of ketones to alcohols could be accomplished by adding ALDH to the above system. The hydrogenation of some ketones were tried. The results are shown in Fig. 8. As ketones, 2-butanone, 2-pentanone, and 2-hexanone were used. All the ketones were hydrogenated and the corresponding alcohols were formed. The turnover numbers of NADP against alcohols after an 8-h reaction were 13, 15 and 10 for 2-butanone, 2-pentanone, and 2-hexanone, respectively. The results show that NADP recycled catalytically in this system, and that ketone hydrogenation by hydrogen gas was accomplished.

Since 2-mercaptoethanol was used in order to avoid the induction period of the hydrogenase activation (Fig. 2) in the system, there is a possibility of ketone hydrogenation through the following reaction:

Thus, the hydrogenation of ketone was tried using a system containing 2-mercaptoethanol, ALDH, NADP, and 2-butanone. The results are shown in Fig. 9-(a). The above reaction proceeded and 2-butanol formation was observed. The amount of 2-butanol, however, was much less compared with that of the 2-butanone formed by a reduction with hydrogen gas as (Fig. 9-(b)). Ketone hydrogenation by 2-mercaptoethanol is neglected in this system.

The authors wish to express their thanks to Professor Yoshio Ono for his helpful discussions. This work was supported by a Grant-in-Aid for Scientific Research on Priolity Areas No. 62612505 "Dynamic Interactions and Electronic Processes of Macromolecular Complexes" from the Ministry of Education, Science and Culture.

(Received April 15, 1987)

(−)-8a-*epi*-Swainsonine (**4**), one of the stereocongeners of physiologically interesting indolizidine alkaloid (−)-swainsonine (**1**), has been synthesized starting from known methyl 3-azido-4,6-*O*-benzylidene-3-deoxy-α-D-altropyranoside. The α-D-mannosidase inhibitory activity of **4** was compared with natural **1**.

Swainsonine (**1**), which was isolated from some plants[1-3] and a microorganism,[4] is a novel indolizidine alkaloid. This alkaloid exhibits remarkable physiological effects such as an α-D-mannosidase inhibitory activity and immunoregulating activity.[5] The structure of **1** including absolute configuration was established by Harris and coworkers to be (1*S*, 2*R*, 8*R*, 8a*R*)-octahydro-1,2,8-indolizinetriol.[3] Owing to this structural novelty and the interesting physiological effects of **1**, extensive efforts have been made toward the total synthesis of **1**[6] and its stereocongeners.[7] After completion of the total synthesis of **1**,[6a] we have synthesized two stereocongeners of **1**, namely (−)-8-*epi*- (**2**) and (−)-1,8-di*epi*-swainsonine (**3**), from 3-amino-3-deoxy-D-glucose and -D-galactose derivatives.[8] Herein, we wish to describe a synthesis of another stereocongener, (−)-8a-*epi*-swainsonine (**4**), from readily available methyl 3-azido-4,6-*O*-benzylidene-3-deoxy-α-D-altropyranoside (**6**).[9]

Compound **4** was retro-synthesized to an azido group containing α,β-unsaturated ester (**5**-*E* and **5**-*Z*) by twice C-N bond disconnection as shown in Scheme 1. Hydrogenation of the both geometrical isomers **5** would give a disubstituted 2-piperidinone **13** via a 5-aminooctanoic acid ethyl ester **12**, which tends to cyclize simultaneously resulting a δ-lactam formation. The 2-indolizinone formation of **13** would be achieved by introduction of a suitable leaving group at the primary hydroxyl group in an intramolecular *N*-alkylation fashion. Reduction of the amido group in the resulting **14** would give 1,8-di-*O*-benzylated 8a-*epi*-swainsonine (**15**) and deprotection of **15** would furnish the desired **4**.

The configurations of the four continuous chiral centers in **5** are corresponding to those of C-2 to C-5 of 3-azido-3-deoxy-D-altrose. Therefore, our synthesis of

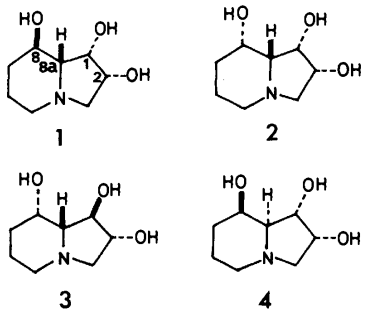

Fig. 1.

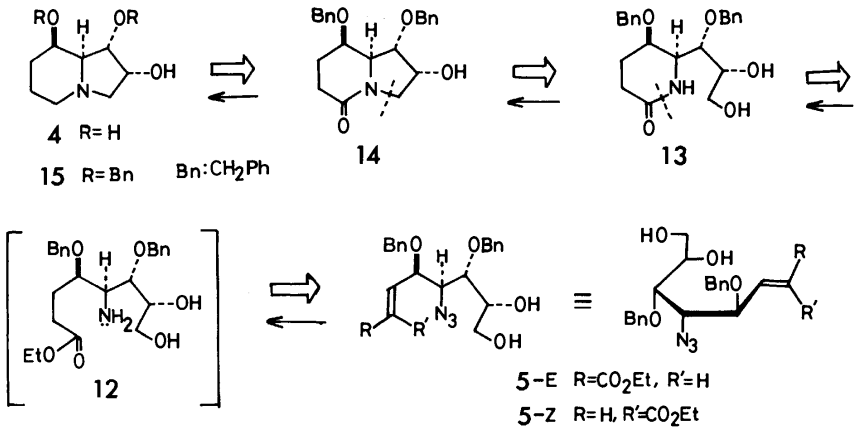

Scheme 1.

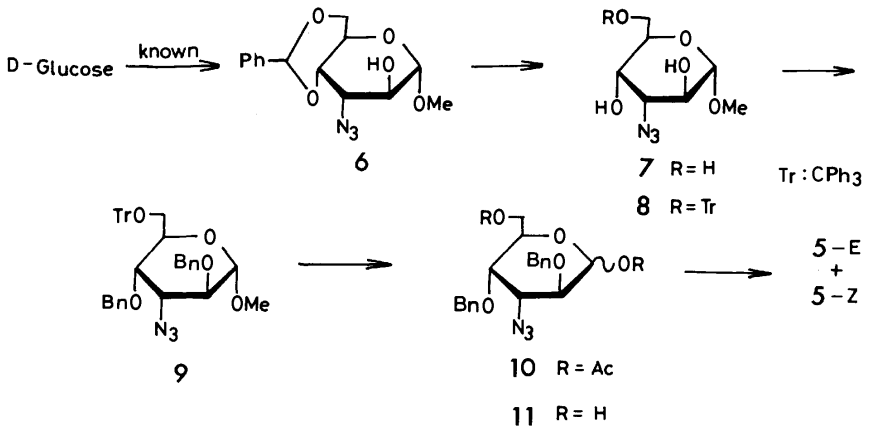

Scheme 2.

4 was started from the known 3-azido sugar **6**, which was readily prepared by regioselective diaxial epoxy ring opening of methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-mannopyranoside[10] (Scheme 2). Hydrolysis of **6** in 50% aqueous acetic acid at 100 °C gave *O*-debenzylidene derivative **7**, and the primary hydroxyl group in **7** was preferentially protected as a trityl ether by treatment with trityl chloride in pyridine in the presence of 4-(dimethylamino)pyridine to provide 6-*O*-trityl derivative **8** in 82% yield. *O*-Benzylation of **8** with excess benzyl bromide in the presence of sodium hydride gave 2,4-di-*O*-benzyl derivative **9** in 94% yield. Acetolysis of **9** in acetic anhydride in the presence of a catalytic amount of sulfuric acid at 0 °C gave an anomeric mixture of **10** in 80% combined yield. The anomeric mixture **10** was *O*-deacetylated with sodium methoxide to provide an anomeric mixture **11**, which was subjected to Wittig olefination for a two-carbon elongation. Treatment of the mixture **11** with (ethoxycarbonylmethylene)triphenylphosphorane in refluxing benzene gave a mixture of ***E***- and ***Z***-α,β-unsaturated esters **5-*E*** and **5-*Z***, which was separated by chromatography on silica gel, in 54% combined yield. The geometrical stereochemistry of each compound was determined by the ^{1}H NMR spectrum. In the ^{1}H NMR of **5-*E***, H-3 (α-olefinic proton of the α,β-unsaturated ester) appeared at δ 6.91 as a double doublet with $J_{2,3}$=18 Hz and $J_{3,4}$=7 Hz supporting a trans geometry of the double bond. On the other hand, H-3 of **5-*Z*** appeared at δ 6.33 as a double doublet with $J_{2,3}$=12 Hz and $J_{3,4}$=8 Hz. The ratio of **5-*E*** and **5-*Z*** was 10:8.5, and no preferential formation of the ***E***-isomer was observed in this Wittig olefination of **11** by stabilized ylide. As expected, hydrogenation of each **5-*E*** and **5-*Z*** in the presence of Raney nickel gave 2-piperidinone derivative **13** in 67 and 73% yields, respectively. No other products were detected in both reaction mixtures. Next, the intramolecular cyclization of **13** for trisubstituted indolizinone **14** was attempted under several conditions (TsCl in pyridine or MsCl in pyridine). The best result was obtained under *O*-tosylation conditions as follows. A solution of **13** in pyridine was stirred with 3.4 mol equivalent of *p*-toluenesulfonyl chloride, which was added in a five portion at 10 h interval, at 70 to 100 °C in the presence of 4-(dimethylamino)pyridine. Consequently, compound **14** was obtained in 60% yield. When *p*-toluenesulfonyl chloride (3.0 mol equiv) was added to a pyridine solution of **13** all at once, and the mixture was stirred at room temperature for 24 h, compound **14** was obtained in 41% yield along with a further *O*-tosylated product of **14** (30%). No intermediate of the reaction was detected, however, the cyclization seems to proceed via a *O*-tosyl derivative of **13** at the primary hydroxyl group. The *O*-tosyl derivative was attacked by amide nitrogen in **13** instantly. Reduction of **14** with borane-Me_2S complex in THF at room temperature, followed by stirring the product in pyridine gave 1,8-dibenzylated 8a-*epi*-swainsonine **15** in 84% yield. For conversion of the initially formed amine-borane complex to **15**, the pyridine-treatment is essential. *O*-Debenzylation of **15** by hydrogenolysis in the presence of 10% Pd on charcoal, or by treatment with refluxing cyclohexene-ethanol in the presence of 20% $Pd(OH)_2$/C, gave a mono-*O*-benzyl derivative. The structure of the mono-*O*-benzyl derivative was not determined. The complete deprotection was achieved by treatment of **15** with iodotrimethylsilane,[11] and purification of the product by PTLC gave the desired **4** as crystals in 75% yield. The structure of **4** was supported by spectral means (IR, ^{1}H and ^{13}C NMR, and mass spectra). The overall yield from **6** to **4** was 9%.

A preliminary assay of **4** for α-D-mannosidase inhibitory activity was investigated. Against a human α-D-mannosidase, compound **4** exhibits a 93% inhibition at 1 mM concentration at pH 4 (optimal pH value). Under the same conditions, swainsonine **1** shows a 99% inhibition.

Experimental

General Procedures. Reactions were carried out at room temperature unless otherwise stated. Reaction mixture, extract, and fraction of chromatography were concentrated under a reduced pressure below 40 °C with a bath by

an evaporator. Melting points were determined with a Mitamura Riken micro mp apparatus and are uncorrected. Specific rotations were measured in a 10 mm cell with a Jasco DIP-4 polarimeter. Column chromatography was performed on Kieselgel 60 (Merck), and thin-layer chromatography (TLC) was performed on a glass plate coated with Kieselgel 60 GF_{254} (Merck), followed by detection by UV light and charring with sulfuric acid. Preparative TLC (PTLC) was performed on a glass plate (20×20 cm) coated with Kieselgel PF_{254} (Merck). IR spectra were recorded with a Hitachi Model 225 (KBr) or with a Jasco Model A-202 ($CHCl_3$) spectrometer. ^{1}H NMR spectra were recorded with a Varian EM-390 (90 MHz) spectrometer in $CDCl_3$ solutions with internal tetramethylsilane. ^{13}C NMR spectra were recorded with a JEOL FX-200 spectrometer in CD_3OD solution with internal tetramethylsilane. High-resolution mass spectra were obtained using a Hitachi M-80 mass spectrometer.

Pyridine was distilled over NaOH, *N*,*N*-dimethylformamide (DMF) was distilled over CaH_2, benzene was distilled over $LiAlH_4$, and tetrahydrofuran (THF) was distilled over $LiAlH_4$ and then over sodium-benzophenone.

Methyl 3-Azido-4,6-*O*-benzylidene-3-deoxy-α-D-altropyranoside (6). This compound was prepared according to the reported pocedure.[10] **6**: Mp 133—134 °C; lit,[10] mp 135—136 °C; $[\alpha]_D^{21}$ +34.2° (*c* 0.85, $CHCl_3$); lit,[10] $[\alpha]_D^{18}$ +37.9° (*c* 1.00, $CHCl_3$).

Methyl 3-Azido-3-deoxy-6-*O*-trityl-α-D-altropyranoside (8). A solution of **6** (2.02 g, 6.56 mmol) in 50% aqueous acetic acid (10 ml) was stirred at 100 °C for 90 min, and diluted with ethyl acetate (60 ml). The solution was extracted with water (50 ml×4), and the combined aqueous layers were concentrated with ethanol. The residue, which consisted of *O*-debenzylidene derivative **7**, was dissolved in pyridine (10 ml) and trityl chloride (4.58 g, 16.4 mmol) and 4-(dimethylamino)-pyridine (0.16 g, 1.31 mmol) were added. The mixture was stirred at 70 °C for 150 min and concentrated with toluene. The residue was partitioned between dichloromethane (60 ml) and water (60 ml). The aqueous layer was extracted with dichloromethane (60 ml×3). The organic layer was dried over Na_2SO_4 and concentrated. The residue was chromatographed on silica gel (180 g, ethyl acetate-hexane=1 : 4 containing 1% triethylamine), and the fraction corresponding to R_f 0.53 (ethanol-toluene=1 : 5) was concentrated to give **8** (2.48 g, 82%) as a colorless syrup. **8**: $[\alpha]_D^{27}$ +31.5° (*c* 1.35, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3760, 2950, 2130, 1460, 1270 cm^{-1}; ^{1}H NMR δ=2.32—2.63 (2H, m, 2×OH), 3.36—3.41 (2H, m, H-6, 6′), 3.43 (3H, s, OCH_3) 3.68—4.09 (4H, m, H-2,3,4,5), 4.56 (1H, d, *J*=2.5 Hz, H-1), 7.16—7.55 (15H, m, $C(C_6H_5)_3$). Found: C, 67.39; H, 5.92; N, 8.84%. Calcd for $C_{26}H_{27}N_3O_5$: C, 67.66; H, 5.90; N, 9.10%.

Methyl 3-Azido-2,4-di-*O*-benzyl-3-deoxy-6-*O*-trityl-α-D-altropyranoside (9). Sodium hydride (60% emulsion in mineral oil, 967 mg, 24.2 mmol) was washed with hexane (2 ml×4), dried and suspended in DMF (8 ml). To the suspension was added a DMF solution (8 ml) of **8** (2.48 g, 5.37 mmol), and the mixture was stirred at 0 °C for 15 min. Benzyl bromide (2.88 ml, 24.2 mmol) was added to the mixture, and stirred for 19 h. The excess base was destroyed by addition of ethanol. After concentration of the mixture, the residue was partitioned between dichloromethane (80 ml) and water (80 ml). The aqueous layer was extracted with dichloromethane (80 ml×3). The combined extracts were dried over Na_2SO_4 and concentrated. The residue was chromatographed on silica gel (hexane containing 1% triethylamine), and the fraction corresponding to R_f 0.74 (ethyl acetate-hexane=1 : 5) was concentrated to give **9** (3.24 g, 94%) as a colorless syrup. 9: $[\alpha]_D^{27.5}$ +28.4° (*c* 0.98, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3060, 3000, 2930, 2110, 1490, 1450, 1260 cm^{-1}; ^{1}H NMR δ=3.00—3.38 (2H, m, H-6,6′), 3.42 (3H, s, OCH_3), 3.57—4.28 (4H, m, H-2,3,4,5), 4.33—4.77 (5H, m, H-1, 2×$OC\underline{H}_2C_6H_5$), 6.98—7.67 (25H, m, 2×$OCH_2C_6\underline{H}_5$, $C(C_6H_5)_3$).

Anomeric Mixture of 1,6-Di-*O*-acetyl-3-azido-2,4-di-*O*-benzyl-3-deoxy-D-altropyranose (10) To a solution of **9** (1.91 g, 2.87 mmol) in acetic anhydride (16 ml) was added concd sulfuric acid (0.3 ml), and the solution was stirred for 2 h at 0 °C. The solution was diluted with water (90 ml) and extracted with dichloromethane (90 ml×3). The extract was washed with 10% aqueous $NaHCO_3$ (50 ml×2), dried over Na_2SO_4 and concentrated. The residue was acetylated with acetic anhydride (5 ml) in pyridine (10 ml) for 1 h. After concentration of the mixture with toluene, the residue was chromatographed on silica gel (150 g, ethyl acetate-hexane=1 : 8). The fractions corresponding to R_f 0.40 and 0.31 (ethyl acetate-hexane=1 : 5) were combined and concentrated to give **10** (1.12 g, 80%) as a colorless syrup. IR $\nu_{max}^{CHCl_3}$ 3000, 2920, 2870, 2120, 1735 1450, 1370 cm^{-1}; ^{1}H NMR δ=1.98, 2.00, 2.06, 2.07 (total 6H, each s, 2×$OCOCH_3$), 3.60—4.85 (10H, m, H-2,3,4,5,6,6′, 2×$OC\underline{H}_2C_6H_5$), 6.00, 6.03 (total 1H, each d, *J*=2.5 Hz, H-1), 7.35 (10H, s, 2×$OCH_2C_6\underline{H}_5$). Found: C, 61.24; H, 5.87; N, 8.86%. Calcd for $C_{24}H_{27}N_3O_7$: C, 61.40; H, 5.80; N, 8.95%.

Ethyl (*E*)- and (*Z*)-5-Azido-4,6-di-*O*-benzyl-2,3,5-trideoxy-altro-2-octenonate, (5-*E*) and (5-*Z*). To a solution of **10** (1.94 g, 4.13 mmol) in dichloromethane (15 ml) was added sodium methoxide (1 mol dm^{-3} in methanol, 9.08 ml, 9.08 mmol) at 0 °C with stirring. After stirring at 0 °C for 30 min, the solution was neutralized with Amberlite IR-120B (H^+). The resin was removed by filtration, washed with methanol, and the combined filtrate and washing were concentrated to give crude **11** (R_f 0.03, ethyl acetate-hexane=1 : 3) as a syrup. To a benzene solution (14 ml) of the crude **11** was added (ethoxycarbonylmethylene)triphenylphosphorane (3.60 g, 10.5 mmol), and the mixture was refluxed for 2 h, and then concentrated. The residue was chromatographed on silica gel (120 g, ethyl acetate-hexane=1 : 4). The fraction corresponding to R_f 0.23 (ethyl acetate-hexane=1 : 2) was concentrated to give **5-*Z*** (410 mg, 22%), and the fraction corresponding to R_f 0.19 was concentrated to give **5-*E*** (511 mg, 27%). A mixture of **5-*Z*** and **5-*E*** was obtained (99 mg; total **5-*Z*** and **5-*E***, 1.02 g, 54%). **5-*E*** as a colorless syrup: $[\alpha]_D^{20}$ −14.7° (*c* 1.06, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2925, 2870, 2100, 1720, 1450, 1365, 1300, 1270, 1175 cm^{-1}; ^{1}H NMR δ=1.27 (3H, t, *J*=7 Hz, $COOCH_2C\underline{H}_3$), 3.46—4.05 (8H, m, H-4,5,6,7,8,8′,2×OH), 4.22 (2H, q, *J*=7 Hz, $COOC\underline{H}_2CH_3$), 4.38—4.75 (4H, m, 2×$OC\underline{H}_2C_6H_5$), 6.12 (1H, d, *J*=18 Hz, H-2), 6.91 (1H, dd, *J*=18 and 7 Hz, H-3), 7.34 (10H, s, 2×$OCH_2C_6\underline{H}_5$). **5-*Z*** as a colorless syrup: $[\alpha]_D^{20}$ −64.1° (*c* 1.13, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2930, 2110, 1710, 1455, 1410, 1385, 1190 cm^{-1}; ^{1}H NMR δ=1.27 (3H, t, *J*=7 Hz, $COOCH_2C\underline{H}_3$), 3.00—3.42 (1H, br, OH), 3.58—4.38 (6H, m, H-5,6,7,8,8′, OH), 4.18 (2H, q, *J*=7 Hz, $COOC\underline{H}_2CH_3$), 4.40—4.74 (4H, m, 2×$OC\underline{H}_2C_6H_5$), 5.40 (1H, dd, *J*=8 and 4 Hz, H-4), 6.04 (1H, d, *J*=12 Hz, H-2), 6.33 (1H, dd, *J*=12 and 8 Hz, H-3), 7.48 (10H, s, 2×$OCH_2C_6\underline{H}_5$). Found: C, 63.00; H, 6.61; N, 9.07%. Calcd for $C_{24}H_{29}N_3O_6$ (as a mixture of **5-*E*** and **5-*Z***): C, 63.28; H, 6.42; N, 9.23%.

(5*R*,6*S*)-5-Benzyloxy-6-[(1*S*,2*R*)-1-benzyloxy-2,3-dihydroxypropyl]-2-piperidinone (13). From compound **5-*E***. A solution of **5-*E*** (170 mg, 0.37 mmol) in ethanol (10 ml) was hydrogenated in the presence of Raney nickel T-4 under an atmospheric hydrogen pressure for 15 h. After removal of the catalyst with a Celite pad and washing with ethanol, the combined filtrate and washing were concentrated. The residue was chromatographed on silica gel (15 g, ethanol-toluene=1 : 10), and the fraction corresponding to R_f 0.34 (ethanol-toluene=1 : 5) was concentrated to give **13** (96 mg, 67%) as crystals. **13**: Mp 145—146 °C; $[\alpha]_D^{27}$ −87.9° (*c* 1.00, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3400, 3290, 2910, 1640, 1620, 1470, 1450, 1390, 1325, 1295, 1270, 1210 cm^{-1}; ^1H NMR δ=1.50—2.58 (4H, m, H-3,3′,4,4′), 3.48—4.30 (8H, m, H-5,6, H-1,2,3,3′ of the side chain, 2×OH), 4.32—4.82 (4H, m, 2×$OCH_2C_6H_5$), 7.33 (10H, s, 2×$OCH_2C_6H_5$), 8.04 (1H, s, NH). High-resolution mass spectrum, Found: *m/z* 385.1884, Calcd for $C_{22}H_{27}NO_5$: M, 385.1887. Found: C, 68.32; H, 7.03; N, 3.45%. Calcd for $C_{22}H_{27}NO_5$: C, 68.55; H, 7.06; N, 3.68%. From compound **5-*Z***. Hydrogenation of **5-*Z*** (402 mg) and purification on silica gel as described in the case of **5-*E*** gave **13** (204 mg, 73%).

(1*S*,2*R*,8*R*,8a*S*)-1,8-Bis(benzyloxy)-2-hydroxyoctahydro-5-indolizinone (14). To a solution of **13** (68 mg, 0.16 mmol) in pyridine (3 ml) were added *p*-toluenesulfonyl chloride (24 mg) and 4-(dimethylamino)pyridine (4 mg). The mixture was stirred at 70 °C for 3 h, then at 100 °C. *p*-Toluenesulfonyl chloride was added after 25 h (18 mg), 40 h (30 mg), 50 h (15 mg), and 74 h (15 mg), successively. 4-(Dimethylamino)pyridine (4 mg) was added also after 44 h. The mixture was stirred at room temperature additional 41 h. The mixture was concentrated with toluene. The residue was partitioned between dichloromethane (20 ml) and water (20 ml), and the aqueous layer was extracted with dichloromethane (20 ml×2). The combined organic layers were dried over Na_2SO_4 and concentrated. The residue was chromatographed on silica gel (10 g, ethanol-toluene=1 : 40), and the fraction corresponding to R_f 0.43 (ethanol-toluene=1 : 5) was concentrated to give **14** (37.5 mg, 60%) as crystals. **14**: Mp 88—90 °C; $[\alpha]_D^{22}$ −78.4° (*c* 1.01, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3540, 3000, 2875, 1630, 1455, 1370, 1355, 1325, 1295, 1090 cm^{-1}; ^1H NMR δ=1.66—2.49 (4H, m, H-6,6′,7,7′), 2.53—2.84 (1H, OH), 3.38—3.82 (3H, m, H-3,3′, 8a), 3.84—4.29 (3H, m, H-1,2,8), 4.30—4.72 (4H, m, 2×$OCH_2C_6H_5$), 7.10—7.58 (10H, m, 2×$OCH_2C_6H_5$). High-resolution mass spectrum, Found: *m/z* 367.1776, Calcd for $C_{22}H_{25}NO_4$: M, 367.1781. Found: C, 68.38; H, 6.97; N, 3.48%. Calcd for $C_{22}H_{25}NO_4 \cdot H_2O$: C, 68.56; H, 7.06; N, 3.63%.

(1*S*,2*R*,8*R*,8a*S*)-1,8-Di-*O*-benzyloctahydro-1,2,8-indolizinetriol (15). To a solution of **14** (20.1 mg, 0.055 mmol) in THF (2 ml) was added borane-Me_2S complex (10 mol dm^{-3} in BH_3, 0.02 ml, 0.2 mmol) at 0 °C with stirring. The mixture was stirred at room temperature for 3 h, and then water (8 ml) was added. The aqueous solution was extracted with dichloromethane (15 ml×5), and the extract was washed with water (7 ml). The organic layer was dried over Na_2SO_4 and concentrated. The residue was dissolved in pyridine (2 ml) and the solution was stirred for 17 h. After the mixture was concentrated, the residue was chromatographed on silica gel (ethyl acetate-hexane=1 : 2, then ethanol-toluene=1 : 20). The fraction corresponding to R_f 0.45 (ethanol-toluene=1 : 3) was concentrated to give **15** (16.3 mg, 84%) as a colorless syrup. **15**: $[\alpha]_D^{22}$ −61.1° (*c* 0.97, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2875, 1480, 1435, 1340, 1305, 1220, 1195 cm^{-1}; ^1H NMR δ=1.06—2.25 (7H, m, H-3,5,6,6′,7,7′,8a), 2.30—2.72 (1H, br s, OH), 2.87—3.21 (1H, m, H-5′), 3.48 (1H, dd, *J*=11 and 7 Hz, H-3′), 3.35—4.73 (7H, m, H-1,2,8,2×$OCH_2C_6H_5$), 7.12—7.64 (10H, m, 2×$OCH_2C_6H_5$). High-resolution mass spectrum, Found: *m/z* 353.1995, Calcd for $C_{22}H_{27}NO_3$: M, 353.1989.

(1*S*,2*R*,8*R*,8a*S*)-Octahydro-1,2,8-indolizinetriol, 8a-*epi*-Swainsonine (4). A solution of **15** (19.5 mg, 0.065 mmol) in chloroform (0.5 ml) in the presence of iodotrimethylsilane (0.09 ml, 0.65 mmol) was stirred in dark for 15 h. To the mixture was added methanol (2 ml), and the solution was stirred for 2 h and concentrated. The residue was partitioned between dichloromethane (10 ml) and water (10 ml), and the organic layer was extracted with water (10 ml). The combined aqueous layers were concentrated. The residue was purified on PTLC (aqueous ammonia-1-butanol-chloroform-ethanol=1 : 4 : 4 : 4), and a ninhydrin positive band (R_f 0.39 on the same solvents) was extracted with methanol to give **4** as crystals (7.2 mg, 75%). Analytical sample was obtained by recrystallization from chloroform. **4**: Mp 122—124 °C (decomp); $[\alpha]_D^{19}$ −64.5° (*c* 0.95, MeOH); IR ν_{max}^{KBr} 3440, 3320, 2940, 2830, 2820, 1445, 1385, 1345, 1330, 1320, 1240, 1205, 1160, 1130, 1110 cm^{-1}; ^1H NMR (D_2O) δ=1.31—2.40 (6H, m, H-5,6,6′,7,7′,8a), 2.81—3.17 (1H, br s, H-3), 3.22—3.60 (2H, m, H-3′,5′), 3.79—4.48 (3H, m, H-1,2,8). ^{13}C NMR δ=20.87, 32.26, 54.10, 62.83, 64.71, 68.18, 70.91, 72.51, High-resolution mass spectrum, Found: *m/z* 173.1050, Calcd for $C_8H_{15}NO_3$: M, 173.1050.

We are grateful to Professor Anthony C. Richardson (Queen Elizabeth College, University of London) for his continuous interest and encouragement to this work. One of us (B. W.) also thanks to the International Children's Aid and Research Endowment for Mannosidosis for support to this work. We also thank to Mr. Akio Takahashi for his elemental analyses.

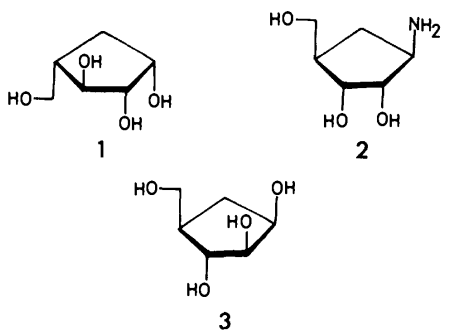
Transformation of D-Xylose to (1*R*,2*R*,3*R*,4*R*)-2,3,4-Trihydroxy-1-(hydroxymethyl)cyclopentane, Pseudo-β-D-arabinofuranose

Kin-ichi TADANO,* Hiroshi KIMURA, Masahide HOSHINO, Seiichiro OGAWA,* and Tetsuo SUAMI†
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
(Received April 21, 1987)

The known 3-*O*-benzyl-D-xylose was converted into methyl (4*S*,5*R*,6*R*)-4,6,7-triacetoxy-5-benzyloxy-2-(methoxycarbonyl)heptanoate (**8**) by employing Knoevenagel condensation of 2,4,5-tri-*O*-acetyl-3-*O*-benzyl-*aldehydo*-D-xylose with dimethyl malonate as a key reaction. *O*-Deacetylation of **8** and successive glycol cleavage followed by acetylation gave a mixture of (1*S*,4*R*,5*R*,6*R*)-5-acetoxy-6-benzyloxy-4-methoxycarbonyl-2-oxobicyclo[2.2.1]heptan-3-one and dimethyl (2*R*,3*R*,4*S*)-2,4-diacetoxy-3-benzyloxy-1,1-cyclopentanedicarboxylate (**12**), which was converted into **12** exclusively. This enantiomerically pure highly oxygenated cyclopentane dicarboxylate **12** was converted into (3*S*,4*S*)-3-benzyloxy-1-(*t*-butyldiphenylsilyloxymethyl)-4-hydroxy-1-cyclopentene (**15**) by 1) thermal demethoxycarbonylation accompanied by β-elimination of the acetoxyl group, 2) diisobutylaluminium hydride reduction, and 3) selective protection of thus formed 1-cyclopentene-1-methanol. Pyridinium chlorochromate oxidation of **15** followed by reduction with sodium borohydride gave a 6.4 : 1 mixture of (3*S*,4*R*)-3-benzyloxy-1-(*t*-butyldiphenylsilyloxymethyl)-4-hydroxy-1-cyclopentene (**18**) and **15**. Hydroboration of *O*-desilyl derivative of **18** proceeded stereoselectively from the less hindered α-face, and (1*R*,2*R*,3*R*,4*R*)-2,4-diacetoxy-1-acetoxymethyl-3-(benzyloxy)cyclopentane (**21**) was obtained after acetylation. Deprotection of **21** gave pseudo-β-D-arabinofuranose.

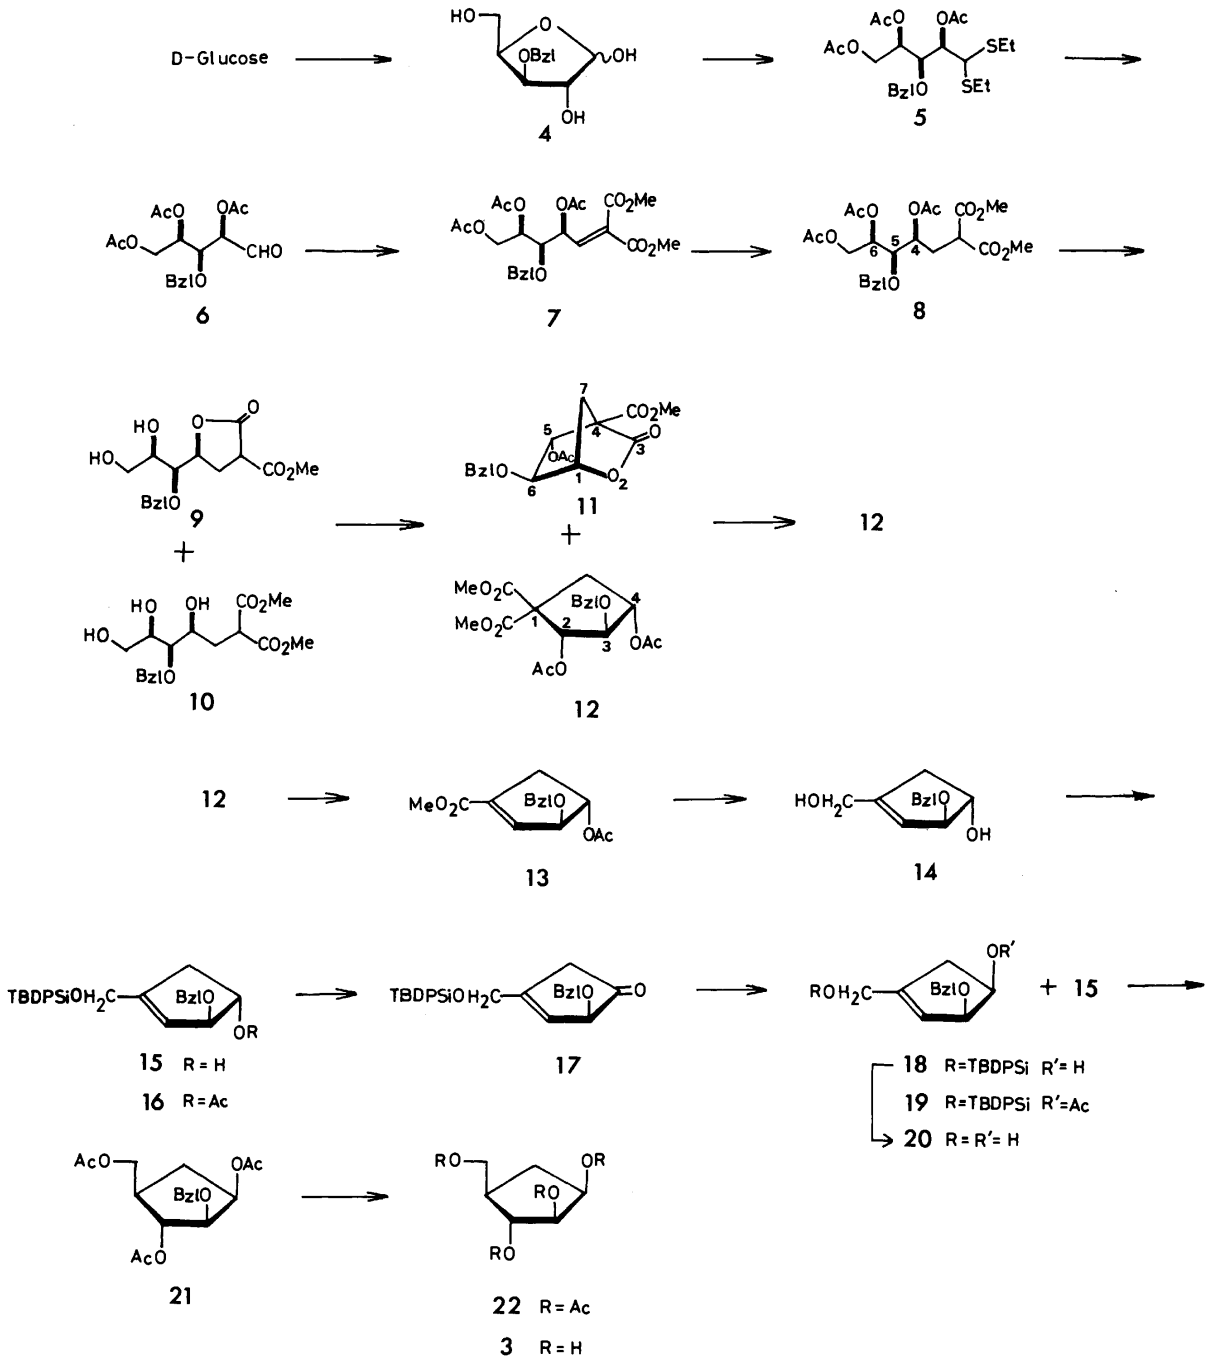
In our consecutive synthetic efforts on the access to enantiomerically pure highly oxygenated six- and five-membered carbocycles from carbohydrates, we developed several novel approaches to pseudo-sugars [stereoisomers of 2,3,4,5-tetrahydroxy-1-(hydroxymethyl)cyclohexane and those of 2,3,4-trihydroxy-1-(hydroxymethyl)cyclopentane][1a-f] and shikimate[1g] syntheses. In recent articles,[1e] we described the synthesis of (1*S*,2*S*,3*S*,4*S*)-2,3,4-trihydroxy-1-(hydroxymethyl)-cyclopentane, pseudo-β-L-arabinofuranose (**1**), starting from D-erythrose. The synthetic utility of **1** was verified by conversion of **1** into some enantiomerically pure pseudo-pentofuranoses and a key intermediate for the carbocyclic antibiotic (−)-aristeromycin synthesis, (1*R*,2*S*,3*R*,4*R*)-2,3-dihydroxy-4-hydroxymethyl-1-cyclopentanamine (**2**).[2] In this article, we describe a synthesis of (1*R*,2*R*,3*R*,4*R*)-2,3,4-trihydroxy-1-(hydroxymethyl)cyclopentane (**3**), an enantiomer of pseudo-β-L-arabinofuranose **1**. The synthesis of **3** was started from the known 3-*O*-benzyl-D-xylose, and the crucial cyclopentane ring formation was accomplished by an intramolecular aldol cyclization strategy, which has been developed in our laboratory for the synthesis of **1**.[1e]



Results and Discussion

The starting material, 3-*O*-benzyl-D-xylose (**4**), was prepared from D-glucose by a modified known procedure (Scheme).[3] Dithioacetal formation of **4** with ethanethiol in concd HCl followed by acetylation gave an acyclic diethyl dithioacetal **5** in 95% yield. An aldehyde group was regenerated by treatment of **5** with mercury(II) chloride in an aqueous acetonitrile giving 2,4,5-tri-*O*-acetyl-3-*O*-benzyl-*aldehydo*-D-xylose (**6**). The Knoevenagel condensation of **6** with dimethyl malonate in a mixture of acetic anhydride and pyridine resulted in a formation of α,β-unsaturated diester **7**, which was reduced with sodium borohydride at −15 °C to give the key intermediate **8** by a 1,4-conjugate addition of the hydride. The overall yield of **8** from **5** was 62%. *O*-Deacetylation of **8** with sodium methoxide provided an inseparable mixture of (4*S*,5*R*,6*R*)-5-benzyloxy-4,6,7-trihydroxy-2-(methoxycarbonyl)heptan-1,4-olide (**9**) and methyl (4*S*,5*R*,6*R*)-5-benzyloxy-4,6,7-trihydroxy-2-(methoxycarbonyl)heptanoate (**10**). The stereochemistry at C-2 of **9** was not determined. The glycols at C-6 and C-7 of the mixture **9** and **10** were cleaved by sodium periodate in an aqueous dioxane and the products were acetylated to give a mixture of (1*S*,4*R*,5*R*,6*R*)-5-acetoxy-6-benzyloxy-4-(methoxycarbonyl)-2-oxabicyclo[2.2.1]heptan-3-one (**11**) and dimethyl (2*R*,3*R*,4*S*)-2,4-diacetoxy-3-benzyloxy-1,1-cyclopentanedicarboxylate (**12**). The mixture was separated by silica-gel chromatography, and the ratio of **11** and **12** was approximately 8 : 1. As expacted, the desired intramolecular aldol cyclization occurred under the conditions of glycol cleavage. Based on this

†Present address: Department of Chemistry, Faculty of Science and Technology, Meisei University, Hodokubo, Hino, Tokyo 191.



Scheme.

result, we assume that the ratio of **9** and **10** is same as that of **11** and **12**. On the ^{1}H NMR spectrum of **11**, H-5 (H-C-OAc) appeared at δ 5.56 as a broad singlet. This indicates that H-5 and H-6 (H-C-OBzl) is an endo-exo relationship as depicted.[4] The stereochemistry of the newly introduced chiral center on **12** (C-2) was assigned to be (R) based on the ^{1}H NMR spectrum, in which H-2 appeared at δ 5.90 as a doublet with $J_{2,3}$=3 Hz.[5] When a methanol solution of the mixture **11** and **12** in the presence of Amberlite IR-120 (H^+) resin was refluxed, the bicyclic compound **11** was converted into **12** after acetylation. The overall yield of **12** from **8** was 59% without separation of the mixture **11** and **12**. The fact that the sterically less crowded products **11** and **12** were formed predominantly on the aldol cyclization is parallel to our previous result on the aldol cyclization performed for the similar model.[1e]

Thermal demethoxycarbonylation of **12** in an aqueous DMSO at 110—160 °C in the presence of NaCl accompanied a β-elimination of the acetoxyl group to give methyl (3*S*,4*S*)-4-acetoxy-3-benzyloxy-1-cyclopentene-1-carboxylate (**13**) as a somewhat volatile liquid. The crude **13** was reduced with diisobutylaluminium hydride (DIBAL-H) at −78 °C to give (3*S*,4*S*)-3-benzyloxy-4-hydroxy-1-cyclopentene-1-methanol (**14**) in 75% yield. The primary hydroxyl group in **14** was

protected as a silyl ether with *t*-butylchlorodiphenylsilane and imidazole to provide **15** in 73% yield. Compound **15** was oxidized with pyridinium chlorochromate (PCC) giving (3*S*)-3-benzyloxy-1-(*t*-butyldiphenylsilyloxymethyl)-1-cyclopenten-4-one (**17**), which was reduced with sodium borohydride in methanol solution. The reduction gave (3*S*,4*R*)-1-cyclopentene-1-methanol **18** and **15** in 64 and 10% yield, respectively. The stereoselectivity of the reduction was 6.4 : 1 with preferential hydride attack from the less hindered α-side. The inversion at C-4 in **15** to *R* configuration was apparent by comparing the ^{1}H NMR sectra of the corresponding acetates **16** and **19**, both of which were prepared by acetylation of **15** and **18**. The *t*-butyldiphenylsilyl group was deprotected with tetrabutylammonium fluoride to give **20** as crystals in 90% yield. Hydroboration of **20** with borane–THF complex, oxidation of the product with hydrogen peroxide in an aqueous NaOH solution followed by acetylation gave a fully protected pseudo-β-D-arabinofuranose, (1*R*,2*R*,-3*R*,4*R*)-2,4-diacetoxy-1-acetoxymethyl-3-(benzyloxy)-cyclopentane (**21**), in 65% yield. The hydroboration occurred stereoselectively from the less hindered α-face of **20**, and the (1*S*,2*S*,3*R*,4*R*)-diastereomer, a derivative of pseudo-α-L-ribofuranose, was not detected. Removal of the benzyl group in **21** with cyclohexene in the presence of 20% $Pd(OH)_2$ on charcoal[6] followed by acetylation gave a fully acetylated pseudo-β-D-arabinofuranose **22** in 90% yield. The ^{1}H NMR spectrum of **22** was identical with that of the L-enantiomer,[1e] and the $[\alpha]_D$ value of **22** ($[\alpha]_D^{23}$ −4.8°) coincided with that of the L-enantiomer ($[\alpha]_D^{23}$ +4.1°). *O*-Deacetylation of **22** with sodium methoxide gave pseudo-β-D-arabinofuranose (**3**) in a quantitative yield.[7]

Experimental

Gereral. Reactions were carried out at room temperature unless otherwise described. Reaction mixture, extracts, and fraction of column chromatography were concentrated under a reduced pressure at below 40 °C with a bath. Melting points were determined with a Mitamura Riken micro melting point apparatus and are uncorrected. Specific rotation was measured by a Jasco DIP-4 polarimeter with a 10 mm cell. Column chromatography was performed with Silicagel 60 (Katayama Chemicals, K070), and thin-layer chromatography (TLC) by a glass plate coated with Kieselgel 60 GF_{254} (Merck), followed by UV light detection and charred with sulfuric acid. IR spectra were recorded with a Hitachi 225 spectrometer or with a Jasco A-202 spectrometer. ^{1}H NMR spectra were recorded with a Varian EM-390 (90 MHz) spectrometer for solutions in $CDCl_3$ with an internal standard of Me_4Si. High resolution mass spectra were obtained by a Hitachi M-80 spectrometer.

Dichloromethane and *N*,*N*-dimethylformamide (DMF) were dried over CaH_2 and distilled. Pyridine was distilled over NaOH. Tetrahydrofuran (THF) was distilled over $LiAlH_4$ and then over Na-benzophenone.

3-*O*-Benzyl-D-xylose (4). This compound was prepared from D-glucose according to the reported procedure.[3] In our case, acid hydrolysis of the intermediate, 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-xylofuranose, was performed in refluxing 80% aqueous acetic acid in place of the reported sulfuric acid in refluxing 50% methanol. The overall yield of **4** from 1,2 : 5,6-di-*O*-isopropylidene-α-D-glucofuranose was 51%. **4**: Mp 115—116 °C, lit,[3] 89—91 °C. Found: C, 59.92; H, 6.67%. Calcd for $C_{12}H_{16}O_5$: C, 59.99; H, 6.71%.

2,4,5-Tri-*O*-acetyl-3-*O*-benzyl-D-xylose Diethyl Dithioacetal (5). A solution of **4** (23.5 g, 98.0 mmol) in concd HCl (80 ml) in the presence of ethanethiol (120 ml) was stirred at −15 °C for 30 min, and neutralized by addition of aqueous ammonia. The solution was concentrated, and the residue was suspended in ethanol, then concentrated. Ethanol (1 l) was added to the residue, and insoluble solids were removed by filtration, washed with ethanol (1 l). The combined filtrate and washing were concentrated, and the residue was acetylated with acetic anhydride (100 ml) in pyridine (100 ml) for 13 h. The mixture was concentrated, and the residue was chromatographed on silica gel (500 g, ethyl acetate–hexane=1 : 15), and the fraction corresponding to R_f 0.78 (ethyl acetate–hexane=1 : 3) was concentrated to give **5** (44.1 g, 95%) as a colorless syrup. **5**: $[\alpha]_D^{24.5}$ −5.3° (*c* 0.71, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2950, 2860, 1740, 1490, 1450, 1370, 1210, 1110, 1070 cm^{-1}; ^{1}H NMR δ=1.21, 1.23 (3H×2, each t, *J*=6 Hz, 2×$SCH_2C\underline{H}_3$), 2.01, 2.04, 2.10 (3H×3, each s, 3×$OCOCH_3$), 2.48—2.86 (4H, m, 2×$SC\underline{H}_2CH_3$), 3.93—4.53 (4H, m, H-1,3,5,5′), 4.73 (2H, s, $OC\underline{H}_2C_6H_5$), 5.18—5.39 (2H, m, H-2,4), 7.31 (5H, s, $OCH_2C_6\underline{H}_5$). Found: C, 56.00; H, 6.73%. Calcd for $C_{22}H_{32}O_7S_2$: C, 55.91; H, 6.83%.

Methyl (4*S*,5*R*,6*R*)-4,6,7-Triacetoxy-5-benzyloxy-2-(methoxycarbonyl)heptanoate (8). A solution of **5** (8.39 g, 17.6 mmol) in a mixture of acetonitrile (200 ml) and water (200 ml) in the presence of mercury(II) chloride (48.2 g, 176.0 mmol) and calcium carbonate (20.25 g, 202 mmol) was stirred for 30 min. Insoluble solids were removed by filtration with a Celite-pad, washed with ethyl acetate (1 l). The combined filtrate and washing were washed with 1 mol dm^{-3} aqueous KI solution (400 ml×5), 20% aqueous sodium thiosulfate solution (400 ml×3), and brine (400 ml×2) successively. The organic layer was dried over Na_2SO_4 and concentrated to give crude **6**, which was subjected to the Knoevenagel condesation directly. **6**: ^{1}H NMR δ=2.00, 2.19 (6H and 3H, each s, 3×$OCOCH_3$), 3.90—4.45 (3H, m, H-3, 5,5′), 4.70 (2H, s, $OC\underline{H}_2C_6H_5$), 5.20—5.45 (2H, m, H-2, 4), 7.36 (5H, s, $OCH_2C_6\underline{H}_5$), 9.60 (1H, s, CHO).

A solution of the crude **6** and dimethyl malonate (20.1 ml, 176 mmol) in a mixture of acetic anhydride (63 ml) and pyridine (90 ml) was stirred for 36 h. The mixture was diluted with ethyl acetate (900 ml) and washed with water (300 ml×3). The aqueous layer was extracted with ethyl acetate (300 ml×3). The combined organic layers were dried over Na_2SO_4 and concentrated to give crude **7**, which was used to next step without purification. In a separate small scale experiment, the crude **7** was purified on silica-gel chromatography (ethyl acetate–hexane=1 : 3). **7** as a colorless syrup, TLC R_f 0.31 (ethyl acetate–hexane=1 : 3): $[\alpha]_D^{24}$ +10.0° (*c* 1.15, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2925, 1730, 1650, 1490, 1425, 1360, 1210, 1060^{-1}; ^{1}H NMR δ=2.00, 2.05 (3H and 6H, each s, 3×$OCOCH_3$), 3.79 (6H, s, 2×$COOCH_3$), 3.66—4.53 (3H, m, H-5,7,7′), 4.65 (2H, s, $OC\underline{H}_2C_6H_5$), 5.10—5.53 (1H, m, H-6), 5.72—5.95 (1H, m, H-4), 6.92 (1H, d, *J*=7 Hz, H-3), 7.33 (5H, s, $OCH_2C_6\underline{H}_5$).

A solution of the crude **7** in methanol (150 ml) containing

sodium borohydride (799 mg, 21.1 mmol) was stirred at −15 °C for 30 min. After concentration of the mixture to ca. 50 ml, water (300 ml) was added. This aqueous solution was extracted with dichloromethane (300 ml×3), and the extracts were dried over Na_2SO_4, then concentrated. The residue was chromatographed on silica gel (500 g,. ethyl acetate-hexane=1 : 5). The fraction corresponding to R_f 0.47 (ethyl acetate-hexane=2 : 3) was concentrated to give **8** (5.24 g, 62%) as a colorless syrup. **8**: $[\alpha]_D^{25.5}$ −0.6° (*c* 1.32, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2950, 1735, 1435, 1370, 1225 cm^{-1}; ^1H NMR δ=1.98, 2.01, 2.05 (3H×3, each s, 3×$OCOCH_3$), 1.86—2.30 (2H, m, H-3,3′), 3.30 (1H, dd, *J*=6 and 9.5 Hz, H-2), 3.61—4.45 (3H, m, H-5,7,7′), 3.70, 3.72 (3H×2, each s, 2×$COOCH_3$), 4.65 (2H, s, $OCH_2C_6H_5$), 5.00—5.45 (2H, m, H-4, 6), 7.32 (5H, s, $OCH_2C_6H_5$). Found: C, 57.16; H, 6.26%. Calcd for $C_{23}H_{30}O_{11}$: C, 57.26; H, 6.27%.

Dimethyl (2*R*,3*R*,4*S*)-2,4-Diacetoxy-3-benzyloxy-1,1-cyclopentanedicarboxylate (12). A solution of **8** (6.50 g, 13.5 mmol) in methanol (160 ml) containing sodium methoxide (1 mol dm^{-3} in methanol, 20.0 ml, 20.0 mmol) was stirred at 0 °C for 2 h. The mixture was neutralized with Amberlite IR-120 (H^+), and the resin was removed by filtration, washed with methanol. The combined filtrate and washing were concentrated to give an approximately 8 : 1 mixture of **9** and **10**, which was used directly to next step.

To a solution of the mixture of **9** and **10** in dioxane (190 ml), an aqueous solution (22 ml) of sodium periodate (4.28 g, 20.0 mmol) was added with stirring. After stirring the mixture for 50 min, an aqueous solution (15 ml) of the oxidizing reagent (2.89 g, 13.5 mmol) was added. The mixture was stirred additional 1 h, and insoluble solids were removed by filtration. The filtrate was diluted with water (500 ml), and extracted with dichloromethane (800 ml×3). The extract was dried over Na_2SO_4 and concentrated. The residue was acetylated with acetic anhydride (60 ml) in pyridine (60 ml) for 18 h. The mixture was concentrated, and the residue was dissolved in toluene and then concentrated to give a mixture of **11** and **12**, which was subjected to next step without separation. In a separate experiment, **8** (456 mg) was converted to the mixture of **11** and **12** by the same procedure as described above. The mixture was separated by chromatography on silica gel (ethyl acetate-hexane=1 : 10) to give **11** (147 mg, 47%) and **12** (24 mg, 6%). **11** as a colorless syrup, TLC R_f 0.55 (ethyl acetate-hexane=1 : 2): $[\alpha]_D^{25}$ +87.8° (*c* 1.32, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2960, 1800, 1740, 1450, 1440, 1375, 1350, 1330, 1310, 1280, 1220, 1165, 1090 cm^{-1}; ^1H NMR δ=2.10 (3H, s, $OCOCH_3$), 2.53—2.72 (2H, m, H-7,7′), 3.66—4.00 (1H, m, H-6), 3.79 (3H, s, $COOCH_3$), 4.62 (1H, broad s, H-1), 4.70 (2H, ABq, *J*=11 Hz, $OCH_2C_6H_5$), 5.56 (1H, broad s, H-5), 7.32 (5H, s, $OCH_2C_6H_5$). Found: C, 61.04; H, 5.57%. Calcd for $C_{17}H_{18}O_7$: C, 61.05; H, 5.43%.

A solution of the crude mixture of **11** and **12** in methanol (200 ml) was refluxed in the presence of Amberlite IR-120 (H^+) (30 g). The resin was added after 6 h (20 g), 12 h (30 g), 16 h (15 g), 17 h (20 g), and 19 h (20 g) successively, and the mixture was refluxed additional 4 h. After removal of the resin by filtration and washing with methanol, the combined filtrate and washing were concentrated. The residue was acetylated with acetic anhydride (110 ml) in pyridine (110 ml) for 18 h. The mixture was concentrated with toluene. The residue was chromatographed on silica gel (130 g, ethyl acetate-hexane=1 : 7), and the fraction corresponding to R_f 0.59 (ethyl acetate-hexane=1 : 2) was concentrated to give **12** (3.26 g, 59%) as a colorless syrup. **12**: $[\alpha]_D^{27}$ +40.8° (*c* 0.53, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2950, 2910, 2850, 1730, 1430, 1370, 1230 cm^{-1}; ^1H NMR δ=2.02 (6H, s, 2×$OCOCH_3$), 2.30—2.45, 2.75—3.10 (1H×2, each m, H-5,5′), 3.69, 3.73 (3H×2, each s, 2×$COOCH_3$), 3.97 (1H, t, *J*=3 Hz, H-3), 4.63 (2H, d, *J*=1.5 Hz, $OCH_2C_6H_5$), 4.83—5.15 (1H, m, H-4), 5.90 (1H, d, *J*=3 Hz, H-2), 7.30 (5H, s, $OCH_2C_6H_5$). Found: C, 58.58; H, 6.04%. Calcd for $C_{20}H_{24}O_9$: C, 58.82; H, 5.92%.

(3*S*,4*S*)-3-Benzyloxy-4-hydroxy-1-cyclopentene-1-methanol (14). A solution of **12** (556 mg, 1.36 mmol) in a mixture of DMSO (44 ml) and water (2 ml) containing NaCl (239 mg, 4.09 mmol) was heated from 110 to 160 °C for 2 h. The mixture was heated at 160 °C additional 4 h. After cooling to room temperature, water (300 ml) was added. The aqueous mixture was extracted with dichloromethane (300 ml×2). The extract was dried over Na_2SO_4 and concentrated at below 9 °C until ca. 10 ml volume. The remaining liquid contained **13**, which was reduced directly. In a separate experiment, the crude **13** was purified on silica gel chromatography (ethyl acetate-hexane=1 : 15). **13** as a somewhat volatile colorless liquid, TLC R_f 0.73 (ethyl acetate-hexane=1 : 2): $[\alpha]_D^{27}$ +94.7° (*c* 0.44, $CHCl_3$): IR $\nu_{max}^{CHCl_3}$ 2950, 1720, 1630, 1435, 1370, 1290, 1240, 1220, 1170 cm^{-1}; ^1H NMR δ=2.01 (3H, s, $OCOCH_3$), 2.25—2.60, 3.04—3.40 (1H×2, each m, H-5,5′), 3.75 (3H, s, $COOCH_3$), 4.53—4.70 (1H, m, H-3), 4.63 (2H, s, $OCH_2C_6H_5$), 5.20—5.39 (1H, m, H-4), 6.60—6.75 (1H, m, H-2), 7.33 (5H, s, $OCH_2C_6H_5$). High-resolution mass spectrum, Found: *m/z* 290.1147, Calcd for $C_{16}H_{18}O_5$: M, 290.1152.

To a solution of the above concentrate in dichloromethane (14 ml), DIBAL-H (1.5 mol dm^{-3} in toluene, 18.1 ml, 27.2 mmol) was added at −78 °C with stirring under an argon atmosphere. The reducing reagent was added after 100 min (18.1 ml), 140 min (18.1 ml), and 160 min (9.1 ml) successively at −78 °C. The mixture was stirred at the same temperature additional 80 min and diluted with water (70 ml). The resulting insoluble solids were removed by filtration. The filtrate was diluted with water (200 ml) and extracted with dichloromethane (300 ml×6). The extract was dried over Na_2SO_4 and concentrated. The residue was chromatographed on silica gel (15 g, ethyl acetate-hexane=2 : 3) and the fraction corresponding to R_f 0.18 (ethyl acetate-hexane=1 : 1) was concentrated to give **14** (225 mg, 75%) as a colorless syrup. **14**: $[\alpha]_D^{25}$ +100.0° (*c* 0.99, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3350, 2900, 2850, 1650, 1490, 1455 cm^{-1}; ^1H NMR δ=1.95—2.26, 2.50—2.87 (1H×2, each m, H-5,5′), 3.15—3.65 (2H, broad s, 2×OH), 4.01 (2H, s, CH_2OH), 4.20—4.43 (2H, m, H-3,4), 4.54 (2H, s, $OCH_2C_6H_5$), 5.60 (1H, broad s, H-2), 7.30 (5H, s, $OCH_2C_6H_5$). High-resolution mass spectrum, Found: *m/z* 220.1097, Calcd for $C_{13}H_{16}O_3$: M, 220.1073.

(3*S*,4*S*)-3-Benzyloxy-1-(*t*-butyldiphenylsilyloxymethyl)-4-hydroxy-1-cyclopentene (15). To a solution of **14** (218 mg, 0.99 mmol) in DMF (4 ml), *t*-butylchlorodiphenylsilane (0.16 ml, 0.60 mmol) and imidazole (81 mg, 1.19 mmol) were added with stirring. Each 0.08 ml of the silylating reagent and 40.5 mg of imidazole was added after 5, 24, and 29 h. The mixture was stirred totally 31 h, and diluted with ethyl acetate (300 ml). The solution was washed with water (50 ml×3). The organic layer was dried over Na_2SO_4 and concentrated. The residue was chromatographed on silica gel (15 g, ethyl acetate-hexane=1 : 8), and the fraction corresponding to R_f 0.45 (ethyl acetate-hexane=1 : 3) was concentrated to give **15** (332 mg, 73%) as a colorless syrup. **15**: $[\alpha]_D^{20}$

+50.4° (*c* 1.00, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3420, 3075, 3055, 2960, 2940, 2860, 1590, 1500, 1470, 1460, 1430, 1390, 1360 cm^{-1}; ^1H NMR δ=1.02 (9H, s, $OSiC(CH_3)_3$), 1.88—2.22 (2H, m, H-5, OH), 2.45—2.82 (1H, m, H-5′), 4.08 (2H, s, CH_2OSi), 4.13—4.40 (2H, m, H-3,4), 4.49 (2H, s, $OC\underline{H}_2C_6H_5$), 5.60 (1H, m, H-2), 7.20—7.75 (15H, m, $OCH_2C_6\underline{H}_5$, $OSi(C_6\underline{H}_5)_2$). Found: C, 76.02; H, 7.55%. Calcd for $C_{29}H_{34}O_3Si$: C, 75.94; H, 7.47%.

(3*S*,4*S*)-4-Acetoxy-3-benzyloxy-1-(*t*-butyldiphenylsilyloxymethyl)-1-cyclopentene (16). Compound **15** (15 mg, 0.032 mmol) was acetylated with acetic anhydride (1 ml) in pyridine (1 ml) for 2 h. The mixture was concentrated, and the residue was purified on preparative TLC (20×20 cm, Merck Kieselgel 60 PF_{254}, ethyl acetate-hexane=1 : 3). The band corresponding to R_f 0.85 (ethyl acetate-hexane=1 : 3) was extracted with $CHCl_3$ and concentrated to give **16** (14 mg, 87%) as a colorless syrup. **16**: $[\alpha]_D^{19.5}$ +45.8°(*c* 0.65, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2930, 2860, 1725, 1450, 1430, 1370, 1250, 1170, 1110 cm^{-1}; ^1H NMR δ=0.85 (9H, s, $OSiC(CH_3)_3$), 1.83 (3H, s, $OCOCH_3$), 1.75—2.10, 2.50—2.90 (1H×2, each m, H-5,5′), 4.00 (2H, s, CH_2OSi), 4.20—4.50 (1H, m, H-3), 4.41 (2H, d, *J*=3 Hz, $OC\underline{H}_2C_6H_5$), 4.98—5.23 (1H, m, H-4), 5.55 (1H, d, *J*=2 Hz, H-2), 7.10—7.60 (15H, m, $OCH_2C_6\underline{H}_5$, $OSi(C_6\underline{H}_5)_2$). Found: C, 74.18; H, 7.32%. Calcd for $C_{31}H_{36}O_4Si$: C, 74.36; H, 7.25%.

(3*S*,4*R*)-3-Benzyloxy-1-(*t*-butyldiphenylsilyloxymethyl)-4-hydroxy-1-cyclopentene (18). To a solution of **15** (251 mg, 0.55 mmol) in dichloromethane (24 ml), PCC (2.36 g, 10.9 mmol) and molecular sieves (4A, powder, 1 g) were added. The mixture was stirred for 30 min. The mixture was applied on silica-gel column (40 g), and eluted with ether. The fraction corresponding to R_f 0.79 (ethyl acetate-hexane =1 : 4) was concentrated to give **17** (223 mg) as a colorless syrup. To a solution of **17** in methanol (8 ml), sodium borohydride (31 mg, 0.82 mmol) was added with stirring at 0 °C. After stirring at 0 °C for 1 h, the mixture was neutralized with 1 mol dm^{-3} HCl and diluted with water (50 ml). The solution was extracted with dichloromethane (80 ml×4), and the extracts were combined, dried over Na_2SO_4, and concentrated. The residue was chromatographed on silica gel (11 g, ethyl acetate-hexane=1 : 25), and the fraction corresponding to R_f 0.53 (ethyl acetate-hexane=1 : 4) was concentrated to give **18** (160 mg, 64%) as a colorless syrup. The fraction corresponding to R_f 0.33 was concentrated to give **15** (25 mg, 10%) **18**: $[\alpha]_D^{21.5}$ +33.1° (*c* 1.17, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3550, 2940, 2860, 1650, 1590, 1470, 1430, 1390, 1160, 1110 cm^{-1}; ^1H NMR δ=1.09 (9H, s, $OSiC(CH_3)_3$), 2.28—2.50 (2H, m, H-5,5′), 2.00—3.00 (1H, broad, OH), 4.15—4.50 (4H, m, CH_2OSi, H-3,4), 4.66 (2H, s, $OC\underline{H}_2C_6H_5$), 5.70—5.85 (1H, m, H-2), 7.25—7.75 (15H, m, $OCH_2C_6\underline{H}_5$, $OSi(C_6\underline{H}_5)_2$). Found: C, 75.67; H, 7.50%. Calcd for $C_{29}H_{34}O_3Si$: C, 75.94; H, 7.47%.

(3*S*,4*R*)-4-Acetoxy-3-benzyloxy-1-(*t*-butyldiphenylsilyloxymethyl)-1-cyclopentene (19). Compound **18** (11 mg, 0.024 mmol) was acetylated with acetic anhydride (1 ml) in pyridine (1 ml) for 13 h. The mixture was concentrated, and the residue was chromatographed on silica gel (1 g, ethyl acetate-hexane=1 : 30). The fraction corresponding to R_f 0.47 (ethyl acetate-hexane=1 : 8) was concentrated to give **19** (11 mg, 90%) as a colorless syrup. **19**: $[\alpha]_D^{22.5}$ +35.1° (*c* 0.49, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 3000, 2960, 2930, 2860, 1725, 1250, 1170, 1110 cm^{-1}; ^1H NMR δ=1.05 (9H, s, $OSiC(CH_3)_3$), 2.03 (3H, s, $OCOCH_3$), 2.40—2.65 (2H, m, H-5,5′), 4.21 (2H, s, CH_2OSi), 4.50—4.68 (3H, m, $OC\underline{H}_2C_6H_5$, H-3), 5.30 (1H, q, *J*=6.5 Hz, H-4), 5.73—5.86 (1H, m, H-2), 7.30—7.80 (15H, m, $OCH_2C_6\underline{H}_5$, $OSi(C_6H_5)_2$). Found: C, 74.46; H, 7.28%. Calcd for $C_{31}H_{36}O_4Si$: C, 74.36; H, 7.25%.

(3*S*,4*R*)-3-Benzyloxy-4-hydroxy-1-cyclopentene-1-methanol (20). To a solution of **18** (156 mg, 0.34 mmol) in THF (10 ml), tetrabutylammonium fluoride (1 mol dm^{-3} in THF, 0.51 ml, 0.51 mmol) was added with stirring. After stirring for 2 h, the mixture was concentrated. The residue was chromatographed on silica gel (6 g, ethyl acetate-hexane=1 : 2), and the fraction corresponding to R_f 0.14 (ethyl acetate-hexane=1 : 1) was concentrated to give crystals of **20** (68 mg, 90%), mp 74—75 °C. **20**: $[\alpha]_D^{23}$ +75.4° (*c* 0.985, $CHCl_3$), IR $\nu_{max}^{CHCl_3}$ 3400, 2925, 2860, 1650, 1495, 1450, 1395, 1330, 1210, 1160 cm^{-1}; ^1H NMR δ=2.39 (2H, broad s, H-5,5′), 2.91 (2H, broad s, 2×OH), 4.10 (2H, broad s, CH_2OH), 4.25—4.50 (2H, m, H-3,4), 4.60 (2H, s, $OC\underline{H}_2C_6H_5$), 5.69 (1H, broad s, H-2), 7.34 (5H, s, $OCH_2C_6\underline{H}_5$). High-resolution mass spectrum, Found: *m/z* 220.1104, Calcd for $C_{13}H_{16}O_3$: M, 220.1098.

(1*R*,2*R*,3*R*,4*R*)-2,4-Diacetoxy-1-acetoxymethyl-3-(benzyloxy)cyclopentane (21). To a solution of **20** (65 mg, 0.29 mmol) in THF (5 ml), borane-THF complex (1 mol dm^{-3} in THF, 1.19 ml, 1.19 mmol) was added at 0 °C with stirring under an argon atmosphere. After 90 min stirring, borane-THF (0.59 ml) was added. The mixture was stirred additional 90 min at 0 °C, and water (1.8 ml), aqueous NaOH (3 mol dm^{-3}, 2.1 ml) and aqueous hydrogen peroxide (35%, 2.3 ml) were added successively. After stirring at room temperature for 3 h, saturated aqueous sodium sulfite (2.5 ml) was added and the mixture was concentrated with ethanol. The residue was passed through a short column of silica gel (3 g), and eluted with ethanol. The fraction corresponding to R_f 0.35 (ethanol-toluene=1 : 5) was concentrated. The residue was acetylated with acetic anhydride (5 ml) in pyridine (5 ml) for 18 h. The mixture was diluted with water (50 ml) and extracted with dichloromethane (50 ml×3). The extracts were dried over Na_2SO_4 and concentrated. The residue was chromatographed on silica gel (6 g, ethyl acetate-hexane=1 : 10), and the fraction corresponding to R_f 0.42 (ethyl acetate-hexane=1 : 3) was concentrated to give **21** (71 mg, 65%) as a colorless syrup. **21**: $[\alpha]_D^{23.5}$ −2.2° (*c* 0.9, $CHCl_3$); IR $\nu_{max}^{CHCl_3}$ 2930, 1740, 1730, 1450, 1365, 1230, 1220 cm^{-1}; ^1H NMR δ=2.03, 2.06 (6H, 3H, each s, 3×$OCOCH_3$), 1.95—2.40 (3H, m, H-1,5,5′), 3.89 (1H, t, *J*=4.5 Hz, H-3), 4.18 (2H, dd, *J*=3 and 6 Hz, $C\underline{H}_2OAc$), 4.59 (2H, s, $OC\underline{H}_2C_6H_5$), 5.00—5.30 (2H, m, H-2,4), 7.31 (5H, s, $OCH_2C_6\underline{H}_5$). Found: C, 62.75; H, 6.77%. Calcd for $C_{19}H_{24}O_7$: C, 62.63; H, 6.64%.

(1*R*,2*R*,3*R*,4*R*)-2,3,4-Triacetoxy-1-(acetoxymethyl)cyclopentane (22). A solution of **21** (68.5 mg, 0.19 mmol) in a mixture of ethanol (3 ml) and distilled cyclohexene (6.5 ml) in the presence of 20% $Pd(OH)_2$ on charcoal (150 mg) was refluxed for 4 h. The catalyst was removed by filtration with a Celite-pad, and the filtrate was concentrated. The residue was chromatographed on silica gel (3 g, ethyl acetate-hexane=1 : 4), and the fraction corresponding to R_f 0.19 (ethyl acetate-hexane=1 : 2) was concentrated. The residue was acetylated with acetic anhydride (1 ml) in pyridine (1 ml) for 2 h. The mixture was concentrated, and the residue was chromatographed on silica gel (3 g, ethyl acetate-hexane=1 : 6). The fraction corresponding to R_f 0.44 (ethyl acetate-hexane=1 : 2) was concentrated to give **22** (53.5 mg, 90%) as a colorless syrup. $[\alpha]_D^{23}$ −4.8° (*c* 0.87, $CHCl_3$), $[\alpha]_D^{23}$ +4.1° (*c* 1.07, $CHCl_3$) for the enantiomer of **22**.[1e] The IR and

^{1}H NMR spectra of **22** were identical with those of the (1*S*,2*S*,3*S*,4*S*)-enantiomer. Found: C, 53.37; H, 6.18%. Calcd for $C_{14}H_{20}O_8$: C, 53.16; H, 6.34%.

(1*R*,2*R*,3*R*,4*R*)-2,3,4-Trihydroxy-1-(hydroxymethyl)cyclopentane, Pseudo-β-D-arabinofuranose (3). To a solution of **22** (47 mg, 0.15 mmol) in methanol (2 ml), sodium methoxide (1 mol dm^{-3} in methanol, 0.45 ml, 0.45 mmol) was added at 0 °C with stirring. After stirring at 0 °C for 2 h, the mixture was neutralized by addition of Amberlite IR-120 (H^+). The resin was removed by filtration, washed with methanol. The filtrate and washing were concentrated to give **3** (22 mg, quantitatively). An analytical sample was obtained by PTLC (chloroform-methanol=2:1). **3** as a colorless syrup, TLC R_f 0.41 (chloroform-methanol=2:1): $[\alpha]_D^{22}$ +9.7° (*c* 0.72, MeOH), $[\alpha]_D^{14}$ −8.8° (*c* 0.56, MeOH) for the (1*S*,2*S*,3*S*,4*S*)-enantiomer **1**.[1e,8] The ^{1}H NMR sepctrum of **3** was identical with that of **1**. High-resolution mass spectrum, Found: *m/z* 149.0781. Calcd for $C_6H_{13}O_4$: M+H, 149.0812.

We thank to Mr. Akio Takahashi of our university for his elemental analyses.

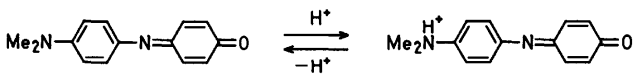
Influence of Hexasulfonated Calix[6]arenes on the Reactivities of Arenediazonium Ions in an Aqueous System

Seiji SHINKAI,* Seiichi MORI, Koji ARAKI, and Osamu MANABE
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852
(Received April 17, 1987)

The pK_a of Phenol Blue shifted from 4.6 to 6.2 because of complexation of protonated Phenol Blue in the cavity of hexasulfonated calix[6]arene with dodecyl substituents (**2C**$_{12}$). The finding stimulated us to examine whether the analogs (**2C**) suppress the dediazoniation of arenediazonium ions in an aqueous system as crown ethers do in organic solvents. We have found that **2C** can suppress the dediazoniation in an aqueous system where neither 18-crown-6 nor anionic micelles are effective. The magnitude of the inhibition effect was 4—5 fold. The reaction rate of the diazo coupling with *N,N*-dimethylaniline was significantly suppressed in the presence of **2C**, suggesting that arenediazonium ions are deactivated through complexation with **2C**. The novel stabilization effects were explained by the strong anionic reaction field which neither 18-crown-6 nor anionic micelles have: that is, **2C** has a peculiar architecture that six sulfonato groups are circularly arranged on the edge of the calixarene cavity.

Recently, Gutsche and co-workers[1,2] have reported on a series of new cyclic molecules called "calixarenes" which are cyclic oligomers made up of benzene units as cyclodextrins are made up of glucose units. Several groups have reported on the ionophoric properties of calixarenes,[3-7] but almost nothing is known with certainty as to the inclusion properties of calixarenes in solution. In 1984, we reported the synthesis and properties of hexasulfonated calix[6]arenes, the first example of water-soluble calixarenes.[8] The subsequent investigations on these calixarenes established that they can form host-guest-type complexes with a variety of guest molecules in an aqueous system.[9-12] During these studies, we noticed an interesting spectral change in Phenol Blue: In the presence of hexasulfonated calix[6]arene (**2C**$_{12}$), the absorption maximum (658 nm in water) moves to 592 nm at low concentration region followed by a relatively small blue shift (630 nm) at high concentration region.[9] The λ_{max} 630 nm was equal to the blue shift induced by the sodium dodecyl sulfate(SDS) micelle,[9] but the origin of the unusually large blue shift to 592 nm was not explained until recently. We found, as described in this paper, that this blue shift is due to "protonation" of Phenol Blue in neutral aqueous solution (Eq. 1). The finding suggests that hexasulfonated calix[6]arenes, which have six anionic groups on the upper rim of the calixarene cavity, have some special architecture effecive to stabilize included cationic species.



(1)

In 1973, Gokel and Cram[13] found that crown ethers of the proper dimensions can solubilize several arenediazonium salts in nonpolar media (e.g., chloroform). Subsequent spectroscopic studies established that the solubilization is caused by complexation, like complexation between crown and metal cation, the linear Ar-N^+≡N inserting into the hole of the crown ring with its oxygen atoms turned inward toward the positive charge as shown in structure **1**.[13-19] As expected from the complex structure, the association constants (K) for crown-arenediazonium complexes are affected by both electronic effects and steric effects:[13-20] for example, strongly electron-donating groups (e.g, Et_2N-) in arenediazonium salts depress complexation to such extent that the K values cannot be determined[20] and the sterically hindered 2,6-dimethylbenzenediazonium salt is not complexed by crown ethers.[14] Of additional interest is the finding that the thermal decomposition of arenediazonium salts is slowed down when the salts are complexed by crown ethers.[17-19,21-23] This stabilization effect is attributed to the attenuation of the positive charge at the diazonium group in the complex[13,14,19] and to the retardation of the decomplexation rate.[23]

3Cl: R=Cl

Based on the foregoing results, we considered that **2C** may form stable complexes with arenediazonium salts (**3R**) and may stabilize them even in an aqueous system.[24] We here report that (i) the absorption maximum of Phenol Blue undergoes the unusual blue shift in the presence of **2C**$_{12}$ due to electrostatic stabilization of protonated Phenol Blue, (ii) the dediazoniation of **3R** is significantly suppressed by complexation with **2C** even in an aqueous system where neither crown ethers nor anionic micelles are effective, and (iii) the rates of diazo coupling with *N,N*-dimethyl-

aniline and 3-hydroxy-2,7-naphthalenedisulfonate (R-acid) are selectively slowed down.

Experimental

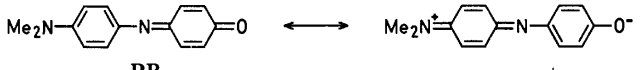
Materials. Preparations of 5,11,17,23,29,35-hexasulfonato-37,38,39,40,41,42-hexamethoxycalix[6]arene (**2C**$_1$), 5,11,17,23,29,35-hexasulfonato-37,38,39,40,41,42-hexakis(hexyloxy)calix[6]arene (**2C**$_6$), and 5,11,17,23,29,35-hexasulfonato-37,38,39,40,41,42-hexakis(dodecyloxy)calix[6]arene (**2C**$_{12}$) were described in a previous paper of this series.[9]

Kinetic Measurements. The rate constants for the dediazoniation were estimated as follows. Compound **3R** was prepard from aniline (or *p*-hexylaniline) by the reaction with $NaNO_2$ in 0.05 M† H_2SO_4 solution at 0—5 °C and then diluted with 0.024 M H_2SO_4 solution. This solution (containing [**3R**]=1.00×10^{-3} M) was mixed with **2C** and maintained in the dark at 30 °C in a thermostated water bath. Aliquots were withdrawn from the reaction mixture and treated with 3-hydroxy-2,7-naphthalenedisulfonate in 0.10 M Na_2CO_3 solution. The concentration of unreacted **3R** was determined using a calibration curve by the absorption band (490 nm) of the diazo-coupling product. The plots of OD_{490} vs. reaction time were first-order for up to three half-lives.

The reaction between *p*-chlorobenzenediazonium ion **3Cl** and *N,N*-dimethylaniline (or 3-hydroxy-2,7-naphthalenedisulfonate) was followed spectrophotometrically at 30 °C. *p*-Chloroaniline was diazotized with $NaNO_2$ and diluted with an aqueous solution buffered to pH 6.92 (0.05 M phosphate) for *N,N*-dimethylaniline and to pH 4.80 (0.05 M acetate) for 3-hydroxy-2,7-naphthalenedisulfonate. This solution was equilibrated to 30 °C in a spectrophotometer and then mixed with 100 μl of aqueous *N,N*-dimethylaniline (or 3-hydroxy-2,7-naphthalenedisulfonate): [*p*-chlorobenzenediazonium ion]=4.96×10^{-5} M, [*N,N*-dimethylaniline]=1.51×10^{-3} M, [3-hydroxy-2,7-naphthalenedisulfonate]=1.10×10^{-3} M. The pseudo-first-order rate constants were estimated from the time-dependent appearence of a new absorption band for the product (440 nm for *N,N*-dimethylaniline and 490 nm for 3-hydroxy-2,7-naphthalenedisulfonate).

Results and Discussion

Absorption Spectra of Phenol Blue in the Presence of 2C. Brooker and Sprauge[25] suggested the use of Phenol Blue (PB) as a solvent property indicator; the absorption maximum (668 nm in water;[25] 658 nm according to our measurement at 30 °C) shifts to shorter wavelengths in nonpoler solvents e.g., 552 nm in cyclohexane). The blue shift is attributed to destabilization of the charge-separated excited state PB$^{\pm}$.



PB PB$^{\pm}$ (2)

In the presence of **2C**$_{12}$ at pH 5.6 (no buffer), the λ_{max} of PB shifts to 592 nm at around [**2C**$_{12}$]/[PB]≈1 and then moves to 630 nm at [**2C**$_{12}$]/[PB]>1 (Fig. 1). The absorption band at 592 nm is attributable to protonated species of PB, because (i) the similar absorption

† 1 M=1 mol dm^{-3}.

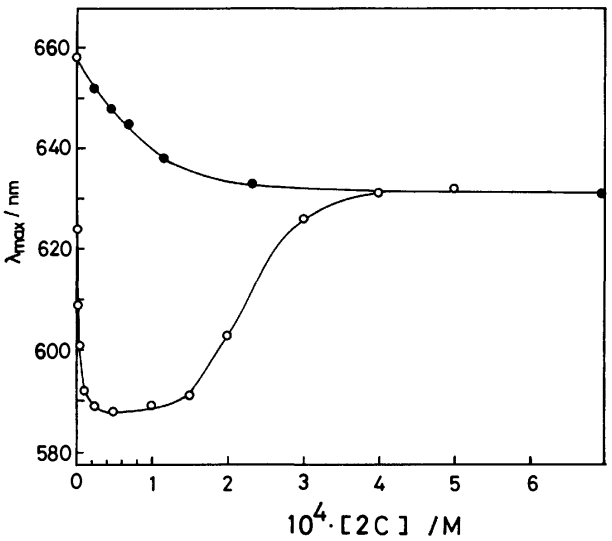


Fig. 1. Absorption maximum of Phenol Blue vs. 2C$_{12}$ concentration: ○ at pH 5.6 (no buffer), ● at pH 8.7 with 0.02 M borate buffer. 30 °C, [Phenol Blue]=1.00×10^{-5} M.

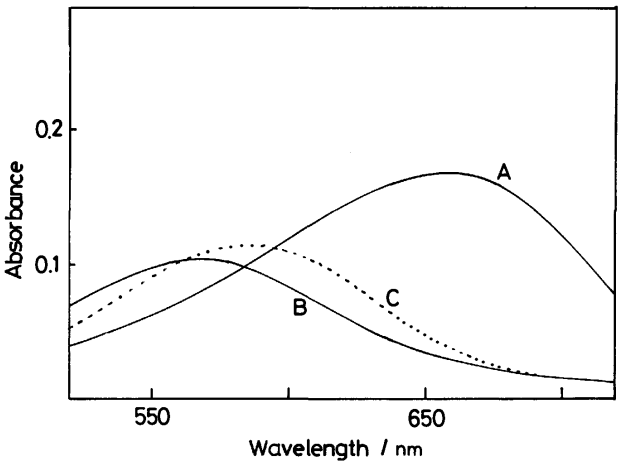

Fig. 2. Absorption spectra of Phenol Blue (1.00×10^{-5} M) at 30 °C: (A) pH 5.6 (no buffer), (B) pH 3.2 (with HCl), (C) pH 5.6 (no buffer, [**2C**$_{12}$]=1.00×10^{-4} M).

spectra (λ_{max} 570—590 nm) can be reproduced in acidic aqueous solution in the absence of **2C**$_{12}$ (Fig. 2) and (ii) the biphasic dependence of λ_{max} disappears in buffered aqueous solution (pH 8.7 with 0.02 M borate) (Fig. 1). This finding supports that protonated PB is strongly stabilized through inclusion in the cavity of **2C**$_{12}$. In Fig. 3, OD_{650} is plotted against pH. The solution pH was adjusted by HCl below pH 6 and aqueous NH_3 above pH 6. Thus, the pK_a of PB was estimated to be 4.6. In the presence of **2C**$_{12}$ the pK_a shifted to 6.2 (ΔpK_a=1.6), indicating that the included PB behaves as an apparently stronger base. The similar pK_a shift was also observed in the presence of the SDS micelle (pK_a=5.4; ΔpK_a=0.8), but the magnitude of the pK_a shift was about one-half.

The remarkable stabilization effect of $2C_{12}$ would be explained in two ways: That is, (i) oxonium ions are locally concentrated around $2C_{12}$ owing to the electrostatic interaction, resulting in a facile protonation of PB and (ii) hexa-anionic sulfonato groups stabilized the included, protonated PB through the host-guest-type electrostatic interaction. The effect (i) should be operative in the present system because addition of inorganic salts (e.g., NaCl) reduces the magnitude of the pK_a shift. This can be rationalized in terms of competitive binding of Na^+ and H_3O^+ to the anionic sulfonato groups. The effect (ii) should be also important. We have found that the "cone" conformation is favorably adopted when a guest molecule is included in the cavity of calixarenes.[26] When **2C** adopts the cone conformation, six sulfonato groups are circularly arranged on one side of the calixarene cavity (Scheme 1). This unusual architecture would exert the remarkable stabilization effect on included cationic species. It is not easy to distinguish two effects on the basis of the present qualitative experiments. Probably, it is reasonable to consider that two effects are operative synergisticallly. If the effect (ii) contributes to the pK_a shift to a significant extent, one can extend this study to an interesting idea: That is, arenediazonium ions could be also stabilized through complexation with **2C**.

Stabilization of Arenediazonium Ions. In the thermal decomposition of **3H**, we found by a GLC method that phenol is afforded in 58—65% yield as a sole detectable product in the absence and the presence of **2C**([$2C_{12}$]=2.00 mM, 50 °C, 24 h). This indicates that the dediazoniation proceeds according to the ionic reaction path and the radical reaction path is not included.

The first-order rate constants (k_d) for the dediazoniation of **3H** and $3C_6$ are summarized in Table 1 and plots of k_d vs. [**2C**] for **3H** are illustrated in Fig. 4. Examination of Table 1 leads to the following conclusions: (i) in an aqueous system, neither 18-crown-6 nor anionic micelles suppress the thermal decomposition

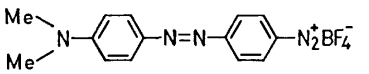
a) Sodium dodecylsulfate: the cmc is 6.6 mM. b) Sodium dodecylbenzenesulfonate: the cmc is 1.2 mM.

of **3R** to a significant extent, (ii) 1,5-naphthalenedisulfonate, which is used as a stabilizer for arenediazonium salts in the solid state, is also ineffective, and (iii) the k_d values decrease with increasing concentration of **2C** and in particular, $2C_{12}$ can reduce the k_d to 20—23% of those observed in the absence of **2C**. The fact (iii) is sharply contrastive to the fact (i) that 18-crown-6 can stabilize arenediazonium salts only in certain organic solvents but not at all in an aqueous system. These findings suggest that hexasulfonato calixarene derivatives have some specific architecture to stabilize **3R** even in an aqueous system. From the scheme depicted in Eq. 3, we estimated the association constans (K) and the intra-complex dediazoniation rate constants ($k_{complex}$) for 3H assuming the formation of a 1 : 1 complex:[††] K=ca. 10^2 M^{-1} for $2C_1$, 4.2×10^6 M^{-1} for $2C_6$, and 5.6×10^4 M^{-1} for $2C_{12}$; $k_{complex}=8.62\times10^{-5}$ s^{-1} for $2C_1$, 2.92×10^{-5} s^{-1} for $2C_6$, and 1.91×10^{-5} s^{-1} for $2C_{12}$. These results support that hexa-anionic **2C** can form stable complexes with cationic **3H**. Since the K values for $2C_6$ and $2C_{12}$ are much greater than that for $2C_1$, not only the electrostatic interaction but also the hydrophobic force is operative in the association with **3H**. We previously found that $2C_6$ forms micelle-like aggregates, the cmc being detected at 0.6 mM while $2C_{12}$ acts as a "unimolecular" micelle at 10^{-5}—10^{-3} M region forming host-guest type 1 : 1 complexes with guest molecules.[9] The fact that the K for $2C_6$ is greater by a factor of 75 than that for $2C_{12}$ may be due to the aggregate formation of $2C_6$.

$$\begin{array}{ccc} 3H + 2C & \overset{K}{\rightleftharpoons} & 3H\cdot 2C \\ \downarrow k_0(=9.52\times10^{-5}s^{-1}) & & \downarrow k_{complex} \\ \text{product} & & \text{product} \end{array} \qquad (3)$$

To obtain an insight into the binding mode of **3R** into the calixarene cavity, we examined the solvent effect on the dediazoniation rate because the hydrophobic effect in an aqueous system is partly reproduced by the solvent effect. We used 4-(4-dimethylaminophenylazo)benzenediazonium tetrafluoroborate (**4**) as a spectroscopic probe. The absorption maximum of **4** shifts to shorter wavelengths in nonpolar solvents: For example, λ_{max} 612 nm in water, 579 nm in tetrahydrofuran, and 558 nm in dioxane (30 °C). In Fig. 5, the λ_{max} is plotted against the dioxane concentration in water. The λ_{max} shifts to shorter wavelengths with increase in the dioxane concentration. In an aqueous system, the λ_{max} was not affected by the addition of $2C_1$ (2.00 mM) but shifted to 609 and 595 nm in the presence of $2C_6$ and $2C_{12}$ (2.00 mM), respectively. These wavelenghts correspond to the aqueous solutions containing 25 and 85 vol% of dioxane. This implies that **3R** is bound to the relatively hydrophobic site in the calixarene cavity.



4

In Fig. 6, the k_d values are plotted against the λ_{max} of **4**. The open circles indicate the rate constants obtained for **3H** in an aqueous system in the presence of additives, and the filled circles indicate the rate constants obtained for benzenediazonium tetrafluoroborate in a dioxane-water system. It is seen from Fig. 6 that the plots for most additives are not so different from those for a dioxane-water system, but two plots

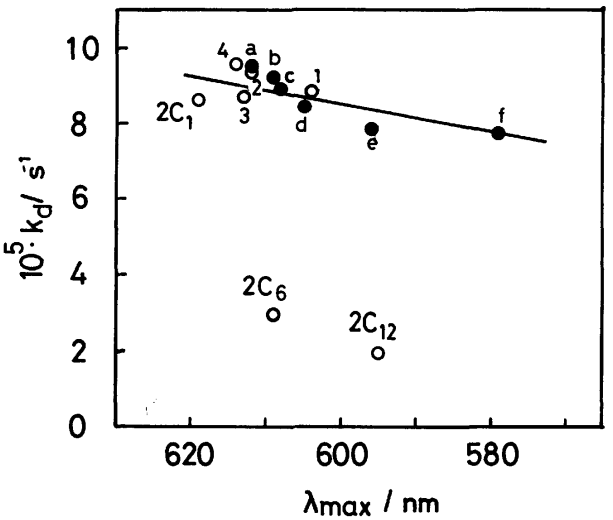

Fig. 6. First-order rate constant for the dediazoniation of **3H** vs. absorption maximum of **4** (the longer the wavelength, the more hydrophobic): (1) SDS (2.00×10^{-2} M), (2) sodium *p*-toluenesulfonate (5.00×10^{-3} M), (3) sodium dodecylbenzenesufonate (4.70×10^{-2} M), (4) disodium naphthalene-1,5-disulfonate (4.58×10^{-3} M). (a)—(f) indicate a water-dioxane system; the dioxane concentrations (vol%) are (a) 0, (b) 25, (c) 33, (d) 49, (e) 82, (f) 93.

[††]The detailed calculation method equivalent to Eq. 3 was described previously: S. Shinkai, T. Minami, Y. Kusano, and O. Manabe, *J. Am. Chem. Soc.*, **105**, 1851 (1983).

for $2C_6$ and $2C_{12}$ are distinctly deviated from this relationship. This implies that the stabilization effect of $2C_6$ and $2C_{12}$ is not fully explained by the hydrophobic effect. We believe that the specific stabilization is due to the strong anionic field brought about by six sulfonato groups on the edge of the calixarene cavity. Therefore, the hexasulfonated calix[6]arene has an architecture very favorable to stabilize the complexed arenediazonium ions.

Influence on the Diazo-Coupling Reactions. The decomposition of arenediazonium ions is efficiently suppressed through complexation with hexasulfonated calix[6]arenes. As a next stage, it is of a great significance to examine the reactivity of these stabilized arenediazonium ions in the diazo-coupling reactions. However, this seems fairly difficult because in contrast to the unimolecular dediazoniation the rate of the bimolecular diazo-coupling reaction reflects not only the reactivity of arenediazonium ions but also the local concentration effect. We chose the reaction with neutral species, *N*,*N*-dimethylaniline (DA) in order to obviate at least the complexity arising from the electrostatic interaction and repulsion between charged reactants. As **3H** and $3C_6$ did not exhibit a measurable reactivity toward DA, we employed more reactive arenediazonium ion, *p*-chlorobenzenediazonium (**3Cl**).

First, we tested whether the dediazoniation of **3Cl** is really suppressed by **2C**. The reaction was carried out at 60 °C because **3Cl** decomposed very slowly at 30 °C. As shown in Fig. 7, this reaction is also slowed down in the presence of $2C_6$ and $2C_{12}$: $K=5.0\times10^4$ M and $k_d/k_0=0.18$ for $2C_6$ (2.00 mM) and $K=5.2\times10^4$ M and $k_d/k_0=0.30$ for $2C_{12}$ (2.50 mM). In Fig. 8, the pseudo-first-order rate constants (k_c) for the diazo-coupling reaction at 30 °C are plotted against the calixarene concentrations. The k_c for sodium dodecyl sulfate (SDS; the cmc is 6.6 mM) sharply increased at 0—7 mM region and then decreased at higher concentration region. The biphasic dependence can be explained by the micellar effect on the bimolecular reaction:[27] The rate acceleration at the low concentration region would be due to the formation of a hydrophobic ion pair[27,28] between **3Cl** and SDS leading to the enhancement in the local concentration, whereas the rate retardation at the high concentration region would be due to the so-called dilution effect caused by the micellar aggregates.[27] The effect of added **2C** is quite contrasting: $2C_6$ and $2C_{12}$ which strongly associated with arenediazonium ions decelerated the reaction monotonously, while $2C_1$, which associated with arenediazonium ions only weakly accelerated the reaction to some extent. The typical rate constants are summarized in Table 2.

Probably, one has to take two different effects into consideration to account for the kinetic results in Fig. 8. The first is the stabilization of **3Cl** through complexation with **2C**, leading to the rate retardation. The second effect is the concentration of reactants in the calixarene cavity, leading to the rate acceleration as seen for the SDS system. As shown in Fig. 8 and Table 2, the k_c values were decreased by 11—13 fold in the presence of $2C_6$ and $2C_{12}$ in spite of the expected, positive contribution of the concentration effect. This suggests that arenediazonium ions included in the calixarene cavity are considerably deactivated. However, it is also possible to explain the kinetic data in a different way on the basis of the concentration effect: For example, possible explanations are (i) the cavity of **2C** can accept only one guest molecule and therefore

retards the rate of the bimolecular diazo coupling and (ii) **2C** has two binding sites, one consisting of sulfonated benzene rings suitable to bind a cationic guest molecule (e.g., **3Cl**) and the other consisting of alkyl (hexyl or dodecyl) groups suitable to bind a neutral guest molecule (e.g., DA). In either case, the reaciton rate should be suppressed by the apparent dilution of reactants. In particular, the case (ii) is likely because $2C_1$, in which the binding site consisting of alkyl (methyl) groups is relatively weak accelerates the reaction rate (Fig. 8). At present we believe that the efficient rate retardation results from both the deactivation of **3Cl** and the dilution of **3Cl** and DA.

The effect of added **2C** may be shown more clearly by the combination with the electrostatic repulsion. This combination may be of some significance because the diazo-coupling reaction usually includes the attack of cationic arenediazonium ions at anionic species (e.g., phenolate anion). We chose 3-hydroxy-2,7-naphthalenedisulfonate (pK_a 9.42 under the present reaction conditions). The kinetic results are illustrated in Fig. 9. We found that the reaction is strongly inhibited by $2C_6$ and $2C_{12}$, the rate constants being smaller by 42—63 fold than that in a non-additive system (Table 2). A similar rate retardation was observed for SDS, the inhibition effect (50 fold) being comparable with that for $2C_6$ and $2C_{12}$. One can thus envisage a reaction mode such **3Cl** is bound to the anionic calixarene or to the SDS micelle by the electrostatic interaction and 3-hydroxy-2,7-naphthalenedisulfonate is separated by the electrostatic repulsion. Since the inhibition effect is comparable between **2C** and SDS, this reaction should be primarily governed by the electrostatic effect and the stabilization of **3Cl** by **2C** should play only a secondary role. It is worthy mentioning, however, that $2C_6$ and $2C_{12}$ sufficiently inhibit the reaction at 10^{-4} M region while the same inhibition is attained by 10^{-2} M SDS. This implies that the electrostatic effect of **2C** is much superior to that of the SDS micelle.

Conclusion

The present study demonstrated that hexasulfonated calixarene can provide a very strong anionic environment which is effective to suppress the dediazoniation and the diazo coupling. The novel behaviors arise from the peculiar architecture of **2C** which has six anionic charges on the upper rim of the calixarene cavity. Further applications to host molecules, catalysts, etc. are now continued in this laboratory.

Asymmetric Radical Reaction in the Coordination Sphere. III.[1] Asymmetric Addition of Trichloromethanesulfonyl Chloride and Carbon Tetrachloride to Olefins Catalyzed by a Ruthenium(II) Complex with Chiral Ligand

Masayuki KAMEYAMA and Nobumasa KAMIGATA*
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158
(Received April 23, 1987)

The asymmetric addition of trichloromethanesulfonyl chloride to styrene in the presence of a catalytic amount of a ruthenium(II) complex with chiral ligands, Ru_2Cl_4[(−)-diop]$_3$ or Ru_2Cl_4[(+)-diop]$_3$, proceeds under mild conditions to give optically active 1 : 1 adducts, 1,1,1,3-tetrachloro-3-phenylpropane (**2**), with the extrusion of sulfur dioxide. When (−)-DIOP or (+)-DIOP was used as a chiral ligand of the ruthenium(II) complex, (*R*)-(+)-(**2**) or (*S*)-(−)-(**2**), was obtained with about 10% enantiomeric excess, respectively. A reaction mechanism involving a radical redox transfer mechanism was proposed; the asymmetric induction was attributed to the restricted configuration of the radical intermediates confined in the coordination sphere of the ruthenium complex with chiral ligands.

We recently reported that the addition reaction of arene- and alkanesulfonyl chlorides with olefins catalyzed by a dichlorotris(triphenylphosphine)ruthenium(II) under mild conditions affords 2-chlorosulfones in high yield.[2] On the other hand, the addition of trichloromethanesulfonyl chloride to olefins catalyzed by the ruthenium(II) complex affords 1 : 1 adducts, 1,1,1,3-tetrachloropropanes, with the extrusion of sulfur dioxide.[3] A reaction mechanism involving a radical redox transfer process is proposed. The intermediate radicals generated by interactions of sulfonyl chlorides with the ruthenium(II) complexes are considered to be confined in the coordination sphere of the metal complexes and to have different features from such a free radical as that initiated by irradiation or decomposition of peroxides.

We suppose that the relation between a free radical and the radical in the coordination sphere of the metal complex closely resembles the relation between a carbene and a carbenoid. Nozaki and Noyori first reported that an asymmetric addition of alkyl diazoacetate with olefins catalyzed by a copper complex with chiral ligand gave optically active cyclopropanes.[4] This reaction involves a carbenoid intermediate generated by an interaction of the diazoacetate with the metal complex. The carbenoid was affected by the chiral ligand and differentiated the enantioface of the olefin in the addition step. Thus, an asymmetric induction is expected in the reaction of sulfonyl chloride with olefin, which proceeds by a radical reaction in the coordination sphere. In a preliminary paper, we reported that arene- and alkanesulfonyl chlorides reacted with styrenes in the presence of a ruthenium(II) complex with chiral ligand, Ru_2Cl_4[(−)-diop]$_3$ ((−)-**1**) or Ru_2Cl_4[(+)-diop]$_3$ ((+)-**1**), as a catalyst to give optically active 1 : 1 adducts.[5] We report, herein, an asymmetric radical addition of trichloromethanesulfonyl chloride to olefins catalyzed by the ruthenium(II) complex with chiral ligand **1**.

Results and Discussion

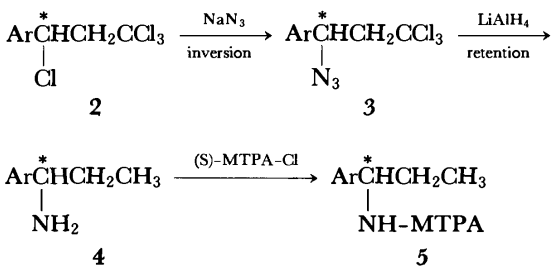
The reaction of trichloromethanesulfonyl chloride with olefin was carried out by using the ruthenium(II)-DIOP complex **1** as a catalyst. When Ru_2Cl_4-[(−)-diop]$_3$ ((−)-**1**) was used, the reaction of trichloromethanesulfonyl chloride with styrene at 100 °C for 6 h in a degassed tube gave 1 : 1 adduct (**2a**) quantitatively with extrusion of sulfur dioxide. The adduct showed a specific rotation $[\alpha]_D$ +12° (*c* 12, benzene). Similarly, the reaction of trichloromethanesulfonyl chloride with styrene in the presence of Ru_2Cl_4[(+)-diop]$_3$ ((+)-**1**) was carried out; adduct **2a** was obtained quantitatively and showed $[\alpha]_D$ −10° (*c* 11, benzene).

$$Cl_3CSO_2Cl + ArCH{=}CH_2 \xrightarrow[-SO_2]{Ru_2Cl_4(diop)_3\ (1)} Ar\overset{*}{C}HCH_2CCl_3 \quad (Cl)$$

2

The enantiomeric excess and absolute configuration of products **2** in the present reactions were estimated by converting to a known optically active compound. The adduct (−)-**2a**, which showed $[\alpha]_D$ −10° (*c* 11, benzene), was treated with sodium azide to give 3-azido-1,1,1-trichloro-3-phenylpropane (**3a**),[6] which was reduced with lithium aluminum hydride to afford 1-amino-1-phenylpropane (**4a**).[7] Amine **4a** showed $[\alpha]_D$ +2.1° (*c* 2.3, benzene) and was determined to be 10% enantiomeric excess and (R)-configuration. In a similar way, the adduct (+)-**2a** ($[\alpha]_D$ +12° (*c* 12, benzene)) was converted to amine **4a**, which showed $[\alpha]_D$ +3.1° (*c* 1.7, benzene) and corresponded to 14% ee of (S)-isomer.

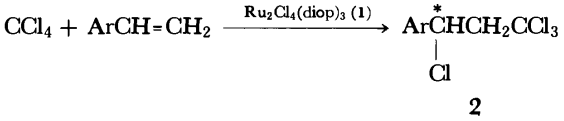
The optical yield of **2a** was also determined by a HPLC analysis of the diastereomer (**5a**) derived from the amine **4a**. Amine **4a** was treated with (*S*)-MTPA-Cl,[8] prepared by the reaction of (*S*)-MTPA (MTPA=2-methoxy-2-trifluoromethylphenylacetic acid) with thionyl chloride, to give the diastereomeric MTPA-



amide (**5a**). The diastereomer **5a** was separated into two isomer peaks by HPLC. Thus, the optical yield of adduct **2a** was estimated to be 14% ee. Similarly, the addition of trichloromethanesulfonyl chloride to several styrenes was carried out, and the optical purity of the products (**2b—d**) was also determined by HPLC analysis of the diastereomeric MTPA-amide. The results are summarized in Table 1.

The reaction products, 1,1,1,3-tetrachloro-3-arylpropanes, in the reaction of trichloromethanesulfonyl chloride with olefins corresponded to the adducts obtained by the addition of carbon tetrachloride to olefins. Matsumoto and Nagai have reported that a radical addition reaction of carbon tetrachloride with olefin catalyzed by the ruthenium(II) complex proceeds by a radical redox transfer mechanism and the intermediate radicals are considered to be confined in the coordination sphere of the ruthenium complex.[9] Thus, an asymmetric radical addition of carbon tetrachloride to olefins can also be expected by using the ruthenium(II) complex with chiral ligands as a catalyst.

When the ruthenium(II)-(−)-DIOP complex (−)-**1** was used as a catalyst, the addition reaction of carbon tetrachloride with styrene at 100 °C for 6 h gave 1 : 1 adduct (**2a**) in 73% yield.



Adduct **2a** showed a specific rotation $[\alpha]_D$ +12° (*c* 6.1, benzene). Similarly, when (+)-**1** was used as a catalyst, adduct **2a** was obtained in 68% yield and showed $[\alpha]_D$ −10° (*c* 5.3, benzene). The optical yields and absolute configurations of products **2** were determined by comparing the optical rotation of **4**, which was derived

Table 1. Reaction of Trichloromethanesulfonyl Chloride with Styrene Derivatives

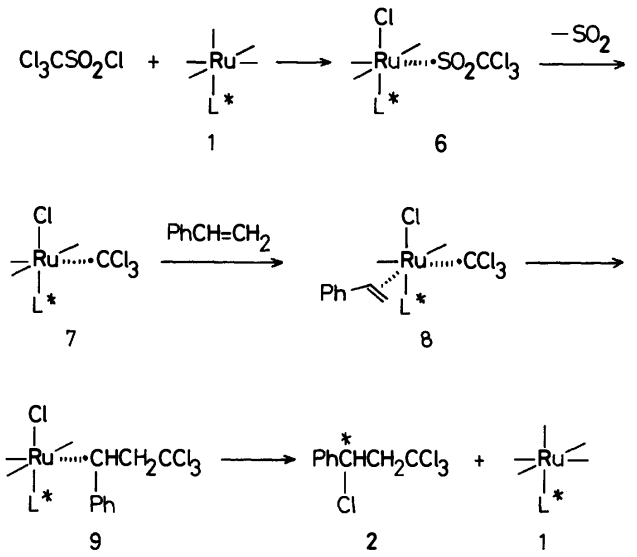
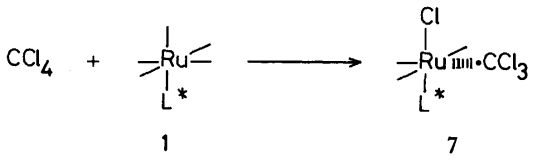
from **2**, with that of known optically active amine and by HPLC analysis of the MTPA-amides **5**. The reaction of carbon tetrachloride with various styrenes was carried out in a similar way and the results are summarized in Table 2.

There are a few reports in an asymmetric addition of polyhaloalkane to olefin. Boutevin and Dongala have reported the addition of carbon tetrachloride to an optically active olefin, menthyl acrylate, catalyzed by iron or copper salts.[10] Murai and Sonoda studied the asymmetric addition of bromotrichloromethane to styrene catalyzed by RhCl[(−)-diop].[11] They obtained optically active (*S*)-(−)-3-bromo-1,1,1-trichloro-3-phenylpropane with 32% ee when the rhodium-DIOP complex was employed as the catalyst. However, no mechanistic aspects are described.

The addition reaction catalyzed by the ruthenium(II) complex can be explained by the following mechanism involving a radical redox transfer process in the coordination sphere of the ruthenium(II) complexes (Scheme 1). In the case of the reaction of trichloromethanesulfonyl chloride, the ruthenium(II) catalyst **1** selectively activates a sulfur-chlorine bond of trichloromethanesulfonyl chloride, which is weaker than a carbon-chlorine bond, to give a trichloromethanesulfonyl radical confined to the coordination sphere of the ruthenium(III) species (**6**). The intermediate **6** readily loses sulfur dioxide to give a trichloromethyl radical confined to the ruthenium(III) species (**7**). Then, the intermediate **7** forms a π-complex (**8**) with styrene and the coordinated styrene reacts with the confined carbon radical to give 3,3,3-trichloro-1-phenylpropyl radical confined to the ruthenium(III) species (**9**). The carbon radical in **9** abstracts the chlorine atom from the ruthenium(III) species containing chiral ligands to give the adduct **3** and regenerate the ruthenium(II) catalyst **1**. It also may be probable that



Scheme 1.



Scheme 2.

7 directly reacts with styrene to give **9** without forming the intermediate **8**. As shown in Scheme **1**, the trichloromethanesulfonyl, trichloromethyl, and 3,3,3-trichloro-1-phenylpropyl radical are considered to be confined in the coordination sphere of the ruthenium complexes containing chiral ligands. An enantioface differentiation may be occurred in the last step in Scheme **1**, abstracting the chlorine atom from the ruthenium(III) species **9** with chiral ligand by the carbon radical. The asymmetric addition in the reaction of carbon tetrachloride with olefin will be similar to that of the reaction of trichloromethanesulfonyl chloride with olefin. Carbon tetrachloride reacts with the ruthenium(II) complex **1** to give the intermediate **7**, (Scheme 2) which reacts with styrene and to afford optically active **2** in a similar way as shown in Scheme **1**.

In conclusion, asymmetric induction was definitely observed in the addition of sulfonyl chloride or carbon tetrachloride to olefin catalyzed by the ruthenium(II) complex containing chiral ligand such as (−)-DIOP or (+)-DIOP. The results support our assumption that the radicals generated by interaction of the ruthenium(II) complexes are confined in the coordination sphere of the metal complexes. The radical in the coordination sphere should be called "RADICALOID" since a carbene-metal complex is called a carbenoid. The enantiomeric excess of the products obtained in the present reaction was not satisfied, while high enantioselective addition was achieved in the chiral copper carbenoid reaction and applied to the synthesis of industrially valuable chrysanthemic acid.[12] This suggests that the "RADICALOID" coordinates to the metal complex more loosely compared with that of carbenoid.

The present work has been supported by a Grant-in-Aid for Scientific Research No. 60470027 from the Ministry of Education, Science and Culture.

Experimental

Measurement. Melting points and boilng points were uncorrected. The infrared absorption spectra were determined on a Hitachi Model 260-10 spectrophotometer with samples as either neat liquids or KBr disks. The proton magnetic resonance spectra were recorded at 60 MHz by using a JNM-PMX 60 SI spectrometer with Me_4Si as an internal standard in $CDCl_3$. The optical rotations were measured with a JASCO DIP-140 polarimeter. The high-performance liquid chromatography system consisted of a

Hitachi 655 liquid chromatograph equipped with a Rhedyne 7125 sample injector. Elutions were monitored at 260 nm using a Hitachi 638-41 variable-wavelength UV monitor. The gel permeation chromatography was performed by using a JAI LC-08 liquid chromatograph with a JAIGEL-1H column (20ϕ×600 mm×2, chloroform as an eluent). Mass spectra were determined with a JEOL JMX-DX 300 mass spectrometer with JEOL JMA 5000 Mass Data System at an ionizing voltage of 20—70 eV.

Materials. The ruthenium(II) complexes such as Ru_2Cl_4-[(−)-diop]$_3$ ((−)-**1**) and Ru_2Cl_4[(+)-diop]$_3$ ((+)-**1**) were prepared by the methods described in the literature.[13] Trichloromethanesulfonyl chloride, carbon tetrachloride, styrene, *p*-methylstyrene, *p*-chlorostyrene (Tokyo Kasei Chemicals), and *m*-nitrostyrene (Aldrich Chemicals) were purified by distillation under nitrogen prior to use.

General Procedure for the Reaction of Trichloromethanesulfonyl Chloride with Olefins. A solution containing of 5.0 mmol of trichloromethanesulfonyl chloride, 7.5 mmol of olefin, 0.05 mmol of **1** in 10 cm^3 of benzene was degassed and heated in a sealed tube at 100 °C for 6—24 h. The reaction mixture was chromatographed on silica gel using benzene as an eluent. The products were identified by their infrared absorption spectra, proton magnetic resonance spectra, mass spectra, and high-resolution mass spectra. The physical and spectral data of the compounds (**2a**—d) are as follows.

(*R*)-(+)-1,1,1,3-Tetrachloro-3-phenylpropane (2a): Bp 85—88 °C/0.3 mmHg† (Kugelrohr); IR (neat) 1490, 1450, 1420, 1200, and 970 cm^{-1}; ^{1}H NMR (CCl_4) δ=3.49 (2H, d, J=6.0 Hz), 5.17 (1H, t, J=6.0 Hz), and 7.25 (5H, s); MS m/z 256 (M$^+$); HRMS m/z 255.9428 ($C_9H_8Cl_4$ requires 255.9380).

A solution containing 5.0 mmol of carbon tetrachloride, 20.0 mmol of olefin, 0.05 mmol of **1** in 10 cm^3 of benzene was degassed and heated in a sealed tube at 100 °C for 6—24 h. The reaction mixture was chromatographed on silica gel using benzene as an eluent. The products were identified by comparing their boiling points, IR spectra, ^{1}H NMR spectra, mass spectra with that of the products **2** obtained by the reaction of trichloromethanesulfonyl chloride with olefins.

Preparation of 1-Amino-1-arylpropane (4). A solution of 1.4 g (5.4 mmol) of 1,1,1,3-tetrachloro-3-phenylpropane (**2a**) which showed $[\alpha]_D$ −10° (*c* 11, benzene) and 1.0 g (15 mmol) of sodium azide in 15 cm^3 of ethanol-water=4:1 (v/v) was heated at 70—75 °C for 5 d. After cooling, 50 cm^3 of water and 100 cm^3 of ether were added to the reaction mixture. The organic layer was extracted and dried over sodium sulfate. The solvent was removed to give 1.0 g of an oil which was found to contain a starting material **2a** by TLC analysis. Purification by gel permeation liquid chromatography using chloroform as an eluent gave 0.75 g (65%) of 3-azido-1,1,1-trichloro-3-phenylpropane (**3a**) as a yellow oil: IR (neat) 2100 cm^{-1}; ^{1}H NMR (CCl_4) δ=3.07—3.14 (2H, m), 4.90 (1H, t, J=6.0 Hz), 7.29 (5H, s); MS m/z 263 (M$^+$).

A solution of 0.69 g (2.6 mmol) of the azide **3a** in 60 cm^3 of dry dibutyl ether was added dropwise to a stirred suspension of 2.0 g (53 mmol) of lithium aluminum hydride in 40 cm^3 of dry dibutyl ether at room temperature. After the addition was completed, the mixture was heated at 100 °C for 24 h, then cooled in an ice bath, and treated with 2.0 cm^3 of 15% sodium hydroxide, and 6.0 cm^3 of water. After stirring for additional 30 min, the mixture was filtered, and the precipitate was washed with ether. The combined ethereal solution was washed with 15% hydrochloric acid, the acidic aqueous layer was made basic with 15% sodium hydroxide, and the aqueous layer was extracted with ether. The organic layer was dried over sodium sulfate and the solvent was removed to give 0.15 g (43%) of 1-amino-1-phenylpropane (**4a**): $[\alpha]_D$ +2.1° (*c* 2.3, benzene); IR (neat) 3300 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.84 (3H, t, J=6.0 Hz), 1.45—1.92 (4H, m), 3.64—3.86 (1H, m), and 7.22 (5H, s); MS m/z 134 (M$^+$−1).

Preparation of 2-Methoxy-2-trifluoromethylphenylacetic Acid (MTPA) Amides (5). The sample of optically active (*R*)-(+)-1-amino-1-phenylpropane **4a** (45 mg, 0.33 mmol) was added to a solution of 42 mg (0.17 mmol) of (*S*)-(−)-2-methoxy-2-trifluoromethylphenylacetyl chloride (MTPA-Cl), which was prepared by refluxing (*S*)-(−)-MTPA, excess thionyl chloride, and sodium chloride in 3 cm^3 of dichloromethane for 2 d and then removing the excess thionyl chloride in vacuo. The mixture was stirred at room temperature for 24 h. The amine hydrochloride precipitated was filtered off and the solvent was removed under reduced pressure to give 75 mg of the crude MTPA amide (**5a**) as a yellow oil: IR (neat) 3400, 3300, 2950, 1690, 1510, 1270, 1170, and

† 1 mmHg=133.322 Pa.

1110 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.73—1.05 (3H, m), 1.50—2.00 (2H, m), 3.29—3.40 (3H, m), 4.68—5.07 (10H, m); MS *m/z* 351 (M^++1).

Separation of the MTPA Amides (5). The HPLC separation of the MTPA amides **5** was performed with a Waters Radial PAK Cartridge Silica Column (8mm×10 cm, particle size 10 μm) using hexane–ethyl acetate=30 : 1 (v/v) as an eluent at a flow rate of 1.0 $cm^3\,min^{-1}$.

Anodic Cyanation of 1-Methylimidazoles

Kunihisa YOSHIDA* and Hirohito KITABAYASHI
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received April 30, 1987)

The electrooxidation of several 1-methylimidazoles was performed in MeOH that contains NaCN at a platinum anode in a divided cell. Replacement of an aromatic hydrogen by a cyano group occurred. With 1,2,4,5-tetramethylimidazole, the 2,5-addition of cyano groups to the imidazole ring was achieved, and besides side-chain substitution occurred concurrently.

It has been shown that an electrochemical technique makes possible the direct introduction of cyano groups either by substitution or addition into aromatic compounds.[1,2] This method is especially useful for five-membered heterocycles.[3]

The present paper describes synthetic application of the method to 1-methylimidazoles. The possible products α-amino nitriles are useful as the synthetic intermediates. Heretofore, in electrooxidation reactions, imidazoles were often used as nucleophiles rather than as substrates.[4,5]

Results

Controlled-Potential Electroreaction (CPE). The potentiostatic oxidations of 1-methylimidazoles were performed in a divided cell with a Pt anode at room temperature. The reference electrode was an SCE. The electroreaction medium was MeOH–0.4 M NaCN (1 M=1 mol dm^{-3}). After the theoretically calculated amount of charge had passed, the solvent was removed. The residue was triturated with chloroform, filtered, concentrated, and analyzed by GLC. The products reported in Table 1 were isolated by preparative GLC. They were identified by the elemental and ^{1}H NMR, IR, and mass spectroscopic analyses and by comparison with the authentic samples prepared by other routes. Current efficiencies (CEs) are based on the total charge passed; the formation of 1 mol of each product is assumed to require 2 F.

The replacement of an aromatic hydrogen by a cyano group occurred at a position lacking the substituent on the imidazole ring. MI gives all three possible ring-substitution products, 5-, 2-, and 4-cyano isomers in an approximate ratio of 5 : 2 : 1. A similar product distribution has been reported for the electroreaction in aqueous cyanide (presumably as a potassium salt, experimental details including melting points of some products were not furnished).[6] The reaction point in the present anodic reaction is of particular interest because conventional electrophilic substitution by a cyano group occurs exclusively at the 2 position.[7]

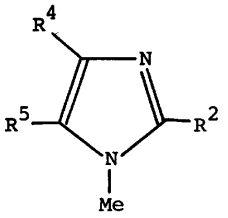
For TEMI obstructed all of the replaceable positions by the methyl substituents, the 2,5-addition of cyano groups across the diene system of an imidazole was achieved, and besides side-chain substitution occurred concurrently at the substituent methyl group in the 5 position. The transformation of the adduct **2** to the side-chain-cyanation product **1h** during GLC analysis was not observed. For the 2,5-dicyano adduct of 1,2,5-trimethylpyrrole, such a rearrangement of a cyano group has been reported.[8]

The CE for the formation of these carbonitriles

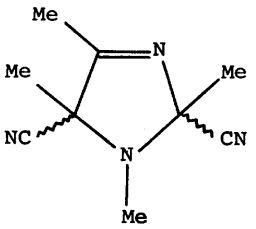
Table 1. Anodic Cyanation of 1-Methylimidazoles. Voltammetric Data and Products

Reactant	E_p[a] / V	PCPE[b] / V	n[c] / F mol^{-1}	Product	CE[d] / %
1-Methylimidazole (MI)	≈1.75	1.80	2.7	1-Methyl-2-imidazolecarbonitrile (**1a**)	17
				1-Methyl-4-imidazolecarbonitrile (**1b**)	8
				1-Methyl-5-imidazolecarbonitrile (**1c**)	42
1,2-Dimethylimidazole (1,2-DIMI)	1.54	1.54	2.1	1,2-Dimethyl-4-imidazolecarbonitrile (**1d**)	7.5
				1,2-Dimethyl-5-imidazolecarbonitrile (**1e**)	79
1,5-Dimethylimidazole (1,5-DIMI)	1.47	1.47	2.1	1,5-Dimethyl-2-imidazolecarbonitrile (**1f**)	32
				1,5-Dimethyl-4-imidazolecarbonitrile (**1g**)	36
1,2,4,5-Tetramethylimidazole (TEMI)	1.12	1.10	2.1	2,5-Dihydro-1,2,4,5-tetramethyl-2,5-imidazoledicarbonitrile (**2**)	13
				1,2,4-Trimethylimidazole-5-acetonitrile (**1h**)	11

a) Peak potential for cyclic voltammetry; Pt anode, MeOH, 0.4 M NaCN, SCE. Scan rate is 0.1 V s^{-1}. Substrate concentration is 2×10^{-2} M. All voltammograms showed no cathodic peak corresponding to reversible reduction of an initially formed cation radical. b) Potential for controlled-potential electroreaction. c) Controlled-potential coulometry. d) Current efficiency (based on **2e** process). This value corresponds to the yield based on imidazole used since the reaction was terminated at the stage when 2 F mol^{-1} of electricity was passed.



1a, R^2=CN; R^4=R^5=H
b, R^2=R^5=H; R^4=CN
c, R^2=R^4=H; R^5=CN
d, R^2=Me; R^4=CN; R^5=H
e, R^2=Me; R^4=H; R^5=CN
f, R^2=CN; R^4=H; R^5=Me
g, R^2=H; R^4=CN; R^5=Me
h, R^2=R^4=Me; R^5=CH_2CN



2

increases with decreasing amounts of passed electricity. It would be ascribable to that, the oxidation of the background solvent-electrolyte system becomes conspicuous with decreasing concentration of the electroactive substrate.

The GLC retention time of 4-carbonitriles is remarkably long compared with that of the other positional isomers (e.g., t_R=14, 14, and 98 min for **1a**, **1c**, and **1b**, respectively; PEG 6000 column, 190 °C).

The intensity of C≡N stretching vibration in IR spectra varied with structure. Ring substitution products have a strong band in the region of the C=N stretching vibration, whilst the intensity of the nitrile absorption band in 2,5-addition or side-chain-substitution product is weaker.

Preparative-Scale Electroreaction. The larger preparative electroreactions were conducted at constant current of 0.05 A. After usual workup, the products were separated by column chromatography. The CEs for constant-current electroreaction were lower than those for CPE. There was some difference in product ratios using the different reaction conditions. At the nonpotentiostatic conditions, a portion of the primary product would be consumed by further oxidations.

Experimental

General. Spectrometers and electrochemical equipment have been described previously.[9]

Materials. MeOH and reagent grade NaCN were used without purification.

MI and 1,2-DIMI were obtained commercially and were purified by distillation. TEMI was also a commercial sample and was purified by column chromatography on silica gel using pentane–chloroform (1:2) as an eluent and by recrystallization; mp 58.0—61.0 °C (from petroleum ether, lit,[10] mp 51—54 °C).

1,5-DIMI was prepared by the hydrazine reduction of 1-methyl-5-imidazolecarbaldehyde according to the method of Martin, et al.[11] The desired aldehyde was obtained by oxidation of the corresponding alcohol with activated manganese dioxide in benzene according to the method of Loozen, et al.[12] The procedures of Jones and McLaughlin were followed for the preparation of 1-methyl-5-(hydroxymethyl)-imidazole.[13-15]

^{1}H NMR ($CDCl_3$): MI, δ=3.66 (3H, s), 6.84 (1H, m), 7.00 (1H, m), 7.38 (1H, br s); 1,2-DIMI, δ=2.37 (3H, s), 3.56 (3H, s), 6.78 (1H, d, J=1.2), 6.86 (1H, d, J=1.2); 1,5-DIMI, δ=2.17 (3H, d, J=1.0), 3.50 (3H, s), 6.72 (1H, br s), 7.32 (1H, s); TEMI, δ=2.07 (3H, s), 2.09 (3H, s), 2.30 (3H, s), 3.35 (3H, s).

The following reference materials were obtained by dehydration of the oximes with acetic anhydride according to the procedure of Anderson,[16] which describes the preparation of 2-pyrrolecarbonitrile from the corresponding oxime: **1a—c** and **1e**. Their precursors aldehydes were prepared according to the literature. 1-Methyl-2-imidazolecarbaldehyde[12] was obtained from oxidation of the corresponding alcohol[17,18] with active manganese dioxide. 1-Methyl-4-imidazolecarbaldehyde was prepared by an eight-step method of Martin, et al.[11] The desired α-acetamidoacrylic acid was obtained according to the literature.[19,20] The preparation of 1-methyl-5-imidazolecarbaldehyde was described above. 1,2-Dimethyl-5-imidazolecarbaldehyde was made by the literature procedure.[12,21]

Cyclic Voltammetry. Voltammograms were recorded for each compound as described previously.[9] The E_p value are in Table 1.

CPE. The cell and general procedure have been described.[9] Oxidations in MeOH, 0.4 M NaCN were performed at controlled potentials as indicated in Table 1. The reactions were usually terminated after passage of ≈2 F mol^{-1} of added imidazole. The workup procedure consisted of evaporation of much of the MeOH (*caution*: HCN), addition of chloroform, and filtration of NaCN. The chloroform extract was concentrated and analyzed by GLC using a PEG 6000 column. Each isomeric product was separated in pure form by preparative GLC.[22] They were identified by the elemental and ^{1}H NMR, IR, and mass spectroscopic analyses (Table 2).

Preparative-Scale Electroreaction of MI. The electroreaction was carried out in a two-compartment H-type cell with glass frit separating the compartments fitted with Pt foil electrodes (2×2 cm). The anolyte was made up of 3.3 g (0.04 mol) of MI, 2.5 g (0.05 mol) of NaCN, and 50 ml of MeOH. The catholyte was the same medium in the absence of the substrate. The anode and cathode compartments were kept under a nitrogen atmosphere and the anolyte was stirred magnetically. The reaction was performed at 0.05 A of constant current by using a direct-current power supply at room temperature until ≈2 F mol^{-1} of added imidazole had passed through the electrolyte, which generally took 24 h.

After completion of the oxidation, the solvent was removed under aspirator vacuum. The residue was triturated with chloroform, filtered, concentrated,[25] and chromatographed on silica-gel column using chloroform as the eluant. The elution of products was followed by IR spec-

troscopy. The first product to elute was **1a**, the second **1c**, followed by unreacted substrate and successive elution of **1b**. Separation of the isomers was accomplished without loss.

Preparative-Scale Electroreaction of TEMI. The method of oxidation, workup, and product isolation was identical to that described for MI. 2,5-Dihydro-1,2,4,5-tetramethyl-2,5-imidazoledicarbonitrile (**2**; 0.35 g, 5% CE) was isolated as the first fraction by column chromatography, followed by unidentified substances. 1,2,4-Trimethylimidazole-5-acetonitrile (**1h**) as well as the adduct **2** could be separated from the reaction mixture by preparative GLC using a PEG 6000 column at 190 °C.

Asymmetric Allylation with a New Chiral Allylating Agent Prepared from Tin(II) Triflate, Chiral Diamine, and Allylaluminum

Nobuto MINOWA and Teruaki MUKAIYAMA
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received May 2, 1987)

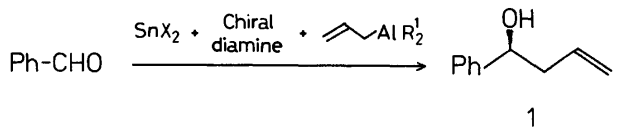
A chiral allylating agent, readily generated from tin(II) trifluoromethanesulfonate (tin(II) triflate), chiral diamines derived from (S)-proline and allylaluminum, is efficiently employed in the asymmetric allylation of aldehydes and an epoxide. Reaction of a chiral 2-methyl-2-propenylating (methallylating) agent with aldehydes also proceeds smoothly to afford the corresponding homoallylic alcohols in good yields with high enantioselectivities. According to a similar procedure, asymmetric propargylation of aldehydes affords homopropargylic alcohols in good optical purities.

Asymmetric synthesis is one of the most important approaches for producing optically active substances and recently a wide variety of methods have been reported by many research groups.[1] Asymmetric synthesis may be divided into two distinct sections; those processes in which, (i) the chiral auxiliary is incorporated into either (or both) reacting partners (ii) the chiral auxiliary is not covalently bonded to either of the reactants. Incorporation of a chiral source into either (or both) of the reactants has met with great success and many examples have been reported.[1] However, incorporation of the chiral auxiliary into reactants and the subsequent necessary removal of it from the reaction products is a disadvantage of this method.

The latter of these two approaches should be a very convenient method for asymmetric synthesis and seems to warrant concentrated investigation, however, so far it has not met with much success.[1] Utilization of metal chelates for inter- or intramolecular interactions seems to be one of the solutions leading to successful asymmetric synthesis of this type, in which the chiral auxiliary is not covalently bonded to the reactants. During the course of our synthetic investigation, we found that utilization of the chelation of chiral diamines derived from (*S*)-proline to tin(II) enolate enables a highly efficient asymmetric cross aldol reaction.[2] Thus, divalent tin, having vacant d orbitals, is able to accept a bidentate ligand, and chiral diamines are efficient ligands in certain asymmetric reactions by virtue of forming a rigid five-five membered fused ring chelate in the transition state. In an extension of this concept, we have reported a convenient and efficient asymmetric acylation[3] and asymmetric reduction[4] using a new chiral reducing agent prepared from tin(II) chloride, chiral diamine derived from (*S*)-proline and diisobutylaluminum hydride as the reductant. It was considered that this new method for asymmetric reduction should be applicable to asymmetric carbon-carbon bond forming reactions and hence we examined asymmetric allylation of carbonyl compounds utilizing tin(II) compound, chiral diamine and allylating reagent. The asymmetric allylation reaction is useful for asymmetric carbon-carbon bond formation,[5] and several successful methods have been reported using chiral allylic organometallics as the allylating agent[6] or , using chiral acetals as chiral acceptors.[7] However, in these reactions tedious procedures for the attachment and removal of the chiral sources are necessary. Hence a simple procedure for the asymmetric allylation utilizing chiral chelating agents is desirable. We investigated the effective combination of tin(II) compound, chiral diamine and allylating reagent, and found that a new chiral allylating agent prepared by the treatment of tin(II) triflate, chiral diamine derived from (*S*)-proline and allyldialkylaluminum as the allylating reagent is efficient for asymmetric allylation of aldehydes, as we have briefly reported in a preliminary communication.[8] We now describe in full the results of our investigation on asymmetric allylation with this new reagent and the application of the present method to asymmetric methallylation and propargylation.

Results and Discussion

Asymmetric Allylation of Aldehydes with Chiral Allylating Agent. Allyldialkylaluminum is easily prepared by treatment of allylmagnesium bromide with dialkylaluminum chloride at 0 °C in Et_2O,[9] followed by exchange of solvent from Et_2O to CH_2Cl_2. This solution of allyldialkylaluminum in CH_2Cl_2 was employed in the reactions described below. In the first place, we examined suitable reaction conditions using benzaldehyde as a model substrate, and these results are summarized in Table 1.



1

The reactions were carried out as follows: To a suspension of tin(II) compound in CH_2Cl_2 was added chiral diamine in CH_2Cl_2 at room temperature. After the solution was cooled to −78 °C, allyldialkylaluminum was added, followed by the addition of benzalde-

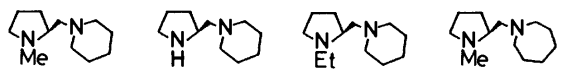
a) The mixture of tin(II) compound, divalent tin, chiral diamine, and allylaluminum was run for 30 min at −78 °C, before benzaldehyde was added. (Entries 9—20). All reactions were carried out at −78 °C for 1 h. b) Tin(II) compound-chiral diamine-allylalminum-benzaldehyde A=1.0 : 1.0 : 1.0 : 0.7, B=1.3 : 1.3 : 1.0 : 0.7 C=2.0 : 2.0 : 1.0 : 0.7, D=1.6 : 1.6 : 1.0 : 0.7, E=1.1 : 1.1 : 1.0 : 0.7, F=0.8 : 0.8 : 1.0 : 0.7. c) Isolated yield. Yields are based on benzaldehyde. All the products have S-configuration. d) Based on $[\alpha]_D^{18}$ −48.7° (*c* 6.92, PhH) for (*S*)-1-phenyl-3-buten-1-ol.[6c)] e) Determined by ^{19}F NMR measurement of the ester from (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride.

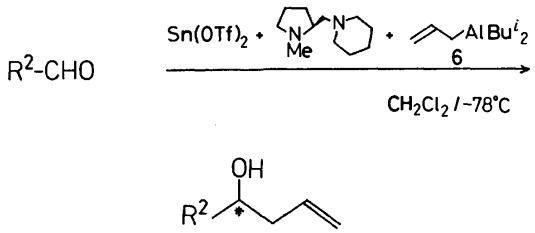


2 3 4 5

hyde at the same temperature, and the reaction mixture was stirred for an additional hour at −78 °C. Usual workup of the reaction mixture afforded 1-phenyl-3-buten-1-ol (**1**). The substituents of the tin(II) compound influenced remarkably the optical purity of the homoallylic alcohol **1** produced by the present allylation reaction (Entries 2—6). When tin(II) chloride or bromide was used, the enantioselectivity of the reaction was low, however, introduction of electron-withdrawing group such as trifluoromethanesulfonate as substituents of the tin(II) species increased the enantioselectivity of the reaction. Thus, when tin(II) triflate was used, good optical purities were attained, while the optical purity of the product dramatically decreased on use of tin(II) methanesulfonate instead of tin(II) triflate (Entries 20). It is assumed that as tin(II) triflate has electron-withdrawing group such as trifluoromethanesulfonate as substituents, that the tin(II) compound can strongly bind to the chiral diamine leading to effective enhancement of the enantioselectivity of the reaction.

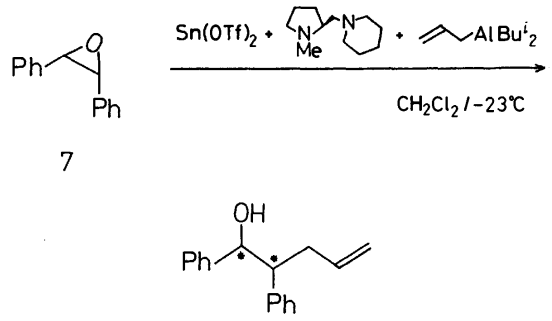
In order to find the most suitable solvent for the present allylation reaction, the influence of various solvents on the reaction was examined (Entries 6—8). These results indicate that CH_2Cl_2 is the preferred solvent and that using THF, a highly coordinating solvent, led to a sharp decrease in the optical purity of the product. This implies that the chelate structure existing in the transition state plays an important role in the enantioselectivity. It was also found that reverse addition of the reactants also affects the optical purity. That is, when allyldiethylaluminum was added to the mixture of tin(II) triflate, chiral diamine and benzaldehyde at −78 °C, the optical purity decreased dramatically from 42 to 6% ee. In addition, when benzaldehyde was added at −78 °C, after the mixture of tin(II) triflate, chiral diamine and allyldiethylaluminum was run for 30 min at −78 °C, optical purity increased from 42 to 52% ee. (Entry 9) Judging from these results, initial formation of the complex, chiral allylating agent, prepared from tin(II) triflate, chiral diamine and allylaluminum seems to be important for this asymmetric allylation. The effect of the *N*-substituents in the ligand diamines on the enantioselectivity in the present allylation reaction was also examined by using *N*-substituted diamines (Entries 10—13). Relatively high enantioselectivity was achieved when (*S*)-1-methyl-2-[(1-piperidinyl)methyl]pyrrolidine (**2**) was used as the ligand diamine. It was also found that the substituents of the allylaluminum had a

significant effect on the enantioselectivity of the product (Entries 13—15). When allyldiisobutylaluminum (**6**) having bulky substituents was employed as the allylaluminum, the enantioselectivity of the reaction increased from 61 to 84% ee. In contrast, the molar ratio of each reactant did not have any remarkable effect on the enantioselectivity of the reaction, however, the enantioselectivity of the reaction decreased from 80 to 67% ee, when the molar ratio of tin(II) triflate and diamine decreased from 1.1 to 0.8 (Entries 15—19). These results indicate that this chiral allylating agent consists of a 1 : 1 : 1 complex of tin(II) triflate, diamine and allylaluminum. Finally, the use of other allylic organometallics instead of allylaluminum was studied. When trisallyl borane,[10] allyllithium,[11] allylmagnesium bromide and allyltriphenyltin was used, asymmetric induction could not be observed indicating that the aluminum atom of allyla luminum plays an important role in the present reaction.



Having optimized the reaction conditions, the reaction with various aldehydes was examined and these results are summarized in Table 2. The allylation with other aldehydes proceeded smoothly to afford the corresponding homoallylic alcohols in high yield in any case. In the cases of aromatic aldehydes, fairly good optical purities were achieved. Electron-withdrawing groups or electron-donating groups in the aryl substituent did not have any remarkable effect either on the synthetic or on the optical yield. On the other hand, in the case of aliphatic aldehydes, satisfactory results could not be obtained, however, relatively good optical purities were attained when α,β-unsaturated aldehydes were employed.

Asymmetric Allylation of Epoxide with Chiral Allylating Agent. Highly selective transformations of enantiotopic groups in prochiral or meso compounds are well-known in enzymatic processes,[12] however, only a few enantioselective chemical approaches have been reported.[13] In order to study the asymmetric carbon-carbon bond forming reaction to meso compound, we examined the asymmetric reaction of the chiral allylating agent with a meso *cis*-epoxide. The allylation was carried out using *cis*-stilbene oxide (**7**) as a *cis*-epoxide. The research mixture of tin(II) triflate and chiral diamine **2** was cooled to 0 °C, and



allylaluminum **6** and *cis*-stilbene oxide (**7**) were added successivly at 0 °C. The mixture was stirred for 1 h at

Table 2. Asymmetric Allylation of Aldehydes with Chiral Allylating Agent[a]

Entry No.	Aldehyde	Yield[b] %	$[\alpha]_D$ (c, solvent)	% ee (Configuration)

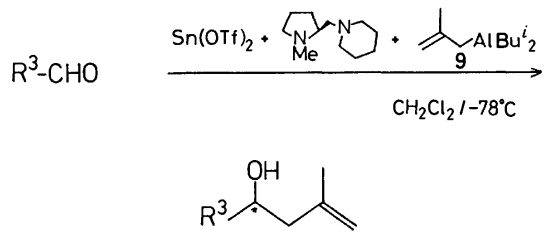
10	Nonanal	86	$[\alpha]_D^{23}$+5.22° (3.12, PhH)	40[c]

a) All reactions were carried out as described in Entry 15 in Table 1. b) Isolated yield. Yields are based on carbonyl compounds. c) The % ee was determined by ^{19}F NMR measurement of the ester from (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride. d) Optically pure (*S*)-1-phenyl-3-buten-1-ol gives $[\alpha]_D^{18}$—48.7° (*c* 6.92, PhH).[6c] e) Determined by ^{19}F NMR measurement of the ester from (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride in the presence of $Eu(fod)_3$. f) Optically active (*S*)-1-phenyl-1,5-hexadien-3-ol gives $[\alpha]_D^{20}$+3.60° (*c* 10.08, Et_2O).[6c] g) Optically active (*R*)-1-phenyl-5-hexen-3-ol gives $[\alpha]_D^{20}$+16.9° (*c* 1, $CHCl_3$).[6c]

the same temperature to gave 1,2-diphenyl-4-penten-1-ol (**8**) in 69% yield with optical purity of 40% based on NMR analysis of the corresponding MTPA ester. Examination of effect of temperature shows that lowering the temperature from 0 to −23 °C increased the enantioselectivity of the reaction from 40 to 50% ee. However, at the temperature lower than −23 °C, the reaction did not produce the corresponding bis homoallylic alcohol. Although the enantioselective deprotonation[13b,d] and ring-opening with thiols[13i] of a meso epoxide have been accomplished, the present result is, to our knowledge, the first example of an enantioselective allylation of a meso epoxide.

Asymmetric Methallylation of Aldehyde with Chiral Methallylating Agent. Next, we examined the asymmetric methallylation reaction with aldehyde based on the above mentioned consideration: Diisobutyl(2-methyl-2-propenyl)aluminum (diisobutylmethallylaluminum) (**9**) is readily prepared by treatment of diisobutylaluminum chloride with methallyl magnesium chloride at 0 °C in Et_2O, followed by exchange of solvent to CH_2Cl_2 in a similar procedure to that for allylaluminum. This solution of methallylaluminum **9** in CH_2Cl_2 was used for the reactions with aldehyde. The



reactions were carried out according to a procedure similar to the previous asymmetric allylation and the results are summarized in Table 3. The reaction of aldehyde with chiral methallylating agent affords the corresponding methallylated product in good yields with high optical purities. The absolute configuration of the product which was obtained by the reaction with benzaldehyde was S-configuration as that of allylation. In the case of both aromatic and aliphatic aldehydes, relatively high optical purities were attained compared with those observed in the asymmetric allylation. Interestingly, in the case of nonanal, the enantioselectivity of the reaction increased from 40 to 73% ee.

Asymmetric Propargylation of Aldehyde with Chiral Propargylating Agent. Asymmetric propargylation is as useful as asymmetric allylation for asymmetric carbon-carbon bond forming reaction. The successful asymmetric propargylation of aldehydes with chiral allenylboronic ester has been reported by Yamamoto.[14] In this reaction, the chiral auxiliary is incorporated into the propargylating reagent. In order to explore the scope of the asymmetric carbon-carbon bond formation utilizing a chiral chelating agent, the asymmetric propargylation with aldehydes was studied. Asymmetric propargylation could be achieved by use of propargylaluminum instead of allylaluminum. The propargylaluminum derivative **10** was prepared as follows: To a solution of diisobutylaluminum chloride in hexane was added the Grignard reagent prepared from propargyl bromide and magnesium in Et_2O at 0 °C and the solvent was changed to CH_2Cl_2. In the first place, the reaction of benzaldehyde with the above solution of **10** afforded the desired homopropargylic alcohol and none of the allenic alcohol was obtained. The same results are reported by Eiter in the reaction of propargylaluminum derivative, derived from aluminum amalgam and propargyl bromide, with carbonyl compounds.[15] It is recognized that the propargylic organometallics are in equilibrium with allenic organometallic and that propargylic alcohols are obtained by the reaction of allenic organometallics with carbonyl compounds via a allylic rearrangement of the allenic organometallics.[16] These results indicate that allenic structure predominates in the above solution of propargylaluminum derivative. The reaction of the propargylating agent, prepared from **10**, tin(II) triflate, and chiral diamine, with aldehyde were carried out according to a procedure similar to that for the asymmetric allylation. We examined the effect of the *N*-substituents in the ligand diamines on the enantioselectivity by using some *N*-substituted diamines. When chiral diamine **2** was used, relatively high enantioselectivity was attained. The reaction with benzaldehyde under these condi-

Table 3. Asymmetric Methallylation of Aldehydes with Chiral Methyllylating Agent

Entry No.	Aldehyde	Yield[a] %	$[\alpha]_D$ (c, solvent)	% ee[b]
1	Benzaldehyde	80	$[\alpha]_D^{21}$−46.6° (1.97, PhH)	87[c]

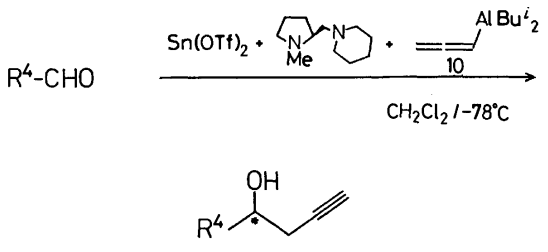
a) Isolated yield. Yields are based on aldehydes. b) The % ee was determined by ^{19}F NMR measurement of the ester from (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride. c) S-Configuration. Based on Ref. 6a.



tions affords (*S*)-1-phenyl-3-butyn-1-ol in 60% ee. The reaction with other aldehydes also affords the corresponding homopropargylic alcohols in good yield with good optical purity as shown in Table 4. Interestingly, none of the allenic alcohols were obtained in any case as same as the reaction of **10** with aldehyde.

A highly enantioselective allylation of aldehydes has been accomplished by this new chiral allylating agent. The precise mechanism of the present allylation reaction that enables high enantioselectivity is not clear, however, the high enantioselectivity in the present reaction is assumed to be dependent on the following factors: The chiral allylating agent is generated from a 1 : 1 : 1 complex of chiral diamine **2**, tin(II) triflate and allylaluminum **6**. In this complex, **2** is coordinated to the tin(II) metal center, and in addition one of the oxygen atoms of tin(II) triflate is coordinated to the aluminum of **6** as shown in Fig. 1. Tin(II) triflate, **2** and **6** can form a rigid complex, because tin(II) triflate can strongly bind to the chiral diamine and aluminum has a strong affinity for oxygen. Thus, the chiral diamine **2** as chiral auxiliary and allylaluminum **6** as allylating reagent are brought into proximity by the chelation with tin(II) triflate. As a result, the direction of approach of the aldehyde to this complex is limited by the chiral diamine **2** and the isobutyl group, bulky substituents of the allylaluminum **6** in this complex

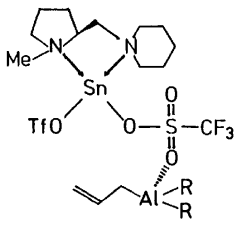


Fig. 1.

leading to high optical purities. In the case of the asymmetric methallylation, relatively high optical purities were attained compared with those of the asymmetric allylation. In this case, the direction of approach of the aldehyde to the complex is extremely restricted by **2** and the isobutyl and methallyl group of **9** leading to relatively high optical purities.

It is noted that treatment of tin(II) triflate, chiral diamine, and allylaluminum generates a new chiral allylating agent. This chiral agent is efficient for the enantioselective synthesis of homoallylic alcohols with satisfactory chemical and optical yields. The present procedure is the first example of the asymmetric allylation reaction with high optical purity induced by the chelation of a chiral auxiliary to active intermediate species. Furthermore, this newly introduced method is applicable to asymmetric methallylation and propargylation.

Experimental

IR spectra were recorded on a Hitachi 260-30 spectrometer. ^{1}H NMR spectra were recorded on a Hitachi R-24B (60 MHz) using TMS as an internal standard. ^{19}F NMR spectra were recorded on a Varian EM-390 (90 MHz) using hexafluorobenzene as an internal standard. Optical rotations were recorded on a JASCO DIP-181 automatic polarimeter using 1-dm thermostated microcell.

All reactions were carried out under an atmosphere of argon. CH_2Cl_2 was distilled successively from P_2O_5 and calcium hydride. Et_2O was freshly distilled from sodium metal using benzophenone ketyl as indicator. The (*R*)-3,3,3-trifluoro-2-methoxy-2-phenylpropionates (MTPA esters) were prepared according to Mosher's procedure[17] using the acid chloride derived from (*R*)-(+)-MTPA supplied from Aldrich (99+%).

Optical purity was determined by ^{19}F NMR of the MTPA esters of the alcohols or ^{19}F NMR of the MTPA esters in the presence of Eu(fod)$_3$.

Tin(II) Trifluoromethanesulfonate (Tin(II) Triflate). Tin(II) triflate was prepared from $SnCl_2$ and trifluoromethanesulfonic acid according to a procedure similar to that of Ref. 2. All handling of tin(II) triflate was carried out under argon atmosphere.

Preparation of Chiral Diamine. Chiral diamines were prepared from (*S*)-proline by a procedure similar to that of Ref **2**.

(*S*)-1-Methyl-2-[(1-piperidinyl)methyl]pyrrolidine: bp 116—

Table 4. Asymmetric Propargylation of Aldehydes with Chiral Propargylating Agent

a) Isolated yield. Yields are based on aldehyde. b) The % ee was determined by ^{19}F NMR measurement of the ester from (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride. c) S-Configuration. Based on Ref. 14.

118 °C/20 mmHg (1 mmHg=133.322 Pa); IR (neat) 2935, 2770, 1450 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.28—1.88 (m, 10H), 1.88—2.50 (m, 8H), 2.4 (s, 3H), 2.92—3.15 (m, 1H); $[\alpha]_D^{21}$ −66.9° (*c* 0.32, EtOH).

Preparation of Allyldiisobutylaluminum. To a solution of diisobutylaluminum chloride (6.25 mmol) in 10 ml of hexane was added dropwise allylmagnesium bromide (6.25 mmol) in 10 ml of Et_2O at 0 °C under argon atmosphere. After warming to room temperature, the reaction mixture was stirred for 3 h at this temperature and evaporated. A minimum amount of CH_2Cl_2 was added to the residue and the mixture was evaporated in vacuo. The same operation was repeated again and finally 25.0 ml of CH_2Cl_2 was added. The resulting suspension was decanted and the supernatant used for the reaction.

Methallyldiisobutylaluminum was prepared from methallylmagnesium chloride and diisobutylaluminum chloride by an analogous procedure. Propargyldiisobutylaluminum derivative was prepared from propargylmagnesium bromide and diisobutylaluminum chloride by an analogous procedure.

Asymmetric Allylation of Aldehydes with Chiral Allylating Agent (Table 2). A typical reaction procedure is described for the reaction of benzaldehyde using (*S*)-1-methyl-2-[(1-piperidinyl)methyl]pyrrolidine (Entry 1); to a suspension of tin(II) triflate (224 mg, 0.54 mmol) and (*S*)-1-methyl-2-[(1-piperidinyl)methyl]pyrrolidine (97.9 mg, 0.54 mmol) in 4 ml of CH_2Cl_2 was added dropwise allyldiisobutylaluminum (2.1 ml of a stock solution in CH_2Cl_2, 0.42 mmol) at −78 °C under argon atmosphere. After the yellow solution was stirred for 30 min, benzaldehyde (29.5 mg, 0.28 mmol) in 2 ml of CH_2Cl_2 was added dropwise at −78 °C. The resulting mixture was stirred for 1 h at the same temperature, then quenched with sat. NH_4Cl aq and 1M HCl (1M=1 mol dm^{-3}). The organic layer was extracted with CH_2Cl_2 and dried over anhydrous Na_2SO_4. After concentration in vacuo the resulted oily substance was purified by preparative TLC (hexane-Et_2O=8:3) to yield 1-phenyl-3-buten-1-ol (37.2 mg, 91%). IR (neat) 3400, 1640, 1490, 1450 cm^{-1} ^1H NMR (CCl_4) δ=2.02 (s, 1H), 2.28 (t, *J*=6.6 Hz, 2H), 4.45 (t, *J*=6.6 Hz, 1H), 4.70—6.00 (m, 3H), 7.16 (s, 5H).

1-Dodecen-4-ol (Entry 10). IR (neat) 3350, 2920, 2850, 1640, 1460 cm^{-1}; ^1H NMR (CCl_4) δ=0.88 (t, *J*=5.0 Hz, 3H), 1.30 (br s, 15H), 1.95—2.30 (m, 2H), 3.25—3.70 (m, 1H), 4.80—6.10 (m, 3H).

Asymmetric Allylation of *cis*-Stilbene Oxide with Chiral Allylating Agent. To a suspension of tin(II) triflate (202 mg, 0.49 mmol) and (*S*)-1-methyl-2-[(1-piperidinyl)methyl]-pyrrolidine (88.5 mg, 0.49 mmol) in 4 ml of CH_2Cl_2 was added dropwise allyldiisobutylaluminum (1.9 ml of a stock solution in CH_2Cl_2, 0.37 mmol) at −23 °C under argon atmosphere. After the yellow solution was stirred for 5 min, *cis*-stilbene oxide (43.3 mg, 0.22 mmol) in 2 ml of CH_2Cl_2 was added dropwise at −23 °C. The resulting mixture was stirred for 1 h at the same temperature, then quenched with sat. NH_4Cl aq and 1M HCl. The organic layer was extracted with CH_2Cl_2 and dried over anhydrous Na_2SO_4. After evaporation of the solvent, the crude product was purified by (hexane-Et_2O=7 : 4) preparative TLC to afford 1,2-diphenyl-4-penten-1-ol (33.2 mg, 63%). IR (neat) 3400, 1640, 1600, 1500 cm^{-1}; ^1H NMR (CCl_4) δ=1.34 (s, 1H), 1.80—2.20 (m, 2H), 3.69 (d, *J*=8.0 Hz, 1H), 3.90—4.40 (m, 1H), 4.58—6.20 (m, 3H), 7.12 (s, 10H); $[\alpha]_D^{17}$ −7.24° (*c* 2.21, CH_2Cl_2).

The optical purity of the product was determined by conversion to the diastereoisomeric mixture of (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetic acid esters. ^{19}F NMR analysis showed two clearly separated peaks with a ratio of 75 : 25.

Asymmetric Methallylation of Aldehydes with Chiral Methallylating Agent (Table 3). A typical reaction procedure is described for the reaction of benzaldehyde (Entry 1); to a suspension of tin(II) triflate (184 mg, 0.44 mol) and (*S*)-1-methyl-2-[(1-piperidinyl)methyl]pyrrolidine (80.4 mg, 0.44 mmol) in 4 ml of CH_2Cl_2 was added dropwise methallyldiisobutylaluminum (1.7 ml of a stock solution in CH_2Cl_2, 0.34 mmol) at −78 °C under argon atmosphere. After the yellow solution was stirred for 30 min, benzaldehyde (24.3 mg, 0.23 mmol) in 2 ml of CH_2Cl_2 was added dropwise at −78 °C. The resulting mixture was stirred for 1 h at the same temperature, then quenched with sat. NH_4Cl aq and 1M HCl. The organic layer was extracted with CH_2Cl_2 and dried over Na_2SO_4. After evaporation of the solvent, the crude product was purified by preparative TLC (hexane-Et_2O=7 : 3) to yield 1-phenyl-3-methyl-3-buten-1-ol (29.5 mg, 80%). IR (neat) 3400, 1650, 1500, 1450 cm^{-1}; ^1H NMR (CCl_4) δ=1.75 (s, 3H), 1.91 (s, 1H), 2.32 (d, *J*=7.0 Hz, 2H), 4.67 (t, *J*=7.0 Hz, 1H), 4.76 (br s, 2H), 7.19 (s, 5H).

Other spectral data are presented: 1-(4-Chlorophenyl)-3-methyl-3-buten-1-ol (Entry 2). IR (neat) 3400, 1650, 1500, 1450 cm^{-1}; ^1H NMR (CCl_4) δ=1.62 (s, 3H), 1.95 (s, 1H), 2.18 (d, *J*=7.0 Hz, 2H), 4.55 (t, *J*=7.0 Hz, 1H), 4.60—4.90 (m, 2H), 7.14 (s, 4H); Found: *m/z* 196.0629. Calcd for $C_{11}H_{13}OCl$: M, 196.0653.

1-Phenyl-5-methyl-5-hexen-3-ol (Entry 4). IR (neat) 3400, 2940, 1650, 1600, 1500, 1460 cm^{-1}; ^1H NMR (CCl_4) δ=1.30—1.90 (m, 6H), 2.10 (d, J=7.0 Hz, 2H), 2.50—3.00 (m, 2H), 3.62 (tt, J=7.0, 7.0 Hz,1H), 4.50—5.10 (m, 2H), 7.12 (s, 5H); Found: m/z 190.1397. Calcd for $C_{13}H_{18}O$: 190.1357.

1-Phenyl-5-methyl-1,5-hexadien-3-ol (Entry 3). IR (neat) 3400, 1650, 1600, 1500, 1450 cm^{-1}; ^1H NMR (CCl_4) δ=1.78 (s, 3H), 1.94 (s, 1H), 2.25 (d, J=7.0 Hz, 2H), 4.30 (dt, J=6.0, 6.0 Hz, 1H), 4.79 (br s, 2H), 5.8—6.8 (m, 2H), 7.22 (s, 5H).

2-Methyl-1-dodecen-4-ol (Entry 5). IR (neat) 3400, 2930, 1640, 1450 cm^{-1}; ^1H NMR (CCl_4) δ=0.88 (t, J=6.0 Hz, 3H), 1.30 (br s, 15H), 1.74 (s, 3H), 1.90—2.20 (m, 2H), 3.30—3.80 (m, 1H), 4.60—4.90 (m, 2H).

Asymmetric Propargylation of Aldehydes with Chiral Propargylating Agent (Table 4). A typical reaction procedure is described for the reaction of benzaldehyde (Entry 1); to a suspension of tin(II) triflate (208.5 mg, 0.50 mmol) and (*S*)-1-methyl-2-[(1-piperidinyl)methyl]pyrrolidine (91.2 mg, 0.50 mmol) in 4 ml of CH_2Cl_2 was added dropwise propargylaluminum derivative (2.0 ml of a stock solution in CH_2Cl_2, 0.39 mmol) at −78 °C under argon atmosphere. After the yellow solution was stirred for 30 min, benzaldehyde (30.2 mg, 0.29 mmol) in 2 ml of CH_2Cl_2 was added dropwise at −78 °C. The resulting mixture was stirred for 2 h at the same temperature, then quenched with sat. NH_4Cl aq and 1M HCl. The organic layer was extracted with CH_2Cl_2 and dried over Na_2SO_4. After concentration in vacuo the resulted oily substance was purified by preparative TLC (hexane-Et_2O=7 : 3) to yield 1-phenyl-3-butyn-1-ol (32.2 mg, 77%). IR (neat) 3400, 3300, 2100, 1500, 1460 cm^{-1}; ^1H NMR (CCl_4) δ=1.88 (t, J=2.5 Hz, 1H), 2.50 (dd, J=2.5, 6.6 Hz, 2H), 2.40 (s, 1H), 4.72 (t, J=6.6 Hz, 1H), 7.26 (s, 5H). Other spectral data are presented.

1-(1-Naphthyl)-3-butyn-1-ol (Entry 2). IR (neat) 3400, 3300, 2100, 1600, 1500 cm^{-1}; ^1H NMR (CCl_4) δ=1.90 (t, J=2.5 Hz, 1H), 2.40—2.95 (m, 3H), 5.10—5.55 (m, 1H), 7.05—8.10 (m, 7H); Found: m/z 196.0825. Calcd for $C_{14}H_{12}O$: M, 196.0887.

1-Phenyl-5-hexyn-3-ol (Entry 3). IR (neat) 3400, 3300, 2920, 2100, 1600, 1500, 1450 cm^{-1} ^1H NMR (CCl_4) δ=1.50—2.00 (m, 3H), 2.27 (dd, J=2.5, 6.0 Hz, 2H), 2.40—3.00 (m, 3H), 3.30—3.90 (m, 1H), 7.08 (s, 5H); Found: m/z 174.1039. Calcd for $C_{12}H_{14}O$: M, 174.1043.

1-Phenyl-1-hexen-5-yn-3-ol (Entry 4). IR (neat) 3400, 3300, 2100, 1650, 1490, 1450 cm^{-1}; ^1H NMR (CCl_4) 1.92 (t, J=2.5 Hz, 1H), 2.43 (dd, J=2.5, 6.0 Hz, 2H), 2.72 (s,1H), 4.05—4.50 (m, 1H), 5.75—6.70 (m, 2H), 7.15 (s, 5H); Found; m/z 172.0934. Calcd for $C_{12}H_{12}O$: M, 172.0887.

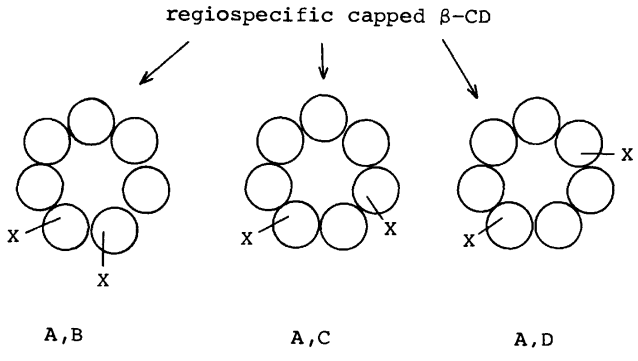
400 MHz Two-Dimensional NMR Studies of Cyclodextrin Derivatives for ^{1}H and ^{13}C Chemical Shift Determination

Iwao TABUSHI, Tatsuya NABESHIMA, Kazuo YAMAMURA,* and Haruo FUJITA
Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto 606
(Received May 2, 1987)

Two-dimensional (2D) NMR spectroscopies, proton (400 MHZ)- proton (400 MHz) and carbon (100 MHz)-proton (400 MHz) chemical shift correlation spectroscopy, were developed as a reliable technique for the strict assignment of crowded and complicated NMR absorptions of substituted cyclodextrin derivatives, pentakis[2,6-*O*-(*t*-butyldimethylsilyl)]-*A*,*B*-bis-[2-*O*-(*t*-butyldimethylsilyl)-6-deoxy-6-(methylthio)]-β-cyclodextrin (**2**) and *A*,*B*-bis[6-deoxy-6-(methylthio)]-β-cyclodextrin (**1**).

Cyclodextrins bind a large variety of guest molecules of appropriate shapes and sizes in their "hydrophobic" cavities in aqueous solution.[1] This concept of molecular recognition in water has led the authors to a new concept of artificial enzymes or artificial receptors[2,3] and the approaches to realize these have been attempted via attachment of appropriate functional groups onto the "rim" of cyclodextrins. For specific derivatization of cyclodextrins, the explicit determination of the product structures is necessary and important. For the purpose, ^{13}C and ^{1}H NMR[4–16] have been especially useful.

More important, however, is the macrocyclic regiochemistry (see Scheme 1), since it seems very crucial to the development of artificial enzymes or receptors.[17,18] Nevertheless, this regiochemistry on cyclodextrins is not explicitly determined by simple spectroscopies[16,19] other than NMR (high magnetic field) spectroscopy. But instead, a great deal of effort of synthetic[19] or enzymatic[20,21] approach has been made to overcome the drawback.



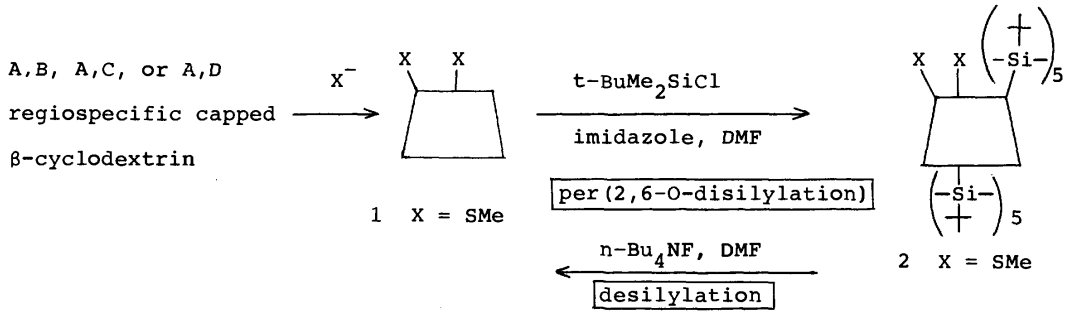
Scheme 1. Regiochemistry of prim-disubstituted β-cyclodextrin.

Recently two-dimensional (2D) NMR spectroscopy[22] has been developed rapidly for the structure determinations of complicated molecules such as natural products,[23] proteins,[24] or carbohydrates.[25] 2D NMR gives much more reliable and well defined informations of chemical shifts or coupling constants than the convensional one-dimensional NMR. Parent α- and β-cyclodextrins were studied by 250 or 270 MHz 2D NMR, and the assignments of individual ^{13}C absorptions of C_1 to C_6[25c] have been successfully made. Substituted cyclodextrins, however, usually show finely separated and delicately overlapped complex absorptions of ^{13}C (or ^{1}H), probably due to appreciable remote substituent effects on chemical shifts and also due to minor but often important conformational changes.

Now we wish to report a complete study of pentakis[2,6-*O*-(*t*-butyldimethylsilyl)]-*A*,*B*-bis[2-*O*-(*t*-butyldimethylsilyl)-6-deoxy-6-(methylthio)]-β-cyclodextrin (**2**) by using 400 MHz 2D NMR by taking proton-proton[27] (400 MHz) and proton-carbon chemical shift correlation[28] (400—100 MHz). Explicit assignments of C_1–C_6 carbons are presented herein.

Results and Discussion

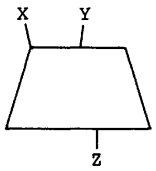
Per(2,6-*O*-disilylation) of disubstituted cyclodextrin derivative **1** with *t*-$BuMe_2SiCl$[14] was carried out (see



Scheme 2.

Scheme 2). This persilylation is important because of the following reasons; (a) separation and isolation of the silylated derivatives are easily achieved by a usual silica-gel column chromatography, (b) the silylated compounds are satisfactorily stable under weak acidic or from weak to strong basic conditions, (c) an appropriate substituent can be conveniently introduced into the unsilylated C_3-OH groups, and (d) desilylation is readily carried out by treatment with n-Bu_4NF in DMF at room temperature (Scheme 2). By use of this silylation-desilylation technique, a promising possibility of constructing sophisticated enzyme models or receptor models through preparation of regiospecific prim,prim-disubstituted cyclodextrins with or without additional appropriate functional group at the secondary position can be done without serious difficulty (Fig. 1).

Pentakis[2,6-*O*-(*t*-butyldimethylsilyl)]-*A*,*B*-bis[2-*O*-(*t*-butyldimethylsilyl)-6-deoxy-6-(methylthio)]-β-cyclodextrin (**2**), which was prepared according to Scheme 2, gave a very crowded conventional ^1H NMR spectrum (400 MHz) (Fig. 2) like other cyclodextrin derivatives. Direct analysis of the spectrum does not afford enough informations to determine the structure of **2** explicitly. Only ^1H absorptions for C_1-H bond appeared at δ 4.80—4.89 separately from other ^1H absorptions. The assignment is based on the comparison with the known ^1H chemical shift for C_1-H protons of the parent cyclodextrin. The ^1H absorptions at δ 2.73—3.04 may be ascribed to H_{6A} ($H_{6A'}$) and H_{6B} ($H_{6B'}$) protons tentatively (Fig. 3), since these are reasonable as CH_2 protons α to the SMe substituent. For other ^1H absorptions, however, explicit assignments were difficult, particularly for other protons attached



X, Y = substituent at primary rim of cyclodextrin

Z = substituent at C_3

Fig. 1. Regiospecific prim-disubstituted β-cyclodextrin with an appropriate functional groups at secondary C_3 carbon.

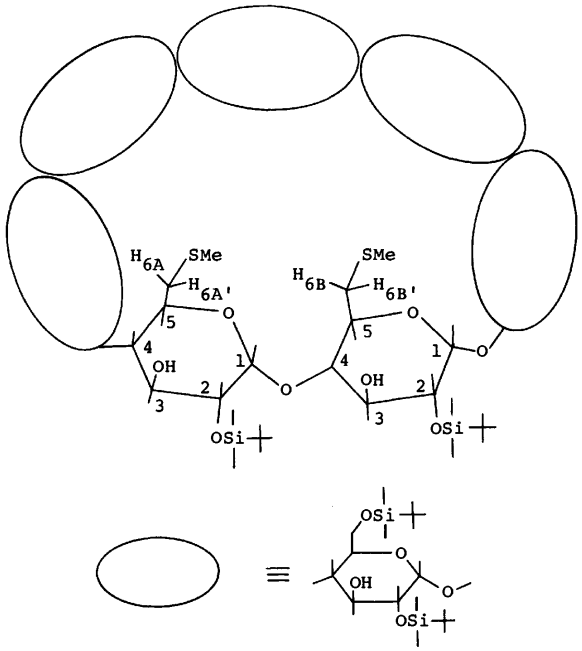


Fig. 3. Structure of **2**. Two H_6 protons on the same ring are interchangeable in the NMR assignment.

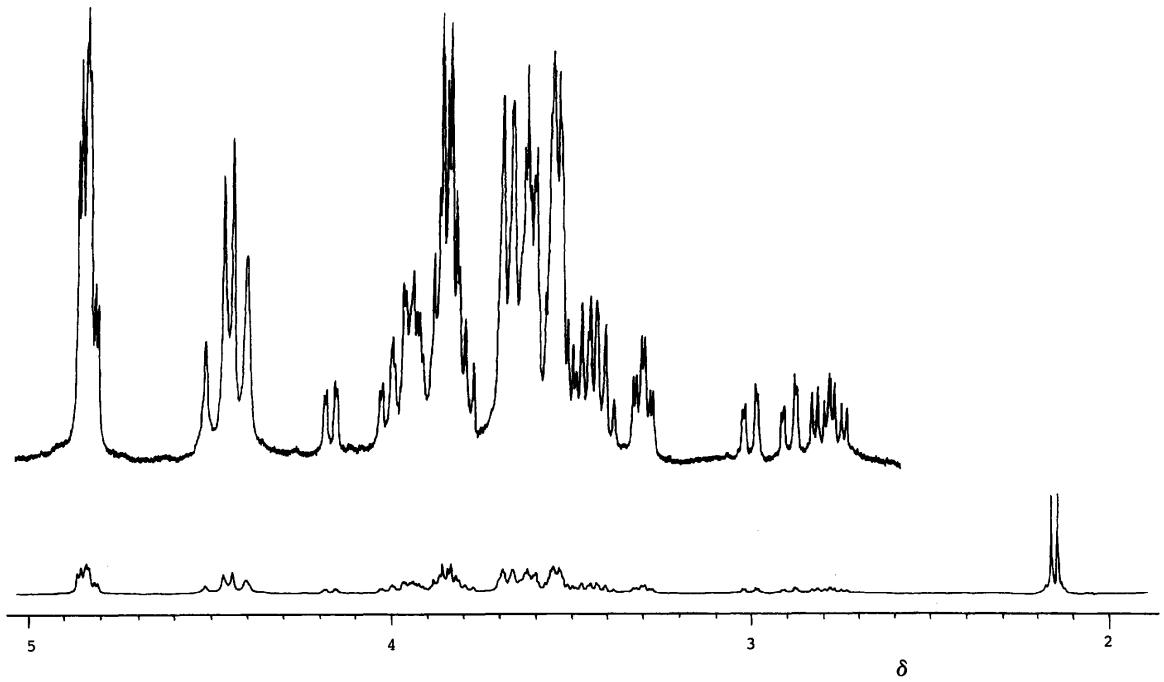

Fig. 2. 400 MHz ^1H NMR spectrum of **2**.

to carbons of cyclodextrin skeleton, because of the extreme complexity of the spectrum.

^{13}C NMR, satisfactorily well-separated absorptions were obtained at 100 MHz NMR (Fig. 4), in which fine structures of the ^{13}C absorptions provide a useful information not only as to the skeletal structure but also as to the possible conformation. Clearly, groups of the ^{13}C absorptions which appeared at well-separated magnetic fields centered at δ 103.0, 82.1, and 62.0 are to be assigned to C_1, C_4, and C_6, respectively, by comparison with ^{13}C absorptions of parent β-cyclodextrin. Thus, $C_{4A,B}$ and $C_{6A,B}$ carbons are tentatively ascribed to the carbon absorption peaks centered at δ 86.4 and 35.9 respectively, by considering the substituent effect of MeS group, while unequivocal determinations of C_2, C_3, C_5, and $C_{5A,B}$ are not feasible from the present one-dimensional NMR spectrum. The lack of NMR data of related compounds suitable for mutual comparison makes the further assignment difficult. Therefore, it is important and necessary to obtain a series of different types of well resolved NMR spectra and to combine information of ^{13}C and

a) Assignments A and B are tentative and interchangeable.

^1H NMR spectra for strict structure and conformation determination of cyclodextrin derivatives.

Figures 5 and 6 depict the 2D ^1H-^{13}C chemical shift correlation spectrum and 400 MHz ^1H COSY spectrum of **2**, respectively. Figure 5 displays proton chemical shift information in f_1 (vertical axis) and carbon shifts in f_2 (horizontal axis), one signal appearing for each directly bonded carbon-proton pair. Thus, in the ^1H-^{13}C shift correlation, H_{4A}-C_{4A} correlation and H_{6A}-C_{6A} correlation are clearly seen (Fig. 5), suggesting that the ^1H absorptions at δ 3.28—3.34 and 2.73—3.04 (see also Fig. 2) are assigned unambiguously to H_{4A} (H_{4B}) and H_{6A} (H_{6B}), respectively. Similarly, ^1H COSY spectrum clearly depicts the H_6-H_5 correlation (see Fig. 6), strongly indicating that H_{5A} (H_{5B}) proton absorbs at δ 3.88 (3.95) though hidden by a very complicated ^1H absorptions. Finally the H_{5A}-C_{5A} correlation found in Fig. 5 strongly indicates that C_{5A} and C_{5B} carbons absorb at δ 71.2 and 71.8, one of which is overlapped by the ^{13}C absorptions of C_3 carbons. The presence of H_{5A}-H_{4A} correlation observed (Fig. 6) also supports the mutual consistency of the present assignment. It is clear that the H_4-H_5-H_6 network on A and B rings of **2** has been successfully solved by the 2D NMR technique, providing considerable increase in resolving power and information content over that obtainable using conventional methods.

The 2D NMR technique was found also effective in the assignment of H_1-H_2-C_2 network of **2**. Thus, from ^1H COSY spectrum, H_1-H_2 correlation has led to the clear assignment of H_2 protons (Fig. 6). Therefore, a decisive assignment, ^{13}C absorption at δ 74.8—75.2 due to C_2 carbons, was made clearly. The complete ^{13}C absorptions together with their assignments are summarized in Table 1.

The absorptions due to C_3-OH protons were concluded to have appeared at δ 4.3—4.6 region (see Fig. 2), since a clear correlation was seen between H-C_3 and C_3-O-H in the ^1H COSY spectrum.

H_{6A} (H_{6B}) (see Fig. 7) are coupled to $H_{6A'}$ ($H_{6B'}$) with the coupling constant of J=14 Hz and the two $H_{6A,A'}$ ($H_{6B,B'}$) protons coupled again to H_{5A} (H_{5B}) but with different coupling constants of 6 and 2.5 Hz (6.5 and 2.5 Hz) (see Table 2), suggesting the preference of rotamers around the C_5 -C_6 axis (most populated position in the freely or restrictedly rotating substituted methylene) at certain angle (ca. 40° or ca. 200°) twisted from C_5-C_4. One H_6 proton absorbing at δ 4.14—4.23 obviously belongs to the unsubstituted glucose ring. Therefore, H_6 protons may be used as the rotamer probe for the dihedral angle change.

In conclusion, the 2D NMR technique was very effective, particularly for the explicit assignment of ^{13}C NMR absorptions of the glucose ring carrying the substituent (SMe) at C_6 carbons of *A,B*-disubstituted cyclodextrin derivative, **2**. The technique was found also powerful for the desilylated compound, *A,B*-bis[6-deoxy-6-(methylthio)]-*β*-cyclodextrin (**1**), which was obtained via the desilylation of **2** (Scheme 2). The ^{13}C NMR absorptions of **1** together with their assignments are given in Table 1. The correlation of ^{13}C NMR assignments between **1** and **2** was satisfactory as shown in Table 1.

Experimental

Instruments and Apparatus. ^1H (400 MHz), ^{13}C (100 MHz), and 2D correlation NMR spectra were recorded on a JEOL JNM-GX 400 spectrometer. Chemical shifts in $CDCl_3$ are given in *δ* values from tetramethylsilane (TMS) used as an internal standard. ^{13}C and 2D NMR spectra were obtained with a coaxial dual cell. The inner tube (5 mm*φ*) contained 1% TMS in $CDCl_3$, which was used as an external standard by taking the chemical shift of the central peak of $CDCl_3$ from TMS as *δ* 77.02. The outer tube (10 mm*φ*) contained a DMSO-d_6 solution of a cyclodextrin derivative to be measured. Both tubes were purchased from Wilmad Glass Co. 2D homonuclear chemical shift correlation (COSY) spectrum (512×1024 matrix after Fourier transformation) was obtained from 512 spectra of 2048 points. The spectral width was 2200 Hz, and 90° pulse of ^1H was 9.1 μs. In carbon-proton chemical shift correlation spectra, spectral widths of two axes were 2200 Hz (^1H axis) with 512 data points and 12000 Hz (^{13}C axis) with 4096 data points. 90° pulse widths of ^{13}C and ^1H were 19.4 and 26.5 μs, respectively. All measurements were carried out at 30±1 °C.

IR spectra were obtained using a Hitachi model 260-50 spectrophotometer. $CDCl_3$ (99.8%), DMSO-d_6 (99.9%), and TMS were purchased from Aldrich or E. Merck.

Materials. Commercially available *N,N*-dimethylformamide was kept standing over CaH_2 overnight at room temperature, and then distilled under reduced pressure (ca. 20 mmHg (1 mmHg=133.322Pa)) before use. Imidazole was freshly recrystallized from benzene, and then dried in vacuo at room temperature before use. Methanethiol sodium salt (15% aqueous solution, Tokyo Kasei) was used without further purification.

Per(2,6-*O*-disilylation) of cyclodextrin derivatives were carried out by treatment of the corresponding unsilylated cyclodextrin derivatives with a mixture of *t*-butyldimethylchlorosilane and dry imidazole in dry DMF according to the reported procedure.[14] The persilylated compounds were purified by silica-gel column chromatography (3×30 cm) at least twice using $CHCl_3$ as an eluent. The purity was checked by TLC using $CHCl_3$ or benzene-AcOEt (100 : 1, v/v).

A typical procedure for desilylation of silylated cyclodextrins—A silylated cyclodextrin derivative (0.5 g) was treated with tetrabutylammonium fluoride (1.0 g) in 30 mL of DMF at room temperature overnight. After the mixture was evaporated to dryness in vacuo, 30 mL of water and 1 mL of tetrachloroethylene were added to the residue. The mixture was stirred for 1 h at 0 °C to afford white precipitates, which were collected by suction filtration. The precipitates were dissolved in ca. 100 mL of 30—40% aqueous EtOH, and then tetrachloroethylene and the solvent were evaporated to dryness at 30 °C, finally at 80 °C at 20 mmHg. This procedure was repeated at least three times for the complete removal of tetrachloroethylene included in the cyclodextrin cavity.

***A,B*-Bis[6-deoxy-6-(methylthio)]-*β*-cyclodextrin (1).** *m*-Benzenedisulfonyl-capped *β*-cyclodextrin[20] (2.8 g, 2.1 mmol) was treated with 20 g (43 mmol) of a 15% aqueous MeSNa solution at 80 °C for 14 h under Ar. The mixture was acidified to pH 4 by the addition of 3M hydrochloric acid (1M=1 mol dm^{-3}) to give a pale yellow precipitates, which were collected by filtration. The filtrate was stirred with 1 mL of tetrachloroethylene at 0 °C for 1 h. The precipitates thus formed (containing tetrachloroethylene) were collected. Tetrachloroethylene included in the precipitates was removed as described above. The removal of tetrachloroethylene was ascertained by IR, viz., by the disappearance of the 775, 910 cm^{-1} absorptions. The precipitates were combined and dried in vacuo at 90 °C overnight, giving 0.9 g of **2**: IR (KBr) 3350 (br), 2910, 1150, 1030, 935, 755 cm-1; ^1H NMR (DMSO-d_6) *δ*=2.06 (s, Me-S, 3H), 2.10 (s, Me-S, 3H), 2.63 (dd, S-C(6)-H, *J*=8, 14 Hz, 1H), 2.75 (dd, S-C(6)-H, *J*=8, 14 Hz, 1H), 3.01 (d, S-C(6)-H, *J*=14 Hz, 1H), 3.13 (d, S-C(6)-H, *J*=14 Hz, 1H), 3.23—3.86 (m, other H), 4.40—4.56 (m, C(6)-OH, 5H), 4.80—4.91 (m, C(1)-H, 7H), 5.67—5.93 (m, C(2)-OH and C(3)-OH, 14H).

Pentakis[2,6-*O*-(*t*-butyldimethylsilyl)]-*A,B*-bis[2-*O*-(*t*-butyl dimethylsilyl)-6-deoxy-6-(methylthio)]-*β*-cyclodextrin (2). *A,B*-Bis[6-deoxy-6-(methylthio)]-*β*-cyclodexttrin (0.9 g, 0.75 mmol) was treated with *t*-butyldimethylchlorosilane (4.5 g, 30 mmol) and dry imidazole (4.3 g, 63 mmol) in 40 mL of dry DMF in a reported way,[14] giving 250 mg of the corresponding per(2,6-*O*-disilylated) compound **2** after the chromatographic purification as described above. **2**: IR (KBr) 3455 (br), 2960, 2940, 2900, 2865, 1470, 1365, 1260 (Si-CH_3), 1160, 1140, 1095, 1045, 1010, 860, 840, 785 cm^{-1}; ^1H NMR ($CDCl_3$) *δ*=0.01—0.07 (m, Me_2Si-O-C(6), 30H), 0.12—0.19 (m, Me_2 Si-O-C(2), 42H), 0.85—0.90 (m, *t*-BuSi-O-C(6), 45H), 0.90—0.96 (m, *t*-Bu-O-C(2), 63H), 2.15 (s, Me-S-C(6), 3H), 2.17 (s, Me-S-C(6), 3H), 2.76 (dd, S-C(6)-H, *J*=6, 14 Hz, 1H), 2.81(dd, S-C(6)-H, *J*=6.5, 14 Hz, 1H), 2.89 (dd, S-C(6)-H, *J*=2.5, 14 Hz, 1H), 3.00 (dd, S-C(6)-H, *J*=2.5, 14 Hz, 1H), 3.25—4.21 (m, other H, 49 H), 4.39—4.67 (m, C(3)-OH, 7H), 4.80—4.89 (m, C(1)-H, 7H); Found : C, 53.76 ; H, 9.54%. Calcd for $C_{116}H_{242}O_{33}S_2Si_{12}$: C, 54.29 ; H, 9.51%.

Preparation of New Nitrogen-Bridged Heterocycles. 16.[1] Facile Synthesis of Thieno[2,3-*b*]indolizine Derivatives

Akikazu KAKEHI,* Suketaka ITO, Yasuhiro OHNO, Shouji SHIBA, and Sakashi KAMATA
Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380
(Received May 6, 1987)

2-Ethoxycarbonyl-3-methyl- and 3-phenylthieno[2,3-*b*]indolizine derivatives were first synthesized in moderate to good yields by the treatment of tricyclic 5,5a-dihydropyrido[2,1-*c*]thieno[3,2-*e*][1,4]thiazines with a dehydrogenating agent. In contrast to the cases of bicyclic 1,9a-dihydropyrido[2,1-*c*][1,4]thiazines, all of the thienoindolizines obtained here were rearranged products and no desulfurized product could be obtained.

Our recent papers in this series have described the novel ring contraction reactions of pyrido[2,1-*c*]-[1,4]thiazines and pyrido[1,2-*d*][1,3,4]thiadiazines generated in situ from their dihydro compounds.[1,2] These reactions are not only convenient preparative methods for some indolizines and pyrazolo[1,5-*a*]-pyridines which are not obtainable by other methods but also good models for studying the behavior of the heterocyclic compounds having a $4n\pi$ electron system.[3] The wide versatility and the ready availability of starting materials and the synthetic and mechanistic interests prompted us to extend these reactions to a fused system with an aromatic ring in anticipation of the stabilization of reaction intermediates and of a new skeletal synthesis. In this paper we wish to report the isolations of some stable dihydropyridothiazines fused with a thiophene ring and their transformations to the corresponding thieno[2,3-*b*]indolizine derivatives and will also discuss about the effect of the fused aromatic ring on the reaction courses.

Results and Discussion

Preparations of 3-(1-Pyridinio)thiophene-2-thiolates. These pyridinium betaines **3a—e** bearing a thiophene ring were synthesized in 54—90% yields by the intramolecular condensations of pyridinium 1-methylides **2a—e**, readily obtainable from the reactions of 1-acetonyl- **1a** and **1b** and 1-phenacylpyridinium chlorides **1c—e**, carbon disulfide, and ethyl bromoacetate in the precence of base (Scheme 1).

The structures of pyridinium methylides **2a—e** and 3-(1-pyridinio)thiophene-2-thiolates **3a—e** were decided by their elemental analyses and by their spectral comparisons with those of analogous types of compounds.[4]

Preparations of 5,5a-Dihydropyrido[2,1-*c*]thieno-[3,2-*e*][1,4]thiazines. When the *S*-alkylations of pyridinium betaines **3a—d** with reagents such as bromoacetonitrile **4a**, methyl bromoacetate **4b**, ethyl bromoacetate **4c**, phenacyl bromide **4d**, *p*-chlorophenacyl bromide **4e**, and *p*-bromophenacyl bromide **4f** in chloroform followed by the treatment of the resulting pyridinium salts **5a—x** with 1,8-diazabicyclo[5.4.0]-undec-7-ene (DBU) in chloroform at 0 °C were carried out, the corresponding 2-ethoxycarbonyl-1-methyl- and 1-phenyl-5,5a-dihydropyrido[2,1-*c*]thieno[3,2-*e*]-[1,4]thiazines **6a—l** and **7a—x** were formed in considerable yields as crystalline compounds, respectively. On the other hand, the expected tricyclic adducts **6y**+**7y** and **6z**+**7z** could not be obtained by the alkaline treatment of pyridinium salts **5y** and **5z** which were

similarly obtained from the reactions of pyridinium betaine **3e** bearing a methyl group at the 2-position with bromoacetonitrile **4a** and ethyl bromoacetate **4c**. (Scheme 2) The inaccessibility of adducts **6y+7y** and **6z+7z** from 2-methylpyridinium salts **5y** and **5z** suggested a large steric hinderance against the cyclization between the 2-methyl group and the bulky thiophene moiety.

In contract to bicyclic dihydropyridothiazines[1] the adducts **6a—l** and **7a—x** were fairly stable compounds and scarcely decomposed at room temperature. The elemental analyses of adducts **6a—l** and **7a—x** were in good accord with the proposed compositions, and the chemical shifts and the signal patterns due to the dihydropyridothiazine moiety in their proton NMR (^{1}H NMR) spectra (see Table 1) were similar to those of bicyclic ones.[1] The latter also showed that adducts **6a—l** and **7a—l** were cis and trans mixtures with respect to the 8a and 9 positions and **7m—x** only trans isomers. The isomer ratios are shown in Scheme 2.

Preparations of 2-Ethoxycarbonyl-3-methyl- and 3-phenylthieno[2,3-*b*]indolizines. Although the reactions of dihydropyridothienothiazines **6a—l** and **7a—x** with lead tetraacetate did not afford the expected ring

contraction products, the treatment with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) in chloroform at 0 °C formed the corresponding thieno[2,3-*b*]indolizine derivatives **8a—z** as dark red or black crystals in 19—96% yields. Furthermore, the same products **8a—z** could be also obtained from adducts **6a—l** and **7a—x** by the action of palladium on carbon at room temperature, but their yields were low in compared with those using DDQ (Scheme 3).

Very interestingly, all of products **8a—x** were not the desulfurized thienoindolizines such as **9** but the rearranged ones regardless of the kinds of the substituent (R_3).[1,2]

The thienoindolizines, **8a—x**, were comparatively stable compounds at room temperature, but their 3-phenyl derivatives **8c**, **8d**, **8g**, **8h**, **8k**, **8l**, **8o**, **8p**, **8s**, **8t**, **8w**, and **8x**, in particular, were easily decomposed at the refluxing temperature of ethanol to give polymeric substances. The instability of these thienoindolizines **8a—x** must be caused by both the strained thiaazapenta-

a) The coupling constants are as follows: $J_{5,6}=J_{6,7}=7.0$, $J_{7,8}=10.0$, $J_{6,8}=2.0$ Hz, and $J_{Et}=7.0$ Hz.
b) Overlapped with the phenyl proton signals.

lene skeleton and the steric repulsion between the 3-substituent (R) and the 5-proton.

The elementary analyses of these products **8a—x** were in accord with the compositions of the thieno[2,3-*b*]indolizines carrying a thio group at the 9-position. The IR spectra of thienoindolizines **8a—d** exhibited also clearly the precence of a thiocyanato group (2141—2151 cm^{-1}). The proton signals (Table 2) on the pyridine ring in compounds **8a—x** appeared in the range of δ 5.28—8.28, and the values (δ 5.97—8.28) except those (δ 5.28—5.93) due to the 5- and 6-protons of 3-phenyl derivatives **8c**, **8d**, **8g**, **8h**, **8k**, **8l**, **8o**, **8p**, **8s**, **8t**, **8w**, and **8x** are not contradictory to those of aromatic indolizine derivatives.[1,5] These high field shifts observed largely for the 5- and 6-protons in 3-phenyl derivatives must be caused by the shielding effect of the 3-phenyl group whose resonance-stabilized planar conformation is prevented owing to the proximity of great extent between the 3-phenyl group and the 5-proton. From these data, the products

a) Starting materials. b) This compound is a cis and trans mixture.

were concluded to be 5-thiocyanato- **8a—d**, 9-(alkoxycarbonylthio)-**8e—l**, and 9-(aroylthio)thieno-[2,3-*b*]indolizine derivatives **8m—x**, respectively.

Reaction Mechanisms. Possible mechanisms for the formation of the rearranged thienoindolizines **8a—x** from the corresponding dihydropyridothienothiazines **6a—l** and **7a—x** are shown in Scheme 4. The most remarkable feature in these ring contraction reactions is that only the rearranged tricyclic indolizines were formed regardless of the kinds of the R_3 group and the desulfurized compounds as described in similar reactions of bicyclic dihydropyridothiazines were not at all.[1] The reason why the desulfurized indolizines were not afforded in this tricyclic system is still uncertain, but, perhaps, the rapid ring opening from tetracyclic thiirane **11** to indolizinium 9-thiolate **12** possessing an aromatic thiophene ring may take place prior to the desulfurization to **9**.

In contract to the observations obtained by other investigators,[3,6] a strong trend toward the rearrangement was found in our pyrido[2,1-*c*][1,4]thiazine system, and further efforts to explain this phenomenon will be done.

Experimental

Melting points were measured with a Yanagimoto micro-melting point apparatus and are uncorrected. Microanalyses were carried out on a Perkin-Elmer 240 Elemental Analyzer. The ^{1}H NMR spectra were determined with a Varian EM360A spectrometer in deuteriochloroform with tetramethylsilane as an internal standard. The chemical shifts are expressed in δ values. The IR spectra were taken with a Hitachi 260-10 Infrared spectrophotometer.

Preparations of Pyridinium Methylides 2a—e. These pyridinium 1-(dithiocarboxy)methylides **2a—e** were prepared from the reactions of 1-acetonyl- **1a** and **1b** and 1-phenacylpyridinium chlorides **1c—e**, carbon disulfide, and ethyl bromoacetate in the presence of base according to the procedure described in the literature.[4] Some data of compounds **2a—e** are as follows: **2a**, 90%, yellow flakes (from ethanol), mp 162—164 °C, IR (KBr) 1730 cm^{-1} (CO). Found: C, 52.48; H, 5.06; N, 4.76%. Calcd for $C_{13}H_{15}NO_3S_2$: C, 52.50; H, 5.08; N, 4.71%. **2b**, 76%, yellow flakes (from ethanol), mp

170—172 °C, IR (KBr) 1730 cm^{-1} (CO). Found: C, 53.77; H, 5.47; N, 4.76%. Calcd for $C_{14}H_{17}NO_3S_2$: C, 54.00; H, 5.50; N, 4.50%. **2c**, 73%, yellow needles (from ethanol), mp 190—192 °C, IR (KBr) 1720 cm^{-1} (CO). Found: C, 59.98; H, 4.93; N, 3.90%. Calcd for $C_{18}H_{17}NO_3S_2$: C, 60.14; H, 4.77; N, 3.90%. **2d**, 84%, yellow needles (from ethanol), mp 191—193 °C, IR (KBr) 1730 cm^{-1} (CO). Found: C, 61.26; H, 4.79; N, 3.93%. Calcd for $C_{19}H_{19}NO_3S_2$: C, 61.10; H, 5.13; N, 3.75%. **2e**, 54%, yellow prisms (from ethanol), mp 183—185 °C, IR (KBr) 1720 cm^{-1} (CO). Found: C, 60.93; H, 5.11; N, 3.95%. Calcd for $C_{19}H_{19}NO_3S_2$: C, 61.10; H, 5.13; N, 3.75%.

Preparations of 3-(1-Pyridinio)thiophene-2-thiolates 3a—e. General Method: An ethanolic solution (100 ml) of pyridinium 1-methylide (10 mmol) and DBU (1.82 g, 12 mmol) was heated under the reflux temperature on a water bath until the disappearance of yellow spot of pyridinium 1-methylide was confirmed by the TLC monitoring of the reaction solution. (2—5 h) The resulting red solution was cooled to room temperature and then the product crystallized was collected by filtration. Recrystallizations from ethanol gave 3-(1-pyridinio)thiophen-2-thiolates **3a—e** as red needles. Some data of compounds **3a—e** are shown below. **3a**, 68%, mp 205—207 °C, IR (KBr) 1685 cm^{-1} (CO). Found: C, 55.80; H, 4.70; N, 5.09%. Calcd for $C_{13}H_{13}NO_2S_2$: C, 55.89; H, 4.69; N, 5.01%. **3b**, 83%, mp 202—205 °C, IR (KBr) 1670 cm^{-1} (CO). Found: C, 57.47; H, 5.08; N, 4.68%. Calcd for $C_{14}H_{15}NO_2S_2$: C, 57.31; H, 5.15; N, 4.77%. **3c**, 87%, mp 244—246 °C, IR (KBr) 1675 cm^{-1} (CO). Found: C, 63.09; H, 4.44; N, 4.16%. Calcd for $C_{18}H_{15}NO_2S_2$: C, 63.32; H, 4.43; N, 4.10%. **3d**, 76%, mp 242—244 °C, IR (KBr) 1685 cm^{-1} (CO). Found: C, 64.32; H, 4.69; N, 3.95%. Calcd for $C_{19}H_{17}NO_2S_2$: C, 64.20; H, 4.82; N, 3.94%. **3e**, 60%, mp 217—221 °C, IR (KBr) 1690 cm^{-1} (CO). Found: C, 63.99; H, 4.93; N, 4.04%. Calcd for $C_{19}H_{17}NO_2S_2$: C, 64.20; H, 4.82; N, 3.94%.

Preparations of 5,5a-Dihydropyrido[2,1-*c*]thieno[3,2-*e*]-[1,4]thiazines 6a—l and 7a—x. General Method. A mixture of pyridinium betaine (2 mmol) and alkyl bromide (2.2 mmol) was dissolved in chloroform (20 ml) and the resulting solution was kept at room temperature until the spot of pyridinium betaine disappeared (1—7 d, by TLC monitoring). The solution was concentrated under reduced pressure and the residue was washed three times with ether to remove the unaltered alkylating agent. To the chloroform solution (50 ml) of the pyridinium salt prepared above DBU (0.38 g, 2.5 mmol) was added dropwise at 0 °C in an ice bath, and then stirred for further 10 min at the temperature. The resulting solution was concentrated under reduced pressure and the residue was separated by column chromatography (alumina) using chloroform as an eluent. The chloroform layer was concentrated under reduced pressure. Recrystallizations from chloroform-hexane or ether-hexane gave pure products as pale yellow prisms (**6a+7a** and **6f+7f**). pale yellow needles (**6b+7b—6e+7e**, **6g+7g—6i+7i**, and **7m**), yellow prisms (**6j+7j** and **7v**), yellow needles (**6k+7k**, **6l+71**, **7n—7s**, and **7u**), or orange needles (**7t**, **7w**, and **7x**).

On the other hand, similar treatment of pyridinium salts **5y** and **5z** gave complex mixtures and any significant product could not be isolated.

There results and some physical and spectral data are summarized in Tables 1 and 3.

Preparations of Thieno[2,3-*b*]indolizines 8a—x. General Method. To a chloroform solution (50 ml) of dihydropyridothienothiazine (0.2—0.5 g) an equimolar amount of DDQ was added under stirring at 0 °C in an ice bath and the resulting mixture was stirred at the temperature until the material was disappeared (TLC monitoring). (about 2—4 h) The solution was filtered to remove insoluble substances and then the filtrate was concentrated under reduced pressure at below 40 °C. The residual oil was separated by column chromatography (alumina) using chloroform as an eluent. The evaporation of the solvent and recrystallization of the residue from chloroform-hexane gave the corresponding thieno[2,3-*b*]indolizine derivatives as dark red needles (**8a—c**, **8j**, **8n**, **8t**, and **8v**) or black needles (**8d—i**, **8k—m**, **8o—s**, **8u**, **8w**, and **8x**).

These thienoindolizines could be also obtained in moderate yields from the reactions of dihydropyridothienothiazines with palladium on carbon (5%) in dry benzene at room temperature.

These results and some data are listed in Tables 2 and 4.

Autoxidation of 1-Methyl- and 1,3-Dimethylazulenes in Polar Aprotic Solvents: Structural Proof for Products and Reaction Pathways[1)]

Shin-ichi TAKEKUMA, Yoshiharu MATSUBARA,* Hiroshi YAMAMOTO,†,* and Tetsuo NOZOE††

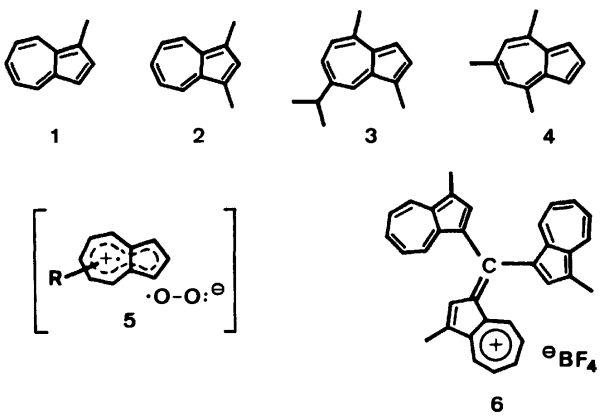
†Deparment of Chemistry, Okayama University, Okayama 700
††Tokyo Research Laboratories, Takasago Corporation, 5-36-31 Kamata, Ohta-ku, Tokyo 144
(Received May 11, 1987)

Autoxidation of the title azulenes at 100 °C in HMPA or DMF afforded a wide variety of products: Namely, the oxidation products of the side-chains, 1-substituted azulenes, 1*H*-inden-1-ols, naphthoquinones, benzenoids, and dimeric and trimeric compounds, with or without rearrangements. ^{1}H NMR (200-MHz) parameters of various azulene derivatives are given for comparative study. Possible reaction pathways for the formation of these products are discussed in comparison with the results of the previous studies on guaiazulene and 4,6,8-trimethylazulene.

We reported recently[2-4)] that autoxidation of naturally occurring guaiazulene (**3**) and synthetic 4,6,8-trimethylazulene (**4**) in *N*,*N*-dimethylformamide (DMF) or hexamethylphosphoric triamide (HMPA) gave a wide variety of products possessing interesting structures of azulenequinone, naphthoquinone, 1-indenone, and dimeric forms. It has been presumed[4)] that the oxidation is initiated by the formation of an electron-transferred complex **5**, which would then lead to a covalent linkage between the azulene nucleus and active radical species (produced during the oxidation) at various positions according to the ease of their affinity and steric requirement. Consequently, the autoxidation of **3** and **4** can be classified into such several types of reactions as oxidative dimerization, oxidation of side chains, azulenequinone formation, intermolecular one-carbon transfer reactions, and rearrangements to naphthalenoids, benzenoid, and 1*H*-inden-1-one derivatives. In these oxidation and coupling reactions, the facility of the radical attack on the C-1 and C-3 position of the azulene nucleus appeared to exceed usually that on various positions of the seven-membered ring,[5)] as in the case of many other electrophilic reactions of azulenes.[6)]



We now wish to report in this paper the detailed study on autoxidation of two other alkylazulenes **1** and **2** having methyl substituent(s) on the C-1 and C-3 position(s). This study was conducted to compare the mode of the oxidation with that of the trialkylazulenes **3** and **4** and to establish a further general aspect of the reaction mechanism of oxidation of azulenes. This information would in turn become important in view of an increasing interest in the potential utility of the physicochemical properties as well as biological activity of some synthetic azulene derivatives, exemplified by polyazulenes[7)] and azulenequinones.[8)]

Results and Discussion

Autoxidation of 1-Methylazulene (1). The oxidation was conducted in a manner similar to that described for the trialkylazulenes **3** and **4**.[2-4)] Thus, finely bubbling oxygen was passed into a soln of the substrate **1** in HMPA (or DMF) at 100 °C, while the reaction was monitored by the use of the reversed phase high-pressured liquid chromatography (HPLC) or silica-gel TLC. As in the case of the previous study, the reaction products were separated into each compo-

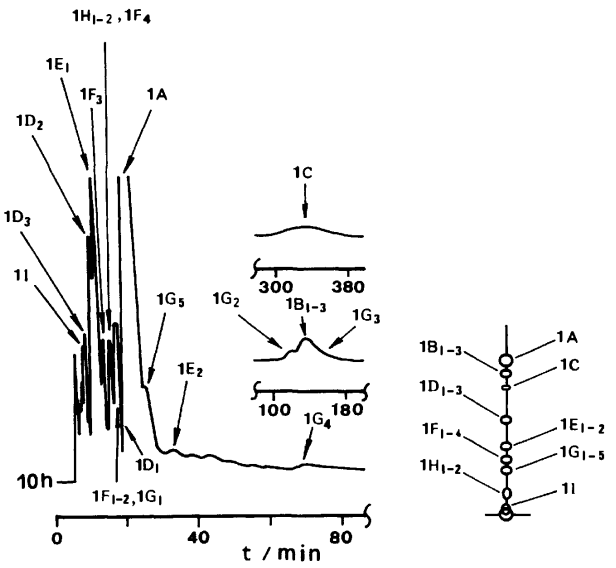


Fig. 1. HPLC and TLC diagrams of the autoxidation products from **1**.

nent by using chromatography, when about a half of the starting material was consumed (10 h); see HPLC and TLC diagrams in Fig. 1. The products thus obtained as pure components [19 altogether besides the recovered starting material **1** (**1A**)] are referred to as Compounds **1A—I** according to the same definition employed in the previous study.[2-4]

In Chart 1 are summarized structures of these products which were established by spectroscopy and chromatography as will be explained below; for the purpose of comparison in determining the structures of the oxidation products, the 200-MHz ^{1}H NMR parameters[9] for azulene derivatives obtained in the present study are summarized in Table 1. Amont these products, the followings were identified as all known compounds: **1B$_1$**,[10] **1D$_1$**,[11] **1D$_2$**, **1D$_3$**,[12] **1E$_1$**,[13] **1F$_1$**,[14] **1F$_2$**,[15] **1G$_1$**,[14] **1H$_1$**,[16] **1H$_2$**,[17] and **1I**[18] (for their spectral and other data, see Table 1 and the Experimental Section). The theoretical yields of these isolated products totaled to 25.2%; besides these, ca. 60% (w/w) yield of unidentified resinous polar products of rather high molecular weights were obtained.

Both Compounds **1B$_2$** and **1B$_3$** were shown to have a composition of $C_{22}H_{18}$ by MS and structures of 1′,3-dimethyl-1,2′-biazulene and 3,3′-dimethyl-1,1′-biazulene were respectively assigned to these minor products by the careful comparison of the ^{1}H NMR spectral data (see Table 1) with those of the starting material **1**.

Compound **1C** ($C_{34}H_{28}$ by MS), a major product, was found by spectroscopy to be 1,1′,1″-methylidynetris[3-methylazulene]; while the chemical shifts of other signals of **1C** in the ^{1}H NMR spectrum (Table 1) closely resembled those of **1**, an appreciable upfield shift (ca. 0.5 ppm) was observed for the H-2 signal presumably due to an electronic as well as an anisotropic effect by a nonplanar conformation of the three azulene nuclei owing to the steric repulsion. Although on allowing to stand at room temperature **1C** was gradually converted into a blue, polar substance (R_f=0.0), it remained stable when kept with a small proportion of an antioxidant (hydroquinone). Treatment of **1C** with triphenylmethylium tetrafluoroborate afforded the tetrafluoroborate **6**.[19]

Compound **1E$_2$** was an extremely minor product which possessed a dimeric composition ($C_{23}H_{20}O$ by MS) having an extra-carbon atom and a carbonyl group (1690 cm^{-1}). The ^{1}H NMR data indicated the presence of a 3-methyl-1-azulenylmethyl moiety attached to a certain nucleus ($C_{11}H_9O$) that exhibited a methyl group (at δ 1.78, doublet, J=1.0 Hz, coupling with a ring-proton at 6.56, quartet), a methine proton (at 5.38, singlet), and four olefinic ring-protons (6.04—6.56); the methylene proton signals of an AB type (at 3.31 and 3.37, J=14 Hz) should also be noticed. All of

a) Chemical shifts (δ) are parts per million from Me_4Si measured in $CDCl_3$ (concn <ca. 0.5% v/v). Coupling constants (J, Hz) were confirmed by double resonance. b) Me. c) $J_{2,3}$=4.0 Hz. d) $J_{4,5}$, $J_{5,6}$, $J_{6,7}$, and $J_{7,8}$: 10.0 Hz. $J_{4,6}$, $J_{5,7}$, and $J_{6,8}$: 1 Hz. e) CH_2-1. f) CH-1. g) $J_{4,5}$, $J_{5,6}$, $J_{6,7}$, and $J_{7,8}$: 9.5 Hz. h) CH_2-1, J=14 Hz. i) H-3a, singlet. j) $J_{2,Me(3)}$=1.0 Hz, $J_{5,6}$=$J_{6,7}$=6.0 Hz, $J_{7,8}$=10 Hz. k) CHO. l) $J_{2,Me(3)}$=1.5 Hz. m) $J_{5,7}$=2.0 Hz, $J_{7,8}$=8.0 Hz. n) $J_{6,7}$=7.5 Hz, $J_{6,8}$=2.0 Hz, $J_{7,8}$=8.0 Hz. o) $J_{4,6}$=1.5 Hz, $J_{6,7}$=7.5 Hz. p) COOH. q) $J_{4,5}$=1.5 Hz, $J_{6,7}$=10.0 Hz, $J_{6,8}$=1.0 Hz, $J_{7,8}$=9.5 Hz.

these signals appeared at slightly up-field compared with the corresponding proton signals of other azulene derivatives described in this paper. Based on these spectral data, 3-methyl-1-[(3-methyl-1-azulenyl)methyl]-4(3aH)-azulenone was tentatively assigned to **1E$_2$** as the most likely structure;[20] see Table 1 for the assignments of the ^{1}H NMR signals of **1E$_2$**.

Compound **1F$_3$** was a pale yellow oil which appeared to be hitherto unknown 3-methyl-1*H*-inden-1-one by judging from the R_f values (on HPLC and TLC) in comparison with those of 5-isopropyl-3,8-dimethyl-1*H*-inden-1-one.[2,4] However, on allowing to stand at room temp **1F$_3$** gradually changed into a rather unstable dimer (**1F$_4$**, $C_{20}H_{16}O_2$ by MS).[21]

Compound **1G$_2$** ($C_{23}H_{18}O$ by MS) was a minor product which showed a similar ^{1}H NMR spectrum to that of **1G$_1$** (except for the aldehyde signal of the latter). Therefore, structure of bis(3-methyl-1-azulenyl) ketone was assigned for **1G$_2$**. Both Compounds **1G$_3$** and **1G$_4$** ($C_{22}H_{16}O_2$) were found spectroscopically to possess a 3-methyl-1-azulenyl group attached to a 2-methyl-1,4-naphthoquinone moiety; a careful analysis of the ^{1}H NMR data (Table 1) led to the most likely coupling positions of **1G$_3$** and **1G$_4$** at C-6 and C-5 of the naphthoquinone nucleus, respectively. Compound **1G$_5$** ($C_{21}H_{16}O$ by MS), on the other hand, was found to possess a 3-methyl-1-azulenyl group attached to a 3-methyl-1*H*-inden-1-one moiety at C-5 on the evidence of ^{1}H NMR spectral data (Table 1).

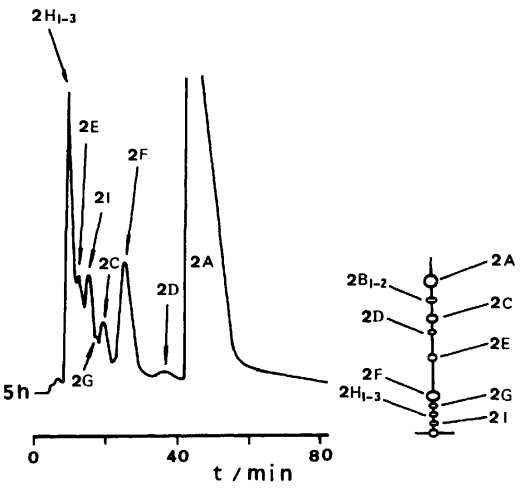

Fig. 2. HPLC and TLC diagrams of the autoxidation products from **2**.

Autoxidation of 1,3-Dimethylazulene (2). The oxidation was carried out in HMPA or DMF at 100 °C for 5 h in a manner similar to that described for **1**; compared with that of **1**, the oxidation of **2** was observed to take place slightly faster at 100 °C (HPLC). The resulting mixture (see HPLC and TLC in Fig. 2)

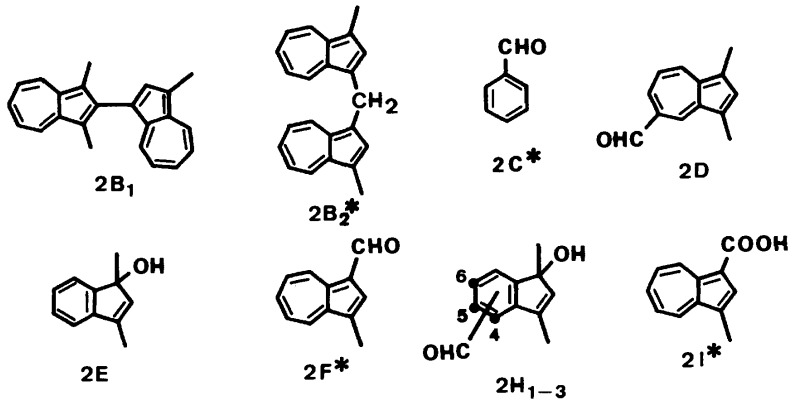

Chart 2. Structures of the autoxidation products of 2; *previously known compounds.

was carefully separated by using chromatography, and 11 products (**2A—I**) were obtained besides the recovered starting material **2** (**2A**). Structures of these products which have been similarly established are shown in Chart 2; among these, Compounds **2B**$_2$,[10] **2C**, **2F**,[14] and **2I**[17] were identified to be already known. The total theoretical yields of these isolated products were 35.4%. Besides these, a large amount (ca. 60%, w/w) of unidentified polar products of relatively high molecular weights were obtained.

Compound **2B**$_1$ ($C_{23}H_{20}$ by MS) was readily found to possess an asymmetric structure, 1′,3,3′-trimethyl-1,2′-biazulene, on the basis of the ^{1}H NMR data (Table 1) which closely resembled those of **1B**$_2$ except for the presence of a Me-3′ signal of **2B**$_1$.

Compound **2D** ($C_{13}H_{12}O$), a minor product, was proved to be 1,3-dimethyl-5-azulenecarbaldehyde on the evidence of spectral data (UV, ^{1}H NMR, and MS).

Compound **2E** ($C_{11}H_{12}O$ by MS) possessed the structure of 1,3-dimethyl-1*H*-inden-1-ol on the evidence of UV, IR, and ^{1}H NMR data, whereas Compounds **2H**$_{1\text{-}3}$ which remained inseparable by chromatography were found spectroscopically to be a mixture of 1-hydroxy-1,3-dimethyl-1*H*-indene-4-, 5-, and 6-carbaldehydes in an approximate ratio of 1 : 2 : 1, respectively.

Compound **2G** was an extremely minor product but its structure has remained to be clarified owing to the limited amount for sufficient spectroscopic data.

Possible Reaction Pathways for the Formation of Autoxidation Products of 1 and 2. As was observed for the trialkylazulenes **3** and **4**, the autoxidation of **1** and **2** has resulted in the simultaneous formation of many kinds of products by competitive processes. An attempt will now be made here to suggest the most probable reaction pathways for the formation of the major products (and in some cases minor products as well) after having been divided into four groups according to the type of reactions involved: (a) Side chain oxidation, (b) one-carbon transfer reactions, (c) rearrangement reactions to naphthoquinonoids, benzenoids, and indenols, and (d) oxidative dimerization, as illustrated in Schemes 1 and 2. Although the yield of each product may not necessarily reflect the ease of the corresponding reaction pathway, the combined yields of the products formed by the above reactions from alkylazulenes **1**—**4** are summarized in Table 2 for comparison.

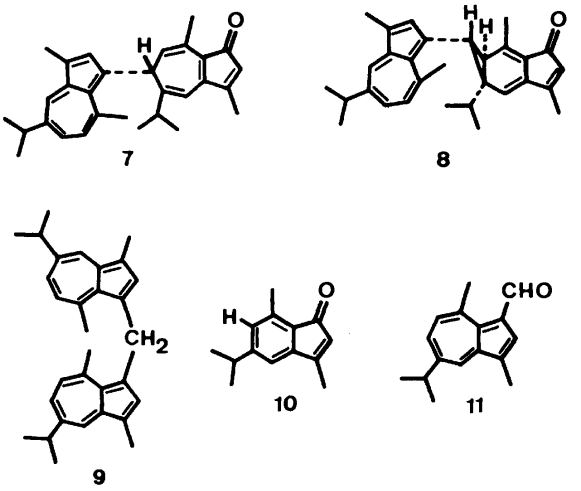

Table 2. Combined Yields (%, Isolated) of the Autoxidation[a] Products Classified into the Reaction Pathways

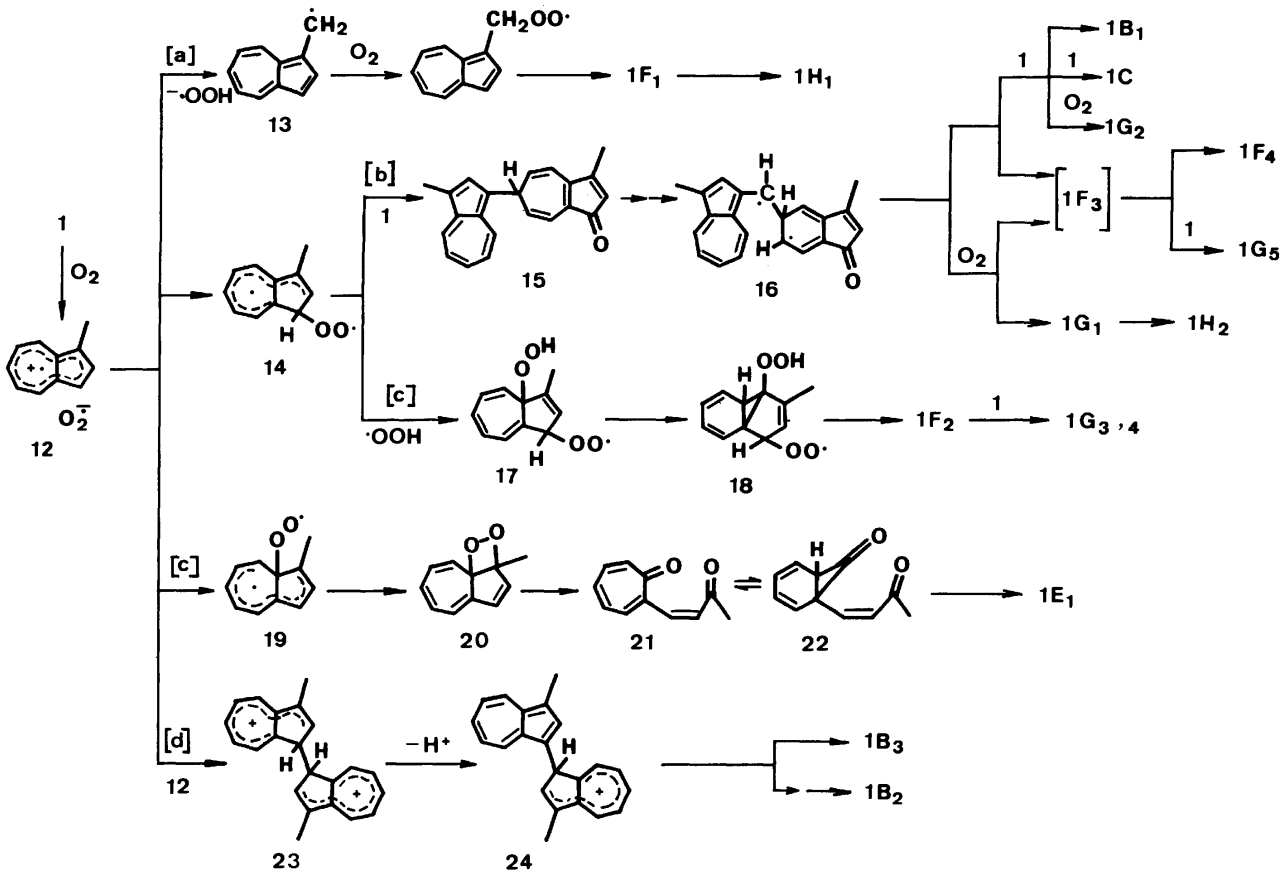
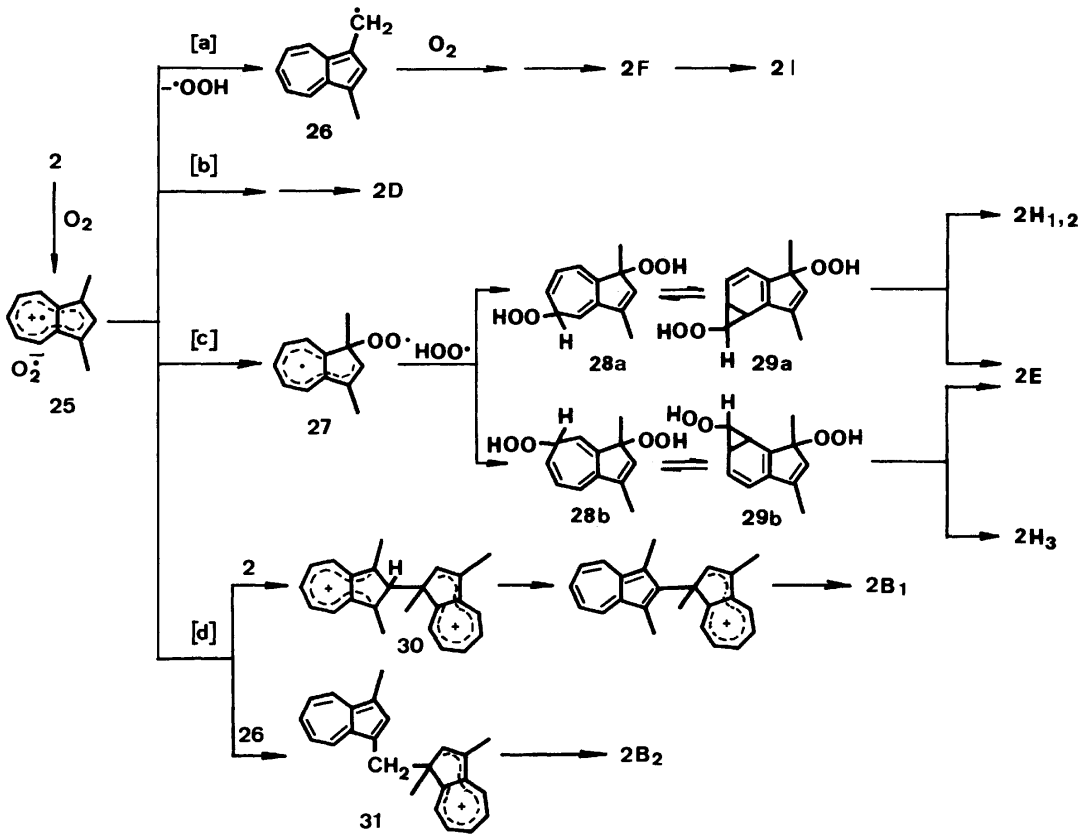
Reaction pathways	Starting alkylazulene			
	1	**2**	**3**[b]	**4**[c]
[a]	4	20.7	9.7	0.5
[b]	14.8	0.7	21.3	17.5
[c]	5.6	6.7	12.8	1.3
[d]	0.6	6.6	7.7	0
[e]	0	0	1.5	4.6
[f]	60	60	34	59

Reaction pathways: [a], side-chain oxidation; [b], one-carbon transfer reactions; [c], rearrangement reactions to naphthalenoids, benzenoids, and indene derivatives; [d], oxidative dimerization; [e], 1,5- and 1,7-azulenequinone formation; [f] polar resinous substance formation. a) Oxygenation in DMF or HMPA at 100 °C. b) From Refs. 2 and 4. c) From Refs. 3 and 4 (oxygenation at 120 °C).



Scheme 1. Possible reaction pathways for the autoxidation products from **1**.



Scheme 2. Possible reaction pathways for the autoxidation products from **2**.

a) As was postulated in the case[4] of **3** and **4**, the facile oxidation of **1** and **2** with molecular oxygen is likely to form the radical cation complexes **12** and **25**, respectively, from which various products are derived (see Schemes 1 and 2). Then the transformation of these complexes into the radical intermediates **13** and **26** (path [a]) would result in the oxidation of the side chain, thus yielding 1-azulenecarbaldehydes **1F**$_1$ and **2F**, respectively, by the consecutive oxidation with another molecule of oxygen in a manner similar to the well-accepted mechanism for the autoxidation of side chains of alkylbenzenes and naphthalene.[22] Further autoxidation of these aldehydes in the usual way gives the 1-azulenecarboxylic acids **1H**$_1$ and **2I**. It is particularly a characteristic feature, in comparison with the case[4] of **3** and **4**, that oxidation of a side chain on the C-1 and 3 positions of azulene nucleus constitutes an exclusive process in the autoxidation of **2**, while it takes place only moderately in **1** under the present conditions (see Table 2).

b) It is significant in the present autoxidation that compounds having extra-carbon(s) such as 1,1′-methylenebis[3-methylazulene] (**1B**$_1$), and related compounds **1C**, **1G**$_1$, **1G**$_2$, and **1H**$_2$ have been obtained in relatively high yields from **1**, whereas **2** has afforded 1,3-dimethyl-5-azulenecarbaldehyde (**2D**) as the only compound of this type in an extremely low yield.

Meanwhile, we have recently isolated[23] both the dimeric cycloheptatriene form **7** and its norcaradiene isomer **8** on autoxidation of guaiazulene (**3**) either at 85 °C in DMF–0.5 M sulfuric acid (1 M=1 mol dm^{-3}) or at 25—35 °C on the surface of a filter paper. These compounds were shown to exist in an equilibrium and to constitute important intermediates for the intermolecular one-carbon transfer reactions. For examples, treatment of **8** with one equivalent of **3** under nitrogen exclusively yields 3,3′-methylenebis[guaiazulene] (**9**) and 5-isopropyl-3,7-dimethyl-1*H*-inden-1-one (**10**), whereas **8** is transformed into 3-guaiazulenecarbaldehyde (**11**) and indenone **10** on exposure to air.

From these facts, similar dimeric cycloheptatriene **15** (formed by the coupling of the 3-methyl-1-azulenylperoxyl diradical **14** with **1**) and its equilibrated norcaradiene isomer (similar to the structural formula **8**) are also considered to be the most likely key intermediates for the one-carbon transfer reactions (path [b] in Scheme 1). The fragmentation of the latter intermediate through a dimeric diradical **16** in the presence of **1** would give 1,1′-methylenebis(3-methylazulene) (**1B**$_1$) and 3-methyl-1*H*-inden-1-one (**1F**$_3$); the latter is unstable and gradually changes to its dimer **1F**$_4$. Further oxidative coupling of **1B**$_1$ (or of its precursor) with another molecule of **1** would form the trimer **1C**. Concomitantly, oxidative cleavage of **16** would give 3-methyl-1-azulenecarbaldehyde **1G**$_1$ (and its carboxylic acid derivative **1H**$_2$) and **1F**$_3$, whereas bis(3-methyl-1-azulenyl) ketone (**1G**$_2$) appears to be derived from **16** through oxidation of a subsequent, yet unclarified intermediate (Scheme 1). It should be noticed that this type of reaction involving one-carbon transfer constitutes the major pathway in the oxidation of **1** (see Table 2).

In contrast, **2D** apparently formed as the result of the intermolecular one-carbon transfer reaction (path [b] in Scheme 2) was isolated in an extremely small amount (Table 2). Although this pathway seems to be of interest in view of the reactivity of the azulene nucleus, the exact mechanism has remained to be clarified.

c) As in the case[4] of the oxidative rearrangement of guaiazulene **3** to naphthoquinonoids, addition of another molecule of oxygen (or ·OOH) to C-3a of **14** (Scheme 1) is expected to give the intermediate **17** (path [c]) that can be converted into 2-methyl-1,4-naphthoquinone (**1F**$_2$) through the equilibrated norcaradiene form **18**. It is more likely that (*Z*)-4-phenyl-3-buten-2-one (**1E**$_1$) obtained from **1** in the highest yield among the benzenoid compounds is derived by transformation of **12** into the diradical **19** (path [c]) and then into the dioxetane intermediate **20**, followed by the ring opening, the tropone-norcaradiene dicarbonyl equilibrium between **21** and **22**, and then by facile decarbonylation of **22** accompanied by isomerization of the olefinic side chain.

On the other hand, possible reaction pathways for the formation of the rearrangement products (1-indenols **2E** and **2H**$_{1\text{-}3}$) from **2** are shown as path [c] in Scheme 2: transformation of **25** into 1,3-dimethyl-1-azulenylperoxyl diradical **27**, followed by addition of peroxyl radical to the C-5 (or C-7) position, would give an intermediate such as hydroperoxide **28a** (or **28b**) that rearranges into 1,3-dimethyl-1*H*-inden-1-ols **2E** and **2H**$_{1\text{-}3}$ presumably through the equilibrated norcaradiene form **29a**/**29b**.

d) Dimerization of the radical cation **12** is expected to give **23**, from which the proton loss would lead to the intermediate **24** (path [d] in Scheme 1). This yields then 3,3′-dimethyl-1,1′-biazulene (**1B**$_3$) and a smaller proportion of the 1,2′-isomer **1B**$_2$ through a 1,2-rearranged intermediate as in the case of guaiazulene **3**.[4] It is another significant feature that these dimers from **1** were isolated in extremely small proportions in comparison with the case of the oxidation of **3**. On the other hand, the radical coupling of **25** with **2** and **26** is likely to afford dimeric intermediates **30** and **31**, respectively, and then loss of the methyl group on C-1 from these dimeric intermediates would result in the formation of the oxidative dimers **2B**$_1$ and **2B**$_2$ as illustrated in Scheme 2 (path [d]). The dimers **1G**$_{3\text{-}5}$ are apparently derived as the result of oxidative couplings of **1** with the rearranged monomers **1F**$_2$ and **1F**$_3$, as illustrated in Scheme 1.

It is noteworthy that neither 3-methyl-1,5- nor 1,7-azulenequinone was isolated in the present autoxidation of **1** or **2** (Table 2). This is most likely due to lability of these unknown azulenequinones under the

reaction conditions presently employed (at 100 °C),[24] taking into account the melting points of e.g. parent 1,5- and 1,7-azulenequinones: both mp 100 °C decomp.[8d]

The detailed mechanistic consideration for the formation of other minor compounds is not made here because of the limited evidences at this stage with regard to the reaction pathways. Besides these isolated compounds described so far, considerable amounts (ca. 60%) of intractable resinous substances are accompanied also by the present autoxidation of **1** and **2** as was observed particularly in the case[3,4] of **4** (Table 2).

Nevertheless, it has now become apparent that the autoxidation of the alkylazulenes **1** and **2** is highly competitive involving oxidation of the nucleus and side chains (exclusively at C-1 position), substitutions, ring contraction, and other reactions such as rearrangement to naphthoquinones in a similar manner to the oxidation of the previously studied trialkylazulenes in many respects. However, depending upon the kinds and positions of alkyl substituents on the azulene nucleus, some significant differences in the reactivities between them were also observed as described above. Thus, although the exact mechanism is under further investigation in detail by employing azulene itself and other alkylazulenes under various reaction conditions, the present findings are believed to provide valuable information on autoxidation of azulenoid compounds.[24]

Experimental

Melting points were determined with a Yanagimoto MP-S3 instrument and are uncorrected. Column chromatography was performed with Wako C-300 silica-gel. TLC was conducted on plates precoated with silica-gel 60F-254 (0.25 mm, Merck) by using 15:85 AcOEt–hexane as eluant. HPLC was carried out with Hitachi gel #3011 packed in a Pyrex column (ϕ 5 mm, 500 mm length) with 1:9 hexane-MeOH as solvent.

UV and IR (both in $CHCl_3$ unless otherwise stated) spectra were taken on a Hitachi 323 spectrophotometer and a Nihonbunko IR-A-202 Grating spectrometer, respectively. NMR spectra were recorded in $CDCl_3$ (unless otherwise stated) with a JEOL-FX200 cryospectrometer (200-MHz for ^1H and 50-MHz for ^{13}C) at 27 °C. Chemical shifts are reported as δ values in parts per million rel to tetramethylsilane (δ 0.0) as the internal standard. The assignments of all signals were made by employing a first-order analysis with the aid of decoupling technique and the parameters were confirmed by a computer-assisted simulation analysis; those values for azulene derivatives are summarized in Table 1. Mass spectra were taken on a JEOL JMS-HX100 (with a JEOL JMA-DA5000 mass data system) high-resolution instrument and are given in terms of m/z (rel intensity) compared with the base peak.

Oxidation of 1-Methylazulene (1) in HMPA. A soln of **1**[25] (1.00 g) in freshly distilled HMPA (20 g) was placed in a Pyrex flask (ϕ 1.8 cm, 60 cm height) and subjected to autoxidation by allowing finely bubbling oxygen to pass through the soln (from the bottom of the flask) for 10 h at 100±5 °C. After cooling, the mitxture was diluted with water (200 cm^3) and extracted with ether (4×50 cm^3). The combined organic layers were washed with water, dried (Na_2SO_4), and evaporated in vacuo, giving a brown oil (0.96 g); the HPLC and TLC diagrams of this crude mixture are given in Fig. 1. This oil was preliminarily separated into five fractions by means of preparative HPLC with Hitachi gel #3019 (100 g) using methanol as eluant. Then each fraction was carefully separated by silica-gel column or thin layer with AcOEt-hexane; when necessary, this chromatographic procedure was repeated. Thus, the following 19 products were obtained as pure substances (**1A—I**), besides the reccovered starting material **1** (**1A**: 0.50 g; R_f=0.83; ^1H NMR, see Table 1) and polar resinous substances [0.30 g, 60% (w/w); R_f=0.0]. The yield of each product is based on the consumed starting material (0.50 g).

1,1′-Methylenebis[3-methylazulene][10] **(1B$_1$):** Dark blue prisms; 30 mg (6.0% yield); mp 79 °C (Ref. 10, 79—80 °C); R_f=0.76; UV 245 (log ε 4.65), 288 (4.83), 345 (sh, 4.23), 355 (4.29), 410 (sh, 2.80), 430 (sh, 2.70), 590 (sh, 2.70), 640 (sh, 2.80), and 652 nm (2.81); MS m/z 296 (M^+; 100), 281 (65), 265 (55), 252 (11), 239 (6), and 155 (24); ^1H NMR, see Table 1. (Found: m/z 296.1549).

1′,3-Dimethyl-1,2′-biazulene (1B$_2$): A yellow-green oil; 1 mg (0.2%); R_f=0.76; UV 245 (log ε 4.69), 251 (4.72), 257 (4.74), 263 (4.76), 272 (4.76), 301 (4.70), 315 (4.68), 350 (sh, 4.35), 410 (3.91), 580 (sh, 2.94), 634 (3.04), and 676 nm (sh, 3.02); MS m/z 282 (M^+; 100), 265 (26), and 252 (11); ^1H NMR, see Table 1.

Found: m/z 282.1446. Calcd for $C_{22}H_{18}$: M, 282.1409.

3,3′-Dimethyl-1,1′-biazulene (1B$_3$): Dark green paste; 2 mg (0.4%); R_f=0.76; MS m/z 282 (M^+; 100), 276 (5), 265 (31), 252 (20), 239 (7), 141 (13), 132 (9), 126 (8), and 119 (4); ^1H NMR, see Table 1.

Found: m/z 282.1421. Calcd for $C_{22}H_{18}$: M, 282.1409.

1,1′,1″-Methylidynetris[3-methylazulene] (1C): Dark blue prisms; mp 138 °C; 20 mg (4.0%); R_f=0.68; UV 245 (log ε 4.50), 280 (sh, 4.54), 290 (4.55), 349 (sh, 4.26), 358 (4.29), 370 (4.29), 596 (sh, 2.76), and 636 nm (2.80); MS m/z 436 (M^+; 100), 421 (41), 405 (13), 391 (12), 377 (5), 294 (25), 279 (80), 265 (23), 252 (10), 239 (5), 218 (8), 195 (7), 155 (13), 141 (10), 115 (7), 83 (4), 71 (6), 57 (9), and 43 (6); ^1H NMR, see Table 1; ^{13}C NMR 139.45, 137.06, 134.78, 133.44, 132.97, 132.74, 124.56, 120.88, 120.53, 35.21, and 12.73.

Found: m/z 436.2262. Calcd for $C_{34}H_{28}$: M, 436.2191.

Treatment of **1C** with an equivalent of triphenylmethylium tetrafluoroborate in dry acetonitril at 20 °C for 1 h gave the tetrafluoroborate (**6**) as dark blue-green crystals: mp>300 °C; UV 643 nm.

Triphenylcarbinol[11] **(1D$_1$):** Colorless prisms; 5 mg (1.0%); mp 163 °C (Ref. 11, 161—162 °C); R_f=0.49; MS m/z 260 (M^+; 100); ^1H NMR, identical with the spectrum of the authentic sample.

Benzaldehyde (1D$_2$): Colorless oil; 1 mg (0.2%); R_f= 0.49; MS m/z 106 (M^+; 100); ^1H NMR, identical with the spectrum of the authentic sample.

(1*Z*),(4*Z*)-1,5-Diphenyl-1,4-pentadien-3-one[12] **(1D$_3$):** Colorless prisms; 1 mg (0.2%); mp 103 °C (Ref. 12, 104—107 °C); R_f=0.49; MS m/z 234 (M^+; 100); ^1H NMR, identical with that of the authentic sample.

(*Z*)-1-Phenyl-1-buten-3-one[13] **(1E$_1$):** Colorless prisms; 5 mg (1.0%); mp 41 °C (Ref. 13, 39—41 °C); R_f=0.36; MS m/z 146 (M^+; 100); ^1H NMR, identical with that of the authentic sample.

3-Methyl-1-[(3-methyl-1-azulenyl)methyl]-4(3a*H*)-azulenone[20] **(1E$_2$):** Green prisms; 2 mg (0.4%); mp 143 °C; R_f=0.36; UV (MeOH) 243 (log ε 4.55), 285 (4.57), 340 (sh, 4.17), 351 (4.22), 380 (sh, 3.37), 430 (sh, 3.20), 580 (sh, 2.80), 600 (sh, 2.84), 626 (2.87), 650 (sh, 2.81), and 684 nm (sh, 2.80); MS *m/z* 312 (M^+; 4%), 297 (1), 279 (1), 265 (1), 252 (1), 170 (1), 155 (100), 141 (4), 128 (3), and 115 (3); IR (KBr) 1690 cm^{-1} (C=O); ^1H NMR, see Table 1.

Found: *m/z* 312.1575. Calcd for $C_{23}H_{20}O$: M, 312.1635.

1-Azulenecarbaldehyde[14] **(1F$_1$):** Red oil; 15 mg (3.0%); R_f=0.28; MS *m/z* 156 (M^+; 100); ^1H NMR, identical with the reported spectrum.[14]

2-Methyl-1,4-naphthoquinone[15] **(1F$_2$):** Pale yellow needles; 5 mg (1.0%); mp 105 °C (Ref. 15, 105—107 °C; R_f=0.28; MS *m/z* 172 (M^+; 100); ^1H NMR, identical with that of the authentic sample.

Compound 1F$_3$: Pale yellow oil; 1 mg (0.2%); R_f=0.28. This product, which was presumed to be hitherto unknown 3-methyl-1*H*-inden-1-one, gradually changed to Compound **1F$_4$**:[21] colorless oil; R_f=0.28; UV 242 (log ε 3.17), 255 (sh, 3.13), and 285 nm (sh, 2.82); IR 1730—1680 cm^{-1} (C=O); MS *m/z* 288 (M^+; 24%), 144 (100), and 116 (8).

Found: *m/z* 288.1169. Calcd for $C_{20}H_{16}O_2$: M, 288.1150.

3-Methyl-1-azulenecarbaldehyde[14] **(1G$_1$):** Dark violet needles; 10 mg (2.0%); mp 73 °C (Ref. 14, 73 °C); R_f=0.23; MS *m/z* 170 (M^+; 100); ^1H NMR, identical with the reported spectrum.[14]

Bis(3-methyl-1-azulenyl) Ketone (1G$_2$): Dark green prisms; 3 mg (0.6%); mp 163 °C; R_f=0.23; UV 242 (log ε 4.48), 280 (sh, 4.51), 295 (4.60), 315 (4.54), 327 (sh, 4.46), 422 (4.39), 566 (2.71), and 596 nm (sh, 2.65); MS *m/z* 310 (M^+; 100), 295 (63), 281 (12), 267 (27), 252 (27), 239 (6), 215 (2), 189 (2), 169 (13), 153 (11), 141 (34), 126 (11), 115 (40), 97 (9), 85 (11), 71 (18), 57 (30), and 43 (28); IR 1720 cm^{-1} (C=O); ^1H NMR, see Table 1.

Found: *m/z* 310.1354. Calcd for $C_{23}H_{18}O$: M, 310.1357.

2-Methyl-7-(3-methyl-1-azulenyl)-1,4-naphthoquinone (1G$_3$): Dark violet prisms; 5 mg (1.0%); mp 122 °C; R_f=0.23; UV (MeOH) 250 (log ε 4.37), 294 (4.34), 360 (sh, 3.44), 380 (sh, 3.43), and 500 nm (3.35); MS *m/z* 312 (M^+; 100), 295 (9), 239 (8), 215 (11), 165 (5), 141 (20), 118 (17), 108 (5), 97 (7), 83 (8), 69 (8), 55 (9), and 44 (16); IR 1655 cm^{-1} (C=O); ^1H NMR, see Table 1.

Found: *m/z* 312.1057. Calcd for $C_{22}H_{16}O_2$: M, 312.1150.

1-Methyl-3-(3-methyl-1,4-dioxo-5-naphthyl)azulene (1G$_4$): dark blue violet prisms; 5 mg (1.0%); mp 192 °C; R_f=0.23; UV 245 (sh, log ε 4.52), 251 (4.53), 257 (4.52), 263 (4.52), 290 (4.53), 340 (sh, 4.11), 375 (3.40), 590 (3.13), and 670 nm (sh, 3.00); MS *m/z* 312 (M^+; 100), 297 (61), 286 (11), 269 (4), 260 (1), 243 (2), 228 (2), 215 (4), 141 (2), 71 (1), and 57 (1); IR 1665 and 1660 cm^{-1} (C=O); ^1H NMR, see Table 1.

Found: *m/z* 312.1163. Calcd for $C_{22}H_{16}O_2$: M, 312.1150.

3-Methyl-5-(3-methyl-1-azulenyl)-1*H*-inden-1-one (1G$_5$): Dark brown prisms; 5 mg (1.0%); mp 80 °C; R_f=0.23; UV 246 (log ε 4.11), 299 (4.09), 306 (sh, 4.08), 353 (3.25), 458 (3.24), 620 (2.42), and 670 nm (sh, 2.34); MS *m/z* 284 (M^+; 100), 253 (5), 239 (18), 215 (7), and 141 (16); IR 1700 cm^{-1} (C=O); ^1H NMR, see Table 1.

Found: *m/z* 284.1208. Calcd for $C_{21}H_{16}O$: M, 284.1201.

1-Azulenecarboxylic Acid[16] **(1H$_1$):** Red needles; 5 mg (1.0%); mp 182 °C (Ref. 16, 181—182 °C); R_f=0.10; MS *m/z* 172 (M^+; 100); ^1H NMR, identical with the reported spectrum.[16]

3-Methyl-1-azulenecarboxylic Acid[17] **(1H$_2$):** Dark violet needles; 5 mg (1.0%); mp 196 °C (Ref. 17, 196 °C); R_f=0.10; MS *m/z* 186 (M^+; 100); ^1H NMR, identical with the reported spectrum.[17]

Cinnamic Acid[18] **(1I):** Colorless prisms; 1 mg (0.2%); mp 130 °C (Ref. 18, 132—133 °C); R_f=0.04; MS and ^1H NMR, identical with those of the authentic sample.

Autoxidation of 1 in DMF. The same oxidation procedure was employed, and virtually the same products were obtained as in the case of the oxidation in HMPA described above.

Oxidation of 1,3-Dimethylazulene (2) in HMPA. Autoxidation of **2**[25] (0.40 g) in HMPA (16 g) was carried out for 5 h at 100±5 °C in a manner similar to that described for **1**, thus affording, after the careful chromatographic separation, 11 products (**2A—I**; see Fig. 2 for HPLC and TLC), besides the recovered starting material **2** (**2A**, 0.25 g, R_f 0.83: ^1H NMR, see Table 1) and polar resinous substances [0.09 g, 60% (w/w); R_f 0.0]; the yield of each product is based on the consumed starting material (0.15 g).

1′,3,3′-Trimethyl-1,2′-biazulene (2B$_1$): Green prisms; 5 mg (3.3%); mp 78 °C; R_f=0.74; UV 245 (log ε 4.37), 277 (4.52), 300 (4.51), 310 (sh, 4.47), 355 (4.18), 436 (3.25), 572 (sh 2.62), 624 (2.67), and 680 nm (sh, 2.65); MS *m/z* 296 (M^+; 100), 281 (17), 279 (17), 265 (44), and 252 (8); ^1H NMR, see Table 1.

Found: *m/z* 296.1562. Calcd for $C_{23}H_{20}$: M, 296.1564.

1,1′-Methylenebis[3-methylazulene][10] **(2B$_2$):** Dark blue prisms; 5 mg (3.3%); mp 79 °C; R_f=0.74; MS and ^1H NMR, identical with those of **1B$_1$** obtained by the oxidation of **1** in HMPA or DMF as described above.

Benzaldehyde (2C): Colorless oil; 1 mg (0.7%); R_f=0.64; MS and ^1H NMR, identical with those of the authentic sample.

1,3-Dimethyl-5-azulenecarbaldehyde (2D): Yellow green oil; 1 mg (0.7%); R_f=0.56; UV 245 (log ε 4.03), 284 (sh, 4.09), 292 (4.13), 304 (sh, 4.12), 332 (sh, 3.74), 415 (3.42), 620 (2.76), and 672 nm (sh, 2.72); MS *m/z* 184 (M^+; 100), 169 (41), and 155 (19); IR 1690 cm^{-1} (C=O); ^1H NMR, see Table 1.

Found: *m/z* 184.0881. Calcd for $C_{13}H_{12}O$: M, 184.0888.

1,3-Dimethyl-1-indenol (2E): Colorless oil; 7 mg (4.7%); R_f=0.42; UV 248 (sh, log ε 4.17), 253 (4.18), 265 (sh, 4.12), 271 (sh, 4.08), 276 (sh, 4.06), 282 (sh, 4.04), and 294 nm (sh, 3.86); MS *m/z* 160 (M^+; 61%), 145 (100), 128 (12), 127 (12), and 115 (32); IR 3750—3100 cm^{-1} (OH); ^1H NMR 1.55 (3H, s, Me-1), 1.66 (1H, brs, HO-1), 2.02 (3H, d, $J_{2,Me(3)}$=1.5 Hz, Me-3), 5.92 (1H, q, H-2), 7.06 (1H, ddd, $J_{6,7}$=7.0 Hz, $J_{5,7}$=1.3 Hz, $J_{4,7}$=0.6 Hz, H-7), 7.12 (1H, ddd, $J_{5,6}$=7.2 Hz, $J_{4,5}$=7.0 Hz, H-5), 7.19 (1H, ddd, H-6), and 7.31 (1H, ddd, H-4).

Found: *m/z* 160.0885. Calcd for $C_{11}H_{12}O$: M, 160.0888.

3-Methyl-1-azulenecarbaldehyde[14] **(2F):** Dark violet needles; 30 mg (20%); R_f=0.19; MS and ^1H NMR, identical with the spectra of **1G$_1$** described above.

Compound 2G: Yellow crystals; R_f=0.14; UV 245 (sh, log ε 3.90), 255 (3.94), 360 (sh, 3.46), 378 (3.49), 398 (sh, 3.45), 430 (sh, 2.97), 460 (sh, 2.76), 496 (sh, 2.48), and 530 nm (sh, 2.13); MS *m/z* 160 (MS^+; 100), 131 (63), 104 (20), 103 (20), 78 (19), 77 (20), and 51 (20).

1-Hydroxy-1,3-dimethyl-1*H*-indene-4-, 5-, and 6-carbaldehyde (2H$_1$, 2H$_2$, and 2H$_3$): (as a ca. 1:2:1 mixture, respectively): Colorless oil; 3 mg (2.0%); R_f=0.10; MS *m/z* 188 (M^+; 100), 173 (89), 159 (50), 145 (59), 128 (22), 127 (22), and 115 (59); IR 3750—3150 (OH) and 1690 cm^{-1} (C=O); ^1H NMR (DMSO-d_6) **2H$_1$** δ= 1.41 (3H, s, Me-1), 2.27 (3H, d,

$J_{2,Me(3)}$=1.5 Hz, Me-3), 5.10 (1H, brs, HO-1), 6.20 (1H, q, H-2), 7.24 (1H, t, $J_{5,6}=J_{6,7}$=7.5 Hz, H-6), 7.51 (1H, dd, $J_{5,7}$=1.5 Hz, H-7), 7.69 (1H, dd, H-5), and 10.40 (1H, s, CHO-4), **2H**$_2\delta$=1.43 (3H, s, Me-1), 2.02 (3H, d, $J_{2,Me(3)}$=1.5 Hz, Me-3), 5.10 (1H, brs, OH-1), 6.17 (1H, q, H-2), 7.27 (1H, brd, $J_{6,7}$=8.0 Hz, H-7), 7.72 (1H, brd, $J_{4,6}$=1.5 Hz, H-4), 7.74 (1H, dd, H-6), and 9.88 (1H, s, CHO-5), and **2H**$_3\delta$=1.41 (3H, s, Me-1), 2.03 (3H, d, $J_{2,Me(3)}$=2.0 Hz, Me-3), 5.10 (1H, brs, HO-1), 6.04 (1H, q, H-2), 7.46 (1H, brd, $J_{4,5}$=8.0 Hz, H-4), 7.55 (1H, d, $J_{5,7}$=1.5 Hz, H-7), 7.61 (1H, dd, H-5), and 9.88 (1H, s, CHO-6).

Found (for the mixture of **2H**$_{1,3}$): *m/z* 188.0839. Calcd for $C_{12}H_{12}O_2$: M, 188.0837.

3-Methyl-1-azulenecarboxylic Acid[17] **(2I):** Dark violet needles; mp 196 °C (Ref. 17, 196 °C); 1 mg (0.7%); R_f=0.06; MS and ^{1}H NMR, identical with the spectra of **1H**$_2$ described above.

Autoxidation of 2 in DMF. The same procedures as those for **2** in HMPA were employed, and virtually the same products were obtained.

We wish to thank Professors Kahei Takase (Tohoku Univ.) and Ichiro Murata (Osaka Univ.) for valuable discussion.

Effect of Substituents on the Oxidation Potential of Phthalocyanines and Electrocrystallization

Yuji ORIHASHI, Michinori NISHIKAWA, Hiroyuki OHNO, Eishun TSUCHIDA,* Hiro MATSUDA,†

(Received May 14, 1987)

A series of tetra- or octasubstituted phthalocyaninatocobalt derivatives were prepared and their oxidation behaviors were examined in relation to the nature of substituents. The oxidation potentials of phthalocyanines, especially those of rings were affected by the nature of both substituents and axial ligands. These oxidation potentials were in a linear relation with the Hammett's constants for substituents or axial ligands. The electrocrystallization proceeded when an oxidation potential higher than that for the phthalocyanine ring was given to the solution. This potential shift was therefore revealed to be an important factor to control the electrocrystallization of these phthalocyanines.

Phthalocyanines are being widely used as dyes, catalysts, photocatalysts, major component for solar energy conversion systems, conductive materials, and so on. The redox processes of metallophthalocyanines have been well analyzed in detail,[1] because it is quite important to design geared redox cycles as well as models for biologically active metalloporphyrins. On the other hand, we have reported the preparation of inherently conductive crystals of metallophthalocyanine by way of the electrocrystallization technique.[2] The applied potential was revealed to have a considerable effect on the efficiency of the crystal growth.[2c] These experimental results triggered us to examine the relation between the structure and the oxidation potential of phthalocyanines to get the best conditions for the electrocrystallization. The redox reaction of phthalocyanine occurs both at the central metal ion and on the phthalocyanine ring. The redox processes of some unsubstituted phthalocyanines have clearly been identified by cyclic voltammetry, coulometry, UV/Visible spectroscopy, and ESR spectroscopy.[3,4] Indeed, two successive oxidations and four successive reductions of the ring have been reported.[3] Effects of solvent, chemical environment or axial ligand on the redox potentials of metallophthalocyanines have also been reported.[4] Substituents to the phthalocyanine ring are also expected to be effective for the shift of oxidation potential, but only a few examples have hitherto been reported, such as tetrasulfonated compounds.[1a,3]

The effects of substituents on the oxidation potential of the ring of phthalocyaninatocobalt derivatives were examined in this paper for the purpose of obtaining useful data with regard to electrocrystallization.

Experimental

Materials. Substituted phthalocyaninatocobalt(II) derivatives prepared in this study are summarized in Table 1.

Phthalocyaninatocobalt(II).[5] Phthalonitrile (29.0 g: 0.23 mol) and cobalt(II) acetate (12.0 g: 0.07 mol) were dissolved in 1000 ml of dehydrated methanol. 1,8-Diazabicyclo[5.4.0]-undec-7-ene (DBU) (38 ml) was added dropwise into the methanol solution under stirring at room temperature, then the solution was refluxed for 24 h. After cooling, the red-purple colored precipitate was filtered. The crude product was boiled in 10%-HCl then in 10%-NaOH aqueous solution, washed with water until the aqueous solution reached neutral. The washed precipitate was dried in vacuo. Ten grams of phthalocyaninatocobalt(II) was obtained with 30% yield. Calcd for $C_{32}H_{16}N_8Co$: C, 67.3; H, 2.8; N, 19.6; Co, 10.3%. Found: C, 68.1; H, 2.7; N, 20.0; Co, 9.1%.

Tetranitrophthalocyaninatocobalt(II).[6] **(a) 4-Nitrophthalonitrile:** A total of 30.0 g (0.16 mol) of 4-nitrophthalic anhydride and 84.0 g (1.40 mol) of urea was suspended in 500 ml of 1,2,4-trichlorobenzene, heated at 150 °C for 72 h under stirring. The precipitate was filtered and then washed with aqueous ammonia, yielding 16.6 g of 4-nitrophthalamide with 49.6% yield.

4-Nitrophthalamide (16.0 g: 0.08 mol) was suspended in 200 ml of dehydrated *N,N*-dimethylformamide. Trichloromethyl chloroformate (30 ml) was added dropwise to the solution under vigorous mixing at 5 °C, and kept under moderate stirring for 72 h. The solution was poured into 1000 ml of ice water, and then the phase-separated precipitate was filtered. A crude product was purified as light yellow needle with 73% yield by sublimation at 150 °C under

a) 
10^{-2} Torr (1 Torr=133.322 Pa). Mp 140 °C. IR (cm^{-1}) 2240 (C≡N).

(b) Tetranitrophthalocyaninatocobalt(II): A total of 8.6 g (0.04 mol) of 4-nitrophthalonitrile and 2.1 g (0.01 mol) of cobalt(II) acetate was dissolved in 300 ml of freshly distilled nitrobenzene and stirred at 150 °C for 24 h. The precipitate was filtered and washed with methanol. The crude product was washed with 10%-HCl then with 10%-NaOH as described above. Yield 20%. Calcd for $C_{32}H_{12}N_{12}O_8Co$: C, 51.1; H, 1.6; N, 22.4; Co, 7.8%. Found: C, 50.0; H,1.9; N, 21.6; Co, 8.1%. IR (cm^{-1}): 1530, 1340 (NO_2).

Tetraaminophthalocyaninatocobalt(II).[7] Tetranitrophthalocyaninatocobalt(II) (2.0 g: 2.7×10^{-4} mol) was mixed with sodium hydrogensulfide (1.5 g: 2.7×10^{-2} mol) in 100 ml of *N,N*-dimethylformamide at 100 °C for 5 h. After cooling, 6 M-NaOH (1M=1 mol dm^{-3}) was slowly added until the pH reached 10 to precipitate the product. A dark-blue product was filtered and washed with distilled water until the solution was completely neutralized. Yield 65%. Calcd for $C_{32}H_{20}N_{12}Co$: C, 60.9; H, 3.2; N, 26.6; Co, 9.3%. Found: C, 61.9; H, 3.0; N, 25.8; Co, 9.3%. IR (cm^{-1}): 3400, 3200, 1600(NH_2).

Tetracarboxyphthalocyaninatocobalt(II).[8] Trimellitic anhydride (20.0 g: 0.10 mol), urea (48.0 g: 0.80 mol), cobalt(II) acetate (6.9 g: 0.45 mol) and ammonium molybdate (0.20 g: 1.7×10^{-1} mol) were suspended in 300 ml of freshly distilled nitrobenzene, then the suspension was heated at 150 °C with stirring for 24 h. After cooling, the precipitate was filtered and washed with dehydrated methanol. Crude tetracarbamoylphthalocyaninatocobalt(II) (10.0 g) was obtained as a blue-purple precipitate. Then it was treated with 2 M-KOH aqueous solution under reflux. After the gas evolution ceased, 200 ml of pure water was further added, then filtered again. The filtrate was acidified to pH 2 with 6 M-HCl aqueous solution to precipitate the product. The precipitate thus obtained was washed with distilled water for several times. The product was dissolved in 500 ml of KOH aqueous solution (pH 10). The filtrate was again acidified to pH 2. This purification procedure was repeated three times. A red-purple product was obtained with 35% yield. Calcd for $C_{36}H_{16}N_8O_8Co$: C, 57.8; H, 2.1; N, 15.0; Co, 7.9%. Found: C, 56.0; H, 2.3; N, 14.6; Co, 8.3%. IR (cm^{-1}), 1720 (COOH).

Octacyanophthalocyaninatocobalt(II).[9] Tetracyanobenzene (6.0 g: 0.31 mol) and cobalt(II) acetate (0.74 g: 4.8×10^{-3} mol) were dissolved in 500 ml of *N,N*-dimethylformamide and heated at 150 °C for 2 h. The solution was slowly dropped into 2000 ml of diethyl ether under stirring, then the obtained precipitate was filtered and washed with dehydrated methanol. Yield 50%. Calcd for $C_{40}H_8N_{16}Co$: C, 62.3; H, 1.0; N, 29.1; Co, 7.6%. Found: C, 61.9; H, 1.2; N, 28.9; Co, 8.0%. IR (cm^{-1}): 2225 (C≡N).

Octacarboxyphthalocyaninatocobalt(II).[9] Octacyanophthalocyaninatocobalt(II) (0.5 g: 6.5×10^{-4} mol) was treated with KOH in ethylene glycol-water mixture (15/2 by vol) at 160 °C for 24 h. The reaction mixture was diluted with 100 ml of water and then filtered. The filtrate was acidified to pH 2 to precipitate the product. The blue product was filtered and purified by the same procedure as that for tetracarboxy derivative. Yield 50%. Calcd for $C_{36}H_{16}N_8O_{16}Co$: C, 49.4; H, 1.8; N, 12.8; 0, 29.3; Co, 6.7%. Found: C, 49.2; H, 1.7; N, 13.0; O, 29.2; Co, 6.7%. IR (cm^{-1}) 1700 (COOH).

Octamethylphthalocyaninatocobalt(II).[10] **(a) 1,2-Dibromo-4,5-dimethylbenzene:**[11] A few mg of iron powder and iodide were added to a cooled (5 °C) *o*-xylene (220 g: 2.06 mol). When the characteristic color for iodine disappeared, 660 g (4.1 mol) of bromine was added dropwise. When a half amount of bromine was added, 200 ml of dichloromethane was added to dilute the reaction medium. A residual amount of bromine was added slowly and the solution was maintained at 5 °C for 72 h. Dichloromethane (200 ml) was added and the excess bromine was neutralized with sodium bisulfite. An organic extract was washed with distilled water and dried over $MgSO_4$, evaporated to complete dryness. Recrystallization from hexane yielded white crystals with 40% yield. Mp 87.5—88 °C. ^1H NMR (CCl_4) δ=2.1 (s, 6H, $-CH_3$), 7.15 (s, 2H, arom).

(b) 1,2-Dicyano-4,5-dimethylbenzene: 1,2-Dibromo-4,5-dimethylbenzene (90.0 g: 0.34 mol) was heated under reflux for 5 h with CuCN (86.0 g: 0.96 mol) in 950 ml of *N,N*-dimethylformamide. After cooling, the reaction mixture was poured slowly into 1000 ml of aqueous ammonia and stirred for 12 h with air bubbling agitation. The blue solution was filtered and washed with distilled water until the filtrate was neutralized. The product was extracted with ether by Soxhlet extractor. Recrystallization from methanol yielded 24 g of white crystals. Yield 45%. Mp 117—117.5 °C. ^1H NMR ($CDCl_3$)δ=2.3 (s, 6H, $-CH_3$), 7.5 (s, 2H, arom).

(c) Octamethylphthalocyaninatocobalt(II): 1.2-Dicyano-4,5-dimethylbenzene (8.0 g: 0.05 mol) and cobalt(II) acetate (2.70 g: 0.02 mol) were heated under reflux for 24 h in 400 ml of ethylene glycol. After cooling, the blue-purple product was filtered and purified by treating with 1M-NaOH aqueous solution and then with 1M-HCl aqueous solution. Yield 30%. Calcd for $C_{40}H_{32}N_8Co$: C, 70.3; H, 4.7; N, 16.4; Co, 8.6%. Found: C, 70,3 ; H, 4.8 ; N, 15.9 ; Co, 9.0%.

Octamethoxyphthalocyaninatocobalt(II).[6] **(a) 1,2-Dibromo-4,5-dimethoxybenzene:** Veratrole (75.0 g: 0.54 mol) was dissolved in carbon tetrachloride (220 ml), then bromine (29 ml: 1.1 mol) was added dropwise into the solution at 0—5 °C. The mixed solution was stirred for 48 h. The reaction mixture was washed with 10%-NaOH aqueous solution and then with distilled water. The solvent was evaporated, and the obtained white product was recrystallized from chloroform. Yield 71%. Colorless plate crystals. Mp 81.5—82 °C. ^1H NMR (d_6-acetone)δ=3.9 (s, 6H, OCH_3), 7.0 (s, 2H, arom).

(b) 1,2-Dicyano-4,5-dimethoxybenzene: The reaction conditions were very close to those for 1,2-dicyano-4,5-dimethylbenzene. A mixture of 1,2-dibromo-4,5-dimethoxybenzene (15.8 g: 0.05 mol) and CuCN (13.4 g: 0.15 mol) was heated under reflux for 5 h in 200 ml of *N,N*-dimethylformamide. The follow-up procedure was the same as that for 1,2-dicyano-4,5-dimethylbenzene described above. Recrystallization from methanol yielded 6.0 g of white needles. Yield 64%. Mp 180—180.5 °C. ^1H NMR ($CDCl_3$) δ=3.9 (s, 6H, OCH_3), 7.1 (s, 2H, arom).

(c) Octamethoxyphthalocyaninatocobalt(II): 1,2-Dicyano-4,5-dimethoxybenzene (2.60 g: 1.5×10^{-2} mol) and cobalt(II) acetate (0.80 g: 4.5×10^{-3} mol) were mixed in 100 ml of ethylene glycol and refluxed for 24 h. The reaction mixture was cooled and filtered, then washed with methanol. The purification procedure with 1M-NaOH and 1M-HCl aqueous solution was the same as described above. Calcd for $C_{40}H_{32}N_8O_8Co$: C, 59.2; H, 3.9; N, 13.8; O, 15.8; Co, 7.3%. Found: C, 58.6; H, 4.0; N, 13.4; 0, 16.0; Co, 8.0%.

Potassium (dicyanophthalocyaninato)cobaltate(III).[12] As tetra- or octasubstituted (dicyanophthalocyaninato)cobaltate(III) derivatives were synthesized and purified with the same procedure, a representative method is mentioned here.

Procedure (a): Phthalocyaninatocobalt(II) (2.1 g: 3.7×10^{-3} mol) was suspended in 70 ml of nitrobenzene with thionyl chloride (14 ml: 0.2 mol) and heated at 60 °C for 6 h. After cooling, the mixture was filtered and washed with dehydrated methanol. Dichlorophthalocyaninatocobalt(III) obtained as a brown precipitate,[13] was dried in vacuo. Yield 76%. Calcd for $C_{32}H_{16}N_8Cl_2$: C, 59.8; H, 2.5; N, 17.5; Co, 9.2; Cl, 11.1%. Found: C, 58.7; H, 2.6; N, 17.1; Co, 10.3; Cl, 11.3%.

Dichlorophthalocyaninatocobalt(III) (3.80 g: 6.0×10^{-3} mol) and KCN (5.85 g: 9.0×10^{-3} mol) were mixed in 200 ml of ethanol and was heated under reflux for 72 h. The blue-purple product was filtered and washed with cold water. The product was placed in a thimble of Soxhlet extractor and extracted with dehydrated acetone for 72 h. The extract was evaporated and the product was recrystallized from dehydrated acetone to yield purple crystals with 78% of yield.

Procedure (b): Phthalocyaninatocobalt(II) (3.4 g: 6×10^{-3} mol) was mixed with KCN (7.5 g: 0.12 mol) in 350 ml of ethanol and heated for 72 h. After cooling, the product was filtered and washed with cold water. The purification procedure was the same as that for procedure (a). Yield 50%. Calcd for $C_{34}H_{16}N_{10}CoK$: C, 61.6; H, 2.4; N, 21.1; Co, 8.9; K, 5.9%. Found: C, 61.8; H, 3.0; N,20.5; Co, 8.7; K, 5.9%. IR (cm^{-1}) 2130 (C≡N).

Potassium (dithiocyanatophthalocyaninato)cobaltate(III). Dichlorophthalocyaninatocobalt(III) (1.65 g: 2.6×10^{-3} mol) was suspended in 200 ml of dehydrated ethanol with KSCN (0.75 g: 7.7×10^{-3} mol) for 6 h. After cooling, the blue-purple product was filtered and washed with cold water. The product was purified with the same procedure as that for potassium (dicyanophthalocyaninato)cobaltate(III). Yield 82%. Calcd for $C_{34}H_{16}N_{10}S_2K$: C, 56.2; H 2.2; N, 19.3; S, 8.8; Co, 8.1; K, 5.4%. Found: C, 56.4; H, 2.1; N, 19.4; S, 8.3; K, 5.6%. IR (cm^{-1}) 2100 (C≡N).

Cyclic Voltammetry. Cyclic voltammograms were obtained with a Pt plate electrode coated with phthalocyaninatocobalt(II) derivatives in an acetonitrile solution containing 0.1 M tetraethylammonium chloride (TEAC). In case of soluble potassium [dicyano(or dithiocyanato)phthalocyaninato]cobaltate(III) derivatives, a Pt wire was used as working electrode in an acetonitrile solution of phthalocyanine. Cyclic voltammetry was carried out with a Hokuto Denko HA-501G potentiostat and a Hokuto Denko HB-105 function generator, at a scan rate of 50 mV s^{-1}.

Spectroscopies. IR spectra were obtained with Hitachi 260-30. ESR spectra were obtained with JES-FE-3X, Nippon Denshi Co. Ltd. UV/Visible spectra were obtained with Varian Cary 17D. Details of the spectroscopic measurements were mentioned in previous papers.[2]

Results and Discussion

I) Oxidation Behaviors of Substituted Phthalocyanine Derivatives. The oxidation potentials of metallophthalocyanines have been reported by Lexa et al.,[14] and Wolberg et al.[15] They measured the oxidation potentials of metallophthalocyanines in *N,N*-dimethylformamide or 1-chloronaphthalene by cyclic voltammetry. The oxidation potential of the phthalocyanine ring was about 1.0 V vs. SCE. The oxidation potential of 0.9 V vs. Ag-AgCl in acetonitrile was obtained in our measurements, this result seemed reasonable comparing with the data in Table 2. The oxidation or reduction of the phthalocyanine ring directly reflects the electrostatic interaction between the ring and metal.[3] For OTi(IV), OV(IV), Ni(II), Cu(II), or Zn(II) complexes, the central metal ions do not show its oxidation until the phthalocyanine ring was oxidized. On the other hand, Fe(II) and Co(II) derivatives showed the ring oxidation at oxidation potentials after the oxidation of central metal ions and the reduction was also followed by the reduction of metal.[1a,14-17] In the potential range from 0 to +2.0 V (vs. Ag-AgCl) the oxidation between Co(II)/Co(III) occurred, but the oxidation processes for the phthalocyanine ring and metal were clearly distinguished with each other.

Only a few redox processes for octasubstituted phthalocyanine have hitherto been reported. Redox processes for octa-*t*-butyl-[18] and octacyanophthalocyaninatozinc(II)[19] have been reported, and the latter showed reversible four step one-electron redox reac-

tions. The oxidation potentials of the phthalocyanine ring we measured are summarized in Table 3, and some of the cyclic voltammograms are shown in Fig. 1. Electron-withdrawing groups, such as cyano and carboxyl groups were expected to reduce the negative charge on the phthalocyanine ring. On the contrary, electron-donating groups, such as methoxyl and methyl groups were expected to increase it. Octacyano derivative showed the oxidation peak of the ring at +1.80 V and octacarboxy derivative at +1.65 V, as expected. On the contrary, methoxyl groups shifted it negatively by 0.13 V as shown in Table 3. The oxidation potential of octasubstituted derivatives was in the order of the following substituents;

$$-CN > -COOH > -H > -OCH_3 > -CH_3. \quad (1)$$

A good linear relation between the oxidation potential and the Hammett's constant for benzene derivatives[20] is observed as shown in Fig. 2. This suggests that the Hammett's constant for benzene derivatives is effective for the estimation of the oxidation potential of substituted phthalocyanine derivatives. The oxidation potential (E_{ox}) was expressed as a function of the

Hammett's constant (K) as shown in Eq. 2.

$$E_{ox} = 1.30\,K + 0.96 \quad (2)$$

This relationship should be useful not only for the estimation of a suitable potential for electrocrystallization as described later but also for the regulation of oxidation potential of phthalocyanines for the design of some catalytic systems.

For tetrasubstituted derivatives, the substituents also affect the oxidation potential just as the octasubstituted derivatives do. Though the redox processes of tetrasubstituted phthalocyanines such as tetra-*t*-butyl-, tetrasulfo-, and tetrakis(dodecanesulfonylamino)phthalocyanine have also been reported,[1a,3,21] the effects of substituent on the oxidation have not been summarized yet. The oxidation potentials of tetrasubstituted phthalocyaninatocobalt(II) derivatives were measured with cyclic voltammetry (Fig. 3), and are

summarized in Table 4. The solvents are weak donors, but the solvent coordination does not perturb strongly the oxidation as summarized in Table 5. Tetranitro and tetracarboxy derivatives showed positive oxidation potentials than unsubstituted phthalocyaninatocobalt(II) as expected from the results for octasubstituted ones. For tetrasubstituted derivatives, nitro groups shifted its oxidation potential to more positive side by 0.40 V, and carboxyl groups by 0.34 V. It was found as well that tetramethoxy and tetraamino derivatives which showed their oxidation peak at +0.73 V and +0.72 V, respectively, which is smaller than it for unsubstituted one. The oxidation potential for tetrasubstituted compound was shifted by their substituents as the following order;

$$-NO_2 > -COOH > -H > -OCH_3 > -NH_2. \quad (3)$$

This sequence was also characterized by the Hammett's constant. The relation between the oxidation potential of tetrasubstituted phthalocyaninatocobalt(II) and the Hammett's constant for benzene derivatives is shown in Fig. 4. It is a similar relationship to that for octasubstituted ones as shown in Fig. 2. This also delivers the following equation:

$$E_{ox} = 0.59\,K + 0.88 \quad (4)$$

The potentials of tetra-*t*-butyl- and tetrasulfophthalocyaninatocobalt(II) which have been measured in dichlorobenzene and *N,N*-dimethylformamide, respectively,[3,22] are also shown in Table 5. These data also lied on this relation as shown in Fig. 4. As mentioned above, the oxidation potentials of substituted metallophthalocyanine have not been investigated substantially. For the potentials of substituted derivatives examined here, a good linear relationship between the oxidation potential and the Hammett's constant of substituent was firstly found for both tetra- and octasubstituted complexes. In our experimental data a potential shift as much as about 1.0 V is noted, though it has been reported that the redox potential shift was generally seen within 100 mV by substituent such as chloro, methyl, *t*-butyl, sulfo, and carboxyl group.[3]

The oxidation potentials of potassium dicyano derivatives were also analyzed by cyclic voltammetry. The results are summarized in Table 6. The relation between the oxidation potential and the Hammett's constant of substituent which was found for octa- and tetrasubstituted derivatives was also available for these compounds. A similar linear relationship should be observed as long as the compounds had the same axial ligands.

II) Effect of Axial Ligand on the Oxidation Behavior Effects of axial ligand on the oxidation potentials of metallophthalocyanine have been reported widely by Lever et al.,[1e,3,23] and Dolphin et al.,[24] through the analyses in several coordinating solvents. The effects of coordinating solvents on the oxidations are recognized for the strength of σ-donor ability of solvent, which means the occurrence of π-back donation. The stronger the σ-donor ability of solvent, the lower the potential shifts. The oxidations at the central metal ion are considered to be affected similarly, for example when strong σ-donor solvents bind to the Co(II) or Fe(II) complex, electrons in dz^2 orbital of metal are destabilized and the oxidation of metal (d^6-d^7) should occur more easily. The potential shift and the strength of σ-donor ability of solvent are the following.

$$\text{DMAc} = \text{DMF} > \text{DMSO} > \text{pyridine (redox potential)} \quad (5)$$

$$\text{DMAc} = \text{DMF} < \text{DMSO} < \text{pyridine } (\sigma\text{-donor ability}) \quad (6)$$

For these solvent systems, relation between the Gutmann Donicity Number[25] of solvent and the oxidation potential is depicted as linear.[26] For the reduction of Co(II)/Co(I) system, the same tendency was observed.[26] But contrary to these results, the potential is more positive with the strength of σ-donor ability for Fe(III)/Fe(II) system. This seemed to be the reason that the π-back donation in d^6 state (Fe(II)) was stronger than that in d^5 state (Fe(III)) by higher charge density in metal ion.[26]

Similar effects are expected for the phthalocyanine complexes which have the same two axial ligands, such as CN^- or SCN^-. With CN^- which is an electron-withdrawing group bound to metallophthalocyanine, the oxidation potential of the ring shifted to more positive side than that for uncoordinated complex. Furthermore, the CN^- coordinated derivative gave more positive oxidation potential than the SCN^- coordinated one as shown in Fig. 5. This is because CN^- withdraws electrons more strongly than SCN^-. For these phthalocyanine compounds, only one axial ligand can be replaced, for example to pyridine. It has been found that the stronger σ-donor axial ligand shifts the CN band to lower frequency in the IR spectrum.[12,27] This is one of the proofs that σ-donor ability of axial ligand affects the oxidations.

III) Effect of Central Metal Ion on the Oxidation Potentials of Substituted Metallophthalocyanines. We prepared tetracarboxyphthalocyaninatoiron(II) and that of copper(II). Their oxidation potentials of the phthalocyanine ring were +1.26 and +1.22 V vs. Ag-AgCl, respectively. Fe, Co, or Cu was introduced into tetracarboxy derivatives as central metal ion, the sequence of the oxidation potential (Fe> Co> Cu) was the same as that for unsubstituted metallophthalocyanines. This suggests that though an interaction between the central metal ion and the phthalocyanine ring did affect the oxidation potential, its magnitude was much less than that of the effect of substitution on rings. The relation between the metal and the oxidation potential of the ring might be explained as follows. The increase in the number of d-electrons of transition metal shifted the oxidation potential to a lower side, suggesting a strong coordination of nitrogen atoms in the ring to metal ion. When the $3dx^2$-y^2 orbital was empty as for Fe(II) and Co(II) complexes, this coordination bond should accommodate the oxidation of the ring. On the other hand, when the $3dx^2$-y^2 orbital was filled as for Cu(II) complex, charges on the metal made it easier to ionize the ring, i.e., oxidize.[15] This could be the main reason for the unusual oxidation potential of phthalocyaninatocopper(II).

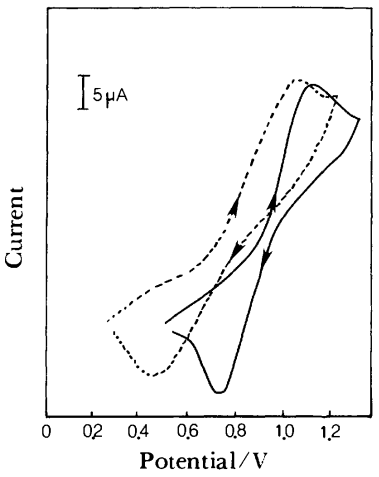

Fig. 5. Cyclic voltammograms for $K^+[PcCo(X)_2]^-$ in acetonitrile solution. Scan rate: 50 mV s^{-1}. X= CN: (——), X=SCN: (----). The electrode potential was measured vs. Ag-AgCl.

IV) Control of Electrocrystallization with Applied Potential. Electrocrystallization was carried out for potassium (substituted dicyanophthalocyaninato)cobaltate(III) in acetonitrile. A cell construction has already been shown elsewhere.[2b] It was found that electrocrystallization occurred when the solution was stored under the oxidative moiety of the phthalocyanine ring in the case of cyanophthalocyaninatocobalt(III).[2] The relation between the yield of crystals and applied potential for substituted phthalocyanine was shown in Fig. 6. Not all phthalocyanine derivatives could be crystallized in electric field because of the presence of structural isomers for tetrasubstituted derivatives. Even though, those were crystallized when the solution was stored under the oxidative moiety of the ring. It was clear that the drastic decrease in the solubility of phthalocyanines through the oxidation of phthalocyanine rings was the essential factor for the electrocrystallization. The difference in the crystal yield as shown in Fig. 6 is therefore attributed to the difference in the solubility of oxidized compounds. Though cyanophthalocyaninatocobalt(III) obtained

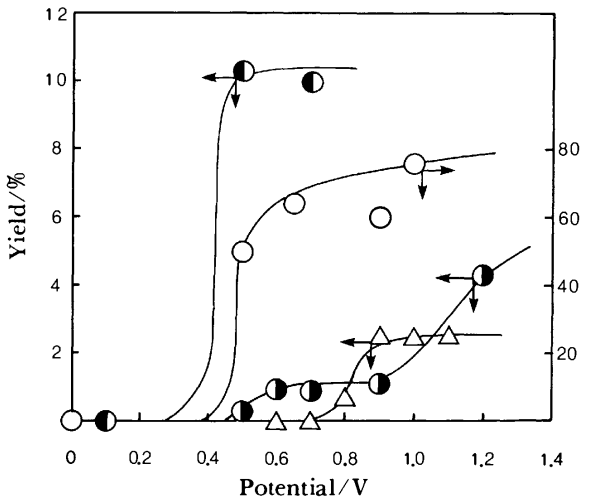

Fig. 6. Relation between the yield of crystals and the applied potential for electrocrystallization of substituted phthalocyanines.
○: Cyanophthalocyaninatocobalt(III), ◑: octamethyl-substituted derivative, ◐: octamethoxy-substituted derivative, △: thiocyanatophthalocyaninatocobalt(III).

through electrocrystallization was insoluble in organic solvents, introducing substituents to phthalocyanine ring probably made the solubility higher. For this reason, the crystals were partially soluble in the solution which made the yield low. The lower yield for the system having thiocyanato group as axial ligand could also be explained in terms of this. There are four structural isomers in the case of tetrasubstituted derivatives. They are generally more soluble than octasubstituted ones owing to the decrease of symmetry (except the increased solubility by the nature of functional group). But it is clear that the existence of isomers is a negative factor for electrocrystallization. Octasubstituted derivatives gave better results on electrocrystallization. The mechanism of electrocrystallization seemed therefore to be as follows.

$$\text{anode} \quad [Pc^{2-}Co^{3+}(CN)_2]^- \xrightarrow{-e} [Pc^{1-}Co^{3+}(CN)_2] \longrightarrow Pc^{2-}Co^{3+}CN + \cdot CN$$

$$\text{cathode} \quad K^+ \xrightarrow{+e} K$$

At first, $[Pc^{2-}Co^{3+}(CN)_2]^-$ anion was oxidized at the anode surface to produce $[Pc^{1-}Co^{3+}(CN)_2]$. This complex seemed to be unstable, and it immediately changed to $[Pc^{2-}Co^{3+}CN]$, and the CN radical changed to $(CN)_2$. On the other hand, metallic potassium deposited on the cathode. As crystal growth was observed only on the anode surface, this oxidation should occur on the crystal surface through the electron-transfer reaction in the crystals. However, stable phthalocyaninatocobalt(III) radical complexes such as $Pc^{1-}Co^{3+}Cl_2$ and $Pc^{1-}Co^{3+}Br_2$ were reported,[14] and no $Pc^{1-}Co^{3+}(CN)_2$ was obtained when $K^+[PcCo(CN)_2]^-$ was prepared from $Pc^{1-}Co^{3+}Cl_2$. This suggests strongly that $[Pc^{1-}Co^{3+}(CN)_2]$ should be unstable. Though $(CN)_2$ have not been detected yet, the mechanism described above is considered reasonable. The molecular arrangements and conductivities of crystals will be reported elsewhere.

Conclusion

A series of tetra- or octasubstituted phthalocyaninatocobalt(II) were synthesized, and the effect of substituent group on the oxidation was examined in terms of the Hammett's constant. A linear relationship between the oxidation potential of the ring and the Hammett's constant of substituent was confirmed for all cases of tetra-, octasubstituted derivatives and even for derivatives with different axial ligands. Electrocrystallization of phthalocyanine derivatives was initiated by the oxidation of the phthalocyanine ring, that was suggested from the effect of applied potential on the crystal yield for a series of substituted phthalocyanines.

Oxidation of $(CD_3)_2\dot{C}X$ Radicals. I. Reaction of Propane and Isopropyl Radicals with Atomic Oxygen

Nobuaki WASHIDA
Division of Atmospheric Environment, The National Institute for Environmental Studies,
P.O. Tsukuba-gakuen, Ibaraki 305
(Received April 10, 1987)

The reaction of oxygen atoms with propane-1,1,1,3,3,3-d_6, $(CD_3)_2CH_2$, in a fast-flow system was studied with a photoionization mass spectrometer. Isopropyl-d_6 radicals, $(CD_3)_2\dot{C}H$, formed by the initial hydrogen abstraction at the 2-position were detected directly.

$$(CD_3)_2CH_2 + O(^3P) \rightarrow (CD_3)_2\dot{C}H + OH \quad (3)$$

The subsequent reaction of $(CD_3)_2\dot{C}H$ radicals with atomic oxygen proceeds by both an deuterium abstraction (61%) and an oxygen addition reaction (39%). The product in the deuterium abstraction was CD_2CHCD_3 and those in the oxygen addition were $(CD_3)_2CO$ (18%) and CD_3CHO (21%).

$$(CD_3)_2\dot{C}H + O(^3P) \rightarrow \begin{cases} CD_2CHCD_3 + OD & (4a) \\ (CD_3)_2CO + H & (4b) \\ CD_3CHO + CD_3 & (4c) \end{cases}$$

Competition experiments show that $(CD_3)_2\dot{C}H$ radicals react (0.029 ± 0.004) times as fast with O_2 as with $O(^3P)$. In the presence of an excess of O_2, CD_2CHCD_3 was observed in decreased yield (20%) and $(CD_3)_2CO$ and CD_3CHO increased to 32 and 44%, respectively. The rate data for Reaction 3 were fitted by an Arrhenius expression:

$$k_3 = (2.0^{+1.0}_{-0.7}) \times 10^{-10} \exp[-(6086 \pm 392 \text{ cal mol}^{-1})/RT]^{\dagger}$$

$cm^3 molecule^{-1} s^{-1}$ (381—627 K). The rate constant of Reaction 3 obtained from the yields of products was 7.9×10^{-15} $cm^3 molecule^{-1} s^{-1}$ at 298K.

Reaction of alkyl radicals with atomic oxygen, $O(^3P)$, has been investigated for t-C_4H_9[1] and *cyclo*-C_6H_{11}[2] using the technique of discharge-flow-photoionization mass spectrometry. In the case of t-C_4H_9, it has been suggested[1] that the reaction of $O(^3P)$ with t-C_4H_9 is very fast, and that the large rate constant was explained by the hydrogen abstraction from nine equivalent hydrogen atoms in the t-C_4H_9 radical (formation of isobutene was 80% of the total reaction). Formation of acetone (20%) by the addition of an oxygen atom to the radical was observed as an alternative channel. Similar results have been obtained in the reaction of *cyclo*-$C_6H_{11}+O(^3P)$.[2] Formation of the two types of products (olefins by hydrogen abstraction and aldehydes or ketones by the oxygen addition reaction) has also been reported in reactions of C_3H_7+O,[3,4] t-C_4H_9+O,[4-6] and *neo*-$C_5H_{11}+O$,[6] although Hoyerman and Sievert[7] reported no formation of olefins.

The primary attack of ground state $O(^3P)$ atoms to propane is expected to be hydrogen abstraction producing a propyl radical:

$$O(^3P) + C_3H_8 \rightarrow C_3H_7 + OH \quad (1)$$

Propyl radicals should react with oxygen atoms very rapidly and produce several products:

$$C_3H_7 + O(^3P) \rightarrow \text{Products} \quad (2)$$

In the discharge-flow experiments reported previously,[3,4] the formation of CH_3CHO, $(CH_3)_2CO$, C_3H_6, C_2H_5CHO, C_2H_6, C_2H_4, CH_2O, CH_4, CO_2, H_2O, and H_2 (including both primary and secondary products) has been reported.

In the previous $O+C_3H_8$ studies, however, it was not clear whether propyl or isopropyl radicals (or both) were produced by Reaction 1. Also it was not possible to clarify the reaction mechanism of the $O(^3P)+C_3H_7$ reaction. In the present study, the reaction of oxygen atoms with propane-1,1,1,3,3,3-d_6, $(CD_3)_2CH_2$, is studied by using a photoionization mass spectrometer[8,9] coupled with a fast-flow reactor. In this case the primary attack of O atoms can be identified by measuring the mass number of the propyl radicals produced. Subsequent reactions of propyl radicals with atomic and molecular oxygen are then analyzed.

Experimental

A schematic diagram of a fast-flow reactor and a photoionization mass spectrometer is shown in Fig. 1. Most of the components are as described previously[10-12] except for two improvements; 1) three diffusion pumps (10, 4, and 6 inches in diameter for A, B, and C, respectively) with liquid nitrogen traps were used to evacuate the ionization chamber, the quadrupole mass filter, and the detector region; 2) a 0.4 mm (in diameter) Pyrex orifice was used to sample the gases into the ionization region. About 5×10^4 counts s^{-1} of signal was obtained for 1 mTorr NO(1 Torr=133.322 Pa) in the flow reactor when it was ionized by a Kr lamp having a MgF_2 window.

Oxygen atoms were generated by a microwave discharge in a helium-oxygen mixture (0.05—2% in helium), and their concentration was determined by titration with NO_2 according to the reaction $O+NO_2 \rightarrow NO+O_2$. Then known partial

†1 cal=4.184 J.

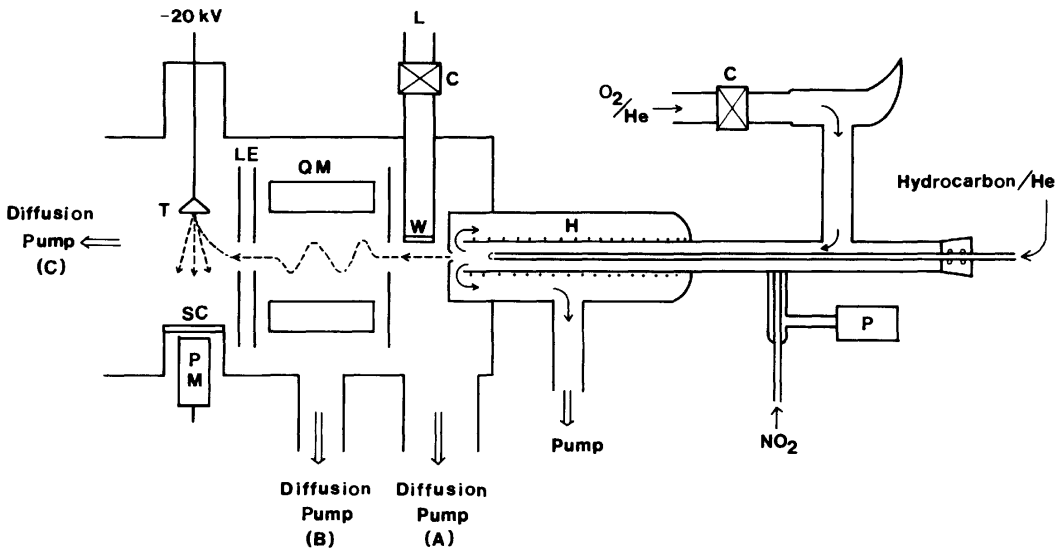

Fig. 1. Schematic diagram of the apparatus; C, microwave cavity; P, MKS Baratron pressure gauge; H, coiled Nichrome wire heater; L, VUV lamp; W, window; QM, quadrupole mass filter; LE, lens; T, Al coated Stainless steel target; SC, Al coated plastic scintillator; PM, photomultiplier.

pressures of NO were added to calibrate the instrument sensitivity. Propane-1,1,1,3,3,3-d_6, $(CD_3)_2CH_2$, was diluted in helium (about 10% in helium) and entered the main flow through a movable inlet with six small radially directed holes. Total and partial pressures of gases were measured by a capacitance manometer (MKS Baratron 170M-35). These pressures were converted to concentrations by using a separate calibration of the flow as a function of pressure and temperature. The linear flow velocity measured with a bubble meter was 16.5 m s^{-1} at 2 Torr, 19.9 m s^{-1} at 4 Torr, and 21.4 m s^{-1} at 6 Torr at 298K. The various photoionization lamps used to ionize radicals and molecules were powered by a microwave discharge. Most of the measurements were done at room temperature, 298±3K. Some experiments were carried out at high temperature, 420—630K. The reaction zone was heated with a coiled Nichrome wire heater. Temperature was measured with a pair of Alumel Chromel thermocouples suspended in the central reactant-inlet tube. Temperature uniformity was ±2K.

The gases O_2 (Nippon Sanso, 99.99%), He (Nippon Sanso, 99.9999%), NO (Matheson, 99.0%), NO_2 (Matheson, 99.5%) were used without further purification. The propane-1,1,1,3,3,3-d_6, $(CD_3)_2CH_2$, (98%) was from Merck Sharp & Dohme. Part of the $(CD_3)_2CH_2$ used was synthesized[13] in this laboratory from $(CD_3)_2CO$. Both $(CD_3)_2CH_2$ from Merck Sharp & Dohme and the synthesized material contained 1—2% of olefins (mostly CD_2CHCD_3). These were removed by passing the sample through a solution of $KMnO_4$ and drying on a column of $CaCl_2$. After this purification, the CD_2CHCD_3 contained in the $(CD_3)_2CH_2$ was less than 0.005%. Oxygen-18($^{36}O_2$ about 20%) from Merk Sharp & Dohme was analyzed by the mass spectrometer, and the $^{36}O_2$ content was determined to be 19.2±0.7%. All measurements were done under the condition $[O] > 0.5[(CD_3)_2CH_2]$.[14]

Results

A. Radicals and Molecules Detected in the Reaction of $(CD_3)_2CH_2+O(^3P)$. Preliminarily, the measurement of radicals and molecules produced in the reaction of C_3H_8+O was investigated. A signal at $m/z=43$ was detected by using a Xe resonance lamp with a sapphire window (8.44 eV) as a photoionization light source. When a Kr lamp with a CaF_2 window (10.03 eV) was used, signal at $m/z=42$ and 58 were also observed. The signal at $m/z=44$ was observed in addition to the above signals when a Kr lamp with a MgF_2 window (10.03 and 10.64 eV) was used. Mass spectra of these signals are shown in Fig. 2. Ionization potentials together with values of heats of formation for possible radicals and molecules are listed in Table 1. The signal at $m/z=43$ shown in Fig. 2c should be from C_3H_7 radicals produced in the reaction of C_3H_8+O.[29] However, it was not possible to identify the radical as either an *n*-propyl or an isopropyl radical. The signal at $m/z=42$ might be from C_3H_6 and/or CH_2CO and at $m/z=58$ from $(CH_3)_2CO$ and/or C_2H_5CHO produced by the reaction of propyl radicals with the excess of oxygen atoms.[29] The signal at $m/z=44$ shown in Fig. 2a should be from CH_3CHO.[29] In addition to the signals shown in Fig. 2, signals for CH_3 (Kr lamp), C_2H_4 (Ar lamp), and CH_2O (Ar lamp) were observed at $m/z=15$, 28, and 30, respectively. Although the radicals and molecules were observed as expected, the kinetic analysis of the reaction is not possible because of the failure to determine the branching ratio for the formation of *n*-propyl and isopropyl radicals.

Isopropyl-d_6 radicals, $(CD_3)_2\dot{C}H$ were observed at $m/z=49$ when oxygen atoms reacted with propane-1,1,1,3,3,3-d_6, $(CD_3)_2CH_2$. The radical was detected by using a Xe resonance lamp with a sapphire window (8.44 eV). The mass spectra are shown in Fig. 3. No significant signal of propyl-1,1,3,3,3-d_5 radicals, $\cdot CD_2CH_2CD_3$, was observed at $m/z=48$. Other prod-

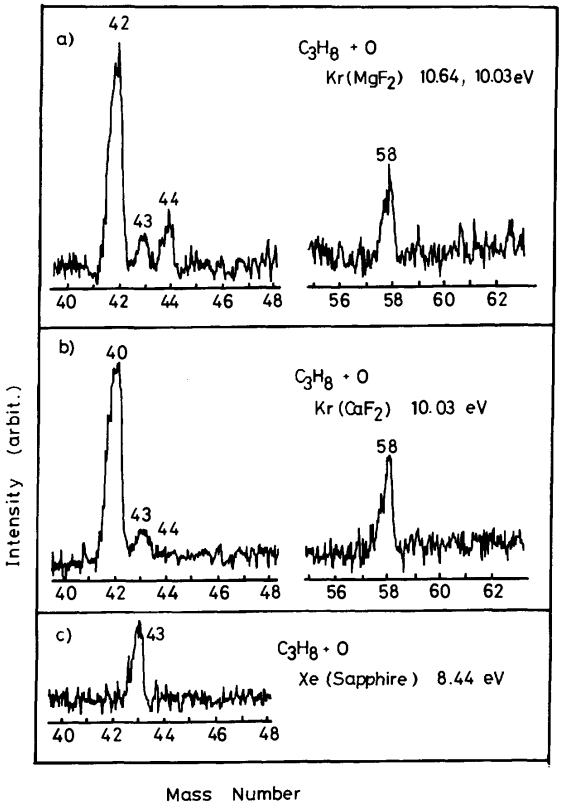

Fig. 2. Mass spectra of the reaction products produced in O+C_3H_8. Kr lamps having a MgF_2 window (10.64 and 10.03 eV) and a CaF_2 window (10.03 eV), and a Xe lamp having a sapphire window (8.44 eV) were used. The conditions: $[O]_0$= 3.6 mTorr; $[C_3H_8]_0$=1.4 mTorr; reaction time 4.5 ms; total pressure 4.3 Torr.

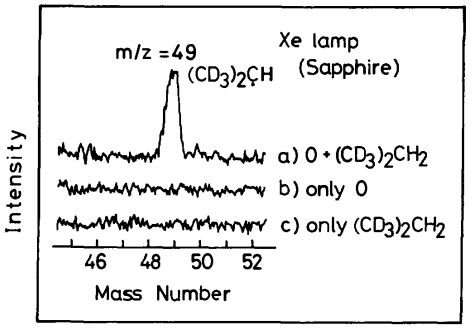

Fig. 3. Mass spectra of the $(CD_3)_2\dot{C}H$ radical produced in O+$(CD_3)_2CH_2$. A Xe lamp with a sapphire window (8.44 eV) was used for the photoionization. The conditions: partial pressure (mTorr), $[O]_0$=3.7, $[(CD_3)_2CH_2]$=1.5; reaction time=4.5 ms; total pressure=4.3 Torr.

ucts produced by subsequent reactions and the parent molecule were not photoionized by this lamp.

$$(CD_3)_2CH_2 + O(^3P) \rightarrow (CD_3)_2\dot{C}H\ (m/z=49) + OH \quad (3)$$

From the ratio of the signal at m/z=49 to the back ground noise at m/z=48, it was concluded that more than 95% of the total reaction of $(CD_3)_2CH_2$+O forms $(CD_3)_2\dot{C}H$ radicals by abstraction of the 2-hydrogen from $(CD_3)_2CH_2$.

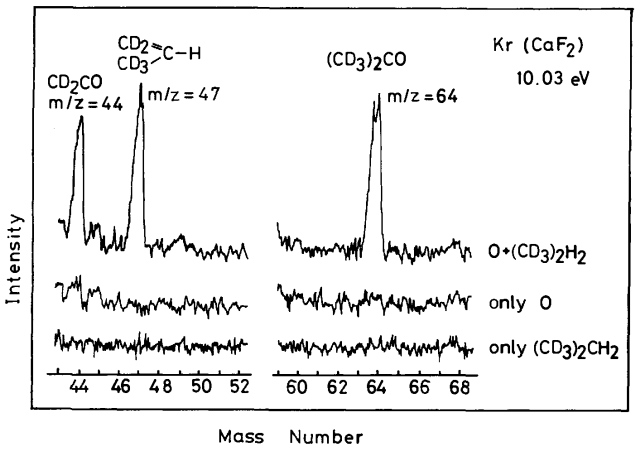

Fig. 4. Mass spectra of the reaction products produced in O+$(CD_3)_2CH_2$. A Kr lamp having a CaF_2 window (10.03 eV) was used for the photoionization. The conditions: partial pressure (mTorr), $[O]_0$=3.5, $[(CD_3)_2CH_2]$=0.7; reaction time=4.5 ms; total pressure=4.3 Torr.

Table 1. Ionization Potentials and Heat of Formations of Radicals and Molecules[a)]

m/z	Molecule	I.P. / eV	ΔH^0_{f298} (g) / kcal mol^{-1}
42	C_3H_6	9.7	4.88
42	CH_2CO	9.6	−14.6
43	n-C_3H_7	8.1	20.7
43	i-C_3H_7	7.5	17.6
44	C_3H_8	11.0	−24.8
44	CH_3CHO	10.2	−39.7
48	$(CH_3)_2CO$	9.7	−52.0
58	C_2H_5CHO	9.9	−45.9

a) Quoted from Ref. 28.

Possible products produced by the reaction of O+$(CD_3)_2\dot{C}H$ are as follows:

$$(CD_3)_2\dot{C}H + O \rightarrow \begin{cases} CD_2CHCD_3\ (m/z=47) + OD & (4a) \\ (CD_3)_2CO\ (m/z=64) + H & (4b) \\ CD_3CHO\ (m/z=47) + CD_3 & (4c) \end{cases}$$

where Reaction 4a is deuterium abstraction, 4b and 4c result from the addition reaction of an oxygen atom to carbon. Signals at m/z=44, 47, and 64 were observed when the Kr lamp having a CaF_2 window (10.03 eV) was used (see Fig. 4). Among the signals observed, the signal at m/z=64 should be from $(CD_3)_2CO$. The signal at m/z=47 should be from CD_2CHCD_3 not from CD_3CHO, since as shown in Table 1, the ionization potential of propene is 9.7 eV, while that of acetaldehyde is 10.2 eV. The signal at m/z=44 would be from ketene, CD_2CO, produced in the secondary reaction of CD_3CHO+O.[29)]

As mentioned before, since acetaldehyde was observed in the reaction of O+C_3H_8, CD_3CHO (m/z=47) should be observed in the present case when the Kr lamp having a MgF_2 window (10.03 and 10.64 eV) was used. However, it is difficult to distinguish CD_2-$CHCD_3$ and CD_3CHO, because these have the same

mass number. In order to distinguish between these two molecules, $(CD_3)_2CH_2$ was reacted with ^{18}O (19.2% of $^{36}O_2$ in $^{32}O_2$ was diluted in helium and discharged by microwave). Mass spectra observed in the region from m/z=43 to 53 by using the Kr lamp with the MgF_2 window are shown in Fig. 5. Possible molecules corresponding to the significant signals observed are listed in Table 2. Signals of ketene, CD_2CO, propene, CD_2CHCD_3, and acetaldehyde, CD_3CHO was observed as expected. In addition, the signal of CD_3CDO was observed. CD_3CDO might be a secondary product in the reaction of CD_2CHCD_3+O (reaction mechanisms will be discussed later). Among the above signals, the signal at m/z=49 ($CD_3CH^{18}O$) can be used to monitor the concentration of acetaldehyde produced in Reaction 4c because, as will be described later, the concentration of $(CD_3)_2\dot{C}H$ radicals is in the steady-state concentration under the present experimental conditions (the signal intensity of $(CD_3)_2\dot{C}H$ is independent of the reaction time), while the concentration of $CD_3CH^{18}O$ increases linearly with reaction time. In this way the signals from $CD_3C^{18}O$ and $(CD_3)_2\dot{C}H$ can be distinguished.

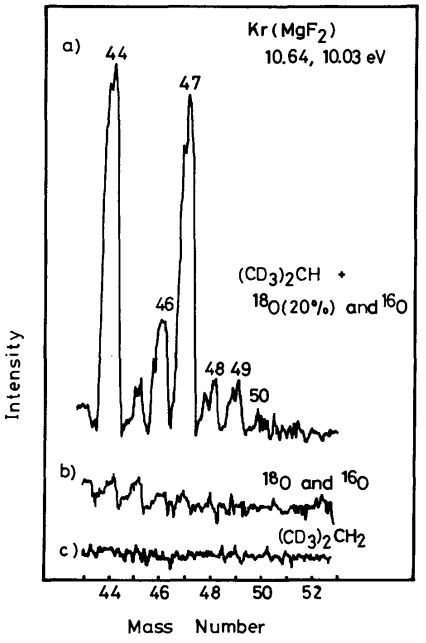

Fig. 5. Mass spectra of the reaction products produced in $(CD_3)_2CH_2$+^{18}O(20%)+^{16}O(80%). A Kr lamp with a MgF_2 window (10.64 and 10.03 eV) was used to photoionize molecules. The conditions: partial pressure (mTorr), $[O]_0$=3.4, $[(CD_3)_2CH_2]$= 0.9; reaction time=4.5 ms; total pressure=4.3 Torr.

Table 2. Signals Observed and Possible Molecules in the Reaction of ^{18}O+$(CD_3)_2CH_2$ (19.2%) and ^{16}O+ $(CD_3)_2CH_2$ (80.8%) over the Mass Number Region from 43 to 53. The Kr Lamp with a MgF_2 Window Was Used as a Photoionization Light Source

m/z	Possible molecule
44	CD_2CO
45	Isotope (^{13}C) signal of m/z=44
46	$CD_2C^{18}O$
47	CD_2CHCD_3, CD_3CHO
48	CD_3CDO, isotope (^{13}C) signal of m/z=47
49	$CD_3CH^{18}O$, $(CD_3)_2CH$ radical
50	$CD_3CD^{18}O$

B. Competition between $O(^3P)$ and O_2 for $(CD_3)_2\dot{C}H$. The time dependence of the $(CD_3)_2\dot{C}H$ radical signal was measured by changing the reaction time of $(CD_3)_2CH_2$ and oxygen atom. No significant change of signal was observed for the conditions of 3—6 mTorr of oxygen atoms, 1 mTorr of $(CD_3)_2CH_2$, and 0.5—10 ms of reaction time. When the concentration of $(CD_3)_2CH_2$ was increased, the signal for $(CD_3)_2\dot{C}H$ increased in proportion to the $(CD_3)_2CH_2$ concentration. This means that Reaction 4 is very rapid and that $(CD_3)_2\dot{C}H$ radicals are in their steady-state concentration

$$[2\text{-pr}]_{ss} = \frac{k_3}{k_4}[P]. \tag{5}$$

Here $[2\text{-pr}]_{ss}$ and [P] represent the steady-state concentration of $(CD_3)_2\dot{C}H$ radicals and the initial concentration of $(CD_3)_2CH_2$, respectively. When molecular oxygen was added to the system, the steady-state concentration of $(CD_3)_2\dot{C}H$ decreased. This decrease is caused by the competition between $O(^3P)$ and O_2 for $(CD_3)_2\dot{C}H$ radicals and the competition results in a Stern-Volmer-type of equation.

$$\frac{[2\text{-pr}]^0_{ss}}{[2\text{-pr}]_{ss}} = 1 + \frac{k_7[O_2]}{k_4[\bar{O}]}, \tag{6}$$

where the superscript zero refers to the conditions in the absence of O_2 and k_7 is the effective second-order rate constant for the reaction of $(CD_3)_2\dot{C}H+O_2$.

$$(CD_3)_2\dot{C}H + O_2 \rightarrow \text{Products} \tag{7}$$

The results of the O_2 addition for two different conditions are presented in Fig. 6. The average concentration of oxygen atoms, $[\bar{O}]$, was calculated[36] using a stoichiometric factor of n=6. The correction for oxygen-atom consumption was 0.5% or less. The concentration of O_2 was calculated from $[O_2]_{added}+[O_2]_0 - 1/2[O]_0$, where $[O_2]_0$ and $[O]_0$ refer to the original concentraiton of O_2 in the O_2/He mixture before the discharge, and the original oxygen-atom concentration produced in the O_2/He discharge, respectively. The value of $[O_2]_0-1/2[O]_0$ corresponds to the concentration of O_2 surviving from the O_2/He discharge. The two points shown on the left-hand side in Fig. 6 are obtained with just $[O_2]_0-1/2[O]_0$ present.

Values for $[2\text{-pr}]^0_{ss}$ were determined by plotting $([2\text{-pr}]_{ss})^{-1}$ against $[O_2]/[\bar{O}]$ and then determining $([2\text{-pr}]^0_{ss})^{-1}$ from the intercept of a least-square fit in order to remove the effect of the O_2 surviving from the discharge. The value for k_7/k_4 calculated from the slope in Fig. 6 is 0.029±0.004. Error limits due to the scattering of plots were calculated by the least square with

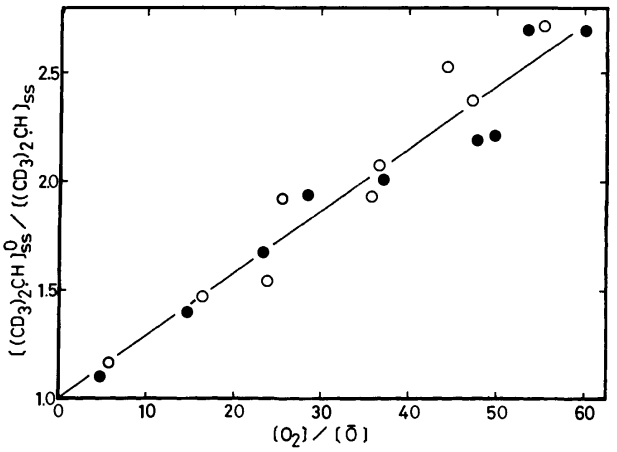

Fig. 6. Stern-Volmer plot for the competition between O_2 and $O(^3P)$ for the $(CD_3)_2CH$ radicals. Conditions for the open symbols: partial pressure (mTorr), $[O]_0$=3.32, $[\bar{O}]$=3.30, $[(CD_3)_2CH_2]$=1.31, $[O_2]_0$=19.44; total pressure 4.151 Torr; reaction time=4.46 ms. Conditions for the filled symbols: partial pressure (mTorr), $[O]_0$=2.99, $[\bar{O}]$=2.97, $[(CD_3)_2CH_2]$=1.003, $[O_2]_0$=15.43; total pressure= 4.32 Torr; reaction time=4.51 ms. $[O_2]$ was calculated from $[O_2]_{added.}+[O_2]_0-1/2[O]_0$.

the 95% confidence limits.

C. Yields of CD_2CHCD_3 and $(CD_3)_2CO$. The dependence of the CD_2CHCD_3 (m/z=47) and $(CD_3)_2CO$ (m/z=64) signals on the reaction time was measured by using a Kr lamp having a CaF_2 window and is shown in Fig. 7. The signal of $(CD_3)_2CO$ (open triangles) rises linearly with reaction time, while the signal of CD_2CHCD_3 (solid circles) increased but not linearly. The nonlinear increase of CD_2CHCD_3 with reaction time results from the consumption of CD_2CHCD_3 by Reaction 8.

$$CD_2CHCD_3 + O(^3P) \rightarrow \text{Products} \qquad (8)$$

If CD_2CHCD_3 is produced in Reaction 3 followed by Reaction 4a and consumed in Reaction 8, the concentration of CD_2CHCD_3 observed is given by Eq. 9, assuming that Reaction 4 is much faster than Reaction 3,

$$[CD_2CHCD_3] = \frac{k_3 f_{4a}[P]_0}{(k_8 - k_3)} (e^{-k_3[\bar{O}]t} - e^{-k_8[\bar{O}]t}) \qquad (9)$$

where f_{4a}, $[P]_0$, and $[\bar{O}]t$ represent the fraction of Reaction 4a in the total reaction of $(CD_3)_2\dot{C}H+O$, the original concentration of $(CD_3)_2CH_2$, and the product of the average oxygen-atom concentration and the reaction time,[36] respectively. In the present study, since the rate constant for Reaction 3 is very small, 7.91×10^{-15} cm^3 molecule^{-1} s^{-1} at 298K as will be described later, and the rate of Reaction 8, $(3.3—4.50)\times10^{-12}$ cm^3 molecule^{-1} s^{-1} [16,38] for $O+C_3H_6$, is 500 times faster than that of Reaction 3, the value of $\exp(-k_3[\bar{O}]t)$ is nearly 1 and k_8-k_3 is nearly equal to k_8 under the present experimental conditions; $[\bar{O}]t<1.5\times10^{12}$ molecule s cm^{-3}. Thus Eq. 9 is simplified to Eq. 10.

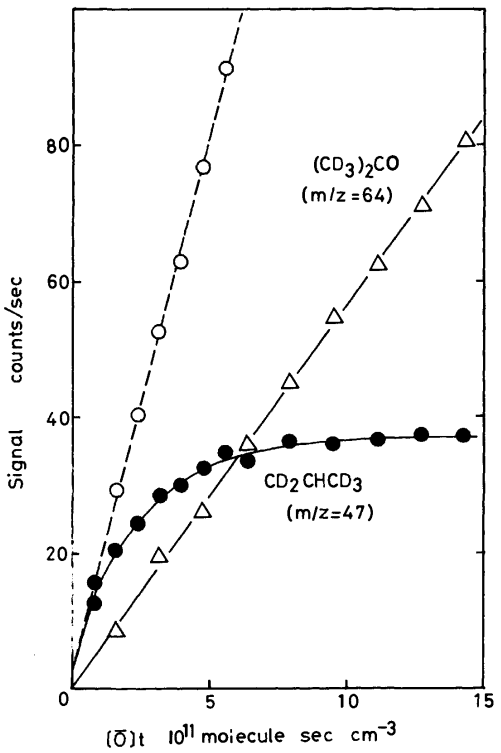

Fig. 7. Time dependence of CD_2CHCD_3 (solid circles) and $(CD_3)_2CO$ (open triangles) signals produced in the $O+(CD_3)_2CH_2$ reaction. A Kr lamp with a CaF_2 window (10.03 eV) was used for the photoionization. The conditions: partial pressure (mTorr), $[O]_0$=5.34, $[(CD_3)_2CH_2]$=0.95, $[O_2]_0$=24.60; total pressure=4.46 Torr. $[O_2]_0$ refers the amount of O_2 added to the O_2/He discharge. Reaction times used were 0.5—8.1 ms. Corrections for $[\bar{O}]$ were 1% or less. The CD_2CHCD_3 signals are corrected for the subsequent reaction to give $[CD_2CHCD_3]_T$ as indicated by open circles.

$$[CD_2CHCD_3] = \frac{f_{4a}k_3}{k_8}[P]_0(1-e^{-k_8[\bar{O}]t}) \qquad (10)$$

Equation 10 shows the CD_2CHCD_3 approaches a constant concentration at long reaction time. When the plots of CD_2CHCD_3 shown in Fig. 6 are fitted to Eq. 10, a value for k_8 of $(4.06\pm0.18)\times10^{-12}$ cm^3 molecule^{-1} s^{-1} was calculated, which agrees well with the reported rate constants for $O+C_3H_6$.[16,38] The indicated errors due to the scattering of plots were calculated by the least square with the 95% confidence limits. The best fit line for Eq. 10 is shown as a solid line in Fig. 7. The total amount of CD_2CHCD_3 produced by Reaction 4a, $[CD_2CHCD_3]_T$, is given by Eq. 11,

$$[CD_2CHCD_3]_T = f_{4a}k_3[P]_0[\bar{O}]t \qquad (11)$$

Therefore, the total amount of CD_2CHCD_3 can be calculated by multiplying each observed CD_2CHCD_3 signal by $k_8[\bar{O}]t[1-\exp(-k_8[\bar{O}]t)]^{-1}$. These corrected points are shown as open circles in Fig. 7, and they are represented by the dashed straight line. The ratio of the slope of the dashed straight line to that for $(CD_3)_2CO$ is 2.8. The relative sensitivity of the photoi-

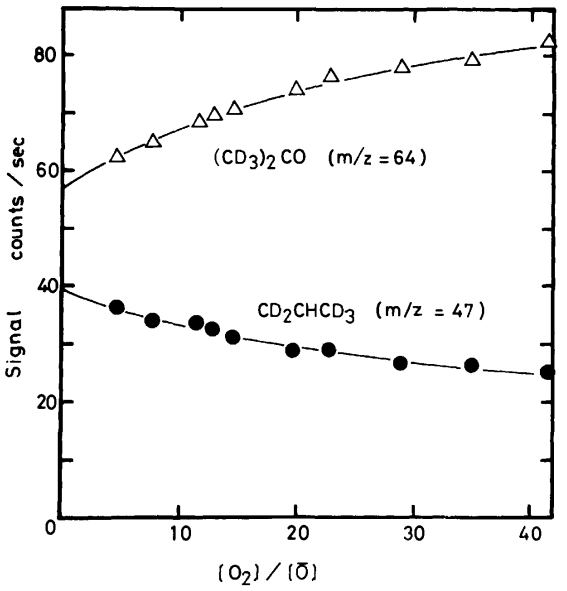

Fig. 8. Change of signals of CD_2CHCD_3 and $(CD_3)_2CO$ with the addition of O_2. Conditions: partial pressure (mTorr) $[O]_0$=5.34, $[\bar{O}]$=5.32, $[(CD_3)_2CH_2]$=0.95, $[O_2]_0$=27.27; reaction time= 6.30 ms; total pressure=4.46 Torr. $[O_2]$ was calculated from $[O_2]_{added.}+[O_2]_0-1/2[O]_0$. The points shown on the left-hand side are obtained from just $[O_2]_0-1/2[O]_0$ (no $[O_2]_{added.}$).

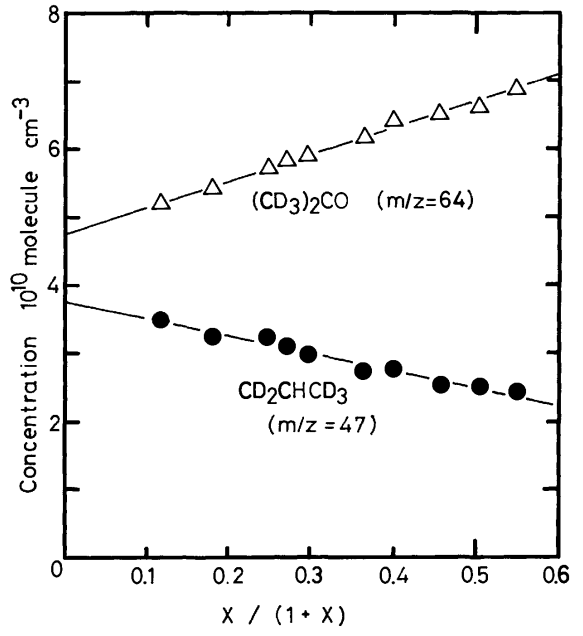

Fig. 9. The absolute concentrations of CD_2CHCD_3 and $(CD_3)_2CO$ are plotted against $X/(1+X)$ (see the text). Conditions are the same as in Fig. 8.

onization mass spectrometer for NO, C_3H_8, and $(CH_3)_2CO$ was mesured as 1 : 7.1 : 8.1 by using a Kr lamp (CaF_2). Assuming that the sensitivities of CD_2CHCD_3 and $(CD_3)_2CO$ are equal to those of C_3H_8 and $(CH_3)_2CO$, respectively, the ratio of the rate of formation of these two products was CD_2CHCD_3: $(CD_3)_2CO$=3.2 : 1 for the above conditions. Corrections for the consumption of acetone in the reactor is not important because the rate of the O+acetone reaction is very slow at room temperature[39] (5—7×10^{-16} cm^3 $molecule^{-1}s^{-1}$).

The effect of the O_2 surviving from the O_2/He discharge on the yield of products might not be neglected. The CD_2CHCD_3 and $(CD_3)_2CO$ signals were measured when molecular oxygen was added to the system. The signal of CD_2CHCD_3 decreased and that of $(CD_3)_2CO$ increased when O_2 was added, as shown in Fig. 8. The two points on the left-hand side are obtained with only the O_2 surviving from the O_2/He discharge (no addition of O_2). In Fig. 8, CD_2CHCD_3 is in its steady-state concentration and $(CD_3)_2CO$ is not under these experimental conditions. If the fraction of CD_2CHCD_3 produced in Reaction 7 is represented by s_{7a}, the steady-state concentration of CD_2CHCD_3 is given by Eq. 12 when both $O(^3P)$ and O_2 are present, where X is defined in Eq. 13.

$$[CD_2CHCD_3]_{ss} = \left\{f_{4a} + \frac{(s_{7a}-f_{4a})X}{1+X}\right\}\frac{k_3}{k_8}[P] \quad (12)$$

$$X = \frac{k_7}{k_4}\frac{[O_2]}{[\bar{O}]} \quad (13)$$

Similarly, the concentration of $(CD_3)_2CO$ at reaction time t is represented by Eq. 14;

$$[(CD_3)_2CO] = \left\{f_{4b} + \frac{(s_{7b}-f_{4b})X}{1+X}\right\}k_3[P][\bar{O}]t \quad (14)$$

where s_{7b} refers to the fraction of $(CD_3)_2CO$ produced in Reaction 7. Since the ratio of k_7/k_4 was determined previously, the concentrations of CD_2CHCD_3 and $(CD_3)_2CO$ can be plotted against $X/(1+X)$, as are shown in Fig. 9. The absolute concentrations of CD_2CHCD_3 and $(CD_3)_2CO$ were calculated using the instrumental sensitivities to propylene, C_3H_6 and acetone, $(CH_3)_2CO$, as measured by adding known partial pressures of both molecules to the reactor. Since the initial concentration of $(CD_3)_2CH_2$ and reaction time are known, values for f_{4a} and f_{4b} can be determined from the intercepts of the two lines and those for s_{7a} and s_{7b} are determined from the slopes. Here the value for k_3 of 7.91×10^{-15} cm^3 $molecule^{-1}s^{-1}$ was used, as will be discussed later, and the value for k_8 of 4.06×10^{-12} cm^3 $molecule^{-1}s^{-1}$ was used. Values obtained are (0.61±0.07), (0.17±0.01), (0.20±0.02), and (0.31±0.02), for f_{4a}, f_{4b}, s_{7a}, and s_{7b}, respectively. The indicated errors due to the scattering of plots were calculated by the least square with the 95% confidence limits.

D. Yield of CD_3CHO. The dependence of the signal at m/z=49 shown in Fig. 4 on the reaction time was measured by using a Kr lamp having a MgF_2 window and is shown in Fig. 10. The signal at m/z=66, $(CD_3)_2C^{18}O$, is also plotted as a reference. The signal at m/z=49 increased with reaction time but the increase was not linear. The nonlinear increase results

from the consumption of $CD_3CH^{18}O$ by Reaction 15, and so the concentration of $CD_3CH^{18}O$ can be expressed by Eq. 16,

$$CD_3CHO + O(^3P) \rightarrow \text{Products} \quad (15)$$

$$[CD_3CH^{18}O] = \frac{0.192\, f_{4c} k_3}{k_{15}} [P](1-e^{-k_{15}[\bar{O}]t}) \quad (16)$$

where the value of 0.192 represents the fraction of $^{18}O(^3P)$ in the sum of $^{18}O(^3P)$ and $^{16}O(^3P)$. When the measured values of $CD_3CH^{18}O$ shown in Fig. 10 are fitted to Eq. 16, a value for k_{15} of $(5.6\pm0.5)\times10^{-13}$ cm^3 molecule^{-1} s^{-1} was calculated, which agrees well with the reported rate constants for $O+CH_3CHO$,[16,33,40] $(4.3—5)\times10^{-13}$ cm^3 molecule^{-1} s^{-1}. The indicated errors due to the scattering of plots were calculated by the least square with the 95% confidence limits. The best fit line for Eq. 16 is shown as a solid line in Fig. 10. The large intercept results from the signal due to $(CD_3)_2\dot{C}H$ radicals. As described before, the $(CD_3)_2\dot{C}H$ radicals should be in the steady-state concentration and the signals of $(CD_3)_2\dot{C}H$ are independent of the reaction time under the experimental conditions shown in Fig. 10. Each signal at m/z=49 minus the intercept is taken to be the signal of $CD_3CH^{18}O$. The total amount of $CD^3CH^{18}O$ produced in Reaction 4c, $[CD_3CH^{18}O]_T$, can be calculated by multiplying each observed $CD_3CH^{18}O$ signal by $k_{15}[\bar{O}]t[1-\exp(-k_{15}[\bar{O}]t)]^{-1}$. These corrected points are shown as open circles in Fig. 10, and they are represented by the dashed straight line. The ratio of the slope of the dashed line to that for $(CD_3)_2C^{18}O$ is 0.12. The relative sensitivity of the photoionization mass spectrometer for CH_3CHO, and $(CD_3)_2CO$ was measured as 1:9.87 by using a Kr lamp with a MgF_2 window. The ratio of the rate of formation of these two products was estimated to be $CD_3CH^{18}O$: $(CD_3)_2C^{18}O$=1 : 0.86 for the above conditions.

Signals at m/z=49 and 66 were measured when molecular oxygen containing 19.2% of $^{36}O_2$ in O_2 was added to the system. The results are listed in Table 3. The signal at m/z=66, $(CD_3)_2C^{18}O$, increased with addition of O_2 but the apparent signal at m/z=49 was nearly constant. As shown in Fig. 10, the signal at m/z=49 consists of $CD_3CH^{18}O$ and $(CD_3)_2\dot{C}H$. Between them, the signal of $(CD_3)_2\dot{C}H$ should decrease by the addition of O_2. This decrease is given by Eq. 6. Since the value for k_7/k_4 of 0.029 was determined previously and the signal intensity for the steady-state concentration of $(CD_3)_2\dot{C}H$ ($[2\text{-pr}]_{ss}$=17.2 counts s^{-1}) under the condition of $[O_2]/[\bar{O}]$=3.66 was determined from the intercept of the line in Fig. 10, the signal intensity for $[2\text{-pr}]^0_{ss}$, of 19.2 counts s^{-1} was calculated by Eq. 6. Using this value of $[2\text{-pr}]^0_{ss}$, the signal intensity for $[2\text{-pr}]_{ss}$ was calculated for each $[O_2]/[\bar{O}]$ by Eq. 6 as is shown in Table 3. The signal for $CD_3CH^{18}O$ was obtained from the difference between the total signal at m/z=49 and the calculated signal of $[2\text{-pr}]_{ss}$.

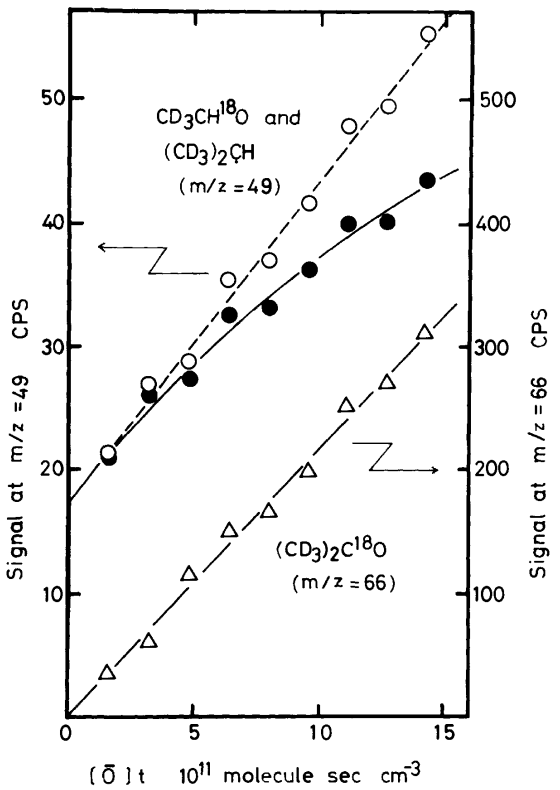

Fig. 10. Time dependence of $CD_3CH^{18}O$ (solid circles) and $(CD_3)_2C^{18}O$ (open triangles) signals produced in the $^{18}O+(CD_3)_2CH_2$ reaction. 19.2% of $^{36}O_2$ in O_2 was diluted in He and discharged. A Kr lamp with a MgF_2 window (10.64 and 10.03 eV) was used for the photoionization. The conditions: partial pressure (m Torr), $[O]_0$=5.42, $[(CD_3)_2CH_2]$=2.37, $[O_2]_0$=22.28; total pressure=4.48 Torr. $[O_2]_0$ refers to the amount of O_2 added to the O_2/He discharge. Reaction times used were 0.9—8.1 ms. Corrections for $[\bar{O}]$ were 1.5% or less. The $CD_3CH^{18}O$ signals are corrected for subsequent reaction to give $[CD_3CH^{18}O]_T$ as indicated by open circles. The large intercept for the signal at m/z=49 resulted from the signal of $(CD_3)_2\dot{C}H$ radicals.

The signal of $CD_3CH^{18}O$ increased with the addition of O_2 as shown in Table 3. The absolute concentrations of $CD_3CH^{18}O$ and $(CD_3)_2C^{18}O$ were determined using the measured instrumental sensitivities to CH_3CHO and $(CD_3)_2CO$.

As shown in Table 3, the formation of both $CD_3CH^{18}O$ and $(CD_3)_2C^{18}O$ increased when molecular oxygen was added to the system. The concentrations of $CD_3CH^{18}O$ and $(CD_3)_2C^{18}O$ were plotted against $X/(1+X)$, where X is given by Eq. 13. The plots are shown in Fig. 11. As described before, from the slopes and intercepts of these straight lines values for f_{4b}, f_{4c}, s_{7b}, and s_{7c} can be determined,[41] where s_{7c} refers to the fraction of CD_3CHO produced in Reaction 7. In these calculations, the fraction of ^{18}O in O (19.2%) was used and the effect of the consumption of $CD_3CH^{18}O$ by Reaction 15 was taken into account.[41] The values calculated are (0.18±0.02), (0.21±0.03), (0.32±0.03), and (0.44±0.08), for f_{4b}, f_{4c}, s_{7b}, and s_{7c}, respectively.

Table 3. Observed Signals at m/z=49 and 66 and Absolute Concentrations of $CD_3CH^{18}O$ and $(CD_3)_2C^{18}O$ in the Reaction of $(CD_3)_2CH_2+{}^{18}O+{}^{18}O_2$[a]

207.00	42.31	41.47	8.61	32.86	3.24	335.31	3.35

a) Experimental conditions are: $[{}^{18}O]/([{}^{18}O]+[{}^{16}O])=0.192$, $[{}^{36}O_2]/([{}^{36}O_2]+[{}^{32}O_2])=0.192$, $[O]_0=5.42$ mTorr, $[(CD_3)_2CH_2]=2.37$ mTorr, $[O_2]_0=22.28$ mTorr, reaction time=6.299 ms, $[\bar{O}]=5.36$ mTorr, and total pressure=4.48 Torr. b) $[O_2]$ was calculated by $[O_2]_s+[O_2]_{added}$, where $[O_2]_s=[O_2]_0-1/2[O]_0$ refers to the O_2 surviving from the O_2/He discharge. c) The value for $[2\text{-pr}]_{ss}$ were calculated form Eq. 6 as follows; each value for $[2\text{-pr}]^0_{ss}/[2\text{-pr}]_{ss}$ can be calculated by using the known values of k_7/k_4 and $[\bar{O}_2]/[O]$. The absolute intensity for $[2\text{-pr}]^0_{ss}$ of 19.2 counts s^{-1} was determined from the intercept of the line shown in Fig. 10, in which the values for $[O_2]/[\bar{O}]$ and $[2\text{-pr}]_{ss}$ were 3.66 and 17.2 counts s^{-1},respectively. d) Signal intensity for $CD_3CH^{18}O$ was determined from (signal at m/z=49)−(signal for $[2\text{-pr}]_{ss}$). e) The absolute concentrations for $CD_3CH^{18}O$ and $(CD_3)_2C^{18}O$ were determined by the instrumental sensitivities to CH_3CHO and $(CH_3)_2CO$ as measured by adding known partial pressures of both gases to the reactor.

These values for f_{4b} and s_{7b} are in good agreement with the values obtained from Fig. 9. Combining the results obtained from Figs. 9 and 11, the branching fractions in Reactions 4 and 7 are:

$$(CD_3)_2\dot{C}H+O \xrightarrow{(61\pm7)\%} CD_2CHCD_3$$
$$\xrightarrow{(18\pm2)\%} (CD_3)_2CO$$
$$\xrightarrow{(21\pm3)\%} CD_3CHO \quad (4)$$

$$(CD_3)_2\dot{C}H+O_2 \xrightarrow{(20\pm2)\%} CD_2CHCD_3$$
$$\xrightarrow{(32\pm3)\%} (CD_3)_2CO$$
$$\xrightarrow{(44\pm8)\%} CD_3CHO \quad (7)$$

The values for f_{4b} and s_{7b} are averaged for the two measurements.

E. Rate Constant for $(CD_3)_2CH_2+O(^3P)$ Reaction. As described before, the determination of the rate constant for Reaction 3 is necessary in order to determine the fractions in Reaction 4. Since the rate of Reaction 3 at room temperature is too slow to measure by the pseudo-first-order decay of $(CD_3)_2CH_2$ under the present experimental conditions, the pseudo-first-order decay of $(CD_3)_2CH_2$ was measured over a temperature range of 381—627K in a large excess of oxygen atoms $[O]\gg[(CD_3)_2CH_2]$ by changing the contact time of $(CD_3)_2CH_2$ with oxygen atoms. An Ar lamp having a LiF window (11.83 and 11.62 eV) was used to photoionize $(CD_3)_2CH_2$. Since there was no signal from reaction product at m/z=50 when $(CD_3)_2CH_2$ reacted with atomic oxygen (see Fig. 4), the bimolecular rate of Reaction 3 can be measured from the decay of the signal of $(CD_3)_2CH_2$ at m/z=50. The results are presented in Table 4. The 95% confidence limits were calculated from the least squares line using ten points (ten different reaction times) for each run.

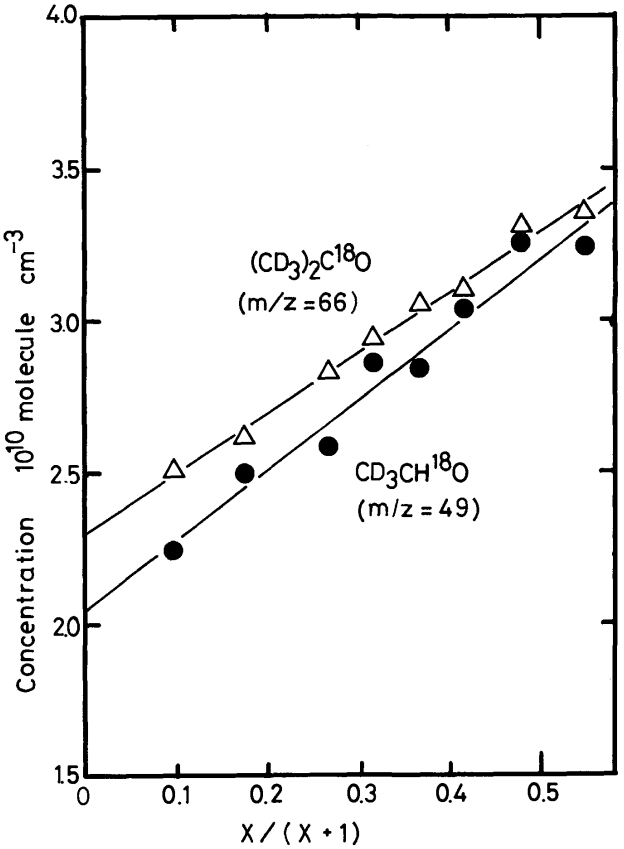

Fig. 11. The absolute concentrations of $CD_3CH^{18}O$ (solid circles) and $(CD_3)_2C^{18}O$ (open triangles) are plotted against $X/(1+X)$. Conditions are the same as those in Table 3.

The bimolecular rate constants of k_3 are plotted in

Table 4. Rate Data[a] for $O(^3P)+(CD_3)_2CH_2$ at 385—627 K

T	$[P]_0$[b]	$[O]_0$	Total pressure	Flow rate	k_3
K	mTorr	mTorr	Torr	m s^{-1}	10^{-14} cm^3molecule^{-1} s^{-1}
627	0.052	1.681	5.68	43.4	198±22
605	0.073	3.837	5.26	40.9	113±18
573	0.101	4.129	5.83	41.2	93.8±9.6
561	0.103	6.836	5.73	41.0	80.2±6.5
491	0.114	5.801	5.62	36.2	34.6±4.2
485	0.102	7.026	5.31	36.1	36.4±5.3
426	0.098	8.381	6.18	31.7	15.1±1.3
421	0.182	10.79	6.07	31.9	14.0±1.6
385	0.146	12.52	6.68	28.3	6.71±0.73
381	0.102	13.32	6.65	28.1	7.46±0.66

a) The rate constant was calculated from the equation of $\ln [P]/[P]_0=-k_3[\bar{O}]t$, where [P] and $[P]_0$ represent the signal of $(CD_3)_2CH_2$ in the presence and absence of oxygen atoms, respectively. b) $[P]_0$ represents the original concentration of $(CD_3)_2CH_2$.

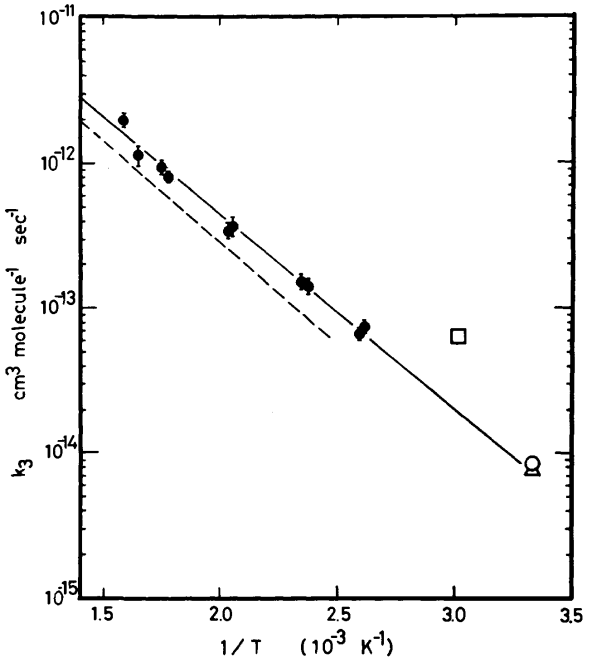

Fig. 12. Arrhenius plot for reaction O+propane. ● This work for $O+(CD_3)_2CH_2$; solid line drawn is obtained by the least-square fit. □: Harker and Burton[46] for $O+C_3H_8$. △: Jewell et al.[3] for $O+C_3H_8$. Dashed line is consensus rate constant for $O+C_3H_8$ by Klemm et al.[47] The open circle is obtained in this work from the yields of reaction products.

Fig. 12 vs. the reciprocal of the absolute temperature. A linear least square treatment yields the Arrhenius expression:

$$k_3 = (2.0^{+1.0}_{-0.7}) \times 10^{-10} \exp\left(\frac{-6086 \pm 392 \text{ cal mol}^{-1}}{RT}\right) \quad (17)$$

in units of cm^3 molecule^{-1} s^{-1}. The indicated errors were calculated by the least-square with 95% confidence limits. The rate constant for Reaction 3 at 298K calculated from Eq. 17 is 6.94×10^{-15} cm^3 molecule^{-1} s^{-1}.

The rate constant for Reaction 3 can also be calculated from the sum of the absolute yields of the three reaction products; CD_2CHCD_3, $(CD_3)CO$, and CD_3CHO. The value for k_3 of 7.9×10^{-15} cm^3 molecule^{-1} s^{-1} was calculated[42] from absolute concentrations of products produced initially by Reaction 4. The value is in reasonable agreement with that calculated from Eq. 17. Therefore, the value of 7.91×10^{-15} cm^3 molecule^{-1} s^{-1} was used for k_3 in all calculations in this study.

Discussion

The observation of propyl radicals by photoionization using the Xe resonance lamp (8.44 eV) is reasonable because the ionization potentials for the propyl radicals are low (Table 1). The detection of propyl radicals using photoionization by the Xe lamp has been reported by Bayes et al.[43] Only the $(CD_3)_2\dot{C}H$ radical was formed in the reaction of $O+(CD_3)_2CH_2$. For comparison, the reaction of oxygen atoms with propane-2,2-d_2, $(CH_3)_2CD_2$, gave both $\cdot CH_2CD_2CH_3$ (m/z=45) and $(CH_3)_2\dot{C}D$ (m/z=44). The ratio of the signal at m/z=44 to 45 was about 3 : 2. Therefore, the abstraction of the 1- or 2-hydrogen from propane is very sensitive to the small difference in the bond dissociation energies of C-H and C-D. Jewell et al.[3] observed the formation of $(CH_3)_2CO$ and C_2H_5CHO in the $O+C_3H_8$ system. This result also suggests that both n-propyl and isopropyl radicals are produced by the primary attack of O atoms on C_3H_8.[29]

CD_2CHCD_3, $(CD_3)_2CO$, and CD_3CHO were observed as major products of the $O+(CD_3)_2\dot{C}H$ reaction. In addition, the signal of CD_2CO was observed in this study. Since the signals for CD_2CO were proportional to the square of $[\bar{O}]t$, CD_2CO probably is produced by secondary reactions.[29] In the previous discharge-flow experiments involving $O+C_3H_8$,[3,4] the formation of C_2H_5CHO, C_2H_6, C_2H_4, CH_2O, CH_4, CO_2, CO, H_2O, and H_2 has been reported in addition to propene, acetone and acetaldehyde. These products, except for C_2H_5CHO, are probably produced in secondary reactions.

Propene, CD_2CHCD_3, was a major product of the $O+(CD_3)_2CH$ reaction. Propene can be produced by

hydrogen abstraction, Reaction 4a. Similar hydrogen abstraction reactions were found for O+t-C_4H_9[1] and O+$cyclo$-C_6H_{11}.[2] These results disagree with the findings by Hoyerman and Sievert,[7] who observed no formation of olefins in the reactions of O+alkyl radicals.

As shown in Table 2 and Fig. 5, the products CD_3CDO (m/z=48) and $CD_3CD^{18}O$ (m/z=50) were observed in the ^{16}O and ^{18}O+$(CD_3)_2CH_2$ systems. These products might be produced by secondary reactions following O+CD_2CHCD_3. According to the previous studies on O+C_3H_6,[37,44,45] Reaction 8 proceeds as follows:

$$CD_2CHCD_3 + O \rightarrow (CD_3CHDCDO)^* \rightarrow CD_3CHD + CDO \quad (8a)$$

$$CD_2CHCD_3 + O \rightarrow (CD_3(CO)CHD_2)^* \rightarrow CD_3 + CHD_2CO \quad (8b)$$

$$(CD_3(CO)CHD_2)^* \rightarrow CHD_2 + CD_3CO \quad (8c)$$

Since no signals at m/z=63 were observed as shown in Fig. 4, the vibrationally hot $CD_3CHDCDO$ and CD_3COCHD_2 were not stabilized for the present experimental conditions. CD_3CHD produced in Reaction 8a reacts with oxygen atoms and can produce CD_3CHO and CD_3CDO.

$$CD_3CHD + O \rightarrow CD_3CDO + H \ (m/z=48) \quad (18a)$$

$$CD_3CHD + O \rightarrow CD_3CHO + D \ (m/z=47) \quad (18b)$$

CD_3CDO shown in Table 2 and Fig. 5 might be produced in Reaction 18a. As described before, yields of acetaldehyde were determined from the signals of $CD_3CH^{18}O$ (m/z=49). If Reaction 18b occurred, the yield of $CD_3CH^{18}O$ was overestimated. The fraction of Reaction 18b should be less than 18a because of the difference of the bond energy of C-H and C-D. Therefore, the signal of $CD_3CH^{18}O$ from Reaction 18b should be smaller than that of $CD_3CD^{18}O$ (m/z=50). From the measurement of the signal intensities at m/z=49 and 50 in the ^{18}O+$(CD_3)_2CH_2$ reaction, it was determined that the effect of Reaction 18b on the total signal of $CD_3CH^{18}O$ was less than 20%. Thus the lower error limit of the yield of acetaldehyde should be increased in 20%; $f_{4c}=0.21^{+0.03}_{-0.07}$.

The value for k_7/k_4 of 0.029±0.004 was obtained from the competition experiment between O and O_2 for the $(CD_3)_2\dot{C}H$ radical. The rate constant for the reaction of isopropyl radicals, i-C_3H_7, with molecular oxygen has been reported[43], to be $(14.1\pm2.4)\times10^{-12}$ cm^3 $molecule^{-1}$ s^{-1} at 298K. Assuming that the rates of reactions of $(CD_3)_2CH+O_2$ and i-$C_3H_7+O_2$ are equal, the value for k_4 can be calculated as 4.9×10^{-10} cm^3 $molecule^{-1}$ s^{-1}. The rate of Reaction 4 is very rapid, but slower than the rate of reaction of t-butyl radical+O,[1] 8.7×10^{-10} cm^3 $molecule^{-1}$ s^{-1}.

Propene, CD_2CHCD_3, was produced by deuterium abstraction. The excess energy of Reaction 4a is about 63 kcal mol^{-1}. The yield of propene was 61% of the total O+$(CD_3)_2CH$ reaction. Yields of olefins from other O+alkyl radical reactions were 80% (isobutene) from O+t-C_4H_9,[1] and 52% (cyclohexene) from O+$cyclo$-C_6H_{11}.[2] These yields appear to correlate with the number of hydrogen atoms which can be abstracted; nine equivalent hydrogen atoms in the t-butyl radical to produce isobutene, six in the isopropyl radical to produce propene, and four in the cyclohexyl radical to produce cyclohexene.

Acetone, $(CD_3)_2CO$, and acetaldehyde, CD_3CHO, were formed by the oxygen atom addition. The isopropoxyl radical, $(CD_3)_2CH$-O·, formed in Reaction 4 would have approximately 90 kcal mol^{-1} excess energy and should rapidly decompose to $(CD_3)_2CO$+H and $CD_3CHO+CD_3$. Excess energies for Reactions 4b and 4c are 77.1 and 82.9 kcal mol^{-1}, respectively. Yields of acetone (18%) and acetaldehyde (21%) are similar, reflecting the similar exothermicities. The ratio of deuterium abstraction to oxygen atom addition was 1.6:1.

In the presence of an excess of O_2 the same products were observed but in different proportions; propene decreased to 20% and acetone and acetaldehyde increased to 32 and 44%, respectively. This trend is very similar to the case of the t-butyl radical.[11] It is proposed that the formation of these products occurs by the reaction of propylperoxyl radicals with atomic oxygen.

$$(CD_3)_2\dot{C}H + O_2 \xrightarrow{+M} (CD_3)_2C(H)OO \quad (7')$$

$$(CD_3)_2C(H)OO + O \rightarrow CD_2CHCD_3 + OD + O_2 \quad (19a)$$

$$(CD_3)_2C(H)OO + O \rightarrow (CD_3)_2CO + H + O_2 \quad (19b)$$

$$(CD_3)_2C(H)OO + O \rightarrow CD_3CHO + CD_3 + O_2 \quad (19c)$$

Here Reaction 19a is a deuterium abstraction reaction from the peroxyl radical by $O(^3P)$; after abstraction, O_2 departs from the peroxy biradical (·$CD_2CH(CD_3)OO$·) and propene is produced. In Reactions 19b and 19c oxygen atoms attack the radical oxygen (-O-O·). The resulting hot propoxyl radical decomposes to the fragements $(CD_3)_2CO$+H and $CD_3CHO+CD_3$. Reactions 19a and 19c are 49 and 55 kcal mol^{-1} exothermic, respectively.

Various studies of the rate of the O+C_3H_8 reaction are summarized in Fig. 12. Harker and Burton[46] measured the OH radical produced by Reaction 1 by molecular modultion spectroscopy. They obtained a value for k_1 of 6.5×10^{-14} cm^3 $molecule^{-1}$ s^{-1} at 329K. Jewell et al.[3] measured the decay of O-atoms and also propane in the O+C_3H_8 discharge-flow system and proposed a value for k_1 of 7.8×10^{-15} cm^3 $molecule^{-1}$ s^{-1} at 306K. In a recent article, Klemm et al.[47] reported the measurement of the rate of the O+C_3H_8 reaction by both flash photolysis-resonance fluorescence and discharge flow-resonance fluorescence techniques over a temperature range of 411—1018K; they proposed the Arrhenius expression: $k_1=(1.66\pm0.16)\times10^{-10}$ exp[$(-6290\pm120$ cal $mol^{-1})/RT$] in unit of cm^3 $molecule^{-1}$

s^{-1}. Rate constants for $O+(CD_3)_2CH_2$ obtained in this study agree well with the value by Klemm et al. in both activation energy and frequency factor considering the error of the measurements. The rate constant extrapolated to room temperature, 6.94×10^{-15} cm^3 $molecule^{-1}$ s^{-1}, using Eq. 17 differs by 1.6 factor with the value of k_3 calculated from the absolute yields of products, 7.81×10^{-15} cm^3 $molecule^{-1}$ s^{-1}. Both values of k_3 at room temperature agree well with the rate constant for $O+C_3H_8$ at 306K reported by Jewell et al.

Conclusion

(1) Isopropyl-d_6 radicals, $(CD_3)_2CH$, produced in the reaction of propane-1,1,1,3,3,3-d_6, $(CD_3)_2CH_2$, with atomic oxygen were detected directly by the photoionization mass spectrometer.

(2) The reaction of $(CD_3)_2\dot{C}H$ radicals with atomic oxygen proceeds by deuterium abstraction (61%) and by an oxygen atom addition reaction (39%).

(3) The product in the deuterium abstraction was propene-1,1,3,3,3-d_5, CD_2CHCD_3. Acetone-d_6, $(CD_3)_2CO$ and acetaldehyde-2,2,2-d_3, CD_3CHO were produced by the oxygen atom addition reaction with yields of 18 and 21%, respectively.

(4) The reaction of $(CD_3)_2\dot{C}H$ radicals with molecular oxygen was 0.029 ± 0.004 times as fast as that with atomic oxygen. From the rate constant for the $O_2+C_3H_7$ reaction reported, the rate constant for the reaction of O+isopropyl radicals was estimated to be 4.9×10^{-10} cm^3 $molecule^{-1}$ s^{-1}.

(5) In the reaction of isopropylperoxyl radicals with molecular oxygen, the yield of CD_2CHCD_3 decreased to 20% and the yields of $(CD_3)_2CO$ and CD_3CHO increased to 32 and 44%, respectively.

(6) The rate data for the reaction of $O+(CD_3)_2CH_2$ were fitted by an Arrhenius expression; $k_3=(2.01^{+1.0}_{-0.7})\times 10^{-10}\exp[(-6086\pm392\ \text{cal mol}^{-1})/RT]$ cm^3 $molecule^{-1}$ s^{-1} (381—627 K). The rate constant obtained from the yields of products was 7.9×10^{-15} cm^3 $molecule^{-1}$ s^{-1} at 298K.

The author wishes to thank Professor Kyle D. Bayes of UCLA for his kind and helpful suggestions and discussions. The assistance of Hiroo Takagi in the early stage of this work is gratefully acknowledged.

14) Reaction of propane with atomic oxygen starts by the hydrogen abstraction reaction

$$C_3H_8+O\rightarrow C_3H_7+OH \quad (A)$$

OH radicals can also be produced by the subsequent radical-atom reactions. OH radicals can react with C_3H_8 faster than Reaction A

$$C_3H_8+OH\rightarrow C_3H_7+H_2O \quad (B)$$

The rate constants for Reactions A and B at 298K have been reported to be $(8—15)\times10^{-15}$ (Refs. 3, 15, 16) and $(0.8—2)\times10^{-12}$ cm^3 $molecules^{-1}$ s^{-1} (Refs. 17—23), respectively. OH radicals are destroyed by the following two reactions:

$$OH+O\rightarrow H+O_2 \quad (C)$$

$$OH+\text{wall}\rightarrow\text{removal of OH} \quad (D)$$

Therefore, in order to avoid an effect of the OH radicals on the formation of C_3H_7 radicals, the ratio of $k_B[C_3H_8]/k_C[O]$ must be less than 0.1. The rate constant of Reaction C has been reported to be $(3—4)\times10^{-11}$ cm^3 $molecule^{-1}$ s^{-1} (Refs. 24—27) at 298K. The above requirement means that the kinetic experiments should be done under the condition that the concentration of oxygen atoms must be at least twice as large as the concentration of propane.

29) The reaction of $O+C_3H_8$ might proceed as follows:

$$O + C_3H_8 \begin{cases} \rightarrow n\text{-}C_3H_7 + OH & (E) \\ \rightarrow i\text{-}C_3H_7 + OH & (F) \end{cases}$$

$$n\text{-}C_3H_7 + O \begin{cases} \rightarrow C_3H_6 + OH & (G) \\ \rightarrow C_2H_5CHO + H & (H) \\ \rightarrow CH_2O + C_2H_5 & (I) \end{cases}$$

$$i\text{-}C_3H_7 + O \begin{cases} \rightarrow C_3H_6 + OH & (J) \\ \rightarrow (CH_3)_2CO + H & (K) \\ \rightarrow CH_3CHO + CH_3 & (L) \end{cases}$$

Ketene, CH_2CO (see Ref. 30), can be produced by a secondary reaction (Ref. 31) such as;

$$CH_3CHO + O \rightarrow CH_3CO + OH \quad (M)$$
$$CH_3CO + O \rightarrow CH_2CO + OH \quad (N)$$

30) Since the photoionization mass spectrometer is very sensitive to ketene (5—20 times more sensitive than other organic compounds), its absolute concentration is much smaller than is suggested by the signal intensity.

31) N. Washida and K.D. Bayes, unpublished data.

32) $CH_3CO+O \rightarrow CH_3+CO_2$ (Refs. 31 and 33) subsequent to Reaction M in Ref. 29.

33) G. P. R. Mack and B. A. Thrush, *J. Chem. Soc., Faraday Trans. 1*, **70**, 178 (1974).

34) $CH_3+O \rightarrow CH_2O+H$ from Refs. (13 and 35).

35) H. Niki, E. E. Daby, and B. Weinstock, *J. Chem. Phys.*, **48**, 5729 (1968).

36) The consumption of oxygen atoms in the reactor was corrected as follows: Oxygen atoms are destroyed by Reactions 3, 4, O, and P.

$$OD + O \rightarrow O_2 + D \quad (O)$$
(or $OH + O \rightarrow O_2 + H$)
$$CD_3 + O \rightarrow CD_2O + D \quad (P)$$

Further, a major part of the CD_2CHCD_3 produced in Reaction 4a and a small part of the CD_3CHO produced in Reaction 4c react with atomic oxygen. According to the results by Kanofsky et al. (Ref. 37), the major routes of the $O+C_3H_6$ reaction are:

$$O + C_3H_6 \begin{cases} \rightarrow CHO + C_2H_5 & (Qa) \\ \rightarrow CH_3 + CH_3CO & (Qb) \end{cases}$$

Therefore, the stoichiometric factor, n, for the number of oxygen atoms consumed per $(CD_3)_2CH_2$ reacted varies from 2.5 to 8 depending on the reaction time. A value $n=6$ was used for all experiments in the present study. The value of $[\bar{O}]t$, which is a product of the average oxygen-atom concentration and the reaction time, were calculated by Eq. R.

$$[\bar{O}]t = [O]_0 \int_0^t \exp(-nk_3[P]t)\,dt \quad (R)$$

where, $[O]_0$, k_3, and [P] are the original oxygen-atom concentration, the rate constant for Reaction 3, and the concentration of $(CD_3)_2CH_2$, respecrively. The value for k_3 of 7.91×10^{-15} cm^3 molecule^{-1} s^{-1} was used for this calculations as will be discussed later.

N. Pitts, Jr., *J. Chem. Phys.*, **67**, 38 (1977).

39) P. F. Ambridge, J. N. Bradley, and D. A. Whytock, *J. Chem. Soc., Faraday Trans. 1*, **72**, 1870 (1976); J. H. Lee and R. B. Timmons, *Int. J. Chem. Kinet.*, **9**, 133 (1977).

40) D. L. Singleton, R. S. Irwin, and R. J. Cvetanovic, *Can. J. Chem.*, **55**, 3321 (1977).

41) For $(CD_3)_2C^{18}O$, since ^{18}O used is 19.2% in O, f_{4b} and s_{7b} were determined by Eq. S.

$$[(CD_3)_2C^{18}O] = \left\{f_{4b} + \frac{(s_{7b}-f_{4b})X}{1+X}\right\} 0.192k_3[P][\bar{O}]t \quad (S)$$

For $CD_3CH^{18}O$, f_{4c} and s_{7c} were calculated by Eq. T since a correction of the consumption of $CD_3CH^{18}O$ by Reaction 15 is necessary.

$$[(CD_3)_2C^{18}O] = \left\{f_{4c} + \frac{(s_{7c}-f_{4c})X}{1+X}\right\} 0.192k_3[P][\bar{O}]t \, \frac{1-e^{-k_{15}[\bar{O}]t}}{k_{15}[\bar{O}]t} \quad (T)$$

42) The amount of $(CD_3)_2CO$ produced when $[O_2]$ is zero was calculated to be 4.76×10^{10} molecule cm^{-3} in the case of Fig. 9. In the case of Fig. 11, the total amount of actone produced when $[O_2]$ is zero was 12.36×10^{10} molecule cm^{-3} (the amount of $(CD_3)_2C^{18}O$ was 2.37×10^{10} molecule cm^{-3}). The ratio of the yield of three reaction products produced initially by Reaction 4, $f_{4a}:f_{4b}:f_{4c}$, was 3.56 : 1 : 1.16. Therefore, the sums of the amounts of three products are 27.24 and 69.36×10^{10} molecule cm^{-3} in cases of Figs. 9 and 11, respectively. Since the values for $[O]t$ were 11.06 and 11.14×10^{11} molecule s cm^{-3} for Figs. 9 and 11, respectively, values for k_3 calculated from $k_3[O][(CD_3)_2CH_2]t$=[total products] are 7.86 and 7.96×10^{-15} cm^3 molecule^{-1} s^{-1} for Figs. 9 and 11, respectively. The average value of 7.91×10^{-15} cm^3 molecule^{-1} s^{-1} was used for all subsequent calculations.

Oxidation of $(CD_3)_2\dot{C}X$ Radicals. II. Reaction of $(CD_3)_2CHCl$ and $(CD_3)_2\dot{C}Cl$ Radicals with Atomic Oxygen

Nobuaki WASHIDA* and Shiro HATAKEYAMA
Division of Atmospheric Environment, The National Institute for Environmental Studies,
P.O. Tsukuba-gakuen, Ibaraki 305
(Received April 10, 1987)

The reaction of oxygen atoms with $(CD_3)_2CHCl$ in a fast flow system was studied with a photoionization mass spectrometer. The $(CD_3)_2\dot{C}Cl$ radical formed by the initial hydrogen abstraction at the 2-position was detected directly.

$$(CD_3)_2CHCl + O(^3P) \rightarrow (CD_3)_2\dot{C}Cl + OH \quad (1)$$

The rate data for Reaction 1 were fitted by an Arrhenius expression: $k_1=(3.5^{+1.2}_{-0.9})\times10^{-11}$ exp[(−4973±278 cal mol^{-1})/RT]† cm^3 molecule^{-1} s^{-1} (399—628 K). Among the products formed in the subsequent reaction of $(CD_3)_2\dot{C}Cl$ radicals with atomic oxygen, $CD_3CCl=CD_2$ (31%) produced by the deuterium abstraction and $(CD_3)_2CO$ (24%) by the oxygen addition were observed. Competition experiments show that $(CD_3)_2\dot{C}Cl$ radicals react (0.0079 ±0.0010) times as fast with O_2 as with $O(^3P)$. In the presence of an excess of O_2, $CD_3CCl=CD_2$ was observed in decreased yield (3.5%) and $(CD_3)_2CO$ increased to 56%.

Since the formation of $(CD_3)_2\dot{C}H$ radicals was confirmed in the reaction of atomic oxygen with $(CD_3)_2CH_2$, the reaction of $(CD_3)_2CHCl$ with atomic oxygen is investigated in the present study as an analogy of the reaction. In the reaction of O+$(CD_3)_2CHCl$, it is supposed that the $(CD_3)_2\dot{C}Cl$ radical is produced by the initial attack of $O(^3P)$ on $(CD_3)_2CHCl$.

$$(CD_3)_2CHCl\ \ O(^3P) \rightarrow (CD_3)_2\dot{C}Cl + OH \quad (1)$$

The subsequent reaction of the $(CD_3)_2\dot{C}Cl$ radicals with atomic oxygen can be considered as follows by the analogy of the O+propyl radical reaction:

$$(CD_3)_2\dot{C}Cl + O(^3P) \rightarrow \begin{cases} CD_3CCl=CD_2 + OD & (2a) \\ (CD_3)_2CO + Cl & (2b) \\ CD_3CClO + CD_3 & (2c) \end{cases}$$

A question of interest is the change of the branching ratio of each process, 2a—c, due to a chlorine substitution for a hydrogen at 2-position of propane.

Experimental

The experimental setup and procedures were the same as those mentioned before.[1] $(CD_3)_2CHCl$ was synthesized[2] in this laboratory. All measurements were done at room temperature, 298±3 K, under the conditions [O]>0.5 $[(CD_3)_2CHCl]$.[3]

Results and Discussion

A. Radicals and Molecules Detected in the $(CD_3)_2CHCl$+O Reaction. Radicals produced in the reaction of $(CD_3)_2CHCl$ with atomic oxygen were detected at m/z=83 and 85 when a Xe lamp with a sapphire window (8.44 eV) was used as a photoionization light source. Mass spectra measured are shown in Fig. 1. Other products produced by subsequent reactions and the parent $(CD_3)_2CHCl$ were not photoionized by this lamp. Radicals observed at m/z=83 and 85 are $(CD_3)_2\dot{C}^{35}Cl$ and $(CD_3)_2\dot{C}^{37}Cl$, respectively. The ratio of the signal intensities at m/z=83 and 85 corresponds to the ratio of the natural abundance of ^{35}Cl (75.5%) and ^{37}Cl (24.5%). No observation of the signals at

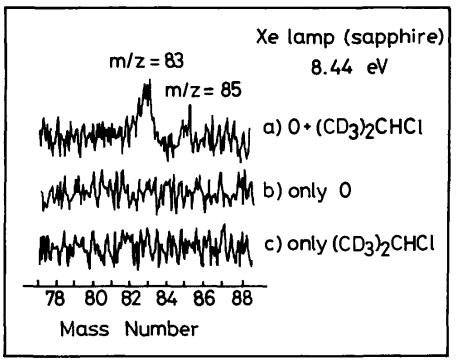

Fig. 1. Mass spectra of the $(CD_3)_2\dot{C}Cl$ radical produced in the O+$(CD_3)_2CHCl$ reaction. A Xe lamp having a sapphire window (8.44 eV) was used for the photoionization. The conditions: Partial pressure (mTorr), $[O]_0$=3.5, $[(CD_3)_2CHCl]$=0.82; reaction time=4.6 ms; total pressure=3.6 Torr.

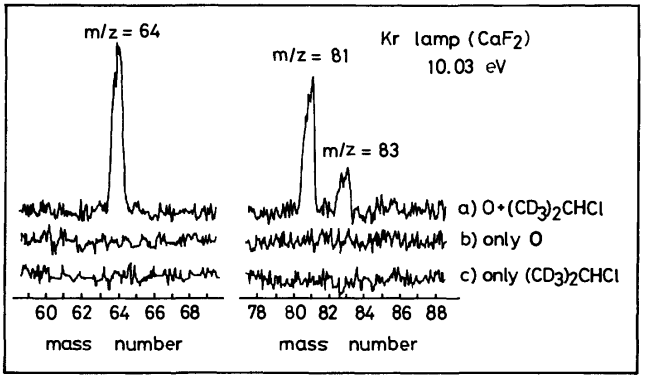

Fig. 2. Mass spectra of the reaction products produced in the O+$(CD_3)_2CHCl$ reaction. A Kr lamp having a CaF_2 window (10.03 eV) was used for the photoionization. The conditions: partial pressure (mTorr), $[O]_0$=3.1, $[(CD_3)_2CHCl]$=0.63; reaction time=4.6 ms; total pressure=3.6 Torr.

† 1 cal=4.184 J.

Table 1. Rate Data for $O(^3P)+(CD_3)_2CHCl$ at 399—628 K

T	$[P\text{-}Cl]_0$[a]	$[O]_0$	Total pressure	k_3
K	mTorr	mTorr	Torr	10^{-14} cm^3 molecule^{-1} s^{-1}
628	0.102	6.211	5.38	67.2±5.3
621	0.099	5.689	5.21	57.1±5.2
606	0.081	6.338	5.54	62.9±6.6
588	0.113	4.996	5.61	48.2±5.2
513	0.121	5.932	5.38	25.8±4.1
496	0.098	6.018	6.07	24.6±3.6
421	0.123	6.230	6.12	9.02±0.81
414	0.139	8.440	6.80	8.11±0.74
408	0.114	6.795	6.65	8.83±0.44
399	0.141	6.833	6.83	6.31±0.73

a) $[P\text{-}Cl]_0$ represents the original concentration of $(CD_3)_2CHCl$.

m/z=82 and 84 (deuterium abstraction by $O(^3P)$) shows that the initial attack of $O(^3P)$ on $(CD_3)_2CHCl$ occurs in selective abstraction of a hydrogen at 2-position of $(CD_3)_2CHCl$; Reaction 1.

Products produced in the reaction of oxygen atoms with $(CD_3)_2\dot{C}Cl$ radicals were measured by using a Kr lamp having a CaF_2 window (10.03 eV). Mass spectra obtained are shown in Fig. 2. Signals for $(CD_3)_2CO$ (m/z=64), $CD_3C^{35}Cl{=}CD_2$ (m/z=81), and $CD_3C^{37}ClCD_2$ (m/z=83) were observed as expected in Reaction 2.

Since ionization potential for acetyl chloride, CH_3COCl, has been reported[4] to be 11.02 eV, CD_3COCl formed by Reaction 2c cannot be ionized by the Kr resonance line but should be ionized by the Ar resonance lines (11.83 and 11.62 eV). Detection of CD_3COCl was investigated by using an Ar lamp with a LiF window. Since mass numbers of CD_3COCl and $CD_3CCl{=}CD_2$ are identical in the present case, $(CD_3)_2CHCl$ was reacted with ^{18}O (19.2% of $^{36}O_2$ in $^{32}O_2$ was diluted in helium and discharged by microwave) and the measurement of the signals for $CD_3C^{18}O^{37}Cl$ at m/z=85 was investigated. However, no significant signal at m/z=85 was observed except the isotope (^{13}C) signal of the parent $(CD_3)_2CH^{35}Cl$ molecule. In order to determine whether CD_3COCl is produced in Reaction 2 or not, the sensitivity measurement of acetyl chloride to the instrument when the Ar lamp was used as a photoionization light source was carried out by adding known partial pressures of CH_3COCl to the reactor. Surprisingly, no signal was observed even when up to 1 mTorr†† of CH_3COCl was added to the reactor. Since about 5×10^4 counts s^{-1} signals were obtained for 1 mTorr of NO in the reactor, we have to conclude that acetyl chloride cannot be ionized by the Ar resonance lines, and it cannot be determined whether Reaction 2c occurs or not.

B. Rate Constant for the $(CD_3)_2CHCl$ Reaction. The pseudo-first-order decay rates of $(CD_3)_2CHCl$ by Reaction 1 were measured over a temperature range of 399—628 K in a large excess of oxygen atoms by changing the contact time of $(CD_3)_2CHCl$ with oxygen atoms. An Ar lamp with a LiF window was used to photoionize $(CD_3)_2CHCl$ and the bimolecular rates of Reaction 1 were measured from the decay of the signal of $(CD_3)_2CH^{37}Cl$ at m/z=86. Values for k_1 obtained are listed in Table 1. The 95% confidence limits were calculated from the least squares line using ten points for each run. The concentration of oxygen atoms was corrected using a stoichiometric factor of n=6 as described in the preceeding paper.[1] The correction for oxygen atom consumption was 5% or less.

The linear least square treatment for the values of k_1 shown in Table 1 yields the Arrhenius expression of $k=A\exp(-E_a/RT)$.

$$k_1 = (3.5^{+1.2}_{-0.9}) \times 10^{-11} \exp\left(\frac{-4973\pm278 \text{ cal mol}^{-1}}{RT}\right); \quad (3)$$

in unit of cm^3 molecule^{-1} s^{-1}. The indicated errors were calculated by the least-square with 95% confidence limits. The rate constant for Reaction 1 at 298K calculated by Eq. 3 is 7.8×10^{-15} cm^3 molecule^{-1} s^{-1}.

The rate constants for the reaction of atomic oxygen with 2-chloropropane, $(CH_3)_2CHCl$, have been measured over a temperature range of 336—622K by Herron and Huie.[5] The Arrhenius expression obtained from their data was $k=(4.3^{+0.9}_{-0.6})\times10^{11}\exp[(-5206\pm139)/RT]$ cm^3 molecule^{-1} s^{-1} with a value at 298K of $k=6.5\times10^{-15}$ cm^3 molecule^{-1} s^{-1}. Values of Arrhenius activation energy, frequency factor, and the rate at 298K obtained in the present study for the $O+(CD_3)_2CHCl$ reaction are in good agreement with those measured in the $O+(CH_3)_2CHCl$ reaction by Herron and Huie.

C. Competition between $O(^3P)$ and O_2 for $(CD_3)_2\dot{C}Cl$. The steady-state concentrations of $(CD_3)_2\dot{C}Cl$ radicals were evidenced by no change of signals by changing the contact time of the reaction of $(CD_3)_2CHCl$ with oxygen atoms. The competition between $O(^3P)$ and O_2 for the $(CD_3)_2\dot{C}Cl$ radicals was measured by adding molecular oxygen to the system. The steady-state concentration of $(CD_3)_2\dot{C}Cl$ was decreased by the addition of O_2 and the competition results in a Stern-Volmer-type of equation,

†† 1 Torr=133.322 Pa.

$$\frac{[\text{pr-Cl}]^0_{ss}}{[\text{pr-Cl}]_{ss}} = 1 + \frac{k_5[O_2]}{k_2[O]} \quad (4)$$

where $[\text{pr-Cl}]_{ss}$ represents the steady-state concentration of $(CD_3)_2\dot{C}Cl$ radicals, the superscript zero refers to the condition in the absence of O_2 and k_5 is the effective second-order rate constant for the reaction of $(CD_3)_2\dot{C}Cl$ radicals with molecular oxygen.

$$(CD_3)_2\dot{C}Cl + O_2 \rightarrow \text{Products} \quad (5)$$

Figure 3 shows the result of an O_2 addition experiment. The concentration of $(CD_3)_2\dot{C}Cl$ radical was monitored by the signal at m/z=83, $(CD_3)_2\dot{C}^{35}Cl$. A value for $[(CD_3)_2\dot{C}Cl]^0_{ss}$ was determined by the method mentioned before.[5] The concentration of oxygen atoms, $[\bar{O}]$, was corrected using a stoichiometric factor of n=6 (the correction was 0.4%). The value for k_5/k_2 calculated from the slope is 0.0079±0.0010. Error limits due to the scatter of plots were calculated by the least square with the 95% confidence limits.

The value for k_5/k_2 suggests that the rate of the reaction of $(CD_3)_2\dot{C}Cl+O_2$ is 127 times slower than that of the $(CD_3)_2\dot{C}Cl+O$ reaction. This competition ratio of 127 is larger than that in the case of $(CD_3)_2\dot{C}H$ radicals where the ratio was 35. This result suggests that the rate of the reaction of $(CD_3)_2\dot{C}Cl+O_2$ is much slower than that of $(CD_3)_2\dot{C}H+O_2$ if the rate of the reaction of $(CD_3)\dot{C}Cl+O(^3P)$ and that of $(CD_3)_2\dot{C}H+O$ are close.

D. Time Dependence of Products. The dependence of the $(CD_3)_2CO$ and $CD_3CCl=CD_2$ signals on the reaction time was measured. Solid circles in Fig. 4 show the $CD_3C^{35}Cl=CD_2$ signal at m/z=81 in the $O+(CD_3)_2CHCl$ reaction. $CD_3CCl=CD_2$ approaches a constant concentration at long reaction time. This results from the fast reaction of $O+CD_3CCl=CD_2$, Reaction 6,

$$CD_3CCl=CD_2 + O \rightarrow \text{Products} \quad (6)$$

This approach to the steady-state concentration is

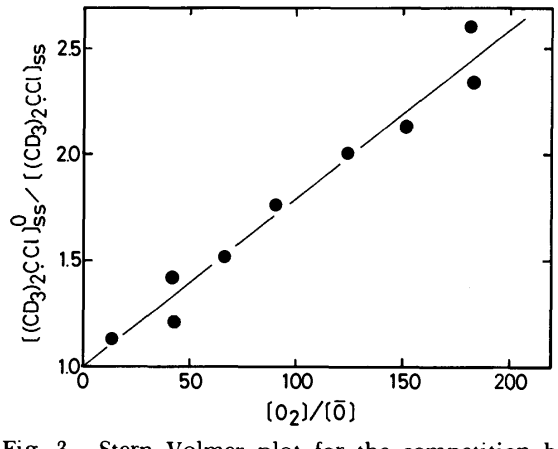

Fig. 3. Stern-Volmer plot for the competition between O_2 and $O(^3P)$ for the $(CD_3)_2\dot{C}Cl$ radicals. Conditions: Partial pressure (mTorr), $[O]_0$=2.03, $[\bar{O}]$=2.02, $[(CD_3)_2CHCl]_0$=0.71; $[O_2]_0$=29.65; total pressure=3.58 Torr; reaction time=4.59 ms. $[O_2]$ was calculated from $[O_2]_{added}+[O_2]_0-1/2[O]_0$.

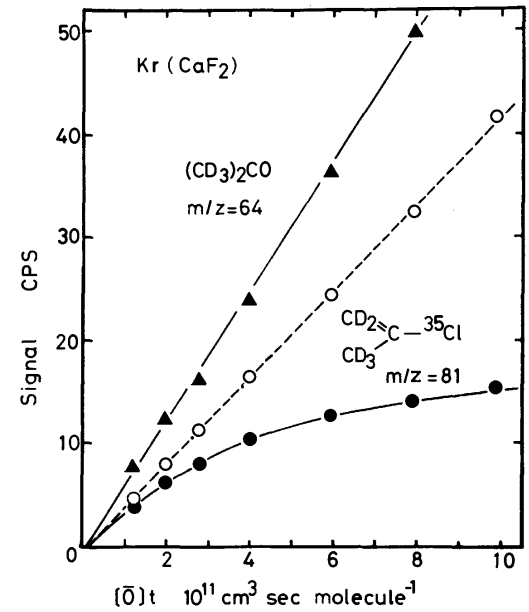

Fig. 4. Time dependence of $CD_3CCl=CD_2$ (solid circles) and $(CD_3)_2CO$ (solid triangles) signals produced in the $O+(CD_3)_2CHCl$ reaction. A Kr lamp with a CaF_2 window (10.03 eV) was used for the photoionization. The conditions: partial pressure (mTorr), $[O]_0$=2.62, $[(CD_3)_2CHCl]_0$=0.75, $[O_2]_0$=26,53; total pressure=3.55 Torr. Reaction times used were 1.4—11.5 ms. Correction for $[\bar{O}]$ were 0.7% or less. The $CD_3CCl=CD_2$ signals are corrected for the subsequent reaction to give $[CD_3CCl=CD_2]_T$ as indicated by open circles.

given by Eq. 7, assuming that Reaction 2 is much faster than Reactions 1 and 6.

$$[CD_3CCl=CD_2] = \frac{f_{2a}k_1}{k_6}[\text{P-Cl}][1-\exp(-k_6[\bar{O}]t)] \quad (7)$$

Here f_{2a} and [P-Cl] represent the fraction of Reaction 2a in the total reaction of $(CD_3)_2\dot{C}Cl$ radicals with atomic oxygen, Reaction 2, and the original concentration of $(CD_3)_2CHCl$. The values of $[\bar{O}]t$, which is a product of the average oxygen atom concentration and the reaction time, were calculated by using a stoichiometric factor n=6 as described before. The correction for oxygen atom consumption was less than 0.7%. When the plots shown by solid circles are fitted to Eq. 7, a value for k_6 of $(2.5\pm0.1)\times10^{-12}$ cm^3 molecule^{-1} s^{-1} is calculated. The best fit line for Eq. 7 is shown as a solid line in Fig. 4. The total amount of $CD_3CCl=CD_2$ produced by Reaction 2a, $[CD_3CCl=CD_2]_T$, is given by Eq. 8.

$$[CD_3CCl=CD_2]_T = f_{2a}k_1[\text{P-Cl}][\bar{O}]t \quad (8)$$

Therefore, the total amount of $CD_3CCl=CD_2$ can be calculated by multiplying each observed $CD_3CCl=CD_2$ value by $k_6[\bar{O}]t[1-\exp(-k_6[\bar{O}]t)]^{-1}$. These corrected points are shown as open circles in Fig. 4, and they are represented by the dashed straight line.

The time dependence of the $(CD_3)_2CO$ signal at m/z=64 produced in the $O+(CD_3)_2CHCl$ reaction is

shown as triangles in Fig. 4. Since the reaction of $O+(CD_3)_2CO$ is slow on the time scale shown, $(CD_3)_2CO$ rises linearly.

The rate constant for the $O+CD_3CCl=CD_2$ reaction was determined to be $(2.5\pm0.1)\times10^{-12}$ cm^3 molecule^{-1} s^{-1}. There is no previous determination of the rate constant for the reaction of O+2-chloropropene, $CH_3CCl=CH_2$, with which the value of k_6 can be compared. Since the standard sample of 2-chloropropene was not available, the pseudo-first-order decays were measured for the reaction of oxygen atoms with 1-chloro-1-propene, $CH_3CH=CHCl$ (cis- and trans-mixture from Tokyo Kasei), and 3-chloro-1-propene, $CH_2ClCHCH_2$ (from Tokyo Kasei). Results are listed in Table 2 with the value of the rate constants for $O+CD_3CCl=CD_2$ and $CD_3CH=CD_2$ reactions obtained by the steady-state approach method. In the measurements, since $CH_3CH=CHCl$ can be ionized by a Kr lamp with a CaF_2 window (10.03 eV) but $CH_2ClCH=CH_2$ cannot, an Ar lamp with a LiF window (11.83 and 11.62 eV) was used to ionize $CH_2ClCH=CH_2$. The rate for the $O+CD_3CCl=CD_2$ reaction is faster than that for the $O+CH_2ClCH=CH_2$, slower than that for the $O+CD_3CH=CD_2$, and close to that for the $O+CH_3CH=CHCl$ reaction. The rate constants for the reactions of 2-fluoro-1-propene and 3-fluoro-1-propene with oxygen atoms have been reported.[6,7] These values are close to those of chloropropenes and are also listed in Table 2.

It has been noted[8-10] for olefins that there is a good correlation between the rate constant with atomic oxygen and ionization potential. In the present case, since the rate constant for the $O+CH_3CH=CHCl$ reaction is close to that for $O+CD_3CCl=CD_2$, tentatively $CH_3CH=CHCl$ can be used as a standard sample to estimate the absolute concentration of $CD_3CCl=CD_2$. Supposing that the ionization cross sections of $CH_3CH=CHCl$ and $CD_3CCl=CD_2$ for the Kr resonance line of 10.03 eV are equal, the absolute concentrations of $CD_3CCl=CD_2$ were calculated using the instrumental sensitivity of $CH_3CH=CHCl$. The ratio of the slope of the dashed straight line to that for $(CD_3)_2CO$ is 0.67. The relative sensitivity of the instrument for $CH_3CHCH^{35}Cl$ and acetone was measured as 1 : 1.8 by using a Kr lamp (CaF_2). Thus the ratio of the rate of formation of these two products was tentatively $CD_3CCl=CD_2$:$(CD_3)_2CO$=1.2 : 1 considering the natural abundance of ^{35}Cl and ^{37}Cl.

E. Yields of the Products. The effect of the O_2 on the products was measured by adding O_2 to the system. The signal of $CD_3CCl=CD_2$ decreased and that of $(CD_3)_2CO$ increased when O_2 was added. Results are shown in Fig. 5. The two points on the left-hand side

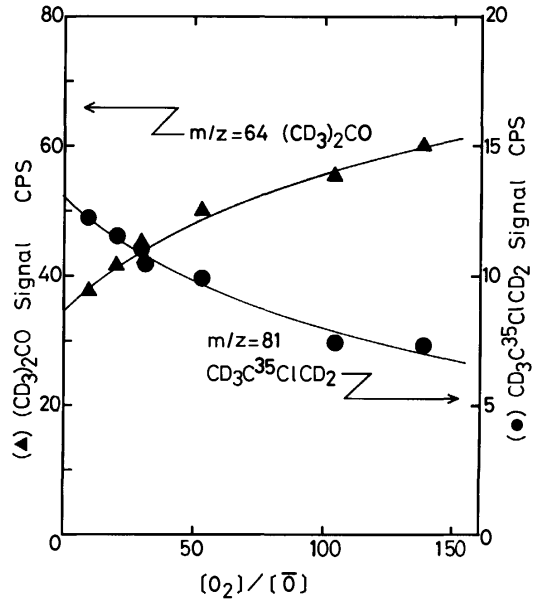

Fig. 5. Changes of signals of $(CD_3)_2CO$ at m/z=64 and $CD_3C^{35}Cl=CD_2$ at m/z=81 by the addition of O_2. Conditions: partial pressure (mTorr) $[O]_0$= 2.63, $[\bar{O}]$=2.62, $[(CD_3)_2CHCl]_0$=0.75, $[O_2]_0$= 26.53; reaction time=6.89ms; total pressure= 3.55 Torr. $[O_2]$ was calculated from $[O_2]_{added}+[O_2]_0-1/2[O]_0$. The points shown on the left-hand side are obtained from just $[O_2]_0-1/2[O]_0$ (no $[O_2]_{added}$).

Table 2. Rate Constants for the Reaction of $O(^3P)$+Chloro- and Fluoro-Propene at 298 K

Reaction	Rare constant at 298K / 10^{12} cm^3 molecule^{-1} s^{-1}	Method	Reference
$O+CH_3CH=CHCl$ (Cis- and trans-mixture)	(2.1±0.2)	Pseudo-first-order decay[a]	This work
$O+CH_2ClCH=CH_2$	(0.77±0.05)	Pseudo-first-order decay[b]	This work
$O+CD_3CCl=CD_2$	(2.5±0.1)	Steady-state approach	This work
$O+CD_3CH=CD_2$	(4.1±0.2)	Steady-state approach	Ref. 1
$O+CH_2FCH=CH_2$	0.73	Hg photosens. decomp of N_2O	Refs. 6, 7
$O+CH_3CF=CH_2$	1.7	Hg photosens. decomp of N_2O	Refs. 6, 7

a) The pseudo-first-order decay of $CH_3CH=CHCl$ was measured under the conditions: $[CH_3CH=CHCl]_0$= 0.023 Torr, $[O]_0$=1.24 mTorr, total pressure=4.5 Torr and reaction time 0.9—7.3 ms. A Kr lamp with a CaF_2 window (10.03 eV) was used to photoionize $CH_3CH=CHCl$. The decay of the signal was measured at m/z=76. b) The pseudo-first-order decay of $CH_2ClCH=CH_2$ was measured under the conditions: $[CH_2ClCH=CH_2]_0$=0.022 Torr, $[O]_0$=2.14 mTorr, total pressure=4.5 Torr and reaction time 0.9—7.3 ms. An Ar lamp with a LiF window (11.83 eV and 11.62 eV) was used to photoionize $CH_2ClCH=CH_2$. The decay of the signal was measured at m/z=76.

are the points obtained by the O_2 just surviving from the O_2/He discharge (no addition of O_2). If the fraction of $CD_3CCl{=}CD_2$ produced in Reaction 5 is represented by s_{5a}, the concentration of $CD_3CCl{=}CD_2$ at reaction time t is given by Eqs. 9 and 10 when both $O(^3P)$ and O_2 are present.

$$[CD_3CCl{=}CD_2] = f_{2a} + \left\{\frac{(s_{5a}-f_{2a})X}{1+X}\right\}\frac{k_1}{k_6}[\text{P-Cl}]\times [1-\exp(-k_6[\bar{O}]t)] \quad (9)$$

$$X = \frac{k_5}{k_2}\frac{[O_2]}{[\bar{O}]} \quad (10)$$

Similarly, the concentration of $(CD_3)_2CO$ at reaction time t is represented by Eq. 11;

$$[(CD_3)_2CO)] = f_{2b} + \left\{\frac{(s_{5b}-f_{2b})X}{1+X}\right\}k_1[\bar{O}][\text{P-Cl}]\,t \quad (11)$$

where s_{5b} refers to the fraction of $(CD_3)_2CO$ produced in Reaction 5 and [P-Cl] represents the concentration of $(CD_3)_2CHCl$. Since the value for k_5/k_2 was determined before, the concentrations of $CD_3CCl{=}CD_2$ and $(CD_3)_2CO$ can be plotted against $X/(1+X)$, as shown in Fig. 6. Using the values for k_1 and k_6 determined before and known initial concentration of $(CD_3)_2CHCl$ and the reaction time, values for f_{2a} and f_{2b} can be determined from the intercepts of the two lines. The values for s_{5a} and s_{5b} can be calculated from the slopes of the two straight lines in Fig. 6. Here, the instrumental sensitivity of $CH_3CH{=}CHCl$ was used in order to estimate the absolute concentrations of $CD_3CCl{=}CD_2$ ($^{35}Cl{+}^{37}Cl$). Values obtained are 0.31±0.03 for f_{2a}, 0.24±0.03 for f_{2b}, 0.035±0.003 for s_{5a}, and 0.56±0.05 for s_{5b}.

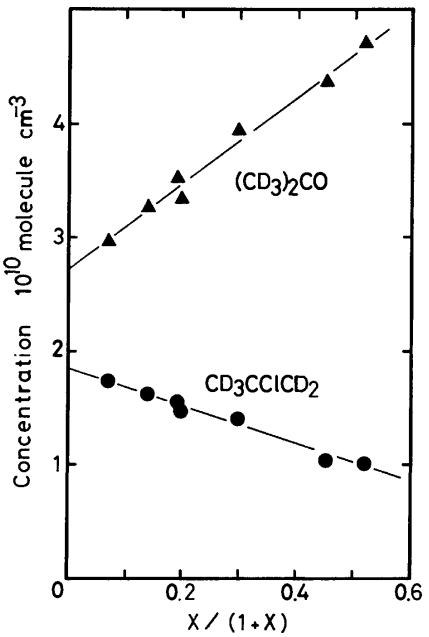

Fig. 6. The absolute concentrations of $(CD_3)_2CO$ and $CD_3CCl{=}CD_2$ ($^{35}Cl{+}^{37}Cl$) are plotted against $X/(1+X)$. Conditions are the same as the case of Fig. 5.

Table 3. Sum of the Heat of Formation of the Products of Reaction of $(CH_3)_2CH{+}O$ and $(CH_3)_2CCl{+}O$

Reaction	ΔH/kcal mol^{-1} a)
$C_3H_6{+}OH$	14.2
$(CH_3)_2CO{+}H$	−0.9
$CH_3CHO{+}CH_3$	−5.7
$CH_3CCl{=}CH_2$ b)$+OH$	3.3
$(CH_3)_2CO{+}Cl$	−22.9
$CH_3COCl{+}CH_3$	−24.2

a) Values of H^0_{298} are from Ref. 4. b) Calculated by the group additivity rule, Ref. 11.

$$(CD_3)_2\dot{C}Cl + O \xrightarrow{31\pm3\%} CD_3CCl{=}CD_2$$
$$\xrightarrow{24\pm3\%} (CD_3)_2CO \quad (2)$$

$$(CD_3)_2\dot{C}Cl + O_2 \xrightarrow{3.5\pm0.3\%} CD_3CCl{=}CD_2$$
$$\xrightarrow{56\pm5\%} (CD_3)_2CO \quad (5)$$

The yield of $CD_3CCl{=}CD_2$ from the oxygen atom reaction was 31%. This yield is smaller than the corresponding formation of $CD_3CH{=}CD_2$ (61%) in the reaction of $O{+}(CD_3)_2\dot{C}H$. On the other hand the yield of $(CD_3)_2CO$ (24%) is larger than that obtained in the $O{+}(CD_3)_2\dot{C}H$ reaction (18%). The results suggest that the probability of the deuterium abstraction from the radicals is decreased by the chlorine substitution for a hydrogen at 2-position of the isopropyl radical. The results might be explained from the exothermicity of the product channels shown in Table 3. The exothermicity of the addition routes was relatively raised by the chlorine substitution. Although the formation of CD_3COCl could not be observed, the most probable product corresponding to the residual 45% is CD_3COCl.

The channel of the deuterium abstraction (the $CD_3CCl{=}CD_2$ formation) decreased by the addition of O_2 and that of the oxygen atom addition (the $(CD_3)_2CO$ formation) increased as the case of the $(CD_3)_2\dot{C}H$ radical. These products are probably produced by the reaction of oxygen atoms with $(CD_3)_2CCl(O_2\cdot)$ radicals as described in the case of the $(CD_3)_2\dot{C}H$ radical.

$$(CD_3)_2\dot{C}Cl + O_2 \xrightarrow{+M} (CD_3)_2CCl(O_2\cdot) \quad (5)$$

$$(CD_3)_2CCl(O_2\cdot) + O \rightarrow \begin{cases} CD_3CCl{=}CD_2 + OD + O_2\ (3.5\%) & (12a) \\ (CD_3)_2CO + Cl + O_2\ (56\%) & (12b) \\ CD_3COCl + CD_3 + O_2\ (40\%) & (12c) \end{cases}$$

In the case of Reaction 12, product channels are affected more directly by the exothermicity.

Oxidation of $(CD_3)_2\dot{C}X$ Radicals. III. Reaction of 2-Propanol and $(CD_3)_2\dot{C}(OH)$ Radicals with Atomic Oxygen

Nobuaki WASHIDA
Division of Atmospheric Environment, The National Institute for Environmental Studies,
P.O. Tsukuba-gakuen, Ibaraki 305
(Received April 10, 1987)

The reaction of oxygen atoms with 2-propanol was studied in a fast flow system coupled with a photoionization mass spectrometer. Radicals formed in the primary attack of $O(^3P)$ atoms on 2-propanol were photoionized by the Xe lamp and identified as the $(CH_3)_2\dot{C}(OH)$ radical from $(CH_3)_2CH(OH)$ and $(CH_3)_2CD(OH)$ and the $(CD_3)_2\dot{C}(OH)$ radical from $(CD_3)_2CH(OH)$. The major primary product in the subsequent reaction of $O+(CD_3)_2\dot{C}(OH)$ was found to be acetone, $(CD_3)_2CO$, (62±4%). Formation of 1-propen-2-ol, $CD_3C(OH)=CD_2$, by deuterium abstraction and acetic acid, CD_3COOH, by oxygen addition were observed in the reaction of $O+(CD_3)_2\dot{C}(OH)$. In the reaction of $^{18}O+(CD_3)_2\dot{C}(OH)$, the acetone produced was mostly $(CD_3)_2CO$. This fact shows that acetone is produced predominantly by the hydrogen abstraction by $O(^3P)$ from the O-H in the $(CD_3)_2\dot{C}(OH)$ radical. A part of the acetone is produced also by the addition of $O(^3P)$ to the $(CD_3)_2\dot{C}(OH)$ radical; i.e., a small but significant signal of $(CD_3)_2C^{18}O$ was observed in the reaction of $^{18}O+(CD_3)_2\dot{C}(OH)$. The competition experiment between $O(^3P)$ and O_2 for the $(CD_3)_2\dot{C}(OH)$ radical shows that $(CD_3)_2\dot{C}(OH)$ react (0.16±0.02) times as fast with O_2 as with $O(^3P)$. This result suggests that the reaction of $(CD_3)_2\dot{C}(OH)$ with O_2 is very rapid. It is proposed that the rapid reaction is hydrogen abstraction by O_2 from the O-H in the $(CD_3)_2\dot{C}(OH)$ radical to form acetone and HO_2.

The study is extended[1] to reactions of oxygen atoms with 2-propanol and $(CD_3)_2\dot{C}(OH)$ radicals. There have been a few reports on the mechanism and the rate of the O+2-propanol reaction. Kato and Cvetanovic[2] studied the reaction of 2-propanol with oxygen atoms produced by the mercury photosensitized decomposition of dinitrogen monoxide. They suggested that abstraction of an α-hydrogen atom from 2-propanol to give $(CD_3)_2\dot{C}(OH)$ radicals takes place in the primary step, because they found the formation of pinacol, $[C(CH_3)_2OH]_2$, as a product. A large amount of acetone observed in the system was explained as a product of the radical-radical reaction. A kinetic investigation[3] reports that the rate constant for the reaction of $O(^3P)$ with 2-propanol is 1.3×10^{-14} cm^3 molecule^{-1} s^{-1} at 298K with an activation energy of 2.2 kcal mol^{-1}.

$$(CH_3)_2CH(OH)+O(^3P)\rightarrow(CD_3)_2\dot{C}(OH)+OH \quad (1)$$

In the present study, the reaction of oxygen atoms with 2-propanol was investigated in a fast-flow reactor coupled with a photoionization mass spectrometer in order to examine the following questions: (1) Can the $(CD_3)_2\dot{C}(OH)$ radical produced by the selective abstraction of an α-hydrogen suggested by Kato and Cvetanovic be detected by the photoionization mass spectrometry ?; (2) What products are produced by the radical-atom reaction ? Possible radical-atom reaction processes in both hydrogen abstraction and the oxygen atom addition are:
abstraction;

$$(CD_3)_2\dot{C}(OH)+O\rightarrow\begin{cases}(CH_3)_2CO\ (m/z=58)+OH & (2a)\\ CH_3C(OH)CH_2\ (m/z=58)+OH & (2b)\end{cases}$$

addition;

$$(CD_3)_2\dot{C}(OH)+O\rightarrow\begin{cases}(CH_3)_2CO\ (m/z=58)+OH & (2c)\\ CH_3COOH\ (m/z=60)+CH_3 & (2d)\end{cases}$$

subsequent to Reaction 1. In the previous study of the reaction of oxygen atoms with 1-hydroxyethyl radicals,[4] formation of acetaldehyde produced by hydrogen abstraction, a type of Reaction 2a, was observed as a major product (80%). Formation of vinyl alcohol, and formic and acetic acids, types of Reactions 2b and 2d, respectively, could not be observed.

Experimental

The experimental apparatus and procedures were the same as those mentioned before.[1] 2-Propanol (from Wako Pure Chemical Ind.), propan-2-*d*-2-ol, $(CH_3)_2CD(OH)$, and propan-1,1,1,3,3,3-d_6-2-ol, $(CD_3)_2CH(OH)$, (both from Merck Sharp & Dohm) were used without further purification except degassing. All measurements were done at room temperature, 298±3K, under the conditions $[O]>2[2\text{-propanol}]$.[5]

Results

A. Reaction of 2-Propanol with $O(^3P)$. Radicals produced by the initial attack of $O(^3P)$ on three different 2-propanols such as $(CH_3)_2CH(OH)$, $(CH_3)CD(OH)$, and $(CD_3)_2CH(OH)$ were detected when a Xe resonance lamp having a sapphire window (8.44 eV) was used as a photoionization light source. Radical signals observed are shown in Fig. 1. Possible radicals produced by abstraction of an α-hydrogen (a) and a β-hydrogen (b) in each 2-propanol are as follows:

$$(CH_3)_2CH(OH)+O\rightarrow\begin{cases}(CD_3)_2\dot{C}(OH)\ (m/z=59)+OH & (1a)\\ \cdot CH_2CH(CH_3)(OH)\ (m/z=59)+OH & (1b)\end{cases}$$

$$(CH_3)_2CD(OH)+O \rightarrow (CD_3)_2\dot{C}(OH)\ (m/z=59)+OD \quad (3a)$$
$$\rightarrow \cdot CH_2CD(CH_3)(OH)\ (m/z=60)+OH \quad (3b)$$

$$(CH_3)_2CH(OH)+O \rightarrow (CD_3)_2\dot{C}(OH)\ (m/z=65)+OH \quad (4a)$$
$$\rightarrow CD_2CH(CD_3)(OH)\ (m/z=64)+OD \quad (4b)$$

Isotopic measurements shown in Fig. 1 demonstrate that the radicals observed are produced by selective abstraction of an α-hydrogen in 2-propanol as suggested by Kato and Cvetanovic.[2] Since no significant signals were observed at m/z=60 and 64 in Reactions 3 and 4 considering the natural abundance of ^{13}C (1.11%) and the background noise, it is concluded that more than 99% of the primary attack of $O(^3P)$ atoms on 2-propanol is abstraction of α-hydrogen (or deuterium).

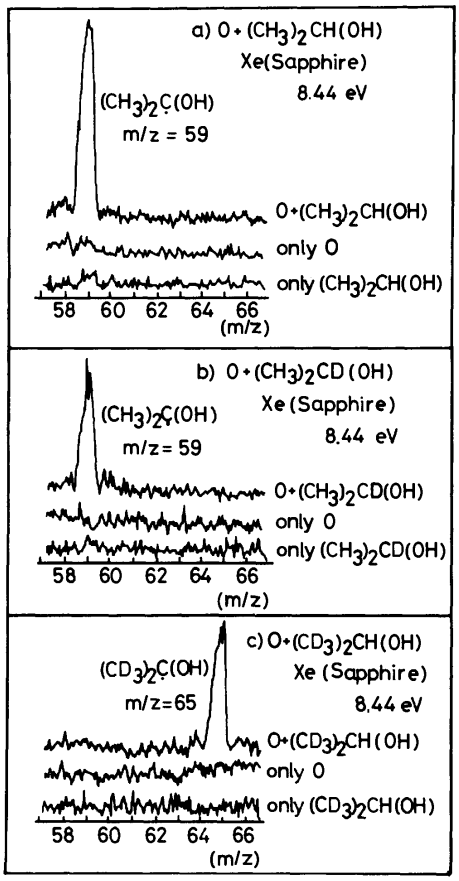

Fig. 1. Mass spectra of $(CH_3)_2C(OH)$ and $(CD_3)_2C(OH)$ radicals produced in O+2-propanol. A Xe lamp with a sapphire window (8.44eV) was used for the ionization. a) O+$(CH_3)_2$CH(OH); b) O+$(CH_3)_2$CD(OH); c) O+$(CD_3)_2$CH(OH). The conditions: $[O]_0$=0.87 mTorr; [2-propanol]$_0$=0.41 mTorr; reaction time 4.4 ms; total pressure 3.8 Torr.

The pseudo-first-order decay rates of $(CD_3)_2CH(OH)$ were measured in the presence of a large excess of oxygen atoms. $(CD_3)_2CH(OH)$ was photoionized by the Ar lamp with a LiF window (11.83 and 11.62 eV) and measured at m/z=66 (M^+). Values for k_4 obtained are listed in Table 1. The 95% confidence limits were calculated form the least-squares line using 8 points for each run and 24 points for the average values. The value of $(4.3\pm0.4)\times10^{-13}$ cm^3 molecule^{-1} s^{-1} for k_4 is 33 times larger than the rate for the reaction $(CD_3)_2$CH(OH)+O reported by Ayub and Roscoe.[3] The rate constant for the reaction O+$(CD_3)_2$CD(OH) was also measured and shown in Table 1. The rate for Reaction 3 was about 40% slower than that for Reaction 4 at 298K. The rate of reaction O+$(CH_3)_2$CH(OH) could not be measured[8] because signals for $(CD_3)_2CH(OH)$ coincide with one of the signals of products formed in the reaction of O+$(CH_3)\dot{C}$(OH) as will be described later.

B. Radical-Atom Reactions. Products produced in the reaction of oxygen atoms with radicals produced in Reactions 1, 3, and 4 were measured by using a Kr lamp having a CaF_2 window (10.03 eV). Mass spectra observed in the reaction of $(CH_3)_2CH(OH)+O$ are shown in Fig. 2a. The signal observed at m/z=58 should be from acetone, $(CH_3)_2CO$, and/or 1-propen-2-ol, $CH_3C(OH)CH_2$, which are expected in Reaction 2. The signal at m/z=59 is the isotope (^{13}C) signal of the molecule at m/z=58. The same mass spectra were observed in the reaction of $(CD_3)_2CD(OH)+O$. A small signal at m/z=63 and a large signal at m/z=64 were observed when $(CD_3)_2CH(OH)$ reacted with oxygen atoms (Fig. 2b). Possible reaction processes of the reaction $(CD_3)_2\dot{C}(OH)+O$ in both hydrogen abstraction and the oxygen addition reaction are:
abstraction;

$$O+(CD_3)_2\dot{C}(OH) \rightarrow (CD_3)_2CO\ (m/z=64)+OH \quad (5a)$$
$$\rightarrow CD_3C(OH)CD_2\ (m/z=63)+OH \quad (5b)$$

addition;

Table 1. First-Order Decay Rate for the Reaction[a] of 2-Propanol with Atomic Oxygen at 298K

	Total pressure	Flow velocity	$[O]_0$	[2-propanol]$_0$	$k\times10^{13}$
	Torr	m s^{-1}	mTorr	mTorr	cm^3 molecule^{-1} s^{-1}
O+$(CD_3)_2$CH(OH)	4.593	22.3	6.192	0.101	4.1±0.6
	4.642	22.3	4.127	0.0837	4.5±0.4
	4.638	22.3	8.236	0.0842	4.2±0.5
					Av. 4.3±0.4
O+$(CH_3)_2$CD(OH)	4.602	22.3	6.827	0.0923	2.7±0.3

a) Reaction time used was 0.9—9 ms for each run.

$$O+(CD_3)_2\dot{C}(OH)\rightarrow (CD_3)_2CO\ (m/z=64)+OH \quad (5c)$$
$$\rightarrow CD_3COOH\ (m/z=63)+CD_3 \quad (5d)$$

subsequent to Reaction 4. Since the ionization potential of acetic acid has been reported[9] to be 10.4 eV, acetic acid cannot be ionized by the Kr lamp with the CaF_2 window (10.03 eV). This was confirmed by the test that no signal of CH_3COOH was observed by adding known partial pressures of CH_3COOH to the reactor. Therefore, the signal observed at m/z=63 in Fig. 2b should be from 1-propen-2-ol $CD_3C(OH)=CD_2$. Since the signal intensity of $CD_3C(OH)=CD_2$ is much weaker than that of $(CD_3)_2CO$, most of the signal at m/z=58 in Fig. 2a might be from $(CH_3)_2CO$.

Signals obtained when the Ar lamp with the LiF window (11.83 and 11.62 eV) was used are shown in Fig. 3. Figures 3a′, 3b′, and 3c′ show mass spectra of three different isotopic 2-propanols. Parent ions of 2-propanols were observed in all cases. In addition to the parent ions, fragment ions produced by an α-hydrogen (deuterium) elimination from the 2-propanols are observed. In reactions of atomic oxygen with each 2-propanol, signals of acetic acid, CH_3COOH (m/z=60) for $(CH_3)_2CH(OH)$ and $(CH_3)_2CD(OH)$, and CD_3COOH (m/z=63) for $(CD_3)_2CH(OH)$, were observed in addition to the large signals of acetones. Since the instrumental sensitivities to acetone and acetic acid are 45 and 25 times higher than that for 2-propanol, respectively, the real concentrations of the products are much lower than they appear in Fig. 3.

In the reaction O+2-propanol, three products (acetone, acetic acid, and 1-propen-2-ol were observed as expected. Among them, acetone is the largest. Ace-

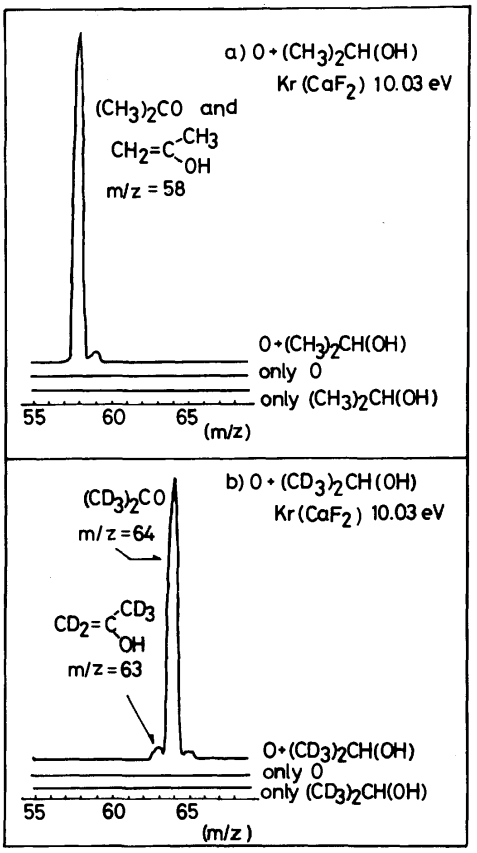

Fig. 2. Mass spectra of the reaction products produced in O+2-propanol. A Kr lamp having a CaF_2 window (10.03 eV) was used. a) O+$(CH_3)_2CH(OH)$; b) O+$(CD_3)_2CH(OH)$. The conditions: $[O]_0$=0.84 mTorr; [2-propanol]$_0$=0.27 mTorr; $[O_2]_0$=15 mTorr; reaction time 4.4 ms; total pressure 3.9 Torr.

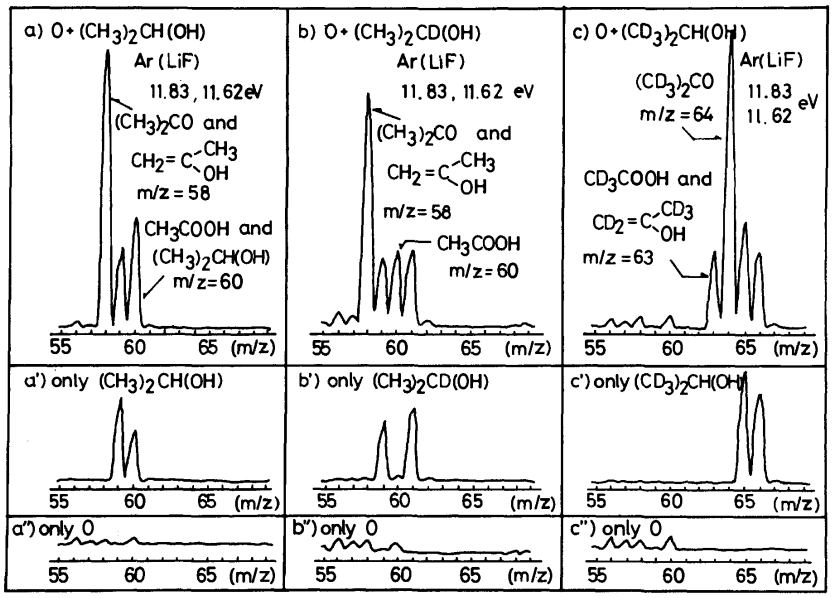

Fig. 3. Mass spectra of the reaction products produced in O+2-propanol. An Ar lamp with a LiF window (11.83 and 11.62 eV) was used. a) O+$(CH_3)_2CH(OH)$; b) O+$(CH_3)_2CD(OH)$; c) O+$(CD_3)_2CH(OH)$. The conditions: $[O]_0$=0.98 mTorr; [2-propanol]$_0$=0.28 mTorr; $[O_2]_0$=5.8 mTorr; reaction time 4.3 ms; total pressure 4.0 Torr.

tone can be produced by both hydrogen abstraction and oxygen addition reactions. In order to distinguish these two possibilities, 2-propanol was reacted with ^{18}O (19.2% of $^{36}O_2$ in $^{32}O_2$ was diluted in helium and discharged). When the $(CH_3)_2\dot{C}(OH)$ and $(CD_3)_2\dot{C}(OH)$ radicals react with the $^{18}O(^3P)$, the acetone produced by hydrogen abstraction and by oxygen addition should be different:

$$(CH_3)_2\dot{C}(OH)+{}^{18}O \rightarrow \begin{cases} (CH_3)_2CO(m/z=58)+{}^{18}OH & \text{abstraction} \quad (2a') \\ (CH_3)_2C^{18}O(m/z=60)+OH & \text{addition} \quad (2c') \end{cases}$$

$$(CD_3)_2\dot{C}(OH)+{}^{18}O \rightarrow \begin{cases} (CD_3)_2CO(m/z=64)+{}^{18}OH & \text{abstraction} \quad (5a') \\ (CD_3)_2C^{18}O(m/z=66)+OH & \text{addition} \quad (5c') \end{cases}$$

The mass spectra obtained are shown in Fig. 4. Weak signals at $m/z=60$ and 66 were observed in $^{18}O+(CH_3)_2\dot{C}(OH)$ and $^{18}O+(CD_3)_2\dot{C}(OH)$ reactions, respectively. Relative signal intensities at $m/z=58$ and 60 in the $(CH_3)_2\dot{C}(OH)+{}^{18}O$ reaction and at $m/z=64$ and 66 in the $(CD_3)_2\dot{C}(OH)+{}^{18}O$ reaction were observed to be 100 : 3.04±0.02 and 100 : 3.10±0.04, respectively. Since the 19.2% oxygen-18 was used in this study, acetone produced by the oxygen addition reaction is about 15% of the total acetone produced under these particular conditions and most of acetone is produced by the hydrogen abstraction from the OH of the radicals.

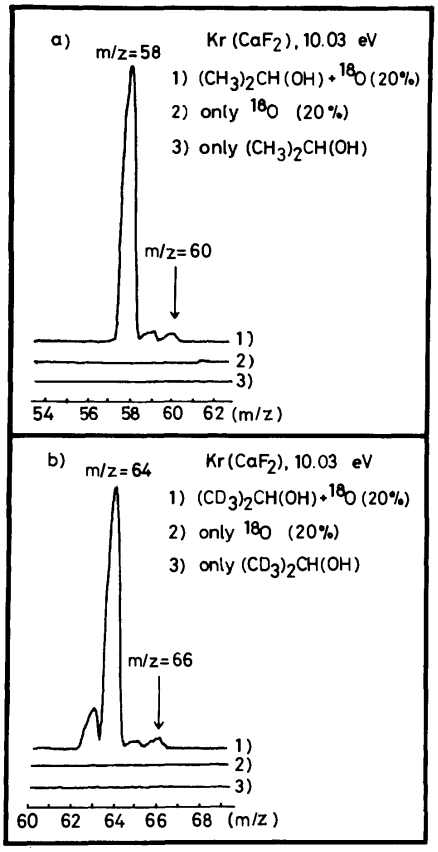

Fig. 4. Mass spectra of the reaction products produced in 2-propanol+^{18}O (19.2% of $^{36}O_2$ in $^{32}O_2$ was diluted in He and discharged). A Kr lamp with a CaF_2 window (10.03 eV) was used for the photoionization. a) $(CH_3)_2CH(OH)+{}^{18}O$; b) $(CD_3)_2CH(OH)+{}^{18}O$. The conditions: $[O]_0$= 0.61 mTorr; [2-propanol]$_0$=0.26 mTorr; $[O_2]_0$=3 mTorr; reaction time 4.4 ms; total pressure 3.9 Torr.

C. Competition between $O(^3P)$, O_2, and NO for $(CD_3)_2\dot{C}(OH)$. The signal obtained by Reaction 4a increased linearly with $(CD_3)_2CH(OH)$ partial pressure up to a few mTorr. The $(CD_3)_2\dot{C}(OH)$ signal was almost independent both of reaction time (0.5—5 ms) and oxygen atom concentration (0.2—1 mTorr†). This means that $(CD_3)_2\dot{C}(OH)$ radicals are in their steady-state concentration due to the balance between Reactions 4 and 5. The steady-state concentration of $(CD_3)_2\dot{C}(OH)$ radicals decreased when molecular oxygen was added to the system. This decrease is caused by the competition between $O(^3P)$ and O_2 for the $(CD_3)_2\dot{C}(OH)$ radicals and the competition would result in a Stern-Volmer type of equation,

$$\frac{[(CD_3)_2\dot{C}(OH)]^0_{ss}}{[(CD_3)_2\dot{C}(OH)]_{ss}} = 1 + \frac{k_7[O_2]}{k_5[\bar{O}]} \qquad (6)$$

where the superscript zero indicates the conditions with no O_2 present and k_7 is the effective second-order rate constant for the reaction of $(CD_3)_2\dot{C}(OH)$ with O_2.

$$(CD_3)_2\dot{C}(OH)+O_2 \rightarrow \text{Products} \qquad (7)$$

Results of O_2 addition experiment are presented in Fig. 5 by an open triangle and open circles. A value for $[(CD_3)_2\dot{C}(OH)]^0_{ss}$ was determined by plotting $([(CD_3)_2\dot{C}(OH)]_{ss})^{-1}$ against $[O_2]/[\bar{O}]$ and then determining $([(CD_3)_2\dot{C}(OH)]^0_{ss})^{-1}$ from the intercept of a least-square fit in order to remove the effect of O_2 surviving from the discharge. The average oxygen-atom concentration, $[\bar{O}]$, was calculated by the method mentioned before[1] using the value of $n=5$[10] (the correction was 4.6%). The amount of O_2 in the system was calculated from $[O_2]_{added}+[O_2]_0-1/2[O]_0$, where $[O_2]_0$ and $[O]_0$ represent the concentration of O_2 in the O_2-He mixture before discharge and the original concentration of oxygen atoms when the O_2-He mixture was discharged, respectively. The open triangle in Fig. 5 is the point which was obtained with no added O_2 (effect of O_2 just surviving from the discharge). The value for k_7/k_5 calculated from the slope of the plots (an open triangle and open circles) in Fig. 5 is (0.16±0.02). Error limits due to the scatter of plots were calculated by the least square with the 95% confidence limits. The value for k_7/k_5 suggests that the rate of the reaction of $(CD_3)_2\dot{C}(OH)+O_2$ is 6.4 times slower than that of the $(CD_3)_2\dot{C}(OH)+O(^3P)$ reaction.

When oxygen atoms were produced by NO titration of N atoms formed in a microwave discharge through

† 1 Torr=133.322 Pa.

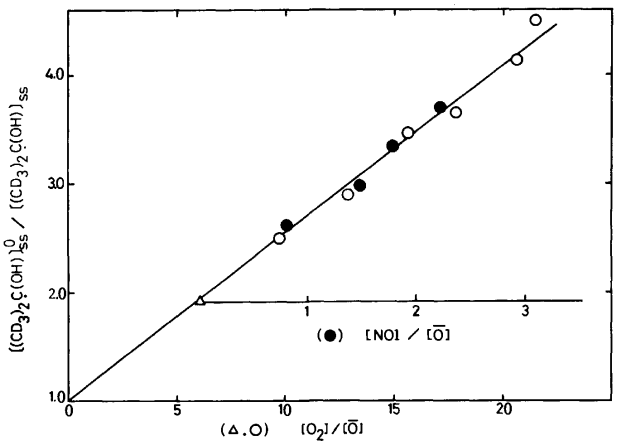

Fig. 5. Stern-Volmer plot for the competition between O_2 and $O(^3P)$ (open symbols), and NO and $O(^3P)$ (filled symbols) for $(CD_3)_2C(OH)$ radicals. A Xe lamp with a sapphire window (8.44 eV) was used to photoionize $(CD_3)_2C(OH)$. The conditions: $[O]_0$=0.632 mTorr; $[\bar{O}]$=0.588 mTorr; $[(CD_3)_2CH(OH)]$=0.288 mTorr; $[O_2]_0$=4.073 mTorr; reaction time=4.540 ms; total pressure= 3.909 Torr. $[O_2]$ was calculated from $[O_2]_{added}+[O_2]_0-1/2[O]_0$.

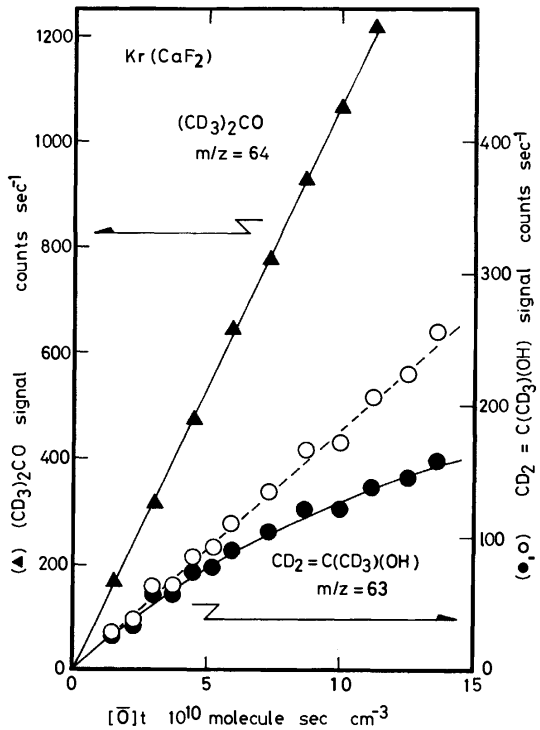

Fig. 6. Time dependence of $(CD_3)_2CO$ and $CD_3C(OH)=CD_2$ produced in the $O+(CD_3)_2CH(OH)$ reaction. A Kr lamp with a CaF_2 window (10.03 eV) was used for the photoionization. The conditions: $[O]_0$=0.517 mTorr; $[(CD_3)_2CH(OH)]_0$= 0.362 mTorr; $[O_2]_0$=1.667 mTorr; total pressure= 3.699 Torr. Reaction time used was 0.91—9.11 ms. Corrections for [O] were 12% or less. The $CD_3C(OH)=CD_2$ signals are corrected for the subsequent reaction to give $[CD_3C(OH)=CD_2]_T$ as indicated by open circles (see the text).

N_2-He mixture and were reacted with $(CD_3)_2CH(OH)$, signals of $(CD_3)_2\dot{C}(OH)$ radicals were quenched by the excess of NO. This means that the reaction of $(CD_3)_2\dot{C}(OH)+NO$ should be extremely fast. In order to measure the rate of the reaction $(CD_3)_2\dot{C}(OH)+NO$, small amount of NO were added to the system of $(CD_3)_2\dot{C}(OH)+O+O_2$. In these experiments, NO was added under the conditions shown by an open-triangle in Fig. 5 (the O_2 present in the reactor is just from the O_2 surviving from the discharge). The decrease of the steady-state concentrations of $(CD_3)_2\dot{C}(OH)$ radicals by the addition of the small amounts of NO are shown by the value of $[(CD_3)_2\dot{C}(OH)]^0_{ss}/[(CD_3)_2\dot{C}(OH)]_{ss}$ (solid circles in Fig. 5). From the slope of the plots of solid circles, the value for k_8/k_5 of (0.780±0.085) was obtained. Here, k_8 is the rate of the reaction $(CD_3)_2\dot{C}(OH)+NO$.

$$(CD_3)_2\dot{C}(OH)+NO \rightarrow (CD_3)_2CO+HNO \qquad (8)$$

The rate of the reaction of $(CD_3)_2\dot{C}(OH)+NO$ is extremely rapid. The rate is close to that of the $(CD_3)_2\dot{C}(OH)+O$ reaction. The large rate constant can be explained by a hydrogen atom abstraction by NO from the $(CD_3)_2\dot{C}(OH)$ radical. This was confirmed by measuring the signals of products. In the presence of NO, signals of acetic acid and 1-propen-2-ol disappeared and only the signal of acetone was observed.

D. Yields of the Products. Two products, $(CD_3)_2CO$ and $(CD_3)_2C(OH)CD_2$, were observed during the $O+(CD_3)_2CH(OH)$ reaction when the Kr lamp with the CaF_2 window was used. The time dependences of these products are shown in Fig. 6. On the time scale shown, $(CD_3)_2CO$ rises linearly with reaction time, while $CD_3C(OH)=CD_2$ increases not linearly. The time dependence of the $CD_3C(OH)=CD_2$ can be understood as the result that the $CD_3C(OH)=CD_2$ can react further with oxygen atoms.

$$CD_3C(OH)=CD_2+O \rightarrow \text{Products} \qquad (9)$$

The concentration of $CD_3C(OH)=CD_2$ is expressed by Eq. 10.

$$[CD_3C(OH)=CD_2] = \frac{f_{5b}k_4[(CD_3)_2CH(OH)]}{k_9 - k_4} \times (e^{-k_4[\bar{O}]t} - e^{-k_9[\bar{O}]t}) \qquad (10)$$

Here f_{5b} represents the fraction of Reaction 5b in the total reaction of $(CD_3)_2C(OH)+O$. Since the value for k_4 of 4.3×10^{-13} cm^3 $molecule^{-1}$ s^{-1} was determined, the plots of $CD_3C(OH)=CD_2$ shown in Fig. 6 can be fitted to Eq. 10. The best fit line is shown by a solid line in Fig. 6, and a value for k_9 of $(7.1\pm0.5)\times10^{-12}$ cm^3 $molecule^{-1}s^{-1}$ was calculated. The indicated errors due to the scattering of plots were calculated by the least square with the 95% confidence limits. The rate for Reaction 9 is 1.7 times faster than the rate for the reac-

tion O+ propene. It is possible to correct the observed $CD_3C(OH)=CD_2$ signals for subsequent reactions by multiplying each observed value by $k_9[\bar{O}]t[1-\exp(-k_9[\bar{O}]t)]^{-1}$ in order to give the total amount of $CD_3C(OH)=CD_2$ formed, $[CD_3C(OH)=CD_2]_T$. These corrected points are shown as open circles in Fig. 6, and they are well represented by the dashed straight line.

Signals for $(CD_3)_2CO$ at $m/z=64$ and CD_3COOH+ $CD_3C(OH)=CD_2$ at $m/z=63$ observed by using the Ar lamp with a LiF window are shown in Fig. 7. Since the rate for the reaction of acetic acid with atomic oxygen is expected to be very slow, the signal only from CD_3COOH should rise linearly with reaction time. This was confirmed in the reaction $O+(CH_3)_2\dot{C}D(OH)$, in which the signal of CH_3COOH can be observed without overlapping of other signals (see Fig. 3b).

The effect of O_2 on the yield of products was measured by adding O_2 to the system. The results are shown in Fig. 8. The signal of $(CD_3)_2CO$ increased while signals of $CD_3C(OH)=CD_2$ and CD_3COOH decreased[11] when O_2 was added. The two points on the left-hand side in each Figs. 8a and 8b are the points obtained from the O_2 just surviving from the O_2/He discharge (no addition of O_2). Since the standard sample gas of 1-propen-2-ol is not available, the absolute concentration of $CD_3C(OH)=CD_2$ cannot be determined. The absolute concentration of $(CD_3)_2CO$ was determined from the sensitivity of acetone to the instrument. The concentration of $(CD_3)_2CO$ is represented by Eqs. 11 and 12 when both $O(^3P)$ and O_2 are present in the system.

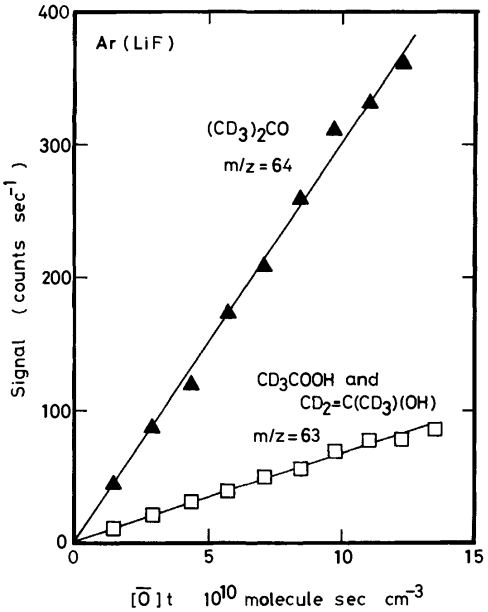

Fig. 7. Time dependence of signals at $m/z=63$ and 64 in the O+$(CD_3)_2CH(OH)$ reaction. An Ar lamp with a LiF window (11.83 and 11.62 eV) was used. The conditions: $[O]_0=0.496$ mTorr; $[(CD_3)_2CH(OH)]_0=0.289$ mTorr; $[O_2]_0=1.748$ mTorr; total pressure=3.791 Torr. Reaction time used was 0.91—9.11 ms. Corrections for $[\bar{O}]$ were 5% or less.

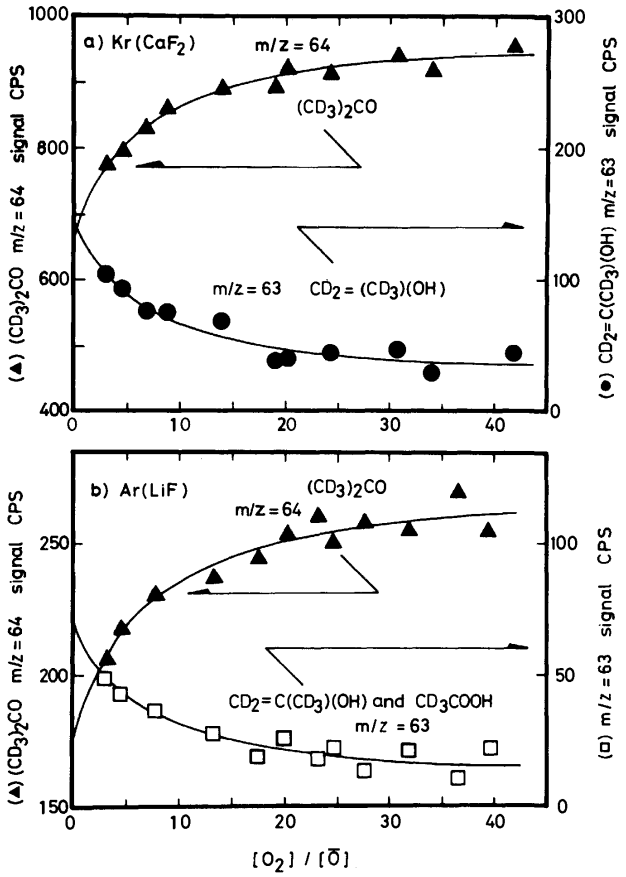

Fig. 8. Change of signals at $m/z=63$ and 64 with the addition of O_2. A Kr lamp with a CaF_2 window (a) and an Ar lamp with a LiF window (b) were used for the photoionization. The conditions for (a): $[O]_0=0.517$ mTorr; $[\bar{O}]=0.487$ mTorr; $[(CD_3)_2CH(OH)]_0=0.362$ mTorr; $[O_2]_0=1.667$ mTorr; reaction time=4.556 ms; total pressure=3.699 Torr. The conditions for (b): $[O]_0=0.496$ mTorr; $[O]_0=0.473$ mTorr; $[(CD_3)_2CH(OH)]_0=0.289$ mTorr; $[O_2]_0=1.748$ mTorr; reaction time=4.556 ms; total pressure=3.791 Torr. $[O_2]$ was calculated from $[O_2]_{added}+[O_2]_0-1/2[O]_0$. The points shown on the left-hand side are obtained from just $[O_2]_0-1/2[O]_0$ (no $[O_2]_{added}$).

$$[(CD_3)_2CO] = \left\{(f_{5a}+f_{5c})+\frac{(s_{7a}-f_{5a}-f_{5c})X}{1+X}\right\}\times k_4[(CD_3)_2CH(OH)][\bar{O}]t \quad (11)$$

$$X=\frac{k_7}{k_5}\frac{[O_2]}{[\bar{O}]} \quad (12)$$

Here s_{7a} is the fraction of $(CD_3)_2CO$ produced in Reaction 7. Using the value for k_7/k_4 determined before, the absolute concentrations of $(CD_3)_2CO$ are plotted against $X/(1+X)$ and are shown in Fig. 9. Under each experimental condition, values for $(f_{5a}+f_{5c})$ determined from the intercepts of lines in Figs. 9a and 9b are (0.64±0.05) and (0.60±0.06), respectively. From the

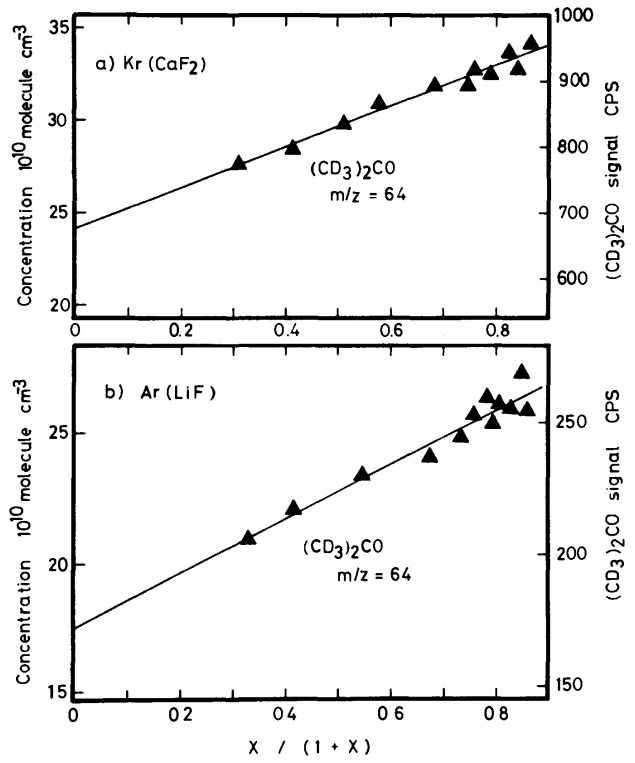

Fig. 9. The absolute concentrations of $(CD_3)_2CO$ are plotted against $X/(1+X)$. The conditions for (a) and (b) are the same as the cases of (a) and (b) in Fig.8, respectively.

slopes of straight lines shown in Figs. 9a and 9b, values for s_{7a} of (0.94±0.07) and (0.96±0.14) were calculated, respectively. The indicated errors due to the scattering of plots were calculated by the least square with the 95% confidence limits.

$$(CD_3)_2C(OH)+O \xrightarrow{(62\pm4)\%} (CD_3)_2CO \qquad \text{(5a) and (5c)}$$

$$(CD_3)_2C(OH)+O_2 \xrightarrow{(95\pm8)\%} (CD_3)_2CO \qquad \text{(7a)}$$

Signals at m/z=63 observed by the use of the Ar lamp consist of the signals of $CD_3C(OH)=CD_2$ and CD_3COOH. From the mass spectra shown in Figs. 3a, b, and c, however, it is probable that the greater part of the signal at m/z=63 is from CD_3COOH. Supposing that all the signals at m/z=63 is from acetic acid, the absolute concentrations of CD_3COOH were determined from the instrumental sensitivity of acetic acid. From the slope and intercept of the plots of $X/(1+X)$ vs. absolute concentrations of CD_3COOH, values for f_{5d} and s_{7d} can be calculated to be (0.28±0.04) and (0.02±0.06), respectively. Therefore, tentatively;

$$(CD_3)_2\dot{C}(OH)+O \xrightarrow{(28\pm4)\%} CD_3COOH \qquad \text{(5d)}$$

$$(CD_3)_2\dot{C}(OH)+O_2 \xrightarrow{(2\pm6)\%} CD_3COOH \qquad \text{(7d)}$$

Discussion

The selective abstraction of an α-hydrogen (deuterium) in the primary attack of $O(^3P)$ atoms on 2-propanol agreed well with the suggestion of Kato and Cvetanovic.[2] The result of the α-hydrogen abstraction agreed also with the case of O+ethanol reaction.[4] The rate constant for the reaction $O+(CD_3)_2CH(OH)$ at 298K, $(4.3\pm0.4)\times10^{-13}$ cm^3 $molecule^{-1}$ s^{-1}, was 33 times larger than the rate constant for $O+(CH_3)_2CH(OH)$ reaction reported by Ayub and Roscoe.[3] In the present study, the rate measurements were carried out under the conditions of $[O]_0/[2\text{-propanol}]_0 \geqslant 50$. Under these conditions, the consumption of oxygen atoms in the reactor (reaction time was 0.9—10 ms) was less than 5% of the original oxygen atom concentration on the basis of a stoichiometric factor of n=5.[10] On the other hand, the rate measurements by Ayub and Roscoe were done by observing the decay of oxygen atoms under a large excess of 2-propanol. Probably, many subsequent reactions are possible under their experimental conditions and their estimation of the stoichiometric factor for the decay of oxygen atoms is not correct.

The major primary product in the subsequent reaction of $(CD_3)_2\dot{C}(OH)$ radicals with atomic oxygen was found to be acetone (62±4%). Formation of 1-propen-2-ol and acetic acid was observed in addition to $(CD_3)_2CO$. In the previous work of the O+ethanol reaction system[4] acetaldehyde (79±8%), which is equivalent to acetone in the present reaction system, was found to be major primary product in the reaction of 1-hydroxyethyl radical with atomic oxygen. No formation of vinyl alcohol, formic and acetic acids were observed. In the present study, however, it was demonstrated that the yield of products was largely affected by the amount of O_2 surviving from the discharge; i.e., the yield of acetone (acetaldehyde for O+ethanol) increased and yields of 1-propen-2-ol (vinyl alcohol for O+ethanol) and acetic acid (formic or acetic acids for O+ethanol) decreased in the presence of O_2. Therefore, in the previous O+ethanol system, vinyl alcohol and formic or acetic acids probably could be observed if the measurements were carried out carefully taking notice of the effect of O_2.

The isotope (^{18}O) experiments showed that acetone was produced predominantly by the hydrogen abstraction by $O(^3P)$ from the O-H in the $(CD_3)_2\dot{C}(OH)$ radical, Reaction 5a′. The result is consistent with that obtained in the O+ethanol system. In the present study, however, it was found that acetone can also be produced by the addition of $O(^3P)$ to the $(CD_3)_2\dot{C}(OH)$ radical, Reaction 5c′, in small but significant yield.

The reaction of $(CD_3)_2\dot{C}(OH)$ radicals with molecular oxygen was very rapid. The rate of the reaction of $(CD_3)_2\dot{C}(OH)+O_2$ was just 6.4 times slower than that of the $(CD_3)_2\dot{C}(OH)+O(^3P)$ reaction. This competition ratio is quite similar to the case of the 1-hydroxyethyl radical.[4] The rate of the reaction of $(CD_3)_2\dot{C}(OH)$+NO was found to be much faster. The reaction proceeds as fast as with atomic oxygen. These rapid reactions can be explained by the two body reactions to form acetone and HO_2 (HNO), Reactions 7a

and 8.

$$(CD_3)_2\dot{C}(OH) + O_2 \rightarrow (CD_3)_2CO + HO_2 \qquad (7a)$$

Reaction 7a was proved by the isotope (^{18}O) experiment; that is, in the experiment shown in Fig. 4b, the signal at m/z=66, $(CD_3)_2C^{18}O$, disappeared by adding the $^{18}O_2$ (20%)/$^{16}O_2$ mixture gas. The formation of acetone by Reaction 7a is consistent with the results obtained from the photooxidation of 2-propanol in air.[12]

Conclusion

(1) $(CD_3)_2\dot{C}(OH)$ and $(CD_3)_2\dot{C}(OH)$ radicals produced by a selective abstraction of an α-hydrogen in the primary attack of $O(^3P)$ atoms on 2-propanol were detected directly by the photoionization mass spectrometer. The results of the present and earlier study[4] show that $O(^3P)$ atoms react with simple alcohols by abstracting the most weakly bonded hydrogen atoms in the alcohol molecules.

(2) The major primary product in the reaction of $(CD_3)_2\dot{C}(OH)$ radicals with atomic oxygen is acetone, $(CD_3)_2CO$, (62%). Formation of 1-propen-2-ol and acetic acid was also observed.

(3) Acetone is produce predominantly by the hydrogen abstraction by $O(^3P)$ from the O-H in the $(CD_3)_2\dot{C}(OH)$ radical. A part of acetone is produced also by the addition of $O(^3P)$ to the $(CD_3)_2\dot{C}(OH)$ radical.

(4) The rate of the reaction of $(CD_3)_2\dot{C}(OH)$ radicals with molecular oxygen is 6.4 times slower than the reaction with atomic oxygen. This rapid reaction is explained by the hydrogen abstraction by O_2 from the O-H in the $(CD_3)_2\dot{C}(OH)$ radical.

4) N. Washida, *J. Chem. Phys.*, **75**, 2715 (1981).

5) The reaction of 2-propanol with atomic oxygen is initiated by hydrogen abstraction, Reaction 1. The OH radicals produced react with 2-propanol faster than atomic oxygen. The rate constant of the 2-propanol+OH reaction has been reported[6,7] to be $(5—7)\times10^{-12}$ cm^3 molecule^{-1} s^{-1}. OH radicals are destroyed by the reaction OH+O→H+O_2 with a rate constant of $(3—4)\times10^{-11}$ cm^3 molecule^{-1} s^{-1}. Therefore, in order to make the effect of OH radicals on the formation of $(CD_3)_2\dot{C}(OH)$ radicals less than 10%, the concentration of oxygen atoms must be at least twice as large as the 2-propanol concentration.

8) Signals at m/z=59 ($M-1^+$) and 60 (M^+) were observed when $(CH_3)_2CH(OH)$ was photoionized by the Ar lamp with the LiF window (11.83 and 11.62 eV). As will be demonstrated later in Fig. 3, signals for $(CH_3)_2CO$ and CH_3COOH were observed at m/z=58 and 60, respectively when $(CH_3)_2CH(OH)$ was reacted with oxygen atoms. Further, the isotope (^{13}C) signal of $(CD_3)_2CO$ appeared at m/z=59. Since the sensitivities of the instrument to $(CH_3)_2CO$ and CH_3COOH were 45 and 25 times higher than that to $(CH_3)_2CH(OH)$, respectively, when the Ar lamp was used, the effect of the signals of both products on the $(CD_3)_2CH(OH)$ signals at m/z=59 and 60 can not be neglected. In the rate measurements of the reaction $(CH_3)_2CD(OH)$+O, signals for $(CH_3)_2CD(OH)$ were measured at m/z=61. The signal at m/z=61 coincides with the isotope (^{13}C) signal of CH_3COOH. In this case, however, since the signal of CH_3COOH was not so strong as $(CH_3)_2CO$, the effect of the isotope signal of CH_3COOH on the $(CH_3)_2CD(OH)$ signal at m/z=61 was less than 6% even when the 50% of $(CH_3)_2CD(OH)$ ws consumed in the reactor.

10) A stoichiometric factor of n=5 was used in the present study, because, as will be described later, the yield of acetone in the O+2-propanol reaction is much higher than that in the O+propane reaction, and acetone produced does not react further under the present experimental conditions.

11) The decrease of acetic acid by the addition of O_2 was confirmed also in the reaction of O+$(CH_3)_2CD(OH)$, in which the signal of CH_3COOH can be observed without the overlapping of the 1-propen-2-ol signal.

Heat Capacity and Thermodynamic Properties of Bismuth in the Range 333 to 923 K

Walid Ahmad BADAWI,*,† H. A. BROWN-ACQUAYE, and Ali Esa EID
Department of Chemistry, Faculty of Science, Al-Fateh University, Tripoli, Libya
†P. O. Box 13539, Tripoli, Libya
(Received May 9, 1986)

Calorimetric studies on the behavior of the heat capacity of bismuth have been carried out in the range 333 to 923 K. Values of the enthalpy and entropy have been determined for selected temperatures. The enthalpy and entropy of fusion at 544.54 K are 11.360±0.014 kJ mol^{-1} and 20.86±0.03 JK^{-1} mol^{-1}, respectively. Appropriate polynomial temperature functions of the C_p for solid and liquid bismuth are given. Earlier reported increasing C_p at temperatures above 800 K proved not to be reliable. The heat capacity at constant volume decreased from 25.80 to 21.14 JK^{-1} mol^{-1} over the region 544.54 to 873 K. Due to beginning of higher-order transformation, the C_v of solid bismuth showed an excess over the harmonic value (3R).

Studies on the heat capacity and thermodynamic properties of solid and liquid bismuth have been undertaken with the views to obtain more accurate values of the C_p and of enthalpy and entropy of fusion since earlier ones showed discrepancies.[1-4]

Earlier works[4] on liquid bismuth showed increasing heat capacity at temperatures above 800 K. This was a somewhat surprising observation since decreasing C_p behavior is common for liquid metals. In order to understand this unusual behavior, we have been studying bismuth in the range 333 to 923 K.

The most recent study on solid bismuth[3] showed an excess of the C_v over the harmonic value ($3R$). This behavior was attributed to beginning of higher-order transformation. On the other hand, the curve of the C_v against temperature has not indicated any signal (such as a bend) which points to beginning transformation. This phenomenon has attracted our interest to investigate the C_v behavior in the solid region using adiabatic calorimeter for the C_p measurements.

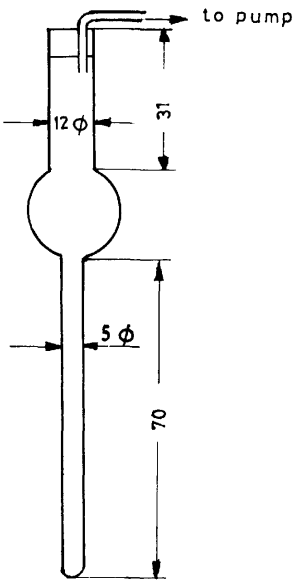

Fig. 1. Zintl funnel.

Experimental

Metal. Bismuth of extra purity grade procured from E. Merck Company was further purified by means of a melting device (similar to a Zintl funnel: Fig. 1). By this melting device, while the clean metal flows down into the lower tube of silica glass, the oxide layer remains apart in the first one. Analysis of the metal showed the presence of the following impurities in ppm by mass: Na: 0.1, Be: 0.1, Zn: 0.1, Pb: 0.1, Ag: 0.1.

Sample. The cylindrical metallic sample (ϕ=5 mm, h=20 mm) weighing 65.288 g was sealed in the sample container of Pyrex glass. Since bismuth expands on solidification after completion of the measurements, a cord of Pyrex glass was coiled spirally in the space of the sample to prevent breakage of the container. The external dimensions of the sample container were similar to the internal ones of the calorimeter (small corrections for small C_p).

Procedure and Calorimetric Technique. The measurement technique and calorimeter were described before.[5] The procedure employed depended on the method of primary indirect provision of energy under adiabatic conditions. The slightly modified calorimeter was tested by measurements on the heat capacity of a standard α-Al_2O_3 sample. The accuracy was estimated to 0.3%. The heating of the calorimeter occured with a speed of 0.6 K min^{-1} while that of the adiabatic shield was regulated to a speed of 0.5 K min^{-1}.

The sample container with a cover possessing holes for heater and thermopile was sealed in a calorimeter of silver which was suspended inside the shield of Cu-Al alloy (90 at-% Cu) with enclosed heater. Both calorimeter and shield were placed in a vertical tube furnace which in turn was protected by another larger one (principle of double shielding).

The temperature differences between the calorimeter and the shield were measured by means of a set of twelve differential Pt-to-(Pt+10 pass per cent Rh) thermopiles. These were connected in series and calibrated as follows: On comparing the thermal potential of these thermopiles with that of a standard Pt-Pt/Rh, we obtain a calibration curve giving the values of temperature with an accuracy of ±0.1 K. The measurement of the thermal potential of the thermopiles was made by means of a digital millivoltmeter (Hewlett-Packard Model 2401 C). The temperature drifts of the shield from the calorimeter temperature were of negligible importance. The observed short-term fluctuation of the null-point was mea-

sured to 2.5×10^{-4} K min^{-1}. The time needed to reach the adiabatic state was registered to 20 min. Excellent regulation of the temperature was obtained by means of a p-regulator.[6] A constant current supply (John Fluke Calibrator Model 382 A) was used in the measurement processes. The mueller bridge (Leeds & Northrup Model 8072, used in the current circuit) and other instruments were controlled by a digital computer. The thermometer resistance was measured with a Mueller bridge automated with stepping motors and a gated null-detector, operated by a computer of the type Hewlett-Packard 2224 B. Calibration of the platinum resistance thermometer used for determination of the fusion temperature of bismuth was made at the triple point of water and the melting points of tin and zinc on IPTS-68.[7] The derived temperatures were judged to correspond to the IPTS-68 to within 0.01 at 500 K and 0.1 at 1000 K. In fact the temperature increments were precisely measured to 0.0002 K.

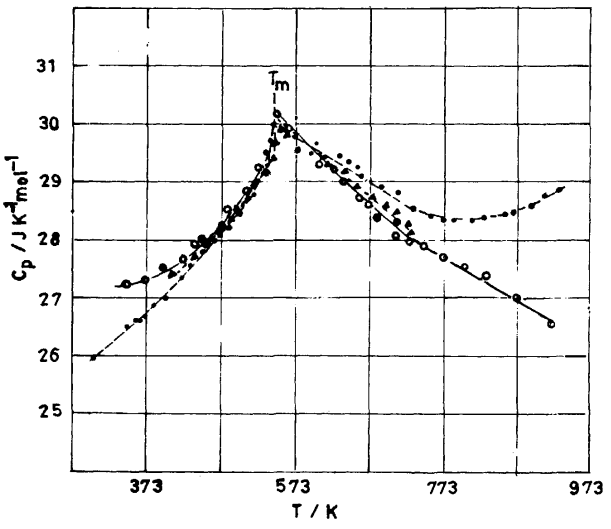

Fig. 2. Heat capacity of bismuth, —○— represents present results, —●— results by Grønvold,[4] —▲— results by Okhotin.[3]

The heat capacity of the empty calorimeter which represented 10 to 15% of the total heat capacity was indirectly measured: From measurements of the heat capacity for samples of silver of different masses and comparing these results with each other, the C_p of the empty calorimeter was calculated at the temperature of measurement. Neglect of this C_p value in the calculation of the total C_p would cause an error of about 0.10 to 0.15%. For this reason small corrections were derived to obtain accurate values of the C_p of bismuth.

From the calibration of the calorimeter on the exactly measured enthalpy of a standard sample of tin (Ref. 5), the "Interchange of heat constant" of the calorimeter has been determined in the whole region of temperature.

Results and Discussion

Heat Capacity of Bismuth. In Table 1 are listed the values of the heat capacity of bismuth in chronological order as determined in the present study. The reader can infer the approximate temperature increments in the determinations from the adjacent mean temperature in the table.

Figure 2 shows the curves of the C_p of solid and liquid bismuth, versus temperature. From curve-fitting calculations of the C_p values illustrated in Table 1, the appropriate temperature functions for solid and liquid bismuth were derived, respectively as

$$C_p = 24.081 + 9.023\times10^{-3}\,T - 3.1\times10^{-7}\,T^2 \quad \text{J K mol}^{-1},$$

$$C_p = 35.000 - 9.023\times10^{-3}\,T - 3.1\times10^{-7}\,T^2 \quad \text{J K mol}^{-1}.$$

The deviations ranged from 0 to 0.36% for solid bismuth and from 0.2 to 0.365% for liquid bismuth.

The most recently reported heat capacity measurements by Okhotin[3] carried out in the region 417 to 733 K, are in agreement with the present ones.

In the region 333 to 400 K, the values of the heat capacity of bismuth reported by Grønvold[4] differ from our values, although comparable results are obtained in the melting point region and in the liquid state from 545 to 634 K. The differences in the two results could not have been caused by temperature gradients in the calorimeter used in the present study since the temperature excursions of the shield from calorimeter in the null-point period were found to be negligible. Another area of differing results in the region 840 to 923 K, where the present studies show decreasing heat capacity while increasing C_p is reported by others.[4,8] To decide the dependency of the C_p on temperature and to shed light on the factors determining the behavior of the C_p in this striking region of temperature, we redetermined the measurements of the heat capacity in the whole range of temperature. It was found that the deviations of the comparable C_p values in both series of experiments which ranged from 0 to 0.05% are of negligible importance. Furthermore, C_p measurements were carried out in a wider range of temperature (333 to 960 K). The C_p value at 940, 950, and 960 K were measured to 26.20, 26.10, and 26.00 $JK^{-1}mol^{-1}$, respectively. This means that the C_p of liquid bismuth does not show the tendency to increase at high temperatures. Such behavior of the C_p is common to many metallic liquids. The decreasing heat capacity at high temperatures can be related to the pair correlation behavior. In the case of bismuth, the bonding changes into that of a mono-atomic gas with heat capacity decreasing toward $5R/2$ (20.35 $JK^{-1}mol^{-1}$). Taking this theory by Kincaid and Eyring[9] into consideration, the present C_p data at temperatures above 800 K seemed to be more reliable. It is also noteworthy that the existence of mono-atomic liquid bismuth was decided by other authors.[10] Also the present study could confirm the existence of mono-atomic liquid bismuth through X-ray diffraction study (to be published). It was observed that the neighbour distances of the straight chains in the structure decreased regularly with increasing temperature as follows: 850 K: 3.43 Å, 900 K: 3.60 Å, 950 K: 3.81 Å. This means that the potential energy of the system decreased with increasing temperature to reach the value of zero for a mono-atomic gas. As a result of this the C_p must decrease with increasing temperature to reach a certain value at $E_{pot}=0$. On the basis of the above discussion, earlier reported[4,8] increasing heat capacity at temperatures above 800 K proved not to be reliable.

Thermodynamic properties of bismuth. The values of C_p, $H°(T)-H°$ (298.15 K), and $S°(T)-S°$ (298.15 K) are collected in Table 2 for selected temperatures. For the solid region up to 542.52 K, the results have been least squares fitted by a polynomial expression, with a standard deviation of 0.29% for a single measurement. Similarly fitted expression with a standard deviation of 0.28% has been derived for liquid bismuth in the region beginning from 646.98 K. The accuracy of the obtained thermodynamic functions values was estimated to 0.2%. The present results of the enthalpy and entropy vary between 1 and 3% from those reported by other workers[1,2] and are in reasonable agreement with the values obtained by some researchers.[3,4]

In Table 3 are presented the results of the fractional enthalpy of fusion determination on bismuth. The values of the enthalpy and entropy of fusion are found to be

$$\Delta H°_{fus} = 11.360 \pm 0.14 \text{ kJ mol}^{-1},$$
$$\Delta S°_{fus} = 20.86 \pm 0.03 \text{ J mol}^{-1}.$$

As reported by Westrum,[11] the pre-melting excess heat capacity can be calculated through the following equation:

Table 2. Thermodynamic Properties of Bismuth

T/K	C_p/$JK^{-1}mol^{-1}$	$H°(T)-H°$(298.15 K)	$S°(T)-S°$(298.15 K)

$$C_i(\text{prem}) = x'RT_f^2/[(T_f - T_i)^2 - (\Delta T/2)^2],$$

where x' is the total mole fraction of impurities, T_i the temperature and ΔT the temperature interval to which C_i (prem) refers. It was found that the pre-melting excess heat capacity is caused by impurities of about 1×10^{-4} M (1 M=1 mol dm^{-3}). These liquid-soluble and solid-insoluble impurities in the sample constrain 0.1 of bismuth to melt 1.1 K below the ideal melting point. This was taken into consideration to include slight pre- and post-melting contributions above the extrapolated heat capacities of solid and liquid bismuth in the above given enthalpy and entropy of fusion values. These values differ 2% from those obtained in earlier studies. On the basis of fractional melting experiments (Table 3), about 96% of the bismuth sample fused at 544.54 K and zero pressure. The calibration of the platinum resistance thermometer used for the determination of the T_f occured as described before. The observed melting point of bismuth is in good agreement with that one reported earlier.[3]

Constant volume heat capacity of bismuth. Table 4 represents the values of the heat capacity at constant volume for selected temperatures, calculated according to the following equation:

$$C_v = C_p - (\alpha^2/x)vT,$$

where α is the thermal coefficient, x the compressibility, and v the molar volume. The curve of the C_v against temperature is shown in Fig. 3.

The molar volume of solid and liquid bismuth was computed from the lattice data, while the study by Lucas[12] provided the data for liquid bismuth and for the thermal coefficient values. The compressibility values were derived from many sources.[13-19]

An excess over the harmonic value $3R$ is shown in the present estimate of the C_v of solid bismuth. This behavior is not common for all metals. In the case of bismuth, the expansion on solidification would cause a considerable dilation contribution in the C_v value due to lattice vibrations. On the other hand, the anharmonic contributions are small if compared with

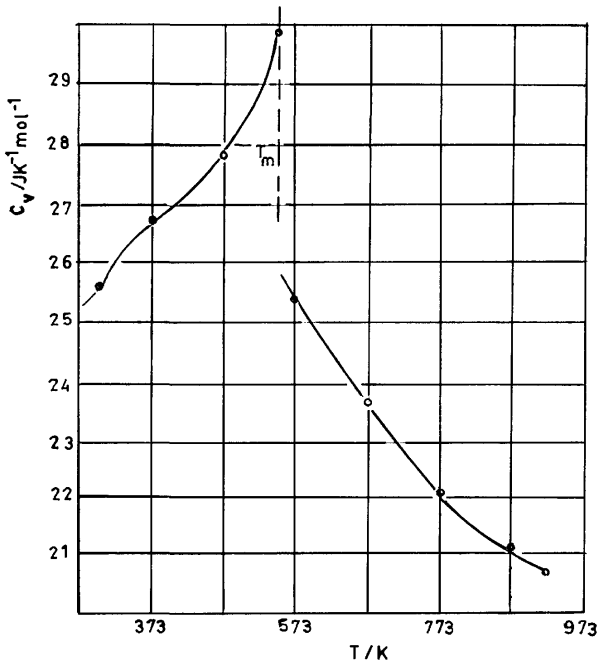

Fig. 3. Constant volume heat capacity of bismuth.

the dilation contributions observed in our study. This is due to the fact that the excess heat capacity from the disorder in the structure of the low-melting bismuth is small. Therefore, the excess over the harmonic value could be attributed to a beginning higher-order transformation. It is also noteworthy that the transformation to a new metallic phase was reported earlier.[10]

For liquid bismuth, the present C_v value is as low as 21.14 $JK^{-1}mol^{-1}$ at 873 K, calculated on decreasing C_p value over the region 840 to 900 K as compared to a value of 22.6 $JK^{-1}mol^{-1}$ at 900 K by Grønvold[4] who based his calculations on values of increasing C_p over the same region of temperature. The present value of C_v at 900 K seemed to be close to that limiting value given by Brillouin.[10] The observed drop in the C_v value over the region 540 to 900 K points to eventual radial distribution in this range of temperature.

Behavior of the Enthalpy of Formation in the Tin-Antimony System

Walid Ahmad BADAWI*,† and Ali Esa EID
Department of Chemistry, Faculty of Science, Al-Fateh University, Tripoli, Libya
†P. O. Box 13539, Tripoli, Libya
(Received May 9, 1986)

Calorimetric studies on the behavior of the enthalpy of formation in the tin-antimony system have been carried out at five different compositions (43.3—55 at -% Sb). The enthalpy of dissolution has been determined at 796.15 and 768.15 K. The enthalpy of formation is negative and takes a maximum value (2.906±0.002 kJ mol^{-1}) at 298.15 K for 50 at-% Sb. The molar enthalpy of mixing is more positive than that of formation. On comparing with partial molar enthalpy of mixing, the partial molar enthalpy of formation of tin is shifted to more negative values, while that of antimony to more positive values.

In recent years, the study of thermodynamic properties of binary systems of metals has attracted much interest. One such system, namely tin-antimony has been studied by some researchers eg. phase diagram by Predel and Schwermann[1] and heat of mixing by Wittig and Gehring[2] and other authors.[3] Also in this laboratory, work has been carried out in order to study the behavior of the enthalpy of formation of the β'-phase in the tin-antimony system[4] and to obtain the ratio of the enthalpies of formation to those of mixing. This would facilitate interpolation of the behavior of the enthalpy of formation at positions having indefinite structures.

Experimental

Sample. The metals used were of extra purity grade. These were procured from Riedel de Haen Co. The alloys samples were produced in cylindrical forms (ϕ=4.5—5mm; h=12—16 mm) by means of a melting device (Fig. 1). By this melting device, while the clean liquid metal flows down into the lower tube of quartz, the oxide layer remains apart in the first one. The mixture of tin and antimony was stirred mechanically with a stirrer made of ceramic for 30 min at 873 K. In order to reduce the effect of oxidation, argon gas was used as a protector during the melting process. The samples were tempered for 6 h at 673 K, 6 h at 623 K, and 192 h at 483 K.

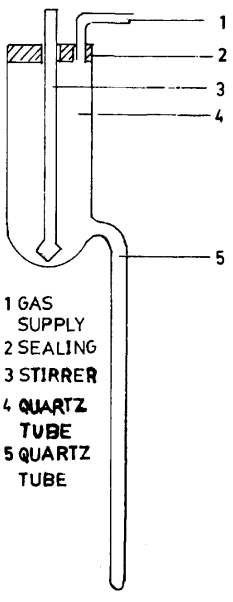

Fig. 1. Melting device.

Table 1. Lattice Constant of the β'-Phase in Sn Sb System (Found/Ref.)

x_{Sb}	a in Å (Found)	a in Å	(Ref.)
0.433	6.118	6.133	6
0.450	6.103	[6.136]	7
0.500	6.116	[6.120]	8
0.525	6.100	[6.136]	8
0.550	6.118	[6.134]	1

The values between the brackets were calculated from KX. The reported a values for 50 at-% Sb are different. They fluctuate between 6.104 and 6.138 Å.

The homogeneity of all the composition studied was established through testing the polished pictures prepared as described by Czochralski and Przyjemski.[5] Also X-ray (powder) photograph of the samples was taken and lattice constants have been determined (Table 1).

Calorimeter. The calorimeter used was a slightly modified version of the type described by Wittig and Gehring.[2]

Theory and Procedure

The enthalpy of dissolution of solid antimony in liquid tin can be determined at the temperature T_1 through the equations

$$-(1-x_2)\cdot \mathrm{Sn}(l, T_1)-x_2\cdot \mathrm{Sb}(s, T_1)+\mathrm{Sn}_{1-x_2}\mathrm{Sb}_{x_2}(l, T_1)=0, \quad (1)$$

$$h^s=-(1-x_2)\cdot h_1(T_1)-x_2\cdot h_2(T_1)+h_3(T_1), \quad (2)$$

where, h^s is the enthalpy of dissolution of solid antimony in liquid tin, h_3 the enthalpy of the alloy at the mole fraction of antimony x_2.

The enthalpy of dissolution has been determined at 796.15 and 768.15 K.

The enthalpy of formation is the special form of the enthalpy of reaction evolved by the formation of the substance from the elements. In the case of the tin-antimony alloy, the formation reaction is

$$-(1-x_2)\cdot \mathrm{Sn}(s, T_0)-x_2\cdot \mathrm{Sb}(s, T_0)+\mathrm{Sn}_{1-x_2}\mathrm{Sb}_{x_2}(s, T_0)=0, \quad (3)$$

where, T_0 is the initial temperature.

The enthalpy of formation is then

$$h^F=-(1-x_2)\cdot h_1(T_0)-x_2\cdot h_2(T_0)+h_3(T_0). \quad (4)$$

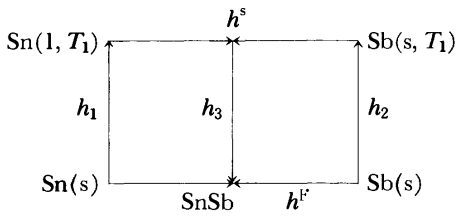
The indices 1, 2, and 3 indicate tin, antimony, and the alloy, respectively.

Subtraction of Eq. 4 from Eq. 2 yields

$$h^s-h^F=-(1-x_2)\cdot[h_1(T_1)-h_1(T_o)]-x_2[h_2(T_1)-h_2(T_o)]+[h_3(T_1)-h_3(T_o)]. \quad (5)$$

The term $h_3(T_1)-h_3(T_o)$ which appears in Eq. 5 is the enthalpy difference of the alloy; this was measured between 298.15 and 768.15 K; between 483.15 and 796.15 K. The enthalpy differences $h_1(T_1)-h_1(T_o)$ and $h_2(T_1)-h_2(T_o)$ are measured accurately (s. Table 3).

This procedure can be illustrated with reference to the following scheme:



The non-measurable process of the enthalpy of formation at T_o will be substituted by (1) heating of tin and antimony at T_1, (2) measurement of the enthalpy difference of the single miscible phase between T_o and T_1 and (3) measurement of the enthalpy of dissolution at T_1. Employing the present procedure, the enthalpy of formation has been experimentally determined at five different compositions. From the obtained values of the enthalpy of formation an appropriate polynomial function is given (Eqs. 6 and 7).

Results and Discussion

(i) Lattice Constants. Results of the lattice constant determinations are presented in Table 1 together with the values reported by other authors.[1,6-8] The quoted lattice constants of the β'-Sn Sb vary regularly with the composition. The a value for 50 at-% Sb is in agreement with that reported by Osawa,[8] while those for other compositions differ 0.245 to 0.59% from earlier ones.

(ii) Enthalpy of Dissolution. Table 2 represents values of the enthalpy of dissolution of solid antimony in liquid tin at 768.15 and 796.15 K. The results have been least squares fitted by a polynomial expression, with a standard deviation of 0.4% for a single measurement. The enthalpy of dissolution varies regularly with the composition as the associated lattice constant data do.

(iii) Enthalpies. Table 3 represents values of $h_1(T)-h_1$(298.15 K); $h_1(T)-h_1$(483.15 K) and $h_2(T)-h_2$(298.15 K); $h_2(T)-h_2$(483.15 K) as determined by the present study. The average error of the individual measurement was found to be 0.32%, while the deviation of the single measurement of the earlier reported data (s. Ref. 9) was estimated to be 1—2%.

Values of $h°$(768.15 K)$-h°$(298.15 K) and $h°$(796.15 K)$-h°$(483.15 K) of the alloys are collected in Table 4 at five compositions. The deviation is 0.3% for a single measurement.

(iv) Integral and Partial Molar Enthalpy of Formation. The integral and partial molar enthalpies of formation at 298.15 and 483.15 K are illustrated in Table 5 for five different compositions. The average error of the individual measurement was found to be 0.41% for T=298.15 K and 0.3% for T=483.15 K.

Using the data in Table 5, it was possible to derive empirically, equations which represent the shapes of the curves drawn in Figs. 2 and 3 as follows:

Table 2. Experimentally Determined Enthalpy of Dissolution of Solid Antimony in Liquid Tin in J mol^{-1}

0.525	(2559) 2549	10103	4266	(2726) 2787	10643	4437
0.550	(2189) 2200	10563	4662	(2338) 2324	11130	4856

$$h^F=-5.387-3.606x_2+17.12x_2^2;\ T=298.15\ K, \quad (6)$$

$$h^F=-5.642-3.970x_2+18.14x_2^2;\ T=483.15\ K. \quad (7)$$

It is apparent that the enthalpy of formation depends insignificantly on the temperature (Figs. 2 and 3).

The data in Table 5 clearly indicate that the enthalpy of formation increased with the increase of antimony mole fraction. This behavior is expected due to the charging of the Brillouin zones.

For a heteropolar behavior, a minimum of the enthalpy of formation is expected to appear at 40 at-% Sb. This minimum could not be observed in the normally experimental values. This is due to the fact that the deformation energy constrains the minimum of the enthalpy of formation to shift from a stoichiometric composition to other mole fraction of antimony.

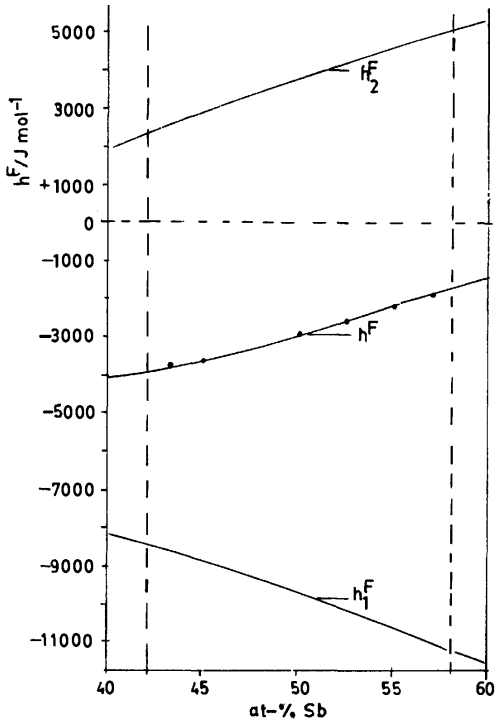

Fig. 2. Integral and partial enthalpy of formation in the tin-antimony system at 298.15 K.

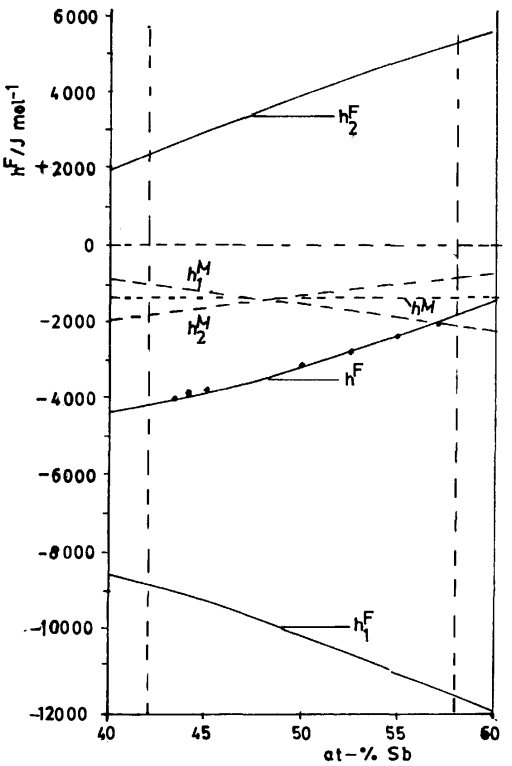

Fig. 3. Integral and partial enthalpy of formation in the tin-antimony system at 483.15 K.

The partial molar enthalpies of formation of tin and antimony are given by

$$h_1^F=h^F-x_2\cdot(\partial h^F/\partial x_2)_{T,p}, \quad (8)$$

and

$$h_2^F=h^F-(x_2-1)\cdot(\partial h^F/\partial x_2)_{T,p}. \quad (9)$$

Using Eqs. 6, 7, 8, and 9, we have

$$h_1^F=-5.385-17.12\,x_2^2 \quad h_2^F=+8.13-17.12\,(x_2-1)^2 \quad T=298.15\ K, \quad (10)$$

$$h_1^F=-5.642-18.14\,x_2^2 \quad h_2^F=+8.527-18.14(x_2-1)^2 \quad T=483.15\ K. \quad (11)$$

The curve in Fig. 3 shows that the partial molar enthalpy of antimony is positive and shifts to more positive values at higher composition. This is due to the insertion of the larger antimony atom in the structure of Sn Sb which becomes instable at higher mole fraction of antimony. The structure exhibits a higher tension resulting from the deformation work which is associated with the insertion of the antimony atom in th structure.

The partial molar enthalpy of tin is negative and becomes more negative at higher composition.

A hypothetical illustration of this behavior is probably that a poor fraction of tin p-electrons builds a weak bond with antimony ions. At higher mole fraction of antimony, the equilibrium shifts for the benefit of the delivery of further electrons on antimony.

On the basis of the above discussion, we come to the

following conclusion:

(1) The average molar enthalpy of mixing is more positive than that of formation.

(2) On comparing with partial molar enthalpy of mixing, the partial molar enthalpy of formation of tin is shifted to more negative values, while that of antimony to more positive values.

The Study of Planarized and Planar Cyclohexane Rings on the Basis of Molecular Mechanics

Helena Dodziuk
Institute of Organic Chemistry, Polish Academy of Sciences Warsaw 00-961, Kasprzaka 44, Poland
(Received June 25, 1986)

Recent rapid development of synthetic and theoretical methods has yielded molecules with unusual stereochemistry on carbon atom. One of the most interesting examples of such earlier unsought of arrangements is provided by planar cyclohexane rings. Few molecules of this kind have been synthesized and two others have been postulated on the basis of molecular mechanics calculations. In the present article a critical review of existing experimental and theoretical results is supplemented with a molecular mechanics study of a series of cyclohexanes fused with up to six 3-, 4-, and 5-membered rings causing the flattening of C_6 ring. The existing experimental data and the results of the calculations seem to indicate that the flattening is more pronounced when smaller and/or larger number of rings are fused. The applicability and limitations of molecular mechanics with the MM2 parameterization to the study of the flattening of cyclohexane ring have been critically analyzed. The synthetic efforts in this field seem to indicate that some results calculated for hypothetical molecules will be checked in the near future. Similarly to hypothetical [6]asterane and hexaprismane, the planarity of [6.3]coronane has been postulated.

Until recently, the following stable conformations of a cyclohexane ring has been taken into account: chair, twist, boat (and half-chair for a ring with a double bond). In their review on the nonchair conformations of cyclohexane rings published in 1974 Kellie and Riddell[1] limited themselves with the former three conformations. The half-chair and boat rings have been also lately discussed by Vereshchagin.[2] Due to a rapid development of synthetic and theoretical methods in the last 15 years molecules with considerable distortions from a standard cyclohexane geometry toward a planar cyclohexane ring or even those with completely planar rings have been reported. Several derivatives of *cis*- and *trans*-tris-σ-homobenzenes (**1**—**3**, complexes of **4**) have been found to exhibit planar sixmembered rings by means of X-ray analysis.[3-6] *trans*-Tris-σ-homobenzene **5** has been synthesized by Engelhardt and Lüttke.[7] The authors claimed that the central ring in the molecule is planar but no sound arguments in favor of the planarity have been given. A highly strained diplanar structure of hexamethylated derivative **6** with the torsional angle between the planes close to 180°[8] seems to validate the planarity of the parent molecule **5**. Planar C_6 rings have been also postulated for other types of hypothetical molecules by Osawa and Musso **7**[9] and Allinger and Eaton **8**[10] on the basis of molecular mechanics calculations.

Molecules with flattened but not completely planar cyclohexane rings are much more common. A *cis*-fusion of a 4- or 5-membered ring in **9** and **10**[11,12] was reported to yield a distorted C_6 ring with a flattening along the junction and an enhanced twisting in the other part of the ring and a fusion with cyclopropane is known to result in a half-chair conformation.[2,13] The overall flattening effect of a cis-fusion can be estimated by means of a sum of the absolute values of torsional angles within the C_6 ring α. The lowering of the α value from the cyclohexane value of 336°[14] is small for bicyclo[4.3.0]nonane (**9**), it increases for bicyclo[4.2.0]octane (**10**) and is the biggest for bicyclo[4.1.0]heptane (**11**) where the six-membered ring assumes a half-chair conformation (the corresponding values are given in Table 1). A cis-substitution of subsequent small rings seem to cause further flatten-

ing of the ring under investigation. Examples of this type include several derivatives of *cis*- and *trans*-tricyclo[5.1.0.0^{3,5}]octanes (**12**) and those of *cis*- and *trans*-tricyclo[5.1.0.0^{2,4}]octanes (**13**).[2,15-17]

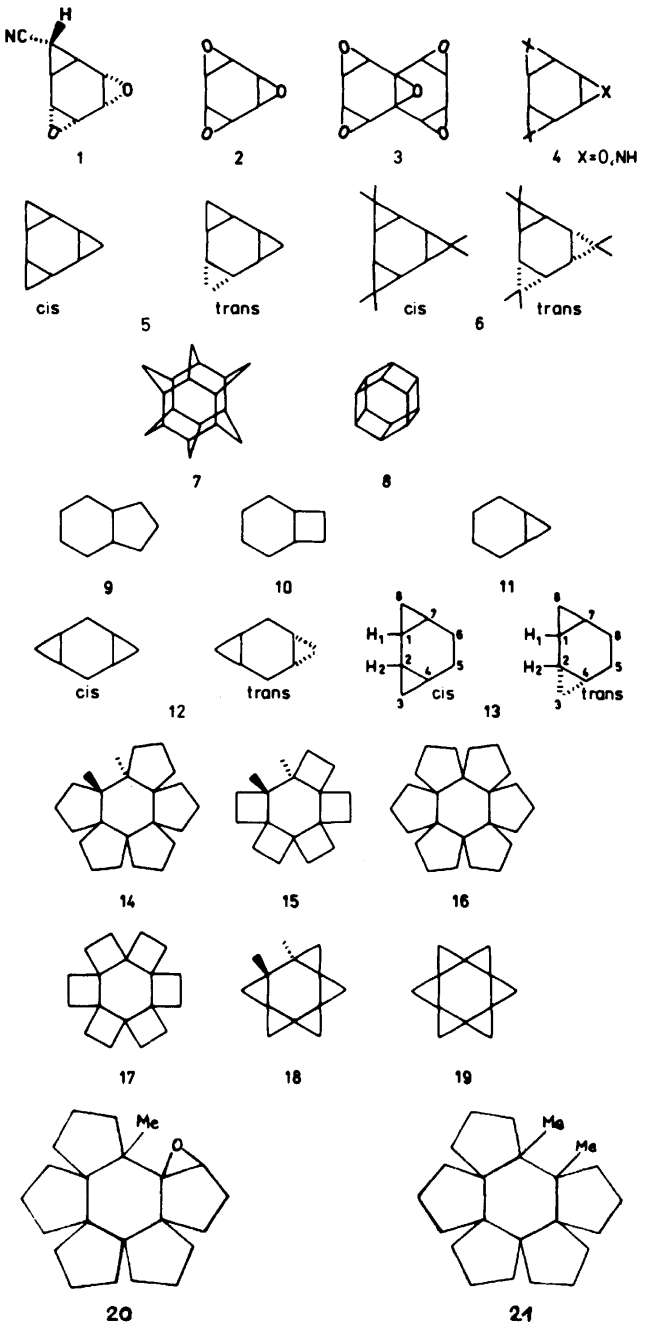
Recent elegant syntheses carried out by Fitjer and coworkers[18,19] yielded derivatives of polycycles **14** and **15** (exhibiting a considerable flattening of the C_6 rings) with the purpose to obtain the corresponding coronanes **16** and **17**.

Some molecular mechanics[20] studies of the molecules under investigation have been reported but they are inconsistent and deal only with some particular aspects. Boyd and coworkers[21] calculated thermochemical properties of a series of bicyclic molecules using their own force field. They have reported the calculated values of bond angles and torsional angles for the molecules **9**—**11** but, having no experimental data to compare with, they did not discuss the geometrical results obtained. In their electron diffraction study of *cis*- and *trans*-bicyclo[4.3.0]nonanes (**9**) Enden and Geise[11] repeated the molecular mechanics calculations for the molecules using the force field proposed by Ermer and Lifson.[22] Spelbos et al. repeated[12] the Boyd force field calculations similarly, in addition to their electron diffraction study of *cis*- and *trans*-fused bicyclo[4.2.0]octanes. An old diffraction work on bicyclo[4.1.0]heptane (**11**) has also been accompanied by simplified molecular mechanics calculations using still another force field.[13]

Heat of formation values (HOF) for **9** and **10** have been also calculated by Allinger[24] using his MM2 parameterisation[23] and the MM2 calculations for **11** has been only cited as unpublished results.[25] The same force field used by Osawa and coworkers[26] for tricyclic systems *cis*- and *trans*-**13** yielded results somewhat different from these reported in the present paper. They will be discussed below in some detail.

The aim of this work was to analyze by means of molecular mechanics[20] with the MM2 parameterization[23] the flattening of cyclohexane ring forced by *cis*-fusion of small ring(s) to find out regularities and to check the applicability of the method to the study of this interesting problem. For the sake of completeness the following series of molecules has been studied: **9**—**11**, *cis*- and *trans*-**13**, *cis*- and *trans*-**5**, *tarans*-**6**, **14**—**19**, and **21**. *cis*- and *trans*-tricyclo[5.1.0.0^{3,5}]octanes (**12**) have not been included into the series in view of the unreliability of one parameter involved in the calculations which will be discussed below.

The available experimental data and the results of the calculations carried out in the present work seem to indicate that *cis*-fusion of a small ring flattens cyclohexane ring and the flattening is more pronounced when more and smaller rings are involved in fusion with the C_6 ring. In the limiting case of *cis*- and *trans*-tris-σ-homobenzenes (**5**) and that of the hypothetical [6.3]coronane (**19**) the cyclohexane ring is completely planar. The calculations yielded also the HOF values



for the molecules under investigation.

Method

The calculations have been carried out using MM2-type program KNOW[27] on Mera 400 computer with the standard MM2 parameterization.[23] The molecules *cis*- and *trans*-**5**, *trans*-**6**, *cis*- and trans-**13**, **14**—**19**, and **21** represent highly strained systems for which the method could be of limited accuracy[28,29] or even fail since minor inaccuracies in potential functions and/or parameters used, which do not impair results for less congested molecules, can influence them for highly strained systems. Therefore, the calculations are also of value for detection of deficiencies and limitations of

the method itself. The problem is further complicated by the fact that the corresponding experimental data to compare with are scarce and the ones at our disposal often refer to solid state X-ray of derivatives of the molecules under investigation. In cases when such a comparison could be carried out (*trans*-**6**, **13**—**15**, **20**, **21**)† the results of the calculations performed in the present work seem to indicate that (1) the method yields reliable estimation of torsional angles (see Tables and discussion below) and, therefore, seems suitable for the analysis of planarity of cyclohexane ring. (2) On the other hand, it performs badly for bond lengths in highly congested systems. In particular, contrary to the report by Osawa et al.[26] we were not able to reproduce the bond lengths for *cis*- and *trans*-**13**.†† Consequently, (3) poor reproducibility of bond lengths and the condition for ring closure lead to wrong values of bond angles. Therefore, the calculations reported here seem to underline the need for further refinement of the MM2 force field parameters involving cyclopropane ring. On the other hand, the magnitude of the V_3 torsional constant of the type 22-22-1-22 chosen in Ref. 25 raises more serious objections. The value of 4.5 kcal mol^{-1} assigned to this constant in the MM2 parameterization has been questioned by Rüchardt et al.[28] We also believe that this value is unreliable since it is about 10 times bigger than other constants of similar type. Thus, as stated above, the lack of this constant precluded the performance of the calculations for the *cis*- and *trans*-tricyclo[5.1.0.0^{3,5}]octanes (**12**).

It is well-known that local minima pose a serious problem in molecular mechanics calculations.[20,30] In our case for the molecules **14** and **15** (and for the hypothetical molecules **17**—**19** and **21**) the minimization ends at local minima if one starts from a cyclohexane chair geometry. Only the use of the strongly planarized C_6 rings as input geometry guarantees the achievement of the absolute minimum.

Results and Discussion

The calculated steric energies E_s, heats of formation HOF, and the values of the sum of torsional angles within the C_6 ring in the molecules under investigation α are collected in the Table 1 together with the available experimental results and the calculated data from the literature. The trends exhibited by some torsional angles within the series **9**—**11** and **16**, **17**, and **19** are given in Table 2.

Some remarks should be made on the calculated steric energies. E_s values represent actually energies relative to hypothetical reference system. As such they can be compared on a physically sound basis only for isomers. For obvious reason the values calculated for the *cis*-compounds **5** and **13** are higher than those for the *trans*-molecules. More interesting seems the fact that the closure of the last ring in polycycles **14**—**19** yielded a higher value of the steric energy of [6.4]coronane **17** than the value for **15** while the corresponding values for [6.5]coronane (**16**) and [6.3]coronane (**19**) are lower than the ones for the molecules **14** and **18**, respectively.

Table 2. Calculated and Experimental (in Parentheses) Values of Selected Torsional Angles (in Degrees)

		ϕ_1	ϕ_2
	n=1 (**11**)	−2.9	64.4
	n=2 (**10**)	−30.1	63.8
		(−32.8)[12]	(64.4)[11a]
	n=3 (**9**)	−47.5	58.0
		(−46.6)	(58.2)[11]
	n=1 (**19**)	0.0	
	n=2 (**17**)	22.6	
	n=3 (**16**)	39.5	

a) This value has not been given in the original Ref. 12 and is incorrectly cited as C5-C9-C8-C7 angle in the Table 5 of the Ref. 11 but the model calculations cited in the former reference prove that this is the largest torsional angle in the C_6 ring.

As was stated above, very few experimental data are known to compare with. Experimental heats of formation values have been reported only for the molecules **9**—**11**[31] and the HOF values for *cis*- and *trans*-**5**, *trans*-**6**, *cis*- and *trans*-**13**, **14**—**19**, and **21** can be considered as an estimation of the values which are very difficult, if possible, to obtain experimentally. The calculated MM2 HOF values for the molecule *cis*-**5** is reasonably close to the corresponding MINDO/3 value calculated in Ref. 32 (see footnote i to the Table 1).

An inspection of the α values collected in the Table 1 seems to indicate that in the cases where the corresponding experimental data have been published there is a reasonable agreement between the calculated and experimental results. The difference is equal to 5° for bicyclo[4.2.0]octane (**10**) and is equal to ca. 20° between the analogous molecules **14** and 13-(3,5-dinitrobenzoyloxy)hexacyclo[12.2.0.0^{1,4}.0^{4,7}.0^{7,10}.0^{10,13}]hexadecane (**22**), and **20** and **21**. It seems that even the last value of 20° is not big since (a) it corresponds to an average error of less than 4° and (b) the molecules in comparison are not identical but rather close analogues.

For the molecules *trans*-**6** and *cis*- and *trans*-**13** the reported experimental data are insufficient to calculate the corresponding α values but the results of the calculations reproduce with a reasonable accuracy the available experimental torsional angles. For example,

†The calculated results of the present paper as well as those of references **11**—**13** for the molecules **9**—**11** reproduce all available experimental data satisfactorily.

††The values of the C_1-C_2 bond length for *cis*- and *trans*-**13** calculated in Ref. 26 are lower than the natural bond lengths which is very unusual.

for *trans*-**6** the central ring has been found to be approximately diplanar with the interplane angle of 163° and the corresponding calculated value is equal to 158°. Similarly, the calculated and experimental values of torsional angles for *cis*- and *trans*-**13** are very close. The angle $\varphi_{4,2,1,7}$ is equal to 16.7° (exp.[17]), 14.9° (calcd MM2, this work), and 14.4° (calcd MM2[26]) for *trans*-**13**; and to 17.9° (exp.[17]), 18.0° (calcd MM2, this work), and 18.8° (calcd MM2[26]) for *cis*-**13**.

The reasonable results obtained for **9**, **10**, **13**, **14**, and **21** and especially those for *trans*-**6** seem to validate the use of molecular mechanics method with the MM2 parameterization to analysis of the flattening in even highly strained cyclohexane rings. The available experimental data and the results of the calculations seem to indicate that fusion of a 3-membered ring or fusion of several 4- and 5-membered rings leads to a similar flattening since the corresponding values are similar for **11** and **15** ($\alpha \cong 135°$) and for *cis*- and *trans*-**13** and for **16** and **18** ($\alpha \cong 200°$). The experimental data for the molecule **15** and **17** are not known at present but synthetic effort by Prof. Fitjer and his group allows to hope that they will be available in the near future. Similarly, the synthesis of *cis*-**5** carried out at present by the Prof. Prinzbach's group should yield another check of the predictive power of the method if the substances will crystallize enabling X-ray analysis to be carried out.

As was stated in Chapter 2, the calculated values for bond angles do not reproduce the experimental ones, but a general trend of enlarging the angles upon ring planarization holds since it is enforced by the conditions of ring closure.

Conclusion

In spite of the inaccuracies in the MM2 parameterization involving cyclopropane ring molecular mechanics calculations seem to reproduce the flattening of a cyclohexane ring upon fusion with small ring(s). The experimental data and the results of the calculations presented in this work seem to indicate that the flattening is more pronounced when smaller and/or more ring(s) are fused to a cyclohexane ring. On the basis of calculations a hypothetical [6.3]coronane is postulated to exhibit a planar C_6 ring. The calculations yielded also an estimation of the HOF values for the molecules *cis*- and *trans*-**13**, **14**—**19**, **21** which are unavailable at present. The value of 4.5 kcal mol^{-1} for the V_3 parameter of the type 22-22-1-22 proposed in the MM2 parameterization is questioned and further refinement of other parameters for highly strained and/or cyclopropane containing molecules is postulated.

Further studies of the molecules with planar cyclohexane rings are in prospects. The synthetic efforts by the Prof. Prinzbach's group in the field of heteroanalogues of *cis*-tris-σ-homobenzenes and those by the Prof. Fitjer's group in the field of coronanes seem especially promising in this respect. If the substances will crystallize they will enable an additional check of the present calculations in the near future.

I thank Prof. Fitjer for providing me with the results of X-ray analysis of **20** prior to its publication. Critical remarks by Prof. A. Zamojski and Dr. L. Stefaniak are gratefully acknowledged.

Aryliminodimagnesium Reagents. XII. The Distribution of Products in the Condensation with Nitrobenzothiazoles. Reduction of Electron-Donating Ability of Reagent by the Interaction with Thiazolyl Group

Masao Ōkubo,* Keiko Asao, and Hiroyuki Hyakutake
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjō-machi, Saga 840
(Received April 2, 1987)

The 4-, 5-, 6-, and 7-nitro derivatives of benzothiazole condense with $ArN(MgBr)_2$ giving unsym-azoxy and -azo products. The product distribution indicated the mild nature of the reaction, and could be explained in terms of a reduced electron-donating ability of the reagent due to an interaction with thiazolyl group.

The electron transfer initiated condensation of aryliminodimagnesium reagent($ArN(MgBr)_2$, aryl-IDMg) with nitroarenes[1] and diaryl ketones[2] has been developed in our laboratory. Independently of the manners of reactions of IDMg (condensation) and ArMgBr (addition) as well as those of other magnesium reagents, the principal factor governing the distribution of normal and abnormal (radical) products is a combination of electron-donating and -accepting abilities (EDA and EAA) of reactants:[3,4] The combination represents the relative efficiency of an electron transfer. The efficiency is generally estimated (as the first approximation in fifteen reactions of various magnesium reagents with aromatic substrates) by the value of the difference between the oxidation and reduction potentials of reactants.[4]

A Grignard reaction with nitroarenes had attracted no attention until 1977, since the formation of a large amount of radical product was unavoidable.[5] However, during the past decade, Bartoli and his coworkers have investigated the reaction at lower temperatures, and have established the deoxygenative conjugate addition mechanism involving an electron transfer.[6] Among a lot of nitroarenes, nitrobenzothiazoles, which were first used by the Italian authors,[7] attracted our attention from the EDA-EAA viewpoint since these substrates seemed to be favorable for affording "normal" conjugate addition product as the result of a moderate electron transfer.

The IDMg reagent has a weaker EDA than that of ArMgBr.[8] If IDMg condense with nitrobenzothiazoles in the usual manner,[1] the product distribution is expected to be similarly explainable by a much milder

electron transfer. This expectation was verified. The effect of the thiazolyl group on the reaction is discussed in this paper.

Results and Discussion

Product Distribution in IDMg Reaction with Nitrobenzothiazoles. In a reaction of aryl-IDMg with 4-, 5-, 6-, and 7-nitrobenzothiazoles (Scheme 1), unsymmetrical(*unsym*-) azoxy- and azobenzothiazoles (**1** and **2**) and symmetrical (*sym*-) azobenzenes (**3**) were obtained. The product **1** was formed via condensation with IDMg, **2** via a subsequent deoxygenation of **1** with excess IDMg, and **3** via an oxidative coupling of reagent molecules. The types of products are same with those obtained in reactions with nitrobenzenes.[1] The yields of **1**—**3** obtained under fixed reaction conditions are summarized in Table 1 (Runs 1—15); four previous results (Runs 01—04)[1] are also listed for a comparison. As described in the following, the notable features of product distribution meet the expectation given above.

The first feature is that the recovery of the substrate was observed in all cases using two molar equuivalents of reagents. Two molar equivalents of *p*-ClC_6H_4-IDMg, having the weakest EDA,[8] leads to a large amount of recovery (Runs 7 and 12), and seven molar equivalents are needed for a complete conversion (Runs 8 and 13). In the case of *p*-MeC_6H_4-IDMg, having a stronger EDA,[8] five molar equivalents are needed (Run 6). In contrast, in cases of nitrobenzenes (Runs 01—04), no recovery was observed, even upon using two molar equivalents of *p*-ClC_6H_4-IDMg (Run 04).

The second feature is that, even in Runs 6, 8, 11, and 13 using a large excess of IDMg, the yield of *unsym*-azoxy product **1** was always much higher than those of the corresponding *unsym*-azo product **2**. This indicates that **1** was quite sluggishly deoxygenated by IDMg, as compared to the previous results (Runs 01—03).[1] As previously reported, the IDMg deoxygenation of azoxyarenes is accelerated and/or retarded, depending on their EAA's.[1,9]

a) Melting points are undetermined because the trace amounts of samples were not purified completely.
b) For AB-quartets of aromatic protons, all the ΔJ values are 8—9 Hz.

The third feature is that the yields of **1** and **2** in reactions of the 4-nitro isomer (Runs 1—3) having neighboring nitrogen atom are lower than those in cases of other isomers (Runs 4, 5, 7, 9, 12, 14, and 15). Even the 7-nitro isomer, having a neighboring sulfur atom, gave **1** and **2** in yields comparable to those in cases of 5- and 6-nitro isomers. Thus, the anomaly indicates that 4-nitro group is less favorable for the condensation with IDMg, probably due to a steric repulsion caused by the neighboring nitrogen atom, whereas the "normal" yields in cases of the 7-isomer may be ascribed to the long C_{Ar}-S bond causing no appreciable repulsion. The retardation of IDMg condensation by some ortho substituents of nitrobenzene was observed.[10] In this connection, the Grignard reagent[7] converts the 4-nitro isomer into a non-deoxygenative product(*vide supra*) different from the deoxygenative ones obtained in cases involving the other isomers.

Reduction of EDA of Reagent Caused by Coordination of Thiazolyl Group to Mg Atom. The first and second features of the product distribution seem to indicate that the electron transfer involved in the reaction of Scheme 1 is milder than those in the IDMg reaction with nitro- and azoxybenzenes.[1,9] However, the normalized reduction potentials of the nitro- and azoxybenzothiazoles are lower than or comparable to those of the corresponding benzene derivatives, as shown below(BT=benzothiazolyl).

Nitroarenes ($ArNO_2$):

Ar	V (redox)
p-$MeOC_6H_4$	−1.508
p-MeC_6H_4	−1.418
p-ClC_6H_4	−1.254
4-BT	−1.314
5-BT	−1.299
6-BT	−1.220
7-BT	−1.142

Azoxyarenes (Ar^1-N(O)=N-Ar^2):

Ar^1	Ar^2	V (redox)
p-$MeOC_6H_4$	*p*-$MeOC_6H_4$	−1.748
p-$MeOC_6H_4$	C_6H_5	−1.642
C_6H_5	C_6H_5	−1.596
p-$MeOC_6H_4$	*p*-ClC_6H_4	−1.574
p-MeC_6H_4	*p*-ClC_6H_4	−1.524
C_6H_5	*m*-ClC_6H_4	−1.423
5-BT	*p*-$MeOC_6H_4$	−1.608
5-BT	*p*-ClC_6H_4	−1.443
6-BT	*p*-$MeOC_6H_4$	−1.732
6-BT	*p*-ClC_6H_4	−1.359

The lower values of the reduction potentials indicate a stronger EAA; this seems to be in conflict with the suggestion of a mild electron transfer. However, when the oxidation peak potential of *p*-MeC_6H_4-IDMg in THF was measured in the presence of an equimolar amount of unsubstituted benzothiazole, the normalized potential value (1.055 V) was reproducible and was found to be higher than that (0.941 V) obtained in its absence.[8] This indicates that (in the reaction of Scheme 1) the actual EDA is much weaker, due to an interaction with the thiazolyl group, and gives rise to a mild electron transfer.

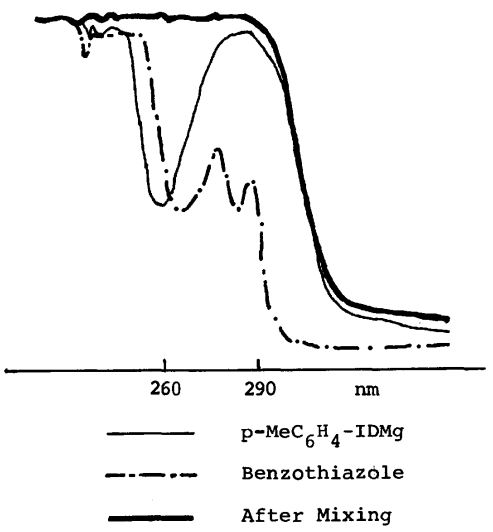

Fig. 1. Shift of n→π* transition band of benzothiazole by mixing with *p*-MeC_6H_4-IDMg.

The interaction arises from a coordination of the thiazolyl group to Mg atom of IDMg, as shown by the electronic absorption spectra measured in degassed THF solutions (Fig. 1). The λ_{max} of n→π* transition of *p*-MeC_6H_4-IDMg is observed at 290 nm and that of benzothiazole at 275 nm. By mixing two equimolar solutions through breaking the seal, the dip between the n→π* and π→π* bands of the reagent disappeared. The spectrum change is attributed to an overlap of the n→π* band of benzothiazole, shifted by 20—30 nm toward blue, due to coordination of the thiazolyl group (probably via nitrogen atom) to Mg atom of IDMg. Undoubtedly, the coodination gives rise to the first and second features of product distribution, i.e., an appreciable recovery and a sluggish deoxygenation. Among the two reagent molecules, tentatively depicted in Fig. 2, the one is coordinated and deactivated while the other is responsible for the condensation with the nitro group.

According to the discussion given above, Bartoli's Grignard reaction[7] owes its first success (as at least one of the reasons) to the reduction of EAA arising from a similar interaction of the thiazolyl group with the reagent. The EDA-EAA concept is useful for characterizing the reactions of aromatic substrates and magnesium reagents of simple molecular structures,[3,4]

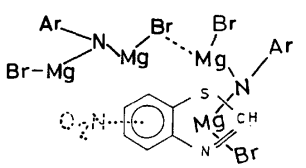

Fig. 2. Schematic depiction for coordination of thiazolyl group to Mg atom of reagent.

however, the modification of the concept on the basis of special molecular structures of substrates must be taken into account.

Experimental

Melting points are uncorrected.

Materials and Procedures. Four isomeric nitrobenzothiazoles were prepared by the nitration of benzothiazole, and separated by recrystallization, steam distillation, and repeated column chromatography on silica gel.[11]

The IDMg reactions were carried out according to the reported procedures; the reaction mixtures of substrates (3.0 or 5.0 mmol) with the given molar amounts of IDMg in THF (30 or 50 ml) were stirred at 55 °C for 3 h. The products were separated by column and thin-layer chromatographies on silica gel(Wako Gel C-200, C-300, and Merck's Kiesel Gel 60G).

Elemental analyses of the products gave satisfactory results. The melting points and ^{1}H NMR data of azoxy- and azobenzothiazoles (**1** and **2**) are summarized in Table 2.

The measurement of reduction potentials of nitro and azoxy compounds using bis(biphenyl)chromium(I) tetraphenylborate (BCTB) as internal reference was carried out according to the reported procedures.[4,9]

The gift of samples of BCTB by Prof. Gerhard Gritzner, University of Linz, is gratefully acknowledged. The authors thank Mr. Toshiki Tsutsumi and Mr. Kōji Matsuo for their assistance in polarographic measurements. The authors are grateful to the Ministry of Education, Science, and Culture for a financial support by a Grant-in-Aid for Scientific Research (No. 60470026).

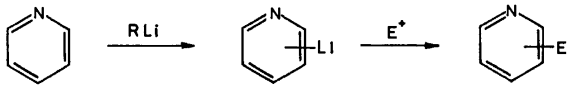
An Ab Initio Molecular Orbital Study of Lithiopyridines

Osamu KIKUCHI,* Hideo TOGO, and Naomichi FURUKAWA
Department of Chemistry, The University of Tsukuba, Sakura, Ibaraki 305
(Received May 9, 1987)

Synopsis. Ab initio molecular orbital calculations were performed for 2-, 3-, and 4-lithiopyridine monomers, and the molecular and electronic structures of lithiopyridines and their reactivity with electrophiles were examined.

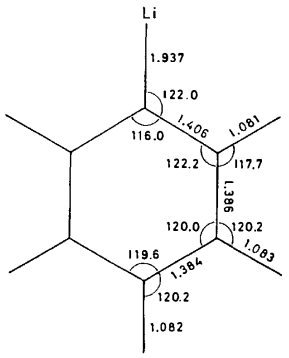
Aryllithium compounds react with various electrophiles to afford the corresponding substituted compounds, and they are very important species for synthetic purposes.[1,2] Lithiopyridines are considered to be the intermediates in the following synthetic route to the substituted pyridines.[2] Since phenyllithium, **1**, is



tetrametric in the solid phase and in solution,[3] lithiopyridines may exist in the aggregation state with a solvent in solution. However, the study of the lithiopyridine monomers is essential to understand the electronic properties of lithiopyridines. The present note will examine the molecular and electronic structures and reactivity of 2-, 3-, and 4-lithiopyridines on the basis of MO calculations.

The molecular structures of phenyllithium, **1**, and of lithiopyridines, **2**—**4**, were optimized by means of ab initio calculations with the STO-3G basis set[4] by assuming planar molecular structures. Their energies were obtained with the 6-31G basis set.[5] The molecular strcture of **1** is shown in Fig. 1, while those of **2**—**4** are shown in Fig. 2. The energies of **2**—**4** and some electronic properties of **1**—**4** are listed in Table 1.

The molecular structures of **3** and **4** can be estimated from those of phenyllithium and pyridine; the STO-3G structure of pyridine has 1.352 Å for the CN bond and 115.6° for the CNC angle. The structures around the N atom in **3** and **4** resemble that of pyridine, while those around the C-Li bond resemble that of phenyllithium. The calculated C-Li bond lengths of **1**, **3**, and

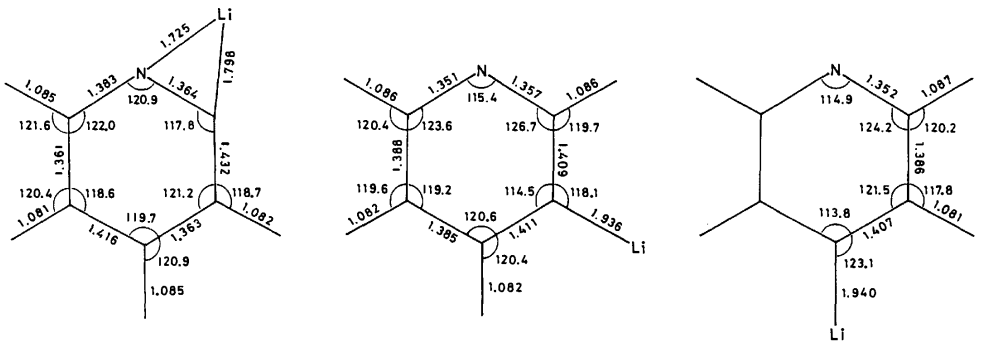


1

Fig. 1. The STO-3G structure of phenyllithium. Bond lengths are in Å, and bond angles are in degrees.

4 are shorter than the C-Li bond in alkyllithium, 2.001,[6] and longer than those between the Li atom and the olefinic carbon atom, 1.776—1.863.[7] The structure of **2** was found to be very different from **3** and **4**; the interaction between the Li atom and the lone-pair electrons of the N atom is strong enough to give the bridged structure. A similar bridged structre has been reported for LiHNOH.[8] The energies of **3** and **4** are comparable and are higher than **2** by about 50 kJ mol^{-1}. The lower energy of **2** is due to the stabilization of the Li atom by the lone-pair electrons. As was pointed out above, lithiopyridines may be stabilized in solution by the Li-solvent interaction; the relative stabilities among the three isomers in solution can not, however, be estimated here.

Since the electrophilic substitution at the C-Li carbon atom is a typical reaction of lithiopyridines, the reactivity of **1**, **3**, and **4** with electrophiles was com-



2 3 4

Fig. 2. The STO-3G structures of 2-lithiopyridine (**2**), 3-lithiopyridine (**3**), and 4-lithiopyridine (**4**). Bond lengths are in Å, and bond angles are in degrees.

Table 1. Energies and Some Electronic Properties of 2-, 3-, and 4-Lithiopyridines and Phenyllithium

Compound	Energy[a]	Q(Li)[b]	q(C)[c]	q_π(C)[d]	$\varepsilon_{HOMO}(\pi)$[e]
2-Lithiopyridine (**2**)	−253.44542 (0.0)	0.088	5.932	0.678	−7.52
3-Lithiopyridine (**3**)	−253.42588 (51.5)	0.217	6.054	0.851	−6.68
4-Lithiopyridine (**4**)	−253.42633 (50.2)	0.228	6.035	0.816	−7.06
Phenyllthium (**1**)		0.190	6.042	0.849	−6.23

a) The 6-31G calculation for the STO-3G structures. The values are in atomic units, and the values in parentheses are relative energies in kJ mol^{-1}. b) Charge at the Li atom. c) Electron population at the carbon atom of the C-Li bond.
d) π-Electron population at the carbon atom of the C-Li bond. e) Orbital energy of the highest occupied π-orbital. The values are in eV.

pared. As may be seen from Table 1, the electron population on the C-Li carbon atom is in the order of **3**>**1**>**4**, while the π-electron population on the carbon atom in the order of **3**≅**1**>**4**. These findings suggest that the S_E2-type displacement of the Li atom occurs in **3** more easily than in **4**. The orbital energies of HOMO(π) of **3** and **4** are more negative than **1**; this indicates that the reactivity of **3** and **4** is lower than **1** for the orbital-controlled reaction. The calculated positive charges of the Li atom are in the order of **4**>**3**>**1**≫**2**. The small value in **2** is due to the participation of the lone-pair electrons of nitrogen.

All the calculations were performed on the FACOM M-380 computer at The University of Tsukuba using the ABINIT program written by our group. The work was supported by University of Tsukuba Project Research.

Theoretical Estimation of the Solubilities of Lanthanoid Iodates in Dimethyl Sulfoxide-Water Mixtures

Takehiro ABE
College of General Education, Tohoku University, Kawauchi, Sendai 980
(Received March 14, 1987)

Synopsis. By using a Modified Born equation, the solubilities of sparingly soluble lanthanoid iodates in dimethyl sulfoxide-water mixtures have been successfully estimated.

Recently Miyamoto et al.[1] have reported the solubilities of lanthanoid iodates in dimethyl sulfoxide (DMSO)-water mixtures. They have qualitatively accounted for these values of solubilities, using the theory of Davis, Ricci, and Sauter[2] for solubility. In their theory, the famous Born equation[3] is applied to the calculation of the interaction energy of an ion with a solvent. Recently, Abe[4] has modified the Born equation by considering a distance-dependent relative permittivity of a solvent. The modified equation better reproduces the observed solvation free energies of ions than does the Born equation. Moreover, Ehrenson[5] has shown that the solvent parameter in Abe's equation is the best in the inverse exponential radial dielectric function family of the modified Born equations for the correlation of the free energies of solvation. In this paper, therefore, an attempt has been made to account quantitatively for the solubilities of lanthanoid iodates by using Abe's equation instead of the Born equation in the theory of Davis, Ricci, and Sauter.

Theoretical Treatment

Let us consider that a sparingly soluble salt, $A_{\nu+}B_{\nu-}$, dissolves in a given solvent i at a concentration of c_i (molarity) and that the salt is completely dissociated into spherical ions:

$$A_{\nu+}B_{\nu-} \longrightarrow \nu_+ A^{(z_+)+} + \nu_- B^{(z_-)-} \tag{1}$$

Following the theoretical treatment of Davis et al.[2] one obtains the following final equation by replacing the Born equation with Abe's equation:[4]

$$\ln\left(\frac{c_2}{c_1}\right) = \frac{e^2}{2kT} \times \frac{z_+z_-}{z_+ + z_-} \times \left(\frac{z_+}{r_+} + \frac{z_-}{r_-}\right) \times \{\eta'_1(\varepsilon_{r,1}) - \eta'_2(\varepsilon_{r,2})\} - A \times (z_+z_-) \times \left\{\frac{I_1^{1/2}}{(T\varepsilon_{r,1})^{3/2}} - \frac{I_2^{1/2}}{(T\varepsilon_{r,2})^{3/2}}\right\}, \tag{2}$$

where e the charge of the proton; k, the Boltzmann constant; T, the temperature (K); r_+ and r_-, the radii of the cation and the anion respectively; $\varepsilon_{r,i}$, the relative permittivity of the solvent i, and $A=4.2013\times10^6$ $mol^{-1/2}\,dm^{1/2}\,K^{3/2}$. Here,

$$\eta'_i(\varepsilon_{r,i}) = \frac{1}{\ln\varepsilon_{r,i}} - \frac{1}{\varepsilon_{r,i}\ln\varepsilon_{r,i}}, \tag{3}$$

and

$$I_i = \frac{1}{2} \times (\nu_+ z_+^2 + \nu_- z_-^2) c_i. \tag{4}$$

The second term on the right-hand side of Eq. 2 is the logarithmic mean activity coefficients, that have been calculated by the limiting Debye-Hückel equation on the assumption that the activity coefficients corresponding to the molarity and mole fraction are approximately the same for sufficiently dilute solutions of the salt.[6] When the Born equation is used instead of Abe's, one obtains an equation corresponding to Eq. 2 in which $\{\eta'_1(\varepsilon_{r,1})-\eta'_2(\varepsilon_{r,2})\}$ is replaced with $(1/\varepsilon_{r,1}-1/\varepsilon_{r,2})$.

In applying Eq. 2, as the solvent 1 we must choose a standard solvent whose c_1 value is already known. It is, however, impossible to evaluate explicitly the c_2 value by using the $\varepsilon_{r,2}$ value, because the c_2 value is contained not only in $\ln(c_2/c_1)$ but also in the ionic strength of I_2, according to Eq. 4. The c_2 value was, therefore, numerically obtained as follows. The pure solvent of water for which the solubility of the lanthanoid iodate is the highest was chosen as the standard solvent. The solubility, therefore, decreases in the DMSO-water mixture with an increase in the component of DMSO. Accordingly, by gradually decreasing the c_2 value, independent calculations of the values of both the right- and left-hand sides of Eq. 2 could be repeated by means of a computer until a close agreement (within 10^{-4}) between the values of the two sides was obtained. Thus, the c_2 value was evaluated.

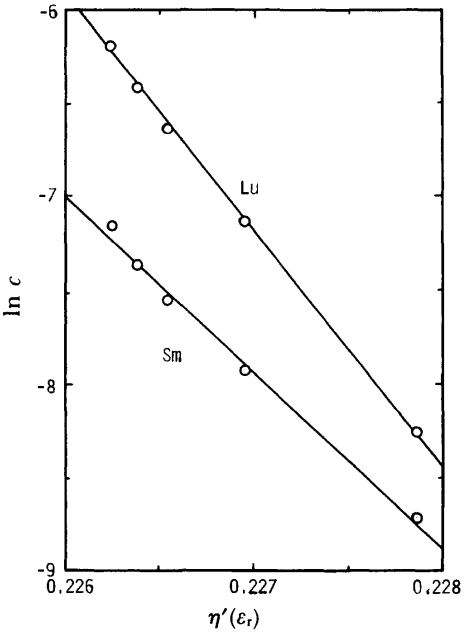

Fig. 1. Relation between $\ln c$ and $\eta'(\varepsilon_r)$ for samarium and lutetium iodates in DMSO-water mixtures.

a) Data from Ref. 1.

Results and Discussion

In applying Eq. 2 to the data of solubilities for the lanthanoid iodates in DMSO-water mixtures,[1)] the crystal radii of the trivalent rare earth ions[7)] were used as the r_+ values. The reported radius of 0.182 nm[8)] for IO_3^- was used as the r_- value. The ε_r values used for the DMSO-water mixtures were those indicated in a previous paper.[1)] Miyamoto et al. have shown examples of the relation between ln c and $1/\varepsilon_r$ for samarium and lutetium iodates.[1)] The corresponding relation between ln c and $\eta'(\varepsilon_r)$ is shown in Fig. 1. The figure shows that the values of ln c are linearly proportional to the values of $\eta'(\varepsilon_r)$. This means that the first term in Eq. 2 contributes dominantly to the value of ln (c_2/c_1) in the present case. The observed and calculated solubilities (c_2) for the three representative lanthanoid iodates are shown in Table 1. Table 1 shows that the solubilities calculated by the use of Eq. 2 agree, to a gross approximation, with the corresponding observed values. When the Born equation was used, similar calculations gave solubilities too much higher for the mixtures of high-DMSO components.

Binary solvent mixtures, such as the DMSO-water mixture, are accompanied by the problem of selective solvation.[9)] The observed solubilities of the lanthanoid iodates may be influenced to some extent by the selective solvation. However, the finding that Eq. 2 gives grossly approximate values of the observed solubilities means that the effects of the selective solvation are small in the present case. This is supported by the following facts. The selective solvation of ions in binary solvent mixtures depends on the standard increase of molar Gibbs function ($\Delta G°$) for the solvation of the ions in the two pure solvents.[9b)] Up to 10 mol% of DMSO, $d\Delta G_t°/dx_{DMSO}$ is nearly zero for some ions in the mixtures of DMSO and water,[9c)] where $\Delta G_t°$ is the $\Delta G°$ value of the transfer of an ion from water to the mixture and x_{DMSO}, the mole fraction of DMSO.

Thus, by using Eq. 2, one may calculate the approximate solubilities for a sparingly soluble salt in binary mixtures, as long as there is no strong selective solvation.

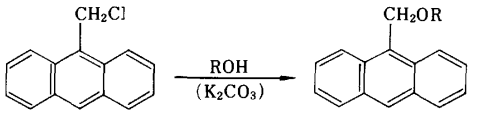
Effects of $CH_3 \cdots O$ Hydrogen Bond on the Rotamer Populations in 9-(Alkoxymethyl)-1,4-dimethyltriptycenes

Yoshio TAMURA, Gaku YAMAMOTO, and Michinori ŌKI*
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received March 24, 1987)

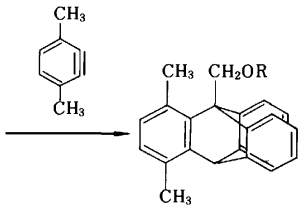
Synopsis. Rotamer populations in 9-(alkoxymethyl)-1,4-dimethyltriptycenes, where the alkyl is an ethyl, a methyl, or a 2,2,2-trifluoroethyl, were examined by ^1H NMR spectra. The populations of the *sc* isomer decreased as the alkyl group becomes electronegative. The population ratio, *sc*/*ap*, of the methyl compound was almost the same with that for 1,4-dimethyl-9-(phenoxymethyl)triptycene to indicate that the populations of the rotamers in this and related series of compounds are determined on a delicate balance of various factors such as van der Waals repulsive and charge-transfer attractive interactions.

As an extension of the investigation on the factors affecting the rotamer populations, we have prepared 9-(methoxymethyl)-1,4-dimethyltriptycene to find that the population ratio, *sc*/*ap*, was 0.45 at −49.6 °C. The result was surprising because the corresponding 9-(phenoxymethyl) compound gave the ratio of 0.44 at −49.4 °C:[1] Though the electron-density of the phenolic oxygen is supposed to be lower than that of methanol-oxygen, the rotamer populations in these compounds were almost the same. The results may imply that, though the basicity of the oxygen atom in the methoxy compound is higher than that of the phenoxy compound, the van der Waals radius of the methoxy-oxygen is larger than the phenoxy-oxygen to counterbalance the attractive $CH_3 \cdots O$ interactions with the van der Waals repulsion, since high electron-density of an atom means a large steric size. Thus we felt it would be worthwhile to examine the electronic effects on the rotamer populations in 9-(alkoxymethyl)-1,4-dimethyltriptycenes to find whether the effects again would support the existence of the $CH_3 \cdots O$ hydrogen bond. This paper reports the results of such an investigation.

Syntheses of the compounds in question were carried out in analogous ways to those reported previously:[1] 9-(Chloromethyl)anthracene (**1**) was treated with the corresponding alcohol, in the presence of a base if necessary, and the resulting 9-(alkoxymethyl)-anthracene (**2**) was treated with 3,6-dimethylbenzyne to produce the desired 9-(alkoxymethyl)-1,4-dimethyltriptycene (**3**). As alkyl groups, other than a methyl, an ethyl and a 2,2,2-trifluoroethyl were chosen, the former giving a more basic oxygen and the latter giving a less basic oxygen than the methoxy-oxygen.



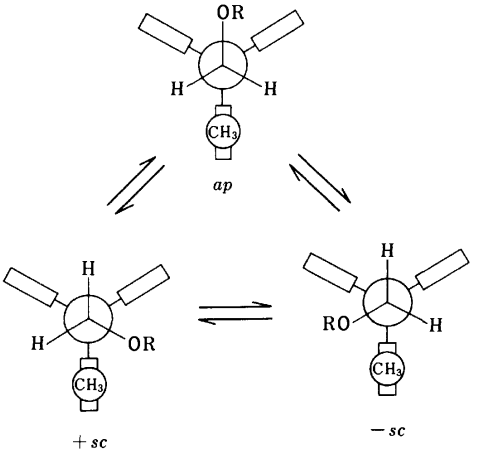
1 2



3

The rotamer populations were determined by 400 MHz ^1H NMR spectra at low temperatures. Assignment of the conformations was straightforward from the methylene signals (see Scheme 1).[1] The results are shown in Tables 1 and 2. The population of the *sc* form was divided by 2 to accommodate the fact that there are two (+ and −) equivalent conformations for the *sc* form.

The results clearly indicate that, as the alkyl group becomes electronegative and consequently the proton affinity of the oxygen atom in the 9-substituent decreases, the population ratios (*sc*/*ap*) become small and the free energy differences between the *sc* and the *ap* rotamers become large. The results are consistent with the presence of the $CH_3 \cdots O$ hydrogen bond, if we compare the populations in the 9-(alkoxymethyl)-1,4-



Scheme 1. Rotational circuit.

Table 1. Rotamer Populations in 9-(Alkoxymethyl)-1,4-dimethyltriptycenes in $CDCl_3$ at Various Temperatures

Alkyl	Population ratio[a] (Temperature/°C)
CH_3CH_2	0.346 (−49.5) 0.354 (−39.6) 0.372 (−9.7)
CH_3	0.225 (−49.6) 0.240 (−39.6) 0.269 (−29.6) 0.278 (−19.7) 0.304 (−9.7)
CF_3CH_2	0.149 (−49.5) 0.163 (−39.6) 0.175 (−29.6) 0.188 (−19.7)

dimethyltriptycene series.

As was discussed previously, the 9-(alkoxymethyl) group in these compounds is placed in a space where other neighboring groups are in close proximity. Therefore, the repulsive interactions between the alkoxy-oxygen and the 1-methyl group is especially severe in the *sc* conformation, where the attractive $CH_3 \cdots O$ interaction is also possible. We believe that the bulkiness effects of the methoxy-oxygen compensate the stabilization by the $CH_3 \cdots O$ hydrogen bond in 9-(methoxymethyl)-1,4-dimethyltriptycene to make the apparent rotameric populations of the compound about the same with that of 1,4-dimethyl-9-(phenoxymethyl)triptycene.

We conclude that the $CH_3 \cdots O$ hydrogen-bond effects on the rotamer populations do exist in this series but care should be exercised in comparing the population ratios of rotamers in different series of compounds, if the molecules are in congested states.

Experimental

Determination of Population Ratios. The ^1H NMR spectra at low temperatures were obtained with the use of a JEOL GX-400 NMR spectrometer. The indicated temperatures were calibrated with a thermocouple. For the determination of populations, the integrated intensities were obtained by cutting the chart papers and weighing them for several times. The peaks for the integration were those due to 9-methylene protons.

9-(Ethoxymethyl)anthracene. A solution of 0.15 g (0.66 mmol) of 9-(chloromethyl)anthracene[3] in 20 mL of ethanol was stirred for 10 h at room temperature. The mixture was poured into water and extracted with dichloromethane. The solvent was evaporated, after drying over magnesium sulfate, to afford 0.14 g (90%) of practically pure 9-(ethoxymethyl)-anthracene. This compound was directly used for the syntheses of the corresponding triptycene. The following ^1H NMR data ($CDCl_3$, δ) were recorded: 1.27 (3H, t, J=6.0 Hz), 3.70 (2H, q, J=6.0 Hz), 5.43 (2H, s), 7.1—8.6 (8H, m), 8.43 (1H, s).

9-[(2,2,2-Trifluoroethoxy)methyl]anthracene. A mixture of 0.20 g (0.88 mmol) of 9-(chloromethyl)anthracene, 1.30 g (13.0 mmol) of 2,2,2-trifluoroethanol, and 0.12 g (0.86 mmol) of potassium carbonate in 40 mL of acetone was refluxed for 3 d. The precipitate was filtered off and the product was taken up into dichloromethane by shaking the filtrate with a mixture of water and dichloromethane. The organic layer was washed with aqueous sodium hydroxide and dried over magnesium sulfate. Evaporation of the solvent afforded 0.20 g of the crude product which was recrystallized from dichloromethane-hexane. The mother liquor was submitted to preparative TLC (silica gel, 2:1 hexane-dichloromethane) to afford a further crop. The desired product was obtained in 0.16 g (62%) yield. This compound was directly used for the triptycene synthesis. The following ^1H NMR data ($CDCl_3$, δ) were recorded: 3.89 (2H, q, J=9.0 Hz), 5.66 (2H, s), 7.3—8.6 (8H, m), 8.48 (1H, s).

9-(Methoxymethyl)-1,4-dimethyltriptycene. To a boiling solution of 0.46 g (2.1 mmol) of 9-(methoxymethyl)anthracene[3] in 20 mL of dichloromethane, were simultaneously added from two separatory funnels a solution of 2.23 g (13.5 mmol) of 3,6-dimethylanthranilic acid[4] in 70 mL of acetone and that of 3.92 g (33.5 mmol) of isopentyl nitrite in 70 mL of dichloromethane in 3 h. The whole was refluxed for further 30 min and the solvent was evaporated. The residue was submitted to chromatography on alumina with a 4:1 hexane-dichloromethane eluent. The desired product, mp 219—220 °C, was obtained in 20% yield after recrystallization of the product from dichloromethane-hexane. Found: C, 88.50; H, 6.49%. Calcd for $C_{24}H_{22}O$: C, 88.31; H, 6.79%. ^1H NMR ($CDCl_3$) δ=2.43 (3H, s), 2.52 (3H, s), 3.70 (3H, s), 5.03 (2H, br s), 5.56 (1H, s), 6.58 and 6.66 (2H, ABq, J=8.1 Hz), 6.8—7.8 (8H, m).

9-(Ethoxymethyl)-1,4-dimethyltriptycene. Mp 167.5—169 °C, was prepared in 84% yield similarly. Found: C, 88.24; H, 7.27%. Calcd for $C_{25}H_{24}O$: C, 88.19; H, 7.11%. ^1H NMR ($CDCl_3$) δ=1.33 (3H, t, J=6.3 Hz), 2.40 (3H, s), 2.50 (3H, s), 3.83 (2H, q, J=6.3 Hz), 5.03 (2H, br s), 5.54 (1H, s), 6.4—8.0 (10H, m).

1,4-Dimethyl-9-[(2,2,2-trifluoroethoxy)methyl]triptycene. Mp 151—152 °C, was prepared similarly in 41% yield. Found: C, 76.01; H, 5.67%. Calcd for $C_{25}H_{21}F_3O$: C, 76.13; H, 5.37%. ^1H NMR ($CDCl_3$) δ=2,44 (3H, s), 2.50 (3H, s), 4.18 (2H, q, J=9.0 Hz), 5.34 (2H, br s), 5,58 (1H, s), 6.4—7.6 (10H, m).

We thank Dr. Shigeru Murata, Institute for Molecular Science, for the measurement of the ^1H NMR spectra.

(3*E*)-Laureatin and (3*E*)-Isolaureatin, Halogenated C-15 Non-Terpenoid Compounds from the Red Alga *Laurencia nipponica* Yamada[1)]

Minoru SUZUKI* and Etsuro KUROSAWA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received May 2, 1987)

Synopsis. (3*E*)-Laureatin and (3*E*)-isolaureatin have been isolated as major metabolites from the red alga *Laurencia nipponica* Yamada, and their structures were confirmed on the basis of spectral and chemical evidence.

In the course of our continuing studies on the constituents of the red marine algae of the genus *Laurencia* (family Rhodomelaceae), we have reported that *L. nipponica* Yamada ("Ura-sozo"), one of the Japanese species, displayed a marked variation in the major chemical components which seems to be mainly dependent upon the growth locality. The major metabolites from this species collected in the warm current region in Hokkaido are, with some exception,[2,3)] composed of halogenated C-15 non-terpenoids.[4)] As part of our investigations for this species, we have newly collected at several separate locations in Hokkaido and at two locations in Honshū, Oga (Akita Prefecture), and Shichigahama (Miyagi Prefecture). The specimens collected in Hokkaido, as anticipated, contained C-15 non-terpenoids as major metabolites. Laurencin (**1**),[4a)] laureatin (**2**),[4b)] and epilaurallene (**3**)[4c)] were obtained from the specimens of six collecting sites, single site, and two sites, respectively. The major metabolite of Oga's specimen was also C-15 non-terpenoid, laureatin (**2**). On the other hand, the Shichigahama's specimen contained (3*E*)-laureatin (**4**) and (3*E*)-isolaureatin (**5**) as major metabolites, which have previously been obtained as minor components from this species.[5)] We report here the isolation and structural confirmation of these compounds.

(3*E*)-Laureatin (**4**), $C_{15}H_{20}O_2Br_2$, showed the ^1H NMR spectrum very similar to that of laureatin (**2**),[4b)] which has previously been isolated from this species collected at Moheji, except for the signals due to acetylenic and olefinic protons. In the ^1H NMR spectrum of **4**, the signal due to the acetylenic proton was observed in upfield region (δ=2.84) compared with that (δ=3.13) in **2** and the coupling constant between the olefinic protons was 16 Hz. Above-mentioned data coupled with the close resemblance of the ^{13}C NMR spectra (Table 1) of **4** and **2** indicate that **4** is the geometric isomer of the double bond at C-3 of laureatin (**2**). Hydrogenation of **4** over platinum oxide in ethyl acetate gave the hexahydro derivative, $C_{15}H_{26}O_2Br_2$, which was identical with hexahydrolaureatin (**6**)[4b)] in all respects.

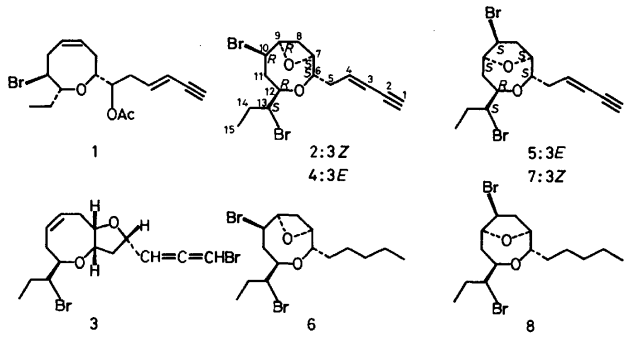
a) Measured at 25.0 MHz in $CDCl_3$ (TMS=0).
#, †, §, ‡; Assignments may be reversed.

The ^1H and ^{13}C NMR (Table 1) spectra of (3*E*)-isolaureatin (**5**), $C_{15}H_{20}O_2Br_2$, again were very similar to those of isolaureatin (**7**),[4b)] an isomer of **2**, except for the signals due to the acetylenic and olefinic protons, thus indicating that **5** is also the geometric isomer of the double bond at C-3 of **7**. Confirmation of the structure of **5** was also obtained by hydrogenation reaction. Hydrogenation of **5** gave the same hexahydro derivative (**8**)[4b)] as that derived from **7**. Accordingly, the structures of (3*E*)-laureatin and (3*E*)-isolaureatin were established as formulae **4** and **5**, respectively.



Experimental

The melting point was uncorrected. The IR spectra were recorded on a JASCO A-102 spectrophotometer and the UV spectra on a Shimadzu UV-240 spectrophotometer. The ^1H and ^{13}C NMR spectra were measured on a JEOL JNM-FX 100 spectrometer, using $CDCl_3$ as the solvent and tetramethylsilane as the internal standard. The low and high resolution mass spectra were obtained by a JEOL JMS-D300 spectrometer. Specific rotations were measured on a JASCO DIP-140 polarimeter in $CHCl_3$ unless otherwise stated. Aluminium oxide (Merck, activity II—III) and silica gel (Merck, Kieselgel 60, 70—230 mesh) were used for column chromatography. Silica gel 60 F_{254} (Merck) was used for preparative thin-layer chromatography. All known com-

pounds were identified by comparison of the spectral data with those of the authentic specimens.

Collection. Algae were collected in Hokkaido at Kabutosaki ('Kabutoiwa')[4a,6] (Oshoro Bay, near Otaru, May 7, 1982), Ebisuiwa (Oshoro Bay, May 7, 1982), Poromaisaki (Oshoro Bay, May 7, 1982), Bikuni (East Shakotan, June 30, 1982), Moiwa (Tomari, West Shakotan, June 30, 1982), Terugishi (West Shakotan, June 30, 1982), Raiden (near Iwanai, June 24, 1982), Sametorima (near Raiden, June 24, 1982), and Benkei Point (Suttsu, June 24, 1982). Furthermore, algae were collected in Honshū at Oga (Akita Prefecture, July 20, 1981) and Shichigahama (near Shiogama, Miyagi Prefecture, April 26, 1982).

Extraction and Isolation. Extraction and isolation were carried out by conventional methods as described in the case of Shichigahama's specimen. Major metabolites; laurencin (**1**): Kabutosaki (10% of the extract), Bikuni (13%), Terugishi (15%), Raiden (15%), Sametorima (10%), and Benkei Point (15%); laureatin (**2**): Moiwa (15%, isolaureatin 5%) and Oga (17%, isolaureatin 5%); epilaurallene (**3**): Ebisuiwa (20%) and Poromaisaki (13%, laurencin 5%).

Isolation of (3*E*)-Laureatin (4) and (3*E*)-Isolaureatin (5). Dried alga (150 g) collected at Shichigahama was extracted with methanol, and the methanol extract was treated with 10% aqueous Na_2CO_3 in the usual manner to give a neutral brown oil (3 g). The neutral oil (1.2 g) was chromatographed over alumina column. The earlier benzene fraction was further chromatographed over silica-gel column to yield crude (3*E*)-isolaureatin (**5**) (60 mg as a pale yellow oil) and (3*E*)-laureatin (**4**) (130 mg as crystals). The successive benzene fraction was subjected to repeated preparative TLC to afford prepacifenol (20 mg),[7] pacifenol (70 mg),[8] and diacetate of laurediol (20 mg).[5] Purification of **4** and **5** was performed by recrystallization and preparative TLC, respectively.

4: Mp 77—78 °C (methanol); $[\alpha]_D^{18}$ +36.6° (*c* 0.95); UV (ethanol), λ_{max} 224 nm (ε 16000) and λ_{inf} 215 (ε 13000) and 231 nm (ε 13000); IR ($CHCl_3$), ν_{max} 3310, 1285, 1140, 1085, 1045, 967, 947, 905, and 803 cm^{-1}: ^1H NMR (100 MHz), δ=1.08 (3H, t, *J*=7 Hz, H-15), 1.7—2.0 (2H, m, H-14), 2.4—3.1 (6H, m, H-5, H-8, and H-11), 2.84 (1H, d, *J*=2 Hz, H-1), 3.7—4.0 (2H, m, H-6 and H-13), 4.21 (1H, ddd, *J*=10, 7, 3 Hz, H-10), 4.45 (1H, ddd, *J*=5, 5, 4 Hz, H-12), 4.65 (1H, ddd, *J*=8, 5.5, 1.5 Hz, H-7), 4.97 (1H, ddd, *J*=8, 5.5, 3 Hz, H-9), 5.47 (1H, br dd, *J*=16, 2 Hz, H-3), and 6.18 (1H, ddd, *J*=16, 7, 7 Hz, H-4); ^{13}C NMR, in the Table 1; EI-MS (70 eV), *m/z* (rel intensity) 394, 392, 390 (0.2:0.4:0.2; M^+), 329, 327, 325 (0.6:1.3:0.7; $M^+-C_5H_5$), 313, 311 (0.9:0.8; M^+—Br), 247, 245 (21:22), 179, 177 (25:27), 165 (66), 149 (19), 147 (44), 119 (37), 107 (35), 105 (27), 93 (47), 91 (33), 81 (24), 79 (43), 77 (38), 71 (20), 69 (30), 67 (59), 65 (44), 57 (22), 55 (54), 53 (28), 44 (37), 43 (27), and 41 (100). Found: *m/z* 391.9815. Calcd for $C_{15}H_{20}O_2{}^{79}Br^{81}Br$: M, 391.9809.

5: Colorless oil; $[\alpha]_D^{15}$ −8.73° (*c* 1.11); UV (ethanol), λ_{max} 224 nm (ε 14000) and λ_{inf} 214 (ε 11000) and 232 nm (ε 11700); IR ($CHCl_3$), ν_{max} 3310, 2150, 1287, 1135, 1110, 963, 945, and 842 cm^{-1}; ^1H NMR (100 MHz), δ=1.07 (3H, t, *J*=7 Hz, H-15), 1.6—2.7 (8H, m, H-5, H-8, H-11, and H-14), 2.83 (1H, d, *J*=2 Hz, H-1), 3.56 (1H, dd, *J*=7, 7 Hz, H-6), 3.8—4.5 (5H, m, H-7, H-9, H-10, H-12, and H-13), 5.55 (1H, br dd, *J*=16, 2 Hz, H-3), and 6.23 (1H, ddd, *J*=16, 7, 7 Hz, H-4); ^{13}C NMR, in the Table 1; EI-MS, *m/z* 394, 392, 390 (0.5:0.9:0.4; M^+), 329, 327, 325 (0.4:0.9:0.5; $M^+-C_5H_5$), 313, 311 (1.6:1.6; M^+—Br), 247, 245 (45:47), 179, 177 (32:33), 165 (80), 149 (20), 147 (46), 119 (33), 109 (18), 107 (29), 105 (21), 95 (25), 93 (44), 91 (22), 81 (27), 79 (31), 77 (21), 69 (38), 68 (22), 67 (53), 65 (30), 55 (60), 53 (21), 43 (31), and 41 (100). Found: *m/z* 389.9847. Calcd for $C_{15}H_{20}O_2{}^{79}Br^{79}Br$: M, 389.9830.

Hydrogenation of (3*E*)-Laureatin (4). **4** (12 mg) was hydrogenated in ethyl acetate over PtO_2-catalyst to give **6** (10 mg); oil; $[\alpha]_D^{20}$ +26.5° (*c* 1.00) and $[\alpha]_D^{18}$ +28.3° (*c* 0.78, CCl_4); whose spectral data were consistent with those of hexahydrolaureatin (**6**)[4b] derived from laureatin (**2**).

Hydrogenation of (3*E*)-Isolaureatin (5). **5** (9 mg) was hydrogenated in ethyl acetate over PtO_2-catalyst to yield **8** (9 mg); oil; $[\alpha]_D^{18}$ +5.79° (*c* 0.97) and $[\alpha]_D^{19}$ −0.62° (*c* 0.69, CCl_4); whose spectral data were identical with those of hexahydroisolaureatin (**8**)[4b] derived from isolaureatin (**7**).

We are grateful to Dr. Yuzuru Saito, Faculty of Fisheries, Hokkaido University, for collection and identification of the algae.

(*E*)-2-Tridecyl-2-heptadecenal, an Unusual Metabolite from the Red Alga *Laurencia* Species[1)]

Minoru SUZUKI,* Etsuro KUROSAWA, and Kazuya KURATA*,†
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
†Department of Industrial Chemistry, Hakodate Technical College, Hakodate 042
(Received May 2, 1987)

Synopsis. The structure of an unusual α,β-unsaturated aldehyde isolated from the red algae *Laurencia undulata* and *L. papillosa* was established as (*E*)-2-tridecyl-2-heptadecenal by synthetic method.

In connection with our interest on the halogenated metabolites of the marine seaweeds, we have investigated various Japanese species of the genus *Laurencia* (Rhodomelaceae; Rhodophyta) and found as the major metabolites many halogenated compounds with unique structural features in the extracts of *L. nipponica* Yamada (Ura-sozo),[2)] *L. okamurai* Yamada (Mitsude-sozo),[3,4)] *L. venusta* Yamada (Hime-sozo),[5)] *L. majuscula* Harvey (Aka-sozo),[6)] and *L. pinnata* Yamada (Hane-sozo).[7)] On the other hand, *L. intermedia* Yamada (Kuro-sozo),[3a)] *L. capituliformis* Yamada (Maru-sozo),[3a)] and *L. cartilaginea* Yamada (Kata-sozo)[8)] displayed no halogenated metabolite in their extracts. Furthermore, *L. undulata* Yamada (Kobu-sozo) and *L. papillosa* (Forsk.) Greville (Papira-sozo) also contained no halogenated compound and instead an unusual α,β-unsaturated aldehyde **1**, whose structure is described in this note.

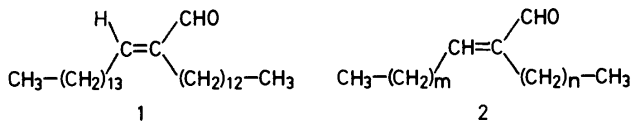
The neutral methanol extract was subjected to repeated column and thin-layer chromatography to give a new aldehyde **1** in 5% yield of the extract along with fatty acid esters.

Compound **1**, $C_{30}H_{58}O$, showed in its ^{1}H NMR spectrum the signals due to two methyl groups at δ=0.88 (6H, br t, J=7 Hz), a vinyl proton at δ=6.43 (1H, dd, J=7, 7 Hz), and an aldehyde proton at δ=9.35 (1H, s). The presence of a disubstituted α,β-unsaturated aldehyde moiety was evident on the basis of UV (λ_{max} 230 nm (ε 10800)), IR (ν_{max} 2730, 1680, and 1640 cm^{-1}), and ^{13}C NMR (δ=195.3 (s), 155.2 (d), and 143.9 (s)) spectra. Furthermore, ^{13}C NMR spectrum (INEPT method) revealed the presence of methyl groups at δ=14.1, methylene groups at δ=22.7—32.0, and no methine group and no other double bonds except for the above-mentioned trisubstituted double bond. Therefore, compound **1**, having two degrees of unsaturation, must be composed of branched-chain carbon skeleton, permitting a formula **2** (m+n=25) to be assigned to this unique aldehyde.

At this stage we noticed the previous report[9)] that 2-dodecyl-2-hexadecenal (formula **2**: m=12 and n=11) was isolated as the major constituent from *L. spectabilis* collected from Southern California along with other α,β-unsaturated aldehydes (range from C_{22} to C_{34}). Thus, formula **2** (m=13 and n=12) could be assigned to our aldehyde. The stereochemistry of the double bond was established as *E*-configuration by the observation of a strong NOE between the aldehyde proton and the vinyl proton on the NOE difference spectra. Confirmation of the structure of **1**, 2-tridecyl-2-heptadecenal, was obtained by synthesis from pentadecanal.

Aldol condensation of pentadecanal, which was obtained from commercially available 1-pentadecanol by oxidation with the chromium trioxide–pyridine complex,[10)] gave (*E*)-2-tridecyl-2-heptadecenal[11)] in 83% yield which was identical with natural aldehyde **1** in all respects.

Consequently, the structure of the unique aldehyde is represented by formula **1**.



1 **2**

Experimental

The IR spectra were measured on a JASCO IR-S or a JASCO A-102 spectrophotometer. The UV spectrum was taken with a Shimadzu UV-240 spectrophotometer. The ^{1}H and ^{13}C NMR spectra were recorded on a JEOL JNM-FX 100 or a JEOL JNM-GX 270 spectrometer, using tetramethylsilane as an internal standard. The low and high resolution mass spectra were measured by a JEOL JMS-D300 spectrometer. Silica gel (Merck, Kieselgel 60, 70—230 mesh) and silica gel 60 F_{254} (Merck) were used for column and thin-layer chromatography, respectively.

Collection. *Laurencia undulata* Yamada were collected at Zagashima, Ago Bay, Mie Prefecture, late in June 1983, and at Shirahama, Wakayama Prefecture, late in May 1976. *Laurencia papillosa* (Forsk.) Greville was collected at Hedomisaki, Okinawa Prefecture, late in May 1976. These three specimens showed almost identical thin-layer chromatogram.

Isolation of (*E*)-2-Tridecyl-2-heptadecenal (1). Half-dried alga (40 g) collected at Ago Bay was extractcd with methanol, and the methanol extract was percolated with ether. The ethereal solution was shaken with 0.5M aqueous KOH (1 M=1 mol dm^{-3}) and saturated brine. After drying over anhydrous Na_2SO_4, the ether was evaporated to give a neutral brown oil (160 mg) which was chromatographed on silica-gel column. The earlier benzene fraction was further subjected to preparative thin-layer chromatography to yield **1** (10 mg) as white crystals. Recrystallization of **1** has been unsuccessful.

1: UV (C_2H_5OH), λ_{max} 230 nm (ε 10800); IR ($CHCl_3$), ν_{max} 2730, 1680, and 1640 cm^{-1}; ^{1}H NMR (100 MHz; $CDCl_3$), δ=0.88 (6H, br t, J=7 Hz), 1.0—1.7 (46H, br s), 2.0—2.5 (4H, m), 6.43 (1H, dd, J=7, 7 Hz), and 9.35 (1H, s); ^{13}C NMR (67.9 MHz; $CDCl_3$) (INEPT), CH_3: δ=14.1; CH_2: δ=22.7, 24.1, 28.7, 28.8, 29.0, 29.4, 29.5, 29.6, 29.7, and 32.0; CH: δ=155.2; C: δ=143.9 and 195.3; LR-EI-MS (70 eV), m/z (rel intensity)

434 (19; M^+), 265 (9), 255 (11), 237 (20), 169 (16), 149 (11), 135 (17), 123 (14), 121 (19), 119 (15), 111 (21), 109 (25), 98 (38), 97 (38), 95 (41), 83 (46), 81 (48), 71 (40), 69 (55), 67 (46), 57 (93), 55 (78), and 43 (100). HR-EI-MS; Found: *m/z* 434.4481. Calcd for $C_{30}H_{58}O$: M, 434.4487.

Aldol Condensation of Pentadecanal. To a solution of pentadecanal (100 mg) in ethanol (1 ml) was added saturated methanolic KOH solution (4 ml), and the mixture was stirred at room temperature for 1 h, acidified with 6M HCl, and extracted with ether. The ethereal solution was washed with 1M HCl and water. After drying over anhydrous Na_2SO_4, the ether was evaporated to give an oily substance which was chromatographed on silica-gel column to yield (*E*)-2-tridecyl-2-heptadecenal (**1**) (42 mg) as crystals, whose spectral properties were consistent with those of natural **1**.

We are grateful to Dr. Yuzuru Saito, Faculty of Fisheries, Hokkaido University, and Dr. Washiro Kida, Mie University, for collection and identification of *L. undulata*, and also to Dr. Hiroshi Yabu, Faculty of Fisheries, Hokkaido University, for collection and identification of *L. papillosa*.

Majusculone, a Novel Norchamigrane-Type Metabolite from the Red Alga *Laurencia majuscula* Harvey[1)]

Minoru SUZUKI,* Etsuro KUROSAWA, and Kazuya KURATA*,†
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
†Department of Industrial Chemistry, Hakodate Technical College, Hakodate 042
(Received May 2, 1987)

Synopsis. The structure of majusculone, a novel norchamigrane-type terpene isolated from the red alga *Laurencia majuscula* Harvey, was deduced from the spectral data.

As part of our continuing studies on the constituents of the red algae genus *Laurencia* (family Rhodomelaceae), we have reported in the previous papers[2)] the structures of two halogenated chamigrene derivatives, **1** and **2**, with an unique vinyl bromide moiety at C-3(15) double bond which have been isolated as the major metabolites from the red alga *L. majuscula* Harvey ("Aka-sozo"). Further investigation of the minor components of this alga has led to the isolation of a novel norchamigrane-type metabolite **3**, designated as majusculone, along with *E*-isomers, **4** and **5**,[3,4)] and also microcladallene C,[3,5)] a non-terpenoid C-15 compound which has previously been obtained from *L. microcladia* collected on the French coast at Cap Ferrat. We wish to describe herein the isolation and structural elucidation of majusculone (**3**).

A combination of column and thin-layer chromatography of the neutral methanol extract afforded majusculone (**3**) in 1.6% yield.

Majusculone (**3**) had the molecular formula of $C_{14}H_{18}O_2$. Its ^{1}H NMR spectrum revealed the presence of two tertiary methyl groups at δ=1.10 and 1.12 (each 3H, s), one vinyl methyl group at δ=1.97 (3H, d, J=1.5 Hz), and three vinyl protons at δ=5.98 (1H, br s), 6.29 (1H, d, J=10.5 Hz), and 6.78 (1H, d, J=10.5 Hz). The IR spectrum exhibited an absorption maximum at ν_{max} 1660 cm^{-1} characteristic of α,β-unsaturated carbonyl group. The ^{13}C NMR spectrum (Table 1) of **3** showed the signals due to two carbonyl carbon atoms at δ=197.3 and 197.5, thus indicating the presence of two α,β-unsaturated ketone moieties which was supported by the UV spectrum, λ_{max} 241 nm (ε 19900). Furthermore, the ^{13}C NMR spectrum revealed the presence of two quaternary carbons at δ=47.4 and 41.0 and three methylene carbons at δ=48.6, 35.1, and 27.5. Above-

Table 1. ^{13}C NMR Chemical Shifts of **2**, **3**, and **5**[a)]

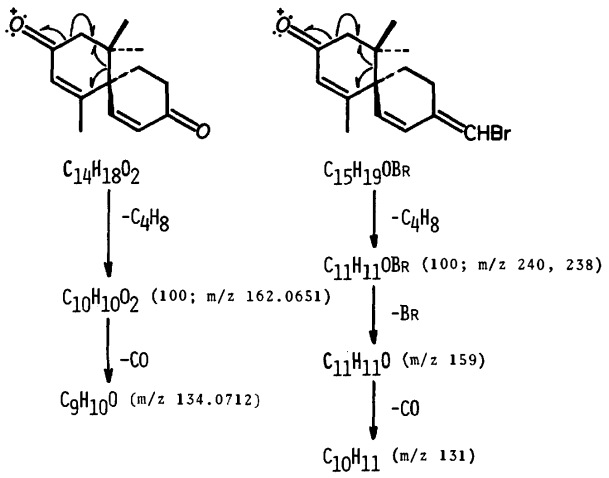

Scheme 1.

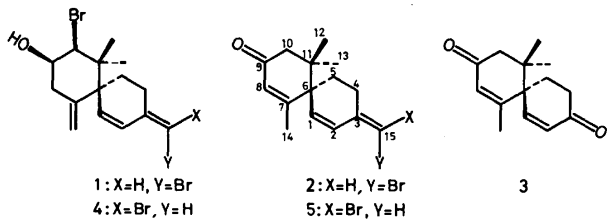

Fig. 1. Partial structures (■; quaternary carbon).

-CO-CH=C(CH$_3$)-■ -CO-CH=CH-■ ■-CH$_2$-CH$_2$-■
■-CH$_2$-■ ■-CH$_3$X2 ■X2

mentioned spectral properties coupled with ^{1}H-^{1}H 2D COSY spectrum indicated the presence of the following partial structures (Fig. 1) in the molecule of **3**. Moreover, the ^{13}C NMR spectrum of **3** showed ten carbon signals compatible with those of **2** and **5**. In view of the above-mentioned data together with co-occurrence of **2**, **3**, and **5** in the same alga, formula **3** could readily be assigned for majusculone. The gross structure **3** was further supported by the mass spectrum. The EI-MS spectrum of **3** displayed a base peak at m/z 162 due to $C_{10}H_{10}O_2$, derived from a loss of C_4H_8 which was resulted from cleavage at C_9-C_{10} and C_{11}-C_6 bonds (Scheme 1). On the other hand, compounds **2**

and **5** revealed in their mass spectra the base peak at *m/z* 240 and 238 ($M^+-C_4H_8$).

Majusculone (**3**) may be biosynthesized from **2** or **5** via epoxidation at C-3(15) double bond.

Majusculone (**3**) is the first example of sesquiterpenoid with a norchamigrane skeleton from marine or terrestrial organisms.

Experimental

The melting point was uncorrected. The IR spectrum was measured on a JASCO A-102 spectrophotometer and the UV spectrum on a Shimadzu UV-240 spectrophotometer. The ^1H and ^{13}C NMR spectra were recorded on a JEOL JNM-FX 100 or a JEOL JNM-GX 270 spectrometer, using tetramethylsilane as an internal standard. The low and high resolution mass spectra were taken with a JEOL JMS-D300 spectrometer. Specific rotation was measured on a JASCO DIP-140 polarimeter. Aluminium oxide (Merck, activity II—III) and silica gel (Merck, Kieselgel 60, 70—230 mesh) were used for column chromatography. Silica gel 60 F_{254} (Merck) was used for preparative thin-layer chromatography.

Isolation of Majusculone (3). *Laurencia majuscula* Harvey was collected at Nyudogatane, Okino-shima, Kochi Prefecture, early in June 1977, and extracted with methanol. The neutral methanol extract (8.5 g) obtained by the conventional methods was fractionated by column chromatography over alumina. The fraction eluted with ethyl acetate gave an oily substance (850 mg) which was repeatedly subjected to silica-gel column and thin-layer chromatography to give majusculone (**3**) as crystals (140 mg).

Majusculone (3): Mp 91.1—92.0 °C (diisopropyl ether); $[\alpha]_D^{19}$ +145° (*c* 0.965, $CHCl_3$); UV (EtOH), λ_{max} 241 nm (ε 19900); IR ($CHCl_3$), ν_{max} 1660, 1615, 1469, 1450, 1437, 1427, 1390, 1377, 1328, 1280, 1269, 963, 905, 855, and 833 cm^{-1}; ^1H NMR (270 MHz; $CDCl_3$), δ=1.10 (3H, s), 1.12 (3H, s), 1.97 (3H, d, *J*=1.5 Hz), 2.08 (1H, m), 2.3—2.7 (5H, m), 5.98 (1H, br s), 6.29 (1H, d, *J*=10.5 Hz), and 6.78 (1H, d, *J*=10.5 Hz); ^{13}C NMR, in the Table 1; EI-MS (70 eV), *m/z* (rel intensity) 162 (100; $M^+-C_4H_8$), 147 (11; $M^+-C_4H_8-CH_3$), 134 (52; $M^+-C_4H_8-CO$), 133 (19), 119 (11), 91 (25), 77 (11), 57 (15), 55 (13), 44 (37), 43 (24), 41 (17), and 40 (47). FI-HR-MS; Found: *m/z* 218.1279. Calcd for $C_{14}H_{18}O_2$: M, 218.1305.

We are grateful to Dr. Yuzuru Saito, Faculty of Fisheries, Hokkaido University, for collection and identification of the alga.

Autoxidation of Indolo[3,2,1-*de*][1,5]naphthyridines

Hajime IRIKAWA* and Yasuaki OKUMURA
Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422
(Received May 9, 1987)

Synopsis. The yellow keto lactam and the blue dimeric pigment were formed by the autoxidation of indolo[3,2,1-*de*]-[1,5]naphthyridines.

Autoxidation of indole compounds gave various products via indoleninyl hydroperoxides.[1] The well known conversion of indoxyl into indigo and the synthesis of trichotomine dimethyl ester (**3**)[2,3] prompted us to study the autoxidation of indolo[3,2,1-*de*][1,5]-naphthyridines **2c** and **7**.

L-Tryptophan was condensed with 2-oxoglutaric acid to give **1a** and **2a**,[4] which were converted into **1b**[5] and **2b** with methanolic hydrogen chloride. The proton at C-3a in **2b** was suggested to have the same β-configuration as the corresponding proton in **1b** had, since the CD spectrum of **2b** ($[\theta]_{221}$−28800) was similar to that of **1b** ($[\theta]_{232}$−22600).[6]

When **1b** (mp 202—203 °C) was heated at 205—208 °C for 30 min, it changed into blue oil. Separation of the colored product afforded the blue pigment **3** (1%), which was identical with **3** synthesized by the procedure of Iwadare et al. (TLC, IR, and ^{1}H NMR).[2]

Similarly, **2b** was heated above its melting point, but no blue spot was detected on the TLC. In order to protect the NH group, **2b** was converted into the acetate **2c**. When **2c** was heated at 168—172 °C for 30 min, it changed into green oil, which showed the yellow and blue spots on the TLC. Separation of the colored products gave the yellow compound **4** and the blue pigment **5** in very low yields.

On the other hand, pyridinium dichromate oxidation of **2c** in *N*,*N*-dimethylformamide (20 °C, 18 h) afforded **4** (20%), which showed the same R_f value on the TLC as **4** obtained above. The structure of **4** was in agreement wih the spectral data: UV 402 nm (ε 11400); ^{1}H NMR ABX signals of C-1 and C-2 protons and a singlet of C-4 proton at δ=6.49; ^{13}C NMR signals of four carbonyl carbons at δ=152.1, 169.8, 170.6, and 177.6.

The dimeric structure **5** was suggested for the blue pigment, since the coloration of **1b** above its melting point resulted from the formation of **3**. In order to confirm the structure, **5** was synthesized as follows.

Shono et al. reported the α-methoxylation of carbamates by electrolysis.[7] Since **2c** showed the anodic peak at 1.57 V vs. SCE in the cyclic voltammetry, it was electrolyzed at 1.3 V vs. SCE in methanol to give **6**, which showed a singlet at δ=3.00 (3H, OCH_3) in the ^{1}H NMR spectrum. Treatment of **6** with formic acid in chloroform under argon afforded **7**. When a colorless solution of **7** in 1-butanol was stirred at room temperature for 47 h, it became blue. Separation of the products gave **4** (6%) and **5** (12%), the latter of which was identical with that obtained by the autoxidation of **2c** (TLC, IR). The structure of **5** was in line with the spectral data: UV 648 nm (ε 38700); ^{1}H NMR ABX signals of C-1 and C-2 protons and a singlet of C-4 proton at δ=8.57; MS *m*/*z* 644 (M^+).

The autoxidation of **2c** at elevated temperature might proceed via **7**. Formation of **4** and **5** from **7** seemed to proceed via the plausible intermediate **8**, since the autoxidation of **7** is similar to that of indoxyl.[8]

Experimental

All melting points were uncorrected. IR spectra were recorded on a Hitachi EPI-G_3 in $CHCl_3$. ^{1}H NMR spectra were obtained on a Varian EM-390 (90 MHz) in $CDCl_3$, and ^{13}C NMR on a JNM-PFT-60 (15 MHz) or a JNM-FX-99 (22.5 MHz) in $CDCl_3$. UV spectra were measured on a JASCO UVIDEC-510 in CH_3OH, and CD spectra on a JASCO J-500 in CH_3OH. Mass spectra were obtained on a Hitachi M-52 or M-80 operating with an ionization energy (70 eV). The cyclic voltammetry of **2c** was recorded on a Yanaco P-1100 in

acetonitrile containing tetrabutylammonium perchlorate (0.10 mol dm^{-3}). Preparative and analytical TLC were carried out on silica-gel plates (Kieselgel 60 F_{254}, E. Merk).

Preparation of 2b. According to the literature,[4] a solution of L-tryptophan (25.0 g) and 2-oxoglutaric acid in 4 mol dm^{-3} hydrochloric acid (250 ml) was heated at 87—91 °C for 2 h. The precipitate was collected and dried. A suspension of the precipitate in 4 wt% hydrogen chloride-CH_3OH (500 ml) was refluxed for 6 h and cooled to room temperature to give the hydrochloride of **2b** (13.1 g), which was freed with aqueous $NaHCO_3$ and crystallized from CH_3OH to give **2b**: mp 154—156 °C; UV 240 (ε 20300), 264 (10400), 292 (4360), and 301 nm (4220); IR 1742 and 1710 cm^{-1}; ^1H NMR δ=1.5—3.2 (7H, m), 3.81 (3H, s), 3.7—4.1 (2H, m), 7.1—7.5 (3H, m), and 8.32 (1H, m); ^{13}C NMR δ=24.9, 28.9, 33.0, 50.2, 52.3, 56.6, 111.8, 116.1, 118.0, 124.0, 124.6, 129.4, 134.8, 135.7, 167.8, and 172.8; MS m/z 284 (M^+); CD $[\theta]_{300}$ −9600, $[\theta]_{276}$ 0, $[\theta]_{267}$ +5100, $[\theta]_{253}$ 0, $[\theta]_{221}$ −28800, and $[\theta]_{211}$ 0. Anal. ($C_{16}H_{16}N_2O_3$) C, H, N.

The mother liquor was concentrated. The residue was neutralized with aqueous $NaHCO_3$, followed by isolation with $CHCl_3$ to give **1b** (3.9 g).[5]

Preparation of 2c. A solution of **2b** (0.91 g) in acetic anhydride (8 ml) and pyridine (8 ml) was allowed to stand at 11—13 °C for 18 h, and concentrated. The residue was crystallized from CH_3OH to give **2c** (1.0 g): mp 168—169 °C; $[\alpha]_D$ +165° (c 0.185, CH_3OH); UV 240 (ε 20800), 264 (10700), 292 (4620), and 300 nm (4480); IR 1747, 1713, 1659, and 1644 cm^{-1}; ^1H MNR δ=2.25 (3H, s), and 3.53 (3H, s); ^{13}C NMR δ=22.7, 23.9, 27.1, 33.4, 49.2, 52.6, 56.2, 110.5, 116.2, 118.2, 124.1, 124.9, 128.5, 133.0, 135.2, 167.8, and 170.8; MS m/z 326 (M^+); CD $[\theta]_{301}$ −8300, $[\theta]_{281}$ 0, $[\theta]_{268}$ +17800, $[\theta]_{255}$ +10400, $[\theta]_{250}$ +15000, $[\theta]_{243}$ 0, $[\theta]_{221}$ −53500, and $[\theta]_{210}$ 0. Anal. ($C_{18}H_{18}N_2O_4$) C, H, N.

Autoxidation of 1b. Colorless crystals of **1b** (103 mg) were placed in a 100 ml Erlenmeyer flask and heated at 205—208 °C for 30 min, open to the atmosphere. Separation of the resulting blue oil with column chromatography afforded **3**[2] (1 mg) in addition to **1b** (77 mg).

Autoxidation of 2c. Colorless crystals of **2c** (104 mg) were placed in a 100 ml Erlenmeyer flask and heated at 168—172 °C for 30 min, open to the atmosphere. The resulting green oil showed the yellow spot of **4** (R_f 0.59), the blue spot of **5** (R_f 0.74), and the spot of **2c** (R_f 0.45) on TLC (ethyl acetate). Separation with column and thin-layer chromatography afforded **4** (<0.1 mg) and **5** (<0.3 mg), respectively, in addition to **2c** (83 mg).

Oxidation of 2c with Pyridinium Dichromate. To a solution of **2c** (98 mg) in DMF (4 ml) was added PDC (1.7 g). The mixture was stirred at 20 °C for 18 h, and poured into water. Isolation in a usual way, purification with column chromatography, and crystallization with $CHCl_3$-hexane afforded **4** (20 mg) in addition to the starting material **2c** (12 mg). **4**: mp 188—190 °C; UV 211 (ε 35400), 248 (12600), 275 (13400), 324 (10600), and 402 nm (11400); IR 1745, 1722, 1697, 1663, 1615, and 1606 cm^{-1}; ^1H NMR δ=2.49 (3H, s), 3.22 (1H, dd, J=18.0 and 6.0 Hz), 3.66 (1H, dd, J=18.0 and 1.8 Hz), 3.71 (3H, s), 5.79 (1H, dd, J=6.0 and 1.8 Hz), 6.49 (1H, s), 7.2—7.7 (3H, m), and 8.33 (1H, m); ^{13}C NMR δ=23.4 (t), 24.7 (q), 53.4 (q), 55.4 (d), 112.3 (d), 117.0 (d), 121.5 (d), 122.7 (s), 125.9 (d), 127.7 (s), 129.7 (d), 138.6 (s), 143.7 (s), 152.1 (s), 169.8 (s), 170.6 (s), and 177.6 (s). Found: C, 63.79; H, 4.23; N, 7.94%. Calcd for $C_{18}H_{14}N_2O_5$: C, 63.90; H, 4.17; N, 8.28%.

Anodic Oxidation of 2c. A mixture of **2c** (74 mg), tetrabutylammonium tetrafluoroborate (330 mg), and CH_3OH (80 ml) was placed in a beaker-type undivided cell, and glassy carbon rods were used as an anode and a cathode, respectively. After electrolysis at constant potential of 1.3 V vs. SCE (electricity: ca. 3 F mol^{-1} (1 F=96480 C)), the electrolytic solution was concentrated. The residue was dissolved in benzene, washed with water, and dried over Na_2SO_4. Evaporation of the solvent and crystallization from CH_3OH gave **6** (45 mg): mp 130—134 °C; UV 238 (ε 21200), 263 (11500), 292 (6200), and 302 nm (6570); IR 1749, 1716, 1661, and 1643 cm^{-1}; ^1H NMR δ=2.50 (3H, s), 2.6—3.5 (4H, m), 3.00 (3H, s), 3.07 (1H, dd, J=16.8 and 5.7 Hz), 3.50 (1H, dd, J=16.8 and 2.1 Hz), 3.57 (3H, s), 5.85 (1H, m), 7.2—7.6 (3H, m), and 8.43 (1H, m); ^{13}C NMR δ=22.8 (t), 24.0 (q), 31.5 (t), 33.3 (t), 49.2 (q), 52.5 (q), 56.3 (d), 84.2 (s), 116.4 (s), 116.8 (d), 118.9 (d), 124.3 (d), 126.2 (d), 126.9 (s), 129.8 (s), 135.7 (s), 167.6 (s), 171.6 (s), and 173.0 (s). Found: m/z 356.1393. Calcd for $C_{19}H_{20}N_2O_5$: M, 356.1371.

Treatment of 6 with HCOOH. To a solution of **6** (40 mg) in $CHCl_3$ (10 ml) was added 99% HCOOH (0.2 ml) under argon. The solution was kept at 20 °C for 24 h, washed with aqueous $NaHCO_3$, and dried over Na_2SO_4. Evaporation of the solvent gave **7** in almost quantitative yield. **7**: IR 1743, 1703, 1659, and 1605 cm^{-1}; ^1H NMR δ=2.38 (3H, s), 3.06 (1H, dd, J=16.8 and 6.0 Hz), 3.51 (1H, d, J=16.8 Hz), 3.62 (3H+2H, s), 5.5—6.2 (2H, m), 7.2—7.6 (3H, m), and 8.37 (1H, m); ^{13}C NMR δ=23.3, 23.4, 35.4, 52.8, 53.8, 110.3, 112.4, 116.3, 119.0, 124.6, 126.0, 126.5, 128.8, 134.8, 165.2, 170.0, and 170.6. Found: m/z 324.1096. Calcd for $C_{18}H_{16}N_2O_4$: M, 324.1108.

Without further purification, **7** was subjected to the next autoxidation.

Autoxidation of 7. A solution of **7**, obtained above, in 1-butanol (20 ml) was stirred at 15—20 °C for 47 h. The resulting blue solution was concentrated. Separation with column and thin layer chromatography afforded **4** (2.2 mg) and the blue oil, which was precipitated with $CHCl_3$ and hexane to give **5** (4.6 mg): UV 228 (ε 59600), 264 (22300), 302 (15200), 348 (12900), 607 (40500), and 648 nm (38700); IR 1742, 1671, 1615, and 1601 cm^{-1}; ^1H NMR δ=2.17 (1H×2, dd, J=18.0 and 6.0 Hz), 2.94 (3H×2, s), 3.20 (1H×2, d, J=18.0 Hz), 3.52 (3H×2, s), 5.87 (1H×2, d, J=6.0 Hz), 7.2—7.5 (3H×2, m), 8.38 (1H×2, m), and 8.57 (1H×2, s). ^{13}C NMR δ=22.8, 24.6, 52.8, 53.7, 115.1, 116.3, 116.6, 120.2, 125.1, 127.1, 128.0, 128.3, 129.5, 130.8, 137.3, 159.9, 170.5, and 170.8; MS m/z 644 (M^+). Found: m/z 644.1887. Calcd for $C_{36}H_{28}N_4O_8$: M, 644.1905.

We would like to thank Professor Akira Tatematsu and Dr. Hiroshi Sakurai of Meijo University, and Dr. Yoshikazu Shizuri of Keio University for obtaining the mass spectra. We also express our thanks to Dr. Kanzo Sakata and Mr. Akihito Yagi of Shizuoka University for measuring the ^{13}C NMR spectra.

The Crystal Structure of 9-Ethyl-8-hydroxyguanine

Hiroshi KASAI,* Susumu NISHIMURA, Yoshiharu TORIUMI,† Akiko ITAI,† and Yoichi IITAKA†
Biology Division, National Cancer Center Research Institute, Chuo-ku, Tokyo 104
†Faculty of Pharmaceutical Sciences, University of Tokyo, Bukyo-ku, Tokyo 113
(Received May 25, 1987)

Synopsis. Analysis of the crystal structure of 9-ethyl-8-hydroxyguanine using X-ray diffraction showed that it is in C-8 keto form. As compared with 9-ethylguanine, significant differences were observed in bond lengths and bond angles of the imidazole ring.

8-Hydroxyguanine (8-OH-Gua) in DNA, induced by oxygen radicals,[1] is a newly encountered form of DNA damage. Many mutagens or carcinogens which form oxygen radicals produce an 8-OH-Gua moiety in DNA in vitro. These agents include mutagenic reducing agents (ascorbic acid, hydrazine, hydroxylamine),[1] asbestos-H_2O_2,[2] polyphenol-H_2O_2-Fe^{3+},[3] and ionizing radiation.[4] The modified base, 8-OH-Gua, is also produced in cellular DNA by ionizing radiation,[5] and it is reasonable to speculate that it may be one of the forms of DNA damage responsible for mutation or carcinogenesis. In fact, misreading was observed during DNA replication in vitro at 8-OH-Gua residue and at adjacent residues.[6] To elucidate the mechanism of mispairing by the 8-OH-Gua residue in DNA, it is important to compare the molecular structure of 8-OH-Gua with that of Gua. It is also important to determine which tautomer of 8-OH-Gua, the 8-enol form or the 8-keto form, is favoured in solution, although the 8-keto form has been proposed for 8-hydroxyguanosine based on ^{13}CNMR shift.[7] This communication describes the analysis of the crystal structure of 9-ethyl-8-hydroxyguanine (9-Et-8-OH-Gua), a model compound of N-9 substituted 8-OH-Gua.

Experimental

9-Et-8-OH-Gua was prepared from *N*-9-ethylguanine (9-Et-Gua, SIGMA) by the treatment with 1 mM $FeSO_4$ (1 M=1 mol dm^{-3}), 5 mM EDTA, 10 mM ascorbic acid, 100 mM phosphate buffer (pH 6.8) in the presence of oxygen gas (Udenfriend system[8]). A 15% yield of pure 9-Et-8-OH-Gua was obtained after fractionation of the reaction mixture using high-performance liquid chromatography. Crystals of 9-Et-8-OH-Gua were then grown in an aqueous solution.

A crystal of approximate dimensions 0.6×0.1×0.1 mm was mounted on a Philips PW1100 diffractometer. The Setting angles for twenty-five high angle reflections and intensity data were measured using Cu $K\alpha$ monochromatic radiation reflected by a graphite plate. Crystal data: 9-Ethyl-8-hydroxyguanine monohydrate (9-Et-8-OH-Gua monohydrate), $C_7H_9O_2N_5$ H_2O, MW=213.2. Triclinic, space group $P\bar{1}$, Z=2. Lattice constants, a=9.937(5), b=9.745(5), c=5.304(6) Å, α=99.95(5), β=92.52(4), γ=114.09(6)°, U=458.1 Å^3. Dcal=1.546 g cm^{-3}, μ for Cu $K\alpha$=1.54 cm^{-1}. Intensities were measured using a 2θ—ω scan method with a scan speed of 4° $2\theta s^{-1}$. The reflections having net intensities (I) above the $2\sigma(I)$ level were recorded as observed. Intensities of three standard reflections, whose values remained within ±2.5%, were monitored every 2 h. 1574 Independent structure factors, out of a theoretically possible 1879, were obtained within the 2θ range from 6—156°. The crystal structure was solved by the direct method, using the computer program MULTAN, and refined by the least-squares method with block-diagonal-matrix approximations. All eleven hydrogen atoms were located on a difference electron-density map and their positional and isotropic thermal parameters were included in the least-squares refinement. The final R value was 0.038 for the 1574 observed structure factors.

Results and Discussion

Analysis of the crystal structure of 9-Et-8-OH-Gua clearly shows it to be in the C-8 keto form, with a

proton attached to the N-7 position and with a C(8)-O(12) bond length of 1.237 Å (Fig. 1). Within the crystal, the molecules of 9-Et-8-OH-Gua are linked together and to water molecules by the seven kinds of hydrogen bonds. When the bond lengths and bond angles of 9-Et-8-OH-Gua were compared with those of 9-Et-Gua,[9] significant differences were observed in the imidazole ring due to the 8-keto structure (Tables 1 and 2). Bond lengths, C(8)-N(7) and C(8)-N(9) of 9-Et-8-OH-Gua are considerably longer than those of 9-Et-Gua, and there is a highly significant deviation in the bond angles C(8)-N(7)-C(5), N(9)-C(8)-N(7), and C(13)-N(9)-C(8) from the corresponding bond angles in 9-Et-Gua. In contrast, the structure of pyrimidine ring of 9-Et-8-OH-Gua is very similar to that of 9-Et-Gua. Based on ^{13}C NMR studies, it has been reported that 8-hydroxyguanosine favors the syn-conformation.[7] Our finding based on ^{1}H and ^{13}C NMR spectra suggest 8-OH-dG can also adopt the syn-conformation (unpublished results). From these results it is concluded that misreading by 8-OH-dG observed during DNA replication in vitro,[6] may be due either to formation of Hoogsteen type base-pairing by 8-OH-dG (6,8-diketo form and syn-conformation) or to disturbance of the tertially structure of DNA around 8-OH-dG residues. To elucidate the actual effect of the 8-OH-Gua residue in DNA, the tertiary structure of selfcomplementary oligodeoxynucleotides containing 8-OH-Gua at specific position need to be studied, and work on this line is now in progress.

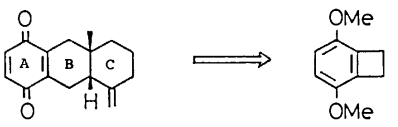
The Simple Synthesis of Cordiachrome B, a Terpenoid Benzoquinone from Cordia Millenii

Takashi WATABE, Yasushi HOSODA, Keiji OKADA, and Masaji ODA*
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received May 27, 1987)

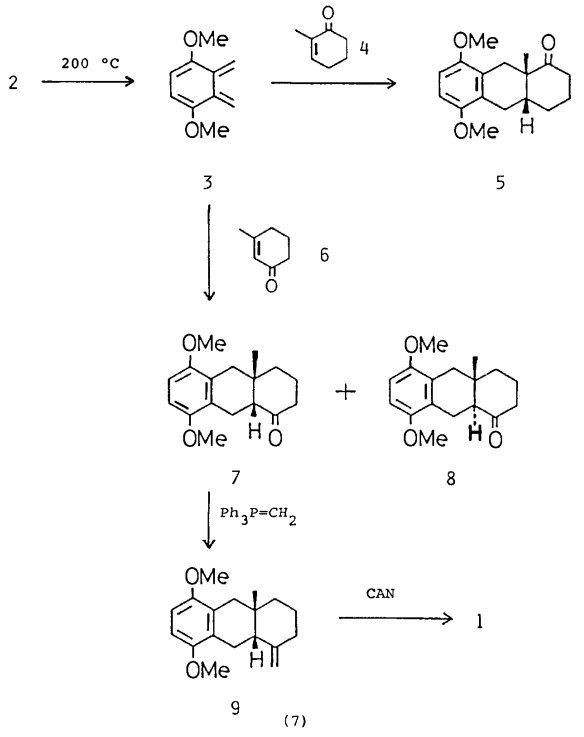
Synopsis. Cordiachrome B, a tricyclic terpenoid *p*-benzoquinone isolated from Cordia millenii, was synthesized in three steps from 1,2-dihydro-3,6-dimethoxybenzocyclobutene employing a Diels-Alder reaction in a key step.

Cordiachrome B (**1**) is a tricyclic sesquiterpene quinone isolated from the heartwood of *Cordia millenii*.[1] Its structure is featured by the cis configuration at the B-C ring juncture, which could be advantageously constructed by a Diels-Alder reaction. In the course of our studies on benzocyclobutene-3,6-quinones,[2] we have prepared 1,2-dihydro-3,6-dimethoxybenzocyclobutene (**2**) which would be a useful synthon for **1** and other polycyclic benzoquinones owing to its thermal isomerization to 1,4-dimethoxy-5,6-dimethylene-1,3-cyclohexadiene (**3**), a reactive *o*-quinodimethane. Generation of **3** through debromination of 3,6-dimethoxy-α,α'-dibromo-*o*-xylene and its trapping with typical dienophiles have been reported by Laduranty et al.;[3] however, the *o*-quinodimethane **3** thus generated seems not suitable for Diels-Alder reactions with weak dienophiles, since it will undergo ring-closure to **2** and oligomerization in competition with the Diels-Alder reaction. This situation would be improved by employing **2** as a synthetic equivalent because **3** can be thermally and reversibly generated from **2** under a high concentration of dienophiles. We here describe the first, short-step synthesis of **1** starting from **2**.



1 2

At first, thermolytic Diels-Alder reaction of **2** with 2-methyl-2-cyclohexen-1-one (**4**) was examined. Reaction of **2** and **4** (5 equivalents) in *o*-dichlorobenzene at 200 °C in an ampoule gave the cycloadduct **5** in a good yield of 75%. Less reactive 3-methyl-2-cyclohexen-1-one (**6**) required somewhat more forced conditions (8.8—10 equivalents of **6** at neat) for satisfactory cycloaddition and afforded a rather complex mixture mainly composed of the desired adduct **7** (16—28% isolated yield) and its trans-isomer **8** (30—40%). The trans adduct **8** was probably formed by epimerization of the cis adduct **7** under the reaction conditions. The higher thermodynamic stability of **8** over **7** was actually demonstrated by smooth epimerization of **7** to **8** on treatment with methanolic sodium hydroxide. Methylenation of **7** with methylenetriphenylphosphorane gave the *exo*-methylene compound **9** in 68% yield without noticeable epimerization. Finally, oxidation of **9** with ammonium cerium(IV) nitrate[4] afforded Cordiachrome B (**1**) in 74% yield. The synthetic quinone **1** was identical with the authentic sample in all respects (Mp, TLC, IR, and ^{1}H NMR).



Experimental

Melting points were measured on a Mettler FP2 apparatus and are uncorrected. IR spectra were recorded on a Hitachi EPI-G3 grating spectrophotometer. ^{1}H NMR spectra were taken on a Varian XL-100 or JEOL PMX-60SI spectrometer. Column chromatography was performed with Merck Kieselgel 60.

Thermolytic Diels-Alder Reaction of 1,2-Dihydro-3,6-dimethoxybenzocyclobutene (2) with 2-Methyl-2-cyclohexen-1-one (4). A solution of **2** (164 mg, 1.0 mmol) and **4** (550 mg, 5.0 mmol) in *o*-dichlorobenzene (3 cm^3) was heated at 200 °C in an ampoule for 15 h. The solvent and excess **4** were removed in vacuo. Chromatography of the residue on silica gel eluted with hexane-ethyl acetate (95:5 v/v) gave the cycloadduct **5** (205 mg, 75%). Recrystallization from hexane gave colorless prisms; mp 102—103 °C; IR (KBr) 1703, 1599, 1481, 1264, 1080, 952, 808 cm^{-1}; ^{1}H NMR ($CDCl_3$), δ=1.04 (s, 3H), 1.3—3.1 (m, 11H), 3.67 (s, 6H), 6.43 (s, 2H). Found: C, 74.14; H, 8.08%. Calcd for $C_{17}H_{22}O_3$: C, 74.42; H. 8.08%.

Thermolytic Diels-Alder Reaction of 2 with 3-Methyl-2-cyclohexen-1-one (6). A mixture of **2** (492 mg, 3.0 mmol) and **6** (3.0 cm^3, 26.4 mmol) was heated at 210 °C in an ampoule for 22 h. Excess **6** was recovered by distillation in vacuo and the residue was chromatographed on silica gel to give the cis adduct **7** (130 mg, 16%) and trans adduct **8** (327

mg, 40%) in the order of elution. Other minor components were not persued.

Cis adduct **7**: Mp 85—86 °C; IR (KBr) 1710, 1602, 1484, 1260, 1083, 790 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.06 (s, 3H), 1.6—3.5 (m, 11H), 3.68 (s, 3H), 3.75 (s, 3H), 6.52 (s, 2H). Found: C, 74.22; H, 8.06%. Calcd for $C_{17}H_{22}O_3$: C, 74.42; H, 8.08%.

Trans adduct **8**: Mp 166—168 °C; IR (KBr) 1713, 1600, 1482, 1262, 1083, 945, 808 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.75 (s, 3H), 1.8—3.1 (m, 11H), 3.72 (s, 6H), 6.53 (s, 2H).

Methylenation of The Cis Adduct 7. To a suspension of methyltriphenylphosphonium iodide (545 mg, 1.35 mmol) in dry tetrahydrofuran (8 cm^3) was added a hexane solution of butyllithium (1.25 mmol) under nitrogen atmosphere at 0 °C. A solution of **7** (124 mg, 0.45 mmol) in dry tetrahydrofuran (2 cm^3) was added and the mixture was stirred for 2.5 h during which time temperature was allowed to rise to room temperature. Aqueous ammonium chloride was added and products were extracted with ether. After removal of the solvents, the residue was chromatographed on silica gel to give the exo-methylene compound **9** (84 mg, 70%): Colorless prisms from hexane; Mp 87—88 °C; IR (KBr) 1645, 1602, 1482, 1257, 1088, 890, 794 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.98 (s, 3H), 3.72 (s, 3H), 3.75 (s, 3H), 4.38 (br. s, 1H), 4.62 (br. s, 1H), 6.54 (s, 2H). Found: C, 79.36; H, 8.92%. Calcd for $C_{18}H_{24}O_2$: C, 79.37; H, 8.88%.

Cordiachrome B(1). To a solution of the compound **9** (84 mg, 0.31 mmol) and 2,6-pyridinedicarboxylic acid *N*-oxide (150 mg, 0.78 mmol) in 20% aqueous acetonitrile (2 cm^3) was added a solution of ammonium cerium(IV) nitrate (425 mg, 0.78 mmol) in 50% aqueous acetonitrile (2 cm^3) at 0 °C. After stirring for 1 h, the mixture was diluted with water and extracted with dichloromethane. Removal of the solvents and chromatographic purification of the product on silica gel column gave **1** as yellow crystals; Mp 63—64 °C (lit,[1] 64—65 °C). The IR and ^1H NMR spectra of the synthetic material were superimposable to those of the authentic sample given from Prof. R. H. Thomson.

The authors are grateful to Prof. Ronald H. Thomson for a generous gift of natural Cordiachrome B and a copy of its ^1H NMR spectrum.

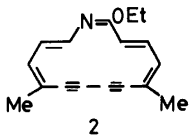
Synopsis. The title aza[12]annulene has been synthesized by Beckmann rearrangement of the oxime from the methano[11]annulenone, followed by alkylation of the resulting lactam. Examination of the ^{1}H NMR spectrum indicates that the aza[12]annulene is slightly paratropic.

Several diatropic methano-bridged aza[10]annulene derivatives (e.g. **1**) were prepared previously.[1] Also, the bisdehydroaza[14]annulene **2** as well as its higher analogs was prepared and proved to sustain ring current.[2] Of these azaannulene family of pyridine type, the 12π-analogue is unknown. We have now synthesized the title aza[12]annulene derivative by the reaction sequence used to prepare **2**,[2] in order to discover whether the same alternation of tropicity between $(4n+2)\pi$- and $(4n)\pi$-electron systems occurs in the azaannulene series as has already been demonstrated in the carbocyclic annulene series.[3] This synthetic objective has been verified experimentally.

1



2

Although several attempts of rearrangement reactions with phosphorus pentachloride were fruitless, the oxime **3**, obtained from 4,9-methano[11]-annulenone,[4] when heated with *p*-toluenesulfonyl chloride in pyridine,[5] gave Beckmann rearrangement product, the lactam **4**, in 26% yield. The alkylation of **4** with triethyloxonium tetrafluoroborate gave the desired aza[12]annulene **5** in 10% yield. The substance was unstable to diffused light and air.

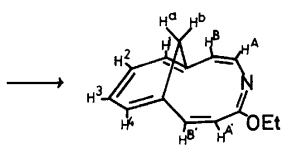
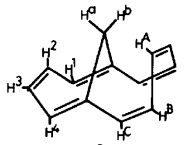
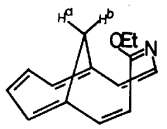
4



5



6



5a

The ^{1}H NMR chemical shifts of **5** are listed in Table 1, together with those of the closely related methano-[12]annulene **6**. Table 1 shows that **5** is slightly paratropic as espected for a 12π-electron system, since the annulene outer protons resonate at relatively high field and the H^b proton of the bridged methylene group do at relatively low field, as compared with the usual olefinic and methylene protons. This also suggests that **5** exists in syn-form **5a** as similarly to the case of **6**.[6] However, comparison of the chemical shifts of the corresponding protons between **5** and **6** shows that the paratropicity of **5** is smaller than that of **6**, revealing that an incorporation of a nitrogen atom and a substitution of ethoxyl group into and upon the molecular perimeter of **6** hinder conjugation of π-electrons to some extent.

Variable-temperature ^{1}H NMR spectra of the aza[12]-annulene **5** were run over the range from −60 to 60 °C, and the results show all the spectra to be essentially temperature-independent, ruling out a change in the conformation **5a** between these temperatures.

Experimental

All melting points are uncorrected. IR spectra were measured on Hitachi 260-50 spectrophotometer as KBr disk; only significant maxima are reported. UV spectra were taken on Hitachi 220A spectrophotometer and were recorded in nm, in tetrahydrofuran solution. ε-Values are given in parentheses, the shoulders being denoted by sh. Mass spectra were measured with JEOL JMS-200 spectrometer at 75 eV using a direct inlet system. ^{1}H NMR spectra were taken on JEOL FX-90Q (90 MHz) or GX-270 (270 MHz) spectrometer, and refer to solutions in $CDCl_3$, unless otherwise stated, in δ-values with TMS as an internal standard. The coupling constants (J) are given in Hz. Alumina (II—III) was used for column chromatography. Preparative TLC was carried out on 20×20 cm silica-gel plates (Merck, 0.5 mm thick). Dichloromethane was distilled over calcium hydride before use. Organic extracts were dried over anhyd sodium sulfate prior to solvent removal.

Table 1. ^{1}H NMR Chemical Shifts of Methanoaza[12]annulene **5** (270 MHz) and Methano-[12]annulene **6** (90 MHz) in $CDCl_3$ (δ Value: Internal Standard TMS)

1-Hydroxyimino-4,9-methanocycloundeca-2,4,6,8,10-pentaene (3). To a stirred soln of the 4,9-methano[11]-annulenone[4] (586 mg, 3.44 mmol) in methanol (40 ml) and THF (10 ml) was added a soln of hydroxylamine hydrochloride (4.8 g) in water (10 ml) at 38 °C in one portion. After stirring for further 10 h at the same temp, further quantities of hydroxylamine hydrochloride (each 5.0 g in water (10 ml)) were added after every 40 h. After stirring for a total of 5 d at 38 °C, the soln was poured into water. The precipitates formed were filtered off under suction, giving **3** (444 mg, 70%). Recrystallization from chloroform afforded orange needles: Mp 196—197 °C; MS *m/z* 185, (M^+, 96%) and 141 100); mol wt 185.2; IR 3140 (OH), 1610 (C=N), and 680 cm^{-1} (cis C=C); UV λ_{max} 213 sh (9710), 229 (14400), 280 (36700), and 341 nm (3220); ^1H NMR (90 MHz, DMSO-d_6) δ=11.31 (s, 1H, OH, exchangeable with D_2O), 7.03—6.96 (m, 2H, H^2, H^3), 6.89 (d, 12, 1H, H^B), 6.71 (d, 12, 1H, $H^{B'}$), 6.69—6.59 (m, 2H, H^1, H^4), 6.09 (d, 12, 1H, $H^{A'}$), 5.86 (d, 12, 1H, H^A), 6.84 (d, 11, 1H, H^b), and 0.54 (d, 11, 1H, H^a).

Found: C, 77.89; H, 5.93; N, 7.40%. Calcd for $C_{12}H_{11}NO$: C, 77.81; H, 5.99; N, 7.56%.

5,10-Methanoazacyclododeca-3,5,7,9,11-pentaen-2-one (4). A soln of *p*-toluenesulfonyl chloride (1.75 g, 9.20 mmol) in pyridine (10 ml) was added to a stirred soln of the oxime **3** (340 mg, 1.84 mmol) in pyridine (50 ml). After stirring for 6 h at 90 °C, further quantities (1.5 g) of the chloride were added and stirring was continued for further 6 h at 90 °C. Then the mixture was poured onto water and extracted with benzene. The extracts were washed with 2M-hydrochloric acid (1 M=1 mol dm^{-3}), aq sodium hydrogencarbonate soln, and aq sodium chloride soln, and dried. The dark red semisolid obtained after solvent removal was chromatographed on alumina (4.3×8 cm). The fractions eluted with dichloromethane afforded the lactam **4** (87 mg, 26%). Recrystallization from hexane-benzene afforded yellow needles: Mp 146—147 °C; MS *m/z* 185 (M^+, 72%) and 156 (100); mol wt 185.2; IR 3140 (NH), 1640, and 1605 cm^{-1} (C=O, C=C); UV λ_{max} 249 (25300) and 344 nm (2300); ^1H NMR (270 MHz) δ=6.89 (d, 11.7, 1H, $H^{B'}$), 6.74—6.10 (m, 7H, H^1, H^2, H^3, H^4, H^A, H^B, NH), 5.98 (d, 11.7, 1H, $H^{A'}$), 3.08 (d, 13.5, 1H, H^b), and 2.18 (d, 13.5, 1H, H^a).

Found: C, 78.07; H, 6.02; N, 7.80%. Calcd for $C_{12}H_{11}NO$: C, 77.81; H, 5.99; N, 7.56%.

The following fractions eluted with 10% ethanol in dichloromethane gave the recovered oxime **3** (107 mg).

12-Ethoxy-4,9-methanoaza[12]annulene (5). To a stirred soln of the lactam **4** (50 mg, 0.27 mmol) in dry dichloromethane (14 ml) was added dropwise a soln of triethyloxonium tetrafluoroborate (1.54 g, 8.10 mmol) in dry dichloromethane (14 ml) during 40 min at room temp. After stirring for 5 h at room temp, the soln was cooled in an ice-bath and aq. 50% potassium carbonate soln (8 ml) was cautiously added. Then the mixture was poured into water and extracted with dichloromethane. The residue after solvent removal was chromatographed on alumina (4.2×8.5 cm). The fractions eluted with hexane gave a semisolid, which was further purified by preparative plate chromatography (dichloromethane-hexane (1 : 1) as eluent). The fast moving, yellow band gave the azaannulene **5** (6.0 mg, 10%). Recrystallization from hexane-benzene afforded yellow needles: Mp 67—68 °C; IR 1200 1120, and 1070 cm^{-1} (-O-); UV λ_{max} (ε) 252 (41900) and 310 nm sh (18600); ^1H NMR (270 MHz) δ=6.56 (dd, 10.5, 5.6, 1H, H^2), 6.41 (dd, 10.5, 5.6, 1H, H^3), 6.41 (d, 10, 1H, $H^{B'}$), 6.13 (d, 5.6, 1H, H^4), 6.04 (s, 2H, H^A, H^B), 5.97 (d, 5.6, 1H, H^1), 5.39 (d, 12.1, 1H, H^b), 5.09 (d, 10, 1H, $H^{A'}$), 4.35—4.23 (m, 1H, $-CH_2CH_3$), 4.17—4.05 (m, 1H, $-CH_2CH_3$), 1.62 (d, 12.1, 1H, H^a), and 1.36 (t, 7, 3H, $-CH_2CH_3$).

HRMS: Found: *m/z* 213.1120. Calcd for $C_{14}H_{15}NO$: M, 213.1151.

Synopsis. A cathodic photocurrent produced by chromatophores was measured in the presence of 1-methoxy-5-methylphenazinium methyl sulfate (methoxy-PMS). The magnitude of the photocurrent was a function of the wavelength of the incident light, and the photocurrent action spectrum was in agreement with the absorption spectrum of chromatophores. The photocurrent also depended on the concentration of methoxy-PMS or of chromatophores.

Many studies have demonstrated the possibility of employing photoactive biological components in photoelectrochemical cells, in connection with studies regarding the mechanism of photosynthetic primary process as well as solar energy conversion projects. From this viewpoint, we[1] reported that a cathodic photocurrent was produced, upon illumination, at a platinum electrode immersed in a chromatophore suspension under potentiostatic conditions. This phenomenon was largely enhanced by adding 1-methoxy-5-methylphenazinium methyl sulfate (methoxy-PMS) to the suspension. Although an enhancement of the photocurrent was presumed, that methoxy-PMS functioned as a mediator between the electrode and chromatophore particles, a further discussion was not given because of insufficient data. This paper reports on subsequent measurements of the photocurrent in the presence of methoxy-PMS.

Experimental

The carotenoid-less blue-green mutant strain (G-9) of *Rhodospirillum rubrum* was used throughout the present study. The cells were grown anaerobically at 30 °C for 3 days under continuous illumination from tungsten lamps.[2] Chromatophores were prepared from light-grown cells by sonication,[3] suspended in a 0.12 M (M=mol dm^{-3}) GTA buffer (pH 8.0) which consisted of an equimolar mixture of 3,3-dimethylglutaric acid, tris(hydroxymethyl)aminomethane and 2-amino-2-methyl-1,3-propanediol, and stored at 4 °C in the dark. The concentration of chromatophores was expressed in terms of absorbance of bound bacteriochlorophyll at 873 nm (A_{873}; corresponding to 7.1 μM of bound bacteriochlorophyll[4]).

A schematic diagram of a photoelectrochemical measurement is shown in Fig. 1. The experimental cell, in which the light path length was 0.4 mm, consisted of a platinum plate working electrode (2×3 cm^2 of surface area), a platinum wire counter electrode and a saturated calomel reference electrode. All potentials listed in this paper are corrected against the normal hydrogen electrode. For a potentiostatic measurement, the potential of the electrode was controlled with a Hokuto Model potentiostat HA-101 or HA-501 and the resulting current was recorded. A photocurrent was measured after electrolyzing for 30 minutes in the dark at an arbitrary potential. As the light source, a 60 W tungsten lamp was usually used in combination with a 12 cm thick water filter in order to eliminate the thermal effect; a 500 W

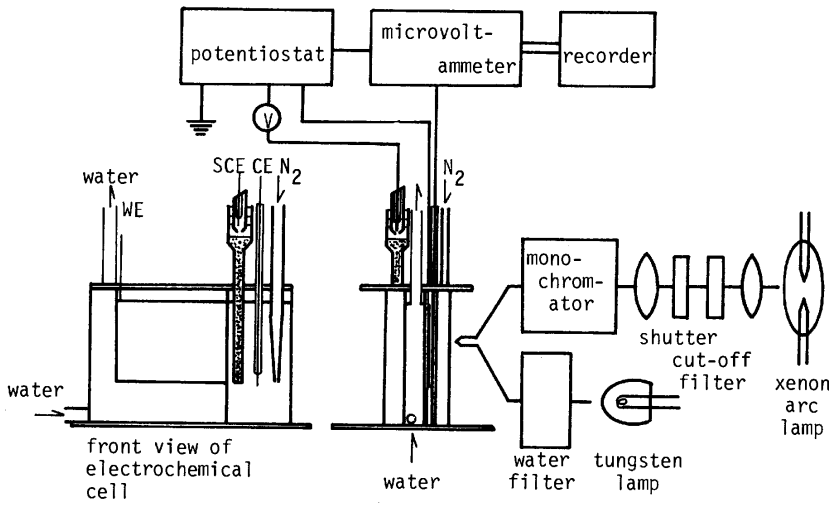

Fig. 1. Electrolytic cell arrangement for measuring photocurrent. The experimental cell was all made of borosilicate glass. A cellulose membrane divides between main compartment (chromatophore suspension) and subcompartment (buffer solution). WE, working electrode; CE, counter electrode; SCE, saturated calomel reference electrode.

xenon arc lamp (Wacom Model MX-500) was used in combination with a JASCO Model CT-25N grating monochromator equipped with a cut-off filter UV-39 or VR-69 for measuring the photocurrent action spectrum. 10 Units ml^{-1} of glucose oxidase, 2 mM of glucose and 13 units/ml of catalase were added to the suspension in order to remove dissolved oxygen and oxygen-free nitrogen was passed through into the suspension for 30 minutes. The suspension was kept constant at 25°C with a help of a thermostat. Methoxy-PMS was synthesized as described.[5,6]

Results and Discussion

When the cathodic photocurrent by chromatophores was measured in the presence of methoxy-PMS, it was largely enhanced.[1] The photocurrent increased with a greater cathodic shift of the applied potential up to about −200 mV and then gradually decreased. Since methoxy-PMS showed a large enhancing effect of the photocurrent, the behavior of the photocurrent in the presence of methoxy-PMS was examined in some detail. The magnitude of the cathodic photocurrent was a function of the wavelength of the incident light. The resulting action spectrum is shown in Fig. 2. There are three maxima (600, 800, and 875 nm) in agreement with the maxima of the absorption spectrum (588, 804, and 873 nm, ascribed to chromatophore-bound bacteriochlorophyll[7]) of the chromatophore suspension, and not with that of methoxy-PMS solution (508 nm). This suggests that the enhanced photocurrent is independent of the photoexcitation of methoxy-PMS: that is, the photocurrent is not due to a light-induced electron transfer from the electrode to methoxy-PMS, and the photocurrent is actually due to the light absorbed by chromatophores.

The effect of the concentration change of methoxy-PMS or of chromatophores on the photocurrent is shown in Fig. 3. In this figure, a linear relationship can be observed between the photocurrent and the concentration of methoxy-PMS or of chromatophores. If

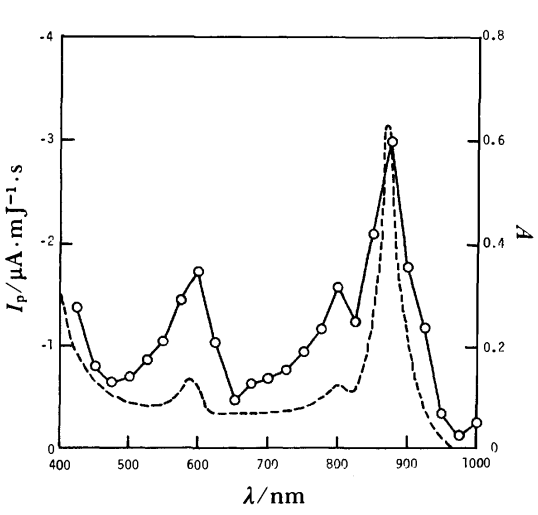

Fig. 2. Comparison of photocurrent action spectrum with absorption spectrum. The concentrations of chromatophores and methoxy-PMS were kept constant at A_{873}=75 and 100 μM, respectively. The photocurrent was measured at −200 mV of applied potential. The dotted line shows the absorption spectrum of chromatophore suspension.

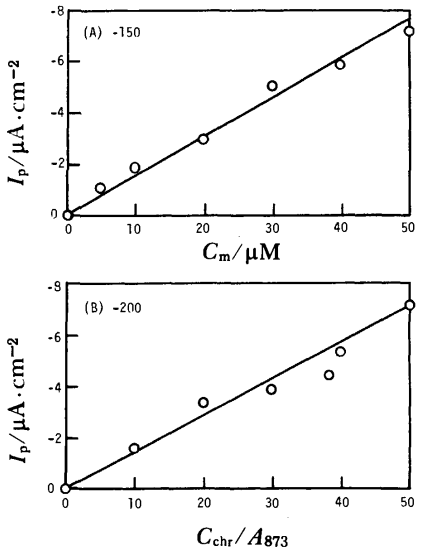

Fig. 3. Dependence of photocurrent on concentration of methoxy-PMS (A) or of chromatophores (B). Numbers in the figure represent the applied potential by mV. The concentration of chromatophores (A) and that of methoxy-PMS (B) were kept constant at A_{873}=75 and at 100 μM, respectively. The illumination was carried out at 6000 lx of illuminance.

the enhancing effect of the photocurrent is based on the ability of methoxy-PMS as the electron mediator,[1] the concept of a catalytic current[8] can be applied to an analysis of the reaction. According to the concept of a reaction layer as a maximal approximation for the treatment of the catalytic current, the enhanced photocurrent is

$$I_p = nF\mu k_f C_{chr} C_m,$$

where I_p, C_{chr}, and C_m are the enhanced photocurrent, bulk concentration of chromatophores and that of methoxy-PMS, respectively. Thus, I_p comes to be proportional to C_{chr} or C_m. As shown in Fig. 3, the result that linear relationship was observed between the photocurrent and the concentration of chromatophores or methoxy-PMS suggests that the methoxy-PMS function as the mediator between the platinum electrode and chromatophore particle, as expected. Moreover, the photocurrent increased with an increasing concentration of the reduced form of methoxy-PMS.[1] This suggests that the main reactant with chromatophores in the production of photocurrent is the reduced form of methoxy-PMS. This suggestion is supported by a study[9] on flash photolysis and electron paramagnetic resonance, in which an electron transfer from PMS in reduced form to reaction center bacteriochlorophyll (BChl) cation was observed.

In conclusion, it has become clear that the photocurrent produced by chromatophores at a platinum electrode under potentiostatic conditions is greatly enhanced in the presence of methoxy-PMS, and that the enhancing effect is based on the ability of methoxy-PMS as an electron mediator. A possible mechanism for the production of photocurrent is shown below.

$$BChl \cdot I \cdot Q \cdot Fe \xrightarrow{h\nu} BChl^* \cdot I \cdot Q \cdot Fe \longrightarrow BChl^+ \cdot I \cdot Q^- \cdot Fe \text{(in chromatophores}^{10)})$$

$$BChl^+ \cdot I \cdot Q^- \cdot Fe + \text{methoxy-PMS (reduced)} \longrightarrow BChl \cdot I \cdot Q^- \cdot Fe + \text{methoxy-PMS (oxidized)}$$

$$\text{methoxy-PMS (oxidized)} + e \longrightarrow \text{methoxy-PMS (reduced) (production of photocurrent)}$$

(Received April 24, 1987)

Synopsis. The effects of the following treatments on the stability of the Langmuir-Blodgett (L/B) film of fatty acid salt in vacuo have been investigated by radiotracer method: (I) Skeletonization of the L/B film. (II) Transformation of the fatty acid molecules remaining in the L/B film into its soap molecules. (III) Perfect formation and deposition of the metal soap monolayer.

Langmuir-Blodgett (L/B) films of tritiated fatty acid are expected to be an excellent ^{3}H-source for the measurement of the electron anti-neutrino mass:[1] The measurement requires a source that is highly radioactive, homogeneous, very thin, uniform and nonvolatile in vacuo. Concerning the volatility in vacuo, however, the L/B film of fatty acid is not so stable,[2-4] and the desorption of the source molecules becomes the origin of the main background in the measurement.

Roberts and Gaines[2] reported that almost 90% of the ^{14}C-octadecanoic acid film on a quartz backing was evaporated after one hour evacuation at a pressure of 10^{-4} Pa and room temperature, while only 10% of the barium ^{14}C-octadecanoate film was evaporated at the same conditions. This suggests that the L/B film of metal soap is more stable in vacuo than that of the free acid. Most of L/B films of metal soap, in addition, do not consist of only pure metal soap molecules: They include more or less the original acid molecules which evaporate easily.[5] The increase of the metal soap content in the molecules consisting the L/B film is therefore expected to make the L/B film more stable even under high vacuum conditions.

In the present study we investigated the desorption behaviours of ^{3}H-molecules from the L/B films of barium or cadmium $^3H_2$-octadecanoate in solvent and/or in vacuo, trying to improve the stability of the L/B film with various procedures such as (I) preremoval of the free acid molecules by rinsing the L/B film in a solvent (skeletonization), (II) transformation of the free acid molecules in the L/B film to the metal soap molecules by immersing the L/B film in a concentrated $BaCl_2$ aqueous solution under high pH conditions, and (III) complete formation and deposition of monolayer of pure metal soap.

Experimental

A sample of 9,10-$^3H_2$-octadecanoic acid (sp. ac. of 16 Ci mol^{-1}) was synthesized[6] the addition of hydrogen gas to 9,10-$^3H_2$-octadecenoic acid (sp. ac. of 5700 Ci mol^{-1}, Amersham Co.) diluted with pure 9-octadecenoic acid (purity $\gg$ 99.5%, Merck Co.). The sample was purified by repeated recrystallization from hexane and dissolved in benzene to make a spreading solution of 1×10^{-3} mol dm^{-3}.

Organic solvents and inorganic salts were the purest grade reagents of Wako Pure Chemical Co., Osaka. The former were distilled prior to use and the latter were used without further purification. Iron(III) octadecanoate (the purest grade of Tokyo Kasei Industry Co., Tokyo) was used for the pretreatment of surface of substrate plate (ferrotype plate whose size was 15 mm ×25 mm×0.8 mm).

Water for the subphase solution was triply distilled, the second distillation being from alkaline permanganate, and was contained in a Teflon trough (8 cm×20 cm×1 cm) with a waxed silk thread as the movable barrier. The trough had a pocket (1.5 cm×4 cm×1 cm) in its bottom for the dipping of the substrate plate. The pH of the solution was adjusted by adding a solution of NaOH or $Ba(OH)_2$. All the solutions were not buffered. The pH value was determined prior to and after the built-up procedure. The change of pH was less than 0.3 unit. L/B films were deposited at a surface pressure of 29.5 mN m^{-1} using 9-octadecenoic acid (Merck reagent grade) as a piston oil. The plate was dipped to 10 mm in depth of the subphase water and withdrawn through the monolayer at a velocity of 0.1—0.5 cm s^{-1} by means of a synchronous motor. In order to determine the transfer ratio of the monolayer onto the substrate plate, we used an another Teflon trough (2.5 cm×20 cm×2 cm) with an inside that was hydrophilic.[7] A thin mica plate (23 mm×30 mm×0.1 mm) coated with paraffin was placed on the surface of the solution in the trough and used as a movable barrier. The floating barrier can move smoothly by the repulsion[8] between the hydrophilic trough and the hydrophobic ends of the movable barrier. From the movement of the barrier in the deposition process we evaluated the transfer ratio of the monolayer. The transfer ratio, thus obtained, for each deposition process was almost unity (0.97—1.00).

The radioactivity of the L/B films of Ba- or Cd-$^3H_2$-octadecanoate was measured with a 2π-windowless gas flow counter (Aloka Model FC-1E) using Q-gas as the counting gas.

Results and Discussion

A good linear relationship was obtained between the radioactivity and the number of layers of barium $^3H_2$-octadecanoate film deposited on the ferrotype plate under the conditions of pH=6.2—11.2. From the radioactivity results and the movements of the movable barrier, it was confirmed that two monolayers were always deposited onto the substrate plate in one dipping and withdrawing process of the plate even at high pH region. Autoradiographs of the other samples with two molecular films of Ba-$^3H_2$-octadecanoate similarly prepared were taken using LKB Biofilm-^{3}H (Akom Co., Tokyo); they were fairly uniform.

Five kinds of L/B films were prepared under the following depositional conditions and by post-treat-

Table 1. The Effects of Immersing in $BaCl_2$ Solution and Rinsing in Benzene on the Stability for the L/B Film of Octadecanoic Acid

Film	No. of monolayer	Built-up condition[a)]	Fraction of remaining radioactivity after immersing in $BaCl_2$ solution of 1×10^{-3} mol dm^{-3} at pH=9.2	Fraction of remaining radioactivity after rinsing in benzene for 30 s
(a)	4	pH=6.2		
(b)	4	pH=9.0		
(c)	4	pH=6.2		0.885
(d)	2	pH=11.2		0.940
(e)	4	pH=6.2	1.00 (1 min immersing)	0.679
(f)	4	pH=6.2	0.935 (1.5 h immersing)	0.822

a) Built-up process for these L/B film was carried out at the surface of $BaCl_2$ solution of 1×10^{-4} mol dm^{-3} at ca. 288K.

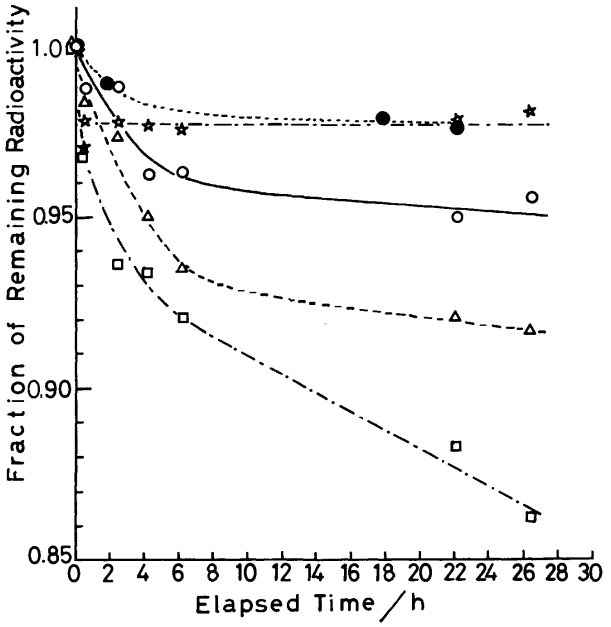

Fig. 1. The effect of post-treatments of the L/B film on its removal at a pressure of 133 Pa and a source temperature of 288 K; ○, L/B film (a) was composed of four molecular layers transfered from the $^3H_2$-octadecanoic acid monolayer spread on an aqueous $BaCl_2$ solution of 1×10^{-4} mol dm^{-3} at pH=6.2; ●, film (b), four layers transfered from the acid monolayer spread on $BaCl_2$ solution of 1×10^{-4} mol dm^{-3} at pH=9; △, film (c), the same as the film (a), but was rinsed in benzene for 30 seconds; □, film (e), the same as the film (a), but was immersed in $BaCl_2$ solution of 1×10^{-3} mol dm^{-3} at pH=9.2 for one minute and then rinsed in benzene for 30 seconds; ☆, film (f), the same as the film (a), but was immersed in the above $BaCl_2$ solution for 1.5 hours and then rinsed in benzene for 30 seconds.

ments. Film (a): four-layers film deposited from the $^3H_2$-octadecanoic acid monolayer spread on the aqueous $BaCl_2$ solution of 1×10^{-4} mol dm^{-3} at pH=6.2, film (b): four-layers film deposited from the acid monolayer spread on a $BaCl_2$ solution of 1×10^{-4} mol dm^{-3} at pH=9, film (c): the same as the film (a) but was rinsed in benzene for 30 seconds, film (d): two-layers film deposited from the acid monolayer spread on a $BaCl_2$ solution of 1×10^{-4} mol dm^{-3} at pH=11.2 and then rinsed in benzene for 30 seconds, film (e): the same as the film (a) but was immersed in a $BaCl_2$ solution of 1×10^{-3} mol dm^{-3} at pH=9.2 for one minute and then rinsed in benzene for 30 seconds, film (f): the same as the film (a) but was immersed in the above $BaCl_2$ solution for 1.5 hours and then rinsed in benzene for 30 seconds.

The desorption ratio of the above films (c—f) into solvent are tabulated in Table 1 as a remaining fraction of the radioactivity. Film (d) deposited at high pH was more stable against rinsing in benzene than film (c) deposited at low pH. Barium octadecanoate, being resistant against dissolution in benzene,[5)] might be easily formed at a high pH region. The fatty acid monolayer, however, tends to desorb into the subphase solution at the highest pH region, even during the deposition process. The radioactivity of the film (e) was not changed by one-minute immersing in the $BaCl_2$ solution of pH=9.2. The succeeding rinsing of the film (e) in benzene, however, decreased its radioactivity considerably. The one-minute immersing of the L/B film of fatty acid in $BaCl_2$ solution of high pH does not improve the conversion of fatty acid to its barium soap in the film, but seems to distort the arrangement of the acid molecules and to loosen the lateral bondings among the molecules by the electrical repulsions of their dissociated carboxyl groups. Although the long period of immersing of the L/B film in the $BaCl_2$ solution is expected to progress the conversion, a slight removal of the film material was resulted.

Figure 1 shows the evaporation profiles of the $^3H_2$-octadecanoic acid from the L/B films under a condition of 133 Pa and 288 K. For the films (c), (e), and (f), the initial radioactivity is defined as that obtained just after their rinsing in benzene. Evaporation of the acid molecules from the film (e), was most significant. This is also due to the distortion of the arrangement of the molecules. Film (b) strongly resisted the removal of molecules. The evaporation rate for the skeletonizated film (c) was much higher than that for film (a); the skeletonized films did not resist the thermal desorption of the film molecules. Beischer[9)] reported that copper 1-^{14}C-octadecanoate molecules, whose neighboring octadecanoic acid molecules were excluded, evaporated much easier than copper octadecanoate molecules in the pure L/B film.

Film (f) seems to be better than film (a) in the resistance against the thermal removal of film molecules. However, the total remaining fraction of the radioactivity (0.749=0.935×0.822×0.975) of film (f) is smaller than that (0.929) of film (a).

Consequently, an increase of the metal soap content in the film is essential to obtain a L/B film stable in vacuum without the skeletonization for the film.

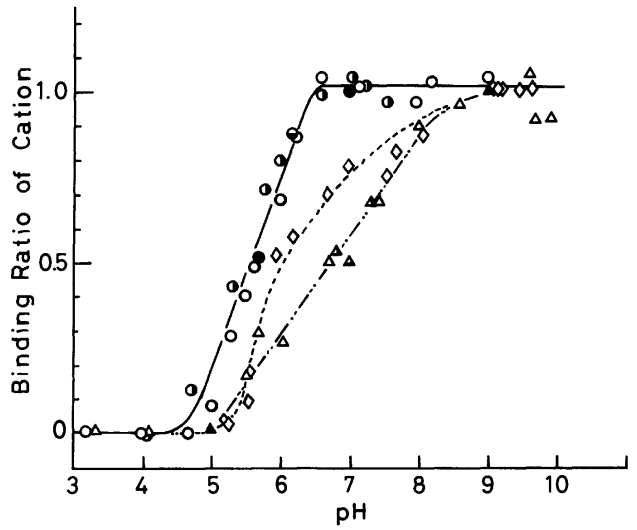

Fig. 2. The pH dependence of the ratio of binding of divalent cations to fatty acid monolayers. Circles denote the ratio of binding for cadmium ion, diamonds that for calcium ion and triangles that for barium ion. The marks ○ and △ are from neutron activation analysis study[10] for icosanoic acid; ● and ▲ are the Blodgett's data[11] for icosanoic acid and ◭ is the Ehlert's data[12] for octadecanoic acid (both data were obtained by the skimming method); ▲ and ◇ are IR-spectroscopic data[13,14] for octadecanoic acid; ◒ is from the photometric study of dissolved multilayers of icosanoic acid;[15] ◑ is the Kobayashi's data[16] for icosanoic acid by ESCA.

Figure 2 shows the metal-ion bindings in the monomolecular films of octadecanoic and icosanoic acids[10-16] in their L/B films. The binding ratio of the barium cation to the above fatty acids is only 0.4 at pH=6.2, that is, ca. 60 mole-percent of the fatty acid seems to remain as the original fatty acid at the surface of the barium solution of pH=6.2. Cadmium cation binds perfectly in the icosanoic acid monolayer above at pH=6.5, whereas both calcium and barium cations do above pH=9. The former pH is close to the pH of distilled water (pH=5.8): This is suitable for preparing a perfect metal soap L/B film because we need not use much undesirable ions such as Na^+, K^+, PO_4^-, or CO_3^{2-} for adjusting the pH of the subphase solution. New samples of L/B film of Cd-$^3H_2$-octadecanoate were therefore prepared by using a $CdCl_2$ solution of 1×10^{-3} mol dm^{-3} (pH=7.2; the NaOH concentration of the solution was ca. 1.7×10^{-6} mol dm^{-3}) as the subphase solution and evacuated under the pressure of 133 Pa and temperature 288 K. The radioactivities of the L/B films remained unaltered for two days within an error of ±3%; the fatty acid molecule anchored by the cadmium ion seems not to evaporate from the L/B film.

Concequently, in order to obtain a L/B film stable in vacuum, the increase of metal soap content in the L/B film is absolutely essential without skeletonization of the film or without new formation of metal soap. For the increase of the metal soap content, in addition, the cadmium solution can be more advantageously used than the calcium or barium solution.

Measurement of Concentration Profile of Dye at Glass-Solution Interface by Photoacoustic Spectrometry Coupled with Total Internal Reflection Technique

Teruo HINOUE,* Masaaki KAWABE, and Yu YOKOYAMA
Department of Chemistry, Technological University of Nagaoka, Nagaoka 940-21
(Received April 18, 1987)

Synopsis. Photoacoustic signals were measured as a function of a penetration depth by changing an angle of incidence of an excitation beam. Concentration profiles were obtained from a relationship between the signal magnitude and the penetration depth by an inverse Laplace transformation. The smallest value of the penetration depth used was 34 nm.

In the previous works,[1-4] we developed photoacoustic spectrometry coupled with a total internal reflection technique (PAS-TIR) and could measure dye concentrations in a solution layer of submicrometer from a glass-solution interface. In the present paper, we demonstrate measurement of the photoacoustic signal (PAS) as a function of an angle of incidence of the excitation beam in PAS-TIR and discuss relationships between the PAS magnitude and concentration profile in the solution layer at the interface.

Experimental

Apparatus. A spectrometer and cell design used in the present study is similar to that used previously[3] except an argon ion laser (Spectra-Physics, 162D) and an active band path filter (NF Co., Ltd., UF-1BP). The laser of 15 mW at 488.0 nm was modulated at 40 Hz by an optical chopper and the plane of polarization of the laser was perpendicular to that of incidence. The laser beam passed through a convex lens (f=300 mm), entered a hemicylindrical internal reflection element made of dense flint glass from the cylindrical surface, and was focused on the axis of the hemicylinder on the opposite plane in contact with the solution. The PAS caused by absorption of the intermittent laser beam was detected by a piezoelectric transducer (MURATA MFG. Co., Ltd., 7D-15-4000 BKA) and was amplified by a lock-in amplifier (NF Co., Ltd., LI 574A) through a preamplifier (NF Co., Ltd., LI 75A) and the band path filter. The angle of incidence was changed by a rotary optical stage driven by a stepping motor (Oriental Motor Co., Ltd., UPD 569) and a programmable controller (Oriental Motor Co., Ltd., PC 100). The angle of incidence was changed stepwise and the corresponding PAS magnitudes were recorded on a Y-t recorder.

Reagents and Optical Parameters. New Coccine (NC) supplied from Tokyo Kasei Co., Ltd. was used without further purification. A 0.1 M (M=mol dm^{-3}) NC aqueous solution was prepared from distilled water for the measurement. The penetration depth of the beam was calculated according to expressions derived by Hansen.[5] Optical parameters used in the calculation are listed in Table 1. In general the refractive index of a solution containing light absorbing species is affected by the extinction coefficient of the solution due to anomalous dispersion.[5-7] However, the extinction coefficient of the 0.1 M NC solution is so small that the refractive index is not virtually susceptible to the anomalous dispersion.[6,7] Thus the refractive index of the NC solution was estimated to be equal to that of pure water at 488.0 nm.

Results and Discussion

Figure 1 schematically illustrates a total internal reflection. When the light beam progresses from the glass internal reflection element with a higher refractive index, n_1, toward the solution with a lower refractive index, n_2, at the angle of incidence, θ_1, beyond the critical angle, θ_c, the light beam is totally reflected and the evanescent wave emerges from the interface toward the solution. A mean square electric field strength of the evanescent wave exponentially attenuates with distance, x, from the interface. The distance at which the strength is reduced to 1/e of that at the interface is called the penetration depth, d, and is expressed by[5]

$$d=(-\lambda/4\pi)/\mathrm{Im}\{[(n_2-ik_2)^2-n_1^2\sin^2\theta_1]^{1/2}\}. \quad (1)$$

Here the extinction coefficient of the solution, k_2, is equal to $2.303\cdot\varepsilon c\lambda/4\pi$, where ε, c, and λ denote the molar absorption coefficient, the concentration of the light absorbing species, and the wavelength of the light in vacuum, respectively. That is, the penetration depth at a constant wavelength is a function of the angle of incidence, the refractive indices of the internal reflection element and the solution, and the extinction coefficient. Therefore, the penetration depth depends only on the angle of incidence for a particular internal reflection system. Figure 2(a) shows the PAS magni-

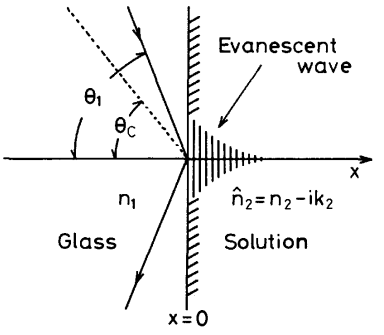

Fig. 1. Illustration of total internal reflection. n_1: refractive index of internal reflection element, n_2: refractive index of solution, k_2: extinction coefficient of solution, $\hat{n}_2$: complex refractive index of solution, θ_1: angle of incidence, θ_c: critical angle.

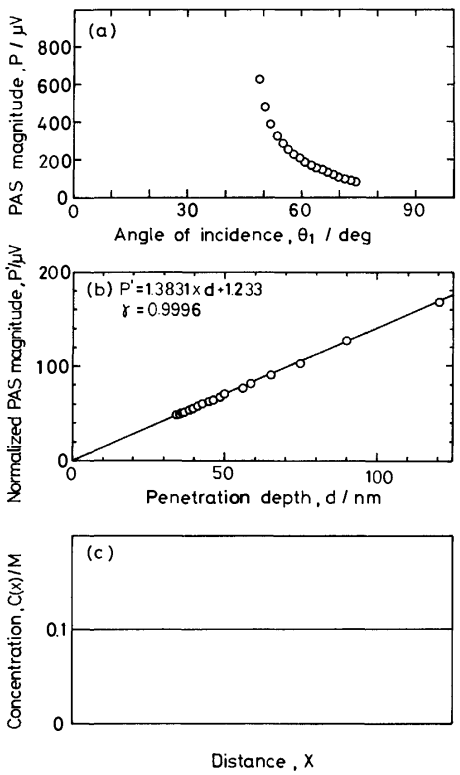

Fig. 2. (a) Relationship between PAS magnitude and angle of incidence, (b) relationship between normalized PAS magnitude and penetration depth, (c) concentration profile.

tudes for a 0.1 M NC aqueous solution against the angle of incidence from 49 to 74.5 degree.

On the other hand, the mean square electric field strength at a given position of x (see Fig. 1) is expressed by $S \cdot \exp(-x/d)$, where S is a sensitivity factor, depending on an optical coupling at the interface,[5,6,8] and was calculated from the optical parameters of the system in a similar manner to the calculation for the penetration depth.[5] The absorbed light power at x is, therefore, proportional to $\varepsilon cS \cdot \exp(-x/d)$. The overall absorption is expressed by the integration from $x=0$ to $x=\infty$. Thus the PAS magnitude, P, is given as follows:

$$P = S\int_0^\infty K\varepsilon c \cdot \exp(-x/d)\mathrm{d}x, \quad (2)$$

where K is a coefficient depending on instrumental parameters and photoacoustic characteristics of the internal reflection system.[3] When the molar absorption coefficient and the photoacoustic characteristics of the solution are constant over the full range, Eq. 2 is rearranged to

$$P' = P/SK\varepsilon = \int_0^\infty c(x) \cdot \exp(-x/d)\mathrm{d}x. \quad (3)$$

Hereafter P' is called the normalized PAS magnitude. The right hand side of Eq. 3 expresses a Laplace transformation of the concentration profile, $c(x)$, when $1/d$ is considered as a parameter. Consequently, the concentration profile can be obtained by the inverse Laplace transformation of the normalized PAS magnitude as a function of the penetration depth. In practice, three concentration profiles were assumed and compared with a regression function for a plot of the

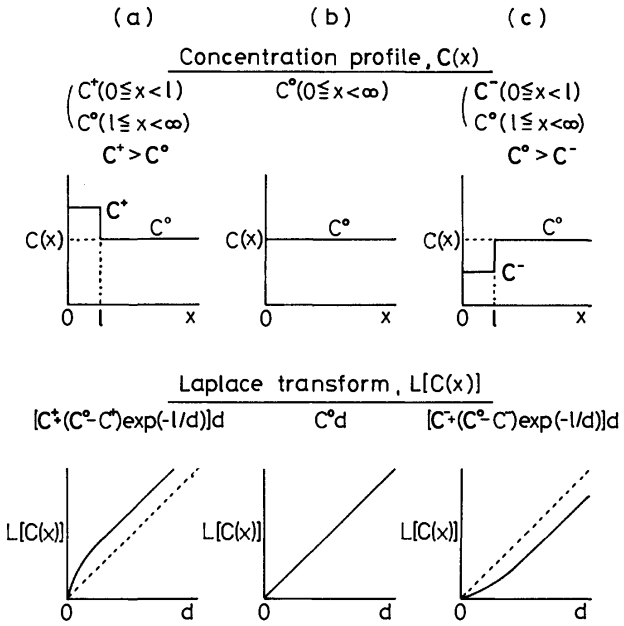

Fig. 3. Assumed concentration profiles, $c(x)$, and the corresponding Laplace transformations, $L[c(x)]$.

normalized PAS magnitude against the penetration depth at each angle of incidence. Figure 3 shows the assumed concentration profiles and the corresponding Laplace transformations. The first (a) represents the enrichment of the species at the interface accompanying an interfacial phenomenon such as adsorption, the second (b) corresponds to the concentration profile of uniform distribution over the range considered, and the last (c) is the reverse case to the first. The plot derived from the results in Fig. 2(a) and the corresponding regression function are shown in Fig. 2(b). As can be seen in Fig. 2(b), the regression function can be regarded as a straight line through the origin, that is, the normalized PAS magnitude is directly proportional to the penetration depth. Accordingly, the present case corresponds to (b) in Fig. 3 and it is concluded that the concentration of the dye is constant over the solution range from the interface to the bulk. Here it should be noted that the distance from the interface, x, is a different variable from the penetration depth, d, and that graduations on the abscissa in Fig. 2(c) can not be determined, because of the nature of the Laplace transformation. However, it is significant that the above conclusion can be derived from the measurement of the PAS magnitude against the penetration depth of submicrometer.

As described previously, the available range of the penetration depth is limited by the optical parameters of the internal reflection system examined and the angle of incidence. In this study, the smallest penetration depth was 34 nm. This limit is still inadequate for exact observation of a thinner layer adjacent to the interface, such as an adsorption layer. Figure 4 shows a dependence of the relative penetration depth, d/λ, on the angle of incidence for two internal reflection elements with the different refractive indices, that is, (a) 1.819 and (b) 2.417. As expected from Fig. 4, the shorter penetration depth will be approached by using the

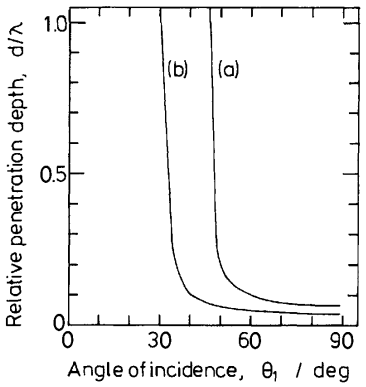

Fig. 4. Dependence of relative penetration depth on angle of incidence. (a) Refractive index of internal reflection element, n_1=1.819 and refractive index of solution, n_2=1.337, (b) n_1=2.417 and n_2=1.337.

larger angle of incidence, the higher refractive index of the internal reflection element, and the shorter wavelength of the laser. The complex concentration profiles, which are due to adsorption, electrochemical operation, and mass transfer of species in membrane, will be examined by the proposed spectrometric technique.

Preparations and Structures of 3-Chloro-ONN-4′-methylazoxybenzene and 4-Methoxy-ONN-4′-methylazoxybenzene†

Jiro YAMAMOTO,* Takashi TSUBOI, Yasunori SUMI, Noriyasu ODA, and Keiichi FUKUYAMA††
Department of Industrial Chemistry, Faculty of Engineering, Tottori University, Tottori 680
(Received March 26, 1987)

Synopsis. A treatment of 3-chloro-NNO-4′-methylazoxybenzene (**1β**) with CrO_3 in acetic acid gave 3-chloro-**ONN**-4′-methylazoxybenzene (**1α**) in good yield, whereas 4-methoxy-**ONN**-4′-methylazoxybenzene (**2α**) isomerized partially to 4-methoxy-**NNO**-4′-methylazoxybenzene (**2β**) under the same conditions. The structures of **1α** and **2α** have been determined by X-ray analysis.

The transformations of azoxybenzene into 4-hydroxyazobenzene[1] and small amounts of 2-hydroxyazobenzene[2] were discovered by Wallach and Belli, respectivelly. A number of investigations on the Wallach rearrangement for various substituted azoxybenzenes have since followed. However, little has been studied regarding the Wallach rearrangement of unsymmetrically substituted azoxybenzenes or on the isomerization of the azoxybenzenes under the conditions of the Wallach rearrangement.[3-5] Recently, the α,β-isomerization††† based on a migration of an azoxy-oxygen atom was found in the reaction of some unsymmetrically substituted azoxybenzenes with sulfuric acid.[6-8] In order to reveal the mechanism of the Wallach rearrangement through the behavior of unsymmetrically substituted azoxybenzenes, it is necessary to determine their structure unambiguously, i.e. the relative position of the oxygen atom on the azoxy group. Here, we report on the preparation of 3-chloro-**ONN**-4′-methylazoxybenzene (**1α**) and 4-methoxy-**ONN**-4′-methylazoxybenzene (**2α**) and the structures of **1α** and **2α** determined by X-ray crystallographic analysis.

Results and Discussion

It was shown that some β-isomers converted into α-isomers upon treating with CrO_3 in acetic acid [4-(phenyl-**NNO**-azoxy)beozoic acid,[9] 4-nitro-**NNO**-azoxybenzene[10]]. When **1β** was warmed with CrO_3 in acetic acid, an oxygen atom of it transfered to a nitrogen atom, binding with 4-tolyl group (β,α-isomerization). In the reaction of a mixture of **2α** and **2β** with CrO_3 under some conditions (i.e. by using four different starting mixtures in molar ratio and changing the reaction time, adding amounts of CrO_3, and volume of AcOH), the preparation of pure **2α** was unsuccessful. However, an azoxy-oxygen atom partialy transfered to a remote nitrogen atom from the 4-tolyl group in a α,β-ratio (2α : 2β=0.5 : 1.0) in each case (Table 1).

4-Methoxy-**NNO**-4′-methylazoxybenzene
2β

In order to separate the α and β-isomer of unsymmetrically substituted azoxybenzenes from each other, a fractional crystallization technique was spplied using ethanol [methyl 4-(phenylazoxy) benzoates,[9] 4-methylazoxybenzenes,[7] 4-phenylazoxybenzoic acid[9]]. When a hot equimolar ethanol solution of **2α** and **2β** was allowed to stand at room temperature, deposited first crystals had the same isomeric ratio as the starting mixture. In an effective separation of **2α** from a mixture of **2α** and **2β**, the deposited crystalline substance are filtered off from an ethanol solution at 50 °C. The structures of **1α** and **2α**, determined by the X-ray analyses, are shown in Fig.1. It could be guaranteed that both **1α** (δ 1.97) and **2α** (δ 1.98) had an azoxy-oxygen atom on the nitrogen atom, binding the 4-tolyl group, respectively.

Experimental

Preparation of 3-Chloro-4′-methylazoxybenzene (3). *p*-Nitrosotoluene (**4**) (6.3 g, 52.0 mmol) was dissolved in an equal volume solution of acetic acid and ethanol (40 ml in each) with warming; was added an acetic acid solution of *m*-chloroaniline (4.6 g, 45.6 mmol) to it. After the reaction, the mixture was kept at 50 °C for 30 min, and then allowed to stand overnight. A dark brown precipitate was filtered and washed throughly with water. The precipitate was dissolved in ether and the ether solution was washed with water: 3% NaOH aq soln, 5% HCl aq soln, and water. After the ether solution was dried, crude **3** was obtained by recrystallization with ethanol (150 ml). Mp 106.0—107.0 °C. Methyl signal δ=2.05. 4-Methyl-4′-methoxyazobenzene (**5**) (86.5%) was also

prepared in a reaction of 4 with *p*-anisidine: mp 111.0 °C (lit,[11] 110.0—111.0 °C) δ=2.07.

Preparation of 3-Chloro-ONN-4'-methylazoxybenzene (1α). An acetic acid solution (500 ml) of **3** (5.0 g, 24.2 mmol) was kept at around 65 °C with 30% H_2O_2 (50 ml). When the orange-reddish solution changed to yellow, the reaction mixture was poured into water. The precipitate was filtered and washed with water until the smell of acetic acid disappeared. An equimolar mixture of **1**α (δ=1.97) and 4-methyl-**ONN**-3'-chloroazoxybenzene (**1**β) (δ=2.09) was obtained (5.3 g, 97.1%) mp 76.5—77.0 °C. The mixture (5.0 g, 22.3 mmol) was kept in the range 30—40 °C in acetic acid and CrO_3 (5.1 g, 51.0 mmol) was added in three portions during 30 minutes. After the reaction mixture was warmed in the range 55—60 °C for 3 h and allowed to stand over night, it was poured into cold water and filtered. **1**α was thoroughly washed with water and dried (4.25 g, 85.0%). The oxidation of **5** with H_2O_2 was carried out by the same procedure and an equimolar mixture (85.0%) of **2**α (δ=1.98) and **2**β (δ=2.08) was obtained. An ethanol solution (80 ml) of the mixture was kept in the range 60—70 °C. When the temperature of the solution dropped to 50 °C, the deposited crystals were filtered and dried (5.1 g, 81.0%), (**2**α:**2**β=5.67:1.00). The same procedure was applied for a mixture (5.1 g, 24.6 mmol) using ethanol (100 ml) again. After being worked up, pure **2**α (2.86 g, 55.0%) was obtained mp 110.5—111.0 °C (δ=1.98).

Crystallographic Measurements. The diffraction data of the crystals of **1**α and **2**α were measured at room temperature on a microcomputer-controlled four-circle diffractometer.[12] The crystal data are as follows: **1**α; $C_{13}H_{11}N_2OCl$, M=246.7, monoclinic, space group $P2_1/n$, a=12.133(5), b=12.805(5), c=7.738(4) Å, β=93.69(5)°, V=1199.7 Å^3, Z=4, D_c=1.37 g cm^3. **2**α: $C_{14}H_{14}N_2O_2$, M=242.3 monoclinic, space group $C2$, a=25.485(7), b=3.986(3), c=13.428(5) Å, β=116.42(5)°, V=1221.6 Å^3 Z=4, D_c=1.32 g cm^3. The intensities were measured up to 2θ=120° by a θ—2θ scan technique using Ni-filtered Cu $K\alpha$ radiation. The reflections with $F>2\sigma_F$ were used for subsequent caluculations. The numbers of measured and significant reflections were 1784 and 1368, respectivelvely,for **1**α, and 1019 and 778, respectively for **2**α. Periodically monitored reflections showed no significant change in intensity. The intensities were corrected for the Lorenz and polarization factors.

Structure Determination. The structure of **1**α was solved by the direct method.[13] Since an attempt to solve the structure of **2**α by a direct method was unsuccessful, the vector search method[14] was applied; the parameters of the orientation and the translation of azoxybenzene were deter-

mincd by the program RICS.[15] The renaining non-hydrogen atoms were located in a successive Fourier synthesis. Positional and anistropic temperature factors for **1α** and **2α** were refined by a block diogonal least-squares method.[16] All hydrogen atoms of **1α** were located in the difference Fourier synthesis and included in the subsequent refinement. The positions of the hydrogen atoms of **2α**, except those of the methyl group, were caluculated geometrically and included in the refinement. The isotopic temperature factors of these hydrogen atoms of **2α** were fixed to those of the atoms to which they were bonded. The weighting scheme used in the final cycle of the refinement for **1α** was $w=1.0$ for $F_o \leqq 18$ and $w=[1.0+0.25(F_o-18)]^{-1}$, for $F_o>18$ and that for **2α** was $w=1.0$ for $F_o \leqq 30$ and $w=[1.0+0.2(F_o-30)]^{-1}$ for $F_o>30$. The final R values are 0.071 and 0.083 for **1α** and **2α**, respectivelly. The final atomic parameters are given in Tables 2 and 3.[17] The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[18]

We thank Shigeo Fujii and Yoshikuni Takiyama for the assistance of X-ray analysis.

(Received April 24, 1987)

Synopsis. Singlet-oxygen oxidation of 2-[hydroxy(4-nitrophenyl)methyl]tropone gave 6,7-dioxabicyclo[3.2.2]-nona-3,8-dien-2-one derivatives in good yields. A change of regioselectivity of the oxygenation with a remarkable rate of enhancement (23 times) in deuteriomethanol vs. methanol could be best explained in terms of the quenching of singlet oxygen by the free hydroxyl group in the vicinity of the reaction site. Similarly studied were 2-(1-hydroxy-2-oxo-2-phenylethyl)tropone and 2-benzyltropone. The stereochemistry of the oxygen adducts was elucidated by a ^{1}H NMR chemical-shift comparison.

Sensitized photooxygenation of tropones is a useful method for preparing 2,5-dihydroxytropones which are important starting materials for functionalized troponoids such as *p*-tropoquinones.[2] Among those, tropone (**1**)[3] and 2-methoxytropone (**2**)[4] gave corresponding single endoperoxides, 6,7-dioxabicyclo[3.2.2]-nona-3,8-dien-2-one and its 1-methoxy derivative (**3** and **4**), while 2-aryltropones (**5**) gave two regioisomers, 1- and 3-aryl derivatives (**6** and **7**), the former of which was predominant (ca. 2.3 : 1).[5] Thus, the oxygenation takes place predominantly at electron-rich 2,5-positions rather than less-hindered 4,7-positions. Contrary to the previous cases, 2-[hydroxy-(4-nitrophenyl)methyl]tropone (**8**)[6] and 2-(1-hydroxy-2-oxo-2-phenylethyl)tropone (**9**),[7] have now been found to react predominantly at the 4,7-positions, while 2-benzyltropone (**10**) reacted at both positions in a 1 : 1-ratio. Herein, we describe the findings.

First of all, **10** gave a 1 : 1-mixture of photooxygenation products (**11** and **12**) upon irradiation with a tungsten lamp in the presence of a sensitizer, hematoporphyrin (HMP), under an oxygen atmosphere. The reaction rate was considerably larger than those of the other substrates taken in this study. The structures of **11** and **12** were elucidated by a ^{1}H NMR analysis to be 3-benzyl-6,7-dioxabicyclo[3.2.2]nona-3,8-dien-2-one and 1-benzyl-6,7-dioxabicyclo[3.2.2]nona-3,8-dien-2-one, respectively; in **11**, there were three vinylic proton signals together with the five-proton singlet for the phenyl group, and in **12**, there were four vinylic proton signals together with rest of signals which closely resembled those of **11**. No other product was detectable in spite of the careful check of every chromatographic fraction.

The oxygenation of **8** gave four endoperoxides **13**—**16** in good yields. They were all of the possible [4+2] cycloadducts, and their structures were easily identified by the ^{1}H NMR spectroscopy; the less polar **13** and **14** were 1-substituted 6,7-dioxabicyclo[3.2.2]nona-3,8-dien-2-ones, while the more polar **15** and **16** were 3-substituted derivatives.

Similarly, **9** gave diastereomeric mixtures of 1-substituted products **17** and **18** and 3-substituted products **19** and **20**. Their stereostructure was deduced by chemical-shift comparisons; i.e., one can assume that the preferential conformer of each product must possess the internally-hydrogen-bonded structure for the C-2 carbonyl and the benzylic hydroxyl groups. As a result, one of the isomers should have the up-field shifted C-8 proton signal and a low-field shifted C-a proton signal, depending on the relative geometry to the anisotropic phenyl group. The cases were two pairs of 1-substituted derivatives: **13** and **14** and **17** and **18**. In the 3-substituted derivatives, the chemical shifts of the a-protons led to an assignment of their orientation as depicted in Chart 2.

Thus, the photooxygenation reaction of **10** yielded a 1 : 1-mixture of **11** and **12**. However, the hydroxyl-carrying substrates all produced the 3-substituted products preferably, and retardations in the rates of the oxygenation were recognized to some extent. This would be due to a quenching effect of the hydroxyl group to singlet oxygen. This has been confirmed when the photooxygenation of **9** was carried out in methanol-d_4: the rate was much improved, as large as 23 times that in methanol; the product distribution, the ratio of (**17**+**18**) : (**19**+**20**), was changed to 44:56. The rate enhancement in deuterio solvent is interpreted in terms of an increased lifetime of the singlet oxygen; the degree of the rate-enhancement effect by the medium was theoretically estimated as being ca. 8—10.[9] The present figure is, therefore, attributable to not only the medium effect, but also a quenching effect of the hydroxyl group in the vicinity of the reaction site.[10] This is related to the inversed ratio of the formation of **19** and **20** vs. **17** and **18**. The results are cited in Table 2.

2-(4-Nitrobenzoyl)tropone (**21**) gave no photooxygenation product after prolonged irradiation; this is parallel to the general tendency of the reaction with singlet oxygen, e.g., an introduction of the electron-withdrawing substituent into tropones retarded the oxygenetion.[11]

Table 2. The Product Distributions of the Photooxygenation of **9**

Solv.	Yield/%		Recovery
	(**19**+**20**)	(**17**+**18**)	
Acetone	64	36	
CH_3OH	5.7	7.3	87
CD_3OD	51	40	9

A mild base treatment of **15** and **16** gave 5-hydroxytropolone derivative **22** quantitatively; unfortunately, its attempted conversion to the tropoquinone derivative has not yet been successful.[2]

Experimental

Sensitized Photooxygenation of 2-Benzyltropone (10). Formation 11 and 12. An acetone solution of **10** (114.8 mg) was oxygenated with HMP (10.5 mg) by a 500-W tungsten lamp under oxygen stream. After 4 h, the mixture was chromatographed on a silica-gel column to give **11** [a yellow oil, 43 mg; 32%. Found: C, 73.41; H, 5.29%; *m/z*, 228.0745 (M^+). Calcd for $C_{14}H_{12}O_3$: C, 73.67; H, 5.30%; M, 228.0787. ^{13}C NMR δ[8]= 37.8, 74.8, 90.3, 126.0, 127.1, 128.5 (2C), 130.9 (2C), 131.7, 134.8, 139.0, 142.8, and 195.7. IR ν: 3040, 1680, 1495, 1450, 1240, 1005, 965, 825, 750, and 700 cm^{-1}. UV λ_{max}^{MeOH}: 208 (ε=13900), 241 (1400, sh), and 383 (1000)] and **12** [a yellow oil, 41.2 mg; 31%. Found: C, 73.74; H, 5.40%; *m/z* 228.0787 (M^+). ^{13}C NMR δ=36.3, 75.5, 85.8, 123.5, 126.7, 128.8 (2C), 129.4 (2C), 138.1, 138.8, 140.7, 142.1, and 195.5. IR ν: 3025, 1675, 1490, 1450, 1365, 1220, 960, 790, 730, and 695 cm^{-1}. UV λ_{max}^{MeOH}: 206 nm (ε=13900, sh) and 260 (2200)].

Sensitized Photooxidation of 8. An acetone solution (50 cm^3) of **8** (617 mg) was irradiated for 8.5 h with HMP (22 mg) under an O_2 stream. The reaction mixture was evaporated in vacuo and the residue was chromatographed on a silica-gel column to give **13**[pale yellow needles, mp 110—114 °C, 87.2 mg; 14%. Found: C, 58.00; H, 3.85; N, 5.10%. Calcd for $C_{14}H_{11}NO_6$: C, 58.13; H, 3.83, N, 4.84%. ^{13}C NMR δ=71.1, 75.8, 89.2, 122.6, 123.1 (2C), 128.8 (2C), 131.3, 139.9, 144.3, 144.5, 147.6, and 197.5. Found: *m/z*, 272.0641 (M$^+$). ^{13}C NMR δ=71.5, 75.2, 85.5, 123.5, 129.4 (4C), 133.7, 134.4, 138.2, 140.7, 144.7, 193.8, and 198.0 for **19**; δ=70.9, 75.2, 85.5, 123.5, 129.0 (4C), 133.7, 134.4, 138.2, 140.5, 144.7, 194.3, and 198.4 for **20**. IR ν: 3450, 1690, 1600, 1580, 1450, and 1380 cm^{-1}. UV λ_{max}^{MeOH}: 246 nm (ε=13300) and 292 (1200)].

Sensitized Photooxygenation of 9 in CD_3OD. An anhydrous CD_3OD solution (0.5 cm^3) of **9** (13.3 mg) was irradiated by a 500-W tungsten lamp in the presence of HMP (1.4 mg) under an O_2 stream for 3 h. The rate of the oxygenation was ca. 23 times larger than in MeOH. The ratio of (**17**+**18**) and (**19**+**20**) was analyzed to be 44:56 according to ^{1}H NMR spectrometry.

Sensitized Photooxygenation of 9 in CH_3OH. An MeOH solution (0.5 cm^3) of **9** (13.3 mg) was irradiated in the presence of HMP (1.3 mg) under an O_2 stream for 10 h. The ratio of (**17**+**18**): (**19**+**20**) was analyzed to be 56:44.

Base-Catalyzed Isomerization of 15. A benzene solution (7 cm^3) of **15** (21.5 mg) was stirred in the presence of Et_3N (1 mg) for 2 d at room temperature. The precipitates were filtered off and washed with benzene to give **22** [yellow powders, 20.2 mg; 93%. Found: *m/z*, 289.0621 (M$^+$). Calcd for $C_{14}H_{11}NO_6$: M, 289.0586. ^{1}H NMR (CD_3OD) δ=6.36 (1H, s), 6.95 (1H, dd, *J*=11, 3 Hz), 7.26 (1H, d, *J*=11 Hz), 7.66 (2H, d, *J*=9 Hz), 7.79 (1H, d, *J*=3 Hz), and 8.10 (2H, d, *J*=9 Hz). ^{13}C NMR (CD_3OD) δ=71.7, 123.9, 124.1, 124.5 (2C), 127.2, 129.0 (2C), 145.9, 148.8, 152.4, 160.4, 165.8, and 169.9. IR ν: 3600—3200, 1590, 1510, 1400, and 1345 cm^{-1}. UV λ_{max}^{MeOH}: 219 nm (ε=19100), 241 (22500), 266 (13300, sh), 340 (8300), 380 (8500, sh), and 394 (8800)].

Base-Catalyzed Isomerization of 16. A benzene solution (13 cm^3) of **16** (38.0 mg) was similarly treated with Et_3N (1 mg) at room temperature for 2 d to give **22** [35.0 mg; 94%], which was identical with the sample prepared from **15**.

Attempted Oxygenation of 21. An acetone solution (2 cm^3) of **21** (16.2 mg) and HMP (2 mg) was photooxygenated under an O_2 stream at room temperature for 15 h. The silica-gel column chromatogram of the mixture gave **21** quantitatively.

Attempted DDQ-Dehydrogenation of 22. An acetone solution (5 cm^3) of **22** (52.5 mg) and DDQ (74.2 mg) was stirred at room temperature for 1.5 h. The thin-layer chromatography of the mixture confirmed that no reaction occurred.

We wish to thank The Ministry of Education, Science and Culture for a financial assistance through a Grant-in-Aid for Scientific Research to A. M. (No. 60470025).

10) A change of life-time of $^1O_2$ by the deuteration of the solvent in bulk may not cause an inversed change in the product distributions. And a change of hydroxyl- to deuteroxyl group on the ethereal substituents of 2-alkoxytropones is least likely to alter the steric effect or electronic properties of the reactant tropones. It is true that the reactivity of $^1O_2$ is known to decrease by introducting oxygen functions; e.g., 3-hydroxyalkenes. A duallity due to the cyclic structures in present cases verified this in terms of the product distributions.

A Convenient One-Pot Cyanosilylation of Aldehydes and Ketones Using Potassium or Sodium Cyanide Impregnated on Amberlite XAD Resin and Trimethylsilyl Chloride

Kazuaki SUKATA

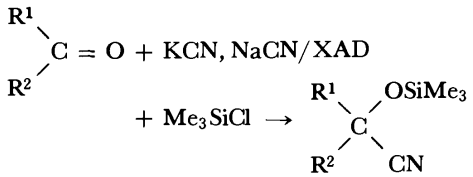
(Received May 22, 1987)

Synopsis. In the cyanosilylation of benzaldehyde, the combination of potassium or sodium cyanide impregnated on Amberlite XAD resin and trimethylsilyl chloride has been found to be a good one-pot cyanosilylation agent. Although acetonitrile is the best solvent, substantial yields of the product is obtained even in a nonpolar solvent or without any solvent. In the reaction with other aldehydes or ketones, this method gives the corresponding silylated cyanohydrins in extremely high yields.

Cyanosilylation of aldehydes and ketones using trimethylsilyl cyanide (Me_3SiCN) gives the corresponding α-trimethylsilyloxy nitriles which are versatile and important as acyl anion equivalents[1] and intermediates.[2] Although this reaction gives good yields of the products,[3] independently prepared Me_3SiCN, which is toxic and moisture sensitive, has been used. Furthermore, in general, the synthesis of Me_3SiCN is tedious and the isolated yields are not very good.[2,4] To overcome this disadvantage, a one-pot cyanosilylation using trimethylsilyl chloride (Me_3SiCl) and KCN with or without catalysts has been reported.[5] This method, however, requires very long reaction times and high reaction temperatures in acetonitrile or *N,N*-dimethylformamide, even in the presence of 18-crown-6 or ZnI_2 as a catalyst.

On the other hand, in a previous paper,[6] it has been shown that the reaction of alkylsilyl chloride with KCN or NaCN impregnated on Amberlite XAD resins (KCN/XAD, NaCN/XAD) produces good yields of alkylsilyl cyanide. This paper describes a mild and convenient method for the one-pot cyanosilylation of aldehydes and ketones using KCN/XAD or NaCN/XAD and Me_3SiCl.



Results and Discussion

In a preliminary experiment, the one-pot cyanosilylation was performed with benzaldehyde, Me_3SiCl, and KCN/XAD-4 in various solvents. Table 1 shows the results. In acetonitrile, the reaction was very fast and the complete conversion of the aldehyde occured at 60 °C in 4 h. Interestingly, in nonpolar solvents or without any solvent, 50—63% of the product was obtained at 60 °C in 8 h and the reaction was substantially faster than those in more polar solvents such as 1,2-dimethoxyethane (DME) and tetrahydrofuran (THF). The order of reaction rates was acetonitrile ≫ hexane ≥ benzene ≈ none > dichloromethane > DME ≈ THF. This order is in contrast to that in the reaction of Me_3SiCl with KCN/XAD-4, that is, acetonitrile ≫ DME ≈ THF ≈ none > benzene ≈ hexane.[6]

Table 1. Cyanosilylation of Benzaldehyde with KCN/XAD-4 and Me_3SiCl in Various Solvents[a]

Solvent	Time/h	Temp/°C	Yield/%[b]
Acetonitrile	4	60	≈98
	4	60	≈98[c]
DME	8	60	27
THF	8	60	21
CH_2Cl_2	8	40	20
	24	40	30
Benzene	8	60	55
	8	40	36
	24	40	43
Hexane	8	60	63
None	8	60	50

a) Unless otherwise noted, reactions were carried out with benzaldehyde (5 mmol), KCN (15 mmol)/XAD-4 (3.75 g), Me_3SiCl (7.5 mmol), and a solvent (20 ml). b) Determined by GLC. c) Sodium cyanide (15 mmol) was used.

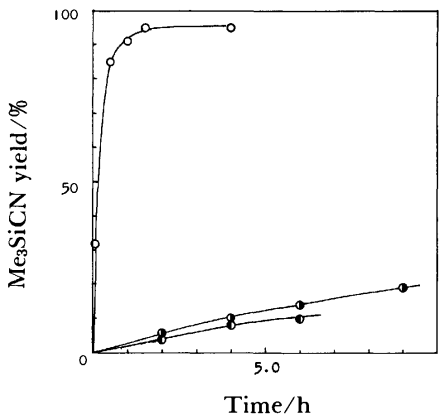


Fig. 1. Plots of Me_3SiCN yield vs time. Reactions were carried out with KCN (15 mmol)/XAD-4 (3.75 g), Me_3SiCl (7.5 mmol), and a solvent (20 ml) at 60 °C. ○: In acetonitrile; ◑: in DME; ◐: in benzene.

Figure 1 shows the relationship between the yield of Me_3SiCN and reaction time in the reaction of Me_3SiCl with KCN/XAD-4. The yields of Me_3SiCN in acetonitrile and other solvents were ca. 85% (0.5 h) and 1—2% (0.5 h), respectively. This finding indicates that the cyanosilylation of benzaldehyde in acetonitrile is performed predominantly by the process of Eq. 1, whereas those in the other solvents are performed mainly by the process of Eq. 2.

$$Me_3SiCl \xrightarrow{KCN/XAD} Me_3SiCN \xrightarrow{PhCHO} PhCH(OSiMe_3)CN \quad (1)$$

$$PhCHO \xrightarrow{KCN/XAD} PhCH(O^-K^+)CN \xrightarrow{Me_3SiCl} PhCH(OSiMe_3)CN \quad (2)$$

This also indicates that the cyanosilylation in acetonitrile occurs in the bulk organic phase, while those in the other solvents occur on the surface of the XAD resin. In the reaction using other solvents with the exception of acetonitrile, mass transfer seems to be important similar to the reaction of acyl chloride with KCN/XAD.[7]

Figure 2 shows the relationship between the conversion of benzaldehyde and the molar ratio Me_3SiCl/KCN. The reactions were carried out in acetonitrile. In both cases of the molar ratio KCN/benzaldehyde=3 and Me_3SiCl/benzaldehyde=1.5, the conversion of benzaldehyde rapidly slowed down over the molar ratio Me_3SiCl/KCN=0.5. Although at present I have no explanation for this fact, it is clear that the molar ratio Me_3SiCl/KCN=0.5 is the optimum value.

The method using Me_3SiCl and KCN/XAD was applied to the cyanosilylation of other aldehydes and ketones. Table 2 shows the results. In both cases of aliphatic and aromatic carbonyl compounds, the reaction was smooth and gave the corresponding silylated cyanohydrins in extremely high yields in the absence of any catalyst such as crown ether or Lewis acids. The impregnated KCN, which has strong nucleophilicity,[8] catalyzed the reaction. In the reaction of enolizable carbonyl compounds, it is predicted that silyl enol ethers are formed as by-products.[5] The present method, however, gave substantially no silyl enol ethers. In the case of crotonaldehyde, only 1,2-adduct was obtained as expected.[3] The reaction of fluorenone required higher reaction temperature than those of the other carbonyl compounds probably because of its

a) Unless otherwise noted, reactions were carried out with carbonyl compound (10 mmol), KCN (30 mmol)/XAD (7.5 g), Me_3SiCl (15 mmol) in acetonitrile (40 ml) at 60 °C. b) Isolated yields. Values in parentheses are the yields determined by GLC. c) A: XAD-4, B: XAD-2. d) The reaction was carried out at 80 °C.

steric hindrance. In general, XAD-4 more rapidly produced products than XAD-2, which was probably due to the difference in the surface area.

In conclusion, the combination of Me_3SiCl and KCN or NaCN/XAD was found to be a good reagent for the cyanosilylation of aldehydes and ketones. This reagent can be used for other cyanosilylations in substitution for Me_3SiCN.

Experimental

Materials. Actonitrile, benzene, and hexane were dried with molecular sieves 4A. Tetrahydrofuran was passed through an alumina column, distilled, and dried with molecular sieves 4A. 1,2-Dimethoxyethane was refluxed with Na and distilled. Dichloromethane was washed with aqueous Na_2CO_3, distilled, and dried with molecular sieves 3A. Trimethylsilyl chloride (Toray Silicone Co.) was used as obtained. Carbonyl compounds (Wako Pure Chemicals Ind. Co.) were used without further purification. Amberlite XAD resins (Organo Co.) were washed with methanol, methanol-benzene, and methanol, and then dried under vacuum. KCN/XAD and NaCN/XAD were prepared by the method previously reported:[8] To a solution of KCN or NaCN (15 mmol) in 4 ml of aqueous methanol (50 vol%) was added XAD resin (3.75 g) and then the solvent was removed under reduced pressure (≈15 mmHg, 1 mmHg=133.322Pa) at 60 °C with vigorous shaking. The half-dried KCN or NaCN/XAD was further dried under vacuum (0.1 mmHg) for 4 h at 90 °C.

Typical Procedure for the Cyanosilylation with KCN or NaCN/XAD and Me_3SiCl. In all reactions, Me_3SiCl and carbonyl compounds were added directly to the flask in which the KCN or NaCN/XAD had been made and dried. All the products were known compounds and satisfactory IR spectra for these compounds, which had no CN absorption band, were obtained.[3c]

Cyanosilylation of Benzaldehyde Using Me_3SiCl and KCN/XAD-4 in Various Solvents. After a mixture of KCN (0.98 g, 15 mmol)/XAD-4 (3.75 g), Me_3SiCl (0.81 g, 7.5 mmol), and a solvent (20 ml) was stirred for several minutes, benzaldehyde (0.53 g, 5.0 mmol) was added to the mixture. The resulting mixture was stirred at 60 °C for the indicated time. The yield of the product was determined by GLC (Silicone OV-17, 3 m×3 mm, 160 °C) using tetradecane as an internal standard.

Crotonaldehyde Cyanohydrin Trimethylsilyl Ether: A mixture of KCN (1.95 g, 30 mmol)/XAD-4 (7.5 g), Me_3SiCl (1.62 g, 15 mmol), and acetonitrile (40 ml) was stirred for several minutes at room temperature, followed by the addition of crotonaldehyde (0.70 g, 10 mmol). The mixture was stirred at 60 °C for 4 h. GLC (Silicone OV-17, 3 m×3 mm, 140 °C) showed almost complete conversion of the aldehyde. The solid material was filtered and washed well with benzene (100 ml). After removal of the solvent, the residue was distilled under reduced pressure, giving 1.44 g (85%) of the product, bp 80—81 °C/12 mmHg (lit,[3b] 80.5 °C/12 mmHg). IR (neat): 1670 (C=C), 1253, 1100, 1056, 960, 870, 844, 752 cm^{-1} no CN.

4-Methoxybenzaldehyde Cyanohydrin Trimethylsilyl Ether: A mixture of KCN (1.95 g, 30 mmol)/XAD-4 (7.5 g), Me_3SiCl (1.62 g, 15 mmol), and acetonitrile (40 ml) was stirred for several minutes at room temperature followed by the addition of 4-methoxybenzaldehyde (1.36 g, 10 mmol). The mixture was stirred at 60 °C for 6 h. After the same treatment as crotonaldehyde, the solvent was removed and the residue was distilled under reduced pressure, giving 2.23 g (95%) of the product, bp 103—104 °C/0.35 mmHg (lit,[5] 95 °C/0.13 mmHg). IR (neat): 1250, 1088, 872, 844, 760 cm^{-1} no CN.

Cyclohexanone Cyanohydrin Trimethylsilyl Ether: The reaction of cyclohexanone (0.98 g, 10 mmol) similar to that of 4-methoxybenzaldehyde was performed. The same treatment as 4-methoxybenzaldehyde gave 1.81 g (92%) of the product, bp 96—97 °C/14 mmHg (lit,[3b] 92.5 °C/12 mmHg). IR (neat): 1250, 1122, 878, 844, 754 cm^{-1} no CN and no C=C.

Acetophenone Cyanohydrin Trimethylsilyl Ether: The reaction of acetophenone (1.20 g, 10 mmol) similar to that of 4-methoxybenzaldehyde was performed. The same treatment as 4-methoxybenzaldehyde gave 2.12 g (97%) of the product, bp 84—85 °C/3mmHg (lit,[3c] 237—238 °C/760 mmHg). IR (neat): 1252, 1116, 845, 758 cm^{-1} no CN and no C=C.

Fluorenone Cyanohydrin Trimethylsilyl Ether: The reaction of fluorenone (1.80 g, 10 mmol) similar to that of 4-methoxybenzaldehyde was performed at 80 °C for 8 h. The solid material was filtered and washed well with benzene (100 ml). Removal of the solvent gave 2.80 g of the crude product as the residual solid, mp 88—94 °C, recrystallization of which gave 2.51 g (90%) of the pure product, mp 94.5—95.5 °C (lit,[3b] 95—96 °C). IR (Nujol): 1250, 1114, 1096, 868, 844, 764, 752, 726 cm^{-1} no CN.

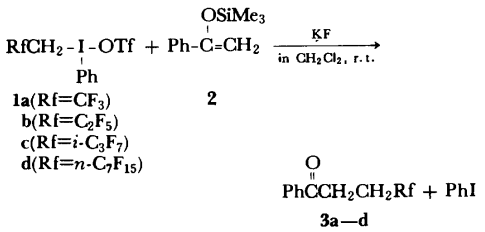
Synopsis. The reaction of enol trimethylsilyl ethers of carbonyl compounds with (1*H*,1*H*-perfluoroalkyl)phenyliodonium triflates was promoted successfully by potassium fluoride in dichloromethane at room temperature, giving β-perfluoroalkyl (Rf; CF_3, C_2F_5, *i*-C_3F_7, *n*-C_7F_{15}) carbonyl compounds in good yields. An enol silyl ether of an α,β-unsaturated carbonyl compound gave a δ-Rf-α,β-unsaturated carbonyl compound selectively.



Much attention is being denoted to polyfluoroalkyl groups from the viewpoint of the development of new chemicals or materials having characteristic properties, because they have high electronegativity, stability, lipophilicity, strong surface intension- and refractive index-decreasing effects, and so on.[2] Among them, trifluoromethyl (CF_3) or 2,2,2-trifluoroethyl (CF_3CH_2) group in particular has been of increasing importance in the development of new medicines or agricultural chemicals owing to its unique effects on the bioactivity.[2,3] However, the introduction of the fluoroalkyl groups into the desired sites of the organic molecules was troublesome.[4]

Recently we have developed (1*H*,1*H*-perfluoroalkyl)-phenyliodonium triflates **1** (FMITS) as the most reactive reagents for the source of $RfCH_2$ cations.[5,6] In this paper, we described potassium fluoride-promoted 1*H*,1*H*-perfluoroalkylation of enol silyl ethers with FMITS under mild conditions, giving β- or δ-CF_3 carbonyl compounds or their higher perfluoroalkyl (Rf) homologues in good yields.[7]

Results and Discussion

We examined the reaction of **1** with α-(trimethylsiloxy)styrene (**2**), and the results are shown in Table 1. It was found that **1a** smoothly reacted with an equimolar amount of **2** in dichloromethane at room temperature in the presence of a large excess of potassium fluoride (KF) as an additive to give phenyl 3,3,3-trifluoropropyl ketone (**3a**) in a high yield along with an almost quantitative yield of iodobenzene (Run 1). The product **3a** was also contaminated with the starting acetophenone, the amount of which increased as the yield of **3a** decreased. **3a** was easily purified by chromatography on silica gel. When **1a** was treated with **2** without an additive, the yield of **3a** was low (Run 10). When using 2,4,6-collidine, *N*-(2,2,2-trifluoroethyl)-pyridinium triflate was obtained in a 60% yield along with **3a** (30%) (Run 9). Sodium bicarbonate as a solid base afforded a trace of **3a** (Run 7). Since the treatment of an enol trimethylsilyl ether with methyllithium in tetrahydrofuran (THF) has been known as the effective method for the generation of an enolate anion,[8,9] the results of Run 8 indicated that the direct reaction of **1a** with an enolate anion of acetophenone in THF resulted in the low yield of **3a**. One of the causes may be that the enolate anion competitively abstracted a proton from the acidic CH_2 protons of **1a**, since triflates **1** were found to be easily deprotonated with such a base as sodium hydride.[5b] KF is insoluble in dichloromethane and the reaction of **1a** with **2** proceeded slightly without an additive. Moreover, it is reasonable that electron-deficient iodine atom-containing **1** forms a complex with electron-rich double bond-containing **2**. From the above facts and discussion, it may be suggested that solid KF successfully promoted

Table 1. 2,2,2-Trifluoroethylation of **2** with **1a**

Run	Additive(equiv)[a]	Solv.	Temp	Time/h	Yield/%[b]/**3a**
1	KF(5.2)	CH_2Cl_2	R.t.	1.5	87
2	KF(2)	CH_2Cl_2	R.t.	3	40
3	KF(5.5)	$CHCl_3$	R.t.	4	45
4	KF(5.5)	Et_2O	R.t.	4	39
5	KF(5.5)	THF	R.t.	5	38
6	CsF(3)	CH_2Cl_2	R.t.	11[c]	23
7	$NaHCO_3$(1.2)	CH_2Cl_2	R.t.	5	<7
8[c]	MeLi (1)	THF	0 °C→R.t.	1	27
9	2,4,6-Collidine(1)	CH_2Cl_2	R.t.	1	30[d]
10	None	CH_2Cl_2	R.t.	5	16

a) KF used was spray-dried KF.[10] The values in parentheses mean the molar equivalency of the additive to **1a**. An equimolar amount of **2** to **1a** was used in all the runs. b) Isolated Yields except for Run 6 (GC Yield). c) **1a** was added after **2** was allowed to react with MeLi at 0 °C in THF for 15 min. d) *N*-(2,2,2-Trifluoroethyl)pyridinium triflate as another product was obtained in a 60% yield. e) Overnight.

Table 2. 2,2,2-Trifluoroethylation of Enol Silyl Ethers with **1a**

Run[a]	Silyl ether	Product		Yield/%[b]
1	$PhC(OSiMe_3)=CHCH_3$	$PhC(=O)CH(CH_2CF_3)CH_3$	(**4**)	55
2	$PhCH=CHC(OSiMe_3)=CH_2$	$PhCH=CHC(=O)CH_2CH_2CF_3$	(**5**)[c]	75
3	$PhC(OSiMe_3)=CHCH=CH_2$	$PhC(=O)CH=CHCH_2CH_2CF_3$	(**6**)[d]	42
		$PhC(=O)CH(CH_2CF_3)CH=CH_2$	(**7**)	0.8
4			(**8**)	53
5			(**9**)	49
6			(**10**)	71

a) In all the runs, 5—5.5 equimolar amounts of spray-dried KF and dichloromethane as a solvent were used. b) Isolated yields.

the reaction of the complex of **1** with **2** giving **3**, by attacking the silyl site of the enol silyl ether moiety of the complex under the conditions of Run 1. The use of cesium fluoride (CsF) which is expected to have better solubility than KF resulted in the low yield of **3a** (Run 6). This may be explained by the high reactivity of CsF, compared to KF, which can disturb the triple-molecular reaction.

This method was successfully applied to the 2,2,2-trifluoroethylation of a variety of carbonyl compounds (Table 2). An enol trimethylsilyl ether of an α,β-unsaturated ketone underwent selective γ-trifluoroethylation (Run 3). Only a trace of the α-trifluoroethylated product was obtained. Similarly, keten trimethylsilyl acetals derived from esters gave α-CF_3CH_2 esters in good yields.

We also examined the reaction of **1** having a long chain of Rf group with the enol silyl ethers in the presence of KF (Table 3). Since the reactivity decreased as the carbon number of Rf group increased, the high reaction temperature or long reaction time was needed.

Since a variety of the enol silyl ethers can easily be prepared by the advanced synthetic methods,[9] our technique with FMITS reagents is expected to be widely utilized for the preparation of the β- and δ-Rf carbonyl compounds.

Experimental

General. Melting points were uncorrected. ^1H NMR spectra were recorded with a Varian XL-100 NMR spectrometer, a Varian EM 390 NMR spectrometer, or a Bruker AM-400 NMR spectrometer with chloroform-*d* as a solvent and tetramethylsilane as an internal standard. ^{19}F NMR spectra were measured with a Varian XL-100 NMR spectrometer or a Hitachi R-20 B NMR spectrometer, and chloroform-*d* as a solvent. ^{19}F NMR chemical shifts were

reported in ppm upfield from trichlorofluoromethane as an internal standard. IR spectra were measured on a Jasco A-202 diffraction grating infrared spectrometer. Mass spectra were recorded on a Hitachi RMU-6MG spectrometer at 70 eV and 100 °C.

Materials. FMITS reagents were prepared according to the method reported previously.[5] The enol silyl ethers were prepared by the usual methods.[9] Spray-dried KF[10] commercially available from Morita Kagaku Company, Japan, was dried under vacuum at 140 °C for 11 h before use.

1*H*,1*H*-Perfluoroalkylation of Enol Silyl Ethers with 1. General Procedure; **1** (1 mmol) was added into a mixture of an enol silyl ether (1 mmol) and spray-dried KF (5—5.5 mmol) in 3 ml of dry dichloromethane under argon atmosphere and the mixture was stirred for 1.5 h at room temperature. After the filtration through the short column of silica gel, the resulting residue was purified by thin-layer chromatography on silica gel to give the Rf carbonyl compounds. **3a**: Mp 59—60 °C; ^{1}H NMR δ=2.20—2.80 (2H, m, CH_2), 3.10—3.35 (2H, m, CH_2), 7.30—7.70 (3H, m, *m,p*-PhH), 7.83—8.10 (2H, m, *o*-PhH); ^{19}F NMR 65.3 (t, J=11 Hz, CF_3); IR (KBr, cm^{-1}) 1690 (CO); MS 202 (M^+). Synthetic Polyether Dicarboxylic Acids Exhibiting Lithium Ion-Selective Transport[1)]

Kazuhisa HIRATANI* and Kazuhiro TAGUCHI
Industrial Products Research Institute, Higashi 1-chome, Yatabe-machi, Tsukuba-gun, Ibaraki 305
(Received January 29, 1987)

Polyether dicarboxylic acid carriers with several alternate units of oxytrimethylene and oxy-*o*-phenylene groups have been synthesized. They exhibit lithium ion selectivity in the competitive cation transport among lithium, sodium, and potassium ions through liquid membranes. On the basis of the cation extraction and the spectroscopic behavior, it is proposed that these carriers form a coiled structure into which the lithium ion becomes selectively incorporated to exhibit lithium ion-selective transport.

Since Pedersen has reported for the macrocyclic polyethers, the so-called crown ethers,[2)] a large number of macrocyclic polyethers exhibiting cation-selectivity have been synthesized.[3)] On the other hand, it has attracted considerable attention that naturally-occurring antibiotic ionophores can transport cations through biomembranes.[4)] One of the properties of both such artificial and natural ionophores is that they incorporate cations into the cavity by means of the electrostatic interactions of electron-donating hetero atoms. It should be noted that there are a number of noncyclic polyether carboxylic acids among such natural ionophores which exhibit a high selectivity toward alkali and alkaline earth metal ions. We have now studied these structures and functions and have synthesized a series of noncyclic polyether compounds.[5)]

In general, the cation complexes of synthetic and noncyclic polyethers have low stability constants and have less ability to extract cation from aqueous to organic solutions compared with cyclic ones.[6)] Therefore, these compounds have attracted less attention than have macrocyclic polyethers. However, as has been reported by the works of Vögtle, Simon, and other groups, various functionalized noncyclic polyethers have been synthesized.[7,8)] Noncyclic polyethers with carboxyl end groups have been reported as carriers for the cation transport through liquid membranes.[9–12)] The introduction of carboxyl groups results in the rapid formation of salts with cations, and it is particularly useful for cation transport and also for cation extraction into an organic solvent from an aqueous solution. It has been found that cation selectivity with the polyether carboxylic acids depends on the residual parts of polyether structures.

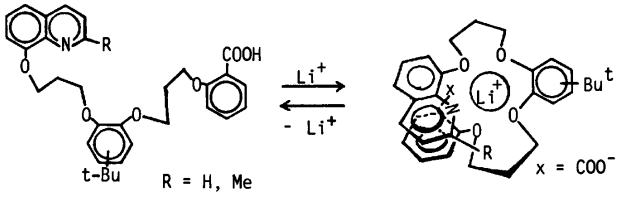

Fig. 1. Uptake of Li^+ ion by the conformational change of **5**.

As previously reported, the noncyclic polyether **5** is an ionophore which can selectively transport lithium ions through liquid membranes against the concentration gradient.[13)] In this case, it has been inferred that lithium ions form the salt with the carboxyl group and become incorporated into the pseudocavity thus formed, as is shown in Fig. 1. Such a conformation has been suggested on the basis of the CPK model building and supported spectroscopically.[14)]

By the way, the lithium ion has the smallest naked ionic radius among the alkali metal ions, while it has the largest hydrated ionic radius and the largest hydration energy. There is no naturally-occurring ionophore which exhibits an excellent lithium ion-selectivity, but several synthetic lithium ion-selective ionophores have been reported in noncyclic,[15,16)] cyclic,[17–21)] and bicyclic[22)] compounds. Wide applications can be expected for lithium ion-selective ionophores, e.g., in the selective separation of lithium ions by transport through liquid membranes and by solvent extraction, and also in monitoring lithium-ion activity in blood during therapy for manic-depressive psychosis.[23)]

If the carrier **5** can wrap around the lithium ion by means of conformational change, as is shown in Fig. 1, even polyethers with fairly long chain structures can be expected to transport lithium ions selectively. In this paper, we wish to report on the synthesis of polyethers with long polyether chains and on their transport of alkali metal ions through liquid membranes.

Experimental

General. The IR and the UV spectra were recorded with JASCO A-3 Infrared and Hitachi 330 spectrophotometers respectively. The ^1H NMR spectrum was recorded with a Varian EM-360 spectrometer. The chemical shifts for the $CDCl_3$ solution are reported from internal tetramethylsilane (TMS).

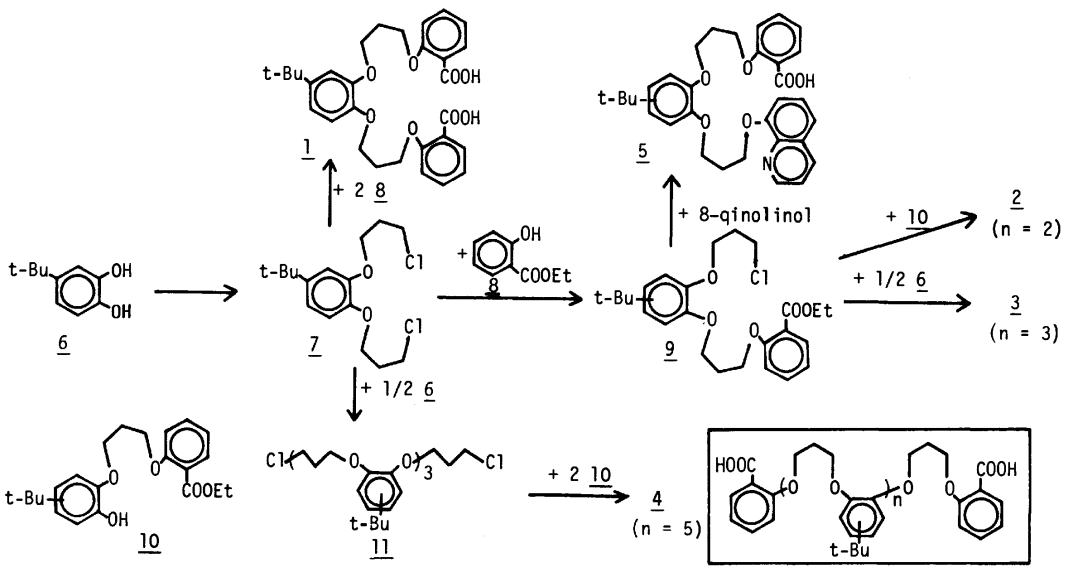
Synthesis of Noncyclic Polyethers. The ethyl salicylate, 4-*t*-butylcatechol, and potassium *t*-butoxide used were extra-pure-grade reagents of Wako Pure Chemical Industries, Ltd.

Extra pure-grade *N,N*-dimethylformamide (DMF) was used as the solvent after having been dried with molecular sieves. The 1,2-bis(3-chloropropoxy)-4-*t*-butylbenzene (**7**), 1-[3-(*o*-ethoxycarbonylphenoxy)propoxy]-2-(3-chloropropoxy)-4(or 5)-*t*-butylbenzene (**9**), and 2-[3-(*o*-ethoxycarbonylphenoxy)-propoxy]-4(or 5)-*t*-butylphenol (**10**) were prepared as previously reported.[13] The 1,2-bis[3-(*o*-carboxyphenoxy)-propoxy]-4-*t*-butylbenzene (**1**)[22] and 1-[3-(*o*-carboxyphenoxy)propoxy]-2-[3-(8-quinolyloxy)propoxy]-4(or 5)-*t*-butylbenzene (**5**)[13] which were used in the transport experiment for comparison were also prepared as previously reported. Compounds **2**—**4**, with long polyether chains, were prepared by the reaction process shown in Scheme 1.

1,3-Bis[1-[2-(*o*-carboxyphenoxy)propoxy]-4(or 5)-*t*-butylphenoxy]propane (2). A mixture of 1.9 g (5 mmol) of 2-[3-(*o*-ethoxycarbonylphenoxy)propoxy]-4(or 5)-*t*-butylphenol (**10**) and 0.56 g (5 mmol) of potassium *t*-butoxide was stirred in 30 ml of DMF until it became homogeneous. To the solution we then added 2.3 g (5 mmol) of 1-[3-(*o*-ethoxycarbonylphenoxy)propoxy]-2-(3-chloropropoxy)-4(or 5)-*t*-butylbenzene (**9**) and a small amount of KI, after which the mixture was stirred at 80 °C for 24 h. Then, after cooling, 150 ml of water was added to the solution after and extraction with benzene (100 ml) was carried out. The benzene layer was washed with water three times and dried with $MgSO_4$. After the removal of the benzene, the residue was submitted to column chromatography on silica gel, with ethyl acetate–hexane as the eluent, to give 1.4 g (36%) of the ethyl ester of **2** as a viscous, clear oil. A solution of the diethyl ester of **2** (1.0 g, 1.3 mmol) in ethanol (70 ml) and potassium hydroxide (0.5 g) was mixed and heated at reflux overnight. After the solvent has evaporated, water (100 ml) was added. The aqueous phase was acidified with concentrated hydrochloric acid and extracted with chloroform (3×50 ml). The combined organic phase was washed with water, dried with $MgSO_4$, and evaporated. The residue was submitted to column chromatography on silica gel, with chloroform–ethanol as the eluent, to give 0.8 g (85%) of **2** as a pale yellow, glassy solid: IR (KBr) 3300 and 2600 (COOH), 1735 and 1700 (C=O), 1605 and 1580 (aromatic C=C), 1055 cm^{-1} (C–O); ^1H NMR ($CDCl_3$) δ=1.29 (18H, s, $C(CH_3)_3$), 2.0—2.6 (6H, m, $OCH_2C\underline{H}_2CH_2O$), 4.0—4.7 (12H, m, $OC\underline{H}_2CH_2C\underline{H}_2O$), 6.8—7.8 (12H, m, aromatic), 8.17—8.4 (2H, m, aromatic); UV ($CHCl_3$), λ_{max}=283 nm, ε=10000. Found: C, 70.25; H, 6.98%. Calcd for $C_{43}H_{52}O_{10}$ (MW 728.88): C, 70.86; H, 7.19%.

1,2-Bis[3-[2-[3-(*o*-carboxyphenoxy)propoxy]-4(or 5)-*t*-butylphenoxy]propoxy]-4(or 5)-*t*-butylbenzene (3). A mixture of 3.7 g (10 mmol) of 2-[3-(*o*-ethoxycarbonylphenoxy)propoxy]-4(or 5)-*t*-butylphenol (**10**) and 1.1 g (10 mmol) of potassium *t*-butoxide was stirred in 30 ml of DMF until it became homogeneous. To the solution we then added 1.6 g (5 mmol) of 1,2-bis(3-chloropropoxy)-4-*t*-butylbenzene (**7**) and a small smount of KI, after which the mixture was stirred at 80 °C for 48 h. After the same post-treatment as in the case of **2**, 1.5 g (32%) of the ethyl ester of **3** was obtained as a viscous, pale yellow oil. In a manner similar to the hydrolysis described above, **3** (1.2 g, 85%) was obtained as a pale yellow, glassy solid: IR (KBr) 3300 and 2500 (COOH), 1740 and 1700 (C=O), 1605 and 1580 (aromatic C=C), 1050 cm^{-1} (C–O); ^1H NMR ($CDCl_3$) δ=1.30 (27H, s, $C(CH_3)_3$), 2.0—2.6 (8H, m, $OCH_2C\underline{H}_2CH_2O$), 4.0—4.7 (16H, m, $OC\underline{H}_2CH_2C\underline{H}_2O$), 6.8—7.8 (15H, m, aromatic), 8.2—8.45 (2H, m, aromatic); UV ($CHCl_3$) λ_{max}=282 nm, ε=12000. Found: C, 71.23; H, 7.84%. Calcd for $C_{56}H_{70}O_{12}$ (MW 935.16): C, 71.93; H, 7.55%.

1,2-Bis[3-[2-[3-[2-[3-(*o*-carboxyphenoxy)propoxy]-4(or 5)-*t*-butylphenoxy]propoxy]-4(or 5)-*t*-butylphenoxy]propoxy]-4(or 5)-*t*-butylbenzene (4). A mixture of 1.7 g (10 mmol) of *t*-butylcatechol (**6**) and 2.3 g (20 mmol) of potassium *t*-butoxide was stirred in 50 ml of DMF under a nitrogen atmosphere until it became homogeneous. To the solution we then added 10 g (31 mmol) of 1,2-bis(3-chloropropoxy)-4-*t*-butylbenzene (**7**) and a small amount of KI, after which the mixture was stirred at 80 °C for 24 h. After the post-treatment described above, 3.1 g (42%) of 1,2-bis[3-[2-(3-chloropropoxy)-4(or 5)-*t*-butylphenoxy]propoxy]-4(or 5)-*t*-butylbenzene (**11**) were obtained. Then a mixture of 2.8 g



Scheme 1.

(7.5 mmol) of 2-[3-(*o*-ethoxycarbonylphenoxy)propoxy]-4-(or 5)-*t*-butylphenol (**10**) and potassium *t*-butoxide (0.85 g, 7.5 mmol) was stirred in 50 ml of DMF until it became homogeneous. To the solution we then added 1.8 g (2.5 mmol) of **11** and a small amount of KI, after which the mixture was stirred at 80 °C for 48 h. After the same post-treatment, 1.2 g (34%) of the ethyl ester of **4** were obtained. The hydrolysis of the ethyl ester as described above gave **4** (0.9 g, 78%) as a pale yellow, glassy solid: IR (KBr) 3300 and 2550 (COOH), 1740 and 1700 (C=O), 1605 and 1580 (aromatic C=C), 1050 cm^{-1} (C-O); ^1H NMR ($CDCl_3$) δ=1.30 (45H, s, $C(CH_3)_3$), 2.0—2.6 (12H, m, $OCH_2\underline{C}H_2\underline{C}H_2O$), 4.05—4.7 (24H, m, $OC\underline{H}_2CH_2C\underline{H}_2O$), 6.9—7.8 (18H, m, aromatic), 8.25—8.5 (2H, m, aromatic); UV ($CHCl_3$) λ_{max}=282 nm, ε=17000. Found: C, 72.69; H, 8.26%. Calcd for $C_{82}H_{106}O_{16}$ (MW 1347.73): C, 73.08; H, 7.93%.

General Procedure of Cation Transport. Reagents: Chloroform (extra-pure grade) was used without further purification. Each aqueous solution which was used in either the source or receiving phase was prepared by the dilution of one normal alkali hydroxide and/or one normal acid.

Procedure: A U-type or H-type glass tube as previously reported was used for measuring the transport of alkali metal ions.[13] In the case of the use of chloroform as the membrane solvent, a U-type glass tube was used. First, 30 ml of chloroform containing the carrier (0.03—0.15 mmol) was poured into the tube. Then, 15 ml of a solution of 0.1 M† LiOH+0.1 M NaOH+0.1 M KOH+0.1 M H_2SO_4 and 15 ml of a solution of 0.05 M H_2SO_4 were simultaneously poured into the source and receiving phases respectively. The tube was then placed in a water bath whose temperature was kept at 25±0.2 °C. Each phase was agitated at 200 min^{-1} mechanically with a pair of glass stirrers. On the other hand, in the case of the use of toluene, an H-type glass tube was used. In this case, first the aqueous solution containing metal hydroxides described above and an acidic solution (0.05 M H_2SO_4) were poured into the source and receiving phases respectively. Subsequently, a 30-ml portion of chloroform containing the carrier was poured into the tube.

The transport of cations was initiated by the addition of the solutions and by then stirring each phase. At each time point, 50 μl of the solution was withdrawn from each aqueous phase and the concentration of each cation was adjusted by using a measuring flask and determined by means of a Shimadzu AA-646 atomic absorption spectrometer.

The transport of cations in the blank systems was negligible. The detailed conditions are shown in the table.

Extraction of Cations. Polyether (0.05 mmol) was added to 5 ml of a 0.1 M LiOH aqueous solution in a 30-ml Erlenmeyer flask. The mixture was stirred overnight at room temperature. Then, 10 ml of chloroform was added to it. After the mixture had been vigorously stirred for 6 h, the amounts of the lithium salt of the polyethers in the aqueous solution were measured by means of the UV spectrum.

Results and Discussion

Cation Transport through Liquid Membranes. Cation transport through liquid membranes was carried out by using the **2**—**4** carriers, and also for the sake of comparison, **1** and **5** which were previously reported. Figure 2 shows the plots of the amounts of cation transported versus the running time in the case of carrier **4**, which has five repeating units of the 2-propoxy-4(or 5)-*t*-butylphenoxy group. Apparently, among the three alkali metal ions, the lithium ion can be transported with the most appreciable selectivity in the competitive transport. The cation transport by this carrier ceased within 1 day under these conditions because of the pH-decrease in the source phase. The results for cation transport by **1**—**5** are summarized in Table 1. Carrier **1**, which has the shortest chain structure, with two carboxyphenyl terminal groups, transported hardly any alkali metal ions although **1** can selectively transport either Ca^{2+} or Mg^{2+}, depending on the transport conditions[24] It should be noted that the longer the polyether chain, the better the ability of transport for monovalent cations, especially the lithium ion, by carriers which have two

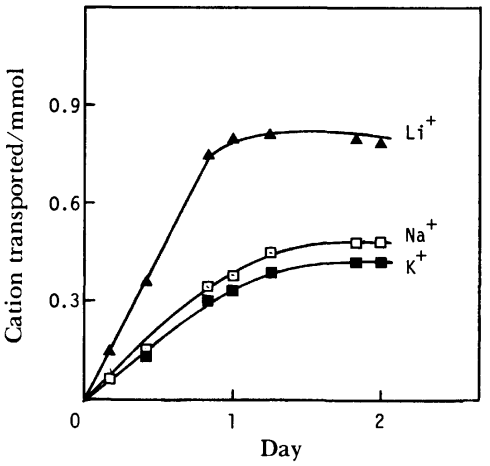


Fig. 2. Plots of amounts of cation transported by carrier **4** vs. the running time.

Table 1. Cation Transport through Liquid Membranes

Carrier	Transport rate/μmol h^{-1}			Selectivity	
	Li	Na	K	Li/Na	Li/K
1	0.1	<0.1	0	—	—
2	11.3	3.4	2.6	3.3	4.3
3	35.6	18.7	16.9	1.9	2.1
4	36.6	15.0	13.1	2.4	2.8
5	18.8	6.3	3.4	3.0	5.5

Reproducibility: ±10% or better.
Initial transport conditions (25 °C):

carboxyphenyl terminal groups. Carrier **5**, which can selectively transport the lithium ion, as has previously been reported,[13] exhibits the selectivity ratios of Li/Na=3.0 and Li/K=5.5 under these transport conditions. Carrier **2**, with a relatively short chain, has a small cation-transport rate compared with carrier **5**, which has one carboxyl group, whereas carriers **3** and **4**, which have longer polyether chains, show a more than 2-fold enhancement in the transport of monovalent cations over **5**. However, the lithium-ion selectivity has a tendency to be reduced as the polyether chain lengthens. The lithium-ion transport rate by **3** and **4** is nearly two times larger than that by **5**. It is presumed that the two carboxyl groups on **3** and **4** act effectively in cation transport. That is, it is probable that one carrier has the ability to carry two cations at the same time in the case of carriers **3** and **4**. The relatively long polyether chain in these carriers, which can form a looser conformation for the uptake of cations, may be responsible for the increase in the ability of sodium- and potassium-ions transport.

In Table 2, the influence of the carrier concentration and the liquid-membrane solvent on the cation transport are summarized. The greater the concentration of **4** in chloroform, the larger both the transport rate and the amounts of cations transported after 2 days. When toluene was used as the liquid-membrane solvent in the H-type glass tube, the transport rates of cations by **4** are relatively small compared with those in the same concentration of **4** in chloroform (see Runs 2 and 3 in Table 2). However, it should be noted that appreciable cation transport by **4** through toluene (Run 3) can occur, whereas **5** in toluene transports scarcely no cations. This means that carriers with long polyether chains, such as **4**, can selectively transport lithium ion even in the more nonpolar solvent, toluene.

Thus, it is noteworthy that compounds **3** and **4**, with relatively long polyether chains can exhibit the selective transport of the lithium ion, which has the smallest naked ion radius among alkali metal ions. We have proposed the hypothesis that carrier **5** forms a pseudocyclic conformation to pass through an organic solvent, and that then the ion (i.e., the lithium ion), which can be well incorporated into the pseudocavity[13], can be selectively transported. Can compounds **3** and **4**, with long polyether chains, form such a conformation? The length between the two carboxyl groups of **1** is too short to take the conformation incorporating the lithium ion. In this case, the electrostatic repulsion between the two terminal carboxylato anions occurs inevitable when **1** forms a complex with two lithium ions. In the case of **2**, with a polyether chain of an intermediate length, it is also difficult for the carrier to wrap two lithium ions at the same time. Nevertheless, it is possible for one cation to be incorporated by **2**, though the salt of **2** with the lithium ion might not have enough solubility in organic solvents. Therefore, the transport ability of **2** is considered to decrease compared with that of **5**. On the contrary, carriers **3** and **4** are expected to have chains long enough to be able to wrap two lithium ions inside the pseudocavity formed. Recently, Nakahama et al. have also reported that a synthetic carboxylic ionophore with eight ether oxygens and five aromatic rings can complex with the potassium ion, and that the resulting complex has a coiled conformation, with coordination of the ether oxygen atoms to the potassium ion. This was presumed by means of the NMR spectrum.[25]

From these results, it can be inferred that the lithium complex of carriers **3** and **4** becomes more lipophilic than that of **1** and **2**. The lithium-ion complexes of **3** and **4** can be expected to dissolve more easily in an organic solvent than in water because of their lipophilicity. Therefore, their ability of cation extraction was investigated.

Cation Extraction. All carriers except **4** (0.05 mmol) are completely soluble in 5 ml of an aqueous solution containing 0.1 M LiOH after it has been stirred overnight at room temperature. Carrier **4**, with sufficiently hydrophobic groups, is insoluble in such a solution, while carrier **3** becomes foamy on the surface of an aqueous solution; that is, **3** seems to have surface activity. Then, chloroform (10 ml) was added to this alkaline solution or mixture containing the carrier, and the mixture was stirred. After that, the amounts of lithium salt of carriers remaining in the aqueous solution were determined by means of the UV spectrum. It was confirmed that one polyether formed

Table 2. Effects of Carrier Concentration and Membrane Solvent on the Cation Transport

Run	Concn of carrier	(mM)	Membrane solvent	Transport rate/μmol h^{-1} Li	Na	K
1	**4**	1.0	$CHCl_3$	5.5	1.7	1.3
2	**4**	2.5	$CHCl_3$	13.1	4.4	3.0
3	**4**	2.5	Toluene	9.7	4.4	3.4
4	**4**	5.0	$CHCl_3$	36.6	15	13.1
5	**5**	5.0	Toluene	0	0	0

Initial transport conditions: see Table 1.
Reproducibility: ±10% or better.

Table 3. Partition of Li^+ Salt of Polyethers between Aqueous and Chloroform Phases

Polyether	**1**	**2**	**3**	**4**	**5**
In aqueous phases/%	100	51	8	≈3	≈1

Initial conditions
Aqueous phase: 5 ml of 0.1 M LiOH solution.
$CHCl_3$ phase: 10 ml of $CHCl_3$ containing 0.5×10^{-4} mol of carrier.

salts with two lithium ions under these conditions. These results, shown in Table 3, are in good agreement with favorably those of the cation transport. Two equimolar lithium salts of **1** are not at all removed from the aqueous to the chloroform phase. The lithium salt of **2** has small solubility in chloroform. On the contrary, carriers **3** and **4** can extract two equimolar lithium ions almost quantitatively from aqueous to chloroform phase. Carrier **5**, with one carboxyl group, can also extract the lithium ion completely to the chloroform phase. These results reflect the cation-transport rate and the amounts of cation transported, as is shown in Table 1.

Figure 3 depicts the plots of the initial lithium ion-transport rate and the partition ratio of lithium salt of carriers between chloroform and aqueous solutions versus the number of ether oxygen atoms of each carrier. Apparently carriers **3** and **4** are superior to carriers **1** and **2** in both the distribution to chloroform and in the ability of lithium ion transport through liquid membranes.

Conformations of Cation Salts of Carriers in Chloroform. As has been indicated for the cation transport and cation extraction, **3** and **4** exhibited an appreciable selectivity toward the lithium ion, although **3** and **4** have rather long polyether chains, containing 8 and 12 ether oxygens respectively. Furthermore, carriers **3** and **4** can transport about twice as many cations as the polyether monocarboxylic acid **5** and can capture two equivalent lithium ions at the same time by means of the two carboxyl terminal groups.

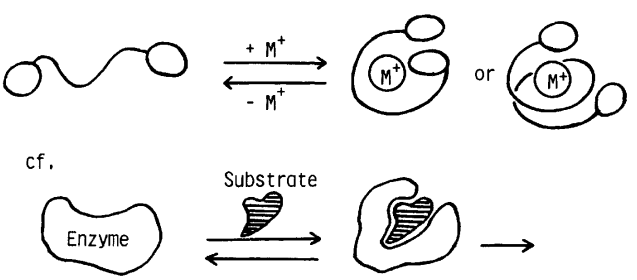
Figure 4 shows the signal for the methyl protons on three *t*-butyl groups in **3** and its lithium salt. One sharp singlet for the methyl protons in free **3** becomes appreciably broad, when free **3** becomes its lithium salt. It can be inferred that the splitting of the proton signal for *t*-butyl groups is attributable to the proton-nonequivalency of each *t*-butyl group when **3** forms a complex with the lithium ion in chloroform. Such a change in the NMR spectrum was also observed in the case of carrier **4**. Additionally, a study of the NMR spectra confirms that the lithium salts of **3** and **4** do not contain water.

From these results, we would like to propose that **3** and **4** take the conformation shown in Fig. 5, where

two lithium ions become incorporated into the pseudocavity formed and can selectively transport lithium ions through liquid membranes. When the carriers take such a conformation, the protons for the *t*-butyl groups situated adjacent to the carboxyl terminal groups and those in the middle position seem to be at least nonequivalent. Therefore, the lithium salts can dissolve in a hydrophobic solvent and transport lithium ions selectively. An inspection of the CPK models suggests the formation of a small pseudocavity in which the lithium ion best fits. However, in carrier **1**, with the shortest polyether chain, electrostatic repulsion between lithium salts of two terminal carboxylato groups results in the deformation of the pseudocavity. Therefore, water molecules around the lithium ion presumably cannot be removed, and the salt of **1** does not dissolve in organic liquid membranes. Because the lithium salt of carrier **2**, with a medium chain length, is soluble in the organic phase, at least to some extent, it is considered that **2** can transport cations, although the ability of ion-transport is smaller even than that of monocarboxylic acid **5**.

Conclusion

Thus, we could show that compounds with rather long polyether chains can recognize the lithium ion as a guest, accompanied by a drastic conformational change. Cyclic polyether (crown ethers), cryptands, and spherands,[26] which have a preorganized cavity, can selectively incorporate ions which fit well inside. On the contrary, the noncyclic compounds with long polyether chains used in this study can wrap around cations by changing their conformation, as is shown in Scheme 2. Such a conformational change accompanies a large energetic loss and causes a decrease in the complex stability and in the rate of cation uptake compared with those of preorganized compounds. Such a dynamic conformational change reminds us of the induced-fit theory in enzymatic reactions proposed by Koshland,[27] although an enzyme has a much larger molecular weight and can recognize a substrate much more precisely compared with the noncyclic polyethers reported here.



Scheme 2.

It should be noted that the selectivity for cations can change when the chain structures on the carriers change appropriately. In this study, the chain structures containing oxytrimethylene groups can result in the lithium-ion selectivity, whereas those containing oxyethylene groups can exhibit potassium- ion selectivity, as has been reported by Nakahama et al.[25] Thus, the importance of the chain structure in producing ion-selectivity should also be pointed out.

(Received March 31, 1987)

The behavior in vitreous silica of hydrogen isotopes, which had been introduced by 80-keV D^+-ion implantation, thermal D_2 doping, or recoil tritium implantation (2.7 MeV), was studied by means of FT-IR spectroscopy, ESR spectroscopy, and radioassay with a liquid scintillation counter. The hydrogen isotopes are trapped by forming hydroxyl bonds (OD, OT). In the D^+-ion implantation, OD bonds are formed mainly by the rupture of the ≡Si-O-Si≡ bonds. In the thermal D_2 doping, however, OD bonds are formed mainly by the isotope-exchange reaction between the preexisting OH bonds and D_2 molecules. When vitreous silica implanted by recoil tritium is heated to about 1150 K, HTO and HT are released. The OD bonds produced by D^+ implantation decrease upon annealing at 1150 K. The OD bond-rupture is controlled by the diffusion of hydrogen isotopes trapped as OD(OT) bonds to the surface of vitreous silica. The mechanism of the diffusion of the hydrogen isotopes through vitreous silica was explained in terms of a repetition of the chemical reaction of ≡SiOD(OT)+≡SiOSi≡ ⟶ ≡SiOSi≡+≡SiOD(OT). The diffusion coefficient (D_T(HTO)) of tritium according to the above mechanism was obtained as:

$$D_T(\mathrm{HTO}) = 2.3 \times 10^{-4} \exp[-1.7 \times 10^2(\mathrm{kJ\ mol^{-1}})/RT]\ \mathrm{cm^2\ s^{-1}}$$

Nonmetallic materials are used in fusion reactors as tritium diffusion barriers, first-wall coatings, or diagnostic window materials for the reactors. Hydrogen generally diffuses much more slowly in oxides than in metals. The first-wall materials are irradiated with high-energy tritium, neutrons, and high levels of γ-rays. The high energy tritium, injected into the material, is trapped there or diffuses through the material. In order to prevent tritium fuel from permeating through the fusion material, it is very important to elucidate the interactions between the high-energy hydrogen and the material.

Previous studies of the interaction, however, have been concerned mainly with the physical interaction, such as the sputtering of the solid surface, the production of radiation damage, and a depth-profile of the injected hydrogen. Since hydrogen isotopes are reactive species, the chemical interactions between injected hydrogen and the materials also play a significant role. The chemical interactions consist of several microscopic processes, such as hydrogen trapping, detrapping, diffusion, and desorption. The role of chemical reactions in these processes is shown in Fig. 1. Though physical interactions are not neglected in these processes, they are omitted from Fig. 1. When hydrogen isotopes with a high energy are injected into a material, they are trapped by the formation of chemical bonds. Since the first-wall material is held at a high temperature or under the high radiation field, the hydrogen isotopes are detrapped by the rupture of the chemical bonds and diffuse through the material to its surface, where the diffusion involves a chemical reaction in some cases. The hydrogen isotopes are released from the surface by surface reactions. Since the chemical interactions have been studied in only a few cases, the chemical

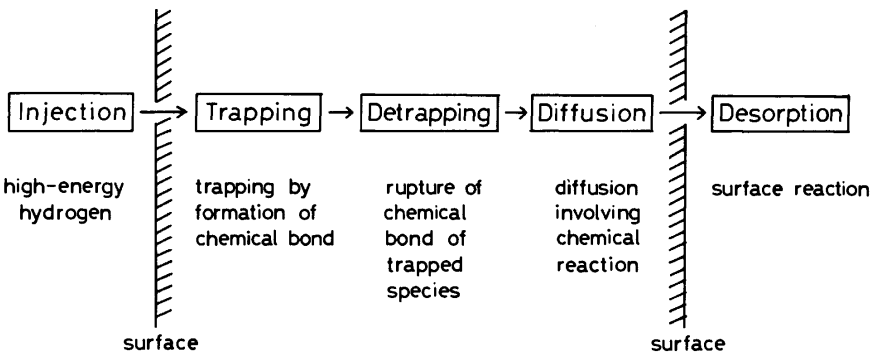

Fig. 1. The role of chemical interactions between high-energy hydrogen and materials.

interactions between hydrogen isotopes and vitreous silica (silica) will be reported here.

Silica, one of the most popular oxides, has the following characteristic properties: a relatively simple structure, a high softening point, transparent properties, a low cross-section for neutron-capture reactions, and a high activation energy for tritium diffusion.[1] In addition, the impurity content of silica can be controlled. Since the presence of OH bonds may affect the chemical interactions of hydrogen isotopes, the concentration of the OH bonds in silica was varied from 5 to 4000 ppm in this study. Several studies of silica have been reported previously. The compaction effects on silica by irradiation were reviewed by Primak.[2] The diffusion of hydrogen isotopes in silica have also been studied,[3,4] as has the hydrogen-ion implantation in SiO_2.[5,6] The presence of the radiation damage produced by the ion-implantation protects the radiation-induced detrapping of D atoms.[6] Moreover, the kinetic behavior of H and D atoms in silica has been investigated by means of ESR spectroscopy.[7]

In this study, hydrogen is introduced into silica by 80-keV D^+-ion implantation, 2.7 MeV-recoil tritium implantation, and D_2 gas-doping at high temperatures. The interaction between the hydrogen isotopes and silica was studied here by means of infrared Fourier transform spectroscopy (FT-IR), electron spin resonance spectroscopy (ESR), and tritium analysis using a liquid scintillation counter. Since it is difficult to elucidate the microscopic processes in Fig. 1 by using only one method, we have here studied these processes by a combination of the several methods mentioned above. The elucidation of the following problems is the main purpose of this study: (1) It was reported previously[8,9] that D_2 gas is trapped thermally in silica to form OD bonds by an isotope-exchange reaction between preexisting OH bonds (as inherent impurities) and D_2. Is the efficiency of the trapping of deuterium or tritium, injected with a high energy, affected by the preexisting OH bonds? If deuterium with a high energy is trapped to form OD bonds,[6] what is the mechanism of the formation of the OD bonds? (2) The deuterium and tritium trapped as OD (OT) bonds are released by thermal heating above 700 K. What is the mechanism of the release of hydrogen isotopes from the trapping sites? (3) How much is the value of the diffusion coefficient of tritium in silica?

Experimental

The four types of vitreous silica used here are Spectrosil, obtained from the Thermal American Fused Quartz Co.; Fused silica glass, obtained from the Asahi Glass Co., and Silica T1030 and Silica T2230, obtained from the Toshiba Ceramic Co. The concentrations of preexisting hydroxyl bonds in the four kinds of silica range from 5 to 4000 ppm.[10] The OH-bond concentration of the sample was measured by means of an infrared Fourier transform spectrometer (FT-IR)[11] at room temperature. It was estimated from the O-H stretching band at 3670 cm^{-1} [8,9] taking the extinction coefficient at the wavenumber as 77.5 l/mol cm.[12] The amounts of the OH bond and metal impurities[13] contained in the samples are summarized in Table 1. The samples which contain the OH bonds at 5, 610, 960, and 4000 ppm will be denoted hereafter as silica A, B, C, and D respectively. The samples for deuterium implantation were cut in the form of plates measuring 3.3×9×0.3 mm, while those for tritium implantation were cut in the form of plates measuring 5×10×1 mm.

The deuterium implantation was performed with a low-energy ion accelerator which has previously been described in detail.[14] Deuterium ions accelerated to 80-keV were injected into the target at an ion-beam flux of 2.5×10^{14} ions $s^{-1}cm^{-2}$. The compositions of the deuterium ions were D^+(78%), D_2^+(13%), and D_3^+(9%). The total deuteron fluence was 2.7×10^{18} D/sample. The sample chamber was evacuated to 10^{-5} Pa during irradiation.

The tritium implantation was performed by the use of recoil tritium atoms from the reaction of ^6Li (n, α) T, where ^6Li-enriched lithium chloride was used as the tritium source. It was prepared from lithium metal obtained from Oak Ridge National Laboratory; the ^6Li content was 95%. An aliquot of lithium chloride solution was dried on a 7×12×1 mm polyethylene plate. Then it was wrapped with a mylar sheet. The wrapped plate was tightly attached to the sample. The assembly was put into a quartz ampoule which was sealed in vacuo. The ampoules were irradiated by neutrons in the JRR-4 reactor in JAERI for 10 min at the ambient temperature. The thermal neutron flux was 8×10^{13} n_{th} cm^{-2} s^{-1} at the irradiation port. The amount of tritium activity doped in the sample was about 37 kBq (1 μCi).

Thermal-deuterium doping was performed by the

following method. The sample was saturated with D_2 gas of 7.5×10^5 Pa for 280 h at 723 K or for 1—5 h at 923—1173 K.

After deuterium-implantation or thermal-D_2 doping, the infrared absorption spectra of the sample were measured at room temperature with an infrared Fourier transform spectrometer.[11] The ESR spectra of the sample were also measured at 77 K with an ESR spectrometer.[15] In the study of the thermal desorption of trapped deuterium, the samples were held for 6 h at 1173 K in vacuo.

After tritium implantation, the sample was heated at a constant rate (5 K min^{-1}) from room temperature to 1373 K and was then held for 180 s at the maximum temperature. The HTO and HT released during the annealing were measured.[16] Then the release rate of the HTO and HT components were calculated as a function of the heating temperature. The device for the isochronal annealing of the tritium-implanted sample has previously been described in detail.[17] The tritium component, which remained in the sample even after the thermal treatment, was measured by means of a liquid scintillation counter after the sample has been chemically etched by using a hydrofluoric acid solution.

In order to measure the initial distribution of tritium contained in a tritium-implanted specimen, the samples were gradually etched from the surface by 2% hydrofluoric acid to release the trapped tritium. The distribution of tritium in the sample was determined by measuring both the released tritium and the thickness of the sample. In this measurement, the amount of tritium was radioassayed by the use of a liquid scintillation counter.

Results

When hydrogen isotope was injected into silica, the spatial distribution and the range of the trapped hydrogen depend on both the injection energy and the injection method. Figure 2 shows the results of chemical-etching experiments on tritium-implanted silica. The experimentally measured range of recoil tritium with 2.7 MeV is about 39 μm, which coincides with the calculated value (39 μm) for recoil tritium in SiO_2.[18] The distribution of the recoil-injected tritium into the silica shows a linearly decreasing distribution with the distance from the surface.

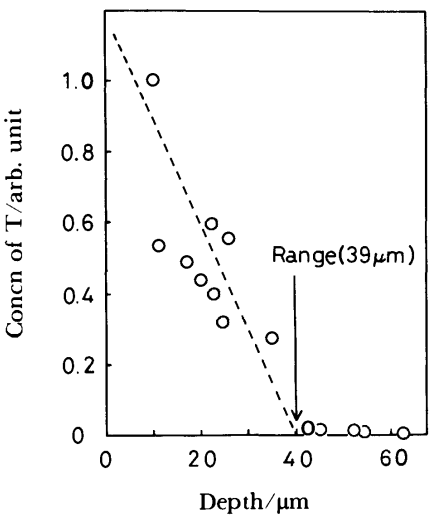

Fig. 2. Depth profile of tritium-implanted silica by ^6Li (n, α)T (2.7 MeV) reaction.

In the 80-keV D^+-ion implantation, we did not measure the distribution of the trapped deuterium. The trapped depth of the deuterium was calculated, using the TRIM code,[19] as about 0.5 μm from the surface. According to the study of 20-keV D^+ implantation in vitreous silica by Arnold et al.,[5] the deuterium is trapped between 0.2 and 0.5 μm from the surface.

In the thermal-D_2 doping, the distribution of the trapped deuterium can be expressed by a model of a tarnishing reaction,[20,21] in which the range (d) of trapped deuterium from the surface in the partially deuterated silica is estimated by the use of Eq. 1:

$$d = L \cdot C/(2C_f) \quad (1)$$

where L, C, and C_f are the thickness of silica, the concentration of OD bonds of partially deuterated silica, and the OD concentration of completely deuterated silica respectively. The ranges of the trapped deuterium in this study were varied from 7 to 125 μm from the surface by controlling the amount of deuteration at 923 K, where a model of the tarnishing reaction can be applied.[21]

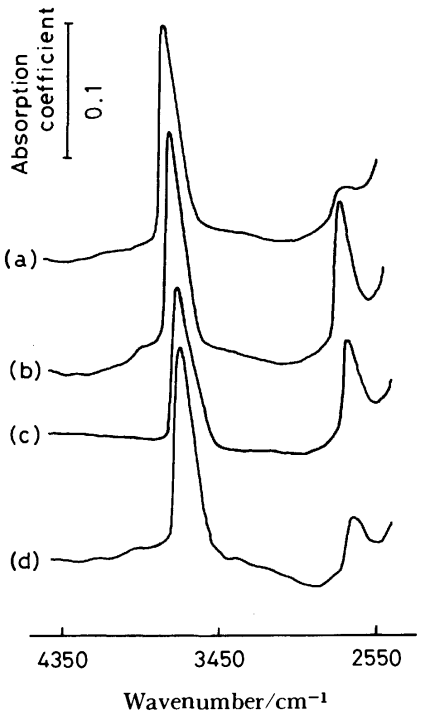

Fig. 3. Infrared absorption spectra of fused silica B (OH 610 ppm). (a) Before deuterium treatment, (b) after 80-keV D^+ ion implantation, (c) after thermal D_2 doping in which silica was stored in 7.5×10^5 Pa gas at 723 K, and (d) after annealing the sample of Fig. 3(b) at 1173 K for 6 h.

Figure 3(a) shows the infrared absorption (IR) spectrum of silica B before deuterium treatment. The absorption band at 3670 cm^{-1} in the figure is the O-H stretching band, which agrees with the previously reported values (3690,[8] 3640[9] cm^{-1}) of the O-H stretching band. When the silica is implanted with 80-keV D^+ ions or doped by D_2 gas at a high temperature, OD bonds are formed.[6] In a previous study,[6] however, the amount of deuteration was very small. In order to examine the effect of deuteration on the preexisting OH bonds, the OD bonds were produced in very high yields in this study. Figure 3(b) shows an IR spectrum of silica B after 80-keV D^+-ion implantation. The appearance at 2670 cm^{-1} of the absorption band, which is identified as the O-D stretching band in silica on the basis of previous studies,[6,8,9] indicates the formation of OD bonds in the sample by the ion-implantation, while the amounts of the preexisting OH bonds are not changed by the OD-bond formation. Figure 3(c) shows an IR spectrum of silica B after thermal-D_2 doping at 723 K for 280 h. The absorption band at 2670 cm^{-1} indicates the formation of OD bonds by such treatment in silica B, where the amounts of the OH bonds decrease. The amount of OD bonds in the silica was estimated from the intensity of the O-D stretching band at 2670 cm^{-1}, where the extinction coefficient (ε_{OD}) of the OD band was taken as $0.53 \times \varepsilon_{OH}$.[22] Figure 3(d) shows the spectrum of the sample of Fig. 3(b) after annealing at 1173 K for 6 h. The amounts of OD bonds decrease drastically upon the thermal annealing.

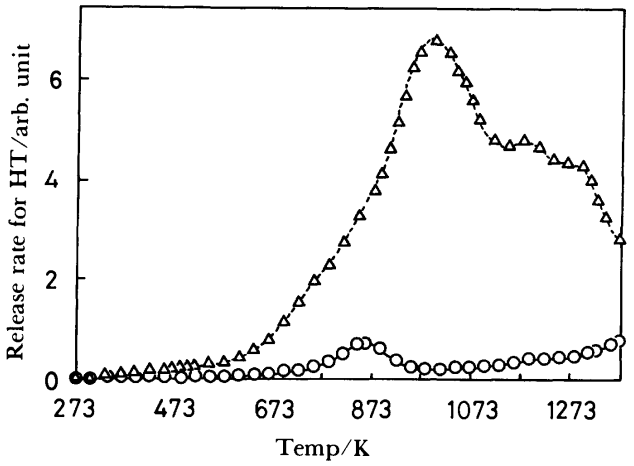

Fig. 4. Release spectra of HT in annealing at the same heating rate (5 K min^{-1}) from T-irradiated silica A (OH 5 ppm: Δ----Δ), and from T-irradiated silica D (OH 4000 ppm: O—O).

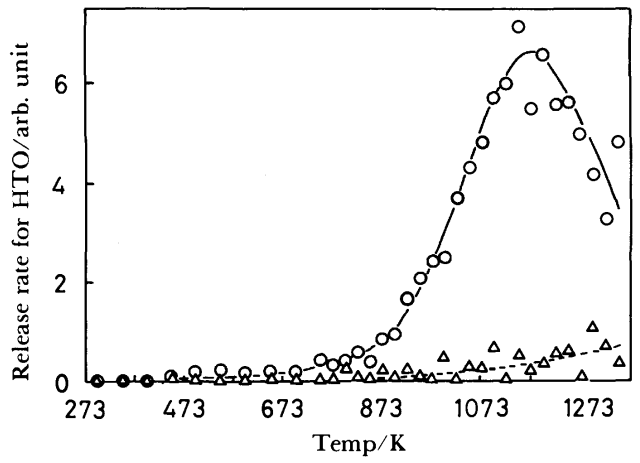

Fig. 5. Release spectra of HTO in annealing at the same heating rate (5 K min^{-1}) from T-irradiated silica A (OH 5 ppm: Δ----Δ), and from T-irradiated silica D (OH 4000 ppm: O—O).

When the recoil tritium-implanted silica is heated at a high temperature, the trapped tritium is released from the silica as HT and HTO. Figure 4 shows the releasing behavior of HT from tritium-implanted silica A and D at a heating rate of 5 K min^{-1}. The evolution of HT begins around 700 K and reaches a peak at 970 K.

Figure 5 shows the releasing behavior of HTO from tritium-implanted silica A and D at the same heating rate as that in Fig. 4. HTO is released gradually around 900 K and reaches a peak around 1150 K. It can be seen from the results in Figs. 4 and 5 that tritium from silica A, which contains OH bonds at 5 ppm, is released almost entirely as HT, whereas tritium from silica D, which contains 4000-ppm OH bonds, is released as HTO.

Discussion

Trapping of Hydrogen Isotopes in 80-keV D^+-Ion Implantation, Thermal D_2 Doping, and Recoil T Implantation.

1. Trapping Efficiency and Preexisting Hydroxyl Bonds. When deuterium is injected into silica by 80-keV D^+ implantation or thermal D_2 doping deuterium is trapped by the formation of OD bonds (cf. Figs. 3(b) and 3(c)). The hydroxyl-bond formation by ion implantation and hydrogen gas-doping was reported previously.[5,6] The OD-bond formation may be the main trapping process in the D^+-ion implantation for the following reasons. First, since trapped D atoms were not observed in the D^+ ion-implanted silica by ESR spectroscopy, deuterium must be trapped in silica by the formation of a chemical bond. Second, the SiD-bond formation is another possible process of trapping. The IR absorption spectrum of SiD bonds is expected to appear around 1600 cm^{-1},[23] but the spectrum of the SiD bonds could not be observed in D^+-implanted silica (silica B), not even by the subtraction of the spectrum of silica before the implantation from that after the implantation. Third, the total amount of OD

bonds in D^+-implanted silica is about 2.4×10^{21} bonds cm^{-3}, which is approximately the same as the saturation value (2.1×10^{21} D atoms cm^{-3})[5] of the total trapped deuterium in D^+-implanted silica. Fourth, when T-implanted silica is heated, HT is released at a high temperature such as 970 K. If HT molecules are trapped physically in the implanted silica, HT is released, probably at a much lower temperature. Thus, tritium is not trapped as hydrogen molecules after T-implantation. HT is produced by some chemical reaction upon thermal annealing.

The effect of preexisting OH bonds on the deuterium-trapping has been studied here by the use of silica containing the OH bonds at different concentrations. The relative yields of OD bonds produced by D^+ implantation and D_2 doping are summarized in Table 2, where the yields in silica A is taken as 1.0. A radiation-damage center produced by 80-keV D^+-implantation can be observed clearly by means of ESR spectroscopy.[6] The relative yields of the radiation-damage center, also shown in Table 2, do not depend on the OH-bond concentration. In the recoil tritium-implantation, the total amount of tritium trapped in silica can be measured by the use of a liquid scintillation counter after the irradiated sample has been etched. The relative yields of the total trapped tritium are also shown in Table 2. The total amounts of trapped tritium are almost independent of the concentration of preexisting OH bonds. The yields of the OD bonds produced by D^+-implantation also do not depend on the concentration of preexisting OH bonds. In the thermal D_2-gas doping, however, the yields of OD bonds increase with an increase in the preexisting OH bonds, though the OD-bond yields are not linearly proportional to the concentration of the OH bonds.

2. Mechanism of Trapping Reaction. The production of OD bonds is an important process for the trapping of deuterium in the D^+-ion implantation or the D_2-gas doping. The injected D^+ ions are neutralized in the silica and change into D atoms. Thus, the production mechanisms of the OD bonds in the D^+-implantation and the D_2-doping may be given as follows:

$$\equiv\text{Si-O-Si}\equiv + D(D_2) \longrightarrow \equiv\text{Si-OD} + P \quad (2)$$

$$\equiv\text{Si-OH} + D(D_2) \longrightarrow \equiv\text{Si-OD} + Q \quad (3)$$

where P and Q are some other products in these reactions. Reaction 2 represents the OD-bond formation by the insertion reaction accompanying the scission of the $\equiv$Si-O-Si$\equiv$ bonds. Reaction 3 represents the substitutional reaction between H in preexisting hydroxyl bonds and $D(D_2)$, where the formation of OD bonds accompanies the decrease in the amount of the OH bonds.[24]

Figures 3(a) and 3(b) show that the amounts of preexisting OH bonds are not affected by the formation of OD bonds in the D^+-implantation, but Figs. 3(a) and 3(c) show that those of the OH bonds decrease in the D_2-gas doping. In order to analyze the results in Figs. 3(a), (b), and (c) quantitatively, the relation between the increase in the OD bonds and the decrease in the OH bonds is shown in Table 3. The values of $-\Delta OH/\Delta OD$ in silica represent the fraction of Reaction 3 to the total OD-bond formation in the deuterium treatment. The formation of OD bonds in the D^+-implantation is not accompanied by a drastic decrease in the preexisting OH bonds. Therefore, in the ion-implantation, hydroxyl bonds are formed mainly by the insertion reaction (cf. Reaction 2). D^+ ions, implanted into silica, are neutralized in silica and so become hot D atoms. The hot atoms may react with $\equiv$Si-O-Si$\equiv$ bonds to form $\equiv$Si-OD bonds. A part of the hot D atoms are thermalized and may react with $\equiv$Si-O radicals, which are produced along the trajectory of hot D atoms by the radiolysis of the $\equiv$Si-O-Si$\equiv$ bond, to form $\equiv$Si-OD bonds. Both possibilities are represented by Reaction 2.

In the D_2-doping, however, about 60% of the OD-bond yields correspond to the decrement of the preexisting OH bonds. Thus, the OD bonds in the thermal doping are produced mainly by the substitu-

Table 2. Trapping of D (T) in Silica

Silica	Impurity		Method of injection[a]			
			80-keV D^+-implantation		Thermal D_2-doping	Recoil T-implantation
	OH ppm	Metal ppm	Yield of radiation damage	Yield of OD bond	Yield of OD bond	Total T yield
Silica A	5	23	1.0	1.0[b]	1.0	1.0[c]
Silica B	610	62	2.1	0.8	3.3	0.9
Silica C	960	23	1.5	0.9	2.5	1.1
Silica D	4000	15	1.2	1.1	5.6	1.4

a) Yields are expressed by relative values. The yield in silica A is taken as 1.0. b) The amount of OD bonds is 1.2×10^{-7} mol/sample. c) The amount of tritium is 1.1 μCi, that is, 3.8×10^{-11} mol/sample.

tional reaction (cf. Reaction 3). Since some metal ions may exist near OH bonds as impurities, D_2 gas may react with the OH bonds by some catalytic effect of the metal ions to form OD bonds.

Release of Trapped Hydrogen Isotopes.

1. Diffusion-Controlled Release of OD Bonds. As is shown clearly in Figs. 3(b) and (d), the amounts of OD bonds produced by the D^+-ion implantation decrease upon the thermal annealing at 1173 K for 6 h to become about 30% of the initial amounts of the OD bonds. The question of whether the process of the detrapping of deuterium from OD-bond sites is a reaction-controlled process or a diffusion-controlled one will be discussed here. In order to solve this problem, the distributions of OD bonds in silica were varied by partial D_2-doping. The silicas with OD bonds distributed at different depths from the surface were annealed at 1173 K for 6 h in vacuo. The efficiency of the decrease in OD bonds by the annealing are shown in Table 4, together with that for the OD bonds produced by D^+-ion implantation and that for the preexisting OH bonds.

If the dissociation reaction of the OD bond is a rate-determining process, the efficiency of the decrease in OD bonds should be independent of the depth of the OD-bond distribution. The results in Table 4, however, show clearly that the efficiency of the decrease depends on the depth of the OD-bond distribution. The efficiency increases with a decrease in the depth of the OD-bond distribution. The D, as OD bonds near the surface, can easily diffuse to the surface and decompose there to form some product, such as HDO. Therefore, it may be concluded that the process of the detrapping of deuterium from OD bond sites, followed by the formation of HDO, is not a reaction-controlled (bond-rupture) process, but a diffusion-controlled one.

2. HTO and HT Formation from Tritiated Silica. In order to detect thermally-released products from hydrogen-implanted silica, tritium analysis is the most convenient method because of its high sensitivity. When silica implanted by recoil tritium is annealed from room temperature to 1373 K, HTO and HT are released from the silica (cf. Figs. 4 and 5). Since HTO is released at a higher temperature (1150 K) than that for HT (970 K), HTO and HT must be produced by different mechanisms.

The amount of OD bonds, which are one of the main trapped species in D^+-implanted silica, decreases upon thermal annealing. Table 5 compares the release of trapped tritium in the recoil T-implanted silica with the decrease in the OD bonds in the D^+-implanted silica. Both the release of the trapped tritium and the decrease in the OD bonds take place efficiently upon heating at 1200—1300 K. If it is assumed that HTO is produced by the thermal decomposition of OT bonds, the HTO formation corresponds to the decrease in the OT bonds in the thermal annealing. Since the decrease in OD bonds is a diffusion-controlled process, the decrease in OT

Table 3. Ratio of Decrement of the OH Bond to the Increment of the OD Bond in 80 keV D^+-Implantation and Thermal D_2-Doping in Silica[a)]

Silica OH/ppm	$-\Delta OH/\Delta OD$	
	80 keV D^+-implantation	Thermal D_2-doping
610	0.1	0.58
960	0.2	0.75

a) $-\Delta OH$ represents the decrement of the amount of preexisting OH bonds on the D^+-implantation or the D_2-doping. ΔOH represents the increment of the amount of OD bonds on the same deuterium treatment.

Table 4. Efficiency of Decrease of the OD Bond and Depth of OD-Bond Distribution from the Surface[a)]

Method of injection	Hydroxyl group	Depth μm	Efficiency of decrease[d)]
D^+-implantation	OD	0.5[b)]	≈0.7
Thermal	OD	7[c)]	0.61
D_2-doping	OD	13[c)]	0.42
	OD	23[c)]	0.27
	OD	125[c)]	0.11
Inherent impurity	OH	125	0.13

a) Silica was heated at 1173 K for 6 h. Silica D was used here. b) Estimated theoretically.[19)] c) Estimated by a model of a tarnishing reaction.[21)] d) 1−[(amount of OD(OH) after heating)/(amount of OD(OH) before heating)].

Table 5. Release of Trapped Tritium from T-Implanted Silica and Decrease of OD Bonds from D^+-Implanted Silica on Thermal Annealing

Sample	D^+-implantation[a)]		Recoil T-implantation[b)]	
	Efficiency of decrease in OD bonds[c)]	Efficiency of release of trapped tritium[d)]	Composition of released tritium/%	
			HTO	HT

Silica B	0.79	0.45	23	77
Silica C	0.55	0.34	41	59
Silica D	0.66	0.53	71	29

a) D^+-implanted silica is heated at 1173 K for 6 h. b) HTO and HT are produced when T-implanted silica is heated from room temperature to 1373 K. c) The efficiency is 1−[(amount of OD after heating)/(amount of OD before heating)]. d) The efficiency is (amount of released tritium)/(amount of total trapped tritium before heating).

bonds and the HTO formation may also be controlled by diffusion to the surface. Therefore, the diffusion coefficient of tritium trapped in silica can be estimated from the releasing behavior of HTO.

From the results of the measurement of the depth profile of tritium, implanted into silica by the recoil reaction of ^{6}Li(n,α)T(2.7 MeV) (cf. Fig. 2), the distribution of the recoil-injected tritium in silica is shown to be that of tritium, implanted from a tritium source of infinite size. In this depth profile, the solution of Fick's second law can be given by the following equation:[25,26]

$$F(t) = 4[D \cdot t/(\pi \cdot R^2)]^{1/2} \quad (4)$$

where $F(t)$ is the fractional release of HTO at an annealing time of t at a constant temperature, while R represents the recoil range of tritium (39 μm) in silica. The diffusion coefficients (D_T(HTO)) can be obtained from the slope of the plot of $t^{1/2}$ vs. $F(t)$ in the isothermal annealing of tritium-implanted silica; they are shown in Fig. 6 in relation to $10^3/T$. They are expressed by the following equation:

$$D_T(\mathrm{HTO}) = 2.3 \times 10^{-4} \exp[-1.7 \times 10^2 (\mathrm{kJ\ mol^{-1}})/RT]\ \mathrm{cm^2\ s^{-1}} \quad (5)$$

Table 6 compares an activation energy for the diffusion in this work with the reported values of hydrogen diffusion in silica. The activation energy for diffusion in Eq. 5 is much larger than the energies for the diffusions of H(D) atoms, H_2, D_2, and H_2O molecules. Thus, the diffusing species for the HTO formation in silica can not be these atoms and molecules, but must be some other species. The diffusing species has not yet been conclusively identified. As has discussed in the previous section, the decrease in OD bonds upon heating is controlled by their diffusion to the surface, where the OD bonds do not rupture during diffusion, but decompose only at the surface. Thus, one plausible mechanism is that tritium in an OT bond migrates from one oxygen site to a neighboring oxygen site as a consequence of the forllowing chemical reaction, and then repeats this reaction to the surface of silica. Then, the OT bond decomposes into HTO at the surface, and tritium is released from silica:

$$\equiv\mathrm{Si\text{-}OT} + \equiv\mathrm{Si\text{-}O\text{-}Si}\equiv \longrightarrow \equiv\mathrm{Si\text{-}O\text{-}Si}\equiv + \mathrm{TO\text{-}Si}\equiv \quad (6)$$

$$\equiv\mathrm{Si\text{-}OT} \xrightarrow{\text{at surface}} \mathrm{HTO} + \mathrm{S} \quad (7)$$

where S represents some products at the surface. Tritium migration by the repetition of a chemical reaction like Reaction 6 was also suggested for the tritium migration in MgO.[27]

The authors wish to thank Mr. Nobuhiko Kuribayashi of the Japan Atomic Energy Research Institute for his help in the measurement of metal impurities in the sample, and Mr. Kazuo Kobayashi of Nagoya University for his help in the experiment on thermal D_2-doping. This work was supported in part by a Grant-in-Aid for Scientific Research from the Japanese Ministry of Education, Science and Culture. This work was done under the Collaboration Program between the Japan Atomic Energy Research Institute and Nagoya University, and under the Collaboration Research Program of the Research Center for Resource and Energy Conservation, Nagoya University.

Pressure Dependence of the Reaction of Thiolane with H and D Atom

Jie TANG,* Tohru KAMO, Muneyoshi YAMADA, and Akira AMANO
Department of Applied Chemistry, Faculty of Engineering, Tohoku University,
Aoba, Aramaki, Sendai 980
(Received April 2, 1987)

The title reaction was investigated at room temperature and under pressures ranging from 133 to 2660 Pa, using a conventional discharge flow reactor. 1-Butanethiol, butane, and 1-butene were the main products, whose compositions varied according to the pressure. In the reaction with deuterium atom, 1-butene was monodeuterated, while 1-butanethiol and butane were dideuterated. The following mechanism was proposed to account for the product compositions and their pressure dependencies as well as the deuterium labeling of the products.

$$(CH_2)_4S + H \longrightarrow CH_2(CH_2)_3SH \quad (1)$$
$$CH_2(CH_2)_3SH + H \longrightarrow CH_3CH_2CH_2CH_2SH^* \quad (2)$$
$$CH_3CH_2CH_2CH_2SH^* \longrightarrow CH_3CH_2CH_2CH_2SH \quad (3)$$
$$\longrightarrow CH_3CH_2CHCH_2 + H_2S \quad (4)$$
$$\longrightarrow CH_3CH_2CH_2CH_2 + HS \quad (5)$$
$$CH_3CH_2CH_2CH_2 + H \longrightarrow CH_3CH_2CHCH_2 + H_2 \quad (6)$$
$$\longrightarrow CH_3CH_2CH_2CH_3 \quad (7)$$

In the comparatively few mechanistic studies, the common initial step being characteristic of direct attack on sulfur has been proposed for the reactions of hydrogen atom with cyclic sulfides. The subsequent decomposition paths of trivalent sulfur complexes so formed, however, were quite different from each other. With the thiirane[1] and thietane[2] the concerted decomposition mechanisms were proposed as

$$(CH_2)_2S + H \longrightarrow CH_2CH_2 + SH$$
$$(CH_2)_3S + H \longrightarrow CH_3CHCH_2 + SH.$$

With thiolane, to account for the predominant formation of 1-butanethiol, the distinct C-S bond cleavage and subsequent reactions, Reactions 1—4, were proposed in our previous study[3]

$$(CH_2)_4S + H \longrightarrow CH_2(CH_2)_3SH \quad (1)$$
$$CH_2(CH_2)_3SH + H \longrightarrow CH_3CH_2CH_2CH_2SH^* \quad (2)$$
$$CH_3CH_2CH_2CH_2SH^* \longrightarrow CH_3CH_2CH_2CH_2SH \quad (3)$$
$$\longrightarrow CH_3CH_2CHCH_2 + H_2S. \quad (4)$$

An asterisk denotes a vibrational energized species. Reaction 4, a molecular H_2S elimination channel for the decomposition of chemically activated 1-butanethiol, was tentatively proposed on the analogue to the decomposition of alkyl halide or aliphatic alcohol to interpret the formation of 1-butene, one of the hydrocarbon products. Butane, another hydrocarbon product, was interpreted to be produced via secondary reactions of 1-butanethiol and 1-butene.

In very little studies up to date of our study on 1-butanethiol, thermal reactions of thiols have been reported to proceed either by a free radical chain mechanism or by a molecular H_2S elimination mechanism, neither of which have conclusive evidence for the validity.[4,5] Recently, we have studied the thermal decomposition of 1-butanethiol, using low pressure pyrolysis technique combined with deuterium labeling method, and reached the conclusion that the decomposition is through two parallel channels, Reactions 4′ and 5′[5]

$$CH_3CH_2CH_2CH_2SH \longrightarrow CH_3CH_2CHCH_2 + H_2S \quad (4')$$
$$CH_3CH_2CH_2CH_2SH \longrightarrow CH_3CH_2CH_2CH_2 + HS. \quad (5')$$

On the other hand, we have studied the reaction of dibutyl disulfide with hydrogen atom,[6] and found that we have to propose another parallel decomposition channel to Reaction 4, Reaction 5

$$CH_3CH_2CH_2CH_2SH^* \longrightarrow CH_3CH_2CH_2CH_2 + HS \quad (5)$$

of chemically activated 1-butanethiol formed in the reaction to give a satisfactory explanation on the product compositions and their pressure dependencies as well as deuterium distributions in the products. Reactions 4 and 5 were also shown to be flexible in giving an explanation of reaction of 1-butanethiol with hydrogen atom,[7] where chemically activated 1-butanethiol was also considered to be formed.

These facts aroused our attempt to reinvestigate the reaction of thiolane with hydrogen (and deuterium) atom over a wide pressure range for acquiring a clearer picture of the chemically activated species in this reaction.

Experimental

The adopted apparatus and procedure were similar to those described in our previous work.[3] In brief, the apparatus consisted of discharge flow reactor, reactant vaporizer, liq. N_2 chilling traps for trapping product, flow

control line, and evacuation system. Thiolane and H_2 (or D_2), both diluted in excess of He, were introduced into a Pyrex reactor of 400 mm in length and 27 mm in inside diameter. Flow rate of thiolane, H_2 (or D_2), and He were 0.001 ml(NTP) s^{-1}, 0.01 ml(NTP) s^{-1}, and 0.72—14.4 ml (NTP) s^{-1}, respectively. Hydrogen atom (or deuterium atom) was generated by passing H_2 (or D_2) through a microwave cavity at upstream side of reactor. To prevent hydrogen atom (or deuterium atom) from recombination, the reactor surface was coated with boric acid.

The reaction was carried out at room temperature and under pressures ranging from 133 to 2660 Pa. Many attempts were made to get observation at low conversions. Reaction gas mixture was intermittently withdrawn through a nozzle and was isolated into an arm chilled by liq. N_2. The isolated sample was then analyzed by gas chromatography (GC) and gas chromatograph-mass spectrometer (GC-MS), using VZ-10 column (2 m, 55 °C) for hydrocarbons and polyethylene glycol (3 m, 80 °C) for organosulfur compounds.

Commercially available purest grade thiolane was purified by trap-to-trap distillation, and the middle one third fraction of better than 99% purity was used. Cylindered gases of H_2, D_2, and He were dried by passing through a train of liq. N_2 traps.

Results

Course of reaction was followed up to conversion of 60%. Product composition vs. conversion relations observed under 133, 530, and 2660 Pa are shown in Figs. 1, 2, and 3, respectively. Although 1-butanethiol was by far the most important, all the three major components including 1-butene and butane were evidently the initial products. The adequacy of interpretation that butane was an initial product will be presented in detail later in discussion. Small amounts of fragmental products such as propane, propylene, ethane, and ethylene were also formed. However, they all decreased to a negligible amount as pressure increased.

When deuterium atom was used instead of

hydrogen atom, quite similar results were obtained with respect to the composition-conversion behavior as shown in Figs. 2 and 3 by filled points. Practically no isotopic mixing was observed with thiolane left unreacted in the reaction with deuterium atom. Deuterium distributions observed with butane and 1-butene are listed in Table 1 for a few different conversions. Two deuterium atoms were introduced into each butane molecule produced, and one into each 1-butene. 1-Butene[D_2] and butane[D_3] were observed as progressively important with the increase of conversion. The GC-MS analysis also showed that only one deuterium atom was introduced into each 1-butanethiol molecule produced.

Both butane/1-butanethiol and 1-butene/1-butanethiol ratios tend to increase linearly as the conversion increases. The trend is illustrated in Fig. 4. The

(Filled points denote reaction with deuterium atom.)

values of 0.020, 0.016, 0.006 for butane/1-butanethiol, and of 0.239, 0.077, 0.029 for 1-butene/1-butanethiol at 133, 530, 2660 Pa were obtained when extrapolating the ratios at various pressures to zero conversion. Clearly these values exhibit certain pressure dependencies of the initial product compositions.

Discussion

Primary Reaction. The fact that no isotopic mixing was observed with thiolane left unreacted in the reaction with deuterium atom eliminated the possibility of hydrogen abstraction-addition on ring. This approved the characteristic hydrogen atom attack on sulfur proposed previously to be valid. Thus the Reactions 1—4 proposed previously kept their validity for reasons that they give a proper interpretation of primary formations of 1-butanethiol and 1-butene.[3] However, butane is not referred to in Reactions 1—4. In fact, butane was shown not to be formed from the reactions of 1-butene and 1-butanethiol with hydrogen atom, the conclusive diagnosis of which will be presented in the discussion on secondary reaction later. Thus, to interpret the primary formation of butane, we add Reaction 5, a parallel decomposition channel to Reaction 4 for chemically activated 1-butanethiol, and subsequent Reactions 6 and 7. The reaction formulas 1—7 should be written as follows,

$$(CH_2)_4S + D \longrightarrow CH_2(CH_2)_3SD \quad (1)$$

$$CH_2(CH_2)_3SD + D \longrightarrow CH_2DCH_2CH_2CH_2SD^* \quad (2)$$

$$CH_2DCH_2CH_2CH_2SD^* \longrightarrow CH_2DCH_2CH_2CH_2SD \quad (3)$$

$$\longrightarrow CH_2DCH_2CHCH_2 + HDS \quad (4)$$

$$\longrightarrow CH_2DCH_2CH_2CH_2 + DS \quad (5)$$

$$CH_2DCH_2CH_2CH_2 + D \longrightarrow CH_2DCH_2CHCH_2 + HD \quad (6)$$

$$\longrightarrow CH_2DCH_2CH_2CH_2D. \quad (7)$$

For the sake of clearity, we hereafter write D standing for both hydrogen and deuterium atoms.

According to this scheme, 1-butene[D_1], butane[D_2], and 1-butanethiol[D_2] should be given when deuterium atom was used. The initial deuterium distribution of 1-butene and butane was in conformity with this inference, while the GC-MS observation on 1-butanethiol was apparently inconsistent with this inference. However, by a contrast analysis of the separately prepared 1-butanethiol[S-D] using a direct sampling quadrupole mass spectrometer, we verified that, even if the mercapto-hydrogen is deuterated perfectly, conventional GC-MS analysis can not give any evidence about the mercapto-deuterium due to the retro H–D exchange with residual water in the column and in the ionization chamber. It may therefore be concluded that 1-butanethiol was actually dideuterated in the course of reaction, and that the

result as observed with GC-MS just should be interpreted as monodeuteration of butyl group of 1-butanethiol.

The Reactions 6 and 7 are the well-known disproportionation and recombination reactions for an alkyl radical with hydrogen atom. From the reported values for the reactions of ethyl radical with hydrogen atom[8] and of propyl radical with methyl radical,[9] we can reasonably estimate the k_6/k_7 to be about 0.05. Thus, the predominant source of 1-butene was plausibly molecular H_2S elimination of chemically activated 1-butanethiol, Reaction 4, rather than Reaction 6.

Secondary Reaction. Table 2 shows rate constants of some related species with hydrogen atom at room temperature. Thiolane, 1-butanethiol, and 1-butene all have a much higher reactivity over butane toward hydrogen atom. We may therefore ignore the reaction of butane with hydrogen atom in formulating a group of secondary reactions.

Conceivable reactions of 1-butanethiol with hydrogen atom can be cited from our study[7] on the reaction of 1-butanethiol with hydrogen atom as follows

$$CH_2DCH_2CH_2CH_2SD + D \longrightarrow CH_2DCH_2CH_2CH_2S + D_2 \quad (8)$$

$$\longrightarrow CH_2DCH_2CH_2CH_2 + D_2S. \quad (9)$$

Reactions subsequent to Reaction 8 are

$$CH_2DCH_2CH_2CH_2S + D \longrightarrow CH_2DCH_2CH_2CH_2SD^* \quad (10)$$

and Reactions 3—5. Reactions subsequent to Reaction 9 are Reactions 6 and 7. For 1-butene, the secondary reaction with hydrogen atom is the well-known addition to double bond giving butyl and *s*-butyl radicals. The reactions of these radicals with hydrogen atom result in the formation of butane, 2-butenes, and regeneration of 1-butene.

The decreases of the composition of 1-butanethiol and 1-butene with the increase of conversion shown in Figs. 1, 2, and 3 indicate the secondary reactions of 1-butanethiol and 1-butene with hydrogen atom. Moreover, from Fig. 4, the almost fixed 1-butene/1-butanethiol ratio relative to the conversion exhibits the similar reactivity toward hydrogen atom of both. This fact is also in quite accord with the reported rate constant data listed in Table 2. As a net result of secondary reactions of 1-butene and 1-butanethiol, butane/1-butanethiol solely increased with the increase of conversion, as shown in Fig. 4.

On account of secondary reaction, one may predict the change of deuterium distribution in products when deuterium atom was used. Secondary reaction of 1-butanethiol can not introduce any additional deuterium into 1-butene, butane, and itself, while the secondary reaction of 1-butene introduces two more deuterium atoms into butane, one more into 1-butene, leading to the formation of butane[D_3] and 1-butene[D_2]. Table 1 shows that the abundances of butane[D_3] and 1-butene[D_2] increased as conversion increased, and the both approached to zero at low conversion. The latter fact makes primary formation of butane evident, because 1-butanethiol is known to be never more reactive toward hydrogen atom than 1-butene.

Pressure Dependence of Primary Products and Decomposition of Chemically Activated 1-Butanethiol. The pressure dependence of the initial proportion of 1-butene gives an undoubted evidence for the formation of chemically activited 1-butanethiol in this reaction. The initial proportion of butane was so small that its pressure dependence was submerged into experimental error. Therefore we can not say any about its pressure dependency arbitrarily, but we can conclude that the chemically activated 1-butanethiol formed in this reaction has a higher selectivity to the concerted channel of 4 over 5.

According to the proposed reaction mechanism, the following formula may be deduced to relate the initial products composition with k_4/k_5.

$$\frac{[\text{1-butene/1-butanethiol}]}{[\text{butane/1-butanethiol}]} = \frac{k_6}{k_7} + \frac{k_4}{k_5}\left(1+\frac{k_6}{k_7}\right)$$

Table 3 listed the evaluated values of k_4/k_5 for thermal decomposition of 1-butanethiol and decomposition of chemically activated 1-butanethiol created from different reactions. A comparison can be made between the values of k_4/k_5 and the energized level of

1-butanethiol. The relevancy between the two may give a rough explanation of the difference in the values of k_4/k_5.

Interactions between a Synthetic Phospholipid Vesicle and Cationic Surfactants

Mitsuhiro TAKASAKI, Noboru TAKISAWA, and Keishiro SHIRAHAMA*
Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840
(Received April 9, 1987)

The interaction between a synthetic phospholipid derivative, the 1,3-ditetradecyl-*rac*-glycerophosphatidylcholine ($2C_{14}$-Gly-PC) vesicle, and two cationic surfactants, *N*-tetradecylpyridinium bromide (TDPBr) and *N*-tetradecyltrimethylammonium bromide (TDTMABr), were investigated in the hope of obtaining a better understanding of the mechanism of the growth of the vesicle size by the "surfactant-removal" method. The binding isotherms of these surfactants to the lipid vesicle obtained by the surfactant selective electrode were characterized by two-step binding processes; the Langmuir adsorption mechanism in the initial binding, followed by a markedly positive cooperative process. The variation in the hydrodynamic radius, as measured by quasi-elastic light scattering, and the quenching kinetics of pyrene fluorescence with the TDPBr surfactant solution as measured by a stopped-flow method, share a tendency with the binding behavior. The van't Hoff plots of the initial binding data give a slightly negative enthalpy change, $\Delta H°$, for TDPBr and a relatively large positive $\Delta H°$ for TDTMABr. The microenvironmental polarity around pyrene in the molecular assemblies was assessed by means of fluorescence spectroscopy.

When amphiphiles such as lecithin are dispersed in water, they form molecular assemblies with a bilayer structure called a vesicle, which is excellent in mimicking biological membranes.[1-3] Vesicles comparable in size with a biological cell will facilitate study of the mechanism of cellular reaction. A vesicle formed in water is usually much smaller than biocells and a multilamellar structure, even if the vesicle is prepared by the sonication method. It is known that a vesicle is solubilized by a surfactant, which is subsequently removed by dialysis or some other method above the transition temperature of the gel-liquid crystal, T_C of the lipid; there, then produced a large homogeneous, unilamellar vesicle. However, the "surfactant-removal" method has not been well understood yet[4-6] in spite of its biochemical significance.[7-9] We have investigated the interaction of the 1,3-ditetradecyl-*rac*-glycerophosphatidylcholine ($2C_{14}$-Gly-PC) vesicle with two cationic surfactants, *N*-tetradecylpyridinium bromide (TDPBr) and *N*-tetradecyltrimethylammonium bromide (TDTMABr). It has been known that $2C_{14}$-Gly-PC behaves much like lecithin, having the corresponding alkyl chains,[10] and it is chemically stable and suitable for investigating the vesicle-surfactant interaction, since the ether bond between two alkyl chains and the phosphatidylcholine group is resistant against hydrolysis.

The binding of TDPBr and TDTMABr to the vesicle was measured by using surfactant-electrodes which have been successfully utilized in our laboratory,[11-13] and the thermodynamic aspects of binding were discussed. The hydrodynamic radii of the vesicle were obtained by means of quasi-elastic light scattering (QELS). Pyrene fluorometry was useful in the static and kinetic study of the interaction mechanism.

Experimental

Materials. The $2C_{14}$-Gly-PC (Fig. 1) was purchased from Sogo Pharmaceutical, Tokyo, and was used as received. The TDPBr was synthesized by a method similar to that used for dodecylpyridinium bromide[12] and was recrystallized three times from acetone. A triple recrystallization of TDTMABr (Tokyo Kasei) from acetone was also carried out. The critical micelle concentrations (cmc) in an aqueous solution, as determined by the electric conductivity method, are 2.82 and 3.60 mmol dm^{-3} at 30 °C for TDPBr and TDTMABr respectively; these values are in good agreement with the literature.[14] For convenience, we use the abbreviation 1 M=1 mol dm^{-3} throughout this paper.

Sample Preparation. The vesicle-forming agent, $2C_{14}$-Gly-PC, was dispersed in doubly distilled water and treated in a bath-type sonicater (VELVO CLEAR VS-20, Iuchi) for 1 hour at about 50 °C. Surfactant-containing samples were incubated at about 50 °C and used after they had been allowed to stand for a day or so for a complete equilibration of the system.

Surfactant-Selective Electrode. Poly(vinyl chloride) (PVC; 0.9 g) and bis(2-ethylhexyl) phthalate (2.1 g) were mixed well, after which 6 ml of tetrahydrofuran was added to the slurry mixture. The whole mixture was then heated at 60 °C. After a while, a clear and viscous solution was obtained; it was cast on a flat glass plate. The solvent was gradually removed in a silica-gel desiccator for two days, and then the gel membrane (about 0.2 mm thick) was obtained. The membrane was cut out and glued on one end

1,3-ditetradecyl-rac-glycero-phosphatidyl choline
($2C_{14}$-Gly-PC)

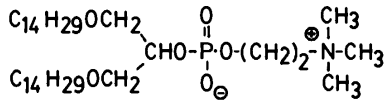

Fig. 1. Structure of $2C_{14}$-Gly-PC amphiphile.

of a PVC tube (9 mm in inner diameter, 11 cm long) and "annealed" at 40—50 °C under reduced pressure.

The binding of the surfactant to the vesicle was measured by using the surfactant-selective electrode in a thermostated cocylindrical cell. The concentration cell formula was as follows.

Ag/AgCl	KCl agar bridge	C_0 mM surfactant	M	C_1 mM surfactant (+vesicle)	KCl agar bridge	AgCl/Ag

in which M is the surfactant-selective electrode membrane; C_0, the inner (reference) surfactant concentration, and C_1, the outer surfactant concentration. The electromotive force, emf, was measured with a digital multimeter (Advantest TR-6845).

Pyrene Fluorometry. The fluorescence of pyrene was measured by means of a Shimadzu digital spectrophotomerer RF-510 (temperature controlled with LAUDA RM3 MODEL S-1 thermostat). The fluorometry was carried out from both static and kinetic points of view. The static experiment was done only with the system using TDTMABr. The variation in the I/III ratio found in the vibronic fine structure in the pyrene fluorescence spectrum was measured by changing the surfactant concentration in the 350—450 nm emission-wavelength region.[15] As for the kinetic experiment, the vesicle dispersions containing pyrene (p-dispersion) and TDPBr as a fluorescent quencher (q-dispersion) were quickly mixed by the used of a stopped-flow mixer (Union Giken MX-7) and the fluorescence intensity was followed with time, where the excitation wavelength, λ_{ex}=337 nm, and the emission one, λ_{em}=391 nm, were both used. The mixing was also carried out by a conventional "manual fast mixing"; i.e., the q-dispersion was poured into the p-dispersion in a cuvette cell, and the mixture was stirred with a tiny plastic rod as quickly as possible.

Quasi-Elastic Light Scattering (QELS). The hydrodynamic radii of the molecular assemblies were measured for the TDPBr system by the QELS method.

Results and Discussion

Figure 2 shows the relation between the emf and the logarithm of the TDPBr concentration. The electrode exhibits the Nernstian response for the TDPBr surfactant without a vesicle. In the coexistence of the $2C_{14}$-Gly-PC vesicle, however, a deviation from linearity is observed. The deviation may result from a partial binding of TDPBr to the vesicle. From the deviation, we can obtain the equilibrium surfactant concentration, C_f, and the bound surfactant concentration, $C_b=C_t-C_f$, where C_t is the concentration actually weighed-in. The surfactant-selective electrode responds equally well to TDTMABr. The binding isotherms were obtained by plotting the amount of binding per unit of lipid concentration, C_b/C_v, against C_f; they are shown in Figs. 3 and 4 for TDPBr and TDTMABr respectively. In the lower C_f region, the C_b/C_v amount is not so large, and it increases gradually with C_f before increasing sharply.

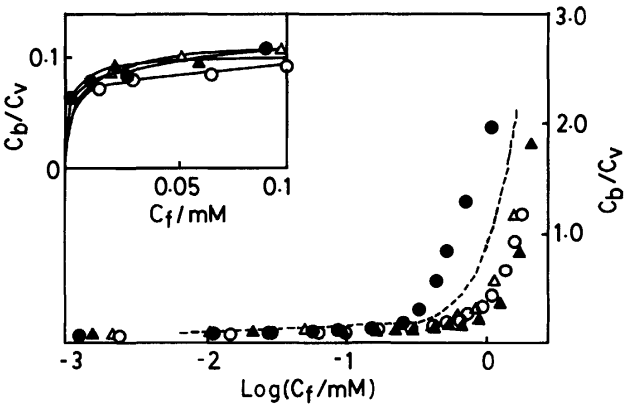

Fig. 4. Binding isotherms for TDTMABr.
Temperature at ▲: 283 K, △: 293 K, O: 303 K, ●: 313 K. ----: For TDPBr at 303 K.

In Fig. 4, a typical isotherm for TDPBr at 303 K is also shown by a dashed line for the sake of comparison. It appears that the C_b/C_v amount for TDPBr are slightly larger than those of TDTMABr, indicating a stronger

affinity of the pyridinium analog to the lipid vesicle. These isotherms depend a little on the temperature.

When the surfactants bind multiply and independently to the binding sites, which are mainly located on the surface of the vesicle, binding is expressed by the Langmuir isotherm:[16]

$$C_b/C_v = \frac{mKC_f}{1+KC_f} \quad (1)$$

where m is the maximum amount of binding and K, a sort of equilibrium constant. The Scatchard equation[16] derived from Eq. 1,

$$\frac{C_b/C_v}{C_f} = -K(C_b/C_v) + Km \quad (2)$$

is plotted for TDPBr and TDTMABr in Fig. 5. The data points support a straight line, with a negative slope at the lower concentrations; a different behavior

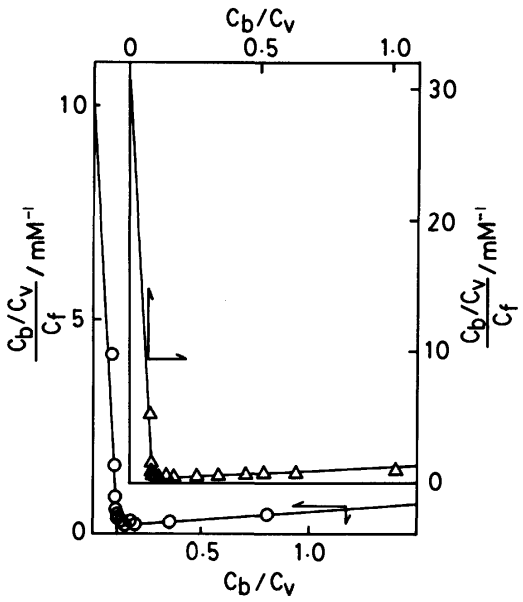

Fig. 5. Scatchard plots at 283 K.
△: For TDPBr, ○: for TDTMABr.

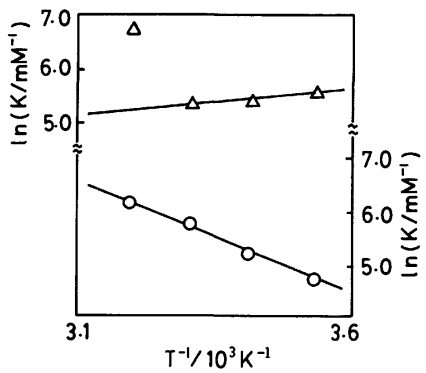

Fig. 6. The temperature dependence of K.
△: TDPBr, ○: TDTMABr.

with a positive slope is seen in the higher-concentration region, indicative of cooperative binding.[16,17] From the straight line in the lower-concentration region, the equilibrium constant, K, and the maximum amount of binding, m, were obtained. The maximum amount of binding is about 10 mol% irrespective of the kind of surfactant and the temperature; the further addition of a surfactant exceeding m may induce the formation of a mixed micelle. The van't Hoff plot for TDPBr in Fig. 6 has a slightly positive slope from 283 to 303 K, and the point at 313 K deviates from linearity, while all the data points for the TDTMABr system support linearity, with a relatively large negative slope. The different behavior at 313 K between the two systems may be related to the difference in the binding enthalpy, which is very much affected near the gel-liquid crystal transition temperature[10] of the vesicle, but the details remain still to be studied. The Langmuir parameters and ΔH°'s are listed in Table 1. In the Langmuir region, TDPBr binds to the vesicle exothermically, and TDTMABr, endothermically. This difference probably originates from the difference in the head group, since the two surfactants have the same hydrophobic chain-length. The difference in the ΔH° of binding between the surfactants, $\Delta\Delta H^\circ = \Delta H^\circ_{\text{TDPBr}} - \Delta H^\circ_{\text{TDTMABr}}$, may be governed by the electrostatic interaction between the phosphate anion and the cationic head group of each surfactant, and may result from the electrostatic energy difference. The phosphate ion group may approach the pyridinium ring plane closer so that electrostatic energy becomes less. The three bulky methyl groups of TDTMABr may interfere with such a close approach to the vesicular phosphate group.

QELS Measurement. The hydrodynamic radii, R_H, are obtained from the observed autocorrelation function, which decays single-exponentially, as

Table 1. Thermodynamic Parameters in the Langmuir Binding Process for (a) TDPBr and (b) TDTMABr Systems

(a)

T/K	m	K/mM^{-1}	ΔH°/kJ mol^{-1}
283	0.093	258	-7.7×10^0
293	0.112	220	
303	0.125	209	
313	0.105	801	

(b)

T/K	m	K/mM^{-1}	ΔH°/kJ mol^{-1}
283	0.107	115	3.43×10^1
293	0.118	183	
303	0.092	313	
313	0.096	450	

shown by an insert in Fig. 7. The variation in the R_H with C_f is shown in Fig. 7. In the lower-surfactant-concentration region, the R_H's are nearly invariant with C_f; the growth in the molecular assembly size appears above the same concentration range, where the binding deviates from the Langmuir isotherm. A similar constancy was previously observed with the system of a synthetic surfactant vesicle and nonionic surfactants.[4]

Pyrene Fluorescence. Pyrene shows a significant fine structure: the five well-defined peaks are numbered I—V from th lowest wavelength.[15] Since the intensity ratio, I/III, changes with the microenvironmental polarity around a pyrene molecule,[15] it will be used to assess the environment of pyrene molecules. Figure 8 shows how the polarity changes with the surfactant concentration. Pyrene dissolved in water shows a I/III ratio of about 1.5, as is indicated by the arrow in Fig. 8. The pyrene containing TDTMABr solution shows a sharp decrease in its I/III ratio near the cmc of TDTMABr and then a leveling-off. In contrast, pyrene shows a very low polarity in the vesicular medium at a low TDTMABr concentration, but its polarity increases to as much as that of pure micelle with an increase in the TDTMABr concentration, suggesting the formation of mixed micelles with the lipid molecules.

Quenching Kinetics of Pyrene Fluorescence. As soon as the pyrene-containing vesicle (p-vesicle) and the quencher-containing vesicle (q-vesicle) are mixed, quenching begins. It is considered to be controlled by the collision between the two kinds of vesicles. The frequency of collision may be very slow because of the large vesicular size, and so the quenching may also be very slow. The fluorescent intensity, $I(t)$ at 391 nm, decayed immediately until it reached about half the initial intensity. This may be due to the quenching of the free pyrene by the free quencher. Following this very rapid process, a relatively slow single-exponential decay was observed in the lower-TDPBr-concentration region, while in the higher-surfactant-concentration region the quenching kinetic trace seems a double-exponential process. By plotting the quantity, $\ln(I(t)-I(\infty))/(I(0)-I(\infty))$ against the time, the first order reaction constant, k, is obtained; it is shown in Fig. 9, where it may be seen that k is independent of C_f when C_f is low, but the k value increases rather abruptly at higher C_f values. It may be considered that the slow process results from a collision between the p-vesicle and the q-vesicle. At a higher cationic surfactant concentration, a part of the lipid is solubilized to form mixed micelles with the lipid and pyrene; the small molecular assemblies are efficient for quenching since they are moving quickly. The labile structure of a mixed micelle may also be preferable for efficient quenching.

All these experimental results for TDPBr are summarized in Fig. 10, where the various observed

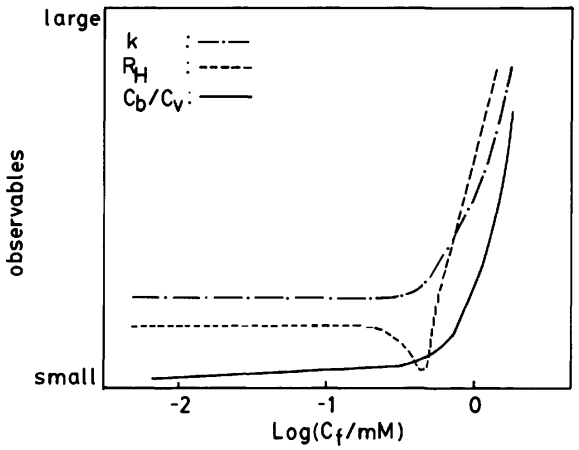

Fig. 10. Various observable vs. log C_f plot for TDPBr. —·—; k, ----; C_b/C_v, ——; R_H.

results are plotted as a function of the logarithm of C_f. It is notable that there is a close resemblance among the tendencies of all these observed data; the addition of the surfactant to the Langmuir binding limit causes drastic change in the behavior of the system. It may be concluded that the cationic surfactants are bound to the vesicle that remains the original vesicular structure in the lower-surfactant-concentration regions, and that, with an increase in the surfactant concentration, the sudden change in the observables in the present work may result from the formation of the mixed micelle. The growth of the vesicular size may also occur by the collision between the mixed micelle and the vesicular aggregation.[18]

In the QELS measurements we are grateful to the kind support of Professor Mitsuru Tanaka's laboratory of Fukuoka University. We are also thankful to Professor Masao Okubo of Saga University for lending the stopped-flow mixer. The author (K.S.) thanks "the Asahi Glass Foundation for Industrial Technology" for partially supporting this work.

Excited-State Reactions of Coumarins in Aqueous Solutions. IV. The Fluorescence Quenching of 7-Ethoxycoumarins by Inorganic Ions in Micellar Solutions of Sodium Dodecyl Sulfate

Tetsuo MORIYA
Electrotechnical Laboratory, 1-1-4 Umezono, Sakura-mura, Niihari-gun, Ibaraki 305
(Received April 18, 1987)

The effect of added salts (NaCl, NaBr, CsCl) on the fluorescence behavior of 7-ethoxycoumarin (7EC) and 7-ethoxy-4-methylcoumarin (7E4MC) has been studied in aqueous micellar solutions of sodium dodecyl sulfate (SDS). Data on the fluorescence quenching as a function of the salt concentration are analyzed in terms of a proposed two-reactive-state (aqueous and micellar phases) model. The results are in good accord with the model and permit the evaluation of the quenching-rate constants attributable to Br^- and Cs^+ respectively in the two phases. Quenching mechanisms influencing the fluorescence yield are discussed on the basis of the electrostatic force among micelles and quenchers, the electron-transfer reaction from anion to fluorescer, and the hydration degree of the quencher ions.

Since most coumarin derivatives in solutions have a strong fluorescence which depends on interactions with the surroundings, they can be used as fluorescent probes for the investigation of various reactions among organic molecules, inorganic ions, and molecular aggregations. In previous papers,[1,2] the fluorescence quenching of 7-ethoxycoumarin (7EC) and 7-ethoxy-4-methylcoumarin (7E4MC) by halide ions has been studied in aqueous solutions. Generally, halide ions are able to quench the fluorescence of dissolved fluorophores by the external heavy-atom effect[3] or the charge-transfer interaction.[4,5] It has been revealed that bromide and iodide ions in neutral aqueous solutions are very efficient fluorescence quenchers of 7EC and 7E4MC, whereas a chloride ion showed no such effect.[1] In acidic aqueous solutions, however, a chloride ion, as well as bromide and iodide ions, had a pronounced quenching effect on the fluorescence, because the photo-excited state of 7EC and 7E4MC preferred to associate with a proton in the solution, and, subsequently, the generated cationic fluorophore interacted attractively with the chloride ion.[2] In addition to these interactions of the fluorescers with inorganic ions, it has recently been found that 7EC and 7E4MC are easily solubilized into the micelle formed in an aqueous solution of sodium dodecyl sulfate (SDS).[6] The solubilization property of fluorescers and their microenvironment in micelles will be made clear by a spectroscopic investigation of the fluorophores distributed in the aqueous and micellar phases respectively.

In the present work, the absorption and fluorescence spectra of aqueous micellar solutions containing 7EC and 7E4MC are measured precisely upon the addition of several inorganic fluorescence quenchers. Since SDS forms anionic micelles, the solubilized fluorophore is protected from the quenching reaction with anionic quenchers. On the other hand, the quenching by cationic ions is enhanced because the quencher concentration near the surface of SDS micelles becomes higher as a result of electrostatic attraction. Based on a generalized scheme for quenching reactions in aqueous micellar systems, these aspects will be proved quantitatively through the determination of the quenching-rate constants for typical inorganic ions.

Experimental

Materials. The high-purity-grade reagents of 7-ethoxycoumarin (7EC) and 7-ethoxy-4-methylcoumarin (7E4MC) were obtained from Molecular Probes, Inc., and were used without further purification. The sodium dodecyl sulfate (SDS, Wako) was of a biochemical grade. The sodium chloride, sodium bromide, and cesium chloride were pure in quality (Wako). The water was permeated and distilled.

Methods. The UV-absorption spectra were obtained on a Hitachi 323 spectrophotometer, while the measurements of the fluorescence spectra and the fluorescence yields were made on a Hitachi MPF 4 spectrofluorometer with an S-5 type photomultiplier. The temperature of the sample cuvette was thermostated with circulating water from a constant-temperature bath (25±0.1 °C).

The wavelengths of the excitation light were chosen to be 326 nm for 7EC and 323 nm for 7E4MC; these values nearly coincided with their absorption maxima under various conditions, and there was no disturbing absorption of surfactants or ions at these wavelengths. The aqueous micellar solutions in high ionic concentrations were so labile that ultrasonic agitation and warming-up procedures of the solution were necessary to ensure homogeneity, and the fluorescence measurement was done as quickly as possible so as not to change the equilibrium conditions of the sample. The concentration of 7EC and 7E4MC was $4—5\times10^{-5}$ mol dm^{-3} unless otherwise mentioned.

Results

When 7EC and 7E4MC are dissolved in aqueous SDS solutions with concentrations higher than the critical micelle concentration (cmc),[7] they become distributed between the micellar and aqueous phases. The absorption spectra of 7EC and 7E4MC are

changed from those in the absence of SDS with a peak-position red-shifted by ≈1.5 nm and with a slightly decreased peak-value of the molar extinction coefficient (ε). Compared to this, the dependence of the fluorescence spectra on the SDS concentration becomes much larger, as may be seen from Fig. 1. By the addition of 0.025 mol dm^{-3} SDS, the fluorescence intensities are decreased to 74% (7EC) and 88% (7E4MC) at 25 °C, and the peak position of a fluorescence band is blue-shifted by ≈4 nm without changing the original spectral shape.[6] The 7EC and 7E4MC solubilized in the micellar phase are believed to have lower fluorescence yields than in the aqueous phase, because those in less polar water-organic mixed solvents such as water-dioxane are also low; in them a microenvironment similar to the micellar interior may be realized.[6]

The fluorescence quenching phenomena of these fluorophores by halide ions in aqueous solutions have been investigated in a previous paper.[1] The addition of NaCl to the solution did not result in any noticeable change in the fluorescence spectrum (at least for [NaCl]≦0.5 mol dm^{-3}), while NaBr could strongly quench the fluorescence, whose dependence on the salt concentration approximately followed the linear Stern-Volmer relation in the concentration range of interest, if we neglect a small deviation (a few percent) which becomes a discernible amount only for [NaBr]>0.3 mol dm^{-3}. The order of the quenching ability of the halide ions homogeneously distributed in the aqueous phase was shown to be: $I^- > Br^- \gg Cl^- \approx 0$.[4] CsCl also quenches the fluorescence, but the degree of quenching is very low compared to that in the case of NaBr. Taking into consideration the fact that NaCl (the pair of Na^+ and Cl^-) does not contribute to the quenching in the aqueous phase, Br^- is classified as a very efficient quencher, and Cs^+, as a very weak one. Usually the quenching ability of halide ions for coumarin derivatives of a neutral form is much greater than that of alkali ions with similar atomic weights, e.g., $I^- \gg Cs^+$ (I=53, Cs=55). Therefore, the fluo-

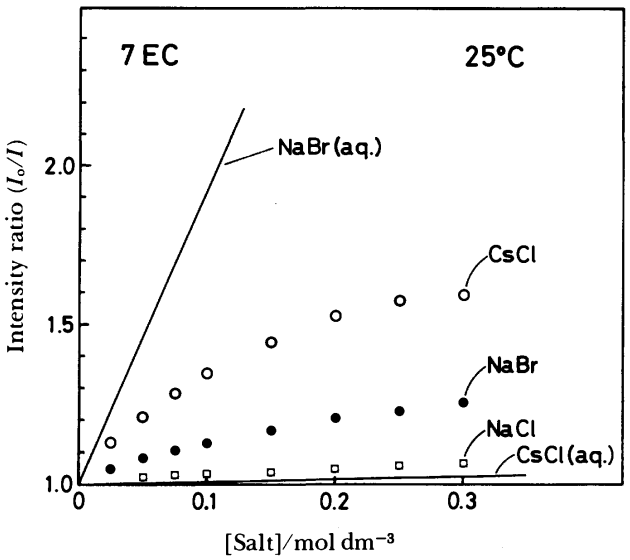

Fig. 2. Dependence of the fluorescence intensity ratio, I_0/I, of 7EC on the concentration of salts in aqueous solutions (solid lines) and in 0.025 mol dm^{-3} SDS solutions (data points) at 25 °C.

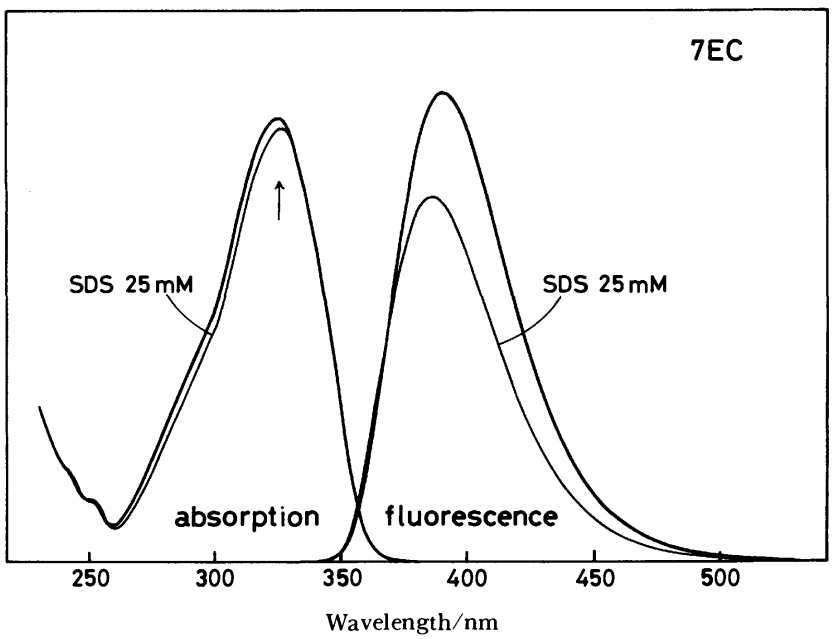

Fig. 1. UV absorption and emission spectra of 7EC in the pure water (thick lines) and in the aqueous solution of 0.025 mol dm^{-3} SDS (thin lines), respectively. The arrow indicates the wavelength of excitation for the emission spectra.

rescence quenching attributable to these inorganic ions cannot be explained consistently by the external heavy-atom effect; rather, it is possibly attributable to a charge-transfer interaction or an electrically induced perturbation among fluorophores and ions. Figures 2 and 3 show, by thin solid lines, the Stern-Volmer plots for I_0/I vs. [NaBr] and [CsCl], where I and I_0 are the fluorescence intensities in the presence and in the absence of added salts respectively. The quenching constants, K_{sv}, evaluated for Br^- and Cs^+ in the aqueous phase at 25 °C are cited in Table 1.

The solubilization phenomena of fluorophores combined with the fluorescence quenching due to inorganic ions bring about additional complexities in the fluorescence analysis, but these complexities will permit the study of various reaction mechanisms occurring in the solution. When NaCl, NaBr, and CsCl are added to the aqueous 7EC and 7E4MC solutions in which 0.025 mol dm^{-3} SDS has been dissolved, the absorption spectra do not change very much except for a slight decrease in ε (a few percent). In spite of the similar absorption spectra, the fluorescence intensity is appreciably decreased by the addition of NaBr and CsCl, which have the fluorescence quenching ability attributable to Br^- and Cs^+ in aqueous solutions without any surfactant. Figures 2 and 3 show plots of I_0/I vs. the concentration of salts in the presence of SDS micelles at 25 °C. It can readily be seen, by comparing the data with the thin solid line (upper), that the quenching ability of NaBr is suppressed by the micelle formation, while, on the contrary, that of CsCl is enhanced. These results can be understood qualitatively, considering that the electrostatically attractive force between the anionic SDS micelle and Cs^+ catalyzes the fluorescence-quenching reaction of the fluorophore embedded in the micelle interior, whereas the repulsive interaction between the micelle and Br^- decreases the probability of a quenching reaction. For Br^- and Cs^+ quenchers in micellar solutions, the Stern-Volmer relation does not hold any more to show nonlinear downward deviations (Figs. 2 and 3).

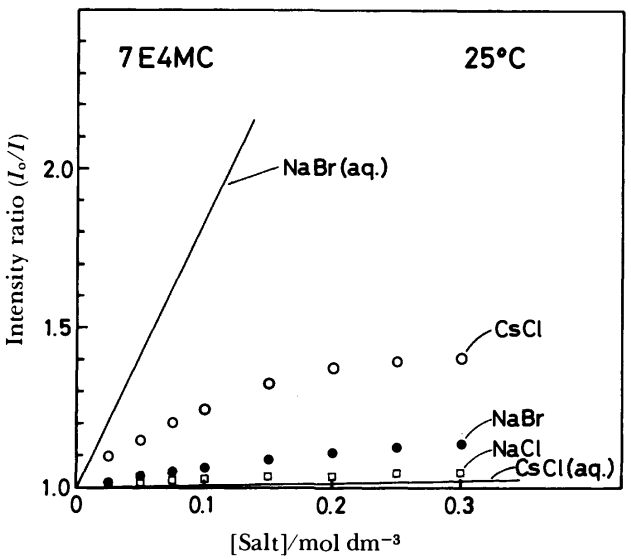

Fig. 3. Dependence of the fluorescence intensity ratio, I_0/I, of 7E4MC on the concentration of salts in aqueous solutions (solid lines) and in 0.025 mol dm^{-3} SDS solutions (data points) at 25 °C.

The addition of NaCl has also induced a decrease of several percent in the fluorescence intensity, probably caused by the change in such micelle parameters as cmc, the aggregation number (n), and the degree of ionization of a micelle (α). These factors are subtly affected by the ionic strength of the solution and will determine the micelle density and the microenvironment around the solubilization site of fluorophores. Since Cl^- has no quenching ability in the aqueous phase and is electrically repelled from the negatively charged head-group of SDS on the surface of sphere-like micelles, we need not think of the quenching from Cl^-. While Na^+ also has no quenching ability in the aqueous phase, there is a possibility that the quenching of the solubilized fluorophore may take place as a consequence of a number of Na^+ ions being attracted onto the negatively charged micelle surface. However, by using the optical detection of magnetic resonance (ODMR), Ghosh et al.[8] proved the absence of perturbation on the π-electron distribution of the fluorophore due to added Na^+ in a naphthalene-sodium n-alkyl sulfate micelle system, in spite of the

Table 1. Quenching Constants, K_{sv} and K'_{sv}, and Quenching-Rate Constants, k_q and k'_q, in the Aqueous and Micellar Phases Respectively of the 0.025 mol dm^{-3} SDS Solution at 25 °C

a) $\tau = 1.8$ ns (7EC) and $\tau = 2.1$ ns (7E4MC) at 25 °C were used,[1] and τ' was estimated by the use of $\tau' = \tau \cdot (\eta'/\eta)$.

large effect from Cs^+. Furthermore, the addition of NH_4Cl, $NaClO_4$, and Na_2SO_4 with the same ionic strength as NaCl, all of which are, in many cases, thought to have little or no quenching efficiency against coumarin derivatives, induced small changes in the fluorescence intensity, very similar to the case of NaCl. Therefore, Na^+, NH_4^+, Cl^-, ClO_4^-, and SO_4^{--} are not 'fluorescence quenchers,' although a small effect attributable to the ionic-strength change is found for all these ions and cannot be neglected.

Discussion

Model for the Fluorescence Change. To analyze the fluorescence quenching phenomena of fluorophores in an aqueous micellar solution containing various salts as quenchers, we may adopt the following general scheme of the light-emitting mechanism (two-reactive-state model):

$$\begin{array}{l} \mathrm{N} \xrightarrow{G\frac{\varepsilon[\mathrm{N}]}{\varepsilon[\mathrm{N}]+\varepsilon'[\mathrm{D_nN}]}} \overset{*}{\mathrm{N}} \begin{cases} \xrightarrow{k} \mathrm{N}+h\nu \\ \xrightarrow{k_n} \mathrm{N} \end{cases} \\ \qquad\qquad \overset{*}{\mathrm{N}} + \mathrm{Q} \xrightarrow{k_q} \mathrm{N} + \mathrm{Q} \\ \mathrm{D_nN} \xrightarrow{G\frac{\varepsilon'[\mathrm{D_nN}]}{\varepsilon[\mathrm{N}]+\varepsilon'[\mathrm{D_nN}]}} \mathrm{D_n}\overset{*}{\mathrm{N}} \begin{cases} \xrightarrow{k'} \mathrm{D_nN}+h\nu' \\ \xrightarrow{k_n'} \mathrm{D_nN} \end{cases} \\ \qquad\qquad \mathrm{D_n}\overset{*}{\mathrm{N}} + \mathrm{Q} \xrightarrow{k_q'} \mathrm{D_nN} + \mathrm{Q} \end{array} \tag{1}$$

$$\mathrm{D_n} + \mathrm{N} \overset{K_{eq}}{\rightleftharpoons} \mathrm{D_nN} \tag{2}$$

Here, D_n represents the micelle formed of n surfactants. N and D_nN are the ground states of the fluorophore in the aqueous and micellar phases respectively; $\overset{*}{N}$ and $D_n\overset{*}{N}$ are their excited states generated on light illumination. G is the flux of illuminating light, and ε and ε' are the molar extinction coefficients of N and D_nN respectively at the excitation wavelength. $h\nu$ and $h\nu'$ are the light quanta emitted from each molecular species. k's are the rate constants for the radiative transition of $\overset{*}{N}$ and $D_n\overset{*}{N}$ to their ground states, and k_n's are the rate constants for the nonradiative transition. k_q's are the bimolecular quenching-rate constants resulting from the collision with added quencher ions, Q. Assuming that the fluorophore in the aqueous phase is in equilibrium with that in the micellar phase (Eq. 2), the equilibrium constant is given by $K_{eq}=[D_nN]/[D_n][N]$.[6] It may be noted that the fluorophore cannot be transferred between the aqueous and micellar phases in its lifetime of the optically excited state because the time constant needed to attain such equilibriation is of the order of microseconds,[9] while the fluorescence lifetime is about 2 ns, as will be discussed later.

When N and D_nN are excited by the light at a fixed wavelength with a flux, G, the generation rates of $\overset{*}{N}$ and $D_n\overset{*}{N}$ are in proportion to ε and ε' respectively. Therefore, based on the fact the fluorescence spectrum of $\overset{*}{N}$ bears a close resemblance to that of $D_n\overset{*}{N}$, the total fluorescence intensity is given by the summation of the respective intensities at the peak position:

$$I = I_N + I_{D_nN} = \frac{G}{\varepsilon[\mathrm{N}]+\varepsilon'[\mathrm{D_nN}]} \times \left\{\frac{\varepsilon\eta[\mathrm{N}]}{1+K_{sv}[\mathrm{Q}]} + \frac{\varepsilon'\eta'[\mathrm{D_nN}]}{1+K'_{sv}[\mathrm{Q}]}\right\} \tag{3}$$

where the quantum efficiencies of the fluorescers in the aqueous and micellar phases are defined by $\eta=k/(k+k_n)$ and $\eta'=k'/(k'+k_n')$ respectively; their fluorescence lifetimes are $\tau=1/(k+k_n)$ and $\tau'=1/(k'+k_n')$, and the quenching constants are given by $K_{sv}=k_q\tau$ and $K'_{sv}=k_q'\tau'$. Using Eq. 2 and letting the value of I at $[Q]=0$ be I_0, the relative fluorescence intensity is written as:

$$\frac{I}{I_0} = \frac{1+\frac{\varepsilon'}{\varepsilon}K^0_{eq}[\mathrm{D_n}]^0}{1+\frac{\varepsilon'}{\varepsilon}K_{eq}[\mathrm{D_n}]} \cdot \frac{1}{1+\frac{\varepsilon'\eta'}{\varepsilon\eta}K^0_{eq}[\mathrm{D_n}]^0} \times \left\{\frac{1}{1+K_{sv}[\mathrm{Q}]} + \frac{\frac{\varepsilon'\eta'}{\varepsilon\eta}K_{eq}[\mathrm{D_n}]}{1+K'_{sv}[\mathrm{Q}]}\right\} \tag{4}$$

where K^0_{eq} and $[D_n]^0$ are the equilibrium constant and the density of micelles at $[Q]=0$. Apparently, $I_0/I\to 1$ at $[Q]\to 0$. If the dependence of $K_{eq}[D_n]$ on [Q] is small, the first term on the right-hand side of Eq. 4 reaches to unity. Then, at $K_{sv}[Q]$, $K'_{sv}[Q]\ll 1$, $I_0/I\approx 1+aK_{sv}[Q]+bK'_{sv}[Q]$, where $a=1/(1+\frac{\varepsilon'\eta'}{\varepsilon\eta}K_{eq}[D_n])$ and $b=\frac{\varepsilon'\eta'}{\varepsilon\eta}K_{eq}[D_n]/(1+\frac{\varepsilon'\eta'}{\varepsilon\eta}K_{eq}[D_n])$. A more careful inspection of Eq. 4 leads to the prediction that the plot of I_0/I vs. [Q] curves nonlinearly downward apart from the linear relation, $I_0/I=1+aK_{sv}[Q]+bK'_{sv}[Q]$.

If the effect of the ionic strength, i.e., the dependence of $K_{eq}[D_n]$ on [Q], cannot be ignored, the reference of the fluorescence intensity must be replaced, in order to get a tractable formula, by the value under a hypothetical condition, $K_{sv}=K'_{sv}=0$, where no quenching reaction occurs. Letting this reference intensity be $\bar{I}_0$, Eq. 4 is, therefore, rewritten as:

$$\frac{I}{\bar{I}_0} = \frac{1}{1+\frac{\varepsilon'\eta'}{\varepsilon\eta}K_{eq}[\mathrm{D_n}]} \cdot \left\{\frac{1}{1+K_{sv}[\mathrm{Q}]} + \frac{\frac{\varepsilon'\eta'}{\varepsilon\eta}K_{eq}[\mathrm{D_n}]}{1+K'_{sv}[\mathrm{Q}]}\right\} \tag{5}$$

Finally, we attain:

$$\frac{1}{(I/\bar{I}_0)(1+K_{sv}[Q])-1} = \frac{1+\frac{\varepsilon'\eta'}{\varepsilon\eta}K_{eq}[D_n]}{\frac{\varepsilon'\eta'}{\varepsilon\eta}K_{eq}[D_n]} \cdot \times\left(\frac{K'_{sv}}{K_{sv}-K'_{sv}}+\frac{1}{K_{sv}-K'_{sv}}\cdot\frac{1}{[Q]}\right) \quad (6)$$

Equation 6 shows that the plot of $1/\{(I/\bar{I}_0)(1+K_{sv}[Q])-1\}$ vs. $1/[Q]$ is linear if the first term on the right-hand side of Eq. 6 is insensitive to [Q]. Therefore, the quenching constants can be known by means of the slope and intercept of this plot.

Interpretation of the Fluorescence-Quenching Data. The concentrations of 7EC and 7E4MC (C_N) for fluorescence measurements are fixed around 4—5×10^{-5} mol dm^{-3}. Above the cmc, it can reasonably be assumed that a spherical micelle of n surfactant molecules with a diameter of about 4 nm is generated in the solution and that the surfactant-monomer concentration in the bulk-water phase remains constant. Then, the number-density of micelles (C_M) is estimated by using the total concentration of the added surfactant (C_S) as $C_M=(C_S-\text{cmc})/n$. For the aqueous solution of SDS at 25 °C, the cmc and n are 8×10^{-3} mol dm^{-3} and 62 respectively.[10,11] As $C_S=2.5\times10^{-2}$ mol dm^{-3}, C_M is estimated to be $\approx3\times10^{-4}$ mol dm^{-3}, which is greater than the added fluorophore concentration (C_N) by one order of magnitude. Under such conditions, almost all fluorophores are solubilized into the micelle,[6] and the concentration of empty micelles is given simply by $[D_n]\approx C_M-C_N\approx2.5\times10^{-4}$ mol dm^{-3}. The molar extinction coefficients of 7EC and 7E4MC in the micelle (ε') and in the bulk water (ε) are independently measurable at $C_S\gg$cmc and at $C_S=0$ respectively. The ε'/ε values in an aqueous SDS micellar solution at the excitation wavelength are 0.972 (7EC) and 0.965 (7E4MC). The ratio of the quantum efficiencies, η'/η, can be estimated, by the use of a method described earlier,[6] as 0.74 (7EC) and 0.88 (7E4MC). Anyhow, if the salt effect does not seriously change the situation, the factor, $\varepsilon'\eta'/\varepsilon\eta$, in Eq. 4 should be a constant slightly less than unity.

The fluorescence-yield change shown in Figs. 2 and 3 as a function of the concentration of added salts is essentially explained by Eq. 4. However, such nonlinear plots for micelle-quencher systems are so complex to analyze that a more convenient expression to argue quantitatively (Eq. 6) has been proposed. First, the reference intensity ($\bar{I}_0$) corresponding to the case of $K_{sv}=K'_{sv}=0$ must be determined in accordance with the experiments. As has been mentioned earlier, the addition of NaCl to the micellar system induces a slight decrease in the fluorescence intensity. Since Cl^- has no quenching ability in the aqueous phase and is repelled from the negatively charged SDS micelle, this ion, apparently, cannot contribute to the fluorescence quenching in the micellar phase. In spite of the attractive interaction with SDS micelles, Na^+ has been proved to cause no electronic reaction against the molecule embedded in SDS micelles; this is in contrast to the case of Cs^+, which is confirmed by means of the ODMR technique.[8] Therefore, the fluorescence decrease upon the addition of NaCl is not caused by the quenching effect, but by the change in ionic strength, forcing micelles to alter their characteristic parameters (cmc, n, and α). Thus, $\bar{I}_0$ can be determined as the fluorescence intensity of the solution in which NaCl of the same ionic strength as the quenchers employed (NaBr and CsCl) is dissolved. Experimentally, C_M and, consequently, $[D_n]$ do depend on the amount of salt added through the change in cmc and n. Moreover, the salt effect on K_{eq} may also be important.[12] It is very difficult, at present, to know quantitatively the exact effect from the ionic-strength changes. Irrespective of all such complexities, however, it should be noted that the standard of the fluorescence intensity has always been taken from the solution with an appropriate amount of NaCl.

As the $I/\bar{I}_0$ appearing on the left-hand side of Eq. 6 can thus be calculated at each [Q] by using the experimentally determined $\bar{I}_0$ value, and since K_{sv} has already been known from an independent experiment in a simple aqueous solution (Table 1), it now becomes possible to plot $1/\{(I/\bar{I}_0)(1+K_{sv}[Q])-1\}$ vs. $1/[Q]$. These plots are shown for Br^- in Fig. 4 and for Cs^+ in Fig. 5. The signs on both sides of Eq. 6 are reversed for the Cs^+ quencher because the sign of $K_{sv}-K'_{sv}$ depends on the charge of the quencher ions. The data points in Figs. 4 and 5 obey very well the expected linear relationship, thus showing the good applicability of the proposed model irrespective of the charge type of the inorganic quenchers. The quenching constants (K'_{sv}) of the fluorescer solubilized in SDS micelles due to Br^- and Cs^+ are calculated by dividing the intercept by the slope of the plots in Figs. 4 and 5; they are cited in Table 1. For Br^-, K'_{sv} is much less than K_{sv}. This reduction is caused by the repulsive force between the anionic micelle and the anionic quencher. For Cs^+, on the contrary, K'_{sv} becomes larger by about two orders of magnitude than K_{sv}, the change being more drastic than in the case of Br^-. The associative interaction of the positively charged Cs^+ ion with the anionic micelle catalyzes to quench the fluorescence. Similar phenomena were observed by Eftink and Ghiron[13] for indole derivatives in a SDS micelle-Cs^+ system, but their analysis was only a primitive one insufficient for discussing the quenching mechanism in detail.

The lifetimes (τ) of 7EC and 7E4MC in the aqueous solution have been measured in Ref 1. The lifetimes (τ') in the micelle can be calculated by the use of $\tau'=\tau\cdot(\eta'/\eta)$. Then the quenching-rate constants k_q

($=K_{sv}/\tau$) and k_q' ($=K_{sv}'/\tau'$) are obtained as is shown in Table 1. It is reasonable that 7EC and 7E4MC have the same order of k_q values, for these molecules are different only in the substituent at the 4-position. The k_q and k_q' values of 7EC are always larger than those of 7E4MC. Since this tendency is independent of the charge on quencher ions, and also of the environmental conditions in the aqueous and micellar phases, the quenching reaction seems to be partly screened off by the 4-methyl substituent. The ratio of k_q values for 7EC and 7E4MC in the aqueous phase is nearly equal to the ratio in the micellar phase, irrespective of whether the quencher is Br^- or Cs^+. If the screening effect of the 4-methyl substituent is equally operative in both phases, this parallelism shows that the solubilization sites of the fluorophore should be essentially identical in position. It has already been shown that the polarities felt by these fluorophores

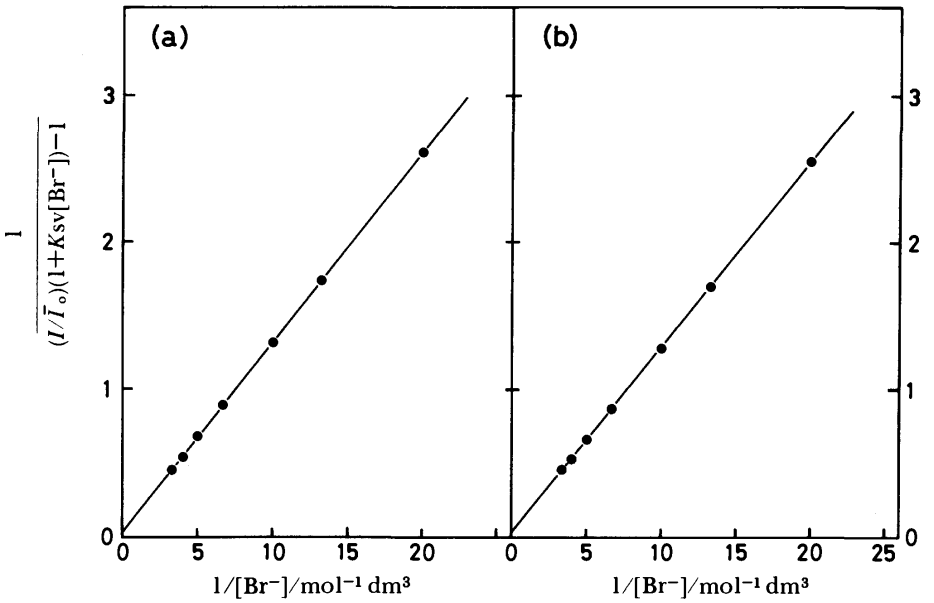

Fig. 4. Plots of $1/\{(I/\bar{I}_0)(1+K_{sv}[Br^-])-1\}$ vs. $1/[Br^-]$ in the 0.025 mol dm^{-3} SDS solution at 25 °C. (a), 7EC; (b), 7E4MC.

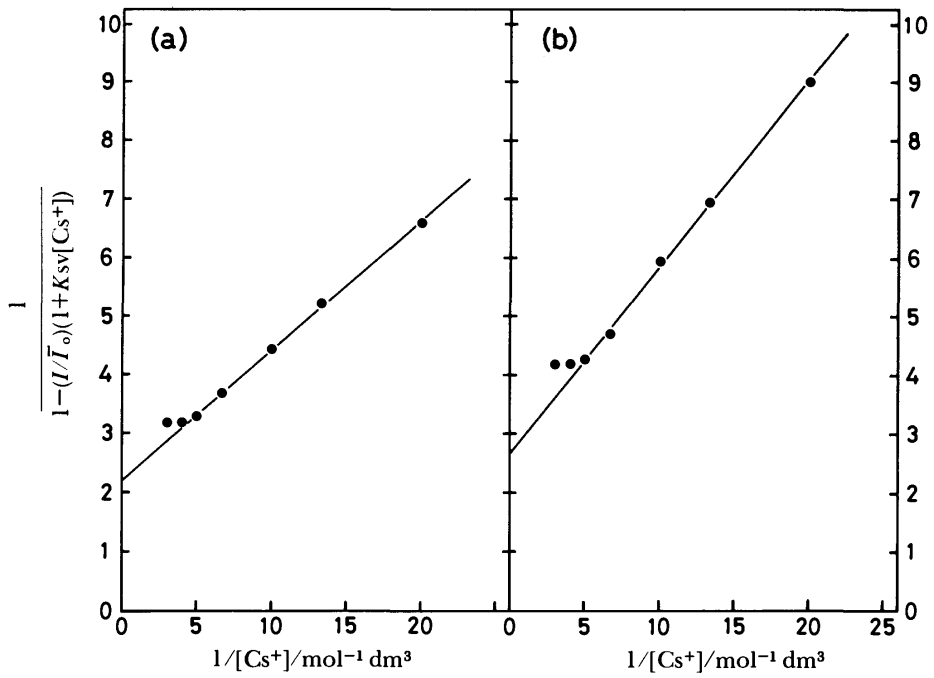

Fig. 5. Plots of $1/\{1-(I/\bar{I}_0)(1+K_{sv}[Cs^+])\}$ vs. $1/[Cs^+]$ in the 0.025 mol dm^{-3} SDS solution at 25 °C. (a), 7EC; (b), 7E4MC.

within the SDS micelle are very similar,[6] a finding which supports the conclusion presented above.

The most probable quenching mechanism for Br^- is the charge-transfer interaction between the ion and the fluorophore, as has been pointed out in earlier works.[1,4,5] If the encounter distance between the fluorescer and quencher, R, and the sum of the diffusion coefficients of each species in aqueous solutions, D, at 25 °C are reasonably assigned as 0.7 nm and 1.5×10^{-5} cm^2 s^{-1} by means of the Stokes-Einstein relation (fluorophore radius ≈0.47 nm; van der Waals radius of Br^-≈0.23 nm), the diffusion-limited value of the quenching-rate constant (k_1) for Br^- is estimated to be $\approx8\times10^9$ mol^{-1} dm^3 s^{-1}, with $k_1=4\pi NRD$, where N is the Avogadro number. If all collisional events among fluorescers and quenchers result in the quenching reaction, k_q will coincide with k_1 and the quenching efficiency (γ) will become unity. Since the experimentally obtained k_q for Br^- (Table 1) is about one-half of k_1, $\gamma\approx0.5$. In contrast to this, k_q' for Br^- is only 1.5—2% of k_1 (Table 1). Such a situation can readily be understood on the basis of the idea that Br^- impinging on the micelle surface is repelled instantaneously by the negatively charged SDS head-groups as a result of electrostatic repulsion and the quenching reaction with the solubilized fluorophore rarely occurs. When I^- is employed as a quencher instead of Br^-, large quenching effects have been observed in both the aqueous and micellar phases. Because the quenching ability of I^- against 7EC and 7E4MC is very high, and because the Stern-Volmer relation does not hold even in a simple aqueous solution,[1] it has been impossible to treat the case of I^- quantitatively within the framework developed here. Quina et al.[14] have investigated the I^- quenching of a pyrene derivative in SDS micelles; they have analyzed it in terms of a two-reactive-state model in which only one of the states (the aqueous phase) is quenchable. This assumption, which represents a special case of the generalized scheme given by Eq. 1, is insufficient for the analysis of a coumarin derivative-SDS micelle system, as is apparent from the investigation of Br^-.

The fluorescence-quenching mechanism due to inorganic cations in aqueous solutions has not been so clear as in the case of inorganic anions, such as halides and pseudohalides.[4,5] As is cited in Table 1, the k_q values for Cs^+ in the aqueous phase are smaller than the values for Br^- by about two orders of magnitude. 7EC and 7E4MC are neutral molecules, and the cations and anions of interest (e.g., Rb^+, Cs^+, Br^-, and I^-) have similar mobilities in aqueous solutions.[15] Therefore, the collisions between the fluorescer and the various quenchers will be nearly equal in probability; if so, the heavy-atom effects from Rb^+ and Br^- and from Cs^+ and I^- should be of the same order. Nevertheless, the experimentally determined quenching-ability order is $I^->Br^-\gg Cs^+>Rb^+$, irrespective of the order of the atomic weights, which are rough measures of the spin-orbit coupling. Further, the ionic radii and the enthalpy changes for the hydration of Br^- and Cs^+ are so similar that there is no positive explanation for the widely different quenching abilities of Cs^+ and Br^- in terms of the participation of heavy-atom effect. The charge-transfer mechanism may, instead, be operative for the cation-quenching. The quenching ability of halide ions is known to increase as the ionization energy of the ion ($X^-\rightarrow X$) is decreased; therefore, the origin of quenching was concluded to be the electron transfer from the quencher to the fluorescer.[4,5] Since the electron-affinity order of alkali ions ($M^+\rightarrow M$) is $Na^+>K^+>Rb^+>Cs^+$, the quenching ability caused by the charge-transfer from the fluorescer to the quencher, if possible, must align in the same order. This idea is not applicable to the present problem, however, because the quenching ability is ordered experimentally as $Cs^+>Rb^+>K^+\approx Na^+\approx0$. The electron-transfer from the cation to the fluorescer that generates dication is energetically more improbable. Although these contradictions will be partly mitigated by the subtle hydration effect that depends on the ionic radius, it is unreasonable to think that either the heavy-atom effect or the charge-transfer interaction is mainly responsible for the weak cationic quenching in the aqueous phase. The most natural explanation possible at present is that the weaker hydration of Cs^+ than of the other cations, indicated by the smaller Stokes' radius for hydrated ions,[15] enables it to come in closer contact with the fluorescer; consequently, an induced electronic perturbation increases the non-radiative deactivation of the fluorescer.

The quenching-rate constant of Cs^+ for the fluorescer in micelles (k_q') becomes larger than k_q by more than two orders of magnitude. This increase in k_q' is qualitatively expected from the attractive interaction between the SDS micelle and Cs^+. However, there occurs the problem which of 'static' and 'bimolecular' quenching mechanisms will really operate in the solution. When the Na^+ of the original counterion of SDS is gradually replaced by Cs^+ by adding CsCl, the concentration of Cs^+ near the micelle surface steadily becomes higher than that in the bulk water. Under such circumstances, it is predictable for a ground-state complex like D_nN-Cs^+ to be generated, thus leading to an instantaneous deactivation of the optically excited state. However, it has not been detected by the measurement of the absorption spectra at any high concentration of added Cs^+. The 'static' or ground-state-complex induced quenching, therefore, can be discarded or need not be taken into account. It can be justified, on the basis of this result, that, at the beginning of analysis, the quenching effect predicted by Eq. 1 is based on the bimolecular interaction

between fluorescers and quenchers. Using the van der Waals radius of Cs^+ ($r_v \approx 0.2$ nm), the diffusion-limited value of the quenching constant, k_1, becomes $\approx 9\times10^9$ $mol^{-1}\,dm^3\,s^{-1}$. The k_q values are so small compared to k_1 that the Cs^+ in the aqueous phase is only a weak quencher. Since the SDS micelle is a spherical particle with a radius of about 2 nm, the collisional rate between the micelle and ion amounts to $\approx 2\times10^{10}$ $mol^{-1}\,dm^3\,s^{-1}$. Considering that the k_q' values for Cs^+ are several tenths of this value, the collisions between Cs^+ and the micelle would lead to a nonradiative deactivation of the excited state only when Cs^+ has come close to the solubilized fluorophore, possibly residing in the micelle interior, but very near the surface. Among bimolecular mechanisms, a contact-type interaction of Cs^+ such as a heavy-atom effect cannot be effective for a fluorescer embedded in the micelle interior across the palisade layer with an interfacial potential barrier. As has been mentioned in the case of the bulk-water phase, there is also no physical reason for the effective occurrence of charge-transfer interaction between the fluorescer and Cs^+. Ghosh et al.[8] have shown that the association of Cs^+ ions with SDS micelles can serve to decrease the extent of the hydration of the micelle, making a less polar environment for the fluorophore. Since the fluorescence yield of 7EC and 7E4MC is sensitively dependent on the polarity of the microenvironment,[6] the polarity change due to the cation becomes a possible candidate for a reasonable explanation. The quenching ability of Cs^+ in the aqueous phase is very low, but it becomes very large for the solubilized fluorophore by virtue of the incident flux of Cs^+ ions toward the micelle surface. Cs^+ impinges against the surface by thermal agitation and electrostatic attraction, and will be exchanged with loosely bounded counterions. Since Cs^+ has a smaller hydrated Stokes' radius than Na^+,[15] it can approach closer to the micelle interface to induce the environmental-polarity change around the fluorophore. It is instructive to notice that the photoionization yields of perylene in SDS micelles was decreased by the addition of monovalent inorganic salts,[16] although the electron-liberation process occurring under a high-energy UV excitation has no direct correlation with the quenching process of the present problem. The binding degree of the counterion at the micelle interface seems to depend on the size of the hydrated ions, and the change in the photoionization efficiency has been understood in terms of the expectation that smaller hydrated ion radii favor a closer approach to the surface and decrease the interfacial electric potential extensively. Considering these results and the difficulty that hydrated inorganic ions have in penetrating deep into the hydrophobic core region of micelles, the solubilization site of the fluorophore must be near to the micelle interface rather than in the micelle core in order that the Cs^+ quenching caused by the collision of Cs^+ against the micelle surface operates efficiently. In addition, it may be possible to generate an activated encounter-complex described by a structure like $D_n^*N\cdots Cs^+\cdots(H_2O)_n$, where D_n^*N is the fluorescer in the micelle, H_2O is solvated water, and the dots describe loose couplings as presented in the 'outer-sphere' reaction between a metal ion and a ligand of metal-complexes. The role of such a cation-bridged complex was emphasized by Shporer et al.[17] to explain the electron-transfer reaction between cyano-metal complexes in a solution in which cations have been dissolved as catalysts; they found that the reaction rate increases from Li^+ to Cs^+. In the present case, although it seems unlikely that the electron transfer really occurs between the fluorescer and solvated water, the cation-assisted complexation may contribute effectively to the nonradiative deactivation of excited fluorophores. It is believed that the polarity change and the formation of the excited-state complex will act in concert to enhance the quenching ability of Cs^+ in the anionic micellar system.

Limitation on the Applicability of the Proposed Model. The discussion has hitherto proceeded by assuming that the first term on the right-hand side of Eq. 6, $\left(1+\frac{\varepsilon'\eta'}{\varepsilon\eta}K_{eq}[D_n]\right)/\frac{\varepsilon'\eta'}{\varepsilon\eta}K_{eq}[D_n]$, is independent of the added salt concentration. If $(\varepsilon'\eta'/\varepsilon\eta)K_{eq}[D_n] \gg 1$, this assumption is valid no matter how much the term depends on the salt concentration. By means of the slope of the plots in Fig. 4 and the obtained K_{sv} and K_{sv}' values shown in Table 1, the value for Br^- can be estimated to be $(\varepsilon'\eta'/\varepsilon\eta)K_{eq}[D_n] \approx 6.1$ (7EC) and ≈ 38.6 (7E4MC), which satisfy the assumption. Further, the C_M ($=(C_S-\text{cmc})/n$) necessary for the estimation of $[D_n]$ is only weakly dependent on the ionic strength under the experimental condition employed, as cmc is decreased while, on the contrary, n is increased by the addition of salts. These two reasons for the insensitiveness of the first term in Eq. 6 to the ionic strength confirm that the data follow very generally the theoretically predicted linear relationship. Since the counterion of an aqueous SDS micelle, Na^+, is not changed by the addition of NaBr, the factor of $\varepsilon'\eta'/\varepsilon\eta$ can be approximated by the value with no added salt (salt-free conditions).[6] Then, the $K_{eq}[D_n]$ values are 8.4 (7EC) and 45.7 (7E4MC). When the 'solubilization ratio' of the fluorophore is defined by $p=[D_nN]/([D_nN]+[N])$, p is rewritten as $p=K_{eq}[D_n]/(K_{eq}[D_n]+1)$; its values are estimated to be 0.89 (7EC) and 0.98 (7E4MC). These p values are very close to those in a salt-free SDS micelle[6] and show that the majority of fluorophores exist in the micelle even in NaBr is added to the solution. If $[D_n]$ should be approximated by $[D_n] \approx C_M - C_N \approx 2.5\times10^{-4}$ mol dm^{-3}, as carried out before under salt-free conditions, the K_{eq} values can be calculated as 3.4×10^4 $mol^{-1}\,dm^3$ (7EC) and 1.8×10^5

$mol^{-1}\,dm^3$ (7E4MC); these values are in good accord with the value based on a different method[6] in spite of the approximations used here and the existence of the additive.

From Fig. 5, the $(\varepsilon'\eta'/\varepsilon\eta)K_{eq}[D_n]$ values for Cs^+ are calculated to be 0.85 (7EC) and 0.61 (7E4MC), smaller than the values for Br^- by one or more orders of magnitude. If the first term of Eq. 6 varies through the dependence of $K_{eq}[D_n]$ on $[Cs^+]$, the applicability of the linear relationship is restricted. As may be seen in Fig. 5, data have deviated systematically from the theory at high concentrations of CsCl (at small $1/[Cs^+]$). The region where the proposed model seems valid is, at most, from $[Cs^+]=0.05$ to $0.2\,mol\,dm^{-3}$. There may be another possibility that the static quenching process mentioned earlier begins to contribute at higher Cs^+ concentrations, although no sign of the ground-state complex formation has yet been detected spectroscopically. When the counterions of the micelle are changed from Na^+ to Cs^+, ε' shows no observable change. η' will decrease with this change through the generation of a less polar environment by the Cs^+ attachment to the micelle surface. However, the amount of decrease is believed to be not very large, for the fluorescence yields of 7EC and 7E4MC are a smoothly varying function of the environmental polarity,[6] which cannot explain the drastic decrease in $(\varepsilon'\eta'/\varepsilon\eta)K_{eq}[D_n]$. Possibly, $K_{eq}[D_n]$ or p is affected by the polarity change around the solubilization site, which serves to make the state of the solubilized fluorophores unstable. The latter may be the main reason for the observed decrease in the solubilization ratio. It must be mentioned in this connection that, if η' is decreased by adding CsCl instead of NaCl or NaBr, the k_q' value for Cs^+ in Table 1 understimates the quenching reaction, for η' under salt-free conditions is employed in the estimation.

Hautala et al.[18] have reported large and complex effects of oxygen on the fluorescence lifetimes of naphthalene in aqueous micellar solutions in addition to the fluorescence-quenching effects attributable to inorganic ions. The situation is different from the case of coumarin derivatives because the fluorescence lifetimes of 7EC and 7E4MC ($\tau\approx2$ ns) are too short to be affected by a quenching process caused by oxygen in comparison with the case of naphthalene ($\tau\approx40$ ns). Experimentally, no quenching phenomenon caused by dissolved oxygen has been found through the examination of deaerated samples.

The author wishes to thank Dr. Hiroyuki Anzai of this laboratory for his helpful advice and stimulating discussions. This work was supported by the special research program on "Molecular Electronics" of the Ministry of International Trade and Industry, Agency of Industrial Science and Technology.

Energetics of the Sequential Electroreduction and Electrooxidation Steps of Benzenoid Hydrocarbons[1)]

Tanekazu KUBOTA,* Kenji KANO, Bunji UNO, and Tomonori KONSE
Gifu Pharmaceutical Universtiy, 5-6-1 Mitahora-higashi, Gifu 502
(Received May 6, 1987)

The first and second reduction ($E^{red}_{1/2\cdot1}$, $E^{red}_{1/2\cdot2}$) and the first oxidation ($E^{oxd}_{1/2\cdot1}$) standard potentials of benzenoid alternant hydrocarbons (BAH) were experimentally determined by means of cyclic voltammetry (CV) in nonaqueous solvents. The second standard oxidation potential ($E^{oxd}_{1/2\cdot2}$) was, however, estimated by checking the scan rate dependence of the irreversible CV curve. The equations pertinent to these potentials and their mutual relations were formulated from the points of view of the Born-Haber-type thermodynamic energy cycle and SCFMO calculations. Of the SCFMO calculations, the MO-paring property established in the PPP-type π-electron theory was very successful in the discussion of the equations given above. Under the acceptable assumptions that the solvation energies due to mono- and dications are put equal to those of the mono- and dianions respectively, and using the MO-pairing property, the equation of $(E^{oxd}_{1/2\cdot1}+E^{red}_{1/2\cdot1})=(E^{oxd}_{1/2\cdot2}+E^{red}_{1/2\cdot2})$ was derived. The experimental results were well described by this equation. The solvation-energy values were evaluated by applying the experimentally determined reduction or oxidation potentials to the theoretical equations. An examination of the solvation energies has shown that these values can be interpreted by means of the Born-type equation.

It is well-known that the voltammetric reduction and oxidation of usual organic substances show two waves in nonaqueous solvents;[2-5)] these waves are correlated with the formation of the monoanion radical R^- and the dianion $R^=$ for the reduction and the monocation radical R^+ and the dication R^{++} for the oxidation. Especially, the voltammetric reduction and oxidation behavior of aromatic hydrocarbons in nonaqueous solvents has been studied by many workers in connection with their investigations of the radical ions themselves or electrochemical and chemical reactions immediately following the radical-ion formation.[6-8)] The molecular orbital description for the first half-wave reduction ($E^{red}_{1/2\cdot1}$) and oxidation ($E^{oxd}_{1/2\cdot1}$) potentials was also discussed[6-15)] and written by the sum of the LUMO (ε_{lu}) or HOMO (ε_{ho}) energy and the solvation energy, as is given by Eqs. 1 and 2:[7-15)]

$$FE^{red}_{1/2\cdot1}(R^-/R) = \Delta G^\circ - \varepsilon_{lu} - \Delta E^-_{solv} \quad (1)$$

$$FE^{oxd}_{1/2\cdot1}(R^+/R) = \Delta G^\circ - \varepsilon_{ho} + \Delta E^+_{solv} \quad (2)$$

where the absolute potential of a reference electrode is denoted by ΔG°[16)] and where $\Delta E^-_{solv}=(E^-_{solv}-E_{solv})$ and $\Delta E^+_{solv}=(E^+_{solv}-E_{solv})$ are the solvation-energy difference between monoanion and neutral species and that between monocation and neutral species respectively. The linear relation of the $E^{red}_{1/2\cdot1}$ vs. ε_{lu} plot or the $E^{oxd}_{1/2\cdot1}$ vs. ε_{ho} plot has been reported using HMO or semiempirical SCFMO;[6-15,17-19)] also, the values of ΔE^-_{solv} and ΔE^+_{solv} have been estimated by means of Eqs. 1 and 2.[12)] In turn, Hush and Blackledge[20)] discussed first the reduction potential difference between $E^{red}_{1/2\cdot1}$ and $E^{red}_{1/2\cdot2}$ (the second half-wave reduction potential) by using π-SCFMO in neutral species, showing that the difference stands for the free-energy change pertinent to the disproportionation $2R^- \rightleftarrows R+R^=$ and is in intimate correlation with the two-electron-repulsion-integral γ_H at LUMO.[20,21)] However, the monoanion and dianion are necessarily in a quite different electronic structure from that of the neutral species, so that their discussion is only qualitative. Keeping this fact in mind, in a previous paper[19)] we ourselves again discussed and formulated the mutual relation between $E^{red}_{1/2\cdot1}$ and $E^{red}_{1/2\cdot2}$ from the points of view of the Born-Haber-type thermodynamic energy cycle and SCFMO calculation under the assumption that the above reduction waves are for a reversible system. The theoretical equations thus formulated were experimentally examined using stilbene derivatives as model substances, with the result that the theoretical and experimental outcomes were found to be reasonably compatible.[19)] Here we have newly derived the equations with regard to the mutual relation between the first ($E^{oxd}_{1/2\cdot1}$) and the second ($E^{oxd}_{1/2\cdot2}$) half-wave oxidation potentials. The equations mentioned above on the first and second reduction and oxidation potentials and their mutual correlations have been quantitatively examined using benzenoid alternant hydrocarbons (BAH) in order to verify their reliability, because the BAH's are the fundamental substances for testing a theoretical treatment. In addition, the solvation energies of the monoanion, monocation, dianion, and dication were evaluated using the above equations. The details of these examinations will be reported here.

Experimental

Cyclic Voltammetry. The half-wave reduction potentials of various kinds of BAH were polarographically reported by Hoytink et al.[2,6)] and later by other workers in nonaqueous solvents.[7-12,22,23)] Hoytink's data were mainly obtained in 75 and 96 % aqueous dioxanes vs. a saturated calomel electrode (SCE).[2,6)] However, the data of $E^{red}_{1/2\cdot2}$ were not sufficient. Parker and his colleagues[8,15)] also carried out

much work on the nonaqueous voltammetries of BAH and other organic substances; they recommended the use of neutral alumina,[24] which is added in a nonaqueous sample solution in order to remove the moisture thoroughly from nonaqueous solvents so that one can record the reversible cyclic voltammograms (CV) for $E^{red}_{1/2\cdot2}$ as well as the $E^{red}_{1/2\cdot1}$ and $E^{oxd}_{1/2\cdot1}$, and also for $E^{oxd}_{1/2\cdot2}$ in some organic substances. For our present purpose, the measurement of reduction and oxidation potentials in reversible redox systems of BAH is, of course, to be hoped for, so much effort was made along these lines using Parker's alumina method.[24] Our experiments were as follows: The instruments used for the CV measurements were the same as were employed in our foregoing study.[19] In the present experiment, however, positive feedback circuits were added to the above instruments for a so- called IR-drop compensation, though the instruments consist of a three-electrode system.[19,25,26] The CV curves were recorded at various sweep rates. The working electrode was a platinum rod, 1 mm in diameter and sealed in a soft glass tube with a diameter of ca. 6.5 mm.[27] Just before use, we polished the plane head of the platinum electrode with a polishing powder, "Royal Diamond Compound," commercially available. The nonaqueous electrolysis cell used here was the same as that previously reported.[18,19,26,28] A saturated calomel electrode (SCE) was employed as a reference electrode.

Purification of Solvents. The solvents for the reduction and oxidation CV measurements were *N,N*-dimethylformamide (DMF) and acetonitrile (AN) respectively, in which 0.1 mol dm^{-3} of tetrapropylammonium perchlorate (TPAP) had been dissolved as a supporting electrolyte. The purification of DMF (Dotite Spectrosol) was carefully done by the method recommended by Juillard;[29] i. e. the impurities were removed by treatment with P_2O_5, KOH, and picric acid, its distillation always being carried out in reduced pressure under a nitrogen atmosphere. Just after the purification, we used the DMF for our experiments. AN of Dotite Spectrosol was first treated overnight with CaH_2 and then distilled, all the operations being done in a stream of N_2.[19,26] According to the method of Hammerich and Parker,[24] the AN was then passed through a column of a neutral alumina (Woelm W 200, active-grade Super I; water addition, 0%; ICN Biomedicals) into the vessel under an N_2 atmosphere.

Experimental Procedure. The sample solutions were prepared as follows. The necessary amounts of the samples and TPAP were weighed into a 20-ml volumetric flask; then the flask as well as a nonaqueous electrolysis cell were dried overnight in a vacuum desiccator. In a dry box completely filled with N_2 gas, the samples in the flask were dissolved with DMF or AN, and then transferred into the electrolysis cell, containing about 10 g of the above neutral alumina, a good suspension of which is required, before recording the CV curves. All the measurements were carried out at 25±0.1 °C at a concentration of 0.5—1×10^{-3} mol dm^{-3}. The dissolved oxygen was removed by bubbling N_2 gas through the sample solution, and then the inactive gas was passed over the solution surface during the measurement. The trace of moisture in the N_2 gas was removed by immersing the N_2-gas guide tube into a liquid-nitrogen bath. The method of purifying TPAP was the same as previously reported.[18,19,26,28] The neutral alumina was always kept in a nitrogen atmosphere.

Samples. The hydrocarbons employed in the present study are listed in Table 1. All of them were commercially available from Aldrich and Wako Chemical Co. The samples were recrystallized several times from ether, methanol, ethanol, benzene, benzene plus ethanol, benzene plus methanol, and toluene for Samples No. (**1**), (**2**), (**5**,**6**,**10**,**13**), (**7**,**12**), (**3**), (**11**), and (**9**) respectively.[30] High-vacuum sublimation was also used to purify Samples **3**, **4**, **8**, and **9**. All the melting points agreed well with those in the literature, and the elemental analyses of all the samples were in good agreement with the calculated values.

MO Calculation

In order to interpret the relations between $E^{red}_{1/2\cdot1}$ and $E^{red}_{1/2\cdot2}$ and also between $E^{oxd}_{1/2\cdot1}$ and $E^{oxd}_{1/2\cdot2}$ values, MO calculations were carried out by using the methods of Pariser-Parr-Pople (PPP), CNDO/2, and the ab initio STO-3G basis set for closed shell systems, such as neutral molecules and their dianions and dications.[31,32] In the case of monoanion and monocation radicals in their doublet ground states, we have applied a restricted Longuet-Higgins-Pople type open-shell SCFMO (LP-SCFMO) calculation for π-electron systems.[33,34] The molecular geometries of BAH were determined using the Nishimoto-Forster equation,[35] $r_{cc}=1.517-0.180P_{cc}$, where r_{cc} and P_{cc} are the bond distance and the π-bond order on the nearest neighbor carbon atoms. PPP calculations of neutral species started from the regular hexagon of $r_{cc}=1.396$ Å. After repeating the calculation, final r_{cc} values in the self-consistent as regards P_{cc} were obtained. In this case, the bond angles were altered within 120±2° so as to keep the molecular symmetry.[36] In the PPP- and LP-SCFMO calculations, Nishimoto-Mataga's equation[37] was employed for the evaluation of the two-center-repulsion-integrals, and the core resonance integral, β^{core}_{cc}, was fixed as −2.37 eV for the sake of convenience.[36] The total energies were calculated using the CNDO/2 and ab initio STO-3G methods. The PPP calculation was carried out with an NEC PC-9801 microcomputer, but the other calculations were performed with the FACOM M-382 and HITAC M-680H computers in the Nagoya University Computation Center and the Okazaki Institute for Molecular Science respectively.

Results and Discussion

Theoretical Correlation of the First and Second Half-Wave Potentials Pertinent to Reversible Reduction or Oxidation Processes. In the foregoing paper we discussed the physical meaning of $E^{red}_{1/2\cdot2}$, $(E^{red}_{1/2\cdot1}+E^{red}_{1/2\cdot2})$, and $(E^{red}_{1/2\cdot1}-E^{red}_{1/2\cdot2})$ from the points of view of the thermodynamical energy cycle and the MO calculation, and also by referring to the derivation of Eq. 1. Equations 3—5 were thus obtained:[19]

$$FE^{red}_{1/2\cdot2}(R^{=}/R^{-}) = \Delta G^{\circ} - \varepsilon^{-}_{so} - \gamma^{-}_{ss} - \Delta E^{=}_{solv} \qquad (3)$$

$$F(E^{red}_{1/2\cdot1} + E^{red}_{1/2\cdot2}) = 2\Delta G^\circ - (\varepsilon^-_{so}+\varepsilon_{1u}+\gamma^-_{ss}) - (\Delta E^-_{solv}+\Delta E^=_{solv}) \quad (4)$$

$$F(E^{red}_{1/2\cdot1} - E^{red}_{1/2\cdot2}) = (\varepsilon^-_{so}-\varepsilon_{1u}+\gamma^-_{ss}) + (\Delta E^=_{solv}-\Delta E^-_{solv}) \quad (5)$$

where the electronic structures of neutral species, monoanion, and dianion are considered separately, ε_{lu} and ε^-_{so} being the LUMO and SOMO (singly occupied MO) energies for neutral and anion radical species respectively. The Coulomb-repulsion integral caused by the two electrons in the SOMO of a monoanion is written as γ^-_{ss}. The solvation energy terms, $\Delta E^=_{solv}$, $(\Delta E^=_{solv}-\Delta E^-_{solv})$, and $(\Delta E^-_{solv}+\Delta E^=_{solv})$, are given by $(E^=_{solv}-E^-_{solv})$, $(E^=_{solv}+E_{solv}-2E^-_{solv})$, and $(E^=_{solv}-E_{solv})$ respectively.[38] Equation 4 is very important for evaluating the solvation energy of a dianion (see below), and Eq. 5 is in intimate correlation with the disproportionation equilibrium of a monoanion, as Hush and Blackledge pointed out qualitatively.[20] In this paper we have newly established the mutual relation of the first and the second half-wave oxidation potentials, $E^{oxd}_{1/2\cdot1}$ and $E^{oxd}_{1/2\cdot2}$, by applying a Born-Haber-type thermodynamical cycle. The $E^{oxd}_{1/2\cdot1}$ value for a reversible redox couple is expressed by Eq. 2, where the energy level is put in vacuo. The energy (IE^+) necessary to produce a dication from a monocation can now be represented by the orbital approximation as $IE^+=-\varepsilon^+_{so}-\varepsilon_{coul}$; here, ε^+_{so} is the SOMO energy of the monocation radical, while $-\varepsilon_{coul}$ is the extra energy needed in order to eject an electron from the cation species by overcoming the Coulomb-stabilization energy, ε_{coul}, between the electron and the cationic core field. This $-\varepsilon_{coul}$ term may be put equal to the two-center-repulsion integral, γ^+_{ss}, using SOMO, as the CNDO/2 semiempirical theory adopted this model also. Thus, $IE^+=-\varepsilon^+_{so}+\gamma^+_{ss}$; also, the IE^+ should correspond to the LUMO energy, ε^{++}_{lu}, of the singlet dication from the point of view of the orbital approximation. The solvation energy term, ΔE^{++}_{solv}, is now given by $\Delta E^{++}_{solv}=E^{++}_{solv}-E^+_{solv}$, E^{++}_{solv} being the solvation energy of the dication. $E^{oxd}_{1/2\cdot2}$ is thus written as Eq. 6 with reference to the derivation of Eq. 2:

$$FE^{oxd}_{1/2\cdot2}(R^{++}/R^+) = \Delta G^\circ - (\varepsilon^+_{so}-\gamma^+_{ss}) + \Delta E^{++}_{solv} \quad (6)$$

The combination of Eqs. 6 and 2 leads to:

$$F(E^{oxd}_{1/2\cdot1} + E^{oxd}_{1/2\cdot2}) = 2\Delta G^\circ - (\varepsilon_{ho}+\varepsilon^+_{so}-\gamma^+_{ss}) + (\Delta E^+_{solv}+\Delta E^{++}_{solv}) \quad (7)$$

and:

$$F(E^{oxd}_{1/2\cdot2}-E^{oxd}_{1/2\cdot1}) = (\varepsilon_{ho}-\varepsilon^+_{so}+\gamma^+_{ss}) + (\Delta E^{++}_{solv}-\Delta E^+_{solv}) \quad (8)$$

The same consideration as is given in Eqs. 3—5 indicates that the solvation energy terms in Eqs. 7 and 8 are given by $(\Delta E^+_{solv}+\Delta E^{++}_{solv})=(E^{++}_{solv}-E_{solv})$ and $(\Delta E^{++}_{solv}-\Delta E^+_{solv})=(E^{++}_{solv}+E_{solv}-2E^+_{solv})$. The physical meaning of Eqs. 7 and 8 is the same as that of Eqs. 4 and 5 except that the former is for the cation species. Equation 7 is especially important for estimating the solvation energy of the dication.

Correlation between Orbital Energy Approximation and Overall Calculations. Here it should be pointed out that $(\gamma^+_{ss}-\varepsilon_{ho}-\varepsilon^+_{so})$ in Eq. 7 is equivalent to the $(E^{++}_t-E_t)$, where E^{++}_t and E_t are the total energies of the dication and the neutral molecules respectively. This is because, under Koopmans' theorem,[39] $IE=-\varepsilon_{ho}$, and $IE^+=\gamma^+_{ss}-\varepsilon^+_{so}$ are the quantities pertinent to the total energy difference, expressed by $(E^+_t-E_t)$ and $(E^{++}_t-E^+_t)$ respectively.[19] Similarly, $(\varepsilon^+_{so}-\gamma^+_{ss})$ should correspond to ε^{++}_{lu}, which is the LUMO energy derived from the overall calculation of the dication. The correlation of the $(\gamma^+_{ss}-\varepsilon_{ho}-\varepsilon^+_{so})$ to $(E^{++}_t-E_t)$, and also that of $(\varepsilon^+_{so}-\gamma^+_{ss})$ to ε^{++}_{lu}, were checked by the actual MO calculation of the present BAH's. The total energy values were obtained by the use of the CNDO/2 and ab initio STO-3G methods, while the other quantities were evaluated by means of the PPP-SCF and LP-SCF methods (vide supra). All the calculation results are listed in Table 1. The application of the least-squares method led to the following results:

$$\varepsilon^{++}_{lu} = 0.852(\varepsilon^+_{so}-\gamma^+_{ss}) - 0.104 \quad (9)$$

with r (correlation coefficient) = 0.998 for n=11 (Compounds **1**—**11**).

$$(E^{++}_t-E_t) = a(\gamma^+_{ss}-\varepsilon_{ho}-\varepsilon^+_{so}) - c \quad (10)$$

with a=1.749, c=16.961, r=0.988 (n=11, Compounds **1**—**11**) for the CNDO/2 total energies, and with a=1.366, c=17.526, and r=0.986 (n=10, Compounds **1**—**11** except **5**) for the STO-3G calculation. As was discussed in the foregoing paper,[19] we have similarly obtained Eqs. 11 and 12:

$$\varepsilon^=_{ho} = 0.852(\varepsilon^-_{so}+\gamma^-_{ss}) - 1.655 \quad (11)$$

with r=0.998 for 11 compounds **1**—**11** and:

$$(E^=_t-E_t) = a(\varepsilon_{1u}+\varepsilon^-_{so}+\gamma^-_{ss}) + c \quad (12)$$

with a=1.546, c=6.538, and r=0.977 (n=11, Compounds **1**—**11**) for the CNDO/2 calculation, and with a=1.454, c=13.617, and r=0.985 (n=10, Compounds **1**—**11** except **5**) for the STO-3G calculation. The mutual correlation shown in Eqs. 9—12 is surprisingly good despite the adoption of different calculation methods, indicating that the orbital approximation employed here is quite good for the present systems. It may also be noted that the relations of Eqs. 9—12 are especially good for such polyacenes as Substances **1**—**4**, the correlation coefficient for these cases being more than 0.99976.

Table 1. The Values of the Orbital Energies (ε) and Two-Center-Repulsion Integrals (γ) Obtained by PPP-Type Approximation for Neutral and Ion Species, and the Total Energy (E_t) Differences between Neutral and Ion Species, as Calculated by CNDO/2 and STO-3G Methods on Benzenoid Hydrocarbons[a)]

a) All the values are in eV units. b) HOMO energy of neutral species. c) LUMO energy of neutral species. d) SOMO energy of monoanion species. e) Values at SOMO calculated by the Nishimoto-Mataga equation for anion and cation species, both of which values come out the same because of the pairing theorem (see text). f) HOMO energy of dianion species. g) SOMO energy of monocation species. h) LUMO energy of dication speies. i) Ab initio STO-3G values are given in parentheses. j) Total energy difference between dianion and neutral species. k) Total energy difference between dication and neutral species. l) These values are the same for the cation and anion species because of the MO-pairing property (see text). m) The MO-pairing theorem is broken for this compound. The values in parentheses are for the energies given in the parentheses in the title.

Examination of the First and Second Reduction Potentials of Benzenoid Alternant Hydrocarbons by Means of MO Calculations. When we use the experimental method employed here, reversible or quasireversible reduction voltammograms for all the BAH's, except for naphthalene and phenanthrene, have been recorded not only for the first wave, but also for the second reduction wave under the voltage sweep rates of 50 mV s^{-1}—250 V s^{-1}, in depending on the substance. However, only the first reduction wave was observed as a reversible voltammogram on naphthalene and phenanthrene. An example of cyclic voltammograms is illustrated in Fig. 1 for perylene. The reversible half-wave reduction potentials were determined using the equation $E^{red}_{1/2}=(E_{cp}+E_{ap})/2$, where E_{cp} and E_{ap} are the cathodic and anodic peak potentials of a CV curve. All of these experimental data are listed in Table 2.[27] It should be noted that the $E^{red}_{1/2.1}$ and $E^{red}_{1/2.2}$ values listed in Table 2 are consistent with those reported by Jensen and Parker[40] for Compounds **2**, **6**, **7**, **9**, and **12**, though their data were obtained at 11 °C and with 0.2 mol dm^{-3} tetramethylammonium bromide as the supporting electrolyte.[41]

Let us now discuss the application of Eqs. 1, 3, 4, and 5 to the present experimental results. As has already been reported by other authors,[6,13-15,17] the

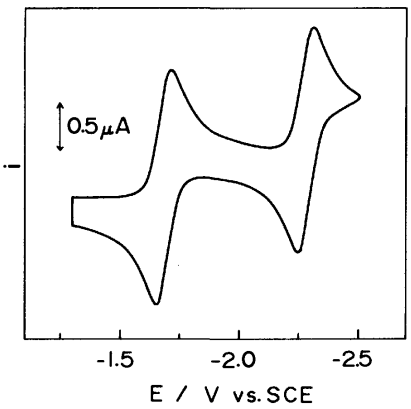

Fig. 1. Cyclic voltammogram of perylene in reduction process at a Pt electrode. Solvent is DMF containing 0.1 mol dm^{-3} TPAP and ca. 10 g of neutral alumina, the sample concentration being 9.3×10^{-4} mol dm^{-3}. The voltammogran was recorded at $v=$ 50 mV s^{-1} and 25 °C.

a) These values were obtained from reversible or quasireversible CV curves using a Pt electrode in DMF containing 0.1 mol dm^{-3} TPAP. b) These values were obtained by CV measurements with a Pt electrode in AN containing 0.1 mol dm^{-3} TPAP. Although the first oxidation waves are reversible or quasireversible, the second ones are irreversible for all the samples employed except for Compound **13**, which gave a quasireversible one. See text for the method of evaluating $E^{oxd}_{1/2.2}$. c) Ionization potentials.[52] d) Electron affinities.[43] e) The first oxidation wave was irreversible at $v<200$ V s^{-1}. f) Insoluble in AN. g) Three or four oxidation waves were observed. h) Reduction potentials were also measured in AN containing 0.1 mol dm^{-3} TPAP. These are given in parentheses. i) Average values are given in parentheses.

data in Tables 1 and 2 indicate a good linear relation to satisfy Eq. 1, written as $E^{red}_{1/2\cdot1}=-0.895\varepsilon_{lu}-4.681$, with $r=0.985$ and $n=12$ (Compounds **1—12**). The absolute value (0.895) of the slope is near to the theoretical value of unity. The first reduction potential, $E^{red}_{1/2\cdot1}$, is then well expressed by Eq. 1.[42,43] We next test Eq. 3 again using the data in Tables 1 and 2. The $E^{red}_{1/2\cdot2}$ vs. $(\varepsilon^{-}_{so}+\gamma^{-}_{ss})$ plot is $E^{red}_{1/2\cdot2}=-0.549\ (\varepsilon^{-}_{so}+\gamma^{-}_{ss})-1.327$, with $r=0.897$ and $n=9$ (Compounds **2—4, 6—11**). Since $\varepsilon^{=}_{ho}$ is in a good correlation with $(\varepsilon^{-}_{so}+\gamma^{-}_{ss})$, as may be understood from Eq. 11, we attempted to establish the plot of $E^{red}_{1/2\cdot2}$ against $\varepsilon^{=}_{ho}$; it is illustrated in Fig. 2 along with the correlation equation.[44] The above linearity seems to be relatively good, but the absolute values of the slope and the correlation coefficients are both smaller than those of the $E^{red}_{1/2\cdot1}$ vs. ε_{lu} plot. As would be expected, one of these factors may be attributed to the lower accuracy of the orbital-energy calculations of the mono- and dianion species in comparison with those of the neutral one. However, another important reason is the different contribution from the molecular electronic states and the solvation-energy terms between the redox systems of $R+e\rightleftarrows R^{-}$ (Eq. 1) and $R^{-}+e\rightleftarrows R^{=}$ (Eq. 3). It is well known that the π-electron distribution on each carbon atom in neutral alternant hydrocarbon is the same,[45] so that their π-dipole moment is zero, thus leading to a small solute-solvent interaction. However, generally speaking, the electron density of the anion radical of BAH is not uniformly distributed in the molecules,[46] because π-electrons in the LUMO are distributed mainly over the atomic orbitals determined by its orbital symmetry.[44] This tendency turns out to be much larger for the dianion than for the monoanion, so the possibility of a specific solute (ion)-solvent interaction seems to be larger for the former than the latter.[47] This must play an important role for that the correlation coefficient of the $E^{red}_{1/2\cdot2}$ vs. $(\varepsilon^{-}_{so}+\gamma^{-}_{ss})$ or $\varepsilon^{=}_{ho}$ plot is less than that of the $E^{red}_{1/2\cdot1}$ vs. ε_{lu} plot. In addition, the BAH's studied here extend from small-ring-size molecules (small cavity radius in solution) to large ones (large cavity radius). Therefore, a Born-type equation[48] indicates that the contribution from the solvation-energy term is not constant in the strict sense; this tendency is more important in the $E^{red}_{1/2\cdot2}$ step than in the $E^{red}_{1/2\cdot1}$ step (see below). This fact is discussed in the Appendix from the point of view of multivariate analysis. As a result, we can expect a positive correlation of $E^{red}_{1/2\cdot2}$ to $\Delta E^{=}_{solv}$ (Eq. 3). In other words, the values of both $E^{red}_{1/2\cdot2}$ and $\Delta E^{=}_{solv}$ move to a small negative value with an increase in the ring size (vide infra). This may cause the decrease in the slope value of the $E^{red}_{1/2\cdot2}$ vs. $(\varepsilon^{-}_{so}+\gamma^{-}_{ss})$ or $\varepsilon^{=}_{ho}$ plot.

Let us now turn to a discussion of Eq. 4. Using the linear relations of Eqs. 11 and 12, the plots of $(E^{red}_{1/2\cdot1}+E^{red}_{1/2\cdot2})$ to $(E^{=}_{t}-E_{t})$, $(\varepsilon_{lu}+\varepsilon^{=}_{ho})$, and $(\varepsilon_{lu}+\varepsilon^{-}_{so}+\gamma^{-}_{ss})$ led to good linear relations as follows: $(E^{red}_{1/2\cdot1}+E^{red}_{1/2\cdot2})=-a(E^{=}_{t}-E_{t})-b$ with $a=0.417$ (0.459), $b=2.287$ (−1.212), and $r=0.990$ (0.987) for the CNDO/2 and ab initio STO-3G calculations (the latter is given in parentheses); $(E^{red}_{1/2\cdot1}+E^{red}_{1/2\cdot2})=-0.808(\varepsilon_{lu}+\varepsilon^{=}_{ho})-6.781$ with $r=0.962$; $(E^{red}_{1/2\cdot1}+E^{red}_{1/2\cdot2})=-0.734(\varepsilon_{lu}+\varepsilon^{-}_{so}+\gamma^{-}_{ss})-5.113$ with $r=0.942$. The compounds employed are Nos. **2—4** and **6—11**. An example is illustrated in Fig. 3. We think that the theoretical Eq. 4 is quite well satisfied from the experimental point of view. The relatively large difference in the slope values between the orbital-energy approximation and the total energy calculations may be attributed to the different models adopted here; i. e., the "*a*" value of Eq. 12 shows large deviation from 1.

Let us next consider the physical meaning of the $(E^{red}_{1/2\cdot1}-E^{red}_{1/2\cdot2})$ given by Eq. 5, where we can easily understand that the γ^{-}_{ss} values make the largest

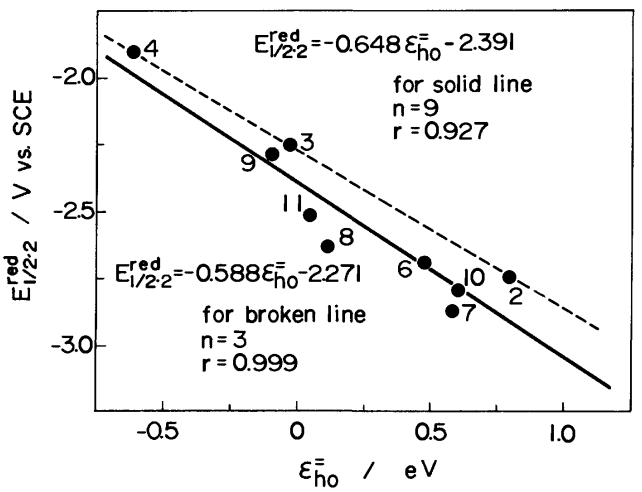

Fig. 2. Linear relation of $E^{red}_{1/2\cdot2}$ values to $\varepsilon^{=}_{ho}$ for BAH's. Each sample number is the same as given in Table 1. See text for detail.

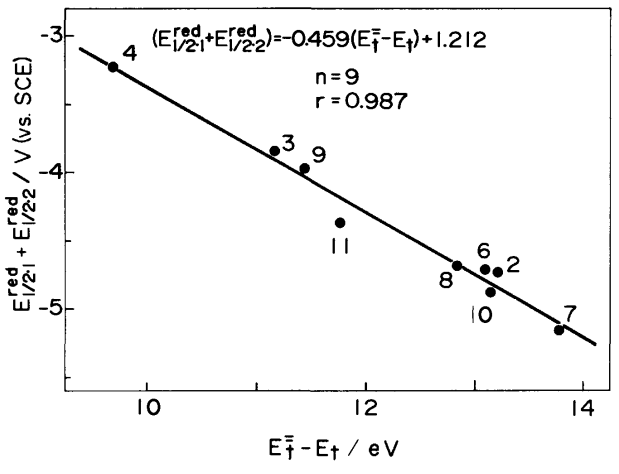

Fig. 3. Linear relation of $(E^{red}_{1/2\cdot1}+E^{red}_{1/2\cdot2})$ values to $(E^{=}_{t}-E_{t})$ calculated by ab initio STO-3G method for BAH's. Each sample number is the same as given in Table 1. See text for detail.

contribution to $(E^{red}_{1/2\cdot1}-E^{red}_{1/2\cdot2})$, as Hush and Blackledge[20] first pointed out, for if all the energy discussions are made for neutral molecules, $(\varepsilon^{-}_{so}-\varepsilon_{lu})=0$. Now it should be noted that the $\Delta G°$ term does not appear in Eq. 5, and the solvation energy term $(\Delta E^{=}_{solv}-\Delta E^{-}_{solv}$: negative value) cancels out the contribution from the orbital energy term $(\gamma^{-}_{ss}+\varepsilon^{-}_{so}-\varepsilon_{lu}$: positive value), so that, as may be seen in Fig. 4, the value of $(E^{red}_{1/2\cdot1}-E^{red}_{1/2\cdot2})$ becomes small and varies within a smaller range than in the structure change of $(\gamma^{-}_{ss}+\varepsilon^{-}_{so}-\varepsilon_{lu})$, in which γ^{-}_{ss} makes the largest contribution (see Table 1).[49,50] This fact seems to be the main reason why the slope of the $(E^{red}_{1/2\cdot1}-E^{red}_{1/2\cdot2})$ vs. $(\gamma^{-}_{ss}+\varepsilon^{-}_{so}-\varepsilon_{lu})$ plot becomes small.

Examination of the First and Second Oxidation Potentials of Benzenoid Alternant Hydrocarbons by Means of MO Calculations. Under the experimental conditions described above, the voltammetric study of the oxidation processes in AN using a platinum electrode shows that, although a reversible or quasireversible oxidation CV curve is recorded in the first oxidation process by selecting a suitable voltage-scan rate of 0.1—60 V s^{-1}, we could not succeed in obtaining a reversible or a quasireversible CV curve for the second oxidation process. An example is given in Fig. 5 for perylene. These experimental results show that the dications of BAH are more unstable than the dianions. However, note that if the strongly reactive 9- and 10-positions of anthracene are protected by CH_3 substitution, a reversible CV curve is safely recorded for both the first and second oxidation steps (see Table 2). The standard potential of the first oxidation step was evaluated by the use of $E^{oxd}_{1/2\cdot1}=(E'_{ap\cdot1}+E'_{cp\cdot1})/2$, where the superfix (′) of $E_{ap\cdot1}$ and $E_{cp\cdot1}$ indicates the first oxidation system. In the case of the second oxidation step, $E^{oxd}_{1/2\cdot2}$ was estimated by means of the $E^{oxd}_{1/2\cdot2}=E'_{ap\cdot2}-(E'_{ap\cdot1}-E^{oxd}_{1/2\cdot1})$ equation, which indicates that the $E^{oxd}_{1/2\cdot2}$ value occupies a position less positive than $E'_{ap\cdot2}$ by the same amount as $(E'_{ap\cdot1}-E^{oxd}_{1/2\cdot1})$ relative to the quasireversible first oxidation CV curve (see Fig. 5). For this treatment to get $E^{oxd}_{1/2\cdot2}$, we have employed the CV data at the sweep rate of v, where the $(E'_{ap\cdot2}-E'_{ap\cdot1})$ value becomes almost independent of an increasing v. At this scan rate, it appears reasonable to assume that an electron-transfer step at the electrode may play an important role in determining $E^{oxd}_{1/2\cdot2}$,[51] but the effect from succeeding chemical reactions may be diminished. All these experimental results are included in Table 2. As was reported by earlier workers,[14,15,17] the correlation of the $E^{oxd}_{1/2\cdot1}$ vs. ε_{ho} plot is quite good, as $E^{oxd}_{1/2\cdot1}=-0.770\varepsilon_{ho}-5.493$, with $r=0.963$ and $n=9$ (Compounds **2**, **3**, **6—12**). Only coronene deviates from the straight line, so when we delete it from the plotting the values of 0.989, −0.849, and −6.083 were obtained for the r, the slope, and the constant term respectively. If we use the vertical ionization potential (I_P) reported by Clar et al.[52] in lieu of the $-\varepsilon_{ho}$, the equation of $E^{oxd}_{1/2\cdot1}=0.853I_P-4.961$ is obtained, with $r=0.938$ and $n=9$. The slope is compatible with that of the $E^{oxd}_{1/2\cdot1}$ vs. ε_{ho} plot.[53] To examine Eq. 6, the mutual relation of $E^{oxd}_{1/2\cdot2}$ and $(\varepsilon^{+}_{so}-\gamma^{+}_{ss})$ was studied. The result is $E^{oxd}_{1/2\cdot2}=-0.528(\varepsilon^{+}_{so}-\gamma^{+}_{ss})-5.636$, with $r=0.875$ and $n=6$ (Compounds **3**, **6—9**, **11**), but if ε^{++}_{lu} is employed in place of $(\varepsilon^{+}_{so}-\gamma^{+}_{ss})$, we obtain the results illustrated in Fig. 6. Here, anthracene is excluded from the plotting because of its

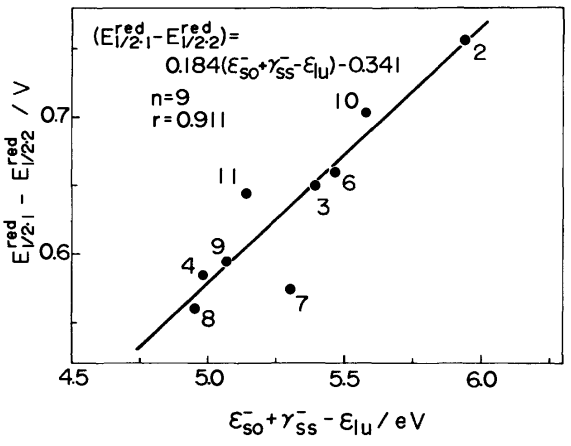

Fig. 4. Linear relation of $(E^{red}_{1/2\cdot1}-E^{red}_{1/2\cdot2})$ values to $(\varepsilon^{-}_{so}+\gamma^{-}_{ss}-\varepsilon_{lu})$ for BAH's. Each sample number is the same as given in Table 1. When $\varepsilon^{=}_{ho}$ is adopted instead of $(\varepsilon^{-}_{so}+\gamma^{-}_{ss})$, the correlation is: $(E^{red}_{1/2\cdot1}-E^{red}_{1/2\cdot2})=0.235(\varepsilon^{=}_{ho}-\varepsilon_{lu})-0.147$ with $r=0.925$.

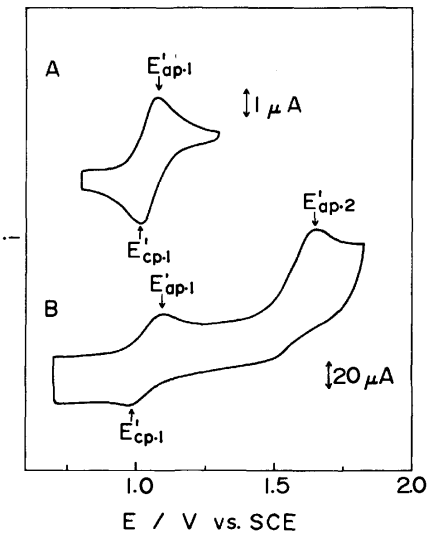

Fig. 5. Cyclic voltammograms of perylene in oxidation process at a Pt electrode. Solvent is AN containing 0.1 mol dm^{-3} TPAP and ca. 10 g of neutral alumina, the sample concentration being 1.0×10^{-3} mol dm^{-3}. The voltammograms were recorded at $v=0.2$ V s^{-1} for A and 22.4 V s^{-1} for B at 25 °C. $E'_{ap\cdot1}$, $E'_{cp\cdot1}$, and $E'_{ap\cdot2}$ indicate the peak potentials of the first anodic, cathodic, and the second anodic waves, respctively (see text).

large deviation from the linear relation. This deviation should be ascribed to the large reactivity of the 9- and 10-positions of the anthracene dications, so the $E^{oxd}_{1/2\cdot2}$ value is not so accurate as the other values.[54] Just as in the aforementioned $E^{red}_{1/2\cdot2}$ vs. $(\varepsilon^{-}_{so}+\gamma^{-}_{ss})$ correlation, the relation of $E^{oxd}_{1/2\cdot2}$ to $(\varepsilon^{+}_{so}-\gamma^{+}_{ss})$ indicates that, in comparison with the case of the $E^{oxd}_{1/2\cdot1}$ vs. ε_{ho} plot, the correlation coefficient is not so good and the slope value is small. The same discussion as has been made for interpreting Eq. 3 can also be applied to the present case. In addition, the problem that the reversibility of the second oxidation wave is not sufficient is not neglected here.

Our next discussion will be focused on Eq. 7. The relations of $(E^{oxd}_{1/2\cdot1}+E^{oxd}_{1/2\cdot2})$ to $(\varepsilon_{ho}+\varepsilon^{+}_{so}-\gamma^{+}_{ss})$ or $(\varepsilon_{ho}+\varepsilon^{++}_{lu})$ or $(E_t-E_t^{++})$ are as follows: $(E^{oxd}_{1/2\cdot1}+E^{oxd}_{1/2\cdot2})=-0.714(\varepsilon_{ho}+\varepsilon^{+}_{so}-\gamma^{+}_{ss})-13.229$ with $r=0.957$, $n=6$; $(E^{oxd}_{1/2\cdot1}+E^{oxd}_{1/2\cdot2})=-0.794(\varepsilon_{ho}+\varepsilon^{++}_{lu})-13.477$, with $r=0.979$ and $n=6$; $(E^{oxd}_{1/2\cdot1}+E^{oxd}_{1/2\cdot2})=-0.360(E_t-E_t^{++})-5.246$, with $r=0.999$ and $n=6$ for the CNDO/2 calculation; $(E^{oxd}_{1/2\cdot1}+E^{oxd}_{1/2\cdot2})=-0.492(E_t-E_t^{++})-3.697$, with $r=0.998$ and $n=6$ for the STO-3G calculation. Compounds **3**, **6—9**, **11** were employed for the correlation study. Again, anthracene was omitted from the plotting for the aforementioned reason. An example is shown in Fig. 7. The theoretical Eq. 7 seems to be well satisfied. However, quite a large difference between the total-energy-calculation models and the orbital-energy approximation is found for the slope values of the linear-regression equations. This is the same phenomenon as was observed and discussed in the correlations of $(E^{red}_{1/2\cdot1}+E^{red}_{1/2\cdot2})$ against $(\varepsilon^{-}_{so}+\varepsilon_{lu}+\gamma^{-}_{ss})$ or $(\varepsilon^{=}_{ho}+\varepsilon_{lu})$ or $(E^{=}_{t}-E_t)$ values (vide supra).

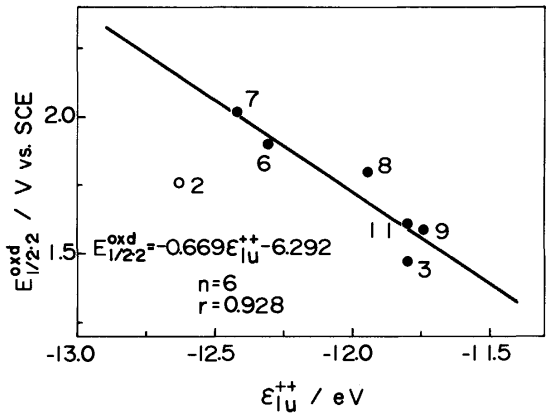

Fig. 6. Linear relation of $E^{oxd}_{1/2\cdot2}$ values to ε^{++}_{lu} for BAH's. Each sample number is the same as given in Table 1. See text for detail.

Next, let us consider the physical meaning of $(E^{oxd}_{1/2\cdot2}-E^{oxd}_{1/2\cdot1})$ given by Eq. 8, whose form is closely similar to Eq. 5 pertinent to $(E^{red}_{1/2\cdot1}-E^{red}_{1/2\cdot2})$, so that the same discussion as was made for Eq. 5 would be possible. It is well-known that the so-called "pairing property"[45,55] of the MO's obtained by the PPP method holds between occupied and unoccupied MO's of neutral BAH molecules and also between the SOMO or unoccupied MO's of the anion radicals and the SOMO or occupied MO's of the cation radicals. Our present calculations verified this, so the values of γ^{+}_{ss} and $(\varepsilon_{ho}-\varepsilon^{+}_{so})$ are equal to γ^{-}_{ss} and $(\varepsilon^{-}_{so}-\varepsilon_{lu})$ respectively. As a result, $(\varepsilon_{ho}-\varepsilon^{+}_{so}+\gamma^{+}_{ss})$ and $(\varepsilon^{-}_{so}-\varepsilon_{lu}+\gamma^{-}_{ss})$ are the same value. Also, the present calculations suggest that the values of $(\varepsilon^{=}_{ho}-\varepsilon_{lu})$ and $(\varepsilon_{ho}-\varepsilon^{++}_{lu})$ are equal to each other, because the pairing property found between the anion and cation radicals of BAH again holds between the MO's of the dianion and dication species as well as between the $\varepsilon^{=}_{ho}$ and ε^{++}_{lu}. This can also be inferred from the relations of Eqs. 9 and 11. Keeping in mind the above fact, we can expect that, judging from the comparison of Eqs. 5 and 8, the values of $(E^{oxd}_{1/2\cdot2}-E^{oxd}_{1/2\cdot1})$ should be the same as those of $(E^{red}_{1/2\cdot1}-E^{red}_{1/2\cdot2})$ if (i) the solvation effect on reversible redox potentials is not so different between DMF and

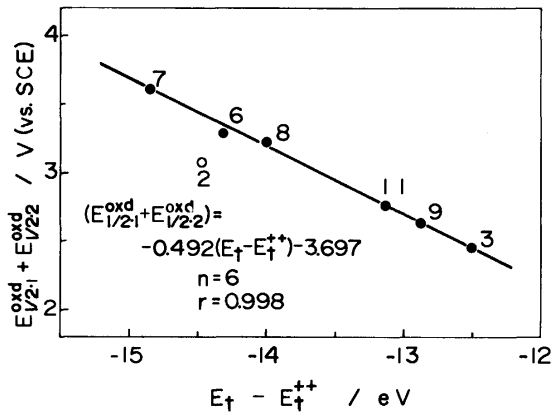

Fig. 7. Linear relation of $(E^{oxd}_{1/2\cdot1}+E^{oxd}_{1/2\cdot2})$ values to $(E_t-E_t^{++})$ calculated by ab initio STO-3G method for BAH's. Each sample number is the same as given in Table 1. See text for detail.

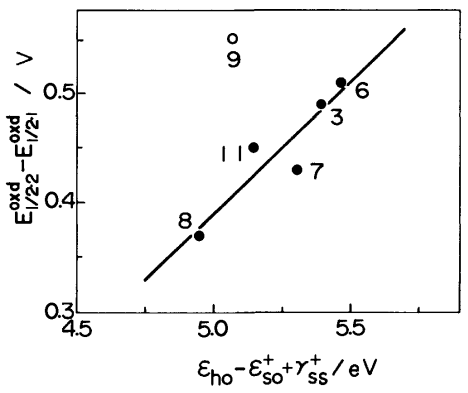

Fig. 8. Linear relation of $(E^{oxd}_{1/2\cdot2}-E^{oxd}_{1/2\cdot1})$ values to $(\varepsilon_{ho}-\varepsilon^{+}_{so}+\gamma^{+}_{ss})$ for BAH's with the slope=0.243, the constant term=−0.826, and $r=0.918$. Each sample number is the same as given in Table 1. See text for detail.

AN[56] and (ii) the solvation energies coming from mono- and dianions are the same as those of the mono- and dications (vide infra). In the present experiments, $E^{red}_{1/2\cdot1}$, $E^{red}_{1/2\cdot2}$, and $E^{oxd}_{1/2\cdot1}$ are for the reversible or quasireversible CV curves, but $E^{oxd}_{1/2\cdot2}$ is not and it is, therefore, less positive than the value in a reversible curve. The one exception is perylene, whose $(E^{oxd}_{1/2\cdot2}-E^{oxd}_{1/2\cdot1})$ value is quite close to the value of $(E^{red}_{1/2\cdot1}-E^{red}_{1/2\cdot2})$, as Table 2 shows, so we suppose that the $E^{oxd}_{1/2\cdot2}$ value of perylene in Table 2 may be near that of a reversible monocation and dication redox system. The correlation of Eq. 8 is: $(E^{oxd}_{1/2\cdot2}-E^{oxd}_{1/2\cdot1})=0.243(\varepsilon_{ho}-\varepsilon^{+}_{so}+\gamma^{+}_{ss})-0.826$, with $r=0.918$ and $n=5$; also, $(E^{oxd}_{1/2\cdot2}-E^{oxd}_{1/2\cdot1})=0.304(\varepsilon_{ho}-\varepsilon^{++}_{lu})-0.543$, with $r=0.922$ and $n=5$. The compounds employed for the correlation are **3**, **6—8**, **11**. Perylene deviates greatly from the above equations, so we have excluded it from the linear plotting, as is shown in Fig. 8. The reason is clear from the discussion above. In turn, for the same reason as was discussed in detail in connection with Eq. 5, the value of $(E^{oxd}_{1/2\cdot2}-E^{oxd}_{1/2\cdot1})$ comes out small and varies in a smaller range than in the case of $(\varepsilon_{ho}-\varepsilon^{+}_{so}+\gamma^{+}_{ss})$, where γ^{+}_{ss} makes the largest contribution (see Table 1).[49,50] Therefore, the slope of the $(E^{oxd}_{1/2\cdot2}-E^{oxd}_{1/2\cdot1})$ vs.$(\varepsilon_{ho}-\varepsilon^{+}_{so}+\gamma^{+}_{ss})$ plotting turns out to be small, as was seen in the discussion of Eq. 5.

Mutual Relation between Standard Reduction and Oxidation Potentials. In a series of alternant hydrocarbons, it is well-known[45,57] and has been experimentally verified that the sum of I_P and E_A is almost constant. The data shown in Table 2 support this relation, and Mulliken's electro-negativity $((I_P+E_A)/2)$[58] is constant in BAH and is 4.06 eV for the data in Table 2. This kind of property can be well described using just the PPP-SCFMO employed here; i. e., the pairing property of MO is well satisfied. In terms of the MO language employing Koopmans' theorem,[39] $(I_P+E_A)/2$ corresponds to $-(\varepsilon_{ho}+\varepsilon_{lu})/2$ for neutral molecules. The present calculations led to -5.92 eV for $(\varepsilon_{ho}+\varepsilon_{lu})/2$ and for the pairing orbitals between anion and cation radicals (e. g., $(\varepsilon^{+}_{so}+\varepsilon^{-}_{so})/2$) and also for those between dianion and dication species (e. g., $(\varepsilon^{++}_{lu}+\varepsilon^{=}_{ho})/2$). When we use Eqs. 1 and 2, the value of $(E^{oxd}_{1/2\cdot1}+E^{red}_{1/2\cdot1})/2$ is written by Eq. 13:

$$(E^{oxd}_{1/2\cdot1}+E^{red}_{1/2\cdot1})/2 = \Delta G^{\circ}-(\varepsilon_{1u}+\varepsilon_{ho})/2+(\Delta E^{+}_{solv}-\Delta E^{-}_{solv})/2 \quad (13)$$

where the eV unit is used for the energies. Taking into consideration the fact that Eqs. 1 and 2 are well fulfilled experimentally, the ΔE^{+}_{solv} term can be expected to cancel out the ΔE^{-}_{solv} term, so the term $(E^{oxd}_{1/2\cdot1}+E^{red}_{1/2\cdot1})$ turns out to be constant.[59] The values are listed in Table 2; the average potential is -0.342 ± 0.030 V. Now, we can estimate the ΔG° from Eq. 13 by putting $\Delta E^{+}_{solv}=\Delta E^{-}_{solv}$ (vide infra). Using the value of 5.92 eV for $-(\varepsilon_{lu}+\varepsilon_{ho})/2$, we obtain $\Delta G^{\circ}=-6.26$ eV.[60] However, when we use $(I_P+E_A)/2$ in place of $-(\varepsilon_{lu}+\varepsilon_{ho})/2$, $\Delta G^{\circ}=-4.40$ eV where we employ 4.056 ± 0.061 eV for the average value of the former (see Table 2). This ΔG° value is reasonable in view of the literature values.[11,61,62] Hereafter, therefore, we will use $\Delta G^{\circ}=-6.26$ eV for PPP orbital treatment, but

a) Second oxidation potential calculated by means of this equation: $E^{oxd}_{1/2\cdot2}=E^{oxd}_{1/2\cdot1}+E^{red}_{1/2\cdot1}-E^{red}_{1/2\cdot2}$. See text for the details. b) Solvation energy of monoanion species. Calculations were made using Eq. 1; $E^{-}_{solv}\simeq(E^{-}_{solv}-E_{solv})=-FE^{red}_{1/2\cdot1}-\varepsilon_{1u}-6.26$ for [A], but $-FE^{red}_{1/2\cdot1}+E_A-4.40$ for [B]. c) Solvation energy of monocation species. Calculations were made using Eq. 2; $E^{+}_{solv}\simeq(E^{+}_{solv}-E_{solv})=FE^{oxd}_{1/2\cdot1}+\varepsilon_{ho}+6.26$ for [C], but $FE^{oxd}_{1/2\cdot1}-I_P+4.40$ for [D]. d) Solvation energy of dianion species. Calculatations were made using Eq. 4; $E^{=}_{solv}\simeq(E^{=}_{solv}-E_{solv})=-F(E^{red}_{1/2\cdot1}+E^{red}_{1/2\cdot2})-(\varepsilon^{-}_{so}+\gamma^{-}_{ss}+\varepsilon_{1u})-12.52$ for [E], but $-F(E^{red}_{1/2\cdot1}+E^{red}_{1/2\cdot2})-(\varepsilon^{=}_{ho}+\varepsilon_{1u})-12.52$ for [F]. e) Solvation energy of dication species. Calculations were made using Eq. 7; $E^{++}_{solv}\simeq(E^{++}_{solv}-E_{solv})=F(E^{oxd}_{1/2\cdot1}+E^{oxd}_{1/2\cdot2})+(\varepsilon^{+}_{so}-\gamma^{+}_{ss}+\varepsilon_{ho})+12.52$ for [G], but $F(E^{oxd}_{1/2\cdot1}+E^{oxd}_{1/2\cdot2})+(\varepsilon^{++}_{lu}+\varepsilon_{ho})+12.52$ for [H].

−4.40 eV in the consideration of the experimental I_P and E_A values.

Now we would like to discuss the mutual relation between $E^{oxd}_{1/2\cdot2}$ and $E^{red}_{1/2\cdot2}$. Taking the summation of Eqs. 3 and 6, and by dividing it by two, we obtain Eq. 14 (in eV units):

$$(E^{red}_{1/2\cdot2}+E^{oxd}_{1/2\cdot2})/2 = \Delta G^\circ - (\varepsilon^-_{so}+\varepsilon^+_{so})/2 + (\gamma^+_{ss}-\gamma^-_{ss})/2 + (\Delta E^{++}_{solv}-\Delta E^{=}_{solv})/2 \quad (14)$$

The MO-pairing property of the anion and cation PPP-SCFMO for BAH shows that $\gamma^+_{ss}-\gamma^-_{ss}=0$, and $(\varepsilon^+_{so}+\varepsilon^-_{so})/2=(\varepsilon_{ho}+\varepsilon_{lu})/2=-5.92$ eV. Provided that $\Delta E^{++}_{solv}-\Delta E^{=}_{solv}\simeq0$ just like $\Delta E^{+}_{solv}\simeq\Delta E^{-}_{solv}$ in Eq. 13, Eq. 14 comes out to be equal to Eq. 13, -i. e., $(E^{oxd}_{1/2\cdot1}+E^{red}_{1/2\cdot1})=(E^{oxd}_{1/2\cdot2}+E^{red}_{1/2\cdot2})$. Note that $E^{red}_{1/2\cdot1}$, $E^{red}_{1/2\cdot2}$, and $E^{oxd}_{1/2\cdot1}$ were experimentally determined from the reversible or quasireversible CV curves; therefore, we can calculate $E^{oxd}_{1/2\cdot2}$ by employing this equation: $E^{oxd}_{1/2\cdot2}=E^{oxd}_{1/2\cdot1}+E^{red}_{1/2\cdot1}-E^{red}_{1/2\cdot2}$. The calculated values are given in Table 3, while the correlation of the observed $E^{oxd}_{1/2\cdot2}$ values with the calculated values is illustrated in Fig. 9. We can see there that the observed and calculated $E^{oxd}_{1/2\cdot2}$ values, except for perylene and anthracene, fall as a good linear-least-squares correlation line. The observed values are positive-shifted by ≈0.2 V from the calculated values. This is reasonable, since the experimental values were determined from irreversible CV curves. Therefore, the effect of the succeeding chemical reaction on them could not be neglected, but the effect is in the same order in the above five substances. Anthracene deviated largely to the positive side from the regression line, showing that the effect of the following chemical reaction on it is very large; this tendency of anthracene was always found in the present correlation study of the oxidation processes. In turn, Fig. 9 indicates that perylene is in a position close to, but a little positive-shifted from, the theoretical line. Its $E^{oxd}_{1/2\cdot2}$ value should be near to that of the reversible equilibrium; this conclusion is the same as that derived from the foregoing discussion of the $(E^{oxd}_{1/2\cdot2}-E^{oxd}_{1/2\cdot1})$ value.

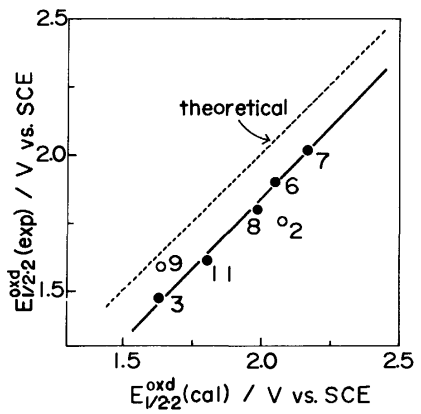

Fig. 9. Linear relation of the experimental $E^{oxd}_{1/2\cdot2}$ values to the calculated $E^{oxd}_{1/2\cdot2}$ ones given in Table 3 for BAH's. Each sample number is the same as given in Table 1. Regression equation is $E^{oxd}_{1/2\cdot2}(exp)=1.049E^{oxd}_{1/2\cdot2}(cal)-0.260$ with $r=0.995$, $n=5$ (full circles). See text for detail.

Evaluation of Solvation Energies of Ion Species. Now, let us discuss the solvation energies of anions or cations of BAH by applying Eqs. 1, 2, 4, and 7. From the former two equations, we can estimate the $(E^-_{solv}-E_{solv})\simeq E^-_{solv}$ and $(E^+_{solv}-E_{solv})\simeq E^+_{solv}$ values, and the latter two give the estimated values of $(E^{=}_{solv}-E_{solv})\simeq E^{=}_{solv}$ and $(E^{++}_{solv}-E_{solv})\simeq E^{++}_{solv}$, although the CV reversibility pertinent to the $E^{oxd}_{1/2\cdot2}$ value is not very good. Of course, ΔG° should be −6.26 eV for the PPP-orbital approximation,[60] but −4.40 eV for I_P and E_A. The calculated results are listed in Table 3, from which one can conjecture that, in the case of E^-_{solv} and E^+_{solv}, the values evaluated from the PPP calculations and the I_P or E_A value are both of almost the same order of magnitude, though the absolute values calculated from the experimental I_P and E_A values are a little larger than in the orbital approximation, and that their structure dependence is small, as is to be expected from the regression equations of the $E^{red}_{1/2\cdot1}$ vs. ε_{lu} (or E_A) and $E^{oxd}_{1/2\cdot1}$ vs. ε_{ho} (or I_P) relationships. On the other hand, the absolute values of $E^{=}_{solv}$ and E^{++}_{solv}, as estimated using $\varepsilon^{=}_{ho}$ and ε^{++}_{lu} in lieu of $(\varepsilon^-_{so}+\gamma^-_{ss})$ and $(\varepsilon^+_{so}-\gamma^+_{ss})$ (see Eqs. 4 and 7), are about 2 eV smaller than those obtained employing $(\varepsilon^-_{so}+\gamma^-_{ss})$ and $(\varepsilon^+_{so}-\gamma^+_{ss})$ directly. This is understandable when we take into consideration the correlation of Eqs. 9 and 11. However, the solvation energies themselves of the dianion or dication calculated using $\varepsilon^{=}_{ho}$ or ε^{++}_{lu} are more accurate than those obtained from $(\varepsilon^-_{so}+\gamma^-_{ss})$ or $(\varepsilon^+_{so}-\gamma^+_{ss})$, because the latter values are for the orbital approximation to the former values, derived from the overall MO calculation, just like the ε_{lu} or ε_{ho} in Eqs. 1 and 2. Now, in comparing the solvation energies of the dianion and dication with those of the monoanion and monocation under the same calculation models, we can see in Table 3 that $|E^{=}_{solv}|=4.2(\pm0.2)|E^-_{solv}|$ for Columns F and A and $|E^{++}_{solv}|=4.3(\pm0.2)|E^+_{solv}|$ for Columns H and C. In addition, the change in $|E^{=}_{solv}|$ with the ring size seems to be in a reasonable direction; e. g., $|E^{=}_{solv}|$ decreases gradually with the structure change of **2**→**3**→**4**, as would be inferred from the discussion of Eq. 3 (vide supra). These results can be understood on the basis of the Born-type equation pertaining to solvation energies, whose generalized form may be written as:[63]

$$E_{solv} = -\frac{1}{2}\left(1-\frac{1}{\varepsilon}\right)\sum_{A,B}\frac{Q_A\cdot Q_B}{R_{AB}} \quad (15)$$

where ε, Q_A and Q_B, and R_{AB} indicate a solvent's dielectric constant, the atomic charges on the A and B

atoms, and the atomic distance between A and B respectively. When A=B, R_{AB} stands for atomic radius. If we put $\sum_{A,B}(Q_A \cdot Q_B)/R_{AB} \equiv (Ze)^2/r$ (r is the cavity radius), according to original Born's equation,[64] then the solvation energies on the dianion or dication come out about four times as large as those of the monoanion or monocation. Also, with an increase in the r, i. e., with an increase in the molecular size, the solvation energies may decrease. Of course, this tendency is made prominant in doubly charged species than in singly charged ones, as can actually be found in Table 3. In the case of neutral molecules of BAH, the π-formal charge at each carbon atom is zero in the PPP calculations; their molecular dipole moments are also zero in a good approximation. Our CNDO/2 calculations gave similar results. These circumstances suggest that the solute-solvent interactions and the solvation energies of neutral BAH's turn out to be the same order for any BAH and very small[45] in comparison with those of the ionic species. Thus, we believe that the solvation energies here evaluated are quite close to those of the ion species themselves, although the values are obtained as the difference between the ion species and the neutral species. Finally, we can say that the standard reduction and oxidation potentials of BAH attributable to the formation of mono- and dianions and mono- and dications, and their mutual relations, can both be well-understood by applying the theories of the PPP-type semiempirical molecular orbitals and the Born-type solvation energies. The present quantitative discussion, pertinent to dianions and dications throughout the monoanions and monocations and to their mutual correlations, seems to be the first to treat BAH.

Appendix

Let us consider Eq. A-1, written as a linear combination of two variables, x_1 and x_2:

$$y = a_0 + a_1x_1 + a_2x_2 \qquad \text{(A-1)}$$

The condition necessary to satisfy simultaneously both equations, $y=a_0'+a_1x_1$ and $y=a_0''+a_2x_2$, is that the correlation coefficient, r_{12}, between x_1 and x_2 be perfectly zero. However, when the linear relation $y=b_0+b_1x_1$ is experimentally or theoretically assumed, then it can easily be verified that the x_2 should fulfill either one of the conditions, that x_2 be constant or be in a linear relation to the y values, i. e., $y=b_0'+b_2x_2$. Multiple regression analysis[65] shows, that if the above r_{12} is not zero, the a_2 value in Eq. A-1 is equal to the regression coefficient relevant to the single regression equation of y to the "residual," which is obtained by removing the x_1 effect from x_2. The same situation also holds for the physical meaning of the a_1 value in Eq. A-1, so that the a_1 and a_2 values in Eq. A-1 are theoretically somewhat complex, especially in the case of a large r_{12} value.

The authors wish to express their thanks to Professor Kōsuke Izutsu of the Faculty of Science, Shinshu University, for his encouragement and his helpful discussions on the problem of the mutual relation between reduction and oxidation potentials throughout the first and second steps.

41) A rather large difference is found in the $E^{red}_{1/2\cdot2}$ value of **7** (chrysene), −2.730 V having been reported by Jensen and Parker.[40]
42) Also, we would expect a linear $E^{red}_{1/2\cdot1}$ vs. E_A (electron affinity) relation for the present BAH series, since E_A is parallel with ε_{lu}. The results are $E^{red}_{1/2\cdot1}=1.154E_A-2.759$, with $r=0.946$ and $n=6$ (Compounds **1**, **2**, **5**—**7**, **10**), the E_A values being cited from Ref. 43 and given in Table 2.
43) W. E. Wentworth, E. Chen, and J. E. Lovelock, *J. Phys. Chem.*, **70**, 445 (1966).
44) As may be understood from Fig. 2, if we choose such polyacenes as Compounds **2**—**4**, the $E^{red}_{1/2\cdot2}$ vs. $\varepsilon^{=}_{ho}$ plot of Eq. 3 gives a very good linear correlation. This kind of result was also found on the other plottings. The topological MO and molecular features of polyacenes may play an important role in this result.

52) R. Boschi, E. Clar, and W. Schmidt, *J. Chem Phys.*, **60**, 4406 (1974).
53) Dewar et al. reported this equation;[14] $E^{oxd}_{1/2\cdot1}=0.996I^{cal}_{P}-6.607$, with $r=0.987$ and $n=9$, and where I^{cal}_{P} is the I_P calculated by them.
54) It is well known that the dications of 9,10-dimethyl- (see Table 2) and 9,10-diphenylanthracenes[24] are cyclic voltammetrically stable.
55) a) A. D. McLachlan, *Mol. Phys.*, **4**, 49 (1961). b) A. D. McLachlan, *Mol. Phys.*, **2**, 271 (1959). c) T. Shida and S. Iwata, *J. Am. Chem. Soc.*, **95**, 3473 (1973).
56) In the case of the $E^{red}_{1/2\cdot1}$ and $E^{red}_{1/2\cdot2}$ measurements, DMF and AN gave almost the same values for perylene when a Pt electrode was used (see Table 2). This fact is reasonable judging from the Born equation, because the dielectric constants[29] of DMF (37.0) and AN (36.0) are almost equal to each other.
57) N. S. Hush and A. J. Pople, *Trans. Faraday Soc.*, **59**, 600 (1955); R. M. Hedges and F. A. Matsen, *J. Chem. Phys.*, **28**, 950 (1958); R. S. Becker and W. E. Wentworth, *J. Am. Chem. Soc.*, **85**, 2210 (1963); J. R. Hoyland and L. Goodman, *J. Chem. Phys.*, **36**, 21 (1962).
58) R. S. Mulliken, *J. Chem. Phys.*, **2**, 782 (1934); **3**, 537 (1935).
59) a) This relation was employed by Senda and Takahashi[22,23] to determine the standard electrode potential in nonaqueous solvents. b) Our data in Table 2 were obtained in DMF for reduction, but in AN for oxidation; thus, we can not omit the error due to the solvation-energy difference brought about by DMF and AN, though the difference is quite small.[56] Parker[15] reported the values of

$(E^{oxd}_{1/2\cdot1}+E^{red}_{1/2\cdot1})/2$ for BAH in AN; they are -0.313 ± 0.022 V (n=10) and $\Delta E^{+}_{solv}=\Delta E^{-}_{solv}$ within the limits of experiment error, though they adopted irreversible CV data for $E^{oxd}_{1/2\cdot1}$.

60) The coefficient of ε_{lu} or ε_{ho} in Eqs. 1 and 2 is constrained to unity on the assumption that, if the MO evaluation of the energies is correct, the coefficient becomes 1.

61) Parker[15] reported $\Delta G°=-4.4$ eV vs. SCE on the basis of the same treatment as was used here. Peover et. al.[16] reported $\Delta G°=-4.70$ eV in the case of the (Ag/Ag^{+}) electrode in AN. Alternatively, $\Delta G°$ values of -4.36 to -4.41 eV have also been reported for SCE.[62]

The Phase Transition of 1-Alkyl-4-aza-1-azoniabicyclo[2.2.2]octane Bromides, C_n-DABCO-Br ($11 \leqq n \leqq 22$)

Kengo IMAMURA, Takashi NOGAMI,* Yasuhiko SHIROTA, Tsutomu ISHIOKA,† and Masamichi KOBAYASHI*,†

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadaoka, Suita, Osaka 565

†Department of Macromolecular Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560

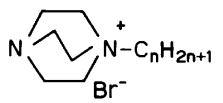
(Received May 25, 1987)

The phase transitions of a series of 1-alkyl-4-aza-1-azoniabicyclo[2.2.2]octane bromides were studied on the basis of DSC, measurements of the ionic conductivities of the bromide anion, and Raman spectroscopy. Two endothermic signals were observed at the temperatures of T_{c1} and T_{c2} ($T_{c1}<T_{c2}$) for most of the materials. The transition enthalpies and transition entropies were not very different for the transitions at T_{c1}, irrespective of the alkyl-chain lengths attached to DABCO nitrogens. On the other hand, these values tended to increase with an increase in the alkyl-chain lengths for the transitions at T_{c2}. The temperature dependences of the ionic conductivities of the bromide anion showed abrupt increases in the conductivities by a factor of 2—10. The conductivity jumps were observed around T_{c2}. The temperature dependences of the Raman spectra gave detailed information on the phase transition; (1) the change in the subcell structure took place at T_{c1}, with the concomitant occurrence of a conformational change in the alkyl group; (2) above T_{c2}, the alkyl chain takes a liquid-like disordered form, and a rotational motion of the DABCO portion sets in.

The solid-solid phase transitions of a series of bis(quaternary alkyl halides) of 1,4-diazabicyclo[2.2.2]-octane (DABCO) have been studied on the basis of DSC, IR absorption spectroscopy, and measurements of the ionic conductivities of the halide anion.[1-5] The phase transitions of quaternary alkyl bromide salts of 1-azabicyclo[2.2.2]octane were also studied.[6] Symmetric bis(quaternary alkyl halide) salts of DABCO showed endothermic signals at the transition temperatures (T_c) when the samples were heated from room temperature.[1,2] They showed exothermic signals around T_c when the samples were cooled after they had been heated above T_c. The absolute values of the endothermic and exothermic heats were equal, within the limits of experimental error. Abrupt increases in the ionic conductivity of the halide anion by a factor of 630—3600 were observed around at T_c. As the temperature was increased, the IR absorption spectra of the symmetric salts showed a sudden disappearance of the band progressions due to the CH_2 rocking-twisting branch at T_c. This fact shows that the trans-zigzag conformation of the long alkyl chains in the low temperature phase is destroyed and changes to a disordered form above T_c. The concomitant formation of voids facilitates the halide-anion transport above the transition temperature, giving rise to the conductivity jump.

The unsymmetric bis(quaternary alkyl bromides) of DABCO showed phenomena different from those of the symmetric salts.[3-5] Endothermic signals were also observed at the transition temperatures (T_c) when the virgin samples[7] were heated from room temperature. However, the exothermic signals were observed at much lower temperatures (T_c') than T_c when the samples were cooled after they had been heated above T_c. The temperature dependence of the IR absorption spectra of the unsymmetric salts revealed that a metastable phase was produced first when the samples had been cooled from a temperature above T_c. For some unsymmetric salts, the metastable phase was converted to the stable phase within a week when the salts were kept at room temperature. The thermodynamic properties of the unsymmetric salts could be explained on the basis of the free energy-temperature relation. Conductivity jumps of the bromide anion by a factor of 100—6000 were also observed around T_c for the virgin samples and around T_c' for the annealed samples.[7]

All of the previous studies were made on the phase transitions of bis(quaternary alkyl halides) of DABCO; it seems that it also be interesting to compare the phase transitions of mono(quaternary alkyl bromides) of DABCO with those of the bis(quaternary salts). Mono(quaternary alkyl bromide salt) of DABCO possesses both a hydrophilic DABCO cation and a hydrophobic alkyl group. Thus, it has a possibility of forming a Langmuir-Blodgett membrane[8] and may be useful in a molecular device by using abrupt changes in the ionic conductivities of the bromide anion and/or the disappearance of the birefringence above the transition temperatures.[2] We have studied the phase transitions of mono(quaternary alkyl bromides) of DABCO on the basis of DSC, the



n= 11,12,13,14,15,16,17,18,22

Fig. 1. Mono(quaternary alkyl bromide) salts of DABCO.

measurements of the ionic conductivities of the bromide anion, and Raman spectroscopy. The materials studied are shown in Fig. 1. The names of the materials are abbreviated by the numbers of the alkyl carbons attached to DABCO nitrogens. For example, 4-dodecyl-1-aza-4-azoniabicyclo[2.2.2]octane bromide is abbreviated as C_{12}-DABCO-Br. Thus, the names of the materials in Fig. 1 are generally abbreviated as C_n-DABCO-Br ($11 \leqq n \leqq 22$). The names of the symmetric bis(quaternary alkyl bromide salts) of DABCO are similarly abbreviated as C_n-DABCO-C_n-Br_2.

Experimental

Syntheses of Mono(quaternary alkyl bromides) of DABCO. The mono(quaternary alkyl bromides) of DABCO were synthesized by the method reported previously.[3]

Measurements. The DSC and the measurements of the ionic conductivities of the bromide anion and the IR spectra were made by the methods reported previously.[1,2] The Raman spectra were measured on a JASCO CT-1000D double monochromator, using the 514.5 nm line (Ar ion laser) as the excitation source. The temperature of the sample was regulated by means of a Thermal Controller E5D (Omron Co., Ltd). In order to quench the fluorescence caused by unknown impurities, the sample held above T_{c2} was irradiated with the excitation beam for several h before the measurement.

Results and Discussion

DSC Measurements. The DSC measurements were made at the heating (or cooling) rate of 5 °C min^{-1}. Figure 2 shows the DSC thermogram of C_{17}-DABCO-Br as a typical example. Most of the samples gave two endothermic signals at the T_{c1} and T_{c2} temperatures ($T_{c1}<T_{c2}$) on heating. As will be shown later, abrupt increases in the ionic conductivities of the bromide anion occurred around T_{c2}. Thus, the phase transitions at T_{c1} and T_{c2} seem to be different in origin. The absolute values of the transition enthalpies at T_{c1} and T_{c2} are denoted as $\Delta H_{en,1}$ and $\Delta H_{en,2}$ respectively. However, C_{13}-DABCO-Br showed three transitions (assigned tentatively as one at T_{c1} and two at T_{c2}).[9] When the samples were cooled after they had once been heated above T_{c2}, exothermic signals were observed. However, the temperatures of the exothermic transitions were usually much lower than the corresponding endothermic temperatures, T_{c1} and T_{c2}. The thermal histories of the samples seem to influence the exothermic transition temperatures and the shapes of the DSC curves. On the other hand, the endothermic transition temperatures (T_{c1} and T_{c2}) were reproducible when the samples were heated after several heating/cooling cycles. $\Delta H_{en,1}$ and $\Delta H_{en,2}$ tend to decrease slightly when the cycles are repeated. Part of Table 1 shows the materials, T_{c1}, $\Delta H_{en,1}$, T_{c2}, $\Delta H_{en,2}$, and the transition entropies ΔS_1 ($=\Delta H_{en,1}/T_{c1}$) and ΔS_2 ($=\Delta H_{en,2}/T_{c2}$).

Figure 3 plots the transition temperatures (T_{c1} and T_{c2}) against the carbon numbers of the alkyl chains. This figure also shows the transition temperatures of the symmetric bis(quaternary alkyl bromide) salts of

DABCO (C_n-DABCO-C_n-Br_2)[2] for the sake of comparison. T_{c1} tends to increase with the increase in the alkyl-chain lengths for C_n-DABCO-Br ($n \geqq 13$). The variations in T_{c2} with the change in the alkyl-chain lengths were larger than those in T_{c1}. The transition temperatures of most of the symmetric bis(quaternary alkyl bromide) salts of DABCO were higher than T_{c1} and T_{c2}. This is reasonable because the molecular interaction arises mainly from the Coulomb force between N^+ and Br^-. Thus, the molecular interaction between the bis(quaternary salts) is stronger than that between the mono(quaternary salts); this gives rise to the higher transition temperatures for the former materials.

Figure 4 plots the transition enthalpies ($\Delta H_{en,1}$ and $\Delta H_{en,2}$) against the carbon numbers of the alkyl chains. This figure also shows the transition enthalpies of the symmetric bis(quaternary alkyl bromide) salts of DABCO (C_n-DABCO-C_n-Br_2)[2] for the sake of comparison. It is noteworthy that the $\Delta H_{en,1}$'s are close to 30 kJ mol^{-1}, irrespective of the alkyl-chain lengths.[10] On the other hand, the variations in the $\Delta H_{en,2}$'s with the alkyl-chain length are much larger than those in the $\Delta H_{en,1}$'s. These facts suggest that the origin of the phase transition at T_{c1} is common for all of the mono(quaternary salts) of DABCO. This point will be clarified by Raman spectroscopy later in this paper. Both the $\Delta H_{en,1}$ and $\Delta H_{en,2}$ values and their sum are smaller than the transition enthalpies of the symmetric bis(quaternary salts) with the same alkyl chain. This also comes from the fact that the intermolecular interaction of the bis(quaternary salts) is stronger than that of the mono(quaternary salts). No even-odd number effect of the alkyl carbons on the transition enthalpies was observed, unlike the cases of the bis(quaternary salts).[2,3] Similar characteristics described for the transition enthalpies were also applicable to the transition entropies (ΔS_1 and ΔS_2). It is especially noteworthy that the variations in ΔS_1 (78—99 J mol^{-1} K^{-1}) with the change in the alkyl-chain length are much smaller than those in ΔS_2.

Ionic Conductivities of the Bromide Anion. All of the samples were confirmed to be ionic conductors of the bromide anion by the method described previously.[1] The ionic conductivities were measured for sample pellets which had been dried overnight under a dynamic vacuum above T_{c2}. The conductivities less than 10^{-10} S cm^{-1} were below the lower limit of our

measurement. Figures 5 and 6 show the temperature dependences of the ionic conductivities of the bromide anion of the mono(quaternary alkyl bromide salts) of DABCO, possessing odd and even numbers of alkyl carbons respectively. The broken and solid lines in these figures represent T_{c1} and T_{c2} respectively. The numbers near these lines represent the numbers of the alkyl carbons attached to the DABCO nitrogens.

All of the samples exhibited conductivity jumps. Table 1 shows the ratios of the conductivities below (σ_l) and above (σ_h) the temperature of the conductivity jumps. The σ_h/σ_l values (2—10) were two to three orders of magnitude smaller than those of the bis-(quaternary alkyl bromide salts) of DABCO; the latter salts gave σ_h/σ_l values of about 100—6000.[1-5] Figures 5 and 6 show that the temperatures of the conductivity jumps are much higher than T_{c1}. On the other hand, they are close to T_{c2} for C_n-DABCO-Br (n=12, 13, 16, 17, 22) and are about 10—20 °C higher than T_{c2} for C_n-DABCO-Br (n=14, 15, 18). From the above experimental results, it can be said that the conductivity jump is not caused by the transition at T_{c1}, but is more closely related to the transition at T_{c2}.[10] It can be said that the conductivities become lower with the increase in the alkyl-chain length. It is also noteworthy that the plots of the conductivities against the temperature are nearly parallel with each other for the DABCO salts, possessing even numbers of alkyl carbons both below and above the conductivity jumps (Fig. 6). On the other hand, the conductivities above the conductivity jumps are much closer to each other than are those below the conductivity jumps in the cases of the quaternary DABCO salts possessing odd numbers of alkyl carbons (Fig. 5). In this connection, a series of the bis(quaternary alkyl bromide salts) of DABCO exhibited somewhat different phenomena; their ionic conductivities of the bromide anion above the transition temperatures were very close, irrespective of the alkyl-chain lengths while they were very different below the transition temperatures.[1-5] The reasons for these different phenomena remain to be clarified.

Raman Spectroscopy. The DSC measurements showed that the $\Delta H_{en,1}$'s were close to each other (≈30 kJ mol^{-1}), irrespective of the alkyl-chain length attached to the DABCO nitrogens. The measurements of the ionic conductivities of the bromide anion revealed that the conductivity jump is not caused by the transition at T_{c1}, but is more closely related with the transition at T_{c2}. These results suggest that the transitions at T_{c1} and T_{c2} are different in origin. In order to clarify these two transitions, the temperature dependences of the Raman spectra of C_{17}-DABCO-Br and C_{22}-DABCO-Br were measured for powder samples as typical examples. Since similar changes in the Raman spectra were observed for these materials, only the Raman spectra of C_{17}-DABCO-Br are shown in Fig. 7.

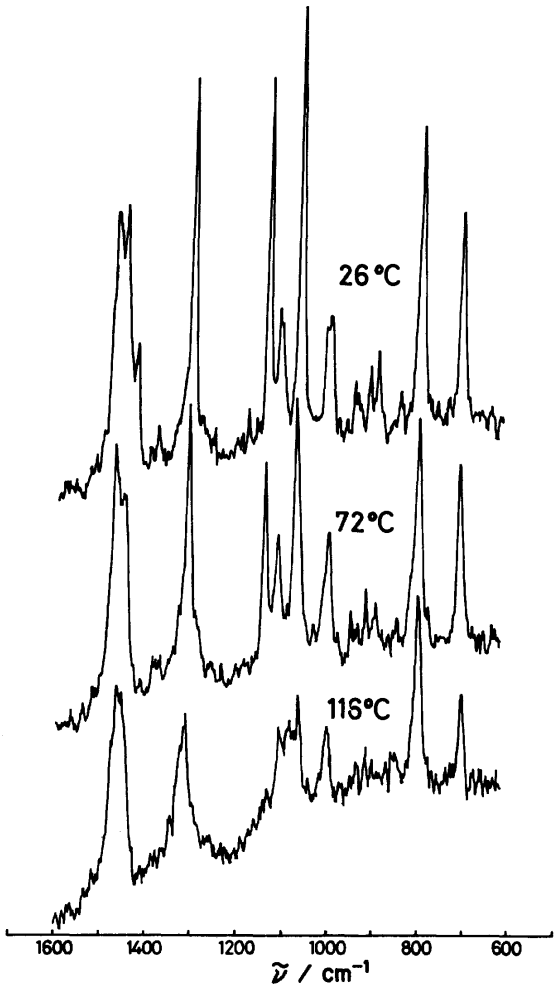

Fig. 7. Temperature dependence of the Raman spectra of C_{17}-DABCO-Br. T_{c1}=65°C, T_{c2}=99°C.

The most conspicuous spectral change at T_{c1} is the disappearance of the 1415 cm^{-1} band above T_{c1}. This band is associated with the A_g split component of the CH_2 scissoring $\delta(CH_2)$ mode,[11-13] and is characteristic of the $O_\perp$-type subcell, where the zigzag planes of the nearest neighboring alkyl chains are packed nearly perpendicular to each other. Therefore, the disappearance of this band means that, at the transition, the subcell structure changes to another type. This is consistent with the change observed in the IR spectrum, i.e., the split pairs due to the $\delta(CH_2)$ [at 1476 and 1463 cm^{-1}] and the CH_2 rocking $r(CH_2)$ modes [at 731 and 720 cm^{-1}] change to the singlets in the temperature range of $T_{c1}<T<T_{c2}$.

As for the subcell structure in the $T_{c1}<T<T_{c2}$ range, there are two possibilities, judging from the infrared and Raman spectra. One is the $T_{//}$-type packing, where the zigzag planes are all parallel to each other, and the other is the hexagonal type with a rotationally disordered orientation of the zigzag planes.[14-17]

When the spectra are measured on powder samples, as in the present case, these two subcells give rise to quite similar spectra and can hardly be distinguished from each other. Judging from the very large value of $\Delta H_{cn,1}$, the hexagonal packing may be the more plausible.

The strong Raman bands at 1295 cm^{-1} [the CH_2 twisting $t(CH_2)$ mode], 1131 cm^{-1} [the symmetric CC stretch $\nu_s(CC)$ mode], and 1062 cm^{-1} [the antisymmetric CC stretch $\nu_a(CC)$ mode], which appear in the lowest-temperature phase below T_{c1}, are characteristic of the all-trans conformation of the alkyl chain.[18-20] They decrease in intensity as the amount of conformational disorder accommodated in the chain increases, and smear into very broad bands when the chain takes a disordered form, as in the liquid alkanes.[18-20] In the $T_{c1}<T<T_{c2}$ temperature range, although these bands still exist with a strong intensity and with a narrow band width, the intensities decrease with an increase in the temperature. This indicates that, in this phase, a partial conformational disordering takes place in the alkyl chain. Above T_{c2}, all of these conformational-sensitive Raman bands change to those of the liquid alkanes, indicating that the alkyl chain may be assumed to take a liquid-like disordered form in the highest-temperature phase.

There are sharp Raman bands at 793 and 704 cm^{-1} in the present series of compounds, the positions being independent of the alkyl-chain length. They are associated with the C-C and C-N stretch modes of the bicyclic system.[21] Before and after the T_{c1} transition, these bands show no changes in either intensity or band width. Above T_{c2}, the 704 cm^{-1} band appreciably decreases in intensity. In the case of the bis(quaternary alkyl halides) of DABCO, a strong Raman band [due to the totally symmetric (NC_4) stretch mode] appears in the frequency region of 700—730 cm^{-1}; this band is broadened above the transition point, suggesting the onset of a rotational motion of the bicyclic system in the high temperature phase.[21] The spectral features of the present monosubstituted compounds are somewhat different from those of the disubstituted compounds.[22] The intensity depression of one of the ring bands indicates the occurrence of some disordering, either statically or dynamically, in the ionized bicyclic system above T_{c2}; it may be related to the abrupt increase in the ionic conductivity.

Summary

The phase transitions of a series of mono(quaternary alkyl bromides) of DABCO were studied on the basis of the DSC, the measurements of the ionic conductivities of the bromide anion, and Raman spectroscopy. The comparison of the phase transitions of the present materials with those of the bis(quaternary alkyl bromides) of DABCO will be discussed below. The present materials exhibited two transitions, at T_{c1} and T_{c2}, whereas the bis(quaternary alkyl bromides) or DABCO showed only one transition.[1-5] This comes from the difference in the crystal structure to be described below. The mono(quaternary salts) seem to possess an $O_\perp$-type subcell, judging from the presence of the crystal-field splitting in the Raman and IR spectra. On the other hand, no crystal-field splitting was observed for the bis(quaternary salts); they seem to possess either hexagonal packing or a $T_{/\!/}$-type packing.[23] The mono(quaternary salts) exhibited phase transitions at T_{c1}, probably arising from the conversion from the $O_\perp$-type subcell to hexagonal packing. On the other hand, the bis(quaternary salts) did not show such transitions; this was because of the different packing structures of the alkyl chain from those of the mono(quaternary salts). These facts demonstrate the difference in the number of transitions. As to the thermodynamic properties, no metastable phase was observed for C_n-DABCO-Br and C_n-DABCO-C_n-Br_2. On the other hand, a series of C_m-DABCO-C_n-Br_2 ($m \neq n$) gave rise to the metastable phase when they had been heated above the transition temperature and then cooled. Abrupt increases in the ionic conductivity by a factor of 2—10 were observed for the present materials around T_{c2}. These values were two to three orders of magnitude smaller than those of the bis(quaternary salts). This difference in values arises from the fact that the molecular motion of the bis(quaternary salts) seems to be more vigorous than that of the mono(quaternary salts) above the transition temperature.[22]

We are grateful to Professor Shigekazu Kusabayashi and Dr. Shunsuke Takenaka, Faculty of Engineering, Osaka University, for the use of the DSC apparatus.

7) The virgin sample and the annealed sample indicate the synthesized sample and the sample heated at least once above T_{c2} respectively.

8) The monolayer of C_{18}-DABCO-Br was found to be formed by the Langmuir method, and its surface pressure became larger than 30 mN m^{-1}. We are grateful to Dr. Masahiro Irie, Institute of Scientific and Industrial Research, Osaka University, for the measurement of the π-A curve.

9) The transitions at 78 and 86 °C of C_{13}-DABCO-Br (Table 1) are tentatively assigned to T_{c2}, because the change in the Raman spectra at these temperatures are similar to those of C_{17}-DABCO-Br at T_{c2} (see the description of the Raman spectra).

10) In the case of C_{11}-DABCO-Br, the temperature of the conductivity jump is, exceptionally, close to T_{c1}. However, the separation between T_{c1} and T_{c2} is small (≈8 °C). Thus, the conclusion that the conductivity jump is related to the transition at T_{c2} can not be drawn for this material.

22) The temperature dependence of the Raman spectra of the symmetric bis(quaternary salts) of DABCO exhibited an almost complete disappearance of the signal ascribable to the C-C skeltal mode above the transition temperature (unpublished data). This is in sharp contrast to Fig. 7, which shows the presence of this signal even above T_{c2}.

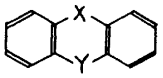
23) In order to determine which of the two possibilities is true, the polarized Raman spectra must be measured for a single crystal. Since the hexagonal packing rarely exists over a wide temperature range, the low temperature phase probably possesses $T_{//}$-type packing.

The Molecular Structure of Thioxanthone as Studied by Gas Phase Electron Diffraction

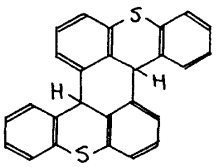
Kinya IIJIMA,* Isao OONISHI,† Shoji FUJISAWA,† and Shuzo SHIBATA
Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422
†Department of Chemistry, Faculty of Science, Toho University, Miyama, Funabashi 274
(Received May 27, 1987)

The molecular structure of thioxanthone has been determined from gas electron-diffraction data. The molecular parameter values and their uncertainties are r_g(C-C)=1.401±0.001 Å, r_g(C-H)=1.099±0.007 Å, r_g(C-S)=1.751±0.002 Å, r_g(C-C_c)=1.498±0.004 Å, r_g(C_c-O)=1.232±0.006 Å, ∠CSC=103.4±0.3°, ∠CC_cC=119.4±0.6°, and θ(dihedral angle)=169.0±1.6°, where the angle parameters are r_α parameters. The dihedral angle of thioxanthone is much larger than those of related molecules.

The crystal structure studies of heterocyclic molecules such as type **1** have revealed that the dihedral angle between the two benzene rings changes in the wide range.[1-5] For example, the dihedral angles of thianthrene (X,Y=S),[1] thioxanthene (X=S, Y=CH_2),[4] and thioxanthone 10-oxide (X=SO, Y=CO)[5] are 128.1°, 135.3°, and 155.7°, respectively. On the other hand, the gas-phase electron diffraction study of thianthrene[6] has shown that this molecule vibrates with large amplitude by folding on the X-Y line, and that the minimum of the potential energy is at 128—130° of the dihedral angle.[6]



1



2

The compound **2** was synthesized from thioxanthone (X=S,Y=CO), but it was not obtained from condensation of thioxanthene which was the half of the object compound.[7] The difference in the molecular structures between thioxanthone and thioxanthene might be one of the factors proceeding the reaction. Thus we undertook the molecular structure determination of thioxanthone by means of a gas electron-diffraction method.

Experimental

O-Mercaptobenzoic acid was allowed to react with sulfuric acid in benzene by heating on a water bath. The crude product was purified by recrystallization from acetic acid solution, and then by sublimation in vacuum.

Electron diffraction photographs were taken by the use of an r^3-sector on Kodak Electron-Image plates at camera distances of 293.70 and 143.98 mm. The sample was sublimed at 455 K by a high-temperature nozzle. The accelerating voltage was 40 kV and the wavelength was determined from the diffraction patterns of thallium(I) chloride.[8] The exposure times were about 60 and 130 s for the long and the short camera-distance photographs, respectively, with an electron-beam current of 0.7 μA. The pressure in the diffraction chamber was 6.7×10^{-4} Pa during the experiment. Four and three plates were selected for the long and the short camera-distance photographs, respectively, and their optical densities were measured at 0.4 mm intervals by the use of a digital microphotometer. The electron diffraction unit and the digital microphotometer used in the present study have been described elsewhere.[9]

Analysis and Results

The scattering intensities in the range of q=9.0—52.5 $Å^{-1}$ were obtained from the long camera-distance

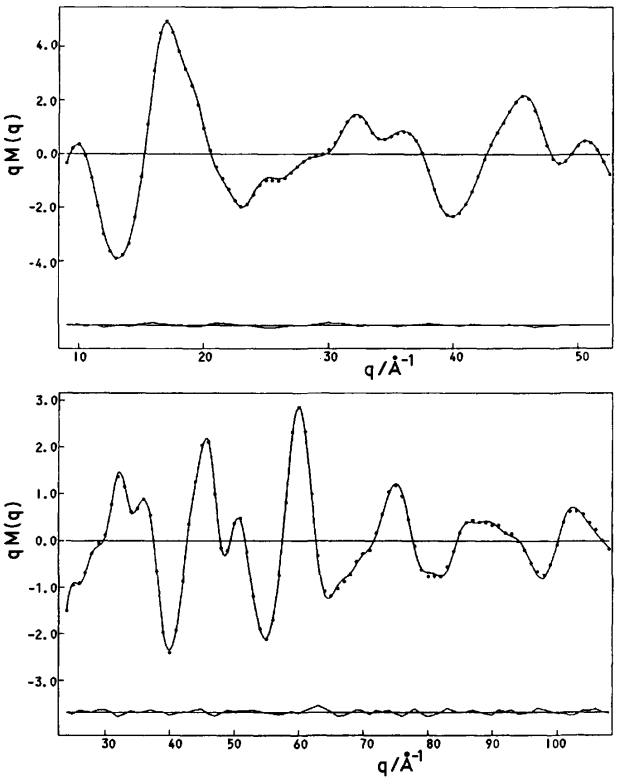


Fig. 1. Molecular intensities for thioxanthone. The upper figure shows the long camera-distance data and the lower figure the short camera-distance data. Dots represent the observed ones and solid curves the calculated ones. The residuals are shown at the lower parts of the figures.

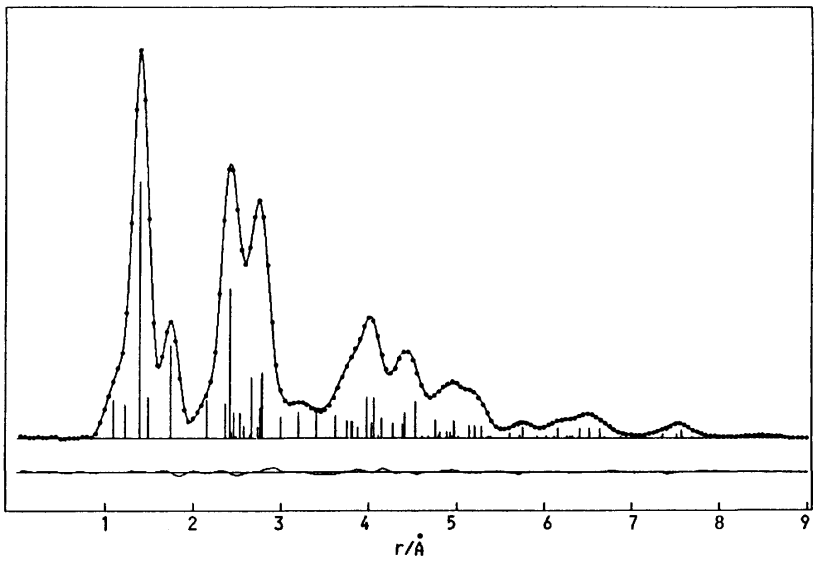

Fig. 2. Radial distribution curve for thioxanthone. Dots represent the experimental one, solid curve the theoretical one, and the difference is shown below. The vertical bars represent bond distances and the scattering powers.

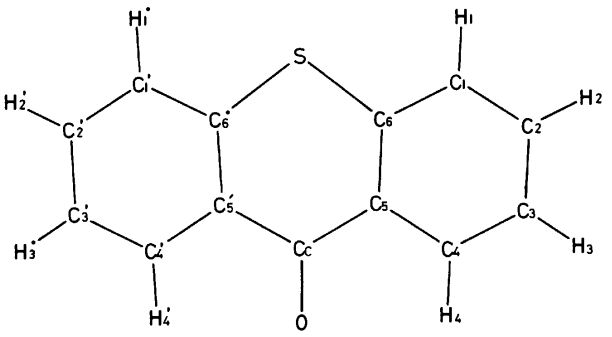

Fig. 3. Numbering of atoms in thioxanthone.

Table 1. Urey-Bradley Force Field for Thioxanthone

K(C-C)	5.46	H(CC(O)C)	0.15
K(C-H)	4.56	H(CCO)	0.40
K(C-S)	2.00	π(H)	0.30
K(C-C(O))	3.70	π(O)	0.62

H(CCC(O))	0.15	F(C(CO)C)	0.30

The potential function was defined as $V=1/2\sum K\Delta r^2 + 1/2\sum H(r\Delta\theta)^2 + 1/2\sum F\Delta q^2 + 1/2\sum Y\Delta\tau^2 + 1/2\sum \pi\Delta\sigma^2$, where the force constants of bond stretching, K, angle deformation, H, and repulsion between nonbonded atoms, F, are in 10^2 N m^{-1}, while those of torsion, Y, and out-of-plane, π, are in 10^{-18} N m.

plates and those in the range of q=24.0—108.0 Å^{-1} from the short camera-distance plates. Here q represents $(40/\lambda)\sin(\theta/2)$, where λ is the wavelength and θ is the scattering angle. They were leveled by using theoretical backgrounds, and the intensities for each camera distance were averaged. The elastic and inelastic scattering factors were taken from the tables prepared by Schäfer et al.[10] and by Cromer,[11] respectively. The inelastic scattering factor for hydrogen atom was taken from the table by Tavard et al.[12] The experimental molecular intensities obtained are shown in Fig. 1. Figure 2 shows the experimental radial distribution function, which is the Fourier transform of the modified molecular intensities, $qM(q)\exp(-bq^2)$, where the damping factor b was 0.0002 in the present study. The molecular model of thioxanthone and the numbering of the atoms are shown in Fig. 3.

The molecular parameters were obtained from least-squares analysis of the molecular intensities on the basis of the following assumption: 1) The molecule has C_s symmetry. 2) The benzene ring is a regular hexagon. 3) The sulfur and carbonyl carbon atoms are on the plane of the benzene ring. 4) The oxygen atom is on the $C_5C_cC_5'$ plane. With these assumption,the geometrical papameters, r_α,[13] refined by least-squares analysis were as follow; $r(C_1-C_2)$, $r(C_1-H_1)$, $r(C_6-S)$, $r(C_5-C_c)$, $r(C_c-O)$, $\angle SC_cC_5$, $\angle C_cC_5C_6$, and θ(dihedral angle).

The vibrational mean amplitudes and the shrinkage corrections, r_a-r_α,[13] were calculated from a Urey-Bradley force field. Since the normal vibration analysis of this molecule has not been performed, the force constants were refered from thianthrene[6] and acetone,[14] as listed in Table 1. The calculated mean

a) Limits of error (see text). b) Dihedral angle. c) Dependent parameter.

amplitudes and the shrinkage corrections of some atomic pairs which give a large contribution to the electron diffraction intensities are listed in Table 2. The mean amplitudes of $l(C_1-C_2)$, $l(C_1\cdots C_3)$, $l(C_1-H_1)$, $l(C_6-S)$, $l(C_5-C_c)$, and $l(C_c-O)$ were refined by the least-squares calculations, and other mean amplitudes and the shrinkage corrections were fixed to the calculated values throughout the analysis. All the asymmetry parameters, κ,[13] were ignored.

The r_g parameters were calculated from the r_a paremeters obtained in the least-squares calculations,[13] and they are listed in Table 3 with dependent parameters and their limits of error. The observed mean amplitudes are listed in Table 4. The limits of error in the distances are the square root of the sum of the squares of the random and systematic errors, and those in the angles are the random errors. The random errors were 2.6 times as large as the errors

estimated by the least-squares calculations. The systematic errors were estimated from the errors in both the measurements of camera distance (0.03%) and wavelength (0.09%). The best-fit molecular intensities and the theoretical radial distribution function are shown in Figs. 1 and 2, respectively. The experimental intensities, the experimental smooth backgrounds, and the correlation matrix for the molecular parameters are deposited in Document No. 8765 at the Office of the Editor of the Bulletin of the Chemical Society of Japan. The least-squares calculations were carried out on a HITAC M-280H computer in the Computer Center of the University of Tokyo.

Discussion

The value of the C_1-C_2 distance in Table 3 represents the average of all the C-C bond distances of the benzene rings in thioxanthone because of the assumption of a regular hexagon. The lower symmetry of the benzene ring of C_{2v} with the equal C-C bond distances, where the two fold axis lies along the $C_1\cdots C_4$ bond, was assumed in the analysis, but the structure of the benzene ring converged to a regular hexagon and the other molecular parameters agreed with the values in Table 3 within the limits of error. The observed mean amplitude of the C_1-C_2 bond is a little larger than the calculated value, but we did not try the further analysis, because the force constants used to calculate the mean amplitudes were tentative ones transfered from the related molecules.

The molecular parameters of thioxanthone and related molecules are listed in Table 5. The C-C and C-H distances of the benzene ring in thioxanthone are in good agreement with those of benzene.[15] The C-O distance of the central ring is much longer than that of acetone,[16] and the mean amplitude of this bond is larger than the calculated value. These facts seem to indicate that the double bond character of carbonyl group decreases in a cyclic molecule. Infrared absorption spectra showed similarly that the wave number of the C-O stretching in thioxanthone,

Distance parameters of gas molecules are r_g parameters.
a) Average value of C-C distances in the benzene rings.

1645 cm^{-1}, was much lower than that in acetone, 1738 cm^{-1}.[14]

Gillean et al. have shown that the C-S and C-C distances in the central ring of a heterocyclic molecule are in the range of 1.77—1.78 Å and 1.50—1.53 Å, respectively, and that they are insensitive to the oxidation state of sulfur atom and substitutions on the central carbon atom.[4] The C-S distance of gaseous thioxanthone, however, is 0.02 Å short out of the above range. The CSC angle is about 4° larger than the corresponding values of the other related molecules, though it is in agreement with that of gaseous thianthrene.[6]

The dihedral angle between the two benzene rings in thioxanthone is notably larger than those of thianthrene[6] and thioxanthene.[4] The flatness of the molecular plane of thioxanthone may be due to the sp^2 hybridization of the carbonyl carbon. Gallaher and Bauer have pointed out in the electron diffraction study[6] that thianthrene vibrates with large amplitude. However, we could not detect such a large amplitude motion in the analysis of thioxanthone. The inversion motion of thioxanthone may be also fixed by the carbonyl group of the central ring.

Entropy Changes in the Inclusion Complex Formation of α-Cyclodextrin with Alcohols as Studied by the Titration Calorimetry†

Hideaki FUJIWARA,* Haruyuki ARAKAWA, Saburo MURATA, and Yoshio SASAKI
Faculty of Pharmaceutical Sciences, Osaka University, 1-6 Yamada-Oka, Suita, Osaka 565
(Received June 5, 1987)

The inclusion complex formation of α-cyclodextrin(α-CD) with various alcohols has been studied by means of titration calorimetry. The titration curve was analyzed successfully by the formation of a 1:1 host-guest complex, and the thermodynamic parameters were determined. The entropies of reaction are estimated from the statistical thermodynamics of molecules. However, the estimated values are found to deviate by an order of magnitude from the experimental ones. To resolve such a discrepancy, α-CD in solution is assumed to include a definite number(n) of water molecules which are replaced by a guest molecule with the progress of reaction. The entropies thus estimated depend extensively on the value of n, and a value of n is determined for each alcohol so that it reproduces just the experimental entropy. The resulting n values are nearly constant for various alcohols studied and are within a reasonable range expected from the data reported in crystal, supporting the model of interpretation.

In a previous report of this series,[1] we have studied with especially the entropy term of reactions of dichlorodimethylstannane with pyridine measured by the titration calorimetry: A solvation model was presented to interpret discrepancy between the entropies observed and those estimated by statistical thermodynamics. To investigate further the validity of such a simple treatment of the entropy term for an elucidation of the role of solvent in reactions, the model is extended to the inclusion complex formation of α-cyclodextrin with alcohols in the present study.

Cyclodextrins are well-known in their ability to form inclusion complexes with various kinds of compounds. They are applied widely in industry,[2] such as for the pharmaceutics and food chemistry as well as for the analytical chemistry. They are also interested as an enzyme model in biochemistry.[3-5] All these applications make use of the "hydrophobic" cavity in cyclodextrin which can "include" different kinds of organic molecules, leading to the inclusion complexes. The inclusion complex formation has been studied quantitatively by not a few investigators and equilibrium constants and enthalpies and entropies have been discussed in relation to the driving forces for the inclusion phenomena.[2,3,5-9] Hitherto, hydrophobic, van der Waals, and hydrogen-bonding interactions between the host and guest molecules, conformational changes in cyclodextrin, and solvation of species in water are pointed out to be responsible to this phenomenon. Here, a release of less hydrogen-bonded water molecules in the cavity to the fully hydrogen-bonded bulk water surely contributes *enthalpically* much to the stabilization of the complex. This effect is pronounced in α-cyclodextrin (α-CD), where smaller number of water molecules are located in the cavity before inclusion occurs and hence hydrogen bonding between these water molecules is less extensive.

† Solvation Effect on the Reactions in Solution. II. See Ref. 1 for I.

In the present study, the entropy changes observed in the inclusion complex formation of α-CD with several alcohols in aqueous solution are interpreted on the basis of the statistical thermodynamics, from which the number of water molecules included in a free state of α-CD *in solution* can be estimated.

Experimental

Alcohols were all distilled in a glass vessel and α-CD from Tokyo Kasei Co. was recrystallized from water. Calorimetric titration was performed on a Tronac 558 isothermal/isoperibol calorimeter equipped with a CCP930 Programmer under an isothermal mode.[10a] α-CD was dissolved in the reaction vessel at a constant molarity, and alcohol was dissolved in the titrant solution. A total of 2 ml titrant was added in 20 steps to 50 ml solution in a stainless steel reaction vessel. Also a 20 ml titration buret was used for 1-hexanol and cyclohexanol, for which solubility in water is not so high as the other alcohols. The heat of reaction was measured within an error of ±0.04 J at 25.0 °C (±0.2 m°C).

Analysis of the titration data was made in a similar way as stated in Ref. 10.b. All these calculations and the calculation of the entropy terms discribed below were done on a NEAC ACOS-1000 computer at the Computation Center in Osaka University. Personal computers NEC PC-9800 were also used for the treatment of experimental data.

Results

The titration experiments were done several times for each alcohol. A typical run is shown in Fig. 1. The titration data were analyzed by the program CONDEP modified to the calorimetric experiments[10b] on the basis of a 1:1 complex formation. Standard deviation σ between the observed and the recalculated heats was smaller than 0.04 J, and systematic deviations were not observed between them. In the program CONDEP, integrated heat Q_i was dealt with originally under the incremental addition of titrant. In the present study, data were also processed with the differential heat q_i. These two calculations were confirmed to afford consistent results.[11]

The equilibrium constants determined are 9.7, 29.1, 81.4, 326, 801, and 56.4 $dm^3 mol^{-1}$ for ethanol, 1-propanol, 1-butanol, 1-pentanol, 1-hexanol, and cyclohexanol, respectively, at 25 °C. The enthalpies and entropies are summarized in Table 1 together with those hitherto published by other investigators. Reproducibility of these parameters was better than 95, 90, and 90% for K, ΔH^0, and ΔS^0, respectively, in the repeated experiments in the present study. The unit of concentration adopted is mol dm^{-3} (M) in the present study, and thermodynamic parameters also correspond to this unit. In Table 1, values cited from other sources are converted to correspond to the same unit when necessary.[14] In the Table, ΔH^0's for the same alcohol are rather in good agreement although method and experimental conditions differ among different investigators. As this contrast, ΔS^0 changes more or less depending on the sources of data. This would be inevitable because of the small contribution of ΔS^0 as judged by comparing $T\Delta S^0$ with ΔH^0.

Table 1. Enthalpies and Entopies for the Inclusion Complex Formation of α-Cyclodextrin with Several Alcohols[a)]

Alcohol	ΔH^0			ΔS^0		
	This work	Ref. 12	Ref. 13	This work	Ref. 12	Ref. 13
Ethanol	−2.4			11.2

The molarity of α-CD changes:
1; 0.014—0.012 M, 2; 0.0194—0.0187 M, 3; 0.0067—0.0064 M, 4; 0.0042—.0.0040 M, 5; 0.015—0.009 M, 6; 0.012—0.007 M. A half of C_{ROH} is plotted in curve 1 to save a space in the Figure.

Discussion

A thermochemical cycle is given in Fig. 2 for the entropies, where α-CD is assumed to include n molecules of water in solution that will be released with the progress of reaction. Following equations hold for this cycle:

$$\Delta S^0_{gas} = S^0_{CD\cdot B} + nS^0_{H_2O} - S^0_{CD\cdot nH_2O} - S^0_B \quad (1)$$

$$\Delta S^0_{soln} = \Delta S^0_{gas} + (\Delta S^s_{CD\cdot B} + n\Delta S^s_{H_2O} - \Delta S^s_{CD\cdot nH_2O} - \Delta S^s_B) \quad (2)$$

Note that nH_2O is attached to α-CD in the left-hand side of the formula in Fig. 2 to allow for the inclusion of water molecules in the cavity. These water molecules are considered to "solvate" strongly (or bind) to α-CD. That is to say, n molecules of water in the cavity are assumed to behave as if they constitute a rigid part of a whole molecule.[15] As this contrast, normal and weak "solvation" of each species is considered to be compensated for by the entropy of solution.

Estimation of ΔS^0_{gas} in Eq. 1 is not straightforward since calculation of $S^0_{CD,B}$ and S^0_{CD,nH_2O} needs detailed data on the vibrations in CD·B and CD·nH_2O which are lacking. However, most of the vibrational parts

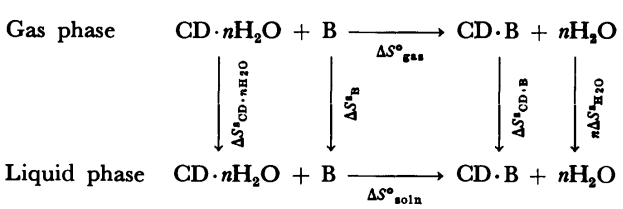

Fig. 2. A reaction scheme for the entropy changes in the inclusion complex formation of cyclodextrin(CD) with alcohols(B).
ΔS^s's are the entropies of solution of the components. In a free state, CD is assumed to include n molecules of water, which are released with the progress of reaction.

are expected to be cancelled out between those for the reactants and those for the products. The translational and the rotational parts of entropy can be estimated according to following Eqs.:[16]

$$S_{tr} = R(1.5\ln M + 2.5\ln T - \ln P - 1.1650) \quad (3)$$

$$S_{rot} = R(0.5\ln I_A I_B I_C + 1.5\ln T - \ln\sigma - 2.7106) \quad (4)$$

where the symbols have usual meanings. Such calculations afforded $\Delta S^0_{gas,calcd}$ as listed in Table 2, when n was set equal to two, a typical value reported first for a single crystal of α-CD hexahydrate.[17]

The value of $\Delta S^0_{gas,calcd}$ can be converted to that of $\Delta S^0_{soln,calcd}$ by means of Eq. 2 if the entropy of solution is predictable for each component. The experimental values are available for different compounds including water and alcohols, and the value is known to be linearly correlated with the thermodynamic third-law entropy of solute x in gas phase, $S^0_{298,x}(g)$. For example, Eq. 5 is reached in aqueous solution.[18] It is later reported that the coefficients in Eq. 5 may change depending on the types of compounds treated.[19]

$$\Delta S^s_x = -0.46\, S^0_{298,x}(g) + 27.5 \quad (5)$$

However, Eq. 5 is considered to be valid for the present case, since in Eq. 2 ΔS^s appears as the difference between that of water and that of alcohol and also as the difference between that of the cyclodextrin hydrate and that of its inclusion complex. Then Eq. 6 is reached from Eqs. 1, 2, and 5.

$$\Delta S^0_{soln} = 0.54\,\Delta S^0_{gas} + (n-1)\cdot 27.5 \quad (6)$$

Next, a correction is necessary for the difference in standard states. The thermodynamic third-law entropy $S^0_{298}(g)$ corresponds to a standard state of 1 atm, whereas the entropy of reaction is given against a standard state of 1 mol dm^{-3} in the present study. Therefore, following relation holds:

$$S^0_{298,x}(g) = S^0_x + R\cdot\ln 24.5 \quad (7)$$

where S^0_x is the standard entropy of x in gas phase corresponding to 1 mol dm^{-3} (1/24.5 atm) at 25 °C and an ideal gas behavior is assumed. The values of ΔS^0_{soln} thus estimated are also listed in Table 2.

The entropies calculated are all positive and very large compared to the experimental ones. If the vibrational and internal-rotational entropies are included into the calculation, the resulting $\Delta S^0_{gas,calcd}$ will be increased more or less. In fact, $\Delta S^0_{gas,calcd}$ was increased by 16% in the previous case of Me_2SnCl_2 plus pyridine.[1] Therefore, it is quite clear that above calculation fails to explain the experimental values of ΔS^0_{soln}. As a cause of this discrepancy, an error in n can be pointed out. Hitherto, two different values have been reported other than two stated above for the number of water molecules included in the α-CD cavity in crystal, i.e., n=1[20] and n=2.57[21] for different crystal modifications. In fact, the values of ΔS^0_{gas} and ΔS^0_{soln} calculated were found to depend highly on the value of n. Therefore, n was determined according to Eq. 8 so as to reproduce just the experimental value of ΔS^0_{soln}. Equation 8 was derived from Eqs. 1, 2, 5, and 7.

$$n = \frac{\Delta S^0_{soln} - 0.54(S^0_{CD\cdot B} - S^0_{CD\cdot nH_2O} - S^0_B) + 27.5 - 0.46R\cdot\ln 24.5}{0.54\, S^0_{H_2O} + 27.5 - 0.46R\cdot\ln 24.5} \quad (8)$$

The results are summarized in Table 3.[22] It is seen that n is nearly constant throughout the alcohols studied, although the experimental entropies do change depending on the alcohol. Such a constancy in n indicates that a same number of water molecules are released from the cavity when alcohols with a small size (ethanol) to a relatively large size (1-hexanol) are included, and supports that all of the water included in the cavity are expelled from the cavity on forming the complexes with these alcohols. This trend in solution is consistent with the results in crystal.[23] Also, the constancy in n means that ΔS^0_{soln} depends only on ΔS^0_{gas} (Eq. 6). This, in turn, means that ΔS^0_{soln} changes linearly with S^0_B on changing the alcohol studied, since in Eq. 1 $S^0_{H_2O}$ and S^0_{CD,nH_2O} are

a) Calculated from data in this work(*a*), in Ref. 12(*b*), and in Ref. 13(*c*).

constant and $S^0_{CD,B}$ is almost constant for different alcohols because of an overwhelming size of cyclodextrin. In fact, ΔS^0_{soln} was observed to change linearly with the thermodynamic third-law entropy of alcohol in the present study. These correlations are under further study including various kinds of guest molecules. In this way n is said to be 1.4 on average for the alcohols studied here. Such a non-round number may result from a dynamic equilibrium of water in between the cavity and the bulk water. That is, the non-round number reflects only a statistical average of the number of water molecules included in the cavity in solution.

In conclusion, calculation of the entropy of reactions is expected to be valuable for the elucidation of the state and the role of water in the host-guest molecular interactions in solution.

11) If an unexpectedly large error occurs in an incremental step of k in titration, the error will be included to all the integrated heat Q_i later than $i=k$, although it is included to only q_k when differential heat is treated. On this contrary, random errors which occur in every step of titration will be reduced for the integrated heat Q_k by a partial cancellation in the summation of the differential heats q_i between $i=1$ to k. The consistent results reached from the analysis of Q_i and from than of q_i may be interpreted to indicate sufficiently small errors in the present experiment.

14) Following equations were utillized for the conversion from mole fraction to mol dm^{-3}, the primed symbols corresponding to the unit of mole fraction.

$$\ln K = \ln K' - \ln(1000/MV)$$
$$\Delta H = \Delta H' + \alpha R \cdot T^2$$
$$\Delta S = \Delta S' + R\{\ln(1000/MV) - \alpha T\}$$

Here, MV is the molar volume of solute and α is the thermal expansion coefficient of solution.

15) A fraction of the water molecules may still be included in the cavity of α-CD in CD·B. However, this is not assumed in Fig. 2 for simplicity. When this is the case, say m molecules of water "bind" strongly to CD·B, the value of n discussed below needs be replaced by that of $n-m$ which is equal to a number of water molecules released in the reaction. However, as stated in the Discussion section, all of the water molecules included within the cavity are considered to be expelled from the cavity after the reaction.

22) The vibrational part of entropy is not included in the calculation of $S^0_{CD,B} - S^0_{CD,nH_2O} - S^0_B$ because of the lack of full vibrational data. This part is actually equal to that of the reaction of $CD \cdot nH_2O + B \rightarrow CD \cdot B + nH_2O$ because of a negligible amount of the vibrational part in H_2O. Accordingly, this part is expected to be small since the vibrational entropies for the latter reaction will be cancelled out between those for the reactants and those for the products. If the vibrational entropy of this kind is assumed to amount to 16% of $\Delta S^0_{gas,calcd}$ likely to the previous case,[1] $\Delta S^0_{CD,B} - \Delta S^0_{CD,nH_2O} - S^0_B$ in Eq. 8 is increased by 16 J K^{-1} mol^{-1} and the resulting n will be decreased by about 16%.

A Simple Model for the Kinetics of Beta Meander Formation of Homopolypeptide Chains

Hiroshi MAEDA
Department of Chemistry, Faculty of Science, Nagoya University, Nagoya 464
(Received June 5, 1987)

A simple kinetic theory is presented concerning the irreversible formation of intramolecularly folded β-structure of homopolypeptide chains through a bend formation. To reduce the number of parameters, the number of strands is limited to be less than five and the growth rate of the third and fourth strands is assumed to be so fast that the final strand length is attained immediately after the bend formation. Numerical calculations were carried out on relevant ranges of rate costants for relatively short chains. It was shown that experimentally found diverse kinetic patterns were all explicable based on the present model.

Folding of single homopolypeptide chains into the β-structure occurs, in principle, at any site on the chain and hence it is a stochastic process. Therefore, it differs from that of globular proteins, where the folding pathway is determined nearly uniquely by the amino acid sequence.[1-3] It is interesting and also important to know the difference between the folding of homopolypeptide chains and proteins containing the β-structure.

Several experimental studies have been done on the kinetics of intramolecular β-structures of poly(L-lysine) (PLL)[4-8] and its side-chain homolog,[9] poly(L-tyrosine) (PLT),[10,11] and poly(*S*-carboxymethyl-L-cysteine) (poly[Cys(CH_2COOH)]).[12] Thermally induced α-helix-to-β-structure conversion of PLL showed single exponential behavior,[5,6,8] while its pH-induced coil-to-β-structure conversion at high temperatures showed a lag phase when followed with light scattering or fluorescence.[7] In the case of poly(L-tyrosine), pH-induced coil-to-β-structure change was successfully described with two exponential terms and no lag phase was observed.[10] Time domains in these studies for the formation of the β-structure were about 10—10^2 min for PLL and poly[Cys(CH_2COOH)][12] but 10—10^2 s for PLT. Different behaviors of PLT from those of PLL were noticable as pointed out.[10] Fast changes in 10^{-2}—0.1 s region were observed in a recent study on PLT; the results were approximately fitted with two exponential terms but multi-relaxation time character was also observed.[11] Thermal coil-β-structure conversion of poly[Cys(CH_2COOH)] showed multi-relaxation time behavior.[12]

Since intramolecular folding of single polypeptide chain certainly consists of several steps, rate constants of these steps should be related to the time constants observed in experiments. However, such an attempt has been scarcely reported.

In view of the complex nature of the whole process of chain folding and also to reduce the number of parameters, we wish to present a highly approximate model in the present report. The model is of phenomenological nature and quantitative analyses of experimental data based on the present model are not intended. However, various kinetic behaviors such as single exponential, tow exponential terms, or lag phase, are all predicted from this simple model. Therefore, all the experimental data on homopolypeptides to data can be consistently interpreted according to this model.

Model. A symmetric polymer chain consisting of L units is considered. Directional nature of polypeptide chain is tentatively neglected. Each unit can assume three states: disordered state with no hydrogen bonds, β-conformation with one and two hydrogen bonds. Three basic assumptions of the model are:

1) Only the formation of the β-conformation is considered. No reversible reaction is considered.
2) Initiation of β-strand formation is thoroughly due to bend formation. Initiation by collision of two units distant apart on the chain is excluded.
3) Multiple initiation is inhibited.

Other assumptions are introduced below in the course of the description of the present model depicted in Fig. 1.

First bend occurs with a rate constant k_i between the η-th and $(\eta+1)$-th units of a random coil chain. Units are counted from one end of a symmetric chain. No units are incorporated in the bend portion (assumption 4). It is simple to modify the present theory to take into account any (fixed) number of units in the bend portion. We make assumption 4 only for the sake of simplicity. Two β-strands thus initiated grow with a rate constant k_+. At any stage of the growth, second bend can be formed with a rate constant k_b at either of the two junctions between random coil region and the growing β-strands. Growth of the third strand is assumed to be very fast compared with k_+ and k_b and hence final strand length is attained immediately after the second bend is formed (assumption 5). Third bend is restricted to take place, in our model, at the remaining junction between random coil region and the first two β-strands. Formation of the fourth strand is assumed to take place instantly, just as the third strand. No further bend formation is

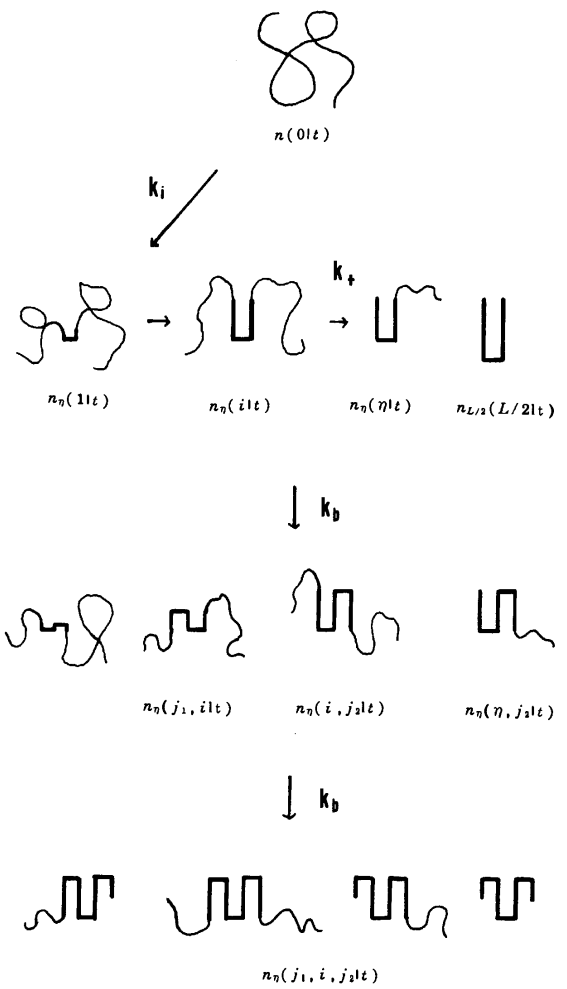

Fig. 1. Schematic representation of the model. Thick lines and thin curves represent the β-strands and random coil portions, respectively.

allowed (assumption 6). Some of these assumptions will be discussed later.

In this way, only those species consisting of two, three and four strands are considered in this model. We hope this simple model contains essentials of a general model where any number of strands is allowed. It is to be noted that three-strand species known as β-meander,[13] which are frequently found in proteins, are major products in this model.

At this stage, it is pertinent to consider the nature of the unit in the model. The unit does not necessarily correspond to a peptide unit nor an amino acid residue. Instead, it may correspond to p peptide groups together. Hence, chain length L of the model does not necessarily represent the degree of polymerization of actual polypeptide chain (DP). By virtue of this extension of the definition of unit, we need not calculate these cases with large L, say more than 100. If p is taken to 10, L=10 is sufficient to describe a chain of DP=100. With this definition of unit, the present model is also applicable to random and sequential copolypeptides, if p is taken to the repeating unit (or greater) in the latter case. Initiation rate constant k_i is not taken as position-dependent. Actually, however, an initiation near chain end is not effective, because two unstable short strands thus formed are dissociated and other initiation at the site much distant from chain ends will occur subsequently. If we take a value of p as such that formation of the β-conformation at p-th site from the chain end is stable enough, then in the present model we can assign the same value of k_i to the units near chain end as well as to other units in the interior of the chain. On the other hand, this extention of the definition of unit invalidates quantitative analyses of experimental data based on this model, unless p is evaluated reasonably. This is the reason why present model is of phenomenological nature.

Rate Equations and Solutions. All number concentrations n's are normalized to give unity at any time when they all are summed up. Time course of the concentration of random coil species, $n(0|t)$, is governed by Eq. 1.

$$dn(0|t)/dt = -Lk_i n(0|t) = -k_0 n(0|t) \tag{1}$$

where k_0 is defined as Lk_i. Let $n_\eta(i|t)$ denotes the concentration of a species at time t with two β-strands of length i starting from the first bend between η- and $(\eta+1)$-th units. Since the chain is symmetric, only those species of $\eta \leqq L/2$ are considered explicitly. Final results will be doubled in due course.

Rate equations for $n_\eta(i|t)$'s are as follows. For $\eta \leqq L/2-1$,

$$dn_\eta(1|t)/dt = k_i n(0|t) - (k_+ + 2k_b) n_\eta(1|t) \tag{2}$$

$$dn_\eta(i|t)/dt = k_+ n_\eta(i-1|t) - (k_+ + 2k_b) n_\eta(i|t) \quad (2 \leqq i \leqq \eta - 1) \tag{3}$$

$$dn_\eta(\eta|t)/dt = k_+ n_\eta(\eta-1|t) - k_b n_\eta(\eta|t) \tag{4}$$

$$dn_{L/2}(L/2|t)/dt = k_+ n_{L/2}(L/2-1|t) \quad (\eta = L/2) \tag{5}$$

For three strand species, $n_\eta(j_1,i|t)$ and $n_\eta(i,j_2|t)$ and four strand species, $n_\eta(j_1,i,j_2|t)$, their concentration changes are described by the following equations.

$$dn_\eta(j_1,i|t)/dt = k_b n_\eta(i|t) - k_b n_\eta(j_1,i|t) \tag{6}$$

$$dn_\eta(i,j_2|t)/dt = k_b n_\eta(i|t) - k_b' n_\eta(i,j_2|t) \tag{7}$$

$$dn_\eta(j_1,i,j_2|t)/dt = k_b n_\eta(j_1,i|t) + k_b n_\eta(i,j_2|t) \tag{8}$$

Here, j_1, j_2, and k_b' are defined as follows: j_1=Min(i, η–i), j_2=Min(i, $L-\eta$–i) and $k_b'=k_b (i \leqq \eta-1)$ or 0 $(i=\eta)$.

Initial conditions at t=0 are: concentrations of all species except random coil are zero and $n(0|0)$=1. Solutions of rate equations consistent with the initial conditions are given below.

$$n(0|t) = \exp(-k_0 t) \tag{9}$$

$$n_\eta(i|t) = (k_i/k_+)(k_+/k)^i \exp(-k_0 t)\gamma(i,kt)/(i-1)! \tag{10}$$

$$n_\eta(\eta|t) = (k_+/k_b) n_\eta(j_1, i=\eta-1|t) \quad (n \leqq L/2-1) \tag{11}$$

$$n_{L/2}(L/2|t) = k_i(k_+/k)^{L/2-1}\left[\frac{(1-\exp(-k_0t))}{k_0} - \sum_{r=0}^{L/2-2}\frac{k^r}{(k_++2k_b)^{r+1}}\gamma[r+1,(k_++2k_b)t]/r!\right] \quad (12)$$

For $1 \leqq i \leqq \eta$,

$$n_\eta(j_1,i|t) = k_i(k_+/k)^{i-1}(k_b/k)\left[\frac{(\exp(-k_0t)-\exp(-k_bt))}{k_b-k_0} - \frac{\exp(-k_bt)}{k_++k_b}\sum_{r=0}^{i-1}\left(\frac{k}{k_++k_b}\right)^r\gamma[r+1,(k_++k_b)t]/r!\right] \quad (13)$$

$$n_\eta(i,j_2|t) = n_\eta(j_1,i|t) \quad (i \leqq \eta-1) \quad (14a)$$

$$n_\eta(\eta,j_2|t) = (k_+/2k_b)n_\eta(j_1,i=\eta-1,j_2|t) \quad (14b)$$

$$n_\eta(j_1,i,j_2|t) = \frac{2k_ik_b^2}{k(k_0-k_b)}(k_+/k)^{i-1}\times\left[\frac{(1-\exp(-k_bt))}{k_b}\left(\frac{k}{k_++k_b}\right)^i-\frac{(1-\exp(-k_0t))}{k_0}\right] + \frac{2k_ik_b^2}{k(k_++k_b)}(k_+/k)^{i-1}\sum_{r=0}^{i-1}\left(\frac{k}{k_++k_b}\right)^r\times\left[\sum_{l=0}^{r}\frac{(k_++k_b)^l}{(k_++2k_b)^{l+1}}\gamma[l+1,(k_++2k_b)t]/l!\right] \quad (15)$$

In the above equations, k is defined as $k_++2k_b-k_0$ and $\gamma(i,x)$ is the incomplete gamma function defined below.

$$\gamma(i,x) = \int_0^x e^{-y}y^{i-1}dy = (i-1)![1-e^{-x}\sum_{r=0}^{i-1}\frac{x^r}{r!}] \quad (16)$$

From the concentrations given above, fraction f of the β-conformation or hydrogen-bonded units can be readilly calculated. Contributions from two-, three-, and four-strand species are denoted as f_1, f_2, and f_3, respectively. Calculations and the results are given in Appendix.

The extent of reaction Δf is defined as follows.

$$\Delta f(t) = [f(\infty)-f(t)]/f(\infty) \quad (17)$$

Here, $f(t)=f_1+f_2+f_3$ and $f(\infty)$ represents the final amount at $t=\infty$. The final amounts are also given in Appendix. After substituting these results in Appendix into the above three terms, the extent of reaction is explicitly represented in the below as a function of time. In the case of the fraction of the β-conformation f_β,

$$\Delta f_\beta(t) = a_1\exp(-k_0t)+a_2\exp(-k_bt) + \left[\sum_{r=0}^{L/2-2}a_{3,r}\frac{(kt)^r}{r!}\right]\exp\{-(k_++2k_b)t\} + \left[\sum_{r=0}^{L/2-2}a_{4,r}\sum_{l=0}^{r}(k_++k_b)^lt^l/l!\right]\exp\{-(k_++2k_b)t\} + \left[\sum_{r=0}^{L/2-2}a_{5,r}\sum_{l=0}^{r}(k_++2k_b)^lt^l/l!\right]\exp\{-(k_++2k_b)t\} \quad (18)$$

Here, $a_{i,r}$'s are complex functions of k_b/k_+, k_i/k_+, and L.

We confine ourselves for the moment to the case $k_+ \gg k_b$. Under this condition, strands can grow up to a considerable length before the next bend is formed. Since number of strands is limited to be smaller than five, fraction of the β-conformation will be very small in otherwise case $k_+ < k_b$. Under the limiting case considered here, the last three terms of Eq. 18 become functions of k_+t and Eq. 18 is reduced to a simple form. For a small t ($k_+t \ll 1$), first two terms can be approximated to be constant and the last three terms are expanded in power series of k_+t. After truncation of higher order terms in k_+t, Eq. 19 results.

$$\Delta f_\beta(k_+t \ll 1) = 1 - (a_{3,0}-a_{3,1}-a_{4,0}-a_{5,0})k_+t + O(k_+^2t^2) \quad (19)$$

Here, the following obvious relation is used.

$$\Delta f_\beta(0) = a_1 + a_2 + a_{3,0} + \sum_{r=0}^{L/2-3}a_{4,r} + \sum_{r=0}^{L/2-2}a_{5,r} = 1 \quad (20)$$

Since,

$$a_{3,1} - a_{3,0} = -(1-2/L)2k_+k_b/k^2 \approx O(k_i/k_+)$$

and

$$a_{4,0} \approx a_{5,0} \approx O(k_ik_b/k_+^2),$$

the coefficient of k_+t term in Eq. 19 is much smaller than unity under the limiting case considered. This means the presence of a lag phase. However, whether or not a lag phase is significant depends on the ratio t_0/τ_1, where t_0 and τ_1 denote a lag time and the time constant of the reaction, respectively.

Results of Numerical Calculations. Numerical calculations were carried out on the following sets of rate constants for chains of L=12, 24, and 48. (For simplicity, L is taken to be a multiple of 12)

$k_b/k_+ = 1\times10^{-1}$, 1×10^{-2}, and 1×10^{-3}

$k_b/k_i = 1$, 10, and 10^2.

One of the most complex behavior obtained is shown in Fig. 2 which was obtained for L=24, k_b/k_+=

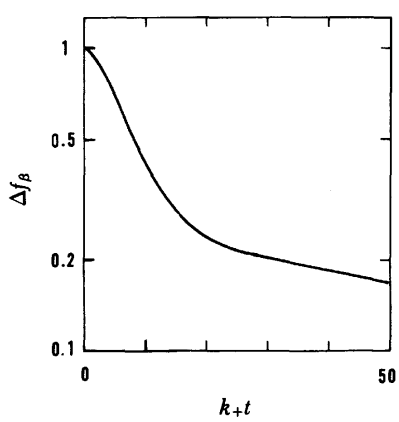

Fig. 2. A general kinetic pattern where log Δf_β is given as a function of reduced time k_+t.
L=24, $k_b/k_+=k_i/k_+=1\times10^{-2}$, $k_0/k_+=0.24$.

$k_i/k_+=1\times10^{-2}$. The time course is well approximated with the following formula of four parameters for a time range $t>t_0$.

$$\Delta f_\beta(t) = A_1 \exp[-(t-t_0)/\tau_1] + (1-A_1)\exp[-(t/\tau_2)] \quad (21)$$

In Table 1, values for the parameters are given for 26 cases. As seen from Table 1, many kinetics examined show simpler behavior than that shown in Fig. 2 or represented by Eq. 21. For about 9 examples, the time course can be approximated with single exponential term. About 6 examples show single exponential behavior accompanying a lag time t_0. Time course with two exponential terms without a lag time is found on 6 examples. A lag phase is discriminated when t_0/τ_1 exceeds 0.03.

At $k_b/k_+=1\times10^{-3}$ ($k_+\gg k_0$ or k_b), a general trend is seen which is valid irrespective of chain length. Two exponential character $0.7\exp(-k_0t)+0.3\exp(-k_bt)$ prevails if $k_0\gg k_b$ but single exponential dependence $\exp(-k_0t)$ is dominant if $k_b\gg k_0$. Examples of time course of various species are shown in Fig. 3 for a chain of $L=24$. In Fig. 3(a) where $k_0\gg k_b$ the contribution from two-strand species first reaches about 65% of the final fraction of the β-conformation, which is close to $A_1(0.73)$, with a rate constant close to k_0. The rest amount (35%) comes out as two-strand species are converted into three-strand species with a rate constant k_b. When k_0/k_b is reduced, as shown in Figs. 3(b) and (c), three-strand species are formed before two-strand species fully grow up, which is seen by a decrease of amplitude A_1 in Table 1. The rate of the formation of three-strand species is given by k_0 (which is now smaller than k_b).

This behavior resembles what is predicted from a following simple Scheme 1.

$$\text{Random coil} \xrightarrow{k_0} \text{Two-strand species} \xrightarrow{k_b} \text{Three-strand species}$$

Scheme 1.

At two other values of k_b/k_+, transition from two exponential character to single exponential one similarly takes place, as k_0/k_b is reduced. The following features are further noticed. In initiation-controlled regime ($k_b>k_0$), single exponential character prevails but the presence of a lag phase becomes significant, as k_+ approaches k_b, i.e., $k_b/k_+=1\times10^{-2}$ and 0.1. In bend-formation-controlled regime ($k_0>k_b$), on the other hand, two exponential character remains but the contribution of a lag phase becomes vanishing, as k_b/k_+ increases.

According to Scheme 1, a lag phase is expected if $k_0\sim k_b$. Some lag phases in Table 1 can be understood based on Scheme 1. However, lag phase in two exponential regime as well as in the initiation-controlled regime cannot be interpreted based on simple Scheme 1. In this case, recourse should be made to Eq. 18 to understand the origin and nature of the lag phase.

Table 1. Summary of Kinetic Patterns

$k_b/k_+=1\times10^{-3}$			
k_b/k_i	1	10	10^2

$L=24$	$0.73\ e^{-1.08\,k_0(t-t_0)}+0.21\ e^{-1.0\,k_bt}$ ($k_+t_0=4$; 3%)	$0.24\ e^{-1.42\,k_0t}+0.76\ e^{-1.3\,k_bt}$	$e^{-0.96\,k_0t}$
$L=48$	$0.73\ e^{-0.96\,k_0(t-t_0)}+0.27\ e^{-1.3\,k_bt}$ ($k_+t_0=5$; 5%)	$0.64\ e^{-1.08\,k_0t}+0.36\ e^{-1.1\,k_bt}$	$e^{-0.86\,k_0t}$
$k_b/k_+=1\times10^{-2}$			
k_b/k_i	1	10	10^2
$L=12$	$0.69\ e^{-1.08\,k_0t}+0.31\ e^{-1.1\,k_bt}$	$e^{-0.94\,k_bt}=e^{-0.78\,k_0t}$	$e^{-1.0\,k_0t}$
$L=24$	$0.73\ e^{-0.73\,k_0(t-t_0)}+0.27\ ^{-0.97\,k_bt}$ ($k_+t_0=1.3$; 6%)	$e^{-0.71\,k_0t}=e^{-1.7\,k_bt}$	$e^{-0.96\,k_0t}$
$L=48$	$0.71\ e^{-0.29\,k_0(t-t_0)}+0.29\ e^{-1.0\,k_bt}$ ($k_+t_0=1$; 3%)	$0.52\ e^{-1.15\,k_0(t-t_0)}+0.48\ e^{-1.2\,k_bt}$ ($k_+t_0=5$; 6%)	$e^{-0.86\,k_0t}$
$k_b/k_+=1\times10^{-1}$			
k_b/k_i	1	10	10^2
$L=12$	$0.73\ e^{-0.43\,k_0t}+0.28\ e^{-0.87\,k_bt}$	$e^{-0.92\,k_b(t-t_0)}=e^{-0.77\,k_0(t-t_0)}$ ($k_+t_0=1.3$; 5%)	$e^{-1.0\,k_0(t-t_0)}$ ($k_+t_0=6$; 3%)
$L=24$	$0.54\ e^{-0.17\,k_0t}+0.46\ e^{-1.20\,k_bt}$	$e^{-1.3\,k_b(t-t_0)}$ ($k_+t_0=1.2$; 7%)	$e^{-0.96\,k_0(t-t_0)}$ ($k_+t_0=4$; 4%)
$L=48$		$e^{-1.3\,k_b(t-t)}$ ($k_+t_0=0.6$; 3%)	$e^{-0.92\,k_0(t-t_0)}$ ($k_+t_0=5.5$; 10%)

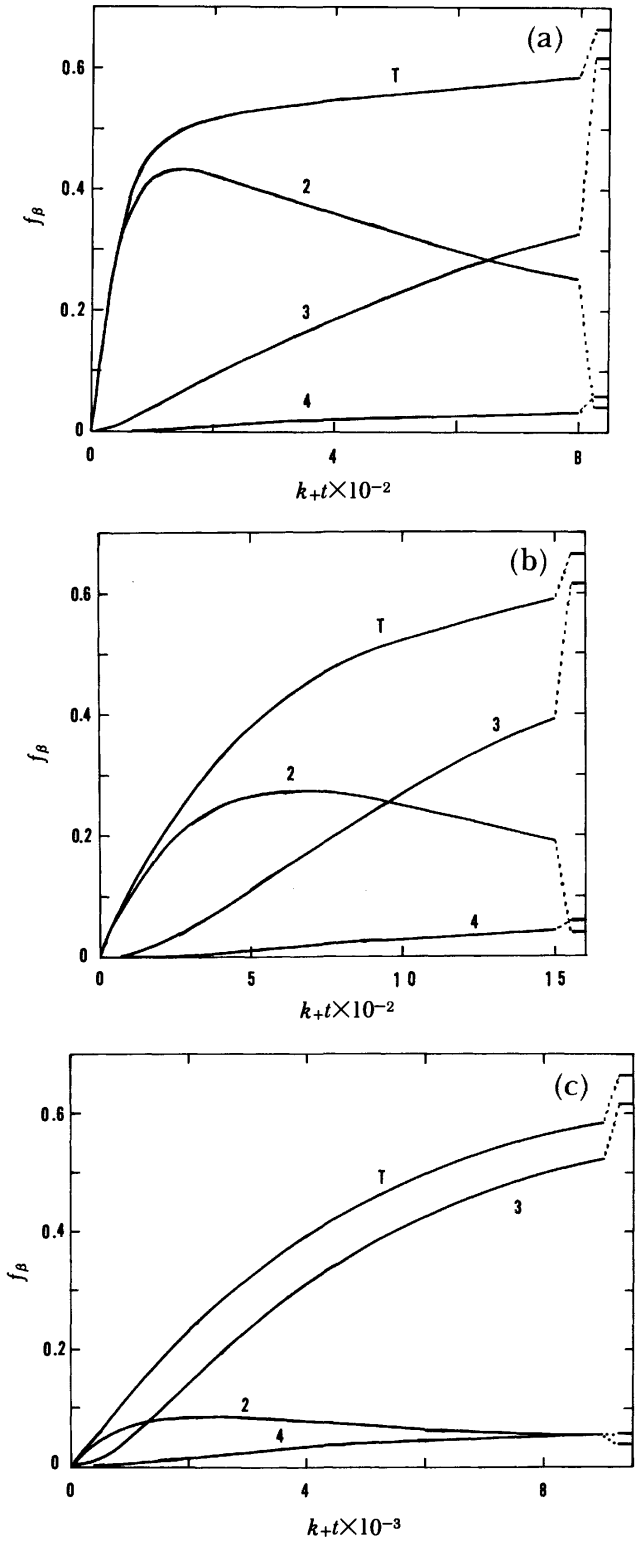

Fig. 3. Time course of various species under the condition where Scheme 1 holds approximately L=24, $k_b/k_+=1\times10^{-3}$. k_i/k_b: (a) 1, (b) 0.10, and (c) 1×10^{-2}.
In each figure (a)—(c), curves labelled as 2, 3, 4, and T represent the contributions from two- three-, four-strand species and their sum. Final values at $t=\infty$ are indicated by horizontal bars.

It is to be noted in Fig. 3 that final products are mostly three- strand species (β-meander). The population of four-strand species is significant under the situation $k_b/k_+=0.1$ in the case of L=24.

Experimental data on homopolypeptides published to date are systematically interpreted in terms of the present model. Their kinetics are not different from each other in essence but they all are explicable with the present model. The time constants obtained are expected to be related not to k_+ but rather to k_0 in the case of PLL[6-8] or to k_b and k_0 in the case of PLT.[10]

Recently, a progress has been made on the equilibrium theory of coil-β-structure conversion.[14-17] However, no attempt was made to evaluate various parameters from the comparison with experimental data. This indicates the difficult situation in the study of the β-structure to obtain proper experimental results consistent with the requirements of theories. The situation is worse in kinetic aspects than equilibrium ones. Hence, in the present study, no attempt is made to evaluate various rate constants from the comparison with published kinetic data.

Discussion

Some assumptions introduced in the present study are discussed briefly here.

(1) **Irreversibility.** It is desirable to take the reverse reaction into account. However, most experimental data were obtained under the condition that β-structure was nearly completely formed. Reverse reaction can be neglected under this condition. Furthermore, even under the condition where the fraction of the β-conformation is appreciably smaller than unity, there are several indications suggesting two processes; the first fast process followed by a slow annealing process.[12] It is likely that the fast growth step occurs irreversibly in a practical sense. Reversible nature of the reaction is partly taken into account even in the present model, for example, in the definition of unit or in the following discussion on (5).

(2) **Initiation through Bend Formation.** Formation of the β-structure was much slower in buffers than in unbuffered solutions under otherwise identical conditions in the case of PLL[7] and poly[Cys-(CH_2COOH)] (unpublished result). The findings indicate that collision of two random coil chains is much less effective than bend formation to initiate the β-structure. Since reaction between two random coil portions within a chain does not differ much from that between two random coil chains, the assumption is pertinent.

(3) **Multiple Initiation is not Considered.** For long chains, the fraction of the β-conformation reaches a limit, which is far below completion, even the limitation on the number of strands is removed. Therefore, initiation occurs at a unit outside of the

first β-sheet region and hence multiple initiation is a generally expected event. When all these locally formed β-sheets encounter each other, the first irreversible growth step terminates. Then, second annealing step follows where reversible nature of the reaction plays an essential role. The net increase in the fraction of the β-conformation is not big, however, accompanying this second step, although stability of the β-structure increases. Hence, the second step can be tentatively ignored. Then, present model can be applied to the case of multiple initiation, only by modifying the original chain length L_0 to L, the latter being roughly given by $L_0 f_\beta(\infty; L_0)$.

(4) **Calculations are Restricted under the Condition $k_+ > k_b$.** In the reverse situation of $k_b > k_+$, major products will be such that chains consisting of many bends connected by short strands. We are not interested in these species in the present study. Further, to examine the kinetics of the formation of such species, limitation on the number of strands (assumption 6) should be removed.

(5) **Propagation Rate.** Propagation rate of the first two strands is taken to be much smaller than that of the following strands. This partly takes reversible nature of strand growth into account in the present model. Since the first two strands are not as stable as the following ones, their propagation step proceeds in a more stochastic way.

(6) **Comparison with Helix-Coil Conversion.** Present analysis suggests that information about k_+ is not obtained from published experimental data. Consequently, it is misleading to compare slow formation rate of the β-structure with results on the fast propagation rate of helix formation.[18]

Since β-bend type III is equivalent to 3_{10} helix,[19] elementary processes in the α-helix initiation and bend formation are expected to be rather similar. However, there is at least one difference. For strand growth to occur significantly in the case of the β-structure, sufficient length will be required for both sides of an initiation site. Therefore, a given β-bend formation is not always valid for subsequent strand growth. For a helix to develop, on the other hand, it is required that either side of initiation site has a sufficient length. This different situation certainly makes considerable difference with respect to effective initiation rate constants between the α-helix and the intramolecular β-structure.

Appendix

Calculations of the Fraction of the β-Conformation. From the expressions on the concentrations given in the text, fraction f of the β-conformation or hydrogen-bonded units can be readilly calculated.

The contribution from two-strand species f_1 is explicitly written as follows.

$$f_1 = f_{11} + f_{12} + f_{13} \tag{A1}$$

$$f_{11} = (2m_1/L) \sum_{i=1}^{L/2-1} \sum_{\eta=i+1}^{L/2} i n_\eta(i|t)$$
$$= (2m_1/L) \sum_{i=1}^{L/2-1} i(L/2-i) n_\eta(i|t) \tag{A2}$$

$$f_{12} = (2m_1/L) \sum_{i=1}^{L/2-1} i\, n_i(i|t) \tag{A3}$$

$$f_{13} = (m_1/2) n_{L/2}(L/2|t) \tag{A4}$$

Similarly, contributions from three-strand species f_2 and four-strand species f_3 are given as follows.

$$f_2 = f_{21} + f_{22} + f_{23} \tag{A5}$$

$$f_{21} = (2m_2/L)[\sum_{i=1}^{L/4} \sum_{\eta=2i}^{L/2} i\, n_\eta(j_1=i,i|t)$$
$$+ \sum_{i=1}^{L/4} \sum_{\eta=i+1}^{L/2} i\, n_\eta(i,j_2=i|t)$$
$$+ \sum_{i=L/4+1}^{L/3-1} \sum_{\eta=i+1}^{L-2i} i\, n_\eta(i,j_2=i|t)]$$
$$= (2m_2/L)[\sum_{i=1}^{L/4} i(L/2-2i+1) n_\eta(j_1=i,i|t)$$
$$+ \sum_{i=1}^{L/4} i(L/2-i) n_\eta(i,j_2=i|t)$$
$$+ \sum_{i=L/4+1}^{L/3-1} i(L-3i) n_\eta(i,j_2=i|t)] \tag{A6}$$

$$f_{22} = (2/L)[\sum_{i=2}^{L/4} \sum_{\eta=i+1}^{2i-1} (\eta+m_3 i) n_\eta(j_1=\eta-i,i|t)$$
$$+ \sum_{i=L/4+1}^{L/2-1} \sum_{\eta=i+1}^{L/2} (\eta+m_3 i) n_\eta(j_1=\eta-i,i|t)$$
$$+ \sum_{i=L/4+1}^{L/3} \sum_{\eta=L-2i+1}^{L/2} (L-\eta+m_3 i) n_\eta(i,j_2=L-\eta-i|t)$$
$$+ \sum_{i=L/3+1}^{L/2-1} \sum_{\eta=i+1}^{L/2} (L-\eta+m_3 i) n_\eta(i,j_2=L-\eta-i|t)]$$
$$= (2/L)[\sum_{i=2}^{L/4} i(i-1)(3/2+m_3) n_\eta(j_1=\eta-i,i|t)$$
$$+ \sum_{i=L/4+1}^{L/2-1} (L/2-i)\left(m_3 i + \frac{L+2i+2}{4}\right) n_\eta(j_1=\eta-i,i|t)$$
$$+ \sum_{i=L/4+1}^{L/3} (i-L/4)(2i+L/2+2m_3 i-1)$$
$$n_\eta(i,j_2=L-i-\eta|t)$$
$$+ \sum_{i=L/3+1}^{L/2-1} \left(\frac{L-2i}{4}\right)(2m_2 i-1-i+3L/2)$$
$$n_\eta(i,j_2=L-i-\eta|t)] \tag{A7}$$

$$f_{23} = (2/L)[\sum_{i=1}^{L/3} m_2 i\, n_i(i,j_2=i|t)$$
$$+ \sum_{i=L/3+1}^{L/2-1} (L-i+m_3 i)\, n_i(i,j_2=i|t)] \tag{A8}$$

$$f_3 = f_{31} + f_{32} + f_{33} \tag{A9}$$

$$f_{31} = (2m_4/L) \sum_{i=1}^{L/4} \sum_{\eta=2i}^{L/2} i n_\eta(j_1=i,i,j_2=i|t)$$
$$= (2m_4/L) \sum_{i=1}^{L/4} (L/2-2i+1) i\, n_\eta(j_1=i,i,j_2=i|t) \tag{A10}$$

$$f_{32} = (2/L)[\sum_{i=2}^{L/4} \sum_{\eta=i+1}^{2i-1} (\eta+m_1 i)\, n_\eta(j_1=\eta-i,i,j_2=i|t)$$

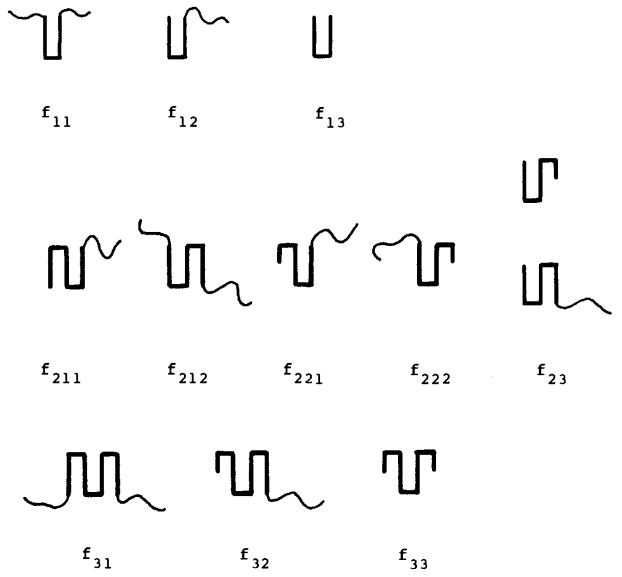

Fig. 4. Schematic representation of various species corresponding to respective contributions given in Eqs. A1—A12. Thick lines and thin curves represent the β-strands and random coil portions, respectively.

$$+\sum_{i=L/4+1}^{L/3}\sum_{\eta=i+1}^{L-2i}(\eta+m_1 i)\,n_\eta(j_1=\eta-i,i,j_2=i|t)$$
$$=(2/L)[\sum_{i=2}^{L/4} i(i-1)(3/2+m_1)\,n_\eta(j_1=\eta-i,i,j_2=i|t)$$
$$+\sum_{i=L/4+1}^{L/3}(L+2m_1 i-i+1)\left(\frac{L-3i}{2}\right)$$
$$n_\eta(j_1=\eta-i,i,j_2=i|t)] \quad \text{(A11)}$$

$$f_{33}=(2/L)[\sum_{i=L/4+1}^{L/3}\sum_{\eta=L-2i+1}^{L/2}(L-i+m_3 i)$$
$$n_\eta(j_1=\eta-i,i,j_2=L-\eta-i|t)$$
$$+\sum_{i=L/3+1}^{L/2-1}\sum_{\eta=i+1}^{L/2}(L-i+m_3 i)$$
$$n_\eta(j_1=\eta-i,i,j_2=L-\eta-i|t)]$$
$$=(2/L)[\sum_{i=L/4+1}^{L/3}(2i-L/2)(L-i+m_3 i)$$
$$n_\eta(j_1=\eta-i,i,j_2=L-\eta-i|t)$$
$$+\sum_{i=L/3+1}^{L/2-1}(L+m_3 i-i)(L/2-i)$$
$$n_\eta(j_1=\eta-i,i,j_2=L-\eta-i|t)] \quad \text{(A12)}$$

In the above equations except Eq. A4, a factor of 2 appears in order to take species with η greater than $L/2$ into account. In the above, (m_1, m_2, m_3, m_4) is (2, 3, 1, 4) for f_β (fraction of the β-conformation) or (1, 2, 0, 3) for f_{hb} (fraction of hydrogen bonded units). In Fig. 4, various species corresponding to each f_{ij} term are schematically represented.

Final Amounts of the β-Conformation or Hydrogen-Bonded Units. As the reaction proceeds, f reaches the final value $f(\infty)$ at $t=\infty$.

$$f(\infty)=f_{13}(\infty)+f_{23}(\infty)+f_{31}(\infty)+f_{32}(\infty)+f_{33}(\infty) \quad \text{(A13)}$$

These final values are functions of k_i/k_0 and k_b/k_+. Since $k_i/k_0=1/L$, the final values are solely determined by the ratio k_+/k_b for a given chain length L. Introducing $\xi=k_+/(k_++2k_b)$, they are written as follows.

$$f_{13}(\infty)=(m_1 k_i/2k_0)\xi^{L/2-1}$$
$$f_{23}(\infty)=(2k_i/Lk_0)[m_2\sum_{i=1}^{L/3} i\xi^{i-1}+\sum_{i=L/3+1}^{L/2-1}(L-i+m_3 i)\xi^{i-1}]$$
$$f_{31}(\infty)=\frac{4m_4 k_i k_b}{Lk_0 k_+}\sum_{i=1}^{L/4} i(L/2-2i+1)\xi^i$$
$$f_{32}(\infty)=\frac{4k_i k_b}{Lk_0 k_+}[(3/2+m_1)\sum_{i=2}^{L/4}(i^2-i)\xi^i$$
$$+(1/2)\sum_{i=L/4+1}^{L/3}(L-3i)(L-i+2m_1+1)\xi^i]$$
$$f_{33}(\infty)=\frac{4k_i k_b}{Lk_0 k_+}[\sum_{i=L/4+1}^{L/3}(2i-L/2)(L-i+m_3 i)\xi^i$$
$$+\sum_{i=L/3+1}^{L/2-1}(L/2-i)(L-i+m_3 i)\xi^i] \quad \text{(A14)}$$

The Microwave Spectra, Dipole Moments, and Two Isomers of Cyclopentadiene-1-carbonitrile

Takeshi SAKAIZUMI,* Hiromi KIKUCHI, Osamu OHASHI, and Ichiro YAMAGUCHI
Department of Chemistry, Faculty of Science and Technology, Sophia University,
Kioi-cho, Chiyoda-ku, Tokyo 102
(Received June 8, 1987)

The microwave spectra of two isomers of cyclopentadiene-1-carbonitrile generated by the pyrolysis of 1*H*-benzotriazole have been observed in the frequency range from 8.0 to 40.0 GHz. The rotational constants (MHz) have been determined as A=8353.7(9), B=1904.24(1), and C=1565.38(1) for 1,3-cyclopentadiene-1-carbonitrile, and A=8235.0(13), B=1902.07(2), and C=1559.67(2) for 1,4-cyclopentadiene-1-carbonitrile. The dipole moments (Debye) obtained are μ_a=4.15(15), μ_b=0.27(3), and μ_{total}=4.16(17) for 1,3-cyclopentadiene-1-carbonitrile and μ_a=4.36(25), μ_b=0.77(10), and μ_{total}=4.42(35) for 1,4-cyclopentadiene-1-carbonitrile.

Since 6-iminofulvene (**2**) is important as an intermediate molecular species[1] in organic chemical reactions, as shown in Scheme 1, we have tried to generate **2** by pyrolysis of 1*H*-benzotriazole (**1**) and to observe its spectrum by microwave spectroscopy.

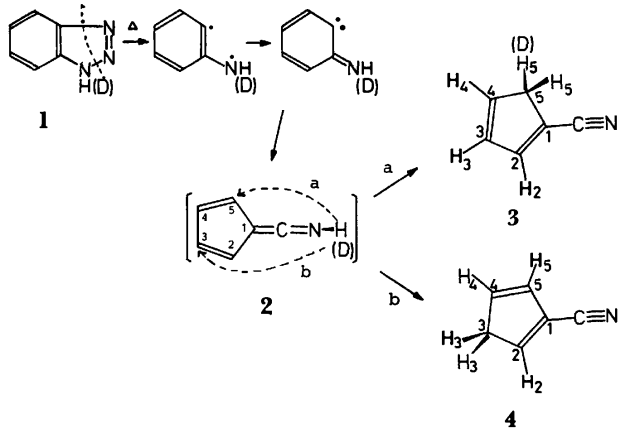
Although the spectrum of **2** could not be assigned, we have observed the spectra of two isomers of cyclopentadiene-1-carbonitrile (1,3-cyclopentadiene-1-carbonitrile (**3**) and 1,4-cyclopentadiene-1-carbonitrile (**4**)).

Wentrup and Crow[2] have reported the formation of **3** from the pyrolysis of **1** by their NMR spectroscopic study. They have assigned the product isolated to the structure **3**, which is the thermodynamically stable isomer. Furthermore, they have indicated the presence of another isomer, which must be the structure **4**.

Ford and Seitzman,[3] using microwave spectroscopy, have reported the rotational constants (A, B, and C) and the a-component of the dipole moment of **3**.

In this study we observed the spectra of two isomers in the ground and excited vibrational states and of one deuterated species in the ground vibrational state. Beside the rotational constants and the a-component of the dipole moment of **3**, we determined the centrifugal distortion constants, the b-component of the dipole moment of **3**, which were not reported by Ford and Seitzman,[3] the rotational and centrifugal distortion constants and the dipole moment for **4**, and the ratio of formation for two isomers. The molecules **3** and **4** could not be differentiated immediately from only the comparison of the observed and calculated rotational constants. Therefore, we have identified one of the observed species as **3** from the r_s coordinate of the hydrogen atom in the methylene group, and the other species was identified as **4** from comparison of the observed and calculated dipole moments.

We will discuss the molecular structure and dipole moments of the pyrolysis products and the possible pyrolysis mechanism of 1*H*-benzotriazole (**1**).



Scheme 1.

Experimental

The sample of 1*H*-benzotriazole obtained from Aldrich Co. was used without further purification. The deuterated precursor (-ND-) was prepared by refluxing the mixture of 1*H*-benzotriazole and CH_3OD (99.5% D) in D_2O (99.75% D). The deuterated precursor was confirmed by ^1H NMR and mass spectroscopy.

The pyrolysis mass spectrum of 1*H*-benzotriazole was observed by using a quadrupole mass spectrometer (ANELVA AQA-360). The molecular ion peak generated at 800 °C was m/z 91.

The pyrolysis apparatus consisted of an unpacked horizontal quartz tube (300 mm length and 5 or 20 mm i.d.) heated in a handmade electric furnace. The precursor was warmed at 90 °C with a pipe-type heater. The temperature of the electric furnace was monitored with a thermocouple fitted on the external wall of the quartz tube. The tube was connected to an inlet port on the side of a Stark waveguide cell (3m long X-band). The cell had large inlet and outlet ports at the ends to allow a rapid flow of vapour through the cell. The pressure at the exit end of the cell was 0.02 to 0.04 Torr (1 Torr=133.322 Pa). A pyrolytic temperature of 800 °C was chosen to generate **3** and **4** because the strongest spectral lines of the two isomers appeared at this temperature.

The microwave spectrometer employed was a conventional 100 kHz Stark modulated instrument. The microwave sources employed were a signal generator (HP 8672A) in the frequency range from 8 to 18 GHz and YIG-tuned GaAs oscillators (WJ 5600-301F and WJ 5610-302FD) from 18.0 to 26.5 GHz and from 26.5 to 40 GHz, respectively.

Results and Discussion

The spectrum of the pyrolysates at 800 °C consisted of four equidistantly spaced groups of spectrum lines between 26.5 and 40.0 GHz which were readily assigned to a-type R-branch transitions with J=8←7 to J=11←10 ($B+C\approx3450$ MHz). The spectrum lines of each group were dense, presumably due to the presence of two isomers and their vibrationally-excited states.

The typical spectra of two isomers observed by using the quartz tubes of 5 and 20 mm inner diameter at 800 °C are shown in Figs. 1(a) and (b), respectively. Although the spectra of Figs. 1(a) and (b) were observed under the same condition for the sample pressure, Stark voltage, and output power of microwave, the intensities of the spectrum lines in the ground and first excited state of set II in 10(0,10)←9(0,9) transition, as shown in Fig. 1(a), are weaker by about one falf than those in Fig. 1(b). Such a difference for set II was also observed in other transitions. The difference of the relative intensities of Figs. 1(a) and (b) is attributed to the differences of formation. This means that the observed spectrum lines can be assigned to two different molecules by using quartz tubes of two different inner diameters.

The spectrum lines of each K_{-1} value were assigned by their Stark effects. The stronger and weaker spectrum lines in each set were assigned to $v=0$ and $v=1$, respectively, as listed in Tables 1 to 4. The rotational and centrifugal constants were obtained by the least-squares method; they are listed in Table 5. The observed and calculated transition frequencies are in good agreement.

The values of $\Delta I(I_c-I_a-I_b)$ obtained for the stronger lines ($v=0$) of set I and set II are −3.040 and −3.047 uÅ^2, respectively. These values are almost the same as −3.102 uÅ^2 observed for cyclopentadiene.[4] The value suggests that the skeleton of the heavy atoms is planar and that two hydrogen atoms are located out of the molecular skeletal plane.

In order to identify the molecules of set I and set II, the rotational constants were calculated for the molecular models of fourteen candidates with unsaturated 3-, 4-, and 5-membered rings, under the

a) $\Delta\nu=\nu_{obsd}-\nu_{calcd}$.

condition that the value of m/z is 91 (C_6H_5N), as evidenced from the pyrolysis mass spectrum. The structural parameters used were taken from fulvene,[5] methanimine,[6] cyclopentadiene,[4] diazoacetonitrile,[7] and 1,3-cyclopentadiene-1-carbonitrile,[3] as shown in Table 6. Among fourteen candidates, the rotational constants calculated for **2**, **3**, and **4** were very close to those observed, as shown in Table 7. Although the rotational constants observed for set I and set II are similar to those predicted for **2**, neither set I or set II can be assigned to **2** because the values of ΔI observed are quite different from those predicted for **2**, in which only one hydrogen atom of NH group is located out of the molecular skeletal plane. Both the rotational constants and ΔI predicted for **3** and **4** are very close to those observed. However, the estimated rotational constants for **3** and **4** are quite similar and can not distinguish clearly between set I and set II.

The model calculation for **3** and **4** suggests that the a-coordinates of their methylenic hydrogen atoms are quite different. We observed spectra of their deuterated species to identify the carrier of the spectra of set I and set II. The spectrum of the pyrolysates of a deuterated precursor was very complicated because of the appearance of the mixture of a deuterated and normal species. The spectrum lines of the deuterated species were distinguished from the comparison with those of the normal species. The spectrum lines were assigned by their Stark effects. The assigned transition frequencies of the monodeuterated species are listed in Table 8. The observed rotational and centrifugal distortion constants are shown in Table 9. The observed value of ΔI, −4.489 uÅ^2, is consistent with that of −4.543 uÅ^2 obtained for monodeuterated species of cyclopentadiene[4] in which the hydrogen atom of methylene group is replaced by a deuterium atom. The rotational constants and ΔI observed were compared with those calculated for the deuterated species, as shown in Table 9. The rotational constants observed are close to those calculated for *3*-H_5-*d*. Furthermore, from the moments of inertia obtained for the monodeuterated species and set I of the normal species, the r_s coordinate of the hydrogen atom was calculated by using Kraitchman's equation.[8] The

observed and calculated coordinates of the hydrogen atom in the methylene group are shown in Table 10. The r_s coordinate obtained for the hydrogen atom is consistent with that calculated from the model of **3**, as shown in Table 10. Therefore, the set I was concluded to be 1,3-cyclopentadiene-1-carbonitrile(**3**). This is consistent with the result reported by Ford and Seitzman.[3]

The spectrum of **4**-H_3-*d* species could not be observed because of very weak absorption intensities. However, the set II was assigned to 1,4-cyclopentadiene-1-carbonitrile (**4**) because the a- and b-components of the dipole moment observed for set II are in good agreement with those of **4** calculated from the group moments, as discussed in the following paragraph.

Table 2. Observed Rotational Transitions (MHz) of 1,3-Cyclopentadiene-1-carbonitrile (Set I) in the First Excited Vibrational State

a) [MHz/(V/cm)^2]$\times 10^{-4}$. b) Figures in parentheses indicate the uncertainty attached to the last figures, estimated from 2.5 times the standard deviations. c) The dipole moments were calculated from the group moments of cyclopentadiene (0.420 D)[4] and benzonitrile (4.14 D).[10] d) Assumed to be zero by symmetry.

Dipole Moment. The dipole moments in the ground vibrational state were determined from the Stark coefficients of M=0, 1, and 2 in 3(0,3)←2(0,2) and M=0 and 1 in 5(2,4)←4(2,3) transition for **3**, and of M=0 and 1 in 3(0,3)←2(0,2) and M=1 in 5(2,4)←4(2,3) transition for **4**, as shown in Table 11. The electric field strength in the absorption cell was calibrated using the dipole moment of the OCS molecule, 0.71521 D.[9] The c-components of the dipole moments for two isomers were assumed to be zero because of the plane of symmetry. The a-component of the dipole moment of **3** is the same as that of **4** within the limits of error. On the other hand, the b-component of the dipole moment of **3** is much smaller than that of **4**. The a- and b-components of the dipole moments observed for two isomers are consistent with those calculated from the group moments of cyclopentadiene (0.42 D)[4] and benzonitrile (4.14 D),[10] as shown in Table 11. This leads to the conclusion that set I and set II should be assigned to **3** and **4**, respectively. The a-component of the dipole moment observed for **3** is in

good agreement with that reported by Ford and Seitzman.[3]

Vibrationally-Excited State. The spectrum lines of the first excited vibrational state could be easily assigned by their Stark behaviour. The values of ΔI obtained for set I and set II are -7.338 and -7.811 uÅ^2, as listed in Table 5. The absolute values of ΔI are much larger than those in the ground vibrational state. This suggests that the assigned spectrum lines come from the first excited vibrational state of the out-of-plane vibrational mode.[11] The vibrational frequencies of set I and set II (v=1) were found to be 150±50 cm^{-1} and 110±50 cm^{-1}, respectively, from the relative intensity measurement. The vibrational mode may be of ring twisting or of ring bending. However, the lines due to the second excited state could not be found. If the vibrational mode were harmonic, the spectrum lines of the second excited state could be found easily at the frequencies which are predicted from the rotational constants linearly extrapolated to v=2 from v=0 and v=1. But the spectrum lines of this state could not be found at the predicted frequencies. This means that the separation of the vibrational levels for the out-of-plane vibrational mode is not equidistant.

Ratio of Formation for Two Isomers. In order to obtain the ratio of formation for two isomers, the relative intensities were observed directly from the peak intensities at higher Stark voltage, because the a-component of the dipole moment of **3** is the same as that of **4**, within the limits of error. The transitions observed by using the quartz tube of 20 mm i.d. for two isomers are 8(0,8)←7(0,7), 8(2,6)←7(2,5), 9(2,8)←8(2,7), 9(2,7)←8(2,6), 9(1,8)←8(1,7), 10(1,10)←9(1,9), 10(0,10)←9(0,9), and 10(2,8)←9(2,7), because these are not disturbed by other lines. The ratio of **3** to **4** were determined to be 2:1.

Pyrolysis Mechanism. On the possible pyrolysis mechanism of 1H-benzotriazole (**1**), the ring contraction into 6-iminofulvene (**2**) obviously proceeds through a 1,3-biradical via the carbene species,[12,13] and it is reasonable to assume that the new molecules of **3** and **4** shown in scheme 1 are generated according to paths(a) and (b) of the hydrogen atom of the imino group in **2**. The pyrolysis mechanism of path(a) may be explained by using a deuterium atom as tracer. The findings of the monodeuterated species (**3**-H_5-*d*) suggest that the deuterium atom in the ND group of **2** migrates to the position of C_5 according to path (a) to form the molecule of **3**-H_5-*d*.

Recently, Rodler et al.[14] have observed ketenimine (H_2C=C=NH) which has a structure similar to that of **2**, by microwave spectroscopy. Ketenimine, whose lifetime is less than 1 s, turns immediately into acetonitrile (H_3C–C≡N), which is the more stable species. The behaviour of the hydrogen atom in the imino group of **2** is supposed to be quite similar to that in ketenimine. Thus the hydrogen of NH group in 6-iminofulvene (**2**) probably migrates immediately to form 1,3-cyclopentadiene-1-carbonitrile (**3**) or 1,4-cyclopentadiene-1-carbonitrile (**4**).
